The measurements of potential distribution in the bed and electrolyte showed that the electrode potentials both in a static and 15% fluidized beds were uniform throughout most of the bed except at a region corresponding to the top of the bed (Figs. 10 and 11). In the uniform distribution of potential electrode reactions occuring at low current densities, the comparable values of the charge-transfer coefficient and the effective specific conductance of the electrolyte which were 0.2247 $ohm^{-1} cm^{-1}$ and 0.53 $ohm^{-1} cm^{-1}$, respectively, in the present work, might be the important factor.

In comparison of Figs. 10 and 11 shows that the deviation of the fluidized bed curve from the static bed curve seems to indicate that there is more current supported at the top of the bed by the fluidized bed than the static bed.

Theoretical Studies on the Disproportionation of Carbon Monoxide on Nickel Clusters

Arun K. Srivastava,* Isao Kojima,† and Eizo Miyazaki†

(Received February 13, 1989)

In the framework of CNDO (Complete neglect of differential overlap method, VOIP (Valence orbital ionization potential) has been evaluated using the method of Anno and Sakai and for exchange integrals Wolfsberg-Helmholtz approximation has been used. With these the problem of parametrization with reference to transition metals becomes rather less troublesome. In its present form the method has been used for studying the disproportionation of carbon monoxide on a nickel cluster having five atoms. A large number of theoretical models were devised, which are based upon various mechanistic possibilities; for each of these, bond energies between different atoms were calculated and plotted against the distance, with an aim of studying the formation and desorption of CO_2. The present studies suggest that this reaction may follow a dissociative path, where in the first step one molecule of CO dissociates, leaving adsorbed carbon and oxygen on the Ni surface, followed by subsequent reaction of this adsorbed oxygen with another molecule of CO from the gas phase or it may follow disproportionation.

At higher temperatures the exposure of crystalline nickel surface to carbon monoxide results in the buildup of carbon. Below 180°C also the buildup of carbon can be brought about by using electrons of sufficiently high energy.[1-4] The adsorption of CO and the subsequent buildup of carbon on the catalyst surface is of great importance since these are the key steps in methanation:

$$3H_2 + CO \rightarrow CH_4 + H_2O$$

and Fischer-Tropsch synthesis. Although Auger data and flash desorption results show 10—20% overlayers of carbide like carbon on the surface following the reaction,[5] but the overall mechanism is not understood very clearly.

The proceeding of a chemical reaction may be described well by the splitting of one and formation of other bonds and consequently the changes in various bond energies may be expected to throw interesting light on the disruption (weakening) and formation of various bonds. The CNDO method as described here may, therefore, be expected to become a good method for studying the course of a reaction mainly because the bond energy is explicity defined in its framework.

Method

The local core matrix elements U_{ii} have been estimated from the atomic data using the following expression.

$$U_{ii} = I_p(i) - (N - 1)\,\gamma_{ss} - M\gamma_{sd} \qquad (1)$$

Where $I_p(i)$ is the valence state ionization potential, N denotes the total number of electrons in the valence s and p orbitals and M represents the number of electrons in the d orbital.

The I_p's have been evaluated by using the method of Anno and Sakai.[6]

The exchange integral H_{ij} was calculated with the Wolfsberg-Helmholtz[7] approximation,

$$H_{ij} = KS_{ij}\,(H_{ii} + H_{ij})/2. \qquad (2)$$

Thus in the present work only K, which is a dimensionless parameter, has been empirically assigned a value of 1.50. The electronic configuration $3d^M4s^2$ or $3d^M4s4p$ was considered for the ground state of the nickel atom. The orbital exponents suggested by Veigele et al.[8] were used for nickel and the Slater values were used for C and O.

The bond energies between atoms A and B were evaluated by the following equation,

$$E_{AB} = \sum_{\gamma}^{A}\sum_{S}^{B}(2P_{rs}\,\beta_{rs} - 1/2P_{rs}^2\,\gamma_{AB}) + (Z_AZ_BR_{AB}^{-1} - P_{AA}V_{AB} - P_{BB}V_{BA} + P_{BB}P_{AA}\gamma_{AB}). \qquad (3)$$

E_{AB} is not identical with the bond energy and in fact represents a simple two-center energy decomposition scheme within the framework of zero differential overlap approximation. In the present communication we use this as a parameter for our theoretical studies. All the terms in Eq. 3 have their usual meaning. The method in the present form has been found to produce satisfactory results[9] on various properties of diatomic molecules of the first transition series and has also been successful in giving valuable information about the mechanism of oxidation of carbon monoxide on nickel clusters.[10] The present method has also been successfully applied to the chemisorption of CO on Ni clusters.[11]

Results and Discussion

At present there are following two main streams in the discussion of mechanism of the carbon deposition on the nickel surface exposed to carbon monoxide at high temperatures and by bombardment with electrons of sufficiently high energy.

1. Dissociative Mechanism: It is claimed that the dissociation of CO is the first step resulting in the formation of Ni-C and Ni-O bonds (2Ni+CO→Ni-C+Ni-O) followed by the CO_2 formation (Ni-O+CO→CO_2).

2. Disproportionation Mechanism: It predicts the reaction between two CO molecules on the surface (2 $CO \rightarrow CO_2(g) + C_{ad}$).

Disproportionation is thermodynamically favorable but there is evidence[13] that the dissociative adsorption is also possible.

For our studies we have visualized three different possibilities for this reaction.

(i) Reaction between two adsorbed CO molecules [Models (1) and (2)].

$$CO_{ad} + CO_{ad} \rightarrow CO_2(g) + C_{ad}.$$

(ii) Reaction between two CO molecules, one of which is in chemisorbed state and the other reacts from the gas phase [Model (6)].

$$CO_{ad} + CO(g) \rightarrow CO_2(g) + C_{ad}.$$

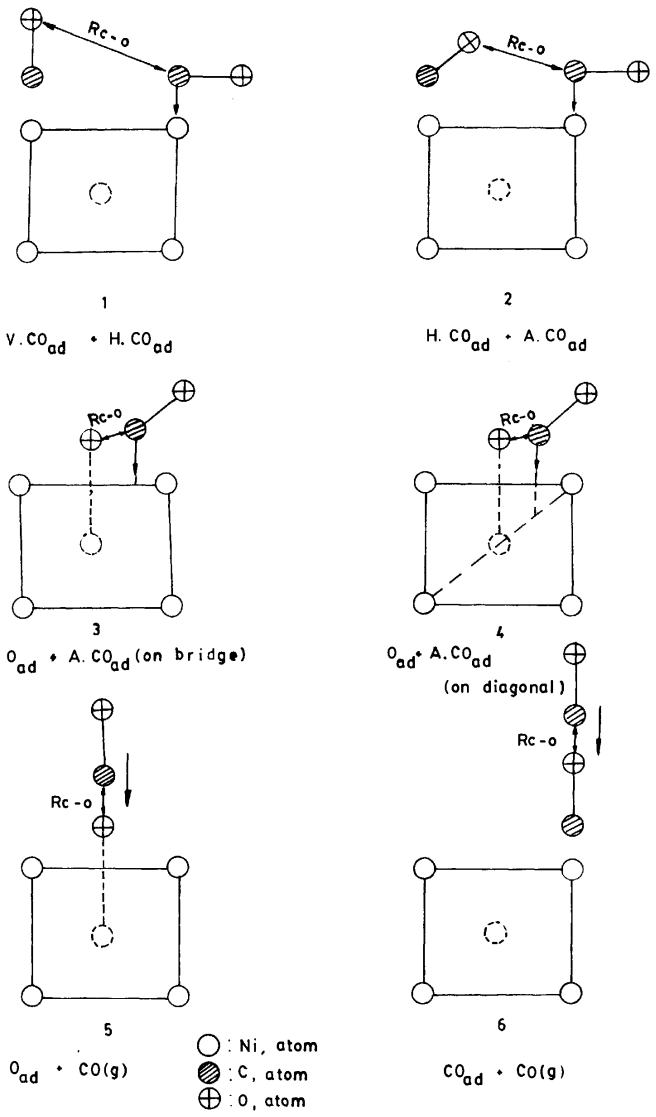

Fig. 1. Models used for studying the disproportionation of carbon monoxide on a 5-atom nickel cluster.

(iii) Dissociation of CO to adsorbed C_{ad} and O_{ad} species followed by a reaction of adsorbed O_{ad} with CO either from the gas phase [Model (5)] or in an adsorbed state [Model (3)] and [Model (4)].

$$CO \rightarrow C_{ad} + O_{ad}.$$

$$O_{ad} + CO(g) \rightarrow CO_2(g) \text{ (Eley-Rideal)}$$

$$O_{ad} + CO_{ad} \rightarrow CO_2(g) \text{ (Langmuir-Hinshelwood)}$$

Based on the above three theoretically possible mechanisms, different models involving Ni_5 cluster were designed (Fig. 1) and in these models horizontal and tilted (30°) forms of adsorbed CO have also been included besides the familiar vertical form. For all these models the energy of interaction E_{int} of a CO molecule to the rest of cluster was calculated by using the following definition.

$$E_{int} = E_t - E_a \qquad (6)$$

Where E_t is the total energy of the system containing all the atoms as shown in each model and E_a is the total energy of the system which has one molecule of CO less than the original model. The bond energy of

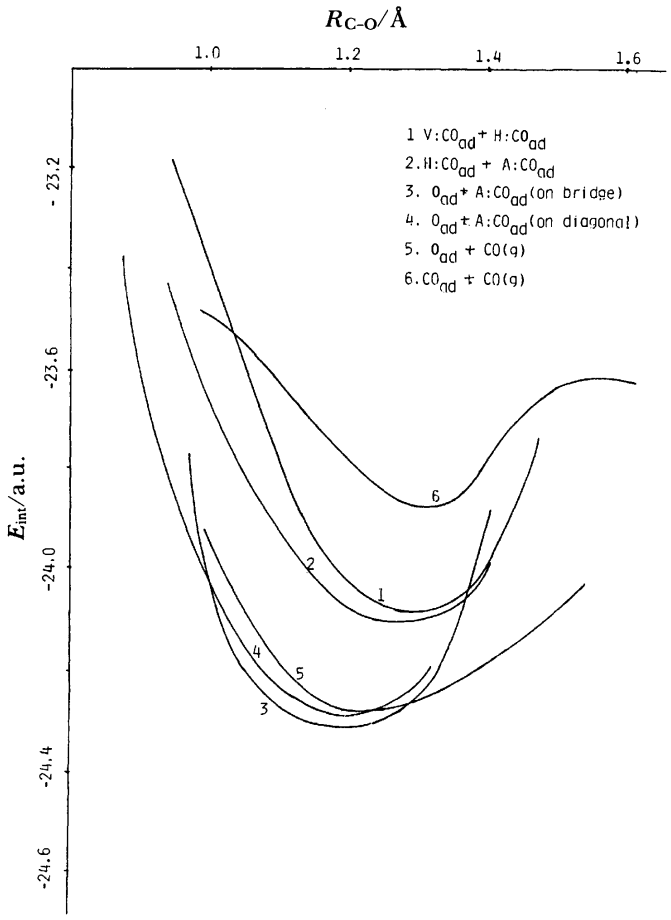

Fig. 2. Plot of E_{int} against $R_{C\text{-}O}$.

CO bond (the new bond which is being formed and is essential for the formation of CO_2) i.e. E_{C-O} as well as sum of the bond energies of all the Ni-C and Ni-O bonds i.e. $\sum E_{Ni-C}+\sum E_{Ni-O}$ have also been calculated. All these energies have been plotted against R_{C-O} i.e. the distance between C and O atoms involved in the new bond formation. The plots of E_{int} and E_{C-O} against R_{C-O} are good indices on the formation on CO_2, and plots of $\sum E_{Ni-O}+\sum E_{Ni-C}$ vs. R_{C-O} may give information regarding the desorption of the CO_2 molecules.

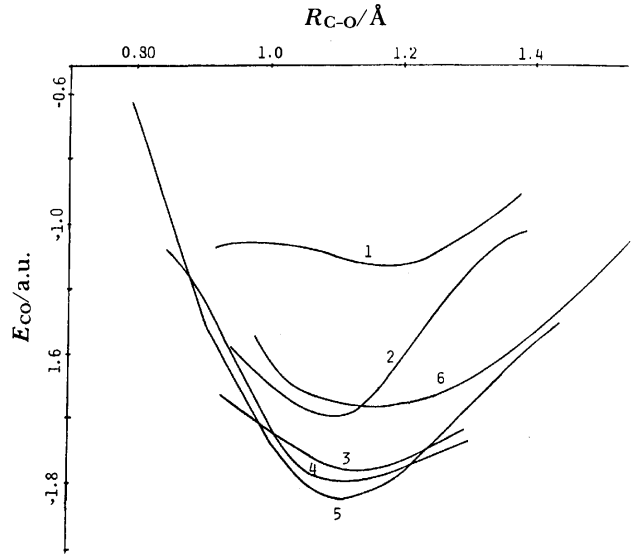

Fig. 3. Plot of E_{C-O} against R_{C-O}.

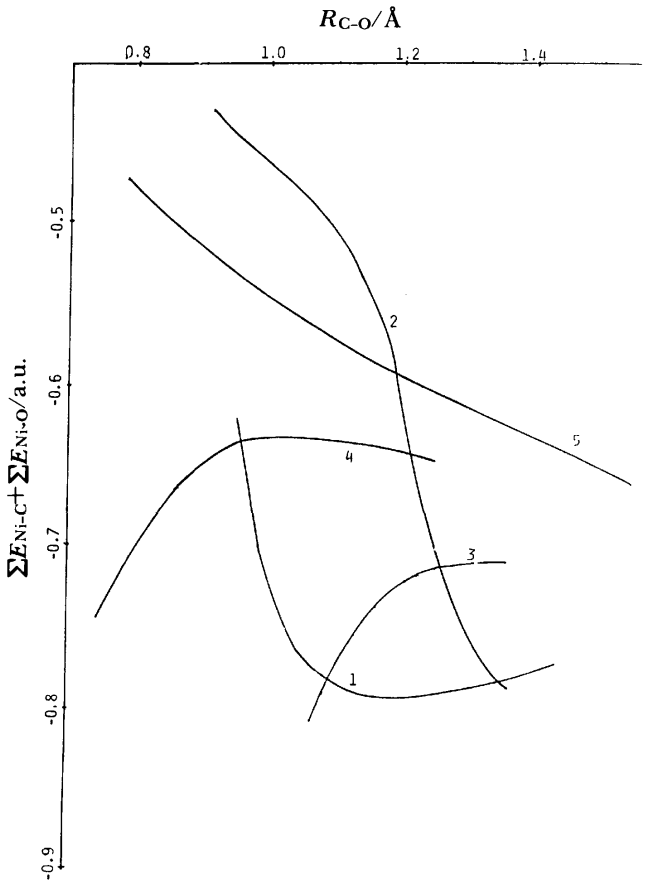

Fig. 4. Plots of $\sum E_{Ni-C}+\sum E_{Ni-O}$ vs. R_{C-O}.

Studies on Ni_5 Cluster: In Fig. 2, the interaction energy E_{int} of CO with the rest of the cluster has been plotted against R_{C-O}, and it seems that models (2), (3), (4), and (5), all of which represent a dissociation path, may be mechanistically more probable.

Figure 3 contains the plots of E_{C-O} vs. R_{C-O} and a comparative study of various curves shows that models (2), (3), (4), and (5) represent a pathway for the reaction which is more favorable for the formation of CO_2.

A study of Fig. 4 which includes plots of $\sum E_{Ni-C}+\sum E_{Ni-O}$ against R_{C-O} reveals that as far as the possibility of desorption of CO_2 is concerned models (2) and (5) may be comparatively better suited.

On the basis of the qualitative studies of Ni_5 it seems that models (2) and (5), representing disproportionation and dissociative path respectively, are the only two suitable paths for the reaction under study.

Conclusion

The qualitative studies presented in this paper on Ni_5 cluster have shown that there are following two plausible mechanisms for this reaction.

1. Disproportionation Mechanism: It has been proposed that the disproportionation reaction occurs between two CO molecules adsorbed on the top of two adjacent Ni atoms. However, our studies are in favor of the scheme with one of these being adsorbed horizontally parallel and the other one tilted at an angle of about 30° to the surface.

$$CO \rightarrow H:CO_{ad} \text{ (Horizontally adsorbed)}$$

$$CO \rightarrow A:CO_{ad} \text{ (Tilted at an angle 30°)}$$

$$H:CO_{ad} + A:CO_{ad} \rightarrow CO_2(g) + C_{ad}$$

The studies of Keim et at.[12] based on ellipsometry and Auger electron spectroscopy suggest disproportionation of the absorbed CO on Ni (100) surface due to bombardment by electrons of very high energy. Our studies presented here suggest that the disproportionation involves a reaction between a horizontally adsorbed CO molecule with a tilted CO molecule adsorbed on an adjacent site (Model 2).

2. Dissociative Mechanism: It is proposed that in the first step the CO molecule dissociates leaving O adsorbed at a four fold symmetrical site, which finally reacts with another molecule of CO from the gas phase to leave adsorbed C and simultaneously form CO_2 which desorbs immediately (Model 5)

$$CO \rightarrow C_{ad} + O_{ad}$$

$$O_{ad} + CO(g) \rightarrow CO_2(g)$$

A dissociative mechanism has also been proposed by Madden and Ertl[4] on the basis of their LEED and AES studies and by Caputi et al.[13] on the basis of their kinetic studies.

Gas-Phase Dehydrogenation of Alkylbenzenes on Rh/$AlPO_4$ Catalysts

Felipa M. BAUTISTA, Juan M. CAMPELO, Angel GARCÍA, Diego LUNA, and José M. MARINAS*
Department of Organic Chemistry, Córdoba University, E-14004 Córdoba, Spain
(Received March 1, 1989)

The nonoxidative dehydrogenation of alkylbenzenes (ethylbenzene, propylbenzene, and isopropylbenzene) has been carried out at 693—853 K on rhodium catalysts at 1 wt% supported on two different types of $AlPO_4$. In similar experimental conditions, the specific catalytic activity of the Rh/$AlPO_4$ catalysts is higher than that obtained previously for Ni/$AlPO_4$ (20 wt%) catalysts. Besides, a linear free energy relationship (LFER) was also obtained, manifesting itself through a "compensation effect" between the $\Delta H^{\neq}$ and $\Delta S^{\neq}$ activation parameters obtained from the Eyring equation (and between $\ln A$ and E_a, from the Arrhenius equation). Furthermore, no extensive metal-support interaction effect was obtained as in the case of Ni/$AlPO_4$ catalysts in spite of exhibiting the same concerted mechanism previously described for the nonoxidative dehydrogenation of alkylbenzenes on supported nickel catalysts.

The dehydrogenation of ethylbenzene to styrene is a very important industrial reaction actually carried out in the vapor phase on iron oxide stabilized with several promotors in the presence of water vapor.[1] However, considerable work has been done in recent years to produce other catalysts such as metallic oxides,[2-4] several oxide salts[5-7] or supported metal catalysts.[8-10] With respect to the latter we studied[11] the nonoxidative dehydrogenation of several alkylbenzenes at 673—823 K on nickel catalysts at 20 wt% supported on Al_2O_3, SiO_2, and two different types of $AlPO_4$ synthesized according to Kearby.[12] Acid and basic sites did not exhibit catalytic activity. However, the acid-basic nature of the supports, through the effects of a strong metal-support interaction were found to play an important part in determining the catalytic activity of the supported nickel catalysts. These metal-support interaction effects were evaluated through several isokinetic parameters obtained from the existence of a linear correlation between the $\Delta H^{\neq}$ and $\Delta S^{\neq}$ activation parameters obtained from the Eyring equation (and between $\ln A$ and E_a, from the Arrhenius equation) known as the compensation effect.

These metal-support interaction effects were previously obtained in the liquid-phase hydrogenation of the olefinic double bond on $AlPO_4$-supported nickel[13-15] and rhodium[16-18] catalysts showing the behavior of $AlPO_4$ as excellent metal supports. In this connection, aluminum phosphates have also been used as supports for platinum[19] and palladium,[20] respectively.

In the present study we investigate the nonoxidative dehydrogenation of some alkylbenzenes (R=Et, *n*-Pr, and *i*-Pr) over rhodium catalysts at 1 wt% supported on the same two $AlPO_4$ supports previously employed as nickel supports[11] which lets us compare the influences of the two metals (rhodium and nickel) since the experimental conditions of this work are also same as those previously used with supported nickel catalysts.[11]

Experimental

Catalysts. Two Rh/$AlPO_4$ catalysts (1 wt% Rh) have been used. The $AlPO_4$ supports (Al/P=1) were obtained by precipitation with ammonia (F) or propylene oxide (P). The supported rhodium catalysts (Rh/$AlPO_4$-F, Rh/$AlPO_4$-P) were prepared by impregnation to incipient wetness with aqueous rhodium chloride solution followed by oven drying (24 h, 390 K) and reduction in flowing hydrogen (200 cm^3 min^{-1}) at 473 K as has been described elsewhere.[21] Besides, metal surface area, S, was, previously, obtained[21] from volume mean diameter, d_v, determined by TEM measurements assuming a spherical geometry of the metal particles (Rh/$AlPO_4$-F: d_v=4.2 nm and S=115 m^2 g_{Rh}^{-1}; Rh/$AlPO_4$-P: d_v=5.4 nm and S=90 m^2 g_{Rh}^{-1}).

The acid-base properties of the catalysts were determined by a spectrophotometric method previously described[22,23] that allows titration of the amount of irreversibly adsorbed benzoic acid (pK_a=4.19) or pyridine (pK_a=5.25) employed as titrant agents of basic and acid sites, respectively. For rhodium catalysts and supports (Rh/$AlPO_4$-F, Rh/$AlPO_4$-P, $AlPO_4$-F, and $AlPO_4$-P) the concentration of basic sites was 156, 152, 200, and 166 mol g^{-1}, and the concentration of acid sites 165, 163, 190, and 227 mol g^{-1}, respectively.

Apparatus and Procedure. The experiments were carried out in a tubular fixed-bed reactor (15×120 mm) with a continuous flow system at atmospheric pressure. The reactor was heated by a tubular electric furnace and the prescribed temperature (693—853 K) was monitored by a thermocouple located in the reactor wall. Isothermal temperatures were measured within an accuracy of ±1 K. The top section of the reactor which functioned as a vaporizer and preheater was packed with glass beads. Fresh catalyst was used in each experiment. The standard pretreatment of the catalyst consisted in heating in a 120 cm^3 min^{-1} nitrogen (99.999%, H_2O<3 ppm) stream for 1 h at the reaction temperature.

The starting materials: ethyl- (EB), propyl- (*n*-PB), and isopropylbenzene (*i*-PB) were supplied by Merck p.a., and purified by distillation under reduced pressure and low temperature. Each substrate was fed at several rates (F in the interval 10—0.1 cm^3 min^{-1}) by means of a microfeeder (Perfusor VI B. Braun), vaporized and passed through the catalyst zone. Nitrogen was used as a carrier gas with a

constant flow of 120 cm^3 min^{-1}.

The liquid products were condensed and analyzed by gas chromatography using 5% polyphenylene oxide on Chromosorb G-AW DMCS 80/100 column. Furthermore, a spectrophotometric analysis of the different samples was made due to the low conversion values obtained (<0.5%) at the higher F values. These experiments are developed at the wavelength of the maximum absorption of the dehydrogenation products in cyclohexane solutions (spectroscopic grade, Merck) and between the concentrations where the Lambert-Beer law fits.

Results and Discussion

The gas chromatographic analysis for all runs indicated that the only reaction products obtained were those corresponding to the dehydrogenation reaction of the alkylbenzenes: styrene, α-, and β-methylstyrene, respectively.

Dehydrogenation reactions were carried out under conditions where the reaction rate, R, was not influenced by diffusion. Thus, the average particle size of the catalysts used (<0.149 mm) determines that the reactions were not influenced by internal diffusion. On the other hand, the representation of R (obtained for 0.4 g of catalyst at several feed rates, F) against F, as shown in Fig. 1a, indicated the absence of external diffusion effects in the present experimental conditions for feed rates over 1.2×10^{-4} mol s^{-1}. According to these results, the bulk of the kinetic runs was performed at a fixed ratio of catalyst mass (0.4 g) and at least three feed rates in the interval $1.2—14\times10^{-4}$ mol s^{-1}, at temperatures between 693—853 K.

In the present experimental conditions the reaction can take place in a negligible extension in the absence of the catalyst, especially at the highest temperatures. Furthermore, identical negligible activities are obtained when the different supports are used as cata-

	853	2.81	2.45	1.21	1.05	4.60	4.00

lysts. Accordingly it may be assumed that the catalytic activity is exclusively developed on the rhodium metal surface, as occurs in nickel catalysts.[11]

The initial conversion data, X (<5%) (defined as the number of moles of dehydrogenated alkylbenzene per mole of alkylbenzene fed) are fitted in a first-order rate equation, Fig. 1b, at residence times lower than 4000 g s mol^{-1}.

$$\ln 1/(1 - X) = k(W/F) \quad (1)$$

The slope of the straight lines yields the value of the reaction rate constant, k (in mol g^{-1} s^{-1}). In Table 1 the k and specific reaction rate constants, k_S (in mol s^{-1} m$^{-2}_{Rh}$) values for the three alkylbenzenes with the two catalysts at each temperature are collected.

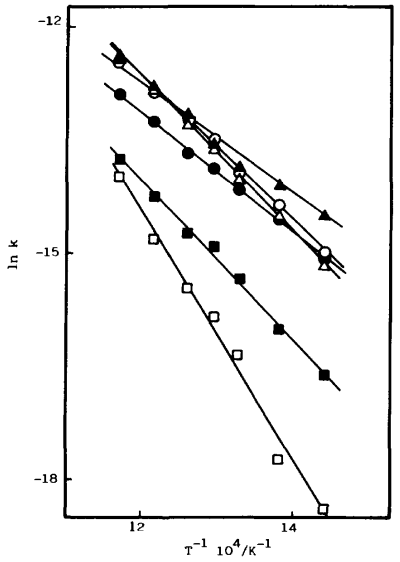

Fig. 2. Arrhenius plots for the dehydrogenation of ethylbenzene: (○) Rh/AlPO$_4$-P, (●) Rh/AlPO$_4$-F; propylbenzene: (□) Rh/AlPO$_4$-P, (■) Rh/AlPO$_4$-F; and isopropylbenzene: (△) Rh/AlPO$_4$-P, (▲) Rh/AlPO$_4$-F.

The results collected in Table 1 show that the catalytic activities of both supported rhodium catalysts are similar so that they do not exhibit a metal-support interaction effect as previously obtained with supported nickel catalysts in the same experimental conditions.[11] With respect to this, we see that specific catalytic activity of rhodium catalysts is clearly higher (between 2 and 3 times) than those obtained with nickel catalysts in the dehydrogenation of EB and *i*-PB. Such differences are not as high in *n*-PB.

The results obtained in the temperature range studied are summarized in Fig. 2 where we can see the evolution of catalytic activity with temperature which lets us apply the Arrhenius equation obtaining the corresponding values of apparent activation energies, E_a, and Arrhenius constants, ln A, collected in Table 2.

Furthermore, the Eyring equation also evaluates the temperature dependence of reaction rate constants in terms of transition state theory by separating enthalpy, $\Delta H^{\neq}$, and entropy, $\Delta S^{\neq}$, components. Their corresponding values, obtained by plotting $\ln(k_S T^{-1})$ against T^{-1} are also shown in Table 2.

We can also see in Fig. 3 how the kinetic parameters $\Delta H^{\neq}$ against $\Delta S^{\neq}$ for rhodium catalysts, in Table 2, and nickel catalysts, previously obtained,[11] fit straight lines for each alkylbenzene. This enthalpy-entropy relationship may be adscribed to the existence of a linear free energy relationship (LFER):

$$\Delta G^{\neq}_{const} = -\theta R \ln K^{\neq} = \Delta H^{\neq} - \theta \Delta S^{\neq} \quad (2)$$

known as the "compensation effect" or "isokinetic relationship" (IKR)[24-26] although the most habitual representation is through the equation

$$\ln A = \ln \alpha + E_a/\theta R \quad (3)$$

where R is the gas constant, θ the isokinetic temperature at which identical values of reaction rate constant $k=\alpha$ are obtained, $K^{\neq}$ the equilibrium

Table 2. Apparent Activation Energies, E_a (kJ mol^{-1}), Arrhenius Constants, ln A (mol s^{-1} m$^{-2}_{Rh}$), Activation Enthalpies, $\Delta H^{\neq}$ (kJ mol^{-1}) and Activation Entropies, $\Delta S^{\neq}$ (J mol^{-1} K^{-1}) with Their Respective Standard Deviations, for the Catalysts and Substrates Studied

Substrate		Rh/AlPO$_4$-P	Rh/AlPO$_4$-F

	$\Delta S^{\neq}$	−274.0±2.0	−292.0±2.0
Propylbenzene	E_a	137.0±6.0	87.0±3.0
	ln A	5.0±1.0	−1.4±0.4
	$\Delta H^{\neq}$	131.0±6.0	81.0±3.0
	$\Delta S^{\neq}$	−217.0±2.0	−274.0±3.0
Isopropylbenzene	E_a	84.0±1.0	64.0±4.0
	ln A	−0.5±0.2	−3.5±0.7
	$\Delta H^{\neq}$	78.0±1.0	58.0±4.0
	$\Delta S^{\neq}$	−267.0±2.0	−291.0±6.0

constant of the activated complex and $\Delta G^{\neq}$ the activation free energy. Thus, the values of isokinetic parameters for each substrate (θ, $\ln \alpha$, $K^{\neq}$, and $\Delta G^{\neq}$) are obtained from slopes and intercepts in Eqs. 2 and 3 and collected in Table 3.

Furthermore, if an IKR holds for any set of reactions of the same type exhibiting the same value of $\Delta G^{\neq}$ throughout the experimental temperature range, a single common interaction mechanism can be expected.[24,27,28] In agreement with this and on the basis of the results shown in Fig. 3 and Table 3 we have to conclude that the nonoxidative gas-phase dehydrogenation of alkylbenzenes on $Rh/AlPO_4$ catalysts is carried out through the identical concerted mechanism previously described for $Ni/AlPO_4$ catalysts,[11] developed throughout the reversal of the steps of a classical Horiuti-Polanyi type noncompetitive mechanism,[29] and describing the hydrogenation of an olefinic double bond.

This concerted character can also be accounted for by consideration of the kinetic parameters presented in Table 2. Thus, the negative values of $\Delta S^{\neq}$ indicate that, on going from the ground state to the transition state, an extensive restriction in the degrees of freedom must be considered. This highly ordered transition state is consistent with a reaction mechanism whose slowest step is the stabilization and immobilization of reactant molecules on catalyst active sites. With respect to this, the reaction rate is proportional to the quantity of adsorbed reactant molecules, and the reverse reaction is negligible. Besides, the relatively low $\Delta H^{\neq}$ values appear to be consistent with a concerted evolution in the limiting adsorption step which also must be associated with the low values $\Delta S^{\neq}$.

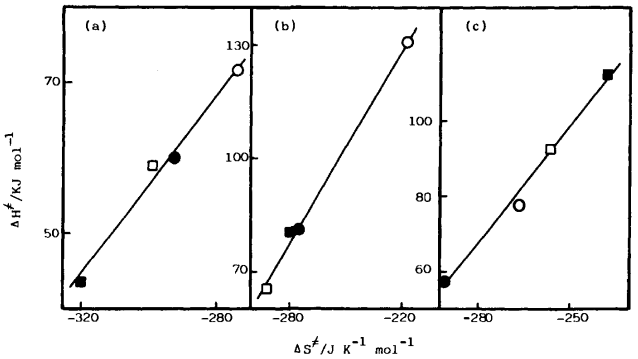

Fig. 3. Compensation effect between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for (a) ethylbenzene, (b) propylbenzene, and (c) isopropylbenzene with different catalysts: (○) $Rh/AlPO_4$-P; (●) $Rh/AlPO_4$-F; (□) $Ni/AlPO_4$-P; and (■) $Ni/AlPO_4$-F.

In the present mechanism, the active sites on the metal surface are looked on as surface complexes[29-32] with three degrees of coordinative unsaturation where it is possible to absorb two hydrogens and an olefin at the same time in the transition state. The transfer of the two hydrogen atoms from the alkylbenzenes throughout a concerted process, where the interaction with the catalyst removes the symmetry restrictions imposed by the Woodward-Hoffmann rules, leads directly to the olefinic double bond and a hydrogen molecule formation.[33] In agreement with this, Wang et al.[3,34] described the nonoxidative dehydrogenation of ethylbenzene over TiO_2-ZrO_2 catalysts through a concerted two center mechanism, where zirconium ions act like Lewis acid, and titanium ion as a base.

On the other hand, the reaction rate is only determined by the number of active sites present in the reaction. This number is determined not only by the metal surface area (related to the catalyst weight and metal dispersion) but also to the density of active sites on the metal surface, which is closely associated to the metal-support interaction effects. In this way, the higher catalytic activity of $Rh/AlPO_4$ with respect to $Ni/AlPO_4$ catalysts ought to be related to their different behavior in relation to the metal-support interaction effects. Thus, while in supported nickel catalysts the metal deposition induced a strong decrease in the number of acid sites while the number of basic sites remained almost unchanged,[11] in the $Rh/AlPO_4$ catalyst, according to the present results, the metal deposition practically does not induce appreciable changes in either the number of acid sites or basic ones. However, the potential effect of the different metal content ought to be also considered in order to explain this differential behavior between Ni and Rh supported catalysts.

According to Bartholomew et al.[35,36] such metal-support interaction can be attributed to a transfer of electrons between the nickel atoms and the acid sites on the support surface. Possibly due to the higher reduction potential in rhodium atoms, such electron transfer is not developed in $Rh/AlPO_4$ catalysts thus obtaining an enhanced catalytic activity with respect to $Ni/AlPO_4$ catalysts, as also obtained habitually in liquid-phase catalytic hydrogenation of the olefinic double bond.[13,16,17,37] So, here we have an interesting

Table 3. Values of $\ln \alpha$ and θ^a (K) Obtained from the Representation of $\ln A$ againt E_a and Values of θ^b (K), $\Delta G^{\neq}$ (kJ mol^{-1}), and $\ln K^{\neq}$ Obtained from the Representation of $\Delta H^{\neq}$ againt $\Delta S^{\neq}$, Corresponding to Substrates

Substrate	$\ln \alpha$	θ^a	θ^b	$\Delta G^{\neq}_{const}$	$\ln K^{\neq}$
Ethylbenzene	−17.0±1.0	613±67	596±65	235±19	−47±6
Propylbenzene	−13.7±0.6	870±40	867±40	319±11	−44±3
Isopropylbenzene	−10.7±0.8	1038±74	1028±74	355±19	−42±4

difference between the catalytic behavior of Rh and Ni supported catalysts: The former does not exhibit important metal-support interaction effects which could explain in part its excellent catalytic activity. In spite of this, it has not been studied extensively to date as evidenced by the absence of publications during the last few years.

Extraction Spectrophotometric Determination of Bismuth(III) with Iodide and Amidines

Alpana GHOSH, Khageshwar Singh PATEL, and Rajendra Kumar MISHRA*
Department of Chemistry, Ravishankar University, Raipur (M. P.), 492010, India
(Received December 22, 1988)

A new simple and rapid spectrophotometric method for the extraction and determination of bismuth(III) is described. The reaction of *N,N'*-diphenylbenzamidines and its 10 derivatives (HA) with bismuth(III) in presence of iodide have been investigated photometrically in chloroform. The value of molar absorptivity of the complexes with these compounds lies in the range $(0.84—1.35)\times10^4$ l mol^{-1} cm^{-1}. Of these, the most sensitive compound *N*-(2-methylphenyl)-*N'*-phenylbenzamidine hydrochloride (MPPBA) was selected for detailed studies. The detection limit of the method is 0.2 μg Bi cm^{-3}. The elements which are commonly associated with the metal e.g. Cu, Ni, Co, Mn, Cr, Zn, Hg, Ti, Zr, Mo, W, V, Al, Sb, etc. do not interfere. The method has been applied for the determination of the metal to soil and ore.

In earlier communications, amidines were used for the extraction and spectrophotometric determination of Sb(III) and Au(III) as halogeno ternary complexes.[1,2] In this paper, *N,N'*-diphenylbenzamidine and its 10 derivatives are reported for extraction and spectrophotometric determination of microgram amounts of bismuth(III) in the presence of iodide ions. The formation of iodobismuthite complex in the water and in the organic solutions is the absence of amidine were examined at the conditions mentioned in the procedure. The value of molar absorptivity of the complex in the aqueous solution is found to be 8500 l mol^{-1} cm^{-1} at 445 nm and its extraction by polar solvents 1-pentanol, methyl isobutyl ketone, ethyl acetate suffers by unstability of the extract at room temperature. Moreover, the classical iodide method commonly used is complicated because it is applicable in sulfurous acid media and suffers form interferences of metal ions e.g. Sb, Pb, Hg, etc.[3,4] Tetrabutyl ammonium ion[5] and dyes[6—9] were claimed to improve the selectivity of classical iodide method, although they suffers from interference of the metal ions. Thiourea is widely used for spectrophotometric determination of metal in perchloric acid medium. However, it is not sensitive and involves the serious interference of Sb.[3,4] Dithizone is employed for the spectrophotometric determination of metal in alkaline solution using cyanide as masking agent to overcome the interference of heavy metals.[10] Recently mucic acid has been used as a colorimetric reagent for the determination of the metal over pH range 4.0 — 5.0 but it is not sensitive.[11]

The present method remarkably enhances the selectivity and sensitivity of the classical iodide method. The complex is stabilized by amidine in the organic solution unlikely to polar solvents e.g., 1-pentanol, MIBK or ethyl acetate. This method also improves the selectivity of other established methods.

Experimental

Apparatus: A Carl Zeiss "SPEKOL" equipped with 1-cm quartz cells were employed for the absorbance measurements.

Reagents: The standard solution and bismuth(III) was prepared by dissolving a weighed amount of bismuth sulfate in dilute sulfuric acid (0.5 mol dm^{-3}) and standardized volumetrically with EDTA using Pyrocatechol Violet as an indicator.[12] A freshly prepared potassium iodide solution (5% w/v) containing ascorbic acid (1% w/v) was employed. A 0.4% (w/v) solutions of amidines in chloroform was used for all extraction work. All chemicals used were analytical grade and their solutions were prepared in deionized water.

Procedure: Place an aliquot of standard bismuth(III) solution containing 25—450 μg of the metal in a 150-cm^3 separatory funnel. To this add 1 cm^3 of 5% KI solution. Adjust the acidity to the required value with 10 mol dm^{-3} H_2SO_4 and dilute to 10 cm^3 with deionized water. Add 10 cm^3 chloroform solution of the reagent. Shake the content of the funnel vigorously for 2 min and allow the phase to separate. Dry the chloroform extract over anhydrous sodium sulfate in a 50-cm^3 beaker. Wash the aqueous layer with 3×2 cm^3 fresh portions of chloroform. Transfer all the extracts to 25-cm^3 volumetric flask and dilute with chloroform to the mark. Measure it at λ_{max} against reagent blank.

Results and Discussion

Absorption Spectra: The absorption spectra of the ternary complex is chloroform, binary complex in the aqueous solution and that of reagent blank in chloroform are shown in Fig. 1. The maximum absorbance of the ternary and binary complexes lies at 490 nm and 440 nm, respectively. The formation of ternary shows a slight hyperchromic shift and a strong bathochromic shift as shown in Fig. 1. The reagent blank in chloroform shows some absorption at λ_{max} hence it was used as a reference blank for all measurements.

Selection of Extracting Solvents: The influence of various solvents e.g., benzene, toluene, carbon tetrachloride, chloroform, and cyclohexane were examined for the extraction of the complex with *N*-(2-methylphenyl)-*N'*-phenylbenzamidine hydrochloride (MPPBA). The complex is quantitatively extractable into toluene

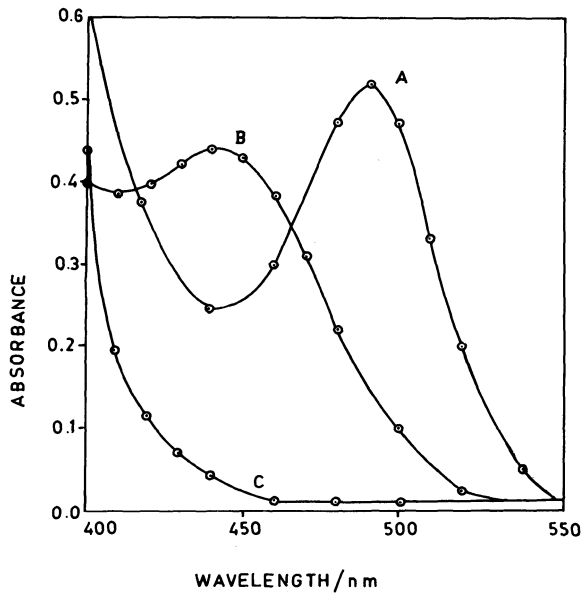

Fig. 1. Absorption spectra of bismuth(III) with iodide in aqueous solution and with iodide and amidine (MPPBA) in chloroform and the reagent blank in chloroform.
(A) $C_{Bi}=3.8\times10^{-5}$ mol dm^{-3}; $C_{KI}=0.03$ mol dm^{-3}; $C_{MPPBA}=0.014$ mol dm^{-3}; $C_{H_2SO_4}=2.0$ mol dm^{-3}. (B) $C_{Bi}=3.8\times10^{-5}$ mol dm^{-3}; $C_{KI}=0.03$ mol dm^{-3}; $C_{H_2SO_4}=2.0$ mol dm^{-3}. (C) $C_{KI}=0.03$ mol dm^{-3}; $C_{H_2SO_4}=2.0$ mol dm^{-3}; $C_{MPPBA}=0.014$ mol dm^{-3}.

and chloroform; whereas partially extracted into aromatic hydrocarbons while no extraction in carbon tetrachloride. The value of molar absorptivity and absorption maximum of the complex in these solvents are: Toluene (λ_{max}-490 nm, ε=13400 l mol^{-1} cm^{-1}), chloroform (λ_{max}-490 nm, ε=13500 l mol^{-1} cm^{-1}). Of these, chloroform is used as a solvent for further extraction work due to high distribution ratio of the reagent in it. Effect of acidity and quantitative extraction of the metal: The effect of acids like sulfuric and hydrochloric acids on the extraction of the metal with iodide and amidines were examined. Hydrochloric acid cannot be used for acidification because of the formation of the chloro complexes which suppress the extraction in the present investigation. Therefore, sulfuric acid has been selected for further extraction work.

The data obtained show that the optimum acidity range for the maximum and constant absorbance of the complex in the organic solution is 0.5—4.0 mol dm^{-3} H_2SO_4. A 100, 200, and 400 μg of Bi(III) is extracted separately as in the procedure. The extract is evaporated, digested with acid treatment and estimated by perchloric acid method. The metal recovered was found to be more than 99%.

Effect of Reagents, Time, Temperature, and Volume of Aqueous Phase: The effect of the concentration of reagents on the extraction of Bi(III) with KI and MPPBA were studied. The extraction is quantitative when the concentration of MPPBA in chloroform is higher than 0.009 mol dm^{-3}. The concentration of potassium iodide should be between 0.0075 to 0.09 mol dm^{-3} in aqueous solution. The function of ascorbic acid added is to prevent the oxidation of iodide as well as to remove any oxidizing materials present in aqueous solution. The order of addition of reagents is not critical. A shaking time of 1 min was sufficient for complete extraction of the metal and further extraction upto 10 min did not cause any adverse effect. The absorbance of the extract was stable for at least 5—6 h at room temperature (25±2 °C). The effect of dilution upon extraction of the metal with MPPBA was examined. The results indicates that the absorbance of the extraction remained unchanged when the volume ratio of organic phase to aqueous phase was 2:1 to 1:10. The reaction temperature of the medium is critical and it should be between 20 and 30 °C. Beyond this temperature the color intensity of the complex decreases.

Optimum Concentration Range, Sensitivity, and Precision of the Method: A linear calibration graph passing through the origin was obtained by the recommended procedure over concentration range 1—18 μg Bi cm^{-1} with MPPBA. The detection limit of the method was determined by taking known microgram amount of the metal in total aqueous phase (5 ml) containing 0.2 ml KI and 1 ml sulfuric acid (10 mol dm^{-3}) and it was shaken with a few drops of chloroform solution of amidine. The experiment was repeated until the orange color of the organic phase has been appeared. The detection limit of the method is 0.2 μg Bi cm^{-3}. The molar absorptivity of the complex obtained by this method is 1.35×10^4 l mol^{-1} cm^{-1}. The relative standard deviation of the method for 10 replicate measurements at 150 μg Bi 10 cm^{-3} was ±1.2%.

Effect of Amidines: The effect of substitution in *N*-phenyl ring of the amidine on the color intensity of the extract was examined (Table 1). The introduction of CH_3 or Cl groups in amido N-ring except 2-CH_3 decrease the color intensity of the complex. The breaking of the conjugation as seen with benzyl and octyl groups greatly suppress the color of the complex. The increase in degree of substitution also causes adverse effect. The position of substituents enhances the color intensity in the order: *p*-<*m*-<*o*-.

Composition of the Complex: Bismuth(III) reacts with iodide in sulfuric acid medium to give colored iodo complex which is extracted as iodo-ternary complex with reagent MPPBA into chloroform. The metal to ligand ratio was determined by plotting log *D* (distribution ratio) versus log *M* molar concentration of the reagents and which give slope of 3.9 and 1.8 for iodide and amidine respectively (Fig. 2). The reaction mechanism can be expressed as following:

Table 1. Spectral Data of Iodobismuth Complex with Various Amidines in Chloroform

	$C_6H_5-C(=N-R')-R-N-H$ R	R′	λ_{max} nm	ε l mol^{-1} cm^{-1}	Sandell's sensitivity μg cm^{-2}

11	$C_6H_5CH_2$	C_6H_5	490	9360	0.022

Table 2. Determination of Bismuth(III) in Complex Materials

Sample No.[a]	Bismuth found (ppm) Present method	Bismuth found (ppm) Thiourea method	Relative standard deviation of the present method[b]
a	37.0	39.0	±1.2%
b	12.5	14.0	±1.1%

a) a: Soil sample obtained from Sonakhan Mines. b: Galena sample obtained from Zawar Mines, Udaipur.
b) Average of six determinations.

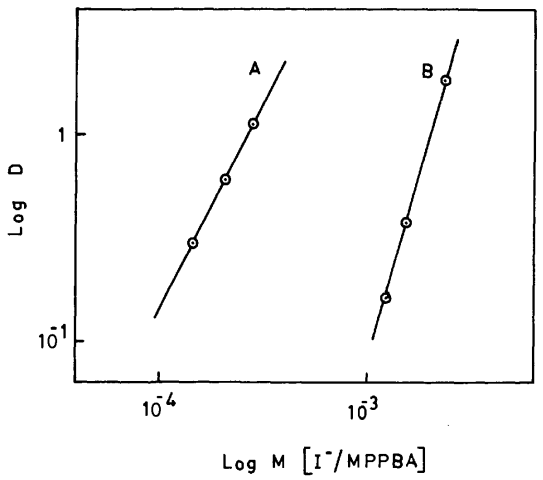

Fig. 2. Determination of composition of the complex in chloroform by curve-fitting method.
C_{Bi}=9.6×10^{-5} mol dm^{-3}; $C_{H_2SO_4}$=2.0 mol dm^{-3}. (A) log D vs. log[MPPBA]; C_{KI}=0.03 mol dm^{-3}. (B) log D vs. log[I$^-$]; C_{MPPBA}=0.014 mol dm^{-3}.

$$Bi^{3+} + 4I^- + H^+ + 2HA_o \rightleftharpoons \{[BiI_4][H(HA)_2]\}_o$$

where subscripts o and HA denote the organic phase and amidine respectively.

Effect of Diverse Ions: The effect of diverse ions in the determination of 175 μg Bi(III) was studied. The complex was extracted as described in the recommended procedure. Interference was considered to occur if the error in the absorbance exceeded ±2%. The tolerance limit of various diverse ions (in mg) are summarized in parentheses as: Cd, Pb (0.7); Ag (1); Sb (3); V, W (4); Hg, Cu, Re (5); Mo, La (30); U (50); Al (70); Ti (80); Th (90); Zr, Cr (100); Be, Mn (120); Zn, Co (200); Ni (300); Br$^-$, $C_2O_4^{2-}$ (50); PO_4^{3-}, Cl$^-$ (80); EDTA (80); NH_2CSNH_2 (50).

Application of the Method: The method has been applied for recovery of the metal to soil and galena samples. A weighed amount of the sample (5 g) is digested with aqua regia (10 cm^3) and dried sample is treated with 5 cm^3 of concentrated hydrochloric acid to remove excess of nitrate ions. It is evaporated upon dryness and then treated with 3—4 cm^3 of concentrated sulfuric acid. The dry residue is then dissolved in water, filter and make up to 50 cm^3 with deionized water. Bi is prior separated by cupferron extraction as described in the literature.[3] The metal content of the sample is determined by standard addition method as described in the procedure. The results indicated that this method is reproducibly applicable to these samples for recovery of the metal.

We are thankful to Ravishankar University for providing fellowship to one of them (A. G.).

Extractive Separation and Determination of Lead in Alloys and Environmental Samples

Bhanu RAMAN and V. M. SHINDE*
Analytical Laboratory, Department of Chemistry, Institute of Science,
15, Madam Cama Road, Bombay 400032, India
(Received February 16, 1989)

A method is proposed for the solvent extraction of lead salicylate using triphenylphosphine oxide as an extractant. The optimum extraction conditions were evaluated from a critical study of effects of pH, sodium salicylate concentration and triphenylphosphine oxide concentration. The probable composition of the species has been deduced from log-log plots and the extraction mechanism is suggested. The method has been used to separate lead from commonly associated elements such as copper, nickel, antimony; and also from chromium, iron, and mercury. The method has been further extended to separate and estimate lead in standard alloys, gasoline, and air-borne particulate samples.

The environmental chemistry of lead owes its importance to the pollution caused by autoexhaust emission. The chief source of atmospheric lead is comprised by the variety of antiknock additives in the gasoline which serves the internal combustion engine. Organic lead poisoning is primarily due to the inhalation of the antiknock additive compound viz. tetraethyllead. Lead and its compounds constitute one of the most important industrial health hazards. It is a cumulative poison; hence the toxicity of lead is not immediately felt. It could remain in the bone immobilized for several years. Chronic exposure to lead causes nephritis, scaring, and shrinking of kidney tissues; while, short but intense exposure causes only functional injury. Premature loss of teeth in lead poisoning, is attributed to a demineralization caused by the chemical displacement of the jaw bone calcium by the lead present in the circulatory blood.

In view of the toxic effects of environmental lead, and its compounds, the separation and estimation of lead from the air-borne particulates is desired.

In the various extraction methods available, use has been made of neutral extractants,[1-13] acidic extractants,[14-18] and basic extractants.[19-26] These methods however, have a shortcoming in that, they require a prolonged shaking period,[4,9,13,19] suffer from interference and co-extraction of common cations[9,15] and require high acid concentration for extraction.[19] It is also conspicuous that none of these methods have been applied for the determination of lead in atmospheric air particulate samples.

The proposed method is simple and rapid. It finds a wide range of applications in the separation and determination of lead from a variety of samples.

Experimental

Apparatus and Reagents. A Pye Unicam SP-200 Spectrophotometer and Varian Techron-Model 70 Atomic Absorption Spectrophotometer were used for absorbance measurements. Measurement of pH values was done on a Control Dynamics pH meter.

The stock solution of lead was prepared by dissolving 2.00 g of lead nitrate in 250 ml of distilled water containing 0.5 ml of concentrated nitric acid. The solution was standardized complexometrically[27] using EDTA and test solutions of lower concentration were prepared by suitable dilutions.

A 5% solution of triphenylphosphine oxide (Fluka Grade, mp 156—158 °C) in toluene was used for all extractions.

A 0.1% aqueous solution of 4-(2-pyridylazo)resorcinol was used for spectrophotometric determination of lead.

All other chemincals used were of guaranteed grade and pure, distilled solvents were used throughout the work.

General Extraction Procedure. To an aliquot of solution containing 1 mg of lead, was added 40 mg of sodium salicylate in order to make its concentration of 0.01 M (1 M=1 mol dm^{-3}) in a total volume of 25 ml. The pH of the solution was adjusted to 6.5 with dilute nitric acid and sodium hydroxide solutions. The solution was then transferred to 125 ml separatory funnel and shaken for 90 s with 10 ml of 5% triphenylphoshine oxide in toluene. After separating the two phases, lead was stripped from the organic phase by shaking for 1 min with distilled water (2×10 ml containing 0.5 ml of 0.05 M nitric acid) and estimated complexometrically.[27]

For microgram amounts of lead, the extraction was done using 5 ml of 5% triphenylphosphine oxide solution. The lead was backstripped with distilled water (3×4 ml containing a drop of 0.05 M nitric acid) and estimated spectrophotometrically as follows:

The pH of the aqueous solution was adjusted to 6.5; 1 ml of 0.1% aqueous soltion of PAR was added and diluted to 25 ml. The absorbance of the orange-colored complex was measured at 520 nm[28] against a reagent blank prepared analogously.

Results and Discussion

Extraction Conditions. The extraction of lead was investigated at varying pH (4.0—9.0), salicylate concentration (1.0×10^{-3}—2.0×10^{-2} M) and triphenylphosphine oxide concentration (1—5%). It was observed, that quantitative extraction of lead (in mg amounts) takes place with 10 ml of 5% triphenylphosphine oxide solution from 9.0×10^{-3}—1.0×10^{-2} M sodium salicylate concentration at pH 6.0—6.7. For microgram amounts of lead (25—100 μg) quantita-

tive extraction of lead is obtained using 5 ml of 5% triphenylphosphine oxide solution. The optimum extraction conditions are reported in Table 1 and illustrated in Figs. 1 and 2.

Nature of Extracted Species. The log-log plots of distribution ratio versus salicylate concentraion, at fixed pH and triphenylphosphine oxide concentration, (Fig. 3 and Table 2) and versus triphenylphosphine oxide concentration, at fixed pH and sodium salicylate concentration (Fig. 4 and Tabel 3) indicate a molar ratio of 1:2 with respect to both salicylate ion and triphenylphosphine oxide. Hence, the probable extracted species is, $Pb(Sal)_2\cdot2TPPO$ where Sal stands for salicylate ion and TPPO stands for triphenylphosphine oxide. Thus, the probable extraction mechanism can be expressed as:

$$Pb(H_2O)_2^{2+} + 2(HOC_6H_4COO)^- + 2TPPO \rightleftharpoons Pb(HOC_6H_4COO)_2\cdot2TPPO + 2H_2O$$

Extracted species

The extraction may be due to the solvation of lead salicylate by triphenylphosphine oxide molecules.

Effect of Foreign Ions. A number of ions were tested for the interference in the extraction of lead. The study showed that for the extraction and photometric estimation of 50 μg of lead, a large number of cations and anions did not interfer (as shown by less than 1% error in analytical recovery of lead). However, ions such as uranium(VI), thorium(IV), and oxalate did offer interference. The results of the study of interfering ions is reported in Table 4.

Separation of Lead from Chromium(VI), Iron(III), Antimony(III), Copper(II), Nickel(II), and Mercury(II). Ions such as chromium(VI) , iron(III), antimony(III), copper(II), and nickel(II) are not extracted into triphenylphosphine oxide under the optimum extraction conditions of lead. Hence, it is possible to separate lead from these elements in their binary mixtures. The unextracted ions were detemined spectrophotometrically using known methods while lead is estimated spectrophotometrically using PAR as described in the general procedure.

Under the extraction conditions of lead, mercury shows partial extraction. However, by selective stripping of lead with distilled water, which does not backstrip mercury, the two ions can be quantitatively separated from each other. The partially extracted mercury is backstripped with acetate buffer (pH 4.7); combined with the major portion of unextracted mercury and estimated complexometrically.[29]

The recovery of lead and the added ions is ≥99.0%. The results of the separation of binary mixtures is reported in Table 5.

Analytical Applications. 1. Analysis of Alloys. 0.5 g of each of two different standard alloys containing lead, were weighed accurately. Then, 10 ml of concentrated nitric acid was added to each of them and were evaporated to dryness. The residue was taken up with dilute nitric acid (4 M) and the precipitate of metastannic acid was filtered off. The filtrate was diluted to 50 ml and an aliquot of this solution was used for the extraction and estimation of lead using the proposed method.

2. Analysis of Gasoline. 25 ml of Gasoline containing tetraethyllead was evaporated slowly on a water bath (≃80 °C) to remove all the volatile liquids. To the oily residue, 3 ml of concentrated nitric acid was added, slowly, with due care, in order to convert organolead to lead nitrate. This was heated on a water bath for 20 minutes. After cooling, the oily part was removed by extracting it with benzene while the lead

nitrate formed in situ was estimated by recommended procedure.

3. Analysis of Air-Borne Particulates. Filter paper strips containing adsorbed lead particles from polluted air samples were supplied by Air Pollution Monitoring and Research Laboratory, Municipal Corporation of Greater Bombey, Khar. The samples belonged to different subrban areas of Bombay such as Parel, Khar, and Tilaknagar. The separation and determination of lead in these glasswool filter papers (containing adsorbed air particulates) were done as follows:

Sample filter paper strips (8 sq cm area) were digested with 10 ml of 50% nitric acid for about 15 minutes. This was then diluted with distilled water to 15 ml volume and filtered to remove the insoluble glasswool filter paper residue and other dust particles. The filtrate was used for the extration and estimation of lead by the proposed method.

The results of the above sample analysis are reported in Table 6. All the samples were also analyzed for comparison of results, using Atomic Absorption Spectrophotometer. The results so obtained were in good agreement with each other.

Our thanks are due to C. S. I. R., New Delhi for financing the project and also to Air Pollution Monitoring and Research Laboratory, Municipal Corporation of Greater Bombay, Khar, for providing the samples.

Polar and Dipolar Substituent Effects and Transition State in the Reaction between Substituted Anilines and Nitrosobenzene. An Evaluation of Ortho and Electrostatic Effects

Carla C. SCHMITT, Carlos A. MORITZ, Moacir G. PIZZOLATTI, and Rosendo A. YUNES*
Departamento de Química, Universidade Federal de Santa Catarina, 88049 Florianópolis, SC, Brazil
(Received September 2, 1988)

The rate constants of the hydronium catalyzed attack of substituted anilines on nitrosobenzene, to give azobenzene, exhibit a large dependence on the substituent constant σ^- ($\rho^-=-1.92$). The relatively high value of ρ^- compared to that obtained from the equilibrium of protonation of anilines ($\rho^-=-2.77$) and the solvent effect on the rate constants support the idea that the transition state involves a large amount of nitrogen-nitrogen bond formation and therefore a strong charge development on the nitrogen and oxygen of the amino and nitroso groups, respectively. A good correlation between basicity and nucleophilic reactivity is obtained by the Brönsted equation ($\beta=0.65$, $r=0.988$) for the para and meta dipolar substituents. Aminobenzoates show a significantly higher reactivity than that calculated from the Brönsted line and this is attributed to an electrostatic participation of the carboxylato group. Nevertheless, this effect is somewhat compensated by repulsion between the carboxylato and the negatively charged oxygen of the nitroso group.

The substituent effects of charged and dipolar groups can be used in order to obtain information about the nature of the transition state of organic reactions. Some authors[1] are of the opinion that charged groups cannot be included with the dipolar groups in one general scale of electronic substituent constant, but others[2] list values of substituent constants for charged groups using results obtained mainly by equilibria or physical properties. Rate data are prime sources of information about the substituent effects on the transition state of the reactions but, in spite of this, few studies have been made dealing with the effect of the carboxylato group on reactivity. Capon[3] studied the participation of the carboxylato group in the hydrolysis of 2-bromopropionate, Bordwell and Knipe[4] in the hydrolysis of α-bromophenylacetic acid that follows an S_N1 mechanism with formation of a zwitterionic-like transition state and Anderson and Fife[5] in the hydrolysis of benzaldehyde disalicylacetal.

In this work we have studied the substituent effects, especially of the carboxylato group, in the reaction of substituted anilines with nitrosobenzene in order to i) obtain a better understanding of the transition state structure of the rate determining step and ii) to evaluate the electrostatic participation of the carboxylato group and the ortho effect of the substituents.

The reaction between anilines and nitrosobenzene was previously studied[6-9] and Yunes et al.[9] showed that the mechanism of this reaction is similar to that of the reaction of weakly basic amines with benzaldehydes and other carbonyl substances.[10] Therefore, attack of the amine is rate-determining under acidic conditions and dehydration of an addition intermediate becomes rate-determining in neutral or basic pH.

Experiments were carried out in MeOH 15% wt and acid pH such that the hydronium-catalyzed attack of aniline on nitrosobenzene (k_H) is the rate-determining step (Eq. 1).

$$\mathrm{PhNO + PhNH_2} \overset{\text{slow}}{\underset{k_H}{\rightleftharpoons}} \mathrm{PhN(OH)\overset{+}{N}H_2Ph} \rightleftharpoons \mathrm{PhN(OH)NHPh} \xrightarrow{k_d} \mathrm{PhN{=}NPh + H_2O} \quad (1)$$

The reaction was also studied in different mixed solvents considering that the less polar media could provide better conditions for electrostatic participation of the carboxylato group and could be a simple model for the participation of charged groups in enzyme-catalyzed reactions.

Results

The first-order constant for condensation of aminobenzoic acids with nitrosobenzene in excess of amines in 15% methanol and 85% water by weight, $\mu=0.5$ M (1 M=1 mol dm^{-3}) (KCl), at 25 °C varies linearly with total amine concentration at constant pH. This behavior implies the absence of general acid or base catalysis by the aminobenzoic acids in the concentration range studied. The same result was observed with aniline.[9,10]

The rate law for aminobenzoic acids can be written as:

$$k_{obs} = k_o^{NC}[NC] + k_o^{A}[A] + k_H^{NC}[NC][H^+] + k_H^{A}[A][H^+] \quad (2)$$

where k_o^{NC} is the rate constant of the pH independent reaction of NC. k_o^{A} is the rate constant of the pH independent reaction of A. k_H^{NC} is the rate constant of the hydronium ion-catalyzed reaction of NC. k_H^{A} is the rate constant of the hydronium ion-catalyzed reaction of A. NC and A are the uncharged and anionic species, respectively (Scheme 1).

Rate constants of the pH-independent reaction are negligible in comparison to those for the hydronium-catalyzed reaction (2.5×10^{-4} M^{-2} min^{-1} and 5.1×10^{3} M^{-2} min^{-1} respectively for aniline) and therefore Eq. 1 reduces to:

$$k_{obs} = k_H^{NC}[NC][H^+] + k_H^A[A][H^+] \quad (3)$$

From Eq. 3 and data at different pH the third-order rate constants k_H^{NC} and k_H^A were calculated.

For the other amines the second-order and the third-order rate constants were calculated following methods previously described.[10]

The hydronium ion-catalytic rate constants are collected in Table 1.

In order to evaluate the relation between basicity and nucleophilicity, a Brönsted type relation (4) was used.

$$\log k_H = \beta pK_a + C \quad (4)$$

The parameters determined from the data for compounds **1**, **2**, **4**, **6**, and **7** (Table 1) are β=0.65, C=0.69 and the correlation coefficient r=0.988. The plot is shown in Fig. 1. All the aminobenzoate ions give rate constants larger than those predicted by the Brönsted equation. The largest positive deviation was for the *p*-aminobenzoate ion.

The catalytic rate constants for the hydronium ion-catalyzed reactions of substituted anilines **1**, **2**, **6**, and **7** were plotted logarithmically against the σ substituent constant,[11] yielding a ρ value of −2.08 (r=0.955). If compound **4** is included in the plot a better correlation is obtained with σ^-[12] and ρ^- is −1.92 (r=0.978).

The ratios of the rate constants of the hydronium ion-catalyzed reactions for formation of azobenzene from *o*- and *p*-substituted anilines are collected in Table 2. With the uncharged substituents chloro, methyl, and carboxyl groups the ratio is less than unity, whereas for the carboxylato group the ratio is greater than unity. It is interesting to note that the corresponding ratios for similar reactions of substituted benzaldehydes with a variety of nitrogen nucleophiles, including hydroxylamine, semicarbazide, *p*-toluidine, and phenylhydrazine are considerably greater than unity.[13-17] This result has been attributed to greater electronic delocalization in benzaldehydes brought about by para substituents, as

$k_H^{p\text{-}COO^-}$	3900	31500
$k_H^{o\text{-}COO^-}/k_H^{o\text{-}COOH}$	72	2285
$k_H^{m\text{-}COO^-}/k_H^{m\text{-}COOH}$	11	379
$k_H^{p\text{-}COO^-}/k_H^{p\text{-}COOH}$	18	787

a) 15 wt% and 53 wt% methanol, at 25 °C.

compared with ortho substituents.[15,17]

The reaction between *o*-methyl-, *p*-methyl-, and unsubstituted aniline with nitrosobenzene was studied in different mixtures of ethanol-water (Table 3). Increasing the proportion of ethanol decreases the ratio $k_H/k_H^{o\text{-}CH_3}$, but the ratio $k_H/k_H^{p\text{-}CH_3}$ stays practically constant.

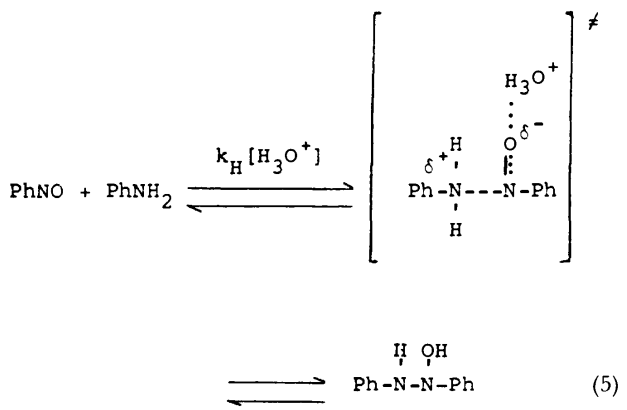
Condensation of aniline, aminobenzoic acids, and aminobenzoate ions with nitrosobenzene was studied in 53 wt% of methanol-water (Table 4). The rate constant for the hydronium ion-catalyzed reaction between aniline and nitrosobenzene decreases approximately 10 times when the proportion of methanol is changed from 15 wt% to 53 wt%. With *o*-, *m*-, and *p*-aminobenzoic acids the rate decrease is 4 to 6 fold, and with aminobenzoate ions the rates increase by factors of 6 to 8. Reaction of the *o*-aminobenzoate ion should have a rate constant of $2.5\times10^3\,M^{-2}\,min^{-1}$ in 53 wt% methanol if its response to the change of methanol proportion was similar to that for *o*-aminobenzoic acid, but it has a hydronium-catalytic rate constant of $7.0\times10^4\,M^{-2}\,min^{-1}$ and thus the reaction is 28 times faster. *m*- and *p*-Aminobenzoate ions show similar behavior. The $k_H^{COO^-}/k_H^{COOH}$ ratios are given in Table 4. Correlations of the catalytic constants of hydronium ion for compounds **1**, **2**, **3**, **4**, and **5** (Table 1) using the substituent constants of McDaniel and Brown,[11] in Hammett plots, yield the following values: $\rho=-2.62$ ($r=0.952$) for the reaction in MeOH 15 wt% and $\rho=-4.78$ ($r=0.820$) for the reaction in MeOH 53 wt% (plots are not shown).

Discussion

For aniline protonation in water at 25 °C based on σ^- constants the ρ^- value equals −2.77.[18] This value is considered a measure of the susceptibility of the reaction to substituent effects and is an indication of the complete charge development at the nitrogen atom adjacent to the ring in passing from reagents to products. The correlation with σ^- shows that the conjugation, existing in aniline, between the amino group and the substituents is not present between the ammonio group and the substituents in the anilinium ion. This last assumption is reasonable, theoretically, because the nitrogen on the ammonio group has no unshared electron pair and, being a first-row element, cannot expand its valence shell to accommodate more than eight electrons.

The correlation of nucleophilic reactivity towards the nitroso group, in methanol 15 wt% at 25 °C, and σ^-, gives $\rho^-=-1.92$. Even considering the solvent effect, this value is large, compared with that of aniline protonation in pure water, and is an indication of an extensive charge formation on the nitrogen of the amino group in going from the initial state to the transition state. The good correlation with σ^- shows that there is a clear difference of resonance interaction between the substituents and the reaction center (the amino group) in the initial state and in the transition state. Indeed the delocalization of the unpaired electrons of the amino group in the aniline should be very much reduced in the transition state and consequently the formation of the N-N bond must have proceeded to a considerable extent.

Other piece of evidence about the nature of the transition state is the correlation by the Brönsted equation. The β value for the addition of a proton to aniline, with complete formation of the positive charge, is by definition 1. This value should be smaller for the complete addition of the polarized nitroso group, because it is somewhat less electropositive than the proton. In consideration of this, the value of β obtained 0.65 indicates that the dependence of the reaction on basicity is large. This fact indicates that there should be a large amount of positive charge developed in the attacking nucleophile in the transition state.[10,19] All these results suggest a probable transition state structure that is represented in Eq. 5.



(5)

Considering that the negative charge on the oxygen of the nitroso group is somewhat stabilized by the

catalyst, the strong charge formation on the nitrogen of the amino group would be the main reason for the observed decrease of the catalytic rate constant of aniline and its derivatives with dipolar substituents when the solvent polarity is lowered (Tables 3, 4); under the same conditions, the delocalization of positive charge on the nitrogen of the amino group explains the increase of the rate constants of the attack of water[20] on Schiff bases.

The pK_a of substituted anilines measures the electronic and steric effects of the substituents to protonation of the amino group, however the electron-donating methyl group and the electron-withdrawing chloro atom at the ortho position of aniline give rate constants that fall below the correlation line of the Brönsted plot (Fig. 1) and ortho/para ratios smaller than unity (Table 2). This can be explained by a greater steric effect on the reaction than on the protonation of anilines because the electronic effects of the substituents should be similar in kinetics and equilibria. Wepster[21] has suggested that steric hindrance to solvation of the protonated species is the principal cause of the low basic strength of *o*-alkyl anilines. The reactivity of anilines in different mixtures of ethanol–water (Table 3) suggests that in reaction (5) the steric hindrance to solvation of the transition state is one cause of the smaller experimental value of the catalytic rate constants for ortho-substituted anilines with respect to the value obtained from the Brönsted line. Thus, the $k_H/k_H^{o\text{-}CH_3}$ ratio decreases when the solvating power of the solvent decreases (increasing the ethanol proportion) showing the steric effect of the *o*-methyl group on the transition state solvation. For the *p*-methyl group, where the steric hindrance of transition state solvation is negligible, the $k_H/k_H^{p\text{-}CH_3}$ ratio stays constant. Other steric effects can exist as was indicated by Fujita and Nishioka,[22] in their analysis of ortho effect, but it is evident from the results that they should not be so important to explain the deviation mentioned above. The rate constant of the hydronium ion-catalyzed reaction of *o*-aminobenzoic acid falls on the correlation line of the Brönsted plot. An explanation of this behavior is that there should exist an internal association between the $-\overset{+}{N}H_2$ and the -COOH groups, in the transition state, as is suggested by ^{13}C NMR spectral data[23] of protonated *o*-aminobenzoic acid.

Spectral studies, dipole moment data,[24,25] and kinetic data[15-17] indicate that, when the ortho substituents are in the electrophilic reagent as in the reaction between substituted benzaldehydes and nitrogen nucleophiles,[16,17] steric effects are unimportant. The reaction of *o*-methylnitrosobenzene and aniline gives a hydronium-catalyzed rate constant of 4.8×10^3 $M^{-2}\,min^{-1}$ [26] while the rate constant for the unsubstituted compounds is 5.1×10^3 $M^{-2}\,min^{-1}$; this small decrease should be attributed to electronic effects of the methyl group and indicates that in this case the ortho substituent does not affect significantly the attack of aniline and the solvation of the transition state. This last result can be explained because in the transition state the substituents are sufficiently separated from the charged atoms to affect their stabilization by solvation.

One of the most striking facts of this reaction is that the carboxylato-substituted anilines react faster than predicted by the Brönsted plot (for the anilines with uncharged meta and para substituents) giving a different line with a smaller slope (dashed line in Fig. 1 that was drawn considering the points of *m*- and *p*-aminobenzoates). Bruice and Lapinski[27] have shown that the reactivities of a series of nitrogen nucleophiles toward *p*-nitrophenyl acetate fall on lines of slopes 0.8 but with separate lines for substituted imidazols, pyridines, and anilines. It has also been shown for the reactivities of primary, secondary and tertiary amines toward different substracts.[28] Now it is reported that the reactivities toward nitrosobenzene of the same nucleophile aniline, with charged and uncharged substituents, fall in different lines.

A large number of factors may affect the nucleophilic reactivity of the carboxylato anilines and it is possible that their high reactivity should not depend on a single cause. However, the dramatic increase in the rate constant for these anilines on changing from methanol 15 wt% to methanol 53 wt% indicates an electrostatic participation of the carboxylato group which stabilizes the transition state of the reaction. The participation of electrostatic effect in reactions with charged nucleophiles was demonstrated in different systems.[29] However, in this case, the question is why the electrostatic participation of the carboxylato group is different in kinetics and in equilibria. Basicity of anilines in aqueous solution depends strongly, as the amines in general, on specific solvation of their conjugated acids by hydrogen bonding to the solvent.[21,30] In the transition state of the reaction between anilines and nitrosobenzene there is a smaller adhesion, by hydrogen-bonded structure, of solvent molecules on the charged reaction center surface of the activated complex. Thus, the less polar character of the cavity of low dielectric constant near the reaction center, according to the model of Kirwood-Westheimer,[31] make possible a greater electrostatic effect of the carboxylate group on the transition state.

Considering the arguments discussed above it seems probable that the stabilization of the anilinium positive charge by ion–dipolo interactions with the solvent molecules should be smaller than the corresponding to the positive charge of the activated complex of the reaction between anilines and nitroso-

benzene. As the ortho substituents in aniline should affect more the solvent molecules that interact by ion-dipolo forces than those that interact by hydrogen bonding it is possible to interpret the greater steric effect of *o*-methyl and *o*-chloro substituents to the solvation of the transition state of the reactions than to the solvation of the products of the equilibrium.

The reactivity of the aminobenzoates follows the order of stabilization of the zwitterionic species of aminobenzoic acids: meta>ortho>para, but the order of positive deviation of the values of the experimental catalytic rate constants with respect to the values calculated from the Brönsted lines is: para>meta> ortho (2.9; 2.4; and 1.9 times respectively). In the zwitterions there is a positive charge on the ammonio group but in the proposed structure of the transition state, in addition to the positive charge on the nitrogen of the amino group, there is a negative charge on the oxygen of the nitroso group that, although somewhat stabilized by the catalyst, should cause some repulsive interaction with the carboxylato group. The order of positive deviation corresponds to the distance between the carboxylato and the nitroso groups since the electrostatic repulsion decreases with distance. The strong deviation of the *o*-aminobenzoate, considering the small distance between the two negative groups, can be explained by an intramolecular hydrogen bond between the ortho carboxylato and the positive amino group in the transition state.[23]

The application of the Hammett equation to the hydronium-catalytic rate constants of compounds with polar and dipolar groups (**1**, **2**, **3**, **4**, and **5** of Table 1) using the substituent constants of McDaniel and Brown[11] gives a good correlation for the reaction in MeOH 15 wt% and a bad correlation for the reaction in MeOH 53 wt%. This result can be attributed to the significant increase of the electrostatic effect of pole (carboxylato group) with the change of the solvent and support the observation of Wepster et al.[32] that the variation of σ values of poles is so large, considering the conditions of the reactions, that it probably makes no sense to average σ values of poles.

The principal conclusions drawn from this work are the following:

i) The transition state of the reaction of formation of azobenzenes from nitrosobenzene and aniline when the rate-determining step is the attack of aniline on nitrosobenzene involves a large amount of nitrogen-nitrogen bond formation and consequently a strong charge formation on the nitrogen and on the oxygen of the amino and nitroso group, respectively.

ii) There exists a clear ortho effect, due principally to inhibition of the transition state solvation, in the reaction between nitrosobenzene and *o*-substituted anilines whereas there is none when the reaction is between aniline and *o*-substituted nitrosobenzene.

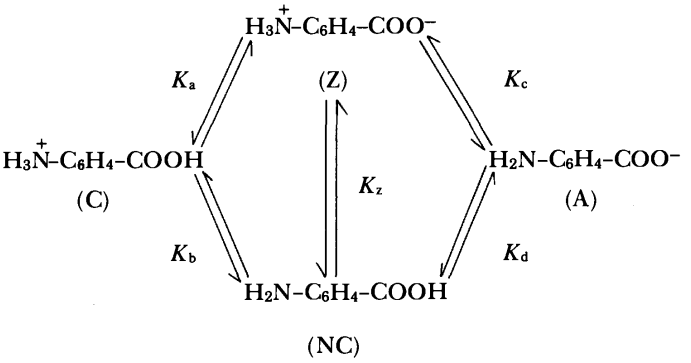
iii) The substituents and ortho effects, specially of poles, depend significantly on the transition state structure and on the reaction media.

Experimental

Materials: Nitrosobenzene was synthesized according to standard procedures[33] and purified by sublimation. Anilines were redistilled or recrystallized and their solutions were prepared just prior to use.

Kinetic measurements were carried out spectrophotometrically at 25 °C with a Shimadzu 210 A ultraviolet spectrophotometer. Reactions were monitored by observing the appearance of the bands of azobenzene at 435 and 350 nm in solutions containing initial concentrations of 3.33×10^{-4} M and 10^{-1} to 10^{-2} M, or 10^{-2} to 10^{-3} M and 1.6×10^{-5} M, for nitrosobenzene and the anilines respectively. The kinetic studies were performed with nitrogen-degassed solutions. The pH range was between 1 to 5. The error of the obtained rate constants was never higher than 3%, for *p*-carboxylato substituted anilines agreement was within 5%.

Calculations of Concentrations of Anilines: The concentrations of all the aminobenzoic acids and aminobenzoates were calculated considering the equilibria of Scheme 1 and Eqs. 6, 7, and 8 that give the relation between the microscopic constants K_a, K_b, K_c, and K_d and the macroscopic constant K_1 and K_2 given in the literature as acidity constants of the aminobenzoic acids.



Scheme 1.

$$K_1 = K_a + K_b \tag{6}$$

$$1/K_2 = 1/K_c + 1/K_d \tag{7}$$

$$K_z = K_a/K_b = K_d/K_c \tag{8}$$

The total concentration of aminobenzoic acid is

$$[AMT] = [C] + [NC] + [A] + [Z] \tag{9}$$

and considering the equilibria of Scheme 1, it is possible to obtain Eqs. 10 and 11 that permit calculation of the concentrations of the reactives species NC and A:

$$[NC] = \frac{1}{(1 + K_z)(1 + [H^+]/K_1 + K_2/[H^+])} \cdot [AMT] \tag{10}$$

$$[A] = \frac{1}{1 + [H^+]^2/K_1 \cdot K_2 + [H^+]/K_2} \cdot [AMT] \tag{11}$$

The pK_a values of anilines under the experimental conditions: MeOH 15 wt%, μ=0.5 M [KCl], [anilines] 10^{-1}—10^{-2} M, [nitrosobenzene] 3.33×10^{-4} M were assumed to be the same as in water at zero ionic strength because the opposing effects of a higher ion strength and a change in polarity of the solvent tend to cancel.[34] The values of K_1 and K_2 for aminobenzoic acids[35] given at 20 °C were corrected to 25 °C using the method of Perrin[36] for the values of K_b and K_c.[35] The value of K_z was calculated from Eq. 8.

Reactions of nitrosobenzene (10^{-2} to 10^{-3} M) with *p*-chloro- and *p*-methylaniline (1.66×10^{-5}) were run in MeOH 15 wt%, μ=0.5 M (KCl) using the apparent pK_a's of anilines (see pK_a determinations) to calculate the third-order rate constant. As anilines react in the form of free base the kinetic expression is:

$$v = k_H(PhNO)(An)_l(H^+) \quad (12)$$

where $(An)_l$: aniline as free base concentration. $(An)_l$ can be written as a function of total aniline concentration: $(An)_t$

$$(An)_l = \frac{(An)_t \cdot K_a'}{K_a' + (H^+)} \quad (13)$$

K_a': acid dissociation constant of anilinium ion determined in the same conditions of the reactions.

Combinations of Eqs. 12 and 13 leads to

$$v = k_H \frac{(PhNO)(An)_t(H^+)K_a'}{K_a' + (H^+)} \quad (14)$$

and as the reaction is carried out with a large excess of nitrosobenzene Eq. 14 takes the form that permit us to determine the third-order rate constant: k_H

$$k_{obs} = v/(An)_t = k_H \frac{(PhNO)(H^+)K_a'}{K_a' + (H^+)} \quad (15)$$

The values obtained with this method agree with corresponding values of the first method. The second method was also used in the determination of third-order rate constant in MeOH 53 wt% according to Eq. 16 for aminobenzoic acids. The values of the apparent constant K_1 and K_2 of the aminobenzoic acids were from Mentré[37] and corrected to 25 °C using the above mentioned method (the error introduced is negligible).

$$k_{obs} = k_H^{NC} \frac{[PhNO][H^+]}{(1+K_z)(1+[H^+]/K_1+K_2/[H^+])} + k_H^{A} \frac{[PhNO][H^+]}{1+[H^+]^2/K_1K_2+[H^+]/K_2} \quad (16)$$

The K_z value for *m*-aminobenzoic acid was considered to be 0.1 (calculated from thermodynamic values[35]) and to be negligible for ortho and para aminobenzoic acids.

pK_a Determination: The apparent values of pK_a were determined following the spectrophotometric method of Albert and Serjeant.[36] The apparent pK_a of *p*-chloro- and *p*-methylaniline in methanol 15 wt%, μ=0.5 M, (KCl) 25 °C were 3.71 and 4.99 respectively. The apparent pK_a of aniline in methanol 53 wt% was 3.18.

Preparation of Tetraalkylsilanes from Trichloromethylsilane and Trioctylaluminum

Edward T. SABOURIN* and Anatoli ONOPCHENKO
Chevron Research Company, Richmond, California 94802, U.S.A.
(Received October 13, 1988)

The synthesis of methyltrioctylsilane has been achieved in a single-step from commercially available trichloromethylsilane and trioctylaluminum. Co-products resulting from alkyl group redistribution are minimized by addition of sodium or lithium halides. Use of potassium or rubidium halides drastically changes the course of the reaction to produce methyldioctylsilane as the major product.

Silicon derivatives of hydrocarbons have great potential as high-performance lubricants and hydraulic fluids because of their excellent thermal stability. Tetraalkylsilanes with one short chain and three long chains are of particular interest because they exhibit excellent viscosity characteristics over a wide temperature range and have low pour points. Previously, such compounds have been prepared using Grignard or alkyllithium reagents with chlorosilanes,[1,2] or via hydrosilation of 1-alkenes.[3] The Griganard procedure is cumbersome and not suited to large scale production. The hydrosilation procedure is more elegant, but methylsilane, the required starting material, is not available in commercial quantities and would require a difficult reduction step. Therefore, we sought a route based on commercially available starting materials.

Methyltrioctylsilane was selected as the initial target. We considered the reaction of trioctylborane with trichloromethylsilane (Eqs. 1 and 2).

$$6\,RCH{=}CH_2 + B_2H_6 \longrightarrow 2\,(RCH_2CH_2)_3B \quad (1)$$

$$CH_3SiCl_3 + (RCH_2CH_2)_3B \longrightarrow CH_3Si(CH_2CH_2R)_3 + BCl_3 \quad (2)$$

Serveral attempts at this sequence confirmed that step 2 was not feasible as predicted by thermodynamic calculations.[4] We then turned to the reaction of trialkylaluminums with chlorosilanes, a thermodynamically favored process (Eq. 3).[4]

The reaction of trichloromethylsilane with trialkylaluminum compounds is best represented by a series of equilibria (Eq. 4).

$$CH_3SiCl_3 + Al(C_8H_{17})_3 \longrightarrow CH_3Si(C_8H_{17})_3 + AlCl_3 \quad (3)$$

$$CH_3SiCl_3 + R_3Al \rightleftarrows CH_3RSiCl_2 + R_2AlCl \rightleftarrows CH_3R_2SiCl + RAlCl_2 \rightleftarrows CH_3R_3Si + AlCl_3 \quad (4)$$

The reaction of trialkylaluminum compounds with chlorosilanes was first reported by Jenkner who also noted that the addition of one mole of alkali metal chloride per mole of aluminum shifted the equilibrium to the right by formation of metal tetrachloroaluminates.[5] Russell approached the equilibrium from the right by reacting aluminum chloride with tetraalkylsilanes.[6] Hungarian and Russian researchers studied the equilibria starting with alkylaluminum chlorides or sesquichlorides trying to maximize the intermediate products.[7-9] In all the previous studies, only results with methyl or ethyl groups were reported. When methyl and ethyl compounds were used simultaneously, some alkyl-alkyl interchange was noted in addition to the alkyl-chloro exchange.[9]

We now report the results of our use of longer alkylaluminums. The chemistry is much more complex than indicated by Eq. 4. In addition to the intermediates depicted above, the following types of co-products were observed:

1. Products from silicon to silicon alkyl transfer.
2. Products containing silicon-hydrogen bonds.
3. Dimers of the initial alkyl group.
4. Silanes containing alkyl groups derived from dimers.
5. Silanes containing alkyl groups derived from impurities in trioctylaluminum.
6. Products with silicon-oxygen bonds.

Experimental

Chromatographic analyses were performed on a Hewlett-Packard 5880A (FID) instrument using a 25 m, 2% OV-101, fused silica capillary column programmed from 50 to 300 °C at 8 °C min^{-1}. The IR spectra were recorded on a Perkin-Elmer Model 597 spectrometer. GC/MS data were obtained on a Finnigan 4510 system with an electron impact source at 70 eV. Trioctylaluminum (Ethyl Corp.) and alkylchlorosilanes (Aldrich and Petrarch) were used as received.

General Procedure. Reactions were carried out in a thick-walled glass reactor connected to a nitrogen pressure manifold with Fisher-Porter compression fittings. Similar fittings connected a side arm to a wide-bore Hoke valve and a rubber septum. Heat was supplied with a heating mantle and controlled with a West-800 controller. An egg-shaped magnetic stirrer supplied adequate agitation.

The reactor was charged with alkali metal halide and connected to the nitrogen system. The system was purged by pressuring to 30 psig and venting ten times. Trioctylaluminum was added via syringe followed by trichloromethylsilane. Stirring and heating were started. Approximately 25—35

minutes were required to attain temperature. Reaction time was measured as the time at temperature. When the reaction was terminated, the vessel was allowed to cool to room temperature and vented. At this point, the reaction mixture was not pyrophoric. The reactor was disconnected from the nitrogen system and an equal volume of heptane was added. Methanol was added to quench unreacted alkylaluminum and to convert any remaining chlorosilanes to methoxysilanes. The mixture was transferred to a separatory funnel. Water was added to facilitate separation of the layers. The organic layer was dried over magnesium sulfate, filtered, and stripped on a rotary evaporator. The crude product was analyzed by gas chromatography.

Results and Discussion

Physical Aspects of the Reaction. Previous work had been performed in metal autoclaves. Our initial work has employed a thick-walled glass reactor. While the pressure limitations of the glass undoubtedly reduced yields and possibly rates because a significant portion of the volatile trichloromethylsilane remained in the vapor space, the system proved excellent for observing the physical state of the reaction mixture. In a typical run, as the mixture of salt, trichloromethylsilane and trioctylaluminum is heated the following sequence of events occurs:

1. As the boiling points of the volatile components are exceeded the pressure rises and refluxing occurs. The salt remains as a discrete solid until a minimum reaction temperature, characteristic of the particular salt, is attained.
2. At reaction temperature the salt dissolves. The pressure starts to drop.
3. The liquid phase becomes cloudy. If the stirrer is stopped two liquid phases separate rapidly.
4. With time the upper phase diminishes while the lower phase grows.

During this period the pressure remains relatively constant.

5. The upper phase reaches a minimum. The pressure once again begins to drop as the upper phase begins to increase again. When the amount of upper phase stabilizes, the reaction is terminated.
6. Upon cooling, the lower layer solidifies.

Figure 1 gives a graphical representation of this behavior. The relative time periods for the various parts of the sequence vary with reaction temperature and the type and amount of salt employed.

The lower liquid phase obviously is some sort of complex between the salt and the other constituents. It does not appear to be a simple complex of trioctylaluminum and salt, since heating trioctylaluminum and sodium chloride for one hour at 180 °C showed no evidence of dissolution of the salt. Since alkylaluminum chlorides are much stronger Lewis acids than trialkylaluminum and are well-know to form complexes with alkali metal halides,[10] it would appear that initial exchange of alkyl and chloro

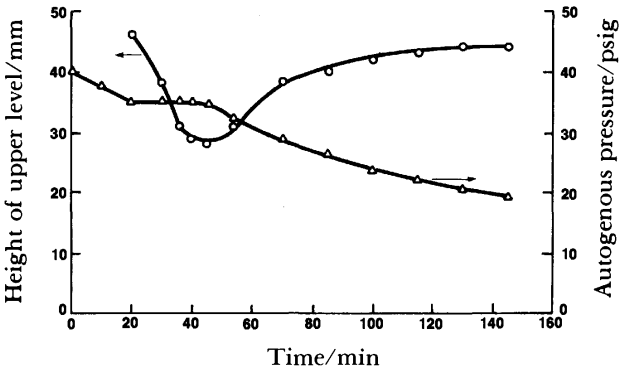

Fig. 1. Profile of autogenous pressure (△) and height (○) of product containing layer with time.

groups are required before the complex can form. The cause of the period of static pressure during the growth of the complex is not understood at this time. If the reaction is terminated at the maximum complex formation (minimum upper layer), the product distribution is similar to that for a typical longer run; but yield is lower.

Effect of Amount of Salt. Runs listed in Table 1 illustrate the effect of the amount of added sodium chloride. Only those reaction products which are severely altered are shown. With no added sodium chloride, extensive transfer of alkyl groups from silicon to silicon occurs. Addition of 0.5 mol of salt per mole of aluminum greatly improves the selectivity to methyltrioctylsilane. Lesser amounts have little effect. Larger amounts show no further improvement. Varying the reaction time between 1 and 6 hours produces no major change in the product distribution. The main effect of sodium chloride appears to be inhibition of alkyl group redistribution rather than shifting the equilibrium as suggested by Jenkner.[5]

Alkyl group redistribution could result from postalkylation equilibrium (Eq. 5).

$$(CH_3)_4Si \rightleftarrows (CH_3)_3(C_8H_{17})Si \rightleftarrows (CH_3)_2(C_8H_{17})_2Si \rightleftarrows CH_3(C_8H_{17})_3Si \rightleftarrows (C_8H_{17})_4Si \quad (5)$$

Alternatively, a prealkylation equilibration of the chlorosilanes could cause the same product distribution (Eq. 6).

$$SiCl_4 \rightleftarrows CH_3SiCl_3 \rightleftarrows (CH_3)_2SiCl_2 \rightleftarrows (CH_3)_3SiCl \rightleftarrows (CH_3)_4Si \quad (6)$$

Aluminum chloride is a known catalyst for the equilibration depicted in Eq. 5.[6] To assess the magnitude of such a reaction, 50 mmol of methyltrioctylsilane and 10 mmol of aluminum chloride were heated to 160 °C for one hour. Gas chromatography revealed that the product contained only 59% of the initial silane. Repetition of the experiment with

	3	3 h	24.8	—	4.5	—	18.2	3.1	49.4

a) Tentative assignments made by sequentially spiking a sample of 1-octene with the suspected components. $(CH_3)_2SiCl_2$ could not be separated from CH_3SiCl_3 under the conditions employed. b) 100 mmol $(C_8H_{17})_3Al$, 100 mmol NaCl, 89 mmol CH_3SiCl_3, reaction temperature 190°C. c) 50 mmol $(C_8H_{17})_3Al$, 40 mmol CH_3SiCl_3, reaction temperature 190°C.

10 mmol of added sodium chloride gave a product with 76% starting silane. This indicates that sodium chloride is indeed effective in stopping alkyl redistribution. Presumably, in a typical reaction, very little free aluminum chloride ever forms because of prior complexation with the alkali metal salt leading to the direct generation of the inactive tetrachloroaluminate.

To determine if Eq. 6 was of any importance, the composition of the vapor phase of runs with and without sodium chloride was determined by gas chromatography. Table 2 summarizes the results. Some other silicon compounds not present in the feed do form under the reaction conditions. The relative proportions are about the same, with or without sodium chloride, and remain roughly constant throughout the reaction. The isobutene present is derived from impurities in the trioctylaluminum. In the absence of sodium chloride the 1-octene in the vapor phase is gradually isomerized.

These experiments indicate that a small portion of the alkyl redistribution is due to prealkylation equilibria; but, major redistribution is the result of postalkylation equilibria when insufficient sodium chloride is present.

Effect of Type of Salt. While the literature indicated that the alkali metal halides were interchangeable,[5] the obvious importance of the complex to the reaction suggested that different salts should have some effect. The strength of the various alkali metal halides as complexing agents for alkylaluminums increases with the increasing radius of the cation and with the decreasing size of the halide ion.[11] This is usually manifested in a lower temperature of complex formation. If the reaction complex could be formed at lower temperature, the reaction might proceed with greater selectivity.

Based on this premise, reactions were carried out using sodium, potassium, or rubidium chloride with trioctylaluminum and trichloromethylsilane wherein the mixtures were heated at a uniform rate until the salt dissolved. At this point the temperature was stabilized and held. The dissolution temperature and the approximate time from dissolution to separation of the two liquid phases followed the expected trend (Table 3). However, analysis of the products of the potassium and rubidium runs revealed that methyltrioctylsilane was no longer the major product! Infrared showed a strong Si–H absorption at 2120 cm^{-1}. Co-injection with an authentic sample confirmed the major product as methyldioctylsilane.

A series of runs at constant temperature varying both the cation and the halide shows that both affect the product distribution (Table 4). The tendency to form methyldioctylsilane instead of methyltrioctylsilane increases in the sequence Li<Na<K<Rb and in the sequence I<Br<Cl. The fluoride run is somewhat out of line. However, fluoride frequently gives anomalous behavior when compared to the other halides. A decrease in the amount of alkyl redistribution also occurs in the same sequences. Mixtures of two salts gave product distributions intermediate between the individual salts.

Runs with potassium or rubidium chloride produce two to three times as much octene dimers (mainly 2-hexyl-1-decene by GC/MS) as the analogous runs with sodium or lithium chloride. Also, no traces of alkylation by the $C_{16}H_{33}$ group are found when potassium or rubidium salts were present. This suggests that these complexes prefer to expel dimeric molecules as the olefin at some stage of the reaction leaving aluminum hydride residue. Presumably, the hydride is then transferred to silicon in the same manner as an alkyl group. The relatively large loss of octyl groups to dimers probably accounts for larger amounts of partially alkylated silanes rather than inability of potassium to shift the equilibrium.

The relative distribution of the silicon compounds in the vapor phase for potassium runs was similar to that of a sodium run indicating no drastic change in the prealkylation equilibria. Only traces of 1-octene were found. Two closely spaced, unidentified peaks comprised approximately 45% of the vapor phase. Based on gas chromatography retention time, a crude estimate of the molecular weight would be ca. 140—150. Unfortunately, the materials were not stable. No trace could be found after work up.

Reactivity of Silicon-Hydrogen Bonds. The presence of silicon-hydrogen bonds in the vapor phase, even in the sodium chloride runs raised the question of the ability to replace the hydrogen with an alkyl group. Dichloromethylsilane produced predominantly methyltrioctylsilane (Eq. 7).

$$CH_3SiHCl_2 + Al(C_8H_{17})_3 \longrightarrow \underset{43\%}{CH_3(C_8H_{17})_3Si} + \underset{25\%}{CH_3(C_8H_{17})_2SiH} \quad (7)$$

also produced some alkylation (Eq. 8); but, the reaction of Si–H bond is definitely much slower than the Si–Cl bond. In this case the sodium chloride never changes from its granular state and probably does not enter into the reaction.

$$C_6H_{13}SiH_3 + Al(C_8H_{17})_3 \longrightarrow \underset{31\%}{C_6H_{13}(C_8H_{17})SiH_2} + \underset{20\%}{C_6H_{13}(C_8H_{17})_2SiH} \quad (8)$$

Effect of Impurities in the Feed. The trichloromethylsilane used in this study was chromatographically pure. The vapor phase results indicate that a near steady state concentration of the disproportionation products is achieved very quickly. Since these same disproportionation products are the impurities usually found in technical grade trichloromethylsilane, its use would have no drastic effect.

In the case of trioctylaluminum the effect of impurities is much greater. Since each desired product molecule contains three octyl chains derived from trioctylaluminum, each non-desired alkyl chain can waste up to two octyl chains by its reaction, i.e. one mole percent impurity in the trioctylaluminum produces three mole percent impurities in the product. Preparation of trioctylaluminum is generally accomplished by displacement of isobutylene from triisobutylaluminum with 1-octene. Failure to displace all the isobutyl groups in the preparation of the trioctylaluminum can lead to silanes containing one or more isobutyl substituents. Coinjection with authentic diisobutylmethyloctylsilane and isobutylmethyldioctylsilane confirmed the presence of traces of the former and up to 2% of the latter in a typical run.

Vinylidene impurities present in 1-olefins represent another source of impurity in the trioctylaluminum. In the case of 1-octene this results in the introduction of 2-ethylhexyl substituents. The presence of 2-ethylhexyl-containing silanes was confirmed by independent synthesis and co-injection. Use of longer chain alkylaluminums would exacerbate this problem.

Oxygen Containing Co-Products. In this work any excess of unreacted alkylaluminum was generally quenched with water or methanol. This also hydrolyzes any partially converted chlorosilanes to disiloxanes or methoxysilanes.

Synthesis and Characterization of Some New Organophosphonates and Their Adducts with Some Metal Salts

Ebtsam A. SAAD and Ramadan M. RAMADAN*,†
Chemistry Department, Faculty of Science, Ain Shams University, Cairo, Egypt
(Received November 4, 1988)

The synthesis of the new monobasic organophosphonates $(C_2H_5O)RPO(OH)$, R=benzyl, benzoyl, or butanoyl group, by the hydrolysis of the neutral esters $(C_2H_5O)_2RPO$ is reported. The IR spectra of the new ligands showed that they were existed in solutions as dimers. The p*K*a values in 50% aqueous ethanol found to be 4.46, 3.98, and 3.48 for the benzyl, butanoyl, and benzoyl derivatives, respectively. These values were consistent with the calculated π-electron charge density. Solid complexes of the benzoylphosphonate with Pr, Eu, Er, and Co metal ions as well as the benzyl-Eu complex were isolated. The complex ratios were found to be 1:2 metal to phosphonate dimer. The octahedral arrangements were completed by the presence of a coordinated bidentate NO_3 group. Ionic properties of these complexes were ruled out from conductometric measurements. The IR spectra as well as the calculated π-electron charge density for the benzoyl complexes showed that the preference site for complex formation was from the carbonyl oxygen in contrast with the benzyl one where complexation through the phosphoryl group in addition to the hydroxyl oxygen.

It is well-established that the organophosphorus compounds of the type $(RO)_2PO(OH)$, $(RO)PO(OH)_2$, (RO)R'PO(OH), R'PO(OH)$_2$, and R'HPO(OH), where R and R' are alkyl or aryl group, exist in dimeric forms.[1] These compounds were used as complexing agents for various transition and inner transition metal salts.[2] Neutral alkyl esters of phosphonic acid and phosphoric acid were also used in the formation of adducts with metal salts. However, isolation of crystalline compounds were generally not easily to perform.[3]

Here, we report the preparation of the new monobasic organophosphonates $(C_2H_5O)RPO(OH)$, R=benzyl, benzoyl, and butanoyl group as hydrolyzed products of the neutral esters $(C_2H_5O)_2RPO$. The IR spectra of these ligands and their complexes with some lanthanoid metals are also reported.

Experimental

The infrared spectra of the organophosphonates and their metal adducts were performed on a Perkin-Elmer infrared spectrophotometer Model 1430 with the use of KBr disc technique or in carbon tetrachloride solutions. Liquid film spectra (NaCl cell, 1.0 mm) were also carried out for the liquid ligands.

A Pye-Unicam pH-meter with expandable scale Model 290 Mk2 was used for the potentiometric titrations. It was connected to a Pye-Unicam glass combination electrode and was calibrated by using universal buffers.

The phosphonate ligands $(C_2H_5O)_2RPO$, R=benzyl, benzoyl, and butanoyl group, were purchased from Alfa Products, 99% purity, and were used without further purifications. Praseodymium, europium, erbium, and cobalt nitrates were supplied from British Drug Houses Ltd. Sodium hydroxide was of AnalaR grade. All the solvents used were purified by using the standard methods[4] and stored under nitrogen atmosphere.

Hydrolysis of the neutral phosphonates were carried out by using the following procedure:[5] The phosphonate reagent was mixed with aqueous sodium hydroxide solution in molar ratio of 1:6 (phosphonate:hydroxide). The mixture was stirred at 80 °C for 5 h in a sealed flask under nitrogen. The solution was left to cool and then shaked with benzene several times to remove the formed alcohol and any unhydrolyzed ester. The aqueous layer was separated and acidification with HCl was carried out to isolate the ligand in the acid form which was then extracted in benzene. The organic layer was separated and the acid was recovered by evaporating the benzene and any remaining alcohol by vacuum distillation.

The acid ionization constants of the new ligands were determined by titration of fixed amounts (20 ml) of

phosphonate solutions in 50 and 25% ethanol-water mixtures with standardized sodium hydroxide solutions at 25 °C. A stream of nitrogen gas was flushed through the solution during the titration. The pK_a values were computed by using the corrected pH values.[6] The results are given in Table 1.

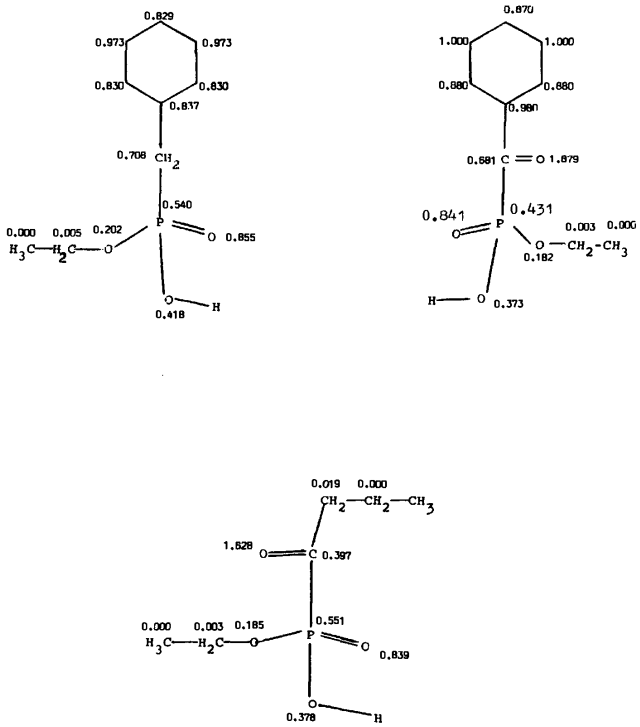
Solid complexes of the benzoyl phosphonate derivative with Co, Pr, Eu, and Er metal nitrates as well as the benzyl phosphonate with europium nitrate were synthesized by mixing equimolar amounts of both reagents with slight excess of the ligand in 50% aqueous ethanol and left to stand at room temperature for 24 h. (The benzyl complex took longer time ca. 40 h with the formation of white amorphous solid). White to pale yellow crystalline needles were isolated, washed with ethanol and left to dry under vacuum. Attempts to prepare the butanoyl analogous were unsuccessful; they decomposed above 0 °C. Elemental analysis were consistent with 1:2 adduct formations. Results for elemental analysis as well as melting points are given in Table 2.

Conductometric measurements were performed on a Griffin conductance bridge Model PJK-301. The conductance of 0.5 g metal complex dissolved in 50 ml of nitrobenzene or methylene chloride solvent was measured at different time intervals at 25 °C.

Results and Discussion

Hydrolysis of the organophosphonate compounds $RPO(OC_2H_5)_2$, R=benzyl, benzoyl, or butanoyl group, by sodium hydroxide solutions led to the formation of the monobasic $RPO(OH)(OC_2H_5)$ derivatives. The infrared spectra of these phosphonate compounds were measured from 4000—600 cm^{-1} in CCl_4 solutions or as a liquid film spectra. All the three compounds showed strong bands in the range of 2880 cm^{-1} (Table 1) which were indicative of the presence of bonded OH groups.[1,5,7] Dilute CCl_4 solutions did not show any stretching frequency due to free OH group. The phosphoryl region showed a lower field shift from the free P=O region as expected for bonding phosphoryl group.[7] Thus, these compounds would have dimeric structures with arrangements, presumably, similar to that proposed previously.[1]

The acid ionization constants of the phosphonate ligands were calculated from potentiometric titrations of known amounts of the phosphonate against standardized sodium hydroxide solutions. The pK_a values, listed in Table 1, clearly show that the acidity increases in the order benzyl<butanoyl<benzoyl derivative. This can be attributed to the effect of the R group on the electron density of the phosphorus atom and consequently on the ionization of the OH moiety. The π-electron densities on the different atoms of the three phosphonates, calculated by the use of simple HMO method,[8] are shown in Scheme 1. The π-electron density on the hydroxyl oxygen is decreased in the order benzyl>butanoyl≈benzoyl. This order is consistent with the order of increasing acidity and accounts for the closest pK_a values of both butanoyl and benzoyl derivatives, 3.98 and 3.48, respectively.



Scheme 1. The π-electron density on the different atoms of the benzyl-, benzoyl-, and butanoylphosphonate derivatives.

Addition of the new phosphonate ligands to solutions of Co(II), Pr(III), Eu(III), and Er(III) nitrates resulted in the formation of the corresponding metal complexes. The pH of the solutions was found to be decreased by time. Attempts to prepare the butanoyl metal complexes were unsuccessful due to their decomposition above 0 °C. The solid complexes were air stable white to pale yellow needle crystals (the benzyl derivative was amorphous solid). The elemental analysis, melting points, and the important IR data of the new complexes are listed in Table 2. The stoichiometry of these complexes were found to be 1:2 metal to phosphonate dimer. The formation of these complexes was accompanied by the release of two protons per one complex as found from solvent extraction and potentiometric analysis of these and other similar complexes.[9]

The infrared sectra of the new complexes in either CCl_4 solutions or in solid state (KBr disc technique) showed that two different types of phosphoryl groups present in the same spectrum. One of them was assigned to the P=O bonded to the OH group (hydrogen bonding) with about the same position as in case of the free ligand. The other has a position dependent on the type of the complex. In case of the benzyl complex, the second phosphoryl group showed lower field shift due to bonding to metal (donation to metal ion was stronger than hydrogen bonding). The interesting facet was the case of the benzoyl complexes. There, the second phosphoryl group showed upfield shift referred to unbonded P=O group, while the carbonyl stretching frequency exhibited a lower field shift. From Scheme 1, one can see that the carbonyl oxygen of the benzoylphosphonate derivative carried higher π-electron density than the phosphoryl oxygen. Thus, it can be concluded that the CO group of this ligand might be involved in the complex formation and donation from its site to the metal ion is predominant rather than from the phosphoryl oxygen. Recall that the synthesis of the benzylphosphonate complex, which has no CO group, took longer time and gave amorphous solid. It is not obvious that why the butanoyl derivative did not form stable complexes. Presumably, the presence of the phenyl group in the benzoyl derivative stabilized the complex formation.

The new complexes were found to be neutral species where a nitrate group was linked to the metal as a bidentate ligand. Effect of nitrate concentration on the extraction of these complexes in hexane revealed the presence of one NO_3 group in the complex sphere.[9] Also, the IR spectra of these complexes showed stretching frequencies attributed to such linkage,[7,10] Table 2. The formation of neutral complexes with the trivelent lanthanoid metal ions is obvious. In case of Co(II) complex it should be ionic. However, conductometric measurements for all cmplexes in nitrobenzene or CH_2Cl_2 solutions gave conductance due to nonelectrolyte materials which ruled out the presence of ionic nitrate. Two possibilities for the Co complex, thus, can be considered. First, the complex is very weak electrolyte where detection of conductance can not be observed. The second possibility is that cobalt in this complex existed with a formal +3 charge presumably due to delocalization of one of its electrons onto the ligand through the carbonyl moiety. The latter assumption does not seem unreasonable; heating the cobalt(II) semiquinone complex (Co_4(3,5-di-*t*-butylsemiquinone)$_8$) with bipyridyl resulted in the formation of the complex (3,5-di-*t*-butylcatecholato)-(3,5-di-*t*-butylsemiquinone)(bipyridyl)cobalt(III). The formation of Co(III) species was confirmed from an X-ray crystal structure determination of the complex.[11] Also, reaction of $Cr(CO)_6$ (zerovalent metal) with 1,2-chrysenequinone gave the semiquinone derivative Cr(chrysenesemiquinone)$_3$ with a formal +3 charge on the metal part.[12]

According to the available data the comlexes may have octahedral arrangements where the metal is linked to two ligands of the phosphonate dimer as well as a bidentate nitrate group. However, as a referee suggested, we can not rule out possibility of formation of rare earth complexes with higher coordination number than six. Here, the ligand dimer could act as a tridentate where it attached to the metal from a phosphoryl and a carbonyl group of one moiety and the OH group of the other moiety with the release of a proton.

The authors thank Prof. J. C. Merlin and Ms. R. Genevieve, Faculty of Science, Claud Bernard, Lyon 1, France, for their assistance in the IR measurements.

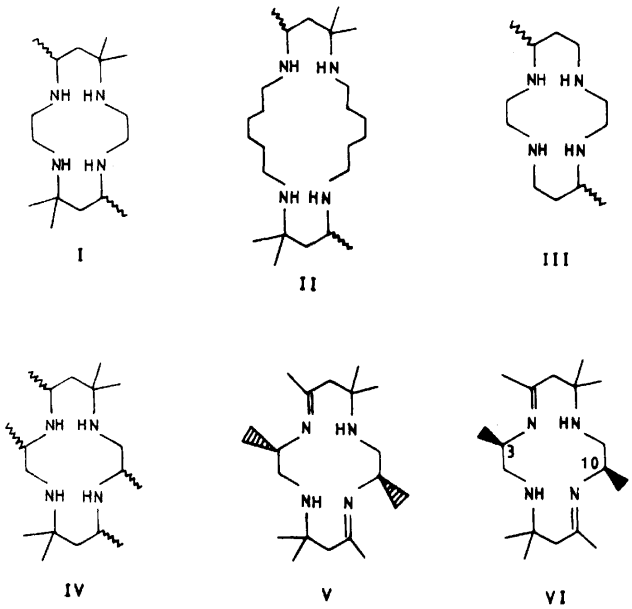
(Received January 20, 1989)

Reduction of 3,5,7,7,10,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradeca-4,11-diene (Me8[14]diene) with sodium borohydride yields three diastereomeric Me8[14]anes. These diastereomers can be separated through fractional crystallization from xylene. The structure of these isomers has been established on the bseis of their NMR spectra. The structure of one isomer has been confirmed by X-ray crystallography.

The importance of polyaza macrocycles is now well-documented and needs no elaboration. These macrocycles and their metal complexes present intriguing stereochemical problems. The stereochemistry of Me6[14]anes[1] (**I**), Me6[22]anes[2] (**II**), and Me2[14]-anes[3,4] (**III**), all of which give two isomers, the C-meso and C-rac forms, has been quite comprehensively investigated. No isomers of Me8[14]ane (**IV**) have been isolated, although this macrocycle with four chiral centers is expected to give several isomeric species. However, some reports have indeed appeared on the isomeric nickel(II) complexes of Me8[14]anes.[5] These species have been prepared by the reduction of the nickel(II) complex of 3,10-*C-rac*-Me8[14]diene (**V**). In this paper we report the isolation and characterization of three isomeric 3,10-*C-meso*-Me8[14]anes.



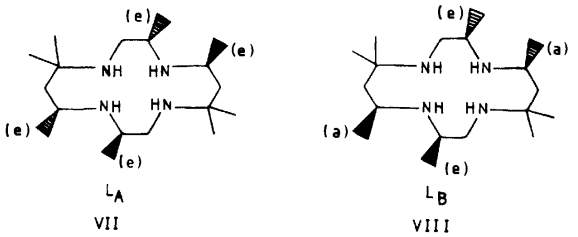
Results and Discussion

Synthesis. 1,2-Propanediamine reacts with acetone to yield Me8[14]diene, an octamethyl derivative of the 14-membered tetraaza macrocycle. The reaction is completely stereospecific and yields Me8[14]diene (**VI**) with the methyls at 3,10 positions in a meso-configuration. This assignment has been confirmed by X-ray studies.[6] The 3,10-*C-rac*-isomer (**V**) cannot be recovered from the mother liquor. The IR spectra of **VI** shows $\nu_{C=N}$ band at 1660 cm^{-1}. This C=N bond can be readily reduced with sodium borohydride to yield the corresponding saturated macrocycles. The infrared spectrum of the product shows no band around 1650 cm^{-1} assignable to $\nu_{C=N}$ and shows a ν_{NH} band at 3200 cm^{-1}. The reduction of **V**, which has a 3*S**,10*R** configuration, generates two new chiral carbons at positions 5 and 12. During the course of reduction, the 3*S**,10*R** configuration is retained. As a consequence, 3,10-*C-meso*-Me8[14]diene (**V**) would give three isomeric 3,10-*C-meso*-Me8[14]anes. These isomers, L_A, L_B, and L_C have been separated by fractional crystallization from xylene. Each isomer gave (i) a single spot on thin-layer chromatograms (TLC) using 80:20% methanol–chloroform mixture as a developing solvent, (ii) a distinct mp, and (iii) showed differences in solubilities in some common solvents like chloroform, methanol, xylene, and trifluoroacetic acid. Isomer L_A showed very low solubility in these solvents except for trifluoroacetic acid.

Structure Assignment. On the basis of the overall macrocyclic structure, some broad conclusions about the expected patterns of the ^1H NMR spectra can be made. The most prominent feature of ^1H NMR spectra of these macrocycles would be that the geminal dimethyl groups would give two singlet signals corresponding to six protons each. The chiral methyl groups should appear as doublets due to coupling with the protons attached to the adjacent carbon. The upfield doublet would be due to an equatorially oriented methyl group, while the downfield doublet would be due to an axially oriented methyl group. The various methylene protons on the macrocyclic ring would appear as multiplets due to complicated coupling patterns. On the other hand, on the basis molecular models, the chiral methyls can be assigned to be equatorial or axial. In each molecular model structure, the ring is placed in a chair form with minimum hydrogen–hydrogen interactions and two adjacent carbons in a gauche conformation. Compar-

ison of the predicted space orientations with the conclusions drawn from ^{1}H NMR spectra, permit assignment of structures to these isomers. A similar method has been successfully used in assigning the isomeric structures of the Co(III) complexes with *C-meso*- and *C-rac*-Me$_2$[14]anes.[7,8]

The 400 MHz ^{1}H NMR spectrum of isomer $\mathbf{L_A}$ (Fig. 1a) shows a sharp methyl singlet at δ 1.6 and an unresolved multiplet at δ 1.7. The singlet at δ 1.6 can be assigned to an equatorial methyl of the gem-dimethyl groups. The other methyl of the gem-dimethyl which is expected to appear at a position downfield in comparison, overlaps with doublets arising from the methyls at C_3, C_5, C_{10}, and C_{12} positions. This type of pattern is suggestive of a completely symmetrical C-meso structure in which C_3, C_5, C_{10}, and C_{12} methyls are all equatorial. This conclusion is based on the fact that a similar assignment has been made for [Ni(tet'a')](ClO$_4$)$_2$[9] (**I**); where the two chiral methyls have an equatorial orientation. It has been concluded that those isomers which show only one methyl singlet for the gem-dimethyl group and an unresolved multiplet, must be meso or racemic diastereomers with all the methyls equatorial. Since in the case of Me$_8$[14]anes, C_3 and C_{10} must have only a meso-configuration by virtue of the method of the synthetic procedure adopted,[6] occurence of a racemic diastereomers is ruled out. Therefore, isomer $\mathbf{L_A}$ is assigned a completely C-meso configuration with the ring lying in a chair form and the four chiral methyls in an equatorial position (**VII**). This requires these centers to be C_3,*S**; C_5,*S**; C_{10},*R**; C_{12},*R**. An X-ray crystal structure determination of the cobalt(III) complexes of $\mathbf{L_A}$ showed complete agreement with the above configuration of the chiral methyls. Details of this work will be published elsewhere.



$\mathbf{L_A}$ VII $\mathbf{L_B}$ VIII

Isomer $\mathbf{L_B}$ shows two singlets at δ 1.08 and 1.16 (Fig. 1b) corresponding to 6 protons each that can be assigned to the gem-dimethyl groups. The spectrum also shows two doublets at δ 0.99 and 1.03, each corresponding to 6 protons. This requires that the C_3, C_{10} and C_5, C_{12} methyl groups should be in a pairwise equivalent configuration. The upfield doublet at δ 0.99 can be assigned to equatorial methyls and downfield doublet at δ 1.03 to axial methyls. A diequatorial-diaxial arrangement is possible in the structure in which the C_5, C_{12} methyls occupy a meso-configuration (**VIII**) opposite to that in $\mathbf{L_A}$.

The structure assigned to $\mathbf{L_B}$ on the basis of its ^{1}H NMR spectra is in complete agreement with the one obtained from X-ray crystallographic studies. A perspective view of the molecule is presented in Fig. 2.

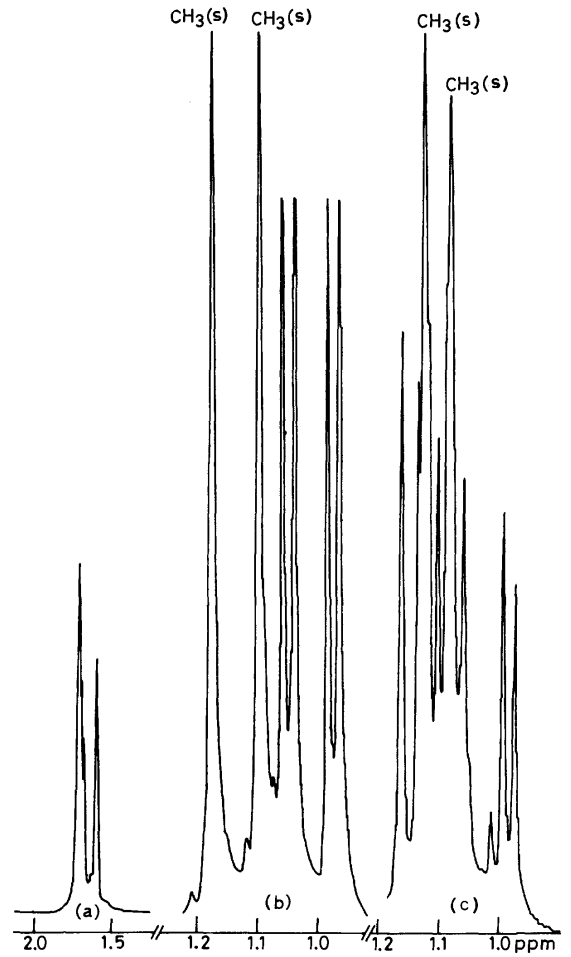


Fig 1. 400 MHz ^{1}H NMR spectrum of $\mathbf{L_A}$ (in CF_3COOH), $\mathbf{L_B}$, and $\mathbf{L_C}$ (both in $CDCl_3$).

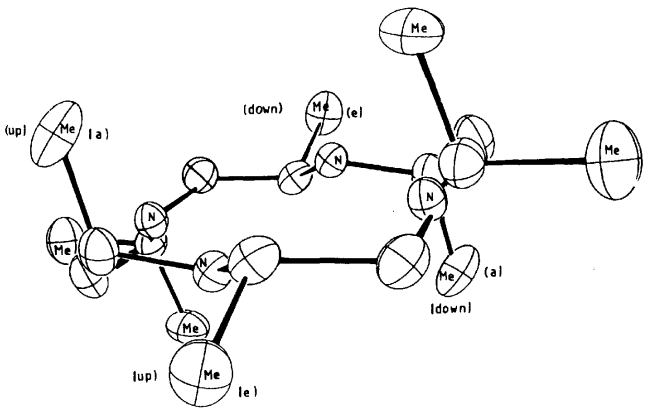

Fig 2. ORTEP perspective view of $\mathbf{L_B}$. Atoms are represented at 50% probability level. Hydrogen atoms have been omitted for clarity.

Included in the unit cell is a water molecule of solvation sitting on a crystallographic two fold center. The molecule is located at an inversion center. This determination shows that the ring lies in a chair form. The bond distances, bond angles, and torsion angles for $\mathbf{L}_B$ are presented in Tables 1—4.

Isomer $\mathbf{L}_C$ shows two singlets at δ 1.07 and 1.11 (Fig. 1c) corresponding to six protons, each assignable to gem-dimethyl groups. The spectrum also shows three doublets at δ 0.99, 1.08, and 1.14 in the ratio of 2:1:1, corresponding to 6, 3, and 3 protons each. The signal at δ 0.99 can be assigned to a pair of equivalent equatorial methyls. The δ 1.08 doublet appears due to an equatorial methyl and the δ 1.14 doublet due to an axial methyl. Such an arrangement is possible if the C_5, C_{12} methyls are in a diequatorial configuration and C_3, C_{10} methyls in an equatorial-axial configuration (IX). The chiral centers then have the forms: C_3,*S**; C_5,*S**; C_{10},*R**; C_{12},*R**. This assignment of the configuration of chiral methyl groups is confirmed by the X-ray structure determination of the Nickel(II) complex of $\mathbf{L}_C$. Details of this work will also be published elsewhere.

^{13}C NMR Spectra. ^{13}C NMR spectra gives a separate resonance for each stereochemically distinct carbon atom. Therefore, the method is a sensitive means of characterizing isomers.[10] However, a major problem encountered is that the resonances observed for the methyl carbons cannot be assigned to a particular group on the basis of ^{13}C NMR spectra alone. This is a real limitation on the method for assigning isomeric structures.[11]

The ^{13}C NMR spectra (Figs. 3—5) of the three isomers, $\mathbf{L}_A$, $\mathbf{L}_B$, and $\mathbf{L}_C$ show nine, nine and eighteen resonances respectively. The macrocycles contain

X XI XII

eighteen carbons each. In case of L_A and L_B, only nine peaks are observed due to pairwise equivalence of carbon atoms. This observation is in support of the symmetric 'all equatorial' and 'diaxial-diequatorial' arrangements as has already been assigned on the basis of ^1H NMR spectra. The symmetry of structure L_B has also been confirmed by X-ray crystallography. In contrast, isomer L_C gives eighteen peaks which corresponds to eighteen nonequivalent carbon atoms indicating no symmetry in the molecule.[11-13] The results of ^1H NMR spectra also show that this isomer lacks symmetry. These conclusions are supported by similar observations with Me_4[14]dienes. Two isomeric nickel(II) complexes of Me_4[14]diene (ttcd), *Aα*-$[Ni(ttcd)]^{2+}$ (**X**) and *Bα*-$[Ni(ttcd)]^{2+}$ (**XI**) both containing fourteen carbon atoms show fourteen and seven peaks respectively.[11] Similar observations have been obtained in the case of two isomers[12] of *trans*-$[Co([15]ane)Cl_2]^+$ (**XII**). In another study, the *C-meso*- and *C-rac*-Me_6[22]ane (**II**) are also found to show twelve peaks, equivalent to half the number of total carbon atoms[2] due to the pairwise equivalence of each carbon atom.

In case of ligand L_A and L_B, the first four peaks can be assigned to the eight carbons (pairwise equivalent) of peripheral methyl groups and the next five peaks to the remaining ten carbons (pairwise equivalent) in the ring. On the other hand, the first eight peaks observed in the case of L_C correspond to the eight nonequivalent carbon atoms of peripheral methyl groups and the remaining ten resonances to ten different carbon atoms of the macrocyclic ring. The range of chemical shifts assigned for the peak positions of methyl carbons (δ 15—30) and ring carbons (δ 40—65) is the one which has already been reported for similar type of ligands and for their complexes.[11]

Experimental

Microanalysis, ^{13}C NMR, and the mass spectral measurements were carried out at the University of Stirling, Scotland. 400 MHz ^1H NMR were recorded at the Regional Sophisticated Instrumentation Centre, Central Drug Research institute, Lucknow, India. IR spectra were run on a Beckman IR 20 Spectrophotometer as KBr discs. TLC was performed on 8×2.5 cm glass plates coated with a 0.25—0.5 mm layer of silica gel (BDH, without binder).

Synthesis: 3,10-*C*-*meso*-Me$_8$[14]diene (**VI**) was prepared as described.[6] 10.5 g of 3,10-*C*-*meso*-Me$_8$[14]diene suspended in 400 cm^3 of hot 1:1 water-methanol mixture was reduced by the slow addition of 15 g of sodium borohydride with constant stirring and heated for 2 h on a steam bath. Methanol was then removed on a rotatory evaporator and the pH raised to above 12 with solid NaOH. The solution was again heated on a steam bath for about half an hour and the reduced material extracted several times with chloroform from the hot mixture. The chloroform extracts were dried over anhydrous sodium sulfate and the chloroform stripped off on a rotatory evaporator leaving behind a yellow oily liquid which on cooling gave a white solid. The product of the reduction process consists of a mixture of isomeric 3,10-*C*-*meso*-Me$_8$[14]anes.

50 g of the reduced material obtained above was suspended in 200 cm^3 of xylene and heated on a steam bath for about half an hour at 80—85 °C. The solution was filtered hot and the insoluble white product was washed with hot xylene. The product is Me$_8$[14]aneA (**L$_A$**); yield 9.59 g (19%), mp 350 °C (decomp) (Found: C, 69.2; H, 12.9; N, 17.9%. Calcd for $C_{18}H_{40}N_4$: C, 69.2; H, 12.9; N, 17.9%).

The filtrate from above on standing overnight at room temperature yielded needle shaped crystals of Me$_8$[14]aneB (**L$_B$**). The isomer **L$_B$** was filtered off, washed thoroughly with cold xylene and dried in vacuum. The product was recrystallized from hot ether; yield 19 g (38%), mp 122 °C; (Found: C, 65.7; H, 12.9; N, 17.1%. Calcd for $C_{18}H_{40}N_4 \cdot H_2O$: C, 65.5; H, 12.7; N, 17.0%).

The filtrate after removal of isomer **L$_A$** and isomer **L$_B$** was allowed to stand in the open for several days, when cubic shaped crystals of Me$_8$[14]aneC (**L$_C$**) were deposited. Another crop of isomer **L$_C$** could be collected on standing the mother liquor for another two days. The isomer **L$_C$** was recrystallized from hot ethers; yield 11 g, (22%), mp 85 °C; (Found: C, 69.1; H, 12.9; N, 17.9%. Calcd for $C_{18}H_{40}N_4$: C, 69.2; H, 12.9; N, 17.9%).

The purity of the isomers was checked on thin-layer chromatographic plates of 8 cm×2.5 cm coated with silica gel without any binder. The chromatograms were eluted with 80:20% methanol-chloroform mixture and exposed to iodine vapor. Each isomer gave a single spot on these plates.

The mass spectra of each isomer showed M^+ peak at m/z 312 for $C_{18}H_{40}N$. An additional (M^++1) peak at m/z 313 is observed in case of **L$_B$**.

X-Ray Crystallography.[14] Crystals of **L$_B$** for X-ray crystallography were grown by slow evaporation of its dilute solution in xylene.

Crystal Data. Me$_8$[14]aneB (**L$_B$**), $C_{18}H_{42}N_4O$, M=330.56. Monoclinic, a=11.391(3), b=14.596(4), c=12.481(4) Å, β=99.23(2)°, V=2048(1) Å^3 (by least squares refinement on diffractometer angles for 21 reflections in the range $10<2\theta<32°$), Mo $K\alpha$ radiation, λ=0.71073 Å, space group $C2/c$, Z=4, D_c=1.072 g cm^{-3}. Crystal dimensions: 0.37×0.42×0.26 mm, μ=0.63 cm^{-1}.

Data Collection and Processing. CAD4 automated diffractometer, $\omega/2\theta$ mode with scan width=0.60+0.35 tan θ, speed 10.1 to 1.6 deg min^{-1}, graphite-monochromated Mo $K\alpha$ radiation; 2552 reflections measured, 2431 unique [merging R=0.020] giving 1376 with $I>\sigma(I)$.

Structure Analysis and Refinement.[15] Direct methods program MITHRIL[16] was used. Full matrix least squares refinement on F_o minimising the function where $|F_o|$ and $|F_c|$ are the observed and calculated structure factor amplitudes respectively and the weighting factor is given by $\omega=4F_o^2/\sigma^2(F_o^2)|$. The neutral atom scattering factors were calculated from the analytical expression for the scattering factor curves.[17] The f' and f'' components of anomalous dispersion[18] were included in the calculation for all non-hydrogen atoms.

All hydrogen atoms were included at their idealized calculated positions, assuming C–H 0.95 Å and appropriate sp^2 or sp^3 geometries. The methyl hydrogens were fitted by least squares to peaks observed in a difference Fourier. These atoms were then included in the calculations with fixed, isotropic thermal parameters 1.2 times that of the attached atom and constrained to 'ride' with this atom. The largest shift in any parameter was 0.03 times its estimated standard deviation and the error in an observation of unit weight was 2.71 e.

Induced Circular Dichroism and Molecular Orientations of β-Cyclodextrin Inclusion Complexes with 9,10-Anthraquinone and 9,10-Phenanthrenequinone

Masafumi ATA, Yoshihiro KUBOZONO, Yasunobu SUZUKI, Makoto AOYAGI, and Yasuhiko GONDO*
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashi-ku, Fukuoka 812
(Received November 19, 1988)

Synopsis. The induced circular dichroism (ICD) spectra of β-cyclodextrin inclusion complexes with 9,10-anthraquinone and 9,10-phenanthrenequinone have been measured, and the electronic structures and molecular orientations of the guests are discussed in terms of the ICD signs and theoretical results.

Cyclodextrins (CDxs) are known as typical hosts in inclusion chemistry. One of the most important spectroscopic benefits brought about by inclusion-complex formation is induced circular dichroism (ICD); since a CDx is composed of several D(+)-glucopyranose units, the Cotton effect is induced on the electronic absorption bands of an achiral guest molecule. On the basis of the coupled oscillator theory, it has been shown that the guest electronic transition polarized perpendicular to the CDx cavity axis exhibits a negative ICD, whereas that polarized parallel exhibits a positive ICD.[1,2] The ICD measurement of CDx-inclusion complexes has been shown to be a very simple and useful tool in the assignment of electronic absorption bands both for neutral molecules[1-5] and for radical ions.[6] In other words, information on the molecular orientation can be gathered from knowledge of the directions of the transition dipole moments in the guest molecule.[4,5] In this report, we will discuss the inclusion orientations and assignment of the electronic absorption spectra of 9,10-anthraquinone (9,10-AQ) and 9,10-phenanthrenequinone (9,10-PhQ) on the basis of the observed ICD signs and the results of the published molecular orbital calculations.[7-9]

Results and Discussion

Figures 1 and 2 show the electronic absorption and ICD spectra of the β-CDx inclusion complexes with 9,10-AQ and 9,10-PhQ respectively in an aqueous solution as observed at room temperature, while Table 1 compares the experimental and theoretical spectral data.[8] Since the nπ* transitions overlap with the ππ* transitions, the precise discussion is restricted to the ππ* transitions; accordingly, the theoretical spectral data cited in Table 1 are concerned solely with the ππ* transitions.

Referring to the molecular orientation of the β-CDx inclusion complex with 1,4-naphthoquinone,[5] the two oxygen atoms of 9,10-AQ are seemingly not fully included in the β-CDx cavity, while one of the benzene moieties can be included. Namely, as is illustrated in Fig. 3, 9,10-AQ is partially included to take an axial orientation with β-CDx; hence, the electronic transitions polarized along the long and short molecular axes should be positive and negative respectively in

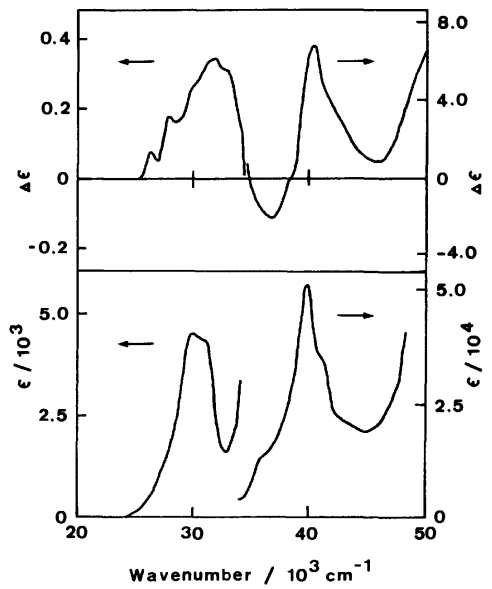

Fig. 1. ICD (upper) and electronic absorption (lower) spectra of β-CDx inclusion complex with 9,10-AQ in aqueous solution observed at room temperature.

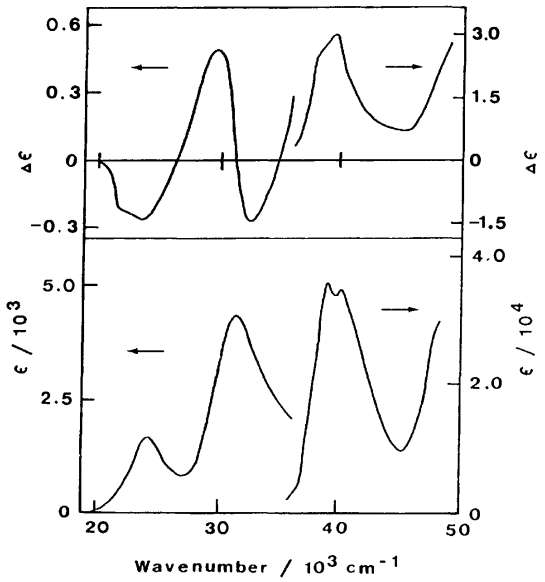

Fig. 2. ICD (upper) and electronic absorption (lower) spectra of β-CDx inclusion complex with 9,10-PhQ in aqueous solution observed at room temperature.

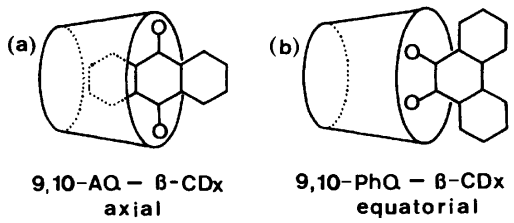

Fig. 3. Probable partial inclusion and molecular orientations in the β-CDx inclusion complexes with 9,10-AQ (a) and 9,10-PhQ (b).

ICD sign. Thus, the absorption bands at 29750 and 39630 cm^{-1} are found to be polarized along the long molecular axis, while the shoulder band at 35900 cm^{-1} is polarized along the short molecular axis. When the axial inclusion is assumed, the theoretical prediction based on the PPP method[8] is in good agreement with the ICD spectrum, as is shown in Table 1, as far as the ππ* transtions are concerned. The absorption bands appearing at 29750, 35900, and 39630 cm^{-1} can be correlated to the ^1L_a, ^1L_b, and ^1B_b bands of anthracene respectively. The structure around 27000 cm^{-1} in the ICD spectrum is due to either the ππ* vibronic or nπ* transition;[7-9] no definite conclusion can be deduced, since the nπ* band overlaps with the ππ* band.[10,11]

Now, let us turn to the β-CDx inclusion complex with 9,10-PhQ. In what follows, we assume that the above-mentioned ICD-sign rule for the guest electronic transitions[1,2] can also be applied when, as is illustrated in Fig. 3(b), a substantial portion of the guest is located outside the CDx cavity. According to the theoretical data in Table 1 obtained on the basis of the PPP method,[8] the first ππ* transition is polarized along the long molecular axis. The second and third transitions are predicted to be polarized differently from each other and to appear around 33000 cm^{-1}; actually, the ICD spectrum in Fig. 2 exhibits two differently polarized transitions in the 28000—35000 cm^{-1} region. The fourth transition is predicted to be short-axis polarized and to be located at 39040 cm^{-1}. If 9,10-PhQ is axially included in β-CDx, the ICD signs should be plus, minus, plus, and minus in order from the low- to the high-energy region; this is in disagreement with the ICD signs shown in Fig. 2. From the correlation between the theoretical and experimental results, the ICD spectrum can be ascribed to such an equatorial inclusion complex as is illustrated in Fig. 3. The minimum and maximum molecular dimensions of a 9,10-PhQ molecule are estimated to be 8.0 and 11.6 Å respectively, inclusive of the van der Waals radii of the hydrogen and oxygen atoms. Thus, in view of the cavity size of β-CDx, 9,10-PhQ is included in β-CDx, not completely but partially, as well as equatorially, with the *o*-benzoquinone moiety located in the cavity; the major binding force between 9,10-PhQ and β-CDx seems to be brought about by intermolecular hydrogen bonding between the carbonyl groups of 9,10-PhQ and the hydroxyl groups of β-CDx. An nπ* transition with out-of-plane polarization must be negative in ICD sign, irrespective of whether the inclusion is axial or

equatorial. The negative shoulder at 21250 cm^{-1} in the ICD spectrum is possibly due to the nπ* transition,[9] but no definite conclustion can be deduced since, just as in the case of 9,10-AQ, the nπ* band overlaps with the ππ* band.[10,11] The theoretical fifth intense transition cannot be identified in the ICD spectrum, probably because it falls outside the spectral range studied.

In conclusion, the ICD spectra of 9,10-AQ and 9,10-PhQ can be ascribed to the axial and equatorial inclusion complexes with β-CDx respectively, as is illustrated in Fig. 3. The respective molecular orientations of the two quinones studied can be interpreted as natural consequences of the intermolecular hydrogen bonding between the quinones and the host.

Experimental

The 9,10-AQ and 9,10-PhQ (Tokyo Kasei, GR) were recrystallized from ethanol (Wako, SSG). The β-CDx (Tokyo Kasei, GR) was recrystallized five times from water and then dried under a vacuum at 80 °C. The deinoized and distilled water was used as a solvent. The electronic absorption and ICD spectra of the β-CDx inclusion complexes were recorded at room temperature, about a day after the sample-preparation, on a Shimadzu MPS 50-L spectrophotometer and on a JASCO J-500C circular dichrograph respectively. A JASCO J-501N data processor was used for the accumulation of the ICD spectra. The concentration of β-CDx was set at 1.5×10^{-2} mol dm^{-3}, while those of the quinones were adjusted so that the maximum absorbances fell in the range of 1.2—1.5.

The authors are indebted to Professor Emeritus Seizo Misumi, Professor Yukito Murakami, and

Professor Tadashi Yonemitsu for providing the facilities for the circular dichroism measurements.

(Received April 27, 1989)

Synopsis. The analytical method for determining the distribution of the polymerization degree of the oxyethylene (OE) chain in commercially available poly(oxyethylene) alkyl ether (C_mE_n) was investigated by means of thin-layer chromatography with flame-ionization detection (TLC-FID). It was found that the method of calculating the relative response factors of every OE chain to FID could be determined, and the analysis of the distribution of the polymerization degree of the OE chain in commercially available C_mE_n became possible using the TLC-FID method.

It is known that the distribution as well as the mean length of the oxyethylene (OE) chain in nonionic surfactants greatly affects various surface-chemical characteristics.[1-3] Gas chromatography and high-performance liquid chromatography are now used as general analytical methods for determining the distribution of the polymerization degree of the OE chain.[4-6] Considering the time required for the analysis and the use of a detector, it is difficult to operate every routinely the instruments in order to acquire reproducible data. The present authors have recently reported an advanced separating method of the OE chain using thin-layer chromatography with flame-ionization detection (TLC-FID) as a rapid alternative method.[7] It is necessary to find the relative response factor of each peak to the hydrogen ionization detector (FID) and to correct it in order to determine the real distribution of the polymerization degree of the OE chain from the chromatogram drawn.

The method of calculating the relative response factor of a alkyl ether-type nonionic surfactant to FID and the method of analyzing the distribution of the polymerization degree were investigated in this study. This method should also be applicable for the determination of polyethylene glycol as a by-product in poly(oxyethylene)-type nonionic surfactants.

Experimental

Materials. The poly(oxyethylene) alkyl ether (C_mE_n: $C_mH_{2m+1}O(C_2H_4O)_nH$) with a single chain length and a relatively narrow distribution of OE[8] was obtained from the Nikko Chemicals Co., Ltd. Guaranteed reagents of benzene, ethyl acetate, and acetic acid were used as the developing solvents.

Measurement by TLC-FID. The TLC-FID instrument, the thin-layer rod, and the analytical conditions were the same as those described in a previous report.[7]

Results and Discussion

Calculation of Relative Response Factor. Figure 1 illustrates the relationship between the OE-chain length (n) in C_mE_n with a single-chain length and the peak area (A) in the TLC-FID chromatogram. When the alkyl-chain lengths (m) are the same, the relationship between A per gram and n is linear. The relationship between A and n in each C_mE_n can, therefore, be expressed by the following formula:

$$A = -Pn + b \quad (1)$$

where P is the slope for each straight line in Fig. 1, b is the A of the corresponding higher alcohol, and b is proportional to m, as is shown in Fig. 1. The relationship between P and m in C_mE_n is also linear, as is shown in Fig. 2. This relationship is represented by the following equation:

$$P = 0.095m - 0.50 \quad (2)$$

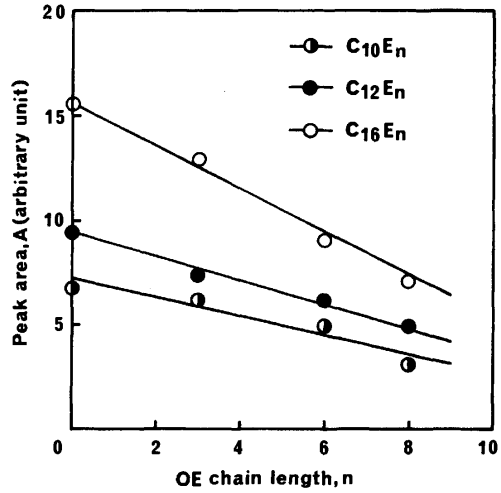

Fig. 1. Relationship between OE chain length in nonionic surfactant and peak area.

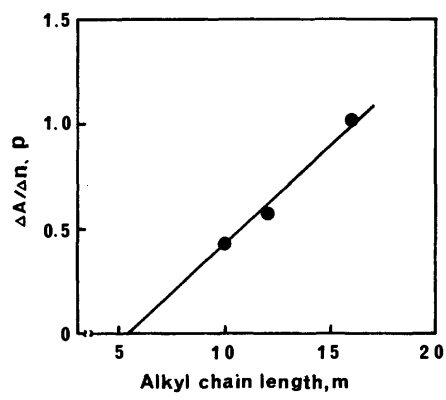

Fig. 2. Plots of P vs. m according to Eq. 2.

Table 1. OE Distribution and Statistical Analysis of Commercially Available $C_{12}E_5$ (n=4)

OE number	Relative response factors	Molar distribution	Weight distribution	SD/X(%)
1	1.00	0.0109	0.0062	13.1
2	1.08	0.0523	0.0354	4.2
3	1.17	0.1552	0.1220	2.2
4	1.28	0.2224	0.1990	1.1
5	1.41	0.2113	0.2120	1.6
6	1.58	0.1525	0.1696	0.7
7	1.78	0.0974	0.1189	2.0
8	2.05	0.0526	0.0699	5.2
9	2.41	0.0305	0.0438	6.3
10	2.92	0.0149	0.0231	9.9

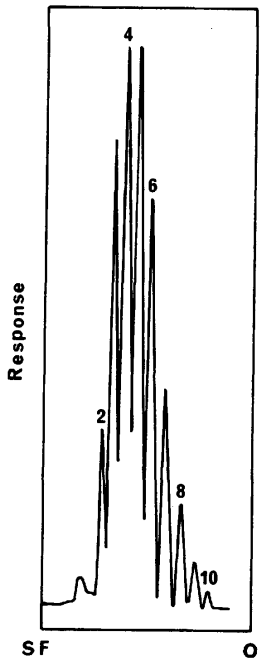

Fig. 3. TLC-FID chromatogram of commercially available $C_{12}E_5$. The peak number corresponds to the number of OE chains. SF: solvent front, O: origin. Mobile phase: 1st development, benzene-ethyl acetate (6/4, vol%), 10 cm; 2nd development, ethyl acetate-acetic acid-water (8/1/1, vol%), 8 cm; gas flow: H_2, 160 mL min^{-1}; air, 2 L min^{-1}; scanning speed: 35 s/scan.

The A value per gram of C_mE_n and the relative response factors of C_mE_n to FID can be calculated from Eqs. 1 and 2. This analytical method is applicable to C_mE_n with m and n values that satisfy $A>0$.

As compared with the previous TLC-FID method,[7] one can calculate the relative response factors of the OE chain for a series of C_mE_n by this method. This method is also widely applicable to the determination of the OE-chain distribution of nonionic surfactants.

Analysis of Chromatogram. Figure 3 shows the TLC-FID chromatogram of commercially available $C_{12}E_5$. Each peak in the chromatogram was identified by using each C_mE_n with a single-chain length. The results indicate that the peaks were detected in the order of the added number of moles of the OE chains. The peaks are satisfactorily separated in the chromatogram. The actual molecular weight distribution was determined using the chromatogram and the relative response factors calculated from Eqs. 1 and 2. The relative response factors are defined as the ratio of the A value per gram of each $C_{12}E_n$ to that of $C_{12}E_1$. All the values were measured relative to $C_{12}E_1$ ($C_{12}E_1$=1.00). The results are shown in Table 1. The table shows that the molecular weight distribution of commercially available $C_{12}E_5$ can be accurately determined. Since the TLC-FID method is a simple, rapid method of analysis requiring no chemical modification, as was stated in the previous report,[7] it is useful for determining the distribution of the OE chain in a poly(oxyethylene)-type nonionic surfactant. In addition, the distribution of the OE chain in any series of C_mE_n can be determined because the relative response factor can be calculated, even for commercially unavailable products,[9] with a single chain. Therefore, the TLC-FID method can be applied to the determination of the OE-chain distribution in other poly(oxyethylene)-type nonionic surfactants by selecting appropriate developing solvents.

Temperature Change of Graphite Surface Due to Electrochemical Intercalation of ClO_4^- Ion

Yasuhisa MAEDA
Materials Science, Toyohashi University of Technology, Tempaku-cho, Toyohashi 440
(Received May 24, 1989)

Synopsis. Anodic intercalation and cathodic deintercalation of ClO_4^- ions were shown to cause exothermic and endothermic changes, respectively, on a graphite surface. This suggests the occurrence of an increase in entropy for the deintercalation process and a decrease for the case of intercalation.

Studies on the syntheses, structure, properties, and applications of graphite intercalation compounds have been actively carried out. There have been several reports concerning electrochemical intercalation on graphite.[1-10] This process is important because it may provide both kinetic and thermodynamic interpretations for intercalation behavior. It has been reported[11-13] that useful information concerning electrochemical reactions may be obtained by the detection of heat due to electrolysis. In the present study in-situ measurements of the temperature changes of graphite surfaces due to electrochemical intercalation were carried out in order to reveal heat behavior during the intercalation process.

Experimental

Measurements of the temperature change were based on the differential thermal method; two thermistors (Takara Industry Co., type: PXK-67) were used, the one of which was attached to the surface of the graphite electrode and the other placed in the bulk of the solution. The temperature difference between them was detected by a bridge (Fuso Seisakusho Co., model: 362A). The solution (volume: 0.1 dm^3) was stirred and N_2 gas bubbled during electrolysis. By circulating thermostated water outside the solution, its temperature was maintained at 20 °C. A graphite sheet (Toyo Tanso Co., size: 12×10×0.5 mm) was used as the working electrode. The counter electrode was a platinum wire, and the reference electrode was an oxidized silver wire galvanostatically (at 1 mA for 10 min) placed in 1 mol dm^{-3} hydrochloric acid. Electrolytic solutions were prepared by the dissolution of anhydrous $LiClO_4$ into distilled propylene carbonate (PC), acetonitrile (AN), and nitromethane (NM). The electrochemical intercalation of ClO_4^- ions was performed by cyclic voltammetry. Simultaneously, the temperature change of the graphite surface was measured during electrolysis.

Results and Discussion

It has been reported[1,2] that anodic oxidation of graphite in organic solutions containing perchlorate causes the intercalation of ClO_4^- ions, as follows:

$$nC + ClO_4^- \rightleftarrows C_n^+ ClO_4^- + e$$

In this case, the reaction on the left represents the cathodic deintercalation of ClO_4^- ions.

Figure 1 shows the cyclic voltammogram (CV) as well as the relation between the temperature change and the electrode potential (ΔT-E) of graphite in a 0.2 mol dm^{-3} $LiClO_4$-PC solution. Regarding the sign of ΔT, the positive and the negative signs represent a rise and a fall in temperature, that is, exothermic and endothermic changes, respectively. Concerning the CV in Fig. 1, the anodic current and the corresponding cathodic current peak were observed. The former indicates the intercalation process of the ClO_4^- ion and the latter its deintercalation. The ΔT-E relation showed a marked increase in temperature with the anodic current; also, the peak of the fall in temperature nearly fit the cathodic peak.

Figure 2 shows the CV and the ΔT-E relation of graphite in a 0.2 mol dm^{-3} $LiClO_4$-AN solution. The anodic current and the corresponding cathodic peak due to the intercalation and deintercalation of ClO_4^- ions, respectively, were observed. The ΔT-E relation showed an increase in temperature with the anodic current; also, the peak of the fall in temperature nearly fit the cathodic peak.

Figure 3 shows the CV and the ΔT-E relation of graphite in a 0.1 mol dm^{-3} $LiClO_4$-NM solution. In this case, a similar rise and a fall in temperature occurred during the processes of intercalation and deintercalation of ClO_4^- ions, respectively, though the fit of the fall in temperature with the cathodic peak

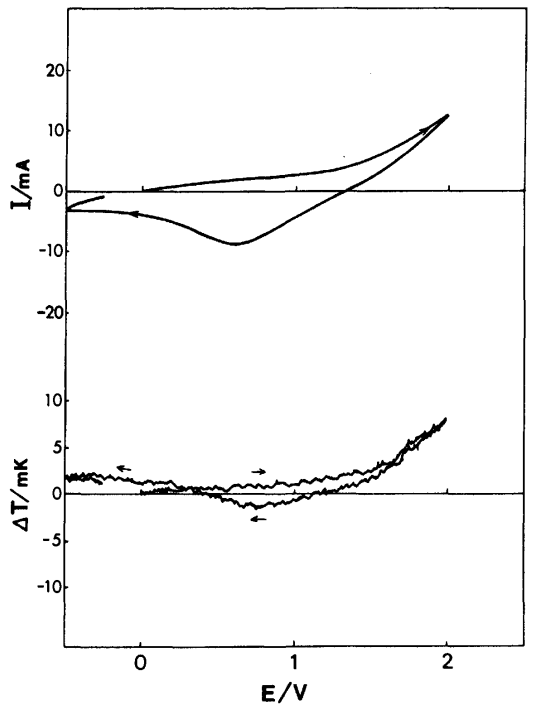

Fig. 3. The CV and the ΔT-E relation of the graphite in a 0.1 mol dm^{-3} $LiClO_4$-NM solution. Scan rate: 10 mV s^{-1}.

was not clear.

At the electrode/electrolyte interphase, the absorbed heat dQ during the electrolysis period dt can be expressed as

$$dQ = \frac{(T\Delta S + Q^*)|I|dt}{nF} - |I|\,\eta\,dt - I^2 R\,dt, \quad (1)$$

where ΔS is the molar entropy change of electrode reaction, Q^* the heat of transfer, I the current, η the overpotential and R the electric resistance. The relation between the temperature change and the absorbed heat at the interphase is given by

$$\Delta T = -K\frac{dQ}{dT}, \quad (2)$$

where K is a positive constant. In Eq. 1, the first term is called the electrochemical Peltier heat. Q^* equals $T\Delta S^*$, where ΔS^* is the molar entropy change of transfer of ions. Since the value of $\Delta S^*/nF$ (except the case of H^+ or OH^- participating) is within +0.08—−0.08 mV deg^{-1} (much smaller than that of $\Delta S/nF$[14]), virtually the first term could be regarded as being the heat due to the entropy change of electrode reaction. The second term represents the heat due to polarization, and the third is the Joule heat. Both the second and third terms are always exothermic, though the first one depends on the sign of ΔS: an increase or decrease in entropy leads to an endothermic or exothermic change, respectively.

The fit of a peak of a fall in temperature with the cathodic peak in Figs. 1 and 2 suggests that the heat in the cathodic process may be mainly due to an entropy change for the deintercalation of ClO_4^- ions in $LiClO_4$-PC and $LiClO_4$-AN solutions. The obscure fit of the fall in temperature with the cathodic peak in an $LiClO_4$-NM solution could be explained by the contribution of not only the first, but also the second and third terms. The endothermic change in the cathodic deintercalation of ClO_4^- ions suggests the occurrence of an increase in entropy and may also lead to a decrease due to intercalation.

It is possible to obtain information concerning the entropy change of the electrode reaction by measuring the temperature-dependence of the electrode potential.[14] The thermal temperature coefficient of the electrode potential $(dE/dT)_{th}$ is expressed as

$$(dE/dT)_{th} = \frac{\Delta S}{nF} + \frac{\Delta S^*}{nF}. \quad (3)$$

Thus, the value of $(dE/dT)_{th}$ for the graphite oxidized anodically in these solutions (that is, after the intercalation of ClO_4^- ions) was checked while changing the temperature of only the graphite electrode. Figures 4 and 5 show the temperature-dependence of the electrode potential of the graphite after anodic oxidation in $LiClO_4$-PC and $LiClO_4$-NM solutions, respectively. In this case, the potential was measured versus a saturated calomel electrode (at room temperature) separated from the compartment of the working electrode by a vessel filled with the electrolyte using a Luggin cappillary and a KCl salt bridge. From the slope of the linear relation by the method of least squares, the values of $(dE/dT)_{th}$ were +1.30 mV deg^{-1} and +3.55 mV deg^{-1} for $LiClO_4$-PC and $LiClO_4$-NM solutions, respectively. Thus, the estimated values of ΔS were +125 J mol^{-1} K^{-1} and +343 J mol^{-1}

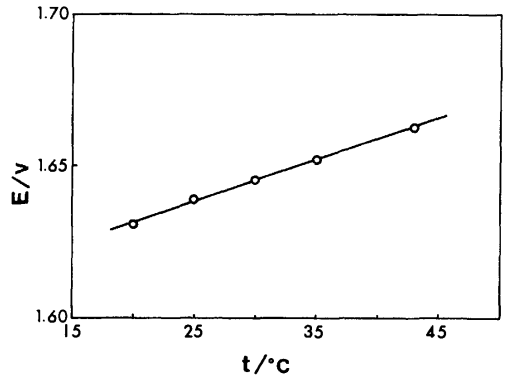

Fig. 4. The temperature-dependence of the electrode potential of the graphite after anodic oxidation (at +2.0 V for 1 h) in a 0.2 mol dm^{-3} $LiClO_4$-PC solution.

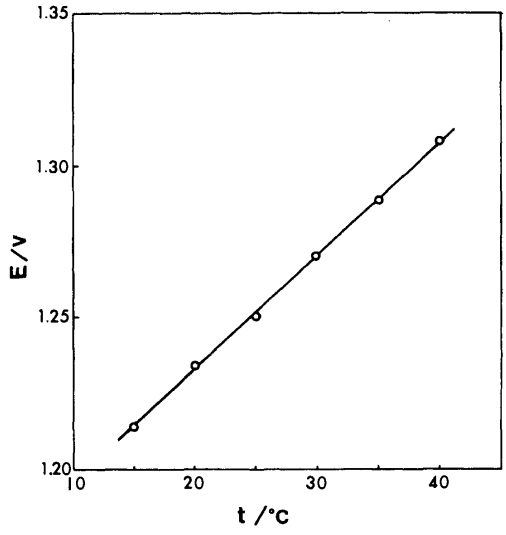

Fig. 5. The temperature-dependence of the electrode potential of the graphite after anodic oxidation (at +2.0 V for 1 h) in a 0.1 mol dm^{-3} $LiClO_4$-NM solution.

K^{-1}, respectively, by supposing that ΔS^* might be negligible. The positive value obtained in $LiClO_4$-PC and $LiClO_4$-NM solutions suggests an increase in entropy due to the deintercalation of ClO_4^- ions. The measurement of $(dE/dT)_{th}$ for graphite oxidized anodically in an $LiClO_4$-AN solution was impossible because of the unstable electrode potential. Nevertheless, also in this case, the occurrence of an increase in entropy could be supported by the thermal result, as mentioned above. This thermal method has the advantage of providing information concerning entropy change directly and promptly by the detection of the heat due to electrolysis.

Studies of Collectors. X. Complexing Ability of Amino Hydroxamic Acid Ligands with Dioxouranium(VI) in Aqueous Solution

Yoshifumi KOIDE,* Masazumi UCHINO, Hideto SHOSENJI, and Kimiho YAMADA
Department of Applied Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860
(Received March 27, 1989)

Synopsis. Complexing ability of ligands bearing hydroxyaminocarbonyl group and amino group with UO_2^{2+} in an aqueous solution were examined by the potentiometric method using MINIQUAD program. Stability constants of 2-aminoacetohydroxamic acid complex with UO_2^{2+} are $\log \beta_1=10.45$, $\log \beta_2=18.95$. They are far larger than those of acetohydroxamic acid complexes. The β_1 and β_2 are almost the same as β_1 and β_2 of the acetamide oxime (acetoamidoxime) complexes.

The N^2-hydroxyamidino group in amidoximes, hydroxyaminocarbonyl group in hydroxamic acids, and the pyridyl group are known as affinity groups for uranium.[1,2] The stabilities of the latter two are less than that of the former. A chelating surfactant bearing hydroxyaminocarbonyl group and pyridyl or amino group exerted an excellent flotation-effect for the uranium in seawater.[3] The effect is considered to be caused by the coordination of the amino group to UO_2^{2+}, in addition to the complexation of the hydroxyaminocarbonyl group. However, such a chelate effect was unknown. Moreover, the UO_2^{2+} chelate of *o*-hydroxybenzohydroxamic acid[4] is less stable than the complex of benzohydroxamic acid (B-Hx).[5,6] In this study, the stability constants of the 2-aminoacetohydroxamic acid (A-AHx)-UO_2^{2+} and the *o*-aminobenzohydroxamic acid (B-AHx)-UO_2^{2+} complexes are determined by the potentiometric method and compared with those of acetohydroxamic acid (A-Hx), B-Hx, and acetamide oxime (amidoxime ligand).

Experimental

A-Hx was purchased, and A-AHx, B-Hx, and B-AHx were prepared by the treatment of the corresponding esters (ethyl aminoacetate, ethyl benzoate, and methyl *o*-aminobenzoate) with hydroxylamine.[7] They were refined by recrystallization, and their structures were confirmed by mp, IR (KBr), ^{1}H NMR, and elementary analyses. A-Hx Found: C, 31.86; H, 6.62; N, 18.59%; A-AHx: C, 26.68; H, 7.02; N, 30.95%; B-Hx: C, 61.16; H, 5.04; N, 10.09%; B-AHx: C, 55.17; H, 5.21; N, 18.72%. Standard solutions of HNO_3, UO_2, and NaOH were prepared from 60% HNO_3, $UO_2(NO_3)_2$, and a 50% NaOH solution after removing the Na_2CO_3 precipitate, respectively. Water was deionized by passing through an ion-exchange column and then distilled. Ionic strengths of all the solutions were adjusted to 0.1 M (1 M=1 mol dm^{-3}) with KNO_3.

The equilibrium measurements were carried out with a Recording Auto Titrator (Hiranuma type RAT-11) using a glass electrode (DKK combined type 6155). All titrations were performed at 25.0±0.05 °C under an atmosphere of N_2 in a double-walled titration cell of 100 cm^3 capacity. The potentiometer was calibrated with JIS standard buffer solutions. The pH meter reading, pH_M, was converted into $-\log[H]$ on titrating 4.0×10^{-3} M HCl with 0.01 M NaOH: $-\log[H]=pH_M-0.063$. The apparent ionic product of water, pK'_w, was determined by titrating 0.1 M KNO_3 with 0.01 M NaOH: $pK'_w=pH_M-\log[OH]=13.79$, from which relation the OH^- concentration was calculated. The ligand concentration was adjusted to 4×10^{-3} M in most cases, being twice that of the UO_2^{2+}. The UO_2^{2+} concentration was determined by titration with ethylenediaminetetraacetic acid. The free ligand was first titrated with 0.02 M HNO_3 and then back-titrated with 0.01 M NaOH. In the presence of UO_2^{2+}, the titrations with 0.01 M NaOH were performed by starting from the ligand solutions containing a two-fold excess of acid. For each system two titrations were performed, and each of the titration curves contained more than 50 experimental points.

Results and Discussion

Acid dissociation constants of the amine residue in A-AHx and B-AHx, and stability constants of the UO_2 complexes have not previously been determined.

The dissociation equilibrium of amino hydroxamic acid ligand (HL) may be represented by Eqs. 1 and 2.

$$H_2L^+ \rightleftharpoons HL + H^+ \qquad pK_{a1} \qquad (1)$$

$$HL \rightleftharpoons L^- + H^+ \qquad pK_{a2} \qquad (2)$$

The average number of protons bound to the ligand were calculated in the ligand concentration range of $3.3—4.0\times10^{-3}$ M, and pK_{a1} and pK_{a2} were determined by the calculation using ACBA program.[8]

In the A-AHx system, the pK_{a1} and pK_{a2} were found to be 7.458 and 9.237, respectively. Hydroxyaminocarbonyl group in the A-AHx would dissociate more than that in A-Hx (pK_a 9.328) because of the inductive effect of the electron on the $-NH_3^+$. On the other hand, the absorption of $-NH_3^+$ (HL form: 2550—3100 cm^{-1}) in the IR spectrum dissappeared when A-AHx was treated with two-fold of sodium methoxide, and the absorption of the free amine (L^- form) appeared in 3400—3500 cm^{-1}. Therefore, the pK_{a1} (7.458) and the pK_{a2} (9.237) were assigned to the hydroxyaminocarbonyl group and the amino group, respectively.

Next, the pH titration of A-AHx in the presence of UO_2^{2+} was carried out and the titration curve was obtained over a range of $-\log[H]<6$, above which a precipitate was formed. The stability constant, β_n, was calculated by the MINIQUAD program.[9]

$$UO_2^{2+} + L^- \rightleftharpoons UO_2L^+ \qquad \beta_1 \qquad (3)$$

$$UO_2^{2+} + 2L^- \rightleftharpoons UO_2L_2 \qquad \beta_2 \qquad (4)$$

UO_2^{2+}, with coordination number six, is appreciably hydrolyzed, so that the hydrolyses of UO_2^{2+} were

Table 1. Stability Constants of UO_2^{2+} Complexes[a)]

Ligand	pK_{a1}	pK_{a2}	$\log \beta_1$	$\log \beta_2$	Ref		
					pK_a	$\log \beta_1$	$\log \beta_2$
A-Hx	9.328 (0.006)		8.22 (0.03)	15.30 (0.07)	9.40[13)]		
A-AHx	7.458 (0.005)	9.237 (0.010)	10.45 (0.02)	18.95 (0.04)	7.40[14)]		
B-Hx	8.757 (0.005)		7.49 (0.03)	14.17 (0.07)	8.75[14)]	7.72[5)] 8.71[6)]	16.77[6)]
B-AHx	2.682 (0.010)	8.818 (0.004)	7.82 (0.01)	14.71 (0.02)	9.0[15)]		

a) Conditions: 25 °C, I=0.1 M. Values in parentheses are estimated standard deviations.

considered in the calculation.[10,11)] Thus, stability constants of the 1:1 and 1:2 complexes of A-AHx with UO_2^{2+} were determined to be $\log \beta_1$=10.45 and $\log \beta_2$=18.95. Similar calculations in the A-Hx, B-AHx, and B-Hx systems were carried out, and the pK_a and $\log \beta$ are given in Table 1.

Stability constants of the A-AHx-UO_2^{2+} complex are about 170 (β_1) and 4500 times (β_2) those of the A-Hx complexes. The high stabilities of A-AHx complex were considered to be caused by the chelate effect between the amino group and the hydroxyaminocarbonyl group, that is, in addition to the complexation of the bidentate hydroxyaminocarbonyl group, the six-membered rings of the chelate should increase the stability constant. The strong affinity of the N^2-hydroxyamidino group for UO_2^{2+} is well-known and the stability constants of acetamide oxime-UO_2^{2+} complex were estimated to be $\log \beta_1$=10.6 and $\log \beta_2$=18.8.[12)] Therefore, β_1 and β_2 of the A-AHx complex proved to be almost the same as those of the acetamide oxime-UO_2 complex.

In B-AHx, the pK_{a1} (2.682) and pK_{a2} (8.818) should be assigned to the anilinium ion and the hydroxyaminocarbonyl group respectively, because of the similar resonance to aniline (pK_a 4,65) and nearly the same value to the pK_a of B-Hx. β_1 and β_2 of the B-AHx-UO_2 complex are a little higher than those of the B-Hx-UO_2 complex. The basicity of the amine donor in B-AHx is weak, and the chelates should be seven-membered rings. Therefore, the stability of the B-AHx complex would not become so great.

In the distributions of the UO_2^{2+} complexes, 1:1 and 1:2 species of the A-AHx complex were formed much more than those of the A-Hx complex on the basis of the chelate effect, but the difference of distributions in the B-Hx and B-AHx systems was small.

Thus, it has become apparent that the complexing ability of the amino hydroxamic acid ligand with UO_2^{2+} is greater than that of the hydroxamic acid ligand and is almost the same as that of the amidoxime ligand.

The authors are sincerely grateful to Assistant Professor Akinori Jyo for his help and useful suggestions.

Temperature Dependence of Adsorption of Caesium Ions on Crystalline Hydrous Titanium Dioxide Fibers

Hiromichi HAYASHI,* Takashi IWASAKI, Yoshio ONODERA, and Yoshinori FUJIKI†
Government Industrial Research Institute, Tohoku, Sendai 983
†National Institute for Research in Inorganic Materials, Tsukuba 305
(Received June 1, 1989)

Synopsis. The distribution coefficient of caesium ions, K_d, measured as a function of pH at 25—100 °C, decreased with increasing temperature. Enthalpy change of the adsorption of Cs^+ on $H_2Ti_4O_9 \cdot nH_2O$ estimated from the plot of $\log K_d$ vs. T^{-1} in the range of 25—85 °C was −4.6 kcal mol^{-1}. Above 95 °C, K_d values were lower than those extraporated from the plot due to a decrease in the crystallinity of the fibers.

We have worked to develop the techniques to recover caesium ions from geothermal brine and suitable inorganic adsorbents have been investigated by revealing adsorption behavior of caesium ions in hot water.[1] The adsorbents for caesium ions in geothermal brine need selectivity for the ions and hydrothermal stability. It is known that crystalline hydrous titanium dioxide fibers, $H_2Ti_4O_9 \cdot nH_2O$, have high selectivity for caesium ions and that the distribution coefficient for alkali metal ions in weak acid solution at 25 °C increases in the order: Li<Na≪K, Rb<Cs.[2]

The present paper deals with the adsorption of caesium ions on the fibers. The distribution coefficient of caesium ions was measured as a function of pH at 25—100 °C and the enthalpy change was estimated; in addition, X-ray powder diffractometry was done for checking the structural change of fibers.

Experimental

The hydrous titanium dioxide fibers ($H_2Ti_4O_9 \cdot nH_2O$) were prepared by acid treatment of $K_2Ti_4O_9$.[3,4] Adsorption experiments were carried out in batchwise operations in a water bath thermostated at temperatures between 25 and 100 °C.

Glass ampules of 20 cm^3 capacity were used to obtain equilibrium between the solid (0.05 g) and the aqueous solution (10 cm^3) containing caesium ions. The initial concentration of caesium choride was 1 mmol dm^{-3}, and pH was adjusted with hydrochloric acid. The glass ampules were kept in the water bath, and shaken gently at intervals. The reaction time was 7 d, when the equilibrium was sufficiently attained, and then the fibers were separated by a membrane filter with 0.45 μm pores.

The concentration of caesium ions in the aqueous solution was determined by a Hitachi Z-6000 polarized Zeeman atomic absorption spectrophotometer. The pH of the solution was measured by a TOA HM5ES pH meter equipped with GS-5015C pH combination electrode. X-Ray powder patterns were obtained by a Rigaku Denki RAD-IIB diffractometer with Cu $K\alpha$ radiation.

Results and Discussion

The distribution coefficient, K_d, was calculated as

$$K_d = (C_1/\mathrm{g})/(C_2/\mathrm{cm^3}), \quad (1)$$

where C_1 is the amount of adsorbed caesium ions per 1 g of the solid, and C_2 is the concentration of caesium ions per 1 cm^3 of the aqueous solution.

Figure 1 gives the plot of $\log K_d$ vs. pH in aqueous phase for six different temperatures. As the temperature was increased, the $\log K_d$-pH lines shifted downward. The slope of $\log K_d$-pH lines was about +1 except for that at 100 °C. The adsorption of caesium ions on the fibers, therefore, can be represented by an ion-exchange reaction formula:[3]

$$H(s) + Cs^+(aq) = Cs(s) + H^+(aq), \quad (2)$$

where the subscripts "s" and "aq" denote the solid and aqueous phase respectively. The equilibrium constant, K_c, of Eq. 2 is defined as

$$K_c = [Cs(s)][H(aq)]/[Cs(aq)][H(s)]. \quad (3)$$

K_c is rewritten as Eq. 4 using K_d:

$$\log K_c = \log K_d - pH + \text{const.} \quad (4)$$

If the K_d values for different temperatures are compared at identical pH, the enthalpy change of Cs-H ion-exchange reaction can be estimated from $\log K_d$ vs. T^{-1} plot.

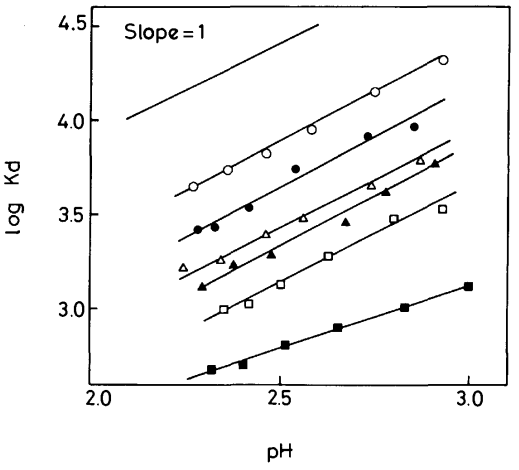

Fig. 1. Distribution coefficients of caesium ions as a function of pH in the aqueous phase at various temperatures. The ion exchanger is 0.05 g of $H_2Ti_4O_9 \cdot nH_2O$. The aqueous solution is 10 cm^3 of hydrochloric acid solution with an initial caesium concentration of 1×10^{-3} mol dm^{-3}. Temperature is (○): 25 °C, (●): 50 °C, (△): 75 °C, (▲): 85 °C, (□): 95 °C, (■): 100 °C.

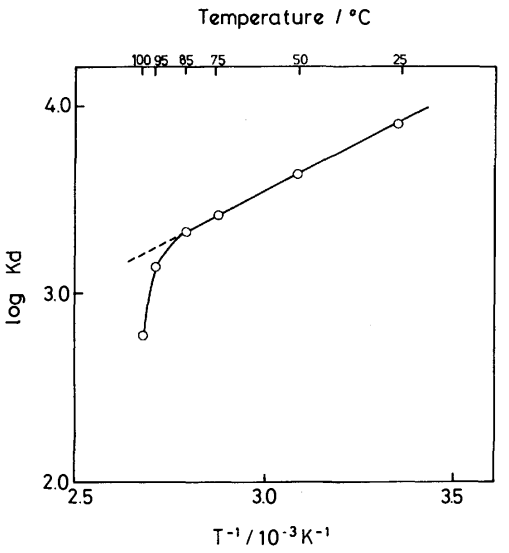

Fig. 2. Distribution coefficients of caesium ions at pH=2.5 in the aqueous phase as a function of temperature.

Figure 2 gives the plot of log K_d vs. T^{-1} at pH 2.5. The log K_d values were on a straight line in the range 25 to 85 °C as expected when enthalpy change (ΔH) is constant. And from the slope of the line, ΔH is obtained by Eq. 5:

$$\Delta H = -2.303\, R\, \mathrm{d}\log K_d/\mathrm{d}\,(1/T), \quad (5)$$

where T is the absolute temperature, and R is the gas constant.[5] The ΔH estimated from Fig. 2 in the range between 25 and 85 °C was −4.6 kcal mol^{-1}. Kraus et al. reported that the enthalpy change of ion exchange reaction between caesium ions and protons on a cation-exchange resin was −3.4 kcal mol^{-1} at 25 °C.[5] Although the enthalpy change values of the both cases are somewhat different, uni-uni valent ion exchange such as proton and caesium ion is supposed to be an exothermic reaction, irrespective of inorganic and organic ion exchangers.[6]

As shown in Fig. 2, K_d values at 95 and 100 °C were lower than those extraporated from the plot. Figure 3 gives the X-ray powder diffraction patterns of the solid treated with caesium solution at temperatures between 50 and 100 °C. The layered structure of the fibers is characterized by very strong (200) reflection with an interplanar spacing, d(200), of ca. 9.1 Å.[7]

The fibers treated at temperatures below 95 °C showed almost similar diffraction patterns to those of the original fibers. This fact indicates that the structure of the fibers remains unchanged below 95 °C. Above 95 °C, however, the fibers converted into the poorly crystallized phase with an interlayer distance smaller than that of the crystalline fibers. This result agrees with that reported by Komatsu et al. in the case of adsorption of cobalt ions.[4] Consequently, the K_d value of caesium ions must be influenced only by the exothermic reaction below 95 °C. Above 95 °C, the

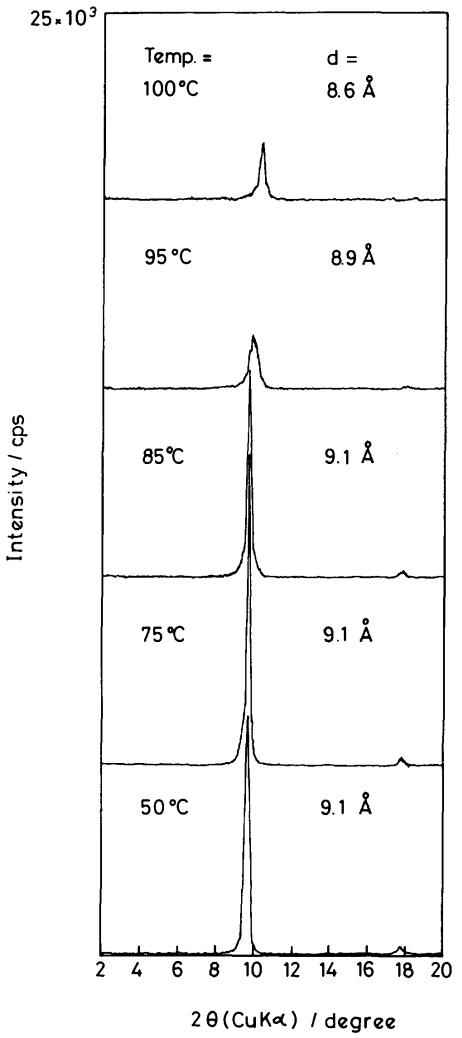

Fig. 3. X-Ray powder diffraction patterns of the solid samples treated with aqueous solutions at various temperatures.

structural change of the fibers causes the decrease of K_d in addition to the temperature effect as an exothermic reaction.

Accordingly, the desired temperature should be below 95 °C when the fibers is utilized for an adsorbent for caesium ions from geothermal brine.

Association of Carbon Tetrachloride, Chloroform, and Dichloromethane with Cyclodextrins in Aqueous Medium

Makoto NISHIMURA, Toshio DEGUCHI, and Isao SANEMASA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received June 14, 1989)

Synopsis. The 1:1 host (cyclodextrin, CyD)-guest (CCl_4, $CHCl_3$, and CH_2Cl_2) association constants at 25 °C have been determined by making use of the volatilization rate of guest from aqueous into gaseous phase. No association was observed between γ-CyD and the three guests and between β-CyD and CH_2Cl_2.

Cyclodextrins (CyDs) are cyclic oligomers forming distinctive cavity; α-, β-, and γ-CyD are composed of 6, 7, and 8 glucoses, respectively. While the outside of the CyD molecule is hydrophilic, the cavity inside is a hydrophobic environment, and various hydrophobic substances in aqueous medium can be included therein as the guest, when they are spatially fitted in the cavity. Owing to this unique property of CyD, much interest has been drawn to its applications such as catalysts in organic syntheses or a modifier in solvent extraction.

Intermediates such as trichloromethyl cation and dichlorocarben derived in situ in CyD with the suitable cavity size from CCl_4 and $CHCl_3$, respectively, play a predominant role in the selective reaction of phenolates.[1] CyDs were also used to modify partition of hydrophobic solutes between organic and aqueous phase.[2,3] In these applications, association constants of CyD with CCl_4, $CHCl_3$, and CH_2Cl_2 in water are essential information to be needed, because the complexation in the aqueous medium plays an important role. On the other hand, when water-insoluble CyD derivatives are used in organic solvent,[4] knowledge of the extent of affinity of the organic solvent molecule with the cavity of parent CyD is required.

A wide variety of guest compounds have been known to be accepted in CyD cavities, but there are no available data concerning carbon tetrachloride, chloroform, and dichloromethane. This is probably due to the lack of suitable methods to detect the free- or associated-guest species in water. UV absorption and fluorescence methods, which are generally used to evaluate the CyD–guest association, cannot be applied to these guests, because they have neither absorption peaks in the ordinary accessible ultraviolet region, nor fluorescence. We have recently proposed a method which can be applied to such guests without any UV absorption and fluorescence.[5] The only requirement is the guest volatility. The guests dealt with in this study are highly volatile and hence ideal objects for our method to be applied.

Experimental

Materials and Preparation of Sample Solutions. Distilled deionized water was used throughout this work. Carbon tetrachloride, chloroform, and dichloromethane (Wako Pure Chemicals Co.) used as guests and cyclodextrins (α-, β-, and γ-CyD, Nakarai Chemical Co.) used as hosts were all of analytical reagent grade and were used as received. An aqueous solution saturated with each guest was prepared by a vapor-circulation method using an apparatus described in the previous paper.[6] The saturated guest concentration was not determined, but taken from the literature.[7] By diluting the saturated aqueous solution with water, each 1.60×10^{-4} M (M≡mol dm^{-3}) solution was prepared. A suitable portion (10 cm^3 for CCl_4 and CH_2Cl_2, 20 cm^3 for $CHCl_3$) was transferred into a 2.5φ×25 cm cylindrical glass tube and diluted with water, with or without addition of CyD aqueous solution, to 50 cm^3 for CCl_4 and CH_2Cl_2 or to 90 cm^3 for $CHCl_3$. CyD aqueous solutions were prepared daily by dissolving suitable amounts of CyD which had been dried over phosphorus pentaoxide under vacuum.

Apparatus and Procedures. Nitrogen gas was blown at a constant flow rate of 15 cm^3 min^{-1} into the aqueous guest solution placed with or without CyD in the cylindrical glass tube immersed in a bath thermostated at 25±0.1 °C. The N_2 gas leaving the sample solution was passed through a collector (a tapered glass tube of 0.5φ×17 cm, packed with Tenax GC resin beads of 60—80 mesh in 10 cm length) for a fixed time. The amount of guest collected at definite time intervals, ΔQ_ϕ, and that collected during a sufficiently long time (1 h in most cases, during which almost all guest molecules were to be driven out of the sample solution), Q_ϕ, were determined by a Shimadzu GC-12A gas chromatograph. An injection port of the chromatograph was connected with a furnace (Shimadzu flush sampler FLS-3) to feed the guest sample; a collector tube was heated to above 200 °C in one min. A SE-30 (60—80 mesh) column of 2 m long was used at 80 ° and a flame ionization detector was used. A Shimadzu Chromatopac C-R6A was used to determine the peak areas.

Results and Discussion

Under the present experimental condition that host molecules are always excessive over guest molecules, the possible host–guest association reactions are:

$$\mathrm{CyD} + \phi \rightleftharpoons \mathrm{CyD}\cdot\phi, \quad K_1, \tag{1}$$

$$\mathrm{CyD}\cdot\phi + \mathrm{CyD} \rightleftharpoons \mathrm{CyD_2}\cdot\phi, \quad K_2, \tag{2}$$

and

$$\phi(\mathrm{aq}) \longrightarrow \phi(\mathrm{gas}), \quad k, \tag{3}$$

where φ refers to a guest molecule, K_1 and K_2 are the corresponding stepwise association constants, and k is the rate constant for the transfer of guest molecules from aqueous to gaseous phase.

We assume that the release of guest molecules at a constant N_2 flow rate is of first-order with respect to the concentration of free species present at any time t in the solution as follows:

$$dQ_\phi V^{-1}/dt = k[\phi], \tag{4}$$

Table 1. The 1:1 (Host:Guest) Formation Constant at 25 °C[a]

α-CyD	2.65—8.32	28±14
β-CyD	1.11	b)
γ-CyD	8.33	b)

a) In the present runs, the concentration of each guest in the aqueous solution before aeration was set at constant, 1.60×10^{-4} mol dm^{-3}. b) The host-guest association was not observed at the given CyD concentration. c) C_{CyD} was not changed, and the formation constant was determined on the assumption of 1:1 association.

where V is the volume of aqueous solution.

An equation to estimate K_1 and K_2 can be derived using the total concentrations of host (C_{CyD}) and guest (C_ϕ) and the total amount of guest released, Q_ϕ (the sum of ΔQ_ϕ from time 0 to t), in the same way as described in the previous paper[5] as follows:

$$\ln(C_\phi - Q_\phi V^{-1}) = -kt/(1 + K_1C_{CyD} + K_1K_2C_{CyD}^2) + \ln C_\phi$$
$$= -k't + \ln C_\phi, \quad (5)$$

where

$$k' = k/(1 + K_1C_{CyD} + K_1K_2C_{CyD}^2). \quad (6)$$

Rearrangement of Eq. 6 yields:

$$1/k' = K_1K_2C_{CyD}^2/k + K_1C_{CyD}/k + 1/k. \quad (7)$$

For each host-guest combination, plots according to Eq. 5 at a constant C_{CyD} gave a similar straight line to that shown in our previous papers.[5] From inclination of the straight line, k' (and k) was determined and plotted according to Eq. 7. The $1/k'$ vs. C_{CyD} plots appeared to be linear, showing that K_2 can be neglected. In the case of $CHCl_3$-β-CyD, the CyD concentration was not changed, and K_1 was estimated on the assumption that this host-guest forms a 1:1 complex. When γ-CyD was used as the host, $1/k'$ values for the three guests were found to be in accordance with $1/k$ within experimental error. It was thus assumed that γ-CyD does not associate with each of guests studied. This is also the case for β-CyD-CH_2Cl_2. The K_1 value evaluated in this work for each combination is given in Table 1.

Molecular sizes of both host and guest being taken into account, the inclusion models are illustrated in Fig. 1; the guest molecule is oriented so that it enters as deeply as possible into the CyD cavity. CCl_4 molecule is only partly included in α-CyD, and a part of $CHCl_3$ molecule protrudes out of the α-CyD cavity, while the CH_2Cl_2 is completely accomodated in the cavity. Contrary to our expectation, however, the association constant of the α-CyD-CH_2Cl_2 complex is rather small. This is probably relevant to the polarity of the guest molecule.

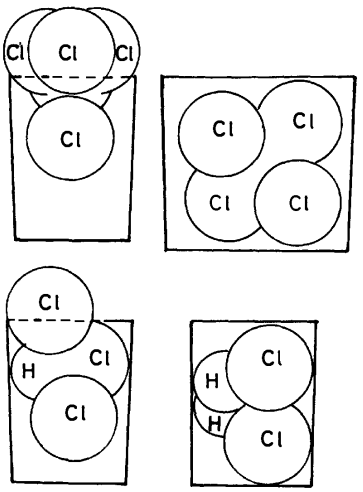

Fig. 1. Inclusion model. The larger cage refers to β-CyD ($CHCl_3$-β-CyD model is omitted).

The guest has to loose surrounding water molecules before it enters the CyD cavity. The free-energy change associated with this process can be estimated from Henry's law constant, K_H, as follows: $\Delta G_{dehyd} = -RT \ln K_H$. Using K_H values reported in the literature,[8] $-\Delta G_{dehyd}$ at 25 °C are evaluated to be 18.4 (CCl_4), 13.2 ($CHCl_3$), and 11.9 kJ mol^{-1} (CH_2Cl_2). The ΔG_{dehyd} is a quantitative measure of guest hydrophobicity: a guest with larger $-\Delta G_{dehyd}$ can be more easily transferred from aqueous into gaseous phase.

CCl_4 molecule is suitably accomodated in the β-CyD cavity. This accounts for larger K value of the β-CyD complex than that of the α-CyD complex. On the other hand, β-CyD is a little large for $CHCl_3$ and too large for CH_2Cl_2 to be fitted in with the cavity. In addition, relatively high polarity of CH_2Cl_2 may also be responsible for unobserved association of this guest with β-CyD. The large cavity of γ-CyD seems to explain the cause of the results that any association between this host and the three guests studied in this work has not been observed.

The association constant of CCl_4 with β-CyD is comparable to that of benzene with β-CyD. Molecular volume of CCl_4 (86.82×10^{-3}) is similar to that of benzene (80.33×10^{-3} nm^3),[9] and benzene also suitably fits with the β-CyD cavity. When we consider that $-\Delta G_{dehyd}$ for CCl_4 is much larger than that of benzene, 14.4 kJ mol^{-1}, a much larger association of CCl_4 with β-CyD will be expected. This may indicate that stabilization such as van der Waals does not work, or even it works, to a lesser extent for CCl_4 than benzene.

It is generally observed that CyDs dissolved in water in relatively high concentrations precipitate upon

shaking with some organic solvents; γ-CyD easily precipitates with chloroform. Some workers believe that this arises from the organic solvent molecule forming stable complexes with CyDs.[2] It is not true because γ-CyD does not form any complex with $CHCl_3$. The precipitation seems to occur through the change in the polarity of aqueous solution caused by organic solvent dissolving in water.

It is now rationalized why the selective syntheses of benzoic acids and benzaldehydes from phenolates using CyDs as catalysts can be performed;[1] α-CyD–dichlorocarben, α- and β-CyDs–chroloform, and β-CyD–carbon tetrachloride are successful combinations but γ-CyD cannot be used for the purpose.

It should be mentioned that the present study does not necessarily exclude the possibility of formation of a CyD complex with more than one guest molecules, because such an association cannot take place under our experimental condition that C_{CyD} is much higher than C_{ϕ}.

The Reaction of *N*″-Cyanoguanidine with Formaldehyde. IV. The Formation Pathway of 4-Cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine

Ryuichi SHIBA,* Miyuki TAKAHASHI, Toichi EBISUNO,† and Michiaki TAKIMOTO†

(Received March 17, 1989)

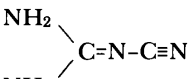
Synopsis. An investigation of reactions involving *N*″-cyanoguanidine (CG) and its methyl derivatives with formaldehyde as well as the consideration of the molecular structures of CG and 4-cyanoimino-3-(methoxymethyl)-perhydro-1,3,5-oxadiazine elucidated the formation pathway of the latter compound from CG: CG → *N*-hydroxymethyl-*N*″-cyanoguanidine → *N*,*N*′-bis(hydroxymethyl)-*N*″-cyanoguanidine → 4-(cyanoimino)perhydro-1,3,5-oxadiazine → 4-cyanoimino-3-(hydroxymethyl)perhydro-1,3,5-oxadiazine → 4-cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine.

The maximum number of formaldehyde molecules added to *N*″-cyanoguanidine (CG) can be anticipated to be 4 by analogy with urea, which has an analogous structure to that of CG, and is allowed to react with formaldehyde into 3,5-bis(methoxymethyl)perhydro-1,3,5-oxadiazin-4-one (**1**), tetrakis-substituted urea.[1-3] However, the exhaustive hydroxymethylation of CG with a large excess of formaldehyde provided no tetrakis-substituted CG but, rather, 4-cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine (**8**) as the major product.[4]

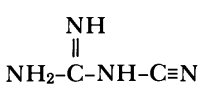
In our present report we wish to elucidate the reasons why the maximum number of formaldehyde molecules added to CG is not 4, but 3, and to propose a formation pathway for **8**.

Results and Discussion

Two possible molecular structures of CG (**I** and **II**) had previously been proposed.[5-6] A study[7] concerning the IR spectrum of CG suggested that structure **I** is more appropriate than structure **II**. Furthermore, our results concerning the ^{1}H NMR spectrum of CG have revealed that the structure CG is **I** over a wide pH range, including 7—10, since only one signal of the amino proton (δ=6.57 (s, 4H)) was observed. These facts exclude the possibility that the maximum number of formaldehyde molecules may be determined by three hydrogen atoms in the amino and imino groups in the structure of **II**.

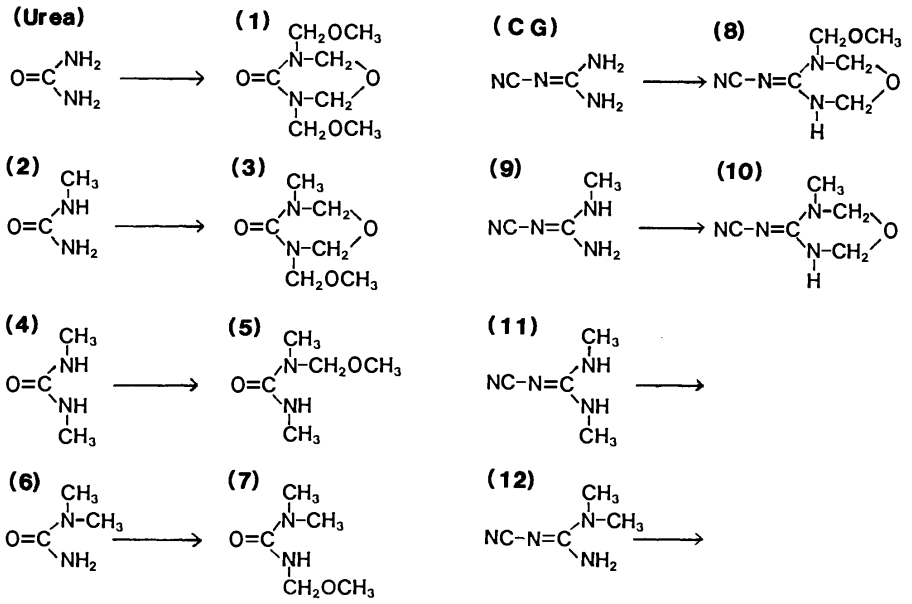


(**I**)



(**II**)

In a previous report,[3] we proposed a new formation pathway of **1** which was derived from urea and formaldehyde via tris(hydroxymethyl)urea and 3-(hydroxymethyl)perhydro-1,3,5-oxadiazin-4-one. The oxadiazine-ring formation may be a rate-determining



Scheme 1. The reactions of urea or *N*″-cyanoguanidine and its methyl derivatives with formaldehyde. Major products from the reactions of urea or *N*″-cyanoguanidine and its methyl derivatives with formaldehyde are shown and blank spaces represent that starting materials were recovered unchanged.

step in this formation, probably because the steric hindrance of the hydroxymethyl groups interferes with the addition of a fourth formaldehyde molecule to tris(hydroxymethyl)urea.

In order to examine the difference in the reactions of CG with formaldehyde and of urea with formaldehyde, CG and its methyl derivatives were allowed to react with a large excess of formaldehyde. The hydroxymethylated products were etherified by MeOH in order to isolate them. The major products from urea or CG and its methyl derivatives with formaldehyde are shown in Scheme 1 together with their reaction equations. Although the maximum number of formaldehyde molecules added to urea was 4, only one formaldehyde molecule was added to *N,N'*- or *N,N*-dimethylurea (**4** and **6**) into *N*-methoxymethyl-*N,N'*- or *N*-methoxymethyl-*N',N'*-dimethylurea (**5** and **7**). On the other hand, 3-methoxymethyl-5-methylperhydro-1,3,5-oxadiazin-4-one (**3**) was produced from methylurea (**2**) and formaldehyde. These results could be explained by the importance of a steric hindrance; a decrease in the steric hindrance enabled a further addition of formaldehyde molecule to the fourth hydrogen atom in the amino groups.

The reactivity of CG can be understood in terms of a steric hindrance of the cyanoimino group and of a difference in the electron-attracting nature between =O (in urea) and =N-C≡N (in CG). The latter reason may explain why **11** could not react with formaldehyde. However, it may also be explicable in terms of the former reason, since the cyanoimino group in **11** may restrict the movement of the methyl group in the proximal methylamino group; thus, this methyl group may interfere with the addition of a formaldehyde molecule to the other methylamino group. Figure 1 shows the molecular structures of urea, CG and **8**. Four atoms (one oxygen, one carbon, and two nitrogen atoms) in urea lie on the same plane. Each of the six atoms (two carbon and four nitrogen atoms) in CG and **8** lie nearly on the same plane, respectively. The cyanoimino group is located unequivalently in the two amino groups in CG in the crystalline state while the two amino groups in urea are equivalent. The double-bond character of C(1)-N(2), N(2)-C(2), C(2)-N(3), and C(2)-N(4) in CG and **8** can be calculated by using the theoretical single- and double-bond lengths reported by Schomaker and Stevenson[10]: 85, 50, 45, and 59% in CG, and 73, 67, 56, and 60% in **8**, respectively. Therefore, the planary structure of CG can be expected to remain while in solution. Thus, the two amino groups in CG are not equivalent to the addition of a formaldehyde molecule, because of a steric hindrance of the cyanoimino group. This steric

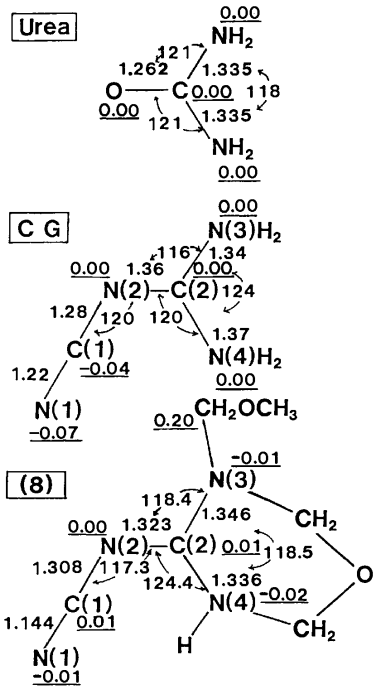


Fig. 1. The molecular structures of urea, *N''*-cyanoguanidine (CG), and 4-cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine (**8**) with the selected numbering scheme. Underscored numbers are the heights of Å of the atoms above or below the planes which are composed of four atoms in urea, four atoms (guanidine moiety) in CG and six atoms (*N''*-cyanoguanidine moiety) in **8**, respectively. The signs of ← → represent bond angles and other small numbers represent bond lengths in Å. These data were cited from Vaughan and Donohue's (urea),[8] Hughes' (CG),[6] and our report (**8**).[9]

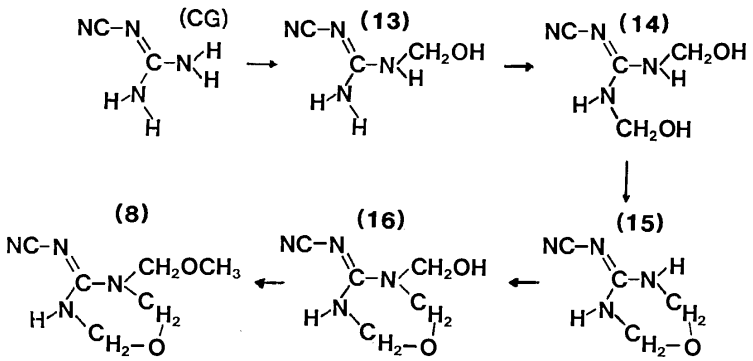

Scheme 2. Proposed formation pathway of 4-cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine (**8**).

hindrance is supported by the assembly of the CPK model for CG.

We wish to propose a formation pathway of **8**, shown in Scheme 2. The first addition of a formaldehyde molecule occurs on the most remote hydrogen atom from the cyanoimino group, producing *N*-hydroxymethyl-*N''*-cyanoguanidine (**13**); the second addition of a formaldehyde molecule on the hydrogen atom in a different amino group produces *N,N'*-bis(hydroxymethyl)-*N''*-cyanoguanidine (**14**). The two hydroxymethyl groups condense into an oxadiazine ring by eliminating water to produce 4-(cyanoimino)-perhydro-1,3,5-oxadiazine (**15**); a decrease in the steric hindrance of the hydroxymethyl groups enables a third addition of a formaldehyde molecule on the remote hydrogen atom from the cyanoimino group to produce 4-cyanoimino-3-(methoxymethyl)perhydro-1,3,5-oxadiazine (**16**). Thus, **8** is derived from **16** and MeOH.

Experimental

The Reaction of CG and Its Methyl Derivatives with Formaldehyde. According to the published procedure,[4] **8** was prepared from CG and a large excess of formaldehyde. *N*-Methyl-*N''*-cyanoguanidine (**9**) and *N,N'*- and *N,N*-dimethyl-*N''*-cyanoguanidine (**11** and **12**) were prepared from a mixture of ammonia or methylamine with *N*-cyano-*N'*-methyl-*O*-ethylisourea or *N*-cyano-*N',N'*-dimethyl-*O*-ethylisourea,[11] which was prepared from cyanamide according to a virtually identical procedure described by Suyama and Odo.[12] The methyl derivatives of CG and a large excess of formaldehyde (the feed mole ratio of **9**, **11**, or **12**/formaldehyde=1/5) were mixed and the pH of the solution was adjusted to 9.0. The solution was stirred for 30 min at 95 °C. 4-Cyanoimino-3-methylperhydro-1,3,5-oxadiazine (**10**) was derived from **9** and formaldehyde. However, no products were obtained and the starting materials were recovered unchanged in the reaction of **11** or **12** with formaldehyde.

4-Cyanoimino-3-methylperhydro-1,3,5-oxadiazine (10): Yield: 42%: Mp 121—122 °C (decomp): Found: C, 42.57; H, 5.86; N, 39.82%: Calcd for $C_8H_8N_4O$: C, 42.85; H, 5.75; N, 39.98%: ^{1}H NMR (DMSO-d_6): δ=8.20 (s, 1H, -NH-), 4.79, 4.74 (s, 2H, $-CH_2-$), 2.81 (s, 3H, $-CH_3$).

[Cycloalkyl(phenylseleno)methylene]triphenylphosphoranes: Synthesis and Reactions of (Phenylseleno)alkenes

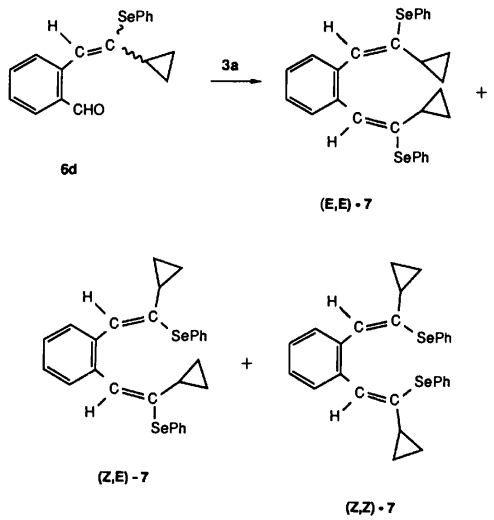
Toru MINAMI,* Yasuo UMEZU, Shoji SHIKITA, and Yoshiharu OKADA
Department of Applied Chemistry, Kyushu Institute of Technology, Sensuicho, Tobata, Kitakyushu 804
(Received March 25, 1989)

Synopsis. The Wittig reaction of [cyclopropyl(phenylseleno)methylene]- and [cyclobutyl(phenylseleno)methylene]-triphenylphosphoranes with aldehydes produced (*Z*)- and (*E*)-(1-cyclopropyl-1-phenylseleno)- and (1-cyclobutyl-1-phenylseleno)alkenes in moderate to good yields. The oxidation of the (*E*)-selenoalkenes to the corresponding selenoxides and subsequent thermolysis of the selenoxides led to cyclopropyl- and cyclobutylacetylene derivatives in good yields.

We have recently reported the synthesis of [cycloalkyl(phenylseleno)methyl]triphenylphosphonium salts by the reaction of (cycloalkylmethylene)triphenylphosphoranes with benzeneselenenyl bromide.[1] Although selenenylated phosphonium salts are expected to be useful intermediate reagents, their synthetic utilization has, to our knowledge, been little reported.[1-4] In this paper we report the reaction of [cycloalkyl(phenylseleno)methylene]triphenylphosphoranes derived from the corresponding selenophosphonium salts and base with various aldehydes; we also report on a convenient synthesis of cycloalkylacetylene derivatives from the resulting selenoalkenes.

Results and Discussion

Treatment of a [cyclopropyl(phenylseleno)methyl]-triphenylphosphonium salt **2a** with 1.1 molar equiv of *n*-BuLi at room temperature for 0.5 h in THF, followed by a reaction with benzaldehyde (**4a**) at room temperature for 1 h, gave a 1:1 mixture of (*Z*)- and (*E*)-1-cyclopropyl-2-phenylethene (**5a**) (76%) together with butyl phenyl selenide (75%). This result indicates that the phosphonium salt **2a** underwent facile deselenation with *n*-BuLi to give (cyclopropylmethylene)triphenylphosphorane (**1a**). Replacement of *n*-BuLi by NaH in the same reaction led to a mixture of **5a** (30%) and (*Z*)- and (*E*)-1-cyclopropyl-1-phenylseleno-2-phenylethene (**6a**) (2:3 mixture, 48%), while the reaction using lithium bis(trimethylsilyl)amide [LiN(SiMe$_3$)$_2$] as the base produced a 3:4 mixture of (*Z*)- and (*E*)-**6a** in 70% yield. The Wittig condensation of various aldehydes **4a—d** with the phosphorane **3a**, generated from **2a** and LiN(SiMe$_3$)$_2$, gave mixtures of (*Z*)- and (*E*)-(phenylseleno)alkenes **6b—d** in 26—89% yields (see Table 1). Further treatment of isolated **6d** with **3a** led to a 7:6:1 mixture of (*E,E*)-, (*Z,E*)-, and (*Z,Z*)-*o*-bis[2-cyclopropyl-2-(phenylseleno)ethenyl]benzene (**7**) in 62% yield (Eq. 1). Treatment of **3a** with



(1)

paraformaldehyde smoothly led to the formation of 1-cyclopropyl-1-(phenylseleno)ethene (**6e**) in 74% yield. The [cyclobutyl(phenylseleno)methyl]triphenylphosphonium salt **2b**,[1] on similar treatment with NaH or LiN(SiMe$_3$)$_2$ and **4a** in THF, afforded a 1:1 mixture of (*Z*)- and (*E*)-1-cyclobutyl-1-phenylseleno-2-phenylethene (**8**) (23 or 54%) along with 1-cyclobutyl-2-

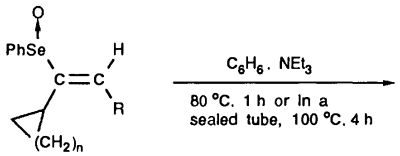
5	**2a**	**4c** (MeCH=CH)	$LiN(SiMe_3)_2$		**6c** (26, 1:3)
6	**2a**	**4d** (*o*-C_6H_4CHO)	$LiN(SiMe_3)_2$		**6d** (62, 1:1)
7	**2a**	**4e** (H)	$LiN(SiMe_3)_2$		**6e** (74)
8	**2b**	**4a** (Ph)	BuLi	**5b** (70, 3:2)	
9	**2b**	**4a** (Ph)	NaH	**5b** (6)	**8** (23, 1:1)
10	**2b**	**4a** (Ph)	$LiN(SiMe_3)_2$	**5b** (8)	**8** (54, 1:1)

a) Unless othewise indicated, all reactions were carried out using **2** (1 mmol), **4** (1.2 mmol), and base (1.1 equiv) in THF (5 cm^3). b) Isolated yields. c) Based on ^1H and/or ^{13}C NMR spectrum.

phenylethene (**5b**) (Table 1, Entries 9 and 10). This result exhibits that, even using $LiN(SiMe_3)_2$ as well as NaH, the salt **2b** underwent not only deprotonation but deselenation to generate ylides **1b** and **3b**, leading to the products (Scheme 1).

In an attempt to investigate the reactivities of alkenyl selenides, the oxidation of the selenides (**6a, b, 7**, and **8**) with H_2O_2 at room temperature was carried out to produce the corresponding selenoxides (**9a, b, 10**, and **11**) in good yields.

Selenoxides (*E*)-**9a** and (*E*)-**11** were smoothly converted in benzene containing triethylamine at 80 °C for 1 h into cyclopropylethynyl- and cyclobutylethynylbenzenes (**12** and **13**) in 74 and 79% yields. The thermolysis of



(E)-9a, (E)-11, (1E,3E)-9b

(3)

Thus, we have found that phosphonium salts **2a, b** can be used as useful intermediate reagents for the synthesis of alkenes and alkynes bearing small-membered cycloalkyl substituents.

Experimental

General. ^1H NMR spectra were obtained on a JEOL JNM-FX-60 spectrometer in $CDCl_3$ operating at 60 MHz with Me_4Si as an internal standard. IR spectra were recorded with a Shimadzu IR-408 instrument. Mass spectra were taken with a JEOL DX-300 spectrometer.

Reaction of 2a, b[1] with *n*-BuLi (or NaH) or $LiN(SiMe_3)_2$ and 4a—e. General Procedure. To solutions of phosphonium ylides, generated in situ from **2a, b** (1 mmol) and *n*-BuLi or $LiN(SiMe_3)_2$ (1.1 mmol) in dry THF (5 cm^3) at 0 °C for 0.5 h or −75 °C for 1 h, was added **4a—e** (1.2 mmol). The mixture was stirred at room temperature for 10 or 12 h. After an aqueous NH_4Cl solution was added to the reaction mixture the mixture was concentrated in vacuo, extracted with CH_2Cl_2, washed with water, and dried over Na_2SO_4. After evaporation of CH_2Cl_2, the residue was chromatographed on preparative TLC (silica gel, Wakogel B-5F, hexane) to give pure samples **5a, b** (or **5a, b** and **6a** or **8**) and butyl phenyl selenide or **6a—e** and **8**. The yields of the products are summarized in Table 1.

1-Cyclopropyl-2-phenylethene (**5a**): yield 0.11 g; IR (neat) 1650, 1600 cm^{-1}; ^1H NMR δ=0.39—0.97 (m, 4H, CH_2), 1.20—2.20 (m, 1H, CH), 5.00 (dd, J=9.67 Hz, 11.43 Hz, 0.5H, cis ***H***C=CPhH), 5.65 (dd, J=8.43 Hz, 15.70 Hz, 0.5H, trans ***H***C=CPhH), 6.31 (d, J=11.43 Hz, 0.5H, cis HC=CPh***H***), 6.43 (d, J=15.70 Hz, 0.5H, trans HC=CPh***H***); Found: *m/z* 144.0987. (*Z*)-1-Cyclopropyl-1-phenylseleno-2-phenylethene [(*Z*)-(**6a**)]:[8] yield 58 mg; IR (neat) 1595, 1580 cm^{-1}; ^1H NMR

δ=0.30—1.00 (m, 4H, CH_2), 1.00—1.90 (m, 1H, CH), 6.83 (s, 1H, CH=C); Found: *m/z* 300.0417. Calcd for $C_{17}H_{16}Se$: M, 300.0416.

(*E*)-1-Cyclopropyl-1-phenylseleno-2-phenylethene [(*E*)-(**6a**)]:[8] yield 85 mg; IR (neat) 1595, 1580 cm^{-1}; ^1H NMR δ=0.25—0.69 (m, 4H, CH_2), 1.70—2.30 (m, 1H, CH), 6.89 (s, 1H, CH=C); Found: *m/z* 300.0443. Calcd for $C_{17}H_{16}Se$: M, 300.0416.

(*Z*)-1-Cyclobutyl-1-phenylseleno-2-phenylethene [(*Z*)-(**8**)]:[7,8] yield 35 mg.

(*E*)-1-Cyclobutyl-1-phenylseleno-2-phenylethene [(*E*)-(**8**)]:[7,8] yield 35 mg.

(1*E*,3*Z*)-1-Cyclopropyl-4-phenyl-1-phenylseleno-1,3-butadiene [(1*E*,3*Z*)-(**6b**)]:[7,8] yield 65 mg.

(1*E*,3*E*)-1-Cyclopropyl-4-phenyl-1-phenylseleno-1,3-butadiene [(1*E*,3*E*)-(**6b**)]:[7,8] yield 225 mg.

1-Cyclopropyl-1-phenylseleno-1,3-pentadiene (**6c**):[7] yield 70 mg.

o-[2-Cyclopropyl-2-(phenylseleno)ethenyl]benzaldehyde (**6d**):[7] yield 205 mg.

1-Cyclopropyl-1-phenylselenoethene (**6e**)]:[7] yield 165 mg.

o-Bis[2-cyclopropyl-2-(phenylseleno)ethenyl]benzene (**7**).

The reaction was carried out as described above by using **2a** (0.57 g, 1 mmol) and **6d** (0.38 g, 1.2 mmol) to produce 0.33 g (62%) of a 7:6:1 mixture of (*E,E*)-, (*E,Z*)-, and (*Z,Z*)-**7**.[8] Pure samples of individual (*E,E*)-, (*E,Z*)-, and (*Z,Z*)-**7**, were isolated by preparative TLC (hexane).

(*E,E*)-**7**: IR (neat) 1575 cm^{-1}; ^1H NMR δ=0.54—0.71 (m, 8H, CH_2), 1.59—2.05 (m, 2H, CH), 6.82 (s, 2H, CH=C); MS, *m/z* 522 (M^+).

(*E,Z*)-**7**: IR (neat) 1575 cm^{-1}; ^1H NMR δ=0.53—0.75 (m, 8H, CH_2), 1.25—1.98 (m, 2H, CH), 6.69 (s, 1H, CH=C); 6.75 (s, 1H, CH=C); MS, *m/z* 522 (M^+).

(*Z,Z*)-**7**: IR (neat) 1575 cm^{-1}; ^1H NMR δ=0.54—0.81 (m, 8H, CH_2), 1.36—1.69 (m, 2H, CH), 6.68 (s, 2H, CH=C); MS, *m/z* 522 (M^+).

Oxidation of the Selenides 6a, b, 7, and 8. General Procedure. A solution of selenide (1 mmol) in CH_2Cl_2/H_2O (1/1, 10 cm^3) containing H_2O_2 (5 equiv) was stirred at room temperature for 5 h. The reaction mixture was then extracted with CH_2Cl_2, washed with water, and dried over Na_2SO_4. After evaporation of CH_2Cl_2, the residue was chromatographed on preparative TLC (ethyl acetate) to give selenoxides **9a, b, 10**, and **11**.

(*Z*)-1-Cyclopropyl-1-phenylseleninyl-2-phenylethene [(*Z*)-(**9a**)]: yield 258 mg (82%); IR (neat) 1595, 1575 cm^{-1}; ^1H NMR δ=0.00—1.10 (m, 4H, CH_2), 1.60—2.20 (m, 1H, CH), 6.83 (s, 1H, CH=C), 7.00—7.90 (m, 10H, phenyl H).

(*E*)-1-Cyclopropyl-1-phenylseleninyl-2-phenylethene [(*E*)-(**9a**)]: yield 300 mg (95%); IR (neat) 1595, 1575 cm^{-1}; ^1H NMR δ=0.20—1.80 (m, 5H, CH_2 and CH), 7.0—8.0 (m, 11H, CH=C and phenyl H).

(1*E*,3*E*)-1-Phenyl-4-cyclopropyl-4-phenylseleninyl-1,3-butadiene [(1*E*,3*E*)-(**9b**)]:[7] yield 229 mg (70%).

(*E,E*)-*o*-Bis[2-cyclopropyl-2-(phenylseleninyl)ethenyl]benzene [(*E,E*)-(**10**)]:[7] yield 552 mg (quant).

(*E,Z*)-*o*-Bis[2-cyclopropyl-2-(phenylseleninyl)ethenyl]benzene [(*E,Z*)-(**10**)]:[7] yield 550 mg (quant).

(*Z*)-1-Cyclobutyl-1-phenylseleninyl-2-phenylethene [(*Z*)-(**11**)]:[7] yield 330 mg (quant).

(*E*)-1-Cyclobutyl-1-phenylseleninyl-2-phenylethene [(*E*)-(**11**)]:[7] yield 330 mg (quant).

Thermolysis of the Selenoxides (*E*)-9a, (*E*)-11, (*E,E*)-10, (*E,Z*)-10, or (1*E*,3*E*)-9b. General Procedure. A solution of a selenoxide (1 mmol) in dry benzene (5 cm^3) containing small amounts of triethylamine was heated under reflux for 1 h or at 100 °C for 4 h in a sealed tube. After evaporation of benzene, the residue was chromatographed on preparative TLC (hexane or ethyl acetate) to give an acetylene.

(Cyclopropylethynyl)benzene (**12**): yield 105 mg (74%); IR (neat) 2240 cm^{-1}; ^1H NMR δ-0.50—1.00 (m, 4H, CH_2), 1.00—1.70 (m, 1H, CH); Found: *m/z* 142.0754. Calcd for $C_{11}H_{10}$: M, 142.0782.

(Cyclobutylethynyl)benzene (**13**):[7] yield 123 mg (79%).

o-Bis(cyclopropylethynyl)benzene (**15**):[7] yield 198 mg (96%).

(*Z*)-1-Cyclopropylethynyl-2-[2-cyclopropyl-2-(phenylseleninyl)ethenyl]benzene (**16**):[7] yield 375 mg (quant).

1-Phenyl-4-cyclopropyl-1-buten-4-yne (**14**):[7] yield 62 mg (37%).

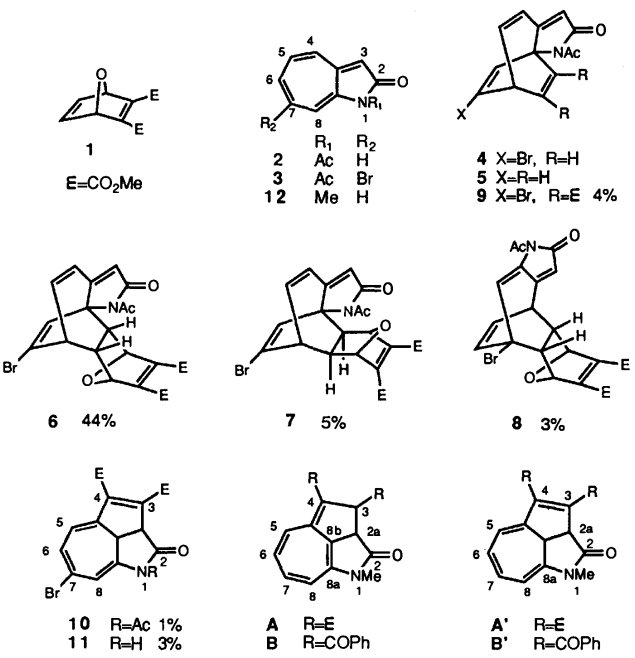
(Received March 27, 1989)

Synopsis. A high-pressure cycloaddition reaction of 1-acetyl-7-bromocyclohepta[*b*]pyrrol-2(1*H*)-one and 2,3-bis-(methoxycarbonyl)-7-oxanorbornadiene and a further thermolysis of [4+2] cycloadducts gave 2-acetyl-9-bromo-2-azatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one, which was photorearranged to 9-methylenebarbaralane and 5-methylenetricyclo[4.3.0.0^{2,9}]nonadiene derivatives. The product distribution of the photolysis was altered by a bromine atom.

From a comparative point of view of the results of 2,3-bis(methoxycarbonyl)-7-oxabicyclo[2.2.1]heptadiene (**1**) with 2*H*-cyclohepta[*b*]furan-2-ones, we investigated[2] the reaction of **1** with 1-acetylcyclohepta[*b*]-pyrrol-2(1*H*)-one (**2**) in order to observe both [4+2] and [8+2] cycloadducts, the latter of which are of interest in regard to a possible entry to azulene derivatives.[3]

Since the introduction of an electronegative halogen substituent into a seven-membered ring may alter the reaction course, it should be worthwhile carrying out the reaction with an easily available bromo derivative of **2**. Herein, we describe the result for **1** and 1-acetyl-7-bromocyclohepta[*b*]pyrrol-2(1*H*)-one (**3**),[4] disclosing that the heptafulvene structures, formerly proposed by Abe and Takehiro for [8+2] cycloadducts,[5] were shown to be revised. Furthermore, the photorearrangement of 2-acetyl-9-bromo-2-azatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one (**4**), the cycloreversed product, gave a different product distribution from that of 2-acetyl-2-azatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-one (**5**).[2]

When a chlorobenzene solution of **1** and **3** was heated at 120 °C under 3000 bar, six products (**6**—**11**) were isolated. A major product (**6**) was an endo [4+2] cycloadduct from NMR spectral data, whereas product **7** was an exo [4+2] isomer. Product **8** was another endo [4+2] adduct, whose NMR spectrum closely resembled that of the corresponding adduct from **1** and **2**.[2] Product **9** was formally an adduct between **3** and dimethyl butynedioate.



Scheme 1.

The structures of the remaining products (**10** and **11**) were determined as follows: From the rather small values of the coupling constants ($J_{5,6}$=6.6—7.0 Hz for **10** and **11**), the position of a double bond should be located between C_6 and C_7 since the coupling constant across the single bond is smaller than that across the double bond.[6] Therefore, the structures of **10** and **11**

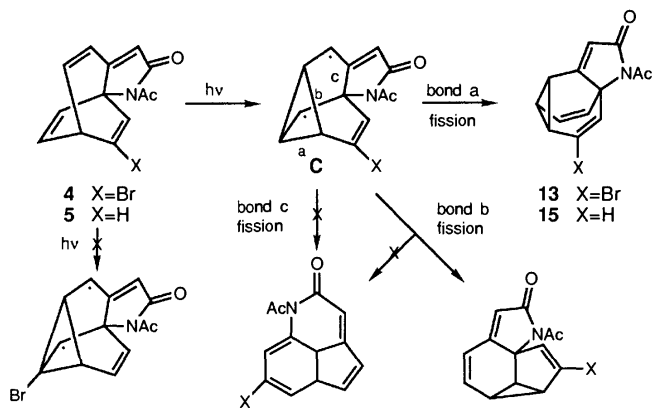
were determined as shown in Scheme 1. According to a recent paper regarding the reactions of 1-methylcyclohepta[*b*]pyrrol-2(1*H*)-one (**12**) and acetylenes,[5] heptafulvene structures **A** and **B** have been proposed on the basis of an NMR analysis. However, since their ^{1}H NMR and UV data were very similar to **10** and **11**, except for the appearance of an H_7 proton and up-field shifted neighboring proton signals (Tables 1 and 2[7]), they should be revised to **A'** and **B'**. In the new structures the values of the coupling constants ($J_{6,7}$=9.8 Hz and $J_{7,8}$=6.1 Hz for **B**) are more consistent and the chemical shifts of H_8 around 5.7 are reasonably explained in terms of the electron donation of the nitrogen atom. Furthermore, a small difference in the chemical shift between two methoxy groups and very large difference (over 1 ppm) in the chemical shift of two methine protons are also compatible with the revised structures.

In the reactions of **3** and **1**, the formations of [4+2] adducts were predominated over [8+2] adducts ([4+2]/[8+2]=56/4), while the ratio of [4+2] and [8+2] adducts was 14/16 from **2** and **1**.[2] Thus, the chemical reactivity of **3** toward **1** was different from that of **2**.

The thermal cycloreversion of **6** afforded **4**, the structure of which was elucidated by comparison with spectral data of **5**.[2] The irradiation of **4** with a 400-W high-pressure mercury lamp gave two products (**13** and **14**). The structures of **13** and **14** were determined to be substituted 9-methylenebarbaralane and 5-methylenetricyclo[4.3.0.0^{2,9}]nonadiene derivative by a comparison with the spectral data of **15** and **16**.[2] Among the photoproducts from **4**, a methylenedihydroindene derivative (**17**) was not detected, despite an intensive effort. This was in contrast to the fact that **5** gave a methylenedihydroindene derivative (**18**).



Scheme 2.

The mechanism of the photorearrangement of **4** was considered to be similar to that of **5**.[2] There are two bridging sites between the extended enone and an etheno bridge in **4**. The structure of **14** indicated that the bridging occurred at the etheno bridge carrying no bromine atom to give the intermediate (**C**). Certainly, the bromine atom prevented sterically the formation of the bridged intermediate (**D**).

On the other hand, an absence of methylenedihydroindene derivative, **17**, in the photorearrangement of **4** suggests that **13** and **14** were products via a triplet state: Namely, it has already been clarified, in the photorearrangement of 2-oxatricyclo[6.2.2.0^{1,5}]dodeca-4,6,9,11-tetraen-3-ones,[8] that methylenedihydroindenes were formed via a singlet excited state, and it was conceivable that the intersystem crossing of the singlet state to the triplet one would be facilitated for the brominated **4**, diminishing the formation of methylenedihydroindene **17**.[9]

Experimental

Cycloaddition Reaction of 1 and 3 under 3000 bar. A chlorobenzene solution (2.5 cm^3) of **1** (320 mg) and **3** (150 mg) was heated at 120 °C under 3000 bar for 20 h. The solvent was evaporated under reduced pressure and the residue was purified via silica-gel column chromatography, which followed by HPLC, to give **6** (98.5 mg, 44%), **7** (12 mg, 5%), **8** (7 mg, 3%), **9** (7 mg, 4%), **10** (2.4 mg, 1%), **11** (5.4 mg, 3%), and recovered **3** (26.3 mg).

6: Colorless crystals, mp 191—193 °C; ^{1}H NMR[10] δ=2.25 (1H, dd, J=8.8, 0.7 Hz), 2.54 (1H, dd, J=8.8, 1.1 Hz), 2.66 (3H, s), 3.63 (1H, dm, J=8.4 Hz), 3.78 (3H, s), 3.81 (3H, s), 5.04 (1H, d, J=1.1 Hz), 5.70 (1H, s), 5.78 (1H, s), 6.31 (1H, d, J=10.3 Hz), 6.49 (1H, dd, J=1.1, 0.7 Hz), and 6.77 (1H, dd, J=10.3, 8.4 Hz); ^{13}C NMR δ=26.6, 47.0, 49.1, 50.5, 52.5 (2C), 72.4, 83.6, 85.4, 118.4, 120.4, 123.3, 127.2, 141.8, 144.6, 146.4, 158.3, 162.6, 162.7, 170.2, and 171.4; IR 1720, 1635, and 1285 cm^{-1}; UV (MeOH) 245.8 (ε 8600) and 285.6 nm (6300).

Found: C, 53.01; H, 3.84; N, 2.75%. Calcd for $C_{21}H_{18}NO_7Br$: C, 52.96; H, 3.81; N, 2.94%.

7: Colorless crystals, mp 223 °C; ^{1}H NMR δ=2.64 (3H, s), 2.80 (1H, dd, J=8.8, 5.8 Hz), 3.68 (1H, d, J=8.8 Hz), 3.76 (3H, s), 3.8 (1H, m), 3.82 (3H, s), 4.57 (1H, d, J=1.1 Hz), 4.86 (1H, d, J=1.1 Hz), 5.88 (1H, s), 6.37 (1H, d, J=1.8 Hz), 6.46 (1H, dd, J=10.3, 8.8 Hz), and 6.55 (1H, dd, J=10.3, 1.8 Hz); ^{13}C NMR δ=25.8, 43.0, 47.2, 47.6, 52.4, 52.6, 72.0, 79.8, 83.3, 119.6, 124.6, 127.5, 131.5, 135.9, 145.5, 145.7, 157.0, 161.7, 162.4, 169.8, and 170.1; IR 1720, 1630, and 1280 cm^{-1}; UV (MeOH) 244.2 (ε 9600) and 283.6 nm (7500).

Found: C, 53.11; H, 3.84; N, 2.87%. Calcd for $C_{21}H_{18}NO_7Br$: C, 52.96; H, 3.81; N, 2.94%.

8: Colorless crystals, mp 183—184 °C; ^{1}H NMR δ=2.47 (1H, d, J=7.7 Hz), 2.55 (3H, s), 3.11 (1H, d, J=7.7 Hz), 3.81 (3H, s), 3.83 (1H, d, J=8.1 Hz), 3.85 (3H, s), 5.12 (1H, d,

J=1.5 Hz), 5.52 (1H, d, J=1.5 Hz), 5.91 (1H, d, J=1.8 Hz), 5.96 (1H, ddm, J=9.2, 8.1 Hz), 6.63 (1H, d, J=9.2 Hz), and 8.00 (1H, d, J=1.8 Hz); ^{13}C NMR δ=26.6, 39.8, 46.0, 52.6 (2C), 57.3, 61.1, 86.5, 86.7, 116.4, 126.4, 132.0, 135.5, 142.0, 144.8, 146.1, 152.1, 162.3, 162.5, 168.0, and 170.8; IR 1715, 1600, and 1305 cm^{-1}; UV (MeOH) 240.2 (ε 9100) and 274.0 nm (8200).

Found: C, 53.07; H, 3.84; N, 2.88%. Calcd for $C_{21}H_{18}NO_7Br$: C, 52.96; H, 3.81; N, 2.94%.

9: Colorless crystals, mp 189 °C; ^{1}H NMR δ=2.56 (3H, s), 3.72 (3H, s), 3.79 (3H, s), 4.43 (1H, dd, J=8.1, 2.2 Hz), 5.92 (1H, s), 6.19 (1H, d, J=10.3 Hz), 6.40 (1H, d, J=2.2 Hz), and 6.66 (1H, dd, J=10.3, 8.1 Hz); ^{13}C NMR δ=24.8, 48.8, 52.7, 53.0, 70.7, 121.0, 122.1 (2C), 122.6, 130.5, 135.3, 136.6, 148.5, 163.5, 164.4, 168.6, and 169.6; IR 1725, 1435, 1370, and 1300 cm^{-1}; UV (MeOH) 234.4 (ε 11900) and 285.7 nm (sh 6100).

Found: m/z 407.0008 (M$^+$ for ^{79}Br) and 409.0049 (M$^+$ for ^{81}Br). Calcd for $C_{17}H_{14}NO_6Br$: 407.0005 (M for ^{79}Br) and 408.9984 (M for ^{81}Br).

10: A colorless oil; IR 1760, 1725, 1610, 1590, and 1220 cm^{-1}.

Found: m/z 406.9999 (M$^+$ for ^{79}Br) and 408.9955 (M$^+$ for ^{81}Br). Calcd for $C_{17}H_{14}NO_6Br$: 407.0002 (M for ^{79}Br) and 408.9992 (M for ^{81}Br).

11: A colorless oil; IR 1720, 1430, and 1280 cm^{-1}.

Found: m/z 364.9904 (M$^+$ for ^{79}Br) and 366.9807 (M$^+$ for ^{81}Br). Calcd for $C_{15}H_{12}NO_5Br$: 364.9900 (M for ^{79}Br) and 366.9877 (M for ^{81}Br).

DDQ-Oxidation of 10. A C_6D_6 solution (0.5 cm^3) of **10** (1.5 mg) and DDQ (3 mg) was heated at 80 °C for 4 h in a NMR tube. The reaction was monitored by the ^{1}H NMR spectra. No change was observed.

Thermal Cycloreversion of 6. A chlorobenzene solution (1 cm^3) of **6** (60 mg) was heated for 24 h at 130 °C. The solvent was evaporated and the residue was chromatographed on a silica-gel column and HPLC to give **4** (24 mg, 65%) and 3,4-bis(methoxycarbonyl)furan (16 mg, 69%).

4: A colorless oil; ^{1}H NMR δ=2.61 (3H, s), 3.94 (1H, tm, J=8.0 Hz), 5.79 (1H, s), 6.05 (1H, d, J=10.3 Hz), 6.25 (1H, dt, J=7.0, 1.1 Hz), 6.37 (1H, d, J=1.1 Hz), 6.52 (1H, dd, J=8.0, 7.0 Hz), and 6.65 (1H, dd, J=10.3, 8.0 Hz); ^{13}C NMR δ=25.1, 48.9, 70.8, 119.1, 120.8, 123.3, 131.1, 131.5, 137.7, 151.2, 169.4, and 169.5; IR 1720, 1700, 1685, and 1290 cm^{-1}; UV (MeOH) 264.2 nm (ε 8200).

Found: m/z 290.9925 (M$^+$ for ^{79}Br) and 292.9824 (M$^+$ for ^{81}Br). Calcd for $C_{13}H_{10}NO_2Br$: 290.9896 (M for ^{79}Br) and 292.9875 (M for ^{81}Br).

