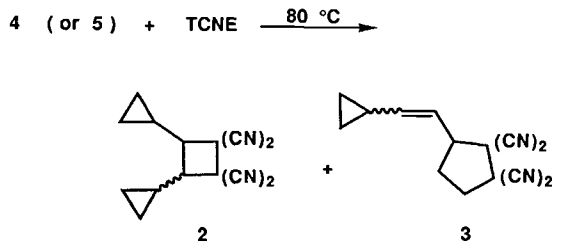
In 1,2-dichloroethane (48 h at 80 °C), **3** was found to be the major product (82%) accompanied by **2** (16%). Both **2** and **3** obtained in this solvent were more rich in the cis isomer (9 : 1 and 24 : 1, respectively) than those obtained in acetonitrile. In benzene, the reaction was found to proceed slowly to give 4% of **2** and 62% of **3**,[15] which were practically free from contamination of the corresponding trans isomer. The recovered **4** was also not contaminated by **5**. Since TCNE was hardly soluble in carbon tetrachloride, even at 80 °C, the reaction in this solvent was heterogeneous throughout; stereochemically, though, nearly single **2** and **3** were produced in 4 and 43% yields, respectively, after 40 d at 80 °C (73% conversion).[15]



The trans isomer **5** behaved similarly to **4**, except for the fact that the production of **3** was more prominent than that observed in the reaction of **4**. Thus, after 48 h at 80 °C in acetonitrile (81% conversion), **2** and **3** were produced in 45 and 44% yields, respectively. In a separate experiment, a 38% yield of **2** (*cis* : *trans*=20 : 80)[13,16] and 30% of **3** (*cis* : *trans*=4 : 96) was isolated; the recovered olefin was found to be a mixture of **4** and **5** (see Table 1). GC analysis of the product mixture obtained in the reaction of **5** in 1,2-dichloroethane indicated that **2** was practically absent, and quantitatively produced **3** was free from the corresponding geometrical isomer. Similarly, *trans*-**3** (66%) was the sole detectable adduct produced in benzene. In a reaction in carbon tetrachloride, although a small amount of **2** (ca. 3% yield) was detected, the major product was pure *trans*-**3** (45% yield).[15]

Reactions of Other Cyclopropylethylenes. Since the type-II process is observed to occur even in reactions of disubstituted **4** and **5**, we were interested in examining the reactions of **6**, **7**, **9**, and **10**, as well as **8**. In acetonitrile, although both **6** and **7** produced practically no **3**, a small amount (2—10%) of **3** (R^2 or R^3=Me) was found in the product mixtures obtained in 1,2-dichloroethane or in benzene. In contrast to the reactions of **4** and **5**, however, **2** (R^2 or R^3=Me) remained the major product (25—31%), even in benzene.[15] The stereochemical results (Table 1) were similar to those observed in the reactions of **4** and **5**.

The reaction of parent **8** proceeded nicely in acetonitrile to give **2** (R^1=R^2=R^3=H) in 65% yield after 8 h at 80 °C (83% conversion). In 1,2-dichloroethane, the reaction proceeded much more slowly to give **2** (69% yield), which was not contaminated by **3** (GC). In a reaction in benzene (38 d at 80 °C; 57% conversion), no **2** could be isolated, although its production was suggested by observing the signals of fragments on the ^{1}H NMR analysis of the product mixture.[15] It should be noted, however, that no peak corresponding to **3** was observed in the GC analysis. Apparently, the type-II process is totally unimportant in the reaction of **8**.

The reactivities of **9** and **10** were much lower than those of **4**—**8** and, hence, a prolonged reaction time was required. We failed to isolate **2** in these reactions, probably because of the thermal instability of **2**; however, a small amount of **3** (R^2 or R^3=*i*-Pr or *t*-Bu; 4—10% yield) was unambiguously produced, as indicated by a GC analysis.[15]

Reaction of 2,3-Dicyclopropyl-2-butene. Since it appears that **4** and **5** are somewhat exceptional among the substrates examined for undergoing a preferential type-II reaction, it is of interest to investigate the reaction of a tetrasubstituted ethylene which maintains a substitution pattern similar to that of **4** or **5**. Accordingly, we studied the reaction of 2,3-dicylopropyl-2-butene (**12**). Although this olefin was readily prepared by a McMurry coupling[17] of cyclopropyl methyl ketone, the separation of stereoisomers was unsuccessful in all attempts. Thus, a 6 : 4 mixture of the stereoisomers was unavoidably used in the present study. The olefin **12** reacted smoothly with TCNE in acetonitrile to give a 76% yield of **2** and 6% yield of **3** after 2 h at 80 °C (87% conversion). In 1,2-dichloroethane, **12** gave **2** in 17% yield and **3** in 65% yield. We anticipated that tetrasubstituted **12** would give **3** in an amount larger than that produced in the reaction of **4** or **5**; actually, though, **12** produced a somewhat smaller amount of **3**. The calculated yields of **2** and **3** to be produced in the reaction of a 4 : 6 mixture of **4** and **5** are 57 and 32% in acetonitrile and 6 and 91% in 1,2-dichloroethane, respectively.

The aforementioned results indicate that **4** and **5** are two particular substrates prone to undergo a type-II reaction. In the reactions of 1-cyclopropyl-1-alkenes only a limited amount of **3** is produced, even in a solvent of low polarity. From steric grounds, **4** and **5** should be intermediate between **6**—**7** and **9**—**10**. Therefore, it can be concluded that the steric hindrance around the π bond is not the major factor for the relative importance of the type-II process. The present results might perhaps be rationalized in a way similar to that proposed in previous cases,[2-4,18] since **4** and **5** (IP^V=8.4 eV, E_p^{ox} vs. SCE=1.5 V[19]) can be oxidized more readily than **6**, **7** (IP^V=8.9 eV, E_p^{ox} vs. SCE=1.7 V) or **8** (IP^V=9.3 eV,[20] E_p^{ox} vs. SCE=2.1 V). However, the thermal SET, even in the case of **4** or **5**, is expected to be highly endothermic.[21] If we grant that the previous scheme for the formation of **3** can be applied in the present cases, we must therefore assume that the cation radical, which is produced only in

a very minute amount, is extremely prone to be attacked by a nearly TCNE anion radical. Since it is known that the cyclopropane to be cleaved in a nucleophilic attack should be substituted by appropriate activating groups, preferably by two electron-withdrawing groups in a geminal manner,[22] the cyclopropyl group in the present type-II reaction should be activated by some means. Although activation of the cyclopropyl group in the transformation of **1** to $\mathbf{1}^{\ddagger}$ and the anticipated nucleophilicity of the TCNE anion radical may make the ring cleavage probable, the highly endothermic nature of the SET process requires further consideration. A mechanistic justification must, therefore, await additional investigations.

It was unfortunate that considerable isomerization of the starting olefin took place, particularly in acetonitrile. However, the isomerization was less significant in 1,2-dichloroethane and practically absent in benzene; the **2** and **3** produced in benzene were nearly, or totally, free from contamination of the stereoisomer. From these results it may be concluded that both the type-I and type-II cycloadditions are stereospecific, at least in a solvent of low polarity. The extensive isomerization of the starting olefin observed in acetonitrile may be due to the reversibility of the type-I cycloaddition.[23]

In conclusion, it is demonstrated that both the type-I and type-II reactions may be the two principal modes of the reaction of **1** with TCNE. In the reaction of 1,1-disubstituted substrates, the type-I process is so facile[2,3] that the type-II process can hardly compete with it. However, when the type-I reactivity of the substrate is relatively low, as in **4**—**7** and **9** and **10**, the type-II process gains significance to a certain extent. The fact that the type-II process is somewhat less prominent in the reaction of **12** than those of **4**/**5** might be rationalized on the basis that the intermediate for the type-I process produced in the reaction of **12** holds the tertiary carbocationic center, whereas that yielded in the reaction of **4**/**5** merely has a secondary carbocationic portion. The type-I process is therefore somewhat more facilitated in the reaction of **12**.

Experimental

General Methods. IR spectra were recorded on a Hitachi 270-30 spectrophotometer. ^{1}H NMR spectra were recorded on either a JEOL FX-100, JEOL GX-270, JEOL FX-500, or Hitachi R-600 NMR spectrometer and are reported in parts per million downfield of internal tetramethylsilane. Mass spectra were taken on a JEOL LMS-D300 mass spectrometer. GC analyses were carried out with Hitachi 063 and 163 gas chromatographs with a column packed by APL 15% on Celite 545, 2m, and with temperature programing from 80 to 220 °C, unless otherwise specified. In analyses of stereoisomeric olefins, an $AgNO_3$–glycerol column was used. HPLC analyses were performed with Hitachi 635 and 655 liquid chromatographs with a μ-Polasil column. A mixture of hexane–ether (2:1) was used as an eluant and a UV detector was set at 215 nm. E^{ox} were obtained in the same manner as reported previously.[4b] IP^{V} were obtained from the UPS spectra, which were recorded on a VG ADES400 photoelectron spectrometer with a He(I) resonance lamp. The resolution was 34 meV for the Ar(^{3}P) signal. Elemental analyses were performed at the Center for Instrumental Analysis of Hokkaido University. The melting and boiling points are uncorrected.

Substrates. Olefins rich in the cis isomer were prepared by the Wittig reaction.[6] The cis/trans ratios observed in the preparation of **4**,[6] **6**,[7] **9**, and **10** were 86/14, 73/27, 90/10, and >99/<1, respectively. Stereochemically pure substrates (> 99%) were obtained with preparative GC. Trans olefins **5**[6] and **7**[7] were alternatively prepared by the addition of dibromocarbene to 1-cyclopropyl-1,3-butadiene[10b,24] or 1,3-pentadiene, both rich in the trans isomer, followed by reduction with sodium in ethanol.[9] As in the reactions with the Seyferth's reagent, however, an addition of dibromocarbene to the 1-substituted-1,3-butadiene under the phase-transfer reaction conditions was not as regioselective as that observed in the addition of fluorenylidene to 1-cyclopropyl-1,3-butadiene.[7] Accordingly, the overall yields of **5** and **7** were relatively low. Vinylcyclopropane (**8**) was prepared by following procedures reported previously.[9]

***cis*-1-Cyclopropyl-3,3-dimethyl-1-butene (10).** In a 500 ml three-necked flask fitted with a mechanical stirrer and a reflux condenser, 20.2 g (110 mmol) of sodium bis(trimethylsilyl)amide in 200 ml of THF was placed. Under a nitrogen atmosphere, 43.7 g (110 mmol) of (cyclopropylmethyl)triphenylphosphonium bromide[6] was added; the mixture was refluxed for 1 h. A resulting orange suspension was cooled to −78 °C, and then 9.5 g (110 mmol) of 2,2-dimethylpropanal was slowly added with a syringe. The mixture was stirred at −78 °C for 1 h, and then at room temperature for 12 h. To the resultant mixture, 200 ml of water was added and organic material was extracted with 5 portions of pentane (100 ml). The combined pentane solution was washed with dilute hydrochloric acid, aqueous sodium hydrogencarbonate, and water, and dried over anhydrous sodium sulfate. An oily residue obtained by evaporation of the solvent was distilled to give a fraction boiled at 55—85 °C at 150 Torr (15.1 g; 1 Torr=101, 325/760 Pa), which was found to contain 10.0 g (74%) of *cis*-**10** (GC); *trans*-**10** was not detected. Rectification of the fraction gave pure *cis*-**10** (7.1 g, 53% yield); Bp 130—134 °C; IR (liquid film) 3088, 3008, 2960, 1660 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=5.27 (d, 1H, J=12 Hz), 4.53 (dd, 1H, J=12, 10 Hz), 1.90—1.57 (m, 1H), 1.17 (s, 9H), 0.83—0.54 (m, 2H), 0.50—0.03 (m, 2H); MS (70 eV) m/z (rel intensity) 124 (M^+, 33), 67 (100). Anal. (C_9H_{16}) C, H.

***cis*-1-Cyclopropyl-3-methyl-1-butene (9).** In a similar manner, **9**, which was contaminated by 10% of the trans isomer, was obtained in 62% yield. Pure **9** was obtained by preparative GC followed by distillation: Bp 116—117 °C; IR (liquid film) 3088, 3008, 2960, 2872, 1655 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ= 5.14 (dd, 1H, J=9, 11 Hz), 4.61 (dd, 1H, J=9, 11 Hz), 2.93—2.57 (m, 1H), 1.72—1.37 (m, 1H), 1.00 (d, 6H, J=6.5 Hz), 0.80—0.21 (m, 4H); MS (70 eV) m/z (rel intensity) 110 (M^+, 33), 43 (100). Anal. (C_8H_{14}) C, H.

2,3-Dicyclopropyl-2-butene (12). A McMurry coupling of cyclopropyl methyl ketone with a low valent titanium reagent prepared from titanium trichloride and metallic magnesium[25] gave **12** in 17% yield. Separation of geometrical isomers by means of GC was unsuccessful in all attempts. Accordingly, the mixture was used in the following investigations: Bp 75—

80 °C at 17 Torr; IR (liquid film) 3084, 3004, 2920, 1650, 1600 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=2.2—1.5 (m, 2H), 1.52 (s, 3.6H), 1.39 (s, 2.4H), 0.9—0.3 (m, 8H). Anal. ($C_{10}H_{16}$) C, H.

GC Analyses of the Reactions. The relative reactivities of **4**—**10** with TCNE under given conditions were determined by following the consumption of the starting olefin at appropriate time intervals. The time required for the half-consumption of the olefin in 1,2-dichloroethane at 80 °C was: **4**: 18 h, **5**: 10 h, **6**: 32 h, 7: 32 h, **8**: 32 h, **9**: 168 h, and **10**: 312 h. The reactions of **4** and **5**, but not those of others, with TCNE were analyzed directly by GC (see Table 1).[11]

Reaction of 4 with TCNE in Acetonitrile. A reddish violet solution obtained on mixing of **4** (108 mg, 1.0 mmol) with TCNE (135 mg, 1.06 mmol) in acetonitrile (10 ml, containing 56 mg of octane as an internal standard) was degassed and sealed in a tube. After being heated at 80 °C for 48 h, the tube was opened (the consumption of **4** being 83% and recovered olefin being a mixture of **4** and **5** in a 41 : 59 ratio). The solution was then concentrated and a residue (230 mg) was subjected to column chromatography with silica gel (40 g). Elution of the column with chloroform gave a white solid (159 mg), which was recrystallized from cyclohexane to give colorless needles (121 mg, 62%) as a mixture of *cis*-**2** and *trans*-**2** in a ratio of 84 : 16. Repeated recrystallizations from cyclohexane gave an analytically pure *cis*-**2** (R^2=*cyclo*-Pr, R^1=R^3=H), mp 156—158 °C (lit,[2] mp 165—167 °C). Since the mp of the adduct differed significantly from that reported previously, the product was subjected to a precise analysis. IR (KBr disc) 3092, 3016, 2250 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=2.66—2.42 (AA'XX', 2H, J_{AA}=9, J_{AX}=11, J_{AX}=0.3 Hz), 1.49—1.20 (m, 2H), 1.10—0.70 (m, 4H), 0.56—0.28 (m, 4H); MS (70 eV) *m*/*z* (rel intensity) 236 (M^+, 0.2), 91 (100). Anal. ($C_{14}H_{12}N_4$) C, H, N.

A yellow oil obtained in the concentration of mother liquors of the recrystallizations (42 mg) was analyzed by GC and found to be a mixture of two components. These were collected by preparative GC to give 21 mg (11%) of a 52 : 48 mixture of *cis*-**3** and *trans*-**3**. Each isomer was purified by repeated GC collections. *cis*-**3** (R^2=*cyclo*-Pr, R^1=R^3=H): Oil; IR (liquid film) 3012, 2250, 1656 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=5.36—5.26 (AA'XX', 2H, $J_{AA'}$=11, J_{AX}=9, J_{AX}=0.7), 4.06 (ddd, 1H, *J*=9, 7, 4 Hz), 2.92 (ddd, 1H, *J*=14.5, 9, 6 Hz), 2.83 (ddd, *J*=14.5, 10.5, 6 Hz), 2.54 (dddd, 1H, *J*=17, 9, 6, 7 Hz), 2.12 (dddd, 1H, *J*=17, 10.5, 6, 9 Hz), 1.65—1.53 (m, 1H), 1.02—0.86 (m, 2H), 0.63—0.46 (m, 2H); MS (70 eV) *m*/*z* (rel intensity) 236 (M^+, 39), 93 (100). Anal. ($C_{14}H_{12}N_4$) C, H, N. *trans*-**3** (R^3=*cyclo*-Pr, R^1=R^2=H): Oil; IR (liquid film) 3012, 2250, 1664, 968 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=5.57—5.42 (AA'XX', 2H, $J_{AA'}$=16, J_{AX}=7, J_{AX}=0.7), 3.45 (ddd, 1H, *J*=9, 7, 4.5 Hz), 2.89 (ddd, 1H, *J*=14.5, 9, 6 Hz), 2.78 (ddd, 1H, *J*=14.5, 10.5, 6 Hz), 2.44 (dddd, 1H, *J*=18, 9, 6, 4.5 Hz), 2.15 (dddd, 1H, *J*=18, 10.5, 6, 9 Hz), 1.56—1.44 (m, 1H), 0.92—0.80 (m, 2H), 0.55—0.44 (m, 2H); MS (70 eV) *m*/*z* (rel intensity) 236 (M^+, 29), 93 (100). Anal. ($C_{14}H_{12}N_4$) C, H, N.

Reaction of 5 with TCNE in Acetonitrile. A reddish purple solution of **5** (109 mg, 1.01 mmol), TCNE (132 mg, 1.03 mmol), and octane (54 mg, as an internal standard) in acetonitrile (10 mL) was degassed in a tube and heated at 80 °C for 48 h. The consumption of **5** was 86%; recovered olefin was a mixture of **4** and **5** in a 12 : 88 ratio. After concentrating the resultant brown solution, a residue (254 mg) was subjected to column chromatography with silica gel (40 g). Elution of the column with chloroform gave adduct fractions comprising a white solid and a liquid (178 mg). Recrystallization of the solid from cyclohexane gave colorless needles (77 mg, 38% yield), mp 143—153 °C, which were a mixture of *cis*-**2** and *trans*-**2** in a 20 : 80 ratio. Repeated recrystallizations of the needles from cyclohexane gave analytically pure *trans*-**2** (R^3=*cyclo*-Pr, R^1=R^2=H): Mp 153—155 °C (lit,[2] mp 159—160.5 °C); IR (KBr disc) 3100, 3012, 2250 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=2.53—2.27 (AA'XX', 2H, J_{AA}=11, J_{AX}=9, J_{AX}=0.4 Hz), 1.25—0.74 (m, 6H), 0.66—0.43 (m, 4H); MS (70 eV) *m*/*z* (rel intensity) 236 (M^+, 0.1), 91 (100). Anal. ($C_{14}H_{12}N_4$) C, H, N. From the oily portion of the product, 61 mg (30%) of **3** (cis : trans=4 : 96) was obtained.

Reaction of 5 in 1,2-Dichloroethane. The reaction produced *trans*-**3** quantitatively (Table 1). When the reaction (108 mg, 1.00 mmol, of **5**, 132 mg, 1.03 mmol of TCNE, and 57 mg of octane in 10 ml of the solvent) was carried out in the presence of methanol (325 mg, 10 equivalent), **3** (cis : trans=4 : 96) was produced in 64% GC yield (46% by isolation). In no fraction on the silica-gel column chromatography was the MeO signal observed by ^1H NMR spectroscopy.

Reaction of 6. In acetonitrile (15 ml, containing 102 mg of heptane as an internal standard), the reaction of **6** (123 mg, 1.50 mmol) with TCNE (198 mg, 1.55 mmol) at 80 °C for 27 h (77% conversion; recovered olefin being a mixture of **6** and 7 in a 27 : 73 ratio) gave a geometrical mixture of **2** (cis : trans=6 : 4, 158 mg, 65%). In 1,2-dichloroethane at 80 °C for 144 h (78% conversion), the same reaction produced **2** (cis : trans=4 : 1, 155 mg, 63%) and **3** (5 mg, 2%). From this product mixture, *cis*-**2** (R^2=Me, R^1=R^3=H) was isolated by repeated recrystallization: Mp 156—157 °C; IR (KBr disc) 3008, 2250 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=3.40 (dq, 1H, *J*=9.1, 7.2 Hz), 2.54 (dd, 1H, *J*=10.6, 9.1 Hz), 1.63 (d, 3H, *J*=7.2 Hz), 1.87—1.10 (m, 1H), 0.97—0.33 (m, 4H); MS (70 eV) *m*/*z* (rel intensity) 210 (M^+, 0.15), 67 (100). Anal. ($C_{12}H_{10}N_4$) C, H, N.

In the reaction in benzene at 80 °C for 912 h (48% conversion), 47 mg (31%) of *cis*-**2**, mp 155.0—156.5 °C, and 7 mg (5%) of **3** were isolated. The type-I adduct was not contaminated by *trans*-**2** (100 MHz ^1H NMR) in this case. From the combined oily products, *cis*-**3** (R^2=Me, R^1=R^3=H) was isolated by preparative GC: Oil; IR (liquid film) 3028, 2952, 2250, 1662 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=6.09 (dq, 1H, *J*=10.7, 7.1 Hz), 5.57 (ddq, 1H, *J*=9.3, 10.7, 1.8 Hz), 3.94 (q, 1H, *J*=9.3 Hz), 2.97—2.78 (m, 2H), 2.70—1.95 (m, 2H), 1.85 (dd, 3H, *J*=7.1, 1.8 Hz); MS (70 eV) *m*/*z* (rel intensity) 210 (M^+, 5.4), 67 (100). Anal. ($C_{12}H_{10}N_4$) C, H, N.

Reaction of 7. In a similar manner (see Table 1 for the reaction conditions), the reaction of **7** (124 mg, 1.51 mmol) with TCNE (200 mg, 1.56 mmol) in acetonitrile (15 ml) gave colorless needles (181 mg, 67%), which were a 3 : 7 mixture of *cis*-**2** and *trans*-**2**, and oily **3** (3 mg, 1%). In 1,2-dichloroethane, practically pure *trans*-**2** (120 mg, 47%) was obtained in addition to oily **3** (8 mg, 3%). *trans*-**2** (R^3=Me, R^1=R^2=H): Mp 113—115 °C; IR (KBr disc) 3012, 2980, 2250 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=3.24 (dq, 1H, *J*=11, 6.4 Hz), 2.17 (dd, 1H, *J*=11, 9.3 Hz), 1.51 (d, 3H, *J*=6.4 Hz), 1.38—1.15 (m, 1H), 1.11—0.38 (m, 4H); MS (70 eV) *m*/*z* (rel intensity) 210 (M^+, 0.14), 67 (100). Anal. ($C_{12}H_{10}N_4$) C, H, N.

The reaction in benzene gave 49 mg (25%) of *trans*-**2** and 20 mg (10%) of **3**, from the latter, pure *trans*-**3** (R^3=Me, R^1=R^2=H) was obtained: Oil; IR (liquid film) 2968, 2250, 1672, 968 cm^{-1}; ^1H NMR (100 MHz, $CDCl_3$) δ=6.05 (dq, 1H, *J*=15,

6.4 Hz), 5.50 (dd, 1H, J=15, 7.9 Hz), 3.47 (dt, 1H, J=10, 8.6 Hz), 3.01—2.76 (m, 2H), 2.67—2.00 (m, 2H), 1.85 (d, 3H, J=6.4 Hz); MS (70 eV) m/z (rel intensity) 210 (M^+, 4.3), 67 (100). Anal. ($C_{12}H_{10}N_4$) C, H, N.

Reaction of 8. In degassed acetonitrile (20 ml), a mixture of **8** (136 mg, 2.00 mmol), TCNE (264 mg, 2.06 mmol), and octane (130 mg) was heated at 80 °C for 8 h (83% conversion) in an ampoule. From the reaction mixture, **2** (R^1=R^2=R^3=H; 211 mg, 65%), mp 123.5—124.5 °C (lit,[2] mp 124—125 °C), was obtained as colorless plates. Similarly, **2** was obtained in 69% yield in 1,2-dichloroethane (80 °C for 90 h; 81% conversion). In a reaction in benzene (912 h at 80 °C; 57% conversion), **2** did not crystallize out after a work-up as mentioned above. ^{1}H NMR analyses of fractions obtained on silica-gel column chromatography indicated the occurrence of fragmentation. In no case was the formation of **3** indicated by GC analyses.

Reaction of 9. A mixture of **9** (110 mg, 1.00 mmol), TCNE (134 mg, 1.05 mmol), and octane (103 mg) in degassed acetonitrile (10 ml) was heated in an ampoule for 648 h (45% conversion). Work-up of the reaction mixture (as mentioned above) gave an oily product (30 mg), from which oily **3** (4 mg, 4%) was obtained by preparative GC. The same reaction in 1,2-dichloroethane (66% conversion) gave 16 mg (10%) of *cis*-**3** (R^2=*i*-Pr, R^1=R^3=H): Oil; IR (liquid film) 3012, 2964, 2872, 2252, 1660 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$) δ=5.79 (t, 1H, J=11 Hz), 5.29 (t, 1H, J=11 Hz), 3.86 (q, 1H, J=10 Hz), 2.90 (ddd, 1H, J=15, 9, 5 Hz), 2.82 (ddd, 1H, J=15, 11, 6 Hz), 2.63 (dq, 1H, J=17, 6 Hz), 2.45 (ddt, 1H, J=14, 6, 9 Hz), 2.14—2.06 (m, 1H), 1.11 (d, 3H, J=7 Hz), 1.02 (d, 3H, J=7 Hz); MS (70 eV) m/z (rel intensity) 238 (M^+, 4.9), 69 (100). Anal. ($C_{14}H_{14}N_4$) C, H, N. Most of the material in the reaction mixture did not elute out of the silica-gel column.

Reaction of 10. In acetonitrile, the reaction of **10** with TCNE did not proceed to a reasonable extent, even after 14 days at 80 °C. In 1,2-dichloroethane, 58% consumption of **10** was noted after 648 h at 80 °C. From the reaction mixture (124 mg, 1.00 mmol, of **10** and 132 mg, 1.03 mmol, of TCNE in 10 ml of the solvent), 35 mg of an oil was isolated after the work-up mentioned above. The oil comprised 4 products (GC), from which *cis*-**3** (R^2=*t*-Bu, R^1=R^3=H; 10 mg, 7% yield) was isolated: Oil; IR (liquid film) 2964, 2872, 2252, 1660 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=5.91, (d, 1H, J=12 Hz,)5.23 (dd, 1H, J=12, 10 Hz), 4.22 (dt, 1H, J=9, 10 Hz), 2.94—2.76 (m, 2H), 2.67—1.98 (m, 2H), 1.20 (s, 9H); MS (70 eV) m/z (rel intensity) 252 (M^+, 1.7), 41 (100). HRMS Calcd for $C_{15}H_{16}N_4$: M, 252.1375. Found: m/z 252.1356.

Reaction of 12. A mixture of **12** (136 mg, 1.00 mmol), TCNE (132 mg, 1.03 mmol), and dodecane (60 mg) in acetonitrile (10 ml) was heated at 80 °C under a nitrogen atmosphere. After 2 h, 87% consumption of **12** was noted by GC analysis. Concentration of the reaction mixture gave a brown oil (270 mg), which was subjected to silica-gel colume chromatography (20 g). Elution of the column with benzene gave a white solid and a pale yellow oil (total of 188 mg). The solid was recrystallized from 99% ethanol to give colorless needles (158 mg, 69%), mp 130—135 °C, which was assigned to be **2** (R^1 and R^2 or R^3=Me, R^2 or R^3=*cyclo*-Pr): IR (KBr disc) 3012, 2250 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.9—1.35 (m, 2H), 1.26 (s, 3.4H), 1.09 (s, 2.6H), 0.9—0.3 (m, 8H); MS (70 eV) m/z (rel intensity) 264 (M^+, 0.4), 105 (100). Anal. ($C_{16}H_{16}N_4$) C, H, N. The oily portion obtained in the column chromatography comprised mostly **2** (60 MHz ^{1}H NMR; **2**:**3**=93:7), and hence the total yield of **2** was calculated to be 76%. Concentrated mother liquors of the recrystallization gave an oil, from which **3** (R^1 and R^2 or R^3=Me, R^2 or R^3=*cyclo*-Pr; 13 mg, 6% yield) was isolated.

The reaction in 1,2-dichloroethane (2 h at 80 °C, 81% conversion) gave **2** in 17% and **3** in 65% yield, respectively. In the reaction in benzene (18 h at 80 °C; 85% conversion), 60 MHz ^{1}H NMR spectral analysis of the adduct fraction revealed no formation of **2**. An oily product obtained in silica-gel column chromatography was found to be **3** (68% yield). Repeated preparative GC of the products allowed isomeric **3** to be separated, although stereochemical assignments were not accomplished:

3-I: Oil; IR (liquid film) 3088, 3008, 2260, 1630 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=4.77 (t, 1H, J=9 Hz), 2.95—2.78 (m, 2H), 2.48—2.23 (m, 2H), 2.0—1.4 (m, 1H), 1.85 (s, 3H), 1.60 (s, 3H), 0.90—0.50 (m, 4H); MS (70 eV) m/z (rel intensity) 264 (M^+, 39), 121 (100). Anal. ($C_{16}H_{16}N_4$) C, H, N.

3-II: Oil; IR (liquid film) 3088, 3004, 2260, 1632 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=4.28 (t, 1H, J=9 Hz), 2.94—2.78 (m, 2H), 2.49—2.17 (m, 2H), 2.1—1.5 (m, 1H), 2.00 (s, 3H), 1.58 (s, 3H), 0.90—0.50 (m, 4H); MS (70 eV) m/z (rel intensity) 264 (M^+, 49), 121 (100). Anal. ($C_{16}H_{16}N_4$) C, H, N.

Fragmentation of 2. Since **2** is known to decompose during a GC analysis,[10] the decomposed material of **2** (R^1=R^3=H, R^2=*cyclo*-Pr and R^1=R^2=H, R^3=*cyclo*-Pr) was collected. From 25.0 mg (0.11 mmol) of *cis*-**2**, 20.4 mg (82%) of colorless liquid was obtained, which was found to be **11**: Oil; IR (liquid film) 3032, 2232, 1600 cm^{-1}; ^{1}H NMR (100 MHz, $CDCl_3$) δ=6.63 (d, 1H, J=11 Hz), 2.35—1.99 (m, 1H), 1.57—0.96 (m, 4H); MS (70 eV) m/z (rel intensity) 118 (M^+, 27), 91 (100). Anal. ($C_7H_6N_2$) C, H, N. Similarly, *trans*-**2** gave **11** in 71% yield.

The present research was supported by a Grant-in-Aid for Scientific Research No. 01430005 from the Ministry of Education, Science and Culture to which we are very grateful. We thank Professor Masahiro Kawasaki of Hokkaido University, Research Institute of Applied Electricity, for generous loan of the ADES400 spectrometer.

Palladium Catalyzed Reaction of Silacyclobutanes with Acetylenes

Yoshihiro TAKEYAMA, Kyoko NOZAKI, Kozo MATSUMOTO, Koichiro OSHIMA,* and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 6, 1990)

Whereas the reaction of 1,1-dimethyl-1-silacyclobutane (**1a**) with dimethyl acetylenedicarboxylate in the presence of Pd catalyst provides dimethyl 1,1-dimethyl-1-sila-2-cyclohexene-2,3-dicarboxylate almost exclusively, the reaction of **1a** with phenylacetylene affords allyldimethylstyrylsilane as a major product. The reaction of silacyclobutane with phenylallene provided three isomeric products.

Strained small ring molecules are versatile building blocks and often provide short and elegant routes in organic synthesis. From the interest in the development of synthetic use of silacyclobutane, we have studied stereoselective formation of silacyclopentanes by the reaction of silacyclobutane with lithium carbenoids[1] and the base induced reaction of silacyclobutane with aldehyde to give oxasilacyclohexanes.[2] During the course of these studies, accidentally, it was found that the palladium catalyzed reaction of silacyclobutane with acetylenes provided a mixture of silacyclohexene derivatives and allylvinylsilane derivatives.

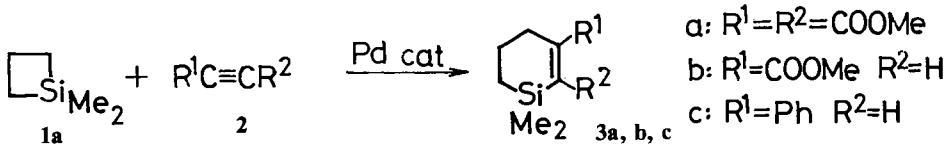
Sakurai and Imai have reported[3] that 1,1-dimethyl-1-silacyclobutane (**1a**) reacted smoothly with dimethyl acetylenedicarboxylate, methyl propiolate, or phenylacetylene to give dimethyl 1,1-dimethyl-1-sila-2-cyclohexene-2,3-dicarboxylate (**3a**), methyl 1,1-dimethyl-1-sila-2-cyclohexene-3-carboxylate (**3b**), or 1,1-dimethyl-3-phenyl-1-sila-2-cyclohexene (**3c**), respectively (Scheme 1).

Meanwhile, we have found that allylvinylsilane derivative **4** was formed in addition to the silacyclohexene derivative **3** in the reaction of **1** with acetylenic compounds. For instance, $PdCl_2(PPh_3)_2$ catalyzed reaction of 1,1-dimethyl-1-silacyclobutane (**1a**) with methyl propiolate in benzene under an argon atmosphere gave a mixture of methyl 1,1-dimethyl-1-sila-2-cyclohexene-3-carboxylate (**3b**) and methyl (*E*)-4,4-dimethyl-4-sila-2,6-heptadienoate (**4b**, **3b**/**4b**=4/6, Scheme 2). The representative results are summarized in Table 1.

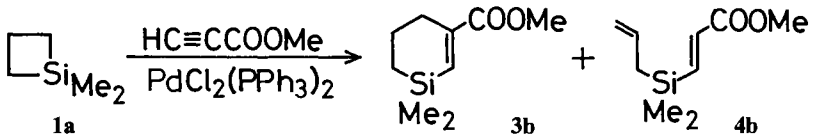
As shown in Table 1, the ratios of two types of the products, silacyclohexene **3** and allylvinylsilane derivative **4** heavily depend on the nature of acetylenic compounds. The reaction of silacyclobutane with dimethyl acetylenedicarboxylate provided the former product, silacyclohexene **3**, as a major product. In contrast, the reaction with phenylacetylene afforded the latter allylvinylsilane derivative **4** mainly. Whereas palladium complexes such as $Pd(PPh_3)_4$ and $PdCl_2(P(o\text{-tolyl})_3)_2$ were as effective as $PdCl_2(PPh_3)_2$, $PdCl_2(Ph_2PCH_2CH_2PPh_2)$ was not effective as a catalyst and phenylacetylene was recovered unchanged in the reaction with **1a**. The catalysts prepared in situ from $PdCl_2$ and PPh_3 or $PdCl_2(PPh_3)_2$ and pyridine were also ineffective. The ratios of two products were not affected by the ligand on palladium complex. Thus, the ratio of **3c** and **4c** was always 1/9—2/8 in the reaction of 1,1-dimethyl-1-silacyclobutane with phenylacetylene ($PdCl_2(PPh_3)_2$, 1/9; $PdCl_2(P(o\text{-tolyl})_3)_2$, 2/8; $PdCl_2$–$2P(OEt)_3$, 1/9). Tetrahydrofuran and dimethylformamide as well as benzene were suitable solvent for the reaction. Regioselective formation of single isomers **3** and **4** was observed for the reaction of methyl propiolate or phenylacetylene.

Prosaic acetylenic compound such as 1-dodecyne reacted very sluggishly to give the corresponding products in poor yield (17%, 3-decyl-1,1-dimethyl-1-sila-2-cyclohexene/(*E*)-allyl(1-dodecenyl)dimethylsilane=4/6).

Treatment of 3-deuterio-3-methyl-1,1-diphenyl-1-silacyclobutane **5**[4] with acetylenic compounds in the presence of $PdCl_2(PPh_3)_2$ gave the corresponding products

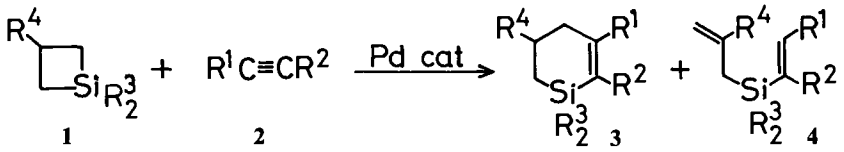


Scheme 1.



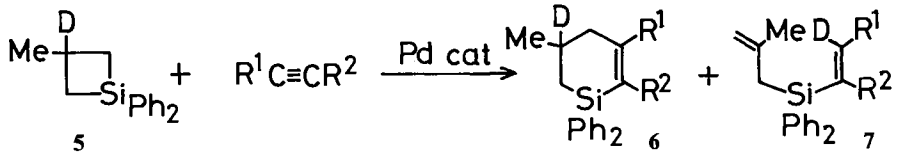
Scheme 2.

Table 1. Palladium Catalyzed Reaction of Silacyclobutanes with Acetylenes[a)]

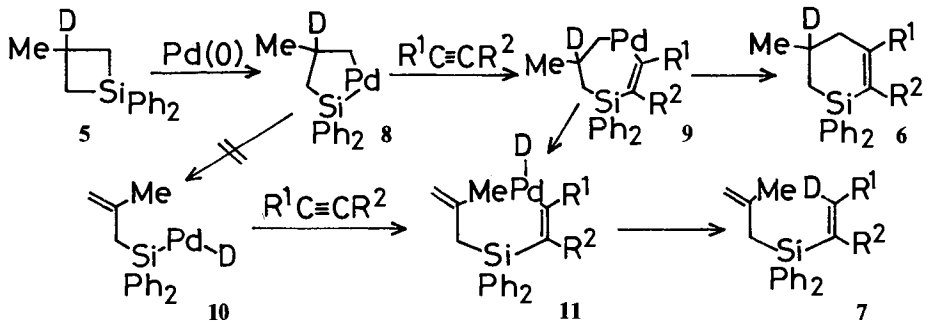


Entry	Silacyclobutane 1		Acetylene 2		Yield/%	
	R^3	R^4	R^1	R^2	3	4
1	Me	H (1a)	COOMe	COOMe	50 (3a)	18 (4a)
2	Me	H (1a)	COOMe	H	27 (3b)	41 (4b)
3	Me	H (1a)	Ph	H	6 (3c)	51 (4c)
4	Ph	H (1b)	COOMe	COOMe	86 (3d)	7 (4d)
5	Ph	H (1b)	COOMe	H	50 (3e)	26 (4e)
6	Ph	H (1b)	Ph	H	16 (3f)	60 (4f)
7	Me	Me (1c)	COOMe	COOMe	61 (3g)	13 (4g)
8	Me	Me (1c)	COOMe	H	43 (3h)	32 (4h)
9	Me	Me (1c)	Ph	H	12 (3i)	29 (4i)
10	Ph	Me (1d)	COOMe	COOMe	82 (3j)	4 (4j)
11	Ph	Me (1d)	COOMe	H	71 (3k)	26 (4k)
12	Ph	Me (1d)	Ph	H	50 (3l)	36 (4l)

a) One mmol of silacyclobutane, 1 mmol of acetylene, and a catalytic amount of $PdCl_2(PPh_3)_2$ were employed. The reaction mixture was refluxed for 2 h.



Scheme 3.

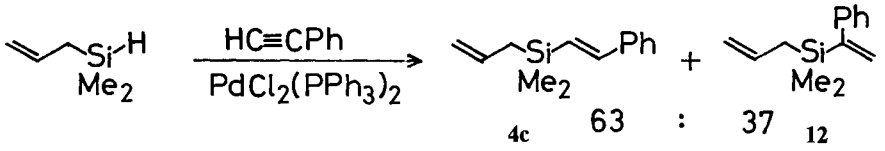


Scheme 4.

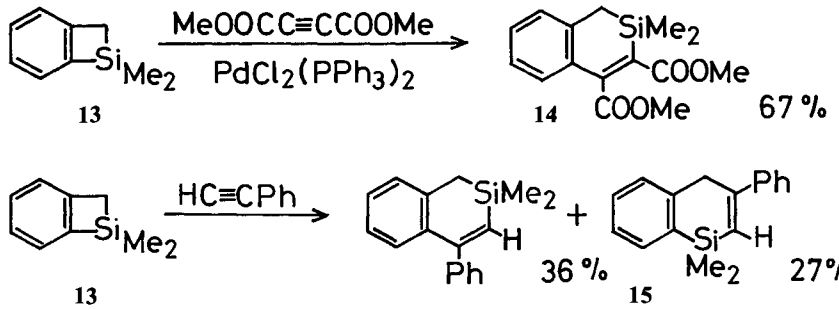
6 and **7**. In the case of the reaction with methyl propiolate, methyl (*E*)-2-deuterio-6-methyl-4,4-diphenyl-4-sila-2,6-heptadienoate **7b** (R^1=COOMe, R^2=H) was obtained (12% yield) along with methyl 5-deuterio-5-methyl-1-sila-2-cyclohexene-3-carboxylate **6b** (R^1=COOMe, R^2=H, 76% yield). Deuterium occupied 2-position of 4-sila-2,6-heptadienoate **7b**. The ^{1}H NMR signal of δ=6.30 for the corresponding compound **4k** (methyl 6-methyl-4,4-diphenyl-4-sila-2,6-heptadienoate) completely disappeared in the product **7b**. The reaction with phenylacetylene or dimethyl acetylenedicarboxylate also provided the corresponding deuterated compounds **6** and **7** (Scheme 3)

Based on these results, we are tempted to assume the following reaction mechanism: (1) Insertion of Pd(0) into silacyclobutane leading to ring-expanded compound **8**,[5)] (2) regioselective silylpalladation of acetylenic compounds to provide seven-membered ring intermediate **9**, and (3) reductive elimination of Pd(0) to afford silacyclohexene **6** or β-elimination of Pd–D followed by reductive elimination of Pd(0) to give allylvinylsilane derivative **7** (Scheme 4).[10)]

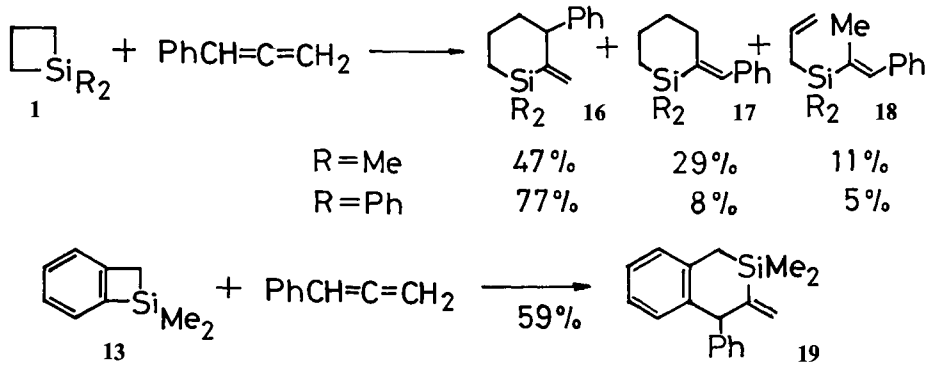
Alternatively, the formation of allylvinylsilane derivatives **7** might be explained by the addition of CH_2=$CMeCH_2SiPh_2$–Pd–D (**10**), which is derived by β-elimination of Pd–D from **8**, to acetylenic compounds providing **11** and successive reductive elimination of Pd(0) from **11**. However, this route was ruled out by



Scheme 5.



Scheme 6.



Scheme 7.

the following fact. Treatment of phenylacetylene with allyldimethylsilane in the presence of $PdCl_2(PPh_3)_2$ gave a regioisomeric mixture of allyldimethylstyrylsilane **4c** and allyldimethyl(1-phenylvinyl)silane **12** in low yield (<15% combined yield, **4c**/**12**=63/37) as depicted in Scheme 5.

The reaction of 1,2-dihydro-1,1-dimethyl-1-silabenzocyclobutene (**13**), which has no β-hydrogen, with dimethyl acetylenedicarboxylate or phenylacetylene under similar conditions gave the corresponding dihydrosilanaphthalenes, **14** or **15**, respectively (Scheme 6).

Phenylallene also easily reacted with silacyclobutanes in the presence of $PdCl_2(PPh_3)_2$ catalyst to give a mixture of three components, **16**, **17**, and **18**. On the other hand, 1,2-dihydro-1-silabenzocyclobutene **13** provided 1,2,3,4-tetrahydro-2-silanaphthalene **19** in 59% yield as a single product (Scheme 7).

Experimental

Distillations of the products were performed by use of Kugelrohr (Büchi), and boiling points are indicated by air-bath temperature without correction. ^1H NMR and ^{13}C NMR spectra were taken on a Varian XL-200 spectrometer, $CDCl_3$ was used as solvent, and chemical shifts being given in δ with tetramethylsilane as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer. The elemental analyses were carried out at the Elemental Analyses Center of Kyoto University.

Preparation of Silacyclobutane Derivatives. 1,1-Dimethyl-1-silacyclobutane (**1a**) was purchased from Shinetsu Silicone Chemicals and used as delivered. 1,1-Diphenyl-1-silacyclobutane (**1b**) was prepared in 86% yield by treatment of 1,1-dichloro-1-silacyclobutane (obtained from Petrarch Systems) with phenylmagnesium bromide in ether. 1,1,3-Trimethyl-1-silacyclobutane (**1c**) and 3-methyl-1,1-diphenyl-1-silacyclobutane (**1d**) were obtained from 2-methylallyl chloride. Hexachloroplatinic(IV) acid catalyzed hydrosilylation with $HSiClMe_2$ or $HSiClPh_2$ followed by treatment of the resulting $ClSiMe_2CH_2CH(Me)CH_2Cl$ or $ClSiPh_2CH_2CH(Me)CH_2Cl$ with Mg provided **1c** or **1d** in 26% or 35% overall yield, respectively.[4] 1,2-Dihydro-1-silabenzocyclobutene (**13**) was prepared following the reported procedure.[11]

General Procedure for the Reaction of Silacyclobutane with Acetylenic Compounds or Phenylallene in the Presence of Pd Catalyst. The reaction of 1,1-dimethyl-1-silacyclobutane with methyl propiolate is representative. A catalytic amount of $PdCl_2(PPh_3)_2$ (115 mg, 0.02 mmol) was added to a solution of 1,1-dimethyl-1-silacyclobutane (**1a**, 0.20 g, 2.0 mmol) and methyl propiolate (0.17 g, 2.0 mmol) in benzene (5 ml) under an argon atmosphere. The pale yellow mixture

was heated at reflux for 2 h. The resulting dark brown mixture was concentrated in vacuo and the residual oil was submitted to silica-gel column chromatography to give a mixture of methyl 1,1-dimethyl-1-sila-2-cyclohexene-3-carboxylate (**3b**[3], 0.10 g, 27% yield) and methyl (*E*)-4,4-dimethyl-4-sila-2,6-heptadienoate (**4b**, 0.15 g, 41% yield). **4b**: Bp 65 °C (1.0 Torr, 1 Torr=133.322 Pa, bath temp); IR(neat) 2948, 1730, 1308, 1271, 1250, 1227, 1168, 995, 846 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.13 (s, 6H), 1.62 (d, J=8.0 Hz, 2H), 3.75 (s, 3H), 4.86 (bd, J=9.5 Hz, 1H), 4.87 (bd, J=17.6 Hz, 1H), 5.74 (ddt, J=9.5, 17.6, 8.0 Hz, 1H), 6.25 (d, J=18.9 Hz, 1H), 7.23 (d, J=18.9 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=−4.03, 22.69, 51.17, 114.0, 133.7, 134.4, 148.1, 166.2. Found: C, 58.38; H, 9.05%. Calcd for $C_9H_{16}O_2Si$: C, 58.65; H, 8.75%.

Methyl (*E*)-3-Methoxycarbonyl-4,4-dimethyl-4-sila-2,6-heptadienoate (4a): Bp 95 °C (1.0 Torr, bath temp); IR(neat) 2952, 1728, 1436, 1341, 1238, 1198, 1174, 1039, 890 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.19 (s, 6H), 1.69 (d, J=8.0 Hz, 2H), 3.73 (s, 3H), 3.81 (s, 3H), 4.90 (d, J=17.5 Hz, 1H), 4.91 (d, J=8.0 Hz, 1H), 5.73 (ddt, J=17.5, 8.0, 8.0 Hz, 1H), 6.08 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=−4.45, 21.98, 52.02, 114.8, 129.5, 132.8, 154.0, 164.4, 170.8. Found: C, 54.37; H, 7.43%. Calcd for $C_{11}H_{18}O_4Si$: C, 54.52; H, 7.49%.

(*E*)-Allyldimethylstyrylsilane (4c): Bp 90 °C (1.0 Torr, bath temp); IR(neat) 3074, 2954, 1629, 1604, 1572, 1493, 1248, 1154, 988, 851, 687, 645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.16 (s, 6H), 1.66 (d, J=8.0 Hz, 2H), 4.87 (d, J=10.2 Hz, 1H), 4.89 (d, J=16.9 Hz, 1H), 5.83 (ddt, J=10.2 Hz, 1H), 6.50 (d, J=19.3 Hz, 1H), 6.91 (d, J=19.3 Hz, 1H), 7.15—7.45 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−3.46, 23.66, 113.2, 126.4, 127.4, 128.1, 128.5, 134.8, 138.2, 144.5. Found: C, 76.95; H, 9.09%. Calcd for $C_{13}H_{18}Si$: C, 77.16; H, 8.96%.

Dimethyl 1,1-Diphenyl-1-sila-2-cyclohexene-2,3-dicarboxylate (3d): Bp 200 °C (1.0 Torr, bath temp); IR(neat) 2946, 1719, 1600, 1430, 1280, 1236, 1191, 1145, 1114, 1050, 1029, 776, 730, 698, 661 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18—1.33 (m, 2H), 1.88—2.08 (m, 2H), 2.62 (t, J=5.8 Hz, 2H), 3.48 (s, 3H), 3.79 (s, 3H), 7.33—7.70 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=9.62, 19.83, 31.64, 51.52, 52.30, 127.8, 129.8, 132.6, 133.3, 135.4, 155.3, 169.4. Found: C, 68.56; H, 6.00%. Calcd for $C_{21}H_{22}O_4Si$: C, 68.82; H, 6.05%.

Methyl (*E*)-3-Methoxycarbonyl-4,4-diphenyl-4-sila-2,6-heptadienoate (4d): Bp 200 °C (1.0 Torr, bath temp); IR(neat) 2948, 1726, 1430, 1339, 1239, 1197, 1173, 1112, 1036, 897, 770, 736, 699 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.32 (d, J=7.8 Hz, 2H), 3.66 (s, 3H), 3.72 (s, 3H), 4.93—5.10 (m, 2H), 5.84 (ddt, J=17.6, 9.8, 7.8 Hz, 1H), 6.10 (s, 1H), 7.35—7.68 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=19.97, 51.97, 52.06, 116.2, 128.1, 130.3, 131.2, 132.2, 133.5, 135.6, 150.6, 164.4, 170.3. Found: C, 68.59; H, 6.25%. Calcd for $C_{21}H_{22}O_4Si$: C, 68.82; H, 6.05%.

Methyl 1,1-Diphenyl-1-sila-2-cyclohexene-3-carboxylate (3e): Bp 150 °C (0.3 Torr, bath temp); IR(neat) 3066, 3000, 2922, 1715, 1590, 1428, 1293, 1221, 1112, 776, 734, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18—1.33 (m, 2H), 1.88—2.08 (m, 2H), 2.56 (t, J=5.8 Hz, 2H), 3.76 (s, 3H), 7.30—7.70 (m, 11H); ^{13}C NMR ($CDCl_3$) δ=9.07, 20.96, 29.32, 52.02, 128.0, 129.7, 133.7, 134.9, 135.3, 150.1, 167.3. Found: m/z 308.1227. Calcd for $C_{19}H_{20}O_2Si$: M, 308.1233.

Methyl (*E*)-3-(Allyldiphenylsilyl)acrylate (4e): Bp 150 °C (0.3 Torr, bath temp); ^1H NMR ($CDCl_3$) δ=2.25 (d, J=1.1 Hz, 2H), 3.75 (s, 3H), 4.90—5.08 (m, 2H), 5.82 (ddt, J=17.0, 10.1, 7.9 Hz, 1H), 6.31 (d, J=18.9 Hz, 1H), 7.30—7.70 (m, 11H); ^{13}C NMR ($CDCl_3$) δ=20.43, 51.68, 115.5, 128.0, 129.9, 132.7, 132.8, 135.8, 137.6, 143.8, 165.8.

1,1,3-Triphenyl-1-sila-2-cyclohexene (3f): Bp 145 °C (0.2 Torr, bath temp); IR(neat) 3064, 2918, 1589, 1565, 1493, 1427, 1110, 794, 729, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.28 (m, 2H), 2.10 (m, 2H), 2.74 (t, J=5.5 Hz, 2H), 6.42 (s, 1H), 7.25—7.75 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=20.00, 21.29, 33.10, 119.7, 125.6, 127.6, 128.2, 129.3, 129.9, 134.9, 136.7, 138.8, 144.9. Found: C, 84.56; H, 6.73%. Calcd for $C_{23}H_{22}Si$: C, 84.61; H, 6.79%.

(*E*)-1,1,3-Triphenyl-3-sila-1,5-hexadiene (4f): Bp 145 °C (0.2 Torr, bath temp); IR(neat) 3064, 2918, 1428, 1110, 794, 731, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.26 (d, J=7.9 Hz, 2H), 4.91 (d, J=9.9 Hz, 1H), 4.98 (d, J=17.2 Hz, 1H), 5.89 (ddt, J=17.2, 9.9, 7.9 Hz, 1H), 6.75 (d, J=19.4 Hz, 1H), 6.98 (d, J=19.4 Hz, 1H), 7.25—7.88 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=21.30, 114.8, 122.9, 126.7, 127.7, 127.9, 128.45, 128.54, 129.5, 133.8, 134.8, 135.4, 148.3. Found: C, 84.83; H, 6.79%. Calcd for $C_{23}H_{22}Si$: C, 84.61; H, 6.79%.

Dimethyl 1,1,5-Trimethyl-1-sila-2-cyclohexene-2,3-dicarboxylate (3g): Bp 90 °C (1.0 Torr, bath temp); IR(neat) 2950, 1719, 1604, 1432, 1229, 1144, 830, 801 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.19 (s, 3H), 0.21 (s, 3H), 0.45 (dd, J=14.3, 12.8 Hz, 1H), 0.87 (d, J=14.3 Hz, 1H), 1.08 (d, J=6.2 Hz, 3H), 1.80—2.03 (m, 1H), 2.04 (dd, J=18.1, 10.8 Hz, 1H), 2.53 (d, J=18.1 Hz, 1H), 3.75 (s, 3H), 3.77 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=−2.75, −2.54, 20.25, 25.91, 27.53, 38.96, 51.57, 52.02, 136.4, 151.0, 169.0, 170.1. Found: C, 56.36; H, 8.12%. Calcd for $C_{12}H_{20}O_4Si$: C, 56.22; H, 7.86%.

Methyl (*E*)-3-Methoxycarbonyl-4,4,6-trimethyl-4-sila-2,6-heptadienoate (4g): Bp 90 °C (1.0 Torr, bath temp); IR(neat) 2950, 1725, 1637, 1434, 1338, 1235, 1195, 1172, 1037, 843 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.23 (s, 6H), 1.719 (s, 3H), 1.723 (s, 2H), 3.75 (s, 3H), 3.83 (s, 3H), 4.54—4.60 (m, 1H), 4.68—4.73 (m, 1H), 6.11 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=−3.88, 25.12, 25.75, 51.95, 110.1, 129.3, 141.5, 154.4, 164.4, 170.8. Found: C, 56.27; H, 8.01%. Calcd for $C_{12}H_{20}O_4Si$: C, 56.22; H, 7.86%.

Methyl 1,1,5-Trimethyl-1-sila-2-cyclohexene-3-carboxylate (3h): Bp 70 °C (1.0 Torr, bath temp); IR(neat) 2950, 1717, 1434, 1272, 1249, 1219, 1059, 1048, 850, 801 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.110 (s, 3H), 0.114 (s, 3H), 0.37 (dd, J=14.3, 12.8 Hz, 1H), 0.81 (d, J=14.3 Hz, 1H), 1.08 (d, J=6.2 Hz, 3H), 1.60—1.93 (m, 2H), 2.50—2.73 (m, 1H), 3.75 (s, 3H), 7.00 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=−2.27 −2.20, 20.38, 26.42, 28.56, 37.27, 51.78, 138.0, 147.2, 167.5. Found: C, 60.46; H, 9.33%. Calcd for $C_{10}H_{18}O_2Si$: C, 60.56; H, 9.15%.

Methyl (*E*)-4,4,6-Trimethyl-4-sila-2,6-heptadienoate (4h): Bp 70 °C (1.0 Torr, bath temp); IR(neat) 2952, 1732, 1436, 1306, 1271, 1251, 1227, 1195, 1168, 997, 843, 803 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.17 (s, 6H), 1.65 (s, 2H), 1.70 (s, 3H), 3.76 (s, 3H), 4.49—4.53 (m, 1H), 4.62—4.65 (m, 1H), 6.27 (d, J=18.9 Hz, 1H), 7.27 (d, J=18.9 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=−3.49, 25.18, 26.71, 51.63, 109.3, 134.1, 142.3, 148.5, 166.1. Found: C, 60.49; H, 9.30%. Calcd for $C_{10}H_{18}O_2Si$: C, 60.56; H, 9.15%.

1,1,5-Trimethyl-3-phenyl-1-sila-2-cyclohexene (3i): Bp 100 °C (1.0 Torr, bath temp); IR(neat) 2950, 2902, 2876, 1589, 1568, 1492, 1453, 1442, 1206, 847, 787, 693 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.10 (s, 3H), 0.12 (s, 3H), 0.42 (dd, J=14.0, 12.8 Hz, 1H), 0.84 (d, J=14.0 Hz, 1H), 1.11 (d, J=6.4 Hz, 3H), 1.83—2.10 (m, 1H), 2.18 (ddd, J=16.9, 10.5, 2.4 Hz, 1H), 2.57 (ddd, J=16.9, 3.1, 1.6 Hz, 1H), 6.01 (s, 1H), 7.20—7.53 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−1.47, −1.37, 20.75, 26.79, 29.23, 41.47, 124.2, 125.5, 127.1, 128.1, 145.2, 156.6. Found:

C, 77.50; H, 9.54%. Calcd for $C_{14}H_{20}Si$: C, 77.71; H, 9.32%.

(*E*)-3,3,5-Trimethyl-1-phenyl-3-sila-1,5-hexadiene (4i): Bp 95 °C (1.0 Torr, bath temp); IR(neat) 2956, 1636, 1604, 1493, 1447, 1247, 987, 852 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.19 (s, 6H), 1.67 (s, 2H), 1.73 (s, 3H), 4.53—4.58 (m, 1H), 4.60—4.68 (m, 1H), 6.47 (d, J=19.2 Hz, 1H), 6.90 (d, J=19.2 Hz, 1H), 7.25—7.53 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−2.87, 25.29, 27.73, 108.6, 126.4, 128.0, 128.5, 138.3, 143.4, 144.3. Found: C, 77.97; H, 9.58%. Calcd for $C_{14}H_{20}Si$: C, 77.71; H, 9.32%.

Dimethyl 5-Methyl-1,1-diphenyl-1-sila-2-cyclohexene-2,3-dicarboxylate (3j): Bp 180 °C (0.3 Torr, bath temp); IR(neat) 2948, 2918, 1719, 1601, 1429, 1236, 1191, 1144, 1111, 1039, 779, 730, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (dd, J=14.5, 13.0 Hz, 1H), 1.11 (d, J=6.3 Hz, 3H), 1.30 (d, J=14.5 Hz, 1H), 1.95—2.20 (m, 1H), 2.27 (dd, J=18.5, 10.9 Hz, 1H), 2.66 (d, J=18.5 Hz, 1H), 3.49 (s, 3H), 3.79 (s, 3H), 7.30—7.78 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=18.99, 26.11, 27.40, 39.72, 51.51, 52.28, 127.8, 127.9, 129.77, 129.85, 132.3, 133.2, 135.3, 135.4, 155.1, 169.3. Found: C, 69.18; H, 6.43%. Calcd for $C_{22}H_{24}O_4Si$: C, 69.44; H, 6.36%.

Methyl (*E*)-3-Methoxycarbonyl-6-methyl-4,4-diphenyl-4-sila-2,6-heptadienoate (4j): ^1H NMR ($CDCl_3$) δ=1.60 (s, 3H), 2.30 (s, 2H), 3.65 (s, 3H), 3.72 (s, 3H), 4.62 (s, 1H), 4.70 (s, 1H), 6.15 (s, 1H), 7.30—7.80 (m, 10H). Analytically pure sample could not be obtained because of its small yield.

Methyl 5-Methyl-1,1-diphenyl-1-sila-2-cyclohexene-3-carboxylate (3k): Bp 155 °C (0.3 Torr, bath temp); IR(neat) 2948, 2918, 1715, 1597, 1454, 1429, 1271, 1219, 1113, 1057, 790, 776, 732, 712, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.92 (dd, J=14.0, 12.0 Hz, 1H), 1.14 (d, J=5.8 Hz, 3H), 1.37 (d, J=12.0 Hz, 1H), 1.80—2.20 (m, 2H), 2.67—2.92 (m, 1H), 3.77 (s, 3H), 7.25—7.70 (m, 11H); ^{13}C NMR ($CDCl_3$) δ=18.34, 26.52, 28.51, 37.50, 52.04, 128.0, 129.7, 133.6, 134.8, 134.9, 135.1, 149.6, 167.2. Found: C, 74.20; H, 6.91%. Calcd for $C_{20}H_{22}O_2Si$: C, 74.49; H, 6.88%.

Methyl (*E*)-6-Methyl-4,4-diphenyl-4-sila-2,6-heptadienoate (4k): Bp 155 °C (0.3 Torr, bath temp); IR(neat) 2948, 1720, 1429, 1271, 1224, 1190, 1169, 1112, 789, 777, 732, 712, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.58 (s, 3H), 2.25 (s, 2H), 3.76 (s, 3H), 4.60 (bs, 1H), 4.70 (bs, 1H), 6.30 (d, J=19.0 Hz, 1H), 7.25—7.75 (m, 11H); ^{13}C NMR ($CDCl_3$) δ=24.66, 25.50, 51.78, 111.2, 129.9, 133.3, 135.3, 137.5, 141.5, 144.4, 165.9. Found: C, 74.63; H, 6.90%. Calcd for $C_{20}H_{22}O_2Si$: C, 74.49; H, 6.88%.

5-Methyl-1,1,3-triphenyl-1-sila-2-cyclohexene (3l): Bp 175 °C (0.3 Torr, bath temp); IR(neat) 3064, 3016, 2948, 2916, 2864, 1591, 1565, 1492, 1444, 1428, 1264, 1207, 1187, 1111, 843, 793, 758, 730, 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.93 (dd, J=13.3, 14.1 Hz, 1H), 1.16 (d, J=6.4 Hz, 3H), 1.39 (d, J=14.1 Hz, 1H), 2.00—2.26 (m, 1H), 2.35 (ddd, J=17.1, 10.7, 2.4 Hz, 1H), 2.73 (d, J=17.1 Hz, 1H), 6.38 (s, 1H), 7.24—7.75 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=18.75, 26.80, 29.10, 41.65, 119.6, 125.7, 127.6, 127.8, 128.2, 129.3, 134.8, 135.0, 145.0, 159.7. Found: C, 84.53; H, 7.04%. Calcd for $C_{24}H_{24}Si$: C, 84.65; H, 7.10%.

(*E*)-5-Methyl-1,3,3-triphenyl-3-sila-1,5-hexadiene (4l): Bp 170 °C (0.3 Torr, bath temp); IR(neat) 3064, 3018, 2960, 2914, 1638, 1599, 1570, 1493, 1446, 1428, 1277, 1263, 1110, 1028, 997, 873, 795, 733, 697 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.62 (s, 3H), 2.26 (s, 2H), 4.61 (s, 1H), 4.67 (s, 1H), 6.79 (d, J=19.1 Hz, 1H), 6.96 (d, J=19.1 Hz, 1H), 7.24—7.75 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=25.30,25.60, 110.5, 123.4, 126.7, 127.8, 128.4, 128.5, 129.5, 135.1, 135.5, 138.1, 142.4, 148.2. Found: C, 84.48; H, 7.04%. Calcd for $C_{24}H_{24}Si$: C, 84.65; H, 7.10%.

Preparation of 3-Deuterio-3-methyl-1,1-diphenyl-1-silacyclobutane (5). The title compound was obtained following the procedure described for the preparation of **1d**. Hydrosilylation of 2-methylallyl chloride with diphenyldeuteriochlorosilane ($Ph_2Si(D)Cl$) in the presence of platinum catalyst gave 3-chloro-2-deuterio-2-methylpropyldiphenylchlorosilane in 36% yield: Bp 130—150 °C (0.2 Torr); IR(neat) 3068, 3048, 2998, 2962, 2870, 1457, 1429, 1378, 1283, 1246, 1115, 815, 766, 727, 697, 652 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00 (s, 3H), 1.31 (d, J=15.1 Hz, 1H), 1.68 (d, J=15.1 Hz, 1H), 3.40 (d, J=10.7 Hz, 1H), 3.44 (d, J=10.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=20.27, 21.27, 31.18, (t, J=20.1 Hz), 53.11, 128.1, 130.5, 130.6, 134.1, 134.2. Treatment of 3-chloro-2-deuterio-3-methylpropyldiphenylchlorosilane with Mg gave **5** in 79% yield: Bp 100 °C (0.3 Torr, bath temp); IR(neat) 3064, 3046, 3010, 2946, 2912, 2854, 1450, 1428, 1196, 1151, 1114, 842, 789, 736, 717, 696 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (d, J=15.6 Hz, 2H), 1.23 (s, 3H), 1.69 (d, J=15.6 Hz, 2H), 7.38—7.78 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=22.25, 27.49, 129.6, 134.5, 134.7, 135.9, 137.1. The signal for the carbon bearing deuterium could not be observed even with high concentrated sample. Found: C, 80.48; H, 7.85%. Calcd for $C_{16}H_{17}DSi$: C, 80.27; H, 8.00%.

The Reaction of 5 with Dimethyl Acetylenedicarboxylate. Heating a benzene solution of **5** (0.23 g, 0.97 mmol), dimethyl acetylenedicarboxylate (0.14 g, 1.0 mmol), and $PdCl_2(PPh_3)_2$ (7 mg, 0.01 mmol) at 80 °C for 3 h under argon atmosphere. The resulting mixture was concentrated in vacuo and the residual oil was submitted to silica-gel column chromatography to give **6a** (0.31 g, 84%) and **7a** (12 mg, 3%). Methyl 5-deuterio-5-methyl-1,1-diphenyl-1-sila-2-cyclohexene-2,3-dicarboxylate (**6a**): Bp 180 °C (0.3 Torr, bath temp); IR(neat) 2948, 2916, 1719, 1602, 1450, 1429, 1238, 1205, 1192, 1145, 1113, 1040, 898, 779, 759, 733, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.99 (d, J=14.6 Hz, 1H), 1.10 (s, 3H), 1.29 (d, J=14.6 Hz, 1H), 2.26 (d, J=19.0 Hz, 1H), 2.65 (d, J=19.0 Hz, 1H), 3.49 (s, 3H), 3.79 (s, 3H), 7.36—7.75 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=18.86, 26.02, 39.65, 51.54, 52.31, 127.8, 127.9, 129.8, 129.9, 135.3, 135.4, 155.2, 169.4. The signal for the carbon bearing deuterium could not be observed. Found: C, 68.98; H, 6.40%. Calcd for $C_{22}H_{23}DO_4Si$: C, 69.26; H, 6.60%.

Reaction of Allyldimethylsilane with Phenylacetylene in the Presence of $PdCl_2(PPh_3)_2$ or H_2PtCl_6. A benzene solution of allyldimethylsilane (0.15 g, 1.5 mmol) and phenylacetylene (0.10 g, 1.0 mmol) was heated in the presence of catalytic amount of $PdCl_2(PPh_3)_2$ (10 mg, 0.014 mmol) at reflux for 2 h. The resulting dark brown solution was concentrated and the residual oil was submitted to silica-gel column chromatography to give a mixture of allyldimethylstyrylsilane (**4c**) and allyldimethyl(1-phenylvinyl)silane (**12**, 30 mg, **4c**/**12**=63/37) in <15% combined yield. **12**: ^1H NMR ($CDCl_3$) δ=5.65 (d, J=2.9 Hz, 1H), 5.90 (d, J=2.9 Hz, 1H). Meanwhile, stirring a mixture of allyldimethylsilane (0.30 g, 3.0 mmol) and phenylacetylene (0.30 g, 3.0 mmol) in the presence of $H_2PtCl_6 \cdot 6H_2O$ (5 mg) at room temperature for 15 h gave a mixture of **4c** and **12** (0.31 g, **4c**/**12**=2.4/1) in 52% yield.[12]

Dimethyl 1,2-Dihydro-2,2-dimethyl-2-silanaphthalene-3,4-dicarboxylate (14): Bp 119 °C (1.0 Torr, bath temp); IR(neat) 2950, 1734, 1715, 1584, 1554, 1435, 1302, 1231, 1208, 1070, 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.20 (s, 6H); 2.19 (s, 2H), 3.77 (s, 3H), 3.91 (s, 3H), 7.10—7.24 (m, 4H); ^{13}C NMR ($CDCl_3$) δ=−3.96, 20.77, 51.82, 52.40, 126.0, 129.1, 129.9, 131.4, 131.9,

137.5, 145.4, 153.3, 169.6, 169.9. Found: C, 61.89; H, 6.32%. Calcd for $C_{15}H_{18}O_4Si$: C, 62.04; H, 6.25%.

1,2-Dihydro-2,2-dimethyl-4-phenyl-2-silanaphthalene (15a): Mp 76.5—77.0 °C (hexane); IR(neat before crystallization) 3040, 2945, 2840, 1570, 1540, 1475, 1435, 1242, 1203, 822, 797, 761, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.13 (s, 6H), 2.22 (s, 2H), 6.14 (s, 1H), 6.98—7.30 (m, 4H), 7.37 (bs, 5H); ^{13}C NMR ($CDCl_3$) δ=−3.63, 21.41, 125.0, 127.1, 127.3, 128.0, 128.2, 129.4. Found: C, 81.52; H, 7.11%. Calcd for $C_{17}H_{18}Si$: C, 81.54; H, 7.24%.

1,4-Dihydro-1,1-dimethyl-3-phenyl-1-silanaphthalene (15b): Bp 120 °C (0.3 Torr, bath temp); IR(neat) 3052, 2952, 1595, 1492, 1436, 1247, 1136, 844, 772, 741, 693 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.32 (s, 6H), 4.07 (s, 2H), 6.33 (s, 1H), 7.25—7.68 (m, 9H); ^{13}C NMR ($CDCl_3$) δ=−1.21, 38.78, 123.9, 125.7, 125.8, 127.5, 128.3, 128.6, 128.8, 133.1, 134.0, 144.7, 144.8, 155.1. Found: C, 81.38; H, 7.26%. Calcd for $C_{17}H_{18}Si$: C, 81.54; H, 7.24%.

2-Methylene-1,1-dimethyl-3-phenyl-1-silacyclohexane (16a): Bp 100 °C (1.0 Torr, bath temp); IR(neat) 2954, 2920, 2852, 1729, 1630, 1599, 1491, 1447, 1250, 1154, 1121, 1073, 1032, 961, 892, 835, 758, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.12 (s, 3H), 0.17 (s, 3H), 0.50—0.80 (m, 1H), 0.80—1.00 (m, 1H), 1.60—1.90 (m, 2H), 1.90—2.03 (m, 1H), 2.03—2.13 (m, 1H), 3.40—3.60 (m, 1H), 4.84 (t, J=2.5 Hz, 1H), 5.24 (t, J=2.5 Hz, 1H), 7.10—7.45 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−3.05, 15.19, 23.61, 36.77, 52.50, 122.0, 125.9, 128.1, 128.5, 143.8, 155.7. Found: C, 77.82; H, 9.50%. Calcd for $C_{14}H_{20}Si$: C, 77.71; H, 9.32%.

2-Benzylidene-1,1-dimethyl-1-silacyclohexane (17a): Bp 100 °C (1.0 Torr, bath temp); IR(neat) 2950, 2916, 2848, 1729, 1598, 1492, 1445, 1429, 1249, 1139, 1111, 900, 871, 828, 776, 751, 732, 712, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.17 (s, 6H), 0.65—0.80 (m, 2H), 1.40—1.70 (m, 2H), 1.75—1.95 (m, 2H), 2.55—2.70 (m, 2H), 6.68 (s, 1H), 7.10—7.50 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−3.49, 15.36, 24.37, 30.70, 31.60, 126.3, 128.0, 128.9, 134.1, 138.1, 145.5. Found: C, 77.75; H, 9.47%. Calcd for $C_{14}H_{20}Si$: C, 77.71; H, 9.32%.

Allyldimethyl(α-methylstyryl)silane (18a): Bp 90 °C (1.0 Torr, bath temp); IR(neat) 2954, 2922, 2852, 1630, 1598, 1490, 1447, 1250, 1153, 1120, 1072, 1031, 961, 930, 892, 835, 758, 694 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.15 (s, 6H), 1.66 (d, J=8.0 Hz, 2H), 1.94 (d, J=1.8 Hz, 3H), 4.80—5.00 (m, 2H), 5.83 (ddt, J=17.0, 10.0, 8.0 Hz, 1H), 6.77 (s, 1H), 7.10—7.50 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=−4.26, 16.57, 22.74, 113.1, 122.0, 126.5, 128.0, 128.5, 129.0, 135.0, 137.8, 138.2, 138.6. Found: C, 77.77; H, 9.56%. Calcd for $C_{14}H_{20}Si$: C, 77.71; H, 9.32%.

2-Methylene-1,1,3-triphenyl-1-silacyclohexane (16b): Bp 175 °C (0.25 Torr, bath temp); IR(neat) 3062, 3048, 3020, 2916, 2850, 1491, 1451, 1429, 1111, 938, 814, 732, 711, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.15—1.45 (m, 1H), 1.45—2.12 (m, 4H), 2.18—2.35 (m, 1H), 3.52 (d, J=10.0 Hz, 1H), 5.06 (s, 1H), 5.20 (s, 1H), 7.10—7.80 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=12.45, 23.88, 36.87, 52.81, 126.0, 127.0, 127.7, 128.2, 128.5, 129.47, 129.52, 134.0, 134.7, 135.2, 135.5, 143.7, 151.2. Found: C, 84.56; H, 7.20%. Calcd for $C_{24}H_{24}Si$: C, 84.65; H, 7.10%.

2-Benzylidene-1,1-diphenyl-1-silacyclohexane (17b): Bp 175 °C (0.4 Torr, bath temp); ^1H NMR ($CDCl_3$) δ=1.25—2.20 (m, 6H), 2.65—2.80 (m, 2H), 6.67 (s, 1H), 7.20—7.80 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=12.64, 24.14, 30.42, 32.15, 126.6, 127.9, 128.0, 129.0, 135.5, 139.3, 141.2. Found: C, 84.36; H, 6.98%. Calcd for $C_{24}H_{24}Si$: C, 84.65; H, 7.10%.

Allyldiphenyl(α-methylstyryl)silane (18b): Bp 175 °C (0.3 Torr, bath temp); ^1H NMR ($CDCl_3$) δ=2.07 (s, 3H), 2.35 (d, J=8.0 Hz, 2H), 4.85—5.03 (m, 2H), 5.80—6.15 (m, 1H), 6.90 (s, 1H), 7.20—7.80 (m, 15H); ^{13}C NMR ($CDCl_3$) δ=17.65, 20.53, 114.8, 126.9, 127.8, 128.1, 129.1, 134.1, 134.4, 135.6, 142.4. Found: C, 84.57; H, 6.96%. Calcd for $C_{24}H_{24}Si$: C, 84.65; H, 7.10%.

1,2,3,4-Tetrahydro-2,2-dimethyl-3-methylene-4-phenyl-2-silanaphthalene (19): Mp 85—86 °C (hexane); IR(neat before crystallization) 3058, 3026, 2944, 1491, 1481, 1447, 1246, 922, 834, 805, 776, 754, 736, 697, 649 cm^{-1}; ^1H NMR ($CDCl_3$) δ=−0.04 (s, 3H), 0.06 (s, 3H), 1.65 (d, J=14.8 Hz, 1H), 1.84 (d, J=14.8 Hz, 1H), 4.72 (s, 1H), 5.59 (d, J=2.6 Hz, 1H), 5.91 (d, J=2.6 Hz, 1H), 7.05—7.38 (m, 9H); ^{13}C NMR ($CDCl_3$) δ=−2.42, −0.80, 20.87, 60.58, 125.5, 125.9, 126.5, 127.1, 127.5, 128.1, 130.0, 130.9, 138.0, 140.8, 141.7, 151.3. Found: C, 81.72; H, 7.57%. Calcd for $C_{18}H_{20}Si$: C, 81.76; H, 7.62%.

Financial support by the Ministry of Education, Science and Culture (Grant-in-Aid for Scientific Research No. 02650624) is acknowledged.

10) The rate of reductive elimination is enhanced by electron abstraction from palladium metal. For instance, Schwartz et al. have reported that reductive elimination proceeded smoothly in the presence of maleic anhydride (J. S. Temple, M. Riediker, and J. Schwartz, *J. Am. Chem. Soc.*, **104**, 1310 (1982)). Thus, the difference in the product ratio (**3**:**4**) between dimethyl acetylenedicarboxylate and phenylacetylene might be ascribed to the electron density on palladium in the intermediate **9**. The electron density on palladium in the compound **9** (R^1=R^2=COOMe) might be lower than that in the intermediate **9** (R^1=Ph, R^2=H) and facile reductive elimination would take place in the compound **9** (R^1=R^2=COOMe) to give silacyclohexene derivative mainly.

Stereochemical Control in Microbial Reduction. 18. Mechanism of Stereochemical Control in the Diastereoselective Reduction with Bakers' Yeast

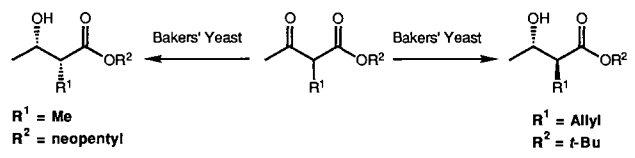
(Received December 25, 1990)

Reduction of a variety of 2-alkyl-3-oxobutanoates with bakers' yeast yields the corresponding L-(3*S*)-hydroxy esters with exclusive enantioselectivity, while the diastereoselectivity, syn/anti ratio, varies depending on the structure of the alkoxyl moiety. In order to elucidate the mechanism for this stereochemical control, oxidoreductases that reduce 2-alkyl-3-oxobutanoate have been isolated from the cells of bakers' yeast and purified. Two dominant competing 2-alkyl-3-hydroxybutanoate oxidoreductases have been obtained: one of them reduces 2-alkyl-3-oxobutanoates stereoselectively yielding the corresponding L-*syn*-hydroxy esters, whereas the other affords a mixture of L-*syn*- and L-*anti*-hydroxy esters. The experimental results on stereoselectivity have nicely been simulated using kinetic parameters elucidated.

Optically active 2-alkyl-3-hydroxyalkanoates are versatile chiral building blocks in organic synthesis[1] because they have two chiral centers necessary for asymmetric synthesis as well as two functional groups that are readily convertible into many other functions. A number of researchers have made efforts to obtain the compounds of this class.[2-4] Recently, we developed the methods to synthesize optically active 2-alkyl-3-hydroxy esters under the catalysis of biological systems:[5-10] bakers' yeast reduces various 2-alkyl-3-oxobutanoates affording the corresponding L-(3*S*)-hydroxy esters with exclusive enantioselectivity, while the diastereoselectivity varies depending on the structure of the alkoxyl group. The presence or absence of a substituent at the carbon adjacent to the alkoxyl oxygen is crucial to control the reduction course leading to the *syn*- or *anti*- product.[11] For example, the reduction of neopentyl 2-methyl-3-oxobutanoate (**1c**) affords the corresponding (2*R*,3*S*)-*syn*-hydroxy ester with 92% diastereomer excess (d.e.), whereas the reduction of *t*-butyl 2-allyl-3-oxobutanoate (**2b**) yields the corresponding (2*S*,3*S*)-*anti*-hydroxy ester with 88% d.e. (Scheme 1).

In order to clarify the mechanism for stereochemical control in microbial reduction, we isolated certain β-hydroxy ester oxidoreductases effective to the reduction of 2-alkyl-3-oxobutanoates from the cells of bakers' yeast and studied the kinetics as well as stereochemical properties of the enzymes. In the previous paper of this series, we reported that the studies at the enzyme level is successful to explain stereochemical behavior of their host microbe under various reaction conditions at least qualitatively.[12]



Scheme 1.

Experimental

Instruments. ^{1}H NMR spectra were recorded on a Varian VXR-200 spectrometer in $CDCl_3$ with Me_4Si as an internal standard. Gas chromatograms were recorded on a Yanaco G-2800 (PEG-20M, 1.5 m) and a Shimadzu GC-14A (PEG-20M Bonded, 25 m) gas chromatographs. Preparative gas chromatography was done on a Varian Aerograph Model 920 gas chromatograph (PEG-20M, 1.5 m, 150 °C). UV spectra were obtained on a Hitachi U-3210 spectrophotometer. Optical rotation was measured with a Perkin-Elmer 241 polarimeter.

Materials. Organic reagents and solvents were purchased from Nacalai Tesque Co., Tokyo Kasei Co., and Aldrich Chemical Co. unless otherwise indicated. Bakers' yeast was purchased from Oriental Yeast Co. and stored in a refrigerator. The substrates (**1a—c**) and (**2a—c**) were prepared according to the method described in our previous paper.[7] The detailed procedure for purification of the enzymes was described in the previous paper.[12]

Enzyme Assay. A 50 μl aliquot of a fraction of chromatography was added to a 3.10 ml solution (0.10 M potassium phosphate buffer at pH 7.0, 1M=1 mol dm^{-3}) containing ethyl 2-allyl-3-oxobutanoate (**2a**) (9.32×10^{-4} M) and NADPH (9.00×10^{-5} M). The kinetics was followed spectrophotometrically at 30 °C following the decreases in absorbance of NADPH at 340 nm. One unit of the enzyme activity was defined as the amount of an enzyme which catalyzes the oxidation of 1 μmol NADPH per minute at 30 °C under the assay conditions.

Reduction of Alkyl 2-Alkyl-3-oxobutanoate with Enzymes. In a 10 ml round-bottomed flask equipped with magnetic stirrer and silicone stopper, were placed a concentrated solution of an enzyme (1 unit), NADPH (8 mg), a substrate (5 mg), and 0.1 M phosphate buffer (pH 7.0, 4 ml). The flask

†† Present address: Nissei Kagaku Kogyo Co., Ltd., 1-8-7 Fukumachi, Nishiyodogawa-ku, Osaka 555.

was protected from light and the mixture was stirred for 24 h at 30 °C. The mixture was extracted with ether, washed with water and brine, and dried over anhydrous sodium sulfate. The diastereomer excess (% d.e.) in the hydroxy ester was determined by gas chromatographic analyses (PEG-20M Bonded, 25 m, 90 °C for 2-methyl-3-hydroxy esters and 150 °C for 2-allyl-3-hydroxy esters).[13]

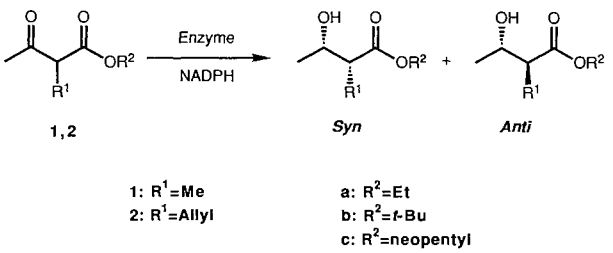
Results

Purification of 2-Alkyl-3-hydroxybutanoate Oxidoreductases. 2-Alkyl-3-hydroxy ester oxidoreductases were separated from the cell-free solution of bakers' yeast by column chromatography on DEAE-Toyopearl anion exchange resin, and two enzymes were found to exert the desired activity. One of them (E1) was not adsorbed on the anion exchange resin, whereas the other (E2) was adsorbed on it at pH 7.0 (10 mM phosphate buffer). Both enzymes were further purified with chromatographic techniques including ion-exchange, hydrophobic, and gel filtration chromatographies. The activity was determined based on the velocity of the reduction of ethyl 2-allyl-3-oxobutanoate (**2a**). Both enzymes utilize NADPH preferentially as the coenzyme. Total activities of these enzymes measured under the assay and preparative conditions are summarized in Table 1.

In the previous paper, we reported that bakers' yeast has four β-hydroxy ester oxidoreductases. Two of them (L-enzymes) afford the corresponding L-hydroxy esters, whereas the other two (D-enzymes) give the D-hydroxy esters.[12] Since the yeast reduction of 2-alkyl-3-oxobutanoates affords the corresponding L-(3*S*)-hydroxy esters exclusively, it is probable that these two 2-alkyl-3-hydroxy ester oxidoreductases are identical with the two L-enzymes reported previously. In order to confirm the identity, the substrate specificities of E1 and E2 were kinetically studied for the reductions of ethyl 4-chloro-3-oxobutanoate and found, together with the chromatographic evidence, that non-adsorbed enzyme (E1) and adsorbed enzyme (E2) are identical with the previously reported L-enzyme-1 and L-enzyme-2, respectively. Detailed descriptions of the purification methods and enzyme properties are given in the previous paper.[12]

The diastereoselectivity in the reduction of various esters of 2-methyl-3-oxobutanoates (**1**) or 2-allyl-3-oxobutanoates (**2**) with these two enzymes were determined (Scheme 2) and the results are summarized in Table 2.

In order to characterize the enzymes, the kinetic parameters, K_M and V_{max}, for the present particular substrates were elucidated from the Lineweaver–Burk plot[14] and the results are listed in Table 3.



Scheme 2.

Table 1. Total Activities of Enzymes for Ethyl 2-allyl-3-oxobutanoate (**2a**) as Substrate

Enzyme	Total activity (unit)	
	[S]=1 mM[a]	[S]=40 mM[b]
E1	8.8[c]	102
E2	93	273

a) Substrate concentration under the assay conditions. b) Substrate concentration under the preparative reaction conditions. c) Note that [S]≪K_M under the assay conditions.

Table 2. Reduction of Alkyl 2-Methyl- and 2-Allyl-3-oxobutanoates (**1**) and (**2**) with Isolated Enzymes

Substrate	*syn*:*anti* Ratio in the product	
	E1	E2
1a	>99:1	82:18
1b	97:3	51:49
1c	>99:1	96:4
2a	>99:1	6:94
2b	>99:1	3:97
2c	>99:1	19:81

Table 3. Kinetic Parameters for the Enzymes[a]

Substrate	K_M/mM		k_{cat}/s^{-1}		$10^6 V_{max}$/M s^{-1} mg^{-1} protein		$10\,k_{cat}/K_M$/s^{-1} mM^{-1}	
	E1	E2	E1	E2	E1	E2	E1	E2
1a	6.4	3.1	4.06	0.179	41.0	1.80	6.35	0.577
1b	15	2.3	2.87	0.070	28.9	0.701	1.91	0.302

2c	1.1	1.0	1.90	0.403	19.1	4.06	17.3	4.03

a) Errors in K_M and k_{cat} are estimated to be less than ±10%. b) The error in this value is about ±20% because the solubility of this substrate is only 3 mM.

Discussion

Several hydroxy ester oxidoreductases have been isolated from bakers' yeast. Shieh et al. isolated three kinds of β-hydroxy ester oxidoreductases, which reduced ethyl 4-chloro-3-oxobutanoate.[15] One of them possesses similar properties to fatty acid synthetase (FAS) and reduces β-keto esters to afford D-hydroxy ester. One of the other enzymes also gives D-hydroxy ester (D-enzyme), whereas the last one yields L-hydroxy ester (L-enzyme). Their L-enzyme is distinct from our both L-enzymes since there have different molecular weight and kinetic constants. Furuich et al. isolated a β-hydroxy ester oxidoreductase from bakers' yeast.[16] It reduces benzyl 2-methyl-3-oxobutanoate affording the corresponding L-hydroxy ester (L-enzyme). This enzyme differs from our enzymes, because the latter enzymes are able to reduce ethyl 2-methyl-3-oxobutanoate (**1a**), whereas the former inactive toward this substrate. Although they reported the isolation of another oxidoreductase from *Saccharomyces fermentati*, this enzyme also differs from our enzymes both in molecular weight and substrate specificity.[17]

As listed in Table 2, E1 is distinct from E2 in diastereoselectivity of the reduction. The former affords the L-*syn*-hydroxy ester with exclusive stereoselectivity for all the substrates. On the other hand, the diastereoselectivity of the latter enzyme depends on the structure of the substrate; not only on the structure of the alkoxyl group but also on the structure of the substituent at the C_2-position. The substrates (**1**) that have a methyl group at the C_2-position tend to afford the corresponding *syn*-hydroxy esters under the catalysis of E2, whereas the substrates (**2**) having an allyl group at the same position prefer to afford the corresponding *anti*-hydroxy esters under the same reaction conditions.

In the reaction with E2, the values of K_M remains almost constant regardless of the structure through all of the substrates employed. However, this tendency is not held in the reaction with E1: the K_M for the neopentyl ester is small but that for the *t*-butyl ester is large in both of 2-methyl and 2-allyl derivatives. That is, it has been elucidated that the active site of E1 is adopted to the neopentyl derivative more effectively than to the ethyl derivative. The *t*-butyl derivative is the least effective substrate.

In addition, it is interesting to compare the substrate selectivity of E1 with that of E2 from the viewpoint of the stereochemistry at the C_2-position. Only the (2*R*)-isomer can be recognized by E1 as the substrate affording the (2*R*)-*syn*-product exclusively. The (2*S*)-isomer is not reduced until it is converted into the (2*R*)-isomer by isomerization equilibrium. This characteristics of the reaction is independent of the structure of the substituent at the C_2-position. On the contrary, E2 has a rather wide selectivity on stereochemistry at the C_2-position: although a substrate which has the 2-methyl substituent exerts a tendency to react as the (2*R*)-isomer, the selectivity at the C_2-position depends largely on the structure of the alkoxyl moiety. Namely, the neopentyl ester (**1c**) is reduced almost exclusively through the (2*R*)-isomer (2*R*:2*S*=96:4), whereas there is no enantiomeric discrimination between the (2*S*)- and (2*R*)-configurations in the *t*-butyl ester (**1b**) (2*R*:2*S*= 51:49).

In the reduction with E2, the substrate with the 2-allyl substituent reacts mainly through the (2*S*)-isomer. Among three substrates studied, the *t*-butyl ester (**2b**) exerts the largest (2*S*)-selectivity, which is a distinct contrary to the selectivity on the 2-methyl derivative mentioned above. In other words, it may be concluded that the *t*-butoxyl group prefers to afford the (2*S*)-*anti*-product, but the neopentyloxyl group suits to yield the (2*R*)-*syn*-product.

Knowing relative activities of the enzymes in bakers' yeast and the concentration of the substrate, we can simulate the stereoselectivity of the microbial reduction theoretically. The substrate concentration employed for the present preparative reactions is 40 mM.[7] Although **1a** and **2a** have enough solubility to maintain this stoichiometric concentration during the reaction, **1b**, **1c**, **2b**, and **2c** are less soluble to water and their concentrations in saturated aqueous solutions are about 12, 3, 3, and 1 mM, respectively. That is, the effective concentrations of the substrates in the latter group are much smaller than 40 mM in the preparative reactions. Therefore, the diastereoselectivities of the reduction can be evaluated based on the effective concentrations of the substrates, the relative activities: velocity (listed in Table 3) × total unit (listed in Table 1), and the syn/anti selectivities of these two competing enzymes. The results are summarized in Table 4. The diastereoselectivities experimentally observed for the reduction with bakers' yeast[7] are also listed in Table 4 for comparison. It is apparent that the calculated selectivities are in good agreement with the experimental values.

The mechanism for stereochemical control in the reduction with bakers' yeast by modification of the alkoxyl group is thus explicated by kinetic parameters

Table 4. Calculated Diastereoselectivity of the Reduction Based on Kinetic Parameters

Substrate	*syn*:*anti* Ratio in the product	
	Bakers' yeast[a]	Calcd
1a	87:13	92:8
1b	72:28	78:22
1c	96:4	99:1
2a	35:65	31:69
2b	6:94	9:91
2c	56:44	37:63

a) Ref. 8.

for the combinations of various substrates and enzymes. The K_M values for E2 do not change appreciably upon the modification in structure of the alkoxyl group, whereas those for E1 change so that they increase when the alkoxyl oxygen is bound directly to a tertiary carbon such as in the *t*-butyl group, and decrease when a methylene group is inserted between the alkoxyl oxygen and a bulky alkyl group such as in the neopentyl group.

It is conceivable that the binding site of E1 has a shape such that there is no enough room to set a bulky tertiary carbon in the vicinity of the alkoxyl oxygen. The steric tension in the pocket can be released, however, by the insertion of a methylene group between the alkoxyl oxygen and a bulky alkyl group because the molecule now procures an ability to fracture the bulky substituent to assume the least volume.[7] Consequently, the presence or absence of a methylene group adjacent to the alkoxyl oxygen is crucial to control the diastereoselectivity of the reduction.

The pocket of E2, on the other hand, is so vague that not only the structure of the alkoxyl group but also the stereochemistry at the C_2-position are not discriminated strictly by this enzyme. It is assumed that a substrate can be contained in the pocket of E2 setting either of its 2*S*- and 2*R*-isomer against the reacting function of the enzyme without causing serious steric strain. The dominant effect to choose the isomer is the force to set the substrate in the stable form in the pocket of the enzyme. The *syn*- and *anti*-products are, therefore, afforded in various ratios under the catalysis of E2 depending on the structure of substituent at the C_2-position.

The enzymatic studies of bakers' yeast for other substrates are now in progress in our laboratory and will be reported elsewhere.

We thank financial support for this research by the Ministry of Education, Science and Culture, under the Grant-in-Aid Nos. 01470022, 01303007, and 02303004.

Enantio- and Diastereo-Selective Synthesis of (+)-Grandisol

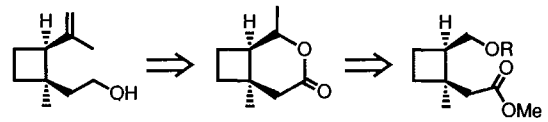
Koichi NARASAKA,* Hiroyuki KUSAMA, and Yujiro HAYASHI
Department of Chemistry, Faculty of Science, The University of Tokyo,
Hongo, Bunkyo-ku, Tokyo 113
(Received December 27, 1990)

(+)-Grandisol, an insect pheromone having cyclobutane skeleton, is synthesized enantio- and diastereoselectively. The key steps in the synthesis are the asymmetric [2+2] cycloaddition reaction catalyzed by a chiral titanium reagent and the diastereoselective conjugate addition reaction by the combined use of Me_2CuLi and trimethylsilyl trifluoromethanesulfonate.

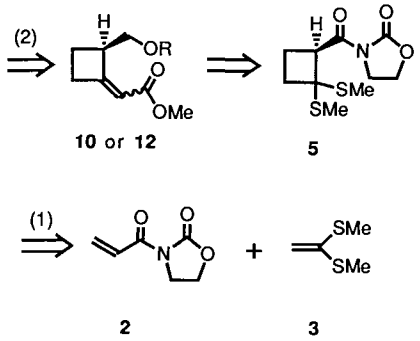
(+)-Grandisol, which was first isolated by Tumlinson et al. in 1967,[1] is one of the components of the male-produced pheromone of the cotton boll weevil (*Anthonomus Grandis*). This compound attracted much attention of many synthetic organic chemists not only due to its biological activity but also to its unique cyclobutane structure, and many synthetic studies have been reported[2,3] including several asymmetric syntheses.[4-6] The crucial step in these asymmetric syntheses is the preparation of optically active cyclobutanes, which includes optical resolutions of cyclobutane derivatives,[4] syntheses from chiral building blocks of natural compounds,[5] and diastereoselective [2+2] photocycloaddition reactions using substrates having chiral auxiliaries.[6]

We have recently reported the asymmetric [2+2] cycloaddition reaction between 3-acryloyl-1,3-oxazolidin-2-one derivatives and ketene dithioacetal promoted by a catalytic amount of the chiral titanium reagent prepared from dichlorodiisopropoxytitanium and a tartrate-derived chiral diol.[7] This reaction gives chiral cyclobutane derivatives in high enantioselectivity and, furthermore, both enantiomers of the chiral cyclobutanes are easily obtained by choosing the appropriate enantiomer of the chiral 1,4-diol. These chiral products are expected to be synthetically useful chiral building blocks. In fact, the total synthesis of carbocyclic oxetanocin analogues was performed starting from the optically active [2+2] adduct.[8] For a further application, the asymmetric synthesis of (+)-grandisol **1** has been attempted and, in this report, the detail of the synthesis is summarized.

In the following retrosynthetic scheme, the key steps are: (1) the construction of the chiral cyclobutane **5** with high enantioselectivity, (2) the diastereoselective introduction of α-methyl group to the methyl cyclobutylideneacetate **10** or **12**.

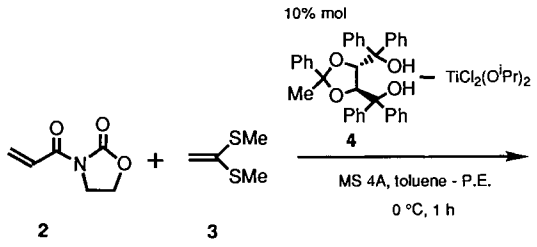


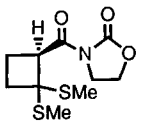
(+)-Grandisol **1**



Results and Discussion

The asymmetric [2+2] cycloaddition reaction between 3-acryloyl-1,3-oxazolidin-2-one (**2**) and 1,1-bis(methylthio)ethylene (**3**) was examined. The chiral titanium reagent was prepared *in situ* by mixing dichlorodiisopropoxytitanium and (−)-(2*S*,3*S*)-1,1,4,4,-tetraphenyl-2,3-*O*-(1-phenylethylidene)-1,2,3,4-butanetetrol (**4**) derived from (−)-tartaric acid.[9] The reaction of **2** and **3** in the presence of 10% mol of the above chiral titanium catalyst and Molecular Sieves 4A in a toluene–petroleum ether mixture at 0 °C for 1 h afforded the corresponding cyclobutanecarboxylic acid derivative **5** in 80% yield with 88% ee.





80% yield, 88% ee
recryst. from benzene - hexane >98% ee

The optically pure material **5** (>98% ee) was obtained by the recrystallization from benzene–hexane. The optical purity was checked by the 500 MHz ^{1}H NMR analysis of the Mosher's (+)-methoxy trifluoromethyl phenyl acetate ((+)-MTPA ester)[10] derived from **7**. The X-ray crystallographic analysis of the single crystal of **5** was shown in the following figure. Although the absolute configuration of **5** could not be determined by this X-ray analysis, it is considered to be *S* based on the previously reported [2+2] cycloaddition reaction of 3-[3-(methoxycarbonyl)acryloyl]-1,3-oxazolidin-2-one and ketene dithioacetal **3**.[7]

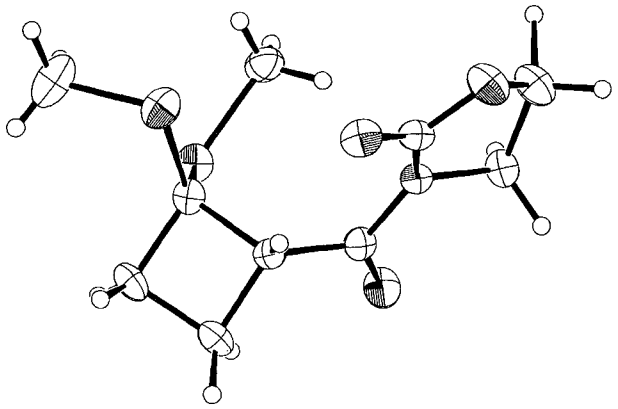


Fig. 1. The ORTEP drawing of **5**.

The transformation of the optically pure cyclobutane **5** to the α,β-unsaturated ester **10a** was performed as shown in Scheme 1. Treatment of **5** with magnesium methoxide gave the methyl ester **6**. Reduction of **6** with $LiAlH_4$ afforded the alcohol **7**, whose hydroxyl group was protected as *t*-butyldiphenylsilyl (TBDPS) ether **8** in 94% overall yield from **5** in 3 steps. Subsequently, hydrolysis of dithioacetal group of **8** with *N*-chlorosuccinimide and silver nitrate[11] gave the cyclobutanone **9** in 95% yield. The Peterson olefination of **9** [$LiN(c\text{-}C_6H_{11})_2$, $TMSCH_2CO_2Me$ (TMS=trimethylsilyl)][12] gave the (*Z*)-α,β-unsaturated ester **10a** quantitatively as a single stereoisomer.

Then, the introduction of methyl group to the (*Z*)-ester **10a** was investigated. The (*Z*)-**10a**, a β,β-disubstituted unsaturated ester, was considered to be a poor Michael acceptor toward organocopper(I) reagents.[13] In fact, as shown in Table 1, the reactions of **10a** with lithium dimethylcuprate(I) and methylcopper-(I) did not proceed (Entries 1 and 2). The mixed reagents, MeCu–BF_3·OEt_2 or Me_2CuLi–BF_3·OEt_2,[13,14] also did not give the methylated product (Entries 3 and 4). By the use of Me_2CuLi–TMSCl,[15,16] however, the addition product **11a** was obtained, but the yield was not sufficiently high (60%) (Entry 5). Since more effective activation reagent was thought to be required, the reaction was examined by using trimethylsilyl trifluoromethanesulfonate (TMSOTf), a much stronger Lewis acid (Entry 6). Treatment of **10a** with Me_2CuLi in the presence of TMSOTf in Et_2O at −78 °C afforded the addition product **11a** almost quantitatively as an inseparable mixture of *cis* and *trans* isomers (*cis*:*trans*= 2.5:1). Relative stereochemistry of these two isomers were determined by NOESY spectrum (see Experimental Section).

In order to realize much higher stereoselectivity, the reaction was further examined in detail. And it was found that the stereoselectivity was not influenced on

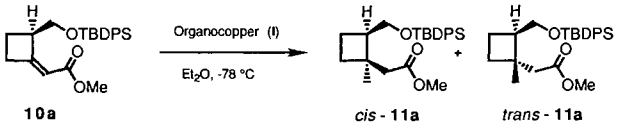

Table 1. The Conjugate Addition Reaction of Organocopper (I) Reagents with **10a**

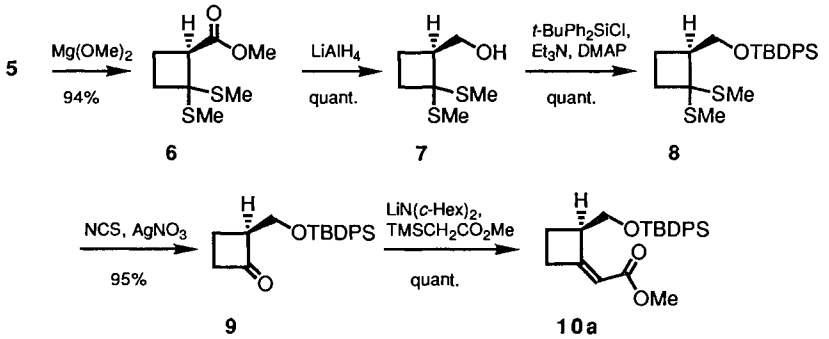
Entry	Organocopper (I)	Lewis acid	Yield (*x*/%)	**11a** *cis*:*trans*[a]
1	MeCu		0	
2	Me_2CuLi		0	
3	MeCu	BF_3·OEt_2	0	
4	Me_2CuLi	BF_3·OEt_2	0	
5	Me_2CuLi	TMSCl	60	2:1
6	Me_2CuLi	TMSOTf	quant.	2.5:1

a) The ratio of *cis*:*trans* was determined by the integration ratio of the singlet peak of the quaternary methyl groups (500 MHz ^{1}H NMR).



Scheme 1.

the solvent and the reaction temperature. The use of higher order organocuprates(I) was also ineffective. On the other hand, the diastereoselectivity was found to be largely dependent on the protective group of the hydroxyl group and the geometry of the α,β-unsaturated ester moiety.

The (*E*)-α,β-unsaturated esters having various hydroxyl protective groups were prepared from the (*Z*)-ester **10a** as shown in Scheme 2. The desilylation of the (*Z*)-ester **10a** with $Bu_4N^+F^-$ in THF at room temperature was accompanied with the isomerization to the (*E*)-ester **13**, though the complete racemization occurred at the same time with the fluoride anion. The isomerization was, therefore, tried with PhSLi in THF and the (*E*)-ester **12a** was obtained in 73% yield (the (*Z*)-ester **10a** was recovered in 26% yield). Deprotection of **12a** with hydrochloric acid in MeOH and the introduction of various protective groups gave the corresponding (*E*)-esters **12b,c**. By the ^1H NMR analysis of the (+)-MTPA ester[10] of the alcohol **13**, no sign of racemization could be detected. The (*Z*)-esters **10b,c** were prepared by desilylation of **10a** with hydrochloric acid followed by the protection of the resulting alcohol.

The addition reaction to various (*Z*)- and (*E*)-esters **10** and **12** were examined with Me_2CuLi and TMSOTf at −78 °C in Et_2O. When the (*Z*)- or (*E*)-esters protected as *t*-butyldiphenylsilyl ether or methyl ether **10a,b** and **12a,b** were employed, the stereoselectivity was not improved (Table 2, Entries 1—4). In the case of the reaction of the (*Z*)-ester having TMS ether **10c**, the selectivity was also low (Entry 5). On the contrary,

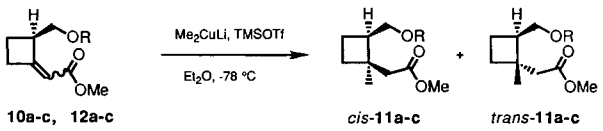


Table 2. The Conjugate Addition Reaction to (*Z*) and (*E*)-Esters **10** and **12**[a]

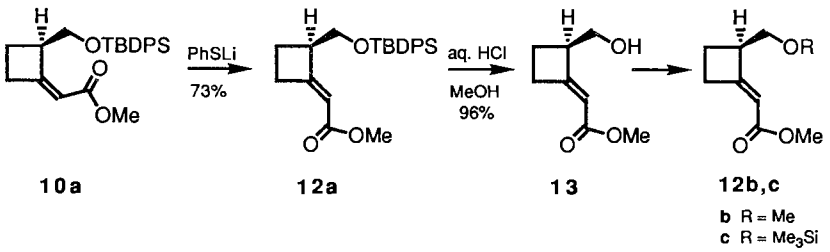
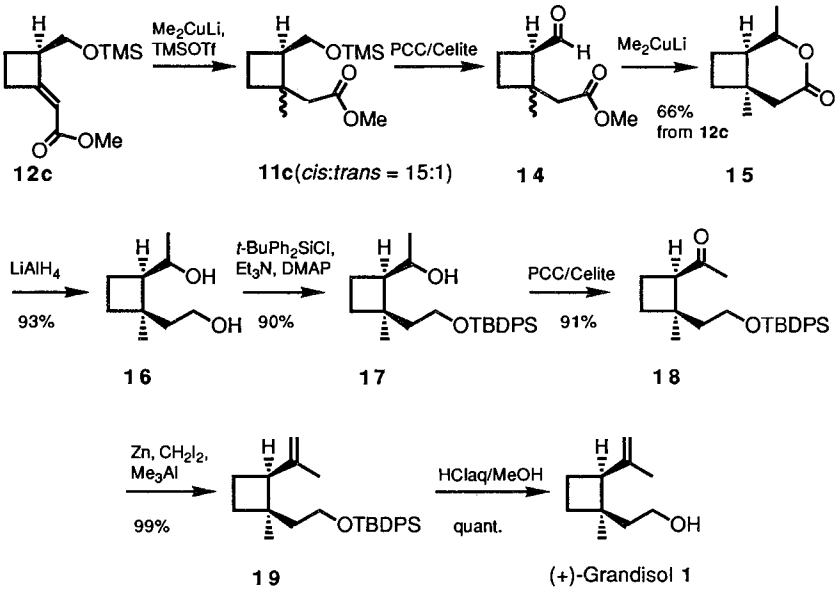
Entry	R		**11a—c** ratio of *cis*:*trans*[b]
1	*t*-$BuPh_2Si$	**10a**	2.5:1
2	*t*-$BuPh_2Si$	**12a**	2.5:1
3	Me	**10b**	1.5:1
4	Me	**12b**	2:1
5	Me_3Si	**10c**	2:1
6	Me_3Si	**12c**	15:1

a) The yields of the addition products **11a—c** were almost quantitative. b) The ratio of *cis*:*trans* was determined by the integration ratio of the quaternary methyl peaks (500 MHz ^1H NMR).



Scheme 2.



Scheme 3.

it was noted that the reaction of the TMS ether of the (*E*)-ester **12c** gave the addition product **11c** in high stereoselectivity (the ratio of *cis*:*trans*=15:1) (Entry 6). These results indicate that the introduction of a small silyl group and the (*E*)-geometry of the double bond are indispensable to achieve high stereoselectivity.

Then the transformation of the stereoselectively prepared **11c** to (+)-grandisol **1** was executed as shown in Scheme 3. Oxidation of the crude Michael product **11c** (*cis*:*trans*=15:1) with pyridinium chlorochromate (PCC)/Celite in CH_2Cl_2 followed by the treatment with Me_2CuLi in Et_2O gave the *cis* bicyclic lactone **15** as a single stereoisomer (stereochemistry not determined) in 66% yield from **12c** in 3 steps. Reduction of the lactone **15** with $LiAlH_4$ afforded the diol **16** (93% yield), whose primary hydroxyl group was protected as *t*-butyldiphenylsilyl ether **17** in 90% yield. Oxidation of **17** with PCC/Celite (91% yield) and the treatment of the resulting ketone **18** with Zn, CH_2I_2 and Me_3Al[17] gave the methylenation product **19** in 99% yield. Finally, deprotection of **19** with hydrochloric acid in MeOH afforded (+)-grandisol **1** quantitatively.

The overall yield of **1** from **2** was ca. 25% in 17 steps. The spectral data were in good agreement with those of the literature.[4b,c,5b] The optical rotation of the synthesized (+)-grandisol was $[\alpha]_D^{27}$ +18.6° (*c*=1.00, hexane). The dextrorotatory of **1** confirmed the absolute stereochemistry of **5** to be *S* as expected.

To avoid the risk of determining the optical purity from the $[\alpha]_D$ value, the present sample **1** was converted to the corresponding Mosher's (+)-MTPA ester.[10] By the 500 MHz ^{1}H NMR analysis of this (+)-MTPA ester, the optical purity of our (+)-grandisol was confirmed to be >98% ee.

Experimental

General. NMR spectra were recorded on Hitachi R24B and Bruker AM500 spectrometers using tetramethylsilane as the internal standard. $CDCl_3$ was used as solvent. IR spectra were measured with Horiba FT-300S spectrometer. High-mass spectra were obtained with JEOL JMS-D300 mass spectrometer operating at 70 ev. The optical rotations were measured with JASCO DIP-370 digital polarimeter.

Column chromatography was conducted on silica gel (E. Merck, 7734, 70—230 mesh) and Florisil (Wako, 100—200 mesh) and medium pressure column chromatography was performed with the YFLC-254 system of Yamazen Corp. Preparative thin-layer chromatography (TLC) was carried out on a silica gel (Wakogel B-5F).

Dichloromethane was distilled from P_2O_5, then from CaH_2, and dried over MS 4A. Toluene and petroleum ether were distilled and dried over MS 4A. Tetrahydrofuran (THF) and diethyl ether (Et_2O) were freshly distilled from sodium diphenylketyl. Dichlorodiisopropoxytitanium was prepared from titanium(IV) chloride and titanium(IV) isopropoxide according to the literature method.[18] 1,1-Bis(methylthio)-ethylene (**3**)[19] and (2*S*,3*S*)-1,1,4,4-tetraphenyl-2,3-*O*-(1-phenylethylidene)-1,2,3,4-butanetetrol (**4**)[9] were prepared according to the literature procedures. All the operations were performed under an argon atmosphere.

3-Acryloyl-1,3-oxazolidin-2-one (2). To a THF suspension (200 ml) of NaH (60% oil dispersion, 12.2 g, 0.30 mol) was added 1,3-oxazolidin-2-one (26.5 g, 0.30 mol) and the mixture was heated to reflux for 1 h and then cooled to 0 °C. A THF solution (100 ml) of acryloyl chloride (25.0 g, 0.28 mol) was added dropwise, and the mixture was stirred for 4 h. The pH 7 phosphate buffer was slowly poured into the mixture and the organic materials were extracted with ethyl acetate. The organic layers were washed with brine and dried over Na_2SO_4 with a catalytic amount of hydroquinone to prevent polymerization at 0 °C. Solvent was evaporated in vacuo below 10 °C. When the solvent was removed, the crude product was immediately purified by column chromatography (silica gel, dichloromethane) to give the title compound **2** (12.6 g, 42% yield). The pure material should be kept in a refrigerator. ^{1}H NMR (60 MHz) δ=3.83—4.13 (2H, m), 4.28—4.57 (2H, m), 5.82 (1H, dd, *J*=2.0, 10.0 Hz), 6.47 (1H, dd, *J*=2.0, 16.8 Hz), 7.43 (1H, dd, *J*=10.0, 16.8 Hz).

(*S*)-3-[2,2-Bis(methylthio)-1-cyclobutylcarbonyl]-1,3-oxazolidin-2-one (5). Toluene (300 ml) was added to dichlorodiisopropoxytitanium (1.40 g, 5.9 mmol), the chiral diol **4** (3.12 g, 5.9 mmol), and Molecular Sieves 4A (powder, 3.0 g) at 0 °C and the mixture was stirred for 30 min. Then **2** (10.0 g, 71 mmol) and petroleum ether (200 ml) were added. And a petroleum ether solution (100 ml) of **3** (10.0 g, 83 mmol) was added to the mixture, which was stirred at 0 °C for 1 h. The reaction was quenched by pH 7 phosphate buffer and inorganic materials were removed by filtration. The organic materials were extracted with ethyl acetate and the extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=5:1) to afford the title compound **5** (14.8 g, 80% yield, 88% ee). The optically pure **5** was obtained by two recrystallizations from benzen–hexane (80% recovery). The optically pure **5** was used in the following experiments. Mp 90.5—92.0 °C; IR (KBr) 1780, 1690 cm^{-1}; ^{1}H NMR (500 MHz) δ=2.00 (3H, s), 2.12 (3H, s), 2.25—2.31 (1H, m), 2.32—2.38 (1H, m), 2.42—2.47 (1H, m), 2.53—2.60 (1H, m), 4.07 (2H, dt, *J*=5.5, 8.1 Hz), 4.41 (2H, t, *J*=8.1 Hz), 4.61—4.65 (1H, m); ^{13}C NMR (125 MHz) δ=12.36, 12.66, 18.81, 33.61, 42.62, 49.47, 61.55, 61.96, 153.03, 170.51; $[\alpha]_D^{26}$ −59.4° (*c* 1.17, CH_2Cl_2), >98% ee; Anal. Calcd for $C_{10}H_{15}NO_3S_2$: C, 46.00; H, 5.78; N, 5.36; S, 24.53%. Found: C, 45.88; H, 5.69; N, 5.36; S, 24.92%.

Crystallographic data: M. F.=$C_{10}H_{15}NO_3S_2$, M. W.=261.35, orthorhombic, *a*=8.285 (3), *b*=22.304 (7), *c*=6.726 (2) (Å), *V*=1242.8 (7) (Å^3), space group $P2_12_12_1$, *Z*=4, D_c=1.40 g cm^{-3}, μ(Mo*K*α)=4.11 cm^{-1}. Data collection: crystal size=0.10×0.25×1.00 mm, T_c=25 °C, Mo*K*α radiation (graphite monochrometer), 1704 reflections (2θ<55.0°). The structure was finally refined anisotropically for S, C, O, and N, and isotropically for H to give an *R* factor of 0.052 for 1192 independent reflections with $I>3.0\sigma(I)$.

Methyl (*S*)-2,2-Bis(methylthio)cyclobutane-1-carboxylate (6). Dry methanol (40 ml) and a few drops of carbon tetrachloride was added to metal magnesium (1.9 g, 78 mmol) at 0 °C to generate magnesium methoxide. When all the magnesium dissolved, a THF (30 ml) solution of the [2+2] adduct **5** (6.7 g, 26 mmol) was added. The reaction was

immediately quenched with saturated aqueous ammonium chloride solution and the methyl ester was extracted with ethyl acetate. The organic layers were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=14:1) to afford the methyl ester **6** (5.0 g, 94% yield). IR (KBr) 1736 cm^{-1}; ^1H NMR (500 MHz) δ=2.01 (3H, s), 2.10 (3H, s), 2.21—2.34 (3H, m), 2.51—2.56 (1H, m), 3.38—3.42 (1H, m), 3.73 (3H, s); ^{13}C NMR (125 MHz) δ=12.27, 12.69, 16.80, 33.43, 51.53, 51.71, 60.70, 171.12; $[\alpha]_D^{24}$ −119.3° (*c* 1.12, CH_2Cl_2); HRMS Found: *m/z* 206.0431. Calcd for $C_8H_{14}O_2S_2$: M, 206.0436.

(*S*)-[2,2-Bis(methylthio)-1-cyclobutyl]methanol (7). A THF solution (20 ml) of **6** (2.66 g, 12.9 mmol) was added to a THF suspension (30 ml) of lithium aluminum hydride (1.0 g, 26 mmol) at 0 °C and the mixture was stirred for 5 min. Then saturated aqueous sodium sulfate solution was added dropwise until hydrogen evolution ceased. Inorganic materials were removed by filtration and washed with portions of hot isopropyl alcohol. The filtrate was concentrated in vacuo. The crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=9:1) to give the title compound **7** (2.30 g, quant.). IR (KBr) 3394 cm^{-1}; ^1H NMR (500 MHz) δ=1.89—1.94 (1H, m), 2.05 (3H, s), 2.07 (3H, s), 2.20—2.29 (4H, m), 2.65—2.69 (1H, m), 3.73 (1H, dd, *J*=4.8, 11.7 Hz), 3.83 (1H, dd, *J*=7.8, 11.7 Hz); ^{13}C NMR (125 MHz) δ=12.39, 12.50, 19.08, 33.59, 49.33, 61.04, 63.46; $[\alpha]_D^{25}$ −34.1° (*c* 1.02, CH_2Cl_2); HRMS Found: *m/z* 178.0485. Calcd for $C_7H_{14}OS_2$: M, 178.0487.