Photorearrangement of 4. A $CDCl_3$ solution (0.5 cm^3) of **4** (65 mg) was irradiated with a 400-W high-pressure mercury lamp for 2.5 h. After the evaporation of the solvent, the residue was chromatographed on a silica-gel column and HPLC to give **13** (10 mg, 24%), **14** (5.6 mg, 14%), and recovered **4** (21 mg).

13: A colorless oil, ^{1}H NMR δ=2.57 (3H, s), 2.86 (1H, m), 3.01 (1H, td, J=7.7, 2.2 Hz), 3.13 (1H, dd, J=7.7, 7.0 Hz), 5.76 (1H, s), 5.84 (1H, dd, J=9.2, 6.2 Hz), 6.38 (1H, dd, J=9.2, 0.7 Hz), and 6.56 (1H, d, J=2.2 Hz); ^{13}C NMR δ=21.8, 25.2, 29.9, 37.0, 67.5, 111.3, 114.2, 119.7, 127.7, 129.0, 159.5, 169.1, and 169.7; IR 1730, 1695, 1660, 1380, and 1305 cm^{-1}; UV (MeOH) 274.8 (ε 16900) and 273.6 nm (2400).

Found: m/z 290.9929 (M$^+$ for ^{79}Br) and 292.9824 (M$^+$ for ^{81}Br). Calcd for $C_{13}H_{10}NO_2Br$: 290.9896 (M for ^{79}Br) and 292.9875 (M for ^{81}Br).

14: Colorless crystals, mp 153 °C; ^{1}H NMR δ=2.16 (1H, td, J=7.3, 4.4 Hz), 2.55 (3H, s), 2.81 (1H, ddm, J=7.3, 6.6 Hz), 3.02 (1H, dd, J=7.3, 6.6 Hz), 5.21 (1H, d, J=0.7 Hz), 5.71 (1H, s), 6.24 (1H, dd, J=9.9, 4.4 Hz), and 6.65 (1H, d, J=9.9 Hz); ^{13}C NMR δ=25.4, 26.2, 37.3, 45.8, 73.4, 115.4, 122.6, 123.3, 130.9, 132.7, 159.3, 169.5, and 169.6; IR 1725, 1635, 1600, 1375, and 1305 cm^{-1}; UV (MeOH) 231.6 (ε 9975) and 298.0 nm (4800).

Found: m/z 290.9917 (M$^+$ for ^{79}Br) and 292.9824 (M$^+$ for ^{81}Br). Calcd for $C_{13}H_{10}NO_2Br$: 290.9896 (M for ^{79}Br) and 292.9875 (M for ^{81}Br).

The authors wish to express their thanks to Dr. Noritaka Abe of Yamaguchi University for supplying samples (**A′** and **B′**) to measure UV spectra.

Photoaffinity Labeling of Pepsin

Hiroo YONEZAWA* and Tetsuya WADA
Department of Chemistry, Faculty of Science, Kagoshima University,
1-Korimoto, Kagoshima 890
(Received May 13, 1989)

Synopsis. Photoaffinity reagents for pepsin [Ala-Gly-Phe(N_3), Gly-Gly-Phe(N_3)-Phe-Gly-OEt, Gly-Gly-Phe-Phe(N_3)-Gly-OEt] were synthesized by a solution method. The pentapeptides were cleaved rapidly at the peptide bond between two aromatic amino acid residues by pepsin. This shows that Phe(N_3) residues of the photoaffinity reagents bind with the S_1 or S_1' site of pepsin. Pepsin was irradiated with photoaffinity reagents and the remaining activity was measured. The pepsin activity was decreased more rapidly in the presence of photoaffinity reagents, compared with that in the absence of photoaffinity reagents. Photoaffinity labeling occured at pH 2.0; however, did not occur at pH 4.0. Photoaffinity labeling of pepsin with ^{3}H-labeled Gly-Gly-Phe(N_3)-Phe-Gly-OEt showed that about 9% of the pepsin bound covalently with the photoaffinity reagent.

The specificity of a protease toward substrates was explained by an interaction between subsites of the protease and substrate side chains. Studies of pepsin specificity have shown that the enzyme has at least five subsites: three toward the NH_2-terminate from the sensitive bond (S_3, S_2, S_1) and two toward the COOH-terminate (S_1', S_2'). The S_1 and S_1' sites of pepsin are obviously the primary determinant of specificity.[1] The S_1 and S_1' sites gave a strong preference for aromatic L-amino acid residures. For example, Z-His-Phe-Phe-OMe is hydrolyzed much more rapidly at the Phe-Phe bond than both Z-His-Leu-Phe-OMe and Z-His-Phe-Leu-OMe.[2] Andreeva et al. suggested that the phenolic rings of substrates occupied two hydrophobic pockets which were formed by hydrophobic amino acid residues.[3] These residues are inert in the usual modification reaction. However, it is possible to modify these residues by the use of photoaffinity labeling.[4] The carbenes and nitrenes which were produced by irradiation are very reactive and nonselective in terms of amino acid residues. A peptide containing *p*-azido-L-phenylalanine [Phe(N_3)] at the position of P_1 or P_1' can bind strongly with pepsin, and it may be a good photoaffinity reagent.

Hollands et al. reported that Gly-Gly-Phe(NO_2)-Phe-Gly-OMe was a good substrate of pepsin.[5] Consequently, a peptide which contains an azido group instead of a nitro group of the substrate [Gly-Gly-Phe(N_3)-Phe-Gly-OEt] may covalently bind with the S_1 site of pepsin by irradiation. Similarly, Gly-Gly-Phe-Phe(N_3)-Gly-OEt may covalently bind with the S_1' site. Furthermore, photoaffinity labeling of chymotrypsin with a reagent of product type was carried out.[6] Therefore, Ala-Gly-Phe(N_3) may act as a photoaffinity reagent. In this paper, we report on the synthesis of these three peptides and the photoaffinity labeling of pepsin with these peptides.

Results and Discussion

The substrate and photoaffinity reagents were synthesized by a solution method. A protected tripeptide, Boc-Ala-Gly-Phe(N_3), was prepared by the coupling of Boc-Ala-Gly and Phe(N_3) via an active ester method.[7] The obtained protected tripeptide was treated with hydrogen chloride in ethyl acetate to cleave the protecting group, and free tripeptide was precipitated from aqueous solution.

On the other hand, *p*-azido-L-phenylalanine containing pentapeptides were synthesized by another process. Z-Gly-Gly and Phe(NO_2)-Phe-Gly-OEt or Phe-Phe(NO_2)-Gly-OEt were coupled and the resulting protected pentapeptide esters were hydrogenated. Then, the obtained pentapeptide esters were converted to the corresponding azido compounds by treatment with sodium nitrite and sodium azide. The ^{3}H-labeled Gly-Gly-Phe(N_3)-Phe-Gly-OEt was synthesized by the same procedure. The crude pentapeptides were applied to droplet countercurrent chromatography to give pure peptides. The obtained photoaffinity reagents were employed for enzymatic experiments.

As shown in Fig. 1, these two photoaffinity reagents were cleaved at the same rate as that of the substrate. It is well-known that pepsin cleaves the peptide bond between two aromatic amino acid residues. It is clear that Phe(N_3) residues of the photoaffinity reagents bind with the S_1 or S_1' site of pepsin.

When pepsin was irradiated in the presence of the photoaffinity reagents, the pepsin activity decreased more rapidly than in the absence of the reagents (Fig. 2). The difference in the remaining activities of both cases was small, within 5 minutes. Then, the pepsin activity was decreased enormously after irradiation for 15 minutes, even in the absence of photoaffinity reagents. It was concluded that the appropriate

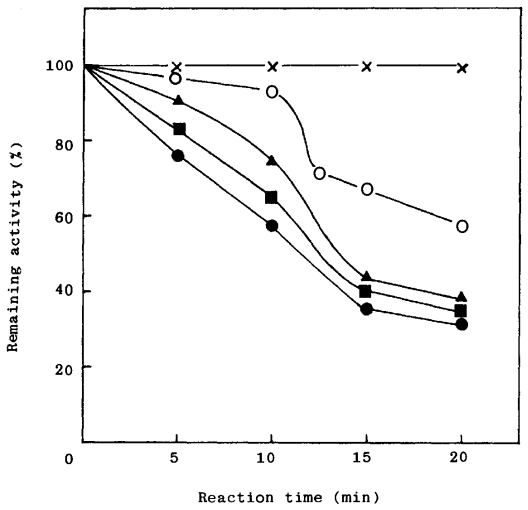

Fig. 2. Effect of irradiation time on photoaffinity labeling. (×) in dark; (○) absence of photoaffinity reagent; (▲) Ala-Gly-Phe(N_3); (■) Gly-Gly-Phe-Phe(N_3)-Gly-OEt; (●) Gly-Gly-Phe(N_3)-Phe-Gly-OEt.

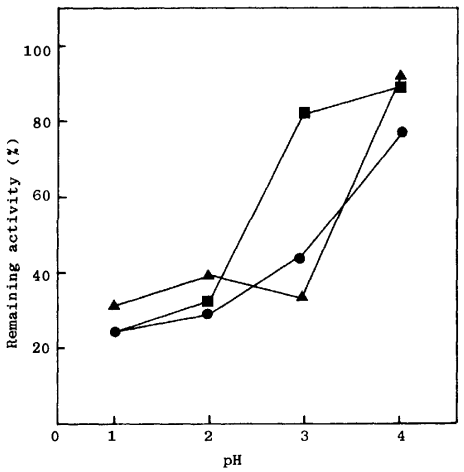

Fig. 3. Effect of pH of solution on photoaffinity labeling. (▲) Ala-Gly-Phe(N_3); (■) Gly-Gly-Phe-Phe(N_3)-Gly-OEt; (●) Gly-Gly-Phe(N_3)-Phe-Gly-OEt.

irradiation time should be 10 minutes. At this time, the remaining pepsin activities were as follows: 93% (absence of the photoaffinity reagent), 68% [Ala-Gly-Phe(N_3)], 65% [Gly-Gly-Phe-Phe(N_3)-Gly-OEt], 60% [Gly-Gly-Phe(N_3)-Phe-Gly-OEt].

The effect of pH on photoaffinity labeling was determined. As shown in Fig. 3, all photoaffinity reagents did not act at pH 4.0. Photoaffinity reagets which contained the azido group at the P_1 acted at pH 3.0; however, the reagent which contained an azido group at the P_1' did not act at this pH.

Then, pepsin was irradiated with a ^{3}H-labeled photoaffinity reagent and the incorporated radioactivity was measured. In this experiment, the measurement was made at concentrations of 0.05 mM of pepsin and 1 mM of the photoaffinity reagent (1 M=1 mol dm^{-3}). The amount of radioactivity incorporated into 4.75×10^{-8} mol of pepsin was 5820 dpm, which corresponded to 4.2×10^{-9} mol of the photoaffinity reagent. Consequently, about 9% of the pepsin was labeled upon irradiation. At this time, the remaining pepsin activities were 89 and 68%, respectively, in the absence and presence of the photoaffinity reagent. The decreased pepsin activity was larger than the amount of incorporated photoaffinity reagent.

Gennari et al. reported the photooxidation of chymotrypsin by *N*-acetyl-3-nitrotyrosine.[8] The possibility of a photooxidation reaction of pepsin with Phe(N_3) residues is not ruled out in these procedures. However, when pepsin was irradiated with 2 mM of Phe(N_3), the remaining activity was equal in the absence of Phe(N_3), indicating that a nonspecific photooxidation reaction did not occur. It may be possible to identify the amino acid residues which form S_1 and S_1' sites of pepsin by photoaffinity labeling.

Experimental

Boc-Ala-Gly-Phe(N_3) (I). This was prepared from Phe(N_3) (410 mg, 2 mmol) and Boc-Ala-Gly-OSu (690 mg, 2 mmol) using the usual procedure. The product was recrystallized from methanol-ether-petroleum ether; yield, 710 mg, (82%); mp 127—128 °C; $[\alpha]_D^{25}$ +18.0° (*c* 1, MeOH); Found: C, 52.35; H, 6.29; N, 19.48%. Calcd for $C_{19}H_{26}O_6N_6$: C, 52.52; H, 6.03; N, 19.35%.

Ala-Gly-Phe(N_3) (II). The **I** (434 mg, 1 mmol) was dissolved in 1.5 M HCl in ethyl acetate (5 ml) at 0 °C. The solution was stirred for 30 min at 0 °C and the resulting crystals were collected and washed with a mixed solvent of ethyl acetate and ether (1 : 1 v/v). The crystals were dissolved in cold water (5 ml) and the free tripeptide was separated by the addition of pyridine to pH 7. The resulting crystals were filtered and washed with a small amount of cold water; yield, 170 mg, (51%); mp 215 °C; $[\alpha]_D^{25}$ +38.9° (*c* 1, 0.1 M HCl); Found: C, 50.24; H, 5.46; N, 25.19%. Calcd for $C_{14}H_{18}O_4N_6$: C, 50.29; H, 5.43; N, 25.14%.

Boc-Phe-Gly-OEt (III). This was prepared from Boc-Phe (5.30 g, 20 mmol), and Gly-OEt·HCl (2.80 g, 20 mmol) by the 1-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ) method. The product was recrystallized from ethyl acetate-petroleum ether; yield, 6.31 g, (90%); mp 88—89 °C; $[\alpha]_D^{25}$ −6.0° (*c* 1, MeOH).

Boc-Phe(NO_2)-Phe-Gly-OEt (IV). The **III** (3.50 g, 10 mmol) was dissolved in 1M HCl in acetic acid (50 ml). After 1 h at room temperature, the solution was evaporated and treated with ether. The obtained crystals were coupled with Boc-Phe(NO_2) (3.10 g, 10 mmol), as described above. Recrystallization from DMF-ether gave 4.20 g, (77%); mp 207—209 °C; $[\alpha]_D^{25}$ −14.0° (*c* 1, DMF); Found: C, 60.01; H, 6.17; N, 10.41%. Calcd for $C_{27}H_{34}O_8N_4$: C, 59.77; H, 6.32; N, 10.33%.

Z-Gly-Gly-Phe(NO_2)-Phe-Gly-OEt (V). This was prepared from Z-Gly-Gly (1.06 g, 4 mmol) and Phe(NO_2)-Phe-Gly-OEt·HCl (1.92 g, 4 mmol) by EEDQ method. The product was recrystallized from DMF-ether; yield, 2.38 g, (86%); mp 187—190 °C; $[\alpha]_D^{25}$ −15.1° (*c* 1, DMF); Found: C, 59.34; H, 5.38; N, 12.01%. Calcd for $C_{34}H_{38}O_{10}N_6$: C, 59.12; H, 5.55; N, 12.17%.

Gly-Gly-Phe(NH_2)-Phe-Gly-OEt·2HCl (VI). The **V** (2.76 g, 4 mmol) was suspended in a mixed solvent of H_2O-acetic acid-methanol (30 ml), and concd HCl (0.7 ml) was added. The **V** was hydrogenated in the presence of palladium black at room temperature. After 24 h, the

catalyst was filtered off, and the filtrate was evaporated in vacuo. The resulting crystals were collected with the aid of acetone; yield, 1.97 g, (82%); mp 219—221 °C; $[\alpha]_D^{25}$ −7.1° (*c* 1, 0.1 M HCl); Found: C, 50.33; H, 6.42; N, 13.51%. Calcd for $C_{26}H_{34}O_6N_6 \cdot 2HCl \cdot H_2O$: C, 50.57; H, 6.20; N, 13.61%.

Gly-Gly-Phe(N_3)-Phe-Gly-OEt·HCl (VII). To a solution of **VI** (1.07 g, 1.78 mmol) in 2 M HCl (1.78 ml), was added a solution of 2 M $NaNO_2$ (0.89 ml, 1.78 mmol) at 0 °C and stirred for 1 h at 0 °C. To the solution was added a solution of 2 M NaN_3 (0.89 ml, 1.78 mmol); the reaction solution was then stirred for 1 h at 0 °C. To the solution was added NaCl until saturated; resulting precipitate was then filtered and dried. The resulting crude **VII** (250 mg) was purified by droplet countercurrent chromatography,[9] using the mixed solvent of cyclohexane-1-butanol-acetic acid-water (1:4:2:5 v/v); the upper phase of the mixture was used as a moving phase. Fractions containing **VII** were collected and evaporated. The precipitate was collected with the aid of ether; yield, 170 mg, (16%); mp 204—205 °C; $[\alpha]_D^{25}$ −31.0° (*c* 1, DMF); Found: C, 51.41; H, 5.85; N, 18.50%. Calcd for $C_{26}H_{32}O_6N_8 \cdot HCl \cdot H_2O$: C, 51.44; H, 5.81; N, 18.46%.

Gly-Gly-Phe-Phe(NH_2)-Gly-OEt·2HCl (VIII). This was prepared from Z-Gly-Gly-Phe-Phe(NO_2)-Gly-OEt (4.14 g, 6 mmol), as described for the preparation of **VI**; yield, 3.18 g, (88%); mp 241—242 °C; $[\alpha]_D^{25}$ −11.2° (*c* 1, 0.1 M HCl); Found: C, 50.71; H, 6.34; N, 13.48%. Calcd for $C_{26}H_{34}O_6N_6 \cdot 2HCl \cdot H_2O$: C, 50.57; H, 6.20; N, 13.61%.

Gly-Gly-Phe-Phe(N_3)-Gly-OEt·HCl (IX). The **VIII** (1.00 g, 1.67 mmol) was converted to the corresponding azido compound according to the same manner described above and recrystallized from a mixed solvent of 1-butanol-acetic acid-pyridine-ethanol (4:2:2:1 v/v)-acetone; yield, 760 mg, (77%); mp 208—209 °C; $[\alpha]_D^{25}$ −46.6° (*c* 1, DMF); Found: C, 48.61; H, 6.09; N, 17.44%. Calcd for $C_{26}H_{32}O_6N_8 \cdot HCl \cdot 3H_2O$: C, 48.56; H, 6.11; N, 17.42%.

Gly-Gly-^{3}H-Phe(N_3)-Phe-Gly-OEt·HCl (X). This compound was prepared by the mentioned reaction sequence, starting with 230 mg (1.1 mmol, 0.6 mCi) of ^{3}H-labeled *p*-nitro-L-phenylalanine. The obtained crude product was purified by droplet countercurrent chromatography; yield, 210 mg. The specific radioactivity was 2298 dpm μg^{-1}.

Enzymatic Study. The substrate used was Gly-Gly-Phe(NO_2)-Phe-Gly-OEt·HCl. The cleavage of the substrate was measured at 37 °C, and 0.1 M sodium citrate buffer (pH 4.16) was used to control the pH. Fifty μl of pepsin solution (0.06 mM) was added to 10 ml of the substrate solution (0.25 mM) and the increase in absorbance at 310 nm was measured.[10] The kinetic constant of the substrate was K_m=0.83 mM, k_{cat}=5.5 s^{-1}.

Hydrolysis of VII and IX with Pepsin. Fifty μl of pepsin solution (0.06 mM, pH 4.16) was added to the substrate (**VII** or **IX**) solution (0.5 mM, 10 ml) and incubated at 37 °C. At selected intervals, 0.1 ml of the reaction mixture was taken out and the rate of the cleavage was determined by the ninhydrin method.[11]

Effect of Irradiation Time on Photoaffinity Labeling. Pepsin and photoaffinity reagents were dissolved in a 0.1 M sodium citrate buffer (pH 2.0). A mixture of 0.5 ml of a pepsin solution (0.06 mM) and 0.5 ml of the photoaffinity reagent solution (2 mM) was incubated for 10 min at room temperature and cooled in an ice-bath for 5 min. The solution was irradiated with a Toshiba mercury lamp H400-P at a distance of 60 cm at 0 °C. At selected intervals, 0.1 ml of the solution was taken out and the remaining activity was measured.

Effect of pH of Solution on Photoaffinity Labeling. Mixtures of 0.5 ml of a pepsin solution (0.06 mM) and 0.5 ml of the photoaffinity reagents solution (2 mM) of various pH were irradiated for 15 min at 0 °C under the same conditions described above and the remaining activity was measured.

Photoaffinity Labeling with X. A mixture of 0.5 ml of a pepsin solution (0.1 mM, pH 2.0) and 0.5 ml of a **X** solution (2 mM, pH 2.0) was irradiated for 10 min at 0 °C under the same conditions described above. To the solution, 2 M TCA (1 ml) was added and allowed to stand for 20 min. The reaction mixture (1.9 ml) was filtered with a glass fiber filter, Whatman GF/B and the filter was washed twice with 1 M TCA (1 ml) and ethanol (1 ml). The filter was dried and the radioactivity measured.

Cis/Trans Isomerization of Perinaphthothioindigo Dye Adsorbed on Silica Gel

Koushi FUKUNISHI,* Masaya KOBAYASHI, Akihiro MORIMOTO, Masaki KUWABARA, Hiroki YAMANAKA, and Mototeru NOMURA

(Received May 19, 1989)

Synopsis. The photoinduced and thermal cis/trans isomerization of the title compound adsorbed on silica gel has been studied by the immersion method. The cis/trans photoisomerization of the adsorbed state can be reversibly induced by irradiation. Thermal isomerization of the cis-to trans-isomer proceeds very fast on the surface. The results are compared with those obtained in solution.

Although the reversible cis/trans isomerization of olefins is a well-known phenomenon, it is limited for the studies in liquid phase as well as in polymer matrix. More recently, interest has increased in the photochemical reactions of organic molecules which are imposed by adsorption on the surface such as silica gel or alumina.[1-3] Organic molecules often change their spectroscopic and photochemical properties when adsorbed and immobilized on surfaces of solids. Breuer and Jacob studied the photoisomerization of thioindigo adsorbed on alumina by photoacoustic spectroscopy and showed that while the trans-to-cis isomerization can be induced by irradiation, the cis-isomer cannot be back converted.[2] The reverse change for thioindigo adsorbed on silica gel was reported by Mostoslavskii and Nazariko; while the cis-isomer can isomerize to the trans-isomer on irradiation, the photoconversion of the trans- to cis-isomer does not occur.[3]

We describe here the photochemical study and thermal kinetics of the perinaphthothioindigo dye (PNTI) adsorbed on silica gel by the immersion method. There is a growing interest in the field of application of writing and erasing of information with visible light.[4] This application requires that the photochromic process is reversible on the solid surface.

Experimental

General Methods. UV spectra were obtained by using a Hitachi UV-340 spectrometer and an Ohtsuka Denshi MCPD (multichannel photodiode array detector) spectrometer. The solvents used in measuring spectra were spectroanalytically pure cyclohexane, benzene, and chloroform. Nitrobenzene was distilled twice under reduced pressure before use. PNTI (bis[perinaphtothiopyran-(2)]-indigo, HRMS Calcd for $C_{24}H_{12}O_2S_2$: M, 808.4043, Found: m/z 808.4029.) was prepared by intramolecular Friedel-Crafts acylation of α-naphthalenethioacetic acid, followed by oxidative dimerization.[5] Silica gel for thin-layer chromatography (Silica gel 70 Plate-Wako/glass plate) was employed and activated by heating in an oven at 120 °C for at least 3 hours. In some cases, silica gel was treated in the oven of 650—700 °C in order to decrease the silanol group on silica gel, although the reduced amount of the group was not determined. Silica gel/glass plate(s) prepared by adsorbing PNTI in a $CHCl_3$ solution onto nonhydrated silica gel and suspending the glass plate(s) in cyclohexane, was utilized for optical studies. Light scattering in this heterogenious system was minimized by the refractive indices of the solvent and silica gel. The large-pore silica gel employed is characterized by its supplier as having a surface of 450 $m^2 g^{-1}$, and a surface density of 5 equivalents of SiOH group/nm^2. PNTI was adsorbed in the concentration of $1-10\times10^{-6}$ mol g^{-1} of silica gel.

Determination of Quantum Yield Ratios of Cis/Trans Photoisomerization of PNTI in Solvents. The apparatus used consisted of an optical bench with light source (150 W tungusten-helogen lamp), filters (KL-54 and Toshiba L-42 filters, and a cold filter CF-A) and sample holders to permit simultaneous irradiation of two samples. The samples were in 1-cm quartz cell and the $\phi_{t\to c}/\phi_{c\to t}$ ratios were determined from cis:trans ratios of photostationary state on irradiation of 540 nm by using the following equation, [cis]/[trans]= $(\phi_{t\to c}/\phi_{c\to t})(\varepsilon_t/\varepsilon_c)$.

Determination of Quantum Yields of Cis/Trans Photoisomerization of PNTI in Solvents and on Silica Gel. The apparatus used was the same as that for the quantum yield ratios determination, with exception of the filter system, where KL-63, Toshiba L-42, CF-A, and a reduced filter ND-40 for the trans-to-cis isomerization and KL-51, L-42, CF-A, and ND-40 for the cis-to-trans isomerization were used. The silica gel/glass plate(s) was perpendicularly placed in 1-cm quartz cell. The qauntum yields of the cis/trans photoconversion were measured relative to the Reinecke's salt (aqueous $KCr(NH_3)_2(NCS)_4$) actinometer.[6] As the photoisomerization of PNTI adsorbed on silica gel accompanied a relatively fast thermal cis-to-trans isomerization, corrections of the thermal reaction during irradiation were made. The results are shown in Table 1.

Kinetics for Thermal Cis-to-Trans Isomerization of PNTI. The cis isomer of PNTI in solvents and on silica gel was prepared from the corresponding trans isomer by irradiation of filtered light (λ>620 nm). The thermal isomerization of the cis-isomer was followed spectrometrically by monitoring the increase in absorption of the trans isomer. Plots of $-\ln(A_\infty-A_t)/(A_\infty-A_0)$ vs. time were almost linear. The rate constants, k, were obtained from the straight portion whose correlation factors were more than 0.99. The results are shown in Table 2.

Results and Discussion

Solution of PNTI dissolved in organic solvent was violet blue. The color of PNTI adsorbed on silica gel was similar to that in solution. Table 1 shows that the color derives from an intense band ($\varepsilon_{\lambda_{max}}$=20740 $M^{-1} cm^{-1}$ in benzene; 1 M=1 mol dm^{-3}) with λ_{max} 615—635 nm. A π-π^* assignment for the band is reasonable in view of its intensity and the red shift with increasing solvent polarity. The absorption in longer wavelength was observed on silica gel as well as in nitrobenzene.[7] Exposure of *trans*-PNTI solution to visible light of >600 nm revealed a pink-red color, which was

Table 1. Spectral Shifts of PNTI and Quantum Yields for Trans/Cis Photoisomerization

Silica gel[b]	644—661 (—)	540 (—)	575	0.0011	0.0046	—

a) Ratios were determined from photostationary states. b) Silica gel was dried at 700 °C.

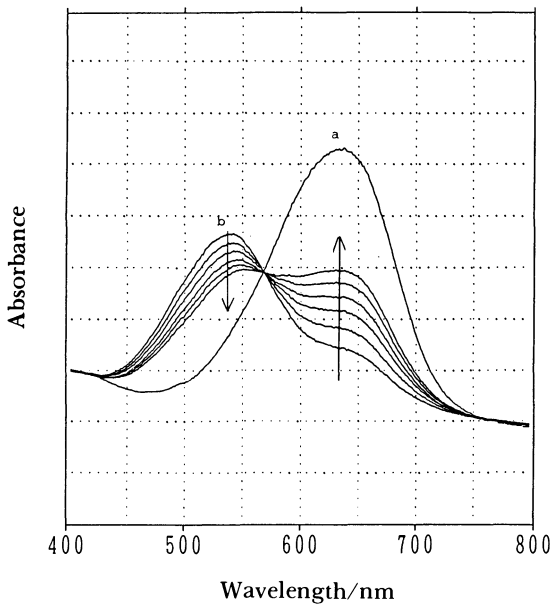

Fig. 1. Absorption spectra of PNTI adsorbed on silica gel/cyclohexane; (a) *trans*-PNTI, (b) *cis*-PNTI. The thermal cis-to-trans isomerization is shown by the arrow.

assigned to *cis*-PNTI. The electronic spectral changes resulted in about 120 nm blue shift, affording the cis-isomer of the intense visible transition ($\varepsilon_{\lambda_{max}}$=8370) with an isosbestic point at 536 nm in benzene. The extent of red shift of the cis-isomer by increasing solvent polarity was higher in compared to that of the trans-isomer. The reverse cis-to-trans photoisomerization was possible with visible light of 510 nm. Such photochromic phenomena were also observed on silica gel dipped in cyclohexane solvent. When immersed in cyclohexane, essentially all of PNTI was adsorbed on silica gel, as evidenced by the absence of PNTI absorption band of the supernatant liquid or the filtered solution. Figure 1 depicts such changes in the cis/trans isomerization on silica gel. If the sample of spectrum (a) was irradiated with light of >600 nm, spectrum (b) was obtained. Similarly, irradiation of the sample (b) with light of 510 nm easily converted into curve (a) with an isosbestic point at 571 nm.

Each of the trans- and the cis-isomer in solution or on silica gel was effectively converted into the another isomer on irradiation with 630 nm and 510 nm light, respectively. Exposure to 540 nm light (i.e., near isosbestic point) brought about the photostationary state containing the mixture of two isomers. Quantum yields ($\phi_{t\to c}$ and $\phi_{c\to t}$) and their ratios ($\phi_{t\to c}/\phi_{c\to t}$) of the isomerization were determined on the direct irradiation of 630 nm, 510 nm, and 540 nm, respectively. Quantum yields in solution and on silica gel were rather small. The ratios of quantum yields, $\phi_{t\to c}/\phi_{c\to t}$, in benzene and nitrobenzene were estimated to be 0.2 and 0.9, respectively, suggesting that the ratio depends upon the polarity of solvent used. Such a polar contribution should be reflected in surface photochemistry of dyes. The ratio on silica gel seems to have the similar propensity to that in nitrobenzene because of high polarity of silica gel. However, the present experiment shows that quantum efficiencies of PNTI on silica gel are less than those in solvents. This lowering of quantum efficiencies might imply the presence of some constraints upon the molecule motions of PNTI adsorbed on silica gel or the formation of a hydrogen-bonding between the carbonyl oxygen of PNTI and a silanol group at the excited state.

The thermodynamically less stable cis-isomer is thermally or catalytically converted to the trans-isomer. This thermal cis-to-trans isomerization of PNTI in the dark proceeded at lower rates ($t_{1/2}$=ca. 30 h at 30 °C) in three solvents examined, whereas the thermal isomerization on silica gel occurred quite rapidly ($t_{1/2}$=ca. 0.3 h at 18.5 °C). The surface of silica gel is characterized by the presence of silanol groups, siloxane bridges, and accompanying water molecules, and often bears an acidic property. Present marked increase in the isomerization rate may be due to the acidic ability of silica gel used[8] and this catalytic isomerization will be explained by a protonation of α,β-unsaturated carbonyl groups.[9] Since silanol groups change into siloxane groups on heating at high temperature, the thermal isomerization of PNTI adsorbed on heat-treated silica gel was expected to retard relative to that on untreated one. The thermal isomerization on silica gel was reduced with the decrease in the silanol groups, though the variable amount was not so large as shown in Table 2. Thus, silanol groups on silica gel may not only exert as active sites of adsorption but also promote the thermal cis-to-trans isomerization

Since the dehydration of the silanol groups leads to the raise of the hydrophobic property and/or to the reduction in acidity, the spectroscopic and photochemical properties of PNTI adsorbed are changeable.

Table 2. Rate Constants of Thermal Cis-to-Trans Isomerization of PNTI

	(°C)	$k\times10^4/s^{-1}$	$t_{1/2}$/h
Benzene	30	0.0614	31.3
Chloroform	30	0.0629	30.6
Nitrobenzene	30	0.0666	28.9
Silica gel	18.5	6.09	0.31
Silica gel[a)]	18.5	2.7—4.8	0.71—0.40

a) Silica gel was dried at 700°C.

In fact, the cis/trans photoisomerization and the thermal cis-to-trans isomerization of PNTI on silica gel were influenced, as stated above. However, the λ_{max} value for the trans-isomer on the absorbent reached to around 660 nm, depending upon the heat-treated conditions of silica gel, as the surface became more hydrophobic. This may be explained by an assumption that the thermal treatment of silica gel may result in the change of the adsorption mode, from the unimolecular to the multimolecular adsorption or the solid-like state,[10] which leads to the additional red shift in the absorption spectra of PNTI on silica gel.

Our results on PNTI are somewhat different from those on thioindigo adsorbed on silica gel obtained by other authors.[3] No trans-to-cis photoisomerization of thioindigo adsorbed is observed. This may result in the effective cancellation of the trans-to-cis photoisomerization by the thermal back-reaction during irradiation.

In conclusion, reversible cis/trans photoisomerization of PNTI on silica gel surface is possible, even though with poor quantum efficiencies. The dark reversion rate is makedly accelerated by silica gel, the effect being changed by variable amounts of silanol groups.

Chiral Aryl Grignard Reagents-Generation and Reactions with Carbonyl Compounds

Makoto KAINO, Kazuaki ISHIHARA, and Hisashi YAMAMOTO*
Department of Applied Chemistry, Faculty of Engineering,
Nagoya University, Chikusa, Nagoya 464-01
(Received May 19, 1989)

Synopsis. Chiral aryl Grignard reagents are generated in situ from homochiral 2-halobenzaldehyde acetal, *t*-butyllithium, and magnesium bromide. These reagents react with aromatic aldehydes to moderate diastereoselectivities.

The homochiral acetal method plays an increasingly important role in asymmetric synthesis.[1] We have shown that the Lewis acid catalyzed coupling of homochiral acetals with various nucleophilic organometallic reagents proceeds in a highly diastereoselective manner, ultimately providing a route for generating chiral secondary alcohols in high chemical and optical yields.[2,3] Especially six-membered ring acetals derived from (2*R*,4*R*) or (2*S*,4*S*)-2,4-pentanediols react with excellent diastereoselectivities to give products from which the chiral auxiliary is easily removed.[3] Asymmetric induction produced by the acetal derived from (2*R*,4*R*)-2,4-pentanediol is ascribed to a stereospecific coordination of the Lewis acid to one of the acetal oxygens.

As part of a program aimed at exploring a scope and limitations of homochiral acetal methodology, we now report diastereoselective addition of Grignard reagents which have an adjacent homochiral acetal group.

Results and Discussion

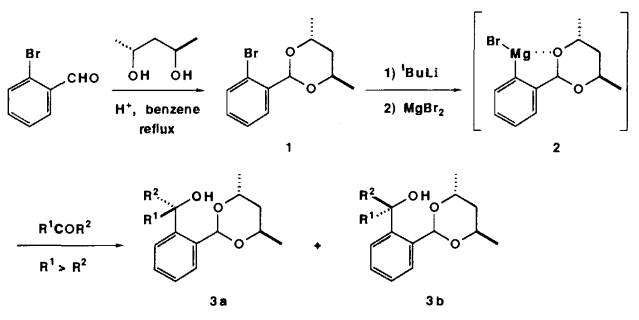
Homochiral aryl Grignard reagent **2** was readily prepared as shown in Scheme 1: Acetalization of 2-bromobenzaldehyde with (−)-(2*R*,4*R*)-2,4-pentanediol, lithiation with *t*-butyllithium, and finally transmetallation with magnesium bromide. The reactions of the Grignard reagent **2** with various carbonyl compounds were carried out in toluene-ether at −78 °C. Some of our results are listed in Table 1. Using an aromatic carbonyl compound as the electrophile, the Grignard reagent **2** gave high diastereoselectivity providing the predominant product **3a** (Entries 1, 4, and 5). The less stereoselectivity, on the other hand, was obtained in the reactions with the other organometallic reagents (Entries 2, 3, and 10) and the reactions with aliphatic aldehydes (Entries 6 and 8).

Evidence for the stereochemical course of the process depicted in Scheme 1 was obtained by the transformation shown in Scheme 2. The product **3a** (R^1=Ph, R^2=H; 88% de) in Entry 1 was converted into phenyl-*o*-tolylmethanol (**6**) whose stereochemistries were already established.[4] Thus, hydrolysis of **3a** with *p*-toluenesulfonic acid afforded hemiacetal **4**, which was further converted to hydrazone **5** by hydrazine. Treatment of **5** by potassium *t*-butoxide gave the compound **6** ($[\alpha]_D^{23}$ =−0.53°, *c* 1.0, benzene) having the *S*-configuration.[4] The stereochemistries of the major product **3a** of the other cases were tentatively assigned from mechanistic analogy.

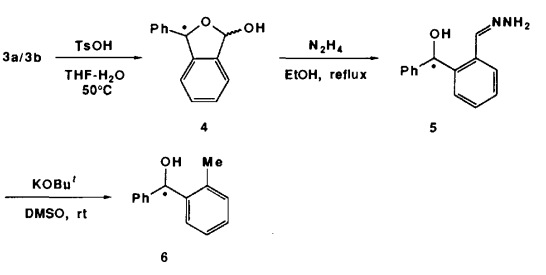
Table 1. Grignard Reaction via Homochiral Acetal

Entry	Substrate	R^1COR^2 R^1	R^2	Yield(%)	Ratio **3a**:**3b**
1	**1**	Ph	H	91	94 : 6
2[a]				73	72 : 28
3[b]				50	60 : 40
4		*p*-$CF_3C_6H_4$	H	72	89 : 11
5		Ph	Me	34	83 : 17
6		*t*-Bu	H	85	82 : 18
7		PhCH=CH	H	66	74 : 26
8		*c*-Hex	H	69	65 : 35
9		Ph	H	47	82 : 18
10[b]				50	73 : 27

a) $Ti(O\text{-}i\text{-}Pr)_4$ was used instead of $MgBr_2$. b) R^1COR^2 was added after lithiation.



Scheme 1.



Scheme 2.

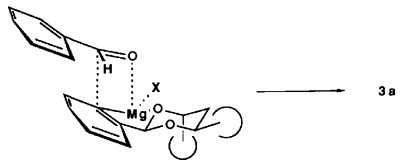


Fig. 1.

Although the detailed stereochemical course is not ascertained, the formation of **3a** as predominant products may be reasonably explained by the attack of the Grignard reagents from *re*-face side in the structure of organometallic reagent on the *re*-face of the carbonyl compounds as shown in Fig. 1. Namely, the magnesium metal is intramolecularly fixed by a stereospecific coordination to one of the acetal oxygen atoms leading to the formation of the five-membered ring structure. Then electrophiles approach to the less hindered side of the magnesium reagent as in the figure.

The study described above illustrates the suitability of optically active alcohols. One obvious advantage of our methodology is that product **3a** could be further transformed into other new chiral compounds by a diastereoselective cleavage of the remaining homochiral acetal group.

Experimental

The IR spectra were determined on a Hitachi 260-10 spectrometer. The ^{1}H NMR spectra were recorded on a Varian Gemini-200 spectrometer, using TMS (tetramethylsilane) as an internal standard. Splitting patterns are indicated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. The microanalyses were performed at the Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University. Analytical gas-liquid phase chromatography (GLC) was performed on Gaskuro Kogyo model 370 instruments with a flameionization detector and a capillary column of PEG-HT (0.25×25000 mm) using nitrogen as the carrier gas. Ether and tetrahydrofuran (THF) were distilled from benzophenone ketyl. Toluene and benzene were dried over sodium metal. All experiments were carried out under an argon atmosphere. Purification of the product was carried out by column chromatography on silica gel Fuji-Davison BW-300. (−)-(2*R*,4*R*)-2,4-pentanediol was purchased from Wako Pure Chemical Industries Ltd. and used after checking the optical purity; $[\alpha]_D^{23} = -41.2°$ (*c* 9.99, chloroform). Unless otherwise noted, other chemicals were purchased from commercial suppliers and used without further purification.

General Method for Preparation of Homochiral Acetals. The mixture of corresponding aldehyde or ketone (10.0 mmol), *p*-toluenesulfonic acid (10 mg) and (−)-(2*R*,4*R*)-2,4-pentanediol (1,14 g, 11.0 mmol) in 10 ml of benzene was refluxed with continuous azeotropic removal of water for 2 h. The resulting mixture was poured into saturated sodium hydrogen carbonate and the product was extracted twice with hexane. The organic layers were dried over magnesium sulfate and concentrated in vacuo. Purification of the crude oil by column chromatography on silica gel (hexane/ethyl acetate as eluent) afforded the corresponding acetal. The physical data of acetals are listed below.

(4*R*,6*R*)-2-(2-Bromophenyl)-4,6-dimethyl-1,3-dioxane (1): Quantitative yield; IR (CCl_4) 2986, 1366, 1148, 1129, 996 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.31 (d, J=6.2 Hz, 3H, C(equatorial)-H$_3$), 1.40—1.52 (m, 1H, H(equatorial)CH), 1.55 (d, J=6.8 Hz, 3H, C(axial)H$_3$), 1.92—2.10 (m, 1H, H(axial)CH), 4.24 (dqd, J=2.4, 5.9, 11.8 Hz), 1H, OCH(axial)CH$_3$), 4.48 (m, 1H, OCH(equatorial)CH$_3$), 6.13 (s, 1H, O$_2$CH), 7.19 (ddd, 1H, J=1.8, 7.6, 7.6 Hz, ArH), 7.35 (ddd, 1H, J=1.3, 7.7, 7.7 Hz, ArH), 7.53 (dd, 1H, J=1.3, 7.7 Hz, ArH), 7.74 (dd, 1H, J=1.8, 7.7 Hz, ArH). Anal. ($C_{12}H_{15}O_2Br$) C, H.

(4*R*,6*R*)-2-(2-Bromophenyl)-2,4,6-trimethyl-1,3-dioxane: Quantitative yield; IR (neat) 3000, 2950, 2375, 2350, 1460, 1440, 1385, 1378, 1275, 1245, 1185, 1175, 1130, 1030, 970, 765 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.26 (d, J=2.6 Hz, 3H, C(equatorial)-H$_3$), 1.29 (d, J=2.6 Hz, 3H, C(axial)H$_3$), 1.46—1.67 (m, 2H, CH$_2$), 1.70 (s, 3H, O$_2$CCH$_3$), 3.55—3.72 (m, 1H, OCH(axial)-CH$_3$), 4.12—4.29 (m, 1H, OCH(equatorial)CH$_3$), 7.14 (ddd, J=1.8, 7.6, 7.6 Hz, 1H, ArH), 7.32 (ddd, J=1.4, 7.6, 7.6 Hz, 1H, ArH), 7.61 (dd, J=1.4, 7.8 Hz, 1H, ArH), 7.81 (dd, J=1.8, 7.8 Hz, 1H, ArH). Anal. ($C_{13}H_{17}O_2Br$) C, H.

General Procedure for the Grignard Type Coupling of the Homochiral Acetal. To a solution of the acetal (0.5 mmol) in toluene (3 ml) was added *t*-butyllithium (0.26 ml, 0.6 mmol, 2.32 mol dm^{-3} in pentane solution) at −78 °C and the resulting yellow solution was stirred at 0 °C for 30 min. After cooling to −78 °C, a solution of magnesium bromide (1.0 mmol) in ether (3 ml) (prepared in another flask from magnesium turnings (29.2 mg, 1.2 mmol) and 1,2-dibromoethane (0.0862 ml, 1.0 mmol) at room temperature for 30 min) was added at −78 °C, and after 30 min, the corresponding aldehyde (0.5 mmol) was added at the same temperature. The mixture was sirred at −78 °C for 30 min, poured into aqueous ammonium chloride, extracted with ether, and dried over magnesium sulfate. Evaporation of solvents and purification of the residue by column chromatography on silica gel (hexane/ethyl acetate as eluent) gave the corresponding hydroxy acetals (**3a** and **3b**). The diastereomeric ratio of the adducts was determined by ^{1}H NMR. The physical properties and analytical data of the adducts obtained are listed below.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(α-hydroxybenzyl)phenyl]-1,3-dioxane (**3**, Entries 1, 2, and 3): IR (CCl_4) 3461 (OH), 2999, 2956, 1453, 1381, 1156, 1134, 1106, 1036, 1019, 996, 763, 696 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.30 (d, J=6.2 Hz, 3H, C(equatorial)H$_3$), 1.47 (d, J=7.0 Hz, 3H, C(axial)H$_3$), 1.97—2.12 (m, 1H, H(axial)CH), 1.33—1.43 (m, 1H, H(equatorial)CH), 3.72 (d, J=3.5 Hz, 1H, OH (**3a** isomer)), 3.95 (d, J=4.8 Hz, 1H, OH (**3b** isomer)), 4.21 (dqd, J=2.2, 6.2, 12.2 Hz, 1H, OCH(axial)-CH$_3$), 4.48—4.60 (m, 1H, OCH(equatorial)CH$_3$), 5.92 (s, 1H, O$_2$CH (**3b** isomer)), 6.08 (s, 1H, O$_2$CH (**3a** isomer)), 6.34 (d, J=4.8 Hz, 1H, CHOH (**3b** isomer)), 6.43 (d, J=3.5 Hz, 1H, CHOH (**3a** isomer)), 7.10—7.65 (m, 9H, ArH). Anal. ($C_{19}H_{22}O_3$) C, H.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(4-trifluoromethyl-α-hydroxybenzyl)phenyl]-1,3-dioxane (**3**, Entry 4): IR (neat) 3400 (OH), 2975, 2930, 2880, 1615, 1455, 1410, 1375, 1320, 1140, 1020, 925, 860, 810, 758 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.27 (d, J=6.0 Hz, 3H, C(equatorial)H$_3$), 1.47 (d, J=7.2 Hz, 3H, C(axial)H$_3$), 1.39—1.53 (m, 1H, H(equatorial)CH), 1.95—2.10 (m, 1H, H(axial)CH), 3.91 (d, J=3.7 Hz, 1H, OH (**3a** isomer)), 3.93 (d, J=2.6 Hz, 1H, OH (**3b** isomer)), 4.13—4.28 (m, 1H, OCH(axial)CH$_3$), 4.44—4.57 (m, 1H, OCH(equatorial)-CH$_3$), 5.92 (s, 1H, O$_2$CH (**3b** isomer)), 6.05 (s, 1H, O$_2$CH (**3a** isomer)), 6.44 (d, J=3.7 Hz, 1H, CHOH (**3b** isomer)), 6.51 (d, J=2.6 Hz, 1H, CHOH (**3a** isomer)), 6.97—7.65 (m, 8H, ArH). Anal. ($C_{20}H_{21}O_3F_3$) C, H.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(1-hydroxy-1-phenylethyl)phenyl]-1,3-dioxane (**3**, Entry 5): IR (neat) 3423, 2993, 2943, 1443, 1373, 1155, 1135, 1036, 985, 925, 758, 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.08 (d, J=8.0 Hz, 3H, C(equatorial)H$_3$), 1.28 (d,

J=8.0 Hz, 3H, C(axial)H_3), 1.25—1.5 (m, 1H, H(equatorial)-CH), 1.75—2.0 (m, 1H, H(axial)CH), 3.46—3.66 (m, 1H, OCH(axial)CH_3), 4.24—4.41 (m, 1H, OCH(equatorial)CH_3), 5.31 (s, 1H, O_2CH (**3b** isomer)), 5.61 (s, 1H, O_2CH (**3a** isomer)), 6.79—8.4 (m, 9H, ArH). Anal. ($C_{20}H_{24}O_3$) C, H.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(1-hydroxy-2,2-dimethylpropyl)-phenyl]-1,3-dioxane (**3**, Entry 6): IR (neat) 3450, 2970, 2950, 2880, 1372, 1125, 1031, 983, 753 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.97 (s, 9H, *t*-Bu), 1.25 (d, J=6.2 Hz, 3H, C(equatorial)H_3), 1.46 (d, J=7.0 Hz, C(axial)H_3), 1.39—1.51 (m, 1H, H(axial)CH), 1.92—2.08 (m, H(equatorial)CH), 2.16 (d, J=2.6 Hz, 1H, OH (**3a** isomer)), 2.27 (d, J=2.0 Hz, 1H, OH (**3b** isomer)), 4.16 (dqd, J=2.2, 6,2, 12.4 Hz, OCH(axial)CH_3), 4.40—4.54 (m, 1H, OCH(equatorial)CH_3), 4.83—4.86 (m, 1H, CHOH), 6.22 (s, 1H, O_2CH), 7.26—7.75 (m, 4H, ArH). Anal. ($C_{17}H_{16}O_3$), C, H.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(1-hydroxy-3-phenyl-2-propenyl)-phenyl]-1,3-dioxane (**3**, Entry 7): IR (neat) 3450, 3040, 2980, 2945, 2880, 1500, 1450, 1408, 1380, 1159, 1135, 1108, 1041, 990, 928, 760, 699 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.30 (d, J=6.0 Hz, C(equatorial)H_3), 1.43—1.58 (m, 1H, H(equatorial)CH), 1.52 (d, J=6.8 Hz, 3H, C(axial)H_3), 1.98—2.14 (m, 1H, H(axial)CH), 3.58 (d, J=3.0 Hz, 1H, OH (**3a** isomer)), 3.66 (d, J=3.4 Hz, OH (**3b** isomer)), 4.26 (dqd, J=2.6, 6.0, 12.0 Hz, OCH(axial)-CH_3), 4.53 (m, 1H, OCH(equatorial)CH_3), 5.94—5.99 (m, 1H, CHOH), 6.15 (s, 1H, O_2CH), 6.52 (dd, J=4.6, 16.0 Hz, CH=CHPh), 6.88 (dd, J=1.7 Hz, 16.0 Hz, CH=CHPh), 7.21—7.63 (m, 9H, ArH). Anal. ($C_{21}H_{24}O_3$) C, H.

(4*R*,6*R*)-4,6-Dimethyl-2-[2-(cyclohexylhydroxymethyl)phenyl]-1,3-dioxane (**3**, Entry 8): IR (neat) 3443, 2973, 2918, 2700, 1440, 1373, 1148, 1125, 1100, 1033, 980, 918, 753 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (d, J=6.0 Hz, 3H, C(equatorial)H_3), 1.49 (d, J=6.8 Hz, 3H, C(axial)H_3), 1.92—2.08 (m, 1H, H(axial)CH), 0.89—2.18 (m, 12H, C_6H_{11} and H(equatorial)CH), 2.49—2.54 (m, 1H, OH), 4.20 (dqd, J=2.1, 6.0, 12.0 Hz, 1H, OCH(axial)CH_3), 4.40—4.54 (m, 1H, OCH(equatorial)CH_3), 4.72 (dd, J=2.6, 8.0 Hz, 1H, CHOH (**3b** isomer)), 4.80 (dd, J=2.6, 8.2 Hz, CHOH (**3a** isomer)), 6.08 (s, 1H, O_2CH (**3a** isomer)), 6.12 (s, 1H, O_2CH (**3b** isomer)), 7.24—7.67 (m, 4H, ArH). Anal. ($C_{19}H_{28}O_3$) C, H.

(4*R*,6*R*)-2,4,6-Trimethyl-2-[2-(α-hydroxybenzyl)phenyl]-1,3-dioxane (**3, Entries 9 and 10**): IR (neat) 3500, 2980, 2948, 1450, 1382, 1248, 1178, 1162, 1121, 1039, 1019, 962, 921, 765, 739, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25—1.30 (m, 6H, 2CHCH_3), 1.52—1.82 (m, 2H, CH_2), 1.78 (s, 3H, O_2CCH_3), 3.70—3.81 (m, 1H, OCH(axial)CH_3), 4.02 (d, 1H, J=4.0 Hz, OH), 4.21—4.32 (m, 1H, OCH(equatorial)CH_3), 6.40 (d, J=3.8 Hz, 1H, CHOH (**3a** isomer)), 6.61 (d, J=5.0 Hz, 1H, CHOH (**3b** isomer)), 6.98—7.66 (m, 9H, ArH). Anal. ($C_{20}H_{24}O_3$) C, H.

Procedure for the Conversion of 3a/3b to 6. The mixture of **3a**/**3b** (94:6, 1.24 g, 4.2 mmol), *p*-toluenesulfonic acid (200 mg), water (15 ml), and THF (15 ml) was stirred at 50 °C for 5 h. Then the mixture was poured into saturated sodium hydrogen carbonate aqueous solution and extracted with ether. The combined extracts were dried over magnesium sulfate, filtered, and evaporated. Column chromatography (gradient elution, hexane/ethyl acetate, 5:2) gave **4** as a colorless oil (0.863 g, 98% yield).

To a solution of **4** (0.863 g, 4.1 mmol) prepared as detailed above in ethanol was added hydrazine monohydrate (0.971 ml, 20 mmol) at room temperature. After warming to 50—70 °C, the mixture was stirred at the same temperature for 8 h. After cooling to room temperature, the resulting solution was concentrated in vacuo. Column chromatography (gradient elution, Et_2O) gave **5** as a colorless oil (0.731 g, 79% yield).

To a rapidly stirred mixture of sublimed potassium *t*-butoxide and anhydrous dimethyl sulfoxide (20 ml) was added a solution of **5** in anhydrous dimethyl sulfoxide (20 ml) in very small portions over 1 h period. The solution turned deep green. Stirring was continued for 30 min. It was worked up with water and extracted with dichloromethane. The organic layer was washed with water, dried, and concentrated in vacuo. Column chromatography (gradient elution, benzene) gave **6** (455 mg, 71% yield).

3-Phenyl-2-oxaindan-1-ol (**4**): ^1H NMR ($CDCl_3$) δ=3.51 and 3.57 (d, J=7.4 Hz, 1H, OH), 6.13 (s, 1H, CHPh (trans isomer)), 6.36 (d, J=1.7 Hz, 1H, CHPh (cis isomer)), 6.61 (d, J=7.4 Hz, 1H, CHO_2 (trans isomer)), 6.72 (dd, J=1.7, 7.4 Hz, 1H, CHO_2), 7.05—7.53 (m, 9H, ArH).

2-(α-hydroxybenzyl)benzaldehyde Hydrazone (**5**): ^1H NMR ($CDCl_3$) δ=5.49 (br, 3H, NH_2 and OH), 5.99 (s, 1H, PhCH), 7.10—7.44 (m, 9H, ArH), 7.82 (s, 1H, CH=N).

Phenyl-*o*-tolylmethanol (**6**): ^1H NMR ($CDCl_3$) δ=2.30 (d, J=5.0 Hz, 1H, OH), 2.25 (s, 3H, CH_3), 6.00 (d, J=5.0 Hz, 1H, CHOH), 7.12—7.55 (m, 9H, ArH). The %ee of this compound ($[\alpha]_D^{23}$=−0.53°, *c* 1.0, benzene), determined from ^1H NMR by a shift reagent Eu(hfc)$_3$, was 72%.

(Received June 5, 1989)

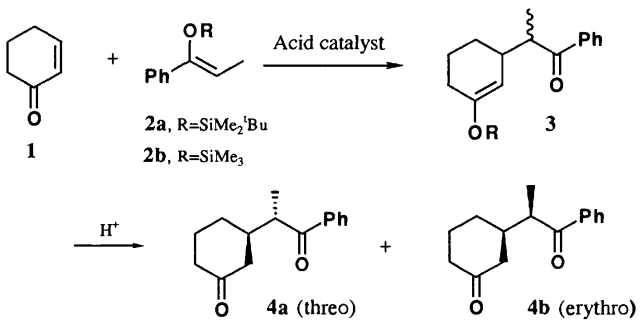
Synopsis. 1,5-Dicarbonyl compounds and their enol silyl ethers were prepared by the reaction of α,β-unsaturated ketones and enol silyl ethers or ketene silyl acetals by using an electrogenerated acid (EG acid) as a catalyst. Similar reaction of 1-trimethylsiloxy-1,3-butadiene with enones produced six-membered adducts as the result of a double-Michael process.

The conjugate-addition of basic enolates to α,β-unsaturated carbonyl compounds (i.e. the Michael reaction) is an important tactics for the preparation of 1,5-dicarbonyl compounds.[1] Recently, the reaction has been greatly improved by using enol silyl ethers as an equivalent of enolates in the presence of a stoichiometric amount of Lewis acids such as $TiCl_4$, $Ti(OC_3H_7\text{-}i)_4$, and $SnCl_4$ (the Mukaiyama-Michael reaction),[2] which may suppress side-reactions, e.g. self-condensation, proton transfer, 1,2-addition, and so on. Cesium fluoride (CsF) can catalyze 1,4-addition of enol silyl ethers in a heterogeneous medium.[3] Besides these reagents, homogeneous catalysts such as tris(dimethylamino)sulfonium difluorotrimethylsiliconate (TAS-F)[4] and a number of triphenylmethyl (trityl) salts[5] have currently been developed in order to achieve the 1,4-addition stereoselectively, giving rise to the adducts as a form of enol silyl ethers.

In the preceding paper, we reported the electrogenerated acid (EG acid)-catalyzed aldol reactions, cyanations, allylations, and hydride additions of organosilicon compounds.[6] In continuation of our study on EG acid-catalyzed carbon-carbon bond making reactions, we describe here the EG acid-catalyzed Michael reaction of α,β-unsaturated kenones with enol silyl ethers or ketene silyl acetals and their stereochemical product distributions.

Procedures employed in the EG acid-catalyzed Michael reaction are as follows: (1) The method A is based on the concurrent electrolysis of enol silyl ethers and enones in a CH_2Cl_2–$LiClO_4$–Bu_4NClO_4–(Pt) system.[6] (2) The method B is relied on the treatment with the pre-generated EG acid in an MeCN–$LiClO_4$–Bu_4NClO_4–(Pt) system.[7] (3) The method C is the reaction catalyzed by the electrochemically prepared trityl perchlorate. Prior to the present study, we have found that trityl perchlorate ($TrClO_4$) can be easily provided by the electrooxidation of phenylthiotriphenylmethane in an MeCN–$LiClO_4$–Bu_4NClO_4–(Pt) system in a divided cell.[8]

The reaction of 2-cyclohexenone (**1**) and 1-*t*-butyldimethylsiloxy-1-phenylpropene (**2a**)[9] was examined with EG acids of methods A—C and the results are shown in Table 1. In each case, the reaction proceeded smoothly at −78 °C to give the corresponding 1,4-adducts **3** in good yields. The enol silyl moiety of **3** was subjected to hydrolysis with 10% hydrochloric acid in MeOH–H_2O (1:10 v/v) to give the corresponding 1,5-diketones **4a**, **b**. The anti/syn (threo/erythro)[10] stereochemistry of **4a**, **b** was assigned according to the data reported[5] and then the diastereomeric ratios were estimated by peak areas at δ 1.16, 1.17 and 1.19, 1.21 in ^1H NMR (500 MHz) spectra (Scheme 1). The anti/syn (threo/erythro) ratios of the 1,5-diketones **4a**, **b** are in the range of 76—77:24—23 and these results are virtually same with that[5] obtained with the chemically prepared trityl perchlorate.[11] Similarly, the 1,4-addition of 1-phenyl-1-trimethylsiloxypropene (**2b**)[9] to the enone **1** was attempted with the EG acid (method A) in dichloromethane, giving the corresponding adducts **4a**, **b**, after the hydrolysis of silyl group, in 80% yield with a threo/erythro ratio of 71:29 (Entry 5). In addition to these acid-catalysts, we



Scheme 1.

Table 1. Michael Reaction of **1** and **2a** to **3**

Entry	Method	Temp(°C)/min	Yield of **3**/%	Threo/Erythro[a]
1	A	−78/30	90	77/23
2	B	−78/20	94	76/24
3	C	−78/90	90	77/23
4	D	−78/90	81	62/38
5[b]	A	−78/60	80	71/29

a) Determined by ^1H NMR (500 MHz). b) Trimethylsilyl ether **2b** was used in place of **2a**.

Table 2. The Reaction of Enones with Enol Silyl Ethers or Ketene Silyl Acetals

Entry	Enones	Enol silyl ethers	Electricity F mol^{-1}	Temp °C	Yield of adducts %	(Isomer ratio)[a]
1			0.05	0	88	
2			0.05	−78	87	(>98/2)
3			0.10	−78	94	
4			0.10	−78	94	(55/45)
5			0.15	−78	88	

a) Determined by ^{1}H NMR (500 MHz) after hydrolysis to dicarbonyl compounds.

examined triphenylsilyl perchlorate (Ph_3SiClO_4)[12] as an acid-catalyst for the reaction of **1** and **2a** in dichloromethane [method D] and threo/erythro ratio of which has changed to 62:38 [Entry 4] as compared with that obtained by acid-catalysts of Methods A—C.

Among the three different electrochemical procedures, the method A was used for the 1,4-addition of a variety of enones with enol silyl ethers or ketene silyl acetals (Table 2). The reaction of 1-phenyl-2-buten-1-one and enol silyl ether **2a** gave the threo adduct preferentially (Entry 2)[13] in good accordance with the reported trityl cation-catalyzed reaction.[5] Enol silyl ether derived from ethyl acetate and *S*-*t*-butyl thiopropionate added to 2-cyclohexenone (**1**), smoothly.

The reactions of enones **6** with 2-trimethylsiloxy-1,3-butadiene (**5**) as a nucleophile, giving the corresponding six-membered adducts **7** in 51—81% yields by a double-Michael process, were attempted in a CH_2Cl_2–$TrClO_4$ system.[5d,14] Apparently, $TrClO_4$ prepared from stable precursors, e.g. phenylthiotriphenylmethane and lithium perchlorate, by electrolysis can be used for Michael reactions as an effective catalyst as that chemically prepared.

Experimental

IR spectra were taken on a JASCO FT-IR-5000 spectrometer. NMR spectra were recorded in $CDCl_3$ on a Varian VXR-500 spectrometer.

General Procedure for the Reaction of Enol Silyl Ether with α,β-Unsaturated Ketones (Method A). Into the electrolysis vessel[6] were added $LiClO_4$ (17 mg, 0.15 mmol) and Bu_4NClO_4 (17.1 mg, 0.05 mmol) and the resulting mixture was dried at about 100 °C under vacuum for 1 h and then purged with argon. To this mixture was added a solution of 1-*t*-butyldimethylsiloxy-1-phenylpropene (**2a**, 149 mg, 0.6 mmol) and cyclohexenone (**1**, 48 mg, 0.5 mmol) in CH_2Cl_2 (3 ml). The entire mixture was electrolyzed under a constant current of 6.7 mA cm^{-2} (applied voltage: 10—15 V) at −78 °C. The progress of the reaction was monitored by TLC and the reaction was quenched with Et_3N (3 drops) when the starting **1** has completely disappeared (it took about 30 min and 0.2 F (1F=96480 C)mol^{-1} of electricity has been passed). The volatiles were removed on a rotary evaporator and the residue was purified by column chromatography (SiO_2, hexane–AcOEt 20:1) to give 155 mg (90%) of **3a**: bp 117 °C/0.02 Torr (1 Torr≈133.322 Pa); IR (neat) 3040, 1680 (C=O), 1660 (C=C), 1595, 1575, 1445, 1365, 1250, 1200, 1175, 980, 910, 835, and 780 cm^{-1}; ^{1}H NMR (500 MHz) δ=0.13, 0.14 (s, 6, $SiMe_2$), 0.85, 0.92 (s, 9, $SiCMe_3$), 1.14, 1.16 (d, *J*=7 Hz, 3, CH_3), 1.18—1.30 (m, 1, CH_2), 1.50—1.80 (m, 3, CH_2), 1.90—2.04 (m, 2, CH_2), 2.64 (m, 1, CH), 3.40 (m, 1, PhCH), 4.87 (brs, 1, OC=CH), 7.44—7.48, 7.54—7.57, and 7.93—7.95 (m, 5, PhH).

Hydrolysis of Enol Silyl Ether. To a solution of **3a** (34 mg, 0.1 mmol) in a mixed solution of MeOH (1 ml) and H_2O (10 ml) was added 10% HCl (2 drops). The mixture was stirred at room temperature for 1.5 h and extracted with AcOEt. Washing with brine and concentration followed by column chromatography (SiO_2, hexane–AcOEt) gave 21 mg (91%) of **4a**, **b**: bp 94—95 °C/0.4 Torr; IR (neat) 3066, 1713 (C=O), and 1682 (C=O) cm^{-1}; ^{1}H NMR (500 MHz) δ=1.17, 1.20 (d, *J*=7 Hz, 3, CH_3), 1.43 (m, 1), 1.58—1.68 (m, 1), 1.83—1.91 (m, 1), 1.98—2.06 (m, 1), 2.13 (m, 1), 2.20—2.31 (m, 2), 2.38—2.44 (m, 1), 2.49 (m, 1), 3.47 (m, 1, COCH), 7.42 (m, 1, PhH), 7.57 (m, 1, PhH), and 7.93 (m, 2, PhH).

Preparation of Trityl Perchlorate from Phenylthiotriphenylmethane. A Typical Procedure. Into the anodic compartment of a divided cell separated by a Nafion 324 diaphragm was added a solution of phenylthiotriphenylmethane (176 mg, 0.5 mmol), $LiClO_4$ (110 mg, 1.0 mmol), and Bu_4NClO_4 (340 mg, 1.0 mmol) in MeCN (7 ml). The mixture was electrolyzed at a constant current at 20 mA (applied voltage; 10—20 V) with platinum electrodes (1.5 cm^2) at room temperature. When the electrolysis was initiated, yellow color has appeared in the anolyte. The progress of the

reaction was monitored by TLC and the anolyte was transferred to a Schlenk tube when the sulfide was completely consumed (it took about 150 min and 1.87 F mol^{-1} of electricity has been passed). The mixture was concentrated under vacuum at ca. 0.1 Torr at 0 °C and yellow solids left were dissolved in CH_2Cl_2 (5 ml). A 1.0 ml portion of this solution was used for the following Michael reactions.

Michael Reaction by Using Electrochemically Prepared Trityl Perchlorate. To a solution of **2a** (298 mg, 1.2 mmol) and **1** (96 mg, 1.0 mmol) in CH_2Cl_2 (3 ml) was added a solution of the above trityl perchlorate (1.0 ml) at −78 °C and stirring was continued for 30 min. The mixture was treated with Et_3N (0.5 ml), concentrated under vacuum, and purified by column chromatography (SiO_2, hexane–AcOEt) to give 310 mg (90%) of the adducts **3a**.

Reaction of 1a and 2a by Triphenylsilyl Perchlorate. A solution of **2a** (149 mg, 0.6 mmol) and **1** (48 mg, 0.6 mmol) in CH_2Cl_2 (3 ml) was treated with a 0.2 M Ph_3SiClO_4[11] (1 M=1 mol dm^{-3}) in CH_2Cl_2 (0.3 ml) at −78 °C. After being stirred for 1.5 h at −78 °C, the reaction was quenched with Et_3N (0.3 ml). Concentration under vacuum followed by purification of the residue by column chromatography on SiO_2 (hexane–AcOEt) gave 156 mg (81%) of the adducts **3a** and 12 mg (11%) of the unprotected **4a, b**.

Spectral data of 1,5-dicarbonyl compounds derived from the Michael adducts in Table 2 are as follows.

1,3-Diphenyl-1,5-hexanedione; IR (neat) 1710 (C=O) and 1680 (C=O) cm^{-1}; ^1H NMR (500 MHz) δ=2.00 (s, 3, $COCH_3$), 2.81—2.96 (m, 2, $COCH_2$), 3.26—3.38 (m, 2, $COCH_2$), 3.89 (m, 1, CH), 7.18—7.21, 7.25—7.30, 7.42—7.45, 7.53—7.56, and 7.91—7.92 (m, 10, PhH).

2,3-Dimethyl-1,5-diphenyl-1,5-pentanedione: IR (neat) 3094 and 1682 (C=O) 692 cm^{-1}; ^1H NMR (500 MHz) δ=1.07 (d, J=6.5 Hz, 3, CH_3), 1.23 (d, J=7 Hz, 3, CH_3), 2.70 (m, 1, CH), 2.74 (d, d, J=16, 9.5 Hz, 1, CH_2CO), 3.59—3.65 (m, 1, COCH), 7.39—7.56, and 7.86—7.96 (m, 10, PhH).

Ethyl (3-Oxocyclohexyl)acetate: IR (neat) 1730 (C=O) and 1710 (C=O) cm^{-1}; ^1H NMR (500 MHz) δ=1.25 (t, J=7 Hz, 3, CH_3), 1.41 (m, 1), 1.71 (m, 1), 1.94 (m, 1), 2.02—2.12 (m, 2), 2.21—2.35 (m, 4), 2.38, 2.45 (m, 2, $COCH_2$), and 4.13 (q, 2, OCH_2).

***S-t*-Butyl 2-(3-Oxocyclohexyl)thiopropionate:** IR (neat) 1710 (C=O) and 1670 (COS) cm^{-1}; ^1H NMR (500 MHz) δ=1.09, 1.13 (d, J=7 Hz, 3, CH_3), 1.29—1.42 (m, 1), 1.428, 1.436 (s, 9, $C(CH_3)_3$), 1.55—1.64 (m, 1), 1.90 (m, 1), 1.98—2.08 (m, 2), 2.14 (m, 1), 2.17—2.26 (m, 1), 2.35 (m, 1), and 2.38—2.44 (m, 2).

Ethyl 5-Oxohexanoate: IR (neat) 1730 (COO) and 1710 (C=O) cm^{-1}; ^1H NMR (500 MHz) δ=1.15 (t, J=7 Hz, 3, CH_3), 1.78 (quintet, 2, J=7 Hz, 2, CH_2), 2.04 (s, 3, $COCH_3$), 2.21 (t, J=7 Hz, 2, $COCH_2$), and 2.40 (t, J=7 Hz, 2, $COCH_2$).

Double-Michael Reaction of 2-Trimethylsiloxy-1,3-butadiene (5). To a solution of **5** (284 mg, 2.0 mmol) and the enone **6a** (R^1=Ph, R^2=Me, 146 mg, 1.0 mmol) in CH_2Cl_2 (3 ml) was added a solution of the electrochemically prepared $TrClO_4$ (1.0 ml) in the manner as above at −78 °C. After stirring at −78 °C for 4 h, the mixture was poured into aqueous saturated NH_4Cl and extracted with AcOEt. Usual workup and purification by column chromatography (SiO_2, hexane–AcOEt) gave 174 mg (81%) of 4-acetyl-3-phenylcyclohexanone (**7a**) as solids: mp 63—65 °C (hexane–AcOEt); IR (KBr) 1711 (C=O), 1603 (C=C), and 1584 cm^{-1}; ^1H NMR (500 MHz) δ=1.88 (s, 3, CH_3CO), 1.90—1.98 (m, 1, CH_2), 2.17—2.23 (m, 1, CH_2), 2.45—2.53 (m, 1, CH_2CO), 2.56 (m, 1, CH_2CO), 2.60—2.64 (m, 2, CH_2CO), 3.17 (m, 1, CH), 3.26 (m, 1, CH), and 7.20—7.34 (m, 5, PhH).

4-Benzoyl-3-methylcyclohexanone (7b): mp 58—59 °C (hexane–AcOEt); IR (KBr) 1711 (C=O), 1676, and 1599 (C=C) cm^{-1}; ^1H NMR (500 MHz) δ=0.98 (d, J=6.5 Hz, 3, CH_3), 1.87—1.95 (m, 1, CH), 2.17—2.22 (m, 2, CH_2), 2.38—2.57 (m, 4, CH_2CO), 3.45—3.50 (m, 1, CHCO), 7.50—7.53 (m, 2, PhH), 7.61 (m, 1, PhH), and 7.94—8.01 (m, 2, PhH).

The present work was partially supported by a Grant-in-Aid for Scientific Research on Priority Areas (Advanced Molecular Conversions, No. 01607001) from the Ministry of Education, Science and Culture. We are grateful to the SC-NMR laboratory of Okayama University for experiments with a Varian VXR-500 instrument.

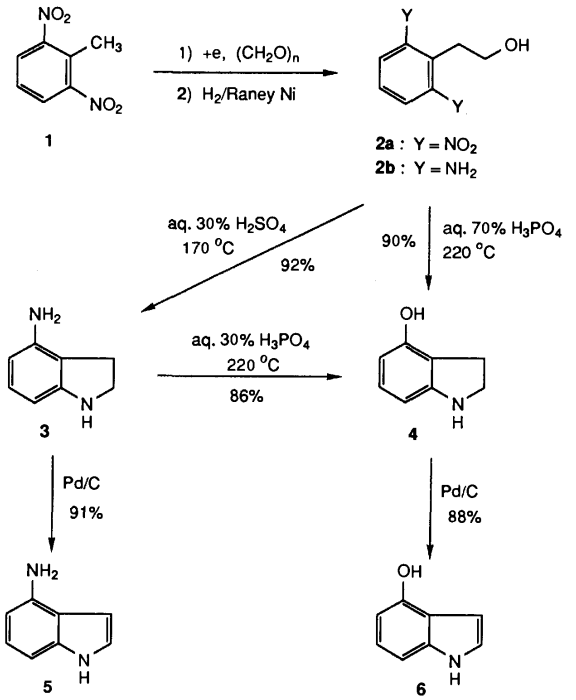
A Facile Synthesis of 4-Hydroxy- and 4-Aminoindoles through Corresponding Indolines

Hideo TANAKA, Yasuo MURAKAMI, Takao AIZAWA, and Sigeru TORII*
Department of Applied Chemistry, Faculty of Engineering,
Okayama University, Tsushima Naka, Okayama 700
(Received June 29, 1989)

Synopsis. 2-(2,6-Diaminophenyl)ethanol can be conducted to 4-hydroxyindoline under heating in aqueous 70% phosphoric acid, and to 4-aminoindoline under heating in aqueous 30% sulfuric acid. Both 4-hydroxy- and 4-aminoindoles were obtained by dehydrogenation of the indolines under refluxing in 1,4-dimethylbenzene over palladium on charcoal.

Indoles bearing an oxygen or nitrogen atom at the 4-position have been of interest for many years because of their potent and diverse therapeutical activities.[1] 4-Amino- and 4-hydroxyindoles (**5** and **6**) are used as versatile intermediates in the synthesis of therapeutical compounds. Most of electrophilic substitution reactions of indoles take place at the 4 and 7-positions and only the tactics reaching the desired 4-substituted indoles **5** and **6** have been required.[2,3] 4-Hydroxyindole (**6**) has been synthesized from 6-benzyloxy-2-nitrotoluene by one-carbon homologation with *N,N*-dimethylformamide dimethyl acetal and subsequent hydrogenative cyclization.[3d,e] 2,6-Dinitrotoluene (**1**) has also been used for the preparation of 4-hydroxyindole (**6**) via 4-aminoindole (**5**).[3f] In the practical sense, however, these procedures are not necessarily satisfactory, suffering insufficient overall yields and/or the use of the expensive chemicals. Herein, we describe a short-cut route to 4-amino- and 4-hydroxyindoles (**5** and **6**) from 2,6-dinitrotoluene (**1**), which involves 1) one-carbon homologation of **1** with formaldehyde followed by the hydrogenation (**2a**→**2b**) and 2) subsequent cyclization, giving the indoline **3**, or a one-pot cyclization-hydroxylation reaction, affording the indoline **4** (Scheme 1).



Scheme 1.

One-carbon homologation of 2,6-dinitrotoluene (**1**) with paraformaldehyde was successfully performed by the action of an electrochemically generated base (EG base). In the previous paper,[4] we have disclosed an EG base-induced hydroxymethylation of the side chain of 2-nitrotoluene with paraformaldehyde. The smooth extension of the method to **1** was verified by obtaining 2-(2,6-dinitrophenyl)ethanol (**2a**) in 94% yield after passage of a catalytic amount of electricity (0.06 F mol^{-1}) in a DMF–Et_4NOTs–$(CH_2O)_n$ system. Hydrogenation of **2a** over Raney Ni catalyst gave 2-(2,6-diaminophenyl)ethanol (**2b**) in 86% yield.

The conversion of **2b** into the 4-amino- and 4-hydroxyindolines (**3** and **4**) was performed by heating with proper acids, respectively (Scheme 1). The dehydrogenative cyclization of **2b** to **3** was achieved by heating in a sealed tube with an aqueous 30% sulfuric acid at 170 °C, affording 4-aminoindoline (**3**) in 92% yield. A similar result was obtained by heating of **2b** in an aqueous 1% phosphoric acid at 220 °C (86% yield).

The hydrolysis of the amino moiety of **3** was, at first, carried out by the conventional diazotization-hydrolysis reaction with sodium nitrate in aqueous 60% sulfuric acid (Method A). The satisfactory yields (>77%) were only achieved under high dilution conditions (<1%). When the concentration of **3** rose up to 3%, the yield of **4** decreased to less than 65%. Consequently, we turned our attention to the hydrolysis of 4-aminoindoline (**3**) to 4-hydroxyindoline (**4**) by heating with acids (Method B). The results obtained with various acids are shown in Table 1. Among the

Table 1. Effect of Acid in the Hydrolysis of 4-Aminoindoline (**3**) to 4-Hydroxyindoline (**4**)[a]

Entry	Acid	Yield of **4**	Recovered **3**
		%[b]	%[b]
1	H_3PO_4	86	3
2	H_2SO_4	23	72
3	HCl	30	60
4	H_3BO_4	7	70
5	NaH_2PO_4	Trace	72
6	$NaHSO_3$	—[c]	—
7	None	—	93

a) Carried out with **3** (2.2 mmol) in aqueous 30% acids (6 g) at 220 °C for 24 h. b) Isolated yields. c) A complex mixture of decomposition products was formed.

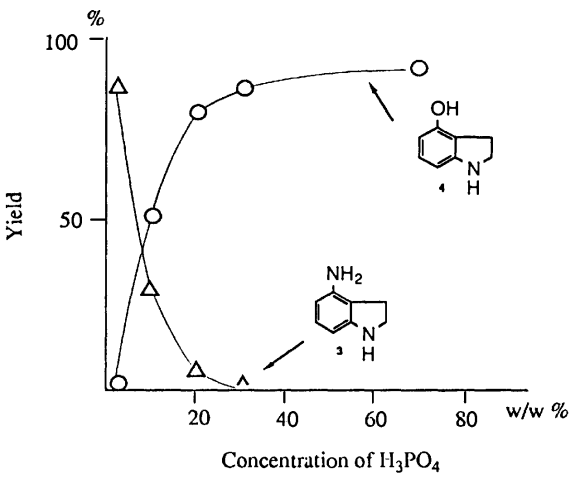


Fig. 1. Effect of concentration of H_3PO_4 on the conversion of 2-(2,6-diaminophenyl)ethanol (**2b**) into 4-amino and 4-hydroxyindolines (**3** and **4**). All experiments were carried out with **2b** (2 mmol) in aqueous H_3PO_4 (6 g) at 220 °C for 24 h.

acids, aqueous 30% phosphoric acid is the best choice, affording the desired product **4** in 86% yield (Entry 1), while sulfuric acid, hydrochloric acid, and boric acid are less effective (Entries 2—4). Sodium dihydrogenphosphate and sodium hydrogensulfite are not feasible for the present purpose (Entries 4 and 5).

As mentioned above, aqueous phosphoric acid is effective both for cyclization of **2b** into 4-aminoindoline (**3**) and for hydrolysis of **3** into 4-hydroxyindoline **4**. This finding, in turn, spurred us to examine a one-pot transformation of 2-(2,6-diaminophenyl)-ethanol (**2b**) into 4-hydroxyindoline (**4**) by heating with an aqueous 1—70% phosphoric acid at 220 °C. As illustrated in Fig. 1, the distribution of the products **3** and **4** was highly dependent on the concentration of phosphoric acid. In fact, the exclusive conversion to **4** was attained with aqueous 70% phosphoric acid.

The 4-substituted indolines **3** and **4** can be readily converted to the corresponding indoles **5** (91%) and **6** (88%) by heating to reflux in *p*-xylene over palladium on charcoal.[5,6] As an alternative route to **6**, hydrolysis of **5** was also attempted under the same conditions as for the hydrolysis of **3**, but all the trials resulted in the formation of a complex mixture.

In conclusion, the preparation of 4-amino- and 4-hydroxyindoles (**5** and **6**) from 2,6-dinitrotoluene (**1**) has been achieved in satisfactory overall yields (64—67%). Further transformation of **5** and **6** into the useful therapeutical compounds are in progress.

Experimental

IR spectra were recorded on a JASCO IRA-1 grating spectrometer and ^1H NMR spectra were measured at 60 MHz with a Hitachi R-24 spectrometer. Chemical shifts are expressed in parts per million downfield from Me_4Si as an internal reference. Melting points are uncorrected. Column chromatography was carried out on Wako gel C-200 (silica gel) with hexane–EtOAc as an eluent.

2-(2,6-Dinitrophenyl)ethanol (2a): Into both anode and cathode compartments of an H-shaped divided cell[4] was placed a DMF solution of Et_4NOTs (420 mg/8 ml each). To the cathode compartment were added 2,6-dinitrotoluene (**1**) (1.04 g, 5.7 mmol) and $(CH_2O)_n$ (220 mg, 7.3 mmol on the basis of formaldehyde). The mixture was electrolyzed under a constant current of 3.3 mA cm^{-2} at room temperature for 50 min (0.06 F mol^{-1}). The catholytes were poured into aqueous 5% HCl and extracted with EtOAc. The extracts were washed with brine, dried (Na_2SO_4), and concentrated in vacuo. The residue was chromatographed to afford **2a**[5b] (1.14 g, 94%): mp 69—71 °C; ^1H NMR ($CDCl_3$) δ=2.05 (1H, s, OH), 3.27 (2H, t, J=6 Hz, $ArCH_2$), 3.90 (2H, t, J=6 Hz, CH_2O), 7.35—8.05 (3H, m, ArH); IR ($CHCl_3$) 3600, 3010, 2885, 1540, 1365, 1050, 910, 705 cm^{-1}.

2-(2,6-Diaminophenyl)ethanol (2b): To a stirred suspension of Raney Ni (W-2, 12.5 g) in MeOH (80 ml) was added at 55—65 °C a solution of 2-(2,6-dinitrophenyl)ethanol (**2a**) (40 g, 0.19 mol) in methanol (180 ml) over a period of 2 h under H_2 atmosphere (5—9 atm). After stirring for additional 2 h, the catalysts were removed by filtration and washed with methanol. The filtrate and washings were combined and concentrated in vacuo. The residue was recrystallized from ethanol to give **2b**[7] (24.7 g, 86%): mp 109—110 °C; ^1H NMR (acetone-d_6) δ=2.63 (2H, t, J=6 Hz, $ArCH_2$), 3.65 (2H, t, J=6 Hz, CH_2O), 4.03 (5H, br s, NH_2, OH), 5.9—6.7 (3H, m, ArH); IR (Nujol) 3370, 3200, 1595, 1463, 1050, 858, 733 cm^{-1}.

4-Aminoindoline (3): 2-(2,6-Diaminophenyl)ethanol (**2b**) (300 mg, 1.97 mmol) and 30% aqueous sulfuric acid (6 g) were charged to a sealed tube and heated at 170 °C for 24 h. The acidic solution was neutralized with aqueous 40% NaOH and extracted with EtOAc. The extracts were washed with brine, dried (Na_2SO_4), and concentrated in vacuo. The residue was chromatographed to give **3**[5b] (245 mg, 92%): mp 44—45 °C; ^1H NMR ($CDCl_3$) δ=2.79 (2H, t, J=8 Hz, $ArCH_2$), 3.1—3.7 (5H, m, CH_2N, NH, NH_2, CH_2N), 5.95 (1H, d, J=8 Hz, ArH), 6.0 (1H, d, J=8 Hz, ArH), 6.7 (1H, t, J=8 Hz, ArH); IR (CH_2Cl_2) 3360, 1633, 1500, 1485, 1315, 1065 cm^{-1}.

4-Hydroxyindoline (4): Method A. To a solution of 4-aminoindoline (**3**) (112 mg, 0.83 mmol) in 70% aqueous H_2SO_4 (11 g) was added 4% aqueous $NaNO_2$ (1.5 ml, 1.0 equiv) at 0—10 °C over a period of 1 h. After stirring at 0—5 °C for 10 h, sulfamic acid (10 mg) was added. The stirring was continued at room temperature for 1 h and at 65—75 °C for additional 4 h. The acidic solution was neutralized with 10% aqueous 40% NaOH and extracted with EtOAc. The extracts were washed with brine, dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed to give **4** (86 mg, 77%): mp 139—140 °C (lit,[2c] mp 147 °C).

Method B: 4-Aminoindoline (**3**) (300 mg, 2.24 mmol) and 30% aqueous phosphoric acid (3 g) were charged to a sealed tube. The mixture was heated at 220 °C for 24 h and then cooled to room temperature. The acidic solution was neutralized with aqueous 40% NaOH, extracted with EtOAc. The extracts were washed with brine, dried (Na_2SO_4), and concentrated in vacuo. The residue was chromatographed to afford **4** (260 mg, 86%), whose IR and ^1H NMR spectra are identical with those of **4** obtained above.

Direct Conversion of 2-(2,6-Diaminophenyl)ethanol (2b) to 4-Hydroxyindoline (4): A mixture of 2-(2,6-diaminophenyl)ethanol (**2b**) (300 mg, 1.97 mmol) and 70% aqueous phosphoric acid (3 g) was charged to a sealed tube and heated at 220 °C for 24 h. The mixture was worked up in a similar manner to that described above to give **4** (240 mg, 90%), whose IR and ^1H NMR spectra are identical with those of **4** obtained above.

4-Hydroxyindole (5): A mixture of 4-hydroxyindoline (**4**)

(68 mg, 0.51 mmol) and 10% Pd/C (10 mg), in *o*-xylene (10 ml) was heated to reflux for 2.3 h under N_2 atmosphere. Usual workup of the mixture afforded **5** (59 mg, 88%): mp 98—98.6 °C (lit,[3b] 96—98 °C); ^{1}H NMR (acetone-d_6) δ= 6.3—7.2 (5H, m, ArH, CH=CHN), 8.1 (1H, s, OH), 9.8 (1H, br s, NH); IR (CH_2Cl_2) 3550, 3435, 1590, 1500, 1450, 1355, 1075, 690 cm^{-1}.

4-Aminoindole (6): A mixture of 4-aminoindoline (**3**) (70 mg, 0.52 mmol) and 10% Pd/C (10 mg) in *p*-xylene (2.0 ml) was heated to reflux for 3 h under N_2 atmosphere. Usual workup of the mixture afforded **6** (63 mg, 91%): mp 104—105 °C (lit,[3d] mp 106—108 °C); ^{1}H NMR ($CDCl_3$) δ=3.76 (2H, br s, NH_2), 6.17—7.06 (5H, m, ArH, C=CH–N, ArCH=C), 7.95 (1H, br s, NH); IR (CH_2Cl_2) 3440, 3350, 1618, 1587, 1500, 1405, 1364 cm^{-1}.

Application of Improved Free-Energy Parameters of RNA Stability to Codon-Anticodon Interactions

Naoki SUGIMOTO* and Muneo SASAKI
Department of Chemistry, Faculty of Science, Konan University,
8-9-1 Okamoto, Higashinada-ku, Kobe 658
(Received June 5, 1989)

Synopsis. Free-energy parameters of the RNA duplex stability have been applied in order to investigate the complex between codon oligomers and anticodon loops in transfer RNA. The results suggested that the very large stability of the complex might be due to the stacking interactions of adjacent bases on the codon-anticodon helix and an additional hydrogen-bond formation of the core helix as well as a conformational change of the nucleic acid.

Even at present an interaction between a codon in the messenger RNA and an anticodon in a transfer RNA (tRNA), which is of central importance in the transfer of genetic information from DNA to proteins, still remains a mystery. It has often been found that the codon-anticodon complexes are more stable than found or predicted for two complementary trinucleotides.[1-3] The possible reason for the large stability of the complex was suggested to be the contribution of a base-pair formation between the 5′ adjacent codon base and the 3′ adjacent anticodon base on the helix.[4] However, this explanation can not be applied to complexes containing terminal mismatches or unpaired nucleotides (dangling ends).

Recently, improved thermodynamic parameters for RNA duplex stability[5-9] have been reported by using a nearest-neighbor model.[2] The improvements have permitted the parameters to provide breakthroughs in difficult structure predictions of tRNAs,[10] ribosomal RNAs,[10] a self-splicing intervening sequence,[11] and intermediate complexes of ribozymes.[12,13] In the present study we have applied the improved free-energy parameters of RNA stability to the interaction between codon oligomers and anticodon loops of tRNAs in order to determine the origin of the very large stability of the complexes.

Methods

The measured free-energy changes, ΔG_m, for the formation of codon-anticodon complexes were obtained from the observed association constants, K, for the binding of codon oligonucleotides to $tRNA^{Phe}$ [3,4,14] and $tRNA^{fMet}$ [15] at 273 K:

$$\Delta G_m = -RT\ln K, \quad (1)$$

where R is the gas constant and T is equal to 273 K. The values of ΔG_m for UUCA binding to the CmU-GmAAYA (m, 2′-*O*-methyl ribose; Y, a hypermodified base in $tRNA^{Phe}$) site of dodecamer[4] was also obtained by the same method.

The measured free-energy increments, $\Delta\Delta G_m$, for dangling ends of codon oligonucleotides were obtained by subtracting ΔG_m for codon trinucleotides from ΔG_m for codon tetranucleotides. For example, the value of $\Delta\Delta G_m$ for the AUGA codon oligomer binding to CmU-CAUAA (anticodon loop of $tRNA^{fMet}$) was calculated as being;

$$\Delta\Delta G_m = \Delta G_m(\mathrm{AUGA}) - \Delta G_m(\mathrm{AUG}) = (-21.7) - (-16.3) = -5.4\ \mathrm{kJ\ mol^{-1}},$$

where ΔG_m(AUGA) and ΔG_m(AUG) were the measured free-energy changes for the formation of codon-anticodon complexes of AUGA and AUG with CmUCAU AA, respectively.

The calculated free-energy changes, ΔG_c, for the formation of codon-anticodon complexes were obtained from nearest-neighbor thermodynamic parameters:[5-9]

$$\Delta G_c = \Delta H_c - T\,\Delta S_c, \quad (2)$$

where ΔH_c and ΔS_c are the enthalpy and entropy changes, respectively, and T is the temperature. For example, the value of ΔG_c for an AUG codon oligomer binding to CmUCAUAA (anticodon loop of $tRNA^{fMet}$) was calculated as follows: The calculated entropy change of a core helix formation for $\overrightarrow{\mathrm{CAU}}/\overleftarrow{\mathrm{GUA}}$ was

$$\Delta S_c(\mathrm{core}) = \Delta S_c(\mathrm{initi}) + \Delta S_c(\overrightarrow{\mathrm{CA}}/\overleftarrow{\mathrm{GU}}) + \Delta S_c(\overrightarrow{\mathrm{AU}}/\overleftarrow{\mathrm{UA}}) = (-45) + (-116) + (-65) = -226\ \mathrm{J\ K^{-1}\ mol^{-1}},$$

where ΔS_c(initi) was the entropy change for a helix initiation associated with the formation of the first base pair in the duplex,[6] $\Delta S_c(\overrightarrow{\mathrm{CA}}/\overleftarrow{\mathrm{GU}})$ and $\Delta S_c(\overrightarrow{\mathrm{AU}}/\overleftarrow{\mathrm{UA}})$ were the propagation entropy changes during the formation of each subsequent base pair;[5] the arrows point from the 5′ to the 3′ direction. Similarly, ΔH_c(core)=−67.8 kJ mol^{-1}. Therefore, according to Eq. 2, ΔG_c(core) at 273 K was −6.1 kJ mol^{-1} for the core helix formation. Since the core helix had two dangling bases of 5′U and 3′A in the anticodon loop, $\Delta G_c(\overrightarrow{\mathrm{UC}}/\underline{\mathrm{G}})$ and $\Delta G_c(\overrightarrow{\mathrm{A}}/\overleftarrow{\mathrm{AU}})$ (−0.4 and −2.9 kJ mol^{-1},[7] respectively) had to be added to ΔG_c(core) in order to obtain the total free-energy change, ΔG_c. Consequently, ΔG_c at 273 K was −9.4 kJ mol^{-1} for AUG binding to the anticodon loop of $tRNA^{fMet}$.

Note that in the ΔG_c calculation for a codon binding to the anticodon of $tRNA^{Phe}$ or the CmUGmAAYA site of the dodecamer, two assumptions were used: One was that the stabilization energy of 2′-*O*-methyl ribose was equal to that of the unmodified ribose, and the other was that a dangling Y base which was the hypermodified base in $tRNA^{Phe}$ had the same stabilization energy as the dangling purine base, since the nearest-neighbor energy parameters for the dangling Y

base were not available. These assumptions were reasonable, since they had been applied to the prediction of secondary structures of tRNAs, and the most probable structure, determined by the calculation, was almost consistent with that from phylogenetic data.[10,11]

The calculated free-energy increments, $\Delta\Delta G_c$, by stacking the dangling bases of the codon oligonucleotides were obtained from the literature.[6-9] The values of $\Delta\Delta G_c$ by the fourth base-pair formation between the dangling bases of the codon oligomer and the anticodon loop (shown in parentheses in Table 1) were calculated by the same method for ΔG_c described above. For example, the complex between AUGA and CmUCAUAA had the possibility of an additional A-U base-pair formation on the G-C base pair. The free-energy increment, $\Delta\Delta G_c$, for this fourth base pair was

$$\begin{aligned}\Delta\Delta G_c &= \Delta H(\overrightarrow{GA}/\underleftarrow{CU}) - T\,\Delta S(\overrightarrow{GA}/\underleftarrow{CU}) \\ &= (-55.7) - (273) \times (-148 \times 10^{-3}) \\ &= -15.3\ \text{kJ mol}^{-1},\end{aligned}$$

where $\Delta H(\overrightarrow{GA}/\underleftarrow{CU})$ and $\Delta S(\overrightarrow{GA}/\underleftarrow{CU})$ were the enthalpy- and entropy-changes for forming the A-U base pair on the G-C base pair.

Results and Discussion

The measured free-energy changes, ΔG_m, and the calculated free-energy changes, ΔG_c, for the formation of codon-anticodon complexes are listed in Table 1. The values of $\Delta\Delta G_c$ (the differences between the calculated free-energy changes of helix formation of the tetranucleotide with anticodon and the calculated free-energy changes of helix formation of the trinucleotide with anticodon) are also listed in Table 1 along with the values of $\Delta\Delta G_m$.

In Table 1, the values of $\Delta\Delta G_c$ in parentheses are quite different from those of $\Delta\Delta G_m$, not only for UUCA binding to $tRNA^{Phe}$ but also for AUGA, UAUG, and GUGA binding to $tRNA^{fMet}$ which can form the fourth base pair. This result suggests that there is either the very weak or no hydrogen-bond formation. It has been shown that hydrogen bonding and stacking compete in a base pair.[16] Stacking interactions are more favorable when hydrogen-bonding interactions are less favorable. Therefore, stacking of dangling nucleotides might contribute to the large stability of the codon-anticodon complex.

Within a few kilojouls per mole (that is, within estimated errors) these $\Delta\Delta G_m$ are equal to the $\Delta\Delta G_c$ calculated by the assumption that the adjacent bases on a codon-anticodon core helix do not make a base pair but, rather, are stacking. The good correspondence between $\Delta\Delta G_c$ and $\Delta\Delta G_m$ is also found in the cases of the other 3′ and 5′ end bases of codon oligomers which can not form the fourth Watson-Crick base-pairs with the anticodon loops. These results show that an adjacent base on a codon-anticodon core helix stabilizes the helix by the stacking interaction, though this stabilization is not sufficiently large to provide a good explanation for the very large stability of the codon-anticodon complex. Therefore, the larger stability of ΔG_m than ΔG_c might come from an unusual base-pair formation of the codon-anticodon core helix.

Because the free-energy change for a codon-anticodon helix initiation is positive, the large stability of ΔG_m

a) From the data of the observed binding constants in Refs. 3, 4, 14, and 15. Estimated errors in ΔG_m are within ± 10%. b) Estimated errors in ΔG_c are within ± 5%. c) The values in parentheses were calculated according to the assumption that the dangling bases of the codon oligomer and the anticodon loop were able to make the fourth base-pair.

for helix formation is mainly due to the formation of Watson-Crick base pairs and a G-U base pair. However, as shown in Table 1, the measured stability of ΔG_m is significantly larger than the calculated stability of ΔG_c, which was obtained by the free-energy value of not only the base pairs, but also the stacking interaction of the adjacent bases in a codon oligomer. The differences in the stability between ΔG_m and ΔG_c are -4.6, -6.3, -6.9, and -6.9 kJ mol^{-1} for UUC and UUU binding to $tRNA^{Phe}$ and for AUG and GUG binding to $tRNA^{fMet}$, respectively. The value for each binding suggests a possible explanation for the large stability of the complex: An additional hydrogen bond contributes to the stability of a codon-anticodon helix, since it is known that the addition of a hydrogen bond for terminal and interior base pairs in RNA oligomers changes the free energy for duplex formation by -4 to -7 kJ mol^{-1} [16] and, especially, the value of -7 kJ mol^{-1} is consistent with the free energy increment recently predicted for a hydrogen bond formation between base pairs in the absence of competing stacking interactions.[17] Furthermore, the stability of ΔG_m for UUCA binding to dodecamer is well predicted by the calculated free-energy change, ΔG_c, which does not contain the stability by an additional hydrogen-bond formation. Therefore, the results and the fact that the dodecamer can not form a loop suggest that the additional hydrogen bond on the codon-anticodon helix might come from the other base in an anticodon loop of tRNA as well as a conformational change of the nucleic acid during the formation of the complex.

(Received June 10, 1989)

Synopsis. The reaction of several substituted benzyl alcohols with 1 equiv of benzyltrimethylammonium tribromide (BTMA Br_3) in carbon tetrachloride under basic or neutral conditions gave the corresponding benzaldehydes, and with 2 equiv of BTMA Br_3 in aqueous alkaline solution and subsequent acid hydrolysis gave the corresponding benzoic acids, respectively, in satisfactory yields.

Benzyltrimethylammonium tribromide (BTMA Br_3) has recently been introduced as a useful brominating agent by us.[2] During the course of our further investigation on the synthetic utility of BTMA Br_3, we have found that this reagent is also an effective oxidizing agent.[3] In this paper we wish to report on the selective oxidation of several benzyl alcohols **1** to the corresponding benzaldehydes **2** or benzoic acids **3** by the use of BTMA Br_3.

Results and Discussion

Although a variety of substituted **1** has been

a) The reaction was done in water without using alkali. b) The desired **2** was separated from the starting material by column chromatography on alumina, and a small amount of the corresponding sodium benzoate was found in the resulting alkaline solutions as by-product. c) A mixtures of **1d** and **2d**, which was not separated by column chromatography on alumina, was obtained. d) The reaction was done in aq Na_2HPO_4 solution (molar ratio: Na_2HPO_4/**1**=2). e) Considerable amount of the starting material was recovered because of its relatively poor reactivity.

converted into the corresponding **2** by means of a number of oxidizing agents,[4] we have found that BTMA Br_3 is also a convenient reagent to oxidize **1** into **2**. That is, the reaction of **1** with 1-equiv of BTMA Br_3 in carbon tetrachloride in the presence of an aqueous alkaline solution, an aqueous solution of Na_2HPO_4, or water, at room temperature or at 70 °C gave **2** in satisfactory yields. The results are summarized in Table 1.

It should also be mentioned that primary alcohols can be oxidized to carboxylic acids by many strong oxidizing agent including chromic acid, permanganate, and nitric acid. However, a few oxidizing agents[5] have been used for the direct conversion of **1** to **3**. We have also found that BTMA Br_3 can be used as a reagent for the oxidation of **1** to **3**. That is, the reaction of **1** with 2-equiv of BTMA Br_3 in an aqueous alkaline solution at room temperature or at 70 °C afforded **3** in good yields. The results are summarized in Table 1.

These reactions, which occurred under basic conditions, can be represented by the following equations:

$$\underset{\mathbf{1}}{\text{Ar-CH}_2\text{OH}} + \text{BTMA Br}_3 + 2\text{NaOH} \longrightarrow \underset{\mathbf{2}}{\text{Ar-CHO}} + \text{BTMA Br} + 2\text{NaBr} + 2\text{H}_2\text{O} \quad (1)$$

$$\mathbf{1} + 2\text{BTMA Br}_3 + 5\text{NaOH} \longrightarrow \underset{\xrightarrow{\text{H}_3\text{O}^+}\ \underset{\mathbf{3}}{\text{Ar-COOH}}}{\text{Ar-COONa}} + 2\text{BTMA Br} + 4\text{NaBr} + 4\text{H}_2\text{O} \quad (2)$$

We assumed that the active species for the oxidation is sodium hypobromite or hypobromous acid, which may be produced from the reaction of BTMA Br_3 with aqueous sodium hydroxide or water, respectively.

As shown in Eqs. 1 and 2, oxidation products **2** or **3** can be obtained selectively from **1** by the use of a stoichiometric amount of BTMA Br_3. However, in these oxidation reactions of **1** (particulary active **1** such as methoxy-substituted benzyl alcohols (e.q., **1e**, **1f**, and **1g**)), an excess amount of alkali was required in order to avoid any aromatic bromination of **1**. Furthermore, the oxidation of **1** (which substituted an electron-attracting group) to **2** required more severe reaction conditions.

We emphasize that the above-mentioned procedure for the oxidation of **1** affording **2** or **3** should be a useful method owing to its simplicity, good yield of the product, and excellent selectivity.

Experimental

All products were characterized by comparing their ^1H NMR spectra and mp or bp with those of authentic samples or reported data.

Oxidation of 4-Methoxybenzyl Alcohol (1e) to 4-Methoxybenzaldehyde (2e); Typical Procedure: A solution of BTMA Br_3 (2.05 g, 5.25 mmol) and sodium hydroxide (0.60 g, 15 mmol) in water (25 ml) was added dropwise into a solution of **1e** (0.69 g, 5 mmol) in carbon tetrachloride (25 ml). The mixture was stirred at room temperature for 15 h until the initial yellow color faded. To the mixture was added 5% aq solution of $NaHSO_3$ (5 ml). Then, the carbon tetrachloride layer was separated and the water layer extracted with dichloromethane (30 ml×3). The organic layer was dried over $MgSO_4$, filtered, and evaporated under reduced pressure to give **2e** as a colorless liquid; yield 0.51 g (75%); bp 243—244 °C/760 mmHg (lit,[6] bp 248 °C/760 mmHg; 1 mmHg≈133.322 Pa).

Oxidation of 3-Chlorobenzyl Alcohol (1j) to 3-Chlorobenzoic Acid (3j); Typical Procedure: Compound **1j** (0.71 g, 5 mmol) was added into a solution of BTMA Br_3 (4.09 g, 10.5 mmol) and sodium hydroxide (1.60 g, 40 mmol) in water (30 ml). The mixture was stirred at 70 °C for 17 h until the initial yellow color faded. To the mixture was added a 5% aq solution of $NaHSO_3$ (5 ml); the mixture was then acidified sufficiently with 6M-HCl. The solution was extracted with ether (40 ml×4) and the ether layer was dried over $MgSO_4$, filtered, and evaporated under reduced pressure to give **3j** as a colorless crystals; yield 0.73 g (94%); mp 156—157 °C (lit,[7] mp 156—157 °C).

Myeloperoxidase Catalyzed Bromination of Nucleic Acid Bases and Related Compounds

Toshio ITAHARA* and Naoko IDE
Institute of Chemistry, College of Liberal Arts, Kagoshima University, Korimoto, Kagoshima 890
(Received June 17, 1989)

Synopsis. Oxidation of cytosine, uracil, adenine, cytidine, and 2′-deoxycytidine by myeloperoxidase in the presence of hydrogen peroxide and potassium bromide in sodium acetate buffer solution at pH 5.0 resulted in bromination of the substrates. A comparison of bromination of 1,3-dimethyluracil catalyzed by peroxidases such as myeloperoxidase, lactoperoxidase, chloroperoxidase, and horseradish peroxidase was also studied.

Myeloperoxidase (MPO) plays an important role for disinfection with H_2O_2 and halide ions in phagolysosome.[1] On the other hand, mutation[2] and carcinogenesis[3] are known to be caused by human phagocytes. Furthermore, halogenated nucleic acid bases and their deoxyribonucleosides such as 5-bromouracil (**2b**)[4] and 5-bromo-2′-deoxyuridine[5] have mutagenic activities. Therefore, MPO catalyzed halogenation of nucleic acids is of interest. Odajima[6] first reported the incorporation of chlorine into RNA and adenine (**3a**) by MPO in the presence of H_2O_2 and NaCl. However, structures of the chlorinated products were not thoroughly determined.[6] As part of the investigation of the enzymatic and non-enzymatic oxidation of nucleic acid bases,[7] MPO catalyzed halogenation of nucleic acid bases was studied.[8]

MPO catalyzed halogenation of nucleic acid bases was carried out in sodium acetate buffer solution at pH 5.0.[6] While oxidation of cytosine (**1a**), uracil (**2a**), and **3a** with H_2O_2 and NaCl in the presence of MPO gave only a trace amount of product, a similar treatment with KBr instead of NaCl gave brominated products in moderate yields. The results are shown in Table 1. Table 1 shows that the yields of brominated products from **1a**, **2a**, and **3a** decrease in that order. On the other hand, no reaction occurred when thymine was similarly treated. The reaction of guanine was not attempted because it was only slightly soluble in the buffer solution. Treatment of cytidine (**4a**) and 2′-deoxycytidine (**5a**) with H_2O_2 and KBr in the presence of MPO also gave 5-bromocytidine (**4b**) and 5-bromo-2′-deoxycytidine (**5b**), respectively. The compounds **1a**, **2a**, **3a**, **4a**, and **5a** were unreactive to H_2O_2 and KBr in the absence of MPO under similar conditions.

In an attempt to further elucidate the MPO catalyzed oxidation, a comparison of oxidation of 1,3-dimethyluracil (**6a**) by MPO, lactoperoxidase (LPO), chloroperoxidase (CPO), and horseradish peroxidase (HPO)

a) Reaction conditions: substrate (1 mmol), for 1 h reaction. b) Yield based on substrate used. c) Yield of the recovered substrate was not determined.

was investigated. As shown in Table 1, MPO and LPO catalyzed reactions of **6a** yielded 5-bromo-1,3-dimethyluracil (**6b**) whereas CPO catalyzed oxidation gave not only **6b** but also 5,5-dibromo-6-hydroxy-1,3-dimethyl-5,6-dihydrouracil (**7**) and 1,3-dimethylparabanic acid (**8**). However, almost no reaction occurred when **6a** was similarly treated with HPO.

Although many reports concerning halogenation of nucleic acid bases and nucleosides have been published,[9] it was found that **1a**, **2a**, **3a**, **4a**, and **5a** were reacted with H_2O_2 and KBr in the presence of MPO to yield the corresponding brominated products. The results are of interest in connection with the mechanism of mutation caused by phagocytes.

Experimental

MPO from human leukocytes (200 U/vial) was purchased from The Green Cross Corporation (Osaka). LPO from bovine milk and CPO from Caldariomyces fumago were purchased from Sigma Chemical Co. (St. Leuis, USA).

MPO Catalyzed Bromination of Nucleic Acid Bases 1a, 2a, and 3a. A solution of nucleic acid base (1 mmol), MPO (200 U), and KBr (2 mmol) in 0.2 mol dm^{-3} sodium acetate buffer solution at pH 5.0 (110 ml) was stirred. The reaction was initiated by addition of H_2O_2 and incubated at 25—27 °C. Hydrogen peroxide (0.4 mmol) in the sodium acetate buffer solution (2 ml) was added into the solution at 10 min intervals. After 60 min, catalase was added to remove any remaining H_2O_2. The reaction mixture was evaporated to give a white solid mass. The residue was extracted with a large amount of methanol. Droplet countercurrent chromatography (Tokyo Rikakikai, DCC-300-G2) was used for separation of the extract. The separation with $CHCl_3$–MeOH–H_2O (5:5:3) by descending method resulted in the isolation of the brominated products. The isolation of **1a**, **2a**, and **3a** was not attempted. The structures of the brominated products were confirmed by comparison of ^1H NMR spectra (JEOL PMX60A spectrometer) and thin-layer chromatography (TLC) (E. Merck, Silica gel 60 sheet F_{254}) with the authentic samples obtained commercially.

Bromination of 4a and 5a. A solution of **4a** and **5a** (1 mmol), MPO (200 U), and KBr (4 mmol) in the sodium acetate buffer solution described before (110 ml) was stirred at 35—38 °C. The reaction was started by adding H_2O_2 (0.5 mmol) in the buffer solution (5 ml). After 30 min, H_2O_2 (0.5 mmol) in the buffer solution (5 ml) was further added into the solution containing MPO. After 60 min, catalase was added. The reaction mixture was evaporated and extracted with a large amount of methanol. The extract was evaporated and chromatographed on silica gel using a mixture of $CHCl_3$ and MeOH (8:2) to yield the brominated products. The products **4b** and **5b** were further purified by liquid chromatography with low pressure pump (Fuji-gel packed column RQ-2 ODS silica gel 24 mmϕ×360 mm, mobile phase: a mixture of water and acetonitrile (10:1), detected at 250 nm). The structures of the products were confirmed by comparison of ^1H NMR spectra and TLC with the authentic samples obtained commercially. The isolation of **4a** and **5a** was not attempted.

Peroxidase Catalyzed Oxidation of 6a. Reaction of **6a** with H_2O_2 and KBr in the presence of MPO was carried out according to the manner described for the MPO catalyzed bromination of **1a**, **2a**, and **3a**. Under similar conditions, LPO catalyzed bromination in 0.25 mol dm^{-3} potassium phosphate buffer solution at pH 6.0 and CPO catalyzed oxidation in 0.25 mol dm^{-3} potassium phosphate buffer solution at pH 3.0 of **6a** were achieved. The reaction mixture was evaporated and extracted with a large amount of $CHCl_3$. The extract was evaporated and chromatographed on silica-gel TLC (Wako Pure Chemical, Wakogel B-5F) using ethyl acetate or a mixture of ethyl acetate and hexane (2:1, v/v) to give **6a**, **6b**, **7**, and **8**. The structures of **6b**,[10] **7**,[10] and **8**[11] were confirmed by comparison of ^1H NMR spectra and TLC with the samples prepared according to the published procedures.

A Convenient Synthesis of Naphtho[1,2-*b*]furans

Wen-Bing KANG, Takashi SEKIYA, Takeshi TORU, and Yoshio UENO*
Department of Applied Chemistry, Nagoya Institute of Technology, Nagoya 466
(Received July 10, 1989)

Synopsis. Acid-catalyzed reductive cyclization of 2-alkyl-substituted 3-ethylthio- and 3-phenylthio-1,4-naphthoquinones gave naphtho[1,2-*b*]furans in high yields.

We have been interested in developing new methods for synthesis of naphthoquinone derivatives. Recently we found that 2-phenylthio- and 2-ethylthio-1,4-naphthoquinones (**1a** and **1b**) could be alkylated with lithium enolates[1,2] or pyridinium ylides[2] to give 2-(2-oxoalkyl)-3-phenylthio- and -3-ethylthio-1,4-naphthoquinones **2** in high yields, respectively, and that these alkylated 1,4-naphthoquinones **2** were cyclized successfully to naphtho[2,3-*b*]furan-4,9-dione derivatives. We have further studied on the synthesis of naphtho[1,2-*b*]furans by starting from 3-alkylated 2-thio-substituted 1,4-naphthoquinones **2**. Several naphtho[1,2-*b*]furan derivatives have interesting biological activities such as spasmolytic, local anesthetic,[3] and bactericidal activities.[4] The naphtho[1,2-*b*]furan moiety has also been used as synthetic intermediates for biologically interesting heterocycles.[5] We report here a new synthesis of naphtho[1,2-*b*]furan derivatives from 2-(2-oxoalkyl)-3-phenylthio- and -3-ethylthio-1,4-naphthoquinones **2**.

Treatment of 2-phenacyl-3-phenylthio-1,4-naphthoquinone **2a** (R^1=R^2=Ph)[2] with tin(II) chloride in the presence of hydrochloric acid in acetic acid at room temperature gave 2-phenyl-4-(phenylthio)naphtho[1,2-*b*]furan-5-ol **3a** in 78% yield. Transformation of 2-(2-oxoalkyl)-3-phenylthio-1,4-naphthoquinone **2b**—**2j** (R^1=Ph, R^2=aryl, alkyl) also afforded naphtho[1,2-*b*]furan derivatives **3b**—**3j** in 70—91% yields. The reaction of 1,4-naphthoquinone **2k** or **2l** having an ethylthio substituent also proceeded smoothly to give naphtho[1,2-*b*]furans **3k**—**3l** in 88—95% yields. All reactions of **2**, except **2i**, was carried out at room temperature during a peried of 10 to 60 min, while the reaction of **2i** (R^1=Ph, R^2=2-naphthyl) took 2.5 h at 40 °C. The structures of all these compounds were supported by spectral data and microanalyses. The results as well as the physical and analytical data of the products were summarized in Table 1.

The reasonable mechanism of this reaction may be as follows: the alkylated 1,4-naphthoquinones **2** are reduced by the action of tin(II) chloride and hydrochloric acid[6] to give 1,4-naphthalenediol **4** which is cyclized by acid catalysis to dihydronaphtho[1,2-*b*]-furans **5**. Dehydration of **5** affords substituted naphtho[1,2-*b*]furans **3**.

In summary, the reductive cyclization reaction of 3-alkylated 2-thio-1,4-naphthoquinones, conveniently obtainable from the alkylation of 2-thio-1,4-naphthoquinones,[1,2] gives a general method for the synthesis of various naphtho[1,2-*b*]furan compounds. A further study on the bioactivities[7] of these substivituted naphtho[1,2-*b*]furans and application of this reaction is currently in progress in our laboratory.

Experimental

Mps were recorded on a Yanaco micro melting point apparatus and are uncorrected. IR spectra were measured as KBr discs on a JASCO A-102 spectrometer. NMR spectra were determined with a Varian XL-200 spectrometer in deuteriochloroform with TMS as internal standard.

General Procedure for the Preparation of Naphtho[1,2-*b*]furans 3. To a suspension of thio-substituted 1,4-naphthoquinone **2** (0.5 mmol) in acetic acid (10 ml) was added a solution of tin(II) chloride dihydrate (2 mmol) in concentrated hydrochloric acid (4 ml). The reaction mixture was stirred for the time listed in Table 1, and then poured into water and extracted with toluene. The organic layer was washed successively with sodium hydrogencarbonate solution and water, and then dried over anhydrous sodium sulfate. After evaporation of solvent the residue was purified by column chromatography on silica gel using toluene as an eluent to afford **3**. All the compounds except **3l**, obtained as an oil, were recrystallized from methanol.

Efficient Reduction of Triphenylmethanol to Triphenylmethane by 9,10-Dihydro-10-methylacridine in the Presence of Perchloric Acid

Masashi ISHIKAWA,† Shunichi FUKUZUMI,* Tatsushi GOTO, and Toshio TANAKA††
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
(Received July 17, 1989)

Synopsis. Reduction of triphenylmethanol (Ph_3COH) to triphenylmethane by an NADH model compound, 9,10-dihydro-10-methylacridine ($AcrH_2$), proceeds very efficiently in the presence of perchloric acid ($HClO_4$) in acetonitrile at 298 K via hydride transfer from $AcrH_2$ to triphenylmethyl cation (Ph_3C^+) which is formed by the dehydration of Ph_3COH with $HClO_4$. Mechanisms of hydride transfer reactions from NADH model compounds to Ph_3C^+ are also discussed.

Acid-stable analogues of dihydronicotinamide adenine dinucleotide (NADH) have been employed as effective reductants in reductions of various carbonyl compounds[1-3] and imines[4] in the presence of acid. It has recently been reported that aryl alcohols can also be reduced by acid-stable NADH model compounds in the presence of acid.[5] However, concentrated acid or high temperature (e.g., refluxing acetonitrile) has so far been required for the reactions to undergo smoothly.[5]

This study reports that very facile reduction of triphenylmethanol occurs by using an acid-stable NADH analogue, 9,10-dihydro-10-methylacridine in the presence of slightly excess concentration of perchloric acid ($HClO_4$) to $AcrH_2$ in acetonitrile at 298 K to yield triphenylmethane. The kinetic investigations have been performed using a stopped-flow technique in order to discuss mechanisms of the facile reduction of triphenylmethanol by $AcrH_2$ as well as those of the hydride transfer reactions from NADH model compounds to triphenylmethyl cation which is prepared independently by the dehydration of triphenylmethanol with $HClO_4$.

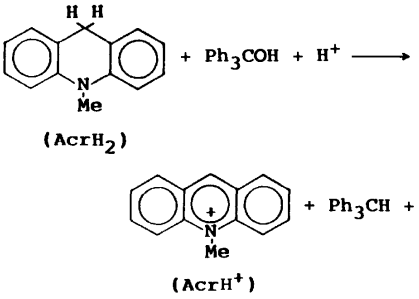
Experimental

Preparation of 9,10-dihydro-10-methylacridine ($AcrH_2$) and 1-benzyl-1,4-dihydronicotinamide (BNAH) was described elsewhere.[6] Triphenylmethyl perchlorate ($Ph_3C^+ClO_4^-$) was prepared by the literature method.[7] Triphenylmethanol (Ph_3COH) and $HClO_4$ (70%) were obtained commercially. Acetonitrile (MeCN) used as a solvent was purified and dried by the standard procedure.[8]

The reactions in the absence and presence of oxygen in CD_3CN were monitored using a Japan Electron Optics JNM-PS-100 ^1H NMR spectrometer. Kinetic measurements were performed using a Union RA-103 stopped flow spectrophotometer. Rates of the reduction of Ph_3COH by $AcrH_2$ in deaerated MeCN at 298 K were followed by the increase in absorbance due to 10-methylacridinium ion ($AcrH^+$) in the visible region (λ_{max}=358 nm, ε=1.80×10^4 dm^3 mol^{-1} cm^{-1}). Rates of the dehydration of Ph_3COH with $HClO_4$ in deaerated MeCN at 298 K were determined by the increase in absorbance at λ_{max}=405, 433 nm due to Ph_3C^+. Rates of the hydride transfer from $AcrH_2$ and BNAH to Ph_3C^+ were also followed by the increase and decrease in absorbance at λ_{max}=358 and 350 nm due to $AcrH^+$ and BNAH under 4 atm of oxygen (or nitrogen), respectively. All the kinetic measurements were carried out under pseudo-first-order conditions where the concentrations of substrates were maintained at more than 10-fold excess of $AcrH_2$ or BNAH. Pseudo-first-order rate constants were determined by the least-square curve fit using a Union System 77 microcomputer. Second-order rate constants were calculated from the slope of the pseudo-first-order rate constants vs. the concentrations of substrates by the least-squares analysis.

Results and Discussion

Reduction of Ph_3COH by $AcrH_2$ in the Presence of $HClO_4$. Upon mixing $AcrH_2$ with Ph_3COH in the presence of $HClO_4$ in MeCN at 298 K, facile reduction of Ph_3COH by $AcrH_2$ occurs to yield $AcrH^+$ and triphenylmethane (Ph_3CH), Eq. 1. The products were



(1)

identified by the ^1H NMR and the electronic spectra. The rates obey the second-order kinetics, showing the first-order dependence on each reactant concentration. The observed second-order rate constants k_{obs} increase with an increase in the $HClO_4$ concentration to reach a maximum value at [$HClO_4$] ca. 1×10^{-3} mol dm^{-3}, and then decrease in the higher concentration region as shown in Fig. 1. Such a decrease of k_{obs} in the higher concenration region of $HClO_4$ may be ascribed to the protonation of $AcrH_2$ by $HClO_4$ to form $AcrH_3^+$ (Eq. 2), since $AcrH_3^+$ is known to be much weaker

$$AcrH_2 + H^+ \rightleftharpoons AcrH_3^+ \quad (2)$$

reductant than $AcrH_2$.[2,3] Thus, the reduction of Ph_3COH by $AcrH_2$ is not catalyzed by $HClO_4$. In such a case, the reduction may proceed via the rate-determining hydride transfer reaction from $AcrH_2$ to Ph_3C^+ (Eq. 3) which is formed by the dehydration of Ph_3COH with $HClO_4$ (Eq. 4). In order to confirm this point, the kinetics of both reactions (Eqs. 3 and 4) have been examined independently.

† Present address: Laboratory of Organic Chemistry, Osaka Women's University, Sakai, Osaka 590.

†† Present address: Department of Applied Physics and Chemistry, Fukui Institute of Technology, Gakuen, Fukui 910.

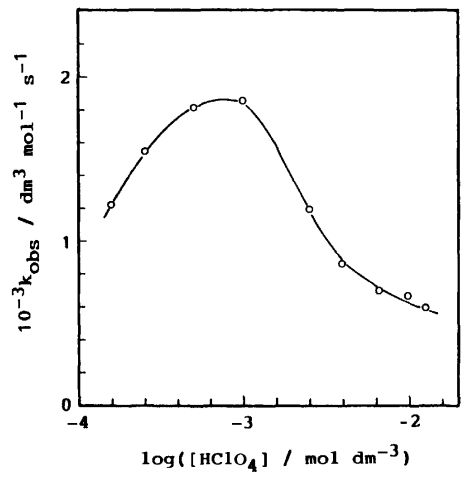


Fig. 1. Dependence of the observed second-order rate constant (k_{obs}) vs. [$HClO_4$] for the reduction of Ph_3COH by $AcrH_2$ in the presence of $HClO_4$ in deaerated MeCN at 298 K.

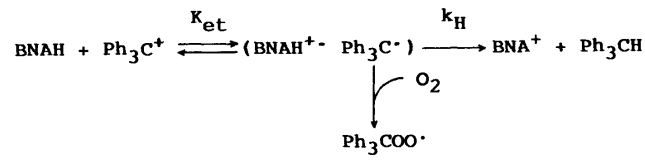
$$AcrH_2 + Ph_3C^+ \longrightarrow AcrH^+ + Ph_3CH \quad (3)$$

$$Ph_3COH + H^+ \longrightarrow Ph_3C^+ + H_2O \quad (4)$$

Rates of both reactions (Eqs. 3 and 4) also obey the second-order kinetics. The observed second-order rate constant of hydride transfer from $AcrH_2$ to Ph_3C^+ (Eq. 4) is determined as 1.7×10^3 dm^3 mol^{-1} s^{-1}. On the other hand, the observed second-order rate constant of the dehydration of Ph_3COH with $HClO_4$ (Eq. 4) is determined as 8.0×10^4 dm^3 mol^{-1} s^{-1} which is much larger than the k_{obs} value of the hydride transfer reaction (Eq. 3). Thus, the dehydration of Ph_3COH with $HClO_4$ to form Ph_3C^+ occurs firstly and then the rate-determining hydride transfer from $AcrH_2$ to Ph_3C^+ takes place to yield $AcrH^+$ and Ph_3CH. In fact, the maximum k_{obs} value (1.8×10^3 dm^3 mol^{-1} s^{-1}) of the reduction of Ph_3COH by $AcrH_2$ at [$HClO_4$]=ca. 10^{-3} mol dm^{-3} (Fig. 1) is nearly equal to the k_{obs} value (1.7×10^3 dm^3 mol^{-1} s^{-1}) of hydride transfer from $AcrH_2$ to Ph_3C^+.

Mechanisms of Hydride Transfer from NADH Model Compounds to Ph_3C^+. With respect to mechanisms of hydride abstraction of Ph_3C^+, it has recently established that hydride transfer from a tungsten-dimethyl complex [$Cp_2W(CH_3)_2$] (Cp=η-C_5H_5) to Ph_3C^+ consists of two-step processes; the exothermic electron transfer from [$Cp_2W(CH_3)_2$] to Ph_3C^+ occurs firstly as indicated by the more negative oxidation potential of [$Cp_2W(CH_3)_2$] (−0.1 V)[9] than the reduction potential of Ph_3C^+ (0.29 V),[10] and the subsequent hydrogen-atom transfer from [$Cp_2W(CH_3)_2$]$^+$ to $Ph_3C\cdot$ occurs to yield Ph_3CH.[11] Evidence for such initial electron transfer has been obtained also for hydride transfer from rhenium-alkyl complexes to Ph_3C^+, although the electron transfer in this case is endothermic.[12] The intermediate radical $Ph_3C\cdot$ formed by the endothermic electron transfer has been successfully trapped by oxygen when the rate of overall hydride transfer is accelerated by the presence of oxygen. Since one-electron oxidation potentials of rhenium-alkyl complexes (e.g., 0.48 V vs. SCE)[12] are rather close to those of NADH model compounds [e.g., 0.57 V vs. SCE for 1-benzyl-1,4-dihydronicotinamide (BNAH)],[6] the hydride transfer from BNAH to Ph_3C^+ may also proceed via initial electron transfer from BNAH to Ph_3C^+, followed by hydrogen transfer from $BNAH^{+\cdot}$ to $Ph_3C\cdot$ to yield BNA^+ and Ph_3CH as shown in Scheme 1.



Scheme 1.

In order to examine the contribution of such an electron-transfer process, the second-order rate constants k_{obs} of hydride transfer from BNAH to Ph_3C^+-ClO_4^- in the absence and presence of oxygen were determined under 4 atm of nitrogen and oxygen, respectively. The k_{obs} values are listed in Table 1, together with the reported k_{obs} values of a rhenium-alkyl complex, [$CpRe(NO)(PPh_3)(CH_2Ph)$].[12] The k_{obs} value of $AcrH_2$ in the presence of oxygen (4 atm) was also determined and the k_{obs} values in the absence and presence of oxygen are also listed in Table 1. In the case of the rhenium-benzyl complex, the k_{obs} value in the presence of air becomes more than 10-fold larger as compared with the value in the absence of oxygen (Table 1). In the case of NADH model compounds (BNAH and $AcrH_2$), however, no acceleration of the rate constant is observed in the presence of oxygen even at 4 atm. It has been confirmed that no oxygen is incorporated into the product, either. Such difference in the effect of oxygen on the reactions of the rhenium-benzyl complex and NADH model compounds may be ascribed to the difference in the reactivities of hydrogen transfer processes of the resulting radical cations formed by the initial electron transfer. According to Scheme 1, the observed overall rate constant consists of the electron transfer equilibrium constant K_{et} of formation of the radical pair and the rate constant of hydrogen transfer k_H as shown in Eq. 5, when the hydrogen transfer is assumed to be the

$$k_{obs} = k_H K_{et} \quad (5)$$

rate-determining step. The K_{et} values can be evaluated from the one-electron oxidation potentials E^0_{ox} of reductants and the one-electron reduction potential E^0_{red} of Ph_3C^+ using Eq. 6. Then, the k_H values can be evaluated from the values of k_{obs}, E^0_{ox}, and E^0_{red} using

$$\log K_{et} = -F(E^0_{ox} - E^0_{red})/(2.3RT) \quad (6)$$

Eqs. 5 and 6. The k_H values thus determined are also listed in Table 1.

The second-order rate constant of the radical trap of $Ph_3C\cdot$ with oxygen is known to be close to the diffusion-limited value, 5×10^8 dm^3 mol^{-1} s^{-1}.[12] In

Table 1. Observed Second-Order Rate Constants k_{obs} of Hydride Transfer Reactions from Reductants (a Rhenium-Alkyl Complex and NADH Model Compounds) to Ph_3C^+ in the Absence and Presence of Oxygen in MeCN at 298 K, the One-Electron Oxidation Potentials E^0_{ox} of Reductants, and the Rate Constants k_H of Hydrogen Transfer from the Radical Cations of Reductants to $Ph_3C\cdot$

Reductant	k_{obs}[a]	E^0_{ox} vs. SCE	k_H
	$dm^3\ mol^{-1}\ s^{-1}$	V	s^{-1}
$PhCH_2$-(Re)[b]	2.3×10[c] (2.4×10^2)[c]	0.48[c]	8.2×10^5
BNAH	8.9×10^4 (8.9×10^4)	0.57[d]	1.3×10^{10}
$AcrH_2$	1.7×10^3 (1.7×10^3)	0.80[d]	7.3×10^{11}

a) The values in parentheses are those determined in the presence of oxygen (4 atm unless otherwise noted). b) [CpRe(NO)(PPh_3)(CH_2Ph)]. c) Determined in CH_2Cl_2 at 208 K. The value in parenthesis is determined in aerated MeCN. The data are taken from Ref. 12. d) Taken from Ref. 6.

such a case, 1×10^{-3} mol dm^{-3} oxygen may be sufficient for the oxygen trap to compete with the intramolecular hydrogen transfer process of the rhenium-benzyl complex, resulting in the increase of the overall reaction rate. In contrast, the k_H values of NADH model compounds (Table 1) are too large for the oxygen trap to compete with the hydrogen transfer process, resulting in no effect of oxygen on the observed rate constant k_{obs} of the overall hydride transfer reactions. In the case of BNAH, the rate constant k_{et} of the forward electron transfer from BNAH to Ph_3C^+ is estimated from the E^0_{ox} and E^0_{red} values using Eq. 7. The estimated value 1.9×10^6 dm^3

$$k_{et} = Z\exp[-F(E^0_{ox} - E^0_{red})/(RT)] \quad (7)$$

$mol^{-1}\ s^{-1}$ is larger than the observed overall rate constant 8.9×10^4 $dm^3\ mol^{-1}\ s^{-1}$. Thus, it is concluded that the hydrogen transfer process (k_H) is the rate determining step following the electron-transfer equilibrium (Scheme 1). In the case of a weaker reductant $AcrH_2$, however, the k_H value becomes close to the frequency factor ($h/kT=6\times10^{12}\ s^{-1}$) and thus, the electron transfer may occur concertedly with the hydrogen transfer. In such a case, the differentiation between electron-hydrogen transfers and one-step hydride transfer becomes dubious and these two mechanisms should be reconciled into single unified one.

(Received May 26, 1989)

Synopsis. The reaction behavior of propylene oxide with boron trifluoride was affected remarkably by solvent. In dioxane, the isomerization to propionaldehyde proceeded smoothly and selectively, while the reaction behavior in heptane, benzene, and tetrahydrofuran was quite different from that in dioxane.

Since Heusser et al. reported the use of boron trifluoride (BF_3) for the isomerization of substituted ethylene oxides,[1] BF_3 has been used widely as a Lewis acid in organic synthesis.[2] In the reaction of propylene oxide, boron trifluoride etherate ($BF_3 \cdot OEt_2$) was used as a polymerization catalyst but has not been reported as an isomerization catalyst.[3] Generally, $BF_3 \cdot OEt_2$ equilibrates in the exchange reactions with cyclic[4] and acyclic[5] ethers, while it dissociates to BF_3 and ether in CH_2Cl_2 to some extent.[6] It is hence expected that the acid strength of BF_3 may be adjusted by selection of solvent. In connection with our studies on epxides,[7,8] we observed an interesting solvent effect in the isomerization of propylene oxide (**1**) to propionaldehyde (**2**) and acetone (**3**) with $BF_3 \cdot OEt_2$. In heptane and benzene, polymerization of **1** occurred as expected, but the reaction behavior was greatly dependent on each solvent. In tetrahydrofuran (THF), the copolymerization of **1** and THF was observed as reported in the literature.[9,10] However, the isomerization to **2** proceeded smoothly and selectively in dioxane. To the best of our knowledge, such a behavior has not been previously described. The findings will be described herein.

Experimental

To a reaction solution (25 cm^3) of **1** (0.5 M)(1 M=1 mol dm^{-3}), a known amount of $BF_3 \cdot OEt_2$ was added and stirred magnetically at room temperature. The progress of the reaction was monitored with a Hitachi 163 model gas chromatograph (3 mmϕ×3 m stainless steel column: 15% PEG 4000 on Uniport B at 70 °C). After a given time, the reaction solution was treated with poly(4-vinylpyridine) (Aldrich; 7.6 mequiv g^{-1}) in order to remove the catalyst and filtered off. The filtrate was evaporated in vacuo at 50 °C until the weight of the residue became constant. In the reaction in THF, the reaction solution was directly analyzed by an IR spectrum . Solvents (Special Grade of Wako Co.), $BF_3 \cdot OEt_2$ (Tokyo Kasei Co.), and **1** (Tokyo Kasei Co.) were used without further purifications. No isomers were found in the commercial **1** gas chromatographically. The IR spectra of the polymers and the reaction solution were recorded as liquid film inserted between NaCl plates. A Shimadzu IR-400 spectrophotometer was used.

Results and Discussion

effect on the reaction behavior of **1** with a catalytic amount of $BF_3 \cdot OEt_2$ (30 mg, 0.21 mmol). In heptane, $BF_3 \cdot OEt_2$ did not dissolve completely but form fine oily drops. Immediately after the catalyst was added to a heptane solution of **1**, a brown oil separated and **1** was not detected in the reaction solution.

As shows in Fig. 1, **1** was consumed slowly in benzene during the reaction, but the isomers were scarcely formed. The product was identified as poly(propylene oxide) (PPO) by its IR spectrum,[3] which was in agreement with the spectrum of the product obtained in heptane [IR ν: 3400, 2850, 1440, 1380, and 1080 cm^{-1}]. In THF, a reverse S-type curve was observed and remarkable constriction of the volume (ca. 2 cm^3) of the reaction medium (25 cm^3) occured to give a viscous solution. The IR spectrum of the reaction solution indicated absorption due to alkyl ethers, overlapped with that of THF, and the absence of **1** [IR ν: 2850, 1450, 1360, 1060, and 900 cm^{-1}]. In the present case, copolymerization of **1** and THF by $BF_3 \cdot OEt_2$ proceeded.[9,10] In contrast, the isomerization of **1** to **2** proceeded smoothly and selectively in dioxane. In order to explain the present results, one should consider and an actual acid strength of $BF_3 \cdot OEt_2$ in each solvent. Table 1 lists the relative acid strength of $BF_3 \cdot OEt_2$ in each solvent (1:2 by mole ratio) estimated by Hammett indicators.[11]

In the case of oxygen-containing solvents, the acid strength of $BF_3 \cdot OEt_2$ was decreased due to equilibrated trapping of free BF_3 from the etherate by the solvent. In benzene, the acid strength of $BF_3 \cdot OEt_2$ was high, because benzene interacts only weakly with $BF_3 \cdot OEt_2$. In heptane, a high acid strength must be held due to the low solubility of the etherate and the lack of Lewis basicity of the solvent. The polymerizatin of **1** therefore must need a relatively high acid strength as is shown in heptane and benzene solvents. The decrease in the reactivity of the polymerization in benzene is probably caused by a weak electron-donating character of benzene to decrease the acid strength of $BF_3 \cdot OEt_2$. In cyclic ether solvents, different reaction behavior was observed, although the acid strength of each, estimated by Hammett indicators, was almost the same. It is known that the order of Lewis basicity of ether is as follows.[12]

THF>dioxane>propylene oxide>diethyl ether>epichlorohydrin

BF_3-catalyzed copolymerization between ethers with different basicities such as THF-**1**[9,10] and THF-epichlorohydrin[10] has been reported. However, in the present study, the isomerization of **1** instead of copolymerization predominated in the presence of $BF_3 \cdot OEt_2$ in dioxane whose basicity is similar to that of **1**. BF_3-catalyzed reactions seem to be remarkably affected by the Lewis basicities of the substrate and the solvent. In the isomerization of **1** to **2**, dioxane was found to be an effective solvent presumably due to the appropriate Lewis acidity arising from the exchange reactions between $BF_3 \cdot OEt_2$, **1**, and dioxane. One may expect that an active species in the BF_3-catalyzed reaction is a neutral oxonium salt as shown in the reaction of $BF_3 \cdot OEt_2$, diethyl ether, and epichlorohydrin to give triethyloxonium tetrafluoroborate.[13,14] However, the participation of such a species was not described in the reports about BF_3-catalyzed alkylation of benzene with ethers and alcohols,[15] BF_3-catalyzed polymerization of cyclic ethers,[9,10] and BF_3-catalyzed isomerization of epoxides in benzene and ether.[16] Our results can also be explained by an action of BF_3 as described above. So we conclude that the present reaction of **1** in each solvent proceeds with BF_3.

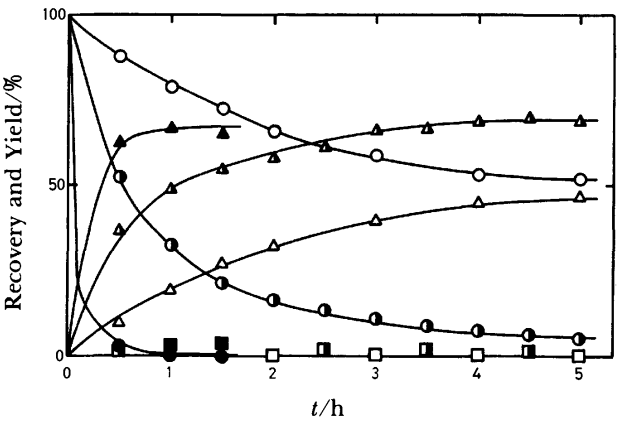

Fig. 2. Isomerization of **1** with $BF_3 \cdot OEt_2$ in dioxane. ○: Recovery of **1**, △: yield of **2**, □: yield of **3**. Open symbols: 0.12 mmol of $BF_3 \cdot OEt_2$, half-filled symbols: 0.21 mmol of $BF_3 \cdot OEt_2$, filled symbols: 0.85 mmol of $BF_3 \cdot OEt_2$.

Effect of Catalyst Amount. The isomerization behavior of **1** to **2** and **3** with different amounts of catalyst are shown in Fig. 2.

In each case, a major product was **2**. The results are reasonable and cosistent with a previous report.[17] On addition of 0.12 mmol of $BF_3 \cdot OEt_2$, the isomerization proceeded almost quantitatively, while the yield of **2** was 46% at 5 h. On addition of 0.21 mmol of the catalyst, the isomerization occurred more rapidly to give 68% yield within 5 h, but the selectivity was relatively poor, because of the polymerization of **1**. After 2 h, about 8% of **1** was isolated as PPO. In the case of 0.85 mmol, the substrate **1** disappeared completely within 30 min to yield 66% of **2**. The final yields of **2** were almost the same whenever 0.21 or 0.85 mmol of the catalyst was used. The addition of an excess of the catalyst in order to increase the yield of **2** thereby led to the polymerization of **1**, resulting in decrease in the selectivity without increase in the yield of **2**. In order to examine the possibility of the copolymerization of **1** and dioxane, the reaction of **1** (101 mmol) and dioxane (203 mmol) with $BF_3 \cdot OEt_2$ (0.21 mmol) was carried out. In this case, only PPO was obtained and no copolymerization occurred.

In conclusion, for the isomerization of **1** to **2**, dioxane was the most favorable solvent. On increasing the amounts of catalyst, the simultaneous polymerization of **1** occured to decrease the selectivity of **2**.

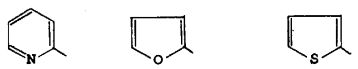
Spectral Studies of Some Coordination Complexes of Pt(II) and Rh(I) with Benzothiazolines

Archana GARG and Jagdish Prasad TANDON*
Department of Chemistry, University of Rajasthan, Jaipur 302004, India
(Received September 12, 1988)

Synopsis. The present paper describes the synthesis and structural features of platinum(II) and rhodium(I) complexes of some benzothiazolines derived by the condensation of various heterocyclic aldehydes viz. 2-pyridinecarbaldehyde, 2-furancarbaldehyde, and 2-thiophenecarbaldehyde. The resulting complexes have been characterized by elemental analyses, conductance measurements and molecular weight determination. The mode of bonding and geometry of these complexes have been suggested on the basis of IR, ^{1}H NMR, electronic spectra, and magnetic studies.

Benzothiazolines derived from the condensation of 2-aminobenzenethiol with the carbonyl compounds constitute an important series of ligands with ONS and NS donor systems.[1] The condensation of 2-mercapto amine with an aldehyde does not normally lead to the isolation of the corresponding Schiff base, but rather to a thiazoline (with a 2-aminobenzenethiol) or a thiazolidine (with a 2-mercaptoalkylamine).[2–5] However, it has been shown that the metal ion acts as a template and favors the formation of the Schiff base rather than the 2,2′-bi(benzothiazoline) form.[6] Later Jadamus et al.[7] reported that even in the absence of metal ion the condensation product of aldehyde and ketone with 2-aminobenzenethiol forms a mixture of benzothiazoline and the Schiff base and an equilibrium may exist between the two as shown below:

where R=



The above equilibrium gets shifted to the right hand side in presence of the metal ion. Singh et al.[8] have studied the reactions of trimethylchlorosilane and dimethylchlorosilane with similar ligands and found that the complexes are five- and six-coordinated. Similarly Tandon et al.[9,10] have studied the reactions of these ligands with transition metals and the geometry of metal complexes have been deduced on the basis of various spectral studies.

Experimental

Preparation of Ligand. Benzothiazolines (HL) were prepared by the condensation of 2-aminobenzenethiol with 2-pyridine-, 2-furan-, and 2-thiophenecarbaldehyde.[11]

Preparation of Complexes. Cyclooctadienyl Complexes of Rhodium [$C_8H_{12}RhL$]: [$C_8H_{12}RhOMe]_2$ was prepared according to the literature method.[12,13] It was then dissolved in ethanol and an ethanolic solution of benzothiazoline in requisite amount was added to it. The solution was refluxed for three hours and cooled. The complex got separated, which was washed repeatedly with cyclohexane and dried in vacuo.

[Pt(HL)$_2$]Cl$_2$: $K_2[PtCl_4]$ was dissolved in a 1:1 mixture of water and ethanol. To this solution, an ethanolic solution of ligand was added and it was then refluxed for about one hour. On cooling, the complex separated out, which was filtered and washed several times with a mixture of water and ethanol and dried in vacuo.

PtL$_2$: The 1:1 water-ethanol solution of $K_2[PtCl_4]$ was mixed with an ethanolic solution of benzothiazoline. Aqueous ammonia was added to the above mixture dropwise until the solution was weakly alkaline. The mixture was refluxed for about two hours and the solid compound was filtered out. It was then washed with the mixture of water and ethanol and dried in vacuo.

Analytical Methods and Physical Measurements. Platinum was estimated gravimetrically[14] and nitrogen by the Kjeldahl's method. Carbon and hydrogen analyses were performed at the microanalytical laboratory of this department. Other measurements were carried out as reported earlier.[11]

Results and Discussion

The 1:1 and 1:2 molar ratio reactions of [$C_8H_{12}RhOMe]_2$ and $K_2[PtCl_4]$ with benzothiazolines in ethanol medium take place as follows:

1. $[C_8H_{12}RhOMe]_2 + 2N\frown SH \longrightarrow 2[C_8H_{12}Rh(N\frown S)_2] + 2MeOH$ **I**

2. $K_2PtCl_4 + 2N\frown SH \longrightarrow [Pt(N\frown SH)_2]Cl_2 + 2KCl$ **II**

3. $K_2PtCl_4 + 2N\frown SH + 2NH_4OH \longrightarrow [Pt(N\frown S)_2] + 2KCl + 2NH_4Cl + 2H_2O$ **III**

All the newly synthesized complexes are colored and monomeric solids. The rhodium complexes are soluble in most of the common organic solvents, whereas complexes of platinum are soluble in *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO). The conductanec date of 10^{-3} M solutions (1 M=1 mol dm^{-3}) of complexes at the room temperature show that the complexes of the type **II** are 1:2 electrolytes (200—210 ohm^{-1} mol^{-1} cm^{-2}) and complexes **I** and **III** are nonelectrolytes (15—20 ohm^{-1} mol^{-1} cm^2). All the solids are diamagnetic as expected for the d^8 square planar complexes.

In the solid state IR spectra of benzothiazoline the absence of ν(SH) and appearance of ν(NH) at ca. 1670 cm^{-1} and 3400—3200 cm^{-1} is strong evidence for a ring structure.[15] Further in metal complexes ν(NH)

disappears and in the complexes of type II band due to ν(SH) is observed at ca. 2520 cm^{-1} and which suggests the coordination of sulfur to the metal atom in these complexes.

However, the disappearance of ν(NH) band in the spectra of metal complexes shows its deprotonation and chelation of nitrogen of the ligand to the central metal atom. Further, in the spectra of metal complexes, a strong band around 1580±10 cm^{-1} may be ascribed to the coordinated >C=N group and this very well supports the fact that the resulting complexes are metal azomethine derivatives, as the benzothiazoline ring rearranges to give the azomethine form which in presence of metal ion finally acts as a monobasic bidentate ligand.

Further, in the spectra of rhodium complexes, a sharp band at ca. 1470 cm^{-1} may be due to ν(C=C) of cyclooctadiene moiety, lowered by coordinaton.[16]

To further confirm the bonding pattern in these complexes, proton magnetic resonance spectra of 2-(2-pyridyl)benzothiazoline and it's metal derivatives have been recorded in DMSO-d_6 using TMS as internal reference. The spectrum of 2-(2-pyridyl)benzothiazoline shows the N-H proton signal at δ 4.58 and it disappears in the corresponding metal complexes due to it's deprotonation. The signal due to azomethine proton is observed at δ 8.00 and shifts downfield (δ 8.40) in the spectra of metal complexes, suggesting coordination of azomethine nitrogen to the metal atom. In the spectra of complexes $[Pt(N\frown SH)_2]Cl_2$, the signal appearing at δ 4.85 is due to the SH group.[17] Further, two signals observed at δ 2.5 and 1.6 in the spectrum of rhodium complex may be assigned to the $-CH_2$ group of cyclooctadiene.

In the electronic spectra of platinum(II) complexes, three d-d spin allowed transitions are observed corresponding to the transitions from the three lower lying d levels to the empty $d_{x^2-y^2}$ orbital. The ground state $^1A_{1g}$ and the excited states corresponding to the above transitions are $^1A_{2g}$, $^1B_{1g}$, and ^1E_g, in order of increasing energy. Three different orbital parameters Δ_1, Δ_2, and Δ_3 have been calculated by first using the corelation, $F_2=10F_4=600$ cm^{-1} for the Slator-Condon interelectronic repulsion parameters (F_2 and F_4) and subseuqently the equations suggested by Gray and Ballhausen.[18] The parameters Δ_1, Δ_2, and Δ_3 lie in the

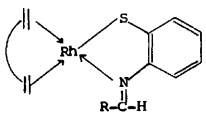
Table 2. Electronic Spectral Data of Pt(II) Complexes

S.No.	Complexes	Spectral bands/cm^{-1}	Transitions	Δ_1	Δ_2	Δ_3
				cm^{-1}		
1.	$[Pt(C_{12}H_{10}N_2S)_2]Cl_2$	20400	$^1A_{1g} \longrightarrow {}^1A_{2g}$			
		24700	$^1A_{1g} \longrightarrow {}^1B_{1g}$	22500	5500	3600
		28600	$^1A_{1g} \longrightarrow {}^1E_g$			
		30000	C.T.			
		31050				
2.	$[Pt(C_{11}H_8ONS)_2]$	20800	$^1A_{1g} \longrightarrow {}^1A_{2g}$			
		25600	$^1A_{1g} \longrightarrow {}^1B_{1g}$	22900	6000	1100
		27000	$^1A_{1g} \longrightarrow {}^1E_g$			

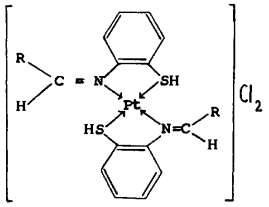
ranges, 22500—22900 cm^{-1}, 5500—6000 cm^{-1}, and 1100—3600 cm^{-1} respectively (Table 2) and which are in close agreement with the values reported earlier for the square planar geometry.[19,20]

In the electronic spectra of rhodium(I) complexes, the d-d transitions generally appear between 20000—30000 cm^{-1}. However, in the present case intense bands appearing at 31000, 34500, and 37000 cm^{-1} may be due to metal to ligand charge transfer transitions.[21]

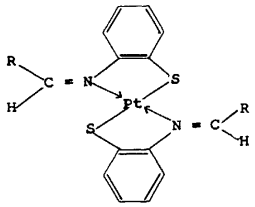
Thus, on the basis of the above discussions the following structure can be proposed for the different type of complexes:



I



II



III

Gravimetric Determination of Nickel with Salicylaldehyde Thiosemicarbazone

S. LALY and Geetha PARAMESWARAN*
Department of Chemistry, University of Calicut, Kerala 673635, India
(Received February 25, 1989)

Synopsis. A study of the use of salicylaldehyde thiosemicarbazone (STSC) in the gravimetric determination of nickel is reported. STSC reacts with Ni(II) in aqueous medium in the pH range 6.5—8.2 to form reddish brown water insoluble complex. The complex can be conveniently filtered at the pump using a G_4 sintered glass crucible and dried at 100—120 °C and weighed as $Ni(C_8H_8N_3OS)_2$. Interference of foreign ions were examined. The influence of concentration, temperature, and pH on the precipitation were studied. The reagent tested in this work was compared with classical 1,2-dioximes[1-3] used in the gravimetric determination of nickel. This method was applied to determine nickel in stainless steel.

The commonly employed organic reagents for the gravimetric determination of nickel were dioximes[1-4] and monoximes.[5-9] Thiosemicarbazones have been used as gravimetric reagent for the estimation of some metal ions.[10-12] In this paper a newly developed gravimetric determination of nickel with salicylaldehyde thiosemicarbazone (STSC) will be described. STSC reacts with Ni(II) in aqueous medium in the pH range 6.5—8.2 to form reddish brown water insoluble complex. The complex is soluble in highly acidic medium, highly alkaline medium, and organic solvents like chloroform, 90—100% ethanol etc. The complex is stable at room temperature for over 24 h. The complex can be conveniently filtered at the pump using a G_4 sintered glass crucible and dried at 100—120 °C and weighed as $Ni(C_8H_8N_3OS)_2$.

The present method is superior to other methods that the pH range is wide and the solubility of the complex in cold and hot water is very low and the complex is partially soluble in rectified spirit or 90—100% ethanol. Its lower conversion factor or high relative molecular masses give appreciably higher sensitivities than classical reagents.

Experimental

Reagents. All chemicals were of reagent grade. Stock solution (0.5%) of STSC in methanol was prepared. The nickel solutions were prepared from nickel chloride and standardized with dimethylglyoxime. 2 mol dm^{-3} sodium acetate solution was prepared.

Synthesis of STSC. Mixture of salicylaldehyde[13] and thiosemicarbazide (1:1 ratio) in 80% ethanol or methanol was refluxed for 2 h. The mixture was cooled and the precipitated STSC was filtered off and dried in a desiccator.

Apparatus. Global digital pH meter, Perkin-Elmer 577 Infrared spectrometer, Gouy-type magnetic balance.

Procedure. An aliquot of Ni(II) solution containing 20 to 40 mg of metal was placed in a 250 ml beaker and was diluted to 100 ml with distilled water. The solution was heated to 70—80 °C and the pH was adjusted to 6.5—8.2 with 2 mol dm^{-3} sodium acetate solution. To this 25—50 ml of 0.5% STSC solution was added with constant stirring and the mixture was heated in a water bath for 30 min. The mixture was allowed to cool and filtered through a weighed G_4 sintered glass crucible. Then it was washed with 40—60% hot methanol solution and finally with distilled water and dried at 110—120 °C. Conversion factor for $Ni(C_8H_8N_3OS)_2$ to Ni is 0.1314.

Results and Discussion

Properties of the Reagents. Salicylaldehyde thiosemicarbazone, was poorly soluble in water but soluble in methanol. Solution in methanol stored at room temperatures was stable for at least 1 month.

Study of Nickel Salicylaldehyde Thiosemicarbazone Complex. Elemental analysis of the nickel complex confirmed the formula $Ni(C_8H_8N_3OS)_2$. A study was made to elucidate the structure. The infrared spectra showed a shift in the C=N stretching vibration bands in relation to the reagent at 1600—1620 cm^{-1} and double bands appeared; on the other hand bands due to the C=S group disappeared and C-S vibration bands showed up. The strong band at 3400 cm^{-1} in the spectrum of the ligand may be due to ν_{-OH}. Since this band is retained almost at the same position, it was an evidence for the nonparticipation of the oxygen atom of the phenolic hydroxyl group in coordination (Fig. 1). A study of the magnetic susceptibility showed that the nickel STSC complex is diamagnetic at 293 K.

From these results it can be concluded that the Ni–STSC complex is square-planar. In general thiosemicarbazones usually react as chelating ligands with transition metal ions by bonding through the sulfur and hydrazine nitrogen atoms.[14]

Determination of Optimum Experimental Conditions for Precipitation. The effect of increasing amounts of reagent was investigated. It was found that for every 10 mg of nickel, 15—20 ml of 0.5% methanolic solution of the reagent sufficed.

Experiments were conducted at various temperatures. Precipitation occurred at room temperature and also at high temperatures. Below 50 °C the solution was found turbid. Therefore precipitation was conveniently conducted above 70 °C.

To determine the optimum pH, complex was precipitated from solutions at different pH, adjusted by

29.24	29.36	+0.12	+0.41

Average of seven determinations.

means of different buffers. The optimum pH was found to be 6.5—8.2.

The influence of various solvents for washing the precipitates was studied. Experiments with different amount of methanol showed that 30—70% methanol water mixture was suitable for washing the precipitate.

Effect of Diverse Ions. Nickel (21.37 mg) was gravimetrically determined in the presence of varying amounts of other cations and anions and the limit of concentration that can be tolerated are given in Table 2.

Composition of the Complex. The amount of precipitate obtained from a known quantity of nickel agreed with the formula $Ni(C_8H_8N_3OS)_2$, which was proved by analysis (Found: C, 42.89; N, 18.58; H, 3.2; S, 13.7%. Calcd: C, 42.98; N, 18.79; H, 3.6; S, 14.3%). The conversion factor is 0.1314. Reproducible results were obtained using varying amounts of nickel as shown in Table 3.

Table 4. Analysis of Stainless Steel

	Ni found using STSC	Ni found using DMG
Sample I	11.29	11.41
Sample II	14.21	14.30
Sample III	29.01	29.21
Sample IV	67.37	67.80

Applications

Determination of Nickel in Stainless Steel. A known weight (1.2 mg) of sample was treated with 50 ml of 12% sulfuric acid and boiled for 1 h nearly to dryness. It was then heated to dryness with 10 ml of concentrated nitric acid, cooled, and added 5 ml concentrated hydrochloric acid. The mixture was boiled, cooled, and made upto 100 ml. Aliquots of this solution (20 ml) was taken, treated with 1:1 ammonia and then filtered through Whatman No. 41 filter paper. The precipitate was dissolved by adding hot hydrochloric acid dropwise and the solution was collected in a beaker, reprecipitated with 50 ml of aqueous ammonia (1:1) and filtered on the same filter paper. The solution was concentrated to 70 ml and nickel was determined with STSC, at pH 7.5 adjusting with sodium acetate solution. The values are given in Table 4.

Unequivocal Synthesis of the Four *d,l*-Pairs of 3-Substituted 2-Aminonorbornane-2-carboxylic Acids

Alberto AVENOZA, Carlos CATIVIELA,*,† Jose A. MAYORAL,† and Miguel A. ROY
Departamento de Química Orgánica, Colegio Universitario de la Rioja, Logroño, Spain
†Departamento de Química Orgánica, Instituto de Ciencias de los Materiales de Aragón, Universidad de Zaragoza, 50009, Zaragoza, Spain
(Received January 17, 1989)

Synopsis. The Diels-Alder reaction between methyl α-cyanocinnamate and cyclopentadiene, as a key step in the synthesis of 2-amino-3-phenylnorbornane-2-carboxylic acids, is studied. The cycloadducts can be easily separated and converted into the amino acids through simple reactions.

Alicyclic amino acids, such as those with a norbornane skeleton are of interest because of their noticeable biological activities.[1] The parent compounds, 2-aminonorbornane-2-carboxylic acids, can be obtained by Diels-Alder reaction between *N*-acyl-α,β-dehydroalaninates and cyclopentadiene.[2] Nevertheless, the Diels-Alder reaction between cyclopentadiene and *N*-acyl-α,β-dehydrophenylalaninates does not lead to the corresponding amino acids. Furthermore, the reaction of ethyl α-nitrocinnamate with cyclopentadiene followed by catalytic hydrogenation and hydrolysis leads to a mixture of diastereoisomers,[3] so we have directed our attention to the development of a new unequivocal synthesis of the four *d,l*-pairs of the 2-amino-3-phenylnorbornane-2-carboxylic acids (**5**, **8**, **11**, **15**). This synthesis is based on the use of a compound with well-defined stereochemistry and two withdrawing groups which are precursors of both, amino and carboxyl groups as a dienophile, the compound being methyl (*E*)-α-cyanocinnamate[4] (**1**).

Experimental

Table 1 shows the conditions and proportions of the reagents used in the Diels-Alder reaction, together with the results obtained. Figure 1 shows the synthetic route leading to the four amino acids (**5**, **8**, **11**, **15**) and the yields obtained in each step. All products were characterized by elemental analysis and ^{1}H NMR spectra. Microanalyses were carried out on a Perkin-Elmer 240-B analyser. ^{1}H NMR spectra were recorded on a Varian XL-200. Deuterochloroform and D_2O were used as solvents with TMS as the internal standard (the chemical shifts are reported in ppm on the δ scale, coupling constants in Hz).

Results and Discussion

Table 1 shows the results obtained in the Diels-Alder reaction between cyclopentadiene and methyl (*E*)-α-cyanocinnamate (**1**); as can be seen, high levels of conversion can be achieved under several conditions. Several authors have reported that the use of water greatly increases the rate of Diels-Alder reactions;[5] together with this effect an increase in endo/exo selectivity is sometimes observed. In our case the use of water noticeably increased the reaction rate, but only a small modification in the ratio of cycloadducts (**2a**:**2b**) was obtained.

Cycloadducts **2a** and **2b** were easily separated and converted into the corresponding amino acids by means of simple reactions, but some difficulties stemming from the low reactivity of the groups placed at the endo position, appeared. So when the partial hydrolysis of the cyano group in **2b** was carried out under the conditions used with **2a** (55 °C, 3 days) an equimolecular mixture of **2b** and **9** was obtained, which was treated again under the same conditions to obtain **9** with a total yield of 70% with regard to the initial amount of cycloadduct **2b**.

The Hofmann rearrangement has been the object of several revisions[6] and the results obtained are strongly dependent on the nature of the starting amide. Under the conditions used amide **6** yielded spirohydantoin **7**, probably due to the low intermolecular reactivity of the intermediate isocyanate. The hydrolysis of this spirohydantoin is difficult because position 5 of the hydantoin ring is completely substituted, whereas position 3 is unsubstituted.[7] Hydrolysis was achieved by heating spirohydantoin **7** with aqueous $Ba(OH)_2$ at 140 °C in a closed flask for three days.

Finally the transformation of amino nitrile **13** into amino acid hydrochloride **14** is again made difficult by the low reactivity of the cyano group at the endo position. The transformation was made by heating amino nitrile **13** with 6M HCl (1 M=1 mol dm^{-3}) at 125 °C in a closed flask for fifteen hours.

To sum up, the described synthetic route constitutes a new way to the synthesis of these four amino acids through very simple reactions.

Heterocycles Synthesis through Reactions of Nucleophiles with Acrylonitriles. 7. A Novel and Facile One-Step Synthesis of 4*H*-Thiopyrans

Fathy Fahim Abdel-Latif
Chemistry Department, Faculty of Science, El-Minia University, El-Minia, A. R. Egypt
(Received February 10, 1989)

Synopsis. Several new 4*H*-thiopyrans were synthesized via a facile one-step method. Structures and reaction mechanisms are also reported and supported by another synthetic routes.

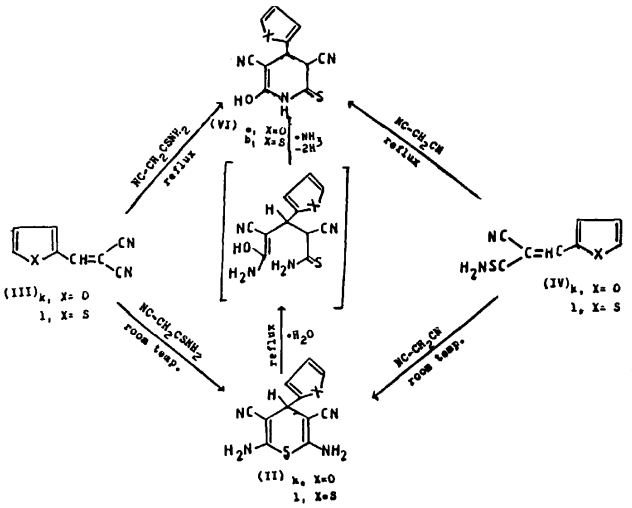
Thiopyrans and pyrans showed considerable biological activities[1-3] and are important as stabilizers for synthetic resins against heat or light.[4] As a continuation of our previous work for the synthesis of heterocyclic compounds of applied value,[5-8] in this work several new 4*H*-thiopyrans were successfully prepared by a facile one-step method from laboratory available chemicals. Stirring cold ethanolic piperidine solution of equimolar amounts of each of substituted benzaldehyde **Ia—j**, malononitrile, and cyanothioacetamide at room temperature afforded 4*H*-thiopyrans **IIa—j**. The structure of **II** was established for the reaction product based on its analytical and various spectral data (c.f. Experimental). For example, **IIb** showed only one cyano absorption band at 2190 cm^{-1} and one singlet due to the two amino groups at 6.5 ppm in the IR and ^1H NMR spectra respectively. This indicates that the molecule has a plane of symmetry and supports the structure of **IIb**.

Formation of **II** is rationalized in terms of the initial condensation of the aldehyde **I** with malononitrile or cyanothioacetamide affording α-cyanocinnamonitrile **III** or 2-cyano-3-phenyl-2-propenthioamide **IV** respectively followed by the Michael addition of the other active methylene compound to the olefinic bond in **III** or **IV** forming the acyclic intermediate **V** which cyclized under the applied conditions to the thiopyran **II** (Scheme 1).

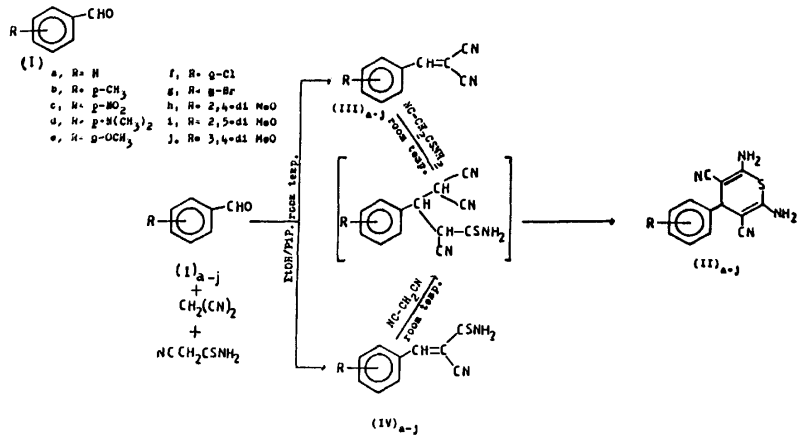
Structural proof was obtained through another route of synthesis by stirring cold ethanolic piperidine solution of an equimolar amount of **III** with cyanothioacetamide at room temperature and also by stirring ethanolic piperidine solution of **IV** with malononitrile at room temperature (c.f. Scheme 1 and Experimental).

On the other hand, synthesis of 2,6-diamino-3,5-dicyano-4-(2-furyl)-4*H*-thiopyran **IIk** was unsuccessful by using furfural instead of substituted benzaldehyde in this one-step method. While preparation of **IIk** was achieved by stirring ethanolic piperidine solution of α-cyano-β-(2-furyl) acrylonitrile **IIIk** and cyanothioacetamide at room temperature.

Compound **IIk** was also synthesized by another route by refluxing cold ethanolic piperidine solution of an equimolar amounts of 2-cyano-3-(2-furyl)-2-propenethioamide **IVk** and malononitrile at room



Scheme 2.



Scheme 1.

temperature (c.f. Scheme 2 and Experimental). In the same mannar, 2,6-diamino-3,5-dicyano-4-(2-thienyl)-4*H*-thiopyrans **III** was synthesized from (**IIIl**) and from **IVl** (c.f. Scheme 2 and Experimental).

In contrast to behavior of both **IIIk,l** toward cyanothioacetamide and/or both **IVk,l** toward malononitrile under the previous conditions, refluxing ethanolic piperidine solution of equimolar amounts of **IIIk,l** and cyanothioacetamide afforded the corresponding 2(1*H*)-pyridinethione derivatives **VIa,b**.

Compounds **VIa,b** were also synthesized by refluxing ethanolic piperidine solution of eqimolar amounts of **IVk,l** and malononitrile.

Formation of **VI** is rationalized in terms of the initial formation of **II** which is the kinetically controlled reaction product followed by its rearrangement via ring opening and recyclization under the applied conditions to the final product (c.f. Scheme 2).

Unequivocal support to the previous mechanism was achieved by synthesis of **VIa,b** by refluxing ethanolic piperidine solution of **IIk,l** (c.f. Scheme 2 and Experimental).

Experimental

All melting points are uncorrected. IR spectra were recorded (KBr) on Shimadzu 408 spectrophotometer. ^{1}H NMR spectra were recorded in DMSO-d_6 on a 90 MHz on a Varian EM-390 spectrometer with Me_4Si as an internal standard and chemical shifts are expressed as δ values. Analytical data were obtained from the microanalytical data unit at Cairo university.

Synthesis of 4*H*-Thiopyrans (II) (General Procedure). Method A: A suspension of equimolar amounts (0.01 mol) of eacn of aromatic aldehyde **Ia—j**, malononitrile, and cyanothioacetamide in ethanol (100 ml) and a catalytic amount of piperidine was stirred at room temperature for 5—6 h. The solid obtained or formed after trituration with water was collected by filtration and crystalized from a proper solvent.

Method B: A suspension of equimolar amounts (0.01 mol) of **IIIa—l** or **IVa—l** was treated with 0.01 mol of cyanothioacetamide or malononitrile and a catalytic amount of piperidine was stirred at room temperature for 3—4 h. The solid product was collected as in method A.

2,6-Diamino-3,5-dicyano-4-phenyl-4*H*-thiopyran (IIa). Colorless crystals (from ethanol), mp 183—184 °C, yield 65%; IR 3460, 3420, 3350, 3210 (NH_2), 2920 (CH stretches), 2200 (CN), and 1635, 1600 cm^{-1} (C=C, δ_{NH_2}). ^{1}H NMR δ=4.2 (s, 1H, thiopyran H-4), 6.5 (s, 4H, 2NH_2), and 7.5 (m, 5H, aromatic protons). Found: C, 61.70; H, 3.80; N, 22.30; S, 12.50%. Calcd for $C_{13}H_{10}N_4S$: C, 61.41; H, 3.93; N, 22.04; S, 12.59%.

2,6-Diamino-3,5-dicyano-4(*p*-tolyl)-4*H*-thiopyran (IIb). Pale yellow crystals (from dil. ethanol), mp 147—149 °C, yield 60%; IR 3470, 3410, 3350, 3210 (NH_2), 2910, 2850 (CH, CH_3 stretches), 2190 (CN), and 1620, 1600 cm^{-1} (C=C, δ_{NH_2}). ^{1}H NMR δ=2.2 (s, 3H, CH_3), 4.1 (s, 1H, thiopyran H-4), 6.5 (s, 4H, 2NH_2), and 7.5 (m, 4H, aromatic protons). Found: C, 62.70; H, 4.40; N, 21.10; S, 11.70%. Calcd for $C_{14}H_{12}N_4S$: C, 62.68; H, 4.47; N, 20.89; S, 11.94%.

2,6-Diamino-3,5-dicyano-4-(*p*-nitrophenyl)-4*H*-thiopyran (IIc). Straw yellow crystals (from dioxane), mp 189 °C, yield 62%; IR 3450, 3410, 3360, 3230 (NH_2), 2920 (CH stretch), 2200 (CN), and 1635, 1610 cm^{-1} (C=C, δ_{NH_2}). ^{1}H NMR δ=4.3 (s, 1H, thiopyran H-4), 6.6 (s, 4H, 2NH_2), and 7.7 (m, 4H, aromatic protons). Found: C, 52.00; H, 2.90; N, 23.40; S, 10.80%. Calcd for $C_{13}H_9N_5O_2S$: C, 52.17; H, 3.01; N, 23.41; S, 10.70%.

2,6-Diamino-3,5-dicyano-4-(*p*-dimethylaminophenyl)-4*H*-thiopyran (IId). Orange crystals (from dioxane), mp 163 °C, yield 85%; IR 3480, 3430, 3320 (NH_2), 2910, 2870 (CH, CH_3 stretches), 2190 (CN), and 1630, 1610 cm^{-1} (C=C, δ_{NH_2}). Found: C, 60.60; H, 5.20; N, 23.70; S, 11.00%. Calcd for $C_{15}H_{15}N_5S$: C, 60.60; H, 5.05; N, 23.57; S, 10.77%.

2,6-Diamino-3,5-dicyano-4-(*o*-methoxyphenyl)-4*H*-thiopyran (IIe). Colorless crystals (from ethanol), mp 180 °C, yield 60%; IR 3400, 3330, 3290 (NH_2), 2950, 2900 (CH, CH_3 stretches), 2210, 2200 (CN), and 1650, 1610 cm^{-1} (C=C, δ_{NH_2}). Found: C, 59.00; H, 4.20; N, 20.00; S, 10.90%. Calcd for $C_{14}H_{12}N_4SO$: C, 59.15; H, 4.22; N, 19.72; S, 11.26%.

2,6-Diamino-3,5-dicyano-4-(*o*-chlorophenyl)-4*H*-thiopyran (IIf). Colorless crystals (from dil. methanol), mp 145—147 °C, yield 50%; IR 3450, 3350, 3250, 3200 (NH_2), 2910, 2800 (CH, stretch), 2200 (CN) and 1625, 1590 cm^{-1} (C=C, δ_{NH_2}). Found: C, 54.10; H, 3.30; N, 19.50; Cl, 12.60; S, 11.10%. Calcd for $C_{13}H_9N_4ClS$: C, 54.07; H, 3.12; N, 19.41; Cl, 12.30; S, 11.09%.

2,6-Diamino-3,5-dicyano-4-(*m*-bromophenyl)-4*H*-thiopyran (IIg). Colorless crystals (from ethanol), mp 189—191 °C, yield 78%; IR 3450, 3350, 3250 (NH_2), 2890, 2850 (CH, stretch), 2200, 2195 (CN) and 1630, 1620, 1600 cm^{-1} (C=C, δ_{NH_2}). Found: C, 47.00; H, 3.00; N, 16.80; Br, 23.70; S, 9.50%. Calcd for $C_{13}H_9N_4BrS$: C, 46.85; H, 2.70; N, 16.81; Br, 24.02; S, 9.61%.

2,6-Diamino-3,5-dicyano-4-(2,4-dimethoxyphenyl)-4*H*-thiopyran (IIh). Pale yellow crystals (from ethanol), mp 159 °C, yield 70%; IR 3450, 3320, 3200 (NH_2), 2910, 2850 (CH, CH_3 stretches), 2200 (CN) and 1635—1620, 1600 cm^{-1} (C=C, δ_{NH_2}). Found: C, 57.10; H, 4.60; N, 18.00; S, 10.30%. Calcd for $C_{15}H_{14}N_4SO_2$: C, 57.32; H, 4.46; N, 17.83; S, 10.19%.

2,6-Diamino-3,5-dicyano-4-(2,5-dimethoxyphenyl)-4*H*-thiopyran (IIi). Colorless crystals (from dil. methanol), mp 152 °C, yield 60%; IR 3450, 3420, 3350, 3200 (NH_2), 2950, 2890, 2850 (CH, CH_3 stretches), 2200, 2192 (CN), and 1630, 1600 cm^{-1} (C=C, δ_{NH_2}). Found: C, 57.20; H, 4.50; N, 17.80; S, 10.10%. Calcd for $C_{15}H_{14}N_4SO_2$: C, 57.32; H, 4.46; N, 17.83; S, 10.19%.

2,6-Diamino-3,5-dicyano-4-(3,4-dimethoxyphenyl)-4*H*-thiopyran (IIj). Yellow crystals (from dil. methanol), mp 140 °C, yield 50%. Found: C, 57.00; H, 4.70; N, 17.60; S, 10.30%. Calcd for $C_{15}H_{14}N_4SO_2$: C, 57.32; H, 4.45; N, 17.83; S, 10.19%.

2,6-Diamino-3,5-dicyano-4-(2-furyl)-4*H*-thiopyran (IIk). Colorless crystals (turns to yellow on standing in light) (from dil. ethanol), mp 170 °C, yield 70% (method B); IR 3400, 3330, 3200 (NH_2), 2900, 2850 (CH stretch), 2185 (CN), and 635—1620 (br), 1605 cm^{-1} (C=C, δ_{NH_2}). ^{1}H NMR δ=3.3 (s, 2H, NH_2), 4.3 (s, 1H, thiopyran H-4), 6.0 (*d*1H, furan H-3), 6.3 (q, 1H, furan H-4), 6.9 (s, 2H, NH_2), and 7.5 (d, 1H, furan H-5). Found: C, 54.40; H, 3.80; N, 23.10; S, 13.30%. Calcd for $C_{11}H_8N_4OS$: C, 64.09; H, 27.00; N, 22.95; S, 13.11%.

2,6-Diamino-3,5-dicyano-4-(2-thienyl)-4*H*-thiopyran (IIl). Gray crystals (from methanol), mp 140 °C, yield 75% (method B), IR 3420, 3320, 3200 (NH_2), 2900, 2850 (CH, stretches), 2190 (CN) and 1635, 1620, 1600 cm^{-1} (C=C, δ_{NH_2}). Found: C, 51.10; H, 2.90; N, 21.40; S, 24.50%. Calcd for $C_{11}H_8N_4S_2$: C, 50.77; H, 3.07; N, 21.53; S, 24.61%.

Synthesis of 2(1*H*)-Pyridinethione (VI) (General Procedure). Method A: To a suspension of an equimolar amount 0.01 mol of **IIIk,l** and/or **IVk,l** in ethanol (50 ml) was added 0.01 mol of cyanothioacetamide and/or malononitrile and catalytic amount of piperidine. The reaction mixture was refluxed for 3 h and then evaporated in vacuo. The residue was triturated with water and acidified with acetic acid. The solid obtained was collected by filtration and recrystallized

from the propar solvent.

Method B: To a solution of **IIk**,l (1.0 g) in ethanol (30 ml) was added 3 drops of piperidine and the reaction mixture was refluxed for 6 h, then left to cool, and then treated as in method A.

3,5-Dicyano-3,4-dihydro-4-(2-furyl)-6-hydroxy-2(1*H*)-pyridinethione (VIa). Red crystals (from ethanol), mp 140 °C, yield 80%, IR, 3450—3100 (br NH, OH), 2900 (CH) 2200 (CN) and br 1670—1630 cm^{-1} (br CO, C=N). ^1H NMR δ=3.1 (s, br, 2H, OH and NH) and 6.5—7.5 (m, 3H, furan 3H). Found: C, 54.50; H, 1.90; N, 17.00; S, 13.40%. Calcd for $C_{11}H_5N_3O_2S$: C, 54.32; H, 2.06; N, 17.28; S, 13.17%.

3,5-Dicyano-3,4-dihydro-4-(2-thienyl)-6-hydroxy-2(1*H*)-pyridinethione (VIb). Yellow crystals (from dil. methanol), mp 190 °C, yield 60%, IR, 3350, 3200 (NH, OH), 2900, 2850 (CH), 2200 (CN) and 11670—1640 (br), 1600 cm^{-1} (CO, C=C). Found: C, 50.80; H; 1.70; N, 16.00; S, 24.40%. Calcd for $C_{11}H_5N_3OS_2$: C, 50.96; H, 1.93, N, 16.22; S 24.71%.

Systematic Enumerations of Highly Symmetric Cage-Shaped Molecules by Unit Subduced Cycle Indices

Shinsaku FUJITA
Research Laboratories, Ashigara, Fuji Photo Film Co., Ltd.,
Minami-Ashigara, Kanagawa-ken 250-01
(Received April 22, 1989)

Cage-shaped hydrocarbons are enumerated, starting from the tetrahedron skeleton ($\mathbf{T}_d$ symmetry). This enumeration stems from an edge strategy in which six edges of the skeleton are substituted by m methylene and n ethylene units. This is accomplished by a new method based on unit subduced cycle indices. This is a versatile methodology for counting cage-shaped hydrocarbons that have a given subsymmetry and an index term, $x^m y^n$, the latter of which corresponds to the molecular formula $C_{4+m+2n}H_{4+2m+4n}$.

Chiral and achiral molecules of high symmetry have been studied both synthetically[1] and theoretically.[2] Two strategies have been applied to the derivation of new compounds of given symmetries. The first is a vertex strategy in which substituents are placed on vertices (nodes) of a parent skeleton.[3] The second (edge strategy) consists of the insertion of methylene or other units into the edges (bonds) of a parent skeleton. In particular, the latter is a versatile methodology used to guide synthetical studies concerning cage-shaped compounds of high symmetry.[4] However, there have emerged no comprehensive studies concerning the following problems: *what symmetries are realized and how many isomers are allowed on the basis of a skeleton of a given symmetry.*

In order to settle the former problem, we now report on the applications of unit subduced cycle indices (USCIs), which are drived by the subduction of coset representations (CRs). In addition, the USCIs are also useful for the latter problem, i.e., an enumeration of isomers with a given symmetry as well as a given molecular formula.

A Set of Equivalent Positions Classified by a Coset Representation. In this paper we choose as an example tetrahedrane (**1**), whose skeleton has $\mathbf{T}_d$ symmetry. The symmetry of the skeleton controls the behavior of its vertices as well as that of its edges. As a result, the vertices and edges are partitioned into several sets of equivalent positions. These sets are called *orbits* according to the terminology of permutation groups.

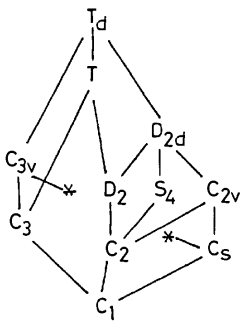

Fig. 1. Subgroup lattice of $\mathbf{T}_d$ group.

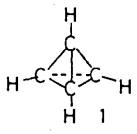
Although all of these orbits are subject to the same $\mathbf{T}_d$ symmetry, they behave differently. The characterization of such behaviors is important for a comprehensive understanding of the molecular symmetry.

The behaviors can be specified by coset representations (CRs) (Appendix A). For example, the six edges of the skeleton (**1**) belong to an orbit that is subject to a CR obtained by the corresponding coset decomposition of $\mathbf{T}_d$ by $\mathbf{C}_{2v}$. The CR is denoted by the symbol ($\mathbf{T}_d(/\mathbf{C}_{2v})$) in the present paper.



6 bonds (edges) on which $\mathbf{T}_d(/\mathbf{C}_{2v})$ acts,
4 hydrogens (nodes) on which $\mathbf{T}_d(/\mathbf{C}_{3v})$ acts, and
4 carbons (nodes) on which $\mathbf{T}_d(/\mathbf{C}_{3v})$ acts

For the purpose of assigning such a CR to an orbit, we define a set of subgroups (SSG) as a list in which the representative subgroups of a given point group are aligned in ascending order of the orders of the subgroups. Note that the respective representatives are selected in such a way that only one is adopted from every set of conjugate subgroups. For the $\mathbf{T}_d$ group, the SSG is represented by

$$\mathrm{SSG} = \{\mathbf{C}_1, \mathbf{C}_2, \mathbf{C}_s, \mathbf{C}_3, \mathbf{S}_4, \mathbf{D}_2, \mathbf{C}_{2v}, \mathbf{C}_{3v}, \mathbf{D}_{2d}, \mathbf{T}, \mathbf{T}_d\}.$$

The group-subgroup relationship is clarified by the subgroup lattice shown in Fig. 1.

In general, a set of equivalent positions (i.e. an orbit) of a $\mathbf{T}_d$ skeleton is subject to one of the eleven CRs that are associated with the eleven subgroups collected in the SSG. Thus, a set of CRs for $\mathbf{T}_d$ symmetry is obtained as follows:

$$\mathrm{SCR} = \{\mathbf{T}_d(/\mathbf{C}_1), \mathbf{T}_d(/\mathbf{C}_2), \mathbf{T}_d(/\mathbf{C}_s), \mathbf{T}_d(/\mathbf{C}_3), \mathbf{T}_d(/\mathbf{S}_4), \mathbf{T}_d(/\mathbf{D}_2), \mathbf{T}_d(/\mathbf{C}_{2v}), \mathbf{T}_d(/\mathbf{C}_{3v}), \mathbf{T}_d(/\mathbf{D}_{2d}), \mathbf{T}_d(/\mathbf{T}), \mathbf{T}_d(/\mathbf{T}_d)\}.$$

Equivalent positions contained in an orbit are interchangeable with each other, if all of the operations of the $\mathbf{T}_d$ point group are considered. On the other hand, if the operations are restricted to those of a subgroup, several positions of the orbit become fixed. The number of the fixed points is obtained for each of the subgroups collected in the SSG; the number of

fixed points is called a *mark* by Burnside.[5] A row vector which lists these numbers in the same order of the SSG is called a *fixed-point vector* (FPV) in the present paper. The FPV is a clue to the assignment of a CR to an orbit.

A table of marks (Appendix B), which comes from Burnside's textbook,[5] is utilized to determine what CR governs an orbit. The table of marks for the T_d group (Table 1) lists the marks of each CR, the numbers of the fixed points for the operations of the respective subgroups of the SSG. Note that each row of a mark table denotes the FPV of the corresponding CR.

An algorithm for choosing a CR contains the following steps: (1) select a set of equivalent positions (i.e. an orbit), (2) calculate the FPV for each of the orbits, and (3) refer to Table 1 (a mark table) and select the CR in which the row of the table is identical to the FPV. For example, the six edges of the skeleton (**1**) afford the FPV, (62200020000). This is identical to the row of $T_d(/C_{2v})$ in Table 1; therefore, the six positions of **1** are subject to $T_d(/C_{2v})$. Thus, if we consider a given skeleton, the classification of the positions into orbits and their assignment to CRs (steps 1 to 3) are easily acccomplished by inspection. A more mathematical treatment of steps 1 to 3 is given in Appendix B.

Table 1. Mark Table of T_d

i/j	C_1	C_2	C_s	C_3	S_4	D_2	C_{2v}	C_{3v}	D_{2d}	T	T_d

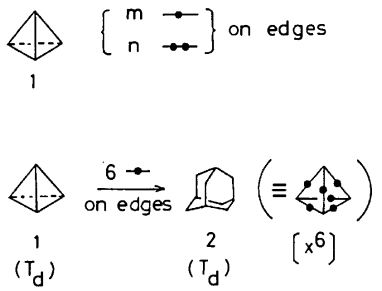
Enumeration of Cage-Shaped Hydrocarbons. Let us consider the insertion of methylene (—●—) or ethylene units (-●-●-) into C-C bonds of the skeleton (**1**). For example, the insertion of six methylenes affords adamantane (**2**).



Although the methodology described in the last paragraph has been widely applied to synthetic studies,[4] an important problem still remains unsolved: how many isomers with given molecular formula and symmetry are allowed by this methodology? This problem is ascribed to an edge-coloring problem which enumerates the isomers substituted by three colors onto the six edges of **1** (e.g., one color to no substitution, a second color for *m* of —●— and a third color for *n* of -●-●-). We call this type of formulation and *edge strategy* for producing molecules of a given symmetry.[6]

A solution to the problem requires a table of unit subduced cycle indices (Appendices C and D) and the inverse of a mark table. These are given as Tables 2 and 3 for T_d symmetry.[7]

An algorithm to solve the problem contains the following steps: (1) classify the positions of a skeleton into orbits, (2) find the corresponding CR for each of the orbits, as shown in the last section, (3) read the rows of the obtained CRs from the table of unit subduced cycle indices (USCIs) (e.g., Table 2), (4) construct a subduced cycle index (SCI) from the set of USCIs for each subgroup (Appendix D), (5) introduce a figure inventory into the SCI and expand the result-

ing equation to give a fixed-point (FP)-counting polynomial for each subgroup (Appendix E), (6) construct a fixed-point matrix (FPM), the each row of which is the FPV for the monomial term of given powers appearing in the polynomials, and (7) multiply the FPM by the inverse of a mark table (e.g., Table 3) to give a matrix, each element of which indicates the number of isomers of a given molecular formula and a given symmetry. The mathematical foundation of these steps is found in Appendices C, D, and E.

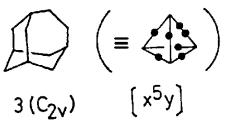
The steps listed above are illustrated by using the skeleton (**1**) as an example. The six edges of **1** are subject to $\mathbf{T_d}(/\mathbf{C_{2v}})$. Hence, the $\mathbf{T_d}(/\mathbf{C_{2v}})$ row of Table 2 is selected in order to construct subduced cycle indices (SCIs). A figure inventory is $s_r=1+x^r+y^r$, where x and y are used to count the methylenes and ethylenes, respectively. We then introduce it into the SCIs:

$\mathbf{C}$: $s_1^6=(1+x+y)^6$, (3⁶)
$\mathbf{C_2}$: $s_1^2s_2^2=(1+x+y)^2(1+x^2+y^2)^2$, (3⁴)
$\mathbf{C_s}$: $s_1^2s_2^2=(1+x+y)^2(1+x^2+y^2)^2$, (3⁴)
$\mathbf{C_3}$: $s_3^2=(1+x^3+y^3)^2$, (3²)
$\mathbf{S_4}$: $s_2s_4=(1+x^2+y^2)(1+x^4+y^4)$, (3²)
$\mathbf{D_2}$: $s_2^3=(1+x^2+y^2)^3$, (3³)
$\mathbf{C_{2v}}$: $s_1^2s_4=(1+x+y)^2(1+x^4+y^4)$, (3³)
$\mathbf{C_{3v}}$: $s_3^2=(1+x^3+y^3)^2$, (3²)
$\mathbf{D_{2d}}$: $s_2s_4=(1+x^2+y^2)(1+x^4+y^4)$, (3²)
$\mathbf{T}$: $s_6=1+x^6+y^6$, (3)

and

$\mathbf{T_d}$: $s_6=1+x^6+y^6$. (3)

These equations are expanded to give the corresponding FP-counting polynomials as generating functions. For example, the FPV for x^5y is (62200020000), the coefficients of the terms (x^5y) of the respective polynomials. Multiplication of FPV by the inverse (Table 3) gives an isomer-counting vector (IMV),(00000010000). The vector shows that there is only one isomer which corresponds to homoadamantane (**3**) with x^5y and $\mathbf{C_{2v}}$ symmetry. Similarly, the IMVs for the other x^my^n terms are obtained as shown in Table 4. The x^my^n term is called an *index term*. The resulting isomer is called an x^my^n *isomer*. The intersection of a subsymmetry column and an x^my^n row (Table 4) indicates the number of x^my^n isomers with the subsymmetry.



Since the term (x^my^n) indicates the substitution of m of —●— and n of -●-●-, it corresponds to the molecular formula $C_{4+m+2n}H_{4+2m+4n}$.

The total number of isomers is 64, among which 21 belong to chiral subgroups ($\mathbf{C_1}$, $\mathbf{C_2}$, and $\mathbf{D_2}$). Figure 2 depicts $\mathbf{C_2}$ molecules (**4** to **12**), the number of which emerges in the $\mathbf{C_2}$ column of Table 4.

There is only one $\mathbf{D_2}$ molecule which corresponds to the term (x^2y^2), as shown in Table 4. An example of

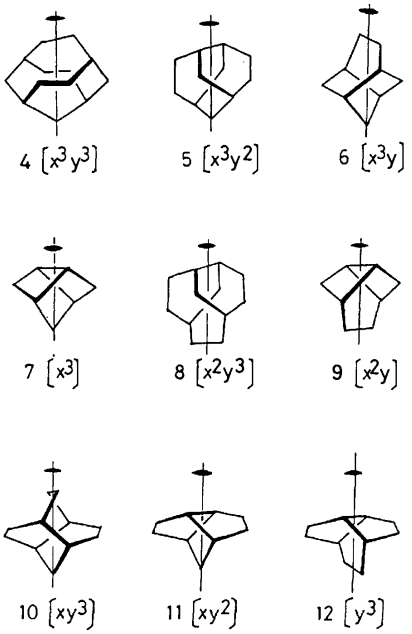


Fig. 2. $\mathbf{C_2}$ Molecules based on a tetrahedron skeleton (**1**).

Table 4. The Numbers of Cage-Shaped Compounds Derived Form the Skeleton (**1**) by an Edge Strategy

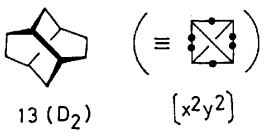
1	0	0	0	0	0	0	0	0	0	0	1	1
Total[a)]	11	9	21	0	0	1	9	6	6	0	1	64

a) The total number is the sum of the numbers in each column over all the index terms. Note that the number of $x^m y^n$ isomers is equal to that of $x^n y^m$.

this type is twistane (**13**), which can be derived by the substitution of 2 methylenes and 2 ethylenes on the edges of the skeleton (**1**) in accordance with the index term. It should be noted that neither C_3 nor **T** molecules can exist. This fact will be discussed later.



Among the total 64 isomers, there exist 43 achiral isomers (C_s, C_{2v}, C_{3v}, D_{2d}, and T_d). Figure 3 lists all of the D_{2d} molecules, the number of which appears in the D_{2d} column of Table 4. Other achiral isomers can be listed in terms of the index terms. There exist no S_4 isomers, as shown in Table 4. It should be emphasized that the results of Table 4 have been obtained by mathematical manipulation. Hence, they are the probes for verifying manual enumerations, which may sometimes contain duplicated or incomplete counting.

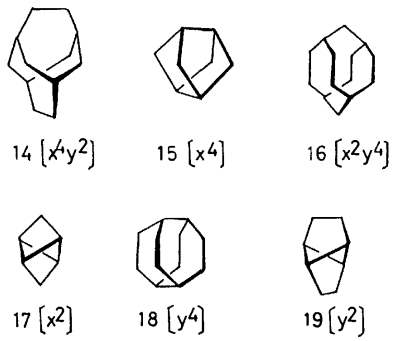


Fig. 3. D_{2d} Molecules based on a tetrahedron skeleton (**1**).

The summation in each column of Table 4 (the bottom) affords the total number of molecules having the corresponding subsymmetry. The number can be obtained by an alternative method (Appendix E). The total number of fixed points concerning each subsymmetry is obtained by introducing $x=y=1$ to the corresponding FP-counting polynomials in order to construct an FPV=(3⁶ 3⁴ 3⁴ 3² 3² 3³ 3³ 3² 3² 3 3), each element of which is the total number. Multiplication of FPV by the inverse (Table 3) affords an IMV=(11 9 21 0 0 1 9 6 6 0 1), the elements of which are identical to those shown in the bottom row of Table 4.

The total number of molecules with the index term ($x^m y^n$) is calculated in the form of a generating function (Appendix E). We use the $T_d(/C_{2v})$ row of Table 2 and the factors collected in the bottom of the same table. We then obtain a cycle index,

$$\mathbf{Z}(\mathbf{T}_d; s_r) = (1/24)s_1^6+(1/8)s_1^2s_2^2+(1/4)s_1^2s_2^2+(1/3)s_3^2+(1/4)s_2s_4$$
$$=(1/24)(s_1^6+9s_1^2s_2^2+8s_3^2+6s_2s_4).$$

The mathematical foundation of this derivation is found in Appendix E. This can be proven to be identical to that obtained alternatively by Pólya's theorem.[8,9] After the introduction of a figure inventory, $s_r=1+x^r+y^r$, into the cycle index, the expansion of the resulting equation provides the following generating function,

$$G(x,y)=\mathbf{Z}(\mathbf{T}_d; 1+x^r+y^r)$$
$$=(1/24)((1+x+y)^6+9(1+x+y)^2(1+x^2+y^2)^2+8(1+s^3+y^3)^2+6(1+x^2+y^2)(1+x^4+y^4))$$
$$=x^6+x^5y+x^5+2x^4y^2+2x^4y+2x^4+3x^3y^3+4x^3y^2+4x^3y+3x^3+\cdots,$$

in which the coefficient of $x^m y^n$ indicates the total number of molecules with $x^m y^n$. These values are identical to those collected in the right-most column of Table 4, which are obtained alternatively by summing up the values in the respective rows.

Selection Rule for Subsymmetries. Table 4 shows that molecules of $\mathbf{C}_3$, $\mathbf{S}_4$, and $\mathbf{T}$ point groups are absent in the above enumeration.[10] Why are these subsymmetries forbidden? This section is devoted to a rationalization of the problem. Note that we consider only achiral substituents.

The existence and nonexistence of molecules having special subgroups can be predicted by examining USCIs. Figure 4 depicts the subgroup lattice of the $\mathbf{T}_d$ point group which contains the USCI of each subgroup in the case of $\mathbf{T}_d(/\mathbf{C}_{2v})$. The USCI indicates the mode of subdivision of the orbit that is subject to $\mathbf{T}_d(/\mathbf{C}_{2v})$. In order to realize a subsymmetry, substituents should occupy the resulting suborbits in accord with the USCI. For example, the USCI (s_3^2) of $\mathbf{C}_{3v}$ is in agreement with the fact that the mode of substitution is A_3B_3 (Fig. 4), where A and B are achiral substituents.

More concretely, let us examine homoadamantane (**3**) of $\mathbf{C}_{2v}$ symmetry that has one ethylene (-●-●-), one methylene (—●—) and four methylenes as respective equivalent positions. This subsitution is in accord with the USCI ($s_1^2 s_4$), which appears in Fig. 4. Further examples are found in Fig. 2, in which each molecule of $\mathbf{C}_2$ symmetry has substituents (—●— and/or -●-●-) in the form of $s_1^2 s_2^2$. Figure 3 depicts various $s_2 s_4$ substitutions that lead to $\mathbf{D}_{2d}$ symmetry.

Since the USCI (s_6) of $\mathbf{T}$ is identical to that of $\mathbf{T}_d$ in the case of $\mathbf{T}_d(/\mathbf{C}_{2v})$, as shown in Fig. 4, the substitution of A_6 onto the suborbit of $\mathbf{T}$ produces no $\mathbf{T}$ but, rather, a superior $\mathbf{T}_d$ molecule. The same reasoning is applicable to $\mathbf{C}_3$ and $\mathbf{S}_4$ cases. Hence, $\mathbf{T}$, $\mathbf{C}_3$, and $\mathbf{S}_4$ subsymmetries are forbidden in case of $\mathbf{T}_d(/\mathbf{C}_{2v})$.

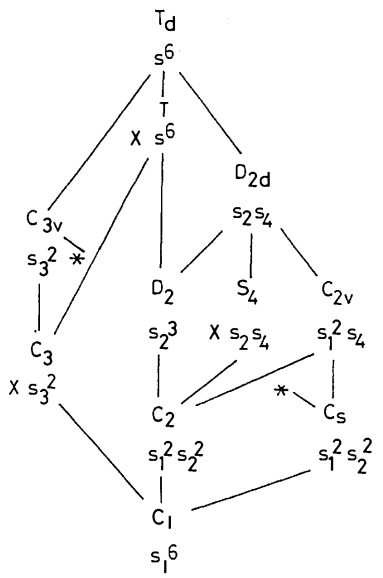

Fig. 4. Allowed and forbidden subsymmetries on the basis of a tetrahedron skeleton (**1**).

In general, because a given skeleton is represented by a set of CRs, a subsymmetry of the skeleton is characterized by a set of USCIs in which the multiplicity of the latter set is identical to that of the former set of CRs. Therefore, if the USCIs of a subgroup are identical to that of any subgroup appearing in an upper level of a subgroup lattice, the former subgroup is forbidden.

Conclusion

Enumerations based on the edge strategy are presented. Thus, a tetrahedrane of $\mathbf{T}_d$ symmetry gives various cage-shaped hydrocarbons of the subsymmetries of $\mathbf{T}_d$ by considering substitution on its edges. The enumerations with respect to subsymmetries and to molecular formulas are accomplished by a novel procedure in which unit subduced cycle indices are utilized. Although we have restricted ourselves to manipulating a tetrahedron skeleton ($\mathbf{T}_d$), we can apply the present method to other $\mathbf{T}_d$ skeletons as well as various skeletons of other symmetries than $\mathbf{T}_d$.

Appendix A. Coset Representations

Let $\mathbf{H}$ be a subgroup of a given finite group $\mathbf{G}$. Then, the elements of $\mathbf{G}$ are partitioned into a set of cosets:

$$\Gamma=\{\mathbf{H}g_1, \mathbf{H}g_2, \cdots, \mathbf{H}g_m\}, \tag{A.1}$$

where g_1 ($=I$), $\cdots$, and g_m are representatives of the cosets. Any element g ($\in \mathbf{G}$) is multiplied onto each coset of Γ to afford

$$\Gamma'=\{\mathbf{H}g_1g, \mathbf{H}g_2g, \cdots, \mathbf{H}g_mg\}. \tag{A.2}$$

The transformation $\Gamma \rightarrow \Gamma'$ is considered to be a permutation represented by

$$\pi_g = \begin{pmatrix} \mathbf{H}g_1, \mathbf{H}g_2, \cdots, \mathbf{H}g_m \\ \mathbf{H}g_1g, \mathbf{H}g_2g, \cdots, \mathbf{H}g_mg \end{pmatrix}, \tag{A.3}$$

which constructs a permutation group homomorphic to the group $\mathbf{G}$. We call this a coset representation (CR) of $\mathbf{G}$ by $\mathbf{H}$, which is denoted as $\mathbf{G}(/\mathbf{H})$. The degree of $\mathbf{G}(/\mathbf{H})$ is $m=|\mathbf{G}|/|\mathbf{H}|$. The coset representation is transitive, so that it has one orbit.

Appendix B. A Table of Marks

Burnside pointed out the importance of a table of marks.[5] Suppose that $\mathbf{G}_i$ ($i=1, 2, \cdots, s$) are an irredundant set of conjugate subgroups of $\mathbf{G}$, where $\mathbf{G}_1=\mathbf{C}_1$ and $\mathbf{G}_s=\mathbf{G}$. We define a set of subgroups as a series of the conjugate subgroups represented by

$$\mathrm{SSG}=\{\mathbf{G}_1, \mathbf{G}_2, \cdots, \mathbf{G}_s\}, \tag{B.1}$$

the elements of which are aligned in the ascending order of $|\mathbf{G}_i|$. The corresponding set of coset representations:

$$\mathrm{SCR}=\{\mathbf{G}(/\mathbf{G}_1), \mathbf{G}(/\mathbf{G}_2), \cdots, \mathbf{G}(/\mathbf{G}_s)\} \tag{B.2}$$

contains all possible transitive representations of the finite group $\mathbf{G}$.

Let the mark of a subgroup **H** in **G** be the number of fixed points of a **G**-set on the action by **H**. When the symbol m_{ij} incidates the mark of subgroup $\mathbf{G}_j$ in $\mathbf{G}(/\mathbf{G}_i)$, we obtain a fixed point vector as

$$\mathrm{FPV}_i=(m_{i1}, m_{i2}, \cdots, m_{is}) \tag{B.3}$$

for each $\mathbf{G}(/\mathbf{G}_i)$. If we collects FPVs for all $\mathbf{G}_j$ (J=1, 2, ···, s) as row vectors, we arrive at a matrix,

$$\mathrm{MT}=(m_{ij})=\begin{pmatrix} m_{11}m_{12}\cdots m_{1s} \\ m_{21}m_{22}\cdots m_{2s} \\ \cdots \\ m_{s1}m_{s2}\cdots m_{ss} \end{pmatrix}, \tag{B.4}$$

which is called a table of marks by Burnside and denoted as a mark table in the present paper.

If a set (Δ) of positions appearing in a given skeleton is a **G**-set in the form of a permutation group ($\mathbf{P}_\mathbf{G}$) acting on the set, it is partitioned into several orbits (i.e. sets of equivalent positions) in accord with

$$\mathbf{P}_\mathbf{G}=\sum_{i=1}^{s}\alpha_i\mathbf{G}(/\mathbf{G}_i), \tag{B.5}$$

where $\mathbf{G}_i$ (i=1, 2, ···, s) belong to the SSG of **G** and $\mathbf{G}(/\mathbf{G}_i)$ are the corresponding coset representations. The multiplicity α_i is obtained by

$$(\mu_1\mu_2\cdots\mu_s)=(\alpha_1\alpha_2\cdots\alpha_s)\mathrm{MT}, \tag{B.6}$$

where $(\mu_1\mu_2\cdots\mu_s)$ is a FPV for the set (Δ) and the $s\times s$ matix is the mark table represented by Eq. B.4. When we define $\bar{m}_{ji}$ as a ji element of an inverse of the mark table (IMT) derived from Eq. B.4, i.e.,

$$\mathrm{IMT}=(\bar{m}_{ji})=\begin{pmatrix} \bar{m}_{11}\bar{m}_{12}\cdots \bar{m}_{1s} \\ \bar{m}_{21}\bar{m}_{22}\cdots \bar{m}_{2s} \\ \cdots \\ \bar{m}_{s1}\bar{m}_{s2}\cdots \bar{m}_{ss} \end{pmatrix}, \tag{B.7}$$

Eq. B.6 is converted to

$$(\alpha_1\alpha_2\cdots\alpha_s)=(\mu_1\mu_2\cdots\mu_s)\mathrm{IMT}. \tag{B.8}$$

Appendix C. Subduced Representations of a Coset Representation

Let us consider a coset representation $\mathbf{G}(/\mathbf{G}_i)$, the element of which homomorphically corresponds to $|\mathbf{G}|$ elements of **G**. Suppose that we restrict the elements of $\mathbf{G}(/\mathbf{G}_i)$ into a set of elements corresponding to a subgroup ($\mathbf{G}_j$). The restricted set is a representation of the subgroup ($\mathbf{G}_j$). This is called a subduced representation (SR) and is denoted by $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ in the present paper. Although $\mathbf{G}(/\mathbf{G}_i)$ is a transitive representation of **G**, the SR, $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$, is an intransitive representation of the subgroup $\mathbf{G}_j$. Equation B.5 is applicable to this case and can be transformed into

$$\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j=\sum_{k=1}^{v_j}\beta_k^{(ij)}\mathbf{G}_j(/\mathbf{H}_k^{(j)}), \tag{C.1}$$

wherein $\mathbf{H}_k^{(j)}$ (k=1, 2, ···, v_j) are conjugate subgroups of the group $\mathbf{G}_j$. The multiplicity $\beta_k^{(ij)}$ (k=1, 2, ···, v_j) are obtained by

$$\nu_1=\sum_{k=1}^{v_j}\beta_k^{(ij)}m_{k1}^{(j)}. \tag{C.2}$$

On the basis of this equation, the $k1$ elements, $m_{k1}^{(j)}$, construct a table of marks for the subgroup $\mathbf{G}_j$. It should be noted that each $\beta_k^{(ij)}$ is constant because $\mathbf{G}(/\mathbf{G}_i)$ and $\mathbf{G}_j$ ($/\mathbf{H}_k^{(i)}$) are strictly decided by their components. On the other hand, the term α_i in Eq. B.5 is dependent on **G**-set even if the group **G** is given.

Appendix D. Table of Unit Subduced Cycle Indices and a Subduced Cycle Index

Let us consider $\mathbf{G}_j(/\mathbf{H}_k^{(j)})$ appearing in Eq. C.1. An orbit that is subject to $\mathbf{G}_j(/\mathbf{H}_k^{(j)})$ has a length represented by

$$d_{jk}=|\mathbf{G}_j|/|\mathbf{H}_k^{(j)}|. \tag{D.1}$$

Hence, we can ascribe a variable $s_{d_{jk}}$ to $\mathbf{G}_j(/\mathbf{H}_k^{(j)})$. The variable $s_{d_{jk}}$ is an index representing a behavior of the orbit on which $\mathbf{G}_j(/\mathbf{H}_k^{(j)})$ acts. We then define *a unit subduced cycle index (USCI)* as being

$$\prod_{k=1}^{v_j}(s_{d_{jk}})^{\beta_k^{(ij)}}. \tag{D.2}$$

The USCI corresponds to Eq. C.1 that represents the subdivision provided by $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$. A collection of the USCIs over all i and all j as shown in Table 5 is useful to various applications. We call such a table *a table of unit subduced cycle indices (USCIs).*

By using USCIs, we define a *subduced cycle index (USCI)* for a subgroup $\mathbf{G}_j$ as follows:

$$Z(\mathbf{G}_j; s_{d_{jk}})=\prod_{i=1}^{s}\left[\prod_{k=1}^{v_j}(s_{d_{jk}})^{\beta_k^{(ij)}}\right]^{\alpha_i} \tag{D.3}$$

$$=\prod_{k=1}^{v_j}(s_{d_{jk}})^{\sum_{i=1}^{s}\alpha_i\beta_k^{(ij)}} \tag{D.4}$$

(for j=1, 2, ···, s),

where each α_i is the multiplicity of $\mathbf{G}(/\mathbf{G}_i)$ obtained by Eq. B.8.

Appendix E. Enumeration of Isomers with a $\mathbf{G}_i$-Symmetry and a W_θ-Formula

Suppose that a given skeleton of **G** symmetry has $|\Delta|$ positions (vertices or edges) which construct a domain,

$$\Delta=\{\delta_1, \delta_2, \cdots, \delta_{|\Delta|}\}.$$

Consider that m_r figures of X_r selected from a codomain,

$$\mathbf{X}=\{X_1, X_2, \cdots, X_r, \cdots, X_{|\mathbf{X}|}\},$$

occupy the positions of Δ. The resulting isomers have a molecular formula (or a weight) represented by

Table 5. Table of Unit Subduced Cycle Indices

	$\downarrow\mathbf{G}_1$	$\downarrow\mathbf{G}_2$	···	$\downarrow\mathbf{G}_j$	···	$\downarrow\mathbf{G}_s$
$\mathbf{G}(/\mathbf{G}_1)$						
$\mathbf{G}(/\mathbf{G}_2)$				···		
···						
$\mathbf{G}(/\mathbf{G}_i)$		···		$\prod_{k=1}^{v_j}(s_{d_{jk}})^{\beta_k^{(i,j)}}$	···	
···						
$\mathbf{G}(/\mathbf{G}_s)$				···		

$$W_\theta=\prod_{r=1}^{|\mathbf{X}|}X_r^{m_r}, \tag{E.1}$$

wherein the subscript θ runs over all partitions of $m_1+m_2+\cdots+m_r+m_{|\mathbf{X}|}=|\Delta|$. Our objective is an enumeration of isomers with W_θ and of a given subsymmetry. Suppose that the domain Δ, which is originally a **G**-set, is now considered to be a $\mathbf{G}_j$-set. Thus, the domain, which is divided by the action of **G** (Eq. B.5), is further subdivided into suborbits by $\mathbf{G}_j$. The accumulated actions are characterized by the subduced cycle index (SCI) represented by Eqs. D.3 and D.4. Hence, the number ($\rho_{\theta j}$) of $\mathbf{G}_j$-isomers with a W_θ formula is obtained by a generating function,

$$\sum_\theta \rho_{\theta j}W_\theta=Z(\mathbf{G}_j;\ s_{d_{jk}}) \tag{E.2}$$

$$\text{for } j=1, 2, \cdots, s,$$

which is substituted by

$$s_{d_{jk}}=\sum_{r=1}^{|\mathbf{X}|}X_r^{d_{jk}}. \tag{E.3}$$

We call the generating function *a fixed-point-couting polynomial.* Since the number $\rho_{\theta j}$ suffers from duplicated counting, its correction is accomplised by

$$\rho_{\theta j}=\sum_{i=1}^{s}A_{\theta i}m_{ij} \tag{E.4}$$

$$(\text{for } j=1, 2, \cdots, s),$$

where $A_{\theta i}$ is the number of $\mathbf{G}_i$-isomers with W_θ and m_{ji} is the mark defined in Eq. B.4. The θj-elements ($\rho_{\theta j}$) coonstruct a matrix, which is called a *fixed-point matrix (FPM).* Each row of the FPM is an FPV.

Suppose that $X_r=1$ ($r=1, 2, \cdots$, and $|\mathbf{X}|$) are introduced into Eq. E.3. This operation results in the transformation of Eq. 2 into

$$\sum_\theta \rho_{\theta j}=|\mathbf{X}|^{\sum_{i=1}^{s}\alpha_i\beta_{ij}} \tag{E.5}$$

$$(\text{for } j=1, 2, \cdots, s),$$

where

$$\beta_{ij}=\sum_{k=1}^{v_j}\beta_k^{(ij)}. \tag{E.6}$$

The term β_{ij} represents the number of suborbits. The summation of Eq. E.4 over all θ gives

$$\sum_\theta \rho_{\theta j}=\sum_\theta\sum_{i=1}^{s}A_{\theta i}m_{ij}=\sum_{i=1}^{s}(\sum_\theta A_{\theta i})m_{ij} \tag{E.7}$$

$$(\text{for } j=1, 2, \cdots, s).$$

Since the term $A_i=\sum_\theta A_{\theta i}$ is the total number of $\mathbf{G}_i$-isomers, Eqs. E.5 and E.7 provide

$$|\mathbf{X}|^{\sum_{i=1}^{s}\alpha_i\beta_{ij}}=\sum_{i=1}^{s}A_im_{ij} \tag{E.8}$$

$$(\text{for } j=1, 2, \cdots, s).$$

When the symbol ρ_j denotes the number of fixed points on the action of $\mathbf{G}_j$, i.e.

$$\rho_j=|\mathbf{X}|^{\sum_{i=1}^{s}\alpha_i\beta_{ij}} \tag{E.9}$$

Equation E.8 can be rewritten by following matrix representation:

$$(\rho_1\rho_2\cdots\rho_s)=(A_1A_2\cdots A_s)\mathrm{MT}, \tag{E. 10}$$

where MT is a table of marks.

The total number (A_θ) of W_θ-isomers is represented by

$$A_\theta=\sum_{i=1}^{s}A_{\theta i}=\sum_{i=1}^{s}\sum_{j=1}^{s}\rho_{\theta i}\bar{m}_{ji}, \tag{E.11}$$

the latter term of which comes from Eq. E.4. Note that $\bar{m}_{ji}$ is the inverse of a table of marks. Hence, a generating function of A_θ takes the following form:

$$\sum_\theta A_\theta W_\theta=\sum_{j=1}^{s}[(\sum_{i=1}^{s}\bar{m}_{ji})\sum_\theta \rho_{\theta j}W_\theta]. \tag{E.12}$$

Because of Eq. E.2,

$$\sum_\theta A_\theta W_\theta=\sum_{j=1}^{s}[(\sum_{i=1}^{s}\bar{m}_{ji})Z(\mathbf{G}_j;\ s_{d_{jk}})], \tag{E.13}$$

where Eq. E.3 is effective. Equation E.13 can be proved to be identical to that obtained alternatively by Polya's theorem; however, the present formulation is quite different and have some advantages over Pólya's theorem. The term

$$\cdot\sum_{i=1}^{s}\bar{m}_{ji}$$

is the sum of the $\mathbf{G}_j$-row of the inverse of a table of marks. This term is positive if and only if $\mathbf{G}_j$ is a cyclic group. Otherwise, it vanishes to zero. The relationship between the present method and Polya's method will be discussed elsewhere.[9]

6) The present enumeration is not concerned with exact conformations. In other words, it is based on the presumption that a molecule has an average conformation. For example, tricyclo[5.5.2.$2^{4,10}$]hexadecane (y^6) is assigned to T_d symmetry in this paper. If we take account of conformation, we find M- and P-conformers of **T** symmetry, which are determined by their helicity. These conformers can be enumerated by using unit subduced cycle indices *with chirality fittingness* (or with helicity fittingness). We will report this type of enumeration later. See S. Fujita, *Bull. Chem. Soc. Jpn.*, in press and S. Fujita, *J. Math. Chem.*, in press.

7) For further applications, tables of USCIs of other point groups should be prepared. The full lists will be

reported elsewhere. For the proof of the equations appearing in Appendices, see S. Fujita, *Theor. Chim. Acta*, in press.

Regioselective Hydrogenation of Unsaturated Alcohol Using Platinum-Alumina Modified with Carboxylic Acid

Hideyuki KUNO,* Kyoko TAKAHASHI, Makoto SHIBAGAKI, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco Inc., 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received May 31, 1989)

Platinum-alumina catalysts modified with carboxylic acid were prepared for the selective hydrogenation of unsaturated alcohols. These catalysts were stable in non-polar solvents. It has been demonstrated that the carbon-carbon double bond which is close to the hydroxyl group is preferentially hydrogenated in the case of several hexenols. This selectivity was applied to the regioselective hydrogenation of geraniol and citronellol was obtained in an 84.5% yield over one of the modified catalyst systems.

It has been difficult to achieve a high regioselective hydrogenation of compounds which had plural unsaturations over a heterogeneous catalyst. It was recently reported that a carbon-carbon double bond far from a hydrophobic site in unsaturated carboxylic acid was more quickly hydrogenated than that near by a hydrophilic site over colloidal palladium or platinum supported on a polymer in a water solution.[1] This selectivity was due to the colloidal micelle. Further, the site-selective epoxidation was also performed over the micelle-type catalyst.[2] On the other hand, highly regioselective reactions, such as esterification,[3,4] were reported to be achieved by using a monomolecular layer which could be prepared on an inorganic solid with carboxylic acid.

In this investigation, the selective hydrogenation of the carbon-carbon double bond was carried out by the application of a monomolecular layer system. The platinum-alumina (Pt/Al_2O_3) catalysts modified with carboxylic acids were prepared and used as catalysts with a monomolecular layer system. The carboxylic acid was presumed to be chemisorbed on an inorganic support as carboxylate anions.[5-8] It was elucidated that the difference in the hydrogenation rates were found in the different positions of the carbon-carbon double bond in unsaturated alcohols. In this paper, we report that the hydroganation rate of the carbon-carbon double bond is dependent on the distance between the double bond and the hydroxyl group in the unsaturated alcohol, and that the regioselective hydrogenation of geraniol is achieved in this catalyst system.

Experimental

Materials. Commercial reagents were used for the reactions without further purification. Five percent platinum on a powdered alumina (Nippon Engelhard Ltd.) was used for the preparation of modified catalysts.

Preparation of Carboxylic Acid-Modified Catalyst (Catalyst A).[2,3] Carboxylic acids (0.1 g) and tridecane or dodecane as an internal standard (0.1 g) were dissolved in 10 cm^3 of *N,N*-dimethylformamide (DMF). A platinum-alumina catalyst (5 w/w% Pt) was immersed in the solution and stirred overnight at room temperature. A catalyst modified with the carboxylic acid was filtered off, washed with a small amount of DMF and dried under reduced pressure. The filtrate was analyzed by gas chromatography (a capillary column OV 101 30 m) in order to determine the adsorbed amount of the carboxylic acid on the catalyst.

Hydrogenation of Hexenols. In a 30-cm^3 round-bottom flask, 10 mg of Catalyst A, or 5 % platinum on alumina (Catalyst B), was suspended in 10 cm^3 of hexane containing 0.1 g of tridecane, and 10 cm^3 of hexane containing *trans*-2-hexen-1-ol (0.1 g or 0.2 g) and/or *trans*-4-hexen-1-ol (0.1 g or 0.2 g) was added with stirring at 0 °C under a hydrogen atmosphere. The reactants and products were analyzed on gas chromatography (a capillary column PEG 20M 30 m). The compounds were assigned and their concentrations were determined using authentic samples and an internal standard.

Hydrogenation of Geraniol. In a 30-cm^3 round-bottom flask, 20 cm^3 of hexane containing tridecane (0.1 g) and geraniol (0.1 g) was stirred with 10 mg of Catalyst A or Catalyst B at 0 °C under a hydrogen atmosphere. The reactants and products were analyzed in a similar manner as described above. The assignment of the products was performed with GC-MS and ^1H NMR spectroscopy.

Results and Discussion

Adsorption of Carboxylic Acid on Alumina. The amounts of several carboxylic acids adsorbed on Pt/Al_2O_3 are listed in Table 1. The amount of myristic acid on Pt/Al_2O_3 was smaller than those of the other carboxylic acids. Monocarboxylic acids were efficiently adsorbed on alumina in comparison with the dicarboxylic acid. The adsorption amounts were not changed when large amounts of carboxylic acids were used in the preparation of the modified catalysts.

Table 1. Amount of Adsorbed Carboxylic Acids on Pt/Al_2O_3

Carboxylic acid	Adsorption amount/mmol g^{-1}
Decanoic acid	0.233
Hexanoic acid	0.240
Myristic acid	0.123
Benzoic acid	0.277
Adipic acid	0.166

Carboxylic acid: 0.1 g, 5% platinum-alumina: 1.0 g, in DMF solution, for overnight at room temperature.

These results showed that an almost saturated amount of the carboxylic acids were adsorbed on Pt/Al_3O_3. Although the prepared Catalyst A was immersed in hexane and stirred under a hydrogen atmosphere overnight, the eliminated carboxylic acid was not detected. Catalyst A was stable in hexane.

Hydrogenation of Some Unsaturated Alcohols. The hydrogenation of *trans*-2-hexen-1-ol and *trans*-4-hexen-1-ol was carried out with catalysts modified by three kinds of carboxylic acids, decanoic acid (Catalyst A-1), hexanoic acid (Catalyst A-2), and myristic acid (Catalyst A-3), and with a non-modified catalyst (Catalyst B). The time-courses of the hydrogenation over Catalyst A-1 are shown in Fig. 1-a. The hydrogenation rate of *trans*-2-hexen-1-ol was higher than that of *trans*-4-hexen-1-ol over Catalyst A-1, while the two hexenols were hydrogenated at similar

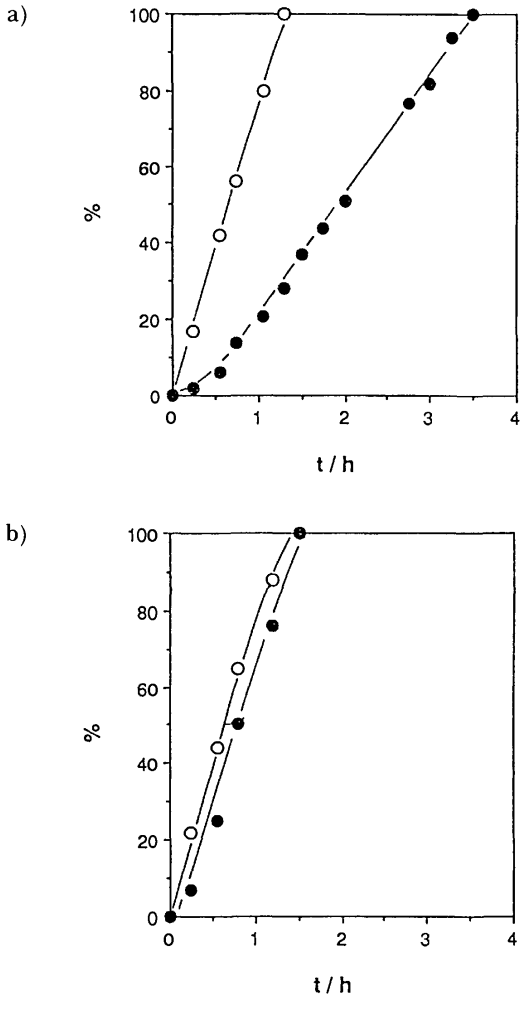

Fig. 1. Hydrogenation of *trans*-2-hexen-1-ol and *trans*-4-hexen-1-ol: a) Catalyst A-1; b) Catalyst B. ○; H_2 uptake in *trans*-2-hexen-1-ol hydrogenation. Conditions: Catalyst: 10 mg, *trans*-2-hexen-1-ol: 0.2 g, tridecane: 0.1 g, hexane: 20 cm^3, reaction temperature: 0 °C. ●; H_2 uptake in *trans*-4-hexen-1-ol hydrogenation. Conditions: Catalyst: 10 mg, *trans*-4-hexen-1-ol: 0.2 g, tridecane: 0.1 g, hexane: 20 cm^3, reaction temperature: 0 °C.

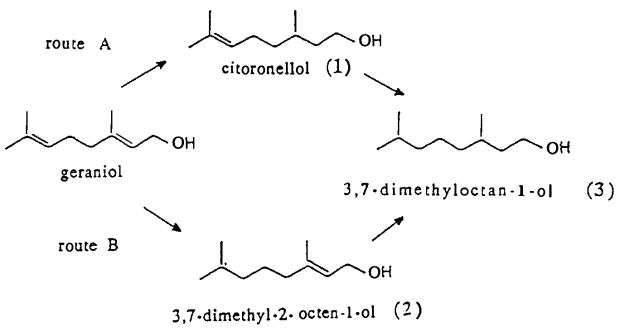

reaction rates over Catalyst B (Fig. 1-b). These results could be explained as follows: in the case of the Catalyst A-1 system, hexenols were adsorbed on the catalyst surface at the hydroxyl group. It was difficult for the carbon-carbon double bond far from the hydroxyl group to approach the active site compared with that of the hydroxyl group nearby because of the long hydrophobic carbon chain of the carboxylic acid which had adsorbed on Pt/Al_2O_3. It is considered that these phenomena are attributable to two effects. One of them is the hydrophilic-hydrophobic effect[9] which is caused by the attached carboxylic acid. Another effect is caused by a steric reguration in the carboxylic acid layer on Pt/Al_22O_3 (matrix effect).[10] Therefore, the hydrogenation of the carbon-carbon double bond near the hydroxyl group was faster than that far from the hydroxyl group. The hydrogenation over Catalyst A-2 or Catalyst A-3 was similar to that over Catalyst A-1. The difference in the rates between *trans*-2-hexen-1-ol and *trans*-4-hexen-1-ol over Catalyst A-1 was largest. It was reasonable that the effect increased with increasing the carbon chain of the adsorbed carboxylic acid; therefore, the matrix effect in Catalyst A-2 was smaller than that in Catalyst A-1. In the case of Catalyst A-3, the matrix effect was lowered because of the small amount of the adsorbed myristic acid.

Competitive hydrogenation of *trans*-2-hexen-1-ol and *trans*-4-hexen-1-ol was carried out on Catalyst A-1, and the results are shown in Fig. 2. Although the hydrogenation rates of the two hexenols were almost the same in the case of the Catalyst B system, *trans*-2-

Table 2. Rate of Hydrogenation for *trans*-2-Hexen-1-ol and *trans*-4-Hexen-1-ol

Catalyst	Initial rate of reaction/mol $g^{-1} h^{-1}$	
	trans-2-Hexen-1-ol	*trans*-4-Hexen-1-ol
Catalyst A-1	3.5×10^{-2}	2.2×10^{-3}
Catalyst A-2	7.0×10^{-2}	8.2×10^{-3}
Catalyst A-3	5.2×10^{-2}	7.9×10^{-3}
Catalyst A-4	4.2×10^{-2}	5.9×10^{-3}
Catalyst A-5	4.5×10^{-2}	5.5×10^{-3}
Catalyst B	7.1×10^{-2}	5.2×10^{-2}

●; H_2 uptake in *trans*-4-hexen-1-ol hydrogenation.

hexen-1-ol was selectively hydrogenated over Catalyst A-1.

As shown in Table 2, the selective hydrogenation was observed by the use of catalysts modified by hexanoic acid (Catalyst A-2), myristic acid (Catalyst A-3), benzoic acid (Catalyst A-4), and adipic acid (Catalyst A-5). This tendency was independent of the variety of the modified carboxylic acids on Pt/Al_2O_3. Thus, selective hydrogenation could be performed for a mixture of some unsaturated alcohols by a catalyst modified with carboxylic acid.

It was expected that the regioselective hydrogenation of an alcohol possessing a plural of carbon-carbon double bonds could be applied, since a difference in the hydrogenation rates was found in a different position of the carbon-carbon double bond in hexenols. The hydrogenation of geraniol was investigated by catalysis with carboxylic acid-modified catalysts. Since the two double bonds were similar in a steric environment, regioselective hydrogenation could not be achieved over the usual heterogeneous catalyst. In fact, the regioselectivity in the hydrogenation of geraniol was low over Catalyst B, as shown in Fig. 3-b. However, by catalysis with Catalyst A-1, a high regioselective hydrogenation of geraniol was achieved and citronellol was obtained in an 84.5% yield (Fig. 3-a). The catalytic hydrogenation of geraniol proceeds via two kinds of pathways, shown to be routes A and B in the scheme; citronellol (**1**) and 3,7-dimethyl-2-octen-1-ol (**2**) were obtained as intermediates between geraniol and 3,7-dimethyloctan-1-ol (**3**). In the case of hydrogenation over Catalyst B, a slightly regioselective hydrogenation was observed, and **2** was detected during an early stage of the reaction. Furthermore, **3** was rapidly produced. In the

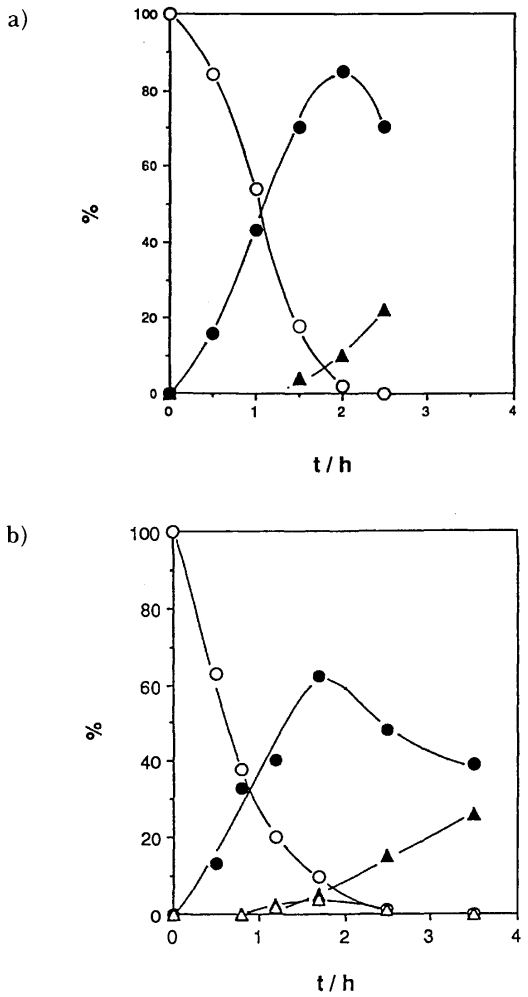

Fig. 3. Hydrogenation of geraniol: a) Catalyst A-1; b) Catalyst B.

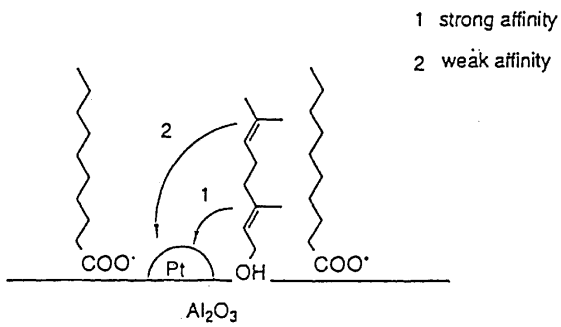

Fig. 4. Reaction model for the hydrogenation of geraniol in Catalyst A system.

hydrogenation on Catalyst A, **2** was never detected and **3** was slowly yielded. As a result, a high regioselectivity was achieved over Catalyst A. By the use of a catalyst modified by other carboxylic acids (for

instance, hexanoic acid, myristic acid, benzoic acid, or adipic acid) high regioselective hydrogenation of geraniol could also be achieved. However, a catalyst modified by decanoic acid was superior in selectivity to the other catalysts.

From these results, the reaction mechanism in the Catalyst A system was assumed to be as follows: by way of the hydroxyl group, as a hydrophilic label, the unsaturated alcohol is attracted in the hydrophilic phase to the surface of alumina and the double bond near the hydroxyl group can more easily approach the platinum by the carboxylic acid layer (Fig. 4). Consequently, the carbon-carbon double bond which was close to the hydroxyl group was easily hydrogenated.

In conclusion, a highly regioselective hydrogenation of the carbon-carbon double bond of the unsaturated alcohol was achieved by carboxylic acid-modified catalysts.

9) The hydrophilic part in unsaturated alcohol has an affinity for the carboxyl group adsorbed on the surface of Pt/Al_2O_3. On the other hand, the hydrophobic part in the substrate has an affinity for the hydrophobic core in the carboxylic acid. Accordingly, the carbon-carbon double bond near the hydroxyl group can preferentially close to the active site in comparison with the double bond in the hydrophobic part.

Electrochemical Studies of the Reduction Mechanism of Tetrazolium Salts and Formazans

Kisaburo UMEMOTO
Department of Pure and Applied Sciences, College of Arts and Sciences,
The University of Tokyo, Komaba, Meguro-ku, Tokyo 153
(Received March 24, 1989)

The electrochemical study clarified that ditetrazolium salts are reduced not only to the half-reduced "monoformazans" but also to the fully-reduced "diformazans" at the potential where the first electron is transferred to generate the "tetrazolinyl radical". The key reaction leading to the simultaneous generation of mono- and diformazans was the disproportionation reaction of the tetrazolinyl radicals. The identification of absorption spectra of reaction intermediates was performed at several reaction stages.

Although tetrazolium salts are useful qualitative reagents for the detection of dehydrogenase[1-3] and superoxide radical,[4-7] their use as quantitative reagents has been less successful because of their complex chemistry.[1-4]

For example, Nitro Blue Tetrazolium chloride (NBT)—a tetrazolium salt most widely used for the detection of superoxide radical—is reduced to a blue colored diformazan by a four-electron reaction, and as such, NBT is taken as a four equivalent reagent in the redox reaction. However, when NBT was used as an electron acceptor in organic solvents, the final reaction product contained not only the diformazan but also the half-reduced monoformazan.[8] The reaction of ditetrazolium salts with sodium ascorbate in ethanolic solution also gave a mixture of the mono- and diformazans.[2]

Although ditetrazolium salts are known to exhibit several reaction stages,[1,2,4,10-16] the reaction paths leading to the simultaneous generation of mono- and diformazans are little known. The purpose of the present work is to clarify the reaction paths of the tetrazolium salts and their formazans in order to elucidate the problems encountered in the quantitative use of the tetrazolium salts.

Experimental

The tetrazolium salts†—2,3,5-triphenyltetrazolium chloride (TTC), Neotetrazolium chloride (NT), Blue Tetrazolium chloride (BT), and Nitro Blue Tetrazolium chloride (NBT)—were obtained from Tokyo Kasei and purified by recrystallization from ethanol-diethyl ether mixture. The formazans of TTC, NT, BT, and NBT were prepared by the method of Altman and Butcher.[2] The preparation of tetraethylammonium perchlorate (TEAP) and the purification of dimethyl sulfoxide (DMSO) were carried out by the usual methods.[8]

† NT: 3,3′-[1,1′-biphenyl]-4,4′-diylbis[2,5-diphenyl-2*H*-tetrazolium] dichloride. BT: 3,3′-(3,3′-dimethoxy[1,1′-biphenyl]-4,4′-diyl)bis[2,5-diphenyl-2*H*-tetrazolium] dichloride. NBT: 3,3′-(3,3′-dimethoxy[1,1′-biphenyl]-4,4′-diyl)-bis[2-(4-nitrophenyl)-5-phenyl-2*H*-tetrazolium] dichloride. The molecular structure and the abbreviation of the molecular species are given in Figs. 2, 6, 8, and 10.

The controlled potential electrolysis was carried out by using an H-type cell equipped with a sintered glass separator. The cathode compartment of the cell was made of a standard 1.00 cm spectrophotometric quartz cell, and the absorption spectra of the reaction products were measured by in-situ method.[8] The cathode was a Pt gauge and the anode was a spiral Pt wire. Potentials were all referred to an SCE. The salt bridge connected to the SCE was put in the anode compartment of the cell. Nitrogen gas was bubbled through both compartments in order to deaerate and to agitate the solution during the electrolysis. All experiments were carried out at the room temperature—ca. 20 °C.

Results and Discussion

Reduction of TTC and Its Formazan.[9] The cyclic voltammogram of TTC is given in Fig. 1a. The peak potential separation of the first redox couple (A/A′) is ca. 60 mV, indicating the electrode reaction is a reversible one-electron reaction. Coulometry at −0.8 V, corresponding to the second wave, revealed the overall electrode reaction is a two-electron reaction, and as the result of the electrolysis, a highly red colored solution of formazan anion (TF^-) was obtained as shown in Fig. 2c. From these results, the following stepwise electron transfer reactions are given.

$$TT^+ + e \rightleftarrows TT\cdot \quad (1)$$

$$TT\cdot + e \rightarrow TF^- \quad (2)$$

When the coulometry at −0.55 V, carried out for an attempt to obtain a solution of tetrazolinyl radical (TT·), was brought to completeness, two electrons, contrary to the probable one electron, were found to be transferred per molecule of TTC. The resulted solution gave no ESR signal and gave exactly the same absorption spectrum as that of TF^-. However, when the electrolysis was interrupted half-way, the ESR spectrum of 2,3,5-triphenyl tetrazolinyl radical[10,11,15] was obtained as shown in Fig. 3, irrespective of the electrolysis potential being either −0.55 V or −0.8 V. The same radical was also generated when TTC was added to a solution containing TF^- alone. These results suggest that the following disproportionation reaction of TT· is operating in the solution.

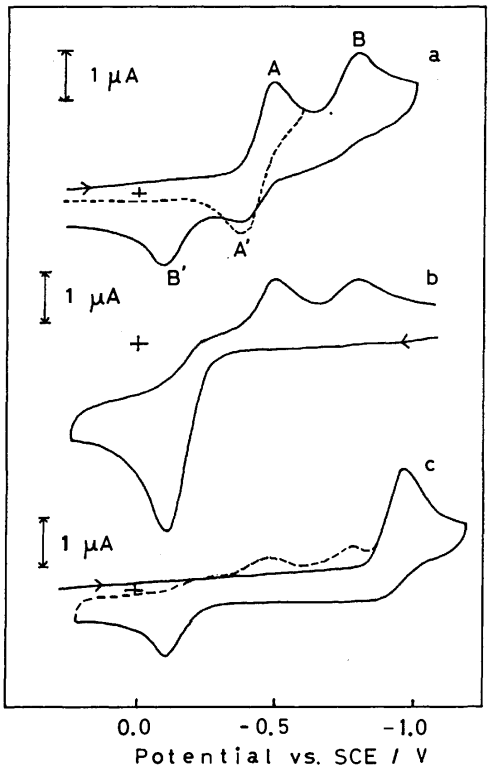

Fig. 1. Cyclic voltammograms of (a) TT^+, (b) TF^- generated by electrochemical reduction of TT^+, and (c) TF. The concentration of depolarizers is 2.5×10^{-4} mol dm^{-3} in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 V s^{-1}.

$$2\,TT\cdot \rightleftarrows TT^+ + TF^- \quad (3)$$

Although the monitoring of the concentration of TT· or TF^- following the controlled potential electrolysis was unsuccessful because the radical disproportionated rapidly, the disproportionation was appreciable on the cyclic voltammetry. As the half-life of the disproportionation reaction is dependent on the concentration of the radical, the cyclic voltammogram of TT^+ was affected by both the scan rate and the concentration of the depolarizer. In order to determine the rate constant of the disproportionation reaction, a series of cyclic voltammograms were taken by carrying out the potential reversal at −0.6 V, immediately after the first cathodic wave. At sufficiently high scan rate (over 0.2 V s^{-1} for a solution containing 1.0×10^{-3} M of TT^+; 1M=1 mol dm^{-3}) or at sufficiently low concentration of the depolarizer (5×10^{-4} M TT^+ at a scan rate of 0.05 V s^{-1}) only the anodic peak of TT·(A′) was observed. With the increase of the length of the time of the potential hold at −0.6 V as well as with the increase of the concentration of the depolarizer or the decrease of the scan rate, the anodic peak of TF^-(B′) increased in hight with the consumption of the anodic peak of TT·. The rate constant of the disproportionation reaction was estimated to be 2.5×10^2 mol^{-1}s^{-1} by the method of Ohmstead and Nicholson.[17]

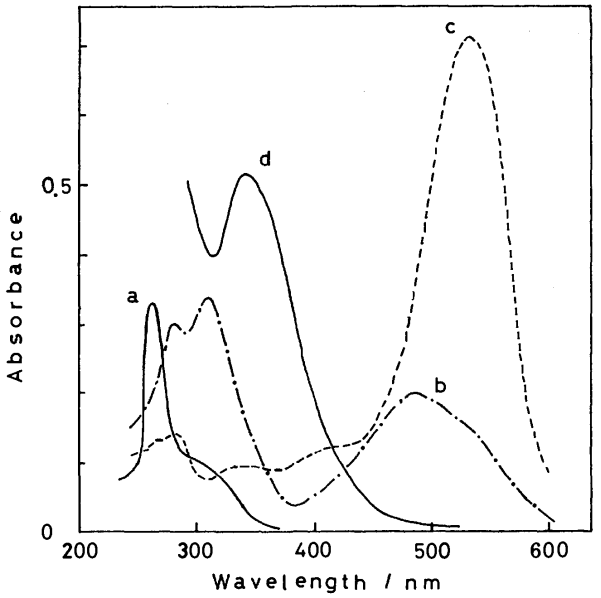

Fig. 2. Absorption spectra of (a) TT^+; 1×10^{-5} mol dm^{-3} in DMSO, (b) TF; 1×10^{-5} mol dm^{-3} in DMSO, (c) TF^- in DMSO generated by electrochemical reduction of TT^+, and (d) TT· generated by the reaction of TF^- with TT^+ in DMSO-benzene mixture (DMSO: benzene=80:20 in volume).

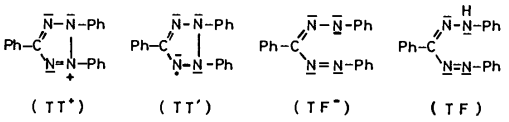

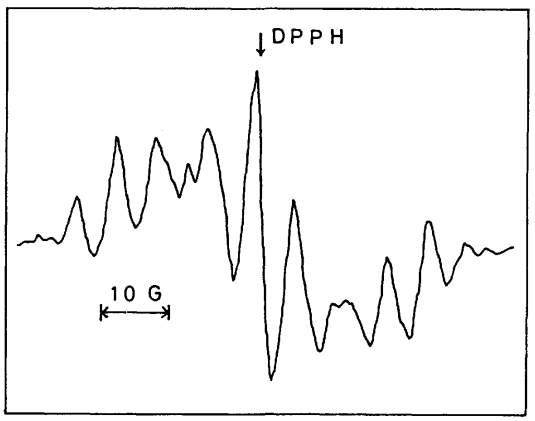

Fig. 3. ESR spectrum of TT· generated by electrochemical reduction of TT^+ in DMSO.

On the absorption spectrum, any band attributable to the radical was not observed. However, when benzene and TTC were added, the color of the solution turned from red to yellow and a new absorption band appeared at 345 nm with the consumption of the absorption band of TF^- as shown in Fig. 2d. The yellow colored solution gave a strong ESR spectrum of TT·. Thus the absorption band at 345 nm was attributed to TT·. This band was gradually substituted by that of TF^- with the increase of the content of DMSO in the DMSO-benzene mixture. The equili-

brium constant of the disproportionation reaction given by Eq. 3 was estimated to be ca. 5×10^2 in pure DMSO.

The cyclic voltammogram of formazan anion TF^-, shown in Fig. 1b, exhibited two cathodic waves at potentials quite close to those of TT^+, indicative of the regeneration of TT^+ by electrochemical oxidation of TF^-. The coulometry of TF^- at +0.2 V revealed the electrode process is a two-electron oxidation, and the original TT^+ was confirmed to be recovered in high efficiency as follows.

$$TF^- - 2e \rightarrow TT^+ \quad (4)$$

The formazan anion TF^- was stable in anhydrous DMSO, but when proton donors—water and acids, such as benzoic acid and acetic acid—were added, TF^- was protonated as follows.

$$TF^- + H^+ \rightarrow TF \quad (5)$$

The cyclic voltammogram of 1,3,5-triphenylformazan (TF) is given in Fig. 1c. The coulometry at −1.0 V revealed TF is reduced to TF^- by a one-electron reaction as follows.

$$TF + e \rightarrow TF^- + H \quad (6)$$

The reaction paths of TTC are summarized in Scheme 1.

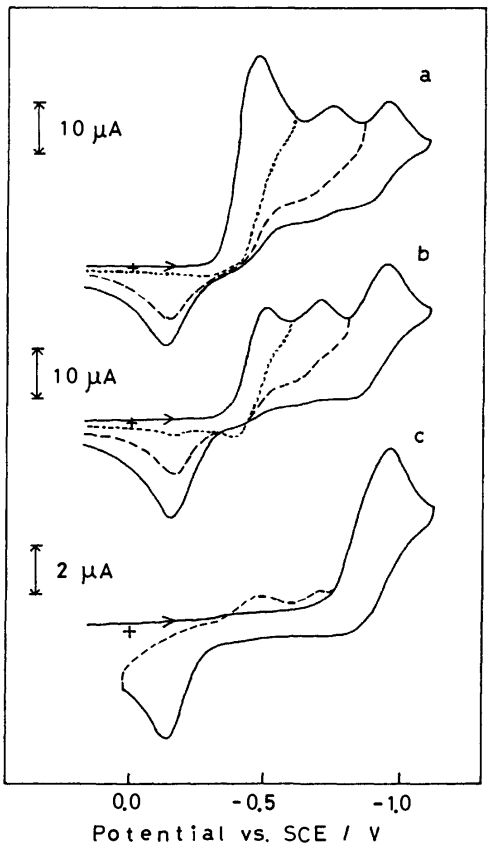

Fig. 4. Cyclic voltammograms of (a) NT^{2+} (1×10^{-3} mol dm^{-3}), (b) $NTMF^+$ (1×10^{-3} mol dm^{-3}), and (c) NTDF (saturated) in DMSO (containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 V s^{-1}.

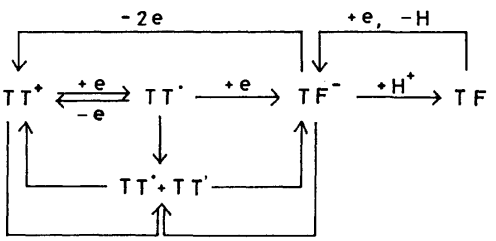

Scheme 1. Reaction paths of TT^+.

Reduction of NT and Its Formazans. Since NT^{2+} is a ditetrazolium ion having a molecular structure composed of two equivalent TT^+, the reaction paths clarified for TT^+ and TF provide the basis for understanding the complicated redox behaviors of NT^{2+} and its formazans. The cyclic voltammograms and absorption spectra of NT^{2+}, NT-monoformazan ($NTMF^+$), and NT-diformazan(NTDF) are given in Figs. 4—6.

As $NTMF^+$ has a molecular structure composed of one teterazolium ring and one formazan moiety, the cyclic voltammogram of $NTMF^+$ revealed the characteristics of both structures. By referring to the cyclic voltammograms of TT^+ and TF, the first and the

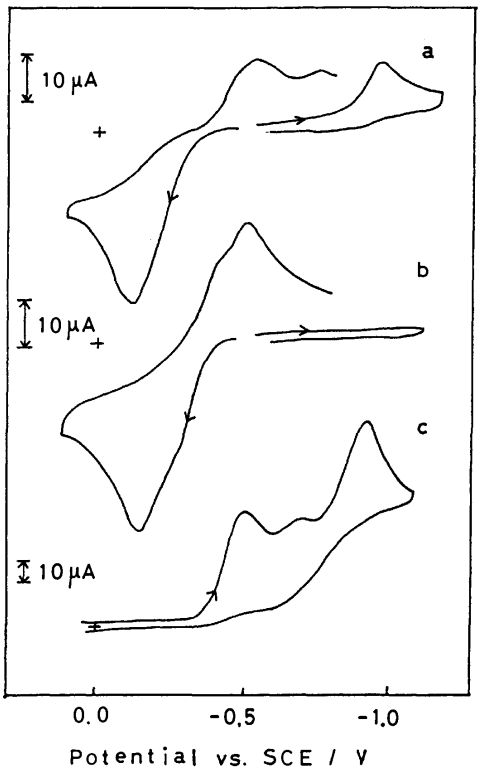

Fig. 5. Cyclic voltammograms of (a) the solution obtained by the exhaustive electrolysis of NT^{2+} at −0.55 V, (b) $NTDF^{2-}$ generated by the reaction of NTDF with tetraethylammonium hydroxide (TEAOH), (c) NT^{2+} in the presence of equimolar amount of acetic acid. The concentration of depolarizers is 1×10^{-3} mol dm^{-3} in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 V s^{-1}.

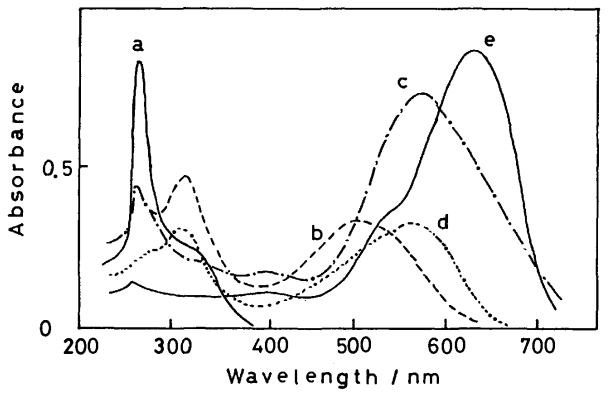

Fig. 6. Absorption spectra of (a) NT^{2+}, (b) $NTMF^+$, (c) NTMF, (d) NTDF, and (e) $NTDF^{2-}$. The concentration is 1.5×10^{-5} mol dm^{-3} in DMSO. The range of absorbance of (d) and (e) is 1/2.

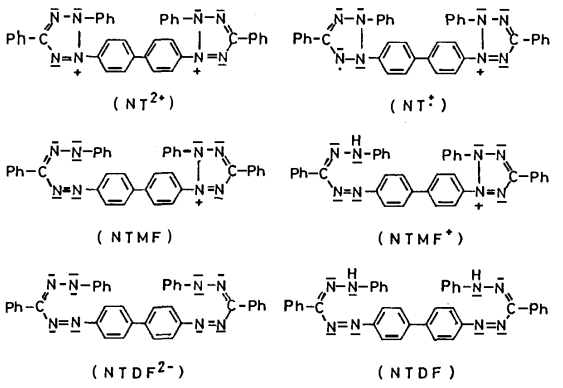

second cathodic waves were attributed to the reduction of the tetrazolium ring. The third wave agreed with the reduction wave of TF.

NTDF exhibited only one cathodic wave at a potential quite close to that of TF, suggesting that there is no or little difference in the potential required for the reduction of any formazan structure in TF, $NTMF^+$, or NTDF. In the presence of base, NTDF dissociated to generate $NTDF^{2-}$, and the cathodic wave of NTDF disappeared as shown in Fig. 5b.

By analogy with $NTMF^+$ the first and the second wave of NT^{2+} were attributed to the reduction of the tetrazolium ring. It is seen that there is no or little difference in the reduction potentials of the mono- and ditetrazolium ions. The observation of the third wave of NT^{2+} indicates the formazan anion of NT is more easily protonated than TF^-. In the presence of proton donor, the formazan peak of NT^{2+} increased in height and the anodic peak of formazan anion disappeared by the protonation reaction as shown in Fig. 5c.

When the coulometry of $NTMF^+$ at -0.55 V, corresponding to the first wave, was completed, overall two electrons were transferred per molecule of $NTMF^+$ as in the case of TT^+. The resulted solution was deep purplish colored. By addition of acids, the solution gave an absorption spectrum of NTDF (λ_{max}=558 nm) as shown in Fig. 6d. These results indicate the reaction paths given by Eqs. 1—5 are exactly working in the reduction of the one-sided tetrazolium moiety of $NTMF^+$ as follows.

$$NTMF^+ + e \rightleftarrows NTMF\cdot \quad (7)$$

$$2\,NTMF\cdot \rightleftarrows NTMF^+ + NTDF^- \quad (8)$$

$$NTDF^- + H^+ \rightarrow NTDF \quad (9)$$

Due to the disproportionation reaction of the tetrazolinyl radical (Eq. 8), the anodic peaks of the cyclic voltammogram of $NTMF^+$ were affected by both the scan rate and the concentration of the depolarizer as in the case of TT^+. The rate constant of the disproportionation reaction was estimated to be 2×10^3 mol^{-1} s^{-1}.

When the constant potential electrolysis of NT^{2+} at -0.55 V was interrupted at the early stage of the electrolysis, the absorption spectrum of NTMF (λ_{max}=570 nm) and an ESR spectrum quite similar to that of TT· were obtained. These species turned to $NTMF^+$ (λ_{max}=500 nm) by addition of acid. These experimental results suggest the reaction paths leading to $NTMF^+$ from NT^{2+} must be the disproportionation reaction of the one-sided tetrazolinyl radical as follows.

$$NT^{2+} + e \rightleftarrows NT^{\ddagger} \quad (10)$$

$$2\,NT^{\ddagger} \rightleftarrows NT^{2+} + NTMF \quad (11)$$

$$NTMF + H^+ \rightarrow NTMF^+ \quad (12)$$

The rate constant of the disproportionation reaction was estimated to be 3×10^3 mol^{-1}s^{-1} by the cyclic voltammetry. As NT^{2+} is a ditetrazolium ion, the generation of a biradical seems to be possible. However, the ESR measurement showed the presence of only one radical species which did not show any line broadening characteristic of the biradical.[15] Such a biradical may be unstable, if existent, since following electron transfer reaction is probable as $NT^{\ddagger}$ must be more stable than NT:.

$$NT^{2+} + 2e \rightarrow NT: \xrightarrow{NT^{2+}} 2\,NT^{\ddagger} \quad (13)$$

When the coulometry of NT^{2+} at the first wave was brought to completeness, the overall reaction was found to be a four-electron reaction. The reaction products were $NTDF^{2-}$ (λ_{max}=626 nm) and its formazans as shown in Fig. 5a. By addition of acid, NTDF (λ=558 nm) was obtained. The generation of diformazan at the first wave suggests the reduction of the residual one-sided tetrazolium ring of NTMF must follow the reactions shown by Eqs. 10 and 11 as follows.

$$NTMF + e \rightleftarrows NTMF^{\cdot-} \quad (14)$$

$$2\,NTMF^{\cdot-} \rightleftarrows NTMF + NTDF^{2-} \quad (15)$$

$$NTDF^{2-} + 2\,H^+ \rightarrow NTDF \quad (16)$$

When NT^{2+} was added into the solution of $NTDF^{2-}$, NTMF was generated. Accordingly, the following disproportionation reaction is also working in the solution.

$$2\,NTMF \rightleftarrows NT^{2+} + NTDF^{2-} \quad (17)$$

As the reduction potential of the one-sided tetrazolium ring of NTMF is almost the same with that of NT^{2+}, the reactions shown by Eqs. 14—17 will occur in parallel with those given by Eqs. 10—13. As the disproportionation reaction given by Eq. 17 is advantageous for the generation of NTMF at high concentration of NT^{2+}, the preferencial generation of monoformazan was observed at the early stage of electrolysis, but the simultaneous generation of both formazans became remarkable on proceeding the electrolysis.

$NTMF^+$ and NTDF gave $NTDF^{2-}$ by the constant potential electrolysis at −1.0 V.

$$NTMF^+ + 3e - H \rightarrow NTDF^{2-} \quad (18)$$

$$NTDF + 2e - 2H \rightarrow NTDF^{2-} \quad (19)$$

As shown above, the complicated reactions of NT^{2+} is considered to be composed of the combination of the fundamental reactions characteristic of the single tetrazolium ion.

Reduction of BT and Its Formazans. BT^{2+} has a molecular structure in which two methoxy groups are introduced into the biphenyl structure of NT^{2+}. The present study was focused on how the fundamental reactions of NT^{2+} are modified by the introduction of methoxy group.

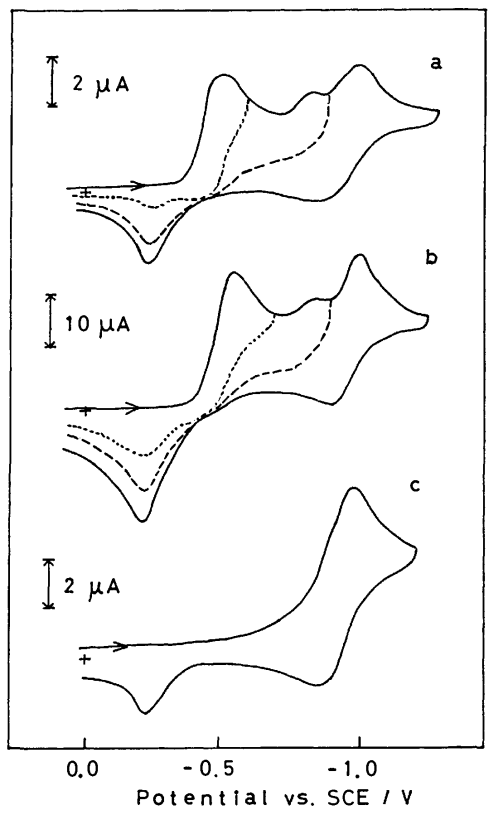

Fig. 7. Cyclic voltammograms of (a) BT^{2+} (saturated -2×10^{-4} mol dm^{-3}), (b) $BTMF^+$ (1×10^{-3} mol dm^{-3}), and (c) BTDF (saturated) in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 V s^{-1}.

The cyclic voltammograms and the absorption spectra of BT^{2+} and its reaction products are given in Figs. 7 and 8. By referring to the results obtained for NT^{2+}, the first two cathodic waves on the cyclic voltammograms of BT^{2+} and $BTMF^+$ were attributed to the reduction of the tetrazolium ring and the third wave to the reduction of the formazan moiety. The anodic wave was attributed to the oxidation of the formazan anion.

The constant potential electrolysis revealed BT^{2+} is reduced to $BTMF^+$ (λ_{max}=540 nm) by a two-electron reaction and to BTDF (λ_{max}=608 nm) by a four-electron reaction at the first cathodic wave. BTDF was reduced to $BTDF^{2-}$ (λ_{max}=640 nm) at −1.0 V, and $BTDF^{2-}$ reacted with BT^{2+} to give BTMF by a disproportionation reaction analogous to Eq. 17.

From these results, it is likely that the reaction paths of BT^{2+} are exactly analogous to those of NT^{2+} given by Eqs. 7—19, indicative of no effect of the methoxy group.

Reduction of NBT and Its Formazans. The cyclic voltammograms and the absorption spectra of NBT^{2+} and its reduction products are given in Figs. 9 and 10.

As $NBTMF^+$ has one tetrazolium structure and one formazan structure, the cyclic voltammogram of $NBTMF^+$ shown in Fig. 9b is well understood by

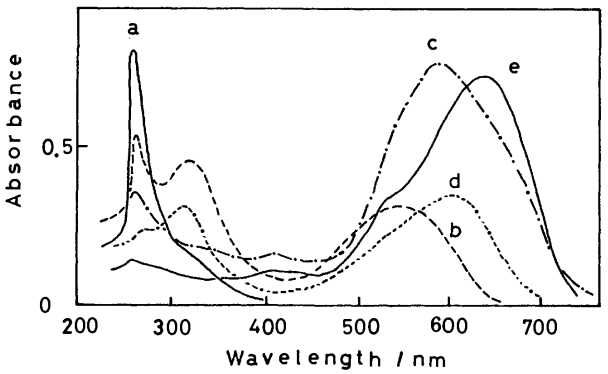

Fig. 8. Absorption spectra of (a) BT^{2+}, (b) $BTMF^+$, (c) BTMF, (d) BTDF, and (e) $BTDF^{2-}$. The concentration is 1.5×10^{-5} mol dm^{-3} in DMSO. The range of absorbance of (d) and (e) is 1/2.

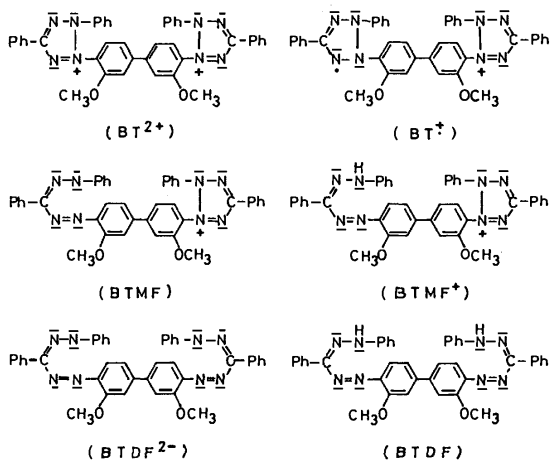

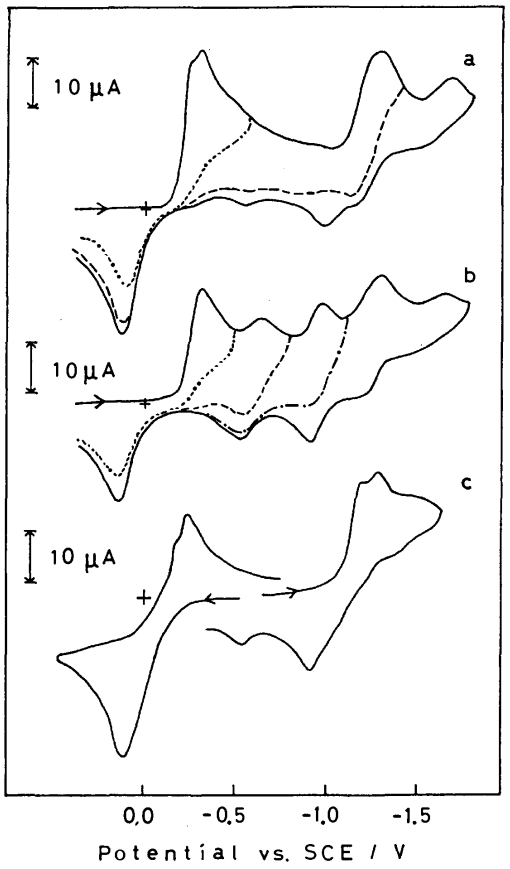

Fig. 9. Cyclic voltammograms of (a) NBT^{2+}, (b) $NBTMF^{+}$, and (c) $NBTDF^{2-}$ generated by the reaction of NBTDF with TEAOH. The concentration of depolarizers is 1×10^{-3} mol dm^{-3} in DMSO containing 0.1 mol dm^{-3} TEAP. Scan rate: 0.05 V s^{-1}.

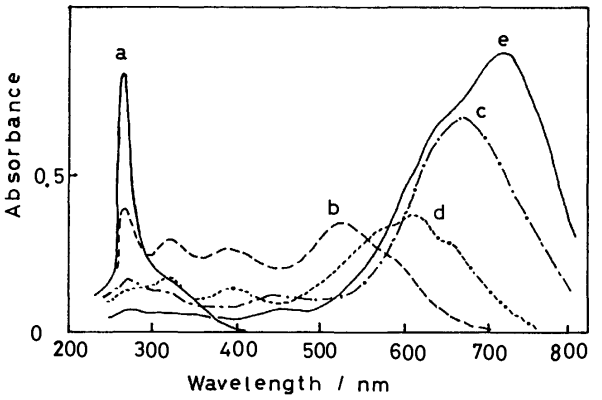

Fig. 10. Absorption spectra of (a) NBT^{2+}, (b) $NBTMF^{+}$, (c) NBTMF, (d) NBTDF, and (e) $NBTDF^{2-}$. The concentration is 1.5×10^{-5} mol dm^{-3} in DMSO. The range of absorbance of (d) and (e) is 1/2.

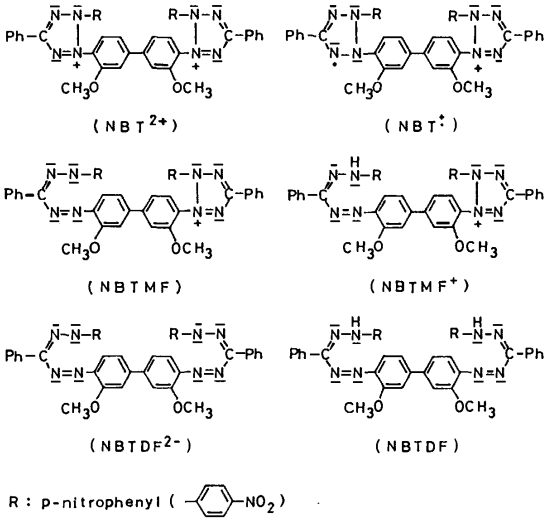

analogy with that of $NTMF^{+}$. The first and the second cathodic waves were characterized to the reduction of the tetrazolium ring, the third wave to the reduction of the formazan structure and the rests to the reduction of the nitro group, since nitrobenzene derivatives gave reduction waves around these potentials.

The coulometry at the first wave revealed that $NBTMF^{+}$ was reduced to $NBTDF^{-}$ (λ_{max}=709 nm) by a two-electron reaction. The reaction paths leading to $NBTDF^{-}$ from $NBTMF^{+}$ are considered to be similar to those of $NTMF^{+}$ shown by Eqs. 7—9. The rate constant of the disproportionation reaction of the tetrazolinyl radical was estimated to be 5×10^{3} mol^{-1} s^{-1} by cyclic voltammetry. The reduction of $NBTMF^{+}$ at the third wave gave $NBTDF^{2-}$ (λ_{max}=724 nm). $NBTDF^{-}$ and $NBTDF^{2-}$ thus generated gave NBTDF (λ_{max}=600 nm) by addition of acid. NBTDF is insoluble not only in DMSO but also in usual organic solvent, such as ethanol, benzene, ether, acetonitrile, and *N,N*-dimethylformamide. However, the DMSO solution of NBTDF appeared to be homogeneous immediately after being shaken with the ultrasonic vibrator, and gave a reproducible absorption spectrum as shown in Fig. 10d. Although the reduction potential of NBTDF could not be determined, the electrolysis of NBTDF was performed at −1.0 V, a potential now specified to be characteristic of the reduction of the formazan structure. Nitrogen purged through the solution for the deaeration secured the continuous contact of NBTDF particle with the Pt mesh electrode. The current density was low, but as the result of the electrolysis, a sky blue solution of $NBTDF^{2-}$ was obtained. $NBTDF^{2-}$ gave a cyclic votammogram as shown in Fig. 9c. The reduction waves at ca. −1.2 V are due to the nitro group. By the electrolysis at +0.2 V, $NBTDF^{2-}$ was oxidized to NBT^{2+}.

The cyclic voltammogram of NBT^{2+} is given in Fig. 9a. By analogy with $NBTMF^{+}$, the first cathodic wave was attributed to the reduction of the tetrazolium ring and the rests to the reduction of the nitro group. The small shoulder at the first wave may discriminate the small difference in the potential of the generation of mono- or ditetrazolinyl radical, but the waves corresponding to the second and the third waves exhibited for NT^{2+} and BT^{2+} were not observed.

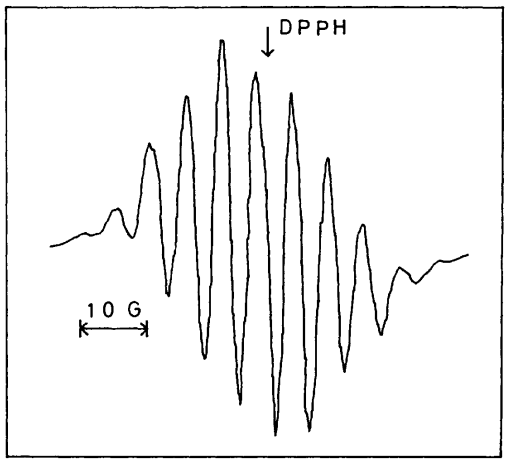

Fig. 11. ESR spectrum of the tetrazolinyl radical generated by electrochemical reduction of NBT^{2+}.

At the early stage of the constant potential electrolysis at −0.4 V, NBT^{2+} gave NBTMF (λ_{max}=680 nm) and a tetrazolinyl radical NBT^{+} which gave an ESR spectrum as shown in Fig. 11. The ESR spectrum with nine line hyperfine structure is characteristic of the tetrazolinyl monoradical, and the biradical of NBT was not evidenced as in the case of NT. The rate constant of the disproportionation reaction of the tetrazolinyl radical was evaluated to be 5×10^3 $mol^{-1}s^{-1}$ by the cyclic voltammetry. By addition of acids, both the ESR spectrum and the absorption spectrum of NBTMF disappeared and the absorption spectrum of $NBTMF^+$ (λ_{max}=530 nm) was obtained.

When the constant potential electrolysis at the first wave was completed, NBT^{2+} was reduced to $NBTDF^{2-}$ by a four-electron reaction. $NBTDF^{2-}$ was stable in anhydrous DMSO and accordingly the cyclic voltammogram of NBT^{2+} did not exhibit any formazan wave. When NBT was added into the solution of $NBTDF^{2-}$, NBTMF was generated by a disproportionation reaction analogous to that shown by Eq. 17.

The reaction scheme shown for NBT^{2+} is exactly understood by reaction paths given by Eqs. 10—19, suggesting no affect of both nitro- and methoxy groups on the fundamental reactions characteristic of the tetrazolium structure.

Summary

Ditetrazolium salts were first reduced to half-reduced monoformazans and successively to fully-reduced diformazans. In both reaction stages, the key reaction leading to the generation of each formazan was the disproportionation reaction of the tetrazolinyl radical generated by one-electron reduction of the tetrazolium structure. As there was almost no difference in the potential required for the generation of tetrazolinyl radical from mono- or ditetrazolium ion, the simultaneous generation of mono- and diformazans appears to be a general feature of the reduction of any ditetrazolium salts. It was only at the early stage of the electrolysis that the half-reduced monoformazan was preferencially generated. In the analytical use of ditetrazolium salts, it was only when the reductant was very weak[2] or the tetrazolium salts existed in vast molar excess over the reductant[4] that the preferential generation of monoformazan secured the quantitative use of the ditetrazolium salts. Otherwise, the separated amount of mono- and diformazan should be determined[3] for the successful application of the tetrazolium method.

The author thanks to Dr. Ryo Hirasawa for his kind permission of using the ESR spectrometer.

(Received May 12, 1989)

The *fac*-$[Rh(edmp)_3]^{3+}$ (edmp=(2-aminoethyl)dimethylphosphine), *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]^+$, and *trans*-$[RhCl_2(dmpe)_2]^+$ (dmpe=1,2-bis(dimethylphosphino)ethane) complexes were prepared and the molecular structures were determined by the single crystal X-ray diffraction method. Crystal data and final R values are: *fac*-$[Rh(edmp)_3]Br_3 \cdot 3H_2O$, orthorhombic, $Pna2_1$, a=26.750(4), b=10.125(1), c=9.592(1) Å, V=2598.2(5) Å^3, Z=4, R=0.039 for 1590 observed unique reflections. *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]PF_6$, monoclinic, $P2_1/a$, a=18.197(4), b=12.574(2), c=8.615(1) Å, β=96.59(2)°, V=1958.2(6) Å^3, Z=4, R=0.032 for 3379 reflections. *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]ClO_4$, triclinic, $P\bar{1}$, a=13.122(2), b=17.952(2), c=12.343(2) Å, α=91.65(2), β=102.46(2), γ=80.74(1)°, V=2802.0(7) Å^3, Z=6, R=0.070 for 7513 reflections. *trans*-$[RhCl_2(dmpe)_2]CF_3SO_3$, monoclinic, $P2_1/a$, a=13.166(2), b=24.337(4), c=8.002(2) Å, β=95.95(2)°, V=2550.1(8) Å^3, Z=4, R=0.040 for 3201 reflections. It was found that the shorter the Rh-P bond length, the larger the trans Rh-N bond elongation. The mean Rh-P bond distance in *trans*-$[RhCl_2(dmpe)_2]CF_3SO_3$ (2.337(2) Å) is longer than those in *fac*-$[Rh(edmp)_3]Br_3 \cdot 3H_2O$ (2.283(4) Å) and *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]PF_6$ (2.252(2) Å). A series of complexes of *trans*(*X,X*),*cis*(*P,P*)-$[RhX_2(edmp)_2]^+$ (X=Cl, Br, I) and *trans*-$[RhX_2(dmpe)_2]^+$ (X=Cl, Br) were also prepared and their absorption spectra were compared with one another and with those of the corresponding cobalt(III) complexes.

In a previous paper,[1] we reported the preparation of trans(*Cl,Cl*),cis(*P,P*) and cis(*Cl,Cl*),trans(*P,P*) isomers of $[RhCl_2(edpp)_2]^+$, where edpp denotes (2-aminoethyl)diphenylphosphine. The X-ray analyses of the complexes revealed the trans influence of P donor atoms on the Rh-N and Rh-P bond lengths. (2-Aminoethyl)dimethylphosphine (edmp) has less bulky substituents on the phosphorus atom than does edpp, and it is interesting to see the steric and electronic effects of the substituent on P on such properties as trans influence.

This paper describes the preparation and X-ray structure analyses of *fac*-$[Rh(edmp)_3]^{3+}$, *trans*-(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]^+$, and the related *trans*-$[RhCl_2(dmpe)_2]^+$ complex. A series of complexes of *trans*(*X,X*),*cis*(*P,P*)-$[RhX_2(edmp)_2]^+$ (X=Cl, Br, I) and *trans*-$[RhX_2(dmpe)_2]^+$ (X=Cl, Br) were also prepared and their absorption spectra were compared with one another and with those of the corresponding cobalt(III) complexes.

Experimental

The edmp[2] and dmpe[3] ligands were prepared according to literature methods, and handled under an atmosphere of nitrogen until they formed air-stable rhodium(III) complexes. Absorption, and ^1H and ^{13}C NMR spectra were recorded on a Hitachi 323 spectrophotometer and a Hitachi R-90H spectrometer, respectively.

Preparation of Complexes. ***fac*-$[Rh(edmp)_3]Cl_3 \cdot 4H_2O$.** A deaerated ethanol solution (10 cm^3) of $RhCl_3 \cdot 3H_2O$ (0.40 g, 1.52 mmol) was heated to reflux. To this solution was added a deaerated ethanol solution (7 cm^3) of edmp (0.74 g, 7 mmol). The mixture was refluxed for 12 h to give a yellow solution together with a white crystalline solid. The mixture was allowed to cool in an ice bath, and the white crystals were collected by filtration. The crude product was dissolved in water (2 cm^3) and filtered. The filtrate was heated and poured into boiling ethanol (25 cm^3). The mixture was allowed to stand at room temperature for a while, and then in a freezer overnight to yield white crystals. They were collected by filtration, washed successively with ethanol and diethyl ether, and air dried. Yield: 0.50 g (55%). Found: C, 24.03; H, 7.19; N, 7.05; Cl, 17.94%. Calcd for $[Rh(edmp)_3]Cl_3 \cdot 4H_2O = C_{12}H_{44}N_3Cl_3O_4P_3Rh$: C, 24.16; H, 7.43; N, 7.04; Cl, 17.82%. Thermogravimetry: loss of weight 127 mg/g sample, i.e. 76.2 g mol^{-1}. Calcd for $[Rh(edmp)_3]Cl_3 \cdot 4H_2O$: 72.1 g mol^{-1}. ^1H NMR (D_2O) δ=1.75—2.05 (18H, four-line multiplet, CH_3), 2.10—2.55 (6H, m, CH_2P), and 2.6—3.5 (6H m, CH_2N). ^{13}C NMR (D_2O) δ=13.6 (six-line multiplet, CH_3), 15.2 (six-line multiplet, CH_3), 34.9 (six-line multiplet, CH_2P), and 42.1 (s, CH_2N). The complex is soluble in water and methanol.

***fac*-$[Rh(edmp)_3]Br_3 \cdot 3H_2O$ (1).** To an aqueous solution (1 cm^3) of *fac*-$[Rh(edmp)_3]Cl_3 \cdot 4H_2O$ (0.10 g, 0.17 mmol) was added a hot aqueous solution (3 cm^3) of NaBr (1.5 g). The solution was allowed to stand overnight for crystallization. The colorless crystals were collected by filtration and washed successively with ice-cold water, ethanol, and di-

ethyl ether and air dried. Yield: 0.10 g (84% based on the chloride). The structure of the complex was determined by X-ray analysis.

***mer*-[RhCl$_3${P(*n*-Bu)$_3$}$_3$].** Attempts to prepare the complex by the published methods[4,5] did not lead to any crystallization of the complex. The complex was prepared by a modified method of Intille.[5] A deaerated ethanol solution (10 cm^3) containing $RhCl_3 \cdot 3H_2O$ (0.94 g, 3.6 mmol) and tributylphosphine (4 cm^3, 16 mmol) was refluxed for 1.5 h to give an orange solution. The solvent was evaporated off under reduced pressure and the residual orange oil was dissolved in hexane (20 cm^3). The solution was then added to water (20 cm^3), and hexane was evaporated slowly (1—2 d) at room temperature. The orange crystals deposited were collected by filtration, washed thoroughly with water and dried in a desiccator over P_4O_{10}. Yield: 2.1 g (72%). Found: C, 52.25; H, 10.11%. Calcd for [RhCl$_3${P(*n*-Bu)$_3$}$_3$]=$C_{36}H_{81}Cl_3P_3Rh$: C, 52.92; H, 10.00%. The ^{1}H NMR spectrum was identical with that reported by Intille.[5]

***trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]PF$_6$ (2a).** To a deaerated stirred benzene solution (50 cm^3) of *mer*-[RhCl$_3${P(*n*-Bu)$_3$}$_3$] (1.63 g, 2.0 mmol) was added dropwise edmp (0.53 g, 5.0 mmol). The mixture was refluxed for 1 h to give a yellow precipitate. After cooling for a while, the precipitate was collected on a glass filter by filtration, washed with diethyl ether and dried in a desiccator over P_4O_{10}. The product (ca. 0.9 g) was hygroscopic, mixed with ethanol (50 cm^3), and the mixture was filtered to leave a small amount of white crystals on the filter. Yield: 0.04 g. This product was *fac*-[Rh(edmp)$_3$]Cl$_3$. The yellow filtrate was evaporated to nearly dryness under reduced pressure, and the residue was redissolved in water (50 cm^3). The solution was passed through a short column (ϕ1.0 cm×3 cm) of SP-Sephadex C-25 in order to remove highly charged species. The yellow eluate was applied on a column (ϕ2.5 cm×30 cm) of SP-Sephadex C-25. The adsorbed product was eluted with 0.05 mol dm^{-3} NaCl. The eluate containing the fastest-moving yellow main band was collected and evaporated to dryness under reduced pressure. The residue was shaken with ethanol (3×20 cm^3) to extract the complex, the solvent was evaporated to dryness under reduced pressure, and the residue was dissolved in water (10 cm^3). The solution was filtered, heated to 90 °C, and to this solution was added a saturated aqueous solution (4 cm^3) of NH_4PF_6. The mixture was allowed to stand at room temperature for a while, and then in a refrigerator overnight to yield yellow crystals. They were collected by filtration, washed successively with ethanol and diethyl ether, and dried in air. Yield: 0.30 g (28%). Found: C, 18.01; H, 4.63; N, 5.32; Cl, 13.27%. Calcd for [RhCl$_2$(edmp)$_2$]PF$_6$=$C_8H_{24}N_2Cl_2F_6P_3Rh$: C, 18.16; H, 4.57; N, 5.30; Cl, 13.40%. ^{1}H NMR ($C_6D_5NO_2$) δ=1.84—1.97 (12H, filled-in-doublet, CH_3), 2.15—2.6 (4H, m, CH_2P), 3.05—3.8 (4H, m, CH_2N), and 4.2—4.65 (4H, br, NH_2). ^{13}C NMR (CD_3CN) δ=10.9 (filled-in doublet, CH_3), 32.9 (filled-in doublet, CH_2P), and 40.8 (s, CH_2N). The complex is soluble in acetonitrile, dichloromethane, ethanol, and water. Single crystals suitable for X-ray analysis were obtained by slow evaporation of a methanol solution of the complex.

***trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]ClO$_4$ (2b).** An aqueous solution of *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]PF$_6$ (ca. 0.1 g) was applied on a column of SP-Sephadex C-25. The complex was eluted with 0.1 mol dm^{-3} NaCl, and the eluate was evaporated to dryness under reduced pressure. The complex was extracted with ethanol, and the solvent was evaporated. The residue was dissolved in water (5 cm^3) and to this solution was added a hot solution of $LiClO_4$ (2 g) in water (2 cm^3). The mixture was allowed to stand for crystallization. Single crystals for X-ray analysis were obtained by recrystallization from ethanol.

***trans*(*Br*,*Br*),*cis*(*P*,*P*)-[RhBr$_2$(edmp)$_2$]PF$_6$.** This complex was prepared from *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]PF$_6$ and KBr. To a hot aqueous solution (12 cm^3) of *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]PF$_6$ (0.1 g, 0.19 mmol) was added a large excess of KBr (5 g, 42 mmol), and the mixture was refluxed for 20 h. The solution was evaporated to dryness under reduced pressure, and the residue was shaken with acetonitrile (ca. 60 cm^3) to extract the products until the extracts were colorless. The combined extracts were evaporated to dryness under reduced pressure. The residue was dissolved in water (60 cm^3) and the solution was applied on a column (ϕ2.5 cm ×15 cm) of Sp-Sephadex C-25. By elution with 0.05 mol dm^{-3}KBr, two yellow bands developed, the slower-moving one remaining almost at the top of the column. The eluate containing the faster-moving band was collected and evaporated to dryness under reduced pressure. The residue was extracted repeatedly with acetonitrile, and the solvent was removed under reduced pressure. The residue was dissolved in boiling water (10 cm^3), and to this solution was added a solution of NH_4PF_6 (0.5 g) in water (2 cm^3). The mixture was allowed to stand first at room temperature and then overnight in a refrigerator to yield yellow crystals. They were collected by filtration, washed successively with ice-cold water and diethyl ether, and dried in air. Yield: 0.05 g (43%). Found: C, 15.57; H, 3.89; N, 4.53%. Calcd for [RhBr$_2$(edmp)$_2$]PF$_6$=$C_8H_{24}N_2Br_2F_6P_3Rh$: C, 15.55; H, 3.91; N, 4.53%.

***trans*(*I*,*I*),*cis*(*P*,*P*)-[RhI$_2$(edmp)$_2$]PF$_6$.** This complex was prepared in a similar method to that for the dibromo complex, NaI in ethanol being used instead of KBr and dichloromethane as the extraction solvent. The product was purified by SP-Sephadex C-25 column chromatography (eluent: 0.05 mol dm^{-3} NaI). Yield: 0.06 g (44%, reddish needles). Found: C, 13.49; H, 3.38; N, 3.95%. Calcd for [RhI$_2$(edmp)$_2$]PF$_6$=$C_8H_{24}N_2F_6I_2P_3Rh$: C, 13.50; H, 3.40; N, 3.94%.

***trans*-[RhCl$_2$(dmpe)$_2$]CF$_3$SO$_3$ (3).** To a deaerated, boiling ethanol solution (50 cm^3) of $RhCl_3 \cdot 3H_2O$ (0.54 g, 2.05 mmol) was added dropwise dmpe (0.8 g, 5.3 mmol). The mixture was refluxed for 2 h to give a yellow solution together with a small amount of brownish precipitate. After cooling to room temperature, the mixture was filtered, and the filtrate was evaporated to dryness under reduced pressure. The yellow residue was washed with diethyl ether and was dissolved in water (50 cm^3). The solution was filtered, and the filtrate was applied on a column (ϕ 2.5 cm×30 cm) of SP-Sephadex C-25. The rest of the procedure was the same as that for *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]PF$_6$ except that $NaCF_3SO_3 \cdot H_2O$ was used instead of NH_4PF_6 for crystallization. Yield: 0.38 g (30%). Found: C, 24.96; H, 5.23; Cl, 11.46; S, 5.82%. Calcd for [RhCl$_2$(dmpe)$_2$]CF$_3$SO$_3$=$C_{13}H_{32}Cl_2F_3O_3SP_4Rh$: C, 25.06; H, 5.18; Cl, 11.38; S, 5.14%. ^{1}H NMR ($C_6D_5NO_2$) δ=1.65—1.90 (24H, b, CH_3) and 2.0—2.4 (8H, m, CH_2). The complex is soluble in acetonitrile, acetone, ethanol, and methanol, and slightly soluble in water. Yellow needle-like crystals grown from aqueous solution were used for X-ray analysis.

Table 1. Crystal Data, Experimental Conditions, and Refinement Details

	1	**2a**	**2b**	**3**

a) This parameter was used to define the origin of the unit cell along z and is listed without e.s.d.

***trans*-[RhBr$_2$(dmpe)$_2$]CF$_3$SO$_3$.** This complex was prepared from trans-[RhCl$_2$(dmpe)$_2$]CF$_3$SO$_3$ and KBr by the same method as that described for *trans*(*Br*,*Br*),*cis*(*P*,*P*)-[RhBr$_2$(edmp)$_2$]$^+$, and isolated as the trifluoromethanesulfonate. Yield: 39%. Found: C, 21.91; H, 4.58%. Calcd for [RhBr$_2$(dmpe)$_2$]CF$_3$SO$_3$=C$_{13}$H$_{32}$Br$_2$F$_3$O$_3$SP$_4$Rh: C, 21.93; H, 4.53%.

Crystal Structure Determination. Experimental conditions and refinement informations are listed in Table 1. For *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[RhCl$_2$(edmp)$_2$]$^+$, structure analysis of the PF$_6$ salt (**2a**) was also performed, because the structure of the ClO$_4$ salt (**2b**) could not be determined accurately ($P\bar{1}$, Z=6, R=0.070). Intensities were measured to 2θ=55° using graphite monochromatized Mo$K\alpha$ radiation (λ=0.71073 Å) on a Rigaku four-circle diffractometer AFC-5. The θ-2θ scan technique was employed at a scan rate of 6° min^{-1} in θ. Lattice constants were determined from 14—36 2θ values ($20<2\theta<30$). Absorption corrections were made by the numerical Gauss-integration method[6] for polyhedral crystals and by utilizing the correction factors[7] for a spherical sample. Systematic absences of **1** indicate that the space group is $Pna2_1$ (No. 33) or *Pnam* [acb setting of *Pnma* (No. 62)]. Since Z=4 and the complex cation is chiral, the space group was determined to be $Pna2_1$. The structure was difficult to solve because Rh and all Br atoms nearly lie on the glide plane at y=1/4 or y=3/4 (see Fig. 3). Position of the Rh atom was obtained from E map, and coordinated P and N atoms were located in the weighted Fourier synthesis. The structure of **2a** was solved by the heavy atom method. C(7) atom in the edmp ligand is disordered (see Fig. 5). The population parameters of two possible positions A and B were estimated to be 0.5. All the non-hydrogen atoms were refined anisotropically. The 7 hydrogen atoms among 36 in **1** and 11 among 30 in **2a** were located by the difference synthesis and others were calculated. Before the structure determination of **2a** was carried out, the structure of **2b** had been determined. The positions of the three independent Rh atoms obtained from the E map were confirmed by Patterson function. The other non-hydrogen atoms were located by Fourier syntheses. In order to reduce the number of parameters, C, N, and O atoms were refined isotropically and H atoms were not

included in the refinement. The structure of **3** was solved by Patterson-Fourier method. There exists structural disorder in the dmpe chelate rings (see Fig. 8). The thermal ellipsoids of the carbon atoms in the P-C-C-P moieties were unusually elongated perpendicular to the chelate ring with B_{eq} values 12—22 Å^2, and the five-membered chelate rings were almost flat with unrealistic C-C bond length of 1.30(1) Å. The split atom model was not introduced for this complex, because several possible conformations could be assigned to the five-membered rings and appropriate positions of the methyl groups corresponding to each conformation should be taken into account. Such a procedure would lead to equivocal results. Fortunately, the positions of the P atoms do not seem to be affected severely by the disorder. Complex neutral-atom scattering factors were used.[8] The calculations were carried out on a FACOM M380R computer at Keio University with the computation program system UNICS-III.[9] The function, $\sum w||F_o|-|F_c||^2$ was minimized by block-diagonal least squares. The final atomic parameters are listed in Table 2 and the bond lengths and bond angles within the complex cations in Table 3.[10]

a) These short distances are unrealistic (see text).

Results and Discussion

fac-**[Rh(edmp)$_3$]$^{3+}$**. The addition of an excess of edmp to rhodium(III) chloride in ethanol yielded [Rh(edmp)$_3$]Cl$_3$. The complex was also obtained as a by-product in the preparation of [RhCl$_2$(edmp)$_2$]$^+$ from *mer*-[RhCl$_3${P(*n*-Bu)$_3$}$_3$] and edmp in benzene. The geometrical configuration of [Rh(edmp)$_3$]$^{3+}$ is assigned on the basis of the ^{13}C NMR spectrum. The complex in D_2O shows one, one, and two kinds of resonances for the NCH_2, PCH_2, and CH_3 groups, respectively. Thus the complex can be assigned to the fac(C_3) configuration, and the assignment was confirmed by the X-ray structure determination (vide infra). Figure 1 compares the absorption spectrum of *fac*-[Rh(edmp)$_3$]$^{3+}$ with that of *fac*-[Co(edmp)$_3$]$^{3+}$ [2] and the data are given in Table 4. The lowest-energy absorption band at 37300 cm^{-1} of the rhodium(III) complex can be assigned to the first d-d absorption band, $^1A_{1g}\rightarrow{}^1T_{1g}(O_h)$. The band is at higher energy by 13600 cm^{-1} than the corresponding band of the cobalt(III) complex. The ratio of postions ($\tilde{\nu}_{Rh}/\tilde{\nu}_{Co}$) of the first absorption band for the complexes is 1.57. It should be noted that the value is very close to the spectrochemical parameter for rhodium(III), 1.56 given by Shimura (the parameter for cobalt(III) is 1.00).[11] The second d-d absorption band, $^1A_{1g}\rightarrow{}^1T_{2g}(O_h)$ of *fac*-[Rh(edmp)$_3$]$^{3+}$ is hidden by the charge-transfer bands. The strong band at 47400 cm^{-1} may be assigned to the Rh-P charge-transfer transition, since such a strong band is not observed for [Rh(en)$_3$]$^{3+}$ [2] (en=ethylenediamine) in this region.

(1)

Fig. 2. A perspective view of *fac*-[Rh(edmp)$_3$]$^{3+}$ (**1**) and edge-on views of the five-membered edmp chelate rings.

mate C_3 symmetry, and the P atoms are arranged in a facial manner as expected from the ^{13}CNMR spectrum. The C-C bonds in the chelate rings are nearly parallel to the pseudo-C_3 axis of the complex ion, and the complex can be designated as the lel_3 isomer. Three methyl groups C(1), C(5), and C(10) are disposed nearly parallel to the pseudo-C_3 axis. The short nonbonded C···C, C···H, and H···H distances among these methyl groups are 3.60(2)—3.70(2), 2.94(14)—3.03(14), and 2.33(17)—2.45(17) Å, respectively. The H···H repulsions are released by adjusting the mutual disposition of C-H bonds in the methyl groups. Such a crowded structure seems to be responsible for a distorted gauche conformation of the two edmp chelate rings (Fig. 2). In *fac*-Λ-$[Co(edmp)_3]^{3+}$, all three chelate rings take a pseudo (distorted) λ-gauche conformation.[2] The Rh-N distance averages 2.171(12) Å, which is significantly longer than that (2.062(7) Å) of $[Rh(en)_3]^{3+}$,[13] and that (2.076(4) Å) of lel_3-$[Rh(chxn)_3]^{3+}$ [14] (chxn=*trans*-1,2-cyclohexanediamine). The elongation of Rh-N distances can be attributed to the strong trans influence of the P donor atoms (vide infra). As seen from Fig. 3, the Br(3) atom lies approximately on the pseudo-C_3 axis of the complex cation of **1** to form three N-H···Br hydrogen bonds. The hydrogen bond distances are listed in Table 5.

Table 5. Intermolecular Hydrogen Bonds (distances in Å)[a]

A···H-B (symmetry code)	A···B	A···H	H-B
1			
Br(3)···H(N1)1-N(1) (iii)	3.441(11)	2.55(14)	0.97(14)

Br(3)···H(N3)1-N(3) (iii)	3.551(15)	2.61(15)	0.97(15)
O(2)···H(N2)2-N(2) (i)	2.907(19)	2.03(14)	1.01(12)
O(3)···H(N3)2-N(3) (ii)	2.870(16)	1.96(12)	0.97(12)

Symmetry code: (i) x, y, z, (ii) $1-x$, $1-y$, $1/2+z$, (iii) $1/2-x$, $3/2-y$, $1/2+z$.
a) There are no hydrogen bonds in **2a** and **3**.

***trans*(*X*,*X*),*cis*(*P*,*P*)-$[RhX_2(edmp)_2]^+$(X=Cl, Br, I) and *trans*(*X*,*X*)-$[RhX_2(dmpe)_2]^+$(X=Cl, Br).** By reaction of *mer*-$[RhCl_3\{P(n\text{-}Bu)_3\}_3]$ with edmp in benzene, $[RhCl_2(edmp)_2]^+$ was formed. Although five geometrical isomers are possible for $[RhCl_2(edmp)_2]^+$, only one isomer was isolated. No fraction indicative of other isomers was obtained in SP-Sephadex column chromatography. The ^{13}CNMR spectrum of this complex exhibits three kinds of signals, indicating that the complex is either of the two trans(*Cl*,*Cl*) isomers. It should be noted that the P-CH_2 and P-CH_3 signals appear as a filled-in doublet. The appearance of the phosphine α-carbon multiplet in the ^{13}CNMR spectrum of a complex containing two phosphorus donor atoms has been shown to be a function of $^2J_{pp}$.[15,16] A filled-in doublet is expected to appear only for a cis(*P*,*P*) complex. Hence

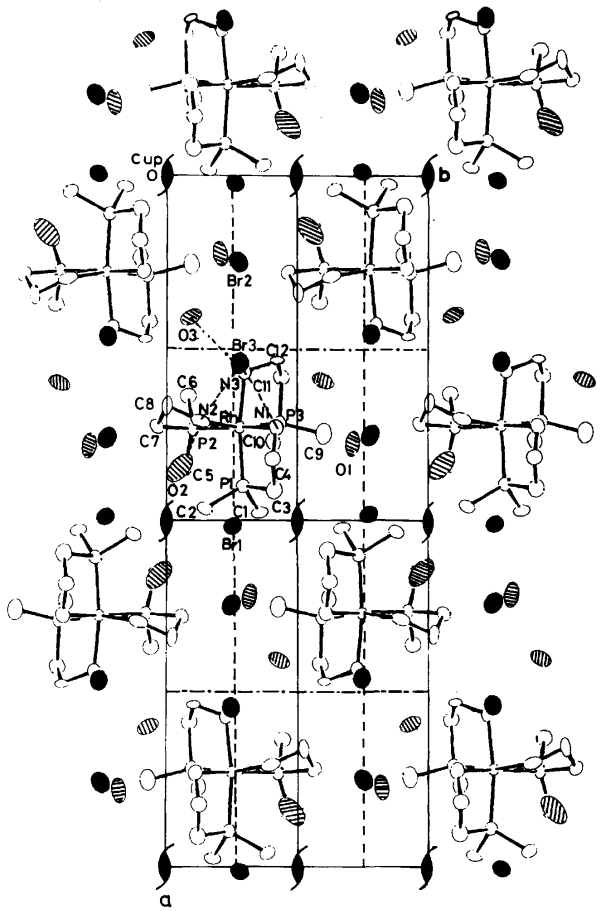

Fig. 3. A projection of the crystal structure of *fac*-$[Rh(edmp)_3]Br_3\cdot 3H_2O$ (**1**) along c. Black and hatched ellipsoids represent Br^- ions and H_2O molecules, respectively.

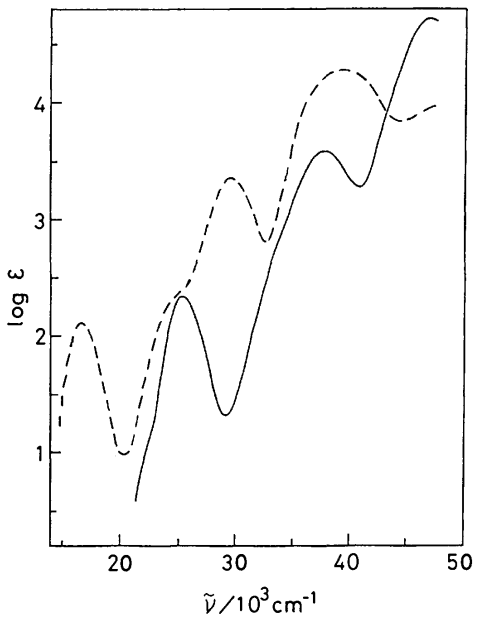

Fig. 4. Absorption spectra of *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-$[RhCl_2(edmp)_2]PF_6$ in methanol (——) and *trans*-(*Cl*,*Cl*),*cis*(*P*,*P*)-$[CoCl_2(edmp)_2]Cl$ in methanol (----).

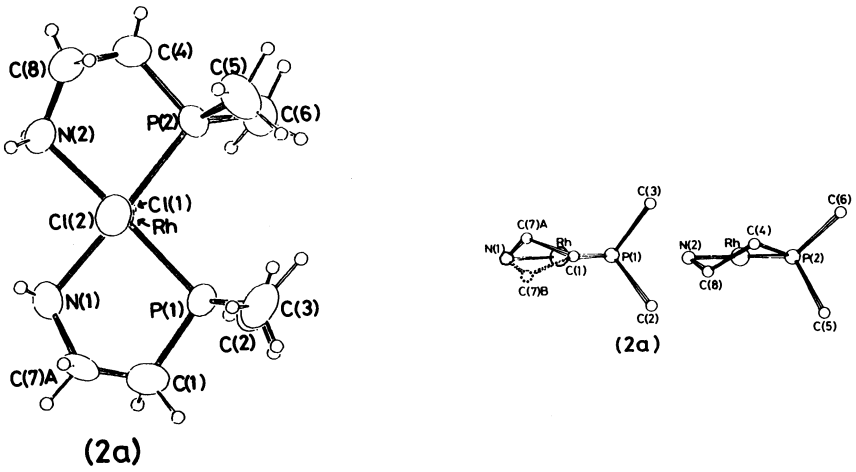

Fig. 5. A perspective view of *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edmp)_2]^+$ (**2a**) and edge-on views of the five-membered edmp chelate rings.

$[RhCl_2(edmp)_2]^+$ can be assigned to trans(*Cl,Cl*), cis(*P,P*). The same structure was suggested by the absorption spectrum. Figure 4 compares the absorption spectrum of the complex with that of *trans*(*Cl,Cl*),*cis*(*P,P*)-$[CoCl_2(edmp)_2]^+$.[17] Both spectra are quite similar in pattern, although all of the bands of the rhodium(III) complex are shifted by 7500—9500 cm^{-1} toward higher energy compared to the corresponding bands of the cobalt(III) complex. Thus the rhodium(III) complex is suggested to have the trans(*Cl,Cl*),cis(*P,P*) configuration. This assignment was confirmed by the X-ray structure determination (vide infra). The low-energy absorption band at 25500 cm^{-1} of the rhodium(III) complex can be assigned to the split component (I_a) of the first absorption band, $^1A_{1g} \rightarrow {}^1T_{1g}$ (Oh). The I_a component is shifted toward higher energy by a factor of 1.5 on going from the cobalt(III) complex (16600 cm^{-1}) to the rhodium(III) complex (25500 cm^{-1}). The I_b and second absorption bands of the rhodium(III) complex are hidden by the strong charge-tansfer bands.

Figure 5 shows a perspective drawing of the complex cation **2a**. **2a** is the trans(*Cl,Cl*), cis(*P,P*) isomer, and the structure agrees with the assignment based on the ^{13}C NMR and absorption spectra. As illustrated in Fig. 5, one of the edmp chelate rings of **2a** is disordered. In **2b**, three independent complex ions take different conformations, $\delta\delta(\lambda\lambda)$, $\delta\lambda$, or $\delta(\lambda)$ envelope, suggesting flexibility of the edmp chelate rings (Fig. 6). The P(1)-Rh-P(2) angle of 98.91(5)° in **2a** is smaller than 105.4(1)° in *trans*(*Cl,Cl*),*cis*(*P,P*)-$[RhCl_2(edpp)_2]^+$,[1] on account of less bulky substituents on phosphorus atoms. The mean Rh-N bond length in **2a**, 2.165(4) Å is longer than that in *trans*-$[RhCl_2(en)_2]NO_3$ (2.063(2) Å)[18] due to trans influence of the coordinated P atom. In Fig. 7, the M-N bond distance (M=Co or Rh) affected by the trans influence is plotted against the M-P bond distance. The elongation is smaller in the *trans*(*Cl,Cl*),*cis*(*P,P*)-

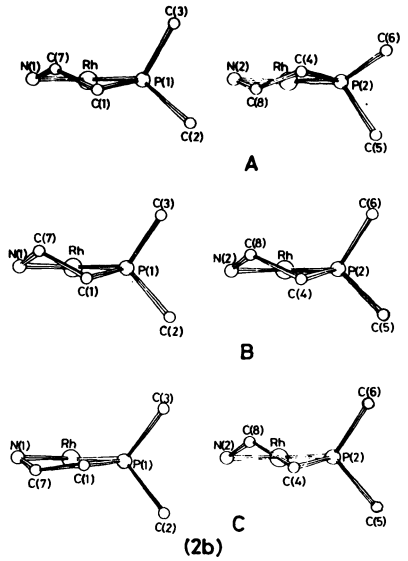

Fig. 6. Edge-on views of the five-membered edmp chelate rings in *trans*(*Cl,Cl*), *cis*(*P,P*)-$[RhCl_2(edmp)_2]$-ClO_4 (**2b**).

$[MCl_2(edpp)_2]^+$ complexes (circular symbols) than those in the others. This trend seems to be due to the longer M-P bond length in the edpp complexes. In general, the shorter the M-P bond length, the larger the M-N bond elongation. The elongations of the Rh-N bond distances (0.07—0.11 Å) by the trans influence are larger than those (0.03—0.07 Å) of the Co-N bond distances. Figure 7 clearly shows that the difference (<0.05 Å) between Rh-P and Co-P bond lengths is much smaller than that (ca. 0.1 Å) between Rh-N and Co-N bond lengths. All these results suggest a stronger affinity of P for Rh^{3+} than for Co^{3+}. The trans influence of P on the Rh-P bond length, the lengthening of mutually trans Rh-P bonds, was observed in the *trans*-$[RhCl_2(dmpe)_2]^+$ complex (**3**). The mean Rh-P bond distance is 2.337(2) Å, which is longer than those in complexes **1** and **2a**, 2.283(4) Å

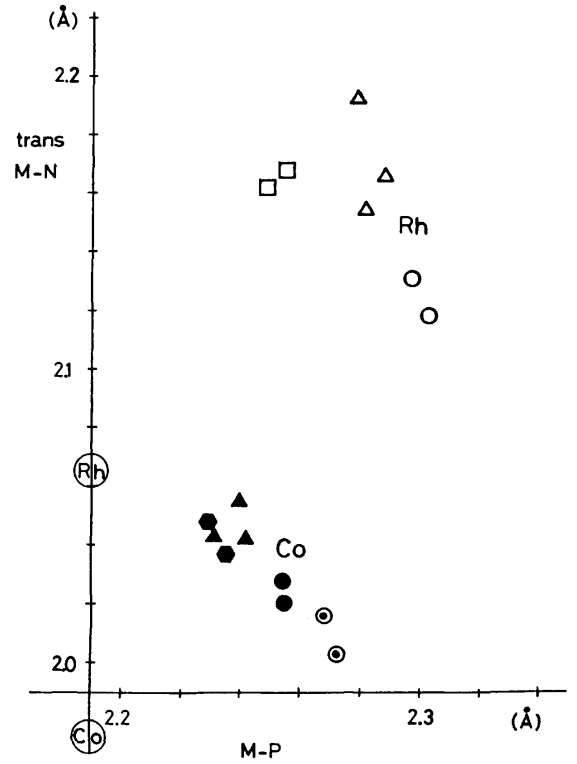

Fig. 7. Plot of the M-N distance (M=Co and Rh) against the trans M-P bond length in Δ=**1**; □=**2a**; ○=*trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[$RhCl_2$(edpp)$_2$]Cl·$2C_2H_5OH$;[1] ▲=*fac*-[Co(edmp)$_3$]Br_3·$3H_2O$;[2] ●=*trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[$CoCl_2$(*R*-ebpp)$_2$]ClO_4[17] (*R*-ebpp=(*R*)-(2-aminoethyl)butylphenylphosphine); ●=*trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-[$CoCl_2$(edpp)$_2$]1/2($CoCl_4$);[17] ⊙=*trans*(*NCS*,*NCS*),*cis*(*P*,*P*)-[Co(NCS)$_2$(edpp)$_2$]Br·$3H_2O$·$(CH_3)_2CO$.[25] The circles on the vertical axis indicate bond distances in the $[M(en)_3]^{3+}$ complexes (M=Co[26] and Rh[13]).

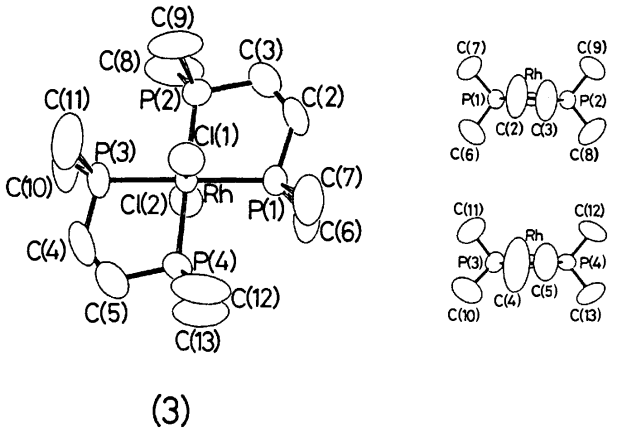

(3)

Fig. 8. A perspective view of *trans*-$[RhCl_2(dmpe)_2]^+$ (**3**) and edge-on views of the five-membered dmpe chelate rings.

and 2.252(2) Å, respectively.

$[RhCl_2(dmpe)_2]^+$ was prepared by refluxing an ethanol solution of $RhCl_3 \cdot 3H_2O$ and dmpe. Butter and Chatt reported that a mixture of the cis and trans

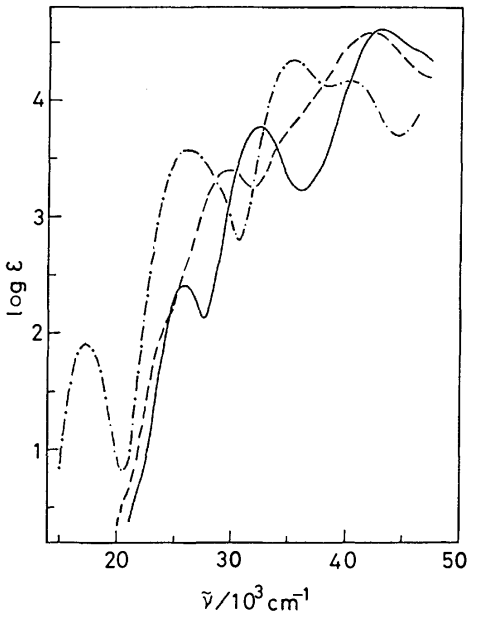

Fig. 9. Absorption spectra of *trans*-$[RhCl_2(dmpe)_2]$-CF_3SO_3 (——), *trans*-$[RhBr_2(dmpe)_2]CF_3SO_3$ (----), and *trans*-$[CoCl_2(dmpe)_2]ClO_4$ (—·—) in methanol.

isomers of this complex was yielded by a similar reaction.[19] We obtained only one isomer, no fraction indicative of the other isomer being obtained in column chromatography. The structure was assigned to the trans isomer on the basis of the ^1H NMR and absortion spectra, and the assignment was confirmed by X-ray analysis (Fig. 8). In the ^1H NMR spectrum, the complex shows a similar spectral pattern to that of *trans*-$[CoCl_2(dmpe)_2]^+$.[20] The ^1H NMR spectral pattern of *cis*-$[CoCl_2(dmpe)_2]^+$ is quite different from that of the trans isomer.[20] The absorption spectral pattern of *trans*-$[RhCl_2(dmpe)_2]^+$ is similar to that of the corresponding cobalt(III) complex; here also the ratio of positions ($\tilde{\nu}_{Rh}/\tilde{\nu}_{Co}$) of the I_a band for the rhodium(III) complex (25900 cm^{-1}) to that for the cobalt(III) complex (17300 cm^{-1})[20] is 1.5 (Fig. 9 and Table 4). The I_a band of *trans*-$[RhCl_2(dmpe)_2]^+$ is at higher energy (25900 cm^{-1}) than that of *trans*(*Cl*,*Cl*),*cis*(*P*,*P*)-$[RhCl_2(edmp)_2]^+$ (25500 cm^{-1}). The trans-dichloro rhodium(III) complexes of en, edpp, and Me_4-en (=*N*,*N*,*N*′,*N*′- tetramethylethylenediamine) show the I_a band at 24600,[21] 24450,[1] and 22000 cm^{-1},[22] respectively. Thus the spectrochemical series for the ligands can be determined as dmpe>edmp>en≧edpp>Me_4-en. The same order has been reported for the trans-dichloro cobalt(III) complexes.[17,20,23] $[RhX_2(edmp)_2]^+$ (X=Br, I) and $[RhBr_2(dmpe)_2]^+$ were prepared by substitution reactions from the trans-dichloro complexes and potassium bromide or sodium iodide. The configurations were retained in the reactions as indicated from the absorption spectra. The absorption spectra of *trans*(*X*,*X*),*cis*(*P*,*P*)-$[RhX_2(edmp)_2]^+$ (X=Cl, Br, I) are

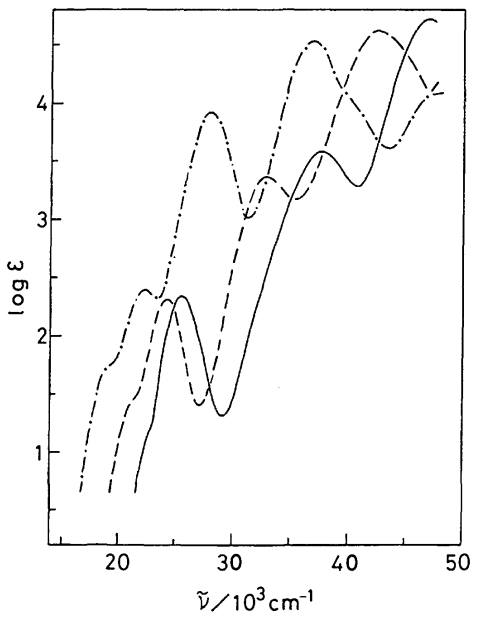

Fig. 10. Absorption spectra of *trans(Cl,Cl),cis(P,P)*-$[RhCl_2(edmp)_2]PF_6$ (——), *trans(Br,Br),cis(P,P)*-$[RhBr_2(edmp)_2]PF_6$ (----), and *trans((I,I),cis(P,P)*-$[RhI_2(edmp)_2]PF_6$ (—·—) in MeOH.

shown in Fig. 10. The spectral patterns of the complexes are similar to one another. In the series, the energy of the I_a component decreases in the order Cl> Br>I. The complexes show a shoulder at the low energy side of the I_a band and the absorption may be assigned to a spin-forbidden transition. The shoulder becomes more pronounced as X proceeds from Cl through Br to I. All of the complexes show two intense charge-transfer bands at energies higher than 28000 cm^{-1}. Both of the charge-transfer bands shift to lower energy in the order X=Cl>Br>I, suggesting that the bands are attributable mainly to the Rh-X charge-transfer transitions. In *trans*-$[CoX_2(dmpe)_2]^+$ (X=Cl, Br, I), the positions of the Co-X charge-transfer transitions change in the same order[20] and in *trans*-$[Co(H_2O)_2(dmpe)_2]^+$ they are missing.[24] Figure 9 shows the absorption spectra of *trans*-$[RhX_2(dmpe)_2]^+$ (X=Cl, Br). The band at 32600 cm^{-1} in the dichloro complex and the band at 29800 cm^{-1} in the dibromo complex are assigned to the Rh-Cl and Rh-Br charge-transfer transitions, respectively. The bands are at lower energy than the corresponding bands in the edmp complexes, and the I_a component of *trans*-$[RhBr_2(dmpe)_2]^+$ is observed as a shoulder by the overlap of the Rh-Br charge-transfer band. The intensity of this Rh-Br charge-transfer band (29800 cm^{-1}, $\log\varepsilon$=3.40) is remarkably smaller than that of the corresponding Rh-Cl charge-transfer band at 32600 cm^{-1} ($\log\varepsilon$=3.78). The same trend is observed in many phosphine and arsine complexes of cobalt(III) and rhodium(III). The origin of the shoulder at ca. 35000 cm^{-1} in the dibromo complex is unknown. The corresponding transition is not observed in the dichloro complex, however, a similar transition is observed in *trans*-$[CoBr_2(dmpe)_2]^+$.[20]

Synthetic Inorganic Ion-Exchange Materials. LII. Ion-Exchange Selectivities of Crystalline Antimonic Acid for Tervalent Metal Ions

Mitsuo ABE,* Masao HIRATA,† and Masamichi TSUJI
Department of Chemistry, Tokyo Institute of Technology, 2-12-1, Ookayama, Meguro-ku, Tokyo 152
(Received May 27, 1989)

The determination of selectivity coefficients for tervalent metal ions/hydrogen ions on cubic crystalline antimonic acid (C-SbA) was carried out for Ga^{3+}, Fe^{3+}, Ce^{3+}, Sm^{3+}, Y^{3+}, Sc^{3+}, and In^{3+} by batch equilibration at 30, 45, and 60 °C in nitric acid media. The selectivity in microamounts showed: $Al^{3+}<Tm^{3+}<Ga^{3+}<Yb^{3+}=Y^{3+}<Er^{3+}<Dy^{3+}<Fe^{3+}<Eu^{3+}<Sm^{3+}<Ce^{3+}<La^{3+}<Sc^{3+}=In^{3+}$. The ion-exchange isotherms of the systems of tervalent metal ions/hydrogen ions have also been studied on C-SbA. The selectivity coefficients in logarithm scale vs. equivalent fraction of metal ions in exchanger showed almost straight line, indicating monofunctional site with steric effect. In order to interpret the selectivity in microamounts of metal ions, hypothetical equilibrium constant was determined by extrapolating to zero loading of metal ions in C-SbA. From these values, the hypothetical thermodynamic data were calculated and evaluated.

During the last two decades much attention has been paid to the development of synthetic inorganic ion exchange materials with higher selectivities and resistance at high temperatures and in intense radiation fields than those of commercial ion-exchange resins.[1-6]

Our works on the systematic studies on adsorption behavior of the hydroxides and hydrous oxides of multivalent metals indicated that "so-called" antimonic acid behaved as an excellent cation exchange material.[7,8] Further studies showed that the antimonic acid can be classified into amorphous, glassy and crystalline materials by different preparative conditions, regardless of starting materials.[9] Recently, monoclinic crystalline antimonic acid was synthesized by treating $LiSbO_3$ with 11 mol dm^{-3} HNO_3 and showed an extremely high selectivity for lithium ion.[10,11] Among them, cubic crystalline antimonic acid (C-SbA) showed excellent ion-exchange properties and an unusual selectivity for various metal ions, compared to strong acid-type cation exchange resins.[13]

The increasing order of selectivity in microamounts shows; $Li^+ \ll K^+ < Cs^+ < Rb^+ \ll Na^+$ for alkali metals,[12-14] and $Mg^{2+} < Ba^{2+} < Ca^{2+} < Sr^{2+}$ for alkaline earth metals.[15,16]

The similar unusual selectivity was observed for bivalent transition metals[17,18] and tervalent metals.[19] It has been known that the selectivity on inorganic ion exchangers strongly depends on the loading of metal ions in the exchangers. An ion-exchange study over various exchange composition may be needed for understanding of their selectivities. However, it is very difficult to study full range of the ion-exchange composition because of incomplete exchange for the limit of steric reason. Moreover, the overall thermodynamic data obtained are not so accurate for those systems, because of long extrapolation from experimental values.

The present paper has been concerned with the interpretation of the selectivity of M^{3+}/H^+ system for "zero loading" of metal ions in C-SbA. From the selectivity coefficient, the hypothetical thermodynamic data may be derived.

Theoretical

The ion exchange process may be represented by the following equation for tervalent metal cation/hydrogen ions system.

$$3\bar{H}^+ + M^{3+} \rightleftarrows \bar{M}^{3+} + 3H^+ \quad (1)$$

where the bar refers to solid phase, and M^{3+} and H^+ are tervalent metal and hydrogen ions.

The thermodynamic equilibrium constant, K, of the above reaction can be defined as

$$K = \frac{m_H^3 \bar{X}_M \gamma_H^3 \bar{f}_M}{m_M \bar{X}_H^3 \gamma_M \bar{f}_H^3} = K_H^M \frac{\bar{f}_M}{\bar{f}_H^3} \quad (2)$$

where K_H^M is defined as the corrected selectivity coefficient. The m_H and m_M are molalities of the cations in solution, γ_H and γ_M are the ionic activity coefficients of H^+ and M^{3+} in solution phase, $\bar{f}_H$ and $\bar{f}_M$ are those in solid phase, and $\bar{X}_H$ and $\bar{X}_M$ are equivalent fractions of H^+ and M^{3+} in the solid phase. The values of the ionic activity coefficient ratio (γ^3_H/γ_M) in solution can be calculated from the following equation.[20]

$$\log(\gamma_H^3/\gamma_M) = 6\frac{S\,I^{1/2}}{1+A\,I^{1/2}} \quad (3)$$

where A and I are the distance of the nearest approach and the ionic strength, and

$$S = 1.8252 \times 10^6 (\rho/\varepsilon^3 T^3)^{1/2}$$

where ρ is the density of water, ε is the dielectric constant of water, and T is the absolute temperature of the system.

The thermodynamic equilibrium constant can be

† Present address: Ooshimizu High School, Fujisawa 251.

evaluated by using a simplified form of the Gaines-Thomas equation,[21] Eq. 4, assuming that the change of water activity in the C-SbA and in the solution is neglected.

$$\ln K = -(Z_M - Z_H) + \int_0^1 \ln K_H^M \, d\bar{X}_M \quad (4)$$

Sometimes, the graph of $\ln K_H^M$ against $\bar{X}_M$, which refers to the Kielland plot,[22] is linear with some inorganic ion exchangers, as follows;

$$\ln K_H^M = 4.606\, C\, \bar{X}_M + (\ln K_H^M)_{\bar{X}_M \to 0} \quad (5)$$

where the term C is called the Kielland coefficient and $4.606C$ is the slope of the line, and $(\ln K_H^M)_{\bar{X}_M \to 0}$ is the value $\ln K_H^M$ when $\bar{X}_M = 0$.

Some investigators have normalized uptakes with the maximum limit of exchange, $(\bar{X}_M)_{max}$, in the case where complete exchange is not obtained. However, this treatment does not allow a comparison between species which are exchanged to different extent.[16,23]

The normalization for C-SbA is based on the assumption that one SbOH group gives one hydrogen ion available for ion exchange. Thus, the theoretical capacity of 5.056 mequiv g^{-1} was used from the experimental formula of $Sb_2O_5 \cdot 4H_2O$.[16]

Experimental

Preparation of C-SbA. The C-SbA was prepared as described previously;[9] the precipitate obtained by hydrolysis of antimony pentachloride solution (1:1) was kept in the mother solution at 40 °C for over 20 d in order to enhance crystallization, and then washed with cold demineralized water until free from chloride ion with an aid of centrifuge (about 10000 rpm). After drying the product was ground and sieved (100—200 mesh size). The collected sample was rewashed with demineralized water in order to obtain clear supernatant solution in the following batch equilibrium experiments.

Distribution Coefficient (K_d). The K_d values were determined by equilibrating C-SbA in hydrogen ion form with a solution containing 1×10^{-4} M (1 M=1 mol dm^{-3}) metal ions and nitric acid at different concentrations. The ratio of volume of the solution to weight of C-SbA was kept in 100 ($cm^3\,g^{-1}$). The K_d values of metal ions were calculated by using following expression;

$$K_d = \frac{\text{amount of metal ions in exchanger}}{\text{amount of metal ions in solution}} \times \frac{\text{cm}^3 \text{ of solution}}{\text{g of exchanger}} \quad (6)$$

Ion-Exchange Equilibria. In the forward reaction, the C-SbA in H^+ form was immersed in a mixed solution of varying ratio of the metal nitrate/nitric acid in a sealed glass tube with intermittent shaking at 30±0.1, 45±0.1, and 60±0.1 °C. The ratio of volume of mixed solution to weight of C-SbA was kept in 100 ($cm^3\,g^{-1}$). The ionic strength in the equilibrium was adjusted to 0.2. The equilibrium concentrations in the solid phase and in aqueous phase were deduced from the change of M^{3+} and H^+ concentration relative to the initial concentration of the solution. The concentration of metal ions in the solutions was determined by spectrophotometric analysis.[24-26] Neutron activation analysis was employed for cross checking the analytical data for Sc, Sm, Eu, and Ce. The emf titration method was employed for determining the H^+ concentration with a standard sodium hydroxide solution.

Results and Discussion

Distribution Coefficient (K_d). Time dependence of adsorption for different metal ions showed that the equilibrium was attained within 20 d for Sc^{3+}, Tm^{3+}, and Eu^{3+}, and about 30 d for Y^{3+} (Fig. 1) The variety of the time dependence from element to element may be due to the rigid structure of C-SbA and rate of the exchange between hydrated water for the element and bulk water molecules in the aqueous solution.

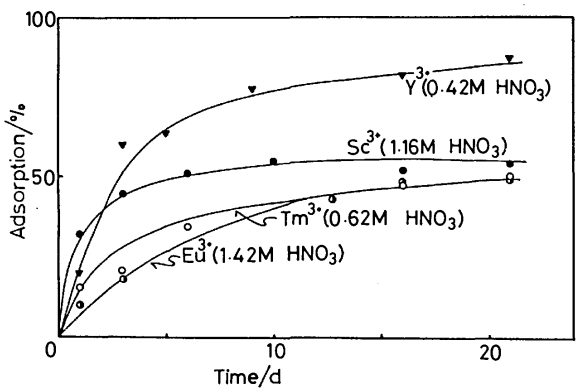

Fig. 1. Time dependence for the adsorption of rare earth ions on C-SbA. Initial concn of metal ions; 1.0×10^{-4} mol dm^{-3}. C-SbA; 0.50 g. Total vol.; 50.0 cm^3. Temp; 30 °C.

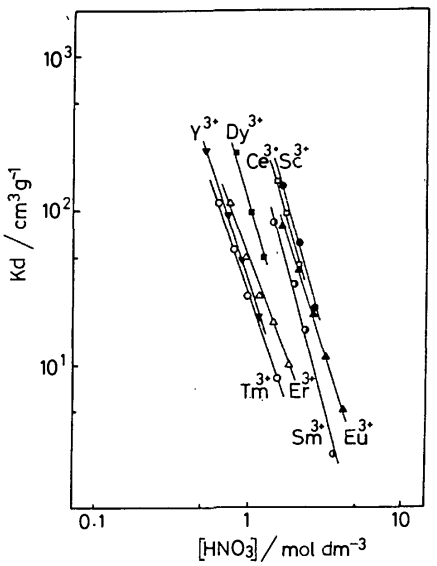

Fig. 2. Logarism K_d values of various metal ions vs. log[HNO_3] on C-SbA. Initial concn of metal ions; 1.0×10^{-4} mol dm^{-3}. C-SbA; 0.20 g. Total vol.; 20.0 cm^3. Temp; 30 °C.

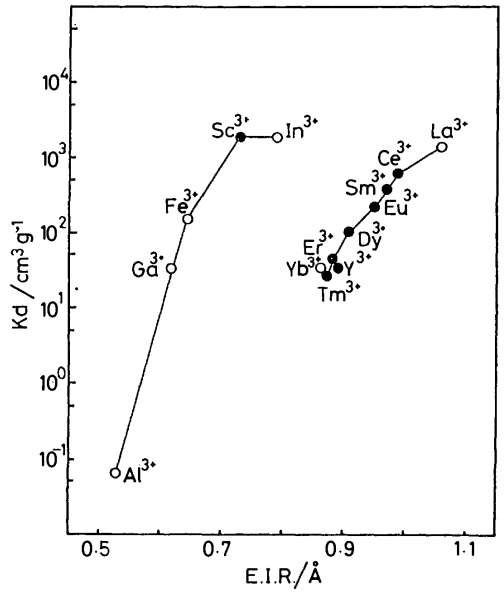

Fig. 3. The K_d of tervalent metal ions as a function of effective ionic radii of metal ions. ●: this work, ○: from Ref. 19.

The log-log plots of K_d vs. [HNO_3] showed that the slopes of dlog K_d/dlog[HNO_3] are about the same as the valency of metal ions studied, indicating the "ideal ion-exchange reaction" (Fig. 2). The equilibrium K_d values in logarithm scale of various tervalent metal ions on C-SbA were plotted against effective ionic radii (EIR)[27] of the metal ion in Fig. 3, after normalizing to a 1 M nitric acid solution. It was difficult to determine the K_d values experimentally higher than 10^3 for detection limit of the spectrophotometric analysis.

The following selectivity series were found for microamounts of tervalent metal ion on C-SbA in nitric acid solution;

$$Al^{3+}<Tm^{3+}<Ga^{3+}=Yb^{3+}<Y^{3+}<Er^{3+}<Dy^{3+}<Fe^{3+}<Eu^{3+}<Sm^{3+}<Ce^{3+}<La^{3+}<Sc^{3+}=In^{3+}$$

Two different selectivity series were found for Al^{3+}, Ga^{3+}, Fe^{3+}, and In^{3+}, and from Tm^{3+} to La^{3+} on C-SbA. The difference in the electron configuration of the ion-exchange cations may be responsible for the results; the latter takes the $s^2p^6f^n$ configuration and the former takes a different configuration. The log K_d values on BIO-RAD AG 50W-X8 increase slightly with increasing EIR[27,28] of exchanging metal ions because of its elastic structure.

Kielland Plot. It has been known that the selectivity on inorganic ion exchangers is much dependent on the concentration of metal ions in the exchanger phase because of their rigid structure mentioned above. It is known that large steric effect may arise in a rigid exchanger which undergoes little swelling or shrinkage, if there is a large difference in the ionic crystal radii of the two exchanging cations.

Among the ion-exchange system of tervalent metal ions/hydrogen ions, Al^{3+}, Ga^{3+}, Fe^{3+}, Sc^{3+}, Y^{3+}, Sm^{3+}, and Ce^{3+}/H^+ were selected in order to interpret the selectivity of tervalent metal ions. The Kielland plot showed fairly good straight line for metal ions/H^+ systems studied (Figs. 4-1 to 4-3). The ln K_H^M values decreased gradually with increasing $\bar{X}_M$, indicating that the steric effect depends on a variety of the exchanging metal ion. The Kielland plots of different tervalent metal ions/H^+ system at 30 °C are summarized in Fig. 4-4. Moving the axis of abscissa from left to right upto $\bar{X}_M$=0.1 in Fig. 4-4, the different selectivity sequences can be found as a function of

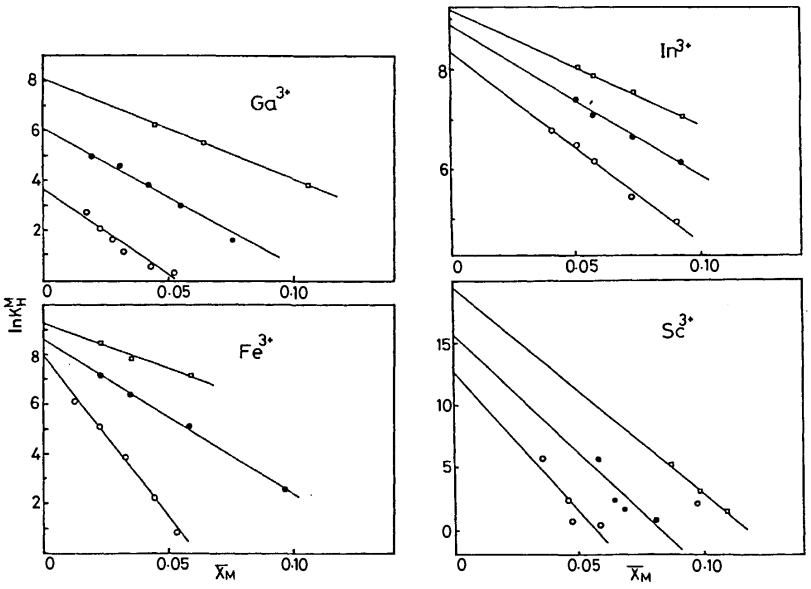

Fig. 4-1. The Kielland plots of Ga^{3+}, Fe^{3+}, In^{3+}, and Sc^{3+}/H^+ exchange systems on C-SbA. Ionic strength: 0.2. Temp, ○: 30, ●: 45, and □: 60 °C.

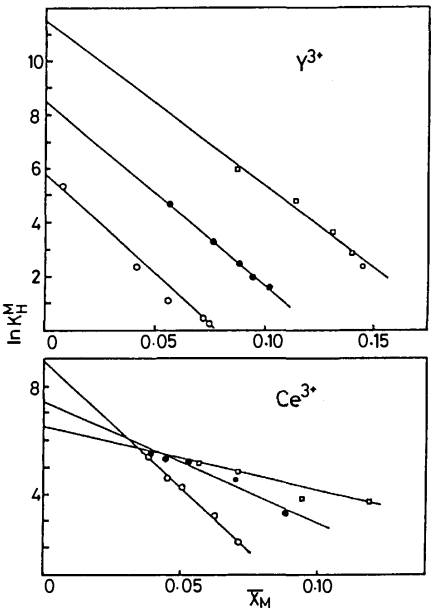

Fig. 4-2. The Kielland plots of Y^{3+} and Ce^{3+}/H^+ exchange systems on C-SbA. Ionic strength: 0.2. Temp, ○: 30, ●: 45, and □: 60 °C.

$\bar{X}_M$ to increase in the order $Al^{3+}<Ga^{3+}<Y^{3+}<Fe^{3+}<In^{3+}<Ce^{3+}<Sm^{3+}<Sc^{3+}$ for range of $\bar{X}_M=0$ to 0.008, and so on.

In general, when small cations in inorganic ion exchangers are exchanged with large cations in the solution, the ingoing ions are initially preferred and become progressively less preferred with increasing loading. This extent can be evaluated by the comparison of numerical values of Kielland coefficient, i.e., a large negative value of Kielland coefficient indicates a large steric effect.

The C/z, which is referred to equivalent Kielland coefficient,[††] for different exchange systems are plotted as a function of EIR in Fig. 5, other published data[14,16,18] being included. This shows that cations

[††] The Kielland coefficient for multivalent metal ions can be compared to those for alkali metal ions/H^+ system by this procedure.

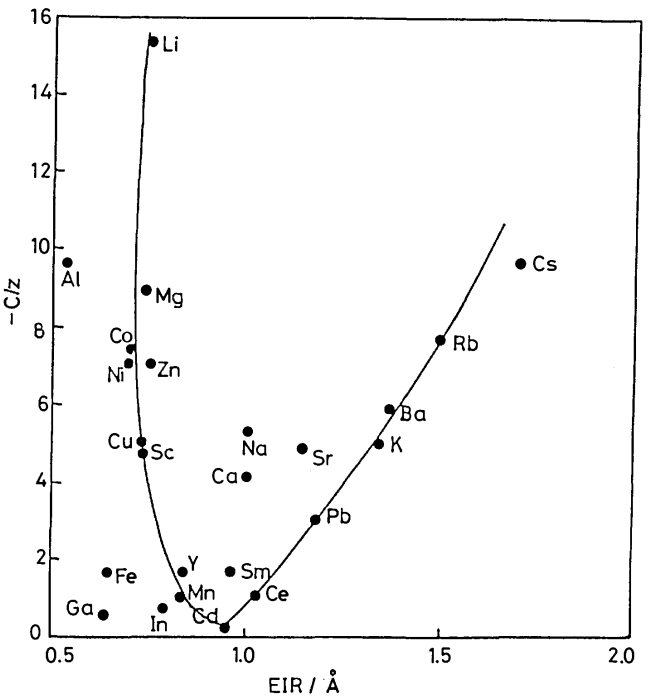

Fig. 5. The equivalent Kielland coefficients of tervalent metal ions/H^+ exchange systems on C-SbA vs. effective ionic radii (EIR) of the metal ions. EIR were taken from Table 1(a) of Shannon and Prewitt.[27]

with an effective ionic radius of about 1.0 Å enter the exchanger with minimum steric hindrance. The C-SbA has a rigid structure in which the change in the

lattice constant is less than 2% for the conversion from the hydrogen form to metal ion form.[14] The small cations, e.g., Li^+, Mg^{2+}, and Al^{3+}, are strongly hydrated in aqueous solution and may be exchanged with keeping their hydration shell. This brings large steric effect in the rigid structure of C-SbA.

The large cations, such as Ba^{2+}, Rb^+, and Cs^+, are less hydrated in the aqueous solution, and can be exchanged with a larger steric effect by increased crystal ionic radii of metal ions. Thus, the minimum steric effect may be interpreted in both contributions.

Hypothetical Thermodynamic Data. The thermodynamic equilibrium constant, K, can be evaluated from Eq. 2 or 4 by assuming that the linear relation between $\ln K_H^M$ vs. $\bar{X}_M$ is valid over the entire range of $\bar{X}_M$ from 0 to 1. However, high accuracy of these values is not obtained for long extrapolation of $\bar{X}_M$ to 1.0. The hypothetical thermodynamic data in infinitesimal concentration were calculated for interpretation of the selectivity of metal ions in microamounts on C-SbA.

The $(\Delta G^\circ)_{\bar{X}_M\to 0}$ is defined as;

$$(\Delta G^\circ)_{\bar{X}_M\to 0} = (-RT/z)\,(\ln K_H^M)_{\bar{X}_M\to 0} \qquad (7)$$

The calculated $(\Delta S^\circ)_{\bar{X}_M\to 0}$ and $(\Delta H^\circ)_{\bar{X}_M\to 0}$ values can be regarded as a constant, because van't Hoff plots, $(\ln K_H^M)_{\bar{X}_M\to 0}$ vs. $1/T$, showed fairly good linearity over the entire range of temperature studied (Fig. 6). The $(\Delta G^\circ)_{\bar{X}_M\to 0}$ values at 298 K were calculated by interpolating or extrapolating the determined $(\Delta G^\circ)_{\bar{X}_M\to 0}$ values to 298 K. The calculated $(\Delta G^\circ)_{\bar{X}_M\to 0}$ values at 298 K were plotted against EIR of the exchanging metal ions (Fig. 7). There appear two maxima which correspond to the selectivity series described above.

The ion-exchange reaction (1) can be separated into the hydration $(-\Delta Y_{hyd})$ and ion-exchange processes (ΔY_{ex}) as follows;

$$1/3\ M^{3+}(aq) + H^+(gas) \rightleftarrows 1/3\ M^{3+}(gas) + H^+(aq) \qquad -Y_{hyd}$$

$$1/3\ M^{3+}(gas) + \bar{H}^+ \rightleftarrows 1/3\ \bar{M}^{3+} + H^+(gas) \qquad \Delta Y_{ex}$$

where the Y represents thermodynamic functions such as G, H, and S. The numerical values of ΔY° contribute to the difference between the thermodynamic function of the ion-exchange (ΔY°_{ex}) and that of hydration (ΔY°_{hyd}) of the cations on the basis of the $\Delta Y^\circ_{hyd}=0$ of the reaction; $H^+(gas)\to H^+(aq)$. The value of ΔY°_{hyd} can be calculated from Rosseinsky's table.[29]

The calculated values of ΔY°, ΔY°_{hyd}, and ΔY°_{ex} were summarized on Table 1.

Large numerical values of $(\Delta H^\circ)_{\bar{X}_M \to 0}$ and $(\Delta S^\circ)_{\bar{X}_M \to 0}$ were found on the systems of Sc^{3+} and Y^{3+}/H^+, as compared with those of other systems studied. The ΔS°_{ex} showed all positive value, except Ce^{3+}/H^+ system. An extremely high value was observed on the systems of Sc^{3+} and Y^{3+}/H^+.

If the ΔS° is zero, where the value of ΔS°_{ex} is equal to that of ΔS°_{hyd}, this suggests that the exchanging cation in exchanger has the same hydration structure as that in aqueous solution. The positive value of ΔS°_{ex} may indicate that degree of freedom of metal ion increases in the cavity of C-SbA. Such an increase of ΔS°_{ex} may occur from dehydration of metal ions or net transfer of water molecules from solid phase to aqueous phase. When the less hydrated cations such as Rb^+ and Cs^+ are the ingoing cations, the degree of freedom may increase by the transfer of some water molecules from a C-SbA cage to the aqueous phase.

In order to understand the unusual selectivities on C-SbA, the values of ΔS°_{ex} were plotted against ionic hydration numbers,[30] h^∞_i being taken from ΔS°_{hyd} (Fig. 8).

The h^∞_i calculated from data of hydration entropy contains the primary and secondary hydration shells. The entropy of the hydration of an ion may be written as in Eq. 8.[31]

$$\Delta S^\circ_{hyd} = R \ln(V_f/V_g) + S_A + S_B + S_C \quad (8)$$

where the $R \ln(V_f/V_g)$ term allows for the fact that the free volume (V_f) accessible to the aqueous solution is not the same as that in the gaseous phase (V_g). The term S_A is a contribution for water molecules forming the primary hydration shell, and the term S_C is the Born-model contribution for water outside the primary hydration shell. The term S_B is the contribution from water in the secondary shell. The values of S_B are probably positive (structure breaking effect) for all alkali and alkaline earth metal ions, except Li^+ and Mg^{2+}. Thus the results bring to form the Frank-Wen three zone model.[32] In zone A, water molecules in primary hydration shell are tightly bonded by the strong coulombic field of the ion. Zone B, interposing between zone A and C, is a structure breaking region.

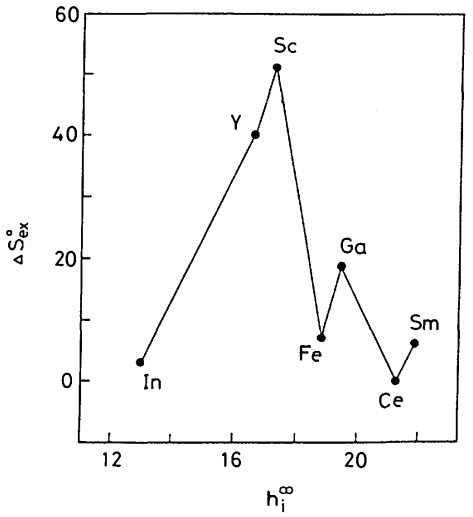

Fig. 8. The correlation between ΔS°_{ex} and hydration number (h^∞_i) for metal ions.

The zone B is less electrostrictive structure than zone A, and is less tetrahedrally coordinated than bulk water in zone C. If there is a contribution of coulombic force to the ion on exchange site enough to break the water structure of the hydration shell, the less hydrated ion can enter the narrow cavity in the exchanger. This may bring an increase in the ΔS°_{ex}. The water molecules of metal ion having small EIR may be tightly bound by the strong coulombic field of the metal ions, such as Mg^{2+}, first-row bivalent transition metal ions and Al^{3+}. It is very interesting in the fact that the electron configuration of Sc^{3+} is essentially the same as that of Y^{3+} and similar numerical value of h^∞_i is given for Sc^{3+} and Y^{3+} in aqueous solution.

When the coulombic force between the ion and the site is not strong enough to break water structure of the primary hydration shell, the small contribution of the ΔS°_{ex} may arise. The large contribution of the ΔS°_{ex} in the Sc^{3+} and Y^{3+}/H^+ systems may be due to both contributions of the net transfer of water molecules from solid phase to the aqueous solution and structure breaking of the water in exchanger.

The larger contribution of ΔS°_{ex} for Sc^{3+}/H^+ system than that of $(\Delta H^\circ)_{\bar{X}_{Sc} \to 0}$ brings a large numerical value of $(\ln K^{Sc}_H)_{\bar{X}_{Sc} \to 0}$, as compared with the system for Y^{3+}/H^+.

Ammonium copper(II) and ammonium calcium *cyclo*-hexaphosphates, $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ and $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$, were prepared by a wet method. TG-DTA, HPLC-FIA, and X-ray diffraction method were used to investigate the thermal decomposition of the *cyclo*-hexaphosphates. The effect of humidity on the pyrolysis was also examined by the use of dry N_2 gas and humid air. $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ was mainly decomposed to oligophosphates by hydrolysis. Parts of the oligophosphates were changed to poly- (n=7—13) and highpolyphosphates through a condensation. The poly- and the highpolyphosphates were more abundant under the dried conditions. Above 280 °C ammonia was liberated. As the crystalline products, $Cu_2P_2O_7$ was identified at 380 °C, and $Cu_2P_4O_{12}$ above 430 °C. $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$ lost almost all its water of crystallization by 177 °C. As ammonia was evolved from 270 to 420 °C, accelerated by humidity, amorphous highpolyphosphates were formed. The formation of the highpolyphosphates was considered to proceed through a radical polymerization, since oligophosphates were scarcely detected in the course of the thermal reaction.

Ammonium calcium *cyclo*-triphosphate and its hydrates have been studied in regard to their formation,[1-4] crystal structures,[5-7] thermal behavior,[5,8] and other properties.[9] Ammonium calcium *cyclo*-tetraphosphate and its hydrate were also investigated mainly in terms of their crystal structures.[10,11] On the other hand, of all the ammonium copper(II) *cyclo*-phosphates, only the *cyclo*-octaphosphate was reported;[12] no ammonium calcium nor ammonium copper(II) *cyclo*-hexaphosphates has been reported in literature.

In the preceding study,[13] the thermal decomposition of ammonium strontium *cyclo*-phosphates was carried out in order to clarify whether a radical polymerization, like the thermal change of ammonium *cyclo*-phosphates to ammonium polyphosphate,[14] took place or not. Finally, it was concluded that the ammonium strontium *cyclo*-phosphates were decomposed to polyphosphates through dehydration-condensation rather than through radical polymerization. Therefore, the dehydration-condensation was supposed to also take place over the course of the thermal decomposition of another ammonium bivalent metal *cyclo*-phosphates.

Several experiments were attempted for the purpose of preparing some ammonium bivalent metal *cyclo*-hexaphosphates, but only the following salts were obtained: Ammonium copper(II) *cyclo*-hexaphosphate $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ and ammonium calcium *cyclo*-hexaphosphate $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$.

The purpose of this series of studies has been to investigate the thermal decomposition of the ammonium bivalent metal *cyclo*-phosphates, especially with regard to the mechanism of the formation of the poly- and/or the highpolyphosphates from the ammonium bivalent metal *cyclo*-phosphates. Since the ammonium copper(II) and the ammonium calcium *cyclo*-hexaphosphates were prepared by wet methods, we studied the thermal decomposition of the two *cyclo*-hexaphosphates in the present work.

The ammonium copper(II) *cyclo*-hexaphosphates were decomposed to oligophosphates through hydrolysis, and polyphosphates generating through the dehydration-condensation of the oligophosphates. However, against our expectation, the ammonium calcium *cyclo*-hexaphosphate was thought to change to the highpolyphosphates via radical polymerization, which was accelerated by the humidity of the atmosphere.

Experimental

The ammonium bivalent metal *cyclo*-hexaphosphates, $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ and $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$, were prepared by wet methods similar to those described in the literature.[13] HPLC-flow injection analyses (HPLC-FIA) for the samples of $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ were carried out after metathesis by the use of a 1% (w/w) sodium sulfide aqueous solution, as reported by Nariai et al.[15] The other analytical procedures were essencially the same as those mentioned in the literature.[13]

$Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ was observed to consist only of *cyclo*-hexaphosphate ions. At least 99.9% of the phosphorus atoms were found to be present as *cyclo*-hexaphosphate ions in $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$.

Results and Discussion

Thermal Decomposition of Ammonium Copper(II) *cyclo*-Hexaphosphate $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$. Figure

1 shows thermal analyses (TG-DTA) in stationary air and in a stream of dry N_2 gas. Since ammonia was not evolved until 280 °C, the water of crystallization caused a large endothermic peak below 150 °C accompanying a loss in weight.

Figure 2 represents the percentage of phosphorus atoms present as *cyclo*-hexa-, oligo- (n=1—6), and polyphosphates (n=7—13) in the products which were obtained by heating to the temperature indicated by arrows in Fig. 1. Figure 2 shows that the amounts of the oligophosphates were obviously larger under the humid conditions than under the dry conditions—these, humid and dry, conditions were the same as those described in Ref. 13. The oligophosphates were found abundantly even under the dry conditions; thus, $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ was thought to be hydrolyzed mainly by its water of crystallization. The amounts of the polyphosphates were less under the humid conditions, and the highpolyphosphates were not observed at all under the humid conditions. The polyphosphates and highpolyphosphates were formed in largest amounts at 280 °C under the dry conditions. Since the primitive products were the oligophosphates, the poly- and the highpolyphosphates were thought to be produced by dehydration-condensation of the oligophosphates. The smaller amounts of polyphosphates and the absence of the highpolyphosphates under the humid conditions must be attributed to a retardation of the dehydration-condensation, caused by an enhanced partial pressure of the water vapor.

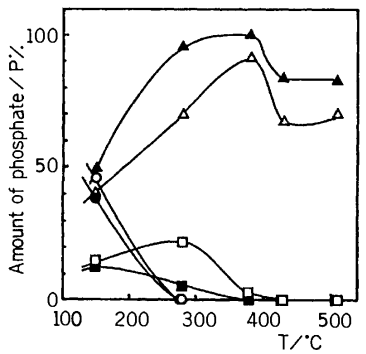

Fig. 2. Amount of phosphates in the decomposition products of $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$.
○ and ●: *cyclo*-Hexaphosphate observed under the dried and the humid conditions, respectively; Δ and ▲: oligophosphates (chain length, n=1—6) observed under the dried and the humid conditions, respectively; □ and ■: polyphosphates (n=7—13) under the dried and the humid conditions, respectively.

Since ammonia gradually evolved for temperatures above 280 °C, several reactions, such as a deammoniation and a dehydration (and besides a liberation of diphosphorus pentaoxide), were considered to take place simultaneously. We therefore could not clarify the process of the decomposition. The products obtained by heating until 150 and 280 °C were amorphous, while the X-ray diffraction patterns of the products heated to 380 °C were those of $Cu_2P_2O_7$. Copper(II) *cyclo*-tetraphosphate, $Cu_2P_4O_{12}$, was the only crystalline material at 430 and 510 °C. The oligophosphates fell off from 380 to 430 °C, which was accompanied with a large weight loss. The endothermic peak at 400 °C can probably be attributed to the formation of *cyclo*-tetraphosphate from the oligophosphates, as reported by Thilo and Grunze.[16] Only under the dry conditions was the *cyclo*-triphosphate anion $P_3O_9^{3-}$ detected at 430 °C. Although the phosphorus present as $P_3O_9^{3-}$ was ca. 16%, there were no X-ray diffraction lines except for those of $Cu_2P_4O_{12}$. Therefore, the *cyclo*-triphosphate was considered to be in the form of an amorphous phase.

Thermal Decomposition of Ammonium Calcium *cyclo*-Hexaphosphate $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$. Figure 3 shows thermal analyses in stationary air and in a stream of dry nitrogen gas. Figure 4 represents the

percentage of phosphorus atoms present as *cyclo*-hexa-, oligo- (n=1—6), and highpolyphosphates, in the products obtained by heating up to the temperature indicated by arrows in Fig. 3.

Ammonia was evolved, as shown in Fig. 5. Until 270 °C, the *cyclo*-hexaphosphate ions were not cleaved and ammonia was hardly evolved. There was little change in weight from 177 to 270 °C. Therefore, the weight loss until 170 °C was attributed to the liberation of the water of crystallization, which caused a series of the endothermic peaks below 177 °C, as expressed by the following equation (Eq. 1):

$$Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O \rightarrow Ca_2(NH_4)_2P_6O_{18} + 7H_2O. \quad (1)$$

Figure 4 shows that highpolyphosphates were produced more rapidly under the humid conditions than under the dry conditions—these conditions were also the same as those mentioned in Ref. 13— in proportion to the disappearance of a *cyclo*-hexaphosphate. Although the *cyclo*-hexaphosphate was decomposed more rapidly under the humid conditions than under the dry conditions, there were only small amounts of oligophosphates, which are the primitive hydrolytic products of the *cyclo*-hexaphosphate, even under the humid conditions. If the highpolyphosphates were produced by a dehydration-condensation, as in the pyrolysis of $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$, they should have been present more abundantly under the dry conditions than under the humid conditions. Therefore, however, the larger amount of the highpolyphosphates under the humid conditions suggests that they were not produced through the dehydration-condensation of the oligophosphates, but through another thermal change.

The TG-curve shows a plateau around 420 °C (Fig. 3). A weight loss of ca. 3.7% from 270 to 420 °C in the dry atmosphere was estimated from the ammonia evolved in this range (ca. 2.6%) and the water remaining at 270 °C in the products (ca. 1.1%). The loss (ca. 3.7%) was close to that actually observed by thermogravimetry (ca. 4.0%); thus, dehydration-condensation was more unlikely as a thermal formation of the highpolyphosphates.

We reported a radical polymerization on the thermal decomposition of ammonium *cyclo*-tetra- and *cyclo*-hexaphosphates.[14] Then, ammonium oligophosphates were yielded little or a little. And it was the "trigger reaction" in the decomposition of the ammonium *cyclo*-phosphates that a small amount of ammonia was liberated.

$Ca_2(NH_4)_2P_6O_{18}$, formed according to Eq. 1, was converted to amorphous highpolyphosphates at between 270 and 420 °C. The conversion was accompanied by a liberation of ammonia (Figs. 4 and 5), as in the case of the pyrolysis of the ammonium *cyclo*-phosphates.[14] The amounts of oligophosphates were small, as shown in Fig. 4, as in the case of the pyrolysis of the ammonium *cyclo*-phosphates.[14] Therefore, it might be concluded that the amorphous highpolyphosphates were produced through a polymerization of the oligophosphate radicals. The thermal change of $Ca_2(NH_4)_2P_6O_{18}$ to the highpolyphosphates can be described according to the following equation (Eq. 2):

$$Ca_2(NH_4)_2P_6O_{18}[\text{crystalline}] \rightarrow 2Ca(NH_4)_{1-x}H_x(PO_3)_3[\text{amorphous}] + 2xNH_3. \quad (2)$$

As shown in Fig. 5, ammonia evolved more abundantly under the humid conditions than under the dry conditions, called the "catalytic effect" of humidity in the literature.[13] The evolution of ammonia caused an endothermic peak at 345 °C (Figs. 3 and 5). The catalytic effect was also shown by a shift in the endothermic peak to a lower temperature by the presence of water vapor.

Figure 3 shows neither an increase in the weight nor a corresponding exothermic peak, resulting from the water-incorporation of oligophosphate radicals, unlike in the pyrolysis of $(NH_4)_4P_4O_{12}$.[14] Perhaps, otherwise, the water molecules supplied by the humid

air might form some weak bondings with the ammonium ions, so accelerating the liberation of ammonia.

It was reported in the literature[13] that ammonium strontium *cyclo*-triphosphate is decomposed to poly- ($n\geq 4$) and oligophosphates ($n=1$—3), e.g., from 250 to 380 °C under humid conditions. Because no observation was made of either an increase in weight nor of a corresponding exothermic peak, we concluded that the formation of the polyphosphates took place through dehydration-condensation. However, some part of the formation must proceed via oligophosphate radicals, especially within the initial temperature range (250—335 °C), since in this range there were hardly any oligophosphates which should appear as the primitive hydrolytic products of the ammonium strontium *cyclo*-triphosphate.

In the thermal decomposition of $Cu_2(NH_4)_2P_6O_{18}\cdot 8.5H_2O$ at higher temperature, a white sublimable material—which was probably diphosphorus pentaoxide—adhered to the inner surface at the outlet of a glass tube placed in a furnace. Although Feldmann reported that ammonium calcium *cyclo*-triphosphate $Ca(NH_4)P_3O_9\cdot aq$ liberated diphosphorus pentaoxide,[8] $Ca_2(NH_4)_2P_6O_{18}\cdot 7H_2O$ did not apparently produce this material under the present conditions.

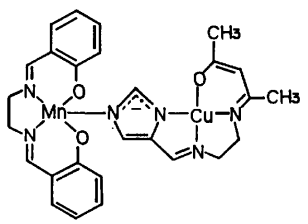
(Received June 7, 1989)

The synthesis, crystal structure, and magnetic property of an imidazolate-bridged manganese(III)-copper(II) dinuclear complex [Mn(salen)Cu(A)]BPh_4 are described, where [H_2salen]=*N*,*N*′-disalicylideneethylenediamine, [H_2A]=4-(6-methyl-8-oxo-2,5-diazanonane-1,5,7-trienyl)imidazole, and BPh_4=tetraphenylborate. The X-ray analysis confirmed an imidazolate-bridged manganese(III)-copper(II) dinuclear structure, in which the coordination geometries of the manganese(III) and copper(II) ions are square pyramid and square planar, respectively. The apical position of the manganese(III) ion is occupied by an imidazolate nitrogen N(3) of the [Cu(A)] moiety with the bond distance of Mn-N(3) 2.165(5) Å. As the temperature is lowered, the effective magnetic moment per molecule decreases gradually from 5.17 B.M. at 300.2 K, reaches the minimum value 4.44 B.M. at 24.9 K, and then increases to 4.73 B.M. at 4.2 K, indicating that antiferro- and ferro-magnetic interactions are co-operative in the complex.

The molecular design of hetero-metal polynuclear complexes has been an attractive subject to mimic some biological metal enzymes[1,2] and to develop ferromagnets and ferrimagnets.[3] Imidazolate-bridged hetero-metal dinuclear structure has been found in the active site of bovine erythrocyte superoxide dismutase (BESOD)[1] and has been one of the candidate structures of the active site of the resting form of cytochrome c oxidase.[2] In order to develop structural model compounds of BESOD, Lippard's group[4-8] and other groups[9-14] have synthesized and characterized a number of imidazolate-bridged di- and polynuclear copper(II) complexes. However, only a few examples of imidazolate-bridged hetero-metal complexes have been reported so far.[15-18] Recently we have shown an effective synthetic route to prepare imidazolate-bridged hetero-metal dinuclear complexes with various combinations of metal ions.[19-23] The complexes thus obtained may provide not only structural model compounds of the metal enzymes but also a novel family of hetero-metal complexes which makes it possible to investigate systematically magnetic interaction between magnetic centers with the different electronic configurations. This paper describes the synthesis, magnetic property, and crystal structure of an imidazolate-bridged manganese(III)-copper(II) complex [Mn(salen)Cu(A)]BPh_4, where [H_2salen]=*N*,*N*′-disalicylideneethylenediamine, [H_2A]=4-(6-methyl-8-oxo-2,5-diazanonane-1,5,7-trienyl)imidazole, and BPh_4=tetraphenylborate. The schematic structure of the complex is shown in the drawing.



Experimental

Syntheses. Component Compounds. The component compounds [Mn(salen)]BPh_4[24] and [Cu(A)]0.5$CHCl_3$[20] were prepared according to the methods reported earlier.

[Mn(salen)Cu(A)]BPh_4. To a solution of [Mn(salen)]-BPh_4 (500 mg, 1 mmol) in 50 cm^3 of methanol was added a solution of [Cu(A)]0.5$CHCl_3$ (342 mg, 1 mmol) in 50 cm^3 of methanol. The mixture was stirred for 10 min on a hot plate and then filtered. The filtrate was left to stand at room temperature overnight. Red-brown crystals precipitated were collected by suction filtration and dried in air (yield ca. 45%). Attempts for recrystallization were unsuccessful, leading to decomposition of the complex. Calcd for $C_{51}H_{48}N_6BO_3MnCu$: C, 66.42; H, 5.25; N, 9.11; Mn, 5.95; Cu, 6.89%. Found: C, 66.96; H, 5.30; N, 9.05; Mn, 6.06; Cu, 6.92%. Λ_M 83 S mol^{-1} cm^2 (acetonitrile).

Physical Measurements. Elemental analyses (C, H, and N) were performed at the Elemental Analysis Center of Kyushu University. Elemental analyses for Mn and Cu were carried out on a Nippon Jarrel Ash AA 781 atomic absorption and flame emission spectrophotometer. Electrical conductivity was measured on a Denki Kagaku Keiki AOL-10 conductivity meter in ca. 10^{-3} mol dm^{-3} acetonitrile solution. Magnetic susceptibilities were obtained at 4.2—100 K by use of a HOXAN HSM-2000 SQUID magnetometer under the magnetic field of 0.5 T and at 80—300 K by the Faraday balance designed in our laboratory. Data were corrected for magnetization of the sample holder and for the diamagnetism of the component atoms by the use of Pascal's constants. The molar effective magnetic moments were calculated by the equation $\mu_{eff}=2.828(\chi_M T)^{1/2}$.

X-Ray Crystallography. Reflection data were measured on a Rigaku Denki AFC-5 automated four-circle diffractometer with graphite-monochromatized Mo $K\alpha$ radiation at room temperature. Three standard reflections were monitored every 100 reflections and showed no systematic decrease in the intensity. The reflection data were corrected for Lorentz and polarization factors and used in the structure determination. Corrections for absorption and extinction effects were not made. Unit cell parameters were determined by 25 reflections ($20°<2\theta<30°$).

Crystal Data: [Mn(salen)Cu(A)]BPh_4, Formula=$MnCuO_3N_6C_{51}BH_{48}$, F.W.=922.2, triclinic, space group=$P\bar{1}$, crystal dimension 0.2×0.3×0.2 mm, a=14.215(3) Å, b=15.745(3) Å, c=13.944(3) Å, α=121.20(2)°, β=114.28(2)°, γ=58.49(2)°, V=2233.5(1.2) Å^3, μ(Mo$K\alpha$)=7.72 cm^{-1}, d_{calcd}=1.371 g cm^{-3} (Z=2), d_{obsd}=1.36 g cm^{-3} (by floatation method in aqueous KI solution), scan mode θ-2θ, scan speed 6 deg min^{-1}, scan range 2.5°<2θ<45°, scan width (1.2+0.35tanθ)°, octant measured +h, ±k, ±l, no. independent reflections 4698, R=7.32%, R_w=7.29%. the largest residue in the final D-Fourier synthesis 0.8 e Å^{-3}.

The structure was solved by the standard heavy-atom method and refined by the block-diagonal least-squares method, where the function minimized is $\sum w(|F_o|-|F_c|)^2$ and equal weight for all reflections was adopted. The contribution of hydrogen atoms bound to carbon were introduced in the calculated positions. These hydrogen atoms were included in the structure factor calculation but not refined. The atomic scattering factors were taken from literature.[25] All computations were performed on a FACOM M 780 computer at the Computer Center of Kyushu University using the UNICS III program system.[26] The final atomic prameters are given in Table 1. Tables of observed and calculated structure factors, listings of atomic positional and anisotropic thermal parameters, and complete lists of bond lengths and angles with their estimated standard deviations have been deposited as Document No. 8903 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

The component complex [Cu(A)] plays a key role in producing imidazolate-bridged hetero-metal complexes, because [Cu(A)] functions like a monodentate ligand at the imidazolate nitrogen, coordinating to another metal ion to form an imidazolate-bridged complex. The mixed-metal complex was readily prepared by mixing [Mn(salen)]BPh_4 and [Cu(A)] in methanol. The elemental analysis (C, H, N, Cu, and Mn) was consistent with the formula of [Mn(salen)-Cu(A)]BPh_4. Molar electrical conductance in acetonitrile was 83 S mol^{-1} cm^2 which is consistent with 1:1 electrollyte.

Structural Description. The molecular structure of $[Mn(salen)Cu(A)]^+$ with the atom numbering scheme is shown in Fig. 1. Selected bond distances and bond angles are given in Table 2. The X-ray analysis has confirmed that the complex assumes an imidazolate-bridged manganese(III)-copper(II) dinuclear structure. The coordination geometries of the manganese(III) and copper(II) ions are square pyramid and square planar, respectively. In the square pyramid of the manganese(III) ion, the basal coordination plane is occupied by the N_2O_2 donor set of the salen ligand with the bond distances 1.869(4)—1.985(5) Å and the apical position is occupied by the imidazolate nitrogen atom N(3) of the [Cu(A)] moiety with the bond distance of Mn-N(3) 2.125(5) Å. The bond distance of Mn-N(3) 2.125(5) Å is shorter than those of Mn(III)-apical imidazole nitrogen atom of [Mn(HIm)(salen)]ClO_4 (2.231(4) Å) and [Mn(biim)-(salen)]ClO_4 (2.278(5), 2.283(4) Å), where HIm=imidazole and biim=1,4-di(1-imidazolyl)butane.[24] The manganese(III) ion deviates by 0.23 Å toward the apical position from the basal coordination plane. The [Cu(A)] plane is nearly perpendicular to the [Mn-(salen)] plane and intersects it approximately at the Mn-O(2) and Mn-N(1) bonds, where the dihedral angle between the mean planes of these moieties is 86.8°.

Figure 2 shows a packing view of two crystallographically unique units related by the inversion center. As often seen in the metal complexes with salen, two manganese(III) ions are bridged by two phenoxo oxygen atoms O(1) and O(1)* ($-x$, $-y$, $-z$) of the salen in the out-of-plane fashion, where the distance of Mn-O(1)* is 3.103(5) Å. The bond distance is substan-

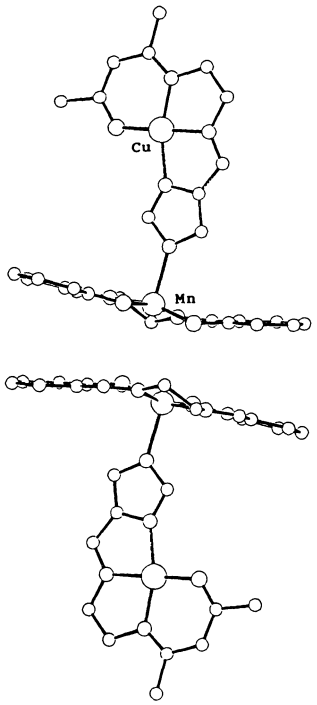

Fig. 2. Arrangement of two cations related by a center of symmetry, showing weak interactions between Mn and O(3)* with out-of-plane fashion.

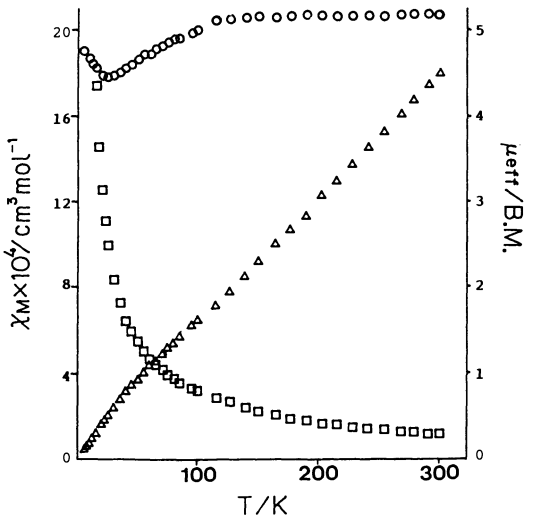

Fig. 3. Temperature dependence of the magnetic susceptibility per molecule (□), the reciprocal magnetic susceptibility per molecule (△), and the effective magnetic moment (○).

cially longer than the corresponding Mn-O bonds of the related manganese(III) complexes [Mn(HIm)(salen)]ClO_4 (2.635(3) Å)[24] and [Mn(hapacen)H_2O]ClO_4(2.305(2) Å),[27] where hapacen denotes the condensation product of acetylacetone, ethylenediamine, and *o*-hydroxyacetophenone with the mole ratio 1 : 1 : 1.

Magnetic Property. The magnetic behavior of the complex is shown in Fig. 3 in the form of the χ_M vs. T, $1/\chi_M$ vs. T, and μ_{eff} vs. T plots, where χ_M denotes the magnetic susceptibility per molecule, μ_{eff} the effective magnetic moment per molecule, and T the absolute temperature. The numerical values of the observed magnetic data are given in the supplementary material.

The effective magnetic moment per molecule at room temperature, 5.17 B.M., is nearly equal to the spin-only value of dinuclear system (5.20 B.M.) assuming no magnetic interaction between high-spin manganese(III) (S_1=2) and copper(II) (S_2=1/2) ions. As the temperature is lowered, the moment decreases gradually from 5.17 B.M. at 300.2 K, reaches the minimum value 4.43 B.M. at 24.9 K, and then increases to 4.73 B.M. at 4.2 K, indicating antiferromagnetic behavior at the higher temperature region and ferromagnetic behavior at the lower temperature region. There are two magnetic interactions which could mainly contribute to this result, i.e., intradinuclear Mn-Cu and interdinuclear Mn-Mn interactions.

First, the magnetic interaction between manganese(III) and copper(II) ions through an imidazolate group is compared with that of the analogous imidazolate-bridged manganese(III)-copper(II) complex [Mn(L)Cu(A)]BPh_4,[22] in which no intermolecular Mn-Mn interaction is feasible because of the completion of six-coordination, where H_2L denotes a quinquedentate ligand 4-methyl-*N*,*N*′-disalicylidene-4-azaheptane-1,7-diamine. The magnetic moment decreases gradually from 5.11 B.M. at 299 K to 3.31 B.M. at 4.3 K through an inflection point 3.86 B.M. at 20 K. In this case the magnetic behavior can be explained by antiferromagnetic coupling between high-spin manganese(III) and copper(II) ions and the zero-field splitting of the spin ground state.

Magnetic interaction between two manganese(III) ions through phenoxo-oxygen atoms similar to the present system[27] can be seen in [Mn(hapacen)H_2O]-ClO_4.[28] Its magnetic moment decreases gradually from 4.84 B.M. at 298 K to 1.70 B.M. at 4.4 K and can be well reproduced by the spin-Hamiltonian $H=-2JS_1S_2$ (S_1=S_2=2) with the parameters of J=−1.68 cm^{-1} and g=2.01.

On the basis of the above facts one could only expect antiferromagnetic interaction for the present complex. At present, we could not yet elucidate the origin of ferromagnetic behavior of the complex and more structural and magnetic data of more complexes are needed to settle the problem.

We thank for the financial support from the Ministry of Education, Science and Culture (No. 63740342).

Cobalt(III) Complexes with Quadridentate Ligands. X.[1] The Preparation and Properties of Isomers of the Salicylaldehydato(quadridentate amine)cobalt(III) Complexes

Eiko TOYOTA and Yoshihisa YAMAMOTO*
Faculty of Pharmaceutical Sciences, Higashi Nippon Gakuen University,
Ishikari-Tobetsu, Hokkaido 061-02
(Received June 10, 1989)

In a recent study, *t*- and *p*-salicylaldehydato[tris(2-aminoethyl)amine]cobalt(III) complexes, *t*- and *p*-[Co(salad)tren]$Cl_2 \cdot H_2O$, and *cis*-β_1- and β_2-*RR,SS*-salicylaldehydato(quadridentate amine)cobalt(III) complexes, *cis*-β_1- and β_2-*RR,SS*-[Co(salad)L]$Cl_2 \cdot nH_2O$ (L: 2,3,2-tet; 3,2,3-tet), have been obtained from a reaction mixture of [$CoCl_2$L]$Cl \cdot nH_2O$ (L: tren; 2,3,2-tet; 3,2,3-tet), Ag_2O, and salicylaldehyde. Two isomers were separated for each complex by SP-Sephadex C-25 column chromatography. The formation ratio of *t*- to *p*-isomers was ca. 1 : 3. The *t*- and *p*-configurations have been established by their absorption and ^{1}H NMR spectra. On the other hand, the formation ratio of cis-β_1 to β_2-*RR,SS*-isomers was ca. 1 : 1 for both L=2,3,2-tet and 3,2,3-tet ligands. Their configurations have been established by their IR, absorption, and NMR spectra. The corresponding cis-α-isomer could not be obtained. Isomerization between *t*- and *p*-isomers or cis-β_1- and β_2-isomers was not observed in water at room temperature. The formation ratio and the absorption spectra of the complexes are different from those of the corresponding salicylato(quadridentate amine)cobalt(III) chloride hydrate, [Co(sal)L]$Cl \cdot nH_2O$ (L: tren; 2,3,2-tet; 3,2,3-tet), previously reported. These differences have been attributed to a carbonyl bond between the carbonyl oxygen of the formyl group and a cobalt atom in the complexes.

Previously, we were concerned with the preparation and properties of isomers of the *cis*-β-salicylaldehydato(triethylenetetramine)cobalt(III) dichloride dihydrate,[2] *cis*-β-[Co(salad)trien]$Cl_2 \cdot 2H_2O$. The corresponding cis-α-isomer has not yet been obtained. The formation of the cis-α-isomer might be due to the configurations of the coordinated quadridentate tetramine ligands and to the coordinate atom of the coordinated organo ligands. We selected two ligands of 3,7-diazanonane-1,9-diamine (abbreviation: 2,3,2-tet) and 4,7-diazadecane-1,10-diamine (abbreviation: 3,2,3-tet) which are relatively strain-free[3,4] compared with trien (2,2,2-tet) ligand from their molecular models. On the other hand, the carbonyl oxygen of the formyl group of the salicylaldehydato (formylphenolato) ligand forms a carbonyl bond to a cobalt atom. This property is different from the carbonyl oxygen of the carboxyl group of salicylato and thiosalicylato (*o*-mercaptobenzoato) ligands. Then, *cis*-α-salicylaldehydatocobalt(III) complexes with 2,3,2-tet and 3,2,3-tet ligands may be obtained. Further, the preparation and properties of octahedral salicylaldehydatocobalt(III) complexes with amine ligands have not been studied, except for *cis*-β-[Co(salad)trien]$Cl_2 \cdot 2H_2O$, because salicylaldehyde reacts with ammine, *N*-alkyl (or *N*-aryl) amine, ethylenediamine, and quadridentate amine, and yields to the corresponding Schiff base ligands.[5-10] Thus, the present paper deals with the preparation and properties of the mixed-ligand cobalt(III) complexes with salicylaldehydato and tris(2-aminoethyl)amine (abbreviation: tren), 2,3,2-tet or 3,2,3-tet ligands as well as with the assignments of the configurations of these complexes.

Experimental

Measurements. The magnetic susceptibilities were measured by Faraday's method using a magnetic balance (Shimadzu) at room temperature. The electric conductivities in aqueous solutions were determined by the use of a conductometric meter, CM-30 (Shimadzu) at room temperature. The IR spectra were recorded in potassium bromide disks with a 270-30 spectrophotometer (Hitachi). The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The NMR spectra were recorded with an FX90Q apparatus (JEOL) for ^{1}H NMR and an FX-60 apparatus (JEOL) for ^{13}C NMR. The melting points were measured on a MP-500D apparatus (Yanako).

Preparation of Complexes. Dichloro[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate, [$CoCl_2$(tren)]$Cl \cdot H_2O$ (1) and *trans*-Dichloro(3,7-diazanonane-1,9-diamine)cobalt(III) Chloride Hydrates, *trans*-[$CoCl_2$(2,3,2-tet)]$Cl \cdot 2.5H_2O$ (2), *trans*-Dichloro(4,7-diazadecane-1,10-diamine)cobalt(III) Chloride Hydrate, *trans*-[$CoCl_2$(3,2,3-tet)]$Cl \cdot H_2O$ (3): Complexes **1** and **2**, **3** were prepared by the methods of Kimura,[11] and Bosnich,[3,12] respectively.

***t*-Salicylaldehydato[tris(2-aminoethyl)amine]cobalt(III) Dichloride Hydrate (4) and *p*-Salicylaldehydato[tris(2-aminoethyl)amine]cobalt(III) Dichloride Hydrate (5):** Complex **1** (5.0 g, 15.17 mmol) was added to moistened fresh Ag_2O, which was made from silver nitrate (5.17 g, 30.43 mmol) and potassium hydroxide (1.71 g, 30.48 mmol). The mixture was stirred for several minutes at room temperature; then, 10 cm^3 of water was added to the mixture. The mixture was stirred for about 30 min at 60 °C, and the precipitated silver chloride was filtered off and washed with a small amount of water. The methanol solution (20 cm^3) of salicylaldehyde (1.85 g, 15.15 mmol) was added, drop by drop, to the reddish-violet filtrate. The solution was stirred at room temperature for 6 h and was then concentrated on a rotary evaporator and dried. Yield: orange complex (a

mixture of **4** and **5**) 3.4 g. The separation of complexes **4** and **5** from the orange complex of 0.5 g was achieved by a column of ion-exchange resin (SP-Sephadex C-25, ϕ2.5×40 cm). On elution with 0.1 mol dm^{-3} NaCl, the effluent of the first orange band (complex **5**, *p*-isomer) and the second red band (complex **4**, *t*-isomer) was collected and concentrated on a rotary evaporator, and the precipitated NaCl was removed by filtration. Complexes **4** and **5** were recrystallized from methanol-ether. Yields: 0.47 g (7.5%) for **4**, 1.36 g (21.6%) for **5**. Found **4**: C, 37.77; H, 6.23; N, 13.76; Cl, 16.85%. **5**: C, 37.30; H, 6.31; N, 13.73; Cl, 17.34%. Calcd for $CoC_{13}H_{25}N_4O_3Cl_2$ (MW 415.20) C, 37.60; H, 6.07; N, 13.50; Cl, 17.08%. Dp: 188—189 °C for **4**, 191—193 °C for **5**. Λ=245 for **4**, 250 S cm^2 mol^{-1} for **5** in water.

***cis*-β-Salicylaldehydato(3,7-diazanonane-1,9-diamine)-cobalt(III) Dichloride Hydrate:** To a mixture of complex **2** (5.0 g, 13.49 mmol) and Ag_2O (26.96 mmol) was added salicylaldehyde (1.64 g, 13.43 mmol) in methanol (20 cm^3) according to the procedure for complexes **4** and **5**. The solution was stirred at room temperature for 20 h and was then concentrated on a rotary evaporator. The concentrated solution was injected onto an alumina column. Upon elution with methanol, the effluent of the first red band was collected and concentrated. Yield: orange complex (a mixture of **6** and **7**) 3.8 g.

***cis*-β_1-Salicylaldehydato(3,7-diazanonane-1,9-diamine)-cobalt(III) Dichloride Dihydrate (6) and *cis*-β_2-Salicylaldehydato(3,7-diazanonane-1,9-diamine)cobalt(III) Dichloride Dihydrate (7):** The separation of complexes **6** and **7** from the orange complex of 0.5 g was achieved by a column of ion-exchange resin (SP-Sephadex C-25, ϕ2.5×70 cm). Upon elution with 0.1 mol dm^{-3} NaCl, the effluents of the upper and lower layers of the orange band were collected and concentrated, respectively. The separated NaCl was removed by filtration. The isolation of complex **6** from the upper layer was achieved by a column of ion-exchange resin by the above method, i.e., the upper layer of orange band was collected again and concentrated. The separated NaCl was removed. Complex **6** was recrystallized from methanol-ether. This procedure was repeated again. The isolation of complex **7** from the lower layer was achieved according to the same procedure for complex **6**. Yields: 0.76 g (12.6%) for **6**, 1.02 g (16.9%) for **7**. Found **6**: C, 37.30; H, 6.41; N, 12.37; Cl, 16.10%. **7**: C, 37.89, H, 6.66; N, 12.25; Cl, 16.08%. Calcd for $CoC_{14}H_{29}N_4O_4Cl_2$ (MW 447.24) C, 37.60; H, 6.54; N, 12.53; Cl, 15.85%. Dp: 201—203 °C for **6**, 206—208 °C for **7**. Λ=225 for **6**, 230 S cm^2 mol^{-1} for **7** in water. IR spectra **6**: 1030, 1045, 1075, 1085 cm^{-1}; 3070, 3100, 3120, 3200 cm^{-1}. **7**: 1030, 1045, 1075, 1085 cm^{-1}; 3060, 3100, 3130, 3200 cm^{-1}.

***cis*-β_1-Salicylaldehydato(4,7-diazadecane-1,10-diamine)-cobalt(III) Dichloride Hydrate (8) and *cis*-β_2-Salicylaldehydato(4,7-diazadecane-1,10-diamine)cobalt(III) Dichloride Hydrate (9):** A mixture of complexes **8** and **9** was prepared from the reaction mixture of complex **3** (5.0 g, 13.98 mmol), flesh Ag_2O (3.4 g, 14.67 mmol), and salicylaldehyde (1.8 g, 14.74 mmol). Complexes **8** and **9** were isolated according to the method for **6** and **7**, and recrystallized from methanol-ether. Yields: 0.93 g (15.0%) for **8**, 1.26 g (20.3%) for **9**. Found **8**: C, 40.86; H, 6.92; N, 12.40; Cl, 16.16%. **9**: C, 40.96; H, 6.40; N, 12.79; Cl, 16.07%. Calcd for $CoC_{15}H_{29}N_4O_3Cl_2$ (MW 443.26) C, 40.64; H, 6.59; N, 12.64; Cl, 16.00%. Dp: 196—198 °C for **8**, 192—194 °C for **9**. Λ=237 for **8**, 233 S cm^2 mol^{-1} for **9** in water. IR spectra **8**: 1035, 1065, 1080, 1090 cm^{-1}; 3070, 3100, 3120, 3170 cm^{-1}. **9**: 1015, 1040, 1060, 1070 cm^{-1}; 3070, 3100, 3130, 3170 cm^{-1}.

Solubility. All complexes were very soluble in water, methanol, and DMSO, and slightly soluble in ethanol but insoluble in common organic solvents, such as ether and acetone.

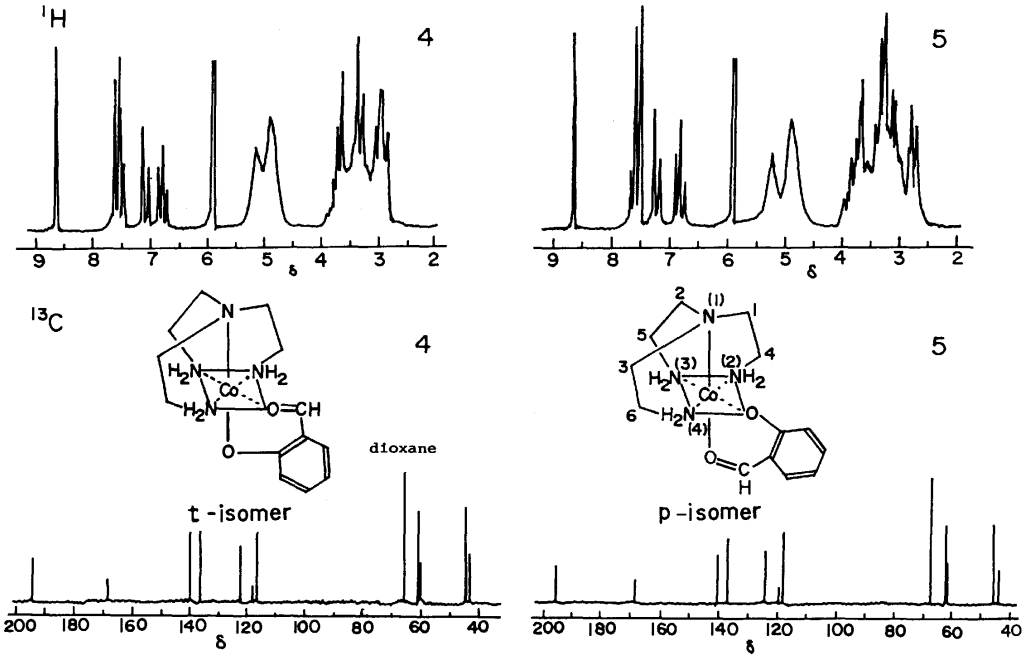

Fig. 1. The *t* and *p* configuration of [Co(salad)tren]$Cl_2 \cdot H_2O$, and ^{1}H and ^{13}C NMR spectra of complexes **4** and **5**.
4: *t*-[Co(salad)tren]$Cl_2 \cdot H_2O$; **5**: *p*-[Co(salad)tren]$Cl_2 \cdot H_2O$. Solvent: ^{1}H NMR, 1.8 mol dm^{-3} D_2SO_4; ^{13}C NMR, D_2O.

Results and Discussion

***t*- and *p*-Salicylaldehydato(tren)cobalt(III) Dichloride Hydrate (*t*: 4, *p*: 5):** Octahedral salicylaldehydato(tren)cobalt(III) complexes exist in two isomeric forms of *t*- and *p*-isomers,[13] as shown in Fig. 1. A mixture of *t*- and *p*-salicylaldehydato(tren)cobalt(III) dichloride hydrate has been obtained from a reaction mixture of $[CoCl_2(tren)]Cl$ (**1**), Ag_2O, and salicylaldehyde. Two geometrical isomers of *t*- (**4**) and *p*- (**5**) of the complex were separated by SP-Sephadex C-25 column chromatography. The formation ratio of **4** to **5** was ca. 1 : 3. The isomerization between **4** and **5** was not observed in water and methanol at room temperature. The electric conductivities for **4** and **5** in aqueous solutions were 245 and 250 $S\,cm^2\,mol^{-1}$, respectively.

The absorption spectra of **4** and **5** were measured in water (Table 1). The absorption bands at around 410 and 500 nm were assigned to a specific absorption band and the first d-d absorption band, respectively.

The ^{13}C NMR spectra of **4** and **5** were measured in D_2O (Fig. 1 and Table 2). Four signals have been observed for the tren ligand and seven signals for the salicylaldehydato ligand. The signals at δ 44.2 and 45.5 for **4** were assigned to the NH_2- side methylene carbons, and those at δ 61.3 and 62.1 were assigned to the -N side methylene carbons.[14] The signals at δ 44.2 and 61.3 were assigned to the C(5) and C(2) carbons, respectively, and those at δ 45.5 and 62.1 were assigned to the C(4), C(6) and C(1), C(3) carbons,[14] respectively. The spectral data of **5** are shown in Table 2.

The ^1H NMR spectra of **4** and **5** were measured in 1.8 mol dm^{-3} D_2SO_4 (Fig. 1). The signals of the NH_2- side and -N side methylene protons, ring and formyl group protons of **4** and **5** were assigned by comparisons with those of *t*- and *p*-salicylato(tren)-

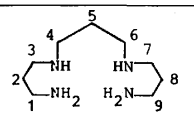
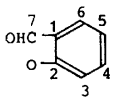
[ ]: The chemical shifts could not be assigned to the individual methylene carbon.



Quadridentate amine



Salicylaldehydato

cobalt(III) chloride hydrate,[14] *t*- and *p*-[Co(sal)-tren]Cl·H_2O (*t*: **10**, *p*: **11**) (Table 1). The amine protons showed two peaks at δ 4.90 and 5.10 for **4** and δ 4.80 and 5.20 for **5** with an intesity ratio of 2:1. The signals at δ 4.90 for **4** and 4.80 for **5** were assigned to $N(2)H_2$ and $N(3)H_2$ protons.[14] Those at δ 5.10 for **4** and at δ 5.20 for **5** were assigned to the $N(4)H_2$ protons.[14]

The chemical shift (δ 4.80) of the proton signal of the NH_2 groups of **5** was at a higher field than that (δ 4.90) of **4**, i.e., the NH_2 group of **5** is considered to be in a position trans to the phenoxyl oxygen of the coordinated salicylaldehydato ligand, which is more electronegative than the formyl oxygen. Also, the methylene proton signals of **5** showed two very sharp peaks[14] in the δ 2.5—2.9 region, but those for **4** did not show the corresponding peaks. In addition, the first absorption band of **4** was at a longer wavelength than that of **5**. These properties of **4** and **5** are in agreement with those of **10** and **11**,[14] respectively. Thus, complexes **4** and **5** have been assigned to *t*- and *p*-isomers, respectively.

The color, melting point, formation ratio, and absorption spectra of **4** and **5** were different from those of **10** and **11**. The color of **4** and **5** was reddish-brown and orange, respectively, but that of **10** and **11** was russet and red, respectively. The melting points (ca. 190 °C) of **4** and **5** were lower than those (ca. 240 °C) of **10** and **11**. The formation ratio of *t*- to *p*-isomers was ca. 1:3 for **4** and **5**, but was ca. 3:1 for **10** and **11**. The specific absorption bands at around 410 nm of **4** and **5** were at longer wavelengths than those at around 330 nm of **10** and **11**, though the first absorption bands at 490—500 nm for **4** and **5** were at a shorter wavelength than those at 515—530 nm for **10** and **11**. These differences are attributed to a carbonyl bond, i.e., the corbonyl oxygen of the formyl group of **4** and **5** is bonded to a cobalt atom, but the carbonyl oxygen of the carboxyl group of **10** and **11** is not bonded to the cobalt atom.

***cis*-β-Salicylaldehydato(2,3,2-tet)cobalt(III) Dichloride Dihydrate (β1: 6, β2: 7) and *cis*-β-Salicylaldehydato-(3,2,3-tet)cobalt(III) Dichloride Hydrate (β1: 8, β2: 9):** Octahedral salicylaldehydato(quadridentate amine)-

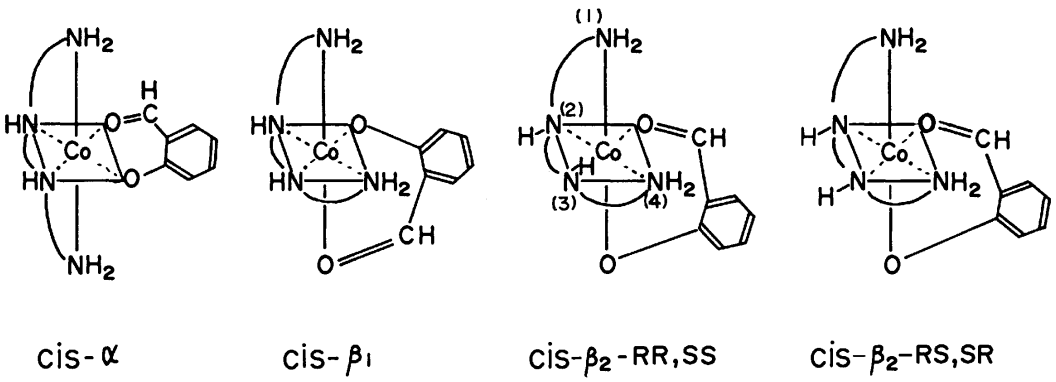


Fig. 2. The cis-α, β1, β2-*RR,SS*, and β2-*RS,SR* configurations of [Co(salad)(quadridentate amine)]cobalt(III) complexes.

cobalt(III) complexes exist in three geometrical isomers of cis-α, cis-β_1, and cis-β_2. The cis-β-isomers exist in two diastereoisomers of *RR,SS* and *RS,SR*, as shown in Fig. 2. *cis*-β-Salicylaldehydato(quadridentate amine)cobalt(III) dichloride hydrate has been obtained from a reaction mixture of *trans*-[$CoCl_2$(2,3,2-tet)]Cl·2.5H_2O (**2**) or *trans*-[$CoCl_2$(3,2,3-tet)]Cl·H_2O (**3**), Ag_2O, and salicylaldehyde. Complexes **6** and **7** or **8** and **9** were separated by SP-Sephadex C-25 column chromatography. Complexes **6—9** are highly hygroscopic. Complexes **8** and **9** were diamagnetic from the magnetic susceptibility. The electric conductivities for **6—9** in aqueous solutions were 225—237 S $cm^2 mol^{-1}$.

The absorption spectra of **6—9** were measured in water, as shown in Table 1. Their absorption bands at around 410 nm and 500 nm were assigned to the specific absorption band and the first absorption band, respectively.

The ^1H and ^{13}C NMR spectra of **6—9** were measured in 1.8 mol dm^{-3} D_2SO_4 and D_2O, respectively. Their center, NH_2- and NH- side methylene protons (and carbons) and salicylaldehydato protons (and carbons) and amine protons were assigned by comparisons with those of *cis*-β-salicylato(quadridentate amine)-cobalt(III) chloride hydrates,[15,16] *cis*-β-[Co(sal)L]Cl·$n H_2O$ (L: trien, β_1: **12**, β_2: **13**; 2,3,2-tet, β_1: **14**, β_2: **15**; 3,2,3-tet, β_2: **16**). Their chemical shifts are shown in Tables 1 and 2. The ^{13}C chemical shifts of the coordinated quadridentate amine ligands were difficult to assign to the individual carbon atoms, but the regions of the chemical shifts of the center, NH_2-, and NH-side methylene carbons were close to those of **12—16**.

The IR spectra of **6—9** showed four absorption bands in the NH_2 twisting region (990—1100 cm^{-1}) and four absorption bands in the NH stretching region (3000—3300 cm^{-1}). The ^{13}C NMR spectra of **6—9** showed 7—8 signals for the quadridentate amine ligand. They indicate that these complexes are assigned to the cis-β-form.[16,17]

A distinction between **6** and **7** was found in the ^1H NMR and absorption spectra. In the ^1H NMR spectra, the methylene proton signals of **6** in the δ 2.2—3.3 region could not be divided into two groups, but those of **7** could be divided into two groups, as shown in Fig. 3. The ε of the first absorption band of **6** was larger than that of **7**, and the band of **6** was at a longer wavelength than that of **7**. These results for **6** and **7** were similar to those of complexes **12**,[15] **14**,[16] and *cis*-β_1-salicylaldehydato(trien)cobalt(III) dichloride dihydrate,[2] *cis*-β_1-[Co(salad)trien]Cl_2·$2H_2O$ (**17**) and complexes **13**,[15] **15**,[16] and *cis*-β_2-[Co(salad)-trien]Cl_2·$2H_2O$ (**18**),[2] respectively. Thus, complexes **6** and **7** were assigned to the cis-β_1 and β_2-isomers, respectively. In complexes **8** and **9**, the ^1H NMR, absorption spectra, and the elution order of the chromatography of **8** and **9** were very close to those of **6**, **17** and **7**, **18**, respectively, i.e., **8** and **9** could be assigned to the cis-β_1 and β_2-isomers, respectively. Next, cis-β-isomer will adopt more stable *RR,SS* configurations; e.g., Buckingham et al. were interested in the stability between the cis-β-*RR,SS* and *RS,SR* configurations of Co(III) complexes with a trien ligand. The *RR,SS* configurations have been shown to be more stable

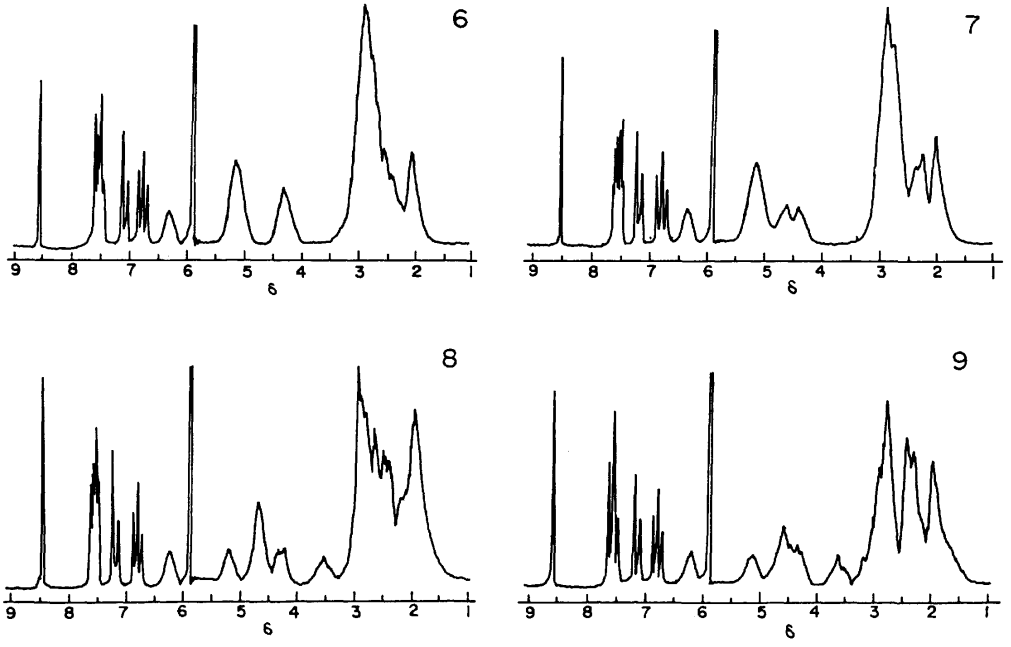

Fig. 3. The ^1H NMR spectra of complexes **6—9** in 1.8 mol dm^{-3} D_2SO_4.
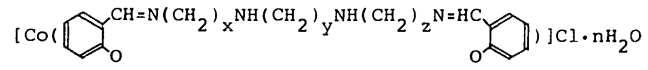
6: *cis*-β_1-*RR,SS*-[Co(salad)2,3,2-tet]Cl_2·$2H_2O$; **7**: *cis*-β_2-*RR,SS*-[Co(salad)2,3,2-tet]-Cl_2·$2H_2O$; **8**: *cis*-β_1-*RR,SS*-[Co(salad)3,2,3-tet]Cl_2·H_2O; **9**: *cis*-β_2-*RR,SS*-[Co(salad)-3,2,3-tet]Cl_2·H_2O.

than the *RS,SR* configurations for a *cis*-β-[CoL_2(trien)]$^{n+}$ (L_2: Cl_2, $(H_2O)_2$, CO_3, gly).[18-20] Also, *cis*-β-[CoL(2,3,2-tet)]$^{n+}$ (L: oxalato, glycinato, alaninato, valinato, and sarcosinato),[21,22] *cis*-β-[Co(ox)(Me_2-2,3,2-tet)]$^+$,[23] and *cis*-β-[CoL(3,2,3-tet)]$^{n+}$ (L: oxalato, acetylacetonato, carbonato)[12,24] have been found to have *RR,SS* configurations by their CD spectra and X-ray diffractions. Thus, we suggest that the structures of **6—9** and **17**, **18** are assigned to the *RR,SS* configurations.

The corresponding cis-α isomer has not been obtained in this study and the corresponding studies.[2,15,16,25] However, *cis*-α-*RR,SS*-[Co(gly)L]$^{2+}$ (gly: $NH_2CH_2COO^-$; L: trien, 3,2,3-tet) has been reported.[22,26] This difference may be due to the coordinate atom of the chelated ligands. Thus, we suggest that the cis-α isomer may be obtained from a reaction mixture of the N-O^- chelate ligand with 2,3,2-tet or 3,2,3-tet ligand.

The color, melting point, and absorption spectra of **6—9** and **17**, **18** were different from those of **12—16**, such as the corresponding tren complexes. Especially, the cis-β_1 of **6**, **8**, and **17** could not be isomerized to the cis-β_2 of **7**, **9**, and **18**, respectively, in water, but the cis-β_1 of **12** and **14** are isomerized to the cis-β_2 of **13** and **15**, respectively,[14] in water at room temperature.

The preparation of the mixed-ligand metal complexes with salicylaldehydato and amine ligands has been difficult, because metal complexes with Schiff base ligands are obtained. In this study, it has been elucidated that the preparation of the mixed-ligand cobalt(III) complexes with salicylaldehydato ligand is dependent upon the reaction temperature. (*N,N'*-Disalicylidene-substituted quadridentate amine)cobalt(III) complexes,[10]



(*x,y,z*: 2,2,2; 2,3,2; 3,2,3; 3,3,3), were prepared from a reaction mixture of $[CoCl_2L]Cl \cdot nH_2O$ (L: quadridentate amine), Ag_2O, and salicylaldehyde in methanol at 50 °C. On the other hand, complexes **6—9**, **17**, and **18** were prepared at room temperature from the same reaction mixture.

(Received July 1, 1989)

The coprecipitation of trace metals with gallium has been investigated in detail especially with respects to the role of magnesium ion in saline or seawater. Gallium does not precipitate even at pH 9 when magnesium ion does not exist. The concentration of gallium in the precipitate increased with increasing that of magnesium in solution. The recoveries of trace metals also showed strong dependence on the concentrations of both gallium and magnesium in the aqueous solution.

Since the concentrations of trace metals in seawater are extremely low, preconcentration prior to analysis is necessary to determine these elements by the convenient analytical measurement method. Among a variety of preconcentration techniques for trace metals in seawater, coprecipitation technique has been widely employed.[1-12] Zirconium,[1] Fe,[2,3,6] Bi,[2,3] Co-APDC,[4,7] In,[8] La,[9] and Mg,[5,10,11] have been used as the coprecipitation reagents for preconcentration of analyte metals from seawater and/or brine samples.

The present authors developed a coprecipitation technique using gallium as a coprecipitation reagent[12] for preconcentration of trace metals in seawater in order to determine them simultaneously by inductively coupled plasma atomic emission spectrometry (ICP-AES). In the study, it was found that gallium precipitates between pH 5—6 and above pH 9 in seawater, while it does not precipitate between pH 7—8. Furthermore gallium did not precipitate in the river water even above pH 9. This characteristic features of gallium precipitation is very helpful for the preconcentration of trace metals in seawater because of negligibly small contamination from chemicals required for pH adjustment.

According to the present authors' survey, the reason why gallium does precipitate at pH 9 in seawater has not been investigated yet. In the present study, hence, the precipitate formation of gallium has been examined by using saline water samples with various compositions so as to elucidate the role of gallium coprecipitation in seawater.

Experimental

Apparatus. An ICP-AES spectrophotometer used for metal analysis was Plasma Atomcomp MK II from Jarrell Ash Co. The operating conditions of the ICP-AES instrument are summarized in Table 1. A double-beam spectrophotometer UV-210A (Shimadzu Co., Ltd.) was used to monitor the formation of the precipitates at the wavelength 660 nm, which was the same wavelength as that for convenient turbidity measurement. The length of the sample cell used was 10 cm and the width of the entrance slit was set at 2 mm. A pH meter model Ionalyzer 407A (Orion Research Inc.) was employed to adjust pH of the test solutions.

Chemicals. The chemicals used were of analytical reagent grade. All acids were of extra pure grade purchased from Wako Chemicals Co. The stock solutions for metals were prepared by dissolving the corresponding metals or oxides in the acids. One g of gallium metal (99.99%; Wako Chemicals Co.) was dissolved in 10 ml of (1+1) nitric acid and diluted to 200 ml with water. Sodium hydroxide solution (9 M; 1 M=1 mol dm^{-3}) used for pH adjustment was prepared from its salt (Suprapur; Merck).

Procedures. The test solution (100 ml) was prepared by dissolving the required amount of magnesium chloride (0, 5, 20, 100, 400 mg Mg/100 ml) in pure water. Then different amounts of gallium (0, 0.02, 0.1, 0.5, 2 mg) were added to all the test solutions. After stirring well, pH of all the test solutions was adjusted to 9 by adding sodium hydroxide solution. The precipitate formation was monitored at 660 nm by measuring turbidity. The precipitate was stood for 24 h, and then filtered with a Nuclepore filter. After washing with 3 ml of pure water, the precipitate collected on the filter was dissolved with 2.5 ml of 1 M hydrochloric acid, and diluted exactly to 5 ml with water. The final solution was supplied to the ICP-AES measurement. In the recovery test, analytes (10 μg for each element) were added to the above solutions.

Table 1. Instrumental Components and Operating Conditions

Spectrometer	Jarrell-Ash Plasma Atomcomp MK II

exit slit width	50 μm
Monochromator	Ebert type (50 cm focal length)

Results and Discussion

pH Dependence of Gallium Precipitation. Since gallium is an amphoteric metallic element, it dissolves in aqueous solution at both low and high pH region. The equilibria and their dissociation constants of gallium hydroxide in solution are as follows.[13]

$$Ga(OH)_3(s)=Ga^{3+}+3OH^- \qquad K=5\times10^{-37}$$
$$Ga(OH)_3(s)=GaO_2^-+H^++H_2O \qquad K=10^{-15}$$

The pH dependences of the precipitate formations for the solutions containing gallium and/or magnesium were examined by measuring transmittance at 660 nm. The experimental results are shown in Fig. 1-(a), (b), and (c). As is shown in Fig. 1-(a), gallium formed the precipitate in aqueous solution at the pH range between 4 and 6, which was observed as the slight decrease of the transmittance of the solution. The pH dependence of the precipitate formation of magnesium in aqueous solution, in which the concentration of magnesium is the same as those in natural seawater, i.e., 1300 mg of Mg/l, is shown in Fig. 1-(b). The transmittance of the solution began to decrease markedly from pH 10. At pH 11 the precipitation of magnesium took place so significantly that the transmitted light could be hardly detected.

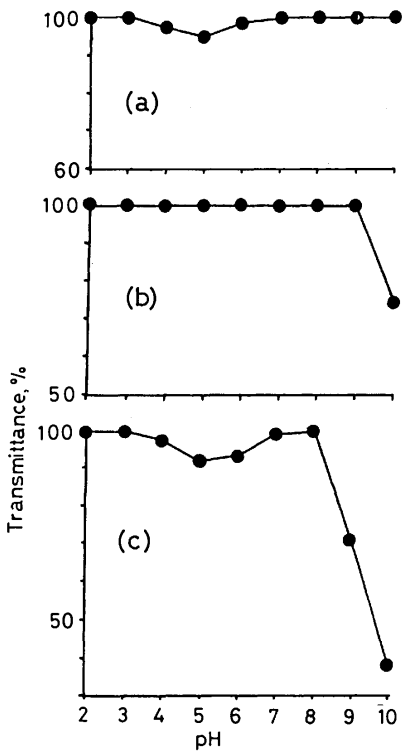

Fig. 1. Precipitation behaviors of gallium and/or magnesium in aqueous solution as a function of pH. Precipitation was monitored as transmittance at 660 nm.
(a); 10 mg of gallium/l, (b); 1300 mg of magnesium/l, (c); 10 mg of gallium/l and 1300 mg of magnesium/l.

The transmittance of the solution containing both gallium (10 mg l^{-1}) and magnesium (1300 mg l^{-1}) at various pH is shown in Fig. 1-(c). Precipitation occurred between pH 4—6 and above pH 9. The precipitation behavior below pH 8 was almost identical to the result obtained for only the gallium solution (see Fig. 1-(a)). On the other hand, above pH 9 the behavior was similar to that of the magnesium solution (Fig. 1-(b)), but the precipitation took place from the lower pH. It should be noted that the mixed solution of magnesium and gallium precipitated at pH 9, where the solution containing only magnesium did not.

pH Dependence of Gallium Precipitation in Seawater Martix Solution. The amounts of seawater-matrix elements (sodium, potassium, calcium, and magnesium) and gallium in the precipitate were analyzed as the pH function, when the gallium coprecipitation was applied to seawater. The compositions of the precipitate were measured by ICP-AES as the relative concentration, where the amount of each element at pH 9 was defined as 1. The experimental results are shown in Fig. 2. In the pH range between 7 and 8, no precipitation took place, and then test was not made. Gallium precipitated almost quantitatively between pH 5 and 6 and above pH 9, as can be seen in Fig. 2. Among the matrix elements in seawater, magnesium and calcium in the precipitate showed a strong dependence on pH around pH 9. The amount of Ca in the precipitate started to increase suddenly above pH 9.3. The amounts of magnesium and gallium in the precipitate at pH 9 were about 5 mg, when 5 mg of gallium is added to 1 l of seawater. They were rather larger than the amounts of calcium, sodium, and potassium in the precipitate (0.05 mg, 0.005 mg, and 0.05 mg, respectively). The strong dependence of the magnesium content in the precipi-

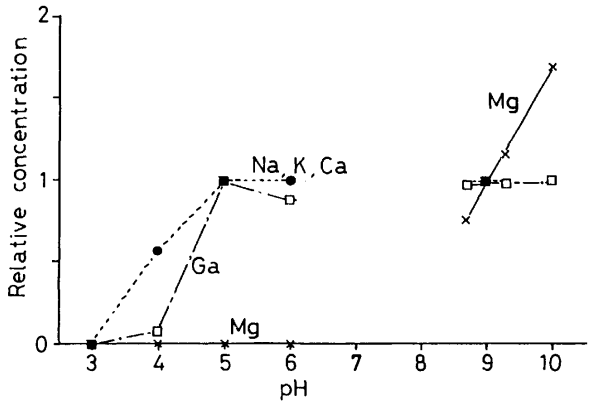

Fig. 2. Concentrations of gallium, alkali and alkaline earth elements in the precipitate at various pH in the case of gallium coprecipitation. Artificial seawater was used. Five mg of gallium was added to 1 l of seawater. The concentrations of all elements at pH 9 are defined as 1.

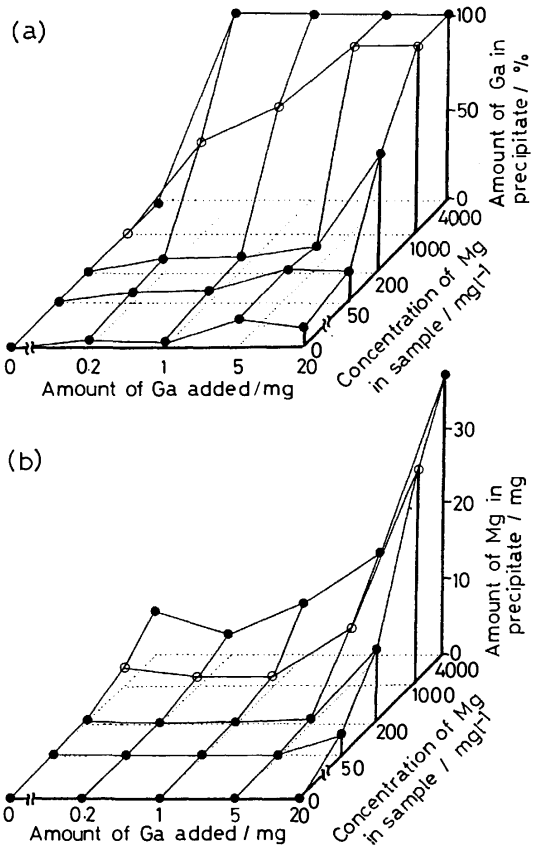

Fig. 3. Dependences of the precipitate compositions on the concentrations of magnesium and gallium at pH 9.0.
(a); amount of gallium in the precipitate (%). (b); amount of magnesium in the precipitate (mg). Open circles indicate the results for the solutions containing magnesium at the seawater level. The experiment was done using 100 ml of test solutions. The values in the figure was converted ones for 1 l of solutions.

tate on pH as well as the precipitate formation of the magnesium and gallium solution (Fig. 1-(c)) suggest the role of Mg in the precipitation of gallium. Therefore, the precipitation behaviors of gallium associated with magnesium in seawater was further investigated at pH 9.

Effect of Amounts of Magnesium and Gallium on Precipitate Formation. The precipitate formation of gallium at pH 9 was investigated using the solutions which contained both gallium and magnesium at various concentrations. The experimental results are shown in Fig. 3. The test solutions were prepared by dissolving required amounts of magnesium chloride in pure water and then different amounts of gallium were added into the solutions, in which the concentrations of magnesium in the test solutions were varied from 0 to 4000 mg l^{-1}, and those of gallium from 0 to 20 mg l^{-1}. The precipitate collected on a filter was dissolved in 1 M HCl solution. The percent recovery of gallium and amount of magnesium in the precipitates are shown in Figs. 3-(a) and -(b), respectively, as the functions of magnesium and gallium concentrations. As is seen in Fig. 3-(a), the percent recovery of gallium in the precipitate showed strong dependence on the concentrations of both gallium and magnesium in the solutions, and it was improved at the higher concentrations of both gallium and magnesium in the solution. When the concentration of magnesium in the sample was 4000 mg l^{-1}, gallium formed completely the precipitate at its concentration larger than 0.2 mg l^{-1}. For the solution containing magnesium at the concentration of seawater level (1000 mg l^{-1}, indicated by open circle in Figs. 3), gallium precipitated quantitatively (100%), when it was added not less than 5 mg l^{-1}. On the other hand, only a few percentage of gallium formed the precipitate when the magnesium concentration was below 50 mg l^{-1}.

Similar dependence was observed for the magnesium precipitation (Fig. 3-(b)). The amount of magnesium in the precipitate increased with the increases of the concentrations of both gallium and magnesium

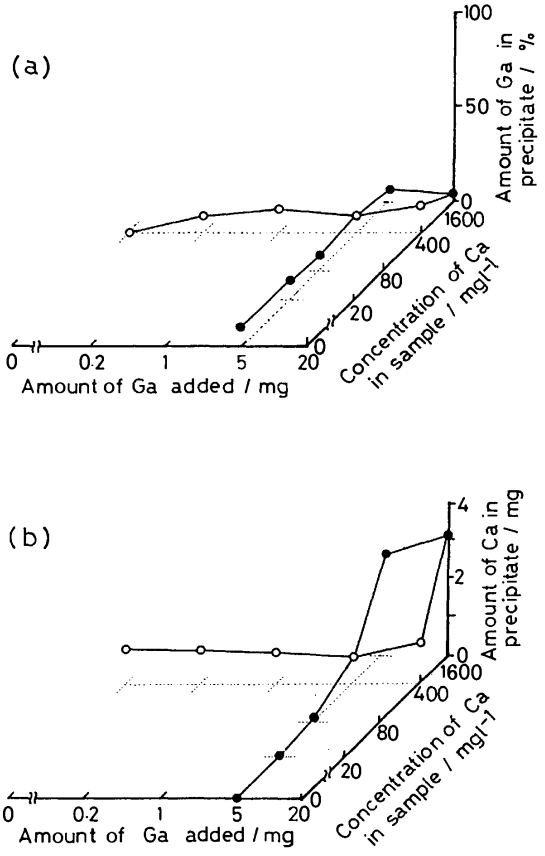

Fig. 4. Dependence of the precipitate compositions on the concentrations of gallium and calcium at pH 9.0.
(a); amount of gallium in the precipitate (%). (b); amount of calcium in the precipitate (mg). Open circles indicate the results for the solutions containing calcium at the seawater level. The experiment was done using 100 ml of test solutions. The values in the figure was converted ones for 1 l of solutions.

Open circles indicate the results for the solutions containing magnesium at the seawater level.

in solution. However, the amount of magnesium in the precipitate did not show proportionality to neither its concentration nor the added amount of gallium in the solution.

The experimental results described above indicate the interactions between magnesium and gallium in their precipitate formations.

Influence of Calcium on Gallium Precipitation. One l of seawater contains about 400 mg of calcium, which is about one third of magnesium content in seawater. The chemical property of calcium is more similar to that of magnesium than those of any other salts in seawater such as sodium and potassium. Thus, it is worthwhile to examine the influence of calcium on gallium precipitation. Such an influence was tested in the same manner as the case of magnesium. The calcium solutions (0—1600 mg l^{-1}) were prepared by dissolving required amounts of calcium chloride in pure water. The concentations of calcium in the test solutions were 0—4 times as large as that in seawater. The pH of the test solutions was adjusted to 9. The experimental results, the percent recovery of gallium and the amount of calcium in the precipitate, are shown in Figs. 4-(a) and (b), respectively. As can be seen in the figures, the percent recovery of gallium was low and did not depend on the gallium amount added or the concentration of calcium in the sample solution. The amount of calcium in the precipitate showed slight dependence on both of them, but it was much lower than that of magnesium (Fig. 4-(b)). Thus it is concluded that calcium had little cooperation in gallium precipitation.

Influence of Anions on Gallium Precipitation. Although large amount of chloride ion is present in seawater, the behavior of magnesium in its precipitation with gallium was investigated, when magnesium ion coexisted with different anion such as nitrate ion. The experiment was carried out by using magnesium nitrate solution. The results obtained for magnesium nitrate were almost similar to those using magnesium chloride. This experimental result may lead to the conclusion that only magnesium ion is responsible for its interaction with gallium in the gallium precipitation. The present result is due to the existence of Mg as the ionic form in high ionic strength solution, according to the calculation by Berner.[14]

Influence of Gallium and Magnesium Matrices on Recoveries of Heavy Metals. The precipitate in the gallium coprecipitation consists of magnesium as

well as gallium. So far only magnesium hydroxide has been used as a coprecipitation carrier.[10,11] Therefore, not only gallium hydroxide but also magnesium hydroxide are expected to collect heavy metals in solution. Hence the recoveries of analyte elements were investigated in terms of the added amount of gallium and the concentration of magnesium in solution. The original concentration of each analyte metal was 10 $\mu g\,l^{-1}$. The experimental results for Cd, Mn, and Y are shown in Figs. 5-(a), (b), and (c), respectively. As can be seen in the figures, the recoveries of analyte metals were dependent on both of the added amount of gallium and the concentration of magnesium in the test solution, i.e., the recoveries of such metals were improved with the increases of gallium and magnesium. Slight differences in the recovery patterns were, however, observed, depending on the analyte metals examined. The recovery of Mn was influenced by the concentration of magnesium rather than that of gallium (Fig. 5-(b)), while the recovery of Y depended more largely on the concentration of gallium (Fig 5-(c)). Iron showed a similar tendency to Mn, but Cu, Co, and V had the similar trends to Y. The tendencies of Zn, As, and Cr were similar to that of Cd. The results may be explained by the difference in chemical affinities of analyte metals with gallium and/or magnesium hydroxides.

Conclusion

The gallium coprecipitation method can be efficiently used for trace metal preconcentration in seawater in association with magnesium in solution. It has been elucidated that the cooperative interaction between gallium and magnesium is necessary in the efficient precipitate formation. The presence of magnesium ion in sample solution helped the quantitative precipitation of gallium added as a coprecipitation reagent, although very small portion of magnesium (about 0.3%) in seawater was found in the precipitate at pH 9. To coprecipitate analyte elements, both gallium and magnesium play as the coprecipitation carriers, which provides some unique advantages[12] in seawater analysis by ICP-AES.

1,7-Dithia-4-selena[7]- and 1,9-dithia-5-selena[9](1,1′)ferrocenophanes were prepared. These compounds, as well as 1,4,7-trithia[7]- and 1,5,9-trithia[9](1,1′)ferrocenophanes, were treated with $(CH_3CN)_4Pd(BF_4)_2$ or $(CH_3CN)_4Pt(BF_4)_2$ to give the corresponding 1/1 complexes in good yield. The spectral data of these complexes confirmed that there exsisted a dative Fe–Pd or Fe–Pt bond in these bimetallic complexes.

Much attention has been focused on the heterobimetallic complexes.[1,2] Such species should be capable of generating unique reactivity by virtue of the close proximity of the adjacent metals. The coordination of the nonbonding e_{2g} electrons of the iron atom in ferrocene to vacant orbitals of a transition metal has also become a topic of interest in recent years. Ferrocene derivatives involving heteroatoms in the 1,1′-positions formed 1/1 complexes (**1**) with various metals.[3] However, it was reported that there was no evidence of an interaction between the iron atom of a ferrocene nucleus and the metal coordinated to the hetero atoms.[4,5] In this connection, Seyferth et al. carried out a reaction of 1,2,3-trithia[3](1,1′)ferrocenophane with tetrakis(triphenylphosphine)palladium(0) to obtain (triphenylphosphine)(1,1′-ferrocenedithiolato-*S,S′,Fe*)palladium(II) (**2a**), which was confirmed by X-ray analysis to have a weak dative Fe–Pd bond.[6,7] A similar Pt(II) complex (**2b**) was also reported.[8] In the same year, Sano et al. reported that the stable metal halide adducts (**3**) of [2](1,1′)ferrocenophane were confirmed by Mössbauer spectroscopy to have a strong bonding interaction between the iron atom and metal halides.[9] On the other hand, thiamacrocyclic compounds are of interest in that these form stable complexes with various transition metals and stabilize an unusual valence of the metal.[10] Since we have already prepared various metal complexes of tetrathia-[*n*]- and trithia[*n*]ferrocenophanes,[11,12] these findings have stimulated us to attempt a reaction of trichalcogeno[*n*]ferrocenophanes with a highly acidic $Pd(BF_4)_2$ or $Pt(BF_4)_2$.[13,14]

Results and Discussion

1,5,9-Trithia[9](1,1′)ferrocenophane (**4**)[12] was allowed to react with $(CH_3CN)_4Pd(BF_4)_2$, which was prepared from the reaction of $(CH_3CN)_2PdCl_2$ and $AgBF_4$,[15] in acetone at ambient temperature. Stable dark-brown fine needles (**5a**) were isolated in good yield, which proved by elemental analysis to be a 1/1 complex. A similar reaction of 1,4,7-trithia[7]-(1,1′)ferrocenophane (**6**)[16] with $(CH_3CN)_4Pd(BF_4)_2$ gave a black 1/1 complex (**7a**) and a green powdery 2/1 complex (**8a**) in 74 and 12% yields, respectively. Complexes **5a** and **7a** contained one equivalent of acetone in the crystals. Upon recrystallization from acetonitrile–diethyl ether, the acetone was replaced by acetonitrile. In order to extend the scope of the reaction, each trithia[*n*]ferrocenophane was treated with $(CH_3CN)_4Pt(BF_4)_2$.[15] Only the reaction of the [9]-ferrocenophane (**4**) with $(CH_3CN)_4Pt(BF_4)_2$ in warm acetonitrile under nitrogen gave a stable 1/1 complex (**5b**) as red needles in good yield.

Dithiaselena[*n*](1,1′)ferrocenophanes could not be synthesized by the procedure used for preparing trithia[*n*](1,1′)ferrocenophanes. For example, 1,1′-bis(3-chloropropylthio)ferrocene (**9**) reacted with sodium selenide to give no desirable product. This failure seems to be due to the low nucleophilicity of sodium selenide compared with sodium sulfide. Thus, the chloride (**9**) was converted to 1,1′-bis(3-iodopropylthio)ferrocene (**11**) by treating **9** with sodium iodide in refluxing 2-butanone for 24 h. Similarly, 1,1′-bis(2-iodoethylthio)ferrocene (**12**) was obtained in good yield from 1,1′-bis(2-chloroethylthio)ferrocene (**10**). The reaction of the iodide **11** with an aqueous solution of sodium selenide[17] in refluxing THF under high-dilution conditions gave the desired product, 1,9-dithia-5-selena[9](1,1′)ferrocenophane (**13**), although in low yield. The ring closure of the iodide **11** using a thiourea method proceeded successfully to give a more sufficient yield. Thus, **11** was treated with thiourea in refluxing ethanol under high-dilution conditions, followed by the addition of 10% aqueous sodium hydroxide; then, refluxing continued for 4 h to give **13** in 33% yield along with the dimeric compound, 1,9,20,28-tetrathia-5,24-diselena[9,9](1,1′)ferrocenophane in 25% yield. In a similar fashion, 1,7-dithia-4-selena[7](1,1′)ferrocenophane (**14**) was synthesized as red plates in 25% yield from 1,1′-bis(2-iodoethylthio)ferrocene (**12**).

1,9-Dithia-5-selena[9](1,1′)ferrocenophane (**13**) reacted with $(CH_3CN)_4Pd(BF_4)_2$ in acetone to give a 1/1 complex (**15a**) as dark-green needles in good yield. The reaction of 1,7-dithia-4-selena[7](1,1′)ferrocenophane (**14**) with the same Pd(II) salt gave a 1/1 complex (**16a**) and a 2/1 complex (**17a**) in 54 and 31% yields, respectively. A platinum analog (**15b**) was successfully obtained from a treatment of **13** with $(CH_3CN)_4Pt(BF_4)_2$ in warm acetonitrile, but the reaction of the [7]ferrocenophane **14** with the same Pt(II) salt gave no isolable complex.

The out-of-plane bending vibration found in ferrocene at 815 cm^{-1} moves to 851 cm^{-1} in the ferricenium ion and is thus known to be a diagnostic probe for examining the oxidation state of the iron atom of ferrocene derivatives.[18] The frequencies of the Pd(II) complexes, **5a**, **7a**, **15a**, and **16a** (Table 1), were shifted to a higher wavenumber region than those of the corresponding free ligands and the $PdCl_2$ complexes. For example, the out-of-plane bending vibration of **5a** appeared at 844 cm^{-1}, while that of the corresponding free lignand and the $PdCl_2$ complex absorbed at 806 and 820 cm^{-1}, respectively.[12] Such a large shift of this band in **5a** to high wavenumber region suggests the occurrence of a strong perturbation in the iron atom of a ferrocene nucleus by the Pd(II) atom through the coordinated sulfur atoms and/or a direct Fe-Pd bonding interaction. In this connection, the frequency of the corresponding vibration is observed at 830 and 838 cm^{-1} in the phosphine complex **2a** which is confirmed by X-ray analysis to have a weak dative Fe-Pd bond.[6,7] The platinum complexes, **5b** and **15b**, also exhibited a similar high wavenumber shift of the out-of-plane bending vibration, as shown in Table 1, indicating similar structural features to those in the palladium analogs, **5a** and **15a**. The ring size of the chalcogenomacrocycle moiety in the Pd(II) complexes exerted a significant influence on the out-of-bending vibration. Thus, the frequencies of the [7]ferrocenophane complexes, **7a** and **16a**, were observed at 830 cm^{-1}. The relatively low wavenumber frequency in **7a** and **16a** compared with that in **5a** and **15a** may suggest a weaker bonding

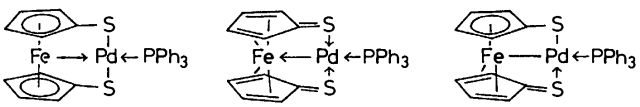
a) From Ref. 11.

interaction in [7]ferrocenophane complexes than that in [9]ferrocenophane complexes.

The ^{1}H NMR spectrum of **15a** (400 MHz, CD_3CN) showed the ferrocenyl ring protons as narrow sextets at δ 5.95 and 6.09, and narrow quintets at δ 3.43 and 3.93. It has been previously shown that in monosubstituted ferrocenyl ring protons adjacent to the substituent (i.e. α-protons) give a 1:2:2:2:1 multiplet pattern while internal protons (i.e. β-protons) give a 1:1:2:2:1:1 pattern.[19] We therefore assigned the signals at δ 3.43 and 3.93 to the α-ring protons and the signals at δ 5.95 and 6.09 to the β-ring protons. The facts that in the 2D H,H-COSY experiment for **15a** the signals at δ 3.43 and 3.93 correlated strongly with the signals at δ 5.95 and 6.09, respectively, and that the latter signals also correlated strongly with each other, provide conclusive evidence for the assignment described above. It is noteworthy that the α-ring protons in complex **15a** appears at a higher field than those of the corresponding free ligand (δ 4.23) and that the β-ring protons produce signals at a considerably low field. Generally, the α- and β-protons of the ferrocenyl ring in the complexes coordinated to a metal atom through the heteroatoms at the 1,1′-positions shift to a lower field than those of the corresponding free ligand, and the α-protons appear at a lower field than the β-protons.[5,11,12,20] The low-field shift can be elucidated by the magnetic anisotropy or the inductive effect of the metal halide.[5] The large separation between the α- and β-proton signals of the ferrocenyl ring and the reversal of their chemical shifts observed in complex **15a** appear to be elucidated only by a magnetic anisotropy of a metal-metal bond between the iron atom of the ferrocene moiety and the Pd(II) atom incorporated in the chalcogenomacrocycle. A similar phenomenon concerning the ferrocenyl ring protons is also observed in complexes **2a** and **2b** which have dative Fe-Pd and Fe-Pt bonds in the molecule, respectively.[6-8] Complexes **5a**, **5b**, **7a**, **15b**, and **16a** also showed the same spectral features concerning the ferrocenyl ring protons, suggesting that these ferrocenophane complexes also have a structure containing an iron-metal bond. The replacement of one of the sulfur atoms in complex **5a** for a selenium atom (producing complex **15a**) exerts little influence on the spectral features of the ferrocenyl ring protons. In platinum complexes **5b** and **15b**, the chemical shifts of the α- and β-proton signals of a ferrocenyl ring show no significant change compared with those in palladium complexes **5a** and **15a**. These results seem to indicate that the iron-metal bond in the [9]ferrocenophane complexes is little influenced by the kind of central metal or the kind of coordinating heteroatoms.

In the ^{13}C NMR spectrum of palladium complex **15a**, the α-ring carbons of a ferrocenyl ring were observed at δ 71.30 and 71.74 and the β-ring carbons appeared at δ 85.22 and 86.70. The assignment of these signals of the ferrocenyl ring carbon could be successfully performed by the C,H-COSY experiment. It has been reported that the coordination of $PdCl_2$ to 1,1′-bis(isobutylthio)ferrocene brings about a high-field shift of the bridge-head carbon signal (Δ 3.4 ppm), though little increase of the separation between the α- and β-carbon signals of a ferrocenyl ring (Δ 0.8 ppm). On the other hand, complex **15a** showed a similar high-field shift of the bridge-head carbon signal compared to the corresponding free ligand **13** (Δ 4.6 ppm); however, the separation between the α- and β-carbon signals is considerably increased upon complexation with $Pd(BF_4)_2$ (Δ ca. 13 ppm). The latter change is mainly due to the large low-field shift of the β-ring carbon signals of a ferrocenyl ring in complex **15a**. The deshielding of the β-carbons of a ferrocenyl ring appears to be in part responsible for the low-field shift of the β-proton signals in the ^{1}H NMR spectrum of **15a** described above.

Cowie et al. proposed three canonical forms, I—III, in order to represent the bonding in the phosphine complex **2a**, and supposed that the actual structure may have significant contributions from all three resonance forms.[7] The ^{1}H NMR spectra of **5** and **15**



can afford some information concerning the structure of the present complexes. The deshielding of the β-protons compared with the α-protons and the large separation between them found in the ferrocenyl moiety of **5** and **15** are similar to those in the ferrocenylmethylium ions [H(α), δ 4.72; H(β), 6.23].[21,22] In the latter comounds, the contribution of a fulvene structure is considered for the substituted cyclopentadienyl ring, since the X-ray analysis shows that ferrocenyldiphenylmethylium tetrafluoroborate can be described as a fulvenecyclopentadienyl cation.[23] The similarity of the ^{1}H NMR spectral features in **5** and **15** to that in the ferrocenylmethylium ions seems to suggest that the resonance forms corresponding to II and III contributed to the actual structure in complexes **5** and **15** much more than in complex **2a**. As mentioned previously, the ^{13}C NMR spectra of complex **15a** showed a deshielding of the β-carbons in the ferrocenyl ring and large separation between α- and β-carbon signals. Similarly, the low-field shift of the β-carbon signals compared with the α-carbon signals of a ferrocenyl ring [C(α)=Δ 17.6 ppm and C(β)=Δ 27.4 ppm) and the large separation between the α- and β-carbon signals (δ 9.8 ppm) are observed when the carbon chemical shifts in ferrocenylmethylium ions are compared with those in the corresponding alcohols.[24,25] These facts may also support the sugges-

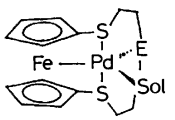
The assignment of the signals in **5a** and **5b** was undergone according to those in **15a** and **15b.** The signals in **7a** were assigned analogously in **16a**.
a) ^{13}C-^{77}Se coupling constant. b) ^{13}C-^{195}Pt coupling constant.

tion described above.

The ^{1}H NMR spectra of the [7]ferrocenophane complexes, **7a** and **16a**, showed the same pattern of ring protons in a ferrocenyl moiety with that found in the [9]ferrocenophane complexes, as shown in Table 2. The separation between the α- and β-proton signals is somewhat small compared with that found in the [9]ferrocenophane complexes. This may partly reflect the decrease in the deshielding in the β-carbons of the ferrocenyl ring in complexes **16a**, as seen in the ^{13}C NMR spectrum (Table 3). The β-carbon resonances in **16a** shift by ca. 6 ppm to a higher field than those in **15a**. These facts seem to suggest that there also exsists an Fe-Pd bond in the [7]ferrocenophane complexes, although it is somewhat weak compared with that in the [9]ferrocenophane complexes. A remarkable feature was observed in the region of the methylene protons of the ^{1}H NMR spectra of the [7]ferrocenophane complexes, **7a** and **16a.** One of the protons attached to C(2) resonated at δ 4.01, the position of which is in a 0.47 ppm lower field than the corresponding proton in the [9]ferrocenophane complex, **15a**. The other proton attached to C(2) appeared at δ 2.27, the chemical shift of which is in a 0.63 ppm higher field than the corresponding proton in **15a**. This can probably be explained by the constrained structure of **16a**, in which one of the protons attached to C(2) is greatly imposed to be in the deshielding zone and the other in the shielding zone of ferrocene.[26] In such strained complexes, **7a** and **16a**, the Fe-Pd(II)-S angle can be no longer 180° because of the small ring size of the thiamacrocycle; thus, that the Pd(II) atom cannot assume a regular square-planar coordination. In these complexes, the distinct distortion from a square-planar (probably to a trigonal-bipyramidal coordination as shown in **18**) seems to



18

occur in terms of a strong coordination of solvent molecules. The weakening of the Fe-Pd bond in the [7]ferrocenophane complexes seems to be probably due to a structural deformation, as mentioned above.

The visible spectrum of the [9]ferrocenophane complex, **5a**, exhibited one strong absorption at 444 nm (ε 6240) and one weak shoulder at 620 nm (ε 206), while the free ligand **4** showed an absorption maximum at 446 nm (ε 211). The square-planer $Pd(BF_4)_2$ complexes of 2,6,10,14-tetrathiapentadecane[15] and 7,16-dimethyl-1,4,10,13-tetrathia-7,16-diazacyclooctadecane[27] showed no absorption above 380 nm.[28] Therefore, either of the two absorptions seems to relate to the Fe-Pd bonding interaction. A similar absorption pattern, as seen in **5a**, was also observed in the phosphine complex, **2a**, which has a dative Fe-Pd bond, although the absorption peaks somewhat shift to a long-wavelength region.[6,7] As shown in Table 1, the replacement of one sulfur atom of trithiamacrocycle in complexes **5** for a selenium atom had no influence on the electronic absorption of the [9]ferrocenophane complexes, while the absorption maxima in the Pt analog **5b** shifted to a short-wavelength compared with those in the Pd analog, **5a** [Δ ca. 70 nm]. A similar blue shift was observed in the phosphine complex, **2b**. The electronic spectra of the [7]ferrocenophane complexes, **7a** and **16a**, were considerably different from those of the [9]ferrocenophane complexes, **5a** and **15a**, respectively. The most remarkable difference was, for example, the appearance of a large and broad band at 812 (ε 2800) in **7a**. A similar band near 800 nm was also observed in the oxidized 1,5,7-trithia[7]ferrocenophane [λ_{max} 850 nm (ε 1150) and 752 nm (ε 955)]. This may suggest that complex **7a** contains a contribution from the ferricenium cation structure, which is generated through an intramolecular redox reaction, as seen in similar copper complexes.[29] However, this is not the fact, since **7a** afforded a clear ^{1}H NMR spectrum. The absorption in the long-wavelength region may be caused by the distorted coordination manner described above.

The Mössbauer spectral data of complexes **5a** and **7a**, along with those of the related complexes, are summarized in Table 4. The QS value of **5a** is similar to that of the corresponding free ligand **4**, while a considerably large QS value was obtained in the $HgCl_2$ adducts (**3**) of [2](1,1′)ferrocenophane.[9] This may suggest that there is no substantial metal-metal bonding interaction between the Fe atom in the ferrocene moiety and the Pd(II) atom coordinated to the thiamacrocycle. However, only a small decrease of the QS value was obtained in the bisthiolate complex **2a**, in which a weak Fe-Pd dative bond was confirmed by X-ray analysis.[6,7] It may also be worth noting that an increased IS value was observed, especially at low temperature, in complexes **2a**, **5a**, and **7a**, in which a metal-metal bonding interaction was assumed. Anyway, at the present stage, no definite conclusion seems to be derived from the Mössbauer parameter.

Table 4. The Mössbauer Spectral Data

Compound	Conditions	IS/mm s^{-1}	QS/mm s^{-1}
4	R.T.	0.43	2.36
4$^+$ BF_4^-	R.T.	0.45	0.72
5a	R.T.	0.49	2.36
	Liq. N_2	0.57	2.39
7a	R.T.	0.50	2.10

	Liq. N_2	0.53	2.03

Experimental

The melting point was measured by using a differential scanning calorimeter (SEIKO DSC-20). The IR spectra were taken by a Hitachi 750-20 Infrared Spectrometer. The electronic spectra were measured by a Shimadzu UV-2000 Spectrometer. The ^{1}H and ^{13}C NMR spectra were taken by a Bruker AM 400 or GEOL FX-90Q Spectrometer, using TMS as an internal standard.

1,1′-Bis(3-chloropropylthio)ferrocene,[16] 1,1′-bis(2-chloroethylthio)ferrocene,[16] 1,5,9-trithia[9](1,1′)ferrocenophane (**4**),[12] 1,4,7-trithia[7](1,1′)ferrocenophane (**6**),[16] dichlorobis(acetonitrile)palladium(II) and -platinum(II)[15] were prepared according to the literature. Silver(I) tetrafluoroborate and selenourea were commercially available.

(1,5,9-trithia[9](1,1′)ferrocenophane-*S,S′,S″,Fe*)palladium(II) Tetrafluoroborate (5a). To a solution of dichlorobis(acetonitrile)palladium(II) (0.16 g, 0.6 mmol) in dry acetone (15 cm^3) was added silver(I) tetrafluoroborate (0.25 g, 1.3 mmol). The mixture was stirred for 1 h and the resulting silver(I) chloride was filtered off. To the filtrate, 1,5,9-trithia[9](1,1′)ferrocenophane (**4**) (0.22 g, 0.6 mmol) was added and then the solution was stirred for 1 h. The resulting brown crystals were collected by filtration to give the title compound (**5a**) containing one equivalent of acetone as dark-brown needles (0.30 g, 73%), mp 250 °C. Found: C, 32.33; H, 3.72%. Calcd for $C_{16}H_{20}B_2F_8S_3FePd \cdot C_3H_6O$: C, 32.48; H, 3.73%. The complex was recrystallized from acetonitrile–diethyl ether to give **5a** containing one equivalent of acetonitrile as black needles, mp 250 °C. Found: C, 31.64; H, 3.41; N, 1.89%. Calcd for $C_{16}H_{20}B_2F_8S_3FePd \cdot C_2H_3N$: C, 31.54; H, 3.38; N, 2.04%.

(1,4,7-Trithia[7](1,1′)ferrocenophane-*S,S′,S″,Fe*)palladium(II) Tetrafluoroborate (7a). A mixture of dichlorobis(acetonitrile)palladium(II) (0.26 g, 1 mmol) and silver(I) tetrafluoroborate (0.40 g, 2.1 mmol) was stirred for 1 h at room temperature and then filtered to remove the resulting silver(I) chloride. To the filtrate diluted with dry acetone (50 cm^3) was added a solution of 1,4,7-trithia[7](1,1′)-ferrocenophane (**6**) (0.34 g, 1 mmol) in dry acetone (50 cm^3) dropwise for a period of 30 min. The mixture was stirred for 1 h and then filtered. A green powder (55 mg, 12%) of bis(1,4,7-trithia[7](1,1′)ferrocenophane-*S,S′,S″*)palladium(II) tetrafluoroborate (**8a**) was obtained. Mp 250 °C. Found: C, 34.95; H, 3.53%. Calcd for $C_{28}H_{32}B_2F_8S_6Fe_2Pd$: C, 35.30; H, 3.39%. IR (KBr): 3120, 2976, 1418, 946, 900, 888, 824, 538, 528, 504, and 488 cm^{-1}. VIS (CH_3CN): λ_{max} 380sh

and 784 nm (log ε 2.7). ^{1}H NMR (90 MHz, CD_3CN): δ=3.32—3.92 (m, 16H, CH_2S), 4.50 (m, 12H, ring-H), and 4.65 (m, 4H, ring-H). The filtrate was evaporated under reduced pressure and then the residue was dissolved in acetone (5 cm^3). The resulting solution was diluted with dry diethyl ether (2.5 cm^3) and kept in a freezer to give the title complex **7a** containing one equivalent of acetone as fine black needles, mp 250 °C. Found: C, 30.49; H, 3.38%. Calcd for $C_{14}H_{16}B_2F_8S_3FePd\cdot C_3H_6O$: C, 30.27; H, 3.29%.

1,1′-Bis(3-iodopropylthio)ferrocene (11). A mixture of sodium iodide (2.24 g, 14.9 mmol) in methyl ethyl ketone (40 cm^3) was refluxed for 1 h under nitrogen. To the resulting solution was added 1,1′-bis(3-chloropropylthio)ferrocene (2.00 g, 4.96 mmol). The mixture was then refluxed for 8 h under nitrogen and cooled to room temperature. The mixture was filtered and the precipitate was washed with methyl ethyl ketone (20 cm^3). The filtrate and the washing were combined and washed with water (60 cm^3), 5% sodium thiosulfate solution (20 cm^3), 5% sodium hydrogencarbonate (20 cm^3), and water (20 cm^3), and then dried over anhyd $MgSO_4$. The solution was evaporated under reduced pressure and the residue was chromatographed on silica gel by elution of hexane-toluene (2 : 1). The title compound (**11**) was obtained as yellow plates (2.66 g, 91%) after recrystallization from ethanol-hexane, mp 49.5—51.5 °C. Found: C, 32.65; H, 3.44%. Calcd for $C_{16}H_{20}I_2S_2Fe$: C, 32.79; H, 3.44%. MS (75 eV): *m/z* 586 (M^+, 100%). IR (KBr): 3076, 2952, 1448, 1422, 1390, 1318, 1238, 1166, 1022, 900, 824, 724, 572, 528, 512, and 456 cm^{-1}. ^{1}H NMR (90 MHz, $CDCl_3$): δ=1.98 (p, *J*=6.8 Hz, 4H, CH_2), 2.66 (t, *J*=6.8 Hz, 4H, SCH_2), 3.25 (t, *J*=6.8 Hz, 4H, CH_2I), and 4.27 (m, 8H, ring-H).

1,1′-Bis(2-iodoethylthio)ferrocene (12). To a solution of sodium iodide (4.07 g, 27.2 mmol) in methyl ethyl ketone (40 cm^3), prepared as described above, was added 1,1′-bis(2-chloroethylthio)ferrocene (1.50 g, 4.00 mmol). The mixture was refluxed for 16 h under nitrogen. After the reaction had been completed, the resulting yellow crystals were collected by filtration. The filtrate was washed with water (80 cm^3), 10% sodium thiosulfate solution (20 cm), 5% sodium hydrogencarbonate solution (20 cm^3), and water (40 cm^3), and then dried over anhyd $MgSO_4$. After evaporation, the residue was chromatographed on silica gel by elution of hexane-toluene (1 : 1). The title compound (**12**) was obtained as yellow plates (mp 136—139 °C). The yield was 1.62 g (72.6%) in all. Found: C, 30.13; H, 2.89%. Calcd for $C_{14}H_{16}I_2S_2Fe$: C, 30.31; H, 2.90%. MS (75 eV): *m/z* 558 (M^+, 100%). IR (KBr): 3076, 1414, 1162, 896, 816, 726, 566, 504, and 454 cm^{-1}. ^{1}H NMR (90 MHz, $CDCl_3$): δ=2.96 (dd, *J*=6.6 and 1.8 Hz, 4H, SCH_2), 3.20 (dd, *J*=6.6 and 1.8 Hz, 4H, SCH_2), 3.20 (dd, *J*=6.7 and 1.8 Hz, 4H, CH_2I), and 4.30 (m, 8H, ring-H).

1,9-Dithia-5-selena[9](1,1′)ferrocenophane (13). A mixture of 1,1′-bis(3-iodopropylthio)ferrocene (**11**) (1.00 g, 1.7 mmol) and selenourea (0.21 g, 1.7 mmol) in ethanol (50 cm^3) was refluxed under nitrogen for 4 h. To the solution diluted with ethanol (800 cm^3) was added 10% aqueous sodium hydroxide (1.8 cm^3) under refluxing; the solution was then refluxed for 4 h. After evaporation, the residue was dissolved in benzene (100 cm^3). The solution was washed with water (60 cm^3) and dried over anhyd $MgSO_4$. The solution was then condensed under reduced pressure and chromatographed on silica gel by elution of hexane-toluene (2 : 1) to give the title compound (**13**) as red crystals (0.26 g, 37%) after recrystallization from ethanol-hexane, mp 62.0—62.5 °C. Found: C, 47.02; H, 4.94%. Calcd for $C_{16}H_{20}S_2SeFe$: C, 46.73; H, 4.90%. IR (KBr): 3092, 2928, 1418, 1290, 1222, 1158, 1024, 882, 810, 516, and 472 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$): δ=2.16 (p, *J*=6.9 Hz, 4H, CH_2), 2.89 (t, *J*=6.7 Hz, 4H, CH_2Se), 3.09 (t, *J*=7.0 Hz, 4H, CH_2S), and 4.22 (s, 8H, ring-H). ^{13}C NMR (100 MHz, $CDCl_3$): δ=23.30 (t, *J*=62.4 Hz, $SeCH_2$), 30.47 (CH_2), 34.85 (SCH_2), 67.88 (C_β), 71.37 (C_α), and 86.87 (C_b).

1,7-Dithia-4-selena[7](1,1′)ferrocenopahne (14). A mixture of 1,1′-bis(2-iodoethylthio)ferrocene (**12**) (0.10 g, 0.18 mmol) and selenourea (25 mg, 0.20 mmol) in tetrahydrofuran (30 cm^3) was refluxed for 3 h under nitrogen. To the solution diluted with tetrahydrofuran (70 cm^3) was added 10% aqueous sodium hydroxide (1.5 cm^3) under refluxing; the solution was then refluxed for 1 h. After evaporation, the residue was disolved in benzene (50 cm^3). The solution was washed with water (50 cm^3) and dried over anhyd $MgSO_4$. After evaporating the solvent, the residue was chromatographed on silica gel by elution of hexane-toluene (2 : 1) to give the title compound (**14**) as red-orange plates (16 mg, 24%) after recrystallization from hexane-toluene, mp 116.5 °C. Found: C, 44.07; H, 4.27%. Calcd for $C_{14}H_{16}S_2SeFe$: C, 43.88; H, 4.21%. IR (KBr): 3096, 3080, 2916, 1416, 1380, 1260, 1160, 1050, 1022, 890, 846, 810, 526, 504, and 474 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$): δ=3.17 (dd, *J*=7.2 and 6.0 Hz, 4H, CH_2Se), 3.46 (dd, *J*=7.2 and 6.0 Hz, 4H, CH_2S), 4.26 (t, *J*=1.8 Hz, 4H, H_α), and 4.31 (t, *J*=1.8 Hz, 4H, H_β). ^{13}C NMR (100 MHz, $CDCl_3$): δ=24.91 (t, *J*=67.9 Hz, $SeCH_2$), 37.99 (SCH_2), 67.87 (C_β), 71.29 (C_α), and 89.24 (C_b).

(1,9-Dithia-5-selena[9](1,1′)ferrocenopahane-*S,S′,Se,Fe*)-palladium(II) Tetrafluoroborate (15a). A mixture of dichlorobis(acetonitrile)palladium(II) (26 mg, 0.1 mmol) and silver(I) tetrafluoroborate (40 mg, 0.2 mmol) in acetone (2 cm^3) was stirred for 1 h at room temperature and then filtered to remove the resulting silver(I) chloride. To the filtrate was added a solution of 1,9-dithia-5-selena[9]-(1,1′)ferrocenophane (41 mg, 0.1 mmol) in dry acetonitrile (5 cm^3); the solution was then stirred for 1 h at room temperature. The solution was evaporated under reduced pressure and the residue was then dissolved in acetonitrile (5 cm^3). The resulting dark-brown solution was diluted with dry diethyl ether and kept in a freezer overnight to give the title compound (**15a**) containing one equivalent of acetonitrile as black needles, mp 250 °C. Found: C, 29.76; H, 3.24; N, 1.94%. Calcd for $C_{16}H_{20}B_2F_8S_2SePd\cdot C_2H_3N$: C, 29.52; H, 3.16; N, 1.91%.

(1,7-Dithia-7-selena[7](1,1′)ferrocenophane-*S,S′,Se,Fe*)-palladium(II) Tetrafluoroborate (16a). To a solution of palladium(II) tetrafluoroborate [prepared as described above and then diluted with dry acetone (20 cm^3)], a solution of 1,7-dithia-4-selena[7](1,1′)ferrocenophane (38 mg, 0.1 mmol) in dry acetone (10 cm^3) was added dropwise for a period of 10 min. After the solution was stirred for 1 h the resulting crystals were filtered. A green powder (16 mg, 31%) of bis(1,7-dithia-4-selena[7](1,1′)ferrocenophane-*S,S′*)-palladium(II) tetrafluoroborate (**17a**) was obtained. Mp 250 °C. Found: C, 32.37; H, 3.02%. Calcd for $C_{28}H_{32}B_2F_8S_4Se_2Fe_2Pd$: C, 32.13; H, 3.08%. IR (KBr): 3116, 2996, 2944, 1416, 1258, 1084, 926, 886, 830, 528, 486, and 456 cm^{-1}. After the filtrate was evaporated under reduced pressure, the residue was dissolved in dry acetonitrile (5 cm^3). The

resulting solution was diluted with dry diethyl ether (5 cm^3) and kept in a freezer overnight to give the title compound (**16a**) containing one equivalent of acetonitrile as black fine needles, mp 250 °C. Found: C, 27.44; H, 2.74; N, 2.37%. Calcd for $C_{14}H_{16}B_2F_8S_2SeFePd \cdot C_2H_3N$: C, 27.28; H, 2.71; N, 1.98%.

(1,5,9-Trithia[9](1,1′)ferrocenophane-*S,S′,S″,Fe*)-platinum Tetrafluoroborate (5b). A mixture of dichlorobis(acetonitrile)platinum(II) (35 mg, 0.1 mmol) and silver(I) tetrafluoroborate (40 mg, 0.2 mmol) in dry acetonitrile (5 cm^3) was refluxed for 2 h under nitrogen. To the resulting mixture was added a solution of 1,5,9-trithia[9](1,1′)-ferrocenophane (36 mg, 0.1 mmol) in dry acetonitrile (5 cm^3). The mixture was refluxed for 1 h and then filtered to remove silver(I) chloride. The filtrate was evaporated under reduced pressure; then, the residue was dissolved in dry acetone–acetonitrile (4:1 v/v, 5 cm^3). The resulting solution was filtered and the filtrate was diluted with dry diethyl ether (2 cm^3) to give the title compound **5b** as red needles (53 mg, 73%), mp 250 °C. Found: C, 26.42; H, 2.76%. Calcd for $C_{16}H_{20}B_2F_8S_3FePt$: C, 26.21; H, 2.75%.

(1,9-Dithia-5-selena[9](1,1′)ferrocenophane-*S,S′,Se,Fe*)-platinum(II) Tetrafluoroborate (15b). This compound was prepared from 1,9-dithia-5-selena[9](1,1′)ferrocenophane (41 mg, 0.1 mmol) according to the procedure described above. The title compound (**15b**) was obtained as red needles (55 mg, 70%), mp 250 °C. Found: C, 24.27; H, 2.54%. Calcd for $C_{16}H_{20}B_2F_8S_2SeFePt$: C, 24.63; H, 2.58%.

Study on the Claisen Rearrangement. VI.[1] Catalytic Effect of Alkali Metal Salts on the Claisen Rearrangement of Allyl *o*- or *p*-Hydroxyphenyl Ether

Takatoshi HAYASHI, Yutaka OKADA,* and Takeshi INABA†
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received June 17, 1989)

The Claisen rearrangement of allyl *o*- or *p*-hydroxyphenyl ether is catalyzed by alkali metal salts. The mechanism of the catalytic effect is different from that by Lewis acids such as zinc chloride. It is considered that the hydroxyl group is dissociated into phenoxide ion $-O^-$ with loss of its proton through attack by the anion residue of an alkali metal salt. Thus, the catalytic effect is attributable to a strong electron-releasing effect of phenoxide ion $-O^-$. Furthermore, for the *o*-isomer, an intramolecular repulsion between the phenoxide ion $-O^-$ and the ethereal oxygen operates.

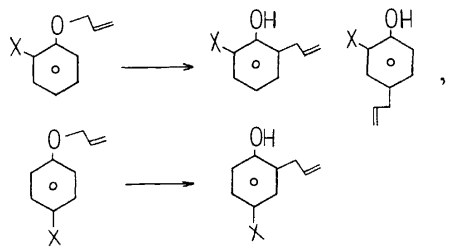
Usually, the Claisen rearrangement is a thermal reaction. However, the rearrangement is accelerated through acid catalysis.[2,3] The authors found an accelerated effect by zinc chloride for the rearrangement of allyl (substituted phenyl) ether (x-APE) and discussed the mechanism.[4] In the transition state of the Claisen rearrangement, the electron density of the ethereal oxygen of allyloxyl group increases.[5] However, in the presence of zinc chloride, the high electron density is reduced by the coordination of the salt to the ethereal oxygen. Therefore, the transition state is stabilized, and the reaction is accelerated.

In this research, alkali metal salts were used as catalysts for the Claisen rearrangement of x-APE. For an methoxy derivative (OCH_3-APE), no catalytic effects by these salts were noticed. However, the rearrangement of hydroxy derivatives (OH-APE) was strongly catalyzed by these salts. The mechanism of this catalytic effect is discussed.

Experimental

Preparation of Materials. The preparation and physical properties of x-APE were reported in the preceding papers.[5,6]

Measurements on the Claisen Rearrangement. The Claisen rearrangement was carried out in a small glass



ampoule as described in a previous paper.[7] x-APE and an alkali metal salt were put into an ampoule with a solvent (methanol or water-methanol). The solvent was 20 times and the catalyst (alkali metal salt) was 0.1—0.5 time in mol as much as the x-APE. The ampoule was heated at a constant temperature in an oil bath. After a measured time, the reaction mixture was cooled. The solvent was evaporated from the reaction mixture. The residue was acidified with 10% HCl and extracted with ether. The amounts of the unreacted material and products were determined by GLC. For *o*-x-APE, the conversion amount is defined as the sum of those of *o*- and *p*-rearranged products.

† Present address: Nissha Printing Co., 3 Mibu Hanai-cho, Nakagyo-ku, Kyoto 603.

Results and Discussion

For the Claisen rearrangement of *o*-OH-, *o*-OCH_3-, and *p*-OH-APEs, the catalytic effect by sodium acetate is shown in Fig. 1, where the magnitude of catalytic effect is defined as the difference between the conversion amounts in the presence and absence of the salt. For *o*-OH-APE, the catalytic effect is observed, increasing with a increasing amount of sodium acetate. For *o*-OCH_3-APE, the catalytic effect is quite small. For *p*-OH-APE, the catalytic effect is observed.

The catalytic effect by sodium acetate will be compared with that by zinc chloride.[4] As shown in Fig. 2, for the methoxy derivative, the effect by sodium acetate is much smaller than that by zinc chloride. However, for the *p*-hydroxy derivative, sodium acetate accelerates the reaction by far more than zinc chloride. It may thus be considered that the mechanism of the

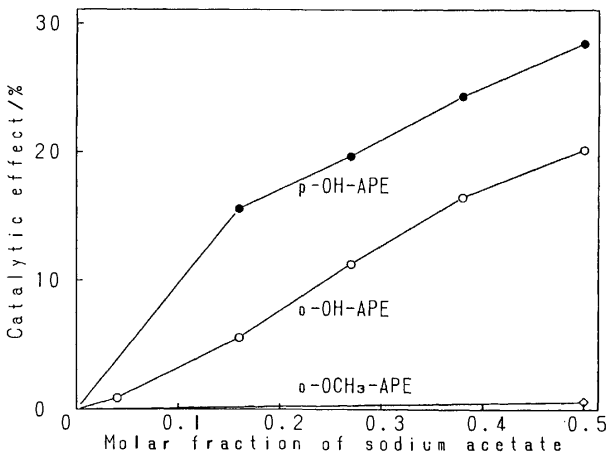


Fig. 1. The catalytic effect of CH_3COONa for the conversion of x-APE (solv.: CH_3OH, reaction time: 1 h, reaction temperature: 145 °C (*o*-isomer), 160 °C (*p*-isomer)).

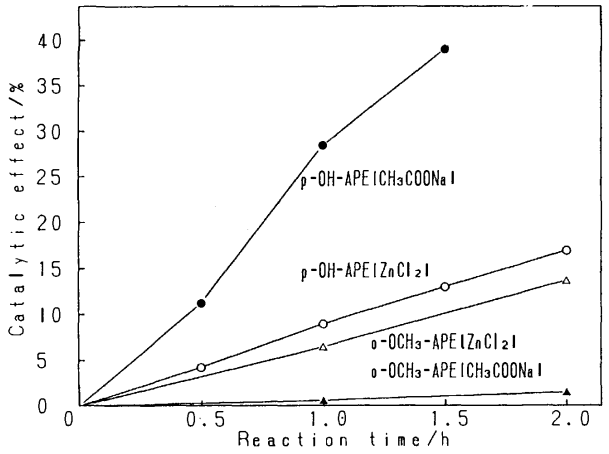

Fig. 2. The catalytic effect of CH_3COONa and $ZnCl_2$ for the conversion of x-APE (solv.: CH_3OH, salt: APE=0.5 : 1, reaction temperature: 145 °C (*o*-isomer), 160 °C (*p*-isomer)).

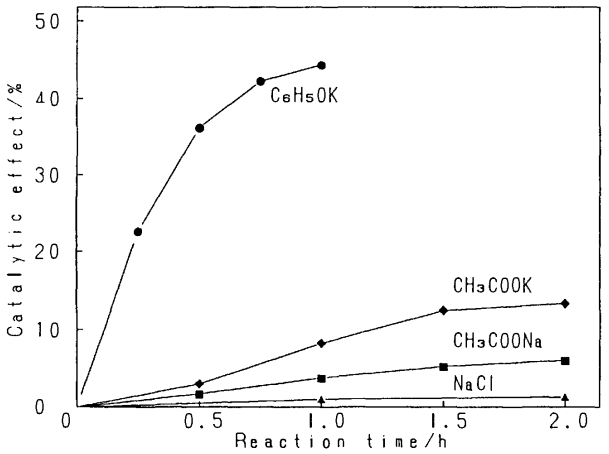

Fig. 3. The catalytic effect of alkali metal salts for the conversion of *o*-OH-APE at 145 °C (solv.: CH_3OH (potassium salt), $CH_3OH : H_2O$=1 : 1 (sodium salt), salt: APE=0.5 : 1).

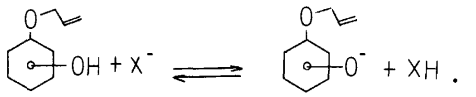
catalytic effect by sodium acetate is different from that by zinc chloride.

As shown in Fig. 3, the order of the catalytic effects by the alkali metal salts is

phenolate > acetate > chloride.

This order is the same as that of the basicities of the anion residues of the salts.[8] The degree of dissociation of the hydroxyl group of OH-APE is largest in the presence of phenolate and smallest in the presence of chloride:



$X^- = C_6H_5O^-, CH_3COO^-, Cl^-$

Table 1. Catalytic Effect of Alkali Metal Salts for the Conversion of *o*-OH-APE at 145 °C (Solv. CH_3OH)[a]

Reaction time/h	Catalytic effect/%		
	CH_3COOLi	CH_3COONa	CH_3COOK
0.5	26.9	10.0	3.0
1.0	43.3	20.2	8.3
1.5	48.8	24.6	12.5

a) CH_3COOM : APE=0.5 : 1.

Table 2. Conversion of *o*-OH-APE in the Presence of Alkali Metal Salts at 145 °C (Solv. CH_3OH)[a,b]

Salt	*o*/%	*p*/%	*p*/*o*	log (*p*/*o*)
None	16.5	9.5	0.58	−0.24
CH_3COOLi	20.8	48.5	2.33	0.37
CH_3COONa	19.4	26.8	1.38	0.14
CH_3COOK	17.3	17.0	0.98	−0.01
C_6H_5OK	18.0	52.4	2.91	0.46

a) Salt : *o*-OH-APE=0.5 : 1. b) Reaction time: 1 h.

For the change in metal ions (Table 1), the order is

Li salt > Na salt > K salt.

In methanol, the degree of solvation of metal ions increases with decreasing ionic radius.[9] This order seems parallel with the stability of the alkali metal ions in methanol. It is in agreement with the order of the degrees of dissociation of the alkali metal salts.

As shown in Table 2, the (para rearranged product)/(ortho rearranged product) value (*p*/*o* ratio) for *o*-OH-APE is increased by the addition of the alkali metal salts. The order of the magnitudes of the *p*/*o* ratios is

phenolate > acetate

and

Li salt > Na salt > K salt.

These orders agree with that of the catalytic effects. As stated in preceding paper,[1] the *p*/*o* ratio is closely

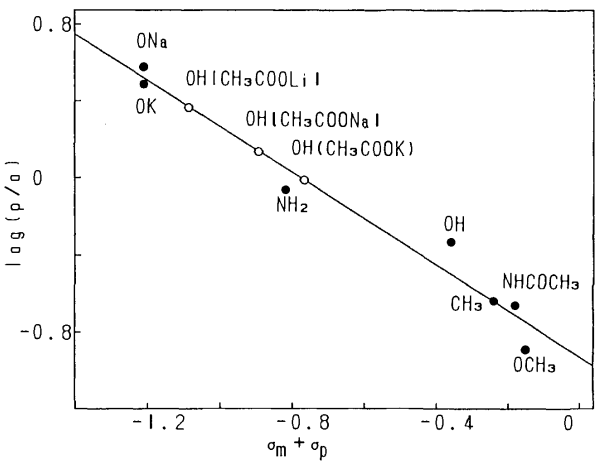


Fig. 4. The relationship between *p*-product to *o*-product (*p*/*o*) in *o*-X-APE and ($\sigma_m+\sigma_p$) (σ_m and σ_p values of -ONa and -OK are used in that of $-O^-$).

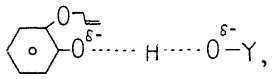
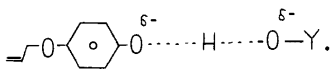
related to the value of substituent constant $(\sigma_m+\sigma_p)$.[10,11] A strongly electron-releasing substituent possesses a negative large value of $(\sigma_m+\sigma_p)$. For the rearrangement of an APE possessing such an electron-releasing substituent, the value of p/o ratio is large. As shown in Fig. 4, the value of $(\sigma_m+\sigma_p)$ of hydroxyl group alone is -0.36, and $\log(p/o)$ in the absence of alkali metal salt is -0.33. However, in the presence of the salt, $\log(p/o)$ is -0.01—0.37. This value corresponds to -0.77— -1.09 of $(\sigma_m+\sigma_p)$ (Fig. 4). The electron-releasing ability of hydroxyl group is increased by the addition of alkali metal salt. It seems that the value of $(\sigma_m+\sigma_p)$ of hydroxyl group increased by the addition of alkali metal salt is close to the values of $(\sigma_m+\sigma_p)$ of pheoxide ion ($-O^-$).

Consequently, the mechanism of the catalytic effect by the alkali metal salts may be interpreted as follows. The hydroxyl group of *o*(or *p*)-OH-APE is converted to phenoxide ion $-O^-$ by the anion residue of the salt:





Y = $COCH_3$, C_6H_5

Therefore, in analogy with APEs bearing metal oxide groups,[1] the benzene ring is stabilized by the strong electron-releasing effect of phenoxide ion $-O^-$. (In the transition state, a positive charge is produced on the benzene ring of APE.[7]) In addition to the above effect, for *o*-isomer, another effect is to be considered: an intramolecular repulsion between the phenoxide ion $-O^-$ and the ethereal oxygen of allyloxyl group. By this repulsion, the ground state is unstabilized and the activation energy for the rearrangement decreased.

For *o*-OH-APE, the rearrangement is accelerated by these two effects (the strong electron-releasing effect and the intramolecular repulsion effect). On the other hand, for *p*-isomer, only the strong electron-releasing effect is put into operation. Therefore, it is expected that the catalytic effect for *o*-OH-APE is larger than that for *p*-OH-APE. In fact, the experimental results agree with this assumption (Fig. 5). However, the difference in catalytic effect between *o*- and *p*-OH-APEs is not so large. The reactivity of *o*-OH-APE alone is much higher than that of *p*-OH-APE (Fig. 5) because, in *o*-OH-APE, an intramolecular hydrogen bond is formed between the hydroxyl group and the ethereal oxygen.[6] The negative charge of the ethereal oxygen produced in the transition state is reduced by this hydrogen bond.[6] But by the addition of alkali metal salt, the above intramolecular hydrogen bonding effect for *o*-OH-APE is caused to disappear. It seems that the observed catalytic effect for *o*-OH-APE by alkali metal salt is not so large as to be balanced by the profit and loss.

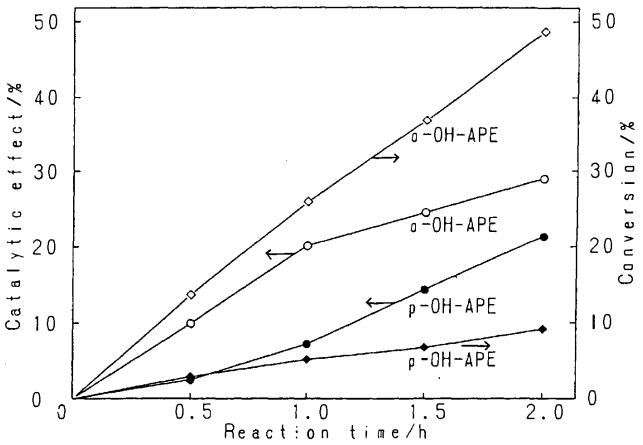


Fig. 5. The conversion and the catalytic effect of CH_3COONa for the conversion of *o*- and *p*-OH-APE at 145 °C (solv.: CH_3OH, salt: APE=0.5 : 1).

The Effect of Sodium Hydroxide on the Stereoselectivity of Hydrogenolytic Asymmetric Transaminations between (*R*)-2-Amino-2-phenylethanol and 2-Keto Acids†

Minoru TAMURA,†† Shozo SHIONO,††† and Kaoru HARADA*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received June 30, 1989)

Hydrogenolytic asymmetric transaminations between (*R*)-2-amino-2-phenylethanol and 2-keto acids were carried out over Pd catalyst in the absence or presence of various amount of sodium hydroxide in water or alcohols. The stereoselectivity of the reaction was significantly influenced by the amount of sodium hydroxide in the reaction mixture. When pyruvic acid was used in water the optical purity of alanine was 22% ee (*R*) and in 1 M (1 M=1 mol dm^{-3}) sodium hydroxide solution it was 62% ee (*S*). When 2-oxobutyric acid was used in ethanol in the absence and presence of sodium hydroxide (1M), the optical yields of 2-aminobutyric acid were 2% ee (*R*) and 81% ee (*S*), respectively. In contrast, the addition of sodium hydroxide had little or no effect on the stereochemistry of the reaction using (*S*)-α-methylbenzylamine as a chiral source in aqueous or ethanolic solution. The substituent, additive, temperature, and solvent effects on the asymmetric reactions were examined in aqueous or ethanolic alkaline solution. Based on these experimental results, a possible explanation for the change in stereoselectivity by using sodium hydroxide is discussed.