Optical Purity of 7. The optical purity was checked by the ^1H NMR (500 MHz) analysis of the corresponding (+)-MTPA ester[10] of the alcohol **7**. The two sets of two singlet signals due to the methylthio groups of the racemate appeared at 1.89, 1.92 and 1.92, 1.95 ppm. In the present sample, only one set of two singlet peaks was observed at 1.92, 1.95 ppm and the other set could not be detected. So this sample was determined to be >98% ee.

***t*-Butyldiphenylsilyl Ether of 7.** To a dichloromethane (CH_2Cl_2) solution (20 ml) of **7** (1.47 g, 8.2 mmol) was added a CH_2Cl_2 solution (5 ml) of triethylamine (1.68 g, 16.6 mmol) at 0 °C. Then a CH_2Cl_2 solution (5 ml) of *t*-butylchlorodiphenylsilane (2.73 g, 9.9 mmol) and a catalytic amount of 4-dimethylaminopyridine were added. After being stirred overnight, the reaction was quenched by pH 7 phosphate buffer and the organic materials were extracted with CH_2Cl_2. The extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=14:1) to afford the TBDPS ether **8** (3.49 g, quant). ^1H NMR (500 MHz) δ=1.04 (9H, s), 1.70—1.77 (1H, m), 2.02 (3H, s), 2.06 (3H, s), 2.07—2.24 (3H, m), 2.77—2.81 (1H, m), 3.58 (1H, dd, *J*=5.8, 10.8 Hz), 3.95 (1H, dd, *J*=8.6, 10.8 Hz), 7.36—7.44 (6H, m), 7.66—7.71 (4H, m); $[\alpha]_D^{25}$ −15.6° (*c* 1.00, CH_2Cl_2).

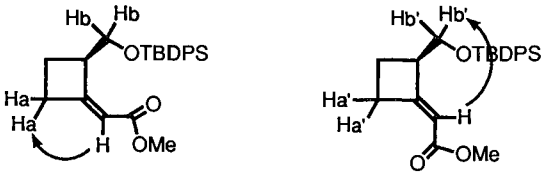
(*S*)-2-*t*-Butyldiphenylsiloxymethyl-1-cyclobutanone (9). A solution of **8** (2.20 g, 5.3 mmol) in acetonitrile (20 ml) was added quickly to a well-stirred solution of *N*-chlorosuccinimide (2.11 g, 15.8 mmol) and silver nitrate (3.14 g, 18.5 mmol) in aqueous 90% acetonitrile (20 ml) at 0 °C. The mixture was stirred for 5 min and treated successively at 1-min intervals with saturated aqueous sodium sulfite, saturated aqueous sodium carbonate, and brine (10 ml each). And then inorganic materials were removed by filtration. The organic material was extracted with ethyl acetate and the organic layers were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=14:1) to give the title compound **9** (1.69 g, 95% yield). IR (KBr) 1784 cm^{-1}; ^1H NMR (500 MHz) δ=1.04 (9H, s), 2.08—2.23 (2H, m), 3.02 (2H, t, *J*=8.5 Hz), 3.40—3.44 (1H, m), 3.70 (1H, dd, *J*=3.8, 10.6 Hz), 3.98 (1H, dd, *J*=4.1, 10.6 Hz), 7.37—7.44 (6H, m), 7.59—7.69 (4H, m); ^{13}C NMR (125 MHz) δ=13.54, 19.28, 26.74, 45.96, 61.23, 62.43, 127.70, 129.71, 133.00, 135.51, 210.85; $[\alpha]_D^{27}$ −16.0° (*c* 1.02, CH_2Cl_2).

Methyl [(*R*),(*Z*)-2-(*t*-Butyldiphenylsiloxy)methyl-1-cyclobutylidene]acetate (10a). A solution of dicyclohexylamine (2.65 g, 14.6 mmol) in THF (20 ml) was treated with BuLi (8.8 ml, 1.66 M (1 M=1 mol dm^{-3}) in hexane) at −78 °C. After the mixture was stirred for 30 min at −78 °C, a solution of methyl trimethylsilylacetate (2.14 g, 14.6 mmol) in THF (10 ml) was added dropwise, and the resulting solution was stirred for 30 min at −78 °C. Then to this solution was added dropwise a THF (10 ml) solution of **9** (2.42 g, 7.2 mmol) at −78 °C. The reaction mixture was stirred for 1 h and then treated with pH 7 phosphate buffer. The organic materials were extracted with ethyl acetate and the extracts were washed with brine and dried over Na_2SO_4. After the solvent was removed in vacuo, the crude material was purified by column chromatography (silica gel, hexane:ethyl acetate=14:1) to afford the title compound **10a** (2.82 g, quant.). IR (KBr) 1718, 1676 cm^{-1}; ^1H NMR (500 MHz) δ=1.05 (9H, s), 2.19—2.24 (2H, m), 2.62—2.69 (1H, m), 2.88—2.96 (1H, m), 3.54 (3H, s), 3.52—3.58 (1H, m), 3.88 (1H, dd, *J*=3.8, 9.9 Hz), 4.03 (1H, dd, *J*=5.5, 9.9 Hz), 5.64 (1H, dd, *J*=2.2, 4.3 Hz), 7.32—7.40 (6H, m), 7.62—7.68 (4H, m); ^{13}C NMR (125 MHz) δ=19.34, 20.70, 26.81, 30.73, 47.78, 50.71, 63.89, 113.55, 127.51, 129.52, 133.70, 135.59, 166.23, 168.09; $[\alpha]_D^{25}$ −124.4° (*c* 0.95, CH_2Cl_2).

Methyl [(*R*),(*E*)-2-(*t*-Butyldiphenylsiloxy)methyl-1-cyclobutylidene]acetate (12a). To a solution of thiophenol (31.7 mg, 0.29 mmol) in THF (2 ml) was added a hexane solution (0.18 ml) of BuLi (1.57 M in hexane) at 0 °C and the resulting solution was stirred for 10 min. Then a THF (2 ml) solution of **10a** (115.4 mg, 0.29 mmol) was added. After the mixture was stirred overnight, the reaction was quenched by pH 7 phosphate buffer and the organic materials were extracted with ethyl acetate. The organic layers were washed with brine and dried over Na_2SO_4. After the solvent was evaporated, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=9:1) to afford the (*E*)-form ester **12a** (83.8 mg, 73% yield) and the recovered starting material **10a** (30.2 mg, 26% yield). Then the same operations with the recovered **10a** were carried out once again. The (*E*)-form compound **12a** was totally obtained in 91% yield. IR (KBr) 1718, 1676 cm^{-1}; ^1H NMR (500 MHz) δ=1.06 (9H,s), 1.85—1.91 (1H, m), 2.15 (1H, ddt, *J*=6.1, 9.3, 11.2 Hz), 2.96—3.10 (2H, m), 3.23—3.28 (1H, m), 3.69 (3H, s), 3.73 (2H, d, *J*=6.4 Hz), 5.74 (1H, dd, *J*=2.4, 4.6 Hz), 7.34—7.45 (6H, m), 7.65—7.68 (4H, m); ^{13}C NMR (125 MHz) δ=19.22, 20.67, 26.80, 31.05, 46.52, 50.84, 65.28, 112.32, 127.65, 129.65, 133.50, 135.59, 166.94, 168.54; $[\alpha]_D^{27}$ +1.5° (*c* 1.61, CH_2Cl_2).

Assignment of the Stereochemistry of 10a and 12a. The stereochemistry (*E* or *Z*) of the α,β-unsaturated ester **10a** and **12a** was determined by NOESY spectra. The NOEs were

observed between the olefinic proton and Ha in **10a** and between the olefinic proton and $H_{b'}$ in **12a** as shown in the figure.



10a (*Z*)-form **12a** (*E*)-form

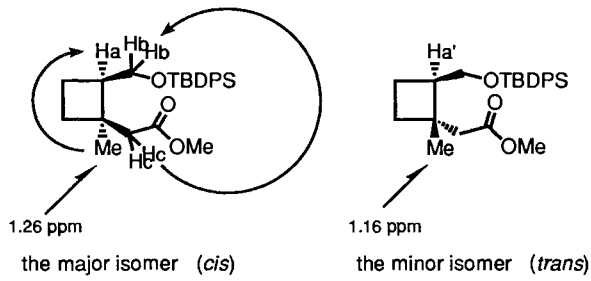
Methyl [(*R*),(*E*)-2-Hydroxymethyl-1-cyclobutylidene]acetate (13). To a methanol solution (10 ml) of **12a** (245 mg, 0.62 mmol) was added a few drops of concd hydrochloric acid at room temperature. After being stirred for 3.5 h, the mixture was treated with pH 7 phosphate buffer and the organic materials were extracted with ethyl acetate. The extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by column chromatography (silica gel, hexane:ethyl acetate=9:1) to give the alcohol **13** (92.8 mg, 96% yield). IR (KBr) 3450, 1711, 1676 cm^{-1}; ^1H NMR (500 MHz) δ=1.61—1.64 (1H, bs), 1.89—1.96 (1H, m), 2.22 (1H, ddt, J=6.1, 9.2, 11.3 Hz), 3.00—3.14 (2H, m), 3.25—3.31 (1H, m), 3.69 (3H, s), 3.68—3.72 (1H, m), 3.78 (1H, dd, J=6.3, 10.9 Hz), 5.74 (1H, dd, J=2.5, 4.8 Hz); $[\alpha]_D^{25}$ +20.7° (*c* 1.45, CH_2Cl_2); HRMS Found: *m/z* 156.0763. Calcd for $C_8H_{12}O_3$: M, 156.0786.

Methyl [(*R*),(*E*)-2-(Trimethylsiloxy)methyl-1-cyclobutylidene]-acetate (12c). A CH_2Cl_2 solution (3 ml) of triethylamine (313 mg, 3.1 mmol) was added to a CH_2Cl_2 solution (5 ml) of **13** (152 mg, 0.97 mmol) at 0 °C. Then a CH_2Cl_2 solution (2 ml) of chlorotrimethylsilane (218 mg, 2.0 mmol) and a catalytic amount of 4-dimethylaminopyridine were added to the mixture. After being stirred overnight at room temperature, the resulting solution was quenched by pH 7 phosphate buffer and the organic materials were extracted with CH_2Cl_2. The organic layers were washed with brine and dried over Na_2SO_4. After the solvent was removed, the crude product was purified by column chromatography (florisil, hexane:ethyl acetate=9:1) to give the TMS ether **12c** (212 mg, 95% yield). IR (KBr) 1716, 1676 cm^{-1}; ^1H NMR (500 MHz) δ=0.09 (9H, s), 1.76—1.83 (1H, m), 2.12—2.20 (1H, m), 2.94—3.08 (2H, m), 3.17—3.23 (1H, m), 3.63 (2H, d, J=7.0 Hz), 3.66 (3H, s), 5.69—5.71 (1H, m); $[\alpha]_D^{23}$ +5.9° (*c* 1.43, CH_2Cl_2).

(*Z*)-form **10c**: ^1H NMR (500 MHz) δ=0.08 (9H, s), 1.97—2.03 (1H, m), 2.16 (1H, ddd, J=8.6, 11.1, 17.3 Hz), 2.58—2.65 (1H, m), 2.77—2.86 (1H, m), 3.38—3.53 (1H, m), 3.65 (3H, s), 3.78 (1H, dd, J=8.1, 10.5 Hz), 3.90 (1H, dd, J=4.0, 10.5 Hz), 5.60—5.62 (1H, m).

Methyl [(*R*)-1-Methyl-2-(trimethylsiloxy)methyl-1-cyclobutyl]-acetate (11c). To an Et_2O suspension (5 ml) of CuI (324 mg, 1.7 mmol) was added dropwise MeLi (3.0 ml, 1.15 M in Et_2O) at −23 °C to generate lithium dimethylcuprate(I). The resulting solution was stirred for 30 min and then cooled to −78 °C. An Et_2O solution (3 ml) of **12c** (77.2 mg, 0.34 mmol) and TMSOTf (375 mg, 1.7 mmol) was added dropwise at −78 °C. After being stirred overnight at that temperature, the mixture was treated with saturated aqueous sodium hydrogencarbonate and inorganic materials were filtered off. The organic materials were extracted with ether and the extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product **11c** was directly used for further transformation. IR (KBr) 1739 cm^{-1}; ^1H NMR (500 MHz) *cis*-**11c** δ=0.07 (9H, s), 1.20 (3H, s), 1.50—1.67 (2H, m), 1.88—2.02 (2H, m), 2.14—2.17 (1H, m), 2.37 (1H, d, J=14.5 Hz), 2.53 (1H, d, J=14.5 Hz), 3.53 (1H, dd, J=6.3, 10.6 Hz), 3.61 (3H, s), 3.59—3.63 (1H, s); *trans*-**11c** δ=1.10 (3H, s), 3.65 (3H, s); ^{13}C NMR (125 MHz) δ=−0.52, 18.64, 27.59, 30.57, 38.73, 40.00, 46.29, 51.09, 63.00, 173.27; HRMS Found: *m/z* 244.1502. Calcd for $C_{12}H_{24}O_3Si$: M, 244.1495.

Assignment of the Stereochemistry of the Conjugate Addition Product. The relative stereochemistry of the conjugate addition products was determined by the NOESY spectrum of **11a**. In the major isomer, the NOEs were observed between the quaternary methyl group and H_a proton, H_b and H_c respectively, as shown in the following figure. The stereochemistry of the major isomer was assigned as *cis* and the minor was *trans*. The singlet signal of the methyl group of the *cis* isomer appeared at 1.26 ppm and that of *trans* isomer appeared at 1.16 ppm.



the major isomer (*cis*) the minor isomer (*trans*)

In the case of the compound **11c**, the stereochemistry was assigned from the chemical shift of the quaternary methyl group. The major isomer of **11c**, whose methyl singlet signal appeared at lower field (1.20 ppm), was determined to be *cis* isomer and the minor isomer (the methyl signal was observed at 1.10 ppm) was assigned as *trans*. These assignments of the stereochemistry were confirmed by the formation of the lactone **15** from the major isomer. The minor isomer (*trans*) could not form a lactone.

Methyl [(*R*)-1-Methyl-2-formyl-1-cyclobutyl]acetate (14). To a well-stirred suspension of pyridinium chlorochromate (PCC) (150 mg, 0.7 mmol) and celite (300 mg) in CH_2Cl_2 (3 ml) was added a CH_2Cl_2 solution (2 ml) of the crude product **11c** at 0 °C. After being stirred for 3 h, the mixture was filtered through silica gel. Then the filtrate was concentrated and the crude product **14** was directly used for further transformation. IR (KBr) 1736, 1714 cm^{-1}; ^1H NMR (500 MHz) the *cis*-isomer δ=1.31 (3H, s), 1.72—1.78 (1H, m), 1.81—1.96 (2H, m), 2.20—2.27 (1H, m), 2.35 (1H, d, J=15.7 Hz), 2.52 (1H, d, J=15.7 Hz), 2.95—2.98 (1H, m), 3.57 (3H, s), 9.81 (1H, d, J=1.8 Hz); the *trans*-isomer δ=1.12 (3H, s), 1.58—1.64 (1H, m), 1.81—1.96 (2H, m), 2.35—2.39 (1H, m), 2.44 (1H, d, J=15.0 Hz), 2.56 (1H, d, J=15.0 Hz), 3.11—3.14 (1H, m), 3.62 (3H, s), 9.76 (1H, s).

(1*R*,6*R*)-2,6-Dimethyl-3-oxabicyclo[4.2.0]octan-4-one (15). To an Et_2O suspension (5 ml) of CuI (325 mg, 1.7 mmol) was added dropwise MeLi (3.0 ml, 1.15 M in Et_2O) at −23 °C to generate lithium dimethylcuprate(I). The resulting solution was stirred for 30 min and then cooled to −78 °C, to which an Et_2O solution (2 ml) of the crude **14** was added dropwise at

−78 °C. After being stirred for 15 min, the mixture was treated with saturated aqueous sodium hydrogencarbonate and inorganic materials were filtered off. The organic materials were extracted with ether and the extracts were washed with brine and dried over Na_2SO_4. After distillation of the solvent, the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=3:1) to give the *cis* bicyclic lactone **15** (34.4 mg) in 66% overall yield from **12c** in 3 steps. IR (KBr) 1739 cm^{-1}; ^1H NMR (500 MHz) δ=1.19 (3H, s), 1.29 (3H, d, J=6.4 Hz), 1.62—1.68 (1H, m), 1.88—1.92 (1H, m), 1.94 (2H, t, J=8.5 Hz), 2.21 (1H, ddd, J=8.7, 12.6, 17.5 Hz), 2.36 (1H, d, J=15.0 Hz), 2.58 (1H, d, J=15.0 Hz), 4.34 (1H, dq, J=6.4, 8.7 Hz); ^{13}C NMR (125 MHz) δ=17.93, 19.06, 28.22, 32.21, 35.71, 42.24, 44.34, 78.93, 173.14; $[\alpha]_D^{24}$ −102.9° (*c* 1.13, CH_2Cl_2); HRMS Found: *m/z* 154.0947. Calcd for $C_9H_{14}O_2$: M, 154.0994.

2-[(1*R*,2*R*)-1-Methyl-2-(1-hydroxyethyl)-1-cyclobutyl]ethanol (16). A THF solution (2 ml) of **15** (43.3 mg, 0.28 mmol) was added to a THF suspension (3 ml) of lithium aluminum hydride (37.0 mg, 0.97 mmol) at 0 °C and the mixture was stirred for 5 min. Then saturated sodium sulfate solution was added dropwise until hydrogen evolution ceased. Inorganic materials were removed by filtration and washed with portions of hot isopropyl alcohol. After the filtrate was concentrated in vacuo, the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=2:1) to give the title compound **16** (41.3 mg, 93% yield). IR (KBr) 3323 cm^{-1}; ^1H NMR (500 MHz) δ=0.99 (3H, d, J=6.1 Hz), 1.11 (3H, s), 1.37—1.44 (1H, m), 1.49—1.60 (3H, m), 1.79—1.85 (2H, m), 2.02 (1H, ddd, J=7.5, 8.7, 14.2 Hz), 3.00—3.10 (2H, bs), 3.60 (1H, ddd, J=4.2, 7.4, 10.5 Hz), 3.71 (1H, ddd, J=6.5, 8.9, 10.5 Hz), 3.81 (1H, dq, J=6.1, 9.7 Hz); $[\alpha]_D^{24}$ +27.3° (*c* 1.59, CH_2Cl_2).

***t*-Butyldiphenylsilyl Ether of 16.** To a CH_2Cl_2–dimethylformamide 1:1 solution (6 ml) of **16** (36.7 mg, 0.23 mmol) was added a CH_2Cl_2 solution (1.5 ml) of triethylamine (79.5 mg, 0.79 mmol) at 0 °C. Then a CH_2Cl_2 solution (1.5 ml) of *t*-butylchlorodiphenylsilane (114 mg, 0.42 mmol) and a catalytic amount of 4-dimethylaminopyridine were added. After being stirred overnight, the mixture was treated with pH 7 phosphate buffer and the organic materials were extracted with CH_2Cl_2. The extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=5:1) to afford the silyl ether **17** (82.8 mg, 90% yield). IR (KBr) 3392 cm^{-1}; ^1H NMR (500 MHz) δ=1.01 (3H, d, J=6.3 Hz), 1.03 (3H, s), 1.05 (9H, s), 1.38—1.48 (2H, m), 1.50—1.60 (2H, m), 1.74—1.82 (2H, m), 1.84 (2H, t, J=7.2 Hz), 3.66—3.71 (1H, m), 3.74—3.81 (2H, m), 7.35—7.43 (6H, m), 7.68—7.72 (4H, m); $[\alpha]_D^{25}$ +15.5° (*c* 0.81, CH_2Cl_2).

(1*R*,2*R*)-2-[2-(*t*-Butyldiphenylsiloxy)ethyl]-2-methyl-1-cyclobutyl Methyl Ketone (18). To a well-stirred suspension of pyridinium chlorochromate (PCC) (42.5 mg, 0.17 mmol) and celite (85 mg) in CH_2Cl_2 (2 ml) was added a solution of the alcohol **17** (34.2 mg, 0.09 mmol) in CH_2Cl_2 (2 ml) at 0 °C. After being stirred for 4 h, the mixture was filtered through silica gel. Then the filtrate was concentrated in vacuo and the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=5:1) to afford the title compound **18** (31.1 mg, 91% yield). IR (KBr) 1705 cm^{-1}; ^1H NMR (500 MHz) δ=1.02 (9H, s), 1.23 (3H, s), 1.54—1.61 (1H, m), 1.68—1.74 (2H, m), 1.79 (1H, ddd, J=6.0, 8.0, 13.4 Hz), 1.99 (3H, s), 2.23 (1H, ddd, J=8.8, 11.2, 18.3 Hz), 2.91 (1H, t, J=8.2 Hz), 3.60 (1H, ddd, J=6.0, 8.0, 10.4 Hz), 3.66 (1H, ddd, J=6.0, 8.0, 10.4 Hz), 7.35—7.43 (6H, m), 7.63—7.65 (4H, m); ^{13}C NMR (125 MHz) δ=16.19, 19.02, 26.80, 28.00, 29.52, 30.42, 37.31, 42.86, 57.28, 60.44, 127.60, 129.55, 133.71, 135.53, 208.34; $[\alpha]_D^{24}$ −29.5° (*c* 1.32, CH_2Cl_2).

***t*-Butyldiphenylsilyl Ether of (+)-Grandisol 19.** The operations were carried out according to the literature procedure.[17] A solution of diiodomethane (220 mg, 0.82 mmol) in THF (3 ml) was added to activated zinc powder (135 mg, 2.1 mmol) and then a hexane solution (1.6 ml) of trimethylaluminum (1.0 M in hexane) was added. The resulting suspension was stirred for 10 min. A THF solution (2 ml) of the ketone **18** (66.2 mg, 0.17 mmol) was added dropwise to the mixture. After being stirred for 1 h, the mixture was cooled to 0 °C and diluted with ether and 1 M hydrochloric acid was added dropwise until all the zinc dissolved. The organic materials were extracted with ether and the extracts were washed with brine and dried over Na_2SO_4. After evaporation of the solvent, the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=5:1) to give the title compound **19** (65.4 mg, 99% yield). ^1H NMR (500 MHz) δ=1.05 (9H, s), 1.08 (3H, s), 1.40 (1H, dddd, J=1.2, 6.1, 8.9, 13.7 Hz), 1.46—1.59 (2H, m), 1.62 (3H, d, J=0.7 Hz), 1.70—1.79 (2H, m), 1.83—1.92 (1H, m), 2.47 (1H, t, J=9.1 Hz), 3.66 (1H, ddd, J=5.8, 8.9, 10.0 Hz), 3.72 (1H, ddd, J=6.0, 8.9, 10.2 Hz), 4.60 (1H, bs), 4.80 (1H, bs), 7.36—7.43 (6H, m), 7.67—7.69 (4H, m); ^{13}C NMR (125 MHz) δ=19.10, 19.15, 23.17, 26.88, 28.41, 29.22, 36.17, 41.29, 52.69, 61.17, 109.55, 127.56, 129.49, 134.08, 135.61, 145.25; $[\alpha]_D^{23}$ +2.6° (*c* 1.28, CH_2Cl_2).

(+)-Grandisol (1). To a methanol solution (5 ml) of **19** (64.0 mg, 0.16 mmol) was added as few drops of concd hydrochloric acid at room temperature. After being stirred for 2 h, the mixture was diluted with pH 7 phosphate buffer and the organic materials were extracted with ether. The extracts were washed with brine and dried over Na_2SO_4. After distillation of the solvent, the crude product was purified by thin-layer chromatography (hexane:ethyl acetate=2:1) to give the (+)-grandisol **1** (25.3 mg, quant.). IR (KBr) 3342, 3080, 2949, 2868, 1645, 1450, 1375, 1240, 1053, 1012, 887 cm^{-1}; ^1H NMR (500 MHz) δ=1.15 (3H, s), 1.42 (1H, dddd, J=1.2, 6.2, 9.4, 13.4 Hz), 1.35—1.45 (1H, m), 1.55—1.67 (2H, m), 1.65 (3H, s), 1.70—1.81 (2H, m), 1.91—1.99 (1H, m), 2.52 (1H, bt, J=9.0 Hz), 3.63 (1H, ddd, J=5.6, 9.4, 10.2 Hz), 3.66 (1H, ddd, J=6.2, 9.4, 10.2 Hz), 4.62 (1H, bs), 4.81 (1H, bs); ^{13}C NMR (125 MHz) δ=19.14, 23.20, 28.34, 29.30, 36.91, 41.28, 52.48, 59.94, 109.73, 145.19; $[\alpha]_D^{27}$ +18.6° (*c* 1.00, hexane), >98% ee.

Optical Purity of 1.[5b] The optical purity of **1** was determined by the ^1H NMR (500 MHz) analysis of the (+)-MTPA ester[10] of **1**. A set of the singlet signals of the methyl group adjacent to the quaternary carbon of the racemate appeared at 1.141 and 1.151 ppm. The corresponding (+)-MTPA ester of the optically active sample **1** showed only one singlet signal of the methyl group at 1.151 ppm. Therefore, the enantiomeric excess of **1** was determined absolutely to be >98% ee.

We thank Toray Industries, Inc. for the kind gift of (−)-tartaric acid.

An Useful Synthetic Method for 3-Substituted δ-Lactones. Synthesis of (±)-Secocrispiolide

Michiharu KATO,* Akihiko OUCHI, and Akira YOSHIKOSHI
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Aoba-ku, Sendai 980
(Received January 23, 1991)

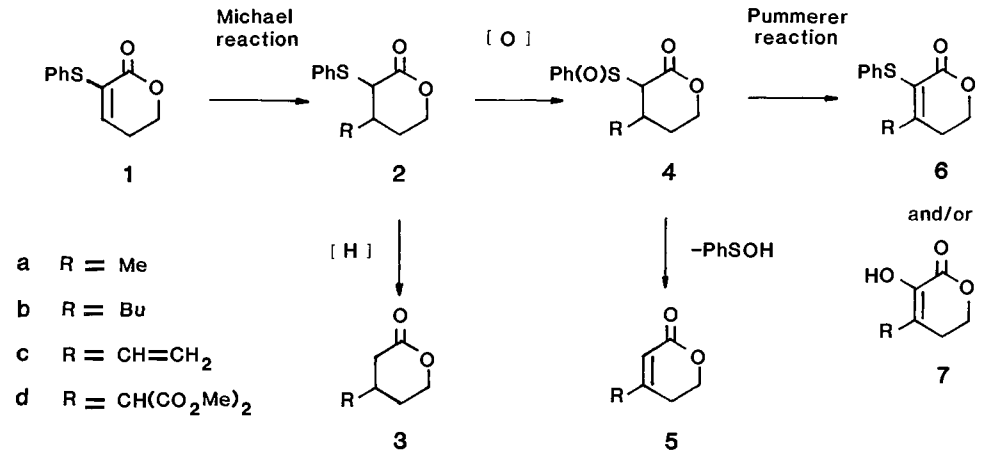
2-Phenylthio-2-penten-5-olide (**1**) acted as a reactive Michael acceptor toward some typical carbon neucleophiles to give 3-substituted 2-phenylthio-5-pentanolides (**2**) which were convertible both to 3-substituted 5-pentanolides by reductive desulfurization and to 3-substituted 2-penten-5-olides by sulfenic acid *syn* elimination of the sulfoxides **4** derived from **2**. The Pummerer rearrangement of **4** provided 3-substituted 2-phenylthio-2-penten-5-olides and/or 2-hydroxy-2-penten-5-olides. (±)-Secocrispiolide was synthesized via the adduct obtained by the Michael reaction of **1** with the Grignard reagent prepared from 2,6-dimethylbenzyl bromide and magnesium.

Lactone function is found as a structural subunit in many classes of natural product.[1] Up to date, considerable attention for the syntheses of natural products having this group has been attracted especially in connection with investigation of their biological activities.[2] Although a variety of efficient methods for construction of γ-lactones have been developed,[3] comparatively a few are general methods for the syntheses of δ-lactones. In the course of our synthetic study on a natural product, we required an efficient preparation of 3-substituted 2-penten-5-olides. However, methodologies for the syntheses of these useful compounds were, to our knowledge, not well defined. We wish to report here a versatile synthetic method for 3-substituted 5-pentanolides and 2-penten-5-olides, starting with 2-phenylthio-2-penten-5-olide (**1**) which acts as a common building block upon this purpose.[4]

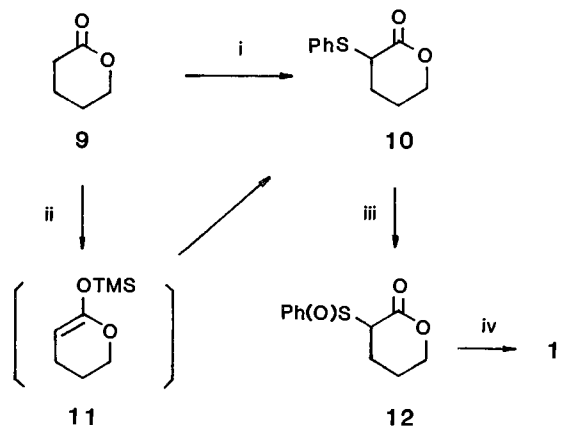
Our contributions to this objective are illustrated in Scheme 1. In contrast to 2-penten-5-olide (**8**), 2-phenylthio-2-penten-5-olide (**1**) was deemed most favorable as a starting material in that the phenylthio group would not only serve as an activator for the Michael reaction,[5] but also subsequently act as a key substituent for introduction of a double bond in the adduct. A series of reactions used in this study is as follows; (i) reactions of **1** with some carbon nucleophiles would proceed exclusively in 1,4 addition fashion to give the required 3-substituted 2-phenylthio-5-pentanolides (**2**) which are convertible to 3-substituted 5-pentanolides (**3**) in reductive cleavage of the phenylthio group, (ii) thermolysis of the sulfoxides **4** derived from **2** provides 3-substituted 2-penten-5-olides (**5**), and (iii) exposure of **4** to the conditions of the Pummerer rearrangement leads to 3-substituted 2-phenylthio-2-penten-5-olides (**6**), which would keep the capacity to act as a reactive Michael acceptor toward 3,3-disubstituted 5-pentanolide synthesis. This strategy has mostly proven to be successful as described below.

Results and Discussion

We started our synthesis with preparation of 2-phenylthio-5-pentanolide (**10**) (Scheme 2). Treatment of freshly distilled δ-valerolactone (**9**) with lithium diisopropylamide (LDA) followed by addition of diphenyl disulfide provided **10** in moderate yield. On this occasion, an attempt to improve the yield of **10** by sulfenylation with *S*-phenyl benzenethiosulfonate[6] was fruitless. Furthermore, sulfenylation of the silyl enol ether **11**, prepared



Scheme 1.



Scheme 2. (i) LDA, THF, HMPA, then Ph_2S_2, −78°C—r.t. (53%): (ii) LDA, Me_3SiCl, THF, then PhSCl, −78°C—r.t. (44%): (iii) *m*CPBA (1.0 equiv), CH_2Cl_2, −15°C: (iv) $(CF_3CO)_2O$, CH_2Cl_2, r.t. (98% from **10**).

Compound	2	3	4	5
a R=Me	91	74	100	72
b R=Bu	80	76	100	79
c R=CH=CH_2	82	42	100	73
d R=$CH(CO_2Me)_2$	73	56	100	80

a) Isolated yield.

from **9** by treatment with LDA (1 equiv) followed by chlorotrimethylsilane, with benzenesulfenyl chloride provided disappointing 44% yield of **10**. The substrate **10** was converted by oxidation with equimolar *m*-chloroperbenzoic acid (*m*CPBA) to the sulfoxide **12** which on exposure to trifluoroacetic anhydride led to **1** in 52% overall yield from **9**.

We turned our attention to conjugate addition of **1** with representative carbon nucleophiles. The nucleophiles used in this study were lithium dimethylcuprate (**i**), lithium dibutylcuprate (**ii**), vinylmagnesium bromide–copper(I) iodide 1:1-complex (**iii**), and dimethyl sodiomalonate (**iv**). Reactions of **1** with eqimolar cuprates, **i** and **ii**, proceeded smoothly, to our expectations, to give the 1,4-addition products, 3-substituted 2-phenylthio-5-pentanolides, **2a** and **2b**, in excellent yields (Scheme 1 and Table 1). On the other hand, on reaction with the reagents, **iii** and **iv**, 2.0 equivalent amount of the reagents was required to maximize yields of the adducts, **2c** and **2d**. While the pentanolides obtained were inseparable diastereomeric mixtures, it would be reasonable to estimate that the thermodynamically stable *trans*-isomers are in large quantities, although relatively small vicinal coupling constants (6.4—6.5 Hz, PhS–CH–CH) were observed in their ^1H NMR spectra. In order to verify the effect of the phenylthio group used as an activator, the Michael reactions of 2-penten-5-olide (**8**) with the nucleophiles, **ii** and **iii**, were examined for comparison, giving 3-butyl-[7] and 3-vinyl-5-pentanolides, (**3b**) and (**3c**), in such poor yields as 45 and 13%, respectively. After all, it was demonstrated that 2-phenylthio-2-penten-5-olide (**1**) has highly electrophilic reactivity enough to act as a common Michael acceptor.

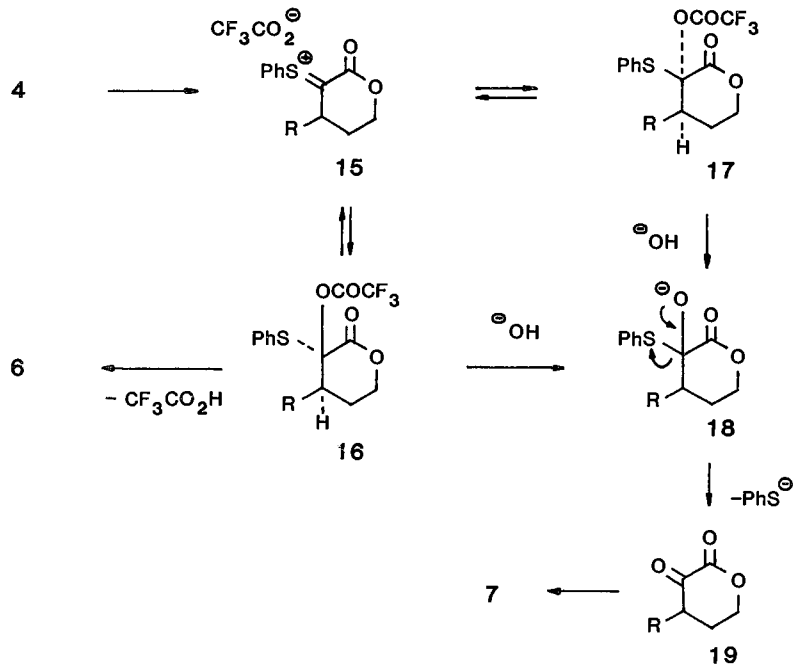
8 13 14

Desulfurization of **2** was next examined (Scheme 1 and Table 1). Reaction of **2b** with W-4 Raney nickel in ethanol proceeded smoothly to give 3-butyl-5-pentanolide (**3b**)[7] in good yield, whereas desulfurization of **2a** and **2c** under the similar reaction conditions produced hydroxy ester **13** and 3-ethyl-5-pentanolide (**14**),[8] respectively, as the result of concomitant ethanolysis for the former and hydrogenation of the vinyl group for the latter. These unexpected results were suppressed as follows. Replacement of ethanol into acetone resulted in good formation of **3a** from **2a**. On the other hand, **3c** was obtained on reduction of **2c** with Raney nickel deactivated with acetone. Finally, **2d** was desulfurized in acetone to afford **3d** in good yield.

Synthesis of 3-substituted 2-penten-5-olides **5a**—**d**[9] was accomplished readily by oxidation of **2a**—**d** with equimolar *m*CPBA followed by refluxing the resulting sulfoxides **4a**—**d** in benzene containing catalytic amount of pyridine, wherein the oxidation and thermal elimination of sulfenic acid proceeded in quantitative and in good yield, respectively, (Scheme 1 and Table 1).

Table 2 details the result obtained by the Pummerer reaction of sulfoxides **4a**—**d**. Contrary to our expectations, the reactions of **4a**—**c** with trifluoroacetic anhydride proceeded considerably slowly to produce unexpected 2-hydroxy-2-penten-5-olides (**7**) as well as the desired 2-phenylthio-2-penten-5-olides (**6**) (Scheme 1), so that this type of reactions showed marked dependence on reaction conditions employed and/or on type of the substituent at C(3) of **4**. Treatment of **4a** with trifluoroacetic anhydride at room temperature afforded a mixture of **6a**[10] and 2-hydroxy-2-penten-5-olide (**7a**),



Scheme 3.

in which the former predominated (Run 1). On the contrary, **7a** was obtained predominantly when the reaction was carried out at low temperature, followed by quenching with aqueous sodium hydrogencarbonate (Run 2). Compound **6b** was derived in fair yield from **4b** along with a trace of 2-hydroxy-2-penten-5-olide (**7b**) which was detectable by the TLC analysis (Run 3). On the other hand, the pummerer reaction of **4c** provided low yield of **6c**, and in this case, the major product isolated in 74% yield was unexpected **5c** (Run 4). In the case of **4d**, the only product obtained in low yield was **7d** (Run 5).

The following mechanism would be surmised to account for the formation of **6** and **7** (Scheme 3). Exposure of the sulfoxide **4** to trifluoroacetic anhydride leads to the Pummerer intermediate **15**. On reacting with a trifluoroacetate anion, **15** provides two kinds of trifluoroacetates, **16** with cis relationship between the trifluoroacetoxy group and the substituent (R), and **17** with trans relationship between the two. These trifluroacetates would exist as comparatively stable intermediates in equilibrium. 2-Penten-5-olide **6** is derived only from **16** in trans elimination fashion of trifluoroacetic acid. On the other hand, hydrolysis of **16** and **17** on hydrolytic workup using aqueous sodium hydrogencarbonate leads to the alkoxide **18**, which spontaneously eliminates the phenylthio group to give α-keto lactone **19**. Subsequent tautomerization of **19** affords 2-hydroxy-2-penten-5-olide (**7**). In the case of **4d** which has a bulky bis(methoxycarbonyl)methyl group as a substituent (R), **17d** whose R and trifluoroacetoxy groups are in a trans relationship is formed exclusively to provide **7d** on hydrolytic workup. Formation of **5c** (Table 2, Run 4) would be rationalized by surmising that, because of high acidity of the allylic β-hydrogen in **4c**, *syn* elimination of sulfenic acid readily occurs, before the Pummerer rearrangement initiates.

A parallel study on the conjugate addition to 3-substituted 2-phenylthio-2-penten-5-olides obtained reproduced the important role of the phenylthio group as the activator: Reactions of **6a** and **6b** with lithium dimethylcuprate provided 3,3-disubstituted δ-lactones, **20**, and **21**, respectively, albeit in low yields, whereas 3-methyl- and 3-butyl-2-penten-5-olides, (**5a**) and (**5b**), were recovered unchanged on treatment with this cuprate reagent. It is noteworthy that reaction of 3-vinyl-2-penten-5-olide (**5c**) with lithium dimethylcuprate underwent regioselective conjugate addition to give a mixture of 1,6-addition products, **22** and **23**.

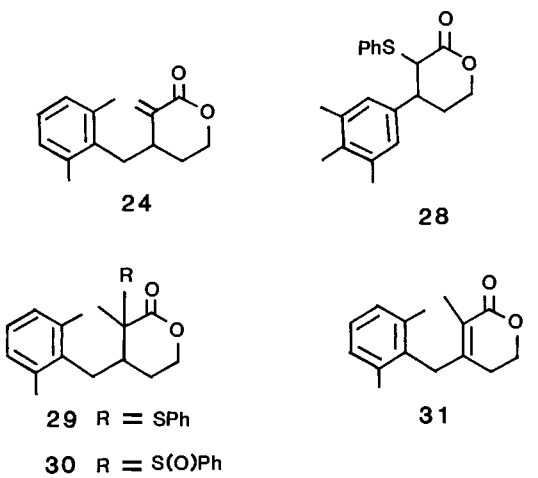
In an effort to extend the scope of this methodology, conjugate addition of **1** with a few benzylic Grignard reagents was examined for the purpose of the synthesis of secocrispiolide **24**,[11] a seco-sesquiterpene lactone isolated from *Plicaria crispa* Sch. Bip. The Grignard reagents **25** used in this study and the results thereby obtained are shown in Scheme 4 and Table 3, respectively.

It is known that condensation of the benzylic Grignard reagent with carbon dioxide or some aldehydes occasionally provides an abnormal product resulting from the so-called allylic rearragement of the reagent.[12] While exposure of **1** to benzyl- and 2-methylbenzylmagnesium bromides, (**25a**) and (**25b**), gave diastereomeric mixtures of the normal adducts, **26a** and **26b**, respectively, (Table 3, Run 1, 2), the abnormal adduct **27c** was produced together with the normal **26c** in a ratio of ca. 2:1, when **1** was treated with 2,6-dimethylbenzylmagnesium bromide (**25c**) (Run 3). These results indicated that the steric bulk at the benzyl face would impose the allylic rearrangement on the ortho-disubstituted benzylic Grignard reagents to give the para addition products. **27c** was an unstable oil and, to our surprise, the structure possessing a cross-conjugate methylenecyclohexadiene skeleton was clarified as follows. Two resonances [δ=5.59 (2H, br s) and 2.28 (6H, d, J= 1 Hz)] in the ^{1}H NMR and those [δ=125.1 (d) and 19.9 (q)] in the ^{13}C NMR showed the presence of two trisubstituted double bonds possessing a methyl group. In addition, resonances due to an *exo*-methylene group appeared at δ=5.04 (2H, br s) in the ^{1}H NMR and δ= 107.7 (t) and 128.2 (s) in the ^{13}C NMR. In fact, aromatization of **27c** with catalytic *p*-toluenesulfonic acid readily occured to give a stable compound **28**. An analogous trend was observed on reaction of **1** with 2,4,6-trimethylbenzylmagnesium bromide (**25d**) (Run 4).

The procurement of the synthetic intermediate **26c** prompted us to complete the synthesis of secocrispiolide (**24**). The lithium enolate obtained from treatment of **26c** with LDA was submitted to methylation with methyl iodide in the presence of hexamethylphosphoric triamide (HMPA), providing 2-methyl-δ-lactone (**29**) as an inseparable 3:1 mixture of diastereomers. Oxidation of **29** with equimolar *m*CPBA followed by elimination of sulfenic acid from the resulting sulfoxide **30** afforded (±)-secocrispiolide (**24**) and an *endo*-olefin regioisomer **31** in 23 and 69% yields, respectively. The spectra (IR, ^{1}H NMR and MS) of the synthetic **24** were identical with those of the natural product.[13]



In conclusion, we have developed an useful method for the synthesis of a variety of 3-substituted δ-lactones starting with 2-phenylthio-2-penten-5-olide (**1**), and (±)-secocrispiolide (**24**) was synthesized via the Michael adduct **26c**.

Experimental

Melting points are uncorrected. IR spectra were obtained with a JASCO A-3 infrared spectrophtometer. ^{1}H NMR spectra were recorded on a JEOL FX90Q spectrometer in deuterochloroform with tetramethylsilane as internal standard. High resolution mass spectra were obtained by a JEOL JMS-DX 300 spectrometer. δ-Valerolactone was purchased from Aldrich Chemical Co. Dry tetrahydrofuran (THF) and diethyl ether were obtained by distillation over sodium benzophenone ketyl. Other organic solvents were purified and dried by using standard procedures. All reactions were carried out under N_2 or Ar atmosphere with use of standard procedures for the exclusion of moisture. Column chromatography was performed by using silica gel (Merck, Kieselgel 60, 70—230 mesh). Kieselgel GF_{254} was employed for preparative thin-layer chromatography (TLC) and a mixed solvent (hexane–ether, 1:2) was used for elution, unless otherwise stated. Na_2SO_4 was employed for the drying of extracts.

2-Phenylthio-5-pentanolide (10). (a) To a stirred solution of diisopropylamine (5.133 g, 50.8 mmol) in THF (50 ml) at −78 °C was added dropwise a 1.5 M solution (1 M=1 mol dm^{-3}) of butyllithium in hexane (30.0 ml, 46.91 mmol). The bath was replaced by an ice bath and the mixture was stirred for 10 min, then recooled at −78 °C. A solution of freshly distilled δ-valerolactone (**9**) (1.959 g, 19.5 mmol) in THF (15 ml) was added dropwise and stirring was continued for 30 min. To the reaction mixture, a solution of diphenyl disulfide (8.535 g, 39.1 mmol) in HMPA (40 ml) and THF (50 ml) was added and the temperature was gradually raised to room temperature over 10 h. The reaction was quenched by addition of saturated aqueous ammonium chloride (30 ml) and the phases were separated. The aqueous phase was extracted with ether. The combined organic solutions were washed with 0.1 M HCl and brine, and dried. Evaporation of the solvent left an oil, which was chromatographed on 50 g of silica gel with ether–hexane (1:3) as the eluant to give **10** (2.139 g, 53%) as a colorless oil: IR (film) 1730 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ= 1.6—2.6 [4H, m, $(CH_2)_2$], 3.92 (1H, t, J=6.5 Hz, SCH), 4.4 (2H, m, CH_2O), and 7.2—7.7 (5H, m, Ph).

Found: C, 63.50; H, 5.85%. Calcd for $C_{11}H_{12}O_2S$: C, 63.45; H, 5.81%.

(b) A solution of lithium diisopropylamide in THF was prepared from a 1.5 M solution of buthyllithium in hexane (35.1 ml, 54.9 mmol) and diisopropylamine (6.05 g, 59.9 mmol) in THF (30 ml), and a solution of **9** (5.00 g, 59.9 mmol) in THF (15 ml) was added dropwise with stirring at −78 °C. After being stirred for 40 min, chlorotrimethylsilane (6.51 g, 59.9 mmol) was added. Two hours later, a solution of benzenesulfenyl chloride (10.83 g, 74.9 mmol) in THF (15 ml) was added and the reaction was warmed to room temperature and stirred for 20 h, then quenched with aqueous ammonium chloride. The mixture was extracted with ether and the combined extracts were washed with brine and dried. Evaporation followed by purification of a residue with column chromatography on silica gel using ether–hexane (1:1) as the eluant gave **10** (4.57 g, 44%) and recovered **9** (1.29 g, 26%).

2-Phenylthio-2-penten-5-olide (1). To a stirred solution of **10** (1.614 g, 7.76 mmol) in CH_2Cl_2 (50 ml) at −16 °C, was added dropwise over 30 min a solution of *m*CPBA (80% purity 1.673 g, 7.76 mmol) in CH_2Cl_2 (20 ml). After stirring for 30 min, the reaction mixture was washed with aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine, and dried. Evaporation of the solvent afforded practically pure sulfoxide **12** (1.617 g) as an oil: IR (film) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.5—2.6 [4H, m, $(CH_2)_2$], 3.6 (1H, t, J=7.5 Hz, SCH), 4.4 (2H, m, CH_2O), and 7.55 (5H, m, Ph). To a solution of **12** in CH_2Cl_2 (10 ml) precooled at −15 °C, trifluoroacetic anhydride (10 ml) was added. The mixture was stirred for 12 h and allowed to warm gradually to room temperature. The mixture was diluted with CH_2Cl_2 and washed with aqueous sodium hydrogencarbonate and brine, and dried. Filtration followed by evaporation left an oil, which was passed through a short silica-gel column with ether to provide **1** (1.644 g, 98%) as an oli: IR (film) 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=2.48 (2H, m, CH_2C=C), 4.41 (2H, t, J=5.4 Hz, CH_2O), 6.25 (1H, t, J=5.5 Hz, C=CH), and 7.40 (5H, m, Ph).

Found: m/z 206.0398. Calcd for $C_{11}H_{10}O_2S$: M, 206.0401.

3-Methyl-2-phenylthio-5-pentanolide (2a). To a stirred mixture of copper(I) iodide (51 mg, 0.27 mmol), dimethyl sulfide (0.5 ml), and ether (3 ml) at −35 °C was added dropwise 1.6 M methyllithium in ether (0.33 ml, 0.53 mmol). After stirring for 50 min at −35 °C, a solution of **1** (50.2 mg, 0.24 mmol) in THF (2 ml) was added, and stirring was continued for an additional 30 min at the range of −35 to −18 °C. The reaction was quenched by addition of aqueous ammonium chloride followed by 25% aqueous ammonia, and the product was extracted with CH_2Cl_2. The combined extracts were washed with brine, and dried. Evaporation of the solvent left an oil which was purified by TLC to give **2a** (49.3 mg, 91%) as a colorless oil: IR (film) 1730 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.25 (3H, d, J=7.2 Hz, Me), 1.4—2.3 (3H, m), 3.41 and 3.85 (1H in total, d, J=6.5 and 6.3 Hz, each, 9:1 ratio by integration, SCH), 4.2—4.5 (2H, m, CH_2O), 7.2—7.6 (5H, m, Ph).

Found: m/z 222.0702. Calcd for $C_{12}H_{14}O_2S$: M, 222.0714.

3-Butyl-2-phenylthio-5-pentanolide (2b). According to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (48.6 mg, 0.26 mmol) with 1.5 M butyllithium in hexane (0.32 ml, 0.51 mmol), followed by addition of **1** (49.8 mg, 0.24 mmol) provided **2b** (51.0 mg, 80%) as a colorless oil: IR (film) 1730 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=0.90 (3H, br t, Me), 1.1—2.3 (9H, m), 3.51 and 3.92 (1H, in total, d, J=6.4 and 5.4 Hz each, 9:1 ratio by integration, SCH), 4.2—4.6 (2H, m, CH_2O), and 7.2—7.6 (5H, m, Ph).

Found: m/z 264.1182. Calcd for $C_{15}H_{20}O_2S$: M, 264.1183.

2-Phenylthio-3-vinyl-5-pentanolide (2c). According to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (388 mg, 2.04 mmol) with 1.09 M vinylmagnesium bromide (1.79 ml, 1.94 mmol) at −55 °C, followed by addition of **1** (200 mg, 0.97 mmol) gave **2c** (185 mg, 82%) as a colorless oil: IR (film) 1730 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.5—2.8 (3H, m), 3.61 and 3.85 (1H in total, d, J=6.4 and 5.0 Hz, 7:1 ratio by integration, SCH), 4.3—4.7 (2H, m, CH_2O), 5.1—5.38 (2H, m, $C\underline{H}_2$=CH), 5.7—6.1 (1H, m, CH_2=$C\underline{H}$), and 7.2—7.6 (5H, m, Ph).

3-[Bis(methoxycarbonyl)methyl]-2-phenylthio-5-pentanolide (2d). To a stirred suspension of 60% sodium hydride in min-

eral oil (20 mg, 0.49 mmol) in ether (4 ml) was added dimethyl malonate (64.2 μl, 0.53 mmol). After stirring for 25 min, a solution of **1** (50 mg, 0.24 mmol) in THF (2 ml) was added at 0 °C and stirring was continued for an additional 1.5 h at 0 °C. The mixture was poured into aqueous ammonium chloride and extracted with CH_2Cl_2. The combined extracts were washed with brine, and dried. Evaporation of the solvent followed by purification of a residue by TLC afforded **2d** (60 mg, 73%) as a colorless oil: IR (film) 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.6—2.2 (3H, m), 2.7 (1H, m), 3.76 and 3.78 (3H, s each, Me), 3.8 (1H, s, SCH), 4.2—4.5 (2H, m, CH_2O), and 7.3—7.6 (5H, m, Ph).

Found: *m/z* 338.0848. Calcd for $C_{16}H_{18}O_6S$: M, 338.0823.

3-Methyl-5-pentanolide (3a). A mixture of **2a** (36 mg), W-4 Raney nickel (500 mg) and acetone (3 ml) was stirred at room temperature for 3.5 h, and filtered through a short celite column. The filtrate was evaporated to leave an oil, whose purification by TLC afforded **3a** (14 mg, 74%) as an oil: IR (film) 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.02 (3H, d, *J*=6.0 Hz, Me), 1.1—2.8 (5H, m), and 4.1—4.5 (2H, m, CH_2O).

3-Butyl-5-pentanolide (3b). (a) According to the procedure described for the preparation of **3a**, treatment of **2b** (60 mg) with W-4 Raney nickel (1 g) in ethanol (10 ml) afforded **3b** (26 mg, 76%) as an oil: IR (film) 1740 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.90 (3H, br t, Me), 1.1—2.8 (11H, m), 4.1—4.6 (2H, m, CH_2O).

(b) According to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (94 mg, 0.49 mmol) with 1.5 M butyllithium in hexane (0.62 ml, 0.98 mmol) at −40 °C, followed by addition of **8** (40 mg, 0.41 mmol) afforded **3b** (29 mg, 45%).

3-Vinyl-5-pentanolide (3c). (a) According to the procedure described for the preparation of **3a**, desulfurization of **2c** (47 mg) in acetone (3 ml) with W-4 Raney nickel (500 mg) deactivated with refluxing acetone provided **3c** (11 mg, 42%) as a colorless oil: ^1H NMR ($CDCl_3$) δ=1.2—2.9 (5H, m), 4.1—4.6 (2H, m, CH_2O), 4.9—5.2 (2H, m, $C\underline{H}_2$=CH), and 5.6—6.0 (1H, m, CH_2=C$\underline{H}$).

Found: *m/z* 126.0679. Calcd for $C_7H_{16}O_2$: M, 126.0680.

(b) According to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (117 mg, 0.61 mmol) with 1.09 M vinylmagnesium bromide (0.52 ml, 0.56 mmol) at −50 °C, followed by addition of **8** (51 mg, 0.52 mmol) gave **3c** (9 mg, 17%).

3-[Bis(methoxycarbonyl)methyl]-5-pentanolide (3d). According to the procedure described for the preparation of **3a**, reaction of **2d** (31 mg) with W-4 Raney nickel (500 mg) in acetone (3 ml) gave **3d** (12 mg, 56%) as an oil: ^1H NMR ($CDCl_3$) δ=1.3—2.8 (5H, m), 3.3 (1H, br d, COCHCO), 3.75 and 3.81 (6H in total, s each, Me_2), and 4.2—4.5 (2H, m, CH_2O).

Ethyl 5-Hydroxy-3-methylpentanoate (13) and 3-Ethyl-5-pentanolide (14). A mixture of **2a** (42 mg), W-4 Raney nickel (500 mg) and ethanol (5 ml) was stirred for 4 h. Workup according to the procedure described for the preparation of **3a** followed by purification of a residue by TLC gave **13** (23 mg, 75%) as a colorless oil: IR (film) 3300 (OH) and 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.98 (3H, d, *J*=6.0 Hz, CH$\underline{Me}$), 1.28 (3H, t, *J*=7.0 Hz, $CH_2\underline{Me}$), 1.6 (2H, m), 2.0 (1H, m, C$\underline{H}$Me), 2.25 (2H, m, CH_2CO), 3.65 (2H, t, *J*=6.0 Hz, $C\underline{H}_2OH$), and 4.17 (2H, q, *J*=6.0 Hz, $MeC\underline{H}_2$).

By the similar procedure, reaction of **2c** (31 mg) with W-4 Raney nickel (500 mg) in ethanol (5 ml) afforded **14** (14 mg, 86%) as an oil: IR (film) 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.1—2.8 (10H, m), 4.1—4.6 (2H, m, CH_2O).

General Procedure for the Preparation of 3-Substituted 2-penten-5-olide (5). To a stirred solution of **2** (0.3 mmol) in CH_2Cl_2 (15 ml) at −10 °C for **2a**, **b**, **d** and at −50 °C for **2c**, was added dropwise over 30 min a solution of *m*CPBA (0.3 mmol) in CH_2Cl_2 (10 ml). After addition was complete, stirring was continued for an additional 10 min at −10 °C for **2a**, **b**, **d** and at −20 °C for **2c**, and the mixture was washed with aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine, and dried. Evaporation gave practically pure and oily sulfoxide **4** in quantitative yield. To a solution of **4** in benzene (10 ml) was added pyridine (100 μl) and the mixture was gently refluxed for 1.5 h. After cooling, the mixture was diluted with benzene and washed with aqueous sodium hydrogencarbonate, aqueous copper(II) sulfate and brine, and dried. Evaporation of the solvent followed by purification of a residue by TLC afforded **5** as a colorless oil.

3-Methyl-2-phenylsulfinyl-5-pentanolide (4a). ^1H NMR ($CDCl_3$) δ=0.75 and 1.30 (3H in total, both d, *J*=6.8 Hz, 1:9 ratio by integration, Me), 1.2—2.4 (3H, m), 3.38 and 3.85 (1H in total, d, *J*=5.4 and 5.7 Hz each, 9:1 ratio by integration, SOCH), 4.1—4.5 (2H, m, CH_2O), and 7.4—8.0 (5H, m, Ph).

3-Butyl-2-phenylsulfinyl-5-pentanolide (4b). ^1H NMR ($CDCl_3$) δ=0.8—2.6 (12H, m), 3.38 and 3.82 (1H in total, d, *J*=4.3 and 5.4 Hz each, 9:1 ratio by integration, SOCH) 4.2—4.7 (2H, m, CH_2O), and 7.4—8.0 (5H, m, Ph).

2-Phenylsulfinyl-3-vinyl-5-pentanolide (4c). ^1H NMR ($CDCl_3$) δ=1.5—2.8 (3H, m), 3.82 and 4.02 (1H in total, both d, *J*=5.4 Hz, 7:1 ratio by integration, SOCH), 4.4 (2H, m, CH_2O), 5.1—5.3 (2H, m, $C\underline{H}_2$=CH), 5.7—6.2 (1H, m, CH_2=C$\underline{H}$), and 7.3—8.0 (5H, m, Ph).

3-[Bis(methoxycarbonyl)methyl]-2-phenylsulfinyl-5-pentanolide (4d). ^1H NMR ($CDCl_3$) δ=1.6—2.4 (2H, m), 2.84—3.5 (2H, m), 3.6—4.0 (7H, m), 4.3—4.7 (2H, m, CH_2O), and 7.3—8.0 (5H, m, Ph).

3-Methyl-2-penten-5-olide (5a). 72% yield from **2a**; IR (film) 1720 (C=O) and 1645 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=2.0 (3H, d, *J*=1.6 Hz, Me), 2.40 (2H, t, *J*=5.8 Hz, $C{=}CCH_2$), 4.38 (2H, t, *J*=6.1 Hz, CH_2O), and 5.80 (1H, q, *J*=1.6 Hz, C=CH).

General Procedure for the Pummerer Reaction of 4. The sulfoxide **4** was prepared by oxidation of **2** with equimolar *m*CPBA according to the aforementioned procedure. Trifluoroacetic anhydride was added to **4** at −60 °C and the

resulting mixture was stirred, and allowed to warm gradually to room temperature. The reaction mixture was diluted with CH_2Cl_2 and washed with aqueous sodium hydrogencarbonate and brine, and dried. Filtration followed by removal of the solvent left an oil, which was purified by TLC to give **6** and/or **7**.

3-Methyl-2-(phenylthio)-2-penten-5-olide (6a) and 2-Hydroxy-3-methyl-2-penten-5-olide (7a). (a) A solution of **4a** (190 mg) prepared from **2a** (183 mg, 0.82 mmol) and trifluoroacetic anhydride (4 ml) was stirred for 3d to give **6a** (94 mg, 52% from **2a**) and **7a** (19 mg, 18% from **2a**).

6a: an oil; IR (film) 1720 (C=O) and 1605 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=2.28 (3H, s, Me), 2.65 (2H, t, *J*=5.7 Hz, C=CCH_2), 4.40 (2H, t, *J*=5.7 Hz, CH_2O), and 7.18 (5H, br s, Ph).

Found: *m/z* 220.0548. Calcd for $C_{12}H_{12}O_2S$: M, 220.0557.

7a: an oil; IR (film) 3350 (OH), 1700 (C=O), and 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.91 (3H, t, *J*=1.3 Hz, Me), 2.47 (2H, tt, *J*=5.3, 1.3 Hz, C=CCH_2), 4.39 (2H, t, *J*=6.3 Hz, CH_2O), and 5.59 (1H, s, OH).

Found: *m/z* 128.0470. Calcd for $C_6H_8O_3$: M, 128.0473.

(b) **4a** (47 mg) prepared from **2a** (42 mg, 0.19 mmol) was treated with trifluoroacetic anhydride (3 ml) and the temperature was gradually raised to 0 °C over 3 h. The reaction mixture was diluted with CH_2Cl_2 and poured into ice-cooled aqueous sodium hydrogencarbonate. Workup gave **6a** (5 mg, 14% from **2a**) and **7a** (14 mg, 59% from **2a**).

3-Butyl-2-phenylthio-2-penten-5-olide (6b). A solution of **4b** (71 mg) prepared from **2b** (63 mg, 0.24 mmol) and trifluoroacetic anhydride (2 ml) was stirred for 2d to give **6b** (31 mg, 49% from **2b**) as an oil: IR (film) 1720 (C=O) and 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, Me), 1.1—1.8 (4H, m), 2.5—2.8 (4H, m, C=CCH_2×2), 4.40 (2H, t, *J*=6.7 Hz, CH_2O), and 7.22 (5H, m, Ph).

Found: *m/z* 262.1026. Calcd for $C_{15}H_{18}O_2S$: M, 262.1027.

2-Phenylthio-3-vinyl-2-penten-5-olide (6c). A solution of **4c** (39 mg) prepared from **2c** (33 mg, 0.14 mmol) and trifluoroacetic anhydride (2 ml) was stirred for 3d to give **6c** (4 mg, 10% from **2c**) and **5c** (13 mg, 74% from **2c**).

6c: a colorless oil; ^1H NMR ($CDCl_3$) δ=2.64 (2H, t, *J*=6.1 Hz, C=CCH_2), 4.48 (2H, t, *J*=6.1 Hz, CH_2O), 5.45 (1H, d, *J*=10.4 Hz, CH_aH_b=CH), 5.52 (1H, d, *J*=18.0 Hz, CH_aH_b=CH), and 6.95 (1H, dd, *J*=10.4, 18.0 Hz, CH_2=CH).

2-Hydroxy-3-[bis(methoxycarbonyl)methyl]-2-penten-5-olide (7d). A solution of **4d** (54 mg) prepared from **2d** (50 mg, 0.15 mmol) and trifluoroacetic anhydride (2 ml) was stirred for 2d to give **7d** (12 mg, 34% from **2d**): IR (film) 3350 (OH) and 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.70 (2H, t, *J*=6.4 Hz, C=CCH_2), 3.81 (6H, s, Me), 4.47 (2H, t, *J*=6.4 Hz, CH_2O), 4.92 (1H, s, COCHCO), and 6.0 (1H, br, OH).

3,3-Dimethyl-2-phenylthio-5-pentanolide (20). Acoording to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (19 mg, 0.10 mmol) with 1.25 M methyllithium in ether (160 μl, 0.18 mmol) at −13 °C, followed by addition of **6a** (18 mg, 0.08 mmol) gave **20** (6 mg, 32%): ^1H NMR ($CDCl_3$) δ=1.24 (6H, s, Me_2), 1.4—2.1 (4H, m), 3.43 (1H, br s, SCH), 4.4 (2H, m, CH_2O), and 7.2—7.7 (5H, m, Ph).

Found: *m/z* 236.0867. Calcd for $C_{13}H_{16}O_2S$: M, 236.0870.

3-Butyl-3-methyl-2-phenylthio-5-pentanolide (21). Acoording to the procedure for the preparation of **2a**, treatment of copper(I) iodide (16 mg, 0.08 mmol) with 1.22 M methyllithium in ether (0.13 ml, 0.16 mmol) at −25 °C, followed by addition of **6b** (18 mg, 0.07 mmol) gave **21** (5 mg, 24%). ^1H NMR ($CDCl_3$) δ=0.9 (3H, br t, Me), 1.1—2.23 (11H, m), 3.52 (1H, br s, SCH), 4.1—4.6 (2H, m, CH_2O), and 7.2—7.7 (5H, m, Ph).

Found: *m/z* 278.1347. Calcd for $C_{16}H_{22}O_2S$: M, 278.1340.

Reaction of 5c with Lithium Dimethylcuprate. Acoording to the procedure described for the preparation of **2a**, treatment of copper(I) iodide (102 mg, 0.54 mmol) with 1.6 M methyllithium in ether (0.67 ml, 1.07 mmol) at −30 °C, followed by addition of **5c** (61 mg, 0.49 mmol) gave **22** (35 mg, 51%) and **23** (6 mg, 8%).

22: IR (film) 1750 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.95 (3H, t, *J*=7.1 Hz, Me), 2.0 and 2.5 (2H, m each, CH_2CH_2O and C=CCH_2Me), 3.3 (2H, m, CH_2CO), 4.2—4.42 (2H, m, CH_2O), and 5.35 (1H, br t, C=CH).

Found: *m/z* 140.0841. Calcd for $C_8H_{12}O_2$: M, 140.0837.

23: IR (film) 1710 (C=O) and 1640 cm^{-1} (C=C); ^1H NMR ($CDCl_3$) δ=0.98 (3H, t, *J*=7.0 Hz, Me), 1.1—2.1 (4H, m), 2.42 (2H, m, CH_2CH_2O), 4.2—4.5 (2H, m, CH_2O), and 6.0 (1H, s, with fine splittings, C=CH).

General Procedure for the Reaction of 1 with Benzylic Grignard Reagents 25. Benzyl or substituted benzyl bromide (3 equiv) was added to a mixture of finely powdered magnesium (30 equiv) and a catalytic amount of 1,2-dibromoethane in ether. The resulting suspension was stirred at room temperature for 30 min, and then with refluxing for an additional 10 min, and cooled at −12 °C. A solution of **1** (1.0 equiv) in THF (1—2 ml) was added with stirring and stirring was continued for an additional 20—30 min. The reaction was quenched by addition of aqueous ammonium chloride, and the product was extracted with CH_2Cl_2, washed with brine, and dried. Removal of the solvent left an oil which was purified by TLC to give **26** and/or **27**, along with recovered **1** on the reactions with the Grignard reagents **25a**, **b**, **d**.

3-Benzyl-2-phenylthio-5-pentanolide (26a). Reaction of **1** (49 mg, 0.24 mmol) with the Grignard reagent **25a**, prepared from magnesium (175 mg, 7.29 mmol) and benzyl bromide (125 mg, 0.23 mmol) in ether (3 ml), gave **26a** (58 mg, 82%) and **1** (8 mg, 16%). **26a**: a colorless oil; IR (film) 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.2—2.8 (3H, m), 3.2 (2H, m, CH_2Ph), 3.58 and 3.75 (1H in total, d, *J*=5.7 and 3.6 Hz each, 9:1 ratio by integration, SCH), 4.2—4.4 (2H, m, CH_2O), and 7.1—7.6 (10H, m, Ph).

Found: *m/z* 298.1026. Calcd for $C_{18}H_{18}O_2S$: M, 298.1027.

3-(2-Methylbenzyl)-2-phenylthio-5-pentanolide (26b). Reaction of **1** (50 mg, 0.24 mmol) with the Grignard reagent **25b** prepared from magnesium (176 mg, 7.33 mmol) and 2-methylbenzyl bromide (139 mg, 0.73 mmol) in ether (4 ml), provided **26b** (47 mg, 62%) and **1** (8 mg, 16%). **26b**: a colorless oil; IR (film) 1730 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.3—2.8 (5H, m), 2.26 (3H, s, Me), 3.57 and 3.80 (1H in total, d, *J*=6.1 and 4.7 Hz each, 9:1 ratio by integration, SCH), 4.1—4.5 (2H, m, CH_2O), and 7.0—7.6 (9H, m, Ph, ArH).

Found: *m/z* 312.1193. Calcd for $C_{19}H_{20}O_2S$: M 312.1183.

3-(2,6-Dimethylbenzyl)-2-phenylthio-5-pentanolide (26c) and 3-(3,5-Dimethyl-4-methylene-2,5-cyclohexadienyl)-2-phenylthio-5-pentanolide (27c).[4b] Reaction of **1** (105 mg, 0.51 mmol) with the Grignard reagent **25c**, prepared from magnesium (350 mg, 14.59 mmol) and 2,6-dimethylbenzyl bromide (195 mg, 1.48 mmol) in ether (4 ml), afforded **26c** (58 mg, 34%) and **27c** (108 mg, 65%).

26: Found: *m/z* 326.1339. Calcd for $C_{20}H_{22}O_2S$: M 326.1340.

27: Found: *m/z* 326.1340. Calcd for $C_{20}H_{22}O_2S$: M 326.1340.

3-(2,4,6-Trimethylbenzyl)-2-phenylthio-5-pentanolide (26d) and 3-(1,3,5-Trimethyl-4-methylene-2,5-cyclohexadienyl)-2-phenylthio-5-pentanolide (27d).[4b] Reaction of **1** (50 mg, 0.4 mmol) with the Grignard reagent **25d**, prepared from magnesium (175 mg, 7.29 mmol) and 2,4,6-trimethylbenzyl bromide (155 mg, 0.72 mmol) in ether (3 ml), gave a mixture of **26d** and **27d** (14 mg in total, 6 and 10%, respectively) and recoverd **1** (37 mg, 75%). The yields of **26d** and **27d** were calculated from the integral ratio of the aromatic and aliphatic methyls in **26d** and **27d**, respectively, in the ^{1}H NMR spectrum of the mixture.

2-Phenylthio-3-(2,4,6-trimethylphenyl)-5-pentanolide (28).[4b] A mixture of **27** (40 mg) and a catalytic amount of *p*-toluenesulfonic acid in anhydrous benzene (1 ml) was allowed to stir at room temperature for 10 h. After removal of the solvent, an oily residue was purified by TLC (CH_2Cl_2) to give **28** (39 mg, 98%) as colorless crystals, mp 107—108 °C.

Found: C, 73.58; H, 6.70%. Calcd for $C_{20}H_{22}O_2S$: C, 73.60; H, 6.79%.

3-(2,6-Dimethylbenzyl)-2-methyl-2-phenylthio-5-pentanolide (29). According to the procedure described for the preparation of **10**, lithium diisopropylamide was prepared from diisopropylamine (62 mg, 0.61 mmol) and 1.5 M butyllithium in hexane (0.37 ml, 0.58 mmol) in THF (5 ml). A solution of **26c** (181 mg, 0.54 mmol) in THF (5 ml) was added to the above solution at −70 °C with rapid stirring, and stirring was continued for an additional 30 min. To this mixture, HMPA (1 ml) followed by methyl iodide (91 mg, 0.64 mmol) was added and the temperature was gradually raised to −10 °C over 3.5 h. The reaction was quenched by addition of aqueous ammonium chloride, and the product was extracted with CH_2Cl_2. The combined extracts were washed with brine and dried. Evaporation followed by purification of a residue by TLC gave a mixture of diastereomers **29** (135 mg, 72%) as an oil; IR (film) 1720 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.59 (3H, s, Me), 1.7 (2H, m, $C\underline{H}_2CH_2O$), 2.35 (6H, s, Ar$\underline{Me}$), 2.2—3.3 (3H, m, $PhC\underline{H}_2C\underline{H}$), 4.2—4.5 (2H, m, CH_2O), 7.0 (3H, br s, Ar$\underline{H}$), and 7.2—7.7 (5H, m, Ph).

Found: *m/z* 340.1498. Calcd for $C_{21}H_{24}O_2S$: M 340.1496.

(±)-Secocrispiolide (24) and 3-(2,6-Dimethylbenzyl)-2-methyl-2-penten-5-olide (31). To a stirred solution of **29** (91 mg, 0.27 mmol) in CH_2Cl_2 (10 ml) at −20 °C was added a solution of 80% *m*CPBA (58 mg, 0.27 mmol) in CH_2Cl_2 (8 ml) over 30 min. The mixture was stirred for 30 min, diluted with CH_2Cl_2, and washed with aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate and brine, and dried. Evaporation of the solvent gave the sulfoxide **30** (94 mg, quantitative), which was dissolved in benzene (5 ml). The resulting solution was gently refluxed for 30 min and cooled to room temperature. Removal of the solvent followed by purification of a residue with TLC gave a mixture of (±)-secocrispiolide (**24**) and **31** in 1:3 ratio (57 mg in total). Separation of the mixture by HPLC (Waters Associates, column 25 cm/0.46 (i.d.), silica gel, 9:2 hexane–chloroform) provided pure **24** and **31**. The spectra (IR, ^{1}H NMR and MS) of the synthetic **24** were identical with those of the natural material.[12]

24: a colorless oil; IR ($CHCl_3$) 1730 (C=O) and 1625 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ=1.9—2.1 (2H, m, $C\underline{H}_2CH_2O$), 2.30 (6H, br s, Me_2), 2.7—3.1 (3H, m, $ArC\underline{H}_2C\underline{H}$), 4.1—4.3 (2H, m, CH_2O), 5.38 (1H, br s, $C\underline{H}_aH_b$=C), 6.42 (1H, br s, $CH_a\underline{H}_b$=C), and 7.04 (3H, s, ArH).

Found: *m/z* 230.1304. Calcd for $C_{15}H_{18}O_2$: M 230.1306.

31: a colorless oil; IR (film) 1710 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.8—2.1 (2H, m, $C\underline{H}_2CH_2O$), 2.08 (3H, s, C=CMe), 2.25 (6H, s, Ar$\underline{Me}$), 3.50 (2H, br s, $PhC\underline{H}_2$), 4.18 (2H, br t, *J*=5 Hz, CH_2O), and 7.05 (3H, br s, Ph).

Found: *m/z* 230.1296. Calcd for $C_{15}H_{18}O_2$: M 230.1306.

Light-Induced Electron-Transfer Reaction into *Rs. rubrum* Chromatophores from a Pt Electrode

Tatsuo ERABI,* Kiyoharu MATSUMOTO, Noritaka TAKAHASHI, Kumiko HIRATA, and Masanori WADA
Department of Materials Science, Faculty of Engineering, Tottori University, Koyama, Tottori 680
(Received August 10, 1990)

A platinum electrode immersed in a chromatophore suspension brought about, upon illumination, a cathodic photocurrent under potentiostatic conditions. The photocurrent action spectrum coincided fairly well with the absorption one of a chromatophore suspension, showing maxima at 600, 800, and 875 nm. The photocurrent increased with an increasing cathodic shift of the applied potential up to about −500 mV; two successive waves were observed on the photocurrent. The mechanism for the generation of the photocurrent is discussed.

Serious environmental problems, including air pollution with NO_x and SO_x and the release of vast amounts of CO_2 into atmosphere, limit the utility of fossil fuels. The development of solar energy technology has therefore been desired, while promising a substantial future contribution to growing energy demands. The primary processes of photosynthesis are the most efficient to convert solar energy to chemical energy and, consequently, could possibly be used as the basis for modified photosynthetic processes applicable in solar energy conversion.[1] Supporting this viewpoint, many studies[2] have demonstrated the possibility of employing photoactive biological components in photoelectrochemical cells, in connection with studies on the mechanism of photosynthetic primary processes as well as solar energy conversion projects. We have been studying photoelectrochemical behavior using a photosynthetic apparatus, chromatophores, of photosynthetic bacterium, *Rhodospirillum rubrum,* at a platinum electrode.[3,4] Still, questions regarding the electron-transfer mechanism between chromatophores and the electrode remain unanswered. The present paper deals with a further detailed photoresponse of chromatophores at a platinum electrode and with a plausible mechanism to account for the photoresponse.

Experimental

A carotenoid-less blue-green mutant strain (G-9) of *Rs. rubrum* was used throughout the present study. The cells were grown anaerobically at 30 °C for 3 days under continuous illumination from tungsten lamps, as described previously.[5] Chromatophores were prepared from light-grown cells by sonication, followed by centrifugation.[6] Chromatophores, thus prepared, were suspended in a 0.12 M (M=mol dm^{-3}) GTA buffer comprising an equimolar mixture of 3,3-dimethylglutaric acid, tris(hydroxymethyl)methanamine, and 2-amino-2-methyl-1,3-propanediol, which was adjusted to various pH values by adding HCl or NaOH. The concentration of chromatophores is expressed in terms of the absorbance of bound bacteriochlorophyll at 873 nm (A_{873}; corresponding to 7.1 μM of bound bacteriochlorophyll[7]). An experimental cell[4] with a light path length of 0.4 mm comprised a platinum plate working electrode (2×3 cm^2 of surface area), a platinum wire counter electrode and a saturated calomel reference electrode. All of the potentials listed in this paper were corrected against a normal hydrogen electrode. For a potentiostatic measurement, the potential of the electrode was controlled with a Hokuto Model potentiostat (HA-104 or HA-501), and the resulting current was recorded. The photocurrent was measured after electrolyzing for 30 min in the dark at a certain potential, while approaching a steady state of electrolysis. The light source was a 300 W projector lamp, usually used in combination with a 12 cm thick water filter in order to eliminate any thermal effects (a 500 W xenon arc lamp (Wacom Model MX-500) was used in combination with a JASCO Model CT-25N grating monochromator equipped with a cut-off filter (UV-39 or VR-69) for measuring the photocurrent action spectrum). The intensity of monochromatic light was measured with a calibrated thermopile (Model 404 of Spectra-Physics). Ten units·ml^{-1} of glucose oxidase, 2 mM of glucose and 13 units·ml^{-1} of catalase were added to the suspension to remove any dissolved oxygen; oxygen-free nitrogen was passed through the suspension for 30 min before electrolysis. The suspension was kept at 25 °C using a thermostat. The electrochemical cell, thus prepared, was placed in a dark box under a nitrogen atmosphere; it was shielded with a common ground against any electromagnetic perturbations.

Results and Discussion

A platinum electrode immersed in a chromatophore suspension brought about, upon illumination, a cathodic photocurrent (I_p) under potentiostatic conditions, as reported previously.[3,4] Although the magnitude of the cathodic photocurrent depended on the concentration of chromatophores, incident light intensity, and applied potential,[3] no anodic photocurrents could be observed, even under anodic polarization. This may be due to a structural anisotropy in the chromatophore membrane at which the functional positions of such electron-transport components as cytochromes, ubiquinone 10 and the reaction center complex are important in consideration of the transfer of electrons and protons within and across the membrane.

If electrons injected into the electron-transport components bound to the chromatophore membrane equilibrate with the electrode during the primary photoact, the action spectrum of the photocurrent should correspond to the absorption one of the chromatophore suspension. The photocurrent action spectra were mea-

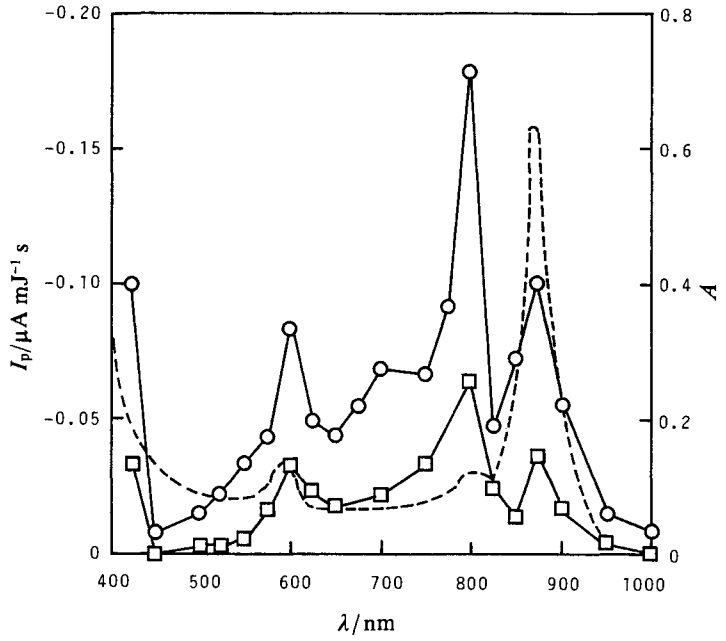

Fig. 1. Photocurrent action spectra (solid lines) and absorption spectrum of chromatophore suspension (dotted line). ○ and □ represent the values of photocurrent obtained at −500 mV and −100 mV of applied potentials, respectively. The concentration of chromatophores was kept constant at A_{873}=75.

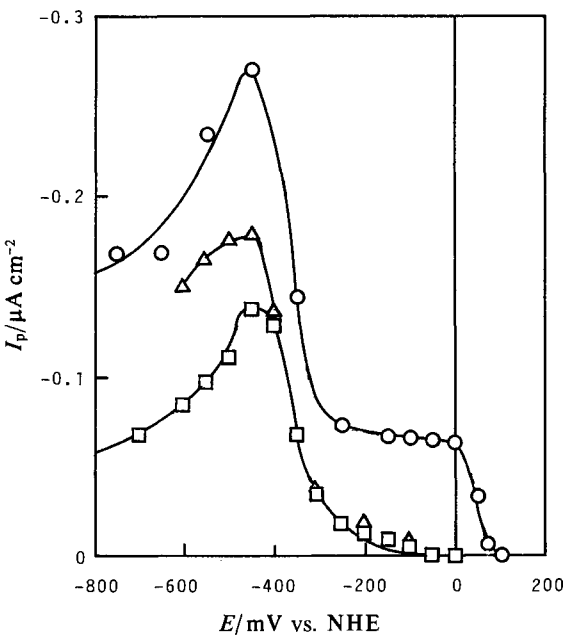

Fig. 2. Dependence of photocurrent on applied potential. ○, □, and △ represent the values obtained by native chromatophores, quinone-extracted ones, and reaction center complexes, respectively. The concentration of chromatophores and reaction centers were at A_{873}=75, and A_{802}=5, respectively. The light intensity was kept at 6000 lx of illuminance.

sured at low light intensity (1—10 J $m^{-2}s^{-1}$) and at different electrode potentials. The results are shown in Fig. 1, together with the absorption spectrum of the chromatophore suspension. It is evident that both the photocurrent action spectra and that for absorption coincide fairly well, showing maxima at 600, 800, and 875 nm assigned to chromatophore-bound bacteriochlorophyll absorption (588, 804, and 873 nm).[8] This result suggests that the bound bacteriochlorophyll, especially the reaction center bacteriochlorophyll called P870, assumes some roles in the generation of the cathodic photocurrent.

In order to specify the electrochemically active species bound to chromatophores the behavior of the photocurrent was examined in some detail against the applied potential under potentiostatic conditions at various pH values. A typical result at pH 8.0 is shown in Fig. 2. In this figure the cathodic photocurrent increases with the more cathodic shift of the applied potential up to about −500 mV, and then decreases. The decrease in the photocurrent in a more cathodic region than about −500 mV may be due to competitive hydrogen evolution resulting from the electrolysis of water, as well as an irreversible reduction of the chromatophore membrane.[9] In addition, two successive waves were observed on the cathodic photocurrent and two potential onsets of the waves were +100 and −275 mV, respectively.

Earlier, Higuti et al.[10] found that 90—95% of ubiquinone 10 and rhodoquinone are easily extractable from lyophilized chromatophores with 2,2,4-trimethylpentane; the various activities, thus depressed, are restored by adding extracts or ubiquinone 10 to the extracted chromatophores. The photocurrent generated by quinone-extracted chromatophores was lowered to about 45% or less than the original level, as also shown in Fig. 2. The effect of extracting ubiquinone 10 was especially larger in the more positive potential region, and the photocurrent became hardly observable. In addition, the voltammetric behavior of ubiquinone 10 bound to chromatophores has been reported,[9] and the redox potential at pH 8.0 was estimated to be +20 mV. These facts indicate a possibility that the first photocurrent-generating component is ubiquinone 10 bound to the chromatophores.

The chromatophore membrane can be easily disintegrated with *N*,*N*-dimethyldodecylamine *N*-oxide; a reaction center complex was purified by repeating molecular-sieve and ion-exchange chromatographies for the disintegrated membrane.[11] When the photocurrent was measured for the reaction center complex, thus prepared, the potential dependence of the cathodic photocurrent was similar to the more negative wave of the photocurrent generated by chromatophores. This result is also shown in Fig. 2. It therefore seems reasonable that the second photocurrent-generating component is one of the photooxidized constituents localized on the outside of the reaction center complex. It is generally accepted that in chromatophores the majority of bacte-

riochlorophyll molecules are harvesters of light quanta and the remainder are functional in driving the electron-transport system (reaction center bacteriochlorophyll, P870). Earlier, Okayama et al.[12] distinguished the reaction center bacteriochlorophyll into two different kinds regarding functions, Liac-860 (E_{m7}=450 mV) and Liac-890 (E_{m7}<−100 mV). In addition, we[9] have reported that chromatophores bound two reactable components on a voltammetric electrode; one is ubiquinone 10 and the other was a component named POC_{-170}, corresponding to Liac-890. It therefore seems presumable that the photooxidized constituent may correspond to a reaction center bacteriochlorophyll, Liac-890. However, it has been indicated by immunological experiments[13] that the reaction center bacteriochlorophyll should be situated at or near the periplasmic aspect of the chromatophore membrane (inside of chromatophore vesicle). It may thus be difficult for the P870 to be directly reduced on the electrode, due to the insulation of the redox center from the electrode by the structure protein. It is now being attempted to specify which of the extrinsic constituents takes role in the generation of a second cathodic photocurrent; more details regarding the photoelectrochemical behavior of reaction center complexes will be reported elsewhere.

Selective Potential Response of a Poly(*N*,*N*-dimethylaniline)/ Poly(*o*-chloroaniline) Dual-Layer Coated Electrode to Dissolved Iodide Ions

Jun YANO
Department of Chemistry, Faculty of Education, Yamanashi University, Kofu, Yamanashi 400
(Received Octover 29, 1990)

Poly(*N*,*N*-dimethylaniline) (PDA) was easily obtained by an anodic oxidation of *N*,*N*-dimethylaniline in acidic media. PDA is a semiconductor having positively charged sites as quaternary ammonium groups in its polymeric backbone. It was possible for a PDA-film coated electrode to incorporate I^- electrostatically; I^- in the film was then oxidized electrochemically. Further, the oxidized products of I^- still remained in the film. Although the electrode responded to dissolved I^- potentiometrically, the response was disturbed by the presence of other redox species. On the other hand, poly(*o*-chloroaniline) (PCA) was also easily prepared by the electro-oxidation of *o*-chloroaniline in acidic solutions. On a PCA-film coated electrode, only the redox wave of I_2/I^- was observed, though PCA, itself, was electroinactive. In other words, the PCA film responded to I^- selectively. The dual-layer (a PDA film incorporated oxidized products of I^- and PCA film) showed a selective Nernstian response to dissolved I^-.

Polyaniline, which is now a familiar conducting polymer, is easily obtained by anodic oxidation of aniline in acidic media. If the anodic oxidation of aniline derivatives, instead of aniline, also gave electroactive conducting polymers, they would have unique properties other than polyaniline. We have already examined the possibility of forming functional polymer films onto Pt electrodes by anodic oxidation.[1] The products of electro-oxidation were classified as follows: (1) deposition of an electroactive polymer film which shows a redox wave of polymer, itself; (2) deposition of an electroactive polymer film which does not show any redox wave of the polymer, itself; (3) formation of soluble products not adhering to an electrode surface; and (4) deposition of an electroinactive polymer film.

The only polymer that belongs to group (2) is poly(*N*,*N*-dimethylaniline) (PDA). PDA can incorporate anionic redox species electrostatically due to its structure, having positively charged sites as quaternary ammonium groups in the polymeric backbone.[2] This means that the PDA-film coated electrodes which incorporate certain oxidized (reduced) products have a potentiometric response to the corresponding dissolved reduced (oxidized) species. For example, a PDA film which incorporates oxidized products of I^- is sure to respond to dissolved I^- potentiometrically. Unfortunately, the response must be disturbed by the presence of other redox species, because PDA is itself conducting.

Only the redox wave of I_2/I^- was obviously observed on some of the polymer films of group (4) described above, although the films were not expected to have any useful functions.[3-5] In other words, those polymer films responded to only I^-, though they were electroinactive. The author would like to employ poly(*o*-chloroaniline) (PCA) here as a representative of group (4).

If a polymer-coated electrode responds to a certain dissolved ion selectively, it would be useful in various fields as a new type of ion sensor. Such a sensor would also have some advantage compared with conventional ion-selective electrodes, particularly regarding miniaturization. There have, however, not been many studies on polymer-coated electrodes used for such sensors. Ohnuki et al. reported that selective film permeation of H^+, Br^-, and Fe^{2+} has been observed in a few polymer-coated electrodes.[6] The electrodes probably act as amperometric sensors for them. On the other hand, a poly(*o*-phenylenediamine)-coated electrode may be applicable to voltammetric pH measurements.[7,8] In studies up to now, the kinds of dissolved ions to be measured (coating polymer materials and so on) have been limited. In this paper the author describes the unique potentiometric sensor of dissolved I^- using the PDA/PCA dual-layer coated electrode.

Experimental

For an electrochemical cell a standard three-electrode system was used for all electrolyses. In measurements of cyclic voltammograms, a platinum wire having a geometry of 1 mm in diameter and 10 mm in length (area=ca. 0.3 cm^2) was employed as the working electrode. In preparing PDA samples for elemental analysis, the electrode substrate used was a platinum plate having a surface area of ca. 8 cm^2. The counter electrode was either a platinum wire or a platinum plate. The reference electrode was a saturated calomel electrode (SCE). The platinum electrodes were treated with 6 M (1 M=1 mol dm^{-3}) HNO_3 and polarized by repeated potential cycling between −0.2 and 1.2 V vs. SCE in 0.1 M H_2SO_4. The electrodes showed the well-known redox waves of platinum. Measurements were carried out with a potentiostat/galvanostat (Model HA-301, Hokuto Denko Co., Ltd.) with a function generator (Model HB-104, Hokuto Denko Co., Ltd.) and an X-Y recorder (Model RW-21, Rikadenki Co., Ltd.).

N,*N*-dimethylaniline and *o*-chloroaniline (Tokyo Kasei Co., Ltd.) were used after distilling under reduced pressure. Other chemicals were of reagent grade and used as received. All of the aqueous solutions were prepared with doubly distilled deionized water.

In order to examine whether dissolved I^- permeates through a PDA film, a technique using a rotating disk electrode (RDE) was employed. Measurements were carried out using an RDE-measuring system (Model HR-103A, Hokuto Denko Co., Ltd.). A platinum disk of 5.0 mm diameter (area=ca. 0.196 cm^2) was used as the working electrode. Prior to use, it was polished and then polarized by repeated potential cycling between −0.2 and 1.2 V vs. SCE in 0.1 M H_2SO_4. A platinum plate (area=ca. 8 cm^2) was used as the counter electrode and an SCE was also used as the reference electrode.

Elemental analyses of carbon, hydrogen, and nitrogen were carried out with a Perkin-Elmer 240-C. Those of chlorine and iodine were carried out by the following method. The PDA samples were subjected to perfect combustion; the gases produced were absorbed in water and the amounts of chlorine and iodine in the aqueous solution determined by ion chromatography (Dionex 2000-I). Procedures for the preparation of the polymer-film coated electrodes are described in more detail in the Results and Discussion sections. All experiments were carried out at room temperature.

Results and Discussion

Preparation of PDA-Film and PCA-Film Coated Electrodes. PDA and PCA films were formed onto platinum electrodes using the same type electrolysis methods as were described in a previous paper,[1] except that the electrolytic solutions were 1.0 M HCl containing 0.5 M respective monomers. Cyclic voltammograms of the film-forming process of PDA onto a platinum electrode are shown in Fig. 1 (a). During the first positive sweep monomeric *N,N*-dimethylaniline was oxidized, exhibiting a distinct irreversible current peak at about 0.85 V. As soon as this peak current flowed, red powdery products were observed near the electrode surface. The products continued to diffuse from the surface to the bulk, while potential cycling was repeated. After about 100 cycles, however, deposition of a brown film on the electrode surface was clearly seen. The potential cycling was further continued for up to 300 cycles in preparation of the PDA-film coated electrode.

Redox peaks at ca. 0.55 V were observed until about the fiftieth cycle. The peaks corresponded to the *N,N,N',N'*-tetramethylbenzidine/the quinone diimine redox pair.[9-11] In Fig. 1 (a), the two anodic peak potentials shift more positively, and cathodic one more negatively, as the number of cycles increases. This is probably due to an *iR* drop of the growing PDA film. In fact, the conductivity of PDA in the dry state was determined to be 6.2×10^{-6} S cm^{-1} by the four-point probe method.[3]

Figure 1 (b) shows cyclic voltammograms for a coating process of the PCA film onto a platinum electrode. The anodic peak current for the oxidation of *o*-chloroaniline diminishes immediately during the first five cycles. This means that the resulting PCA film is electroinactive and quite an insulator.

The morphologies of the PCA films and the PDA films on platinum electrodes were observed using a scanning electron microscope (SEM). The PCA film

(b) Voltammograms for the redox reactions of $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ (A), I_2/I^- (B), and Br_2/Br^- (C) at both a bare platinum electrode (broken line) and the PCA-film coated electrode (solid line). Concentration of the species: $[Fe(CN)_6^{4-}]$=4 mM, $[I^-]=[Br^-]$=2 mM, Supporting electrolyte: acetate buffer solution (pH 3.5), Sweep rate: 20 mV s^{-1}.

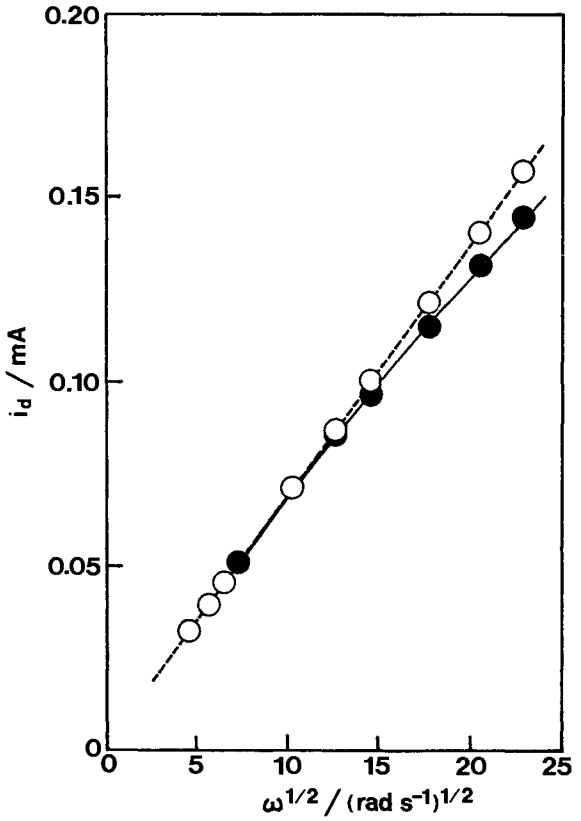

Fig. 4. Plots of the limiting anodic current (i_d) versus the square root of the rotation rate ($\omega^{1/2}$) for the electro-oxidation of dissolved I^- on the PCA-film coated platinum disk electrode (solid line) and a bare platinum disk electrode (broken line). Solution: 0.1 M H_2SO_4 containing 10 mM KI.

had a featureless smooth surface. Figure 2 shows a typical morphology of the PDA films. In contrast to the PCA film, it is interesting to clearly observe defined fibrils on a compact microspheroid underlayer of the polymer. The fibril diameter (ca. 3 μm) is greater than that found in polyaniline (ca. 1 μm).[12] In addition, the dry film thickness of PCA and PDA was determined to be ca. 6 μm and 15 μm, respectively, from observations of the cross-sectional morphologies of the films.

Redox Reactions of Dissolved Species on the PCA-Film Coated Electrode. Figure 3 (b) shows voltammograms for the redox reactions of Br_2/Br^-, I_2/I^-, and $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ at both a naked platinum electrode and the PCA-film coated electrode. Although the PCA film is itself electroinactive (see Fig. 3 (a)), the redox wave of only the I_2/I^- is evident. In addition, the PCA-film coated electrode gave no redox waves for Fe^{3+}/Fe^{2+}, *o*-quinone/catechol, *p*-quinone/hydroquinone, MnO_2/Mn^{2+}, and Tl^{3+}/Tl^+.

Insulator-film coated electrodes do not respond to dissolved species unless the films are permeable. The PCA film is probably permeable to dissolved I^- since it is an insulator.[3] In order to confirm this, the RDE voltammograms for the oxidation of dissolved I^- were measured with both the PCA-film coated disk electrode and a naked platinum disk electrode. The PCA-film coated electrode was prepared by the same type electrolysis described in Fig. 1 (b). The limiting anodic current (i_d) vs. the square root of the rotation rate ($\omega^{1/2}$) plots obtained are shown in Fig. 4. Deviations of i_d for a PCA-film coated electrode from a linear Levich line obtained with a naked platinum electrode gradually increase with the rotation rate, in particular when $\omega^{1/2}>44.7$ $(rpm)^{1/2}$. This is evidence that the PCA film is permeable to dissolved I^-.[13] Therefore, in the selective response of the PCA-film coated electrode, the charge transfer is caused by the following mechanism. Dissolved I^- permeates through the film selectively and is then electro-oxidized on the platinum substrate.

Redox Reactions of Dissolved Species on the PDA-Film Coated Electrode. Most organic conduting polymers, such as polyaniline, have a redox activity; nonconducting polymers do not show such activity. Practically, a PCA film which has no redox activity is nonconducting and electroinative to dissolved species, except for I^- which can permeate the film. The PDA film also produces no redox waves originating from redox reactions of the film, itself (Fig. 5 (a)).[1] However, a marked difference of PDA film is that the film, itself, is

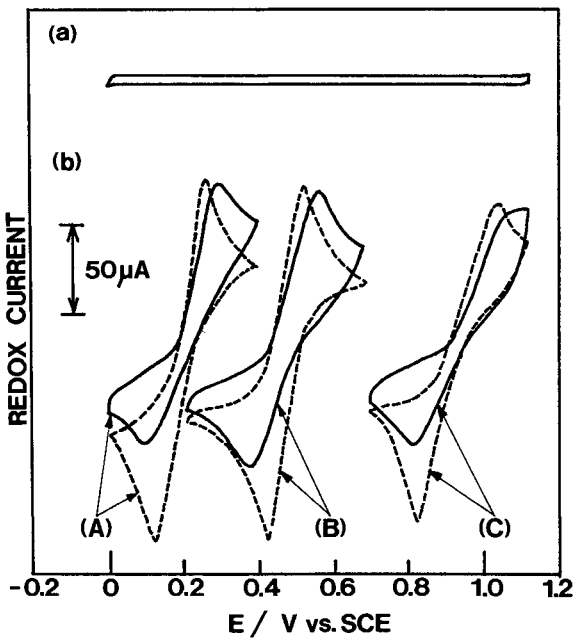

Fig. 5. (a) Voltammogram showing the electroactivity of the PDA film itself in the acetate buffer solution (pH 3.5). Sweep rate: 20 mV s^{-1}. (b) Voltammograms for the redox reactions of $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ (A), I_2/I^- (B), and Br_2/Br^- (C) at both a bare platinum electrode (broken line) and the PDA-film coated electrode (solid line). Concentration of the species: $[Fe(CN)_6^{4-}]$=4 mM, $[I^-]=[Br^-]$=2 mM, Supporting electrolyte: acetate buffer solution (pH 3.5), Sweep rate: 20 mV s^{-1}.

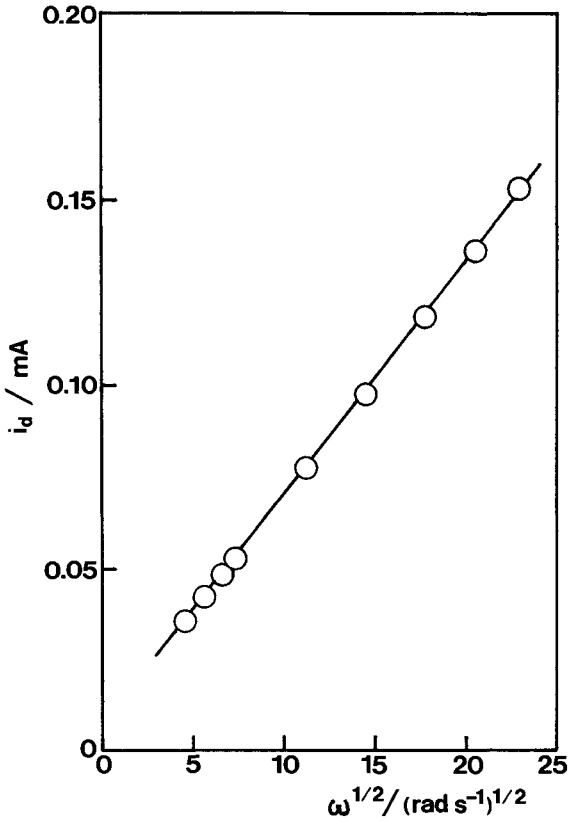

Fig. 6. Levich plots ($\omega^{1/2}$—i_d plots) for the electro-oxidation of dissolved I^- on the PDA-film coated platinum disk electrode. Solution: 0.1 M H_2SO_4 containing 10 mM KI.

electrically conducting.[3] Therefore, a PDA-film coated electrodes is expected to be active towards the electrode reactions of dissolved species. Figure 5 (b) shows voltammograms for the redox reactions of Br_2/Br^-, I_2/I^-, and $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ at both a naked platinum electrode and the PDA-film coated electrode. Although the reversibility of the redox reactions is somewhat poor, compared with that of naked platinum, the PDA film does respond to redox couples. Another characteristics of the PDA film is that the cathodic current of the redox couples is always suppressed with this electrode. A similar behavior was also observed with MnO_2/Mn^{2+}, Tl^{3}/Tl^{+}, Fe^{3+}/Fe^{2+}, *p*-quinone/hydroquinone, and *o*-quinone/catechol. Judging from the conductivity, the PDA film is a typical semiconductor. Suppression of the cathodic current may be correlated, at least in part, to a rectification effect of a *p*-type semiconductor. A polyaniline-film coated electrode is active to dissolved redox species only in the limited potential range where polyaniline, itself, is electroactive.[14] The PDA-film coated electrode has no such limitation. The oxidation peaks of Br^-, Mn^{2+}, and Tl^+ were clearly observed with the PDA-film coated electrode, while the polyaniline-film coated electrode was found to be inactive to these species. A nonconducting polyaniline film, which exhibits no redox wave of polymer, itself, shows a limited response towards the redox reactions of dissolved species.[6] The electrochemical response for such a case was observed only for relatively small ions which can permeate through the film. On the other hand, the PDA-film coated electrode was found to be electroactive to all dissolved species studied, regardless of their size and redox potentials.

In order to examine whether the PDA film is permeable to dissolved species in the redox reactions or not, the RDE technique was employed. An iodide ion was used here as being representative of dissolved species. A PDA-film coated disk electrode was prepared by the same type electrolysis process as shown in Fig. 1 (a). By using this electrode, voltammograms for the oxidation of dissolved I^- were measured at different rotation rates from 200 to 5000 rpm. A Levich plot obtained from the voltammograms is shown in Fig. 6. The limiting anodic current is proportional to the square root of the rotation rate, as can readily be seen in Fig. 6. If dissolved species permeate through polymer films and then electro-oxidized on the electrode substrate, Levich plots do not give a straight line.[13] The proportionality shown in Fig. 6 means that such a permeation does not occur; in other words, it is not on the electrode substrate, but on the PDA film that the electro-oxidation

of I^- takes place.

A polyaniline-film coated electrode is useful only within a limited pH range.[15] For example, the redox wave of $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ is not observed in neutral or alkaline solutions (pH>4). As long as the redox reaction of the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ couple is concerned, the PDA-film coated electrode gave a constant electrochemical response over the entire pH range studied (pH 1—13).

Incorporation of Anionic Redox Species into the PDA Films on Platinum Electrodes. The mechanism of electropolymerization of *N,N*-dimethylanilne has yet not been clarified. Various coupling patterns, such as para–para coupling[9] and ortho–para coupling,[11] have been reported. In any case, the resulting PDA films have structures with positively charged sites as quaternary ammonium groups in their polymeric backbones (Fig. 7).

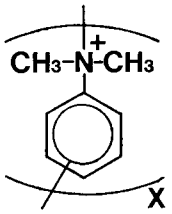

Fig. 7. Possible molecular structure of PDA.

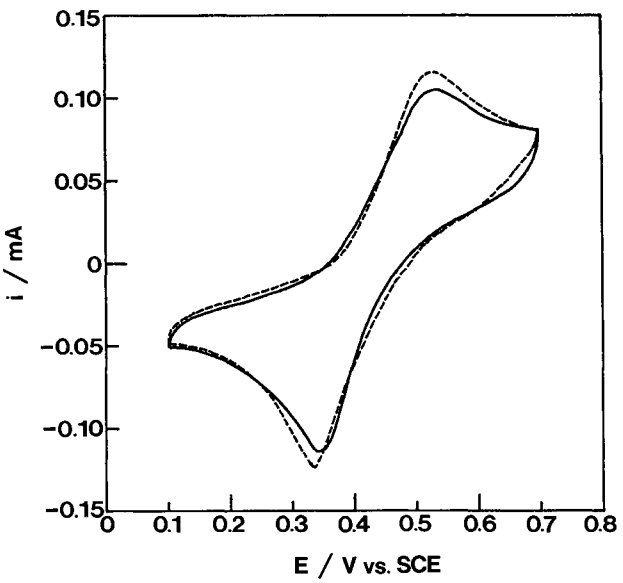

Fig. 8. Redox wave of the I^- incorporated into the PDA film. The broken line indicates the redox wave before the water immersion of one day (see text).

PDA film can incorporate $[Fe(CN)_6]^{4-}$ due to its structure (Fig. 7).[2] Several other multiply-charged anionic redox species can also be incorporated into the PDA film.[16] In order to confirm that the PDA film can incorporate dissolved I^-, the following was carried out. A PDA-film coated electrode was prepared by the same electrolysis method as shown in Fig. 1 (a). After rinsing the deposited PDA layer with water the electrode was immersed in 0.1 M KI aqueous solution for ten minutes.[17] The electrode was rinsed again and then transferred into water for one day. A cyclic voltammogram of the electrode measured in 0.1 M H_2SO_4 is shown in Fig. 8. The redox wave of the I^- incorporated in the film is evident, though the redox charge decreases slightly with water immersion. In this case, the amount of the I^- incorporated in the film was roughly evaluated to be 2.5×10^{-8} mol cm^{-2} by a graphical integration of the voltammogram.

The amounts of Cl^- and I^- ions incorporated into the PDA films were determined by elemental analysis of PDA. Three PDA samples were prepared for this purpose. The first sample (Sample 1) was an original PDA film which was prepared by the electro-oxidation of 1.0 M HCl containing 0.5 M *N,N*-dimethylaniline under continuous potential cycling in the range from −0.2 to 1.0 V on the SCE scale. The second sample (Sample 2) was basically the same as Sample 1, but was immersed in a 1 mM KI aqueous solution for one day. The third sample (Sample 3) was also the same as Sample 1, but was immersed in a 1 mM I_2 aqueous solution for one day. All of the samples were scratched off from the electrode substrate and washed with water sufficiently. They were dried in vacuo at 50 °C for 12 h and subjected to elemental analysis. The obtained results are summarized in Table 1. Although the data lack precise consistency, it is undoubted that the PDA film has anion exchangeability. The original PDA film (Sample 1), which was analysed just after preparation in a 1.0 M HCl solution, contained Cl^- ions with an atomic ratio of roughly 0.6 with respect to the nitrogen content. Hand and Nelson have reported that the electro-oxidation of *N,N*-dimethylaniline gives such secondary amines as *N*-(*p*-dimethylaminobenzyl)-*N*-methylaniline, as well as *N,N*-dimethylanilines.[18] The atomic ratio

Table 1. Elemental Composition of PDA

Sample	Treatment	Elemental composition				
		C	H	N	Cl	I
1	As prepared in HCl[a]	8	10.79	1.07	0.61	
2	1 was immersed in a KI solution[a]	8	10.34	1.06	0.02	0.58
3	1 was immersed in an I_2 solution[a]	8	12.62	1.04	0.43	0.20

a) For details, see text.

being less than unity is probably due to the presence of tertiary amino groups in the polymeric backbone. The data from Sample 2 is evidence regarding the anion exchangeability of the PDA film. The Cl^- ions in the PDA film are almost replaced by I^- ions after immersing the film in a KI aqueous solution, although only a few Cl^- ions still remain. It is noteworthy that not only I^-, but also I_2, which is electroneutral, is incorporated into the PDA film (see the data of Sample 3).

Selective Potential Response of a PDA/PCA Dual-Layer Coated Electrode to Dissolved Iodide Ions. As described previously, dissolved I^- can be incorporated in a PDA-film coated electrode and then electro-oxidized to generate oxidized products of I^-. If these products still remain in the electrode, the electrode will show a potentiometric response to dissolved I^-. Further, if the electrode responds to only I^- by coating the PDA layer with a PCA layer, it is applicable to potentiometric sensing of dissolved I^-.

The PDA/PCA dual-layer coated electrode for potentiometric sensing of I^- was prepared by means of the following. Initially, a PDA-film coated electrode was prepared under the same electrolytic condition as shown in Fig. 1 (a). After adequate rinsing of the electrode with water, the electrode was immersed in an aqueous 0.1 M KI solution for ten minutes. Coating of the PCA film on the electrode was next performed under the same conditions as shown in Fig. 1 (b). The PDA/PCA dual-layer coated electrode obtained was finally held at 0.7 V vs. SCE for five minutes in 0.1 M H_2SO_4 to change the incorporated I^- into its oxidized products. Figure 9 (a) shows the potential response of a bare platinum electrode, a PDA-film coated, and a PDA/PCA dual-layer coated electrode to dissolved I^-. Both the PDA-film coated electrode and the PDA/PCA dual-layer coated electrode have a Nernstian response to I^-, with the slope of -56 mV/log[I^-]. This potential response is evidence that the oxidized products of I^- still remain in the PDA layer. The products seem to be I_2 and a little I_3^-, judging from the slope.

Figure 9 (b) shows the effect of interfering substances on the potential response. The interfering substance in this case is the redox pair of $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$. The PDA/PCA dual-layer coated electrode obviously has the potential response, while the PDA-film coated electrode itself without the PCA-layer coating has no such response. The response of the PDA/PCA dual-layer

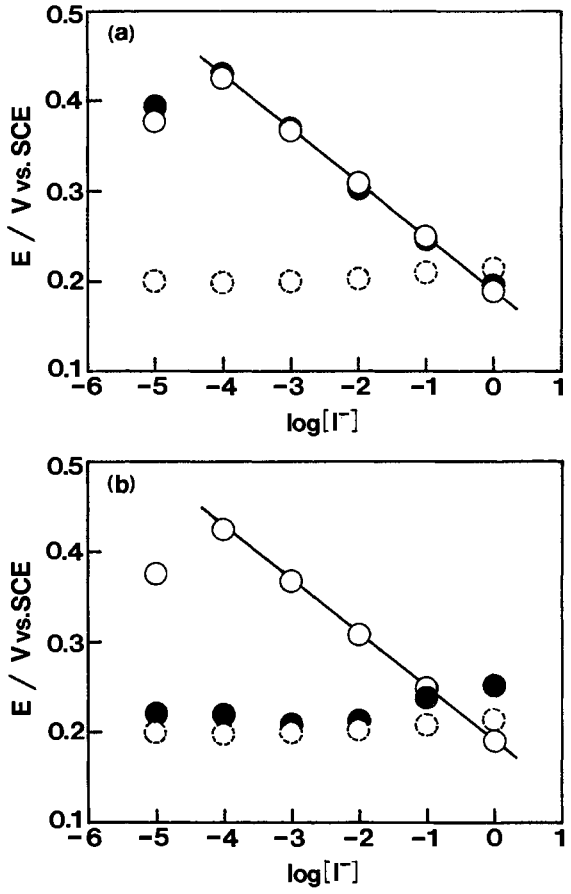

Fig. 9. (a) Potential response of a bare platinum electrode (○), the PDA-film coated electrode (●), and the PDA/PCA dual-layer coated electrode (○) with changes in log[I^-] from -5 to 0. Solution: acetate buffer solutions containing KI (pH 3.5). The response time of the PDA-film coated electrode and the PDA/PCA dual-layer coated electrode were less than ten seconds. (b) Effect of interfering substance on the potential response of (a). The interfering substance was the redox pair of $[Fe(CN)_6]^{4-}/[Fe(CN)_6]^{3-}$. Solution: acetate buffer solutions containing not only KI but also 10 mM $K_4[Fe(CN)_6]$ and $K_3[Fe(CN)_6]$.

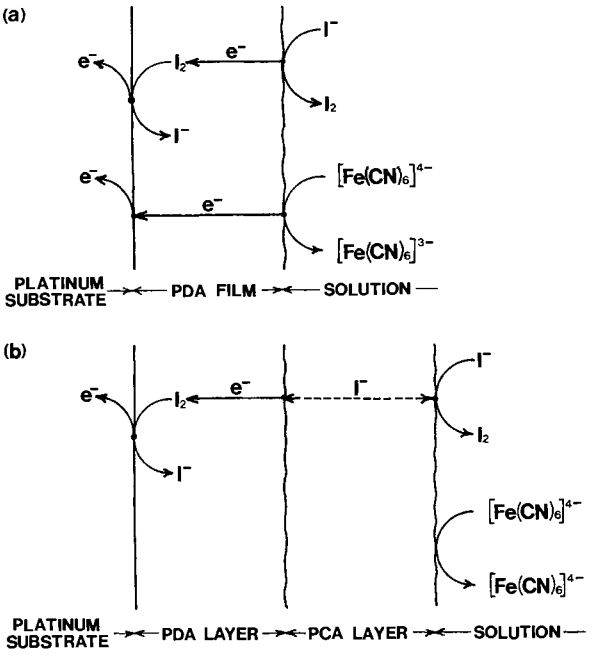

Fig. 10. Schematic depiction of the response mechanisms of dissolved I^- on the PDA-film coated electrode (a) and the PDA/PCA dual-layer coated electrode (b).

coated electrode was not disturbed by the presence of Fe^{3+}/Fe^{2+}, *p*-quinone/hydroquinone, and $Fe(edta)^-/Fe(edta)^{2-}$ and by a change of the solution pH, although they are not illustrated in Fig. 9 (b).

Figure 10 is a schematic depiction explaining how a PDA-film coated electrode and a PDA/PCA dual-layer coated electrode respond to dissolved I^-. In the case of the PDA-film coated electrode, the charge transfer between the oxidized products of I^- in the film and dissolved I^- can occur spontaneously. The oxidized product is regarded as being I_2 in this case. Consequently, the electrode has a Nernstian response to dissolved I^-. The reason why the electrode, itself, does not have a selective potential response is that the PDA film is electrically conducting, as is the electrode substrate. Charge transfer between other redox couples, such as $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$, takes place on the electrode as well, and the response of I^- is disturbed (Fig. 10 (a)). This disturbance can be repressed by a coating with a PCA layer. The PCA layer blocks the permeation of other dissolved species than I^-. As a result, the PDA/PCA dual-layer coated electrode shows a selective potential response to dissolved I^- (Fig. 10 (b)). For $[I^-]<10^{-5}$ M, it does not give a response anymore. However, this limitation might be improved by changing the amount of oxidized products of I^- in the PDA layer, the thickness of the respective layers, and so on.

The author thanks Dr. Akira Kitani and Dr. Kazuo Sasaki, Hiroshima University, for letting him use an RDE-measuring system. This work was partly supported by a grant from the Casio Science Promotion Foundation.

On the Facilitation Effect of Neutral Macrocyclic Ligands on the Ion Transfer across the Interface between Aqueous and Organic Solutions. I. Theoretical Equation of Ion-Transfer-Polarographic Current-Potential Curves and Its Experimental Verification

Hiroaki MATSUDA,* Yutaka YAMADA, Kazuo KANAMORI, Yoshihiro KUDO, and Yasuyuki TAKEDA
Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho 1-33, Chiba 260
(Received November 29, 1990)

A theoretical equation of the reversible polarographic current-potential curves for the ion transfer across the aqueous/organic interface facilitated by the neutral macrocyclic ligand present in the o-phase is derived without any limitation on the magnitude of distribution constant of the ligand. In two limiting cases, which have been employed in common experimental practice, i.e., (A) the bulk concentration of cation, c^*_M, in the aqueous phase $\gg$ that of ligand, c^*_L, in the organic phase and (B) the reverse condition, $c^*_M \ll c^*_L$, the equation of current-potential curves becomes the same in form as that of reversible D. C. polarographic waves. It is shown that the limiting current is controlled by diffusion of ligand in the organic phase for (A) and of cation in the aqueous phase for (B) and, on the other hand, the half-wave potential depends on c^*_M for (A) and on c^*_L for (B). Furthermore, an analysis method to determine the complex formation constants in the organic phase (and in the aqueous phase for favorable cases) from the concentration dependence of the half-wave potential is presented. The theoretical predictions are verified experimentally using dibenzo-18-crown-6 and 18-crown-6 as macrocyclic ligands and sodium, cesium, barium, and oxonium ions as transferred cations.

Natural and synthetic macrocyclic compounds, such as valinomysin, nonactin, and various crown ethers, are known to form selectively stable complexes with a variety of cations, especially alkali and alkaline-earth metal ions, by holding a cation in their central cavity, and then to allow the cation to be transferred from the aqueous phase (w-phase) into the organic phase (o-phase), because of the hydrophobic outer envelope of the complexes thus produced. This function of macrocyclic ligands has stimulated a great deal of interest in various branches of chemistry and biology. Potential applications have been made in liquid membrane ion-selective electrode and in making specific separations by solvent extraction and membrane transport methods. Liquid membrane containing macrocyclic compounds have also been recognized as a good model of the selective and up-hill ion transport through biological membranes.

In recent years, electrochemical methods have been employed for studies on the ion transfer across the water/nitrobenzene or water/1,2-dichloroethane interface facilitated by various natural and synthetic macrocyclic ligands. The studies done with electrochemical methods have been thoroughly reviewed by Koryta.[1-3] However, all the macrocyclic ligands hitherto employed have had large values of the distribution constant. Hence, it has been assumed that the ligands added to the o-phase cannot penetrate the w/o-interface and thus does not exist in the w-phase. Highly lipophilic crown ethers such as dibenzo-18-crown-6 (DB18C6) and its substituted derivatives have been used very frequently as the neutral carriers in ion-selective electrodes and in membrane transport experiments. On the other hand, unsubstituted crown ethers such as 15-crown-5 and 18-crown-6 (18C6), of which the distribution constants are relatively small, have been used for elucidating the behavior of crown ether complexes in the w-phase.

In the present paper, taking into account the above circumstances, we shall derive a theoretical equation of current–potential curves for the ion transfer across the w/o-interface facilitated by neutral macrocyclic ligands, without any limitation on the magnitude of distribution constant of the ligands. Then, the theoretical predictions obtained will be verified experimentally, using the ion-transfer-polarographic method with the electrolyte dropping electrode.[1]

Theory

In deriving a general equation of current-potential curves expressing the facilitation effect of neutral macrocyclic ligands on the ion transfer across the interface of the water drop growing into the organic solution, we shall make the following assumptions:

(i) The expanding plane model, which has been used as a good mathematical model for the dropping mercury electrode in polarography, is employed here for the moving interface between the water drop (w-phase) and the organic solution (o-phase). Then, the w/o-interface is taken as the origin of coordinates (x=0) and the w- and o-phases are placed in the regions: $-\infty \leqslant x \leqslant 0$ and $0 \leqslant x \leqslant +\infty$, respectively.

(ii) The complete dissociation of electrolytes present both in the w- and the o-phase is assumed for the sake of simplicity. Any effect of ion pair formation can be neglected.

(iii) At the beginning of the drop growth, the w-phase contains only the relevant metal ion M^{z+} at the uniform concentration $c_M{}^*$, except for indifferent electrolytes to be added if necessary, while the o-phase con-

tains the neutral macrocyclic ligand L at the uniform concentration c_L^* and an indifferent electrolyte.

(iv) Only the 1:1 complex ML^{z+} is formed in both phases. The rates of the complex formation and dissociation processes are sufficiently large in comparison with the corresponding diffusion rates, so that it may be assumed that the complex formation and dissociation are at equilibrium even when current is flowing. Then we have

$$\beta_1^\alpha = c_{ML}^\alpha / c_M^\alpha c_L^\alpha \quad (\alpha = w, o) \tag{1}$$

where c_j^α and β_1^α denote the concentration of the species j (j=M, L, ML) and the over-all formation constant of ML^{z+} in the α-phase, respectively.

An extention to the more general case, in which a series of complexes, such as 1:1, 1:2,···, 1:n complexes, are formed under the presence of a large excess of the ligand in the o-phase, will be treated in a later section.

(v) The rates of transfer of all relevant species across the w/o-interface are sufficiently large in comparison with the corresponding diffusion rates,[4] so that the interfacial concentrations of all species in question satisfy the equilibrium relations, even when current is flowing. For the electrostatically neutral species L, we have

$$K_D = (c_L^o)_{x=0} / (c_L^w)_{x=0} \tag{2}$$

K_D denotes the distribution constant of L, which is assumed to be independent of the potential difference $\Delta\phi = \phi^w - \phi^o$ at the w/o-interface, where ϕ^α is the inner potential of the α-phase. On the other hand, the distribution constants of the charged species M^{z+} and ML^{z+} may depend on the potential difference and their potential dependence is assumed to be governed by the Nernst equation. Thus we have

$$\exp(\zeta'_M) = (c_M^o)_{x=0} / (c_M^w)_{x=0} \tag{3}$$

$$\exp(\zeta'_{ML}) = (c_{ML}^o)_{x=0} / (c_{ML}^w)_{x=0} \tag{4}$$

with

$$\zeta'_M = (zF/RT)(\Delta\phi - \Delta\phi^{o\prime}_M) \tag{5}$$

$$\zeta'_{ML} = (zF/RT)(\Delta\phi - \Delta\phi^{o\prime}_{ML}) \tag{6}$$

where $\Delta\phi_j^{o\prime}$ is termed the formal potential of the species j for the ion transfer across the w/o-interface. Frequently, the following stoichiometric equation is employed for the facilitated ion trasfer across the w/o-interface:

$$M^{z+}(\text{w-phase}) + L(\text{o-phase}) \rightleftharpoons ML^{z+}(\text{o-phase}) \tag{7}$$

For this process the Nernst equation may be written as

$$\exp(\zeta'_{M/ML}) = (c_{ML}^o)_{x=0} / (c_M^w)_{x=0} (c_L^o)_{x=0} \tag{8}$$

with

$$\zeta'_{M/ML} = (zF/RT)(\Delta\phi - \Delta\phi^{o\prime}_{M/ML}), \tag{9}$$

where $\Delta\phi^{o\prime}_{M/ML}$ denotes the formal potential of the process expressed by Eq. 7. Taking into consideration the relations expressed by Eqs. 1—6, we can readily verify that the following relations hold among $\Delta\phi^{o\prime}_M$, $\Delta\phi^{o\prime}_{ML}$ and $\Delta\phi^{o\prime}_{M/ML}$:

$$\Delta\phi^{o\prime}_{ML} = \Delta\phi^{o\prime}_M - (RT/zF)\ln(K_D\beta_1^o/\beta_1^w) \tag{10}$$

$$\begin{aligned}\Delta\phi^{o\prime}_{M/ML} &= \Delta\phi^{o\prime}_M - (RT/zF)\ln\beta_1^o \\ &= \Delta\phi^{o\prime}_{ML} - (RT/zF)\ln(K_D/\beta_1^w)\end{aligned} \tag{11}$$

(vi) For simplicity we assume that the diffusion coefficients of relevant species in the α-phase (α=w, o) have the common value D^α.

(vii) Any interfacial excess of the relevant species, due to adsorption etc., is assumed to be absent at the w/o-interface.

Under the assumptions (i)—(vii) described above, the boundary value problem for the diffusion processes of the species M^{z+}, L and ML^{z+} can be formulated, as follows:

$$\mathscr{D}^\alpha c_M^\alpha = R_1^\alpha \tag{12}$$

$$\mathscr{D}^\alpha c_L^\alpha = R_1^\alpha \tag{13}$$

$$\mathscr{D}^\alpha c_{ML}^\alpha = -R_1^\alpha \quad (\alpha = w, o) \tag{14}$$

with

$$R_1^\alpha = k_1^\alpha (c_{ML}^\alpha - \beta_1^\alpha c_M^\alpha c_L^\alpha) \tag{15}$$

where the diffusion operator for the expanding plane model, $\mathscr{D}^\alpha$, defined by

$$\mathscr{D}^\alpha = \partial/\partial t - D^\alpha \partial^2/\partial x^2 - (2x/3t)\partial/\partial x, \tag{16}$$

is employed for simplicity of description and k_1 denotes the rate constant of the dissociation process of ML^{z+}. The initial and boundary conditions are derived from the assumptions (iii), (vi), and (vii), as follows:

$$t = 0 : \left\{ \begin{array}{llll} c_M^w = c_M^*, & c_L^w = 0, & c_{ML}^w = 0 \\ c_M^o = 0, & c_L^o = c_L^*, & c_{ML}^o = 0 \end{array} \right\} \tag{17}$$

$$\left. \begin{array}{llll} x \to -\infty : & c_M^w = c_M^*, & c_L^w = 0, & c_{ML}^w = 0 \\ x \to +\infty : & c_M^o = 0, & c_L^o = c_L^*, & c_{ML}^o = 0 \end{array} \right\} \tag{18}$$

$$x=0:\begin{cases}(f_M)_t=-\{D^w(\partial c_M{}^w/\partial x)+D^w(\partial c_{ML}{}^w/\partial x)\}\\ \quad=D^o(\partial c_M{}^o/\partial x)+D^o(\partial c_{ML}{}^o/\partial x) & (19)\\ (f_L)_t=-\{D^w(\partial c_L{}^w/\partial x)+D^w(\partial c_{ML}{}^w/\partial x)\}\\ \quad=D^o(\partial c_L{}^o/\partial x)+D^o(\partial c_{ML}{}^o/\partial x) & (20)\end{cases}$$

where $(f_j)_t$ denotes the total flux of the species j (j=M, L) at the w/o-interface. Here, it is noticed that in spite of the assumption (iv) the reaction term R_l must be added to the diffusion equations of individual species. The reasoning is: since the equilibrium condition given by Eq. 1 is approached only when k_l^α approaches infinity, the term R_l^α becomes indeterminate. This difficulty can be avoided by introducing the total concentrations of the metal ion and the ligand, defined by

$$(c_M^\alpha)_t=c_M^\alpha+c_{ML}^\alpha \tag{21}$$

$$(c_L^\alpha)_t=c_L^\alpha+c_{ML}^\alpha \quad(\alpha=\mathrm{w},\ \mathrm{o}) \tag{22}$$

Then, our diffusion problem can be reduced to

$$\mathscr{D}^\alpha(c_M^\alpha)_t=0 \tag{23}$$

$$\mathscr{D}^\alpha(c_L^\alpha)_t=0 \tag{24}$$

with the initial and boundary conditions:

$$\left.\begin{matrix}t=0\\ x\to\pm\infty\end{matrix}\right\}:\left\{\begin{matrix}(c_M{}^w)_t=c_M{}^*,\ (c_L{}^w)_t=0\\ (c_M{}^o)_t=0,\quad (c_L{}^o)_t=c_L{}^*\end{matrix}\right\} \tag{25}$$

$$x=0:\begin{cases}(f_M)_t=-D^w\{\partial(c_M{}^w)_t/\partial x\}=D^o\{\partial(c_M{}^o)_t/\partial x\} & (26)\\ (f_L)_t=-D^w\{\partial(c_L)_t/\partial x\}=D^o\{\partial(c_L{}^o)_t/\partial x\} & (27)\end{cases}$$

The boundary value problem expressed by Eqs. 23—27 has already been solved in a previous paper,[5] in which it has been shown that the following relations hold between the total interfacial concentration $\{(c_j^\alpha)_t\}_{x=0}$ and the corresponding flux $(f_j)_t$:

$$\{(c_M{}^w)_t\}_{x=0}=c_M{}^*-(D^w)^{-1/2}I_M \tag{28}$$

$$\{(c_M{}^o)_t\}_{x=0}=(D^o)^{-1/2}I_M \tag{29}$$

$$\{(c_L{}^w)_t\}_{x=0}=-(D^w)^{-1/2}I_L \tag{30}$$

$$\{(c_L{}^w)_t\}_{x=0}=c_L{}^*+(D^o)^{-1/2}I_L \tag{31}$$

with

$$I_j=\left(\frac{7}{3\pi}\right)^{1/2}\int_0^t\frac{(f_j)_t u^{2/3}\mathrm{d}u}{(t^{7/3}-u^{7/3})^{1/2}}\quad(\mathrm{j}=\mathrm{M},\ \mathrm{L}) \tag{32}$$

Hence we obtain immediately from Eqs. 28—31

$$\{(c_M{}^w)_t\}_{x=0}+\xi\{(c_M{}^o)_t\}_{x=0}=c_M{}^* \tag{33}$$

$$\{(c_L{}^w)_t\}_{x=0}+\xi\{(c_L{}^o)_t\}_{x=0}=\xi c_L{}^* \tag{34}$$

where

$$\xi=(D^o/D^w)^{1/2} \tag{35}$$

Substituting the relations expressed by Eqs. 1—4 and 10 into Eqs. 33 and 34 and performing some calculations yields

$$(c_M{}^w)_{x=0}\{(1+\exp\zeta_M)+\beta_1{}^w(1+\exp\zeta_{ML})(c_M{}^w)_{x=0}\}=c_M{}^* \tag{36}$$

$$(c_L{}^w)_{x=0}\{(1+\xi K_D)+\beta_1{}^w(1+\exp\zeta_{ML})(c_M{}^w)_{x=0}\}=\xi c_L{}^* \tag{37}$$

with

$$\zeta_M=\zeta_M'+\ln\xi=(zF/RT)(\Delta\phi-\Delta\phi_M^{o\prime})+\ln(D^o/D^w)^{1/2} \tag{38}$$

$$\zeta_{ML}=\zeta_{ML}'+\ln\xi=(zF/RT)(\Delta\phi-\Delta\phi_{ML}^{o\prime})+\ln(D^o/D^w)^{1/2} \tag{39}$$

Eliminating $(c_M{}^w)_{x=0}$ from Eqs. 36 and 37, we obtain the algebraic equation of the second order with respect to $(c_L{}^w)_{x=0}$, the solution of which is

$$(c_L{}^w)_{x=0}=\xi c_L{}^*(1-\Psi)/(1+\xi K_D) \tag{40}$$

with

$$\Psi=\frac{2\gamma_M}{\left[\left(1+\dfrac{1+\xi K_D}{\beta_1^w c^*}\,\dfrac{1+\exp\zeta_M}{1+\exp\zeta_{ML}}\right)+\left\{\left(1+\dfrac{1+\xi K_D}{\beta_1^w c^*}\,\dfrac{1+\exp\zeta_M}{1+\exp\zeta_{ML}}\right)^2-4\gamma_M\gamma_L\right\}^{1/2}\right]} \tag{41}$$

$$c^*=c_M{}^*+\xi c_L{}^* \tag{42}$$

$$\gamma_M=c_M{}^*/c^*,\quad \gamma_L=\xi c_L{}^*/c^*\quad(\gamma_M+\gamma_L=1) \tag{43}$$

Substituting Eq. 40 into Eq. 36 and performing some rearrengements yields

$$(c_M{}^w)_{x=0}=(c_M{}^*-\xi c_L{}^*\Psi)/(1+\exp\zeta_M) \tag{44}$$

Introducing Eqs. 40 and 44 into Eq. 1 with α=w, we obtain

$$(c_{ML}{}^w)_{x=0}=\xi c_M{}^*\Psi/(1+\exp\zeta_{ML}) \tag{45}$$

The current flowing, i, is defined as the total amount

of the net positive charges transferred from the w- to the o-phase per unit time. Hence, the current can be related to the total flux of metal ion at the interface, $(f_M)_t$, as follows:

$$i = zFA(t)(f_M)_t \tag{46}$$

where $A(t)$ denotes the surface area of the water drop. If the water drop is assumed to be a complete sphere as for the dropping mercury electrode in polarography, we obtain

$$A(t) = 4\pi(3vt/4\pi)^{2/3} \tag{47}$$

where v is the constant volume flow rate of aqueous solution.

Therefore, substituting Eqs. 44—46 into Eq. 28 yields

$$\left(\frac{7}{3\pi}\right)^{1/2}\int_0^t \frac{(i/zFA)u^{2/3}\mathrm{d}u}{(t^{7/3}-u^{7/3})^{1/2}} = \frac{\sqrt{D^w}\,c_M^*}{1+\exp(-\zeta_M)} + \left\{1-\frac{1+\exp(-\zeta_{ML})}{1+\exp(-\zeta_M)}\right\}\frac{\sqrt{D^o}\,c_L^*\Psi}{1+\exp(-\zeta_{ML})} \tag{48}$$

This is the Abel integral equation with respect to (i/zFA), which can readily be solved by using the standard method.[6] Thus we obtain

$$i = i_M + \left\{1-\frac{1+\exp(-\zeta_{ML})}{1+\exp(-\zeta_M)}\right\} i_{fw} \tag{49}$$

where

$$i_M = (i_d)_M/[1+\exp(-\zeta_M)] \tag{50}$$

$$i_{fw} = (i_d)_L\Psi/[1+\exp(-\zeta_{ML})] \tag{51}$$

with

$$(i_d)_M = \sqrt{7/3\pi}\; zFA(t)\sqrt{D^w}\,c_M^*/\sqrt{t} \tag{52}$$

$$(i_d)_L = \sqrt{7/3\pi}\; zFA(t)\sqrt{D^o}\,c_L^*/\sqrt{t} \tag{53}$$

Here, $(i_d)_M$ and $(i_d)_L$ denote the limiting diffusion currents, expressed by the Ilkovic equation, which are obtained when the currents would be controlled completely by the diffusion processes of M in the w-phase and of L in the o-phase, respectively. Equation 49 with Eqs. 50 and 51 is the general expression for the reversible current–potential curves. The first term on rhs of Eq. 49 denotes the current due to the transfer of M^{z+}, which would be obtained without adding L to the o-phase, while the second term expresses the current facilitated by the presence of L in the o-phase.

Now, our consideration will be resticted to the case, in which well-defined facilitated waves are observed at sufficiently more negative potentials than $\Delta\phi_M^{o\prime}$. Then, within the potential region where the facilitated wave appears, we have

$$\exp(-\zeta_M) \longrightarrow \infty$$

Hence the facilitated current is given by i_{fw}, the expression of which can be given, after introducing the explicit expression for Ψ, as follows:

$$i_{fw} = \frac{(i_d)_M + (i_d)_L}{1+\exp(-\zeta)} \times \frac{2\gamma_M\gamma_L}{1+\left\{1-4\gamma_M\gamma_L\left(\frac{1+\exp(-\zeta_{ML})}{1+\exp(-\zeta)}\right)^2\right\}^{1/2}} \tag{54}$$

where

$$\left.\begin{aligned}\gamma_M &= \frac{c_M^*}{c^*} = \frac{(i_d)_M}{(i_d)_M+(i_d)_L},\\ \gamma_L &= \frac{c_L^*}{c^*} = \frac{(i_d)_L}{(i_d)_M+(i_d)_L}\end{aligned}\right\} \tag{43'}$$

$$\begin{aligned}\zeta &= \zeta_{ML} - \ln\{(1+\xi K_D+\beta_1^w c^*)/\beta_1^w c^*\}\\ &= \zeta_M - \ln\{(1+\xi K_D+\beta_1^w c^*)/K_D\beta_1^o c^*\}\end{aligned} \tag{55}$$

Under the limiting current conditions we have

$$\exp(-\zeta) \longrightarrow 0 \text{ and } \exp(-\zeta_{ML}) \longrightarrow 0$$

Hence, the limiting current, $(i_{fw})_{lim}$, can be given as

$$(i_{fw})_{lim} = \begin{cases}(i_d)_L \text{ for } c_M^* > \xi c_L^* \;(\gamma_L/\gamma_M < 1) & (56)\\ (i_d)_M \text{ for } \xi c_L^* > c_M^* \;(\gamma_M/\gamma_L < 1) & (56')\end{cases}$$

This equation indicates that the limiting current is controlled only by the diffusion process of the species with smaller bulk concentration.

If we solve Eq. 54 with respect to $\Delta\phi$, the formula of current-potential curves can be rewritten as

$$\begin{aligned}\Delta\phi = \Delta\phi_M^{o\prime} &- \frac{RT}{zF}\ln\xi\\ &+ \frac{RT}{zF}\ln\left\{\frac{1+\xi K_D+\beta_1^w c^*[1-2\gamma_M\gamma_L(x_M+x_L)]}{K_D\beta_1^o c^*(1-x_M)(1-x_L)/(x_M+x_L)}\right\}\\ &+ \frac{RT}{zF}\ln\frac{1}{2}\left\{1+\left[1-4\gamma_M\gamma_L(1-x_M)(1-x_L)\right.\right.\\ &\left.\left.\times\left(\frac{\beta_1^w c^*}{1+\xi K_D+\beta_1^w c^*[1-2\gamma_M\gamma_L(x_M+x_L)]}\right)^2\right]^{1/2}\right\}\end{aligned} \tag{57}$$

with

$$x_M = i_{fw}/(i_d)_M, \quad x_L = i_{fw}/(i_d)_L \tag{58}$$

The half-wave potential can be obtained by introducing into Eq. 57 $i_{fw}=\frac{1}{2}(i_d)_L$ for $c_M^* \geqslant \xi c_L^*$ and $i_{fw}=\frac{1}{2}(i_d)_M$ for $\xi c_L^* \geqslant c_M^*$, respectively, as follows:

$$\Delta\phi_{1/2} = \begin{cases} \Delta\phi_M^{\circ\prime} - \dfrac{RT}{zF}\ln\xi + \dfrac{RT}{zF}\left[\ln\left(\dfrac{1+\xi K_D+\beta_1^w c_M^*}{K_D\beta_1^\circ c_M^*}\right)\right. \\ \quad - \ln\left(1-\dfrac{1}{2}\dfrac{\gamma_L}{\gamma_M}\right) \\ \quad + \ln\dfrac{1}{2}\left\{1+\left[1-\left(\dfrac{\gamma_L}{\gamma_M}\right)\left(2-\dfrac{\gamma_L}{\gamma_M}\right)\right.\right. \\ \quad \left.\left.\times\left(\dfrac{\beta_1^w c_M^*}{1+\xi K_D+\beta_1^w c_M^*}\right)^2\right]^{1/2}\right\}\Bigg] \\ \qquad \text{for } c_M^* \geqslant \xi c_L^* \ (\gamma_L/\gamma_M \leqslant 1) \end{cases} \tag{59}$$

$$\begin{cases} \Delta\phi_M^{\circ\prime} - \dfrac{RT}{zF}\ln\xi + \dfrac{RT}{zF} \\ \quad [\text{terms obtained by exchanging } c_M^* \text{ and } \xi c_L^*] \\ \qquad \text{for } \xi c_L^* > c_M^* \ (\gamma_M/\gamma_L < 1) \end{cases} \tag{59'}$$

In most experimental practice, the two limiting conditions, i.e., (A) $c_M^* \gg \xi c_L^*$ and and (B) $\xi c_L^* \gg c_M^*$, have been employed, in order to simplify analysis of current-potential curves. In the following we shall examine these two cases in some detail.

(A) $c_M^* \gg c_L^*$

When the condition:

$$\gamma_L/\gamma_M = \xi c_L^*/c_M^* \leqslant \frac{z}{25}\left(1+\frac{\beta_1^w c_M^*}{1+\xi K_D}\right) \tag{60}$$

is satisfied, the general formula of facilitated waves can be simplified very much within errors of ca. 1 mV and Eq. 57 can be reduced to

$$\Delta\phi = \Delta\phi_{1/2}^A + (RT/zF)\ln[i_{fw}/\{(i_d)_L - i_{fw}\}] \tag{61}$$

with

$$\Delta\phi_{1/2}^A = \Delta\phi_M^{\circ\prime} - \frac{RT}{zF}\ln\xi + \frac{RT}{zF}\ln\left(\frac{1+\xi K_D+\beta_1^w c_M^*}{K_D\beta_1^\circ c_M^*}\right) \tag{62}$$

Hence the log-plots of the current-potential curve, i.e., $\log[i_{fw}/\{(i_d)_L - i_{fw}\}]$ vs. $\Delta\phi$ plots, yield a straight line with a reciprocal slope of 2.3 (RT/zF), as in D. C. polarography. Equation 62 indicates that the half-wave potential depends only on the bulk concentration of metal ion, which is present in the w-phase in a large excess in comparison with the bulk concentration of ligand in the o-phase. Figure 1 is a schematic diagram showing the concentration dependence of the half-wave potential. As can readily be seen from the figure, the behavior of the concentration dependence can be divided into three types, as follows:

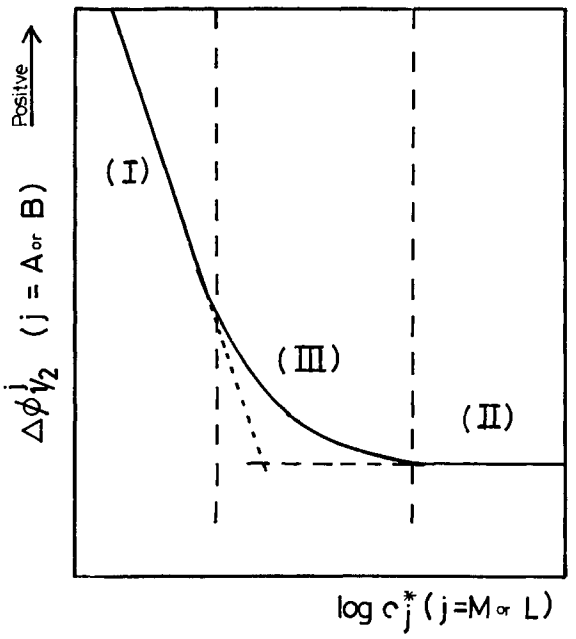

Fig. 1. Schematic diagram showing the concentration dependence of the half-wave potential. $\Delta\phi^A_{1/2}$ vs. $\log c^*_M$ plot for the cell (A). $\Delta\phi^B_{1/2}$ vs. $\log c^*_L$ plot for the cell (B).

Type (I): The plots of $\Delta\phi_{1/2}^A$ vs. $\log c_M^*$ yields a straight line with the slope of -2.3 (RT/zF). This type can be obtained when the following condition is satisfied:

$$(1+\xi K_D) \geqslant 20\,\beta_1^w c_M^* \tag{63}$$

Type (II): The half-wave potential becomes independent of $\log c_M^*$ and the plot of $\Delta\phi_{1/2}^A$ vs $\log c_M^*$ gives a horizontal line. For this type the following inequality holds:

$$\beta_1^w c_M^* \geqslant 20(1+\xi K_D) \tag{64}$$

Type (III): This is the intermediate type between the types (I) and (II). In this case we have

$$(1+\xi K_D) \sim \beta_1^w c_M^* \tag{65}$$

In order to analyze the concentration dependence of the half-wave potentials precisely, we introduce the following function F_A:

$$F_A \equiv \exp(zF/RT)(\Delta\phi_{1/2}^A - \Delta\phi_M^{\circ\prime})$$
$$= (\beta_1^w/\xi K_D\beta_1^\circ) + \{(1+\xi K_D)/\xi K_D\beta_1^\circ\}(1/c_M^*) \tag{66}$$

Then the plots of the function F_A vs. $(1/c_M^*)$ yields a straight line, of which the slope and the intercept are $\{(1+\xi K_D)/\xi K_D\beta^o{}_1\}$ and $(\beta^w{}_1/\xi K_D\beta^o{}_1)$, respectively. Hence, if the value of ξK_D is known, we can determine the values of the complex formation constants both in the w- and the o-phase from the slope and the intercept, respectively. In practice, however, it frequently happens that the $\Delta\phi^{\wedge}_{1/2}$ vs. $\log c_M^*$ curve belongs to the type (I) and the F_A vs. $(1/c_M^*)$ plot passes through the origin within experimental errors. In such a case we can obtain only the value of the complex formation constant in the o-phase from the slope. For the complex formation constant in the w-phase we obtain only the following inequality condition from Eq. 63:

$$\beta_1^w \leqslant (1 + \xi K_D)/\{20(c_M^*)_{max}\} \tag{67}$$

where $(c_M^*)_{max}$ denotes the maximum concentration of metal ion employed in the experiment. On the other hand, in some case the concentration dependence of the half-wave potential belongs to the type (II) and the F_A vs. $(1/c_M^*)$ plot becomes a horizontal line within experimental errors. In this case only the ratio $(\beta^w{}_1/\beta^o{}_1)$ is determinable from the intercept, and from Eq. 64 we have the following inequality condition:

$$\beta_1^w \geqslant 20(1 + \xi K_D)/(c_M^*)_{min} \tag{68}$$

where $(c_M^*)_{min}$ is the minimum concentration of metal ion used in the experiment.

(B) $c_L^* \gg c_M^*$

For the case:

$$\gamma_M/\gamma_L = c_M^*/\xi c_L^* \leqslant \frac{z}{25}\left(1 + \frac{\xi\beta_1^w c_L^*}{1 + \xi K_D}\right) \tag{69}$$

the general equation 57 can be simplified to

$$\Delta\phi = \Delta\phi^B_{1/2} + (RT/zF)\ln[i_{fw}/\{(i_d)_M - i_{fw}\}] \tag{70}$$

with

$$\Delta\phi^B_{1/2} = \Delta\phi^{o\prime}_M - \frac{RT}{zF}\ln\xi + \frac{RT}{zF}\ln\left(\frac{1 + \xi K_D + \xi\beta_1^w c_L^*}{\xi K_D\beta_1^o c_L^*}\right) \tag{71}$$

within errors of ca. 1 mV. Further we introduce the following function F_B:

$$F_B \equiv \exp(zF/RT)(\Delta\phi^B_{1/2} - \Delta\phi^{o\prime}_M) = (\beta_1^w/\xi K_D\beta_1^o) + \{(1 + \xi K_D)/\xi K_D\beta_1^o\}(1/\xi c^*{}_L) \tag{72}$$

Equations 70—72 can also be obtained by exchanging c_M^* by ξc_L^* in Eqs. 61, 62, and 66, respectively. Hence, all arguments described above in (A) may be applicable to the present case.

Extention to More General Case. It has been known in solvent extraction and membrane transport experiments that when the ionic crystal diameter of metal ion is somewhat larger than the cavity size of macrocyclic ligands, the 1:2 complex, i.e., the so-called sandwich type complex, as well as the ordinary 1:1 complex are formed under the presence of a large excess of the macrocyclic ligands in the o-phase. Hence, we shall extend the above theory to the more general case, in which a series of complex species ML_p^{z+} (p=1, 2,···, n) are formed under the condition (B).

In this case, the total concentrations of the metal ion and the ligand are defined as

$$(c_M^\alpha)_t = c_M^\alpha + \sum_{p=1}^{n} c_{ML_p}^\alpha \tag{73}$$

$$(c_L^\alpha)_t = c_L^\alpha + \sum_{p=1}^{n} p c_{ML_p}^\alpha \quad (\alpha = w,\ o) \tag{74}$$

Then these two total concentrations satisfy the diffusion boundary value problem defined by Eqs. 23—27 and thus the solutions are given by Eqs. 28—31. The successive complex formation in the α-phase may be characterized by the following over-all formation constant:

$$\beta_p^\alpha = c_{ML_p}^\alpha/c_M^\alpha(c_L^\alpha)^p \quad (\alpha = w,\ o;\quad p = 1,\ 2,\cdots,\ n) \tag{75}$$

On the other hand, the transfer of complex species ML_p^{z+} (p=0, 1, 2, ···, n) across the w/o-interface may be governed by the Nernst equation:

$$\exp(\zeta'_{ML_p}) = (c_{ML_p}{}^o)_{x=0}/(c_{ML_p}{}^w)_{x=0} \tag{76}$$

with

$$\zeta'_{ML_p} = (zF/RT)(\Delta\phi - \Delta\phi^{o\prime}_{ML_p}) \tag{77}$$

where $\Delta\phi^{o\prime}_{ML_p}$ is the formal potential of the complex species ML_p^{z+} for the ion transfer across the w/o-interface and may be related to $\Delta\phi^{o\prime}_M$ as follows:

$$\Delta\phi^{o\prime}_{ML_p} = \Delta\phi^{o\prime}_M - (RT/zF)\ln(K_D^p\beta_p^o/\beta_p^w) \tag{78}$$

Hence, introducing Eqs. 75 and 76 into Eqs. 33 and 34 yields

$$(c_M{}^w)_{x=0}\{(1 + \exp\zeta_M) + \sum_{p=1}^{n}\beta_p{}^w(1 + \exp\zeta_{ML_p})[(c_L{}^w)_{x=0}]^p\} = c_M^* \tag{79}$$

$$(c_L{}^w)_{x=0}\{(1 + \xi K_D) + (c_M{}^w)_{x=0}\sum_{p=1}^{n} p\beta_p{}^w(1 + \exp\zeta_{ML_p})[(c_L{}^w)_{x=0}]^p\} = \xi c_L^* \tag{80}$$

Elimination of $(c_M{}^w)_{x=0}$ from the above two equations

results in an algebraic equation of $(n+1)$-th order with respect to $(c_L^w)_{x=0}$. Under the condition (B), in which $c_L^* \gg c_M^*$ holds, this $(n+1)$-th order algebraic equation can be factorized and the solution becomes

$$(c_L^w)_{x=0} = \xi c_L^*/(1 + \xi K_D) \tag{81}$$

Hence, we can obtain the expression for $(c_M^w)_{x=0}$ by substituting Eq. 81 into Eq. 79 and then the expression of $(c_{ML_p}^w)_{x=0}$ can be derived from introducing $(c_M^w)_{x=0}$ thus obtained and Eq. 81 into Eq. 75. Substituting the interfacial concentrations of a series of complex species obtained in this way into Eq. 73 and performing some calculation by using the Eq. 78, we have

$$\{(c_M^w)_i\}_{x=0} = c_M^*/\{1 + \exp(zF/RT)(\Delta\phi - \Delta\phi_{1/2}^B)\} \tag{82}$$

with

$$\Delta\phi_{1/2}^B = \Delta\phi_M^{\circ\prime} - \frac{RT}{zF}\ln\xi + \frac{RT}{zF}\ln\left\{\frac{1 + \sum_{p=1}^{n}\beta_p^w[\xi c_L^*/(1 + \xi K_D)]^p}{1 + \sum_{p=1}^{n}\beta_p^\circ[\xi K_D c_L^*/(1 + \xi K_D)]^p}\right\} \tag{83}$$

Hence, introducing Eqs. 46 and 82 into Eq. 28 yields the Abel integral equation similar to Eq. 48, the solution of which gives for current–potential curves

$$i = (i_d)_M/\{1 + \exp(zF/RT)(\Delta\phi - \Delta\phi_{1/2}^B)\} \tag{84}$$

where $\Delta\phi_{1/2}^B$ is the half-wave potential given by Eq. 83. Of course, for $n=1$ Eq. 83 can be reduced to Eq. 71.

Very frequently, especially for hydrophobic macrocyclic ligands, the following conditions are satisfied:

$$K_D \gg 1, \quad K_D \gg (\beta_p^w)^{1/p} c_L^*$$

In such a case Eq. 83 may be reduced to

$$\Delta\phi_{1/2}^B = \Delta\phi_M^{\circ\prime} - (RT/zF)\ln\xi - (RT/zF)\ln\{1 + \sum_{p=1}^{n}\beta_p^\circ(c_L^*)^p\} \tag{85}$$

This equation is the same in form as that of the reversible half-wave potential for the polarographic reduction of complex metal ions. Therefore, by using the DeFord–Hume method[7] in polarography, we can determined the values of β_p° ($p=1, 2, \cdots, n$) succesively from the concentration dependence of the half-wave potential.

Experimental

Chemicals. Nitrobenzene, employed as the o-phase, was purified by the method described by Kakutani et al.[4] Four-times distilled water was used to prepare the aqueous electrolyte solutions. Tetrabutylammonium tetraphenylborate (TBATPB), which was used as the supporting electrolyte in the o-phase, was prepared by the equimolar addition of an aqueous solution of sodium tetraphenylborate (Kanto Chemical Co.) to an aqueous solution of tetrabutylammonium chloride (Kanto Chemical Co.). The resulting precipitate was solved into 1,2-dichloroethane (DCE), washed repeatedly with distilled water, and then recrystallized by pouring the DCE solution into distilled ethanol. Commercial DB18C6 (Merck, Schuchardt) and 18C6 (Nippon Soda Co.) were recrystallized from benzene and acetonitrile, and dried under reduced pressure. All other chemicals were of analytical grade and used without further purification. The nitrobenzene solution of TBATPB and the aqueous solution were equilibrated with each other by shaking overnight before use.

Electrochemical Measurements. The electrolysis cell employed here is essentially the same as that described by Kihara and Yoshida,[8] except for wearing the water jacket around the cell. The cell temperature was controlled at 25±0.3 °C by circulating thermostated water through the jacket. The aqueous solution was dropped upword into the nitrobenzene solution from a teflon capillary (diameter 0.8 mm) with the volume flow rate $\nu=(5—15)\times10^{-3}$ cm^3 s^{-1} and the drop time $t_d=2—5$ s. The potential difference at the test electrode was controlled by means of a four-electrode potentiostat (Huso-seisakusho, defferential potentiostat HECS 310B) with a positive feedback circuit for iR compensation.

The galvanic cells employed for the control or the measurement of the potential difference at the w/o-interface were the following two cells, corresponding to the conditions (A) $(c^*_M \gg c^*_L)$ and (B) $(c^*_L \gg c^*_M)$, respectively:

Cell (A):

(RE1) Ag	AgCl	0.05 mol dm^{-3} TBACl	0.05 mol dm^{-3} TBATPB + y mmol dm^{-3} L
		I (w)	II (o)

*	z mol dm^{-3} $M^{I}Cl$ or $M^{II}Cl_2$	sat. KCl salt bridge	0.05 mol dm^{-3} NaCl	
	III (w)		IV (w)	

AgCl | Ag (RE2)

Cell (B):

(RE1) Ag	AgCl	0.05 mol dm^{-3} TBACl	0.05 mol dm^{-3} TBATPB + y' mol dm^{-3} L
		I (w)	II (o)

$$\left|\begin{array}{l|l|l} z' \text{ mmol dm}^{-3}\ \mathrm{M^{I}Cl} & \text{sat. KCl} & 0.05\ \text{mol dm}^{-3} \\ +\,0.1\ \text{mol dm}^{-3}\ \mathrm{MgSO_4} & \text{salt bridge} & \mathrm{NaCl} \end{array}\right|^{*}$$

III (w) IV (w)

$$\mathrm{AgCl}\ |\ \mathrm{Ag\,(RE2)}$$

Here the test interface is marked by asterisk and L and M denote the macrocyclic ligand and the cation in question, respectively. The reference electrode for the nitrobenzene phase, RE1, was a Ag|AgCl|0.05 mol dm^{-3} TBACl(W) electrode, which was connected to nitrobenzene phase II through sintered glass. On the other hand, the reference electrode for the aqueous phase, RE2, was a Ag|AgCl|0.05 mol dm^{-3} NaCl(W) electrode and connected to aqueous phase III through a salt-bridge containing saturated KCl solution. For the cell (B), 0.1 mol dm^{-3} $MgSO_4$ was added to the aqueous phase III as a supporting electrolyte. Two counter electrodes were platinum wires immersed in two aqueous MCl solutions, which, in turn, were connected to the aqueous phase I and III through sintered glass, respectively. The linear sweep voltage was applied at the rate of 2 mV s^{-1} by means of a potential scanner (Huso seisakusho, potential sweep unit HECS 321B) and polarograms were recorded using a X-Y recorder (Graphtec Co., WX 1200).

The voltage, V_{app}, applied to the cells was defined as the potential of the terminal of RE2, E_{RE2}, against to that of RE1, E_{RE1}, i.e., $V_{app}=E_{RE2}-E_{RE1}$. Therefore, if we neglect the potential difference through the salt bridge, we obtain $V_{app}=\Delta\phi$ +const. The constant term was evaluated under the well-known extrathermodynamic assumption that the standard transfer free energies of tetraphenylarsonium cation ($TPhAs^+$) and tetraphenylborate anion ($TPhB^-$) are equal,[9] as follows: using the cells (A) and (B) in the absence of any ligand in the o-phase, we measured the half-wave potential of tetramethylammonium ion (TMA^+), from which we determined the formal potential, $(\Delta\phi^{o'}_{TMA})_{meas}$, after correcting the diffusion coefficient term $(RT/F)\ln\sqrt{D^o/D^w}=-0.009$ V.[10] Since the literature value of $\Delta\phi^{o'}_{TMA}$ under the TPhAs-TPhB assumption is 0.035 V,[2] we have $\Delta\phi=V_{app}-[(\Delta\phi^{o'}_{TMA})_{meas}-0.035\ \mathrm{V}]$. The values of potential $\Delta\phi$ given in the present paper are those calculated in this way and designated as V vs. TPh(As/B)E.

The flow of the positive charge from the w- to the o-phase was taken as the positive current. The current values used for the wave-form analysis were corrected appropriately for the residual currents which were obtained using the cells in the absence of ligands in the o-phase.

Results and Discussion

In the following we shall verify experimentally the theoretical predictions obtained above, especially for the two limiting conditions (A) and (B). As typical macrocyclic ligands we employ DB18C6 and 18C6, of which the distribution constants are very large ($K_D=2.3\times10^4$)[11] and relatively small ($K_D=0.10$),[11] respectively. On the other hand, sodium, cesium, barium, and oxonium ions are chosen as the cations yielding facilitated waves. The wave-form analysis is performed in the same mannar as in the polarographic practice.

DB18C6.

(1) DB18C6-Na^+ System. First, we examine the behavior of DB18C6-Na^+ complex, using both the cells (A) and (B). The well-defined facilitated waves were always observed at the potentials 150—200 mV more negative than the final rise. The limiting currents were diffusion-controlled with respect to the ligand in the o-phase for the cell (A) and to the metal ions in the w-phase for the cell (B), as proved from the fact that the diffusion current constant, defined by

$$(I_d)_j = (i_d)_j/m^{2/3}t_d^{1/6}c^*_j \quad (j = \mathrm{L\ or\ M}),$$

was constant within experimental errors, when values of c^*_j (0.2—1 mmol dm^{-3}), ν (5—15×10^{-3} cm^3 s^{-1}) and t_d (2—6 s) were changed. The ratio, $(I_d)_L/(I_d)_M$, of the diffusion current constants obtained for the cells (A) and (B), respectively, was 0.50. The log-plots of current-potential curves yielded straight lines with the reciprocal slopes of 61±2 mV/decade for the cell (A) and of 63±1 mV/decade for the cell (B). These facts indicate that the facilitated waves of DB18C6-Na^+ system are reversible and diffusion-controlled.

In Fig. 2, the half-wave potentials obtained both for the cells (A) and (B), $\Delta\phi^A_{1/2}$ and $\Delta\phi^B_{1/2}$, are given in

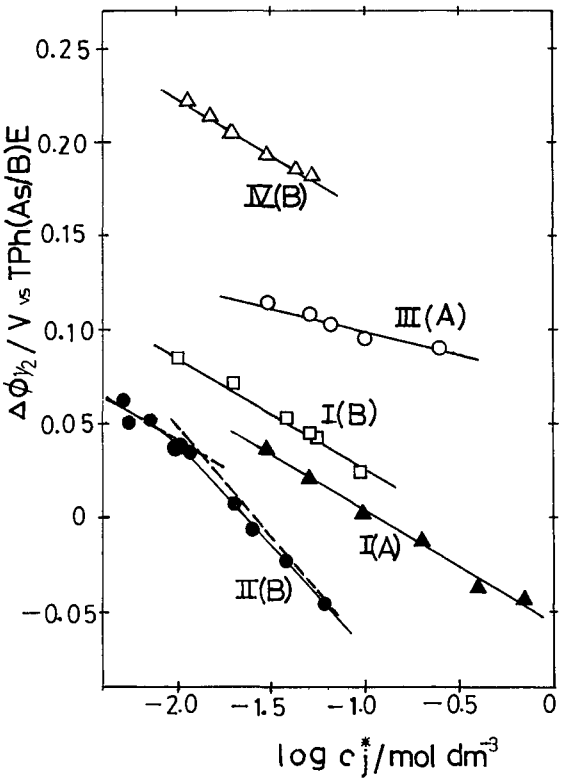

Fig. 2. Half-wave potentials of the DB18C6 complexes in dependence of log c^*_j (j=M for the cell (A) and L for the cell (B)). I: Na^+, II: Cs^+, III: Ba^{2+}, and IV: H_3O^+. (A) and (B) denote the kind of cell employed.

dependence of $\log c^*_M$ and $\log c^*_L$ by the curves I(A) and I(B), respectively. For both cases, we have straight lines with the slope of −60 mV/decade, indicating that the DB18C6–Na^+ system corresponds to the type (I) described in Fig. 1. As can readily be seen from Fig. 2, the straight line I(A) is located at ca. 20 mV more negative potential than that of I(B). Comparing Eq. 62 with Eq. 71 yields for $c^*_M=c^*_L$

$$\Delta\phi^A_{1/2} - \Delta\phi^B_{1/2} = (RT/zF)\ln\xi \quad (86)$$

Therefore, this value of −20 mV may be comparable to the theoretical prediction of −18 mV, which can be calculated from the above equation with $\xi=(I_d)_L/(I_d)_M=0.50$.

In Fig. 3, the values of functions F_A and F_B calculated from Eqs. 66 and 72 with $\Delta\phi^\circ_{Na}=0.355$ V vs. TPh(As/B)E[12] are plotted against $(1/c^*_j)$ (j=M for I(A) and L for I(B)). These plots fall on straight lines with the slope of 1.3×10^{-7} mol^{-1} dm^3 for I(A) and 2.8×10^{-7} mol^{-1} dm^3 for I(B) and with the intercept of zero for both I(A) and I(B) within experimental errors. The fact that the slope of I(B) is ca. 2.1 times larger than that of I(A) may be explained from the following relation: [slope of F_B vs. $(c^*_L)^{-1}$ plot]/[slope of F_A vs. $(c^*_M)^{-1}$ plot]$=\xi^{-1}$, which can be derived from Eqs. 66 and 72.

As described in the theoretical part, we can evaluate the complex formation constant in the o-phase from the value of slope to be $\log\beta^\circ_1=6.8$. On the other hand, the formation constant in the w-phase cannot be determined, sicne the value of intercept becomes zero. From Eq. 67 we obtain only the following inequality condition: $\log\beta^w_1<2.9$. In this connection the literature value of $\log\beta^w_1$ is 1.16.[13]

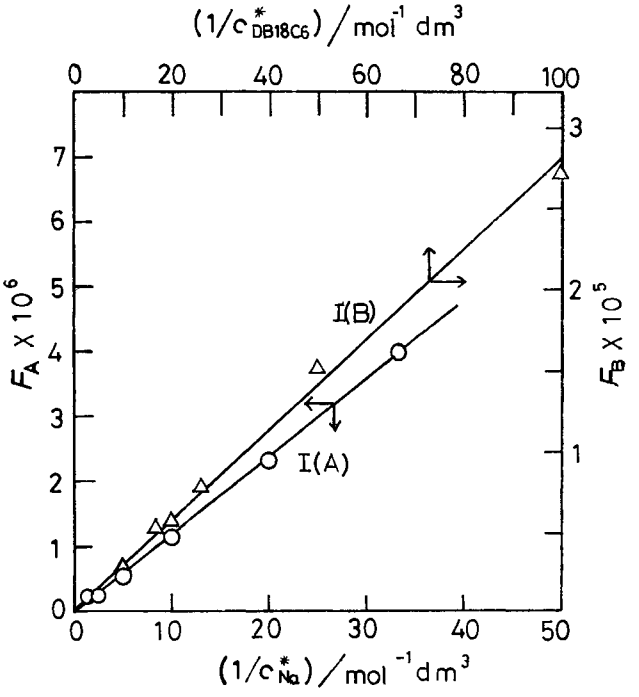

Fig. 3. F_A vs. $(1/c^*_{Na})$ and F_B vs. $(1/c^*_{DB18C6})$ plots for DB18C6–Na^+ system. I(A): F_A vs. $(1/c^*_{Na})$, I(B): F_B vs. $(1/c^*_{DB18C6})$.

(2) DB18C6–Cs^+ System. As is well-known, cesium ion is bulky compared with the other alkali metal ions, so that the standard ion-transfer potential becomes relatively negative. Hence, if we employ the cell (A), the corresponding potential window becomes very narrow, and we cannot observe any well-defined facilitated wave. On this ground, the behavior of facilitated waves of cesium ion was examined only for the cell (B).

In the absence of ligand in the o-phase, we observed a well-defined wave at the potential ca. 100 mV more negative than the final rise, which was regarded as being due to the transfer of cesium simple ion across the w/o-interface. This wave was reversible and diffusion-controlled, as verified from the constancy of diffusion current constant and the log-plot analysis of current–potential curves. The half-wave potential obtained is 0.131 V vs. TPh(As/B)E.

Addition of DB18C6 in the o-phase in a large excess (c_L^*=5—40 mmol dm^{-3}) shifted the wave of cesium ion to the potential region +0.06—−0.05 V vs. TPh(As/B)E. The limiting currents of these facilitated waves are diffusion-controlled with respect to Cs^+, as verified from the constancy of diffusion-current constant. The log-plots of current-potential curves yield straight lines with the reciprocal slope of 63±3 mV/decade. The half-wave potentials determined from log-plots are given in dependence of $\log c_L^*$ by curve II(B) in Fig. 2. As can readily be seen from figure, curve II(B) is asymptotic to a straight line with the slope of −120 mV/decade at high ligand concentration, while it approaches a straight line with the slope of −60 mV/decade with a decrease in ligand concentration. In accord with the fact that the ionic radius of Cs^+ (1.67 Å)[14] larger than the cavity radius of DB18C6 (1.34—1.43 Å),[15] this result suggests that the cesium ion forms the so-called sandwich type 1:2 (metal to ligand) complex with DB18C6 at higher ligand concentration. Since K_D-value of DB18C6 is very large (2.3×10^4) and the literature value of $\log\beta_1^w$ is 0.83,[13] the concentration dependence of the half-wave potential may be expressed by Eq. 85. Hence, we can evaluate the values of β°_p (p=1, 2, ···) by means of the DeFord–Hume method[7] in polarography. We define the DeFord–Hume F_o-function as

$$F_o \equiv \exp(zF/RT)\{(\Delta\phi^B_{1/2})_M - \Delta\phi^B_{1/2}\} = 1 + \sum_{p=1}^{n}\beta_p^\circ(c^*_L)^p \quad (87)$$

where $(\Delta\phi^B_{1/2})_M$ denotes the half-wave potential of simple cesium ion. Then, we define, in general, the DeFord–Hume F_p-function (p=1, 2, ···) as

$$F_p = \{F_{p-1} - \lim(c_L^* \longrightarrow 0)F_{p-1}\}/c_L^* \quad (88)$$

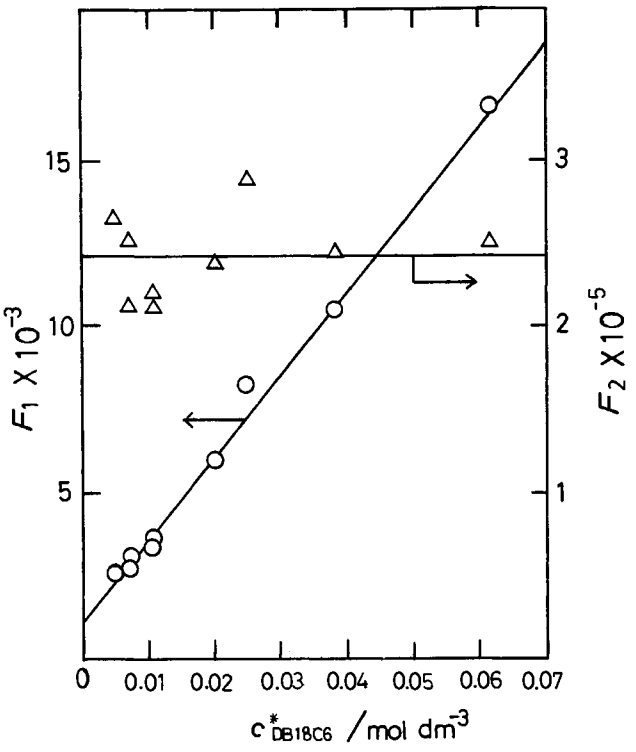

Fig. 4. DeFord-Hume functions F_1 and F_2 in dependence of c^*_L for the DB18C6-Cs^+ system.

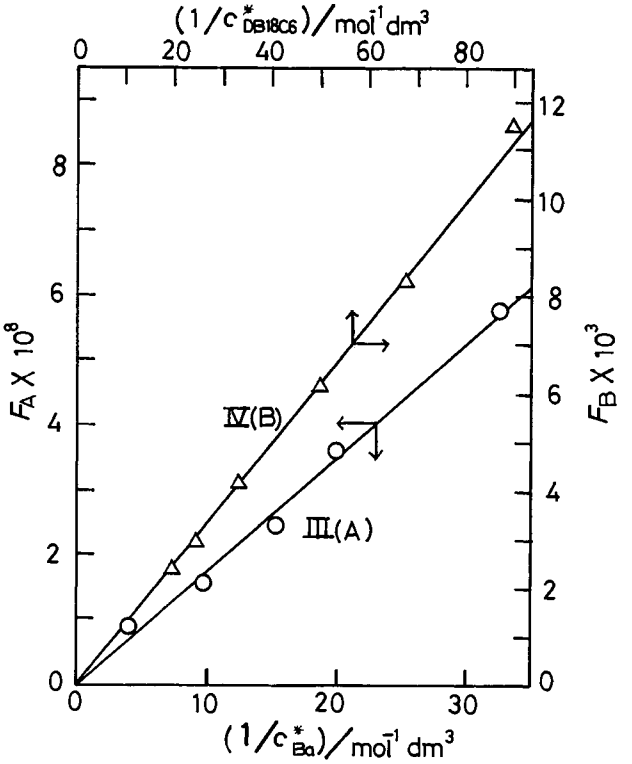

Fig. 5. F_A vs. $(1/c^*_{Ba})$ plot for the DB18C6-Ba^{2+} system and F_B vs. $(1/c^*_{DB18C6})$ plot for the DB18C6-H_3O^+ system. III(A): DB18C6-Ba^{2+}, IV(B): DB18C6-H_3O^+.

where $\lim(c_L^* \to 0)F_p$ denotes the value of F_p extrapolated to $c_L^*=0$, which is equal to β^o_p, as can be seen from Eqs. 87 and 88. In this way, from the extrapolated values of F_p (p=1, 2, ···) vs. c_L^* plots, we can evaluate succesively the values of β^o_1, β^o_2, ···.

In Fig. 4, the DeFord-Hume functions F_1 and F_2 are plotted against c_L^*, where the experimentally determined value of 0.131 V vs. TPh(As/B)E is employed for $(\Delta\phi^B_{1/2})_{Cs}$. As can be seen from the figure, the extrapolated values of these functions yield $\log \beta^o_1=3.1$ and $\log \beta^o_2=5.4$.

(3) DB18C6-Ba^{2+} System. As an example of alkaline earth metal ions, we examined the behavior of barium ion, using the cell (A). The well-defined facilitated waves were always observed at the potential ca. 100 mV more negative than the final rise. The limiting currents were verified to be diffusion-controlled with respect to the ligand and the value of diffusion current constant was ca. 1.8 times larger than that of DB18C6-Na^+ complex obtained for the cell (A). The log-plot analysis of current-potential curves yielded straight lines with the reciprocal slope of 32±2 mV/decade. These results indicate that these facilitated waves correspond to the reversible transfer of divalent cation across the w/o-interface as can readly be expected. The half-wave potentials determined from the log-plot analysis are plotted against the logarithm of Ba^{2+} bulk concentration in Fig. 2 (see curve III(A)). This plot yields a straight line with the slope of −28 mV/decade, indicating that the DB18C6-Ba^{2+} system corresponds to the type (I). The F_A vs. $(1/c^*_{Ba})$ plot is given by curve III(A) in Fig. 5, where the values of F_A have been calculated using the literature value $\Delta\phi^o_{Ba}$=0.328 V vs. TPh(As/B)E.[2] We can see that this plot yields a straight line passing through the origin within experimental errors. Since $K_D \gg 1$, we can obtain directly from the slope the value of $\log \beta^o_1$ as 8.8. For the value of β^w_1, from Eq. 64 we have only the inequality equation, $\log \beta^w_1 < 3.0$, while the literature value of $\log \beta^w_1$ is 1.95.[13]

(4) DB18C6-H_3O^+ System. The facilitation effects of DB18C6 on oxonium ion were small, so that we employed here only the cell (B), because we could not separate the facilitated waves from the final rise for the cell (A) containing a large excess of oxonium ion in the w-phase. The facilitated waves were observed at the potenitals only 40—60 mV more negative than the final rise. Hence the data obtained were rather inaccurate comparing with those of other cases, although corrections for residual currents were carried out as carefully as possible. The limiting currents were proved to be diffusion-controlled from the constancy of diffusion current constant. The log-plot analysis yielded straight lines with a reciprocal slope of 56±4 mV/decade, though the data were fairly scattered. The plot of half-wave potentials vs. $\log c_L^*$ yields a straight line with the

slope of −61 mV/decade, as shown by curve IV(B) in Fig. 2. The plot of F_B vs. $(1/c^*_L)$ is shown by curve IV(B) in Fig. 5, where F_B values have been calculated with $\Delta\phi^\circ_H$=0.337 V vs. TPh(As/B)E.[12] As can be seen from the figure, this plot yields a straight line passing through the origin. For the cell (B), we can obtain from the slope the value of log $(\xi\beta^\circ_1)$ as 3.7. The value of ξ for this complex was estimated as follows: the diffusion current constant $(I_d)_H$ is 1.5 times larger than that of Na^+ obtained for the cell (B). Further, the value of ξ for the DB18C6–Na^+ system is 0.5, as given above. Hence the value of ξ for DB18C6–H_3O^+ system may be estimated to be 0.5/1.5=0.33. Using this value of ξ yields log β°_1=4.2.

18C6.

Since the K_D-value of 18C6 is 0.10, the interfacial concentration of L in the w-phase may become 10 times larger than that of the o-phase. Hence, the diffusion layer formed in the vicinity of the w/o-interface in the w-phase may be presumed to become unstable, especially for the cell (B) for which the ligand is present in a large excess. On this ground, we examined the behavior of current–potential curves only for the cell (A). Even when the cell (A) was employed, a gradual decrease in the limiting current was observed during repeating measurements for a long time, due to loss of ligand from the o- to the w-phase. Hence, in order to obtain reproducible results, it was required to start measurements as soon as possible after constructing the cell.

(1) 18C6-Na^+ System. The well-defined facilitated waves were obtained at the potentials about 160 mV more negative than the final rise, with the diffusion-controlled limiting currents with respect to the ligand concentration. The log-plot analysis of current–potential curves yielded straight lines with the reciprocal slope of 63±4 mV/decade. The half-wave potentials in dependence of log c^*_{Na} are shown by curve I(A) in Fig. 6. As can be seen from the behavior of the curve, the concentration dependence of the half-wave potential belongs to the intermediate type(III). The F_A vs. $(1/c^*_M)$ plot is given in Fig. 7, from which we can see that the plot points fall on a straight line with non-zero values of both the slope and the intercept. Hence, we can fortunately, in this case, determine the formation constants both in the w- and the o-phase. Using K_D=0.10 and assuming ξ=0.5 yields log β^w_1=0.7 and log β°_1=8.5. The former value may compare with the literature value of log β^w_1=0.8 obtained by calorimetry.[16]

(2) 18C6-Ba^{2+} System. The 18C6–Ba^{2+} complex yields well-defined facilitated waves at the potentials 100 mV more negative than the final rise, with limiting currents controlled by diffusion of the ligand. The log-plot analysis of current–potential curves gives straight lines with the reciprocal slope of 32±3 mV/decade, indicating that the transfered ion is divalent. The concentration dependence of the half-wave potential is given by curve III(A) in Fig. 6, from which we can see that the

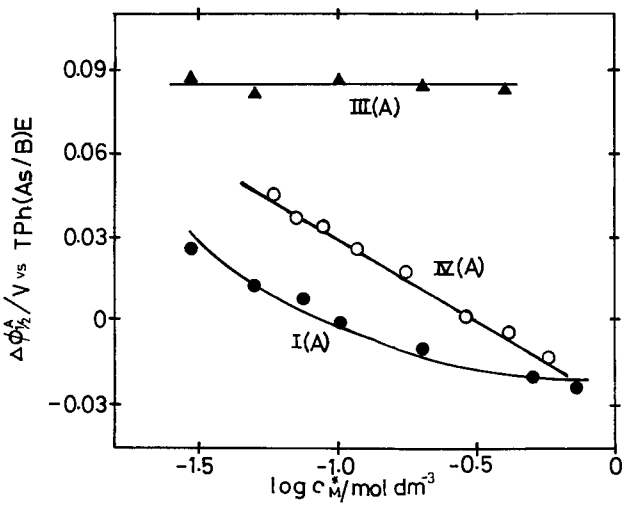

Fig. 6. Half-wave potentials of the 18C6 complexes in dependence of log c^*_M. I(A): Na^+, III(A): Ba^{2+}, and IV(A): H_3O^+.

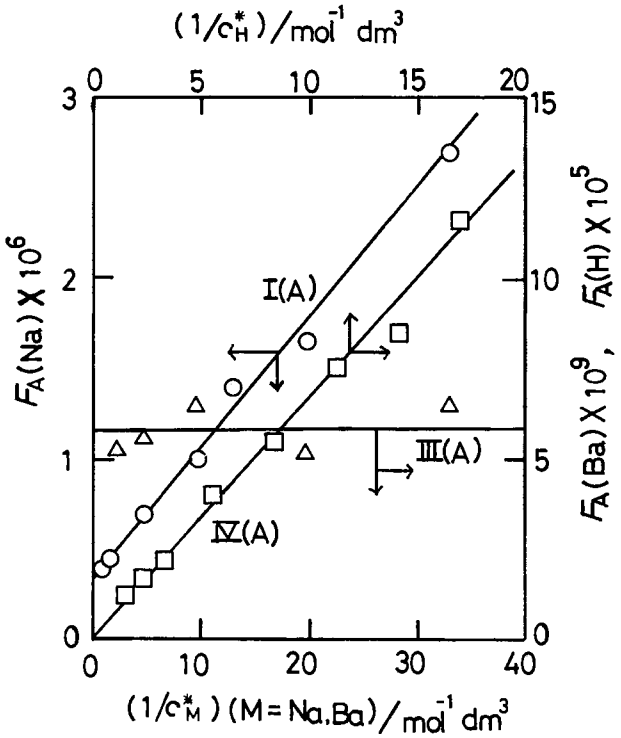

Fig. 7. F_A vs. $(1/c^*_M)$ plots for the 18C6–Na^+, –Ba^{2+}, and –H_3O^+ systems. I(A): 18C6-Na^+, III(A): 18C6–Ba^{2+}, IV(A): 18C6–H_3O^+.

half-wave potential is independent of the Ba^{2+}-concentration and this system belongs to the type (II). The F_A vs. $(1/c^*_{Ba})$ plot yields a straight line with zero slope within experimental errors, as seen from Fig. 7. Hence, we can obtain only the ratio β°_1/β^w_1 from the value of intercept. Using K_D=0.10 and ξ=0.5 yields log $(\beta^\circ_1/\beta^w_1)$= 9.5. If we use the literature value of 3.87 for log β^w_1,

which has been obtained by Izatt et al.[16] using calorimetry, we obtain $\log \beta^{o}{}_{1}=13.4$. On the other hand, from Eq. 68 we obtain the following inequality equation: $\log \beta^{w}{}_{1}>3$, which is consistent with the literature value.

(3) 18C6-H_3O^+ System. Finally we examined the behavior of oxonium ion. In contrast to the DB18C6-H_3O^+ system, the 18C6-H_3O^+ system exhibited well-defined facilitated waves at the potential ca. 120 mV more negative than the final rise, with diffusion-controlled limiting currents with respect to the ligand concentration. The log-plot analysis of current-potenial curves yielded straight lines with the reciprocal slope of 59±3 mV/decade. The half-wave potentials obained are plotted against $\log c^{*}{}_{H}$ in Fig. 6 (curve IV(A)). As can be seen from the figure, this plot gives a straight line with the slope of −57 mV/decade, indicating that the 18C6-H_3O^+ system belongs to the type (I). In Fig. 7, the values of F_A are plotted against $(1/c_L^*)$, from which we can see that this plot yields a straight line passing through the origin, in spite of small K_D-value of 18C6. From the value of slope we obtain $\log \beta^{o}{}_{1}=7.5$, where ξ is assumd to be 0.5, since for the cell (A) the diffusing species in both the w- and o-phases may be regarded as the ligand. On the other hand, for $\beta^{w}{}_{1}$, we have only the inequality equation: $\log \beta^{w}{}_{1}\leqslant -1$, from Eq. 67. Hence it can be seen that the formation constant of oxonium ion in the w-phase is very small.

In conclcusion, it can be stated that the theoretical equation derived without any limitation on the magnitude of distribution constants of macrocyclic ligands explaines extensively the behavior of facilitated ion transfer across the water/introbenzene interface and allows to evaluate the complex formation constants in the nitrobenzene phase and for favorable cases those of both the nitrobenzene and water phase.

In the present paper we have selected the polarographic method with the electrolyte dropping electrode from various electrochemical methods available at present. However, the theoretical equations obtained here can easily be transformed to those of other various polarographic and voltammetric techniques in the same manner as done in usual polarography and voltammetry.

(Received December 10, 1990)

An ESR study was carried out on two polyaniline perchlorates prepared by different chemical methods: Soluble perchlorate I prepared by the use of copper(II) perchlorate as an oxidative coupling agent, and perchlorate II (corresponding to polyemeraldine perchlorate) obtained by treating a polymer base with perchloric acid. The ESR signal intensity of perchlorate I shows a thermally activated temperature dependence at temperatures between 95 and 300 K. The ESR signal intensity of perchlorate II was temperature-independent. When this polymer adsorbed oxygen, the ESR signal showed a thermally activated paramagnetism resembling that of perchlorate I. These paramagnetic properties can be explained by polaron spins that are antiferromagnetically coupled with each other, and are different from the Pauli-type paramagnetism. This suggests that the charge-transport cannot be explained by the migration of paramagnetic polarons along a polymer chain alone.

The charge transport of polyaniline is sensitively dependent on the protonation of the polymer chains,[1,2] and the protonation results in a significant enhancement of paramagnetism.[1-3] The relation between the charge transport and the magnetic properties is the important subject of the conducting polyaniline. Usually electroconducting polymers contain a significant number of unpaired electrons due to defects of polymer chains. The susceptibility of these defect spins is strongly temperature-dependent. This makes it difficult to study the intrinsic paramagnetism, which is expected to be weakly temperature-dependent. Recently, we have reported that a polymerization of aniline by the use of copper(II) perchlorate as an oxidative coupling agent yields a polyaniline perchlorate that has a doping level of ca. 0.4 per polymer unit and is soluble in dimethyl sulfoxide (DMSO).[4] The solubility is expected to be due to a low degree of chain defect and/or cross linking of polymer chains. Therefore, the new polyaniline perchlorate is a good material for studying the intrinsic magnetism of conducting polyaniline. Preliminarily we have reported that the electron spin resonance (ESR) signal intensity of this perchlorate shows a thermally activated temperature dependence differing from the Pauli-type paramagnetism.[5] The present paper is the full report of the ESR study.

Experimental

Perchlorate I in Table 1 was prepared by the method reported in our previous paper:[4] Freshly distilled aniline was polymerized by the use of copper(II) perchlorate as an oxidative coupling agent in acetonitrile. The resulting powder material was washed with acetonitrile in a Soxhlet extractor to eliminate possible oligomer components and copper perchlorate. The obtained polymer did not show an ESR signal attributable to Cu(II) species. A polymer base was obtained by treating the perchlorate with 4.5 M NH_3 solution for 20 h. By treating this polymer base with 3 M perchloric acid for 3 h, perchlorate II was obtained. The compositions determined by elemental analyses for the three polymers are shown in Table 1 together with the room-temperature conductivity. The elemental analyses were performed by Huffman Laboratories, Golden, CO., U.S.A.

Table 1. ESR Data Observed for Polyanilines at Room Temperature: g Value and Molar Magnetic Susceptibility χ (in emu mol^{-1}) per $-C_6H_4NH_y-$ Unit and Peak-to-Peak Width W in Oxygen-Free and Oxygen-Adsorbing States

Polyaniline	σ/S cm^{-1}	g	$10^6\chi$	W/G	
				O_2-free	O_2-ads
Perchlorate I[a]	1.3	2.0027	40	0.28	2.0
Polymer base[b]	10^{-10}	2.0036	0.3	8.5	8.5
Perchlorate II[c]	1.8	2.0027	45	0.42	1.5

a) As-prepared perchlorate: $[(-C_6H_4NH-)(ClO_4)_{0.4}\cdot 0.4H_2O]_n$. b) Base: $[(-C_6H_4NH-C_6H_4NH-)_{1-x}(-C_6H_4N=C_6H_4=N-)_x\cdot 0.4H_2O]_n$ ($x\approx 0.6$). c) Perchlorate prepared from the base: $[(-C_6H_4NH-)(ClO_4)_{0.4}\cdot 0.6H_2O]_n$.

The ESR spectra were obtained with the aid of a JEOL SCXA ESR spectrometer. The sample temperature was controlled by flowing a cold nitrogen gas between 95—300 K. Mn^{2+}/MgO and DPPH were used as references. The ESR spectra were recorded on the two conditions for each material: 1) The oxygen-free samples were sealed with He gas in a quartz tube after kept in dynamic vacuum for 3—4 h, and 2) the oxygen-adsorbing samples were sealed in a cell with He gas after equilibrated with atmospheric oxygen. Each observed derivative curve was digitized and doubly integrated: The error of the integration was ca. 20%. The magnetic susceptibility was calculated by referring to the signal intensity of Mn^{2+}/MgO powder used as a marker, the susceptibility of which was calibrated with DPPH. The molar susceptibility was calculated for each $-C_6H_4NH_y-$ unit. The electrical conductivity was determined on the compressed pellets of the powder materials by van der Pauw's four-probe method.

Results

Electrical Conductivities. The room-temperature conductivities are shown in Table 1. The two perchlorates show a semiconductive property with an activation energy of 0.04 eV at high temperatures, and the temperature dependence throughout the temperature range investigated (80—300 K) is explained by the variable-range hopping model (Figs. 1 and 2):[6]

$$\sigma = (T_0/T)^{1/2}\exp[-(A/kT)^{1/4}] \quad (1)$$

The parameters obtained were: T_0=4.2×10^{11} K and A/k=3.2×10^6 K for perchlorate I, and T_0=5.5×10^{12} K and A/k=4.5×10^6 K for perchlorate II. No significant difference is appreciable for the charge-transport properties of the two perchlorates.

ESR of Perchlorate I (As-Prepared Perchlorate). The ESR spectrum of perchlorate I showed a symmetric signal with a g value of 2.0027 and a peak-to-peak width W of 0.28 G (G=10^{-4} T). The g value was temperature-independent. In contrast, the W was temperature-dependent as shown in Fig. 3: It showed a maximum at 185 K. The magnetic susceptibility calculated from the signal intensity at 297 K was 0.3×10^{-6} emu g^{-1}, which gave a molar magnetic susceptibility of 40×10^{-6} emu mol^{-1} for each aniline unit. Figure 4 shows the temperature dependence of the relative signal intensity I_r= $I(T\,\mathrm{K})/I(297\,\mathrm{K})$, which is proportional to the magnetic susceptibility. The I_r gradually decreased with decreasing temperature, differing from that reported for polyemeraldine salts[3] prepared by the use of ammonium peroxodisulfate, $(NH_4)_2S_2O_8$, as an oxidative coupling agent.

When the perchlorate was exposed to air, the peak-to-peak width increased (W=2.0 G at 297 K), and showed a strong temperature-dependence (Fig. 3). The ESR relaxation is markedly influenced by the adsorption of oxygen molecules. On the other hand, the integrated signal intensity was unchanged by oxygen adsorption.

ESR of Polymer Base. The treatment of perchlorate I with an alkaline solution yielded an insulating polymer base $[(-C_6H_4-NH-C_6H_4-NH-)_{1-x}(-C_6H_4-N=C_6H_4=N-)_x]_n$

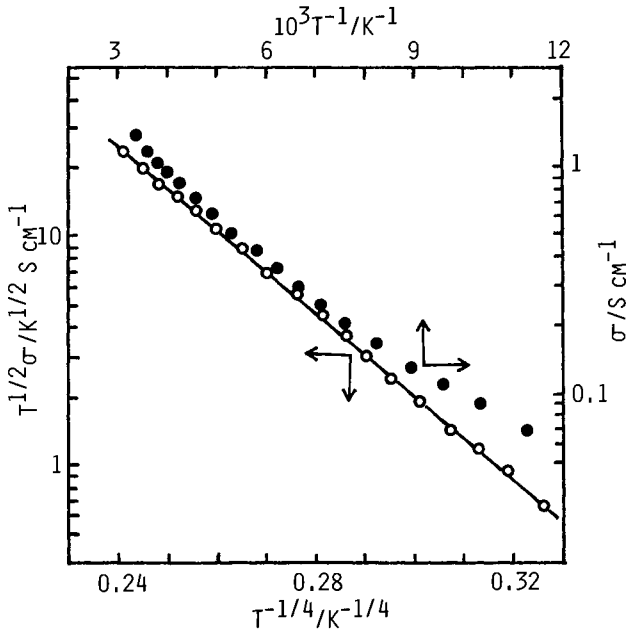

Fig. 1. Electrical conductivity σ of the as-prepared polyaniline (perchlorate I). The solid line shows the hopping model.

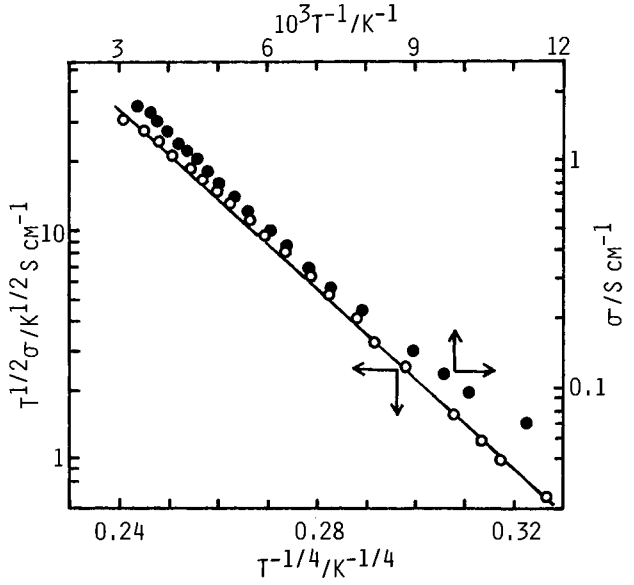

Fig. 2. Electrical conductivity σ of perchlorate II obtained by the protonation of polyemeraldine base. The solid line shows the hopping model.

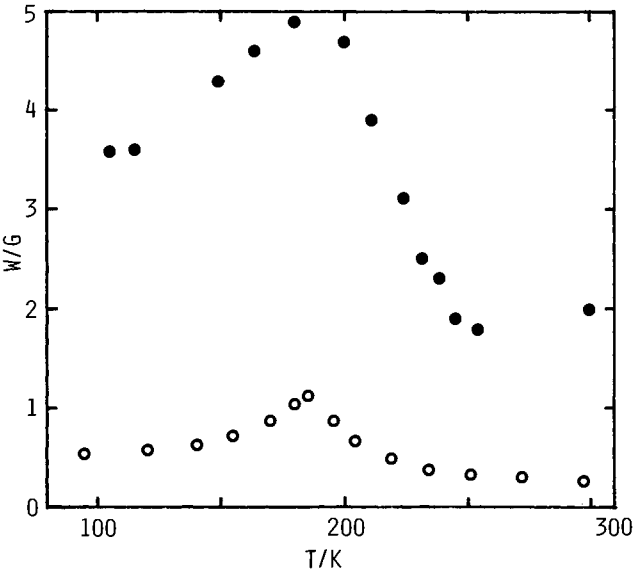

Fig. 3. Temperature dependence of the peak-to-peak width W/G (G=10^{-4} T) of perchlorate I in oxygen-free (○) and oxygen-adsorbing (●) states.

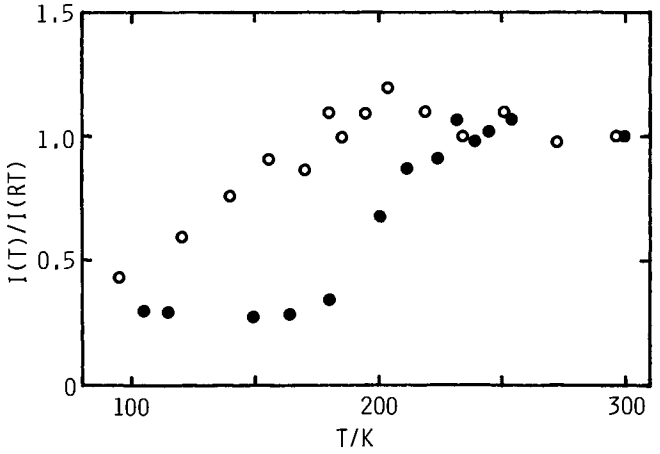

Fig. 4. Temperature dependence of the relative signal intensity $I(T\ \mathrm{K})/I(\mathrm{Room\ Temp})$ of perchlorate I in oxygen-free (○) and oxygen-adsorbing (●) states.

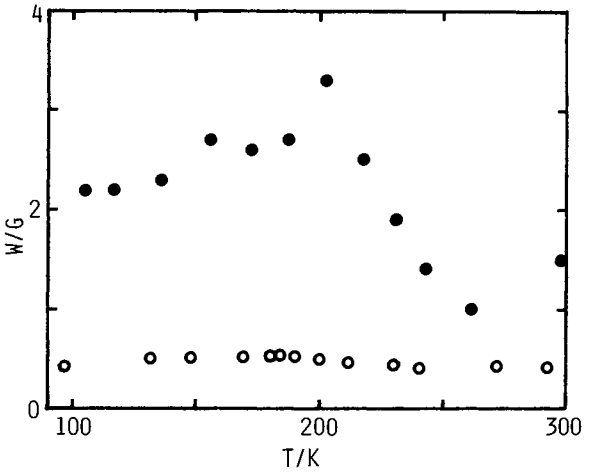

Fig. 5. Temperature dependence of the peak-to-peak width W/G (G=10^{-4} T) of perchlorate II in oxygen-free (○) and oxygen-adsorbing (●) states.

with $x\approx0.6$; the composition is practically identical with that of polyemeraldine base. The polymer base showed a broad ESR signal with a g value of 2.0036 and a peak-to-peak width W of 8.5 G at 297 K. These ESR parameters were temperature-independent throughout the temperature range investigated. The magnetic susceptibility was 3×10^{-9} emu g^{-1}: This gave a molar susceptibility of 3×10^{-7} emu mol^{-1} for each $-C_6H_4NH_y-$ unit. The signal intensity $I_r=I(T\ \mathrm{K})/I(297\ \mathrm{K})$ obeyed the Curie–Weiss law $I_r=C/(T-\theta)$ with $\theta=-21$ K throughout the temperature range investigated (95—300 K). These magnetic properties were not substantially influenced by adsorption of oxygen: g=2.0036, W=8.5 G at 297 K, and $\theta=-14$ K for the oxygen-adsorbing polymer. The Curie constant C was calculated to be 9×10^{-5} emu K mol^{-1} for each ring by referring to the room temperature susceptibility. A spin system containing one unpaired electron on each site has the Curie constant 0.375 emu K mol^{-1}. The ratio C/0.375 gave a spin density of 2×10^{-4} per $-C_6H_4NH_y-$ unit. This spin density is much smaller than that reported for polyemeraldine base prepared by the conventional method.[3] The polymer obtained by the use of the new oxidant contains a very small number of chain defects.

ESR of Perchlorate II (Perchlorate Obtained from Polymer Base). When the polymer base was treated with perchloric acid, the ESR signal narrowed (W= 0.42 G and g=2.0027 at 293 K), and the signal intensity increased by a factor of 100. The susceptibility of this perchlorate was equal to that of the as-prepared polymer (perchlorate I) within the experimental error (Table 1). Figures 5 and 6 show the peak-to-peak width W and the signal intensity I_r, respectively, as functions of temperature. The I_r showed a very weak temperature-dependence. Upon adsorbing oxygen, the signal broadened markedly (Fig. 5), whereas the integrated signal intensity at room temperature was unchanged. The I_r of the oxygen-adsorbing sample showed a thermally

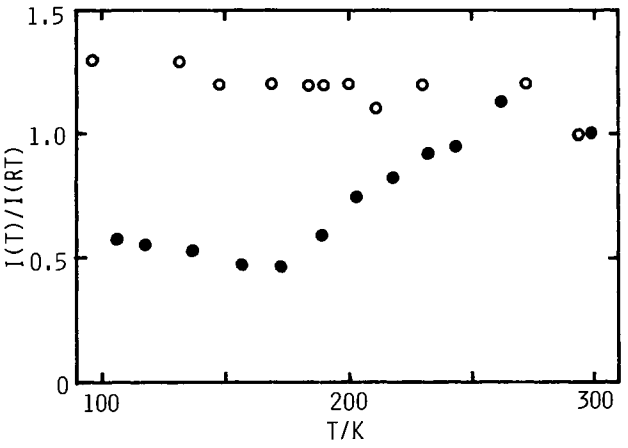

Fig. 6. Temperature dependence of the relative signal intensity $I(T\ \mathrm{K})/I(\mathrm{Room\ Temp})$ of perchlorate II in oxygen-free (○) and oxygen-adsorbing (●) states.

activated temperature dependence (Fig. 6), in contrast to the oxygen-free sample.

Discussion

The solution electronic spectrum of the as-prepared polymer (perchlorate I) shows that the charge carriers are paramagnetic polarons rather than diamagnetic bipolarons.[4] The intrinsic magnetism of the polarons is expected to be observed for the polymer. The nature of the ESR spectra is markedly influenced by oxygen adsorption. The similar oxygen-adsorption effect has been extensively studied for polyacetylene, and it has been interpreted by the coexistence of mobile spins and trapped spins, although the ESR signals of the two different spin species have not been observed individually.[7] The ESR peak-to-peak width W of perchlorate I markedly increases upon oxygen adsorption. The oxygen-adsorbing polymer shows a clear maximum of

W at ca. 185 K. Around this temperature, the differential scanning calorimetry showed no appreciable thermal anomaly; usually, a sudden change of ESR relaxation accompanies a phase transition. Therefore, it is probable that additional spin sites are formed by oxygen adsorption, as proposed for polyacetylene: The temperature dependence of W can be explained by the presence of two spin species, line-widths of which exhibit different temperature dependence. The more important experimental result is that the temperature dependence of the signal intensity observed for the polymer is different from that reported for polyemeraldine salts. The signal intensity of the latter polymer increases with decreasing temperature, but it deviates from the Curie–Weiss law. This magnetic behavior has been explained by the superposition of a strong Curie-type paramagnetism and a weak temperature-independent paramagnetism.[1-3,8] In contrast, the signal intensity of polyaniline perchlorate I decreases with decreasing temperature. Obviously, at least one of the two possible spin species in perchlorate I shows a thermally activated temperature dependence, although their ESR signals cannot be distinguished from each other. This magnetic property is not explained by the Pauli-type paramagnetism. In polyaniline, the molecular planes of the neighboring $-C_6H_4NH-$ groups are twisted with one another due to a steric effect,[2,9] and hence the electronic band formed by the π-electron overlap is not expected to be wide enough to show the Pauli paramagnetism. A thermally activated paramagnetism similar to that of the perchlorate has been reported for a variety of paramagnetic compounds that have a strong antiferromagnetic interaction via superexchange interaction mechanism.[10] This type of magnetic interaction is operative between unpaired electrons that reside on the conjugated system of a polymer chain.[11] A conceivable interaction mechanism for polyaniline is schematically shown in Fig. 7: A polaron spin that resides on a positively charged nitrogen atom induces a spin polarization of a π electron on the adjacent carbon atom, and this spin polarization is induced in succession until another unpaired electron is encountered on a nitrogen atom. Consequently, the two unpaired electrons are antiferromagnetically coupled with each other. This antiferromagnetic interaction may occur among a number of polaron spins existing on a polymer chain. The ground level of this spin system is singlet and the paramagnetism is induced by a thermal activation.

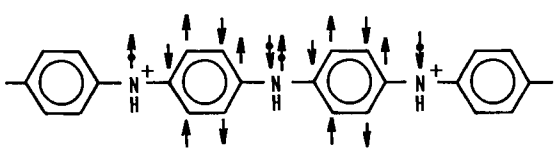

Fig. 7. Superexchange interaction operative between two polaron spins in a polyaniline chain. An unpaired electron on a positively charged nitrogen atom causes the spin polarization of a π electron on the adjacent carbon atom. The spin polarization is induced in succession until another unpaired electron is encountered. Consequently, the two unpaired electrons are coupled antiferromagnetically.

In the course of the treatment of a polymer base with acid, protonation is expected to occur in preference at the quinone-imine nitrogen and to yield bipolarons that have no unpaired electron. The magnetic susceptibility of the resulting polymer salt, however, is a factor of 100 larger than that of the parent polymer base. On the basis of this observation, Ginder et al.[8] have proposed that a bipolaron produced by protonation is converted to two polarons by an internal redox reaction and the resulting polarons migrate successively so as to reduce the Coulomb repulsion. This mechanism well explains the origin of the paramagnetism induced by protonation. On the other hand, the X-ray photoelectron spectra (XPS) of polyemeraldine salts exhibit a weak nitrogen Is peak attributable to bipolarons in addition to a strong polaron peak.[12-14] The solution electronic spectrum and the XPS of polyaniline perchlorate II have evidenced that a small number of bipolarons coexist with polarons in the polymer chains, whereas perchlorate I contains no significant number of bipolarons.[4,14] This is an important structural difference between perchlorates I and II. A bipolaron that is diamagnetic may be thermally excited to two neighboring paramagnetic polarons. When these two states are in a thermal equilibrium, a thermally activated magnetism is expected to be observed. The interconversion between a bipolaron state and a two-polaron state is, however, accompanied by a polymer conformation rearrangement,[4] which requires a large activation energy. In a normal temperature range, therefore, the thermal activation of a bipolaron to two polarons in solid state is hardly observed in the susceptibility vs. temperature curve. On the other hand, the superexchange interaction is readily influenced by the electronic state of intervenient atoms between interacting polarons. In this manner, bipolarons that coexist with polarons in perchlorate II may result in the difference between the magnetic properties of the two perchlorates in oxygen-free states. In oxygen-adsorbing states, the two perchlorates show an identical temperature dependence of signal intensity. Since the oxygen-adsorbing materials show a stronger temperature dependence than that of the corresponding oxygen-free materials, the oxygen-adsorption enhances the magnetic interaction between polarons, so that the effect of the structural difference is smeared out.

The charge-transport of polyaniline has been explained by the hopping of paramagnetic polarons along the polymer chains. The present study has shown that the polyaniline chains do not show the Pauli-type paramagnetism. Two explanations are conceivable: 1) Hopping polarons responsible for charge-transport do

not show the Pauli-type paramagnetism, and 2) there is no direct relation between the two physical properties. The second case is consistent with a recent theoretical calculation of doped polyaniline, which has indicated that large spin densities are distributed on nitrogen atoms whereas large net-charge densities exist on phenyl rings.[9] These results suggest that the charge transport in polyaniline cannot be explained by paramagnetic polaron migration along a polymer chain alone. An additional effect contributes to the charge transport. For example, a charge transfer between phenyl rings that face to each other in proximity may be one of the important contributing factors.

Reproduction of Bifurcation Structure of Belousov–Zhabotinskii Reaction in Flow System by Oscillatory Flow Term Oregonator

Shinji SAKANOUE, Chiaki MURASE,† and Mitsuo ENDO*
Department of Chemistry, Faculty of General Education, Tokyo University of Agriculture and Technology, Saiwaicho, Fuchu, Tokyo 183
† Department of Physics, Faculty of General Education, Tokyo University of Agriculture and Technology, Saiwaicho, Fuchu, Tokyo 183
(Received December 28, 1990)

Simulation has been made on the oscillatory flow term Oregonator model (OFO) proposed in our previous paper for the Belousov–Zhabotinskii reaction (BZ reaction) accompanying constant feed. When the amplitude of the forced oscillation term in OFO is taken extremely small, the computational simulation with this model finely reproduces the oscillatory mode, many types of wave patterns including nonperiodic chaotic behaviors and the bifurcation structure, which appear in the experimental results of the BZ reaction in flow system.

There have been numbers of experimental and theoretical studies[1-5] on the Belousov–Zhabotinskii reaction (BZ reaction) in a continuous-flow stirred tank reactor. Hudson et al.[1] have investigated experimentally BZ reaction in the flow system and found complex phenomena such as several types of periodic multipeak oscillations and chaotic(nonperiodic) behavior. In our previous paper[6,7] for the purpose of reproducing these phenomena by computational simulation, we proposed a model in which a flow term was added to the original Oregonator's equation[8] proposed by Tyson[9], i.e. Oregonator+flow term. Mathematically the model can be expressed by the following differential equations:

$$\mathrm{d}\boldsymbol{X}/\mathrm{d}t = \boldsymbol{O}(\boldsymbol{X}) + R(\boldsymbol{X}^{\mathrm{I}} - \boldsymbol{X}), \tag{1A}$$

where the first term $\boldsymbol{O}(\boldsymbol{X})$ denotes the original Oregonator and the second term $R(\boldsymbol{X}^{\mathrm{I}}-\boldsymbol{X})$ the flow term; or more explicitly,

$$\begin{aligned} \mathrm{d}X/\mathrm{d}t &= (1/\varepsilon)(X + Y - qX^2 - XY) + R(X^{\mathrm{I}} - X), \\ \mathrm{d}Y/\mathrm{d}t &= -Y + fZ - XY + R(Y^{\mathrm{I}} - Y), \\ \mathrm{d}Z/\mathrm{d}t &= (1/p)(X - Z) + R(Z^{\mathrm{I}} - Z), \end{aligned} \tag{1B}$$

where all variables are set dimensionless; and X, Y, and Z are the component of the concentration $\boldsymbol{X}$ corresponding to the concentrations of the three chemical species $HBrO_2$, Br^-, and Ce^{4+}, respectively; and ε, p, and q are the parameters with regard to the rate constants of elementary reactions and f is the paprameter with reference to a stoichiometric coefficient, R corresponds to the flow rate, and t is the time variable. The terms containing R in Eq. 1 are the flow terms to be added to the original Oregonator $\boldsymbol{O}(\boldsymbol{X})$. The X^{I}, Y^{I}, and Z^{I} in them are the components of inflow term $\boldsymbol{X}^{\mathrm{I}}$, and they consist of both the time-independent term $\boldsymbol{X}^0(X^0, Y^0, Z^0)$ and the time-dependent one $\boldsymbol{X}^{\mathrm{I}}(X^{\mathrm{I}}, Y^{\mathrm{I}}, Z^{\mathrm{I}})$:

$$\boldsymbol{X}^{\mathrm{I}} = \boldsymbol{X}^0 + \boldsymbol{X}^{\mathrm{I}}(t), \tag{2A}$$

and the components of $\boldsymbol{X}^{\mathrm{I}}$ are taken as follows

$$\begin{aligned} X^{\mathrm{I}} &= X^0 + Q_x \sin(-\Omega t), \\ Y^{\mathrm{I}} &= Y^0 + Q_y \cos \Omega t, \\ Z^{\mathrm{I}} &= Z^0 + Q_z \sin(-\Omega t), \end{aligned} \tag{2B}$$

where Ω is the angular frequency of the oscillation of the time-dependent term $\boldsymbol{X}^{\mathrm{I}}(t)$, and Q_x, Q_y, and Q_z are the amplitudes of the oscillation of $\boldsymbol{X}^{\mathrm{I}}(t)$. We called the above model the "oscillatory flow term Oregonator" ("OFO"). When $\boldsymbol{X}^{\mathrm{I}}=\boldsymbol{X}^0$, that is the OFO without the time-dependent term $\boldsymbol{X}^{\mathrm{I}}$, we called it the "constant flow term Oregonator" ("CFO"). Here we took the time-independent term $\boldsymbol{X}^0(X^0, Y^0, Z^0)$ to be the steady state of the original Oregonator. Figure 1 shows the three types of global behaviors of the trajectories of CFO projected onto Y–Z plane, which we call the extended state, the intermediate state and the localized state as shown in Fig. 2. In the intermediate state an orbit falls into $\boldsymbol{X}^0$, but a large part of a limit cycle, which we call the semi-global limit cycle, remains around $\boldsymbol{X}^{\mathrm{S}}$. One of the steady state $\boldsymbol{X}^0$ of CFO is common with the steady state of the original oregonator $\boldsymbol{O}(\boldsymbol{X})$ in Eq. 1 and exist for all values of flow rate R. The additional

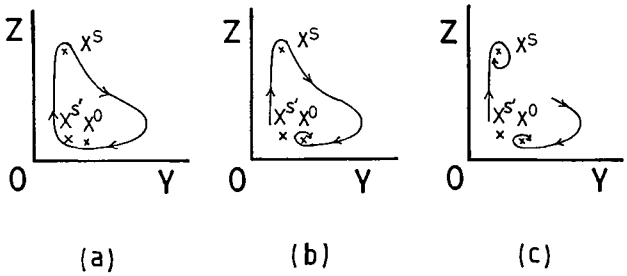

Fig. 1. Schematic representation of three types of behaviors of trajectories of the constant flow term Oregonator (CFO model) in Y–Z plane. $\boldsymbol{X}^0$, $\boldsymbol{X}^{\mathrm{S}}$, $\boldsymbol{X}^{\mathrm{S}'}$; steady states. (a) extended state, (b) intermediate state, and (c) local state.

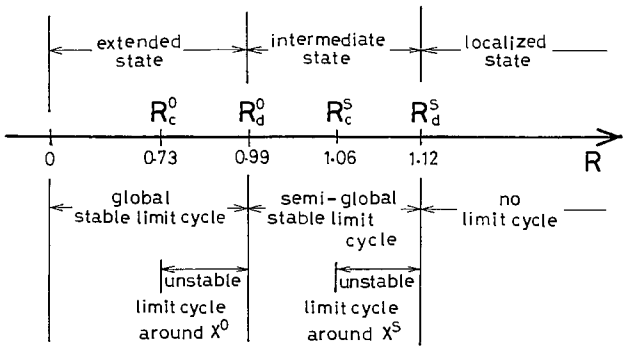

Fig. 2. Relation between three types of global behaviors of CFO and the existence of limit cycles for the ranges of flow rate R.

two steady states X^S and $X^{S'}$ of CFO exist in the flow rate range $0.54<R<5.99$. For the range of the flow rate 0.95—1.10 to be considered later three steady states exist; and consequently, CFO is in a multisteady state. The cross signs in Fig. 1 denote the positions of these three steady states. The CFO can also have a stable and an unstable limit cycle in a certain range of R as shown in Fig. 2.

In the previous paper[6] we showed the behavior of OFO in which the parameters ε, q, f, p, and Ω in Eq. 1 were chosen as follows;

$$\varepsilon = 0.05, \quad q = 0.01, \quad f = 1.8, \quad p = 3 \quad \Omega = 0.75, \quad (3)$$

and the components of the amplitude $\boldsymbol{Q}$ of the forced oscillation in Eq. 2 were set to

$$Q_x = 2, \quad Q_y = 0.5, \quad Q_z = 1. \quad (4)$$

These values of the amplitude $\boldsymbol{Q}$ were chosen about 1/15—1/40 of the amplitude of the stable limit cycle of the original Oregonator. This implies that the forced oscillation very weakly acts in OFO. In order to distinguish the combined parameter set of (3) and (4) from the parameter set in this paper, we call it the "OFO-I". In the previous paper[6] we indicated that the OFO-I could qualitatively exhibit the characteristic features of the experimental results by Hudson et al., but we could not succeed in reproducing the fine details of the oscillatory modes, the wave patterns and the nonperiodic chaotic behaviors which appear in the experiment on the BZ reaction of flow system.

In this study we take the values of the amplitude $\boldsymbol{Q}$ as

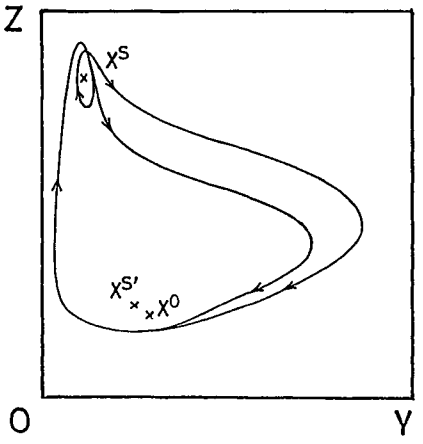
$$Q_x = 0.07, \quad Q_y = 0.0175, \quad Q_z = 0.035, \quad (5)$$

which is extremely smaller than the values of (4) of OFO-I. These magnitudes of the amplitude of forced oscillation are about 1/1000—3/1000 of the amplitude of the limit cycle of the original Oregonator, and is about 1/29 of the amplitude of forced oscillation of OFO-I. The other parameters ε, q, p, f, and Ω are set fixed again to the same values of the set (3). We call the OFO with the combined parameter set of (3) and (5) the "OFO-II". The following would show that the simulational results on the OFO-II can exhibit not only the elementary features of the experiment qualitatively, but also a fine agreement with the experimental results on the oscillatory modes, the wave patterns and the nonperiodic chaotic behaviors. Simply speaking the OFO-II can reproduce the detailed bifurcation structure of the flow rate R.

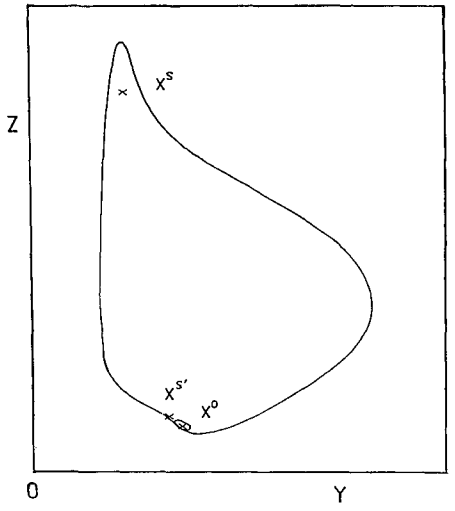
Results

We carry out the computational simulation on the OFO model of the Eq. 1 with the parameter set of the OFO-II, where the magnitudes of the amplitude $\boldsymbol{Q}$ in the time-dependent term X^1 in Eq. 2B are set extremely small values of Eq. 5. The time variation of the OFO-II is determined by the Runge–Kutta Gill's method. The value of the flow rate R is varied by the increase of 0.002 throughout the range of 0.950—1.100, which include both the upper end of the extended state and all the range of the intermediate state of CFO shown in Fig. 2. Figure 3 shows the projections of the typical trajectories of both the OFO-I and the OFO-II onto Y–Z plane, where the three steady states X^0, X^S, and $X^{S'}$ of CFO are marked with the crosses. In the range of R mentioned above, X^0 is a stable focus while X^S changes from an unstable focus to a stable focus, and $X^{S'}$ is a saddle point as shown in Fig. 4. As can be seen from Fig. 3, the orbit of OFO-I turns around X^S while that of OFO-II passes through X^S and turns around X^0. For $0.73<R<0.99$, CFO has an unstable limit cycle around X^0 as shown in Fig. 2. The typical oscillatory wave patterns from the OFO-II are shown in Figs. 5—7 for the series of values of the flow rate R. In these figures the patterns from the experiment by Hudson et al.[1] are also shown for comparison. Here we adopted the abbreviated notations of the mode for oscillatory patterns introduced by Tomita et al.[10] like as; (1) $\Pi(n)$ denotes an n-peaked periodic mode, (2) $\Pi_{l_n,l_m}(n, m)$ a periodic switching between l_n times $\Pi(n)$-like and l_m times $\Pi(m)$-like mode, (3) $\chi(n, m)$ a chaotic switching between $\Pi(n)$-like and $\Pi(m)$-like modes. We introduce the notation $\Pi(S)$ for the periodic oscillation with a small amplitude only.

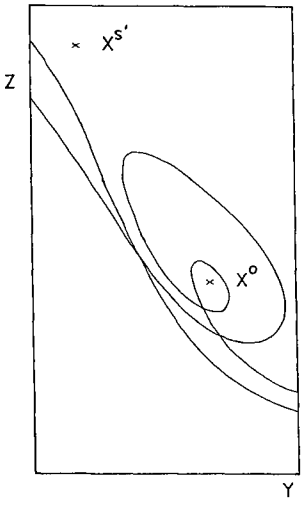
We have ever summarized the qualitative features of oscillation behaviors of the results of the experiment by Hudson et al.[1] into the following three points; (a) two types of the peaked oscillations, one with a large amplitude and the other with a small amplitude, (b) multi-peaked oscillations with a large amplitude and some small amplitudes, and (c) the mixing of two types of oscillations and the sandwiched structure in the bifurcation structure for the flow rate R. We could express these three features more explicity using the notation of oscillation mode mentioned above; (a) the 2-peaked



(a) OFO-I Q_x=2.0, Q_y=0.5, Q_z=1.0, R=1.06.



(b) OFO-II Q_x=0.07, Q_y=0.0175, Q_z=0.035, R=1.00.



(c) Magnification of orbit around X^0 in (b).

Stationary state	R				
	0	0.54	0.73	0.74	1.06
$\boldsymbol{X}^0$	UF		SF		
$\boldsymbol{X}^S$	—	UN		UF	SF
$\boldsymbol{X}^{S'}$	—	S			

Fig. 4. Change of local behaviors of orbits around steady states with varitaion of flow rate R. UF: unstable focus, SF: stable focus, UN: unstable node, S: saddle, —: nonexistence of the stationary state.

oscillation $\Pi(2)$, for example, is composed of one large amplitude oscillation and one small amplitude oscillation, (b) $\Pi(5)$, for example, expresses the 5-peaked oscillation with one of the large amplitude and four of the small amplitude, (c) $\Pi_{1,1}(1,3)$, for example, implies the mixing oscillation of $\Pi(1)$ and $\Pi(3)$, and the sandwiched structure of those two types of modes means that the range of the flow rate R at which $\Pi_{1,1}(1,3)$ appears is sandwiched by the range of $\Pi(1)$ and that of $\Pi(3)$. In the previous paper we have showed that OFO-I can properly exhibit three qualitative features of experimental results. While, as we can see in Figs. 5—7, the OFO-II not only can exhibit the qualitative features (a)—(c) above mentioned, but also can reproduce all kinds of periodic oscillatory modes and wave patterns to be found in the Hudson's experimental results. Only the exception on this correspondence is that the mode $\Pi(4)$ from the experiment could not be found stably in the simulational results, but appear temporarily. For example the mode $\Pi(4)$ sometimes appears near the flow rate R=1.066 and continue to exist for some time, but as time goes on some other modes always mix with $\Pi(4)$ mode. This seems to mean that the mode $\Pi(4)$ cannot exist stably in OFO-II model, and we have judged that $\Pi(4)$ cannot be found in our simulation.

Figure 8 shows the bifurcation structures of oscillatory modes both from the simulation with OFO-II and from the Hudson's experiment. In the figure of the bifurcation structure we put the mark "○" on the value of R at which a periodic oscillation appears, and no mark on the other values of R at which nonperiodic oscillations, i.e. chaotic behaviors, are realized. The simulational results of the bifurcation structure agree very well qualitatively with the experimental one. On this correspondence there are two exceptions that the mode of $\Pi(4)$ can not be found in the simulational results as mentioned above, and the modes $\Pi_{1,1}(1,3)$ and $\Pi(2)$ are situated in reverse order one another on the increase of R value between (a) and (b) in Fig. 8.

From the analysis of the Hudson's experimental data Tomita et al.[10] found that the period T_p of a p-peaked periodic mode obeys a simple rule, namely

$$T_p = T + (p-1)\tau, \tag{6}$$

Table 1. Periods from Simulations and from Theoretical Formula (6)

Flow rate	Multiplicity	Periods	
R	p in π (P)	T_p(obs)[a]	T_p(theor)[b]
0.952	1	10.41	10.41
1.024	2	16.78	17.81
1.080	3	25.13	25.21
1.090	5	41.93	40.01

a) T_p(obs): period obtained from simulations. b) T_p(theor)$=T+(p-1)\tau$, $T=10.41$, $\tau=7.40$ (6).

where $p=1,2,3,4$, and 5, and both of T and τ are constants. Tomita gave $\tau=0.48$ and $T=0.96\approx 2\tau$. Here, we tried to apply this rule to our simulational data based on OFO-II. When $\tau=7.40$ and $T=10.41$, we confirmed very good agreement between the period predicted from Eq. 6 and the period obtained by the simulation data. The result is indicated in Table 1, where T_p(theor) is the period predicted from Eq. 6 and T(obs) is that of the simulational data. Here the value of $T(=10.41)$ is smaller than $2\tau=2\times 7.40=14.80$ and $\tau(=7.40)$ is also slightly smaller than the value of the period $2\pi/\Omega=8.38$ to be expected from the angular frequency Ω of the oscillation. It is interesting, however, that the every difference is not so large.

Discussion

We studied the behaviors of the oscillatory flow term Oregonator (OFO model) to compare our results with the experimental results of Hudson et al.[1] The simulation of OFO has been made under the values of parameters of OFO-II which is same as OFO-I except the extremely small amplitude of the forced oscillation. It can be concluded that the OFO-II model is very suitable for reproducing the experimental results by Hudson et al.

In the previous paper[6,7] we have shown that the trajectory of CFO changes both globally and locally according to the value of the flow rate R as shown in Fig. 1. And the behavior of CFO is primarily determined by the competitions among some attractors like as steady states and a stable or an unstable limit cycle. We think that these behaviors of CFO still perform a part of the background of the behaviors of OFO because the only difference of OFO from CFO is the existence of the forced oscillation term of which amplitude is set extremely small of order 1/500 compared with the amplitude of the limit cycle of CFO. Therefore, the steady states, $\boldsymbol{X}^0$, $\boldsymbol{X}^S$, $\boldsymbol{X}^{S'}$, and the limit cycles in CFO may also be at work as the latent attractors in OFO. In the previous paper we summarized the following conditions for the exhibition of the characteristic features of the Hudson's experimental results by OFO: (1) The CFO, which could be the background of the OFO, should have two steady states $\boldsymbol{X}^0$ and $\boldsymbol{X}^S$ at least. (2) The stability of steady states $\boldsymbol{X}^0$ and $\boldsymbol{X}^S$ should become larger with the increase of the flow rate R. (3) The value of R should be taken near the value at which the CFO could realize the intermediate state as shown in Fig. 2. (4) The curved surface formed by the orbits near $\boldsymbol{X}^S$ should be enough flat to be able to form the turning orbit around it.

Here, it is newly confirmed that in order to reproduce more finely the Hudson's experimental results by OFO the following conditions should be added. (5) The amplitude of the oscillation in the time-dependent term

of OFO should be extremely smaller than that of OFO-I. Thus the forced oscillation should be so weak that the trajectory is attracted not to the steady state X^S, but to the steady state X^0 and turns around it. (6) The stability of X^0 should be moderate; or more definitely, the stability of X^0 should be as high as a running orbit can be attracted to X^0 and turns around X^0 while it should be as low as the trajectory finally falls not to the steady state X^0, but comes out to the global stable limit cycle which may surpass X^0 in stability. If an unstable limit cycle exists around X^0, the curved surface formed by the orbit inside this unstable limit cycle should be also flat enough, which is same as the condition (4) around X^S. This circumstance corresponds to the condition that the stability of the focus X^0 should be as low as that mentioned in (6). If the stability of X^0 is comparatively low and at the same time the magnitude of the amplitude Q is larger than a certain threshold, the trajectory passes through near X^0 without turning around it. In this case the oscillatory modes, the wave patterns and the bifurcation structure would differ in fine details from those of Hudson's experimental results.

Here, we must pay attention to the fact that no forced oscillation was set in the Hudson's experimental system[1] while the OFO has the time-dependent flow term implying a forced oscillation. This is a discrepancy between the Hudson's experimental system and the OFO model. From the microscopic point of view, however, local fluctuation in concentrations of chemical species necessarily comes always into the experimental system. The time-dependent term in OFO could be regarded as a correspondence on this fluctuation. Now, there are two discrepancies between the experimental results and the simulational results based on OFO-II. Namely, one of them is the lack of the mode $\Pi(4)$ in the simulational results and the other is an inversion in the order of the appearance of the mode $\Pi_{1,1}(1,3)$ and $\Pi(2)$ with the increase of R. These discrepancies would be due to the difference between the random fluctuation in the expeprimental system and the trigonometric functional oscillation in the OFO model system. But we think that the discrepancies between two results are not so significant and not so essential because qualitatively the OFO-II shows totally a very good reproduction of the bifurcation structure of the experimental results. If these considerations are appropriate, the simulational results mean that the smaller amplitude of forced oscillation in the OFO model guarantees the better correspondence between the OFO model and the real experimental system. From this point of view it can be said that the OFO-II model may have better correspondence to the experimental system than the OFO-I model.

We would like to thank Dr. A. Kouda for valuable discussion. The authors are much indebted to Dr. J. L. Hudson, Dr. M. Hart, and Dr. D. Marinko for kindly permitting us to quote many figures in their paper of Ref. 1.

Physical Characteristic and Molecular Structure of Spin-Crossover Iron(III) Complexes of Monoclinic Form with Hexadentate Ligands Derived from Triethylenetetramine and Salicylaldehyde [Fe(sal$_2$trien)]BPh$_4$·acetone

(Received October 18, 1990)

Iron(III) complexes of [FeL]BPh$_4$·acetone containing the hexadentate ligand derived from triethylenetetramine and salicylaldehyde have been synthesized. These complexes were grown in two crystalline forms, monoclinic and the twin crystals. The crystal structure of the monoclinic form was determined at 290 K, at which temperature the complex is in a transition spin-state between high- and low-spin states; the spin-state interconversion rate of the monoclinic form is as fast as the inverse of the Mössbauer lifetime (1×10^{-7} s) above 200 K. The monoclinic crystal of [FeL]BPh$_4$·acetone is of space group $P2_1/a$, with a=27.418(4), b=10.097(2), c=14.726(3) Å, β=98.00(1)°, and Z=4. The average bond distances of Fe–O (1.875 Å), Fe–N_{imine} (1.988 Å), and Fe–N_{amine} (2.069 Å) are in good agreement with the expected values for the transition spin-state between high- and low-spin states. Twin crystals are in a high-spin state over the temperature range 78—320 K.

The dynamics of spin-state interconversion in a solution and a solid at ambient temperature have been the subject of a number of papers.[1-3] The measured ^{2}T(LS)$\rightleftharpoons$ ^{6}A(HS) relaxation rates are of the order of 10^7 s^{-1} in the solution state at high temperature; there are few solids for which both the solution and solid-state spin-state interconversion rates have been determined.[4,5] The solid-state rates are supposed to be consistently slower than the corresponding solution rates.

The spin-state interconversion rates in [FeL]Y (H_2L; Schiff base derived from triethylenetetramine and salicylaldehyde) with Y=PF_6^-, NO_3^-, BPh_4^-, I^-, and Cl^- in solution were measured by Tweedle and Wilson, and are about 10^7 s^{-1}.[5] The magnetic properties and the crystal structures for some of their solid complexes have been reported and the interconversion rate for the PF_6 salt has been estimated to be slower than 10^7 s^{-1}.[6]

Some examples in which the electronic spin-state is dependent on the crystal form are known. For example, Fe(phen)$_2$(NCS)$_2$ and Fe(bpy)$_2$(NCS)$_2$ have polymorph,[7-9] and the magnetic behaviors are different from each other. [Fe(oep)(3-Clpy)$_2$]ClO$_4$[10,11] (oep: octaethylporphyrin, 3-Clpy: 3-chloropyridine) of monoclinic form is a quantum-admixed intermediate-spin state; the triclinic one shows a thermal spin equilibrium, although the solution susceptibilities of both crystalline forms are identical.

We are interested in the differences in the spin-state interconversion rates between the solution- and solid-state, and in the effect of the difference of the crystal forms on the spin-crossover.

Experimental

Sample Preparation. The ligand was prepared by slowler adding 0.73 g (5 mmol) of triethylenetetramine in 20 ml of methanol to 1.22 g (10 mmol) of salicylaldehyde in 100 ml of methanol; the mixture was kept for 1 h at room temperature.[12] Then, 1.12 g (20 mmol) of KOH in 50 ml of methanol was added to the mixture. This mixture was used without separating the ligand as a solid. Iron complexes were prepared by the addition of 2.0 g (5 mmol) of iron nitrate in 50 ml of methanol to the ligand solution. The precipitation was separated with a glassfilter and 1.36 g (4 mmol) of sodium tetraphenylborate in 50 ml of methanol was slowly poured into the filtrate. The crude product was collected by filtration, washed with methanol and recrystallized from acetone. Two crystal forms were produced, filtrated, washed with acetone and separated mechanically. The crystals of each form were collected and recrystallized from acetone. The analytical data for [FeL]BPh$_4$·acetone are as follows: Found for monoclinic crystals: C, 72.01; H, 6.40; N, 7.15%. Found for twin crystals: C, 71.93; H, 6.51; N, 7.23%. Calcd for $BC_{47}H_{50}FeN_4O_3$: C, 71.85; H, 6.42; N, 7.13%.

Physical Measurements. The magnetic susceptibilities of the polycrystalline samples were measured by the Faraday method using a type-2002 (Cahn Instruments) electrobalance with an electromagnet (8000 G, 0.8 T). The temperature was controlled over the range 78—320 K by using a digital temperature controller (model 3700; Scientific Instruments). Compound HgCo(NCS)$_4$ was used as a calibration standard. Effective magnetic moments were calculated by using the formula $\mu_{eff}=2.84\,(\chi_M T)^{1/2}$, where χ_M is the molar susceptibilities after applying a diamagnetic correction.

The Mössbauer spectra were measured with a constant-acceleration spectrometer (Austin Science Associates). Data were stored in a 1024-channel pulse-height analyzer (type 5200; Inotech Inc.). The temperature was monitored with a calibrated copper–constantan thermocouple within a variable-temperature cryostat (type ASAD-4V). A cobalt 57 source of 10 mCi diffused into a palladium foil was used for the absorption measurement. All spectra were fitted by Lorentzian line shapes using a least-squares fitting procedure at the Computer Center, Kyushu university. The velocity scale was normalized with respect to the centre of the spectrum of metallic iron at 296 K.

The relaxation fits were based on the method reported in Ref. 13 for relaxation between two quadrupole split doublets representing the low- and high-spin electronic states. The quadrupole splittings of the low- and high-spin doublets in these fits were kept constant at 2.85 and 0.28 mm s^{-1}, respectively. The high- and low-spin population fractions determined from the magnetic data were used. We used values of 2.58 BM for the low-spin electronic state and 5.60 BM for high-spin electronic state, of which value is popularly observed for high-spin iron(III) complexes. The line widths for the doublets were assumed to be 3.03 mm s^{-1} for the low-energy line 0.86 mm s^{-1} for the high-energy line of the high-spin species; those for low-spin species were 0.44 and 0.31 mm s^{-1}, respectively. The values were varied according to the fraction of the high-spin/low-spin population in fitting as inevitable management, since the high-spin species shows very broad line widths due to spin-spin relaxation. (The values used in practice for fitting were less than 2.199 mm s^{-1}, although 3.03 mm s^{-1} appeared to be too large.)

The IR spectra for both samples were measured using a JASCO FT/IR-5000; the peak positions of N–H or C=N stretching vibration for monoclinic crystals (complex **a**) were similar to those for the twin crystals. No existence of strong hydrogen bonding in N(2)–H(23)–OS(1) is supposed for both complexes.

Electron paramagnetic resonance data at the X-band frequency were collected on a FEX (JEOL, Ltd) spectrometer.

Crystal Structure Determination of Monoclinic [Fe(sal$_2$trien)]BPh$_4$·acetone. Suitable single crystals of monoclinic [FeL]BPh$_4$·acetone were obtained by slow evaporation of acetone at room temperature.

Crystal Data. $BC_{47}H_{50}FeN_4O_3$, M=785.5. Monoclinic, a=27.418(4), b=10.097(2), c=14.726(3)A, β=98.00(1)°, V=4037(0)Å^3 (by least squares refinement on diffractomer angles 25°<2θ<30° for 50 automatically centered reflections, λ=0.71073 Å), space group $P2_1/a$ (No. 14), Z=4, D_c=1.29 g cm^{-3}, D_o=1.30 g cm^{-3}, blue black, crystal dimensions: 0.2×0.2×0.3 mm, μ(Mo $K\alpha$)=16.46 cm^{-1}.

Data Collection and Processing. Diffraction data were collected at 290 K on a Rigaku AFC5 four-circle diffractometer using the $\omega-2\theta$ scan technique; graphite monochromated Mo $K\alpha$ radiation; 10333 reflections measured(−35<h<35, 0<k<13, 0<l<19), 5287 independent data with $|F_o|>3\sigma(F_o)$. The crystal was covered with glue in order to avoid any release of acetone molecules from the crystal during measurements. The intensities of the three standard reflection were monitored every 100 reflections, and showed no greater fluctuations during the data collection than that expected from Poisson statistics. Intensity data were corrected for both Lorentz and polarization factors, but not for adsorption and extinction.

Structure Analysis and Refinement. The structure was solved by the conventional heavy-atom method and refined by a block-diagonal least-squares method with anisotropic thermal parameters for non-hydrogen atoms and isotropic for Hydrogen atoms. The weighting scheme $w=[\sigma_c^2+(0.025|F_o|)^2]^{-1}$ was employed, where σ_c was estimated from the counting statistics. The final indices, R and R', were 7.2 and 9.3%, respectively, which are defined as $R=\Sigma(|F_o|-|F_c|)/\Sigma|F_o|$ and $R'=[\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$. The atomic scattering factors for non-hydrogen atoms were taken from Ref. 14, and those for hydrogen atoms from Stewart et al.[15] The effects of anomalous scattering for non-hydrogen atoms were corrected for in structure factor calculations. A determination of the structural parameters was carried out with the universal Crystallographic Computation Program System UNICS III,[16] using a HITAC M-680 Computer at the Computer Center of The Institute for Molecular Science. The final atomic coordinates are given in Table 1.

Results and Discussion

We isolated solids of two crystalline forms with a solvent. The temperature-dependent magnetic susceptibilities for the two crystalline forms were different from each other. The crystal structure of the monoclinic form, which shows thermal spin-crossover, was determined. Twin crystals give a different powder X-ray diffraction pattern from the monoclinic one and are in a high-spin state over the temperature range 78–320 K.

Magnetic Susceptibilities and ESR. Figure 1 shows variable temperature magnetic data for both complexes. The data for the monoclinic form indicate an anomalous magnetic behavior characteristic of an LS⇌HS spin-crossover behavior; the magnetic susceptibility is of an intermediate value at 296 K, and the electronic

state of 40% high-spin and 60% low-spin states. The twin crystals remain fully in the high-spin state, even at 78 K.

ESR spectra were measured for both samples. As the temperature of complex **a** was decreased, the low-spin signals (g_1=2.20, g_2=2.194, g_3=1.944) increased in intensity at the expense of the high-spin signals(g=4 and 2). These high- and low-spin ESR signals are typical for ferric centers of this type. In the twin crystals broad signals at g=2.1, 3.7, and 5.3 were observed at 296 K.

Mössbauer Spectra. The Mössbauer spectra of the monoclinic form were measured at various temperatures (Fig. 2). The spectrum at 78 K is typical of low-spin iron(III); the residual paramagnetic species was not observed, although the magnetic moment (2.58 BM at 80 K) is more than the spin-only value (1.98 BM). The full widths at half maximum(FWHM) at high temperature became broad due to a spin-spin interaction. The spectral data reported in Table 2 characterize anomalous magnetic properties arising from a spin-state interconversion; the spectra are not a superimposition of

both high- and low-spin absorptions, but comprise the time-averaged state in both electronic spin-states. The quadrupole splitting values are decreased with increasing population of the high-spin state. These facts indicate that the lifetimes of the low- and high-spin states are as short as or less than the Mössbauer lifetime of ^{57}Fe (1×10^{-7} s).

If we assume that the magnetic moments for low- and high- spin states of the monoclinic crystals are 2.58 and 5.60 BM, respectively, and temperature-independent values are assumed for the low- and high-spin effective magnetic moments, the high-spin population fraction (x) at ambient temperature can be calculated using the $\mu_{obs}^2=x\mu_{hs}^2+(1-x)\mu_{ls}^2$ relation (collected in Table 2).