There have been many studies on the hydrogenolytic asymmetric transamination between chiral amines or amino acid derivatives and 2-keto acids or their esters, and some of them have been explained by the chelation mechanism.[1-6]

In the previous study,[6] a hydrogenolytic asymmetric transamination between pyruvate and (*R*)-2-amino-2-phenylethanol (**1a**) in organic solvent was carried out. The configuration of the resulting amino acid was (*S*), and its optical purity increased with the decrease of the polarity of the solvent used. Such an effect and also substituent effect on the stereoselectivity were explained by the chelation mechanism.

In the present study, hydrogenolytic asymmetric transaminations between 2-keto acids and **1a** were carried out in aqueous and alcoholic alkaline solutions (Scheme 1). As a result, we found that (*S*)-selectivity increased by the addition of sodium hydroxide. This result could not be explained by the chelation mechanism, because (*S*)-selectivity should be decreased with the increase of the solvent polarity.

Figure 1 shows the results of the preliminary experiments of hydrogenolytic asymmetric transamination between pyruvic acid and **1a** in the mixtures of methanol or ethanol and 1 M of aqueous NaOH (1 M=1 mol dm^{-3}). With the increase of the content of 1 M NaON, the optical purites of the products (52, 57%) decreased and reached a minimum (8,13%) with a 33% content of 1 M NaOH and then increased (61, 62%).

Figure 2 shows the result of the experiments carried out in the mixtures of water and methanol in various ratios at certain alkali concentrations. It was found that the addition of sodium hydroxide increased the optical yeild of the product, while an increase of water content decreased the optical purity. It was therefore concluded that the increase of (*S*)-selectivity in the reaction was mainly due to sodium hydroxide.

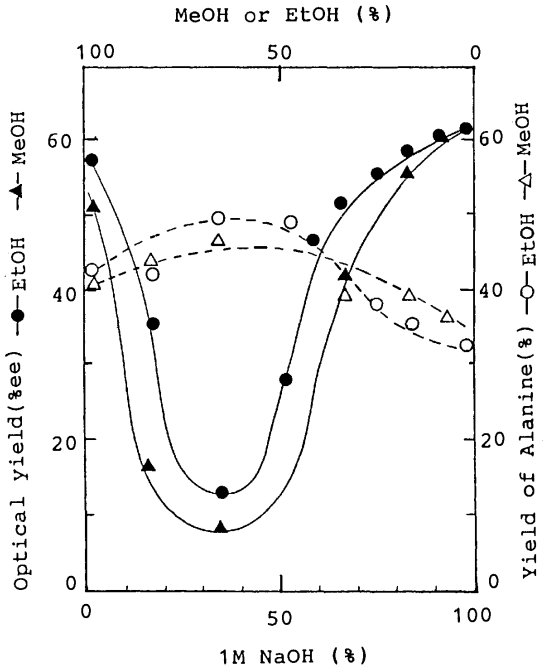

Fig. 1. Asymmetric hydrogenation in a mixture of alcohol and 1M NaOH aq.

Catalytic Hydrogenation in Aqueuous Solution. Asymmetric transaminations between **1a** and pyruvic acid or 2-oxobutyric acid were carried out in aqueous solution containing various amounts of sodium hydroxide (Fig. 3). The optical yield of the products increased considerably by the addition of sodium

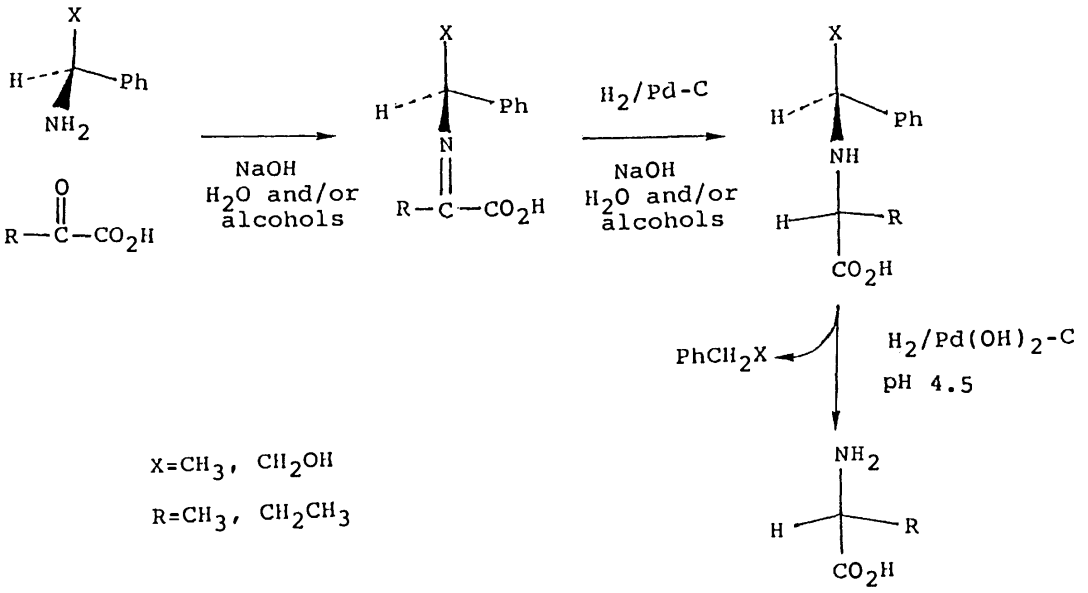

Scheme 1. Hydrogenolytic asymmetric transamination in aqueous and alcoholic alkaline solutions.

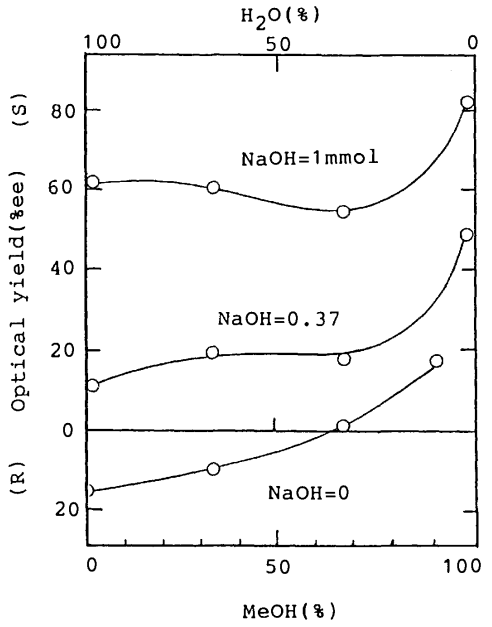

Fig. 2. Asymmetric hydrogenation in a mixture of MeOH and water in the presence of different amount of NaOH.

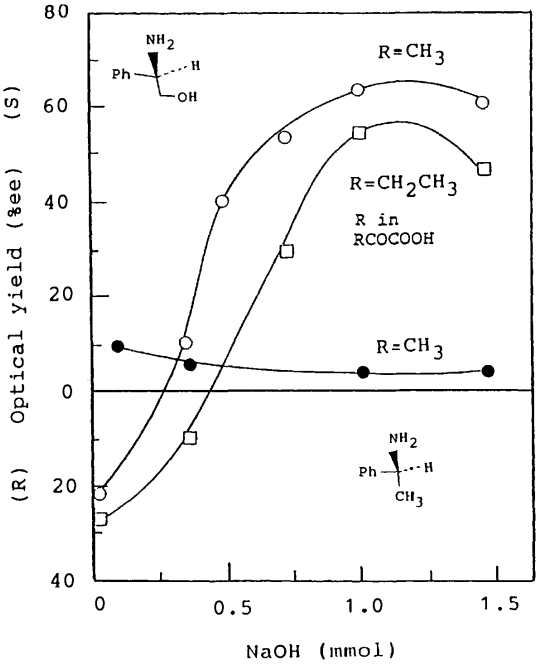

Fig. 3. Effect of NaOH on the optical yield of the asymmetric transamination in aqueous solution.

hydroxide. When the amount of sodium hydroxide was zero or small, (*R*)-product was obtained in excess. With an increase of sodium hydroxide, the configuration of the product inverted from (*R*) to (*S*), and the optical purity of the product increased to 62% ee (alanine) or 54% ee (2-aminobutyric acid) at 1 mmol of sodium hydroxide. By further increasing the amount of sodium hydroxide, the optical yield decreased slightly.

In order to examine whether the hydroxyl group of the chiral source was involved or not in the improvement of the optical yield in alkaline solution, (*S*)-α-methylbenzylamine (**1b**) was used as a chiral source, in which the hydroxymethyl group of **1a** is replaced with a methyl group. The addition of sodium hydroxide had no significant effect on the stereochemistry of the catalytic hydrogenation with **1b** (Table 1, Fig. 3). This result suggested that the hydroxyl group plays an important role in determining the steric course of the reaction in the presence of sodium hydroxide.

Table 2 shows the effect of various additives on the optical purity of the product obtained in aqueous

solution. When alkali halides or triethylamine were added to the reaction mixture, the (*S*)-product was obtained in a small excess. The effects of potassium hydroxide and lithium hydroxide were similar to that of sodium hydroxide. When NaCl or urea was added together with sodium hydroxide, the optical yield was lower than that with sodium hydroxide alone. These results indicated that the effect of sodium hydroxide on optical yield is mainly caused by hydroxide ion.

The temperature effect was examined by the use of pyruvic acid (Fig. 4). The temperature dependence on the optical yield was not high. This result was apparently different from that with phenylglycine,[4] in which the optical yield decreased with increase of the temperature.

		0.73		31	28 (*R*)	
		1.1		16	21 (*R*)	

a) Et_3N (1 equiv mol, 0.37 mmol) was added to the reaction mixture. b) These values were the averages of the results from independent experiments. c) The reaction was carried out in the presence of NaOH (1 mmol) and NaCl (0.5 mmol).

The substituent effect was examined by the use of several 2-keto acids in the presence of sodium hydroxide (Table 3). When pyruvic acid, 2-oxobutyric acid, and phenylpyruvic acid were used, the optical purities were 62, 54, and 11% ee (*S*), respectively. When benzoylformic acid was used, the configuration of the product was inverted. The selectivity of (*S*)-product decreased in the order of CH_3->CH_3CH_2->$PhCH_2$->Ph-. This order agreed with the effective bulkiness of R group of 2-keto acids.[5]

Catalytic Hydrogenation in Ethanolic Solution. In order to examine the alkali effect in ethanol, the reaction was performed in ethanol containing various amounts of sodium hydroxide using pyruvic acid and 2-oxobutyric acid (Table 4, Fig. 5). When pyruvic acid was used in the absence of sodium hydroxide (1 equiv mol of triethylamine was used in the reaction), the optical yield of alanine was 48% ee (*S*). With the increase of the amount of sodium hydroxide, the optical purity increased to 85% ee (*S*). When 2-oxobutyric acid was used in the absence of sodium hydroxide, (*R*)-2-aminobutyric acid was favored slightly. Addition of sodium hydroxide resulted in the inversion of configuration of the product, and a sudden increase in the selectivity of (*S*)-configuration was observed. When 1 mmol of sodium hydroxide was used, (*S*)-2-aminobutyric acid was obtained in an optical yield of 87% ee. In the reaction with 2-oxobutyric acid, the chemical yields decreased with increasing amount of sodium hydroxide.

When (*S*)-α-methylbenzylamine was used in the reaction with 2-oxobutyric acid, the configuration of the product was (*R*). The addition of sodium hydroxide had little effect on the optical yield in contrast to the result with **1a**. These results clearly indicate that the hydroxyl group in the substrate is involved in the stereochemistry of the reaction.

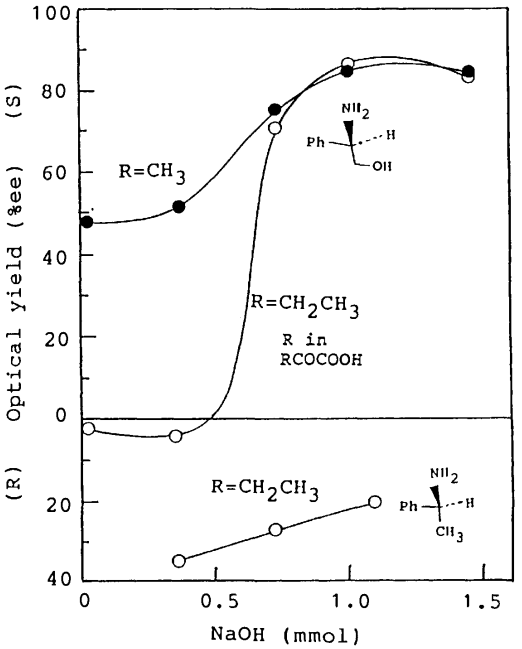

Fig. 5. Effect of NaOH on the optical yield of the asymmetric hydrogenation in ethanolic solution.

In Table 4, the optical yield of the products were further confirmed by DNP method. The optical yields determined by GLC method were in good agreement with those by DNP method.

The effect of substituents in 2-keto acids was examined. The reaction was carried out using several 2-keto acids in the presence of 1 mmol of sodium hydroxide in ethanol. The results are shown in Table 5. When 2-oxobutyric acid was used, the optical yield of the resulting 2-aminobutyric acid was similar to that with pyruvic acid. The selectivity of (*S*)-product was as follows CH_3->C_2H_5->$PhCH_2$->Ph-.

Table 5. Asymmetric Transamination with Several α-Keto Acids in Ethanolic Alkaline Solution[a]

	1.1 (3.0)		49	1 (*R*)

a) The values in parentheses were equivalent mol of triethylamine to starting 2-keto acids.

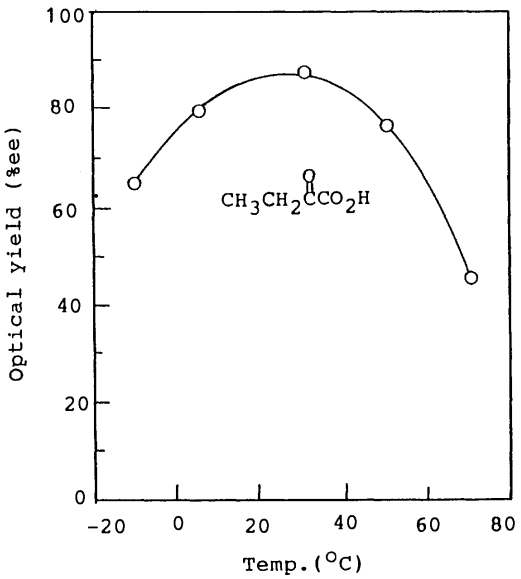

Fig. 7. Temperature effect on the optical yield of the asymmetric hydrogenation in ethanolic alkaline solution.

The solvent effect on the asymmetric transamination in the presence of 1 mmol of sodium hydroxide is shown in Fig. 6. When methanol was used as the solvent, the optical purity of the (*S*)-product was slightly lower than that with ethanol. When isopropyl alcohol or *s*-butyl alcohol was used, the optical yield of the reaction was much lower than that with ethanol. The order of the optical purity with these alcohols is: EtOH>MeOH>*i*-PrOH>*s*-BuOH. And this order was not consistent with the order of the polarity of the solvent.

The temperature effect on the optical yield of the reaction of 2-oxobutyric acid with **1a** is shown in Fig. 7. The plots of the optical yield versus temperature gave a bell-shape profile with a maximum at 30 °C.

In order to examine whether the optical yield was influenced by bases other than sodium hydroxide, the reactions were carried out in the presence of different amounts of triethylamine (Table 6). The change of the amount of triethylamine had no effect on the optical yield with pyruvic acid or 2-oxobutyric acid in the range of 0.37 to 1.1 mmol, although chemical yields decreased with the increase of triethylamine.

Experimental

The amino acid analyses were performed with a Yanagimoto LC-5S and Durrum model 500. The gas chromatographic analyses were carried out with a Hitachi 163 type gas chromatograph. Chirasil-Val glass capillary column was purchased from Applied Science Laboratories, Inc., U.S.A. The specific rotations were measured with a JASCO DIP-181 type polarimeter using a 50 mm cell. (*S*)-Methylbenzylamine (**1b**) was purchased from Aldrich Chemical Co., Inc. and distilled under nitrogen before use (**1b**; $[\alpha]_D$ −42.6, benzene).[7] (*R*)-2-Amino-2-phenylethanol (**1a**) was synthesized from (*R*)-phenylglycine as described previously[6] (**1a**; $[\alpha]_D$ −26.4, benzene). Palladium on charcoal (5% Pd-C) was obtained from Nippon Engelhard, Inc. Palladium hydroxide on charcoal was prepared according to the method of Hiskey and Northrop.[8] Pyruvic acid and 2-oxobutyric acid were distilled before use.

General procedure of the hydrogenolytic asymmetric transamination was as follows: Compound **1a** (50 mg, 0.365 mmol) and 2-keto acid (0.365 mmol) were dissolved in 1 ml of water or alcohol containing a given amount of sodium

hydroxide. The mixture was stirred under nitrogen for 12 h to form corresponding Schiff base. Asymmetric hydrogenation was carried out by using 5% Pd-C (100 mg) at 30 °C under 1 atm of hydrogen for 3 days. The catalyst was removed by filtration and washed with a small volume of 3 M HCl. The solution was evaporated to dryness, and the residue was dissolved in about 3 ml of water. After the pH of the solution was adjusted to 4.5 with sodium hydrogencarbonate, hydrogenolysis was performed with $Pd(OH)_2$ on charcoal (200 mg) at room temperature under 3 atm of hydrogen for 12 h or under 1 atm for 4 days. The catalyst was removed by filtration and washed with a small volume of 3 M HCl. The solution was evaporated to dryness and a small portion of the aqueous solution was applied to an amino acid analyzer to determine the chemical yield of the resulting amino acid. The optical purities of amino acids were determined by gas chromatographic analysis with a chiral column (GLC-method). Some of the values (Table 4) were confirmed by polarimetry after DNP-ylation.

Determination of Optical Purity. i) GLC-method—The synthesized amino acid, not isolated, was esterified by reflux with isopropyl alcohol saturated with HCl gas and then trifluoroacetylated with trifluoroacetic anhydride in dichloromethane. The derivatives were applied to gas chromatograph equipped with Chirasil-Val,[9] (0.3 mm i.d.×25 m). The column temperature was raised from 90 to 150 °C at a rate of 4 °C min^{-1}. The gas chromatographic analysis was repeated three times each and the peaks were integrated with a Hitachi 834-30 chromato-processor.

ii) DNP-method—The dinitrophenylation of amino acids was carried out as described in the earlier paper. The DNP-derivatives of the amino acids were purified with thin layer chromatography. The specific rotations of the purified DNP-amino acids were measured in 1 M NaOH. The following values were used as the specific rotations of optically pure DNP-amino acids; DNP-(*S*)-alanine, $[\alpha]_D$−143.9 (1 M NaOH); DNP-2-aminobutyric acid, $[\alpha]_D$−98.8 (1 M NaOH).[7] When the DNP-method was used for determining the optical yield, the reaction was carried out in ten-fold scale of the standard procedure described above.

Discussion

There have been many studies on the asymmetric transamination, but few dealing with the effect of alkali.[5] Alkali effects on the stereoselectivity have been studied on the hydrogenation of C=C or C=O double bond over Pd,[10–16] although the mechanism of the effect have not been fully clarified. It was also reported that the hydroxide ion has strong affinity to Pd surface,[17] and that hydroxide ion adsorbed on the Pd catalyst.[11]

Based on the experimental results and the examination with molecular model, a possible steric course for the catalytic hydrogenation in the absence or presence of sodium hydroxide are discussed below. Possible mechanism for the hydrogenation in aqueous and alcoholic solutions.

In the absence of sodium hydroxide, the hydroxyl group of the substrate could have low affinity with the catalyst. Under these conditions, the preferred conformation of the substrate on the catalyst in aqueous solution was thought to be **A**, which would lead to (*R*)-configuration (Fig. 8). In the presence of alkali, the hydroxyl group of the substrate could interact with hydroxide ion adsorbed on the catalyst, presumably by the formation of hydrogen bond. Consequently, the prefered conformation in the adsorption step was assumed to be **B**, in which the carboxyl group would be placed away from hydroxymethyl group owing to steric repulsion. (*S*)-Product is expected to form through structure B. This hypothetical mechanism is supported by the fact that the selectivity of the (*S*)-product of the reaction decreased with the increase of the bulkiness of the alkyl group of 2-keto acids

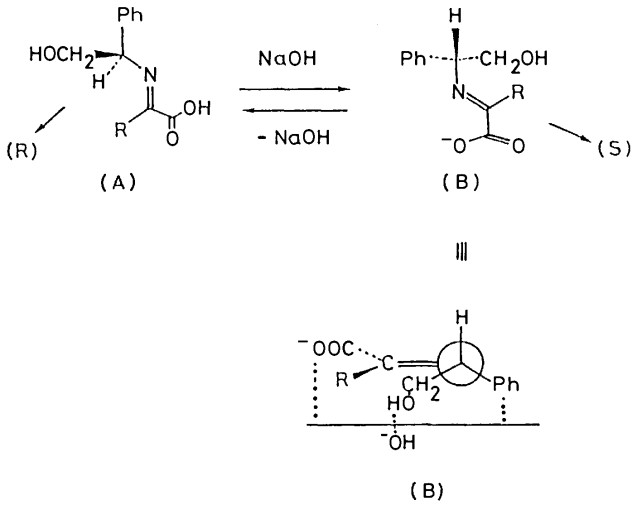

Fig. 8. Possible conformation in the catalytic hydrogenation in aqueous solution in the absence and presence of NaOH.

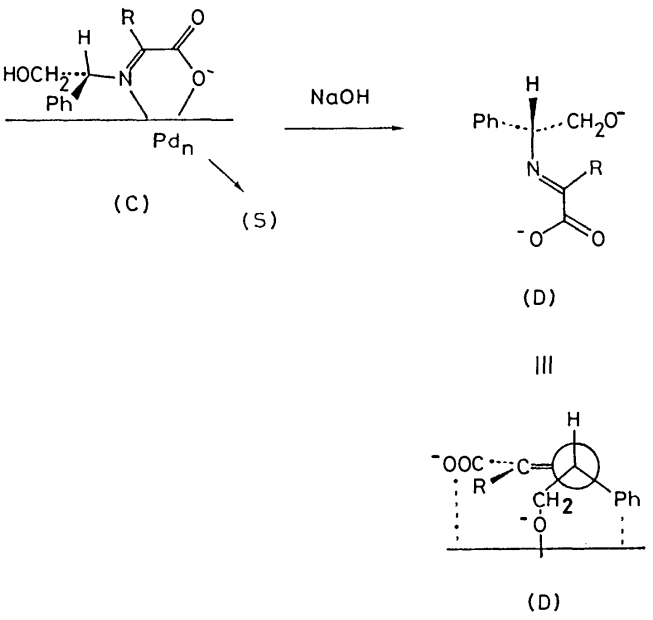

Fig. 9. Possible conformations of the substrate in the absence and presence of NaOH in alcoholic solvent.

(Table 3). The decrease of the optical yield by addition of NaCl together with sodium hydroxide could be caused by the replacement of hydroxide ion with chloride ion on the catalyst surface (Table 2).

When the amount of sodium hydroxide was none or small in alcoholic solution, the experimental results could be interpreted by the chelation mechanism (Fig. 9).[1,2,7] When pyruvic acid was used, conformation **C** was thought to be preferable,[6] which would lead to the (*S*)-product.

In the presence of alkali, the preferred conformation of the substrate was thought to be **D**. This conformation is similar to the conformation **B** except that the proton of hydroxyl group in asymmetric moiety is dissociated and that the distance between the substrate and the catalyst surface is shorter. In this conformation, the carboxyl group is apart from the alkoxide anion by steric and electrostatic repulsion. When 2-oxobutyric acid was used, the relative bulkiness of the R group increase compared with that of pyruvic acid. However, the carboxyl group is thought to be placed away from alkoxide anion as in the conformation **D** owing to the electrostatic repulsion. That may be a reason why the optical yield with 2-oxobutyric acid was similar to that with pyruric acid. When benzoylformic acid was used, the (*R*)-product was preferably obtained. The inversion of the configuration was explained by the dominant steric repulsion between R and alkoxide anion over the electrostatic repulsion between carboxylate and alkoxide anion.

It was also shown that the optical yield was lower in less polar solvent such as *i*-PrOH and *s*-BuOH than that in more polar solvents. This result may be due to the difference of the solvation ability of these alcohols to the alkoxide anion. The stabilization of alkoxide ion by the solvation may not be sufficient in less polar solvents.

The examination of the temperature effect showed that the peak of the optical yield was at around 30 °C. This result might related to the fact that the dissociation is generally accelerated by a rise of the temperature to some extent and decrease at higher temperature.[18]

In summary, it was found that the preferred conformation of the substrate in aqueous or alcoholic solution changed by the modification of the Pd catalyst surface with hydroxide ion. The hydroxyl group of the substrate also played an important role on the adsorbed stage on the catalyst in the hydrogenation process. The alkali concentration effect, additive effect, temperature effect, substituent effect in the hydrogenolytic asymmetric transaminations in both aqueous and alcoholic solutions support the possible mechanism presented for the hydrogenation in the presence of sodium hydroxide.

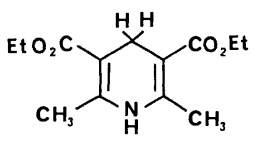
(Received July 1, 1989)

Imines are reduced into the corresponding amines in high yields by Hantzsch ester in the presence of silica gel. The reduction shows high chemoselectivity and stereoselectivity. Reduction of α,β-unsaturated imines proceeds with high regioselectivity to yield allylic amines (1,2-reduction products).

The reduction of imines is very important in organic synthesis[1] and has been studied intensively, especially in connection with the syntheses of alkaloids[2] and amino acids.[3] Although there has been many investigations contributing to this subject, the procedures generally employed at the present time seem to involve certain problems to be improved. For example, a carbonyl group will be reduced into hydroxyl group by hydride reagents and a carbon-carbon double bond will be saturated by catalytic hydrogenation. These poor chemoselectivities seem to make it difficult to apply these methods to the reduction of such molecules that bear various functional groups along with an imino group.

On the other hand, from the viewpoint of biomimetic reactions of NAD$^+$-coenzymes,[4] reduction of imines[5-11] and iminium salts[12-14] as well as that of carbonyl compounds has been studied intensively. It is shown that reduction of imines with NAD(P)H models is susceptible to acid-catalysis such as proton[5-8] or metal cation.[9-11]

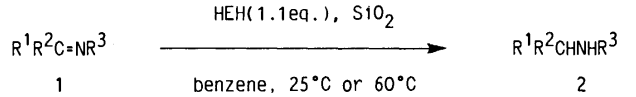
Recently, it was found that diethyl 2,6-dimethyl-1,4-dihydro-3,5-pyridinedicarboxylate (Hantzsch ester, HEH) acted as a mild and selective reducing agent for electron-defficient olefins in the presence of silica gel.[15-19] The HEH-SiO_2 reduction has some unique characteristic features. For example, it shows an excellent chemoselectivity, that is, olefins conjugated with a nitro, a formyl, or a keto group are reduced in quantitative yields whereas those conjugated with an alkoxycarbonyl, or a cyano group are not affected at all.[15-17] It also shows a high regioselectivity in the reduction of conjugated dienones.[18] The reduction proceeds in a manner of 1,4-reduction to afford γ,δ-unsaturated ketones. These features of HEH-SiO_2 reduction system seem to be very attractive for the syntheses of certain natural products that bear various functional groups susceptible to reduction. In fact, the system was applied to the convenient syntheses of some natural products.[19] In the present paper, application of this HEH-SiO_2 system to the reduction of imines is described.



Hantzsch ester, HEH

Results and Discussion

The HEH-SiO_2 system has been proved to be effective for the reduction of imines into the corresponding amines (Scheme 1) as it was in the reductions of certain carbon-carbon double bonds. Table 1 shows that the reduction of *N*-benzylideneaniline (**1a**) with HEH was highly accelerated by silica gel. Without silica gel, the reduction gave **2a** only in 15% yield after 12 h, whereas the reaction completed within 1 h in the presence of silica gel. Solvent effect was so significant and only nonpolar solvents such as hexane or benzene gave satisfactory results. It can be considered that polar solvents retard the adsorption of HEH and imine **1a** onto the silica gel surface. Aluminum oxide (basic or acidic) was also proved to be a good catalyst for the reduction.[20] A variety of imines derived from ketones and aldehydes were also reduced smoothly in high yields as shown in Table 2. It is



Scheme 1.

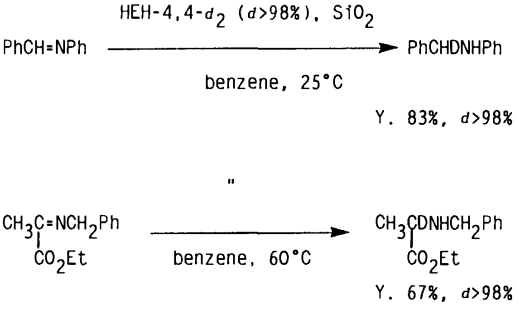
a) Reaction temperature: 25 °C for a, b, c, d, h. 60 °C for e, f, g. b) Isolated yield.

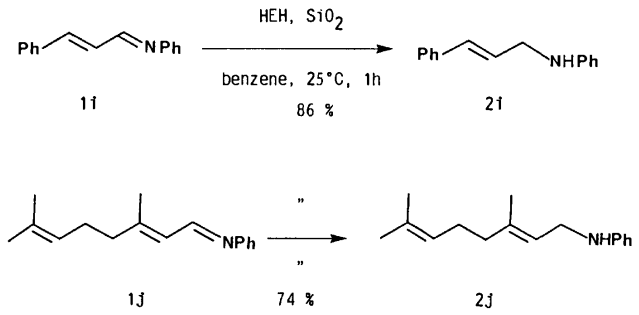
notable to find that the reductions of aldimines (**1a—d, h**) completed within 3 h at 25 °C, whereas the reductions of ketimines (**1e—g**) required higher temperature of 60 °C. *N*-(1-Ethoxycarbonylethylidene)benzylamine (**1g**) and *N*-(2,6-dimethyl-5-heptenylidene)aniline (**1h**) was reduced chemoselectively into *N*-benzylalanine ethyl ester and *N*-(2,6-dimethyl-5-heptenyl)aniline (**2h**) respectively. The high chemoselectivity of the HEH-SiO_2 system was further demonstrated by the following competition reactions. Reduction of a mixture of **1a** and 4-phenyl-3-buten-2-one (**3**), or a mixture of **1a** and *N*-(α-methylbenzylidene)aniline (**1e**) was carried out with 1.1 equivalent amounts of HEH at 25 °C. In the former reaction, **1a** was converted into **2a** in 95% yield (on GLC) in 1 h whereas most of **3** remained unchanged. An apparent predominance of **1a** over **1e** was also observed in the latter reaction. The aldimine **1a** was reduced to give **2a** in 86% yield after 1 h while only a trace amount of the ketimine **1e** was converted into **2e** within the same reaction time.

Preparation of α-deuteriated amines and α-deuteriated amino esters can be easily performed with HEH-4,4-d_2 (d>98%) (Scheme 2). Reduction of **1a** and **1g** with HEH-4,4-d_2 indicates that the deuterium atom was regioselectively transferred onto the carbon atom in the imine moiety without any contamination.

Investigation on the regioselectivity of the reduction of α,β-unsaturated imines **1i** and **1j** revealed that the reduction with the HEH-SiO_2 system proceeded in a manner of 1,2-reduction to afford allylic amines **2i** and **2j** (Scheme 3) which is in a flat contrast to the reduction of α,β-unsaturated ketones.[19] In the reduction



Scheme 2.



Scheme 3. Regioselectivity in the reductions of α,β-unsaturated imines.

of α,β-unsaturated ketones, it was reported that the 1,4- vs. 1,2-regioselectivity is affected by the reactivity of the reducing agents.[21] In the present system, since the reducing agent is kept unchanged, the difference in the regioselectivity between the α,β-unsaturated imines and ketones may reflect the difference in reactivity of the substrate.

Substituent effect on the stereochemical properties of the present reduction were also examined. As an example of acyclic imines, reduction of (*R*)-*N*-(α-methylbenzylidene)-α-methylbenzylamine (**1k**) was carried out and the product was characterized on ^1H NMR analysis[11] to contain 80% of the (*R*,*R*)-isomer and 20% of the (*S*,*R*)-isomer (Scheme 4). Reductions of methyl-substituted *N*-(cyclohexylidene)benzylamines (**1l—n**) represents the stereoselectivity for the cyclic systems (Table 3). The results revealed that thermodynamically more stable isomer was preferred in each case, which suggests that the reduction under-

goes through the product-like transition state. It is notable that stronger steric effect was observed for methyl substituent at the 4-position than that at the 2 or 3-position.

Applications of the present reduction system to certain natural products are now in progress in our laboratory.

Experimental

Instruments. ^{1}H NMR srectra were measured at 90 MHz with a Hitachi R-90H FT-NMR spectrometer, and at 400 MHz with a JEOL GX400 Fourier Transfer NMR spectrometer. IR spectra were recorded on a JASCO IR-810 infrared spectrophotometer. Gas chromatography analyses were performed on a Shimadzu GC-12A gas chromatograph. GC-Mass spectra were measured with a Hitachi M-80A GC-Mass spectrometer.

Materials. Hantzsch ester (HEH) and its 4,4-dideuteriated analog (HEH-4,4-d_2) were prepared as reported in a previous paper.[22] The deuterium content in HEH-4,4-d_2 was confirmed to be over 98% by 400 MHz ^{1}H NMR analysis. Imines **1a—n** were prepared as described in the literature.[23] Solvents were distilled immediately prior to the use. Silica gel (Nakarai Silica Gel 60, 35—70 mesh) was activated in an oven at 80 °C for a few days and stored in a desiccator. Other chemicals were purchased from Wako Pure Chemicals Industries Ltd. and Nakarai Chemicals Ltd.

Reduction of Imine. A mixture of 1.0 mmol of an imine, 293 mg (1.1 mmol) of HEH, 1.50 g of silica gel and 10 ml of absolute benzene was stirred at 25 °C (**1a**, **1b**, **1c**, **1d**, **1h**, **1i**, **1j**), or at 60 °C (**1e**, **1f**, **1g**, **1k**, **1l**, **1m**, **1n**) under a nitrogen atmosphere for an appropriate reaction time (1—3 h). The silica gel was removed by filtration and the residue was subjected to a column chromatography on silica gel using dichloromethane as an eluent to afford the corresponding amine. Chemical yields were: **2a**, 86%; **2b**, 78%; **2c**, 83%; **2d**, 68%; **2e**, 85%; **2f**, 64%; **2g**, 58%; **2h**, 72%; **2i**, 86%; **2j**, 74%; **2k**, 74%; **2l**, 85%; **2m**, 73%; **2n**, 89%.

***N*-Benzylaniline-α-*d* and *N*-Benzylalanine-2-*d* Ethyl Ester.** Reduction of **1a** and **1g** with HEH-4,4-d_2 was carried out by the same procedure as described above. The analysis of the 400 MHz ^{1}H NMR spectrum revealed that the deuterium was incorporated in the α-position of the product. The deuterium content determined was 98%. Chemical yields were 83% for **2a** and 67% for **2g**.

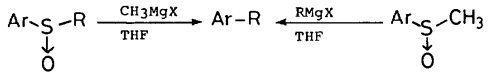
A Cross-Coupling Reaction of Methylsulfinylarene

Shoji WAKABAYASHI,* Takakazu TANAKA, Yukihiro KUBO, Junichi UENISHI, and Shigeru OAE*
Department of Chemistry, Faculty of Science, Okayama University of Science, Ridai-cho, Okayama 700
(Received July 19, 1989)

Cross-coupling product 2-(2-pyridyl)quinolines were obtained in the reaction of 2-(methylsulfinyl)-quinolines and 2-(methylsulfinyl)pyridines with methylmagnesium bromide. Attempts of cross coupling in the reaction of other substrates were unsuccessful.

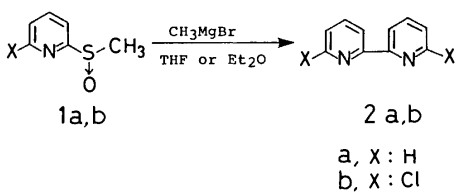
Earlier, we have reported many ligand coupling reactions of sulfoxides with various types of Grignard reagents.[1] This reaction provides a new carbon-carbon bond formation between α and ipso carbons of arylsulfinyl group or ipso carbon and the Grignard reagent with retention of the configuration.[2] In this coupling reaction which is typically described in Scheme 1, R is usually a benzylic, allylic, aromatic, and azaaromatic group,[1,3] otherwise the reaction becomes messy and gives no desired coupling product.



Scheme 1.

When R is methyl or other alkyl group, a dimeric compound is a major product. For example, in the coupling reaction of 2-(methylsulfinyl)pyridine (**1a**) with methylmagnesium bromide, 2,2′-bipyridyl (**2a**) was formed in moderate yields.[4] This is quite a unique reaction because it involves ligand coupling of two azaaromatic groups after initial ligand exchange on the sulfoxide and has promised to be a productive method for preparation of biazaaromatics.[5]

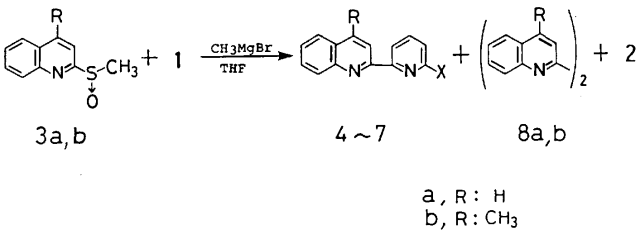
In the extension of these studies, we were interested in cross-coupling reaction between two different azaaromatic sulfoxides, and have found some successful examples. In this article the details are described.



Scheme 2.

Results and Discussion

A mixture of 2-(methylsulfinyl)quinoline (**3a**) and **1a** was treated with methylmagnesium bromide in THF at room temperature. The reaction completed in about 15 min and gave 2-(2-pyridyl)quinoline (**4**) in 57% yield. Homo-coupling product 2,2′-biquinolyl (**8a**) and **2a** were also formed in 42 and 23% yields respectively. Results of the other combination of the reactions between **3a**, **b** and **1a**, **b** are summarized in Table 1, in which the cross coupling products **4—7** were obtained in 20 to 57% yield.



Scheme 3.

Meanwhile, the cross coupling reaction of **1a** and **1b** provides unsymmetric 2,2′-bipyridyl along with symmetric bipyridyls **2a** and **2b**. But somehow the yield of unsymmetric bipyridyl was low, only 16% of 6-chloro-2,2′-bipyridyl (**9**) was obtained. The yields of **2a** and **2b** were 36 and 77% respectively. Reaction of **3a** and **3b** gave three kinds of 2,2′-biquinolyls, thus 4-methyl-2,2′-biquinolyl (**10**), **8a** and **8b**, which were hard to be purified by chromatographic techniques. The product ratios of **10**, **8a**, and **8b** were found to be 6:4:7 approximately determined by ^{1}H NMR spectrum of the mixture.

Table 1. Cross-Coupling Reaction of **3** and **1**

Starting		Sulfoxide R	X	Cross-coupling product (yield/%)		Homo-coupling product (yield/%)

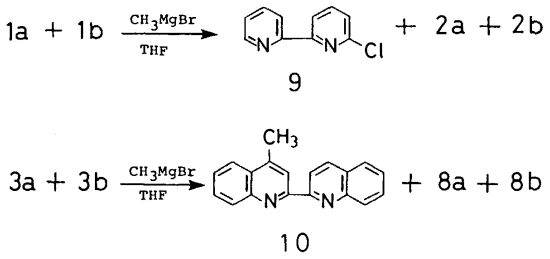

Scheme 4.

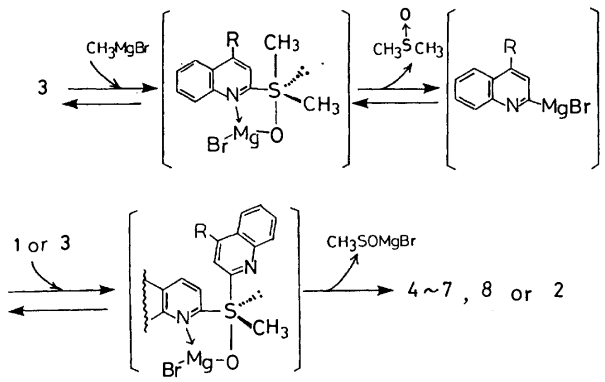

Chart 1.

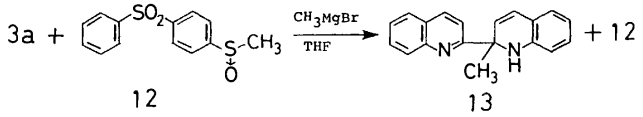
The mechanism of the reaction has been examined carefully in the cases of 2-(alkylsulfinyl)pyridines and proposed by Oae et al.[4] According to the mechanism, an initial attack of the methylmagenesium bromide on the sulfur atom of **3** forms a σ-sulfurane intermediate followed by dispropotionation to release dimethyl sulfoxide and 2-quinolylmagnesium bromide, which subsequently reacts with another sulfoxide **1** or **3** to promote a normal ligand coupling, and finally affording the cross coupling product **4**—**7** as well as the homo-coupling products **8** and **2**.

The coupling reaction of **3a** with 2-(*t*-butylsulfinyl)-pyridine (**11**) also gave the desired cross couling product **4** in 22% yield along with **8a** in 8% yield but none of **2a** was detected in the reaction mixture.[13] The rest of the starting sulfoxide **11** was recovered in 71% yield. The result would be due to the steric hindrance of the *t*-butylsulfinyl group, thus the rate of formation of the intermediary σ-sulfurane derived from 2-quinolylmagnesium bromide and **11** is anticipated to be considerably slow. The cross coupling reaction obviously competes with the usual ligand coupling reaction as well as other side reactions involving simple ligand exchange or disulfide formation. Thus the reaction is not simple. In fact, no cross couling was observed between **3a** and 1-methylsulfinyl-4-(phenylsulfonyl)benzene (**12**). The major product was 2-methyl-1,2-dihydro-2,2′-biquinolyl (**13**) along with 90% recovery of the other sulfoxide **12**. The compound **13** is known to be produced by treatment of two equivalents of methylmagnesium bromide and **3a**.[5]



Scheme 5.

Reactions of **3a** with other substrates, 2-(methylsulfinyl)pyrimidine, methylsulfinylbenzene, and their *t*-butylsulfinyl derivatives gave almost similar results in which no cross coupling product was detected among the reaction mixtures. In the reaction of **1a** and **12**, the dimeric compound **2a** was obtained in 89% yield and the sulfoxide **12** was recovered quantitatively.

Experimental

Melting points were determined with Yanaco micromelting point apparatus and were uncorrected. ^{1}H NMR spectra were run on JEOL-GX400 spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. Chemical shifts are given as σ value. Infrared spectra were obtained with JASCO IR-A spectrometer. Low- and high-resolution mass spectra were taken on JEOL-JMS 303HF spectrometer with a direct inlet method at 70 eV. Only strong and/or structurally important peaks are reported here for IR and MS. Column chromatography was carried out on silica gel (Wako gel 200). THF for the reactions was dried over sodium benzophenone ketyl and freshly distilled just before use. Methylmagnesium bromide was purchased from Kanto Chemical Co. as THF solution.

Typical Procedure of the Cross-Coupling Reaction. To a mixture of sulfoxide (1 mmol) and another sulfoxide (1 mmol) in THF (5 ml) was dropped methylmagnesium bromide (2 ml, 1M solution in THF) at room temperature during a min under Argon atmosphare. The reaction mixture was stirred for 15 min at the same temperature. It was quenched with aq. ammonium chloride (2 ml) and extracted with chloroform (60 ml). The extract was washed with water (4 ml×2) and brine (4 ml), dried over $MgSO_4$ and evaporated under reduced pressure. The residue was purified by column chromatography on silica gel. Characteristic properties of the products are the following.

4: Colorless crystals, mp 98—99 °C (EtOH) (lit,[6] 99 °C); ^{1}H NMR δ=7.36 (1H, td, J=6.4, 1.8 Hz), 7.56 (1H, td, J=7.1, 1.5 Hz), 7.74 (1H, dt, J=7.9, 1.5 Hz), 7.85 (1H, d, J=8.5 Hz), 7.88 (1H, td, J=7.3, 1.9 Hz), 8.19 (1H, d, J=8.7 Hz), 8.29 (1H, d, J=8.2 Hz), 8.56 (1H, d, J=8.2 Hz), 8.66 (1H, dd, J=8.1, 1.1 Hz), 8.75 (1H, ddd, J=4.7, 1.9, 1.1 Hz).

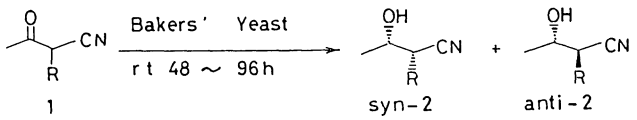
(Received May 13, 1989)

The bakers' yeast reduction of 2-alkyl-3-oxobutyronitrile gave optically pure 2-alkyl-3-hydroxybutyronitriles. Especially 2-phenyl-3-oxobutyronitrile gave only syn diastereomer of 2-phenyl-3-hydroxybutyronitrile in high optical yield.

Nitrogen-functionalyzed optically active secondary alcohol derivatives are sometimes found in biologically active compounds as important moiety for their activity.[1] It is, therefore, required to develop the efficient and convenient methods to supply nitrogen-functionalized alcohol derivatives. Since the bakers' yeast has been recognized as a useful reducing agent for asymmetric reduction of various functionalized ketones to produce optically active secondary alcohols under mild conditions and simple operations.[2] Chemical yield and enantioselectivity in the yeast reduction of various substrates, however, are not always satisfactory i.e. it has sometimes been observed that low enantioselectivity and decomposition of the substrate occured. Although much efforts have been paid for screening microbes which have good ability to reduce various kind of ketones with high enantioselectivity, it is also important to get a knowledge for the functional groups which have a good affinity toward the microbe.[3] We would like to report in this paper that the bakers' yeast reduction of 2-alkyl β-keto nitriles into the corresponding hydroxy nitriles with high enantioselectivity (Scheme 1). Since the cyano group is a functional group widely used as a precursor of both of amino group and carbonyl group,[4] hydroxy nitriles obtained should become wide variety of useful key intermediates in the synthesis of optically active natural products which are involving nitrogen functional group and carbonyl group.



Scheme 1.

Results and Discussion

Several keto nitriles, i.e. 2-methyl- (**1a**), 2-ethyl- (**1b**), 2-butyl- (**1c**), and 2-phenyl-3-oxobutyronitrile (**1d**) were prepared by the reaction of acetyl chloride with α-lithiated nitriles and subjected to the reduction with bakers' yeast. Results of the present microbial reduction of β-keto nitriles are summarized in Table 1.

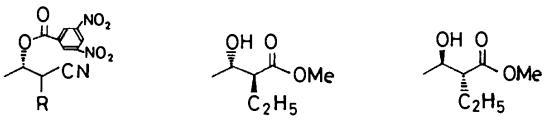
The products **2** consisted of syn and anti isomers, which could be separated into each of pure diastereomers as 3,5-dinitrobenzoates by silica gel flash column chromatography except for the case of nitrile **2c**. Each of benzoates were converted into (+)-α-methoxy-α-(trifluoromethyl)phenylacetates (MTPA esters) of 2-alkyl-3-hydroxybutyronitriles by treatment with lithium aluminum hydride followed by (+)-MTPA chloride for determination of their enantiomeric excess by ^{1}H NMR and ^{19}F NMR analysis.[5] Completely enantioselective reduction was achieved (Entries 2, 3, and 4), except for the reduction of 2-methyl-3-oxobutyronitrile (Entry 1). To determine the configuration, each of diasteromers of **2b** were converted into the correesponding hydroxy esters. According to ^{1}H NMR analysis of the hydroxy ester,[6] the assignment of diastereomers could be achieved. Consequently it was found that the chemical shift of the methine proton at 2-position of *syn*-**2b** was in lower field than the anti one, in analogy with compounds **2a** and **2c**, the isomers which have higher value of chemical shift of the methine proton were presumed to be the syn isomers. Hence the ratio of each of diastereo-

Table 1. Results of the Bakers' Yeast Reduction of 3-Oxobutyronitriles

Entry	Product	R	Yield/%	syn : anti[a]	$[\alpha]_D$ in EtOH, *c* ca. 1	
					syn-**2**	*anti*-**2**
1	**2a**	CH_3	69	56 : 44	+17.3°(82%ee, 3*S*)[b]	−11.9° (74%ee, 3*S*)[b]
2	**2b**	C_2H_5	46	54 : 46	+ 9.5°(>98%ee, 3*S*)[b]	−18.8° (>98%ee, 3*S*)[b]
3	**2c**	*n*-C_4H_9	43	58 : 42	+14.3°(>98%ee, 3*S*)[b]	—[c]
4	**2d**	Ph	61	>99 : <1	−33.3°(>98%ee, 3*S*)[b]	

a) Determined by ^{1}H NMR analysis. b) The enantiomeric excess was determined by ^{1}H and ^{19}F NMR analyses of (+)-MTPA ester.[5] c) Anti isomer could not be isolated in pure state by the flash column chromatography on silica gel.

mers of yeast reduction products of **2a**, **2b**, and **2c** could be determined by ^{1}H NMR analysis. For the determination of the absolute configuration, anti isomer of 2-ethyl-3-hydroxybutyronitrile (**2b**) was converted into the corresponding hydroxy ester **4**. Comparing the specific rotation of methyl (2*S*,3*R*)-2-ethyl-3-hydroxybutanoate (**5**) which was derived from methyl (3*R*)-3-hydroxybutanoate,[7] the absolute configuration of the starting nitrile *anti*-**2b** was assigned to be 2*R*, 3*S*.

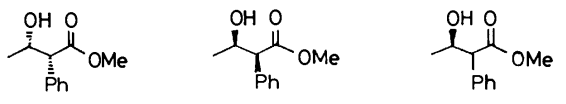


3 4 5

Fig. 1.

Absolute configuration of 3-position of **2a** and **2c** were presumed by the specific rotations and the chemical shift of the methoxyl group of (+)-MTPA esters by comparison with the result in the case of (3*R*)-2-ethyl-3-hydroxybutyronitrile which was assigned by the method above mentioned.

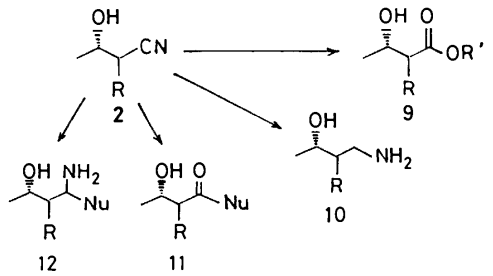
Although the starting material was racemic at C-2 position, only single diastereoisomer was obtained in the case of the reduction of 2-phenyl-3-oxobutyronitrile (**1d**) in optically pure state (Entry 4). To determine the absolute configuration, nitrile **2d** obtained by bakers' yeast reduction was converted into the hydroxy ester **6** by the acid hydrolysis of the cyano group followed by treatment of diazomethane. ^{1}H NMR spectrum of the acetate of **6** agreed completely with that of syn isomer of (±)-**6**.[8] The absolute configuration of nitrile **2d** at C-2 and C-3 position was presumed to be 2*R*, 3*S* on the basis of the sign of the optical rotation of the hydroxy ester **6** with that of (−)-(2*S*, 3*R*)-**7**. This result agreed with a general rule for the enantioselectivity in the bakers' yeast reduction.[9]



6 7 8

Fig. 2.

This microbial reduction of 3-oxobutyronitriles possesses two outstanding characteristics for the preparation of optically active building blocks for organic synthesis. First, the reduction of 2-phenyl-3-oxobutyronitrile gave a single diastereoisomer of the hydroxy nitrile in optically pure state in good yield. We presumed the reason of this extremely high syn diastereoselectivity of the reduction of 2-phenyl-3-oxobutyronitrile was due to the enhanced enolization of the 3-oxo group[10,11] by the phenyl group. Recently, it has been reported that details of the diastereoselectivity of the bakers' yeast reduction of 2-alkyl-3-oxobutanoate.[12] The keto nitrile **1d** is regarded as equivalent in 2-phenyl-3-oxobutanoate. The bakers' yeast reduction of methyl 2-phenyl-3-oxobutanoate, however, gave a corresponding hydroxy ester in very low yield. In addition, only the reduction of **1d**, the high diastereoselectivity was observed. Other ketones of **1a**, **1b**, and **1c**, however, the bakers' yeast reduction provided good enantioselectivity but poor diastereoselectivity. It is of much interest to compare the results of this microbial reduction of 3-oxobutyronitrile **1** with those of 2-alkyl-3-oxobutanoates[12] in considering the factor which define the stereoselectivity in the enzymatic systems of the yeast. Second, the reduction products involve a cyano group in the molecule. Since the cyano group is a precursor of both of amino group and carbonyl group,[4] hydroxy nitriles **2** obtained in this reaction should become useful building blocks for the synthesis of variety of optically active natural products. As described above, 3-hydroxy esters **9** could be converted from the nitrile **2** easily. And the reduction of **2b** at room temperature for 24 h with 10 mol% of PtO_2 under hydrogen atmosphere[13] provided the amino alcohol **10** in 85% yield. Nitriles react with some nucleophilic reagents under presence of acidic catalyst,[4] both of β-hydroxy ketone **11** and γ-amino alcohol **12** may also be derived from **2** (Scheme 2).



Scheme 2.

It should be emphasized here that the most important thing is to use yeast as a reagent in organic synthesis in designing the substrate to supply the microbial reduction and to modify the substrate which could become a good chiral synthon after reduction. In the present reaction, it has been revealed that the bakers' yeast could play an important role to reduce 3-oxobutyronitriles giving 3-hydroxybutyronitriles with high optical purity.

Experimental

Instruments. NMR spectra were recorded on Varian VXR-200, VXR-500, and JEOL MH-100 spectrometers in $CDCl_3$ with tetramethylsilane (TMS) as an internal reference. Optical rotations were measured with a JASCO DIP-

4 digital polarimeter. IR spectra were recorded on JASCO A-102 spectrometer on KBr disk.

Materials. Solvents and commercially available starting materials were generally used without additional purification unless otherwise indicated. Flash chromatography was done on a column of silica gel (Wako gel C-300). Tetrahydrofuran (THF) and diethyl ether (Et_2O) were freshly distilled from sodium benzophenone ketyl. Pyridine and dichloromethane were refluxed on calcium hydride for 5 h and distilled and stored under argon in the presence of Molecular Sieves 4A.

Preparation of 2-Alkyl-3-oxobutyronitrile (1). To a solution of lithium diisopropylamide (LDA) in 30 mL of THF was added a solution of a nitrile (30 mmol) in 60 mL of THF at −50 °C under argon atmosphere and the solution was stirred for 3 h to produced a white sluggish solution, then THF (15 mL) solution of acetyl chloride (1.178 g, 15 mmol) was added one portion into the sluggish solution at −78 °C. After the addition was complete the mixture was stirred and allowed to warm to 0 °C. The reaction mixture was acidified with 2 M HCl solution, then extracted with ethyl acetate. The organic layer was dried over $MgSO_4$, filtered, and concentrated in vacuo to give the crude product. Purification by silica gel flash chromatography (ethyl acetate/hexane=1 : 20 to 1 : 5) gave 3-oxobutyronitrile **1** in 51 to 80% yields. Chemical yield (%), boiling point (°C/mmHg; 1 mmHg≈133.322 Pa), R_f value on silica gel TLC, ^{1}H NMR spectral data (100 MHz, δ TMS in $CDCl_3$), and IR spectral data of ketones **1** are summarized below.

1a: 60%; 60/75 mmHg by Kugelrohr; 0.4 (AcOEt/hexane=1 : 2); 1.5 (3H, d, J=7.8 Hz), 2.4 (3H, s), and 3.7 (1H, q, J=8.4 Hz) ; 3000, 2950, 2310 (CN), 1725 (C=O), 1480, 1360, and 1170 cm^{-1} (neat).

1b: 58%; 85/75 mmHg by Kugelrohr; 0.4 (AcOEt/hexane=1 : 2); 1.1 (3H, t, J=6.6 Hz), 1.8—2.1 (2H, m) , 2.3 (3H, s), and 3.5 (1H, t, J=7.0 Hz) 2970, 2920, 2870, 2230 (CN), 1720 (C=O), 1360, 1160, and 1010 cm^{-1} (neat).

1c: 51%; 110/25 mmHg by Kugelrohr; 0.5 (AcOEt/hexane=1 : 5); 1.0 (3H, t , J=6.5 Hz) , 1.2—2.2 (6H, m), 2.5 (3H, s) 3.5—3.9 (1H, t, J=4.0 Hz); 2970, 2930, 2250 (CN), 1720 (C=O) cm^{-1} (neat).

1d: 80%; mp 97 °C; 0.5 (AcOEt/hexane=1 : 1); 2.3 (3H, s), 4.8 (1H, s), and 7.6 (5H, s); 3050, 2950, 2200(CN), 1730(C=O), 1360, and 1140 cm^{-1} on KBr disk.

Reduction of 2-Alkyl-3-oxobutyronitrile with Bakers' Yeast. To a stirred solution of 30 g of D-glucose in 200 mL of water was added 25 g of bakers' yeast (Oriental Yeast Co.) and the suspension was stirred for 30 min, then, 20 ml of an ethanol solution of 2-phenyl-3-oxobutyronitrile (**1d**) (0.815 g, 5.12 mmol) was added. The mixture was stirred at room temperature for 48 h, and then the yeast suspension of 25 g of yeast, 30 g of D-glucose in 200 mL of water was added and stirred for an additional 148 h. The mixture was filtered through a Celite pad. The filtrate was saturated with NaCl, and extracted with ethyl acetate. The extracts were concentrated in vacuo and the residue was subjected to silica gel flash column to give the alcohol **2d** (0.502 g, 3.12 mmol, 65%) as a yellow oil. The chemical yield of another alcohols **2** obtained by the same method as above are described as followed. **2a**=69%, **2b**=46%, and **2c**=43%. The ratio of diastereomers was determined by 200 MHz ^{1}H NMR analysis. In the case of the reduction of **1d**, no diastereomer could not be detected in **2d** produced in the yeast reduction using 500 MHz ^{1}H NMR.[14]

Preparation of 3,5-Dinitrobenzoates (3).[15] To a solution of **2** (1.0 mmol), pyridine (1.0 mmol), and 4-dimethylaminopyridine (DMAP)(0.1 mmol) in 2.5 mL of dichloromethane (CH_2Cl_2) solution was added 1.5 mmol of 3,5-dinitrobenzoyl chloride in 1.5 mL of CH_2Cl_2 under argon at 0 °C and stirred for 3 h at room temperature. Some pieces of crashed ice were then added to the reaction mixture, and this mixture was extracted with CH_2Cl_2. The organic layer was dried over $MgSO_4$ and concentrated in vacuo to give a yellow solid. Separation of diastereomers could be performed by silica gel flash column chromatography or silica gel TLC. Chemical yield (%), melting point (°C), R_f value on silica gel TLC, and IR spectral data(KBr disk) are summarized below.

3a: 95%; 70 (syn), 65 (anti); 0.6 (syn) and 0.5 (anti), AcOEt/hexane=1 : 1 after 5 times of development; 3100, 2960, 2240(CN), 1730(CO) , 1550, 1170, 920, 720 cm^{-1}.

3b: 95%; 70 (syn), 92 (anti); 0.6, (syn), 0.45 (anti), AcOEt/hexane=1 : 5, after 4 times of development; 3100, 2960, 2920, 2240(CN) , 1730(CO) , 1550, 1340, 1270, 1170, 920, 720 cm^{-1}.

3c: 87%; 98 (syn); 0.65 (syn), AcOEt/hexane=1 : 5, after 10 times of development; 3150, 2950, 2850, 2230(CN), 1730(CO), 1550, 920 cm^{-1}.

3d: 61%; 115; 0.25, AcOEt/hexane=1 : 3, after 3 times of development; 3110, 2950, 2850, 2230 (CN), 1780 (CO), 1530, 950 cm^{-1}.

Spectral data, each diastereomers of the esters of **3** of ^{1}H HMR (200 MHz, δ, $CDCl_3$, J/Hz), ^{13}C NMR (50 MHz, δ, $CDCl_3$, ppm) are summarized below.

Lithium Aluminum Hydride Reduction of 3. To a suspension of 45 mg (1.16 mmol) of lithium aluminum hydride in 1.8 mL of THF at −78°C under argon was added a solution of 144.1 mg (0.469 mmol) of **3b** in 4 mL of THF, and the solution was stirred for 3.5 h. After quench reaction by the addition of wet ether and aqueous solution saturated with Na_2SO_4, the reaction solution was dried by anhydrous K_2CO_3, filtration through a glass filter and evaporation provided a crude oil. Kugelrohr distillation gave **2b** as a colorless oil (47.4 mg, 0.419 mmol, 89%). By the same method other benzoyl esters **3** could be coneverted into the alcohol **2** in 80 to 99% yield. Specific rotation in EtOH at 23°C, boiling point, IR spectral data and elemental analyses of **2** are summarized below.

2a: (syn) +17.3°, c 1.00, (anti) −11.3°, c 0.890; 80°C/1.5 mmHg (Kugelrohr); 3430, 2930, 2240(CN), 1460, 1120 cm^{-1} (neat); Calcd for C_5H_9ON: C, 60.58; H, 9.15; N, 14.13%. Found: C, 60.62; H, 9.29; N, 14.25%

Underlined signals are presumed to be of anti isomer's.

2d(syn): 1.330 (3H, d, J=6.18), 2.002 (1H, s, OH), 3.911 (1H, d, J=6.24), 4.09 (1H, dq, J_1=6.21, J_2=6.16), 7.20—7.50 (5H, m); 19.842, 46.254, 70.150, 76.933, 128.217, 128.593, 129.154, 132.354; 90.119(single peak), >98%ee.

Methyl (2*R*,3*S*)-2-Ethyl-3-hydroxybutanoate (4). A solution of *anti*-**2b** (49.3 mg, 0.436 mmol) with 5 mL of concd HCl was refluxed for 8 h. After dilution with 10 mL of ethyl acetate, the organic layer was washed with brine, dried, and evaporated to give a colorless oil. The oil was diluted with ether and treated with diazomethane. Purification by silica gel TLC gave **4** as a colorless oil (21.3 mg, 0.146 mmol, 33%).

$[\alpha]_D^{23}$+8.48° (c 0.825, $CHCl_3$); R_f 0.75, AcOEt/hexane=1 : 2; ^1H NMR (100 MHz, δ, $CDCl_3$), 0.9 (3H, t, J=4.4 Hz), 1.2 (3H, d, J=6.0 Hz), 1.3—1.8 (2H, m), 2.2 (1H, q, J=6.4 Hz), 3.0 (OH, s), 3.7 (3H, s), 3.7—4.1 (1H, m); IR (neat), 3430, 2960, 2860, 1730, 1430, 1260, 1200, 1020, and 795 cm^{-1}.

Methyl (2*S*,3*R*)-2-Ethyl-3-hydroxybutanoate (5).[7] To a solution of 6.0 mmol of LDA in 3 mL of THF was added a THF (2.0 mL) solution of 351.4 mg (2.97 mmol) of methyl (3*R*)-3-hydroxybutanoate, $[\alpha]_D^{23}$+43.0° (neat), under argon at −50°C and the solution was stirred for 2 h. Into the resulting orange solution of dianion was added a solution of 1.404 g (19.00 mmol) of ethyl iodide in THF (1.0 mL) and 1.3 mL of HMPA and the mixture was stirred allowed to warm to −25°C for 8 h. After quenching of the reaction by the addition of 2 M HCl, the mixture was extracted with ethyl acetate. The organic layer was dried and evaporated to give a colorless oil. Purification by silica gel TLC gave **5** as a colorless oil in 58% yield (251.3 mg, 1.72 mmol, anti:syn=98.2:1.8). $[\alpha]_D^{23}$ −9.21° (c 1.086, $CHCl_3$); ^1H NMR (100 MHz, δ, $CDCl_3$) 0.9 (3H, t, J=4.4 Hz), 1.2 (3H, d, J=6.4 Hz), 1.3—1.8 (2H, m), 2.2 (1H, q, J=6.4 Hz), 3.0 (1H, broad s, OH), 3.7 (3H, s) 3.7—4.1 (1H, m).

Methyl (2*R*,3*S*)-2-Phenyl-3-hydroxybutanoate (6). The nitrile **2d** (105.5 mg, 0.657 mmol) was converted into the ester **7** (55.6 mg, 0.554 mmol) by the acid hydrolysis of the cyano group followed by the treatment of diazomethane as described above in 65% yield.

$[\alpha]_D^{23}$ +99.8° (c 1.85, $CHCl_3$); R_f 0.6, AcOEt/hexane=1 : 5, after 10 times of development; ^1H NMR (100 MHz, δ, $CDCl_3$) 1.1 (3H, d, J=13.0 Hz), 2.9 (1H, s, OH), 3.4 (1H, d, J=8.4 Hz), 3.6 (3H, s), 4.0—4.5 (1H, m), and 7.2—7.6 (5H, broad s); IR (neat) 3345, 3000, 1740 (C=O), 1240, 1060, 960, 730, and 700 cm^{-1}.

Methyl (±)-2-Phenyl-3-hydroxybutanoate (8).[8,16] To a solution of 10 mmol of LDA in 10 mL of THF was added 1.502 g (10.0 mmol) of methyl 2-phenylacetate at −78°C under argon and the solution was stirred for 1.5 h and was added a solution of 0.44 g (10 mmol) of acetaldehyde in THF (5 mL) at the same temperature and stirred for 1.0 h. After addition of 2 M HCl, the solution was extracted with ether, and the organic layer was dried, evaporated and purification using silica gel flash column chromatography to give *syn*-**8** (0.590 g, 3.04 mmol, 30%) and *anti*-**8** (0.587 g, 3.01 mmol, 30%) as a colorless oil respectively.

syn-**8**: ^1H NMR (100 MHz, δ, $CDCl_3$), 1.1 (3H, d, J=13.0

Hz), 2.9 (1H, s, OH), 3.4 (1H, d, J=8.4 Hz), 3.6 (3H, s), 4.0—4.5 (1H, m), 7.2—7.6 (5H, broad s); IR (neat) 3400, 3000, 1740 (C=O), 1240, 960, and 730 cm^{-1}. *anti*-**8**: ^1H NMR (100 MHz, δ, $CDCl_3$) 1.0 (3H, d, J=6.5 Hz), 3.0 (1H, s, OH), 3.5 (1H, d, J=10.9 Hz), 4.1(3H, s), 4.2—4.5 (1H, m), 7.3—7.5 (5H, m).

Acetate of *syn*-8: ^1H NMR (200 MHz, δ, $CDCl_3$), 1.292 (3H, d, J=6.40 Hz), 1.801 (3H, s, OAc), 3.669 (3H, s, OMe), 3.719 (1H, d, J=8.80 Hz), 5.527 (1H, dq, J_1=8.80 Hz, J_2=6.20 Hz), 7.20—7.30 (5H, m); ^{13}C NMR (50 MHz, δ, $CDCl_3$), 18.650 (4C), 20.831 ($\underline{C}H_3CO$), 52.146 (2C), 56.943 ($COO\underline{C}H_3$), 70.622 (3C), 127.590, 128.429, 128.753, 135.240, 169.954(1C), 171.736 ($CH_3\underline{C}OO$). Acetate of *anti*-**8**: ^1H NMR (200 MHz, δ, $CDCl_3$), 1.048 (3H, d, J=6.20 Hz), 2.042 (3H, s, OAc), 3.666 (3H, s), 3.701 (1H, d, J=10.4 Hz), 5.495 (1H, dq, J_1=10.4 Hz, J_2=6.2 Hz), 7.2—7.3 (5H, m); ^{13}C NMR (50 MHz, δ, $CDCl_3$) 17.673(4C), 21.124, 52.079 (2C), 57.427, 71.785 (3C), 128.070, 128.581, 128.876, 134.782, 180.011 (1C), and 171.974.

Methyl (2*S*,3*R*)-2-Phenyl-3-hydroxybutanoate (7). To a suspension of 91.5 mg (0.387 mmol) of *syn* acetate of **8** in 2.0 mL of 0.1 M phosphate buffer (pH 7.2) was added 46 mg of lipase A6 (from *Aspergillus niger* by Amano Co.), and the suspension was stirred at room temperature for 143 h (30% conversion determined by ^1H NMR). Extraction from the reaction mixture with ethyl acetate and purification by silica gel TLC gave the alcohol **7** as a colorless oil (16.9 mg, 0.087 mmol, 22%).

$[\alpha]_D^{26}$ −97.0° (*c* 1.71, $CHCl_3$), 96%ee determined by the 200 MHz ^1H NMR analysis using chiral shift reagent Eu(hfc)$_3$. When 30 mol% of Eu(hfc)$_3$ was added into the $CDCl_3$ solution of **7**, the methoxy peak at δ 3.70 (s) was split up into two peaks at δ 3.97 and 4.21. According to the ratio of the peak intensity of these two peaks (the low field peak: the high field one=92:2), the absolute configuration at C-3 position of **7** was presumed as 3*R* because this ratio was just the same tendency of the chemical shift of the ester methyl group of 74%ee of methyl (2*R*,3*R*)-2-phenyl-3-hydroxybutanoate,[16] $[\alpha]_D^{23}$ +57.0° (*c* 1.05, $CHCl_3$) in ^1H NMR analysis in the presence of the same chiral shift reagent of 30 mol% of Eu(hfc)$_3$.

We are grateful to professors Masanori UTAKA of Faculty of Engineering at Okayama University and Toshio Sato of Faculty of Science at Tokyo Institute of Technology for their helpful discussions through all of this work. We also thank Mr. Eiichiro Amano of Faculty of Engineering at Okayama University for the elemental analysis.

(Received March 16, 1989)

The association constants (K) for aqueous complexes with water-soluble p-sulfonatocalix[n]arene ($\mathbf{1}_n$: n=4, 6, and 8) were determined by the NMR method. It was found that $\mathbf{1}_4$ and $\mathbf{1}_6$ form 1 : 1 complexes with guest molecules (trimethylanilinium chloride and 1-adamantyltrimethylammonium chloride), whereas $\mathbf{1}_8$ forms 1 : 2 $\mathbf{1}_8$/guest complexes. The finding supports the view that calixarenes $\mathbf{1}_n$'s are capable of molecular recognition on the basis of the ring size. Examination of the thermodynamic parameters for the association process established that the complexation with $\mathbf{1}_4$ is mainly due to the electrostatic force, whereas that with $\mathbf{1}_6$ and $\mathbf{1}_8$ is mainly due to the hydrophobic force. The coalescence temperatures (T_c's) for calixarene ring inversion were subject to the template effect by these molecules. The activation parameters for the rate of ring inversion were estimated by a computer-assisted spectrum simulation: it was found that the T_c increase, observed in the presence of these guest molecules acting as templates, is caused by the increase in $\Delta H^{\neq}$. These findings provide new insights into the association characteristics of water-soluble calixarenes.

Calixarenes are cyclic oligomers which belong to the class of [$\mathbf{1}_n$]cyclophanes. A variety of calixarenes may now be synthesized in good yields.[2,3)] Since they have a cavity-shaped architecture, they have been expected to be useful as a basic skeleton in the design of new functionalized host molecules.[2-5)] However, unequivocal evidence for the formation of host-guest-type complexes was not found for a long time since the discovery of calixarenes. Conceivably, the difficulty is related to the poor solubility in solvents, particularly, in water. Beginning in 1984, we synthesized and studied p-sulfonatocalixarenes, the first example for water-soluble calixarenes.[6)] Using these water-soluble calixarenes, we found substantial evidence that they can form host-guest-type complexes in an aqueous system.[6-8)]

The next (and probably, most urgent) approach to the design of functionalized host molecules would be to test if the calixarene cavity is capable of molecular recognition in solution. Several groups have reported on the ionophoric properties of calixarenes.[9-12)] In contrast, the study of molecular recognition of organic molecules has been very limited and the question remained unresolved. We report here the NMR method, which is more complicated but applicable to a variety of guest molecules. We have determined the association constants (K), $\Delta H°$, and $\Delta S°$ for the complexation of p-sulfonatocalix[n]arene (n=4, 6, and 8 : $\mathbf{1}_n$) with trimethylanilinium chloride (**2**) and 1-adamantyltrimethylammonium chloride (**3**). During this study we unexpectedly found unequivocal evidence for the formation of the 1 : 2 complexes with $\mathbf{1}_8$.

2

3

Experimental

The synthesis of $\mathbf{1}_n$ was reported previously.[7)] ^{1}H NMR spectra were measured with a JEOL GX-400 NMR apparatus.

The association constants were estimated from plots of δ_{obs} versus [$\mathbf{1}_n$]/[**2**]. The concentrations of $\mathbf{1}_n$'s were maintained constant while that of **2** was varied. The results were analyzed by the computer-assisted nonlinear least-squares procedure (see Results and Discussion).

The temperature-dependent ^{1}H NMR spectra of $\mathbf{1}_4$ in the absence and the presence of the guest molecules were simulated by the computer-assisted line shape analysis method. In particular, we were concerned with peaks for the ArCH$_2$Ar protons which sensitively reflected the calixarene conformation. Further details are described in Results and Discussion.

Results and Discussion

NMR Determination of Association Constants. Since the present study is related to molecular recognition, the measurements must be carried out below the critical micelle concentration (if any). As reported previously, the critical micelle concentration can be easily detected by ^{1}H NMR or conductance.[7,13)] We confirmed that none of $\mathbf{1}_4$, $\mathbf{1}_6$, and $\mathbf{1}_8$ form the micelle-like aggregate under the experimental conditions.

Figure 1 shows the chemical shift of **2** in the presence of $\mathbf{1}_4$ in D_2O at 25 °C. Clearly, all peaks shift to higher magnetic field with increasing [$\mathbf{1}_4$]/[**2**] ratio. This indicates that **2** interacts with $\mathbf{1}_4$ and undergoes the effect of the ring current of the calixarene benzene components. The fact that the shift width of the four

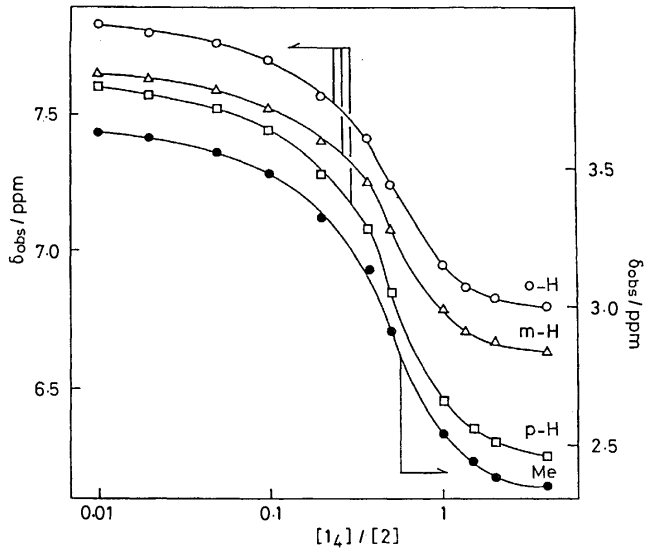

Fig. 1. Plots of δ_{obs} versus $[\mathbf{1}_4]/[\mathbf{2}]$. The concentration of $\mathbf{1}_4$ was maintained constant (1.00 mM) while that of **2** was varied (0.25—100 mM): D_2O, 25 °C, pD 7.3 with 0.1 M phosphate buffer, internal standard DSS.

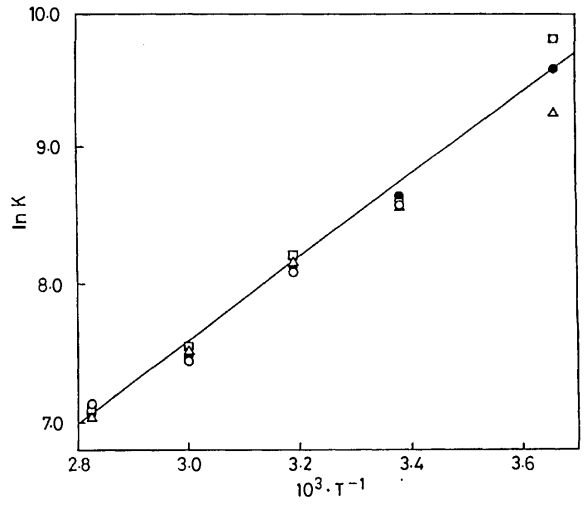

Fig. 2. Plots of $\ln K$ versus T^{-1} for the $\mathbf{1}_4$-**2** system: ○ ortho-H, △ meta-H, □ para-H, ● methyl.

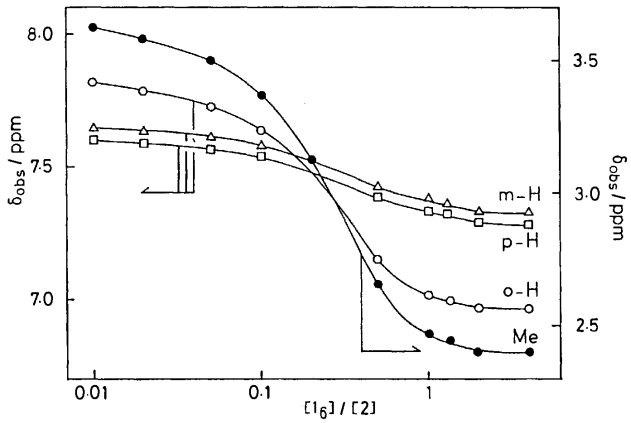

Fig. 3. Plots of δ_{obs} versus $[\mathbf{1}_6]/[\mathbf{2}]$. The measurement conditions are recorded in a caption to Fig. 1.

different protons is similar suggests that the binding of **2** to the $\mathbf{1}_4$ cavity is not specific to give a single complex structure but rather "nonspecific" to give time-averaged, various complexes. It is also seen from Fig. 1 that the change in the chemical shifts is almost saturated at $[\mathbf{1}_4]/[\mathbf{2}]=1.0$, supporting the formation of the 1 : 1 complex. The observed chemical shift (δ_{obs}) appears as an average of the free **2** (δ_{free}) and the complexed **2** ($\delta_{complex}$). Assuming the formation of a 1:1 complex ($\mathbf{1}_n+\mathbf{2} \rightleftarrows \mathbf{1}_n\cdot\mathbf{2}$), δ_{obs} is expressed by Eq. 1.

$$\delta_{obs}=\delta_{free}(([\mathbf{1}_n]_0-[\mathbf{1}_n\cdot\mathbf{2}])/[\mathbf{1}_n]_0)+\delta_{complex}([\mathbf{1}_n\cdot\mathbf{2}]/[\mathbf{1}_n]_0) \quad (1)$$

where $[\mathbf{1}_n]_0$ is the initial concentration of $\mathbf{1}_n$. Thus, this equation is rewritten as Eq. 2.

$$\delta_{obs}=[\mathbf{1}_n]_0+[\mathbf{2}]_0+K^{-1}\pm((([\mathbf{1}_n]_0+[\mathbf{2}]_0+K^{-1})^2 -4[\mathbf{1}_n]_0[\mathbf{2}]_0)^{1/2}(2[\mathbf{2}]_0)^{-1}(\delta_{complex}-\delta_{free})+\delta_{free} \quad (2)$$

where $[\mathbf{2}]_0$ is the initial concentration of **2**. The K value was determined from Eq. 2 by the computer-assisted nonlinear least-squares procedure: $K=5.39\times 10^3$ M^{-1}.** The similar plots of δ_{obs} vs. $[\mathbf{1}_4]/[\mathbf{2}]$ were made at 0, 40, 60, and 80 °C, and the K values were determined at each temperature. As shown in Fig. 2, plots of $\ln K$ vs. T^{-1} shows a good linear relationship with $r=0.99$. This supports the formation of the 1 : 1 complex between $\mathbf{1}_4$ and **2**. The $\Delta H°$ and $\Delta S°$ were determined from the slope ($-\Delta H°/R$) and the intercept ($\Delta S°/R$) by the least-squares procedure: $\Delta H°=-6.2$ kcal mol^{-1} and $\Delta S°=-3.6$ cal mol^{-1}deg^{-1}. From these thermodynamic parameters we calculated the most reliable association constant at 25 °C (Table 1).

The NMR peaks of **2** measured at 25 °C also shifted

Table 1. Association Constants and Thermodynamic Parameters for **2**

Parameter	$\mathbf{1}_4$	$\mathbf{1}_6$	$\mathbf{1}_8$	
			1 : 1	1 : 2
$10^{-2}\cdot K/M^{-1}$ (at 25 °C)	56.0±2.5	5.5±0.4	52.0±0.5	46.0±0.5
$\Delta G°$/kcal mol^{-1} (at 25 °C)	−5.1±0.5	−3.7±0.2	−5.1±0.2	−5.0±0.1
$\Delta H°$/kcal mol^{-1}	−6.2±0.3	−0.25±0.10	0.0±0.10	0.0±0.10
$\Delta S°$/cal mol^{-1} deg^{-1}	−3.6±0.8	11.7±0.3	17.0±0.3	16.7±0.1

** 1 M=1 mol dm^{-3}.

to higher magnetic field with increasing [$\mathbf{1}_6$]/[**2**] ratio and suggest the formation of a 1 : 1 complex (Fig. 3). We repeated the similar measurements at 0, 40, 60, and 80 °C in addition to 25 °C. Plots of $\ln K$ vs. T^{-1} showed a good linear relationship (r=0.99: data not shown here). Thus, we could determine the K and thermodynamic parameters for the 1 : 1 complex with $\mathbf{1}_6$ (Table 1). In contrast, plots for $\mathbf{1}_8$ showed an unusual biphasic dependence (Fig. 4): the NMR peaks of **2** shifted to higher magnetic field at [$\mathbf{1}_8$]/[**2**]<0.5, while the slight downfield shift occurred at [$\mathbf{1}_8$]/[**2**]>0.5. The similar biphasic dependence was also observed at 0, 40, 60, and 80 °C. The new finding that a break point appears at [$\mathbf{1}_8$]/[**2**]=0.5 supports the formation of a 1 : 2 $\mathbf{1}_8$/**2** complex. We thus assumed the following two-step association scheme and estimated K_1 and K_2 independently. The results are summarized in Table 1.

$$\mathbf{1}_8 + 2 \overset{K_1}{\rightleftarrows} \mathbf{1}_8 \cdot 2 \quad (3)$$

$$\mathbf{1}_8 \cdot 2 + 2 \overset{K_2}{\rightleftarrows} \mathbf{1}_8 \cdot (2)_2 \quad (4)$$

We carried out the ^{1}H NMR measurements about **3**, the larger guest molecule at 0, 25, 40, 60, and 80 °C.

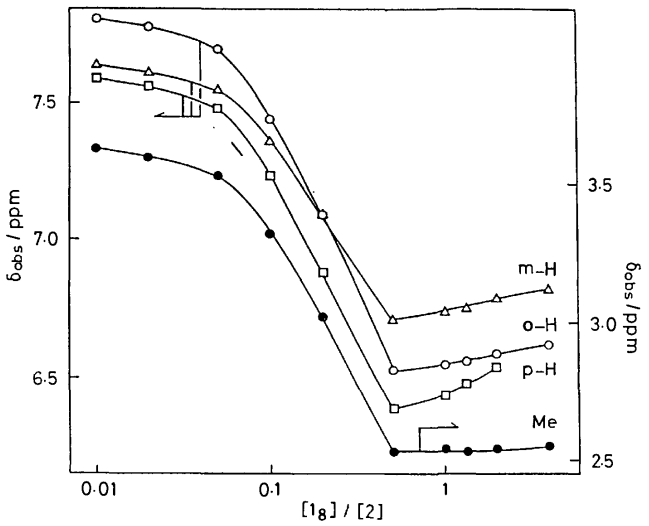

Fig. 4. Plots of δ_{obs} versus [$\mathbf{1}_8$]/[**2**]. The measurement conditions are recorded in a caption to Fig. 1.

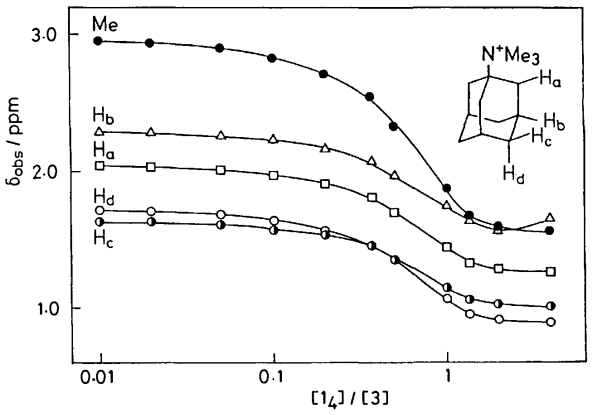

Fig. 5. Plots of δ_{obs} versus [$\mathbf{1}_4$]/[**3**]. The concentration of $\mathbf{1}_4$ was maintained constant (1.00 mM) while that of **3** was varied (0.25—100 mM): D_2O, 25 °C, pD 7.3 with 0.1 M phosphate buffer, internal standard DSS.

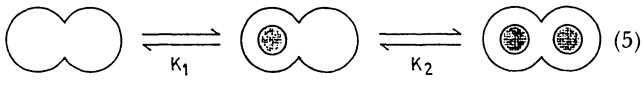
Table 2. Association Constants and Thermodynamic Parameters for **3**

Parameter	$\mathbf{1}_4$	$\mathbf{1}_6$	$\mathbf{1}_8$	
			1 : 1	1 : 2
$10^{-3} \cdot K/M^{-1}$ (at 25 °C)	21.0±1.5	1.0±0.3	19.0±0.5	17.0±0.5
$\Delta G°$/kcal mol^{-1} (at 25 °C)	−5.9±0.4	−4.1±0.2	−5.8±0.2	−5.8±0.1
$\Delta H°$/kcal mol^{-1}	−5.7±0.3	−0.15±0.10	0.0±0.10	0.0±0.10
$\Delta S°$/cal mol^{-1} deg^{-1}	0.65±0.6	13.3±0.3	19.6±0.3	19.3±0.2

The results are illustrated in Figs. 5—7. It is seen from these figures that $\mathbf{1}_4$ and $\mathbf{1}_6$ form the 1 : 1 complexes with **3**, whereas $\mathbf{1}_8$ form the 1 : 2 complex indicating that the cavity of $\mathbf{1}_8$ is still big enough to accept two **3** molecules. From the plots of $\ln K$ vs. T^{-1} we determined $\Delta H°$ and $\Delta S°$. The results are summarized in Table 2.

The formation of the 1 : 2 complex with $\mathbf{1}_8$ is primarily attributed to the large ring size. This means that in principle, the "hole-size" selectivity is operative in molecular recognition by water-soluble calixarenes. In this connection, it is interesting to note that among *p*-alkylcalix[*n*]arenes (*n*=4, 6, and 8) only *p*-alkylcalix[8]arene is capable of extracting alkali metal cations in a 1 : 2 calixarene/M^+ ratio.[14] We consider that in addition to the ring size, the ring flexibility plays an important role in the binding of the second guest molecule. It is known that β- and γ-cyclodextrins can include two guest molecules in the cavity.[15-17] In these 1 : 2 complexes K_2 is usually greater than K_1. This situation is observed because the molecular size of the first guest is smaller than the cyclodextrin cavity and the cavity is just filled up by the binding of the second guest. In other words, the cyclodextrin cavity is relatively rigid. In the binding of **2** and **3** to $\mathbf{1}_8$, on the other hand, we observed the relation $K_1 \approx K_2$. The fact that the thermodynamic parameters for K_1 are similar to those for K_2 supports the view that the binding mechanism for K_1 and K_2 is also similar. The results can be reasonably rationalized in terms of the flexibility of $\mathbf{1}_8$ called a "pinched conformation":[2,3] flexible calix[8]arene can "pinch" transannularly to provide two half-cavities. Hence, the first guest is included in the cavity in an induced-fit manner and the circumstance is similar to the remaining half-cavity for the binding of the second guest (Eq. 5). Comparison of Fig. 4 with Fig. 7 manifests, however, that in the $\mathbf{1}_8 \cdot \mathbf{2}$ complex the highest chemical shifts are attained for the 1 : 2 complex (i.e., at $[\mathbf{1}_8]/[\mathbf{2}]=0.5$), whereas in the $\mathbf{1}_8 \cdot \mathbf{3}$ complex the chemical shifts are similar between the 1 : 1 and 1 : 2 complexes (i.e., constant δ_{obs} at $[\mathbf{1}_8]/[\mathbf{3}] \geqq 0.5$). This suggests that two **2** molecules can adopt, although in some probability, a face-to-face orientation, undergoing the anisotropic effect of each benzene π-system.



(5)

The *K* value for $\mathbf{1}_4$ is apparently comparable with K_1 and K_2 for $\mathbf{1}_8$. Careful examination of Tables 1 and 2 indicates, however, that the thermodynamic parameters are quite different: the binding to $\mathbf{1}_4$ occurs owing to negative $\Delta H°$, whereas that to $\mathbf{1}_8$ occurs owing to positive $\Delta S°$. The results suggest that the association of $\mathbf{1}_8$ with **2** and **3** is primarily based on hydrophobic interactions, whereas that of $\mathbf{1}_4$ with **2** and **3** is rather supported by electrostatic interactions. What is the origin of this difference? The first difference is that the cavity of calix[4]arene is very rigid and open like a bowl.[2,3] Since hydrophobic interactions are based on stacks between host and guest,[18] it seems fairly difficult for rigid, open $\mathbf{1}_4$ to adopt such an association mode favorable for hydrophobic interactions. The second difference is related to the strong, anionic electrostatic field provided by $\mathbf{1}_4$. We have found that *p*-sulfonatocalixarenes, having anionic sulfonato groups on one side of the calixarene cavity, provide a strong anionic field.[7,19] In particular, *p*-sulfonatocalix[4]arene, having four sulfonato groups on the small cavity showed the strongest electrostatic effect.[19,20] These characteristics of $\mathbf{1}_4$ would lead to the negative $\Delta H°$.

Another interesting point seen from Tables 1 and 2 is that the *K* values for $\mathbf{1}_6$ are generally smaller than those for $\mathbf{1}_4$ and $\mathbf{1}_8$. Examination of the thermodynamic parameters for $\mathbf{1}_6$ reveals that the $\Delta H°$ values are not so negative as those for $\mathbf{1}_4$ while the $\Delta S°$ values are not so positive as those for $\mathbf{1}_8$. Probably, the association with $\mathbf{1}_6$ is an intermediary case between $\mathbf{1}_4$ and $\mathbf{1}_8$ where neither the electrostatic force nor the hydrophobic force operates efficiently.

The *K* values for **3** are greater by a factor of about 5 than those for **2**. When the thermodynamic parameters for **3** are compared with those for **2**, we notice that the *K* values are enhanced owing to the increase in $\Delta S°$. This is well-accounted for by the hydrophobic effect of the adamantyl group.

The complexation geometry of **2** and **3** can be

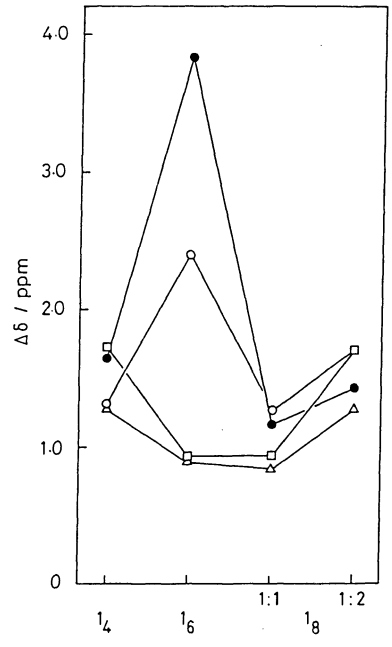


Fig. 8. Shifts of the ^1H NMR peaks of **2** to higher magnetic field. The shift width was calculated for 100%-complexed **2** from the parameters obtained by the nonlinear least-squares procedure (Eq. 2) used for the determination of *K* in Figs. 1, 3, and 4.

presumed from the magnitude of the higher magnetic-field shifts. As shown in Fig. 8, the shift width observed for the $\mathbf{1}_4$ and $\mathbf{1}_8$ complexes is rather similar among all protons, suggesting that **2** is bound in a nonselective manner. In contrast, the *N*-methyl and ortho protons particularly shift to higher magnetic field on the addition of $\mathbf{1}_6$. This suggests that the ammonium moiety, rather than the phenyl moiety, is incorporated into the aromatic cavity of $\mathbf{1}_6$. A similar trend is observed for **3** (Fig. 9). The unusual chemical shifts were also observed by Stauffer and Dougherty[21] for **3** bound to water-soluble cyclophanes. They proposed an ion-dipole interaction between guest N^+ and host π-system. At present, we are not sure if this is the case in our system. Probably, the ion-dipole interaction is hidden in an aqueous system but becomes operative when the hydrophobic interaction between the guest and the host cavity is mismatched. This may be related to the small *K* values for $\mathbf{1}_6$.

Guest Template Effects. What influence does included **2** (or **3**) have on the calixarene conformation? It is known that the temperature-dependent ^{1}H NMR spectrum displays a singlet resonance for the $ArCH_2Ar$ methylene protons at high temperature and a pair of doublets at low temperature. Thus, the coalescence temperature (T_c) appears at intermediary temperature. This behavior has been interpreted in terms of a conformational change from "alternate" to "cone" (Fig. 10).[2,3,22,23] We estimated the influence of added **2** (or **3**) on T_c of $\mathbf{1}_4$ in D_2O. The T_c in the absence of a guest molecule appeared at 9 °C (Table 3). Very interestingly, we found that the T_c values are significantly enhanced in the presence of **2** or **3**. This indicates that these organic guest molecules act as template cations. The Corey-Pauling-Koltun molecular model buildings and the recent X-ray crystallographic studies show that the "cone" conformation provides a cavity-shaped stoma more suitable to guest-binding than the "alternate" conformation.[24-26] The circular dichroism studies also support the view that the conformation of water-soluble calixarenes is fixed to "cone" upon inclusion of guest molecules.[27] Probably, **2** and **3** act as efficient templates not only because of electrostatic interactions between NMe_3^+ and oxide anions but also because of inclusion of a phenyl or adamantyl group into the "cone"-shape hydrophobic cavity of $\mathbf{1}_4$.

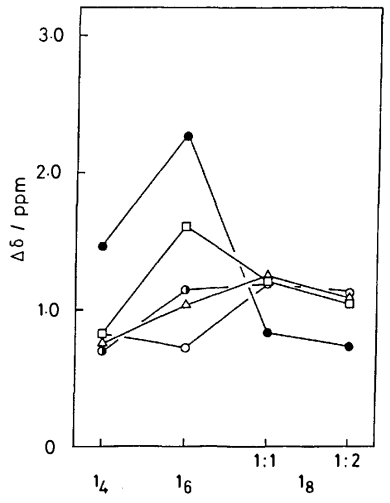

Fig. 9. Shifts of the ^{1}H NMR peaks of **3** to higher magnetic field. The shift width was calculated for 100-complexed **3** from the parameters obtained by the nonlinear least-squares proceduce (Eq. 2) used for the determination of *K* in Figs. 5—7.

2 (0.005)	20
2 (0.010)	43
2 (0.020)	50
2 (2.00)	65
3 (0.005)	25
3 (0.010)	50
3 (0.020)	57

a) pD 8.9 with 0.5 M borate buffer, $[\mathbf{1}_4]=1.10\times10^{-2}$ M.

In order to obtain a further insight into the template effect we applied computer-assisted spectrum simulation (complete line shape analysis)[28] to the temperature-dependent ^{1}H NMR spectra of $\mathbf{1}_4$ in the absence and the presence of these guest molecules. The typical example is shown in Fig. 11: the observed spectral change (*A*) was simulated assuming the lifetime (τ) at each temperature (*B*). Excellent agreement is seen between the observed and the simulated spectra. Plots of $\log k$ (rate constant for the spin exchange τ^{-1}) vs. T^{-1} afforded excellent linear relationships ($r>0.99$), as shown in Fig. 12, from which we obtained $\log A$ and E_a. From these values we calculated $\Delta G^{\ddagger}_{298}$, $\Delta H^{\ddagger}$, and $\Delta S^{\ddagger}$ (Table 4).

As mentioned above, the spectral change has been interpreted in terms of a conformational change from "cone" to "alternate".[2,3,22,23] However, the continuity in the Arrhenius plots indicates that such a conformational transition does not exist. This means that the spectral change is best understood as a consequence of the temperature-dependent rate

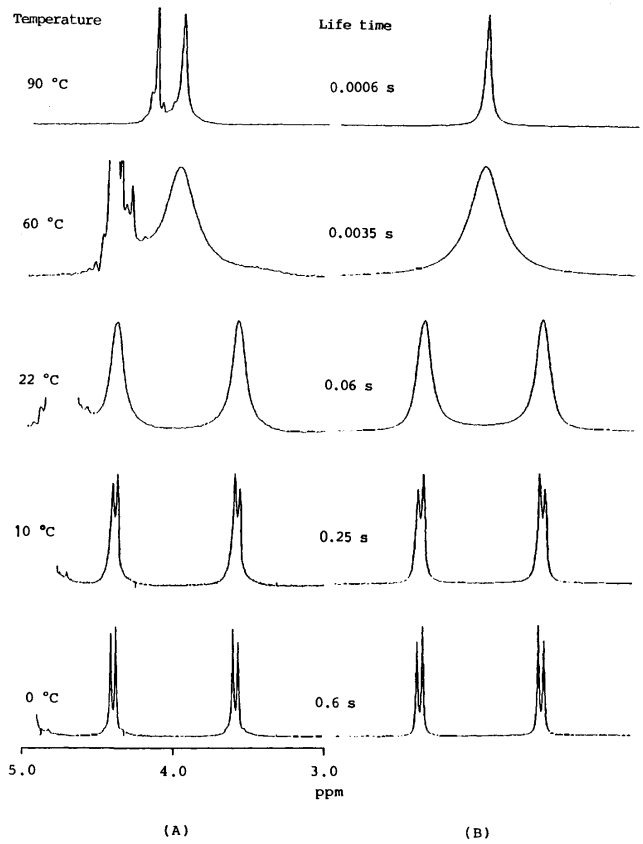

Fig. 11. Observed (A) and simulated spectra (B) of the $ArCH_2Ar$ protons in $\mathbf{1}_4$ (1.00×10^{-2} M) in the presence of **2** (2.00×10^{-2} M).

change for ring inversion between "cone" conformations.[29]

Examination of Table 4 represents an interesting view: $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ compensates each other and the $\Delta G^{\ddagger}_{298}$ increase, observed in the presence of **2** or **3**, is caused by the $\Delta H^{\ddagger}$ increase. On the contrary, the $\Delta S^{\ddagger}$ value increases in the presence of these guest molecules, indicating that from a steric viewpoint,

Table 4. Activation Parameters for the Spin Exchange in $\mathbf{1}_4$ (0.010 M)[a]

Guest (concn/M)	$\Delta G^{\ddagger}_{298}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$

None	14.1±0.3	10.4±0.1	−12±1.3
2 (0.020 M)[b]	15.7±0.6	14.6±0.3	−1.8±3.0
3 (0.020 M)[c]	16.7±1.4	18.7±0.7	6.7±4.0

a) pD 7.3 with 0.1 M phophate buffer, [$\mathbf{1}_4$]=1.00×10^{-2} M. b) Under the measurement conditions (25 °C) 98.3% of $\mathbf{1}_4$ include **2**. c) Under the measurement conditions (25 °C) 99.5% of $\mathbf{1}_4$ include **3**.

guest inclusion makes the ring inversion easier. In order to attain the ring inversion, the $\mathbf{1}_4$-guest complex should be dissociated once at a transition state. This dissociation process would be reflected by the $\Delta H^{\ddagger}$ increase. On the other hand, it is not easy to elucidate the $\Delta S^{\ddagger}$ increase reasonably. We believe that complexed $\mathbf{1}_4$ is sterically more hindred than vacant $\mathbf{1}_4$, leading to entropic destabilization of the initial state.

Conclusion

The present study demonstrated that the association properties of water-soluble calixarenes are conveniently estimated by the NMR methods. Of particular significance are the unexpected findings that only $\mathbf{1}_8$ can form the 1:2 complexes with organic guest molecules and that these guests serve as efficient templates to fix the calixarene conformation. This suggests that in principle, calixarene cavities are capable of molecular recognition. We believe that in near future calixarenes would become a useful building block to design enzyme mimics in totally synthetic systems.

We are indebted to Professor Hiroki Kondo and Mr. Yuichiro Ohama for measurements of 400 MHz NMR spectra. This research was supported by the Grant-in-Aid from the Ministry of Education.

(Received June 7, 1989)

Irradiation of contact charge transfer (CCT) bands (320—370 nm) of 4-methoxystyrene (**1a**) and 4-methylstyrene (**1b**) with molecular oxygen in acetonitrile and benzene resulted in the formation of the corresponding *cis*- and *trans*-1,2-diarylcyclobutanes (**2** and **3**) as well as benzaldehydes (**4**), oxidative cleavage products. In the case of **1b**, 7-methyl-1-(4-tolyl)-1,2,3,4-tetrahydronaphthalene (**5**) and 6-methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalen-1-one (**6**) were also afforded. The formation of these products is reasonably explained by electron transfer in the excited CCT pair followed by addition of the resulting **1** cation radical to ground-state **1** to form a dimer cation radical; its cyclization leads to the dimeric products and trapping of a cyclic dimer cation radical by oxygen affords ketone **6**.

In photochemical reactions, oxygen has often been investigated only as an oxidant. It is well-known that singlet oxygen generated by dye sensitization oxidizes olefins to afford hydroperoxides, endoperoxides, and dioxetanes.[1] In contrast to active studies on singlet oxygen, another role of oxygen as an electron acceptor has attracted little attention.[2]

The formation of contact charge transfer (CCT) complexes between organic compounds and oxygen has been observed.[3] However, their roles in photochemical reactions had not been recognized until a few years ago. Recently, the copolymerization of styrene and its derivatives with oxygen was reported to be initiated by irradiation of the CCT bands between the olefins and oxygen.[4] Also, the excitation of the CCT band between hexamethylbenzene and oxygen in methanol-benzene was shown to produce 2,3,4,5,6-pentamethylbenzyl cations followed by their reaction with methanol to give 1-methoxy-2,3,4,5,6-pentamethylbenzene.[2b] Furthermore, in dye-sensitized photooxygenation of *trans*-stilbene, oxygen was reported to serve as an electron acceptor.[5]

In a previous communication,[6] we demonstrated that the photoexcitation of CCT complexes of 4-methoxy- and 4-methylstyrene with oxygen in acetonitrile induces electron transfer from the styrenes to oxygen to generate cation radicals of the styrenes followed by their addition to the styrenes finally affording dimers of the styrenes.[7] The present paper describes a full account of our work on the photochemical reactions of the olefins resulting from their CCT band excitation.

Results

Formation of CCT Complexes of 4-Methoxy- and 4-Methylstyrene with Oxygen. The longest wavelength end of the absorption band of 4-methoxystyrene (**1a**) lies at 325 nm under argon in acetonitrile or benzene (Fig. 1a). On saturation with oxygen a new absorption band appeared in the range of 320—370 nm in both solvents. Figure 1c shows a difference spectrum of **1a** under argon and oxygen. This band disappeared reversibly on introduction of argon to exclude oxygen, and therefore, is reasonably assigned to a CCT pair of **1a** and oxygen. 4-Methylstyrene (**1b**) exhibited a similar absorption due to its CCT pair with oxygen in the region of 310—370 nm in acetonitrile (Fig. 1e).

On addition of 1,4-dicyanobenzene (DCNB) under nitrogen in acetonitrile, **1a** exhibited a new absorption band in the region of 320—390 nm (Fig. 1f). This band can be assigned to a charge transfer (CT) complex.

Irradiation of 4-Methoxystyrene (1a). Direct irradiation of **1a** under nitrogen in acetonitrile with 254- or 313-nm light afforded head-to-head cycloadducts, *cis*- and *trans*-1,2-bis(4-methoxyphenyl)cyclobutane

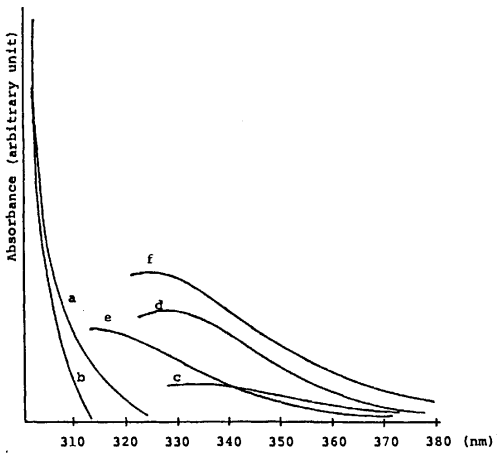

Fig. 1. UV spectra of CCT pairs.
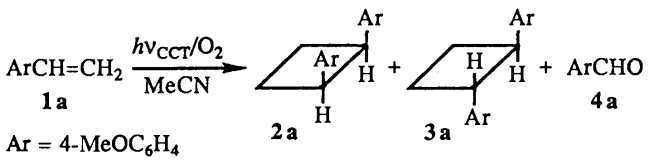
a: **1a** under argon in MeCN. b: **1b** under argon in MeCN. c: **1a** under oxygen in MeCN. d: **1a** under oxygen in PhH. e: **1b** under oxygen in MeCN. f: **1a** in the presence of DCNB in MeCN.

(**2a** and **3a**, respectively, 63—65% yield) in a ratio of ca. 90/10.

Irradiation of **1a** under oxygen in acetonitrile with 366-nm light gave **2a** and **3a** (31%, **2a**/**3a**=5/95) together with 4-methoxybenzaldehyde (**4a**, 32%), an oxidative cleavage product (Scheme 1). However, no reaction products were essentially detected on irradiation under nitrogen. The results on irradiation of **1a** under various conditions are summarized in Table 1.

Irradiation of **1a** at 313 or 366 nm in the presence of DCNB under nitrogen in acetonitrile afforded **3a** predominantly with a small amount of **2a** (**2a**/**3a**=2/98, Runs 11 and 12 in Table 1). On benzophenone-sensitized irradiation (366 nm) under otherwise similar conditions, **1a** gave the dimers in an isomer ratio of **2a**/**3a**=13/87 (Run 10). 4-Methoxybenzaldehyde (**4a**) hardly sensitized the dimerization under 366-nm illumination; however, with 313-nm light **4a** sensitized the dimerization to produce **2a** and **3a** in a ratio of 22/78 (Run 9).



Scheme 1.

Irradiation of 4-Methylstyrene (1b). Irradiation of **1b** in acetonitrile under oxygen with 313-nm light led to the formation of three cyclodimers (20%), *cis*- and *trans*-1,2-bis(4-tolyl)cyclobutane (**2b** and **3b**, respectively, head-to-head cycloadducts) and a tetralin derivative, 7-methyl-1-(4-tolyl)-1,2,3,4-tetrahydronaphthalene (**5**) (isomer ratio, **2b**:**3b**:**5**=58:33:9), and a dimeric ketone, 6-methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalen-1-one (**6**, 20%) together with 4-methylbenzaldehyde (**4b**, 8%) (Scheme 2). On the other hand, the irradiation of **1b** under nitrogen gave cyclodimers **2b**, **3b**, and **5** in a ratio of 83:10:7, but no dimeric ketone **6**.

Irradiation of **1b** at 313 nm in the presence of DCNB under nitrogen in acetonitrile afforded 1-(4-cyanophenyl)-6-methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalene (**7**) as a main product (30%) together with the olefin dimers (5%, **2b**:**3b**:**5**=11:11:78). The results are summarized in Table 2.

Discussion

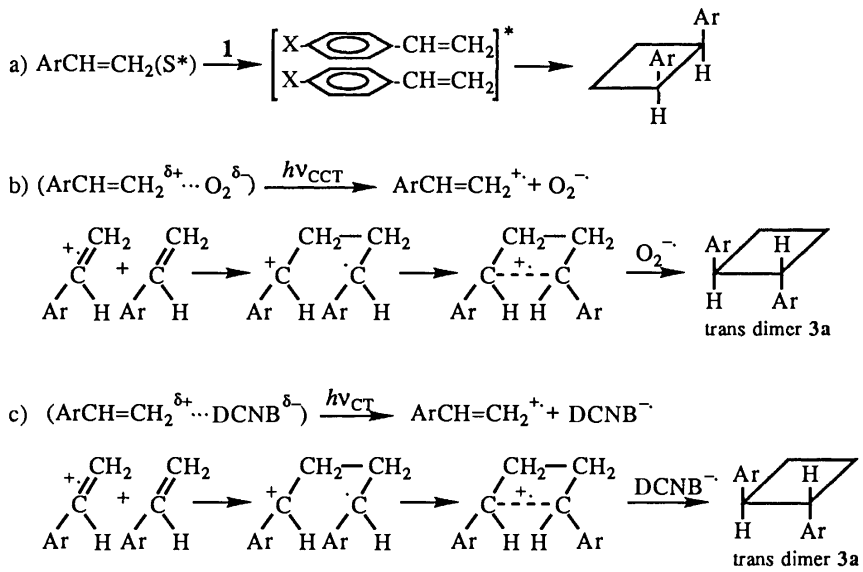
Photochemical Reactions of 4-Methoxystyrene on CCT Band Excitation. Direct irradiation of 4-methoxystyrene (**1a**) with 254- or 313-nm light in acetonitrile under nitrogen gave cis and trans cyclodimers **2a** and **3a** in a ratio of ca. 90/10. The predominant formation of **2a** indicates that the dimerization proceeds through an excimer with the geometry in which the aromatic rings are overlapped with each other, collapsing mainly into the cis dimer, as previously proposed for the dimerization of styrene[8)] (Scheme 3a).

Excitation of the CCT pair of **1a** and oxygen at 366 nm in the same solvent gave **2a** and **3a** in a contrasted ratio of 5/95 together with 4-methoxybenzaldehyde (**4a**); however, a similar irradiation in benzene gave no dimers. This remarkable solvent effect suggests that the excitation of CCT pair in polar solvents results in electron transfer from the olefin to molecular oxygen to afford the olefin cation radical and superoxide anion. The former either adds to **1a** in the ground state to form a dimer cation radical which is finally converted to the dimer (Scheme 3b) or accepts an electron from the latter to give the original olefin.

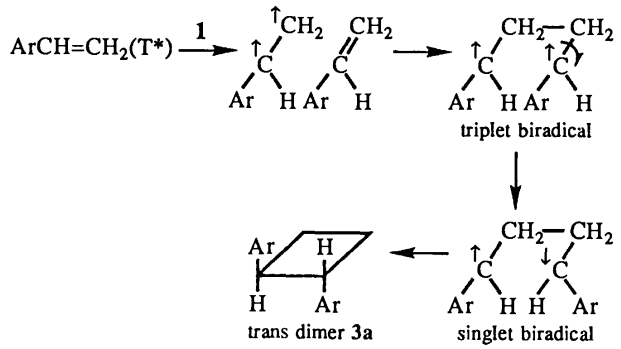
Irradiation under oxygen with light of wavelengths shorter than 366 nm tends to decrease the ratio of the trans isomer; 313-nm light resulted in a **2a/3a** isomer ratio of 16/84 and 254-nm light led to a ratio of 63/37. These results can be understood in terms of competitive excitation of the olefin and its CCT pair, leading to the formation of the excimer and cation radical, respectively.

Excitation of the CT band of **1a** and DCNB in acetonitrile also gave cis and trans dimer **2a** and **3a** in a ratio of 2/98 (Scheme 3c) as previously reported by Yamamoto et al.[7a)] This isomer ratio is very similar to that obtained in the CCT pair excitation. Yamamoto proposed a mechanism that excited **1a** interacts with DCNB to give the cation radical of **1a** finally resulting in dimerization of **1a**.[7a)] However, in the present case, the CT band excitation resulted in the dimerization of **1a**, indicating that the CT pair excitation also induces the electron transfer from **1a** to DCNB to generate $\mathbf{1a}^{+\cdot}$ and $DCNB^{-\cdot}$.

On triplet sensitization with benzophenone under nitrogen in acetonitrile, **1a** gave the dimers in an isomer ratio (**2a/3a**=13/87) different from that in the above dimerization under oxygen (Scheme 4). 4-Methoxybenzaldehyde (**4a**) also sensitized (313 nm) the dimerization of **1a** to produce **2a** and **3a** (**2a/3a**=22/78); however, 366-nm irradiation of **4a** did not induce the dimerization. These results rule out a possibility that on irradiation of **1a** under oxygen with 366-nm



Scheme 3.



Scheme 4.

light the resulting **4a** would sensitize the reaction.

Photochemical Reaction of 4-Methylstyrene. Excitation of the CCT pair of **1b** and oxygen in acetonitrile gave three cyclodimers (**2b**, **3b**, and **5**) and a dimeric ketone (**6**), and that of the CT pair of **1b** and DCNB afforded 1-(4-cyanophenyl)-6-methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalene (**7**) together with the olefin dimers (**2b**:**3b**:**5**=11:11:78). Ketone **6** and diaryltetralin **7** are products from a tetralin-type dimer cation radical trapped by oxygen species (O_2 or O_2^{-}) and DCNB (neutral molecule or anion radical), respectively, as depicted in Scheme 5, because tetralin-type dimer **5** is reported to be produced only through olefin cation radicals.[7b] In fact, benzophenone-sensitized dimerization of **1b** in benzene gave only cyclodimers **2b** and **3b** (20/80) but no tetralin-type dimer **5**.[7b] Therefore, the production of dimeric ketone **6** indicates that the excitation of the CCT pair of **1b** and oxygen caused dissociation of the excited CCT pair into the **1b** cation radical and superoxide anion.

Arnold et al. reported the trapping of triene intermediates through an ene reaction in photochemical electron-transfer dimerization of 1,1-diphenylethene or cross-cycloaddition of 1,1-diphenylethene with 2-methylpropene in the presence of acrylonitrile or methyl acrylate.[9] However, it should be noted that such quenching products of dimer cation radicals as **6** and **7** have scarcely been reported.

Role of Oxygen as an Electron Acceptor. The free energy change ($\Delta G°$) associated with the electron transfer from excited singlet **1** to molecular oxygen or in the CCT pair is given by Eq. 1,[10] where $E(D^+/D)$ and $E(A/A^-)$ are the oxidation potential of donor (D) and the reduction potential of acceptor (A), respectively. The term $e_o^2/\varepsilon a$ is the coulombic energy (ca. 0.06 eV in MeCN) gained by bringing the two ion radical species to encounter distance a in a solvent of dielectric constant ε, and $E_{0,0}$ is the electronic excitation energy of **1** or the CCT pair.

$$\Delta G°(\text{kcal mol}^{-1}) = 23.06[E(D^+/D) - E(A/A^-) - e_o^2/\varepsilon a] - E_{0,0} \quad (1)$$

The $\Delta G°$ values for electron transfer from excited singlet **1a** to oxygen and in the CCT pairs of **1** with oxygen are estimated to be highly negative as shown in Table 3. These values indicate that the photochemical electron transfer can easily take place as the primary process of the present reactions. Large negative $\Delta G°$ values are also estimated for electron transfer from excited singlet **1a** and **1b** to DCNB (Table 3). Thus, the CCT pairs, on excitation, will undergo electron transfer to generate **1** cation radicals and superoxide anions. The former will either add to **1** in the ground state to give dimer cation radicals or undergo back electron transfer to generate **1** triplets.

The triplet state of **1** might be responsible for the present reaction. The free energy of the pair of ion

	$E(D^+/D)$	$E(A/A^-)$	$E_{0,0}$	$E_{0,0}$(CCT)[b]	$\Delta G°$
	V[a]	V[a]	kcal mol^{-1}	kcal mol^{-1}	kcal mol^{-1}
1a/O_2	1.15	−1.28	94	78	−39[c] or −23[d]
1a/DCNB		−2.00			−23[c] or −7[d]
1b/O_2	1.38	−1.28	97	78	−39[c] or −18[d]
1b/DCNB		−2.00			−20[c] or −1[d]

a) Vs. Ag/0.1 mol dm^{-3} $AgNO_3$ in MeCN. b) Energies of CCT pairs calculated from the wavelength of their CCT bands. c) Calculated using $E_{0,0}$. d) Calculated using $E_{0,0}$ (CCT).

radicals $\mathbf{1a}^+$ and O_2^- in acetonitrile can be estimated to be 54 kcal mol^{-1} over the ground-state molecules. The singlet excitation energy of **1a** is estimated to be 94 kcal mol^{-1} from its fluorescence spectrum and its triplet excitation energy to be nearly 60 kcal mol^{-1} because styrene has a triplet excitation energy of 62 kcal mol^{-1}.[11] Such estimation enables us to exclude a possibility of production of **1a** triplets through back electron transfer, since this process is endothermic by ca. 6 kcal mol^{-1}. The situation is similar in **1b**.

Therefore, it is reasonable to conclude that on excitation of the CCT pair the resulting olefin cation radical adds to ground-state olefin to give a dimer cation radical to which an electron is reverted from a superoxide anion finally to give the olefin dimer. In the interaction of the cation radical and the olefin molecule to give the dimer cation radical, the aromatic rings substituted in the ethylenic linkage will avoid steric crowding, therefore, to take a trans configuration.

Experimental

^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL JMN-MN-100 spectrometer and a JEOL FX-100 spectrometer, respectively. Infrared (IR) and UV spectra were obtained on a Hitachi 260-50 spectrophotometer and a Hitachi 200-20 spectrophotometer, respectively. Mass spectra were determined with a Hitachi RMU-6MC mass spectrometer. The oxidation and reduction potentials were determined by means of cyclic voltammetry in acetonitrile using a Ag/Ag^+ (0.1 mol dm^{-3}) electrode as a reference electrode and 0.1 mol dm^{-3} tetraethylammonium perchlorate as a supporting electrolyte. Irradiations were carried out with a 400-W high-pressure mercury lamp (Riko UVL-400HA) or with a 160-W low-pressure mercury lamp (Riko UVL-160LA).

Materials. 4-Methoxystyrene (**1a**) and 4-methylstyrene (**1b**) were prepared by decarboxylation of the corresponding cinnamic acids as described in the literature.[12] Acetonitrile and benzene were guaranteed reagents and distilled before use.

Contact Charge Transfer (CCT) and Charge Transfer (CT) Absorption Spectra of Styrene Derivatives. A solution of **1a** (0.59 mol dm^{-3}) in acetonitrile or benzene or of **1b** (0.61 mol dm^{-3}) in acetonitrile was placed in a sample cell and a reference cell, and a stream of oxygen was passed for several minutes through the solution in the sample cell. Spectra were measured at room temperature. Immediately after a spectrum was recorded, argon was passed through the solution in the sample cell and a spectrum was again measured.

A solution of **1a** (0.59 mol dm^{-3}) and DCNB (50 mg, 0.39 mmol) was prepared immediately before measurement and placed in a sample cell. In a reference cell was placed an acetonitrile solution of **1a** in the same concentration as in a sample cell.

Photochemical Reaction. a) Isolation of Reaction Products. *cis*-1,2-Bis(4-methoxyphenyl)cyclobutane (2a). 4-Methoxystyrene (2 g, 15 mmol) was irradiated in acetonitrile (250 cm^3) with a 160-W low-pressure mercury lamp under a nitrogen stream at room temperature. After 48 h, 4-methoxystyrene was completely consumed as determined by GLPC analysis. Column chromatography of the concentrated reaction mixture on silica gel with hexane as eluent gave an oily product, the structure of which was determined as *cis*-1,2-bis(4-methoxyphenyl)cyclobutane (**2a**) based on the following spectral data. GLPC analysis showed that the product contained the trans isomer (**3a**) (**2a**/**3a**=91/9).

2a: oil; MS: *m/z* 268 (M^+), 240, 225, 134 (M^+/2, 100%), 119; ^{1}H NMR ($CDCl_3$) δ=2.36 (q, 4H, CH_2), 3.64 (s, 6H, OMe), 3.68 (m, 2H, CH), 6.52—6.84 (q, 8H, aromatic H); ^{13}C NMR ($CDCl_3$) δ=157.4 (s), 133.7 (s), 128.8 (d), 113.0 (d), 55.0 (q), 44.5 (d), 24.5 (t).

***trans*-1,2-Bis(4-methoxyphenyl)cyclobutane (3a).**[7a] Irradiation of **1a** (500 mg, 3.7 mmol) in acetonitrile (5 cm^3) under oxygen atmosphere with a 400-W high-pressure mercury lamp through a Pyrex filter for 24 h gave trans dimer **3a** (320 mg, 64%) after separation by chromatography on silica gel with benzene as eluent.

3a: oil; MS: *m/z* 268 (M^+), 266, 240, 225, 160, 134 (M^+/2, 100%) 119; ^{13}C NMR ($CDCl_3$) δ=158.0 (s), 136.8 (s), 127.6 (d), 113.7 (d), 55.2 (q), 47.8 (d), 26.0 (t).

***cis*-1,2-Bis(4-tolyl)cyclobutane (2b).**[7b] 4-Methylstyrene (1.8 g, 15 mmol) was irradiated in acetonitrile (250 cm^3) with a 160-W low-pressure mercury lamp under an argon stream at room temperature for 48 h. The solvent was evaporated in vacuo and the residue was separated by chromatography on silica gel to give **2b** (1 g, 56%) and trace amounts of **3b** and **5**.

2b: oil; MS: *m/z* 236 (M^+), 208, 193, 178, 132, 118 (M^+/2, 100%), 90; ^{13}C NMR ($CDCl_3$) δ=138.6 (s), 134.7 (s), 128.3(d), 127.8 (d), 44.9 (d), 24.6 (t), 21.0 (q).

***trans*-1,2-Bis(4-tolyl)cyclobutane (3b).**[7b] A solution (3 cm^3) of **1b** (216 mg, 1.83 mmol) in acetonitrile was irradiated in the presence of benzophenone (100 mg, 0.55 mmol) in a uranium glass tube with a 400-W high-pressure mercury lamp under argon atmosphere at room temperature to give **2b** and **3b** in a ratio of 30/70 but no tetralin dimer **5**.

3b: MS: *m/z* 236 (M^+), 234, 221, 219, 206, 193, 191, 179, 178, 144, 118 ($M^+/2$, 100%), 105, 90.

1-(4-Tolyl)-7-methyl-1,2,3,4-tetrahydronaphthalene (5).[7b] Oil; MS: *m/z* 236 (M^+), 221, 208, 193, 144 (M^+—4-MeC_6H_4, 100%), 129, 118; ^{13}C NMR ($CDCl_3$) δ=144.5 (s), 139.1 (s), 135.1 (s), 134.8 (s), 134.3 (s), 130.4 (d), 128.7 (d), 128.6 (d), 126.6 (d), 45.0 (d), 33.3 (t), 29.3 (t), 21.0 (t and q).

6-Methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalen-1-one (6). 4-Methylstyrene (1.8 g, 15 mmol) was irradiated in acetonitrile (60 cm^3) under oxygen atmosphere with a 400-W high-pressure mercury lamp through a Pyrex filter at room temperature. After 72 h, **1b** was completely consumed as determined by GLPC analysis and **6** was separated from other dimers (**2b**, **3b**, and **5**) by chromatography on silica gel using benzene as eluent.

6: oil; MS: *m/z* 250 (M^+, 100%), 235, 222, 208; IR (neat): 1670 cm^{-1}, $\nu_{C=O}$; ^1H NMR ($CDCl_3$) δ=2.34 (s, 3H, CH_3), 2.30—2.65 (m, 4H, CH_2CH_2), 4.0—4.25 (m, 1H, CH), 6.7—8.0 (m, 7H, aromatic H); ^{13}C NMR ($CDCl_3$) δ=197.7, 146.4, 144.3, 140.7, 136.2, 130.6, 129.8, 129.2, 128.4, 127.9, 127.2, 44.8, 36.5, 31.9, 21.7, 21.0. The phenylhydrazone of **6**, mp 131—133 °C (decomp); Found: C, 84.73; H, 7.10; N, 8.26%. Calcd for $C_{24}H_{24}N_2$: C, 84.66; H, 7.10; N, 8.22%.

1-(4-Cyanophenyl)-6-methyl-4-(4-tolyl)-1,2,3,4-tetrahydronaphthalene (7). 4-Methylstyrene (1.8 g, 15 mmol) was irradiated in the presence of 1,4-dicyanobenzene (1 g, 8 mmol) in acetonitrile (250 cm^3) with a high-pressure mercury lamp under a nitrogen stream at room temperature. After 44 h, the solvent was evaporated in vacuo and silica-gel chromatography of the residue gave dimers (**3b** and **5**, trace) and **7** (570 mg, 21%) as a 1:1 mixture of cis and trans isomers, the assignment of which was based on ^{13}C NMR spectrum.

7: colorless amorphous; mp 111—112 °C from hexane-methanol; MS: *m/z* 337 (M^+), 245 (100 %), 234, 219, 208; IR (KBr): 2210 cm^{-1}, $\nu_{C\equiv N}$; ^1H NMR ($CDCl_3$) δ=1.6—2.1 (m, 4H, CH_2CH_2), 2.16 and 2.18 (s, 3H, CH_3), 2.30 (s, 3H, CH_3), 3.95—4.35 (m, 2H, 2CH), 6.6—7.55 (m, 11H, aromatic H); ^{13}C NMR ($CDCl_3$) δ=153.3, 153.2, 144.0, 143.9, 139.6, 136.3, 136.1, 135.7, 135.3, 135.2, 132.1, 131.0, 130.7, 129.9, 129.6, 129.0, 128.6, 127.5, 127.3, 119.0, 109.9, 45.7, 45.6, 45.3, 44.8, 30.9, 30.1, 29.7, 21.0. Found: C, 89.03; H, 6.87; N, 4.16%. Calcd for $C_{25}H_{23}N$: C, 88.97; H, 6.87; N, 4.15%.

b) Determination of Product Yields. Irradiations with a High-Pressure Mercury Lamp. A solution (3 cm^3) of 4-methoxystyrene (238 mg, 1.78 mmol) in acetonitrile or benzene was irradiated under oxygen or nitrogen atmosphere in a Pyrex tube or a uranium glass tube with a 400-W high-pressure mercury lamp for 16 h at room temperature. The yields of all products were determined by GLPC analysis on a Hitachi 163 gas chromatograph equipped with a flame ionization detector using 2-m columns of 5% polyethylene glycol 20M and 5% Silicone GE SE-30.

A solution (3 cm^3) of **1b** (216 mg, 1.86 mmol) in acetonitrile was irradiated under oxygen or nitrogen atmosphere in a Pyrex or a uranium glass tube with a 400-W high-pressure mercury lamp at room temperature for 20 h using a merry-go-round apparatus. The yields of the products were determined by GLPC analysis.

A solution (3 cm^3) of **1a** (238 mg, 1.78 mmol) in acetonitrile was irradiated in the presence of **4a** (56 mg, 0.41 mmol) or DCNB (50 mg, 0.39 mmol) in a Pyrex or a uranium glass tube with a high-pressure mercury lamp under nitrogen atmosphere at room temperature. The yields of products were determined by GLPC analysis.

Irradiations with a Low-Pressure Mercury Lamp. A solution (3 cm^3) of **1a** (238 mg, 1.78 mmol) in acetonitrile was irradiated in a quartz tube with a 160-W low-pressure mercury lamp under oxygen or nitrogen atmosphere for 16 h at room temperature. The yields of products were determined by GLPC analysis.

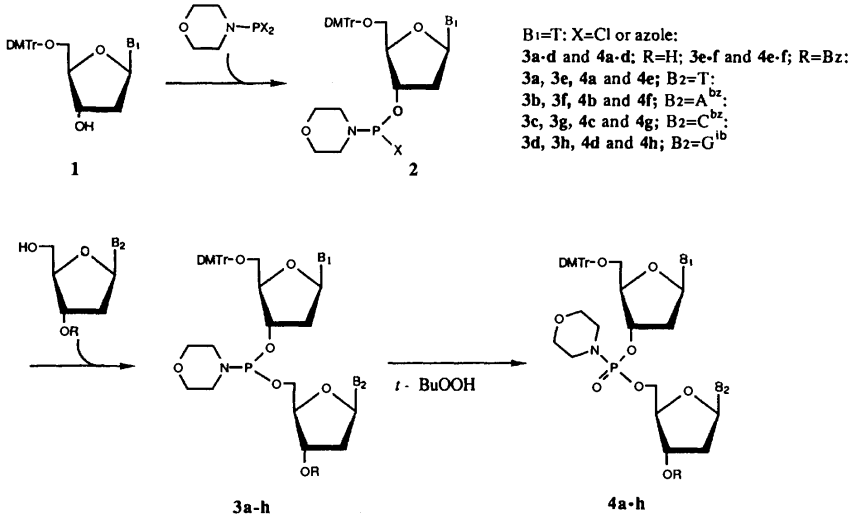
Synthesis of Bis(deoxyribonucleoside) Phosphoromorpholidate Derivatives for Oligodeoxyribonucleotide Preparation by Use of a Selective Phosphitylating Reagent

Hiroaki OZAKI, Shuhei YAMOTO, Seiichirou MAIKUMA, Kenichi HONDA, and Takeo SHIMIDZU*
Division of Molecular Engineering, Graduate School of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received June 17, 1989)

Sequence-defined bis(deoxyribonucleoside) phosphoromorpholidate derivatives as stable intermediates to prepare oligodeoxyribonucleotides have been synthesized using morpholinodi(1-tetrazolyl)phosphine as a phosphitylating reagent. The general procedure is composed of following steps (in situ); a) a reaction of 5'-O-protected deoxyribonucleoside with morpholinodi(1-tetrazolyl)phosphine (phosphitylation), b) a reaction of the resulting 5'-O-protected deoxyribonucleoside phosphorobisamidite with the second deoxyribonucleoside (coupling), and c) a nonaqueous oxidation with *t*-BuOOH (oxidation). In the coupling step, the 5'-O-protected deoxyribonucleoside phosphorobisamidite was selectively reacted with 5'-OH group of the second deoxyribonucleoside, and therefore, a protection of hydroxyl groups of the second deoxyribonucleoside is not necessary. As the resulting P-N bond in the phosphoramidate linkage after oxidation is stable both in acidic and basic conditions, the morpholino function as a phosphoryl protecting group may have many potential use in the synthetic chemistry of oligonucleotide. A thymidine trimer can be obtained in a high yield by extending the present synthetic method.

Since Letsinger[1] and Caruthers[2] introduced phosphite and phosphoramidite approaches to the synthesis of oligonucleotides, extensive research has been directed toward developments of more promising methodologies by using the efficient phosphitylating reagents.[3,4] Moreover, it is of particular importance to develop a method for a large scale synthesis of sequence-defined oligonucleotides in order to solve many genetic phenomena by physical chemical studies and to use them for new medicines. The purpose of our study has been focused on a rapid and large scale synthesis of sequence-defined oligonucleotides by using the selective phosphitylating reagents. Previously, we have developed tris(azolyl)phosphines as phosphitylating reagents which react selectively with the cis-glycol of ribonucleosides. Based on the selective phosphitylation, homo-oligoribonucleotides can be obtained directly from unprotected ribonucleosides by the chemical polymerization approach.[5,6] A new class of phosphitylating reagents, (dialkylamino)-dichlorophosphine possessing the same selectivity to the ribonucleoside hydroxyl groups, were synthesized and adapted to the solution phase synthesis of oligoribonucleotides having defined sequences.[7]

The next objective of our research is to use the phosphitylating reagent for synthesizing sequence-defined oligodeoxyribonucleotides and their analogs. We have developed the convenient procedure for the synthesis of sequence-defined bis(deoxyribonucleoside) derivatives having phosphoromorpholidate linkage, which contains the following steps (Scheme 1); i) a reaction of 5'-O-protected deoxyribonucleoside with morpholinodi(1-tetrazolyl)phosphine (phosphitylation), ii) a reaction of the resulting 5'-O-protected deoxyribonucleoside phosphorobisamidite with the second deoxyribonucleoside (coupling), and



Scheme 1.

iii) a nonaqueous oxidation of resulting phosphoromorpholidite linkage by using *t*-butyl hydroperoxide (*t*-BuOOH) (oxidation).[8,9] In order to demonstrate the possibility of a chain elongation, the synthesis of a trimer was performed by repeating the procedure described above.

Additionally, our present approach may provide a useful method for the preparation of biologically interesting oligonucleotide analogs having phosphoramidate linkages. In the literature, several oligonucleotide analogs having various internucleotide bonds were synthesized and it was shown that they had resistance in cleavage by a variety of nucleases.[10,11] Also, nonionic oligonucleotide analogs having methylphosphonates have been synthesized,[12] and shown to form complexes with complementary DNA or RNA with different stabilities and to exert inhibitory effects on a protein synthesis.[13] The oligodeoxyribonucleotide analogs having phosphoramidate linkages could be also expected to have biochemical and biological effects and the analogs were synthesized by H-phosphonate method.[14] The present synthetic method is a simple and convenient procedure for the synthesis of oligonucleotide analogs having phosphoramidate linkage.

In this paper, we describe the synthesis of the sequence-defined bis(deoxyribonucleoside) phosphoromorpholidate derivatives, as the stable intermediates for the synthesis of oligodeoxyribonucleotides by use of a selective phosphitylating reagent.

Results and Discussion

Phosphitylation of 5′-O-Protected Deoxyribonucleoside (Scheme 2). Several (dialkylamino)dichlorophosphines have been prepared and their reactivity and selectivity have been examined in the reaction with ribonucleosides.[7] Among them, dichloromorpholinophosphine was found to be highly reactive toward the secondary hydroxyl groups of ribonucleosides. We therefore tried to use the reagent for the phosphitylation of 5′-O-protected deoxyribonucleoside. However, it was found that the reaction of 5′-*O*-[bis(4-methoxyphenyl)phenylmethyl]thymidine (5′-*O*-dimethoxytritylthymidine, d-DMTrT) with the phosphitylating reagent is non-selective and gave a considerable amount of an undesired 3′,3′-linked dithymidylate analog, **5**. On the contrary, the use of its azolide instead of the chloride for the phosphitylation improved the selectivity. Results are summarized in Table 1. In case of using monoazolide derivatives as the phosphitylating reagent, a significant amount of side products were still yielded. A good selectivity in the reaction was obtained by using di(triazolide) and di(tetrazolide) derivatives. From the practical point of view, morpholinodi(1-tetrazolyl)-phosphine was found to give the phosphitylated product **2** in a yield of over 80% within 30 min under the present condition.

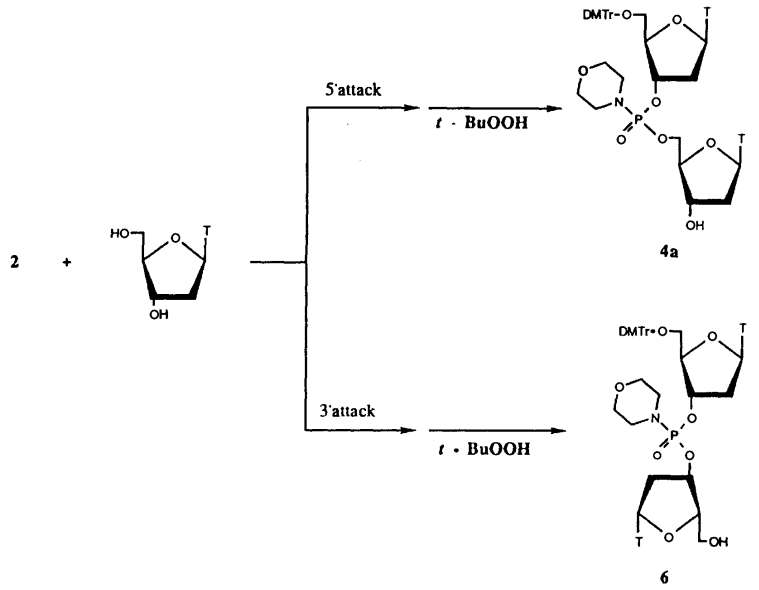
Scheme 2.

Table 1. Selectivity in the Phosphitylation of d-DMTrT with $X_1X_2PN(CH_2CH_2)_2O$

$X_1X_2PN(CH_2CH_2)_2O$		Yield[b]		
X_1[a]	X_2[a]	**1**	**2**	**5**
Im	Cl	30.6	20.4	49.0
Im	Im	92.2	7.8	—
Tri	Cl	35.2	22.9	41.9
Tri	Tri	41.1	58.6	—
Te	Cl	16.9	60.3	22.8
Te	Te	9.3	82.1	8.6

a) Im, imidazolyl; Tri, triazolyl; Te, tetrazolyl. b) d-DMTrT was phosphitylated by $X_1X_2PN(CH_2CH_2)_2O$ in CH_2Cl_2–pyridine at 0 °C under N_2 for 30 min. After the reaction mixture was treated by absolute CH_3OH, TLC analysis was carried out.



Scheme 3.

Selectivity in the Coupling Reaction (Scheme 3). d-DMTrT phosphorobisamidite **2** (X=tetrazolyl) thus obtained was allowed to react with thymidine. The reaction was completed within 30 min which is indicated by TLC and HPLC. After the in situ oxidation using *t*-BuOOH, 3′-5′ linked dithymidine phosphoromorpholidate **4a** was obtained as a main product together with only a little amount of an undesired 3′-3′ linked product **6** (**4a**/**6**=96.2/3.8). The result clearly indicates that compound **2** reacts predominantly with the 5′-OH of the second deoxyribonucleoside in the coupling reaction. Therefore, this highly selective reaction provides a simple and convenient route to the synthesis of bis(deoxyribonucleoside) derivatives without any protection of 3′-OH of the second deoxyribonucleoside.

Oxidation of Phosphoromorpholidite Linkage. Since an intermediate **3a** having a phosphoromorpholidite linkage is sensitive to atmospheric oxygen and moisture, its isolation by recrystallization or silica-gel column was not successful. Preliminary experiments showed that the in situ oxidation of **3a** with I_2-H_2O and *m*-chloroperbenzoic acid gave a large number of side products. We have solved this problem by using *t*-BuOOH.[8,9] The reaction product was also analyzed by ^{31}P NMR (Fig. 1). ^{31}P NMR shows that after the oxidation of **3a** with 3 M *t*-BuOOH in toluene (1 M=1 mol dm^{-3}) for 10 min at 0 °C, **3a** (138.4 ppm) completely disappeared to give the single peak (7.08 ppm) due to the phosphoromorpholidate derivative **4a**. This result indicated that the phosphoromorpholidite linkage in **3a** was smoothly converted to the corresponding phosphoromorpholidate linkage without any side reactions.

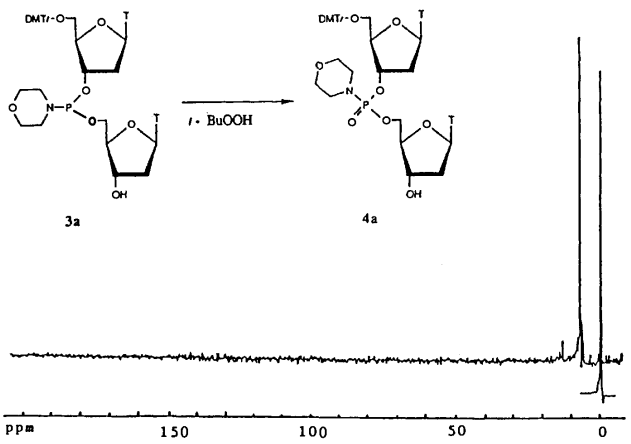


Fig. 1. ^{31}P NMR of bis(deoxyribonucleoside) derivative (**4a**) obtained by use of *t*-BuOOH (in $CDCl_3$, relative to external 85% H_3PO_4).

Effect of (*i*-Pr)$_2$NEt. We examined the effect of ethyldiisopropylamine ((*i*-Pr)$_2$NEt) on coupling reaction. When the synthesis of **4a** was carried out by using (*i*-Pr)$_2$NEt of 2 equiv for the phosphitylating reagent, namely equimolar amounts of hydrochloride released to the system, a lot of unknown products were formed in the reaction (Fig. 2). On the other hand, when it was carried out by using (*i*-Pr)$_2$NEt of 4 equiv for the phosphitylating reagent, unknown products decreased and desired products (**4a**) increased. This result suggests that it is required to trap the released tetrazolium ion by using base in order to conserve the phosphoromorpholidite linkage and to increase efficiency of the coupling reaction.

Synthesis of Bis(deoxyribonucleoside) Phosphoromorpholidate Derivatives (4a—d). The applicability of the synthetic route described above was tested in the syntheses of bis(deoxyribonucleoside) phosphoromorpholidate derivatives having different sequences. The yields and physical chemical data of the obtained

bis(deoxyribonucleoside) phosphoromorpholidate derivatives (**4a—d**) were summarized in Table 2. **4a—d** agreed with 3′-5′ linked bis(deoxyribonucleoside) phosphoromorpholidates derived from **4e—h** (Scheme 1) on HPLC, which were synthesized by use of 3′-O-protected deoxyribonucleosides as the second deoxyribonucleosides in the similar procedure. In the every case, the desired 3′,5′-linked bis(deoxyribonucleoside) phosphoromorpholidate derivatives were obtained with good yields by the convenient method without the protection of the hydroxyl groups of the second deoxyribonucleosides.

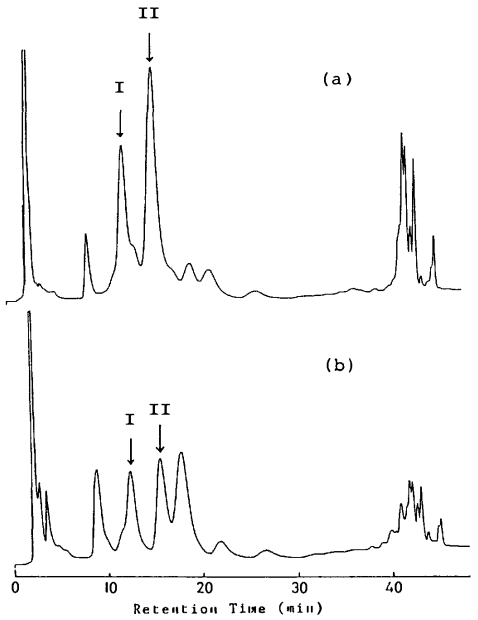

Fig. 2. Effect of $(i\text{-Pr})_2$NEt on dithymidine derivative (**4a**) synthesis. (a) 4 equiv of $(i\text{-Pr})_2$NEt for phosphitylating reagent. (b) 2 equiv of $(i\text{-Pr})_2$NEt for phosphitylating reagent. HPLC condition: column, Cosmosil $5C_{18}$ (4.6 mm i.d. ×150 mm length); eluent, 70—100% CH_3OH gradient in H_2O; flow rate, 1 mL min^{-1}; detect: UV at 254 nm. The peaks of **4a** are indicated by the arrows.

Stability of Phosphoromorpholidates. Table 3 shows the stability of the P-N bond in **4a** under various conditions. The P-N bond was stable in 80% acetic acid, concentrated aq. NH_3, and 0.5 M NaOH. Since the phosphoromorpholidate linkage is stable for acid and alkaline, the fully protected dimer block, **4e**, can be used to elongate the nucleotide chain both toward 3′- and 5′-direction from 3′-free derivatives obtained by alkaline treatment and 5′-free derivatives obtained by acid treatment, respectively. Moreover, it is possible to introduce phosphoramidate at all or any specific sites within oligodeoxyribonucleotides and these molecules are expected to have several interesting biological effect.

Removal of Phosphoryl Protecting Group (Scheme 4). Since hydroxylamine is known to hydrolyze phosphoramidates,[15,16] it appeared a potential deprotection agent for a phosphoramidate link. The P-N bond underwent hydrolysis to phosphodiester by a treatment with hydroxylamine. In the case of treat-

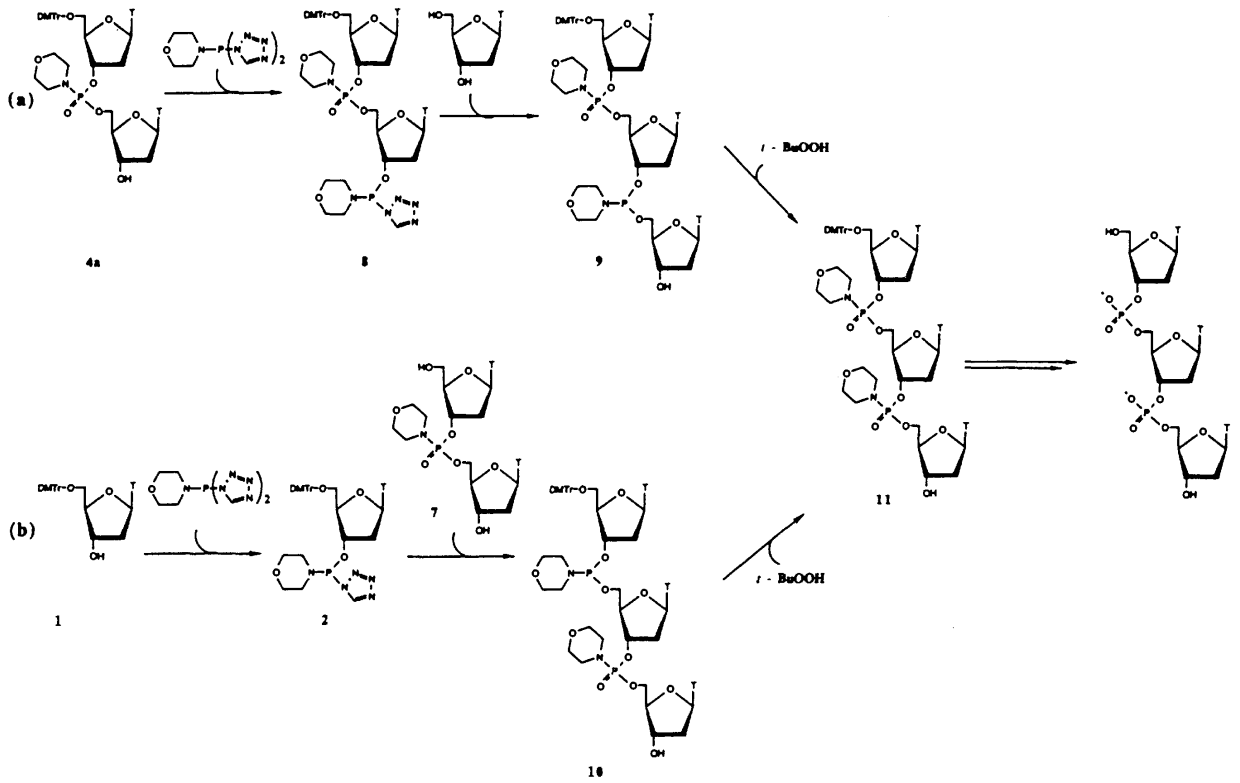


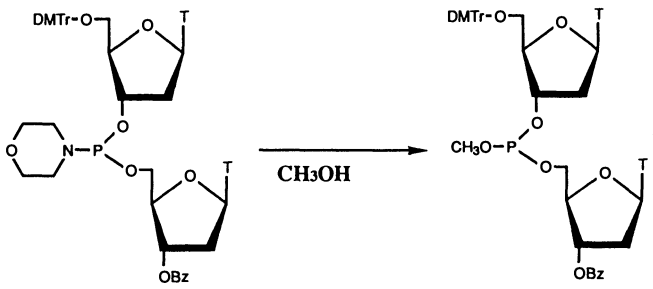
Scheme 5.

ing compound **7** with 4.0 M aqueous hydroxylamine, a small amount of unknown product formed. Compound **7** was treated with 2.0 M aqueous hydroxylamine at 50 °C. Based on HPLC analysis, the reaction resulted in complete deprotection within one week to give thymidylyl(3′-5′)thymidine (d(T-T)). The structure of this product was confirmed by an authentic sample, and a degradation with snake venom phosphodiesterase and spleen phosphodiesterase.

Chain Elongations of Bis(deoxyribonucleoside) Derivatives Both toward 3′- and 5′-Direction. In order to demonstrate chain elongations of bis(deoxyribonucleoside) derivative toward 3′- and 5′-direction, syntheses of $(dT)_3$ derivatives, trimer, were attempted by the coupling of the dithymidine derivatives such as **4a** or **7**, and thymidine or d-DMTrT **1**, respectively. First, the trimer synthesis was carried out in the similar synthetic method of bis(deoxyribonucleoside) phosphoromorpholidate derivatives by use of compound **4a** (3′-OH free derivative) as a starting material and unprotected thymidine as a coupling deoxyribonucleoside (Scheme 5a). After oxidation the total products were analyzed by HPLC. Yield of compound **11** was 77% (based on HPLC). ^{31}P NMR (in $CHCl_3$) δ=6.47 ppm (relative to external 85% H_3PO_4). The structure was confirmed by the following method. The product isolated by HPLC was treated with 80% acetic acid for 30 min at room temperature to remove the 5′-O-protecting group. After the reaction mixture was evaporated, 2.0 M aqueous hydroxylamine was added to the residue, and then the mixture was stirred at 50 °C for one week to remove phosphoryl protecting group. The resulting thymidine trimer $(dT)_3$ was confirmed by an agreement with an authentic sample (Sigma) on HPLC and a degradation method with snake venom phosphodiesterase and spleen phosphodiesterase.

Also, d-DMTrT **1** as a starting material and **7** (3′,5′-OH free dithymidine derivative) as a second deoxyribonucleoside derivative were used (Scheme 5b). The other conditions were similar to those of the above-mentioned trimer synthesis. The structure of the obtained product **11** was confirmed in the similar manner as the identification of **11** obtained above. Yield of compound **11** in this procedure was 67% based on HPLC analysis. This results indicate that chain elongations both toward 3′- and 5′-direction from dithymidine derivatives were carried out with as high yield as dithymidine derivative synthesis (74%, see Table 2).

Conversion of 3e into Phosphorous Triester. The phosphoramidite in **3e** can easily be converted to phosphorous triester by reaction with alcohol (Scheme 6). Accordingly, **3e** was readily converted to **12** by a reaction with methanol, and this intermediate **12** is widely used in phosphite chemistry. This experiment was examined by ^{31}P NMR. The addition of absolute CH_3OH (3.0 equiv) to a solution of **3e** resulted in the complete disappearance of the signal at 138.4 ppm (in $CDCl_3$) and its replacement by two new singlets at 141.7 and 142.0 ppm, which were in agree-



Scheme 6.

ment with the structure of **12**, as expected for two diastereomers. This result suggests that bis(deoxyribonucleoside) phosphoromorpholidite derivatives can be adapted as a key intermediate which can easily be converted to compounds bearing other phosphite linkages by the reaction of nucleophilic reagents.

Conclusion

The present approach using morpholinodi(1-tetrazolyl)phosphine provides a simple and convenient procedure for synthesizing bis(deoxyribonucleoside) derivatives, which does not require any protection of hydroxyl group of the second deoxyribonucleoside. The phosphoromorpholidite linkage can be used as a key intermediate capable of converting to other phosphite compounds and the stability of the P-N bond in the phosphoromorpholidate linkage provides a phosphoryl-protecting group in the oligodeoxyribonucleotide synthesis. In addition, it is expected that the present method to synthesize the bis(deoxyribonucleoside) derivatives having phosphoramidate linkages is applied to the syntheses of several functional oligonucleotide derivatives whose phosphorus is linked with fluorescent, intercalating and cross-linking moiety, through the reaction of nucleoside and phosphorus derivatives bearing those moieties.

Experimental

HPLC was carried out on a Shimadzu LC 6A apparatus using Cosmosil $5C_{18}$ analytical column (4.6 mm i.d. × 150 mm length, Nacalai Tesque Co.). The eluents were 70—100% CH_3OH gradient in water (eluent A) or 8—25% CH_3CN gradient in 0.1 M ammonium acetate solution (eluent B). TLC was carried out on Merck silica-gel plates (No. 5554 for analysis or No. 5717, 13793 for preparative work). Preparative silica-gel column chromatography was performed on Wako gel C-200 (Wako Pure Chemicals Co.). Middle pressure liquid chromatography was carried out on a Yamazen 540-3 apparatus using LC-SORB SP-B-SI preparative column (30 mm i.d. × 300 mm length, Chemco Scientific Co., Ltd.). ^{31}P NMR were recorded on a Hitachi R-900FT NMR (^{31}P 36.43 MHz) or a JEOL JNM-EX90 (^{31}P 36.23 MHz) relative to external 85% H_3PO_4.

Thymidine, deoxyadenosine, deoxycytidine, and deoxyguanosine were supplied from Yamasa Shoyu Co., Ltd. d-DMTrT was synthesized according to published procedures.[17] N^6-benzoyldeoxyadenosine (d-bzA),[18] N^4-benzoyldeoxycytidine (d-bzC),[18] N^2-isobutyryldeoxyguanosine (d-ibG),[18] 3′-*O*-benzoylthymidine (d-TBz),[19] N^6, 3′-*O*-dibenzoyldeoxyadenosine (d-bzA(Bz)),[20] N^4, 3′-*O*-dibenzoyldeoxycytidine (d-bzC(Bz)),[20] and 3′-*O*-benzoyl-N^2-isobutyryldeoxyguanosine (d-ibG(Bz))[20] were also synthesized according to published procedures. These compounds were coevaporated with pyridine prior to use. CH_2Cl_2 was refluxed over CaH_2 and distilled immediately prior to use. Pyridine was refluxed over CaH_2, distilled and stored over 4A Molecular Sieves. Ethyldiisopropylamine ($(i\text{-Pr})_2NEt$) was refluxed over CaH_2, distilled over CaH_2, and then stored over CaH_2. *t*-Butyl hydroperoxide (*t*-BuOOH) in toluene (3 M solution) was purchased from Aldrich Chemicals Co. and stored over 4A Molecular Sieves. Other reagents were used without further purification.

Preparation of Dichloromorpholinophosphine. A solution of morpholine (86.5 mL, 1.0 mol) in 100 mL of dry ether was added dropwise over 2 h to a vigorously stirred solution of phosphorus trichloride (43.6 mL, 0.5 mol) in 300 mL of dry ether at 0 °C. After stirring for 1 h, the amine hydrochloride was removed by filtration and ether was distilled at atmospheric pressure. The residue was distilled from cesium fluoride under reduced pressure and the desired material was isolated in a pure form (Yield: 56.9 g (60.5%), 58.0 °C/1.0 mmHg; 1 mmHg=133.322 Pa). ^{31}P NMR ($CDCl_3$) δ=156.5. Found: C, 25.48; H, 4.33; N, 7.66; P, 16.63; Cl, 37.45%. Calcd for $C_4H_8NOPCl_2$: C, 25.55; H, 4.29; N, 7.45; P, 16.47; Cl, 37.71%.

Preparation of Azolylchloromorpholinophosphine. A solution of azole (0.55 mmol) in CH_2Cl_2-pyridine (1:1 v/v, 1 mL) was added dropwise to dichloromorpholinophosphine (77.5 mL, 0.55 mmol) in CH_2Cl_2 (1 mL) containing (i-Pr)$_2$NEt (0.2 μL) with stirring at 0 °C under N_2 and the solution was stirred for 20 min. These phosphitylating reagents prepared in situ were then used in the phosphitylation of d-DMTrT.

Preparation of Bis(azolyl)morpholinophosphine. A solution of azole (1.1 mmol) in CH_2Cl_2-pyridine (1 : 1 v/v, 1 mL) was added dropwise to dichloromorpholinophosphine (77.5 μL, 0.55 mmol) in CH_2Cl_2 (1 mL) containing (i-Pr)$_2$NEt (0.2 mL) with stirring at 0 °C under N_2 and the solution was stirred for 20 min. These phophitylating reagents prepared in situ were then used in the phosphitylation of d-DMTrT.

Phosphitylation of d-DMTrT. A solution of d-DMTrT (272.5 mg, 0.5 mmol) in CH_2Cl_2 (1.5 mL) was added dropwise over a period of 10 min to azolylchloromorpholinophosphine (0.55 mmol) or bis(azolyl)morpholinophosphine (0.55 mmol) in CH_2Cl_2 (1.0 mL) containing (i-Pr)$_2$NEt (0.2 mL) with stirring at 0 °C under N_2. After the appropriate time intervals, the aliquot of the reaction mixture was treated with absolute CH_3OH. The resulting thymidine phosphoramidite derivatives were analyzed by TLC (on siica gel, CH_2Cl_2-EtOAc-Et_3N, 40/50/10, v/v/v).

General Procedures for the Preparation of Bis(deoxyribonucleoside) Phosphoromorpholidate Derivatives (4a—h). A solution of tetrazole (77.1 mg, 1.1 mmol) in CH_2Cl_2-pyridine (1 : 1 v/v, 1.0 mL) was added dropwise to dichloromorpholinophosphine (77.6 μL, 0.55 mmol) in CH_2Cl_2 (1 mL) containing (i-Pr)$_2$NEt (0.2 mL). After the reaction mixture was stirred at 0 °C for 20 min under N_2, a solution of

d-DMTrT (272.5 mg, 0.5 mmol) in CH_2Cl_2 (1.5 mL) was added dropwise over a period of 10 min to the solution with stirring at 0 °C. After 30 min, the solution was added dropwise to thymidine (243 mg, 1.0 mmol) in CH_2Cl_2–pyridine (1 : 2 v/v, 3 mL) containing (i-Pr)$_2$NEt (0.2 mL) with stirring and the reaction mixture was stirred for an additional 30 min. Further 3 M t-BuOOH in toluene (0.2 mL) was added to the reaction mixture and the solution was stirred for 10 min at 0 °C. The mixture was evaporated and coevaporated with toluene. Analysis of HPLC (in eluent A) revealed two major peaks corresponding to a diastereomeric mixture of compound **4a**. The mixture was applied to a silica-gel column and eluted with $CHCl_3$–CH_3OH (95 : 5 v/v). The appropriate fractions were collected, evaporated, and precipitated with CH_2Cl_2 (5 mL) into hexane (300 mL). The white precipitate was collected by filtration, washed and dried over P_2O_5 in vacuo. Isolated yield of **4a** was 67% (307.2 mg)(for d-DMTrT) and the purity was analyzed by HPLC (>90%). Isomer I, Found: C, 57.06; H, 5.61; N, 7.65%. Calcd for $C_{45}H_{52}O_{14}N_5P$: C, 58.88; H, 5.71; N, 7.63%, mp 137—139 °C. Isomer II, Found: C, 56.91; H, 5.62; N, 7.50%, mp 135—138 °C.

Compound **4b** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-bzA (355.4 mg, 1.0 mmol) in pyridine (3 mL). Yield was 62% (based on HPLC). Isomer I, Found: C, 59.10; H, 5.37; N, 10.25%. Calcd for $C_{52}H_{55}O_{13}N_8P$: C, 60.58; H, 5.38; N, 10.87%, mp 144—148 °C. Isomer II, Found: C, 59.58; H, 5.12; N, 10.67%, mp 142—144 °C.

Compound **4c** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-bzC (331.4 mg, 1.0 mmol) in pyridine (5 mL). Yield was 55% (based on HPLC). Isomer I, Found: C, 59.15; H, 5.26; N, 7.99%. Calcd for $C_{51}H_{55}O_{14}N_6P$: C, 60.83; H, 5.50; N, 8.35%, mp 146—149 °C. Isomer II, Found: C, 59.43; H, 5.41; N, 8.17%, mp 146—147 °C.

Compound **4d** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-ibG (337.3 mg, 1.0 mmol) in pyridine (3 mL). Yield was 70% (based on HPLC). Isomer I, Found: C, 55.29; H, 5.44; N, 10.90%. Calcd for $C_{49}H_{57}O_{14}N_8P$: C, 58.10; H, 5.67; N, 11.06%, mp>159 °C. Isomer II, Found: C, 56.43; H, 5.51; N, 10.41%, mp>155 °C.

Compound **4e** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-Tbz (173.2 mg, 0.5 mmol) in CH_2Cl_2–pyridine (1 : 2 v/v, 3 mL). Yield was 62% (based on HPLC, isomer I/isomer II=33/67). Isomer I, ^{31}P NMR ($CDCl_3$) δ=7.03, UV (CH_3OH): λ_{max} 266 and 231 nm, λ_{min} 250 nm. R_f (on silica gel, $CHCl_3$: CH_3OH=8 : 1)=0.57. Found: C, 59.57; H, 5.42; N, 6.77%. Calcd for $C_{52}H_{56}O_{15}N_5P$: C, 61.11; H, 5.52; N, 6.85%, mp 137—139 °C. Isomer II, ^{31}P NMR ($CDCl_3$) δ=6.96, UV (CH_3OH): λ_{max} 266 and 231 nm, λ_{min} 250 nm, R_f (on silica gel, $CHCl_3$: CH_3OH= 8 : 1)=0.57. Found: C, 59.24; H, 5.46; N, 6.75%, mp 140—141 °C.

Compound **4f** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-bzA(Bz) (229.7 mg, 0.5 mmol) in pyridine (3 mL). Estimated yield from ^{31}P NMR was 72%. ^{31}P NMR ($CHCl_3$) δ=6.87.

Compound **4g** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-bzC(Bz) (217.2 mg, 0.5 mmol) in pyridine (3 mL). Estimated yield from ^{31}P NMR was 64%. ^{31}P NMR($CHCl_3$) δ=6.33.

Compound **4h** was prepared by the similar procedure, except that the second deoxyribonucleoside was d-ibG(Bz) (220.7 mg, 0.5 mmol) in CH_2Cl_2–pyridine (1:2 v/v, 3 mL). Estimated yield from ^{31}P NMR was 41%. ^{31}P NMR ($CHCl_3$) δ=6.06.

Conversion of 4e to 7. Compound **4e** was treated with methanolic ammonia at room temperature overnight and extracted with $CHCl_3$ three times. The organic layer was evaporated to dryness and the residue was treated with 80% acetic acid at room temperature for 30 min. The mixture was evaporated to dryness and freed from acetic acid by three coevaporation with hexane. The residue was dissolved in H_2O and washed with EtOAc three times. Compound **4e** was quantitatively converted into **7** on the basis of HPLC analysis. ^{31}P NMR (H_2O) δ=7.92.

Removal of Phophoryl Protecting Group. Compound **7** was treated with 2.0 M aqueous hydroxylamine (pH 4.75) at 50 °C. Analysis by HPLC in eluent B revealed that **7** was completely converted to d(T-T) in one week. The resulting unprotected d(T-T) was confirmed by a degradation of snake venom phosphodiesterase and spleen phosphodiesterase.

Chain Elongation of Dithymidine Derivative. Route a: (dT)$_3$ derivative was synthesized from compound **4a** as starting material and unprotected thymidine as a coupling deoxyribonucleoside. The synthesis was carried out in the similar procedure as the preparation of bis(deoxyribonucleoside)phosphoromorpholidate derivatives. Yield of compound **11** was 77% (based on HPLC). ^{31}P NMR ($CHCl_3$) δ=6.47 (relative to external 85% H_3PO_4). The structure was confirmed by the following method. The product isolated by HPLC was treated with 80% acetic acid for 30 min at room temperature to remove the 5′-O-protecting group. After the reaction mixture was evaporated, 2.0 M aqueous hydroxylamine was added to the residue, and then the mixture was stirred at 50 °C for one week to remove phosphoryl protecting group. The resulting thymidine trimer (dT)$_3$ was confirmed by an agreement with an authentic sample (Sigma) on HPLC and a degradation method with snake venom phosphodiesterase and spleen phosphodiesterase.

Route b: d-DMTrT **1** as a starting material and compound **7** as a second deoxyribonucleoside derivative were used. The synthetic procedures were similar to those of the synthetic route a. The structure of the obtained product **11** was confirmed in the same manner as the identification of **11** obtained by the above-mentioned synthetic procedure. Yield of compound **11** in this procedure was 67% based on HPLC analysis.

Preparation of 5′-*O*-[Bis(4-methoxyphenyl)phenylmethyl]-3′-thymidine 3′-*O*-Benzoyl-5′-thymidine Methylphosphite (12). The preparation of **3e** was repeated in preparation of **4e**. At the stage before oxidation an absolute CH_3OH was added to the reaction mixture. The mixture was washed with $NaHCO_3$ (5% aq.). The organic layer was dried over Na_2SO_4. Analysis by TLC on silica gel using 10% benzene in EtOAc containing 1% Et_3N revealed two spots (R_f=0.44 and 0.57). The product was dissolved in 1 mL of a mixture of 40% benzene in EtOAc containing 1% Et_3N, applied to a silica-gel column and eluted with 30% benzene in EtOAc containing 1% Et_3N. The appropriate fractions were collected and evaporated to dryness. The residue was taken up in 2 mL $CHCl_3$ and added dropwise to 200 mL hexane at

−20 °C (47.6 mg, 50%). UV ($CHCl_3$): λ_{max} 246 and 268 nm; λ_{min} 252 nm. ^{31}P NMR ($CDCl_3$) δ=141.7 and 142.0. R_f (10% benzene in EtOAc containing 1% Et_3N)=0.44 and 0.57.

We would like to thank Dr. Kazushige Yamana, Himeji Institute of Technology, and Mr. Hiroshi Kawabata, Kyoto University, for NMR measurements and variable suggestions. We wish to thank Dr. Yoshihiro Hayakawa, Nagoya University, for the helpful suggestion with oxidizing agents.

Non-Catalyzed Thermal Reactions of Acylquinones with Allylstannanes

Kazuhiro MARUYAMA* and Yoshihiro MATANO
Department of Chemistry, Faculty of Science, Kyoto University, Kitashirakawa, Sakyo-ku, Kyoto 606
(Received June 28, 1989)

Thermal reactions of acylquinones with allylstannanes in benzene afforded several kinds of product after column chromatography on silica gel; acyl allyl quinones, acyl allyl epoxy quinones, cyclopentanoid compounds including stannyl moiety, allyl hydroxy quinones, acyl hydroquinones, and acyl allyl hydroquinones. The main product comprises cyclopentanoid compounds, which are novel [2+3] cyclo adducts with 1,2-migration of trialkylstannyl moiety. Spectroscopic examinations (^{1}H NMR and Vis-UV) enabled us to confirm the reaction pathways that four types of precursors were initially generated via polarized tight pair and inverted to isolated products during purification by column chromatography. Similar reactions in acetonitrile showed a remarkable difference in the reactivity, that is, acyl allyl quinones and the corresponding hydroquinones are obtained, but the [2+3] cyclo adducts are not produced at all. From ^{1}H NMR examination, it was confirmed that three types of precursor are generated via solvent separated ion pairs at the initial stage. The rather strong reactivity of acylquinones towards allylstannanes will be due to electron withdrawing ability of acyl group.

In recent years, organotin chemistry has been dramatically developed.[1] A variety of organotin compounds have been applied as reagents or catalysts in the field of synthetic organic chemistry.[2] Allylstannanes are the best reagents for allylation of electrophilic substrates, but, in general, activation of substrates or transmetallation of reagents by Lewis acid is necessary for smooth and selective allylation.[3] For example, Lewis acid such as BF_3 coordinates to the carbonyl oxygen and enhances the electrophilicity of the substrate.

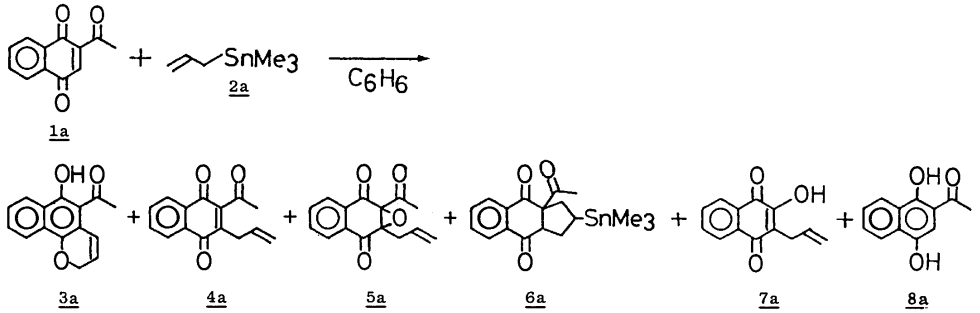
Electron deficient acylquinones exhibit unique reactivity, and several investigations relating to acylquinones have been reported by different groups.[4-7] We have reported Lewis acid catalyzed thermal reactions of acylquinones with allylstannanes, which are the key step of the total synthesis of antibiotics such as deoxyanthracyclinones[8] and pyranonaphthoquinones.[9] In these reactions, one or two allyl adducts are afforded in high yields. On the other hand, acylquinones react with allylstannanes even in the absence of Lewis acid, owing to both electron withdrawing ability and resonance efficiency.

In this paper, the thermal reactions of acylquinones with allylstannanes in the absence of catalyst will be discussed from products analyses, ^{1}H NMR, and Vis-UV. The characteristic diversity in the reactivity of acylquinones is considered from the steric and electronic nature of the relating reagents and polarity of solvents.

Results

Thermal Reactions of Acetylquinones with Allylstannanes. Thermal reactions of two kinds of acetylquinone (**1a,b**) with allylstannanes (**2a,b**) were investigated by examining the products and spectroscopic (^{1}H NMR and Vis-UV) analyses.

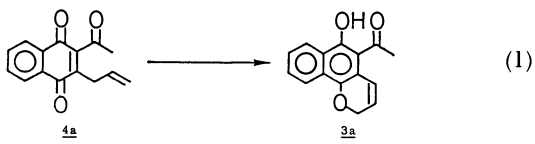
2-Acetyl-1,4-naphthoquinone **1a** (1 mmol) and allyltrimethylstannane **2a** (2 mmol) were dissolved in benzene (25 ml) and allowed to stand for 24 h under argon atmosphere. After treating the reaction mixture by column chromatography on silica gel, six compounds were isolated as the major products 5-acetyl-2*H*-benzo[*h*]chromene-6-ol **3a** (3%), 2-acetyl-3-allyl-1,4-naphthoquinone **4a** (20%), 2-acetyl-3-allyl-2,3-epoxy-2,3-dihydro-1,4-naphthoquinone **5a** (20%), 3a-acetyl-2-trimethylstannyl-2,3,3a,4,9,9a-hexahydro-1*H*-cyclopenta[*b*]naphthalene-4,9-dione **6a** (32%), 3-allyl-2-hydroxy-1,4-naphthoquinone **7a** (3%), and 2-acetyl-1,4-naphthalenediol **8a** (20%) (Scheme 1). The identification of these isolated products was carried



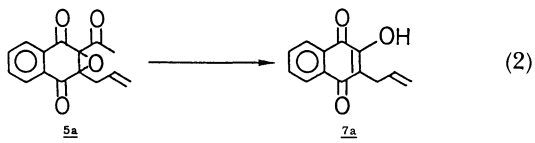
Scheme 1.

out on the basis of ^{1}H NMR, ^{13}C NMR, IR, mass spectroscopy, elementary analysis, and comparison with the authentic samples. Several spectral data which were characteristic of each product are described below. The IR spectrum of **3a** showed characteristic bands due to hydrogen bonded hydroxyl and carbonyl group at 3300 and 1600 cm^{-1}, respectively, and the allyl position methylene signal appeared at δ 4.77 as a doublet in its ^{1}H NMR spectrum. The IR spectrum of **4a** showed absorption bands due to carbonyl group at 1705 and 1665 cm^{-1}, and that of **5a** showed characteristic bands due to carbonyl group at 1710, 1695, and 1680 cm^{-1}. In their ^{1}H NMR spectra, the allyl methylene of **4a** appeared at δ 3.28 as a doublet (J=6 Hz), while that of **5a** showed diastereomeric peaks at δ 2.49 (dd, J=7, 15 Hz) and 3.00 (dd, J=7, 15 Hz). In the mass spectrum of **5a**, the parent peak and the ion peak arising from elimination of acetyl group appeared at m/z 256 (M^+) and 213 (M^+-43). All spectral data of **5a** was consistent with those of the authentic sample synthesized through another route.[6] The IR and ^{13}C NMR spectra of pale yellow compound **6a** showed characteristic bands due to carbonyl group at 1710, 1695, 1680 cm^{-1} and δ 203, 196, 194. Since ^{1}H NMR spectrum of **6a** showed only one peak due to trimethylstannyl group at δ 0.06, only one diastereomer was generated, and cis stereochemistry has been assigned to **6a** based upon analysis of the ^{13}C-^{119}Sn coupling constant.[10] In its mass spectrum, ion peaks arising from elimination of methyl group appeared at m/z 391 and 389 (M^+-15) along with those of tin isotopes ^{120}Sn and ^{118}Sn. Compound **7a** and **8a** were identified by comparison with the authentic samples.[6,11]

Of these isolated products, **3a** and **7a** were generated from **4a** and **5a**, respectively, during the treatment with silica gel. Furthermore, the generation of the cyclopentanoid adduct **6a** is worth mentioning, because it is a [2+3] cycloaddition product resulted via migration of trimethylstannyl moiety. A similar [2+3] cycloaddition reaction of allylstannanes was recently reported by Herndon.[12]



(1)



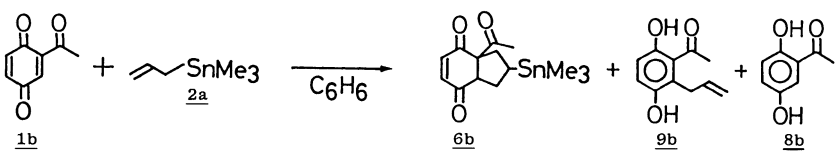
(2)

Although the thermal reaction between **1a** and **2a** in dichloromethane gave the same products as those obtained in benzene in a slightly different distribution, remarkable differences were observed in the reaction in acetonitrile. The color of an acetonitrile solution changed from yellow to dark green soon after mixing **1a** with **2a** and the reaction completed within 30 min. It seems interesting that compounds **3a**, **4a**, **5a**, **7a**, and **8a** were generated but the cyclopentanoid compound **6a** was not obtained at all.

Similarly, thermal reaction of **1b** with **2a** in benzene gave 3a-acetyl-2-trimethylstannyl-2,3,3a,4,7,7a-hexahydrindene-4,7-dione **6b** (23%), 2-acetyl-1,4-benzenediol **8b** (36%), and 2-acetyl-3-allyl-1,4-benzenediol **9b** (27%) as the major products after purification by column chromatography on silica gel (Scheme 2). On the contrary, in acetonitrile, a yellow solution changed to dark green immediately after mixing **1b** with **2a**, and the reaction completed within 10 min. After the usual examination, **8b** (18%) and **9b** (18%) were identified but the cyclopentanoid compound **6b** was not observed at all.

A similar reactivity of **1a,b** in the reaction with allyltributylstannane **2b** was recognized. The results are summarized in Table 1. Compared with other p-quinones such as non-substituted quinones, halogeno quinones, alkyl quinones, alkoxy quinones, and so on, the reactivity of 2-acetyl-1,4-quinones **1a,b** was quite specific in the aspects as follows. First, the reaction proceeds spontaneously without activation of reagents. In general, the reaction of p-benzoquinone with **2** does not proceed without irradiation or catalyst. Second, polarity of solvents strongly affects both the reaction rate and products distribution. Thus, in a nonpolar solvent such as benzene, the reaction proceeded relatively slowly, resulting in the formation of [2+3] cycloadducts **6a,b**. On the other hand, in a polar solvent such as acetonitrile, the reaction proceeded quickly, but **6a,b** were not given.

In order to clarify the reaction pathways, ^{1}H NMR measurement was carried out in the reaction of **1a** with **2a**. When a benzene-d_6 solution containing **1a** (ca. 10^{-2} M; 1 M=1 mol dm^{-3}) and **2a** (ca. 10^{-2} M) was allowed to stand in an NMR sample tube under argon atmosphere, many new peaks emerged stepwisely, but



Scheme 2.

Table 1. Thermal Reactions of Acetylquinones (**1**) with Allylstannanes (**2**)

Quinone	Tin	Reaction Conditions		Isolated yields/%							
1a	**2a**	C_6H_6	21h	**3a**(3)	**4a**(20)	**5a**(12)	**6a**(32)	**7a**(3)	**8a**(21)		
1a	**2a**	CH_2Cl_2	20h	**3a**(2)	**4a**(23)	**5a**(12)	**6a**(41)	**7a**(3)	**8a**(3)		
1a	**2a**	CH_3CN	1h	**3a**(1)	**4a**(28)	**5a**(28)		**7a**(4)	**8a**(12)

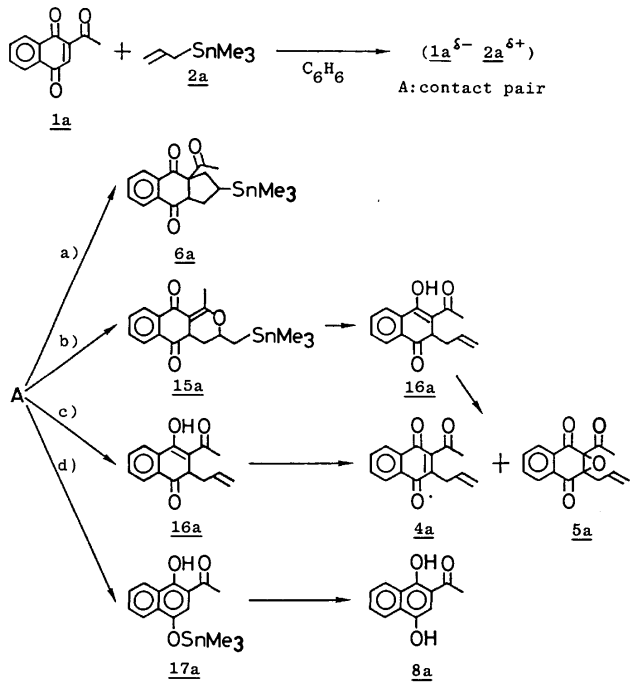
a) **10a**:  b) **10b**: 
the peaks gradually disappeared due to the starting reagents. After standing for 24 h, trace amounts of **1a**, **2a**, and four main products were observed. Compared with the ^{1}H NMR spectra of the authentic samples and structurally related substrates, these four products were assigned to **6a** (40%), **15a** (40%), **16a** (10%), and **17a** (3%) as shown in Scheme 3. The assignments were accomplished by using (2-deuterioallyl)trimethylstannane **2c** instead of **2a**, but several unidentified peaks remained.[13] To our surprise, the isolated products **3a**, **4a**, **5a**, **7a**, and **8a** were not observed during this measurement. It was thus confirmed that these five isolated products were the resultants of **15a**, **16a**, and **17a**. The ^{1}H NMR spectrum of **15a** showed characteristic bands due to acetyl group and trimethylstannyl group at δ 2.42 (3H, d, J=2 Hz) and 1.12 (9H, s), respectively. In addition, similar resonances arising from the diastereomer of [4+2] cycloadduct **15a** were observed at δ 2.44 (3H, d, J=2 Hz) and 1.13 (9H, s). The relative ratio of diastereomers was estimated to be 6/1 from integral values of each peak at δ 2.42 and 2.44. The ^{1}H NMR spectrum of **17a** showed characteristic singlet peak due to trimethylstannyl group at δ 0.24 (9H, s). However, any attempts to isolate **15a** and **17a** have failed so far. Furthermore, the reaction mixture was passed through a very short silica-gel column after standing for 24 h, and then, all fractions were collected, concentrated, and measured similarly by ^{1}H NMR. Five compounds, **4a** (4%), **5a** (2%), **6a** (38%), **8a** (5%), and **16a** (45%) were observed, but **15a** and **17a** completely disappeared. The quantity of cyclopentanoid compound **6a** was little affected by treating with silica-gel column, but the quantity of **16a** slightly increased.[14] In the presence of Lewis acid such as BF_3, compound **16a** was given as the sole allyl adduct.

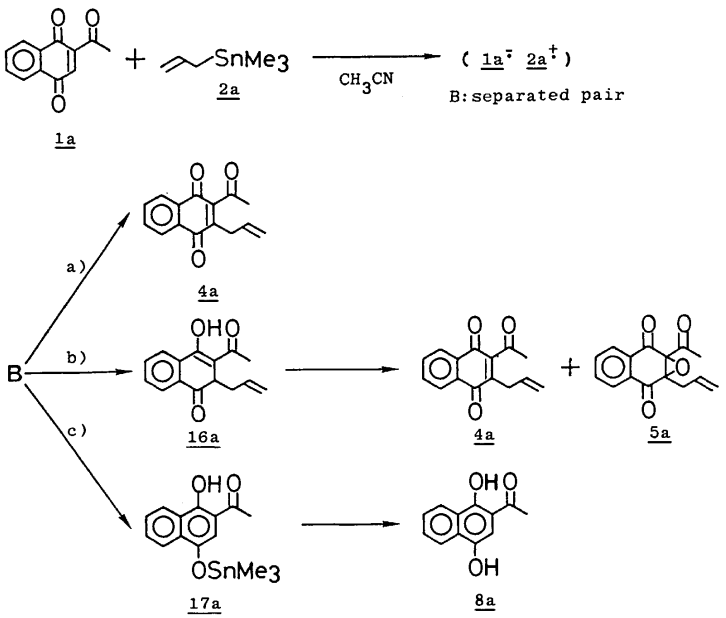


Scheme 3.

(3)

A similar ^{1}H NMR measurement in acetonitrile-d_3 was also undertaken. In this case, the color of a solution changed from yellow to green soon after mixing of **1a** with **2a**. The peak of the 3-position of **1a** broadened instantly and new peaks emerged quickly. The starting acylquinone **1a** was completely consumed within 30 min, and three products, **4a** (10%), **16a** (55%), and **17a** (17%) were observed. The cyclized products, **6a** and **15a**, involving trimethylstannyl moiety were not generated in this case. After treating the reaction mixture with silica gel, **4a** (9%), **5a** (2%), **8a** (15%), and **16a** (50%) were identified (Scheme 4).

Furthermore, we have applied Vis-UV absorption method to follow the reaction of **1a** with **2b** in benzene. Addition of **2b** to a benzene solution of **1a** resulted in a development of absorption bands corre-



Scheme 4.

sponding to each product with three isosbestic points at 328, 371, and 425 nm, which were not influenced by concentrations of two reagents (Fig. 1). These facts suggest that each product was generated via an identical intermediate. In other words, the rate determining step of the reaction seems to be the formation of the common intermediate.

Thermal Reactions of Related Acylquinones with Allylstannane. The thermal reactions of other acylquinones **1c—f** (1 mmol) with allyltrimethylstannane **2a** (2 mmol) were carried out in benzene (25 ml). By the reaction of 2-propionyl-1,4-naphthoquinone **1c** with **2a**, several kinds of product were given after purification by column chromatography on silica gel and spectroscopically identified; chromene **3c**, allyl quinone **4c**, allyl epoxy quinone **5c**, [2+3] cycloadduct **6c**, allyl hydroxy quinone **7a**, and hydroquinone **8c**. On the other hand, the thermal reactions of 2-pivaloyl-1,4-naphthoquinone **1d** and 2-acetyl-3-methyl-1,4-naphthoquinone **1e** with **2a** did not proceed at all.[15] The reaction of 2-acetyl-8-methoxy-1,4-naphthoquinone **1f**, in which electron donating methoxyl group was introduced to phenyl ring, with **2a** gave allyl quinone **4f**, [2+3] cycloadduct **6f**, and hydroquinone **8f**. The results are summarized in Scheme 5.

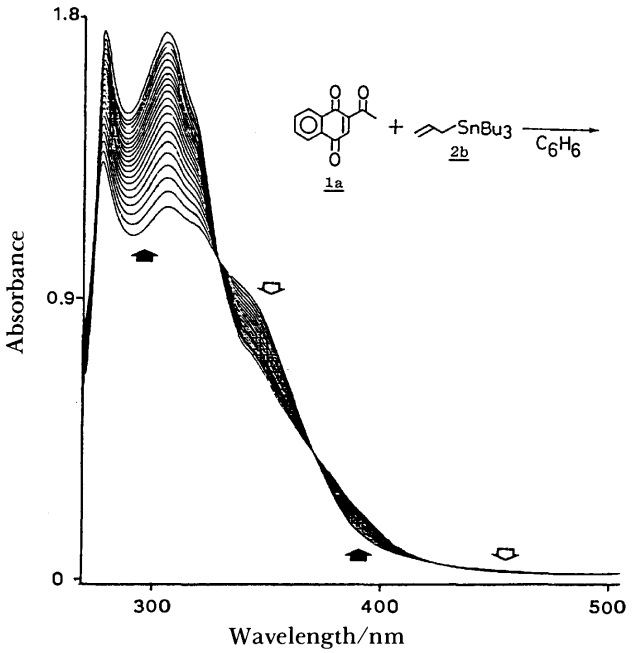


Fig. 1. Absorption spectral change observed during the reaction of **1a** with **2b** in benzene.

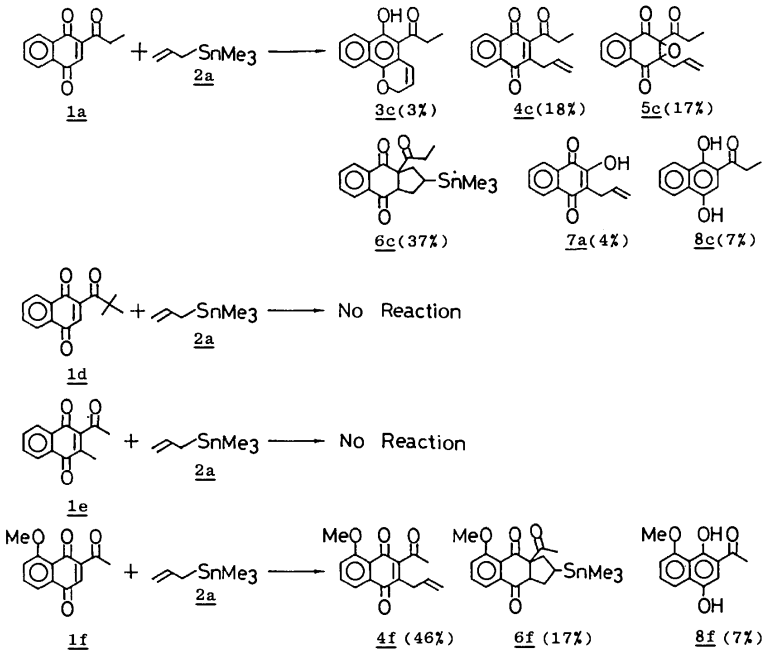
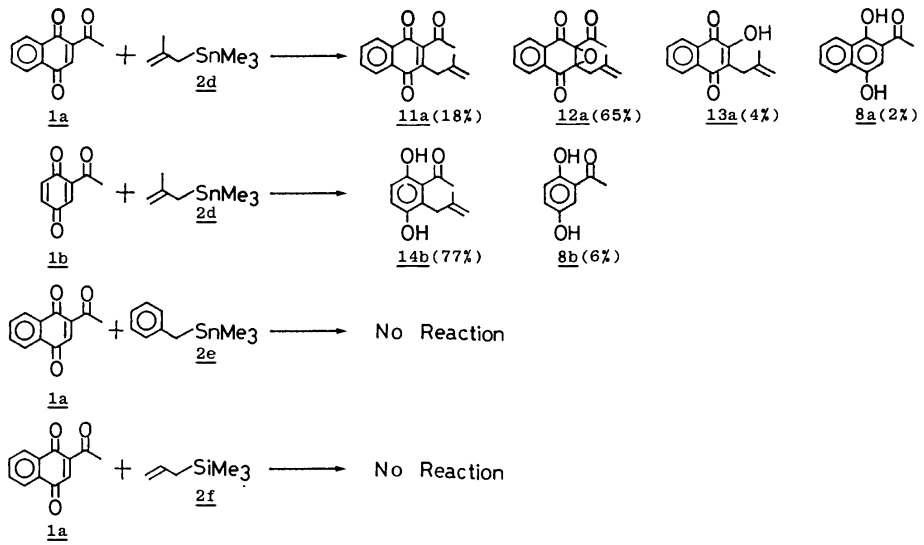
Thermal Reactions of Acetylquinones with Methallyl- or Benzylstannanes or Allylsilane. In the thermal reaction of 2-acetyl-1,4-naphthoquinone **1a** with (2-methylallyl)trimethylstannane **2d**, allylated products **11a** and **12a** were obtained as usual, but [2+3] cycloadduct like **6a** was not formed. In the thermal reaction of **1a** with benzyltrimethylstannane **2e** or with allyltrimethylsilane **2f** in benzene, no progress of reactions was recognized. The results are summarized in Scheme 6.

Discussion

The reactivity of acylquinones with allylstannanes was quite specific from two aspects: 1) thermal reaction proceeded spontaneously without activation of reactants and 2) solvent polarity strongly affected the distribution of product ratio. These characteristics seem to derive from both strong oxidizing power and resonance ability of acyl group under anionic state of acylquinones **1**, and from both mild reducing power and probable cleavage of carbon-tin bond under



Scheme 5.



Scheme 6.

cationic state of allylstannanes **2**. During these reactions, acylquinones **1** behave as electron acceptors and allylstannanes **2** behave as electron donors.

Based upon the above results, reaction pathways were proposed as given in Schemes 3 and 4. The reaction between **1a** and **2a** was selected as a representative.

In a nonpolar solvent such as benzene, polarized species are not stabilized by solvent molecules, and the charge transfer can therefore occur only in the case that two species are brought sufficiently close and the polarized two species $\mathbf{1a}^{\delta-}$ and $\mathbf{2a}^{\delta+}$ will be kept in a tightly contacted pair in solvent cage (intermediate pair **A**). In general, the 3-position of $\mathbf{1a}^-$ shows highly electrophilic reactivity toward electron rich reaction center and the negative charge is stabilized by resonance effect of acyl group. The following four pathways a—d) from tight pair **A** will be most reasonable. As for the generation of compound **6a**, since tin stabilizes its cationic β-position by hyperconjugative interaction, [2+3] cycloaddition between $\mathbf{1a}^-$ and $\mathbf{2a}^+$ will occur before C-Sn bond cleavage of $\mathbf{2a}^+$ with 1,2-migration of trimethylstannyl moiety.[16] Similarly to the path a), generation of compound **15a** will proceed by [4+2] cycloaddition before C-Sn bond cleavage of $\mathbf{2a}^+$. In this path, cationic β-carbon of $\mathbf{2a}^+$ will be trapped by resonant acetyl-carbonyl oxygen. Contrary to the cases a) and b), generation of compound **16a** will proceed by allylation of $\mathbf{1a}^-$ at the 3-position with C-Sn bond cleavage of $\mathbf{2a}^+$. The H

atom of hydroxyl group at the 1-position may be released from solvent molecules. As for the compound **17a**, escaped $\mathbf{1a}^-$ from solvent cage will abstract H atom from solvent molecules and remaining anionic oxygen atom may trap trimethylstannyl cation.

Probably, three compounds **15a**, **16a**, and **17a** convert to the corresponding isolated products during the usual working-up process such as silica-gel long column chromatography (Scheme 3). The six membered [4+2] cycloadduct **15a** generated via path b) has enol structure in its skeleton, and converts into **16a** with C-Sn bond cleavage under acidic condition followed by aromatization to 2-acetyl-3-allyl-1,4-naphthalenediol, which will be easily autoxidized to the corresponding quinone **4a** with air or remaining **1a**. Thus, both **15a** and **16a** are the precursors of **4a** and **5a**, and **17a** converts into **8a**.

On the other hand, in a polar solvent such as acetonitrile, polarized species can be stabilized by solvent molecules, and electron transfer will occur even in the case that two reactants are apart somewhat each other. From two facts that the color of the reacting solution turned from yellow to green soon after mixing the reagents and that the 3-position of **1a** broadened instantly in ^{1}H NMR examination, single electron transfer seems to occur from **2a** to **1a**, resulting in the formation of solvent separated loose radical ion pair between $\mathbf{1a}^{\cdot-}$ and $\mathbf{2a}^{\cdot+}$ (intermediate pair **B**). Owing to the high $\sigma_{C\text{-}Sn}$ bond orbital energy and to electropositive character of tin, $\mathbf{2a}^{\cdot+}$ tends to undergo rapid generation of allyl radical and trimethylstannyl cation, so C-C bond formation between $\mathbf{1a}^{\cdot-}$ and allyl radical will occur.[17] Therefore, the cyclized compounds having trimethylstannyl moiety such as **6a** and **15a** will not be obtained under these conditions. The remarkable difference between the reactivity of the reactions in benzene and that in acetonitrile should be ascribed to the difference in the activation energy of formation of the two intermediates **A** and **B**.

The results in the reactions of related acylquinones **1c—f** with **2a** in benzene provided information on steric and electronic effects for the reactivity. Thus, introduction of electron donating methoxyl group to phenyl ring or introduction of methyl group to acetyl group did not affect reactivity as a whole, that is, [2+3] cycloadducts and allylated quinones were obtained as the case of **1a**. On the other hand, introduction of *t*-butyl group as a part of acyl group (**1d**) or introduction of methyl group to the reacting 3-position (**1e**) diminished the reactivity completely. From these results, it is concluded that decreasing oxidizing power of acylquinones can not appreciably reduce the reactivity toward **2a**, but that increasing steric hindrance around the 3-position of acylquinone entirely reduces the reactivity.[18]

Thermal reactions of **1a,b** with methallylstannane **2d** in benzene afforded allylated products, but [2+3] cycloadduct such as **6a** was not obtained at all. This is due to the inductive effect of methyl group which stabilizes the intermediary cationic β-position of $\mathbf{2d}^+$ and the effect of the steric hindrance between methyl group and trimethylstannyl group. The 1,2-migration of the trimethylstannyl moiety was thus suppressed. Thermal reactions of **1a,b** with benzylstannane **2e** or allylsilane **2f** did not proceed at all, due to the lower electron donating ability of **2e** and **2f**.

Experimental

General Remarks. All melting points were determined on a Yanagimoto micro-melting point apparatus and uncorrected. Mass spectra were measured by a JEOL JMS-DX-300 mass spectrometer. ^{1}H NMR spectra were obtained by a JEOL JNM-PX-100 and a JEOL JNM-GX-400 spectrometers. ^{13}C NMR spectra were obtained by a JEOL JNM-GX-400 spectrometer. Chemical shifts were recorded as δ values in parts per million (ppm) from tetramethylsilane as an internal standard. IR spectra were obtained by a JASCO IRA-1 spectrometer for KBr pellets or neat oil on NaCl. The electronic spectra were obtained by a Shimadzu UV-3000 spectrometer. Column chromatography was done on Wakogel C-200 and Merck Kieselgel 60H for flash column chromatography. Elementary analyses were performed by the Microanalytical Laboratory of Kyoto University. Cyclic voltammetry was carried out by a PAR Model 174 with working electrodes of platinum wire.

Starting Materials. Benzene was used after distillation from sodium wire. Acetonitrile and dichloromethane were used after distillation from phosphorus pentaoxide. Benzene-d_6 and acetonitrile-d_3 were commercially available and used after distillation. 2-Acetyl-1,4-naphthoquinone **1a**, 2-acetyl-1,4-benzoquinone **1b**, 2-propionyl-1,4-naphthoquinone **1c**, 2-pivaloyl-1,4-naphthoquinone **1d**, 2-acetyl-3-methyl-1,4-naphthoquinone **1e**, and 2-acetyl-8-methoxy-1,4-naphthoquinone **1f** were synthesized by the previously reported methods.[6,19] All acylquinones were purified by recrystallization and sublimation. Allylic- and benzylstannanes **2a—e** were prepared by the reported methods.[20,21] All tin reagents were purified by distillation. Allyltrimethylsilane **2f** was commercially available and used without further purification.

General Procedures. Acylquinone (1 mmol) and allylstannane (2 mmol) were dissolved in benzene or acetonitrile (25 ml) and allowed to stand for suitable time under argon atmosphere. The reaction mixture was concentrated, subjected to column chromatography on silica gel, and eluted with hexane–ether.

Physical Properties of the Products. 5-Acetyl-2*H*-benzo[*h*]chromene-6-ol (**3a**): Yellow needles from hexane–chloroform; mp 119—123 °C. MS; *m/z* 240 (M^+). Found: C, 74.82; H, 4.82%. Calcd for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%. IR (KBr); 3300 (OH), 1600 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.63 (3H, s), 4.77 (2H, d, *J*=4 Hz), 5.8 (1H, dt, *J*=9, 4 Hz), 6.75 (1H, d, *J*=9 Hz), 7.5—7.7 (2H, m), 8.12 (1H, d, *J*=8 Hz), 8.42 (1H, d, *J*=8 Hz), 13.8 (1H, s).

5-Propionyl-2*H*-benzo[*h*]chromene-6-ol (**3c**): Yellow needles from hexane–ether; mp 69—72 °C. MS; *m/z* 254 (M^+). High resolution MS; Found: *m/z* 254.0944. Calcd for $C_{16}H_{14}O_3$: M, 254.0944. IR (KBr); 3400 (OH), 1605 (C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$); δ=1.25 (3H, t, *J*=7 Hz), 2.94 (2H,

q, J=7 Hz), 4.78 (2H, d, J=4 Hz), 5.88 (1H, dt, J=9, 4 Hz), 6.74 (1H, d, J=9 Hz), 7.5—7.7 (2H, m), 8.11 (1H, d, J=8 Hz), 8.41 (1H, d, J=8 Hz), 13.66 (1H, s).

2-Acetyl-3-allyl-1,4-naphthoquinone (**4a**): Yellow needles from hexane-chloroform; mp 57—59 °C. MS; m/z 240 (M^+). High resolution MS; Found: m/z 240.0789. Calcd for $C_{15}H_{12}O_3$: M, 240.0785. IR (KBr); 1705 (C=O), 1665 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=2.50 (3H, s), 3.28 (2H, d, J=6 Hz), 5.1—5.3 (2H, m), 5.8—6.0 (1H, m), 7.8—7.9 (2H, m), 8.1—8.3 (2H, m).

2-Propionyl-3-allyl-1,4-naphthoquinone (**4c**): Yellow oil. MS; m/z 254 (M^+). High resolution MS; Found: m/z 254.0937. Calcd for $C_{16}H_{14}O_3$: M, 254.0944. IR (neat); 1705 (C=O), 1660 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=1.20 (3H, t, J=7 Hz), 2.76 (2H, q, J=7 Hz), 3.25 (2H, d, J=7 Hz), 5.1—5.2 (2H, m), 5.8—5.9 (1H, m), 7.75—7.85 (2H, m), 8.1—8.2 (2H, m).

3-Acetyl-2-allyl-5-methoxy-1,4-naphthoquinone (**4f**): Pale yellow crystals from hexane-ether; mp 127—129 °C. MS; m/z 270 (M^+). Found: C, 70.99; H, 5.10%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%. IR (KBr); 1705(C=O), 1650 (C=O), 1630 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=2.47 (3H, s), 3.23 (2H, d, J=7 Hz), 4.01 (3H, s), 5.12 (2H, m), 5.83 (1H, m), 7.2—7.4 (1H, m), 7.6—7.8 (2H, m).

2-Acetyl-3-allyl-2,3-epoxy-2,3-dihydro-1,4-naphthoquinone (**5a**): Pale yellow needles from hexane-chloroform; mp 88—90 °C. MS; m/z 213 (M^+−43). Found: C, 70.23; H, 4.66%. Calcd for $C_{15}H_{12}O_4$: C, 70.31; H, 4.72%. IR (KBr); 1710 (C=O), 1695 (C=O), 1680 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=2.46 (3H, s), 2.49 (1H, dd, δ=7, 15 Hz), 3.00 (1H, dd, J=7, 15 Hz), 5.19 (2H, m), 5.85 (1H, m), 7.7—7.8 (2H, m), 8.0—8.1 (2H, m).

3-Allyl-2-propionyl-2,3-epoxy-2,3-dihydro-1,4-naphthoquinone (**5c**): Yellow crystals from hexane-ether; mp 53—55 °C. MS; m/z 270 (M^+). High resolution MS; Found: m/z 270.0929. Calcd for $C_{16}H_{14}O_4$: M, 270.0892. IR (neat); 1725 (C=O), 1690 (C=O), 1680 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=1.16 (3H, t, J=7 Hz), 2.5—2.9 (4H, m), 5.1 (2H, m), 5.85 (1H, m), 7.7—7.9 (2H, m), 8.0—8.1 (2H, m).

3a-Acetyl-2-trimethylstannyl-2,3,3a,4,9,9a-hexahydro-1*H*-cyclopenta[*b*]naphthalene-4,9-dione (**6a**): Pale yellow crystals from hexane-ether; mp 93—95 °C. MS; m/z 391 (M^+−15, ^{120}Sn), 389 (M^+−15, ^{118}Sn). Found: C, 53.27; H, 5.39%. Calcd for $C_{18}H_{22}O_3Sn$: C, 53.37; H, 5.47%. IR (KBr); 1705 (C=O), 1680 (C=O), 1670 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=0.06 (9H, s), 1.50 (1H, m), 1.92 (1H, t, J=13 Hz), 2.0—2.2 (5H, m), 3.07 (1H, dd, J=8, 13 Hz), 3.62 (1H, dd, J=8, 11 Hz), 7.75—7.85 (2H, m), 8.05—8.15 (2H, m). ^{13}C NMR($CDCl_3$); δ=−11.2, 20.1, 26.6, 34.2, 39.6, 53.8, 77.6, 127.0, 133.8, 134.1, 134.8, 194.5, 196.2, 202.6.

3a-Acetyl-2-trimethylstannyl-2,3,3a,4,7,7a-hexahydrindene-4,7-dione (**6b**): Yellow crystals from hexane-chloroform; mp 45—47 °C. MS; m/z 341 (M^+−15, ^{120}Sn), 339 (M^+−15, ^{118}Sn). Found: C, 47.44; H, 5.64%. Calcd for $C_{14}H_{20}O_3Sn$: C, 47.37; H, 5.68%. IR (neat); 1700 (C=O), 1680 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=0.03 (9H, s), 1.32 (1H, m), 1.83 (1H, t, J=13 Hz), 2.0—2.2 (5H, m), 2.86 (1H, dd, J=7, 12 Hz), 3.45 (1H, dd, J=6, 10 Hz), 6.63 (1H, d, J=17 Hz), 6.67 (1H, d, J=17 Hz).

3a-Propionyl-2-trimethylstannyl-2,3,3a,4,9,9a-hexahydro-1*H*-cyclopenta[*b*]naphthalene-4,9-dione (**6c**): Pale yellow needles from hexane-ether; mp 59—62 °C. MS; m/z 405 (M^+−15, ^{120}Sn), 403 (M^+−15, ^{118}Sn). Found: C, 54.72; H, 5.78%. Calcd for $C_{19}H_{24}O_3Sn$: C, 54.45; H, 5.77%. IR (KBr); 1710 (C=O), 1680 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=−0.01 (9H, s), 0.85 (3H, t, J=7 Hz), 1.41 (1H, m), 1.85 (1H, t, J=12 Hz), 2.09 (2H, t, J=10 Hz), 2.46 (2H, q, J=7 Hz), 3.01 (1H, dd, J=7, 13 Hz), 3.54 (1H, dd, J=9, 10 Hz), 7.65 (2H, m), 7.9—8.0 (2H, m).

3a-Acetyl-2-trimethylstannyl-5-methoxy-2,3,3a,4,9,9a-hexahydro-1*H*-cyclopenta[*b*]naphthalene-4,9-dione (**6f**): Pale yellow crystals from hexane-ether; mp 113—115 °C. MS; m/z 421 (M^+−15, ^{120}Sn), 419 (M^+−15, ^{118}Sn). Found: C, 52.48; H, 5.59%. Calcd for $C_{19}H_{24}O_4Sn$: C, 52.45; H, 5.56%. IR (KBr); 1695 (C=O), 1680 (C=O), 1665 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=0.06 (9H, s), 1.47 (1H, m), 1.75 (1H, t, J=13 Hz), 2.10 (1H, m), 2.16 (3H, s), 2.23 (1H, m), 3.13 (1H, dd, J=7, 13 Hz), 3.71 (1H, dd, J=7, 10 Hz), 3.93 (3H, s), 7.15—7.25 (1H, m), 7.55—7.65 (2H, m).

2-Allyl-3-hydroxy-1,4-naphthoquinone (**7a**): Yellow crystals from hexane-ether; mp 113—116 °C. MS; m/z 214 (M^+). High resolution MS; Found: m/z 214.0626. Calcd for $C_{13}H_{10}O_3$: M, 214.0629. IR (KBr); 3350 (OH), 1655 (C=O), 1640 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=3.37 (2H, d, J=7 Hz), 5.10 (2H, m), 5.91 (1H, m), 7.35 (1H, s), 7.6—7.8 (2H, m), 8.0—8.2 (2H, m).

2-Acetyl-1,4-naphthalenediol (**8a**): Yellow powders from ethanol; mp 209—210 °C. MS; m/z 202 (M^+). IR (KBr); 3280 (OH), 1600 (C=O) cm^{-1}.

2-Acetyl-1,4-benzenediol (**8b**): Yellow crystals from ethanol; mp 201—203 °C. MS; m/z 152 (M^+). IR (KBr); 3220 (OH), 1600 (C=O) cm^{-1}.

2-Propionyl-1,4-naphthalenediol (**8c**): Yellow crystals from ethanol; mp 182—184 °C. MS; m/z 216 (M^+). High resolution MS; Found: m/z 216.0786. Calcd for $C_{13}H_{12}O_3$: M, 216.0786. IR (KBr); 3360 (OH), 1625 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=1.28 (3H, t, J=7 Hz), 3.03 (2H, q, J=7 Hz), 4.96 (1H, s), 7.55—7.70 (2H, m), 8.10 (1H, d, J=8 Hz), 8.46 (1H, d, J=8 Hz), 13.70 (1H, s).

2-Acetyl-8-methoxy-1,4-naphthalenediol (**8f**): Yellow crystals from ethanol; mp 153—155 °C. MS; m/z 232 (M^+). High resolution MS; Found: m/z 232.0741. Calcd for $C_{13}H_{12}O_4$: M, 232.0736. IR (KBr); 3500 (OH), 3220 (OH), 1620 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=2.66 (3H, s), 4.06 (3H, s), 5.21 (1H, s), 6.96 (1H, d, J=7 Hz), 7.10 (1H, s), 7.56 (1H, dd, J=7, 8 Hz), 7.75 (1H, d, J=8 Hz), 13.50 (1H, s).

2-Acetyl-3-allyl-1,4-benzenediol (**9b**): Pale yellow crystals from ethanol; mp 78—80 °C. MS; m/z 192 (M^+). IR (KBr); 3400 (OH), 1670 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=2.11 (3H, s), 2.93 (2H, d, J=6 Hz), 4.33 (1H, s), 4.5—4.6 (2H, m), 5.5—5.6 (1H, m), 6.2—6.3 (2H, m), 13.80 (1H, s).

3a-Acetyl-2-tributylstannyl-2,3,3a,4,9,9a-hexahydro-1*H*-cyclopenta[*b*]naphthalene-4,9-dione (**10a**): Pale yellow needles from hexane-ether; mp 48—49 °C. MS; m/z 475 (M^+−57, ^{120}Sn), 473 (M^+−57, ^{118}Sn). Found: C, 61.28; H, 7.53%. Calcd for $C_{27}H_{40}O_3Sn$: C, 61.04; H, 7.59%. IR (KBr); 1700 (C=O), 1670 (C=O) cm^{-1}. ^1H NMR($CDCl_3$); δ=0.6—0.8 (15H, m), 1.2—1.4 (6H, m), 1.5—1.6 (7H, m), 1.92 (1H, t, J=13 Hz), 2.1—2.3 (5H, m), 3.12 (1H, dd, J=8, 13 Hz), 3.66 (1H, dd, J=8, 10 Hz), 7.75—7.85 (2H, m), 8.05—8.15 (2H, m). ^{13}C NMR($CDCl_3$); δ=8.2, 13.5, 19.8, 26.5, 27.2, 29.0, 34.5, 40.0, 53.8, 77.7, 127.0, 127.1, 133.7, 134.1, 134.7, 194.3, 196.0, 202.5.

3a-Acetyl-2-tributylstannyl-2,3,3a,4,7,7a-hexahydrindene-4,7-dione (**10b**): Yellow oil. MS; m/z 483 ($M+H^+$, ^{120}Sn), 481 ($M+H^+$, ^{118}Sn). Found: C, 57.12; H, 8.15%. Calcd for

$C_{23}H_{38}O_3Sn$: C, 57.40; H, 7.96%. IR (neat); 1700 (C=O), 1680 (C=O) cm^{-1}. ^1H NMR ($CDCl_3$); δ=0.7—0.9 (15H, m), 1.2—1.4 (6H, m), 1.5—1.6 (7H, m), 1.83 (1H, t, J=13 Hz), 2.1—2.3 (5H, m), 2.86 (1H, dd, J=7, 12 Hz), 3.45 (1H, dd, J=6, 10 Hz), 6.7 (2H, m).

2-Acetyl-3-(2-methylallyl)-1,4-naphthoquinone (**11a**): Yellow needles from hexane-ether; mp 53—55 °C. MS; m/z 254 (M^+). High resolution MS; Found: m/z 254.0948. ^1H NMR Measurements. 2-Acetyl-1,4-naphthoquinone **1a** (0.03 mmol) and allyltrimethylstannane **2a** (0.04 mmol) were dissolved in benzene-d_6 (0.5 ml) and allowed to stand for 24 h under argon atmosphere in an NMR sample tube. The ^1H NMR measurements were carried out several times during the reaction. Then, the reaction mixture was poured into silica-gel short column, and all fractions were concentrated, dissolved in benzene-d_6, and measured again.

^1H NMR Spectral Data of Products in Benzene-d_6. Compound **15a** (diastereomer A): δ=1.12 (9H, s), 0.93 (1H, dd, J=7, 12 Hz), 0.97 (1H, dd, J=9, 12 Hz), 2.05 (1H, m), 2.26 (1H, m), 2.42 (3H, d, J=2 Hz), 3.13 (1H, ddq, J=6, 11, 2 Hz), 3.74 (1H, m), 7.0—7.2 (2H, m), 8.03 (1H, d, J=7 Hz), 8.44 (1H, d, J=7 Hz).

Compound **15a** (diastereomer B): δ=1.13 (9H, s), 0.90—0.95 (2H, m), 2.44 (3H, d, J=2 Hz), 3.8 (1H, m). Other peaks overlapped and were unable to be analyzed. The ratio A/B was estimated to be 6/1 from integral values of each peak at δ=2.42 and 2.44. Compound **15a** was not isolated.

Compound **16a**: δ=1.66 (3H, s), 2.00 (1H, m), 2.20 (1H, m), 3.25 (1H, dd, J=5, 7 Hz), 4.6—4.7 (2H, m), 5.3—5.4 (1H, m), 7.0—7.2 (2H, m), 7.84 (1H, d, J=8 Hz), 7.96 (1H, d, J=8 Hz).

Compound **17a**: δ=0.24 (9H, s), 2.25 (3H, s), 6.67 (1H, s), 6.9—7.1 (2H, m), 7.95 (1H, d, J=7 Hz), 8.38 (1H, d, J=7 Hz).

Compound **4a**: δ=2.15 (3H, s), 3.14 (2H, d, J=7 Hz), 4.9—5.1 (2H, m), 5.7—5.9 (1H, m), 7.0—7.1 (2H, m), 7.8—7.9 (2H, m).

Compound **5a**: δ=2.09 (3H, s), 2.41 (1H, dd, J=7, 15 Hz), 2.88 (1H, dd, J=7, 15 Hz), 4.9—5.0 (2H, m), 5.8—5.9 (1H, m), 6.9—7.0 (2H, m), 7.7—7.8 (2H, m).

Compound **6a**: δ=−0.03 (9H, s), 1.26 (1H, m), 1.8—2.1 (6H, m), 2.89 (1H, dd, J=8, 13 Hz), 3.64 (1H, dd, J=8, 10 Hz), 7.0—7.1 (2H, m), 8.02 (1H, d, J=7 Hz), 8.15 (1H, d, J=7 Hz).

Compound **8a**: δ=0.95 (1H, s), 2.25 (3H, s), 6.18 (1H, s), 7.2—7.4 (2H, m), 8.21 (1H, d, J=8 Hz), 8.68 (1H, d, J=8 Hz).

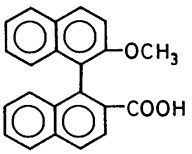
(Received July 28, 1989)

Axially chiral 2′-methoxy-1,1′-binaphthyl-2-carboxylic acid (**1**) was effectively utilized as chiral derivatizing agent for discrimination of enantiomeric alcohols and amines by ^{1}H NMR with the aid of Eu(fod)$_3$. Among a pair of the diastereomeric esters or amides prepared from (a*S*)-**1** and an α-chiral alcohol or amine, the methoxyl protons of the (a*S*,*R*)-diastereomer showed the larger lanthanoid-induced downfield shift than those of the (a*S*,*S*)-counterpart. Thus, addition of up to 0.5—1.0 equiv amount of Eu(fod)$_3$ caused base-line separation of those protons, allowing determination of the enantiomeric purities and assignment of the absolute configurations of the enantiomeric alcohols and amines. An X-ray crystallographic analysis of the amide ((a*S*,*S*)-**2**) obtained from (a*S*)-**1** and (*S*)-1-phenylethylamine showed structural resemblance between the amides and esters of **1**. Steric models which explain the NMR behavior of the diastereomeric esters and amides are presented based on X-ray analyses. Also reported are two methods to regenerate free acid **1** from amide **2** to afford axially homochiral **1**.

Recently a variety of chiral derivatizing agents have been developed for determination of absolute configurations and enantiomeric purities of optically active compounds,[1] among which Mosher's α-methoxy-α-trifluoromethylphenylacetic acid (MTPA) has been most widely used for discrimination by NMR.[2] In our previous paper[3] we have reported the optical resolution of 2′-methoxy-1,1′-binaphthyl-2-carboxylic

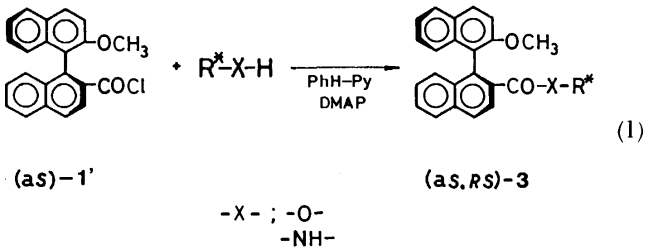


1

acid (**1**) and the use of atropisomeric **1** as highly efficient chiral derivatizing agent for differentiation of enantiomeric alcohols and amines by high-performance liquid chromatography (HPLC). In our continuing efforts to extend the scope and the utility of **1** as a chirality-recognizing element, we have studied ^{1}H NMR behavior of the diastereomeric esters and amides of **1**. Herein we wish to report that the methoxyl group serves as a chiral probe, as the MeO protons of a pair of the diastereomeric esters or amides were nicely separated at 60 MHz by addition of up to 0.5 to 1.0 equiv amount of Eu(fod)$_3$ (tris(6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedionato)europium). Also reported are alternative procedures for optical resolution of **1** by fractional crystallization of the diastereomeric *N*-(1-phenylethyl)amides (**2**).

Results and Discussion

^{1}H NMR Study of the Diastereomeric Esters and Amides of (a*S*)-1.[4] The preparation of the samples of



(1)

diastereomeric esters or amides of (a*S*)-**1** from partially active alcohols or amines has been reported in the previous paper unless otherwise noted (Eq. 1).[3] NMR measurements of those samples showed that the shift differences of respective ^{1}H absorptions of a pair of the diastereomers were not always large enough to enable quantitative analysis at 60 MHz (Table 1). However, it was found that the lanthanoid-induced downfield shifts of the MeO signals of the (a*S*,*R*)-diastereomers were consistently larger than those of the corresponding (a*S*,*S*)-isomers, causing base-line separation of those signals by addition of up to 0.5 to 1 equiv amount of Eu(fod)$_3$. Results summarized in Table 1 show that axially chiral **1** is useful as chiral derivatizing agent for discrimination of enantiomeric alcohols and amines not only by HPLC but also by ^{1}H NMR. A potential problem of kinetic resolution by use of **1** has been discussed in the previous paper.[3] Emphasis should be placed on the discrimination of the amide diastereomers (vide infra). As a typical example, Fig. 1 shows the induced shift of the MeO signals of *N*-[(*R*)- and (*S*)-1-methylhexyl]amide of (a*S*)-**1** ((a*S*,*R*)- and (a*S*,*S*)-**4**)) by successive addition of Eu(fod)$_3$. It should be noted that addition of Eu(fod)$_3$ did not apparently cause collapse of the MeO signals; although the lanthanoid-induced shift (LIS) method

a) Measured in C_6D_6 using TMS as internal standard at 60 MHz.

has been successfully applied to diastereomeric MTPA esters for discrimination of a wide range of alcohols,[2,5)] it has rarely been used for MTPA amides because of the broadening of the signals by addition of Eu(fod)$_3$.[6)] Table 1 also contains the examples of the discrimination of β-chiral amines[7)] (Runs 18—20).

X-Ray Crystallographic Analysis of (a*S*,*S*)-2. Figure 2 shows an ORTEP drawing of (a*S*,*S*)-**2**. It was shown that the dihedral angle θ between the two naphthalene rings is 97.5°, and that the -CO-NH-CH- atoms are almost on a same plane, the -CO-NH- linkage being *s*-trans conformation and the dihedral angle ϕ of C_1-C_2-C=O being 52.6° as schematically depicted in Fig. 3. The structure is similar to that of (−)-menthyl ester of (a*S*)-**1** except that the plane which contains the ester linkage -CO-O-CH- is almost on the same plane of the relevant naphthalene ring (ϕ=0—10°).[3)] In case of the amide, the deviation of the dihedral angle ϕ from coplanarity with the naphthalene ring seems to be caused by the steric repulsion between the amide proton and the other naphthalene ring (Fig. 3). In any event, these X-ray analyses suggest the structural resemblance between the amides and the esters derived from axially chiral **1**.

Configuration Correlation Models to Explain the Lanthanoid-Induced Shifts. The lanthanoid-induced shifts of the diastereomeric MTPA esters have been rationalized in terms of the steric interactions for the

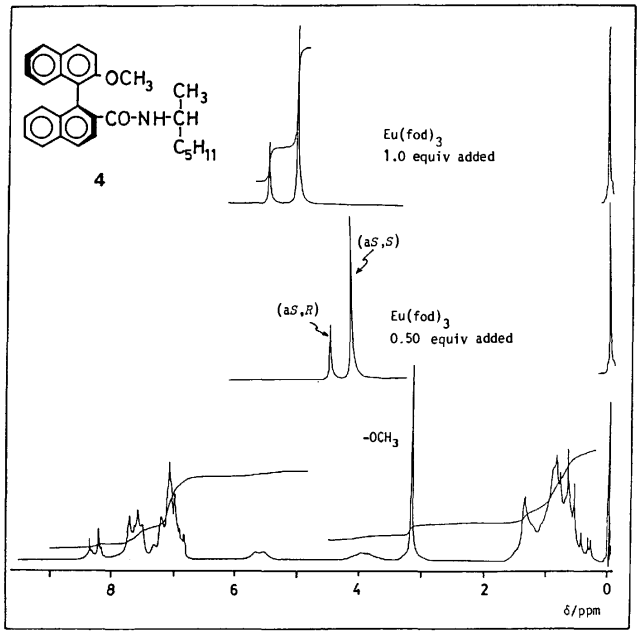

Fig. 1. ^{1}H NMR spectra of a pair of the diastereomeric amides prepared from (*S*)-2-heptanamine (50% ee) and (a*S*)-**1** in the presence or absence of Eu(fod)$_3$.

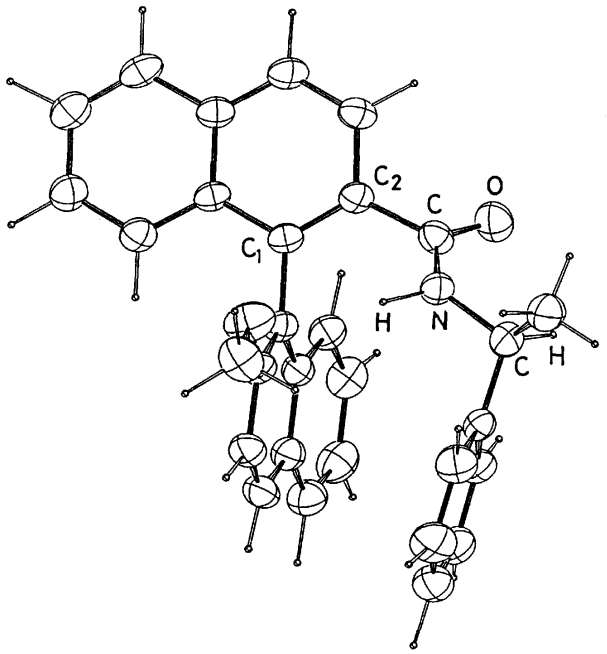

Fig. 2. ORTEP drawing of (a*S*,*S*)-**2**.

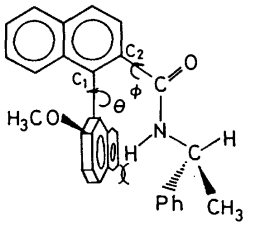

Fig. 3. Schematic view of crystal structure of (a*S*,*S*)-**2**.

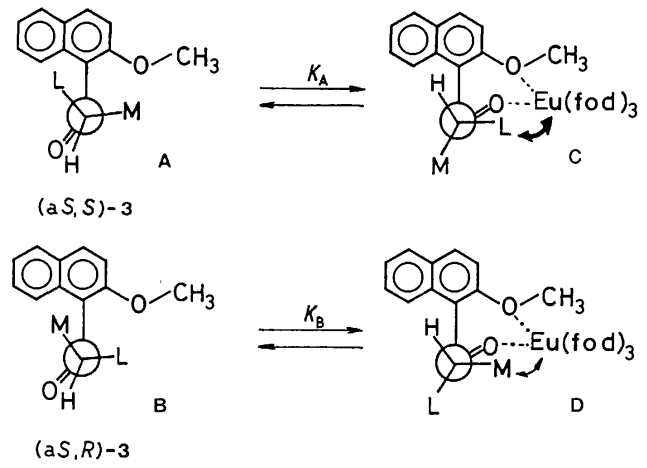
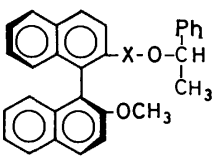


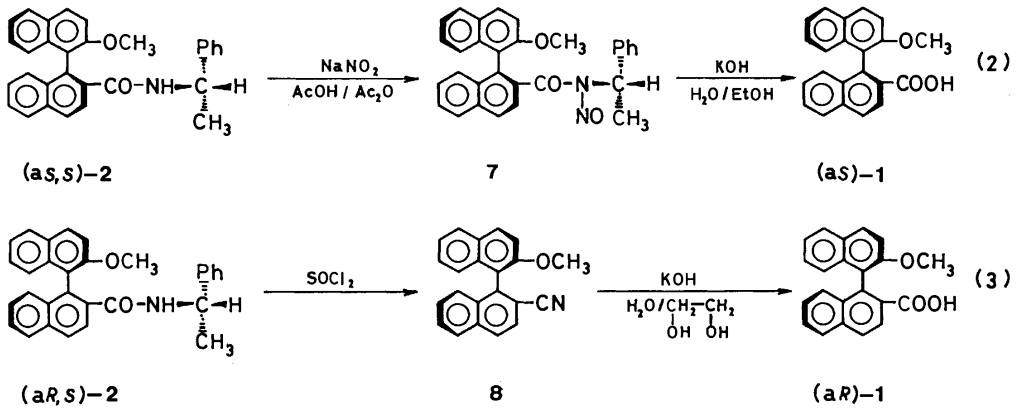
Scheme 1.

complex formation between the esters and Eu(fod)$_3$.[2,5] Application of the models with slight modifications to the diastereomers of α-chiral esters and amides of **1** (**3**) also explains the shift behavior listed in Table 1 (Scheme 1): On the basis that preferred conformations of these diastereomers in solutions are deducible from the X-ray crystallographic analyses as suggested in the previous paper,[3] the conformations of (a*S*,*S*)- and (a*S*,*R*)-**3** are schematically depicted as structures **A** and **B**, respectively, where L and M stand for the largest and the medium substituent on the carbinyl (C-1) carbon of the original alcohol or amine. Structures **C** and **D** represent empirical models of the complexes of **3** with Eu(fod)$_3$, where the esters or amides coordinate to Eu(fod)$_3$ by virtue of the two oxygen atoms from the methoxyl and carbonyl group of the (a*S*)-2′-methoxy-1,1′-binaphthylcarboxylic acid moiety. In the complex **C**, the largest ligand L is arrayed toward the Eu-metal, while in the complex **D** the medium ligand M directs toward the metal-center posing less steric repulsions. Thus, the complexation constant K_A for the formation of **C** may be smaller than that (K_B) for the formation of **D**, inducing the larger downfield shifts of the MeO signals for the (a*S*,*R*)-**3** complexes as are observed. The reasoning could not be applied to 1-methoxy-3-phenyl-2-propanamine (Run 17); the steric bulk of methoxymethyl group is seemingly smaller than that of benzyl group, which does not agree with the priority order of the two groups by the *R* and *S* designation. However, this exceptional behavior of the amine may be



(a*S*,*RS*)-**5** ; -X- = -CO-

(a*S*,*RS*)-**6** ; -X- = -CH$_2$-



explained by assuming that the 1-methoxyl group of the (a*S*,*S*)-amide effectively competes with the binaphthyl 2′-methoxyl group for the coordination site of Eu (**C**; L=CH_2OMe), thus reducing the magnitude of the lanthanoid-induced shift of the latter MeO protons.

To demonstrate the importance of the coordination to Eu(fod)$_3$ by the carbonyl oxygen as well as the 2′-methoxyl oxygen, the shift behavior of ester diastereomers **5** was compared with that of the ether counterparts **6**. As Table 1 shows, methoxyl groups of diastereomeric **5** are good probes for discrimination of the 1-phenylethyl moiety with the aid of Eu(fod)$_3$. On the other hand, the magnitude of the induced shifts of the MeO protons of (a*S*,*S*)- and (a*S*,*R*)-**6** were not only small but also almost identical on addition of up to 2 equiv amounts of Eu(fod)$_3$ (see Experimental).

Optical Resolution of 1 via *N*-(1-Phenylethyl)-amides. Racemic **1** was converted into the acid chloride (**1′**), which was then treated with (*S*)-1-phenylethylamine to give the mixture of diastereomeric amides ((a*S*,*S*)- and (a*R*,*S*)-**2**)) in quantitative yield. The mixture was crystallized twice from hexane-ethyl acetate to give diastereomerically pure (a*S*,*S*)-**2** as fine cubic crystals in a 55% yield based on one enantiomer present in the racemate; suitable one of the crystals was used for X-ray analysis (vide supra). Subsequent column chromatography of the mother liquor readily afforded (a*R*,*S*)-**2** of 100% diastereomeric excess (de) in a 63% yield as the first eluting component.

The amide bond of **2** was highly resistant to acidic or alkaline hydrolysis,[8] but regeneration of the axially chiral acids was achieved by either of the two routes without racemization. These are, 1) nitrosation to *N*-nitroso amide **7** followed by alkaline hydrolysis (Eq. 2),[9] and 2) conversion into nitrile **8** by treatment with thionyl chloride (the von Brawn reaction)[10] followed by alkaline hydrolysis (Eq. 3).[11] Although **1** can be resolved by column-chromatographic separation of the diastereomeric esters,[3] it should be pointed out that the amide routes disclosed here enable treatment of a larger amount of the diastereomeric mixture because of the crystallization out of one of the diastereomers and better separability of the amides on silica-gel column than that of the ester diastereomers.[12]

Experimental

Instruments and materials were those disclosed previously unless otherwise noted.[3] Partially active (*R*)-2-phenyl-1-propanamine was prepared by referring to a literature procedure;[13] IR (KBr) 3500—3300 (br) and 900—800 (br); $[\alpha]_D$ +8.0° (*c* 1.38, EtOH) (lit,[14] $[\alpha]_D$ max +34.0° (*c* 1.0, EtOH)). Commercial (*S*)-3-(aminomethyl)pinane (HCl salt) and (*S*)-2-ethyl-1-hexanamine (HCl salt) were allowed to react with partially active (a*S*)-**1′** (ca. 50% ee) as before[3] to prepare diastereomeric amide samples for ^{1}H NMR measurements.

NMR Shift Studies. Discrimination of 2-heptanamine enantiomers is representative. Partially active (*S*)-2-heptanamine (prepared to be ca. 50% ee by mixing (*S*)-isomer with the racemate) was treated with (a*S*)-**1′** as before to give a mixture of the diastereomeric amides ((a*S*,*S*)- and (a*S*,*R*)-**4**).[3] A part of the sample (15 mg, 0.035 mmol) was dissolved in ca. 0.40 ml of C_6D_6. ^{1}H NMR spectra of the sample were taken with successive addition of 1 M† solution of Eu(fod)$_3$ in C_6D_6, and the magnitudes of the induced shift of MeO signals were recorded (Fig. 1). The further shifted, smaller MeO signal was readily assigned to (a*S*,*R*)-**4** by comparing the peak areas, and the diasteromeric composition was calculated to be 49.7% de by integrating those MeO signals.

Preparation of (a*S*,*RS*)-6 and Its Shift Study. Diastereomerically pure (−)-menthyl ester of (a*S*)-**1**[3] (0.17 g, 0.36 mmol) was boiled with $LiAlH_4$ (0.30 g) in ether (10 ml) for 3 h. The reaction was worked up as usual, and TLC on silica gel/$CHCl_3$ gave 92 mg of (a*S*)-2-hydroxymethyl-2′-methoxy-1,1′-binaphthyl (**9**) (81%); $[\alpha]_D^{23}$ +75.0° (*c* 1.09, $CHCl_3$) (lit,[15] for (a*R*)-isomer of 96% ee, $[\alpha]_D$−71.4° (*c* 0.15, $CHCl_3$)). To a solution of **9** (90 mg, 0.29 mmol) in acetic acid (15 ml) was added dropwise 0.80 ml of 48% HBr at 80 °C for 30 min, and the mixture was stirred at this temperature for another 30 min. The mixture was diluted with 70 ml of water, and treated as usual. Volatiles were removed in vacuo to give (a*S*)-2-bromomethyl-2′-methoxy-1,1′-binaphthyl (104 mg, 94%), which was dissolved in DMF (5 ml). This was added dropwise to a solution of sodium (*S*)-1-phenylethoxide in 5 ml of DMF (prepared from (*S*)-1-phenylethanol of ca. 30% ee (35 mg, 0.29 mmol) and NaH). The mixture was stirred overnight at ambient temperature,

† 1 M=1 mol dm^{-3}.

and then heated at 80 °C for 10 h. After a usual work-up, (a*S*,*RS*)-**6** enriched in (a*S*,*S*)-isomer was obtained by TLC on silica gel/$CHCl_3$ (70 mg, 61%); ^1H NMR δ=1.20 and 1.25 (3H, d, J=6.9 Hz, C-CH_3), 3.04 and 3.12 (3H, s, O-CH_3), 3.8—4.6 (3H, m, CH and CH_2), and 6.8—8.2 (17H, m, Ar-H).

The methoxyl protons of (a*S*,*R*)-**6** which appeared at δ 3.04 shifted to δ 3.12 and 3.17 on addition of 1 and 2 equiv amounts of Eu(fod)$_3$, respectively. On the other hand, those of (a*S*,*S*)-**6** which appeared at δ 3.12 shifted to δ 3.20 and 3.24 on addition of 1 and 2 equiv Eu(fod)$_3$, respectively.

Preparation and Resolution of 2. To a stirred solution of (*S*)-1-phenylethylamine (12.9 g, 107 mmol) and 4-dimethylaminopyridine (1.25 g) in benzene (250 ml) was added dropwise a solution of acid chloride **1′** (prepared from 16.7 g of (±)-**1** (50.9 mmol)) in benzene (250 ml) under a nitrogen atmosphere at ambient temperature. The mixture was stirred at this temperature for 5 h, and then heated at 60 °C for 3 h. The reaction mixture was diluted with benzene, washed successively with 2 M HCl, 1 M Na_2CO_3, and water, and dried over Na_2SO_4. Evaporation of volatiles under reduced pressure gave 22.8 g of a crude mixture of the diastereomeric amides (104%). HPLC of the mixture on a silica-gel column eluting with hexane-2-propanol (3%) showed two peaks of (a*S*,*R*)- and (a*S*,*S*)-**2** in the ratio of 50.06:49.94 (by absorptions at 254 nm) in the order of increasing retention volume. The mixture was crystallized from hexane-ethyl acetate (8/5) to give 7.85 g of (a*S*,*S*)-**2** of 93% de, and recrystallization of which from the same solvent system afforded 6.08 g of diastereomerically pure (a*S*,*S*)-**2** (55% based on one of the enantiomers of **1**). Concentration of the recrystallization mother liquor gave additional 1.09 g of (a*S*,*S*)-**2** (98.4% de) as crystals, and 0.50 g of (a*S*,*S*)-**2** of 0.8% de was recovered from the filtrate.

The mother liquor of the initial crystallization was concentrated and subjected to column chromatography on silica gel (825 g) eluting with hexane-ethyl acetate with varing the composition of the eluent from 5/1 to 5/3, to give five fractions as follows: (1) 6.86 g (63% yield), (a*R*,*S*), 100% de; (2) 1.32 g, (a*R*,*S*), 86.0% de; (3) 2.16 g, (a*S*,*S*), 12.6% de; (4) 1.24 g, (a*S*,*S*), 65.4% de; (5) 0.14 g, (a*S*,*S*), 93.4% de. Total recovery of optically active **2** amounted to 89% yield based on the starting (±)-**1**.

(a*S*,*S*)-2: mp 161—163 °C; $[\alpha]_D^{23}$ +72.7° (c 1.0, $CHCl_3$); IR (KBr) 3475, 1642, 1510, and 1246 cm^{-1}; ^1H NMR (C_6D_6, TMS) δ=0.89 (3H, d, J=6.7 Hz, CH_3), 3.12 (3H, s, OCH_3), 4.8—5.2 (1H, m, CH), 6.2—6.5 (1H, br, NH), and 6.5—8.4 (12H, m, Ar-H).

(a*R*,*S*)-2: mp 61—65 °C; $[\alpha]_D^{23}$+122.4° (c 1.0, $CHCl_3$); IR (KBr) 3395, 1654, 1505, and 1247 cm^{-1}; ^1H NMR (C_6D_6, TMS) δ=0.67 (3H, d, J=6.7 Hz, CH_3), 3.04 (3H, s, OCH_3), 4.7—5.3 (1H, m, CH), 5.9—6.4 (1H, br, NH), and 6.5—8.4 (12H, m, Ar-H).

Regeneration of 1 from 2. Typical examples are as follows.

Method A: To a stirred mixture of 5.87 g of (a*S*,*S*)-**2** (13.6 mmol) in acetic acid (13.6 ml) and acetic anhydride (68.0 ml) was added portionwise 24.4 g of $NaNO_2$ (0.299 mol) over 5 h at 0 °C, followed by stirring for another 5 h at this temperature. After the mixture was allowed to stand for 20 h at ambient temperature, it was heated at 40 °C for 4 h. The mixture was diluted with water (150 ml), extracted with portions of ether. The combined organic layers were washed with 5% aq Na_2CO_3 and then with water, and dried over Na_2SO_4. Evaporation of volatiles in vacuo left *N*-nitroso amide **7** (5.5 g), which was directly boiled for 3 h in a solution of KOH (30 g) in ethanol (300 ml) and water (30 ml). The mixture was diluted with 0.5 M NaOH (1 dm^{-3}) and extracted with portions of ether. The aqueous layer was made acidic by addition of concd HCl, and precipitated solid was taken into ether and worked up as usual to give 3.40 g of (a*S*)-**1** (76%): $[\alpha]_D^{23}$ −24.6° (c 1.05, THF) (lit,[16] $[\alpha]_D^{25}$ −25.98° (c 1.22, THF)); IR (KBr) 3045 (br), 1685, and 1260 cm^{-1}; ^1H NMR (DMSO-d_6, TMS) δ=3.60 (3H, s, OCH_3), 6.5—8.2 (12H, m, Ar-H), and 12.2 (1H, br, COOH). The sample was more than 99.5% ee as evidenced by HPLC on Pirkle column as methyl ester eluting with hexane-2-propanol (2%).

Method B: A sample of 670 mg of (a*R*,*S*)-**2** (1.55 mmol, >99.5% de) was boiled in ca. 5 ml of thionyl chloride for 3 h. After careful evaporation of excess thionyl chloride, the residue was diluted with ether, washed successively with 2 M NaOH, 2M HCl, and then water, and dried over Na_2SO_4. Trap-to-trap distillation gave a small amount of (*R*)-1-phenylethyl chloride, $[\alpha]_D^{23}$ +1.6° (c 6.84, $CHCl_3$), leaving 2-cyano-2′-methoxy-1,1′-binaphthyl **8** as the residue, IR (KBr) 2300 cm^{-1}. The residue was boiled for 6 h in a solution of KOH (10 g) in 45 ml of a 8:1 mixture of ethylene glycol and water. After the reaction, the mixture was diluted with water and extracted with ether. The aqueous phase was made acidic by addition of concd H_2SO_4. White precipitate was extracted with ether and worked up as usual to give 0.34 g of (a*R*)-**1** (67%), IR (KBr) 1685 cm^{-1}, which was enantiomerically pure as evidenced by HPLC on Pirkle column as above.

Crystal Structure Determination of (a*S*,*S*)-2. A colorless crystal of (a*S*,*S*)-**2** with the dimensions of 0.10×0.20×0.25 mm was used for the data collection on a Rigaku-Denki automated four-circle diffractometer (Rigaku AFC-5R), equipped with a rotating anode (40 kV, 200 mA), using graphite monochromated Cu $K\alpha$ radiation (λ=1.5418 Å). Crystal data are as follows: M.F.=$C_{30}H_{25}NO_2$, M.W.=431.5, orthorhombic space group $P2_12_12_1$, a=10.119(1), b=24.581(3), c=9.250(1) Å, V=2300.8(5) Å^3, Z=4, D_{calcd}=1.25 g cm^{-3}, μ(Cu $K\alpha$)=5.724 cm^{-1}. A total of 1921 reflections within 2θ=126° were collected by the θ-2θ scan mode at a 2θ scan rate of 4° min^{-1}. The structure was solved by the direct method using RANTAN81 program with some modifications.[17] After the block-diagonal least-squares refinement for non-hydrogen atoms with anisotropic temperature factors, hydrogen atoms were almost located from the difference Fourier map, some methyl hydrogen atoms were calculated, and then included in the refinement with isotropic temperature factors. The final R factor was 0.060 (R_w=0.064) for 1781 reflections with $|F_o|>3\sigma(|F_o|)$.

The atomic scattering factors from the International Tables for X-ray Crystallography[18] were used. All the computations were carried out by a ACOS 2000 computer using the applied library program of UNICS III system.[19]

Tables of final atomic coordinates, temperature factors, bond lengths and bond angles, and the F_o—F_c structure factors are kept at the Chemical Society of Japan (Document No.8907).

The authors wish to express their deep gratitude to Professor Emeritus Harukichi Hashimoto, Tohoku

University, and Professor Shozo Yamaguchi, Tohoku Gakuin University, for their encouragement and helpful suggestions throughout this study. This work was partially supported by the Asahi Glass Foundation for Industrial Technology, and a Grant-in-Aid for Scientific Research (No. 62550539) from the Ministry of Education, Science and Culture.

Stereoselective Synthesis of Conjugated 2,4-Alkadienoates via the Palladium-Catalyzed Cross-Coupling of 1-Alkenylboronates with 3-Bromo-2-alkenoates

Teiji YANAGI, Takayuki OH-E, Norio MIYAURA, and Akira SUZUKI*
Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received July 28, 1989)

(2*E*,4*E*)-, (2*Z*,4*E*)-, and (2*E*,4*Z*)-2,4-Alkadienoates can be synthesized in high yields by the cross-coupling of ethyl (*E*)-3-bromoacrylate, methyl (*E*)-3-bromo-2-methylpropenoate, ethyl (*Z*)-3-bromocrotonate,1-bromo-2-(ethoxycarbonyl)cyclohexene, and 4-bromocoumarin with 2-[(*E*)-1-alkenyl]-1,3,2-benzodioxaboroles or diisopropyl (*Z*)-1-hexenylboronate in the presence of 3 mol% of $Pd(OAc)_2$, 6 mol% of PPh_3, and 2 equivalents of Na_2CO_3 or K_2CO_3 in alcoholic solvents while retaining the original configuration of the double bonds in β-bromo esters and 1-alkenylboronates. Although the coupling reaction with 1-hexenylboronate with (*Z*)-3-bromoacrylate gave a mixture of ethyl (2*Z*,4*E*)- and (2*E*,4*E*)-nonadienoates in a ratio of 63 : 37, it was found that the use of bis(diphenylphosphino)ferrocene as a ligand of palladium brought about the stereoselective coupling under mild conditions.

2,4-Alkadienoic acid esters are versatile intermediates for a variety of chemical reactions such as Diels-Alder, and are also frequently found in skeletons of natural products. The Wittig or Horner olefin synthesis[1a] provides the most general and flexible approach for the synthesis of stereoisomers of these esters. Conjugated addition of vinylcopper reagents to acetylenic esters also gives a particularly facile route to stereodefined 2,4-dienoates.[1b,c] Although such methods have their own excellence, the scope of these reactions has still been limited to the synthesis of one or two stereoisomers among four, or they have often suffered the disadvantage that an accurate estimate of the stereochemical course of reaction is difficult. Recently, we have reported[2] a stereoselective synthesis of alkadienes and trienes by the palladium-catalyzed cross-coupling reaction of 1-alkenylboronates with 1-halo-1-alkenes. Synthesis of conjugated dienones[3] by the reaction of 1-alkenylboronates with 3-halo-2-alken-1-ones was also demonstrated. In this paper, we describe the development of the reaction for the synthesis of stereodefined 2,4-alkadienoates (**5**, **8**, and **11**)[4] as shown in Eqs. 2—4.

1 2 3

4 5

The cross-coupling reaction of 1-alkenylboron compounds with organic halides proceeds in the presence of a suitable base and palladium catalyst. The organic halides with electron-withdrawing groups such as 3-bromoacrylate are highly susceptible to SN2 displacement at the bromine position with base or saponification of the ester group. For example, the reaction of 2-(1-hexenyl)-1,3,2-benzodioxaborole with 3-bromoacrylate in the presence of 3 mol% of $Pd(PPh_3)_4$ and 2 equivalents of sodium ethoxide, such reaction conditions of which are employed in most cases of the coupling reaction[2] of 1-alkenylborates, lead to extremely fast formation of 3-ethoxyacrylate without any formation of the desired coupling product. Thus, the conditions used for usual haloalkenes can not be applicable for such substrates. Although relatively strong bases such as NaOH or NaOR were required for the coupling of 1-alkenylborates with unfunctionalized haloalkenes, we found that Na_2CO_3 or K_2CO_3 suspended in an alcoholic solvent was effective for the reaction with 3-bromoacrylate. A combination of palladium(II) acetate and two equivalents of triphenylphosphine was recognized to be more effective than $Pd(PPh_3)_4$ commonly used. Thus, we used the conditions using $Pd(OAc)_2$ (3 mol%), PPh_3 (6 mol%), and Na_2CO_3 or K_2CO_3 (2 equivalents) in refluxing methanol or ethanol as a general procedure for the present reaction. The representative results are summarized in Table 1.

(*E*)-1-Alkenylboronates can be most conveniently prepared by hydroboration[5] of alkynes with catecholborane (1,3,2-benzodioxaborole) (Eq. 1). 2-[(*E*)-1-Alkenyl]-1,3,2-benzodioxaboroles derived from terminal and internal alkynes gave 2,4-alkadienoates in good yields by the reaction with (*E*)-3-bromoacrylate, their methylated derivatives, or cyclic α,β- unsaturated β-bromo esters. The dienoates thus obtained were indicated to be (2*E*,4*E*)-isomers by ^1H NMR and GLC analysis, and their isomeric purity is 99% in each case.

We previously reported[2a] that (*Z*)-1-alkenylboronates couple with 1-halo-1-alkenes preserving their *Z*-configuration. (*Z*)-1-Alkenylboronates[6] are readily prepared by the hydroboration of 1-bromo-1-alkynes with dibromoborane-dimethyl sulfide, followed by the reaction with 2-propanol and then with

Table 1. Synthesis of 2,4-Alkadienoate

Run	1-Alkenylboronate (3)		Haloester	Conditions[a]	Product	Yield/%[b]
	R^1=	R^2=				
1	C_6H_{13}	H		A		89(>99)
2	$Cl(CH_2)_4$-	H		A		71(>99)
3	C_2H_5	C_2H_5		A		88(>99)
4	C_4H_9	H		B		73(>95)
5	C_4H_9	H		C		53(>99)
6	C_4H_9	H		C		88(>(99)
7				C		43(>98)
8				D		95(>98)

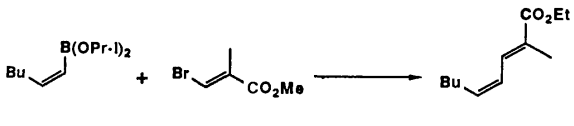
a) The coupling reactions are conducted under the following conditions. A: $Pd(OAc)_2$ (3 mol%), PPh_3 (6 mol%), and Na_2CO_3 (2 equiv) in 75% ethanol at refluxing temperature for 4 h. B: $Pd(OAc)_2$ (3 mol%), DPPF (3 mol%), and K_2CO_3 (2 equiv) in 75% ethanol for 24 h at room temperature. C: $Pd(OAc)_2$ (3 mol%), PPh_3 (6 mol%), and K_2CO_3 (2 equv) in dry ethanol at refluxing temperature for 3—5 h. D: The same conditions with C, except methanol is used in place of ethanol. b) GLC yields are based on the bromoesters employed, and the isomeric purity in each case is shown in the parenthesis.

Table 2. Effect of Catalysts for Cross-Coupling of (*Z*)-3-Bromoacrylate (Eq. 4)

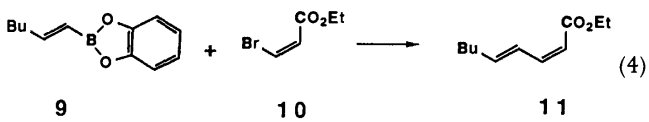
Catalyst[a]	Temp/°C	Time/h	Yield/%	(2*E*,4*E*)/(2*Z*,4*E*)
$Pd(OAc)_2(PPh_3)_2$	Reflux	5	70	37/63
$Pd(OAc)_2$(dppe)	Reflux	5	86	80/20
$Pd(OAc)_2$(dppf)	Reflux	5	86	23/77
$Pd(OAc)_2$(dppf)	50	5	71	19/81
$Pd(OAc)_2$(dppf)	20	24	73	5/95

a) Dppe and dppf are bis(diphenylphosphino)ethane and bis(diphenylphosphino) ferrocene.

potassium hydrotriisopropoxyborate. The above conditions also gave a good result for the reaction of (*Z*)-1-hexenylborate (**6**) to give (2*E*,4*Z*)-isomer (**8**) in a yield of 95% with the isomeric purity of 98% (Eq. 3).



6 7 8 (3)



9 10 11 (4)

On the other hand, the reaction between (*E*)-1-hexenylboronate (**9**) and (*Z*)-3-bromoacrylate (**10**) also took place readily. However, 2,4-nonadienoate thus obtained under such conditions was a mixture of (2*Z*,4*E*)- and (2*E*,4*E*)-isomers in a ratio of 63 : 37. Pre-

sumably, isomerization[7] may occur while the boron compound and Pd complex are bound or before the reductive elimination proceeds in the mechanism[2a] of cross-coupling reaction. Bis(diphenylphosphino)-ferrocene (DPPF)[8] is known as a ligand to accelerate the reductive elimination from diorganopalladium complexes, and to minimize the isomerization around the double bond. By using DPPF as a ligand of palladium, the yield in Eq.4 was improved to give 73% yield of ethyl (2*Z*,4*E*)-2,4-nonadienoate and the isomeric ratio of (2*Z*,4*E*):(2*E*,4*E*) to be 95:5 (Table 2). However, such isomerization appears to be highly dependent on the structure of 3-bromo-2-alkenoates since no remarkable isomerization was observed in the reaction of 3-bromocrotonate (Run 7 in Table 1).

There have been some published procedures for the synthesis of α,β-unsaturated esters including conjugated 2,4-alkadienoates from alkynes via hydrometallation, for example, the palladium-catalyzed cross-coupling reaction of ethyl (*E*)- or (*Z*)-3-(tributylstannyl)propenoate[9] with 1-iodo-1-alkenes, and (*E*)-1-alkenylaluminum[10] or zirconium compounds with 3-bromoacrylates. We previously reported that the methoxycarbonylation[11] of 1-alkenylboronates with carbon monoxide and methanol in the presence of palladium catalyst provides a convenient procedure for synthesis of α,β-unsaturated ester, stereoselectively. The present method affords a convenient alternative procedure for the synthesis of the titled compounds.

Experimental

All reactions were carried out under nitrogen atmosphere. 1-Hexyne, 1-octyne, and 2-butyne were commercial products and purified by distillation before use. 6-Chloro-1-hexyne,[12] 1-ethynyl-2,6,6-trimethylcyclohexene,[13] ethyl (*E*)- and (*Z*)-3-bromoacrylates,[14] methyl (*E*)-3-bromo-2-methylpropenoate,[15] and ethyl (*Z*)-3-bromocrotonate[16] were prepared according to the literature procedures. 1,3,2-Benzodioxaborole (cathecolborane) from Aldrich Chemical Co. was used after distillation. 1-Bromo-(2-ethoxycarbonyl)-cycloheptene was prepared by the oxidation[17] of 2-bromo-1-formylcycloheptene[2d] with manganese(IV) oxide in the presence of sodium cyanide, followed by esterification with *N*,*N*-dimethylformamide diethyl acetal.

The ^{1}H NMR spectra were measured with a Hitachi R-90H (90MHz) spectrometer (solvent, $CDCl_3$; TMS as an internal reference). Mass spectra were recorded on a JEOL JMS-D 300 for high resolution analysis and Finnigan ITD 800. GLC analyses were performed with a Hitachi 023 gas chromatograph using a fused silica capillary column (OV-101, 25m).

1-Alkenylboronate (3). Preparations of (*E*)-1-hexenyl-, (*E*)-1-octenyl-, [(*E*)-6-chloro-1-hexenyl]-, and [(*E*)-1-methyl-1-propenyl]-1,3,2-benzodioxaboroles were reported[2a] previously. Hydroboration of 1-ethynyl-2,6,6-trimethylcyclohexene was carried out as follows. A dry 10 ml flask equipped with a septum inlet and a magnetic stirring bar was flushed with nitrogen, and was charged with the enyne (1.48 g, 10 mmol) and dry benzene (2 ml). 1,3,2-Benzodioxaborole (1.2 ml, 10.8 mmol) was added dropwise by a hypodermic syringe. The reaction mixture was stirred for 20 h at 70 °C, and then 0.1 ml of methanol was added at room temperature to destroy the residual hydride. The flask was quickly attached to Kugelrohr and flushed with nitrogen. Distillation under reduced pressure gave the dienylboronate (2.2 g 76%), bp 170 °C/0.55mmHg (1 mmHg= 133.322Pa); ^{1}H NMR ($CDCl_3$) δ=1.10 (s, 6H), 1.4—1.7 (m, 4H), 1.79 (s, 3H), 1.95—2.20 (m, 2H), 5.79 (d, 1H, *J*=18.6 Hz), 6.95—7.25 (m, 4H), and 7.45 (d, 1H, *J*=18.6 Hz).

Standard Procedure for the Synthesis of 2,4-Alkadienoate (Eq. 2). A 200 ml flask equipped with a septum inlet, a reflux condenser and a magnetic stirring bar was flushed with nitrogen. The flask was charged with $Pd(OAc)_2$ (0.067 g, 0.3 mmol), PPh_3 (0.15 g, 0.6 mmol), Na_2CO_3 (2.12g, 20 mmol), and 40 ml of 75% ethanol (Conditions A in Table 1) or K_2CO_3 (2.76 g, 20 mmol) and 40 ml of dry ethanol (Conditions C). Ethyl (*E*)-3-bromoacrylate (1.79 g, 10 mmol) and 2-(1-alkenyl)-1,3,2-benzodioxaborole (11 mmol) were then added by a hypodermic syringe through septum inlet. The reaction mixture was heated gradually to reflux and then to keep reflux for 4 h. The product was extracted with 60 ml of 1:1 benzene–hexane, washed with water, and dried over $MgSO_4$. Analytically pure ester was obtained by chromatography over silica gel or distillation by Kugelrohr. GLC yields using hydrocarbons as internal standards are shown in Table 1.

The dienoates prepared by employing the above procedure are as follows.

Ethyl (2*E*,4*E*)-2,4-Undecadienoate: IR (neat) 1720, 1645, and 1620 cm^{-1}; ^{1}H NMR δ=0.90 (t, 3H, *J*=6.5 Hz), 1.30 (t, 3H, *J*=7.5 Hz), 1.25—1.70 (m, 8H), 2.05—2.30 (m, 2H), 4.13 (q, 2H, *J*=7 Hz), 5.71 (d, 1H, *J*=15 Hz), 6.0—6.4 (m, 2H), and 7.16 (ddd, 1H, *J*=3, 7, and 15 Hz); MS *m*/*z* 210, 165, 153, 125; Found: C, 74.07; H, 10.49%. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54%.

Ethyl (2*E*,4*E*)-9-Chloro-2,4-nonadienoate: IR (neat) 1710, 1645, and 1620 cm^{-1}; ^{1}H NMR δ=1.28 (t, 3H, *J*=7.5 Hz), 1.5—2.0 (m, 4H), 2.1—2.4 (m, 2H), 3.51 (t, 2H, *J*=6 Hz), 4.16 (q, 2H, *J*=7 Hz), 5.73 (d, 1H, 16Hz), 6.0—6.4 (m, 2H), and 7.19 (dd, 1H, *J*=10 and 16 Hz); MS *m*/*z* 216, 171, 143, and 125; Found: C, 61.29; H, 7.91%. Calcd for $C_{11}H_{17}O_2Cl$: C, 61.97; H, 7.91%.

Ethyl (2*E*,4*E*)-4-Ethyl-2,4-heptadienoate: IR (neat) 1715 and 1625 cm^{-1}; ^{1}H NMR δ=0.99 (t, 3H, *J*=7 Hz), 1.0 (t, 3H, *J*=7 Hz), 1.23 (t, 3H, *J*=7 Hz), 2.0—2.4 (m, 4H), 4.11 (q, 2H, *J*=7 Hz), 5.71 (d, 1H, *J*=15.5 Hz), 5.77 (t, 1H, *J*=7 Hz), and 7.1 (d, 1H, *J*=15.5 Hz); Found: C, 72.28; H, 9.93%. Calcd for $C_{11}H_{18}O_2$: C, 72.49, H, 9.95%.

1-[(*E*)-1-Hexenyl]-2-(ethoxycarbonyl)cycloheptene: IR (neat) 1715, 1640, and 1595 cm^{-1}; ^{1}H NMR δ=0.895 (t, 3H, *J*=7 Hz), 1.31 (t, 3H, *J*=7 Hz), 1.1—1.9 (m, 10H), 1.9—2.3 (m, 2H), 2.3—2.6 (m, 4H), 4.21 (q, 2H, *J*=7.3 Hz), 5.85 (dt, 1H, *J*=7 and 16 Hz), and 6.75 (d, 1H, *J*=16 Hz); MS *m*/*z* 250, 205, 193, and 165; Found: *m*/*z* 250.1934. Calcd for $C_{16}H_{26}O_2$: M, 250.1933.

4-[(*E*)-1-Hexenyl]coumarin: Mp 67 °C; IR (Nujol) 1720, 1650, and 1610 cm^{-1}; ^{1}H NMR δ=0.96 (t, 3H, *J*=7 Hz), 1.2—1.6 (m, 4H), 2.2—2.5 (m, 2H), 6.41 (s, 1H), 6.43 (dt, 1H, *J*=6 and 21 Hz), 6.73 (d, 1H, *J*=21 Hz), and 7.1—7.9 (m, 4H); MS Found: *m*/*z* 228.1138. Calcd for $C_{15}H_{16}O_2$: M, 228.1151.

Ethyl (2*Z*,4*E*)-5-(2,6,6-Trimethylcyclohexenyl)-3-methylpentadienoate: IR (neat) 1715, 1615, 1230, and 955 cm^{-1};

^{1}H NMR δ=1.07 (s, 6H), 1.27 (t, 3H, J=7.2 Hz), 1.5—2.2 (m, 6H), 1.77 (s, 3H), 2.04 (s, 3H), 4.16 (q, 2H, J=6.8 Hz), 5.64 (s, 1H), 6.58 (d, 1H, J=16.3 Hz), and 7.63 (d, 1H, J=16.3 Hz); MS m/z 262, 246, 217, 189, and 119; Found: m/z 262.1915. Calcd for $C_{17}H_{26}O_2$: M, 262.1933.

Cross-Coupling of (*E*)-1-Hexenyl-1,3,2-benzodioxaborole (9) with Ethyl (*Z*)-3-Bromoacrylate (10) (Eq. 4). A mixture of the catalyst (0.03 mmol), K_2CO_3 (2 mmol), ethyl (*Z*)-3-bromoacrylate (1 mmol), and 2-[(*E*)-1-hexenyl]-1,3,2-benzodioxaborole (1.1 mmol) in 3 ml of 75% ethanol was stirred under the conditions indicated in Table 2. After the reaction was over, the product was extracted with benzene, washed with water and dried over $MgSO_4$. Chromatography over silica gel with hexane-ether gave **11**: IR (neat) 1713, 1640, and 1600 cm^{-1}; ^{1}H NMR δ=0.93 (t, 3H, J=7 Hz), 1.28 (t, 3H, J=7 Hz), 1.2—1.7 (m, 4H), 2.1—2.4 (m, 2H), 4.16 (q, 2H, J=7 Hz), 5.52 (d, 1H, J=11 Hz), 5.99 (dt, 1H, J=7 and 15 Hz), 6.47 (dd, 1H, J=11 and 11 Hz), 7.41 (dd, 1H, J=11 and 15 Hz); MS m/z 182, 153, 137, 125, and 109; Found: C, 71.63; H, 9.69%, Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.95%. The results are summarized in Table 2.

Synthesis of (*Z*)-1-Hexenylboronate (6) and Its Reaction with 7 (Eq. 3). To a solution of diisopropyl (*Z*)-(1-bromo-1-hexenyl)boronate (2.2 mmol) in ether (4 ml) was added 4 ml of a solution of potassium hydrotriisopropoxyborate in THF (0.6M solution, 2.4 mmol) at 0 °C. The reaction mixture was stirred for 15 min at 0 °C, and then for 30 min at room temperature. After evaporation of the solvent under reduced pressure, the residue **6** was dissolved in 8 ml of methanol. $Pd(OAc)_2$ (0.06 mmol), PPh_3 (0.12 mmol), K_2CO_3 (4 mmol), and methyl (*E*)-3-bromo-2-methylpropenoate (2 mmol) were added, and the mixture was refluxed for 5 h. The reaction mixture was diluted with benzene (30 ml), washed with water, and dried over $MgSO_4$. The product was isolated by chromatography over silica gel with benzene/ethyl acetate (20:1). Analysis by GLC revealed the formation of **8** (1.9 mmol, 95%): IR (neat) 1710, 1635, 1605, 1115, and 735 cm^{-1}; ^{1}H NMR δ=0.91 (t, 3H, J=7 Hz), 1.2—1.5 (m, 4H), 1.93 (s, 3H), 2.1—2.4 (m, 2H), 3.76 (s, 3H), 5.75 (dt, 1H, J=7.6 and 11.2 Hz), 6.27 (dd, 1H, J=11.2 and 11.6 Hz), and 7.49 (d, 1H, J=11.6 Hz); MS m/z 182, 151, and 125; Found: m/z 182.1289. Calcd for $C_{11}H_{18}O_2$: M, 182.1297.

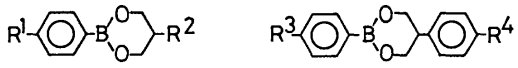
(Received July 31, 1989)

2,5-Diaryl-1,3,2-dioxaborinane derivatives having various terminal groups were synthesized and found to form mesomorphic phases in a wide temperature range. They provide a new series of liquid-crystalline compounds containing a boron atom in the principal structure.

The majority of liquid-crystalline molecules consist of carbon, oxgen, nitrogen, and hydrogen atoms. Though a few examples containing heteroatoms are known,[1] liquid crystalline materials containing metal atoms are of special interest since they are expected to have unique properties based on the incorporation of metals having special electric and magnetic properties.

In general, organometallic compounds are thermally and chemically unstable, however, 1,3,2-dioxaborinane derivatives are fairly stable and we recently reported a preliminaly result that the compounds having 2,5-disubstituted 1,3,2-dioxaborinane structure **1** form stable nematic and/or smectic mesophases.[2] They are the first examples of thermotropic liquid-crystalline molecules with a boron atom in the principal structure. Boron atoms have vacant p-orbitals and are electron-deficient, hence conjugation between the p-orbital and aromatic π-electron system may be expected for 2-aryl-1,3,2-dioxaborinane derivatives. This conjugation may give a double bond character to the bond between boron atom and aromatic ring, resulting in a rigid core structure favorable to liquid-crystalline materials.

In this paper we report in detail on the synthesis and properities of liquid-crystalline compounds **2** which are constructed by three rings containing the dioxaborinane ring as the principal structure. And we wish to discuss especially the influence of terminal groups on mesomorphic properties, as well as the comparison with other liquid-crystalline materials



1 2

having the analogous structure.

Results and Discussion

A simple approach to the synthesis of compound **2** has been developed according to Scheme 1. The synthetic intermediate **4** was prepared by the palladium-(0)-catalyzed cross-coupling reaction of ethyl cyanomalonate with aryl halides **3**.[3] The aryl halides were prepared by the halogenation of arenes according to a literature method.[4] Although a small amount of the ortho-substituted isomer was formed as a by-product, a mixture of the isomers was used for the coupling reaction, since the ortho-isomer has a less reactivity and recrystallization gave pure diols **5**.

Boronic acids **6a**—c were obtained by the reaction of Grignard reagents with trimethoxyborane in tetrahydrofuran at temperatures below −60 °C. Boronic acid **6a** was converted to **6d** by oxidation with potassium permanganate in an alkaline solution.[5] *p*-Cyanophenyl derivative **6e** was prepared according to Scheme 2. The intermediate **8** was transformed into **9** by a literature method.[6]

Finally, condensation between **5** and **6** was carried out in a toluene solution and we obtained dioxaborinane derivatives **2** in nearly quantitative yields. Pur-

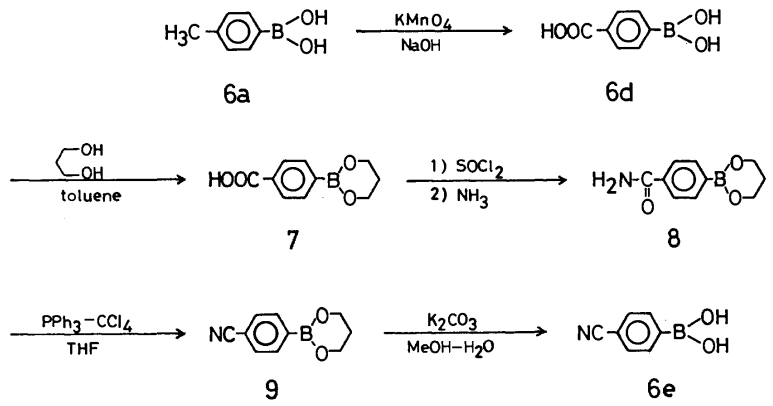

Scheme 2.

ification of **2** was achieved by column chromatography and recrystallization. The structures of compound **2** are consistent with analytical data including mass, IR, and NMR spectra. The present method for the preparation of **2** has a great advantage because their various derivatives are prepared easily by the simple condensation of selected pairs of **5** and **6**. A number of 2,5-disubstituted 1,3,2-dioxaborinanes thus synthesized are listed in Table 1. The table shows that the dioxaborinane derivatives form mesophases with a variety of terminal groups, indicating that the dioxaborinane ring provides a suitable core structure for the formation of liquid crystals.

The terminal groups can promote the formation of mesophases in the following order, -CN>-OMe, -Cl>-Me>-COOMe. The order is almost same as the tendency for organic liquid-crystalline materials shown by Gray et al.[7] Especially, the cyano gruop is a good terminal group for the formation of mesophases. It is known that cyano groups lead molecules to a dimer structure favorable to the formation of liquid crystals.

In order to investigate the influence of alkyl chain length on the formation of mesophases, compounds **2**, (R^3=CN or CH_3O) bearing a variety of alkyl groups (R^4) were synthesized, and the results are summarized in Tables 2 and 3. The compounds having a cyano group at the terminal form a stable nematic phase for various alkyl chains, while those having a methoxyl group exhibit only a monotropic nematic phase. The transition temperatures for the compounds having a cyano group are plotted against the alkyl chain length in Fig. 1. An odd-even effect was observed for the nematic-to-isotropic (N-I) transition temperatures,

and the longer alkyl groups showed the wider temperature range of mesophases. These facts also agree with the tendency of liquid-crystalline materials reported by Gray et al.[7,8] As described later, the dioxaborinane derivatives show lower N-I transition temperatures than other liquid-crystalline materials having analogous three-ring structures.

The dioxaborinane derivatives have a unique structure containing a metalloid atom, boron, in the principal structure, however, they are fairly stable in air and moisture, and showed similar thermal properties of organic liquid-crystalline materials.

It is known that the structures of rigid core in liquid-crystalline materials give strong influence to their clearing points, that is mesophases-to-isotropic transition temperatures. For examples, displacement of the central benzene ring in a terphenyl system by other six-membered rings such as cyclohexane and dioxane results in lowering the clearing points.[9] The dioxaborinane ring exhibited the same influence and compound **9** showed the lowest clearing point among the compounds summarized in Table 4.

Experimental

Measurements of transition temperatures and observations of mesophases were made using Olympus BH-2 polarising microscope in conjunction with Metler FP52 heating stage and FP5 control unit. ^{1}H NMR spectra were measured for solutions in $CDCl_3$ with tetramethylsilane as internal standard using a Bruker WM-360 spectrometer. IR spectra were recorded with a Hitachi 295 infrared spectrophotometer, and mass spectra were taken on a JEOL JMS06 instrument.

Diethyl 4-Butylphenylmalonate.[3] To a suspension of potassium *t*-butoxide (6.73 g, 60 mmol) in 1,2-dimethoxyethane (50 ml), ethyl cyanoacetate (3.97 g, 35 mmol) was added at room temperature with stirring. After 10 min 4-butylphenyl iodide (**3**, R=C_4H_9, X=I, 7.80 g, 30 mmol) and a catalytic amount of dichlorobis(triphenylphosphine)-palladium (600 mg, 0.85 mmol) were added, and then the mixture was heated at 70 °C for 8 h under nitrogen. After cooling the reaction mixture, 1 M hydrochloric acid was added and the product was extracted with ether. The extract was washed with water and dried over sodium sulfate. After evaporation of ether the residue was purified by chromatography on silica gel using hexane/dichloromethane as eluent. The viscous, oily product was distilled using a Kugelrohr bulb-to-bulb distillation apparatus to give ethyl 4-butylphenylcyanoacetate (as a colorless oil; yield 4.13 g (56%); IR (neat) 2240 (CN), and 1760 cm^{-1} (C=O). The product obtained here was contaminated by a small amount of impurity, but the next procedure for saponification of the cyano group was carried out without further purification of the product. A mixture of the crude cyanoacetate (4.00 g), ethanol (15 ml), concd hydrochloric acid (18.6 ml), calcium chloride (20.1 g), and benzene (6 ml) was stirring at room temperature for 3 h, then heated at 55 °C for 2 h, and finally under reflux for 5 h. After cooling to room temperature, water was added and the product was extracted with benzene. The extract was dried over sodium sulfate, and after concentration the crude product was purified by chromatography on silica gel using dichloromethane as an eluent. The resultant oily product was distilled using a Kugelrohr bulb-to-bulb distillation apparatus, affording diethly 4-butylphenylmalonate as a colorless oil; yield 3.32 g (70%); IR (neat) 1765 and 1750 cm^{-1} (C=O); ^{1}H NMR δ=0.90—2.10 (13H, m, alkyl), 2.50 (2H, t, J=8 Hz, $CH_2C_6H_4$), 4.20 (4H, q, J=7 Hz, CH_2O), 4.57 (1H, s, CH), and 7.27 (m, 4H, Ar).

2-(4-Butylphenyl)-1,3-propanediol (5, R=C_4H_9). To a suspension of lithium aluminum hydride (0.76 g, 20 mmol) in diethyl ether (60 ml), diethyl 4-butylphenylmalonate (2.92 g, 10 mmol) in diethyl ether (10 ml) was added dropwise with stirring at 0 °C. And then the reaction mixture was heated to reflux temperature. After 6 h the mixture was cooled to 0 °C again, and ethyl acetate (5 ml), and 5% sodium hydroxide solution (10 ml) were added successively. After the reaction at room temperature for 10 h, the inorganic salt precipitated was separated by filtration, then the organic layer was separated and the aqueous layer was extracted with ether. The combined ether solution was dried over sodium sulfate. After evaporation of ether, the resultant product was purified by recrystallization from hexane, affording 2-(4-butylphenyl)-1,3-propanediol as white needles; yield 3.32 g (70%); mp 74.5—76.0 °C; IR (Nujol) 3250 cm^{-1} (OH); ^1H NMR δ=0.87—1.59 (7H, m, alkyl), 2.57 (2H, t, J=8 Hz, $C\underline{H}_2C_6H_4$), 3.02 (1H, m, CH), 3.86—3.96 (4H, m, OCH_2), and 7.11 (4H, s, Ar).

***p*-Tolylboronic Acid (6a).** To a solution of trimethoxyborane (20.4 g, 194 mmol) in dry tetrahydrofuran (100 ml), *p*-tolylmagnesium bromide, prepared from *p*-bromotoluene (22.4 g, 131 mmol) and magnesium (3.41g, 140 mmol), was added dropwise at −70 °C. After the Grignard reagent had been added, the reaction mixture was stirred below −60 °C for one hour, and then hydrolyzed with 10% sulfuric acid (70 ml). The inorganic salt formed was filtered off and the tetrahydrofuran layer was separated and then the aqueous layer was extracted with ether. The combined organic layer was washed with water and dried over sodium sulfate. Consentration of the solution gave white crystals, which was washed with hexane and water, affording pure *p*-tolylboronic acid; yield 15.0 g (86%); mp 245—247 °C; IR (Nujol) 3480, 3400 (OH), and 1365 cm^{-1} (BO).

Similarly, *p*-chloro- (**6b**) and *p*-methoxyphenylboronic acid (**6c**) were prepared by starting from *p*-chloro and *p*-methoxyphenyl bromide, respectively.

4-Carboxyphenylboronic Acid (6d).[5] *p*-Tolylboronic acid (6.8 g, 50 mmol) was dissolved in 40 ml of water containing sodium hydroxide (4 g), and then 290 ml of water was added to the solution. Into the agitated mixture a solution of potassium permanganate (16.6 g, 105 mmol) in water (500 ml) was added in the following way. The permanganate solution was devided into eight volumes, and each volume was added in turn every one hour. After all portions of the permanganate solution had been added, the mixture was stirred overnight. Excess of permanganate was destroyed by addition of ethanol (20 ml) at 50 °C, and the manganese dioxide was filtered off. The filtrate was concentrated to about 200 ml below 40 °C, and then acidified carefully with hydrochloric acid. The crystal separated was collected, washed with water, and recrystallized from water; yield 4.82 g (58%); mp 232—234 °C; IR (Nujol) 3500—2500 (OH), 1700 (C=O), and 1355 cm^{-1} (BO).

2-(4-Carboxyphenyl)-1,3,2-dioxaborinane (7). 4-Carboxyphenylboronic acid (4.82 g, 29 mmol) was reacted with 1,3-propanediol (2.23 g, 29 mmol) in toluene (100 ml) under reflux for 2 h. During the reaction the water formed was removed azeotropically using a Dean-Stark apparatus. When the reaction was completed, the mixture was cooled to room temperature and the crystals separated were collected by filtration; yield 5.78 g (92%); mp 211—213 °C; IR (Nujol) 3400—2500 (OH), 1695 (C=O), and 1315 cm^{-1} (BO).

2-(4-Carbamoylphenyl)-1,3,2-dioxaborinane (8). 2-(4-Carboxyphenyl)-1,3,2-dioxaborinane (5.56 g, 24.9 mmol) was reacted with thionyl chloride (12 ml) in the presence of *N,N*-dimethylformamide under reflux for 2 h. Removal of excess thionyl chloride under a reduced pressure afforded the acid chloride, which was used for the next reaction, ammonolysis, without further purification. To a 28% of aqueous ammonia (65 ml), a solution of the acid chloride in tetrahydrofuran (130 ml) was added dropwise at 0 °C, and then stirred at room temperature for 30 min. The solvent and aqueous ammonia were removed by evaporation, and toluene (100 ml) was added to the residue in order to remove water azeotropically. After completion of dehydration, toluene was distilled away, and the resultant residue was extracted with acetone. Concentration of acetone solution gave 2-(4-carbamoylphenyl)-1,3,2-dioxaborinane as pale yellow crystals; yield 2.87 g (52%); mp 204—206 °C; IR (Nujol) 3550, 3100 (NH), 1685 (C=O), 1625, and 1615 cm^{-1} (NH).

4-Cyanophenylboronic Acid (6e).[6] To a solution of triphenylphosphine (7.32 g, 27.9 mmol) in carbon tetrachloride (30 ml), 2-(4-carbamoylphenyl)-1,3,2-dioxaborinane (**8**, 2.87 g, 13.9 mmol) dissolved in tetrahydrofuran (30 ml) was added, and then the mixture was warmed to 50 °C for 20 h. Insoluble solids precipitated were separated, and the filtrate was concentrated. The residue was extracted with warm hexane, and removal of hexane give crude nitrile (**9**), 2.05 g (78%); IR (Nujol) 2220 (CN), and 1310 cm^{-1} (BO).

Finally, the protective group of boronic acid was taken off as follows. A mixture of (**9**) (2.05 g, 10.9 mmol) and potassium carbonate (3.75 g) in water and methanol (10 ml) was stirred at room temperature for 10 h. Insoluble solids were filtered off, and methanol was removed in vacuo. The aqueous alkali solution was cooled and acidified carefully with hydrochloric acid. The crystal separated was collected by filtration and washed with water; yield 1.26 g (78%); mp>300 °C; IR (Nujol) 3550, 3440 (OH), 2220 (CN), and 1345 cm^{-1} (BO).

2,5-Diaryl-1,3,2-dioxaborinanes (2). General Procedure. A mixture of 4-substituted phenylboronic acid (**6**, 0.5 mmol), 2-(4-substituted phenyl)-1,3-propanediol (**5**, 0.5 mmol), and toluene (25 ml) was stirred under reflux for 2 h. During the reaction the water formed removed azeotropically using a Dean-Stark apparatus. When the reaction was completed, toluene was distilled away, and the resultant residue was purified by chromatography on silica gel using dichloromethane as an eluent. Recrystallization from hexane gave the corresponding products (**2**).

2-(4-Methylphenyl)-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (2a). Found: C, 74.08; H, 7.80%. Calcd for $C_{20}H_{26}BO_3$: C, 73.86; H, 8.06%; IR (Nujol) 1315 cm^{-1} (BO); ^1H NMR δ=0.97 (3H, t, J=8 Hz, $CH_2C\underline{H}_3$), 1.45—1.52 (2H, m, $C\underline{H}_2CH_3$), 1.75 (2H, m, $OCH_2C\underline{H}_2$), 2.36 (3H, s, $C\underline{H}_3C_6H_4$), 3.25 (1H, m, CH), 3.95 (2H, t, J=6 Hz, $OC\underline{H}_2CH_2$), 4.14 (2H, dd, J=11 and 11 Hz, $OC\underline{H}_2CH$, ax), 4.24 (2H, dd, J=5 and 11 Hz, $OC\underline{H}_2CH$, eq), 6.88 (2H, d, J=9 Hz, Ar), 7.12 (2H, d, J=9 Hz, Ar), 7.17 (2H, d, J=8 Hz, Ar), and 7.70 (2H, d, J=8 Hz, Ar).

2-(4-Chlorophenyl)-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (2b). Found: C, 66.09; H, 6.53; Cl, 10.10%. Calcd for $C_{19}H_{23}BClO_3$: C, 66.02; H, 6.71; Cl, 10.26%; IR (Nujol) 1315 cm^{-1} (BO); ^1H NMR δ=0.97 (3H, t, J=7 Hz, CH_3), 1.46—1.52 (2H, m, $CH_2C\underline{H}_3$), 1.76 (2H, m, $OCH_2C\underline{H}_2$), 3.25 (1H, m, CH), 3.95 (2H, d, J=6 Hz, $OC\underline{H}_2CH_2$), 4.14 (2H, dd, J=11

and 11 Hz, OCH_2CH, ax), 4.25 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 6.89 (2H, d, J=9 Hz, Ar), 7.12 (2H, d, J=9 Hz, Ar), 7.33 (2H, d, J=8 Hz, Ar), and 7.73 (2H, d, J=8 Hz).

2-(4-Methoxyphenyl)-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (2c). Found: C, 70.52; H, 7.42%. Calcd for $C_{20}H_{25}BO_4$: C, 70.61; H, 7.41%; IR (Nujol) 1315 cm^{-1} (BO); ^1H NMR δ=0.93 (3H, t, J=7 Hz, CH_2CH_3), 1.37—1.46 (2H, m, CH_2CH_3), 1.78 (2H, m, OCH_2CH_2), 3.25 (1H, m, CH), 3.83 (3H, s, OCH_3), 3.98 (2H, d, J=6 Hz, OCH_2CH_2), 4.14 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.24 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 6.87 (2H, d, J=9 Hz, Ar), 6.89 (2H, d, J=9 Hz, Ar), 7.12 (2H, d, J=9 Hz, Ar), and 7.75 (2H, d, J=9 Hz); MS, m/z 340 (M^+).

2-(4-Cyanophenyl)-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (2d). Found: C, 71.92; H, 6.62; N, 3.96%. Calcd for $C_{20}H_{22}BNO_3$: C, 71.66; H, 6.62; N, 4.18%; IR (Nujol) 2220 cm^{-1} (CN); ^1H NMR δ=0.93 (3H, t, J=7 Hz, CH_3), 1.17—1.45 (2H, m, CH_2CH_3), 1.74—1.80 (2H, m, OCH_2CH_2), 3.27 (1H, m, CH), 3.94 (2H, d, J=6 Hz, OCH_2CH_2), 4.17 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.28 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 6.89 (2H, d, J=9 Hz, Ar), 7.12 (2H, d, J=9 Hz, Ar), 7.63 (2H, d, J=8 Hz, Ar), and 7.89 (2H, d, J=8 Hz, Ar).

2-(4-Methylphenyl)-5-(4-hexylphenyl)-1,3,2-dioxaborinane (2f). Found: C, 78.39; H, 8.67%. Calcd for $C_{22}H_{29}BO_2$: C, 78.58; H, 8.69%; IR (Nujol) 1310 cm^{-1} (BO); ^1H NMR δ=0.88 (3H, t, J=7 Hz, CH_2CH_3), 1.28—1.36 (6H, m, alkyl), 1.58—1.62 (2H, m, $CH_2CH_2C_6H_4$), 2.37 (3H, s, $CH_3C_6H_4$), 2.59 (2H, t, J=7 Hz, $CH_2C_6H_4$), 3.28 (1H, m, CH), 4.18 (2H, dd, J=10 and 10 Hz, OCH_2CH, ax), 4.27 (2H, dd, J=4 and 10 Hz, OCH_2CH, eq), 7.13 (2H, d, J=9Hz, Ar), 7.17 (2H, d, J=9 Hz, Ar), 7.18 (2H, d, J=8Hz, Ar), and 7.70 (2H, d, J=8 Hz, Ar).

2-(4-Chlorophenyl)-5-(4-hexylphenyl)-1,3,2-dioxaborinane (2g). Found: C, 70.91; H, 7.06; Cl, 9.99%. Calcd for $C_{21}H_{26}BClO_2$: C, 70.71; H, 7.35; Cl, 9.94%; IR (Nujol) 1320 cm^{-1} (BO); ^1H NMR δ=0.88 (3H, t, J=7 Hz, CH_3), 1.30—1.36 (6H, m, alkyl), 1.56—1.62 (2H, m, $CH_2CH_2C_6H_4$), 2.59 (2H, t, J=8 Hz, $CH_2C_6H_4$), 3.28 (1H, m, CH), 4.18 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.27 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 7.12 (2H, d, J=9 Hz, Ar), 7.17 (2H, d, J=9 Hz, Ar), 7.33 (2H, d, J=8 Hz, Ar), and 7.73 (2H, d, J=8 Hz, Ar).

2-(4-Methoxyphenyl)-5-(4-hexylphenyl)-1,3,2-dioxaborinane (2h). Found: C, 75.25; H, 8.16%. Calcd for $C_{22}H_{29}BO_3$: C, 75.00; H, 8.29%; IR (Nujol) 1320 (BO) and 1240 cm^{-1} (Ar-O); ^1H NMR δ=0.88 (3H, t, J=7 Hz, CH_2CH_3), 1.31—1.36 (6H, m, alkyl), 1.56 (2H, m, $CH_2CH_2C_6H_4$), 2.58 (2H, t, J=8 Hz, $CH_2C_6H_4$), 3.27 (1H, m, CH), 3.82 (3H, s, OCH_3), 4.16 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.26 (2H, dd, J=5 and 11 Hz OCH_2CH, eq), 6.89 (2H, d, J=8 Hz, Ar), 7.12 (2H, d, J=8 Hz, Ar), 7.16 (2H, d, J=8 Hz, Ar), and 7.76 (2H, d, J=8 Hz, Ar); MS, m/z 352 (M^+). Elemental analysis for the derivatives of **2h** are listed in Table 5.

2-(4-Cyanophenyl)-5-(4-hexylphenyl)-1,3,2-dioxaborinane (2i). Found: C, 76.21; H, 7.59; N, 3.92%. Calcd for $C_{22}H_{26}BNO_2$: C, 76.09; H, 7.54; N, 4.03%; IR (Nujol) 2220 (CN) and 1310 cm^{-1} (BO); ^1H NMR δ=0.88 (3H, t, J=7 Hz, CH_3), 1.31 (6H, m, alkyl), 1.60 (2H, m, $CH_2CH_2C_6H_4$), 2.59 (2H, t, J=8 Hz, $CH_2C_6H_4$), 3.29 (1H, m, CH), 4.19 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.29 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 7.12 (2H, d, J=8 Hz, Ar), 7.18 (2H, d, J=8 Hz, Ar), 7.62 (2H, d, J=8 Hz, Ar), and 7.88 (2H, d, J=8 Hz, Ar). Elemental analysis for the derivatives of **2i** are listed in Table 6.

2-[4-(Methoxycarbonyl)phenyl]-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (2e). 2-(4-Carboxyphenyl)-5-(4-butoxyphenyl)-1,3,2-dioxaborinane (177 mg, 0.50 mmol), prepared from 4-carboxyphenylboronic acid (**6d**) and 2-(4-butoxyphenyl)-1,3-propanediol (**5**, R=C_4H_9O), was reacted with methanol (15 ml) in the presence of sulfuric acid (0.3 ml) under reflux for 6 h. After cooling the reaction mixture, excess methanol was removed off, and the residue was purified by chromatography on silica gel using dichloromethane as an eluent. Recrystallization from hexane gave pure product (**2e**); yield 124 mg (67%); Found: C, 68.76; H, 6.71%. Calcd for $C_{21}H_{25}BO_5$: C, 68.49; H, 6.84%; IR (Nujol) 1735 (C=O), 1320 (BO), and 1280 cm^{-1} (COC); ^1H NMR δ=0.97 (3H, t, J=8 Hz, CH_2CH_3), 1.46—1.52 (2H, m, CH_2CH_3), 1.72—1.80 (2H, m, OCH_2CH_2), 3.27 (1H, m, CH), 3.92 (3H, s, CH_3OCO), 3.95 (2H, t, J=7 Hz, $CH_2OC_6H_4$), 4.17 (2H, dd, J=11 and 11 Hz, OCH_2CH, ax), 4.27 (2H, dd, J=5 and 11 Hz, OCH_2CH, eq), 6.89 (2H, d, J=9 Hz, Ar), 7.13 (2H, d, J=9 Hz, Ar), 7.87 (2H, d, J=8 Hz, Ar), and 8.01 (2H,

Splitting of ^{1}H NMR Signal of Long Methylene Chain with Various Terminal Substituent in Aromatic Solvent

Takashi HOSHINO*,† and Yoshio IMAMURA
Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received May 6, 1989)

The splitting of the methylene peaks in ^{1}H NMR spectra was studied for alkyl compounds with various substituents in 1-chloronaphthalene solutions. The solvent shifts for the higher field split methylene peak and the α-methylene peak varied with a dependence on the magnitude of the electric group moment of the terminal substituent; those for the lower- and middle-field split methylene peaks and the terminal methyl peak remained constant. It was found that the different behaviors of the solvent shifts of the methylene signals could be ascribed to the origin of the peak splitting observed for long alkyl compounds.

For long-chain alkanes (number of carbons $n_c > 16$) it was known that the methylene ^{1}H NMR peak was observed to split into a doublet in 1-chloronaphthalene.[1] After the discovery for *n*-alkanes, similar phenomena have been observed for long alkyl compounds with a terminal substituent, such as *N*-alkylmaleimides[2] and alkyl 11-maleimidoundecanoates.[3] On the other hand, methylene-peak splittings were observed for the long alkyls of surfactant molecules in water upon the addition of an aromatic solubilizate;[4-9] these phenomena have been discussed regarding the solubilization site of aromatics in surfactant micelles.

The first theoretical investigation of such splittig phenomena of the methylene peak was carried out by Ando and Nishioka.[10-12] They performed a chemical shift calculation and concluded that the splitting of peaks in an aromatic solvent arises from an increase in the number of gauche forms for long-chain hydrocarbons. On the other hand, Winnik et al. concluded that the splitting was due to a solvent effect associated with the chain end, and conclusively rejected the presence of slowly interconverting gauche and trans conformations for long alkyl chains.[13] Furthermore, several papers have been published which discuss the origin of these phenomena.[14,15]

The present authors studied the ^{1}H NMR spectra for the methyl alkanoates of various alkyl lengths in 1-chloronaphthalene and observed that the methylene peak splits into a doublet for a longer alkyl with $n_c \geq 12$ and into a triplet for $n_c \geq 20$.[16] We also studied aqueous dispersed systems of several surfactants of various chain lengths, and found that the methylene peaks of the ^{1}H spectra also split upon the addition of aromatic solubilizates, as similar manner in a homogeneous solution.[17] From those observations of the dependence of the chain length on the methylene ^{1}H NMR spectra for solutions and solubilizated dispersions, we speculated that the origin of the splitting phenomena can be ascribed to a solute-solvent interaction.

In this paper we will describe the relation between the solvent shifts in long alkyl compounds and the electric group dipole moment of their terminal substituent, the assignment of the methylene signal to 3 split peaks and, consequently, the origin of the splitting of the methylene peaks by aromatic solvents.

Experimental

Long-chain compounds with the following substituted groups were applied in this study: $-CH_3$, $-C_6H_5$, $-SH$, $-NH_2$, $-OH$, $-Cl$, $-Br$, $-COOCH_3$, $-NCO$, $-COCl$, $-COC_6H_5$, and $-CN$. These substances consist of long alkyl groups with carbon numbers of n_c=12 or 18. For compounds with a carbonyl function, the carbonyl carbon is included within the carbon number, n_c. The terminal group for nonsubstituted *n*-alkanes (dodecane and octadecane) could be represented by $-CH_3$. All the reagents used in this study were of commercially highest grade.

Samples were prepared in about a 0.5 mol dm^{-3} solution of chloroform-*d* or a mixed solvent of 90 vol% 1-chloronaphthalene/10 vol% benzene-d_6. (The latter benzene-d_6 was used to provide the deuteriumlock signal.)[15] Tetramethylsilane (TMS) was used as an internal standard. ^{1}H NMR spectra were observed using a JEOL FX-100 NMR spectrometer operated at 100 MHz at ambient temperature.

Results and Discussion

For the alkyl compounds with various terminal substituents, splittings of the methylene signal were observed in 1-chloronaphthalene, similar to that found for normal alkanes. For the compounds with the substituents, $-NH_2$, $-OH$, $-COOCH_3$, $-NCO$, $-COCl$, and $-CN$, the methylene signals (excluding of α- and β-methylenes) were observed to split into doublets for compounds of n_c=12 and into triplets for n_c=18. In the other compounds used in this study, i.e. $-CH_3$, $-C_6H_5$, $-SH$, $-Cl$, $-Br$, and $-COC_6H_5$ derivatives, the methylene signals did not split for n_c=12 but, rather, split into a doublet for n_c=18. Generally, the splitting for n_c=12 was observed for compounds with the terminal substituent of a larger electric dipole moment.

In Fig. 1 the values of the solvent shifts ($\Delta\delta$= $\delta(CDCl_3)-\delta$(1-chloronaphthalene)) of the signals are plotted against the electric dipole moment of the substituents, where δ are chemical shift of solute relative to TMS in $CDCl_3$ or 1-chloronaphthalene. The absolute magnitudes of these solvent shifts must be interpreted with caution since there were negative solvent shifts relative to the internal TMS standard. The observed solvent shifts are the difference in the specific interaction on the reference and the solute. Thus, the relative magnitude of the solvent shifts and their dependence on the terminal substituents are discussed. For low molecular weight compounds, the aromatic solvent-induced shift (ASIS) has been well studied. For example, ASIS for compounds of CH_3-X in benzene have been known to depend on its dipole moment or the group moment of substituent (X).[18,19] In Fig. 1 ASIS vs. the dipole moment (μ) of the CH_3-X compounds are also plotted. It should be noted that the aromatic and inert solvents used for CH_3-X were not the same as those used in this study.

We now discuss the relative solvent shifts of split methylene signals compared with those of small molecules. For the higher-field split methylene and α-methylene peaks, the solvent shifts depended on the electric dipole moment of the terminal substituent, as in CH_3-X compounds; however, no dependence was found for the other peaks, i.e. lower- and middle-field split methylene peaks and terminal methyl peaks. Thus, the higher-field split-methylene and α-methylene peaks behaved in a similar manner to ASIS for simple compounds, such as CH_3-X. Though the solvent shifts for the lower and middle methyene peaks and the terminal methyl peaks are different from that for CH_3-X regarding behavior, they are not affected by the choice of the terminal substituents.

Similarities in the solvent shifts for compounds of n_c=12 and 18 are as follows. For α-methylene and the higher-field split methylene peaks, solvent shifts depended on μ; for other peaks, however, they were independent. The dependence of the solvent shifts on μ for α- and higher-field methylene peaks did not vary for n_c=12 and n_c=18. In Fig. 2 the solvent shifts for α- and higher-field split methylene peaks of n_c=12 are plotted against those of n_c=18. It can be recognized that the ASIS for these peaks is not affected by the chain length, but is affected by the substituent. Figure 1 shows that the dependence of the solvent shifts on μ for n_c=18 is smaller than those for CH_3-X compounds; data are sometimes scattered. However, this phenomena is interpreted as having the same origin in both cases, i.e. an interaction between aromatics and substituent.

The difference in the splittings at n_c=12 and 18 was that the former splitting was observed to be dependent on the types of terminal substituents; the later splitting, however, into a triplet or doublet was always observed, irrespective of the substituents. (It may be noted that the splitting was observed exceptionally for longer alkyls than n_c=20 for some compounds.)

In the series of methyl alkanoates, the intensity of the higher-field split peak relative to that of lower-field split peak decreased with an increase in the total

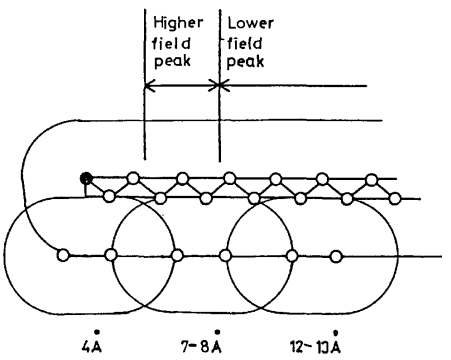

Fig. 4. Model for long alkyl compounds.

chain length. The region of the alkyl chain which experiences the solvent shifts varies with X, and is considered to consist of a definite number of methylene units. Since the solvent shifts for higher-field split peaks behaved in the same manner as those for α-methylene peaks, a definite number of methylene units neighboring the substituent are considered to be shielded by an aromatic solvent. In order to estimate the number of methylene units of the alkyl chain affected by the magnetic anisotropy of the aromatic solvent, the authors tried to assign the methylene signal to three peaks for the series of methyl alkanoates of various chain lengths from an estimation of the intensities of the split signals. The numbers of methylene units estimated for split peaks are plotted against the total carbon numbers of the alkyl chain, n_c, in Fig. 3. The contribution of the higher-field split peaks, which is affected by an aromatic solvent, was about 3 methylene units and almost constant regardless of the chain length. The contribution of the lower-field split peaks increased with n_c. This contribution increased linearly with the carbon numbers of alkyls, n_c, while the contribution of the middle peak was about 7 methylene units and almost constant. Thus, the shielded region by aromatic molecules next to the substituent consists of about 5 methylene units, in which α and β methylenes are included.

Since the behavior of solvent shifts for alkyl compounds with various substituent (X) is similar to that for CH_3-X compounds and the shielded region of alkyl chains consists of a definite number of methylene units, the solvent shifts for such long alkyl compounds can be interpreted as having the same origin as that for small molecules such as CH_3-X compounds. In the ASIS phenomena for small molecules, the association of the solute and the solvent is considered to be favorite in the so-called "solvation sphere". For long alkyl containing molecules, the corresponding solvation sphere would be restricted to local areas of the polar end of the alkyl chain.

Based on the time-averaged cluster model for ASIS,[20,21] the associated states between a long-size solute and a small solvent is considered to involve a variety of orientations of aromatic molecules and their interaction energies. However, some distinct orientations which shield about 5 methylene units are favorite around the polar end of the alkyl chain. These orientations of aromatic molecules are remarkable regarding the first neighbors, just around the polar groups. The aromatic molecules around alkyl chains far from the polar site are randomly oriented around the alkyl methylene units.

The distinct energy difference of the orientation between the first and second neighbors produces a splitting of the methylene signals. In the case of a small energy difference, for example in the substituent of -Cl and -Br, there was observed only a broadening of the methylene signals, but no splitting, was observed.

A schematic representation of the solvent effect for long alkyls is shown in Fig. 4 using Kihara's core model.[22] A distance of 70 to 80 nm from the substituent corresponds to the size of the aromatic molecule in the first neighbors and include approximately 5 methylene units.

In conclusion, observations on the peak splitting of methylene proton signals in terminal substituted alkyl compounds indicated a larger aromatic solvent shift of the terminal end methylenes than the methylene envelopes. These different behaviors of the solvent shifts between the methylenes neighboring of the polar end group and those distant from it in a long alkyl compound are concluded to be the origin of the peak splitting of the methylene signals in long alkyl compounds in aromatic solvents. A schematic molecular model for the aromatic solvent effect on a long alkyl compounds has been proposed as the result of the assignment of split methylene signals for methyl

alkanoates.

(Received June 7, 1989)

The low-energy absorption edge due to the intervalence charge-transfer (IVCT) transition from Pt^{II} to Pt^{IV} has been investigated at 4.2 K and room temperature in single crystals of $[Pt(en)_2][PtBr_2(en)_2]Y_4$ {Y=ClO_4(PBC), HSO_4(PBHS)}, $[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS) and $[Pt(en)_2][PtX_2(en)_2](SO_4)_2 \cdot 6H_2O$ {X=Cl(PCSW), Br(PBSW), I(PISW)}. The IVCT absorption edges in PCSW, PBSW, and PISW shifted to the lower-energy side (i.e. red shift), while those in PBC, PBHS, and PIHS shifted to the higher-energy side (i.e. blue shift) with an increase in temperature. We consider that the thermal effect of the valence fluctuation of the Pt mixed-valence state causes a red shift of the IVCT absorption edge and that the thermal effect of the hydrogen bond between the Pt^{II} complex ion and the Pt^{IV} complex ion causes a blue shift of the IVCT absorption edge. These two effects coexist and compete with each other in one complex. The dominant effect of the two effects determines the direction of the shift of the IVCT absorption edge, namely, the temperature dependence of the Pt mixed-valence state.

In recent years,[1-3] one-dimensional halogen-bridged mixed-valence complexes analogous to Wolffram's Red Salt (WRS) $[Pt(C_2H_5NH_2)_4][PtCl_2(C_2H_5NH_2)_4]Cl_4 \cdot 4H_2O$ have been investigated from the viewpoints of physics and chemistry as a model of one-dimensional mixed-valence compounds. Figure 1 shows the structure of the Pt chain bridged by halogens in these Wolffram's Red Salt Analogues (WRA) mixed-valence complexes. The bridging halogen is not at the middle point between Pt^{II} and Pt^{IV}, but closer to Pt^{IV} than Pt^{II}. The electronic state of Pt is not strictly bivalent or quadrivalent, and approaches that of Pt^{III} by the medium of a charge-transfer interaction between the electronic state of Pt^{II} and that of Pt^{IV}.

The solid state properties in WRS and WRA mixed-valence complexes as a one-dimensional electron system have been investigated both experimentally and theoretically on the basis of the extended Peierls-Hubbard model.[4,5] The dependence of the solid state properties and the mixed-valence state on chemical members of the complexes has been investigated, mainly through substitution of the metal atom and the bridging halogen. Very recently, we reported the investigation on the idea that the influence of the substitution of a counter ion on the mixed-valence state can be interpreted by a hydrogen bond network from a comparison of the optical properties of the sulfate complexes and the hydrogensulfate complexes at 4.2 K.[6] On the other hand, it has been reported that the lattice constants along the Pt chain of $[Pt(NH_3)_4][PtX_2(NH_3)_4](HSO_4)_4$ (X=Cl, Br)[7,8] decrease, while those of $[Pt(NH_3)_4][PtI_2(NH_3)_4](HSO_4)_4 \cdot 2H_2O$[8] and $[Pt(en)_2][PtX_2(en)_2](ClO_4)_4$ (X=Cl, Br, I),[9] where en denotes ethylenediamine, increase with an increase in temperature. These results show that there are two kinds of temperature dependences regarding the Pt-Pt distance: One is that the Pt-Pt distance becomes longer with an increase in temperature; the other is that the Pt-Pt distance becomes shorter with an increase in temperature. This suggests that there are also two kinds of temperature dependences regarding the Pt mixed-valence state. We expect that the temperature dependence of the Pt mixed-valence state is dominated by the constituents of the complexes as the metal ion, the bridging halogen, the in-plane ligand amine and the counter ion. However, the temperature dependence of the mixed-valence state has not yet been investigated in detail. We have investigated the temperature dependence of the optical properties in some WRA mixed-valence complexes in order to clarify the temperature dependence of the mixed-valence state. In this paper we report on the optical properties of single crystals at 4.2 K and at room temperature in $[Pt(en)_2][PtX_2(en)_2](SO_4)_2 \cdot 6H_2O$ {X=Cl(PCSW), Br(PBSW), I(PISW)}, $[Pt(en)_2][PtBr_2(en)_2]Y_4$ {Y=ClO_4(PBC), HSO_4(PBHS)}, $[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS). In addition, we also report on the synthesis, structure and the mixed-valence state of a new WRA mixed-valence complex, PCSW. From these experimental results, we discuss the temperature dependence of the Pt mixed-valence state on the basis of the hydrogen bond network.

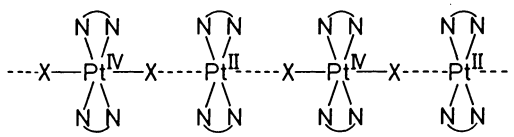

Fig. 1. The Pt chain structure of the halogen-bridged mixed-valence platinum complexes.

† Present address: Department of Chemistry, College of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153.

Experimental

Preparation. The Pt^{II}-Pt^{IV} mixed-valence complexes (PBHS, PIHS, PBSW, PISW) were prepared; these single crystals were obtained according to a previously described method.[6] The PBC was prepared by a procedure of Bekaroglu et al.[10] Single crystals of the low-temperature phase** of PBC were obtained at 13 °C by recrystallization from an aqueous solution. The above-mentioned mixed-valence complexes were identified by elemental analysis and a powder X-ray diffraction method.

$[Pt(en)_2][PtCl_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PCSW): $[PtCl_2(en)_2](HSO_4)_2$ was obtained by the oxidation of $[Pt(en)_2]Cl_2$ with an aqueous hydrogen peroxide solution, and then by the addition of a small amount of hydrochloric acid and an excess of aqueous sulfuric acid to the oxidized platinum complex solution. Its Pt^{IV} complex (1.7 mmol) and $[Pt(en)_2]Cl_2$ (1.7 mmol) were dissolved in water (ca. 100mL). Yellow plate-like single crystals, which show dichroism, were obtained by a slow concentration of this colorless solution. Found: C, 9.63; H, 4.46; N, 11.31; O, 22.44; S, 6.45; Cl,7.06%. Calcd for $C_8H_{44}Cl_2N_8O_{14}Pt_2S_2$: C, 9.61; H, 4.44; N, 11.21; O, 22.41; S, 6.42; Cl, 6.89%.

Elemental analysis was carried out by "The Laboratory for Organic Elemental Microanalysis" of Kyoto University.

Instrumental Measurements. Powder X-ray diffraction patterns were recorded at room temperature (20 °C for PBC) on a Rigaku diffractometer using the θ-2θ scan technique and graphite-monochromated Cu $K\alpha$ radiation (λ=1.5418 Å). It was confirmed that crystals of PBC were the low-temperature phase. The crystals of PBC in the low-temperature phase were used for measurements of the absorption spectra.

The TGA of PCSW was performed on a Rigaku TG DTA 8112S apparatus in the temperature region from room temperature to 200 °C.

The absorption spectra of single crystals were measured at 4.2 K and room temperature with a Jasco CT-100 spectrometer using a tungsten lamp for the light source and a Glan-Taylor prism for polarizing light. A lock-in system working with HTV R376 and R316 photomultipliers and a PbS photoconductive cell was used for detection. The sample measured at 4.2 K was placed in a double glass Dewar's vessel and immersed in liquid helium to cool. The measurement at room temperature was carried out by irradiating the sample with monochromatic light to prevent thermo-damage of the single crystal due to white light.

Results and Discussion

PCSW. TGA shows that the content of the crystallized water (10.8%) calculated from the chemical formula of PCSW corresponds with the weight loss (10.6%, 48—121 °C) on heating. The powder X-ray diffraction pattern shows that PCSW is isomorphous to PBSW and PISW in structure. The lattice constants of PCSW (a=13.74, b=11.54, c=9.19 Å, β=101.7°) was determined by the powder X-ray diffraction pattern of PCSW with index numbers which were numbered by reference to that of PBSW and PISW. To our knowledge, it is the first example that Cl-, Br-, and I-bridged complexes are isomorphous in the WRA mixed-valence complexes whose chemical entities are the same, except for the bridging halogen. Figure 2 shows the absorption spectra of a single crystal of PCSW at 4.2 K. The absorption edge P for the light polarized parallel to the Pt chain axis (***E*//** chain) is the low-energy absorption edge due to the IVCT transition from the d_{z^2} of Pt^{II} to the d_{z^2} of Pt^{IV}. The energy of the IVCT absorption edge of PCSW (22.3×10^3 cm^{-1}) is higher than that of PBSW (17.7×10^3 cm^{-1})[6] and PISW (9.5×10^3 cm^{-1}).[6] The energies of the IVCT absorption edge in complexes comprising a bivalent counter ion are in the order I<Br<Cl, as well as those in complexes comprising a univalent counter ion. The energy of the IVCT absorption edge of PCSW is higher than that of $[Pt(en)_2][PtCl_2(en)_2](ClO_4)_4$ (PCC) (19.1×10^3 cm^{-1})[11] as well as that of PBSW, being higher than that of PBHS (8.4×10^3 cm^{-1})[6] and PBC (7.5×10^3 cm^{-1}). In other words, the energy of the IVCT absorption edge of a complex comprising a bivalent counter ion is higher than that of the complexes comprising a univalent counter ion, also in the chloro-bridged mixed-valence complexes. As previously described in our paper,[6] complexes comprising a univalent counter ion have more hydrogen bonds which link a platinum atom with an adjacent platinum on the same chain by way of the amine and the counter ion than the complexes comprising a bivalent counter ion. This is because the molar ratio of the counter ion for a platinum atom in the former complexes is twice as large as that in the latter complexes. Thus, the bond between a platinum atom and an adjacent platinum atom on the same chain in univalent counter ion complexes is more strongly supported by the hydrogen bond network than that in

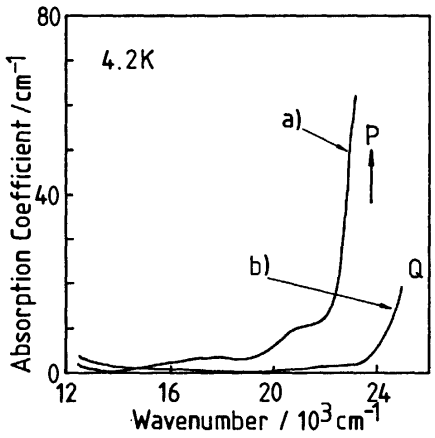

Fig. 2. Single crystal absorption spectra of $[Pt(en)_2][PtCl_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PCSW) at 4.2 K. Curve a) is the spectrum for the light polarized parallel to the Pt chain axis (***E*//**chain). Curve b) is the spectrum for the light polarized perpendicular to the Pt chain axis (***E*⊥**chain).

** The structure phase transition occurs in PBC at ca. 30 °C. The high-temperature phase is orthorhombic and the low-temperature phase is monoclinic.

the bivalent counter ion complexes. Therefore, the result of PCSW and PCC can also be explained by the effect of this hydrogen bond network. The peak energy of the IVCT band obtained by a Kramers-Kronig transformation of the reflection spectra of $[Pt(chxn)_2][PtCl_2(chxn)_2](ClO_4)_4$ (Pt-chxn-Cl-ClO_4) (3.2 eV), where chxn denotes 1,2-cyclohexanediamine, is much higher than that of PCC (2.72 eV),[4] and the crystal color of Pt-chxn-Cl-ClO_4 is the same yellow as that of PCSW. These results show that the mixed-valence state of PCSW is comparable to that of Pt-chxn-Cl-ClO_4. We can explain the change in the mixed-valence state with a change from en to chxn as follows. The distinction between the electronic state of Pt^{II} and that of Pt^{IV} becomes large with a decrease in the effect of the hydrogen bond network, since the C_6H_{10} ring of chxn blocks the formation of the hydrogen bonds between the $-NH_2$ of chxn and the counter ion ClO_4^-. The influence of the substitution from the univalent counter ion as ClO_4^- or HSO_4^- to the bivalent counter ion as SO_4^{2-} on the mixed-valence state is comparable to that of the substitution of the in-plane ligand amine from en to chxn. In other words, this fact is proof that the hydrogen bond between the counter ion and the amine contributes to the mixed-valence state.

Temperature Dependence of the Mixed-Valence State. Figures 3—5 show the IVCT absorption edges for the *E*//chain at 4.2 K and at room temperature in PBC, PBHS, and PIHS, respectively; Table 1 shows those energies. The energies of these IVCT absorption edges at room temperature are higher than those at 4.2 K. Namely, the IVCT absorption edges in PBC, PBHS, and PIHS shifted to the higher-energy side with an increase in temperature. This blue shift is opposite to a broadening of the spectra due to an increase in temperature. Therefore, this result shows that the energy distinction between the electronic state of the Pt^{II} and that of the Pt^{IV} in the mixed-valence state increases with an increase in temperature.

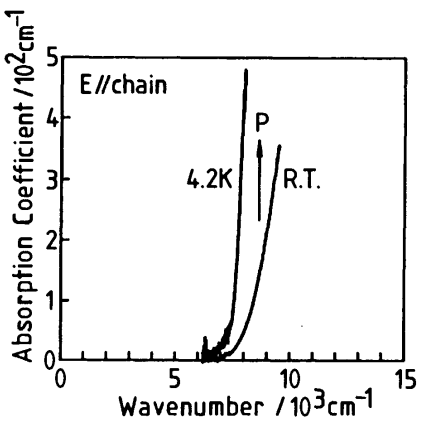

Fig. 3. The IVCT absorption edges of the single crystal of $[Pt(en)_2][PtBr_2(en)_2](ClO_4)_4$ (PBC) for *E*//chain at 4.2 K and room temperature (R.T.).

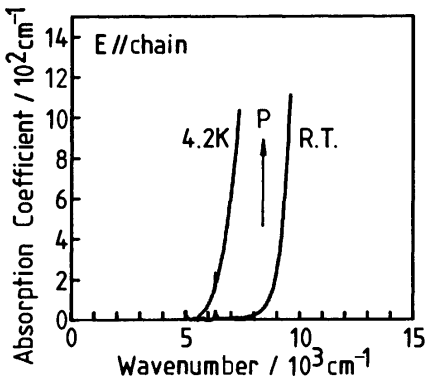

Fig. 5. The IVCT absorption edges of the single crystal of $[Pt(en)_2][PtI_2(en)_2](HSO_4)_4 \cdot 4H_2O$ (PIHS) for *E*//chain at 4.2 K and room temperature (R.T.).

Table 1. The Energy of the IVCT Absorption Edges at 4.2 K and Room Temperature

Complex	Energy/10^3 cm^{-1}	
	4.2 K	Room temp
PBC	7.5	8.3
PBHS	8.4	10.2
PIHS	6.4	9.0
PCSW	22.3	19.8
PBSW	17.7	14.8
PISW	9.5	7.3

Figures 6—8 show the IVCT absorption edges for the *E*//chain at 4.2 K and at room temperature in PCSW, PBSW, and PISW, respectively; Table 1 shows those energies. The energies of these IVCT absorption edges at room temperature are lower than those at 4.2 K. Namely, the IVCT absorption edges in PCSW, PBSW, and PISW shifted to the lower-energy side with an increase in temperature. This result shows that the energy distinction between the electronic state of the Pt^{II} and that of the Pt^{IV} in the mixed-valence state decreases with an increase in temperature, for the following reasons. The lower-energy side shift, i.e. the red shift (2000—3000 cm^{-1}), is much larger than

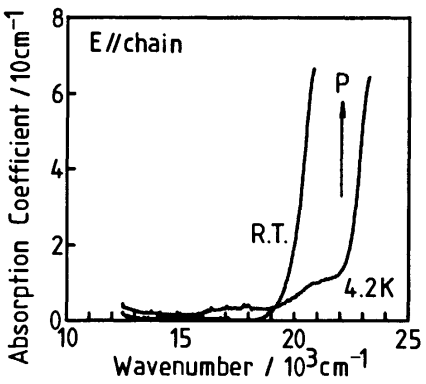

Fig. 6. The IVCT absorption edges of the single crystal of $[Pt(en)_2][PtCl_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PCSW) for *E*//chain at 4.2 K and room temperature (R.T.).

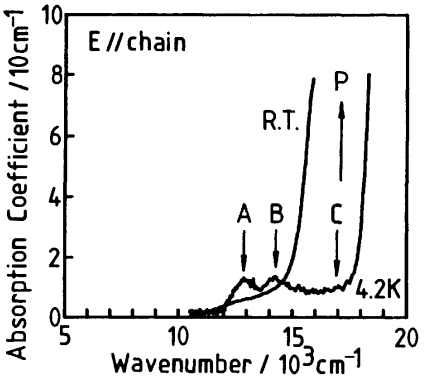

Fig. 7. The IVCT absorption edges of the single crystal of $[Pt(en)_2][PtBr_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PBSW) for *E*//chain at 4.2 K and room temperature (R.T.).

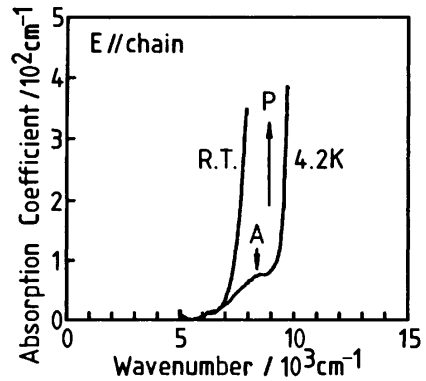

Fig. 8. The IVCT absorption edges of the single crystal of $[Pt(en)_2][PtI_2(en)_2](SO_4)_2 \cdot 6H_2O$ (PISW) for *E*//chain at 4.2 K and room temperature (R.T.).

the temperature broadening of the spectra. Its large red shift cannot be explained by both a broadening of the spectra and an increase in the energy distinction between the electronic state of the Pt^{II} and that of the Pt^{IV}, which was mentioned above. In addition, we have found that the peak energy of the reflection spectra of PBSW at room temperature is lower than that at 77 K.[12] The result of the reflection spectra is consistent with the absorption spectral result of PBSW. Therefore, the result of the red shift of the IVCT absorption edge shows that the energy distinction between the electronic state of Pt^{II} and that of Pt^{IV} in the mixed-valence state decreases with an increase in temperature.

We found that there are two kinds in the temperature dependences of the mixed-valence state from the absorption spectra. These two dependences are consistent with the two types of temperature dependences of the mixed-valence state obtained from the structural result: that there are two kinds in the temperature dependences of the Pt-Pt distance along the Pt chain. To interpret the two types of temperature dependences of the mixed-valence state, we propose two types of thermal effects contributing to the mixed-valence state as follows.

One is an effect that the electronic state of the Pt^{II} and that of the Pt^{IV} approach each other with an increase in temperature. A positional fluctuation of the bridging halogen becomes vigorous by a thermal excitation of the Pt^{IV}-X stretching vibration with an increase in temperature. This fluctuation induces a valence fluctuation of the Pt mixed-valence state by the medium of the electron-phonon coupling, which is one of characteristics of this WRA system. This valence fluctuation becomes vigorous with an increase in temperature, and approaches the electronic state of the Pt^{II} and that of the Pt^{IV} to that of the Pt^{III}, respectively. Consequently, the distinction between the energy level of the d_{z^2} of Pt^{II} and that of Pt^{IV} in the mixed-valence state decreases with an increase in temperature. As a result, this change in the Pt electronic state causes a red shift of the IVCT absorption edge. Equally, the negative thermal expansion coefficient of the lattice constant along the Pt chain axis of $[Pt(NH_3)_4][PtX_2(NH_3)_4](HSO_4)_4$ (X=Cl, Br)[7,8] is theoretically interpreted as the valence fluctuation.[13]

The other is an effect that the electronic state of the Pt^{II} and that of the Pt^{IV} are more distinguishable from each other with an increase in temperature. Positional fluctuations of the hydrogen atom of the in-plane ligand amine and the oxygen atom of the counter ion become vigorous by thermal excitation with an increase in temperature. These fluctuations weaken the link by the hydrogen bond between the Pt^{II} complex ion and the Pt^{IV} complex ion. Consequently, the weak link of the hydrogen bond weakens the intervalence charge-transfer bond between the $Pt^{II}$and the Pt^{IV}. Therefore, the electronic state of the Pt^{II} and that of the Pt^{IV} at higher temperatures become more distinguishable than those at lower temperatures. As a result, this change in the Pt electronic state causes a blue shift of the IVCT absorption edge.

In a comparison between the crystal structure of $[Pt(NH_3)_4][PtBr_2(NH_3)_4](HSO_4)_4$ at 298 K and that at 134 K, the Pt-Pt distance becomes long, and the N(-H)···O distance becomes short with a decrease in

temperature.[8] The change of the Pt-Pt distance is consistent with the red shift, and the change of the N(-H)···O distance is consistent with the blue shift. This result regarding the structure shows that both effects causing the red and blue shifts coexist together and compete with each other in one WRA mixed-valence complex, since changes in both the Pt-Pt distance and the N(-H)···O distance coexist. In addition, from the results concerning the IVCT absorption edge, the dominant effect of the two competing effects determines the direction of the shift of the IVCT absorption edge. In the sulfate complexes, PCSW, PBSW, and PISW, the effect of the valence fluctuation due to the thermal vibration of the bridging halogen (namely, the effect causing the red shift) dominates. In PBC, PBHS, and PIHS, the effect regarding the weakening of the hydrogen bond link due to the thermal vibration (namely, the effect causing the blue shift) dominates. Furthermore, we consider which of the thermal effects (the valence fluctuation or the hydrogen bond) dominates the temperature dependence of the mixed-valence state. This dominance can be explained from the effect of the hydrogen bond network. As mentioned above, the dependence of the energy of the IVCT absorption edges on the substitution of the counter ion and that of the in-plane ligand amine is explained from this effect of the hydrogen bond network. Relatively speaking, the perchlorate and hydrogensulfate complexes comprising the univalent counter ion belong to a system in which the effect of the hydrogen bond network is stronger, while the sulfate complexes comprising the bivalent counter ion belong to a system in which that effect is weaker. This classification is used because the composition ratio of the counter ions for a platinum atom in the former is twice as much as that in the latter.[6] First, in the former system, in which the effect of the hydrogen bond network is stronger, the temperature dependence of the mixed-valence state is dominated by the thermal effect of the hydrogen bond rather than the thermal effect of the valence fluctuation. Therefore, the energy distinction between the electronic state of Pt^{II} and that of Pt^{IV} becomes larger, namely, the IVCT absorption edge shows a blue shift with an increase in temperature. On the other hand, in the latter system, in which the effect of the hydrogen bond network is weaker, the temperature dependence of the mixed-valence state is dominated by the thermal effect of the valence fluctuation rather than the thermal effect of the hydrogen bond. Therefore, the energy distinction between the electronic state of Pt^{II} and that of Pt^{IV} becomes smaller, namely, the IVCT absorption edge shows a red shift with an increase in temperature.

In the above discussion, the mixed-valence state and its temperature dependence in the perchlorate and hydrogensulfate complexes are not only dominated by the direct contribution due to the interaction between the Pt^{II} and the Pt^{IV} through the bridging halogen, but are also dominated by the hydrogen bond between the amine and the counter ion. On the other hand, the mixed-valence state and its temperature dependence in the sulfate complexes are almost dominated by the direct contribution and are little dominated by the hydrogen bond.

To confirm the temperature dependences of the mixed-valence state by the reflection spectra, measurements of the reflection spectra in PBC, PBHS, PIHS, PCSW, and PISW are in progress. To clarify the relation between the temperature dependence of the IVCT spectra and that of the structure, studies of the temperature dependence of the crystal unit cell for PBHS, PIHS, PCSW, PBSW and PISW, and that of the IVCT absorption edges of $[Pt(NH_3)_4][PtX_2(NH_3)_4](HSO_4)_4$ (X=Cl, Br) and $[Pt(NH_3)_4][PtI_2(NH_3)_4](HSO_4)_4 \cdot 2H_2O$ are necessary.

The authors wish to thank Dr. Koshiro Toriumi of I.M.S. and Dr. Masahiro Yamashita of Nagoya University for valuable discussions concerning the crystal structure. We are also indebted to Dr. Naohilo Watanabe of Kyoto University for his kind help and advice concerning data processing computer programs. This study was supported by a Grant-in-Aid for Scientific Research No. 63540485 from the Ministry of Education, Science and Culture.

Analysis of Cyclic Voltammograms for Polypyrrole-as-Deposited Pt/poly[tris(4-vinyl-4′-methyl-2,2′-bipyridine)ruthenium(II) perchlorate] Electrodes

Kenji MURAO,* Naoki TANAKA, and Kazuhiro SUZUKI
Advanced Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185
(Received July 29, 1989)

Oxidation waves in cyclic voltammograms (CVs) observed during repeated potential cyclings of polypyrrole-as-deposited Pt/poly-1 electrodes (poly-1: poly[tris(4-vinyl-4′-methyl-2,2′-bipyridine)ruthenium-(II) perchlorate]) in 0.1 M TBAP/acetonitrile, that lead to the bilayer (BL) electrochemistry, have been quantitatively analyzed. As the potential cycling is repeated, the CV change occurs, i.e., decrease of the peak current and positive shift of the peak potential. This is shown to be the result of logarithmic decrease in the complementary charge transfer coefficient β in the totally irreversible thin-layer (TITL) electrochemistry. k°_{TL} (standard rate constant for polypyrrole oxidation) and C°_{TL} (initial concentration of the reduced sites in polypyrrole) have been determined to be 5.50×10^{-9} cm mol^{-1} s^{-1} and 3.15×10^{-3} mol cm^{-3}, respectively, by fitting CV data to the theory of the TITL model. The subsequent onset and growth of the CV waves in the higher potential region are explained as being due to progressive partitioning of polypyrrole sites from the TITL mode to the BL mode in which polypyrrole sites are oxidized. The partition coefficient θ, defined as the ratio of polypyrrole sites oxidized in the BL mode to all the polypyrrole sites, has been found to approximately depend on the logarithm of β. In the BL mode, a linear relationship is found between peak current and peak potential. Simulation of the CV waves has been performed based on the theoretical models of TITL and BL electrochemistry, and has revealed that a model assuming separation of polypyrrole sites into the TITL and BL modes prior to each cyclic sweep explains the occurrence of the significantly separated current peaks in both modes. These results are discussed in terms of Electrochemically driven Phase Separation (ECPS), in which the decrease in β is directly related to the separation of the mixed poly-1 and polypyrrole phase.

Fabrication of microstructures with conducting polymers such as polypyrrole[1] has been the subject of recent keen interest because of both their basic importance in solid state physics[2] and potential applications.[3-7] We previously[8] reported on the successful deposition of polypyrrole onto an electrochemically active polymer film, poly-1 (poly[tris(4-vinyl-4′-methyl-2,2′-bipyridine)ruthenium(II) perchlorate]), giving an electrode expressed as Pt/poly-1/polypyrrole. Preparation of the bilayer electrodes consists of the following two steps; 1) electropolymerization of pyrrole at a Pt/poly-1 electrode, 2) repeated potential cyclings between 2+/3+ and 2+/1+ redox potentials of the $[Ru(vbpy)_3]^{2+}$ center (vbpy: 4-vinyl-4′-methyl-2,2′-bipyridine) in 0.1 M TBAP (tetrabutylammonium perchlorate)/acetonitrile (1 M=1 mol dm^{-3}). In step 1), electropolymerization of pyrrole occurs at the platinum substrate as a result of permeation of the monomer molecules throughout the poly-1 layer, as is evidenced by the CVs (cyclic voltammograms) which indicate direct charge exchange between the polypyrrole layer and the platinum substrate.[8] This means that a mixed phase of poly-1 and polypyrrole is formed in this stage. However the subsequent potential sweeps (step 2)) ultimately result in the bilayer electrochemistry in which redox reactions of polypyrrole are totally mediated by the $[Ru(vbpy)_3]^{2+}$ sites in the poly-1 layer. These electrochemical processes contrast with those employed for the preparation of bilayer electrodes based on electro-nonconducting redoxing polymers,[9] although our electrodes finally obtained through the above steps behave essentially in the same way. During step 2), a series of characteristic CV changes have been recorded as shown in Fig. 1

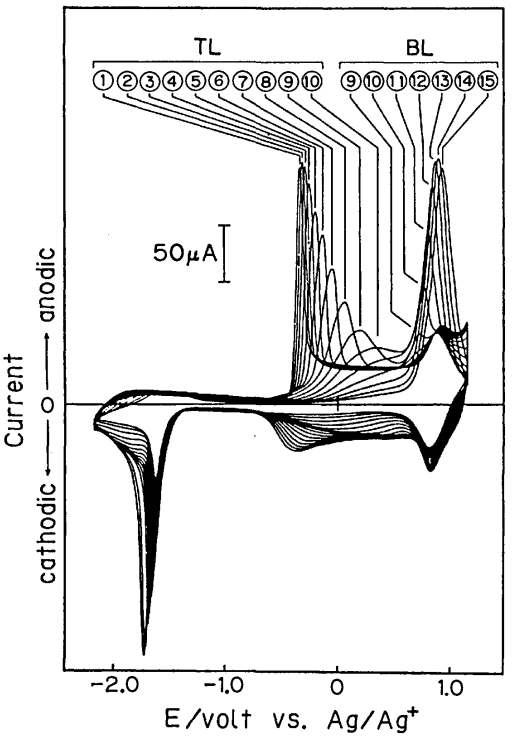

Fig. 1. Cyclic voltammograms of a polypyrrole-as-deposited Pt/poly-1 electrode measured upon repeated potential sweeps in 0.1 M TBAP/acetonitrile. Sweep rate: 0.1 V s^{-1}. (A part of this figure is reproduced from Fig. 2(b) of Ref. 8 with permission.)

(partially reproduced from Fig. 2(b) of Ref. 8). These CVs have aroused our great interest because they seem to represent certain unknown electrochemical processes that involve dynamic changes taking place in the polymer matrix. To account for the electrochemical changes, we proposed Electrochemically driven Phase Separation (ECPS) of the mixed phase from optical studies.[10] Polythiophenes have been found to undergo similar electrochemical processes.[11,12]

We show here that the CVs in Fig.1 represent a gradually developing crossover from a regime essentially described by totally irreversible thin layer electrochemistry[13] (TL regime) to bilayer electrochemistry (BL regime), associated with systematic decrease in β (complementary charge-transfer coefficient, $\equiv 1-\alpha$ where α is the charge-transfer coefficient). This finding not only supports the hypothesis of the ECPS scheme[10,14] but also provides insight into the implications of the charge-transfer coefficient in the electrochemistry of polymer-coated electrodes. The electrochemistry of polymer-coated electrodes has been studied[15-18] in relation to that of chemisorbed systems[19,20] which have the same basis as thin-layer electrochemistry.

Experimental

Materials. Preparation of the monomer precursor of poly-1, $[Ru(vbpy)_3]^{2+}$ $2PF_6^-$ was described in previous papers.[8,10] Acetonitrile was used after distillation. Commercial TBAP was purified by recrystallizing from an EtOH/H_2O 2:3 mixed solvent and was dried in vacuo at 80 °C for 32 h.

Electrochemistry. Platinum disks (3 mm diameter) embedded in glass were used as the working substrates. The surface of the platinum substrates was polished with 1 μm diamond paste. Each working electrode was sonicated three times in freshly distilled acetone, two times in trichloroethylene, two times in distilled water, and then dried at 80 °C. All of the electrochemical experiments were performed under argon-purged conditions. Electropolymerizations and electrochemical measurements were performed in a one-compartment cell with an Ag/Ag^+ quasi-reference electrode which showed 290 mV vs. SCE (saturated calomel electrode) in 0.1 M TBAP/acetonitrile. Potentials are all indicated vs. Ag/Ag^+. Deposition of poly-1 and polypyrrole were described in previous papers.[8,10] Electrochemical experiments were performed on a PAR Model 175 Universal Programmer and a 173 Potentiostat, and were recorded on a YEW 3086 X-Y Recorder.

Results and Discussion

Nature of the Cyclic Voltammograms. Figure 1 depicts the CVs for polypyrrole-as-deposited Pt/poly-1 electrode, recorded during repeated potential sweeps at a sweep rate of 0.1 V s^{-1} in 0.1 M TBAP/acetonitrile. The repeated potential sweeps lead to the bilayer electrochemistry.[8] Just after the break-in,[8] the oxidation waves of polypyrrole show sharp peaks which are not observed for Pt/polypyrrole electrodes. The following potential sweeps (**1—8**) cause shifts in $E_{p,TL}$ (peak potential for polypyrrole oxidation wave in the TL regime) in the positive direction associated with decrease in $i_{p,TL}$ (peak current for polypyrrole oxidation waves). In this stage, all of the polypyrrole sites are oxidized in the TL regime. Subsequently repeated potential sweeps evolve current peaks near the 2+/3+ redox potential of poly-1 (**9,10** in the BL regime), owing to the onset of mediated oxidation of polypyrrole, which increases with further sweeps, eventually leading to the oxidation of all polypyrrole sites in the BL mode.

To prove the nature of the sharp peaks, CVs were measured for a separate electrode (Fig. 2) in a stage approximately corresponding to **1—4** of Fig. 1. These CVs are anomalous in the sense that, although the sharp oxidation peak ③ is a result of direct electron transfer to the electrode, its rereduction ① is

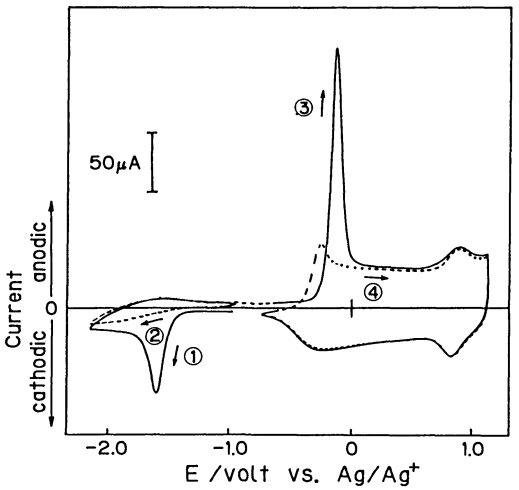

Fig. 2. Cyclic voltammograms of similarly prepared electrode as that of Fig. 1 measured in 0.1 M TBAP/acetonitrile at a sweep rate of 0.1 V s^{-1}. The CVs approximately correspond to the stage of the sweeps **1—4**. Numbers in circles indicate the sequence of the sweeps.

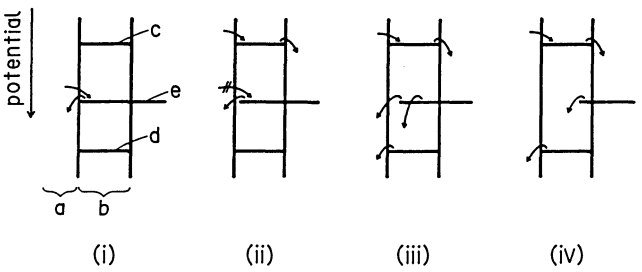

Fig. 3. Representation of possible electron transfer modes inferred on the basis of the electrochemistry depicted in Figs. 1 and 2. a: platinum electrode; b: poly-1 layer; c,d: 2+/1+ and 2+/3+ redox levels of $[Ru(vbpy)_3]^{2+}$ centers in poly-1, respectively; e: redox level of polypyrrole where the extent of phase separation is represented by relative positions of the bar.

mediated by the 2+/1+ redox level of poly-1. This implies that the sharp current peak ③ is due to the totally irreversible oxidation of polypyrrole. The nature of this peak is essentially faradaic because optical changes due to the polypyrrole oxidation are substantiated by the peak.[21]

These points are illustrated in Fig. 3. In the initial stage (i), both oxidation and reduction reactions of polypyrrole occur only through direct charge exchange with the platinum electrode. The above mentioned anomaly is shown in (ii) in which the oxidative and reductive charge transfers are effected asymmetrically. Stage (iii) corresponds to sweeps **9—12**, where both direct and indirect (mediated) oxidation modes of polypyrrole occur in a single sweep, while its rereduction is totally mediated. Stage (iv) represent the finally achieved bilayer electrochemistry corresponding to **13—15**. Hence, the electrochemistry involved in Fig. 1 can be summarized as follows; the current waves denoted by TL in Fig. 1 represent totally irreversible oxidations of polypyrrole. The following repeated potential sweeps increase the portion of polypyrrole sites that is mediatively oxidized by poly-1, eventually leading to the mediated oxidation of the whole polypyrrole sites. This suggests that the TL regime may be analyzed on the basis of the thin layer model for totally irreversible electrode processes.[13]

Analysis of Cyclic Voltammograms Using the Thin Layer Model for Totally Irreversible Electrode Processes (TITL Model). CVs for polypyrrole-as-deposited Pt/poly-1 electrodes were measured in the same way as for Fig. 1, for three separate electrodes, A—C. Coverages of poly-1 (mol cm^{-2}) and charge densities passed during the electropolymerization of pyrrole (mC cm^{-2}) are as follows, respectively; A: 3.45×10^{-9}, 40.0; B: 3.86×10^{-9}, 39.6; C: 2.68×10^{-9}, 41.2. Since the CVs involving polypyrrole include non-faradaic components significantly,[21a,b,22-24] their quantitative analysis of the whole waveforms is not straightforward. Therefore, the following analysis only considers peak currents and peak potentials which are expected to be less affected by non-faradaic contributions as mentioned above. Table 1 lists peak currents and peak potentials for electrodes A—C. Sweep number **1** for each electrode in Table 1 are determined as the sweep by which peak currents in the TL regime reach the initial saturation level after break-in.[8] Subsequent sweep numbers, as indicated in Fig. 1, are given for every consecutive three sweeps.

According to the TITL model,[13] oxidative currents upon a linear potential sweep are given by

$$i_{TL}=n_{TL}FS\,k^{\circ}_{TL}\,C^{\circ}_{TL}\exp\left\{\frac{\beta n_{o,TL}F}{RT}(E-E^{\circ}_{TL})-\frac{SRTk^{\circ}_{TL}}{\beta n_{o,TL}FVr}\exp\left[\frac{\beta n_{o,TL}F}{RT}(E-E^{\circ}_{TL})\right]\right\} \quad (1)$$

n_{TL} : number of electrons per reaction center oxidized
$n_{o,TL}$: number of electrons per reaction center oxidized in the rate-determining step
k°_{TL} : standard rate constant (cm mol^{-1} s^{-1})
C°_{TL} : initial concentration of reduced centers (mol cm^{-3})
F : Faraday constant
R : gas constant
T : absolute temperature of the reaction system
V : volume of the reaction system
S : electrode area
r : sweep rate of electrode potential (V s^{-1})
E°_{TL} : standard electrode potential

By differentiation, peak current, $i_{p,TL}$, and peak potential, $E_{p,TL}$, are obtained.

Table 1. Observed Peak Currents and Peak Potentials

a) 10^{-6} A. b) V vs. Ag/Ag^{+}.

$$i_{p,TL}=\frac{\beta n_{o,TL}\, n_{TL}\, F^2\, V\, r\, C^\circ_{TL}}{eRT} \quad (2)$$

$$E_{p,TL}=E^\circ_{TL}+\left(\frac{RT}{\beta n_{o,TL}\, F}\right)\ln\left(\frac{\beta n_{o,TL}\, FVr}{SRTk^\circ_{TL}}\right) \quad (3)$$

Since β values for each ($i_{p,TL}$, $E_{p,TL}$) set are not known, direct evaluation of the data in Table 1 with Eqs. 2 and 3 is not practical. By combining Eqs. 2 and 3, $\beta n_{o,TL}$ is eliminated to give

$$f(i_{p,TL})\equiv\frac{n_{TL}\, FVr\, C^\circ_{TL}}{ei_{p,TL}}\ln\frac{ei_{p,TL}}{n_{TL}\, FSC^\circ_{TL}\, k^\circ_{TL}}=(E_{p,TL}-E^\circ_{TL}) \quad (4)$$

An alternative criterion is to see if the sets ($i_{p,TL}$, $E_{p,TL}$) in Table 1 systematically fit in with Eq. 4. Since the exact values of V and C°_{TL} for polypyrrole sites are not available, the (V, k°_{TL}, C°_{TL}, E°_{TL}) set that fits the (i_{TL}, E_{TL}) data was sought. As a result, a linear fit to $f(i_{p,TL})$ vs. $(E-E^\circ_{TL})$, though only for a part in the TL regime, has been found for electrode A as shown in Fig. 4(a), when $V_A=0.636\times10^{-6}$ cm^3, $k^\circ_{TL}=5.50\times10^{-9}$ cm mol^{-1} s^{-1}, $C^\circ_{TL}=3.15\times10^{-3}$ mol cm^{-3}, $E^\circ_{TL}=-0.535$ V and $n_{TL}=n_{o,TL}=1$. Here, each peak current is assumed to include a background current of 5 μA. Owing to the fact that the E°_{TL} (or $E^{\circ\prime}_{TL}$) value cannot be pinpointed

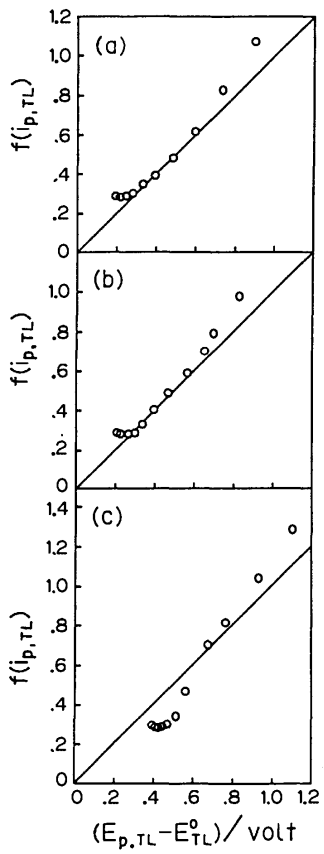

Fig. 4. Plots of $f(i_{p,TL})$ vs. $(E_{p,TL}-E^\circ_{TL})$, according to Eq. 4. $k^\circ_{TL}=5.50\times10^{-9}$ cm mol^{-1}s^{-1}, $C^\circ_{TL}=3.15\times10^{-3}$ mol cm^{-3}. E°_{TL} values: (a) −0.535 V; (b) −0.600 V; (c) −0.720 V. (a)—(c) correspond to electrodes A—C, respectively.

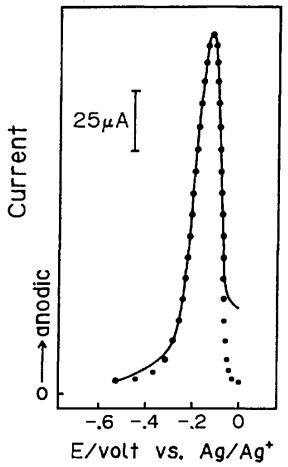

Fig. 5. Fitting of the voltammogram calculated based on Eq. 1 by using the same (V, k°_{TL}, C°_{TL}, E°_{TL}) parameters for electrode A as in Fig. 4(a) (dots). β=0.525. The solid line represents the oxidation wave of the sweep number **6** of electrode A.

in the original CV, the parameter set (V, k°_{TL}, C°_{TL}) that gives similar linearity can exist not uniquely because of the small changes in E°_{TL}. However, it has been found that current waves calculated based on Eq. 1 using the above particular parameter set fit in with the experimental waveforms, as exemplified for electrode A in Fig. 5. Here the same amount of background current, 5 μA, is assumed as in Fig. 4. This result also gives further evidence that the sharp oxidation peaks in the TL regime in Fig. 1 are essentially faradaic.

Furthermore, it has been found that, when V_B and V_C are given by 'normalization' as indicated below, ($i_{p,TL}$, $E_{p,TL}$) sets of the electrodes B and C also show linearity similar to Fig. 4 (a), as shown in Fig. 4(b) and (c), respectively, with precisely the same (k°_{TL}, C°_{TL}) set used in Fig. 4(a). This normalization is based on the $i_{p,TL}$ values of sweep number **1** of each electrode so that $V_B=V_A\times i_{p,TL}(B)/i_{p,TL}(A)$ and $V_C=V_A\times i_{p,TL}(C)/i_{p,TL}(A)$. This normalization is not unreasonable since the peak current is known to be proportional to V (or S for surface systems) in thin layer[13] and chemisorbed[19,20] systems, regardless of their electrochemical reversibility. The fact that precisely the same set of (k°_{TL}, C°_{TL}) fits the ($i_{p,TL}$, $E_{p,TL}$) sets of the separate electrodes with apparently different coverages (A, B, and C) is a strong indication that major portions of the data in Table 1 can be described essentially by the TITL model. Different E°_{TL} values are obtained for the three electrodes by the fitting procedure, i.e., A: −0.535 V; B: −0.600 V; C: −0.720 V. Such differences persist even when different (k°_{TL}, C°_{TL}, E°_{TL}) sets, that give the similar linearity, are used. Since the deviations of the plots from the linearity are larger in Fig. 4(c) than in the other two cases, E°_{TL} values of electrodes A and B seem to be more reliable. In fact, the E°_{TL} values for electrodes A and B are only slightly different from $E^{\circ\prime}$ values of

polypyrrole estimated on the basis of the separations of E_{pa} and E_{pc}.[25,26]

Significant deviations from the linearity are seen in Fig. 4 for both smaller and larger sweep numbers. Although the electrochemical mechanism that governs the initial sweeps is not known, it may be due to some strong interactions between polypyrrole and the electrode substrate. The deviations in larger sweep numbers ($\geq$8), in which BL mode oxidation also occurs, are understood as a result of the reductions in $i_{p,TL}$ due to partial consumption (oxidation) of C°_{TL} in the BL mode. This partitioning of C°_{TL} from the TL to BL mode is further analyzed in the following sections.

Estimation of Complementary Charge Transfer Coefficient. In plotting Fig. 4, all parameters in Eq. 4 are fixed except for β. Hence, the different values of $f(i_{p,TL})$ are assumed to be generated by the changes in β values in Eqs. 2 and 3 for each cyclic sweep. Thus the β values can be obtained from these equations. However, it should be noted that, because of the partitioning of C°_{TL} from the TL to BL modes for sweep numbers larger than **8** as mentioned above, β values obtained from Eq. 2 can be inaccurate. Therefore, β is alternatively estimated, by using experimental $E_{p,TL}$ values and the parameter set used in Fig. 4, based on Eq. 3 in which β is not dependent on C°_{TL}. The result of the calculations are shown in Fig. 6. It is seen from Fig. 6 that β values decrease logarithmically as the sweep number increases, meeting the condition of $0 \leq \beta \leq 1$ for $E_{p,TL}$ values that fit linearly in with Fig. 4. On the other hand, β values obtained for $E_{p,TL}$ values from ($i_{p,TL}$, $E_{p,TL}$) sets, that deviate significantly from the linearity in Fig. 4, deviate from the linearity and/or violate the $\beta \leq 1$ condition.

If one gets 'intact' $i_{p,TL}$ values without TL$\rightarrow$BL partitioning ($i^{\circ}_{p,TL}$) from Eq. 2, by using β values in Fig. 6 and the same (V, C°_{TL}) set in Fig. 4, then one should be able to estimate the deviation of the experimental $i_{p,TL}$ values from the corresponding $i^{\circ}_{p,TL}$. Such calculations for electrodes A—C have shown that the deviation defined by $\delta \equiv (i^{\circ}_{p,TL} - i_{p,TL})/i^{\circ}_{p,TL}$ increases approximately linearly as the sweep number increases from **8** (Fig. 7(a)). δ should be directly related to the partition coefficient θ (defined as the ratio of polypyrrole sites oxidized in the BL mode to all the polypyrrole sites), since $i_{p,TL}$ is proportional to C°_{TL} (Eq. 2). Estimation of δ (and hence θ) as above is possible only for sweep numbers smaller than **12**, because well defined current peaks are detectable only for them. Since $\ln\beta$ is approximately proportional to sweep number (Fig. 6), the results in Fig. 7(a) suggest that δ may be proportional to $\ln\beta$. δ vs. $\ln\beta$ plots in Fig. 7(b) confirms such expectation, where both values are roughly proportional each other. The result in Fig. 7(b) implies that the progress of the crossover, and hence the phase separation of poly-1 and polypyrrole,

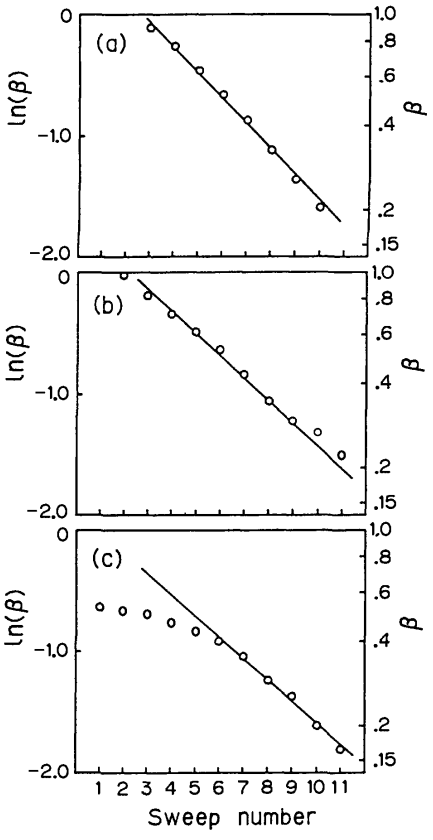

Fig. 6. Plots of ln β vs. the sweep number. β values were obtained based on Eq. 3 using the same parameters as in Fig. 4. β values exceeding unity are neglected. (a)—(c) correspond to electrodes A—C, respectively.

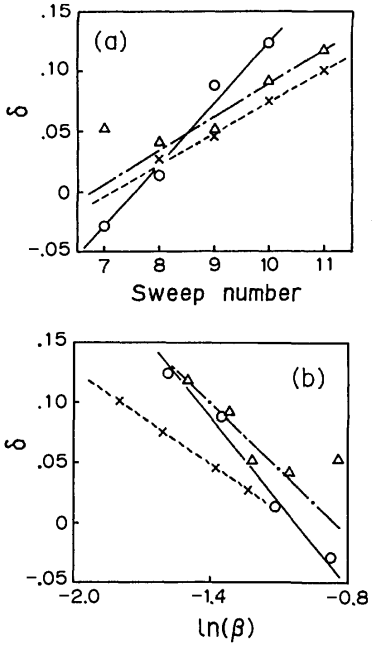

Fig. 7. (a): plot of δ vs. sweep number I; (b): plot of δ vs. ln β (β: complementary charge transfer coefficient). $\delta \equiv (i^{\circ}_{p,TL} - i_{p,TL})/i^{\circ}_{p,TL}$. —O—, —·—△—·—, and ···×··· represent electrode A, B, and C, respectively.

may be expressed as a function of β.

Analysis of the Mediated Oxidation Waves of Polypyrrole (BL Regime). A linear relationship has been found between the peak currents in the BL regime, $i_{p,BL}$, and the peak potentials ($E_{p,BL}-E^{\circ\prime}_{BL}$) ($E^{\circ\prime}_{BL}$: formal oxidation potential of $[Ru(vbpy)_3]^{2+}$ centers of the inner layer, +0.85 V), as shown in Fig. 8, although contributions by the inner layer are neglected here.

A theoretical treatment of bilayer electrochemistry[9b,27] has been presented for a case in which the e^- transfer process across the interface is the rate-determining step and a Nernstian equilibrium is established throughout the inner layer except for the interface layer.

$$i_{BL}=n_{ch,BL}\,FS\,k^{\circ}_{BL}\,\phi^2\{1+\exp[f(E_{init}-E^{\circ\prime}_{BL})]\}^{p} \times\{1+\exp[f(E_{init}+rt-E^{\circ\prime}_{BL})]\}^{-p-1} \times\exp[f(E_{init}+rt-E^{\circ\prime}_{BL})] \quad (5)$$

where

$$p=\frac{k^{\circ}_{BL}\phi^2}{\Gamma^{\circ}_{BL}fr},\quad f=\frac{n_{BL}F}{RT}$$

$n_{ch,BL}$: number of electrons per reaction center oxidized on e^- transfer across the inner layer/outer layer interface

n_{BL}: number of electrons per reaction center oxidized

k°_{BL}: rate constant for e^- transfer across the interface ($cm^2\,mol^{-1}\,s^{-1}$)

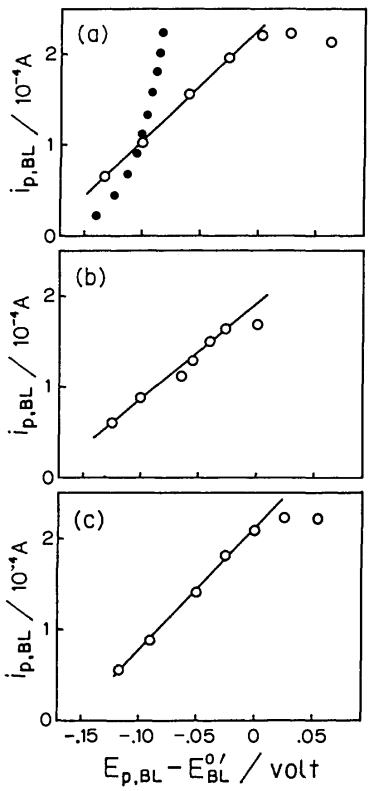

Fig. 8. Plots of $i_{p,BL}$ vs. ($E_{p,BL}-E^{\circ\prime}_{BL}$). Closed circles represent calculated values based on Eqs. 6 and 7. (a)—(c) correspond to electrodes A—C, respectively.

ϕ: coverage that can participate in direct charge transfer across the interface (mol cm^{-2})

E_{init}: potential at which positive potential sweep is initiated

$i_{p,BL}$ for $E_{init}\ll E^{\circ\prime}_{BL}$ are given by differentiating Eq. 5',

$$i_{p,BL}=\frac{n_{BL}\,n_{ch,BL}\,F^2\,S\,r\,\Gamma^{\circ}_{BL}}{RT}\left(1+\frac{1}{p}\right)^{-p-1} \quad (6)$$

$$E_{p,BL}=E^{\circ\prime}_{BL}-\frac{1}{f}\ln p \quad (7)$$

Closed circles in Fig. 8 represent the calculated [$i_{p,BL}$, ($E_{p,BL}-E^{\circ\prime}_{BL}$)] values based on Eqs. 6 and 7, which show no linear relationship. This would imply that assumptions employed in deriving Eqs. 5—7 are not valid in the present case. Inappropriateness of the assumptions have been noted.[27] Plots in Fig. 8 imply how $i_{p,BL}$ and $E_{p,BL}$ change when the coverage of the outer layer (number of polypyrrole sites) is variously changed as a result of increasing partitioning. $i_{p,BL}$ is also found to linearly depends on sweep number. This means that $i_{p,BL}$ and $E_{p,BL}$ may be proportional to C_{BL} or Γ_{BL}, since δ is also approximately proportional to sweep number.[28] These results povide a guideline in obtaining the analytical equations to describe the electrochemistry of the BL mode.[29]

Simulation of Cyclic Voltammograms. Simulation of the CVs in Fig. 1 has been studied on the basis of TITL model accompanying subsequent crossover to the BL mode. The following simulation is based on the assumption that portions of polypyrrole sites contributing to TL and BL mode oxidations are given separately at the beginning of each cyclic sweep (separation model). The change in β upon repeated potential sweeps is formulated according to the result of Fig. 6.

$$\beta=\exp[-0.2\times(I-1)] \qquad I\text{: sweep number} \quad (8)$$

Partition coefficient θ for each sweep is given arbitrarily, since it cannot be known for larger sweep numbers ($12\leq I$). For $12\leq I$, the BL mode oxidation prevails and no current peaks in the TL regime are detectable. Since we have not found analytical formulations that successfully describe the electrochemistry of the BL mode where charge transfer processes within both layers are considered as rate-limiting steps,[27] Eq. 5 is alternatively used to show overall waveforms at the expense of the detailed waveforms in the BL mode. The result is shown in Fig. 9. In spite of such limitations, the waveforms simulate the overall changes including the crossover phenomenon.

An alternative model on the progress of the crossover is possible as follows. The partitioning from TL to BL progresses competitively as a function of the applied potential (parallel progress model or PP model), instead of initial separation of polypyrrole sites into two distinct portions. In the PP model,

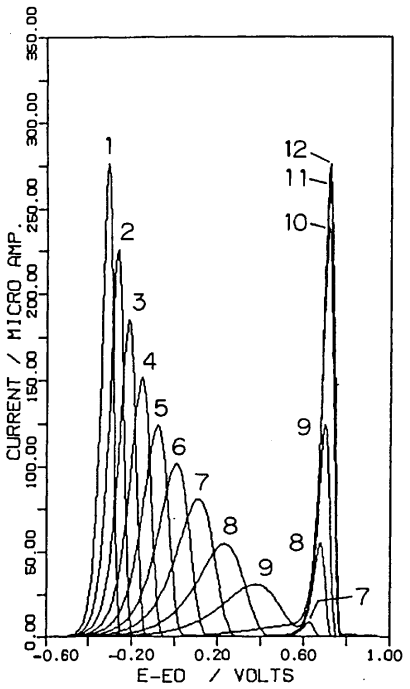

Fig. 9. Cyclic voltammograms generated based on Eqs. 1, 5, and 8, according to the separation model. E°_{TL}=−0.535 V; E°_{BL}=+0.850 V; E_{init}=−0.6 V. The same k°_{TL} (5.50×10^{-9} cm mol^{-1} s^{-1}) and C°_{TL} (3.15×10^{-3} mol cm^{-3}) values are used as in Fig. 4. $n_{TL}=n_{o,TL}=n_{ch,BL}=n_{BL}=1$; $k^{\circ}_{BL}=8.00\times10^{15}$ cm^2 mol^{-1} s^{-1}; $\phi=0.483\times10^{-10}$ mol cm^{-2}. Partition coefficient θ is given as; sweep number I=1—6: 0; I=7: 0.03; I=8: 0.2; I=9: 0.45; I=10: 0.86; I=11: 0.96; I=12: 1.0. β is changed from unity to 0.11.

oxidation of reduced polypyrrole sites proceeds in both modes competitively, according to the different potential dependencies defined by Eqs. 1 and 5. Simulations based on the PP model, however, have proved that this model fails to produce large current peak separations like sweep **9** of Fig. 1 in TL and BL modes in a single sweep. This model also does not produce any deviation of $i_{p,TL}$ from $i^{\circ}_{p,TL}$.

To account for the substantial change in the β value, the following explanation may be possible. The charge carriers in the oxidized state of polypyrrole are bipolarons.[2] The generation and rereduction of bipolarons in polypyrrole occur at different levels, i.e., at valence band edge and at bipolaron level, respectively. Because of this situation, polypyrrole present in the polymer matrix (poly-1) may be subject to such assymetric electrochemistry as in Fig. 2. On the other hand, the progress of phase separation of polypyrrole and poly-1 should change the distance to be moved in the reaction coordinate to achieve the oxidation of polypyrrole. This change in the distance in the reaction coordinate, associated with the above assymetry, would change β significantly.

It should be stressed that the consideration of a simple voltage-loss process in the polypyrrole oxidation cannot explain the systematic changes of the CVs in Fig. 1.

To our knowledge, there has been little preceding work on the relevance of spatial factors in polymer-coated electrodes to the charge transfer coefficient. Essentially the same CV changes have been recorded for poly(3-methylthiophene)- and poly(2,2′-bithiophene)-as-deposited Pt/poly-1 electrodes.[11] If examples of ECPS are found for other redoxing polymers without a capacitive effect, more detailed analyses will be possible, because they would provide precise experimental information on the concentration, electrochemical coverage of reaction centers, $E^{\circ\prime}$ and i_{TL} values. The ECPS scheme may find applications as means for fabricating microstructures using electroactive polymers.

Conclusion

CV changes observed during the electrochemical potential sweeps of polypyrrole-as-deposited Pt/poly-1 electrodes have been found to be essentially described by a thin layer model for totally irreversible electrode processes (TITL model) with a subsequent gradual crossover to bilayer electrochemistry (BL model). Systematic shifts of peak potential associated with the decrease in peak current in the TL mode are ascribed to the result of logarithmic decrease of the complementary charge transfer coefficient β as the sweep number increases. After each cyclic sweep of potential, the system is reset to the initial state, except that smaller β values are given after each cycle. It has been found that the model, which assumes that reduced polypyrrole sites are separated into portions of TL and BL mode oxidations prior to each cyclic potential sweep, well simulate the CV changes of Fig. 1.

The present results shed light on the electrochemical aspect of polymer phase separation. We assume that the decrease in the β value in the present study should be related to the progress of the polymer phase separation.

28) Since the slope for the plot of δ vs. I (sweep number) in Fig. 7(a) is only about 0.04, extrapolation to sweep number **14** does not yield the 100% crossover. Hence the linearity between δ and I may be established only for small I values.
29) Interestingly, we have observed similar non-linear $i_{p,TL}$ vs. $E_{p,TL}$ relationship as the closed circles of Fig. 8 for Pt/poly-1/polypyrrole electrodes with very small coverages of the inner layer ($\leqq 1.6\times10^{-9}$ mol cm^{-2}). This is probably due to the significantly reduced rate-limiting character of the inner layer.

The Thermotropic Liquid-Crystalline Behavior of Alkylammonium Benzenesulfonates and Related Salts

Masato Ito, Yoshio Matsunaga,* Hiroyuki Matsuzaki, and Saeko Shimojima
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 2, 1989)

Alkylammonium benzene-, pyridine-3-, *p*-toluene-, and *p*-ethylbenzenesulfonates were found to be smectogenic when the cation carries an octyl or longer alkyl group. The thermal stability of the mesophase usually reaches its maximum at the octadecylammonium salt. The temperature range of stable existence is in the following order: pyridine-3-sulfonate > *p*-toluenesulfonate > benzenesulfonate > *p*-ethylbenzenesulfonate, suggesting the presence of a specific interaction between the ammonium ion and the nitrogen atom in the pyridine ring.

Several series of long-chain alkylammonium salts have been known to exhibit liquid-crystalline phases. They include salts containing counter ions as simple as halide ions and also two-dimensional sheets of tetrahalometallate ions.[1-5] In our previous paper, the thermotropic liquid-crystalline properties of alkylammonium alkanesulfonates were described.[6] Because the thermal stability of the mesophase in these salts was considerably affected by the counter ions, we then decided to extend our study of alkylammonium salts employing a wide range of aromatic anions. As will be described below, the picrate ion was found to be of limited use; however, benzenesulfonic acid was discovered to form mesomorphic salts with many long-chain alkylamines. As a large number of derivatives of the latter acid are readily available, we may be able to examine the effects on the mesomorphic behavior of various substituents carried by the aromatic nuclei. This paper will present the results of our work on the benzenesulfonates and three related series of salts.

Experimental

Materials. The benzene-, pyridine-3-, *p*-toluene-, *p*-ethylbenzenesulfonic acids, picric acid, and 2,4-dinitro- and 2,6-dinitrophenols are commercially available. Equimolar amounts of an alkylamine and an acid dissolved in boiling methanol were mixed. The salt thus precipitated was purified by recrystallization until a sharp mesomorphic-isotropic transition was recorded on the calorimetric curve during the processes of heating and cooling at the same temperature. For example, Found: C, 67.27; H, 10.52; N, 3.33; S, 7.59%. Calcd for $C_{18}H_{37}NH_3^+ \cdot C_6H_5SO_3^-$: C, 67.40; H, 10.60; N, 3.28; S, 7.50%.

Measurements. The calorimetric and X-ray diffraction measurements were carried out as described in our previous paper.[6]

Results and Discussion

Many benzene-, pyridine-3-, *p*-toluene-, and *p*-ethylbenzenesulfonates can produce a smectic phase. Table 1 presents their melting and clearing points, the associated enthalpies, and the layer spacings as measured within 10 °C above the melting points. The

a) The second quantities are in parentheses. b) The number of carbon atoms in the alkyl group.

rather broad peak due to melting recorded for several salts, mostly benzenesulfonates, suggests the presence of a solid-solid transition just below the melting point. In these cases, the temperature range estimated by taking into consideration the normal peak width due to melting is presented in the table; the value of enthalpy change is given for the whole peak. Solid-solid transitions well separated from the melting were also recorded quite often, but they are not included in this table.

In Fig. 1, the melting and clearing points of the benzene- and pyridine-3-sulfonates are plotted against the number of carbon atoms (n) in the cation. In this diagram, the upper limit of the temperature range indicated in Table 1 is taken as the melting point. The narrow temperature range of the mesophase found in the decylammonium salt in the former series is widened by the destabilization of the crystalline phase and by the stabilization of the mesophase with an increase in the alkyl chain length. While the melting point ceases to fall soon and then gradually rises (see Curve a), the clearing point continues to rise (see Curve b). In the hexadecyl-, heptadecyl-, and octadecylammonium salts, the mesophase exists over 35 °C. The pyridine-3-sulfonate exhibits a mesophase when the cation carries a dodecyl group. The melting point shows a marked even-odd alternation, but it remains within a range of only a few degrees (see Curve c). The mesophase is rapidly promoted by the increase in the number of carbon atoms in the alkyl group with a marked even-odd alternation, providing an additional check on the purity (see Curve d). The temperature range of the stable existence of the mesophase exceeds 80 °C in the octadecylammonium salt.

As is depicted in Fig. 2, the alkyl group attached to the aromatic nucleus significantly influences the thermal stability of the mesophase. The phase is metastable in nonylammonium p-toluenesulfonate, but it becomes stable in the next homologous member. The melting point is lowered with an increase up to n=14, but thereafter it remains at almost the same temperature (see Curve a). On the other hand, the clearing point is raised to n=17 (see Curve b). The mesophases in the hexadecyl-, heptadecyl-, and octadecylammonium salts are stable over 48 °C. The melting point and clearing point in octylammonium p-ethylbenzenesulfonate are not distinguishable from each other in the process of heating, but the two can easily be separated in the process of cooling. The mesophase is stable in the next member, but again metastable in the following two. The melting point then changes nearly in parallel to that of the p-toluenesulfonate in a slightly higher temperature range (see Curve c). As the clearing point increases only slowly with n (see Curve d), even the widest temperature range of stable existence achieved with the octadecylammonium salt is no more than 26 °C, the narrowest among the four series examined in the present work.

In the benzene-, p-toluene-, and p-ethylbenzenesulfonates, the enthalpy change at the clearing point decreases with the number of carbon atoms in the alkylammonium ion. Such a tendency is in agreement with what we found for the alkanesulfonates studied previously.[6] The value tends to be high in the p-toluenesulfonates. On the other hand, the pyridine-3-sulfonate is transformed into an isotropic

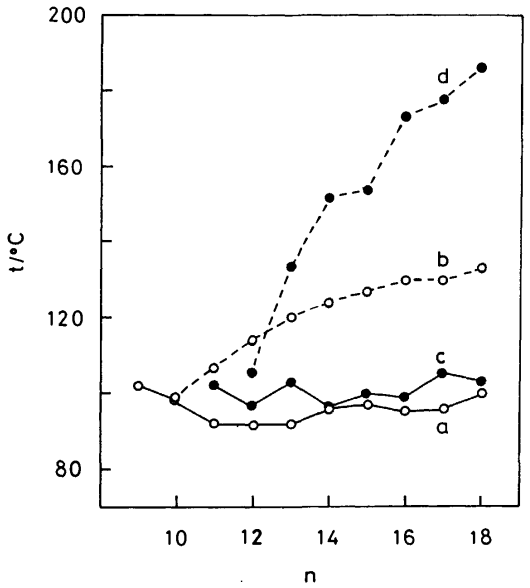

Fig. 1. Plots of transition temperatures against the number of carbon atoms in the alkyl group (n). (a) Melting point, (b) clearing point of alkylammonium benzenesulfonates, (c) melting point, and (d) clearing point of the pyridine-3-sulfonates.

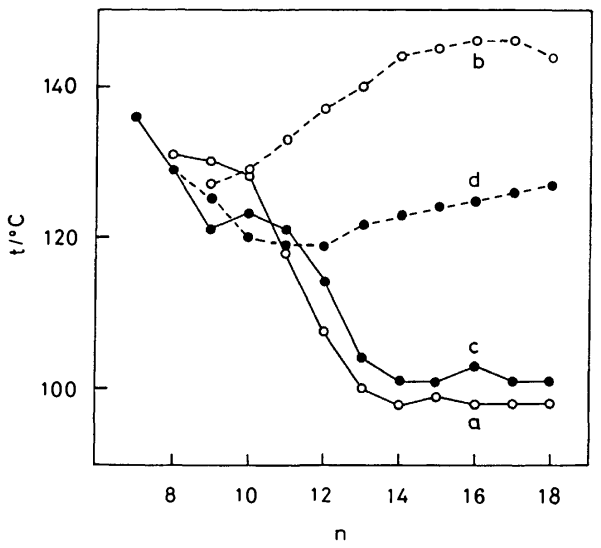

Fig. 2. Plots of transition temperatures against the number of carbon atoms in the alkyl group (n). (a) Melting point, (b) clearing point of alkylammonium p-toluenesulfonates, (c) melting point, and (d) clearing point of the p-ethylbenzenesulfonates.

liquid with a rather small enthalpy change. Besides, the value increases as the homologous series ascends.

In all the salts, the X-ray diffraction pattern recorded for the mesophase consists of a sharp inner peak and a diffuse outer one, indicating that the phase is of the smectic A or C type. The inner peak is accompanied by a weaker one assignable to the second-order reflection. The plot of the layer spacing in the mesophase of the benzenesulfonates against the number of carbon atoms in the cation gives a slope of 0.125 nm per methylene unit, in conformity with the fully-extended configuration of the alkyl group (see Line a in Fig. 3). The same slope is obtained by the plot for the pyridine-3-sulfonates. The latter salts give layer spacings longer by about 0.2 nm than the corresponding benzenesulfonates, even though the two anions are of nearly the same size (see Line b).

When the alkyl group in the cation is relatively short, the layer spacing in the *p*-toluenesulfonate is longer by about 0.1 nm than that of the corresponding benzenesulfonate; however, the deviation from the slope of 0.125 nm per methylene in the higher homologous members is so appreciable that the octadecylammonium salt exhibits essentially the same spacing as that given by the corresponding benzenesulfonate. The spacing shown by the *p*-ethylbenzenesulfonate comes intermediate between the benzene- and *p*-toluenesulfonates and deviates from the slope of 0.125 nm per methylene on ascending the homologous series. The mesophases given in these sulfonates may be concluded to be of the smectic A type on the basis of the observed slope of 0.125 nm per methylene and also the pseudo-isotropic texture, with oily streaks. The lateral spacing is about 0.45 nm for all the series.

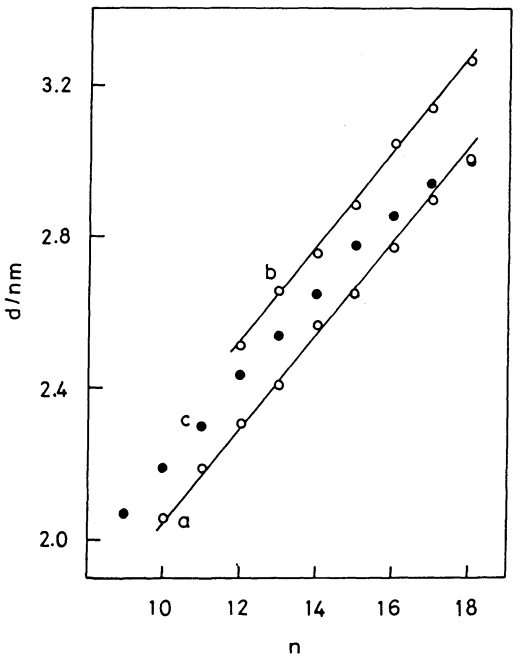

Fig. 3. Plots of layer spacings (d) in mesophases against the number of carbon atoms in the alkyl group (*n*) for alkylammonium benzenesulfonates (a), pyridine-3-sulfonates (b), and *p*-toluenesulfonates (c).

Previously, we showed that the layer spacing measured for the alkylammonium methanesulfonates agrees well with the sum of the lengths of the cation and anion and proposed a structure in which ion-pairs are alternatively oriented so that the long alkyl chains can be interdigitated with each other.[6] Similar models have been employed to represent the mesophases of alkylammonium chlorides by Busico et al., 1-methyl-4-dodecylpyridinium salts by Sudhölter et al., and 1-alkyl-4-methylpyridinium halides by Bazuin et al.[1,7,8]

The octadecylammonium ion in the most extended configuration is estimated to be about 2.60 nm long, employing a van der Waals radius of the methyl group of 0.20 nm, a C-C bond length of 0.154 nm, a C-N bond length of 0.147 nm, a tetrahedral angle, and a thermochemical radius of the ammonium ion of 0.14 nm. The difference between the calculated length of the cation and the spacing in the octadecylammonium benzenesulfonate, 3.01 nm, is no more than 0.41 nm. This value is much shorter than the estimated length of the anion, 0.95 nm, but it is long enough to accommodate the charged head group of the anion. Apparently, the long axis of the rigid anion cannot be in line with the alkylammonium ion orthogonally oriented to the layer plane. The length of the anion may be calculated on the basis of the following data; a van der Waals radius of hydrogen atom in C-H bond of 0.12 nm, a C-H bond length of 0.110 nm, an aromatic C-C bond length of 0.140 nm, a C-S bond length of 0.182 nm, and a thermochemical radius of the sulfate ion of 0.26 nm. The required thermochemical radii were taken from a table compiled by Jenkins and Thakur.[9]

As to the pyridine-3-sulfonates, the longer spacing and also the higher thermal stability of the mesophase relative to that in the benzenesulfonates may imply the presence of a specific interaction between the ammonium ion and the nitrogen atom in the anion. Indeed, the formation of a hydrogen-bonded complex cation between triethylammonium ion and pyridine has been shown by the work of Masri and Wood.[10] Therefore, the side-by-side hydrogen bonding in the sheet of ion-pairs may promote the smectic thermal stability, thus providing additional lateral intermolecular attraction. The layer structure may be destroyed only when the long alky chains are conformationally more disordered—in other words, more liquid-like, as is suggested by the relatively small enthalpy changes at the clearing point.

The fact that the spacing in the *p*-toluenesulfonate is longer by 0.1 nm than that in the corresponding benzenesulfonate may be explained by the difference between the sum of the van der Waals radius of the methyl group and the C-C bond length, 0.35 nm, and

the sum of the van der Waals radius of the hydrogen atom and the C-H bond length, 0.23 nm. The shorter spacing in the *p*-ethylbenzenesulfonates may be an indication that the alkyl group attached to the anion is dissolved into the layer formed by the paraffinic parts of the cations. We have shown that the layer spacing decreases as the alkyl group on the anion becomes longer in the alkanesulfonates and that the spacings in the 1-propanesulfonates are shorter by 0.30 nm than those in the corresponding methanesulfonates.[6]

As the temperature range of the stable existence of the mesophase is wide in the octadecylammonium pyridine-3-sulfonate, we examined the layer spacing as a function of the temperature. The spacing decreases monotonously from 3.27 nm at 110 °C to 3.12 nm at 170 °C, suggesting that the increased conformational disorder gives rise to some decrease in the layer spacing. The deviations in the spacing from the linear relationship observed for the *p*-toluene- and *p*-ethylbenzenesulfonates are within the above-mentioned change caused by the temperature increase and might be ascribed to the extensive conformational disorder of the long paraffinic chains.

Octadecylammonium and heptadecylammonium picrates are smectogenic. While the former solid salt is transformed into a smectic phase at 120 °C with an enthalpy change of 66 kJ mol^{-1}, and then into an isotropic liquid at 135 °C with a change of 0.6 kJ mol^{-1}, the mesophase given by the latter is metastable. When the melt formed at 114 °C with an enthalpy change of 51 kJ mol^{-1} is cooled, a smectic phase appears at 113 °C with 0.4 kJ mol^{-1}. The layer spacing of 3.33 nm found for the octadecylammonium salt is the longest among those recorded in this work, but it is still not long enough to position the long axis of the anion perpendicular to the layer plane. No mesophase was observed with the hexadecylammonium salt which melts at 113 °C. Neither the octadecylammonium 2,4-dinitrophenolate nor the 2,6-dinitrophenolate was found to be mesogenic.

The present work was supported by a Grant-in-Aid for Scientific Research (No. 60470001) from the Ministry of Education, Science and Culture.

Laser Flash Photolysis Study of the Magnetic Field Effects on the Biradicals Generated from Aromatic Ketone-Xanthene Bifunctional Chain Molecules

Yoshifumi TANIMOTO,* Masanobu TAKASHIMA, and Michiya ITOH
Faculty of Pharmaceutical Sciences, Kanazawa University, Takara-machi, Kanazawa 920
(Received June 26, 1989)

The external magnetic field effects (MFE) on the biradicals generated from the intramolecular photoreactions of bifunctional chain molecules, α-(xanthone-2-carbonyloxy)-ω-(xanthene-2-carbonyloxy)alkanes (**XO-*n*-XH**, *n*=2—12) and Ar-12-**XH** (Ar=anthraquinone-4-carbonyloxy (AQ), 4-benzoylphenoxy (BP), and 4-acetylphenoxy (AP)) were studied by laser flash photolysis. All biradicals exhibit significant MFE. The simultaneous observation of the effects on the two radicals at the ends of the chain, generated from **XO-12-XH**, AQ-12-**XH**, and BP-12-**XH**, presents unequivocal evidence that the respective two radical centers correlate magnetically each other. The *n* dependence of the effects on biradicals generated from XO-*n*-**XH** indicates that the singlet-triplet degeneracy of the biradical occurs at the chain length of around *n*=6, i.e., the interradical distance of about 15 Å.

In the middle of 1970's, magnetic field effects (MFE) on radical reactions have been successfully interpreted in terms of the radical pair mechanism, in which the triplet (T)-singlet (S) intersystem crossing (isc) of a radical pair, a short-lived intermediate, is affected by a magnetic field.[1] It is speculated that the significant MFE could be observable when the lifetime of a pair is considerably long. In homogenous solution, however, the diffusive separation of the components of a pair competes with isc, leading to the shortening of the lifetime of the pair. These considerations suggest that MFE on bimolecular reactions in homogeneous solutions are rather insignificant, if any. In this regard, such a microheterogeneous solution as a micellar solution is expected to present us an ideal environment for sufficient T-S development of a radical pair. In an aqueous micellar solution, for example, the separation of the component radicals in a radical pair is considerably slow, because of the dimentionality of the micelle, and the microviscosity and polarity in it. Therefore, the isc, which is the magnetic field dependent process, can become the rate-controlling process. Based on the above-mentioned argument, quite a few numbers of research groups have studied MFE on photoreactions in micellar solutions and microemulsions.[2-7] Our main interest has been the MFE on the hydrogen abstraction reaction of aromatic ketones in micellar solutions.[5] Particularly, in order to confirm the mechanism, the MFE have been examined in detail in the hydrogen abstraction reaction of xanthone from xanthene.[5e] Then, new questions arise as for the roles of a micellar cage. a) What is the key factor for the significant effect, though dimentionality, polarity, microviscosity and others are expected to influence the lifetime of a radical pair? b) At what distance between the two radicals does the S-T degeneracy of a pair occur? However, the analysis of the photoreactions in microheterogeneous systems is too complex to answer these questions, since a micellar solution is the statistical ensemble of micelles with different sizes, and since microviscosity and polarity in a micelle depend on location in it.[8]

In order to answer these questions and to elucidate the governing factors in MFE, we have designed the end-to-end photoreactions of bifunctional chain molecules in homogeneous solutions as the intramolecular analogue of the bimolecular reaction of aromatic carbonyls in micellar solutions. First example was the intramolecular photoreaction of *n*-alkyl anthraquinone-2-carboxylates,[9] as the analogue of the reaction of anthraquinone in micellar solution.[5c,d] The hydrogen abstraction reaction of the excited triplet quinone from its methylene side chain generates the biradicals composed of alkyl and semiquinone radicals. It was shown that the S-T degeneracy of the biradicals occurs at the chain length of *n*=12 or so, from the MFE on the reaction yields under the steady-state photolysis. This system was, however, found to be inadequate for the dynamical study of MFE on the biradicals, since the rate-controlling step was not the isc but the generation of biradicals. In the present paper,[10] we report on MFE on the dynamics of the biradicals generated from the intramolecular abstraction reaction of the bifunctional chain molecules composed of the aromatic carbonyls (H acceptor) and xanthene (H donor) moieties, as the analogue of the radical pairs generated from the corresponding reaction in micellar solution.[5]

Experimental

Materials. Xanthone-2-carboxylic acid and xanthene-2-carboxylic acid were prepared with the literature procedure.[11,12] Xanthone-2-carboxylic acid (9.6 g, 0.04 M) in *N*,*N*-dimethylacetamide (DMAc, 130 ml) was slowly added into a hot DMAc solution (40 ml) of 1,12-dibromododecane (39.4 g, 0.12 M) and K_2CO_3 (6.1 g, 0.044 M), and the solution was then stirred at 90 °C for 6 h (1 M=1 mol dm^{-3}). The reaction mixture was treated with water, extracted with chloroform, and purified by chromatography, yielding a

white solid of α-bromo-ω-(xanthone-2-carbonyloxy)dodecane (12.7 g): Mp 78—79 °C. ^{1}H NMR (60 MHz, $CDCl_3$): δ=1.18—2.00 (s, 20H, $-CH_2-$), 3.35 (t, 2H, $-CH_2-Br$), 4.32 (t, 2H, $-CO_2-CH_2-$), 7.10—8.92 (m, 7H, aromatic). IR (KBr): 2920—2850 (methylene), 1720 (aromatic ester), 1663 cm^{-1} (aromatic ketone). Calcd for $C_{26}H_{31}O_4Br$: C, 64.07; H, 6.41%. Found C, 64.26; H, 6.53%. M, 488.

α-Bromo-ω-(xanthone-2-carbonyloxy)dodecane (12.18 g, 0.025 M) was added into a hot DMAc solution (40 ml) of xanthene-2-carboxylic acid (5.99 g, 0.0265 M), and K_2CO_3 (4.14 g, 0.03 M), and the solution was stirred at 90 °C for 8 h. The reaction mixture was treated with water, extracted with chloroform, and purified by chromatography and recrystallization, yielding a white solid of α-(xanthone-2-carbonyloxy)-ω-(xanthene-2-carbonyloxy)dodecane (XO-12-XH, 6.6 g).

Other chain molecules, Ar-*n*-XH (Ar=xanthone-2-carbonyloxy (**XO**, *n*=2—10), anthraquinone-2-carbonyloxy (AQ, *n*=12), 4-benzoylphenoxy (BP, *n*=12), 4-acetylphenoxy (AP, *n*=12)), and 1-(xanthone-2-carbonyloxy)dodecane (**XO**-12) were prepared in an analogous manner. Their melting points are shown in Table 1, and the typical spectral data of chain molecules are given as follows:

XO-12-XH. ^{1}H NMR (60MHz, $CDCl_3$): δ=1.18—2.00 (s, 20H, $-CH_2-$), 4.02 (s, 2H, methylene of XH), 3.97—4.47 (m, 4H, $-CO_2-CH_2-$), 6.87—8.93 (m, 14H, aromatic). IR(KBr): 2910—2830 (methylene), 1725 (aromatic ester), 1673 cm^{-1} (aromatic ketone). Calcd for $C_{40}H_{40}O_7$: C, 75.93; H, 6.37%. Found: C, 75.71; H, 6.34%. M, 632.

AQ-12-XH. ^{1}H NMR($CDCl_3$): δ=1.18—2.00 (s, 20H, $-CH_2-$), 4.02 (s, 2H, methylene of **XH**), 4.2—4.46 (m, 4H, $-CO_2-CH_2-$), 6.83—8.87 (m, 14H, aromatic). IR(KBr): 2910—2840 (methylene), 1730 (ester), 1678 cm^{-1} (ketone). Calcd for $C_{41}H_{40}O_7$: C, 76.37; H, 6.25%. Found: C, 76.42; H, 6.25%. M, 645.

BP-12-XH. ^{1}H NMR ($CDCl_3$): δ=1.18—2.00 (s, 20H, $-CH_2-$), 4.03 (s, 2H, methylene of XH), 3.85—4.37 (m, 4H, $-CO_2-CH_2-$, $-O-CH_2-$), 6.76—7.84 (m, 16H, aromatic). IR(KBr) 2920—2840 (methylene), 1710 (ester), 1640 cm^{-1} (ketone). Calcd for $C_{39}H_{42}O_5$: C, 79.29; H, 7.17%. Found: C, 79.38; H, 7.19%. M, 591.

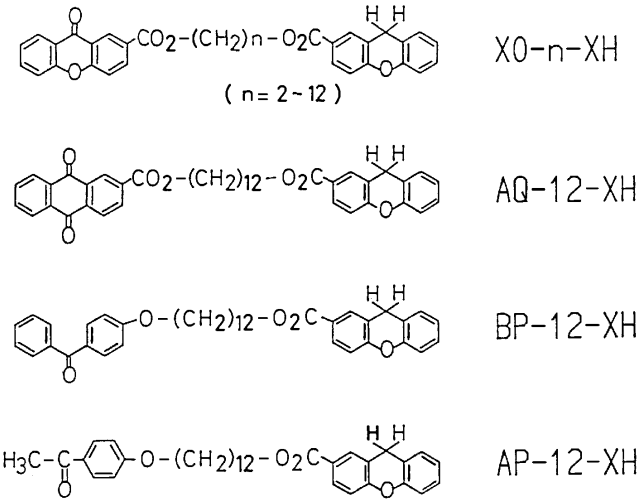
Table 1. Melting Points of Chain Molecules

Ar-*n*-XH	Mp/°C	Ar-*n*-XH	Mp/°C
XO-2-XH	214—215	XO-10-XH	165—166
XO-3-XH	140—141	XO-12-XH	121—122
XO-4-XH	189—190	AQ-12-XH	135—136
XO-5-XH	156	BP-12-XH	82—83
XO-6-XH	177—178	AP-12-XH	99—100
XO-8-XH	149—150	XO-12	79—80

AP-12-XH. ^{1}H NMR($CDCl_3$): δ=1.18—2.00 (s, 20H, $-CH_2-$), 2.49 (s, 3H, $-CO-CH_3$), 4.02 (s, 2H, methylene of **XH**), 3.83—4.36 (m, 4H, $-O-CH_2-$, CO_2-CH_2-), 6.69—7.95 (m, 11H, aromatic). IR(KBr): 2920—2840 (methylene), 1710 (ester), 1670 cm^{-1} (ketone). Calcd for $C_{34}H_{40}O_5$; C, 77.24; H, 7.63%. Found C, 77.17; H, 7.91%. M, 528.

Spectrograde acetonitrile (AcCN) and benzene were used as received. Concentrations of solutes were ≈10^{-4} M and all solutions were deaerated by freeze-pump-thaw cycles.

Laser Flash Photolysis. Figure 1 shows the experimental setup for a nanosecond laser flash photolysis. A sample cell (10×5 mm) placed between pole pieces of a small



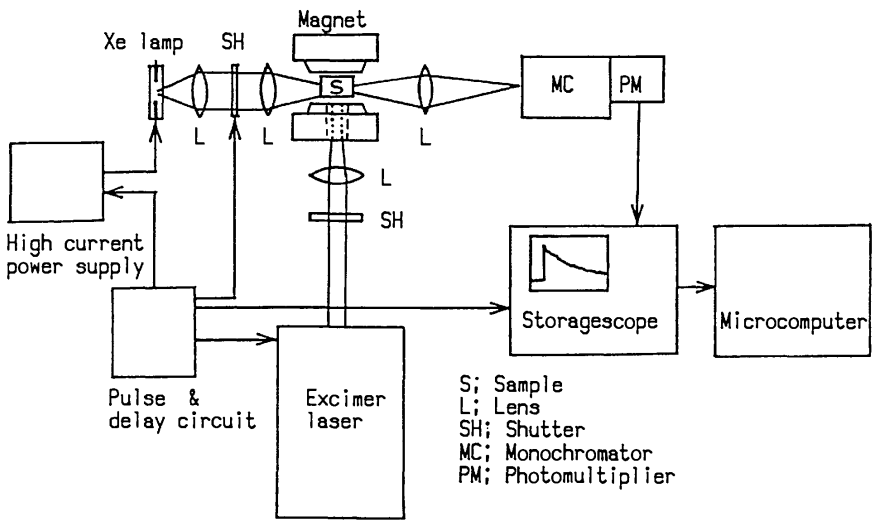


Fig. 1. Experimental setup of a laser flash photolysis apparatus.

electromagnet (Tokin SEE-9, <1 T) was irradiated by a light from an excimer laser (Lambda Physik EMG-50E, 308 nm) or an N_2 laser (Molectron UV-12, 337 nm) through a small hole (10 mm in diameter) on a pole piece. A xenon arc lamp (Ushio UXL-500-O) was used as a probe light source, whose intensity was intensified by applying a pulse of a high electric current (100 A, 3 ms). A laser, a probe light, and a high-speed electric shutter (Copal No. 0) were synchronized with a home-made pulse and delay circuit. The transient signal was detected by a combination of a monochromator (Ritsu NC-10N), a photomultiplier (HTV R-666), and a storagescope (Iwatsu TS-8123), and was fed into a microcomputer (Fujitsu FM-11BS) for analysis. Residual field of an electromagnet was canceled by applying a dc current (<0.3 mT).

In analysis of transient decay curves, the initial decaytime (1/e) was defined as the apparent lifetime (τ), as, in some cases, they deviated slightly from an exponential function.

Calculation of Interradical Distance. The radical-radical distance at the two ends of a methylene chain was calculated at 25 °C for biradicals generated from XO-*n*-XH by the direct enumeration method described in detail in the literature.[13] Here, the radical centers were assumed to be the carbon atoms at 9-position of XO and XH, respectively. The model considered for the methylene chain was the rotational isomeric state model, where all the C-C bonds of the methylene chain were assumed to be one of the three rotational isomers, trans (t), gauche (g^+, 120°), and gauche (g^-, −120°), and the relative orientation of C=O and O-C bonds at the ester was fixed in the trans form. Conformational energies were allotted as 0 cal mol^{-1} for t, 500 cal mol^{-1} for $g^{\pm}$, respectively. For $g^{\pm}g^{\mp}$ sequence, 2000 cal mol^{-1} was added.

Results and Discussion

1. Magnetic Field Effects on the Transient Absorption of Ar-12-XH. XO-12-XH. Figure 2 shows transient absorption spectra of XO-12-XH and XO-12 in acetonitrile. An intense and broad band around 620 nm (τ, 2 μs) of XO-12, having no XH chromophore, is assigned to the triplet-triplet (T-T) absorption of the xanthone (XO) chromophore.[5e,14] Absence of the absorption band of a xanthone ketyl radical around 490 nm[14] indicates that the hydrogen abstraction of the excited triplet XO, ^{3}XO*, from its methylene chain and the solvent is insignificant in the present time scale (<10 μs).

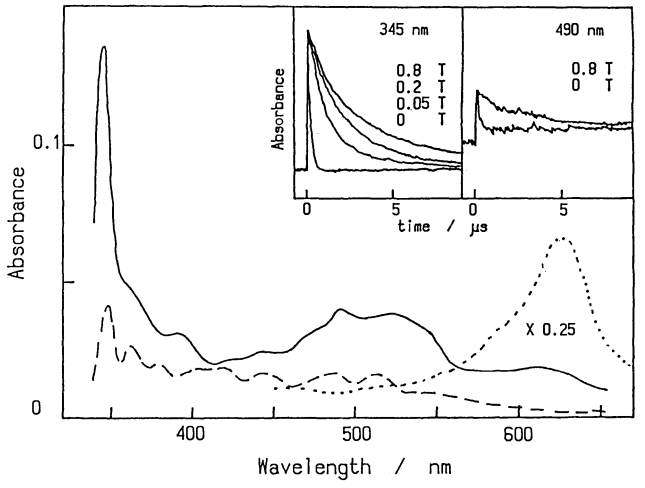

Fig. 2. Transient absorption spectra of XO-12-XH and XO-12 in acetonitrile. —— and ---- are the spectra of XO-12-XH monitored at 0.15 and 0.4 μs delay after laser excitation, respectively. ····· is the spectrum of XO-12 at 0.2 μs delay. Insets are magnetic field effects on the decay curves of transients.

In the spectra of XO-12-XH, a sharp band at 345 nm and a weak one around 500 nm are assigned to the xanthenyl (Ẋ) and xanthone ketyl (ẊOH) radical, respectively, from the comparison with the spectra reported in the literature.[5e,14,15] Since they appear concurrent with the rapid decrease (<10 ns) of the T-T absorption of XO around 620 nm, the hydrogen abstraction of the excited triplet, ^{3}XO*, of XO from the XH chromophore at the other end of the chain, results in the generation of a triplet biradical of Ẋ and ẊOH, ^{3}(ẊOH-12-Ẋ). Intermolecular photoreaction is not involved in the reaction of XO-12-XH in the present time scale, since the generation of a xanthenyl radical is very slow (risetime, 780 ns) in the corresponding intermolecular reaction of xanthone (1.4×10^{-4} M) and xanthene (1.4×10^{-4} M).

The effects of external magnetic fields on the decay curves of Ẋ (345 nm) and ẊOH (490 nm) chromophores are shown in the insets of Fig. 2. Significant MFE were observed in the intramolecular reaction of XO-12-XH, though no appreciable effect was detected in the corresponding intermolecular reaction of xanthone and xanthene. Lifetimes of Ẋ and ẊOH in the ẊOH-12-Ẋ biradicasl are 0.14 and 0.18 μs at zero field, respectively, while they are 3 and 4 μs at 0.8 T, respectively. Small disagreement of the lifetimes determined from the two chromophores may result from the contamination of photoproducts. The simultaneous observation of MFE on the two radicals presents unequivocal evidence that the two radicals at the ends of the chain correlate magnetically each other. These findings are in good agreement with our previous observation that two radicals composing a pair exhibit MFE simultaneously in a micellar cage.[5f]

Furthermore, analogous MFE were observed for the transients of XO-12-XH in benzene solution (Table 2). The lifetime of ẊOH-12-Ẋ in a magnetic field is about two times longer in benzene than in acetonitrile. This might be attributable to the conformational difference and/or the different reactivity of the biradical in the two solvents. Since XO-12-XH is less soluble in acetonitrlie than in benzene, its average conformation in acetonitrile may be rather compact compared with that in benzene. This difference of conformations may somewhat affect the lifetime in magnetic fields. An alternative explanation is the reactivity of the biradical The diffusion-controlled reaction-rate in benzene is considered to be about two times smaller

than in acetonitrile, taking into account of the viscosity of two solvents (acetonitrile (0.345 cp; 1 p=0.1 Pa s) and benzene (0.649 cp)). Thus, in a high field, the lifetime of the biradical may be shorter in acetonitrile than in benzene, if diffusion-controlled bimolecular reactions take place substantially. The polarity of a solvent itself, therefore, does not affect the magnitude of MFE on the neutral biradical significantly.

Other Bifunctional Chain Molecules. Analogous chain molecules, AQ-12-XH, BP-12-XH, and AP-12-XH exhibit similar end-to-end photoreactions. Intramolecular hydrogen abstraction from the methylene chain may not be involved significantly in these reactions in the time scale of the present observation (<10 μs), since intramolecular hydrogen abstraction of alkyl anthraquinone-2-carboxylates and alkyl benzophenone-4-carboxylates is insignificant in that time scale,[9,16] and since the excited triplets of anthraquinone, benzophenone, and acetophenone react readily with xanthene in micellar solution.[5g]

In the transient spectra of AQ-12-XH in benzene (Fig. 3a), absorption bands of Ẋ and anthrasemiquinone radical (ȦQH) appear at 345 and 380 nm, respectively.[5b,17] Here, benzene is used as a solvent on account of solubility. The decay curves of both bands exhibit remarkable MFE as shown in the insets.

In the laser flash photolysis of BP-12-XH in acetonitrile, absorption bands appear around 340 and 530 nm (Fig. 3b). The former band is mostly attributable to the sum of absorptions of Ẋ, benzophenone ketyl radical ḂPH, and T-T absorption of BP.[3a,18] On the other hand, a weak band around 530 nm may be composed of T-T absorption of BP (≈510 nm) and that of ḂPH (≈540 nm), since its peak shifts slightly toward longer wavelengths with time.[3b] Indeed, the transient decay curve monitored at 510 nm is scarcely affected by a magnetic field, as expected. Hydrogen abstraction reaction in BP-12-XH is considered to be slower than XO-12-XH and AQ-12-XH, as the lifetime of the T-T absorption of BP monitored at 510 nm was estimated to be 0.2 μs. Significant MFE were observed on the decay curves at 345 nm (Ẋ and ḂPH) and at 545 nm (ḂPH) as shown in the insets of Fig. 3b, though the accurate determination of the biradical lifetime was difficult due to the interferrence of the T-T band of

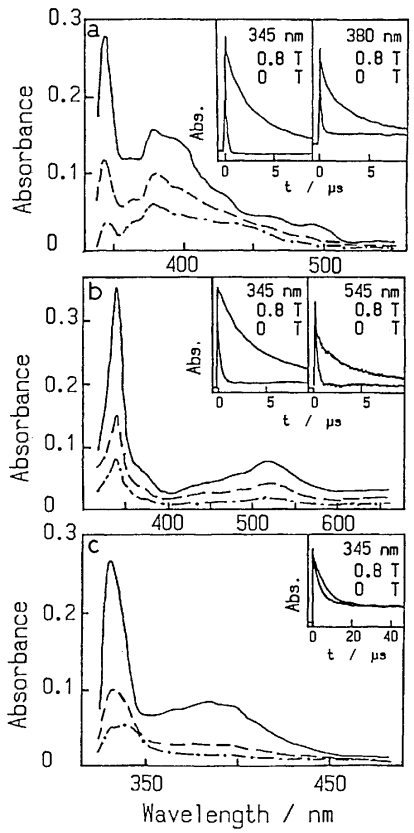

Fig. 3. Transient absorption spectra of bifunctional chain molecules. (a) AQ-12-XH in benzene. Delaytimes are 0.12 (——), 0.5 (----), and 1 μs (—·—). (b) BP-12-XH in acetonitrile. Delaytimes are 0.25 (——), 1 (----), and 5 μs (—·—). (c) AP-12-XH in acetonitrile. Delaytimes are 2 (——), 10 (----), and 20 μs (—·—). Insets in the respective figures are the magnetic field effects on the decay curves of transients.

the BP chromophore in both wavelength region. The lifetime of the biradical determined from the former band, however, seems to be less contaminated by the decay of T-T band, because of high absorption intensities of Ẋ and ḂPH radicals.

In the case of AP-12-XH in acetonitrile (Fig. 3c), the rate of hydrogen abstraction is much slower than that of BP-12-XH. Absorption bands around 320 and 390 nm are mainly assigned to the T-T absorption of

Table 2. Lifetimes of Biradicals[a]

ȦrH-12-Ẋ Solvent	ẊOH-12-Ẋ AcCN	ẊOH-12-Ẋ Benzene	ȦQH-12-Ẋ Benzene	ḂPH-12-Ẋ AcCN	ȦPH-12-Ẋ AcCN
τ(0 T)	0.14 (345 nm)[b]	0.13 (345 nm)	0.14 (345 nm)	0.38[c] (345 nm)	8[c] (345 nm)

AP,[19,20] whose lifetime is estimated to be 3.3 μs. On the other hand, a band around 345 nm observed at 20 μs delay may be assigned to Ẋ, generated from the hydrogen abstraction reaction, indicating the generation of the triplet biradical of the acetophenone ketyl radical (ȦPH) and Ẋ, ^{3}(ȦPH-12-Ẋ). Indeed, only small MFE were detected on the decay curve of Ẋ at 345 nm (see inset of Fig. 3c), though no appreciable effect was detected in the decay curves monitored at 320 and 390 nm. The apparent lifetimes of the 345 nm band, presumably the mixture of the absorptions of ^{3}AP* and Ẋ, are approximately 8 μs at zero field and 10 μs at 0.8 T.

Magnetic field effects on the lifetimes of biradicals are summarized in Table 2. Drastic MFE were simultaneously observed on transient absorptions of two chromophores in ẊOH-12-Ẋ, ȦQH-12-Ẋ, and ḂPH-12-Ẋ. The facts present an unequivocal evidence that two radicals at the ends of methylene chain interact magnetically each other. Small disagreement in lifetimes determined from the respective two chromophores may be due to the contamination of the short-lived T-T absorption of the respective precursors and/or the absorption of photoproducts. In the case of ȦPH-12-Ẋ, its dynamics may be chiefly controlled by its slow formation process, and, for this reason, no significant MFE might be detected. Figure 4 shows the magnetic field dependence of the lifetimes of ẊOH-12-Ẋ, ȦQH-12-Ẋ, and ḂPH-12-Ẋ biradicals. Lifetimes are determined from the decay curves of the 345 nm band of Ẋ because of its high absorbance. In all cases, the lifetimes increase suddenly around 0.05 T and gradually in higher fields (>0.1 T). Saturation of the effects seems to occur at higher fields (>0.5 T).

Furthermore, the magnitude of MFE on these biradicals in both polar and nonpolar solvents is comparable with or greater than that observed in the radical pairs generated from the corresponding bimolecular reactions in micellar solution.[5] These facts indicate that the linking of two radicals by a methylene chain, to hinder their separation, is essential for significant MFE. Therefore, from comparison of results on the present biradicals with those on the radical pairs in micellar solution,[5] we can conclude that, in micellar solution, the dimentionality of a micellar cage, keeping the components of a pair in a short distance, is of the primary factor for significant MFE, as assumed so far in MFE on the photoreactions in micellar solutions. It is also likely that the high microviscosity in a micelle as well as the high solubility of hydrophobic radicals in a micellar phase acts all together to elongate lifetime of the pair in it.

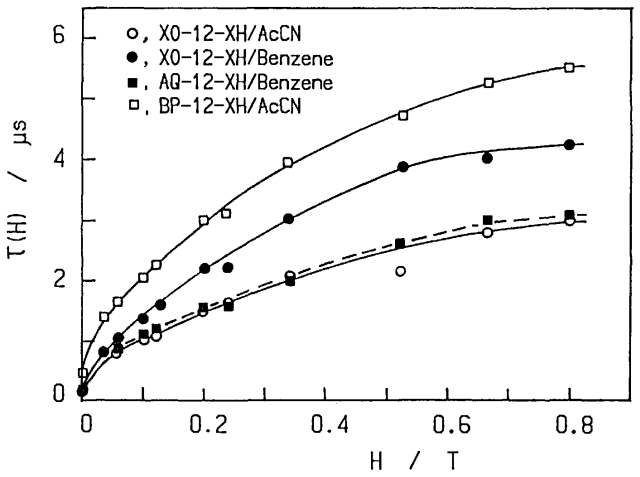

Fig. 4. Magnetic field dependence of the lifetimes of biradicals. Lifetimes were determined from the decay curves at 345 nm.

Reaction Mechanism. All the results mentioned above can be ascribed by the following reaction scheme:

$$\text{Ar-12-XH} \xrightarrow{h\nu} {}^1\text{Ar*-12-XH} \quad (1)$$

$${}^1\text{Ar*-12-XH} \rightarrow {}^3\text{Ar*-12-XH} \quad (2)$$

$${}^3\text{Ar*-12-XH} \rightarrow {}^3(\dot{\text{A}}\text{rH-12-}\dot{\text{X}}) \quad (3)$$

$${}^1(\dot{\text{A}}\text{rH-12-}\dot{\text{X}}) \rightarrow \text{Ar-12-XH} \quad (6)$$

Here, ȦrH is the ketyl or the semiquinone radical generated from aromatic carbonyl, Ar, after the hydrogen abstraction. Upon photoexcitation of Ar in Ar-12-XH, the excited triplet, ^{3}Ar*, of Ar is generated ((1) and (2)). ^{3}Ar* abstracts a hydrogen atom from XH at the other end of the chain to generate the triplet biradical of ȦrH and Ẋ, ^{3}(ȦrH-12-Ẋ). ^{3}(ȦrH-12-Ẋ) deactivates via isc to the singlet biradical, ^{1}(ȦrH-12-Ẋ) (4), from which the product formation (5) and the back reaction (6) may occur. For simplicity, bimolecular reactions such as the reaction between two biradicals are not included in the scheme as the reaction of the triplet biradical, since the concentration of Ar-12-XH is as low as ca. 10^{-4} M. They may be of minor importance in the time scale shorter than 10 μs, though, in the presence of a high magnetic field, they might also take place to some extent.

Now let's consider the mechanism of MFE observed for the present biradicals. The magnetic field effects on a radical pair or a biradical can be interpreted in terms of four mechanisms, i.e., (a) the Δg mechanism, (b) the hyperfine coupling (hfc) mechanism, (c) the relaxation mechanism, and (d) the triplet mechanism.[1,21] In (a), a difference in the electron-spin Larmor frequencies of the two radicals caused by the different electron g values induces the T-S isc of the pair. In (b), a local field generated by nuclear spins (i.e., electron-nuclear hfc) induces the isc, and, in high field, the rates are reduced because of the electronic Zeeman splitting of triplet sublevels (T_+, T_0, and T_-). On the other hand, in (c), electron spin relaxation due to the dipole-dipole anisotropic interaction of an elec-

tron and nuclear spins is affected by the Zeeman splitting of triplet sublevels. Finally, in mechanism (d), spin polarization in an excited triplet precursor is transferred to a radical pair, when the pair formation is fast compared with the relaxation in the excited triplet. Unequal distribution among triplet sublevels in the pair may affect the magnetic field dependence of the lifetime of a radical pair.

Mechanism (a) is not operative in the present magnetic fields (<1T), since the g factors of a xanthenyl radical and a xanthone ketyl radical are the same within experimental error (g=2.0033±0.0005).[22] The hfc-induced isc rate constant k_{isc}(hfc) can be estimated from the effective hfc constants, B_{av}, of radicals in a pair:[23]

$$k_{isc}(\text{hfc})=g\mu B_{av}/\hbar, \quad (7)$$

where μ is the Bohr magneton, and $\hbar$ is the Planck's constant. In mechanism (b), the hfc-induced T-S isc occurs between the energetically degenerated three triplet sublevels and the singlet state at zero field, and the $T_{\pm}$-S isc is quenched in a field much higher than B_{av}, due to the Zeeman splitting of two triplet sublevels. The saturation of the effect appears at a relatively low field (around 0.1 T).

In the case of ẊOH-12-Ẋ, B_{av} is estimated to be 2.5 mT,[24,25] giving k_{isc}(hfc)=10^8 s^{-1} at zero field and 0.3×10^8 s^{-1} at high fields. The observed lifetimes of the biradical are 0.14 μs at zero field and 3 μs at 0.8 T, and the saturation of the effect occurs around 0.8 T, which is much higher than B_{av} (2.5mT). These results indicate that hfc-induced isc is not the rate-determining step at zero field, though one of the three reaction processes (chain dynamics, isc, and cage recombination (product-forming step)) is considered to control the decay rate of the biradical. The chain dynamics may not control it, as the fact that this biradical is formed within a laser pulse width (15—20 ns) confirms the collision of two ends of the chain is a very fast process. The lifetime of ẊOH-12-Ẋ at zero field is, therefore, most probably controlled by the recombination reaction in the singlet state. Furthermore, according to the mechanism (c) the relaxation rate is estimated to be in the order of 10^5—10^6 s^{-1},[26,27] which is compatible with the lifetimes of the present biradical in the higher magnetic fields. On this basis, it is concluded that the lifetime of ẊOH-12-Ẋ is determined by the recombination rate in the singlet at zero field, while in high fields it may be attributable to the relaxation rate, as predicted by the mechanism (c).

The lifetime increases dramatically even in a weak magnetic field (<0.1 T). For example, the lifetimes of this biradical are 0.14 μs (zero field) and 0.77 μs (0.05 T). In low magnetic fields, the hfc-induced isc among non-degenerate spin states may become slower than the cage recombination, and, therefore, the former may be the rate-controlling step at low magnetic fields (<0.1 T). Furthermore, mechanism (d) may be also operative to some extent in addition to the mechanism (c), since the short lifetime of ^{3}XO*-12-XH indicates that the reaction initiates from the spin-polarized triplet state. An analogous argument may hold as for the mechanism in the ȦQH-12-Ẋ biradical. In the case of ḂPH-12-Ẋ and ȦPH-12-Ẋ, however, mechanism (d) may not be involved, since the lifetimes of their precursors seem long enough to attain thermal equilibrium in the excited states.

2. Dependence of the Magnetic Field Effects on Methylene Chain Length of ẊOH-*n*-Ẋ. S-T energy gap of a radical pair or a biradical is considered to be the function of interradical distance, and, therefore, MFE may be affected by the interradical distance. Thus, the influence of the distance between two radical centers on MFE was examined as a function of chain lengths for XO-*n*-XH systems (n=2—12). All bifunctional molecules XO-*n*-XH (n=2—10) exhibit transient spectra similar to that with n=12 in acetonitrile. The magnetic field effect on the lifetimes of these biradicals is shown in Table 3. In the presence of a magnetic field (0.8 T), they increase very remarkably. At zero field, the lifetimes of ẊOH-*n*-Ẋ (n=3—12) are almost independent of the chain length (0.1—0.2 μs), though that of ẊOH-2-Ẋ is considerably long. The facts indicate that the lifetimes of ẊOH-*n*-Ẋ (n=3—12) are likely controlled by the same reaction step, i.e., cage recombination reaction in the singlet state. The lifetime of ẊOH-2-Ẋ may be controlled mainly analogous process to those of other biradicals, since it exhibits considerable MFE. The n dependence of MFE was , therefore, estimated from the lifetime ratio $R=\tau(\text{H})/\tau(0)$ of biradicals, where τ(H) and τ(0) are the lifetimes in the presence and absence of a magnetic field (0.8 T) (Fig. 5). The ratio, R, which may represents the magnitude of the effect, increases with increasing n and reaches a plateau around n=6. The fact implies that the T-S degeneracy of the biradical occurs effectively at the chain length of around n=6. In the case of ẊOH-2-Ẋ, its lifetime (≈1 μs) at zero field is considerably long and the MFE are relatively small compared with those of other biradicals.

Table 3. Lifetimes of Biradicals Generated from XO-*n*-XH in Acetonitrile[a]

n	τ(0 T) / μs	μ(0.8 T) / μs	R[b]
2	0.98	2.7	2.8
3	0.18	0.8	4.4
4	0.22	1.7	7.7
5	0.13	1.1	8.5
6	0.11	1.7	15.5
8	0.16	2.3	14.5
10[c]	0.29	6.0	20.7
12	0.14	3.0	21.4

a) Experimental errors are ±20%. b) Lifetime ratio τ(0.8 T)/τ(0 T). c) Experimental errors are ±30%, because of low solubility.

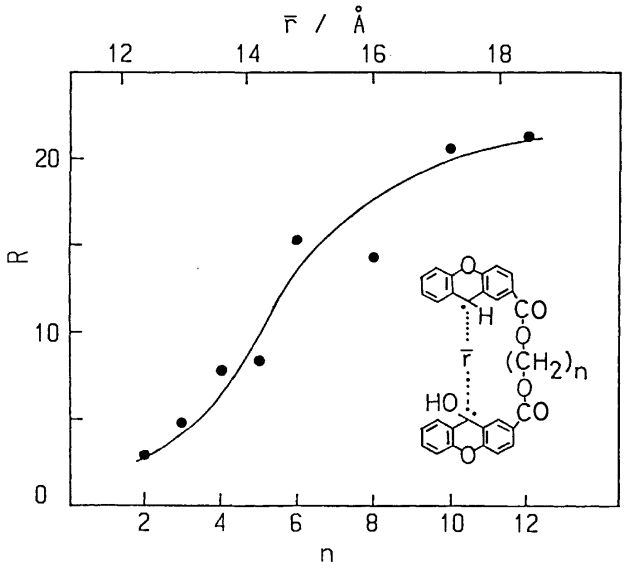

Fig. 5. Methylene chain length n dependence of R of ẊOH-n-Ẋ in acetonitrile. $R=\tau(0.8\,T)/\tau(0\,T)$ is the ratio of the lifetimes τ in the presence and the absence of a magnetic field, 0.8 T. Lifetimes were determined from the decay curves at 345 nm. Top of the figure is the mean distance $\bar{r}$ of two radical centers at the ends of methylene chain. See text.

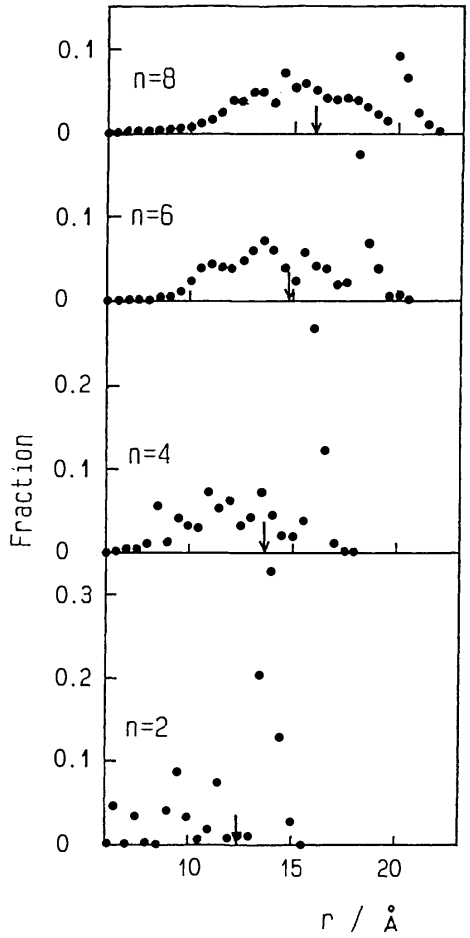

Fig. 6. Typical distribution of the interradical distance r of the ẊOH-n-Ẋ biradicals, the hydroxyl carbon atom of ẊOH and the methylene carbon atom of Ẋ being assumed to be the respective radical centers. Arrows indicate the respective mean interradical distance $\bar{r}$.

In this case, isc may occur among non-degenerate S and T states even at zero field. A steric hindrance and chain dynamics might not be very important, since the generation of this biradical is within the laser pulse width (15—20 ns) as observed for every other molecules.

In order to estimate the distance between the two radical centers at the ends of the chain, we calculated the distribution of interradical distance r and mean interradical distance $\bar{r}$ with the aid of the direct enumeration method, by assuming that the hydroxyl carbon atom of ẊOH and the methylene carbon atom of Ẋ are the respective radical centers. The typical results are shown in Fig. 6. Distribution of interradical distances, especially for short chain molecules, is deviated far from the normal distribution curve. It is mostly because the number of chain conformations are limited due to the fixed conformation of the carboxyl groups in the chain and to the steric hindrance of the bulky aromatic rings. The distance dependence of MFE was, thus, roughly estimated from the mean distance, $\bar{r}$, though it was not a good representative of the ensemble of the conformations. The mean interradical distance for the biradical ẊOH-6-Ẋ, where saturation of MFF occurs, was obtained to be about 15 Å (see Fig. 5). It is most likely that the triplet and singlet states degenerate each other at a mean interradical distance of about 15 Å, and at this distance, therefore, isc in the biradical occurs efficiently. In the case of ẊOH-2-Ẋ, the mean distance was estimated to be as long as about 12 Å, suggesting a very small S-T energy gap. For this reason, MFE might be observed even though the magnitude was relatively small compared with those of longer chain biradicals.

Next, the S-T energy gap ($2J$) of the ẊOH-n-X biradicals was estimated. $2J$ is usually expressed by an exponential function, when it is controlled by the through-space exchange interaction:[28,29]

$$2J=2J_0\exp(-ar). \tag{8}$$

Assuming that $2J_0=1.896\times10^9$ mT and $a=2.136$ Å^{-1}, the $2J$ values were calculated (Table 4). The n dependence of $2J(r)$ values, calculated by weighting the distribution of r, does not reproduce the observed tendency of R shown in Fig. 5. This is attributable to the conformations of biradicals having short interradical distance r, as shown in Fig. 6. Since the exchange energy increases exponentially with decreasing r, averaged energy becomes considerable magnitude, even though fraction of such conformations is quite small. When the mean distance $\bar{r}$ is used for calculation, the trend of $2J(\bar{r})$ fits qualitatively the observed one,

Table 4. Mean Interradical Distance $\bar{r}$ (Å) and Electron Exchange Energy $2J$ (mT) of Biradicals, ẊOH-*n*-Ẋ

n	2	3	4	5	6	7	8
$\bar{r}$	12.4	12.8	13.6	14.3	14.8	15.5	16.1
$2J(r)$[a]	21.8	0.05	0.08	30.7	0.45	30.8	1.1
$2J(\bar{r})$[b]	0.006	0.003	0.001	0.000	0.000	0.000	0.000

a) Averaged over all of $2J(r)$ values for the distribution of r. b) Calculated by using mean distance $\bar{r}$.

though its magnitude is too small to explain the observed results. As was discussed in the CIDNP study of biradicals generated from cyclic ketones,[29] the exponential approximation of $2J$ is incomplete for complex systems like the present ones, since exchange interaction is influenced by mutual orientation of orbitals occupied by unpaired electrons.

Recently, MFE on the dynamics of radical pairs and radical ion pairs (rip) generated from bifunctional chain molecules have been reported. In studies of the MFE on the intramolecular exciplex fluorescence of phenanthrene-$(CH_2)_n$-*N*,*N*-dimethylaniline (n=3—10)[30] and pyrene-$(CH_2)_n$-*N*,*N*-dimethylaniline (n=3—16),[31] the S-T degeneracy of singlet intramolecular rip was reported to occur at the chain length of around n=10. These results are equivalent with the present ones for the triplet biradical, ẊOH-*n*-Ẋ, since they contain two ester groups in the chain. Analogous conclusion on the S-T degeneracy of triplet biradicals were also reported for PhĊH-$(CH_2)_n$-Ċ=O (n=8—10) biradicals[32] and the biradicals generated from α-(4-benzoylphenoxy)-ω-[4-(phenylamino)phenoxy]alkanes (n=2—16).[33] Therefore, it is generally concluded that the S-T degeneracy of biradicals, independent from their spin multiplicity, occurs when the number of chain units becomes larger than 10 or so.

Conclusion

In this paper we have presented a detailed study of MFE on the dynamics of methylene chain linked biradicals. Drastic MFE were observed on the decay of ẊOH-12-Ẋ, ȦQH-12-Ẋ, and ḂPH-12-Ẋ biradicals in both polar and nonpolar solvents. The facts present that the linking of two radicals to hinder their separation is essential for significant effects. These results also suggest that dimentionality of a micellar cage is the key for significant MFE on radical pairs observed previously in micellar solution.

The effects are qualitatively interpreted in terms of the relaxation mechanism, where relaxation in triplet sublevels of biradicals is a rate-controlling step in higher fields. The S-T degeneracy of biradicals, ẊOH-*n*-Ẋ, occurs at the chain length of around n=6, which corresponds to the interradical distance of about 15 Å.

The authors wish to express their thanks to Professor Masahiko Sisido, Kyoto University, for the use of his conformational calculation program, and to Professor Saburo Nagakura and Dr. Ryoichi Nakagaki, Institute for Molecular Science, for several illuminating discussions. This work was supported by the Yamada Science Foundation, the Takeda Science Foundation, and a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

(Received March 13, 1989)

The 2-hydroxy-1,3-propanediamine-*N,N,N′,N′*-tetraacetatocobaltate(III) complex has been optically resolved using strychnine nitrate. The crystal structure of the optically active complex with the resolving agent, $(+)_{589}$-(STC)[Co(dhpta)]·1.5H_2O has been determined from three dimensional X-ray diffraction data. The absolute configuration around the cobalt atom, to which two nitrogen and four oxygen atoms in the ligand are bonded nearly octahedrally, is Δ. The six-membered chelate ring adopts the λ-skew boat conformation. The intermolecular hydrogen bonding between the coordinated oxygen atom of the acetate ring and the protonated nitrogen atom of strychnine, which is one of the asymmetric centers, plays an important role in the diastereomeric discrimination. In contrast, the non-coordinated hydroxyl group in the complex ion does not interact directly with the strychnine molecule. The relationship between the absolute configuration around the cobalt center and the circular dichroism has been examined for the optically active complex ion.

Optical resolution of racemic compounds, which has many empirical aspects, is an important area of chemistry. The optical resolution of the tetragonal Co(III) complex of 2,2′-bipiperidine, which has no net chirality around the central cobalt ion, has been attained by the organic resolving agent ammonium (+)-3-bromocamphor-9-sulfonate in our recent study.[1] By the crystal structure study of the complex having the resolving agent, we reported an indirect type of interaction between the complex cation and the resolving agent anion, implying the importance of the water molecules of crystallization and the asymmetric nitrogen centers caused by coordination,[2] as compared with the known type of direct interaction,[3] in the case of the (+)-3-bromocamphor-9-sulfonate salt. On the other hand, there is little information on the interaction between the anionic complex ion and the organic resolving agent.

Recently, by the preparation of the strychnine salt, the optically active Co(III) complex of 2-hydroxy-1,3-propanediamine-*N,N,N′,N′*-tetraacetic acid (DHPTA) was obtained, in which the carbon atom bonded to the hydroxyl group becomes an asymmetric center by coordination. Strychnine, which has eight asymmetric centers including two asymmetric nitrogen atoms, is a type of alkaloid and can be used as a cationic resolving agent. We report here the preparation and the optical resolution of the cobalt(III) complex of DHPTA, and to our knowledge, the first X-ray structure determination of a Co(III) complex having strychnine as a counter cation. We are interested in this hexadentate ligand, DHPTA, since the existence of the hydroxyl group may afford the opportunities for certain modification, including the tethering of the complex to silica surfaces and polymers.

The X-ray crystal structure study on the complex, (±)-K[Co(dhpta)], has been performed by Kalina et al.,[4] and they indicated that the non-coordinated hydroxyl group significantly interacts with the carboxyl groups in the neighbouring complex ions. Our purpose in undertaking the present X-ray structure determination was fourfold: to determine the absolute configuration around the cobalt center of the $(+)_{589}$-$[Co(dhpta)]^-$ ion, to elucidate the conformation of the six-membered chelate ring involving the *C*-substituted hydroxyl group in the optically active form; to clarify the interaction between the complex anion and the resolving reagent, i.e. the strychnine cation; and to examine relationships between CD curves and absolute configuration at the cobalt center of EDTA-type hexadentate ligands, where EDTA represents ethylenediaminetetraacetic acid.

Experimental

Measurements. The absorption (AB) spectra were recorded on a Shimadzu UV-240 spectrophotometer. The CD spectra were measured with a JASCO J-500A recording spectropolarimeter. These spectra were obtained in water. The ^{13}C NMR spectra were measured on a JEOL GNM JX-400 (400 MHz) spectrometer in D_2O, with dioxane as the internal standard. The optical rotations were measured in a 10 mm tube at 18 °C on a JASCO DIP-360 digital polarimeter.

Materials. All the reagents were of the best commercial grade and were used without further purification.

Preparation of K[Co(dhpta)]·0.5H_2O; 6.0 g of $Na_3[Co(NO_2)_6]$ were dissolved in 30 ml of water. To the solution 5.0 g of 2-hydroxy-1,3-propanediamine-*N,N,N′,N′*-tetraacetic acid were added with stirring. The solution was heated on a water bath at 60 °C until the original orange-yellow color changed to deep purple. During the reaction, a deep purple complex was precipitated from the solution. After cooling to room temperature, the solution was kept in a

refrigerator overnight. The rather insoluble sodium salt of the complex formed was filtered, washed with water, and dried in a desiccator. Yield; 4.90 g. In order to purify the compound, the countercation was changed from sodium to potassium as follows: A large amount of aqueous solution, in which the precipitate was dissolved, was poured onto a cation-exchange resin (Dowex50W-X2, K^+ form) packed in a column. The deep purple eluent from the column, which was flushed with water, was collected and evaporated under reduced pressure to 50 ml. The solution was allowed to stand in a refrigerator for a week, and the crystals formed were collected, washed with cold water, and dried in a desiccator. Found : C, 30.9; H, 3.39; N, 6.54%. Calcd for $C_{11}H_{15}N_2O_{9.5}CoK$: C, 31.1; H, 3.55; N, 6.59%. ^{13}C NMR (D_2O) δ=58.2, 60.6, 64.0, 64.8, 65.7, 69.9, 70.1, 181.2, 181.3, 182.8, and 183.4.

Optical Resolution: Preparation of (+)$_{589}$-(STC)[Co(dhpta)]·1.5H_2O. 1.72 g of K[Co(dhpta)]·0.5H_2O was dissolved in 50 ml of water at 60 °C. To the solution 0.90 g of strychnine nitrate was added as a resolving agent and the solution was warmed at the same temperature until complete dissolution was achieved. After filtration, the solution was kept in a refrigerater for a week. The deep purple prismatic crystals formed were collected, washed with cold water and air-dried. Yield; 0.91 g. The crystals formed after recrystallization in water at 60 °C, gave the same value of the ratio α (589 nm)/ε(absorption coefficient) as that of the crystals before recrystallization. Found: C, 52.0; H, 5.62; N, 7.46%. Calcd for $C_{32}H_{40}N_4O_{12.5}Co$: C, 52.0; H, 5.45; N, 7.58%.

Preparation of (+)$_{589}$-K[Co(dhpta)]·H_2O. (+)$_{589}$-(STC)-[Co(dhpta)]·1.5H_2O was dissolved in water with sonicated stirring. The solution was poured into a column (45×2 cm) containing a cation-exchange resin (Dowex50W-X2, K^+ form). The column was flushed with water to elute the purple complex thoroughly. The eluted solution was collected and evaporated under reduced pressure to 20 ml. Twice this volume of methanol was gradually added to the solution, and then the solution was allowed to stand for overnight at ambient temperature. The resulting crystals were collected and washed with methanol, and dried under reduced pressure. Found: C, 31.5; H, 3.57; N, 6.60%. Calcd for $C_{11}H_{14}N_2O_9CoK$: C, 31.7; H, 3.39; N, 6.73%. $[\alpha]_D$=+874°(in 0.174% aqueous solution). $[M]_D$=+3638°.

Intensity Data Collection. The crystal employed in the data collection was a deep purple prism and bounded by (100), (001), and (010) faces. Crystal size 0.24×0.29×0.17 mm. The diffraction data were measured on a Rigaku AFC-5 diffractometer with graphite monochromatized Mo$K\alpha$ radiation. Unit cell and orientation parameters were determined on the basis of the setting angles of 28 carefully centered reflections (2θ=20—30°). Within the range of 2θ<65°, 3632 independent reflections with $F_o>5[\sigma(F_o)]$ were obtained. Intensities were measured by the ω-2θ scan method. Three check reflections, (3,0,0), (0,4,0), and (0,0,4), were measured every 50 reflections and no significant variation in intensities was found. Lorentz and polarization corrections were applied. An absorption correction was not performed because the absorption coefficient of the compound was low (μ=6.01 cm^{-1}).

Crystal data: Monoclinic, $P2_1$, a=15.536(3) Å, b=11.100(2) Å, c=9.339(2) Å, β=92.86(2)°, and Z=2, D_m=1.55, D_x=1.53 g cm^{-3}.

Solution and Refinement of the Structure. The structure was solved by the heavy-atom method. All the nonhydrogen atoms except for the oxygen atoms of water molecules were located on a difference Fourier map. Subsequent difference Fourier calculations, phased with refined nonhydrogen atoms, gave the coordinates of the oxygen atoms of crystalline water and almost all the hydrogen positions except for those of the water molecules and some in the strychnine residue. Idealized coordinates of the remaining hydrogen atoms of the strychnine molecule were calculated

a) Positional parameters are multiplied by 10^4.

by assuming a tetrahedral coordination about the carbon atoms with a C-H bond distance of 1.08 Å. All the non-hydrogen atoms were refined anisotropically, and hydrogen atoms were refined isotropically. Refinement was carried out by use of a block-diagonal least-squares procedure. The atomic-scattering factors and the anomalous terms for Co, O, N, and C were taken from Ref. 5. The final indicies were $R=0.063$ and $R'=0.072$, where $R=\sum||F_o|-|F_c||/\sum|F_o|$ and $R'=(\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^{1/2}$; $w=1/[\sigma(F_o)]^2$. The final difference Fourier synthesis still showed peaks at heights up to 0.98 e Å^{-3} around the cobalt atom, and 0.68 e Å^{-3} around an oxygen atom of strychnine, although the electron density did not rise above 0.56 e Å^{-3} elsewhere. The final atomic coordinates along with their standard deviations and thermal parameters of non-hydrogen atoms are incorporated in Table 1. Compilations of the anisotropic thermal parameters for non-hydrogen atoms, atomic parameters for hydrogen atoms and observed and calculated structure factors are available.[6] All the calculations were performed on a HITAC M-680H computer at the Computer Center of the University of Tokyo with Universal Program System UNICS III.[7]

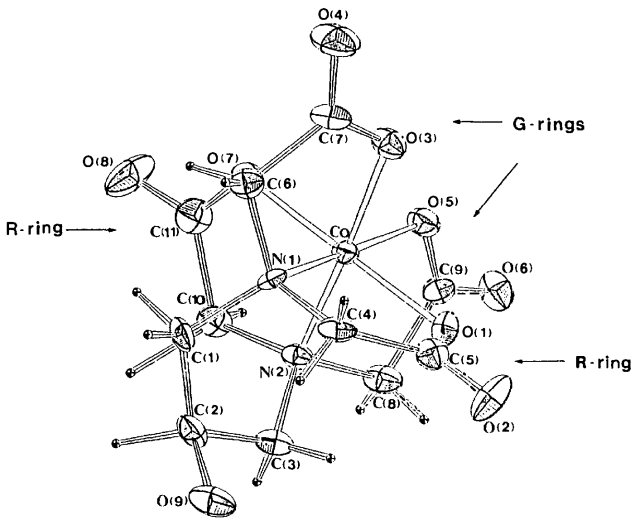
Results and Discussion

Preparation and Optical Resolution. The syntheses of Co(III) complexes coordinated by the hexadentate EDTA type ligands, for instance, ethylenediaminetetrapropionate (EDTP), trimethylenediaminetetraacetate (TNTA), propylenediaminetetraacetate (PDTA) and *trans*-1,2-cyclohexanediaminetetraacetate (CHXNTA) ions, have been well established. In each case, the potassium salt has been prepared in sufficient yield,[8-11] by application of the oxidation reaction from Co^{2+} in the presence of hydrogen peroxide and each ligand. On the other hand, the present complex, $K[Co(dhpta)]\cdot 0.5H_2O$ was synthesized in sufficient yield by the substitution reaction from the starting material $Na_3[Co(NO_2)_6]$, whose cobalt ion is trivalent. In the case of the reaction of ethylenediaminetetraacetic acid disodium salt (Na_2H_2edta) with $Na_3[Co(NO_2)_6]$, it is known that the substitution reaction of the nitro groups occurs incompletely under similar conditions, and the complex, $Na_2[Co(NO_2)(Hedta)]\cdot 2H_2O$ can be obtained in high yield.[12] In contrast, complete substitution was attained in the present case. This result may be related to the less strained ring system of the present complex having the central six-membered chelate ring. This assumption is supported by failure of attempts to prepare a complex in which trimethylenediaminetetraacetate functions as a pentadentate ligand.

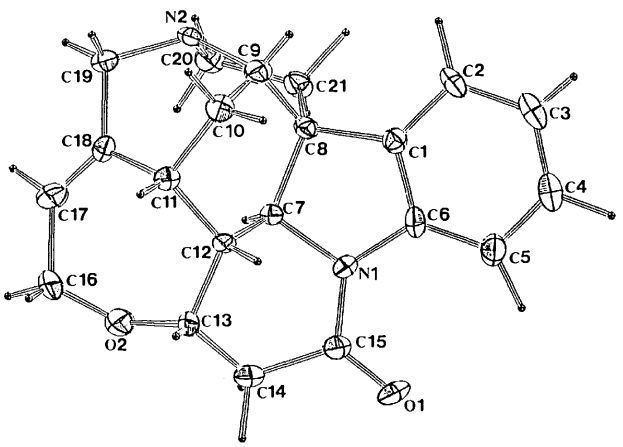
The optical resolution of the ethylenediaminetetraacetatocobaltate(III), through its strychnine salt, was first attained by Busch and Bailar.[13] They obtained the active complex of the $(-)_{589}$-form by the fractionation from mixed solvents, because of the extreme solubility of the salt in water. The resolution of the present complex can be effected by strychnine, and the $(+)_{589}$-form of the complex was adequately obtained from water. Spontaneous resolution was reported by Ogino et al., in the case of $[Co(tnta)]^-$,[14] though in the present case no tendency to resolve spontaneously into optical isomers was observed.

Description of the Molecular Structure. Perspective drawings of the complex anion and strychnine cation showing ellipsoids of thermal motion are given in Fig. 1. Interatomic distances and angles are listed in Tables 2 and 3, respectively.

The cobalt atom is surrounded by two nitrogen atoms and four oxygen atoms from the four carboxyl groups at the apices of a slightly distorted octahedron. Each atom of the complex anion is inequivalent, because of the substituted hydroxyl group on the central carbon atom, through which the pseudo two-fold axis exists. This result agrees with the ^{13}C NMR spectrum of the inactive complex ion before resolution, which shows eleven signals for eleven carbon atoms (see Experimental section). The absolute configuration around the cobalt atom is Δ. This config-



(a)



(b)

Fig. 1. Perspective drawings of (a) the complex anion and (b) strychnine cation with their numbering schemes, shown as 50% probability ellipsoids.

uration was determined by reference of the known absolute configuration of the strychnine molecule used in the optical resolution. The central six-membered chelate ring adopts the λ-skew boat conformation, and both of the G- and R-rings have envelope conformations, where G- and R-rings represent the five-membered glycinate chelate rings as shown in Fig. 1.

The average Co-O bond length of the G-ring chelates and that of the R-ring chelates are 1.920(6) and 1.898(5) Å, respectively. Each of them is slightly long compared with the distances in (±)-K[Co(dhpta)] studied by Kalina et al.,[4] the average Co-O (G-ring) and Co-O (R-ring) distances being 1.875(9) and 1.887(9) Å, respectively. Moreover, in the present case, the average distance between cobalt and coordinated oxygen atoms in G-ring chelates is slightly longer than that in R-ring chelates, contrary to the previous correlation observed in (±)-K[Co(dhpta)]. This relation, between the Co-O bond distances of G-rings and those of R-rings, observed in the present complex ion is also found in the other complex ion of EDTA type ligands,[15-17] excent for the previous report.

X-Ray structure studies on EDTA type Co(III) complexes,[4,15-17] have indicated that the structure of the in-plane G-ring forming a girdle around the cobalt atom is more strained than that of the out-of-plane R-ring. The deviations of the atoms from the individual planes are listed in Table 4. Pronounced deviations are observed of the C(6), C(7), C(8), and C(9) atoms, of which the G-ring chelates consist, whereas the displacements of the carbon atoms in the R-rings from the mean planes are not so significant. Each glycinate ring of the present complex ion is less deformed from defined planes than that of the complex ion previously reported,[4] except for one G-ring,

a) Estimated standard deviations in parentheses.

i.e., the C(8) and C(9) atoms deviate 0.70 and 0.45 Å, respectively from the equatorial plane, the corresponding values being 0.62 and 0.17 Å, respectively.

The other bond distances and angles of the present complex ion are almost comparable with the reported values for (±)-K[Co(dhpta)], except for the relationship described above and of characteristics for the Co(III) complexes of EDTA type ligands. According to the structural study on the Co(III) complexes of EDTA type ligands, which functions as a pentadentate ligand,[18] the relationship mentioned above may be significant, because the coordination site corresponding to one G-ring is substituted by a monodentate ligand in those cases. Easier bond cleavage of Co-O bonds of G-rings than those of R-rings can be interpreted by the correlation.

The structure of the strychnine cation, used as the resolving agent, agrees with the known absolute configurations, and the stereochemistry is almost identical with that previously reported on the molecule and its derivatives.[19]

Description of the Unit Cell and Diastereomeric Discrimination. A perspective drawing of the crystal structure viewed along the b axis is presented in Fig. 2. The unit cell consists of two complex anions, two strychnine counterions, and the four water molecules of crystallization.

Hydrogen bonds of the type O-H···O probably exist between the O(6) atom of the non-coordinated oxygen atom in one G-ring chelate and the O(9) atom of the hydroxyl group in the neighboring complex anion, the O···O distance being 2.75 Å. Such a strong intermolecular hydrogen bond of the same manner was observed in (±)-K[Co(dhpta)]. The O(2) atom of the carboxylato group in one R-ring, which is not coordinated to the cobalt atom, is not only linked to the oxygen OW1 atom of the water but also associated to the other water OW2 atom, by an O-H···O hydrogen bond of distances 2.95 and 3.06 Å respectively. The two water molecules are not connected to any other atoms. In the crystal structures of potassium salts of (+)$_{546}$-[Co(tnta)]$^-$ and (±)-[Co(dhpta)]$^-$, the cationic potassium ions are surrounded through electrostatic attraction by the uncoordinated carboxylate oxygen atoms and also the oxygen atoms of water molecules in defined[15] and nondifined[4] arrangements, respectively. Such a rigid network of electrostatic attraction found in the previous reports, however, among the complex anion, the strychnine, and the water

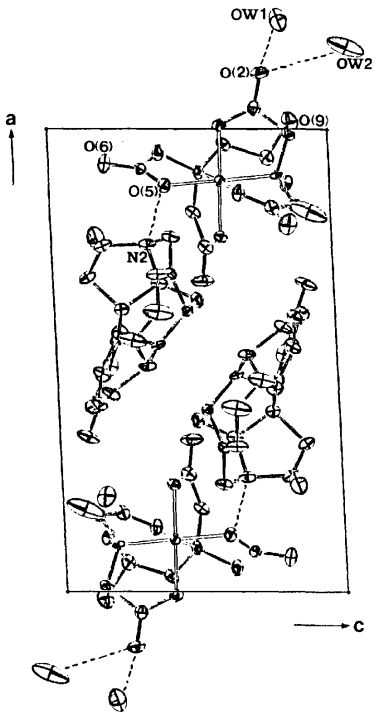

Fig. 2. Perspective drawing of the crystal structure viewed along the b axis. The significant hydrogen bonds among the complex anion, strychnine cation, and water molecules are indicated by the broken line, except for that between O(6) and O(9) atoms.

Table 4 Deviations of the Atoms from Planes

Plane, No.	Atoms defining the plane	Out-of-plane atoms	Distances between out-of-plane atoms, l/Å
1	N(1)	C(1)	−0.54
	Co	C(2)	0.14
	N(2)	C(3)	0.73
2[a]	Co	C(2)	0.13
	O(3)	C(6)	−0.78
	O(5)	C(7)	−0.56
	N(1)	C(8)	0.70
	N(2)	C(9)	0.45
3	Co	C(4)	−0.21
	O(1)	C(5)	−0.18
	N(1)		
4	Co	C(10)	−0.04
	O(7)	C(11)	−0.09
	N(2)		

a) Plane defined by least-square procedure.

molecules can not be observed in the present case.

Significantly the coordinated O(5) atom, of which the same G-ring of the O(6) atom connecting with the O(9) atom of the neighboring complex ion by hydrogen bond consists, is associated with the nitrogen atom N2 of the strychnine cation with an N···O distance of 2.80 Å, by an N-H···O hydrogen bond. It is assumed that a hydrogen atom may be attached to the N(2) atom of the strychnine molecule, though examination of the difference fourier map was unable to reveal a possible hydrogen position near the N2 atom.

The O(2), O(3), and O(4) atoms of the complex ion are near the hydrogen atoms bonded to the carbon atoms of strychnine around the N2 atom, the O···H distances ranging from 2.37 to 2.98 Å, as the result of the hydrogen bond between the O(5) atom of the complex anion and the N2 atom of the strychnine molecule, mentioned above. Moreover, the carbon and hydrogen atoms belonging to the benzene residue of the strychnine interact with the other hydrogen atoms in the hydrophilic sphere of the neighboring strychnine, showing distances from 2.58 to 3.01 Å for C···H intermolecular interaction and from 2.40 to 3.08 Å for H···H interaction, though the self-stacking of the benzene residue of the strychnine molecule can not be observed.

Thus, the close contact by the possible hydrogen bond between the O(5) atom of the complex anion and the N2 atom of the strychnine molecule may play an important role in the diastereomeric discrimination in the present complex, since the N2 atom is one of the asymmetric centers in the strychnine molecule. On the other hand, the O(9) atom of the hydroxyl group bonding to the C(2) carbon atom, which is a resulting asymmetric center by coordination, does not interact directly with the strychnine molecule by an obvious hydrogen bond, though the atom forms the hydrogen bond network together with the O(6) atom in the same G-ring of the O(5) atom. The close contacts between the benzene residue and the atoms in hydrophilic sphere of the neighboring strychnine molecule, described above, probably assist in formation of the diastereomeric compound, i.e., in the optical resolution of the complex.

Absolute Configuration and Circular Dichroism. The AB and CD spectra of the present complex ion $(+)_{589}$-[Co(dhpta)]$^-$ are shown in Fig. 3. Numerical data are summarized in Table 5, along with those of the $(-)_{546}$-[Co(tnta)]$^-$ ion. The shape and positions of AB and CD spectra of the present $(+)_{589}$-form complex are quite similar to those of $(+)_{546}$-[Co(tnta)]$^-$ reported by Ogino et al.[14] X-Ray structure analysis and circular dichroism studies of the series of EDTA type complex, whose CD spectra usually show two Cotton effects of opposite sign in the first absorption region, suggest the following empirical rule: The sign of the CD band in the region can be related to the configuration around the cobalt centers. When they

18.25 (18.20)	142 (131)	16.72 (17.00)	−2.12 (+1.91)
		18.73 (19.00)	+3.01 (−2.41)
26.46 (26.40)	121 (115)	24.39 (24.60)	−0.80 (+0.69)

a) References 8 and 13.

give a positive and negative Cotton effect respectively from the lower energy band of the first absorption region, they should be assigned to the Δ configuration around the asymmetric cobalt center. In the CD spectrum of $(+)_{589}$-[Co(dhpta)]$^-$, which was derived from the crystals of the present work, a negative and a positive Cotton effect has been observed, from the lower energy band in the region. The absolute configuration of the cobalt atom has been determined as Δ from the present study. Consequently, the empirical rule appears to be applicable to the series of EDTA type complex, even though the hydroxyl group exists in the central chelate ring.

Conclusion

Optical resolution of the 2-hydroxy-1,3-propanediamine-*N*,*N*,*N*′,*N*′-tetraacetatocobaltate(III) complex ion has been accomplished by the organic resolving agent, strychnine. By the X-ray structure study

on the crystal involving the resolving agent, the oxygen atom coordinated to the cobalt ion plays an important role in the diastereomeric discrimination through the O···H-N type of hydrogen bond, though the non-coordinated hydroxyl group does not interact directly with strychnine in the same manner. This fact suggests that the coordinated oxygen atom in the G-ring is an essential site for the discrimination of the form of a compound by the complex and certain modification of the corresponding hydroxyl group may not prevent the optically active complex from functioning as a discriminator. The chemical modification of the hydroxyl group in the complex is now in progress.

The authors are grateful to Dr. Takashi Kodama for collecting the X-ray diffraction data and to Dr. Katsuaki Ishida for measurement of NMR spectra. We also thank Prof. Masanobu Hidai at the usage of available instruments of the University of Tokyo and Dr. Andrew Street for his helpful advice on the manuscript. This research was aided in part by a Grant-in-Aid for scientific research on priority areas (Macromolecule Complexes No. 63612003) from the Ministry of Education, Science and Culture.

(Received June 1, 1989)

The title complexes have been synthesized in quantitative yield from [Cu(salpd)] and copper(II) acetate or copper(II) formate , where H_2salpd represents *N,N'*-disalicylidene-1,3-propanediamine. [Cu(salpd-μ-O,O')-(μ-L)Cu(μ-CH_3O)$_2$Cu(μ-L)(salpd-μ-O,O')Cu] crystallizes in the monoclinic space group $P2_1/n$ with formula=$Cu_4C_{40}H_{44}N_4O_{10}$, F.W.=995.0, a=11.826(2) Å, b=17.192(4) Å, c=9.836(2) Å, β=94.08(2)°, V=1994.8(7) Å^3 and Z=2 (R=3.83%), where L=CH_3COO. The complex forms a centrosymmetric molecule made up of two units of [Cu(salpd-μ-O,O')(μ-CH_3COO)Cu] bound by a pair of methoxo bridges; each terminal copper(II) ion forms four short bonds with N and O atoms of salpd and a slightly longer (2.235(4) Å) axial bond with one of the oxygens of the acetato group, whereas each inner copper(II) ion is also pyramidally coordinated by two methoxo oxygens, one of the acetato oxygens, and one of the bridging salpd oxygens, the distant axial position being occupied (Cu–O=2.323(3) Å) by the remaining bridging salpd oxygen. The magnetic susceptibilities of the complexes in the 86.8—299.0 K range have been analyzed on the basis of a four-spin model for the linear copper(II) complexes, and the values of g and J_{ij}, based on the Heisenberg-type Hamiltonian $H=-2\sum J_{ij}S_i\cdot S_j$, have been estimated as g (average)=2.13, J_{12}=−390 cm^{-1}, J_{13}=67 cm^{-1} and J_{14}=J_{34}=0 cm^{-1} in the complex with acetate bridges, and as g (average)=2.20, J_{12}=−263 cm^{-1}, and J_{13}=39 cm^{-1} and J_{14}=J_{34}=0 cm^{-1} in the complex with formate bridges, where the numbering refers to the 3-1-2-4 arrangement of the Cu^{2+} ions.

Intramolecular exchange interaction in multinuclear transition metal complexes has a long history of research work by an enormous number of investigators, yet there remain many unsettled problems. Although a large number of polynuclear complexes with the antiferromagnetic property have been reported, only a limited number of multinuclear complexes with the ferromagnetic property are known.[1-8] In recent years, the present authors have prepared a series of trinuclear Schiff-base complexes in which the central metal ion is different from the terminal ones in its oxidation state or elemental species.[9,10] In the course of a study of the preparation of trinuclear complexes with Schiff-base copper(II) terminal units, new compounds were obtained and were proved to be novel type of tetranuclear copper(II) complexes in which copper ions are linearly linked with methoxide, phenolate, and acetate ions. In this paper we wish to report on the synthesis, structure, and magnetism of these tetranuclear complexes, [Cu(salpd-μ-O,O')(μ-L)Cu(μ-CH_3O)$_2$Cu(μ-L)(salpd-μ-O,O')Cu]. Here, when L=CH_3COO, and HCOO, the compounds are designated by **1** and **2** respectively. The temperature dependence of the magnetic susceptibility showed that the ferromagnetic and antiferromagnetic interactions operate simultaneously in these complexes.

Experimental

Syntheses: 1. Nitrogen gas was bubbled through a methanol solution (60 cm^3) containing copper(II) acetate monohydrate (0.57g, 0.0029 mol) for 10 min. To this solution we added [Cu(salpd)] (1 g, 0.0029 mol) and then triethylamine (0.58 g, 0.0057 mol). The mixed solution was then stirred at room temperature for ca. 36 h. The light green product thus deposited was collected on a sintered-glass filter and washed with methanol and diethyl ether. The product was dried at 60 °C under reduced pressure for 40 min. Yield, 1.45 g (100%). Found: C, 47.91; H, 4.39; N, 5.63; Cu, 26.00%. Calcd for $Cu_4C_{40}H_{44}N_4O_{10}$: C,48.29; H, 4.46; N, 5.63; Cu, 25.55%.

The Preparation of a Single Crystal of 1. The copper(II) acetate monohydrate (0.11 g, 0.00057 mol) and [Cu(salpd)] (0.2 g, 0.00058 mol) were dissolved in methanol (60 cm^3) by using a shaker. When the dark-green solution was allowed to stand in the dark for 5 days, well-formed dark-green prisms were separated. Found: C, 48.10; H, 4.38; N, 5.55%. Calcd. for $Cu_4C_{40}H_4N_4O_{10}$: C, 48.29; H, 4.46; N, 5.63%.

2. Nitrogen gas was bubbled into a suspension containing copper(II) formate tetrahydrate (0.65 g, 0.0029 mol) in methanol (50 cm^3) for 15 to 20 min at room temperature. In to this suspension we then stirred triethylamine (0.59 g, 0.0058 mol) and subsequently [Cu(salpd)] (1 g, 0.0029 mol). The reaction mixture was stirred further at room temperature for ca. 65 h. The green product thus deposited was treated in the same manner as in the case of Complex **1** described above. Yield, 1.34 g (97.1%). Found: C, 46.82; H, 4.20; N, 5.75; Cu, 25.73%. Calcd for $Cu_4C_{38}H_{41}N_4O_{10}$: C, 46.77; H, 4.23; N, 5.74; Cu, 26.04%.

Physical Measurements. The IR spectra were measured with a Hitachi-Perkin-Elmer 225 grating IR spectrometer on KBr disks. The magnetic susceptiblities were measured

by the Faraday method in the range of 80—300 K using a Cahn 2000 electric balance. The apparatus was calibrated using $Hg[Co(NCS)_4]$. Diamagnetic corrections were carried out using Pascal's constants. The molar effective magnetic moment was calculated by the use of the equation: $\mu_{eff}=2.828\sqrt{X_A \cdot T}$.

X-Ray Crystallography. The diffraction data of a single crystal of **1** were obtained on a Rigaku AFC-5 four-circle diffractometer at the Faculty of Science, Kyushu University, using graphite-monochromatized Mo$K\alpha$ radiation at 24±1 °C. The scan mode was θ-2θ, with the scan speed of 6 min^{-1}, $2\theta_{max}=52°$, the scan width of $(1.0+0.35\tan\theta)°$, and the octant measured as $+h$, $\pm k$, and $\pm l$. The intensities of the monitored standard reflections showed no changes during data collection. The unit cell dimensions and standard deviations were obtained by the least-squares fit of 25 reflections ($20°<2\theta<30°$).

The reflections were corrected for the Lorentz-polarization effect, but not for absorption.

Crystal Data: Formula=$Cu_4C_{40}H_{44}N_4O_{10}$, F.W.=995.0, monoclinic system, space group $P2_1/n$. a=11.826(2) Å, b=17.192(4) Å, c=9.836(2) Å, β=94.08(2)°, and V=1994.8(7) Å^3, D_{calcd}=1.657 g cm^{-3}, Z=2. μ(Mo$K\alpha$)=21.71 cm^{-1}, crystal dimensions 0.4×0.5×0.3 mm, 2999 reflections with $|F_o|>3\sigma(|F_c|)$.

The structure was solved by the heavy atom method and refined by the block-diagonal least-squares method, in which the function minimized was $\sum\omega(|F_o|-|F_c|)^2$; the equal weight of ω=1 was adopted for all the reflections. The hydrogen atoms were located on the difference Fourier map and refined. The positions of the non-hydrogen atoms were refined by the use of anisotropic thermal parameters, while those of the hydrogen atoms were refined by the use of the isotropic thermal parameters, giving R=3.83%, and R_w=4.22%. The final difference Fourier synthesis was featureless, where the heighest peak was 0.4 e Å^{-3}. The atomic parameters of the hydrogen atoms, the thermal parameters of non-hydrogen atoms, and the F_o—F_c tables are deposited as Document No. 8902 at the Office of the Editor of Bull. Chem. Soc. Jpn. The caculations were carried out by the use of the UNICS III computer program system[11] on a FACOM M 780 computer at the Computer Center of Kyushu University. The atomic scattering factors were taken from Ref. 12. The final positional parameters are given in Table 1.

Table 1. Atomic Coordinates for [Cu(salpd-μ-O,O')-(μ-CH_3COO)Cu(μ-CH_3O)$_2$Cu($\mu$$CH_3COO$)-(salpd-$\mu$-$O,O'$)Cu][a]

a) Aomic parameters are multiplied by 10^4. Thermal parameters are given by the equivalent temperature factors.

Results and Discussion

Formation of the Acetate-, Methoxide-, and Phenolate-Bridged Tetranuclear Complex. The formation of the tetranuclear copper(II) complex with methoxo bridges, for example, can be represented by this equation:

$$2\,[Cu(salpd)]+2\,Cu(L)_2+2\,CH_3OH \rightarrow [Cu(salpd\text{-}\mu\text{-}O,O')(\mu\text{-}L)Cu(\mu\text{-}CH_3O)_2Cu(\mu\text{-}L)\text{-}(salpd\text{-}\mu\text{-}O,O')Cu]+2\,LH$$

where L=HCOO or CH_3COO. This reaction, accompanied by methoxide-bridging, takes place even without the addition of a base, although the addition of triethylamine makes the reaction quantitative. However, attempts to obtain the tetranuclear copper(II) complex with bridging ethoxide ions instead of methoxide ions were unsuccessful under similar conditions.

Structure of 1. The molecular structure, with its atomic numbering, is shown in Fig. 1, while the bond lengths and bond angles are given in Table 2. The complex is tetranuclear and has a center of inversion. The zigzag-chain structure of the copper(II) ions in the complex is made up of four units of a square pyramid. Each salpd ligand occupies the four equatorial positions of the terminal copper(II) ion, with the bond distances of 1.963(3)—1.978(5) Å, while the apical position is occupied by one of the oxygens of the acetate ion with the bond distance of 2.235(4) Å. Each basal plane of the inner two copper(II) ions is formed by the two bridging methoxide oxygens (1.917(3) Å, 1.927(3) Å), one of the phenolate oxygens (2.027(3) Å) and one of the acetate oxygens (1.926(3) Å). The apical position is occupied by another phenolate oxygen of salpd (Cu(1)-O(2)=2.323(3) Å). It is noteworthy that one of the oxygen atoms of the bridging acetate ion coordinates to Cu(2) at the apical position, while the other oxygen atom coordinates to Cu(1) at an equatorial position.

The Cu(1), OM, Cu(1′), and OM* atoms make a

OM-CM	1.392(7)	Cu(2)-O(4)-C(18)	129.4(3)
Cu(1)-O(1)	2.027(3)	O(3)-C(18)-O(4)	126.2(5)
Cu(2)-O(2)	2.323(3)	O(3)-C(18)-C(19)	115.8(4)
Cu(1)-0(3)	1.926(3)	O(4)-C(18)-C(19)	118.0(5)
Cu(2)-O(1)	1.963(3)	O(1)-Cu(1)-O(2)	70.1(1)
Cu(2)-O(2)	1.924(4)	O(1)-Cu(1)-O(3)	93.8(1)
Cu(2)-O(4)	2.235(4)	O(1)-Cu(1)-OM*	95.3(1)
Cu(2)-N(1)	1.978(5)	O(3)-Cu(1)-OM	92.7(1)
Cu(2)-N(2)	1.992(5)	OM-Cu(1)-OM*	76.1(1)
O(3)-C(18)	1.262(6)	O(1)-Cu(2)-O(2)	80.5(2)
O(4)-C(18)	1.234(6)	O(1)-Cu(2)-N(1)	91.2(2)
C(18)-C(19)	1.500(8)	N(1)-Cu(2)-N(2)	95.7(2)
		Cu(1)-O(1)-Cu(2)	103.0(2)
		Cu(1)-O(2)-Cu(2)	94.2(1)

perfect plane, as required by the crystallographic symmetry.

The most prominent feature of the structure is that the basal planes of the inner copper atoms (Cu(1) and Cu(1′)) are nearly perpendicular to those of the terminal copper atoms (Cu(2) and Cu(2′)), the dihedral angle between the mean basal planes of Cu(1) and Cu(2′) being 108.4°. The basal atoms of terminal copper are slightly distorted toward a tetrahedron, the dihedral angle formed by the Cu(2), O(2), N(2), and Cu(2), O(1), N(1) planes being 163.6°. Cu(2) is lifted by 0.11 Å toward the acetate oxyen.

Table 3. IR Data of Tetranuclear Copper(II) Complexes (cm^{-1})

Complex	Skeletal	ν_{C-O}		ν_{M-OCH_3}	
		ν(as)	ν(s)	ν_{C-O}	ν_{M-O}
1	1538vs 1550vs	1578vs	1390vs	1062vs	535s
2	1540vs 1550vs	1590vs	1346vs	1063vs	530s

The skeletal vibration of [Cu(salpd)] is found at 1538 cm^{-1}.

Infrared Spectra. Some frequencies of the selected bands of the complexes are listed in Table 3. The two bands at 1550 and 1540 cm^{-1} may be assigned to the skeletal vibrations related to the phenolic oxygen of the Schiff-base ligand.[13-15] A similar band was observed at 1538 cm^{-1} for the mononuclear complex [Cu(salpd)]. Since it is known that the phenoxide band shifts to a higher frequency when a singly coordinated phenoxide oxygen further coordinates to another metal ion, the band at 1550 cm^{-1} should be assigned to the vibration related to O(1), which strongly binds to both coppers (Cu(1) and Cu(2)), while the lower-frequency band seems to be due to the vibration related O(2), which is only weakly bound to Cu(1).

Magnetic Properties. Figure 2 represents the temperature variation in the magnetic susceptibilities (χ_A) and the magnetic moment (μ_{eff}) of the tetranuclear complexes in the temperature range of 77.4—296.0 K. The magnetic moments gradually decrease with the lowering of the temperature, as is shown in Fig. 2. This suggests that there is antiferromagnetic interaction between copper(II) ions. Hatfield and Inman proposed the interaction Hamiltonian for a four spin model with superexchange interaction to account for the unusual magnetic properties of the complex, [4-(*o*-hydroxyphenylimino)-2-pentanonato]-copper(II), as given below.[16]

$$\boldsymbol{H}=-2J_{12}\mathbf{S}_1\mathbf{S}_2-2J_{13}(\mathbf{S}_1\mathbf{S}_3+\mathbf{S}_2\mathbf{S}_4) -2J_{14}(\mathbf{S}_1\mathbf{S}_4+\mathbf{S}_2\mathbf{S}_3)-2J_{34}\mathbf{S}_3\mathbf{S}_4 \quad (1)$$

Here the numbering both on the exchange integrals J_{ij} and on the spin vectors **S** refers to the 3-1-2-4 arrangement of the Cu(II) ions. The present study has shown that the magnetic susceptibility expression for this sort of system may be given in an explicit form as follows:

$$\chi_A = Ng^2\beta^2/kT \cdot A/B + TIP \quad (2)$$
$$A = 10\exp[(K/2+N)/(kT)] + 2\exp[(K/2-N)/(kT)] + 2\exp[(-K/2+\sqrt{M^2+L^2})/(kT)] + 2\exp[(-K/2-\sqrt{M^2+L^2})/(kT)]$$
$$B = 5\exp[(K/2+N)/(kT)] + 3\exp[(K/2-N)/(kT)] + 3\exp[(-K/2+\sqrt{M^2+L^2})/(kT)] + 3\exp[(-K/2-\sqrt{M^2+L^2})/(kT)] + \exp[(-K/2-N-\sqrt{(K-N)^2+3L^2})/(kT)] + \exp[(-K/2-N+\sqrt{(K-N)^2+3L^2})/(kT)]$$

where $K=J_{12}+J_{34}$, $L=J_{14}-J_{13}$, $M=J_{12}-J_{34}$, and $N=J_{14}+J_{13}$, β is is the Bohr magneton; N, Avogadro's number; k, the Boltzmann constant, and g, the Lande g factor over copper(II) ions. The magnetic susceptibility data were, therefore, fit to Eq. 2 by using the best-fit method, assuming $J_{14}=J_{34}=0$ and $TIP=60\times10^{-6}$ c.g.s. u. per gram-atom copper; the coupling constants J_{12}, and J_{13} were varied systematically until the standard deviation of the value for Lande g factor reached a minimum in the range of 77.4—296.0 K. The calculation yielded g (average)=2.13, $J_{12}=-390$ cm^{-1}, $J_{13}=67$ cm^{-1} in Complex **1**, and g (average)=2.20, $J_{12}=-263$ cm^{-1}, $J_{13}=39$ cm^{-1} in Complex **2**. The solid curves in Fig. 2 represent the theoretical curves of the best fit of the data to Eq. 2 with the parameters specified above. The magnetic coupling constants in both complexes **1** and **2** indicate the existence of a strong antiferromagnetic superexchange interaction between the inner copper pair and a weak ferromagnetic superexchange interaction between the outer adjacent copper pairs.§

During the last two decades structural factors determining spin exchange coupling in dialkoxo-bridged dicopper(II) complexes have been the subject of continuing discussions by many researchers.[18-26] Among the many structural factors, the Cu-O-Cu angle or the coplanarity of the two coordination planes has been pointed out as the major factor by many workers. These two factors are not independent, but are linked to each other so that each factor may be used for the diagnosis of spin-exchange interaction.[26] In view of this, the strong antiferromagnetic interaction between the inner copper pair observed for the present complexes seems quite natural, since the  bridging system is perfectly coplanar and the Cu-O-Cu angle (103.6°) is fairly large.[20] As for the outer copper (Cu(1), Cu(2)) pair, the geometry of the bridging system is very complicated, as has been described in the preceding section, so that it is not easy to predict the extent of spin coupling in a straightforward manner. However, in many cases of such bridging systems with a very distorted geometry, as is the present complex, only a weak spin coupling has been reported.[27] Thus, the weak ferromagnetism found in this study is not a surprising result.

Judging from the qualitative similarity of the magnetic parameters, the principal configuration of Complex **2** is likely to be similar to that of **1**.

§ It is possible to obtain a tolerable agreement between the experimental data and the theoretical χ-T curve by using a value from a considerably wide range (±30 cm^{-1}) for J_{13}, with a slight adjustment of the J_{12} value. However, we have confirmed that a much less satisfactory agreement be obtained by using a negative J_{13} value.

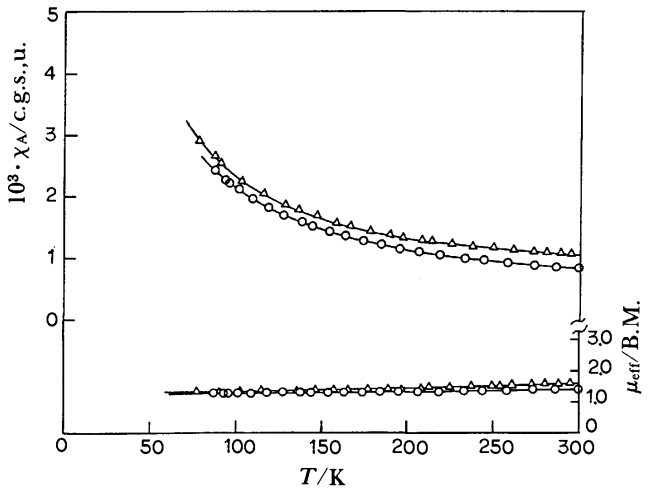

Fig. 2. Temperature variation of the atomic susceptibility (χ_A) and magnetic moment (μ_{eff}) for the tetranuclear complexes: **1** (○) and **2** (△). The solid lines were drawn on the basis of the values of χ_A and μ_{eff} obtained from Eq. 2, when $J_{12}=-390$ cm^{-1}, $J_{23}=67$ cm^{-1}, $J_{14}=J_{34}=0$ cm^{-1}, and $g=2.13$ for complex **1**, and $J_{12}=-263$ cm^{-1}, $J_{13}=39$ cm^{-1}, $J_{14}=J_{34}=0$ cm^{-1}, and $g=2.20$ for complex **2**.

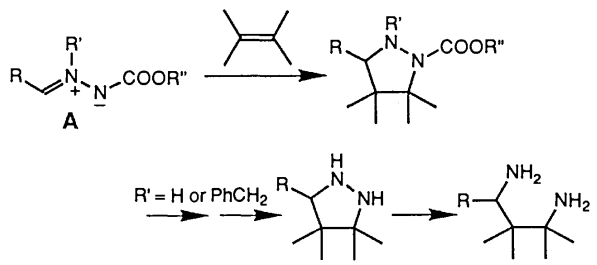
Triethylamine-Mediated Generation of a Synthetic Equivalent of Parent Azomethine Imine by Condensation of Ethyl 3-Benzylcarbazate with Paraformaldehyde

Shuji KANEMASA,* Naoki TOMOSHIGE, Eiji WADA, and Otohiko TSUGE*
Institute of Advanced Material Study, and Department of Molecular Science and Technology, Interdisciplinary Graduate School of Engineering Sciences, Kyushu University, Kasugakoen, Kasuga 816
(Received April 27, 1989)

A synthetic equivalent of parent azomethine imine is accessible by simple heating of ethyl 3-benzylcarbazate with paraformaldehyde under reflux in toluene in the presence of triethylamine, which effectively suppresses the undesired formation of imine dimers. The resulting imines can be trapped with a variety of dipolarophiles.