The relaxation time, τ, is represented by $\tau=\tau_l\tau_h/(\tau_l+\tau_h)$, where τ_l and τ_h are the lifetimes of the low- and high-spin species, respectively. The observed spectra show a rapid relaxation between the high- and low-spin states with the rate of the Mössbauer time scale of 10^{-7} s. Although a fitting is one of many attempts, such a treatment should involve computing the distribution of the relaxation spectra, a correction for the line broadening resulting from the thick absorber and the temperature dependence of the quadrupole splitting for the low-spin species. Such a complex treatment was not attempted herewith and, consequently, the absolute values of the relaxation rate should be taken with caution. Our best fits are illustrated in Fig. 2. The rates for the forward k_1 and reverse k_{-1} rate constants for the spin interconversion LS$\rightleftharpoons$HS are defined as $1/\tau_{ls}$ and $1/\tau_{hs}$, respectively. The low-spin population fraction, f_{ls}, times k_1 is equal to the high-spin fraction, f_{hs}, times k_{-1}, *i.e.*,

$$f_{hs}+f_{ls}=1 \text{ and } k_1f_{ls}=k_{-1}f_{hs}$$

are fulfilled. An equilibrium constant, $K=k_{-1}/k_1$, plot of the temperature-dependent LS$\rightleftharpoons$HS relaxation rates described above deviates from a straight line (Fig. 3); the enthalpy for this process could therefore not be determined accurately. Nonetheless, the fitting of the Mössbauer spectra shown in Fig. 2 can serve as a qualitative of a rapid interexchange system. Sinn et al.[6] have reported that the average rate, $k'=\sqrt{k_1k_{-1}}$, for [FeL]$^+$ in solution is 1.4×10^7 s^{-1} at room temperature. The $\tau=0.6\times10^{-8}$ s in the spectrum (c) of Fig. 2 corre-

sponds to the rate $k'=\sqrt{k_1 k_{-1}}=8.2\times10^7$ s^{-1} and is compared with solution rate. This result is consistent with a report that the spin-state interconversion rates are dependent on the crystal packing and that intermolecular interaction can induce a faster rate than that in an isolated system.[17]

Crystal Structure. The crystal structure of the monoclinic form was determined at 290 K; interatomic distances for the cation and acetone molecule, and bond angles for the cation are listed in Tables 3 and 4, respectively. Steric structure and numbering system for the cation are drawn in Fig. 4 using ORTEP.[18] The structure of the complex contains cation and anion layers in an ac plane, as shown in Fig. 5. The $[FeL]^+$ ion is hydroden bonded via an amine nitrogen (H(23) attached to the nitrogen atom N(2)) to oxygen atom of the

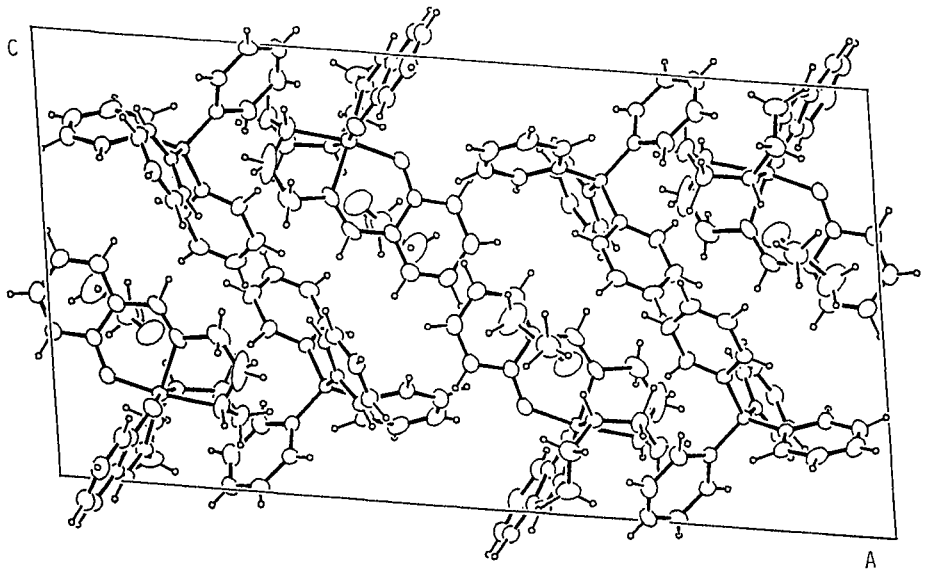

Fig. 5. Packing diagram in ac plane for monoclinic [FeL]BPh$_4$·acetone.

acetone molecule; bond lengths OS(1)–H(23)=2.073 Å, H(23)–N(2)=0.999 Å, OS(1)–N(2)=2.953 Å. The coordination sphere around the iron atom in the cation is approximately octahedral with the two terminal oxygen atom *cis* to each other. The configuration of the hexadentate ligand about the metal atom is analogous to that of low-spin [FeL]NO_3·H_2O (complex **b**) and [FeL]Cl·2H_2O (complex **c**), of which the structures were determined by Sinn et al.[6]; the deviation from octahedral geometry in the FeN_4O_2 unit is larger than those of complexes **b** and **c**. The angles O(1)–Fe–N(2), O(2)–Fe–N(3), and N(1)–Fe–N(4) are 168.0°, 168.8°, and 177.3°, respectively. The iron-ligand bond lengths are Fe–O^{av} 1.875, Fe–N_{imine}^{av} 1.988, and Fe–N_{amine}^{av} 2.069 Å. The Fe–O^{av} bond length for **a** is a little less than those for **b** and **c** 1.885 Å. The Fe–N bond length for **a** is larger than those for **b** and **c**. The bonds to the oxygen atoms are shortest, followed by those to the imine and the amine nitrogen atoms. These bond lengths are less than those for typical high-spin complexes with a Schiff base, in accordance with the electronic spin-state of this complex; i.e. the high-spin population fraction is 40% at 296 K.

With respect to the difference in the bond angles, Fe–O–C, between low-spin [FeL]X(X=NO_3, Cl) and complex **a**, the bond angles of Fe–O(1)–C(1) (129.2°) and Fe–O(2)–C(20) (129.2°) for **a** are about 4° larger than those for **b** or **c** respectively. The difference is larger than those for any other angles; four Fe–N–C angles for **a** are analogous to those corresponding to **b** or **c**. We have pointed out that the ease to transform the Fe–O–C bond angle between both spin-states is important regarding the spin-crossover behavior of FeN_4O_2 Schiff base complexes.[19,20]

The octahedral coordination around an iron atom is stable in the coordination structure represented by Fig. 4; other coordination structures have great strain.[21] Therefore, the coordination structure of twin crystals would be analogous to that shown in Fig. 4, and there would be a faint difference in the molecular structures between the monoclinic- and twin-type crystals.

It is reasonable that the hydrogen bonding interaction produces an increase in the low-spin populations. Complexes **b** and **c** with a strong hydrogen-bonding network are in a low-spin state and, therefore, the electronic states of complex **a** with weak hydrogen bonding and of the desolvated [FeL]BPh_4 may be on the spin-crossover point. It would be very interesting to clarify which difference in the molecular structure in these complexes brings about the spin-state difference. We are now trying to obtain single crystals of the other form (twin crystals).

Desolvated complexes [FeL]BPh_4 are also spin-crossover complexes, and the spin-state interconversion rate is slower than the inverse of the Mössbauer lifetime.[6] It is therefore not necessary to have acetone molecules in the crystal to cause a spin-crossover behavior. Rapid spin-state interconversion may result from the incorporation of acetone molecules, by which any soft modes are devoted to lattice vibration.

Supplementary Materials are Available: Tables of (1) positional parameters except hydrogen atoms, (2) positional parameters for hydrogen atoms, (3) anisotropic temperature factors, (4) mean square displacement tensor for atoms, and (5) observed and calculated structure factors for monoclinic [Fe(sal$_2$trien)]BPh_4·acetone are deposited as Document No. 9110 at the Office of the Editor of Bull. Chem. Soc. Jpn.

(Received November 30, 1990)

EXAFS (extended X-ray absorption fine structure) spectra were measured for *N,N*-dimethylformamide (DMF) solutions containing cobalt(II) ion and its chloro complexes of low concentration (20—40 mmol dm^{-3}) by a laboratory EXAFS spectrometer modified for the fluorescence detection. The analysis of the EXAFS data for a cobalt(II) perchlorate DMF solution showed that cobalt(II) ion in DMF has an octahedral structure with six DMF molecules. The Co–O (DMF) bond length within $[Co(dmf)_6]^{2+}$ in DMF is 206(1) pm and is practically the same as that within $[Co(H_2O)_6]^{2+}$ (208 pm) in water within experimental uncertainties. It was also shown that the tri- and tetrachlorocobaltate(II) complexes in DMF have a tetrahedral structure. The Co–O and Co–Cl lengths within $[CoCl_3(dmf)]^-$ in DMF are 202(1) and 227(1) pm, respectively. The Co–Cl distances within $[CoCl_4]^{2-}$ in DMF and in water are the same and 229(1) pm.

Extended X-ray absorption fine structure (EXAFS) spectroscopy has been widely applied to the structure determination of metal complexes in solution. Most of EXAFS measurements of solution samples were performed by the transmission mode. However, this mode can not be used for dilute solutions. It turned out that the fluorescence detection is effective for very dilute systems.[1,2] In fact, EXAFS spectroscopy by the fluorescence detection is indispensable for the structural determination of metal complexes in nonaqueous media, where solubility of metal complexes is usually very low compared with aqueous media.

Complex formation reactions of divalent transition metal with halide ions have been studied in *N,N*-dimethylformamide (DMF).[3-7] Since metal ions are solvated in solution, solvation structure of metal(II) ions is essential to understand the thermodynamics of complexation. Direct structural information on the solvation structure of copper(II) and cadmium(II) ions in DMF has so far been provided by solution X-ray diffraction.[8,9]

With cobalt(II), a series of mononuclear $[CoCl]^+$, $[CoCl_2]$, $[CoCl_3]^-$, and $[CoCl_4]^{2-}$ complexes are formed in DMF. In particular, the tri- and tetrachloro complexes are extensively formed as the main species at suitable mole ratios of chloride to cobalt(II) ions.[3] However, since the solubility of $((CH_3CH_2)_4N)_2[CoCl_4]$ in DMF is low (less than 20 mmol dm^{-3}), it is difficult to apply the transmission EXAFS method for the structural study. Therefore, in the present study we employed the fluorescent EXAFS method to determine the structure of the solvated cobalt(II) ion and the tri- and tetrachlorocobaltate(II) complexes in DMF. The structure of mono- and dichlorocobalt(II) complexes was not determinable because of their suppressed formation in DMF.

Experimental

Reagents. All chemicals used were of reagent grade. Cobalt(II) perchlorate and cobalt(II) chloride were recrystallized once from water. Cobalt(II) perchlorate DMF solvate was prepared by the same method as described elsewhere.[3] Lithium chloride and tetraethylammonium chloride were used without further purification and dried at 100 °C. *N,N*-Dimethylformamide was purified as described elsewhere.[5]

Preparation of Solutions. Five sample solutions were prepared for EXAFS measurements. Solution AQ0 is an aqueous cobalt(II) perchlorate solution. Solution AQ4 was prepared by dissolving cobalt(II) chloride in an aqueous 13 mol dm^{-3} lithium chloride solution. The former and latter solutions contain $[Co(H_2O)_6]^{2+}$ and $[CoCl_4]^{2-}$ complexes, respectively, of known structure.[10,11] Solution DMF0 is a cobalt(II) perchlorate DMF solution. Solutions DMF3 and DMF4 were prepared by dissolving cobalt(II) perchlorate DMF solvate and tetraethylammonium chloride in DMF at suitable C_{Cl}/C_{Co} mole ratios. The tri- and tetrachlorocobaltate(II) complexes are the main species in solutions DMF3 and DMF4, respectively, according to the stability constants of cobalt(II) chloro complexes in DMF.[3] The compositions of the solutions are given in Table 1.

EXAFS Measurements. EXAFS spectra were measured on a laboratory EXAFS spectrometer[12] modified for the fluorescence detection[13] at the Institute for Molecular Science.

A rotating anode X-ray generator (Rigaku RU-200) was

operated at the voltage of 12 kV and the current of 200 mA. Monochromatized X-rays were obtained by a Johansson cut bent crystal (Ge(220)). Helium bags were placed along the beam path to prevent absorption by air. Sample solutions were held in a 5 mm thick glass cell with a Mylar window.

The incident X-ray intensity I_0 and the fluorescence intensity I were simultaneously measured by an ion chamber and an NaI scintillation counter with 2 inches in diameter combined with a filter (iron foil with thickness of 10 μm), respectively, and more than 1×10^6 counts of I were obtained at each data point above the edge. The observed spectra $\mu\,(=I/I_0)$ are shown in Fig. 1.

Analysis of EXAFS Data. Background other than that for the K edge of cobalt atom was estimated by least-squares fitting first-order polynomial function to the pre-edge and was subtracted from the raw spectrum by extrapolation. The smooth background μ_0 due to an isolated atom was evaluated by fitting a smooth curve to the observed spectrum using an eighth-order polynomial function.

The EXAFS pattern was then extracted and normalized by the following equation;

$$\chi(k) = \{\mu(k) - \mu_0(k)\}/\mu_0(k), \tag{1}$$

where $k(=\{2m(E-E_0)\}^{1/2}/\hbar)$ is the photoelectron wave vector. E represents the energy of the incident X-rays and E_0 is the threshold energy of a K-shell electron. The E_0 value was selected as the position of the half-height of the edge jump in each sample and was set to be 7.722 keV in the present study. The extracted EXAFS spectra weighted by k^3 are depicted in Fig. 2. The $k^3\cdot\chi(k)$ values are converted to the radial structure function $F(r)$ as

$$F(r) = (1/2\pi)^{1/2}\int_{k_{min}}^{k_{max}} k^3\cdot\chi(k)\cdot W(k)\cdot\exp(-2ikr)dk. \tag{2}$$

$W(k)$ is the window function of the Hanning type.[14] The $F(r)$ values are shown in Fig. 3.

A curve fitting procedure in the k-space for the refinements of structure parameters was applied to the Fourier filtered $k^3\cdot\chi(k)_{obsd}$ values to minimize the error-square sum U:

$$U = \Sigma k^6(\chi(k)_{obsd} - \chi(k)_{calcd})^2. \tag{3}$$

The model function $\chi(k)_{calcd}$ is given by the single scattering theory as[15-18]

$$\chi(k)_{calcd} = \Sigma\{n_j/(k\cdot r_j^2)\}\exp(-2\sigma_j^2k^2 - 2r_j/\lambda)F_j(\pi,k) \times\sin(2kr_j + \alpha_j(k)), \tag{4}$$

where $F_j(\pi, k)$ is the backscattering amplitudes from each of n_j scatterers j at distances r_j from the X-ray absorbing atom.

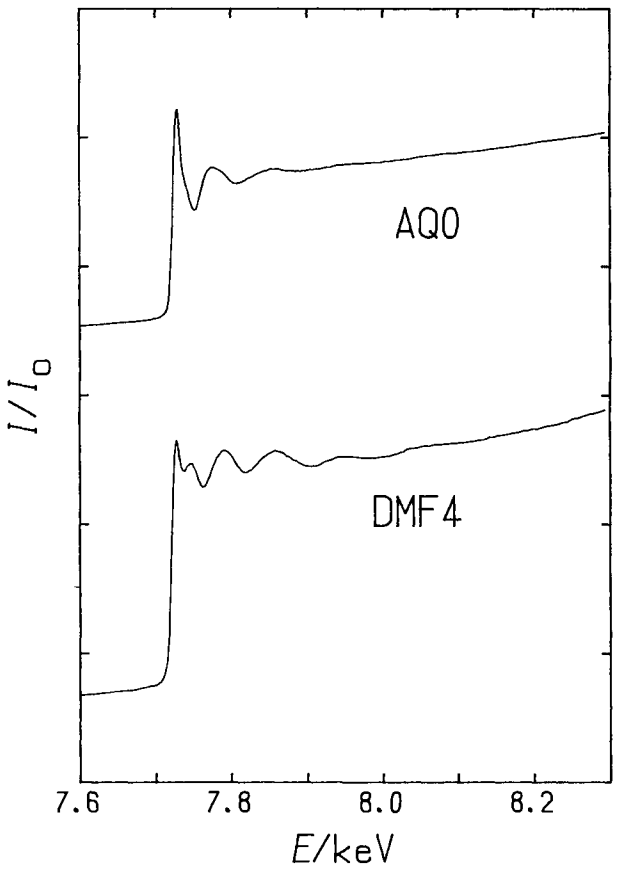

Fig. 1. The raw EXAFS spectra for sample solutions AQ0 and DMF4 of low concentration (ca. 20 mmol dm^{-3}) by the fluorescence detection.

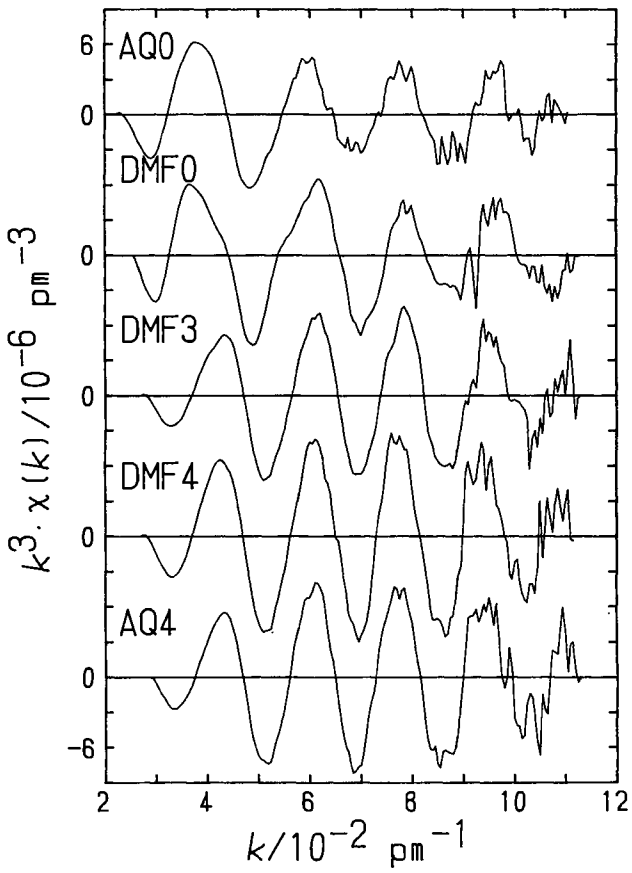

Fig. 2. The extracted EXAFS oscillations multiplied by k^3 for sample solutions. AQ0: $Co(ClO_4)_2$ in water, DMF0: $Co(ClO_4)_2$ in DMF, DMF3: $[CoCl_3]^-$ in DMF, DMF4: $[CoCl_4]^{2-}$ in DMF, and AQ4: $[CoCl_4]^{2-}$ in water.

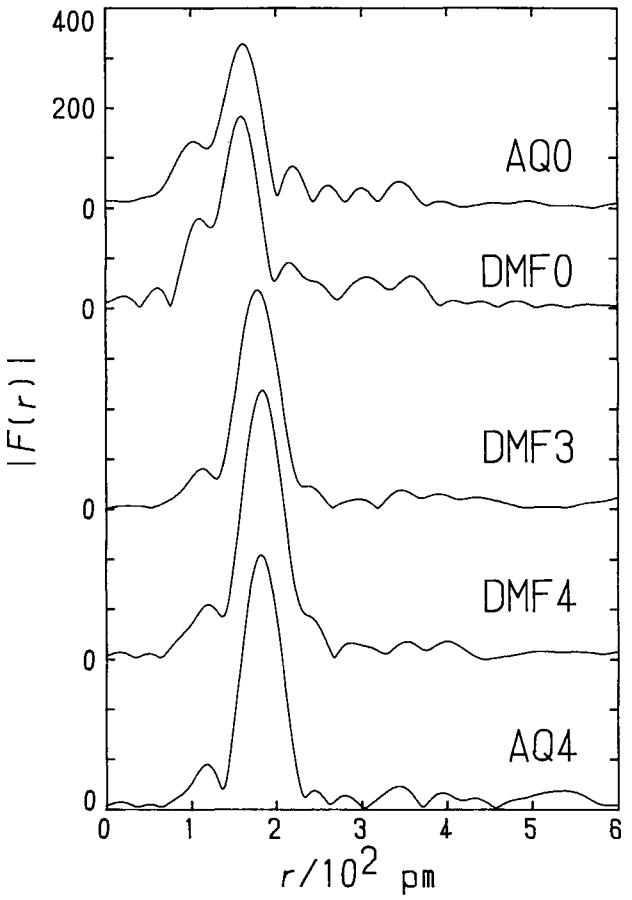

Fig. 3. The Fourier transforms $F(r)$ of the $k^3 \cdot \chi(k)$ curves shown in Fig. 2, phase shift uncorrected.

σ_j^2 is the mean square displacement of the equilibrium distance r_j and λ is the mean free path of the photoelectron. $\alpha_j(k)$ is the total scattering phase shift experienced by the photoelectron. The values of $F_j(\pi, k)$ in Eq. 4 were taken from the tables reported by Teo and Lee.[19] The phase shift $\alpha_j(k)$ was approximated by the function $a_0+a_1k+a_2k^2+a_3/k^3$,[20] where the a_0, a_1, a_2, and a_3 values were obtained by fitting the function to the phase shift values by Teo and Lee.[19] In the least-squares calculations, the parameters a_0, a_1, and λ were first determined from the standard samples of known structure. The a_2 and a_3 values were fixed at the above values during the refinement. An aqueous cobalt(II) perchlorate solution containing $[Co(H_2O)_6]^{2+}$ (AQ0) and a cobalt(II) chloride in a 13 mol dm^{-3} LiCl solution containing $[CoCl_4]^{2-}$ (AQ4) were used as the standard for the Co–O and Co–Cl atom pairs, respectively.[10,11] The parameters were then used as constants in the course of the structural analysis of unknown samples, while r, σ, and n values were optimized.

Results and Discussion

Figure 2 shows the extracted EXAFS oscillations in the form of $k^3 \cdot \chi$ (k) for solutions AQ0, DMF0, DMF3, DMF4, and AQ4. In Fig. 3, the Fourier transforms of the $k^3 \cdot \chi(k)$ values of the test solutions are depicted. The first intense peaks at 150—180 pm are ascribable to the bonds between cobalt(II) ion and oxygen atom and/or chloride ion in the first coordination sphere.

Solutions AQ0 and DMF0 contain the solvated cobalt(II) ion in water and DMF, respectively. Both solutions show a similar pattern in intensity and phase over the k-range of the measurements (Fig. 2). A slightly different feature in the $k^3 \cdot \chi(k)$ curves between solutions AQ0 and DMF0 at 4.5 and 5.5×10^{-2} pm^{-1}, i.e. two shoulders in the curve of solution DMF0, may be due to the nonbonding Co···C (DMF) interactions. Indeed, similar shoulders due to M···C interactions were observed for the aqueous solutions involving copper(II) bidentate chelate complexes.[21] The first intense peaks around 150 pm in the Fourier transform for both solutions are also practically unchanged in intensity and positions as in Fig. 3. Therefore, the structure of solvated cobalt(II) ion in DMF may be octahedral like the hexaaquacobalt(II) ion in water[10]

According to the species distribution of the cobalt(II) chloro complexes in DMF,[3] the tri- and tetrachlorocobaltate(II) complexes are the predominant species in solutions DMF3 and DMF4, respectively. The relative amounts of the predominant complex in the solutions exceed 90%, on the basis of the molar absorption coefficients of individual cobalt(II) chloro complexes in DMF.[3] Hence, we treated solution DMF3 or DMF4 to contain only tri- or tetrachlorocobaltate(II) complex, respectively.

It has been revealed that a structure change from octahedral to tetrahedral around cobalt(II) ion occurs upon the formation of the dichlorocobalt(II) complex on the basis of the thermodynamic quantities of complexation and the electronic spectra of individual cobalt(II) chloro complexes in DMF.[3]

Very similar $k^3 \cdot \chi(k)$ and $F(r)$ curves were in fact obtained for solutions AQ4 and DMF4 as shown in Figs. 2 and 3. This is expected because the two solutions contain the four-coordinate $[CoCl_4]^{2-}$ complex.

The structure parameters of these complexes were finally determined by a least-squares calculation applied to the Fourier filtered $k^3 \cdot \chi(k)$ values over the range $4.0 < k/10^{-2}\,\text{pm}^{-1} < 10.0$. The Fourier filtering was performed over the r-range including the main peak in the $F(r)$ curve for each sample. The phase function and the λ values were first evaluated for the Co–O and Co–Cl atom pairs from respective solutions AQ0 involving the hexaaquacobalt(II) ion[10] and AQ4 involving the tetrachlorocobaltate(II) complex of known structure.[11] In the fitting procedures, the Co–O and Co–Cl bond distances and the numbers of the relevant interactions were fixed at the interature values,[10,11] while the parameters σ, λ, a_0, and a_1 were optimized as independent variables.

The interatomic distances and Debye–Waller factors for the cobalt(II) complexes in DMF were then refined by adopting the phase function and the λ values in water evaluated above. The coordination numbers were fixed during the calculations at the given values in Table 2

Table 2. Results of the Least-Squares Refinements of Structure Parameters for Cobalt(II) Ion and Its Chloro Complexes in *N,N*-Dimethylformamide[a)]

Complex	Solution	Interaction	r/pm	σ/pm	n
$[Co(H_2O)_6]^{2+}$ (in water)	AQ0	Co–O	208[b,c)]	7.3(2)	6[b,c)]
$[Co(dmf)_6]^{2+}$ (in DMF)	DMF0	Co–O	206(1)	6.2(1)	6[b)]
$[CoCl_3(dmf)]^-$ (in DMF)	DMF3	Co–O	202(1)	6.7(6)	1[b)]
		Co–Cl	227(1)	5.1(1)	3[b)]
$[CoCl_4]^{2-}$ (in DMF)	DMF4	Co–Cl	229(1)	5.0(1)	4[b)]
$[CoCl_4]^{2-}$ (in water)	AQ4	Co–Cl	229[b,d)]	5.4(1)	4[b,d)]

Standard deviations are given in parentheses. a) λ_O=630(20) and λ_{Cl}=853(38) pm. b) The values were kept constant during the calculations. c) Ref. 10. d) Ref. 11.

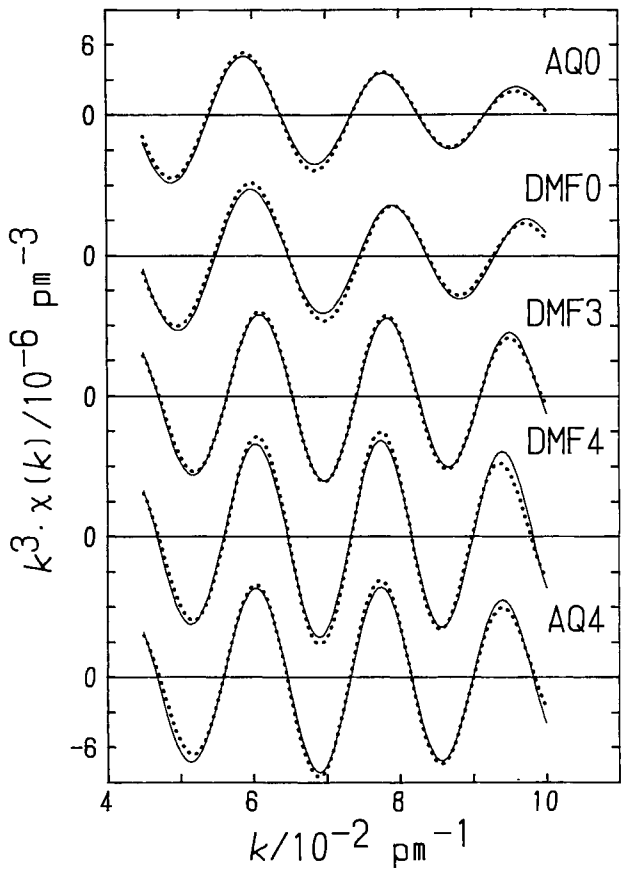

Fig. 4. The Fourier filtered $k^3 \cdot \chi(k)$ curves of the main peak depicted in Fig. 3. The observed values are shown by dots and ones calculated using parameter values in Table 2 by solid lines.

which are suggested by the spectrophotometric and calorimetric studies.[3)] This is reasonable because, when the coordination numbers were also optimized, the numbers converged to 6.2(2) for the Co–O (DMF) bonds of the solvated cobalt(II) ion (solution DMF0) and 4.4(2) for the Co–Cl bonds of the tetrachlorocobaltate(II) complex (solution DMF4), suggesting the six- and four-coordination structures, respectively. The final results are given in Table 2. The solid curves calculated by using the parameter values in the table well reproduce the experimental points, as shown in Fig. 4.

The solvated cobalt(II) ion in DMF has a six-coordinate octahedral structure and described as $[Co(dmf)_6]^{2+}$ similar to $[Co(H_2O)_6]^{2+}$ in water.[10)] The Co–O bond distance within $[Co(dmf)_6]^{2+}$ in DMF is 206(1) pm and is practically the same as that (208 pm) within $[Co(H_2O)_6]^{2+}$ in water[10)] within experimental uncertainties.

Both tri- and tetrachlorocobaltate(II) complexes in DMF have a four-coordinate tetrahedral structure. The Co–Cl bond distances within $[CoCl_4]^{2-}$ in DMF and in water[11)] are the same and 229(1) pm. The Co–Cl bond length within $[CoCl_3(dmf)]^-$ in DMF is 227(1) pm and is practically the same as that within $[CoCl_4]^{2-}$ in DMF within experimental uncertainties. On the other hand, the Co–O bond length within $[CoCl_3(dmf)]^-$ is 202(1) pm and shorter than that within six-coordinate $[Co(dmf)_6]^{2+}$. However, the distance is much longer than that (194 pm) within four-coordinate $[Co(hmpa)_4]^{2+}$ in hexamethylphosphoric triamide (HMPA).[22)].

Studies on the Secondary Structure of Bradykinin in Aqueous Solution. Syntheses, Circular Dichroism Spectra, and Biological Activities of Bradykinin Analogs Containing 5-Aminovaleric Acid Residue

Chikao HASHIMOTO,*,† Makoto TAMAKI,†† Shosuke SOFUKU, and Ichiro MURAMATSU
Department of Chemistry, College of Science, Rikkyo University,
Toshima-ku, Nishi-Ikebukuro, Tokyo 171
(Received November 14, 1990)

Eight bradykinin analogs containing 5-aminovaleric acid residue were synthesized by a solution method. Based on the consideration concerning their CD spectra, the presence of an intramolecular 3→1 hydrogen bond between the carbonyl oxygen of Ser^6 and the amide proton of Phe^8, an intramolecular 4→1 hydrogen bond between the carbonyl oxygen of Pro^2 and the amide proton of Phe^5, and a salt bridge between the guanidino group of Arg^1 and the carboxyl group of Arg^9, was proposed for the secondary structure of bradykinin in aqueous solution. The biological activities of these analogs depend on the presence of both Phe residues at positions 5 and 8, and Arg residues at positions 1 and 9. No correlation between the biological activities and the secondary structure could be found.

Bradykinin (BK) was discovered by Rocha e Silva et al.,[1] isolated by Elliott et al.,[2] and synthesized by Boissonnas et al.[3] This peptide shows mainly activities on uterus and smooth muscle contraction, pain, and blood pressure etc. To date, a large number of BK analogs have been prepared in order to examine the relationship between structure and activity. The secondary structure of BK in solution has been studied by several research groups. Initial studies on the secondary structure of BK were made by Bodanszky et al.[4] and Brady et al.[5] They suggested that BK existed in an extended conformation, namely a random coil, from the results of the ORD and CD spectra. From a study on the CD spectra of BK, its fragments, and model compounds, a secondary structure model of BK was proposed by Cann et al.[6] It has an intramolecular 3→1 hydrogen bond between the carbonyl oxygen of Ser^6 and the amide proton of Phe^8, which was considered to cause the CD band at 234 nm of the peptide. On the basis of studies by electron spin resonance and fluorescence energy transfer, Ivanov et al.[7] suggested ionic bond formation between the guanidino group of Arg^1 and the carboxyl group of Arg^9. A ^{13}C NMR study by London et al.[8] provided evidence for the existence of the 3→1 hydrogen bond, but not for the formation of a salt bridge. Chipens et al.[9] implied a certain similarity in the secondary structure between the BK and *cyclo*-BK analogs from studies of their CD spectra. In the past, we reported on preliminary results of a study of BK analogs containing a 5-aminovaleric acid (5-Ava) residue.[10-12]

In this paper we wish to report on the syntheses, the CD spectra, and the biological activities of eight BK analogs containing the 5-Ava residue shown in Table 1. When each sequence of two adjacent amino acid residues is replaced by one residue of 5-Ava, each amide group is substituted by an ethylene group, and each side chain by a hydrogen atom, respectively. The contributions of each amide bond and each side chain to the secondary structure and the biological activity of BK is discussed here on the basis of the results of the CD spectra and biological activities.

Table 1. Primary Sequences of Bradykinin and Eight Bradykinin Analogs Containing 5-Ava Residue

	1	2	3	4	5	6	7	8	9	
Bradykinin (BK)	H–Arg–	Pro–	Pro–	Gly–	Phe–	Ser–	Pro–	Phe–	Arg–	OH

Results and Discussion

Synthesis of BK Analogs Containing 5-Ava Residue. The synthetic methods for BK analogs containing the 5-Ava residue are shown in Figs. 1—8. All of them were synthesized by a solution method. Following protecting groups were used for synthesizing those compounds: Z[13] or Boc group for the α-amino groups; methyl, ethyl, or benzyl ester group for the carboxyl groups; and nitro group for the guanidino group of arginine. The hydroxyl group of serine was not protected. The above-mentioned protecting groups were deprotected by the following methods: HCl/THF, HCl/dioxane, or TFA for Boc group, HBr/AcOH or H_2/Pd for Z group, saponification for methyl and ethyl ester groups, and H_2/Pd for benzyl ester and nitro groups. For peptide bond formation, DCC,[14] DCC/HOBt,[15]

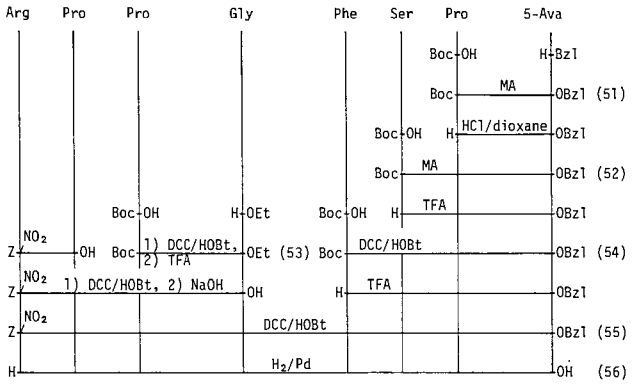

Fig. 8. Synthetic scheme of [5-Ava$^{8-9}$]-BK.

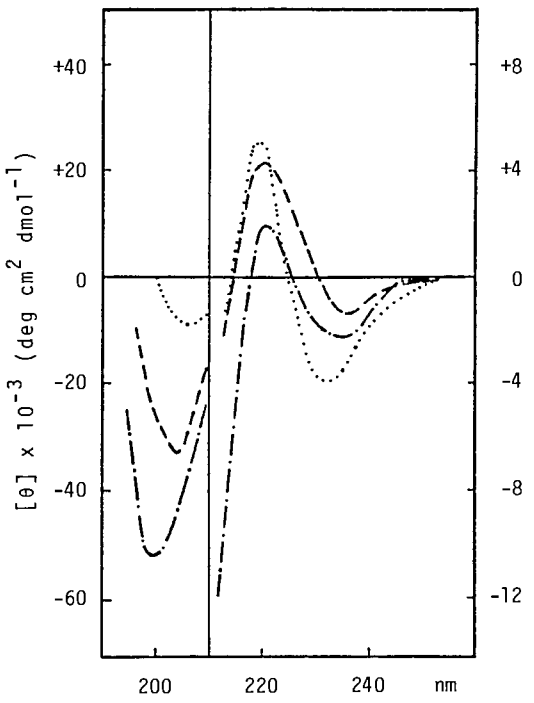

Fig. 9. CD spectra of [5-Ava$^{3-4}$]-BK (**26**) (·····), [5-Ava$^{5-6}$]-BK (**37**) (————), and [5-Ava$^{8-9}$]-BK (**56**) (—·—·—) in water.

MA,[16] azide,[17] active ester,[18] and symmetrical anhydride methods were employed. The final deprotection of protected [5-Ava$^{1-2}$]-BK (**8**), [5-Ava$^{2-3}$]-BK (**15**), [5-Ava$^{4-5}$]-BK (**31**), [5-Ava$^{5-6}$]-BK (**36**), [5-Ava$^{7-8}$]-BK (**49**), and [5-Ava$^{8-9}$]-BK (**55**) was carried out by catalytic hydrogenation. On the other hand, deprotection of protected [5-Ava$^{3-4}$]-BK (**25**) and [5-Ava$^{6-7}$]-BK (**45**) was performed by saponification followed by catalytic hydrogenation.

In coupling of the carboxyl group of 5-Ava, a mixed anhydride method gave some by-products; a DCC method did not afford the expected product. A symmetrical anhydride and DCC/HOBt methods gave satisfactory results. Purification of protected octapeptides was performed by gel filtration on a Sephadex LH-20 column using DMF as the eluent. Free peptides were purified by ion-exchange chromatography on a carboxymethyl cellulose column, gel filtration on a Sephadex G-10 column, and partition chromatography on a Sephadex G-25 column.[19] The purity of all products was confirmed by TLC, elemental analysis, and amino acid analysis. Table 2 shows physical data concerning other compounds, except for those described in the experimental section.

CD Spectra of BK Analogs Containing 5-Ava Residue. The CD spectra were measured in the region of about 190 to 270 nm in aqueous solution. The data are reported as molar ellipticity, [θ], which is expressed in degree square centimeter per decimole.

The CD spectrum of BK shows a negative band at 234 nm, a positive band at 221 nm, and a deep negative band at about 200 nm (Fig. 11). The CD spectra of the BK analogs containing the 5-Ava residue are classified into three types in the region 210—260 nm. The CD spectra of [5-Ava$^{3-4}$]-BK (**26**), [5-Ava$^{5-6}$]-BK (**37**), and [5-Ava$^{8-9}$]-BK (**56**) (Fig. 9) show a negative band near 234 nm and a positive band near 221 nm, resembling that of BK. In the region near 200 nm, [5-Ava$^{3-4}$]-BK shows a considerably shallower trough, as compared with that of BK. The CD spectra of [5-Ava$^{1-2}$]-BK (**9**), [5-Ava$^{2-3}$]-BK (**16**), and [5-Ava$^{4-5}$]-BK (**32**) (Fig. 10) near 234 nm are similar to that of BK, although their peak near 221 nm is lower. Concerning the negative band near 200 nm, [5-Ava$^{1-2}$]-BK and [5-Ava$^{2-3}$]-BK show a much shallower trough. The CD spectra of [5-Ava$^{6-7}$]-BK (**46**) and [5-Ava$^{7-8}$]-BK (**50**) (Fig. 11) do not show a negative band at 234 nm and exhibit a simple peak near 221 nm. The ellipticity of [5-Ava$^{6-7}$]-BK is very large. Regarding the negative band near 200 nm, the ellipticity of [5-Ava$^{7-8}$]-BK is similar to that of BK, although that of [5-Ava$^{6-7}$]-BK is small.

In [5-Ava$^{6-7}$]-BK and [5-Ava$^{7-8}$]-BK, the absence of the negative band at 234 nm suggests that both the amide bonds of Ser^6–Pro^7 and Pro^7–Phe^8 of BK relate to this negative band. That is, these two analogs can

a) Compound **1**[24] has mp 155—157 °C; **2**[24] mp 85—92 °C; **4**[24] mp 155.5—159 °C; **6**[24] mp 110—113 °C; **11**[25] mp 67—69 °C; **17**[26] mp 152—155 °C; **18**[3] mp 126—129 °C; **19**[26] mp 135—138 °C; **20**[3] mp 189 °C; **22**[27] mp 162—164 °C; **24**[28] mp 114—117 °C; **33**[29] mp 87—90 °C; **39**[26] oil; **42**[26] mp 143.5—144 °C. Compound **21** produced in 62% yield; **47** 40% yield; **48** 66% yield; **49** 45% yield: other data of these compounds are unlisted. b) The solvent systems were described in experimental section. Silica-gel plate was used for TLC except when noted herein. c) At 19 °C. d) At 20 °C. e) At 21 °C. f) At 22 °C. g) At 25.5 °C.

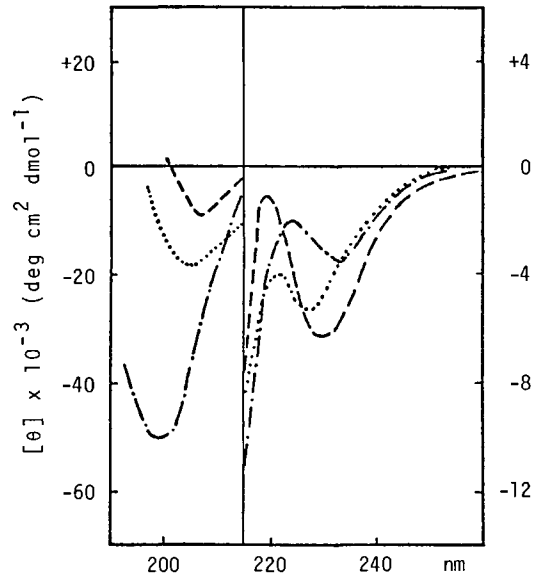

Fig. 10. CD spectra of [5-Ava[1-2]]-BK (**9**) (·····), [5-Ava[2-3]]-BK (**16**) (————), and [5-Ava[4-5]]-BK (**32**) (—·—·—) in water.

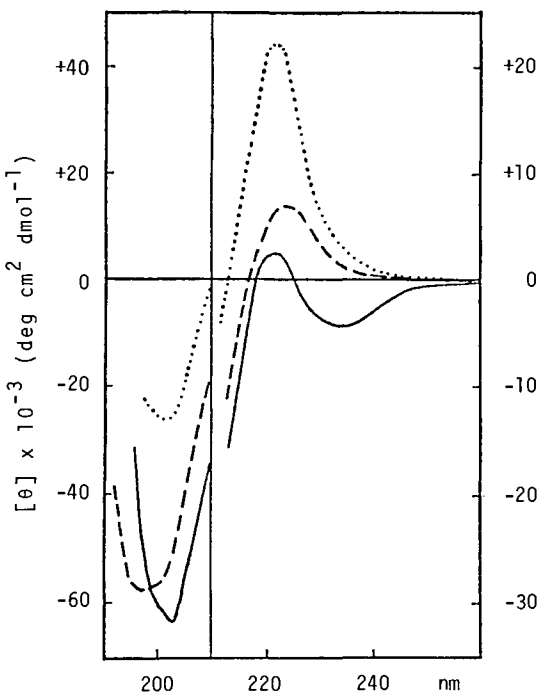

Fig. 11. CD spectra of BK (————), [5-Ava[6-7]]-BK (**46**) (·····), and [5-Ava[7-8]]-BK (**50**) (————) in water.

not form an intramolecular 3→1 hydrogen bond between the carbonyl oxygen of Ser[6] and the amide proton of Phe[8] as the result of replacement with the 5-Ava residue. The existence of the hydrogen bond in the BK molecule was pointed out by Cann et al.[6] Our result provides additional evidence for the formation of the intramolecular 3→1 hydrogen bond.

Cann et al. indicated the importance of an N-terminal sequence and Phe residues as a contribution for the positive band at 221 nm, suggesting an intramolecular 3→1 hydrogen bond between the carbonyl oxygen of Pro^2 and the amide proton of Gly^4.[6] Ivanov et al. proposed four energetically preferable BK-conformers which contain the salt bridge.[7] One of them forms an intramolecular 4→1 hydrogen bond between the carbonyl oxygen of Pro^2 and the amide proton of Phe^5 in the molecule. Although the positive band near 221 nm is generally referred to as arising from a Phe residue, the present result suggests that both amide bonds of Pro^2–Pro^3 and Gly^4–Phe^5 also contribute to this band. This result may be explained by supposing the formation of a partial structure stabilized with the intramolecular 4→1 hydrogen bond. Also, the similarity of the positive bands of [5-Ava^{3-4}]-BK and BK appears to make the 3→1 hydrogen bond in N-terminal sequence unlikely. In addition, the peak of [5-Ava^{1-2}]-BK, which lacks the strongly basic group on the side chain of Arg^1, is lower than those of [5-Ava^{2-3}]-BK and [5-Ava^{4-5}]-BK. This may be due to a change of secondary structure, owing to an impossibility to form the salt bridge between the guanidino group of Arg^1 and the C-terminal carboxyl group, proposed by Ivanov et al.[7] The similarity of the positive bands near 220 nm of BK-amide and [5-Ava^{1-2}]-BK implies the presence of the salt bridge in BK.[12] That is, the stability of the intramolecular 4→1 hydrogen bond is lowered by the incapability of salt-bridge formation because of a blocking of the C-terminal carboxyl group. This impossibility may bring about a decrease of ellipticity near 221 nm. The similarity between the peaks of BK and [5-Ava^{8-9}]-BK, in which the formation of salt bridge is possible, supports this supposition.

The analogs, (in which each sequence of Arg^1–Pro^2, Pro^2–Pro^3, Pro^3–Gly^4, Phe^5–Ser^6, and Ser^6–Pro^7 was replaced with a 5-Ava residue), show a shallower trough near 200 nm, as compared with that of BK; that is, this band probably arises mainly from the both sequences of Arg^1–Pro^2–Pro^3–Gly^4 and Phe^5–Ser^6–Pro^7 in BK.

The contributions for each CD band of BK are suggested as follows: the intramolecular 3→1 hydrogen bond for 234 nm band, Phe residues and the intramolecular 4→1 hydrogen bond for 221 nm band, and the both sequences of Arg^1–Pro^2–Pro^3–Gly^4 and Phe^5–Ser^6–Pro^7 for about the 200 nm band. Much smaller ellipticities of BK, compared with other peptides carrying a rigid conformation, such as gramicidin S, may reflect a higher flexibility in the backbone structure of BK.

Biological Activities of BK Analogs Containing 5-Ava Residue. The biological activities of these analogs were examined for uterus contraction of rat and blood flow of dog. The results shown in Table 3 are expressed as relative activity compared with the threshold dose of BK. [5-Ava^{1-2}]-BK, [5-Ava^{4-5}]-BK, [5-Ava^{5-6}]-BK, [5-Ava^{7-8}]-BK, and [5-Ava^{8-9}]-BK have no activity, while [5-Ava^{2-3}]-BK, [5-Ava^{3-4}]-BK, and [5-Ava^{6-7}]-BK indicate some of the activity, although very weak compared with that of BK. It has been known that the biological activity of BK analogs are drastically reduced by substitution of both or one of the Arg residue at positions 1 and 9 with a neutral amino acid or acidic amino acid residue, whereas the substitution of the Arg residue with other basic amino acids preserves considerable biological activities. [5-Ava^{1-2}]-BK and [5-Ava^{8-9}]-BK lack in Arg residue at positions 1 and 9, respectively. The present results also emphasize the importance of these two basic amino acid residues regarding biological activity. One or two of the Phe residues at positions 5 and 8 in BK can be substituted with an amino acid containing a restricted side chain, such as tyrosine methyl ether and 3-cyclohexylalanine, without any striking change regarding the biological activities.[20,21] However, replacement of the Phe residue by an aliphatic amino acid residue, such as the Ala, Leu, or Ile residue, results in a loss of activity.[21-23] [5-Ava^{4-5}]-BK, [5-Ava^{5-6}]-BK, [5-Ava^{7-8}]-BK, and [5-Ava^{8-9}]-BK did not show any biological activity. These results indicate similarly the importance for biological activity of the Phe residues at positions 5 and 8.

It is an interesting problem to elucidate the relationship between the structure in an aqueous solution and the activities of BK. [5-Ava^{3-4}]-BK, in which the peptide bond substituted with 5-Ava residue does not take part in the intramolecular 4→1 hydrogen bond, showed biological activity. Also, [5-Ava^{2-3}]-BK and [5-Ava^{6-7}]-

Table 3. Biological Activities of Eight Bradykinin Analogs Containing 5-Ava Residue

Compound	Blood flow[a] (dog, femoral artery)	Uterus contraction[b] (rat, isolated)
Bradykinin (BK)	1	1
[5-Ava^{1-2}]-BK (**9**)	Inactive	Inactive
[5-Ava^{2-3}]-BK (**16**)	4×10^{-5}	1×10^{-2}
[5-Ava^{3-4}]-BK (**26**)	1×10^{-3} [c]	1×10^{-3}
[5-Ava^{4-5}]-BK (**32**)	Inactive	Inactive
[5-Ava^{5-6}]-BK (**37**)	Inactive	Inactive
[5-Ava^{6-7}]-BK (**46**)	1×10^{-2}	1×10^{-3}
[5-Ava^{7-8}]-BK (**50**)	Inactive	Inactive
[5-Ava^{8-9}]-BK (**56**)	Inactive	Inactive

a) The threshold dose of BK: 1×10^{-9} g (=1). b) The threshold dose of BK: 1×10^{-9} g ml^{-1} (=1). c) Rat.

BK have biological activity, although not so strong as that of BK, in spite of an absence of the carbonyl oxygen of Pro^2 or Ser^6, which participates in the intramolecular 4→1 hydrogen bond or the intramolecular 3→1 hydrogen bond, respectively. These results imply that the biological activities of BK are affected by the absence of Arg and Phe residues, rather than the one of the intramolecular hydrogen bonds. On account of the structural flexibility of these linear peptides, a number of conformers may exist in equilibrium in solution. Therefore, the contribution of secondary structure for biological activity is ambiguous. We could not find any appreciable relationship between the CD spectra and the biological activities.

Experimental

Melting points were measured by a micro melting-point apparatus (Yanagimoto MFG Co.) and are given as uncorrected values. Optical rotations were determined with a polarimeter 111 (Shimadzu Co.). Amino acid analyses were performed on a JLC-6AS automatic analyzer (JEOL) after acid hydrolysis with 6 M (1 M=1 mol dm^{-3}) HCl in a sealed tube at 110 °C for 16—24 h. The theoretical values of the amino acid ratios are shown in parentheses after each result.

Thin-layer chromatography was performed on a TLC plate of silica gel 60 F_{254} (Merck and Co.) or cellulose (Avicel), using the following solvent systems (volume ratios): R_f^1, chloroform–methanol (9:1); R_f^2, chloroform–methanol–acetic acid (95:5:3); R_f^3, chloroform–methanol–acetic acid (95:15:3); R_f^4, chloroform–methanol–acetic acid (9:1:1); R_f^5, 1-butanol–acetic acid–water (4:1:1); R_f^6, 1-butanol–pyridine–acetic acid–water (15:10:3:12); R_f^7, 1-butanol–pyridine–acetic acid–water (16:3:1:4); R_f^8, 1-butanol–pyridine–acetic acid–water (4:1:1:2); R_f^9, 1-butanol–pyridine–acetic acid–water (16:10:3:12); R_f^{10}, 1-butanol–pyridine–water–ethanol (4:1:5:4). Silica-gel plate was used for TLC if not mentioned otherwise.

CD measurements were performed using a JASCO J-20 CD, ORD spectropolarimeter at 21—23 °C. A 0.50-mm thick cell was used. The measurements were carried out at concentrations of $(3.2—4.2)\times10^{-4}$ M and at pH 5.49—7.30.

Female rats weighing 180—250 g were used in order to assay the ability for the contraction of isolated rat uterus. A uterus horn applied to the load-tension of 0.5 g was suspended in an organ-bath of de Jalon's solution (10 ml) at 26 °C. The uterus contractions caused by the addition of BK analogs were recorded as isometric data using a JD-111S physiological displacement transducer (Nihonkoden Kogyo Co.). A dose-response curve was obtained in the concentration range of 3×10^{-6}—1×10^{-5} g ml^{-1} by using a cumulative method.

After a dog was anesthetized with sodium pentobarbital (30 mg kg^{-1}), hepaline was injected into a vein. The blood flow in the femoral artery of the dog was measured by using an electromagnetic blood flowmeter. The injection-volume into the artery of the BK analogs was $(1—3)\times10^{-5}$ l, and the administration range of these was $2\times(10^{-6}—10^{-4})$ g.

N^{α}-Boc groups were removed by TFA, HCl/THF, or HCl/dioxane with or without anisole, respectively. The reaction was run in an ice-bath or at room temperature according to the requisite. The concentration of HCl in the solution was kept above 2.5 M and at 10—30 equivalents for each peptide. N^{α}-Z groups were removed by H_2/Pd in an acidic solution at room temperature or the treatment with 25% HBr/AcOH for 1.0—2.5 h at room temperature. The symmetrical anhydrides described in the schemes were prepared by DCC. The protected products were purified by the usual methods. Only the typical procedures are herein described.

Z-5-Ava-Pro-Gly-Phe-Ser-Pro-Phe-Arg(NO_2)-OBzl (8) by a DCC/HOBt Method. The deprotection of **6** (0.719 g) with TFA (7.0 ml) and anisole (0.50 ml) in the usual manner gave an oily residue. DCC (0.239 g) in DMF (2.0 ml), and an ice-chilled solution of the above residue and NMM (0.349 ml) in DMF (8.0 ml) were added to an ice-cooled solution of **7** (0.427 g) and HOBt (0.285 g) in DMF (7.0 ml). The mixture was stirred for 1 h in an ice-bath and then for 41 h at room temperature. After the precipitates were removed, the solvent was evaporated. The residue was dissolved in ethyl acetate. The ethyl acetate solution was washed by the routine method. After removing the solvent, the residue was crystallized from diethyl ether. The crude product was further recrystallized from ethyl acetate–diethyl ether: Yield 0.640 g (67%); mp 103—106.5 °C; $[\alpha]_D^{24}$ −31.5° (*c* 0.5, DMF); R_f^1 0.71, R_f^4 0.70, R_f^5 0.80, R_f^8 0.77. Amino acid ratios in acid hydrolyzate: Ser 0.83 (1), Pro 2.21 (2), Gly 1.03 (1), Phe 1.81 (2), 5-Ava 1.19 (1), Arg+Orn 0.93 (1). Found: C, 59.85; H, 6.75; N, 14.01%. Calcd for $C_{59}H_{74}O_{14}N_{12}$: C, 60.29; H, 6.35; N, 14.30%.

Z-5-Ava-Gly-OEt (10) by a Symmetrical Anhydride Method. $(Z\text{-}5\text{-}Ava)_2O$ (3.03 g) was added to a solution of HCl·H-Gly-OEt (1.12 g) and Et_3N (2.50 ml) in chloroform (30 ml). After stirring for 2 d, the solvent was evaporated. The residue was dissolved in ethyl acetate. The organic layer was washed using the usual method. After evaporation of the solvent, the residue was recrystallized from ethyl acetate: Yield 0.81 g (35%); mp 62—64.2 °C; $[\alpha]_D^{24}$ −12.8° (*c* 0.265, DMF); R_f^1 0.59. Found: C, 60.22; H, 7.28; N, 8.86%. Calcd for $C_{17}H_{24}O_5N_7$: C, 60.70; H, 7.19; N, 8.33%.

Boc-5-Ava-Ser-$NHNH_2$ (28). Compound **27** (4.210 g) was dissolved in methanol (12.0 ml), and to this solution was added 80% $NH_2NH_2\cdot H_2O$ (8.05 ml). The mixture was stirred for 45 h at room temperature. The resulting crystals were collected, then washed onto a filter funnel with methanol–diethyl ether (1:1), and further triturated with ethanol: Yield 3.483 g (83%); mp 171—173.5 °C; $[\alpha]_D^{24}$ −1.0° (*c* 1.0, DMF); R_f^8 0.65. Amino acid ratios in acid hydrolyzate: Ser 0.92 (1), 5-Ava 1.08 (1). Found: C, 49.01; H, 8.81; N, 17.65%. Calcd for $C_{13}H_{26}O_5N_4$: C, 49.04; H, 8.23; N, 17.60%.

Boc-5-Ava-Ser-Pro-Phe-Arg(NO_2)-OBzl (29) by an Azide Method. The treatment of **2** (1.961 g) in dioxane (11.1 ml) with 5.04 M HCl/dioxane (11.90 ml) in the presence of anisole (1.0 ml) for 1 h in an ice-bath gave a solid. A solution of **28** (0.952 g) in DMF (12 ml) was cooled below −30 °C. To the solution were added 5.04 M HCl/dioxane (1.79 ml) and isopentyl nitrite (0.402 ml) with stirring. The mixture was stirred for 15 min at −22 °C and then chilled below −30 °C. To the mixture were added Et_3N (1.25 ml) and an ice-chilled solution of the above solid and Et_3N (0.42 ml) in DMF (11 ml). After stirring for ca. 3 d, the solvent was evaporated. The residue was dissolved in ethyl acetate. The organic layer was washed using the usual procedure. After concentration of the solution, the residue was crystallized from diethyl ether. The product was further recrystallized from ethanol–diethyl ether:

Yield 2.156 g (86%); mp 110.5—114.5°C; $[\alpha]_D^{24}$ −36.7° (*c* 0.5, DMF); R_f^1 0.38, R_f^5 0.90. Amino acid ratios in acid hydrolyzate: Ser 0.93 (1), Pro 1.05 (1), Phe 0.99 (1), 5-Ava 1.12 (1), Arg+Orn 0.91 (1). Found: C, 56.60; H, 6.84; N, 15.19%. Calcd for $C_{40}H_{57}O_{11}N_9 \cdot 1/2H_2O$: C, 56.59; H, 6.89; N, 14.85%.

Boc-Pro-5-Ava-Ser-Pro-Phe-Arg(NO_2)-OBzl (30) by an MA Method. Compound **29** (0.400 g) was treated with TFA (4.0 ml) for 50 min to yield a solid in the usual manner. Boc-Pro-OH (0.103 g) was dissolved in THF (2.0 ml) and the solution was chilled below −40 °C. NMM (0.053 ml) and ethyl chloroformate (0.046 ml) were added to this solution. The mixture was stirred for 5 min at −13—−15 °C, and then chilled below −40°C. To the mixture was added an ice-chilled solution of the above solid and NMM (0.083 ml) in DMF (3.5 ml). The mixture was stirred in an ice-bath and then at room temperature for 22 h. After evaporation of the solvent, the residue was dissolved in ethyl acetate. The organic layer was washed in the usual method. After the solution was concentrated, the residue was recrystallized from ethyl acetate–diethyl ether: Yield 0.309 g (69%); mp 103.5—107.5 °C; $[\alpha]_D^{24}$ −45.5° (*c* 0.5, DMF); R_f^1 0.49, R_f^5 0.80. Amino acid ratios in acid hydrolyzate: Ser 0.86 (1), Pro 1.97 (2), Phe 1.04 (1), 5-Ava 1.15 (1), Arg+Orn 0.98 (1). Found: C, 56.13; H, 6.87; N, 14.39%. Calcd for $C_{45}H_{64}O_{12}N_{10} \cdot H_2O$: C, 56.59; H, 6.97; N, 14.67%.

Z-Arg(NO_2)-Pro-Pro-Gly-OH (35). To an ice-chilled solution of **33** (0.506 g) in ethanol (3.0 ml) was added 1.90 M NaOH (0.85 ml). The mixture was stirred for 30 min at room temperature and then 1 M HCl (1.70 ml) was added to this solution in an ice-bath. After evaporation of ethanol, to the residual solution were added ethyl acetate and 5% Na_2CO_3. The aqueous layer was acidified with concd HCl in an ice-bath, and then saturated with NaCl. It was extracted with ethyl acetate and the organic layer was washed with water saturated with NaCl. The aqueous layer was further extracted with ethyl acetate in the same manner. The organic layers were combined and the solvent was evaporated. The residue was crystallized from diethyl ether: Yield 0.463 g (96%); mp 112.5—118 °C; $[\alpha]_D^{24}$ −54.8° (*c* 0.5, DMF); R_f^4 0.17, R_f^5 0.47. Amino acid ratios in acid hydrolyzate: Pro 2.21 (2), Gly 0.79 (1), Arg+Orn 0.60 (1). Found: C, 47.96; H, 5.69; N, 16.69%. Calcd for $C_{26}H_{36}O_9N_8 \cdot 3H_2O$: C, 47.41; H, 6.42; N, 17.01%.

Z-Pro-Gly-Phe-5-Ava-Phe-Arg(NO_2)-OMe (43) by an Active Ester Method. Compound **40** (1.52 g) was treated with 25% HBr/AcOH (3.0 ml) for 1 h at room temperature to afford a solid in the usual way. Compound **42** (0.890 g) was added to a solution of the above solid, Et_3N (0.30 ml), and NMM (0.60 ml) in DMF (5.0 ml). After stirring for 7 d at room temperature, water (200 ml) was added to this mixture. The resulting precipitates were washed onto a filter funnel as usual. The crude product was washed with ethyl acetate, and then recrystallized from ethanol. The product was washed with diethyl ether: Yield 0.960 g (53%); mp 140—143 °C; $[\alpha]_D^{19.5}$ −25.0° (*c* 1.0, DMF); R_f^2 0.32. Found: C, 58.90; H, 6.67; N, 15.35%. Calcd for $C_{45}H_{58}O_{11}N_{10}$: C, 59.07; H, 6.39; N, 15.31%.

H-Arg-Pro-Pro-Gly-Phe-Ser-Pro-5-Ava-OH (56). Compound **55** (201 mg) in a solution of DMF–water–acetic acid (10 – 5 – 1 ml) was hydrogenated over palladium black for 7 d. Water (14 ml) was added to the mixture during the hydrogenation. After the catalyst was removed, the solution was concentrated. The residue was dissolved in ammonium acetate buffer (0.04 M, pH 6.0) (3.0 ml) and subjected to a carboxymethyl cellulose column (1.7×22.3 cm; Whatman CM-52). It was eluted with ammonium acetate buffers (0.04—0.40 M, pH 6.0) by a linear gradient method. Fractions of 3.0 g each were collected and checked by UV absorption at 254 nm, TLC, and amino acid analysis. Fractions 37—42 were combined and concentrated. The residue was dissolved in 4% acetic acid (2.0 ml) and applied to a Sephadex G-10 column (1.7×41 cm) using the same solvent. Fractions 11—17 (2.5 g each) were combined and concentrated. For further purification, the residue was dissolved in 1-butanol–pyridine–acetic acid–water (16 : 10 : 3 : 12) (1.0 ml) and applied to a column (1.7×26.0 cm) of Sephadex G-25. Fractions 12—25 (3.0 g each), including a pure peptide, were combined and concentrated. The residue was lyophilized from water: Yield 72.7 mg (42%); $[\alpha]_D^{22}$ −97.7° (*c* 0.1, H_2O); R_f^9 0.62 (cellulose). Amino acid ratios in acid hydrolyzate: Ser 0.89 (1), Pro 3.07 (3), Gly 0.98 (1), Phe 1.00 (1), 5-Ava 1.14 (1), Arg 0.92 (1). Found: C, 52.60; H, 6.76; N, 16.10%. Calcd for $C_{40}H_{61}O_{10}N_{11} \cdot CH_3COOH \cdot 2H_2O$: C, 52.98; H, 7.30; N, 16.18%.

The authors are grateful to the Research Laboratory of Toyo Jozo Co., Ltd. for the elemental and amino acid analyses. We would also like to thank Toyo Jozo Co., Ltd. for the biological assays of uterus contraction of compounds **9** and **56**, and the Research Laboratory of Nihon Kayaku Co., Ltd. for obtaining the other biological-activity data.

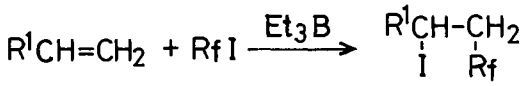
Triethylborane Induced Perfluoroalkylation of Silyl Enol Ethers and Ketene Silyl Acetals with Perfluoroalkyl Iodides

Katsukiyo MIURA, Yoshihiro TAKEYAMA, Koichiro OSHIMA,* and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 6, 1990)

Reaction of perfluoroalkyl iodides with silyl enol ethers mediated by Et_3B in the presence of base such as 2,6-dimethylpyridine provides mixtures of perfluoroalkylated trialkylsilyl enol ethers and α-perfluoroalkylated ketones. The yield and distribution of the products heavily depend on the nature of base employed. Treatment of a reaction mixture consisting of perfluoroalkylated silyl enol ether and α-perfluoroalkylated ketone with concd HCl in THF gives α-perfluoroalkylated ketone as a single product. Reaction of ketene silyl acetals with perfluoroalkyl iodides in the absence of base affords α-perfluoroalkylated esters in excellent yields.

Recently, much attention has been paid to a method of introducing a perfluoroalkyl chain to a carbonyl compound and several reports have appeared in the literature.[1] The methods, however, have some drawbacks and there is still a need for a new method preparing perfluoroalkylated compounds from carbonyl compounds such as aldehydes, ketones, and esters. Previously we have reported that Et_3B induced the successful addition of perfluoroalkyl iodides to acetylenes and olefins (Scheme 1).[2] Here we report further exploitation of this method to (1) the reaction of perfluoroalkyl iodides with trialkylsilyl enol ethers providing perfluoroalkylated silyl enol ethers[3] and (2) the reaction of perfluoroalkyl iodides with ketene silyl acetals affording perfluoroalkylated esters.

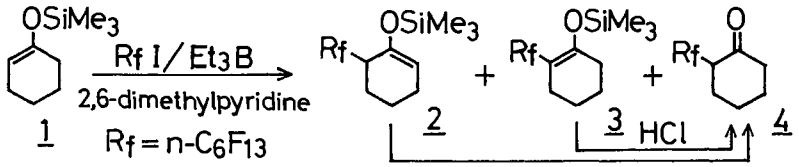


Scheme 1.

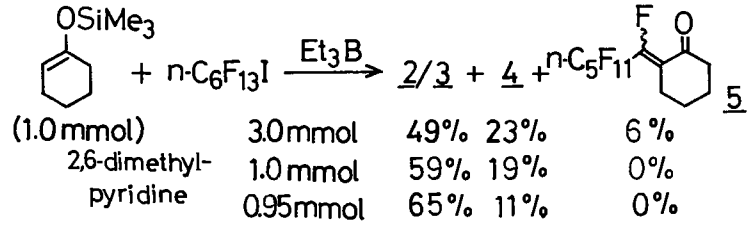
(1) The Reaction of Perfluoroalkyl Iodides with Trialkylsilyl Enol Ethers. Treatment of a hexane solution of 1-trimethylsiloxy-1-cyclohexene (**1**) and perfluorohexyl iodide with a catalytic amount of triethylborane[4] in the presence of base such as 2,6-dimethylpyridine gave a mixture of perfluoroalkylated silyl enol ether (**2** and **3**) and 2-(perfluorohexyl)cyclohexanone (**4**)[1d] in 76% combined yield (**2**+**3**/**4**=86/14, Scheme 2).

The distribution of the products heavily depends on the nature of base employed. The base and the yields of **2**+**3** (ratio of **2**/**3**) and **4** in the reaction between 1-trimethylsiloxy-1-cyclohexene (**1**) and perfluorohexyl iodide are given below: Et_3N, 47 (59/41), 26; 2,2,6,6-tetramethylpiperidine, 63 (68/32), 11; hexamethyldisilazane, 24 (0/100), 44; pyridine, 0, 20; diisopropylethylamine, 12 (65/35), 29. The amount of base also affected the distribution of the products (Scheme 3). The presence of excess base (2,6-dimethylpyridine, 3.0 mmol per 1.0 mmol of silyl enol ether) caused the formation of 2-(perfluorohexylidene)cyclohexanone **5** in 6% yield along with **2**+**3** (49%) and **4** (23%). The use of slightly deficient amount of 2,6-dimethylpyridine suppressed the formation of **5**. The representative results using 2,6-dimethylpyridine (0.95 mmol per 1.0 mmol of silyl enol ether) as a base are summarized in Table 1.

The use of triisopropylsilyl enol ether **6** instead of trimethylsilyl enol ether **1** gave better yields of perfluoroalkylated silyl enol ethers **7** and **8** with less contamination by 2-(perfluoroalkyl)cyclohexanones **4** (Runs 3 and

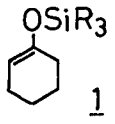


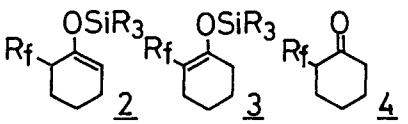
Scheme 2.

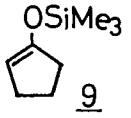


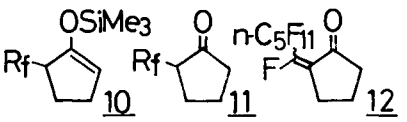
Scheme 3.

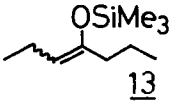
Table 1. Reaction of Silyl Enol Ether with Perfluoroalkyl Iodide[a)]

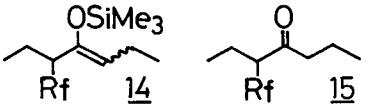
Run	Silyl enol ether		R_fI	Product (%)		
						


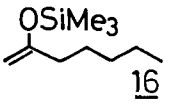


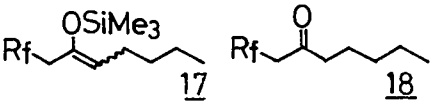
1		R=Me	n-$C_6F_{13}I$	44	21	11
2		R=Me	i-C_3F_7I	41	11	9
3		**6**: R=*i*-Pr	n-$C_6F_{13}I$	57 (**7**)	14 (**8**)	<5
4		R=*i*-Pr	i-C_3F_7I	47	25	<2
						


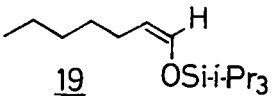


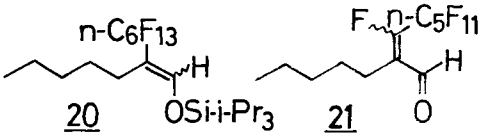
5			n-$C_6F_{13}I$	35	26	3
						




6			n-$C_6F_{13}I$	71 (E/Z=60/40)		16
7			i-C_3F_7I	66 (E/Z=70/30)		<2
						




8			n-$C_6F_{13}I$	54 (E/Z=28/72)		24
9			i-C_3F_7I	56 (E/Z=33/67)		15
						




10			n-$C_6F_{13}I$	38 (88/12)[b)]		46 (71/29)[b)]

a) Silyl enol ether (2.0 mmol), perfluoroalkyl iodide (2.6 mmol), 2,6-dimethylpyridine (1.90 mmol), and triethylborane (0.4 mmol) were employed. b) Stereochemistry could not be determined.

4). Treatment of 1-trimethylsiloxy-1-cyclopentene **9** with perfluorohexyl iodide gave a mixture of 5-(perfluorohexyl)-1-trimethylsiloxy-1-cyclopentene **10**, 2-(perfluorohexyl)cyclopentanone **11**, and 2-(perfluorohexylidene)cyclopentanone **12** in 35, 26, and 3% yields, respectively. 2-(Perfluorohexyl)-1-trimethylsiloxy-1-cyclopentene was not detected in the reaction mixture. The reaction proceeded with acyclic silyl enol ether as well as cyclic silyl enol ether. In the case of silyl enol ether **13** or **16**, derived from acyclic ketone such as 4-heptanone or 2-heptanone, 5-(perfluoroalkyl)-4-trimethylsiloxy-3-heptenes **14** or 1-(perfluoroalkyl)-2-trimethylsiloxy-2-heptenes **17** was obtained as a single regioisomer as the reaction of 1-trimethylsiloxy-1-cyclopentene **9**. The other isomeric silyl enol ether (3-(perfluoroalkyl)-4-trimethylsiloxy-3-heptene or 1-(perfluoroalkyl)-2-trimethylsiloxy-1-heptene) was not observed in the reaction mixture. Reaction of silyl enol ether **19** derived from heptanal afforded a mixture of 2-(perfluoroalkyl)-1-triisopropylsiloxy-1-heptene **20** and 2-(perfluorohexylidene)heptanal **21**.

Treatment of the reaction mixture consisting of **2**, **3**, and **4** with concd hydrochloric acid in THF at 25 °C for 10 min afforded 2-(perfluoroalkyl)cyclohexanone **4** as a single product in 74% overall yield. The yields of perfluoroalkylated carbonyl compounds after acidic workup were 78, 73, and 56% for the reaction described in Runs 6, 8, and 9.

Trifluoromethylated organic compounds are of importance from the biological point of view.[5)] Thus, we focussed our attention on trifluoromethylation of carbonyl compounds and examined the reactions of silyl

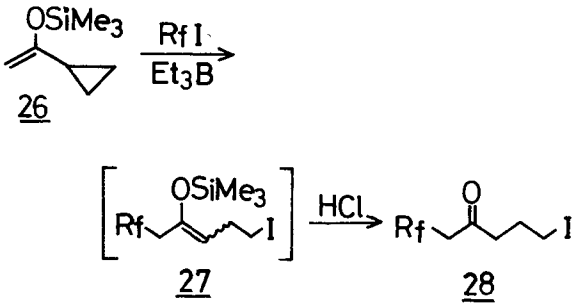
Table 2. Reaction of Silyl Enol Ether with CF_3I or CF_3CH_2I

Silyl enol ether (1.0 mmol)	R–X (mmol)	Reaction time/h	Product	Y/%
 22	CF_3I (10)	40	CF_3CH_2CO-*n*-C_9H_{19} **23a**	64
	CF_3CH_2I (2)	15	$CF_3(CH_2)_2CO$-*n*-C_9H_{19} **23b**	79
 24	CF_3I (10)	48	*n*-$C_4H_9CH(CF_3)CO$-*n*-C_5H_{11} **25a**	32
	CF_3CH_2I (2)	20	*n*-$C_4H_9CH(CH_2CF_3)CO$-*n*-C_5H_{11} **25b**	4

enol ether with trifluoromethyl iodide or 2,2,2-trifluoroethyl iodide (Table 2). Treatment of terminal silyl enol ether **22** with excess trifluoromethyl iodide or 2,2,2-trifluoroethyl iodide gave 1,1,1-trifluoro-3-dodecanone **23a** or 1,1,1-trifluoro-4-tridecanone **23b** in 64 or 79% yield, respectively after quenching the reaction mixture by concd HCl. Meanwhile, the reaction of internal silyl enol ether such as **24** with CF_3I or CF_3CH_2I gave the corresponding trifluoro ketone **25a** or **25b** in poor yield.

Reaction of **26** prepared from cyclopropyl methyl ketone with perfluoroalkyl iodides followed by treatment with concd HCl provided the corresponding 5-iodo-1-(perfluoroalkyl)-2-pentanones under cleavage of cyclopropane ring.[6] The reaction proceeded without base such as 2,6-dimethylpyridine. The intermediary silyl enol ether **27b** was isolated in the reaction of **26** with *i*-C_3F_7I in 85% yield (Scheme 4).

Thus, a new method provided us with a synthetic tool

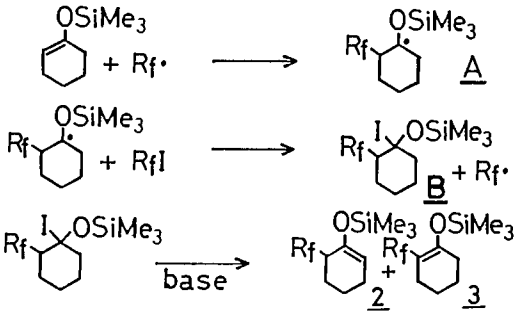


R_f a: *n*-C_6F_{13} 25°C 20 min 88%
b: *i*-C_3F_7 25°C 20 min 83%
c: CF_3 −78°C—5°C 3 h 67%

Scheme 4.

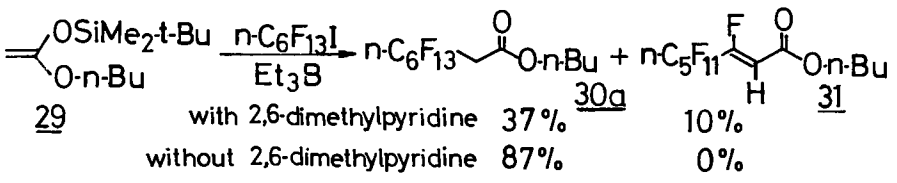
for the preparation of newly functionalized trimethyl silyl enol ethers as well as α-perfluoroalkyl ketones.[7]

We are tempted to assume following reaction mechanism for the formation of perfluoroalkylated silyl enol ethers (Scheme 5): (1) Perfluoroalkyl radical, generated by the action of ethyl radical on perfluoroalkyl iodide, adds to silyl enol ether to give a radical **A**, (2) the radical **A** abstracts iodine from R_fI to give the adduct **B** and regenerates perfluoroalkyl radical, and (3) the coexisting base causes the elimination of HI to give a mixture of two perfluoroalkylated silyl enol ethers (**2** and **3**). The regioselective formation of **B** would be attributed to the electrophilic attack of reactive R_f radical on the electron-rich carbon of silyl enol ether.



Scheme 5.

(2) The Reaction of Perfluoroalkyl Iodides with Ketene Silyl Acetals. Reaction of ketene silyl acetals with perfluoroalkyl iodides also proceeded easily in the presence of triethylborane catalyst to give α-perfluoroalkylated esters in excellent yields. Exposure of ketene silyl acetal **29** (1.0 mmol) to *n*-$C_6F_{13}I$ (1.3 mmol) in the presence of 2,6-dimethylpyridine (0.95 mmol) provided



Scheme 6.

Table 3. Reaction of Ketene Silyl Acetal with Perfluoroalkyl Iodide

Ketene silyl acetal	R_fI	Reaction time/min		Product %
 **29**	*n*-$C_6F_{13}I$	10	 **30**	87 (**30a**)

	CF_3I	12 h		22 (**41c**)

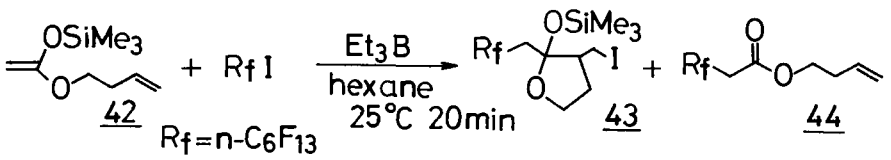
a) TBAF was added prior to work-up. See experimental part.

butyl 2-(perfluorohexyl)acetate (**30a**, 37%) along with butyl 2-(perfluorohexylidene)acetate (**31**, 10%). In contrast, treatment of **29** (2.0 mmol) with *n*-$C_6F_{13}I$ (1.0 mmol) in the absence of 2,6-dimethylpyridine in hexane provided **30a** (87% based on *n*-$C_6F_{13}I$) as a single product (Scheme 6). The yields of **30a** depend on the molar ratio of ketene silyl acetal and perfluoroalkyl iodide employed. The yields of **30a** in the reaction of **34** (x mmol) with *n*-$C_6F_{13}I$ (1.0 mmol) in the presence of catalytic amount of Et_3B (0.2 mmol) are as follows: **34** (2.0 mmol), 96%; **34** (1.5 mmol), 93%; **34** (1.2 mmol), 89%. Slight excess (1.2 equiv) of ketene silyl acetal was enough for the successful reaction. However, the reactions were performed using 2.0 equiv of ketene silyl acetals to obtain better yields and the results are summarized in Table 3.

Not only *n*-$C_6F_{13}I$, *i*-C_3F_7I but also CF_3I[7] or CF_3CH_2I reacted easily to give the corresponding perfluoroalkylated esters in good yields. Perfluoroalkylated ketene silyl acetal could not be detected. Trimethylsilyl acetal (**34** or **35**) reacted equally as dimethyl-*t*-butylsilyl acetal (**29** or **32**) to give the same perfluoroalkylated ester upon treatment with perfluoroalkyl iodides.

Alkyl group substituted ketene silyl acetals (**36**, **38**, and **40**) were prepared and their behavior toward perfluoroalkyl iodides were examined. Whereas the acetals **36** and **38** easily reacted with R_fI to provide the corresponding perfluoroalkylated esters in good yields, the acetal **40** reacted slowly because of its steric hindrance to give ester **41** in poor yields.

Treatment of ketene silyl acetal **42** with *n*-$C_6F_{13}I$ afforded a cyclized product **43** (10%) along with perfluoroalkylated ester **44** (50%) (Scheme 7). The formation of **43** suggests an intermediacy of carbon radical bearing OR and $OSiMe_3$ groups. The result also shows that C–C double bond of ketene silyl acetal is much more reactive than that of simple olefin.



Scheme 7.

Experimental

Distillations of the products were performed by use of Kugelrohr (Büchi), and boiling points are indicated by air-bath temperature without correction. Melting point was obtained on a Yanako MP-50929 melting point apparatus and are uncorrected, too. ^{1}H NMR and ^{13}C NMR spectra were taken on a Varian XL-200 spectrometer, $CDCl_3$ was used as solvent, and chemical shifts being given in δ with tetramethylsilane as an internal standard. ^{19}F NMR spectra were recorded on JEOL JNM-FX 90Q spectrometer and the chemical shifts are given in δ with $CFCl_3$ as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer and the mass spectra on a Hitachi M-80 machine. The analyses were carried out at the Elemental Analyses Center of Kyoto University. Tetrahydrofuran (THF) was freshly distilled from sodium diphenylketyl.

Preparation of Silyl Enol Ethers. Trimethylsilyl enol ethers **1**, **9**, **13**, **16**, **22**, and **24** were prepared by the reported procedure.[8-11] Triisopropylsilyl enol ether **6** and **19** were prepared according to the Corey's method.[12] 1-Trimethylsiloxy-1-cyclopropylethylene was obtained following the reported procedure.[13] The physical data are shown below for the silyl enol ethers whose physical data have not been described in the literature.

1-Triisopropylsiloxy-1-cyclohexene (6): Bp 91—96 °C (1 Torr, 1 Torr=133.322 Pa, bath temp); IR(neat) 2936, 2892, 2864, 1670, 1465, 1367, 1195, 885, 826, 680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.02—1.23 (m, 21H), 1.45—1.57 (m, 2H), 1.60—1.72 (m, 2H), 1.95—2.10 (m, 4H), 4.89 (t, J=3.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=12.66, 17.98, 22.38, 23.27, 23.87, 29.92, 103.6, 150.6; MS (70 eV) m/z (rel intensity) 254 (11), 211 (100), 183 (26), 141 (18), 81 (20), 75 (48), 61 (36), 59 (28), 41 (20). Found: C, 70.54; H, 12.02%. Calcd for $C_{15}H_{30}OSi$: C, 70.80; H, 11.88%.

(Z)-1-Triisopropylsiloxy-1-heptene (19): Bp 81—86 °C (1 Torr, bath temp); IR(neat) 2926, 2864, 1655, 1465, 1256, 1135, 1092, 1069, 882, 683, 662 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.5 Hz, 3H), 1.03—1.20 (m, 21H), 1.22—1.42 (m, 6H), 2.04—2.15 (m, 2H), 4.39 (td, J=7.2, 5.8 Hz, 1H), 6.27 (dt, J=5.8, 1.5 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=11.98, 14.10, 17.74, 22.57, 23.54, 29.39, 31.63, 110.0, 138.9; MS (70 eV) m/z (rel intensity) 270 (2), 228 (20), 227 (100), 103 (21), 75 (24), 61 (15), 59 (29). Found: C, 70.94; H, 12.85%. Calcd for $C_{16}H_{34}OSi$: C, 71.04; H, 12.67%.

2-Trimethylsiloxy-1-undecene (22). This compound was prepared from 2-undecanone in 79% yield along with 2-trimethylsiloxy-2-undecene (93/7): Bp 85—86 °C (1 Torr); IR (neat) 2954, 2924, 2852, 1654, 1637, 1252, 1013, 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.20 (s, 9H), 0.88 (t, J=6.4 Hz, 3H), 1.20—1.53 (m, 14H), 2.01 (t, J=7.3 Hz, 2H), 4.04 (s, 2H); ^{13}C NMR ($CDCl_3$) δ=0.15, 14.11, 22.70, 26.89, 29.15, 29.35, 29.52, 29.60, 31.93, 36.53, 89.75, 159.7; MS (70 eV) m/z (rel intensity) 242 (4), 144 (14), 143 (100), 130 (70), 115 (40), 75 (52), 73 (97), 43 (18), 41 (21). Found: C, 69.57; H, 12.72%. Calcd for $C_{14}H_{30}OSi$: C, 69.35; H, 12.47%.

(E) and (Z)-6-Trimethylsiloxy-5-undecene (24, (E):(Z)=69:31). The title compound was prepared from 6-undecanone in 82% yield: Bp 75—78 °C (1 Torr); IR(neat) 2956, 2926, 2858, 1664, 1251, 1177, 1100, 888, 842 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.17 (s, 9H), 0.89 (t, J=6.5 Hz, 6H), 1.23—1.52 (m, 10H), 1.87—2.07 (m, 4H), 4.44 (t, J=6.8 Hz, 0.31H), 4.60 (t, J=7.6 Hz, 0.69H); ^{13}C NMR ($CDCl_3$) δ=0.37, 0.62, 14.03, 22.25, 22.58, 25.07, 26.57, 26.78, 31.13, 31.47, 31.56, 32.18, 32.96, 36.63, 107.8 (*E*), 108.4 (*Z*), 150.2 (*Z*), 151.4 (*E*); MS (70 eV) m/z (rel intensity) 242 (14), 227 (9), 200 (18), 199 (100), 171 (9), 143 (14), 130 (23), 73 (15), 69 (10). Found: C, 69.09; H, 12.66%. Calcd for $C_{14}H_{30}OSi$: C, 69.35; H, 12.47%.

The Reaction of Silyl Enol Ether with Perfluorohexyl or Perfluoroisopropyl Iodide in the Presence of Base (Procedure A). Perfluoroalkylation of cyclohexanone trimethylsilyl enol ether is representative. Et_3B[4] (1.0 M hexane solution, 0.4 ml, 0.4 mmol, M=mol dm^{-3}) was added to a solution of 1-trimethylsiloxy-1-cyclohexene **1** (0.34 g, 2.0 mmol), perfluorohexyl iodide (1.19 g, 2.6 mmol), and 2,6-dimethylpyridine (0.20 g, 1.9 mmol) in hexane (5 ml) at room temperature. After stirring for 8 h at 25 °C, resulting precipitate was filtered through Celite 545. The filtrate was concentrated in vacuo. The residual oil was submitted to silica-gel column chromatography to give perfluoroalkylated silyl enol ether (**2a** and **3a**, 0.64 g, 65% yield, **2a**/**3a**=68/32) and 2-(perfluorohexyl)cyclohexanone (**4a**,[14] 92 mg, 11% yield). (Procedure A') Treatment of the reaction mixture consisting of **2a**, **3a**, and **4a** with acid afforded 2-(perfluoroalkyl)cyclohexanone (**4a**) as a single product. Thus, the residual oil after concentration of the filtrate was treated with concd aq HCl (35 wt%, 1 ml) in THF (5 ml) for 10 min. Reaction mixture was slowly poured into sat. aq $NaHCO_3$ (40 ml) and extracted with AcOEt (30 ml×2).[15] The combined organic layer was dried over anhydrous Na_2SO_4 and concentrated in vacuo. Purification by silica-gel column chromatography gave only **4a** in 74% yield.

6-Perfluorohexyl-1-trimethylsiloxy-1-cyclohexene (2a): Bp 68—71 °C (1 Torr, bath temp); IR(neat) 2958, 1669, 1324, 1239, 1203, 1146, 1120, 913, 846, 694, 660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.20 (s, 9H), 1.48—1.88 (m, 3H), 1.96—2.16 (m, 3H), 2.95 (tm, J=15.6 Hz, 1H), 5.11 (t, J=4.1 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=—0.10, 18.82, 23.18 (two peaks), 41.77 (t, J=20.4 Hz), 108.6, 141.1. ^{13}C-Signals of perfluorohexyl group could not be observed for all perfluorohexyl compounds; ^{19}F NMR ($CDCl_3$) δ=—81.39 (t, J=9.8 Hz, 3F), —108.1 (dm, J=284 Hz, 1F), —113.8 (dm, J=284 Hz, 1F), —121.2 (bs, 2F), —122.2 (bs, 2F), —123.2 (bs, 2F), —126.4——126.8 (m, 2F); MS (70 eV) m/z (rel intensity) 488 (10), 169 (14), 133 (12), 77 (61), 75 (6), 74 (8), 73 (100), 69 (27), 55 (19), 45 (11), 41 (17). Found: C, 37.17; H, 3.49%. Calcd for $C_{15}H_{17}F_{13}OSi$: C, 36.89; H, 3.51%.

2-Perfluorohexyl-1-trimethylsiloxy-1-cyclohexene (3a): Bp 68—72 °C (1 Torr, bath temp); IR(neat) 2944, 1661, 1375,

1292, 1238, 1204, 1145, 1119, 1074, 1065, 933, 861, 848, 704 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.20 (s, 9H), 1.55—1.75 (m, 4H), 2.14—2.19 (m, 4H); ^{13}C NMR ($CDCl_3$) δ=0.50, 22.10, 22.45, 23.51 (t, J=5.0 Hz), 31.38, 117.1 (t, J=32.7 Hz), 155.8 (t, J=5.5 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.39 (tt, J=9.7, 3.6 Hz, 3F), −108.5 (t, J=14.0 Hz, 2F), −122.1—−123.2 (m, 6F), −126.4—−126.8 (m, 2F); MS (70 eV) m/z (rel intensity) 488 (7), 220 (15), 219 (92), 169 (7), 77 (46), 74 (9), 73 (100), 69 (9), 45 (11), 41 (19). Found: C, 37.15; H, 3.56%. Calcd for $C_{15}H_{17}F_{13}OSi$: C, 36.89; H, 3.51%.

2-(Perfluorohexylidene)cyclohexanone (5): Bp 78—83 °C (7 Torr, bath temp); IR(neat) 1722, 1228, 1204, 1164, 1144, 724 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.81—2.05 (m, 4H), 2.54—2.73 (m, 4H); ^{13}C NMR ($CDCl_3$) δ=25.01, 25.44, 27.45, 43.35, 129.2 (d, J=6.0 Hz), 198.5; ^{19}F NMR ($CDCl_3$) δ=−81.28 (tt, J=9.8, 3.0 Hz, 3F), −114.1—−114.6 (m, 2F), −121.1 (bs, 1F), −123.3 (bs, 2F), −124.1 (bs, 2F), −126.4—−126.7 (m, 2F); MS (12 eV) m/z (rel intensity) 396 (7), 369 (10), 368 (77), 150 (8), 149 (100), 127 (21), 99 (99), 67 (36), 41 (18). Found: C, 36.51; H, 2.09%. Calcd for $C_{12}H_8F_{12}O$: C, 36.38; H, 2.04%.

6-Perfluoroisopropyl-1-trimethylsiloxy-1-cyclohexene (2b): Bp 50—53 °C (1 Torr, bath temp); IR(neat) 2960, 1664, 1287, 1255, 1219, 1159, 1118, 1099, 985, 964, 936, 902, 846 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.18 (s, 9H), 1.33—1.55 (m, 1H), 1.65—2.10 (m, 5H), 3.03—3.22 (m, 1H), 5.03 (t, J=4.4 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=−0.15. 20.92, 23.34, 23.56 (d, J=10.6 Hz), 41.08 (d, J=18.9 Hz), 93.92 (dm, J=205 Hz), 107.3, 121.2 (qd, J=289, 29.3 Hz), 145.2; ^{19}F NMR ($CDCl_3$) δ=−72.99 (d, J=4.9 Hz, 6F), −173.4—−173.9 (m, 1F); MS (70 eV) m/z (rel intensity) 338 (19), 169 (27), 77 (64), 73 (100), 55 (11), 45 (14), 41 (14). Found: C, 42.76; H, 5.23%. Calcd for $C_{12}H_{17}F_7OSi$: C, 42.60; H, 5.06%.

2-Perfluoroisopropyl-1-trimethylsiloxy-1-cyclohexene (3b): Bp 50—55 °C (1 Torr, bath temp); IR(neat) 2942, 1669, 1369, 1299, 1272, 1259, 1217, 1172, 1144, 1065, 967, 956, 899, 848 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.19 (s, 9H), 1.55—1.76 (m, 4H), 2.10—2.21 (m, 4H); ^{13}C NMR ($CDCl_3$) δ=0.89, 22.30 (d, J=3.7 Hz), 22.39, 23.67 (d, J=10.7 Hz), 31.35, 93.21 (dm, J=197 Hz), 101.5 (d, J=22.8 Hz), 121.3 (qd, J=288, 28.7 Hz), 153.1 (d, J=6.0 Hz); ^{19}F NMR ($CDCl_3$) δ=−74.68 (d, J=6.1 Hz, 6F), −177.1 (sep, sep=septet, J=6.1 Hz, 1F); MS (70 eV) m/z (rel intensity) 338 (17), 269 (11), 177 (10), 169 (27), 149 (13), 77 (50), 73 (100), 65 (10), 45 (16), 41 (24). Found: C, 42.49; H, 5.14%. Calcd for $C_{12}H_{17}F_7OSi$: C, 42.60; H, 5.06%.

2-(Perfluoroisopropyl)cyclohexanone (4b): Bp 82—87 °C (36 Torr, bath temp); IR(neat) 1733, 1292, 1274, 1224, 1161, 1134, 1109, 1098, 972 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.60—2.15 (m, 5H), 2.30—2.60 (m, 3H), 3.16—3.30 (m, 1H); ^{13}C NMR ($CDCl_3$) δ=24.61, 27.41, 28.45, 42.74, 51.95 (d, J=20.1 Hz), 92.61 (dm, J=207 Hz), 120.9 (qd, J=288, 27.4 Hz), 202.9 (d, J=4.8 Hz); ^{19}F NMR ($CDCl_3$) δ=−72.85—−73.54 (m, 6F), −178.3—−178.9 (m, 1F); MS (70 eV) m/z (rel intensity) 266 (71), 238 (11), 237 (16), 141 (15), 127 (13), 77 (10), 69 (18), 55 (100), 42 (20), 41 (14). Found: C, 40.90; H, 3.33%. Calcd for $C_9H_9F_7O$: C, 40.61; H, 3.41%.

6-Perfluorohexyl-1-triisopropylsiloxy-1-cyclohexene (7a): Bp 100—105 °C (1 Torr, bath temp); IR(neat) 2946, 2894, 2868, 1668, 1466, 1239, 1200, 1145, 1119, 883, 688, 660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.01—1.26 (m, 21H), 1.55—1.83 (m, 2H), 2.00—2.18 (m 4H), 2.85—3.10 (m, 1H), 5.08 (t, J=4.0 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=12.75, 17.90 (d, J=3.9 Hz), 18.46, 23.08, 23.31, 41.54 (dd, J=21.0, 18.9 Hz), 107.2, 144.3 (t, J=2.7 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.29 (t, J=9.8 Hz, 3F), −107.6 (d, J=271 Hz, 1F), −113.5 (d, J=271 Hz, 1F), −121.4 (bs, 2F), −122.3 (bs, 2F), −123.2 (bs, 2F), −126.6 (bs, 2F); MS (70 eV) m/z (rel intensity) 572 (2), 529 (30), 349 (17), 105 (50), 77 (100), 63 (13), 59 (13), 43 (34), 41 (17). Found: C, 44.22; H, 5.02%. Calcd for $C_{21}H_{29}F_{13}OSi$: C, 44.06; H, 5.11%.

2-Perfluorohexyl-1-triisopropylsiloxy-1-cyclohexene (8a): Bp 98—103 °C (1 Torr, bath temp); IR(neat) 2950, 2868, 1653, 1375, 1240, 1205, 1145, 1073 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.03—1.30 (m, 21H), 1.58—1.80 (m, 4H), 2.10—2.32 (m, 4H); ^{13}C NMR ($CDCl_3$) δ=13.69, 17.83, 22.14, 22.74, 23.82, 31.67, 102.5 (t, J=21.1 Hz), 156.3 (t, J=4.9 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.32 (t, J=9.8 Hz, 3F), −108.6 (bs, 2F), −122.4 (bs, 4F), −123.3 (bs, 2F), −126.4—−126.8 (m, 2F); MS (70 eV) m/z (rel intensity) 530 (M^+−i-Pr+1, 20), 529 (M^+−i-Pr, 79), 105 (50), 77 (100), 63 (15), 59 (12), 43 (24), 41 (19). 3,3,4,4,5,5,6,6,7,7,8,8,8-Tridecafluoro-2-pentyl-1-triisopropylsiloxy-1-octene (20, Minor): Bp 105—110 °C (4 Torr, bath temp); IR(neat) 2950, 2868, 1656, 1466, 1281, 1240, 1202, 1146, 1130, 882, 808, 710, 685 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, J=6.7 Hz, 3H), 1.00—1.50 (m, 27H), 1.98—2.05 (m, 2H), 6.59 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=11.67, 14.01, 17.37, 22.39, 27.78, 30.01, 31.27, 107.3 (t, J=20.3 Hz), 146.8 (t, J=5.7 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.32 (t, J=9.8 Hz, 3F), −108.9—−109.3 (m, 2F); −122.2—−122.7 (m, 4F), −123.3 (bs, 2F), −126.3—−126.8 (m, 2F); MS (12 eV) m/z (rel intensity) 546 (M^+−i-Pr+1, 26), 545 (M^+−i-Pr, 100), 489 (10), 395 (15), 157 (14), 133 (12), 121 (11), 105 (43), 77 (67), 43 (12). Found: C, 44.83; H, 5.54%. Calcd for $C_{22}H_{33}F_{13}OSi$: C, 44.90; H, 5.65%.

3,4,4,5,5,6,6,7,7,8,8,8-Dodecafluoro-2-pentyl-2-octenal (21, Major, Stereochemistry (*E* or *Z*) could not be determined): Bp 91—96 °C (27 Torr, bath temp); IR(neat) 2960, 2932, 2866, 1697, 1658, 1361, 1301, 1237, 1201, 1166, 1145, 1113, 724 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, J=6.7 Hz, 3H), 1.24—1.50 (m, 6H), 2.41—2.51 (m, 2H), 10.00 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=13.75, 22.23, 23.32 (d, J=3.8 Hz), 27.73, 31.46, 132.3 (d, J=9.1 Hz), 187.5 (d, J=8.3 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.25 (t, J=9.8 Hz, 3F), −107.1 (bs, 1F), −111.6 (bs, 2F), −123.3 (bs, 4F), −126.5 (bs, 2F); MS (12 eV) m/z (rel intensity) 412 (7), 384 (23), 364 (19), 357 (34), 356 (53), 335 (50), 143 (100). Found: C, 38.03; H, 2.90%. Calcd for $C_{13}H_{12}F_{12}O$: C, 37.88; H, 2.93%.

3,4,4,5,5,6,6,7,7,8,8,8-Dodecafluoro-2-pentyl-2-octenal (21, Minor): Bp 88—93 °C (24 Torr, bath temp); IR(neat) 2960, 2934, 2874, 1700, 1660, 1362, 1237, 1205, 1144, 1113, 724 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.23—1.46 (m, 6H), 2.26—2.34 (m, 2H), 10.23 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=13.77, 22.17 (two peaks), 29.21, 31.72, 129.3, 187.6 (d, J=18.8 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.26 (t, J=9.8 Hz, 3F), −115.6 (bs, 2F), −123.1 (bs, 4F), −126.2—−126.6 (m, 3F); MS (12 eV) m/z (rel intensity) 412 (0.6), 335 (5), 145 (11), 143 (100), 95 (7), 85 (24), 68 (8), 56 (24). Found: C, 37.58; H, 2.86%. Calcd for $C_{13}H_{12}F_{12}O$: C, 37.88; H, 2.93%.

The Reaction of Silyl Enol Ether with Trifluoromethyl Iodide in the Presence of Base. Typical procedure is as follows. CF_3I (2.88 g, 14.7 mmol) was introduced into the flask pre-cooled to −78 °C, then hexane (7.4 ml), silyl enol ether (**22** (purity: 93%), 354 mg, 1.36 mmol), 2,6-dimethylpyridine (159 mg, 1.47 mmol) and Et_3B (0.96 M hexane solution, 0.30 ml, 0.29 mmol) were slowly added to the flask. After addition of these reagents, the reaction mixture was warmed to room temperature and stirred for 40 h. The resulting precipitate was filtered through Celite 545 and the filtrate was concentrated in vacuo. Treatment of the crude product with concd aq HCl in THF and purification by silica-gel column chromatography gave **23a** in 64% yield. 1,1,1-Trifluoro-3-dodecanone (**23a**): Mp 44.5—45.5 °C; IR($CDCl_3$) 2926, 2854, 1731, 1367, 1341, 1274, 1255, 1160, 1139 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, J=6.4 Hz, 3H), 1.27 (bs, 12H), 1.53—1.70 (m, 2H), 2.53 (t, J=7.3 Hz, 2H), 3.21 (q, J=10.5 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=14.04, 22.63, 23.16, 28.90, 29.21, 29.31, 29.36, 31.83, 43.50, 46.18 (q, J=28.2 Hz), 123.7 (q, J=277 Hz), 200.2; ^{19}F NMR ($CDCl_3$) δ=−62.91 (t,

J=10.3 Hz); MS (12 eV) m/z (rel intensity) 238 (12), 220 (23), 164 (26), 153 (26), 150 (34), 139 (32), 127 (30), 126 (88), 112 (100), 110 (46), 71 (25). Found: C, 60.72; H, 9.10%. Calcd for $C_{12}H_{21}F_3O$: C, 60.49; H, 8.88%.

5-Trifluoromethyl-6-undecanone (25a): Bp 79—84 °C (1 Torr, bath temp); IR(neat) 2958, 2932, 2870, 1729, 1261, 1163, 1123, 1091 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, J=6.8 Hz, 6H), 1.17—1.47 (m, 8H), 1.53—1.99 (m, 4H), 2.47 (dt, J=17.9, 7.1 Hz, 1H), 2.61 (dt, J=17.9, 7.3 Hz, 1H), 3.19 (dqd, J=9.2, 8.9, 4.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=13.59, 13.80, 22.39 (two peaks), 22.70, 25.61, 29.02, 31.07, 43.64, 55.56 (q, J=25.0 Hz), 124.9 (q, J=280 Hz), 204.4; ^{19}F NMR ($CDCl_3$) δ=−67.33 (d, J=8.9 Hz); MS (12 eV) m/z (rel intensity) 238 (3), 167 (4), 126 (5), 100 (7), 99 (100), 85 (4), 72 (4), 71 (19), 56 (6), 43 (7). Found: C, 60.20; H, 9.10%. Calcd for $C_{12}H_{21}F_3O$: C, 60.49; H, 8.88%.

The Reaction of Silyl Enol Ether with 2,2,2-Trifluoroethyl Iodide in the Presence of Base. The reactions were performed according to Procedure A′ described for the reaction of silyl enol ether with R_fI with some variation of the quantity of reagents and reaction time, which are shown below.

1,1,1-Trifluoro-4-tridecanone (23b). Et_3B (0.96 M hexane solution, 0.42 ml, 0.40 mmol) was added to a solution of silyl enol ether (**22** (purity: 93%), 486 mg, 1.86 mmol), CF_3CH_2I (840 mg, 4.00 mmol) and 2,6-dimethylpyridine (205 mg, 1.91 mmol) in hexane (5 ml) at room temperature. The resulting mixture was stirred for 15 h. Acidic work-up followed by purification gave **23b** in 79% yield: Bp 90—95 °C (1 Torr, bath temp); IR(neat) 2926, 2854, 1723, 1442, 1364, 1315, 1256, 1231, 1143, 1091, 612 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.5 Hz, 3H), 1.27 (bs, 12H), 1.52—1.70 (m, 2H), 2.28—2.53 (m, 4H), 2.64—2.72 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=13.99, 22.61, 23.73, 27.86 (q, J=29.8 Hz), 29.11, 29.21, 29.32, 29.36, 31.82, 34.76 (q, J=2.7 Hz), 42.76, 127.0 (q, J=277 Hz), 207.1; ^{19}F NMR ($CDCl_3$) δ=−67.17 (t, J=10.3 Hz); MS (12 eV) m/z (rel intensity) 252 (9), 155 (66), 153 (16), 141 (29), 140 (100), 112 (37), 110 (21), 85 (15), 71 (28), 57 (20). Found: C, 62.04; H, 9.48%. Calcd for $C_{13}H_{23}F_3O$: C, 61.88; H, 9.19%.

5-(2,2,2-Trifluoroethyl)-6-undecanone (25b): Bp 65—70 °C (1 Torr, bath temp); IR(neat) 2956, 2930, 2862, 1719, 1467, 1459, 1378, 1257, 1131, 1102, 1075 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, J=6.8 Hz, 6H), 1.15—1.75 (m, 12H), 1.88—2.21 (m, 1H), 2.48 (t, J=7.5 Hz, 2H), 2.57—2.90 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=13.77, 13.88, 22.44, 22.54, 23.00, 28.79, 31.25, 31.82, 34.53 (q, J=28.4 Hz), 42.80, 44.93 (q, J=2.7 Hz), 126.6 (q, J=277 Hz), 211.5; ^{19}F NMR ($CDCl_3$) δ=−65.50 (t, J=10.8 Hz); MS (12 eV) m/z (rel intensity) 252 (3), 196 (8), 140 (7), 100 (6), 99 (100), 71 (15), 43 (4). Found: C, 62.04; H, 9.46%. Calcd for $C_{13}H_{23}F_3O$: C, 61.88; H, 9.19%.

The Reaction of 1-Trimethylsiloxy-1-cyclopropylethylene (26) with Perfluorohexyl or Perfluoroisopropyl Iodides. Perfluoroisopropylation of **26** is representative. Et_3B (1.0 M hexane solution, 0.20 ml, 0.20 mmol) was added to a solution of silyl enol ether (0.16 g, 1.0 mmol) and i-C_3F_7I (0.50 g, 1.7 mmol) in hexane (2 ml). After stirring for 20 min, the reaction mixture was concentrated in vacuo. Purification by silica-gel column chromatography gave **27b** in 85% yield. Treatment of crude product with concd aq HCl in THF according to Procedure A′ and purification by distillation gave **28b** in 83% yield.

(*Z*), (*E*)-6,7,7,7,-Tetrafluoro-1-iodo-6-trifluoromethyl-4-trimethylsiloxy-3-heptene (27b, (*Z*):(*E*)=81:19): Bp 92—97 °C (1 Torr, bath temp); IR(neat) 2960, 1671, 1374, 1333, 1286, 1222, 1164, 1149, 1121, 1003, 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.22 (s, 9H), 2.53 (dt, J=7.6, 7.0 Hz, 0.38H), 2.60 (td, J=7.4, 7.0 Hz, 1.62H), 2.75 (d, J=21.6 Hz, 1.62H), 2.86 (d, J=21.0 Hz, 0.38H), 3.10 (t, J=7.4 Hz, 1.62H), 3.14 (t, J=7.0 Hz, 0.38H), 4.75 (t, J=7.0 Hz, 0.81H), 4.80 (t, J=7.6 Hz, 0.19H); ^{13}C NMR for (*Z*)-isomer ($CDCl_3$) δ=0.43, 4.00, 30.12, 35.99 (d, J=19.5 Hz), 91.41 (dm, J=207 Hz), 114.5, 120.9 (qd, J=288, 28.8 Hz), 142.4 (d, J=2.6 Hz); ^{13}C NMR for (*E*)-isomer ($CDCl_3$) δ=−0.15, 5.92, 31.21, 31.49 (d, J=19.0 Hz), 111.0, 143.6 (d, J=3.4 Hz), (^{13}C of $^iC_3F_7$ could not be detected); ^{19}F NMR ($CDCl_3$) δ=−76.56 (d, J=6.1 Hz, 4.86F), −76.79 (d, J=7.3 Hz, 1.14F), −182.1 (tsep, J=20.8, 7.3 Hz, 0.19F), −183.0 (tsep, J=22.0, 6.1 Hz, 0.81F); MS (70 eV) m/z (rel intensity) 452 (2), 326 (18), 325 (100), 233 (8), 73 (18). Found: C, 29.16; H, 3.58%. Calcd for $C_{11}H_{16}F_7IOSi$: C, 29.22; H, 3.57%.

6,7,7,7-Tetrafluoro-1-iodo-6-trifluoromethyl-4-heptanone (28b): Bp 73—78 °C (1 Torr, bath temp); IR(neat) 1728, 1338, 1289, 1223, 1165, 1117, 1045, 1002 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.04—2.18 (m, 2H), 2.75 (t, J=7.0 Hz, 2H), 3.11 (d, J=21.9 Hz, 2H), 3.23 (t, J=6.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=5.31, 26.60, 40.55 (d, J=19.0 Hz), 44.69, 90.52 (dm, J=209 Hz), 120.3 (qd, J=288, 27.0 Hz), 199.1; ^{19}F NMR ($CDCl_3$) δ=−76.98 (d, J=4.9 Hz, 6F), −182.8 (bs, 1F); MS (70 eV) m/z (rel intensity) 253 (M^+−I, 61), 211 (100), 155 (14), 95 (14), 69 (36), 42 (19), 41 (27). Found: C, 25.51; H, 2.29%. Calcd for $C_8H_8F_7IO$: C, 25.28; H, 2.12%.

6,6,7,7,8,8,9,9,10,10,11,11,11-Tridecafluoro-1-iodo-4-undecanone (28a): Bp 100—105 °C (1 Torr, bath temp); IR(neat) 1729, 1345, 1241, 1209, 1146 cm^{-1} δ=^{1}H NMR ($CDCl_3$) δ=2.07—2.20 (m, 2H), 2.78 (t, J=6.9 Hz, 2H), 3.22 (t, J=18.6 Hz, 2H), 3.25 (t, J=6.7 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=5.26, 26.52, 43.20 (t, J=22.1 Hz), 44.66, 198.4; ^{19}F NMR ($CDCl_3$) δ=−81.45 (bs, 3F), −111.5 (bs, 2F), −122.2 (bs, 2F), −123.4 (bs, 4F), −126.7 (bs, 2F); MS (70 eV) m/z (rel intensity) 403 (M^+−I, 67), 362 (9), 361 (100), 341 (9), 197 (11), 169 (8), 155 (7), 69 (13), 41 (8). Found: C, 24.85; H, 1.52%. Calcd for $C_{11}H_8F_{13}IO$: C, 24.93; H, 1.52%.

The Reaction of 1-Trimethylsiloxy-1-cyclopropylethylene with Trifluoromethyl Iodide. CF_3I (0.40 ml, 5.0 mmol) was collected in the flask pre-cooled to −78 °C. Hexane (2 ml), silyl enol ether (0.16 g, 1.0 mmol) and Et_3B (0.20 mmol) were added to CF_3I and the mixture was warmed to 5 °C over 3 h. After evaporation of solvent, the crude product was treated with concd aq HCl in THF. Purification by distillation gave **28c** in 67% yield: Bp 65—70 °C (1 Torr, bath temp); IR(neat) 1733, 1419, 1380, 1270, 1223, 1159, 1142, 1091, 626 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.05—2.18 (m, 2H), 2.72 (t, J=6.9 Hz, 2H), 3.24 (t, J=6.6 Hz, 2H), 3.26 (q, J=10.4 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=5.55, 26.30, 43.59, 46.18 (q, J=28.3 Hz), 123.4 (q, J=277 Hz), 198.6; ^{19}F NMR ($CDCl_3$) δ=−62.85 (t, J=9.8 Hz); MS (70 eV) m/z (rel intensity) 153 (M^+−I, 58), 127 (7), 111 (100), 91 (6), 83 (12), 42 (9), 41 (11), 39 (8). Found: C, 25.57; H, 2.79%. Calcd for $C_6H_8F_3IO$: C, 25.74; H, 2.88%.

Preparation of Ketene Silyl Acetals. The following ketene silyl acetals were prepared by the reported procedure.[9,16] The physical data for 1-hexyloxy-2-methyl-1-trimethylsiloxy-1-propene (**40**) is described in the literature.[17] The physical data for other compounds are shown below.

1-Butoxy-1-(*t*-butyldimethylsiloxy)ethylene (29): Bp 66—68 °C (2 Torr); IR(neat) 2958, 2930, 1653, 1277, 1254, 837,

784 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.17 (s, 6H), 0.93 (s, 9H), 0.94 (t, J=7.3 Hz, 3H), 1.33—1.52 (m, 2H), 1.59—1.72 (m, 2H), 3.06 (d, J=2.3 Hz, 1H), 3.22 (d, J=2.3 Hz, 1H), 3.68 (t, J=6.4 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=−4.56, 13.73, 18.09, 19.31, 25.62, 30.95, 60.32, 67.48, 161.5; MS (70 eV) m/z (rel intensity) 230 (9), 174 (14), 159 (13), 131 (78), 117 (91), 75 (100), 73 (67), 57 (15), 43 (14), 41 (23). Found: C, 62.27; H, 11.62%. Calcd for $C_{12}H_{26}O_2Si$: C, 62.55; H, 11.37%.

1-(t-Butyldimethylsiloxy)-1-octyloxyethylene (32): Bp 114—117 °C (2 Torr); IR(neat) 2954, 2928, 2856, 1651, 1276, 1254, 829, 785 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.17 (s, 6H), 0.89 (t, J=6.6 Hz, 3H), 0.93 (s, 9H), 1.28 (bs, 10H), 1.60—1.73 (m, 2H), 3.05 (d, J=2.3 Hz, 1H), 3.22 (d, J=2.3 Hz, 1H), 3.67 (t, J=6.5 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=−4.54, 14.07, 18.13, 22.65, 25.63, 26.11, 28.89, 29.22 (two peaks), 31.80, 60.32, 67.78, 161.5; MS (70 eV) m/z (rel intensity) 286 (2), 187 (28), 175 (18), 119 (17), 117 (100), 75 (67), 73 (44), 43 (23). Found: C, 67.23; H, 12.23%. Calcd for $C_{16}H_{34}O_2Si$: C, 67.07; H, 11.96%.

1-Butoxy-1-(trimethylsiloxy)ethylene (34): Bp 95—101 °C (39 Torr); IR(neat) 2960, 1657, 1278, 1252, 1088, 1023, 849, 757 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.22 (s, 9H), 0.94 (t, J=7.2 Hz, 3H), 1.34—1.52 (m, 2H), 1.60—1.73 (m, 2H), 3.06 (d, J=2.5 Hz, 1H), 3.21 (d, J=2.5 Hz, 1H), 3.70 (t, J=6.4 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=0.05, 13.69, 19.26, 30.91, 60.03, 67.54, 161.2; MS (70 eV) m/z (rel intensity) 188 (3), 131 (26), 117 (94), 75 (100), 73 (97), 72 (23), 57 (22), 56 (41), 45 (26), 43 (80), 41 (43). Found: C, 57.20; H, 10.91%. Calcd for $C_9H_{20}O_2Si$: C, 57.40; H, 10.70%.

1-(Trimethylsiloxy)-1-octyloxyethylene (35): Bp 91—96 °C (1 Torr); IR(neat) 2956, 2926, 2854, 1656, 1277, 1252, 1019, 848 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.22 (s, 9H), 0.88 (t, J=6.5 Hz, 3H), 1.28 (bs, 10H), 1.60—1.73 (m, 2H), 3.05 (d, J=2.5 Hz, 1H), 3.20 (d, J=2.5 Hz, 1H), 3.68 (t, J=6.5 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=0.08, 14.03, 22.62, 26.09, 28.87, 29.22 (two peaks), 31.78, 60.03, 67.85, 161.2; MS (70 eV) m/z (rel intensity) 244 (2), 187 (20), 133 (42), 117 (100), 75 (43), 73 (48), 56 (21), 43 (51), 41 (23). Found: C, 63.62; H, 11.51%. Calcd for $C_{13}H_{28}O_2Si$: C, 63.88; H, 11.55%.

1-Methoxy-1-(trimethylsiloxy)-1-hexene (36, (*E*):(*Z*)=83:17): Bp 102—105 °C (36 Torr); IR(neat) 2956, 1682, 1254, 1227, 1174, 1089, 906, 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.19 (s, 1.53H), 0.23 (s, 7.47H), 0.89 (t, J=6.8 Hz, 3H), 1.25—1.40 (m, 4H), 1.90—2.01 (m, 2H), 3.47 (t, J=6.8 Hz, 0.17H), 3.48 (s, 0.51H), 3.52 (s, 2.49H), 3.67 (t, J=7.1 Hz, 0.83H); ^{13}C NMR for (*E*)-isomer ($CDCl_3$) δ=−0.32, 13.92, 22.20, 24.10, 32.91, 54.76, 85.33, 153.5; MS (70 eV) m/z (rel intensity) 202 (8), 159 (47), 89 (19), 73 (58), 59 (11), 55 (100), 45 (11). Found: C, 59.47; H, 11.22%. Calcd for $C_{10}H_{22}O_2Si$: C, 59.35; H, 10.96%.

1-Methoxy-1-(trimethylsiloxy)-1-octene (38, (*E*):(*Z*)=88:12): Bp 68—70 °C (1 Torr); IR(neat) 2956, 2922, 2852, 1682, 1253, 1227, 1170, 1091, 902, 845 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.19 (s, 1.08H), 0.23 (s, 7.92H), 0.88 (t, J=6.5 Hz, 3H), 1.28 (bs, 8H), 1.89—2.03 (m, 2H), 3.47 (t, J=6.8 Hz, 0.12H), 3.48 (s, 0.36H), 3.51 (s, 2.64H), 3.67 (t, J=7.3 Hz, 0.88H); ^{13}C NMR for (*E*)-isomer ($CDCl_3$) δ=−0.30, 14.07, 22.68, 24.43, 28.85, 30.67, 31.78, 54.78, 85.42, 153.5; MS (70 eV) m/z (rel intensity) 230 (10), 160 (11), 159 (75), 89 (16), 73 (52), 59 (11), 55 (100), 41 (11). Found: C, 62.68; H, 11.63%. Calcd for $C_{12}H_{26}O_2Si$: C, 62.55; H, 11.37%.

1-(3-Butenyloxy)-1-(trimethylsiloxy)ethylene (42): Bp 90—91 °C (39 Torr); IR(neat) 2958, 1653, 1277, 1253, 1088, 1018, 990, 911, 847, 758 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.22 (s, 9H), 2.43 (qt, J=6.7, 1.3 Hz, 2H), 3.07 (d, J=2.6 Hz, 1H), 3.23 (d, J=2.6 Hz, 1H), 3.75 (t, J=6.7 Hz, 2H), 5.08 (ddt, J=10.2, 1.8, 1.3 Hz, 1H), 5.13 (ddt, J=17.0, 1.8, 1.3 Hz, 1H), 5.84 (ddd, J=17.0, 10.2, 6.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=0.09, 33.28, 60.26, 67.00, 117.0, 134.4, 161.0; MS (70 eV) m/z (rel intensity) 186 (3), 101 (21), 75 (61), 73 (100), 55 (73), 54 (85), 43 (45). Found: C, 57.74; H, 9.82%. Calcd for $C_9H_{18}O_2Si$: C, 58.02; H, 9.74%.