The cycloaddition of azomethine imine 1,3-dipoles with olefin dipolarophiles offers a short synthetic method for producing pyrazolidine derivatives.[1] The pyrazolidines which have been synthesized by this route are derivatives bearing at least one *N*-substituent.[2] To the best of our knowledge, not only the parent azomethine imine, itself, but also its synthetic equivalent is unknown.

We planned to establish a route leading to a synthetic equivalent of the parent azomethine imine 1,3-dipole. Cycloadditions of this synthetic equivalent with olefins and a subsequent removal of the *N*-substituents would produce *N*-unsubstituted pyrazolidines. Therefore, the cycloadducts would serve as functionalized cyclic hydrazines in heterocyclic synthesis; a reductive cleavage of the nitrogen-nitrogen bond of *N*-unsubstituted pyrazolidines would provide a new synthetic way to functionalized 1,3-diamines.



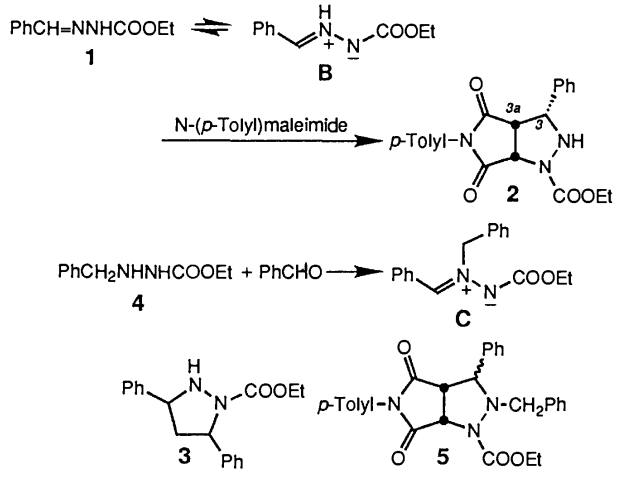
The synthetic equivalent of our choice is azomethine imine **A**, which bears an anion-stabilizing ester group at the terminal nitrogen and the central nitrogen is either unsubstituted or substituted by a removable benzyl group.

In the present work we investigated the condensation of ethyl 3-benzylcarbazate with formaldehyde and its equivalent reactions. It was found that triethylamine could effectively inhibit the formal dimerization of the transient azomethine imine. The generation procedure is simply carried out by heating ethyl 3-benzylcarbazate with paraformaldehyde and triethylamine in toluene in the presence of a dipolarophile.

Results and Discussion

Hydrazones undergo thermal[3] or acid-catalyzed tautomerism[4] generating azomethine imines bearing an unsubstituted nitrogen **A** (R'=H). Ethyl 3-benzylidenecarbazate (**1**) was selected as an imine precursor and its thermal tautomerism was investigated since **1** has an array of functionalities similar to that of the imines of α-amino esters whose thermal tautomerism is known to generate ester-stabilized azomethine ylides.[5]

Heating hydrazone **1** with *N*-(*p*-tolyl)maleimide under reflux in toluene for 72 h gave a single stereoisomer of cycloadduct **2** in 39% yield (Scheme 1). The structure of **2** was assigned as being a 3,3a-cis isomer on the basis of $J_{3\text{-}3a}$=8.8 Hz, indicating the endo-selective cycloaddition of azomethine imine **B**. However, the poor reactivity cancels the advantage of high stereoselectivity. Attempts to trap imine **B** with less reactive olefins, such as methyl acrylate and crotonate (each excess in a sealed tube), were unsuccessful, and attempts to activate hydrazone **1** by the aid of lithium bromide/triethylamine[6] were all in vain. The use of 1-benzylidene-2-(*p*-tolylsulfony)hydrazine, instead of **1**, produced no cycloadducts.



Scheme 1.

Although boron trifluoride etherate[4] showed some catalysis in a hydrazone-azomethine imine tautomerism of **1**, a 5 : 1 stereoisomeric mixture of cycloadduct **3** was obtained only in 38% yield in a reaction with styrene. Similar boron trifluoride-catalyzed reactions with butyl vinyl ether or *N*-(*p*-tolyl)maleimide gave no cycloadducts.

The next generation method employed was the condensation of carbonyl compounds with 1,2-disubstituted hydrazines.[1] For this purpose, hydrazone **1** was reduced with either zinc borohydride or a borane/pyridine complex into ethyl 3-benzylcarbazate (**4**).

Heating **4** with benzaldehyde under reflux in toluene resulted in a quantitative generation of azomethine imine **C**, which was captured by *N*-(*p*-tolyl)maleimide to give a 73:27 mixture of endo and exo isomers of cycloadduct **5** (Scheme 1). Both isomers, which were separated from each other by silica-gel column chromatography by using hexane-ethyl acetate, were assigned on the basis of $J_{3\text{-}3a}$.

In expectation of the generation of a synthetic equivalent of the parent azomethine imine, a reaction of hydrazine **4** with paraformaldehyde was performed under reflux in toluene with a continuous removal of water by the aid of a Dean-Stark trap. The azomethine imine **D** generated was trapped with several olefins such as *N*-(*p*-tolyl)maleimide, dimethyl fumarate, and styrene (Scheme 2). Even when two equimolar amounts of the olefins were employed, the yields of the corresponding cyloadducts **6a,b,d** were low (Table 1, Entries 1, 6, 11). In all these cases, the cycloadducts were accompanied by diethyl 2,5-dibenzylperhydro-1,2,4,5-tetrazine-1,4-dicarboxylate (**7**), the formal dimer of imine **D**, in 15 to 50% yields. Although the yield of **6d** went up to 73% when a large excess of styrene (13 equiv) was used, side-product **7** was still formed in 10% yield (Entry 12).

Scheme 2.

The azomethine imine **D**, thus generated, failed to react with less reactive olefins, such as methyl acrylate and crotonate, dimer **7** being the only product (Entries 23, 25). As anticipated, dimer **7** was formed also in the absence of dipolarophiles. Thus, heating **4** with paraformaldehyde under reflux in toluene produced 24% of **7** after 2 h, and 79% after 42 h. Under these reaction conditions, a thermal cleavage of dimer **7** did not take place, indicating no possibility for the regeneration of azomethine imine **D** by the thermolysis of **7**.

When dipolarophiles are not highly reactive in the simple heating method (Method A), the formation of side-product **7** becomes critical.

Molecular sieves of 4A were used to remove the water formed during the condensation (Method B). Under these conditions, the formation of dimer **7** was significantly suppressed in the reactions with styrene and butyl vinyl ether, so that the relative yields of cycloadducts **6d,j** slightly increased (Entries 13, 28). However, no significant improvement was observed in the reaction with *N*-(*p*-tolyl)maleimide (Entry 2).

The 2-(phenylthiomethyl) derivative of hydrazine **4** is the second precursor of azomethine imine **D** of our choice. Treatment of **4** with aqueous formaldehyde, and then benzenethiol in ethanol at room temperature, gave ethyl 3-benzyl-3-(phenylthiomethyl)carbazate (**8**) in 93% yield (Scheme 3), which is sufficiently stable to be purified by coluumn chromatography over silica gel.

Simple heating of **8** generated azomethine imine **D** which was trapped with electron-deficient activated dipolarophiles, such as *N*-(*p*-tolyl)maleimide and dimethyl maleate, to afford the corresponding cycloadducts **6a,c**. Although the formation of dimer **7** was effectively suppressed during this procedure, the slow generation of imine **D** resulted in the recovery of some starting precursor **8**, even after the lapse of long reaction times (Entries 4, 9). More troublesome, especially in the reaction with *N*-(*p*-tolyl)maleimide as a highly reactive Michael acceptor, was the Michael addition of phenylthiol nucleophile, arising from the elimination of **8**. A considerable amount of *N*-(*p*-tolyl)-2-(phenylthio)succinimide was produced. Poor stereospecificity in the reaction with dimethyl maleate was another disadvantage (Entry 9).

The base-induced azomethine imine generation by treating **8** with sodium hydride, in *N*,*N*-dimethyl-

a) Unless otherwise referred, all reactions were carried out by heating a mixture of a precursor, paraformaldehyde (1.5—2 equiv), and a dipolarophile (2 equiv) under reflux in the solvent shown above with continiuous removal of water by the aid of a Dean-Stark trap. b) As methods A to E, see experimental section. c) Yield of isolated products based on **4** or **8**. d) One equivalent of the maleimide was used. e) Recovered **8**. f) *N*-(*p*-Tolyl)-2-(phenylthio)succinimide. g) The fumarate adduct **6b**. h) A large excess (13 equiv) of styrene was used. i) **6f**: 50%; **6g**: 46%. j) **6h**: 14%; **6i**: 28%. k) Ethyl 4-benzylperhydro-1,3,4-oxadiazole-3-carboxylate.

formamide (DMF) at 0 °C in the presence of butyl vinyl ether, formed complex mixture of many compounds. It was found, however, that the imine generation was effected by an acid catalysis. Thus, the reaction of **8** with styrene was catalyzed by one equivalent of acetic acid, but the formation of dimer **7** was also facilitated in the presence of a large excess of acetic acid (Entries 15—17).

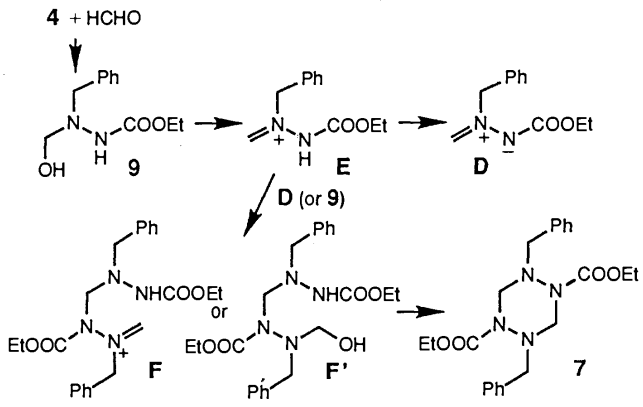
The reaction of hydrazine **4** with aqueous formaldehyde in ethanol at room temperature and evaporation of all the volatile materials left an unstable liquid which was assigned to be ethyl 3-benzyl-3-(hydroxymethyl)carbazate (**9**) on the basis of the ^1H NMR spectrum. The use of **9** as a precursor of azomethine imine **D** was investigated next.

The generation of azomethine imine **D** by the thermal or acid-catalyzed dehydration of (hydroxymethyl)hydrazine **9** accompanied the formation of significant amounts of dimer **7** (Entries 5, 10, 18), and the use of a strong acid catalyst, such as trifluoroacetic acid, resulted in a quantitative formation of dimer **7** (Entry 19). To our delight, however, triethylamine was found to effectively suppress the formation of dimer **7** (Entries 20—22).

We examined the direct generation route of imine **D** by heating hydrazine **4** with paraformaldehyde in the presence of excess (3 equiv) triethylamine. This procedure (Method C) worked well for a variety of olefinic dipolarophiles to produce the corresponding cycloadducts **6a,b,d,j** in excellent yields (Entries 3, 7, 14, 29). Even with less reactive olefins, such as methyl acrylate and crotonate, imine **D** underwent a smooth cycloaddition to give cycloadducts **6f,g** and **6h,i** (Entries 24, 26).

It is apparent that the condensation of hydrazine **4** with formaldehyde initially forms (hydroxymethyl)-hydrazine **9**, which then eliminates water leading to iminium intermediate **E** (Scheme 4). The direct formation of dimer **7** through the cycloaddition dimerization of azomethine imine **D** is thermally forbidden.[7] The most likely path is the nucleophilic addition of azomethine imine **D** or (hydroxymethyl)hydrazine **9** to the iminium intermediate **E** leading to **F** or **F'**. Either of them undergoes a ready cyclization to give dimer **7**.

In the presence of a weak acid catalyst, the dehydra-



Scheme 4.

tion of **9** is facilitated to accumulate iminium salt **E**. The generation of imine **D** competes with the coupling reaction leading to **F** or **F'**. When the catalyst is strongly acidic, deprotonation of **E** becomes difficult, so that the dimer formation becomes a major path. On the other hand, triethylamine catalyzes the deprotonation stage of **E** leading to azomethine imine **D** while minimizing the opportunity for a coupling reaction.

The removal of both the ester and benzyl substituents from the cycloadducts **6a—j** can be readily performed by acid- or base-catalyzed hydrolysis and catalytic hydrogenation on Pd/C, respectively. The use of the resulting heterocycles in organic synthesis is now under investigation; the results will soon be published elsewhere.

Experimental

General. Melting points were determined on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with JASCO IRA-1 and A-702 spectrometers. ^{1}H and ^{13}C NMR spectra were recorded on JEOL FX-100 (100 MHz for ^{1}H NMR and 25.05 MHz for ^{13}C NMR) and GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instruments. Chemical shifts are expressed in parts per million downfield from tetramethylsilane as an internal standard. Mass spectra and high-resolution mass spectra (HRMS) were measured with a JEOL-01SG-2 spectrometer at an ionization energy of 70 eV. Elemental analyses were performed on a Hitachi 026 CHN analyzer. For preparative column chromatography, Wakogel C-200, C-300 (Wako), and Silica gel 60 (Merck) were employed. Flash chromatography was carried out on an EYELA EF-10 apparatus using a column (20×180 mm) packed with Silica gel 60 (Merck, size: 0.04—0.063 mm).

Ethyl 3,3a-*cis*-3a,6a-*cis*-4,6-Dioxo-3-phenyl-5-(*p*-tolyl)-perhydropyrrolo[3,4-*c*]pyrazole-1-carboxylate (2): A mixture of **1** (0.191 g, 1 mmol) and *N*-(*p*-tolyl)maleimide (0.15 g, 0.8 mmol) was heated under reflux in toluene (4 ml) for 72 h. The mixture was evaporated in vacuo and the residue was chromatographed on silica gel by using hexane-ethyl acetate (2:1 v/v) to give **2** (0.117 g, 39%): Colorless prisms (diethyl ether-hexane); mp 203—205 °C; IR (KBr) 3210, 1710, 1365, and 1180 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 1.36 (3H, t, J=7.2 Hz, COOEt), 2.35 (3H, s, *p*-Me), 3.83 (1H, dd, $J_{3a\text{-}3}$=8.8 and $J_{3a\text{-}6a}$=8.1 Hz, 3a-H), 4.32 (2H, m, COOEt), 4.67 (1H, t, $J_{3\text{-}3a}$= $J_{3a\text{-}NH}$=8.8 Hz, 3-H), 4.98 (1H, br d, J=8.8 Hz, NH), 5.48 (1H, d, $J_{6a\text{-}3a}$=8.1 Hz, 6a-H), and 7.0—7.5 (9H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.56 (COOEt), 21.19 (*p*-Me), 52.01 (COOEt), 61.97 (3a-C), 63.37 (6a-C), 66.45 (3-C), 125.41, 127.11, 128.65, 128.81, 129.02, 129.82, 133.37, 138.93 (each Ph), 156.74 (COOEt), 171.89, and 172.94 (each CON). Found: C, 66.66; H, 5.68; N, 10.93%. Calcd for $C_{21}H_{21}N_3O_4$: C, 66.47; H, 5.59; N, 11.08%.

Ethyl 3,5-Diphenyl-1-pyrazolidine-1-carboxylate (3): A solution of **1** (0.191 g, 1 mmol), styrene (0.17 ml, 1.5 mmol), and trifluoroborane etherate (0.16 ml, 1.3 mmol) in dichloromethane (5 ml) was stirred at room temperature for 20 h. The solvent was evaporated in vacuo, and the residue was treated with saturated aqueous sodium hydrogencarbonate; the mixture was then extracted with diethyl ether (25 ml×3). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was chromatographed on silica gel with hexane-ethyl acetate (5:1 v/v) to give the major stereoisomer of **3** (0.112 g, 38%) which was contaminated by a trace of the minor isomer: Colorless liquid; IR (neat) 3250, 1695, 1325, and 1120 cm^{-1}; ^{1}H NMR ($CDCl_3$) major isomer: δ= 1.2—1.3 (3H, COOEt), 2.46 (1H, dt, J_{gem}=12.8 and $J_{4\text{-}3}$=$J_{4\text{-}5}$=6.6 Hz, one of 4-H), 2.81 (1H, ddd, J_{gem}=12.8, $J_{4\text{-}3}$=8.1, and $J_{4\text{-}5}$=4.4 Hz, the other of 4-H), 4.0—4.3 (2H, m, COOEt), 4.62 (1H, dd, $J_{3\text{-}4}$=6.6 and 4.4 Hz, 3-H), 5.02 (1H, dd, $J_{5\text{-}4}$=8.1 and 6.6 Hz, 5-H), and 7.2—7.5 (10H, m, Ph); minor isomer: δ=2.17, 3.10 (each 1H, m, 4-H), 4.34 (1H, dd, $J_{3\text{-}4}$=10.6 and 5.4 Hz, 3-H), and 5.24 (1H, t, $J_{5\text{-}4}$= 9.2 Hz, 5-H); ^{13}C NMR ($CDCl_3$) major isomer: δ=14.61 (COOEt), 45.41 (4-C), 60.96, 61.52, 61.67 (3-, 5-C, and COOEt), 125.76, 126.32, 127.17, 127.40, 128.58, 139.97, 142.30 (each Ph), and 156.12 (COOEt); minor isomer: δ=45.86, 61.88, 63.48, 63.58, 126.81, 127.12, 127.73, 128.25, 128.66, 128.69, 128.85, 129.05, and 142.30. Other ^{1}H and ^{13}C signals of the minor isomer are overlapping with those of the major isomer.

Ethyl 3,3a-*cis*-2-Benzyl-4,6-dioxo-3-phenyl-5-(*p*-tolyl)perhydropyrrolo[3,4-*c*]pyrazole-1-carboxylate (5): A mixture of **4** (0.04 g, 0.2 mmol), benzaldehyde (0.024 g, 0.2 mmol), and *N*-(*p*-tolyl)maleimide (0.038 g, 0.2 mmol) was heated under reflux in toluene (3 ml) for 24 h, during which time the water formed was removed by the aid of a Dean-Stark trap. The solvent was evaporated in vacuo and the residue was chromatographed on silica gel to give 3,3a-*trans*-**5** (0.025 g, 27%) from the fraction eluted with hexane-ethyl acetate (5:1 v/v) and 3,3a-*cis*-**5** (0.069 g, 73%) with ethyl acetate. 3,3a-*cis*-**5**: Colorless prisms (diethyl ether-hexane); mp 98 °C; IR (KBr) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.44 (3H, t, J=7.3 Hz, COOEt), 2.26 (3H, s, *p*-Me), 3.72 (1H, t, $J_{3a\text{-}3}$=$J_{3a\text{-}6a}$=8.6 Hz, 3a-H), 4.12, 4.25 (each 1H, d, J_{gem}=12.7 Hz, $PhCH_2$), 4.42 (2H, m, COOEt), 4.76 (1H, d, $J_{6a\text{-}3a}$=8.6 Hz, 6a-H), 5.11 (1H, d, $J_{3\text{-}3a}$=8.6 Hz, 3-H), 6.21, 7.01 (each 2H, d, J=8.3 Hz, Ar), and 7.3—7.4 (10H, m, Ph); MS *m/z* (rel intensity, %) 469 (M^+, 1), 91 (base peak), and 44 (23). Found: C, 71.37; H, 6.06; N, 8.89%. Calcd for $C_{28}H_{27}N_3O_4$: C, 71.61; H, 5.81; N, 8.95%. 3,3a-*trans*-**5**: Colorless prisms (diethyl ether-hexane); mp 203—204 °C; IR (KBr) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 1.28 (3H, t, J=7.1 Hz, COOEt), 2.43 (3H, s, *p*-Me), 3.89 (1H, d, J_{gem}=12.5 Hz, one of $PhCH_2$), 3.96 (1H, dd, $J_{3a\text{-}6a}$=8.6 and $J_{3a\text{-}3}$=1.3 Hz, 3a-H), 4.1—4.4 (3H, m, COOEt and the other of $PhCH_2$), 4.89 (1H,

br s, 3-H), 5.43 (1H, d, $J_{6a\text{-}3a}$=8.6 Hz, 6a-H), and 7.3—7.5 (14H, m, Ar); MS *m/z* (rel intensity, %) 469 (M^+, 28), 278 (29), and 91 (base peak). Found: C, 71.73; H, 5.77; N, 8.93%. Calcd for $C_{28}H_{27}N_3O_4$: C, 71.61; H, 5.81; N, 8.95%.

General Proceudre for Cycloadditions of Azomethine Imine D with Olefinic Dipolarophiles Leading to 6a—j. The following five procedures were employed for the generation of **D** and its cycloaddition: Method A: A mixture of hydrazine **4** (0.194 g, 1 mmol), paraformaldehyde (1.5—2 mmol), and an olefin (2 mmol) was heated under reflux in toluene (3 ml) with a continuous removal of water by the aid of a Dean-Stark trap. Method B: Similar to Method A, except that the mixture was heated together with Molecular Sieves 4A (1 g). Method C: The same as Method A, except that the mixture was heated in the presence of triethylamine (0.3 g, 3 mmol). Method D: (Phenylthiomethyl)hydrazine **8** (0.316 g, 1 mmol) and an olefin (2 mmol) were heated in the solvent shown in Table 1 in the absence or presence of acetic acid. Method E: Hydrazine **4** (0.194 g, 1 mmol) was treated with aqueous formaldehyde in ethanol (4 ml) at room temperature for 1 h. The ethanol was evaporated in vacuo; then the residue was dissolved in water (25 ml), and extracted with dichloromethane (20 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo. The residue was heated with an olefin (2 mmol) in the absence or presence of a catalyst.

After the reaction had come to completion, the mixture was evaporated in vacuo and the residue was purified by silica-gel chromatography. The eluent used was as follows: **6a**: ethyl acetate; **6b**: hexane-ethyl acetate (3 : 1 v/v); **6c**: hexane-ethyl acetate (5 : 1 v/v); **6d**: hexane-ethyl acetate (3:1 v/v); **6e**: hexane-ethyl acetate (3 : 1 v/v); **6f** and **6g**: hexane-ethyl acetate (2 : 1 v/v); **6h** and **6i**: hexane-ethyl acetate (3 : 1 v/v); **6j**: hexane-ethyl acetate (4 : 1 v/v).

Ethyl 3,3a-*cis*-2-Benzyl-4,6-dioxo-5-(*p*-tolyl)perhydropyrrolo[3,4-*c*]pyrazole-1-carboxylate (6a): Colorless needles (diethyl ether-hexane); mp 143 °C; IR (KBr) 1700, 1380, and 1180 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, t, J=7.2 Hz, COOEt), 2.41 (3H, s, *p*-Me), 3.35 (1H, dd, J_{gem}=12.8 and $J_{3\text{-}3a}$=8.7 Hz, one of 3-H), 3.64 (1H, br d, J_{gem}=12.8 Hz, the other of 3-H), 3.69 (1H, d, J_{gem}=12.0 Hz, one of $PhCH_2$), 3.77 (1H, dt, $J_{3a\text{-}3}$=$J_{3a\text{-}6a}$=8.7 and $J_{3a\text{-}3}$=1.5 Hz, 3a-H), 4.00 (1H, d, J_{gem}=12.0 Hz, the other of $PhCH_2$), 4.17 (2H, m, COOEt), 5.40 (1H, d, $J_{6a\text{-}3a}$=8.7 Hz, 6a-H), and 7.2—7.4 (9H, m, Ar); ^{13}C NMR ($CDCl_3$) δ=14.34 (COOEt), 21.24 (*p*-Me), 47.57 (COOEt), 54.82 (3-C), 60.39, 62.78, 63.34 (each $PhCH_2$, 3a-, and 6a-C), 125.67, 128.02, 128.52, 129.01, 129.74, 130.08, 136.06, 139.17 (each Ar), 155.99 (COOEt), 173.66, and 176.58 (each CON); MS *m/z* (rel intensity, %) 393 (M^+, 36), 202 (31), and 91 (base peak). Found: C, 67.08; H, 5.90; N, 10.64%. Calcd for $C_{22}H_{23}N_3O_4$: C, 67.15; H, 5.90; N, 10.68%.

Dimethyl 3,4-*trans*-1-Benzyl-2-ethoxycarbonyl-3,4-pyrazolidinedicarboxylate (6b): Colorless liquid; IR (neat) 1730, 1380, 1340, and 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (3H, t, J=7.1 Hz, COOEt), 3.15 (1H, dd, J_{gem}=11.7 and $J_{5\text{-}4}$=10.6 Hz, one of 5-H), 3.36 (1H, dd, J_{gem}=11.7 and $J_{5\text{-}4}$=7.3 Hz, the other of 5-H), 3.7—3.8 (2H, m, 4-H and one of $PhCH_2$), 3.75, 3.83 (each 3H, s, COOMe), 4.0—4.2 (3H, m, COOEt and the other of $PhCH_2$), 4.96 (1H, $J_{3\text{-}4}$=8.1 Hz, 3-H), and 7.3—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.38, 48.32 (each COOEt), 52,73, 52.90 (each COOMe), 55.79 (5-H), 61,50, 62.19, 62.66 (each $PhCH_2$, 3-, and 4-C), 127,71, 128.38, 129.76, 136.78 (Ph), 154.90 (COOEt), 170.68, and 171.96 (each COOMe); MS *m/z* (rel intensity %) 350 (M^+, 26), 127 (24), 91 (base peak). Found: C, 58.40; H, 6.42; N, 8.05%. Calcd for $C_{17}H_{22}N_2O_6$: C, 58.27; H, 6.34; N, 8.00%.

Dimethyl 3,4-*cis*-1-Benzyl-2-ethoxycarbonyl-3,4-pyrazolidinedicarboxylate (6c): Colorless liquid; IR (neat) 1740, 1680, 1430, 1380, and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (3H, t, J=7.0 Hz, COOEt), 3.27 (1H, dd, J_{gem}=11.0 and $J_{5\text{-}4}$=7.0 Hz, one of 5-H), 3.4—3.6 (2H, m, 4-H and the other of 5-H), 3.70, 3.76 (each 3H, s, COOMe), 3.97, 4.07 (each 1H, d, J_{gem}=12.3 Hz, $PhCH_2$), 4.17 (2H, q, J=7.0 Hz, COOEt), 4.85 (1H, d, $J_{3\text{-}4}$=8.8 Hz, 3-H), and 7.3—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.68, 47.01 (each COOEt), 52.71, 53.87 (each COOMe), 61.53, 62.25, 62.44 (each $PhCH_2$, 3-, and 4-C), 127.97, 128.69, 129.93, 137.11 (each Ph), 154.85 (COOEt), 170.16, and 170.31 (each COOMe); MS *m/z* (rel intensity, %) 350 (M^+, 12), 127 (22), 103 (20), 91 (base peak), and 58 (24). Found: C, 58.04; H, 6.33; N, 8.09%. Calcd for $C_{17}H_{22}N_2O_6$: C, 58.27; H, 6.34; N, 8.00%.

Ethyl 2-Benzyl-5-phenyl-1-pyrazolidinecarboxylate (6d): Colorless prisms (diethyl ether); mp 81—83 °C; IR (KBr) 1675, 1410, 1330, and 1130 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.19 (3H, t, J=7.1 Hz, COOEt), 2.28 (1H, ddt, J_{gem}=13.0, $J_{4\text{-}5}$=8.2, and $J_{4\text{-}3}$=7.5 Hz, one of 4-H), 2.56 (1H, dddd, J_{gem}=13.0, $J_{4\text{-}5}$=8.2, and $J_{4\text{-}3}$=6.0 and 5.0 Hz, the other of 4-H), 3.0—3.1 (2H, m, 3-H), 3.85 (1H, d, J_{gem}=12.1 Hz, one of $PhCH_2$), 4.0—4.2 (2H, m, COOEt), 4.17 (1H, d, J_{gem}=12.1 Hz, the other of $PhCH_2$), 5.08 (1H, t, $J_{5\text{-}4}$=8.2 Hz, 5-H), and 7.2—7.5 (10H, m, Ph); MS *m/z* (rel intensity, %) 310 (M^+, 5) and 91 (base peak). Found: C, 73.44; H, 7.23; N, 9.11%. Calcd for $C_{19}H_{22}N_2O_2$: C, 73.51; H, 7.16; N, 9.03%.

Ethyl 3a,8a-*cis*-2-Benzyl-1,2,3,3a,4,8a-hexahydroindeno-[1,2-*c*]pyrazole-1-carboxylate (6e): Pale yellow liquid; IR (neat) 1700, 1130, and 750 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (3H, t, J=7.1 Hz, COOEt), 2.9—3.4 (5H, m, 3-, 3a-, and 4-H), 3.58, 3.81 (each 1H, d, J_{gem}=12.1 Hz, $PhCH_2$), 4.1—4.2 (2H, m, COOEt), 5.73 (1H, d, $J_{8b\text{-}3a}$=6.6 Hz, 8b-H), and 7.1—7.7 (9H, m, Ar); MS *m/z* (rel intensity, %) 322 (M^+, 30), 159 (30), 115 (20), and 91 (base peak). HRMS Found: *m/z* 322.1683. Calcd for $C_{20}H_{22}N_2O_2$: M, 322.1680.

Ethyl 2-Benzyl-5-methoxycarbonyl-1-pyrazolidinecarboxylate (6f) and Ethyl 2-Benzyl-4-methoxycarbonyl-1-pyrazolidinecarboxylate (6g): 6f: Colorless liquid; IR (neat) 1740, 1690, 1420, and 1200 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (3H, t, J=7.1 Hz, COOEt), 2.3—2.5 (2H, m, 4-H), 2.9—3.2 (2H, m, 3-H), 3.73 (1H, d, J_{gem}=11.0 Hz, one of $PhCH_2$), 3.79 (3H, s, COOMe), 4.0—4.2 (3H, COOEt and the other of $PhCH_2$), 4.53 (1H, t, $J_{5\text{-}4}$=8.2 Hz, 5-H), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.43 (COOEt), 29.79 (4-C), 51.89 (3-C), 52.45 (COOMe), 59.91 (COOEt), 61.32, 61.88 (5-C and $PhCH_2$), 127.54, 128.33, 129.80, 137.38 (each Ph), 154.96 (COOEt), and 172.92 (COOMe); MS *m/z* (rel intensity, %) 292 (M^+, 29), 91 (base peak), and 69 (37). Found: C, 61.40; H, 7.13; N, 9.36%. Calcd for $C_{15}H_{20}N_2O_4$: C, 61.62; H, 6.91; N, 9.58%. **6g**: Colorless liquid; IR (neat) 1740, 1690, 1430, and 1210 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (3H, t, J=7.1 Hz, COOEt), 3.1—3.3 (3H, m, 3-H and one of 5-H), 3.69 (3H, s, COOMe), 3.81 (2H, s, $PhCH_2$), 3.8—4.0 (2H, m, 4-H and the other of 5-H), 4.11 (2H, m, COOEt), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.56 (COOEt), 43.24 (4-C), 47.33 (5-C), 52.25 (COOMe), 55.16 (3-C), 60.98, 61.64 (COOEt and $PhCH_2$), 127.70, 128.36, 129.69, 136.78 (each Ph), 155.29 (COOEt), and 172.64 (COOMe); MS *m/z* (rel intensity, %) 292 (M^+, 45), 219 (28), 201 (21), 129 (48), 97 (21), 91 (base

peak), and 69 (32). HRMS Found: m/z 292.1403. Calcd for $C_{15}H_{20}N_2O_4$: M, 292.1422.

Ethyl 4,5-*trans*-2-Benzyl-5-methoxycarbonyl-4-methyl-1-pyrazolidinecarboxylate (6h) and Ethyl 4,5-*trans*-2-Benzyl-4-methoxycarbonyl-5-methyl-1-pyrazolidinecarboxylate (6i): **6h:** Colorless liquid; IR (neat) 1740, 1690, 1420, and 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.16 (3H, t, J=7.0 Hz, COOEt), 1.23 (3H, d, J=6.2 Hz, 4-Me), 2.68 (1H, t, $J_{gem}=J_{3\text{-}4}$=11.4 Hz, one of 3-H), 2.8—3.0 (1H, m, 4-H), 3.14 (1H, dd, J_{gem}=11.4 and $J_{3\text{-}4}$=6.2 Hz, the other of 3-H), 3.75 (1H, d, J_{gem}=12.1 Hz, one of $PhCH_2$), 3.83 (3H, s, COOMe), 4.0—4.1 (3H, m, COOEt and 5-H), 4.19 (1H, d, J_{gem}=12.1 Hz, the other of $PhCH_2$), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.40 (COOEt), 15.67 (4-Me), 38.57 (4-C), 52.51 (COOMe), 59.74 (COOEt), 61.80, 61.88 (3-C and $PhCH_2$), 67.14 (5-C), 127.50, 128.30, 129.83, 137.50 (each Ph), 154.98 (COOEt), and 172.94 (COOMe); MS m/z (rel intensity, %) 306 (M^+, 66), 233 (30), 91 (base peak), and 83 (26). Found: C, 62.79; H, 7.52; N, 9.15%. Calcd for $C_{16}H_{22}N_2O_4$: C, 62.72; H, 7.25; N, 9.14%. **6i:** Colorless liquid; IR (neat) 1740, 1690, 1420, and 1030 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.22 (3H, t, J=7.1 Hz, COOEt), 1.52 (3H, d, $J_{5\text{-}4}$=6.6 Hz, 5-H), 3.1—3.3 (3H, m, 3- and 4-H), 3.70 (3H, s, COOMe), 3.77, 4.00 (each 1H, d, J_{gem}=12.5 Hz, $PhCH_2$), 4.0—4.2 (2H, m, COOEt), 4.2—4.3 (1H, m, 5-H), and 7.2—7.5 (5H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.51 (COOEt), 22.22 (5-Me), 50.88 (3-C), 52.24 (COOMe), 54.63 (4-C), 58.53 (COOEt), 61.55, 62.66 ($PhCH_2$ and 5-C), 127.73, 128.38, 129.74, 136.99 (each Ph), 155.80 (COOEt), and 171.74 (COOMe); MS m/z (rel intensity, %) 306 (M^+, 7), 111 (21), 91 (base peak), and 83 (39). HRMS Found: m/z 306.1586. Calcd for $C_{16}H_{22}N_2O_4$: M, 306.1578.

Ethyl 2-Benzyl-5-butoxy-1-pyrazolidinecarboxylate (6j): Colorless liquid; IR (neat) 1690, 1370, 1330, and 1200 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (3H, t, J=7.3 Hz, n-Bu), 1.22 (3H, t, J=7.1 Hz, COOEt), 1.3—1.5, 1.5—1.7 (each 2H, m, n-Bu), 2.2—2.3 (2H, m, 4-H), 3.0—3.2 (2H, m, 3-H), 3.52 (1H, dt, J_{gem}=9.5 and J=6.6 Hz, one of n-Bu), 3.65 (1H, dt, J_{gem}=9.5 and J=6.6 Hz, the other of n-Bu), 3.80 (1H, d, J_{gem}=12.1 Hz, one of $PhCH_2$), 4.0—4.2 (2H, m, COOEt), 4.27 (1H, d, J_{gem}=12.1 Hz, the other of $PhCH_2$), 5.53 (1H, dd, $J_{5\text{-}4}$=4.8 and 3.7 Hz, 5-H), and 7.2—7.5 (5H, m, Ph); MS m/z (rel intensity, %) 306 (M^+, 46), 233 (22), 143 (22), 91 (base peak), and 87 (23). HRMS Found: m/z 306.1941. Calcd for $C_{17}H_{26}N_2O_3$: M, 306.1942.

Diethyl 2,5-Dibenzylperhydro-1,2,4,5-tetrazine-1,4-dicarboxylate (7): A mixture of **4** (0.205 g, 1.1 mmol) and paraformaldehyde (0.054 g, 1.8 mmol) was heated under reflux in toluene (4 ml) for 42 h. The solvent was evaporated in vacuo and the residue was washed with hexane to give **7** (0.179 g, 79%): Colorless prisms (diethyl ether-hexane); mp 139—140 °C; IR (KBr) 1680, 1420, 1340, 1290, and 1150 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.26 (6H, t, J=7.0 Hz, COOEt), 4.08 (4H, br s, $PhCH_2$), 4.20 (4H, q, J=7.0 Hz, COOEt), 4.72 (4H, br s, 3- and 6-H), and 7.2—7.6 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.51, 55.04 (each COOEt), 56.28 ($PhCH_2$), 62.14 (3- and 6-C), 127.86, 128.35, 129.74, 135.75 (each Ph), and 155.85 (COOEt); MS m/z (rel intensity, %) 412 (M^+, 6), 279 (24), 250 (33), and 91 (base peak). Found: C, 63.80; H, 6.82; N, 13.47%. Calcd for $C_{22}H_{28}N_4O_4$: C, 64.05; H, 6.86; N, 13.58%.

Ethyl 3-Benzyl-3-(phenylthiomethyl) carbazate (8): Hydrazine **4** (0.194 g, 1 mmol) was treated with aqueous formaldehyde (37% solution) in ethanol (3 ml) for 1 h at room temperature. The ethanol was evaporated in vacuo, the residue was dissolved in water (20 ml), and extracted with dichloromethane (25 ml×2). The combined extracts were dried over magnesium sulfate, and evaporated in vacuo; the residue was then heated with benzenethiol (0.11 g, 1 mmol) under reflux in toluene (3 ml) for 1 h. The toluene was evaporated in vacuo and the residue was chromatographed on silica gel with ethyl acetate to give **8** (0.294 g, 83%): Colorless solid (purified by silica-gel column chromatography); mp 65 °C; IR (KBr) 3300, 1690, 1515, and 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (3H, t, J=7.1 Hz, COOEt), 3.91 (2H, s, $PhCH_2$), 4.01 (2H, q, J=7.1 Hz, COOEt), 4.55 (2H, s, SCH_2), 6.22 (1H, br s, NH), and 7.1—7.5 (10H, m, Ph); ^{13}C NMR ($CDCl_3$) δ=14.58, 59.82 (each COOEt), 61.30 ($PhCH_2$), 64.31 (SCH_2), 127.12, 127.75, 128.43, 129.32, 129.39, 131.44, 136.00, 136.25 (each Ph), and 155.45 (COOEt); MS m/z (rel intensity, %) 207 (M^+ −109, 10), 109 (38), 91 (base peak), and 65 (30). Found: C, 64.46; H, 6.42; N, 8.75%. Calcd for $C_{17}H_{20}N_2O_2S$: C, 64.52; H, 6.38; N, 8..85%.

Ethyl 3-Benzyl-3-(hydroxymethyl)carbazate (9): Hydrazine **4** (0.194 g, 1 mmol) was treated with aqueous formaldehyde (37% solution) in ethanol (3 ml) for 1 h at room temperature. The ethanol was evaporated in vacuo; the residue was then dissolved in water (20 ml), and extracted with dichloromethadcne (25 ml×2). The combined extracts were dried over magnesium sulfate and evaporated in vacuo to give viscous liquid of **9** (0.22 g, 98%) as an unstable compound, for which only IR and ^1H NMR spectra were recorded: IR (neat) 3300, 1700, 1240, and 740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, t, J=7.5 Hz, COOEt), 3.91 (2H, s, $PhCH_2$), 4.0—4.3 (3H, m, COOEt and OH), 4.38 (2H, s, CH_2OH), 4.92 (1H, s, OH), and 7.2—7.5 (6H, m, Ph and NH).

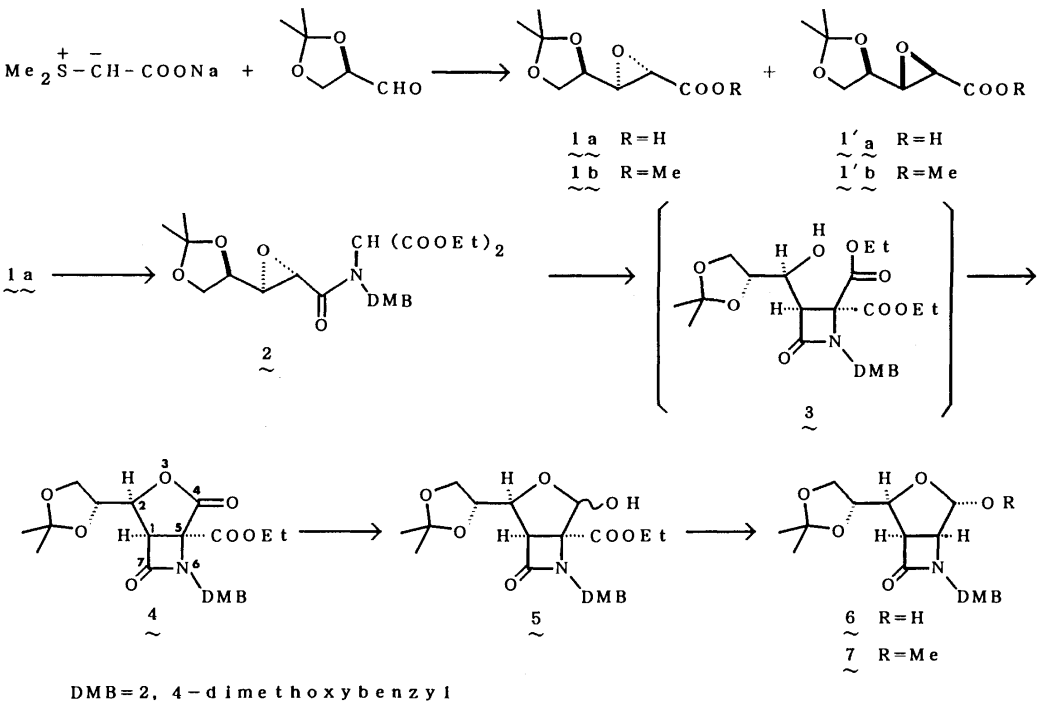
(Received May 10, 1989)

A bicyclic β-lactam (**4**), obtained from 2,3-*O*-isopropylidene-D-glyceraldehyde in 3 steps, was converted to methyl 2-benzamido-2-deoxy-5,6-*O*-isopropylidene-3-*O*-(3-chlorobenzoyl)-α-D-altrofuranoside (**24**) through an additional 8 steps by utilizing the β-lactam nitrogen via the oxidative decarboxylation of diacyl peroxide (**23**). Additionally, it was shown that the bicyclic β-lactam intermediate is a suitable precursor for 2-amino-3-(branched-chain)-2-deoxy-D-furanoside derivatives.

Many effective approaches to the synthesis of amino sugars, which are widely distributed in a variety of glycoconjugates, and which also play many important roles in living bodies, have been developed, and considerable progress has been achieved.[1] However, the synthesis of 2-amino-2-deoxy-D-altrofuranoside derivatives has not been reported, except for the conversion of D-glucose[2] or D-arabinose[3] to 2-amino-2-deoxy-D-altropyranoside analogs. We were interested in developing an alternative approach without using a sugar source, such as D-glucose or D-arabinose, for synthesizing a 2-amino-2-deoxy-D-altrofuranoside derivative. For this purpose, it has been predicted that it is suitable to use the bicyclic β-lactam previously reported[4] to introduce the 2-amino group of 2-amino-2-deoxy-D-altrofuranoside. We thus tried to synthesize a 2-amino-2-deoxy-D-altrofuranoside derivative using this approach and, as a result, could obtain that derivative from 2,3-*O*-isopropylidene-D-glyceraldehyde via bicyclic β-lactam intermediates, even though it was low in total yield. Still, this method via bicyclic 2-azetidinone offers a potential for the syntheses of various stereoisomers of amino sugars by choosing the starting epoxy carboxylic acid, such as **1a** or **1'a**. This method may also provide a route for various stereoisomers of 3-(branched-chain)-2-amino sugars in a stereo-controlled manner. We would like to describe a new procedure for 2-aminoaltrofuranoside analogs.

The treatment of 2,3-*O*-isopropylidene-D-glyceraldehyde[5] in dimethyl sulfoxide (DMSO) with dimethylthetin anion[6] under nitrogen at room temperature for 20 h gave a 2.6:1 mixture of (2*S*,3*R*,4*R*)- and (2*R*,3*S*,4*R*)-2,3-epoxy-4,5-isopropylidenedioxypen-

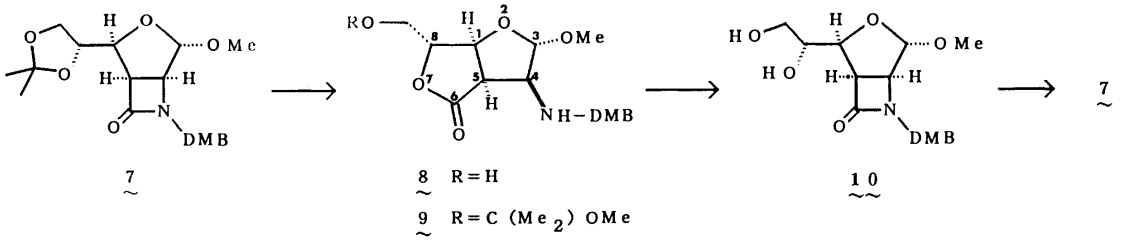


Scheme 1.

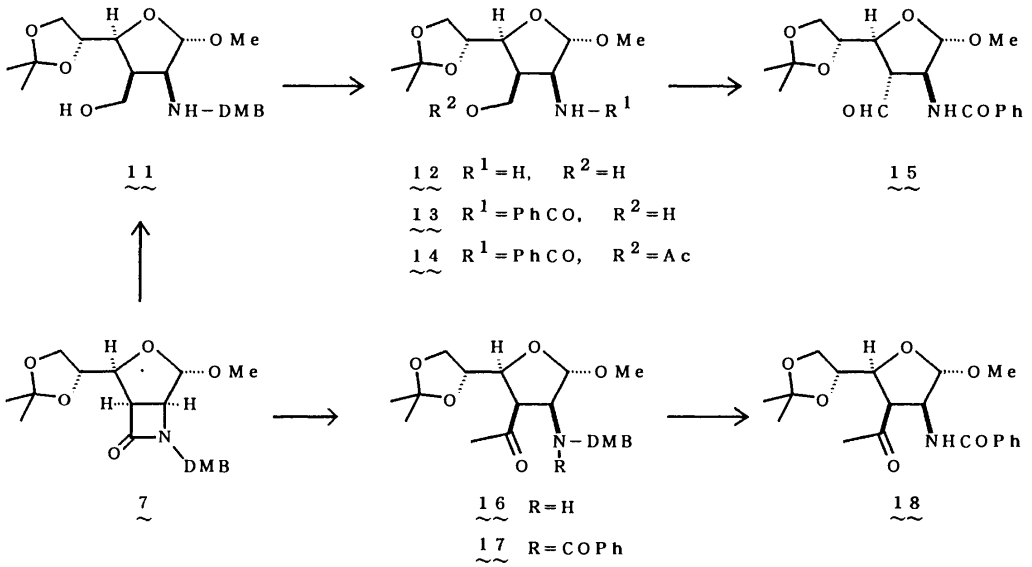
tanoic acid, **1a** and **1'a** in 77% yield (Scheme 1). The ratio of this mixture was determined from a separation of the corresponding methyl esters, **1b**[7] (42%) and **1'b** (16%). Saponification of the methyl ester (**1b**) gave acid **1a**, which was identical with an authentic sample.[8]

Treatment of the optically pure acid **1a** and diethyl 2-(*N*-2,4-dimethoxybenzylamino)malonate[9] with dicyclohexylcarbodiimide (DCC) gave the amide **2**. When a mixture of **1a** and **1'a** was used without separation, **2** was obtained in 22% yield from **1** after chromatographic purification. However, a small amount of isomer (an amide resulting from **1'a**) was an occasional contaminate.[10] Then, an azeotropic treatment of **2** in benzene with a catalytic amount of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to remove the ethanol released during the reaction afforded a bicyclic β-lactam **4** via **3**. If the ethanol released was not removed, the reaction did not complete.

The reduction of **4** with sodium borohydride in methanol containing a catalytic amount of silica gel[11] gave an anomeric mixture of hemiacetal **5**. During this reaction, when the methanol solution is not treated quickly, only esterification by methanol occurs to give the corresponding methyl ester quantitatively; thus, **3** is easily obtained by allowing the ethanol solution of **4** to stand together with a catalytic amount of DBU. However, both **3** and the methyl ester are converted into **4** in good yield by an azeotropic removal of the liberated ethanol or methanol using a catalytic amount of DBU in benzene. The conversion of compound **5** to **6** was achieved by saponification of the ester and successive decarboxylation. The anomeric proton of compound **6** was almost a singlet (by D_2O addition) without only coupling with a neighboring proton on the β-lactam ring. Therefore, the configuration of the anomeric position of **6** must be the *S* configuration. This configuration was also confirmed from a series of experiments (**6**→**7**→**8**→**10**→**7**) (Scheme 2). The glycosidation of **6** with methyl iodide and silver oxide[12] in *N*,*N*-dimethylformamide (DMF) gave **7**. The treatment of crude **7** with 2 equivalents of 2 M hydrochloric acid (1 M=1 mol dm^{-3}) in methanol solution at reflux temperature gave a single product **8**. The structure of **8** was confirmed by an analysis (400 MHz ^1H NMR) of compound **9**. No coupling was observed between the anomeric proton and its neighboring proton in compound **9**. Therefore, it has been elucidated by the Karplus equation that the dihedral angle of these two protons should approach 90°, and that they exist in a trans relationship to each other. As a result, the configuration of the anomeric position of **9** is *S*. A treatment of **8** with methylmagnesium bromide[13]



Scheme 2.



Scheme 3.

gave a β-lactam **10**, which was reprotected with 2,2-dimethoxypropane in DMF containing pyridinium *p*-toluenesulphonate as a catalyst to reproduce **7**. Consequently, the configuration of **7** is (1*R*,2*S*,4*S*,5*S*).

We need to introduce an oxygen atom at the carbon 3 position for the conversion of compound **7** to an altrosamine or mannosamine derivative. At first, we attempted a Baeyer-Villiger oxidation of the C-3 formyl or C-3 acetyl groups to prepare altrosamine and mannosamine analogs.

The C_3-formyl compound **15** was prepared as follows (Scheme 3). The treatment of **7** with lithium aluminum hydride in tetrahydrofuran (THF) at 5 °C gave a C-3 hydroxymethyl compound **11**. Hydrogenolysis of **11** in ethanol by the use of 10% Pd on carbon as a catalyst gave an amino alcohol **12**, which was further converted to a benzamide **13**. Treatment of **13** with pyridinium chlorochromate (PCC)-sodium acetate gave a C_3-formyl compound **15**. The configuration of **15** was elucidated from ^{1}H NMR. Each coupling constant of $J_{1,2}$, $J_{2,3}$, and $J_{3,4}$ was almost zero. This means that the configuration of protons at C_1, C_2, C_3, and C_4 was trans to each other, and that an inversion of the formyl group occurred at C_3.

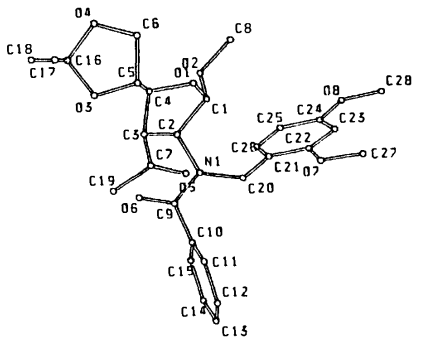


Fig. 1. Molecular structure and atomic numbering of **17**.

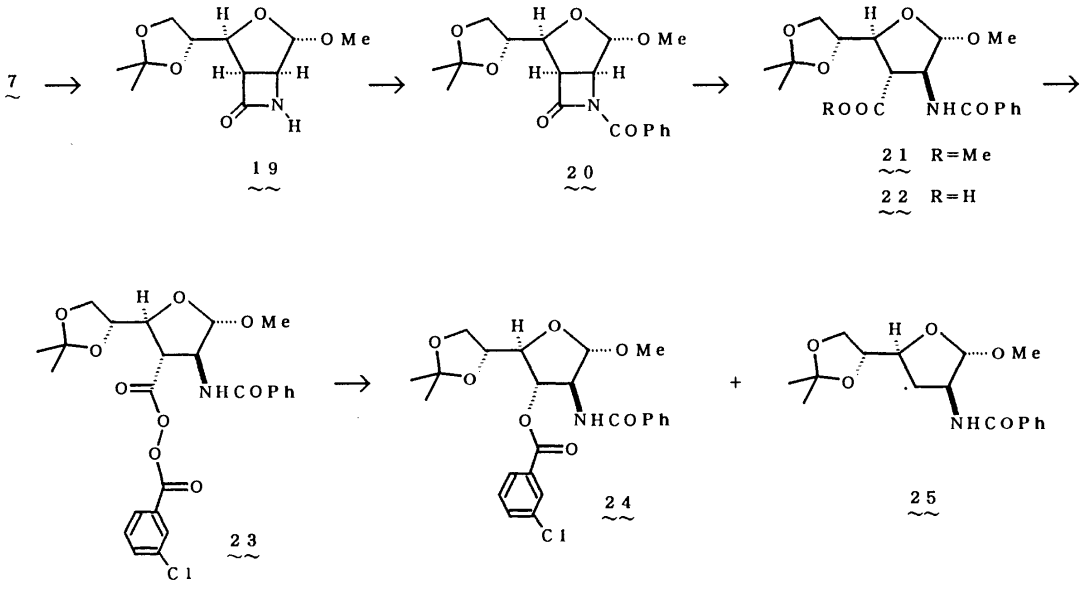
The C_3-acetyl compound **18** was prepared as follows. A treatment of **7** with methyllithium gave C_3-acetyl compounds **16**. This type of reaction with *N*,*N*-disubstituted amides or a single β-lactam with alkyllithium[14] is already known. However, this is the first example, as far as we know, for the reaction of β-lactam fused with a furanoside ring with alkyllithium; this reaction provides a new method for the synthesis of 2-amino-2,3-dideoxy-3-acyl-D-furanoside. Benzoylation of **16** with benzoyl chloride and triethylamine gave **17** as a main product. There was a possibility to epimerize the configuration at the C_3-acetyl group of **16** by a strong base (methyllithium) treatment. However, an X-ray crystallographic analysis of the major product **17** showed that the epimerization of the C_3-acetyl group did not occur (Fig. 1). A deprotection of the 2,4-dimethoxybenzyl group of **17** with cerium(IV) ammonium nitrate (CAN)[15] in acetone-water (1 : 1) gave **18**.

Baeyer-Villiger oxidation of both **15** and **18** with 3-chloroperbenzoic acid in chloroform failed to yield altrosamine and mannosamine analogs, respectively. We therefore tried another route to synthesize an altrosamine analog (Scheme 4). Deprotection of the 2,4-dimethoxybenzyl group of **7** with potassium persulphate-potassium hydrogenphosphate[16] in acetonitrile-water at 78 °C under argon afforded **19**. Benzoylation of **19** yielded **20**. Treatment of **20** in methanol containing DBU as a catalyst at reflux temperature gave **21**. The coupling constant between C_2-H and C_3-H of **21** changed to almost zero. This reveals that epimerization occurred at the C_3 position. This ester **21** was saponified with 1 M NaOH in methanol to give **22**, and X-ray crystallographic analysis further con-



Scheme 4.

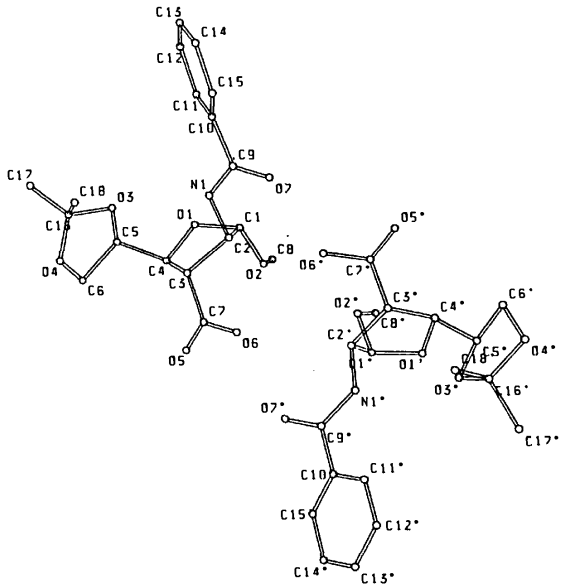


Fig. 2. Molecular structures of the two crystallographically independent molecules in the asymmetric unit, together with the numbering scheme of **22**.

firmed the epimerization (Fig. 2). The reaction of **22** with 3-chloroperbenzoic acid by using DCC as a condensing reagent gave a diacyl peroxide **23**, which was a surprisingly stable compound at room temperature. The obtained **23** was refluxed in octane to give rise to a rearrangent.[17] As a result, an altrosamine analog **24** and a decarboxylated compound **25** were obtained in 32 and 35% yield, respectively. This reaction did not occur in carbon tetrachloride at reflux temperature. The C_3-H chemical shift of **24** shows δ 5.38 shifted from 3.21 of **23**, 3.01 of **22** and 2.91 of **21**, and the coupling constants, $J_{1,2}$, $J_{2,3}$, and $J_{3,4}$, of compound **24** were 0, 0, and 2.2 Hz, respectively. This reveals that an oxygen atom attached directly to the C_3 carbon, and four substituted groups on the tetrahydrofuran ring of **24**, were alternately arranged in a trans relationship.[18] Thus, we could obtain stereoselectively an altrosamine analog **24** from 2,3-*O*-isopropylidene-D-glyceraldehyde via an bicyclic β-lactam intermediate **7** in 12 steps.

Experimental

Melting points were determined on a Yanagimoto micromelting point apparatus and were uncorrected. Optical rotations were obtained by the use of a Perkin-Elmer 241 polarimeter. ^{1}H NMR spectra were recorded using the following spectrometers: at 60 MHz with a Varian T-60, at 270 MHz with a JEOL JNN-270, and at 400 MHz with a JEOL JNN-GX 400. Tetramethylsilane was used as an internal standard (δ value). The IR absorption spectra were determined on a Jasco IR A-2 spectrophotometer. Mass spectra were obtained on a JMS-01SG mass spectrometer. Preparative TLC was performed on silica-gel plates (Merck 60 PF_{245}), and column chromatography was carried out on columns packed with Merck silica-gel 60 (230—400 mesh ASTM) using a slightly increased pressure (1.2 atm) for elution. Elemental analyses were performed by the Analytical Center of the Analytical and Metabolic Research Laboratories, Sankyo Co., Ltd.

A Mixture of (2*S*,3*R*,4*R*)- and (2*R*,3*S*,4*R*)-2,3-Epoxy-4,5-isopropylidenedioxypentanoic Acid, 1a and 1'a. To a solution of dimethylthetin bromide (4.02 g, 20 mmol) in DMSO (20 ml) was added NaH (55% mineral oil dispersion, 2.58 g, 60 mmol) with stirring under nitrogen at 15 °C. The reaction mixture was stirred for 1.5 h at room temperature to produce a suspension of the dimethylthetin anion. To this suspension was added a 2 : 1 mixture of (*R*)-2,2-dimethyl-1,3-dioxolane-4-carbaldehyde and acetic acid (2.14 g, aldehyde=40/3 mmol, acetic acid=20/3 mmol)[5] in DMSO (2 ml) with stirring at ice-cooling temperature. Then, the mixture was stirred for 20 h at room temperature, and poured into ice water (200 ml) with stirring. The mixture was washed twice with ether, and the aqueous layer was acidified with 1 M HCl (50 ml). The whole was then extracted with EtOAc. The organic layer was washed with water and brine, dried over $MgSO_4$, and concentrated in vacuo to give an oily mixture (1.88 g, 77% from the dioxolane) of acids.

Determination of the Ratio, 1a and 1'a. The mixture obtained above was esterified with diazomethane, and the oily mixture was separated to **1b** (42%) and **1'b** (16%) by silica-gel column (**1b** : **1'b**=2.6 : 1). ^{1}H NMR of **1b**: (60 MHz, $CDCl_3$) δ=1.35 (3H, s), 1.44 (3H, s), 3.20—3.35 (1H, m, C_3-H), 3.41 (1H, d, J=2 Hz, C_2-H), 3.79 (3H, s), 3.8—4.3 (3H, m, C_4-H, C_5-H_2). ^{1}H NMR of **1'b**: ($CDCl_3$) δ=1.35 (3H, s), 1.40 (3H, s), 3.20—3.35 (1H, m, C_3-H), 3.47 (1H, d, J=2 Hz, C_2-H), 3.79 (3H, s), 3.8—4.3 (3H, m, C_4-H, C_5-H_2).

(2*S*,3*R*,4*R*)- 2,3-Epoxy-4,5-isopropylidenedioxypentanoic Acid (1a). To a solution of methyl ester **1b** (72 mg, 0.356 mmol) in EtOH (1 ml) was added 0.5 ml of 1 M NaOH. The mixture was allowed to stand at room temperature overnight, diluted with water, and washed with ether. The aqueous layer was acidified with 1 M HCl (0.5 ml), extracted with EtOAc, washed with water and brine, and dried over $MgSO_4$. The concentration of EtOAc gave 57 mg (91%) of **1a**. IR (film): ν_{max} 3600—2500, 1735 cm^{-1}. 60 MHz ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.46 (3H, s), 3.31 (1H, m, C_3-H), 3.43 (1H, d, J=1.5 Hz, C_2-H), 3.8—4.3 (3H, m), 8.0 (1H, bs).

Diethyl 2-[*N*-(2,4-Dimethoxybenzyl)-2,3-epoxy-4,5-isopropylidenedioxypentanamido]malonate (2). To a solution of compound **1a** (42 mg, 0.223 mmol) and *N*-bis(ethoxycarbonyl)methyl-*N*-2,4-dimethoxybenzylamine (80 mg, 0.246 mmol) in CH_2Cl_2 (1 ml) was added DCC (50 mg, 0.242 mmol) at room temperature with stirring. After 30 min, the reaction mixture was filtered to remove a precipitate which was washed with a small volume of CH_2Cl_2. The filtrate was purified on a preparative silica-gel TLC plate. Development with cyclohexane: EtOAc (1 : 1) gave 50 mg (45%) of **2** at the R_f=0.36. IR (film): ν_{max} 1750 (shoulder), 1740, 1668, 1610, 1587 cm^{-1}. 60 MHz ^{1}H NMR ($CDCl_3$) δ=1.18 (3H, t, J=7 Hz), 1.20 (3H, t, J=7 Hz), 1.31 (6H, bs, CH_3×2), 3.27 (1H, m, C_3-H), 3.7—4.4 (14H, m, containing two 3H singlets at δ 3.79 and 3.81, respectively), 4.73 (2H, bs, benzyl), 5.17 (1H, s, NCH), 6.37—6.57 (2H, m), 7.13—7.30 (1H, m). MS m/z 495 (M^+), 449, 434, 394, 364, 348, 292, 166, 151, 121, 101. Found: C, 57.89; H, 6.80; N, 2.91%. Calcd for $C_{24}H_{33}NO_{10}$: C, 58.17; H, 6.71; N, 2.83%.

Ethyl (1*R*,2*S*,5*R*)-6-(2,4-Dimethoxybenzyl)-4,7-dioxo-2-[(1*R*)-1,2-isopropylidenedioxyethyl]-3-oxa-6-azabicyclo-[3.2.0]heptane-5-carboxylate (4). a) Benzene (10 ml) was distilled azeotropically to remove H_2O from a solution of **2** (496 mg, 1 mmol) in benzene (50 ml); then, DBU (40 mg) was added to this solution, and the distillation was continued gradually until the end of the liberation of ethanol. After cooling the reaction mixture was diluted with EtOAc, washed with dil. HCl, H_2O, aq. $NaHCO_3$, and brine, dried over $MgSO_4$, filtered, and concentrated in vacuo to give an oily mixture. A chromatographic analysis of the mixture was quickly performed using a silica-gel (20 g) column. Elution with EtOAc–cyclohexane (1 : 1) gave **4** (235 mg, 52%) as a gum, a by-product (58 mg), and **3** (44 mg, 10%). b) The same treatment of **3** as described above gave **4** quantitatively. IR (film): ν_{max} 1770, 1740 (shoulder), 1613, 1590 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=1.25 (3H, t, J=7 Hz), 1.36 (3H, s), 1.43 (3H, s), 3.80 (6H, s), 3.9—4.6 (9H, m), 6.3—6.5 (2H, m), 7.15 (1H, d, J=9 Hz). MS m/z 450, 449 (M^+), 434, 348, 217, 193, 192, 151, 121, 101, 91, 43. Found: m/z 449.16834. Calcd for $C_{22}H_{27}NO_9$: M, 449.16854. c) A mixture of **1a** and **1'a**, treated successively as described above, gave a mixture of **4** (23% overall yield) and **i** (cf. Scheme 5),[10] which was separated by silica-gel column.

Diethyl 3-[(1*S*,2*R*)-1-Hydroxy-2,3-isopropylidenedioxypropyl]-2-oxoazetidine-4,4-dicarboxylate (3). A solution of **4** (100 mg) in EtOH (10 ml) containing DBU (2 mg) was stirred at 0 °C for 5 min. The concentration and silica-gel column chromatography as described above gave **3**, quantitatively. IR (film): ν_{max} 3440, 1750, 1613, 1588, 1510 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=1.09 (3H, t, J=7 Hz), 1.27 (3H, t, J=7 Hz), 1.39 (3H, s), 1.41 (3H, s), 2.5 (1H, broad, OH), 3.6—4.7 (17H, m, containing 6H singlet at δ 3.78), 6.3—6.5 (2H, m), 7.11 (1H, d, J=9 Hz). Found: C, 58.26; H, 6.50; N, 2.72%. Calcd for $C_{24}H_{33}NO_{10}$: C, 58.17; H, 6.71; N, 2.83%. MS m/z 495 (M^+), 449, 434, 394, 364, 348, 151. Found: m/z 495.20805. Calcd for $C_{24}H_{33}NO_{10}$: M, 495.21035.

A Mixture of Ethyl (1*R*,2*S*,4*R*,5*R*)- and (1*R*,2*S*,4*S*,5*R*)-6-(2,4-Dimethoxybenzyl)-4-hydroxy-2-[(1*R*)-1,2-isopropylidenedioxyethyl]-3-oxa-7-oxo-6-azabicyclo[3.2.0]heptane-5-carboxylate (5). To a solution of compound **4** (3.58 g) in MeOH (80 ml) was added a silica gel powder (50 mg)[10] and then $NaBH_4$ (650 mg) at −40 °C under nitrogen with stirring. After 15 min, the excess $NaBH_4$ was gradually quenched with AcOH (2.5 ml). The reaction mixture was diluted with EtOAc, washed with aq. $NaHCO_3$ and brine, dried over $MgSO_4$, filtered, and concentrated to give a hemiacetal **5**. Purification of crude **5** by silica-gel column chromatography (developed with cyclohexane : EtOAc=1 : 1) gave pure **5** (3.51 g, 98%) as a gummy anomeric mixture. IR (film): ν_{max} 3380, 1760 (shoulder), 1750—1730, 1610, 1588 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=1.50 (3H, t, J=7 Hz), 1.37 (3H, s), 1.40 (3H, s), 1.8 (1H, broad, OH), 3.6—4.6 (15H, m, containing 6H singlet at δ 3.80), 5.00 (1H, d, J=3.5 Hz, changed to a singlet on addition of D_2O), 6.3—6.6 (2H, m), 7.15 (1H, d, J=9 Hz). Found: C, 58.95; H, 6.74; N, 3.28%. Calcd for $C_{22}H_{29}NO_9$: C, 58.53; H, 6.47; N, 3.10%. In this reaction, the corresponding methyl ester of **3** was obtained quantitatively on occasion. However, the same treatment of this compound, as described above in the formation of **4** from **3**, regenerated **4** (94%).

(1*R*,2*S*,4*S*,5*S*)-6-(2,4-Dimethoxybenzyl)-4-hydroxy-2-[(1*R*)-1,2-isopropylidenedioxyethyl]-3-oxa-6-azabicyclo-[3.2.0]heptan-7-one (6). A solution of compound **5** (3.87 g) in pyridine (40 ml), water (2 ml) and DBU (400 mg) was refluxed for 45 min, and concentrated in vacuo to give a crude oily mixture for chromatography by silica-gel column. Elution with cyclohexane : EtOAc (1 : 2) gave **6** (2.59 g, 79%), mp 172—173 °C (needles from EtOAc); IR (Nujol): ν_{max} 3320, 1715, 1612, 1590 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=1.36 (3H, s), 1.42 (3H, s), 3.10 (1H, d, J=2 Hz, OH, D_2O exchangeable), 3.4—4.6 (14H, m, containing two 3H singlets at δ 3.80 and 3.82), 5.17 (1H, d, J=2 Hz, changed to a singlet on addition of D_2O), 6.3—6.6 (2H, m), 7.12 (1H, d, J=9 Hz). $[\alpha]_D^{24}$ −10.5° (c 1.61, $CHCl_3$). MS m/z 379 (M^+), 364, 321, 279, 250, 193, 166, 151, 121, 101. Found: C, 59.86; H, 6.56; N, 3.72%. Calcd for $C_{19}H_{25}NO_7$: C, 60.14; H, 6.64; N, 3.69%.

(1*R*,2*S*,4*S*,5*S*)-6-(2,4-Dimethoxybenzyl)-2-[(1*R*)-1,2-isopropylidenedioxyethyl]-4-methoxy-3-oxa-6-azabicyclo-[3.2.0]heptan-7-one (7). To a solution of compound **6** (379.4 mg, 1.0 mmol) in DMF (5 ml) and methyl iodide (5 ml) was added Ag_2O (700 mg) with stirring at room temperature. After stirring for 4 h the reaction mixture was diluted with EtOAc, and filtered. The filtrate was washed with water and brine, dried over $MgSO_4$, and concentrated in vacuo to give a crude mixture for chromatography by silica-gel column. Elution with cyclohexane : EtOAc (1 : 1) gave a gummy **7** (340 mg, 86%). MS m/z 393 (M^+), 378 (M^+−15), 362, 335, 264, 193, 151, 121, 101, 43. IR (film): ν_{max} 1748, 1610, 1588 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=1.38 (3H, s), 1.43 (3H, s), 3.29 (3H, s), 3.6—4.6 (14H, m, containing 6H singlet at δ 3.83), 4.69 (1H, s, C_1-H), 6.35—6.60 (2H, m), 7.15 (1H, d, J=8.5 Hz).

(1*S*,3*S*,4*S*,5*R*,8*R*)-4-(2,4-Dimethoxybenzylamino)-8-hydroxymethyl-3-methoxy-2,7-dioxabicyclo[3.3.0]octan-6-one (8). A solution of **7** (67 mg) in MeOH (2 ml) and 1 ml of 2 M HCl solution in MeOH was refluxed for 1.5 h and concentrated in vacuo. The residue was dissolved in CH_2Cl_2 (4 ml). $NaHCO_3$ (0.2 g) was added and the mixture was stirred for 30 min. After filtration, the solution was concentrated and the residue was subjected to chromatography by silica-gel column. Elution with EtOAc gave **8** (47 mg, 78%) as a thick oil and an unknown solid (5 mg) having a lower R_f value. IR (film): ν_{max} 3500—3200, 1760 (broad), 1612, 1588 cm^{-1}. 60 MHz ^1H NMR ($CDCl_3$) δ=2.8 (2H, broad, OH and NH, D_2O exchangeable), 3.2—3.6 (5H, m, containing a 3H singlet at δ 3.33), 3.70—3.85 (10H, m), 4.4—4.9 (3H, m, containing a 1H singlet at δ 4.87), 6.3—6.5 (2H, m), 7.11 (1H, d, J=9 Hz). MS m/z 354 (M^++1), 353, 352, 322, 293, 262, 218, 166, 151, 121.

(1*S*,3*S*,4*S*,5*R*,8*R*)-4-(2,4-Dimethoxybenzylamino)-3-methoxy-8-(1-methoxy-1-methylethoxy)methyl-2,7-dioxabicyclo[3.3.0]octan-6-one (9). A solution of **8** (20 mg) in DMF (0.5 ml) and 2,2-dimethoxypropane (1 ml) containing toluene-4-sulfonic acid monohydrate (5 mg) was refluxed for 1.5 h. Concentration and preparative chromatography on a silica-gel plate (developed with cyclohexane–EtOAc=1 : 1) gave 15 mg of **9** (63%) as a gum. IR (film): ν_{max} 1763, 1612, 1588 cm^{-1}. MS m/z 426 (M^++1), 394, 352, 323, 293, 275, 204, 166, 151, 121, 91, 73, 43. 400 MHz ^1H NMR ($CDCl_3$) δ=1.282 (3H, s), 1.299 (3H, s), 1.920 (1H, bs, NH), 3.159 (3H, s), 3.365 (3H, s), 3.365 (1H, dd, J=8—9, 6—7 Hz, C_5-H), 3.469 (1H, dd, J=8.8, 1.0 Hz, C_4-H), 3.520 (1H, dd, J=10.7, 1.9 Hz, C_8-CH), 3.734 (1H, dd, J=10.7, 2.4 Hz, C_8-CH), 3.781 (3H, s), 3.826 (3H, s), 3.700, 3.867 (2H, AB-q, J=13.6

Hz, NCH_2Ar), 4.680 (1H, t, J=1.9—2.4 Hz, C_8-H), 4.715 (1H, d, J=6.8 Hz, C_1-H), 4.896 (1H, s, C_3-H), 6.428 (1H, dd, J=2.4, 8.3 Hz), 6.450 (1H, d, J=2.4 Hz), 7.126 (1H, d, J=8.3 Hz).

(1*R*,2*S*,4*S*,5*S*)-2-[(1*R*)-1,2-Dihydroxyethyl]-6-(2,4-dimethoxybenzyl)-4-methoxy-3-oxa-6-azabicylo[3.2.0]heptan-7-one (10). To a solution of **8** (54 mg, 0.153 mmol) in THF (4 ml) was added 0.6 ml of a 1 M solution of MeMgBr in THF with stirring under nitrogen at −78 °C and then another 1 ml of the same Grignard reagent. After 30 min the reaction mixture was quenched with 1 M HCl (1.6 ml) and extracted with EtOAc. The organic layer was washed with sat. $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated in vacuo to give an oily mixture, which was subjected to chromatography by silica-gel column. Elution with EtOAc gave recovered **8** (9 mg, 17%) and elution with 10% MeOH in EtOAc gave **10** (36 mg, 67%), which was employed for the next reaction.

(1*R*,2*S*,4*S*,5*S*)-6-(2,4-Dimethoxybenzyl)-2-[(1*R*)-(1,2-isopropylidenedioxyethyl]-4-methoxy-3-oxa-6-azabicyclo-[3.2.0]heptan-7-one (7). A solution of **10** (33 mg) and pyridinium *p*-toluenesulfonate (1 mg) in DMF (0.3 ml) and 2,2-dimethoxypropane (0.6 ml) was stirred for 18 h at room temperature. The reaction mixture was concentrated in vacuo, and subjected to chromatography by silica-gel column. Elution with cyclohexane : EtOAc (1 : 1) gave 34 mg of **7** (92%).

Methyl 2,3-Dideoxy-2-(2,4-dimethoxybenzylamino)-3-hydroxymethyl-5,6-*O*-isopropylidene-α-D-mannofuranoside (11). To a solution of β-lactam **7** (200 mg) in THF (4 ml) was added $LiAlH_4$ (60 mg) at 5 °C with stirring. The reaction mixture was quenched with acetic acid, diluted with EtOAc, washed with sat. $NaHCO_3$ and brine, and dried over $MgSO_4$. After filtration, the solvent was concentrated in vacuo, and the residual oil was subjected to chromatography by silica-gel column. Elution with cyclohexane : EtOAc (1 : 4) gave 178 mg of **11** in 88% yield. 270 MHz ^{1}H NMR ($CDCl_3$) δ=1.35 (3H, s), 1.40 (3H, s), 2.67 (1H, quintuplet, J=6.5 Hz, C_3-H), 3.31 (1H, dd, J=2.6, 6.5 Hz, C_2-H), 3.32 (3H, s, C_1-OMe), 3.72, 3.73 (2H, AB-q, J=12.8 Hz, N-CH_2Ar), 3.80 (3H, s), 3.82 (3H, s), 3.88—4.03 (4H, m), 4.11—4.24 (2H, m), 4.77 (1H, d, J=2.6 Hz, C_1-H), 6.42—6.46 (2H, m), 7.11 (1H, d, J=8.4 Hz). IR (film): ν_{max} 3500—3300, 1610, 1588 cm^{-1}. MS m/z 397 (M^+), 382, 339, 306, 236, 166, 151, 121. Found: m/z 397.20715; Calcd for $C_{20}H_{31}NO_7$: 397.20995.

Methyl 2-Amino-2,3-dideoxy-3-hydroxymethyl-5,6-*O*-isopropylidene-α-D-mannofuranoside (12). A solution of **11** (143 mg) in EtOH (8 ml) was hydrogenolyzed on 10% Pd on charcoal for 5 h with stirring under hydrogen. After filtration, the reaction mixture was concentrated and subjected to chromatography by silica-gel (1.0 g) column. Elution with cyclohexane : ethyl acetate (1 : 1) to remove 2,4-dimethoxytoluene and then with methanol : ethyl acetate (1 : 9) gave 43 mg of **12** (48.3%) as a gum. 270 MHz ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.43 (3H, s), 1.90 (3H, bs, D_2O exchangeable, OH and NH_2), 2.68 (1H, quintuplet, J=6.5 Hz, C_3-H), 3.34 (3H, s, C_1-OCH_3), 3.52 (1H, dd, J=1.7, 6.4 Hz, C_2-H), 3.91—4.00 (3H, m), 4.05 (1H, dd, J=7.3, 9.5 Hz), 4.18 (1H, dd, J=6.1, 8.6 Hz), 4.31 (1H, dt, J=9.5, 5.7 Hz), 4.66 (1H, d, J=1.8 Hz, C_1-H). IR (film): ν_{max} 3360 (broad) cm^{-1}.

Methyl 2-Benzamido-2,3-dideoxy-3-hydroxymethyl-5,6-*O*-isopropylidene-α-D-mannofuranoside (13). A mixture of **12** (37 mg), benzoyl chloride (25 mg), and triethylamine (50 mg) in THF (2 ml) was stirred for 15 min at room temperature. Preparative TLC on a silica-gel plate developed with cyclohexane : ethyl acetate (1 : 1) gave **13** (51 mg, 97%) as a gum. IR (film): ν_{max} 3350, 1640 cm^{-1}. 270 MHz ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.41 (3H, s), 2.91 (1H, m, C_3-H), 3.40 (3H, s, C_1-OCH_3), 3.51 (1H, dd, J=5.1, 8.8 Hz, D_2O exchangeable, OH), 3.91—4.03 (2H, m, C_3-CH and C_6- or C_5-H), 4.08 (1H, td, J=5.1, 12.8 Hz, changed to dd, J=5.1 and 12.8 Hz in addition of D_2O, C_3-CH), 4.14—4.27 (3H, m, C_4-H, C_6-H and C_5-H or C_6-H), 4.59 (1H, t, J=6.2 Hz, C_2-H), 4.99 (1H, s, C_1-H), 7.42—7.56 (4H, m, containing CONH), 7.78—7.82 (2H, m).

Methyl 3-Acetoxymethyl-2-benzamido-2,3-dideoxy-5,6-*O*-isopropylidene-α-D-mannofuranoside (14). A solution of **13** (29 mg) in 0.6 ml of pyridine : acetic anhydride (2 : 1) was allowed to stand overnight at room temperature. Evaporation in vacuo gave **14** (quantitatively) which was recrystallized from hexane : EtOAc (9 : 1). Mp 120—121 °C (needles). $[\alpha]_D^{24}$ +48.9° (c 1.13, EtOH). IR (film): ν_{max} 3360, 1737, 1640 cm^{-1}. 270 MHz ^{1}H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.41 (3H, s), 2.04 (3H, s, $OCOCH_3$), 3.19 (1H, m, C_3-H), 3.38 (3H, s, OCH_3), 3.86 (1H, dd, J=6.6, 8.4 Hz, C_5-H or C_6-H), 4.13 (1H, dd, J=7.1, 8.6 Hz, C_5-H or C_6-H), 4.28 (1H, dd, J=5.5, 8.4 Hz, C_4-H), 4.34—4.42 (2H, m, C_3-CH and C_5-H or C_6-H), 4.50 (1H, dd, J=8.1, 11.7 Hz, C_3-CH), 4.79 (1H, ddd, J=1.0, 6.4, 8.8 Hz, C_2-H), 4.84 (1H, d, J=1.0 Hz, C_1-H), 7.08 (1H, d, J=8.8 Hz, NH), 7.40—7.54 (3H, m), 7.77—7.80 (2H, m). MS m/z 378 (M^+−15), 362, 345, 333, 304, 292, 232, 173. Found: C, 61.22; H, 7.13; N, 3.59%. Calcd for $C_{20}H_{27}NO_7$: C, 61.05; H, 6.92; N, 3.56%.

Methyl 2-Benzamido-2,3-dideoxy-3-formyl-5,6-*O*-isopropylidene-α-D-altrofuranoside (15). To a solution of **13** (121 mg, 0.344 mmol) in CH_2Cl_2 (10 ml) were added anhydrous CH_3COONa (280 mg) and pyridinium chlorochromate (740 mg, 3.44 mmol) with stirring at room temperature (24 °C). After 15 min, the reaction mixture was passed through a silica gel (20 g) column eluted with EtOAc (200 ml), and the eluant was washed with saturated $NaHCO_3$ and brine. The EtOAc layer was dried over $MgSO_4$ and concentrated in vacuo to give an oily residue which was subjected to chromathography by silica-gel column. Elution with cyclohexane-EtOAc (3 : 2) gave **15** in 92% yield as a gum. IR (film): ν_{max} 1665—1655, 1601, 1579 cm^{-1}. 270 MHz ^{1}H NMR ($CDCl_3$) δ=1.30 (3H, s), 1.40 (3H, s), 2.75 (1H, d, J=2.9 Hz, C_3-H), 3.61 (1H, dd, J=7.0, 8.8 Hz, C_6-H), 4.18 (1H, dd, J=7.7, 8.8 Hz, C_6-H), 4.55 (1H, dd, J=1.5—1.8, 2.9—3.3 Hz, C_4-H), 4.62 (1H, dt, J=1.5, 7.0—7.7 Hz, C_5-H), 4.91 (1H, s, C_1H), 5.13 (1H, d, J=8.8 Hz, C_2-H), 7.40—7.55 (4H, m, olefinic 3H and NH), 7.78—7.82 (2H, m), 9.87 (1H, s, CHO). MS m/z 334 (M^+−15), 328, 260, 248, 228, 213, 199, 189.

Methyl 3-Acetyl-2,3-dideoxy-2-(2,4-dimethoxybenzylamino)-5,6-*O*-isopropylidene-α-D-mannofuranoside (16). To a solution of **7** (393 mg, 1 mmol) in THF (10 ml) was added MeLi (1.5 ml of 1.4 M solution in diethyl ether) in THF (2 ml) at −78 °C under a nitrogen atmosphere with stirring. After 15 min, the reaction mixture was quenched with acetic acid, diluted with EtOAc, washed with sat. $NaHCO_3$ and brine, dried over $MgSO_4$ filtered, and concentrated in vacuo to give an gummy mixture. The mixture was subjected to chromatography by silica-gel column. Elution with cyclohexane : EtOAc (1 : 1) gave 311 mg of **16** (higher R_f value, 76% yield) and 44 mg of unknown product.

16: Found: *m/z* 409.20950. Calcd for $C_{21}H_{31}NO_7$: 409.21010.

Methyl 3-Acetyl-2,3-dideoxy-2-(*N*-2,4-dimethoxybenzylbenzamido)-5,6-*O*-isopropylidene-α-D-mannofuranoside (17). To a solution of **16** (82 mg, 0.2 mmol) in THF (2 ml) was added Et_3N (50 mg) and benzoyl chloride (30 mg, 0.213 mmol) with stirring at room temperature. Preparative TLC on a silica-gel plate (developed with cyclohexane : EtOAc=3 : 2) gave 76 mg (74%) of **17** as a crystalline solid. Mp 143—146 °C (from EtOAc-cyclohexane). $[\alpha]_D^{24}$ +140.0° (*c* 1.21, $CHCl_3$). IR (Nujol): ν_{max} 1705, 1625, 1607, 1588, 1205 cm^{-1}. 400 MHz ^1H NMR ($CDCl_3$) δ=1.304 (3H, s), 1.492 (3H, s), 2.369 (3H, s, $COCH_3$), 2.960 (3H, s, OCH_3), 3.671 (3H, s, 2′-OCH_3), 3.803 (3H, s, 4′-OCH_3), 3.879 (1H, td, *J*=6.5—6.8, 4.0 Hz, C_5-H), 4.090 (2H, m, C_6-H_2), 4.152 (1H, dd, *J*=5.2, 7.0 Hz, C_4-H), 4.356 (1H, broad, C_3-H), 4.507 (2H, s, N-CH_2Ar), 4.945 (1H, dd, *J*=7.5, 3.0 Hz, C_2-H), 5.052 (1H, d, *J*=3.4 Hz, C_1-H), 6.355 (1H, d, *J*=2.4 Hz, $C_{3'}$-H), 6.509 (1H, dd, *J*=8.3, 2.4 Hz, $C_{5'}$-H), 7.115 (1H, d, *J*=8.3 Hz, $C_{6'}$-H), 7.283 (4H, d, *J*=3.9 Hz), 7.300 (1H, m). Methyl 3-Acetyl-2-benzamido-2,3-dideoxy-5,6-*O*-isopropylidene-α-D-mannofuranoside (18). To a stirred solution of **17** (51 mg, 0.10 mmol) in acetone (1.5 ml) was added a solution of cerium(IV) ammonium nitrate (165 mg, 0.30 mmol) in H_2O (1 ml) at 25 °C. After 15 min, the reaction mixture was diluted with EtOAc and washed with aq. $NaHCO_3$, dried over $MgSO_4$, and concentrated to give a residue which was subjected to chromatography by silica-gel column. Elution with cyclohexane-EtOAc (3 : 2) gave **18** (12 mg, 33%) as a solid. 270 MHz ^1H NMR ($CDCl_3$) δ=1.33 (3H, s), 1.43 (3H, s), 2.35 (3H, s), 3.39 (3H, s), 3.94—3.99 (2H, m), 4.04—4.15 (2H, m), 4.28 (1H, dd, *J*=7.7, 9.2 Hz), 4.69 (1H, dt, *J*=2.2, 6.9 Hz, C_2-H), 5.08 (1H, d, *J*=2.2 Hz, C_1-H), 7.41—7.81 (6H, aromatic 5H and NH). MS *m/z*, 362 (M^+−1), 348 (M^+−15), 332, 227, 199, 167, 122, 105.

(1*R*,2*S*,4*S*,5*S*)-2-[(1*R*)-(1,2-*O*-Isopropylideneethyl]-4-methoxy-3-oxa-6-azabicyclo[3.2.0]heptan-7-one (19). To a solution of **7** (1.3 g, 3.3 mmol) in CH_3CN (70 ml) and H_2O (70 ml), was added $K_2S_2O_8$ (10 g) and K_2HPO_4 (5 g). The mixture was heated at 78 °C for 30 min under an argon atmosphere with stirring. The reaction mixture was concentrated in vacuo, and the residue was extracted with EtOAc. The organic layer was washed with aq. $NaHCO_3$ and brine, dried over $MgSO_4$, and then concentrated to give a residue. The crude material was subjected to chromatography by silica-gel column to give **19** (642 mg, 80%) as a crystalline solid. Mp 166—167 °C. IR (Nujol): ν_{max} 3310, 1750 cm^{-1}; 270 MHz ^1H NMR ($CDCl_3$) δ=1.38 (3H, s), 1.45 (3H, s), 3.36 (3H, s), 3.80—4.08 (4H, m), 4.15 (1H, dd, *J*=6.2, 8.8 Hz), 4.41 (1H, m), 4.89 (1H, s), 5.89 (1H, bs, NH). Methyl 2-Benzamido-2,3-dideoxy-5,6-*O*-isopropylidene-3-methoxycarbonyl-α-D-altrofuranoside (21). A solution of **20** (150 mg) in MeOH containing 10 mg of DBU was refluxed for 30 min. The mixture was concentrated in vacuo to give a residue which was subjected to chromatography by silica-gel column. Elution with cyclohexane-EtOAc (1 : 1) gave 150 mg (90%) of **21** as a viscous gum. IR (film): ν_{max} 3360, 1732, 1662, 1643 cm^{-1}. 270 MHz ^1H NMR ($CDCl_3$) δ=1.32 (3H, s), 1.41 (3H, s), 2.91 (1H, d, *J*=3.7 Hz, C_3-H), 3.32 (3H, s, C_1-OCH_3), 3.70 (1H, dd, *J*=7.0, 8.8 Hz, C_6-H), 3.79 (3H, s, C_3-$COOCH_3$), 4.17 (1H, dd, *J*=7.3, 8.8 Hz, C_6-H), 4.61 (1H, dt, *J*=1.6, 7.3 Hz, C_5-H), 4.75 (1H, dd, *J*=1.7, 3.7 Hz, C_4-H), 4.86 (1H, s, C_1-H), 5.17 (1H, d, *J*=8.8 Hz, C_2-H), 7.33 (1H, d, *J*=8.8 Hz, NH), 7.39—7.51 (3H, m), 7.78—7.82 (2H, m). MS *m/z* 380 (M^++1), 364, 348, 290, 278, 258, 219.

Methyl 2-Benzamido-3-carboxy-2,3-dideoxy-5,6-*O*-isopropylidene-α-D-altrofuranoside (22). A solution of **21** (326 mg, 0.859 mmol) in MeOH (2.6 ml), and aqueous 1 M NaOH (1.03 ml, 1.03 mmol, 1.2 equiv) was refluxed for 30 min. The whole was concentrated in vacuo, acidified with 1 M HCl (1.1 ml), and extracted with EtOAc. The organic layer was washed with H_2O and brine, dried over $MgSO_4$, and concentrated to give 310 mg of an acid **22** (99%) as a crystalline solid. Mp 145—146.5 °C (from EtOAc-hexane). 270 MHz ^1H NMR ($CDCl_3$) δ=1.29 (3H, s), 1.38 (3H, s), 3.01 (1H, dd, *J*=1.3, 4.6 Hz, C_3-H), 3.36 (3H, s, C_1-OCH_3), 3.75 (1H, dd, *J*=7.1, 9.3 Hz, C_6-H), 4.15 (1H, dd, *J*=7.1, 9.3 Hz, C_6-H), 4.58 (1H, dt, *J*=2.1, 7.1 Hz, C_5-H), 4.74 (1H, dd, *J*=2.1, 4.6 Hz, C_4-H), 4.95 (1H, dd, *J*=1.3, 8.1 Hz, C_2-H), 4.97 (1H, s, C_1-H), 7.34 (1H, d, *J*=8.1 Hz, C_2-NH), 7.41—7.57 (3H, m), 7.79—7.82 (2H, m), 9.50 (1H, bs, COOH). $[\alpha]_D^{24}$ −60.0° (*c* 1.06, $CHCl_3$). Found: C, 59.06; H, 6.26; N, 3.74%. Calcd for $C_{18}H_{23}NO_7$: C, 59.17; H, 6.35; N, 3.83%.

Methyl 2-Benzamido-3-(3-chlorobenzoyldioxycarbonyl)-2,3-dideoxy-5,6-*O*-isopropylidene-α-D-altrofuranoside (23). To a solution of **22** (121.8 mg, 1/3 mmol) and 3-chloroperbenzoic acid (80—90%, 75 mg) in CH_2Cl_2 (3 ml) was added DCC (83 mg, 1.2 equiv) at room temperature with stirring. After 15 min, the precipitate was filtered off. The filtrate was concentrated and subjected to chromatography by silica-gel column. Elution with cyclohexane-EtOAc (3 : 2) gave 146 mg of **23** (84%) as a powder. IR (Nujol): ν_{max} 3330, 1800, 1768, 1640, 1602 cm^{-1}. 270 MHz ^1H NMR ($CDCl_3$) δ=1.37 (3H, s), 1.42 (3H, s), 3.21 (1H, dd, *J*=1.1, 4.1 Hz, C_3-H), 3.40 (3H, s), 3.76 (1H, dd, *J*=7.0, 8.8 Hz, C_6-H), 4.20 (1H, dd, *J*=7.3, 8.8 Hz, C_6-H), 4.64 (1H, ddd, *J*=1.8, 4.0, 7.3 Hz, C_5-H), 4.79 (1H, dd, *J*=1.8, 4.0 Hz, C_4-H), 4.98 (1H, s, C_1-H), 5.20 (1H, dd, *J*=1.1, 8.8 Hz, C_2-H), 7.27 (1H, d, *J*=8.8 Hz, C_2-NH), 7.4—8.02 (9H, m). Found: C, 63.28; H, 7.01; N, 4.07%. Calcd for $C_{17}H_{23}NO_5$: C, 63.53; H, 7.21; N, 4.36%. Found: m/z (M^++1) 322.16809. Calcd for $C_{17}H_{24}NO_5$: 322.16549.

X-Ray Crystallography of 17, 22, and vi. Crystals of dimensions 0.7×0.4×0.4 mm for **17**, 0.5×0.4×0.4 mm for **22**, and 0.4×0.3×0.2 mm for **vi** were used for X-ray crystallography. Lattice constants were determined by least-squares fit of angular settings of 20 reflections within the range $15<\theta<30°$. Intensity data were obtained on a Rigaku AFC-5R diffractometer equipped with graphite-monochromatized Cu $K\alpha$ radiation and using θ-2θ scan technique ($2\theta<128°$). During data collection five standards, measured before every 200 reflections, indicated no systematic variation of intensity with time. Of 2591, 3270, and 1904 independent reflections measured, only 2411, 2689, and 1750 for **17**, **22**, and **vi**, respectively, were considered as observed on the basis of the criterion $F_o>2\sigma(F_o)$. All intensities were corrected for Lorentz and polarization effects, but not for absorption.

Crystal data: **17**, $C_{28}H_{35}NO_8$, M_r=513.4. Orthorhombic, space group $P2_12_12_1$, a=22.449(6), b=16.662(5), c=7.219(2) Å, U=2700.4 Å^3, Z=4, D_c=1.26 g cm^{-3}, μ(Cu $K\alpha$)=8 cm^{-1}.

22, $C_{18}H_{23}NO_7$, M_r=365.4. Monoclinic, space group $P2_1$, a=16.380(3), b=7.438(1), c=15.738(5) Å, β=109.51(2)°, U=1807.3 Å^3, D_c=1.34 g cm^{-3}, μ(Cu $K\alpha$)=9 cm^{-1}.

vi, $C_{19}H_{25}NO_7$, M_r=379.4. Orthorhombic, space group $P2_12_12_1$, a=19.719(5), b=9.682(2), c=10.382(2) Å, U=1982.2 Å^3, D_c=1.27 g cm^{-3}, μ(Cu $K\alpha$)=8 cm^{-1}.

The structures of **17**, **22**, and **vi** were solved by MULTAN84,[19] and refined by the block-diagonal least-squares methods. The positions of the hydrogen atoms were estimated using standard geometry. The final refinements with anisotropic temperature factors for the nonhydrogen atoms and isotropic temperature factors for the hydrogen atoms were lowered R values to 0.080 (R_w=0.069, $w=1/\sigma^2(F_o)$), 0.070 (R_w=0.057, $w=1/\sigma^2(F_o)$), and 0.072 (R_w=0.057, $w=1/\sigma^2(F_o)$) for **17**, **22**, and **vi**, respectively.

The complete F_o—F_c data are deposited as Document No. 8900 at the Office of the Editor of Bull. Chem. Soc. Jpn

We thank Mr. Harumitsu Kuwano for measuring the 400 MHz ^{1}H NMR spectra.

Model Compound Studies of Coal Liquefaction with Zinc-Butyl Iodide under Mild Conditions

Yoshiharu YONEYAMA,* Yu AKAKI, and Tsutomu KATO
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received May 25, 1989)

A number of model compounds having representative coal structures were treated with zinc-butyl iodide under mild conditions. Gas chromatography and gas chromatography/mass spectrometry were used to identify the reaction products. Polynuclear aromatic compounds gave the butyl-substituted and butyl-addition products. In a reaction of anthracene, its aromatic backbone was cleaved. Alkoxynaphthalene and dibenzyl ether were butylated along with cleavage of ether linkage, while diphenyl ether gave only the butyl-substituted products without cleavage. Butylation and cleavage also took place in the reactions of diphenylmethane and bibenzyl. In the cases of substitution reaction, some butyl groups were rearranged to *s*-butyl. Because the formation of the most reaction products is interpreted by a similar mechanism to that of Friedel-Crafts alkylation and the formation of some butyl-addition products of polynuclear aromatic compounds is explained by assuming a radical reaction mechanism, it is suggested that both alkyl cation reaction and alkyl radical reaction occur competitively.

A new coal liquefaction concept has recently been developed: Depolymerization of coal by use of zinc metal and butyl iodide under atmospheric pressure at 130 °C.[1] This method can effectively convert coal to benzene-soluble products under mild conditions. For example, Kairan coal (carbon content, 87.2%) can be solubilized in benzene to the extent of 96.7% by this method. The effectiveness of the zinc-butyl iodide for depolymerization of coals has stimulated a further investigation into the mechanism of the conversion. An advantage of coal conversion study using model compounds is that both the starting materials and products are easily characterized by simple analytical techniques.

In the present study, some polynuclear aromatic compounds, aryl ethers, diphenylmethane, and bibenzyl have been treated with zinc-butyl iodide and the products were analyzed by gas chromatography (GC) and gas chromatography/mass spectrometry.

Experimental

The model compounds used in the present study were commercially available and used without further purification except anthracene which was recrystallized. The butylation reaction was carried out as follows: 11.9 mmol of a model compound, 8 g of zinc metal powder and 30 ml of butyl iodide were placed in a three-necked flask attached with a reflux condenser and a Teflon stirrer. While being agitated, the mixture was heated at 130 °C for 5 h under nitrogen stream in an oil bath. The reaction mixture was cooled to room temperature, and then extracted with benzene or pentane. After removing the solvent the products were analyzed by a Hitachi model 163 gas chromatograph (glass capillary column, 12 m×0.28 mm; SE-52) equipped with a YANACO model S-1000 integrator and by a JEOL model JMN-D3000 GC-MS (25 m×0.25 mm; SE-52).[2,3] Naphthalene and phenanthrene were used as internal standards.

Results and Discussion

The model compounds were selected on the basis of the structural information on coals. From time to time, various structures of coals have been suggested, depending upon the extent of knowledge available at the time; e.g., those suggested by Given,[4,5] Hill and Lyon,[6] Wiser,[7] and Heredy and Wender.[8] As coal has no uniform composition, the most widely

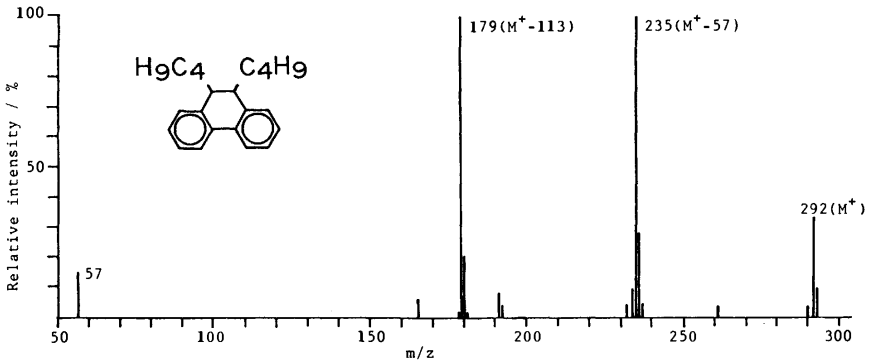

Fig. 2. Mass spectrum of the dibutyl-addition product of phenanthrene.

accepted structural view of bituminous coal contains statistical proportions of groups of fused aromatic and hydroaromatic ring clusters, composed of an average of two to six ring units connected with various aliphatic and ether bridges.

The model compounds selected as polynuclear aromatic compounds for this study are 1-methylnaphthalene, acenaphthene, phenanthrene, and anthracene. Every reaction product contained many components, showing over 200 peaks in each gas chromatogram. Figure 1 shows the gas chromatogram of the product of phenanthrene. Because of small area of each GC peak, the percentage of the components identified was meager: that of 1-methylnaphthalene, acenaphthene, phenanthrene, and anthracene were 83.0, 71.5, 62.5, and 58.5%, respectively. The reaction products and their yields are summarized in Table 1.

The reaction pattern observed with phenanthrene will be discussed first, because it is characteristic of other model compounds. Phenanthrene, when treated by this method, showed the quantitative conversion. The products consist of butyl-substituted derivatives (BSD) and butyl-addition derivatives (BAD)** of phenanthrene.

In our previous paper,[1)] we have reported that no evidence about the formation of butyl-addition products was found in the ^{13}C NMR spectra of the reaction products. However, in the present study, the products included not only the butyl-substituted components but also the butyl-addition components. Stobart and Zaworotko[9)] have shown that polynuclear aromatic compounds (naphthalene, anthracene, and phenanthrene) were hydrogenated, when treated with $AlCl_3$ in hexane and heptane at 20—70 °C. Therefore we considered initially that phenanthrene was hydrogenated, and subsequently butyl-substitution reaction occurred. However it was confirmed that phenanthrene was subjected to butyl-addition reaction. Figure 2 shows the mass spectrum of one of the products of phenanthrene whose molecular mass is 292. The mass spectrum showed the peaks at m/z M^+-57 and M^+-113 which are characteristics of dibutyl-addition compounds.[10)] 9,10-Dibutyl-9,10-dihydrophenanthrene[11)] was assigned to the product, but this product was not stereochemically followed up. Five isomers showing almost the same fragmentation were also observed. Accordingly, it is suggested that the products were formed from the butyl-addition. The use of ^{13}C NMR spectra failed to detect the formation of butyl-addition products, because the amount of these

** Butyl-addition derivatives (BAD) of aromatic compound implies polybutylated derivatives of dihydroaromatic compound.

products was too little to be found. In addition, this butyl-addition products were included also in the reaction products of some other model compounds examined in this study.

1-Methylnaphthalene showed 79.5% conversion. The products were BSD and BAD of 1-methylnaphthalene. Moreover a small amount of the butyldiaddition derivatives (BDAD)*** was also included.

Acenaphthene showed 93.1% conversion. The products were BSD and BAD of acenaphthene. Introducing of alkyl substituents to aromatic rings usually enhances[12] the reactivity of the aromatic compound for alkylation reaction and this is in accord with the fact that the conversion rate of acenaphthene was higher than that of 1-methylnaphthalene.

Anthracene also showed the quantitative conversion, giving BSD, BAD, and BDAD of anthracene. Differing from other three compounds, the products of anthracene included much more BAD than BSD. Furthermore the products included the components breaking the backbone of anthracene; BSD of dipentylbenzene and pentylbenzene, and hexabutylbenzene were 1.4, 2.6, and 3.3%, respectively. The first two compounds probably arose from butyl-addition to the 9 and 10 positions of anthracene, followed by cleavage, and it is suggested that hexabutylbenzene was formed from polybutylation of aromatic fragments which came out in aromatic ring destruction. The attack of the butyl groups at the 9 and 10 positions yields the structure of diphenylmethane type for anthracene and that of biphenyl type for phenanthrene. It is known that the linkage of diphenylmethane can be cleaved easily, but that of biphenyl cannot under various mild liquefaction conditions.[13,14] Therefore it is deduced that the aromatic rings of anthracene break, but those of phenanthrene do not.

As mentioned before, aliphatic linkages play an important role in linking aromatic and hydroaromatic ring clusters in coals. Other model compounds selected for this study include diphenylmethane and bibenzyl. The reaction products of these compounds contained over 100 components. The percentage of products identified in the runs of diphenylmethane and bibenzyl were 81.1 and 80.3%, respectively. Diphenylmethane showed 44.7% conversion. BSD of diphenylmethane was formed in 59.0% yield and the components which cleaves methylene linkage were also included. These were methylbiphenyl (6.2%), its monobutylated derivatives (5.2%), benzyltoluene (9.7%), and its monobutylated derivatives (1.0%). Bibenzyl showed 43.6% conversion, with BSD (69.1%) of bibenzyl, dibenzylated derivatives of bibenzyl (3.4%), their BSD (3.9%), pentylbenzene (2.8%), diphenylmethane (0.6%), and benzyltoluene (0.5%). The products other than BSD of bibenzyl are the compound with cleavage of ethylene linkage. No butyl-addition components were observed in both the reaction products.

Compounds containing aliphatic linkages gave the products with cleaved linkages, though their yields are low. Tuge and Tashiro[15] have reported that easiness of the cleavage of the methylene linkage of diphenylmethane increased with increasing the number of alkyl groups at benzene ring. Since both BSD of diphenylmethane and of bibenzyl in this study have only 1—2 butyl groups, the yields of linkage-cleaved products were low. Because coals themselves include many alkyl substituents on aromatic rings, one would expect that aliphatic linkages in coal structures can be cleaved by this method.

Another important feature of coal involves ether linkages, which are also believed to play an important role in the depolymerization of coal. The model compounds selected for this study include 2-methoxy-, 2-propoxynaphthalene, diphenyl ether, and dibenzyl ether. Every reaction product contained over 100 components. The percentage of the products identified in the reaction of 2-methoxy-, 2-propoxynaphthalene, diphenyl ether, and dibenzyl ether was 86.5, 81.6, 92.2, and 87.2%, respectively. When diphenyl ether was treated under this reaction system, 39.7% conversion was observed, and the products were only BSD (92.2%) of diphenyl ether. No ether linkage-cleaved components were found in the reaction products.

2-Methoxy- and 2-propoxynaphthalene showed 95.4 and 96.2% conversions, respectively. The reaction products of 2-methoxynaphthalene contained its BSD (29.5%) and BAD (23.4%), and similarly BSD (24.1%) and BAD (29.9%) of 2-propoxynaphthalene were found in its reaction products. The reactivity of the substrate did not differ with the alkyl chain length. In the reaction of 2-methoxynaphthalene, ether linkage-cleaved products, BAD (0.3%) of naphthalene, BSD (7.1%), and BAD (26.2%) of butoxynaphthalene were found. Similarly, in the reaction of 2-propoxynaphthalene, BAD (1.0%) of naphthalene, BSD (8.0%), and BAD (18.6%) of butoxynaphthalene were observed. The reaction products of alkoxynaphthalenes included the components which had been subjected to the cleavage of alkyl ether linkages and substituted by butyl groups. Furthermore, by means of a small amount of the components which cleaves the ether O-aromatic carbon linkage, BAD of naphthalene was observed in the reaction of alkoxynaphthalene.

Dibenzyl ether showed the quantitative conversion. All the reaction products were ether linkage-cleaved ones. Most of them were BSD (51.3%) of toluene, pentylbenzene, BSD (28.2%) of benzyltoluene, and its benzylated derivatives (6.3%). Other products were dibutylbenzene (0.5%), diphenylmethane (0.2%), and butyl benzyl ether (0.8%). The yield of the products,

*** Butyl-diaddition derivatives (BDAD) of aromatic compound implies polybutylated derivatives of tetrahydroaromatic compound.

BSD of toluene and pentylbenzene, is shown together, because it is indistinguishable from fragmentation mass spectra whether they are toluene or pentylbenzene derivatives. It is known that alkyl ether linkage is easily cleaved, but aryl ether linkage hardly is.

As described above, it has been found in this reaction system that polynuclear aromatic compounds undergo the butyl-substitution and butyl-addition reactions, and aromatic compounds containing aliphatic linkages and some ether linkages cleave themselves. Therefore, the formation of most reaction products can be interpreted by assuming a similar mechanism to that of Friedel-Crafts reaction.[14,16] However, the formation of butyl-addition products cannot be interpreted. It has been already known that a radical reaction takes place in the early stage of this reaction.[17] The butyl-addition products can be explained by assuming a radical mechanism; butyl radical attacks the nucleus of aromatic compound, and the combination of the resulting radical with another butyl radical yields butyl-addition product.[18] In order to clarify whether this reaction mechanism is radical type or not, the fragmentation of the mass spectra of the products substituted by monobutyl group was analyzed, because butyl radical is not usually rearranged, but butyl cation is likely to be rearranged into *s*-butyl. The mass spectrum of the compound substituted by butyl group shows a peak at m/z M^+-43, whereas that of the compound substituted by *s*-butyl shows a peak at m/z M^+-29.[3] The results obtained on the seven compounds are shown in Table 2. In all the reaction products, a large amount of the components substituted by butyl was contained, but the components substituted by *s*-butyl were also contained. These results do not agree with the rule that rearrangement of the intermediate free radical does not occur.[19] Both of an observation of rearrangement of butyl to *s*-butyl and formation of BSD of polynuclear aromatic compounds can be interpreted by alkyl cation reaction mechanism,[1] whereas formation of BAD in the reaction of polynuclear aromatic compounds can be explained by assuming radical mechanism. Therefore it is suggested that both alkyl-cation and radical reaction occurred competitively in this reaction.

Table 2. Rearrangement of the Butyl Group of the Monobutyl-Substituted Model Compounds

Reactant	Yield of the fraction/area %	
	Butyl	*s*-Butyl
1-Methylnaphthalene	29.6	5.8
Acenaphthene	14.6	1.6
Phenanthrene	15.0	2.6
Anthracene	0.9	Nil
Diphenylmethane	34.0	14.5
Bibenzyl	42.6	15.6
Diphenyl ether	45.7	7.0

In view of the efficiency of this method on coal liquefaction it can be concluded that high benzene extractability of coal can be attained by introducing many butyl groups and the cleavage of the linkages in compounds, such as bibenzyl, diphenylmethane, dibenzyl ether, and alkoxynaphthalene. The reaction product of anthracene includes the components which cleave the aromatic backbone.

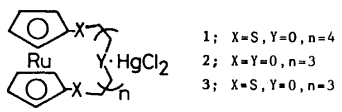
(Received May 30, 1989)

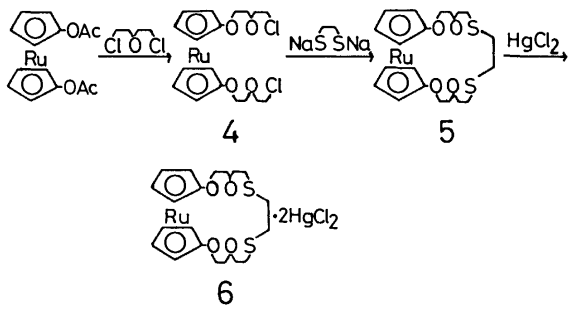
The reaction of 1,1′-bis(6-chloro-1,4-dioxahexyl)ruthenocene with disodium 1,2-ethanedithiolate gave 1,4,13,16-tetraoxa-7,9-dithia[16](1,1′)ruthenocenophane (**5**) in 63% yield. The reaction of **5** with $HgCl_2$ in acetonitrile gave a 1 : 2 complex (**6**) in 47% yield. The crystal structure of complex **6** and its metal free ligand **5** were determined by an X-ray method. Crystal data: **5**, triclinic, a=11.128(2), b=12.720(2), c=10.196(2) Å, α=113.55(1), β=64.13(1), γ=122.01(1)°, U=1074.1 Å^3. $P\bar{1}$, Z=2, D_c=1.54 Mg m^{-3}, μ(Mo $K\alpha$)=9 mm^{-1}. R=0.028. **6**, triclinic, a=16.595(4), b=12.645(3), c=7.401(1) Å, α=104.92(1), β=92.37(1), γ=69.38(2)°, U=1402.4 Å^3, $P\bar{1}$, Z=2, D_c=2.46 Mg m^{-3}, μ(Mo $K\alpha$)=12.2 mm^{-1}, R=0.081. The X-ray analysis of **6** revealed that one Hg atom was bonded to the Ru atom of the ruthenocene nucleus with a distorted trigonal-planar configuration and another Hg atom was bonded to the two sulfur atoms of the macrocycle. This result is completely different from that obtained regarding complex 4,7,10,13-tetraoxa-1,16-dithia[16](1,1′)ruthenocenophane with $HgCl_2$.

It is well-known that mercury forms a very wide range of complexes with thioethers and cyclic thioethers. Mercury halides readily form 1 : 1, 1 : 2, and 2 : 3 complexes with thioethers when the metal and ligands are mixed in aqueous alcoholic solution.[1-4] The 1 : 1 complexes[5] involve essentially linear mercury(II) coordination $[R_2SHgCl]Cl$ (type 1) and the 1 : 2 complexes[5,6] are thought to involve HgX_2 and $[R_2SHgX]X$ units held together by weak chloride bridges (type II), while 2 : 3 complexes[3] appear to be a mixture of 1 : 1 and 1 : 2 complexes. In contrast with the above, the reaction of mercury(II) halide with polyethylene glycols gives complexes of type 1 only.[7-9] Pedersen[10] has reported that mercury(II) chloride does not form a complex with dibenzo-18-crown-6 in methanol. Recently, Kawasaki et al.,[11] however, reported the formation of a mercury(II) chloride complex of dibenzo-18-crown-6 in acetonitrile or toluene. In this complex a linear Cl-Hg-Cl moiety (type 1) was found by X-ray analysis to be held perpendicularly to a quasi-planar ring of O_6. It has also been reported that the reaction of the metallocene with HgX_2 gives various adducts.[12] For example, the complex of ruthenocene with $HgBr_2$ is essentially a simple adduct complicated by the presence of halide bridging. In connection with the above-mentioned viewpoints we have been interested in the complexing manner of the metallocenocrown ethers with $HgCl_2$.



In previous papers,[13,14] we reported on the molecular structures of a 1 : 1 complexes (**1**, **2**, and **3**) of 4,7,10,13-tetraoxa-1,16-dithia[16](1,1′)ruthenocenophane, 1,4,7,10,13-pentaoxa- and 1,13-dioxa-4,7,10-trithia[13](1,1′)ruthenocenophanes with $HgCl_2$. In this paper we report on the molecular structure of a 1 : 2 complex (**6**) of 1,4,13,16-tetraoxa-7,10-dithia[16](1,1′)ruthenocenophane (**5**) with $HgCl_2$ in order to clarify the manner of the complexing.

Syntheses. The following reactions were carried out to obtain complex **6**. The reaction of 1,1′-diacetoxyruthenocene with bis(2-chloroethyl) ether in ethanol in the presence of potassium hydroxide gave **4** in 73% yield. The reaction of **4** with dipotassium 1,2-ethanedithiolate in ethanol gave **5** in 63% yield. A solution of $HgCl_2$ in 1 ml of acetonitrile was added, dropwise, to a solution of 1 ml of acetonitrile containing **5**. The resulting precipitates were filtered and washed with a small amount of acetonitrile to give a 1 : 2 complex (**6**) in 47% yield. In spite of the many attempts to prepare the 1 : 1 complex of **5** with $HgCl_2$ it could not be obtained.



^{1}H NMR spectra of **5** and its mercury(II) complex (**6**) were measured in DMSO-d_6 as the solvent. Upon comparing the ^{1}H NMR spectra of **6** with **5**, the signals of the β-protons of the Cp-rings in **6** were shifted further down field (3.0 ppm) than the α-protons (2.1 ppm). The signals of the methylene protons attached to the sulfur atoms of **6** were also shifted down field (0.05—0.06 ppm), although the change in the chemical shifts of the methylene protons attached to the oxygen atoms was negligible. These results sug-

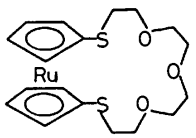
and **6** are illustrated in Fig. 1. The final atomic parameters for **5** and **6** are listed in Tables 1 and 2, and bond lengths as well as bond and torsion angles are given in Tables 3 and 4 for **5** and **6**, respectively. The structure of complex **6** differs completely from that of **1** in which the Hg atom of $HgCl_2$ incorporated in the central cavity of the crown ether moiety forms a distorted hexagonal-bipyramidal geometry with an angle of 172.7(2)° (type 1), even though **1** has the same number of crown moieties as **6** and the positions of the two sulfur atoms in **1** and **6** are the only difference between them. Surprisingly, the one Hg(1) atom of $HgCl_2$ in complex **6** is bonded directly to the Ru atom of the ruthenocene nucleus from the opposite side of the crown ether moiety with a distorted trigonal-planar configuration and one Cl(2)′ atom of the adjacent complex also linked by a weak bond to the Hg atom. Therefore, the Hg(1) atom forms a distorted trigonal-pyramidal geometry. The Ru-Hg(1) interatomic distance in **6** is 2.701 Å, which essentially equals the sums (2.68 Å) of the covalent radii of Ru and Hg atoms.[15] However, the value is intermediate between those (2.65 and 2.74 Å) found in the 2:3 $HgCl_2$ complex[16] and the 1:1 $HgBr_2$ complex[16] of ruthenocene. The sum of the three bond angles about the Hg(1) atom is 353.3° and the deviation of the Hg atom from the Cl(1)-Ru-Cl(2) plane is 0.381°. These values are similar to those found in the 1:1 mercury complexes **2** and **3**.[14] The values (2.470(7)

and 2.564(7) Å of the Hg-Cl(1) and Hg-Cl(2) bonds are even smaller than those (2.55 and 2.60 Å) of the corresponding Hg-Cl bonds in the 2:3 complex[16] of ruthenocene with $HgCl_2$. It may be attributed to the difference in the complexing ratios between ruthenocene and $HgCl_2$. Another Hg(2) atom of $HgCl_2$ is also bonded to the two sulfur atoms of the macrocyclic moiety with a distorted tetrahedral geometry. The lengths (2.576(8) and 2.654(8) Å) of S(12)-Hg(2) and S(15)-Hg(2) bonds and the dihedral angle (62.3(2)°) between the planes defined by S(12)-Hg(2)-S(15) and Cl(3)-Hg(2)-Cl(4) is smaller than those found in μ-(1,4,8,11-tetrathiacyclotetradecane-S^1S^4;S^8S^{11})bis[dichloromercury(II)].[17] It is noteworthy that the Cp ring in **6** deviates from planarity, and its tilting angle is 21.1(1)°, although that in the corresponding metal free ligand **5** is only 2.5(2)°. The large tilting in **6** is attributed to the metal-metal (Ru-Hg(1)) bond formation followed by the steric repulsion between the two Cp-rings and $Hg(1)Cl_2$ units. Finally, the difference in the complexing manner of **6** and **3** with $HgCl_2$ seems to be attributable to: (I) the Hg(2) atom is more easily bonded to the S(12) and S(15) atoms in **5** compared to the two sulfur atoms in the metal free ligand **7** of the corresponding complex **3**, because the direc-



7

tions of the lobes of lone pair electrons of the two sulfur atoms in **5** are more suitable for S-Hg-S bonding compared with those in **7**; (II) the differences of the ring sizes and tilting angles of the two Cp-rings in **5** and **7** are also effected by the complexing manner of the metal free ligands (**5** and **7**) with $HgCl_2$. Therefore, the Hg(2) atom is selectively bonded to the two sulfur atoms in **5** without incorporation into the central cavity of the macrocycle as the linear Cl-Hg-Cl form.

Experimental

Melting points are uncorrected. The ^1H NMR spectra were measured on a JEOL GX400 spectrometer with TMS as the internal standard.

Materials. 1,1′-Diacetoxyruthenocene was prepared according to a method mentioned in a previous paper.[18] The other reagents employed were either commercial or prepared by the usual methods. The solvents were purified by distillation.

1,1′-Bis(6-chloro-1,4-dioxahexyl)ruthenocene (4). 1,1′-Diacetoxyruthenocene (471 mg, 1.36 mmol) was added to 10 ml of potassium hydroxide solution (619 mg, 15.4 mmol) containing catalytic amounts of 18-crown-6 under nitrogen. After the mixture was stirred at reflux temperature, bis(3-chloropropyl) ether (5.488 g, 38.1 mmol) in 10 ml of ethanol was added to the mixture at once. The stirring was continued for 6 h under reflux. The solution was cooled to room temperature, and extracted with three 100 ml portions of ether. The extracts were combined, washed with water, and concentrated in vacuo. The residual oil was chromatographed on silica-gel TLC (hexane : acetone=4 : 1 as eluent). The second band was extracted with acetone at room temperature, followed by filtration and evaporation of the solvent to give **4** as a pale-yellow oil. 73% yield. Found: C, 45.21; H, 5.10%. Calcd for $C_{18}H_{24}Cl_2O_4Ru$: C, 45.38; H, 5.04%. MS(M^+) 476.

1,4,13,16-Tetraoxa-7,10-dithia[16](1,1′)ruthenocenophane (5). A solution of **4** (1.63 g, 3.42 mmol) in THF (120 ml) and a mixture of 1,2-ethanedithiol (1.68 g, 17.8 mmol) and potassium hydroxide (1.46 g, 36.5 mmol) in 120 ml of aqueous ethanol were added to 100 ml of ethanol-THF (1 : 1) solution over 3 h under reflux. The refluxing was continued for 12 h with stirring. The mixture was cooled to room temperature and concentrated in vacuo. The residual oil was chromatographed on silica gel (hexane : acetone=4 : 1 as eluent). The main band was extracted with acetone, and the solution was evaporated in vacuo. Recrystallization of the residue from hexane gave **5** as white needles in 13% yield. Mp 93.0—94.0 °C. Found: C, 48.35; H, 5.55%. Calcd for $C_{20}H_{28}O_4S_2Ru$: C, 48.29; H, 5.63%. ^1H NMR (in DMSO-d_6) δ=4.66 (t, J=1.8 Hz, 4H), 4.27 (t, J=1.8 Hz, 4H), 3.79—3.40 (m, 8H), 3.63 (t, J=6.2 Hz, 4H), 2.80 (s, 4H), 2.70 (t, J=6.2 Hz, 4H). MS (M^+) 497.

Isolation of 1 : 2 Complex of 5 with $HgCl_2$. A solution of **5** (38 mg, 7.6×10^{-2} mmol) in ether (5 ml) was added to a solution containing mercury(II) chloride (26 mg, 9.6×10^{-2} mmol) in 15 ml of ether. As the mixture was concentrated to 10 ml in vacuo, a yellow solid precipitated. Recrystallization of the solid from acetonitrile (2 ml) gave pure mercury complex (**6**) in 47% yield. Mp 159.5—160.5 °C. Found: C, 23.28; H, 2.80%. Calcd for $C_{20}H_{28}O_4S_2Ru(HgCl_2)_2$: C, 23.10; H, 2.69%. ^1H NMR (in DMSO-d_6) δ=4.87 (broad s, 4H), 4.57 (broad s, 4H), 3.78 (t, J=4.6 Hz, 4H), 3.64 (t, J=4.6 Hz, 4H), 3.62 (t, J=6.2 Hz, 4H), 2.86 (s, 4H), 2.75 (t, J=6.2 Hz, 4H).

X-Ray Crystallography of 5 and 6. Crystals of dimensions 0.3×0.3×0.3 mm for **5** and 0.4×0.2×0.1 mm for **6** were used for X-ray crystallography. Lattice constants were determined by a least-squares fit of angular settings of 2θ reflections within the range $15<2\theta<30°$. Intensity data were obtained on a Rigaku AFC-5R diffractometer equipped with graphite-monochromatized Mo $K\alpha$ (λ=0.71069 Å) radiation and using the θ-2θ scan technique ($2\theta<50°$). During data collection, three standards (measured before every 200 reflections) indicated no systematic variation of the intensity with time. Of 3781 and 4928 independent reflections measured, only 3573 and 3999 for **5** and **6**, respectively, were considered as observed on the basis of the criterion $F_o<2\sigma(F_o)$. All intensities were corrected for Lorentz and polarization effects, but not for absorption. Crystal data: **5**, $C_{20}H_{28}O_4S_2Ru$, Mw=497.7. Triclinic, space group $P\bar{1}$, a=11.128(2), b=12.720(2), c=10.196(2) Å, α=113.55(1), β=64.13(1), γ=122.01(1)°, U=1074.1 Å^3, Z=2, D_c=1.54 Mg m^{-3}, μ(Mo $K\alpha$)=0.9 mm^{-1}. **6**, $C_{20}H_{28}O_4S_2RuHg_2Cl_4$, Mw=1040.7. Triclinic, space group $P\bar{1}$, a=16.595(4), b=12.645(3), c=7.401(1) Å, α=104.92(1), β=92.37(1), γ=69.38(2)°, U=1402.4 Å^3, Z=2, D_c=2.46 Mg m^{-3}, μ(Mo $K\alpha$)=12.2 mm^{-1}. The structures of **5** and **6** were solved by the

heavy-atom methods, and refined by the block-diagonal least-squares method. The positions of the hydrogen atoms were estimated using standard geometry. The final refinements with anisotropic temperature factors for the non-hydrogen atoms and isotropic temperature factors for the hydrogen atoms lowered the R values to 0.028 (R_w=0.025, $w=1/\sigma^2(F_o)$) and 0.081 (R_w=0.070, $w=1/\sigma(F_o)$) for **5** and **6**, respectively.[19] Anomalous dispersion corrections were applied to the scattering factors of Hg, Ru, Cl, and S.[20] The complete F_o-F_c data are deposited as Document No. 8904 at the office of the Bull. Chem. Soc. Jpn.

Photochromism of 4-Oxazolyl Fulgides[1)]

Hisao SUZUKI,* Akihiko TOMODA,* Mitsuo ISHIZUKA, Akira KANEKO,

(Received June 15, 1989)

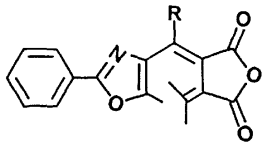
The thermal and photochemical stabilities of 2-[1-(2-phenyl-5-methyl-4-oxazolyl)]alkylidenesuccinic anhydrides (**1**) and (**2**) were studied. These compounds showed good thermal stabilities in PMMA film and low photochemical fatigue (PF $\leq$ 0.03% /cycle) in a dilute toluene solution in the presence of air, compared with 3-furyl fulgide (**3**). Although in PMMA film the photochemical fatigue resistance property of the fulgides was poor, in comparison with that in solution, the addition of an organo-nickel stabilizer improved the property.

In order to use an optical memory device based upon a photochromic system, knowledge concerning the thermal stabilities of the colored and uncolored form (i.e. erase and write modes) is essential.

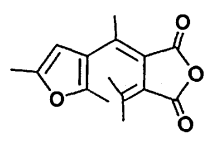
Heller et al.[2)] reported that heterocyclic fulgides, such as 3-furyl and 3-thienyl derivatives, showed good thermal stabilities. With this as a starting point, the possibility of organic photochromic compounds as data storage media have again been elevated as matters of chemical interest, and various investigations have been initiated.

Recently, Irie[3)] reported that diarylethene derivatives were thermally stable photochromic compounds, and more recently Tamaki and Ichimura[4)] showed that chelation of spiroindolinonaphthoxiazine was effective in improving thermal fatigue resistance.

On the other hand, in a previous paper[5)] we showed that 4-pyrazolyl, 3-indolyl, 4-oxazolyl, and 4-thiazolyl fulgide possesses good thermal and photochemical stabilities in comparison with 3-furyl fulgide **3**. However, it seemed that the photo-responsiveness and/or the conversion of these fulgides to the colored form in the photostationary state were too low, except for 4-oxazolyl fulgide. In this study we report on the responsiveness and the photochemical and thermal fatigue resistances of 4-oxazolyl fulgide in detail, and also on the effect of a long alkyl chain substituent.



1 R = CH_3
2 R = $C_{17}H_{35}$



3

Results and Discussion

The absorption spectra of colored and uncolored forms of **1** in dilute toluene solutions (1.0×10^{-4} mol dm^{-3}) and PMMA thin films (ca. 1.0 μm thickness) are illustrated in Fig. 1.

A photostationary state (pss) for coloration, i.e. cyclization reaction, was attained by irradiation with

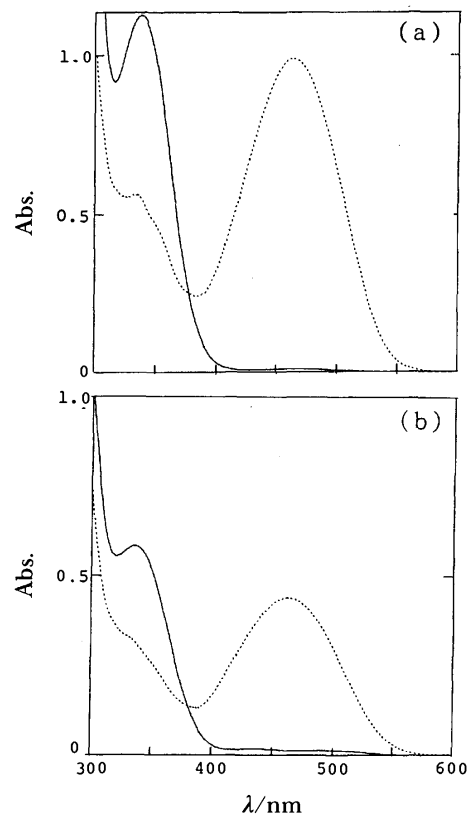


Fig. 1. Absorption spectra of uncolored and colored forms of **1**.
(a) In dilute toluene solutions (1.0×10^{-4} mol dm^{-3}).
(b) PMMA thin films (1.0 μm thickness, 20 wt%).

UV light (366 nm) for 40 s. After subsequent irradiation for 40 s with visible light (>390 nm), it underwent discoloration, i.e. disclosure reaction.

The absorption maximum and its intensity of color are similar, even when a methyl substituent is replaced with a long alkyl chain. Further, 0.20 mol dm^{-3} deuteriochloroform solutions of **1** and **2** in NMR tubes were exposed to UV light. The NMR measurements showed that these were converted nearly quantitatively into colored forms (**1C** and **2C**) in 84 and 91%, respectively.

Photo-responsiveness for coloration and bleaching of **1** and **2** are shown in Fig. 2. It was noticeable that

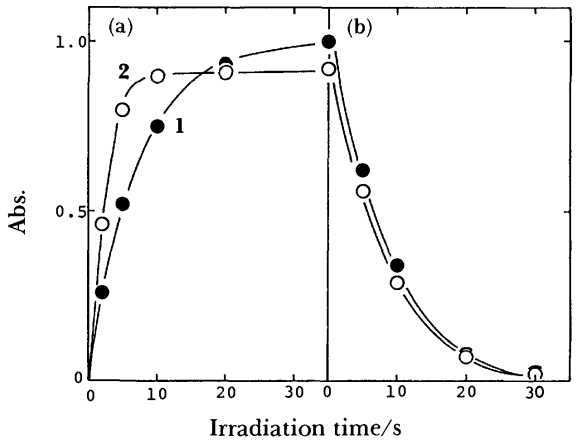

Fig. 2. Photo-responsiveness for coloration (a) and discoloration (b) of **1** and **2** in dilute toluene solutions (1.0×10^{-4} mol dm^{-3}) with UV and visible light irradiation.

fulgide **2** exhibited rapid coloration. The quantum yield (ϕ_c) for coloration of **2** was 0.42. The ϕ_c of **1** was 0.18, which was nearly the same as that for **3**. Kurita et al.[6] reported the relationship between the ϕ_c and the steric interaction for 3-furyl fulgides. According to their study, the introduction of a propyl substituent, instead of a methyl substituent, caused an increase in the ϕ_c, 0.19 to 0.45. They explained that the high efficiency of this cyclization reaction was due to a steric repulsion between the isopropylidene group and the alkyl substituent, which did not favor *E-Z* isomerization.

In our study, the ϕ_c of 3-furyl fulgide substituted with a long alkyl chain was 0.45. These results showed us that the introduction of a bulky alkyl substituent is also effective at improving ϕ_c of oxazolyl fulgide, similar to **3**.

Figure 3 illustrates the photochemical fatigue resistances of **1**, **2** and **3**. 4-Oxazolyl fulgides showed good resistances in a dilute toluene solution in the presence of air. The relative photochemical fatigue PF=$(A_0-A_n)/nA_0$ was evaluated, where A_0 and A_n are the absorbance values at pss attained on the lst and nth cycles of coloration. The values of **1**, **2**, and **3** are 0.03, 0.02, and 0.76%. Similar values were also obtained in an ethyl acetate solution. The photochemical stability of 4-oxazolyl fulgide is attributable to its heteroaromatic structure deactivated by electronegative nitrogen, though photochemical reactions of oxazole, such as photorearrangement[7] or photosensitized oxidation,[8] are known.

Irie et al.[9] evaluated the photochemical fatigue resistances of some photochromic compounds, and indicated that naphthoxazine showed the best stability. It is noteworthly that the excellent durability of naphthoxazine was caused by a slight modification of spiropyran, which showed little resistance. The only structural difference is that C=C bond in the pyran ring is replaced by a C=N bond. This modification improved the resistance remarkably; naphthoxazine could be photo-cyclized more than 2000 times.

As shown in Fig. 3, the replacement of the C=C bond with a C=N bond in the furan ring also improved the fatigue resistance markedly. These facts suggest that the C=N bond plays an important role in reducing photodegradation in a photochromic reaction.

On the other hand, further improvement caused by long alkyl chain substituent seemed to be due to the high ϕ_c of **2**, which reduces the possibility of side reactions.

As shown in Fig. 4, the fatigue resistance in PMMA thin film containing fulgide (20 wt%) was markedly decreased in comparion with that in a dilute solution. The PF values of **1**, **2**, and **3** are 0.63, 0.42, and 2.80%. This undesirable fact suggests the considerable effects of the medium and the concentration of the fulgides on photochemical fatigue.

Chu[10] reported on the photochromic performance

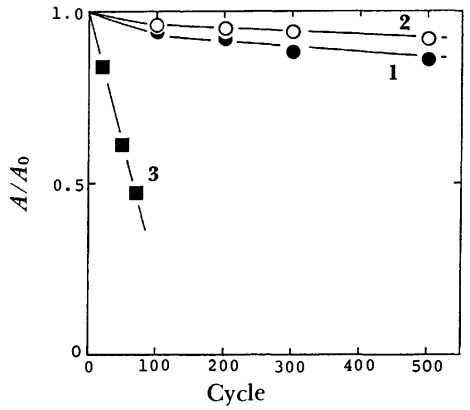

Fig. 3. Photochemical fatigues of fulgides by repeated coloration and discoloration cycles in dilute toluene solutions (1.0×10^{-4} mol dm^{-3}). A_0 and A_n are the absorbance values at pss attained on the 1st and nth cycles of coloration.

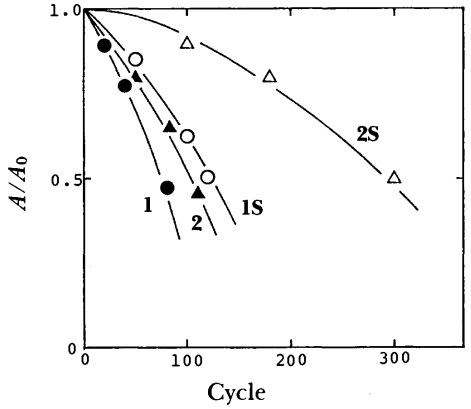

Fig. 4. Photochemical fatigues of fulgides in PMMA thin film (1.0 μm thickness, 20 wt%) and effect of organo-nickel stabilizer. 1 wt% Nickel stabilizer was added into PMMA thin film containing fulgides **1** and **2**; **1S**, **2S**.

of naphthoxazine in plastics. In his study he found that the excellent light fatigue resistance of naphthoxazine could be further improved by an organo-nickel stabilizer. From a practical view point, we also investigated the effect of some nickel stabilizers so as to improve it. Among the various derivatives, the nickel dithiophenolate derivative (bis(1,2,3-trichloro-5,6-dithiophenolate)Ni(II) tetrabutylammonium) which is known as being a light stabilizer for a near-infrared absorbing dye,[11] had the greatest effect on the fatigue resistance. As illustrated in Fig. 4, only 1 wt% of the stabilizer in PMMA film exhibited this effect on the light fatigue resistance.

The thermal degradation of the fulgides in PMMA film at 80 °C in the dark are shown in Fig. 5. Colored forms (**1C** and **2C**) showed good fatigue resistance. Degradation after 11 days was only 7%, and the residues showed a same photochromic performance. Uncolored forms (**1** and **2**) were also investigated. PMMA film containing fulgide had been previously heated for various periods and then irradiated with UV light for coloration. These showed little fatigue, 24% and 18%, respectively, indicating their slight inferiority to colored forms.

Thermal stabilities of fulgide in solution had been investigated in some detail by Heller et al.[12] According to their paper, the colored form of 3-furyl fulgide **3C** was stable below 100 °C. The uncolored form **3** in deuteriochloroform solution (0.20 mol dm^{-3}) on heating at 180 °C turned red, which was not reversible upon exposure to visible light.

As illustrated in Fig. 5, the thermal stability of **3C** in PMMA was much lower than that of **1C** and **2C**, and thermally bleached **3C** showed no photochromism. The uncolored form **3** also showed a similar tendency to the colored form, but thermally colored species were not detected in the absorption spectrum. On the other hand, the photocolorability of **3** in a dilute toluene solution was completely maintained after boiling at 80 °C for 24 h. These facts mean that the degradation in a polymer matrix, such as PMMA, differs from that in solution, and the introduction of a C=N bond is also effective in reducing thermal fatigue in PMMA film because of its higher chemical satability.[12]

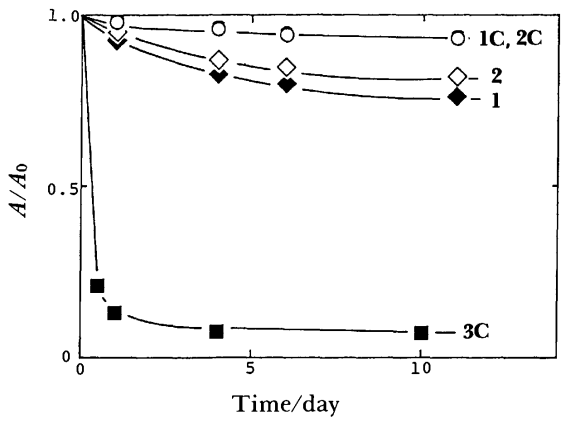

Fig. 5. Thermal degradations of the fulgides in PMMA film at 80 °C in the dark. PMMA films of 1 μm thickness containing fulgides (20 wt%) had been irradiated with UV light leading to the photostationary state for coloration after heating; **1**, **2**. The film had been previously irradiated with UV light for coloration before heating; **1C**, **2C**, **3C**.

Experimental

Materials. 4-Oxazolyl fulgide (**2**). A solution of 5-methyl-2-phenyl-4-stearoyloxazole[13] (4.4 g, 0.010 mol) and diethyl isopropylidenesuccinate (2.7g, 0.012 mol) in *t*-butyl alcohol (10 ml) was added dropwise to a refluxing solution of potassium *t*-butoxide (1.2 g) in *t*-butyl alcohol (15 ml), and the solution was refluxed for 3 h. After removing the solvent, the reaction mixture was poured into water, and extracted with ether. The aqueous layer was acidified, and the liberated half ester was extacted with toluene and dried over anhydrous magnesium sulfate; the solvent was then removed. The residue, yellow oil (6.4 g), was hydrolyzed with 5% ethanolic potassium hydroxide and a solid potassium salt filtered off and acidified. The resulting diacids (4.8 g) were boiled with acetic anhydride. After the solvent was removed, **2** was isolated in 9% yield as *Z*-isomer by column chromatography on silica gel and recrystalized from hexane. Mp 65—67 °C; ^{1}H NMR ($CDCl_3$) δ=0.83 (t, 3H) 1.26 (s, 32H), 2.07 (s, 3H), 2.33 (s, 3H), 2.43 (s, 3H), 7.36—8.13 (m, 5H); mass spectrum, *m/z* 547 (M^+). Calcd for $C_{35}H_{49}NO_4$: C,76.52; H,9.02; N, 2.56; O, 11.68%. Found: C,76.52; H, 9.14; N, 2.61; O, 11.73%.

The *Z*-isomer of this fulgide in toluene solution or PMMA film rapidly isomerized into an *E*-isomer upon UV irradiation.

4-Oxazolyl fulgide (**1**) and 3-furyl fulgide (**3**) were prepared as described above and in the literatures.[2]

Measurements. A mercury lamp (Ushio, 250 W) and a xenon lamp (Ushio, 300 W) were used as light sources for coloration and discoloration reactions. A mercury line, 366 nm (ca. 50 mJ) and visible light beams (>390 nm) were isolated by passing the light through glass filters (Toshiba UV-D36C, UV-35 and L-39). PMMA film (ca. 1.0 μm thickness) was prepared on a glass plate by spin coating a cyclohexanone solution containing fulgide and PMMA (20 : 80 by weight). For the measurement of thermal stability, the surface of the PMMA film was coated with acrylic polymer (SD-17 Dainihon-inki) in 4—5 μm thickness to protect them from sublimation. Quantum yields for coloration were determined by measuring the rate of the photoreaction, which was carried out in a toluene solution (6×10^{-4} mol dm^{-3}) by irradiation of the 311 nm mercury line, using a Quantum Yield Reactor (Model 2001 Applied Photophysics). The light intensity was measured with a potassium iron(II) oxalate actinometer.

The photochemical fatigue of fulgides was investigated by measurements of the absorption spectrums of the colored forms. In the presence of air toluene solution (1×10^{-4} mol dm^{-3}) and PMMA films were irradiated with UV and visible light, alternatively, using a photo-irradiater cycle test system (OMROM).

For evaluating the effect of various organo-nickel stabilizers in improving the fatigue resistance, PMMA films con-

taining 3-furyl fulgide **3** and 4-oxazolyl fulgides **1** and **2** (20 wt%) were used as test samples. These films were prepared as described in the above, except for the addition of the stabilizers to the cyclohexanone solution. Nickel stabilizers such as Cyasorb 1084, AM105 and AM205 (evaluated by Chu) and a nickel dithiophenolate derivative were commercially available from American Cyamid, Ferro. Corp. and Mitsui Toatsu. However, the three stabilizers tested by Chu showed no effect in improving the fatigue resistance of fulgide.

The thermal degradation of PMMA film containing fulgide was carried out in an oven at 80 °C and was monitored by measuring the absorption spectrum of colored forms at room temperature.

UV and ^{1}H NMR spectra were measured with a spectrophotometer (Hitachi U-3200) and 60-MHz spectrometer (JEOL JNM-PMX60 NMR).

Methanol-Incorporated Photoaddition of *N*-Methyl-9,10-phenanthrenedicarboximide to Alkenes. Addition at Carbonyl and Phenanthrene-Ring Carbon Atoms

Yasuo KUBO,* Mikako NANBA, Etsuko HAYASHI, and Takeo ARAKI†
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
(Received June 19, 1989)

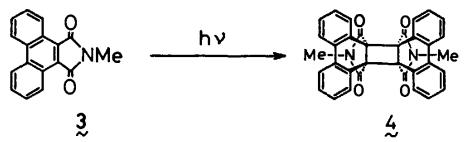
Irradiation of acetonitrile-methanol (2 : 1 v/v) solutions of *N*-methyl-9,10-phenanthrenedicarboximide (**3**) with alkenes **5a—g** gave methanol-incorporated adducts (**9c—f**) at a carbonyl carbon atom in **3**, those (**10c,f**) at a phenanthrene-ring carbon atom, and a methanol-adduct **11g** to alkene **5g**, together with products **4**, **6b,e—g**, **7b,e—g**, and **8e,f** obtained by the photoreactions in benzene. The concentration effect of alkenes **5e,f** on yields of products **6e,f**, **7e,f**, **8e,f**, **9e,f**, and **10f** showed that both **9e,f** and **10f** arose from a relatively short-lived singlet excited state of **3**. The values of the free-energy change associated with an electron transfer (ΔG_{et}) from alkenes **5a—d,g** to the singlet excited state of **3** and fluorescence quenching rate constants support a photochemical electron transfer mechanism for the methanol-incorporated addition. Both $LiClO_4$ and Bu_4NClO_4 caused only slight decreases in the relative ratios **10c/9c** indicating that both the methanol-incorporated addition at the phenanthrene-ring carbon atom and that at the carbonyl carbon atom might arise from a contact ion pair state. The fact that the methanol-incorporated addition at the arene-ring carbon atom was observed only in the reaction of **3** in a series of *N*-methylarenedicarboximides, possessing a five-membered imide ring, is interpreted on the basis of the spin density of the radical anions of the imides derived from the photochemical electron transfer.

The area of electron transfer photochemistry has received much attention with regard to both synthetic and mechanistic aspects in organic photochemisry.[1] A unique feature of transformations occurring by electron transfer mechanisms is that the key reactive intermediates are radical ion and neutral radical species rather than the initially populated excited states. Consequently, the chemical properties and reactivity profiles of these reactive intermediates have been clarified by investigations on the nature of the reactions.

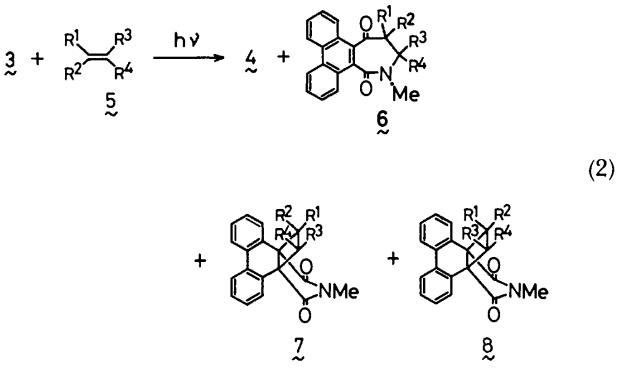
During the course of investigations of the photochemistry of imides, a wide variety of alcohol (solvent)-incorporated intramolecular cyclization[2] and intermolecular addition reactions[3] in the photoreactions of arenedicarboximide-alkene systems, via an electron transfer process, have been found. The position, at which the alcohol-incorporated addition occurs, largely depends on the arene structures of the arenedicarboximides. Thus, the methanol-incorporated addition has been reported to occur only at the carbonyl carbon atoms of the imide for the reactions of the five-membered imides such as *N*-methylphthalimide (**1**),[3a-e] *N*-methyl-1,2-naphthalenedicarboximide (**2**),[3i] and its 2,3-isomer,[3g] while the addition solely at a naphthalene-ring carbon atom has been observed in the reaction of *N*-methyl-1,8-naphthalenedicarboximide, a six-membered imide.[3f,h] Furthermore, a preferential addition at the sterically more hindered carbonyl carbon atom in the reaction of **2** has been found.[3i] The effect of the arene structures has been explained on the basis of the spin density of the radical anion of the arenedicarboximides derived by the photochemical electron transfer.[3h,i]

Here, we report on the methanol-incorporated photoaddition of *N*-methyl-9,10-phenanthrenedicarboximide (**3**) to alkenes in acetonitrile-methanol (2/1 v/v), in which the first example of the methanol-incorporated addition at an arene-ring carbon atom in the reactions of arenedicarboximides with a five-membered imide ring is observed.

We have already reported the photoreactions of **3** with alkenes in benzene.[4] Thus, photoreaction (>400 nm) of **3** gives the syn-dimer (**4**) (Eq. 1). Photoreactions of **3** with alkenes (**5**) give **4**, insertion products (**6**) of the double bond of the alkenes into the C–N bond of **3**, and cyclobutanes (**7** and **8**) (Eq. 2).



3 **4** (1)



5 **6** (2)

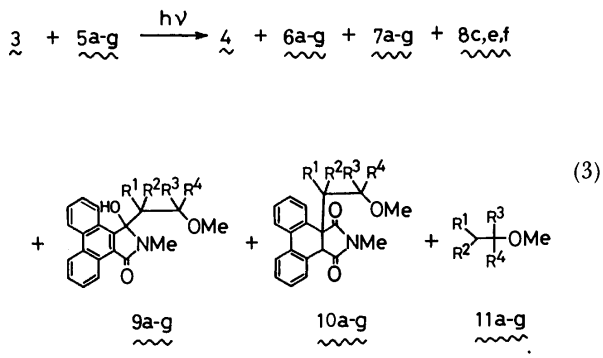
7 **8**

† Present address: Department of Polymer Science and Engineering, Faculty of Textile Science, Kyoto Institute of Technology, Kyoto 606.

The syn dimerization and the insertion occur from the singlet excited state of **3**, and **7** and **8** arises mainly from the triplet excited state of **3** and remarkable heavy atom effect by halides is observed in this system.

Results and Discussion

Results of the photoreactions (>400 nm) of **3** and alkenes **5a—g** in N_2-purged acetonitrile-methanol (2/1 v/v) are summarized in Eq. 3 and Table 1. The



(3)

methanol-incorporated addition was observed in the reactions with ethylenes substituted by more than three alkyl groups, 2-methyl-2-butene (**5c**), 2,3-dimethyl-2-butene (**5d**), as for the reaction with aliphatic alkenes. The fact that the dimerization of **3** to give **4** was only observed in the reaction with 1-hexene (**5a**), an ethylene substituted by one alkyl group, indicates that no interaction occurs between the excited states of **3** and **5a**. Photoreaction with isobutene (**5b**), an ethylene substituted by two alkyl groups, in acetonitrile-methanol and in benzene gave the same products, an insertion product **6b** and a cyclobutane **7b**, as those obtained by the reaction in benzene. The results show that **3** is less reactive on the methanol-incorporated addition than **1** since irradiation of **1** with **5b** gave a methanol-incorporated adduct together with an insertion product.[3d] and **3** has a similar reactivity to **2** because the methanol-incorporated addition was observed in the reactions with the same alkenes **5c,d**.[3i]

Irradiation of **3** with **5c** in acetonitrile-methanol gave a pair of diastereomers of a methanol-incorporated adduct (**9c**, diastereomer ratio=2.8 : 1) at the carbonyl carbon atom of **3** and a pair of diastereomers of a methanol-incorporated adduct (**10c**, diastereomer ratio=1.2 : 1) at a phenanthrene-ring carbon atom with complete quenching of the formation of products **4**, **6c**, **7c**, and **8c** obtained in benzene.[4] The diastereomers of **9c** were isolated as a mixture and those of **10c** were separated by silica-gel column chromatography. The structure of **9c**, including the position of the methyl substituents in the side chain, was supported by the spectral resemblances to the methanol-incorporated adducts obtained by the photoreactions of **1**[3d] and **2**[3i] with **5c**. The structure of **10c** was assigned on the basis of the spectral data: ^{1}H NMR δ=5.07 (s, 1H, CH, for the major diastereomer), 4.35 (s, 1H, CH, for the minor diastereomer); IR 1766 and 1700 (imide moiety for the major diastereomer), 1776 snd 1706 (imide moiety for the minor diastereomer).

Irradiation of **3** with **5d** in acetonitrile-methanol (2/1 v/v) gave no detectable amounts of products. However, irradiation in benzene-methanol (9/1 v/v), a less polar solvent system, gave a methanol-incorporated adduct (**9d**) at the carbonyl carbon atom of **3**. A similar solvent effect was observed in the reactions of **2** with alkenes.[3i]

Irradiation of **3** with styrene (**5e**) in acetonitrile-methanol gave a pair of diastereomers of a methanol-

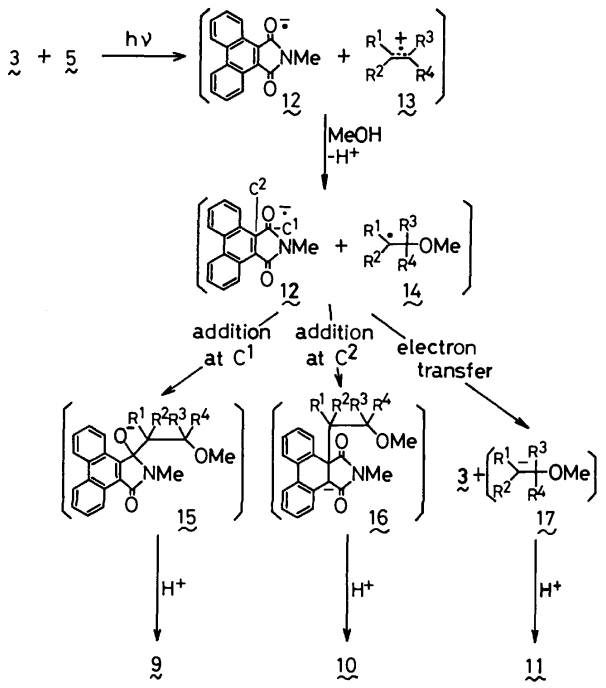
incorporated adduct (**9e**) at the carbonyl carbon atom together with products **6e**, **7e**, and **8e** obtained in benzene.[4] Photoreaction with α-methylstyrene (**5f**) afforded a pair of diastereomers of a methanol-incorporated adduct (**9f**) at the carbonyl carbon atom and a pair of diastereomers of a methanol-incorporated adduct (**10f**) at the phenanthrene-ring carbon atom together with products **6f**, **7f**, and **8f** obtained in benzene.[4]

The concentration effect of the alkenes **5e,f** on the yields of the photoproducts was examined in the reactions with **5e,f** to clarify the multiplicity of the excited states of **3** which led to **9e,f** and **10f**. A marked concentration dependency of the yields of products was observed in the reaction of **3** with **5f** in benzene; the yield of **6f** increased and those of **7f** and **8f** decreased with increase of the concentration of **5f**.[4] These results are rationalized by a mechanistic scheme, in which **6f** arises from the relatively short-lived singlet excited state of **3**, and **7f** and **8f** mainly from the relatively long-lived triplet excited state. A similar concentration dependency of the yields of **6e,f**, **7e,f**, and **8e,f** was observed in acetonitrile-methanol (Table 1). At the same time, the yields of **9e,f** and **10f** increased with increase of the concentration of **5e,f**, indicating that **9e,f** and **10f** arose from the relatively short-lived singlet excited state of **3**.

Irradiation of **3** with 1,1-diphenylethylene (**5g**) in acetonitrile-methanol gave 2,2-diphenylethyl methyl ether (**11g**), an anti-Markovnikoff adduct of methanol to **5g**, and products **6g** and **7g** obtained in benzene. No methanol-incorporated adducts of **3** to **5g** were obtained.

A possible mechanism which can interpret the general feature of the methanol-incorporated addition observed in the photoreaction of **3** with alkenes (**5**) is shown in Scheme 1. The initial step of the reaction is the single electron transfer from the alkenes to the singlet excited state of **3**. The singlet multiplicity of the excited state of **3**, which lead to the methanol-incorporated adducts **9** and **10**, is substantiated by the concentration effect of **5e,f**. The electron transfer mechanism is supported by the estimation of the free-energy changes (ΔG_{et}) associated with the electron transfer from alkenes to the singlet excited state of **3** and the fluorescence quenching rate constants (k_q) (vide infra). Concerning the electron transfer mechanism, **11g** by the reaction with **5g** could be one of the typical electron transfer photosensitized products, as reported by Arnold and his co-workers.[5] The electron transfer photo-sensitized addition of methanol to alkenes giving **11** and the methanol-incorporated addition of alkenes to **3** giving **9** and **10** appear to be closely related processes via common intermediates **12**+**14**. Coupling of the two components at the carbonyl carbon atom (C^1) and that at the phenanthrene-ring carbon atom (C^2) of **12** results in the formation of **9** and **10**, respectively, and the back electron transfer



Scheme 1.

from **12** to **14** gives **3** and **11** (Scheme 1).

The values of ΔG_{et} can be estimated by using[6]

$$\Delta G_{et} = 96.49[E(D/D^+) - E(A^-/A)] - \Delta E_{0,0}. \quad (4)$$

In this equation $E(D/D^+)$ is the oxidation potential of the alkenes, $E(A^-/A)$ is the reduction potential of **3**, and $\Delta E_{0,0}$ is the singlet excitation energy of **3**. With these parameters, we can calculate the ΔG_{et} values for reactions with alkenes **5a—d,g** as shown in Table 2, which shows that the methanol-incorporated addition occurs only in the cases having negative ΔG_{et} values, as expected from the electron transfer mechanism.

An addition of alkenes **5b—g** to air-saturated acetonitrile solutions of **3** (1×10^{-5} M) resulted in a reduction of the fluorescence of **3** without varying the shape and the position of the emission. Stern-Volmer plots of the fluorescence quenching by alkenes **5c—g** gave straight lines against concentration of **5c—g**. The values of k_q in acetonitrile calculated from the Stern-Volmer slopes ($k_q\tau$) using the lifetime of the fluores-

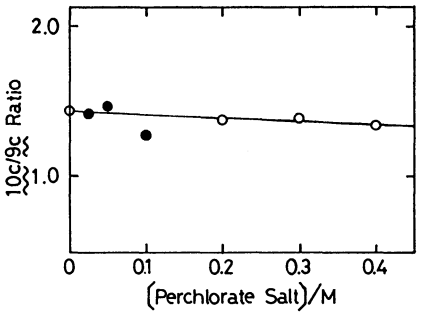

Fig. 1. Methanol-incorporated adducts at a phenanthrene-ring carbon atom to those at the carbonyl carbon atom ratios (**10c**/**9c**) obtained by irradiation of acetonitrile-methanol (2/1 v/v) solutions of *N*-methyl-9,10-phenanthrenedicarboximide (**3**, 1.9 mM) and 2-methyl-2-butene (**5c**, 240 mM) in the presence of varying concentrations of $LiClO_4$ (○) and Bu_4NClO_4 (●).

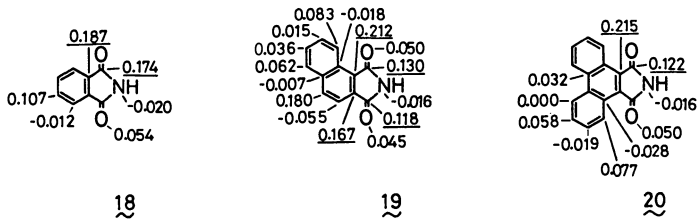
cence of **3**, together with k_q values in benzene, are shown in Table 3. The k_q values in acetonitrile are larger than those in benzene. The large k_q values in acetonitrile may also support the electron transfer mechanism.

In the area of electron transfer photochemistry, chemistry of ion pairs, involving solvent-separated ion pairs and contact ion pairs, have received much attention in recent years.[1,8] The salt effect was examined in the present system to obtain the information on the ion-pair states involved in the reaction, since the salt effect had been known to play a role in determining preferred ion-pair states of photogenerated radical ions.[9] Thus the relative ratios **10c**/**9c** were determined for the photoreactions of **3** with **5c** in acetonitrile-methanol (2/1 v/v) containing increasing concentrations of $LiClO_4$ and Bu_4NClO_4 in the range of 0—0.4 M. The results are shown in Fig. 1, which indicates that $LiClO_4$ causes only slight decreases in **10c**/**9c** and the effect of Bu_4NClO_4 is similar to that of $LiClO_4$. The lithium cation is known to be a much stronger acceptor than Bu_4N^+ in interactions with oxide anion donors.[9] Thus, $LiClO_4$ should be more capable of intercepting the solvent-separated ion pairs and transforming them to free radical ions, compared with Bu_4NClO_4. The results from the salt effect may indicate that both the methanol-incorporated addition at the phenanthrene-ring carbon atom and that at the carbonyl carbon atom arise from the contact ion pair state.

The variation of the arene structures of arenedicarboximides caused a change in the reaction site at which the methanol-incorporated addition occurred. Thus, the methanol-incorporated addition of **1** and **2** occurs exclusively at the carbonyl carbon atoms,[3a-e,g,i] while that of **3**, possessing a more extended arene structures, occurs both at the arene-ring carbon atom and at the carbonyl carbon stom. Whether the carbonyl carbon atom or the arene-ring carbon atom is attacked may depend on the reactivity of the respective carbons in the imide radical anions toward alkyl radicals such as **14** based on the mechanistic scheme shown in Scheme 1. The relative spin density of the respective carbons in the imide radical anions calculated by the McLachlan method[10] can be used as an index for the reactivity. Of course, other factors such as a steric effect can disturb the reactivity estimated from the spin density.[3i] The spin density of the respective carbons in the radical anions of phthalimide (**18**), 1,2-naphthalenedicarboximide (**19**), and 9,10-phenanthrenedicarboximide (**20**), as model compounds for the radical anions of **1**, **2**, and **3**, respectively, is shown in Fig. 2. In a series of the imide radical anions **18—20** the values of the spin density of



18 19 20

Fig. 2. Spin density of radical anions of phthalimide (**18**), 1,2-naphthalenedicarboximide (**19**), and 9,10-phenanthrenedicarboximide (**20**) calculated by McLachlan method.

the arene-ring carbon atoms shown with underlines in Fig. 2 increased and those of the carbonyl carbon atoms shown with underlines in Fig. 2 decreased from **18** to **20**, although the difference in the relative spin density is not large. Therefore, the methanol-incorporated addition at the arene-ring carbon atom should be favorable in the photoreaction of **3** with alkenes compared with those of **1** and **2** with alkenes, in accord with the fact that the methanol-incorporated addition at the arene-ring carbon atom was observed only in the reaction of **3**.

Experimental

^{1}H NMR spectra were obtained on a JEOL JNM-GX-270 (270 MHz) instrument. Chemical shifts are reported in ppm (δ) relative to internal $SiMe_4$. IR spectra were determined by use of a Hitachi 260-50 spectrometer. Fluorescence spectra and lifetimes were recorded by a Hitachi 850 spectrophotometer and by a Horiba NAES-1100 time-resolved spectrofluorometer, respectively. Melting points were recorded by using a Yanagimoto micro melting point apparatus and are uncorrected. Microanalyses were performed on a Yanagimoto CHN corder MT-2.

Materials. *N*-Methyl-9,10-phenanthrenedicarboximide (**3**) was prepared and purified as described previously.[4] Alkenes **5a**—g were commercially available and purified by distillation of liquid.

General Procedure for Irradiation and Product Isolation. UV irradiation of **3** (15 mM) with alkenes **5a**—g in 25 ml of N_2 purged acetonitrile–methanol (2/1 v/v) was carried out at ambient temperature with an Eikosha EHB-W-300 high-pressure Hg-lamp through a 1-cm path-length aqueous filter, prepared from 27 g of $CuSO_4 \cdot 5H_2O$, 30 g of $NaNO_2$, and 50 ml of concd aqueous ammonia diluted with water to 1000 ml (>400 nm).[11] The reaction was monitored by TLC (Merck, Kieselgel 60 F_{254}) analyses and ^{1}H NMR measurements. After evaporation of the solvent, the residue was subjected to column chromatography (Wakogel C-200). Dichloromethane–ether was used as the eluant for the separation of the products.

Irradiation of 3 with 2-Methyl-2-butene (5c). A mixture (2 : 1) of diastereomers of 3-(1,1-dimethyl-2-methoxypropyl)-3-hydroxy-2-methyl-2,3-dihydro-1*H*-dibenz[*e*,*g*]isoindol-1-one (**9c**): mp 172—180 °C: ^{1}H NMR of the major diastereomer δ=0.42 (s, 3H, CMe), 0.99 (d, *J*=6.4 Hz, 3H, CH**Me**), 1.25 (s, 3H, CMe), 3.23 (s, 3H, NMe), 3.45 (s, 3H, OMe), 4.07 (q, *J*=6.4 Hz, 1H, C**H**Me), 6.46 (s, 1H, OH), 7.5—7.8 (m, 4H, Arom H), 8.6—8.8 (m, 3H, Arom H), 9.3—9.4 (m, 1H, Arom H); ^{1}H NMR of the minor diastereomer δ=0.43 (s, 3H, CMe), 1.19 (d, *J*=6.4 Hz, 3H, CH**Me**), 1.25 (s, 3H, CMe), 3.27 (s, 3H, NMe), 3.54 (s, 3H, OMe), 3.97 (q, *J*=6.4 Hz, 1H, C**H**Me), 6.46 (s, 1H, OH), 7.5—7.8 (m, 4H, Arom H), 8.6—9.0 (m, 3H, Arom H), 9.3—9.5 (m, 1H, Arom H); IR (KBr) 3220 (OH), 1666 (lactam), 1438, 1108, 762, 728 cm^{-1}. Found: C, 75.93; H, 7.04; N, 3.67%. Calcd for $C_{23}H_{25}NO_3$: C, 76.00; H, 6.93; N, 3.85%.

A major diastereomer of 3a-(1,1-dimethyl-2-methoxypropyl)-2-methyl-3a,11b-dihydro-1*H*-dibenz[*e*,*g*]isoindol-1,3(2*H*)-dione (**10c**): mp 229—232 °C; ^{1}H NMR δ=0.60 (s, 3H, CMe), 0.95 (s, 3H, CMe), 1.07 (d, *J*=6.3 Hz, 3H, CH**Me**), 2.96 (s, 3H, NMe), 3.12 (s, 3H, OMe), 3.79 (q, *J*=6.3 Hz, 1H, C**H**Me), 5.07 (s, 1H, CHC=O), 7.2—7.5 (m, 5H, Arom H), 7.7—7.9 (m, 3H, Arom H); IR (KBr) 1766 and 1700 (imide), 1448, 1432, 1380, 1118, 750 cm^{-1}. Found: C, 75.75; H, 6.88; N, 3.77%. Calcd for $C_{23}H_{25}NO_3$: C, 76.00; H, 6.93; N, 3.85%.

A minor diastereomer of **10c**: mp 157—160 °C: ^{1}H NMR δ=0.58 (s, 3H, CMe), 1.04 (d, *J*=6.1 Hz, 3H, CH**Me**), 1.31 (s, 3H, CMe), 2.94 (s, 3H, NMe), 3.01 (s, 3H, OMe), 3.26 (q, *J*=6.1 Hz, 1H, C**H**Me), 4.35 (s, 1H, CHC=O), 7.2—7.5 (m, 5H, Arom H), 7.8—8.0 (m, 3H, Arom H); IR (KBr) 1776 and 1706 (imide), 1440, 1386, 1132, 1118, 760 cm^{-1}. Found: C, 75.84; H, 6.70; N, 3.75%. Calcd for $C_{23}H_{25}NO_3$: C, 76.00; H, 6.93; N, 3.85%.

Irradiation of 3 with 2,3-Dimethyl-2-butene (5d). 3-Hydroxy-3-(2-methoxy-1,1,2-trimethylpropyl)-2-methyl-2,3-dihydro-1*H*-dibenz[*e*,*g*]isoindol-1-one (**9d**): mp 178—180 °C; ^{1}H NMR δ=0.55 (s, 3H, CMe), 1.15 (s, 3H, CMe), 1.27 (s, 3H, CMe), 1.37 (s, 3H, CMe), 3.17 (s, 3H, NMe), 3.40 (s, 3H, OMe), 6.42 (s, 1H, OH), 7.6—7.8 (m, 4H, Arom H), 8.68 (d, 1H, Arom H), 8.71 (d, 1H, Arom H), 8.91 (d, 1H, Arom H), 9.40 (d, 1H, Arom H); IR (KBr) 3300 (OH), 1674 (lactam), 1446, 1078, 724 cm^{-1}. Found: C, 76.51; H, 7.06; N, 3.88%. Calcd for $C_{24}H_{27}NO_3$: C, 76.36; H, 7.21; N, 3.71%.

Irradiation of 3 with Styrene (5e). A mixture (1.2 : 1) of diastereomers of 3-hydroxy-3-(2-methoxy-1-phenylethyl)-2-methyl-2,3-dihydro-1*H*-dibenz[*e*,*g*]isoindol-1-one (**9e**): mp 192—197 °C: ^{1}H NMR δ=3.02 (s, 3H, NMe for the minor diastereomer), 3.31 (s, 3H, NMe for the major diastereomer), 3.43 (s, 3H, OMe), 3.60 (s, 3H, OMe), 3.5—3.7 (m, 2H), 3.8—3.9 (m, 2H), 3.9—4.1 (m, 1H), 4.3—4.5 (m, 1H), 4.92 (s, 1H, OH), 6.18 (s, 1H, OH), 6.4—6.6 (m, 2H, Arom H), 6.7—6.9 (m, 4H, Arom H), 6.9—7.2 (m, 3H, Arom H), 7.4—7.9 (m, 8H, Arom H), 8.5—8.8 (m, 7H, Arom H), 9.0—9.1 (m, 2H, Arom H); IR (KBr) 3300 (OH), 1678 (lactam), 1446, 1086, 766, 706 cm^{-1}. Found: C, 78.29; H, 6.01; N, 3.46%. Calcd for $C_{26}H_{23}NO_3$: C, 78.57; H, 5.83; N, 3.52%.

Irradiation of 3 and α-Methylstyrene (5f). A mixture (1.2 : 1) of diastereomers of 3-hydroxy-3-(2-methoxy-1-methyl-1-phenylethyl)-2-methyl-2,3-dihydro-1*H*-dibenz-[*e*,*g*]isoindol-1-one (**9f**): mp 184—188 °C; ^{1}H NMR δ=1.53 (s, 6H, 2CMe), 3.12 (s, 3H, NMe for the minor diastereomer), 3.27 (s, 3H, NMe for the major diastereomer), 3.56 (s, 3H, OMe), 3.58 (s, 3H, OMe), 3.63 and 4.35 (ABq, *J*=9.3 Hz, 2H, CH_2), 3.85 and 4.00 (ABq, *J*=9.8 Hz, 2H, CH_2), 5.84 (s, 1H, OH), 6.07 (s, 1H, OH), 6.7—7.8 (m, 18H, Arom H), 8.5—8.7 (m, 5H, Arom H), 8.77 (d, *J*=7.1 Hz, 1H, Arom H), 8.99 (d, *J*=9.0 Hz, 1H, Arom H); IR (KBr) 3300 (OH), 1676 (lactam), 1448, 1374, 762, 696 cm^{-1}. Found: C, 78.99; H, 6.35; N, 3.45%. Calcd for $C_{27}H_{25}NO_3$: C, 78.81; H, 6.12; N, 3.40%.

A mixture (1.2 : 1) of diastereomers of 3a-(2-methoxy-1-methyl-1-phenylethyl)-2-methyl-3a,11b-dihydro-1*H*-dibenz-[*e*,*g*]isoindol-1,3(2*H*)-dione (**10f**): mp 242—245 °C; ^{1}H NMR of the major diastereomer δ=1.31 (s, 3H, CMe), 2.90 (s, 3H, NMe), 3.30 (s, 3H, OMe), 3.89 and 4.37 (ABq, *J*=9.5 Hz, 2H, CH_2), 4.74 (s, 1H, CHC=O), 6.8—7.5 (m, 10H, Arom H), 7.62 (d, *J*=7.1 Hz, 1H), 7.84 (d, *J*=6.4 Hz, 1H), 7.92 (d, *J*=8.7 Hz, 1 H); ^{1}H NMR of the minor diastereomer δ=1.73 (s, 3H, CMe), 2.86 (s, 3H, NMe), 3.06 (s, 3H, OMe), 3.33 and 3.72 (ABq, *J*=16.8 Hz, 2H, CH_2), 4.25 (s, 1H, OH), 7.0—7.5 (m, 10H, Arom H), 7.74 (d, *J*=9.0 Hz, 1H, Arom H), 7.80 (d, *J*=7.8 Hz, 1H, Arom H), 7.85 (d, *J*=8.1 Hz, 1H, Arom H); IR (KBr) 1773 and 1698 (imide), 1448, 1382, 1296, 1108 cm^{-1}. Found: C, 78.73; H, 6.03; N, 3.37%. Calcd for $C_{27}H_{25}NO_3$: C, 78.81; H, 6.12; N, 3.40%.

Irradiation of 3 and 1,1-Diphenylethylene (5g). 2,2-Diphenylethyl methyl ether (**11g**) was identical with a sample prepared by irradiation of **5g**, *p*-dicyanobenzene, and phenanthrene (sensitizer) in methanol.[12]

(Received July 11, 1989)

The (*E*)- and (*Z*)-isomers (**2E** and **2Z**) of 3-*O*-benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hept-5-eno-1,4-furanose were subjected to Claisen rearrangement with triethyl orthoacetate. Possible two diastereomers were obtained as a 1 to 1 mixture from both of **2Z** and **2E**, and also from their 3-hydroxy or 3-siloxy derivatives. On the other hand, the rearrangement of the corresponding D-ribo derivative (**13Z**) and its 3-*O*-(*t*-butyldiphenylsilyl) derivative proceeded with a high level of diastereoselectivity. By contrast, the (*E*)-isomer of **13Z** showed no significant stereoselectivity, resulting in the formation of a diastereomeric mixture. The configurations of the introduced stereogenic centers by the rearrangements were unambiguously established by chemical transformations.

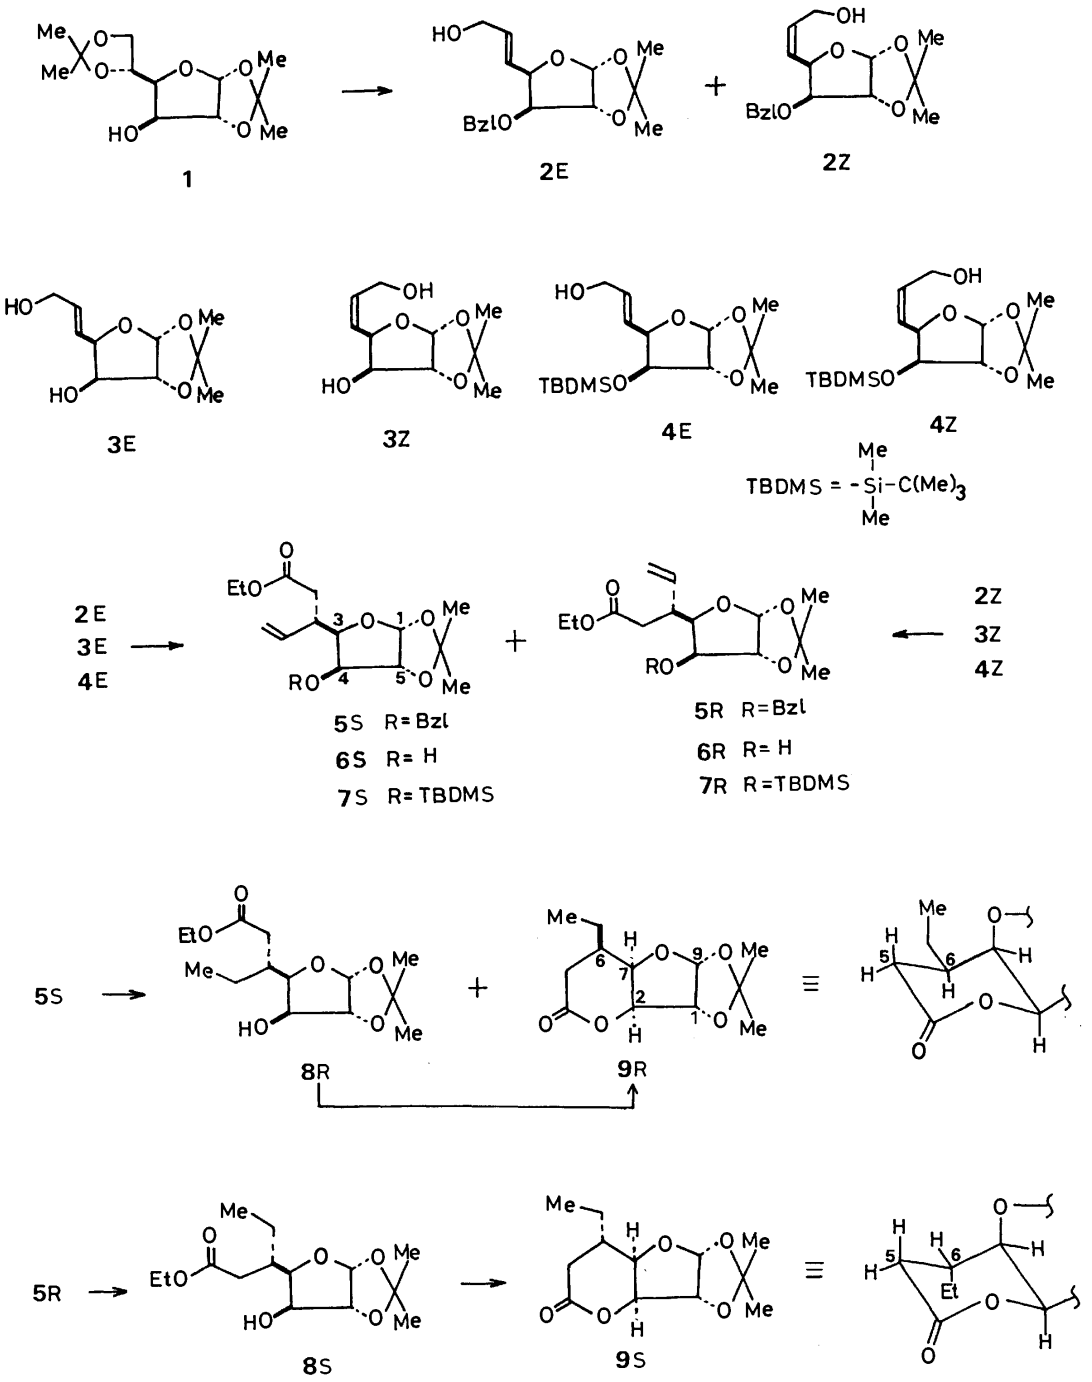
Recent extensive studies on [3.3] sigmatropic rearrangements represented by the Claisen-type rearrangement, as one of the promising protocol for stereoselective carbon-carbon bond forming reactions, widen their values through simple access to complex carbon frameworks found in natural products.[2)] In these several years, we focus our efforts on investigation of the ortho ester Claisen (Johnson-Claisen type) rearrangement of the carbohydrate-derived substrates.[3)] As a result, some versatile chiral building blocks, especially for natural products synthesis, are now available.[4)] In the course of pursuit of versatile chirons,[5)] herein, we report the Claisen rearrangement of two 5,6-dideoxyhept-5-eno-1,4-furanoses and some of their derivatives with triethyl orthoacetate. In the present work, the allyl alcohol part of each substrate is involved in the side chain on the furanose ring. These steric environments make the prediction of the stereochemical outcome of the rearrangement more difficult, in comparing with our previous results[3)] obtained by the rearrangements of 3-deoxy-3-*C*-[3-hydroxy-1-propenyl]hexofuranoses with triethyl orthoesters.

Results and Discussion

Rearrangement of Derivatives of 5,6-Dideoxy-α-D-*xylo*-hept-5-eno-1,4-furanose. We pursued first the Claisen rearrangement of some derivatives of 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hept-5-eno-1,4-furanose, namely, *E* and *Z* isomers of **2**, **3**, and **4**. The allyl alcohols **2E** and **2Z** were prepared from 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose (**1**) according to the known procedure.[6)] Compounds **3E** and **3Z** were prepared from **1** by standard functional group manipulation, namely, 1) selective removal of the 5,6-isopropylidene acetal by acid hydrolysis, 2) glycol cleavage with sodium periodate ($NaIO_4$), 3) Wittig olefination with (ethoxycarbonylmethylene)-triphenylphosphorane,[7)] followed by 4) diisobutylaluminum hydride (Dibal-H) reduction.[8)] The *O*-silyl derivatives **4E** and **4Z** were prepared from the 3-*O*-(*t*-butyldimethylsilyl) derivative of **1** by the analogous reaction sequence used for the preparation of **3**. In the preparation of **4**, acid hydrolysis (60% aqueous AcOH) of 3-*O*-(*t*-butyldimethylsilyl)-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose was troublesome, and the desired mono isopropylidene derivative was obtained in 12% yield along with substantial amount of 1,2-*O*-isopropylidene-α-D-glucofuranose. We did not optimize the reaction conditions.

The Claisen rearrangement of **2E** with triethyl orthoacetate was performed according to the original procedure.[9)] By repeated silica-gel chromatography of the reaction mixture, two rearrangement products **5S** and **5R** were obtained in 42% and 40% yields, respectively. The unreacted **2E** was also recovered in 8% yield. The *Z* isomer **2Z** was exposed to the same reaction conditions, resulting in the non-stereoselective formation of **5S** (35%) and **5R** (29%) along with recovery of **2Z** (13%). Establishment of the introduced stereogenic centers in diastereomers **5S** and **5R** was achieved by chemical transformation (vide infra). The rearrangements were also explored for **3** and **4**. None of **3E**, **3Z**, **4E**, or **4Z** provided the rearrangement product stereoselectively. In the case of **3E**, two diastereomers **6S** and **6R** were obtained in an approximately 1:1.4 ratio.[10)] Besides, the *Z* isomer **3Z** gave two products in an approximately 1:1 ratio. The silyl ether **4E** gave an approximately 1.4:1 ratio of **7S** and **7R** in a combined yield of 79%,[11)] while the *Z*-isomer **4Z** provided a 55% combined yield of the diastereomeric mixture in an approximately 2:1 ratio with a slightly improved formation of **7S**.

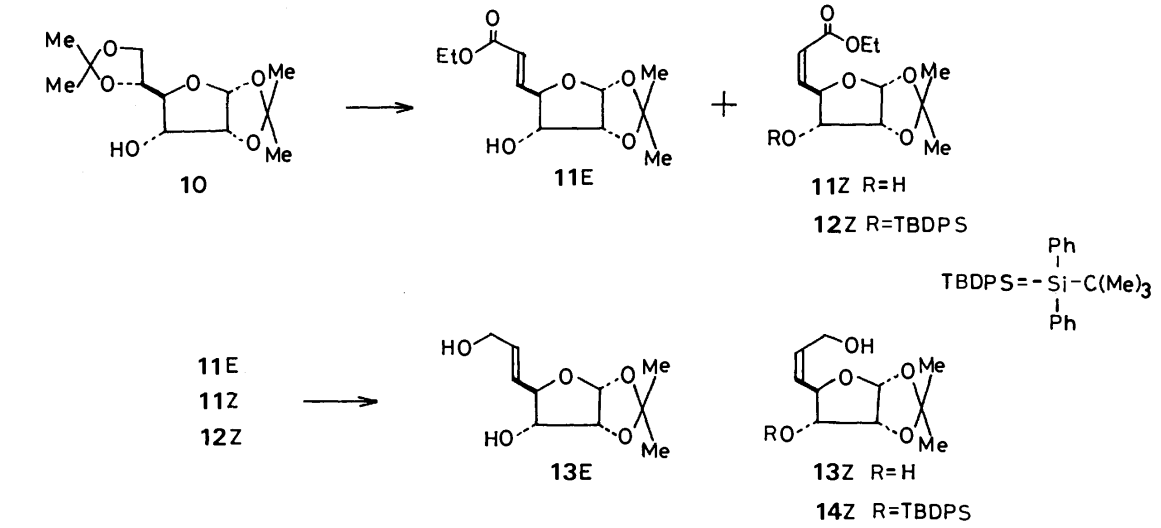
The newly introduced stereogenic centers in **5S** and **5R** were determined by the following transformations. The product with *S*-configuration **5S** was treated with cyclohexene in the presence of $Pd(OH)_2$ on charcoal resulting in the formation of a mixture of **8R** and **9R**. Under these reaction conditions, debenzylation and

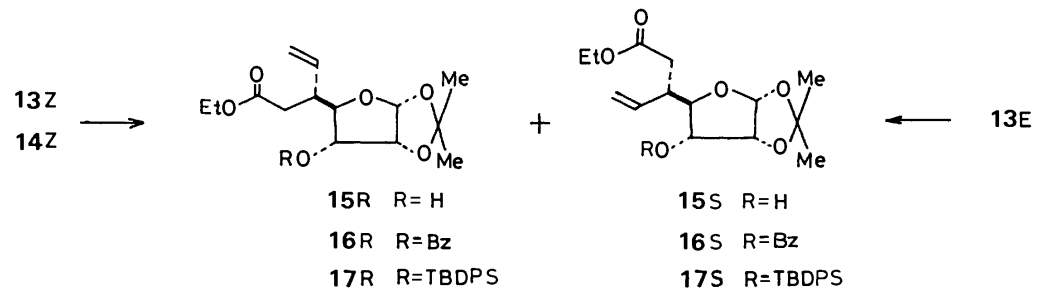


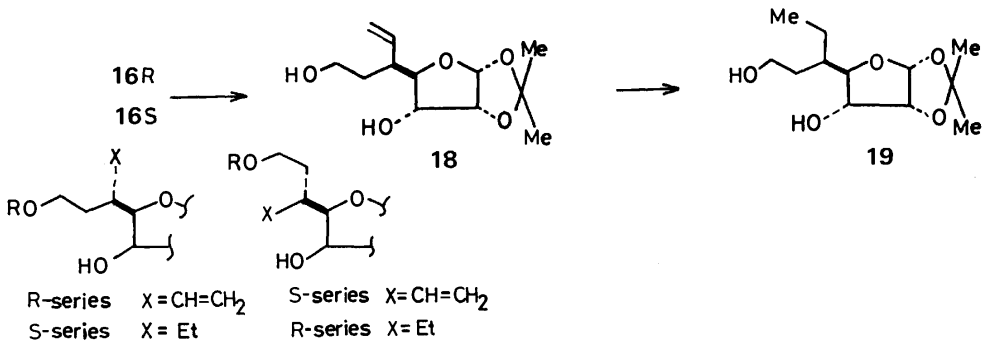
saturation of the double bond took place. δ-Lactonization of **8R** to **9R** was promoted by passage of the mixture through silica gel. The mixture of **8R** and **9R** was treated with silica gel for completion of lactonization. Finally, the tricyclic δ-lactone **9R** was obtained in an overall yield of 66.5%. Analogously, the *R*-diastereomer **5R** was converted into **8S**. Interestingly, no lactonization was observed in this case. Acid (*p*-TsOH) catalyzed lactonization of **8S** smoothly gave the lactone **9S** in 61% from **5R**. Both of ^{1}H NMR spectra (400 MHz) of the tricyclic δ-lactones **9R** and **9S** clarified their structures. The conformations of **9R** and **9S** were also confirmed as depicted. In the ^{1}H NMR spectrum of **9R**, H-5_{ax} and 5_{eq} appeared at δ 2.40 and 2.53 with $J_{5ax,6}$=12.8 Hz, $J_{5eq,5ax}$=17.5 Hz and with $J_{5eq,6}$=5.3 Hz, $J_{5eq,5ax}$=17.5 Hz, respectively. On the other hand, those of **9S** appeared at δ 2.27 and 2.70 with $J_{5ax,6}$=6.8 Hz, $J_{5eq,5ax}$=16.6 Hz, and with $J_{5eq,6}$=5.4 Hz, $J_{5eq,5ax}$=16.6 Hz, respectively. These results indicate that the ethyl groups in **9R** and **9S** are equatorial- and axial-orientations, respectively. Therefore, configurations of the newly introduced stereogenic centers in **5S** and **5R** were unequivocally established.

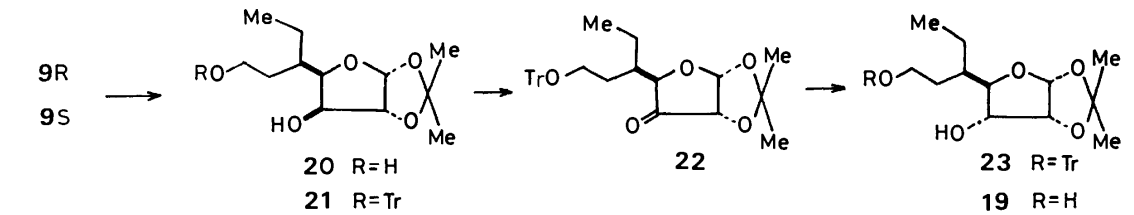
Rearrangement of Derivatives of 5,6-Dideoxy-α-D-*ribo*-hept-5-eno-1,4-furanose. For pursuit of improving the stereoselectivity, we next executed the rearran-

gement of derivatives of 5,6-dideoxy-α-D-*ribo*-hept-5-eno-1,4-furanose, **13** and **14**. The standard procedures from the known 1,2:5,6-di-*O*-isopropylidene-α-D-allofuranose (**10**)[12] provided efficiently the substrates **13** and **14**. Namely, selective removal of the 5,6-isopropylidene acetal in **10** by acid hydrolysis, glycol cleavage of the 5,6-diol with $NaIO_4$ followed by Wittig reaction with (ethoxycarbonylmethylene)triphenylphosphorane resulted in the formation of α,β-unsaturated esters **11E** and **11Z**, which were readily separated by silica-gel chromatography, in 43% and 31% yields from **10**, respectively.[13] Dibal-H reduction of **11E** and **11Z** provided the allyl alcohols **13E** and **13Z** effectively. Besides, silylation of the *Z*-isomer **11Z** with *t*-butyldiphenylchlorosilane gave the silyl ether **12Z** quantitatively. Silylation was carried









out for *Z*-isomer **11Z** by reason that the rearrangement of the *Z*-isomer **13Z** proceeded with significant stereoselectivity (vide infra). Reduction of **12Z** gave the other substrate **14Z**.

The Claisen rearrangement of **13Z** with triethyl orthoacetate gave an inseparable mixture of **15R** and **15S** in a combined yield of 72%. To determine the ratio of **15R** and **15S** accurately, the mixture was converted into the benzoates **16R** and **16S**, which were readily separated by silica-gel chromatography. From the yields of **16R** and **16S**, the ratio of the rearrangement products **15R** and **15S** was determined to be 11 : 70. On the other hand, *E*-isomer **13E** provided a mixture of **15R** and **15S** in a combined yield of 71% with an approximately 1 : 1.3 ratio. *E*-Isomer **13E** showed no significant stereoselectivity. Furthermore, the rearrangement of the silylated derivative **14Z** proceeded with an improved stereoselectivity to afford an inseparable mixture of **17R** and **17S** in a combined yield of 48%. The ratio (approximately 1 : 8) of **17R** and **17S** was determined by conversion of the mixture into separable **16R** and **16S** by desilylation followed by benzoylation.

The stereochemical assignment of the introduced stereogenic centers in **15R** and **15S** was achieved as follows. Both benzoates **16R** and **16S** were converted into **19S** and **19R** via vinyl-alcohols **18R** and **18S** by $LiAlH_4$ reduction of the ester groups followed by hydrogenation of the vinyl groups. On the other hand, the stereochemically defined δ-lactones **9R** and **9S** were converted into diols **20R** and **20S** by $LiAlH_4$ reduction. Tritylation of **20R** and **20S** under the standard conditions gave mono-trityl ethers **21R** and **21S** quantitatively. Pyridinium chlorochromate (PCC) oxidation[14] of **21R** and **21S** and subsequent $NaBH_4$ reduction of the 3-uloses **22R** and **22S** provided **23R** and **23S**, respectively. As anticipated, the hydride attacks to **22R** and **22S** took place exclusively from the less hindered convex-face to give **23R** and **23S**. Exposure of **23R** to *p*-toluenesulfonic acid provided the detritylated product, which was found to be identical with **19R** by direct comparison (mp, IR, and ^1H NMR). The detritylated product of **23S** was identical with **19S** in all respects. Therefore, the structures of **15R** and **15S** were established.

One of the stereocontrolling factors in the Claisen rearrangement is, in general, a steric environment surrounding the six membered transition state that consists of the intermediary allylic ketene acetal. As concerns the stereochemical outcome of the aforementioned ortho ester Claisen rearrangements, it is most likely that the C-3 substituent of each substrate interacts with the intermediary allylic ketene acetal moiety. It was forecasted that the interactions occurred between the C-3 substituents in **2**, **3**, and **4** and each of the intermediary ketene acetal moiety were more severe than those occurred in the case of substrates **13** and **14**. Unexpectedly, the results of the present work revealed that the C-3 substituent in **2**, **3**, or **4** was not likely to work as a stereocontrolling factor, irrespective of its bulkiness or of the allylic geometry. On the contrary, the C-3 substituents of *ribo*-type substrates possessing *Z*-allyl alcohol part, i.e. **13Z** and **14Z**, seem to contribute largely for outcome of the high-stereoselectivity in their rearrangement reactions. In the case of **13Z** and **14Z**, the transition state (A) shown in Fig. 1, which leads the formation of the major *S*-rearrangement product, seems to be favorable than the alternative transition state (B). This assumption is based on that nonbonded interaction between the C-3 substituent and the ethoxy group in the ketene acetal moiety is not negligible in the case of transition state (B). Furthermore, the influence of this interaction on the stereoselectivity of the rearrangement would be proportional to the bulkiness of the C-3 substituent. In fact, the stereoselectivity was slightly improved when a hydroxy group (i.e. **13Z**) was substituted by a (*t*-butyldiphenylsilyl)oxy group (i.e. **14Z**). Speculation of the transtion state, made by using Dreiding models, also reveals that high-stereoselective formation of either diastereomer is not expected for **13E**. No preferential transition state is considered in this case. Although we have no valid evidence for these explanations, the Claisen rearrangement protocol demonstrated in the present work is a practical access to highly functionalized enantiomerically pure building blocks.

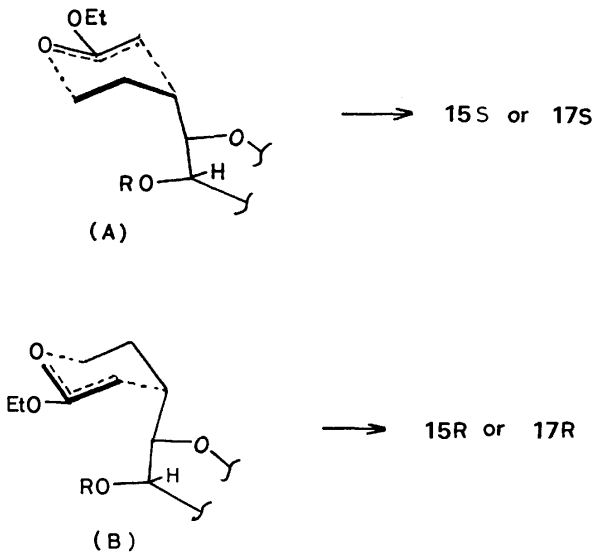


Fig. 1.

Experimental[15]

***E* and *Z* Isomers of 3-*O*-Benzyl-5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hept-5-eno-1,4-furanose (2E and 2Z).** These compounds were prepared according to the reported procedure.[6] **2E**: TLC R_f 0.15 (AcOEt/hexane 1 : 3); $[\alpha]_D^{27}$ −60.9° (*c* 1.22, $CHCl_3$). **2Z**: TLC R_f 0.19 (AcOEt/hexane 1 : 3); $[\alpha]_D^{28}$ −92.9° (*c* 1.10, $CHCl_3$).

***E* and *Z* Isomers of 5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hept-5-eno-1,4-furanose (3E and 3Z).** 1,2-*O*-Isopropylidene-α-D-glucofuranose (2.39 g), which was obtained by hydrolysis of **1** with 80% aqueous AcOH, was subjected to $NaIO_4$ oxidation (3.0 g in aqueous MeOH, 3 : 5 v/v, 64 ml). The reaction mixture was filtered, and the filtrate was concentrated in vacuo to give an aldehyde, which was used without purification. The aldehyde was dissolved in benzene (50 ml) and (ethoxycarbonylmethylene)triphenylphosphorane (5.0 g) was added. The mixture was stirred for 45 min, and concentrated in vacuo. The residue was chromatographed on silica gel (EtOAc/hexane 1 : 4) to give a mixture of *E*- and *Z*- α,β-unsaturated esters and *Z*-δ-lactone (2.44 g). Dibal-H (1.5 mol dm^{-3} solution in $PhCH_3$, 19 ml) reduction of the mixture in CH_2Cl_2 (40 ml) at −60 °C, and silica-gel chromatographic purification of the reaction mixture (AcOEt/hexane 1 : 1) gave **3E** (509 mg, 22%), **3Z** (356 mg, 15%), and a diastereomeric mixture of the hemiacetals derived from *Z*-δ-lactone (584 mg, 25%). **3E**: mp 70—71.5 °C, TLC R_f 0.43 (AcOEt); $[\alpha]_D^{87}$ −54.1° (*c* 1.53, $CHCl_3$); IR (KBr) ν_{max} 3410, 3230, 2965, 2865, 1630, 1375 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.32, 1.50 (3H each, 2 s), 3.50, 3.67 (1H each, 2 br s), 4.08 (1H, d, *J*=2.4 Hz), 4.16 (2H, br s), 4.54 (1H, d, *J*=3.7 Hz), 4.68 (1H, dd, *J*=1.0 and 4.8 Hz), 5.78 (1H, ddt, *J*=15.6, 4.8, and 1.0 Hz), 5.94 (1H, d, *J*=3.7 Hz), 6.05 (1H, ddt, *J*=15.6, 4.9, and 1.0 Hz). Found: C, 55.49; H, 7.19%. Calcd for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46%. **3Z:** mp 90.5—92 °C, TLC R_f 0.51 (AcOEt); IR (KBr) ν_{max} 3435, 2990, 2855, 1640, 1460 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.33, 1.51 (3H each, 2 s), 2.98, 3.20 (1H each, 2 s), 4.12—4.19 (2H, m), 4.30 (1H, dd, *J*=6.8 and 13.1 Hz), 4.57 (1H, d, *J*=3.9 Hz), 4.93 (1H, d, *J*=6.4 Hz), 5.65 (1H, dd, *J*=6.4 and 11.5 Hz), 5.91—5.98 (2H, m). Found: C, 55.54; H, 7.22%. Calcd for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46%.

***E* and *Z* Isomers of 3-*O*-(*t*-Butyldimethylsilyl)-5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hept-5-eno-1,4-furanose (4E and 4Z).** Compound **1** (5.00 g) was silylated with *t*-butylchlorodimethylsilane (4.36 g) in DMF (80 ml) in the presence of imidazole (1.23 g). Extractive work-up and chromatographic purification on silica gel gave the 3-*O*-silyl derivative (6.78 g, 94%) as a colorless oil, TLC R_f 0.18 (AcOEt/hexane 1:30): ^1H NMR (90 MHz, $CDCl_3$) δ=0.13, 0.14 (3H each, 2 s), 0.91 (9H, s), 1.32, 1.40, 1.49 (3H, 3H, 6H, 3 s), 4.04—4.26 (5H, m), 4.34 (1H, d, *J*=3.5 Hz), 5.87 (1H, d, *J*=3.5 Hz).

The 3-*O*-silyl derivative (6.77 g) was hydrolyzed with 60% aqueous AcOH (160 ml) and 1,4-dioxane (10 ml) for 30 min at room temperature. The mixture was concentrated in vacuo, and the residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1:20) to give 3-*O*-(*t*-butyldimethylsilyl)-1,2-*O*-isopropylidene-α-D-glucofuranose (721 mg, 12%) as a colorless oil. This mono-isopropylidene derivative (721 mg) was dissolved in MeOH (26 ml) and $NaIO_4$ (534 mg) in H_2O (4.4 ml) was added. After stirring for 1.5 h, the mixture was filtered. The filtrate was concentrated in vacuo. The residue was dissolved in benzene (25 ml), (ethoxycarbonylmethylene)triphenylphosphorane (1.49 g) was added. The mixture was stirred for 1 h, concentrated in vacuo. The residue was triturated with petroleum ether. The precipitated triphenylphosphine oxide was removed, and the filtrate was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 60) to give the *E*-α,β-unsaturated ester [407 mg, 51%, TLC R_f 0.59 (EtOH/$PhCH_3$ 1 : 30)] and the *Z*-α,β-unsaturated ester [346 mg, R_f 0.72 (EtOH/$PhCH_3$ 1 : 30)]. Each α,β-unsaturated ester was reduced with Dibal-H at −60 °C. After chromatographic purification of the reaction mixture on silica gel, **4E** (99%) and **4Z** (88%) were obtained. **4E**, TLC R_f 0.26 (AcOEt/hexane 1:3): $[\alpha]_D^{26}$ −42.4° (*c* 0.90, $CHCl_3$); IR (neat) ν_{max} 3425, 2925, 2850, 1470, 1460 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.06, 0.09 (3H each, 2 s), 0.90 (9H, s), 1.33, 1.55 (3H each, 2 s), 4.09 (1H, d, *J*=2.9 Hz), 4.15, 4.19 (1H each, 2 s), 4.39 (1H, d, *J*=3.7 Hz), 4.61 (1H, dd, *J*=2.9 and 6.4 Hz), 5.81—5.94 (2H, m), 5.92 (1H, d, *J*=3.7 Hz). Found: C, 57.76; H, 8.83%. Calcd for $C_{16}H_{30}O_5Si$: C, 58.15; H, 9.15%. **4Z**, TLC R_f 0.21 (AcOEt/hexane 1 : 5): $[\alpha]_D^{25}$ −63.6° (*c* 1.28, $CHCl_3$); IR (neat) ν_{max} 3460, 2950, 2880, 1480, 1470 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.07, 0.09 (3H each, 2 s), 0.89 (9H, s), 1.33, 1.51 (3H each, 2 s), 1.93 (1H, s), 4.08 (1H, d, *J*=2.9 Hz), 4.19—4.31 (2H, m), 4.40 (1H, d, *J*=3.6 Hz), 4.91 (1H, dd, *J*=2.9 and 7.4 Hz), 5.51—6.05 (2H, m), 5.93 (1H, d, *J*=3.6 Hz). Found: C, 57.90; H, 8.84%. Calcd for $C_{16}H_{30}O_5Si$: C, 58.15; H, 9.15%.

(1*R*,3*R*,4*S*,5*R*)-4-Benzyloxy-3-[(1*S*)- and (1*R*)-1-(ethoxycarbonyl)methyl-2-propenyl]-7,7-dimethyl-2,6,8-trioxabicyclo[3.3.0]octanes (5S and 5R). From 2E. The reaction was carried out under an argon atmosphere. A solution of **2E** (1.82 g, 5.9 mmol) in freshly distilled triethyl orthoacetate (20 ml) was heated in the presence of 0.013 ml of distilled propionic acid at 135 °C for 5 h. The reaction mixture was then concentrated in vacuo with an aid of $PhCH_3$. The residue was repeatedly chromatographed on silica gel (AcOEt/hexane 1 : 15). The rearrangement products **5S** (940 mg, 42%) and **5R** (901 mg, 40%) were obtained and **2E** (138 mg, 8%) was recovered. **5S**: mp 56—58 °C, R_f 0.21 (AcOEt/hexane 1 : 10); $[\alpha]_D^{28}$ −33.9° (*c* 0.83, $CHCl_3$); IR (neat) ν_{max} 3010, 2960, 2900, 1740, 1650, 1510, 1465, 1380, 1265, 1225 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.22 (3H, t, *J*=7.3 Hz), 1.31, 1.49 (3H each, 2 s), 2.39 (1H, dd, *J*=10.3 and 15.4 Hz), 2.81 (1H, dd, *J*=4.2 and 15.4 Hz), 3.17 (1H,dddd, *J*=4.2, 7.6, and 10.3 Hz), 3.82 (1H, d, *J*=3.0 Hz), 4.03 (1H, dd, *J*=3.0 and 10.3 Hz), 4.10 (2H, q, *J*=7.3 Hz), 4.47, 4.63 (2H each, 2 d, *J*=11.5 Hz), 4.58 (1H, d, *J*=3.9 Hz), 5.06 (1H, dd, *J*=1.5 and 10.3 Hz), 5.14 (1H, dd, *J*=1.5 and 18.8 Hz), 5.67 (1H, ddd, *J*=7.6, 10.3, and 18.8 Hz), 5.90 (1H, d, *J*=3.9 Hz), 7.28—7.37 (5H, m). Found: C, 66.88; H, 7.36%. Calcd for $C_{21}H_{28}O_6$: C, 67.00; H, 7.50%. **5R:** mp 47.5—49 °C, TLC R_f 0.19 (AcOEt/hexane 1 : 10); $[\alpha]_D^{28}$ −27.1° (*c* 0.98, $CHCl_3$); IR (neat) ν_{max} 2990, 2940, 1735, 1650, 1500, 1460, 1375, 1260 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.24 (3H, t, *J*=7.3 Hz), 1.32, 1.48 (3H each, 2 s), 2.16—2.28 (2H, m), 3.07—3.15 (1H, m), 3.85 (1H, d, *J*=3.3 Hz), 4.05 (1H, dd, *J*=3.3 and 9.5 Hz), 4.08 (2H, q, *J*=7.3 Hz), 4.46, 4.73 (2H each, 2 d, *J*=11.7 Hz), 4.64 (1H, d, *J*=3.9 Hz), 5.11 (1H, dd, *J*=1.5 and 10.3 Hz), 5.17 (1H, dd, *J*=1.5 and 17.1 Hz), 5.81 (1H, ddd, *J*=7.8, 10.3, and 17.1 Hz), 5.93 (1H, d, *J*=3.9 Hz), 7.30—7.37 (5H, m). Found: C, 66.78; H, 7.27%. Calcd for $C_{21}H_{28}O_6$: C, 67.00; H, 7.50%.

From 2Z. Compoud **2Z** (1.59 g) was subjected to the Claisen rearrangement under the same reaction conditions as above. Silica-gel chromatography of the reaction mixture gave 675 mg (35%) of **5S** and 563 mg (29%) of **5R**, and 202 mg (13%) of **2Z** was also recovered.

Claisen Rearrangement of 3E and 3Z and Successive $LiAlH_4$ Reduction of the Products. From 3E. Compound **3E** (550 mg) was heated at 135 °C in triethyl orthoacetate (5 ml) in the presence of catalytic propionic acid for 5.5 h.

The reaction mixture was concentrated in vacuo, and the residue was chromatographed on silica gel (AcOEt/hexane 1 : 6) to give a mixture of **6S**, **6R**, and their δ-lactone derivatives (472 mg). This mixture (472 mg) was reduced with $LiAlH_4$ (116 mg) in THF (24 ml) for 1 h. The mixture was quenched with H_2O, filtered, and the filtrate was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 1) to give a diol derived from **6S** (144 mg, 23% from **3E**), a diol derived from **6R** (209 mg, 34%), and a mixture of them (21 mg, 3%). Diol derived from **6S**, TLC R_f 0.59 (AcOEt): $[\alpha]_D^{26}$+12.1° (*c* 1.99, $CHCl_3$); ^1H NMR (90 MHz, $CDCl_3$) δ=1.30, 1.49 (3H each, 2 s), 1.56—2.21 (2H, m), 2.49—2.86 (1H, m), 3.00 (2H, br s), 3.58—4.05 (5H, m), 4.49 (1H, d, *J*=4.0 Hz), 5.15 (1H, dd, *J*=2.7 and 8.4 Hz), 5.22 (1H, dd, *J*=2.7 and 17.8 Hz), 5.65 (1H, dd, *J*=8.4 and 17.8 Hz), 5.89 (1H, d, *J*=4.0 Hz). Diol derived from **6R**, TLC R_f 0.46 (AcOEt): $[\alpha]_D^{26}$=−32.9° (*c* 1.96, $CHCl_3$); ^1H NMR (90 MHz, $CDCl_3$) δ=1.30, 1.48 (3H each, 2 s), 1.42—1.87 (2H, m), 2.44—2.79 (1H, m), 3.34 (2H, br s), 3.47—4.18 (4H, m), 4.50 (1H, d, *J*=3.8 Hz), 5.07—5.24 (2H, m), 5.71 (1H, dd, *J*=9.2 and 17.8 Hz), 5.89 (1H, d, *J*=3.8 Hz).

From 3Z. Rearrangement of **3Z** (327 mg), and successive $LiAlH_4$ reduction of the products as described for **3E** resulted in formation of an approximately 1 : 1 mixture of the diols derived from 6S and **6R** (103.5 mg, 28% from **3Z**). The ratio was estimated based on the ^1H NMR (400 MHz) spectral analysis, though the diastereomers were not separated.

(1*R*,3*R*,4*S*,5*R*)-4-(*t*-Butyldimethylsilyloxy)-3-[(1*S*)- and (1*R*)-1-(ethoxycarbonyl)methyl-2-propenyl]-7,7-dimethyl-2,5,8-trioxabicyclo[3.3.0]octanes (7S and 7R). From 4E. Compound **4E** (376 mg) was heated in triethyl orthoacetate (12 ml) at 135 °C in the presence of catalytic amount of propionic acid for 5 h. Concentration of the reaction mixture, and chromatographic purification of the residue on silica gel (AcOEt/hexane 1 : 25) gave **7S** (202 mg, 44%), **7R** (142 mg, 31%), and a mixture of **7S** and **7R** (16 mg, 4%). **7S:** TLC R_f 0.55 (AcOEt/hexane 1 : 5); $[\alpha]_D^{28}$−27.4° (*c* 1.23, $CHCl_3$); IR (neat) ν_{max} 2990, 2960, 2840, 1740, 1470 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.08, 0.14 (3H each, 2 s), 0.92 (9H, s), 1.22 (3H, t, *J*=7.2 Hz), 1.31, 1.48 (3H each, 2 s), 2.22—2.78 (2H, m), 2.92—3.25 (1H, m), 3.92—4.11 (2H, m), 4.10 (2H, q, *J*=7.2 Hz), 4.36 (1H, d, *J*=3.7 Hz), 5.04—5.07 (1H, m), 5.15—5.17 (1H, m), 5.23—5.26 (1H, m), 5.85 (1H, d, *J*=3.7 Hz). **7R:** TLC R_f 0.48 (AcOEt/hexane 1 : 5); $[\alpha]_D^{28}$−17.5° (*c* 1.27, $CHCl_3$); IR (neat) ν_{max} 2990, 2960, 2860, 1740, 1640, 1470 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.13, 0.16 (3H each, 2 s), 0.92 (9H, s), 1.23 (3H, t, *J*=7.1 Hz), 1.30, 1.47 (3H each, 2 s), 2.27—2.40 (2H, m), 2.84—3.21 (1H, m), 3.94—4.13 (2H, m), 4.11 (2H, q, *J*=7.1 Hz), 4.37 (1H, d, *J*=3.7 Hz), 5.05—5.06 (1H, m), 5.18—5.24 (1H, m), 5.67—5.78 (1H, m), 5.88 (1H, d, *J*=3.7 Hz).

From 4Z. As described above, compound **4Z** (114 mg) was subjected to the Claisen rearrangement to give **7S** (44 mg, 32%), **7R** (22 mg, 16%), and a mixture of **7S** and **7R** (9.5 mg, 7%).

(1*R*,2*S*,6*R*,7*R*,9*R*)-6-Ethyl-11,11-dimethyl-3,8,10,12-tetraoxatricyclo[7.3.0.0^{2,7}]dodecan-4-one (9R). A solution of 5S (88 mg, 0.23 mmol) in a mixture of EtOH (3 ml) and freshly distilled cyclohexene (5 ml) was refluxed for 3 h in the presence of 20% $Pd(OH)_2$ on charcoal (133 mg). The catalyst was removed by filtration, washed with EtOH. The combined filtrate and washings were concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 5) to give **9R** (25 mg, 44%) and a mixture of the hydroxy ester **8R** and **9R** (37 mg). The mixture of **8R** and **9R** (37 mg) was dissolved in AcOEt/hexane (1/5 v/v 1.5 ml), then silica gel (0.2 g) was added. The mixture was kept standing at room temperature for 3.5 d. Then, the silica gel was removed by filtration, washed with AcOEt. The combined filtrate and washings were concentrated in vacuo. The residue was chromatographed on silica gel to give **9R** (12.5 mg, total 37.5 mg, 66.5%) as a colorless oil. **9R:** TLC R_f 0.61 (AcOEt/hexane 1 : 2); $[\alpha]_D^{25}$−8.8° (*c* 0.85, $CHCl_3$); IR (neat) ν_{max} 2970, 2950, 2890, 1745, 1460, 1375, 1300, 1220 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=0.99 (3H, t, *J*=7.5 Hz), 1.34, 1.52 (3H each, 2 s), 1.44—1.68 (2H, m), 1.97—2.06 (1H, m), 2.40 (1H, dd, *J*=12.8 and 17.5 Hz), 2.53 (1H, dd, *J*=5.3 and 17.5 Hz), 4.42 (1H, dd, *J*=2.0 Hz), 4.68 (1H, d, *J*=3.7 Hz), 4.70 (1H, d, *J*=2.0 Hz), 5.92 (1H, d, *J*=3.7 Hz). Found: C, 59.36; H, 7.26%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%.

(1*R*,2*S*,6*S*,7*R*,9*R*)-6-Ethyl-11,11-dimethyl-3,8,10,12-tetraoxatricyclo[7.3.0.0^{2,7}]dodecan-4-one (9S). As desdribed for the preparation of **9R**, 119 mg (0.32 mmol) of **5R** was analogously converted into crude **8S** (99.5 mg), which was lactonized directly. The crude **8S** (99.5 mg) was dissolved in benzene (3 ml) and *p*-TsOH (monohydrate, 15 mg) was added. The mixture was stirred at room temperature for 3 h, and saturated aqueous $NaHCO_3$ (2 ml) was added. This was diluted with benzene (15 ml) and washed with H_2O (10 ml×3). The organic phase was dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 8) to give **9S** (47 mg, 61%), mp 69—70 °C, TLC R_f 0.69 (AcOEt/hexane 1 : 2); $[\alpha]_D^{24}$+28.8° (*c* 1.21, $CHCl_3$); IR (neat) ν_{max} 2970, 2940, 2870, 1730, 1460, 1370, 1250 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.03 (3H, t, *J*=7.3 Hz), 1.34, 1.52 (3H each, 2 s), 1.36—1.60 (2H, m), 2.09—2.17 (1H, m), 2.27 (1H, dd, *J*=6.8 and 16.6 Hz), 2.70 (1H, dd, *J*=5.4 and 16.6 Hz), 4.30 (1H, dd, *J*=3.4 Hz), 4.66 (1H, d, *J*=3.4 Hz), 4.73 (1H, d, *J*=3.4 Hz), 5.95 (1H, d, *J*=3.4 Hz). Found: 59.54; H, 7.29%. Calcd for $C_{12}H_{18}O_5$: C, 59.49; H, 7.49%.

***E* and *Z* Isomers of Ethyl 5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*ribo*-hept-5-eno-1,4-furanuronates (11E and 11Z).** A solution of **10**[12] (4.02g, 15.4 mmol) in 60% aqueous AcOH (80 ml) was stirred for 14 h and concentrated in vacuo. The residue [R_f 0.22 (EtOH/$PhCH_3$ 1 : 5)] was dissolved in MeOH (80 ml), and an aqueous solution (15 ml) of $NaIO_4$ (4.01 g, 18.7 mmol) was added. After being stirred for 1 h, insoluble solids were removed. The filtrate was concentrated in vacuo. The residue was triturated with CH_2Cl_2, and insoluble solids were removed. The filtrate was concentrated in vacuo. The residue [R_f 0.52 (EtOH/$PhCH_3$ 1 : 5)] was dissolved in benzene (80 ml) and (ethoxycarbonylmethylene) triphenylphosphorane (8.07 g, 23.2 mmol) was added. The mixture was stirred at room temperature for 1 h and concentrated in vacuo. The residue was triturated with petroleum ether, and insoluble triphenylphosphine oxide was removed. The filtrate was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 4) to give 1.72 g (43%) of **11E** and 1.24 g (31%) of **11Z** (73 mg of the mixture was also obtained). **11E:** mp 51—52 °C, TLC R_f 0.54 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{27}$ +33.3° (*c* 1.18, $CHCl_3$); IR (KBr) ν_{max} 3470, 2985, 2950, 1720, 1645, 1465, 1445, 1425, 1385 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.29

(3H, t, J=7.1 Hz), 1,38, 1.58 (3H each, 2 s), 2.61 (1H, d, J=10.8 Hz), 4.18 (2H, q, J=7.1 Hz), 3.71—4.42 (2H, m), 4.60 (1H, dd, J=4.2 Hz), 5.86 (1H, d, J=4.2 Hz), 6.13 (1H, dd, J=1.5 and 15.8 Hz), 7.00 (1H, dd, J=4.5 and 15.8 Hz). Found: C, 55.80; H, 6.72%. Calcd for $C_{12}H_{18}O_6$: C, 55.81; H, 7.02%. **11Z:** mp 103—105 °C, TLC R_f 0.58 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{28}$ −23.0° (*c* 1.08, $CHCl_3$); IR (KBr) ν_{max} 3480, 2980, 1720, 1655, 1220 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.29 (3H, t, J=7.0 Hz), 1.38, 1.62 (3H each, 2 s), 3.41 (1H, d, J=9.0 Hz), 3.75 (1H, ddd, J=4.3, 9.0, and 9.0 Hz), 4.19 (2H, q, J=7.0 Hz), 4.60 (1H, dd, J=4.3 Hz), 5.49 (1H, dd, J=7.1 and 9.0 Hz), 5.80 (1H, d, J=4.3 Hz), 5.99 (1H, d, J=11.8 Hz), 6.22 (1H, dd, J=7.1 and 11.8 Hz). Found: C, 55.95; H, 6.79%. Calcd for $C_{12}H_{18}O_6$: C, 55.81; H, 7.02%.

***Z* Isomer of Ethyl 3-*O*-(*t*-Butyldiphenylsilyl)-5,6-dideoxy-1,2-isopropylidene-α-D-*ribo*-hept-5-eno-1,4-furanuronate (12Z).** A mixture of **11Z** (326 mg, 1.3 mmol), *t*-butylchlorodiphenylsilane (0.66 ml, 2.5 mmol), and imidazole (341 mg) in DMF (6 ml) was stirred at room temperature for 7 h. The mixture was diluted with CH_2Cl_2 (30 ml), wahsed with dilute HCl (30 ml), saturated aqueous $NaHCO_3$ (30 ml), and H_2O (30 ml) successively. The organic phase was dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 15) to give **12Z** (614 mg, 98%) as a colorless oil: TLC R_f 0.58 (AcOEt/hexane 1 : 4); $[\alpha]_D^{21}$ −30.8° (*c* 0.96, $CHCl_3$); IR (neat) ν_{max} 2985, 2955, 1720, 1650, 1470, 1425, 1380, 1370 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.04 (9H, s), 1.26, 1.65 (3H each, 2 s), 1.32 (3H, t, J=7.0 Hz), 3.64 (1H, dd, J=4.0 and 8.2 Hz), 3.98 (1H, dd, J=4.0 Hz), 4.20 (2H, q, J=7.0 Hz), 5.55 (1H, d, J=4.0 Hz), 5.68—6.01 (3H, m), 7.29—7.82 (10H, m). Found: C, 67.79; H, 7.10%. Calcd for $C_{28}H_{36}O_6Si$: C, 67.71; H, 7.31%.

***E* and *Z* Isomers of 5,6-Dideoxy-1,2-*O*-isopropylidene-α-D-*ribo*-hept-5-eno-1,4-furanoses (13E and 13Z).** The reaction was carried out under an argon atmosphere. To a solution of **11E** (777 mg, 3.0 mmol) in CH_2Cl_2 (15 ml) was injected Dibal-H (1.5 mol dm^{-3} solution in $PhCH_3$, 7.9 ml, 11.9 mmol) at −78 °C. After being stirred for 90 min, the mixture was quenched with H_2O (0.5 ml). Insoluble solids were removed, washed well with CH_2Cl_2. The combined filtrate and washings were concentrated in vacuo. The residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 15) to give **13E** (514 mg, 79%) as a colorless oil: TLC R_f 0.29 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{27}$ +31.1° (*c* 1.29, $CHCl_3$); IR (neat) ν_{max} 3400, 2990, 1645, 1375, 1215 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.33, 1.54 (3H each, 2 s), 2.4—2.7, 2.8—3.0 (1H each, 2 m), 3.52—3.78 (1H, m), 4.07—4.35 (3H, m), 4.53 (1H, dd, J=4.4 Hz), 5.53—5.79 (2H, m), 6.06 (1H, ddd, J=15.6, 4.6, and 4.6 Hz). Found: C, 55.18; H, 7.30%. Calcd for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46%.

As described above, 720 mg of **11Z** was analogously converted into 568 mg (94%) of **13Z**, mp 105—106 °C: TLC R_f 0.34 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{27}$ +56.6° (*c* 0.86, $CHCl_3$); IR (KBr) ν_{max} 3420, 2995, 1430, 1385, 1250 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.36, 1.57 (3H each, 2 s), 2.5—2.8, 3.1—3.3 (1H each, 2 m), 3.51—3.75 (1H, m), 4.12—4.19 (2H, m), 4.52—4.70 (2H, m), 5.46—5.67 (1H, m), 5.82 (1H, d, J=4.0 Hz), 5.91—6.12 (1H, m). Found: C, 55.51; H, 7.27%. Calcd for $C_{10}H_{16}O_5$: C, 55.55; H, 7.46%.

***Z*-Isomer of 3-*O*-(*t*-Butyldiphenylsilyl)-5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*ribo*-hept-5-eno-1,4-furanose (14Z).** Compound **12Z** (461 mg, 0.93 mmol) was treated with 5 mol equiv of Dibal-H as described for the preparation of **13E** and **13Z**. By chromatographic purification of the reaction mixture on silica gel, 419 mg (99%) of **14Z** was obtained, mp 92.5—93.5 °C: TLC R_f 0.52 (AcOEt/hexane 1 : 3); $[\alpha]_D^{21}$ +4.7° (*c* 1.33, $CHCl_3$); IR (neat) ν_{max} 3440, 2960, 2900, 1590, 1460, 1430, 1380, 1375, 1250 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.07 (9H, s), 1.21, 1.60 (3H each, 2 s), 1.79 (1H, d, J=6.1 Hz), 3.65 (1H, dd, J=4.1 and 8.8 Hz), 3.76 (1H, dd, J=4.1 Hz), 4.18—4.25, 4.32—4.38 (2H, m), 4.84 (1H, dd, J=8.8 Hz), 5.36—5.41 (1H, m), 5.50 (1H, d, J=4.1 Hz), 5.89—5.95 (1H, m), 7.35—7.77 (10H, m). Found: C, 68.35; H, 7.20%. Calcd for $C_{26}H_{34}O_5Si$: C, 68.69; H, 7.53%.

(1*R*,3*R*,4*R*,5*R*)-3-[(1*R*)- and (1*S*)-1-(Ethoxycarbonyl)methyl-2-propenyl]-4-hydroxy-7,7-dimethyl-2,6,8-trioxabicyclo-[3.3.0]octanes (15R and 15S). A solution of **13E** (1.32 g, 6.1 mmol) in freshly distilled triethyl orthoacetate (10 ml) was heated at 135 °C for 6.5 h in the presence of catalytic propionic acid. The reaction mixture was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 5) to give an inseparable mixture of **15R** and **15S** (1.25 g, 71% of combined yield) [TLC R_f 0.58 (EtOH/$PhCH_3$ 1:5)] as a colorless oil.

Analogously, the *Z*-isomer **13Z** (1.18 g) was heated at 135 °C in triethyl orthoacetate (20 ml) in the presence of catalytic propionic acid for 14 h. Concentration of the reaction mixture in vacuo and chromatographic purification of the residue gave the mixture of **15R** and **15S** (1.12 g, 72% of combined yield).

Benzoates 16R and 16S. From the Mixture 15R and 15S Obtained from 13E. The mixture (63 mg, 0.22 mmol) was benzoylated with benzoyl chloride (0.05 ml, 0.43 mmol) in pyridine (2 ml). After being stirred for 30 min, the mixture was concentrated in vacuo. The residue was partitioned between CH_2Cl_2 (20 ml) and H_2O (20 ml). The aqueous phase was extracted with CH_2Cl_2 (20 ml×2). The combined organic phases were dried (Na_2SO_4) and concentrated. The residue was chromatographed on silica gel (Et_2O/hexane 1 : 8) to give 41 mg (48%) of **16S**, 31 mg (36%) of **16R**, and 12 mg (14%) of an approximately 1 : 1 mixture of **16R** and **16S**. **16R:** a colorless oil, TLC R_f 0.20 (Et_2O/hexane 1 : 6); $[\alpha]_D^{23}$ +96.0° (*c* 0.83, $CHCl_3$); IR (neat) ν_{max} 2990, 1725, 1640, 1600, 1450, 1275 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.21 (3H, t, J=7.1 Hz), 1.31, 1.52 (3H each, 2 s), 2.54 (1H, dd, J=8.8 and 15.6 Hz), 2.63 (1H, dd, J=5.9 and 15.6 Hz), 2.91 (1H, dddd, J=3.7, 5.9, 8.8, and 8.8 Hz), 4.10 (2H, q, J=7.1 Hz), 4.35 (1H, dd, J=3.7 and 9.0 Hz), 4.81 (1H, dd, J=4.9 and 9.0 Hz), 4.91 (1H, dd, J=3.9 and 4.9 Hz), 4.93—5.18 (2H, m), 5.75 (1H, ddd, J=8.8, 10.3, and 17.1 Hz), 5.82 (1H, d, J=3.9 Hz), 7.45—8.08 (5H, m). Found: C, 64.87; H, 6.83%. Calcd for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%. **16S:** a colorless oil; TLC R_f 0.14 (Et_2O/hexane 1 : 6); $[\alpha]_D^{25}$ +103.9° (*c* 1.08, $CHCl_3$); IR (neat) ν_{max} 2990, 1725, 1640, 1600, 1450, 1375, 1275 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ=1.23 (3H, t, J=7.1 Hz), 1.31, 1.53 (3H each, 2 s), 2.42 (1H, dd, J=8.8 and 15.1 Hz), 2.71 (1H, dd, J=4.9 and 15.1 Hz), 2.87 (1H, dddd, J=4.9, 7.3, 8.3, and 8.8 Hz), 4.11 (2H, q, J=7.1 Hz), 4.27 (1H, dd, J=7.3 and 8.8 Hz), 4.79 (1H, dd, J=5.2 and 8.8 Hz), 4.92 (1H, dd, J=3.9 and 5.2 Hz), 5.03 (1H, dd, J=1.0 and 10.3 Hz), 5.14 (1H, dd, J=1.0 and 17.1 Hz), 5.76 (1H, ddd, J=8.3, 10.3 and 17.1 Hz), 5.85 (1H, d, J=3.9 Hz), 7.44—8.05 (5H, m). Found: C, 64.79; H, 6.71%. Calcd for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%.

From the Mixture Obtained from 13Z. The mixture of **15R** and **15S** (491 mg) was benzoylated as described above.

Extractive work-up and silica-gel chromatography of the extracts gave **16R** (76 mg, 11%) and **16S** (466 mg, 70%), which were identical with those obtained above (TLC, IR, and ^{1}H NMR).

Claisen Rearrangement of 14Z and Separation of the Diastereomers as the Benzoates 16R and 16S. Compound **14Z** (211 mg, 0.46 mmol) was heated at 135 °C in triethyl orthoacetate (4 ml) in the presence of catalytic propionic acid for 15 h. Then, the reaction mixture was concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 20) to give an inseparable mixture of **17R** and **17S** (118 mg) as a colorless oil [R_f 0.60 (AcOEt/hexane 1 : 3)].

The mixture (118 mg) was dissolved in THF (3 ml) and tetrabutylammonium fluoride (1.0 mol dm^{-3} solution in THF, 0.49 ml) was added. The mixture was stirred at room temperature for 1 h and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 5) to give an inseparable mixture of **15R** and **15S** (54 mg).

The mixture (54 mg) was benzolylated as described above. Silica-gel chromatography of the reaction mixture gave 7.8 mg (4.3% yield from **14Z**) of **16R** and 58.2 mg (32.1%) of **16S**.

(1*R*,3*R*,4*R*,5*R*)-4-Hydroxy-3-[(1*R*)- and (1*S*)-1-(2-hydroxyethyl)-2-propenyl]-7,7-dimethyl-2,6,8-trioxabicyclo[3.3.0]-octanes (18R and 18S). A solution of **16R** (30 mg, 0.07 mmol) in THF (2 ml) was stirred in the presence of $LiAlH_4$ (10 mg, 0.27 mmol) for 1 h. To the mixture was added H_2O (0.02 ml). The resulting solids were removed by filtration. The filtrate was concentrated in vacuo. The residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 15) to give **18R** (17 mg, 92%) as a colorless oil: TLC R_f 0.42 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{23}$ +6.3° (*c* 1.0, $CHCl_3$); IR (neat) ν_{max} 3390, 2940, 1640, 1500, 1455, 1375, 1315, 1220 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.34, 1.55 (3H each, 2 s), 1.62—2.12 (3H, m), 2.37—2.70 (2H, m), 3.46—3.82 (4H, m), 4.49 (1H, dd, *J*=4.3 Hz), 5.02—5.27 (2H, m), 5.74 (1H, d, *J*=4.3 Hz), 5.48—5.93 (1H, m). Found: C, 58.73; H, 8.05%. Calcd for $C_{12}H_{20}O_5$: C, 59.00; H, 8.25%.

Analogously, *S*-diastereomer **16S** (40 mg) was reduced with 3.0 mol equiv of $LiAlH_4$. Silica-gel chromatography of the reaction mixture gave **18S** (23 mg, 92%) as a colorless oil: TLC R_f 0.42 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{25}$ +53.7° (*c* 1.07, $CHCl_3$); IR (neat) ν_{max} 3390, 2940, 1640, 1455, 1380, 1375, 1240 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.35, 1.56 (3H each, 2 s), 1.63—2.12 (3H, m), 2.28—2.64 (2H, m), 3.42—3.94 (4H, m), 4.53 (1H, dd, *J*=4.1 Hz), 5.02—5.31 (2H, m), 5.65 (1H, d, *J*=4.1 Hz), 5.57—6.00 (1H, m). Found: C, 58.64; H, 8.02%. Calcd for $C_{12}H_{20}O_5$: C, 59.00; H, 8.25%.