The Reaction of 1-Butoxy-1-(*t*-butyldimethylsiloxy)ethylene with Perfluorohexyl Iodide in the Presence of 2,6-Dimethylpyridine (Procedure A). This reaction gave a mixture of **30a** and **31** in 37 and 10% yields respectively. Butyl 3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluorooctanoate (**30a**): Bp 76—81 °C (7 Torr, bath temp); IR(neat) 2964, 1754, 1396, 1353, 1241, 1208, 1146, 1122, 1064, 709, 628 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (t, J=7.2 Hz, 3H), 1.31—1.49 (m, 2H), 1.57—1.73 (m, 2H), 3.14 (t, J=17.7 Hz, 2H), 4.20 (t, J=6.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.53, 18.94, 30.37, 37.02 (t, J=22.5 Hz), 65.91, 163.9; ^{19}F NMR ($CDCl_3$) δ=−81.34 (tt, J=7.4, 3.0 Hz, 3F), −111.6—−112.6 (m, 2F), −112.1 (bs, 2F), −123.4 (bs, 4F), −126.3—−126.8 (m, 2F); MS (70 eV) m/z (rel intensity) 434 (0.2), 361 (26), 69 (18), 57 (42), 56 (100), 55 (12), 41 (35). Found: C, 33.45; H, 2.46%. Calcd for $C_{12}H_{11}F_{13}O_2$: C, 33.20; H, 2.55%. (*E*)-Butyl 3,4,4,5,5,6,6,7,7,8,8,8-dodecafluoro-2-octenoate (**31**): Bp 83—88 °C (13 Torr, bath temp); IR(neat) 2964, 1736, 1702, 1350, 1275, 1239, 1206, 1143, 1114, 723, 644 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.96 (t, J=7.3 Hz, 3H), 1.33—1.51 (m, 2H), 1.60—1.76 (m, 2H), 4.24 (t, J=6.6 Hz, 2H), 6.00 (d, J=29.8 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=13.45, 19.02, 30.44, 65.64, 107.2 (t, J=4.0 Hz), 161.6 (d, J=2.7 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.14—−81.43 (m, 3F), −107.7—−108.7 (m, 1F), −118.9—−119.4 (m, 2F), −123.2 (bs, 4F), −126.6 (bs, 2F); MS (12 eV) m/z (rel intensity) 359 ($M^+-C_4H_7$, 6), 341 (5), 57 (5), 56 (100), 55 (2). Found: C, 35.02; H, 2.49%. Calcd for $C_{12}H_{10}F_{12}O_2$: C, 34.80; H, 2.43%.

The Reactions of Ketene Silyl Acetals with Perfluorohexyl Iodide without Base (Procedure B). Following procedure for the reaction of ketene *t*-butyldimethylsilyl acetal derived from butyl acetate with perfluorohexyl iodide is typical. Under argon atmosphere, Et_3B was added to a solution of ketene silyl acetal (**29**, 456 mg, 1.98 mmol) and perfluorohexyl iodide (440 mg, 0.99 mmol) in hexane (4.9 ml). After stirring for 10 min, sat. aq $NaHCO_3$ (5 ml) was added to the reaction mixture. The mixture was vigorously stirred for 40 min, then poured into water (30 ml) and extracted with hexane (30 m×2). The combined organic layer was dried over anhydrous Na_2SO_4 and concentrated in vacuo. The residual oil was purified by silica-gel column chromatography to give **30a** in 87% yield.

Methyl 2-Butyl-3,3,4,4,5,5,6,6,7,7,8,8,8-tridecafluorooctanoate (37a): Bp 98—103 °C (20 Torr, bath temp); IR(neat) 2964, 2936, 2870, 1757, 1458, 1437, 1350, 1239, 1194, 1145, 1116, 712, 695, 652 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (t, J=6.8 Hz, 3H), 1.21—1.47 (m, 4H), 1.74—2.07 (m, 2H), 3.06—3.29 (m, 1H), 3.78 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=13.42, 22.19, 24.87, 28.98, 48.15 (dd, J=22.6, 20.6 Hz), 52.28, 168.1 (d, J=7.8 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.32 (t, J=9.8 Hz, 3F), −113.7 (dm, J=266 Hz, 1F), −116.4 (dm, J=266 Hz, 1F), −121.8—−122.4 (m, 4F), −123.3 (bs, 2F), −126.3—−126.9 (m, 2F); MS (70 eV) m/z (rel intensity) 448 (0.1), 392 (11), 129 (16), 123 (100), 91 (13), 88 (14), 87 (12), 69 (14), 59 (68), 57 (11), 55

(24), 43 (13), 42 (14), 41 (21). Found: C, 34.82; H, 2.84%. Calcd for $C_{13}H_{13}F_{13}O_2$: C, 34.84; H, 2.92%.

Hexyl 3,3,4,4,5,5,6,6,7,7,8,8,8-Tridecafluoro-2,2-dimethyloctanoate (41a): Bp 69—74 °C (2 Torr, bath temp); IR(neat) 2960, 2932, 2862, 1746, 1477, 1277, 1241, 1195, 1177, 1147, 1112, 1063, 697, 658 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.23—1.42 (m, 6H), 1.46 (s, 6H), 1.57—1.71 (m, 2H), 4.14 (t, J=6.5 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.74, 19.99, 22.48, 25.46, 28.29, 31.34, 48.48 (t, J=20.8 Hz), 66.02, 170.6 (t, J=3.1 Hz); ^{19}F NMR ($CDCl_3$) δ=−81.33, (tt, J=9.9, 2.5 Hz, 3F), −112.4 (bs, 2F), −114.7 (bs, 2F), −118.1 (bs, 2F), −123.1 (bs, 2F), −126.3—−126.8 (m, 2F); MS (12 eV) m/z (rel intensity) 407 ($M^+-C_6H_{11}$, 15), 85 (49), 84 (100), 69 (9), 57 (11), 56 (37), 43 (51). Found: C, 39.22; H, 3.89%. Calcd for $C_{16}H_{19}F_{13}O_2$: C, 39.20; H, 3.91%.

The Reaction of Ketene Silyl Acetals with Perfluoroisopropyl Iodide. Et_3B (0.2 mmol) was added to a solution of ketene silyl acetal (2.0 mmol) and perfluoroisopropyl iodide (1.0 mmol) in hexane (5 ml) at 0 °C. After an addition of Et_3B, the reaction mixture was immediately warmed up to room temperature and stirred for appropriate time given in Table 3. Work-up and purification were performed according to Procedure B. In the case of ketene trimethylsilyl acetals **34** or **35**, butyl or octyl 2-(trimethylsilyl)acetate was obtained as by-product. These trimethylsilyacetates could be produced by isomerization of starting ketene acetals **34** and **35** under the reaction conditions. Tetrabutylammonium fluoride (TBAF, 1.0 mmol per 1.0 mmol of ketene silyl acetal) was added to the reaction mixture prior to work-up to remove these by-products from perfluoroalkylated esters **30** and **33**. Thus, TBAF was added and the resulting mixture was stirred for 10 min at room temperature. The resulting mixture was poured into dil aq NH_4Cl (sat. aq NH_4Cl:water=1:10). Extraction and purification by silica-gel column chromatography provided the desired perfluoroalkylated esters.

Butyl 3,4,4,4-Tetrafluoro-3-trifluoromethylbutanoate (30b): Bp 68—73 °C (36 Torr, bath temp); IR(neat) 2962, 1753, 1346, 1296, 1229, 1202, 1168, 1129, 1060, 1004, 703 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.94 (t, J=7.1 Hz, 3H), 1.30—1.48 (m, 2H), 1.57—1.71 (m, 2H), 3.07 (d, J=20.4 Hz, 2H), 4.17 (t, J=6.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.46, 18.91, 30.26, 34.21 (d, J=19.8 Hz), 65.96, 89.98 (dm, J=211 Hz), 120.4 (qd, J=288, 27.9 Hz), 164.4 (d, J=2.5 Hz); ^{19}F NMR ($CDCl_3$) δ=−77.25 (d, J=7.3 Hz, 6F), −182.9 (tsep, J=20.1, 7.3 Hz, 1F); MS (70 eV) m/z (rel intensity) 284 (0.6), 255 (3), 229 (5), 212 (6), 211 (100), 191 (2), 163 (2), 56 (3). Found: C, 38.26; H, 3.94%. Calcd for $C_9H_{11}F_7O_2$: C, 38.04; H, 3.90%.

Octyl 3,4,4,4-Tetrafluoro-3-trifluoromethylbutanoate (33a): Bp 69—74 °C (1 Torr, bath temp); IR(neat) 2958, 2930, 2860, 1754, 1347, 1296, 1230, 1202, 1169, 1061, 1006, 703 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.28 (bs, 10H), 1.59—1.73 (m, 2H), 3.06 (d, J=20.4 Hz, 2H), 4.16 (t, J=6.7 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.94, 22.60, 25.69, 28.26, 29.11 (two peaks), 31.75, 34.22 (d, J=19.9 Hz), 66.24, 89.99 (dm, J=211 Hz), 120.4 (qd, J=288, 28.2 Hz), 164.4; ^{19}F NMR ($CDCl_3$) δ=−77.23 (d, J=6.9 Hz, 6F), −182.9 (tsep, J=20.2, 6.9 Hz, 1F); MS (12 eV) m/z (rel intensity) 229 ($M^+-C_8H_{15}$, 12), 112 (55), 84 (100), 83 (81), 82 (30), 70 (84), 69 (34), 68 (29), 56 (52). Found: C, 46.06; H, 5.81%. Calcd for $C_{13}H_{19}F_7O_2$: C, 45.89; H, 5.63%.

Methyl 2-(Perfluoroisopropyl)hexanoate (37b): Bp 78—83 °C (50 Torr, bath temp); IR(neat) 2962, 2934, 2878, 1757, 1460, 1439, 1282, 1222, 1169, 1135, 1111, 1092, 984, 720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (t, J=7.0 Hz, 3H), 1.15—1.50 (m, 4H), 1.69—1.86 (m, 1H), 1.91—2.12 (m, 1H), 3.10—3.24 (m, 1H), 3.77 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=13.56, 22.12, 25.44, 29.84, 46.90 (d, J=20.1 Hz), 52.51, 91.53 (dm, J=208 Hz), 120.7 (qd, J=289, 29.9 Hz), 168.3 (d, J=6.0 Hz); ^{19}F NMR ($CDCl_3$) δ=−74.04 (d, J=7.3 Hz, 6F), −178.6 (dsep, J=12.2, 6.1 Hz, 1F); MS (70 eV) m/z (rel intensity) 298 (0.2), 267 (23), 255 (21), 242 (80), 173 (100), 141 (11), 129 (18), 59 (13). Found: C, 40.25; H, 4.54%. Calcd for $C_{10}H_{13}F_7O_2$: C, 40.28; H, 4.39%.

Methyl 2-(Perfluoroisopropyl)octanoate (39a): Bp 85—90 °C (24 Torr, bath temp); IR(neat) 2958, 2930, 2860, 1757, 1459, 1439, 1302, 1229, 1168, 1134, 1114, 1093, 976, 718 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.28 (bs, 8H), 1.67—1.89 (m, 1H), 1.92—2.13 (m, 1H), 3.09—3.23 (m, 1H), 3.77 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=13.77, 22.41, 25.69, 27.67, 28.64, 31.38, 46.90 (d, J=20.2 Hz), 52.39, 91.48 (dm, J=209 Hz), 120.6 (qd, J=287, 27.0 Hz), 168.0—168.2 (m); ^{19}F NMR ($CDCl_3$) δ=−74.03 (d, J=6.1 Hz, 6F), −178.7 (dsep, J=13.4, 6.1 Hz, 1F); MS (70 eV) m/z (rel intensity) 326 (2), 297 (25), 295 (13), 255 (58), 242 (100), 173 (91), 59 (17), 55 (14), 43 (17), 41 (16). Found: C, 43.96; H, 5.27%. Calcd for $C_{12}H_{17}F_7O_2$: C, 44.18; H, 5.25%.

Hexyl 3,4,4,4-Tetrafluoro-3-trifluoromethylbutanoate (41b): Bp 72—77 °C (3 Torr, bath temp); IR(neat) 2958, 2932, 2860, 1743, 1472, 1287, 1228, 1190, 1166, 1149, 1116, 1033, 995, 726 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.90 (t, J=6.6 Hz, 3H), 1.26—1.45 (m, 6H), 1.50 (s, 6H), 1.58—1.74 (m, 2H), 4.12 (t, J=6.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.84, 21.23, 22.46, 25.44, 28.15, 31.29, 46.54 (d, J=19.0 Hz), 66.23, 93.87 (dm, J=216 Hz), 121.2 (qd, J=289, 28.7 Hz), 171.4; ^{19}F NMR ($CDCl_3$) δ=−70.76 (d, J=4.9 Hz, 6F), −178.0 (bs, 1F); MS (12 eV) m/z (rel intensity) 257 ($M^+-C_6H_{11}$, 27), 85 (65), 84 (62), 69 (11), 57 (24), 56 (32), 43 (100). Found: C, 45.93; H, 5.81%. Calcd for $C_{13}H_{19}F_7O_2$: C, 45.89; H, 5.63%.

The Reaction of Ketene Silyl Acetals with Trifluoromethyl Iodide. CF_3I (1.0 mmol) was introduced into the flask precooled to −78 °C, then hexane (5.0 ml) and ketene silyl acetal (2.0 mmol) were added to the flask. Et_3B (0.2 mmol) was added and the reaction mixture was immediately warmed up to room temperature. After stirring for several hours (Table 3), extractive work-up followed by purification gave the corresponding trifluoromethylated ester.

Octyl 3,3,3-Trifluoropropanoate (33b): Bp 56—61 °C (1 Torr, bath temp); IR(neat) 2956, 2926, 2856, 1754, 1418, 1399, 1364, 1269, 1221, 1119 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.28 (bs, 10H), 1.59—1.74 (m, 2H), 3.17 (q, J=10.1 Hz, 2H), 4.18 (t, J=6.7 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=14.01, 22.60, 25.69, 28.34, 29.09 (two peaks), 31.72, 39.66 (q, J=30.9 Hz), 65.95, 123.4 (q, J=277 Hz), 164.1 (q, J=4.2 Hz); ^{19}F NMR ($CDCl_3$) δ=−64.02 (t, J=10.4 Hz); MS (70 eV) m/z (rel intensity) 129 ($M^+-C_8H_{15}$, 6), 112 (23), 84 (94), 83 (73), 70 (100), 69 (45), 68 (30), 56 (73). Found: C, 55.21; H, 8.13%. Calcd for $C_{11}H_{19}F_3O_2$: C, 54.99; H, 7.97%.

Methyl 2-Trifluoromethyloctanoate (39b): Bp 78—83 °C (24 Torr, bath temp); IR(neat) 2956, 2928, 2860, 1755, 1459, 1439, 1354, 1272, 1209, 1165, 1107 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.4 Hz, 3H), 1.21—1.41 (m, 8H), 1.67—2.01 (m, 2H), 3.11 (dqd, J=9.9, 8.4, 4.8 Hz, 1H), 3.78 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=13.87, 22.44, 26.11, 26.70, 28.74, 31.37, 50.28 (q, J=27.4 Hz), 52.44, 124.7 (q, J=280 Hz), 168.2 (q,

J=2.7 Hz); ^{19}F NMR ($CDCl_3$) δ=−68.86 (d, J=8.5 Hz); MS (12 eV) m/z (rel intensity) 226 (0.3), 155 (23), 143 (13), 142 (100), 116 (27), 115 (18), 85 (27), 84 (16). Found: C, 53.05; H, 7.82%. Calcd for $C_{10}H_{17}F_3O_2$: C, 53.09; H, 7.57%.

Hexyl 3,3,3-Trifluoro-2,2-dimethylpropanoate (41c): Bp 58—63 °C (5 Torr, bath temp); IR(neat) 2956, 2932, 2860, 1745, 1476, 1401, 1282, 1206, 1152, 1119 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.6 Hz, 3H), 1.24—1.39 (m, 6H), 1.42 (s, 6H), 1.58—1.73 (m, 2H), 4.16 (t, J=6.6 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.87, 19.67, 22.46, 25.36, 28.32, 31.28, 48.45 (q, J=25.5 Hz), 65.84, 126.4 (q, J=282 Hz), 170.5; ^{19}F NMR ($CDCl_3$) δ=−75.42 (s); MS (12 eV) m/z (rel intensity) 157 ($M^+-C_6H_{11}$, 31), 139 (8), 85 (32), 84 (100), 69 (24), 57 (13), 56 (68), 43 (50), 42 (9). Found: C, 55.09; H, 8.18%. Calcd for $C_{11}H_{19}F_3O_2$: C, 54.99; H, 7.97%.

The Reaction of Ketene Silyl Acetals with 2,2,2-Trifluoroethyl Iodide. The reactions were performed according to Procedure B.

Octyl 4,4,4-Trifluorobutanoate (33c): Bp 72—77 °C (1 Torr, bath temp); IR(neat) 2958, 2928, 2858, 1744, 1332, 1265, 1230, 1192, 1145, 1112, 985 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.89 (t, J=6.5 Hz, 3H), 1.30 (bs, 10H), 1.57—1.71 (m, 2H), 2.33—2.63 (m, 4H), 4.11 (t, J=6.7 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=13.99, 22.60, 25.83, 27.09 (q, J=3.3 Hz), 28.50, 29.14 (two peaks), 29.35 (q, J=29.6 Hz), 31.74, 65.26, 126.5 (q, J=277 Hz), 170.9; ^{19}F NMR ($CDCl_3$) δ=−67.56 (t, J=10.4 Hz); MS (12 eV) m/z (rel intensity) 143 ($M^+-C_8H_{15}$, 27), 112 (44), 84 (96), 83 (83), 82 (24), 70 (100), 69 (36), 68 (23), 56 (59). Found: C, 56.84; H, 8.61%. Calcd for $C_{12}H_{21}F_3O_2$: C, 56.68; H, 8.32%.

Methyl 2-(2,2,2-Trifluoroethyl)octanoate (39c): Bp 88—93 °C (24 Torr, bath temp); IR(neat) 2954, 2928, 2858, 1744, 1438, 1381, 1260, 1203, 1153, 1126, 1096 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.5 Hz, 3H), 1.27 (bs, 8H), 1.45—1.77 (m, 2H), 2.05—2.33 (m, 1H), 2.47—2.77 (m, 2H), 3.72 (s, 3H); ^{13}C NMR ($CDCl_3$) δ=13.97, 22.49, 26.68, 28.86, 31.51, 32.52, 35.87 (q, J=29.1 Hz), 39.34, 51.96, 126.2 (q, J=277 Hz), 174.6; ^{19}F NMR ($CDCl_3$) δ=−65.93 (t, J=10.4 Hz); MS (70 eV) m/z (rel intensity) 240 (0.9), 169 (18), 156 (100), 87 (42), 59 (22), 57 (11), 55 (18), 43 (18), 41 (21). Found: C, 54.70; H, 8.18%. Calcd for $C_{11}H_{19}F_3O_2$: C, 54.99; 7.97%.

The Reaction of 42 with Perfluorohexyl Iodide. Following the procedure B, treatment of ketene silyl acetal **42** with perfluorohexyl iodide provided a cyclized product **43** (10%) and perfluoroalkylated ester **44** (50%). 3-Iodomethyl-2-(2,2,3,3,4,4,5,5,6,6,7,7,7-tridecafluoroheptyl)-2-(trimethylsiloxy)-oxolane (**43**): Bp 93—98 °C (1 Torr, bath temp); IR(neat) 2956, 2894, 1363, 1234, 1146, 1123, 1018, 908, 845, 719, 709, 634 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.14 (s, 9H), 1.73—1.94 (m, 1H), 2.28—2.76 (m, 4H), 3.04 (dd, J=10.2, 9.9 Hz, 1H), 3.38 (dd, J=9.9, 4.2 Hz, 1H), 3.81 (ddd, J=10.6, 8.6, 6.2 Hz, 1H), 4.01 (ddd, J=8.6, 8.3, 2.0 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=1.06, 3.54, 32.86, 39.10 (t, J=20.0 Hz), 51.10, 65.81, 103.7; ^{19}F NMR ($CDCl_3$) δ=−81.31 (tt, J=9.8, 3.0 Hz, 3F), −112.7—−114.1 (m, 2F), −122.1 (bs, 2F), −123.4 (bs, 2F), −124.0 (bs, 2F), −126.3—−126.8 (m, 2F); MS (12 eV) m/z (rel intensity) 632 (0.1), 618 (12), 506 (21), 505 (100), 489 (8), 304 (6), 303 (49), 299 (15), 55 (54). Found: C, 28.72; H, 2.96%. Calcd for $C_{15}H_{18}F_{13}IO_2Si$: C, 28.49; H, 2.87%.

3-Butenyl 3,3,4,4,5,5,6,6,7,7,8,8,8-Tridecafluorooctanoate (44): Bp 91—96 °C (27 Torr, bath temp); IR(neat) 1755, 1352, 1241, 1207, 1145, 1122, 709, 628 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.43 (qt, J=6.7, 1.3 Hz, 2H), 3.14 (t, J=17.5 Hz, 2H), 4.26 (t, J=6.7 Hz, 2H), 5.11 (ddt, J=10.2, 1.7, 1.3 Hz, 1H), 5.13 (ddt, J=17.1, 1.7, 1.3 Hz, 1H), 5.78 (ddt, J=17.1, 10.2, 6.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=32.81, 36.92 (t, J=22.5 Hz), 64.99, 117.5, 133.3, 163.8; ^{19}F NMR ($CDCl_3$) δ=−81.31 (tt, J=6.9, 3.0 Hz, 3F), −111.6—−112.5 (m, 2F), −122.2 (bs, 2F), −123.3 (bs, 4F), −126.3—−126.8 (m, 2F); MS (12 eV) m/z (rel intensity) 432 (2), 362 (9), 361 (100), 341 (16), 55 (5), 54 (93). Found: C, 33.49; H, 2.23%. Calcd for $C_{12}H_9F_{13}O_2$; C, 33.35; H, 2.10%.

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. XVIII. Factors Affecting the Rates of Dissociation of N–B Bond in the Coordinated Form of 9-[2-(Dialkylaminomethyl)-phenyl]-9-borabicyclo[3.3.1]nonanes[1)]

Shinji Toyota and Michinori Ōki*

(Received January 7, 1991)

NMR spectra of the title compounds reveal that they exist in the intramolecularly N–B coordinated form. The NMR signals exhibited dynamic behaviors accompanied with the dissociation of the N–B bond and total line shape analyses of the exchanging nuclei afforded kinetic parameters for the topomerization. Entropies of activation are large and positive, typical for the dissociation of coordination bonds. Examination with the multiple probes shows that the nitrogen inversion requires additional energy after the N–B bond dissociation. The barrier for the topomerization is affected by *N*-alkyl groups due to their F-strain. The barrier height is reduced in nonpolar solvents and not influenced by nucleophilicity of solvents. These solvent effects are discussed in connection with polarity of the N–B bond and steric hindrance of the boron atom.

The dynamic NMR method is a convenient technique for observation of dynamic processes of ligands in various coordination compounds,[2-4)] of which uniqueness is that rates of bond dissociation can be determined in the absence of foreign materials in organic solvents. An amine ligand is one of the well investigated examples. The dissociative processes of lignads were observed by NMR for tin–amine,[5)] silicon–amine,[6)] boron–amine,[7,8)] and other complexes.[9)] From the ease of dissociation, the kinetic basicity of an amine ligand or the kinetic Lewis acidity of a metal center can be estimated.

Recently, the kinetic parameters for the N–B bond dissociation in an intramolecular boronate–amine complexes (**1**) were determined by the total line shape analysis.[1)] The low barrier of the dissociation (**1a** $\Delta G^{\neq}_{233}$ 11.5 kcal mol^{-1}) was ascribed to the weak Lewis acidity of the boron atom which accepts electron from two attached oxgen atoms by p_π–p_π interactions. Trialkylborane–amine complexes should exhibit higher barriers to the N–B bond dissociation, since in these compounds the carbon atoms attached to the boron do not bear lone-pair electrons that suppress the acidity of the boron, and indeed trialkylboranes are known to be better electron acceptors than boronates.[10)]

In 1984, Kalbarczyk and Pasynkiewicz reported the synthesis of this type of compound, 9-[2-(dimethylaminomethyl)phenyl]-9-borabicyclo[3.3.1]nonane (**2**), which was stable in the air.[11)] They proposed the intramolecularly coordinated form with a four-coordinated center of boron from the chemical shift data in ^{1}H NMR spectrum. It seemed convincing on one hand, but on the other their ^{13}C NMR data were not in conformity with the expected structure. They reported that the *N*-methyl groups were diastereotopic and the carbon atoms in the positions 2(4) and 6(8) in the borabicyclononane skeleton (2(4)-C and 6(8)-C) and those in the positions 3 and 7 (3-C and 7-C) were isochronous. Since the molecule has a σ plane, passing N, B, 3-C, and 7-C, the *N*-methyl groups should be enantiotopic in the coordinated form. On the other hand, the 2-C/8-C pair as well as the pairs of 4-C/6-C and 3-C/7-C should not be equivalent in the coordinated form. From our experience, however, we were convinced that compounds **2** should exist as a coordinated form in solution and were prompted to reexamine this compound as a model for the trialkylborane-amine complexes. Evidence for the structure, the coordinated form, will be presented in this paper.

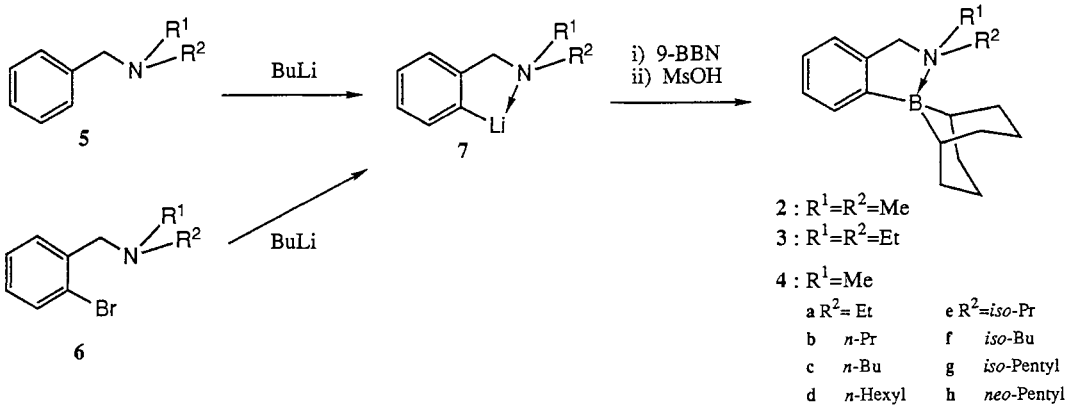
2

The strength of the N–B bond is affected by steric hindrance and solvents in addition to the basicity of the nitrogen atom and the acidity of the boron atom.[1)] Since the barrier to the dissociation in **1b** was lower than that in **1a** due to the steric effect (F-strain), the steric effect is expected to become more important, when the electron acceptor is bulky, as is the case of the 9-borabicyclo[3.3.1]-9-nonyl (9-BBN) group. Polarity and nucleophilicity of the solvent affected the rates of the N–B bond dissociation in **1** by affecting the ground state stability and by assisting the leaving of the amino moiety, respecively. These effects are expected to be affected by the bulkiness of the borane as well. It should be of interest to compare the strength of coordination in the 9-BBN system bearing various *N*-alkyl groups in various solvents because the data can assist us to get further insight into the acid-base properties of the amine-borane complexes in solution.

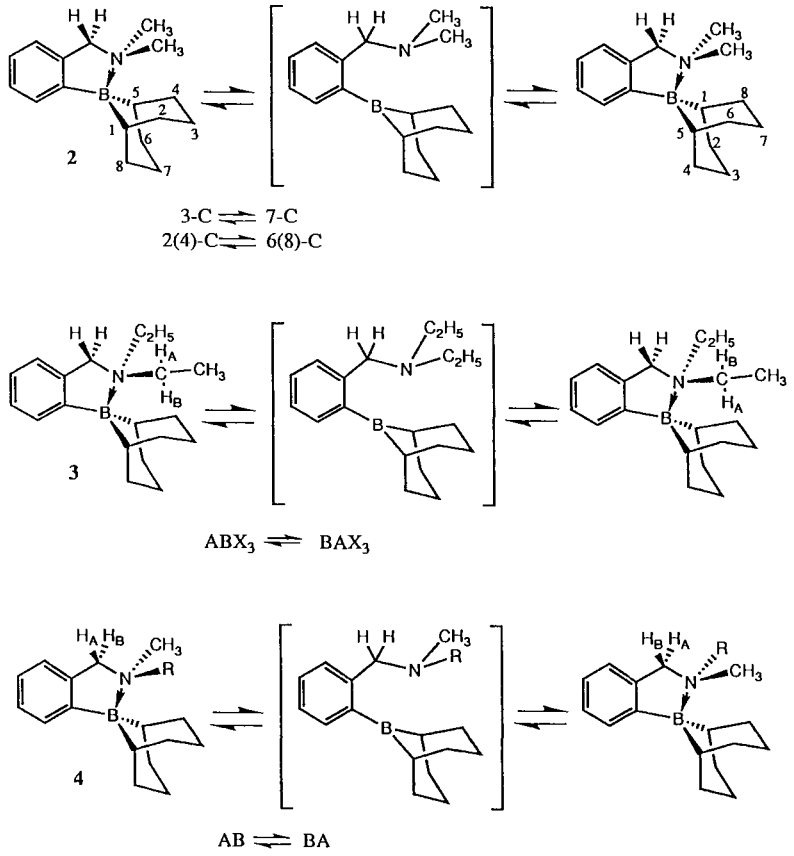
Results and Discussion

Since compound **2** possesses no convenient diastereotopic proton pairs for the NMR line shape analysis, the topomerization process in this compound must be observed by ^{13}C NMR spectra. To make this system amenable to ^{1}H NMR dynamic study, we designed **3** and **4**; instead of two methyl groups in **2**, **3** carries two ethyl groups and **4** a methyl group and an alkyl group.

These compounds were synthesized according to a known method shown in Scheme 1. The treatment of *o*-lithio-*N*,*N*-dialkylbenzylamines (**7**) with 9-BBN afforded the desired compounds. The point which deserves mention here is the steric effect in the preparation of the lithio compounds. The *o*-lithiation of *N*,*N*-diethylbenzylamine with butyllithium requires several days[12] although that of *N*,*N*-dialkylbenzylamine (**5**) proceeds smoothly during a day or so,[13] when one of the alkyl groups is a methyl and another in an alkyl group which has no branch at α- or β-position. For the syntheses of **3**, **4e**, **4f**, and **4h**, the corresponding lithio compounds



Scheme 1.



Scheme 2. Idealized topomerization processes in **2**, **3**, and **4**.

were prepared from *o*-bromo-*N*,*N*-dialkylbenzylamines (**6**) and butyllithium by the halogen–lithium exchange method,[14] because the corresponding benzylamines were too slowly lithiated under ordinary conditions.

Both ^{1}H NMR and ^{13}C NMR spectra were in conformity with the expected structure of compounds **2**, **3**, and **4**. The two methyl groups were equivalent, whereas 2(4)-C and 6(8)-C were not equivalent in **2**. Nonequivalent signals of ring carbons were reported in intermolecular 9-BBN complexes with pyridine.[15] The methylene protons in the ethyl groups were nonequivalent in **3**. Compound **4** showed nonequivalent benzylic methylene protons and other similar characteristics with those mentioned for **2**. These are in accord with the coordinated forms of these compounds.

The methylene protons in the ethyl groups in **3**, which are diastereotopic unless the dissociation of the N–B bond is too rapid on the NMR time scale, exchange their sites after the dissociation of the N–B bond followed by the nitrogen inversion and recoordination. Similarly, the benzylic methylene protons in compound **4** satisfy the requirement as a probe. Idealized topomerization processes in these compounds are shown in Scheme 2.

^{11}B NMR signals of these compounds were observed at 9.5 ppm (**2**), 10.5 ppm (**3**), and 9.3 ppm (**4a**) with reference to BF_3:OEt_2, these shifts being in accord with those in other trialkylborane–amine complexes[15,16] and being at higher fields by ca. 70 ppm relative to the nitrogen-free borane (cf. 9-phenyl-9-BBN; 80.35 ppm).[17] Such a high field shift of a coordinated tetrahedral boron compared with a trivalent one was reported in similar compounds.[8,17]

Kinetic Parameters for Topomerization in 2 and 3. The methylene protons of the ethyl group in compound **3** showed broad signals at room temperature and they became sharp (AB part of the ABX_3 system) at −20 °C. ^{13}C NMR signals due to the carbons at 2(4)-C/6(8)-C exhibited line broadening at room temperature as well. The total line shape analyses of these spectra afforded kinetic parameters for the topomerization shown in Table 1. We could also obtain the kinetic parameters for **2** by taking advantage of the diastereotopic carbon pairs, carbons at 3-C/7-C and 2(4)-C/6(8)-C. The data are also compiled in Table 1.

Several points of interest can be mentioned here. Firstly, both compounds **2** and **3** give much higher barriers to the topomerization than **1**. As expected, the N–B coordination in borane–amine complexes is stronger than that in boronate–amine complexes, although the steric effects could reverse the situation. The result can be well explained by the enhanced Lewis acidity of the boron atom. Secondly, the entropy of activation is large, positive in every case. This value is typical, when the ground state possesses the ionic character which is reduced at the transition state, and is often observed in the dissociation of coordination bonds. The dissociation in borane–amine complexes is no exceptions. Thirdly, there is no concentration effect on the kinetic parameters for the topometrization. Therefore we can compare the parameters obtained in different concentrations directly.

Mechanism of Topometization in 3. The free energies of activation for the topomerization obtained from the proton and the carbon probes in **3** are significantly different, the proton probe giving a 1.2 kcal mol^{-1} higher barrier than the carbon probe (Table 1). We wish to explain the result in the following way.

The site exchange of the methylene protons takes place after dissociation of the N–B bond followed by inversion of the nitrogen atom (and then rotation about an N–C bond) and recombination to form the N–B bond. Thus the difference in barriers obtained by the two probes suggests that the nitrogen inversion requires additional energy after the N–B bond dissociation and that the rate-limiting step is the nitrogen inverstion rather than the N–B bond dissociation.

Nitrogen inversion in *N*,*N*-dialkylbenzylamine complexes was reported to be much faster than the N–M bond scission in boronate–amine complex (**1**)[1] and tertiary amine hydrogen chlorides.[18] Barriers to nitrogen inversion in *N*,*N*-dialkylamines are relatively high (ca. 11 kcal mol^{-1}), although inversion in open-chain amines generally requires lower activation energy than this value.[19] Therefore, unless otherwise affected, nitrogen inversion in general should exhibit lower barriers than the N–B bond dissociation.

However, the nitrogen inversion in compound **3** is specifically affected by the steric effects. The nitrogen inversion is effected by either displacing one of the ethyl groups to the position where the lone pair electrons has occupied before inversion, or by true inverstion of the nitrogen. The latter seems too much energy-requiring because the two ethyl groups which change their posi-

tions will strongly interact with the 9-BBN moiety. Even the former, however, suffers from the steric hindrance of the 9-BBN group because one of the ethyl groups must come very close to the 9-BBN during the site exchange. It may be argued that the nitrogen inversion can take palce after rotation about the benzyl carbon-to-nitrogen bond. This process, however, also requires much energy because the two ethyl groups interfere strongly with the 9-BBN group during the rotation, if nitrogen inversion does not take place.

On the other hand, the site-exchange of the ring carbons is caused by rotation of the C_{Ph}–B bond after the N–B bond dissociation. If the rotation about the bond in question is much faster than the dissociation, the rate-limiting step should be the latter process and the rates of topomerization should be equal to half of the rates of the N–B bond dissociation. Although it is difficult to conclude which is faster by the data presented in this paper, the following paper[20] provides a clue for the diagnosis.

In the paper, dissociation of an S–B bond and sulfur-inversion in a similar complex are discussed. The sulfur-inversion is a faster process than the rotation about the C_{Ph}–B bond. The free energy of activation for the rotation is ca. 12.5 kcal mol^{-1}. Because of the similar steric situations in both compound **3** and the sulfur compoud, in which a lone-pair electron lobe directs toward the 9-BBN group, we may take the activation energy for the sulfur compound as an approximate value for the rotation of the 9-BBN group in **3**. Since this value is well below the activation energy for the topomerization obtained with the carbon probe, we may now conclude that the activation energy obtained with the carbon probe is indeed that of the N–B bond scission.

It is tempting to consider that the entropy of activation observed by the carbon probes are larger, positive than that observed by the proton probe because freedom increases in the transition state for the nitrogen inversion. Although it is difficult to justify or to exclude the possibility that the transition state structure for the nitrogen inversion is such that rotation about the benzylic carbon-to-nitrogen bond takes place to some extent with simultaneous partial exchange of the positions of the ethyl group and the N-lone pair electrons, the results clearly show that nitrogen inversion is a slower process than the N–B bond dissociation.

We conclude that the proton probes and the carbon ones give information on different processes in this molecule: the carbon probes give information on the N–B bond dissociation and the proton probe that on nitrogen inversion. Unfortunately, the information on the nitrogen inversion cannot be quantitative becaues the process is influenced by the N–B bond dissocaiton. This is clear from the entropy of activation for the nitrogen inversion which is large positive. Independent nitrogen inversion is known to show near-zero entropy of activation.[19]

Steric Effects on Rates of Topomerization. The free energy of activation in the dimethyl compound (**2**) was ca. 4 kcal mol^{-1} higher than that in the diethyl compound (**3**), as is revealed by comparison of kinetic parameters obtained by the carbon probes (Table 1). The reduction of the barrier height in **3** is attributed to the steric effect (F-strain).[21] This phenomenon was also observed in the boronate–amine system **1** and the difference in the free energies of activation between the dimethyl and the diethyl compounds was 1.5 kcal mol^{-1}.[1] The more bulky the borane in borane–amine complexes, the more important the F-strain. The result presented here is in accord with this generalization because 9-BBN is a very bulky group.[22]

To get further insight into the steric effects of *N*-alkyl groups on the topomerization, the kinetic parameters for compound **4** were similarly determined. The bezylic methylene protons were used as a probe in unsymmetrical compounds **4**, the carbon probe (3-C/7-C) being also used for **4a** for comparison. The kinetic data thus obtained are listed in Table 2.

Compounds **4a–d**, which possess a methyl group and a straight chain alkyl group, give almost the same barriers to the topomerization. This is reasonable becasue the steric effects on the stability of the ground state is given by the first methylene group which is attached to the nitrogen and those methylene groups in β- and farther positions will direct away from the boron to minimize the steric effects. In addition, the basicity of

a) Obtained from carbon probes in the 9-BBN group.

the amines is not affected appreciably by the chain-length of the alkyl group. Although this situation should affect the entropy of the ground state and consequently the entropy of activation in principle, it does not increase the entropy of activation to a significant extent as is seen in Table 2.

Comparison of free energies of activation for compounds **2**, **3**, and **4a**, obtained with the proton and carbon probes provides other points of interest. On one hand, compound **4a** shows medium barrier height among the compunds, when they are determined with carbon probes. This means the steric effects of the alkyl groups on the amino-nitrogen is significant. On the other hand, if the barrier is determined with proton probes, **4a** gives a higher barrier than that obtained with the carbon probes. This will mean that the steric effects given by a methyl group on inversion of the amine after the N–B bond dissociation is strong enough to make the barrier significantly higher than that for the N–B bond dissociation.

In **4e–g** bearing an isoalkyl group, the free energy of activation decreases in the order **4g**>**4f**>**4e**. Apparently branching at the α-position of the alkyl group which is attached to the nitrogen has a very large effect which lowers the barrier hight. Branching at the β-position has a small effect but that at farther positions inserts little effect on the N–B bond scission. In order to see the effect of further branching at the β-position of the alkyl group, we introduced a neopentyl group. As is seen in Table 2, compound **4h** shows the lowest barrier to the N–B bond dissociation among the compounds examined. This type of steric effects are known as γ-effect in ^{13}C NMR spectroscopy[23] and this is the manifestation of the similar effect in kinetics. The series of compounds **4e**—**4h** together with **4a**—**4d** constitute clear examples which show that destabilization of the ground state without affecting the transition state significantly indeed lowers the barrier to dissociation.

Solvent Effects on Topomerization in 3 and 4a. Kinetic parametrs for the topomeization in **3** and **4a**, determined for solutions of various solvents, are listed in Tables 3 and 4, respectively. Solvents are arranged in the order of their dielectric constants in these tables.

There are unambiguous solvent effects on the rates of topomerization; the more polar the solvent, the larger the free energy of activation at 323 K. The free energy of activation obtained in cyclohexanes, typical nonpolar solvents, are ca. 2 kcal mol^{-1} smaller than those obtained

in polar solvents. Though the proton probes afford the barrier to nitrogen inverstion, it is not separated from the barrier to the bond dissociation and thus the solvent affects the activation parameters. We attribute the results to the stabilization of the ground state in polar solvents. Since the N–B coordination bond is polar, the ground state is more polar than the transition state in the topomerization process. A polar solvent stabilizes the ground state better than the transition state by solvation: Consequently, the barrier to the topomerization is enhanced in the polar solvent.

Similar solvent effects were observed in the boronate–amine complexes (**1a**).[1] Some irregularities, however, existed in rates of dissociation in **1a**. Oxygen-contatining solvents, especially ethers, gave larger rate constants than that expected from their polarity. We postulated that the dissociation of the N–B bond was assisted by solvent molecules in these solvents (S_N2 type dissociation). Such irregularities are insignficant in **3** and **4a**. This difference can be ascribed to the steric environments of the boron atoms. Back-side approach of the solvent molecules to the boron atom is unfavorable in **3** and **4a** because of the bulkiness of the substituents on the boron atom in the 9-BBN group: They resemble the *t*-alkyl case in S_N2 reactions.

The kinetic parameters in **4a** could be obtained even in pyridine-d_5, which is well known to be a good donor, and the rates are normal on the stand point of expectation from its polarity. This result also suggests that solvent polarity rather than nucleophilicity of solvent molecules plays important role in the dissociation processes. Although methanol-d_4 and acetic acid-d_4 were used for a solvent, these solvent were unsuitable for a solvent because of reaction with the complexes.

Experimental

Melting points are uncorrected. Elemental analyses were performed on a Perkin–Elmer 240C analyzer. High resolution mass spectra were measured with a JEOL JMS-DX303 spectrometer. Silica gel used for column chromatography was Wako-gel C-200. *N,N*-Dimethylbenzylamine (Tokyo Kasei Co.) and a THF solution of 9-BBN (Aldrich Chemical Co.) were commercially available. *N*-Alkyl-*N*-methylbenzylamines[24] and *o*-bromo-*N*-alkyl-*N*-methylbenzylamines[14] were prepared according to known methods and these amines were distilled before use. Deuterated solvents for NMR measurements were purchased from Aldrich Chemical Co., E. Merck, or MSD ISOTOPES.

General Procedure for the Syntheses of Compound 2,3, and 4. For the preparation of an *o*-lithio-*N,N*-dialkylbenzylamine solution in ether, *N,N*-dialkylbenzylamines were used for the case of **2**, **4a**—**d**, and **4g** (Method A) and *o*-bromo-*N,N*-dialkylbenzylamines were used for others (Method B).

Method A. To a solution of an *N,N*-dialkylbenzylamine (20 mmol) in 30 ml of dry ether was added 13 ml (20 mmol) of a 1.5 mol dm^{-3} hexane solution of butyllithium at −78 °C under a nitrogen atmosphere. The mixture was allowed to stand until the temperature became ambient and stirred for another 12 h at the temperature. The mixture was slowly transferred to 40 ml of a 0.50 mol dm^{-3} THF solution of 9-BBN and stirred for 10 min at room temperature. To the reaction mixture cooled to 0 °C, 1.3 ml (20 mmol) of methanesulfonic acid was added. Then white precipitate was formed with evolution of hydrogen gas. After the gas evolution ceased, the reaction mixture was stirred for 1 h at room temperature and filtered with a glass filter. The filtrate was evaporated under reduced pressure and the residue was extracted with 30 ml of ether for three times. The combined extracts were evaporated and the crude material was purified by recrystallization from hexane–ether and/or chromatography on silica gel (eluent: hexane).

Method B. To a solution of an *o*-bromo-*N,N*-dialkylbenzylamine (20 mmol) in 40 ml of dry ether was added 13 ml (20 mmol) of 1.5 mol dm^{-3} hexane solution of butyllithium at −78 °C under a nitrogen atmosphere. The mixture was allowed to stand until the temperature became ambient and stirred for another hour at the temperature. The solution was slowly transferred to 40 ml of a 0.50 mol dm^{-3} THF solution of 9-BBN. The following procedures are the same as in Method A.

9-[2-(Dimethylaminomethyl)phenyl]-9-borabicyclo[3.3.1]nonane (2). **2** was obtained in 45% yield. Mp 124.5—126.0 °C. Found: C, 80.10; H, 10.41; N, 5.45%. NMR Measurement and Line Shape Analysis. ^1H and proton-decoupled ^{13}C NMR spectra were measured on a JEOL GSX-400 spectrometer operating at 399.8 MHz and 100.5 MHz, respectively. Temperature were calibrated using the chemical shift differences of methanol and ethylene glycol. Unless otherwise mentioned the concentration of the solution was ca. 30 and 200 mmol dm^{-3} for ^1H and ^{13}C NMR measurement, respectively. The FID data were accumulated more than 8 times for ^1H and more the 100 times for ^{13}C. The line

a) Methylcyclohexane-d_{14}. b) Concentration 200 mmol dm^{-3}. c) 1,1,2,2-Tetrachloroethane-d_2. d) Cyclohexane-d_{12}.

shape analysis was performed using DNMR3K program.[36] The coupling constants and chemical shift differences of exchanging nuclei were checked at several points where the exchange was negligibly slow. The coupling constants were constant throughout the temperature ranges. The chemical shift differences were linearly correlated with temperature. T_2 values were estimated from the line width of exchanging signals at the slow exchange limit. For the simulation of methylene protons of ethyl groups in **3**, the calculations were performed only for the AB part in the $ABX_3 \rightleftarrows BAX_3$ system. The benzylic methylene protons in **4** were simulated as the $AB \rightleftarrows BA$ system. These parameters are listed in Tables 5 and 6. The rate contants are compiled in Table 7.

The line shape analyses for compound **2** were performed by using ^{13}C NMR signals due to 3-C/7-C and 2(4)-C/6(8)-C as the $A \rightleftarrows X$ exchange. Input parameters and rate constants follow: 3-C/7-C: $\Delta\nu$=0.037 t+24.5 Hz, T_2 0.30, 030 s. 2(4)-C/6(8)-C: $\Delta\nu$=−0.071 t+329.1 Hz, T_2 0.36, 0.38 s. Rate constant k/s^{-1} (temperature/°C): 5.0(55.0), 8.5(60.0), 15.6 (65.0), 25(69.9), 40(75.0), 64(79.9), 110(84.9), 190(89.9), 300(95.0), 450(99.9), 1000(109.8) in toluene-d_8.

The carbon signals in **3** and **4a** observed in toluene-d_8 were similarly analyzed. **3** 2(4)-C/6(8)-C: $\Delta\nu$=0.135 t+285.5 Hz; T_2 0.19, 0.20 s; k/s^{-1} (temperature/°C): 49(14.9), 90(20.0), 165(25.0), 280(30.0), 470(35.0), 740(40.0), 1950(49.6). **4a** 3-C/7-C: $\Delta\nu$=29.2 Hz (constant); T_2 0.20, 0.21 s; k/s^{-1} (temperature/°C): 13.5(39.8), 22.5(45.0), 37(50.1), 50(52.9), 65(55.1), 100(60.0).

^{11}B NMR spectra were measured on the same spectrometer operating at 128.2 MHz at room temperature. The chemical shifts were recorded relative to BF_3:OEt_2 used as an external reference.

This work was supported by Grants-in-Aid for Fundamental Scientific Research Nos. 02230108 and 01740320 from the Ministry of Education, Science and Culture. The 400 MHz NMR and mass spectra were measured at the Analytical Center in Okayama University of Science.

Dynamic NMR as a Nondestructive Method for the Determination of Rates of Dissociation. XIX. Sulfur Inversion in 9-[2-(Ethylthiomethyl)phenyl]-9-borabicyclo[3.3.1]nonane Proceeds via Dissociative Mechanism[1)]

Shinji TOYOTA and Michinori ŌKI*

(Received January 7, 1991)

Kinetic parameters for sulfur inversion in the title compound were determined by the dynamic NMR method in CD_2Cl_2 as follows: $\Delta H^{\neq}$ 14.2±0.1 kcal mol^{-1}, $\Delta S^{\neq}$ 11.3±0.3 cal mol^{-1} K^{-1}, $\Delta G^{\neq}_{233}$ 11.6 kcal mol^{-1}. The large and positive entropy of activation suggests that the inversion takes place through dissociative mechanisms. Comparison of the rate constants obtained with multiple probes shows that the rotation about the C_{Ph}–B bond requires further energy after the dissociation of the S–B bond. The solvent effect on the sulfur inversion is small but distinct; the more polar a solvent, the higher the barrier to the inversion. Dynamic behaviors of a related compound are also discussed.

Although inversion at a trivalent sulfur atom is one of the interesting phenomena in stereochemistry, there have been few general methods to investigate mechanisms of the inversion. Dynamic NMR spectroscopy was found to be a useful technique in studying sulfur inversion, especially in coordination compounds.[2,3)] Recently, we reported sulfur inversion in sulfonium salts,[4)] thioether–Lewis acid complexes,[5)] and platinum(II) complexes[6)] by the use of this method. These results are generalized that entropy of activation ($\Delta S^{\neq}$) is a convenient guide for diagnosing the mechanisms of sulfur inversion: Entropy of activation is large positive if the bond dissociation is the rate-limiting step (dissociative mechanism), whereas it is nearly zero if sulfur inversion takes place without bond scission (pyramidal inversion).

An organostannane compound **1** was one of the examples in the former case, but analogous boron compound **2** failed to show dynamic processes even at −90 °C due to low barrier to the S–B bond dissociation.[5)] Many of organoboron–thioether adducts were known to be unstable because of the weak basicity of the sulfur atom toward the boron atom.[7)] We expected that introduction of a boron atom bearing two alkyl groups should enhance S–B bond energy with respect to the boronate S–B bond. Our recent work revealed that the boron atom in 9-borabicyclo[3.3.1]-9-nonyl (9-BBN) group, which has unusual stability as a diakylboryl group,[8)] was a stronger Lewis acid toward amine ligands than that in boronates.[1,9)] We decided to use this boron atom as an acceptor and chose 9-[2-(ethylthiomethyl)phenyl]-9-BBN (**3**) for our study on the dissociation of the S–B bond.

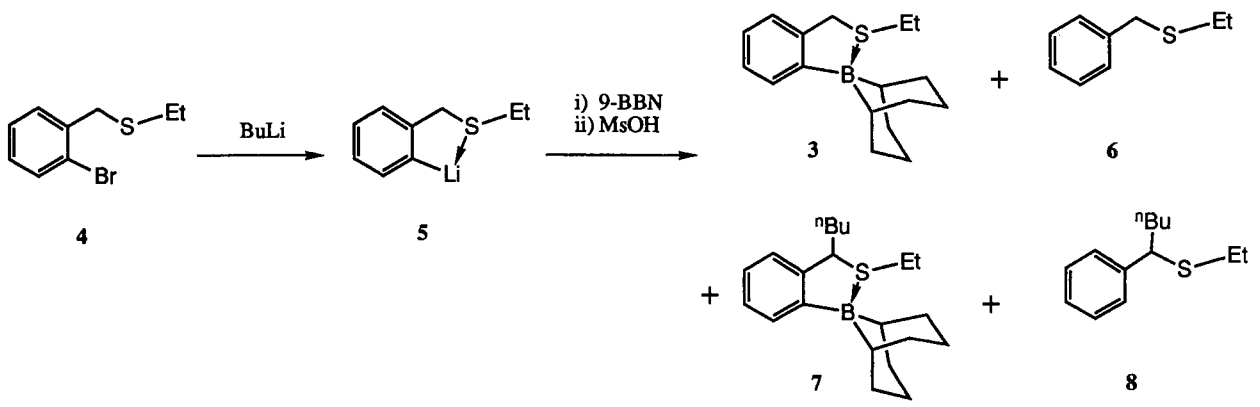
We have been interested in solvent effects on the rates of sulfur inversion as well. The barriers for the inversion in platinum(II)–thioether complexes are independent of solvents, in which the sulfur inverts without bond dissociation.[6)] On the other hand, there is no available information about solvent effects in dissociative mechanisms. Polar solvents decelerate the dissociation of coordination bonds involving a boron atom from our experiences[1,9)] and the same effects are expected in the dissociation of the S–B bond. In order to make the relationship between the inversion mechanism and solvent effects clear, we observed inversion processes of compound **3** in various solvents.

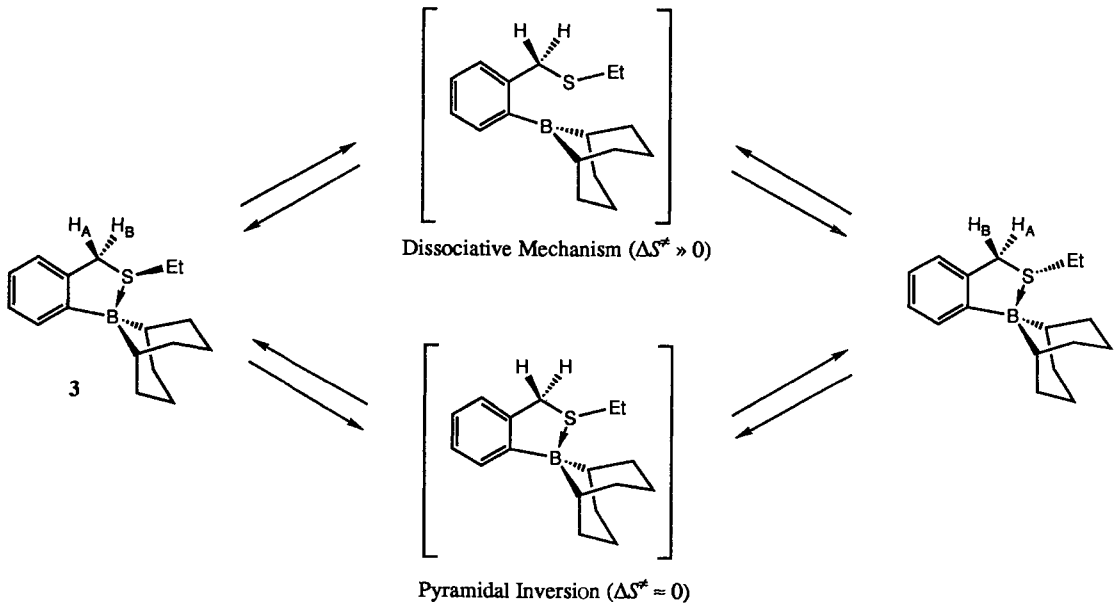
Results and Discussion

Synthesis and NMR Spectra of 3. Compound **3** was prepared in a modified procedure of the known method for the syntheses of 9-aryl-9-BBN's[10)] shown in Scheme 1. A solution of ethyl *o*-lithiobenzyl sulfide (**5**), prepared from 1-bromo-2-(ethylthiomethyl)benzene (**4**) and butyllithium, was treated with 9-BBN followed by methanesulfonic acid to give an oily mixture containing the desired compound. The reaction products were separated by HPLC and subsequent recrystallization afforded **3** in 19% yield as white crystals, which were air stable and soluble in ordinary organic solvents.

Other three products were identified as **6** (39%), **7** (7%), and **8** (4%) from their NMR and mass spectra: Compound **6** is a hydrolysis product of **5** and compounds **7** and **8** are butylated products of **3** and **6**, respectively. We believe that compounds **7** and **8** are formed in the following way. The benzylic protons in **3** and **6** are firstly lithiated by lithium hydride that results



Scheme 1.



Scheme 2. Possible mechanisms for the sulfur inversion in compound **3**.

from treatment of **5** with 9-BBN, although it is difficult to rule out that other lithium species react with them because various lithium sources may exist in the reaction mixture. Then butyl bromide derived from butyllithium attacks the benzylic positions to form compounds **7** and **8**. Prolonged stirring before the addition of methanesulfonic acid increased yields of the butylated compounds; this fact supports the mechanisms mentioned above.

Compound **3** possesses some diastereotopic pairs of protons and carbons which exchange their sites on the topomerization shown in Scheme 2. The benzylic methylene protons exhibited a sharp singlet at room temperature. With lowering the temperature, the signal began to broaden and became an AB quartet signal at −70 °C in CD_2Cl_2. Other proton signals except for the aromatic and the methyl ones also exhibited line shape changes in the temperature range. Carbon signals due to the 9-BBN group were broad even at room temperature and separated into eight signals at −70 °C. These observations suggests that the sulfur atom coordinates to the boron atom in **3** at low temperatures. The sulfur inversion takes place faster than the NMR time scale at room temperature and this process is frozen at −70 °C.

The chemical shift of ^{11}B NMR (**3**: 14.4 ppm) supports a coordinated structure as well. This value is typical for a tetrahedral boron and at a higher field than those in trialkylboranes.[11] The high field shifts caused by sulfur coordinations were observed in 9-halo-9-BBN complexes with dimethyl sulfide relative to free 9-halo-9-BBN's.[12]

Kinetic Parameters and Mechanism of Sulfur Inversion. We firstly selected benzylic methylene protons as a probe for the observation of dynamic processes at the

sulfur atom. Altough the methylene protons in the ethyl group also seemed to satisfy the requirement as a probe, we excluded them because of overlapping of the signals with those of the ring protons. The total line shape analyses were carried out with the use of DNMR3K program[13] and observed and simulated NMR signals for the benzylic methylene protons are shown in Fig. 1. Eyring plot of rate constants thus obtained affords kinetic parameters for the topomerization (Table 1).

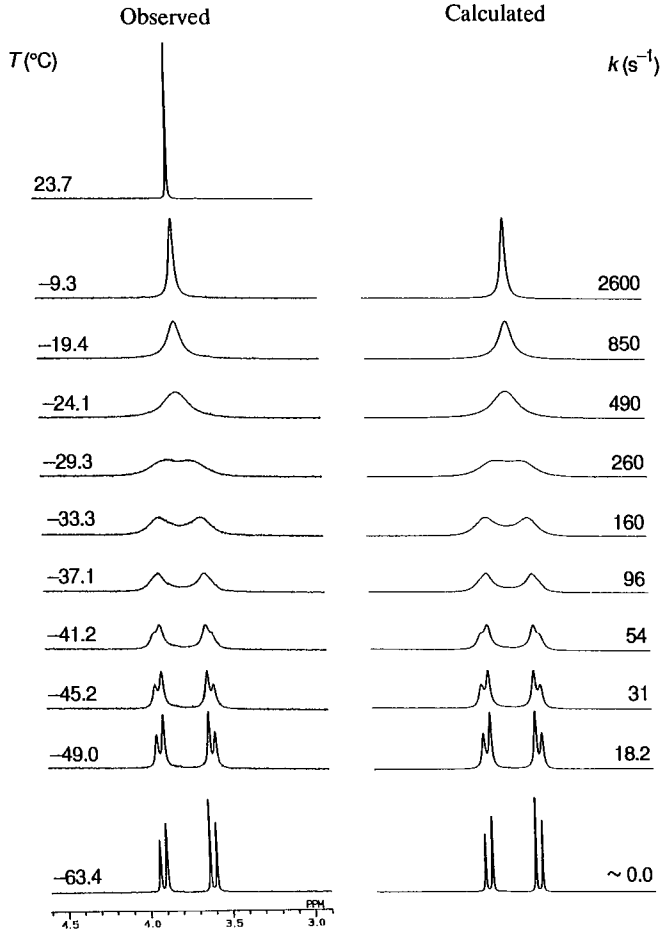


Fig. 1. Observed (solvent CD_2Cl_2) and calculated (DNMR3K program) line shapes for the benzylic methylene protons in compound **3**.

Entropy of activation is large positive as is expected for the dissociative mechanism, in which the ground state is ionic and the transition state is less ionic. Consequently, the dissociation of the S–B bond is the rate-limiting step for the topomerization of the benzylic methylene protons and the topomerization completes after the recombination from another side to form an S–B bond (Scheme 2). Strictly speaking, the rate constants of the topomerization should be doubled when we take account of the dissociation of the S–B bond. The dissociated sulfur atom recoordinates to the boron atom at the same site or at the other site with the same probabilities.

The S–B bond in **3** is more than 3 kcal mol^{-1} stronger than those in boronates (**2**)[15] and ca. 4 kcal mol^{-1} weaker than that in 3,3,4,4-tetramethylthiolane-boron tribromide complex.[5] These results are consistent with the general order of Lewis acidity of the boron atom: trihaloborane>trialkylborane>boronate.[7]

We have reported that, in platinum(II)-thioether complexes, the sulfur inversion takes place without scission of the Pt–S bond.[6] The results reported here contrast in the mechanisms of inversion. In the case of platinum, the pπ–dπ interaction is possible to stabilize the planar transition state for inversion. In the case of boron, the d-orbitals are of so high energy that such an interaction to stabilize the planar transition state for inversion is not effective. These differences must be responsible to the difference in the mechanisms of the sulfur inversion.

Comparison of Kinetic Parameters Obtained from Multiple Probes. We could also obtain kinetic parameters for the topomerization from diastereotopic proton and carbon pairs in the 9-BBN moiety in dichloromethane-d_2, these data being compiled in Table 1. Three probes that follow were used other than the benzylic methylene proton probe: The protons and carbons at 1,5-positions (1,5-H and 1,5-C) and the carbons at 3,7-positions (3,7-C) in the 9-BBN group.

The rate constants obtained from 3,7-C are ca. 7 times smaller than that obtained from the benzylic methylene proton probe. Namely, the topomerization observed by 3,7-C probe requires additional energy, 0.9 kcal mol^{-1}, compared with the latter probe. The site

exchange of 3,7-C requires bond rotaion about the C_{Ph}–B as well as the dissociation of the S–B bond. Although the sulfur inversion without the S–B bond breakage might explain the discrepancy of the rates, this process is eliminated from being the course for the observed topomerization because the inversion took place in dissociative mechanisms as judged from the value of entropy of activation mentioned above. On a steric point of view, pyramidal inversion seems to be an unfavorable process; steric hindrance between the 9-BBN group and the ethyl group must be serious at the transition state for the pyramidal inversion.

The differences in the rates are due to hindered rotation about the C_{Ph}–B bond after the dissociation of the S–B bond. Thus the rate-limiting step for the exchange of 3,7-C is the C–B bond rotation rather than the S–B bond dissociation. A 9-BBN group, in which wing protons overhang outside, is known to be bulky and its bulkiness is superior to that of a *t*-butyl group. It is probable that the rotation about the C_{Ph}–B bond is slow though there is no report on restricted rotation in an *o*-substituted 9-aryl-9-BBN.

The kinetic parameters for the exchanges of 1,5-H and 1,5-C were only determined by the coalescence method because their signals were very broad owing to spin-spin couplings with ^{10}B and ^{11}B. Both of the free energies of activation at the coalescence temperature are almost the same as that obtained from the benzylic methylene probe. This result is natural if one considers the topomerization mechanism; the site exchange of 1,5-positions completes by the sulfur inversion regardless of the C–B bond rotation.

Solvent Effects on the Dissociation of S–B Bond. The rates of dissociation in various solvents are listed in Table 2. As expected, an increase in solvent polarity tends to decelerate the dissociation of the S–B bond. The same effect in N–B bond dissociation has been explained on the basis of better stabilization of the polar ground state in polar solvents than the less polar transition state.[1,9] It is reasonable to assume that this explanation is also the case for the S–B bond dissociation.

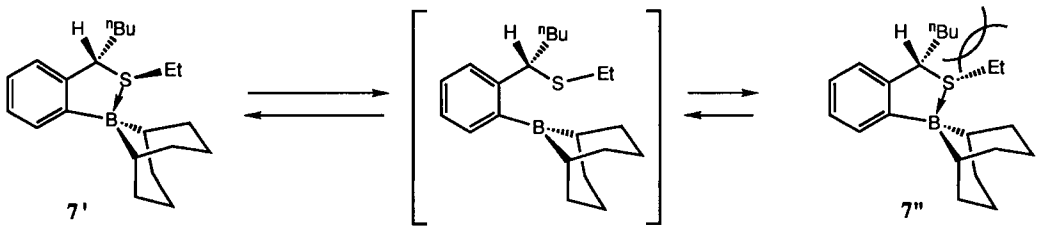
A careful comparison of the rate constants shows that the solvent effect on the S–B bond dissociation in **3** is smaller than that on the N–B bonds: a relative rate constant in methylcyclohexane-d_{14} and DMF-d_7, k(methylcyclohexane-d_{14})/k(DMF-d_7), is 6.5 in **3**, whereas it is 22 in 9-[2-(diethylaminomethyl)phenyl]-9-BBN (**9**).[1] The small solvent effect can be interpreted in terms of polarity of a coordination bond. Since an S–B bond is less ionic than an N–B bond, the solvation which stabilizes the ground state in the dissociation process is less important in the S–B bond case than that in the N–B. Anyway, there are unambiguous solvent effects on the dissociation of the S–B bond.

In contrast, there are little solvent effects on the sulfur inversion in platinum(II)–thioether complexes, in which the inversion took place without bond dissociation.[6] Therefore, solvent effects can be a clue to distinguish the two mechanisms of sulfur inversion; presence of solvent effects described above in the dissociative mechanism and absence of solvent effect in the pyramidal inversion. It is necessary to evaluate the solvent effects carefully because the difference in rate constants tend to be small in the dissociative mechanism.

Solvent assisted dissociation (S_N2 type dissociation) is observed for the N–B bond dissociation in an amine–boronate complex.[9] This assistance seems to be improbable in the 9-BBN system, compound **3** as well as **9**, due to steric hindrance of the bicyclic frame work. The rate constants of the dissociation obtained in donor solvents, diethyl-d_{10} ether, THF-d_8, and DMF-d_7, are not apart from those expected from their polarities. This finding supports the non-assisted dissociation mechanism.

Dynamic Behaviors in 7. The structural feature and some dynamic behaviors of the by-product **7** are also interesting. The structure was determined from its NMR and mass spectra (M^+ 328), these data suggesting existence of an extra butyl group compared with the structure of **3**. Since this compound has a chiral center at the benzylic carbon, two diastereomers should exist if the dissociation of S–B bond is negligibly slow.

The NMR spectra observed at various temperature exhibited line shape changes. This compound gave broad proton and carbon signals in the aliphatic region



Scheme 3. Topomerization process between diastereomers in compound 7.

at room temperature and these signals became sharp at −40 °C. These dynamic processes are also caused by the S–B bond dissociation shown in Scheme 3.

The NMR spectrum observed at −40 °C where the dynamic process is virtually frozen suggests that this compound exist in two forms, the major isomer being in 97% and the minor in 3% from integrated intensities of signals due to the benzylic methine proton. We assume that 7′ should be the major isomer because another isomer 7″, in which the butyl group and the ethyl are eclipsing, is sterically unfavorable. The population of the isomers shows that the major form is more stable by 1.6 kcal mol^{-1} than the minor one. The carbon signals observed at −40 °C are in accord with the structure of 7′.

The signals due to the benzylic methine proton showed line broadening at 0 °C and this change is interpreted in terms of the interconversion between the two isomers. Roughly estimated free energy of activation for the isomerization is 12 kcal mol^{-1} from the major isomer to the minor. This barrier is comparable to that for the S–B bond dissociation in **3**. This is in accord with the idea that the S–B bond scission is the rate-limiting step for the diastereomerization.

Experimental

Melting points are uncorrected. Silica gel 60 (Merck, 70—230 mesh) and Silica gel 60 F_{254} (Merck, 0.25 mm) were used for column and thin-layer chromatography, respectively. Preparative HPLC was carried out with a Hitachi L-6250 intelligent pump using a Chemcosolb Si column (5 μ, 25 mmϕ×500 mm). Elemental analyses were performed by a Perkin-Elmer 240C analyser. Mass spectra were measured with a JEOL JMS-DX303 spectrometer.

NMR Measurement and Line Shape Analysis. ^{1}H and ^{13}C NMR spectra were measured on a JEOL GSX-400 spectrometer operating at 399.8 MHz and 100.5 MHz, respectively. Temperatures were calibrated with a methanol sample. The concentration of the solution was ca. 40 mmol dm^{-3} and ca. 400 mmol dm^{-3} for ^{1}H and ^{13}C NMR measurement, respectively. The line shape analysis was performed by DNMR3K program.[13] Coupling constants and chemical shift differences were measured at several points where rates were almost zero. The chemical shift differences were linearly correlated with temperature, but the coupling constants were constant at every temperature. Spin–spin relaxation times (T_2) were estimated from the line width of exchanging signals at the slow exchange limit and line shapes of non-exchanging signals at the temperature where the exchange takes place. Input parameters for the simulation for the benzylic methylene protons (AB⇄BA) are listed in Table 3. The analyses for the carbon probe (3,7-C) were performed similarly under the A⇄X exchanging system with the use of the following parameters: $\Delta\nu$=54.5 Hz, T_2=0.17 s. The rate constants obtained are shown in Table 4. The barrier for the topomerization of 1,5-H and 1,5-C were determined by the coalescence method. The coalescence temperatures (T_c) and chemical shift differences ($\Delta\nu$) are −28±1 °C and 129.6 Hz for the 1,5-H and −24±1 °C and 201.0 Hz for the 1,5-C probe, respectively.

These were constant throughout the temperature range. c) Spin-spin relaxation times for the signals. d) Concentration ca. 400 mmol dm^{-3}. e) Constant throughout the temperature range.

^{11}B NMR spectra were measured on the JEOL GSX-400 spectrometer with a multinuclear tunable probe operating at 128.2 MHz. The chemical shifts are given to an external BF_3:OEt_2 (δ=0) reference.

9-[2-(Ethylthiomethyl)phenyl]-9-borabicyclo[3.3.1]nonane (3). To a solution of 3.34 g (14.4 mmol) of 1-bromo-2-(ethylthiomethyl)benzene[17] in ether (20 ml) was added 9.25 ml (14.4 mmol) of a 1.5 mol dm^{-3} hexane solution of butyllithium at −30 °C under a nitrogen atmosphere. The mixture was allowed to warm up to 0 °C and added to 28.8 ml (14.4 mmol) of a 0.5 mol dm^{-3} THF solution of 9-borabicyclo[3.3.1]nonane (Aldrich Co. Inc.) at 0 °C during the course of 1 min. Immediately after the addition, methanesulfonic acid (1.39 g, 14.4 mmol) was added at 0 °C and the mixture was stirred for 1 h at room temperature. The precipitate was filtered off by a glass filter and the filtrate was evaporated under reduced pressure. The residue was chromatographed on silica gel with hexane to give 2.34 g of a nonpolar mixture (colorless oil),

which consisted of four major products (R_f=0.42, 0.38, 0.36, and 0.31. eluent: hexane) and other minor products. The fractions containing the desired compound (R_f=0.36) were purified by HPLC (hexane as an eluent). Recrystallization from hexane-ether afforded 0.74 g (19%) of the desired compound as white crystals. Mp 116.0—118.0 °C. Found: C, 75.13; H, 9.41%; M^+, 272. Calcd for $C_{17}H_{25}BS$: C, 75.00; H, 9.26%; M^+, 272. ^1H NMR ($CDCl_3$) δ=1.00 (2H, br s), 1.28 (3H, t, J=7.4 Hz), 1.63—1.72 (2H, br m), 1.76—2.10 (10H, br m), 2.34 (2H, q, J=7.5 Hz), 3.89 (2H, s), 7.08—7.14 (2H, m), 7.19 (1H, dt, J=2.1 and 6.8 Hz), 7.69 (1H, d, J=7.5 Hz). ^{13}C NMR ($CDCl_3$)[18] δ=12.1, 23 (very broad, coupled with ^{10}B and ^{11}B), 24.1, 24.5, 32.8 (br), 37.2, 125.0, 125.1, 126.3, 132.3, 138.5. ^{11}B NMR ($CDCl_3$) δ=14.4.

Following three products were also identified.

9-[2-(1-Ethylthiopentyl)phenyl]-9-borabicyclo[3.3.1]nonane (7). **7** (R_f=0.42) was isolated by recrystallization from hexane. Yield 0.38 g (7%), mp 78.5—80.0 °C. Found: C, 76.80; H, 10.24%; M^+, 328. Calcd for $C_{21}H_{33}BS$: C, 76.81; H, 10.13%; M^+, 328. ^1H NMR ($CDCl_3$, r.t.) δ=0.94 (3H, t, J=7.4 Hz), 0.96 (2H, br), 1.32 (3H, t, J=7.5 Hz), 1.34—2.48 (19H, m), 2.53 (1H, m), 3.95 (1H, m), 7.08 (1H, d, J=7.2 Hz), 7.12 (1H, dt, J=1.0 and 7.2 Hz), 7.19 (1H, dt, J=1.4 and 7.2 Hz), 7.69 (1H, d, J=7.2 Hz). (CD_2Cl_2, −40 °C) δ=0.72 (1H, br s), 0.84 (3H, t, J=7.4 Hz), 0.93 (1H, br s), 1.24 (3H, t, J=7.4 Hz), 1.16—2.10 (18H, m), 2.33 (1H, m), 2.48 (1H, m), 3.89 (1H, dd, J=1.4 and 7.4 Hz, benzylic methine proton for the major isomer), 4.36 (br m, benzylic methine proton for the minor isomer), 6.98—7.17 (3H, m), 7.58 (1H, d, J=7.2 Hz). ^{13}C NMR ($CDCl_3$, r. t.)[18] δ=12.7, 13.9, 22.3, 24.5 (br), 25.5, 30.9, 21—38 (very broad), 56.5, 124.9, 125.0, 126.2, 132.5, 144.1. (CD_2Cl_2, −40 °C) δ=12.4, 13.9, 21.7 (br), 22.3, 24.0, 24.7, 25.4, 27.2 (br), 30.0, 30.9, 31.1, 32.9, 35.0, 37.4, 56.2, 125.0, 124.3, 126.0, 132.4, 144.3, 154.1. ^{11}B NMR ($CDCl_3$) δ=12.9. The free energy of activation for the topomerization between the two diastereomers was determined by the coalescence method with the signals due to benzylic methine protons (δ=3.89 and 4.36) in dichloromethane-d_2. The coalescence temperature was −17± 3 °C and the chemical shift difference was 184.8 Hz. The population of the minor isomer was 3.1% at −40 °C determined from the integration of the signals and the difference in free energies was 1.6 kcal mol^{-1} at the temperature. Other signals due to the minor isomer were not assigned because of various ambiguity.

Ethyl 1-Phenylpentyl Sulfide (8). **8** (R_f=0.38) was not isolated and its yield (0.13 g or 4%) was determined from the signal intensity of ^1H NMR. This compound was synthesized by another method as follows. A solution of α-lithiobenzyl ethyl sulfide (13.1 mmol) in ether (20 ml) prepared from benzyl ethyl sulfide and butyllithium in an ordinary manner was treated with 1-bromobutane (15.7 mmol) at 0 °C. Addition of 1 mol dm^{-3} HCl (20 ml) gave the desired sulfide (2.39 g, 87%) together with recovered benzyl ethyl sulfide (0.17 g, 9%). Bp 92—94 °C/0.4 mmHg (1 mmHg=133.322 Pa). Found: M^+, 208.1274. Calcd for $C_{13}H_{20}S$: M^+, 208.1285. ^1H NMR ($CDCl_3$) δ=0.84 (3H, t, J=7.0 Hz), 1.14 (3H, t, J=7.5 Hz), 1.17—1.37 (4H, m), 1.77—1.92 (2H, m), 2.25 and 2.29 (2H, AB part of the ABX_3 system, J_{AX}=J_{BX}=7,5 Hz, J_{AB}=12.3 Hz), 3.77 (1H, dd, J=6.5 and 8.6 Hz), 7.19—7.34 (5H, m). ^{13}C NMR ($CDCl_3$) δ=13.8, 14.4, 22.4, 24.8, 29.8, 36.2, 49.4, 126.8, 127.7, 128.3, 143.1.

Benzyl Ethyl Sulfide (6). **6** (R_f=0.31), which was obtained in 39% yield, was identified by comparison of ^1H NMR data with an authentic sample prepared by a standard method.[19] ^1H NMR ($CDCl_3$) δ=1.23 (3H, t, J=7.4 Hz), 2.44 (2H, q, J=7.4 Hz), 3.72 (2H, s), 7.21—7.33 (5H, m). ^{13}C NMR ($CDCl_3$) δ=14.3, 25.1, 35.8, 126.8, 128.4, 128.8, 138.5.

When the reaction mixture was stirred for 1 h at room temperature before the addition of methanesulfonic acid in the procedure of synthesis of **3**, yields of the products were 20, 30, 11, and 23% for **3**, **6**, **7**, and **8**, respectively. Separation of the products was tedious.

This work was supported by Grants-in-Aid for Fundamental Scientific Research Nos. 02230108 and 01740320 from the Ministry of Education, Science and Culture. The 400 MHz NMR and mass spectra were measured at the Analytical Center in Okayama University of Science.

Unusual EPR Profile Obtained by Laser Photoreaction of Cardiovascular Tissue

Kouichi NAKAGAWA†
Department of Chemistry, Boston University, Boston, Massachusetts 02215, USA
(Received September 11, 1990)

Using spin trap methods, laser generated free radicals from cardiovascular tissue in high viscosity blood solution have been studied by EPR. The EPR spectra obtained are compared with spectra of free radicals produced by both cw and pulsed excimer laser irradiation. Nitroxide spin adducts produced by excimer laser irradiation show an unusual EPR hyperfine structure. In addition, the EPR spectra obtained by continuous wave (cw) laser irradiation are different from those obtained by excimer laser irradiation. The observed β-hydrogen hyperfine coupling for pulsed laser is approximately 1 Gauss smaller than those for cw laser irradiation. The present EPR results provide firm evidence that different free radical reaction intermediates are produced for each laser mode.

The detection and characterization of transient free radical intermediates generated by laser photoablation of biological tissue are essential to the understanding of the mechanism of laser–tissue interaction. Recently, there has been a great interest in studying the formation and determination of laser ablated molecular intermediates in the area of laser medicine.[1-5] Electron paramagnetic resonance (EPR) techniques using spin trap methods have been employed to determine the nature of free radical fragments which are formed by laser photoablation processes.[3-4] By examining the ablated fragments, it may also be possible to trace back the molecular details of the initial photoproduced events of laser ablation on the tissue surface.

Several experimental attempts have been made to elucidate the mechanism of laser interaction with tissue samples. For example, photoacoustic spectra of normal artery wall and of atherosclerotic plaque are reported by Singleton et al.[1] Threshold fluences (in units of [J cm^{-2}]) for excimer laser ablated gaseous products were calculated from the photoacoustic spectrum. Acoustic measurements of vascular tissue by pulsed laser has been performed by Cross et al.[6] They succeeded in measuring pulsed laser generated thermoelastic stress-waves on a 10 nanosecond time scale using acoustic transducers. Clarke et al.[4] suggested that by comparing two different energy sources, pulsed laser and ultrasound, it could be determined if free radicals are produced by the photoacoustic shock wave following the laser pulse. Gaseous products accompanying cw and pulsed laser ablation of cardiovascular tissue[2] and arterial wall[1] have been determined by gas chromatography. The pulsed laser ablation at high fluence of tissue results in plasma emission. Some of the emitted species have been identified, such as atomic calcium, C_2, and CN.[5] The results imply that radical fragments are common products of secondary reactions occurring in the plasma and should not be used to support mechanistic models for laser ablation. Hence, the formation and characterization of the fragments has not been well established.

† Present address: Department of Chemistry, University of Denver, Denver, Colorado 80208, USA.

Nitroxide spin traps have great potential for application to biological systems. A number of biological systems have recently been investigated to probe the structure of biological free radicals.[7-10] As an extension, the free radicals produced by laser irradiation of tissue samples in high viscosity blood media are investigated. We hope to extend our findings to achieve better understandings of how free radicals are produced and what types of free radicals are produced by laser irradiation of cardiovascular tissue. The results are discussed in terms of the various laser wavelengths and a correlation between the laser generated free radicals produced by the action of continuous wave (cw) vs. pulsed laser irradiation.

Materials and Methods

Tissue sample preparation has been described in elsewhere.[1] A spin trap reagent: *N*-(4-pyridylmethylene)-*t*-butylamine *N,N'*-dioxide (4-POBN) was purchased from Aldrich Chemical Co. and used as is. The water soluble spin trap reagent 4-POBN was chosen because of its stability, solubility in water, and insensitivity to light. 4-POBN was dissolved in canine blood to a concentration of 50 mM (M=mol dm^{-3}). The canine blood containing heparin was used without deoxygenation and centrifuging or filtration in this in vitro experiment. The size of myocardium sample was approximately the diameter of an EPR tube (5 mm) and the tissue sample was mounted in the bottom of the EPR tube. The sample was in contact with a fused silica optical fiber connected to the laser and was directly irradiated through the optical fiber by the output of a focused laser beam.[3] The blood solution without tissue sample was also irradiated through the optical fiber coupled with the laser beam. The laser output power from the optical fiber was kept at ca. 0.3 W. Right after laser irradiation of the tissue sample, the spin trap-blood solution was immediately transferred to an EPR aqueous quartz cell and mounted in the EPR cavity.

EPR measurements were made with a Varian E 104 X-band spectrometer. EPR spectra were recorded at room temperature. The recording conditions were the following: microwave power, 20 mW; microwave frequency, 9.42 GHz; modulation amplitude, 1.0 G; modulation frequency, 100 kHz; time constant, 1.0 s; scan rate, 20 Gauss per minute (1 Gauss=10^{-4} T). The resonance fields were measured relative to the standard free radical, 2,2-diphenyl-1-picrylhydrazyl (DPPH).

Results

The background signals of the spin trap reagent (4-POBN) and the 4-POBN dissolved in blood solution are shown in Fig. 1(A) and (B), respectively. As evidenced by Fig. 1(A) and (B), there is no EPR detectable background signal from the spin trap reagent as well as spin trap-blood solution. The EPR signal of spin trapped free radicals generated by cw 514 nm irradiation of cardiovascular tissue is a doublet of triplet as shown in Fig. 1(C). The laser irradiation of spin trap-blood solution, without tissue sample, irradiated by cw 514 nm argon ion laser is shown in Fig. 1(D). Figure 1(D) shows a nitrogen dominated triplet overlapping with a weak doublet of triplet. This spectrum is indicative of the decomposition of 4-POBN such as di-*t*-butylnitroxide ($a^N \approx 17$ Gauss). These experimental procedures were repeated for cw 351 nm and pulsed 308 nm irradiation. The obtained results are shown in Figs. 2 and 3, respectively. The EPR spectra observed for both cw 514 nm and 351 nm irradiation of tissue sample are very similar as shown in Figs. 1(C) and 2(C), respectively. Both EPR spectra are dominated by a nitrogen triplet hyperfine pattern and further split by β-hydrogen.

Figure 3 shows that the trapped free radicals produced by pulsed UV laser ablation of the tissue sample are not the same as those by the irradiation of spin trap-blood solution. The EPR spectrum obtained on pulsed excimer laser irradiation of tissue under high viscosity blood solution is not a simple nitrogen triplet signal, as shown in Fig. 3(C). This EPR signal is a weak boublet. In addition, the previously obtained EPR spectra for pulsed 308 nm and 351 nm irradiation of tissue sample under low viscosity cyclohexane show a simple three line pattern.[3] In contrast, the EPR spec-

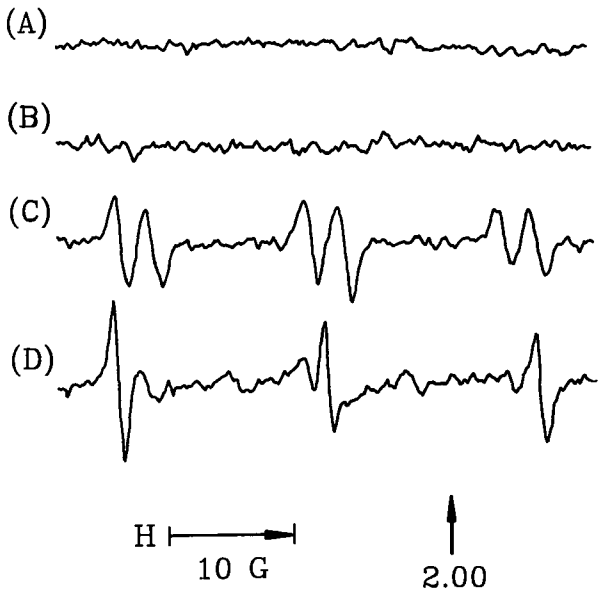

Fig. 1. Observed EPR spectra for cw 514 nm: (A) 4-POBN reagent before laser irradiation; (B) 4-POBN dissolved in blood before irradiation; (C) laser irradiation of myocardium in 4-POBN blood solution; and (D) irradiation of 4-POBN blood solution without myocardium. The calibrated g-value, 2.00_0, is marked. (Not DPPH, g=2.0036) EPR conditions are in the experimental section.

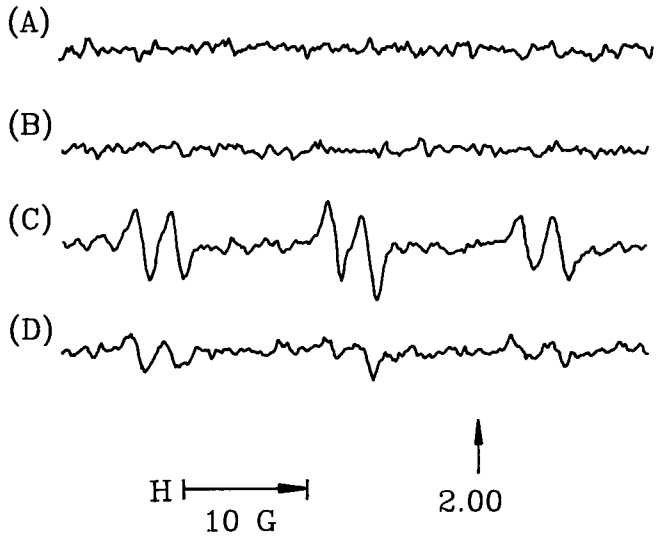

Fig. 2. Observed EPR spectra for cw 351 nm irradiation: (A) 4-POBN reagent before laser irradiation; (B) 4-POBN dissolved in blood before irradiation; (C) laser irradiation of myocardium in 4-POBN blood solution; and (D) irradiation of 4-POBN blood solution without myocardium.

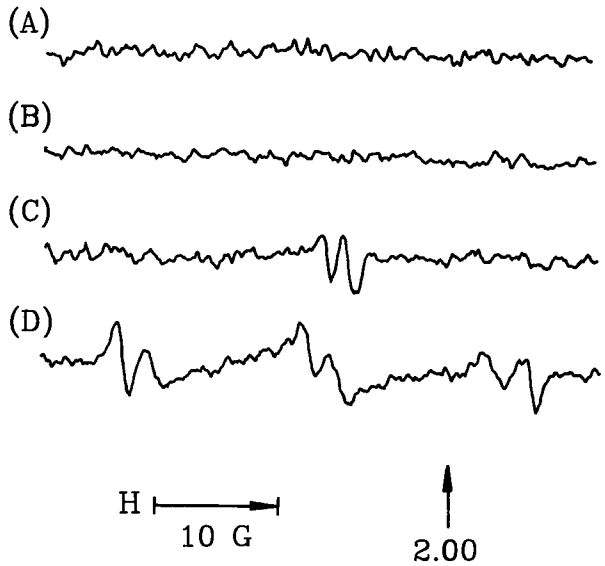

Fig. 3. Observed EPR spectra for pulsed 308 nm: (A) 4-POBN reagent before laser irradiation; (B) 4-POBN dissolved in blood before irradiation; (C) laser irradiation of myocardium in 4-POBN blood solution; and (D) irradiation of 4-POBN blood solution without myocardium.

trum obtained from excimer laser irradiation of blood solution shows a broad nitrogen dominated hyperfine structure (Fig. 3(D)). This EPR pattern presumably consists of di-*t*-butylnitroxide which is formed by photodecomposition 4-POBN and blood cell.

Comparison of the EPR spectra for trapped free radicals generated by laser irradiation of tissue sample is shown in Fig. 4. We immediately recognize three major EPR spectral differences between cw and pulsed laser irradiation. First of all, the hyperfine structure obtained for pulsed laser irradiation is obviously distinct from those obtained for cw laser irradiation. Second, the center line for pulsed laser irradiation is shifted towards high magnetic field. Thus, the *g*-value associated with the photogenerated free radicals is smaller than those for cw laser irradiation. Third, the hyperfine splitting for pulsed excimer laser photolysis is smaller (ca. 1 Gauss) than those for cw laser irradiation, as listed in Table 1. In addition, the pulsed 308 nm ablation of tissue sample did not produce thermal damage to the target site or the surrounding blood solution. However, cw 514 and 351 nm irradiation of the tissue sample resulted in thermal damage to the tissue target site and formed a thermally damaged cloud in the surrounding blood solution.

a) Lipid peroxy radical. b) Units in Gauss.

Addition comparison of the EPR spectra for cw 514 nm, 351 nm, and pulsed 308 nm irradiation of blood solution in the presence of 4-POBN is shown in Fig. 5. Figure 5(A) shows that the decomposition of spin trap results in a sharp three line pattern building on a weak doublet of triplet signal. Changing the laser wavelength to 351 nm a weak doublet of triplet signal is observed. The main spectral differences between (A) and (B) in Fig. 5 are due to the light absorption property of canine blood. The absorption spectrum of canine blood is shown in Fig. 6. A peak at 412 nm is

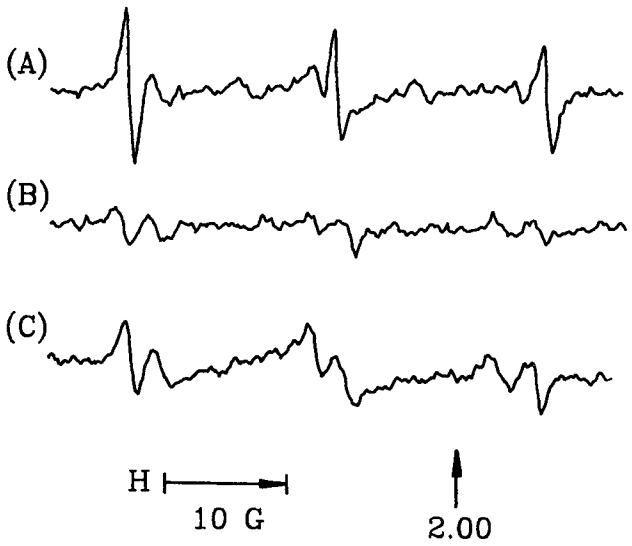

Fig. 5. Comparison of EPR spectra for (A) cw 514 nm, (B) cw 351 nm, and (C) pulsed 308 nm laser irradiation of blood solution in the presence of 4-POBN.

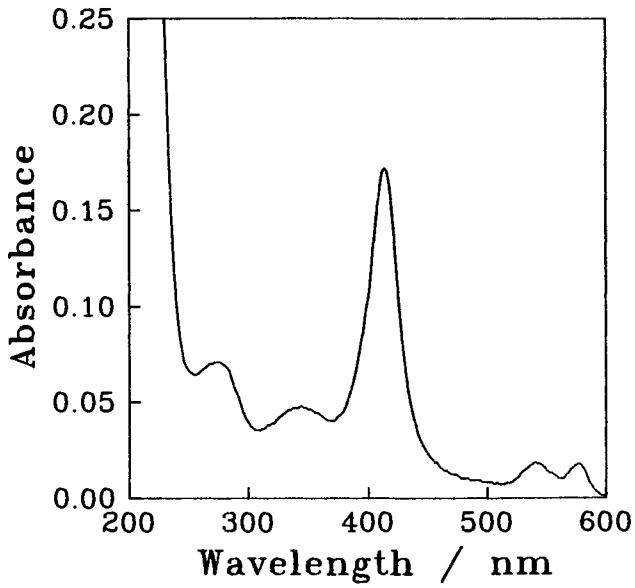

Fig. 6. The canine blood absorption spectrum.

characteristic hemoglobin absorption. The relative intensity of absorption at 351 nm is six times stronger than that at 514 nm. Switching to pulsed 308 nm irradiation of canine blood, a broad doublet of triplet signal is observed without thermal damage to the site. The signal might be due to decomposition of blood cell as well as spin trap. This broad EPR signal might result from slow tumbling motion of the trapped free radicals. Slow molecular motion generally results in the broadness of EPR signals.[11] However, there is no similarity on the EPR signal between laser irradiation of the blood solution and laser ablation of the tissue sample.

Discussion

The mechanism of laser-tissue interaction has been the subject of great concern. The light delivery of cw or pulsed energy has quite different consequences in its effect on the tissue target site. A schematic illustration of laser-tissue interaction is presented in Fig. 7. In the case of light delivered in a cw mode, several groups have reported the extensive thermal damaged to the tissue target site.[2,3,12] In contrast, high energy excimer laser ablates the tissue with no evidence for thermal damage.[1-3,6,12] However, both laser modes cw and pulse involve the production of free radicals accompanying laser interaction with tissue. The species of free radicals are weakly dependent depending on laser wavelengths and strongly dependent on laser operational mode: cw and pulse.

A. CW Laser Irradiation. A photon 514 nm wavelength is equivalent to 2.4 eV. This energy is not enough to break the average C–C bond which is ca. 3.6 eV. The excited molecules at the target site undergo internal coversion to a vibrational excited states, and any subsequent decomposition can be considered as a thermal process in which the photons merely act as a source of thermal energy.[13] This heat accumulation of the tissue may play an important role of the free radical generation and propagation. As a matter of fact, sever thermal damage to the tissue target site was observed for 514 nm laser irradiation of the cardiovascular tissue.

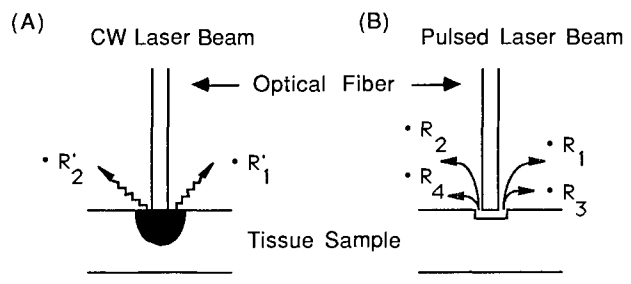

Fig. 7. A schematic illustration of short-lived free radicals produced by laser irradiation of the tissue sample. $\cdot R'_1$ and $\cdot R'_2$ represent cw laser generated free radicals, and $\cdot R'_1$, $\cdot R'_2$, $\cdot R'_3$, and $\cdot R'_4$ represent pulsed laser generted free radicals where pulsed laser produces free radicals more efficient compared to cw laser (Ref. 3). (A) CW laser irradiation shows severe thermal damage to the target site. (B) Excimer laser irradiation shows clean tissue removal without thermal damage.

A photon energy of cw 351 nm wavelength is 3.9 eV. This laser also produces thermal damage to the tissue target site.[3] Thus, the fundamental radical generation scheme might be similar to that for cw 514 nm radiation. However, the tissue sample absorbs more cw 351 nm laser light than cw 514 nm.[14] Thus, the UV laser light excites the tissue sample more effectively and may break weak bonds of the protein sample. The slight differences (ca. 0.2 Gauss) in β-hydrogen splitting in the observed EPR spectra between cw 514 nm and 351 nm, as listed in Table 1, could explain the differences. Both EPR spectra obtained by two different cw laser wavelength irradiations of myocardium may not be distinguished clearly without additional characteristic EPR structure.

Therefore, the trapped radicals for cw visible and ultraviolet laser photolysis should have some similarities, and the free radicals are photothermally produced. Thermally excited water in the tissue and oxygen in blood is involved for their generation and propagation. Oxygen centered free radicals are the most likely produced. Hydrogen radicals may not be trapped because the typical hyperfine values for the trapped hydrogen radical ($a^N \approx 16.3$, $a_\beta^H \approx 10.2$ Gauss[15]) do not match the hyperfine values obtained by laser irradiation of tissue as listed in Table 1.

B. Excimer Laser Irradiation. A photon energy at 351 nm for pulsed laser is the same as that of the cw UV 351 nm. However, the pulsed laser beam is very is very intense, that is, a large number of photons are produced within a 20 nanosecond laser pulse. Such a direct impact of photons from the laser causes nonthermal ablation of the tissue samples and the expulsion of the fragments at supersonic velocities.[13] This pulsed laser excitation could have enough energy to fragment the tissue protein chains without thermal damage at the target site.

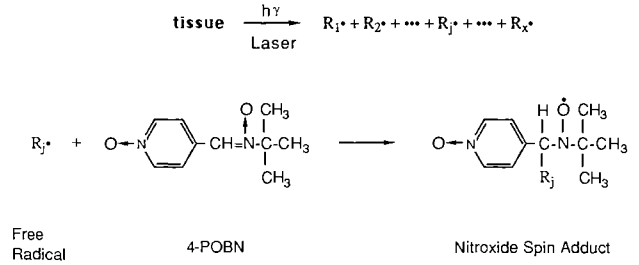
The present results show that there are clear differences in observed EPR spectra between cw and pulsed laser irradiation of the tissue sample under blood solution as well as laser irradiation of the spin trap-blood solution without the tissue sample, as shown in Figs. 4 and 5, respectively. The EPR spectra obtained by cw laser photolysis of the tissue sample show a doublet of triplets. On the other hand, the EPR spectrum obtained by excimer laser ablation has a unique profile (Fig. 4(C)). The unusual EPR profile for excimer laser excitation can be accounted for by the followings: First, recent laser photoablation studies have indicated that various molecules are produced by pulsed UV laser irradiation of biological material and organic polymer.[1-3,5,18,19] If the tissue sample is exposed to a pulsed UV laser beam, it will break down into various molecular fragments of the protein sample. These free radical fragments can subsequently react with 4-POBN and

become stable free radicals. Second, the various size of free radicals might be a key to the unusual EPR spectrum. The tumbling motion of a nitroxide spin adduct affects changes in EPR lines due to loss of spectral symmetry. If the size of the spin adduct is large, the rotational correlation time for the spin adducts increases considerably. Third, viscosity of the blood solution might contribute to the unusual hyperfine structure for excimer laser irradiation of tissue. The viscosity of blood is about 4.8 relative to water.[20] If a nitroxide spin adduct is immobilized due to the higher viscosity, the EPR spectrum loses the spectral symmetry of nitrogen hyperfine structure.[10, 21]

As conformation of the interpretation, Collagen as the model compound was irradiated by excimer laser in the same manner as the irradiation of the tissue samples. The EPR signal obtained by excimer laser ablation of collagen is identical to that of the tissue sample.[22] Therefore, carbon centered various free radicals from the tissue sample can be trapped by excimer laser.

Summary

Considering the above discussed, the possible free radicals for pulsed UV laser ablation are C-terminal with various chain molecules. Various free radicals are produced by pulsed and cw laser operational modes. The contingent reaction scheme is



where R_1·, R_2·, R_j·, and R_x·, represents unidentified free radical fragments formed on either cw or pulse laser irradiation of the tissue. Those free radicals react with 4-POBN and become stable nitroxide spin adducts. For cw laser irradiation, R· can be oxygen centered radicals. C-terminal R· are most likely produced by pulsed laser. The present EPR results suggest that the backbone of amino acids, lipids, or other biological building blocks are cleaved during the ablation. Moreover, the carbon centered long chain free radicals derived from peptide main chain scission were produced by Hg–Xe lamp photolyses[23] and C-terminal radicals are observed by high output power cw laser irradiation of the tissue samples.[24]

Finally, it is interesting to note that those different types of laser generated short-lived free radicals should be converted to stable free radicals by biochemical manner based on the species for practical applications. The present results do not provide full details regarding laser generated free radicals. In the presence of multiple free radicals such as in our system, the identification of unknown radicals becomes more difficult using conventional cw EPR techniques. It is important to see substantial hyperfine structures in the EPR spectrum of the spin adduct. In most cases the hyperfine structure is a key to identification of the trapped radicals. Therefore, it might be useful to employ other techniques to regain some missing details of the hyperfine other techniques to regain some missing details of the hyperfine structure of the spin adducts in order to provide full information regarding the laser generated free radicals.

The author grately acknowleges Dr. J. M. Isner of New England Medical Center for the gift of canine blood sample. He thanks Drs. K. Kuwata, M. Kuwabara, T. Kumagai, and T. Tajima, R. H. Clarke for useful discussion during his visit. He also thanks referees for excellent suggestions on the manuscript.

(Received November 20, 1990)

Mutant β-D-galactosidases containing nonnatural aromatic amino acids were produced by misincorporation during protein overproduction by *Escherichia coli*. The incorporation of 3-(1-pyrenyl)-L-alanine (pyrAla) was confirmed by fluorescence measurement of the produced enzyme, although the replacement frequency was low. Some of mutant enzymes showed improved thermostability.

Chemical treatment and protein engineering have produced many modified or mutant proteins, which are more effective in enzymatic activity than the original ones. In the meantime, the introduction of functional residues by means of chemical modification is limited only to functional groups on the protein surface, where modifying reagents are sterically reachable. On the other hand, site-directed mutagenesis provides a means of substitution at precise position of the sequence with natural amino acids. If protein engineering also enables utilization of nonnatural amino acids, we can design novelly functionalized enzymes easier.

Proofreading system prevents protein biosynthesis from mistranslation in every step of biosynthetic process.[1] However, the system could not function properly against nonnatural amino acids because it works most strictly against naturally occurring amino acids. So far, many kinds of nonnatural amino acids, whose structure is very similar to a natural one, have been introduced into proteins by using *Escherichia coli*. The substitution rate of a target amino acid with a nonnatural amino acid was found to be about 10% to 90% in the cases of alkaline phosphatase,[2-8] aspartate transcarbamylase,[9] β-D-galactosidase[10] human epidermal growth factor (hEGF).[11] Schlesinger and co-workers have succeeded in incorporation of various amino acid analogs into bacterial alkaline phosphatase.[2-7] Alkaline phosphatase gene is expressed under the control of *phoA* promoter that is induced by lowering the phosphate concentration of the culture medium. The biosynthesis of the other probably toxic abnormal proteins is not active under these conditions except the production of abnormal alkaline phosphatase. In this method, Miyazawa and co-workers succeeded in preparing hEGF substituted with one norleucine for methionine by biosynthesis of alkaline phosphatase signal peptide-hEGF fusion protein.[11] On the other hand, incorporation of nonnatural amino acids, whose structure is very different from a natural one, is a difficult task. One of approaches to realize this purpose is that the protein-biosynthesis system is accelerated to obtain the mutant enzymes containing nonnatural amino acids as much as possible.

In this paper, incorporation of fluorescent nonnatural amino acids into β-D-galactosidases was studied by using *E.coli* in the overproduced state on the protein synthesis. 3-(1-Pyrenyl)-L-alanine (pyrAla) was incorporated into β-D-galactosidases and relatively high thermostability was found in some of the mutant enzyme.

Experimental

o-Nitrophenyl β-D-galactopyranoside (ONPG), bovine serum albumin (BSA), and *E.coli* β-D-galactosidase (M.W. 130 kDa) were purchased from Sigma, USA. Bacterial endonucleases BamHI and EcoRV, bacterial alkaline phosphatase (BAP), and T4 DNA ligase were purchased from Toyobo Co., Ltd., Japan. Bacto-Trypton and Bacto-Yeast-Extract were purchased from DIFCO Laboratory, USA. *E.coli* B357 (wild type) and *E.coli* DH5α (F⁻, *endA*1, *hsdR*17 (rk⁻, mk⁺), *supE*44, *thi*⁻¹, *recA*1, *gyrA*96, *relA*1, Δ (*argF*-laczya) U169, φ 80d*lacZ* λ M15, λ⁻) were used for expression of β-D-galactosidase.

Ultraviolet absorption spectra were recorded by a Hitachi Model 200-10 spectrometer. Fluorescence emission and excitation spectra were recorded by a Hitachi MPF-4 autocorrected fluorescence spectrometer. Fluorescence excitation spectra were monitored at wavelength 397 nm for pyrAla and at wavelength 415 nm for 3-(9-anthryl)-L-alanine (antAla).

The recombinant plasmid pUC19Z was synthesized from the plasmid pUC19 and pMC1871 (Pharmacia, Sweden). A 3.0 kbp fragment containing the lacZ gene was excised from the pMC1871 plasmid with BamHI, and ligated into the pUC19, digested with BamHI and dephosphorylated with BAP. The resultant plasmid pUC19Z was transformed into DH5α strain and the transformants exhibiting β-D-galactosidase activity were picked on 2% agar plates of LB-medium (1% (w/w) bacto-trypton/0.5% (w/w) bacto-yeast-extract) in the presence of ampicillin, 5-bromo-4-chloro-3-indolyl β-D-galactopyranoside and isopropyl β-D-galactopyranoside. The plasmid DNA was isolated with the method of alkaline treatment.[15]

The *E.coli* strain DH5α harboring plasmid pUC19Z was precultured in a 500 ml flask containing 100 ml of LB-medium at 37 °C, with shaking for 16 h. The cells were collected by centrifugation at 3,000 rpm for 5 min and suspended in 30 ml of deionized water. An aliquot (1 ml) of the precultured cell

suspension was inoculated into 100 ml of LB-medium in a 500 ml flask and cultivated to the exponential growth phase. Then 10 mg of chloramphenicol was added and the flask was shaken for further 1 h. The cells were harvested by centrifugation and suspended in 30 ml of deionized water again. A portion of cell suspension (20 ml) was inoculated into 2.0 liter of LB-medium in the presence of 50 μg ml^{-1} of nonnatural fluorescent amino acid and 0.1% lactose instead of glucose and cultured to the exponential growth phase at 37 °C. After cultivation, the cells washed with deionized water were suspended in 400 ml of 0.3 M (1 M=1 mol dm^{-3}) potassium phosphate buffer (pH 7.2) in the presence of 3 mM $MgCl_2$. Cell growth was monitored at absorbance of 600 nm. 1 OD corresponds to 10^8 cells ml^{-1}.

Cell-free extracts were prepared by disintegrating the cells with a Braun cell homogenizer (Type 853023, B. Brown, Germany). The cell homogenate was centrifuged at 12,000 rpm for 5 min, the supernatant obtained being further centrifuged at 45,000 rpm for 60 min at 4 °C. The cell-free extract obtained finally was concentrated through a DIAFLOW membrane filter (Ultrafiltration Cell Model 12, AMICON Corp., USA). The total amount of protein was estimated by the Lowry's method.[16] The β-D-galactosidase protein was analyzed with sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE).

The proteins were recovered from the cell-free extracts with saturated ammonium sulfate. It was solubilized again with 100 mM potassium phosphate buffer (pH 7.2) and dialyzed for 24 h at 4 °C against 500-fold volume of the potassium phosphate buffer to remove ammonium sulfate. Thereafter, the fluorescence excitation spectra of the protein solution and the dialyzing buffer were measured at every 2.5 h of dialysis against 500-fold volume of the buffer at 4 °C. After the dialysis for ten times (25 h), the protein solution was added to the same volume of dimethyl sulfoxide (DMSO) and stirred overnight at 4 °C to wash out the nonnatural amino acid followed by further 20 times of the dialysis. The content of the nonnatural amino acid was monitored by following the fluorescence spectrum during the dialysis treatment.

β-D-Galactosidase was purified with a gel-filtration chromatography followed by nondenaturing polyacrylamide gel electrophoresis. The proteins were applied to a Sephacryl S-300 column (2.5×85 cm) equilibrated with 100 mM potassium phosphate buffer (pH 7.2) containing 10 mM $MgCl_2$. A single peak of the β-D-galactosidase activity was found and the fractions were collected and concentrated. The concentrated solution was applied to a nondenaturing polyacrylamide gel electrophoresis (7%) and the gel band corresponding to β-D-galactosidase was excised and eluted out with an Extraphore electrophoretic concentrator (Pharmacia). The preparation finally obtained was used as a purified β-D-galactosidase.

The nonnatural amino acid contents in the β-D-galactosidases were estimated by the fluorescence measurement. The fluorescence from the enzyme is attributed to both the original tryptophan residues and the incorporated nonnatural amino acid residues. Assuming that the fluorescence intensity of the tryptophan residues ($F_{trp}(\lambda)$) gives a maximum at wavelength λ_{trp} and the intensity of the nonnatural amino acid residues ($F_{aa}(\lambda)$) gives a maximum at wavelength λ_{aa}, we have a ratio (R) of the fluorescence intensity from the nonnatural amino acid residues to that from the tryptophan residues as follows.

$$F_{obs}(\lambda) = XF_{trp}(\lambda) + YF_{aa}(\lambda)$$

$$R_{obs} = F_{obs}(\lambda_{aa}) \,/\, F_{obs}(\lambda_{trp})$$

$$R_{trp} = F_{trp}(\lambda_{aa}) \,/\, F_{trp}(\lambda_{trp})$$

$$R_{aa} = F_{aa}(\lambda_{aa}) \,/\, F_{aa}(\lambda_{trp})$$

$$R = YF_{aa}(\lambda_{aa}) \,/\, XF_{trp}(\lambda_{trp})$$
$$= R_{obs}(1 - R_{trp}/R_{obs}) \,/\, (1 - R_{obs}/R_{aa})$$

where $F_{obs}(\lambda)$ represents the observed fluorescence intensity at wavelength λ and X and Y represent the contributions of each fluorescent residue. The nonnatural amino acid content C (mol/mol tryptophan residue) was estimated from a calibration curve for 1 mg ml^{-1} bovine serum albumin solution.

The β-D-galactosidase activity was measured at 30 °C by following the increase in absorbance of *o*-nitrophenol produced through the hydrolysis of ONPG at 405 nm.

Results

The construction of plasmid pUC19Z to express β-D-galactosidase is illustrated in Fig. 1. *E.coli* DH5α was transformed with the pUC19Z. Several transformants exhibiting β-D-galactosidase activity (blue-colored col-

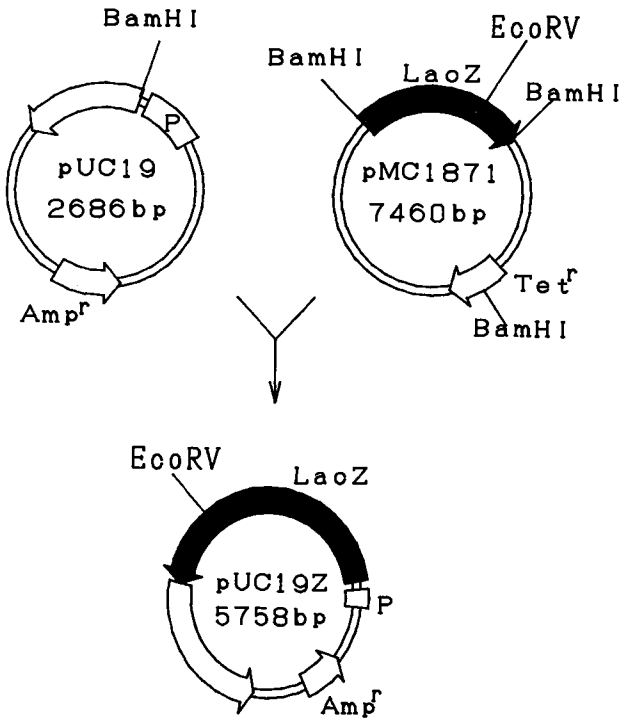

Fig. 1. Construction of β-D-galactosidase expressing plasmid pUC19Z. BamHI and EcoRV represent the restriction sites on the plasmid. P is the promoter, and lacZ is the structural gene of β-D-galactosidase. Some of the colonies were screened for the presence of lacZ gene by agalose electrophoresis. A positive colony had a band corresponding to the open-circular plasmid DNA band digested at the site of EcoRV in lacZ gene.

onies) and having 5.7 kbp fragment of plasmid pUC19Z were obtained. The enzymatic activities of β-D-galactosidase in various *E.coli* strains, grown in the absence of nonnatural amino acids, were measured and are summarized in Table 1. The activity of the wild strain B357 was 73-fold higher in lactose-grown cells than in glucose-grown cells. The protein produced in the presence of lactose from the DH5α strain, transformed with pUC19Z and treated with chloramphenicol, showed two thousands-fold activity of that in the presence of glucose. The content of β-D-galactosidase in the total protein was estimated over 65% judging from the calculation of specific activity (126 μmol min^{-1} mg^{-1} in the cell free extract; 171 μmol min^{-1} mg^{-1} in the purified preparation).

The reduction in growth of strain B357 was within 20% when the concentration of each nonnatural amino acid added in medium was lower than 50 μg ml^{-1}. The amount of proteins produced and β-D-galactosidase activity are shown in Table 2. In the presence of 3-(1-naphthyl)-L-alanine (napAla), both the protein production and the activity per cell increased slightly. In this case, the effect of incorporation of napAla was not observed. In comparison, in the presence of antAla, the protein production per cell increased, while the activity per cell did not increase significantly, and in the presence of pyrAla, the protein production per cell did not decrease, while the activity per cell was reduced considerably. These results might be due to the incorporation of the nonnatural amino acid into β-D-galactosidase.

The amount of a nonnatural amino acid in a protein was estimated by the fluorescence intensity of the nonnatural amino acid taking that of tryptophan in the protein as standard. For the calibration of fluorescence intensity, fluorescence of nonnatural amino acids was measured in the presence of BSA.

The fluorescence intensity ratio R and the residual content C were plotted on log-log graph paper and a calibration curve was obtained by the least-squares method. The curve was expressed by $C=9.28R^{0.615}$ (mmol/mol tryptophan residue) for antAla in the range of $R<15$ and by $C=0.795R^{1.55}$ (mmol/mol tryptophan residue) for pyrAla in the range of $R<10$.

The protein solution from the wild strain B357 grown in the presence of the nonnatural amino acid was added to the same volume of DMSO and the nonnatural amino acid that nonspecifically bound to the protein was removed by dialysis. The fluorescence intensity ratio during the dialysis was followed and is shown in Fig. 2. The ratio was decreased exponentially, but a certain intensity was remained after the sufficient dialysis for 75 h. The minimum R was 0.30 for antAla and

Table 1. β-D-Galactosidase Activity of Various *E. coli* Strains

Strain	Plasmid[b]	Induction[c]	CP[a,d]	Specific activity[e]
B357	None	None	None	0.0645
B357	None	+	None	4.73
DH5α	pUC19Z	+	+	126
DH5α	None	+	+	0.00

a) CP represents chloramphenicol treatment b) Transformation with the plasmid. c) Induction with lactose. d) CP treatment for 1 h. e) Specific activity was expressed in units per milligram of the β-D-galactosidase (μmol min^{-1} mg^{-1}).

Table 2. The Relative Amount of Proteins Obtained from the Cells of Strain B357 and the Relative β-D-Galactosidase Activity

Nonnatural amino acid[a]	Growth[b]	Amount of protein[c]	Specific activity[d]	Change[e]
None	1	1	1	—
Nap	1.04	1.06	1.09	+9%
Ant	0.91	1.38	0.95	−5%
Pyr	0.80	1.35	0.75	−25%

a) Nap, Ant, and Pyr represent 3-(1-naphthyl)-L-alanine, 3-(9-anthryl)-L-alanine, 3-(1-pyrenyl)-L-alanine, respectively. b) The relative growth of the cells. c) The relative amount of proteins per cell. d) The relative specific activity of β-D-galactosidases. e) The change in the specific activity.

was 0.65 for pyrAla. The residual content C was obtained using the calibration curve as 4.5 mmol mol^{-1} for antAla and 0.42 mmol mol^{-1} for pyrAla. In comparison, the protein solution of the B357 grown without nonnatural amino acids was mixed with a solution of 40 μg ml^{-1} nonnatural amino acids and stirred at 4 °C for 24 h. The fluorescence intensity ratio during the dialysis was followed after washing with DMSO. As shown in Fig. 2, the fluorescence of the nonnatural amino acids disappeared in 48 h, indicating that the nonspecifically bound nonnatural amino acids were completely removed by the dialysis.

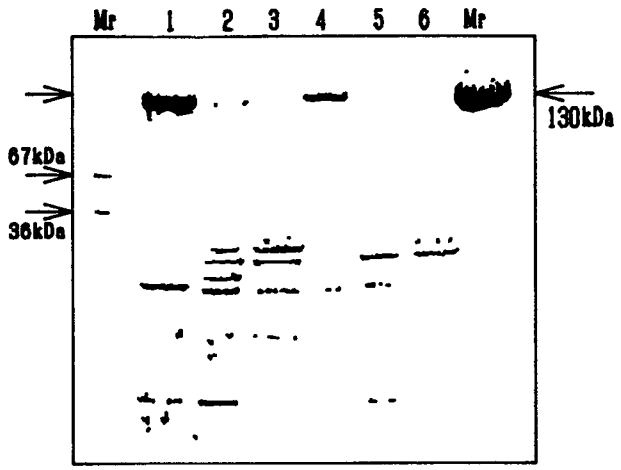

Fig. 3. The SDS-PAGE profile of produced β-D-galactosidases. β-D-Galactosidase was obtained from various strains without nonnatural amino acid. Mr, Marker; lanes 1 and 4, DH5α strain harboring pUC19Z; lanes 2 and 5, DH5α strain harboring pUC19; lanes 3 and 6, DH5α without transformation. Lanes 1, 2, and 3, 20 μg protein each; lanes 4, 5, and 6, 10 μg protein each.

β-D-Galactosidase was purified from the protein solution obtained from the DH5α cells harboring pUC19Z without nonnatural amino acid (Fig. 3). Similarly, β-D-galactosidase was purified from the protein solution obtained from the DH5α cells harboring pUC19Z grown in the presence of 50 μg ml^{-1} nonnatural amino acids. Each 200 μg of purified β-D-galactosidase was obtained from 1 mg of the crude preparation through the nondenaturing polyacrylamide gel electrophoresis.

A significant fluorescence of pyrenyl moiety was observed in the purified β-D-galactosidase obtained from the cells grown in the presence of pyrAla (Fig. 4). It was found that the fluorescence intensity ratio R_{obs} was 0.796 from the fluorescence excitation spectrum of the purified β-D-galactosidase monitored at wavelength 397 nm. The residual content C was determined as 0.556 mmol mol^{-1} from the calibration curve.

β-D-Galactosidases were incubated in a water bath at 60 °C. Aliquots were removed at various times over 180 s period, placed on ice and then measured for the residual activity (Fig. 5). The activity of the purified β-D-galactosidases obtained from the cells grown in the presence of pyrAla or antAla remained after the incubation of 120 s at 60 °C, while that obtained from the cells grown without nonnatural amino acids was lost completely in 120 s. This indicates that the thermostability of β-D-galactosidase was improved by the incorporation of nonnatural amino acids.

It can be derived from the Michaelis-Menten's reaction kinetics that a specific activity of an enzyme is proportional to the rate constant k_{cat} in the case of sufficiently high substrate concentration. The activation energy of the catalytic reaction was calculated from the

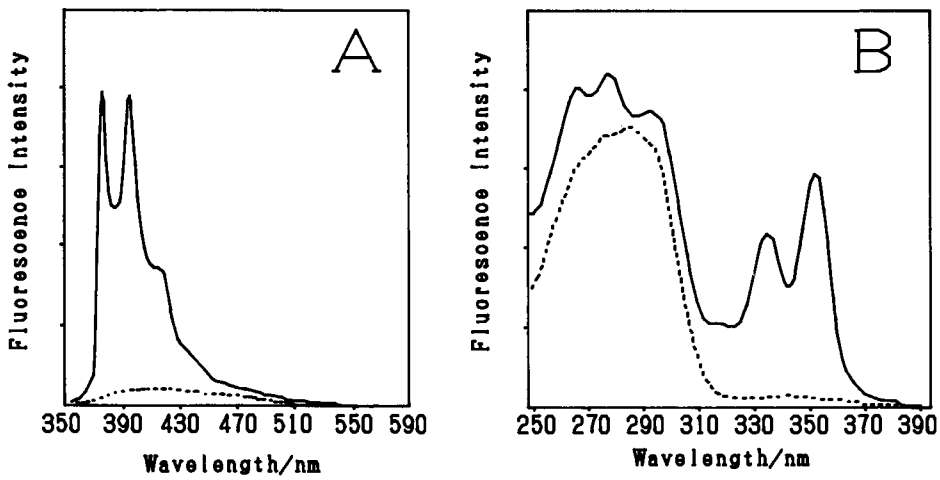

Fig. 4. Fluorescence emission and excitation spectra of the purified β-D-galactosidase obtained from the cells of strain DH5α grown with or without pyrAla. A, fluorescence emission spectra excited at 345 nm; B, fluorescence excitation spectra monitored at 395 nm. —, spectra of the purified β-D-galactosidase obtained from the cells grown in the presence of pyrAla; ···, spectra of that obtained from the cells without nonnatural amino acid.

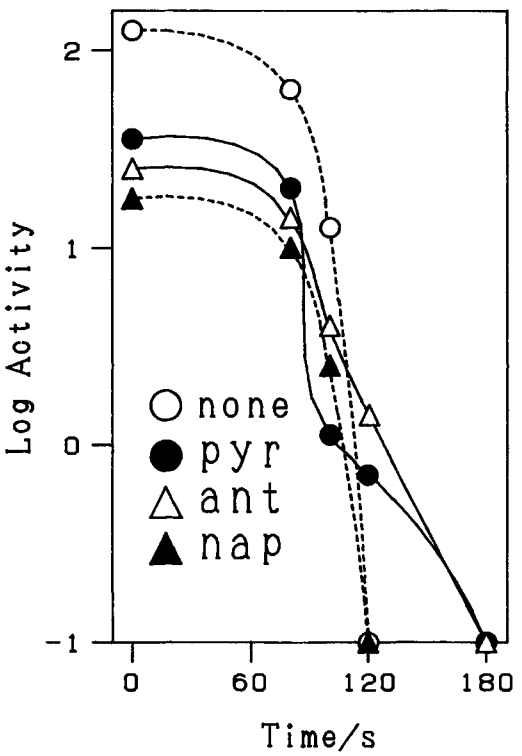

Fig. 5. Thermostability of purified β-D-galactosidases. Log specific activity is plotted against incubation times of 80 s, 100 s, 120 s, and 180 s. ○, Sample obtained from the cells of strain DH5α grown without nonnatural amino acid; ●, △, and ▲, samples obtained from the cells of strain DH5α grown in the presence of pyrAla, antAla, and napAla, respectively.

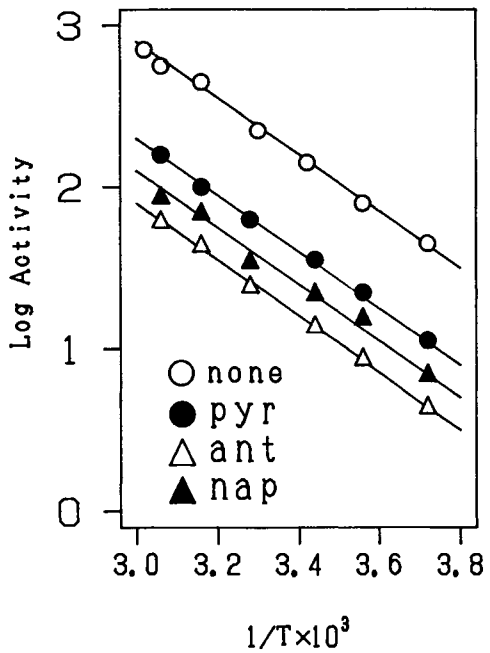

Fig. 6. The log specific activity vs. $1/T$ plot of purified β-D-galactosidases. ○, Sample obtained from the cells of strain DH5α grown without nonnatural amino acid; ●, △, and ▲, samples obtained from the cells of strain DH5α grown in the presence of pyrAla, antAla, and napAla, respectively.

plot of log specific activity against $1/T$ as shown in Fig. 6. The activation energy of β-D-galactosidase obtained from the cells grown in the presence of various nonnatural amino acids was identical with that for β-D-galactosidase obtained from the cells grown without the nonnatural amino acids.

Discussion

In general, a tRNA is not mischarged with nonnatural amino acids, because aminoacyl-tRNA synthetase precisely discriminates the corresponding amino acid from the others. Nonnatural amino acids found in natural polypeptides is usually formed in the process of the posttranslational modification. In some cases, the nonnatural amino acid-containing proteins show resistance to the digestion by proteases. The natural amino acid analogs, such as canavanine, 2-azetidinecarboxylic acid, and 4-fluorophenylalanine, were shown to be incorporated during the accelerated biosynthesis of protein after viral infection of bacteria.[12] The mutant proteins inhibited the self-assembly of the viral proteins. On the other hand, it has been reported that cleavage of the signal sequence of pre-prolactin synthesized in the presence of hydroxynorvaline is inhibited by incorporation of the analog.[12] In most cases, incorporation of analogs resulted in reduction of protein functions. Abnormal (mutant) proteins accumulated in a cell are known to be digested by intracellular proteases. The accumulation of abnormal proteins leads to an expression of protease La, which digests the abnormal proteins.[13] In addition, cell growth will be inhibited because high frequency of production of abnormal proteins may cause reduction of normal protein production. For these reasons, it was difficult to prepare abnormal proteins incorporated with nonnatural amino acids.

Parker reported that the amino acid substitutions did not lead to proteins recognized as grossly abnormal by the proteolysis systems in cells. Abnormal proteins in which substitution frequency was under 10% were not eliminated in a cell, and abnormal subunits of ribosome were found in cells grown normally.[14] Taking these results into consideration abnormal proteins may be prepared by lowering substitution frequency. Abnormal β-D-galactosidase was prepared in the presence of various fluorescent nonnatural amino acids with low frequency of incorporation. In order for the protein not to be recognized as a foreign abnormal protein, β-D-galactosidase was synthesized in *E.coli*. The nonnatural amino acids used in this study were not analogous to any natural amino acids, so that the nonatural amino acids were mischarged to tRNAs to be incorporated into proteins in sufficiently low frequency. Fluorescent amino acids can be detected in abnormal proteins even in low frequency of incorporation.

We have succeeded in overproduction of β-D-galactosidase using the DH5α strain with plasmid

pUC19Z in the level of two thousands times higher than the wild strain (Table 1). AntAla and pyrAla were found in the proteins of the wild strain synthesized in the presence of these nonnatural amino acids (Fig. 2), indicating that *E.coli* utilized these nonnatural amino acids to some extent in protein biosynthesis. Fluorescence emission of pyrenyl moiety was observed in the purified β-D-galactosidase synthesized in the presence of pyrAla, and the residual content was estimated to be 0.556 mmol mol^{-1} tryptophan residue. Thus, one pyrAla residue per 46 molecules of β-D-galactosidase was found because there are 39 tryptophan residues in a β-D-galactosidase molecule. However, pyrAla may be attached to the hydrophobic surface of BSA used in the calibration experiment, so that this value is the minimum in the case of the absence of pyrenyl moiety quenching by surrounding charges or dipoles.

The specific activity of the proteins obtained in the presence of antAla or pyrAla was reduced (Table 2), while the amount of proteins per cell was not affected. This indicates that protein biosynthesis was not lowered by the addition of the nonnatural amino acids. The β-D-galactosidase content of the total proteins was found to increase continuously throughout the cultivation, indicating that the reduction of the specific activity was not the result of proteolytic digestion of abnormal β-D-galactosidase but the result of the production of β-D-galactosidase with low activity. On the other hand, the activation energy of the purified β-D-galactosidase did not decrease (Fig. 6). Thus, it is considered that the nonnatural amino acids were incorporated into the active site of β-D-galactosidase and the activity of some β-D-galactosidase was lost. In this case, incorporated amino acids are thought to be on the protein surface and easily quenched. In addition, incorporation of a highly hydrophobic amino acid into the hydrophilic surface may cause instabilization of β-D-galactosidase.

At least 2.2% of β-D-galactosidase was estimated to have one pyrAla residue. As shown in Fig. 5, several per cent of the mutant β-D-galactosidases resulted in the improved thermostability of the enzyme, indicating that the nonnatural amino acids were incorporated into the hydrophobic region of β-D-galactosidase and a higher-order structure of the enzyme was stabilized. In this case, the incorporated nonnatural amino acids should be located apart from the protein surface and are hardly quenched.

In conclusion, we have succeeded in preparing mutant β-D-galactosidases substituted by the nonnatural amino acids. By lowering substitution frequency, cell growth and protein biosynthesis rate were not reduced.

The authors are grateful to Dr. Yoshihito Inai for his kind gift of napAla and pyrAla and to Dr. Hiroki Sasaki for his generous supply of antAla.

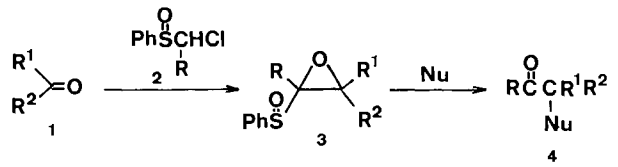
Nucleophilic Ring-Opening of Chlorooxiranes: A New Synthesis of α-Hydroxy α′-Substituted Ketones from Carbonyl Compounds and 1-Chloroalkyl *p*-Tolyl Sulfoxides

Tsuyoshi SATOH, Asako OGURA, Youko IKEDA, and Koji YAMAKAWA*
Faculty of Pharmaceutical Sciences, Science University of Tokyo,
Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162
(Received December 19, 1990)

The addition of 1-chloroalkyl *p*-tolyl sulfoxides to carbonyl compounds gave adducts which were then converted to chlorooxiranes in two steps with good overall yields. The treatment of the chlorooxiranes with various nucleophiles gave α-hygroxy α′-substituted ketones or α-hydroxy ketones in good yields.

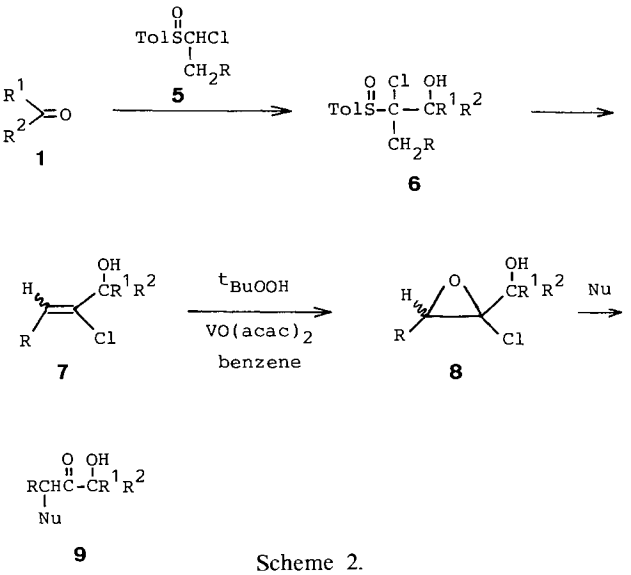
The homologation method of carbonyl compounds from lower carbonyl compounds by carbon–carbon coupling reactions is now one of the most important and extensively used methods for obtaining desired carbonyl compounds.[1] Recently, we reported a method to synthesize α-substituted carbonyl compounds **4** from carbonyl compounds **1** and 1-chloroalkyl phenyl sulfoxides **2** through α,β-epoxy sulfoxides **3** (Scheme 1).[2] In this method the carbonyl carbon of **1** was acylated and



Scheme 1.

the carbonyl oxygen was replaced by nucleophiles.

In a continuation of our study on the use of 1-chloroalkyl aryl sulfoxides in organic synthesis, we describe here a novel method for the synthesis of α-hydroxy α′-substituted ketones **9** from carbonyl compounds **1** and 1-chloroalkyl *p*-tolyl sulfoxides **5** through chlorooxiranes **8** (Scheme 2).[3] It is worth noticing that in this method **5** acted as an α-substituted acyl anion equivalent.

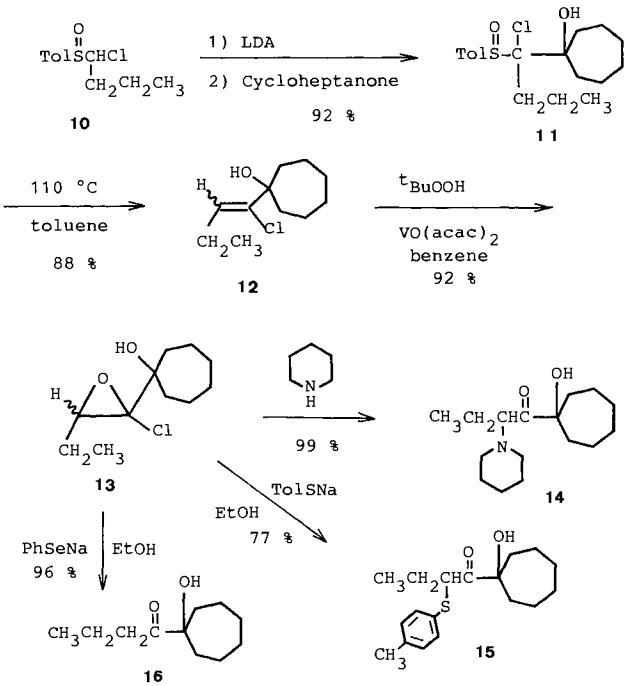


Scheme 2.

Results and Discussion

The representative example of this procedure using 1-chlorobutyl *p*-tolyl sulfoxide **10**[4] and cycloheptanone as a carbonyl compound is as follows. The treatment of **10** with lithium diisopropylamide (LDA) in THF at −60°C and then with cycloheptanone gave chloro alcohol **11** in 92% yield. The sulfinyl group of **11** was found to be prone to eliminate under heating; refluxing **11** in toluene for 5 min cleanly gave the desired vinyl chloride **12** in 88% yield. Among the procedures reported for epoxidation of allylic alcohols[5] we selected a *t*-butyl hydroperoxide (ᵗBuOOH)-vanadyl acetylacetonate ($VO(acac)_2$) system for the epoxidation of vinyl chloride **12**, since the product chlorooxirane **13** was presumed to be unstable under acidic conditions.

The epoxidation of **12** was carried out by adding a solution of ᵗBuOOH (1.2 equivalents) to a dry benzene solution of **12** and $VO(acac)_2$ (0.12 equivalents) at room



Scheme 3.

temperature (**Method A**). A slightly exothermic reaction took place to afford the desired chlorooxirane **13** in 92% yield. Chlorooxirane **13** was found to be stable under these reaction conditions and the usual workup system; it is storable for a few months in a refrigerator without any detectable decomposition.

We next investigated the reactivity of **13** with some nucleophiles. The treatment of **13** with piperidine[2c] without a solvent at room temperature gave the desired α-hydroxy α'-piperidino ketone **14** in quantitative yield within 10 min. The treatment of **13** with sodium *p*-toluenethiolate[2b] in ethanol at room temperature gave α-*p*-tolylthio ketone **15** in 77% yield within 10 min. The treatment of **13** with sodim benzeneselenolate[2a,6] in ethanol at room temperature gave α-hydroxy ketone **16** in 96% yield. From these results it became apparent that the reactivity of chlorooxirane **13** with the nucleophiles was quite similar to that of α,β-epoxy sulfoxides **3**.[2]

Encouraged by these results, we synthesized vinyl chlorides **17**—**20** from **10** or 1-chloroethyl *p*-tolyl sulfoxide (**5**; R=H) with cyclohexanone, cycloheptanone, 3-phenylpropanal, and decanal in a similar way to that described above.

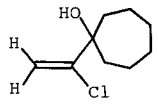
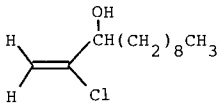
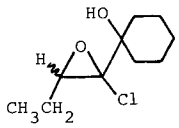
18



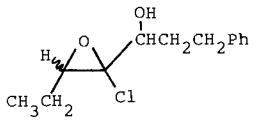
19



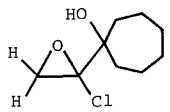
20



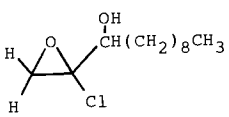
21



22



23



24

The epoxidation of **17** using **Method A** took place smoothly to give chlorooxirane **21** in 86% yield. The reaction of **21** with several nucleophiles gave α-hydroxy α'-substituted ketones **25**—**28** in high yields (see Table 1; Entry 1—4). Even sodium methoxide reacted with **21** at room temperature for 3 h to give α-hydroxy α'-methoxy ketone **27** in good yield (Entry 3).

We came across a problem in the epoxidation of vinyl chloride **18**—**20**. The epoxidation of **18**—**20** using **Method A** gave either no or an incomplete reaction; unfortunately, those vinyl chlorides (**18**—**20**) and chlorooxiranes (**22**—**24**) have the same (or quite close) R_f-value on silica-gel TLC, respectively. The other procedures reported for the epoxidation of allylic alcohols were unsuccessful. For instance, the epoxidation of **19** with ^{t}BuOOH–titanium(IV) isopropoxide or *m*-chloroperbenzoic acid (MCPBA) both gave mainly cycloheptanone and some unknown products.

After several investigations we found that the treatment of vinyl chlorides with ^{t}BuOOH and a very low concentration of $VO(acac)_2$ gave the desired chlorooxiranes in good yields. Thus, for example, to a solution of **18** and ^{t}BuOOH in benzene at 50 °C was added a dilute solution of $VO(acac)_2$ in benzene over a period of 1 h (**Method B**) to give **22** in quantitative yield as a low melting point solid. Monosubstituted chlorooxiranes **23** and **24** were synthesized by **Method B**; however, the yields were rather low compared with the disubstituted ones (**13**, **21**, and **22**). Chlorooxirane **23** was found to be unstable; it decomposed slowly, even on storage in a refrigerator. However, if it was used immediately after being prepared, the desired α-hydroxy α'-substituted ketones (**32** and **33**) were obtained in high yields without any problem. Representative examples for the synthesis of α-hydroxy α'-substituted ketones from carbonyl compounds are summarized in Table 1.

Nucleophilic ring-opening was investigated using some alkylmetals as carbon nucleophiles. The treatment of chlorooxirane **21** with *n*-butyllithium (3 equiv; −55 °C, 1 h), methylmagnesium bromide (3 equiv; −40 °C, 2 h), or lithium dimethylcuprate (3 equiv; 0 °C, 1.5 h) gave almost no reaction.

a) Two-step overall yield from 1-chloroalkyl *p*-tolyl sulfoxide and carbonyl compound. b) See text.

The application of this procedure to a synthesis of α-hydroxy α′,β′-unsaturated ketone was made with **30** (Scheme 4). The α-tolylthio ketone **30** was oxidized with MCPBA to sulfoxide **36** in quantitative yield as a diastereomeric mixture. Heating **36** in refluxing toluene for 2.5 h afforded (*E*)-5-hydroxy-7-phenyl-2-hepten-4-one **37** in 54% yield. In this entire sequence **10** acted as an α,β-unsaturated acyl anion equivalent **38**.

In conclusion a new and versatile procedure for the synthesis of α-hydroxy α′-substituted ketones has been developed from 1-chloroalkyl *p*-tolyl sulfoxides and carbonyl compounds through the reaction of chlorooxiranes with nucleophiles. Because of its simplicity and the good overall yields obtained, we believe that the presented method will prove to be valuable in the synthesis of α-hydroxy ketones, α-hydroxy α′-substituted ketones, and α-hydroxy α′,β′-unsaturated ketones.

Experimental

All of the melting points are uncorrected. The ^1H NMR spectra were measured in a $CDCl_3$ solution with a JEOL FX-100 spectrometer. Electron-impact mass spectra (MS) were obtained at 70 eV by direct insertion. Silica gel BW-127 ZH (Fuji-Devison) containing 2% of fluorescence reagent 254 and

a quartz column were used for column chromatography; products having UV absorption were detected by UV irradiation. In experiments requiring dry solvents, THF was distilled from diphenylketyl; benzene, toluene, and diisopropylamine were dried over CaH_2 and distilled. $VO(acac)_2$ was recrystallized from acetone.

1-(1-Chloro-1-butenyl)-1-cycloheptanol (12). A solution of **10** (1.15 g; 5 mmol) in 3 ml of dry THF was added dropwise to a stirred solution of LDA (6 mmol) in 6 ml of THF at −60 °C. The mixture was then stirred at −60 °C for 10 min; cycloheptanone (0.71 ml; 6 mmol) was then added to the reaction mixture. After 10 min the reaction was quenched with sat. aq NH_4Cl. The entire mixture was extracted with ether–benzene. The usual workup followed by silica-gel column chromatography gave chloro alcohol **11** (1.58 g; 92%) as a colorless oil, IR (neat) 3400 (OH), 1070, 1040 (SO) cm^{-1}.

A solution of **11** (1.3 g) in 15 ml of toluene was refluxed under N_2 for 5 min. The solvent was evaporated under vacuum and residue was separated by flash chromatography (hexane–AcOEt=20 : 1) to give 680 mg (88%) of **12** as a colorless oil. IR (neat) 3410 (OH), 1655 (C=C) cm^{-1}; ^1H NMR δ=1.01 (3H, t, J=7 Hz), 1.2—2.1 (13H, m), 2.21 (2H, quintet, J=7 Hz), 5.78 (1H, t, J=7 Hz); MS m/z (%) 202 (M^+, 22), 173 (73), 145 (96), 41 (100). Found: m/z 202.1127. Calcd for $C_{11}H_{19}ClO$: M, 202.1124.

1-(1-Chloro-1,2-epoxybutyl)-1-cycloheptanol (13). ^{t}BuOOH (anhydrous, 3 M solution in 2,2,4-trimethylpentane, 1 M= 1 mol dm^{-3}; 3.3 mmol) was added dropwise to a solution of **12** (527 mg; 2.6 mmol) and $VO(acac)_2$ (93 mg; 0.35 mmol) in 12 ml of dry benzene. A slightly exothermic reaction took place; the reaction mixture was stirred at room temperature for 1 h. The reaction mixture was passed through a short pad of Florisil. The solvent was evaporated and the residue was purified by silica-gel column chromatography to give **13** as a low melting point solid. IR (neat) 3480 (OH) cm^{-1}; ^1H NMR δ=1.06 (3H, t, J=7 Hz), 1.4—2.3 (15H, m), 3.32 (1H, t, J=7 Hz); MS m/z (%) 219 ([M+H]$^+$, trace), 189 ([M−C_2H_5]$^+$, 0.8), 113 (100).

1-(1-Hydroxycycloheptyl)-2-piperidino-1-butanone (14). A mixture of **13** (113 mg) in 2 ml of piperidine was stirred at room temperature for 10 min. The piperidine was evaporated and the residue was dissolved in benzene. The solution was washed once with water, and then dried over $MgSO_4$. The usual workup followed by silica-gel column chromatography gave **14** (137 mg; 99%) as an oil. IR (neat) 3250 (OH), 1710 (CO) cm^{-1}; ^1H NMR δ=0.78 (3H, t, J=7 Hz), 1.2—2.2 (21H, m), 2.50 (4H, m), 3.58 (1H, dd, J=10, 3 Hz); MS m/z (%) 266 (M^+, 0.2), 238 (0.1), 210 (0.1), 154 (0.3), 126 (100). Found: m/z 266.2118. Calcd for $C_{16}H_{28}NO_2$: M, 266.2118.

1-(1-Hydroxycycloheptyl)-2-(*p*-tolylthio)-1-butanone (15). To 3 ml of EtOH at room temperature was added NaH (0.78 mmol) and then *p*-toluenethiol (105 mg; 0.85 mmol). A solution of **13** (85 mg; 0.39 mmol) in 0.5 ml of EtOH was added to a solution of the thiolate; the reaction mixture was stirred at room temperature for 10 min. Powdered NH_4Cl was added to this mixture, and the EtOH was evaporated under vacuum. The residue was extracted with benzene and the usual workup was followed by silica-gel column chromatography, giving 92 mg (77%) of **15** as colorless crystals. Mp 70—72 °C (AcOEt–hexane); IR (KBr) 3525 (OH), 1690 (CO) cm^{-1}; ^1H NMR δ=0.92 (3H, t, J=7 Hz), 1.3—2.2 (15H, m), 2.33 (3H, s), 4.03 (1H, t, J=7 Hz), 7.0—7.3 (4H, m). Anal. Calcd for $C_{18}H_{26}O_2S$: C, 70.55; H, 8.55; S, 10.46%. Found: C, 70.57; H, 8.60; S, 10.40%.

1-(1-Hydroxycycloheptyl)-1-butanone (16). $NaBH_4$ (153 mg; 4.05 mmol) was added to a solution of diphenyl diselenide (630 mg; 2.03 mmol) in 9 ml of EtOH at room temperature. After all of the $NaBH_4$ reacted, a solution of **13** (147 mg; 0.67 mmol) in 1 ml of EtOH was added to the benzeneselenolate solution. The reaction mixture was stirred at room temperature for 10 min; powdered NH_4Cl was then added. The EtOH was evaporated under vacuum and the residue extracted with benzene–ether. The organic layer was washed once with sat. aq NH_4Cl and the usual workup followed by silica-gel column chromatography gave 119 mg (96%) of **16** as a colorless oil. IR (neat) 3480 (OH), 1700 (CO) cm^{-1}; ^1H NMR δ=0.92 (3H, t, J=7 Hz), 1.3—2.0 (14H, m), 2.52 (2H, t, J=7 Hz); MS m/z (%) 184 (M^+, 0.25), 167 (0.15), 113 (100). Found: m/z 184.1468. Calcd for $C_{11}H_{20}O_2$: M, 184.1462.

1-(1-Chloro-1-butenyl)-1-cyclohexanol (17). This vinyl chloride was synthesized from **10** and cyclohexanone in a similar manner as that described for **12** in 93% overall yield. Colorless oil; IR (neat) 3410 (OH), 1655 (C=C) cm^{-1}; ^1H NMR δ=1.01 (3H, t, J=7 Hz), 1.2—1.9 (10H, m), 2.22 (2H, quintet, J=7 Hz), 5.80 (1H, t, J=7 Hz); MS m/z (%) 188 (M^+, 50), 159 ([M−C_2H_5]$^+$, 100). Found: m/z 188.0965. Calcd for $C_{10}H_{17}ClO$: M, 188.0966.

Vinyl Chloride (18—20). These vinyl chlorides were reported in the previous paper: see Ref. 7.

1-(1-Chloro-1,2-epoxybutyl)-1-cyclohexanol (21). This chlorooxirane was synthesized from **17** in a similar manner (**Method A**) as that described for **13** in 86% yield. Colorless low melting solid. IR (KBr) 3525 (OH) cm^{-1}; ^1H NMR δ=1.06 (3H, t, J=7 Hz), 1.4—2.0 (13H, m), 3.30 (1H, t, J=7 Hz); MS m/z (%) 175 ([M−C_2H_5], 0.3), 146 (3), 99 (100).

4-Chloro-4,5-epoxy-1-phenyl-3-heptanol (22). A solution of $VO(acac)_2$ (106 mg; 0.4 mmol) in 50 ml of dry benzene was added dropwise to a stirred solution of **18** (440 mg; 1.95 mmol) and ^{t}BuOOH (4.5 mmol) in 10 ml of dry benzene at 50 °C over a period of 1 h (**Method B**). The reaction mixture was passed through a short pad of Florisil and the solvent evaporated. The residue was purified by silica-gel column chromatography to afford 457 mg (98%) of **22** as a low melting point solid. IR (KBr) 3400 (OH) cm^{-1}; ^1H NMR δ=1.07 (3H, t, J=7 Hz), 1.4—2.4 (5H, m), 2.6—3.0 (2H, m), 3.14 (1H, t, J=6 Hz), 3.86 (1H, dd, J=8, 4 Hz), 7.22 (5H, m); MS m/z (%) 240 (M^+, 0.5), 205 (2.5), 193 (2), 104 (100). Found: m/z 240.0918. Calcd for $C_{13}H_{17}ClO_2$: M, 240.0916.

Chlorooxirane (23, 24). These chlorooxiranes were synthesized from **19** and **20** in a similar manner as that described for **22** (**Method B**).

1-(1-Chloro-1,2-epoxyethyl)-1-cycloheptanol **23**: Colorless oil; 74% yield; IR (neat) 3475 (OH) cm^{-1}; ^1H NMR δ=1.4—2.3 (13H, m), 3.01 (1H, d, J=5 Hz), 3.24 (1H, d, J=5 Hz); MS m/z (%) 149 (0.5), 113 ([M−C_2H_2ClO]$^+$, 100).

2-Chloro-1,2-epoxy-3-dodecanol **24**: Colorless oil; 62% yield; IR (neat) 3425 (OH) cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=6 Hz), 1.0—2.2 (16H, m), 3.07 (2H, s), 3.82 (1H, m); MS m/z (%) 235 ([M+H]$^+$, 0.3), 234 (M^+, 0.1), 198 (2), 155 (40), 83 (100).

1-(1-Hydroxycyclohexyl)-2-piperidino-1-butanone (25). Colorless oil; IR (neat) 3280 (OH), 1720 (CO) cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=7 Hz), 1.0—2.0 (18H, m), 2.50 (4H, m), 3.54

(1H, dd, J=10, 4 Hz); MS m/z (%) 253 (M^+, trace), 252 (0.2), 126 (100). Found: m/z 253.2026. Calcd for $C_{15}H_{27}NO_2$: M, 253.2039.

1-(1-Hydroxycyclohexyl)-2-(*p*-tolylthio)-1-butanone (26). Colorless crystals; mp 63—64 °C (AcOEt–hexane); IR (KBr) 3510 (OH), 1700 (CO) cm^{-1}; ^1H NMR δ=0.90 (3H, t, J=7 Hz), 1.4—2.0 (12H, m), 2.32 (3H, s), 4.04 (1H, dd, J=8, 7 Hz), 7.0—7.3 (4H, m); MS m/z (%) 292 (M^+, 14), 222 (3), 194 (16), 166 (58), 124 (100). Anal. Calcd for $C_{17}H_{24}O_2S$: C, 69.82; H, 8.27; S, 10.96%. Found: C, 69.58; H, 8.21; S, 10.85%.

1-(1-Hydroxycyclohexyl)-2-methoxy-1-butanone (27). NaH (1 mmol) was added to dry methanol (2.5 ml); a solution of **21** (62 mg; 0.3 mmol) in 0.5 ml of methanol was then added to the methoxide solution. The reaction mixture was stirred at room temperature for 3 h. Powdered NH_4Cl was added to the reaction mixture, and the methanol was evaporated under vacuum. The residue was extracted with benzene–ether. The solution was washed once with water. The usual workup followed by silica-gel column chromatography gave **27** (50 mg; 83%) as a colorless oil. IR (neat) 3510 (OH), 1720 (CO) cm^{-1}; ^1H NMR δ=0.95 (3H, t, J=7 Hz), 1.4—2.0 (12H, m), 3.33 (3H, s), 4.10 (1H, dd, J=6, 5 Hz); MS m/z (%) 200 (M^+, trace), 173 (0.3), 172 (3), 99 (100). Found: m/z 200.1430. Calcd for $C_{11}H_{20}O_3$: M, 200.1411.

1-(1-Hydroxycyclohexyl)-1-butanone (28). Colorless oil; IR (neat) 3510 (OH), 1710 (CO) cm^{-1}; ^1H NMR δ=0.92 (3H, t, J=7 Hz), 1.0—1.9 (12H, m), 2.53 (2H, t, J=7 Hz); MS m/z (%) 170 (M^+, 0.4), 159 (0.5), 99 (100). Found: m/z 170.1303. Calcd for $C_{10}H_{18}O_2$: M, 170.1305.

3-Hydroxy-1-phenyl-5-piperidino-4-heptanone (29). Diastereomeric mixture with respect to the two chiral carbon (ratio about 1:1). Colorless oil; IR (neat) 3450 (OH), 1715 (CO) cm^{-1}; ^1H NMR δ=0.81, 0.85 (each triplet, J=7 Hz), 4.0—4.3 (1H, m), 7.21 (5H, m); MS m/z (%) 288 ($[M-H]^+$, trace), 261 (0.2), 204 (4), 126 (100).

3-Hydroxy-1-phenyl-5-(*p*-tolylthio)-4-heptanone (30). Diastereomeric mixture (ratio about 2:1). Colorless oil; IR (neat) 3510 (OH), 1710 (CO) cm^{-1}; ^1H NMR δ=0.97 (3H, t, J=7 Hz), 1.5—2.2 (4H, m), 2.31 (3H, s), 2.72 (2H, m), 3.50 (2/3H, t, J=7 Hz), 3.76 (1/3H, t, J=7 Hz), 4.22 (1/3H, m), 4.56 (2/3H, m), 7.0—7.4 (9H, m); MS m/z (%) 328 (M^+, 20), 205 (5), 165 (100). Found: m/z 328.1495. Calcd for $C_{20}H_{24}O_2S$: M, 328.1495.

3-Hydroxy-1-phenyl-4-heptanone (31). Colorless oil; IR (neat) 3500 (OH), 1715 (CO) cm^{-1}; ^1H NMR δ=0.91 (3H, t, J=7 Hz), 1.4—2.3 (4H, m), 2.39 (2H, t, J=7 Hz), 2.76 (2H, m), 4.12 (1H, dd, J=8, 3 Hz), 7.21 (5H, m); MS m/z (%) 206 (M^+, 2), 134 (12), 117 (20), 102 (46), 91 (100). Found: m/z 206.1302. Calcd for $C_{13}H_{18}O_2$: M, 206.1305.

1-(1-Hydroxycycloheptyl)-2-piperidino-1-ethanone (32). Colorless crystals; mp 87—89 °C (AcOEt–hexane); IR (KBr) 3225 (OH), 1720 (CO) cm^{-1}; ^1H NMR δ=1.2—2.0 (18H, m), 2.45 (4H, m), 3.29 (2H, s); MS m/z (%) 239 (M^+, trace), 211 (0.7), 149 (0.3), 98 (100). Anal. Calcd for $C_{14}H_{25}NO_2$: C, 70.25; H, 10.53; N, 5.85%. Found: C, 70.42; H, 10.58; N, 5.94%.

1-(1-Hydroxycycloheptyl)-2-(*p*-tolylthio)-1-ethanone (33). Colorless oil; IR (neat) 3510, 3410 (OH), 1705 (CO) cm^{-1}; ^1H NMR δ=1.4—2.0 (12H, m), 2.31 (3H, s), 3.89 (2H, s), 7.0—7.4 (4H, m); MS m/z (%) 278 (M^+, 10), 166 (31), 138 (73), 124 (100). Found: m/z 278.1335. Calcd for $C_{16}H_{22}O_2S$: M, 278.1338.

3-Hydroxy-1-piperidino-2-dodecanone (34). Colorless oil; IR (neat) 3370 (OH), 1720 (CO) cm^{-1}; ^1H NMR δ=0.87 (3H, t, J=7 Hz), 1.0—1.9 (22H, m), 2.42 (4H, m), 3.24 (2H, s), 4.22 (1H, m); MS m/z (%) 283 (M^+, 0.1), 282 (0.3), 196 (1), 155 (10), 98 (100). Found: m/z 283.2490. Calcd for $C_{17}H_{33}NO_2$: M, 283.2509.

3-Hydroxy-1-(*p*-tolylthio)-2-dodecanone (35). Colorless crystals; mp 69—71 °C (AcOEt–hexane); IR (KBr) 3550, 3380 (OH), 1720 (CO) cm^{-1}; ^1H NMR δ=0.88 (3H, t, J=6 Hz), 1.0—1.9 (16H, m), 2.31 (3H, s), 3.72 (2H, s), 4.40 (1H, m), 7.0—7.4 (4H, m); MS m/z (%) 322 (M^+, 32), 137 (48), 124 (100). Anal. Calcd for $C_{19}H_{30}O_2S$: C, 70.76; H, 9.38; S, 9.94%. Found: C, 70.69; H, 9.44; S, 9.70%.

(*E*)-5-Hydroxy-7-phenyl-2-hepten-4-one (37). MCPBA (2.75 mmol) was added to a stirred solution of the sulfide **30** (820 mg; 2.5 mmol) in 30 ml of CH_2Cl_2. The reaction mixture was stirred at −50 °C for 30 min; the mixture was then diluted with CH_2Cl_2 and the solution washed successively with 5% NaOH and sat. aq NH_4Cl. The usual workup followed by silica-gel column chromatography afforded a diastereomeric mixture of sulfoxide **36** (840 mg; 98%).

A solution of **36** (830 mg) in 20 ml of toluene was refluxed under N_2 for 2.5 h. The solvent was evaporated under vacuum and the residue purified by silica-gel column chromatography (hexane:AcOEt=20:1) to afford 265 mg (54%) of enone **37** as a colorless oil. IR (neat) 3470 (OH), 1690 (CO), 1630 (C=C) cm^{-1}; ^1H NMR δ=1.6—2.3 (2H, m), 1.90 (3H, dd, J=7, 1 Hz), 2.76 (2H, m), 4.32 (1H, dd, J=9, 4 Hz), 6.17 (1H, dq, J=16, 1 Hz), 6.96 (1H, dq, J=16, 7 Hz), 7.20 (5H, m); MS m/z (%) 204 (M^+, 0.6), 117 (12), 100 (90), 91 (100). Found: m/z 204.1147. Calcd for $C_{13}H_{16}O_2$: M, 204.1149.

(Received December 20, 1990)

The relationship between the temperature-sensitivity of the release of an entrapped drug from liposome as well as the type of drug or liposome is discussed. The drug release from DPPC liposome (dipalmitoylphosphatidylcholine liposome) has been confirmed to increase abruptly near its phase-transition temperature for both low-molecular-weight compouds (such as calcein) and high-molecular-weight compounds (such as dextran). The amount of temperature-sensitive calcein released from the liposomes was dependent on the method of liposome preparation: that is, the release from REV (reverse phase evaporated vesicle) was the highest; next was that from LUV (large unilamellar vesicle prepered by detergent removal method), and lowest was from SUV (small unilamellar vesicle prepared by an ultrasonication method). In order to examine the size effect of liposomes on temperature-sensitive drug release, REV was fractionated into three groups according to their average sizes and calcein release for each group was investigated. The temperature at which calcein release showed a maximum was almost the same in each of three groups; while as the average liposome size of a group was larger, the initial rate of calcein release became higher and the temperature at which calcein release began became lower. The amount of release of a entrapped drug was primarily dependent on the molecular weight of the drug, in spite of the variety of drugs investigated.

Liposomes have been regarded as having promise for use as a new type of drug carrier. They can encapsulate either hydrophilic or hydrophobic drugs in their inner core or membrane matrix. They can be expected to have different forms of interactions with bioorgan than do other types of drug carriers, such as emulsions or microspheres, judged from a similarity with biological cell membranes regarding both structure and nature. They can also be considered as being biodegradable and to have little toxity.[1,2] One obstacle in putting liposomes to practical use as drug carriers has been a difficulty in controlling the release of encapsulated drugs. Yatbin et al.[3] and Weinstein et al.[4] showed the possibility of medical applications of the so-called "temperature-sensitive liposome", which enables the control of drug release from a liposome using the nature of the phospholipid membrane; the barrier efficiency of the membrane abruptly decreases near the phase transition temperature of a gel-to-liquid crystalline of the phospholipid membrane.[5] This report concerns an extension of their idea. In order to extend the application of a temperature-sensitive liposome, it is especially important to clarify the characteristics of the temperature-sensitive membrane permeability. In this report the effects of various entrapped drugs and the forms of liposomes on the temperature-sensitive drug release were studied. Especially, results concerning the possibility of controlling the release of macromolecule drugs would stimulate the use of temperature-sensitive liposomes for medical applications, since many macromolecular drugs, such as urokinase, are easily inactivated by a variety of inhibitors in the blood;[6] also, their clearance from blood is very rapid.

Experimental

Materials. L-α-phosphatidylcholine from egg yolk (egg PC) was purchased from Green Cross Co. (no less than 99% purity). L-α-dipalmitoylphosphatidylcholine (DPPC) was obtained from Sigma Co. (no less than 99% purity determined by thin-layer chromatography). *N*-octyl β-D-glucoside and calcein (3,3′-bis[*N*,*N*-(dicalboxymethyl)aminomethyl]fluorescein) were obtained from Dojindo Laboratories. Dextran ($\overline{M_W}$; 70000) and inulin were purchased from Wako Chemicals. Urokinase was obtained from Kyorin Co, (the trade name is caltokinase). Sinthesized fluorescenced urokinase substrate, Glutaryl-Gly-Arg-MCA (4-methylcoumarinamide), was obtained from Protein Research Foundation. ^{3}H-dextran (specific activity; 336 μCi mg^{-1}) and ^{14}C-inulin (specific activity; 2.6 μCi mg^{-1}) were obtained from Amercham. Hydrophobic beads used for detergent removal were Amberlite XAD-2 obtained from Tokyo Organic Chemicals. All other reagents were of reagent grade from Wako Chemicals or Nakarai Chemicals.

Methods. Liposome Preparation. DPPC-SUV (small unilamellar vesicle) was prepared according to a method of Weinstein et al.[4] or Watt et al.[7] as follows: a dried, thin film of dipalmitoylphosphatidylcholine was swollen with buffer solution, (if necessary, containing an appropriate drug,) for 2 min at 50°C followed by shaking for 20 s; this process was repeated 3 times. The resulting suspension was sonicated using a probe-type sonicator (Taiyo Seiki Co., model UR-200P) at 50 °C for 60 min, followed by standing for 15 min at 50 °C. The suspension was then ultracentrifuged at 100000×*g* for 15 min using a centrifuge (Hitachi automatic preparative ultracentrifuge, 55p-72). SUV was obtained from the supernatant.

DPPC-LUV (large unilamellar vesicle) was prepared according to a method described in previous papers[8-10] as follows: a dried thin film of phospholipid was solubilized by octyl glucoside (molar ratio of pospholipid to octyl glucoside was 1/10);

the solubilized micellar solution was rapidly passed through a XAD-2-loaded column at 50 °C. The liposomes prepared by this method have been known to be mostly unilamellar vesicle. LUV was obtained after 15 passages through the column.

DPPC- or EggPC-REV (reverse-phase evaporated vesicle) was prepared according to a method of Szoka et al.[11] The preparation of an emulsion during this procedure was accomplished using diisopropyl ether / chloroform (1/1) at 47 °C for DPPC-REV preparation, and diethyl ether at 4 °C for EggPC-REV.

Any untrapped drug was removed by centrifugation for REV or gel chromatography using Sephadex G-50 for LUV or SUV. The drug-loaded liposomes were resuspended in Tris-HCl buffer (150 mM NaCl / 10 mM Tris-HCl / pH 7.4, 1 M=1 mol dm^{-3}) and, if necessary, concentrated or diluted to make an appropriate concentration for succeeding release experiments.

Size Fractionation of REV. Since REV contained various sizes of liposomes, it was fractionated by centrifugation as follows: First, REV suspension was centrifuged at 30000×*g* at 4 °C for 20 min. Small REV (S-REV) was obtained from the supernatant. The precipitate was resuspended in Tris-buffer after being washed by a cold buffer 3 times, and centrifuged at 1000×*g* at 4 °C for 20 min. Medium REV (M-REV) was obtained from the supernatant and large REV (L-REV) from the precipitate. These suspensions were either diluted or concentrated to make an appropriate concentration for the succeeding release experiment.

Entrapping Efficiency and Captured Volume. The entrapping efficiency and captured volume were evaluated by adding a fluorescence quencher in a calcein-containing liposome suspension[12] as follows: liposome was prepared in 10 μM of a calcein solution; the remaining fluorescence intensities were measured after the fluorescence of untrapped calcein was quenched by the addition of an appropriate amount of 100 mM $CoCl_2$. The entrapping efficiency was calculated by using the following equation:

$$\text{entrapping efficiency (\%)} = \frac{f_{in}\, r_1 - f_{total,q}\, r_2}{f_{total} - f_{total,q}\, r_2} \times 100,$$

where f_{in} is the fluorescence intensity of the internal calcein; f_{total} and $f_{total,q}$ are the total fluorescence intensity of the calcein before and after liposome destruction, respectively; r_1 and r_2 are correction factors for the volume increase upon adding a $CoCl_2$ solution and the Triton X-100 solution, respectively. They were 2620/2600 and 2625/2600 in our experiments. The fluorescence intensity of calcein was measured by a fluorophotometer (Shimadzu, difference spectrofluorophotometer, RF-503A) at 490 nm for exitation and 520 nm for emission. The captured volume was defined as being the total internal volume per mole of phospholipid, calculated from the amount of drug captured.

Release Measurement of Entrapped Drug. Calcein release was evaluated by a fluorescence self-quenching method according to Yatvin et al.[3] or Senior et al.[13]; 20 μl of a liposome suspension containing 100 mM of calcein was added to 2.5 ml of a buffer solution which had been kept at the desired temperature in advance. With this method the temperature was rapidly controlled. ^{14}C-inulin and ^{3}H-dextran release was monitored by measuring their radioactivity (using an Aloka scintilation system, LSC-900) in the supernatant by centrifugation at 40000×*g* for 20 min at 4 °C after an appropriate incubation time of the liposome suspensions at the desired temperature.

Urokinase release was monitored enzymatically using a fluorescenced urokinase substrate according to the method of Morita et al.[14]

Other Methods. The liposome size was evaluated by quasielastic light scattering (QELS) using a laser particle analyzing system (Otsuka Electronics Co. LPA 3000/3100). The phase-transition temperature was monitored by calorimetry using a differential scanning calorimeter (2nd Seiko Co. SSC-560). Phospholipid concentrations were determined by the micro method of Bartlet.[15]

Results

Characterization of Liposomes. The size and entrapping efficiency of liposomes prepared by several methods are summarized in Table 1. REV was the largest regarding both size and entrapping efficiency. The stability or barrier efficiency of DPPC-REV in a buffer solution at 4 °C are shown in Table 2. About 90% of the low-molecular-weight compound (calcein) and about 100% of the high-molecular-weight compound (dextran) were retained in the liposomes after 4 weeks of incubation. Judged from these observations, the liposomes could be regarded as having a high barrier efficiency against both low- or high-molecular-weight compounds at a temperature below their phase-transition temperature.

Calcein Release and Phase Transition. In order to examine the characteristics of the temperature-sensitive membrane permeability, the release of calcein from the liposome was investigated under several conditions. In Fig. 1, DSC curve of DPPC-REV and calcein release (%) from the liposome after 2 min incubation at several temperatures are shown. An endthermal peak due to the phase transition of DPPC hydrocarbon chains was observed at 42 °C. At the corresponding temperature

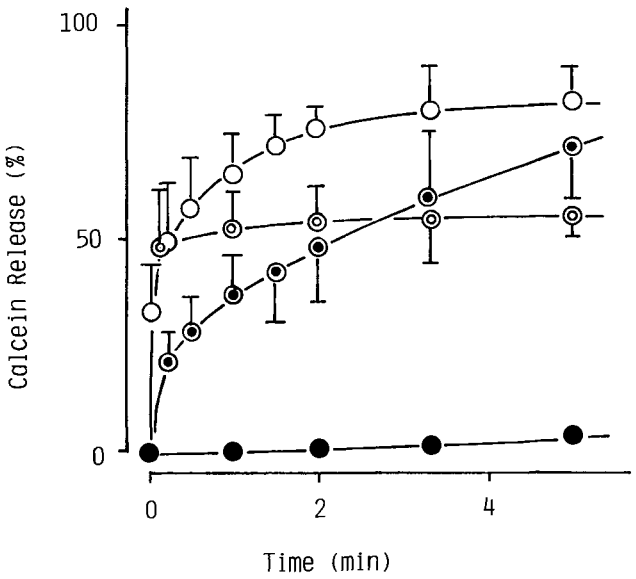

Fig. 2. Time course of calcein release from DPPC-REV. ●, 34.5°C; ◉, 39.3°C; ○, 41.0°C; ◎, 46.0°C. Each point represents the mean±S.D. (n=4—5).

the liposome showed maximum release. The time course of calcein release from DPPC-REV is shown in Fig. 2. The initial rate of calcein release seemed to become faster as the incubation temperature become higher; the rate at 46 °C was the highest measured, while the total amount of calcein released during 2 min of incubation became largest at 41 °C, near the phase-transition temperature, instead of 46 °C. At 46 °C, calcein release plateaued at a levels (ca. 50% of entrapped calcein) after 1 min of incubation. The drastic release observed during the initial stage at 46 °C would be due to the temporary experience of the optimum temperature of calcein release, (that is, the phase-transition temperature of the membrane phospholipid), during a temperature rise from room temperature to 46 °C. The saturation phenomenon regarding release % after 1 min of incubation at 46 °C suggests that the liposome again came to have a high barrier efficiency at a higher temperature than the transition temperature.

The Temperature-Sensitivity of Calcein Release Depending on the Preparation Method of the Liposomes. The calcein release % from liposomes prepared by several methods is shown in Fig. 3. EggPC-REV, whose phase-transition temperature is below 0 °C, did not practically make calcein release within experimental temperature range (24—47 °C), while DPPC liposomes prepared by any method showed (more or less) a temperature-sensitivity in calcein release near 40 °C. The release % of

calcein was dependent on the method of liposome preparation; calcein release % from REV was the highest of all, followed by LUV, and then SUV.

Dextran Release from REV. Concerning DPPC-REV, which had showed the highest temperature-sensitivity for the release of calcein adopted as a model compound for low-molecular-weight drugs, the behavior of dextran release as a model compound for high-molecular-weight drugs was studied. The results are given in Figs. 4 and 5. As shown in Fig. 4, REV showed the maximum release (%) of dextran near 40 °C, similar to the case of a low-molecular-weight compound: that is, REV was found to possess the characteristics of temperature-sensitivity, even for the release of a high-molecular-weight compound. As shown in Fig. 5, the time course of dextran release from REV was also similar to that of calcein; that is, an initial high release followed by a dull release was observed. On the whole, the release % of dextran was smaller than that of calcein. For a high-molecular-weight compound, a saturation phenomenon was observed during its release, even at optimum temperature. The maximum amount of dextran released at the transition temperature was only 20% of encapsulated amount, while that of calcein was 70—90%. These observations suggest the inhomogeneity of the liposome in size and/or property; that is, the coexistance of both vesicles (permeable and inpermeable) for macro molecules, even at the transition temperature.

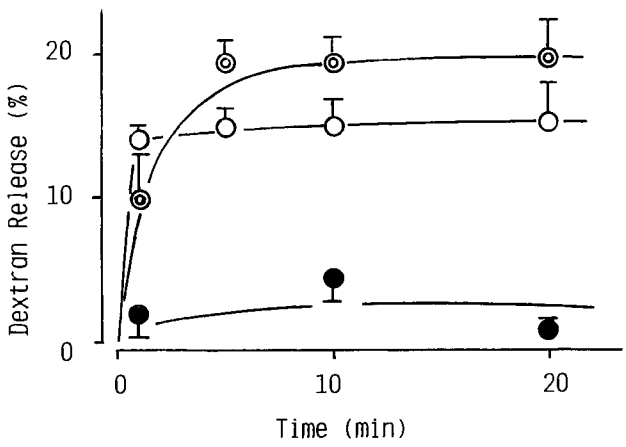

Fig. 5. Time course of dextran release from DPPC-REV at several temperatures. ●, 37 °C; ◎, 40 °C; ○, 42 °C. Each point represents the mean±S.D. (n=4).

Caracteristics of the Temperature-Sensitive Membrane Permeability. A pattern analysis of the time course of calcein release from DPPC-REV was carried out. In Fig. 6, the time course of the remaining percent of calcein in REV at 34.5 °C is shown on a logarithmic scale. At 34.5 °C the rate of calcein release was extremely slow and obeyed the first-order efflux. At 39.7 or 41.0 °C (near phase transition temperature) the efflux pattern seemed to have two or more phases; that is, an initial high efflux followed by a slow efflux was observed. These observations suggest that these liposomes must be inhomogenous in the size and/or property. In order to confirm the above suggestion, these liposomes were tentatively fractionated into 3 groups by centrifugation as S-REV with 100 nm of average diameter, M-REV with 2000 nm and L-REV with 3000 nm; the calcein efflux from each fractionated liposome was tested (data not shown). The calcein release rate was of the order of L-REV, M-REV, and S-REV. The polyphase of the efflux pattern for calcein release from the liposomes would be mainly due to the polydispersity of

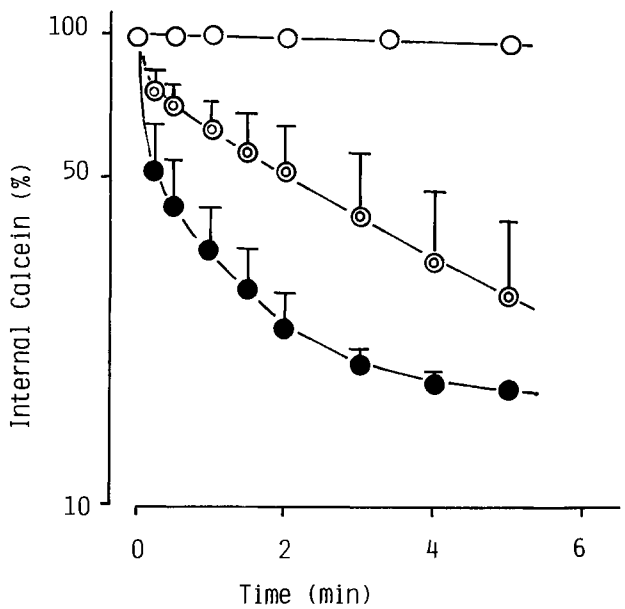

Fig. 6. Time course of remaining calcein (%) in DPPC-REV in logarithmic scale at several incubation temperatures. ○, 34.5 °C; ◎, 39.3 °C; ●, 41.0 °C. Each point represents the mean±S.D. (n=4).

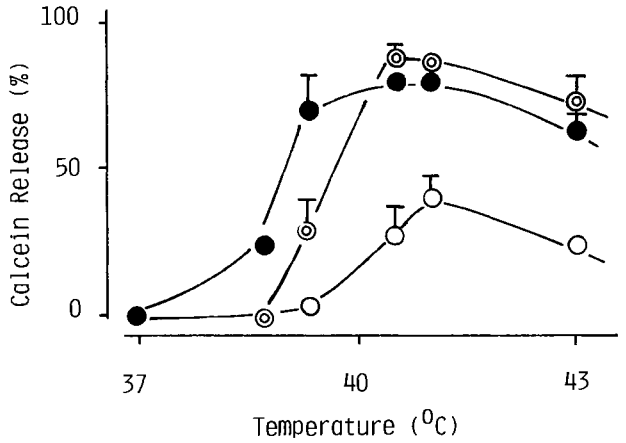

Fig. 7. Effect of liposome size on temperature-dependent calcein release. ●, L-REV; ◎, M-REV; ○, S-REV. Each point represents the mean±S.D. (n=3-4).

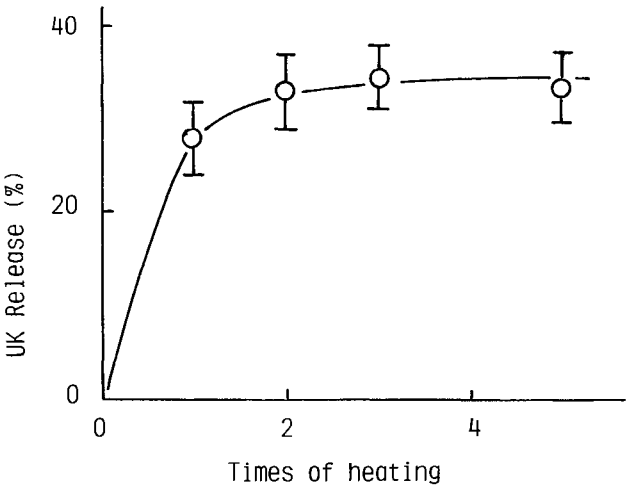

Fig. 8. Influence of the repeated heating on the release of urokinase from DPPC-REV. Each point represents mean±S.D. (n=3).

the liposomes in relation to size. In Fig. 7, the temperature dependence of calcein release for each fraction of the liposomes is shown. The temperature at which calcein release starts was found to shift to a lower temperature as the liposome size became larger. The maximum release % of L-REV and M-REV was almost the same as each other. The release % of S-REV was about half that of M-REV and L-REV. This observation also shows that the liposomes, which are registant for calcein release even at their transition temperature, somewhat exist in the liposome preparations, especially in S-REV.

Urokinase Release by Repeated Heating. One-minute heating of REV contaning urokinase was repeated several times at 5 min intervals. In Fig. 8, the urokinase release % is plotted against the number of repeating times. About 28% of the urokinase release was observed after the first 1 min of heating. Urokinase release upon a second heating was only 5%. After a third heating, no further urokinase release was observed. These results show that drug release from the temperature-sensitive liposome came to completion within two or so minutes heating, as is predicted by Fig. 2 for low-molecular-weight compound, or Fig. 5 for high-molecular-weight compound. Furthermore, these results suggest that there exist about 60% liposomes which are inpermeable for urokinase, even at the transition temperature.

Effect of the Molecular Weight of Encapsulated Compounds on Liposomal Permeation. The releases of several compounds with different molecular weights after 1 min incubation at 43 °C were plotted against the molecular weight in logarithmic scale, as shown in Fig. 9. The plotts fell into one curve according to their molecular weights, independent of the types of compounds: that is, low-molecular-weight organic compounds, proteins, polysaccarides. These results show that the releases of entrapped compounds from temperature-sensitive liposomes near their transition temperatures could be primarily governed by their molecular weight, in spite of the variety of drugs.

Discussion

The initial release rate of both a low-molecular-weight compound (calcein) and a high-molecular-weight compound (dextran) from liposomes became larger as the incubation temperature was elevated within the experimental temperature limit (34.5—46 °C). At temperatures higher than the phase-transition temperature, the release amount attained saturation within a few minutes of incubation. Regarding calcein release at 46 °C, saturation was achieved within 1 min of incubation, and the released calcein upon saturation was about 50% of the calcein entrapped in the

liposome. No further release was added, even after long-time incubation. These observations suggest that the high initial rate at a temperature above the phase-transition temperature might be brought about when the liposome experiences the phase-transition temperature while increasing the temperature from low temperature to a fixed temperature; the liposome might again have a high barrier efficiency after the temperature exeeds the phase transition temperature.

Even at the transition temperature, a saturation phenomenon was also observed in the case of the release of a macromolecule. Saturation was achieved within a few minutes. The amount of release at saturation was dependent on the molecular weight of the compounds entrapped, and was 20—40% of the total macromolecules entrapped. No release exeeding 20—40% was observed, even after long-time incubation. These phenomena might be due to the polydispersity of the liposome size and properties: that is, 2 or more species of liposomes (one liposome could be perturbed enough large to bring about membrane release of macromolecules and the others not,) coexisted. Strictly speaking, even for a low-molecular-weight compound, no 100% release occured at all; thus, about 10% of the liposome was impermeable, even at the transition temperature. Judged from the results that the extent of temperature-sensitivity of drug release from a vesicle was dependent on the method of liposome preparation as well as on fractionation by centrifugation of the liposomes, larger liposomes seemed to generate a higher-temperature-sensitive drug release, suggesting that the extent of structural deformation of the membrane at the phase-transition temperature would vary among liposomes, especially depending on the liposome size.

Regarding the structural deformation of the membrane at the phase-transition temperature, which brings about an abrupt lowering of the membrane barrier efficiency, several hypotheses have been reported: (1) the apearance of a boundary between the gel phase and the liquid crystalline phase accompanying lateral phase separation,[16,17] (2) a change in the lateral compresibility between adjacent phospholipid molecules with an increase in membrane fluidity,[18] and (3) the formation of statistical pores by the rotation of phospholipid molecules with isomerization.[19] Since these hypotheses are based on the behavior of low-molecular-weight compound or ions, it is difficult to restrict the mechanism for such a rapid permeation of a high-molecular-weight compound as observed in our present experiments. In any case, it should at least be concluded that a large perturbation, which enables even a rapid permeation of macromolecules, must arise in a membrane on the occasion of a phase transition; also, the degree of perturbation must vary with the properties of the liposomes, especially regarding their size.

Final products of the photochemical reactions of quinazoline, quinoline, and naphthalene in 1,2,4,5-tetramethylbenzene (durene) mixed crystals are investigated on the basis of the phosphorescence and fluorescence spectra of the products. Quinazoline in durene is considered to transform into a benzene derivative, whereas naphthalene and quinoline tranform into anthracene derivatives. These products are different from a pyrazine derivative found in the case of quinoxaline, which is specific to the reaction in a durene mixed crystal. The cause of this difference is discussed in terms of the configurations of guests in the mixed crystals and the difference of the molecular structures.

One of the interesting features of the chemical reactions in single crystals is the generation of reaction products specific to single crystals.[1,2] Yamauchi, Terazima, and Hirota reported a unique product of the photochemical reaction of quinoxaline (Qx) in a single crystal of 1,2,4,5-tetramethylbenzene (durene (D)).[3] The final product of this reaction was found to be a pyrazine derivative with two hydrogen atoms attached to the benzene ring of Qx. In the hydrogen abstraction reactions of Qx in solution, the reaction product is the 1,4-dihydro-1-quinoxalinyl radical (QxH) with a hydrogen attached to the nitrogen of Qx.[4-8] Pyrazine derivatives have never been found in the reactions in solution.

In a series of papers, we have recently discussed the photochemical reactions of naphthalene (N) and azanaphthalenes (Qx, quinazoline (Qz), and quinoline (Q)) in durene mixed crystals schematically shown by the scheme in Fig. 1. In all cases, the initial steps (1) of the reactions are the hydrogen abstraction reactions of the triplet states of these molecules and quantum mechanical tunneling plays an essential role in these steps.[9-12] We have discussed the observed temperature, pressure and deuterium isotope effects on the reaction rates in terms of the Siebrand model of hydrogen tunneling.[13] As for the final products, we have hitherto discussed only the case of Qx mentioned above. In the present work, we have made a spectroscopic investigation on the reaction products of Qz, Q, and N in mixed crystals of durene (hereafter these systems are abridged as Qz/D, Q/D, and N/D). The final products of these reactions are found to be quite different depending on the system. The reaction product of Qz/D gives a phosphorescence spectrum characteristic of a benzene derivative, whereas the products of Q/D and N/D give fluorescence spectra characteristic of anthracene derivatives, indicating that dimerization of Q (N) and durene occurs. The difference in the products is rationalized on the basis of the configurations of the guest molecules in the mixed crystals and the difference in the molecular structures.

Experimental

Q was purified by vacuum distillation. Qz was purified by vacuum sublimation. N was recrystallized from ethanol and

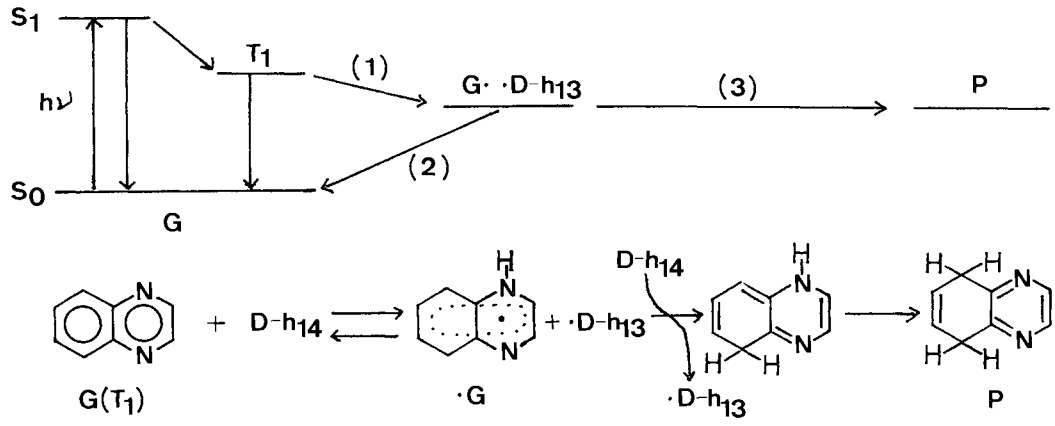

Fig. 1. General reaction scheme of the photochemical reaction of azanaphthalene/durene and naphthalene/durene. Reaction (3) may consist of several steps. G, D-h_{14}, D-h_{13}, and P represent a guest molecule, durene, 2,4,5-trimethylbenzyl radical, and product, respectively. The reaction process of quinoxaline/durene is also shown below the scheme.

zone refined. Indan was purified by vacuum distillation. Durene was recrystallized from ethanol followed by column chromatography and zone refined. Mixed single crystals were grown from melts containing about 0.1 mol% of guest molecules by the standard Bridgman method.

The UV irradiation was provided by a 900 W Xe lamp whose output was passed through a saturated $NiSO_4$ solution and a Toshiba UV-D33S glass filter. Samples were irradiated at room temperature for about 30 min to induce photochemical reactions. Phosphorescence spectra of the reaction products were obtained at 4.2 K with a Spex Model 1704 1-m monochromator equipped with an EMI 9502B photomultiplier. Phosphorescence lifetimes were measured using a mechanical shutter. Fluorescence spectra were observed at room temperature with a Shimadzu fluorometer (RF-502A).

Results and Discussion

Quinazoline/Durene. When Qz/D is irradiated at room temperature, the green fluorescence of a 2,4,5-trimethylbenzyl radical with a maximum peak at 495 nm appears as the phosphorescence of Qz decreases. The phosphorescence of Qz disappears completely after prolonged (30 min.) irradiation. After irradiation, the ESR signal of a pentamethylcyclopentadienyl radical produced via the 2,4,5-trimethylbenzyl radical was obtained.[14] These experimental results are similar to those found for Qx/D,[3] indicating that the 2,4,5-trimethylbenzyl radical is produced by the photoinduced hydrogen abstraction of Qz from durene.

Figure 2(a) shows the phosphorescence spectrum of "Qz/D" at 4.2 K after irradiation at room temperature. The phosphorescence of Qz (0–0 band: 454.4 nm) is absent, but instead a new spectrum with an 0–0 band at 359.7 nm is obtained. The phosphorescence lifetime is 3.2 s. On the analogy of the result of Qx/D, it may be expected that the final product of the photochemical reaction of Qz/D is a pyrimidine derivative. The observed phosphorescence spectrum, however, cannot be due to a pyrimidine derivative, because the phosphorescence lifetime of pyrimidine is about 12 ms.[15] The long lifetime (3.2 s) and the location of the 0–0 band of the phosphorescence indicate that the phosphorescence is likely to arise from a benzene derivative.[16] The energy of the 0–0 band of the observed phosphorescence (27798 cm^{-1}) is very close to that of durene (28000 cm^{-1})[17] and there are two possibilities for the assignment of the observed spectrum.

(1) The energy of the triplet state of the reaction product is lower than that of durene and the observed phosphorescence is genuinely due to the reaction product.

(2) The energy of the triplet state of the reaction product is higher than that of durene and the observed phosphorescence is due to a durene X-trap.

The second possibility cannot be excluded, if the reaction

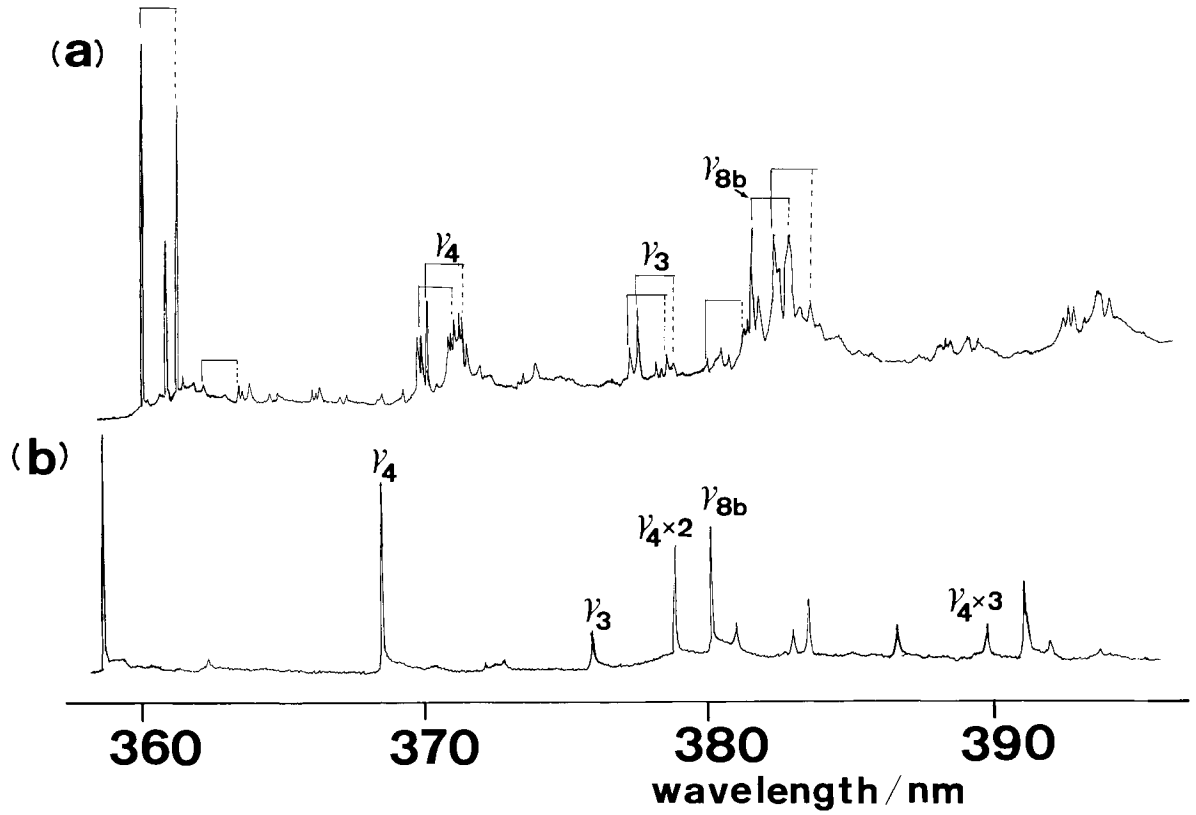

Fig. 2. (a) Phosphorescence spectrum of quinazoline/durene at 4.2 K after irradiation at room temperature. (b) Phosphorescence spectrum of durene X-trap obtained by doping indan in a durene single crystal at 4.2 K.

product is a pyrimidine derivative. This is because the 0–0 energy of $^3(n, \pi^*)$ pyrimidine (28112 cm^{-1} in *p*-xylene and 28240 cm^{-1} in methylcyclohexane[18]) is slightly higher than that of the lowest triplet state of durene.

In order to assign the observed phosphorescence, we have studied the phosphorescence spectrum of a durene X-trap obtained by doping indan in a durene single crystal (Fig. 2(b)). The vibrational analysis and the assignment of the vibronic bands of the phosphorescence are shown in Table 1(a) and (b). The assignment was made on the basis of the Raman data of durene.[19] The energy of the 0–0 band of the durene X-trap is 90 cm^{-1} higher than that of Qz/D after irradiation. Vibronic bands characteristic of the benzene ring can be found in the durene X-trap phosphorescence. The vibronic bands at 760, 1290, and 1582 cm^{-1} are assigned as ν_4, ν_3, and ν_{8b} modes of the benzene ring,[19,20] respectively. These vibrations are the C–C–C out-of-plane bending, the C–H in-plane bending, and the C–C stretching modes, respectively. As for Qz/D after irradiation, vibronic bands from two different sites are clearly observed with a splitting of 91 cm^{-1}. The vibronic bands characteristic of the benzene ring (ν_4, ν_3, and ν_{8b}) are also observed, indicating that the phosphorescence comes from a benzene derivative. There are, however, significant differences between the Qz/D spectrum and the X-trap spectrum. First, in the Qz/D spectrum, there are some bands that are not observed in the durene X-trap, for example, the vibronic bands at 741, 839, 1269 cm^{-1} etc. The band at 741 cm^{-1} may be assigned to the C–H bending mode of an aliphatic skeleton as observed in 1,4-dihydronaphthalene.[21] Second, some overtone (754×2, 754×3) and combination bands in the durene X-trap are not observed in Qz/D. These differences seem to indicate that the phosphorescence of Qz/D after irradiation comes from the reaction product, and not a durene X-trap.

This product comes most likely from Qz for the following reason. The reaction products originating from durene are considered to be 2,4,5-trimethylbenzyl and pentamethylcyclopentadienyl radicals. These radicals give, however, no phosphorescence. Furthermore, in the case of Qx/D and Q/D, no phosphorescence similar to that found for the reaction product of Qz/D is observed, though durene is used as the host in all cases. Moreover, durene neat crystal does not give such phosphorescence after irradiation for about 1 h. Intermediate 1,3-dihydro-1-quinazolinyl and 2,4,5-trimethylbenzyl radicals may combine to produce a 3,4-dihydro-3-(2,4,5-trimethylbenzyl)quinazoline like product. The 0–0 band of the phosphorescence spectrum of such a product, however, should be much lower than that of the observed one because of the conjugation of a double bond with the benzene ring as discussed in Reaction Mechanism.

Quinoline/Durene. Different from the cases of Qx and Qz, no new phosphorescence appears after irradiation at room temperature when observed at 4.2 K. However, very intense blue fluorescence starts to grow gradually as the green phosphorescence of Q diminishes upon irradiation. Figure 3 shows the fluorescence spectrum of the reaction product of Q/D after irradiation for about 30 min at room temperature. The emission spectrum (obtained by irradiation at 285 nm) starts to rise at 361 nm accompanied by two vibronic bands at 418 and 442 nm and a shoulder at 397 nm. The wavelength range of the emission and the interval of the vibronic

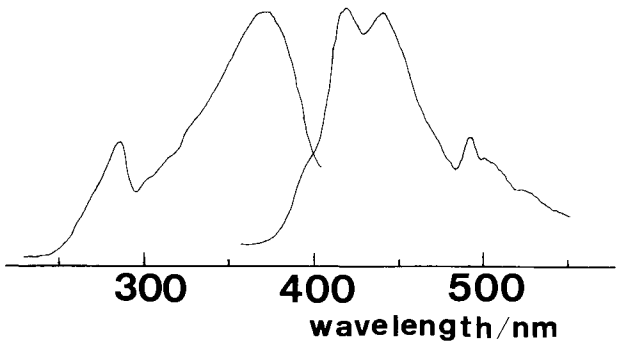

Fig. 3. Fluorescence emission (irradiated at 285 nm) and excitation (monitored at 418 nm) spectra of quinoline/durene at room temperature after irradiation.

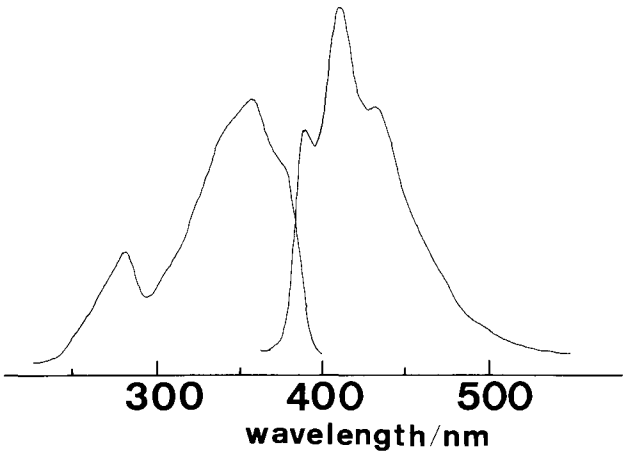

Fig. 4. Fluorescence emission (irradiated at 285 nm) and excitation (monitored at 410 nm) spectra of naphthalene/durene at room temperature after irradiation.

bands (1300 cm^{-1}) are similar to those of anthracene,[22] and the excitation spectrum monitored at 418 nm is also similar to the absorption spectrum of anthracene.[23] Because of the broad nature of the spectrum, we cannot ascertain that this fluorescence arises from only one product. But the above mentioned features of the spectrum seems to indicate that the main fluorescent product is an anthracene derivative.

The fluorescence peaks observed lower than 490 nm are due to the 2,4,5-trimethylbenzyl radical which is produced by the hydrogen abstraction reaction.

Naphthalene/Durene. Intense blue fluorescence increases during the UV irradiation at room temperature as Q/D. Figure 4 shows the fluorescence emission and excitation spectra of the reaction product after irradiation. The emission (irradiated at 285 nm) starts at about 370 nm with three vibronic bands at 389, 410, and 433 nm. The wavelength range of the fluorescence and the interval of the vibronic bands (1300 cm^{-1}) are similar to those of anthracene.[22] The excitation spectrum with a peak at 361 nm (emission at 410 nm) is also similar to the absorption spectrum of anthracene.[23] Therefore, the reaction product of N/D is also considered to be one of the anthracene derivatives as in the case of Q/D.

Neither the fluorescence spectrum of the 2,4,5-trimethylbenzyl radical nor the ESR spectrum of the pentamethylcyclopentadienyl radical was observed. This is probably because the back reaction in the initial hydrogen abstraction process ((2) in Fig. 1) is so efficient that the steady state concentrations of the intermediate 2,4,5-trimethylbenzyl and 1,4-dihydro-1-naphthyl radicals become too low to be detected by ESR.[10] The fluorescence of 2,4,5-trimethylbenzyl radical seems to be much weaker than that of anthracene derivative because of its low steady state concentration and quantum yield.

Reaction Mechanisms. There are three questions about the experimental results given above.

(1) What are the exact structures of the reaction products ?

(2) Why is Qz transformed into a benzene derivative, not a pyrimidine derivative ?

(3) Why are Q and N transformed into anthracene derivatives, but not Qx and Qz ?

We discuss these questions on the basis of the configurations of the guest molecules in the mixed crystals and the molecular structures of the guest molecules.

Figure 5 shows the proposed reaction mechanism of Qz/D. In the case of Qz/D, according to the potential energy calculation by McCool et al., there are two sites for Qz in durene, one rotated by 18° and the other by −25° in the molecular plane with respect to the molecular axis of durene.[24] Figure 6 shows the configuration of Qz at the −25° site in durene as a representative. The following discussion can also be applied to Qz at the +18° site. The hydrogen atom from durene is expected to attack the nitrogen of Qz via tunneling in the initial process of the reaction as reported before.[11] The molecular center of Qz deviates by 0.9 Å from that of durene.[24] The durene nearest to the nitrogen at position 1 of Qz is located along the *c* axis of the lattice (2 in Fig. 6). On the other hand, the durene nearest to the nitrogen at position 3 of Qz is located in the *ab* plane of the lattice (3 in Fig. 6). When a reaction proceeds via tunneling, a reaction rate constant depends sensitively on the tunneling distance (the distance between the nitrogen of Qz and the abstracted hydrogen of durene).[13] For example, a decrease of the tunneling distance by 0.1 Å is known to enhance the reaction rate constant by one or two order of magnitude. Because the tunneling distance for the nitrogen at position 3 of Qz is smaller (0.2 Å for the +18° site and 1.5 Å for the −25° site) than that at position 1, the hydrogen atom from durene is predicted to attack position 3 of Qz preferentially to produce a 1,3-dihydro-1-quinazolinyl radical (QzH). Therefore the hydrogen abstraction at position 1 of Qz is negligible to that at position 3 in the initial process of the reaction.

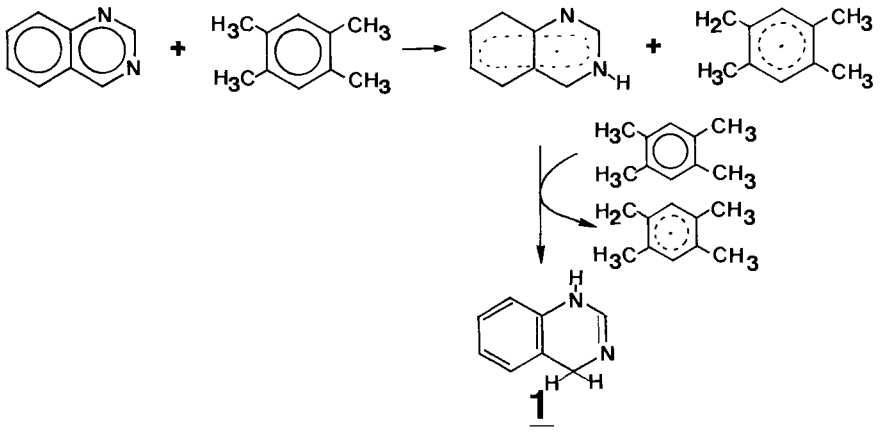

Fig. 5. Proposed reaction mechanism of quinazoline/durene.

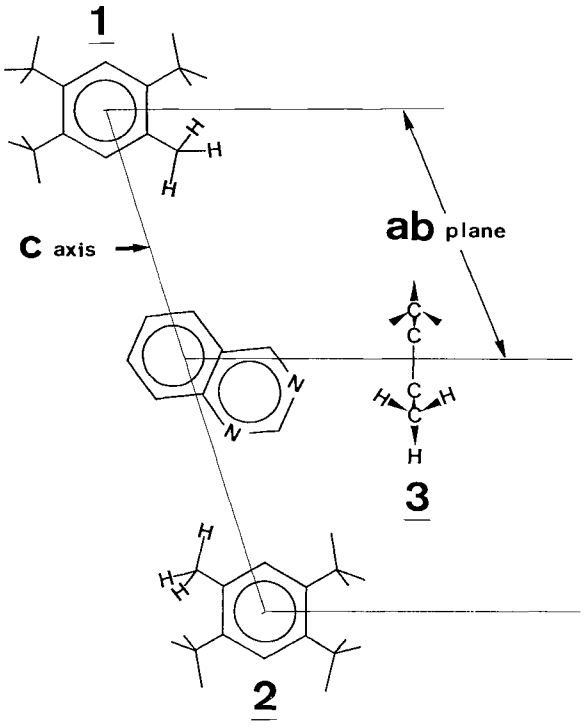

Fig. 6. Configuration of −25° site of quinazoline in durene mixed crystal. Molecules along the *c* axis are not in the same plane in reality.

Hydrogen abstraction via tunneling at the benzene ring of Qz is also negligible to that at the pyrimidine ring because the tunneling distance to the benzene ring is much larger than that to the pyrimidine ring because of the deviation of the molecular center of Qz from that of durene. In order to produce a stable benzene derivative, one more hydrogen must attack the pyrimidine ring of Qz. There are three possible benzene derivatives shown in Fig. 7, but neither product **2** and **3** can be the final product. Because of the conjugation of the double bond with the benzene ring, the triplet energies of products **2**

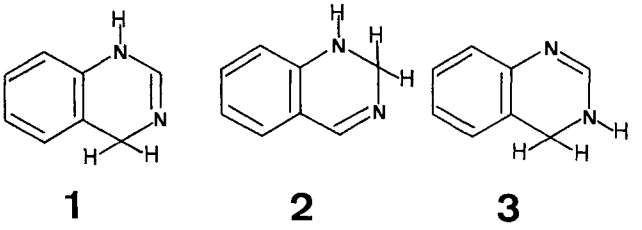

Fig. 7. Possible benzene derivatives produced from quinazoline.

and **3** are expected to be as low as that of 1H-indazole (23590 cm^{-1})[25]. On the other hand, product **1** does not have the conjugaton of the double bond with the benzene ring, producing a triplet energy as high as that of aniline (27659 cm^{-1}).[26] Therefore, we consider product **1** as the final product. Though the vibronic bands corresponding to the N–H bond are not found, the existence of the C–H bending mode of an aliphatic skeleton in the phosphorescence spectrum supports this assignment.

A possible way to explain how the final benzene derivative is produced is the following. The hydrogen of durene along the *c* axis attacks the nitrogen atom at position 1 of QzH, accompanying the transfer of the hydrogen from position 3 to position 4 simultaneously.

Though there is no direct experimental evidence that a pyrimidine derivative is not produced, we consider that the attack of the hydrogen on position 3 of Qz and the deviation of the molecular center of Qz from that of durene inhibit the formation of a pyrimidine derivative. In the case of Qx/D, the molecular axes of Qx is the same as those of durene and the deviation of the molecular center is considered to be small compared to that of Qz. In this system, first, the hydrogen of durene along the *c* axis attacks position 1 of Qx whose tunneling distance is the smallest, producing a 1,4-dihydro-4-quinoxalinyl radical (QxH). Then, the hydrogen attacks position 5 (benzene ring of QxH) which is equivalent to position 1. Finally, the hydrogen attached to position 1 is transferred

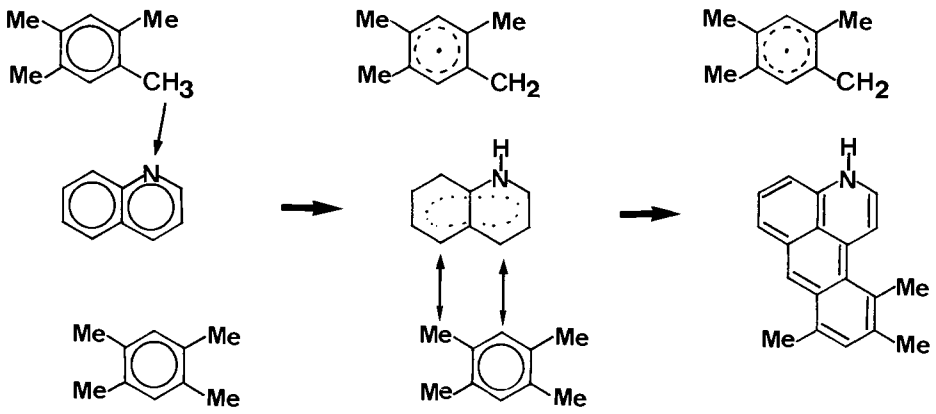

Fig. 8. Probable reaction mechanism of quinoline/durene. The orientation of quinoline and durene in the figure is almost the same as that in durene mixed crystal.

to the neighboring position 8 to produce the pyrazine derivative. The crucial process in proceeding the pyrazine derivative is the attack of the hydrogen of durene on the benzene ring of Qx (position 5). In the case of Qz/D where the hydrogen is attached at position 3, the second hydrogen cannot attack position 5 or 8 because the attachment to these positions destroys the conjugation of the system. The positions in the benzene ring of QzH on which the hydrogen can attack are 6 and 7. The distances from durene to these positions are, however, larger than that of position 5 or 8 on which the hydrogen attacks in Qx/D. Moreover, because the molecular center of Qz deviates by 0.9 Å from that of the replaced durene, the distance between the benzene ring of Qz and durene becomes larger than that for Qx. Therefore, the second hydrogen is expected to attack on the second nearest nitrogen at position 1 of Qz to produce the benzene derivative.

Figure 8 shows a possible reaction mechanism of Q/D. On the analogy of the reaction in solutions[27] and on the basis of the crystal structure,[28] the hydrogen from durene attacks position 1 of Q to produce a 1,4-dihydro-4-quinolinyl radical. After the hydrogen transfers from durene to Q, the 1,4-dihydro-4-quinolinyl radical and durene located at the other position along the *c* axis may dimerize to produce a benzo[*de*]anthracene like derivative. We cannot discuss this dimerization process in detail because the orientation of the intermediate radical is not known. When the orientation of the radical is the same as that of Q, the location of Q and durene along the *c* axis becomes favorable for the dimerization, because Q and durene need not change their orientation greatly to dimerize. However, five hydrogen atoms are released after dimerization. These hydrogen atoms may attach to the neighboring durene molecules to produce pentamethylcyclopentadienyl radicals. On the basis of the fact that the orientation of N is almost the same as that of Q,[29] the photochemical reaction of N/D is also expected to proceed in the same way.

The reason why Qx and Qz do not produce anthracene derivatives may be found in the fact that these molecules have two nitrogen atoms. If such a reaction should occur, durene would attack the nitrogen at position 4 of QxH to form a dimerized product. QxH and durene, however, cannot dimerize because a conjugated system including the nitrogen cannot be formed. In the case of Qz/D, there can be two ways to produce a dimerized product in view of the configuration in the mixed crystal (Fig. 6.) and the attachment of the hydrogen at position 3 of QzH.

(a) Durene 2 attacks the nitrogen at position 1 of QzH.

(b) Durene 1 attacks the carbon at position 4 of QzH.

In the case of (a), the dimerization of QzH and durene 2 does not occur for the same reason as given for Qx. In the case of (b), because of the deviation of the molecular center and the rotation in the molecular plane, the distance between durene 1 and position 4 of QzH becomes much larger than that between durene 2 and position 1 of QzH. Therefore the hydrogen abstraction from durene 2 to QzH is considered to occur more efficiently than the dimerization of QzH with durene 1.

In summary, it is found that the final products of the photochemical reactions of Qx/D, Qz/D, Q/D, and N/D are quite different depending on the system despite the fact that the initial steps of the reactions are similar. This difference can be rationalized on the basis of the difference in the molecular structures and the configuration of the guest molecules in the mixed crystals.

Mechanism of Cis-Trans Isomerization of Fluoranthenylethylenes on Direct Irradiation

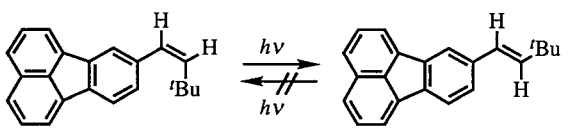
Hideo FURUUCHI, Yasunao KURIYAMA, Tatsuo ARAI,* Hirochika SAKURAGI, and Katsumi TOKUMARU*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received November 19, 1990)

On direct irradiation 8-styrylfluoranthene (SF) and 8-(3,3-dimethyl-1-butenyl)fluoranthene (BF) underwent two-way and one-way isomerizations, respectively, in the triplet manifold after intersystem crossing of the initially produced singlet excited state.

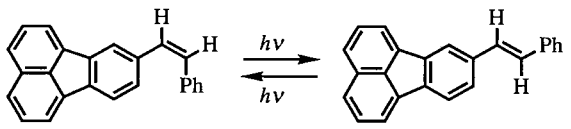
Recently, we have shown that in the triplet sensitized isomerization of olefins the introduction of an anthracene nucleus results in the cis→trans one-way isomerization, no matter which of an alkyl or an aryl group may be substituted on the other ethylenic carbon.[1-3] This is very much contrasted with the mutual two-way isomerization between the cis and trans isomers,[4,5] as well investigated for stilbenes.

Furthermore, we have reported that the olefins substituted by a pyrene[6] or a fluoranthene nucleus[7] whose triplet excitation energy, 48 or 54 kcal mol^{-1},[8] is slightly higher than that of anthracene, 42 kcal mol^{-1},[8] exhibit intermediate behavior between the two-way and one-way isomerizations on triplet sensitization. When a *t*-butyl group is substituted on the other ethylenic carbon, the one-way isomerization occurs with a quantum chain process. On the contrary, when a phenyl group is attached, the two-way isomerization involving a similar quantum chain process takes place.

The direct excitation of olefins also results in their isomerization; however, the mechanism, particularly the spin multiplicity in which the isomerization actually proceeds, depends on the olefins. Stilbene isomerizes in the singlet excited state before intersystem crossing on direct excitation,[9,10] whereas the anthrylethylenes undergo cis→trans one-way isomerization with a quantum chain process on the triplet manifold after intersystem crossing.[1-3] For the olefins exhibiting the intermediate behavior between the two-way and one-way isomerizations, we have recently shown that the direct excitation of the pyrenylethylene with a *t*-butyl group or a phenyl group on the other ethylenic carbon led to the isomerization in the triplet manifold in the same way as the triplet sensitization.[11]



cis-BF *trans*-BF



cis-SF *trans*-SF

These results prompted us to examine whether direct excitation of the fluoranthenylethylenes, whose excitation energies are higher than those of the pyrenylethylenes, brings about the isomerization in the singlet manifold as observed in stilbenes or in the triplet manifold as demonstrated in the anthryl- and pyrenylethylenes.

Experimental

Proton (^{1}H) NMR spectra were recorded on a JEOL JMN-MH-100 spectrometer. Ultraviolet absorption spectra (UV) were taken on a Hitachi 200-20 and a JASCO 660 spectrophotometer. Fluorescence spectra were measured on a Hitachi F-4000 and a Hitachi MPF-4 fluorescence spectrofluorometer. Fluorescence lifetimes were measured using a single photon counting apparatus, Horiba NAES 1100.

Materials. Solvent benzene for photochemical measurements was distilled over calcium hydride. Biacetyl was purified by distillation.

8-Styrylfluoranthene (SF). 8-(Hydroxymethyl)fluoranthene prepared by reducing methyl 8-fluoranthenecarboxylate[12] with lithium aluminum hydride in boiling ether[13] was converted to 8-(bromomethyl)fluoranthene by treating with phosphorus tribromide in the presence of pyridine in chloroform at 0°C.[13]

8-(Bromomethyl)fluoranthene was refluxed with triphenylphosphine in xylene to give (8-fluoranthenylmethyl) triphenylphosphonium bromide.

The Wittig reaction of benzaldehyde with the ylide prepared from (8-fluoranthenylmethyl)triphenylphosphonium bromide with sodium ethoxide in ethanol gave a mixture of *cis*- and *trans*-8-styrylfluoranthene (SF). Column chromatography on silica gel eluting with hexane and benzene (4 : 1) followed by crystallization from hexane afforded *cis*- and *trans*-SF.

cis-SF: Mp 100—101°C; UV (benzene) 304 nm (log ε 4.56), 372 (4.09); ^{1}H NMR ($CDCl_3$, 100 MHz) δ=6.63 (d, 1H, *J*=12.2 Hz, C=CH), 6.69 (d, 1H, *J*=12.2 Hz, C=CH), 7.2—7.9 (m, 14H, ArH). Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%. Found: C, 94.64; H, 5.29%.

trans-SF: Mp 131—133°C; UV (benzene) 322 nm (log ε 4.59), 372 (4.10); ^{1}H NMR ($CDCl_3$, 100 MHz) δ=7.2—7.9 (m, 16H). Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%. Found: C, 94.58; H, 5.25%.

8-(3,3-Dimethyl-1-butenyl)fluoranthene (BF). A mixture

of *cis*- and *trans*-BF was prepared by the Wittig reaction of 2,2-dimethylpropanal with the ylide prepared from (8-fluoranthenylmethyl)triphenylphosphonium bromide with butyllithium in ether. The pure cis and trans isomers were separated by column chromatography on silica gel eluting with petroleum ether.

cis-BF: UV (benzene) 302 nm (log ε 4.65), 330 (3.91).

trans-BF: UV (benzene) 294 nm (log ε 4.56), 327 (3.82), 349 (3.90), 365 (4.95). ^{1}H NMR ($CDCl_3$, 100 MHz) δ=1.06 (s, 9H, $C(CH_3)_3$), 5.77 (d, 1H, J=15 Hz, C=CH), 6.65 (d, 1H, J=15 Hz, C=CH), 7.62—8.08 (m, 14H, ArH). Calcd for $C_{22}H_{20}$: C, 92.91; H, 7.09%. Found: C, 92.61; H, 7.15%.

Steady State Irradiation. Irradiation of benzene solutions containing *cis*- or *trans*-SF was performed with 436-nm light from a 400-W high-pressure mercury lamp through a filter solution ($CuSO_4 \cdot 5H_2O + NaNO_2$). Similarly, benzene solutions of *cis*- and *trans*-BF were irradiated with 313-nm light isolated from a 400-W high-pressure mercury lamp through an aqueous potassium chromate solution filter and a Toshiba UV-D36B glass filter. For measurements of isomerization quantum yields the sample solutions containing the cis or trans isomer (≥98%, checked by HPLC) were deaerated by bubbling with argon, and irradiated so that the conversions of the isomer were within 20%. The concentrations of the cis and trans isomers in the irradiated samples were determined by HPLC (Waters 600 Multisolvent Delivery System) equipped with an LC spectrophotometer (Waters 490 Programmable Multiwavelength Detector).

The light intensity was measured by a potassium tris(oxalato)ferrate(III) chemical actinometer.

Laser Flash Photolysis. Direct excitation of SF with 351-nm light was performed with a XeF excimer laser (Lambda Physik EMG-101, 10-ns fwhm). Direct excitation at 308 and 337 nm, and biacetyl sensitization with 425-nm light of BF were performed with a XeCl excimer laser (Lambda Physik EMG-101, 10-ns fwhm), a nitrogen laser (National Research Group Inc., 5-ns fwhm), and an excimer laser-pumped dye laser (Lambda Physik FL-3002, Stilbene 3), respectively.

The monitoring beam obtained from a xenon lamp was oriented perpendicularly to the exciting laser beam, passed through a sample cell and a grating monochromator (JASCO CT-25C), and detected with a photomultiplier (Hamamatsu Photonix R928, R446, or R212). The amplified signal was recorded as the time profile of a transmittance change on a storage oscilloscope (Iwatsu TS-8123) and transferred to a personal computer where it was analyzed.

Results

Absorption and Fluorescence Spectra. Figure 1 depicts the absorption and fluorescence spectra of cis and trans isomers of BF and SF. The cis and trans isomers exhibit different fluorescence spectra with different lifetimes from each other. The singlet excitation energies corresponding to the maximum wavelengths of fluorescence spectra (λ_{max}^{fl}) are estimated as 60 kcal mol^{-1} for both *cis*- and *trans*-SF, and 63 and 62 kcal mol^{-1} for *cis*- and *trans*-BF, respectively (Table 1). Because of the broad fluorescence band for every fluoranthenylethylene the energy of the 0–0 transition cannot be determined precisely. When the 0–0 band is assumed to correspond

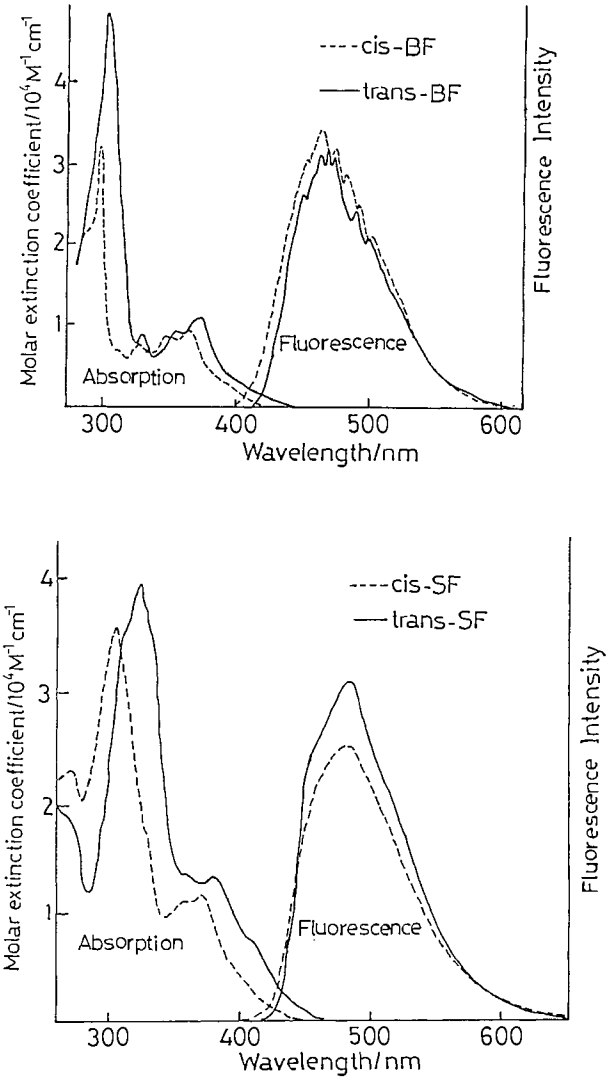


Fig. 1. Absorption and fluorescence spectra of BF and SF in benzene.

to the crossing point of the absorption and fluorescence spectra, the energies of the 0–0 transition are estimated as 67 and 65 kcal mol^{-1} for *cis*- and *trans*-SF, respectively, and 70 and 69 kcal mol^{-1} for *cis*- and *trans*-BF, respectively (Table 1).

In Fig. 1, the differences in energy between the absorption and fluorescence spectra (the Stokes shifts, here defined as the difference in wavelength between the longest absorption maximum and the emission maximum) are calculated as 6000 and 5600 cm^{-1} for *cis*- and *trans*-SF, respectively, and as 5600 and 5200 cm^{-1} for *cis*- and *trans*-BF, respectively. These results indicate that the photoexcitation causes a pronounced change in their structure from the ground states, as reported for the parent hydrocarbon, fluoranthene.[14]

The fluorescence quantum yields (Φ_f) were determined in benzene as 0.40 and 0.48 for *cis*- and *trans*-SF, respectively, and 0.16 and 0.19 for *cis*- and *trans*-BF, respectively, by using anthracene (Φ_f=0.27)[8] (for SF) or

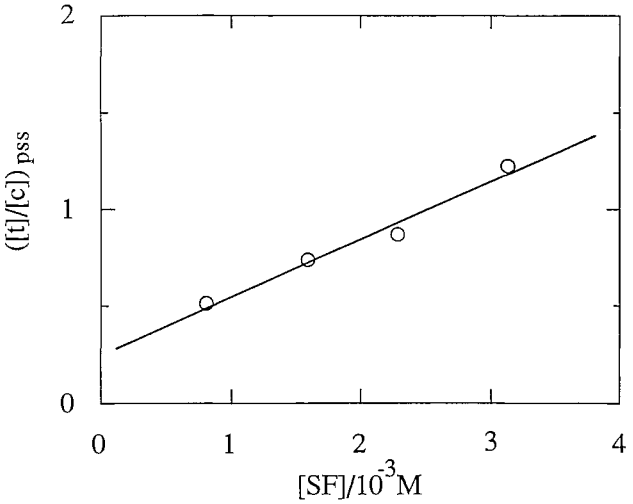

Fig. 3. Plot of the photostationary state isomer ratios against the total SF concentration on direct irradiation in benzene.

fluoranthene (Φ_f=0.30 in hexane)[14] (for BF) as a standard. The singlet lifetimes measured in benzene by the single photon counting method (SPC) are 12.4, 9.7, 28.3, and 19.4 ns for *cis*-SF, *trans*-SF, *cis*-BF, and *trans*-BF, respectively. The fluorescence quantum yields and lifetimes of the BF and SF isomers are summarized in Table 1.

Isomerization Quantum Yields and Photostationary State Isomer Ratio. On direct excitation as well as on triplet sensitized irradiation,[7b] BF underwent cis→trans one-way isomerization. Figure 2 illustrates a concentration dependence of the quantum yield ($\Phi_{c\to t}$) for cis→trans isomerization on direct irradiation. This figure indicates that $\Phi_{c\to t}$ increases with increasing *cis*-BF concentration, attaining nearly 5 at [*cis*-BF]=6×10^{-3} M (1M=1 mol dm^{-3}). On biacetyl sensitization, $\Phi_{c\to t}$ also increased with increasing [*cis*-BF] up to nearly 20 at [*cis*-BF]= 3×10^{-3} M.

The photostationary state isomer composition, ([t]/[c])$_{pss}$, for SF was determined on irradiation with a 436-nm line to be 0.51 at the total olefin concentration of 9×10^{-4}M. The ([t]/[c])$_{pss}$ value increased with increasing olefin concentration to attain 0.94 at [SF]=2.3×10^{-3} M (Fig. 3). The quantum yields of cis-trans isomerization, $\Phi_{c\to t}$ and $\Phi_{t\to c}$ were determined on 436-nm excitation as 0.22 and 0.029, respectively, on starting with pure *cis*- and *trans*-SF at [SF]= 2.3×10^{-3}M.

The ([t]/[c])$_{pss}$ value is expressed by the product of the ratios of isomerization quantum yields and of the extinction coefficients ($\varepsilon_c/\varepsilon_t$) at the irradiation wavelength as described by Eq. 1.

$$([t]/[c])_{pss}=(\varepsilon_c/\varepsilon_t)(\Phi_{c\to t}/\Phi_{t\to c}) \quad (1)$$

The extinction coefficients at 436 nm were determined as 310 and 2500 for *cis*- and *trans*-SF. Thus, at an olefin concentration of 2.3×10^{-3}M the ([t]/[c])$_{pss}$ value is calculated from Eq. 1 as 0.94 [=(310/2500)×(0.22/0.029)], which is in good agreement with the observed value.

Laser Flash Photolysis Studies. The transient absorption spectra were observed on 308- or 337-nm laser excitation of *cis*- and *trans*-BF (4×10^{-4} M) in benzene. Both isomers exhibited the same spectra having two bands at 400—480 and 550—650 nm with the same lifetime (τ_T=25 μs) as measured at the peak wavelengths.

The spectra and lifetimes were essestially identical with those observed on triplet sensitized excitation.[7a] Under similar conditions fluoranthene exhibited its T-T absorption at 400—440 nm (τ_T=30 μs). The transient absorption spectra of SF were effectively quenched by azulene (E_T=39.8 kcal mol^{-1});[15] the quenching rate constant was determined as 3.6×10^{-9} M^{-1} s^{-1} on excitation of *cis*-BF.

On excitation of *cis*- and *trans*-SF (6×10^{-5}M) with 351-nm laser pulses in benzene, both isomers exhibited the same transient absorption spectra with a sharp intense and a broad weak band around 490 and 600 nm, respectively. The spectra decayed with a lifetime of 500 ns under deaerated conditions. The spectral properties are identical with those observed on camphorquinone-sensitized laser excitation.[7b] From these results the observed transient spectra can be reasonably assigned to the trans triplets in both cases.

Discussion

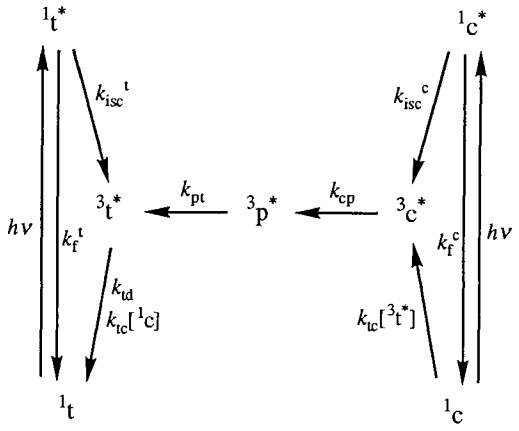
Isomerization Mechanism of BF and SF on Direct Excitation. The results of stationary irradiation and flash photolysis indicate that the triplet mechanism describes the cis→trans one-way isomerization of BF on direct irradiation. Thus, the cis triplet (^{3}c*) produced by intersystem crossing of the cis excited singlet (^{1}c*) undergoes twisting around the double bond to give the trans triplet (^{3}t*), which subsequently undergoes unimolecular deactivation to the trans isomer or energy transfer to the cis isomer to regenerate ^{3}c* leading to a quantum chain process (Scheme 1). According to this mechanism, the quantum yield ($\Phi^{dir}_{c\to t}$) for cis→trans isomerization is expressed by Eq. 2.

$$\Phi^{dir}_{c\to t} = \Phi_{isc}(1 + k_{tc}\tau_T[cis\text{-BF}]) \quad (2)$$

where Φ_{isc}, k_{tc}, and τ_T denote the quantum yield for intersystem crossing of *cis*-BF, the rate constant for energy transfer from ^{3}t* to *cis*-BF, and the lifetime of the trans triplet of BF.

Figure 2 gives a slope, $\Phi_{isc}k_{tc}\tau_T$, of 600 M^{-1}, an intercept, Φ_{isc}, of 0.83, and therefore, $k_{tc}\tau_T$ of 720 M^{-1}. The obtained value for Φ_{isc}, 0.83, is very close to $1-\Phi_f=1-0.16=0.84$, showing that the singlet excited state of *cis*-BF decays through either fluorescence emission or intersystem crossing to ^{3}c*. Dividing the obtained $k_{tc}\tau_T$ values by τ_T (=25 μs, determined by laser flash photolysis) affords k_{tc} of 2.9×10^7 M^{-1} s^{-1}.

In the excited singlet state, the energy transfer from ^{1}t* to ^{1}c leading to the quantum chain process could not compete with the deactivation of ^{1}t* with $k_{td}(=1/\tau_S)=5\times10^7$ s^{-1}; the energy transfer via the resonance mechanism could not operate because of an insufficient overlap of the *trans*-SF emission and *cis*-SF absorption (Fig. 1), and the energy transfer via the exchange mechanism might be much slower ($\ll10^{10}$ M^{-1} s^{-1}) than diffusion-controlled since this process is nearly 1 kcal mol^{-1} endothermic on the basis of the fluorescence data. Thus, the pseudo-first-order energy transfer rate may be $\ll10^7$ s^{-1} in the concentration range of ca. 10^{-3} M. A mechanism involving a ground state complex can be also ruled out since there was no evidence for the formation of such a complex in either absorption or fluorescence spectra for various concentrations of *trans*-BF.



Scheme 1.

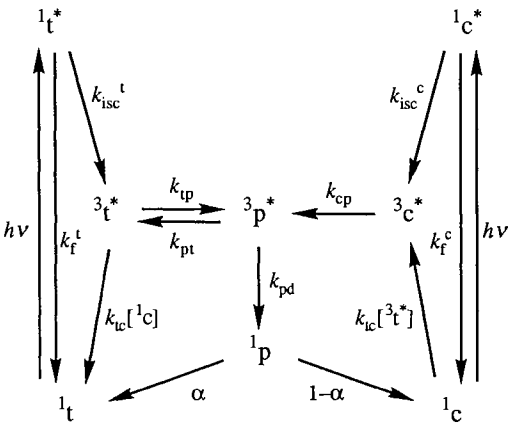
As mentioned above, k_{tc} is determined to be 2.9×10^7 M^{-1} s^{-1}. The following equation is established for endothermic energy transfer:[16]

$$k_{tc} = A\exp(-E_a/RT), \quad (3)$$

where

$$-E_a = \Delta E_T = E_T(trans\text{-BF}) - E_T(cis\text{-BF}) \quad (4)$$

On substituting $k_{tc}=2.9\times10^7$ M^{-1} s^{-1} into this equation and assuming $k_{tc}=5\times10^9$ M^{-1} s^{-1} at $\Delta E_T=0$,[16] the energy transfer from ^{3}t* to *cis*-BF is estimated to be endothermic by 3 kcal mol^{-1}. Therefore, the triplet energy of *cis*-BF is nearly 3 kcal mol^{-1} higher than that of *trans*-BF.



Scheme 2.

Contrary to BF, SF undergoes two-way isomerization on direct irradiation similarly to the previously reported triplet sensitization.[7b] *cis*-SF exhibited the fluorescence spectrum with a different lifetime and different spectral properties from those of *trans*-SF. Moreover, the T–T absorption spectrum was also observed on direct excitation of *cis*-SF. The photostationary state isomer composition $([t]/[c])_{pss}$ increased with increasing total olefin concentration. These results clearly indicate that the isomerization on direct excitation proceeds through the triplet manifold as shown in Scheme 2.

Potential Energy Surface of Fluoranthenylethylenes. The excited singlet states of fluoranthenylethylenes emit fluorescence or undergo intersystem crossing with decay rate constants of $1/\tau_S=8.1\times10^7\ s^{-1}$ for *cis*-SF and $3.5\times10^7\ s^{-1}$ for BF, but the isomerization cannot be detected in the singlet manifold. Therefore, the latter process might be slower than 1/100 of $1/\tau_S$, $10^6\ s^{-1}$. If we assume a frequency factor A of 10^{11}—$10^{12}\ s^{-1}$ for twisting around the double bond as reported for some triplet olefins,[2b,17] the activation barrier for isomerization might be higher than 7 kcal mol^{-1} in the singlet manifold. Thus, the potential energy surfaces of SF are depicted in Fig. 4a taking into account the previously reported triplet energy surface.[7b]

In Fig. 4a, the direct excitation of *cis*- and *trans*-SF produces the respective singlet excited states which emit fluorescence or undergo intersystem crossing to produce the triplet states, which are deactivated to the ground state from either the perpendicular or trans triplet state, resulting in the photostationary mixture of cis and trans isomers.

On direct irradiation, BF undergoes one-way isomerization in the triplet manifold after intersystem crossing, and its potential energy surfaces is similarly drawn in Fig. 4b.

As mentioned above, on direct irradiation the two-way isomerizing olefins such as stilbene usually undergo isomerization in the singlet manifold, while the one-way isomerizing olefins undergo isomerization in the triplet manifold. The fluoranthenylethylenes employed also isomerize in the triplet manifold irrespective of the substituent on the other ethylenic carbon, *t*-butyl or phenyl, therefore behaving similarly to the anthryl- and pyrenylethylenes.

On the triplet energy surface of olefins, the introduction of an aromatic group with a low triplet energy lowers the energy of $^3t^*$ and $^3c^*$ to put them, instead of $^3p^*$, at the energy minima. A similar situation may happen on the singlet energy surface. On substitution of an aryl group on the terminal carbon of styrene, those with low singlet excitation energies like 8-fluoranthenyl (80 kcal mol^{-1})[8] make both $^1c^*$ and $^1t^*$ fluorescent and apt to intersystem cross to the triplet state with considerable efficiencies (Table 1), whereas those with high singlet energies like phenyl (110 kcal mol^{-1})[8] and 2-naphthyl (92 kcal mol^{-1})[8] do not make $^1c^*$ fluorescent but lead it to isomerize in the singlet manifold before intersystem crossing.[8] These results indicate that the substitution of the aromatic group with a low singlet energy sufficiently stabilizes $^1c^*$

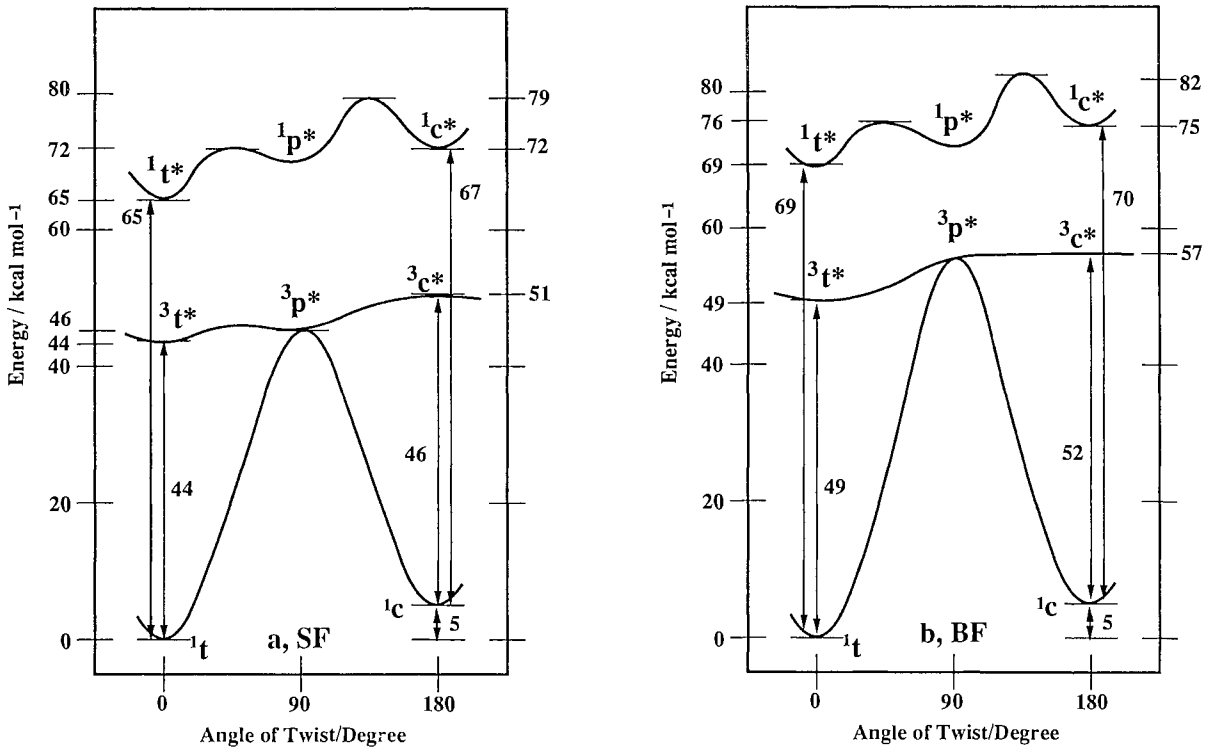


Fig. 4. Potential energy surfaces of cis-trans isomerization of SF (a) and BF (b).

to reside at an energy minimum and to have a sufficient lifetime to emit fluorescence. This situation may reflect the presence of a considerable energy barrier for isomerization in the singlet manifold. Therefore, the isomerization takes place in the triplet state after intersystem crossing. This is contrasted to the effect of substitution of the aromatic group with higher energies as observed in stilbene, where $^1c^*$ is not so stabilized as to fluoresce practically and isomerizes facilely on the singlet energy surface. Therefore, the singlet and triplet excitation energies of the aromatic group on the double bond control the course of isomerization, (1) the spin multiplicity in which the isomerization takes place on direct excitation, and (2) the mode of isomerization, two-way or one-way, in the triplet state.