(1*R*,3*R*,4*R*,5*R*)-4-Hydroxy-3-[(1*S*)- and (1*R*)-1-ethyl-3-hydroxypropyl]-7,7-dimethyl-2,6,8-trioxabicyclo[3.3.0]octanes (19S and 19R). A solution of **18R** (17 mg, 0.07 mmol) in EtOH (2 ml) was hydrogenated under atmospheric hydrogen gas in the presence of Raney nickel T-4 for 3 h. The catalyst was removed through a Celite pad, washed with EtOH. The filtrate and washings were combined and concentrated in vacuo. The residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 20) to give **19S** (16 mg, 91%) as white crystals, mp 47.5—48.5 °C: TLC R_f 0.43 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{25}$ +25.0° (*c* 0.76, $CHCl_3$); IR (KBr) ν_{max} 3295, 2980, 2965, 2930, 2870, 1460, 1380, 1370, 1325, 1245, 1235 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ=0.93 (3H, t, *J*=7.6 Hz), 1.37, 1.57 (3H each, 2 s), 1.38—1.85 (5H, m), 2.20 (1H, br s), 2.75 (1H, d, *J*=8.3 Hz), 3.63—3.83 (4H, m), 4.56 (1H, dd, *J*=4.2 Hz), 5.77 (1H, d, *J*=4.2 Hz). Found: C, 58.29; H, 8.71%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

Analogously, compound **18S** (23 mg) was hydrogenated to give **19R** (19.5 mg, 83%) as white crystals, mp 79.5—81 °C: TLC R_f 0.43 (EtOH/$PhCH_3$ 1 : 5); $[\alpha]_D^{23}$ +26.0° (*c* 0.95, $CHCl_3$); IR (KBr) ν_{max} 3425, 2985, 2975, 2955, 2940, 1460, 1380, 1370, 1320 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ=0.95 (3H, t, *J*=7.3 Hz), 1.37, 1.57 (3H each, 2 s), 1.38—1.72 (5H, m), 2.24 (1H, br s), 2.65 (1H, d, *J*=9.8 Hz), 3.62—3.83 (4H, m), 4.56 (1H, dd, *J*=3.9 and 4.9 Hz), 5.78 (1H, d, *J*=3.9 Hz). Found: C, 58.34; H, 8.73%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

(1*R*,3*R*,4*S*,5*R*)-4-Hydroxy-3-[(1*R*)- and (1*S*)-1-ethyl-3-hydroxypropyl]-7,7-dimethyl-2,6,8-trioxabicyclo[3.3.0]octanes (20R and 20S). A solution of **9R** (99 mg, 0.41 mmol) in THF (2 ml) was stirred with $LiAlH_4$ (38.5 mg, 1.0 mmol) for 1 h. The mixture was quenched with H_2O (0.1 ml). The resulting solids were removed, washed with CH_2Cl_2. The combined filtrate and washings were concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 1) to give **20R** (88 mg, 87%) as a colorless oil: TLC R_f 0.26 (AcOEt/hexane 1 : 1); $[\alpha]_D^{27}$ −21.8° (*c* 0.61, $CHCl_3$); IR (neat) ν_{max} 3400, 2960, 2940, 2880, 1460, 1380, 1250, 1220 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ=0.95 (3H, t, *J*=7.5 Hz), 1.31, 1.49 (3H each, 2 s), 1.25—1.89 (5H, m), 2.71 (2H, br s), 3.63—3.69, 3.76—3.82 (1H each, 2 m), 3.93 (1H, dd, *J*=2.4 and 9.8 Hz), 4.11 (1H, d, *J*=2.4 Hz), 4.50 (1H, d, *J*=3.9 Hz), 5.90 (1H, d, *J*=3.9 Hz). Found: C, 58.85; H, 8.78%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

Analogously, 14.5 mg of **9S** was reduced with $LiAlH_4$ to give 12 mg (84%) of **20S** as a colorless oil: TLC R_f 0.55 (AcOEt); $[\alpha]_D^{26}$ −15.6° (*c* 0.61, $CHCl_3$); IR (neat) ν_{max} 3380, 2960, 2940, 2880, 1460, 1370, 1250, 1210 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ=0.93 (3H, t, *J*=7.5 Hz), 1.32, 1.49 (3H each, 2 s), 1.40—1.91 (5H, m), 2.84 (1H, br s), 3.62—3.68, 3.79—3.84 (1H each, 2 m), 3.89 (1H, dd, *J*=2.0 and 11.0 Hz), 4.18 (1H, d, *J*=2.0 Hz), 4.38 (1H, br s), 4.51 (1H, d, *J*=3.7 Hz), 5.90 (1H, d, *J*=3.7 Hz). Found: C, 58.22; H, 8.73%. Calcd for $C_{12}H_{22}O_5$: C, 58.52; H, 9.00%.

Conversion of 20R into 19R via 21R, 22R, and 23R. To a solution of **20R** (20 mg, 0.08 mmol) in pyridine (1 ml) were added trityl chloride (52 mg, 0.19 mmol) and 4-dimethylaminopyridine (5 mg). After being heated at 65 °C for 3.5 h, the mixture was concentrated in vacuo. The residue was partitioned between CH_2Cl_2 (20 ml) and saturated aqueous $NaHCO_3$ (10 ml). The aqueous phase was extracted with CH_2Cl_2 (20 ml). The combined organic phases were dried (Na_2SO_4) and concentrated. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 10) to give **21R** (39 mg, 98%) as a colorless oil: TLC R_f 0.51 (AcOEt/hexane 1 : 2); $[\alpha]_D^{24}$ −11.1° (*c* 1.19, $CHCl_3$); IR (KBr) ν_{max} 3470, 2970, 2940, 2880, 1600, 1490, 1450, 1380, 1220 cm^{-1}; ^{1}H NMR (90 MHz, $CDCl_3$) δ=0.84 (3H, t, *J*=7.2 Hz), 1.24, 1.38 (3H each, 2 s), 1.10—2.10 (6H, m), 3.06—3.25 (2H, m), 3.83 (1H, dd, *J*=2.8 and 9.2 Hz), 4.04 (1H, d, *J*=2.8 Hz), 4.43 (1H, d, *J*=4.1 Hz), 5.79 (1H, d, *J*=4.1 Hz), 7.17—7.49 (15 H, m).

To a solution of **21R** (48 mg, 0.10 mmol) in CH_2Cl_2 (1 ml) were added anhydrous sodium acetate (17 mg), PCC (221 mg, 1.0 mmol), and molecular sieves (4A, powder, 143 mg). The mixture was stirred for 8 h, and charged on silica-gel column (8 g). The column was eluted with Et_2O containing 1% of triethylamine to give 47 mg of **22R** as a colorless oil: TLC R_f 0.80 (AcOEt/hexane 1 : 2); ^{1}H NMR (90 MHz,

$CDCl_3$) δ=0.85 (3H, t, J=7.5 Hz), 1.34, 1.40 (3H each, 2 s), 1.24—2.01 (5H, m), 2.90—3.20 (2H, m), 4.06 (1H, d, J=3.9 Hz), 4.30—4.36 (1H, m), 5.89 (1H, d, J=3.9 Hz), 7.15—7.46 (15H, m).

The crude **22R** (47 mg) was dissolved in EtOH (1 ml), and $NaBH_4$ (10 mg) was added. After being stirred for 50 min, the mixture was neutralized by addition of 50% aqueous AcOH and concentrated in vacuo. The residue was chromatographed on silica gel (AcOEt/hexane 1 : 5 containing 1% of triethylamine) to give **23R** (35 mg, 72% from **21R**) as a colorless oil: TLC R_f 0.59 (AcOEt/hexane 1 : 2); $[\alpha]_D^{20}$ +64.7° (c 1.68, $CHCl_3$); IR (neat) ν_{max} 3500, 2960, 2930, 2870, 1595, 1490, 1450, 1380, 1370, 1215 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.84 (3H, t, J=7.0 Hz), 1.34, 1.50 (3H each, 2 s), 1.05—2.34 (6H, m), 2.92—3.28 (2H, m), 3.52—3.81 (2H, m), 4.45 (1H, dd, J=4.4 Hz), 5.69 (1H, d, J=4.4 Hz), 7.16—7.49 (15H, m).

A solution of **23R** (28 mg, 0.06 mmol) in MeOH (1 ml) was stirred in the presence of p-toluenesulfonic acid (monohydrate, 10 mg) for 30 min at room temperature. Then, saturated aqueous $NaHCO_3$ (15 ml) was added. This was extracted with CH_2Cl_2 (20 ml×5). The combined organic phases were dried (Na_2SO_4) and concentrated in vacuo. The residue was chromatographed on silica gel (EtOH/$PhCH_3$ 1 : 15) to give **19R** (11 mg, 75%), which was identical with that obtained from **16S** in respects of TLC, mp, $[\alpha]_D$, IR and ^1H NMR.

Conversion of 20S into 19S via 21S, 22S, and 23S. Compound **20S** was converted into **19S** via **21S**, **22S**, and **23S** by the analogous reaction sequence described for **20R**. **21S** (91%): mp 179—180 °C, TLC R_f 0.49 (AcOEt/hexane 1 : 2); $[\alpha]_D^{24}$ +5.8° (c 0.94, $CHCl_3$); IR (KBr) ν_{max} 3440, 2980, 2950, 1620, 1480, 1460, 1380, 1220 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.86 (3H, t, J=7.5 Hz), 1.29, 1.45 (3H each, 2 s), 1.50—2.03 (5H, m), 2.61 (1H, br s), 3.21 (2H, dd, J=6.2 Hz), 3.85 (1H, dd, J=2.4 and 10.8 Hz), 4.05 (1H, br s), 4.47 (1H, d, J=4.1 Hz), 5.85 (1H, d, J=4.1 Hz), 7.18—7.49 (15H, m). **22S:** a colorless oil, TLC R_f 0.80 (AcOEt/hexane 1 : 2); ^1H NMR (90 MHz, $CDCl_3$) δ=0.83 (3H, t, J=7.7 Hz), 1.39, 1.58 (3H each, 2 s), 1.13—2.25 (5H, m), 3.14 (2H, dd, J=6.2 Hz), 4.19—4.37 (2H, m), 5.96 (1H, d, J=4.5 Hz), 7.20—7.58 (15H, m). **23S** (97% from **21S**): mp 96.5—97.5 °C, TLC R_f 0.62 (AcOEt/hexane 1 : 2); $[\alpha]_D^{21}$ +20.6° (c 1.00, $CHCl_3$); IR (KBr) ν_{max} 3540, 2980, 2960, 1480, 1450, 1400, 1380, 1315, 1260 cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=0.85 (3H, t, J=7.0 Hz), 1.34, 1.46 (3H each, 2 s), 1.25—2.40 (6H, m), 3.06—3.20 (2H, m), 3.55—3.79 (2H, m), 4.48 (1H, dd, J=4.0 Hz), 5.70 (1H, d, J=4.0 Hz), 7.17—7.50 (15H, m).

Compound **19S** obtained by p-TsOH hydrolysis of **23S** in 58% yield was identical with that obtained from **16R**.

10) The ratio and stereochemistries of the rearrangement products **6R** and **6S** were determined as follows. The mixture of the rearrangement product was reduced with $LiAlH_4$. The resulting two diols with S- and R-configurations were completely separated by repeated chromatography on silica gel. The ratio of **6S** and **6R** was estimated based on the yields of these diol derivatives. The double bond in each of the diol was then hydrogenated to afford **20R** or **20S**, which were compared with those prepared from structurally defined **9R** and **9S**.

11) The stereochemistries of **7S** and **7R** were confirmed by transformation of them into the diols, which were independently derived from the mixture of **6S** and **6R** (see, Ref. 10), by desilylation follwed by $LiAlH_4$ reduction.

Reduction of a 2-(*p*-tolylsulfinyl)cycloalkanone with sodium borohydride in methanol-triethylamine is accompanied by rapid epimerization at C_2. Under the conditions employed here, the π-facial selectivity of the reduction is directed by the side chain chirality and, among four possible isomers of the corresponding cycloalkanol, one isomer is given with high selectivities up to 85%.

Stereofacial control in nucleophilic additions to cycloalkanones has been recognized as a significant problem for stereoselective construction of cyclic systems.[1] Although the π-facial selection is often controlled by the stereochemistry contained in the cyclic system itself, there are few reports which deal with the selection affected by stereochemistry of the side chain. This may be attributable to the presence of an additional chiral center at the position bonding to this side chain, the configuration of which must be controlled in advance.[2] Recently, an efficient 1,3-asymmetric induction was realized in $NaBH_4$ reduction of α-substituted β-keto sulfoxides under basic conditions: the chirality of the sulfinyl group controls the hydride attack on the β-carbonyl group regardless of the stereochemistry of C_α which rapidly epimerizes under the reaction conditions.[3] This paper describes that the 1,3-stereochemical control accompanied by C_α-epimerization is successfully applied to cyclic systems, i.e., reduction of 2-(*p*-tolylsulfinyl)cycloalkanones with $NaBH_4$ under basic conditions provides a unique method for facial selection directed by the side chain.

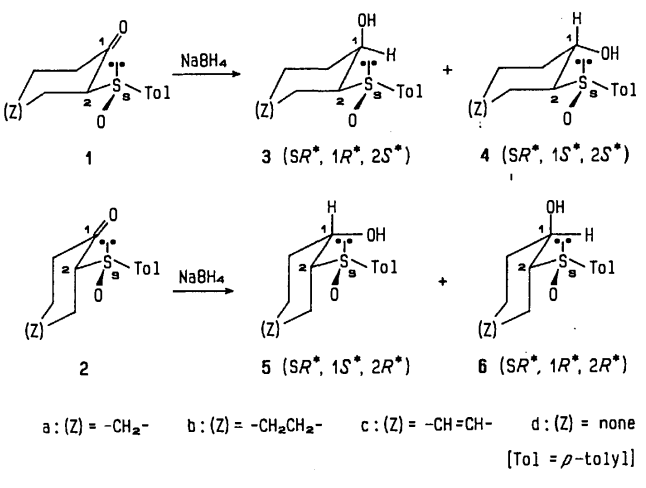
Results and Discussion

When a diastereomeric mixture of 2-(*p*-tolylsulfinyl)cyclohexanone (**1a** : **2a**=54 : 46) was reduced with $NaBH_4$ in methanol (Scheme 1),[4] four possible diastereomers (**3a—6a**) of 2-(*p*-tolylsulfinyl)cyclohexanol were formed in a moderately selective manner (**3a** : **4a** : **5a** : **6a**=48 : 12 : 31 : 9). Preferable formation of **3a** and **5a** (total 79%) predicts that this reduction is mainly directed by the stereochemistry of C_2 since **3a** and **5a** have the same stereochemical relationship between C_1 and C_2. Hence, the chirality of the sulfinyl group seems to less reflect on the new chiral center developing on C_1.

In striking contrast, predominant formation of **3a** (72%) was observed when the reaction was carried out under basic conditions (in a 1 : 1 mixture of MeOH-NEt_3).[5] In addition, it is noteworthy that two major isomers (**3a** and **6a**; their total yield 85%) have the same stereochemical relationship between C_1 and S (hereafter, the position of the sulfur atom is represented by a symbol "S"). Thus, the π-facial selection is strongly directed by the side chain chirality.

The same phenomena were observed for the $NaBH_4$ reduction of other 2-(*p*-tolylsulfinyl)cycloalkanones (**1b—d** and **2b—d**) under the basic conditions. The results are summarized in Table 1. In any case, one diastereomer (**3a—d**) is predominantly formed with high selectivities up to 85%.

Under the basic conditions, the C_2 of **1** and **2** might epimerize rapidly during the reduction. In fact, brief treatment of pure **1a**[6] with a 1 : 1 mixture of triethylamine and MeOH (1 h/room temperature) produces **1a** and **2a** in a ratio of 57 : 43. This rapid epimerization allows $NaBH_4$ to attack preferentially from the most favorable face among four possible ones (axial and equatorial faces[7] of **1** and **2**). In this case, the attack from the equatorial face of **1** giving **3** is predominant. Worthy of comment is that the configuration of **3** is in good accordance with that of the major isomer produced in the reduction of acyclic α-sulfinyl ketones.[3] Thus, the reduction of α-sulfinyl ketones might occur via similar stereochemical course in both acyclic and cyclic systems. This is in sharp contrast with the usual addition of a nucleophile to a carbonyl group.[8]



Scheme 1.

Table 1. Stereoselective Reduction of **1** and **2** with $NaBH_4$[a)]

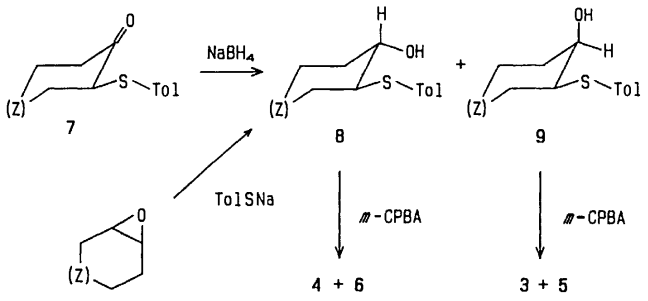
Substrates	(Ratio)	Solvent	Reduction products[b)]	
			Total yield/%	**3**: **4**: **5**: **6**
1a+2a	(54:46)	MeOH-NEt_3 (1:1)	98	72: 6: 9:13
1a+2a	(54:46)	MeOH	99	48:12:31: 9
1a		MeOH	100	65:27: 6: 2
1b+2b	(52:48)	MeOH-NEt_3 (1:1)	97	85: 1:10: 4
1b+2b	(52:48)	MeOH	94	58: 2:35: 5
1c+2c	(53:47)	MeOH-NEt_3 (1:1)	95	75: 4:16: 5
1c+2c	(53:47)	MeOH	95	48: 6:38: 8
1d+2d	(78:22)	MeOH-NEt_3 (1:1)	92	84: 3:12: 1
1d+2d	(78:22)	MeOH	91	78: 4:16: 2

a) Carried out with $NaBH_4$ (1.2—2.0 mol equiv) at 0 °C for ca. 2 h. b) Determined by HPLC analysis (see Experimental section).

Relative configurations of the diastereomers **3**—**6** were assigned as follows. Reduction of 2-(*p*-tolylthio)-cyclohexanone with $NaBH_4$ gave *cis*- and *trans*-2-(*p*-tolylthio)cyclohexanols.[11] In oxidation of *cis*-2-(*p*-tolylthio)cyclohexanol with *m*-chloroperbenzoic acid (*m*-CPBA), a 30:70 mixture of **3a** and **5a** was given. On the other hand, *m*-CPBA oxidation of *trans*-2-(*p*-tolylthio)cyclohexanol resulted in formation of **4a** and **6a** (78:22). Thermolysis of optically active (*SR*)-**3a**, obtainable from a mixture of (*SR*)-**1** and (*SR*)-**2a**,[13] produced (*R*)-2-cyclohexenol. From these facts, the configurations of **3a** and **5a** were assigned to be *SR**, *1R** and *SR**,*1S**,*2R**, respectively.

Since **3a** and **4a** were predominantly given by reduction of one diastereomer (**1a**) in MeOH (Table 1),[15] **4a** has *SR**,*1S**,*2S** configuration. Consequently, the configuration of the final isomer (**6a**) was assigned to be *SR**,*1R**,*2R**.

The stereochemical structure of **5c** was determined by X-ray crystallography. The molecular structure is shown in Fig. 1, which exhibits that **5c** has *SR**,*1S**, *2R** configuration. The configuration of the isomer **3c** was determined to be *SR**,*1R**,*2S**, because both **3c** and **5c** gave the same sulfone (**7**) on oxidation with *m*-CPBA. The structures of the minor products (**4c** and **6c**) were tentatively estimated as depicted in Scheme 1.



Scheme 2.

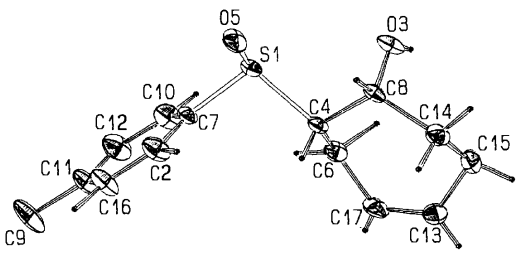


Fig. 1. An ORTEP drawing of **5c**.

Oxidation of *trans*-2-(*p*-tolylthio)cycloheptanol with *m*-CPBA gave **4b** and **6b** in a ratio of 84:16, whereas a 14:86 mixture of **3b** and **5b** was produced by oxidation of *cis*-2-(*p*-tolylthio)cycloheptanol. By considering the analogy between **1b** and **1a** (or **1c**), the configurations of **3b**—**6b** were assigned.

It was also found that *cis*-2-(*p*-tolylthio)cyclopentanol was oxidized with *m*-CPBA to yield **3d** and **5d** (20:80), while the similar oxidation of *trans*-2-(*p*-tolylthio)cyclopentanol resulted in formation of **4d** and **6d** (80:20). By comparision of these facts with oxidation behavior of the corresponding cyclohexanols, the stereochemical structures of **3d**, **4d**, **5d**, and **6d** were tentatively estimated.

In conclusion, a diastereomeric mixture of 2-(*p*-tolylsulfinyl)cycloalkanones can produce (*SR**,*1R**, *2S**)-2-(*p*-tolylsulfinyl)cycloalkanols on reduction with $NaBH_4$ in MeOH-Et_3N, which provides one example for facial selection directed by the side chain.

Experimental

Melting points were determined on a hot-stage microscope apparatus (Yanagimoto) and are uncorrected. ^1H NMR spectra were obtained on Hitachi R-600 (60 MHz), and JEOL JNM-GSX 270 (270 MHz) spectrometers. Infrared spectra were determined with a JASCO A-200 spectrometer. Optical rotations were measured on a JASCO DIP-181 polarimeter. High pressure liquid chromatography (HPLC) analyses were performed with a Hitachi 638-30 using UV detector (270 nm).

2-(*p*-Tolylthio)cycloalkanones. 2-(*p*-Tolylthio)cyclohexanone, 2-(*p*-tolylthio)cyclopentanone, and 2-(*p*-tolylthio)-cycloheptanone are prepared by reaction of an enolate ion of the corresponding cycloalkanones with di-*p*-tolyl disulfide according to the reaction conditions reported for preparing 2-(phenylthio)cycloalkanones.[16]

2-(*p*-Tolylthio)cyclopentanone: A colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.78—2.22 (4H, m), 2.22—2.46 (2H, m), 2.33 (3H, s), 3.49 (1H, t, J=7.9 Hz), 7.10 (2H, d, J=7.9 Hz), and 7.37 (2 H, d, J=7.9 Hz); IR (neat) 1740 cm^{-1}. Found: C, 69.79; H, 6.81%. Calcd for $C_{12}H_{14}OS$: C, 69.86; H, 6.83%.

2-(*p*-Tolylthio)cyclohexanone: A colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.57—2.29 (7H, m), 2.32 (3H, s), 2.91 (1H, m), 3.75 (1H, dt, J=1.3 and 5.6 Hz), 7.10 (2H, d, J=7.9 Hz), and 7.31 (2H, d, J=7.9 Hz); IR (neat) 1710 cm^{-1}. Found: C, 70.53; H, 7.16%. Calcd for $C_{13}H_{16}OS$: C, 70.86; H, 7.31%.

2-(*p*-Tolylthio)cycloheptanone: A colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.23—1.66 (4H, m), 1.71—2.03 (3H, m), 2.16—2.43 (2H, m), 2.32 (3H, s), 2.77 (1H, ddd, J=3.0, 11.9, and 13.2 Hz), 3.67 (1H, dd, J=5.6 and 10.6 Hz), 7.10 (2H, d, J=7.9 Hz), and 7.30 (2 H, d, J=7.9 Hz); IR (neat) 1705 cm^{-1}. Found: C, 71.53; H, 7.74%. Calcd for $C_{14}H_{18}OS$: C, 71.75; H, 7.74%.

Preparation of 2-(*P*-Tolylsulfinyl)cyclohexanone (1 and 2). A Typical Procedure. *m*-Chloroperbenzoic acid (*m*-CPBA) (1.7 g, 9.9 mmol) was added portionwise to a dichloromethane (25 ml) solution of 2-(*p*-tolylthio)cyclohexanone (2.1 g, 9.6 mmol) at 0 °C. After being stirred for an hour at 0 °C and for 3 h at room temperature, the mixture was treated with 20 wt% aqueous K_2CO_3 (40 ml). The aqueous layer was separated and extracted with dichloromethane (40 ml×2). The organic layers are combined, dried over anhydrous $MgSO_4$, concentrated, and subjected to column chromatography (silica gel, benzene-ethyl acetate 6:1) to give 2-(*p*-tolylsulfinyl)cyclohexanone (a 6:4 mixture of **1a** and **2a**) as an oil which soon crystallized. This was identical with an authentic sample (**1a**:**2a**=6:4) which was prepared by intramolecular cyclization of 1-(*p*-tolylsulfinyl)-6-iodo-2-hexanone.[14]

Recrystallization of this diastereomeric mixture from diethyl ether-hexane gave **1a** in a pure form: colorless crystals; mp 99—100 °C: ^{1}H NMR ($CDCl_3$) δ=1.50—1.76 (2H, m), 1.76—2.15 (3H, m), 2.15—2.42 (2H, m), 2.41 (3H, s), 2.42—2.60 (1H, m), 3.37 (1H, ddd, J=1.0, 4.6, and 9.6 Hz), 7.31 (2H, d, J=7.9 Hz), and 7.51 (2H, d, J=7.9 Hz); IR (KBr) 1710 and 1038 cm^{-1}. Found: C, 66.25; H, 6.83%. Calcd for $C_{13}H_{16}O_2S$: C, 66.07; H, 6.82%.

2-(*p*-Tolylsulfinyl)cycloheptanone (1b and 2b): Colorless crystals; 73% yield; mp 104—120 °C (a 52:48 diastereomeric mixture); ^{1}H NMR ($CDCl_3$) δ=1.15—1.65 (4H, m), 1.75—2.10 (4H, m), 2.12—2.28 (1H, m), 2.35—2.53 (1H, m), 2.41 (3H, s), 3.49 and 3.78 (major) [total 1H, dd (J=4.3 and 11.2 Hz) and dd (J=4.3 and 11.9 Hz), respectively], 7.31 (major) and 7.33 (total 2H, d (J=7.9 Hz) and d (J=7.9 Hz), respectively), 7.47 and 7.52 (major) (total 2H, d (J=7.9 Hz) and d (J=7.9 Hz), respectively); IR (KBr) 1700, 1030 cm^{-1}, for the diastereomer mixture. Found: C, 67.17; H, 7.31%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.24%.

2-(*p*-Tolylsulfinyl)cyclopentanone (1d and 2d): A pale yellow oil; 98% yield (a 78:22 diastereomer mixture); ^{1}H NMR ($CDCl_3$) δ=1.70—1.95 (3H, m), 2.05—2.60 (3H, m), 2.41 (3H, s), 3.27 (major) and 3.76 [total 1H, t (J=8.57 Hz) and dd (J=5.77 and 9.07 Hz), respectively], 7.32 (2H, d, J=7.9 Hz), and 7.48 (2H, d, J=7.9 Hz); IR (neat) 1740, 1050, and 1035 cm^{-1}. Found: C, 64.57; H, 6.34%. Calcd for $C_{12}H_{14}O_2S$: C, 64.83; H, 6.34%.

2-(*p*-Tolylsulfinyl)-4-cyclohepten-1-one (1c and 2c): This compound was obtained by a different method from the above one: the reaction of the dianion of (*p*-tolylsulfinyl)acetone with *cis*-1,4-dichloro-2-butene followed by treatment with sodium hydride in DMF.[14]

Reduction of 2-(*p*-Tolylsulfinyl)cyclohexanone (1 and 2) with Sodium Borohydride. (a) Reduction in Methanol: Sodium borohydride (30 mg, 0.81 mmol) was added to a solution involving a 54:46 mixture of **1a** and **2a** (118 mg, 0.50 mmol) in methanol (5 ml) under ice-cooling. After 2 h at 0 °C, water (20 ml) was added and the mixture was extracted with dichloromethane (10 ml×3). The extract was dried ($MgSO_4$), concentrated under reduced pressure, and subjected to column chromatography on silica gel using hexane-ethyl acetate (1:2) as an eluent to give 2-(*p*-tolylsulfinyl)cyclohexanol (117 mg, 99% yield, a mixture of four diastereomers (**3a**:**4a**:**5a**:**6a**=48:12:31:9) as a viscous oil. Found: C, 65.50; H, 7.63%. Calcd for $C_{13}H_{16}O_2S$: C, 65.51; H, 7.61%.

The diastereomer ratio was estimated by HPLC analysis.[17] Retention time (t_R): **3a**, 20 min; **4a**, 31 min; **5a**, 36 min; **6a**, 34 min. In the ^{1}H NMR (270 MHz) of this mixture, the C_1-protons of **3a**, **4a**, **5a**, and **6a** appeared at δ=4.43 (broad s), 3.88 (dt, J=4.7 and 10.4 Hz), 4.32 (broad s), and 4.10 (dt, J=4.6 and 9.9 Hz), respectively.

A single isomer (**1a**) (236 mg, 1.0 mmol) was treated with sodium borohydride (75 mg, 2.0 mmol) in a similar manner to that described above to give a mixture of **3a**, **4a**, **5a**, and **6a** (238 mg, 100% yield), the ratio of which was determined by HPLC analysis to be 65:27:6:2. Found: C, 65.49; H, 7.62%. Calcd for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61%.

(b) Reduction in Methanol-Triethylamine: A diastereomeric mixture (54:46) of **1a** and **2a** (50 mg, 0.21 mmol) was dissolved in methanol-triethylamine (1:1, 4 ml). Sodium borohydride (10 mg, 0.26 mmol) was added to this solution at 0 °C. After 2 h at 0 °C, brine (20 ml) and water (10 ml) were added and the mixture was extracted with dichloromethane (20 ml×1, 10 ml×3). The extract was dried over anhydrous $MgSO_4$, concentrated under reduced pressure, and subjected to column chromatography on silica gel using benzene-ethyl acetate (2:1) as an eluent to give 2-(*p*-tolylsulfinyl)cyclohexanol (49 mg, 98% yield) as a viscous oil. The diastereomeric ratio (**3a**:**4a**:**5a**:**6a**) was estimated by HPLC analysis to be 72:6:9:13.

From this diastereomeric mixture, **3a** was isolated in a pure form by recrystallization from diethyl ether-hexane: colorless crystals; mp 109—112 °C: ^{1}H NMR ($CDCl_3$) δ=1.07—1.29 (1H, m), 1.32—1.51 (2H, m), 1.62—2.11 (4H, m), 2.43 (3H, s), 2.47 (1H, ddd, J=2.3, 5.0 and 14.6 Hz), 3.32 (1H, broad s, OH), 4.43 (1H, broad), 7.34 (2H, d, J=7.9 Hz), and 7.47 (2H, d, J=7.9 Hz); IR (KBr) 1705 and 1025 cm^{-1}. Found: C, 65.48; H, 7.65%. Calcd for $C_{13}H_{18}O_2S$: C, 65.51; H, 7.61%.

Similarly, a diastereomeric mixture of (*SR*)-2-(*p*-tolylsulfinyl)cyclohexanone (**1a** and **2a**)[8] (435 mg, 1.84 mmol) was treated with sodium borohydride (104 mg, 2.76 mmol) in methanol-triethylamine (1:1, 14 ml) to give a mixture of **3a**, **4a**, **5a**, and **6a** having *R* configuration on the sulfur atom (412 mg, 94%) in a ratio of 72:6:9:13. Recrystallization from diethyl ether-hexane gave (1*R*,2*S*,*SR*)-**3a** in a pure form: colorless crystals; mp 117—117.5 °C; $[\alpha]_D^{22}$ +173.5 (*c* 1, $CHCl_3$) (lit,[18] $[\alpha]_D^{22}$ +174 (*c* 1, $CHCl_3$)). The ^{1}H NMR and IR spectra of this compound were in complete accordance with those of racemic **3a**.

Reduction of 2-(*p*-Tolylsulfinyl)cycloheptanone (1b and 2b). A diastereomeric mixture (52:48) of **1b** and **2b** was subjected to the $NaBH_4$ reduction in methanol in a similar

manner described in reduction of **1a** and **2a** to give a 58:2:35:5 mixture of **3b**, **4b**, **5b**, and **6b** (66 mg: 94% yield) as a colorless solid. Found: C, 66.60; H, 7.81%. Calcd for $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99%.

The diastereomeric ratio was determined by a HPLC analysis[17] (t_R: **3b**, 38 min; **4b**, 59 min; **5b**, 62 min; **6b**, 55 min). The ^1H NMR (270 MHz) of this mixture exhibited the C_1-protons of **3b**, **4b**, **5b**, and **6b** at δ=4.63 (1H, diffused t, J=2.6 Hz), 4.25—4.35 (m), 4.12 (diffused q, J=7.3 Hz), and 4.43 (diffused s), respectively.

Reduction of a 52:48 mixture of **1b** and **2b** in methanol-triethylamine was performed in an analogous manner described in reduction of a mixture of **1a** and **2a**. The total yield of **3b**, **4b**, **5b**, and **6b** was 97%, and its diastereomer ratio was determined by the HPLC analysis to be 85:1:10:4. Recrystallization of this mixture from diethyl ether-hexane gave **3b** in a pure form: colorless crystals; mp 122—123 °C: ^1H NMR ($CDCl_3$) δ=1.20—1.83 (8H, m), 1.92—2.13 (2H, m), 2.42 (3H, s), 2.61 (1H, ddd, J=1.7, 3.6, and 10.9 Hz), 2.73 (1H, broad s, OH), 4.63 (1H, diffused t), 7.33 (2H, d, J=8.2 Hz), and 7.47 (2H, d, J=8.2 Hz); IR (KBr) 3340, 1010, and 990 cm^{-1}. Found: C, 66.80; H, 7.97%. Calcd for $C_{14}H_{20}O_2S$: C, 66.63; H, 7.99%.

Reduction of 2-(*p*-Tolylsulfinyl)-4-cyclohepten-1-one (1c and 2c). In a similar manner described in reduction of **1a** and **2a**, a 53:47 mixture of **1c** and **2c** was reduced with $NaBH_4$ in methanol to give a 48:6:38:8 mixture of **3c**, **4c**, **5c**, and **6c** (95% yield) as a colorless solid; mp 147—169 °C. Found: C, 67.15; H, 7.24%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.24%.

The diastereomeric ratio was determined by a HPLC analysis[17] (t_R: **3c**, 29 min; **4c**, 45 min; **5c**, 53 min; **6c**, 48 min). The ^1H NMR (270 MHz) of this mixture exhibited the C_1-protons of **3c**, **4c**, **5c**, and **6c** at δ=4.66 (broad d, J=4.9 Hz), 4.23 (diffused dt, J=4.3 and 8.6 Hz), 4.46 (diffused s), and 4.27—4.76 (m), respectively.

Pure **5c** was isolated by recrystallization of this mixture from diethyl ether-hexane: mp 158—172 °C: ^1H NMR ($CDCl_3$) δ=1.36—1.52 (1H, m), 1.80—1.97 (2H, m), 2.28—2.40 (1H, m), 2.44 (3H, s), 2.52 (1H, ddd, J=1.7, 2.0, and 11.5 Hz), 2.50—2.63 (1H, m), 3.10 (1H, m), 4.34 (1H, broad d, J=1.7 Hz, OH), 4.46 (1H, diffused s), 5.70—5.82 (1H, m), 5.85—5.97 (1H, m), 7.36 (2H, d, J=7.9 Hz), and 7.54 (2H, d, J=7.9 Hz); IR (KBr) 3275, 1018, and 1005 cm^{-1}. Found: C, 67.15; H, 7.21%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.24%.

A 53:47 mixture of **1c** and **2c** was reduced in methanol-triethylamine (1:1) according to the method described in reduction of **1a** and **2a** in methanol-triethylamine. Chromatography of the crude product gave a 75:4:16:5 mixture of **3c**, **4c**, **5c**, and **6c** (95% yield). Recrystallization of this mixture from diethyl ether-hexane gave pure **3c**: colorless crystals; mp 162—168 °C: ^1H NMR ($CDCl_3$) δ=1.55 (1H, diffused t, J=4.9 Hz), 1.83—2.10 (3H, m), 2.40—2.65 (1H, m), 2.43 (3H, s), 2.56 (diffused dt, J=11.9 and 1.8 Hz), 2.87 (1H, diffused t, J=12.2 Hz), 3.10 (1H, broad s, OH), 5.58—5.70 (1H, m), 5.76—5.90 (1H, m), 7.35 (2H, d, J=7.9 Hz), and 7.48 (2H, d, J=7.9 Hz); IR (KBr) 3275, 1082, and 1015 cm^{-1}. Found: C, 67.10; H, 7.09%. Calcd for $C_{14}H_{18}O_2S$: C, 67.16; H, 7.24%.

Recrystallization of a mixture of **1c** and **2c** from diethyl ether-hexane gave almost pure **1c**. When **1c** (15 mg, 0.060 mmol) was reduced with $NaBH_4$ (3.0 mg, 0.79 mmol) in methanol under ice-cooling, a mixture (15 mg) of **3c**, **4c**, and **5c** was produced. The HPLC analysis of this mixture showed that the product ratio was 87:10:3.

Reduction of 2-(*p*-Tolylsulfinyl)cyclopentanone (1d and 2d). A 78:22 mixture of **1d** and **2d** was subjected to the $NaBH_4$ reduction in methanol in a similar manner described in reduction of **1a** and **2a** to give a 78:4:16:2 mixture of **3d**, **4d**, **5d**, and **6d** in 91% yield as a colorless solid. Found: C, 64.28; H, 7.21%. Calcd for $C_{12}H_{16}O_2S$: C, 64.25; H, 7.19%.

The retention times of **3d**, **4d**, **5d**, and **6d** on an HPLC analysis[17] (the eluent: MeOH-H_2O 35:65) were 44 min, 63 min, 66 min, and 57 min, respectively. The ^1H NMR (270 MHz) of this mixture exhibited the C_1-protons of **3d**, **4d**, **5d**, and **6d** at δ=4.53 (diffused q, J=4.6 Hz), 4.18—4.24 (m), 4.58—4.66 (m), and 4.45 (diffused s), respectively.

When a 78:22 mixture of **1d** and **2d** was reduced with $NaBH_4$ in methanol-triethylamine, total yield of **3d**, **4d**, **5d**, and **6d** was 92%. Its diastereomer ratio was determined by the HPLC analysis to be 84:3:12:1. Recrystallization of this mixture from diethyl ether-hexane gave **3d** in a pure form: colorless crystals; mp 110—111 °C: ^1H NMR ($CDCl_3$) δ=1.39—1.65 (2H, m), 1.70—2.02 (3H, m), 2.21—2.38 (1H, m), 2.41 (3H, s), 2.95 (1H, dt, J=5.6 and 8.6 Hz), 3.12 (1H, broad s, OH), 4.53 (1H, diffused q, J=4.6 Hz), 7.31 (2H, d, J=7.9 Hz), and 7.50 (2H, d, J=7.9 Hz); IR (KBr) 3320, 1020, and 1006 cm^{-1}. Found: C, 64.23; H, 7.12%. Calcd for $C_{12}H_{16}O_2S$: C, 64.25; H, 7.19%.

Thermolysis of (*SR*,1*R*,2*S*)-3a. A mixture of (*SR*,1*R*,2*S*)-**3a** (104 mg, 0.44 mmol) and calcium carbonate (160 mg, 1.60 mmol) was heated at 60 Torr[#]/180 °C in a glass tube oven (Sibata GTO-250RS). The fraction was trapped in a collecting vessel cooled with Dry Ice, and was further distilled under reduced pressure (oven temperature: 120 °C/60 Torr) to give (*R*)-2-cyclohexen-1-ol (32 mg, 75% yield): $[\alpha]_D^{20}$ +115.3° (*c* 0.76, $CHCl_3$) (lit,[18] $[\alpha]_D^{23}$ +67.9 (*c* 0.60, $CHCl_3$)).

Oxidation of 3c and 5c. To a solution of **3c** (137 mg, 0.55 mmol) in dichloromethane (3 ml), was added *m*-CPBA (104 mg, 0.60 mmol) and the resulting mixture was stirred under ice-cooling for 2 h. After addition of aqueous K_2CO_3 solution (20 wt%, 5 ml), the mixture was extracted with dichloromethane (5 ml×2). The combined organic layers were dried ($MgSO_4$), evaporated, and subjected to column chromatography on silica gel using benzene-ethyl acetate (4:1) to afford a sulfone (126 mg: 86% yield): colorless crystals; mp 103—105 °C (from diethyl ether-hexane); ^1H NMR ($CDCl_3$) δ=1.38 (1H, diffused t, J=12 Hz), 1.80—2.03 (2H, m), 2.32—2.74 (2H, m), 2.47 (3H, s), 2.93 (1H, diffused d, J=3.3 Hz), 2.90—2.98 (1H, m), 3.29 (1H, t, J=1.8 Hz, OH),[19] 4.55 (1H, diffused s), 5.65—5.79 (1H, m), 5.82—5.98 (1H, m), 7.39 (2H, d, J=7.9 Hz), and 7.78 (2H, d, J=7.9 Hz); IR (KBr) 3450, 1280, 1160, and 1075 cm^{-1}. Found: C, 63.01; H, 6.81%. Calcd for $C_{14}H_{18}O_3S$: C, 63.13; H, 6.81%.

Similarly, **5c** was oxidized with *m*-CPBA to give a sulfone derivative which was identified (by TLC, IR, and ^1H NMR) with the sulfone derived from **3c**.

Reduction of 2-(*p*-Tolylthio)cyclohexanone. A Typical Procedure. Sodium borohydride (121 mg, 3.21 mmol) was added portionwise to a dichloromethane-methanol (1:2, 15 ml) solution of 2-(*p*-tolylthio)cyclohexanone (426 mg, 1.94 mmol) at 0 °C. The mixture was stirred for 1 h at 0 °C and 11 h at room temperature. Water (10 ml) was added and the whole was extracted with dichloromethane (20 ml×1, 10

[#] 1 Torr=133.322 Pa.

ml×3). The extract was dried over anhydrous $MgSO_4$, condensed under reduced pressure, and subjected to column chromatography (silica gel, benzene-hexane 1:1—2:1) to give *cis*- and *trans*-2-(*p*-tolylthio)cyclohexanols (218 mg and 163 mg, respectively; 88% total yield). *cis*-2-(*p*-Tolylthio)cyclohexanol: a colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.20—1.55 (3H, m), 1.58—1.92 (5H, m), 2.33 (3H, s), 2.49 (1H, broad s, OH), 3.25 (1H, dt, J=2.6 and 5.3 Hz), 3.83 (1H, dt, J=3.0 and 6.4 Hz), 7.11 (2H, d, J=7.9 Hz), and 7.35 (2H, d, J=7.9 Hz); IR (neat) 3450 cm^{-1}. Found: C, 70.04; H, 8.17%. Calcd for $C_{13}H_{18}OS$: C, 70.22; H, 8.15%.

trans-2-(*p*-Tolylthio)cyclohexanol was identified by comparison of its IR and ^{1}H NMR spectra with those of an authentic sample which was prepared by the reaction of cyclohexene oxide with sodium *p*-toluenethiolate.[12]

***cis*- and *trans*-2-(*p*-Tolylthio)cyclopentanols:** These were obtained in a ratio of 65:35 (90% total yield) by reduction of 2-(*p*-tolylthio)cyclopentanone with $NaBH_4$) in methanol. The stereochemistry of *trans*-2-(*p*-tolylthio)cyclopentanol was confirmed by an alternative synthesis of the trans isomer.[12] *cis*-2-(*p*-Tolylthio)cyclopentanol: a colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.55—1.82 (3H, m), 1.82—1.92 (2H, m), 1.97—2.13 (1H, m), 2.32 (3H, s), 2.63 (1H, broad s, OH), 3.39 (1H, ddd, J=4.0, 8.6, and 10.9 Hz), 4.03 (1H,diffused t), 7.10 (2H, d, J=7.9 Hz), and 7.33 (2H, d, J=7.9 Hz); IR (neat) 3400 cm^{-1}. Found: C, 68.85; H, 7.79%. Calcd for $C_{12}H_{16}OS$: C, 69.18; H, 7.74%.

***cis*- and *trans*-2-(*p*-Tolylthio)cycloheptanols:** Similar reduction of 2-(*p*-tolylthio)cycloheptanone gave these compounds in 65% and 31% yields, respectively. *cis*-2-(*p*-Tolylthio)cycloheptanol: a colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.28—1.65 (5H, m), 1.65—2.00 (5H, m), 2.33 (3H, s), 2.55 (1H, broad s, OH), 3.33 (1H, dt, J=3.0 and 9.6 Hz), 3.83 (1H, dt, J=3.0 and 6.4 Hz), 7.11 (2H, d, J=7.6 Hz) and 7.35 (2H, d, J=7.6 Hz); IR (neat) 3450 cm^{-1} Found: C, 70.97; H, 8.46%. Calcd for $C_{14}H_{20}OS$: C, 71.13; H, 8.52%.

***trans*-2-(*p*-Tolylthio)cyclohexanol:** A colorless oil; ^{1}H NMR ($CDCl_3$) δ=1.32—1.80 (7H, m), 1.90—2.15 (3H, m), 2.34 (3H, s), 2.90 (1H, dt, J=3.0 and 9.2 Hz), 2.92 (1H, broad s, OH), 3.52 (1H, ddd, J=3.6, 7.9, and 9.2 Hz), 7.12 (2H, d, J=7.9 Hz), and 7.35 (2H, d, J=7.9 Hz); IR (neat) 3375 cm^{-1}. Found: C, 71.36; H, 8.54%. Calcd for $C_{14}H_{20}OS$: C, 71.13; H, 8.52%.

Oxidation of 2-(*p*-Tolylthio)cyclohexanol with *m*-CPBA. A Typical Procedure: A dichloromethane (5 ml) solution of *cis*-2-(*p*-tolylthio)cyclohexanol (86.7 mg, 0.391 mmol) was cooled at 0 °C. To this solution was added *m*-CPBA (70 mg, 0.40 mmol) and the mixture was stirred for 1 h at 0 °C and for 2 h at room temperature. An aqueous solution (20 wt%, 10 ml) of K_2CO_3 was added and the whole was stirred for a while. The aqueous layer was separated and extracted with dichloromethane (10 ml×2). The organic layers were combined, dried over anhydrous $MgSO_4$, condensed under reduced pressure, and subjected to column chromatography on silica gel using benzene-ethyl acetate (6:1) as an eluent to give a mixture of **3a** and **5a** (82 mg, 88%) in a ratio of 30:70, which was determined by the HPLC analysis.

Similarly, *trans*-2-(*p*-tolylthio)cyclohexanol (89 mg, 0.40 mmol) was treated with *m*-CPBA (70 mg, 0.41 mmol) (1 h at

0 °C and 2 h at room temperature) to give a mixture of **4a** and **6a** (86 mg, 90%) in a ratio of 78:22, which was determined by the HPLC analysis.

Oxidation of 2-(*p*-Tolylthio)cycloheptanols: The cis isomer gave a mixture of **3b** and **5b** (92% yield) in a ratio of 14:86, while the trans isomer gave a mixture of **4b** and **6b** (83% yield) in a ratio of 84:16.

Oxidation of 2-(*p*-Tolylthio)cyclopentanols: The cis isomer gave a mixture of **3d** and **5d** (85% yield) in a ratio of 20:80, while the trans isomer gave a mixture of **4d** and **6d** (84% yield) in a ratio of 80:20.

X-Ray Crystallography of 5c. Crystal data are as follows: $C_{14}H_{18}O_2S$, F.W.=250.35, triclinic, space group, $P\bar{1}$, a=8.942(2) Å, b=9.592(5) Å, c=9.404(3) Å; α=108.53(5)°, β=118.01(2)°, γ=87.25(4)°; V=670.20 Å^3; D_x=1.116 g cm^{-3}, Z=2. A computer program UNICS III[20] PRG. MULTAN 80[21] run on a HITACHI M680 at Tokyo University was employed for the analysis. The intensity data were collected in the region $3° \leqq 2\theta \leqq 120°$ at a scan rate 4° min^{-1}. 2233 independent reflections with $F(0) > 3\sigma(F_o)$ were used for a structure analysis. The final refined R value was 0.0682. Atomic positional and thermal parameters, bond distances, bond angles, and torsional angles are summarized in Tables 2—5.

The authors are grateful to Dr. Koreharu Ogata of Chemical Analysis Center of Chiba University for the X-ray crystallographic determination.

The Reactivities of Polyaromatic Hydrocarbons in Catalytic Hydrogenation over Supported Noble Metals

Kinya SAKANISHI, Masato OHIRA, Isao MOCHIDA,* Hiroshi OKAZAKI,† and Mahito SOEDA†
Institute of Advanced Material Study, Kyushu University 86, Kasuga, Fukuoka 816
†Nippon Steel Chemical Co., Ltd., Tobata, Kitakyushu 804
(Received July 5, 1989)

The reactivities of several polyaromatic hydrocarbons (pyrene: P, fluoranthene: FL, anthracene: An, fluorene: F, acridine: Ac, and carbazole: C) in the catalytic hydrogenation were studied and compared over supported noble metals (Pt, Pd, Rh, and Ru on a carbon or alumina support). The specific reactivity and selectivity were found to be strongly dependent upon the combination of the catalyst species and the substrate. The catalysts exhibited the activity order of Rh > Pd ≫ Pt > Ru for tricyclic aromatics of An, F, Ac, and C, although the catalysts provided very variable selectivities of the partially hydrogenated products which were produced via both consecutive and competitive routes, apparently according to the type of ring-skeleton and the presence of a nitrogen atom. The reactivity of the starting substrates and intermediates are compared to the quantum chemical reactivity indices, calculated based on MNDO (modified neglect of diatomic overlap). The values of the LUMO electron density, the π-bond order, and the stability of the product appear to govern the reactivity and selectivity of the hydrogenation, depending upon the combination of the catalyst species and the substrate. No hydrogenation of a substrate proceeds when its reactivity indices are less than the threshold value, which is subject to the activity of the catalyst and the reaction conditions defining product selectivity via both competitive and consecutive schemes.

The selective hydrogenation of polyaromatic hydrocarbons including heterocyclic compounds derived from coals and petroleums is one of the important steps in preparing the intermediates for functional molecules and medicines.[1-4]

The present authors have elsewhere reported the selective hydrogenation of pyrene, fluoranthene, acridine, and isoquinoline using noble metal catalysts under rather milder conditions[5-7] than those reported previously.[8-10] The former two substrates were very selectively converted into particular products of the partially-hydrogenated (especially tetrahydro) derivatives; these products could then be used as powerful hydrogen donors and synthetic intermediates.[11-13]

The selective hydrogenation of acridine was also found in a preceding paper to produce some partially hydrogenated acridines.[14] The reaction pathway of such selective hydrogenation was revealed to be competitive as well as consecutive through kinetic simulation, thermodynamic, and stereochemical comparisons of the hydrogenated products by the aid of quantum chemical calculations of the MNDO (modified neglect of diatomic overlap) method[15] and MM2 (molecular mechanics calculations).[16]

In the present study, the reactivities of several polyaromatic hydrocarbons in the catalytic hydrogenation were compared and rather comprehensively studied over typical noble metal catalysts in order to clarify the factors influencing their selective partial hydrogenation, since the specific reactivity and selectivity were found to be strongly dependent upon the combination of the catalyst species and the substrate. The reactivities of the substrates and their intermediates can be correlated to their quantum chemical indices and their stereochemical structures to explain the reaction schemes and to discuss the interaction between the substrates and the catalysts.

Experimental

Materials. Commercially available polyaromatic hydrocarbons (acridine, carbazole, anthracene, fluorene, pyrene, and fluoranthene) and decalin (reaction solvent) of a guaranteed grade were used without further purification in the present study, since sulfur compounds, which are severe poisons for the noble catalysts, were not detected, the sulfur content being less than 0.1%.

Commercial noble metal catalysts of Pd/Al_2O_3, Pd/C, Pt/Al_2O_3, Pt/C, Rh/Al_2O_3, Rh/C, and Ru/C (Metal content: 5 wt%), supplied by the Nippon Engelhalt Co., were used without any pretreatment.

Hydrogenation Procedures and Product Analyses. One of the polyaromatic hydrocarbons (2 g) was placed in an autoclave (50-ml capacity) together with the solvent (10 g of decalin) and one of the catalysts (0.2 g for FL or 0.5 g for the others). The autoclave was flushed with nitrogen three times to replace the air and then filled with pure hydrogen from a cylinder. The initial pressure of hydrogen was adjusted to give a prescribed pressure of 7 MPa at the reaction temperatures. After heating the reactor to a prescribed reaction temperature (373—523 K), magnetic stirring was started when the reaction time was counted. After the prescribed reaction time, the reactor was cooled with a fan to room temperature within 10 min; the reaction mixture (liquid and solid) was then recovered with THF. The catalyst was filtered out, and the liquid product including the solvent was analyzed by a temperature programmed gas chromatograph (column: SE-30, 2 m, heating rate: 10 K min^{-1} from 373 to 498 K). The hydrogenated derivatives were identified with GC-IR ^1H and ^{13}C NMR after the fractional distillation by reference to commercially available samples and/or the literature. The details of the product identification were described in previous papers.[5,6,14] The structures of the substrates and products are illustrated in Fig. 1.

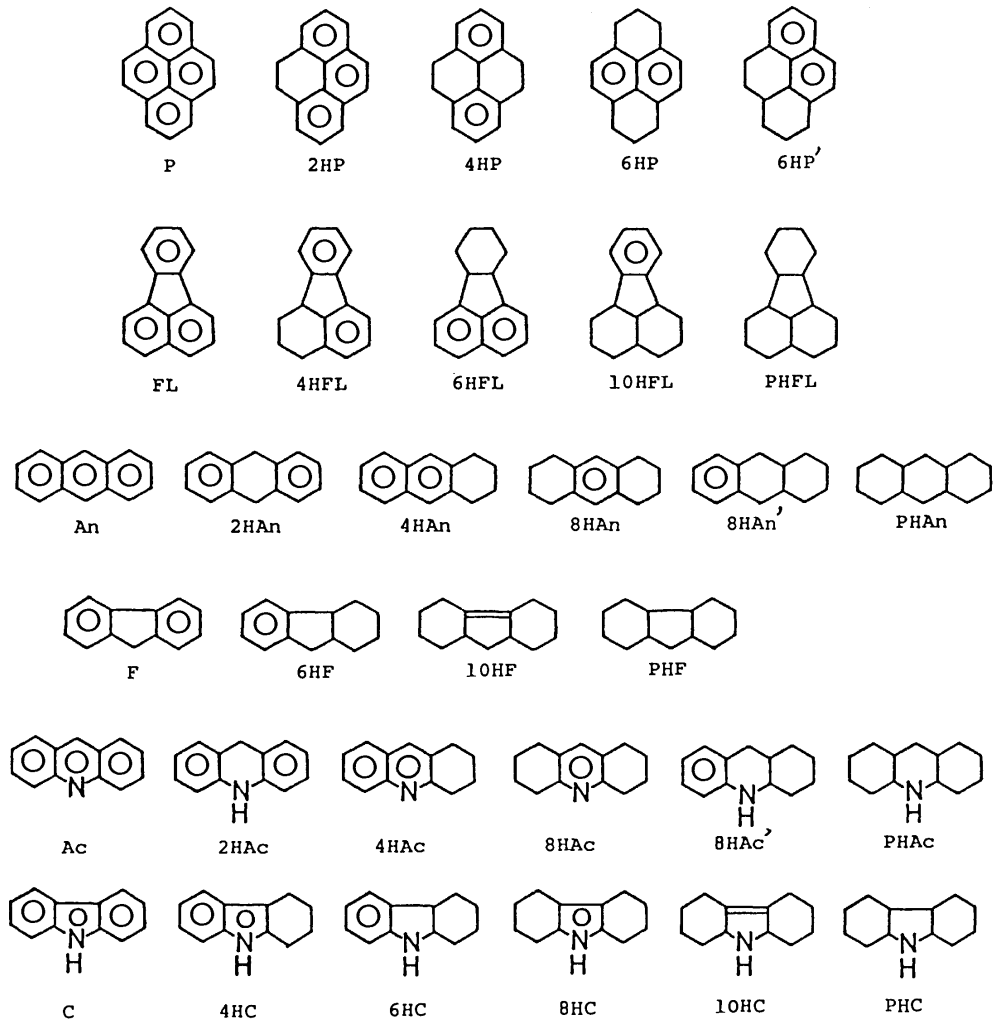

Fig. 1. Structures of the substrates and their hydrogenated products.

Quantum Chemical Calculations. The reactivity indices are calculated by means of the flow diagram shown in Fig. 2. According to the MM2 method,[16] the energetically optimized structures of the respective substrates and their hydrogenated products were determined. The molecular orbitals of the substrates of the determined structure were calculated according to the MNDO method[15] in order to estimate the heats of formation, the electron densities on carbon and nitrogen atoms, and the bond orders of the C-C and C-N bonds. The values thus calculated are more reasonable because the energy calculations are superior to any previously reported.[16]

Results

Hydrogenation Activities of Noble Metal Catalysts on Carbon. Table 1 summarizes the conversions of polyaromatic hydrocarbons in the hydrogenation on various carbon-supporting catalysts under the reaction conditions of 423 K, 7 MPa(H_2), and 30 min. All the catalysts except Ru, which was slightly less active, showed similar activities for pyrene (P) and fluoranthene (FL) of tetracyclic aromatics, although the latter substrate was much more reactive than the former.

The tricyclic aromatics showed very different reactivities, depending greatly on the catalyst used. The activities were in the order of Rh>Pd≫Pt>Ru in anthracene (An), fluorene (F), acridine (Ac), and carbazole (C). It should be noted, however, that the Pt and Ru catalysts exhibited much lower activities particularly for F and C, than did the other two catalysts. Figure 3 illustrates the major products in the hydrogenation of tricyclic aromatics on Rh, Pd, and Pt catalysts. The different selectivities of the catalysts were definite.

Reactivities and Selectivities in the Hydrogenation of Tetracyclic Aromatic Hydrocarbons. The activities and selectivities of the carbon-supported catalysts in the hydrogenations of pyrene (P) and fluoranthene (FL) are summarized in Tables 2 and 3 respectively, where severer and milder conditions than those of Table 1 were selected respectively. Except for Ru, the catalysts again exhibited similar activities under these conditions.

All the catalysts except for Rh/C hydrogenated 70—90% of the pyrene with a similar selectivity under the reaction conditions of 523 K, 5 MPa (H_2), and 6 h,

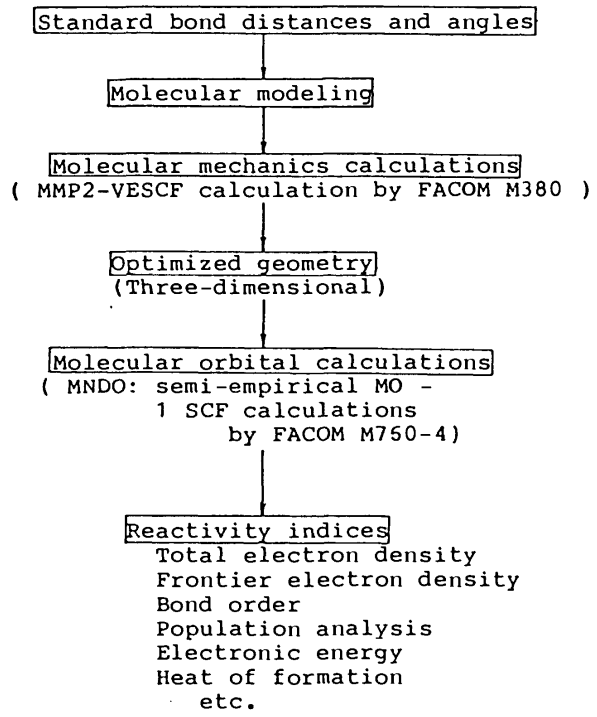

Fig. 2. Calculation diagram of reactivity indices of polyaromatic hydrocarbons.

producing preferentially the dihydro- (2HP) and tetrahydropyrene (4HP) at the selectivities of 40—60% and 30—40% respectively. The consecutive nature of the reaction is definite. The Rh/C catalyst alone produced 1,2,3,6,7,8-hexahydropyrene (6HP) by a considerable selectivity (ca. 30%) at similar conversion levels, suggesting that the competitive reaction may contribute along with the Rh/C catalyst.[5]

Fluoranthene (FL) was more easily hydrogenated than pyrene under the milder conditions of 423 K, 3 MPa (H_2), and 30 min with a smaller amount of the catalyst (0.2 g), as is shown in Table 3. The Pt/C and

a) Reaction conditions: 423 K—3 MPa, 30 min.

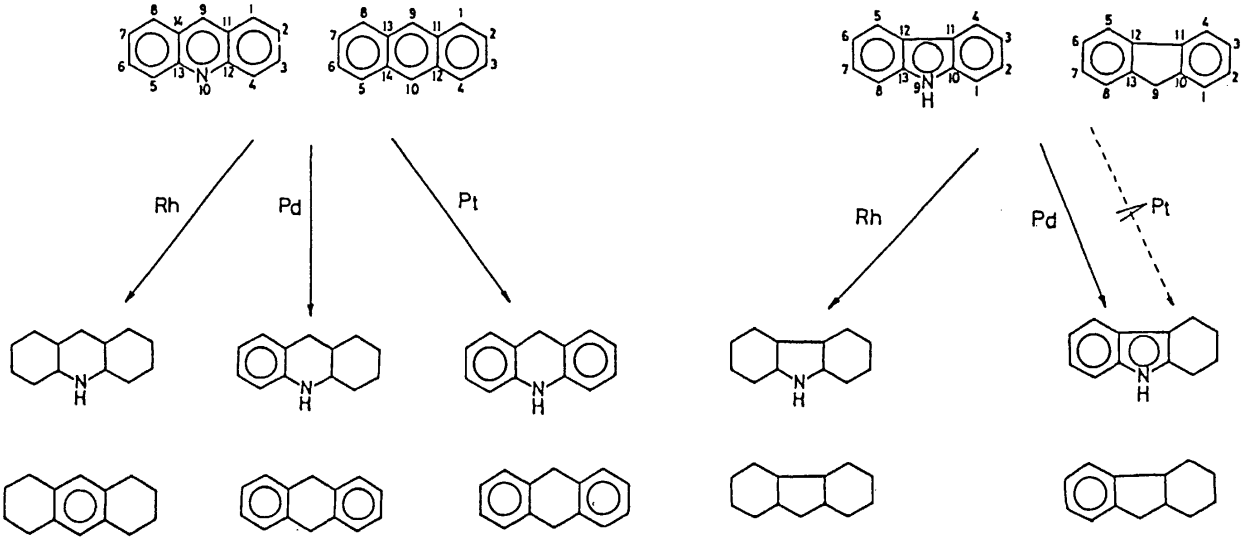

Fig. 3. Main routes in the hydrogenation of tricyclic aromatics on Rh, Pd, and Pt catalysts.

Pd/C catalysts exhibited the highest activity (conversion: 100%), producing 1,2,3,4,5,6,11,12,15,16-decahydrofluoranthene (10HFL) as the major product (selectivity: 75 and 99% respectively). The Rh/C catalyst hydrogenated 92% of the FL, exhibiting the highest selectivity (73%) for tetrahydro FL (4HFL). In marked contrast, the Ru/C catalyst converted only 31% of the FL, mainly into 4HFL (78% selectivity).

Reactivities and Selectivities in the Hydrogenation of Tricyclic Aromatic Hydrocarbons. The reactivities of anthracene (An) and fluorene (F) on alumina-supporting catalysts under some conditions are summarized in Tables 4 and 5 respectively. The Rh catalyst hydrogenated An much faster than the other two catalysts to achieve a 100% conversion within 5 min at 423 K and 7 MPa of H_2, producing principally 1,2,3,4,5,6,7,8-octahydroanthracene (8HAn, 73% selectivity). A minor production of 1,2,3,4,4a,9,9a,10-octahydroanthracene (8HAn') and perhydroanthracene (PHAn) was also observed. The consecutive path of An→4HAn→8HAn→PHAn appears predominant. Dihydro and tetrahydro derivatives were rapidly hydrogenated into octahydro derivatives, which are rather unreactive under these conditions. In contrast, Pd and Pt catalysts produced principally 9,10-dihydroanthracene (2HAn) at a selectivity of 60—70% at the reaction time of 180 min. Tetrahydro derivative (20—30%) was the second major product, the selectivities for the other products being very low.

The Pd and Rh catalysts converted 100% of the fluorene (F) under the conditions of 473 K, 7 MPa (H_2), and 5 min, principally into hexahydrofluorene (6HF, 71% selectivity) and perhydrofluorene (PHF, 72% selectivity). The other products found suggest a consecutive path on both catalysts, although the reaction stopped at their respective products of partial hydrogenation. In contrast, the Pt catalyst exhibited a much lower activity for F under the same conditions, converting only 2.7% of the F into 6HF.

Reactivities and Selectivities in the Hydrogenation of Nitrogen-Containing Aromatics. Tables 6 and 7 summarize the hydrogenation reactivities of acridine (Ac) and carbazole (C) on carbon- and alumina-supporting catalysts respectively. All the catalysts, examined under the conditions of 423 K, 7 MPa, and 10 min, exhibited very high activities against Ac, allowing the conversions of 90—100%. However their selectivities were very different, depending on the metal species, as is shown in Table 6.

The Pd catalyst hydrogenated Ac successively, producing mainly one of 1,2,3,4,4a,9,9a,10-octahydro-Ac (8HAc') via 9,10-dihydro-Ac (2HAc), although the selectivity depended upon the support. The Rh catalysts exhibited the highest activity among the catalysts examined, converting most of the Ac into perhydro-Ac (PHAc) via 1,2,3,4,5,6,7,8-octahydro-Ac (8HAc), regardless of the support.

In contrast, the Pt catalysts exhibited the highest selectivity for 2HAc (59% on Pt/C and 80% on Pt/Al_2O_3), producing very little of the more deeply hydro-

genated products. It should be noted that the selectivity on the Pt catalysts did not significantly change upon much longer reaction times of 120—240 min at 423 K or even at a higher temperature of 473 K until 180 min, as is shown in Table 8. PHAc became the major product at 473 K and 300 min or at 523 K and 30 min; this suggests that the 2HAc was converted directly to a fully hydrogenated product (PHAc). 2HAc, prepared separately, which was alone converted very slowly into more deeply hydrogenated products at 423 K, as is shown in Table 9, the major product being 8HAc′. Its low reactivity and weak adsorption may stop the reaction at this substrate.

Although alumina- and carbon-supporting catalysts showed much the same activities in the hydrogenation of Ac, as is shown in Table 6, less-hydrogenated 2HAc was more selectively produced on the alumina-supporting Pt and Pd catalysts, much less production of deeply hydrogenated products being observed. PHAc was the principal product on the Rh catalysts.

Tetrahydro-C (4HC) was the principal product with Pd on both supports, although a considerable amount of PHC was also produced with the carbon-supporting one. Both Rh catalysts provided PHC as the major product; however, a considerable amount of 8HC was also produced on the alumina-supporting catalyst. The Pt catalysts a exhibited much lower activity (conversion: 10—20%). No marked selectivity was observed. Thus, carbon-supporting catalysts tend to give more deeply hydrogenated products from nitrogen-containing compounds than do alumina-supporting ones, although the extent of hydrogenation varies with the catalyst species. In contrast, supports exhibited a negligible influence on the hydrogenations of such hydrocarbons as P, FL, An, and F which carry no heteroatom.

a) Others are unidentified products.

Discussion

The present study has revealed that the specific reactivity and selectivity in the hydrogenation on supported noble metals were both strongly dependent upon the combination of the catalyst and the substrate.

The catalytic hydrogenation of polyaromatic hydrocarbons follows competitive-consecutive reaction paths. Hence, the selectivity is governed by both the reaction positions of the first hydrogenation and the extent of successive hydrogenation. Thus, the reactivity of the respective positions of the substrate, the hydrogen reactivity activated by the catalyst, and allowed forms of the adsorbed substrate on the catalyst may define the rate and selectivity of the reaction.

The initial reactivity of the respective position in the substrate may be described appropriately by such quantum chemical indices as the LUMO electron density and the π-bond order.[17] Such indices may reflect the reactivity with hydride or the coordination force to the metal for the adsorption. The higher reactivity of hydrogen may lead to the larger rate of the reaction, but it may be less sensitive to the reactivity differences in the reactive positions. In the consecutive reactions, the hydrogenation may progress or cease, depending upon the stability, reactivity, and adsorbed form of the intermediate product, and also the reactivity of hydrogen, the last two factors being strongly influenced by the catalyst species and the reaction conditions. Based on such considerations, the rate and selectivity of the present study can be discussed.

Rh catalysts always exhibited the highest activity for the hydrogenation of the tricyclic aromatic hydrocarbons examined in the present study, although the selectivity for a specific product was always lower than in the other catalysts. The Rh catalysts may most activate molecular hydrogens, failing to distinguish the specific position of the substrate. Hence, the Rh catalysts are not suitable for a selective hydrogenation, but they can provide a considerable amount of a product which is very minor compared with the other catalysts. The nitrogen atom in the substrates is not so influential in the selectivity on the Rh catalysts, no difference in selectivity between anthracene and acridine being observed.

The Pd catalysts exhibited a moderate activity for the selective hydrogenation of polyaromatic hydrocarbons if the optimum reaction conditions were selected in terms of the reaction temperature and the time. The carbon-supported Pd catalyst selectively hydrogenated pyrene and acridine into tetrahydro and octahydro products respectively at very high yields.[5,6] It should be noted that the Pd catalysts exhibited much different selectivities for acridine and anthracene of the same skeleton, whether or not the nitrogen atom is contained. The Pd catalysts produced 8HAc′ at a rather high yield, although they failed to produce 8HAn′ of the same structure as 8HAc′, indicating that the nitrogen atom is influential on the Pd catalysts.

The Pt catalysts exhibited a very limited activity for the hydrogenations of Ac and An, producing principally 2HAc and 2HAn respectively. Their activity for the hydrogenations of C and F was also very low, producing principally tetra- and hexahydrogenated products respectively. The Pt catalysts hydrogenated preferentially or even exclusively the 9,10-positions of An and Ac. Further hydrogenation proceeded only under severer conditions to give deeply hydrogenated products.

The Ru/C catalyst exhibited the lowest activity of all the substrates examined in the present study, reflecting its smallest ability of molecular hydrogen activation among the four noble metals examined.

In contrast to tricyclic aromatic hydrocarbons, tetracyclic hydrocarbons exhibited much less sensitivity to the catalyst species.

The reactivity and selectivity for the hydrogenation of polyaromatic substrates may be supposed to be controlled by the interactions among the LUMOs and/or all π-orbitals of the substrate and the catalyst, and the HOMO (highest occupied molecular orbital) Frontier electron density of adsorbed hydrogen on the catalyst, which may have a form of hydride to interact with the substrate.[17]

The π-bond order as well as the LUMO electron density, summarized in Table 10, are influential on the hydrogenation reactivity of the tetracyclic aromatics, such as pyrene and fluoranthene. The intermediate product, such as pyrene, hydrogenated initially at the 1 position of the highest LUMO electron density is too unstable under the present conditions to survive as the final product. The hydrogenation of pyrene proceeds initially at the pair of positions 4 and 5, where the LUMO electron density is second highest, but the π-bond order is the largest, as is shown in Fig. 4, thus producing 4HP via 2HP as the major products in the consecutive manner in all case of the present study. Only the Rh/C catalyst provided a considerable amount of 6HP. The active catalyst may rapidly hydrogenate the rather unreactive position 2 as well as

C	C_1	0.35	C_1-C_2	0.72

the most reactive positions, 1 and 3. Hydrogenation around room temperature is reported to provide 1,6-dihydropyrene (2HP′), which is produced via the hydrogenation of the most reactive positions, 1 and 6, since the product is stable under these conditions.[12]

The large difference in hydrogenation reactivity between pyrene and fluoranthene can be explained by a combination of the effects of the π-bond order and the LUMO electron density. Fluoranthene has the highest π-bond order and LUMO electron density at the same positions of C_2-C_3, while pyrene has those at the different positions, as has been described above. It is the same reason that tetrahydrofluoranthene (4HFL) is more easily and selectively produced from fluoranthene under milder conditions regardless of the catalyst species. 1,2,3,4,5,6,11,12,15,16-decahydrofluoranthene (10HFL) is the major consecutive product, as is to be expected from the reactivity indices of 4HFL. It should be noted that the less active Pt and Pd catalysts provided more of the consecutive product from this particular substrate than did the active Rh. The high reactivity of the substrate may not discriminate the activity of the catalysts.

The reactivity and selectivity in the hydrogenation of tricyclic substrates are very different from those of tetracyclic systems. Anthracene and acridine have a pair of the most reactive 9,10-positions of the highest LUMO electron densities, yielding very selectively the 9,10-dihydro derivatives as the rather stable initial products on the Pt and Pd catalysts, although their π-bond order is never the largest. The hydrogenation of the positions of the largest π-bond order provide the product with the second largest π-bond order. MNDO suggests a large difference in the stability of 2HP′ and 2HAn, the former of which cannot be a stable product. The further hydrogenation of dihydro products is very slow in the consecutive steps, because the maximum LUMO electron density and π-bond order are much reduced to levels which are not large enough to be consecutively hydrogenated at 423 K on Pd or, more especially, Pt catalysts. The successive reaction at a higher temperature overcomes the barrier to produce 8HAn and 8HAc′ selectively.

Although the Rh catalyst provided deeply-hydrogenated products through consecutive reactions, considerable amounts of 8HAn and 8HAc were also produced, indicating that their largest π-bond order positions may be comparatively reactive on Rh catalysts. However, the higher reactivity of Ac than that of An may reflect its larger LUMO electron density, since their largest π-bond order values were much the same.

Fluorene and carbazole have values of the highest π-bond orders (ca. 0.70) at the C_2-C_3 and C_1-C_2 bonds respectively similar to that of the 9,10-dihydro products of anthracene and acridine, as is shown in Table 10 and Fig. 4. It should be noted that such substrates are hardly hydrogenated at all on the Pt catalysts. The π-bond order (ca. 0.70) of these substrates may be a threshold to restrict the hydrogenation on the Pt catalysts under the present conditions.

Pd catalysts could hydrogenate rather selectively one of phenyl groups in these substrates. The C_2-C_3 and C_1-C_2 positions in fluorene and carbazole, where the LUMO electron density and the π-bond order are at their maximum, are hydrogenated first to complete the hydrogenation of the ring. The second phenyl group resists being hydrogenated because of the reduced reactivity caused by the hydrogenation of the pair. The Rh catalyst is very active in hydrogenating every position in an unselective manner. It is interesting that certain amounts of 10HC and 10HF with a double bond between two rings are produced. Highly hindered olefin of the partially hydrogenated products can survive the hydrogenation.

Nitrogen-containing carbazole is again more reactive than fluorene. Nitrogen increases the reactivity indices.

In conclusion, the first hydrogenation of polyaromatic hydrocarbons is found to be principally governed by the LUMO and/or the π-bond order. Such reactivity indices determine the rate and selectivity of the hydrogenation, reflecting the activity of the catalyst. The active catalyst can hydrogenate the positions of a lower reactivity, performing the consecutive reaction to the more deeply hydrogenated product for a substrate and the competitive reactions to lower the selectivity for another substrate.

Hence, selective hydrogenation can be designed by selecting the catalyst and the reaction conditions to match the reactivity of the reaction position in the particular substrate, as predicted on the basis of quantum chemical calculations.

Noble metals' activation ability against molecular hydrogen and their adsorption ability against an aromatic bond are the origins of their catalytic activity; however, no theoretical explanation is available at present. Their empirical classification may, therefore, practical use at present.

Behavior of the Enthalpy of Mixing in the Ternary Systems Lead-Antimony-Tin, Bismuth-Lead-Tin, and Bismuth-Cadmium-Tin at 950 K. II. Theoretical Aspects

Walid Ahmad BADAWI
Department of Chemistry, Faculty of Science, Al-Fateh University, Tripoli, Libya
(Received November 9, 1988)

Analysis of the experimental results which have been obtained from our studies on the ternary systems Pb-Sb-Sn, Bi-Pb-Sn, and Bi-Cd-Sn revealed a new effect: deduction of a straight line obtained by interpolation between the pairs Sb-Pb and Sb-Sn at $x_{Pb}=x_{Sn}=0.5$ from the partial enthalpy of mixing of antimony, h^m_{Sb}, yields a remainder quantity, ${}^r h^m_{Sb}$. The minimum of this remainder lies at the section drawing $x_{Pb}/x_{Sn}=1$. Further studies on the systems Bi-Pb-Sn and Bi-Cd-Sn indicated that the present "r-effect" is probably a general property of ternary solutions. The sign of the remainder ${}^r h^m_i$ is opposite to that of h^m of the pair of components existing vis-a-vis a third apex-component in the same ternary system. Systems of strong heteropolar character which indicate Wagner effect overlapped by III—V one could also exhibit r-effectt. Rules for the mixing behavior in binary systems are in some cases not applicable on the corresponding pairs in the ternary solutions.

The theory of liquid solution[1] failed to predict statements for the excess functions behavior in binary systems of metals and metalloids, mainly because only atomic parameters were employed to interpret the data of the excess quantities. Also the specification of the liquid state with the aid of statistical thermodynamic treatments is associated with principle difficulties and thus, these theories are only applicable to simple models. For solutions of complicated behavior of mixing, calorimetric studies seemed to be more appropriate. The results obtained from the enthalpy of mixing measurements (e.g. those by Wittig and coworkers[2-4]) proved to be useful in finding statements for the specification of the effects which could contribute in prediction of the behavior of mixing in binary solutions. These could also shed light on the factors which determine the behavior of mixing in some ternary solutions. However, studies on ternary solutions are required in order that a more definite answer to the question be provided. It is also noteworthy that in some cases, the pairs of components in a ternary system show a behavior of mixing which differs from that one observed in the binary system consisting of the same components as those in the pairs belonging to the ternary one.

In the preceeding paper,[5] the experimental results for the enthalpy of mixing in the ternary system Pb-Sb-Sn have been reported together with results for the systems Bi-Pb-Sn and Bi-Cd-Sn. The results obtained (i.e. level minima of the partial molar enthalpy of mixing of Sb and Bi) pointed out the existence of effects (e.g. the III—V effect and a present one) which contribute in determining the behavior of mixing in the ternary solutions. Our intention now is to predict statements for the behavior of mixing in relation to these effects and other possible ones. Accordingly, we report in this paper the analysis of the experimental results and theoretical approach to the ternary solutions.

Theory

The integral and partial quantities of a system of c components are given by

$$Y_i = Y - \sum_{j\neq i} x_j \cdot \left(\frac{\partial Y}{\partial x_j}\right)_{x_k} ; \; j = 1,\cdots c, \tag{1}$$

where x_i is a dependent nonexplicit variable, Y, a function of all $x_j \neq x_i$. The subscript x_k on the partial derivative means that $x_k \neq x_j$, x_i is constant. Equation 1 is compatible to the following relation:

$$Y_i = Y + (1-x_i) \cdot \left(\frac{\partial Y}{\partial x_i}\right)_{x_j/x_k} ; \; i \neq 1,\cdots c, \; i \neq k, \tag{2}$$

where the subscript x_j/x_k is constant for all j, $k \neq i$. In view of Eq. 1 the partial quantity of the third component in the ternary system is given through the following polynominal function:

$$Y_3 = \sum_{k,l} a_{kl} \cdot x_1^k \, x_2^l \, (1-k-l). \tag{3}$$

Equation 3 depends on the average molar function, $\overline{Y}$, which can be expressed as a polynomial function:

$$\overline{Y} = \sum_{k,l} a_{k,l} \cdot x_1^k \, x_2^l \text{ with } \sum a_{00} = \sum_k a_{k0} = \sum_l a_{0l} = 0 \tag{4}$$

By this procedure, the partial quantities can be calculated from the integral ones. The calculation of Y_1 and Y_2 occurs as follows:

(i) The symmetrical procedure: From the coefficients a_{kl}, the coefficients b_{ij} or c_{ij} corresponding to the variation of the dependent variables x_1, x_2, and x_3, can be calculated and thus we obtain Y_1 and Y_2.

(ii) We can keep x_1 and x_2 as independent variables to determine Y_1 and Y_2 from Y (x_1, x_2). This is only possible when the coefficients a_{kl} are known. Applying this procedure, we obtain

$$Y_1 = \sum_{k,l} a_{kl} \, x_1^k \, x_2^l \, (1-k-l) + a_k x_1^{k-1} \, x_2^l \, k, \tag{5}$$

$$Y_2=\sum_{k,l} a_{kl}\, x_1^k\, x_2^l\,(1-k-l)+a_k\, x_1^k\, x_2^{l-1} l, \quad (6)$$

$$Y_3=\sum_{k,l} a_{kl}\, x_1^k \cdot x_2^l\,(1-k-l). \quad (7)$$

The excess quantity of the enthalpy of mixing is given through the following polynomial function:

$$Y^e=Y^e(x_i, x_j)=\sum_{k,l} a_{kl}\, x_i^k\, x_j^l, \quad (8)$$

where i, j=1,2 or 2,3 or 3,1. In this case, the following condition must be satisfied:

$$\sum a_{00}=\sum a_{k0}=\sum a_{0l}=0.$$

Since the total mole fraction of the three components in the ternary system must equal 1, ($x_1+x_2+x_3=1$), the excess quantities can be expressed in three different pairs of mole fraction. Substitution of the dependent mole fraction occurs as follows:

$$Y^e=Y^e(x_1, x_2)=\sum_{k,l} a_{kl}\, x_1^k\, x_2^l=\sum_{k,l} a_{kl} \cdot x_1^k(1-x_1-x_3)^l$$
$$=Y^e(x_1, x_3)=\sum_{i,j} b_{ij}\, x_3^i\, x_1^j. \quad (9)$$

The calculation of the coefficient b_{ij} occurs from those a_{kl}.

Discussion

From the study[2-4] on binary systems, it was possible to derive appropriate expressions which relate the position of the components in the periodic table to the excess function, Y^e. Accordingly, statements for the expected trends and properties of the excess quantities have been predicted in some noninvestigated systems. In views of these investigations and the results from our studies on a series of ternary systems, we have obtained further conclusions concerning the behavior of the enthalpy of mixing. These results will be discussed here together with those obtained from the present study on the system Pb-Sb-Sn.[5]

In the system Bi-Cd-Sn,[5] the partial molar enthalpies of mixing of bismuth and cadmium, h^m_{Bi}, h^m_{Cd}, showed striking level minima. It was observed that the level minimum of h^m_{Cd} and the bend joined to this minimum disappear rapidly when the mole fraction of Sn increases. At the same time, the bend of h^m_{Bi} becomes larger. Consequently, the partial enthalpy of mixing of Bi takes negative values. This was a somewhat surprising observation since h^m_{Bi} in the pair Bi-Cd showed always positive trends. This behavior could not have been caused by a Wagner effect,[6] since the trend of h^m_{Bi} curve differs from that one belonging to the Wagner effect.[6] It was therefore presumed that a cluster formation (caused by covalent bonds) exists. Indeed, it was not possible to derive a strict concentration interval from which conclusions for stoichiometric relations and electronic arrangements may be obtained. We can therefore suggest a valence electron concentration (C_{ve}) equal 3 for the pair Cd-Sn in the ternary system Bi-Cd-Sn. To check the justness of these presumptions we have been studying the system Bi-Pb-Sn. The partial molar enthalpy of mixing of bismuth showed a level minimum in the region lying between the section drawings $x_{Sn}=0$ and $x_{Pb}/x_{Sn}=6/4$. Also in this system the C_{ve} of the value 3 was presumed for the pair Pb-Sn.

Since the origin of the minima observed is presumed to be caused by the combination of an element (of 5 valence electrons) with comparable pairs of elements belonging to group IIIa and having the same Cve as that of the element, it is expected that the system Cd-Sb-Sn shows similar behavior. However, the study of this system is problematic (high vapor pressure of Cd at the melting point of antimony). The system Sb-Sn-Zn shows in the pair Sb-Zn a striking strong Wagner effect. This would overlap the covalent III—V effect so that no further conclusions from this system could be obtained.

The partial molar enthalpy of mixing of antimony, h^m_{SB}, in the system Pb-Sb-Sn goes through a minimum between the quasi-binary section drawings $x_{Sn}=0$ and $x_{Sn}/x_{Pb}=6/4$. This occurs due to the transfer of electrons from antimony in such a way that the C_{ve} reaches the value of 3 at the tin side. The same behavior could be expected for the system Bi-Pb-Sn where the delivery of electrons occurs by bismuth to yield a C_{ve} of 3 at the lead side. The correct-

ness of the above cited view will be quantitatively checked through testing the behavior of the ζ-function[7] which in given by

$$\xi = \frac{y_i}{(1-x_i)^2} , \qquad (10)$$

where y_i is the partial molar quantity of the enthalpy of mixing (h^m_{Sb} or h^m_{Bi}) and x_i the mole fraction of the component Sb or Bi.

Using the data for h^m_{Sb} in the system Pb-Sb-Sn,[5] we obtain values for ζ as illustrated in Table 1. From this table, it is evident that the minimum of ζ lies at side of the pair at which h^m_{Sb} takes the more negative value. This is the pair Sn-Sb where the C_{ve} reaches its maximum at the tin side.

The level form of the minima of the enthalpy of mixing of components (belonging to group Va in the periodic table of elements) at the quasi-binary section drawings x_{Bi}=const. and x_{Sb}=const., was presumed to be related to a convalent III—V effect. In fact, the relation between the form of the minima and the enthalpies of mixing of the pairs of components in ternary systems depends on other effect as observed in the present study. This effect may be explained as follows:

Deduction of a straight line (interpolated between the pairs Sb-Pb and Sb-Sn at $x_{Pb}=x_{Sn}=0.5$) from the partial enthalpy of mixing of antimony, h^m_{Sb}, yields a remainder quantity: $^r h^m_{Sb}$. The minimum of $^r h^m_{Sb}$ lies nearly at the section drawing $x_{Pb}/x_{Sn}=1$ (Fig. 1). The same effect (indicated here as r-effect) is expected to be observed in the system Bi-Sb-Sn where the minimum of $^r h^m_{Bi}$ lies at the section drawing $x_{Sb}/x_{Sn}=1$. In both cases, the "r-effect" is probably overlapped by other properties of pairs of components in the ternary systems.

It is possible that the r-effect is a general property of ternary solutions. The properties of ternary solutions are of two origins:

Characteristic effects which have a relevant physical meaning or other ones of trivial nature e.g. the Gibbs-Duhem relation for partial quantities. On the other hand, these properties may be overlapped by a somewhat stronger effect which depends on the type of the ternary system e.g. the expected stronger effect resulting from the substitution of Sn by Zn in the system Pb-Sb-Sn. Such a substitution leads to more heteropolar character and consequently to a Wagner effect. In such cases it would be easy to find a correlation between the position of the component in the periodic table of elements and the Wagner effect.

In order to prove that the above described "r-effect" is not a property of all planes (belonging to the pairs in the ternary system) where these planes satisfy the Gibbs-Duhem relation, the following plane will be discussed:

$$h^m = 1 - x_3 - (1-x_3)^2 + \frac{x_1 x_2}{(1-x_3)}, \qquad (i)$$

where x_1, x_2, and x_3 are the mole fractions of Sb, Pb, and Sn, respectively. This plane has the pair (1,2) and satisfies the Gibbs-Duhem relation.

For x_3=0, we have $h^m(1,2)=x_1 x_2$, and

$$h^m_3 = h^m - (x_3 - 1)\cdot \left(\frac{\partial h^m}{\partial x_3}\right)_{x_1/x_2} = (1-x_3)^2 .$$

For the section drawing x_3=const., h^m_3 is also constant. Despite the existence of the positive pair (1,2), h^m_3 is without $^r h^m_3$. This means that the plane (i) does not indicate r-effect. With this evidence one may conclude that, $^r h^m_3$, with an opposite sign to that one of the enthalpy of mixing corresponding to the pair which exists at the opposite side to the third component in the same ternary system, is not a trivial property which can be derived from the Gibbs-Duhem relation.

To decide that the above described $^r h^m_{x_i}$ is a general property of other ternary systems and to show how this effect takes place, we discuss the behavior of the

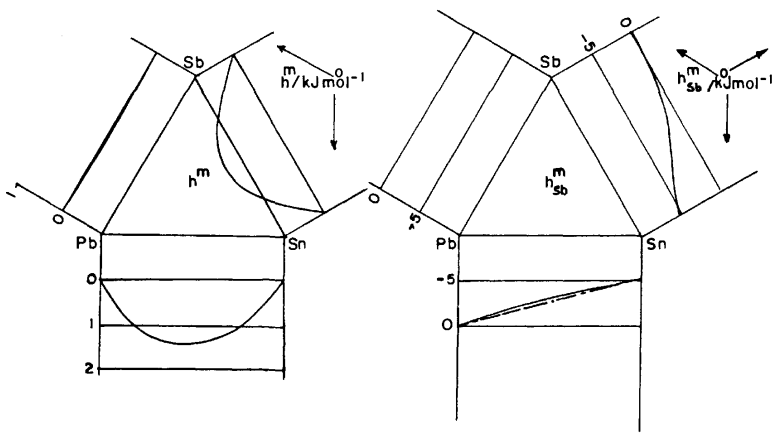

Fig. 1. The molar enthalpy of mixing, h^m, the partial one of antimony, h^m_{Sb}, at the quasi-binary section drawings Sb-Pb and Sb-Sn in the system Pb-Sb-Sn and the "r-effect."

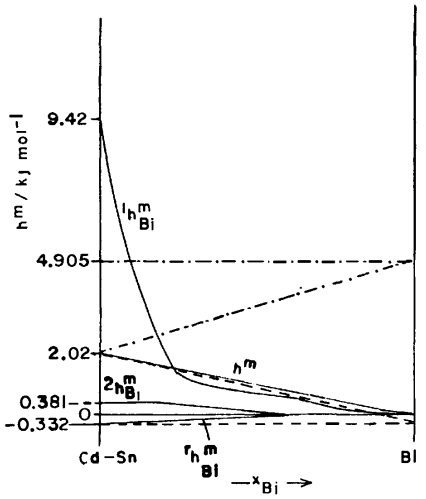

Fig. 2. Representation of the "r-effect" and estimated $^rh^m_{Bi}$ in the system Bi-Cd-Sn.

enthalpy of mixing of bismuth, h^m_{Bi}, using our data for the system Bi-Cd-Sn.[5] The partial molar enthalpy of bismuth is given by

$$h^m_{Bi} = h^m + (1-x_3)\cdot\left(\frac{\partial h^m}{\partial x_3}\right)_{x_1/x_2}, \qquad (11)$$

where x_1, x_2, and x_3 are the mole fractions of Bi, Cd, and Sn, respectively. Figure 2 shows the trends of the partial molar enthalpies of mixing, $^2h^m_{Bi}$ at Sn-Bi and $^1h^m_{Bi}$ at Cd-Bi together with the curve of the molar enthalpy of mixing along the quasi-binary section drawing $x_{Cd}/x_{Sn}=1$ in the ternary system Bi-Cd-Sn.

The partial enthalpies of mixing of bismuth at the spices $x_{Cd}=1$ and $x_{Sn}=1$ are 9.42 and 0.39 kJ mol^{-1}, respectively. From linear interpolation, we can obtain for $x_{Cd}=x_{Sn}=0.5$, the value of 4.91 kJ mol^{-1}. The molar enthalpy of mixing in the system Bi-Cd-Sn at $x_{Cd}=x_{Sn}=0.5$ is 2.02 kJ mol^{-1}. With reference to Eq. 11, the partial enthalpy of mixing of bismuth at this point can reach the average value 4.91 kJ mol^{-1} only when the molar enthalpy of mixing, h^m, starting from 2.88 kJ mol^{-1}, increases. With linear continuous increase where the drop in the value of h^m is, according to $h^m=a(1-x_{Bi})$, proportional to x_{Bi}, the partial molar enthalpy of mixing of bismuth h^m_{Bi} takes, along the whole quasi-binary section drawing $x_{Cd}/x_{Sn}=1$, the value of zero. When h^m without a turning point goes below this straight line, the partial enthalpy of mixing of bismuth, h^m_{Bi}, becomes along the whole quasi-binary section drawing negative. This means that the sign of $^rh^m_{Bi}$ is opposite to that one of the pair which exists at the opposite side of bismuth in the system Bi-Cd-Sn.

On the basis of the above given discussion, we expect that for ternary systems such as Bi-Sb-M (M=metal), in which Bi or Sb exists vis-a-vis a pair with negative enthalpy of mixing, the h^m_{Bi} in the pair Sb-M and h^m_{Sb} in that one Bi-M should have positive $^rh^m_{Bi}$ and $^rh^m_{Sb}$, respectively.

Conclusion

The r-effect is probably a general property of ternary solutions. The level minima of the partial quantities of the enthalpy of mixing in ternary solutions are attributed to the r-effect. Systems of strong heteropolar character which indicate Wagner effect overlapped by III—V effect exhibit also r-effect. Rules for the mixing behavior in binary systems are in some cases not applicable on the corresponding pairs in the ternary solutions.

Contribution to the Study of the Dielectric Relaxation Process of 1-Iodoalkanes

José Muñoz Embid,* José Mª Fornies-Marquina,† and Santos Otin*
Departamento de Química Orgánica-Química Fisica, Facultad de Ciencias, Universidad de Zaragoza, 50009-Zaragoza, Spain
†Departamento de Fisica Aplicada, Facultad de Ciencias, Universidad de Zaragoza, 50009-Zaragoza, Spain
(Received April 14, 1989)

A study of the dielectric relaxation process of 1-iodoalkanes (from 1-iodopropane to 1-iodohexadecane) was carried out by measuring their static dielectric constants at 2 MHz and complex dielectric permittivities at 9.23 and 15.05 GHz, in the range of temperature 293.15—343.15 K. The 1-iodoalkanes are classified as belonging to an unsymmetrical distribution of relaxation times of Cole-Davidson type. Activation enthalpies for the relaxation process are obtained by fitting the data of relaxation time as a function of temperature to the Eyring equation. The influence of the aliphatic chain length in the 1-iodoalkane on the characteristic parameters of the relaxation process is discussed.

Systematic studies of the dielectric relaxation parameters for haloalkanes have been reported previously[1-5] for 1-bromoalkanes at several frequencies and as a function of the aliphatic chain length. In the case of other 1-haloalkanes, only a few suitable data are available in the literature.[1-7]

We report measurements of the static dielectric constants at 2 MHz according to the heterodyne beat method, and complex dielectric permittivities at 9.23 and 15.05 GHz, using rectangular waveguides, for eight 1-iodoalkanes (1-iodopropane, 1-iodobutane, 1-iodopentane, 1-iodohexane, 1-iodoheptane, 1-iodooctane, 1-iodododecane, and 1-iodohexadecane) in the temperature range 293.15—343.15 K.

The aim of this work is to study the influence of the aliphatic chain length of the iodoalkane molecules on their characteristic relaxation parameters.

Experimental

The liquids used were: 1-iodopropane and 1-iodobutane (Fluka AG, Buchs, better than 99 mol%), 1-iodopentane, 1-iodohexane, 1-iodoheptane, and 1-iodooctane (Fluka AG, Buchs, better than 98 mol%), 1-iodododecane (Ventron GMBH, Karlsruhe, better than 98 mol%), and 1-iodohexadecane (Merck-Schuchardt, better than 90 mol%).

Dielectric permittivity measurements were performed with a WTW Dipolmeter (model DM01), using a DFL 2 cell at a constant frequency of 2 MHz. The frequency of 2 MHz is well below the dielectric absorption frequency range of similar systems. The cells were thermostated through the outer water jacket using a water thermostat providing a temperature control to ±0.05 K.

The complex permittivities have been measured using rectangular waveguides at 9.23 and 15.05 GHz, described fully elsewhere.[8] The limits of accuracy achieved were 2% in ε' and 5% in ε''.

Refractive index measurements were carried out (at several temperatures) by means of a thermostated Abbé refractometer. Values were obtained for Na-D light. The reproducibility was as good as ±0.00002. Thermoregulation for the complex permittivity and refractive index measurements was the same as that for dielectric constant measurements.

Results

The experimental values of the complex permittivities ε' and ε'' at 9.23 and 15.05 GHz in temperature range 293.15—343.15 K are given in Table 1 along with the static dielectric constants at 2 MHz, ε_s, and ε_∞ assumed to be equal to n^2 (Figs. 1 and 2).

These results let us classify the 1-iodoalkanes as belonging to an unsymmetrical distribution of relaxation times of Cole-Davidson type[9] in which the com-

1-Iodohexane	7.8
1-Iodoheptane	10.1
1-Iodooctane	9.8
1-Iodododecane	19.3
1-Iodohexadecane	28.4

plex dielectric permittivity is given by

$$\varepsilon^*=\varepsilon_\infty+\frac{\varepsilon_s-\varepsilon_\infty}{(1+j\omega\tau_0)^\beta} \quad (1)$$

where τ_0 is the value of the most probable macroscopic relaxation time and β the characteristic parameter of the distribution. In Fig. 3 the values of β are plotted against the number of carbon atoms, u, in the molecule of iodoalkane. The obtained results for τ_0 are given in Table 2.

Eyring rate equation was used to study the variation of relaxation times with the temperature

$$\ln(\tau_0 T)=\ln\frac{h}{k}-\frac{\Delta S_E}{R}+\frac{\Delta H_E}{RT} \quad (2)$$

were ΔH_E and ΔS_E are the most probable enthalpy and entropy of activation associated to the dielectric process. The values of ΔH_E are listed in Table 3.

Discussion

Figures 1 and 2 show a plot of the complex permittivities ε' and ε'', respectively, at 9.23 and 15.05 GHz, as a function of the chain length of 1-iodoalkane. As it happens with ε_s, the slopes are higher for 1-iodoalkanes of short chain and, from 1-iodooctane up, they tend to the value of ε_∞. On the other hand, a noticeable influence of the length of chain on the dielectric behavior of a molecule in the region of low frequency is observed, although that influence decreases more and more with increasing frequency and it finally becomes hardly significant.

The influence of number, u, of carbon atoms in 1-iodoalkane on the parameter of distribution, β, is illustrated in Fig. 3. As can be seen, β increases at first with u, shows a maximum value between 1-iodobutane and 1-iodohexane, and then diminishes for larger 1-iodoalkanes. This characteristic behavior of β might be put down to an effect of the high mass of I atom. For 1-iodoalkanes with short aliphatic chain the heteroatom represents a high proportion of the molecular mass, but for progressively longer chains, the center of mass moves increasingly away from I atom. This means that the dielectric behavior of short-chain 1-iodoalkanes is basically determined by both volume and mass of I atom, while for longer molecules the hydrocarbon chain exerts a more significant influence.

As Table 2 shows, relaxation time, τ_0, becomes greater as the chain-length increases, which can be imputed to a parallel increase of both viscosity, and molecular mass and volume. Molecules will move slower with increasing length of their aliphatic chains, leading to increasing values of τ_0. 1-Iodododecane and 1-iodohexadecane show a rather extreme behavior as their freezing points lie very close to our experimental temperature and therefore their molecules will move very slowly; with increasing temperature, rapidly decreasing values of τ_0 are expected, as it, in fact, happens.

A similar explanation emerges from observation of the values of ΔH_E. Attributing the unusual behavior of 1-iodododecane and 1-iodohexadecane to a "quasi-crystalline" structure, ΔH_E changes almost lineary with the length of a 1-iodoalkane between $3 \leqq u \leqq 7$, as if the contribution to ΔH_E by each carbon atom (or each $-CH_2-$ group) were constant. The value for 1-iodooctane seems to be the beginning of a constancy of ΔH_E; however, in the absence of any experimental results concerning molecules between $8<u<12$, no definitive conclusion about that is permitted.

Kinetics and Mechanisms of Oxidations by Metal Ions. X.[1] Oxidation of Phosphinic and Phenylphosphinic Acids by Tris(polypyridyl)iron(III) Complexes

Kamla SHARMA, Aditya PRAKASH, and Raj N. MEHROTRA*
Department of Chemistry, University of Jodhpur, Jodhpur 342001, India
(Received December 12, 1988)

A kinetic study on the oxidation of phosphinic(hypophosphorous) and phenylphosphinic acids by trispolypyridyliron(III) complexes using excess of either phosphinic or phenylphosphinic acid has been made in perchloric acid. The pseudo first-order rate constant k_{obs}, with respect to iron(III) complex, is independent of $[H^+]$. The results indicated that phenylphosphinic acid is more reactive than phosphinic acid towards any given iron(III) complex. The formation of an intermediate complex is indicated by the kinetics and supported by the spectrophotometry of the reaction mixture. The differences in the observed thermodynamic parameters of this intermediate complex, probably an outer-sphere complex, and those predicted by the Fuoss equation are discussed. It is suggested that the 'inactive' form of either of the acid is reactive towards the iron(III) complexes. It is also shown that the rate of disproportionation of the intermediate complex is not affected by the form of phosphinic or phenylphosphinic acid entering into the complex formation. The values of β_2 and k_1, the equilibrium constant for the formation of the oxidant-substrate complex and the rate limiting constant for its disproportionation respectively, are reported together with respective thermodynamic and activation parameters.

Efforts continue to identify the tautomeric form of oxoacids of phosphorous in their oxidation by metal or metal-complex ions. It had been shown that permanganate[2] and vanadium(V)[3] oxidations of phosphonic (phosphorous) acid involved the 'inactive' form $HP(O)(OH)_2$. However, Ce(IV) in nitric acid[4] oxidized the 'active' $HP(OH)_2$ form of phosphinic acid. The acid dependence in vanadium(V) oxidation of phenylphosphinic acid[5] indicated simultaneous oxidation of 'active' $C_6H_5P(OH)_2$ form by VO_2^+(aq.) (acid independent path) and 'inactive' $C_6H_5PH(O)(OH)$ form by $V(OH)_3^{2+}$ (aq.) (acid dependent path).

A survey of literature indicated that tris(polypyridyl)iron(III) complexes have not been used as oxidants for the oxoacids of phosphorus although it has been extensively used for the oxidations of both inorganic[6] and organic[7] substrates. Yet another reason for undertaking this study was to test the applicability of the Fuoss and Eigen equation[8] which has been applied successfully to several reactions proceeding through the formation of outer-sphere complex.[9] It might be added that an outer-sphere complex was expected in the present case because the tris(polypyridyl)iron(III) complexes are considered substitution inert.

The results indicated that the 'inactive' form of phosphinic and phenylphosphinic acid is the reactive species and the complex formed between tris(polypyridyl)iron(III) and phosphinic acid does not strictly conform to the outer-sphere complex as predicted by the Fuoss-Eigen equation.[8]

Experimental

Reagents. Phosphinic and phenylphosphinic acids (Fluka) were used as received. The stock solutions were standardized by cerimetry.[10] Sodium perchlorate was prepared by the neutralization of a known weight of sodium carbonate (BDH, AnalaR) by standard perchloric acid (E. Merck, GR). The neutralized solution was boiled to remove any dissolved carbon dioxide and made to volume. It was used to adjust the ionic strength. Lithium perchlorate was received from G. F. Smith and used as such. The stock solution of perchloric acid was standardized against a standard alkali. 1,10-Phenanthroline (E. Merck) and 2,2′-bipyridine (BDH) were used as received. Sodium thiosulfate (BDH, AnalaR) was standardized iodometrically against a standard solution of dichromate (BDH, AnalaR) using starch as the indicator. Twice distilled water, once distilled from an all glass still in presence of alkaline permanganate, was used for the preparation of solutions.

Preparation of $[FeL_3]^{3+}$ Complexes. Iron(III) complexes of 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy), FeL_3^{3+}, were prepared by the interaction of iron(II) sulfate and respective ligand in 1 : 3 ratio. In fact, the ligand was taken in slight excess to ensure complete complexation of Fe(II). The iron(II) complexes were then oxidized by lead dioxide.[11,12] The blue solution of iron(III) complex was filtered through a sintered G4 crucible and the perchlorate salt was precipitated by the addition of minimum quantity of 70% perchloric acid. The solid so obtained was recrystallized from aqueous perchlorate solution.

The standard stock solution of the respective complex was prepared in perchloric acid (10 mol dm^{-3}) by weight and stored in the refrigerator. Although such stock solutions are stated to be stable for at least three months at room temperatures in the dark,[13] the solutions older than 48 hours were discarded. The spectral characteristics of FeL_3^{2+} and FeL_3^{3+} solutions matched well with those reported in the literature.[14]

Stoichiometry. A number of reaction mixtures having different FeL_3^{3+} concentrations and known excess of phosphinic acid were prepared in different $[H^+]$. On complete reduction of the iron(III) complex, the amount of phosphonic acid produced was determined as described below.[15]

The reaction mixtures were suitably diluted or neutralized

to bring down the concentration of perchloric acid to less than 0.1 mol dm^{-3}. A 50 ml of the solution was added to a known solution of iodine in phosphate buffer, and the pH 7.3 was adjusted. After about one hour the solutions in iodine flasks were acidified with 6 mol dm^{-3} acetic acid and immediately titrated for the liberated iodine with a standard thiosulfate solution to a starch-iodine end point. The results of several such estimations indicated that $\Delta[H_3PO_2]/\Delta[FeL_3^{3+}]=0.51\pm0.04$. Hence the stoichiometric equation for the reaction is expressed by Eq. 1.

$$2FeL_3^{3+}+H_3PO_2+H_2O \rightarrow 2FeL_3^{2+}+H_3PO_3+2H^+ \quad (1)$$

Rate Measurements. The rate was measured under pseudo first-order conditions ($[RH_2PO_2]\geq 10[FeL_3^{3+}]$, where R=$C_6H_5$ for phenylphosphinic acid and R=H for phosphinic acid). The reagents, FeL_3^{3+} and phosphinic/phenylphosphinic acid with required concentrations of sodium perchlorate and perchloric acid, were taken separately. These were allowed to attain the thermal equilibrium in a thermostated water bath maintained at the desired temperature with a possible variation of ±0.1 °C. The reaction was initiated by the quick mixing of the desired volumes of FeL_3^{3+} and phosphinic/phenylphosphinic acid solutions.

The kinetics was followed by measuring the absorbance of $Fe(phen)_3^{2+}$ at 510 nm and that of $Fe(bpy)_3^{2+}$ at 520 nm on a Beckman DU-2 spectrophotometer. The quartz cell, 1 cm pathlength, was immediately returned to the cell compartment after the transfer of the reaction mixture. The absorbance of the FeL_3^{2+} complex was quickly measured thereafter.

The slow hydrolysis of $Fe(phen)_3^{2+}$ to free Fe^{2+}(aq.) and 1,10-phenanthroline[16] does not affect the measurements of A_∞ in reactions where the rate of oxidant loss is much faster. It is for this reason that reactions on stopped-flow time scale could be studied for several half lives of the reactions. However, in reactions where the rate of oxidant loss is either of comparable magnitude or slower than the rate of hydrolysis of FeL_3^{2+} there arises a problem both in following the reaction even upto the first half-life and measuring A_∞ because the hydrolyzed product Fe^{2+}, reacting rapidly,[17] vitiates both the kinetics and A_∞. Hence for the measurement of A_∞, the reaction mixture was reduced with a pinch of solid iron(II) sulfate[18] and the absorbance (A_∞) of the resulting solution was immediately recorded.

Since the $t_{1/2}(=0.691/k_{obs})$ with $[H_3PO_2]=0.1$ and $[H^+]=1.0$ mol dm^{-3} at 35 °C approximated to about 4 hours, the rate measurements had to be restricted to the initial 35—40% of the reaction. The plots of $\ln(A_\infty-A_t)$ against time for the mentioned range were linear; where A_∞ and A_t are the absorbance at infinite time and time 't'. The gradient of the linear plots ($=k_{obs}$) was estimated using a computer program based on the method of least squares.

Test for Free Radical. The formation of a free radical during the progress of the reaction was indicated by the polymerization of acrylonitrile added to the reaction mixtures degassed with nitrogen. The individual solutions of FeL_3^{3+} and phosphinic or phenylphosphinic acid, similarly degassed, did not initiate the polymerization of the acrylonitrile monomer.

Spectrophotometry. The visible (450—750 nm) spectra of FeL_3^{3+} and reaction mixtures having FeL_3^{3+} and RH_2PO_2 in the ratios of 1 : 1 and 1 : 10 were recorded on a Shimadzu 240 UV-vis Graphicord spectrophotometer at room temperature (27 °C). The spectra shown in Figs. 1 and 2 are for $Fe(bpy)_3^{3+}$ (8.0×10^{-4} mol dm^{-3}) and phosphinic and phenylphosphinic acids in 2.5 mol dm^{-3} perchloric acid respectively. It is worth noting that absorbance increased with increasing concentrations of oxoacid of phosphorous and a pronounced hump developed near 530 nm for 1 : 10 mixture. The spectra is indicative of the formation of a complex, probably an outer-sphere complex.

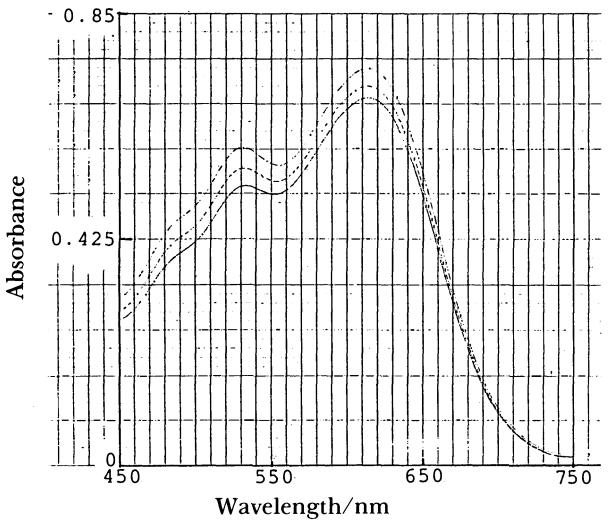

Fig. 1. Visible spectra of the mixtures of $Fe(bpy)_3^{3+}$ and H_3PO_2 at 27 °C in the ratio 1 : 0(——), 1 : 1 (----), and 1 : 10 (—·—) where $[Fe(bpy)_3^{3+}]=8.0\times10^{-4}$ mol dm^{-3}, and $[H^+]=2.5$ mol dm^{-3}.

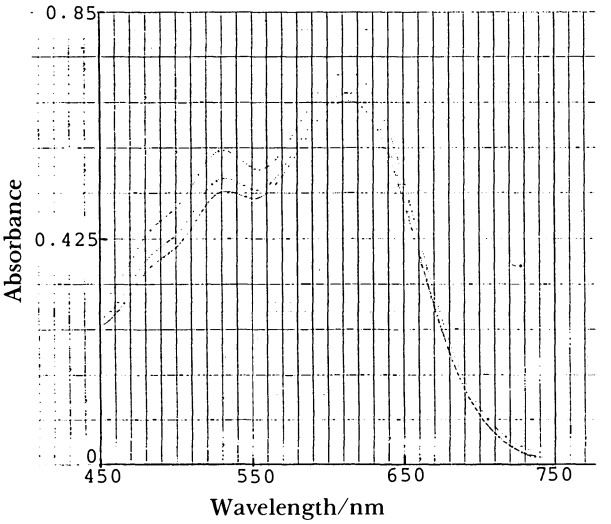

Fig. 2. Visible spectra of $Fe(bpy)_3^{3+}$ and $C_6H_5H_2PO_2$ at 27 °C in the ratio 1 : 0 (——), 1 : 1 (----), and 1 : 10 (—·—) where $10^4[Fe(bpy)_3^{3+}]=8.0$ and $[H^+]=2.5$ mol dm^{-3}.

Results

Dependence on FeL_3^{3+}. The first order reduction of FeL_3^{3+} is confirmed by the invariance of k_{obs} over a ten-fold variation in the initial $[FeL_3^{3+}]$. The results for the oxidation of phenyl phosphinic acid are in

Table 1. Dependence of $k_{obs}(s^{-1})$ on the Initial $[FeL_3^{3+}]$ at 25 °C.

$10^3[C_6H_5H_2PO_2]=3.0$, $[H^+]=0.5$, and $I=1.0$ mol dm^{-3}

$10^5[Fe(phen)_3^{3+}]$	10^5k_{obs}	$10^5[Fe(bpy)_3^{3+}]$	10^5k_{obs}
1.26	10.1	1.46	8.67
5.05	10.0	5.87	8.61
7.58	10.2	8.75	8.77
10.1	9.92	11.7	8.66
12.6	10.1	14.6	8.70

Table 1. The slightly higher k_{obs} value for $Fe(phen)_3^{3+}$ oxidation compared to the value for $Fe(bpy)_3^{3+}$ oxidation is consistent with the higher redox potential of $Fe(phen)_3^{3+}$.

Dependence on [1,10-phenanthroline]. These experiments are designed to know whether the complex between FeL_3^{3+} and oxoacid of phosphorous is formed in accordance with the equilibrium (2). The formation of the complex was indicated by the spectrophotometric studies of the reaction mixtures described earlier.

$$FeL_3^{3+}+nH_3PO_2 \rightleftarrows FeL_{(3-n)}(H_3PO_2)_n^{3+}+nL \quad (2)$$

where n has a maximum value of 1 as indicated by the order of the reaction with respect to phosphinic acid.

A retardation in k_{obs} was expected if $FeL_{(3-n)}(H_3PO_2)_n^{3+}$ is reduced to the products in the rate limiting step. The fact that k_{obs} is independent over more than twelve-fold variation in [1,10-phenanthroline], Table 2, the probability of the formation of an inner-sphere complex is excluded from the purview of any mechanism to be proposed for the reaction.

Dependence on $[Fe(phen)_3^{2+}]$. The rates were measured in terms of disappearance of $Fe(phen)_3^{3+}$ at 360 nm ($\varepsilon_{Fe(phen)_3^{3+}}=5500$ and $\varepsilon_{Fe(phen)_3^{2+}}=1000$ dm^3 mol^{-1}cm^{-1})[19] and then in terms of appearance of $Fe(phen)_3^{2+}$ at 510 nm ($\varepsilon_{Fe(phen)_3^{2+}}=11000$,[20] and $\varepsilon_{Fe(phen)_3^{3+}}=300$ dm^3 mol^{-1}.[21] The values $10^5k_{obs}=5.27$ and 5.37 s^{-1}, obtained at two wavelengths respectively are in agreement with the value $10^5k_{obs}=4.8$ s^{-1} obtained at $[H_3PO_2]=0.10$ mol dm^{-3} in the absence of $Fe(phen)_3^{2+}$ under identical experimental conditions ($10^5[Fe(phen)_3^{3+}]=6.32$, $10^5[Fe(phen)_3^{2+}]=3.16$, $[H_3PO_2]=0.11$, $[H^+]=0.5$ and $I=1.0$ mol dm^{-3} at 36 °C). Hence, reaction (3) or any such other equilibrium has no mechanistic significance.

$$[FeL_3\cdots H_3PO_2]^{3+} \rightleftarrows FeL_3^{2+}+H_3PO_2^+ \quad (3)$$

Dependence on $[H_3PO_2]$. In this study it was noted that k_{obs} did not increase proportionately with $[H_3PO_2]$. The plot between k_{obs} and $[H_3PO_2]$, Fig. 3, is nonlinear. However, the plots between k_{obs}^{-1} and $[H_3PO_2]^{-1}$ are linear with an intercept on the rate ordinate. The results of the temperature dependence study are in Table 3.

Table 2. Dependence of k_{obs} (s^{-1}) on the Initial [1,10-phenathroline] at 30 °C.

$10^5[Fe(phen)_3^{3+}]=6.32$, $[H^+]=0.5$, $[H_3PO_2]=0.1$, and $I=1.0$ mol dm^{-3}

10^5[phen]/mol dm^{-3}	0.5	1.0	2.0	4.0	6.32
$10^5k_{obs}/s^{-1}$	3.45	3.47	3.44	3.46	3.48

M=Li	11.8	10.2	9.93	9.45	9.05	

The concentration shown under $[H^+]$ in the table is the sum of $[H^+]$ from perchloric acid and dissociation of phosphinic acid. A K_a value=0.051, extrapolated from the data of Espension and Binau[22c] is used to calculate the dissociated $[H^+]$ from phosphinic acid. The conclusion of the study is that k_{obs} is independent of $[H^+]$.

Medium Effects. Redox and substitution reactions are affected by the medium effects[23,24] where uncertainties in hydrogen ion effects may be related to differences in the activity coefficients of the counter ions (Na^+ or Li^+) used as perchlorate salts for adjusting the ionic strength to a constant value while varying the $[H^+]$. These effects are usually absent for intramolecular redox reactions.[25] Indeed the presence of medium effects is confirmed by the fact that k_{obs} values corresponding to Li^+ are consistently lower than the values obtained for the corresponding Na^+. The results are in Table 5.

Effect of Ionic Strength. The results, Table 5, indicate that k_{obs} decreased with increasing ionic strength. The plot of logarithmic value of k_{obs} against $I^{1/2}/(1+I^{1/2})-0.05I$ is linear with the slope value=−0.48 for Na^+ and −0.53 for Li^+ which is much less than the theoretical value expected for the reaction between charged ions involved in the reaction. This discrepancy could be due to the presence of more than one equilibrium before the rate determining step.

Empirical Rate Law. All the above results are summarized by the empirical rate law given in Eq. 4.

$$\frac{-d[FeL_3^{3+}]}{dt}=\frac{d[FeL_3^{2+}]}{dt}=\frac{a[RH_2PO_2]_o[FeL_3^{3+}]_o}{1+b[RH_2PO_2]_o} \quad (4)$$

where a and b are empirical constants and subscript "o" denotes the analytical concentration used.

Discussion

Since the rate of the reaction is independent of $[H^+]$, there is a possibility that two equilibria, which are affected by the H^+ in the opposite directions, are present so that the net effect of H^+ is not noticed. The two such equilibria are considered in Eqs. 5 and 6. The consideration of the equilibrium (5) is influenced by the fact that in the tris (1,10-phenanthroline)iron(III) oxidation of ascorbic acid,[19,26] the pK_{1a} of which is much higher[19,25,26] than that of phosphinic acid[22] and phenylphosphinic acid,[27] both undissociated ascorbic acid and hydrogen ascorbate ion are considered reactive. The equilibrium (6) has been considered in several studies.[19,20,28,29] The concentration of the complex $[FeL_3\cdots RH_2PO_2]^{3+}$, formed through the equilibria (7) and (8), remains stationary under any given $[H^+]$ which explains no effect of H^+on the observed rate of the reaction. The mechanism involving reactions (5)—(10) is considered below.

$$RH_2PO_2 \overset{K_a}{\rightleftarrows} RHPO_2^- + H^+ \quad (5)$$

$$H^+ + FeL_3^{3+} \overset{K_c}{\rightleftarrows} HFeL_3^{4+} \quad (6)$$

$$HFeL_3^{4+} + RHPO_2^- \overset{\beta_1}{\rightleftarrows} [FeL_3\cdots RH_2PO_2]^{3+} \quad (7)$$

$$FeL^{3+} + RH_2PO_2 \overset{\beta_2}{\rightleftarrows} [FeL_3\cdots RH_2PO_2]^{3+} \quad (8)$$

$$[FeL_3\cdots RH_2PO_2]^{3+} \overset{k_1}{\rightarrow} RHPO_2^{\cdot} + FeL_3^{2+} + H^+ \quad (9)$$

$$RHPO_2^{\cdot} + H_2O + FeL_3^{3+} \overset{\text{fast}}{\longrightarrow} RH_2PO_3 + FeL_3^{2+} + H^+ \quad (10)$$

It is thus seen that the formation of the complex $[FeL_3\cdots RH_2PO_2]^{3+}$ in equilibrium (7) involved equilibrium (5) and equilibrium (6) whereas it is also formed through equilibrium (8) alone. The exact path of its formation cannot be stated unambiguously because $\beta_2=\beta_1K_aK_c$. The consideration of the above reactions leads to the rate law in Eq. 11.

$$k_{obs}=\frac{2k_1\beta_2[RH_2PO_2]_o}{(1+K_a[H^+]^{-1})(1+K_c[H^+])+\beta_2[RH_2PO_2]_o} \quad (11)$$

Although the rate law in Eq. 11 is not independent of $[H^+]$, yet with the appropriate assumption that $1+\beta_2[RH_2PO_2]_o \gg K_a[H^+]^{-1}+K_c[H^+]+K_aK_c$ because the values of K_a and K_c are much less than 1; the Eq. 11 is thus reduced to Eq. 12 which is independent of $[H^+]$. The Eq. 12 is identical to the empirical rate law in Eq. 4 where $a=2k_1\beta_2$ and $b=\beta_2$.

$$k_{obs}=\frac{2k_1\beta_2[RH_2PO_2]_o}{1+\beta_2[RH_2PO_2]_o} \quad (12)$$

The Eq. 12 holds in the sense that plots of k_{obs}^{-1} against $[RH_2PO_2]_o^{-1}$, Fig. 4, are linear at all temperatures. From the gradient and intercept of such plots, the values of β_2 and k_1 are derived and are given in Tables 6 and 7 respectively.

Alternate Mechanism. A simple and straight forward mechanism providing a rate law independent of $[H^+]$ could also be described by the reactions (8)—(10). The consideration of these reactions leads to the deduction of the rate law given in Eq. 12. There is no way to differentiate between the mechanisms described by reactions (5)—(10) and the one described by the reactions (8)—(10).

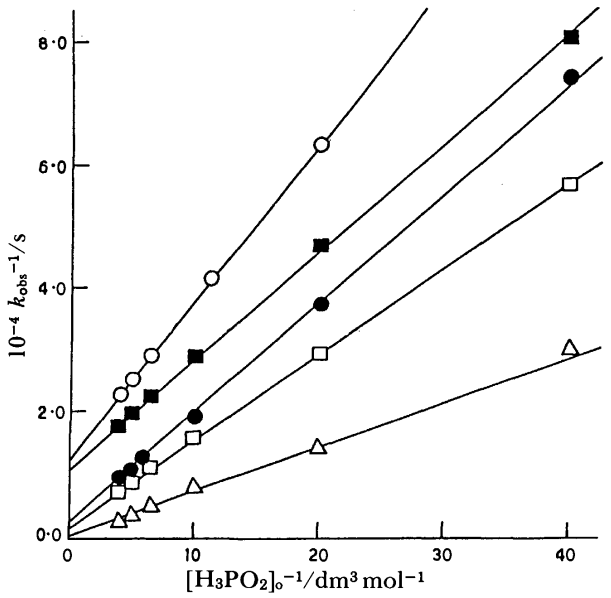

Fig. 4. Plot between k_{obs}^{-1} and $[H_3PO_2]^{-1}$ at different temperatures for the oxidations affected by $Fe(phen)_3^{3+}$ at 30 °C (■), 40.5°C (□), and 50 °C (△) and for the oxidations by $Fe(bpy)_3^{3+}$ at 30 °C (○) and 40.5 °C (●).

The dissociation of ferriin is a first-order reaction[30] in $[H^+]$. Hence in the absence of any dependence of rate on H^+, it is apparent that the dissociation of ferriin is not a part of the mechanism. That there is no dissociation of ferriin is further supported by the results on the effect of variation of 1,10-phenanthroline on the observed rate.

Fuoss equation[8] has been favored as tool to differentiate between an outer-sphere and inner-sphere complex. The Fuoss equation is given in Eq. 13.

$$K_o = \frac{4\pi N_A a^3}{3000} \exp \frac{-z_1 z_2 e^2}{aDkT} + \frac{z_1 z_2 e^2 k}{DkT(1+ka)} \quad (13)$$

where N_A is Avogadro's number, a=the centre to centre separation of the ions at closest approach, e=electronic charge, z_1 and z_2 are the charges on the ions with appropriate sign, D is the dielectric constant, k=Boltzmann's constant, and k the Debye-Hückel parameter.

The approach is based on the theoretical calculation of the association constant and the associated thermodynamic parameters and then these are compared with the experimentally obtained data.

The values of K_o were calculated at different temperatures by considering r=7 Å[16] for $Fe(phen)_3^{3+}$ and 3 Å for phosphinic acid (calculated by the relation $4\pi r^3/3 = M/n_A d$ where M is the molecular weight and d is the density) and a=10 Å and using the value of D at different temperatures.[31] These are given in Table 8 wherein are also reported the calculated thermodynamic parameters. The value of K_o, 4.86 dm^3 mol^{-1}, at 25 °C is somewhat less than the value of β_2 extrapolated to the same temperature. The other differences are (i) K_o increased with the temperature whereas β_2 decreased and (ii) the values of the enthalpy and entropy are positive for K_o whereas these parameters have negative values for β_2. We at this point are not sure whether this is an exception to the applicability of the Fuoss equation or whether the complex formed is an inner-sphere complex. The possibility of the formation of an inner-sphere complex such as proposed in the oxidation of I^- by hexacyanoferrate(III) ion[32] cannot be over ruled. The assignment of an inner-sphere or outer-sphere mechanism to a redox reaction is often difficult.[33]

'Active' vs. 'Inactive' Form. The presence of H^+ in the reaction system requires the consideration of the equilibrium (14). This equilibrium is attractive in the sense that it is independent of $[H^+]$ though the conversion of 'inactive' form to 'active' form is catalyzed by H^+. The active form is thought to be produced as an intermediate in the exchange of phosphorus bonded hydrogen in phosphinic acid with tritium[34] or deuterium.[35] The value of the equilibrium constant is of the order of 10^{-12}.[36]

$$H^+ + H_2P(O)OH \overset{K}{\rightleftarrows} H_2P(OH)(OH^+) \rightarrow H:P(OH)_2 + H^+ \quad (14)$$

Table 8. Values of Outer-Sphere Association K_o, Calculated for $Fe(phen)_3^{3+} \cdots H_3PO_2$ from the Fuoss Equation

Temp/°C	25	30	35	40	45
K_o/dm^3 mol^{-1}	4.86	4.91	4.96	5.01	5.07

$\Delta H°$=1.65 kJ mol^{-1}, $\Delta S°$=18 J K^{-1} mol^{-1}.

The following reactions (15)—(17) duplicate the reactions (8)—(10) and are supposed to have the 'inactive' form as the reactive entity.

$$FeL_3^{3+}+\underset{\text{(inactive)}}{H_2P(O)(OH)} \overset{\beta}{\rightleftarrows} [FeL_3\cdots H_2P(O)(OH)]^{3+} \quad (15)$$

$$[FeL_3\cdots H_2P(O)(OH)]^{3+} \xrightarrow{k} H_2PO_2^{\cdot}+H^+ +FeL_3^{2+} \quad (16)$$

$$FeL_3^{3+}+H_2O+H_2PO_2^{\cdot} \xrightarrow{\text{fast}} H_3PO_3+FeL_3^{2+}+H^+ \quad (17)$$

The consideration of the reactions (14)—(17) and the fact that $1 \gg K$ leads to the rate law in Eq. 18 which is similar to the rate law in Eq. 12.

$$\frac{d[FeL_3^{2+}]}{dt} = \frac{2k\beta[FeL_3^{3+}][H_3PO_2]_o}{1+\beta[H_3PO_2]_o} \quad (18)$$

However, if the 'active' form $H:P(OH)_2$ is reactive then the respective reactions are in Eqs. 14 and 19—21. The rate law based on these reactions, and acknowledging the fact that $1 \gg K$, will have the form given in Eq. 22.

$$FeL_3^{3+}+H:P(OH)_2 \overset{\beta_a}{\rightleftarrows} [FeL_3\cdots H:P(OH)_2]^{3+} \quad (19)$$

$$[FeL_3\cdots H:P(OH)_2]^{3+} \xrightarrow{k_a} :P(OH)_2+H^+ +FeL_3^{2+} \quad (20)$$

$$FeL_3^{3+}+H_2O+:P(OH)_2 \xrightarrow{\text{fast}} HP(O)(OH)_2+H^+ +FeL_3^{2+} \quad (21)$$

$$\frac{d[FeL_3^{2+}]}{dt} = \frac{2k_a\beta_aK[FeL_3^{3+}][H_3PO_2]_o}{1+\beta_aK[H_3PO_2]_o} \quad (22)$$

Thus in the plots between k_{obs}^{-1} and $[H_3PO_2]_o^{-1}$, Fig. 4, the slope and intercept are equivalent to those given in Eq. 23.

$$\text{Slope}=(2k_a\beta_aK)^{-1};\ \text{intercept}=1/2k_a,\ \text{and intercept/slope}=K\beta_a \quad (23)$$

It is thus seen that $k=k_a$ which means that the rate limiting constant for the disproportionation of the complex is not affected by the reactive form of phosphonic acid. However, $\beta=K\beta_a$ so that $\beta_a=\beta/K=10^{12}\beta$ (or $\beta_2=6.4\times10^{12}$ dm^{3}mol^{-1} at 30 °C). Considering that FeL_3^{3+} is inert to substitution this high value of β_a is certainly inadmissible. Hence it is concluded that 'active' form is not the reactive entity thus leaving the 'inactive' form to be the reactive species.

Authors are grateful to CSIR, New Delhi, for the financial support and the award of a Junior Research Fellowship to KS. RNM also thanks Prof. Louis J. Kirschenbaum, Department of Chemistry, University of Rhode Island, Kingston, RI, USA for extending all the facilities in his laboratories where this manuscript was prepared.

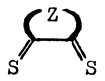
(Received January 5, 1989)

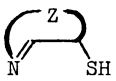
Complexing processes occurring between reactive matrices obtained from Fe(III), Co(III), Ni(II), Cu(II) hexacyanoferrates(II), and alkaline solutions of various nitrogen-sulfur-containing chelating ligands in thin gelatin layers have been studied. With Fe(III) and Cu(II) hexacyanoferrates, complexing process is found out to proceed according to S_N1 mechanism, while in Co(III) and Ni(II) hexacyanoferrates matrices, S_N2 mechanism is realized. The schemes of the processes proceeding in each of the above matrices are given. The examples of the kinetic curves for particular systems "hexacyanoferrate(II)-ligand" as well as spectral characteristics of thin gelatin layers containing chelate complexes formed as a result of the chelating process are presented. The possibility of practical utilization of complexing processes studied for obtaining non-silver photographic images from light-resistant metallorganic dyes is reported.

Modern chemical photographic industry is known to be one of the largest silver-consuming industries which spends annually about 30% of the total output of this precious metal.[1] One of the ways of overall cutting down the silver consumption in this branch of technology is the so called silver recovery. One of the methods of silver recovery process consists in the following: being a "working material" for the formation of a photographic image, by means of a number of specific chemical reactions, silver is substituted for chelate complexes of 3d-elements having various nitrogen-sulfur-containing ligands intensively absorbing in the visible spectrum region. Due to this process, it becomes possible to form in the initial silver halide photographic material non-silver images characterized by an extremely high light resistance and stability towards detrimental atmospheric attacks (oxygen, sulfuric compounds etc.). From the chemical point of view, the formation of non-silver images with such carriers is nothing but a heterogenous complexing process, and the investigation of the latter presents both academic and practical interest.

In the present paper methods of electron spectroscopy and spectrophotometry were used to investigate the processes of heterogenous complexing occurring in thin layers of various silver halide materials containing previously formed and uniformly dispersed in the gelatin binding agent reactive matrices obtained from Fe(III), Co(III), Ni(II), and Cu(II) hexacyanoferrates(II) upon the reaction with alkaline solutions of chelating ligands of types **I** and **II**:



I



II

(where Z is a closed-ring or open-ring group of various atoms).

Experimental

Matrices containing metal hexacyanoferrates(II) were obtained on the basis of the conventionally formed silver images (by the development and fixation of the silver halide photographic material),[2] by means of the two-stage chemical treatment. The first stage includes oxidation of elemental silver into its hexacyanoferrate(II) or halide, alongside with the co-precipitation of Fe(III), Co(III), Ni(II), and Cu(II) hexacyanoferrates(II) upon the reaction with solutions containing potassium hexacyanoferrate(III), $K_3[Fe(CN)_6]$, and a complex with a corresponding metal ion with a certain oxyacid, according to the following schemes (1—4):[3-6]

$$2Fe_2(HCt)(HTart) + 4[Fe(CN)_6]^{3-} + 4Ag + 3K^+ \rightarrow 3KFe[Fe(CN)_6] + Ag_4[Fe(CN)_6] + [Fe(HTart)_2]^{3-} + 2HCt^{3-} \quad (1)$$

$$4[Co(HCt)_2]^{3-} + 4[Fe(CN)_6]^{3-} + 4Ag + 4Cl^- \rightarrow Co_4[Fe(CN)_6]_3 + 4AgCl + 8HCt^{3-} + [Fe(CN)_6]^{4-} \quad (2)$$

$$6[Ni(HCt)_3]^{7-} + 4[Fe(CN)_6]^{3-} + 4Ag + 4Cl^- \rightarrow 3Ni_2[Fe(CN)_6] + 4AgCl + 18HCt^{3-} + [Fe(CN)_6]^{4-} \quad (3)$$

$$6[Cu(ox)_2]^{2-} + 4[Fe(CN)_6]^{3-} + 4Ag \rightarrow 3Cu_2[Fe(CN)_6] + Ag_4[Fe(CN)_6] + 12ox^{2-} \quad (4)$$

(here H_2ox, H_4Ct, and H_4Tart are oxalic, citric, and tartaric acids, respectively).

The second stage involves the transition of $Ag_4[Fe(CN)_6]$ and AgCl into the solution upon the reaction with an aqueous thiosulfate solution according to schemes (5 and 6) at the expense of the formation of a water-soluble complex:

$$Ag_4[Fe(CN)_6] + 8S_2O_3^{2-} \rightarrow 4[Ag(S_2O_3)_2]^{3-} + [Fe(CN)_6]^{4-} \quad (5)$$

$$AgCl + 2S_2O_3^{2-} \rightarrow [Ag(S_2O_3)_2]^{3-} + Cl^- \quad (6)$$

Between the stages, as well as upon the completion of the second stage, the material comprising a metal hexacyanoferrate(II) matrix was washed by the running water for a few minutes, and then the matrix was processed in alkaline solutions of sulfur-containing ligands such as dithiooxam-

ide NH_2-C(=S)-C(=S)-NH_2, its *N,N'*-diphenyl-substituted derivative, 2,3-quinoxalinedithiol  (which can be regarded as a thiol form of a substitution product of two hydrogen atoms for 1,2-phenylene in a dithiooxamide molecule), 8-quinolinethiol  and its 5-chloro- and 5-methylthio derivatives. Ligand concentration in the solution varied in the range of 10^{-3}—10^{-1} mol·dm^{-3}, pH value was maintained at 12.0±0.1, since these parameters provide for the large accumulation of the thiol form of ligands directly involved in heterogenous complexing processes. Besides, a relatively high physicomechanical strength of the gelatin layer is preserved in which a non-silver image is formed. Matrices were kept in alkaline solutions for about 1—10 min at 20 °C. Optical densities of thin layers containing chelate complexes were measured on a "Macbeth TD-504" densitometer (Kodak Co., USA) in the region (0—4) with an accuracy of ±2% (rel.); the absorption spectra were measured on a SPECORD spectrophotometer in the region 10000—30000 cm^{-1} (350—1000 nm). Using the result of the measurements, kinetic curves were plotted in $D=f(D^{Ag})$ coordinates (where D^{Ag} is the density of a thin gelatin layer containing elemental silver. D is the density of a thin layer containing chelate complex formed upon the chemical processing of the gelatin layer having D^{Ag} density) for various time-concentration conditions of heterogenous complexing processes using Fe(III), Co(III), Ni(II), and Cu(II) hexacyanoferrate(II) matrices containing the above mentioned ligands. The examples of such relationships are given in Figs. 1—4. The analysis of these $D=f(D^{Ag})$ relationships enables one to make certain conclusions which are given in the section below.

Results

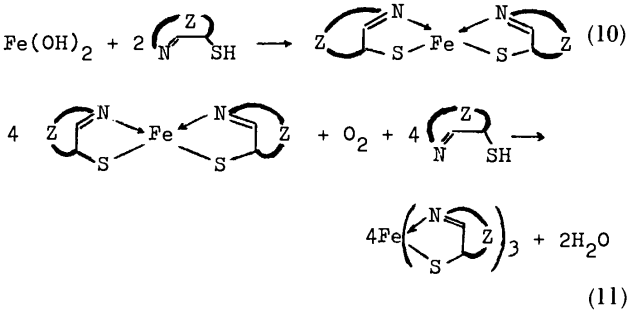
In case of the systems containing Fe(III) and Cu(II) hexacyanoferrate(II) matrices, heterogenous complexing occurs according to pseudo-S_N1 mechanism where ligand entering the internal coordination sphere is preceded by the decomposition of hexacyanoferrate(II) molecules into the corresponding hydroxides, according to schemes (7,8) and (9), respectively.

$$2KFe[Fe(CN)_6]+6OH^- \rightarrow Fe_2O_3+2[Fe(CN)_6]^{4-}+2K^++3H_2O \quad (7)$$

$$KFe[Fe(CN)_6]+2OH^- \rightarrow Fe(OH)_2+[Fe(CN)_6]^{3-}+K^+ \quad (8)$$

$$Cu_2[Fe(CN)_6]+4OH^- \rightarrow 2Cu(OH)_2+[Fe(CN)_6]^{4-} \quad (9)$$

On a Fe(III) hexacyanoferrate(II) matrix, heterogenous complexing was observed only with type II ligands, with the formation of compounds having metal ion/ligand ratio equal to 1 : 3. The process of their formation, unlike other matrices, occurs in the presence of molecular oxygen and consists of two stages, provided that initially formed Fe(II) chelates are oxidized into Fe(III) chelates, which impart to thin



(10)

(11)

gelatin layers different shades of the redbrown color and give absorption in the region of 450—480 nm. For Cu(II) hexacyanoferrate(II) matrices under similar conditions, insoluble 1 : 2 chelates are formed which in a number of cases (e.g. with dithiooxamide or 2,3-quinoxalinedithiol) with an excessive ligand concentration are capable of passing into soluble forms and subsequently diffuse from the thin gelatin layer to a contacting alkaline solution of the respective ligand. The chelates thus formed usually acquire a yellow-brown color or (which is rare) a green-yellow color; absorption spectra of thin gelatin layers containing the above compounds demonstrate the "wings" of intensive bands of charge transfer from the ligand to a metal in the region of 330—370 nm, as well as the bands in the blue (460—490 nm) and the red (620—670 nm) visible spectrum regions. The exception is a dark-green Cu(II) chelate containing dithiooxamide which does not show distinct λ_{max} values. The process of Cu(II) chelate formation can be described by

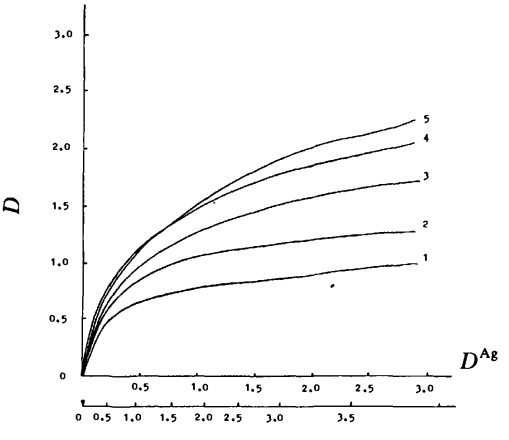


Fig. 1. Kinetic curves in $D=f(D^{Ag})$ coordinates for the system containing $KFe[Fe(CN)_6]$-8-quinolinethiol matrix at the fixed (3×10^{-2} mol·dm^{-3}) ligand concentration in the solution and variable Fe(III) hexacyanoferrate(II) concentrations in the gelatin layer for the complexing process of different durations: 1 min—curve 1; 2 min—2; 4 min—3; 6 min—4; 10 min—5 at 20 °C. Optical densities were measured through the yellow filter with a transmission in the visible spectrum region from its long-wave boundary to 590 nm. C_F is the concentration of hexacyanoferrate(II) in mol·m^2·10^{-2}.

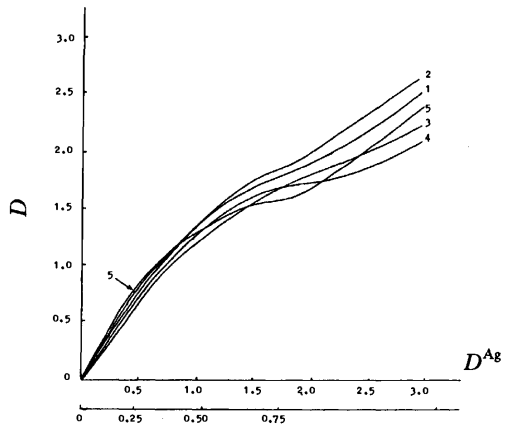

Fig. 2. Kinetic curves in $D=f(D^{Ag})$ coordinates for the system containing $Co_4[Fe(CN)_6]_3$-*N,N'*-diphenyldithiooxamide matrix at the fixed (4×10^{-3} mol·dm^{-3}) ligand concentration in the solution and variable Co(III) hexacyanoferrate(II) concentrations in the gelatin layer for the complexing process of different durations: 1 min—curve 1; 2 min—2; 4 min—3; 6 min—4 and 10 min—5 at 20 °C. Optical densities were measured through the red filter with a transmission maximum at 670 nm.

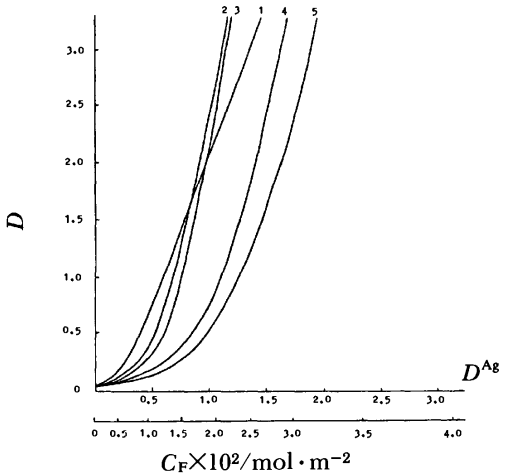

Fig. 3. Kinetic curves in $D=f(D^{Ag})$ coordinates for the system containing $Ni_2[Fe(CN)_6]$-dithiooxamide matrix at the fixed (2×10^{-2} mol·dm^{-3}) ligand concentration in the solution and variable Ni(II) hexacyanoferrate(II) concentrations in the gelatin layer, for the complexing process of different durations: 1 min—curve 1; 2 min—2; 4 min—3; 6 min—4; 10 min—5 at 20 °C. Optical densities were measured through the green filter with transmission maximum at 540 nm.

the equation similar to (10) which for type I ligands acquires the form of (12);

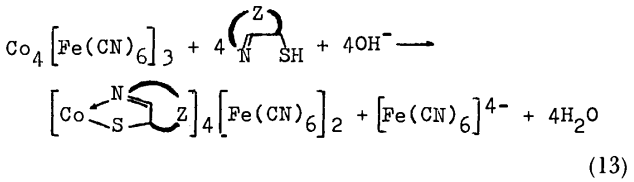
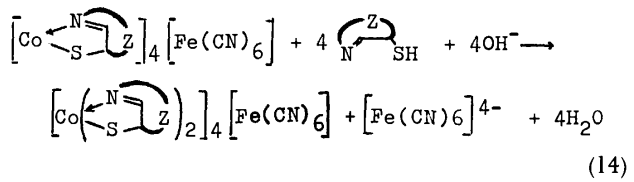
Optical densities were measured through the blue filter with transmission maximum at 450 mm.

(Z' is a deprotonated group Z).

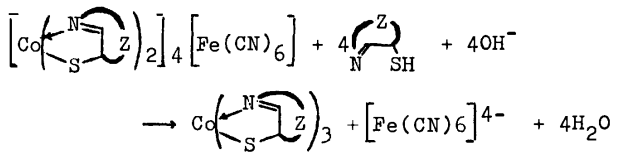
In case of $Co_4[Fe(CN)_6]_3$ and $Ni_2[Fe(CN)_6]$ matrices where S_N1 mechanism of ligand addition is realized, quite another way of heterogenous complexing is observed. In Co(III) hexacyanoferrate(II) matrix, a stepwise addition of ligands takes place, together with the formation of compounds having Co(III) ion/ligand ratio of 1 : 1, 1 : 2, and 1 : 3. The above process is accompanied by a somewhat peculiar change in optical densities of the thin gelatin layer which at first tend to increase, then decrease and finally again are observed to increase; this phenomenon is obviously connected with the relation of molar absorption coefficients (ε_{max}), such as $\varepsilon_{1:1}>\varepsilon_{1:2}<\varepsilon_{1:3}$. The chelates thus formed are of yellow, red-brown or brown colors, and they usually have either maximum at 400—460 nm or contain in the visible spectrum only the "wings" of charge transfer intensive bands coming from UV-region. In this case, complexing process can be described by the equations (13—15) (given for the ligands of type **II**):



(13)

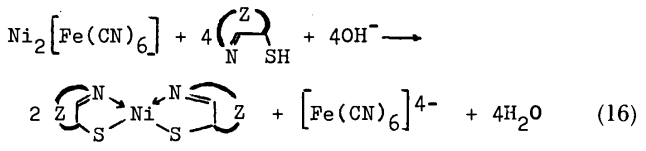


(14)



(15)

Of special importance is Ni(II) hexacyanoferrate(II) for which two different types of a ligand-hexacyanoferrate(II) matrix interaction can be distinguished. In the processes of the first type, such as heterogenous complexing in $Ni_2[Fe(CN)_6]$-8-quinolinethiol or its substitutes, insoluble chelates having a metal/ligand ratio of 1:2 with a singly deprotonated form of a ligand are formed. Such chelates do not decompose significantly even under the influence of excessive ligand concentrations in a solution directly contacting the thin gelatin layer. The color of such chelates is usually from pink to violet in the region 500—550 nm. It should be noted that with pH change, these chelates do not change their optical characteristics; for the ligands of type **II**, the formation process can be described by the general Eq. 16



(16)

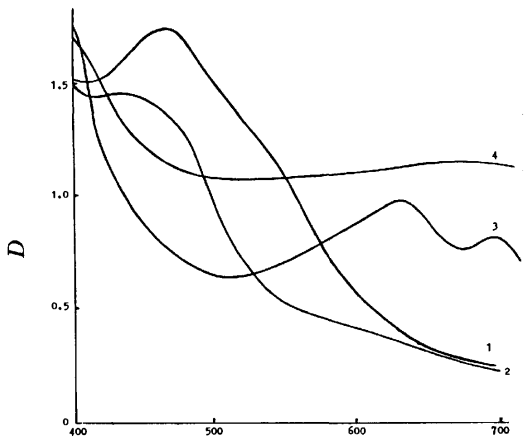


Fig. 5. Spectral characteristics of thin gelatin layers containing: 1—Fe(III) chelate with 8-quinolinethiol (C_F=0.3×10^{-2} mol·m^{-2}, ligand concentration in the solution is 3.0×10^{-2} mol·dm^{-3}, duration of complexing reaction is 2 min at 20 °C); 2—Co(III) chelate with dithiooxamide (C_F=0.4×10^{-2} mol·m^{-2}, ligand concentration in the solution is 1.0×10^{-2} mol·dm^{-3}, duration of complexing reaction is 4 min at 20 °C); 3—Ni(II) chelate with 2,3-quinoxalinedithiol (C_F=3.5×10^{-2} mol·m^{-2}, ligand concentration in the solution is 2.0×10^{-2} mol·dm^{-3}, duration of complexing reaction is 6 min at 20 °C); 4—Cu(II) chelate with dithiooxamide (C_F=4.0×10^{-2} mol·m^{-2}, ligand concentration in the solution is 4.0×10^{-3} mol·dm^{-3}, duration of complexing reaction is 4 min at 20 °C). The thickness of layers is 20000 nm (20 μm).

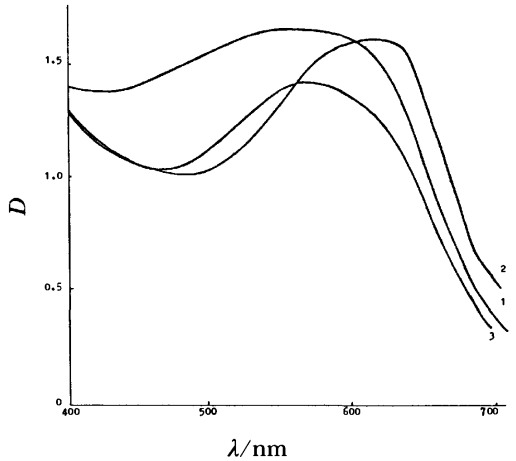

Fig. 6. Spectral characteristics of thin gelatin layers containing: 1—Ni(II) chelate with dithiooxamide of 1:1 ratio comprizing a completely ionized ligand form in the internal sphere (C_F=1.5×10^{-2} mol·m^{-2}, ligand concentration in the solution is 8.0×10^{-3} mol·dm^{-3}, duration of complexing reaction is 6 min at 20 °C); 2—Ni(II) chelate with dithiooxamide of 1:2 ratio (Structure **III**) (C_F=4.0×10^{-2} mol·m^{-2}, ligand concentration in the solution is 4.0×10^{-3} mol·dm^{-3}, duration of complexing reaction is 2 min at 20 °C); 3—Ni(II) chelate with dithiooxamide of 1:1 ratio (Structure **V**) (C_F=4.0×10^{-2} mol·m^{-2}, ligand concentration in the solution is 3.5×10^{-2} mol·dm^{-3}, duration of complexing reaction is 10 min at 20 °C). The thickness of layers is 20000 nm (20 μm).

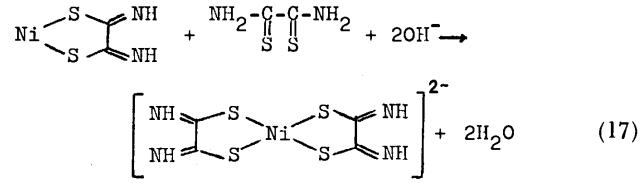
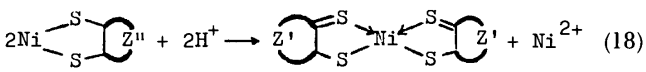
In a number of cases when a ligand is capable of forming a double-deprotonated form, another variant of heterogenous complexing is possible which can be found in systems containing $Ni_2[Fe(CN)_6]$-dithiooxamide and $Ni_2[Fe(CN)_6]$-2,3-quinoxalinedithiol, where two types of insoluble chelates having a partially or completely deprotonated form of the ligand are obtained. For systems of the first type, at a highly excessive ligand concentration, the initially formed insoluble 1:1 complex can pass into the soluble one diffusing from the gelatin layer into the solution; the process is accompanied by the decrease in optical densities of the thin layer:



(17)

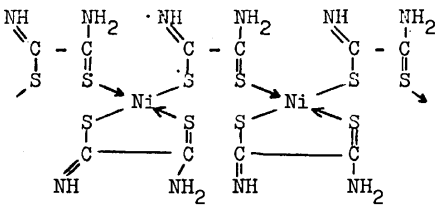
It is interesting to note that in case of such systems, the transition from the chelate with a completely deprotonated form to that with a partially deprotonated ligand form is also observed; the above mentioned transition can be realized simply by pH decrease in the gelatin layer.



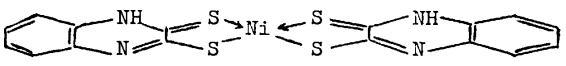
(18)

(Z″ is a double-deprotonated group).

In case of $Ni_2[Fe(CN)_6]$-2,3-quinoxalinedithiol system, the pink color of the thin chelate-containing gelatin layer is changed for the green one, and such color change is accompanied by the shift of absorption maximum from 520 nm up to 630 nm and the emergence of one more band at 700 nm assignable to 1 : 2 chelate.[7] Processing of the gelatin layer containing a cyan chelate results in the reduction of the pink color. In $Ni_2[Fe(CN)_6]$-dithiooxamide system, similar change of colors is observed (from pink-violet into blue) which is accompanied by the bathochromic shift of absorption maximum from 560 nm to 640 nm, but compared to the previously mentioned system, the color change here is found out to be irreversible.[8] The main cause of such differences lies in the structure dissimilarity of "acid" chelates: in case of dithiooxamide, the structure is polymeric **III**, while in 2,3-quinoxalinedithiol it is monomeric **IV**, since steric effects prevent polymer formation. Proton splitting out of the "stiff" polymer structure **III** turns out to be rather difficult and is not observed even at high pH values.

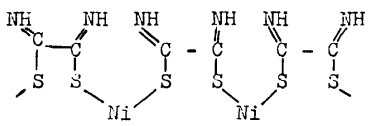


(**III**)



(**IV**)

In the $Ni_2[Fe(CN)_6]$-dithiooxamide system, at high hexacyanoferrate(II) and ligand concentrations, insoluble 1 : 1 chelate complex **V** is also formed having a double-deprotonated ligand form which is uncapable of proton addition; this is associated with the characteristics of a coordination polymer.



(**V**)

Summarizing the above considerations, it should be noted that testing performed with non-silver images containing metallorganic dyes obtained by heterogenous complexing described in this paper, showed that alongside with silver removal and good storability of images, an increase in photographic sensitivity can also be obtained. In a number of cases (such as in the formation of Co(III) dithiooxamide complexes, the sensitivity increase is an order of magnitude greater than the initial value for the silver photographic image, which is of great practical importance. The process described here can also be used for mono- and polychromatic dyeing of silver images and, in particular, for the production of the "blue slides".[9-11] In the near future, the process can be used in the development of a basically new technique of color photography for obtaining "nonageing" images.

Isomerization in the 1,4,7,10,13,16-Hexaazacyclooctadecanecobalt(III) System [Co(hexacyclen)]$^{3+}$, and Ion-Association Enhancement of the Unstable Facial Isomer

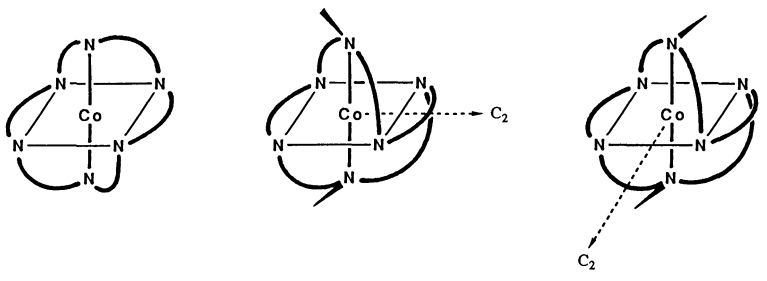
Graeme H. SEARLE
Department of Physical and Inorganic Chemistry, University of Adelaide, Adelaide, S.A. 5001, Australia
(Received March 29, 1989)

The substitution reaction $[Co(NH_3)_5(H_2O)]^{3+}$+hexacyclen·$3H_2SO_4$+6base+charcoal gives *mer*-[Co(hexacyclen)]$^{3+}$ as the major product, and the equilibrium proportion of the *fac* isomer is <1%. The commercial hexacyclen contains linpen (the open chain analogue of hexacyclen, generated by an elimination reaction in the Richman-Atkins cyclization synthesis procedure), so that the synthesis of complex yields [Co(linpen)]$^{3+}$ isomers as co-products which complicate the isolation of the pure [Co(hexacyclen)]$^{3+}$ isomers. Procedures are now given for obtaining the *mer* and *fac* isomers pure. In particular, the unstable *fac* isomer is obtained by isomerization of the *mer* in base in the presence of the strongly associating anion PO_4^{3-}. This yields the new equilibrium mixture *mer*:*fac*:hydrolysis products=71:18:11, wherein the *fac* proportion is enhanced twenty times, enabling the pure *fac* isomer to be obtained in quantity. For the base-catalyzed isomerization reaction *fac* → *mer* in NaOH solutions at 50 °C, procedures are given for following the reaction by analyses of samples using ion-exchange HPLC (Na_2SO_4 elution) and by spectrophotometry. The mechanism must involve intramolecular bond rupture, but the kinetic results are not consistent with a simple SN_1CB mechanism, and a two-step process involving an intermediate is indicated.

The cobalt(III) complex system [Co(hexacyclen)]$^{3+}$ formed by the sexadentate macrocyclic ligand hexacyclen[1] has considerable stereochemical interest since it can exist in several types of isomers (Fig. 1). The ligand can wrap around the cobalt to give the alternative topological arrangements described as *fac* and *mer*. The *fac* has all chelate ring linkages facial and is of approximate symmetry D_{3d}, whereas the *mer* has two meridional linkages and four facial linkages, and has approximate symmetry D_2 in the topological sense (with ring conformations ignored). Thus the *mer* topology is dissymmetric, *Δ* or *Λ*.[2] Additionally for the *mer*, diastereoisomers arise for each of these optical configurations due to the different orientations possible for the N-H bonds at the nitrogen centers coupling the *mer* rings.[2] In acidic conditions where these N-H hydrogen dispositions are prevented from interconverting via hydrogen exchange (and the conformations of the *mer* rings are hence constrained), the effective symmetry of each of the *mer* diastereoisomers is reduced to C_2. Thus there are three geometrically distinct species: the *fac* and the two *mer* racemates *mer*-(*Λδ*/*Δλ*) and *mer*-(*Λλ*/*Δδ*).

This [Co(hexacyclen)]$^{3+}$ system is stereochemically analogous to the $[Co(dien)_2]^{3+}$ system.[1,4] The isomer *sym*-[Co(hexacyclen)]$^{3+}$ corresponds to *sym-fac*-$[Co(dien)_2]^{3+}$. The *mer* isomers of the two complexes are related topologically, as the dien ligands in *mer*-$[Co(dien)_2]^{3+}$ can be coupled together by ethylene bridges in alternative ways to give the *Δ* and *Λ* enantiomeric topologies of *mer*-[Co(hexacyclen)]$^{3+}$. Also, in both of these *mer* complexes the alternative N-H orientations give rise to analogous optical isomerism, in the *δ* and *λ enantiomers* of *mer*-$[Co(dien)_2]^{3+}$, and in the *δ* and *λ diastereoisomers* of each of *Δ* and *Λ mer*-[Co(hexacyclen)]$^{3+}$.

The isomerism of this [Co(hexacyclen)]$^{3+}$ system has been largely elucidated experimentally in previous studies.[5-7] Preparations by substitution reactions between a Co(III)-ammine complex and hexacyclen in the presence of charcoal give all the possible isomers in admixture. The *fac* and *mer* complexes are



fac (D_{3d}) | Λ-*mer*, δ-NH (C_2) | Λ-*mer*, λ-NH (C_2)

Fig. 1. Isomers and diastereoisomers of [Co(hexacyclen)]$^{3+}$. The *mer* diastereoisomers occur as racemates, *Λδ*/*Δλ* and *Λλ*/*Δδ*, and only one optical form is shown for each.

then separable by chromatography on SP-Sephadex cation-exchange resin,[5,8] and the results show that coordination of this ligand is highly stereospecific: the *mer* topology (both diastereoisomers) occurs at >99% proportion at equilibrium, and the *fac* is barely detectable. SP-Sephadex chromatography under acidic conditions has given a partial separation of the *mer* diastereoisomers (each as racemate) and shows these forms to be in comparable proportions,[5] and the ^{13}C NMR spectrum also shows that the isolated *mer* complex contains the NH diastereoisomers in similar amounts.[6]

Isomerizations of CoN_6^{3+}-type complexes have been studied quite extensively.[9-14] The general catalysis of these reactions by charcoal (heterogeneous reaction) or by base (homogeneous reaction) is well-established, but the mechanisms of these processes have not been settled. Several features of this $[Co(hexacyclen)]^{3+}$ system make it attractive for a study of isomerization within a CoN_6^{3+} framework: (1) the system has only two geometric isomers *fac* and *mer*; (2) the *fac* should isomerize essentially completely to *mer* (>99%) so that only one forward reaction should be observed; and (3) the coupling of all the chelate rings in the macrocyclic ligand should restrict the possible modes of ring movements. The present work thus aimed to establish the occurrence or otherwise of the isomerization between the *fac*- and *mer*-$[Co(hexacyclen)]^{3+}$ isomers, and to determine the base dependence of this reaction, and it was hoped that this base dependence might provide some definite evidence concerning the reaction mechanism.

This work required pure samples of the *fac* and *mer* (diastereoisomer mixture) isomers, but isolation of the *fac* from an equilibrium synthetic mixture (<1%) is clearly an impractical means of obtaining this isomer in quantity. It has been demonstrated with the $[Co(dien)_2]^{3+}$ system that ion-association with phosphate anion can markedly shift the equilibrium position and enhance the proportions of more strongly associating isomers, particularly the *sym-fac*,[15] so that the second aim of the work has been to demonstrate that the ion-association effect can also be applied to the analogous hexacyclen complex system to obtain the unstable *fac* isomer in quantity in an isomerization process.

Royer and co-workers have reported interesting observations on isomerizations from the *mer* isomers of $[Co(hexacyclen)]^{3+}$ (and in two other cobalt(III) systems with analogous symmetrical hexaaza macrocycles).[7] Their work is complementary to our results reported herein.

Experimental

^{13}C NMR Spectra. 20.1-MHz NMR spectra of the complexes, broad-band proton-decoupled, were recorded on solutions in acidified D_2O on a Bruker WP-80 DS spectrometer locked to deuterium. An 8192 data table was used. A capillary of *t*-butyl alcohol provided a reference signal: 618.9 Hz, δ 30.79 for CH_3 downfield from $SiMe_4$. (This reference signal was measured for a *t*-butyl alcohol capillary in $CDCl_3$ against $SiMe_4$ as internal reference). As with other cobalt(III) (3+)-charged complexes previously studied, the chemical shifts of the resonances of the $[Co(hexacyclen)]^{3+}$ isomers showed insignificant variations with different anions (generally <0.1 in δ).

Synthesis of *mer*-[Co(hexacyclen)]$Br_3 \cdot H_2O$. A mixture of $[Co(NH_3)_5(H_2O)](ClO_4)_3$ (1.84 g, 0.004 mol), hexacyclen $\cdot 3H_2SO_4$ (2.32 g, 5% excess; Aldrich 98%), $LiOH \cdot H_2O$ (1.06 g) and freshly ground charcoal (0.2 g) in water (60 ml) was heated over a steam bath for 3 h. The charcoal was filtered off, and the orange solution was applied to a column (4.5 cm diam.×40 cm) of SP-Sephadex C-25 cation-exchange resin.

The column was eluted with 0.1 M Na_3PO_4 (1 M=1 mol dm^{-3}) when bands separated as follows:
(1) a fast-moving barely detectable orange band containing *fac*-$[Co(hexacyclen)]^{3+}$ and a trace of $[Co(linpen)]^{3+}$ (**A**) (See Results);
(2) a second very weak orange band;
(3) the main orange-red band of *mer*-$[Co(hexacyclen)]^{3+}$;
(4) considerable purple material extending down most of the column.

The *mer* effluent from band (3) was collected, diluted two times, and applied directly to a column of Dowex 50W-X2 cation-exchange resin, 200—400 mesh, H^+ form (3×4 cm). The complex was washed on with 0.1 M HBr then washed with 1 M HBr to remove all Na^+, then was eluted off with 3 M HBr. The effluent was rotary evaporated to near dryness, and air was sucked through the flask to remove HBr. A little water was added to dissolve the product, followed by gradual addition of ethanol, and crystallization of the diastereoisomer mixture was encouraged by scratching the flask. The resulting orange crystals were filtered off, washed with ethanol and acetone, and air-dried to constant weight. Yield 1.51 g, 66%. Found: C, 25.2; H, 5.4; Br, 43.5; N, 14.5%. Calcd for *mer*-$[Co(C_{12}H_{30}N_6)]Br_3 \cdot H_2O$: C, 25.1; H, 5.6; Br, 41.7; N, 14.6%. The product may have contained a small amount of isomer $[Co(linpen)]^{3+}$ (**D**), although this was not evident in the ^{13}C NMR spectrum. ^{13}C NMR in D_2O/HBr of the approximately 1:1 NH-diastereoisomer mixture: δ 60.5 (2 carbons), 57.0, 55.8, 55.6, 55.2, 53.2, 52.8*, 51.4, 50.6, 50.1, 49.0. [*δ 52.6 for the nitrate salt].

The *mer* isomer could also be obtained from Dowex resin as the less soluble nitrate salt, and HNO_3 eluent concentration was restricted to 1.5 M maximum to avoid precipitation of complex on the resin. Found: C, 26.8; H, 6.1; N, 23.3%. Calcd for *mer*-$[Co(C_{12}H_{30}N_6)](NO_3)_3 \cdot 2H_2O$: C, 26.7; H, 6.3; N, 23.4%.

The *mer* was also obtained as the perchlorate salt by absorbing the complex on a column of Biorex-70 weak-acid cation-exchange resin, 50—100 mesh, Na^+ form, and eluting off with 0.1 M $HClO_4$. Crystallization from the evaporated solution was completed by the addition of ethanol, and the $NaClO_4$ remained in the mother liquor from filtering off the complex.[6]

The *mer* complex could be separated into the two NH-diastereoisomers (as the racemates $\Lambda\delta/\Delta\lambda$ and $\Lambda\lambda/\Delta\delta$) by chromatography down SP-Sephadex using 0.2 M Na_2SO_4/H_2SO_4 pH 2 as eluent.[5] Under these acidic conditions two

approximately equal but incompletely separated bands were obtained, relative R_x(*mer-1*)/(*mer-2*)=1.24. These were collected and the overlap portion was discarded. The two components were isolated as chlorides using Dowex resin with 3 M HCl elution, and characterized by their ^{13}C NMR spectra in D_2O/HCl: for the first eluted diastereoisomer *mer-1* δ 57.0, 55.6 (2 carbons), 53.2, 50.5, 49.1; for *mer-2* δ 60.4 (2 carbons), 55.2, 52.6, 51.6, 50.1.

The combined effluents of the *fac* isomer from the first weak orange Sephadex band (1) from several preparations were worked up using the Dowex/HCl procedure. The ^{13}C NMR spectrum showed that this band (1) contained *fac*-[Co(hexacyclen)]$^{3+}$ (δ 56.1) together with the [Co(linpen)]$^{3+}$ (**A**) isomer (δ 57.6, 57.2 (2 carbons), 55.4, 42.3), but the total amount obtained was very small.

Preparation of *fac*-[Co(hexacyclen)]Cl$_3$ by Isomerization from *mer*. Two solutions of *mer*-[Co(hexacyclen)]Br$_3$·H_2O in 0.1 M Na_3PO_4 (1.80 g in 80 ml, giving [Co] 0.04 M) in stoppered flasks were heated at 80 °C for 12 h. The solutions were diluted (250 ml) and acidified to pH 2 using 1 M HCl, and were then applied to separate columns (4.5×30 cm) of SP-Sephadex cation-exchange resin. The acidification was necessary to avoid partial elution of the *fac* isomer by PO_4^{3-} during the application. After washing on with water, the columns were eluted with 0.1 M Na_3PO_4, when bands separated in the following order:

(1) (first eluted) light-orange *fac*-[Co(hexacyclen)]$^{3+}$ with a trace of [Co(linpen)]$^{3+}$ (**A**);
(2) very weak yellow;
(3) deep orange-red *mer*-[Co(hexacyclen)]$^{3+}$;
(4) a yellow continuum, containing "*mer*";
(5) pink-carmine;
(6) olive-green precipitate.

The *fac* effluents (1) from the two columns were collected and combined, diluted two times, and acidified to pH 2. This solution was applied to a column of Dowex 50W-X2 resin, 200—400 mesh, H^+ form (3×3 cm). After washing on with 0.1 M then washing with 1 M HCl to remove Na^+, the complex was eluted off with 3 M HCl, and the effluent was evaporated to dryness. Ethanol was added to enable the yellow-orange solid to be removed by filtration. This product was washed with ethanol and acetone, and air-dried to constant weight. Yield 0.43 g, 16%. Found: C, 33.7; H, 7.1; Cl, 25.1; N, 19.6%. Calcd for *fac*-[Co($C_{12}H_{30}N_6$)]Cl$_3$: C, 34.0; H, 7.1; Cl, 25.1; N, 19.8%.

The *mer* effluents band (3) from the columns were combined, diluted, and applied directly (without acidification) to a Dowex 50W-X2 column (3×4 cm). The *mer* was recovered as the bromide salt as described previously. Recovery 2.17 g, 60%.

The two isomers could also be obtained as the nitrate salts, although these are less soluble than the halides, and a lower concentration of HNO_3 had to be used (1.5 M maximum) for the elution from Dowex to avoid precipitation of the complexes on the resin. Yields of nitrates from one isomerizaton run: *fac* 15%, *mer* recovery 60%. Found for *fac*: C, 27.5; H, 6.0; N, 24.2%. Calcd for *fac*-[Co($C_{12}H_{30}N_6$)]-(NO_3)$_3$·H_2O: C, 27.6; H, 6.2; N, 24.2%.

The first-obtained *fac*-[Co(hexacyclen)]Cl$_3$ products contained trace amounts of [Co(linpen)]Cl$_3$ (**A**) as shown by small peaks in the ^{13}C NMR spectrum at δ 57.2 and 42.6. [Co(linpen)]$^{3+}$ (**A**) was not apparent however when *mer*-[Co(hexacyclen)]Br$_3$ which had been recovered from previous isomerization runs was used. Recrystallization of the total *fac*-[Co(hexacyclen)]Cl$_3$ from warm 0.01 M HCl by partial rotary evaporation and addition of some ethanol gave the pure *fac* product, when the [Co(linpen)]Cl$_3$ (**A**) was retained in the mother liquor. Rechromatography of this mother liquor gave a substantial separation of the two components: pale orange *fac*-[Co(hexacyclen)]$^{3+}$ eluted first and was isolated pure from the first portion of the band effluent. The latter portion of the band contained yellow [Co(linpen)]$^{3+}$ (**A**), as the major component (^{13}C NMR peaks from **A** at δ 57.6, 57.3 two carbons, 55.4, 42.6) plus some *fac*-[Co(hexacyclen)]$^{3+}$ (δ 56.1). A trace of the *mer* isomer was also evident in this re-chromatography, this *mer* being formed by re-isomerization.

The material within the yellow continuum (4) seems to be a derivative from *mer*-[Co(hexacyclen)]$^{3+}$. On isolation (Dowex/HCl), this material apparently reverted to *mer* since the ^{13}C NMR spectrum then obtained was identical to that of *mer*-[Co(hexacyclen)]$^{3+}$.

The precipitate (6) seems to form only in the Na_3PO_4 solution, and is deposited at the column head. It dissolves and is eluted if the column is slightly acidified.

Determination of Conditions for Optimum Isomerization of *mer*- to *fac*-[Co(hexacyclen)]$^{3+}$. *mer*-[Co(hexacyclen)]-(NO_3)$_3$·$2H_2O$ was dissolved in 0.1 M Na_3PO_4 (0.408 g of complex, chromatographically pure on SP-Sephadex, in 20 ml giving [Co] ca. 0.04 M). The solution was heated in a stoppered flask at 80±2 °C and samples were removed with a calibrated pipette (2.96 ml) at various times (2, 5, 8, 12, 24 h) and acidified (0.7 ml of 1 M HCl). Acidification was necessary to quench the isomerization and to prevent elution by PO_4^{3-} during application to Sephadex. The samples were eluted down SP-Sephadex columns (1.2×20 cm) using 0.1 M Na_3PO_4, and the effluents of the separated *fac* and *mer* isomers were made up to standard volumes with 0.1 M Na_3PO_4 (*fac* made up to 10 ml, *mer* to 50 ml). Cobalt in these solutions was determined by atomic absorption at 240.7 nm using a dinitrogen monoxide-acetylene flame, against solutions of [Co(en)$_3$](ClO_4)$_3$ in 0.1 M Na_3PO_4 as standards. Moles of total hydrolysis products in the samples were calculated by the difference (initial-final) [Co(hexacyclen)]$^{3+}$.

Kinetics of Isomerization of the *fac* Isomer. (a) HPLC Using Strong-Acid Cation-Exchange. The analytical procedure was developed from that described by Larsen.[16,17] The apparatus comprised a Waters HPLC system (Model 5000 solvent delivery unit, U6K injector, 481 variable-wavelength detector), and chromatograms were recorded and integrated using a Hewlett-Packard integrator model 3380S. The column used for HPLC was a Waters Protein-Pak SP-5PW, of dimensions 7.5 mm i.d.×75 mm, having capacity 300 nmol of 3+ complex.[16] All solutions were prepared with distilled and Milli-Q treated water, and were filtered through an all-glass filter unit fitted with a 0.45 μm membrane (Millipore MF type). The HPLC eluent was 0.2 M Na_2SO_4/pH 2 with H_2SO_4.

Runs were carried out at NaOH concentrations 0.05, 0.1, and 0.5 M (I=1.0 with NaCl). Reaction solutions were prepared of about 0.010 g of *fac*-[Co(hexacyclen]Cl$_3$ in 3 ml of the NaOH solution giving [Co] about 0.007 M, and held at 50.0 °C. Constant samples 0.2 ml were removed at intervals, about ten for each run, using an auto pipette (Gilsen "Pipetman" P200) and placed on small columns (5 mm×15

mm) of SP-Sephadex C25, and washed on with water.

At the completion of the run, all these columns were then eluted totally with 0.2 M Na_2SO_4/pH 2, and each effluent was collected and weighed accurately (ca. 4 g). This prechromatography, which conveniently quenched the samples, was necessary to ensure the removal of any strongly retained complexes prior to the HPLC,[16] and the weighing of the effluents permitted normalization between the samples in each run. Each effluent was filtered through a Millex HV4 filter (using a Pasteur pipette and a dry syringe). Constant samples of the effluents 100 μl (Hamilton syringe) were injected for HPLC. Flow rate was 1.0 ml min^{-1}. Detection was at 480 nm, approximately the band I maxima for *fac* and *mer* (but was also checked at 250 nm when similar results were obtained). Chromatograms were recorded from 0—15 min, with full scale absorption in the range 0—0.1 absorption units. This procedure gave about 40 nmol of [Co(hexacyclen)]$^{3+}$ in each injection.

HPLC elution gave (in general) three completely separated peaks due to the isomers *fac*, *mer-1*, and *mer-2*, with typical retention times 3.9, 8.6, and 11.0 min respectively. The amounts of the *fac* and total *mer* components in the different samples were measured as the products of integrated peak area times mass of Sephadex effluent, where the peaks for the *mer* NH-diastereoisomers *mer-1* and *mer-2* were summed. This procedure normalized the different samples taken over a run.

The optical isomers of *mer*-[Co(hexacyclen)]$^{3+}$ were not separated by this HPLC procedure: there was no sign of any separation of the four diastereoisomeric/optical species using HPLC with 0.15 M sodium di-μ-(*R*,*R*)tartrato(4−)-diantimonate(III)/H_2SO_4 pH 2 eluent.[18] Partial resolutions have however been achieved on Sephadex columns using this eluent or sodium (+)-tartrate.[5,7]

(b) Spectrophotometric Runs. Isomerization runs in 0.1 and 0.5 M NaOH solution at 50 °C (I=1.0 M with NaCl) were followed using a Varian-Cary 219 UV/Vis spectrophotometer with timer, wavelength programmer and cell programmer accessories. Absorbances at wavelengths 520, 478, and 416 nm were measured and stored using the Varian 219/210 spectrophotometer "Master Kinetic Storage Programme" on an Apple IIe computer.

The complex *fac*-[Co(hexacyclen)]Cl_3 was weighed (about 0.008 g) and transferred to an appropriate amount (about 5.4 g) of the NaOH/NaCl solution giving [Co] about 0.0034 M. After dissolution, this solution was transferred to a 1 cm cell in a thermostatted holder 50 °C in the spectrophotometer and the recording cycle was started. Recordings were taken at intervals of 15 min (0.1 M NaOH) or 10 min (0.5 M NaOH) and were continued until the absorptions had reached maxima (at 22 h for 0.1 M NaOH, 11 h for 0.5 M NaOH). Absorbance changes for the run in 0.1 M NaOH at 50 °C were: at 478 nm, 0.25 (ε=71) to 0.94 (ε=274) (cf. in 0.01 M HCl at 20 °C, ε_{478}=62 for *fac*, 241 for *mer*); at 416 nm, 0.13 to 0.47.

Results and Discussion

Possible Pathways for Isomerization in [CoN_6]$^{3+}$ Complexes. In the isomerization of [Co(dien)(medien)]$^{3+}$ on charcoal in water the bis complexes [Co(dien)$_2$]$^{3+}$ and [Co(medien)$_2$]$^{3+}$ are also generated, and this must involve complete dissociation of ligands.[10] However, isomerizations in some other circumstances appear to be exclusively intramolecular: the homogeneous isomerization of [Co(dien)(medien)]$^{3+}$ in base is not accompanied by generation of the bis complexes and thus differs clearly from the charcoal reaction above,[10] and Δ-[Co(pn)$_3$]$^{3+}$ [1] with charcoal racemizes faster than coordinated pn exchanges with pn from the solution.[9] For such intramolecular reactions two alternative mechanisms have been envisaged:[20b] Co-N bond rupture whereby a five-coordinate intermediate is generated in which reattachment can occur at a different position, and a twist process wherein six-coordination is preserved. These alternatives should properly be viewed as the limiting mechanisms of a range.

The experimental observations on isomerizations in a number of [CoN_6]$^{3+}$ systems have been interpreted on the basis of predominantly intramolecular bond-rupture mechanisms: [Co(en)$_3$]$^{3+}$ racemization under both charcoal and homogeneous conditions,[12] [Co(dien)(medien)]$^{3+}$ and [Co(dien)$_2$]$^{3+}$ homogeneous,[10,13] *u-fac*-[Co(daes)$_2$]$^{3+}$ charcoal racemization,[1,11] and [Co(tacd)$_2$]$^{3+}$ homogeneous.[1,14] This bond-rupture mechanism more easily accommodates both the observed base dependence of the isomerization rates for these systems, and the occurrence under some conditions of hydrolytic by-products which have been presumed to be [CoN_6(OH)]$^{2+}$ species.[10]

For the racemization of [Co(en)$_3$]$^{3+}$ in the presence of both charcoal and base, Spiro has deduced that the dominant pathway is through the conjugate base and a five-coordinate intermediate, and it was also shown that a Co(III)-Co(II) electron-exchange process is significant only for solutions containing added [Co(en)$_3$]$^{2+}$ + en.[12] Although this latter pathway is less important than was earlier considered for the [Co(en)$_3$]$^{3+}$ system,[21] such a scheme has to be retained as plausible for the isomerization of [Co(dien)(medien)]$^{3+}$ on charcoal since it can accommodate the complete dissociations of ligands.[10]

As well as the above bond-rupture proposals, twist processes remain an intriguing possibility because there is evidence for their occurrence with isomerizations in some complexes of Cr(III)[22,23] and Cr(I)[24] and Fe(II).[25] Although there is little direct evidence for their occurrence in some other Co(III) systems previously studied,[26-28] an interesting situation has been reported recently with the sexadentate complex [Co(stn)]$^{3+}$ which racemizes homogeneously in base and also in the solid state.[1,29] The catalysis of the homogeneous racemization of this complex by hydroxide indicates that deprotonation at a secondary nitrogen is a first step. A bond rupture as a second step can not be seen to lead to inversion of the absolute configuration about the metal, which has therefore been attributed to a trigonal twist (Bailar twist) process. In this system the racemization has to involve inversion of the absolute configurations of all three

asymmetric nitrogens "simultaneously," so that deprotonation at one nitrogen site initially must precede the twist act.[29,30] However, with tris-bidentate complexes (without such ring-coupling) a purely twist process does not readily accommodate the observed base catalysis and the formation of some hydrolysis co-products in Co(III) systems.

Significance of Isomerization in [Co(hexacyclen)]$^{3+}$. The occurrence or otherwise of isomerization between the *fac* and *mer* [Co(hexacyclen)]$^{3+}$ isomers would seem to be definitive in establishing two aspects of the isomerization mechanism. Firstly, no twist process (of the Bailar or Ray-Dutt types) can be envisaged for the *fac* isomer due to the coupling of the chelate rings,[7] so that any isomerization *fac*$\rightleftarrows$*mer* has presumably to be attributed to a Co-N bond-rupture process. Secondly, if the isomerization is base-catalyzed, as with the other CoN_6^{3+} systems studied, this catalysis should probably be attributable to deprotonation occurring at a *s*-NH center (since hexacyclen has only secondary amine sites). These considerations should be relevant also if the reaction proceeded through a labile Co(II) intermediate, in a redox pathway occcurring under charcoal conditions.

Preparation of *mer*-[Co(hexacyclen)]$^{3+}$. Various preparative procedures for [Co(hexacyclen)]$^{3+}$ were examined in anticipation of obtaining the *fac* isomer in greater proportion than that reported previously, $<1\%$.[5,6] However this was not realized and the *fac* was sometimes barely detectable on the Sephadex among co-products of the reactions (including [Co(linpen)]$^{3+}$ isomers, see below). We therefore sought to isolate from the synthesis only the pure *mer* isomer (both diastereoisomers), and thence to obtain the *fac* by isomerization. The linear hexamine linpen,[1] which is the open-chain analogue of hexacyclen, is a troublesome contaminant of hexacyclen, and additional steps in the isolation procedure for [Co(hexacyclen)]$^{3+}$ are necessary to remove [Co(linpen)]$^{3+}$.

The substitution reaction $[Co(NH_3)_5(H_2O)](ClO_4)_3$+hexacyclen$\cdot 3H_2SO_4$+6LiOH in water with charcoal[5] seemed to give the cleanest product mixture, although considerable hydrolysis by-products were unavoidable.

All the products were then separated by cation-exchange chromatography on SP-Sephadex. We found Na_3PO_4 eluent[6] to be more satisfactory for this preparative work than Na_2SO_4/H^+,[5] as the Na_3PO_4 is highly discriminating[31] and effects the best separation of the *fac*- and *mer*-[Co(hexacyclen)]$^{3+}$ isomers[32] from [Co(linpen)]$^{3+}$ co-products (see below) of the substitution synthesis. Also, in the basic conditions of Na_3PO_4 elution the darkly-colored hydrolysis by-products from the synthesis, or from isomerization reactions for [Co(hexacyclen)]$^{3+}$ as below, elute slowly so that the *mer* (diastereoisomer mixture) can be readily separated ahead of them. (With Na_2SO_4/H^+ elution, the by-products appear mainly as two pink bands between the *fac* and *mer* bands. These same hydrolysis product bands were observed from samples from isomerization reactions carried out in 0.1 M Na_3PO_4 separated on Sephadex with Na_2SO_4/H^+). With Na_3PO_4, the *fac* and *mer* bands are also darkened in color, and we ascribe this to some deprotonation at coordinated nitrogen sites.[17,33] Although the isomerization is base-catalyzed, this was not a problem in the Sephadex/Na_3PO_4 chromatography to obtain the two isomers pure, as we found that the amount of *fac* $\rightarrow$*mer* change occurring in 0.1 M Na_3PO_4 pH 12 was negligible over several hours at room temperature, as samples of *fac* then isolated showed no *mer* by ^{13}C NMR.

From its Sephadex/Na_3PO_4 effluent, the *mer* NH-diastereoisomer mixture could be isolated as its bromide or nitrate salt by using Dowex strong-acid cation-exchange resin.

The *mer* diastereoisomers could be subsequently separated by Sephadex chromatography by using acidic conditions, Na_2SO_4/H^+ eluent.[5,7] Experimentally the diastereoisomers are designated as *mer-1* and *mer-2* according to their elution order from Sephadex, but their identities as ($\Lambda\delta/\Delta\lambda$) or ($\Lambda\lambda/\Delta\delta$) remain unknown.[7]

Preparation of *fac*-[Co(hexacyclen)]$^{3+}$ by Isomerization. The cation-exchange elution order of the isomers *fac*$\gg$*mer* with Na_3PO_4 or Na_2SO_4 indicates that the *fac* associates more strongly with these eluent anions.[8,31] Consequently, under conditions where equilibrations between isomers can occur, i.e. in water with charcoal or base,[10,14] the proportion of *fac* should be enhanced in the presence of associating anions such as PO_4^{3-} or SO_4^{2-}. Such enhancements have been demonstrated previously with *s-fac*-[Co(dien)$_2$]$^{3+}$ [15] and *trans*-[Co(tacd)$_2$]$^{3+}$,[14] and where a less stable isomer preferentially associates with an added anion the shift in equilibrium position may be substantial. Thus in [Co(dien)$_2$]$^{3+}$ the *s-fac* proportion formed in synthesis changed from 8% in water (with counter-anions present Cl^-, NO_3^-, or ClO_4^-, all weakly associating) to 59% with added Na_3PO_4 at 20 °C.[15]

This enhancement effect has now been used in the [Co(hexacyclen)]$^{3+}$ system to obtain the unstable *fac* isomer by allowing the *mer* to isomerize in 0.1 M Na_3PO_4 at 80 °C. The time for optimum conversion was determined from small-scale tests which showed that equilibrium was reached by 12 h. The proportions under these conditions were *mer* : *fac* : hydrolysis products=71 : 18 : 11 (see below), so that ion-association enhances the *fac* proportion by about twenty times. Larger scale mixtures thus isomerized were separated by Sephadex/Na_3PO_4 chromatography, and the recovered *mer* was recycled.

Isomerization in Na_2SO_4+charcoal (pH 5) gave little if any *fac* enhancement. These results suggest that in the equilibrium substitution syntheses on

charcoal,[5,6] the ca. 1% *fac* obtained actually represents an enhancement by ion-association with SO_4^{2-} which was the counter anion present, and which is moderately associating.[15] Thus in the presence of only weakly associating anions, the equilibrium *fac* proportion would be expected to be $\ll$1%.

The Occurrence of [Co(linpen)]$^{3+}$ in [Co(hexacyclen)]$^{3+}$. The complex system [Co(linpen)]$^{3+}$ [1] exists in four topological isomers (Fig. 2). These are designated **A**, **B**, **C**, and **D** according to their elution order on Sephadex, and their geometries have been assigned.[34] Our first-isolated *fac*-[Co(hexacyclen)]$^{3+}$ contained [Co(linpen)]$^{3+}$ (**A**) (identified by its chromatographic elution on SP-Sephadex[8] and by its ^{13}C NMR spectrum being closely similar to those of authentic **A**).

The linpen must have been present as an impurity in the starting hexacyclen·$3H_2SO_4$ material, and indeed the ^{13}C NMR spectrum of the hexacyclen·$3H_2SO_4$ (after conversion to hexacyclen·6HCl) showed a peak (δ 43.7) which can be attributed to the main resonance (three carbons of the five different carbons present) of authentic linpen·6HCl. Our recent work on Richman-Atkins cyclization syntheses of cyclic polyamines[35] has demonstrated how a linear analogue can arise as an elimination reaction co-product during a cyclization synthesis, so that linpen has to be expected as a contaminant in hexacyclen.[36]

In the equilibrium substitution preparation of [Co(hexacyclen)]$^{3+}$ all four isomers **A** to **D** should be formed from the linpen. The isomers **D** (73% proportion[34]) and **C** would contaminate *mer*-[Co(hexacyclen)]$^{3+}$, as these all chromatograph similarly.[8] This **D** would then be expected to isomerize to **A** (9% proportion[34]) during the *mer*→*fac* isomerization, and **A** and *fac* chromatograph similarly. Experimentally, **D** was evident in crude samples of *mer* as a yellowish tail to the orange *mer* band on Sephadex chromatography, and initial samples of *fac* contained **A**. However, samples of *fac* obtained from subsequent isomerizations using recycled *mer* were free of **A**, due to the eventual removal of **D** from *mer* by isomerization.

[Co(linpen)]$^{3+}$ contaminants were thus removed as follows: (1) **A**, **B**, and **D** were separable partially from *mer*-[Co(hexacyclen)]$^{3+}$ by Sephadex chromatography;[8] (2) **D** and **C** were partially removed from *mer* by their isomerization to **A** in Na_3PO_4; (3) fractional recrystallization of the final *mer* and *fac* materials removed (**D**+**C**) and **A** respectively.

Conditions for Optimum Isomerization to *fac*-[Co(hexacyclen)]$^{3+}$. The time and yield for optimum isomerization to *fac* were determined from small-scale runs in which pure *mer*-[Co(hexacyclen)]$(NO_3)_3$ was allowed to isomerize in 0.1 M Na_3PO_4 at 80 °C. The solutions were sampled at various times and analyzed.

The mole proportions of *mer*, *fac*, and hydrolysis products versus time thus determined (Fig. 3) show that the isomerization is slow. The proportion of *fac* rises gradually, to become constant at 18% at about 12 h. Hydrolysis (or decomposition) occurs concomitantly, rising rapidly at first, then levelling out at 11% at about 5—8 h. It is evident that equilibrium is attained between the two isomers and the hydrolyzed species, at *mer*:*fac*:hydrolysis=71:18:11, by 12 h. However, the faster generation of hydrolyzed products (the crossover in the *fac* and hydrolysis curves) suggests that the isomerization process is not simple.

This 18% proportion of *fac* was expected to be near the optimum, since the effect of PO_4^{3-} on enhancing the least stable *s*-*fac*-[Co(dien)$_2$]$^{3+}$ reached maximum at 0.08 M Na_3PO_4.[15] Under the equilibration conditions of Na_3PO_4, hydrolysis to the extent of ca. 11%

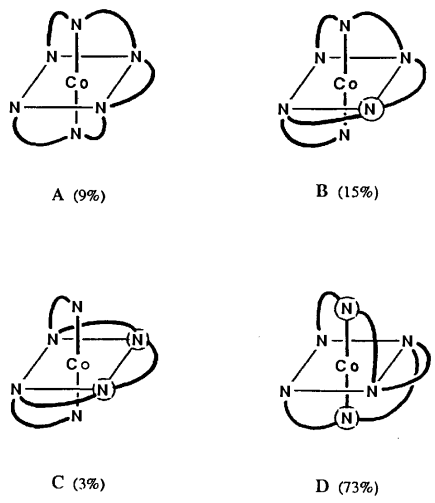


Fig. 2. Topological isomers of Λ-[Co(linpen)]$^{3+}$ and their equilibrium proportions. Diastereoisomers arise from the alternative dispositions (or *R*/*S* configurations) at the circled secondary amines which couple *mer* chelate rings.

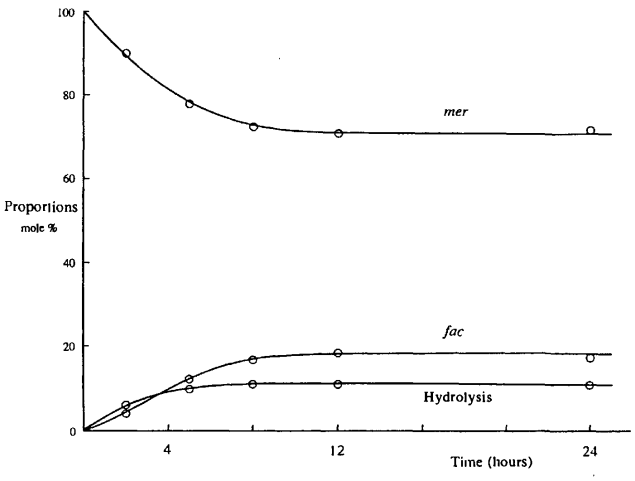

Fig. 3. Isomerization-equilibration of *mer*-[Co(hexacyclen)]$(NO_3)_3$ in 0.1 M Na_3PO_4 at 80 °C. Separation is by Sephadex/Na_3PO_4. Equilibrium mole proportions are *mer*:*fac*:hydrolysis=71:18:11%.

seems to be unavoidable in [Co(hexacyclen)]$^{3+}$.

Kinetic Runs on *fac*→*mer* [Co(hexacyclen)]$^{3+}$ Isomerization. (a) Runs Followed by HPLC Analysis of Samples. The reaction was followed at 50 °C, under the NaOH concentration conditions 0.05, 0.1, and 0.5 M NaOH (I=1.0 M, NaCl). The *fac*-[Co(hexacyclen)]$^{3+}$ complex immediately formed darkish red-brown solutions in base (including 0.1 M Na_3PO_4, as used in elution from Sephadex, see above), giving greater absorption at all wavelengths. These initial darkenings were reversible, so that when the solutions were applied to Sephadex or were acidified, they reverted to pale orange. This conforms to the pattern found with other $[CoN_6]^{3+}$ and $[CoN_4S_2]^{3+}$ systems where very rapid and reversible darkenings occur in base at varying pH values depending on the complex, and we attribute these changes to the formation of darkly colored deprotonated species.[17,33]

In the HPLC procedure, samples from the various solutions removed at intervals were analyzed by HPLC using a strong-acid cation-exchange column. The eluent was Na_2SO_4/H_2SO_4 pH 2, and detection was spectrophotometric. Apparently clean chromatograms were obtained showing completely separated peaks of *fac* and the *mer-1* and *mer-2* diastereoisomers only, over most of the reaction, e.g. up to 12 h for 0.1 M NaOH (Fig. 4).[37] Of the *mer* diastereoisomer products *mer-1* was always observed in slightly greater amount (*mer-1* ≈60—55%, assuming that the two diastereoisomers have similar absorptions), but our kinetic plots were made with respect to *total mer*.

Elution at pH 4 (Na_2SO_4/H_2SO_4) was also tried. Under these conditions the two *mer*-NH diastereoisomers were not completely separated as the absorption recordings did not achieve baseline between the two peaks, and this indicates that the diastereoisomers interconvert at pH 4 over the time scale of the HPLC analysis (although not at pH 2, as above). This is presumably through base-catalyzed N-H exchange involving the deprotonated species, analogously to the racemization of [Co(dien)$_2$]$^{3+}$.[38] However, it seems that the isomerization (pH≥4) in the *mer*-[Co(hexacyclen)$_2$]$^{3+}$ is considerably faster than the analogous racemization (pH>7) of *mer*-[Co(dien)$_2$]$^{3+}$.[38] Although this pH 4 gave similar kinetic plots to those for pH 2, we believe that there are more uncertainties at these higher pH values, as the measured absorptions may have contributions from protonated and deprotonated forms of the two diastereoisomers and from other possible intermediates. In fact, some small shoulders or peaks are evident close to the *fac* peak on the HPLC elution curves, especially in the latter stages of the reactions.

The kinetic plots for disappearance of the *fac* and appearance of the *mer*(total) are irregular for all NaOH concentrations. The amount of *fac* did not decrease in a first order manner, and this was particularly noticeable in the lowest NaOH concentration, 0.05 M, when the *fac* remained nearly constant to about 3 h before decreasing slowly. Also, the 0.1 M NaOH curve for *mer* has a marked hump at 2.5 h (Fig. 5). These observations are consistent with the "*fac*" band in HPLC containing a second species, of a similar *fac* geometry, which builds up slowly, and this is likely to be some longer-lived intermediate.

The irregularities in the *mer* elution kinetic curves

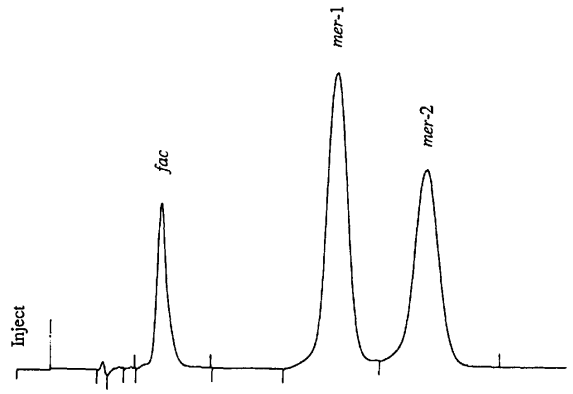

Fig. 4. Typical HPLC chromatogram, Na_2SO_4/H^+ pH 2 elution. (Reaction in 0.1 M NaOH, 50 °C, for 12 h).

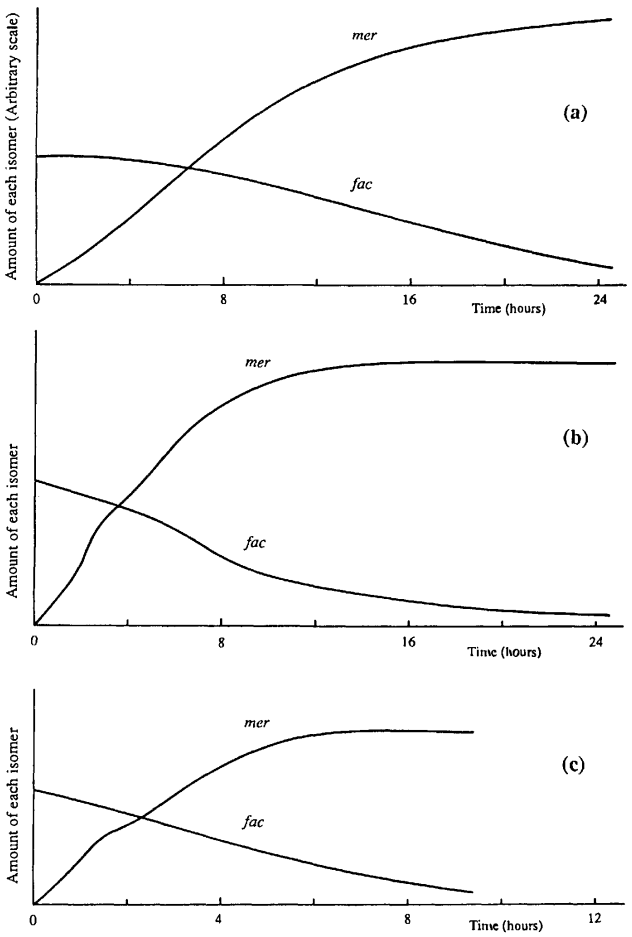

Fig. 5. Kinetic plots from HPLC elutions of isomerization reactions of *fac* at 50 °C: (a) in 0.05 M NaOH; (b) 0.1 M NaOH; (c) 0.5 M NaOH.

were an inflection in the curve for 0.05 M NaOH (≈3 h) and humps for 0.1 M NaOH (≈2.5 h) and 0.5 M NaOH (≈1.5 h) (Fig. 5). Although these irregularities have precluded the precise measurement of reaction rates, the plots of amount of *mer* versus time allow semiquantitative estimates of the rates. For the 0.05, 0.1, and 0.5 M NaOH reactions the half-lives are about 8, 4, and 2 h respectively taking the reactions to be pseudo-first-order, so that there is clearly a base dependence of the rates. The order in hydroxide is approximately first-order, and is in accord with the deprotonation requirement of a bond-rupture process for the *fac*→*mer* isomerization in this system.

(b) Isomerization Followd by Spectrophotometry. Isomerization runs in 0.1 M and 0.5 M NaOH at 50 °C were followed spectrophotometrically. Absorptions were measured at three wavelengths 478 (the λ_{max} for the *mer* isomer where the maximum change occurs), 520, and 416 nm (Fig. 6). Both the initial and the final absorptions were higher at all wavelengths (progressively with increasing OH^- concentration) than those measured in acid (ε_{478} for *fac*: 62 in 0.01 M HCl, initially 71 in 0.1 M NaOH, initially 86 in 0.5 M NaOH). This greater *initial* absorption is attributed to deprotonation.[17,33]

The *subsequent* increases in absorption do not correspond to a single pseudo-first-order reaction, but the absorptions versus time plots show inflections at early stages of the overall reaction. This is particularly clear in the 0.1 M NaOH reaction (Fig. 7), where the inflection in the absorption occurs at 2—3 h. These inflections correspond to the humps on the HPLC versus time plots for the *fac* and the *mer* isomers for the corresponding isomerizations as followed by Sephadex chromatography and HPLC analysis (Fig. 5). With 0.5 M NaOH, irregularities in the absorption versus time plots are evident up to the first 2 h of the reaction as followed both by in-situ spectrophotometry and Sephadex/HPLC chromatography. These plots for the different NaOH concentrations again demonstrate a base dependence of the overall reaction rate.

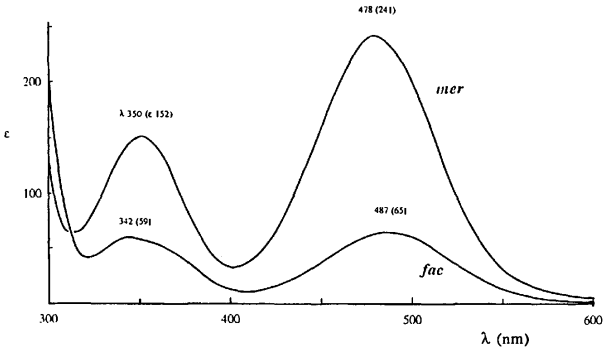

Fig. 6. Absorption spectra in 0.01 M HCl. (a) *mer*-[Co(hexacyclen)]$Br_3 \cdot H_2O$; (b) *fac*-[Co(hexacyclen)]Cl_3.

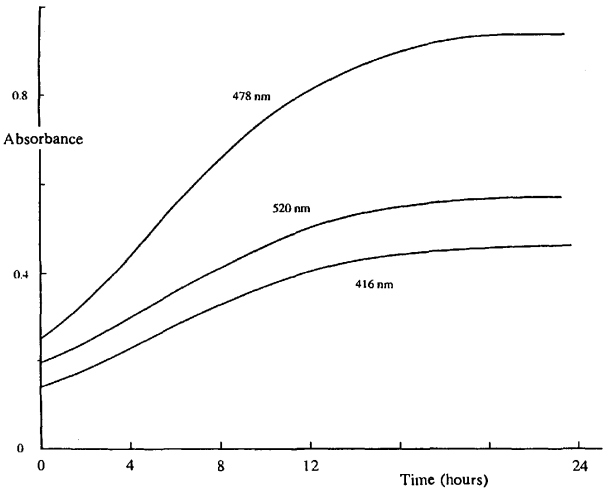

Fig. 7. Absorbance changes during isomerization of *fac* in 0.1 M NaOH at 50 °C.

The occurrence of an inflection (induction period) in the absorbance versus time plots (for different OH^- concentrations and different wavelengths) suggests that the reaction may be described as a series first order scheme **A**→**B**→**C** involving an intermediate **B**.[39] However, plots of the absorbance data as $\log(A_\infty - A_t)$ versus time gave continuous curves having no linear latter sections. We take these results to indicate that the two steps k_1 and k_2 are of comparable rates, or that the overall reaction involves autocatalysis. The steps are not readily analyzed, since the absorbance is a function of at least three varying species.

The Mode of Isomerization. Since a twist is implausible for the *fac*⇄*mer* isomerization, the reaction presumably proceeds by a bond-rupture process. Also, the observed approximately first-order base dependence suggests that a deprotonated intermediate is involved, and the rapid and reversible darkening in base of both isomers is consistent with this proposal.

A scheme of bond rupture and deprotonation steps which can connect all the *fac* and *mer* isomers is shown in Fig. 8. From *fac*, two enantiomeric trigonal-bipyramidal intermediates can arise, and on re-association these could together yield the racemic components ($\Lambda,\delta+\Delta,\lambda$) of *one* the *mer* diastereoisomers. Inversion of configuration at the equatorial nitrogen center in the intermediate (denoted N* in Fig. 8), which is adjacent to the dissociated nitrogen, is required for the detached rings to change their position on re-association to regain octahedral coordination, and the deprotonation thus required at this N* should make the *fac*→*mer* reaction base dependent. Pi-donor bonding to cobalt of this amide group in the trigonal plane could stabilize the five-coordinate intermediate.[20a,40,41] Inversion of configuration is required also at the dissociated nitrogen for the *fac*→*mer* change, but such inversions of free amines are rapid (and should occur within the lifetime of the

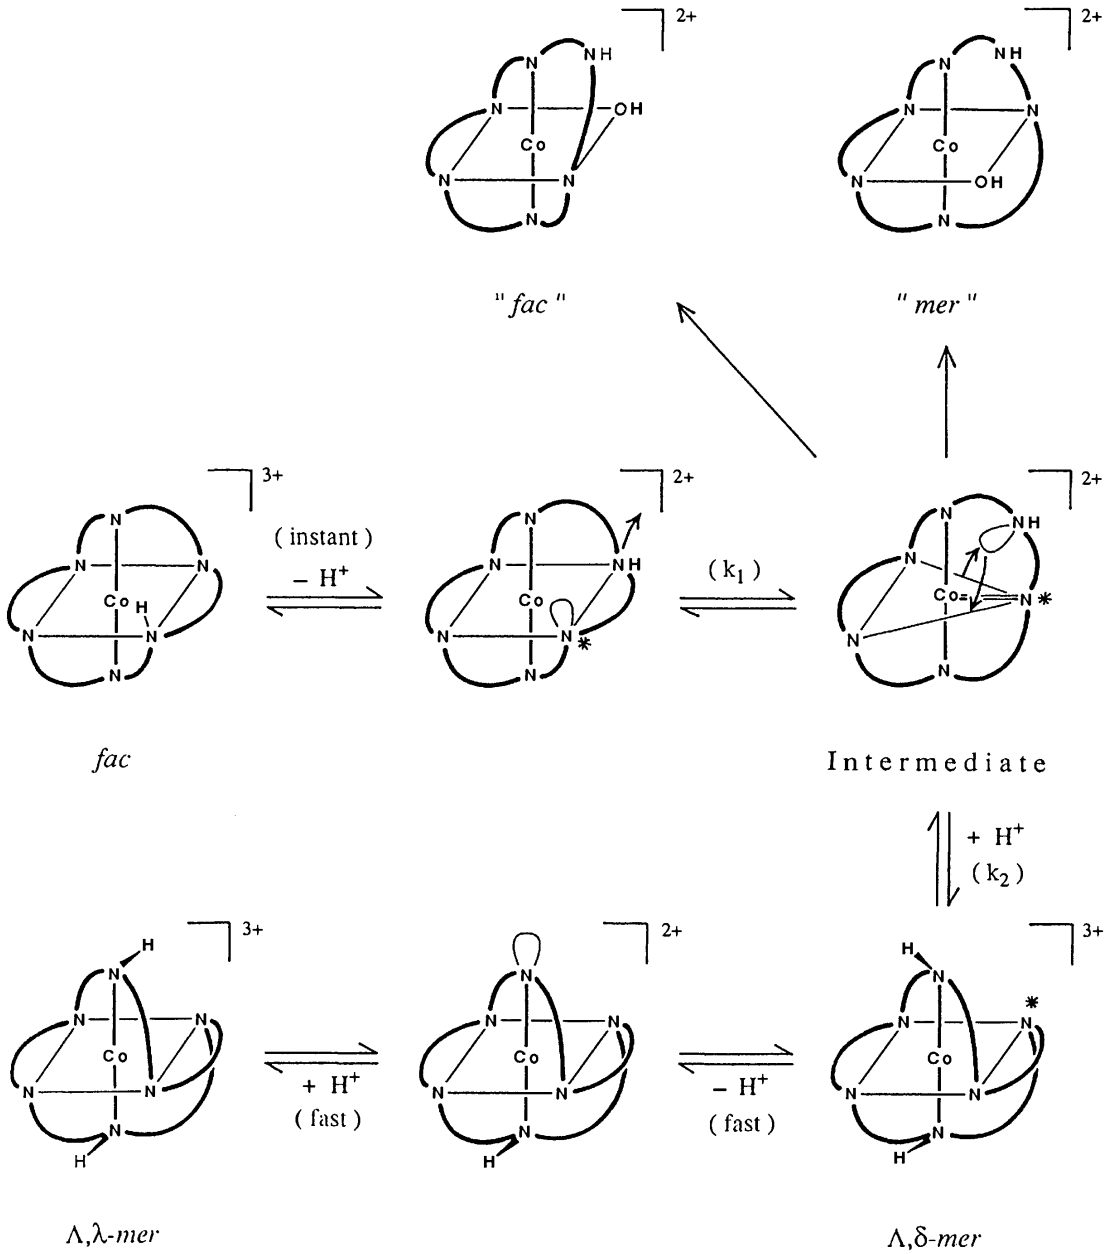

Fig. 8. Bond rupture and deprotonation processes giving *fac* ⇄ *mer* [Co(hexacyclen)]$^{3+}$. Only one enantiomer is shown for the trigonal bipyramid intermediate and for the *mer* diastereoisomers.

trigonal-bipyramid intermediate) and do not exhibit a base dependence.

The HPLC results are consistent with this proposed scheme. The changes in the HPLC "*fac*" peak indicate a slow build up of some intermediate species, since the peak apparently remains constant in magnitude for some time before then decreasing. Also, some residual small peaks (close to the *fac*) become unmasked in the latter stage of reaction when the sharp peak of the octahedral *fac* isomer has largely disappeared. We now identify this intermediate as the proposed trigonal bipyramid, formed slowly by step k_1.

The HPLC *mer* elution versus time plot at 0.05 M NaOH shows an inflection which is consistent with the proposed scheme of consecutive first order reactions involving one intermediate.[39] At the higher NaOH concentrations, however, the *mer* elution curves show in addition humps which indicate that some other species becomes involved under these conditions. It is difficult to see that the hump could be due to an increased amount of the *mer* isomer (irregularly generated, from some other intermediate), and it seems more likely that at these higher NaOH concentrations some other species is formed which elutes similarly to the *mer* so that it is masked, but is detected along with the *mer*.

The spectrophotometric kinetic observations are

also consistent with the proposed consecutive steps scheme, where the rates k_1 and k_2 are indicated to be comparable.

That the isomerization is slow suggests that the trigonal bipyramid intermediate is long-lived, and competition experiments employing strong nucleophiles might be useful to check this. However the present reacting solutions contained Cl^- and OH^- as potential nucleophiles in concentrations greatly exceeding cobalt, and formation of species such as $[Co(hexacyclen)OH]^{2+}$ is plausible (Fig. 8). These may be the species suggested as contributing to the apparent *mer* hump in the HPLC elution curves for the higher NaOH concentration conditions.

The concomitant formation of hydrolysis products (or other substitution products) could be expected, as the proposed five-coordinate intermediate in the *fac*⇄*mer* isomerization (with an uncoordinated amino group) is similar to the intermediate in the generally accepted SN_1CB mechanism for the base hydrolysis of cobalt(III) amine complexes.[40-43] Hydrolysis was especially evident in the isomerization (from *mer*) carried out in phosphate, where the carmine Sephadex band may have contained phosphate-substituted products. It is also relevant that the species *cis*-$[Co(en)_2(mono\text{-}en)(OH)]^{2+}$ is formed as the main product in the base hydrolysis of *cis*-$[Co(en)_2(mono\text{-}enH)Cl]^{3+}$, showing that the free amino group of the monodentate-en ligand does not compete favorably with water for the vacant coordination site in the proposed five-coordinate intermediate.[42] The formation of $[Co(hexacyclen)(OH)]^{2+}$ may be a parallel situation.

With some macrocyclic complex systems closely analogous to $[Co(hexacyclen)]^{3+}$, Royer and coworkers[7] found that equilibrations between *fac* and *mer* isomers were generally facile, and attributed this to the high strain in these macrocyclic structures.[44] We believe that these *fac*→*mer* changes can be accommodated by our proposal of a single Co-N bond rupture, and that the more drastic simultaneous breaking of *two* adjacent Co-N bonds as suggested previously[7] is not necessary.

Although no twist processes are possible for the direct change *fac*→*mer* $[Co(hexacyclen)]^{3+}$, a twist process can be envisaged for direct inversion of one *mer* diastereoisomer, $\Lambda,\lambda \rightleftarrows \Lambda,\delta$ (Fig. 9), and this need not involve deprotonation. Inversion of the other *mer* diastereoisomer Λ,δ does not seem possible directly by a twist, but inversion could occur indirectly through two alternative routes. One path is through the symmetrical *fac* isomer, Λ,δ-*mer*⇄*fac*⇄Δ,λ-*mer*, involving deprotonations and inversions at two nitrogen centers (Fig. 8). The second possible route is through the other diastereoisomer Λ,λ involving one deprotonation and NH inversion step, followed by the twist. We can not envisage direct formation of the $(\Lambda,\lambda/\Lambda,\delta)$-*mer* diastereoisomer from the *fac*, and we

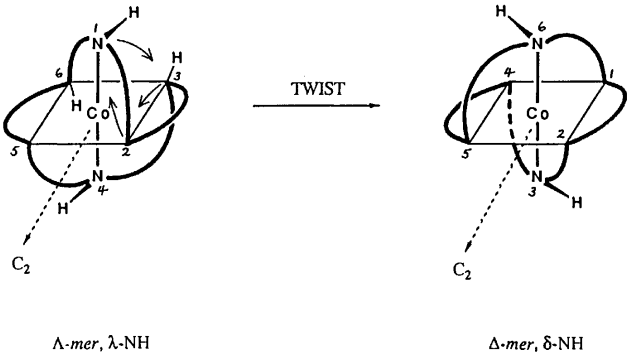

Fig. 9. Possible twist process for *mer*-[Co(hexacyclen)]$^{3+}$ giving inversion around cobalt. The process (as shown) need not involve inversion at a N center, so that it could be independent of pH.

suppose its formation to be via the $(\Lambda,\delta/\Delta,\lambda)$ diastereoisomer (Fig. 8). However, in the present experiments only the total of all the *mer* isomers is calculated, so that the alternative possible routes for the *mer* interconversions are not distinguished.

The present HPLC results show that the interconversion of the *mer* diastereoisomers by NH exchange is rapid, being in evidence at pH 4 over 15 min at 20 °C. The inversion of the *mer* diastereoisomers is of interest, since the relative rates of this inversion and the *mer*→*fac* conversion might provide evidence about the possible *mer* twist process. However, isolation of the *mer* in optically active forms has not yet been achieved. Royer[7] did however obtain a partial resolution of the *mer* material by Sephadex chromatography using acidified 0.3 M sodium (+)-tartrate as eluent, and CD curves were given of two separated fractions, which were both assigned as having the Λ configuration around the cobalt. However, isolation from solution as the perchlorate salt gave only racemic crystals. The structure reported for these was the diastereoisomer $\Lambda,\lambda/\Lambda,\delta$ racemate,[45] but the occurrence of racemization during crystallization precluded identification of this solid with the order of elution of the two *mer* diastereoisomers by Sephadex/Na_2SO_4/H^+ chromatography.

Although the pH conditions used for these experiments were not given, the reported results indicate that inversions of configuration around the cobalt $\Delta \rightleftarrows \Lambda$ in the *mer* geometry are facile.[7] It is difficult therefore to see that these inversions could proceed via the demonstrated slow *mer*→*fac* pathway involving bond rupture, so that a twist process seems likely for these interconversions within the *mer* geometry.

Results obtained recently by Larsen with isomerization of $[Co(aeaps)_2]^{3+}$ in base[1,46] have bearing on the present work. For the reaction of different isomers in 1 M NaOH, a sequential process $A \xrightarrow{k_1\ (fast)} B \xrightarrow{k_2\ (slow)} C$ was found, as deduced herein for the $[Co(hexacyclen)]^{3+}$ system. For this thioether system the individual steps could be separated and were quite slow

($t_{1/2}$=85 s and 23 min at 1 °C) and there seemed to be no evidence (no instant darkening) for a preliminary deprotonation at coordinated amine. The product solution **C** contained at least three species at equilibrium, one of which (20% proportion) was found to be [Co(aeaps)(aeaps-H)]$^{2+}$ [1] involving coordination of a carbanion group on one ligand rather than the thioether sulfur as in the reactants. Although this result is thought provoking, it is likely that this situation of alkyl group coordination is unique to a substrate complex with a six-membered ring having a thioether sulfur donor, and the analogous situation in the [Co(hexacyclen)]$^{3+}$ system seems implausible. Nevertheless, these results clearly show that the isomerization process is not simple and that several products may result.

Finally, cobalt(III) complexes of the types [Co(tetars)X_2]$^{n+}$ [1] and [Co(diars)$_2X_2$]$^{n+}$,[1] each with four tertiary arsine donor centers, are very prone to rapid catalytic substitution and topological equilibration which are supposed to occur via electron transfer with a labile cobalt(II) species.[47,48] These cobalt(II) species are presumed to be produced by spontaneous internal reduction of the cobalt atom and the simultaneous oxidation of the bound ligands X, since the isomerizations occur particularly in concentrated solutions, in reducing solvents like alcohols, and in the presence of excess of X^- where X^- is mildly reducing such as Br^- and NCS^-. These catalytic reactions are characterized by erratic kinetic behavior, such as the non-smooth loss of optical activity in substitution, cis→trans isomerization, or racemization reactions.[47,48] However such involvement of cobalt(II) is expected to be much less with isomerizations in cobalt(III)-amine complexes (amine=NH_3, en, dien, dpt[1]) where spontaneous reductions occur only under forcing conditions.[49,50] Although our work with [Co(hexacyclen)]$^{3+}$ did not involve conditions which were found to favour the catalysis in the arsine systems, there was some evidence of erratic behavior so that the involvement of cobalt(II) in catalytic amounts can not be absolutely excluded in the [Co(hexacyclen)]$^{3+}$ system.[53]

Parts of this work were carried out during leaves at the Departments of Chemistry at University of Otago, Dunedin, New Zealand, and James Cook University, Townsville, Australia. The use of facilities at those Departments and helpful discussions with D. A. Buckingham (Otago) and F. R. Keene (James Cook) are gratefully acknowledged. P. McDuie (Adelaide) kindly assisted with the atomic absorption measurements.

30) The complex tris(2-pyridylmethyl)-1,4,7-triazacyclononaneiron(II), $[Fe(tptcn)]^{2+}$, has topology analogous to that of $[Co(stn)]^{3+}$ but the ring couplings do not involve secondary amines, and recently this complex was elegantly shown to racemize rapidly and without base catalysis, Ref. 25. This probably occurs by a trigonal twist associated with the high-spin state, since this particular ligand gives a "crossover complex" with Fe(II). Such involvement of the high-spin state with Co(III) systems is much less likely.

(Received June 22, 1989)

Synopsis. The structure of the novel heterodinuclear organometallic complex, [(cod)(Ph)Pt-W(CO)$_3$(η^5-C$_5$H$_5$)] has been determined by X-ray crystallography; the Pt-W bond distance is 2.844(1)Å.

Special attention has been drawn recently to heterobimetallic compounds from the viewpoint of their catalytic abilities.[1] Little is so far known, however, about chemistry of heterodinuclear organometallic complexes, especially those containing a direct bond between different transition metals.[2] We have recently reported the preparation of a series of heterodinuclear organometallic complexes containing platinum and tungsten of the type, [(cod)(R)Pt-W(CO)$_3$(η^5-C$_5$H$_5$)] (R=Me, Et, Ph, or tolyl), which show a unique alkyl-transfer reaction from the platinum to tungsten atoms.[3] We describe here the structure of one of these complexes, [(cod)(Ph)Pt-W(CO)$_3$(η^5-C$_5$H$_5$)] established by X-ray crystallography.

Experimental

The title compound was prepared by the method previously reported.[3] The crystals were obtained as deep red plates from dichloromethane-hexane solutions.

Crystal Data. $C_{22}H_{22}O_3PtW$, M=713.4, monoclinic, $P2_1/n$, a=14.291(3), b=12.731(2), c=12.027(3), Å, β=112.48(2)°, U=2021.9(7) Å^3, Z=4, D_c=2.343 g cm^{-3}, μ(Mo $K\alpha$)=133.1 cm^{-1}.

A crystal with approximate dimensions of 0.10×0.50×0.55 mm sealed in a thin-glass capillary under nitrogen was mounted on a Rigaku automated four-circle diffractometer. Accurate unit-cell parameters were determined by the least-squares fit of 2θ values of 25 strong reflections ($21.8<2\theta<29.9°$). Intensity data collection was carried out using Mo $K\alpha$ radiation by the θ-2θ scan mode. The scan speed and range were 4° min^{-1} in 2θ and $\Delta(2\theta)=(1.8+0.7\tan\theta)°$, respectively. The background intensities were measured for 5 s at both ends of a scan. A total of 4413 independent reflections (R_{int}=0.012) were collected with $\sin\theta/\lambda$ up to 0.64. Absorption correction was applied to the intensity data.[4] The minimum normalized transmission factor which was based on intensities obtained by the azimuthal scan of 404 and $\bar{4}0\bar{4}$ reflections was 0.10.

The structure was solved by the heavy atom method and refined by the block-diagonal least-squares procedure using HBLS-V.[5] Non-hydrogen atoms were refined anisotropically except for the C(1), C(20), and O(1) atoms which were refined with the isotropic thermal parameters. All the hydrogen atoms whose positions were estimated from stereochemical consideration were included in the structure factor calculation. At the final stages of refinement, two reflections (200 and 002) were excluded due to the extinction effects. The final R and R_w values are 0.070 and 0.075 for 3778 [$|F_o|>3\sigma(|F_o|)$] reflections. The weighting scheme used in the final refinement cycles is $w=(\sigma_{cs}^2-0.100|F_o|+0.017|F_o|^2)^{-1}$. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[6] The final atomic parameters are listed in Table 1.§

a) As defined by Hamilton.[7]

Computations were done on an ACOS 930 computer at the Research Center for Protein Engineering, Institute for Protein Research, Osaka University.

Results and Discussion

The molecular structure is depicted in Fig. 1 with atomic numbering systems. Bond distances and angles are listed in Table 2. The Pt-W bond distance is 2.844(1) Å, which is corresponding to the sum of

§ Tables for anisotropic temperature factors, for atomic coordinates of hydrogen atoms, and for observed and calculated structure factors are deposited as Document No. 8909 at the Office of the Editor of Bull. Chem. Soc. Jpn.

covalent bond radii of platinum and tungsten [2.85 Å]. This value falls in the range of metal-to-metal bond lengths [2.60—2.90 Å average 2.76 Å] in the platinum-tungsten complexes so far reported[9] but is classified to somewhat long distance among them.

The geometry around the platinum atom is typically square-planar where the carbon (phenyl) atom, the centers of two C=C double bonds of the cod ligand, and the tungsten atom are coplanar to each other [maximum deviation 0.07 Å]. It is noteworthy that the tungsten atom occupies one of four corners of the square-planar geometry, because platinum-tungsten complexes whose structures have been hitherto elucidated[9] always contain bridging μ-ligands between two metal atoms and the arrangement of ligands around the platinum atom is far from square-planer geometry.§§ On the other hand, the geometry around the tungsten atom is square-pyramidal, where the center of the η^5-C_5H_5 ligand is located at an apical position. These geometrical features around both metal atoms are consistent with the d^8 and d^6 electronic configurations of platinum and tungsten, respectively, which are also supported by the spectroscopic results.[3]

W-C(22)-O(3)	168.1(12)		

The other remarkable features of the structure are the existences of strong trans-influence on the platinum atom and of the weak interaction between the platinum atom and two CO groups. Firstly, the Pt-C(11) and Pt-C(12) bonds (trans to C(phenyl)) of 2.381(13) and 2.365(14) Å are obviously longer than the Pt-C(7) and Pt-C(8) bonds (trans to W) of 2.223(14) and 2.186(13) Å. This shows stronger trans-influence from the phenyl group than that from the tungsten atom. Secondly, among three carbonyl groups attached to the tungsten atom, two of them (C(21)≡O(2) and C(22)≡O(3)) are located as if attacking the Pt-W bond from both sides. Although the Pt···C(21) and Pt···C(22) distances of 2.463(12) and 2.488(12) Å are much longer than those expected for the Pt-C bond as the μ-CO ligands, the W-C(21) and

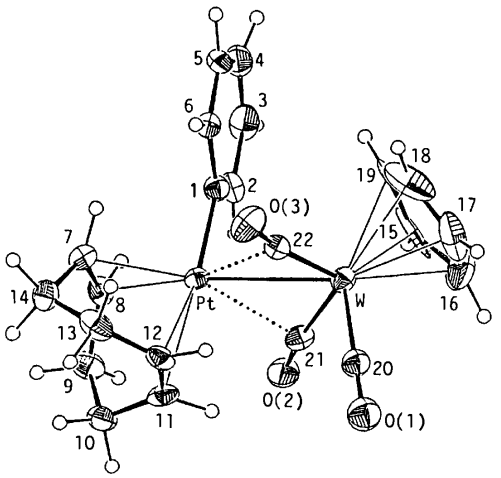

Fig. 1. The molecular structure[8] of [(cod)(Ph)Pt-W(CO)$_3$(η^5-C_5H_5)] together with the numbering scheme (only atomic numbers are shown for carbon atoms). Non-hydrogen atoms are represented by thermal ellipsoids at 30% probability levels, while hydrogen atoms are drawn by spheres with B=1.0 Å^2. Selected coordination angles not appeared in Table 2 are as follows; W-Pt-C(11/12)=100.8, C(1)-Pt-C(7/8)=90.8, C(7/8)-Pt-C(11/12)=83.8 (C(7/8) and C(11/12): midpoints of the C(7)-C(8) and C(11)-C(12) bonds, respectively), CCP-W-Pt=136.5, CCP-W-C(20)=119.9, CCP-W-C(21)=119.4, CCP-W-C(22)=117.9° (CCP: center of gravity of the η^5-cyclopentadienyl ring).

§§ In the hydrido-bridged complex, [(Et$_3$P)$_2$(Ph)Pt(μ-H)W(H)(η^5-C_5H_5)$_2$], the square-planar geometry is apparently observed in case that the bridging hydrido ligand is ignored.[10]

W-C(22) bonds of 1.979(12) and 1.974(13) Å are slightly lengthened and the W-C(21)-O(2) and W-C(22)-O(3) angles of 170.1(11) and 168.1(12)° are slightly bent when compared with those of the other free CO group; W-C(20)=1.940(14) Å and W-C(20)-O(1)=178.0(12)°. These facts simply weak interaction of two CO groups to the platinum atom in spite of the fact that they hardly function as bridging μ-ligands.

The present study was partially supported by the Grant-in-Aids for Scientific Research from the Ministry of Education, Science and Culture (No. 63106006).

(Received May 5, 1989)

Synopsis. 3-Thio-2,4-pentanedionate (tac) complex of platinum(II), [Pt(tac)(PMe_2Ph)$_2$], has been prepared by treating [PtCl(PMe_2Ph)$_3$][PF_6] with 2,3-dithio-1,1,4,4-tetraacetylbutane in a KOH/methanol-acetone mixed solution. This complex has been characterized by IR, ^{1}H, ^{13}C, and ^{31}P NMR, secondary ion mass and ESR spectroscopy and cyclic voltammetry.

Linkage modes of 1,1,2,2-tetraacetylethane(dahd= 3,4-diacetyl-2,4-hexadiene-2,5-diol) to Rh(I) and Pd(II) as well as Pt(II) as bifunctional O_2-chelates and a (C^3,O')-chelate, respectively, have been formerly established.[1-3] The dahd dianion in acidic condition favors symmetrical O-bonding bifunctional chelation, while in basic condition it prefers the (C^3,O')-chelate. In them, the metal-carbon bonded [Pt(dahd-C^3,O')(SEt_2)$_2$] exhibits its unusual behavior.[3] An inversion of one sulfur atom arranged at the trans position to C^3 accompanies a bond dissociation the rearrangement of which may proceed via an intermolecular pathway. An extention of these previous findings has been investigated for the linkage mode of its dithio derivative: 2,3-dithio-1,1,4,4-tetraacetylbutane. A basic treatment of the sulfur compound gave an S-S bond cleavaged product, 3-thio-2,4-pentanedionate dianion (tac^{2-}), whose bonding mode to platinum(II) is, however, unknown so far.

This paper deals with a convenient synthesis of the 3-thio-2,4-pentanedionate Pt(II) complex, [Pt(tac)-(PMe_2Ph)$_2$], by an alkaline treatment of 2,3-dithio-1,1,4,4-tetraacetylbutane with [PtCl(PMe_2Ph)$_3$][PF_6]; the complex has been characterized using ^{1}H, ^{13}C, ^{31}P NMR and SIMS spectroscopy.

Experimental

2,3-Dithio-1,1,4,4-tetraacetylbutane (H_2dttb): H_2dttb was prepared by a method described in the literature.[4] Found: C, 45.28; H, 5.14%. Calcd for $C_{10}H_{14}O_4S_2$: C, 45.79; H, 5.38%. IR(Nujol mull): ν(C=O)+ν(C=O) 1548(br). ^{1}H NMR ($CDCl_3$): δ_{Me}=2.37, δ_{OH}=17.00.

[PtCl(PMe_2Ph)$_3$][BF_4] and Its PF_6^- Salt: 1.7 g of *cis*-$PtCl_2$-(PMe_2Ph)$_2$[5] was dissolved in acetone (partial suspension), and 0.62 g of $AgBF_4$ was added to the solution, producing AgCl (0.4 g; 94% per Pt atom). After filtration of AgCl, the solution was evaporated to give a pale-orange oil, which was dried in vacuo (1.5 g; 84%). Found: C, 32.91; H, 3.69%. Calcd for $C_{16}H_{22}ClP_2BF_4Pt$: C, 32.37; H, 3.74%. 0.6 g of the [Pt_2Cl_2(PMe_2Ph)$_4$][BF_4]$_2$ product was dissolved in acetone, and 0.13 g of PMe_2Ph was added to the solution. This solution was then evaporated to give an orange oil, which was dried in vacuo (0.72 g; 100%). Found: C, 38.34; H, 4.51%. Calcd for $C_{24}H_{35}OClBF_4Pt$ with a solvation of H_2O: C, 38.44; H, 4.71%. ^{31}P{^{1}H} NMR($CDCl_3$) shows a typical AB spin system: δ_A=16.86, δ_B=−3.94 ppm with J(A-B)=21.8, J(^{195}Pt-A)=3496.8 and J(^{195}Pt-B)=2310.9 Hz. An analogous PF_6 salt was prepared by reacting *cis*-$PtCl_2$(PMe_2Ph)$_2$ (1.0 g) with PMe_2Ph (0.3 g) and NH_4PF_6 (0.3 g) in a methanol-acetone solution (yield: 1.4 g; 93%).