Insulator-to-Metal-to-Semiconductor Transitions of One-Dimensional Bis(1,2-dione dioximato)Pt(II) Complexes at High Pressures

Ichimin SHIROTANI,* Akira KAWAMURA, Kazunaga SUZUKI, Wataru UTSUMI,† and Takehiko YAGI†

(Received December 12, 1990)

The electrical resistivities and absorption spectra of one-dimensional bis(1,2-dione dioximato)Pt(II) have been studied at high pressures. The resistivities of needle crystals of $Pt(dmg)_2$ and $Pt(bqd)_2$ were measured in detail under a quasi-hydrostatic pressure of up to 7 GPa. $Pt(dmg)_2$ is an insulator with a resistivity of 10^{15} Ω cm, and $Pt(bqd)_2$ is a semiconductor with 10^3 Ω cm at atmospheric pressure. A pressure-induced insulator (semiconductor)-to-metal transition was observed for both complexes. This transition arises from a crossing of the $5d_{z^2}$ valence and $6p_z$ conduction bands. When the pressure was further increased, a metal-to-semiconductor transition took place at around the pressure that showed a resistivity minimum. A new pressure-induced absorption band was found in the visible region for the Pt complexes. The new band did not shift with pressure; the intensity of the band, however, increased with pressure over a narrow pressure region. The pressure-induced band may be due to intramolecular d–d transitions. The metal-to-semiconductor transition may arise from a change in the electronic states at high pressure, since no anomaly in the strucutre was observed.

Square planar d^8 metal complexes with various kinds of 1,2-dinoe dioximes (Fig. 1) crystallize in columnar structures. These columns are formed by complex molecules with metal–metal distances varying from 3.2 to 3.6 Å in the direction of the stacks.[1] These poorly conducting one-dimensional complexes show an interst-ing behavior at high pressure. The electrical resistivity,[2-5] electronic and infrared spectra,[4-8] and crystal structure[9] of the complexes have already been studied at high pressures. Their resistivities rapidly decrease and an absorption band ascribed to the d–p transition shifts remarkably to a longer wavelength with pressure. The electrical and optical properties of the complexes are very sensitive to the metal–metal distance in a linear chain.

Pressure-induced electrical and optical anomalies in bis(dimethylglyoximato)Pt(II), $Pt(dmg)_2$, were observed at around 6.5 GPa; the electrical resistivity drastically decreases, by a factor 10^{-16}, with increasing pressure up to the pressure that indicates a resistivity minimum.[2,3] A new pressure-induced absorption band at around 540 nm was found above 6 GPa.[4,5] Bis(1,2-benzoquinone dioximato)Pt(II), $Pt(bqd)_2$, has the shortest Pt–Pt dis-tance (3.17 Å) in the known bis(1,2-dione dioximato)Pt(II)

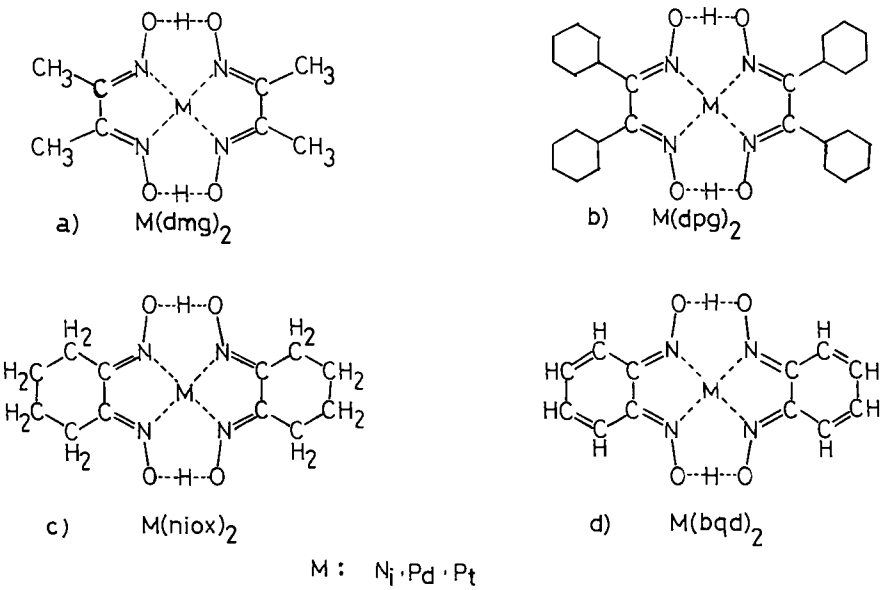

Fig. 1. Molecular structure of bis(1,2-dione dioximato)M(II) (M: Ni, Pd, Pt); a) bis(dimethylglyoximato)M(II), $M(dmg)_2$, b) bis(diphenylglyoximato)M(II), $M(dpg)_2$, c) bis(1,2-cyclohexanedione dioximato)M(II), $M(niox)_2$ (1,2-cyclo-hexanedione dioxime is usually called nioxime), d) bis(1,2-benzoquinone di-oximato)M(II), $M(bqd)_2$.

compounds; it is a semiconductor with a thermal energy gap of 0.25 eV at atmospheric pressure.[10] The resistivity along the needle axis is about $10^3\,\Omega$ cm at room temperature. An absorption band polarized parallel to the linear chain, which is assigned to the electronic transition between $5d_{z^2}$ and $6p_z$, is located at around 1300 nm. The interesting properties are mainly interpreted in terms of a short Pt–Pt distance of 3.17 Å.

We recently reported preliminary results concerning insulator-to-metal-to-semiconductor transitions of $Pt(dmg)_2$ at high pressure; this complex behaves as an insulator(semiconductor) in the pressure range 0—4.5 GPa, as a metal around 5 GPa, and again as a semiconductor above 6 GPa.[5] Similar phenomena have also been observed for $Pt(bqd)_2$ at high presessures.

In this paper we present some findings concerning electrical and optical anomalies in the four platinum complexes shown in Fig. 1 and discuss the mechanism of the phase transitions at high pressure.

Experimental

Platinum complexes were prepared by mixing a hot alcohol solution of 1,2-dione dioximes and an aqueous solution of K_2PtCl_4. The products were purified by repeated recrystallization from *o*-dichlorobenzene or dimethylformamid. The needle crystals were grown from these solutions of the complexes. The compositions of all of the materials used were confirmed by elemental analysis.

Measurements of the electrical resistance were carried out up to 7 GPa in a cubic-anvil press; cemented tungusten carbide anvils had square faces of 6 mm edge length. Each sample was placed in the center hole of a pyrophyllite cube that had an 8 mm edge length. The sample assembly has already been reported in a previous paper.[12] The crystal was covered by an epoxy resin, which was used as a pressure-transmitting medium. The resistance was measured over a temperature range of 25 to 100 °C at various pressures under quasi-hydrostatic conditions.

A diamond-anvil pressure cell was used for the measurement of the absorption spectra at high pressures.[4] The optical system comprised a standard microscope and a monochrometer with an associated photodetection system. The pressure was determined from the pressure shift in the sharp R-line fluorescence spectrum of ruby.[13] Water was used as the pressure-transmitting medium.

Results and Discussion

$Pt(dmg)_2$ is a square planar complex in which each Pt^{2+} ion is surrounded by four nitrogen atoms of two dimethylglyoxime anions. The d orbitals of the Pt^{2+} ion are split by a crystal field of D_{4h} symmetry. The 8 electrons of the Pt^{2+} ion core fill the d_{z^2}, d_{xy}, d_{yz}, and d_{zx} states. The complex crystallizes in columnar structures. The columns are formed by square planar complex molecules with a relatively short Pt–Pt distance of 3.26 Å in a direction of the stacks. The overlap of the d_{z^2} orbitals can, thus, produced a band that is completely filled and separated from the next empty band

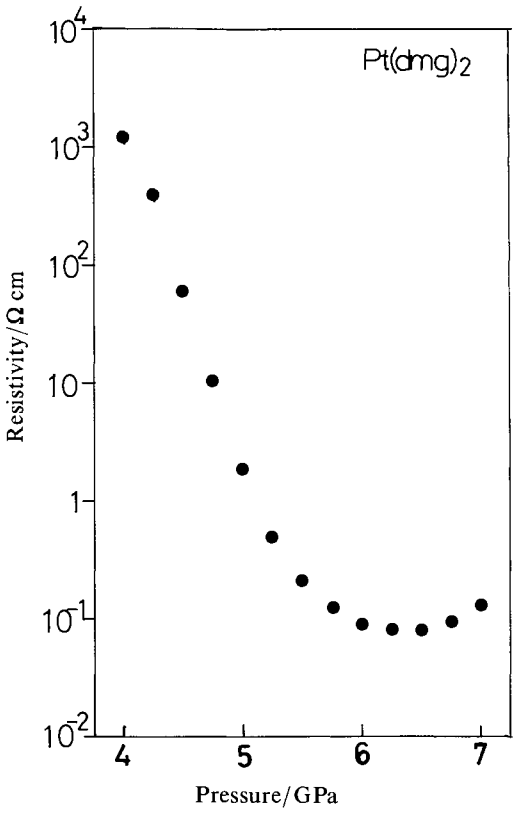

Fig. 2. Electrical resistivity of the single crystal of $Pt(dmg)_2$ at high pressure.

formed by p_z orbitals by a large gap. The complex is an insulator with a resistivity of $10^{15}\,\Omega$ cm at atmospheric pressure.[14]

Figure 2 shows the electrical resistivity along the stacking axis of a single crystal of $Pt(dmg)_2$ at high pressures. The resistivity drastically decreases with pressure up to the pressure that shows the resistivity minimum. The lowest resistivity along the stacking axis of the single crystal is about $10^{-2}\,\Omega$ cm at room temperature and high pressure. Figure 3 shows the temperature dependence of the resistivity at various pressures. The resistivity linearly increases with increasing temperature at around 5 Gpa. A pressure-induced insulator-to-metal transition was observed. The thermal energy gap rapidly decreases with decreasing Pt–Pt distance, reaching zero at around 5 GPa.

The absorption spectrum of $Pt(dmg)_2$ comprises two bands at 320 and 660 nm in the visible region; the former band is ascribed to a metal-to-ligand charge-transfer transition (M–L transition); the latter band is assigned to the $5d_{z^2}$–$6p_z$ transition.[15] This latter band indicates a large red shift with pressure, at a rate of $-2700\,cm^{-1}/GPa$. Since the absorption edge is located at about $12.8\times10^3\,cm^{-1}$, the optical energy gap between the $5d_{z^2}$ and $6p_z$ bands becomes zero at around 5 GPa. Thus, the insulator-to-metal transition at around 5 GPa arises from a crossing of the $5d_{z^2}$ valence and the $6p_z$ conduction bands.

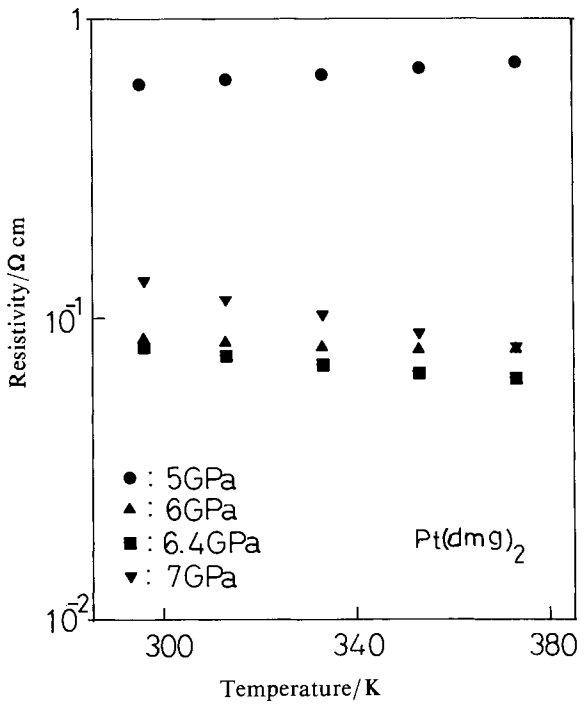

Fig. 3. Temperature dependence of the resistivity of $Pt(dmg)_2$ at high pressures.

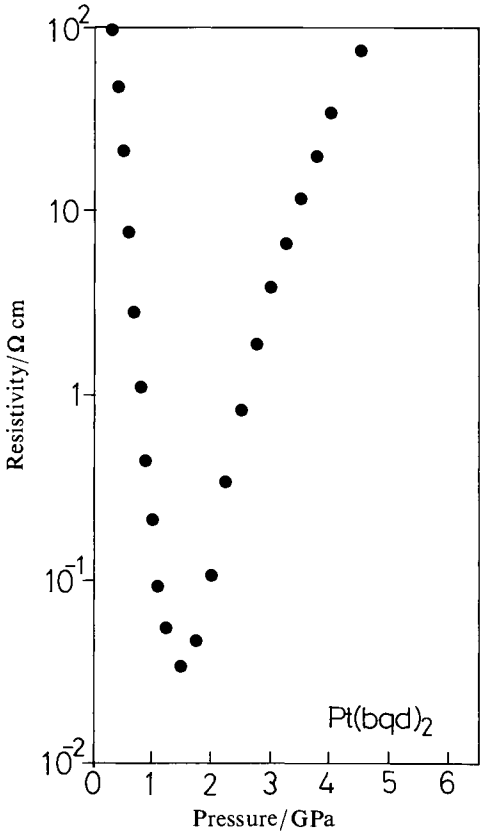

Fig. 4. Electrical resistivity of the needle crystal of $Pt(bqd)_2$ at high pressure.

The effect of pressure on the Pt–Pt distance has already been studied by powder X-ray diffraction.[4] The distance within a linear chain decreases from 3.26 Å at atmospheric pressure to 2.77 Å at 13 GPa. The Pt–Pt distance of metallic $Pt(dmg)_2$ is about 2.90 Å, slightly longer than that of a one-dimensional metal, such as $K_2Pt(CN)_4Br_{0.3}\cdot 3H_2O$ (KCP).

The temperature dependence of resistivity again changed at around 6 GPa; the resistivity slightly decreased with increasing temperature. Semiconductive-like behavior was again observed above 6 GPa. The one-dimensional metal was only stable within a narrow pressure region. This result seems to suggest a Peierls transition, due to the strong one-dimensional character in $Pt(dmg)_2$. Recently, an X-ray study of a single crystal of $Pt(dmg)_2$ was carried out up to 4 GPa.[9] The *a* and *b* lattice constants decrease monotonically with pressure. The Pt–Pt distance within the linear chains, $c/2$, decreases continuously from 3.26 Å at atmospheric pressure to 2.97 Å at 3.84 GPa. This agrees with the result concerning powder X-ray diffraction. The *b*-axis rapidly shrinks with pressure up to 1.5 GPa, but slowly decreases above this pressure. The intermolecular interaction of CH···O type grow stronger by a shrinking of the *b*-axis at high pressure. The intermolecular distance between O and C of the adjacent chains decreases from 3.28 Å at atmospheric pressure to 2.97 Å at 2.38 GPa. The intermolecular interaction between adjacent chains increases with pressure. The anomaly in the crystal structure along the *c*-axis, as anticipated for a Peierls distortion, was not found in the X-ray diffraction of the single crystal at around 7 GPa.[16]

A new pressure-induced absorption band appears at around 540 nm above 6 GPa.[3,4] The absorption intensity of the new band abruptly increases with increasing pressure over a narrow pressure range of 6 to 9 GPa. The absorption peak of the band does not shift with pressure at least up to 15 GPa. On the other hand, Tkacz and Drickamer have found that the intensity of the d–p band exhibits a sharp drop over the same pressure range.[7] The new band grows with a disappearance of the d–p transition. These results suggest that the metal-to-semiconductor transition at around 6 GPa is not due to a Peierls transition but, rather, to a change in the electronic states with pressure.

The resistivity of a needle crystal of $Pt(bqd)_2$ is about $10^3\ \Omega$ cm at room temperature.[10] The complex is a semiconductor with a thermal energy gap of 0.25 eV at atmospheric pressure. Figure 4 depicts the resistivity of a needle crystal at high pressure. The crystals were obtained by recrystallization from an *o*-dichlorobenzene solution. The resistivity rapidly decreases with pressure up to 1.7 GPa; above that pressure it abruptly increases with an increase in the pressure. The resistivity at the resistance minimum is about $10^{-2}\ \Omega$ cm at room temperature and high pressure. Figure 5 shows the temperature dependence of the resistivity at various pressures. The resistivity rises with increasing temperature

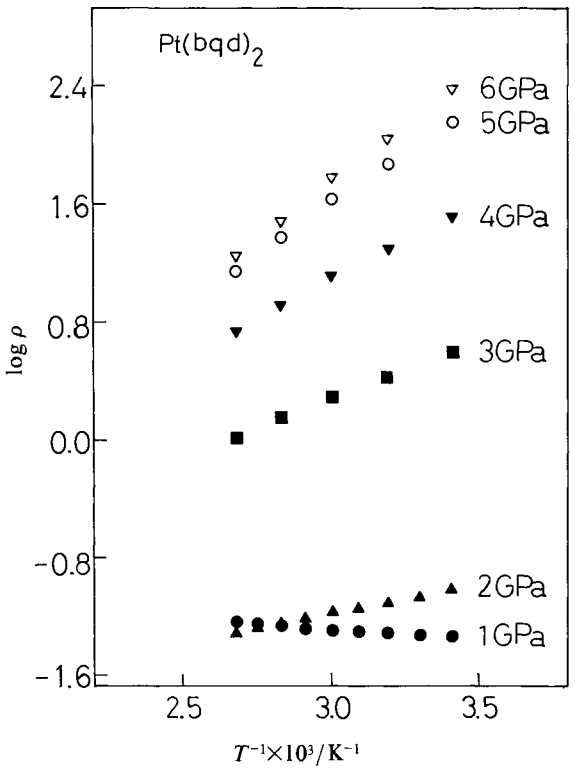

Fig. 5. Temperature dependence of the resistivity of $Pt(bqd)_2$ at high pressures.

at around 1 GPa. The thermal energy gap of 0.25 eV at atmospheric pressure became zero at around 1 GPa. A semiconductor-to-metal transition was found for $Pt(bqd)_2$.

An oriented film of $Pt(bqd)_2$ is prepared by evaporation onto a quartz or a glass substrate held at room temperature in a vacuum of 1.33×10^{-4} Pa (10^{-6} Torr, 1 Torr=133.322 Pa).[17] The absorption bands of the oriented film are located at around 360, 420, and 1300 nm. The latter band is assigned to the $5d_{z^2}$–$6p_z$ transtition. The pressure effect of the bands has not yet been studied. When the Pt–Pt distance of $Pt(dmg)_2$ skrinks from 3.26 Å to the Pt–Pt distance of $Pt(bqd)_2$ (3.17 Å), the peak of the d–p band shifts from 15200 to 13000 cm^{-1}. This value of $Pt(dmg)_2$ is much larger than the energy of the d–p band of $Pt(bqd)_2$, 7700 cm^{-1}. It is therefore expected that the d–p band of $Pt(bqd)_2$ has a very large red shift with pressure. The $6p_z$ conduction band must cross the $5d_{z^2}$ valence band at around 1 GPa.

The temperature dependence of the resistivity again changed at around 1.4 GPa; the resistivity of $Pt(bqd)_2$ decreased slightly with increasing temperature. The metal-to-insulator transition took place at around 1.4 GPa. The complex again behaved as a semiconductor above that pressure. The one-dimensional metal was stable within only a narrow pressure region. Figure 6 shows the absorption spectra of $Pt(bqd)_2$ at high pressures. A new pressure-induced absorption band

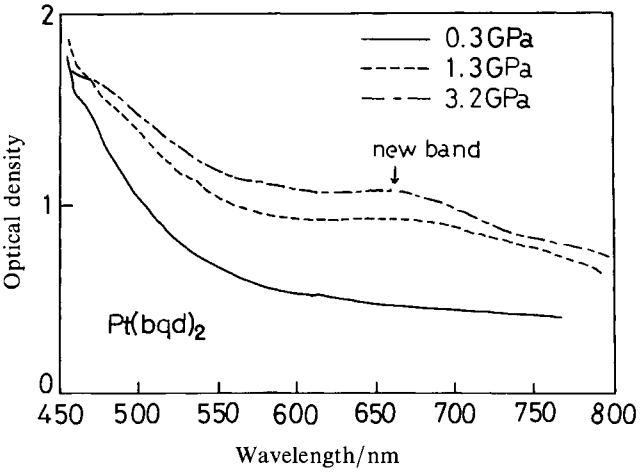

Fig. 6. Pressure effect of absorption spectra of $Pt(bqd)_2$.

appeared at around 660 nm above 1.3 GPa; the absorption intensity of the new band increased with pressure. The metal-to-semiconductor transition was found at around the pressure in which the optical anomaly was observed. Anomalous electronic and infrared spectra have been observed in a evaporated film of $Pt(bqd)_2$ on a NaCl substrate;[17] the 1300 nm band ascribed to the d–p transition disappears an asymmetric O···H–O bridge is formed, and the C=N stretching band splits into 1600 and 1610 cm^{-1}. The optical behavior of $Pt(bqd)_2$ is similar to that of $Pt(dmg)_2$ at high pressure.

The metal-to-semiconductor transition took place at around 6 GPa for $Pt(dmg)_2$, and 1.4 GPa for $Pt(bqd)_2$. The one-dimensional metal of both Pt complexes was stable over a very narrow pressure region. The pressure-induced absorption band and the resistivity minimum were observed near to the transition pressures. The absorption peaks of the new bands did not shift with pressure. An intramolecular d–d transition of metal complexes generally indicates a small blue shift with pressure.[6] The spin-allowed d–d transitions (d_{xy}–$d_{x^2-y^2}$, d_{z^2}–$d_{x^2-y^2}$, d_{yz} and d_{zx}–$d_{x^2-y^2}$) in square planar d^8 complexes can be observed, even though the absorption intensity is weak.[18] However, the transitions did not appear in the Pt complexes at atmospheric pressure. If vibronic modes of the complexes (especially the e_u mode) strongly couple to the d states with pressure, the intensity of the d–d transitions will increase at high pressure. The d–d transitions coupled by an e_u mode may borrow intensity from the M–L and d–p transitions. The absorption intensity of the d–p transition rapidly decreased over the narrow pressure region where the new band appeared. The pressure effect of the intensity of the M–L band has not been studied for Pt complexes. The a and b lattice constants (a=16.774 Å, b=10.579 Å) are so long that the $d_{x^2-y^2}$ orbitals between adjacent complex molecules in the ab plane hardly overlap. It is expected that the d–d bands hardly shift with pressure, since the $d_{x^2-y^2}$ orbital in the

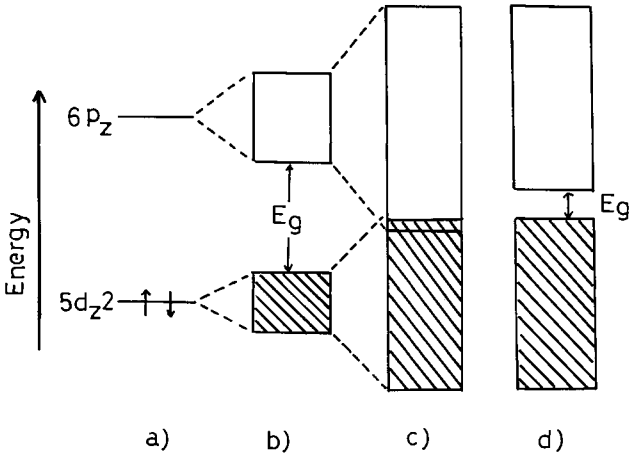

Fig. 7. Schematic energy diagram in $Pt(dmg)_2$ and $Pt(bqd)_2$ complexes; a) the energy separation between the filled $5d_{z^2}$ and the empty $6p_z$ orbitals of the complex molecules, b) the filled $5d_{z^2}$ valence and the empty $6p_z$ conduction bands are produced at atmospheric pressure, c) the $6p_z$ conduction band crosses the $5d_{z^2}$ valence band at high pressure. Pressure-induced insulator-to-metal transition takes place at room temperature, d) the energy gap between the $6p_z$ conduction and the $6p_{z^2}$ valence band is again observed at higher pressures. Pressure-induced metal-to-semiconductor transition takes place at room temperature.

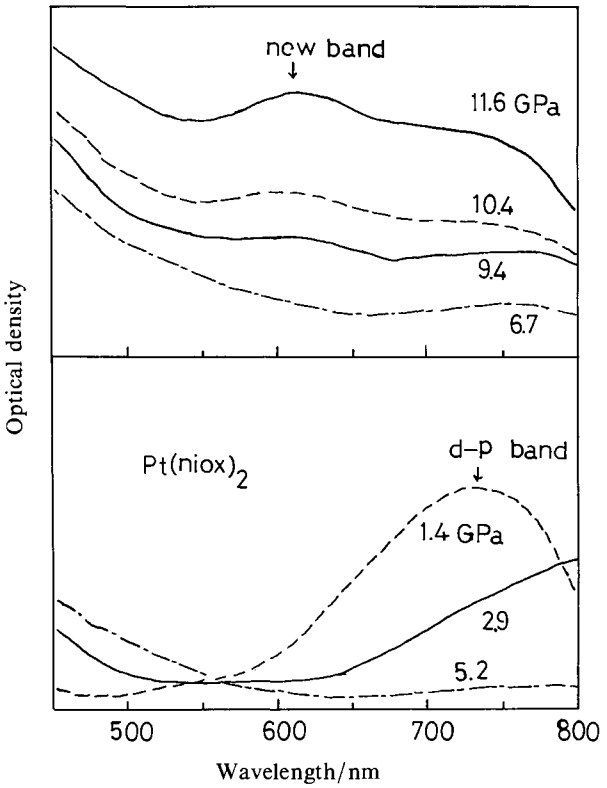

Fig. 8. Pressure effect of absorption spectra of $Pt(niox)_2$.

Pt complexes is not sensitive to pressure. We thus suggest that the new band of the Pt complexes is due to an intramolecular d–d transition as the intensity of the new band becomes stronger with pressure and the absorption peak does not shift with pressure. Therefore, the metal-to-semiconductor transition mainly arises from a change in the electronic states at high pressure.

We have found a pressure-induced insulator (semiconductor)-to-metal-to-semiconductor transitions for $Pt(dmg)_2$ and $Pt(bqd)_2$ over a narrow pressure region. A schematic energy diagram of the Pt complexes is given in Fig. 7.

A thin film of bis(1,2-cyclohexanedione dioximato)Pt(II), $Pt(niox)_2$, was prepared by evaporation in a high vacuum. The absorption spectrum of the thin film is similar to that of $Pt(dmg)_2$. The absorption bands of $Pt(niox)_2$ are located at 320 and 670 nm at atmospheric pressure; the former band is ascribed to the M–L transition, and the latter band is assigned to the d–p transition. Figure 8 exhibits the absorption spectra of $Pt(niox)_2$ at high pressures. The d–p band shifted remarkably toward longer wavelengths; the intensity of the band decreased with pressure. A new pressure-induced band at around 625 nm was observed above 9.5 GPa; the absorption intensity of the band increased with increasing pressure. The resistance of polycrystals of $Pt(niox)_2$ decreases rapidly with pressure, reaching a resistance minimum at 9.4 GPa.[3] The lowest resistivity of the powder sample is about 2 Ω cm at high pressure. A pressure-induced band of $Pt(niox)_2$ was observed around the pressure showing the resistivity minimum. This behavior is smimilar to that of $Pt(dmg)_2$ and $Pt(bqd)_2$. A single crystal of $Pt(niox)_2$ has not yet been prepared. If the resistivity of the single crystal is measured in detail at high pressure, the phase transitions may be found.

The resistivity of bis(diphenylglyoximato)Pt(II), $Pt(dpg)_2$, decreased at least up to 22 GPa; no minimum was found. The lowest resistivity was 3×10^2 Ω cm at room temperature, much higher than that of the other Pt complexes. The band at 550 nm under atomospheric pressure is due to the $5d_{z^2}$–$6p_z$ transition, and the 394 nm band is assigned as the M–L transition. Both bands indicate large red shifts with pressure. No pressure-indued absorption band was found. No electrical or optical anomalies were found at high pressure.

NMR Studies on Reorientational Motion of Hydrated D_2O Molecules of Halaide Ions (F^-, Cl^-, Br^-, and I^-) in Dilute Aqueous Solutions

Akio SHIMIZU and Yoshihiro TANIGUCHI*
Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603
(Received December 25, 1990)

The spin-lattice relaxation rates of the D and ^{17}O nuclei of D_2O molecules have been measured for dilute aqueous solutions of potassium halides (KF, KBr, KCl, KI) in the concentration range below 1.0 mol kg^{-1} at 25 °C. The agreement between the B_X' coefficients of the spin-lattice relaxation rate (reorientational motion) and the B coefficients of the solution viscosity of the anions is somewhat better than that of the cations. The reorientational motion of hydration for D_2O molecules of Cl^-, Br^-, and I^- ions was anisotropic; this anisotropic motion is enhanced with increasing ion radius. On the other hand, the hydration D_2O molecule of the F^- ion was approximately isotropic.

The concentration effect on the reorientational correlation times of hydrated water molecules in electrolyte solutions is both important and necessary in understanding the dynamic features of ionic hydration. Measurements of the spin-lattice relaxation rate (R_1) have mainly been carried out in the high concentration range above 1.0 mol kg^{-1}.[1-9] These data are expressed by a quadrutic polynominal equation as a function of the concentration in order to provide reorientational correlation times of hydrated water molecules for each ion at infinite dilution. We have recently carried out systematic NMR studies concerning the reorientational correlation times of hydrated water molecules in low the concentration range below 1.0 mol kg^{-1} [10-14] in order to elucidate the ion-water interactions. Since R_1 varies linearly with concentration below 1.0 mol kg^{-1}, each hydration sphere of the ions can be isolated from each other.

It is well known that the dynamic properties of aqueous electrolyte solutions are influenced by the ionic radius as well as the charge of ions. The structure-breaking effect of halide ions on the viscosity of solutions is greater than that of alkali metal ions, since the ionic radius of halide ions is larger than that of alkali metal ions. Studies concerning the dynamic properties of hydrated water molecules of ions have attracted both physical and biochemical attention, since the behavior of water in aqueous electrolyte solutions plays an essential role in biological reactions and protein stability.[15]

A D_2O molecule has a D and an ^{17}O nuclei which relax by a quadrupole interaction. Their spin-lattiice relaxation rates have been measured by NMR. The main component of the quadrupole interaction tensor at the D nuclei lies along the O-D bond axis, and the main component at the ^{17}O nucleus is the perpendicular axis to the molecular plane of a D_2O molecule.[16,17] The reorientational correlation times of the D and ^{17}O nuclei furnish information on the reorientational motion of the O-D axis and the axis perpendicular to the D_2O molecular plain.

In the present study we focused attention on the dynamic properties of the hydration D_2O molecule of halide ions (F^-, Cl^-, Br^-, and I^-) and measured the concentration dependence of the D and ^{17}O spin-lattice relaxation rates of D_2O molecules below 1.0 mol kg^{-1}. Comparing the D relaxation rate with that of the ^{17}O nucleus on the basis of the two-state model, we can discuss the dynamic behavior of a hydrated D_2O molecule.

Experimental

Samples. Potassium halide (KF, KCl, KBr, KI) salts from Nakarai Tesque Inc. (extra pure grade) were recrystallized from water. D_2O obtained from CEA contained over 99.8% of D.

NMR Measurement. The D and ^{17}O relaxation times (T_1) were obtained on a JEOL GX-270 spectrometer operating at 41.5 and 36.6 MHz, respectively. T_1 was measured by using the inversion-recovery method (180°-t-90° pulse sequence). The T_1 values were determined for each sample at 16 different time intervals (t); the pulse delay time was more than $10T_1$. The reproducibility of the T_1 measurements was within 2%. The temperature was controlled to 25±0.1° by a GVT 1 temperature-control unit (JEOL).

Results and Discussion

B_X and B_X' Coefficients. The relation between the R_1/R_1^0 values of the D and ^{17}O nuclei of D_2O molecules in potassium halaide aqueous solutions and their concentrations at 25 °C is shown in Figs. 1 and 2. The slopes of the D and ^{17}O nuclei shown in Figs. 1 and 2 are in the following order:

$$KI < KBr < KCl < 1 < KF.$$

This tendency corresponds to the B-coefficient of the solution viscosity. The R_1/R_1^0 values of the D and ^{17}O nuclei vary linearly with increasing concentration up to 1.0 mol kg^{-1}, in a manner similar to other salts;[10-12] the concentration dependences of R_1/R_1^0 are given by the following equations:

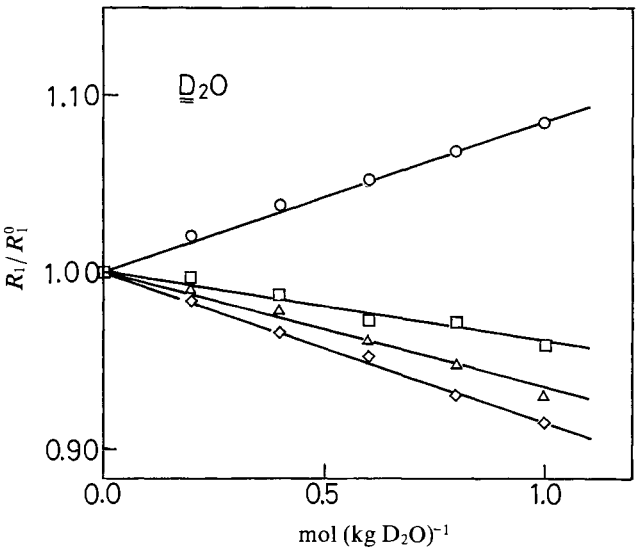

Fig. 1. Plots of D relaxation rates (R_1/R_1^0) of D_2O molecules in potassium halide solutions at 25°C. ○: KF, □: KCl, △: KBr, ◇: KI.

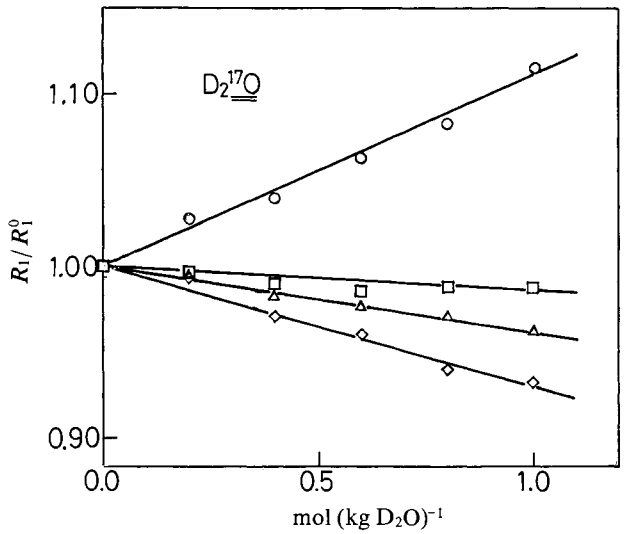

Fig. 2. Plots of ^{17}O relaxation rates (R_1/R_1^0) of D_2O molecules in potassium halide solutions at 25°C. ○: KF, □: KCl, △: KBr, ◇: KI.

$$R_1/R_1^0 = 1 + B_x \cdot m \tag{1}$$

and

$$R_1/R_1^0 = 1 + B_x' \cdot c \quad (x = D \text{ or } {}^{17}O), \tag{2}$$

where R_1 and R_1^0 are the spin-lattice relaxation rates of D_2O molecules at a certain concentration, m (mol kg^{-1}) or c (mol dm^{-3}), and pure D_2O, respectively. The B_X values are separated into contributions from individual ions on the basis of the following conventional assumptions:[18,19]

$$B(KCl) = B^+(K^+) + B^-(Cl^-), \text{ and } B^+(K^+) = B^-(Cl^-). \tag{3}$$

From Eqs. 1 and 3, the following relation is obtained:

$$R_1/R_1^0 = 1 + (B_x^+ + B_x^-)m, \tag{4}$$

where B_X^+ and B_X^- are the contributions from a cation and an anion, respectively. Similarly, $B_X^{+\prime}$ and $B_X^{-\prime}$ were determined by the same method as mentioned above.

The D and ^{17}O nuclei are quadrupole nuclei with spin quantum numbers of $I=1$ and 5/2, respectively. Under an extreme motional narrowing condition, the relation between R_1 and the reorientational correlation time (τ) is given by

$$R_1 = \frac{3}{40}\frac{2I+3}{I^2(2I-1)}\left(\frac{e^2qQ}{\hbar}\right)^2\left(1+\frac{\eta^2}{3}\right)\tau, \tag{5}$$

where, η is an asymmetric parameter, and $e^2qQ/\hbar$ is a quadrupole coupling constant.

The observed R_1 values represent a fractional ($x^{\pm}$) average of the spin-lattice relaxation rate of bulk D_2O (R_1^0), the cation hydrated D_2O (R_1^+), and the anion hydrated D_2O (R_1^-) molecules. When the exchange of D_2O molecules between a hydrated D_2O bulk D_2O is much faster than nucleus relaxation, the follow equation holds:

$$R_1 = (1 - x^+ - x^-)R_1^0 + x^+R_1^+ + x^-R_1^- \tag{6}$$

Further,

$$x^{\pm} = n^{\pm} \cdot m/50.0, \tag{7}$$

where n^+ and n^- are the coordination numbers of the cation and the anion, respectively. From Eqs. 4, 5, 6, and 7 the following relations are obtained:

$$\frac{R_1}{R_1^0} = 1 + \left\{n^+\left(k^+ \cdot \frac{\tau_x^+}{\tau^0} - 1\right) + n^-\left(k^- \cdot \frac{\tau_x^-}{\tau^0} - 1\right)\right\}\frac{m}{50.0} \tag{8}$$

and

$$k^{\pm} = \{(e^2qQ/\hbar)^{\pm}\}^2/\{(e^2qQ/\hbar)^0\}^2. \tag{9}$$

Here, the k^- value of the D and ^{17}O nuclei is 0.69 for the F^- ion, within experimental error.[8] The k^- values for the Cl^-, Br^-, I^- ions are determined by the following method. Ab initio calculations give the D quadrupole coupling constant as a function of the intramolecular O–D bond length of a D_2O molecule. The relation between the O–H distance and the D coupling constant is given by the following equation:[8]

$$(e^2qQ/\hbar)_D^{\pm} = (e^2qQ/\hbar)_D^0 - p(r_{OH}^{\pm} - r_{OH}^0), \tag{10}$$

Table 1. The B_X, $B_{\bar{X}}$, B'_X, and $B_{\bar{X}}'$ of NMR and B^-[a] of Solution Viscosity at 25°C

a) Ref. 19. b) This is the H_2O value, deteils see text.

where p is 18058 KHz/nm, $r^{\pm}_{OH}$ the intramolecular O–H bond length of a hydrated water, and r^0_{OH}=0.098 nm the intramolecular O–H bond length of pure water. The deuterium isotope effect on the O–H bond length has been neglected. The k^+ value of the D nucleus for the K^+ ion, calculated by using Eq. 10 (r^+_{OH}=0.097 nm), is 1.14. Under an extrem narrowing condition, there is no different $k^{\pm}$ value for the D and ^{17}O nuclei of a hydrated water molecule.[8] Since Cl^-, Br^-, and I^- ions are structure-breaking ions similar to K^+ ion, we may use 1.14 as the k^-, value of the D and ^{17}O nuclei for the Cl^-, Br^-, I^- ions. In this case, different orientations of water molecules around the anions and cations may be neglected. Finally, from Eqs. 4 adn 8 we can obtain

$$B^{\pm}_X = \left(k^{\pm}\cdot\frac{\tau^{\pm}_x}{\tau^0_x} - 1\right)\frac{n^{\pm}_x}{50.0}. \tag{11}$$

Table 1 shows the B_X, $B_{\bar{X}}$, B'_X, and $B_{\bar{X}}'$values of the NMR and B^- values[19] of the solution viscosities in potassium halides–D_2O systems. In these cases we assumed that B^- of the F^- ion of the D_2O system is equal to that of the H_2O system, since the solvent isotrope effect on the $B^{\pm}$ values for positive hydration ions is small.[19] The mol kg^{-1} unit of B_X and $B^{\pm}_X$ and the mol dm^{-3} unit of B'_X and $B^{\pm\prime}_X$ have a linear relation to the $B^{\pm}$ (mol l^{-1} unit) of the solution viscosity. The effect of the structure-making F^- ion on the $B^-_{^{17}O}$ value for ^{17}O relaxation is larger than that on B^-_D, and the effect of the structure-breaking Cl^-, Br^-, and I^- ions on the $B_{\bar{X}}$ values is reversed. On the other hand, the effects of the structure-making Li^+ and Na^+ cations and the structure-breaking K^+ and Cs^+ cations on B^+_D are larger than those of $B^+_{^{17}O}$.[10] The relation between $B_{\bar{X}}'$ and B^- in the D_2O system is of the order of $B_{\bar{X}}' \geqq B^-$. These results regarding the D_2O system are in contrast with the relation $B_{\bar{H}} < B^-$ in the H_2O system reported by Hertz et al.[1] The reason is due to a different relaxation mechanism between the ^1H nucleus and the D and ^{17}O nuclei. Although the ^1H nucleus is relaxed by dipole–dipole (intra and intermolecular) interactions, the D and ^{17}O nuclei are relaxed by the quadrupole (intramolecular) interaction. Our experimental condition below 1.0 mol kg^{-1} was different from that for the concentration above 1.0 mol kg^{-1} studied by Hertz et al. The relation

between $B_{\bar{X}}'$ from the NMR method and B^- from the solution viscosity of halide anions is shown in Fig. 3. The observed linear correlations between $B^{\pm\prime}_X$ and $B^{\pm}$ (mol l^{-1} unit) are given by the following equations:

$$B_{\bar{D}}' = 1.0B^- + 0.012 \tag{12a}$$

and

$$B^-_{^{17}O} = 1.0B^- + 0.024 \tag{12b}$$

for anions; for cations[10] it is given by

$$B_{\bar{D}}' = 0.75B^- + 0.0022 \tag{12a}$$

and

$$B^-_{^{17}O} = 0.61B^- + 0.0046 \tag{12b}$$

entational motion) and the B^- values for the solution viscosity of anions is somewhat better than those for the cations.

Reorientational Motion of a Hydrated D_2O Molecule. Van der Maarel et al. estimated the relaxation of both the D and ^{17}O nuclei of the hydrated water molecules of cations in the limit of infinite dilution by using a polynominal relation between R_1/R_1^0 and the salt concentration. Both reorientational correlation times of the D and ^{17}O nuclei of hydrated water molecules of an hydration sphere are equal within the experimental error, as in the case of pure D_2O molecules, i.e., isotropic reorientational motion. On the other hand, the relaxation rate of the D nucleus of hydrated water molecules is smaller than that of the ^{17}O nucleus in the high-concentration range above 1.0 mol kg^{-1}, i.e., anisotropic reorientational motion. From this result at high concentration, they expected anisotropic reorientational motion of hydrated water molecules at infinite dilution. Especially for the F^- ion, being the largest surface-charge density among univalent anions, a significant ion-water interaction was suggested from several experimental results.

Table 2 shows the corrected $(R_1)^-_X/(R_1)^0_X$, $(R_1)^-_X$, τ^-_X, and $\tau^-_D/\tau^-_{^{17}O}$ values at infinite dilution. They were determined from the linear relation between $(R_1)^-_X/(R_1)^0$ given by Eqs 8—11 and the surface charge density of ions, as shown in Fig. 4. As shown in Table 2, although the reorientational motion of a hydrated D_2O molecule in Cl^-, Br^-, and I^- ions (negative hydration anions) is anisotropic, the reorientational motion of a hydrated D_2O molecule in F^- ions is approximetly isotropic. From these results, it is clear that the anisotropy of reorientational motion of an anionic hydrated D_2O molecule is enhanced with increasing anionic radius.

We are indebted to Professor J. C. Leyte of Lyeden University for his helpful discussion.

Phase Separation Coupled with Gelation in Polyethylene Glycol–Gelatin–Aqueous Buffer System

Takashi NEZU and Hiroshi MAEDA*,†
Department of Chemistry, Faculty of Science, Nagoya University, Nagoya 464-01

(Received January 5, 1991)

Phase behavior of a pseudoternary system, gelatin–polyethylene glycol–acetate buffer, was examined. Phase diagram was constructed by determining the compositions of separated phases. One phase contained mostly gelatin but a trace amount of polyethylene glycol. When temperature was lower than the gelation temperature corresponding to the composition of the separated phase, diverse outlooks of the whole system were found. Observation of solutions under an optical microscope revealed microgels or network structure when gelatin was labeled with sirius red. Two different types of microgel formation were noted: nucleation-growth and spinodal decomposition. Size of the microgels formed by spinodal decomposition decreased with quench temperature.

Multicomponent polymer solutions often undergo phase separation either due to mutual incompatibility[1,2] or due to difference between their interactions with solvent ($\Delta\chi$-effect).[3] When one of separated phases gels, it is anticipated that phase separation process becomes involved and diverse outlooks are observed. Furthermore, if gelation takes place before the completion of the phase separation, we can expect to fix intermediate stages of phase separation by gelation. In the present study, we examine phase behavior of aqueous mixtures of gelatin and polyethylene glycol (PEG). Gelatin–water two component system undergoes gelation rather than phase separation when temperature is lowered in contrast to another popular aqueous two component system agarose–water where microgels are produced as a result of phase separation.[4] Microgels of gelatin has been prepared through simple coacervation induced by the addition of a poor solvent such as alcohol.[5] Later, microgels of gelatin was obtained in aqueous media by the addition of polyethylene glycol.[6] This type of phase separation will be examined in the present study.

Experimental

Gelatin (Sigma type B from bovine skin) was dialyzed against distilled water and freeze-dried subsequently. Weight-average molecular weights of polyethylene glycol (PEG) (Wako Pure Chemical Industries, Ltd.) and purified gelatin were $(2.6\pm0.1)\times10^4$ and $(9\pm1)\times10^4$, respectively as determined from light scattering. Both PEG and gelatin samples showed single peaks on GPC. Acetate buffer (pH 5.0; 5×10^{-2} M, 1 M= 1 mol dm^{-3}) was used as solvent unless otherwise stated.

Concentrations of gelatin (C_g) and PEG (C_{PEG}) of separated phases were determined with HPLC (TSK G4000PW gel). Gelatin concentration was determined from absorption at 260 nm where absorption of PEG was negligible (molar extinction of PEG was about 1/20 of that of gelatin). Refractive index increment consisted of contributions from both polymers and their additivity was confirmed from preliminary measurements. PEG concentration was then obtained by subtracting gelatin contribution from the total refractive index increment. Polymer concentrations were expressed in weight percent; grams of one polymer component in 100 g solution. For microscopic observation an Olympus model BHA microscope equipped with a photographing unit PM-10A was used. Stage was thermostatted within ±0.5 °C.

Result

Phase Separation and Gelation. Two examples of various states accompanying the phase separation are shown in Fig. 1(A) and (B) for polyethylene glycol concentration C_{PEG} of 1.5% and 2% respectively. Gelling process taking place in a gelatin-rich phase gives rise to diverse appearance of the whole system. A solid curve in Fig. 1(A) or (B) represents critical solution temperatures, a kind of binodal line. At temperatures higher than this line a single solution phase is stable, while two phases are expected to appear at temperatures below this line. Actually, two solution phases (⊖) appeared at temperatures not far from the line. Sometimes one of the two phases was dispersed in another phase and the whole system looked like a single turbid solution (□). When temperatures were low, sol–gel (◒) or rarely gel–gel (▲) type phase separation took place. When temperature was lowered further, gelation occurred rapidly before separated microdomains merged into a macroscopic phase. In this case, single turbid gel resulted (●). Under certain conditions, flocculates accumulated at the interface between upper sol and lower gel and hence exhibited three phase behavior (sol–flocculates–gel). All these results were reproducible and irrespective of the direction to reach the final temperature either from higher or lower temperature side. Essentially similar results were obtained at other PEG concentrations.

These results are schematically summarized in Fig. 2. A solid curve represents critical solution temperatures (binodal). At temperatures just below the line, liquid–liquid phase separation usually takes place (region II). Region IV, which is below the gelation curve of gelatin, is always associated with gelation. Complex behaviors appear in region III.

In Fig. 3, critical solution temperatures (c—g) or gelation temperatures (a,b) are shown for different PEG concentrations. At C_{PEG}=0.55%, gelation instead of

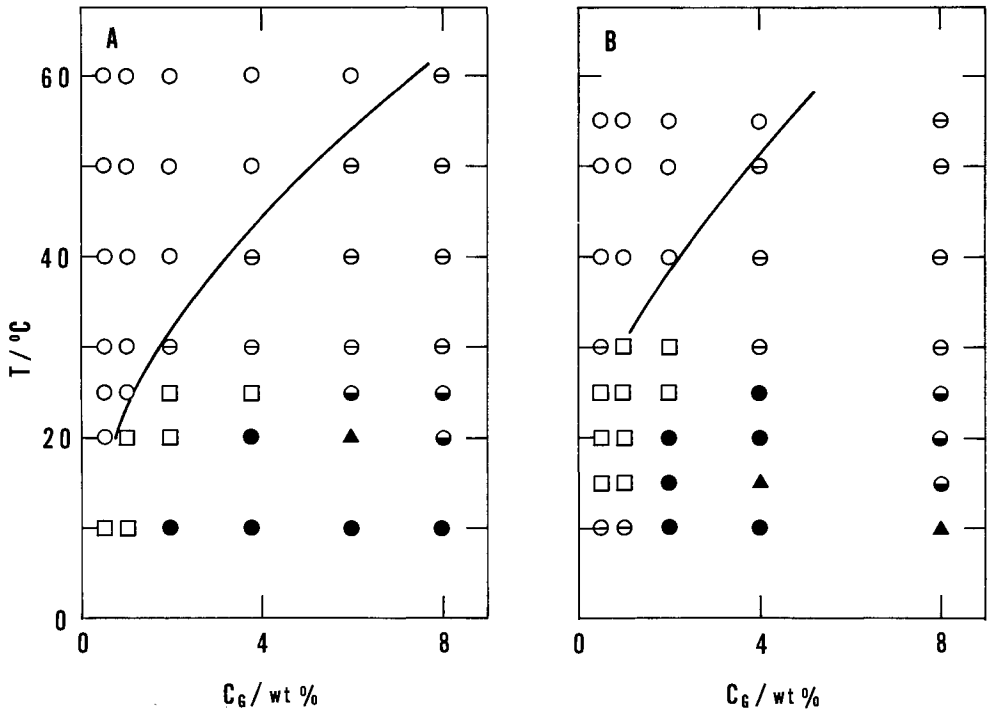

Fig. 1. Phase diagram of gelatin-PEG-aqueous buffer. (A) C_{PEG}=1.5%, (B) C_{PEG}=2.0%. Various symbols representing various apparently different states: (○) single solution, (⊖) two solutions, (◒) solution-gel, (●) gel(turbid), (▲) gel-gel, and (□) emulsion (turbid).

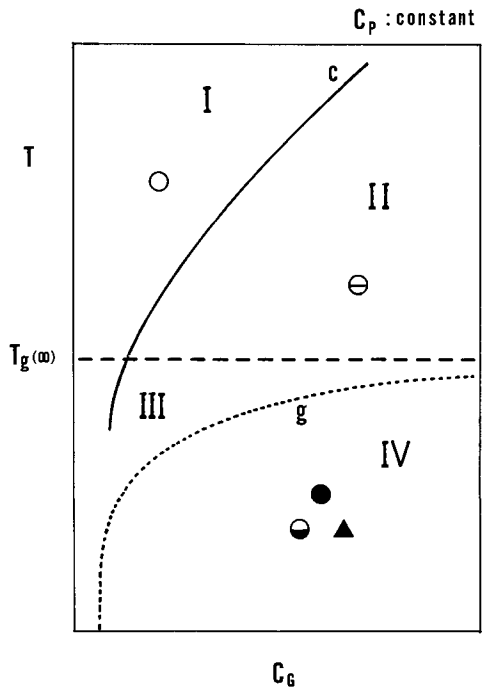

Fig. 2. Schematic presentation of four regions encountered in gelatin-PEG-aqueous buffer. A solid curve c represents critical solution temperatures. Dotted curve g represents gelation temperatures T_g of gelatin solution. $T_g(\infty)$ is the gelation temperature at infinite gelatin concentration.

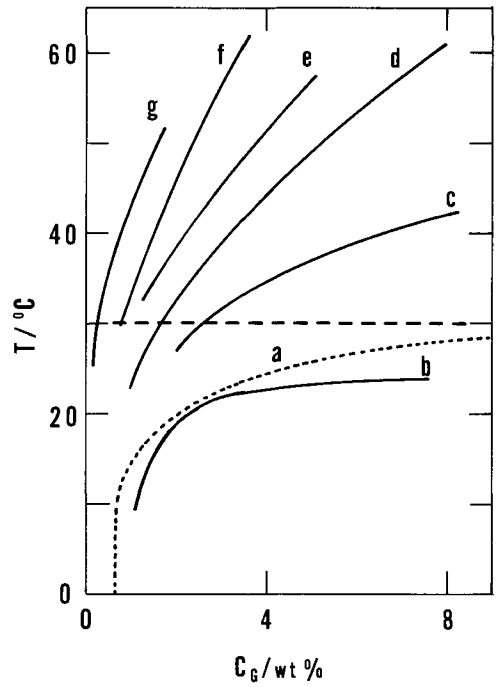

Fig. 3. Effect of PEG concentration on phase behavior. Solid curves represent critical solution temperatures (c—g) or gelation temperatures (b). Dotted curve (a) and dashed curve represent gelation temperatures of gelatin solution and $T_g(\infty)$, respectively. C_{PEG}(%): (a) 0, (b) 0.55, (c) 1.0, (d) 1.5, (e) 2.0, (f) 3.0, and (g) 4.0.

phase separation occurred. Gelation curve (b) at C_{PEG}=0.55% lies at lower temperatures than that of gelatin (a). This indicates that PEG molecules are excluded from gelatin gel and remain in solution phase; 'gel point depression' is expepcted to occur.

Effect of pH was examined at an ionic strength of 0.05 M for pH 5.0, 6.0, and 7.0. Little difference was observed with respect to phase behavior among these pHs. Effect of ionic strength was examined at a pH of 5.1 (10 mM acetate buffer). The solution was turbid in the absence of 0.2 M NaCl but it was clear in the presence of 0.2 M NaCl.

Compositions of Separated Phases. Concentrations of gelatin and PEG in two separated phases were determined with HPLC as described in Experimental section. Results obtained at 40 °C and 25 °C are shown in Fig. 4(A) and (B), respectively. In constructing phase diagrams shown in Fig. 4, we approximated aqueous acetate buffer as a single component. We found that two separated phases showed identical pH which coincided with that of original solution before phase separation. Preferential binding of one of two buffer components to either of the polymer components was thus ruled out. We assumed that buffer concentrations did not differ much on phase separation. As shown in Fig. 4(B), two solutions characterized with different initial compositions give approximately identical compositions of two separated phases, in so far as initial compositions lie on a common tie line. This supports that phase equilibrium was attained in the present study. Binodal lines are close to both axes indicating that separated phases were rich in either of the two components. In particular, PEG concentrations in gel phase were zero within experimental error in all cases examined. This suggests that repulsive interaction between the two polymer components plays an important role to induce the phase separation. Compositions of flocculates in two apparently three-phase systems were examined at 25 °C: C_g=4.0%–C_{PEG}=3.0% and C_g=3.0%–C_{PEG}=2.0%. The compositions were found to be identical to those of gel phase. This has provided a good example indicating that in the present study we dealt with two phase system in thermodynamic sence in spite of three-phase appearance.

All these diverse phase behaviors were expected to originate from inhibited growth or merge of microscopic domains (enriched with gelatin) formed at the initial stage of the phase separation. If gelation had not occurred, these microdomains could have grown and could have merged into three dimensional network (modulated structure in spinodal decomposition) which eventually could have changed into another bulk liquid phase. It is expepcted, therefore, that translational movement of gelatin molecules becomes inhibited by gelation and that the whole process of phase separation is kinetically frozen. If this is to be the case, intermediate stages of phase separation can be visuallized, for example, by staining gelatin with sirius red as was done in the present study.

Observation of Phase Separation under a Microscope. We observed under a microscope solutions containing labeled gelatin. With dilute solutions, a large number of red spherical microgels were observed after phase separation. However, time intervals prior to their emergence differed greatly depending on the compositions of initial solutions. For a solution (C_g=1.25% and C_{PEG}=1.0%) microdroplets first appeared about 8 h after it was brought to the final temperature (25 °C) and sizes of these microbeads did not change appreciably for 24 h. These beads were considered to be produced through nucleation-growth process (NG regime). For another solution (C_g=2.0% and C_{PEG}=1.3%) under the same conditions, on the other hand, microgels appeared immediately after quenching. Phase separation in this case is considered to occur through spinodal decomposition (SD regime). Microdroplets appeared immediately after quenching were not gel-like but of liquid nature. They grew up and merged

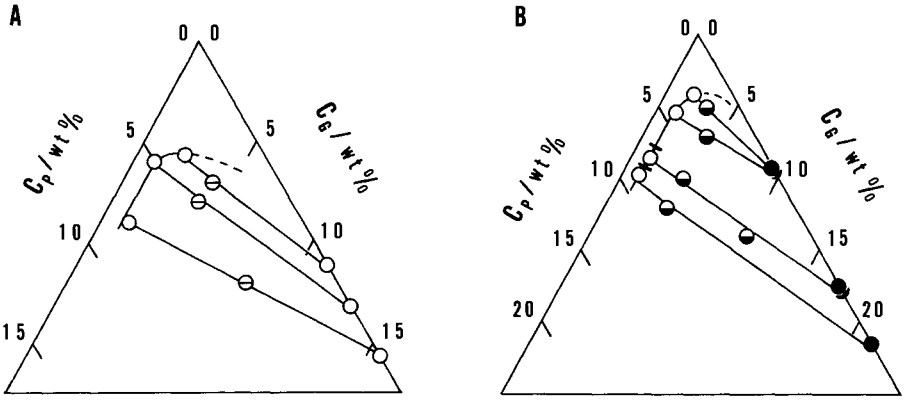

Fig. 4. Phase diagram of gelatin–PEG–aqueous buffer (A) 40°C and (B) 25°C. Symbols are used in the same sense as in Fig. 1 and correspond to the final state.

with each other and their size became bigger with time but reached eventually a constant level at 50—60 min after quenching, probably as a result of loss of fluidity due to advancement of gelation. Their average diameters (d) measured at 55 min. (or later) after quenching were 1.70, 2.01, and 2.76 μm at quench temperatures of 11.7, 16.2, and 20.5 °C, respectively. Calibration of dimension was carried out with polystyrene latex (d=5.854 μm; SD=0.21). Distributions of d about the average value were rather narrow at three temperatures examined. Spinodal temperature (T_S) of the system was determined to be 23.8±1.0 °C from the maximum light scattering intensity. In Fig. 5, values of $\log d$ are plotted against $\log \Delta T$, where $\Delta T(=T_s-T)$ represents a quench depth. The result can be expressed as $d \propto (\Delta T)^{-n}$ with n=0.4±0.1. That is, we get smaller beads as quench depth increases.

When solutions were more concentrated and quenched to low temperatures, we observed network structure (as shown in Fig. 6) rather than dispersed microbeads. This

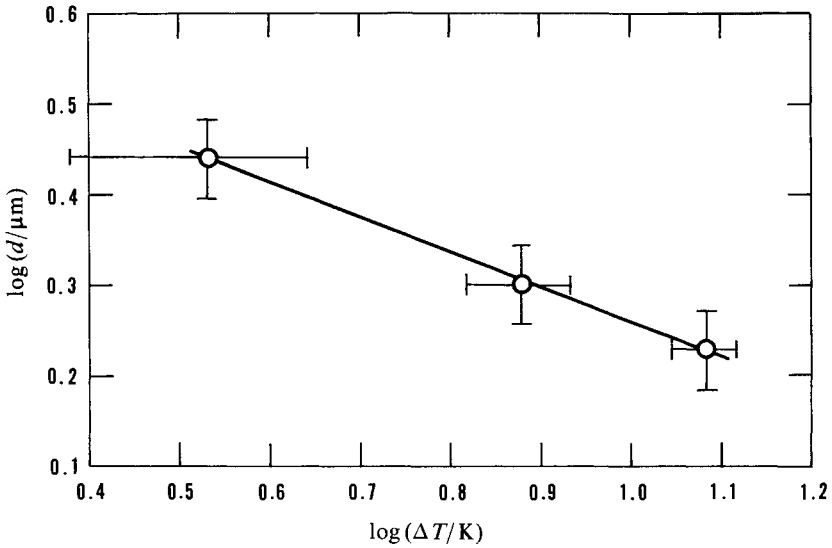

Fig. 5. Dependence of particle diameters d on quench depth ΔT. C_g= 2.0%, C_{PEG}=1.3%, T_s=296.9 K (23.8 °C). Three points correspond to quench temperatures of 11.7, 16.2, and 20.5 °C. Slope of the straight line is −0.4±0.1.

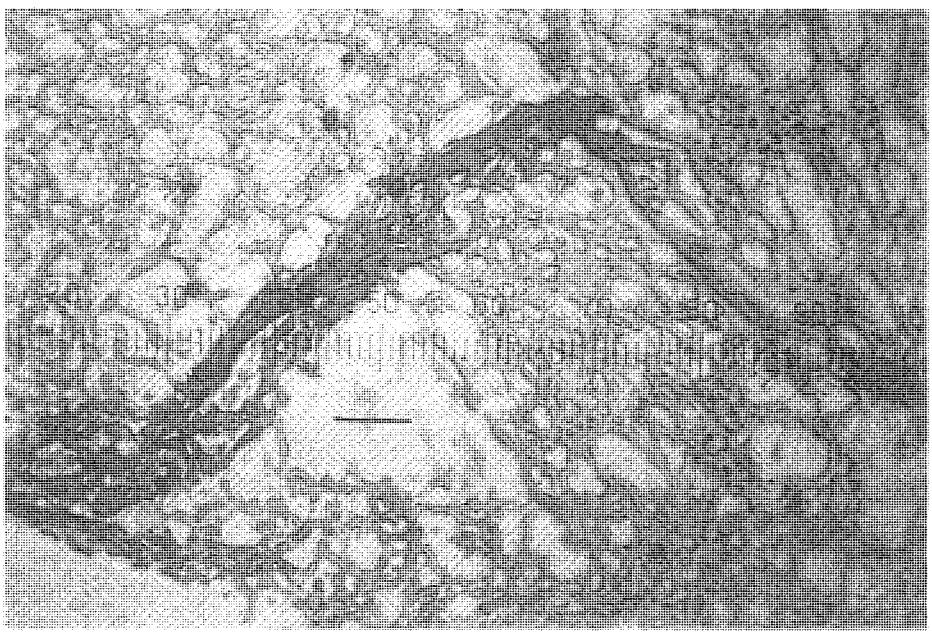

Fig. 6. Network structure consisting of gel (observed at 25 °C) formed at intermediate stage of phase separation at −10 °C. Solution (C_g=2.5% and C_{PEG}= 2.0%) was incubated at −10 °C for 3 h. A horizontal bar corresponds to 100 μm.

picture (Fig. 6) was obtained when a solution (C_g=2.5% and C_{PEG}=2.0%) at 60 °C was quenched at −10 °C for 3 h and then brought to 25 °C for observation. The network structure was stable at 25 °C for more than 30 min indicating it was gel. When the same solution was quenched at −10 °C for 30 min, thin branches melted and only thick branches remained during observation. When quenching duration was further reduced to 10 min, no network structure was seen any more when brought to 25 °C for observation. The dependence of strength of network structure on quenching duration suggests that gelation became predominant over phase separation with decreasing temperature, although both processes became slow at low temperatures. Generally, we can expect this situation from the following consideration. Aggregation of gelatin chains occurs prior to gelation. These aggregates make the phase separation process slower and hence enhance the aggregation further. It is reasonable, therefore, that gelation predominates over phase separation due to this autocatalytic effect.

In Fig. 6, both thin and thick branches consist of gelatin gel. Gelatin concentration in these gels is consistent with phase equilibrium at 25 °C rather than at −10 °C where they were formed. This is because gel composition changed to the equilibrium value at 25 °C during observation primarily through solvent movement. However, observed structural pattern itself reflects the intermediate stages of phase separation at the quench temperature of −10 °C.

Modulated structure has been observed under a microscope for other multicomponent polymer systems.[9-11]

Discussion

In the present study, microgels or network structures were observed in SD regime. It is pertinent to examine whether or not these observations are consistent with, at least qualitatively, the prediction of general theory of SD.

According to Cahn's theory,[7] concentration fluctuation taking place at initial stages of SD is characterized with a particular wavelength λ_m, which is given as follows.[8]

$$\lambda_m = 2\pi\, l\, [3\Delta T/T_s]^{-1/2} \quad (1)$$

Here l is related to some characteristic dimension of poymer coils. It is to be noted that Eq. 1 has been derived for two component systems,[7,8] either polymer–polymer or polymer–solvent. Dependence of λ_m on ΔT originates from a term related to the mixing free energy, which is a function of single concentration variable in the theory.[7,8] On the other hand, mixing free energy depends on two concentration variables in the present pseudoternary system. However, essential step of the phase separation undoubtedly involves translational movement of two kinds of polymers toward opposite directions. Consequently, phase separation in the present study is expected to be approximated with that occurs in a polymer–polymer two component system. If microgels are formed through spinodal decomposition, then their size d should be closely related to the characteristic wavelength λ_m. According to Eq. 1, $\log \lambda_m$ decreases with $\log \Delta T$ with a slope of −0.5. Experimentally, a slope of about −0.4 was observed (Fig. 5). We are not in a position, however, to compare the experimental and the theoretical values of the slope, since there are many uncertain factors to be clarified in both theoretical and experimental aspects.

The authors wish to thank Professors Akira Takahashi (Mie University) and Takashi Inoue (Tokyo Institute of Technology) and Dr. Minoru Ueda (Kuraray Central Research Institute) for their enlightening comments. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 02403004 from the Ministry of Education, Science and Culture.

Combustion Reactions in Methane–Air Premixed Flames

Seishiro FUKUTANI,* Keizo SAKAGUCHI, Nílson KUNIOSHI, and Hiroshi JINNO†
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida-honmachi, Sakyo-ku, Kyoto 606
† Department of Chemistry, Faculty of Science and Engineering, Sophia University, Kioicho 7-1, Chiyoda-ku, Tokyo 102
(Received February 5, 1991)

A reaction scheme reproducing methane combustion by computer simulation under a wide range of stoichiometric ratio has been proposed and applied to flat methane–air premixed flames to elucidate factors determining their propagation mechanisms and the role of C_2 reaction pathways. Main methane combustion reactions, which progress sequentially from the fuel to carbon dioxide, are inhibited at low temperatures due to retarded production of oxygen atoms which are necessary for the oxidation of methyl radicals. The role of C_2 routes have been investigated by comparison of the results obtained by use of the C_2 scheme and a simplified C_1 scheme. Some of the methyl radicals are once recombined to ethane but most of the produced ethane is dissociated again to methyl via ethyl radicals. Then the C_2 routes work as a temporary storage of species and hinder the main combustion reactions which go through C_1 species.

There are two alternative approaches to study in detail the mechanism of a chemical reaction consisting of many elementary reactions; one of them is an analytical approach where the chemical change is divided into the contribution of each elementary reaction based on the measurements of the temperature, the species concentrations and so on, and the other one is a synthetic approach where the chemical change is constructed step by step with possible elementary reactions. The former is usually used in experimental studies and the latter in computer simulations.

This study has simulated methane–air premixed flames using a detailed reaction scheme to investigate the following two points of methane combustion: Why methane flames propagate according to the thermal theory; and how important is the C_2 routes for methane combustion under various conditions. A simplified reaction scheme has also been proposed and used to estimate the second point.

Simulation Model

We used the same assumptions as those described in a previous work[1] in constructing the simulation model, and obtained the following governing equations for flat flames:

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho v) = 0 \tag{1}$$

$$\frac{\partial}{\partial t}(c_p \rho T) + \frac{\partial}{\partial x}(c_p \rho T v) = \frac{\partial}{\partial x}\left(\lambda \frac{\partial T}{\partial x}\right) + \sum_i D_i \rho \frac{\partial h_i}{\partial x}\frac{\partial \omega_i}{\partial x} - \sum_i h_i \phi_i \tag{2}$$

$$\frac{\partial}{\partial t}(\rho \omega_i) + \frac{\partial}{\partial x}(\rho \omega_i v) = \frac{\partial}{\partial x}\left(D_i \rho \frac{\partial \omega_i}{\partial x}\right) + \phi_i \tag{3}$$

$$p = \rho R T \sum_i \frac{\omega_i}{m_i} \tag{4}$$

where ω_i and ϕ_i are, respectively, the mass fraction and the chemical production rate of the i-th species. The other symbols have their usual meanings.

The partial differential terms in the governing equations were transformed into the corresponding finite difference terms according to the control-volume method.[2] The obtained finite-difference equations were solved numerically under the following boundary conditions; at the unburned side the temperature is 298K and the combustible gas mixture is composed of the fuel and air, and at the burned side the gas is heated up to the adiabatic flame temperature, which is evaluated beforehand based on the combustion condition, and has the equilibrium composition at that temperature. The solutions individually converge to certain values independent of the initial condition only when the flow velocity given as one of the boundary conditions just agrees with the burning velocity which is the eigenvalue for the combustion condition.

Reaction Scheme for Methane Combustion

Methane combustion actually consists of a wide variety of elementary reactions including those occurring among C_2 and higher hydrocarbons, particularly when air is supplied insufficiently, because soot is produced under such conditions. Reaction schemes including higher hydrocarbons have been proposed[3-5] and used for combustion of fuels containing eight or more carbon atoms in their molecules. Those schemes are, however, too complicated to be applied to methane combustion, though they should be employed when soot-formation processes, for example, are discussed.

In this investigation, we composed a reaction scheme comprising only C_1 and C_2 hydrocarbons (Table 1), and applied it to methane combustion under various conditions. Nitrogen works as the source of thermal NO_x in actual flames but in this investigation it is assumed to be inert due to the consideration of the production rate of NO_x.[1] Most of the rate coefficients except those of

The rate constants are expressed in m, mol, s units.

hydrogen–oxygen reactions were selected from the values proposed by Westbrook[6] and Warnatz.[7] Some of the frequency factors, however, were modified to make the scheme applicable for combustion of methane under wide conditions and, in addition, for that of ethane, ethylene and acetylene under stoichiometric and lean conditions.

The thermal conductivities and diffusion coefficients of the component gases were evaluated as functions of temperature according to Eucken's and Hirschfelder's approximations,[12] respectively. The values of these properties for the gas mixtures were estimated by summation of the corresponding values of the individual components with multiplication by factors depending on the gas compositions.

Experimental burning velocity[14]/m s^{-1}	1.56	0.78	0.48	0.42

Results and Discussion

Validity of Proposed Reaction Scheme. The calculated burning velocities of methane–air premixed flames with various equivalence ratios were compared with those obtained experimentally[13] (Fig. 1). The predicted burning velocities for stoichiometric ethane–, ethylene–, and acetylene–air flames were also checked with the experimental values (Table 2).

The burning velocity predicted by use of computer simulation is given as an overall result of interactions among chemical and physical processes constituting the model. Good agreement between the predicted and the experimental burning velocities leads to the conclusion that the model including the reaction scheme proposed in this investigation are valid for simulation of actual methane flames.

Combustion Reaction in Stoichiometric Methane Flame. Figure 2 shows the profiles of the temperature and the mole fractions of stable species in a stoichiometric methane–air premixed flame. Water vapor, one of the final combustion products, is already present even at a very early stage; carbon dioxide, on the contrary, is not produced in a large amount until most methane has been consumed. These changes suggest that carbon and hydrogen contained in the fuel molecule are oxidized through different routes in methane combustion.

The mole-fraction profiles of active or intermediate

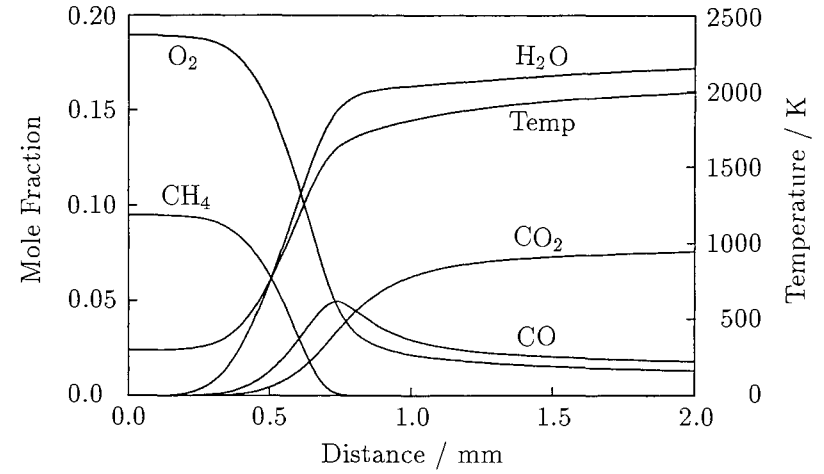

Fig. 2. Profiles of the temperature and the concentrations of stable species in a stoichiometric methane-air premixed flame.

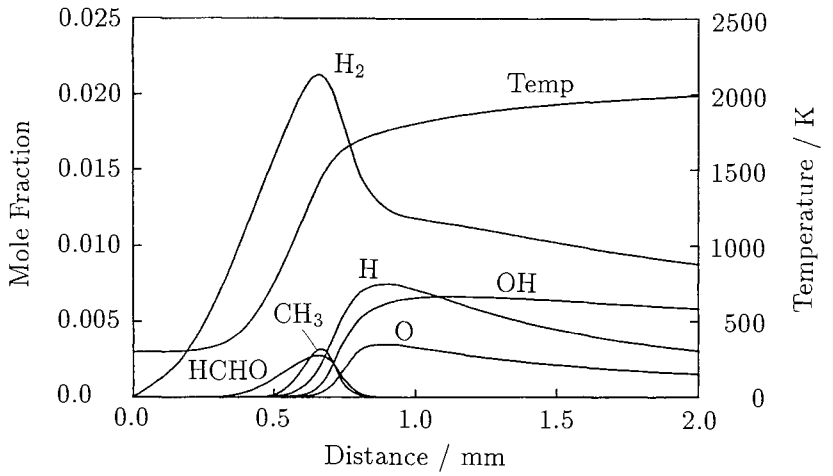

Fig. 3. Profiles of the temperature and the concentrations of active species in the stoichiometric methane-air premixed flame.

species are given in Fig. 3. The three active species, hydroxyl radicals and hydrogen and oxygen atoms, generally holding a decisive role in combustion, do not increase until the temperature becomes higher than 1000 K. These profiles are quite different from those in hydrogen premixed flames,[1] where hydrogen atoms diffusing from the flame front to the low-temperature region carry enthalpy as chemical energy, release it as thermal energy through reactions toward less active species, and raise temperature there.

Figure 4 shows the heat increase rates due to the four possible terms which appear in the conservation equation of thermal energy, Eq. 2, that is, convection, conduction, heat transfer accompanying species diffusion and heat release by chemical reactions. The condition that the summation of the above four contributions must be zero at any position in a steady flame is satisfied. Thermal energy is practically accumulated both by conduction and heat release at low temperatures but increases only by heat release at high temperatures. Species diffusion does not contribute to the transfer of thermal energy as also observed in hydrogen flames.

Temperature must be raised at any part of a flame for its steady propagation. It is easy to raise temperature in the high-temperature region because of the intense heat release through reactions, but is difficult in the low-temperature region; therefore the mode how the temperature is raised there governs the propagation mechanism of the whole flame. Two theories have been proposed for the propagation mechanism of a premixed flame depending on which of the two factors, conduction and heat release, is considered to be responsible for the thermal energy increase in its low-temperature region;[15] the thermal propagation theory, which assumes that the former is predominant, and the active-species diffusion theory, which is constructed on the mechanism that active species diffuse to the low-temperature region from the flame front and are degraded to stable species through exothermic reactions. In the latter theory the active species can be considered to be hydrogen atoms

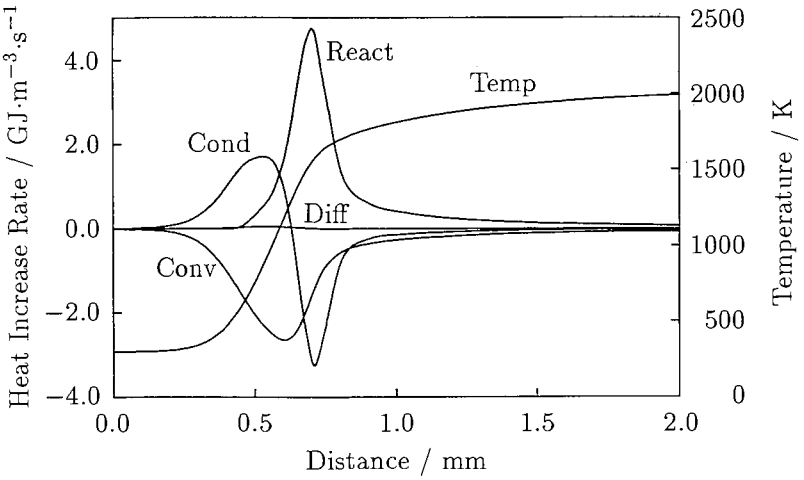

Fig. 4. Rates of the heat increase due to convection (Conv), conduction (Cond), heat transfer accompanying species diffusion (Diff), and heat release through reactions (React) in the stoichiometric methane–air premixed flame.

without substantial error because of their large diffusion coefficient. In the stoichiometric methane–air premixed flame, chemical reactions do not release yet thermal energy in a large amount at low temperatures as shown in Fig. 4, suggesting that this flame is a typical example of thermally-propagating flames.

We now discuss the reasons why the methane flame propagates thermally.

One of the characteristics of the distribution of heat-release rate in the methane flame is that heat is evolved at fairly high temperatures comparing with that in a stoichiometric hydrogen-air flame;[1] the contribution of heat release in the methane flame increases at about 1000K, equals that of conduction at 1120K, and decreases steeply after reaching its maximum at 1550K, while in the hydrogen flame it becomes significant already at about 400K and exceeds the thermal conduction at 450K. This comparison between these changes in the heat-release profiles suggests that initiation of the combustion reaction is retarded in the methane flame.

According to simulation of methane premixed flames, the main combustion reactions proceed sequentially as $CH_4 \rightarrow CH_3 \rightarrow HCHO \rightarrow CHO \rightarrow CO \rightarrow CO_2$ under stoichiometric or lean conditions.[7] At 1550 K in the stoichiometric flame, the reaction pathways are shown in Fig. 5 and the predominant reactions for each step are:

$$CH_4 + OH \rightarrow CH_3 + H_2O, \quad (R2)$$

$$CH_4 + H \rightarrow CH_3 + H_2; \quad (R3)$$

$$CH_3 + O \rightarrow HCHO + H; \quad (R8)$$

$$HCHO + H \rightarrow CHO + H_2, \quad (R15)$$

$$HCHO + OH \rightarrow CHO + H_2O; \quad (R14)$$

$$CHO + M \rightarrow CO + H + M. \quad (R22)$$

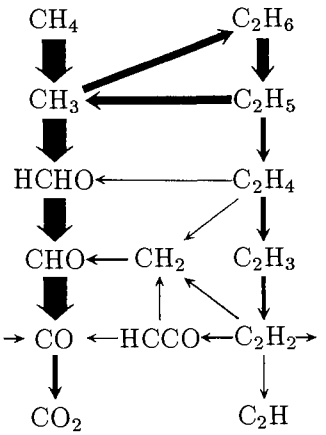

Fig. 5. Reaction pathways at 1550 K in the stoichiometric methane flame. The widths of the arrows are proportional to the rates of the corresponding reactions.

The contributions of reactions (R2) and (R3) are, respectively, 55% and 37% for the total methane dehydrogenation; 88% of the methyl oxidation is ascribed to reaction (R8); 63% and 22% of formyl radicals are produced by reactions (R15) and (R14), respectively; almost all formyl radicals are decomposed to carbon monoxide by reaction (R22).

About 85% of the carbon monoxide cannot be oxidized yet into carbon dioxide even at this temperature. Its oxidation is activated only after the fuel has been exhausted. Almost all carbon monoxide reacts with hydroxyl radicals via reaction

$$CO + OH \rightarrow CO_2 + H. \quad (R23)$$

The slow oxidation of carbon monoxide is explained as follows. There are several reactions consuming hydroxyl radicals such as reactions (R2), (R72), (R14), and

(R23) at high temperatures. The oxidation step of carbon monoxide, however, has the smallest rate constant among them, though it has a negative activation temperature (see Table 1). It can be activated for the first time after all the other consumption reactions of hydroxyl radicals have actually been completed.

Methoxyl radicals are present at low temperatures. At 1120 K, where the rates of heat increase due to conduction and heat release are equal, for instance, about 40% of the methyl radicals are once oxidized to methoxyl radicals via reaction

$$CH_3 + HO_2 \rightarrow CH_3O + OH. \quad (R5)$$

These radicals are further decomposed through reactions

$$CH_3O + M \rightarrow HCHO + H + M \quad (R13)$$

and

$$CH_3O + O_2 \rightarrow HCHO + HO_2, \quad (R12)$$

in the stoichiometric flame. The rest of the methyl radicals are oxidized through reaction (R8). The direct oxidation of methyl to formaldehyde increases with increasing temperature.

A chemical process composed of a sequence of elementary reactions cannot proceed as a whole when any step is delayed. The oxidation step of methyl radicals is mostly due to reaction (R8); therefore oxygen atoms must be present for smooth progression of methane combustion. That species, however, cannot be supplied by diffusion because of its small diffusion coefficient. Hence they must be inevitably supplied by reactions.

Oxygen atoms are produced mostly through a chain-branching reaction

$$H + O_2 \rightarrow OH + O \quad (R69)$$

over a wide range of temperature. As shown in Table 1, this reaction is competing with reaction

$$H + O_2 + M \rightarrow HO_2 + M. \quad (R77)$$

Reaction (R77) is activated in a low-temperature region because of its negative activation energy, so that reaction (R69) becomes faster than reaction (R77) at temperatures as high as 1100K; in other words, oxygen atoms cannot be produced in a sufficient amount and, hence, the whole combustion reaction of methane cannot be accelerated at low temperatures. This is the main reason why methane flames propagate thermally, and has been also confirmed by experiments.[16]

The propagation mechanism of a premixed flame is also controlled by the possibility of efficient formation of free hydrogen atoms; when they are sufficiently produced in a flame its propagation can be explained according to the active-species diffusion theory. Hydrogen atoms initially contained in methane molecules are finally oxidized into water molecules via several kinds of species. The number of hydrogen atoms shared in the fuel decreases almost linearly with rising temperature and instead that shared in water vapor increases, and the number of hydrogen atoms contained in hydrogen molecules is kept around 10% throughout the whole temperature range. The stable final product is directly produced from the fuel at the first step of the combustion, that is, reaction (R2), and holds about half of the hydrogen atoms at temperature as low as 1000 K; thus free hydrogen atoms cannot be appreciably liberated until complete consumption of the fuel.

Heat release due to chemical reactions is caused predominantly by the following reactions: reaction (R1) at low temperatures, reaction (R9) at 950—1300 K, reaction (R8) at 1400—1650 K, reaction (R23) at 1700—1800 K, and reactions (R76) and (R77) at higher temperatures. The contribution of reaction (R8) is the most important; the fairly steep decrease in the heat-release rate after passing its maximum as shown in Fig. 4 is ascribable to the decrease in the rate of this reaction. It is noteworthy that reaction

$$CH_4 + M \rightarrow CH_3 + H + M \quad (R1)$$

proceeds in the reverse direction and release a remarkable amount of thermal energy in a low-temperature region, though this reaction is generally considered to be one of the initiation reactions. The rate constant of its reverse reaction must be exactly evaluated from the viewpoint of the heat release at low temperatures.

Combustion Reactions under Various Conditions and Role of C_2 Routes. The combustion reactions in methane–air premixed flames proceed in various mechanisms depending on their initial fuel concentrations. The reaction paths via C_2 hydrocarbons are not important under the stoichiometric condition as described above though its contribution is not negligible. They are, however, of importance as a combustion route and also a starting step of soot formation under rich conditions. We simulated five other methane flames with various equivalence ratios and carried out a comparative study of their reaction mechanisms.

The equivalence ratios of the additional flames are 1.30, 1.18, 1.06, 0.83, and 0.61, and the calculated burning velocities are 0.33, 0.41, 0.41, 0.30, and 0.14 m s^{-1}, respectively. These velocities are in good agreement with the corresponding experimental values as shown in Fig. 1.

As the equivalence ratio increases, the oxidation of carbon monoxide is naturally suppressed and a larger amount of carbon monoxide is left unburned even at the adiabatic flame temperature. More than 5% of the carbon atoms are, however, contained temporarily in the C_2 hydrocarbons even in the flame with the equivalence ratio of 0.61, and the maximum ratio of the carbon atoms shared in the C_2 hydrocarbons monotonically increases with the increasing equivalence ratio reaching about 14%

in the richest flame among those investigated here; the temperature where the maximum ratio is achieved ranges from 1100K (at the leanest condition) to 1360K (at the richest one).

We estimated the roles of the C_2 routes from chemical viewpoints.

Some of methyl radicals are recombined to ethane through reaction

$$CH_3 + CH_3 \rightarrow C_2H_6, \quad \text{(R9)}$$

and the ethane is predominantly dehydrogenated through

$$C_2H_6 + H \rightarrow C_2H_5 + H_2 \quad \text{(R28)}$$

and

$$C_2H_6 + OH \rightarrow C_2H_5 + H_2O \quad \text{(R27)}$$

in all the flames throughout wide ranges of temperature. It should be noted that more than half of the ethyl radicals dissociate again into methyl radicals by the reaction with hydrogen atoms:

$$C_2H_5 + H \rightarrow CH_3 + CH_3 \quad \text{(R10)}$$

In other words, the C_2 routes partly work just as a temporary storage of the carbon-containing species and, in addition, as radical-consuming steps for methane combustion. Therefore, we evaluated the net roles of the C_2 routes by use of the ratio between the amounts of methyl radicals reacting to methoxyl or formaldehyde and that of ethyl radicals reacting to ethylene. Figure 6 shows those ratios in the stoichiometric and rich flames as functions of temperature. According to this figure, the ratios become minimum at around 1200 K in both flames indicating that the relative importance of the C_2 routes are almost similar as a whole independently of the equivalence ratio and also are remarkable at low temperatures.

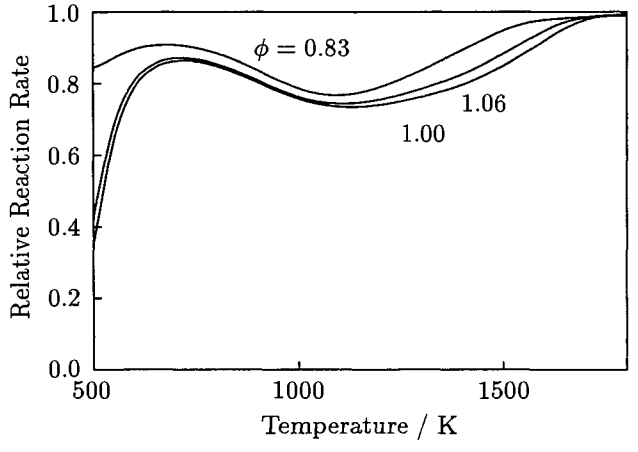

Fig. 6. Relative reaction rates of the C_1 and the C_2 routes in the three methane flames depicted with the equivalence ratio.

About 40% of the ethyl radicals further react as C_2 species. In all the flames simulated in this investigation, the C_2 routes starting from ethyl radicals progress predominantly as $C_2H_5 \rightarrow C_2H_4 \rightarrow C_2H_3 \rightarrow C_2H_2$ though there are some side pathways (see Fig. 5); acetylene is consequently produced through the sequence of reactions

$$C_2H_5 + M \rightarrow C_2H_4 + H + M; \quad \text{(R32)}$$

$$C_2H_4 + H \rightarrow C_2H_3 + H_2, \quad \text{(R34)}$$

$$C_2H_4 + OH \rightarrow C_2H_3 + H_2O; \quad \text{(R33)}$$

$$C_2H_3 + H \rightarrow C_2H_2 + H_2, \quad \text{(R40)}$$

$$C_2H_3 + M \rightarrow C_2H_2 + H + M. \quad \text{(R42)}$$

The contribution of reaction (R32) for the first step is more than 90% at 1550 K in the stoichiometric flame, for instance; those of reactions (R34) and (R33) for the dehydrogenation of ethylene are 73% and 27%, respectively; about 52% and 44% of acetylene is produced through reactions (R40) and (R42), respectively.

More than 80% of the acetylene is oxidized with oxygen atoms by either of the following two reactions, which have almost the same contributions in the above-mentioned flame:

$$C_2H_2 + O \rightarrow HCCO + H \quad \text{(R48)}$$

$$C_2H_2 + O \rightarrow CH_2 + CO. \quad \text{(R49)}$$

The rest of the acetylene is further dehydrogenated through reactions

$$C_2H_2 + H \rightarrow C_2H + H_2 \quad \text{(R44)}$$

and

$$C_2H_2 + OH \rightarrow C_2H + H_2O. \quad \text{(R43)}$$

Application of Simple Reaction Scheme. The reaction paths through C_2 hydrocarbons are not major routes of methane combustion at least under the stoichiometric and lean conditions. Therefore, some combustion phenomena particularly in real flames have been investigated applying simplified reaction schemes to avoid complexities; reaction schemes which are composed of only three or four reactions have been proposed,[17,18] for instance.

Those schemes are useful for confined purposed such as general surveys of combustion reactions in flames having complicated flow fields and discussion in considering chemical reactions only as heat-releasing processes. But they are too simple and, furthermore, are not necessarily composed of so-called elementary reactions; they are not satisfactory at least for the analyses of reaction mechanisms of combustion. Here we made a simple reaction scheme which is composed of C_1 hydrocarbon elementary reactions and, at the same

time, is exact enough to reproduce methane combustion reactions, though they can only be applied for combustion under stoichiometric and lean conditions. The simple reaction scheme is also expected to elucidate the importance of the C_2 routes in comparison with the results obtained by use of the full and the simple reaction schemes.

The proposed simple reaction scheme consists in thirtyseven pairs of elementary reactions (Table 3). At first, we assumed the same rate coefficients, that is, A, n, and E, as those in Table 1 for each reaction of the simple scheme. However, the predicted burning velocity of the stoichiometric methane flame, for example, was as large as $0.49 ms^{-1}$, while both burning velocities obtained by experiments and predicted with the full reaction scheme are around $0.4 ms^{-1}$.

An elementary reaction should universally have the same rate coefficients independently of what reaction scheme it belongs to. This principle, however, is strictly followed only when the reaction is a constituent of a complete scheme. On the contrary, when it belongs to an abbreviated scheme, its rate coefficients may be modified to compensate the influences coming from the omission of reactions, though the omitted reactions individually have only negligible effects on the whole combustion process. A trial and error method led to the

The rate constants are expressed in m, mol, s units.

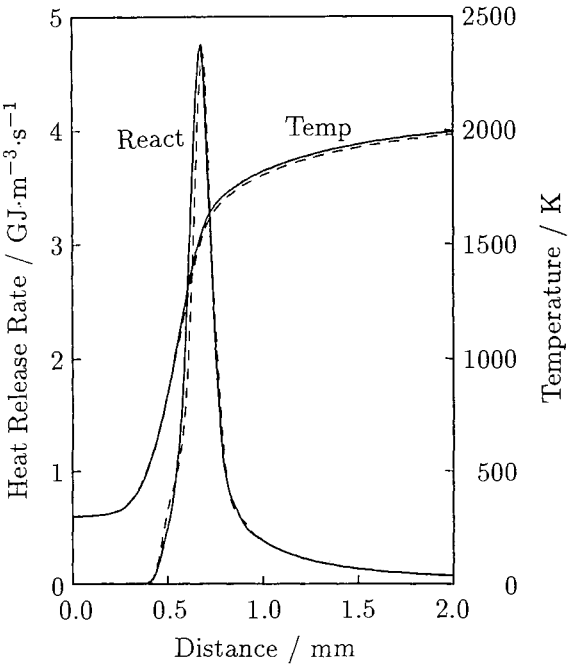

Fig. 7. Comparison of the temperature and the heat-release rate predicted by use of the C_2 scheme (solid lines) and the C_1 scheme (dashed lines).

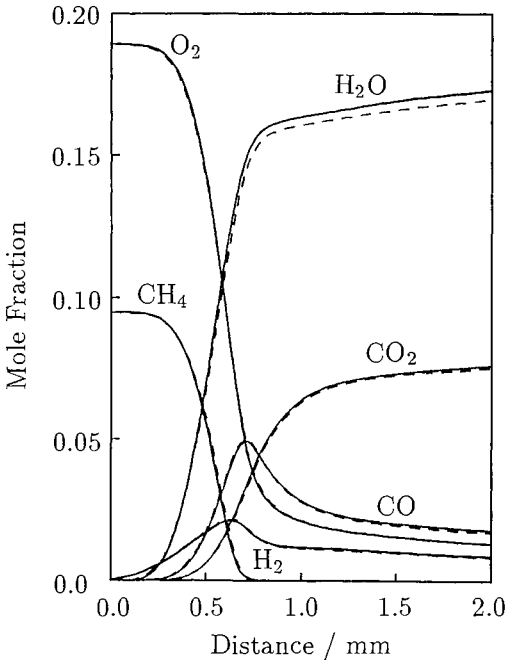

Fig. 8. Comparison of the concentrations of the stable species predicted by use of the C_2 scheme (solid lines) and the C_1 scheme (dashed lines).

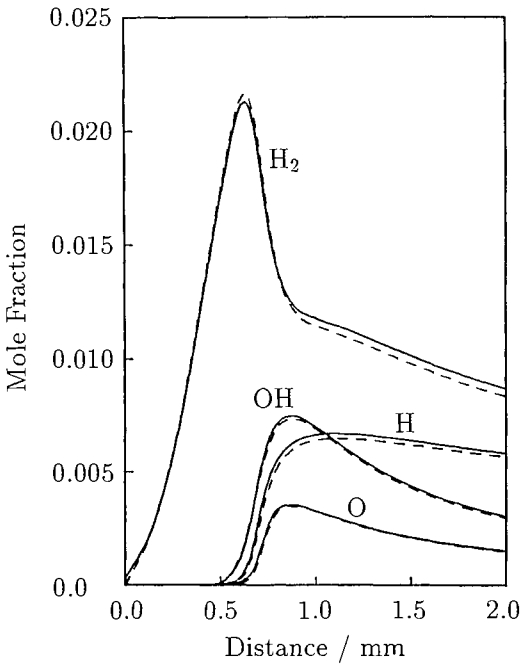

Fig. 9. Comparison of the concentrations of the intermediate species predicted by use of the C_2 scheme (solid lines) and the C_1 scheme (dashed lines).

result that multiplication of the frequency factor of reaction (R22) in Table 1 by a factor of 0.284 is the most suitable modification. The routes via the C_2 hydrocarbons are, therefore, approximately equivalent to the suppression of the rate of the sequential oxidation of methane via the C_1 hydrocarbons. In other words, those routes have inhibiting effects on methane combustion.

Then, the burning velocity was improved to be 0.38 m s^{-1} for the stoichiometric methane flame. Figure 7 shows the profiles of the temperature and the heat-release rate of the stoichiometric methane flame calculated by using both reaction schemes. Figures 8 and 9 designate the mole-fraction profiles of the stable and active or intermediate species, respectively. These profiles are in good agreement except those of water and hydrogen. The number of the carbon atoms shared in the other species except methane, carbon monoxide and carbon dioxide obtained by means of the C_2-hydrocarbon scheme is about 1.5 times as large as that calculated by using the C_1-hydrocarbon reaction scheme.

Conclusions

Two reaction schemes for combustion reactions of C_1 and C_2 hydrocarbons were proposed and applied to flat premixed methane flames. The following conclusions were obtained:

1. Methane combustion proceeds predominantly via the C_1 routes under stoichiometric and lean conditions; the C_2 routes hold only a subordinate role. However the omission of the C_2 routes from the reaction scheme causes increase in the burning velocity because they work as a temporary storage of the species. The rate constant of reaction (R22) should be reduced to compensate the unreasonable raise of the burning velocity in a simplified reaction scheme which comprises only the C_1 routes.

2. A methane premixed flame propagates mainly according to the thermal theory, which is applicable to the propagation of flames where reactions do not occur in the low-temperature regions, because methane combustion reactions have not been activated until the temperature is raised up to about 1100 K; the oxidation of methyl radicals inevitably requires oxygen atoms but these cannot be supplied at lower temperatures due to a competition reaction for their formation.

(Received November 19, 1990)

A novel series of polymethylene-linked heterobinuclear complexes of polypyridine ruthenium(II)/osmium(II) complex $Ru(II)(bpy)_2Mebpy-(CH_2)_n-MebpyOs(II)(bpy)_2$(bpy=2,2′-bipyridine and n=2, 3, 5, and 7), **1**, was prepared. The photophysical behavior was examined in various solvents. The emission spectra of **1** (excitation wavelength: 455nm) showed a nearly complete quenching of $Ru^{II}\rightarrow\pi^*$(bpy) metal-to-ligand charge transfer (MLCT) emission and the enhancement of $Os^{II}\rightarrow\pi^*$(bpy) MLCT emission. The luminescence lifetime measurements by a time-correlated single photon-counting method provided evidence that intramolecular energy transfer is a significant pathway for the observed emission quenching. The rate constants of the intramolecular energy transfer in ethanol are 5.3×10^8, 3.3×10^8, 1.3×10^8, and $1.0\times10^8 s^{-1}$ for **1**(n=2, 3, 5, and 7), respectively. They were found to be proportional to the inverse sixth power on the center-to-center distance of the two complexes. The mechanism is discussed in terms of the Förster (a dipole–dipole interaction) mechanism.

There has been considerable interest in photochemical and photophysical processes of molecular assemblies consisting of polypyridine and porphyrin complexes of the transition metals.[1-5] A possible use of these materials is to control photochemical processes in which optical excitation is followed by spatially directed energy or electron transfer.[6-10] We have studied the photochemical and photophysical properties of $Ru(bpy)_3^{2+}$-containing polymers in which $Ru(bpy)_3^{2+}$ complexes are covalently incorporated into poly(4-methyl-4′-vinyl-2,2′-bipyridine).[11] In our recent study, covalently linked dimers of $Ru(bpy)_3^{2+}$ (complex **2**) as a dimer model for $Ru(bpy)_3^{2+}$-containing polymers exhibited rather different photophysical behaviors in comparison with those of aromatic hydrocarbon and porphyrin dimers.[12-15] In excited **2**, no intramolecular interaction leading to the enhanced quenching between the excited and ground states was found. However, an efficient intramolecular triplet–triplet annihilation process was found under the high intensity irradiation of laser light.[16] These results aroused our interest in the heterobinuclear system.

The intramolecular energy-transfer processes in a variety of weakly coupled dimers of transition metal complexes have been the subjects of both theoretical and mechanistic studies.[17-20] Two major mechanisms for energy transfer in organic systems have been recognized.[21,22] Energy transfer can take place via a dipole–dipole interaction between an electronically excited donor and an acceptor in the ground state (i.e., the Förster mechanism).[23] The other mechanism involved in energy transfer is an electron-exchange mechanism in which a spatial overlap of the donor and acceptor is required (i.e., the Dexter mechanism).[24] Since electronic transition in transition metal complexes are frequently symmetry and spin forbidden, the Förster-type energy transfer based on a dipole–dipole interaction is usually unimportant in these systems. However, it cannot be dismissed for some transition metal complexes. An appreciable amount of singlet character in luminescent excited states of $Ru(bpy)_3^{2+}$ and $Os(bpy)_3^{2+}$ has been recognized.[25,26] There are a few examples of binuclear complexes for which the Förster mechanism is conceivable in the excited state. Schmehl has discussed the intramolecular energy transfer of covalently linked ruthenium(II) dimers in terms of a dipolar coupling mechanism, namely the Förster mechanism.[18] We have also discussed the intramolecular energy transfer of a heterobinuclear complex of polypyridine–ruthenium(II) and –osmium(II), (complex **3**) using the Förster mechanism.[27]

The Förster and Dexter mechanisms are typically distinguished by evaluating the dependence of the rate of energy transfer on the distance of donor–acceptor separation. The dependence of the inverse sixth power of the distance is expected for a dipole–dipole coupling process, while an exponential dependence of distance is observed for the Dexter mechanism. There has been no systematic examination of the distance dependency of energy transfer for covalently linked complexes of this type.

We have recently established a synthetic method regarding polymethylene linked dimers of 4-methyl-2,2′-bipyridine. This work presents 1) the preparation of the ligand dimers and a novel series of polymethylene-linked heterobinuclear complexes comprising the polypyridine ruthenium(II)/osmium(II) complex $Ru(II)(bpy)_2Mebpy-(CH_2)_n-MebpyOs(II)(bpy)_2$ (bpy=2,2′-bipyridine, n=2,3,5 and 7), **1**,

2) their spectroscopic and electrochemical properties,

†† Present Address: Research Institute of Applied Electricity, Hokkaido University, Sapporo 060.

and

3) a kinetic study of intramolecular energy transfer in excited **1** by a time-correlated single-photon counting method. For these complexes, the rate constant of the intramolecular energy transfer (k_{en}) decreases with increasing number of methylene chains. The results are elucidated by the Förster mechanism. Electron localization in the excited MLCT state of the ruthenium part is also discussed in conjunction with the results for Ru(II)(bpy)$_2$Mebpy-[CH$_2$CH(OH)CH$_2$]-MebpyOs(II)-(bpy)$_2$, **3** and Ru(II)(Me$_2$bpy)$_2$Mebpy-[CH$_2$CH(OH)CH$_2$]-MebpyOs(II)(bpy)$_2$, **4**.

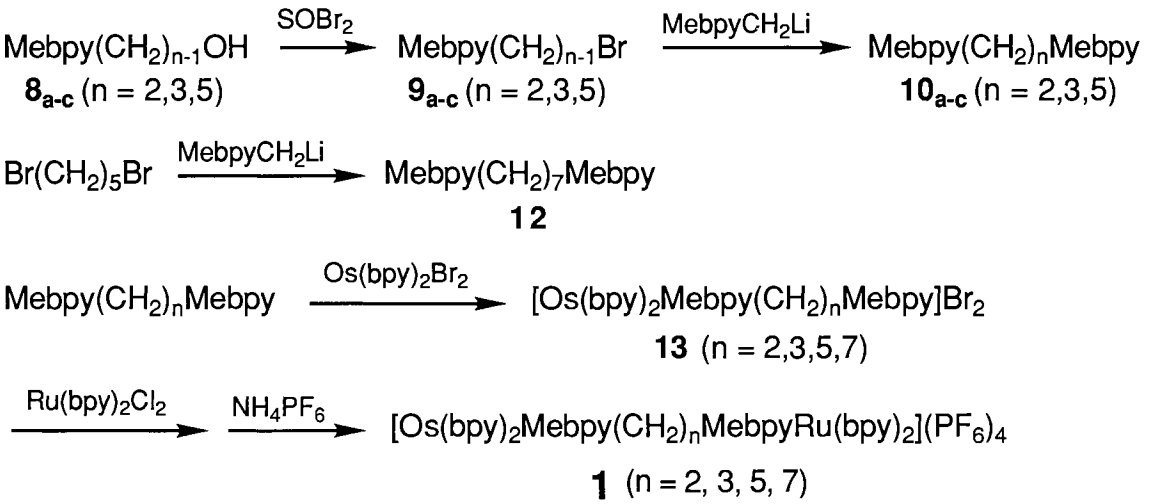
Experimental

Materials. The synthesis of **1** is outlined in Scheme 1. The starting material, 4,4′-dimethyl-2,2′-bipyridine, was purchased from Tokyo Kasei and recrystallized from ethanol.

4-Methyl-2,2′-bipyridine-4′-carbaldehyde (7). A mixture of 4,4′-dimethyl-2,2′-bipyridine (12.5 g, 68 mmol) and selenium dioxide (7.52 g, 68 mmol) in diglyme (120 ml) was stirred at 130—135 °C for 6 h. The reaction mixture was dissolved in 1 l of hot water and filtered to remove selenium metals. The filtrate was adjusted to pH 9—10 with an aqueous NaOH solution (10%) and extracted four times with 300 ml of the $CHCl_3$ portions. The extract was dried ($MgSO_4$) and evaporated to give a pale-yellow solid. Column chromatography on silica gel (ethyl acetate) afforded a white solid **7** (5.3 g, 40%), mp 135—136 °C: ^{1}H NMR ($CDCl_3$) δ=2.5(s, 3H), 7.0—9.0(m, 6H), 10.3 (s, 1H); IR (Nujol) 1710 cm^{-1}. Anal. Calcd for $C_{12}H_{10}N_2O$: C, 72.71; H, 5.08; N, 14.13. Found: C, 72.74; H, 5.11; N, 14.03%.

4-Hydroxymethyl-4′-methyl-2,2′-bipyridine (8a). A solution of **7** (5.3 g, 27 mmol) and sodium borohydride (3 g, 79 mmol) in anhydrous ethanol (350 ml) was stirred at room temperature for 1.5 h. Water (300 ml) was then added dropwise, and the mixture stirred at room temperature overnight. The solution was then extracted with $CHCl_3$ (4×300 ml). The extract was dried ($MgSO_4$) and evaporated to give a white solid. Recrystallization from ethanol provided 4.5 g (84%) of **8a**, mp 124—125 °C: ^{1}H NMR ($CDCl_3$) δ=2.4 (s, 3H), 3.9—4.6 (s, 1H), 4.7 (s, 2H), 7.0—8.6 (m. 6H); IR (Nujol) 3200 cm^{-1}. Anal. Calcd for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99%. Found: C, 72.27; H, 6.08; N, 13.98%.

4-Bromomethyl-4′-methyl-2,2′-bipyridine (9a). A mixture of **8a** (2.0 g, 10 mmol) and thionyl bromide (5 ml, 63 mmol) in 25 ml of CH_2Cl_2 was stirred at room temperature for 3 h under the flow of nitrogen gas. Water (200 ml) was added. The reaction mixture was neutralized (pH 8—9) with a saturated Na_2CO_3 solution and extracted with 500 ml of CH_2Cl_2.



Scheme 1.

After the extract was dried ($MgSO_4$) and evaporated below room temperature, the crude product was chromatographed on a silica-gel column by eluting with ethyl acetate–CH_2Cl_2 (3:2) to give 0.78 g (30%) of white crystals of **9a**, mp 76—77 °C: ^1H NMR ($CDCl_3$) δ=2.4 (s, 3H), 4.5 (s, 2H), 7.0—8.8 (m, 6H). Anal. Calcd for $C_{12}H_{11}N_2Br$: C, 54.77; H, 4.21; N, 10.65%. Found; C, 54.48; H, 4.21; N, 10.56%.

Lithiation of 4,4′-Dimethyl-2,2′-bipyridine. To a solution of 4,4′-dimethyl-2,2′-bipyridine (3.4 g, 18 mmol) in 200-ml of THF, lithium diisopropylamide (12 mmol) in THF (10 ml) was added at 0 °C under an argon atmosphere. After the solution was stirred for 1.5 h it was ready for subsequent steps.

1,2-Bis(4′-methyl-2,2′-bipyridyl-4-yl)ethane (10a). To a stirred solution of lithiated 4,4′-dimethyl-2,2′-bipyridine, **9a** (2.0 g, 7.6 mmol) in 70 ml of THF was added dropwise at room temperature. The mixture was stirred for 1 h. Methanol (10 ml) and then water (100 ml) were added. The resulting solution was extracted with 1 l of ether. The extract was dried ($MgSO_4$) and evaporated. The residue was placed on a silica gel column, eluted with a gradient mixture of ethyl acetate–CH_2Cl_2 from 1:9 to 3:1 to remove any 4,4′-dimethyl-2,2′-bipyridine and unidentified by-products, and with methanol to provide a white solid of **10a**. Recrystallization from ethanol yielded 1.4 g (50%) of **10a**, mp 198—199 °C: ^1H NMR ($CDCl_3$) δ=2.5 (s, 6H), 3.2 (s, 4H), 7.0—9.0 (m, 6H). Anal. Calcd for $C_{24}H_{22}N_4$: C, 78.66; H, 6.05; N, 15.29%. Found: C, 78.66; H, 6.05; H, 15.23%.

4-(2-Bromoethyl)-4′-methyl-2,2′-bipyridine (9b). Using 4-(2-hydroxyethyl)-4′-methyl-2,2′-bipyridine, **8b**[28] (3.0 g, 14 mmol) and thionyl bromide (7.5 ml, 95 mmol) as the starting materials, the reaction was worked up using the procedure described regarding the preparation of **9a**. It provided 1.8 g (46%) of **9b** as a clear oil: ^1H NMR ($CDCl_3$) δ=2.4 (s, 3H), 3.2 (t, 2H), 3.6 (t, 2H), 7.0—8.7 (m, 6H). Anal. Calcd for $C_{13}H_{13}N_2Br$: C, 56.52; H, 4.71; N, 10.07%. Found; C, 56.52; H, 4.82; N. 10.15%.

1,3-Bis(4′-methyl-2,2′-bipyridyl-4-yl)propane (10b). 10b was prepared from **9b** (1.3 g, 5 mmol) by the same procedure described regarding the preparation of **10a**. 4-Methyl-4′-vinyl-2,2′-bipyridine (0.3 g) as a by-product was obtained from the early eluates. Yield of **10b** was 1.2 g (63 %), mp 128 °C: ^1H NMR ($CDCl_3$) δ=2.1 (q, 2H), 2.4 (s, 6H), 2.8 (t, 4H), 7.0—8.7 (m, 12H). Anal. Calcd for $C_{25}H_{24}N_4$; C, 79.04; H, 6.32; N, 14.64%. Found: C, 78.71; H, 6.41; N, 14.61%.

1,3-Bis(4′-methyl-2,2′-bipyridyl-4-yl)-2-propanol (11). Ethyl formate (0.88 ml, 12 mmol) was added dropwise to a solution of monolithiated 4,4′-dimethyl-2,2-bipyridine (30 mmol) in 150 ml of THF at room temperature. The mixture was stirred overnight at room temperature, quenched with 150 ml of water, neutralized (pH 8—9) with 10% (v/v) methanolic HCl, and extracted four times with 100 ml $CHCl_3$ portions. The extracts were dried ($MgSO_4$) and evaporated to give a brownish-yellow solid. Purification of the crude product was achieved through several recrystallizations from methanol to provide a white solid **11** in a yield of 20%, mp 159—160 °C. ^1H NMR ($CDCl_3$) δ=2.45 (s, 6H), 2.93 (dd, 4H), 4.33 (m, 1H), 7.12—8.54 (m, 12H), MS *m/z* 396. Anal. Calcd for $C_{25}H_{24}NO$: C, 75.73; H, 6.10; N, 14.13%. Found: C, 75.93; H, 6.12; N, 13.97%.

4-(4-Hydroxybutyl)-4′-methyl-2,2′-bipyridine (8c). To a solution of lithiated 4,4′-dimethyl-2,2′-bipyridine (48 mmol), 1-bromo-3-(tetrahydro-2-pyranyloxy)propane[29] (10 g, 45 mmol) in 70-ml of THF was added dropwise. The resulting mixture was stirred overnight at room temperature. Methanol (10 ml) and then water (100 ml) were added. The solution was extracted with 1 l of chloroform. The extract was dried ($MgSO_4$) and evaporated. The residue was placed on an alumina column and eluted with benzene to provide 11.7 g of 4-methyl-4′-[4-(tetrahydro-2-pyranyloxy)butyl]-2,2′-bipyridine. ^1H NMR ($CDCl_3$) δ=1.4—1.8 (m, 10H), 2.4 (s, 3H), 2.7 (t, 2H), 3.3—4.0 (m, 4H), 4.6 (t, 2H), 7.0—8.6 (m, 6H). 4-Methyl-4′-(4-tetrahydropyran-2-yloxybutyl)-2,2′-bipyridine (11.7 g) in 300 ml of ethanol was treated with *p*-toluenesulfonic acid to give 3.3 g (30%) of **8c**. ^1H NMR ($CDCl_3$) δ=1.7 (m, 4H), 2.4 (s, 3H), 2.7 (t, 2H), 3.6 (t, 2H), 7.1—8.6 (m, 6H).

4-(4-Bromobutyl)-4′-methyl-2,2′-bipyridine (9c). A mixture of **8c** (3.5 g, 14 mmol) and thionyl bromide (25 g, 120 mmol) in 30 ml of CH_2Cl_2 was stirred at room temperature for 3 h under the flow of nitrogen gas. Water (200 ml) was added. The reaction mixture was neutralized (pH 8—9) with an aqueous solution saturated with Na_2CO_3 and extracted with 500 ml of CH_2Cl_2. After the extract was dried ($MgSO_4$) and evaporated below room temperature, the crude product was chromatographed on a silica-gel column by eluting with ethyl acetate–CH_2Cl_2 (3:2) to give 3.7 g (84%) of **9c**. ^1H NMR ($CDCl_3$): δ=1.8 (m, 4H), 2.4 (s, 3H), 2.7 (t, 2H), 3.4 (t, 2H), 7.1—8.6 (m, 6H).

1,5-Bis(4′-methyl-2,2′-bipyridyl-4-yl)pentane (10c).[30] To a solution of lithiated 4,4′-dimethyl-2,2′-bipyridine (24 mmol), **9c** (3.7 g, 12 mmol) in 30 ml of THF was added dropwise at room temperature. Methanol(10 ml) and then water (100 ml) were added. The resulting solution was extracted with 1 l of chloroform. The extract was dried ($MgSO_4$) and evaporated. The residue was placed on a silica gel column and eluted with a mixture of acetone–CH_2Cl_2 (1:9 v/v) to provide a white solid of **10c**. Recrystallization from methanol yielded 2.4 g (48 %) of **10c**, mp 115—116 °C; ^1H NMR ($CDCl_3$) δ=1.3—1.9 (m, 6H), 2.4 (s, 6H), 2.7 (t, 4H), 7.1—8.6 (m, 12H), MS *m/z* 408. Anal Calcd for $C_{27}H_{28}N_4$: C, 79.38; H, 6.91; N, 13.71%. Found: C, 79.40; H, 6.84; N, 13.70%.

1,7-Bis(4′-methyl-2,2′-bipyridyl-4-yl)heptane (12). To a solution of lithiated 4,4′-dimethyl-2,2′-bipyridine (27 mmol), 1,5-dibromopentane (1.85 ml, 14 mmol) was added dropwise at room temperature. The mixture was stirred for 20 h. The solution was quenched with methanol and neutralized with methanol–HCl. The reaction mixture was diluted with 100 ml of water and extracted with dichloromethane. The extract was dried ($MgSO_4$) and evaporated. The residue was placed on a silica-gel column and eluted with a mixture of CH_2Cl_2–acetone (9:1, v/v) to give a white solid. Recrystallization from ethanol yielded 2.2 g (37%) of **12**, mp 86—87 °C: ^1H NMR ($CDCl_3$) δ=1.36 (m, 6H), 1.69 (q, 4H), 2.43 (s, 6H), 2.67 (t, 4H), 7.11 (d, 4H), 8.21 (s, 4H), 8.53 (dd, 4H). Anal. Calcd for $C_{29}H_{32}N_4$: C, 79.78; H, 7.39; N, 12.83%. Found: C, 79.62, H, 7.36; N, 12.66%.

Os(II)(bpy)$_2$Mebpy-(CH$_2$)$_n$-Mebpy (13) and Ru(II)(bpy)$_2$-Mebpy-(CH$_2$)$_n$-MebpyOs(II)(bpy)$_2$(PF$_6$)$_4$ (1). Compound **13** was obtained by refluxing a mixture (10:1) of α,ω-bis(4′-methyl-2,2′-bipyridyl-4-yl)alkane and $Os(bpy)_2Br_2$ in methanol for 24 h. After the isolation of **13** by chromatography on a Sephadex LH-20 with a methanol eluent, treatment of **13** with $Ru(bpy)_2Cl_2$ in methanol under reflux, and then with ammonium hexafluorophosphate in water, afforded **1**. Compound **1** was purified by the same procedure with **13** and was recrys-

tallized from water as a PF_6^- salt.

Ru(II)(bpy)$_2$Mebpy-[CH$_2$CH(OH)CH$_2$]-MebpyOs(II)(bpy)$_2$ (3) and **Ru(II)(Me$_2$bpy)$_2$Mebpy-[CH$_2$CH(OH)CH$_2$]-MebpyOs(II)(bpy)$_2$, (4).** Compounds **3** and **4** were prepared from **11**, Os(bpy)$_2$Br$_2$, and Ru(bpy)$_2$Cl$_2$ (or Ru(Me$_2$bpy)$_2$Cl$_2$), according to the procedure described for **1**.

Measurements. Samples for luminescence measurements were deoxygenated by purging with argon gas. Solvents for spectroscopic measurements were purchased from Nakarai Chemicals as in spectrograde. Static absorption and luminescence measurements were performed using a Shimadzu UV-2100 spectrometer and an RF-502A spectrofluorimeter, respectively. The luminescence lifetime was measured by the time-correlated single photon counting method, as described elsewhere.[31] The luminescence lifetimes for the complexes at room temperature are listed in Table 1; the reported lifetimes represent the average of several independent determinations. Electrochemical measurements were performed in a conventional single-compartment cell equipped with a glassy carbon or platinum working electrode and a saturated calomel electrode as a reference electrode (SCE). All measurements were carried out using a NF function generator (FG-12113) and a Hokuto Potentiostat (HA-301) at a scan rate 0.2V s^{-1}. Tetrabutylammonium perchlorate (TBAP) was used as the supporting electrolyte and acetonitrile as the solvent. The sample solution (1 mM, 1 M=1 mol dm^{-3}) was deaerated by bubbling with argon gas.

Results and Discussion

The bridging ligand was first coupled with 1/10 equimolar Os(bpy)$_2$Br$_2$ and purified by repeated Sephadex LH-20 chromatography to remove any unreacted bridging ligand and Os(II)(bpy)$_2$Mebpy-(CH$_2$)$_n$-MebpyOs(II)-(bpy)$_2$. Treatment of Os(II)(bpy)$_2$Mebpy-(CH$_2$)$_n$-Mebpy with Ru(bpy)$_2$Cl$_2$ and ammonium hexafluorophosphate afforded **1** as a PF_6 salt. Purification of **1** was achieved by repreated chromatography using Sephadex LH-20 methanol as an eluent. On the basis of lifetime measurements, the possible existence of Ru(II)(bpy)$_2$Mebpy-(CH$_2$)$_n$-MebpyRu(II)(bpy)$_2$ or Ru(II)(bpy)$_2$Mebpy-(CH$_2$)$_n$-Mebpy as impurities was found to be less than 0.5%. (vide infra).