Bis(dimethylphenylphosphine)(2,4-pentanedione-3-thiolato)platinum(II), [Pt(tac)(PMe_2Ph)$_2$]: 1.7 g of [PtCl-(PMe_2Ph)$_3$][PF_6] was dissolved in acetone; to the solution a methanol solution of KOH 0.25 g and H_2dttb 0.57 g were added as the pale-yellow solution turned orange. The solution was stirred for 30 minutes under N_2 as a white solid precipitated (0.5 g: 200% per Pt atom as a summation of KCl and KPF_6 salts). After filtration, the solution was developed by TLC (silica) in CH_2Cl_2–acetone. A yellow band was eluted and recrystallized from CH_2Cl_2–hexane (0.79 g; 61%). Found: C, 41.84; H, 4.81%. Calcd for $C_{21}H_{28}$-O_2P_2SPt: C, 41.93; H, 4.69%. M.W. (CH_2Cl_2) 664(602). The other species, showing orange and brown layers (TLC), have not been characterized.

Dipotassium 3-Thio-2,4-pentanedionate, K_2tac(CH_3OH): 1 g of H_2dttb was dissolved in CH_3OH and to the solution 0.43 g of KOH in CH_3OH was added as the solution turned orange. The solution was reduced in volume under reduced pressure to about 5 cm^3. The addition of diethyl ether to the residual solution, by allowing it to stand in a refrigerator overnight, gave a pale-orange solid (ca. 0.5 g). The product was further reprecipitated from methanol-diethyl ether (the product was moisture sensitive, and a slight weight loss was accompanied in its elemental analysis). Found: C, 28.62; H, 4.34%. Calcd for $C_6H_{11}O_{3.5}SK_2$ with a solvation of CH_3OH and H_2O: C, 28.89; H, 4.45%. IR(Nujol mull): ν(C=O)+ν(C=C)1580(vs) cm^{-1}. ^{1}H NMR (CD_3OD): δ_{Me}=2.08 .

Cyclic Voltammetry of [Pt(tac)(PMe_2Ph)$_2$]: A cyclic voltammograph of [Pt(tac)(PMe_2Ph)$_2$] was produced in acetone [1.16 and 1.74 mM (1 M=1 mol·dm^{-3})], 0.1 M TEAP at a platinum electrode or a glassy carbon electrode using a BAS voltammograph CV-27 and a Ag/AgCl reference electrode. An irreversible oxidation wave was observed, in which the corresponding cathodic wave was small. The anodic peak potential at 100 mV s^{-1} for the wave was E_p=+0.46 V. Controlled-potential coulometry at +0.60 V using a YANACO Potentiostat Model V8 revealed that a total of 0.94 electrons was involved in this oxidation. The nature of the reaction, via an electrochemical reaction, is not known at this time.

Elemental analyses were performed at the Micro Analytical Center, Kyoto University. IR spectra were recorded on a Hitachi 260-10 infrared spectrometer. ^{1}H NMR spectra at 90 MHz, ^{13}C at 22.66 MHz, and ^{31}P{^{1}H} at 36.36 MHz were recorded on a Hitachi R-90H FT NMR(90.04 MHz) operating in the Fourier transform mode. The SIMS spectrum was produced using a Hitachi M-80 mass spectrometer and

a) Measured in $CDCl_3$. Chemical shifts are relative to Me_4Si at 0.00. J(P-C) and $J(^{195}Pt-C)$ are in parentheses and bracket respectively.

3-nitrobenzylalcohol or glycerin as a matrix and Xe gas as the first ion source. The molecular weight was obtained using a CORONA Molecular Weight Apparatus M-117 (vapor pressure osmometry) at 30 °C in CH_2Cl_2. The ESR spectra of the solid were recorded on a Varian E Line Century Series EPR spectrometer, and the diamagnetism of the complex was affirmed.

Results and Discussion

2,3-Dithio-1,1,4,4-tetraacetylbutane (H_2dttb) in solution has a dienolic form (Experimental section). The crystal structure of its tri-thio analog, 2,3,4-trithio-1,1,5,5-tetraacetylpentane, has been established by X-ray diffraction studies[4] to have a dienolic form, which is in analogy with 1,1,2,2-tetraacetylethane (H_2dahd). These previous findings may give rise to a question concerning its linkage mode to the metal: whether it may be stabilized in a form of bifunctional O_2-chelates or another, for example (S,O)-chelates. Unexpectedly, an alkaline treatment of $[PtCl(PMe_2Ph)_3][PF_6]$ with H_2dttb in methanol-acetone gave a diamagnetic 2,4-penatanedione-3-thiolato Pt(II) complex, $[Pt(tac)(PMe_2Ph)_2][tac(2-)$=3-thio-2,4-pentanedionate], which was produced via a S-S bond cleavage of the dttb dianion.

^1H, $^{31}P\{^1H\}$ NMR and IR spectral data of $[Pt(tac)(PMe_2Ph)_2]$ are shown in Table 1, and $^{13}C\{^1H\}$ NMR datum in Table 2. ^{31}P NMR shows an AB spin system with $J(^{195}Pt-P_A)$=3354 and $J(^{195}Pt-P_B)$=2791 Hz. These values are apart from a trans configuration, but rather close to cis configuration for the two phosphorous atoms.[6,7] Me-protons of PMe_2Ph appeared as two resonances, showing that the structure of the complex has low symmetry. Me protons of the tac also appear as two resonances with doublet patterns respectively, which may arise from a coupling with phosphorous nuclei at their trans positions. Its ^{13}C NMR spectrum shows that the circumstances around one acetyl group is distinct from the other. Resonances at 24.5 and 19.7 are due to C^1 and C^2, and each resonance appears as a doublet pattern accompanying ^{195}Pt satellites. The resonance pattern is in accordance with those observed for $[Pt(dahd\text{-}C^3,O')(PMe_2Ph)_2]$ and is consistent with one carbonyl in an enol-form being bound to Pt(II). However, resonance at 180.0 arising from C^4 is in a region close to that of ketonic carbonyl;[8,9] it appeared as a quartet pattern which may arise from a long-range coupling with two phosphorous nuclei. A single resonance at 29.8 is due to C^5. In both resonances no ^{195}Pt satellites could be observed, indicating that the ketonic carbonyl is liberated from the metal. IR bands at 1488 and 1475 cm^{-1} can be assigned to ν(C-O) and 1262 cm^{-1} to ν(C-S), the latter of which is in a region close to that found in the thiolato complex.[10] A

$$[PtCl(PMe_2Ph)_3][PF_6] + K_2\text{-tac} \longrightarrow [Pt(tac)(PMe_2Ph)_2] + KCl + KPF_6 + PMe_2Ph \quad (1)$$

$$[PtCl(PMe_2Ph)_3][PF_6] + H_2\text{-dttb} + KOH \longrightarrow \tfrac{1}{2}[Pt_2(dttb)(PMe_2Ph)_4][PF_6]_2 + KCl + PMe_2Ph$$
$$\tfrac{1}{2}[Pt_2(dttb)(PMe_2Ph)_4][PF_6]_2 + KOH \longrightarrow [Pt(tac)(PMe_2Ph)_2] + KPF_6 \quad (2)$$

Scheme 1.

band at 1621 cm^{-1} can, therefore, be assigned to ν(C=O) or ν(C=C), which is in a lower frequency region than the 1600—1700 region found in metal carbon bonded Pt(II) and Pd(II) complexes of β-diketone.[11,12] Its SIMS spectrum shows an explicit basal peak at M/Z=601 corresponding to the molecular ion (Fig. 1). The result of a molecular weight measurement was consistent with this SIMS data. These spectral data are in accordance with a square planar structure in which 3-thio-2,4-pentanedionate bonds Pt(II) with (*S,O*)-chelate, as shown in Fig. 2. Any other conceivable structure for [Pt(tac)-(PMe_2Ph)$_2$], in which tac may retain an (O-H) or (S-H) group, can be neglected, since no corresponding ^1H NMR resonances have been observed in the region 0—20 ppm. It is also quite unlikely, judging from a molecular model, that the ketonic carbonyl may have any interaction with the metal from the apical site of the coordination tetragonal plane. In fact, by varying the temperature (20—50 °C), we did not observe any spectral change which should correspond to a coordination site exchange, as observed for five-coordinate complexes.[13,14]

[Pt(tac-*S,O*)(PMe_2Ph)$_2$] produced via an S-S bond cleavage[15] of the dttb dianion may be given by supposing two reaction paths: first, the dttb dianion by an attack of OH^- cause an S-S bond cleavage to form the tac dianion and a following metathesis of the complex; second, a dinuclear dttb complex, such as [Pt_2(dahd)(PMe_2Ph)$_4$][BF_4]$_2$, is formed and a subsequent S-S bond cleavage occurs by and attack of the nucleophile OH^-, as attributed in Scheme 1. By treating H_2dttb with KOH in methanol, K_2tac could be obtained. By reacting [$PtCl(PMe_2Ph)_3$][PF_6] with K_2tac, we have also obtained [Pt(tac)(PMe_2Ph)$_2$]. No isolation of a dinuclear complex, such as [Pt_2-(dttb)(PMe_2Ph)$_4$][PF_6]$_2$, have yet succeeded. Another likely type of cleavage for the reaction is via the S-C bond of the dttb dianion. Yet, its details are uncertain at this time.

An author (Shinsaku Yamazaki) appreciate Dr. Hideki Yamagata (Department of Physics, Faculty of Science, Kochi University) for obtaining ESR spectra.

Formation of a Hydrogen Insertion Compound of Hydrated Molybdenum Oxide from Hydrogen Molybdenum Bronze

Kazuo EDA* and Noriyuki SOTANI
College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657
(Received May 15, 1989)

Synopsis. It was found that hydrogen molybdenum bronze, $H_{0.3}MoO_3$, turns into a hydrogen insertion compound of hydrated molybdenum oxide in a 1M HCl aqueous solution at 353 K. It was predictable that the compound has a composition of $H_{0.15}MoO_3 \cdot 0.88H_2O$ and is identical with $Mo_8O_{15}(OH)_{16}$ or a similar compound.

Hydrogen molybdenum bronzes are interesting materials and have been studied extensively.[1-6] The authors have studied the stability of bronzes and have found that one member, $H_{0.3}MoO_3$, changes into a new compound upon treatment at 353 K in a 1M HCl aqueous solution (1 M=1 mol dm^{-3}). In the present study, a characterization of this compound was achieved.

Experimental

Preparation. The sample was prepared from $H_{0.3}MoO_3$ in a 1M HCl aqueous solution at 353 K for one week. It was filtrated, washed by water, and then vacuum dried.

Measurements. Powder X-ray diffraction patterns were obtained by using a RIGAKUDENKI GEIGER D-1 FLEX diffractometer with Cu$K\alpha$ radiation. Samples for X-ray diffraction measurements were mixed with an internal standard (ca. 5 wt% Si powder). The IR spectra were recorded at room temperature by using a JASCO 701G spectrophotometer. Samples for this measurement were pressed into disks (ca. 0.5 wt% in KBr). TG-DTA was carried out on a MAC SCIENCE TG-DTA 2000 at a heating rate of 10 K min^{-1}. The sample weight for the measurement was ca. 20 mg. The hydrogen contents of the samples were determined chemically by Choain and Marion's method.[7]

Results and Discussion

The prepared sample was powder with a bluish gray color. The X-ray diffraction pattern and IR spectrum of the sample are shown in Figs. 1 and 2, respectively. The observed diffraction peaks in Fig. 1 and the IR bands in Fig. 2 are clearly different from those of $H_{0.3}MoO_3$. Those marked with the symbol ★ in these Figures correspond to those of MoO_3. The diffraction peaks with the symbol ○ correspond to those of $Mo_8O_{15}(OH)_{16}$, which have been synthesized from a mixture of $MoO_3 \cdot 2H_2O$ and Mo metal by Glemser and Lutz.[8] According to chemical analysis, the sample contained 0.10 hydrogen atom/Mo atom. Figure 3 shows a TG-DTA curve of the sample. Endothermic peaks appear at 429 and 477 K, and an exothermic peak appears at 621 K. Both endothermic peaks are followed by a large weight loss, which corresponds to 4.2 and 2.6 wt%, respectively. The peak temperature of 429 K is comparable to the releasing temperature of hydrate-water in yellow $MoO_3 \cdot H_2O$.[9] By H-NMR a Pake-doublet (r=0.15 nm) can be observed. Thus, the peaks can be attributed to the release of two kinds of hydrate-water, and a gradual weight loss continues until 573 K after their release. The exothermic peak at 621 K is followed by a weight gain (0.2 wt%). The peak might be attributed to the oxidation of the sample. The structural change at each DTA peak has been investigated. The results by X-ray diffraction and IR spectroscopy measurements are also shown in Figs. 1 and 2. With the release of two kinds of hydrate-water, the diffraction peaks and IR bands without the symbol ★ exhibit apparent changes. On the other hand, those with the symbol exhibit no or little change below 573 K. After the exothermic peak, the sample perfectly changes into MoO_3. The hydrogen contents of the samples heated at 448, 493, 573, and 673 K were 0.09, 0.07, 0.04, and 0.00 H atom/Mo atom, respectively. This shows that a large portion of the inserted hydrogen atoms are released in the temperature region which corresponds to a gradual TG loss. Thus, the release of hydrogen may be associated with a gradual TG loss. On the basis of the above results, the authors propose that the newly found compound by an HCl treatment of $H_{0.3}MoO_3$ is a hydrogen insertion compound of

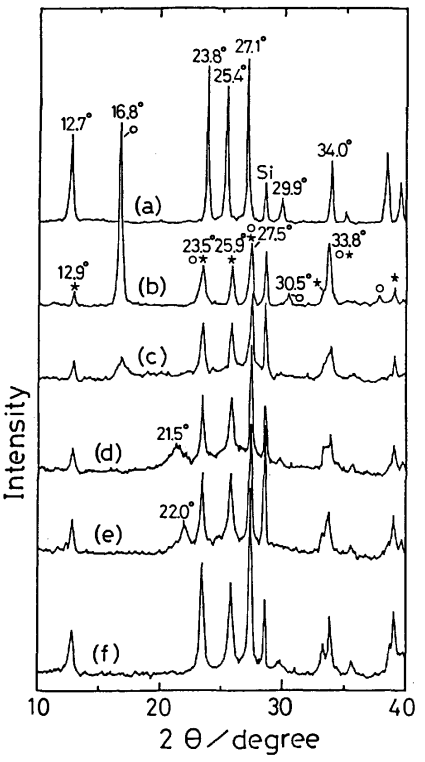

Fig. 1. Powder X-ray diffraction patterns of $H_{0.3}MoO_3$ (a), the sample as prepared (b), the sample heated in air at 448 K (c), at 493 K (d), at 573 K (e), and at 673 K (f).

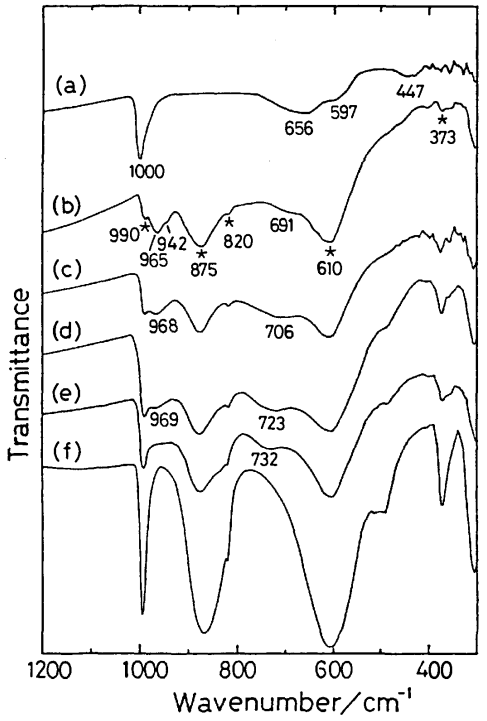

Fig. 2. IR spectra of $H_{0.3}MoO_3$ (a), the sample as prepared (b), the sample heated in air at 448 K (c), at 493 K (d), at 573 K (e), and at 673 K (f).

hydrated molybdenum oxide. However, it is also concluded that the sample is not single phase and contains MoO_3.

The total composition of the as-prepared sample was $H_{0.10}MoO_3(H_2O)_{0.59}$. This composition corresponds to a formula of $0.36MoO_3+H_{0.15}MoO_3 \cdot 0.88H_2O$ ($0.36MoO_3+0.08Mo_8O_{15.40}(OH)_{15.95}$). This formula means that the content of MoO_3 is 33.5 wt%. On the other hand, the content of MoO_3, by an estimation from the change in the intensity ratio of the characteristic diffraction peak at 25.9° by adding known amounts of commercial MoO_3 to the sample, has been 50 wt%, although the intensity of the peak at 25.9° for MoO_3 is appreciably small than that of the peak at 16.8° for the new compound. The real content might deviate from the estimated value to some extent because of the uncertainty of the assumption regarding the estimation that MoO_3 in the sample had

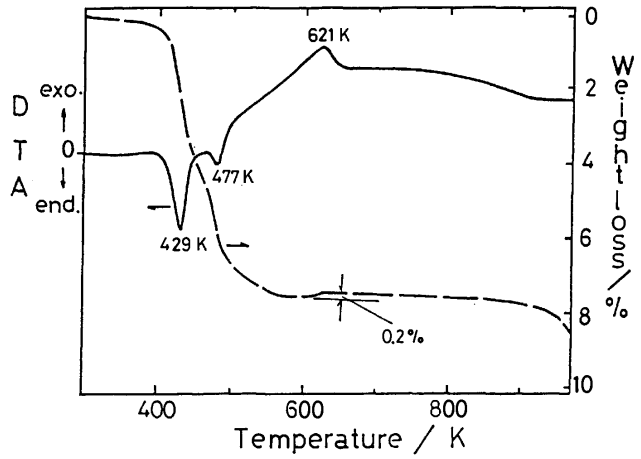

Fig. 3. TG-DTA curve of the sample as prepared.

the same diffraction peak intensity as the commercial one. It is therefore considered that the estimated value supports the above-mentioned large content of MoO_3 (33.5 wt%). On the basis of this discussion and the similarity in the X-ray diffraction pattern, the compound can be predicted to be $H_{0.15}MoO_3 \cdot 0.88H_2O$ which is identical with $Mo_8O_{15}(OH)_{16}$ or a similar compound. A synthesis of the compound as a single phase is in progress.

Crystal Structure and Magnetic Property of Cubane Tetranuclear Copper(II) Complex with Ferromagnetic Coupling

Naohide MATSUMOTO,* Takashi KONDO, Masahito KODERA, Hisashi ŌKAWA, and Sigeo KIDA
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812
(Received June 19, 1989)

Synopsis. The magnetic susceptibility measurement down to the liquid helium temperature and the single-crystal X-ray analysis of alkoxo-oxygen bridged tetranuclear copper(II) complex $[CuL]_4$ have been performed, where H_2L is a tridentate ligand derived from condensation of 3-ethoxymethylene-2,4-pentanedione and 2-aminoethanol. The magnetic data demonstrated that the four unpaired electrons of the four copper(II) ions are ferromagnetically coupled, the ground spin state of the cubane molecule being $S=2$. The structural analysis has confirmed several structural features, i.e., the distorted Cu_4O_4 cubane structure, the square pyramidal coordination geometry, nearly perpendicular arrengement between adjacent basal coordination planes, and inequivalent Cu-O bond distances.

Studies on discrete dinuclear or oligonuclear metal complexes with ferromagnetic spin coupling are fundamental requirement not only for elucidation of the structural and electronic factors governing magnetic interaction between paramagnetic centers but also for developing ferromagnetic materials.[1-4] However, such complexes are relatively rare, while a large number of polynuclear metal complexes with antiferromagnetic interaction have been known.[5]

Previously some of the present authors[6] synthesized copper(II) complex with a tridentate ligand derived from condensation of 3-ethoxymethylidene-2,4-pentanedione and 2-aminoethanol, and measured the magnetic susceptibility in the temperature range 80—300 K. The magnetic susceptibility obeys the Curie-Weiss law ($\chi_A=C/(T-\theta)$) with positive Weiss constants suggesting a ferromagnetic interaction between copper(II) ions. In this study, in order to detect the spin ground state of the molecule and elucidate the structural factors causing ferromagnetic coupling, the complex has been subjected to the magnetic susceptibility measurement down to the liquid helium temperature and the single-crystal X-ray analysis.

Experimental

Synthesis. The complex was prepared according to the method reported previously[6] and recrystallized twice from dichloromethane/methanol solution. Calcd for [CuL], $CuO_3NC_8H_{11}$: C, 41.29; H, 4.76; N, 6.02%. Found: C, 41.16; H, 4.86; N, 5.99%.

Physical Measurements. Elemental analyses were performed at the Elemental Analysis Center of Kyushu University. Magnetic susceptibilities were obtained at 4.2—100 K by use of a HOXAN HSM-D SQUID magnetometer in the magnetic field 0.5 T and at 80—300 K by a Faraday balance designed in our laboratory. The data were corrected for magnetization of the sample holder and for the diamagnetism of the component atoms by the use of Pascal's constants. The molar effective magnetic moment was calculated by the equation $\mu_{eff}=2.828(\chi_A T)^{1/2}$.

X-Ray Crystallography. Reflection data were measured on a Rigaku Denki AFC-5 automated four-circle diffractometer with graphite-monochromatized Mo $K\alpha$ radiation at room temperature. The details of data collection and crystallographic data are summarized as follows: $[CuL]_4$, formula=$Cu_4O_{12}N_4C_{32}H_{44}$, FW=930.91, triclinic, space group $P\bar{1}$, a=12.330(2) Å, b=13.766(4) Å, c=11.109(3) Å, α=97.44(2)°, β=92.05(2)°, γ=85.09(2)°, V=1862.3(7) Å^3, D_m=1.64 g cm^{-3} (by floatation method in aqueous KI solution), D_x=1.66 g cm^{-3} (Z=2), crystal size 0.3×0.3×0.4 mm, μ(Mo $K\alpha$)=23.23 cm^{-1}, scan mode θ-2θ, scan range 2.5—52°, scan width (1.2+0.35 tan θ)°, octant measured $+h$, $\pm k$, $\pm l$, number of observed reflections with $|F_o|>3\sigma(|F_o|)$ 5516, R=4.20%, R_w=5.01%, highest peak on the final D-Fourier 0.4 e Å^{-3}.

The intensity data were corrected for Lorentz and polarization effects but not for absorption and extinction effects. The structure was solved by the standard heavy-atom method and refined by the block-diagonal least-squares method, in which the function minimized is $\sum w(|F_o|-|F_c|)^2$ and the equal weight w=1 was adopted for all the reflections. The atomic scattering factors were taken from Ref. 7. All computations were performed on a FACOM M 780 computer at the Computer Center of Kyushu University using the UNICS III program system.[8] The final atomic coordinates are given in Table 1. Tables of observed and calculated structure factors, listings of atomic positional and anisotropic thermal parameters, and complete lists of bond distances and angles with their estimated standard deviations have been deposited as Document No. 8905 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Magnetic Property. The magnetic susceptibilities have been measured in the 4.2—300 K temperature range. Figure 1 shows the result of $[CuL]_4$, in the forms of the χ_A vs. T, the $1/\chi_A$ vs. T, and the μ_{eff} vs. T plots, where χ_A is the magnetic susceptibility per copper atom, μ_{eff} the effective magnetic moment per copper atom, and T the absolute temperature. The numerical values of the magnetic susceptibilities are given as supplementary materials.

The $1/\chi_A$ vs. T plot follows the Curie-Weiss law ($\chi_A=C(T-\theta)$) above 50 K with a Weiss constant 20 K, suggesting a ferromagnetic interaction. The effective magnetic moment at room temperature is 1.84 μ_B/Cu, which is close to the spin-only value (1.72 μ_B). As the temperature is lowered, the magnetic moment increases from 1.84 μ_B at 297.8 K, reaches a maximum value of 2.49 μ_B at 13 K, and finally decreases to 2.41 μ_B at 4.5 K. The maximum value (2.49 μ_B/Cu=4.98 μ_B/4Cu) agrees well with the spin-only value (4.90 μ_B expected for S=2 spin state effected by a ferromagnetic spin coupling of four unpaired electrons. The decrease of μ_{eff} below 13 K is attributable to either the intermolecular effect or the zero-field splitting of the S=2 ground state. The result clearly demonstrates that a ferromagnetic spin-exchange coupling is oper-

ating within a molecule and the spin ground state of the cubane molecule is $S=2$ and is fully populated below 13 K.

Structural Description. The ORTEP drawing of $[CuL]_4$ with the atom numbering scheme is shown in Fig. 2. The selected bond distances and angles with their estimated standard deviations are available in Table 2. The complex has a cubane-type alkoxo-oxygen bridged tetranuclear structure. The distances of Cu1-Cu3 and Cu2-Cu4 are 3.337(1) Å and 3.316(1) Å, respectively, which are longer than the other four Cu-Cu distances (3.092(1)—3.126(1) Å), indicating a distortion from the ideal cubane struc-

ture. The coordination geometries of the four copper(II) ions are best described as a square pyramid. The apical positions of the square pyramids of Cu1, Cu2, Cu3, and Cu4 are occupied by O3, O4, O1, and O2, respectively, where the Cu-O(apical) bond distances fall in the range 2.370(4)—2.477(3) Å. The basal coordination sites of each copper(II) ion are occupied by the NO_2 donor set of the tridentate ligand L and an alkoxo-oxygen atom of the neighbouring ligand, where the bond distances are in the range 1.892(5)—1.983(4) Å. Adjacent copper(II) ions are bridged by two alkoxo-oxygen atoms inequivalently. For example, Cu1 and Cu2 atoms are doubly bridged by two alkoxo-oxygen atoms O1 and O4 with the bond distances of Cu1-O1 1.963(4) Å, Cu2-O1 1.929(4) Å, Cu1-O4 1.945(4) Å, and Cu2-O4 2.414(4) Å, indicating that one Cu-O bond among the four Cu-O bonds in Cu_2O_2 unit is elongated. The dihedral angle between the basal coordination planes of Cu1 and Cu2 is 78.7°, that of Cu2 and Cu3 94.9°, that of Cu3 and Cu4 92.6°, and that of Cu4 and Cu1 93.4°. Thus, the basal coordination planes are nearly perpendicular to each other.

Complexation Reactions of Copper(II) Ions with 16-Membered and 18-Membered Monocyclic Dioxopolyamines in an Aqueous Solution

(Received July 10, 1989)

Synopsis. The equilibria of complexation reactions of dioxo[16]aneN$_5$, dioxo[18]aneN$_6$, and their related compounds with copper(II) ions were determined potentiometrically. Making a sharp contrast to the 13—15-membered monocyclic dioxotetramine system, they interact with copper(II) ions in their neutral and doubly deprotonated forms, L and $H_{-2}L^{2-}$, yielding stable CuL^{2+} and $CuH_{-2}L^0$ complexes.

In earlier studies on the complexation of 13—15-membered monocyclic dioxotetramines,[1,2] it was demonstrated that these potential quadridentate macrocycles only form square planar N_4 complexes, $MH_{-2}L^0$, with Cu(II) and Ni(II) ions as a result of a double deprotonation of the amides. The binding of the metal(II) is assumed to take place first at the amide group, followed by imidiate amide deprotonation and coordination. The latter coorperative action might occur more readily in the macrocycles than in the linear tripeptides, particularly in those having rigid planarity and suitable cavity sizes for the small metal ions having a stronger tendency to square-planar coordination like Cu(II) and Ni(II) ions.

As a continuation of our equilibrium study concerning the complexation reactions of macrocyclic dioxopolyamines, we have now determined the equilibria of copper(II) complex formations of dioxo[16]aneN$_5$, dioxo[18]aneN$_6$, and their related compounds. Comparisons of the present findings with those for the 13—15-membered macrocyclic dioxotetramines and the relevant linear tripeptides might shed more light on the ligating properties of macromonocyclic dioxopolyamines, leading to an explanation of their useful applications.

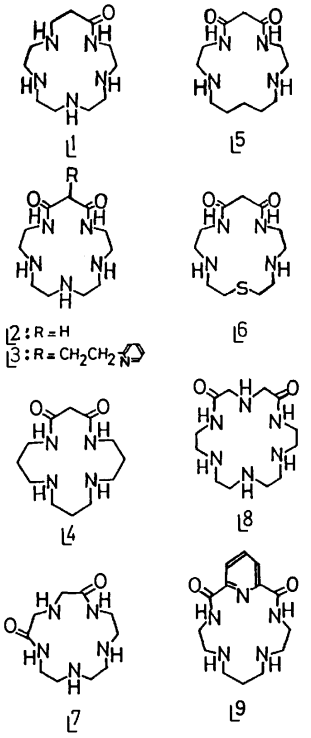

Chart 1.

Experimental

The macrocyclic dioxopolyamines used were prepared according to methods described in the literature[1-4] (Chart 1). The salt $CuSO_4 \cdot 5H_2O$ was an analytical grade chemical and its solutions were standardized by EDTA titration.[5]

The pH-metric titrations were performed with a Mettler automatic titrator[6,7] under a nitrogen or an argon atmosphere at 25±0.2 °C. All of the experimental conditions and procedures employed have been mentioned previously.[6] The values of $-\log[H^+]$ were estimated by applying a correction of −0.13 pH unit to the pH readings.[7] The mixed protonation constants (K_i's) were determined potentiometrically.[4] The mixed protonation constants ($\log K_i$'s) of a new ligand, L^7, were 8.35, 4.85, and ca. 2.6 and those of L^9, 8.73 and 6.22.

Results and Discussion

The equimolar mixture solution of copper(II) and L^4, L^5, L^6, or L^9 in its fully protonated form (H_2L^{2+}) gave titration curves with a buffer region at the titration point $4>a>0$, which fitted to the theoretical equation (16) in Ref. 1 derived for the formation of $CuH_{-2}L^0$ in the dioxotetramine system ($C_M=C_L$). Therefore, the cumulative formation constants, $K_{CuH_{-2}L}(=[CuH_{-2}L^0]\cdot[H^+]^2/[Cu^{2+}]\cdot[L])$, were determined similarly in a graphic way.[1]

In sharp contrast with these ligand systems, the titration curve of an equimolar mixture of Cu(II) and L^2 (dioxo[16]aneN$_5$) in its fully protonated form (H_3L^{3+}) gave two buffer regions at titration points $3>a>0$ and $5>a>3$ (Fig. 1). Two breaks, one occurring at $a=3$ and the other at $a=5$ suggest the complexation equilibria (1) and (2) for the titration points $3>a>0$ and $5>a>3$, respectively. The K_{CuL} value was determined in an analogous way to that described for the complexation of the macromonocyclic triamine with copper(II) ions.[8] The K^{-2H} value was then estimated from the gradient of the straight line between

$$Cu^{2+} + L = CuL^{2+},\ K_{CuL} = [CuL^{2+}]/[Cu^{2+}]\cdot[L] \quad (1)$$

$$CuL^{2+} = CuH_{-2}L^0 + 2H^+,\ K^{-2H} = [CuH_{-2}L^0]\cdot[H^+]^2/[CuL^{2+}] \quad (2)$$

the $(\alpha'/2)/(C_L-\alpha'/2)$ and $[H^+]^{-2}$ (Fig. 2). Here, α' is

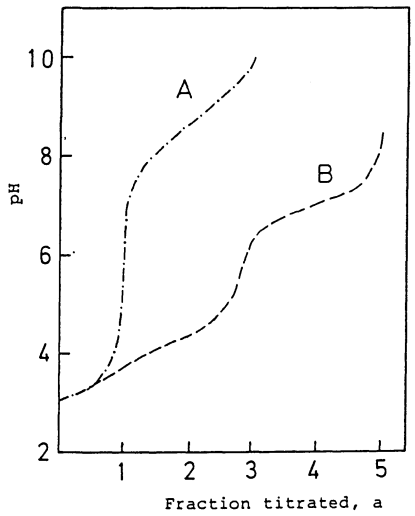

Fig. 1. Titration curves of 1.00 mM dioxo[16]aneN$_5$ (3HCl salt).
Ionic strength (I)=0.20 M, 25 °C, (A) dioxo[16]aneN$_5$ only, (b) dioxo[16]aneN$_5$+1.00 mM Cu(II), sample solution 50.0 ml with 0.100$_0$ M tetraethylammonium solution.

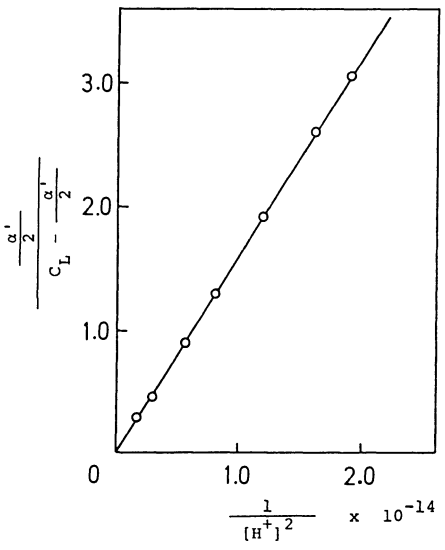

Fig. 2. Plots of $(\alpha'/2)/(C_L-\alpha'/2)$ against $1/[H^+]^2$.
[Cu(II)]=1.00 mM, [dioxo[16]aneN$_5$ 3HCl]=1.00, mM, I=0.20 M, 25 °C.

defined as $(a-3)C_L+[H^+]$, and $(\alpha'/2)/(C_L-\alpha'/2)$ corresponds to the $[CuH_{-2}L^0]/[CuL^{2+}]$ ratio. This also turned out to be the case for the 1:1 Cu(II)-dioxo[18]aneN$_6$(L^8) mixture solution ($4>a>0$, $6>a>4$). The K_{CuL} and K^{-2H} values for the Cu(II) complex of dioxo[18]aneN$_6$ were also estimated in a quite similar way.

In the case of a Cu(II)-monooxo[16]aneN$_5$(L^1, H_4L^{4+}) system, two breaks occurring at a=3 and 5 suggest the formation of $CuHL^{3+}$ and $CuH_{-1}L^+$. The K_{CuHL} (=$[CuHL^{3+}]/[Cu^{2+}]\cdot[HL^+]$ value was determined by using the following equation (3) derived in an identical manner as that employed for the complexation of macromonocyclic pentamines with Zn(II) ions ($C_M=C_L$).[8]

$$\frac{K_{CuHL}\cdot[H^+]}{K_4}(3C_L-\alpha)^2(\alpha_H)_L = (\alpha(\alpha_H)_L-\beta_H C_L)\cdot(3(\alpha_H)_L-\beta_H). \quad (3)$$

Here, K_4 means the 4-th dissociation constant of H_4L^{4+}. As in the case of the dioxo[16]aneN$_5$ system, the K^{-2H} (=$[CuH_{-1}L^+]\cdot[H^+]^2/[CuHL^{3+}]$) value was determined from the gradient of the straight line between the $(\alpha'/2)/(C_L-\alpha'/2)$ (=$[CuH_{-1}L^+]/[CuHL^{3+}]$) value and $[H^+]^{-2}$. The titration of an equimolar mixture of Cu(II) and dioxo[15]aneN$_5$ (L^7, H_3L^{3+}) also gave two breaks at a=4 and 5, suggesting the formation of $CuH_{-1}L^+$ and $CuH_{-2}L^0$. The $K_{CuH_{-1}L}$ (=$[CuH_{-1}L^+]\cdot[H^+]/[Cu^{2+}]\cdot[L]$) and $K^{-H}_{CuH_{-1}L}$ (=$[CuH_{-2}L^0]\cdot[H^+]/[CuH_{-1}L^+]$) values for the Cu(II)-L^7 complex were determined in an identical manner as that previously applied to the Cu(II)-dioxo[12]aneN$_4$ complex formation.[2] All of the equilibrium constants determined in this study are listed in Table 1.

The equimolar mixture solution of Cu(II) ion and dioxo[16]aneN$_5$ at pH 4—5 (at titration point $a<3$) is blue, greatly differing from the pink (λ_{max}=505 nm) shown by the square-planar Cu(II)-dioxo[14]aneN$_4$ complex $CuH_{-2}L^0$,[2,9] However, it turns to violet at pH's higher than 7.0, indicating a certain change in the coordination mode of dioxo[16]aneN$_5$ to the Cu(II) ion. In light of the similarity between the visible spectra of the blue complex and $[Cu(dien)(OH_2)_3]^{2+}$ (λ_{max} for the blue complex is 610 nm and that for the $[Cu(dien)(OH_2)_3]^{2+}$ complex is 611 nm[10]), the tetragonally distorted octahedral structure, where the three amino nitrogen donors and one H_2O stay at

a) $K^{-H}_{CuH_{-1}L}$.

the basal positions, would be assumed for the blue complex. In fact, a Dreiding molecular model study shows that the Cu(II) ion in this complex can have a coordination environment of three amino nitrogen donors and one carbonyl oxygen of L^2 in plan with two H_2O molecules above and below, completing the distorted octahedral coordination. The formation constant, K_{CuL}, determined in this study is slightly larger than that of the copper(II)-diethylenetriamine (dien) complex ($\log K_{CuL}=10.01$).[11] This finding also lends a strong support to the above explanation.

As in the case of the nickel(II)-dioxo[16]aneN$_5$ complex, $NiH_{-2}L^0$,[4] the doubly-deprotonated dioxo[16]aneN$_5$ anion for the violet complex, $CuH_{-2}L^0$, which is formed at pH's higher than 7.0, would encircle the Cu(II) ion in a square-pyramidal configuration with two deprotonated amide nitrogen donors staying at the basal positions, along with the two amino nitrogens, probably completing the distorted octahedral coordination. The 16-membered dioxotetramine, dioxo[16]aneN$_4$ (3,3,3,3)(L^4), forms solely $CuH_{-2}L^0$. Its violet aqueous solution displays visible spectra ($\lambda_{max}=550$ nm) similar to those for the dioxo[16]aneN$_5$ complex, $CuH_{-2}L^0$. Hence, for this complex the distorted octahedral coordination including water molecules must be likely. A molecular model examination shows that the ligand in this complex can encircle the Cu(II) ion with two amino and two deprotonated amide nitrogens staying at the basal positions with two H_2O molecules at the axial coordination sites. The other 16-membered dioxotetramine, L^5, also afforded the $CuH_{-2}L^0$ complex. Its aqueous solution, however, is pink and gives visible spectra quite similar to those of Cu(II)-13—15-membered dioxotetramine complexes.[2,4] This implys that the structure of the Cu(II)-L^5 complex can be described as an extremely flattened tetrahedron or a square-planar geometry.[12] L^9 and L^6 also yielded only stable $CuH_{-2}L^0$ under the present experimental conditions. The significant difference in the magnitude of $K_{CuH_{-2}L}$ value between L^4 and L^5 complexes clearly suggests that the presence of the dioxo-[2.3.2]tetramine moiety is essentially required for the formation of stable doubly-deprotonated $CuH_{-2}L^0$ (Table 1), because the doubly-deprotonated dioxo-[2.3.2]tetramine frame can adapt most easily to the achievement of the rigid square-planar geometry.

As demonstrated by the $K_{CuH_{-2}L}$ values in Table 1, the sulfur and pyridine nitrogen donors incorporated within the 16-membered macrocyclic frame also assist in stabilizing the complex. Dioxo[18]aneN$_6$, L^8, also forms blue CuL^{2+} at pH 3.5—6.0, and mauve doubly-deprotonated $CuH_{-2}L^0$ at pH's higher than 7.5. The fact that dioxo[16]aneN$_5$ and dioxo[18]aneN$_6$ can form CuL^{2+} as well as $CuH_{-2}L^0$, but L^5 gives only $CuH_{-2}L^0$ clearly suggests that neutral dioxopolyamines can encircle the copper(II) ion in their macrocyclic cavity only when three or more amine nitrogens are available for the complexation.

The Magnetic Properties of Copper(II) 3- and 4-Substituted Benzoate Adducts with Quinoline and 4-Methylquinoline

Shuji EMORI,* Satoru MATSUNAGA, and Miyako GOTO
Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
(Received July 12, 1989)

Synopsis. Various copper(II) 3- and 4-substituted and 3,5-disubstituted benzoate adducts with quinoline and 4-methylquinoline have been prepared, and characterized by means of magnetic susceptibility and IR spectroscopy measurements. The variation of their magnetic moments is discussed in terms of the acidities of their parent acids and the resonance effects of 4-substituents.

Most copper(II) carboxylates have bridged dinuclear structures and exhibit strong antiferromagnetic coupling between the pairs of copper(II) ions. With the intention of elucidating the mechanism of the spin-exchange coupling, an attempt has been made to relate the strength of the coupling to the acidity of the parent carboxylic acid.[1-3] While such a correlation has been confirmed for various alkanoate series,[3-5] it remains obscure for arenecarboxylates.[6-8] This is supposed to reflect the versatility of coordination polymerism in arenecarboxylates.[9,10] Besides, their magnetic properties may also be affected by the steric and resonance effects of substituents, as would be expected from the Hammett equation.[11] In order to investigate the resonance effects, we have prepared the quinoline (quin) and 4-methylquinoline (4-Mequin) adducts of a series of copper(II) 3- and 4-substituted benzoates with the substituents of CH_3, Cl, NO_2, CF_3, CH_3O, and CN.

The quinoline adducts of copper(II) 4-substituted benzoates, except 4-cyanobenzoate, were prepared according to the general procedure[9] and recrystallized from *N*,*N*-dimethylformamide containing excess quinoline. The remaining compounds were prepared by treating the ethanol solution of appropriate benzoic acid with a chloroform solution of the quinoline adduct of copper(II) propionate. In most cases the fine green crystals precipitated within a few hours; when this was not the case, the mixture was evaporated under reduced pressure. The effective magnetic moments of these compounds (Table 1) were evaluated from the room-temperature magnetic susceptibilities (χ_M) using the equation $\mu_{eff}=2.83[(\chi_M-\chi_{dia}-N\alpha)T]^{1/2}$. The diamagnetic corrections (χ_{dia}) were estimated from Pascal constants[12] and the temperature-independent paramagnetic contribution ($N\alpha$) was taken as 60×10^{-6} (1 emu$=4\pi\times10^{-6}$ m^3). For the quinoline adducts of copper(II) 3-nitrobenzoate and 3,5-dinitrobenzoate, the temperature dependence of their magnetic susceptibilities was measured in the temperature range of 80—300 K in order to confirm their dinuclear structures. The result agreed well with the Bleaney-Bowers equation,[13] using the parameters of $g=2.17$ and $2J=-276$ cm^{-1} for the 3-nitrobenzoate and $g=2.18$ and $2J=-259$ cm^{-1} for the 3,5-dinitrobenzoate. The IR spectra of the solid compounds show bands characteristic of bridging carboxylate due to unsymmetric and symmetric carboxyl stretching vibrations.[14] The magnetic and IR spectral data indicate that the present compounds have a bridged dinuclear structure, similar to that of copper(II) acetate monohydrate.[15,16]

From an analogy to plots for the corresponding alkanoates,[4,5] the room-temperature magnetic moments (in BM) of the present compounds, together with literature data concerning the corresponding pyridine adducts,[7,16] are plotted in Fig. 1 against $pK_a-0.068pK_a'$ values, where pK_a and pK_a' are the acidities of the parent benzoic acid and the conjugate acid of the addend *N*-heteroaromatic donor. The points for the 3-substituted and 3,5-disubstituted benzoates give a straight line which has the same slope as that for the alkanoates:[4]

$$\mu_{eff}=-0.052(pK_a-0.068pK_a'-4.00)+1.37_1. \quad (1)$$

The variation of the singlet-triplet separation energies (e.g. $-2J=280$, 276, and 259 cm^{-1} for the quinoline adducts of benzoate,[17] 3-nitrobenzoate, and 3,5-dinitrobenzoate, respectively, and $-2J=309$, 307, and 292 cm^{-1} for the pyridine adducts of copper(II) 3-methylbenzoate,[7] benzoate,[18] and 3-bromobenzoate,[7] respectively) is consistent with this equation. Similarly, the carboxyl frequencies (in cm^{-1}) for these compounds show systematic shifts against the acidities of the parent benzoic acids ($\tilde{\nu}_{unsym}=1683-15.0(pK_a-0.068pK_a')$ and $\tilde{\nu}_{sym}=1406+4.9(pK_a-0.068pK_a')$). These relationships indicate that the magnetic properties of the 3-substituted and 3,5-disubstituted benzoates are influenced unambiguously by the inductive effects of substituents. On the other

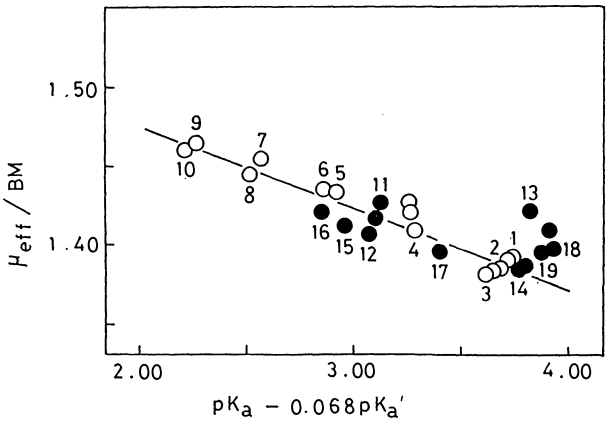

Fig. 1. The magnetic moments at 20 °C plotted against the acidities of the ligands for the copper(II) 3-substituted (○) and 4-substituted (●) benzoate adducts with pyridine, quinoline, and 4-methylquinoline.

hand, the magnetic moments of the present 4-substituted benzoates are rather independent of the acidities of the parent acids (Fig. 1). This discernible trend has already been pointed out for the magnetic properties of the copper(II) 4-substituted benzoate adducts with 1-butanol, since their singlet-triplet separation energies are insensitive to the nature of the substituents.[6] It is plausible that the resonance and inductive effects of 4-substituent[11,19] tend to be cancelled out. For cases where the perturbation on the π-electron density of the carboxyl group may not be disregarded, using $\Delta\mu_\pi$ to represent this correction term, we can write

$$\mu_{eff} = -0.052(pK_a - 0.068pK_a' - 4.00) + \Delta\mu_\pi + 1.37_1. \quad (2)$$

Previously, we have pointed out that the $\Delta\mu_\pi$ term may be correlated with $R-0.38F$,[5] where R and F are the resonance and field constants of Swain and Lupton.[20] The $\Delta\mu_\pi$ values evaluated by the use of Eq. 2 are plotted, in Fig. 2, against $R-0.38F$. The apparent linear correlation indicates that the resonance effect takes a role in determining the magnetic properties of the 4-substituted benzoates. The magnitude of the resonance effect is estimated to be about $-0.03_5(R-0.38F)$, e.g., 0.00_4, 0.01_5, and 0.02_3 BM for

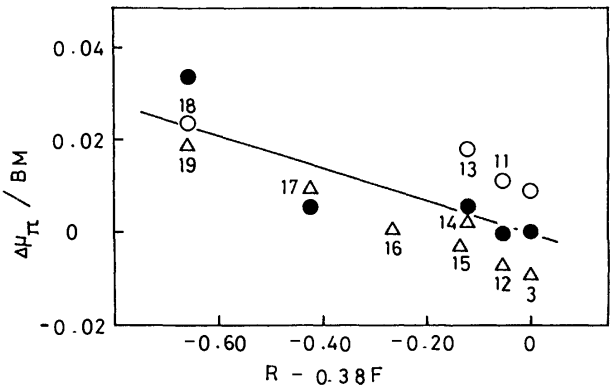

Fig. 2. The correction values $\Delta\mu_\pi$ for the 4-substituted benzoate adducts with pyridine (●), quinoline (○), and 4-methylquinoline (△) plotted against the substitutent constants $R-0.38F$.

the CH_3, Cl, and CH_3O substituents, respectively. These values are much smaller than those found in the case of copper(II) (substituted formate)s.[5] This refers perhaps to the torsion between the planes of the carboxylate and phenyl groups (the dihedral angles of 0.2—27.2°),[21-24] in adition to the long separation between the bridging carboxylato and substituent groups.

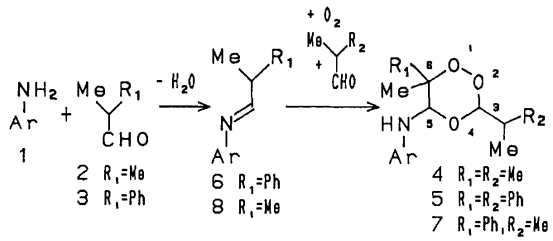
Synopsis. 5-Arylamino-3-isopropyl-6-methyl-6-phenyl-1,2,4-trioxanes were synthesized by autoxidation of imines in the presence of isobutyraldehyde. Their four isomers have been identified and the anomerization of 5-arylamino-1,2,4-trioxanes has been detected by the ^{13}C NMR spectra in chloroform-*d*.

The 1,2,4-trioxanes have attracted the attention of researchers since they play an active role in sesquiterpene Arteannuin,[1] an antimalarial remedy. Several methods for the synthesis of 1,2,4-trioxanes have been reported,[2] while we obtained 5-arylamino-1,2,4-trioxanes **4** and **5** through reactions of arylamines **1** and aldehydes **2** and **3** in the presence of oxygen (Scheme 1).[3] The structures of both the cis($3R^*,5S^*$) and trans ($3R^*,5R^*$) isomers of **4** became apparent based on X-ray crystal-structure analyses;[4] the distinction between these two isomers were established on the basis of ^{13}C NMR chemical shifts.[5] Trioxanes **4** and **5** are composed of an arylamine and two molecules of aldehyde incorporated in the same ring. We now report on the synthesis of trioxanes in which two different kinds of aldehydes are incorporated. The structures of four isomers of trioxanes, thus produced, are characterized.



Ar = a; *p*-tolyl b; *o*-tolyl c; phenyl d; 2-chlorophenyl e; 2,4-xylyl f; 4-chlorophenyl g; *m*-tolyl h; 2,6-xylyl i; mesityl.

Scheme 1.

Results and Discussion

Imines **6**, easily obtained from **1** and **3**, were autoxidized in the presence of **2** for a few days (Scheme 1). After the resulting mixture was separated into five products by HPLC (high-performance liquid chromatography), products were characterized by the use of a mass spectrometer. In the case of **6a**, the product corresponding to the first peak was assigned to be trioxane **4a** (*m/z* 265, M^+) in which two molecules of isobutyraldehyde are incorporated. The other four products showed the same parent ion peaks for new trioxane (*m/z* 327, M^+). A similar tendency in the reaction of imines **6b—g** was also observed by means of HPLC. On the other hand, imines **6h,i** bearing a 2,6-disubstituted phenyl moiety gave only one product. From these mixtures, colorless crystallines of trioxanes **7a—i** were obtained by column chromatography and recrystallization from hexane; they gave satisfactory spectral data (NMR, IR, MS).

Since imine **8** was partly interconverted into imine **6** during autoxidation with **3**, the oxidation of imines **8** in the presence of **3** gave a number of products. In the case of **8a**, these products consisted of **4a**, two isomers of **5a** and four isomers of **7a** on the basis of HPLC and mass spectra. We could not isolate any pure crystallines from these reaction mixtures.

Four isomers of **7** ($3R^*,5S^*,6R^*$, $3R^*,5R^*,6R^*$, $3R^*,5S^*,6S^*$, $3R^*,5R^*,6S^*$) and another four equatorial-axial interconversion conformers are expected by analogy with the case of 1,2,4-trisubstituted cyclohexanes.[6] Since a previous X-ray analysis of **4** suggested that the isopropyl group at C-3 is bonded at an equatorial position, **7** may exists in four isomers which have an isopropyl group bonding at an equatorial position (Fig. 1). ^{13}C NMR was the established method for the conformational analysis of **4**. Therefore, a conformational analysis of **7** was attempted by ^{13}C NMR.

Since the ^{13}C signal of C-3 of **7e,f** appeared at δ 99.8—99.9, the anilino nitrogen at C-5 is located γ-gauche to C-3 and the conformation at C-5 has been determined to be R^*. Since the methyl at C-6 is γ-

a) Newly appeared signals in solution are given in parenthese. b) Typical trioxane of **4**, (3*R**,5*S**)-5-(4-chloroanilino)-3-isopropyl-6,6-dimethyl-1,2,4-trioxane, from Ref. 5).

trans to the nitrogen, from the ^{13}C shift value for this carbon at δ 25.0—25.6, the conformation at C-6 has been determined to be *R**. It may, therefore, be considered that the structure of **7e,f** is **7** (3*R**,5*R**,6*R**). When $CDCl_3$ solutions of **7e,f** were allowed to stand for a few days new ^{13}C signals appeared in lower fields where trioxanes of **7a—d** had shown signals. Similarly, when $CDCl_3$ solutions of **7a—d** were allowed to stand new ^{13}C signals were observed in the higher fields, where those of **7e,f** had appeared. These new signals are shown in parentheses in Table 1. Since these spectral changes can be ascribed to anomerization at C-5 of the 1,2,4-trioxane ring between **7** (3*R**,5*R**,6*R**) and **7** (3*R**,5*S**,6*R**), by analogy with the case of **4**[5] the structure of **7a—d** seems to be **7** (3*R**,5*S**,6*R**). The ^{13}C chemical shifts of C-3 (δ 107.1—107.2) and the methyl carbon (δ 16.2—16.3) support this conformation.

The ^{13}C NMR signals for **7g** were notable for C-5 and C-6 at δ 79.7 (the highest field) and at δ 84.1 (the lowest field), respectively. Since the nitrogen is located γ-gauche to C-3 from its value δ 99.5, the conformation of C-5 has been determined to be *R**. The ^{13}C signal for the methyl carbon at C-6 of this isomer (δ 25.8) was close to that of the anomeric isomer (δ 22.9). This may suggest that the methyl group in each isomer occupies an equatorial position of the trioxane ring and that the conformation of C-6 is *S**. Therefore, the structure of **7g** seems to be **7** (3*R**,5*R**,6*S**) and the anomeric isomer to be **7** (3*R**,5*S**,6*S**). Attempts to analyze **7g** by X-rays were unsuccessful because of the rapid intensity decrease of the reflections during measurement. However, an analysis with a technically insufficient number of reflections may support the 3*R**,5*R**,6*S** conformation of **7g**.[7]

Table 2. Equilibration of **7** in $CDCl_3$ at 25 °C

3*R**,5*S**,6*R** isomer/%		$\Delta G^{oa)}$/kJ mol^{-1}
7a	62±1	1.2±0.1
7b	62±2	1.2±0.2
7c	61±3	1.1±0.3
7d	71±1	2.2±0.1
7e	62±1	1.2±0.1
7f	57±1	0.7±0.1
3*R**,5*R**,6*S** isomer/%		$\Delta G^{ob)}$/kJ mol^{-1}
7g	81±5	3.7±0.8

a) $\Delta G^\circ = G^\circ_{3R^*,5R^*,6R^*} - G^\circ_{3R^*,5S^*,6R^*}$. b) $\Delta G^\circ = G^\circ_{3R^*,5S^*,6S^*} - G^\circ_{3R^*,5R^*,6S^*}$.

The ^{13}C NMR spectra of **7h,i** were very similar to those of **7a—d**, except for the C-5 signal which shifted to lower field (δ 90.9—91.1). It may, thus, be considered that the structure of **7h,i** is **7** (3*R**,5*S**,6*R**) and that the C-5 signal appeared at a low field owing to an anisotropic effect of the twisted aryl group.

The free-energy difference of anomerization was evaluated from the molar fractions of isomers derived from the average intensity of ^{13}C signals at equilibrium (Table 2). These values were smaller than those of trioxane **4**. The phenyl substitution of the ring causes a smaller free-energy differences between the anomeric isomers.

Experimental

Melting points are all uncorrected. Spectral characterizations were carried out with the following instruments: ^{13}C NMR, JEOL JNM-GSX400 spectrometer; ^1H NMR,

Hitachi R-20A spectrometer; MS, JEOL JMS-DX300 mass spectrometer; and IR, Hitachi 215 spectrometer. HPLC was performed by using a JASCO 800 liquid chromatograph with a SIL C18T column (7.2×250 mm, 90% methanol aq as eluent).

General Preparation of Trioxanes 7. The mixture of arylamine **1** (15 mmol) and 2-phenylpropionaldehyde (**3**) (15.5 mmol) was heated in an oil bath (110 °C) under nitrogen for 30 min. A solution of the crude imine **6** and isobutyraldehyde (**2**) (30 mmol) in hexane (25 ml) was autoxidized in a 100 ml Erlenmyer flask at room temperature. After about 2 to 4 days, the solvent and excess **2** were removed under reduced pressure and the residue was chromatographed on silica gel to give the corresponding trioxane **7**.

Stereoselective Bromination of Acetylenes with Bromine in the Presence of Graphite

Mitsuo KODOMARI,* Takaaki SAKAMOTO, and Suehiko YOSHITOMI
Department of Industrial Chemistry, Shibaura Institute of Technology, Shibaura, Minato-ku, Tokyo 108
(Received May 27, 1989)

Synopsis. Acetylenes were stereoselectively brominated with molecular bromine adsorbed on graphite in dichloromethane to produce (*E*)-α,β-dibromoalkenes; isomerization of the *E*-isomer to the *Z*-isomer, usually catalyzed by bromine, did not occur in the presence of graphite.

The use of inorganic solid supports has been attracting widespread interest in organic synthesis.[1,2] Significant improvements of reagent activity or regioselectivity has been achieved in a wide variety of organic reactions by the use of supported reagents formed by the adsorption of reagent molecules onto the surface of a solid support. However, only a few studies on stereoselective control using supported reagents have been reported.[3] In a previous paper,[4] we reported that graphite inhibits the bromine-catalyzed isomerization of (*E*)-α,β-dibromostyrene to the *Z*-isomer, and that the addition of bromine to phenylacetylene produces (*E*)-α,β-dibromostyrene exclusively in the presence of graphite. We further found that the addition of graphite is also effective in the bromination of several other acetylenes. In the present paper we describe these recent results.

Results and Discussion

The bromination of acetylenes with bromine usually produces a mixture of two isomeric dibromoalkenes due to the reversible addition of a halogen atom to the double bond.[5-7] Thus, the *E*/*Z* ratio depends on the reaction conditions; namely, the *E*/*Z* ratio decreases when a prolonged reaction time, higher temperature, and a higher molar ratio of bromine relative to acetylenes are employed. We found, however, that acetylenes are stereoselectively brominated by molecular bromine adsorbed on graphite in dichloromethane to give (*E*)-α,β-dibromoalkenes. The *E*/*Z* ratio in the products mixture was almost independent of the reaction conditions. The results are summarized in Table 1. For example, the treatment of propargyl bromide with 0.5-equiv of bromine in dichloromethane at 20 °C gave a mixture of two isomeric 1,2,3-tribromo-1-propene; the *E*/*Z* ratio was 76/24, and with 1.1-equiv of bromine, the *E*/*Z* ratio was 46/54. In contrast, an appreciable difference in the isomer ratio between a reaction with 0.5-equiv and 1.1-equiv of bromine was hardly observed when the reaction was carried out in the presence of graphite under similar conditions. (*E*)-1,2,3-Tribromo-1-propene was obtained in high yield stereoselectively. The *E*/*Z* ratio was 96/4. The rate of bromination in the presence of graphite was slower than that without graphite. The electron-withdrawing group (*R*) decreased the reactivity of the acetylenes toward bromine as follows:

$$C_6H_5- > HOCH_2-,\ CH_3C(OH)H- > CH_3OOC-.$$

The results show that the bromine-catalyzed isomerization of (*E*)-α,β-dibromoalkenes to the *Z*-isomer does not occur in the presence of graphite.[7] To make sure of the role of graphite, the bromine-catalyzed isomerization of (*E*)- or (*Z*)-α,β-dibromoalkenes was carried out in the presence or in the absence of graphite. Both bromine-catalyzed isomerization of the *E*- to the *Z*-isomer and the *Z*- to the *E*-isomer in dichloromethane readily occurred. In contrast, neither the *E*- nor the *Z*-isomer was isomerized in the presence of graphite under similar conditions. The results are summarized in Table 2. We previously explained the role of graphite on the basis of a heterogeneous reaction on the surface of a solid support. Recently, however, we observed that the photostimulated bromination of toluene with bromine in the presence of

R = C_6H_5, CH_3OOC.

Scheme 2.

graphite occurs by electrophilic substitution rather than free-radical substitution.[8)] This observation suggests that a bromine radical may not be generated in the presence of graphite. Therefore, the inhibition of the isomerization by graphite is more likely to be due to the fact that no bromine radical is generated in the presence of graphite, rather than to a restriction of the rotation around the C-C bond in the radical intermediate adsorbed on graphite, as was previously presumed. Isomerization of (*Z*)-stilbene to the *E*-isomer and dimethyl maleate to dimethyl fumarate are usually catalyzed by bromine. These bromine-catalyzed isomerizations are attributed to the reversible addition of a bromine radical to the double bond. If graphite inhibites the formation of a halogen atom, bromine-catalyzed isomerization of (*Z*)-stilbene and dimethyl maleate as well as α,β-dibromoalkenes may not occur. In fact, these bromine-catalyzed isomerizations did not proceed at all in the presence of graphite.

Experimental

(*E*)-1,2,3-Tribromo-1-propene. General Procedure for Bromination of Acetylenes. Graphite (5 g) was added to a solution of bromine (11 mmol, 1.76 g) in dichloromethane (50 ml), and stirred at room temperature for 0.5 h. To the resulting mixture was added a solution of propargyl bromide (10 mmol, 1.19 g) in dichloromethane (10 ml), and stirring was continued at 20 °C for 4 h. Aqueous sodium thiosulfate was then added, and the mixture was filtered. The organic layer was separated, washed with water and dried. The residue, after evaporation of the solvent, was analyzed by GLC and ^{1}H NMR. The yield of 1,2,3-tribromo-1-propene was 98%, the *E* : *Z* ratio 94 : 6.

Isomerization of (*E*)-1,2,3-Tribromo-1-propene: General Procedure for Isomerization of α,β-Dibromoalkenes. Graphite (5 g) was added to a solution of (*E*)-1,2,3-tribromo-1-propene (0.66 mmol, 0.184 g) in dichloromethane (20 ml), and stirred at 20 °C for 0.2 h. To the resulting mixture was added a solution of bromine (0.132 mmol, 0.02 g) in dichloromethane (10 ml), and stirring was continued at 20 °C for 4 h. Aqueous sodium thiosulfate was added, and the mixture was filtered. The organic layer was separated, washed with water and dried. The residue, after evaporation of the solvent under reduced pressure, was analyzed by ^{1}H NMR.

Isomerization of Dimethyl Maleate. The isomerization was carried out as above using dimethyl maleate (1 mmol, 0.144 g) and bromine (0.1 mmol, 0.016 g) in dichloromethane (30 ml) with or without graphite (5 g) at 50 °C for 5 h under a nitrogen atmosphere and irradiation with a tungsten lamp (30 W). Isomerization without graphite gave dimethyl fumarate in 98% yield; graphite dimethyl maleate was recovered quantitatively.

Isomerization of (*Z*)-Stilbene: (a) Without Graphite. A mixture of (*Z*)-stilbene (1 mmol, 0.180 g) and bromine (0.2 mmol, 0.050 g) in hexane (30 ml) was stirred at 50 °C for 3 h. Aqueous sodium thiosulfate was then added in order to removed bromine. The organic layer was separated, washed with water and dried. The residue, after evaporation of the solvent under reduced pressure, was analyzed by GLC. The *E* : *Z* ratio of the isomers was 86 : 14.

(b) With Graphite. The isomerization was carried out as described above using graphite (5 g). (*Z*)-Stilbene was recovered in 97% yield after 5 h.

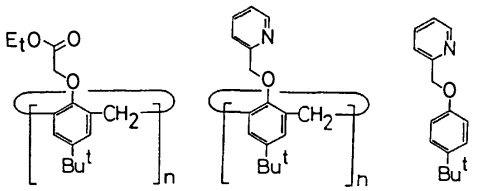
8) Bromination of toluene (10 mmol) with bromine (5 mmol) in carbon tetrachloride was carried out at 50 °C for 1 h in the presence of graphite (5 g) under irradiation with a tungsten lamp (30 W), and bromotoluene was obtained in 84% yield (p/o=2.6). The reaction without graphite under similar conditions gave benzyl bromide in 87% yield.

(2-Pyridylmethoxy)calixarenes: New Versatile Ionophores for Metal Extraction

Seiji SHINKAI,* Toshio OTSUKA, Koji ARAKI, and Tsutomu MATSUDA
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received June 16, 1989)

Synopsis. (2-Pyridylmethoxy)calix[*n*]arenes (*n*=6,8) were newly synthesized. It was shown in two-phase solvent extraction that they can extract not only alkali metal cations but Cu^{2+}, Ag^{+}, and UO_2^{2+} and are stable even at high pH. The results indicate that disadvantages of calixarene esters, which were previously developed as calixarene-based ionophores, can be improved by using the pyridyl group.

"Calixarenes" are cyclic oligomers made up of benzene units.[1,2] It has been expected, therefore, that introduction of appropriate ionophoric groups would append, like that of crown ethers, a new function as ionophores to calixarenes. Several groups have reported on the ionophoric properties of calixarenes which were obtained by introducing ester, ether, and amide groups into the edge of the cylindrical architecture.[3-9] Among them ester derivatives (**1***n*) have been studied most extensively.[3-7] We noticed through our work,[7,10] however, that there exist two inevitable disadvantages about **1***n*: (i) cannot be used at high pH region because of basic hydrolysis of the ester groups and (ii) **1***n* can extract only "hard" metal cations because of the "hard" ionophoric nature. We considered that the defects might be removed by introducing nitrogen base (instead of oxygen base) through the ether linkage (instead of the ester linkage). In order to use them at neutral pH region, aromatic amines with low pK_a values are recommended rather than aliphatic amines with high pK_a values. We thus designed new ionophores **2***n* in which 2-pyridylmethyl groups are appended to the calixarene cavity. We have found that **2***n* can extract not only alkali metal cations but other heavy metal cations and are stable even at high pH.



1*n* **2***n* **3**

Experimental

37,38,39,40,41,42-Hexakis(2-pyridylmethoxy)-*p*-*t*-butylcalix[6]arene (2₆). *p*-*t*-Butyl calix[6]arene (1.0 g; 1.0 mmol), 2-chloromethylpyridine hydrochloride (2.1 g; 13 mmol), and powdered K_2CO_3 (7.0 g) were mixed in 70 mL of anhydrous *N*,*N*-dimethylformamide (DMF), and the mixture was heated at 60—70 °C for 14 h under a nitrogen stream. The solution was diluted with water, the precipitate being collected by filtration. This was dissolved in 100 mL of chloroform and washed with water. The chloroform solution was concentrated in vacuo and the residual oil was crystallized from methanol. Finally, the product (**2₆**) was recrystallized from chloroform–methanol; mp (decomp) 268 °C, yield 45%; IR (Nujol) no ν_{OH}, $\nu_{C=N}$ 1565 cm^{-1}. ^1H NMR ($CDCl_3$): δ=1.05 (9H, s, *t*-Bu), 3.9 (2H, broad s, $ArCH_2Ar$), 4.84 (2H, s, OCH_2), 7.0, 7.3, 8.3 (6H, broad, benzene and pyridine protons). Found: C, 79.87; H, 7.47; N, 5.43%. Calcd for $(C_{17}H_{19}NO)_6$: C, 80.60; H, 7.56; N, 5.53%.

49,50,51,52,53,54,55,56-Octakis(2-pyridylmethoxy)-*p*-*t*-butylcalix[8]arene (2₈). This compound was synthesized from *p*-*t*-butylcalix[8]arene in a manner similar to that described for **2₆**; mp 151—152 °C, yield 24%; IR (Nujol) no ν_{OH}, $\nu_{C=N}$ 1565 cm^{-1}. ^1H NMR ($CDCl_3$): δ=1.03 (9H, s, *t*-Bu), 4.05 (2H, s, $ArCH_2Ar$), 4.74 (2H, s, OCH_2), 6.99 (2H, s, benzene protons), 6.81, 7.00, 7.11, 8.28 (1H each, q, d, q, and d, respectively, pyridine protons). Found: C, 79.90; H, 7.55; N, 5.34%. Calcd for $(C_{17}H_{19}NO)_8$: C, 80.60; H, 7.56; N, 5.53%. The reaction of *p*-*t*-butylcalix[4]arene and 2-chloromethylpyridine under the same reaction conditions afforded di-substituted *p*-*t*-butylcalix[4]arene and no tetra-substituted product. This is attributed to steric crowning in a small calix[4]arene ring. Thus, subsequent extraction experiments were carried out about **2₆** and **2₈**.

The methods of two-phase solvent extraction were described previously.[3-5,11] The detailed extraction conditions were recorded in footnotes to Table 1. In some cases we determined both the concentration of extracted metal cations (by atomic absorption spectroscopy) and that of extracted picrate anion (by absorption spectroscopy). At acidic to neutral pH region the concentration of picrate anion was always higher than those of metal cations. This shows that picrate anion is extracted, in part, as a counteranion of pyridinium cation. In contrast, these two values showed a good agreement (error less than 4%) in extraction from 0.1 M MOH aqueous solution.

The stability of **1₆** and **2₆** against basic hydrolysis was evaluated as follows. A CH_2Cl_2 solution containing **1₆** or **2₆** (2.5×10^{-4} M†) was shaked at 25 °C for one day with a same amount of an aqueous 0.1 M NaOH solution. The CH_2Cl_2 solution containing **2₆** separated clearly from the aqueous phase. We could recover **2₆** (>99%) from the CH_2Cl_2 solution. On the other hand, a considerable amount of white precipitates was formed at the interface between water and **1₆**-containing CH_2Cl_2. They were collected by filtration, acidified by 0.1 M HCl , and extracted with $CHCl_3$. This compound turned out to be 37,38,39,40,41,42-hexakis(carboxymethoxy)-*p*-*t*-butylcalix[6]arene[11] (yield 5%). From the CH_2Cl_2 phase we recovered **1₆** (90%).

Results and Discussion

We first compared the stability of **2***n* and **1***n* in solvent extraction from a strongly basic aqueous phase. It was shown that **2₆** is totally stable against basic hydrolysis whereas **1₆** is hydrolyzed to the carboxylate derivative. Thus, calixarene esters **1***n* are recommended only for the short-period extraction. Interestingly, we could not recover any partly-hydrolyzed carboxylate derivatives from **1₆**. This implies that once the hydrolysis takes place at one

† 1 M=1 mol dm^{-3}.

ester unit, subsequent hydrolysis in the same calixarene ring occurs acceleratively. Presumably, partly-hydrolyzed carboxylate derivatives, which are less soluble in CH_2Cl_2, are adsorbed at the water-CH_2Cl_2 interface and subsequent hydrolysis occurs rapidly thereabout.

In order to estimate the "basicity" of **2**$_n$ and **3** (*p*-(2-pyridylmethoxy)-*t*-butylbenzene: used as a reference compound) at a water-CH_2Cl_2 interface, we carried out picrate extraction as a function of pH. Since sodium picrate was not extracted by **2**$_n$ under the conditions employed (see a caption to Fig. 1), the concentration of extracted picrate anions should be equal to that of protonated pyridine (i.e., pyridinio) units. As shown in Fig. 1, pH-Ex% curves for **2**$_n$ shift to higher pH region than that for **3** (4.1 pH unit for **2**$_6$ and 2.5 pH unit for **2**$_8$) Thus, the "basicity" of **2**$_n$ is considerably strengthened because of the cyclic architecture. This suggests that calixarenes **2**$_n$, in which basic pyridine groups are arranged on the lower rim of the calixarene cavity, have a character of proton cryptates.

Results of two-phase solvent extraction of alkali picrates are summarized in Table 1. Under the present extraction conditions (0.1 M MOH in the aqueous phase) the concentration of extracted picrates was equal to that of M^+ ions, which was confirmed by the separate determinations of [picrate] by absorption spectroscopy and [M^+] by atomic absorption spectroscopy. The previous extraction study with **1**$_n$ established that (i) **1**$_6$ has the extraction ability greater than **1**$_8$ for alkali metal cations and (ii) the order of the ion selectivity is $Cs^+>K^+>Na^+$ for **1**$_6$ and $Cs^+\approx K^+>Na^+$ for large, flexible **1**$_8$.[3,5] Examination of Table 1 reveals that both **2**$_6$ and **2**$_8$ are Cs^+-selective and **2**$_6$ gives the greater Ex% than **2**$_8$ Thus, the size effect operating in **2**$_n$ is basically comparable with that operating in **1**$_n$. As expected, calixarenes **2**$_n$ are capable of extracting heavy metal cations such as Ag^+ and Cu^{2+}. In particular, extraction of Cu^{2+} is ascribed to the affinity of Cu^{2+} with pyridine nitrogens.

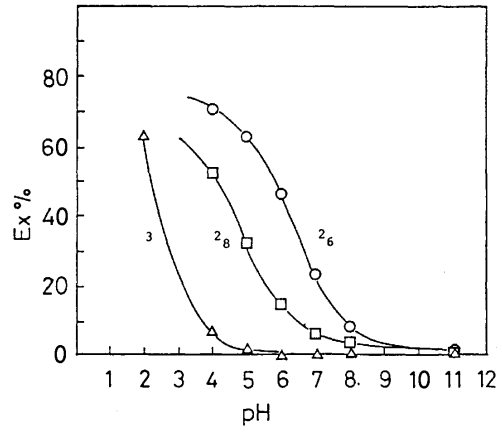


Fig. 1. Extraction of picrate anion by **2**$_n$ and **3** at 25 °C: 2.5×10^{-4} M **2**$_n$ or 2.0×10^{-3} M **3** (=8·[**2**$_n$]) in CH_2Cl_2, 2.5×10^{-4} M picric acid and [Na^+]=0.02 M in water. pH of the aqueous phase was adjusted by 0.02 M acetate buffer for pH 4—5, 0.02 M phosphate buffer for pH 6—8, and NaOH for pH 11. Under the conditions Na^+ was not extracted into the CH_2Cl_2 phase (confirmed by the analysis of the CH_2Cl_2 phase by atomic absorption spectroscopy).

Table 1. Extraction (%) of Metal Picrates in CH_2Cl_2 at 25 °C[a]

Metal	Calixarene	
	2$_6$	**2**$_8$
Na^+[b]	12.7	9.3
K^+[b]	26.7	7.5
Cs^+[b]	51.0	18.2
Ag^+[c]	21.2	24.0
Cu^{2+}[c]	3.3	1.8
UO_2^{2+}[d]	0	5.4
UO_2^{2+}[d] (at 100 °C)	82.1	76.8

a) 2.5×10^{-3} M calixarene in CH_2Cl_2. Extraction time 30 min. b) 2.5×10^{-4} M picric acid in aqueous 0.1 M MOH and 0.5 M MCl. Extractability denotes the percentage of picrate anion extracted by **2**$_n$. c) 2.5×10^{-3} M picric acid in aqueous 5×10^{-4} M metal nitrates at pH 11 (with 1.00×10^{-2} M NH_3) for Ag^+ and at pH 8.0 (with 1.00×10^{-2} M Bis-Tris) for Cu^{2+}. Extractability denotes the percentage of metal cations extracted by **2**$_n$ (determined by atomic absorption spectroscopy). d) 1.0×10^{-4} M calixarene in *o*-dichlorobenzene. 2.0×10^{-5} M $UO_2(CH_3COO)_2$ in aqueous buffer solution (pH 8.0 with 0.01 M *N*-tris(hydroxymethyl)methyl-3-amino-1-propanesulfonate). Extractability denotes the percentage of UO_2^{2+} extracted by **2**$_n$ (calculated by the analysis of UO_2^{2+} remaining in the aqueous phase with Arsenazo III): for details of the extraction method see Ref. 11.

We previously found that among calix[*n*]arenes (*n*=4, 5, and 6) calix[5]arene and calix[6]arene derivatives complex UO_2^{2+} selectively.[11,12] The finding is quite complementary with the X-ray crystallographic data that UO_2^{2+} complexes adopt either a pseudo-planar pentacoordinate or hexacoordinate structure.[11,12] This implies that the structure of these calixarenes is well pre-organized for selective complexation of UO_2^{2+}. We applied **2**$_n$ to solvent extraction of UO_2^{2+}. The rate of UO_2^{2+} extraction was slow at 25 °C. In particular, **2**$_6$ scarcely extracted UO_2^{2+} (see Table 1). On the other hand, efficient UO_2^{2+} extraction took place at 100 °C. It is known that the association of cyclic ligands with large, rod-like UO_2^{2+} ion occurs very slowly because of steric hindrance.[13-15] In the present system the ring structure of **2**$_6$ is expected to be rigid because of six pyridyl groups incorporated into the narrow lower rim of calix[6]arene. This view is supported not only by Corey-Pauling-Koltun molecular models but also by the broadened ^1H NMR spectrum (see Experimental). This suggests that the extraction speed with **2**$_6$ would be fairly slow at room temperature. On the other hand, **2**$_6$ and **2**$_8$ served as excellent neutral uranophiles at high temperature. This is related to the increase in the thermal molecular motion of these calixarenes. The high extractability observed for **2**$_6$ is rationalized in terms of the pre-organized structure suitable for the binding of hexacoordinate UO_2^{2+}. Although **2**$_8$ does not possess such a pre-organized structure, the ring is flexible enough to employ either a pentacoordinate or

a hexacoordinate structure. Presumably, the UO_2^{2+} affinity observed for $\mathbf{2}_8$ is accounted for by "induced-fit" complexation with the large calixarene ring. In fact, the ^1H NMR peaks for $\mathbf{2}_8$ are mostly sharp (see Experimental) supporting the flexible nature of the $\mathbf{2}_8$ ring. Under the identical extraction conditions $\mathbf{1}_n$ (n=4, 6, and 8) could not extract even a trace amount of UO_2^{2+}.

In conclusion, it has been established that new calixarene-based ionophores $\mathbf{2}_n$ display versatile affinity not only for alkali metal cations but also for Ag^+, Cu^{2+}, and UO_2^{2+} and are recommended for solvent extraction from strongly basic aqueous solutions.

We are indebted to Mr. Yoshiharu Shirahama for the determination of Ex% for UO_2^{2+}.

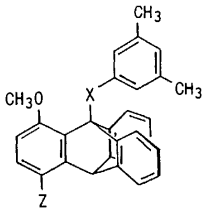
Detailed Dynamic NMR Study of a Molecular Gear, 1-Methoxy-9-(3,5-dimethylbenzyl)triptycene

Gaku YAMAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received June 29, 1989)

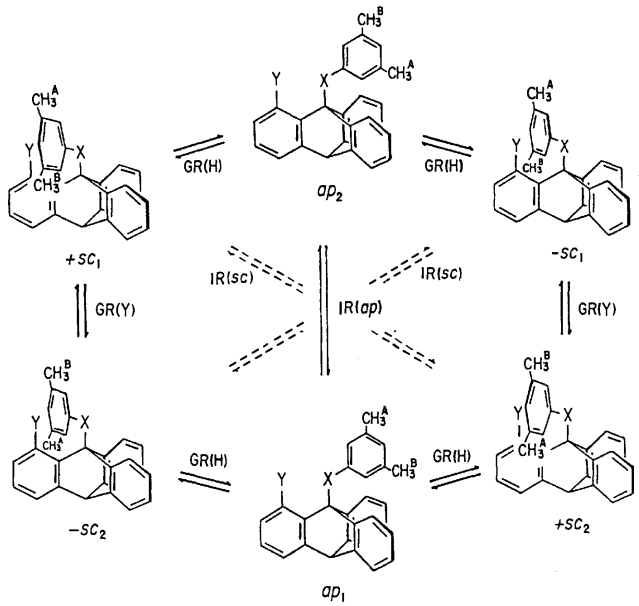
Synopsis. Stereodynamics of the title compound was studied by dynamic NMR spectroscopy. The "isolated" rotation of the aryl group was found to have a lower barrier than the correlated gear rotation.

In 1979, we reported a dynamic NMR study of 9-(3,5-dimethylbenzyl)triptycene derivatives,[1] which behave as molecular gears composed of a two-toothed wheel and a three-toothed one.[2] We pointed out the presence of two fundamental processes, gear rotation (GR), in which the correlated disrotation of the aryl group (Ar) and the triptycene moiety (Tp) occurs, and "isolated" rotation (IR) of the Ar group without rotation of the Tp moiety. At that time, the NMR spectra were measured on a 60-MHz CW spectrometer and the analysis was made by an approximate method, in which only the rate constant at the coalescence temperature was obtained. Thus some of the data were somewhat unreliable and the conclusion drawn therefrom was simplistic. We therefore decided to reinvestigate this topic, by obtaining variable temperature NMR spectra of a typical derivative, 1-methoxy-9-(3,5-dimethylbenzyl)triptycene (**1**), at 270 MHz in the FT mode and analyzing the data by total lineshape analysis.



1 X=CH_2, Z=H
2 X=O, Z=OCH_3

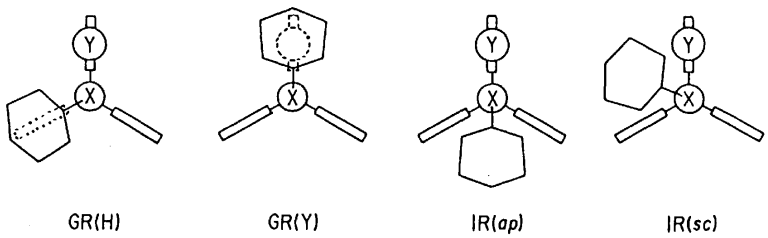
The possible dynamic processes exhibited by the molecules of **1** are shown in Scheme 1. Three sites are available about the Tp-CH_2 bond, i.e. *ap*, $+sc$, and $-sc$, and thus six conformers should be considered if the two *m*-methyl groups are differentiated. Processes shown at the periphery in the Scheme constitute a gear rotational circuit, which comprises two kinds of primary steps; GR(H) in which the aryl group passes over a peri-hydrogen, and GR(Y) in which the aryl group passes over the peri-substituent Y. In each



Scheme 1.

step the edge of the aryl rotor interchanges; each *m*-methyl group points inside and outside alternatively. Two other motions should be taken into account; isolated rotations of the aryl group at the *ap* and $\pm sc$ sites, designated as IR(*ap*) and IR(*sc*), respectively. Isolated rotation of the Tp moiety may be neglected because the plausible transition state of this process, in which the aryl group and one of the benzene ring of the triptycene skeleton becomes coplanar, is highly unlikely. Transition states of these processes are schematically shown as Newman projections along the Tp-X bond axis in Scheme 2. Therefore, four independent rate constants are necessary to describe the whole processes exhibited by the molecule at a given temperature.

At −98.1 °C, the lowest attainable temperature, internal rotation of both the Tp-CH_2 and Ar-CH_2 bonds is frozen and two isomers, *ap* and $\pm sc$, are separately observed in the ^1H NMR spectrum in CD_2Cl_2 (Fig. 1). The major isomer present in 70% at



Scheme 2.

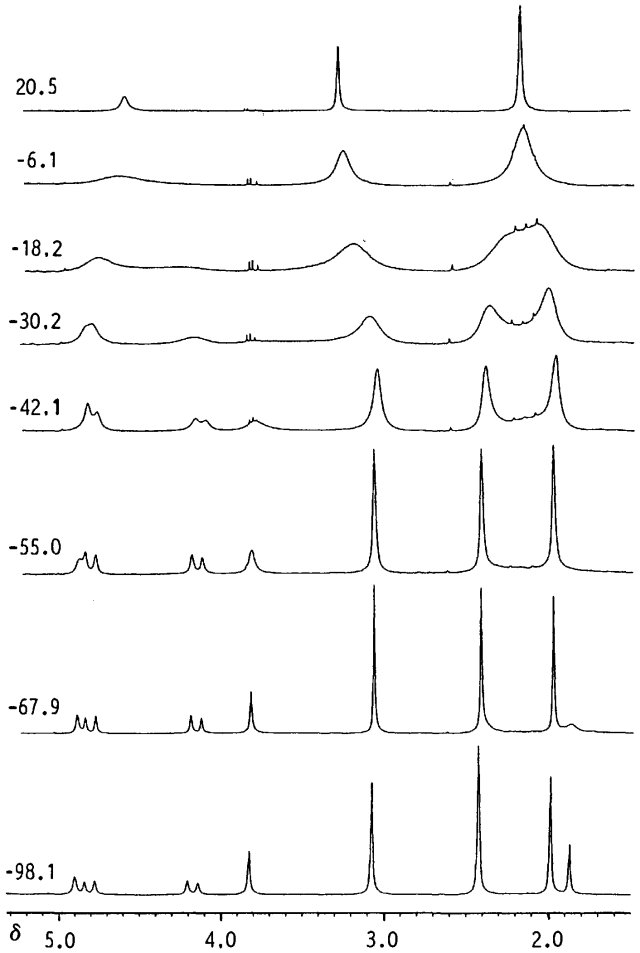


Fig. 1. ^{1}H NMR spectra of **1** in CD_2Cl_2 at several temperatures (°C). Impurity peaks are seen at δ 2.1—2.3, ca. 2.6, and 3.8—3.9 regions.

this temperature is assigned as ±*sc*; the methylene protons give an AB-quartet signal (δ 4.17 and 4.80, J=17.4 Hz) and the methoxyl proton signal appears at a high field of δ 3.07 because of the ring current effect of the benzylic aryl group. The minor isomer assigned as *ap* gives a singlet at δ 4.90 for the methylene protons and a singlet for the methoxyl protons at a normal position of δ 3.82. The *m*-methyl protons of the benzylic aryl group appear as a pair of singlets for each isomer, although the low-field peaks are overlapped (*ap*: δ 1.87 and 2.42; ±*sc*: δ 1.98 and 2.42). The two higher-field singlets are reasonably assigned to the methyl groups pointing inside (CH_3^B in ap_1 and ±sc_1 and CH_3^A in ap_2 and ±sc_2).

The signals broaden and coalesce as the temperature rises, and a broad singlet is observed for each of the methyl, methoxyl and methylene protons at room temperature.

The dynamic NMR behavior of the 1-methoxyl proton signal, in which two unequally intense singlets at low temperature coalesce into a single peak, corresponds to the *ap*⇄±*sc* interconversion which occurs by the GR(H) process and is described by a single rate constant, $k(ap \rightarrow \pm sc)$, which we refer to as $k_{GR(H)}$. The rate constant for the reverse process, $k(\pm sc \rightarrow ap)$, is related to $k_{GR(H)}$ by the equilibrium constant K. Line-shape analysis of the spectra at nine temperatures between −6 and −55 °C as a one-spin two-site system using the DNMR5[3] and/or DNMR3K[4] program affords the best-fit values of $k_{GR(H)}$ and the kinetic parameters for the GR(H) process (Table 1).

Table 1. Kinetic Parameters Obtained from DNMR

Compd	Process	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$	$\Delta G^{\ddagger}_{200}$
		kcal mol^{-1}	cal mol^{-1} K^{-1}	kcal mol^{-1}
1	GR(H)[a]	10.6±0.1	−4.1±0.5	11.5±0.1
	GR(Y)			>12.7
	IR(*ap*)	9.6±0.2	−3.1±0.8	10.2±0.1
	IR(*sc*)			>12.7
2[b]	GR(H)			<7.7[c]
	GR(Y)	11.8±0.2	−0.9±0.7	12.0±0.2
	IR(*ap*)			>12.0
	IR(*sc*)			≫12.0

a) The kinetic parameters refer to the *ap*→*sc* process. b) Ref. 2c. c) Reinvestigated. No splitting down to −100 °C at 500 MHz.

The methylene proton signal is composed of a singlet due to *ap* and an AB-quartet due to ±*sc*. The line-shape is controlled by two independent rate constants. The one is $k_{GR(H)}$ and the other describes the direct interconversion between +*sc* and −*sc* corresponding to the GR(Y) process. Careful examinations revealed that the observed spectra are excellently reproduced with $k_{GR(Y)}$ of zero and $k_{GR(H)}$ obtained from the analysis of the methoxyl signal, suggesting that $k_{GR(Y)}$ is very small relative to $k_{GR(H)}$. Actually, incorporation of $k_{GR(Y)}$ larger than one twentieth of $k_{GR(H)}$ distinctly deviates the calculated spectrum from the observed one. Therefore, the GR(Y) process has a free energy barrier of at least 1.3 kcal mol^{-1} (1 cal= 4.184 J) higher than that of GR(H).

The dynamic NMR behavior of the *m*-methyl proton signal is somewhat complex. Four singlets (apparently three because of the overlap) at low temperature coalesce into a single peak. In the DNMR5 program, the case is treated as a one-spin four-site system. Four sites represent *ap*-in, *ap*-out, *sc*-in, and *sc*-out. The *ap*-in⇄*sc*-out and *ap*-out⇄*sc*-in motions correspond to GR(H) and *ap*-in⇄*ap*-out to IR(*ap*). The *sc*-in⇄*sc*-out conversion may occur either by GR(Y) or by IR(*sc*) and the dynamic NMR analysis can not predict which is actually occurring. *ap*-in⇄*sc*-in and *ap*-out⇄*sc*-out are assumed to be negligible. Detailed analysis of the spectra shows that only two non-zero rate constants corresponding to GR(H) and IR(*ap*) are required to reproduce the observed spectra. Line-shape analysis of the spectra at seven temperatures between −42 and −80 °C using the extrapolated values of $k_{GR(H)}$ obtained as described above affords the best-fit values of $k_{IR(ap)}$ and the kinetic parameters for the IR(*ap*) process (Table 1).

The *sc*-in⇄*sc*-out process and hence both of GR(Y) and IR(*sc*) have again free energy barriers of at least 1.3 kcal mol^{-1} higher than that of GR(H).

It is interesting to compare the present results with

those previously reported for the corresponding ether analog, 1,4-dimethoxy-9-(3,5-dimethylphenoxy)triptycene (**2**).[2c] We assume that the 4-methoxyl group in **2** has no significant effect on the dynamic processes discussed here.

In the ^{1}H NMR spectra of **2**, the 1-methoxyl signal appears as a sharp singlet in the whole temperature range studied, and the methyl protons give a singlet at room temperature but two equally intense singlets below −18 °C.[2c] This indicates that the GR(H) barrier is very low (<7.7 kcal mol^{-1}) and the observed dynamic process should be explained by either GR(Y), IR(*ap*), or IR(*sc*) as the rate-determining step. Molecular mechanics studies by MM2 revealed that GR(Y) has the lowest barrier and therefore the observed process was assigned to GR(Y) as shown in Table 1.[2c]

The results given in Table 1 show that **1** has higher barriers for the GR processes than **2** but lower barriers for the IR processes. This is understood in terms of the differences in valencies (tetravalent in **1** and divalent in **2**) and in bond lengths (1.49—1.55 Å for C-C and 1.36—1.42 Å for C-O), as discussed in detail in the previous papers.[2b,c] The valency effect would predominate over the bond length effect at the GR transition states, where the eclipsing interactions occur at three sites in **1** and at only one site in **2**. Meanwhile the bond length effect would predominate at the IR transition states, where the ortho hydrogens of the Ar group are closer to the Tp skeleton in **2** than in **1**.

In conclusion, in compound **1** the gear rotation is not the minimum energy process while in the ether analog **2** the meshed gearing is the most favorable process.

Experimental

Synthesis of **1** has been described.[1]

Variable temperature ^{1}H NMR spectra were obtained on a JEOL GX-270 spectrometer operating at 270.17 MHz in the FT mode using a ca. 4% (w/v) solution of **1** in CD_2Cl_2. Temperatures were calibrated using a methanol sample and are reliable to ±0.5 °C.

Line-shape analysis was performed either on a Hitac M-680H computer system at the Computer Center of the University of Tokyo using the DNMR5 program[3] or on a NEC PC-9801F personal computer equipped with a Graphtec MIPLOT II plotter using the DNMR3K program.[4] Temperature dependence of the rotamer populations, chemical shift differences, and T_2 values was properly taken into account.

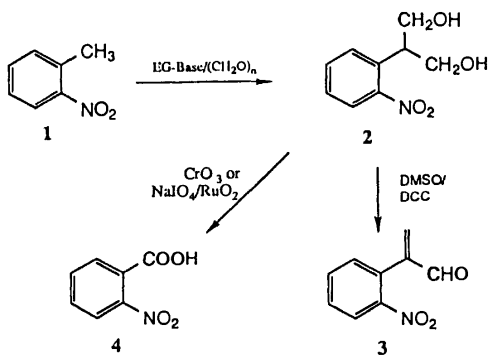
Homologation of the Side Chain of 2-Nitrotoluene. Synthesis of a Tryptophan Precursor

Hideo TANAKA, Yasuo MURAKAMI, and Sigeru TORII*
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Okayama 700
(Received July 3, 1989)

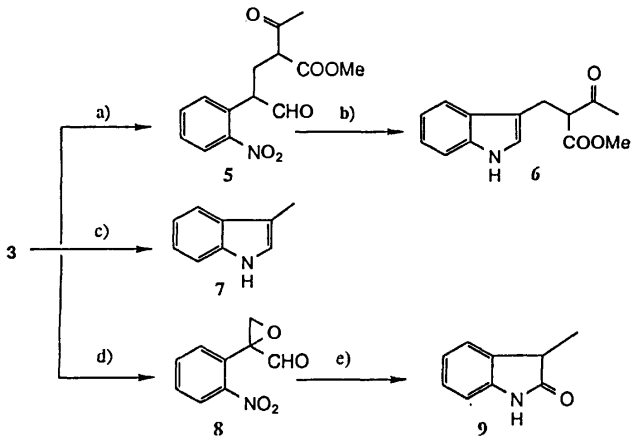
Synopsis. 2-(2-Nitrophenyl)-1,3-propanediol (**2**) was selectively converted to 2-(2-nitrophenyl)propenal (**3**) by the use of a mixture of dicyclohexylcarbodiimide (DCC) and dimethyl sulfoxide in benzene, while 2-nitrobenzoic acid was obtained by the oxidation of the diol **2** with sodium periodate in the presence of a catalytic amount of ruthenium dioxide or with chromic acid. The enal **3** was subjected to further transformation to afford a potent tryptophan precursor and some useful indole derivatives.

A continuing interest in the tryptophan synthesis has led to the development of novel synthetic methodologies.[1] Among them, a straightforward route to tryptophan has been achieved by the homologation of the side chain of 2-nitrotoluene (**1**) followed by the reductive cyclization.[2] The transformation involves a two carbon homologation of the side chain of **1** by a successive treatment with *N,N*-dimethylformamide dimethyl acetal[3] and formaldehyde, leading to 2-(2-nitrophenyl)propenal (**3**) (atropaldehyde). In the previous paper, we reported a facile double hydroxymethylation of 2-nitrotoluene (**1**) with formaldehyde promoted by an electrochemically generated base (EG-base), affording 2-(2-nitrophenyl)-1,3-propanediol (**2**).[4] This finding prompted us to investigate an alternative access to the key intermediate **3** by the oxidative dehydration of **2**. Herein, we describe a selective oxidation of 2-(2-nitrophenyl)-1,3-propanediol (**2**) leading to either the aldehyde **3** or 2-nitrobenzoic acid (**4**) by choosing oxidizing agents.

In the transformation of the diol **2** into the desired enal **3**, one hydroxyl group may serve for the aldehyde group and the other for the olefinic one. After examination of various oxidizing agents, a combination of dicyclohexylcarbodiimide (DCC) and dimethyl sulfoxide (DMSO)[5] was found to be suitable for the present purpose; thus, the oxidative dehydration of **2** to afford **3** took place smoothly (97% yield) by the action of DCC and DMSO in benzene containing pyridine and trifluoroacetic acid at room temperature.



Scheme 1.



(a): $CH_3COCH_2CO_2Me$, NaOMe (0.1 eqiv), MeOH. (b): H_2, Pd/C, MeOH. (c): H_2, PtO_2, MeOH. (d): H_2O_2, aq. NaOH, MeOH. (e): H_2, PtO_2, Ac_2O.

Scheme 2.

Notably, upon oxidation of **2** with chromic acid in acetone (Method A), a completely different reaction occurred to afford 2-nitrobenzoic acid (**4**) in 96% yield. A similar result was obtained by the oxidation of **2** with sodium periodate and a catalytic amount of ruthenium dioxide (Method B). The EG-base-promoted double hydroxymethylation followed by the oxidation (Methods A and B) may offer an access to 2-nitrobenzoic acid (**4**) which has not been prepared by the direct oxidation of **1** efficiently.[6]

2-(Nitrophenyl)propenal (**3**) is an intriguing starting candidate for the indole synthesis. The Michael addition of methyl acetoacetate to the enal **3** in methanol containing a catalytic amount of sodium methoxide afforded adduct **5** (90%). Subsequently, the hydrogenative cyclization of **5** over palladium on charcoal in methanol furnished methyl 2-acetyl-3-(3-indolyl)propionate (**6**, 95%), a potent tryptophan precursor.[7] Under similar hydrogenation conditions, the enal **3** provided 3-methylindole (**7**) which would arise from the hydrogenation of both the olefin and nitro groups. On the other hand, the epoxidation of **3**, leading to **8**, followed by the hydrogenation in acetic anhydride afforded lactam **9**. Although the reaction mechanism is still unclear, the lactam **9** might arise from some mutual interaction between the formyl and the nitro groups.

Experimental

IR spectra were recorded on a JASCO IRA-1 grating spectrometer. ^1H NMR spectra were measured at 60 MHz with a Hitachi R-24 spectrometer. Chemical shifts are expressed in parts per million downfield from Me_4Si used as

an internal reference. Melting and boiling points are uncorrected. Column chromatography was carried out with Merck Kieselgel 60 (silica gel) using hexane–EtOAc as an eluent. Elementary analyses were performed in our laboratory. 2-(2-Nitrophenyl)-1,3-propanediol (**2b**) was prepared by the electrolysis of 2-nitrotoluene (**1**) in a $(CH_2O)_n$–DMF–Et_4NOTs (Pt electrode) system.[4]

2-(2-Nitrophenyl)propenal (3). To a mixture of **2** (592 mg, 3.0 mmol), benzene (10 ml), and DMSO (10 ml) were successively added pyridine (0.24 ml, 3 mmol), trifluoroacetic acid (0.12 ml, 1.5 mmol), and DCC (1.5 g, 7.3 mmol) at room temperature. After stirring at room temperature for 2 h, benzene (20 ml) was added and the precipitates (dicyclohexylurea) were removed by filtration and washed with benzene. The filtrates and washings were combined, washed three times with 20 ml portions of water, dried (Na_2SO_4), and concentrated. The residue was chromatographed to give **3** (516 mg, 97%): mp 53—54 °C (lit,[2] mp 54.5—56 °C).

2-Nitrobenzoic Acid (4). Method A. To a solution of **2** (98.5 mg, 0.5 mmol) in acetone (4 ml), was added dropwise the Jones reagent (0.7 ml, 2.2 mmol) at 0 °C over a period of 30 min. After stirring at room temperature for 6 h, most of the solvent was evaporated and the residue was taken up in CH_2Cl_2. The CH_2Cl_2 solution was washed with aqueous $NaHCO_3$. The aqueous layers were acidified with aqueous 10% HCl, extracted with EtOAc, washed with brine, and dried (Na_2SO_4). After evaporation of the solvent, the residue was chromatographed to afford **4** (83.6 mg, 96%): mp 143—146° (lit,[8] mp 146—148 °C), whose IR and ^1H NMR spectra data were fully identical with those reported.[9]

Method B. To a mixture of **2** (105 mg, 0.53 mmol), EtOAc (2.5 ml), water (4 ml), and RuO_2 (4 mg, 0.02 mmol) was added portionwise $NaIO_4$ (706.7 mg, 3.57 mmol) at room temperature over a period of 10 h. After being stirred for additional 10 h, the reaction mixture was worked up in a similar manner as described above to afford **4** (83.6 mg, 90%).

Methyl 2-Acetyl-4-formyl-4-(2-nitrophenyl)butyrate (5). A mixture of 2-(2-nitrophenyl)propenal **3** (101.3 mg, 0.57 mmol) and methyl acetoacetate (79.2 mg, 0.68 mmol) in MeOH (2 ml) containing NaOMe (3 mg, 0.06 mmol) was stirred for 1 h at −5 °C and for 2 h at room temperature. After being neutralized with aqueous 5% HCl, the mixture was concentrated under reduced pressure, extracted with EtOAc, washed with brine and dried (Na_2SO_4). After evaporation of the solvent, the residue was chromatographed to afford **5** (151 mg, 90%): IR (neat) 3400, 2940, 1740, 1720, 1528, 1435, 1350, 1240, 1000, 990, 782, 743 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.18—2.27 (m, 3H, $COCH_3$), 3.16—3.23 (m, 3H, CO_2CH_3), 2.5—4.8 (m, 4H, $CHCH_2CH$), 7.2—8.1 (m, 4H, ArH), 9.67 (s, 1H, CHO); Found: C, 57.20; H, 5.21; N, 5.18%. Calcd for $C_{14}H_{15}NO_6$: C, 57.34; H, 5.16; N, 5.05%.

Methyl 2-Acetyl-3-(3-indolyl)propionate (6). A mixture of **5** (150 mg, 0.51 mmol) and 5% Pd/C (5 mg) in MeOH (5 ml) was stirred at room temperature under H_2 (1 atm) for 5 h. After the catalysts were removed by filtration, the solvent was evaporated under reduced pressure, the residue was chromatographed to afford **6** (119mg, 95%):[7] IR (neat) 3375, 2943, 1735, 1710, 1458, 1435, 1360, 1218, 1150, 1098, 743 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.07 (s, 3H, $COCH_3$), 3.23—3.98 (m, 3H, $CHCH_2$), 3.59 (s, 3H, CO_2CH_3), 6.8—8.3 (m, 6H, C=CH, NH, ArH).

3-Methylindole (7). A mixture of **3** (32.0 mg, 0.18 mmol) and PtO_2 (3.0 mg) in MeOH (2 ml) was stirred at room temperature under H_2 (1 atm) for 3 h. After the catalysts were removed by filtration, the solvent was evaporated under reduced pressure and the residue was chromatographed to afford 3-methylindole (**7**) (9.6 mg, 40%): mp 92—94 °C (lit,[10] mp 95 °C).

2,3-Epoxy-2-(2-nitrophenyl)propionaldehyde (8). To a mixture of **3** (94.4 mg, 0.53 mmol) and aqueous 31% H_2O_2 (120 mg, 1.1 mmol) in MeOH (2.0 ml) was added dropwise aqueous 24% NaOH (0.03 ml, 0.18 mmol) at −5—0 °C over a period of 30 min. The reaction mixture was stirred for additional 1 h at 10 °C. The usual workup followed by chromatography gave 2,3-epoxy-2-(2-nitrophenyl)propionaldehyde (**8**) (95.7 mg, 93%): mp 64—66 °C; IR ($CHCl_3$) 3050, 2900, 1735, 1530, 1340, 910, 860, 720, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.36 (d, J=5.0 Hz, 1H, CH), 3.64 (d, J=5.0 Hz, 1H, CH), 7.5—8.3 (m, 4H, ArH), 8.98 (s, 1H, CHO); Found: C, 55.88; H, 3.58; N, 7.33%. Calcd for $C_9H_7NO_4$: C, 55.96; H, 3.65; N, 7.25%.

3-Methyl-2-oxoindoline (9). A mixture of **8** (51.0 mg, 0.26 mmol) and Pd/C (10 mg) in acetic anhydride (2 ml) was stirred at room temperature under H_2 (1 atm). After the catalysts were removed by filtration, the mixture was concentrated under the reduced pressure. The residue was taken up with EtOAc, washed with aqueous 5% HCl, brine, and dried (Na_2SO_4). Evaporation of the solvent followed by chromatography afforded 3-methyl-2-oxoindoline **9** (20.6 mg, 53%): mp 117—120 °C (lit,[11] mp 122.5—123.5 °C).

Reaction of Iminophosphoranes with a Diazonium Salt: Synthesis of Wholly Aromatic Aminophosphonium Salts

Makoto TAKEISHI* and Naoyuki SHIOZAWA
Department of Polymer Chemistry, Yamagata University, Yonezawa, Yamagata 992
(Received July 17, 1989)

Synopsis. *N*-Phenyliminotriphenylphosphorane reacts with benzenediazonium tetrafluoroborate to form wholly aromatic *N,N*-diphenylaminotriphenylphosphonium tetrafluoroborate. This synthetic method can be applied to prepare a cationic polymer having the aminophosphonium structure.

Highly polarized iminophosphoranes undergo a variety of nucleophilic reactions.[1] Several decades ago, Staudinger found that they react with alkyl halides to yield aminophosphonium halides.[2] This nucleophilic substitution has been applied for the preparation of *N,N*-dialkylaminotriphenylphosphonium salts,[3,4] and the hydrolysis of these aminophosphonium salts has been investigated to prepare amines carrying bulky alkyl groups.[5] Since aryl halides do not react with iminophosphoranes, no *N,N*-diarylaminophosphonium salt can be synthesized by this method, and no other reaction has been reported for the preparation of wholly aromatic aminophosphonium salts. We report in the present paper that *N*-phenyliminotriphenylphosphorane reacts with a benzenediazonium salt to give such an aromatic aminophosphonium salt.

Results and Discussion

Phosphonium ylids, i.e., Wittig reagents couple directly with diazonium salts: methoxycarbonylmethylenetriphenylphosphorane reacts with benzenediazonium tetrafluoroborate to yield a phosphonium salt which can be converted into a phenylazo-substituted new ylid upon treatment with an aqueous base.[5] Cyclopentadienylidenetriphenylphosphorane also reacts with benzenediazonium chloride, but electrophilic aromatic substitution of the phenylazo group takes place on the cyclopentadienyl ring.[6]

$$(C_6H_5)_3P{=}NC_6H_5 + C_6H_5N_2^{\oplus}BF_4^{\ominus} \longrightarrow (C_6H_5)_3P^{\oplus}N(C_6H_5)_2BF_4^{\ominus} + N_2$$

We have found that *N*-phenyliminotriphenylphosphorane reacts with benzenediazonium tetrafluoroborate with an elimination of nitrogen to afford wholly aromatic *N,N*-diphenylaminotriphenylphosphonium tetrafluoroborate (Table 1). In polar solvents, such as acetonitrile or DMF, the reaction proceeded homogeneously, while the reaction was heterogeneous in benzene because both the diazonium salt and the phosphonium salt formed are less soluble in the solvent. The reaction, however, occurred readily even in the less polar benzene and the IR and NMR spectra of the products were identical with those of the products obtained in the polar solvents. When the orange-colored aminophosphonium salt was dissolved in methanol together with dimethoxybenzene, the spectrophotometric observation showed no definite evidence for the formation of a charge-transfer complex. The results suggest that the positive charge is not dispersed over the aminophosphonium molecule but, rather, localized on the phosphorus atom.

A few polymers carrying phosphonium structures have been reported,[7,8] whereas a number of anion-exchange resins with ammonium structures are available. Therefore, the above-mentioned reaction was applied in order to introduce the aminophosphonium structure into a polymer: poly(*N*-phenylimino-*p*-styryldiphenylphosphorane (P-1) was converted into a

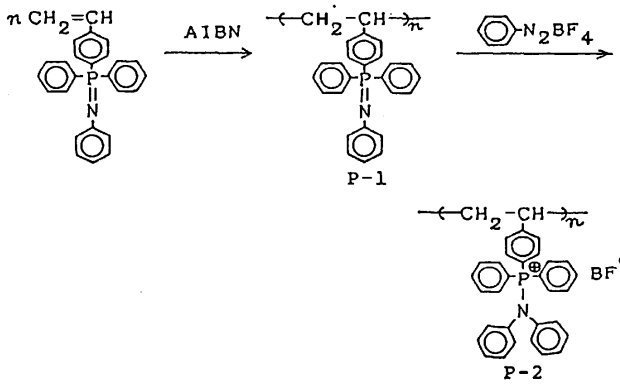

Table 1. Reaction of *N*-Phenyliminotriphenylphosphorane with Benzenediazonium Tetrafluoroborate[a]

Run	Solvent(condition)[b]	Reaction time/h	Yield/%
1	Acetonitrile(homo)	23	83
2	DMF (homo)	19	51
3	Benzene (hetero)	13	79
4	Benzene (hetero)	24	84

a) The reaction conditions are described in the experimental section. b) The reaction mixtures are homogeneous(homo) or heterogeneous(hetero).

Table 2. Reaction of P-1 with Benzenediazonium Tetrafluoroborate[a]

Run	Solvent	Temp/°C	Reaction time/h	Conversion/%
1	DMF	40	26	82
2	DMF	60	24	79
3	Benzene	60	24	72
4[b]	Benzene	60	20	70

a) The reaction conditions are described in the experimental section. b) The concentration of reactants was half compared with that for the other runs.

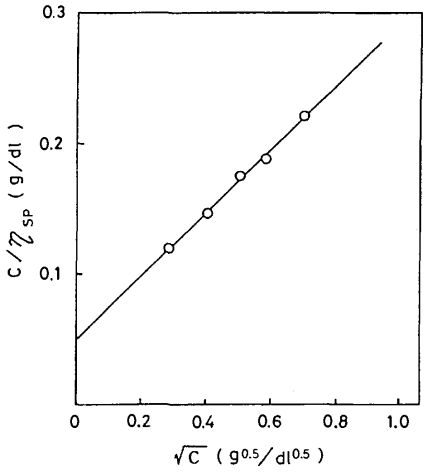

Fig. 2. The Fouss plot of the data of Fig. 1.

polymeric phosphonium salt (P-2) by the reaction with benzenediazonium tetrafluoroborate. The reaction proceeded in less polar benzene as well as in DMF (Table 2). Fig. 1 shows the solution viscosity behavior of P-2 (Run 3 in Table 2), suggesting the characteristic of ionic polymers. The linearity of the Fuoss plot[9] indicates that the physicochemical properties of the polymer are very similar to those of typical ionic polymers (Fig. 2). We previously reported the introduction of the iminophosphorane structure into cross-linked polystyrene beads, which can be utilized to prepare a phosphonium resin whose affinity for anions is different from that of ammonium resins. P-2 is therefore of interest from the viewpoint of chromatografic anion-selectivity.

Experimental

Materials. All reagent grade chemicals were used without further purification. *N*-Phenyliminotriphenylphosphorane and *N*-phenylimino-*p*-styryldiphenylphosphorane were synthesized by the reaction of the corresponding phosphines(*p*-styryldiphenylphosphine was kindly supplied by Hokko Chemical Industry Ltd.) and phenyl azide,[11,12] and freshly prepared benzenediazonium tetrafluoroborate was used.

Diphenylaminotriphenylphosphonium Tetrafluoroborate. Homogeneous Reaction. A solution of benzenediazonium tetrafluoroborate (2 mmol) in acetonitrile (10 ml) was added dropwise to a solution of *N*-phenyliminotriphenylphosphorane (2 mmol) in the solvent (10 ml). The solution turned red with the evolution of nitrogen at room temperature. After the solution was kept at 60 °C for 23 h, the solvent was removed by evaporation and benzene was added to solidify the only residue. The solid product was collected by filtration (yield 83%, Run 1 in Table 1) and was recrystallized from benzene. The IR spectrum of the product was identical with that of the product obtained by the heterogeneous reaction described below.

Heterogeneous Reaction. Benzenediazonium tetrafluoroborate (5 mmol) was added to a solution of *N*-phenyliminotriphenylphosphorane (5 mmol) in benzene (20 ml). The heterogeneous mixture was kept at 60 °C with stirring for 24 h, turning red with evolution of nitrogen. After the reaction mixture was cooled and kept at room temperature for 4 h, the precipitated product was collected (yield 84%, Run 4 in Table 1) and recrystallized from benzene, mp 170 °C. Found: C, 69.4; H, 5.0; N, 3.0; P, 6.2%. Calcd for $C_{30}H_{25}BF_4NP$: C, 69.7; H, 5.0; N, 2.7; P, 6.0%.

Poly(*N*-phenylimino-*p*-styryldiphenylphosphorane)(P-1). *N*-Phenylimino-*p*-styryldiphenylphosphorane (3.2 mmol) was polymerized with α,α'-azobis(isobutyronitrile)(AIBN) (1.6×10^{-5} mol) in benzene (4 ml) at 65 °C for 6 h; the polymer formed was precipitated in methanol and collected by filtration, conversion 71%. Found: C, 82.2; H, 5.8; N, 3.7; P, 8.0%. Calcd for $C_{26}H_{22}NP$: C, 82.3; H, 5.8; N, 3.7; P, 8.2%.

Poly(diphenylamino-*p*-styryldiphenylphosphonium tetrafluoroborate) (P-2). Homogeneous Reaction. A solution of benzenediazonium tetrafluoroborate (1.4 mmol) in DMF (10 ml) was added dropwise to a solution of P-1 (1.4 mmol, based on the monomer unit) in the solvent (10 ml). The evolution of nitrogen was observed and the solution turned red at room temperaure as in the case of monomeric compounds described above. After the solution was kept at 60 °C for 24 h, the phosphonium polymer formed was precipitated in a large excess of ether. The conversion into the phosphonium structure in P-2 was determined on the basis of a conductometric titration with silver nitrate in DMF-H_2O (9 : 1): 79% (Run 2 in Table 2).

Heterogeneous Reaction. Benzenediazonium tetrafluoroborate (1.4 mmol) was added to a solution of P-1 (1.4 mmol, based on the monomer unit) in benzene (10 ml). The heterogeneous mixture was kept at 60 °C for 24 h, turning red with evolution of nitrogen. After the reaction mixture was cooled to room temperature, the precipitated polymer was filtered and purified by reprecipitation from DMF/ether, conversion 72% (Run 3 in Table 2).

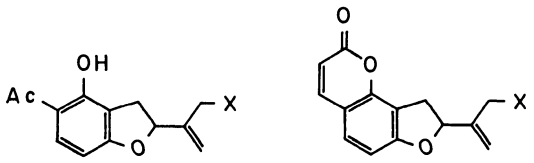
A New Preparative Method of 4-Hydroxybenzofuran-2-carboxylic Acid Derivatives

Seiji YAMAGUCHI,* Ken-ichi YAMAMOTO, Toshinori UEDA, Tetsuya MORIKAWA, and Yoshiyuki KAWASE*
Department of Chemistry, Faculty of Science, Toyama University, Gofuku 3190, Toyama 930
(Received July 17, 1989)

Synopsis. 4-Oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylic acid was prepared from 1,3-cyclohexanedione and ethyl bromopyruvate. Dehydrogenation of this acid or its methyl ester gave 4-hydroxybenzofuran-2-carboxylic acid derivatives.



1a X = H
1b X = OCOCH(CH$_3$)$_2$
1c X = OCOCH(CH$_3$)C$_2$H$_5$

2a X = H
2b X = OH

Chart 1.

We reported the synthesis of some natural dihydrobenzofuran derivatives from optically active 2,3-dihydrobenzofuran-2-carboxylic acid.[1] For a similar synthesis of some natural dihydrobenzofuran derivatives having an *O*-functional group at the 4 position, such as **1a**,[2] **1b**, **1c**,[3] **2a**,[4] and **2b**,[5] 4-hydroxy-2,3-dihydrobenzofuran-2-carboxylic acid (**6**) might be a key compound. However, no effective preparation of 4-hydroxybenzofuran-2-carboxylic (**4**) and **6** has been reported. We now describe a new preparative method of **4** and its conversion to **6**.

A methanolic solution of 1,3-cyclohexanedione and ethyl bromopyruvate was refluxed with sodium methoxide; acidification of this mixture gave 4-oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylic acid (**3a**) in 76% yield. This acid **3a** was readily converted to the corresponding methyl ester **3b** with methanol-*p*-toluenesulfonic acid (76%) or diazomethane (69%).

5	($CDCl_3$)	2.3 (3H, s) 7.1 (1H, dd, *J*=6 and 3 Hz) 7.3 (1H, t, *J*=6 Hz) 7.5 (1H, dd, *J*=6 and 3 Hz) 7.5 (1H, s) 8.3 (1H, s)
6	($CDCl_3$)	4.5 (1H, dd, *J*=14 and 8 Hz) 4.7 (1H, dd, *J*=14 and 7 Hz) 4.9 (1H, dd, *J*=8 and 7 Hz) 6.4 (2H, d, *J*=8 Hz) 7.0 (1H, t, *J*=8 Hz) 9.3 (2H, broad s)

The dehydrogenation of **3a** and **3b** was attempted by the following three methods: A) heating with sulfur,[6] B) bromination with copper(II) bromide followed by dehydrobromination,[7] and C) heating with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ)[8] (summarized in Table 1). In some cases with copper(II) bromide, trans-esterification or esterification was observed. The dehydrogenation of **3a** was most effective with copper(II) bromide in refluxing methanol for 2 h. Interestingly, esters **4b** and **4c** showed a lower carbonyl band than acid **4a** regarding their IR spectra.

4-Hydroxy-2,3-dihydrobenzofuran-2-carboxylic acid (**6**) was obtained by a sodium amalgam reduction of 4-acetoxybenzofuran-2-carboxylic acid (**5**) in 56% yield, which was prepared from **4a** by acetylation with acetic anhydride.

Experimental

The melting points were uncorrected. The IR spectra were measured on a Hitachi EPI-S2 spectrophotometer in KBr disks, and the UV spectra were taken on a Hitachi 220A spectrophotometer in ethanol. The ^{1}H NMR spectra were recorded on a JEOL PMX-60Si NMR spectrometer in CCl_4, $CDCl_3$, or acetone-d_6 and the mass spectra were recorded on a JEOL JMS-OISG-2 mass spectrometer. The yields, some physical data, and elemental analyses are summarized in Tables 1, 2, and 3.

Preparation of 4-Oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylic Acid (3a). To a methanolic solution of sodium methoxide, prepared from sodium metal (2.8 g, 122 mmol) and abs. methanol (45 ml), 1,3-cyclohexanedione (14.5 g, 129 mmol) was added. Then, a solution of ethyl bromopyruvate[9] (25.0 g, 128 mmol) in abs. methanol was added to the mixture with stirring. After refluxing for 4 h, the mixture was allowed to stand for 20 h at room temperature. The solvent was removed under reduced pressure, and the residue was diluted with water and acidified with 10% hydrochloric acid. The mixture was allowed to stand for 2 d to complete cyclization and crystallization. The crystals were collected and recrytsallized from ethanol to give 4-oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylic acid (**3a**) (16.6 g, 76%) as colorless needles. A similar reaction of 1,3-cyclohexanedione and ethyl bromopyruvate with equivalent potassium hydroxide in water-methanol also gave **3a**, but in

poorer yield (31%).

Preparation of Methyl 4-Oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylate (3b). To a solution of **3a** (2.11 g, 11.7 mmol) in methanol (100 ml) was added a small amount of *p*-toluenesulfonic acid; the mixture was refluxed for 24 h. After removing the methanol, the residue was diluted with benzene. The benzene layer was washed with sat. sodium hydrogencarbonate solution and then with sat. sodium chloride solution, and dried over anhydrous sodium sulfate. After removing the solvent, the residue was crystallized from cyclohexane to give methyl 4-oxo-4,5,6,7-tetrahydrobenzofuran-2-carboxylate (**3b**) (1.72 g, 76%) as colorless plates. This methyl ester **3b** was also obtained by esterification of **3a** with an excess of diazomethane ethereal solution in 69%.

Dehydrogenation of 3a or 3b. A) With Sulfur:[6] A mixture of **3b** (903 mg, 4.65 mmol) and sulfur powder (152 mg, 4.74 mmol) was heated at ca. 250 °C on a metal bath for 3 h. After cooling, the mixture was treated with benzene and the benzene solution was extracted with a 5% sodium hydroxide solution. The alkaline aqueous solution was acidified with 10% hydrochloric acid and re-extracted with benzene. The benzene layer was washed with sat. sodium chloride solution and dried over anhydrous sodium sulfate. After removing the solvent, the residue was crystallized from benzene to give 4-hydroxybenzofuran-2-carboxylic acid (**4a**) (105 mg, 13%). A similar heating of acid **3a** with sulfur generated an odour of hydrogen sulfide, but did not give **4a**.[10]

B) With Copper(II) Bromide:[6] To a solution of **3a** (1.93 g, 10.7 mmol) in methanol (50 ml) was added copper(II) bromide (4.60 g, 20.6 mmol), and the mixture was refluxed for 2 h. After cooling, the precipitates of copper(I) bromide were filtered off and washed with benzene. The filtrate and the washings were combined and concentrated at reduced pressure. The residue was diluted again with benzene, and the precipitates of copper(II) bromide were filtered off. After removing the benzene, the residue was crystallized from methanol to give methyl 4-hydroxybenzofuran-2-carboxylate (**4b**) (1.15 g, 56%) as colorless plates. Similar treatments of **3a** or **3b** with copper(II) bromide gave **4a**, **4b**, or **4c**, depending on the solvent used. Ester **4c** was purified by recrystallization from ethanol and obtained as colorless wooly crystals. Acid **4a** was purified by sublimation (150—180 °C at 16 mmHg[11]), followed by recrystallization from benzene, and obtained as colorless wooly crystals. The yields and some physical data are summarized in Tables 1, 2, and 3.

C) With DDQ:[7] To a solution of **3a** (588 mg, 3.27 mmol) in benzene (30 ml) was added 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ)(763 mg, 3.36 mmol), and the mixture was refluxed for 4 h. After cooling, the precipitated hydroquinone was filtered off and washed with benzene. The filtrate and the washings were combined and extracted with a sodium hydrogencarbonate solution. The alkaline extract was acidified with 10% hydrochloric acid and re-extracted with benzene. The benzene layer was dried over anhydrous sodium sulfate and concentrated. The residue was sublimed to give **4a** (29 mg, 5%). A similar treatment of **3b** (513 mg, 2.64 mmol) with DDQ (711 mg, 3.13 mmol) in benzene (30 ml) for 4 h gave **4b** (26 mg, 5%) as a sodium hydroxide extract, which was purified by crystallization from methanol.

4-Acetoxybenzofuran-2-carboxylic Acid (5). A solution of **4a** (1.02 g, 5.73 mmol) in acetic anhydride (5 ml) was heated on a water bath for 3 h. After removing the solvent, the residue was treated with water and the precipitates were collected and recrystallized from benzene to give 4-acetoxybenzofuran-2-carboxylic acid (**5**) (0.92 g, 74%) as colorless needles.

4-Hydroxy-2,3-dihydrobenzofuran-2-carboxylic Acid (6). To a solution of **5** (1.01 g, 4.59 mmol) in an aqueous potassium hydroxide solution (containing 0.5 g of potassium hydroxide in 10 ml of water) was added 2% sodium amalgam (0.32 g of sodium metal in 17 g of mercury); the mixture was stirred for one night. The alkaline aqueous layer was acidified with 10% hydrochloric acid and extracted with ether. After removing the solvent, the residue was recrystallized from benzene to give 4-hydroxy-2,3-dihydrobenzofuran-2-carboxylic acid (**6**) (450 mg, 56%) as colorless crystals.

Oxidation of Aromatic *s*-Alcohols with Cobalt(III) Acetate in the Presence of Sodium Bromide

Masao HIRANO and Takashi MORIMOTO*
Department of Applied Chemistry, Faculty of Technology,
Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received July 26, 1989)

Synopsis. The title oxidation in acetic acid resulted in a selective formation of the corresponding ketones in excellent yields under mild conditions.

Oxidative transformation of alcohols to the corresponding carbonyl compounds constitutes an important part of synthetic chemistry. Thus, a wide variety of metal oxidants have been used for the stoichiometric and/or catalytic oxidation of alcohols. Extensively studied examples are those with lead(IV) acetate,[1] chromium(VI) compounds,[2-4] active manganese(IV) dioxide,[5-7] aluminum alkoxides (Oppenauer oxidation),[8] potassium ferrate(IV),[9] cerium(IV) ammonium nitrate,[10] etc. In economical and environmental terms, however, these procedures are not entirely satisfactory, because of the inherently hazardous toxicity and rather high cost of the reagents. In addition, from an experimental point of view, some limitations, viz. a lack of generality, manipulative complications, low yield of the product etc., have reduced the utility of the reagents for this purpose.

Cobalt salts are potent reagents and have wide applications for the oxidation of various functional groups, especially for the oxidation of alkylaromatics[11-13] and olefins.[14-16] However, there has hitherto been only a small amount of data on the oxidation of alcohols,[17,18] and it is apparent that these are not adequate for estimating the full validity of the reagent for this objective. We have found that cobalt(III) acetate in acetic acid is an efficient reagent for the oxidation of 1,2-glycols;[19-21] this fact prompted us to examine the oxidation of a variety of alcohols. The present paper describes the oxidation of aromatic *s*-alcohols using a cobalt(III) acetate-NaBr system, since this procedure can be expected to overcome the drawbacks attendant on conventional methods.

Results and Discussion

Oxidation of 1-phenylethyl alcohol (**1**) in acetic acid with stoichiometric cobalt(III) acetate [2 equiv per mol of **1**] was performed under an inert atmosphere in order to exclude any influence of autoxidation, since an alcohol has a rather high sensitivity to cobalt(III)-catalyzed autoxidation.[17] After heating the reaction mixture at 60 °C for 2 h in the absence of NaBr, a GLC analysis showed that a considerable amount of unreacted **1** (38%) and only 49% of acetophenone (**2**), along with ca. 7% of 1-phenylethyl acetate (**3**) were involved in the reaction mixture. Upon the addition of a small amount of NaBr ([NaBr]/[Co(III)]=0.05; mole ratio), the conversion of **1** was markedly increased to roughly 94%, whereas **3** decreased to a trace amount. Consequently, NaBr contributes not only to facilitate the reaction, but to inhibit any side reaction. The yield of **2** was independent of the concentration of NaBr in the range [NaBr]/[Co(III)]=0.05—0.5.

Various inorganic bromides (KBr, LiBr, and $MgBr_2$) were also examined. All of the bromides were effective, and there was no marked difference in efficacy between NaBr and them. Thus, subsequent reactions were carried out using NaBr, since the reagent is inexpensive and easy to handle, as compared with the other bromides.

The oxidation of 1-phenylethyl alcohols and diarylmethanols was conducted under comparable conditions and the results are summarized in Table 1. As with the case of **1**, the addition of NaBr commonly resulted in the promotion of the reaction and also in the predominant formation of the corresponding ketones. When the oxidation was carried out with stoichiometric cobalt(III) acetate, the formation of a small amount of the corresponding acetate, possibly due to competitive acetylation of unreacted alcohol, was observed in some cases. Therefore, the experiments were performed with a small excess of the oxidant for the completion of the reaction in such cases. Depending on the conditions used, a concomitant formation of some unidentified by-products was also observed in the oxidation of phenyl-*o*-, -*m*-, and -*p*-tolylmethanol and *o*-methyldiphenylmethanol. This might be partly attributable to the susceptibility of the methyl side chain towards cobalt(III) acetate[11,12] and/or the Co(III)-NaBr system.[13] Thus, the other reaction conditions (temperature, time, and concentration of NaBr) were selected on the basis of the reactivity of alcohol as well as the yield and selectivity of the ketone.

The influence of the position of the substituents on the benzene-ring on the yield of the ketones was investigated (Entries 2—4, 6—8, 9—11, 15—17, and 20—22); interestingly, however, there was no significant difference in the yields of the ketones.

In order to clarify an active species, the independent oxidations of **1** and diphenylmethanol with bromine were carried out in acetic acid under comparable conditions (60 °C, 2 h), since bromine might be formed by the possible interaction of bromide ion with cobalt(III) acetate. Indeed, bromine itself can oxidize the alcohols, but afforded only lower yields of **2** and benzophenone (23 and 18%, respectively). In these reactions acetylation of the alcohols (65 and 64%, respectively) was predominant, showing little contribution of bromine in the present reaction. Moreover, when cobalt(III) acetate was heated without the addition of a substrate under "standard conditions" (60 °C

a) Under argon, $[Co(OAc)_3]=0.2703$ mol dm^{-3}; 0.50 g of alcohols were used in every run.
b) Mole ratio. c) Isolated yield.

for 2 h) in both the presence and absence of NaBr ([NaBr]/[Co(III)]=0, 0.15, 0.25, 0.35, and 0.5), we observed that the concentration of a cobaltic species remained essentially unchanged within the experimental error; the ratios of concentration of remained Co(III) vs. initial concentration of Co(III) were 1, 0.995, 0.974, 0.989, and 0.979, respectively. Based on these observations and on earlier studies,[13,22)] the reacting species is thought to be acetoxybromocobalt(III), formed from a reaction of cobalt(III) acetate with bromide ion. The species, so generated, is presumed as a highly active mononuclear complex.[23)] Its

$$Co(OAc)_3 + Br^- \rightarrow (AcO)_2CoBr + AcO^-$$

highly reactive nature is very consistent with the marked rate enhancement observed in the present reactions. The cobaltic species could abstract the α-hydrogen atom of an alcohol in a radical manner,[22)] finally giving the corresponding ketone by the following oxidation of the resultant carbon radical with cobalt(III) acetate.

Experimental

^{1}H NMR spectra were measured with a JEOL model PMX-60 spectrometer for solutions in carbon tetrachloride. IR spectra were recorded for thin films or KBr disks on a JASCO DS-403G spectrophotometer. GLC was carried out on a Shimadzu GC-6A or GC-4CM instrument with a 2 m column packed with 5% PEG-20M or 1.5% OV-17, respectively, on Chromosorb GAW-DMCS, with temperature programming.

Materials. Cobalt(III) acetate in acetic acid was prepared according to lit.[24)] The concentration was determined by adding an excess of Fe(II) and back-titration with Ce(IV) ion. 1-Phenylethyl alcohol, diphenylmethanol, phenyl-*o*-tolylmethanol and phenyl-*p*-tolylmethanol, *p*-chlorophenyl-phenylmethanol, and benzoin were commercially available. The other alcohols were synthesized by reductions of the corresponding ketones, either with $NaBH_4$ in 90% aqueous EtOH, with $LiAlH_4$ in dry ether, or with aluminum isopropoxide in 2-propanol. All of the alcohols, thus prepared, were purified by distillation or by recrystallization just before use. The commercial inorganic bromides were used without any treatment.

Oxidation Procedures. The following procedures are representative. To a mixture of **1** (0.50 g, 4.10 mmol) and 0.05 mole equiv of NaBr in a round-bottomed flask was added a stoichiometric cobalt(III) acetate (2 mole equiv) in acetic acid (30 ml). The flask was flushed with dry argon, and the reaction was carried out at a controlled temperature in a thermostat with magnetic agitation. After a given period, the reaction mixture was poured into brine and extracted three times with ether. The combined extract was successively washed with brine, 10% aqueous sodium carbonate, and brine and then dried ($MgSO_4$). Removing the ether on a rotary evaporator gave a pale-yellow oil, which was chromatographed on silica gel (hexane–ethyl acetate).

All products so formed were known compounds and their identities were confirmed by comparisons of their NMR and IR spectra with those of authentic samples.

One-Pot *C*-Arylmethylation of Active Methylene Compounds with Aromatic Aldehydes Induced by a Me_3SiCl-NaI-MeCN Reagent

Takashi SAKAI,* Kazuyoshi MIYATA, Sadao TSUBOI, and Masanori UTAKA*
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Tsushima, Okayama 700
(Received August 4, 1989)

Synopsis. Reaction of active methylene compounds with aromatic aldehydes in the presence of chlorotrimethylsilane-sodium iodide-acetonitrile reagent gave *C*-arylmethylated products, the reduced condensation products, although the reaction either with aliphatic primary aldehydes or with isobutyraldehyde afforded alkylidenation products or dihydrofurans.

C-Arylmethylation at α-position of ketonic active methylene compounds is a fundamental and important process in organic synthesis. However the conventional method with arylmethyl halides under basic conditions often suffered from dialkylation and/or self-condensation of the ketonic substrates especially in the case of 1,3-diketones.[1] For example, acetylacetone is required to be converted to a cobalt complex for *C*-benzylation with benzyl bromide. Moreover, the yield remained moderate due to the formation of by-products.[2] In order to avoid the problems, sequential reactions of the Knoevenagel condensation with aromatic aldehyde followed by reduction of the resulting carbon-carbon double bond is sometimes forced to take.[3] In this paper, we describe a development of one pot method for the *C*-arylmethylation by use of aromatic aldehydes and a chlorotrimethylsilane-sodium iodide-acetonitrile reagent.[4] Meanwhile, we recently reported that the reagent can be used for reduction of carbon-carbon double bond of conjugated enones[5a] and for deoxygenation of benzylic alcohols.[5b] On the other hand, chlorotrimethylsilane has been known to catalyze the Knoevenagel condensation.[6] The present reaction is of a successful combination of these reactions and simplified the classical stepwise procedure, although it is not suitable for aliphatic aldehydes. Primary aliphatic aldehydes gave merely Knoevenagel condensation products and isobutyraldehyde yielded dihydrofurans and/or γ-lactones.

In a typical reaction, ethyl acetoacetate (**1a**) (1 mol) was allowed to react with benzaldehyde (**2a**) (1 mol) in the presence of the Me_3SiCl-NaI-CH_3CN reagent (5 mol) in acetonitrile at room temperature to 60 °C for 16 h to give benzylated product **3a** in an 82% yield (Scheme 1, Table 1). The reaction with acetylacetone (**1b**) gave product **3e** quantitatively, much increasing the yield as compared with that in the cobalt complex method (53% yield).[2] Interestingly, methyl ethyl ketone (**1c**), acetophenone (**1d**) and acetone (**1e**) also gave the corresponding benzylated compounds **3h** (67%), **3i** (76%), and **3j** (17%), respectively. The results using various aldehydes are summarized in Table 1.

A possible mechanism is depicted in Scheme 2. Condensation of enol or enol silyl ether **4** with iodinated silyl ether **5**[7] gives β-iodo ketone intermediate **6**,[8,9] which would be readily reduced to ketone **3** by in situ generated HI in a similar manner to that discussed previously.[5] The reaction, thus, requires two moles of the reagents, which are consumed to give hexamethyldisiloxane and iodine. The mechanism is supported by the fact that the reaction of **1a** with **2a** carried out at lowered temperature (0 °C—room temperature) gave ethyl 2-benzylidene-3-oxobutanoate (**7**) (45% yield), exclusively, by elimination of HI from **6**. In addition, ethyl 2-(α-iodobenzyl)-3-

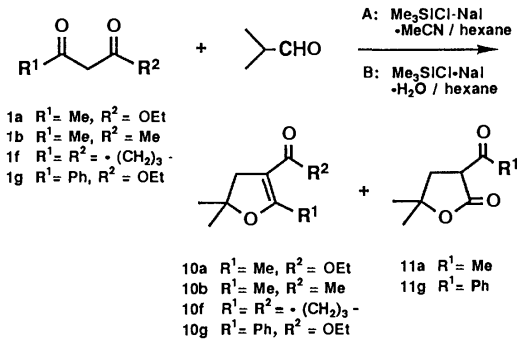
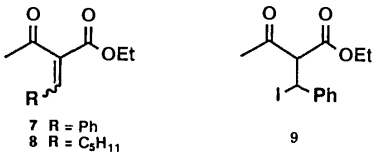


Scheme 3.

oxobutanoate (**9**) could be isolated (68% yield) by changing the solvent to ether.

Application of the present reaction to hexanal gave a mixture of unidentified products, while the reaction using ether as a solvent in place of acetonitrile at 0 °C—room temperature yielded merely a condensation product **8**.



In contrast, the reaction of **1b** with isobutyraldehyde in hexane at reflux temperature provided 4-acetyl-2,2,5-trimethyl-2,3-dihydrofuran (**10b**) in a 33% yield (Scheme 3, Table 2). The yield was markedly improved up to a quantitative one by replacing acetonitrile with the same mole of water. Favorably, the reaction can be done at room temperature. Herein, the water would be consumed to generate anhydrous HI, which may be a promoter of the reaction. The reaction is applicable to 1,3-cyclohexanedione (**1f**), giving **10f**, although the yield was moderate. The present dihydrofuran synthesis also simplified the conventional stepwise method, which involves the Knoevenagel condensation and an acidic (HCl or H_2SO_4) cyclization.[10a] Moreover, the reaction applied to β-keto esters **1a** and **1g** afforded dihydrofurans **10a**, **g** together with γ-lactone derivatives **11a**, **g** in moderate to low yields.

Table 2. Reaction of Active Methylene Compounds with Isobutyraldehyde in the Presence of Me_3SiCl–NaI

Experimental

General. IR spectra were taken on a JASCO A 102 spectrometer. ^1H NMR spectra (60 MHz) were measured with a JEOL JNM-PMX60 SI spectrometer. Chemical shifts are reported in value (ppm) down field from tetramethylsilane. Preparative TLC was done on silica gel (E. Merck, Kiesel gel 60 PF_{254}). Elemental analyses were performed by Mr. Eiichiro Amano of our laboratory using a Yanagimoto MT-3 CHN recorder. All active methylene compounds **1a—e** and aldehydes **2a—e** are commercially available.

General Procedure for the Reaction of Active Methylene Compounds 1 with Aromatic Aldehydes 2. To a stirred mixture of Me_3SiCl (1.28 ml, 10 mmol), NaI (1.50 g, 10 mmol), **1** (2 mmol), and MeCN (10 ml) was added **2** (2 mmol) at 0 °C. The mixture was stirred for 6 h at room temperature and then for additional 10 h at 60 °C. After addition of water, the organic layer was extracted with ether, washed with aqueous $Na_2S_2O_3$ to remove liberated iodine and then with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residual oil was purified by preparative TLC on silica gel (hexane-ether, 3:1) or by vacuum distillation to give product **3**. Compounds **3a**[11a] and **3j** were identified by comparison of the spectral data with that reported in the literature[11a] and with that of authentic sample, respectively. IR and ^1H NMR spectral data, which are not given in the literatures, are shown below.

Ethyl 4-Piperonyl-3-oxobutanoate (3b):[11b] IR (neat) 1745, 1720, 1645, 1613 cm^{-1}; ^1H NMR (CCl_4) δ=1.20 (3H, t, J=7 Hz, CH_3), 2.04, 2.10 (3H, two s with a similar intensity), 2.97 (2H, d, J=7 Hz), 2.60 (1H, dd, J=6 and 7 Hz), 4.08 (2H, q, J=7 Hz), 5.83 (2H, s), 6.57 (3H, s).

Ethyl 2-(*p*-Methoxyphenyl)methyl]-3-oxobutanoate (3c):[11c] IR (neat) 1735, 1712, 1620, 1610, 1600, 1580 cm^{-1}; ^1H NMR (CCl_4) δ=1.13 (3H, t, J=7 Hz), 2.15 (3H, s), 2.95 (2H, d, J=7 Hz), 3.60 (1H, dd, J=6 and 7 Hz), 3.76 (3H, s), 4.12 (2H, q with shoulder, J=7 Hz), 6.50—7.10 (4H, m), 12.80 (s, trace, enol OH).

Ethyl 3-Oxo-2-(3-pyridylmethyl)butanoate (3d):[11d] IR (neat) 1740, 1715, 1595, 1575 cm^{-1}, ^1H NMR (CCl_4) δ=1.23 (3H, t, J=7 Hz), 2.19 (3H, s), 3.10 (2H, d, J=7 Hz), 2.70 (1H, dd, J=6 and 8 Hz), 4.13 (2H, q, J=7 Hz), 6.95—8.65 (4H, m).

3-Benzyl-2,4-pentanedione (3e):[11e] IR (neat) 1730, 1705, 1605 cm^{-1}; ^1H NMR (CCl_4) δ=1.96 (3H, s), 1.99 (3H, s), 3.02 (1.2H, d, J=7 Hz), 3.57 (0.8H, s, $PhC\underline{H}_2$- of enol form), 3.58 (0.6H, t, J=7 Hz), 7.07 (5H, s), 16.69 (0.4H, s, enol OH).

3-[(*p*-Methoxyphenyl)methyl]-2,4-pentanedione (3f):[11f] IR (neat) 1728, 1700, 1612, 1591 cm^{-1}; ^1H NMR (CCl_4) δ=2.00 (6H, s), 2.97 (1.3H, d, J=7 Hz), 3.72 (0.7H, s, $PhC\underline{H}_2$ of enol form), 3.69 (3H, s), 3.78 (0.65H, t, J=7 Hz), 6.50—7.20 (4H, m), 16.64 (0.35H, s, enol OH).

3-(*p*-Tolylmethyl)-2,4-pentanedione (3g):[11g] IR (neat) 1735, 1705, 1605 cm^{-1}; ^1H NMR (CCl_4) δ=2.00 (6H, s), 2.27 (3H, s), 3.00 (1.4H, d, J=7 Hz), 3.55 (0.6H, s, $PhCHPhC\underline{H}_2$ of enol form), 3.81 (0.7H, t, J=7 Hz), 6.94 (5H, s), 16.66 (0.3H, s, enol OH).

3-Methyl-4-phenyl-2-butanone (3h):[11h] IR (neat) 1715 cm^{-1}; ^1H NMR (CCl_4) δ=1.02 (3H, d, J=7 Hz), 1.93 (3H, s), 2.17—3.33 (3H, m), 7.09 (5H, m).

1,3-Diphenyl-1-propanone (3i):[11i] IR (neat) 1680, 1596, 1575 cm^{-1}; ^1H NMR (CCl_4) δ=3.62—2.70 (4H, m), 6.90—8.10 (10H, m).

Ethyl 2-Benzylidene-3-oxobutanoate (7):[12] The reaction was carried out in the presence of Me_3SiCl-NaI-MeCN (5 mol equivalents) in ether at 0 °C—room temperature for 7 h and worked up in a usual manner to give **7** in a 45% yield. The IR and ^1H NMR were consistent with those reported.[12]

Ethyl 2-Acetyl-2-octenoate (8).[13] The reaction was carried out in a manner described above to give **8** (48% yield): IR (neat) 1735, 1680, 1640, 1620 cm^{-1}; ^1H NMR (CCl_4) δ=0.8—1.6 (9H, m), 2.20, 2.24 (3H, s), 2.0—2.5 (2H, m), 4.16, 4.22 (2H, q, J=7 Hz), 6.67, 6.75 (1H, t, J=8 Hz).

Ethyl 2-(α-Iodobenzyl)-3-oxobutanoate (9). The reaction was done at 0—5 °C in a similar manner to that of foregoing experiment. Recrystallization from hexane-ether (10:1) gave crystalline product **9** (67% yield): mp 68.2—70.0 °C; IR (KBr) 1735, 1710, 1275 cm^{-1}; ^1H NMR (CCl_4) δ=0.89, 1.34 (3H t, J=7 Hz), 1.90, 2.35 (3H, s), 3.84, 4.22 (2H, q, J=7 Hz), 4.22, 4.49 (1H, d, J=12 Hz), 5.45, 5.54 (1H, d, J=12 Hz), 7.23 (5H, m). Found: C, 45.37; H, 4.14%. Calcd for $C_{13}H_{15}O_3I$: C, 45.11; H, 4.37%.

3,5,6,7-Tetrahydro-2,2-dimethyl-4(2*H*)-benzofuranone (10f):[10b] IR (neat) 1725, 1625 cm^{-1}; ^1H NMR (CCl_4) δ=1.41 (6H, s), 2.15 (6H, m), 2.52 (2H, m).

3-Benzoyl-5,5-dimethyl-4,5-dihydro-2(3*H*)-furanone (11g): IR (neat) 1765, 1685 cm^{-1}; ^1H NMR (CCl_4) δ=1.36 (3H, s), 1.42 (3H, s), 1.92—2.80 (2H, m), 4.06 (1H, m), 7.36 (3H, m), 7.89 (2H, m). Found: C, 71.35; H, 6.45%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

(Received August 8, 1989)

Synopsis. A 24-epimeric mixture of 24-methyl-19,29-dinorlanost-9(11)-en-3-one was synthesized from 24-methylenecycloartanol. The synthesis comprises acid-cleavage of the cyclopropane ring, 4β-demethylation, the Barton reaction of the 3-nitrile, dehydration of the 11β-hydroxy derivative, and oxidation of the 19-hydroxy derivative followed by photolysis.

As an authentic sample for identification of a triterpene isolated from the plant fossile,[2)] a 24-epimeric mixture of 24-methyl-19,29-dinorlanost-9(11)-en-3-one (=4α,14α,24-trimethyl-19-norcholest-9(11)-en-3-one) (**1**) was prepared from 24-methylene-9,19-cyclo-lanostan-3β-yl acetate (=24-methylenecycloartenyl acetate) (**2**). The synthetic route is given in Fig. 1.

Experimental[3)]

Isolation of the Starting Compound (2). Rice bran oil contains phenolic compounds, named oryzanol A and C, which were reported to be cycloartenyl ferulate and 24-methylenecycloartenyl ferulate, respectively.[4)] Alkaline hydrolysis of a powdery oryzanol mixture[5)] (16 g) followed by acetylation yielded a mixture (10 g), which was shown to be a 1 : 1 mixture of **2** and 9,19-cyclolanost-24-en-3β-yl acetate (cycloartenyl acetate) (**3**) by the gas chromatography-mass spectrometry (GC-MS)[6)] and the proton nuclear magnetic resonance (^{1}H NMR) spectrometry. Since the mixture (**2** and **3**) showed a single spot on the thin-layer chromatography (TLC), the mixture (40.0 g) in CH_2Cl_2 (800 ml) was subjected to selective epoxidation and the reaction was mon-

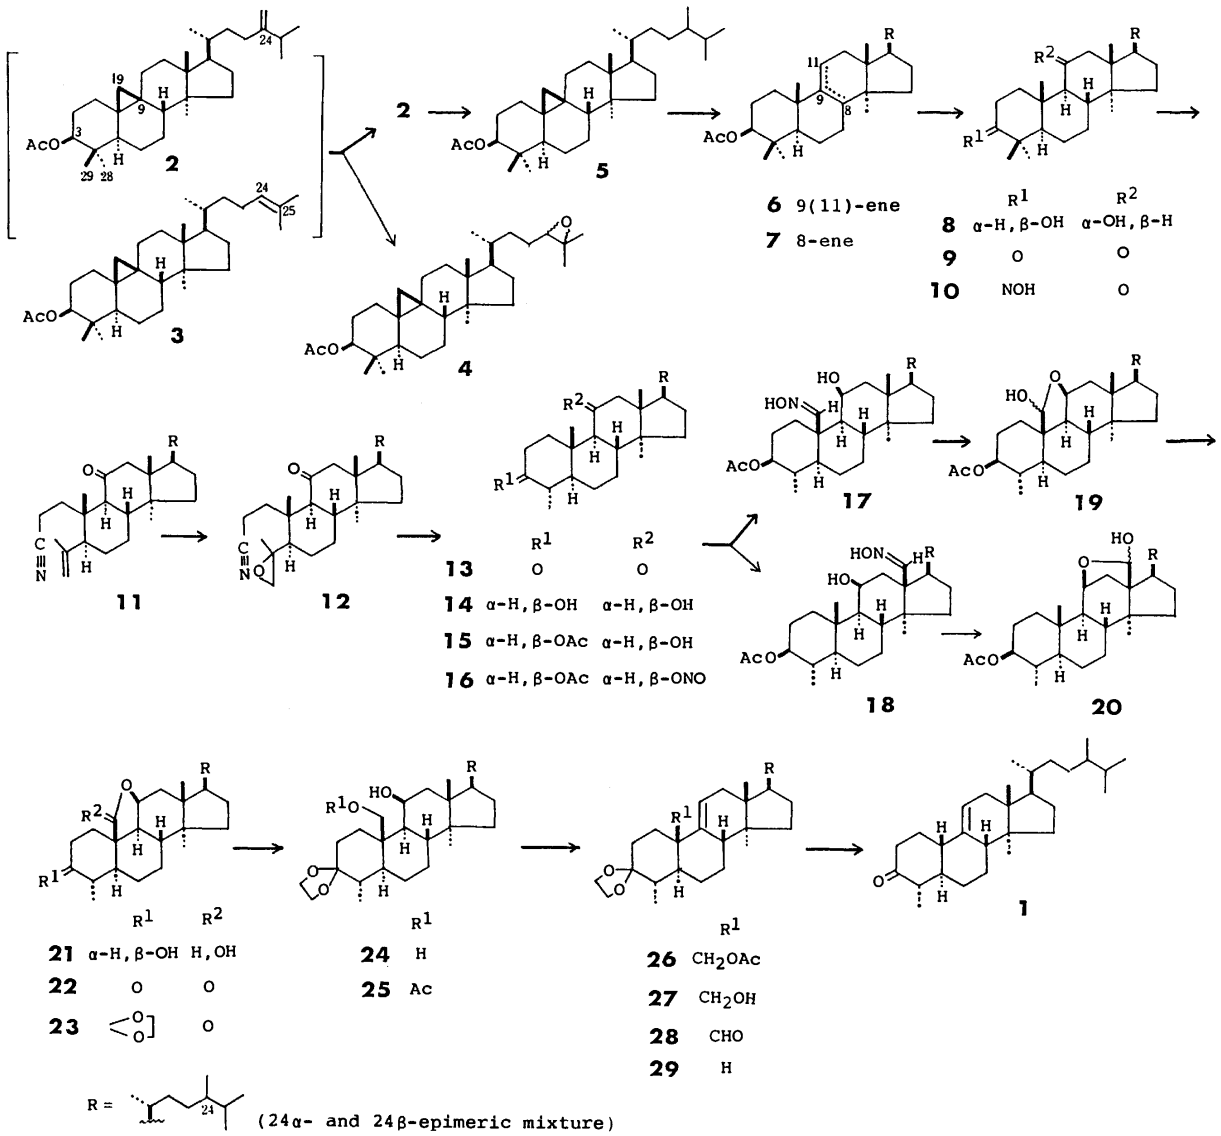

Fig. 1.

itored by GC. The epoxidation with *m*-chloroperbenzoic acid (mCPBA; 80%, 12.3 g) at −40 °C for 6 h gave an epoxide (**4**; 20.1 g) and the unchanged **2** (19.7 g) after column chromatography (SiO_2; 4—40% Et_2O in hexane). **2**: mp 108—109 °C (lit,[4] 116—117 °C); ^1H NMR δ=4.43—4.77 (3H, m; 3α-H and $C_{(24)}$=CH_2).

Hydrogenation of 2. The 24-methylene derivative (**2**; 29.2 g) in ether (1 l) was subjected to catalytic hydrogenation to give a 24-epimeric mixture of 24-methyl-9,19-cyclolanostan-3β-yl acetate[7] (**5**; 29.3 g), mp 125—126 °C; ^1H NMR; δ=0.34 (1H, d, J=4 Hz; 19-H), 0.59 (1H, d, J=4 Hz; 19′-H), 0.75 (3H, s; Me), 0.87—0.93 (6×Me), 0.97 (3H, s; Me), 2.04 (3H, s; OAc), and 4.43—4.70 (1H, m; 3α-H); MS m/z (%) 484 (M^+; 21), 469 (13), 444 (12), 424 (100), 409 (46), 385 (20), 382 (22), 356 (20), 302 (37), and 296 (32).

24-Methyllanostane-3,11-dione (9). Dry hydrogen chloride was introduced into a solution of **5** (11.5 g) in $CHCl_3$ (300 ml) for 2 h.[8] The usual work-up gave a mixture (11.2 g) of 24-methyl-9(11)-lanosten-3β-yl acetate (**6**) and its 8-ene isomer (**7**) in a ratio of 7 : 3, ^1H NMR δ=0.64—1.07 (9×Me), 2.04 (3H, s; OAc), 4.33—4.60 (1H, m; 3α-H), and 5.11—5.30 (0.7H, m; 11-H of **6**).

To a solution of the mixture (65.4 mg) in THF (4 ml) kept at 0 °C, diborane in THF (1.1 mmol^{-1}ml, 0.15 ml) was added and the solution was stirred for 2 d at 40 °C. After addition of water (3 ml), 3 M (1 M=1 mol dm^{-3}) NaOH (0.2 ml), and 30% H_2O_2 (0.2 ml), the reaction mixture was worked up as usual to afford 24-methyllanostane-3β,11α-diol (**8**; 26.5 mg), mp 202—204 °C; ^1H NMR δ=0.75 (3H, s; Me), 0.82—0.92 (6×Me), 0.98 and 1.01 (each 3H, s; Me), 3.08—3.35 (1H, m; 3α-H), and 3.73—4.12 (1H, m; 11β-H); MS m/z (%) 460 (M^+; 11), 442 (29), 427 (30), 424 (14), 409 (31), 399 (13), 238 (86), 223 (100), and 84 (>100).

A solution of **8** (8.45 g) in acetone (500 ml) was treated with Jones reagent (10 ml) for 5 min at 0 °C. The reaction mixture was worked up and chromatographed (SiO_2; 5% Et_2O in C_6H_6) to yield 24-methyllanostane-3,11-dione (**9**; 7.10 g), mp 158—159 °C; ^1H NMR δ=0.75—0.83 (4×Me), 0.89 (3H, s; Me), 1.05—1.09 (3×Me), 1.20 (3H, s; Me), and 2.78—3.13 (1H, m); MS (%) 456 (M^+; 100), 442 (8), 428 (44), 413 (18), 317 (96), and 219 (100).

4β-Demethylation of 9 According to the Pinhey's Procedure.[9] The dione (**9**) was converted into 24-methyl-29-norlanostane-3,11-dione (**13**) by the same procedure as before[1] through 3-hydroxyimino-24-methyllanostan-11-one (**10**), 24-methyl-11-oxo-3,4-secolanost-4(29)-ene-3-nitrile[10] (**11**), and 4,29-epoxy-24-methyl-11-oxo-3,4-secolanostane-3-nitrile[10] (**12**) in 48% overall yield. **10:** mp 215.5—216 °C; IR (KBr) 3320, 1700, and 930 cm^{-1}; ^1H NMR δ=0.73—0.90 (5×Me), 1.07 (6H, s; 2×Me), 1.13 and 1.17 (each 3H, s; Me); MS m/z (%) 471 (M^+; 76), 454 (46), and 140 (100). **11:** as a pale yellow oil, IR (neat) 2250, 1700, 890, and 680 cm^{-1}; ^1H NMR δ=0.75—0.89 (5×Me), 1.10 (6H, s; 2×Me), 1.73 (3H, br s; Me), 4.69 and 4.90 (each 1H, br s; C=CH_2); MS m/z (%) 453 (M^+; 100), 439 (14), 413 (15), and 372 (49). **12:** as a pale yellow oil, IR (neat) 2250, 1700, 820, and 660 cm^{-1}; ^1H NMR δ=0.75—0.89 (5×Me), 1.05, 1.14, and 1.28 (each 3H, s; Me), 2.43, and 2.68 (each 1H, br s); MS m/z (%) 469 (M^+; 43), 455 (12), 441 (100), 370 (55), 317 (42), 291 (53), and 264 (49). **13:** an amorphous solid, IR (KBr) 1710 and 1700 cm^{-1}; ^1H NMR δ=0.76—0.83 (4×Me), 0.90 (3H, s; Me), 0.99 (3H, d, J=6.5 Hz), 1.09, 1.26 (each 3H, s; Me), and 3.05 (1H, ddd, J=13, 6, and 3 Hz); MS m/z (%) 442 (M^+: 100), 428 (13), 414 (11), 317 (40), 288 (23), 274 (27), 221 (29), and 205 (100).

Photolysis of 3β-Acetoxy-24-methyl-29-norlanostan-11β-yl Nitrite (16). The 3,11-dione (**13**; 236 mg) in ether (100 ml) was reduced with LAH (200 mg) to yield 24-methyl-29-norlanostane-3β,11β-diol (**14**; 148 mg), mp 208—209 °C; ^1H NMR δ=0.78—0.93 (6×Me), 1.01, 1.11 (each 3H, s; Me), 2.83—3.25 (1H, m; 3α-H), and 4.10—4.31 (1H, m; 11α-H); MS m/z (%) 464 (M^+; 11), 428 (33), 413 (21), 410 (7), 274 (69), 238 (100), and 208 (78). Acetylation of the diol (**14**; 148 mg) gave 11β-hydroxy-24-methyl-29-norlanostan-3β-yl acetate (**15**; 150 mg), mp 170—171 °C; ^1H NMR δ=0.78—0.87 (6×Me), 0.98, 1.10 (each 3H, s; Me), 2.00 (3H, s: OAc), and 4.07—4.55 (2H, m; 3α-H and 11α-H); MS m/z (%) 488 (M^+; 11), 470 (65), 455 (80), 410 (17), 395 (53), and 238 (100).

A solution of the hydroxy acetate (**15**; 250 mg) in pyridine (25 ml) was treated with NOCl at −30 °C and worked up in the usual manner to afford 3β-acetoxy-24-methyl-29-norlanostan-11β-yl nitrite (**16**; 261 mg) as a pale yellow oil, IR (neat) 1735, 1630, 1600, 1250, 820, 775, and 755 cm^{-1}; ^1H NMR δ=0.77—0.88 (8×Me), 2.02 (3H, s; OAc), 4.12—4.53 (1H, m; 3α-H), and 5.83—6.05 (1H, m; 11α-H); MS m/z (%) 487 (M^+−NO; 2), 470 (7), 455 (20), 433 (9), 426 (15), 395 (20), 249 (23), and 95 (100).

A solution of the nitrite (**16**; 567 mg) in toluene (40 ml) and *t*-butylamine (2 ml) was photoirradiated with a 400 W high-pressure mercury lamp for 10 min under nitrogen. The usual work-up and chromatographic separation (SiO_2; 4% Et_2O in C_6H_6) gave a mixture (246 mg) of 11β-hydroxy-19-hydroxyimino-24-methyl-29-norlanostan-3β-yl acetate (**17**) and its 18-hydroxyimino isomer (**18**) together with **15** (248 mg). The mixture showed two singlet signals due to olefinic protons attached to carbon bearing hydroxyimino groups at δ=7.75 (0.7H) and δ=7.43 (0.3H), the major product being the 19-hydroxyimino isomer (**17**).[11] MS of the mixture: m/z (%) 517 (M^+; 1), 499 (23), 440 (91), and 57 (100).

24-Methyl-3-oxo-29-norlanostan-19,11β-olide (22). The mixture (159.2 mg) of **17** and **18** in acetone (10 ml) was stirred with concd HCl (4 drops) overnight at room temperature. The reaction product was chromatographed (SiO_2; 4—10% Et_2O in hexane) to give 11,19-epoxy-19-hydroxy-24-methyl-29-norlanostan-3β-yl acetate (**19**; 62.4 mg) and its 11,18-epoxy-18-hydroxyimino isomer (**20**; 30.9 mg). **19:** IR (KBr) 1740 and 1250 cm^{-1}; ^1H NMR δ=0.70 (3H, s; Me), 0.76—0.90 (5×Me), 1.04 (3H, s; Me), 2.06 (3H, s; OAc), 4.07—4.27 (1H, m; 11α-H), 4.27—4.64 (1H, m; 3α-H), and 5.35 and 5.63 (total 1H, br s; 19-H's of 19-epimeric mixture of **19**); MS m/z (%) 502 (M^+; 0.4), 484 (1.6), 469 (1.3), 456 (23), 441 (14), 396 (100), and 381 (38). **20:** IR (KBr) 1730 and 1260 cm^{-1}; ^1H NMR δ=0.77 (3H, s; Me), 0.82—1.00 (6×Me), 2.04 (3H, s; OAc), 4.13—4.51 (1H, m; 3α-H), 4.42 (1H, d-like, J=6 Hz; 11α-H), 5.10 (0.7H, d, J=6 Hz; 18-H), and 5.48 (0.3H, d, J=5 Hz; 18-H of the other epimer); MS m/z (%) 484 (M^+ −H_2O; 28), 469 (8), 456 (42), 441 (14), 381 (12), 356 (11), 329 (100), 269 (46), and 207 (82).

The acetate (**19**; 156 mg) in EtOH (50 ml) containing KOH (600 mg) was refluxed for 3 h to afford a hemiacetal, 11,19-epoxy-24-methyl-29-norlanostane-3β, 19-diol (**21**; 161 mg), MS m/z (%) 442 (M^+ −H_2O; 100), 428 (22), 425 (11), 415 (38), 400 (35), 397 (51), 387 (15), and 382 (32). The hemiacetal (**21**; 161 mg) in acetone (30 ml) was treated with Jones reagent (2 ml) and the reaction product was chromatographed (SiO_2; 5% Et_2O in C_6H_6) to afford 24-methyl-3-oxo-29-norlanostan-19,11β-olide (**22**; 86.8 mg), mp 209—210 °C; IR (KBr) 1750 and 1730 cm^{-1}: ^1H NMR δ=0.73—0.94 (6×Me), 1.00 (3H, d, J=6 Hz), 3.30—3.77 (1H, m), 4.67—4.83 (1H, m; 11α-H); MS m/z (%) 456 (M^+; 100), 442 (21), 428 (5), 412 (15), and 397 (6).

3,3-Ethylenedioxy-24-methyl-29-norlanost-9(11)-en-19-al (28). The keto lactone (**22**; 19 mg) was converted into the ethylenedioxy derivative (**23**; 20 mg), mp 211—212 °C, IR (KBr) 1755 cm^{-1}; ^1H NMR δ=0.76—0.92 (7×Me), 2.60—3.05 (1H, m), 3.93 (4H, br s; -OCH_2CH_2O-), and 4.56—4.78 (1H, m; 11α-H); MS m/z (%) 500 (M^+; 16), 485 (2), 472 (8), 100 (100), and 99 (>100). The lactone (**23**; 56.1 mg) in THF (20 ml) was treated with LAH (47 mg) to afford 3,3-ethyl-

enedioxy-24-methyl-29-norlanostane-11β,19-diol (**24**; 60.7 mg), mp 174—175 °C; ^{1}H NMR δ=0.75—0.90 (6×Me), 1.04 (3H, s; Me), 3.58 and 3.91 (2H, ABq, J=12 Hz; 19-H$_2$), 3.95 (4H, br s; -OCH$_2$CH$_2$O-), and 4.17 (1H, m; 11α-H); MS m/z (%) 504 (M$^+$; 0.5), 486 (4), 468 (15), 385 (68), 100 (100), and 99 (>100).

The diol (**24**; 60.7 mg) was acetylated to give 3,3-ethylenedioxy-11β-hydroxy-24-methyl-29-norlanostan-19-yl acetate (**25**; 43.3 mg), mp 105—107 °C; IR (KBr) 3470, 1735, and 1260 cm^{-1}; ^{1}H NMR δ=0.77—0.84 (4×Me), 0.88 (6H, s; 2×Me), 1.00 (3H, s; Me), 2.05 (3H, s; OAc), 3.94 (4H, br s; -OCH$_2$CH$_2$O-), 4.07—4.28 (1H, m; 11α-H), and 4.37 (2H, br s; 19-H$_2$); MS m/z (%) 546 (M$^+$; 10), 528 (4), 486 (32), 454 (15), 444 (48), 385 (100), 384 (>100), and 99 (>100).

The 11β-hydroxy acetate (**25**; 54.1 mg) in pyridine (10 ml) was treated with phosphoryl chloride (0.05 ml) under nitrogen. After the solution was heated at 80 °C for 3 h, the reaction product was chromatographed (SiO$_2$; 5% Et$_2$O in C$_6$H$_6$) to give 3,3-ethylenedioxy-24-methyl-29-norlanost-9(11)-en-19-yl acetate (**26**; 45.6 mg), mp 170—171 °C; IR (KBr) 1745 and 1240 cm^{-1}; ^{1}H NMR δ=0.60 (3H, s; Me), 0.77—0.89 (6×Me), 1.97 (3H, s; OAc), 3.95 (4H, br s; -OCH$_2$CH$_2$O-), 4.27 (2H, br s; 19-H$_2$), and 5.28—5.48 (1H, m; 11-H). Alkaline hydrolysis of **26** (4.8 mg) gave 3,3-ethylenedioxy-24-methyl-29-norlanost-9(11)-en-19-ol (**27**; 4.3 mg), mp 154—155 °C; ^{1}H NMR δ=0.66 (3H, s; Me), 0.75—0.90 (6×Me), 3.56 and 3.74 (2H, ABq, J=11 Hz; 19-H$_2$), 3.95 (4H, br s; -OCH$_2$CH$_2$O-), and 5.37—5.53 (1H, m; 11-H); MS m/z (%) 486 (M$^+$; 11), 471 (9), 455 (42), 441 (9), and 99 (100).

To the Collins reagent prepared from CrO$_3$ (35 mg) and pyridine (0.12 ml) in CH$_2$Cl$_2$ (6 ml) was added **27** (29.3 mg) in CH$_2$Cl$_2$. After the usual work-up, chromatographic separation (SiO$_2$; 5% Et$_2$O in C$_6$H$_6$) afforded 3,3-ethylenedioxy-24-methyl-29-norlanost-9(11)-en-19-al (**28**; 29.0 mg), mp 131—133 °C; IR (KBr) 1720 cm^{-1}; ^{1}H NMR δ=0.57 (3H, s; Me), 0.77—0.90 (6×Me), 3.93 (4H, br s; -OCH$_2$CH$_2$O-), 5.50—5.73 (1H, m; 11-H), and 9.11 (1H, br s; CHO); MS m/z (%) 484 (M$^+$; 3), 469 (2), 455 (85), 441 (12), 411 (4), 393 (12), and 99 (100).

Photo-decarbonylation of 28. Photo-decarbonylation of homoallylic aldehydes was carried out according to the procedure described in literatures.[12a,b] A solution of **28** (29.0 mg) in EtOH (50 ml) was photoirradiated for 30 min using a 400 W-high-pressure mercury lamp. Evaporation of the solvent followed by chromatography (SiO$_2$; C$_6$H$_6$) afforded 3,3-ethylenedioxy-24-methyl-19,29-dinorlanost-9(11)-ene (**29**; 25.9 mg), mp 153—154 °C; ^{1}H NMR δ=0.67 (3H, s; Me), 0.77—0.92 (6×Me), 3.93 (4H, br s; -OCH$_2$-CH$_2$O-), and 5.13—5.33 (1H, m; 11-H); MS m/z (%) 456 (M$^+$; 100), 441 (26), 427 (7), 412 (9), 394 (49), 380 (18), 100 (92), and 99 (>100).

24-Methyl-19,29-dinorlanost-9(11)-en-3-one (1). A solution of **29** (24.3 mg) in acetone was treated with p-TsOH (30 mg) overnight and the reaction product was chromatographed (SiO$_2$; C$_6$H$_6$) to give 24-methyl-19,29-dinorlanost-9(11)-en-3-one (**1**; 16.3 mg), mp 126—128 °C; $[\alpha]_D^{25}$ +70° (c 0.2, CHCl$_3$); $[\theta]_{290}$ +5350 (peak); IR (KBr) 1715 cm^{-1}; ^{1}H NMR (Brucker AM-500, 500 MHz, CDCl$_3$) δ=0.70 (3H, br s), 0.755 (3H, s), 0.786 (3H, d, J=6.9 Hz), 0.790, 0.811 (total 3H, each d, J=6.8 Hz), 0.857, 0.860 (total 3H, each d, J=6.8 Hz), 0.884, 0.893 (total 3H, d, J=6.5 Hz), 1.03 (3H, d, J=6.5 Hz), 2.34—2.50 (3H, m), and 5.30 (1H, d, J=4.5 Hz); MS m/z (%) 412 (M$^+$; 73), 397 (100), 383 (14), 285 (29), 271 (8), 258 (12), 243 (20), 229 (23), 217 (33), and 149 (36); Found: m/z 412.3692. Calcd for C$_{29}$H$_{48}$O: M, 412.3703.

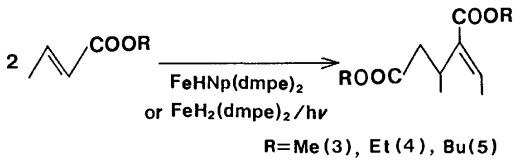
Selective Dimerization of Alkyl Crotonates Catalyzed by Iron(0) Complexes Having 1,2-Bis(dimethylphosphino)ethane Ligands

Sanshiro KOMIYA,* Naohiko OYASATO, and Tomoyuki FURUKAWA
Department of Applied Chemistry, Tokyo University of Agriculture and Technology, 2-24-16 Nakamachi, Koganei, Tokyo 184
(Received August 11, 1989)

Synopsis. Highly selective dimerization of alkyl crotonates has been performed in the presence of a catalytic amount of $FeHNp(dmpe)_2$ or $FeH_2(dmpe)_2$/UV irradiation at room temperature.

Although metal-catalyzed dimerizations of olefins having functional groups under mild conditions have been expected to have wide applications to organic syntheses, only limited examples are known so far such as dimerizations of methyl acrylate[1] and acrylonitrile[2] by comparison with well known metal-catalyzed dimerizations of simple olefins or dienes.[3] Unfortunately the most of these dimerizations in fact are not sufficiently selective and their yields are considerably low, in spite of their severe reaction conditions. We wish to report iron-catalyzed selective dimerization of alkyl crotonates under ambient conditions.

When methyl crotonate was treated with a catalytic amount of $FeHNp(dmpe)_2$, **1** (1 mol%)[4] at room temperature, a methyl crotonate dimer was smoothly obtained in high yield in 2 h (dmpe=1,2-bis(dimethylphosphino)ethane, Np=2-naphthyl). $FeH_2(dmpe)_2$,[5] **2** also catalyzed the dimerization under irradiation of UV light. Results of the catalytic dimerization of alkyl crotonates under various conditions are summarized in Table 1.



The dimerization is selective with high conversion. ^{1}H NMR, GC, and GCMS analyses reveal that the dimer consists of an only head-to-tail dimer (*E* isomer). Trace amounts of trimer and tetramer were detected in the reaction mixture (see experimental). The rate of the catalytic dimerization slightly decreased in the order of methyl, ethyl, and butyl esters, as shown in the time-yield curve of the reactions (Fig. 1). Unfortunately dimerization of other types of unsaturated esters such as methyl acrylate, methyl 3-butenoate and methyl methacrylate has failed.[6] Addition of 1,2-bis(dimethylphosphino)ethane ligand (1 mol/**1**) severely retarded the reaction, suggesting that the formation of a coordinatively unsaturated intermediate such as $[Fe(dmpe)_2]$ is a key step in the catalytic dimerization. Such a coordinatively unsaturated species has been previously proposed in the C-H bond activations by **1**[4] or by **2** under UV irradiation.[5] Rate of the reaction was not significantly affected by changing the solvent from hexane to DMF, excluding the formation of ionic species as reaction intermediates. Thus, for the present catalytic Michael type

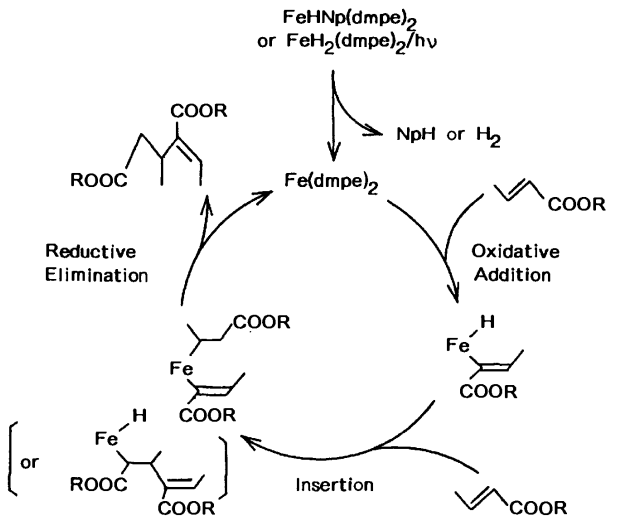
a) All the reactions were carried out for 2 h under N_2 at room temperature. b) UV irradiation with high-pressure Hg lamp. c) An equimolar amount of dmpe ligand (0.0372 mmol) per Fe was added.



Scheme 1. A possible mechanism for the iron-catalyzed dimerization of alkyl crotonates.

dimerization, the following concerted mechanism involving C-H bond oxidative addition followed by insertion of alkyl crotonate and reductive elimination of the dimer has been proposed (Scheme 1).[7] The vinylic C-H bond oxidative addition process as an initial step is reasonable, since the hydrido-(vinyl)-metal complexes were isolated from the reactions of zero-valent iron and ruthenium complexes with alkyl methacrylates.[5,8]

Experimental

General. All the reactions were carried out under nitrogen. Solvents used were dried by usual procedure, distilled, and stored under nitrogen. Reagent grade of unsaturated esters were dried with CaH_2 and distilled before use. $FeH_2(dmpe)_2$ and $FeHNp(dmpe)_2$ were prepared according to the literature methods.[4,5]

Dimerization of Methyl Crotonate. A typical procedure of the dimerization is described below: $FeHNp(dmpe)_2$ (14.0 mg, 0.0289 mmol) was placed in a Schlenk tube under nitrogen and a settled amount of methyl crotonate (0.304 cm^3, 2.89 mmol) was added by using a microsyringe. After stirring the solution for 2 h, the solution was analyzed by GC and GCMS. The results were summarized in Table 1. The dimer was purified by column chromatography (alumina/hexane) and characterized mainly by NMR. **3**, GCMS: m/z=200, ^1H NMR ($CDCl_3$): δ=1.20 (Me, d, 7.1 Hz), 1.85 (Me, d, J=7.3 Hz), 2.59 (H, dd, J=7.1, 15.4 Hz), 2.75 (H, dd, J=7.8, 15,4 Hz), 3.30 (H, ddq, J=7.1, 7.8, 7.1 Hz), 3.63 and 3.72 (OMe, s), 6.83 (H, q, J=7.3 Hz). Traces of trimers (m/z=300, yield=0.7%) and tetramers (m/z=400, yield=2.8%) were also detected, but the detail structure of these oligomers was not characterized. Other reactions were performed analogously. **4**, ^1H NMR ($CDCl_3$): δ=0.93 (Me, t, J=7.2 Hz), 0.97 (Me, t, J=7.1 Hz), 1.28 (Me, d, J=7.1 Hz), 1.57 (Me, d, J=7.3), 2.63 (H, dd, J=6.8, 15.4 Hz), 2.94 (H, dd, J=8.1, 15.4 Hz), 3.37 (H, ddq, J=6.8, 8.1, 7.1 Hz), 3.92 (CH_2, q, J=7.2 Hz), 3.99 (CH_2, q, J=7.1 Hz), 6.84 (H, q, J=7.3 Hz); **5**, δ=0.92 (Me, t, J=7.1 Hz), 0.95 (Me, t, J=7.1 Hz), 1.21 (Me, d, J=7.1 Hz), 1.3—1.7 (CH_2, m), 1.84 (Me, d, J=7.3 Hz), 2.57 (H, dd, J=7.3, 15.4 Hz), 2.74 (H, dd, J=8.1, 15.4 Hz), 3.30 (H, ddq, J=8.1, 7.3, 7.1 Hz), 4.03 (CH_2, t, J=5.6 Hz), 4.12 (CH_2, t, J=6.6 Hz), 6.82 (H, q, J=7.3 Hz). When $FeH_2(dmpe)_2$ was used as a catalyst, UV irradiation with a high-pressure Hg lamp was applied during the reaction. In these cases hydrogen gas was detected in the gas phase after the reaction.

6) In these reactions unreacted esters were recovered. In the reaction of $FeH_2(dmpe)_2$ with methyl acrylate and methyl methacrylate under UV irradiation, stable hydrido-(alkenyl)- and/or methyl(carboxylato)iron complexes, which are not catalytically active and are tentatively characterized by only in situ ^1H NMR (in C_6D_6), were formed. FeH(CH=CHCOOMe)(dmpe)$_2$: 10.3 ppm (d of qui, J(HH)=18.3 Hz, J(PH)=7.3 Hz, FeC<u>H</u>=CH-), 6.26 (d, J(HH)=18.3 Hz, FeCH=C<u>H</u>-), −16.76 (qui, J(PH)=45.2 Hz, FeH). FeH(CH=C(Me)COOMe)(dmpe)$_2$: 10.18 (br, FeCH=), −12.91 (d of q, J(PH)=42, 55 Hz). FeMe(O-COC(Me)=CH_2)(dmpe)$_2$: 5.06 and 5.56 (br, CH_2), −3.23 (qui, J(PH)=7.3 Hz, FeMe). Other signals are obscured due to extensive overlapping with the signals of large free ester.

7) At present we prefer the above mechanism involving C-H bond oxidative addition followed by insertion of methyl crotonate into Fe-H bond, since other mechanisms involving successive insertion into Fe-H bond and β-elimination are not suitable for interpreting the high selectivity of the reaction.

(Received July 3, 1989)

Synopsis. Nitrogen gas containing organic vapor was introduced into a column packed with activated carbon at high temperatures up to 200 °C, and the amounts of the solvents adsorbed were measured. The adsorption equilibrium data for single- and bi-component systems could be correlated by the Freundlich and extended Freundlich isotherms respectively.

The measurement of the adsorption equilibrium is very important to understanding the basic adsorption and desorption characteristics of organic vapor on activated carbon. For example, the vapor in the work environment is collected using a charcoal tube and the amount adsorbed is measured by a thermal desorption method to determine the vapor concentration, the equilibrium data at the desorption temperature are necessary to estimate the thermal desorption efficiency. Although many kinds of organic compounds are used as solvents in work places, there are very few data available on organic vapor-activated carbon systems at high temperatures, because the desorption has usually not been carried out by the thermal-desorption method, but by an extraction method using a harmful organic desorbent such as carbon disulfide.[1] In particular, we have not found out any data for a multicomponent organic vapor system, although most of the organic solvents used in work places are multicomponent ones.

In this paper, we measured the adsorption equilibria of single- and bi-component organic vapor-activated carbon systems at high temperatures up to 200 °C and correlated the data using Freundlich and extended Freundlich isotherms.

Experimental

The adsorption column is made by using a Pyrex glass tube (4 mm in inner diameter), which is inserted into a brass block heated by a band heater. Organic vapors were obtained by means of a generator developed by the authors.[2] PCB Pittsburgh activated carbon (Calgon Co., 12/30 mesh), which is commonly used for the measurement of organic vapor in a work environment, was used as the adsorbent. Before the experiments, the carbon particles were heated at 250 °C for 24 hours under a nitrogen gas flow. The column temperature was measured by the use of a thermocouple and was controlled within ±0.5 °C by means of a relay-controller and a temperature-regulator.

One hundred milligrams of activated carbon particles were put into the heated column, and then pure nitrogen gas was introduced. After steady-state conditions had been obtained, the gas was changed to nitrogen gas containing organic vapor. A part of the column outlet gas was sampled periodically by the use of an auto-gas sampler (Gasukuro Kogyo, GS-5000A), while the vapor concentrations were determined by the use of a gas chromatograph (CC, Shimadzu GC-6A) equipped with a flame-ionization detector. After carbon particles had been recognized from the breakthrough curve as being fully saturated with the solvents, the particles were put into a vial and 2 ml of carbon disulfide was added. After having been kept for about 1 hour to insure the desorption of the adsorbed solvents, a part of the solution was injected into the GC and the amount adsorbed was determined.

Results and Discussion

Single-Component System. Figure 1 shows a Freundlich plot of toluene at various temperatures. The data are expressed by the following Freundlich equation:

$$q = A\,C^{\beta} \tag{1}$$

where C is the vapor concentration, q is the adsorption capacity in equilibrium with C per unit of weight of the activated carbon (equilibrium adsorption capacity), and A and β are constants. The equilibrium adsorption capacity decreased, and the value of β increased with the increase in the temperature. These findings show that the effect of the temperature on the adsorption capacity becomes larger at lower vapor concentrations. Figure 2 shows the isotherms for benzene, toluene, *o*-xylene, and methyl isobutyl ketone (MIBK) at 200 °C. They are commonly used in work places as solvents, but their thermal-desorption efficiencies are relatively low.[3] The experimental data can also be expressed by the Freundlich isotherm.

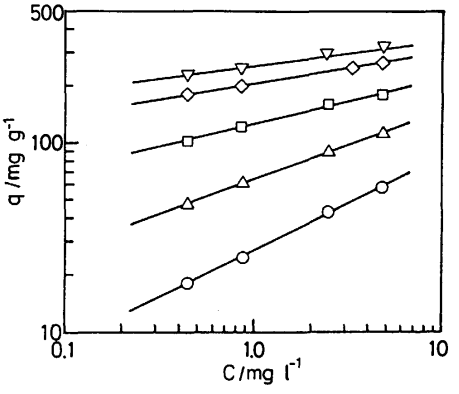

Fig. 1. Adsorption isotherm of toluene. O: 200 °C, △: 150 °C, □: 100 °C, ◇: 50 °C, ▽: 25 °C.

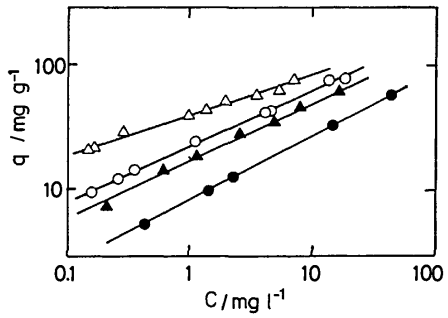

Fig. 2. Adsorption isotherm of organic solvent vapors on activated carbon at 200 °C. ○: toluene; $q=22.5C^{0.45}$, ●: benzene; $q=7.90C^{0.53}$, △: *o*-xylene; $q=42.0C^{0.35}$, ▲: MIBK; $q=17.7C^{0.47}$.

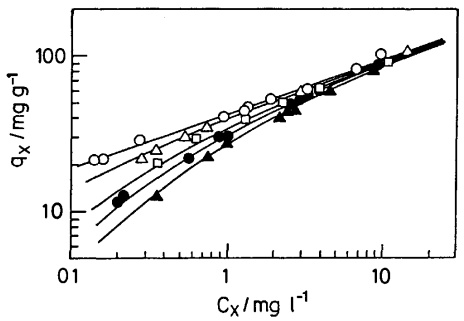

Fig. 4. Adsorption isotherm of *o*-xylene for MIBK–*o*-xylene system at 200 °C. ○: MIBK concentration=0.0 mg l^{-1}, △: 0.9 mg l^{-1}, □: 4.3 mg l^{-1}, ●: 7.0 mg l^{-1}, ▲: 12.5 mg l^{-1}, solid line: estimated by Eq. 2 and Table 1.

The equilibrium adsorption capacity depends on the adsorption affinity, which is itself dominated by the van der Waals force,[4] but it is difficult to obtain the quantitative relationship between the kind of material and the equilibrium adsorption capacities. In our experiment, the component which had the higher saturation vapor pressure tended to have the smaller adsorption capacity. The reason for this is that the higher vapor-pressure component is hard to condense in the pores of the adsorbent. As the saturate vapor pressure depends greatly on the temperature, the adsorption capacity may also be decreased with the temperature, as is shown in Fig. 1.

Bi-Component System. Figures 3 and 4 show the Freundlich plots of the MIBK-*o*-xylene system at 200 °C. The isotherms are shown as convex curves except when the vapor concentration of the co-adsorbed component is zero. This result indicates that the effect of the vapor concentration of the co-adsorbed component becomes larger as the vapor concentration of one component decreases. The equilibrium adsorption capacity of MIBK remarkably decreased with the increase in the *o*-xylene concentration, but the effect of MIBK on the adsorption capacity of *o*-xylene was small. The reason for this is that the MIBK which was adsorbed on activated carbon was easily desorbed and replaced by *o*-xylene because the adsorption affinity of MIBK is weaker than that of *o*-xylene, as can be predicted from the fact that the saturate vapor pressure of MIBK is larger than that of *o*-xylene.

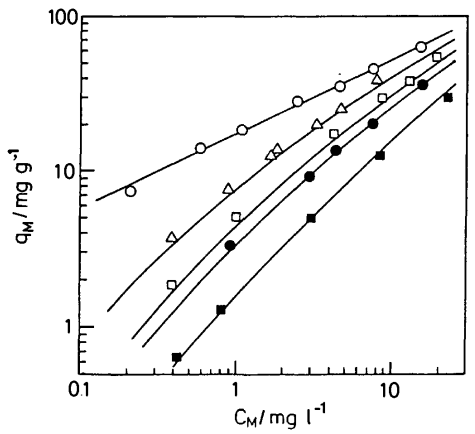

Fig. 3. Adsorption isotherm of MIBK for MIBK(M)–*o*-xylene(X) system at 200 °C. ○: *o*-xylene concentration=0.0 mg l^{-1}, △: 0.55 mg l^{-1}, □: 2.2 mg l^{-1}, ●: 3.9 mg l^{-1}, ■: 14.9 mg l^{-1}, solid line: estimated by Eq. 2 and Table 1.

As the Freundlich isotherm could be applied to the adsorption equilibrium data for the single-component system, we tried to correlate the bi-component adsorption equilibrium data using the following Freundlich isotherm empirically extended.

$$q_1=\frac{A_1C_1^{\beta_1}}{C_1^{\alpha_1}+B_1C_2^{\gamma_1}}\ ,\qquad q_2=\frac{A_2C^{\beta_2}}{C_2^{\alpha_2}+B_2C_1^{\gamma_2}} \tag{2}$$

where A_i, B_i, α_i, β_i, and γ_i (i=1, 2) are constants, and where C_1 and C_2, and q_1 and q_2 are the vapor concentrations and the equilibrium adsorption capacities of Components 1 and 2 respectively. In this paper, Component 1 is the weaker-adsorption-affinity component.

The parameters in Eq. 2 could be determined by Fritz and Schlüender's method.[5] Table 1 shows the values of these parameters for several systems. The values of A_1 and A_2, and $\beta_1-\alpha_1$ and $\beta_2-\alpha_2$, are the same as those of A and β in Eq. 1 respectively. The second term of the denominator indicates the effect of the co-adsorbed component. When the vapor concentration of one component is small, the second term is neglected and Eq. 2 is reduced to Eq. 1. We can know the relative strength of the adsorption affinity from the ratio of B_1 to B_2. Usually, B_1 is larger than B_2, for the effect of C_2 on q_1 is larger than that of C_1 on q_2, but if the adsorption affinities of both components

Table 1. Parameters of the Extended Freundlich Isotherm

	B-T		T-X		M-X	
i	1	2	1	2	1	2
α_i	0.74	0.47	0.50	1.55	0.66	0.79
β_i	1.27	0.92	0.95	1.90	1.13	1.14
γ_i	0.72	0.49	0.86	1.64	0.62	0.82
A_i	7.90	22.5	22.5	42.0	17.7	42.0
B_i	1.36	0.242	1.80	0.055	1.91	0.068

B: benzene, T: *o*-toluene, X: *o*-xylene, M: MIBK.

are almost the same, B_1 may be close to B_2. The lines estimated by means of Eq. 2 and Table 1 are also shown in Figs. 3 and 4. They were in good agreement with the experimental data.

Equations 1 and 2 are empirical equations. However, as the form of these equations are simple, they can be used to estimate the thermal desorption efficiencies of organic solvents from activated carbon. These equations should thus prove useful in future investigations.

(Received July 3, 1989)

Synopsis. Nematic polyitaconates having 4-methoxyazobenzene moieties as mesogen in the side chain were prepared. Thermal properties, polymer composition, and the photoinduced configuration change have been examined to suggest a possible use of the polymers for photosensitive liquid-crystalline materials.

During the last decade, the side chain type of liquid crystalline polymers (LCPs) have been widely investigated on their chemical and physical properties as well as potential application. In these polymers, the mesogenic groups examined were flexible polysiloxanes[1] and different types of vinyl backbone such as polyacrylates,[2,3] polymethacrylates,[2,4] and polyitaconates.[5] In the course of our study on thermotropic behavior and potential uses of LCPs,[6-8] nematic polyitaconates, poly[ethyl ω-[4-(4-methoxyphenylazo)phenoxy]alkyl itaconate]s, Poly**2**, were prepared and their configuration changes were photochemically studied.

Experimental

4-[4-(ω-Hydroxyalkoxy)phenylazo]anisole, **1**: 4-[4-(6-hydroxyhexyloxy)phenylazo]anisole, **1a**, and 4-[4-(11-hydroxyundecyloxy)phenylazo]anisole, **1b** were prepared from the *O*-alkylation of 4-(4-hydroxyphenylazo)anisole with ω-halo-1-alkanol in the presence of KOH and KI according to the method used in the preparation of 4-(ω-hydroxyalkoxy)-benzoic acids.[9]

1a (n=6): 51.0% yield; mp 122—123 °C; ^{1}H NMR ($CDCl_3$) δ=1.13—1.30 (t, J=4 Hz, 3H, -CH$_3$), 1.43—2.17 (m, 8H, HOCH$_2$(CH$_2$)$_4$CH$_2$O-), 3.79 (s, 3H, -OCH$_3$), 3.22—4.15 (m, 4H, HOCH$_2$(CH$_2$)$_4$CH$_2$O-), and 6.55—7.97,(m, 8H, aromatic).

1b (n=11): 65.1% yield; mp 86—87 °C; ^{1}H NMR ($CDCl_3$) δ=1.27—2.28 (m, 18H, HOCH$_2$ (CH$_2$)$_9$CH$_2$O-), 3.42 (s, 3H, -OCH$_3$), 3.68—4.51 (m, 4H, HOCH$_2$ (CH$_2$)$_9$CH$_2$O-), and 7.37—8.66 (m, 8H, aromatic).

Ethyl 3-chloroformyl-3-butenoate: Ethyl 3-chloroformyl-3-butenoate from ethyl 3-carboxy-3-butenoate and thionyl chloride. 85% yield; bp 86—86.5 °C/8 mmHg (1 mmHg≈ 133.322 Pa).

Ethyl ω-[4-(4-methoxyphenylazo)phenoxy]alkyl itaconate, **2**: 0.05 mol of **1** was dissolved in 300 mL of chloroform and 0.10 mol of triethylamine. Then a trace of 1,4-benzoquinone was added with stirring and cooling at 0 °C, and a 0.10 mol portion of ethyl 3-chloroformyl-3-butenoate was dropped into the solution. After stirring for 4 h at 60 °C, ca. 200 mL of water was added to the reaction mixture. The chloroform layer was then washed with water and evaporated to dryness, and the residual solid was recrystallized from ethanol.

4-Ethyl 1-[6-[4-(4-methoxyphenylazo)phenoxy]hexyl] 2-methylenesuccinate, **2a** (n=6): 60.2% yield; mp 82 °C; ^{1}H NMR ($CDCl_3$) δ=1.13—1.30 (t, 3H, J=4 Hz, -CH$_3$), 1.43—2.17 (m, 8H, -OCH$_2$(CH$_2$)$_4$CH$_2$O-), 4.00 (s, 3H, -OCH$_3$), 4.10—4.28 (q, 2H, -CH$_2$-), 4.28—4.64 (m, 4H, -OCH$_2$(CH$_2$)$_4$CH$_2$O-), 5.87—6.06 (m, 1H, H-CH=), 6.55—6.74 (m, 1H, H-CH=), and 7.16—8.52 (m, 8H, aromatic).

Found: C, 67.10; H, 6.23; N, 5.98%. Calcd for $C_{24}H_{30}O_6N_2$: C, 66.94; H, 6.48; N, 6.00%.

4-Ethyl 1-[6-[4-(4-methoxyphenylazo)phenoxy]undecyl] 2-methylenesuccinate, **2b** (n=11): 59.4% yield; mp 64 °C; ^{1}H NMR ($CDCl_3$) δ=0.94—2.11 (m, 18H, -OCH$_2$(CH$_2$)$_9$-CH$_2$O-), 3.25 (s, 2H, -CH$_2$-), 3.78 (s, 3H, -OCH$_3$), 3.79—4.34 (m, 6H, -OCH$_2$(CH$_2$)$_9$CH$_2$-, -CH$_2$-), 5.46—5.61 (m, 1H, H-CH=), 6.06—6.24 (m, 1H, H-CH=), and 6.63—7.84 (m, 8H, aromatic).

Found: C, 70.09; H, 6.35; N, 5.32%. Calcd for $C_{31}H_{40}O_6N_2$: C, 70.31; H, 6.28; N, 5.29%.

Polymerization: The polymerization procedure was the same as that described by Sugiyama.[10] Polymers were reprecipitated twice from benzene and methanol. The copolymerization products from monomer **2** and styrene were analyzed by ^{1}H NMR for the phenyl protons of monomer **2** and styrene. The intrinsic viscosity (dL·g^{-1}) of the polymer was determined in benzene at 30 °C by a Ubbelohde viscometer.

Measurements: The phase-transition temperature was determined by means of differential scanning calorimeter, using a Rigaku Thermoflex DSC 8230B. Microscopic observation was performed by an Olympus microscope with temperature controlling heating stage. The cis-trans isomerization of polymers was carried out as follows: a known amount of the polyitaconate in THF was put in a quartz tube, which was placed on a merry-go-round Rayonet photochemical reactor Model-RMA-400 equipped with 4 RPR-253.7 nm lamps. The distance between the tube and lamps was 10 cm. After irradiating the sample for a given time, an aliquot of the solution was taken for UV measurement by a Shimadzu UV 200S spectrophotometer.

Results and Discussion

Thermal Properites: Monomers **2** are yellow crystals and showed no mesophase. It was found that monomer **2** can polymerize by a free radical reaction to give homopolymers, [Poly**2**] with low intrinsic viscosity as shown in Scheme 1. Poly**2** with various intrinsic viscosity values were prepared by changing the polymerization conditions. All of Poly**2** turned into mesophase, which showed the Schlieren texture and were confirmed to be a nematic phase by observation and polarization microscopy of thin samples. The phase-

a) Polymerized with 2,2′-azobisisobutyronitorile (AIBN) in benzene (1g of **1a**/2 mL of benzene) at 60 °C for 24 h. b) Polymerized with 1,1′-azobis(cyclohexanecarbonitrile)(ACN) in bulk at 100 °C for 7 days. c) Measured in benzene at 30 °C. d) Determined by means of DSC thermogram on heating cycle (rate, 5 K·min^{-1}).

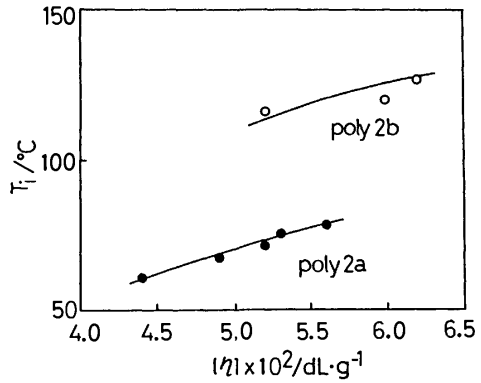

Fig. 1. Relationship between T_i and $[\eta]$ for Poly **2a**.

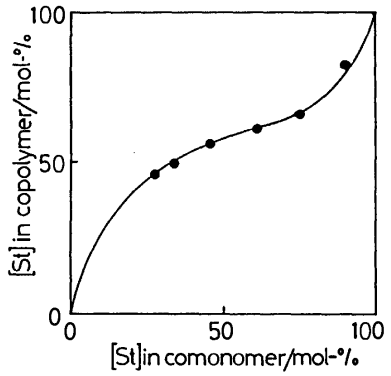

Fig. 2. Composition curve for the polymerization of the monomer **2a** (M_1) and styrene (M_2).

transition temperature determined by DSC was in good agreement with that obtained from the polarization microscopic measurement. The results are listed in Table 1. From the data in Table 1, it can be seen that the phase transition temperature of Poly**2** is influenced by the length of methylene spacer groups as well as intrinsic viscotiy of the polymer. Figure 1 shows the dependence of isotropization temperature (T_i) on intrinsic viscosity of Poly**2**. T_i values of both Poly**2a** and Poly**2b** increase gradually with the increase of intrinsic viscosity values. In general, the phase behavior of LCPs depends on their molecular weight and this influence is strong for low molecular weight,[9,11] for instance, T_i values of liquid crystalline polyacrylates increase with the increase in $[\eta]$ below 0.1.[12]

Copolymerization: Since monomer **2** showed low polymerization reactivity, monomer **2a** (M_1) was radically copolymerized with styrene (M_2) in order to know the monomer reactivity ratio of monomer **2**. Figure 2 shows the composition curves for the copolymerization of monomer **2a** with styrene initiated by AIBN in benzene at 60 °C. Applying the data in Fig. 2 to the curve-fitting method,[13] r_1 and r_2 were calculated to be 0.11 and 0.44, respectively. Monomer **2a** was then found to copolymerize alternatively with styrene. Sato et al.[14] reported that r_1=0.36 and r_2=0.40 for the copolymerization of methyl phenethyl itaconate (4-methyl 1-phenethyl 2-methylenesuccinate) (M_1) and styrene (M_2). The r_1 of monomer **2a** is smaller than that of methyl phenethyl itaconate. This is explained by the bulkiness of mesogenic group in monomer **2a**. From either DSC or polarization microscopic measurements, none of the copolymers exhibited liquid crystalline behavior.

Cis-Trans Isomerization: The photoinduced configuration change due to a cis-trans isomerization of the chromophore such as azobenzene is known to control the permeation of water, ion, etc. through the membrane.[15,16] The configuration change of Poly**2** was photochemically studied for the purpose of applying the polymer to practical separation. The progressive spectral change for Poly**2a** due to the isomerization from *trans*- to *cis*-azobenzene was observed during the irradiation of 253.7 nm light. From a decline of the absorption of trans-azobenzene chromophore (λ_{max}=365 nm) in THF, the first-order rate constant was, estimated to be 0.021 s^{-1} according to the method described by Sugiyama et al.[17] These nematic polyitaconates will have the possibility of use for a photoresponsive membrane material.

Electrical Conduction in Some Ternary Metallo-Organic Solid Complexes of Biological Importance and Compensation Effect

Biswanath MALLIK
Department of Spectroscopy, Indian Association for the Cultivation of Science, Jadavpur, Calcutta: 700032, India
(Received March 13, 1989)

Synopsis. The electrical conduction in some ternary solid complexes of Cu(II) with 2,2′-bipyridyl/1,10-phenanthroline and several amino acids (e.g., α-alanine, leucine, tryptophan, glycine, and norvaline) is studied as a function of temperature. These materials show semiconductivity. Results suggest that true compensation effect is valid for most of the materials studied. Importance of characteristic temperature (T_o) in biological process is pointed out.

Investigations on the electrical conduction properties in biologically important solid materials may bring significant contribution[1,2] to the field of 'bioenergetics'. In general, ternary complexes (mixed ligand complexes) of different metal ions play an important role in biolgical system.[3,4] Copper is one of the essential trace elements[3] present in living organism and in general copper exists in complexed form either with small molecules like amino acids or with macromolecules such as proteins. Several ternary complexes of Cu(II) containing amino acids have been detected recently in human serum.[5-7] The ternary complexes of Cu(II) formed by the interaction of one amino acid and a nonionized ligand like 2,2′-bipyridyl, 1,10-phenanthroline are typical examples[8-11] of such complexes present in biological systems.[3] Such complexes are expected to take part actively in the biological process[12] involving (i) electron transport and (ii) dioxygen transport and metabolism. In spite of the importance of metallo-organic complexes in biological process scant attention has been paid to the measurment of their electrical properties. Therefore, it was though worthwhile to study the electrical properties of some ternary solid metallo-organic complexes. This present paper concerns the validity of compensation rule[13-15] in the electrical conduction process in some ternary solid complexes of Cu(II) with 2,2′-bipyridyl/1,10-phenanthroline and amino acids.

In case of some organic semiconductors as reported[13-15] earlier the different values of activation energy (E) obtained by adsorption of vapors on semiconductor powders and the specific conductivity $\sigma(T)$ at a temperature T are related by the three constant expression

$$\sigma(T)=\sigma_o' \exp(E/2kT_o)\exp(-E/2kT) \quad (1)$$

where k is the Boltzmann constant and the parameters σ_o' and T_o are constants for a particular semiconductor. Thus, the pre-exponential factor σ_o in the usual semiconduction expression

$$\sigma(T)=\sigma_o \exp(-E/2kT) \quad (2)$$

is related to the activation energy (E) by the expression

$$\sigma_o=\sigma_o' \exp(E/2kT_o) \quad (3)$$

As evidenced from expression (3), $\log\sigma_o$ is linearly related to E which is known as compensation effect (or rule). The origin of this effect and the physical significance of T_o is not yet clear. In this paper it is shown that the true compensation effect is valid for some ternary complexes of Cu(II) containing amino acids. The origin of this effect in this case and the possible role of T_o in biological system are discussed.

Experimental

The ternary metallo-organic solid complexes used in this investigation are of the type [Cu(II)·A.L]Cl·H_2O where A represents 2,2′-bipyridyl/1,10-phenanthroline and LH=α-alanine, leucine, tryptophan, glycine, and norvaline. These complexes were synthesized and characterized by usual procedure.[10,11] The reagent chemicals used were of AR or GR quality (E.Merck, BDH, LOBA). This synthesis work was carried out by Prof. M. C. Saxena and his co-workers in the Deptt. of Chemistry, Dr. H. S. Gour University, Sagar: 470003, India. These samples were dried under vacuum before use. The finely powdered sample pressed in a sandwich cell[13,16] between a conducting glass and a stainless steel electrode at moderate pressure by spring clips. The separation between the electrodes was maintained by a two mil (1 mil=0.00254 cm) thick Teflon spacer. The sample cell was then placed in a suitably designed conductivity chamber[13,16] made of brass and fashioned with Teflon. A dc voltage of 27 volts from a dry battery pack was applied across the sample cell. The dark conductivity was measured in vacuum [10^{-3} Torr (1 Torr=133.322 Pa)] using an electrometer, model no. 617, of Keithley Inst. Inc., U.S.A. The thermo emf was measured by a digital panel meter, model no. HIL: 2301, India. Details of the experimental arrangement is similar to that described earlier.[13,16]

Results and Discussion

The electrical conductivity of the materials under investigation was studied in the temperature range 298 K to 345 K. In all the cases an increase in conductivity with increasing temperature was observed which indicates that these materials behave like semiconductors. Each measurement was repeated several times in vacuum. All the measurements gave consistent results. The $\log\sigma$ vs. $1/T$ plots for some complexes under study are shown in Fig. 1. It is seen that all the linear plots intersect the ordinate at wide variety of positions but all they meet at a point of intersection corresponding to a fixed tempereture (307 K) showing that the conductivity at this temperature is same for all these meterials. The linear plots for the complexes containing (bipy·α-ala) and (1,10-phen·leu) are not included in Fig. 1 as the corresponding linear plots do not pass through the common point of intersection.

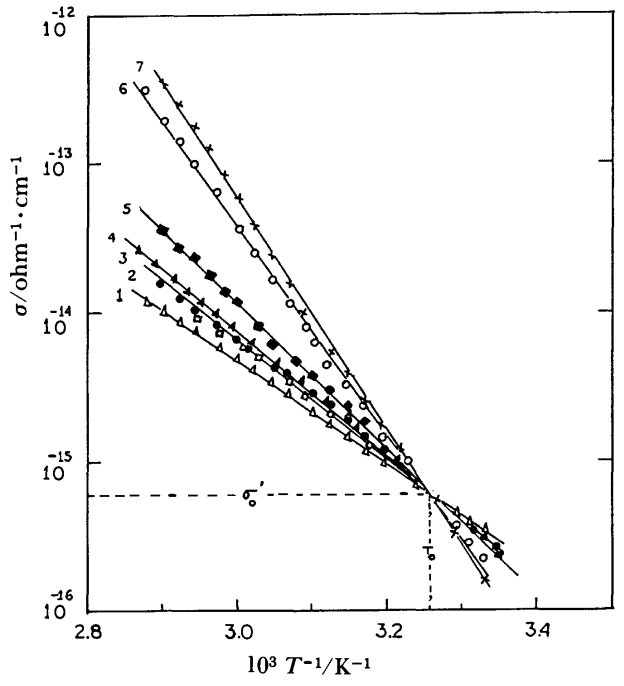

Fig. 1. Plot of $\log\sigma$ value vs. $1/T$ for some ternary solid complexes†† of Cu(II) with 2,2′-bipyridyl/1,10-phenanthroline and several amino acids.
The line (1) for [Cu(II)·1,10-phen·ala]Cl·H_2O [—△—]; (2) for [Cu(II)·bipy·trp]Cl·H_2O [—□—]-this almost overlaps with (3); (3) for [Cu(II)·bipy·leu]Cl·H_2O [—●—]; (4) for [Cu(II)·bipy·norval]Cl·H_2O [—▲—]; (5) for [Cu(II)·1,10-phen·trp]Cl·H_2O [—■—]; (6) for [Cu(II)·1,10-phen·gly]Cl·H_2O [—○—]; and (7) for [Cu(II)·bipy·gly]Cl·H_2O [—×—].
These lines were fitted by the method of least squares. For each linear plot at least 20 data points were considered. To avoid overcrowding of data points (particularly near T_o) only few representative data points are shown for each complex.
The value of T_o=307 K; $\sigma_o'=6.2\times10^{-16}$ $(\Omega\cdot cm)^{-1}$.
††Standard abbreviations used.

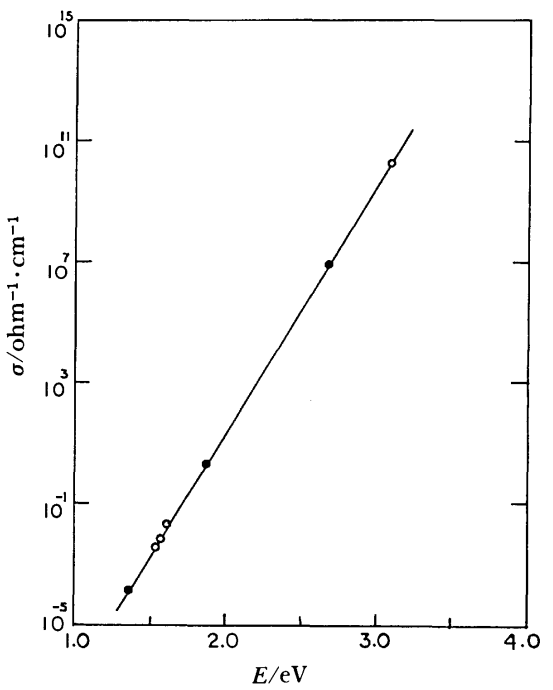

Fig. 2. Plot of $\log\sigma_o$ value vs. E for some ternary solid complexes of Cu(II) with 2,2′-bipyridyl/1,10-phenanthroline and several amino acids.
—○— for complexes with 2,2′-bipyridyl and amino acids; —●— for complexes with 1,10-phenanthroline and amino acids. Value of T_o=307 K; $\sigma_o'=7.55\times10^{-16}$ $(\Omega\cdot cm)^{-1}$.

The reason for this anomally is discussed latter on. The values of E and measured values of σ_o for the complexes are shown in Table 1. The temperature where all the materials show equal conductivity, $\sigma(T_o)$, is known as characteristic or compensation temperature (T_o). The value of σ at T_o gives σ_o' value. The values of T_o and σ_o' obtained from the $\log\sigma$ vs. $1/T$ plots are 307 K and 6.2×10^{-16} $(\Omega\cdot cm)^{-1}$ respectively. To test the validity of compensation effect $\log\sigma_o$ was plotted against E and a linear plot as expected from expression (3) is shown in Fig. 2.

The compensation effect is thought[17] to arise from the existence of a linear relationship between the activation energy and activation entropy of the system. It has been pointed out by Johnston and Lyons[17] that if a true linear free energy relationship (LFER) does hold for a dark conduction process a definite point of intersection for the Arrhenius plots of the experimental data must exist as we have observed in Fig. 1. In the experiment of Johnston and Lyons[17] the $\log\sigma_o$ vs. E plot was linear, but a very poor correlation between $\log\sigma$ and E was observed in one component crystal of anthracene by changing its purity and doping with tetracene. On the basis of that experimental results it was concluded that a simple linear relation between $\log\sigma_o$ and E is not sufficient for judging the validity of compensation effect. However, in the present case it is clearly seen that the true compensation effect is valid.

There are number of theses (models) as mentioned in earlier communications[13,14] about the mechanism

Table 1. The Values of E and σ_o for Some Ternary Solid Complexes[a] of Cu(II) with 2,2′-Bipyridyl/1,10-Phenanthroline and Several Amino Acids

Complexes studied	E / eV	Measured value of $\sigma_o/\Omega^{-1}\cdot cm^{-1}$
[Cu(II)·bipy·leu]Cl·H_2O	1.53	3.54×10^{-3}
[Cu(II)·bipy·trp]Cl·H_2O	1.57	6.41×10^{-3}
[Cu(II)·bipy·norval]Cl·H_2O	1.61	1.64×10^{-2}
[Cu(II)·bipy·ala]Cl·H_2O[b]	1.63	4.25×10^{-2}
[Cu(II)·bipy·gly]Cl·H_2O	3.07	1.71×10^{10}

[Cu(II)·1,10-phen·gly]Cl·H_2O	2.66	7.72×10^{6}

a) Standard abbreviations used. b) Compensation effecct is not valid for this complex.
(The samples are arranged separately for each primary ligand in order of increasing E-value).

of conduction in organic semiconductors leading to compensation effect. The applicability of different models has already been discussed.[13,14] A models depending on the interaction between the electrons and the vibrational motion[18] of the molecules appears suitable[13] to give a possible mechanism behind such compensation effect in case of some polyene[13,14] and nitroaromatic[15] semiconductors.

It has been reported by Sigel et al.[19] that the ternary metal complexes under investigation exist predominantly in a 'folded form'. Similar to common biopolymers (peptides, proteins, DNA), these complexes posses defined conformation[20] in their normal state. In the normal condition each atom performs thermally excited movements around its mean position. Also several energetically similar positions may be occupied by the same groups with comparable probability. Any change of external parameters such as temperature, pressure, electric field etc. will influence this dynamics and flexibility of the structure which may lead to changes[20] of conformations. The particular electronic properties of a complex in its normal state will obviously change with the change in its precise conformation. A change in electronic state (as involved in transport) gives rise to an activation entropy[18] because of a change in vibrational frequencies associated with the conformatinal changs. Each compound possesses a definite value of activation entropy arising from the temperature-dependent conformational changes in the temperature range under consideration. The variation in both the electronic energy gap (E_g) and activation entropy (S) can account for compensation effect if the changes in these parameters are given by[18]

$$E_g = E_{g_o} + nE_{g_1} \text{ and } S = S_o + nS_1$$

where n is a definite number for each compound and E_{g_o}, E_{g_1}, S_o, and S_1 are same for all the compounds. In this case the characteristic temperature is given by

$$T_o = E_{g_1}/(2S_1).$$

Unfortunately due to the fact that the nature of these complexes is not precisely known at present, the activation entropy S (hence S_1) is a relatively obscure quantity and any quantitative estimate of T_o could not be done.

The compensation behavior depends on the molecular property[13-15] of the complexes/materials involved and T_o plays an important role in dark conduction process. Though attempts have been made to understand the compensation behavior as mentioned in the earlier communications,[13,14] the factors on which the value of T_o depends is not yet clear. It should be mentioned here that compensation effect is not valid for the ternary complexes of Cu(II) with 2,2′-bipyridyl and alanine; and 1,10-phenanthroline and leucine ligands possibly due to different types of conformational changes in these complexes on thermal agitation. Such anomaly has also been observed[15] previously in some nitroaromatics on adsorption of several vapors related to an experiment on compensation effect.

The observed value of T_o in most of the reported data is either much higher[13] or lower[14,15] than physiological tempereture. It is interesting to note that the characteristic tempereture for the materials under investigation is near the physiological temperature. Since at this temperature (T_o) the collective electronic properties of these materials are significantly changed, the presence of these materials in a biological system may have some important role in the biological processes involving transfer of electrons (charges) near physiological temperature. Investigation with complexes containing other amino acids as well as other metal ions could be of much interest but unfortunately such experiment could not be performed as the materials were not available at this moment.

The author is thankful to Prof. M. C. Saxena, Department of Chemistry, Dr. H. S. Grour University, Sagar: 470003, India for a generous gift of these ternary Cu(II) solid complexes. Thanks are also due to Prof. T. N. Misra of this department for his constant encouragement.

On the Existence of $NaC_2O_4^-$ Ion Pair Complex

Raj Pal SINGH
Central Analytical and Materials Characterization Laboratories, Metrology Standards and Meterial Division, The Research Institute, King Fahd University of Petroleum and Minerals, Dhahran 31261, Saudi Arabia
(Received March 6, 1989)

Synopsis. Existence of $NaCO_4^-$ ion pair complex formation in solutions has been further documented through the solubility measurements of calcium oxalate monohydrate in sodium chloride, magnesium chloride, and mixtures of sodium and magnesium chlorides.

In a recent publication Berland et al.[1] have argued against the existence of alkali metal oxalate ion pair complexes, such as $NaC_2O_4^-$, in urine. However, the evidence for the nonexistence of such ion pairs, presented by them does not seem to be appropriate since using Hammarsten's data[2] of calcium oxalate monohydrate (COM) solubility in sodium chloride, Finlayson et al.[3,4] have computed a value of about 13 $dm^3 mol^{-1}$ as the stability constant of $NaC_2O_4^-$ ion pair. Further, regarding the conductivity measurements on sodium oxalate solutions, indeed 17% of the oxalate will be bound in a 30 mmol dm^{-3} sodium oxalate solution but only 8.5% of the total sodium ion will participate in the complexation. Since $NaC_2O_4^-$ is also charged, the overall decrease in the equivalent conductivity will be 8.5%. The decrease in equivalent conductivity at lower sodium oxalate concentrations, however, would be even smaller and that might be the reason why a substantial change between measured and calculated conductivity values was not observed.

The existence of alkali metal oxalate ion pair complexes in solutions has also been reported in the literature by other workers. For example, Daniele et al.[5] have used potentiometric titration method to determine the stability constants of sodium and potassium oxalate complexes and found a value of about 10 $dm^3 mol^{-1}$ for $NaC_2O_4^-$ and 9 $dm^3 mol^{-1}$ for $KC_2O_4^-$ at 37 °C. An spectral evidence for the existence of $LiC_2O_4^-$, $KC_2O_4^-$, and $CsC_2O_4^-$ ion pairs has been presented by Kanamori et al.[6] after measuring the Raman spectra of aqueous solutions of lithium, potassium, and caesium oxalates.

Because of high concentrations of sodium and potassium ions in urine, correction for $NaC_2O_4^-$ and $KC_2O_4^-$ ion pairs will be important in the computation of urine supersaturation with respect to COM.[7] This reference has further clarified the presence of such ion pairs in urine snd synthetic solutions containing alkali metals and oxalate.

Experimental

Reagent grade calcium chloride dihydrate, magnesium chloride hexahydrate, and sodium chloride (Merck and B. D. H. Chemical companies) were used. Solutions were prepared using doubly distilled, deionized water (Nanopure II) and standardized by analyzing for chloride with Mettler's Memotitrator system (Model DL-40RC). Standard solution of oxalate at 1000 mg dm^{-3} was made from analytical grade oxalic acid purchased from Baker Chemical Co. Calcium oxalate monohydrate used for solubility measurements was received in powdered form from B. D. H. Chemical Co.

Solubility measurements were carried out by equilibrating approximately 20 mg of COM in 20 cm^3 solulion maintained at 37 °C for over 50 h, to ensure complete equilibrium. After that, samples were filtered and diluted immediately to prevent from any precipitation which could result due to the attainment of supersaturation with respect to COM at lower temperature. Diluted solutions were then analyzed for calcium and oxalate using ion chromatography, and solubility was reported as the mean of four determinations.

Ion-chromatographic measurements were made on a Dionex ion chromatograph model 2120i fitted with conductivity detector. The separation of oxalate was achieved on a Dionex AG4 guard column and an AS4 separator. Calcium was analyzed on a Dionex CS1 separator and a CG1 guard column using a mixture of 0.0025 mol dm^{-3} ethylenediamine and 0.005 mol dm^{-3} hydrochloric acid. The eluent for anion chromatography consisted of a mixture of 0.003 mol dm^{-3} sodium hydrogen carbonate and 0.0024 mol dm^{-3} sodium carbonate. The flow rate in both instances was maintained at 2.0 $cm^3 min^{-1}$. Peak heights were integrated on a Dionex 4217 integrator.

The concentrations of different ionic species in the equilibrated COM solutions were calculated from mass balance and electroneutrality expressions.[8] The corrections for $CaC_2O_4^0$ and $NaC_2O_4^-$ ion pairs when needed, were made by using their respective stability constant values of 2746 $dm^3 mol^{-1}$ [3,4] and 13.2 $dm^3 mol^{-1}$.[3,4] Since the Debye-Hückel equation is inaccurate at high ionic strengths, well adopted extended form of the Debye-Hückel equation[9-11] as proposed by Davies,[12] was used to calculate the activity coefficients at high ionic strengths.

Results and Discussion

The results of solubility of COM in water and different concentrations of sodium chloride are summarized in Table 1. The mean solubility product, $(3.347\pm0.18)\times10^{-9}$ $mol^2 dm^{-6}$, obtained from the solu-

Table 1. Results of Solubility Determinations of COM in Water and Sodium Chloride Solutions at 37 °C

NaCl / mol dm^{-3}	Solubility $Ca^{2+}=C_2O_4^{2-}$ / 10^{-4} mol dm^{-3}	K_{sp}[a] / 10^{-9} $mol^2 dm^{-6}$	K_{so}[b] / 10^{-9} $mol^2 dm^{-6}$
0.00	0.564±0.010	2.18	2.18
0.05	1.364±0.015	3.39	2.20
0.10	1.610±0.020	3.15	2.18
0.15	1.890±0.025	3.50	2.18

a) K_{sp}=Solubility product of COM corrected for ionic strength and $CaC_2O_4^0$ ion pair. b) K_{so}=Thermodynamic solubility product of COM corrected for ionic strength and, $NaC_2O_4^-$ and $CaC_2O_4^0$ ion pairs.

bility values at three different sodium chloride concentrations after $CaC_2O_4^0$ ion pair and ionic strength correction is in good agreement with the value, $(3.289\pm0.03)\times10^{-9}$ mol^2 dm^{-6}, computed by Berland et al.[1] from Hammarsten's data. However, as can be seen from the last column of Table 1, both of the above values are about 50% higher than the corresponding thermodynamic solubility product, K_{so}. The K_{so} was calculated from the solubility of COM in water and sodium chloride solutions following the corrections of both $CaC_2O_4^0$ and $NaC_2O_4^-$ ion pairs, and ionic strength. The marked difference in K_{sp} and K_{so} values (the latter is a constant at a given temperature) clearly emphasizes the importance of taking into account $NaC_2O_4^-$ ion pair correction when calculating the thermodynamic solubilily product from COM solubility in sodium chloride solutions. The mean K_{so}, $(2.185\pm0.01)\times10^{-9}$ mol^{2}dm^{-6}, thus obtained from the solubility results in Table 1, compared well with 2.244×10^{-9} mol^{2}dm^{-6}, the value computed by Finlayson and co-workers from Hammarsten's data of COM solubility in water.[3,4]

Table 2 contains the results of COM solubility in different magnesium chloride solutions, and in the mixtures of magnesium chloride and 0.15 mol dm^{-3} sodium chloride. Magnesium concentrations were kept the same in both instances. The stability constants of $MgC_2O_4^0$ ion pair were calculated from different solubility values and reported in the last two columns of the Table 2. Closely similar values of stability constants (K_1) were obtained from the solubilities of COM in pure magnesium chloride solutions with a mean value of 4037 ± 138 dm^3 mol^{-1}, following $CaC_2O_4^0$ ion pair and ionic strength correction. The mean value of K_1 at 2446 ± 129 dm^3 mol^{-1} obtained from the COM solubilities in the mixtures of magnesium and sodium chlorides after ionic strength and, only $CaC_2O_4^0$ ion pair correction, was found to be approximately 40% lower then the above mentioned value. However, after additional correction of $NaC_2O_4^-$ ion pair, the mean K_1 at 2446 ± 129 dm^3 mol^{-1} changed to 4001 ± 189 dm^3 mol^{-1} (reported as K_2 in the last column of Table 2) and compared excellently well ($p>0.25$) with 4037 ± 138 dm^3 mol^{-1}. A value of approximately 4000 dm^3 mol^{-1} for the stability constant of $MgC_2O_4^0$ ion pair has also been reported by other workers using different methods.[13,14]

In conclusion, the existence of $NaC_2O_4^-$ ion pair in solulion containing sodium and oxalate ions (Tables 1 and 2) has been further confirmed from the results of COM solubility measurements. Direct observations, obtained from Raman spectroscopy by Kanamori et al.,[6] together with the results of potentiometry[5] and COM solubility measurements in different media, all indicated the existence of $NaC_2O_4^-$ or $KC_2O_4^-$ ion pairs in urine or synthetic solutions containing sodium/potassium and oxalate ions. In the light of above it is, therefore, suggested that the correction for these ion pairs should be made when calculating the supersaturation of calcium oxalate phases in synthetic solutions, containing alkali metal and oxalate ions, and urine.

The support of the research Institute, King Fahd University of Petroleum and Minerals and permission to publish the results is greatly appreciated.

A New Crystalline Form of Bis(1,2-diphenyl-1,2-ethenedithiolato)nickel: Asymmetric β-Ni(dpedt)2

Michel MEGNAMISI-BELOMBE* and Bernhard NUBER†
Department of Inorganic Chemistry, Faculty of Science, P.O. Box 812,

†Anorganisch-Chemisches Institut der Universität, Im Neuenheimer Feld 270,
D-6900 Heidelberg 1, West Germany
(Received March 24, 1989)

Synopsis. The full structure of a new crystalline form of bis(1,2-diphenyl-1,2-ethenedithiolato)nickel, β-Ni(dpedt)$_2$, has been determined by single crystal X-ray diffraction at room temperature. The structure was refined by full matrix least-squares to a final R_w=0.038. Comparison of this triclinic ($P\bar{1}$) structure with the monoclinic ($P2_1/n$) α-form established previously reveals that the difference between the two structures is basically due to a different conformation of the phenyl rings, which gives rise to *dissymmetry* in β-Ni(dpedt)$_2$.

Since the discovery of Ni(dpedt)$_2$,[1] bis-dithiolato complexes of transition metals have attracted a great deal of scientific interest in inorganic chemistry. Synthetic and experimental findings[2] as well as structural systematics[3,4] of these materials have been reviewed, and an extensive theoretical treatment has been presented.[5] We recently introduced a new concept[6] for preparing a wide range of stacking solids made up of alternated square planar sulfur (S)-containing, and square planar nitrogen (N)-containing complexes. In an attempt to fabricate solids of this type, we have employed, on the one hand, α-Ni(dpedt)$_2$[3] as the S-containing component and, on the other hand, either bis(1,2-diphenylethanedione dioximato)cobalt(II), Co(dpg)$_2$, or bis(butanedione dioximato)copper(II), Cu(dmg)$_2$, as the N-containing components. Although we failed to produce the desirable stacking materials with so-called pseudo-(SN)$_x$ bundle-structure,[6] we interestingly obtained, in both cases, the novel asymmetric β-Ni(dpedt)$_2$, which may be regarded as a potentially versatile optically active solid system. We therefore have determined its full structure and have compared it with the previously known α-modification,[3] as we report in the following.

Experimental

Material Preparation. Single crystals of β-Ni(dpedt)$_2$ were obtained in two different preparations. In a first preparation, analytical grade Co(dpg)$_2$ (100 mg) was dissolved in a mixture of warm methyl cyanide and chloroform (50 ml+50 ml) and filtered (brown solution). Analytical grade α-Ni(dpedt)$_2$[1,3] (100 mg) was dissolved similarly and filtered (blue-green solution). The two solutions were mixed together and refluxed for 15—20 min. The mixture was filtered warm, and the dark-green filtrate was left to concentrate by slow evaporation at ca. 40 °C. When the solvent volume was reduced to 150 ml, shiny long crystals appeared. They grew larger as concentration of the solution progressed until the volume was reduced to about 50 ml. The long black crystals were separated by filtration, washed with some 100 ml of high purity diethyl ether (sparingly soluble with green color). The yield was 70 mg of slightly dichroic prisms. The density determined by flotation in a mixture of dibromomethane and 1,3,5-trimethylbenzene was D_m=1.44 Mg m^{-3}. The second preparation was carried out in a closely similar manner by using analytical grade Cu(dmg)$_2$ (30 mg) dissolved in warm chloroform (40 ml), and α-Ni(dpedt)$_2$ (55 mg) dissolved in chloroform (40 ml).

Table 1. Experimental and Computational Details

Crystal shape	Prismatic
Crystal size /mm^3	0.2×0.3×0.3
Possible indep. reflections	3878
Reflections observed $I>2.5\sigma(I)$	3256
Reflections for ψ-scans	6
2θ range /°	3—60
Min. transmission (max.=1)	0.90
μ(Mo $K\alpha$)/mm^{-1}	1.094
R_{int} (from merging)	0.014
parameters for least-squares	250
R_w, R	0.038, 0.044
Goodness-of-fit	2.59
Max. shift/error	0.07
Extremes in diff. Fourier/e Å^{-3}	+0.28, −0.32

Structure Determination. A suitable crystal from each batch was analyzed independently by X-ray diffraction at room temperature. Crystal data were collected on a Siemens-Stoe AED 2, or on a Syntex R3, four-circle automatic diffractometer equipped with graphite-monochromated Mo $K\alpha$ radiation (λ=0.7107 Å).

Crystal Data. Virtually identical data were obtained for both batches of crystals. $C_{28}H_{20}NiS_4$, M_r=543.4, triclinic, space group $P\bar{1}$, a=10.135 (2) Å, b=10.212 (1) Å, c=12.631 (1) Å; α=79.53 (3)°, β=89.08 (3)°, γ=82.02 (3)°; V=1273.02 Å^3; Z=2; D_c=1.42 Mg m^{-3}, D_m=1.44 Mg m^{-3}.

Table 1 summarises further experimental and computational details. The structure was solved by the Patterson methods and completed by Fourier syntheses. It was refined by full matrix least-squares, based on F with weight $w=\sigma(|F|)^{-2}$. The phenyl rings were refined as rigid groups. The calculations were carried out on an Eclipse S140 computer with SHELXTL program[7] which uses scattering factors from "International Tables",[8] and takes anomalous dispersion into account.[9] The final refinement with anisotropic thermal parameters for non-hydrogen atoms, and isotropic parameters for hydrogen atoms yielded R (R_w)=0.044 (0.038). An empirical absorption correction (μ(Mo $K\alpha$)=1.094 mm^{-1}) was applied using ψ-scans of 6 reflections (8<2θ<43°).

Results and Discussion

The purpose of this note is to highlight the structural divergence that exists between the two phases of

the same chemical compound, Ni(dpedt)$_2$. Final atomic coordinates with their equivalent isotropic thermal parameters for the β-phase elucidated here are listed in Table 2. Figure 1 displays a molecular view of this phase with atom labeling scheme. For both crystalline forms, such a molecular entity consists of two specific structural cores, namely, the chelate plane NiS_4C_4 (comprising the four non-benzenic C atoms), and the four phenyl rings. Comparison of these molecular spheres between the two modifications reveals rather nicely matching values in terms of corresponding bond distances and angles. For the β-phase, the following bond lengths are observed: Ni-S 2.120—2.127 (1) Å; C=C 1.404—1.424 (6) Å; S-C 1.695—1.701 (4) Å; C-C_{Ph} 1.474—1.488 (5) Å; average $(C\text{-}C)_{Ph}$ 1.395 (0) Å; the following angles are measured: S1-Ni-S3 91.1 (1)° S1-Ni-S4 88.0 (1)° S2-Ni-S4 91.3 (1)° S2-Ni-S3 89.5 (1)° C-S-Ni 105.9—106.1 (2)° S-C=C 117.9—118.9 (3)°.

Angles between selected planes for the β-phase are listed in Table 3. By comparison with the previously established α-phase,[3] it is seen that the basic difference between the two structural modifications arises as a result of different conformations of the phenyl groups.

Table 2. Final Atomic Coordinates ($\times 10^5$) and Their Equivalent Isotropic Thermal Parameters ($\times 10^4$)[a]

Atom	X	Y	Z	B_{eq}/Å^2

a) Equivalent isotropic B_{eq} defined as one-third of the trace of the orthogonalized B_{ij} tensor. Last significant esd digits for each term are given in parentheses.

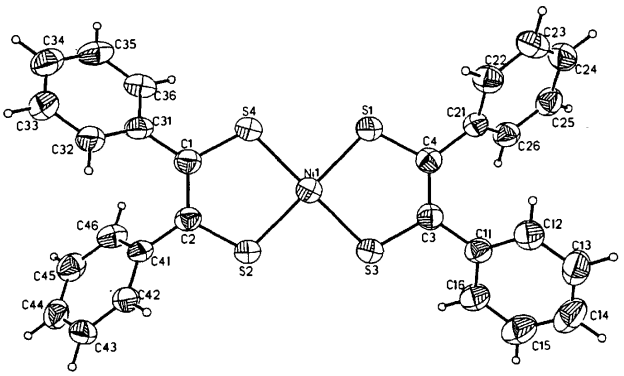

Fig. 1. A molecule of β-Ni(dpedt)$_2$ with atom labeling, seen onto the Ni,S1-S4,C1-C4 plane.

In the α-phase, the conformation allows for the molecule to possess a $\bar{1}$ symmetry; in the β-phase, by contrast, the conformation is such that the molecule totally lacks reflection symmetry, as clearly revealed by Table 3. Thus, β-Ni(dpedt)$_2$ is a *disymmetric* molecule, and is expected to exhibit optical activity. This finding obviously adds a new dimension to the scientific and technological relevance of this chemical compound, which now may be viewed as a potentially versatile chiroptical system in its β-phase.

One may reasonably assume that the stabilization of the phenyl librational energy into this dissymmetric conformation is influenced, during material preparation, by the presence of the Co(dpg)$_2$ or Cu(dmg)$_2$ complexes. It seems rather hard to say, however, *why* and *how* this influence could actually be brought about!

Michel Mégnamisi-Bélombé wishes to thank "Stiftung Volkswagenwerk" (West Germany) for partial support of this work via its "Partnership Program".

We thank Dr. H. Pritzkow, Heidelberg, for his help with a set of diffraction data.