The redox and electronic properties of **1** in the ground state was compared with those of its component complexes, (4,4′-dimethyl-2,2′-bipyridine)bis(2,2′-bipyridine)osmium(II), **5**, and -ruthenium(II), **6**, and a 1:1 mixture of **5** and **6**. Redox potentials in acetonitrile (MeCN) were measured by cyclic voltammetry using a glassy carbon or a platinum electrode. As an illustration, a cyclic voltammogram of **1** (n=3) is shown in Fig. 1. Irrespective of the number of methylene chains, **1** shows two reversible oxidation waves at 0.78 and 1.22 V vs. SCE for the Os(III)/Os(II) and Ru(III)/Ru(II) couples, which correspond to those of **5** and **6**, respectively. The peak-to-peak splitting for these waves is 60—70 mV, indicating that in **1**, two successive one-electron oxidation processes take place. A typical absorption spectrum for **1** (n=3) in methanol is shown in Fig. 2. As showm in Fig. 2, the electronic absorption spectrum of **1** (n=3) is identical with the superimposed spectrum of equimolar **5** and **6**. This was also observed in **1** (n=2,5, and 7). Thus, a comparison for the redox and electronic properties of **1** with its component complexes gave no evidence of an interaction between the ruthenium and osmium moieties of **1** in the ground state. This represents a marked difference from the covalently linked porphyrin dimers, in which the interaction between the porphyrin rings has been reported.[14,15]

The luminescence spectra of **1** (excitation wavelength: 455 nm) was recorded with an argon-gas bubbled methanol solution at room temperature and compared with that of a 1:1 mixture of **5** and **6** at the same substrate concentration. The efficient quenching of emission at 615 nm from a ruthenium complex and the enhancement of emission intensity at 730 nm from osmium complex were observed in **1** (n=3). In a mixture of **5** and **6**, no such quenching process could be observed because of the low substrate concentration (Fig. 3). For all **1** systems, a comparison of the spectra given in Fig. 4 shows that the degrees of quenching at 615 nm and sensitization at 730 nm increase in shorter

methylene chains. The molar absorption coefficients of **5** and **6** at 455 nm are equal. This overlap of absorption endows the equal probability of excitation of the Ru and Os moieties in **1**. In Fig. 4, spectrum e reveals the contribution due to a direct excitation of an osmium complex of **1** at 455 nm. The enhancement of emission at 730 nm indicates that the sensitization of the osmium complex by an excited ruthenium complex occurs through an intramolecular process in **1**.

As for the quenching mechanism, energy transfer from *Ru(II) to Os(II) and reductive electron transfer from Os(II) to *Ru(II) are conceivable. In acetonitrile, the first reduction potential of the $Ru^{2+/+}$ couple is -1.39 V, and the first oxidation potential of the $Os^{3+/2+}$ couple is 0.78 V vs.SCE (by cyclic voltammetry). Since substitution of one bpy-ligand of $Ru(bpy)_3^{2+}$ and $Os(bpy)_3^{2+}$ with 4,4′-dimethyl-2,2′-bipyridine does not show a marked difference in the absorption and emission maxima, the excited energies of the Ru-complex and the Os-complex of **1** can be assumed to be almost the same as those of $Ru(bpy)_3^{2+}$ and $Os(bpy)_3^{2+}$, respectively. The excited-state energy of the Ru-complex and the Os-complex of **1** were estimated to be 2.10[32] and 1.78 eV,[33] respectively. The photophysical behavior of **1** can be described in terms of an energy level diagram that is simply made by superimposing the low-lying excited states of the $Ru(bpy)_3^{2+}$ and $Os(bpy)_3^{2+}$ units on

the redox potentials in the ground state. The reductive quenching of the excited Ru-complex is slightly endergonic (ΔG=0.07 eV) based on a comparison of the reduction potential (0.71 V) for the $Ru^{2+*/+}$ couple with the oxidation potential (0.78 V) for the $Os^{3+/2+}$ couple. On the other hand, energy transfer can be more favorable by 0.32 eV, which corresponds to the observed difference in the emission maxima of the Ru-complex (E_{em}=1.63×10⁴cm⁻¹) and the Os-complex (E_{em}=1.37×10⁴ cm⁻¹) of **1**. The thermodynamical aspect allows us to conclude that energy transfer instead of electron transfer constitutes the quenching mechanism.

The occurrence of energy transfer can be detected by observing the enhancement of the emission intensity of the osmium chromophore along with a decrease in the emission intensity of the ruthenium chromophore. The decay of $Ru^{II}\rightarrow\pi^*$(bpy) MLCT emission at 610 nm and the rise and decay of $Os^{II}\rightarrow\pi^*$(bpy) MLCT emission at 800 nm were measured in various solvents by using a time-correlated single photon counting method[31] (excitation wavelength at 457.9 nm and instrumental width of 300 ps). Deconvolution of the luminescence profiles at 610 nm afforded the best fit by single exponential decay. In some cases, a minor, long-lived component was present (<0.5%). The amplitude of this component was sensitive to the degree of sample purification, it therefore most probably represents an impurity. Figure 5 shows the emission decay profile of an excited Ru-complex of **1** (n=7) in MeCN, with which a computer-calculated fit is superimposed. The fast exponential decay (12.1 ns: 8.3×10⁷ s⁻¹) is attributed to a deactivation of the ruthenium-excited state by an intramolecular energy transfer to the osmium complex. The double exponential analysis for the rise and decay of the excited-osmium complex at 800 nm gave 12 ns (8.3×10⁷ s⁻¹) for a rise corresponding to a decay of the excited ruthenium complex and 56 ns (1.8×10⁷ s⁻¹) for the decay, respectively. Table 1 contains the parameter

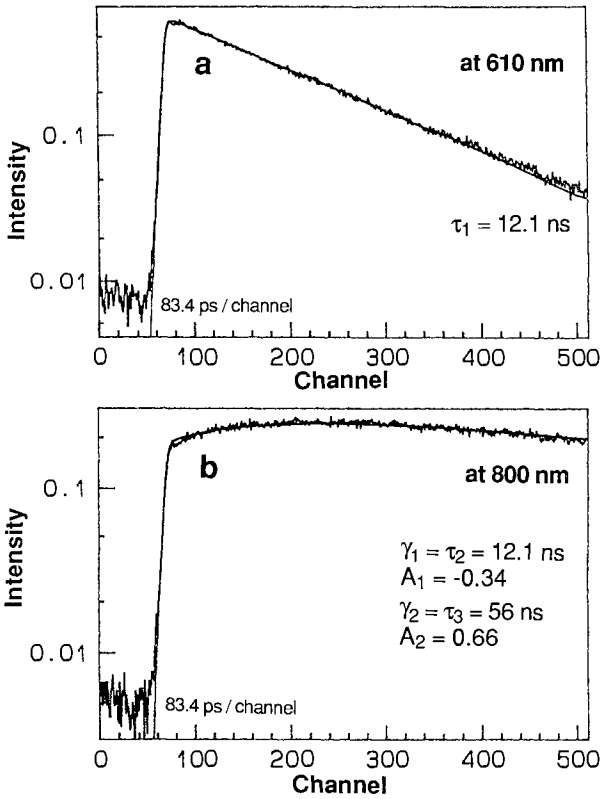

Fig. 5. Emission rise and decay for **1** (n=7) monitored at 610 nm (a) and 800 nm (b). 83.4 ps/channel, [**1**]=1×10⁻⁴M, solvent: MeCN.

Table 1. Emission Lifetimes and Energy-Transfer Rates[a]

Complex	Solvent	τ_1/ns[b]	τ_2/ns[c]	τ_3/ns[c]	k_{en}/s⁻¹[d]

a) All data represent averages and were measured at room temperature. The errors are less than 10%. b) Emission at 610 nm. c) Emission at 800 nm; the number in parenthesis indicates preexponential factors A_1 and A_2 for double exponential fit. d) Calcd from $1/\tau_1-1/\tau_0$; τ_0 is a lifetime of **6**. Values are 518, 729, and 859 ns in H_2O, EtOH, and MeCN, respectively. e) Average value of double exponential decay.

for the fit.

The excitation of **1**, denoted by Ru-C_n-Os at 457.9 nm, affords two excited states, namely *Ru-C_n-Os and Ru-C_n-Os* (Eq. 1a and 1b). In addition to the normal deactivation process (Eq. 1c and 1f), the reductive quenching of *Ru-C_n-Os by an intramolecular electron transfer process (Eq. 1d) and the buildup of Ru-C_n-Os* by the intramolecular energy transfer process (Eq. 1e) are taken into account:

$$\text{Ru-C}_n\text{-Os} \xrightarrow{h\nu} \text{*Ru-C}_n\text{-Os}, \quad (1a)$$

$$\text{Ru-C}_n\text{-Os} \xrightarrow{h\nu} \text{Ru-C}_n\text{-Os*}, \quad (1b)$$

$$\text{*Ru-C}_n\text{-Os} \xrightarrow{k_1} \text{Ru-C}_n\text{-Os} + (h\nu + \Delta), \quad (1c)$$

$$\text{*Ru-C}_n\text{-Os} \xrightarrow{k_{el}} \text{Ru-C}_n\text{-Os}, \quad (1d)$$

$$\text{*Ru-C}_n\text{-Os} \xrightarrow{k_{en}} \text{Ru-C}_n\text{-Os*}, \quad (1e)$$

and

$$\text{Ru-C}_n\text{-Os*} \xrightarrow{k_2} \text{Ru-C}_n\text{-Os} + (h\nu + \Delta). \quad (1f)$$

The relevant rate equations are

$$d[\text{*Ru-C}_n\text{-Os}]/dt = -(k_1 + k_{el} + k_{en})[\text{*Ru-C}_n\text{-Os}] \quad (2a)$$

and

$$d[\text{Ru-C}_n\text{-Os*}]/dt = k_{en}[\text{*Ru-C}_n\text{-Os}] - k_2[\text{Ru-C}_n\text{-Os*}] \quad (2b)$$

Equation (2b) yields

$$[\text{Ru-C}_n\text{-Os*}] = A_1\exp(-\gamma_1 t) + A_2\exp(-\gamma_2 t), \quad (3)$$

where $A_1=k_{en}[\text{*Ru-C}_n\text{-Os}]_0/(\gamma_2-\gamma_1)$, $A_2=[\text{Ru-C}_n\text{-Os*}]_0-A_1$, $\gamma_1=k_1+k_{el}+k_{en}$, $\gamma_2=k_2$, and $[\text{*Ru-C}_n\text{-Os}]_0$ and $[\text{Ru-C}_n\text{-Os*}]_0$ denote the initial concentration. γ_1 can be obtained from the decay time at 600 nm and the rise time at 800 nm. γ_2 can be also obtained from the decay time at 800 nm. The values of k_2 calculated from τ_3 ($=1/\tau_2$) in Table 1 are of the order of $2-5\times10^7$ s^{-1}. The value of k_1 is 2×10^6 s^{-1} based on the lifetime of **6**.

Since the molar absorption coefficients of **5** and **6** at 457.9 nm are quite similar, we can deduce $[\text{*Ru-C}_n\text{-Os}]_0=[\text{Ru-C}_n\text{-Os*}]_0$. The ratio of the preexponential factors is given by

$$A_2/A_1 = (k_2 - k_1 - k_{el})/k_{en} - 2. \quad (4)$$

As indicated in Table 1, the A_2/A_1 values from the parameter for the computer fits of the experimental rise, and the decay profiles at 800 nm are close to -2. Equation 4 yields $(k_2-k_1-k_{el})/k_{en}\approx0$. Since k_2 is of the order of $2-5\times10^7$ s^{-1} and k_1 is 2×10^6 s^{-1}, k_{el} can be estimated to be of the order of 10^7 s^{-1} or less. The values of γ_1 ($=k_1+k_{el}+k_{en}$) calculated from τ_1 in Table 1 are $8-1\times10^8$ s^{-1}. By combining the estimated values of k_1 and k_{el}, k_{en} is found to be of the order of 10^8 s^{-1}; thus, $k_{en}\gg k_{el}$. This implies that the quantum efficiency of the energy transfer is almost 1, irrespective of the length of the methylene chain examined in the present study. Accordingly the electron transfer process by reductive quenching can be ruled out regarding **1**.

The rate constant, k_{en}, of energy-transfer can then be calculated via

$$k_{en} = k_{obs} - k_1, \quad (5)$$

where k_{obs} and k_1 can be calculated from the observed lifetime (τ_1) at 610 nm and the emission lifetime of **6**, $Ru(bpy)_2(dmb)^{2+}$(dmb=4,4′-dimethyl-2,2′-bipyridine), respectively. As presented in Table 1, k_{en} depend strongly on the length of the methylene chain, and increase in shorter methylene chains. Two mechanisms are possible for the present energy-transfer. The Förster mechanism operates via a dipole-dipole interaction between the transition moment and, therefore, requires no direct contact between the energy donor and acceptor. The Dexter mechanism depends upon the electron exchange and, thus, requires a spatial overlap. Discrimination between the Förster and the Dexter mechanisms can be achieved by studying the effect of varying the donor-acceptor separation (R). The rate constant for the Förster dipole-dipole transfer is expected to fall off with the inverse sixth power of R. The rate constant of the Dexter transfer, however, is predicted to parallel any decrease in the electronic overlap with increasing R, which may approximated by an exponential function. Although it is admittedly difficult to estimate the distance of **1** (n=2), space-filling molecular models indicate that, by using the molecular radius 4.7 Å of $Ru(bpy)_3^{2+}$ and assuming a fully extended trans-conformation for alkane bridges of the bridging

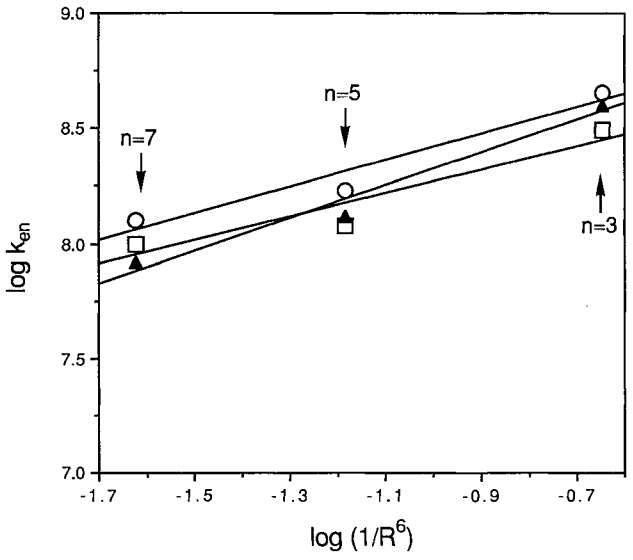

Fig. 6. Dependence of the rate of energy transfer on distance in various solvents. ○: in H_2O, ▲: in EtOH, and □: in MeCN.

ligands, the center-to-center separation distances in **1** are 12.8, 15.8, and 18.6 Å for n=3,5, and 7, respectively. It is adequate to evaluate R for a dipole–dipole interaction with a center-to-center rather than an edge-to-edge distance of both metal complexes. As shown in Fig. 6, the distance dependence of k_{en} in series **1** in water, ethanol, and acetonitrile can be fitted to an inverse sixth power law of the Förster mechanism. Instead, a steep drop of the rate is predicted by the Dexter mechanism in which k_{en} is expressed via an exponential dependence on the distance. Plots of the rate (k_{en}) vs. exp ($-R$) could not give a linear ralationship. These observations led us to conclude that a Förster-type interaction mechanism is operating in the intramolecular energy transfer in **1**.

A quantitative treatment of the Förster mechanism leads to the following expression for k_{en};[23]

$$k_{en} = \frac{9000 \ln 10 \kappa^2 \phi_D}{128\pi^5 n^4 N \tau_D R^6} \int_0^\infty F_D(\nu)\varepsilon_A(\nu)\frac{d\nu}{\nu^4} \qquad (6)$$

Here, ν is the wave number, $F_D(\nu)$ is the spectral distribution of the donor emission in quanta normalized to unity, $\varepsilon_A(\nu)$ is the molar extinction coefficient for the acceptor absorption, n is the refractive index of the solvent, κ is an orientation factor which equals $(2/3)^{1/2}$ for a random distribution of donor and acceptor molecules, ϕ_D is the quantum yield of donor emission, τ_D is the actual donor emission lifetime, N is Avogadro's number, and R is the distance between the donor and acceptor molecules. The overlap integral was calculated from numerical integration over the emission of **6** and the absorption of **5** in water and the value was 5.57×10^{-11} mol^{-1} cm^6. Based on the observed values of ϕ_D=0.028 and τ_D=4.77×10^{-7} s and assuming κ^2=2/3 and R=12.8 Å for **1** (n=3), the calculated k_{en} value was 1.4×10^8 s^{-1}, which was reasonably close to the observed value (4.5×10^8 s^{-1}).

Creutz and Sutin reported that the bimolecular quenching rate constant between excited $Ru(bpy)_3^{2+}$ and $Os(bpy)_3^{2+}$ was 1.5×10^9 M^{-1} s^{-1}, and that the reaction is almost diffusion-controlled.[34] The observed first-order rate constant for **1** seemed unexpectedly small. This fact might result from an electrostatic repulsion between two chromophores of **1**, which prevents any collisional quenching process based on an electron exchange (Dexter mechanism). It has been known that the intramolecular electron transfer via collisional processes in a trimethylene-linked donor-acceptor is influenced the solvent viscosity.[35] The dependence of solvent viscosity on the energy transfer rate (k_{en}) was examined for **1** (n=5) in three different solvents [ethanol(0.012), ethylene glycol (0.17), and glycerol (10.7) (in parentheses: viscosity in poise)]. In spite of the large difference in the viscosity, the observed k_{en} were in good agreement, that is, $(1.1—1.2)\times10^8$ s^{-1} irrespective of the solvent used. This finding also supports the Förster mechanism.

As shown in Table 1, a remarkable difference of k_{en} between **3** and **4** exists. According to the Förster formulation (Eq. 6), the rate constant is proportional to the spectral overlap and the reciprocal value of the radiative lifetime. The emission maxima (E_{em}), quantum yields (ϕ_{em}) and emission lifetime in water are 1.63×10^4 cm^{-1}, 0.028, and 477 ns for $Ru(bpy)_2(dmb)^{2+}$ and 1.61×10^4 cm^{-1}, 0.023, and 333 ns for $Ru(dmb)_3^{2+}$, respectively, which correspond to the ruthenium complex of **3** and **4**. Hence, the true radiative lifetimes are 17.0 μs for $Ru(bpy)_2(dmb)^{2+}$ and 14.5 μs for $Ru(dmb)_3^{2+}$. These values can not explain the observed differences. It is known that the excited electron in MLCT excited state of $Ru(bpy)_3^{2+}$ is fully localized on one of three equivalent ligands, at least for a time long enough for this ligand and its neighboring solvent to adjust to the geometry of fully charged bpy^-. Vibrational relaxation and localization have been suggested to come to completion within a few picoseconds.[36] In **3**, optical electron may preferentially reside on a bridging ligand rather than on a bpy ligand. On the contrary, the MLCT transition involves the π* orbital of dmb ligands, rather than a bridging ligand in **4**. The orientation of the MLCT transition in **4** is possibly more favorable for the dipole–dipole interaction.

In the Förster mechanism, the mutual orientation of donor and acceptor complexes is important for determining the energy transfer rate. The polypyridine complex has two configurational isomers, namely *Δ* and *Λ*-isomers. It has been recognized that the dimer of polypyridine ruthenium complex, **2** (n=3), consists of a 1:1 diastereomeric mixture of (*Δ*–*Δ*) and (*Δ*–*Δ*+*Λ*–*Λ*).[12] **1** is also assumed to have the same composition of configurational isomers. A careful examination of the decay profiles indicates that there is no marked difference in the rate of the intramolecular energy transfer between these configurational isomers. Solvation may also cause a conformational change. The binuclear complex, **3** has an OH group on the bridging ligand. Protic solvents may interact with the OH group of **3**. Since the photophysical behavior of **1** (n=3) and **3** is quite the same, such an interaction is not important for intramolecular energy transfer.

It can be concluded that electrostatic repulsion prevents any collisional interaction between two chromophores of **1**, and that the dipole–dipole interaction is the main pathway for intramolecular energy transfer. The structural difference due to the configuration (*Δ* and *Λ*) of each chromophores is not important in the intramolecular energy transfer in the present case.

(Received December 25, 1990)

A series of push-pull butadiene dyes (new merocyanine dyes) containing 3,6-bis(dimethylamino)fluorenylidene, thioxanthenylidene, or 10-(9-xanthenylidene)-9(10*H*)-anthrylidene chromophore was easily synthesized from the corresponding 1,1-diaryl-2-propyn-1-ol systems. Their absorption spectral properties were examined and the relationship between their light absorption properties and chemical structures is discussed in comparison with the results from PPP-SCF-CI-MO calculations. The influence of the solvent polarity on the $1/\lambda_{max}$(=wave number)-values of the dyes was investigated, and the solvatochromic nature compared with the known solvent polarity parameters such as E_T30, Z, χ_R, π^*_{azo} on 2-[2-[3,6-bis(dimethylamino)fluorenylidene]ethylidene]-1,3-indandione.

Merocyanine dyes are a well-known class of dyes, which have such practical applications as photoconductive or imaging materials (photographic films or electrographic systems);[2)] they have also been proposed as dyes for organic solar cells.[3)] Moreover, these dyes are used as important materials for photophysical[4)] or biochemical investigations.[5)] More recently, special interest has been focused on these dyes as possible candidates for nonlinear optics, owing to the development of optical and laser storage technologies.[6)]

During the course of our studies on the acetylenic analogs of triphenylmethane dyes (triphenylmethane dye ethynologs),[7)] we have developed a simple and convenient method for the preparation of aryl-substituted push–pull butadienes, a family of merocyanine dyes.[8)]

In this paper we report on the syntheses of novel push–pull-type merocyanine dyes containing bis[4-(dimethylamino)]phenylmethylene (**A**), 3,6-bis(dimethylamino)-fluorenylidene (**B**), thioxanthenylidene (**C**), and 10-(9-xanthylenylidene)-9(10*H*)-anthrylidene (**D**) chromophores from the corresponding 1,1-diaryl-2-propyn-1-ols. Successively, a mutual relation between their light-

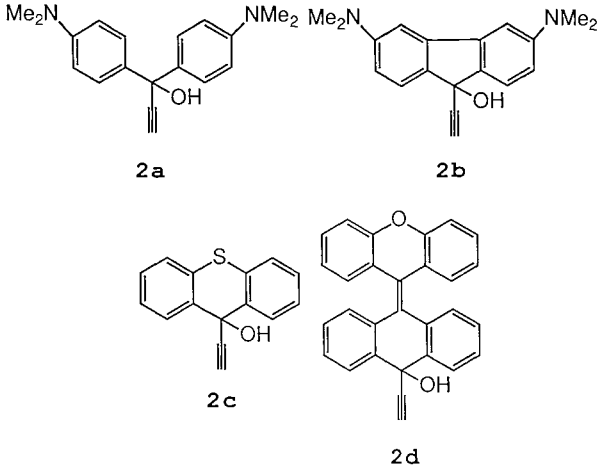
absorption properties and chemical structures was investigated and compared with Pariser–Paar–Pople MO (PPP-MO) calculations. Moreover, the solvatochromic properties were examined on 2-[2-[3,6-(dimethylamino)fluorenylidene]ethylidene]-1,3-indandione (**3b**) as a representative of the prepared dyes.

Results and Discussion

Synthesis of Dyes. Each of the precursors, i.e., the 1,1-diaryl-2-propyn-1-ol systems (**2a—d**), were prepared by ethynylation of the corresponding ketones.[9] Several nucleophiles, i.e., active methylene compounds, were allowed to react with **2a—d**, yielding a variety of new merocyanine dyes [(**3a—d**—**5a—d**), (**6a—c**), (**7a, b**), (**8a, b**), and (**9b**)], as shown in Scheme 1. In some cases the reactions proceeded easily at ambient temperature by mixing the substrates and each reagent without either heating or adding a catalyst, e.g., reactions with barbituric acid or thiobarbituric acid. Although isolated yields were good for the above-mentioned cases; in some cases appropriate heating was necessary to complete the reaction; there were also cases in which no reaction proceeded (see Experimental). It seems apparent that these reactivities depend on both the acidity of the nucleophiles employed and the electrophilicity of the substrates. A sort of acid-catalyzed propargylic rearrangement would participate in the reaction;[10] a plausible reaction process is shown in Scheme 2.



Absorption Spectral Properties. Absorption spectral data for the longest wavelength region of the prepared dyes are listed in Table 1. The bathochromic shift of the absorption band of the push–pull butadiene dyes (**A—D**) (Chart 1) depended on the electron-donating residue according to the sequence: **D>B>A>C**. The influence of the electron acceptor residue similarly followed the

order: 3-(dicyanomethylene)-1-indanone>thiobarbituric acid>barbituric acid>1,3-indandione>malononitrile>anthrone>acetylacetone. The dicyanovinylindanone derivative of 3,6-bis(dimethylamino)fluorenylidene dye (**9b**) absorbs in the longest region among the dyes investigated (707 nm). The calculated results by the PPP-SCF-CI-MO method are also shown in Table 1.[11] The calculations were carried out on some of the **A** and **B** systems with the normal parameter sets proposed by Griffiths.[12] Although reasonable results were obtained in some of the compounds studied, there is some disagreement regarding **3a**, **b** and for the barbiturate series (or thiobarbiturate series), which in some cases showed deviations of 50—70 nm between the observed and calculated results with diketo forms. In barbituric or thiobarbituric acid derivatives, tautomeric effects might be considered to explain the experimental results. From the calculated results of **4b**, considering not only diketo forms but also keto/enol or dienol forms (see Table 2), however, no significant difference was observed between them, giving slightly better results in the keto/enol forms (**4b**$_2$ and **4b**$_3$). The bathochromic behavior of the thiobarbituric acid derivatives, compared with that of barbituric derivatives, agreed well with the calculated results. Also, the bathochromic tendency by ring closure of the *o*- and *o'*-positions of the diphenylmethane

component of **A** to the fluorenylidene component, **B**, was well reproduced by a MO calculation, i.e., a lowering tendency of the LUMO level of the diphenylmethane component by ring closure was elucidated by a comparison of each of the MO energy levels.[13] This shift was calculated to be 18—39 nm, showing reasonable agreement to the experimental shift (21—45 nm in EtOH).

Since one of the most remarkable shifts was observed for **3b**, we further investigated the solvatochromic effect by using 17 kinds of solvents. As shown in Table 3, the linear bathochromicity of the absorption of the longest wavelength was observed according to an increase in the solvent polarity. The correlation was investigated between the solvatochromism of the dye and the commonly used solvent polarity parameters: Dimroth and Reicharts' E_T30;[14] Kosower's Z;[15] Brooker's χ_R;[16] as well as recently proposed Buncel's π^*_{azo}.[17] As shown in Fig. 1, a good correlation was observed for the latter two, which are both based on merocyanine dyes. On the contrary, a weaker correlation was found for the former two (Correlation coefficient: r=0.92 and 0.87), both based on ionic betaine dyes. Because of the case of preparation and clear solvatochromic behavior, **3b** would be a possible candidate for a solvent polarity parameter.

In conclusion, four series of push–pull butadiene-type merocyanine dyes **A**—**D** were prepared by reactions of the corresponding diarylpropynols with various nucleophiles. The absorption spectral properties of **A**—**D** were investigated along with the calculated results by PPP-MO method, showing the characteristic spectral behavior derived from the electron-donating nature of the donor part and electron-withdrawing nature of the acceptor part. The solvatochromic nature of **3b** was estimated by using 17 solvent sets to make comparisons with the commonly used E_T30, Z, χ_R, or π^*_{azo} giving good correlations with the latter two.

Experimental

All of the melting points are uncorrected. UV-visible spectra were recorded on Shimadzu UV-265F and Hitachi 210 spectrometers. IR spectra were obtained on a JASCO IRA 810 spectrophotometer. ^{1}H NMR spectra were measured on a JNM-GX 400 spectrometer; the chemical shifts are given in δ-values with respect to TMS used as an internal standard. MS spectra were taken using a JEOL JMS-DX 303 mass spectrometer.

Preparation of Alcohols (2b—d):[9] **General Method.** The reaction of an excess amount (ca. 5—15 equiv) of lithium acetylide (prepared by Midland's method[18]) with the ketones[19] in THF at −60 °C for several h gave the corresponding alcohols

Synthesis of Merocyanine Dyes: Bis[4-(dimethylamino)-phenyl]methylene System; General Method [Indandione Derivative (3a)]. 1,3-Indandione (50 mg, 0.17 mmol) was mixed with acetylenic alcohol (**2a**) (25 mg, 0.17 mmol) in EtOH (20 ml) at ambient temperature. The resulting violet solution was then heated under reflux for 1 h. After concentrating the reaction mixture under reduced pressure, green needles, thus obtained, were filtered and dried in vacuo while affording an analytically pure sample (55 mg, 76%). Mp 182—183 °C (decomp). Found: C, 79.67; H, 6.31; N, 6.31%. Calcd for $C_{28}H_{26}N_2O_2$: C, 79.59; H, 6.20; N, 6.63%. In the same method, **4a**, **7a**, and **8a** were prepared. The preparations of **5a** and **6a** were already reported.[8]

4a: Deep red crystals, 79%. Mp 269—271 °C (decomp). Found: C, 66.51; H, 6.28; N, 13.35%. Calcd for $C_{23}H_{24}O_3N_4 \cdot 1/2H_2O$: C, 66.81; H, 6.09; N, 13.35%. IR (KBr) 3170 (NH), 1715 (C=O), 1655 (C=O), and 1595 cm^{-1} (C=C); FAB-MS (*m/z*) 405 (M+1); ^{1}H NMR (DMSO-d_6) δ=3.02 (12H, s, NMe_2), 6.76 (2H, d, *J*=10 Hz, ArH), 6.81 (2H, d, *J*=10 Hz, ArH), 7.09 (2H, d, *J*=10, ArH), 7.28 (2H, d, *J*=10 Hz, ArH), 7.83 (1H, d, *J*=14 Hz, olefinic H), 8.20 (1H, d, *J*=14 Hz, olefinic H), and 10.88 (2H, s, NH).

7a: Reddish brown crystals, 45%. Mp 277—278 °C (decomp). Found: C, 82.64; H, 6.62; N, 5.87%. Calcd for $C_{33}H_{30}N_2O \cdot 1/2H_2O$: C, 82.64; H, 6.51; N, 5.84%. IR (KBr) 1650 (C=O) and 1605 cm^{-1} (C=C); EI-MS (*m/z*) 470 (M$^+$); ^{1}H NMR ($CDCl_3$) δ=2.99 (6H, s, Me), 3.09 (6H, s, Me), 6.65 (2H, d, *J*=9 Hz, ArH), 6.81 (2H, d, *J*=9 Hz, ArH), and 6.68—8.42 (14H, m, ArH and olefinic H).

8a: Reddish-orange crystals, 80%. Mp 159—160 °C (decomp). Found: C, 76.49; H, 7.56; N, 7.40%. Calcd for $C_{24}H_{28}N_2O_2$: C, 76.56; H, 7.50; N, 7.44%. IR (KBr) 1650 (C=O) and 1605 cm^{-1} (C=C); EI-MS (*m/z*) 376 (M$^+$). ^{1}H NMR ($CDCl_3$) δ=2.19 (3H, s, Me), 2.43 (3H, s, Me), 3.00 (6H, s, Me) 3.04 (6H, s, Me), 6.61 (2H, d, *J*=9 Hz, ArH), 6.73 (2H, d, *J*=9 Hz, ArH), 6.89 (1H, d, *J*=11 Hz, olefinic H), 7.15 (2H, d, *J*=9 Hz, ArH), 7.30 (2H, d, *J*=9 Hz, ArH), and 7.37 (1H, d, *J*=11 Hz, olefinic H).

3,6-Bis(dimethylamino)fluorenylidene System: General Method [Indandione Derivative (3b)]. To a stirred solution of acetylenic alcohol (**2b**) (0.20 g, 0.68 mmol) in EtOH (40 ml) was added 1,3-indandione (0.11 g, 0.68 mmol) at ambient temperature. After stirring for 3 h, the reaction mixture was concentrated in vacuo to give crystals, which were recrystallized from dichloromethane. Compound **3b** was obtained as deep green crystals (0.24 g, 84%). Mp 240 °C. Found: C, 79.59; H, 5.89; N, 6.58%. Calcd for $C_{28}H_{24}N_2O_2$: C, 79.98; H, 5.75; N, 6.66%. IR (Nujol) 1710, 1660 (C–O), and 1600 cm^{-1} (C=C); EI-MS (*m/z*) 420 (M$^+$); ^{1}H NMR ($CDCl_3$) δ=3.10 (6H, s, Me), 3.11 (6H, s, Me), 6.40—6.60 (2H, m, ArH), 6.80—6.90 (2H, m, ArH), 7.60—8.00 (6H, m, ArH), 8.24 (1H, d, *J*=14 Hz, olefinic H), and 8.55 (1H, d, *J*=14 Hz, olefinic H). In the similar method, barbituric and thiobarbituric acid derivatives (**4b** and **5b**) were prepared.

4b: Deep bluish-violet crystals, 88%. Mp 305 °C. Found: C, 65.70; H, 5.43; N, 13.39%. Calcd for $C_{23}H_{22}N_4O_3 \cdot H_2O$: C, 65.70; H, 5.75; N, 13.33%. IR (Nujol) 1730, 1625 (C=O), and 1603 cm^{-1} (C=C); FAB-MS (*m/z*) 403 (M+1); ^{1}H NMR (DMSO-d_6) δ=3.11 (12H, s, Me), 6.59 (1H, d, *J*=9 Hz, ArH), 6.63 (1H, d, *J*=9 Hz, ArH), 7.25 (2H, d, *J*=9 Hz, ArH), 7.46 (1H, d, *J*=9 Hz, ArH), 7.73 (1H, d, *J*=9 Hz, ArH), 8.19 (1H, d, *J*=14 Hz, olefinic H), 8.84 (1H, d, *J*=14 Hz, olefinic H), 11.00 (1H, s, NH), and 11.06 (1H, s, NH).

5b: Deep blue crystals, 74%. Mp >330 °C. Found: 63.33; H, 5.35; N, 12.85%. Calcd for $C_{23}H_{22}N_4O_2 \cdot H_2O$: C, 63.28; H, 5.35; N, 12.85%. IR (Nujol) 1680, 1640 (C=O), and 1605 cm^{-1} (C=C); FAB-MS (*m/z*) 419 (M+1); ^{1}H NMR (DMSO-d_6) δ=3.14 (12H, s, Me), 6.58 (1H, d, *J*=9 Hz, ArH), 8.20 (1H, d, *J*=14 Hz, olefinic H), 8.81 (1H, d, *J*=14 Hz, olefinic H), 12.10 (1H, s, NH), and 12.17 (1H, s, NH). In the cases of malononitrile, anthrone, acetylacetone, and 3-(dicyanomethylene)-1-indanone derivatives (**6b—9b**), appropriate heating for several hours was necessary due to the low reactivities of the reactants.

6b: Deep green crystals, 78%. Mp 300—305 °C. Found: C, 77.53; H, 5.97; N, 16.38%. Calcd for $C_{22}H_{20}N_4$: C, 77.62; H, 5.92; N, 16.46%. IR (Nujol) 2210 (C≡N) and 1605 cm^{-1} (C=C); EI-MS (*m/z*) 340 (M$^+$); ^{1}H NMR ($CDCl_3$) δ=3.14 (12H, s, Me), 6.40—6.60 (2H, m, ArH), 6.83 (2H, d, *J*=2 Hz, ArH), 6.90 (1H, d, *J*=13 Hz, olefinic H), 7.49 (2H, d, *J*=8 Hz, ArH), and 8.34 (1H, d, *J*=13 Hz, olefinic H).

7b: Deep reddish-violet crystals, 35%. Mp 289—292 °C. IR (Nujol) 1660 (C=O) and 1600 cm^{-1} (C=C); FAB-MS (*m/z*) 469 (M+1); ^{1}H NMR ($CDCl_3$) δ=3.09 (6H, s, Me), 3.15 (6H, s, Me), 6.50—7.10 (4H, m, ArH and olefinic H), 7.35—7.70 (6H, m, ArH and olefinic H), and 7.90—8.45 (6H, m, ArH and olefinic H).

8b: Brown crystals, 28%. Mp 210 °C. Found: C, 76.72; H, 6.68; N, 8.01%. Calcd for $C_{24}H_{26}N_2O_2$: C, 76.98; H, 7.00; N, 7.48%. EI-MS (*m/z*) 374 (M$^+$); IR (Nujol) 1640 (C=O) and 1610 cm^{-1} (C=C); ^{1}H NMR ($CDCl_3$) δ=2.48 (6H, s, Me), 3.10 (6H, s, Me), 3.12 (6H, s, Me), 6.50—6.65 (2H, m, ArH), 6.85—7.10 (3H, m, ArH and olefinic H), 7.40—7.80 (2H, m, ArH), and 8.29 (1H, d, *J*=13 Hz, olefinic H).

9b: Deep green crystals, 84%. Mp 274—278 °C. IR (Nujol) 2230 (C=N), 1700 (C=O), and 1600 cm^{-1} (C=C); EI-MS (*m/z*) 468 (M$^+$); ^{1}H NMR (DMSO-d_6) δ=3.46 (12H, s, NMe_2), 6.49 (2H, dd, *J*=2, 9 Hz, ArH), 7.16 (2H, d, *J*=9 Hz, ArH), 7.68—7.82 (5H, m, ArH), 8.45—8.55 (2H, m, ArH and olefinic H), and 8.97 (1H, d, *J*=14 Hz, olefinic H).

Thioxanthenylidene System: General Method [Indandione Derivative (3c)]. 1,3-Indandione (0.12 g, 0.84 mmol) was added to a stirred solution of acetylenic alcohol (**2c**) (0.20 g, 0.84 mmol) in EtOH. After stirring for 30 min, the reaction

mixture was heated under reflux for 3 h and then evaporated under reduced pressure to give deep reddish-violet crystals, which after recrystallization from dichloromethane yielded 0.13 g (43%). Mp 232 °C. IR (Nujol) 1720, 1690 (C=O), and 1600 cm^{-1} (C=C); EI-MS (*m/z*) 366 (M^+); ^1H NMR ($CDCl_3$) δ=7.37—8.00 (13H, m, ArH and olefinic H) and 8.33 (1H, d, *J*=12 Hz, olefinic H).

4c: Reddish-violet crystals, 38%. Mp 328—329 °C. Found: C, 64.72; H, 3.59; N, 7.85%. Calcd for $C_{19}H_{12}N_2O_3 \cdot 0.3H_2O$: C, 64.51; H, 3.59; N, 7.92%. IR (Nujol) 1640 (C=O) and 1560 cm^{-1} (C=C); FAB-MS (*m/z*) 349 (M+1); ^1H NMR (DMSO-d_6) δ=7.45—7.88 (8H, m, ArH), 8.02 (1H, d, *J*=12 Hz, olefinic H), 8.30 (1H, d, *J*=12 Hz, olefinic H), and 11.15 (2H, s, NH).

5c: Brown crystals, 85%. Mp >300 °C. Found: C, 61.95; H, 3.34; N, 7.20%. Calcd for $C_{19}H_{12}N_2O_2S_2 \cdot 0.2H_2O$: C, 62.01; H, 3.40; N, 7.61%. IR (Nujol) 1640 (C=O) and 1560 cm^{-1} (C=C); FAB-MS (*m/z*) 365 (M+1); ^1H NMR (DMSO-d_6) δ=6.98—7.63 (8H, m, ArH), 8.03 (1H, d, *J*=12 Hz, olefinic H), 8.33 (1H, d, *J*=12 Hz, olefinic H), and 12.25 (2H, m, NH).

6c: Brown crystals, 92%. Mp 290 °C. Found: C, 75.01; H, 3.83; N, 9.34%. Calcd for $C_{18}H_{10}N_2S$: C, 75.49; H, 3.52; N, 9.79%. IR (Nujol) 2240 (C≡N) and 1580 cm^{-1} (C=C); EI-MS (*m/z*) 286 (M^+); ^1H NMR ($CDCl_3$) δ=6.70 (1H, d, *J*=14 Hz, olefinic H), 7.26—7.57 (8H, m, ArH), and 7.81 (1H, d, *J*=14 Hz, olefinic H). Other derivatives, such as anthrone or acetylacetone, could not be prepared, even upon changing the reaction conditions: i.e., raising the reaction temperature by using alcohols with higher boiling points or prolonging the reaction time.

10-(9-Xanthenylidene)-9(10*H*)-anthrylidene System; General Method [Indandione Derivative (3d)]: 1,3-Indandione (37 mg, 0.25 mmol) was added to acetylenic alcohol (**2d**) (0.10 g, 0.25 mmol) in EtOH and the reaction mixture was heated under reflux for 24 h. Reddish-violet crystals were obtained after evaporating the solvent, adding ether, and recrystallizing the resulting crystals (42 mg, 32%). Mp >340 °C. IR (Nujol) 1630 (C=O) and 1590 cm^{-1} (C=C); FAB-MS (*m/z*) 526 (M+1); ^1H NMR ($CDCl_3$) δ=6.64 (2H, d, *J*=9 Hz, ArH), 7.26—7.79 (15H, m, ArH and olefinic H), and 8.70—8.92 (6H, m, ArH and olefinic H).

4d: Violet crystals, 35%. Mp >340 °C. Found: C, 74.40; H, 4.13; N, 5.00%. Calcd for $C_{33}H_{20}N_2O_4 \cdot 1.3H_2O$: C, 74.51; H, 4.28; N, 5.27%. IR (KBr) 1710, 1620 (C=O), and 1595 cm^{-1} (C=C); FAB-MS (*m/z*) 509 (M+1); ^1H NMR (DMSO-d_6) δ=6.69 (2H, d, *J*=9 Hz, ArH), 7.35—7.94 (12H, m, ArH and olefinic H), 8.66 (2H, d, *J*=9 Hz, ArH), 8.75 (1H, dd, *J*=2 and 9 Hz, ArH), 9.16 (1H, d, *J*=2 Hz, ArH), 10.44 (1H, s, NH), and 11.00 (1H, s, NH).

5d: Reddish-violet crystals, 57%. Mp >340 °C. Found: C, 72.49; H, 3.86; N, 4.97%. Calcd for $C_{33}H_{20}N_2O_3S \cdot 1.3H_2O$: C, 72.49; H, 4.16; N, 5.11%. IR (KBr) 1630 (C=O) and 1595 cm^{-1} (C=C); FAB-MS (*m/z*) 524 (M+1); ^1H NMR (DMSO-d_6) δ=6.77—7.00 (2H, m, ArH), 7.29—8.04 (12H, m, ArH and olefinic H), 8.66 (2H, d, *J*=9 Hz, ArH), 8.84 (1H, dd, *J*=2 and 9 Hz, ArH), 9.25 (1H, s, ArH), and 11.54 (2H, s, NH). Other derivatives such as malononitrile, anthrone, or acetylacetone derivatives could not be isolated.

We thank Professors (Emeritus) Masazumi Nakagawa of Osaka University, Masahiko Iyoda of Tokyo Metropolitan University, and Teijiro Kitao of University of Osaka Prefecture for helpful discussions. Financial support by Grants-in-Aid for Scientific Research Nos. 62470035 and 63540406 from the Ministry of Education, Culture and Science is gratefully acknowledged.

Syntheses of Titanium Butoxide Tris(polyfluoroalkanoate) and Surface Modification of Calcium Carbonate

Norio YOSHINO,* Yukihide SHIRAISHI, and Hidefumi HIRAI
Department of Industrial Chemistry, Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received January 29, 1991)

Titanium butoxide tris(5*H*-octafluoropentanoate), $Ti(O^nC_4H_9)[OCO(CF_2)_4H]_3$, titanium butoxide tris(7*H*-undecafluoroheptanoate), $Ti(O^nC_4H_9)[OCO(CF_2)_6H]_3$, titanium butoxide tris(9*H*-hexadecafluorononanoate), $Ti(O^nC_4H_9)[OCO(CF_2)_8H]_3$, and titanium butoxide tris(perfluorooctanoate), $Ti(O^nC_4H_9)[OCO(CF_2)_6CF_3]_3$, were prepared by the reaction of titanium butoxide trichloride with sodium fluoro-substituted acylates in 1,1,2-trichloro-1,2,2-trifluoroethane. These compounds were characterized on the basis of elemental analysis as well as their IR, ^1H NMR, ^{13}C NMR, and ^{19}F NMR spectra. In the compounds produced, a Ti–OCO bond was stable in water, although a Ti–OR bond was only moderately stable in water. A surface modification against calcium carbonate was attempted by using these products. From measurements of the contact angles $\theta(°)$ of water and toluene against a modified calcium carbonate surface, titanium butoxide tris(perfluorooctanoate) was found to be an effective substance for a new-type coupling agent, which increases the affinity between organofluoro polymers and some inorganic substances.

Metal alkoxides have been the subject of extensive research owing to their potential as precursor materials for several applications, such as new-ceramics, adhesives, and coupling agents, which are molecular bridges between the interface of an inorganic filler and an organic polymer. Many alkyl or aryl titanates and their halogenated derivatives were prepared[1] and the reactivities of these titanates towards various types of electron donors (such as amides, amines, ethers, and amino acids) have been reported.[2] The number of worldwide commercial applications for coupling agents established using monoalkoxyl-type titanates, such as titanium isopropoxide tris(2-heptylundecanoate), are now very substantial, as indicated by over one hundred patents.[3-6]

In recent years, dramatic developments have been made in the utilization of organofluoro compounds, resulting in materials with high performance. However, only a few research reports concerning fluoro-substituted alkoxides of metals have appeared in the literature.[7-11] In a previous paper we reported on the syntheses of fluoroalkyl and fluoroaryl titanates[12] as well as the syntheses of fluoroalkyl silicates.[13] Although these alkoxides were expected to be stable against moisture, since many of the compounds having the fluorinated carbon structure possess water repellency, all of the products were very sensitive to water and easy to decompose.

In this paper, the results of the syntheses and characterizations of new titanium compounds having both three fluoro-substituted alkanoyloxyl groups and one butoxyl group are reported. The application for the surface modification against calcium carbonate will be also reported.

Experimental

Special precautions were adopted in order to avoid any hydrolysis of the starting materials and products; all experiments were carried out under an atmosphere of purified nitrogen to preclude oxygen and moisture.

Materials. Titanium tetrachloride (bp 136 °C) and titanium tetrabutoxide (bp 184—185 °C/665 Pa) were commercially available and purified by distillation. Titanium butoxide trichloride (bp 94—96 °C/80 Pa) was synthesized by the method of Jennings;[16] Found: Ti, 20.1; Cl, 46.9%. Calcd for $C_4H_9Cl_3OTi$: Ti, 20.1; Cl, 46.8%. ^1H NMR (in THF-d_8, TMS standard) δ=0.92 (CH_3, t(triplet), J=6.0 Hz), 1.10—1.90 (CH_2–CH_2, m(multiplet)), 4.96 (OCH_2, t, J=6.0 Hz). 5*H*-octafluoropentanoic acid (bp 40—42 °C/120 Pa), 7*H*-undecafluoroheptanoic acid (bp 60—61 °C/100 Pa), 9*H*-hexadecafluorononanoic acid (bp 92—93 °C/53 Pa), and perfluorooctanoic acid (bp 89—90 °C/4000 Pa) were obtained from PCR Inc and purified by distillation. Sodium acylate derivatives were synthesized by the reaction of fluoro-substituted acids with excess sodium hydrogencarbonate in THF. The solvents used were purified by the usual methods. Calcium carbonate powder (specific gravity; 2.60, average particle size; 3.0×10^{-6} m, specific surface area (BET); 5.5 $m^2 g^{-1}$) was obtained from Shiraishi Industries, Ltd.

Measurements. FT-IR spectra were measured in a liquid film or by a KBr method with a JEOL JIR 5300 spectrophotometer. Pulsed Fourier Transform 100-MHz, ^1H and 25-MHz ^{13}C NMR were run in THF-d_8 with TMS as an internal standard using a JEOL JNR-PX-100 spectrometer at room temperature: ^1H NMR spectra (pulse repetition time, 5s; number of accumulations, 20) and ^{13}C NMR spectra (pulse repetition time, 2.0s; number of accumulations, 40000). The FT mode 90-MHz ^{19}F NMR was recorded at 27 °C on a JEOL JNM-FX-90Q in THF with fluorobenzene (−113.6 ppm[14] from $CFCl_3$ in $CDCl_3$) as an external standard: pulse repetition time, 0.5s; number of accumulations, 20. The assignments of the ^{19}F NMR spectra were referred to in the data book.[14] Gas chromatograms were performed with a Hitachi 063 (PEG-6000 supported Chromosorb A NAW 30/60 mesh 5 m packed column, TCD) or Hitachi G-3000 gas chromatograph (OV-1 25 m Fused capillary column, FID) and these intensities were measured with a Hitachi 834 chromato processor or a Hitachi D-2500 chromato integrator. The contact angles $\theta(°)$ were measured at 23 °C with a ELMA-Kougaku Co. Gonio-type apparatus. Ultrasonic operations were carried out using a Branson Ultrasonics Corporation Model 250 Sonifier Cell

Disruptor System (200 W, 20 kHz).

Analytical Methods. Titanium was determined gravimetrically as titanium oxide after the hydrolysis of titanium compounds by adding aqueous ammonia and burned in a quartz crucible. Chlorine was quantified by the Mohr method. Butoxyl group was measured quantitatively as 1-butanol by GLC after hydrolysis of the products by adding a sodium hydroxide solution. The contents of the fluorinated alkanoyloxyl group having hydrogen at the end of the chain were estimated indirectly from the intensities against oxymethylene protons in the butoxyl group by ^{1}H NMR spectra.

Synthesis of Titanium Butoxide Tris(polyfluoroalkanoate). Synthesis of Titanium Butoxide Tris(5*H*-octafluoropentanoate), Ti(O^{n}C$_4$H$_9$)[OCO(CF$_2$)$_4$H]$_3$: To a stirred solution of titanium butoxide trichloride, 2.00 g (8.75 mmol) in 110 ml 1,1,2-trichloro-1,2,2-trifluoroethane, sodium 5*H*-octafluoropentanoate 8.48 g (31.6 mmol) was added at room temperature into a two-necked 200-ml flask connected to a reflux condenser and a three-way stop cock. The heterogeneous mixture was refluxed with stirring for 10 h. Completion of the reaction was checked by adding a silver nitrate solution to a portion of the clear upper solution. Sodium chloride produced and excess sodium 5*H*-octafluoropentanoate were removed by filtration. A transparent slightly brown liquid was obtained after removing the solvent under reduced pressure (yield 5.25 g, 69.8%): IR 2970, 2943, 2883, 1772, 1716, 1684, 1653, 1443, 1400, 1362, 1333, 1275, 1227, 1170, 1130, 1080, 1051, 955, 926, 906, 802, 750, 708, 660, 582, 538, 536, 459 cm^{-1}; ^{1}H NMR δ=0.90(CH$_3$, t, J=8.1 Hz), 1.18—1.84 (CH$_2$, m), 4.30 (OCH$_2$, t, J=6.9 Hz), 6.39 (HCF$_2$, t(t) (triplet(triplet)), J=51.4(5.7) Hz); ^{13}C NMR δ=11.7 (f, s(singlet)), 17.7(g, s), 29.2(h, s), 67.2(i, s), 107.3(a, t(t), J=252.8(30.8) Hz), 107.4(b, t(m), J=255.1 Hz), 108.6(c, t(m)(triplet(multiplet)), J=260.8 Hz), 109.6(d, t(t), J=266.7(31.5) Hz), 157.3(e, t, J=24.9 Hz) for (HC^{a}F$_2$C^{b}F$_2$C^{c}F$_2$C^{d}F$_2$C^{e}OO)$_3$Ti(OC^{f}H$_2$C^{g}H$_2$C^{h}H$_2$C^{i}H$_3$); ^{19}F NMR δ=−25.9(a, d(doublet), J=51.3 Hz), −17.9(b, s), −12.4(c, m), −6.7(d, m, J=11.0 Hz) for (HCF$_2^a$CF$_2^b$CF$_2^c$CF$_2^d$COO)$_3$Ti(O^{n}C$_4$H$_9$). Found: Ti, 5.71; C$_4$H$_9$O, 8.48; H(CF$_2$)$_4$COO, 85.7%. Calcd for C$_{19}$H$_{12}$F$_{24}$O$_7$Ti: Ti, 5.59; C$_4$H$_9$O, 8.54; H(CF$_2$)$_4$COO, 85.9%.

Synthesis of Titanium Butoxide Tris(7*H*-dodecafluoroheptanoate), Ti(O^{n}C$_4$H$_9$)[OCO(CF$_2$)$_6$H]$_3$: The synthesis was carried out in a similar manner to that of titanium butoxide tris(5*H*-octafluoropentanoate). It took about 80 h for the reaction to come to completion. From a reaction of titanium butoxide trichloride 1.20 g (5.28 mmol) and sodium 7*H*-dodecafluoroheptanoate 6.80 g (18.5 mmol) as starting materials, slightly brown liquid product was obtained (4.51 g, yield 74.0%): IR 2972, 2945, 2883, 1772, 1718, 1669, 1558, 1506, 1446, 1402, 1363, 1323, 1203, 1142, 1082, 1061, 970, 926, 862, 837, 795, 766, 725, 671, 602, 565, 538, 509 cm^{-1}; ^{1}H NMR δ=0.95(CH$_3$, t, J=8.6 Hz), 1.20—1.88(CH$_2$, m), 4.38(OCH$_2$, t, J=6.7 Hz), 6.56(HCF$_2$, t(t), J=51.4(5.7) Hz); ^{13}C NMR δ=13.8(h, s), 19.7(i, s), 31.2(j, s), 69.4(k, s), 109.3(a, t(t), J=253.5(30.8) Hz), 111.5(b, t(m), J=249.1 Hz), 112.0(c, t(m), J=252.0 Hz), 112.6(d, t(m), J=255.0 Hz), 113.3(e, t(m), J=249.8 Hz), 113.6(f, t(m), J=260.8 Hz), 159.1(g, t, J=28.4 Hz) for (HC^{a}F$_2$C^{b}F$_2$C^{c}F$_2$C^{d}F$_2$C^{e}F$_2$C^{f}F$_2$C^{g}OO)$_3$Ti(OC^{h}H$_2$C^{i}H$_2$C^{j}H$_2$C^{k}H$_3$); ^{19}F NMR δ=−26.3(a, d, J=51.3 Hz), −17.4 (b, s), −11.1 (c and d, m), −9.6 (e, m), −6.3(f, m) for (HCF$_2^a$CF$_2^b$CF$_2^c$CF$_2^d$CF$_2^e$CF$_2^f$COO)$_3$Ti(O^{n}C$_4$H$_9$). Found: Ti, 4.08; C$_4$H$_9$O, 6.45; H(CF$_2$)$_6$COO, 89.6%. Calcd for C$_{25}$H$_{12}$F$_{36}$O$_7$Ti: Ti, 4.14; C$_4$H$_9$O, 6.32; H(CF$_2$)$_6$COO, 89.5%.

Synthesis of Titanium Butoxide Tris(9*H*-hexadecafluorononanoate), Ti(O^{n}C$_4$H$_9$)[OCO(CF$_2$)$_8$H]$_3$: The solution of titanium butoxide trichloride (8.93 g, 29.5 mmol) in 170 ml 1,1,2-trichloro-1,2,2-trifluoroethane was added to a stirred dispersion of sodium 9*H*-hexadecafluorononanoate (64.6 g, 138 mmol) in 80 ml of 1,1,2-trichloro-1,2,2-trifluoroethane. After refluxing the dispersion with stirring for 200 h, the upper clear solution was checked with silver nitrate as well as the synthesis of titanium butoxide tris(5*H*-octafluoropentanoate), and the precipitate was then removed by filtration and the solvent was removed by evaporation under vacuum. Slightly brown liquid product was obtained (4.51 g, yield 74.0%): IR 2972, 2945, 2883, 1772, 1734, 1668, 1653, 1616, 1558, 1506, 1450, 1446, 1402, 1363, 1338, 1211, 1147, 1084, 999, 860, 804, 768, 731, 698, 661, 538, 507 cm^{-1}; ^{1}H NMR δ=0.87 (CH$_3$, t, J=7.2 Hz), 1.05—1.88 (CH$_2$, m), 4.03 (OCH$_2$, t, J=6.6 Hz), 6.44 (HCF$_2$, t(t), J=51.2(5.3) Hz); ^{13}C NMR δ=12.9(j, s), 19.0(k, s), 30.4(l, s), 69.0(m, s), 108.6(a, t(t), J=253.5(30.8)Hz), 97.2—125.0(b—h, No detectable), 158.0(i, t, J=29.3 Hz) for (HC^{a}F$_2$-C^{b}F$_2$C^{c}F$_2$C^{d}F$_2$C^{e}F$_2$C^{f}F$_2$C^{g}F$_2$C^{h}F$_2$C^{i}OO)$_3$Ti(OC^{j}H$_2$C^{k}H$_2$C^{l}H$_2$C^{m}H$_3$); ^{19}F NMR δ=−25.7 (a, d(m), J=51.3 Hz), −17.0(b, m), −10.7(c, m), −10.0(d, m), −9.2(e, f and g, m), −5.5(h, m) for (HCF$_2^a$CF$_2^b$-CF$_2^c$CF$_2^d$CF$_2^e$CF$_2^f$CF$_2^g$CF$_2^h$COO)$_3$Ti(O^{n}C$_4$H$_9$). Found: Ti, 3.24; C$_4$H$_9$O, 5.13; H(CF$_2$)$_8$COO, 91.5%. Calcd for C$_{31}$H$_{12}$F$_{48}$O$_7$Ti: Ti, 3.29; C$_4$H$_9$O, 5.02; H(CF$_2$)$_8$COO, 91.7%.

Synthesis of Titanium Butoxide Tris(perfluorooctanoate), Ti(O^{n}C$_4$H$_9$)[OCO(CF$_2$)$_6$CF$_3$]$_3$: This procedure and purification technique were almost the same as those for the preparation of titanium butoxide tris(5*H*-octafluoropentanoate). From the reaction (100 h) of titanium butoxide trichloride 2.15 g (9.45 mmol) and sodium perfluorooctanoate 14.90 g (34.2 mmol) as starting materials, slightly brown liquid product was obtained (7.65 g, yield 59.7%): IR 2972, 2945, 2883, 1784, 1716, 1653, 1558, 1506, 1446, 1394, 1363, 1240, 1209, 1149, 1088, 1018, 985, 922, 889, 804, 802, 800, 746, 737, 721, 700, 665, 642, 561, 530 cm^{-1}; ^{1}H NMR δ=0.88 (CH$_3$, t, J=7.9 Hz), 1.10—1.82 (CH$_2$, m), 4.32 (OCH$_2$, t, J=7.0 Hz); ^{13}C NMR δ=13.6 (i, s), 19.7(j, s), 31.1(k, s), 69.4(l, s), 110.7(b, t(m), J=266.1 Hz), 112.0(c, t(m), J=253.9 Hz), 112.1(d, t(m), J=252.7 Hz), 113.4(e, t(m), J=260.0 Hz), 113.6(f, t(m), J=256.9 Hz), 114.9(g, t(m), J=255.7 Hz), 118.4(a, q(t), J=288.0(32.9) Hz), 158.9(h, t, J=28.7 Hz) for (C^{a}F$_3$C^{b}F$_2$C^{c}F$_2$C^{d}F$_2$C^{e}F$_2$C^{f}F$_2$C^{g}F$_2$C^{h}OO)$_3$-Ti(OC^{i}H$_2$C^{j}H$_2$C^{k}H$_2$C^{l}H$_3$); ^{19}F NMR δ=−14.1(b, s), −10.4(c and d, m), −9.7(e and f, m), −6.4(g, m), 30.8(a, m) for (CF$_3^a$CF$_2^b$CF$_2^c$CF$_2^d$CF$_2^e$CF$_2^f$CF$_2^g$COO)$_3$Ti(O^{n}C$_4$H$_9$). Found: Ti, 3.65; C$_4$H$_9$O, 5.33%. Calcd for C$_{28}$H$_9$F$_{45}$O$_7$Ti: Ti, 3.52; C$_4$H$_9$O, 5.38%.

Surface Modification of Calcium Carbonate. In a 50 ml vial, 0.10—0.35 g titanium butoxide tris(7*H*-dodecafluoroheptanoate) was added to the dispersion of calcium carbonate (1.00 g) in 30 ml THF; the heterogeneous mixture was irradiated by ultrasonic waves (200 W, 20 kHz) for 30 min. A surface-modified calcium carbonate powder was obtained after filtration of the mixture through a sintered glass disk; it was then thoroughly washed with THF and dried under reduced pressure. The surface wettabilities of modified calcium carbonate were evaluated by contact angles θ(°) against water and toluene, which were measured by the tablet method. The tablet used to measure the contact angles θ(°) was prepared as follows. Pressed cellulose disks were preliminary made by pressing 40 mg cellulose powder in a die for IR tablets at 200 kg cm^{-2} for 10 min; 0.15 g of surface modified calcium

carbonate was then placed on it. Surface-flattened tablets of the calcium carbonate were obtained by again pressing at 200 kg cm^{-2} for 15 min in the die. The contact angles $\theta(°)$ were measured using 1.0×10^{-6} dm^{-3} of water or toluene drops. The contact angles $\theta(°)$ were evaluated by extrapolating to time zero from a plot of the advancing contact angle $\theta(°)$ vs. time.[15]

Results and Discussion

The reaction of the synthesis of titanium butoxide tris(polyfluoroalkanoate) was heterogeneous in every case; it took long time to complete the reaction, especially in the case where the sodium fluoro-substituted acylate had a longer chain. Although the fluoro-substituted alkoxides of titanium were sensitive to moisture,[12] the prepared titanium butoxide tris(polyfluoroalkanoate)s were insensitive to water, except for the Ti–OC_4H_9 bond. These obtained titanium compounds were seemingly unchanged in excess water upon standing for one month at room temperature and held in an oily state at the bottom of a flask. The ^1H NMR spectrum of the oily state product showed that the intensity ratio of the alkanoyloxyl groups to the alkoxyl group were 3.0:0.8. This result shows that the Ti–OCO bond is stable and that the Ti–OC_4H_9 bond is moderately stable under these conditions. These stabilities against hydrolysis is caused by a steric hindrance of the three fluoro-substituted alkanoyloxyl groups, which exhibit the nature of water repellency.

Figure 1 shows a variation of the contact angles $\theta(°)$ of water against the wt% of titanium butoxide tris(7*H*-dodecafluoroheptanoate) vs. calcium carbonate used for the surface modification of calcium carbonate. From the results given in Fig. 1, the concentration used in the modification was found to be sufficient at 35 wt% titanium compounds against calcium carbonate; the authors thus used this concentration in all of the other runs. The results of the measurements of the contact angles $\theta(°)$ of water and toluene for the modified calcium carbonate by using the synthesized titanium butoxide tris(polyfluoroalkanoate)s are given in Table 1. These results show that the abilities of water and oil repellency of the surface-modified calcium carbonate were affected by the length of the fluorocarbon chains forming the titanium compounds. Also, the ability was more effective for fluorocarbon chains having a CF_3 group at the end of the chain in titanium compounds.

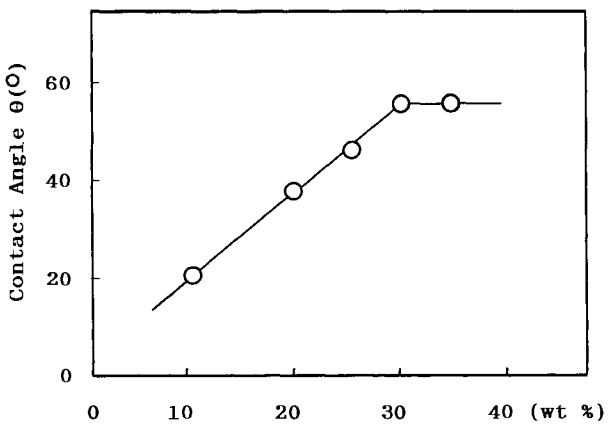

Fig. 1. Relation between contact angles $\theta(°)$ of water against the surface modified calcium carbonate and amount (wt%) of titanium butoxide tris(7*H*-dodecafluoroheptanoate) vs. $CaCO_3$.

Table 1. Extrapolated Contact Angles $\theta(°)$ of the Surface Modified Calcium Carbonate against Water and Toluene

Titanium butoxide tris(polyfluoroalkanoate)	Contact angle $\theta(°)$	
	Water	Toluene
Untreated	0[a]	0[a]
$Ti(O^nC_4H_9)[OCO(CF_2)_4H]_3$	44	14
$Ti(O^nC_4H_9)[OCO(CF_2)_6H]_3$	56	23
$Ti(O^nC_4H_9)[OCO(CF_2)_8H]_3$	65	32
$Ti(O^nC_4H_9)[OCO(CF_2)_6CF_3]_3$	88	74

a) Untreated calcium carbonate absorbed water and toluene drops too rapidly to measure the contact angles, then both of the contact angles were described 0°.

The authors are grateful to Mr. Noboru Komine and Mr. Shin-ichi Tominaga for their assistance in carrying out part of the present experiment.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 62550618 from the Ministry of Education, Science and Culture, to which the authors are also grateful.

Thermal and Electrooptical Properties of Ferroelectric Liquid Crystals Having OH Groups

Kazuo SUGIYAMA,* Koichi KATO, and Kohei SHIRAISHI
Department of Industrial Chemistry, Faculty of Engineering, Kinki University, Hirokoshinkai, Kure, Hiroshima 737-01
(Received November 13, 1990)

Four kinds of ferroelectric liquid crystals (FLCs) possessing OH groups, ((*S*)-2-methylbutyl 4-[4-(11-hydroxyundecyloxy)benzylideneamino]cinnamate **4a**, (*S*)-2-methylbutyl 4-[4-(11-hydroxyundecyloxy)-2-hydroxybenzylideneamino]cinnamate **4b**, (*S*)-2-hydroxypropyl 4-[4-(11-hydroxyundecyloxy)benzylideneamino]cinnamate **4c**, and (*S*)-2-hydroxypropyl 4-[4-(11-hydroxyundecyloxy)-2-hydroxybenzylideneamino]cinnamate **4d**) were prepared in order to understand how the introduction of OH groups in FLCs affect the phase behavior and electrooptical effects. α,ω-Diols **4c** and **4d** show a higher transition temperature of the smectic A (S_A) phase than do ω-hydroxyl compounds **4a** and **4b**. Comparing **4b** and **4d** both of which have an OH group at the *o*-position of the benzylidene group with **4a** and **4c**, the former samples show a higher S_A-isotropization (I) transition temperature than do the latter ones. It is suggested from IR spectroscopic results that inter- and intramolecular hydrogen bonding contribute to the stabilization of the S_A phase. The order of the helical pitch in the chiral smectic C (S_c*) phase was found to be **4b**>**4a**>**4d**>**4c** within 1.8—6.6 μm. From an electrooptical effect due to a deformation of the helical structure in the S_c phase, the rise time of the surface director (τ_{sr}) and the rise time of the bulk director (τ_{br}) were measured to be as follows: τ_{sr} are 850, 1500, 30, and 70 μs, and τ_{br} are 12, 100, 0.17, and 0.35 ms for **4a**, **4b**, **4c**, and **4d**, respectively. It was found that the intramolecular hydrogen bonding results in a slower optical response time, whereas intermolecular hydrogen bonding results in a faster one.

Since the discovery of a ferroelectric property in the S_c* phase by Meyer et al.,[1] (*S*)-2-methylbutyl-4-[4-(decyloxy)benzylideneamino]cinnamate (DOBAMBC) has attracted much attention regarding both fundamental physical science[2-5] and practical view points concerning various types of electrooptical materials with small switching times and memory effects.[6-10] Many scientific and practical efforts have also been concentrated on families of FLCs, such as chiral compounds with benzylideneaniline,[11-13] biphenyl,[14,15] phenylbenzoate[16-18] used as mesogenic units. On the other hand, ferroelectric liquid crystalline polymers (FLCPs) that combine the mechanical properties of polymeric material and the physical properties of FLCs have also been an active, growing area of research interest for many years. FLCPs have been achieved in various polymers having chiral mesogens as a pendant group on the main chain such as polysiloxane,[19,20] polyvinyl[21-23] and polyester backbones.[24-26] Few FLCPs having chiral mesogenic groups as blocks within the main chain are presently known.[27] In previous papers[28-30] we have reported on the properties of terminal-terminal-type FLCs as twin models for the main-chain-type of FLCs which contain mesogenic units interconnected through spacer groups. As a part of an ongoing study of FLCPs, we have prepared novel DOBAMBC analogous with the structures designated **4a**—**4d** in scheme 1. α,ω-FLC diols **4c**, **4d** can be used as mesogenic units in FLCPs with various structures such as polyurethane, polyester, and polycarbonate. In the present study differential scanning calorimetry (DSC) and polarized optical microscopy (POM) were applied to an investigation of the thermal behavior of FLCs, also two types of electrooptical effects, such as a surface-stabilized FLC (SSFLC) cell and a transient scattering mode (TMS) device, were measured for possible applications.

Experimental

Syntheses: Novel types of FLCs **4a**—**4d** were prepared using the following route, as shown in Scheme 1.

4-(11-Hydroxyundecyloxy)benzaldehydes **1**; Aldehyde **1a** and **1b** were obtained from a reaction of 4-hydroxybenzaldehyde or 2,4-dihydroxybenzaldehyde and 11-bromoundecanol in the presence of K_2CO_3 and KI, according to the method of Ringsdorf et al.[31]

4-(11-Hydroxyundecyloxy)benzaldehyde **1a**: 80.5% yield; mp 61—62 °C; ^{1}H NMR ($CDCl_3$) δ=1.12—2.28 (m, 18H), 3.72—3.92 (t, 2H), 4.20—4.44 (t, 2H), 8.32—8.48 (q, 4H), and 10.05 (s, 1H). Found: C, 73.82; H, 9.48%. Calcd for $C_{18}H_{28}O_3$ (M, 292.422): C, 73.93; H, 9.65%.

2-Hydroxy-4-(11-hydroxyundecyloxy)benzaldehyde **1b**: 57.3% yield; mp 56—58 °C; ^{1}H NMR ($CDCl_3$) δ=1.06—2.09 (m, 18H), 3.33—3.69 (t, 2H), 3.81—4.03 (t, 2H), 6.22—7.37 (q, 3H), and 9.18 (s, 1H). Found: C, 70.05; H, 9.02%. Calcd for $C_{18}H_{28}O_4$ (M, 308.421): C, 70.10; H, 9.15%.

(*S*)-2-Hydroxypropyl 4-nitrocinnamate **2a**: To 0.2 mol (*S*)-1,2-propanediol and 50 mL pyridine in 300 mL freshly distilled THF, 0.16 mol 4-nitrocinnamoyl chloride in 100 mL THF was added with stirring at 0 °C for 2 h. After stirring for an additional 10 h at room temperature, the reaction mixture was evaporated to dryness, and ca. 300 mL of chloroform was added to the residue. The chloroform layer was washed with water and evaporated to dryness. The obtained product was recrystallized from methanol to give yellow crystals: 73.3% yield; mp 72—74 °C; ^{1}H NMR ($CDCl_3$) δ=1.12—1.52 (m, 3H), 3.28—3.64 (m, 1H), 4.04—4.60 (m, 2H), 6.60—6.80 (d, J=16 Hz, 1H), and 7.60—8.48 (q, 5H). Found: C, 57.41; H, 5.25; N, 5.34%. Calcd for $C_{12}H_{13}NO_5$ (M, 251.241): C, 57.37; H, 5.22; N, 5.58%.

(*S*)-2-Hydroxypropyl 4-aminocinnamate **3a**: To 0.04 mol **2a** and 0.84 mol $FeCl_2$ in 300 mL methanol, gaseous NH_3 was gently introduced with stirring at room temperature for 1.5 h.

After reduction was completed, the reaction mixture was evaporated to dryness. The residue was extracted three times with 100 mL of dichloromethane. The dichloromethane layer was washed with water and evaporated to dryness. The obtained product was chromatographed on silica gel (Wakogel C-200) with diethyl ether to give yellow crystals; 74.8% yield; mp 83—84 °C; ^{1}H NMR ($CDCl_3$) δ=1.04—1.44 (m, 3H), 3.26—3.84 (m, 1H), 4.04—4.40 (m, 2H), 6.28—6.44 (d, J=16 Hz, 1H), 6.60—7.82 (m, 5H). Found: C, 64.93; H, 6.71; N, 6.10%. Calcd for $C_{12}H_{15}NO_3$ (M, 221.258): C, 65.14; H, 6.83; N, 6.33%.

Shiff Bases 4: An equimolar mixture of aldehyde **1** and 4-aminocinnamate **3** in 10 mL of absolute ethanol was allowed to stand for 24 h. The precipitate was filtered and recrystallized twice from the absolute ethanol; the yield was ca. 90%. The thermal behaviors and characterization of (*S*)-2-methylbutyl 4-[4-(11-hydroxyundecyloxy)benzylideneamino]-cinnamate **4a**, (*S*)-2-methylbutyl 4-[4-(11-hydroxyundecyloxy)-2-hydroxybenzylideneamino]cinnamate **4b**, (*S*)-2-hydroxypropyl 4-[4-(11-hydroxyundecyloxy)benzylideneamino]cinnamate **4c**, and (*S*)-2-hydroxypropyl 4-[4-(11-hydroxyundecyloxy) 2-hydroxybenzylideneamino]cinnamate **4d** are tabulated in Table 1.

Measurements: ^{1}H NMR measurements were carried out with a 100 MHz JEOL JNM-MH 100 spectrometer. The

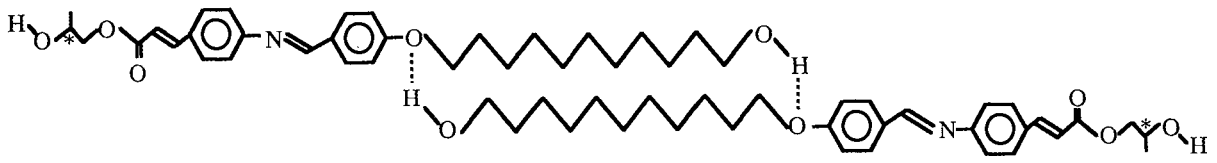

Fig. 1. Structure of intermolecular hydrogen bonds of **4c**.

phase-transition temperature was determined by DSC using a Rigaku Thermoflex apparatus (DSC-8230B). Sample quantities varied from 5 to 10 mg. POM was performed using an Olympus nicroscope (BH-2), with a heating stage attached to a temperature controller. Thin samples were sandwiched between two glass slides, the surfaces of which had been unidirectionally rubbed with cotton wool to obtain a homogeneous alignment. The spacing between the top and bottom glass plates was 25 μm, with a stretched polyester film used as the spacer material. Electrooptical measurements were carried out as follows. The surfaces of glass plates were coated with a transparent conductive material (In_2O_3); the surface resistance was about 100 Ω m^{-2}. The sample cell (thickness: 25 μm) was set without a polarizer in the optical path of a He-Ne laser (NEC-GLG, 5313, wavelength 632.8 nm, and output power 1 mW). The incident light was damped with an attenuator and arranged with a slit. Changes in the transmission upon the application of an electric field were monitored with a photodiode, and processed with a personalcomputer (NEC 9801).

Results and Discussion

Thermal Properties. According to DSC and POM, samples **4a**—**4d** show two or more mesophases upon cooling; at the transition from the I to the S_A phase, a fan-shaped texture with the focal conic texture first appears. Upon further cooling, the S_A phase and the following S_c* phase result, showing a focal conic texture with stripes due to a helical structure.

The phase-transition temperature of a samples determined using DSC is compatible with that obtained by means of POM and the electro-optical measurements mentioned below. The results are summarized in Table 1. From the obtained results it was found that although these samples resemble typical FLC, DOBAMBC (S_H 63 S_c* 95 S_A 118 I) very closely in mesomorphic behavior, their phase-transition temperature is somewhat higher than that of DOBAMBC, itself. The OH stretch vibrations of **4c** and **4d** are broad bands centered at 3425 and 3340 cm^{-1} due to intermolecular hydrogen bonds in the crystalline phase (K), respectively.

It is, thus, suggested that in FLC α,ω-diols **4c** and **4d** hydrogen bonds exist between the hydroxyl hydrogen and the phenyl ether oxygens, as described regarding 4,4′-bis(6-hydroxyhexyloxy)biphenyl.[32] The structure of hydrogen bonding in **4c** is speculated to be as shown in Figure 1. Comparing the thermal behavior of **4b** and **4d** with that of the corresponding liquid crystals, **4a** and **4c**, the former samples show a wider temperature range of both the S_A phase (ΔT_{S_A}) and the S_c* phase (ΔT_{S_c*}) than do that of latter ones. In addition, the phase-

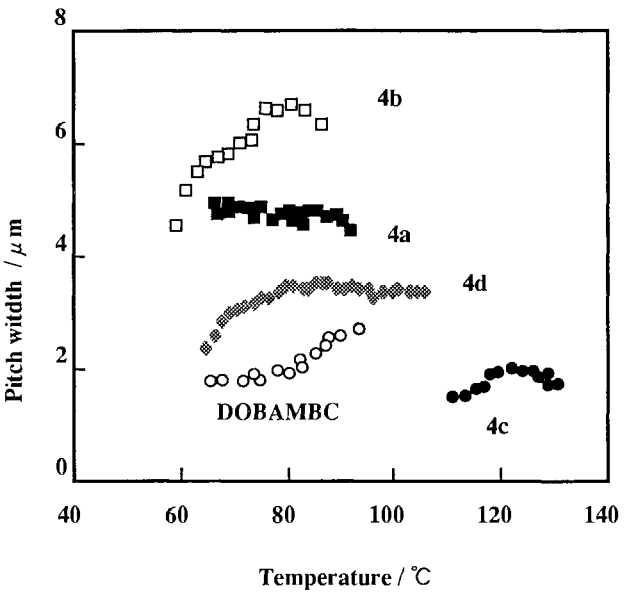

Fig. 2. Temperature dependence of pitch width of helical structure in the S_c* phase of α,ω-diols **4** and DOBAMBC.

transition temperatures of the S_A-I transition of **4b** and **4d** was higher than those of **4a** and **4c**. These results can be explained as follows: the thermal stability of the smectic state in liquid crystals having an OH group at the *o*-position of the benzylidene group, such as in **4b** and **4d**, is increased by an interaction between adjacent molecules in the smectic layers when the hydroxyl hydrogen is intramolecular hydrogen-bonded to give a cis conformation with a narrow molecular breadth and a coplanarity of the two benzene rings.[12,33]

The pitches of the helical structure of the S_c* phase, which are important factors concerning the electrooptical effect in FLCs, were measured by averaging the spacing of the stripes at ten different places in a micrograph of their textures. Figure 2 shows the temperature dependence of the pitch of the helical structure in the S_c* phase. The order of the average pitch of the samples was found to be as follows:

4b>4a>4d>4c.

FLC α,ω-diols (**4d** and **4c**) show a narrower pitch than do the others (**4b** and **4a**), while intramolecular hydrogen bonded **4b** and **4d** show a wider pitch than do **4a** and **4c**. This result may be explained in terms of the

layer spacing in a smectic phase, depending on the hydrogen bonds between the molecular layers.

Electrooptical Properties. FLC α,ω-diols were measured regarding electrooptical effects in order to obtain basic data for practical uses of FLCs. Figure 3 shows the transmission intensity (T) of the He–Ne laser through the **4a** cell upon cooling. When no voltage was applied, T below 91 °C gradually decreased due to light scattering in the wound phase of the helical structure of the S_c* phase. On the other hand, upon application of a d.c. electric field, T never decreased within the temperature range of the S_c* phase. In this measurement, it was found that T decreases slightly just after a d.c. field application, and then increases remarkably. The applied field induces a fluctuation of the boundary due to a reorientation of the molecular alignment in the layer near to the electrode surface resulting in a decrease of T within a short time (τ_{sr}). This electrooptical effect can be regarded as being a response time of a surface-stabilized ferroelectric liquid crystal (SSFLC) cell.[10] On the other hand, the main response (τ_{br}) corresponding to an increase in T is relatively slow. The slow response, called the transient scattering mode (TSM) effect,[34] is believed to be due to a transformation of a wound phase (S_c*) to unwound phase (S_c): that is, a transition from a helical structure to a uniform monodomain structure. The electrooptical response time corresponding to the change in T caused by a d.c. field application was measured over an electric field from 0.4 to 48 kV cm^{-1} at T_{Sc^*} −10 °C (cell thickness; 25 μm). τ_{sr} and τ_{br} are the times taken to reach the stage of a T decrease and increase of up to 90%, respectively. In order to determine the effect of the applied field on the response times, τ_{sr} and τ_{br} were used to measure the S_c* phase by changing the applied voltage. Figures 4 and 5 show the field dependence of the response time in the **4** cell. These figures show that an increase in the applied voltage results in a faster optical response time; an increase in the pitch of helical structure results in a slower response. It was also found by comparing the **4b** and **4d** existing intramolecular hydrogen bonding with **4a** and **4c**, the former samples show a slower optical response time than do the latter ones. In addition, the optical response times of α,ω-FLC diols **4c** and **4d** are faster than that of ω-hydroxyl FLCs **4a** and **4b**. For development of the S_c* phase, it is well known that intermolecular interactions are limited to

Table 2. Thermal and Electrooptical Properties of 4[a)]

4	$T_{S_A\text{-}S_c^*}$ / °C	$T_{S_c^*\text{-}K}$ / °C	Pitch / μm	τ_{sr}[b)] / μs	τ_{br}[b)] / ms
4a	91	23	4.7 (76°C)	850 (76°C)	12 (76°C)
4b	86	24	6.6 (75°C)	1500 (75°C)	100 (75°C)
4c	132	20	1.8 (114°C)	30 (114°C)	0.17 (114°C)
4d	107	40	3.5 (89°C)	70 (89°C)	0.35 (89°C)
DOBAMBC	95	33	1.7 (90°C)	200 (90°C)	120 (75°C)

a) Cell thickness; 25 μm. b) Electric field=16 kV cm^{-1}.

excluded volume effects and dispersive forces. In our case, in addition to the interaction due to these two factors, hydrogen bonding plays an important role in the formation of the S_c^* phase and in the optical response time corresponding to a change in the helical structure in the S_c^* phase. So far, the relationship between the pitch and the response time in our samples is not explicable, since it is not at all clear how large their spontaneous polarization (P_s) and viscosity (η) are. An explanation for this observed interesting relationship will be provided when the P_s and η are measured. The optical response times at 16 kV cm^{-1} are summarized in Table 2. Since the samples obtained as new types of FLCs show a relatively high-speed electrooptical effect with a low-threshold field of less than 5 kV cm^{-1}, these samples can be practically applied as display devices.

From the results concerning the thermal and electrooptical characterization of DOBAMBC analogous FLCs **4a**—**4d**, the following conclusions can be drawn:

1. α,ω-Diols **4c** and **4d** show a higher transition temperature of S_A phase than do ω-hydroxyl compounds **4a** and **4b**. Since α,ω-diols **4c** and **4d** also exhibit a higher S_A transition temperature than does DOBAMBC, the introduction of OH as terminal groups was found to stabilize the S_A phase, based on intermolecular hydrogen bonding.

2. Comparing **4b** and **4d** having an OH group at the *o*-position of the benzylidene group with **4a** and **4c**, the former samples show a higher transition temperature of S_A–I than do the latter ones. It is suggested that intramolecular hydrogen bonding contributes to a stabilization of the S_A phase.

3. Intramolecular hydrogen bonding results in a wider helical pitch, while the intermolecular hydrogen bonding results in a narrower one.

4. From the electrooptical measurements, it was found that a wider helical pitch results in a slower optical response time.

5. The τ_{sr} for SSFLC of **4a**—**d** is slower than that of DOBAMBC, whereas the τ_{br} for TSM is faster than that of DOBAMBC.

(Received November 28, 1990)

The synthesis of methanol from CO_2 and H_2 in a flow reactor was studied over CuO–ZnO catalysts combined with ZrO_2, MgO, Al_2O_3, or Cr_2O_3 under a presssure of 13 atm. CuO–ZnO–Al_2O_3, CuO–ZnO–ZrO_2, and CuO–ZnO–MgO showed higher activity and higher selectivity for methanol than did CuO–ZnO. The selectivity for methanol formation became higher as the reaction temperature was lower, or any of the H_2/CO_2 ratio, the pressure and the space velocity were higher. On the basis of analyses by XRD, XPS, and ultraviolet diffused reflectance spectroscopy, the active centers of CuO–ZnO–ZrO_2 seem to be a Cu^+–ZnO species stabilized by ZrO_2.

Methanol synthesis from CO_2 and H_2 has recently been studied over various mixed oxide catalysts. The binary mixed oxides used were CuO–Al_2O_3,[1,2] CuO–ZnO,[2,3] CuO supported on MgO, La_2O_3, Sm_2O_3, ThO_2–K, and ZrO_2[2] and ZnO supported on MgO, Al_2O_3, SiO_2, TiO_2, ZrO_2, and Nb_2O_5.[4] The ternary mixed oxides used were CuO–ZnO–Al_2O_3,[2,3,5,6] CuO–ZnO–Cr_2O_3,[3] and CuO–ZnO supported on MgO, Y_2O_3, In_2O_3, La_2O_3, Nd_2O_3, ThO_2, and SiO_2.[6] Among these catalysts, CuO–ZnO–MgO, CuO–ZnO–Al_2O_3, CuO–ZnO–La_2O_3, and CuO–ZnO–ThO_2 showed high catalytic activity and selectivity for methanol formation. In the present work, CuO–ZnO–ZrO_2 was examined and the activity and selectivity of CuO–ZnO–ZrO_2 compared with those of CuO–ZnO–MgO, CuO–ZnO–Al_2O_3, and CuO–ZnO–Cr_2O_3; further, the active sites on CuO–ZnO–ZrO_2 were studied by means of XRD, XPS, and ultraviolet diffused reflectance spectroscopy.

Experimental

Catalyst. CuO-ZnO catalysts with different compositions were prepared by the hydrolysis of a mixed solution of $Cu(NO_3)_2$ and $Zn(NO_3)_2$ with an aqueous solution of Na_2CO_3, followed by thoroughly washing the co-precipitates with distilled water and drying overnight. The dried catalysts were calcined in air at 350 °C for 3 h and then at 500 °C for 1 h.

CuO–ZnO–ZrO_2, CuO–ZnO–MgO, CuO–ZnO–Al_2O_3, and CuO–ZnO–Cr_2O_3 catalysts with different compositions were prepared by directly adding $Zr(OH)_4$, $Mg(OH)_2$, $Al(OH)_3$, and $Cr(OH)_3$, respectively, to the $Cu(OH)_2$–$Zn(OH)_2$ co-precipitates obtained above, followed by drying and calcining, as described above. Zirconium tetrahydroxide was obtained by the hydrolysis of $ZrOCl_2$ with aqueous ammonia and $Mg(OH)_2$, $Al(OH)_3$, and $Cr(OH)_3$ were prepared by hydrolysis of the respective nitrates with an aqueous solution of Na_2CO_3.

Catalysts after being sieved to 20—40 mesh size were reduced with H_2 at 300 °C for 6 h in a reactor and subjected to evaluation.

Preparation of Standard Samples. A standard sample of Cu^0 was obtained by etching a pure Cu metal plate with Ar^+ ions at an electric current of 20 μA for 10 min until the O_{1s} lines in the XPS spectra disappeared. Pure CuO sample was prepared by calcining a pure Cu metal plate at 500 °C for 3 h in air. Pure $Cu_2O(Cu^+)$ was obtained by etching the pure CuO with Ar^+ ions in an ultra high vacuum at a lower electronic current (15 μA) for 10 min.[7]

Reaction Procedures. A reaction of CO_2 with H_2 was carried out in a flow reactor. A mixture containing H_2 and CO_2 at a mole ratio 3:1 was fed through a constant volume of catalyst (1.8 cm^3) at a total pressure of 13 atm. The products were analyzed by gas chromatography with a Porapak Q column.

XPS Measurement. XPS spectra were measured by the use of an ESCALAB MK spectrometer (V. G. Scientific Ltd., UK) equipped with an in-situ reaction cell and a pretreatment chamber, using Mg $K\alpha$ radiation ($h\nu$=1253.6 eV). Catalyst specimens were prepared by pressing powder samples to a small plate, followed by evacuation at room temperature of about 10^{-9} Torr in the pretreatment chamber. After being transferred to a small reactor equipped inside the pretreatment chamber, each specimen was reduced with H_2 (1 atm) at 300 °C for 2 h (a mixture of 25% CO_2+75% H_2 (1 atm) was adsorbed on it at room temperature) and then evacuated to 10^{-3} Torr at 250 °C. The specimen was cooled down, and transferred back to the pretreatment chamber, evacuated to about 5×10^{-8} Torr, and then transferred to the analyzing chamber for an XPS measurement. The charging effects of various specimens were minimized by taking the binding energy of the $Zn(2p_{2/3})$ level at 1021.7 eV as the internal standard.

XRD Measurement. The X-ray powder diffraction patterns were recorded by using a Rigaku D/MAX III-A X-ray diffractometer with Cu $K\alpha$ (0.15418 nm) radiation. Samples were mounted on a glass slide by using double-seal tape and inserted into the sample holder.

UDRS Measurements. Ultraviolet diffused reflectance spectra were measured by utilizing a UV-240 spectrometer in the range of 250—800 nm; $BaSO_4$ was used as a standard. Samples were reduced for 6 h and then placed in infrasil front-window cells without exposure to air, either by transfer under nitrogen or by direct reduction in a closed system.

Results and Discussion

Catalytic Activity and Selectivity. Table 1 shows both the activity and selectivity of CuO–ZnO catalysts with different compositions. Only CuO showed a very low activity (CO_2 conversion), no methanol being formed; only ZnO showed low activity and formed

a) Reaction conditions: mole ratio of $H_2/CO_2=3/1$, total pressure 13 atm. The catalyst of 1.8 cm^3 was used after reduction with H_2 at 300 °C for 6 h. b) X_{CO_2}=Conversion of CO_2. c) Y=yield. d) mmol g^{-1} h^{-1}.

methanol, its selectivity being 17%. However, the mixed oxides, CuO-ZnO, showed much higher activity for CO_2 conversion and much higher selectivity for the formation of methanol than did CuO or ZnO alone. A CuO-ZnO catalyst with a molar ratio=47/53 showed the higher yield (12.3%) of methanol at 240 °C, the CO_2 conversion and methanol selectivity being 31 and 39% at 240 °C, respectively.

The results for the reaction of CO_2 with H_2 over CuO-ZnO-ZrO_2 catalysts of different compositions are given in Table 2. The selectivities for methanol were high for all of the CuO-ZnO-ZrO_2 catalysts, compared with that for CuO-ZnO. A CuO-ZnO-ZrO_2 catalyst with a molar ratio of 42/47/11 exhibited the highest yield (17.4%) of methanol at 220 °C, and the highest selectivity (94.8%) for methanol at 160 °C. The lower was the reaction temperature, the higher was the methanol selectivity. On the other hand, the conversion of CO_2 and the selectivity for CO or CH_4 increased with increasing the reaction temperature.

The effects of the H_2/CO_2 ratio, pressure, and space velocity on the activity and selectivity of CuO-ZnO-

ZrO_2 (42/47/11) are shown in Figs. 1, 2, and 3, respectively. With an increase in the H_2/CO_2 ratio, the CO_2 conversion and methanol selectivity increased linearly, and the CO selectivity decreased. With an increase in the pressure, the CO_2 conversion and methanol selectivity increased, and the CO selectivity decreased. With an increase in the space velocity, and methanol selectivity increased over an SV range smaller than 3600 h^{-1}, while a small increase was observed above 3600 h^{-1}; CO selectivity decreased considerably.

Since the addition of ZrO_2 to CuO–ZnO caused a high yield of methanol, we attempted to examine the additive effect of MgO, Al_2O_3, or Cr_2O_3 on the activity and selectivity of CuO–ZnO. As shown in Table 3, the methanol yield was found to be highest over CuO–ZnO–Al_2O_3. The addition of Cr_2O_3 resulted in a marked decrease in the activity. No reaction was appreciable over CuO–ZnO–Cr_2O_3 below 300 °C. Although the amount of Cr_2O_3 was higher than those of the other catalyst supports, the decrease in the activity was so great that it cannot be explained by the amount of support. Thus, the order of methanol yield over verious catalysts is CuO–ZnO–Al_2O_3>CuO–ZnO–ZrO_2>CuO–ZnO–MgO>CuO–ZnO≫CuO–ZnO–Cr_2O_3.

Structure and Surface Area. The XRD powder pattern of a calcined CuO–ZnO sample showed that it comprises of tetragonal CuO and hexagonal ZnO. When a small amount (11 mol%) of ZrO_2 was added, the pattern of CuO–ZnO was not changed, as is shown in Fig. 4, indicating that ZrO_2 forms an amorphous

a) Reaction conditions: mole ratio of $H_2/CO_2=3/1$, total pressure 13 atm. The catalyst of 1.8 cm^3 was used after reduction with H_2 at 300°C for 6 h. b) X_{CO_2}=Conversion of CO_2. c) Y=yield. d) mmol g^{-1} h^{-1}.

phase. With the addition of a larger amount (77 mol%) of ZrO_2, almost all of the patterns of CuO and ZnO disappeared. This disappearance of the patterns is considered to be due to a high dispersion of CuO and ZnO over ZrO_2. The surface area (29 cm^2 g^{-1}) of CuO-ZnO (47/53) increased to 37 cm^2 g^{-1} for CuO-ZnO-ZrO_2 (42/47/11) and 42 cm^2 g^{-1} for CuO-ZnO-ZrO_2 (21/24/55). The activation energy for CO_2 conversion decreased from 71.2 kJ mol^{-1} over CuO-ZnO (47/53) to 61.1 kJ mol^{-1} over CuO-ZnO-ZrO_2 (42/47/11) and 47.2 kJ mol^{-1} over CuO-ZnO-ZrO_2 (21/24/55). These changes seem to be due to the high dispersion of CuO-ZnO over ZrO_2.

Active Centers. Figure 5 shows the ultraviolet diffused reflectance spectra of reduced CuO, ZnO, CuO-ZnO, and CuO-ZnO-ZrO_2. The absorption edges of ZrO_2, ZnO, and Cu^0 were confirmed to be 330, 360, and 560 nm, respectively. The spectral feature of ZnO was observed for CuO-ZnO and CuO-ZnO-ZrO_2, but that of ZrO_2 was not found for those samples. The spectra characteristic of Cu^0 were shifted toward lower frequencies in CuO-ZnO and CuO-ZnO-ZrO_2. The shape of the spectra also changed. The characteristic edge (600—800 nm) of Cu^0 in CuO increased its intensity in CuO-ZnO and CuO-ZnO-ZrO_2 up to 55% of the ZrO_2 content. With increasing the ZrO_2 content to 77%, the characteristic edge of Cu^0 became close to that in CuO. This trend corresponds to a difference in the catalytic activity for methanol formation over CuO and CuO-ZnO-ZrO_2 catalysts with the different ZrO_2 contents shown in Tables 1 and 2. The visible absorption edge of the reduced catalysts was different from those of Cu_2O(610 nm),[8)] Cu(560 nm), CuO(850 nm),[9)] and Cu^{2+} existing in a Cu^{2+}-ZnO solid solution. This characteristic absorption edge was reported to be caused by Cu^+ which existed in Cu^+-ZnO solid solution.[10)] Since Cu^+ and Zn^{2+} are isoelectric ions, the replacement of Zn^{2+} by Cu^+, and resulting dissolution of Cu^+ in ZnO, may be possible. The addition of high valent Zr^{4+} may supply positive charge to Cu^+, thus making dissolution easy. As a result, the intensity of the absorption edges for Cu' is considered to increase.

According to an XPS measurement, the $Cu2p_{3/2}$ peak in CuO has two strong shoulders toward its high-energy side called a "satellite shake up peak".[11)] Although the $Zn2p_{3/2}$ and $Zr3d_{5/2}$ peaks in CuO-ZnO-ZrO_2 were very similar to those of ZnO and ZrO_2, respectively, the two $Cu2p_{3/2}$ shoulder peaks were slightly wider and weaker in intensity than those in CuO. It can be said that Cu ions are located in a center of more distorted symmetry as the intensity ratio of the satellite-to-main peak

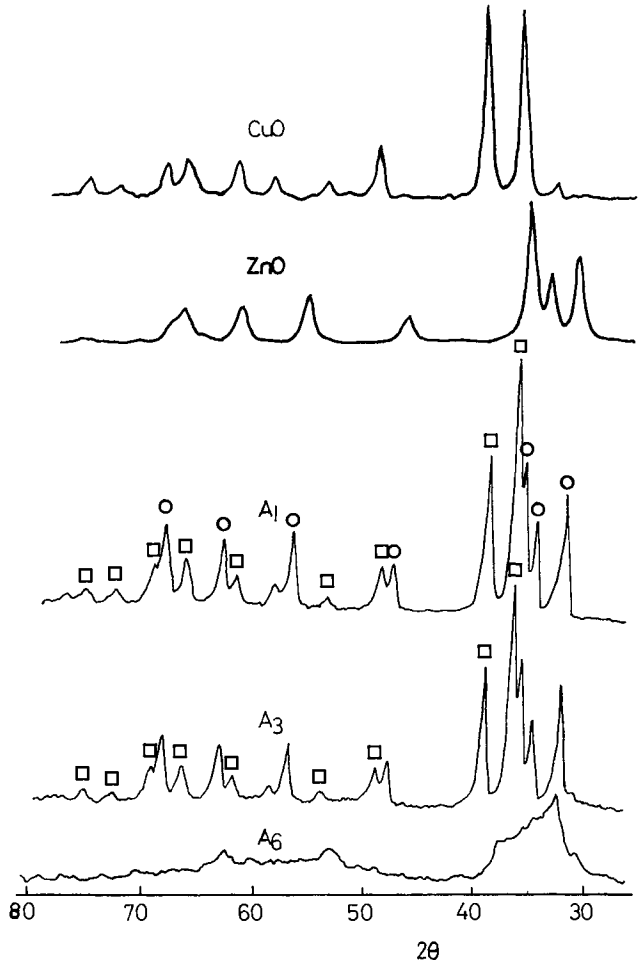

Fig. 4. XRD spectra of pure CuO and calcined samples ($CuO-ZnO-ZrO_2$) A_1, A_3, A_6. O; ZnO, □; CuO.

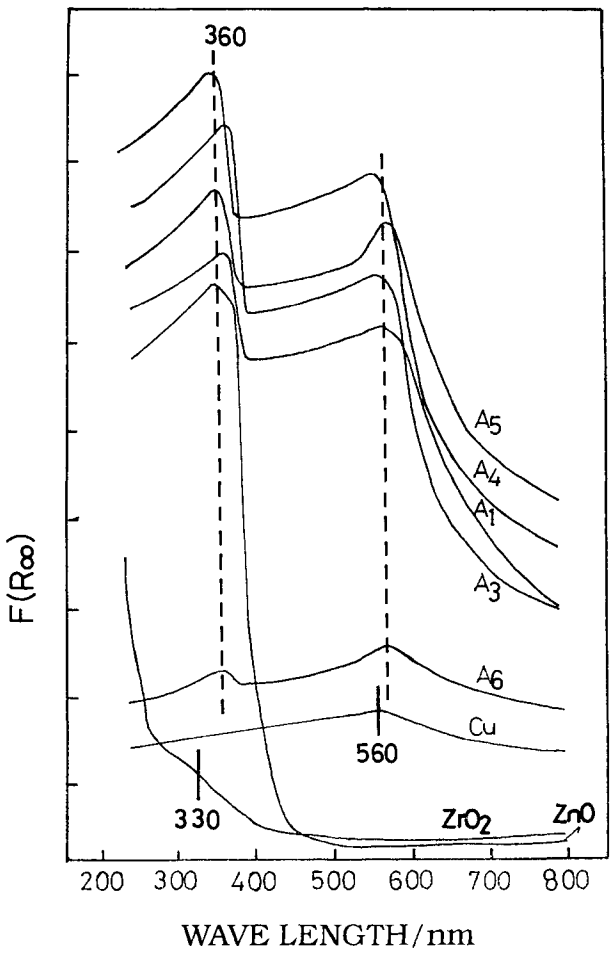

Fig. 5. Ultraviolet diffused reflectance spectra of the $CuO-ZnO-ZrO_2$ catalyst.

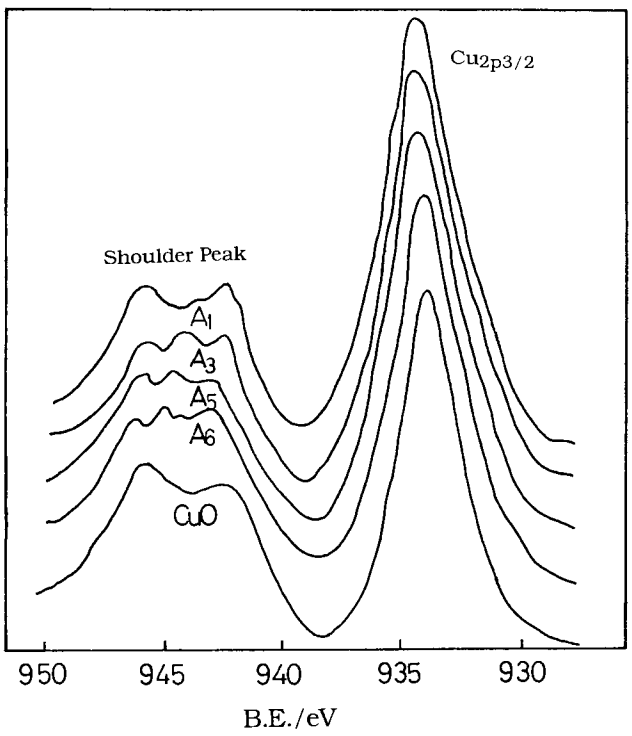

Fig. 6. XPS spectra of $Cu2p_{3/2}$ region for calcined samples. ($CuO-ZnO-ZrO_2$).

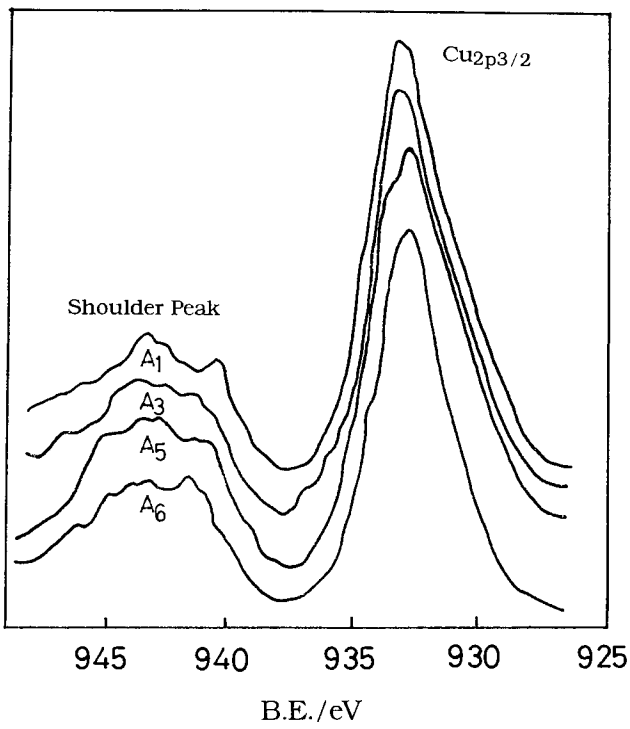

Fig. 7. XPS spectra of $Cu2p_{3/2}$ region for the samples ($CuO-ZnO-ZrO_2$) after reaction.

(S/M) becomes large.[11]

The $Zn2p_{3/2}$ and $Zr3d_{5/2}$ peaks of the used catalysts were the same as those of unused ones, and the $Cu2p_{3/2}$ peak shifted by approximately lev, similar to that of Cu. In contrast, Cu(LMM) Auger electron energy was different from that of Cu and similar to that of Cu_2O. The XPS spectra in the region of $Cu2p_{3/2}$ for the catalysts after calcination and after use for the reaction are shown in Figs. 6 and 7, respectively. Compared with the calcined catalysts, and used catalysts exhibited lower S/M values for the calcined catalysts (A_1, A_3, A_5, and A_6): 0.46, 0.46, 0.41, and 0.42, respectively; they changed to 0.25, 0.20, 0.34, and 0.31, respectively.

The decrease in the S/M value of $Cu2p_{3/2}$ is considered to be due to the formation of a solid solution comprising of Cu^{2+} and ZnO.[12] In used catalysts, although two shoulder peaks of $Cu2p_{3/2}$ also existed, their binding energy shifted toward lower energy, indicating that Cu^{2+} was reduced to lower valencies. However, the similarity of Cu(LMM) of the used catalysts to that of Cu_2O seems to suggest that the reduced Cu is partially oxidized and that the surface is partly converted with oxygen to prevent any further oxidation of Cu.[13] The shoulder peaks are usually observed for CuO, but not for Cu_2O and Cu. However, Cu^{2+} was not detected for the used catalysts in the present work. Therefore, the shoulder peaks of $Cu2p_{3/2}$ are considered to be due to the formation of Cu^+ in a Cu_2O–ZnO solid solution. During the prereduction condition, Cu^{2+} is easily reduced to Cu^+ and dissolved into ZnO, resulting in the formation of a Cu_2O and ZnO solid solution, making it difficult for any further reduction to take place since Cu^+ and Zn^{2+} are isoelectric ions. This result is in agreement with that obtained by UDRS. Thus, Cu^+ and ZnO in Cu_2O–ZnO solid solutions are suggested to be active centers under the reaction conditions.

Methanol synthesis by the reaction of CO_2 with H_2 over Re supported on ZrO_2, CeO_2, La_2O_3, and Al_2O_3 was studied under a pressure of 5atm by the use of a flow reactor. Methanol was formed over Re/CeO_2, Re/ZrO_2, and Re/La_2O_3, but not over Re/Al_2O_3 and ZrO_2 alone. On the basis of XPS analysis, the active state of Re was suggested to be Re^0 for Re/ZrO_2 and Re/CeO_2. For Re/Al_2O_3, Re was incompletely reduced, resulting in no formation of methanol. Methanol synthesis was inferred to proceed via CO in the case of Re/ZrO_2, and via the reaction of CO_2 with surface OH in the case of Re/CeO_2 by FT-IR analysis.

The support effect of rhenium catalyst on methanol synthesis from CO_2 and H_2 under 10 atm was reported to be remarkable, the selectivity for methanol formation being of the order Re/ZrO_2(73%)>Re/Nb_2O_5(52%)>Re/SiO_2(23%)>Re/Zeolon(18%)=Re/MgO (17.5%).[1,2] In the present work, we attempted to examine the effects of CeO_2, La_2O_3, and Al_2O_3, together with ZrO_2, as supports of a rhenium catalyst in the reaction of CO_2 with H_2 under 5 atm; we also studied the active sites and the reaction mechanisms by XPS and FT-IR analysis.

Experimental

Preparation of Catalysts. Supported Re catalysts were prepared by impregnating La_2O_3, CeO_2, ZrO_2, and Al_2O_3 (20—40 mesh) with an NH_4ReO_4 aqueous solution. This was followed by drying in a vacumm at 100 °C and reducing with hydrogen at 200 °C for 2 h, and then at 400 °C for 4 h; they were then cooled down to the reaction temperature under hydrogen and kept at the reaction temperature for 2 h. The amount of Re was adjusted to be 1.5 wt% for all catalysts. La_2O_3 and CeO_2 were obtained by thermal decomposition of $La(NO_3)_3$ and $(NH_4)_2Ce(NO_3)_4$ at 500 °C in air for 24 h. ZrO_2 was prepared by hydrolysis of $ZrOCl_2$ with aqueous ammonia, followed by drying at 110 °C for 12 h and calcining at 500 °C for 12 h. Al_2O_3 was a commercially available γ-Al_2O_3, which was used after calcination at 500 °C for 12 h.

Reaction Procedures. The reaction of CO_2 with H_2 was carried out in a flow reactor within the temperature range: 160—340 °C. A mixture containing H_2 and CO_2 at a mole ratio of 3:1 was fed through a constant volume of catalyst (1.8 ml) at a total pressure of 5 atm. The products were analyzed by gas chromatography using a column Porapak Q.

XPS and IR Measurements. Auger and X-ray photoelectron spectroscopic analyses were carried out by the use of an ESCA LABMK II electronic Auger spectrometer with an Al $K\alpha$ (1486.6 eV) excitation source. The infrared spectra of CO_2 and H_2 adsorbed on a catalyst placed in an in situ vacuum cell with CaF_2 windows were recorded with a NICOLET 5DX FT-IR spectrometer.

Results and Discussion

Catalytic Activity. Methanol was formed over Re/CeO_2, Re/ZrO_2, and Re/La_2O_3, but not over Re/Al_2O_3 and ZrO_2, or CeO_2 alone, although C_1 compounds (CH_3OH, CO, or CH_4) were the main products over all catalysts (Table 1). The product distribution changed, depending on the reaction temperature and space velocity. With an increase in the reaction temperature, the conversion of CO_2 increased and methanol selectivity decreased. With an increase in the space velocity, the conversion of CO_2 decreased, while methanol selectivity increased over the range 3000—12000 h^{-1}. Under the best reaction conditions, the highest selectivity for methanol formation was observed to be 76.7% over Re/CeO_2 at a reaction temperature of 160 °C.

Active Centers. The XPS spectra of Re/ZrO_2, Re/CeO_2, and Re/Al_2O_3 are shown in Figs. 1, 2, and 3, respectively. In both cases of Re/ZrO_2 and Re/CeO_2, the Re_{4f} peaks of those samples which were reduced with hydrogen at 400 °C were similar to the peak of Re metal, Re^0. The spectra of untreated NH_4ReO_4/ZrO_2 and NH_4ReO_4/CeO_2 were also similar to that of NH_4ReO_4, whose oxidation state of Re is 7+. This indicates that Re^{7+} on the surfaces was almost reduced to Re^0 by reduction

with hydrogen at 400 °C.

On the other hand, the spectra of Re/Al_2O_3 were different from that of Re metal, even when reduced with hydrogen at 600 °C; untreated NH_4ReO_4/Al_2O_3 also showed spectra different from NH_4ReO_4 alone. This is considered to be due to a strong interaction between the Re and Al_2O_3 support. This interaction makes the reduction of Re^{7+} to Re^0 difficult. This is in agreement with the conclusion by Yao and Shelef[3)] made on the bases of chemisorption, ESR, and temperature-programmed reduction. They reported that the dispersed phase of Re interacts strongly with the α-Al_2O_3 and, as a result, it can be reduced to a zero-valent state by H_2 only at a high temperature above 500 °C.

The methanol selectivity is considered to be affected by the adsorbed state of CO_2 on Re catalysts and, in particular, the the C–O bond strength. To determine the state of adsorbed CO_2, CO_2 was adsorbed and evacuated at room temperature and the XPS was measured. XPS in the region of O_{1s} are shown in Fig. 4. With the Re/γ-Al_2O_3 catalyst, C_{1s} peaks appeared at 290.3 and 284.6 eV. The former peak was assigned to the CO_3^{2-} species.

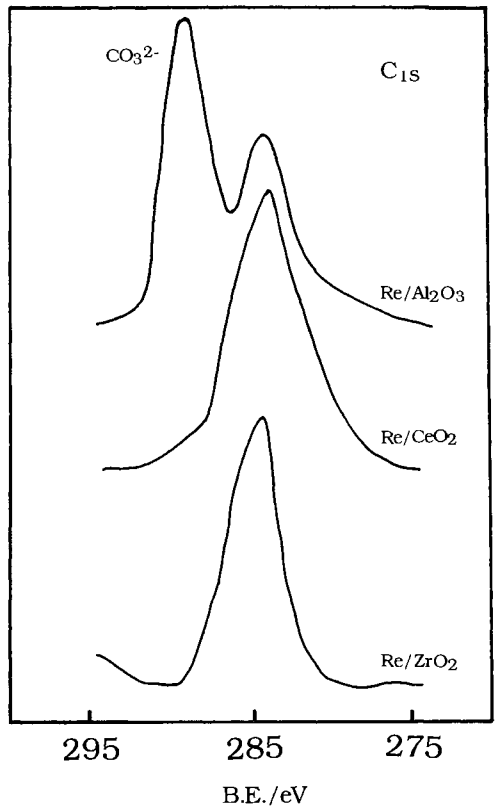

Fig. 4. XPS spectra of Re/CeO_2, Re/ZrO_2, and Re/Al_2O_3 after adsorption of CO_2 followed by evacuation at room temperature.

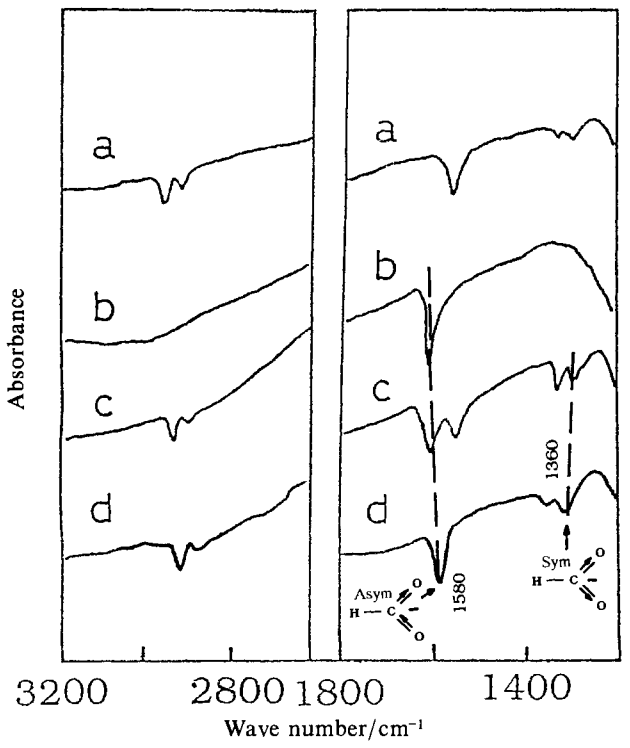

Fig. 5. IR spectra for CO_2/H_2 adsorbed on ZrO_2. a: CO_2/H_2, b: CO_2, c: CO_2/H_2 at 130°C, d: CO_2/H_2 at 230°C.

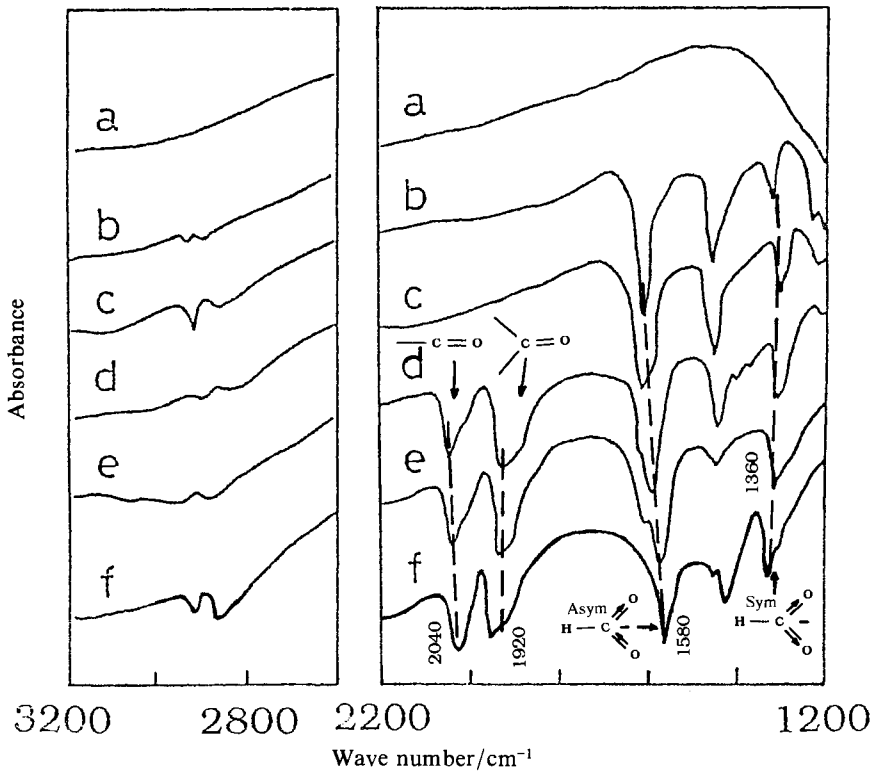

Fig. 6. IR spectra for CO_2/H_2 adsorbed on Re/ZrO_2. a: background, b: at 25°C, c: at 25°C in 8 h, d: at 100°C, e: at 200°C, f: at 300°C.

With Re/CeO_2 and Re/ZrO_2 catalysts, only one peak appeared at 284.6 eV, which was assigned to carbon atom. The C–O bond should be very strong in the state of CO_3^{2-}. No formation of methanol on Re/Al_2O_3 can be interpreted by the strong interaction between Re and γ-Al_2O_3, which causes a strong C–O bond.

Mechanism of Reaction. Figures 5, 6, and 7 show the FT-IR spectra of CO_2 and H_2 adsorbed on ZrO_2, Re/ZrO_2, and Re/CeO_2, respectively. The absorption bands at 1360, 1390, 1580, and 2880 cm^{-1}, which are assigned to $HCOO^-$(ad), appeared on the surfaces of both ZrO_2 and Re/ZrO_2 (Figs. 5 and 6). However, the bands at 2040 and 1920 cm^{-1}, which are assigned to CO(ad), appeared on Re/ZrO_2 (Fig. 6), but not on ZrO_2 (Fig. 5). The bonds at 2040 and 1920 cm^{-1} were assigned to linear and bridging carbonyls, respectively. Since the catalytic activity of Re/ZrO_2 for the reaction of CO_2 with H_2 was found to be much higher than that of ZrO_2, the $HCOO^-$(ad) species is not considered to be the active intermediate in the reaction. It seems likely that the CO(ad) species which was observed over Re/ZrO_2, but not over ZrO_2, is the active intermediate, although it is not certain which carbonyl is the intermediate. Since the CO species appeared at the adsorption temperature of 100 °C, at which no reaction took place, it is considered that the CO species did not result in the product, but from the adsorption of CO_2 and H_2. Thus, the reaction is considered to proceed by the conversion of CO_2 to CO(ad) followed by a reaction of CO(ad) with H(ad) formed on Re. This is in agreement with Iizuka's conclusion drawn from a comparative study between CO_2+H_2 and $CO+H_2$, for a Re/ZrO_2 catalyst.[2)]

The spectra for Re/CeO_2 were different from those for Re/ZrO_2. The band at 1220, 1300, 1410, 1460, and 1570 cm^{-1} were observed at the room temperature. The 1570 cm^{-1} band, which has a shoulder band at 1610 cm^{-1}, decreased its intensity and shifted to 1580 cm^{-1} with an increase in the temperature up to 130 °C, two new weak bands being formed at 1397 and 1550 cm^{-1}. The bands

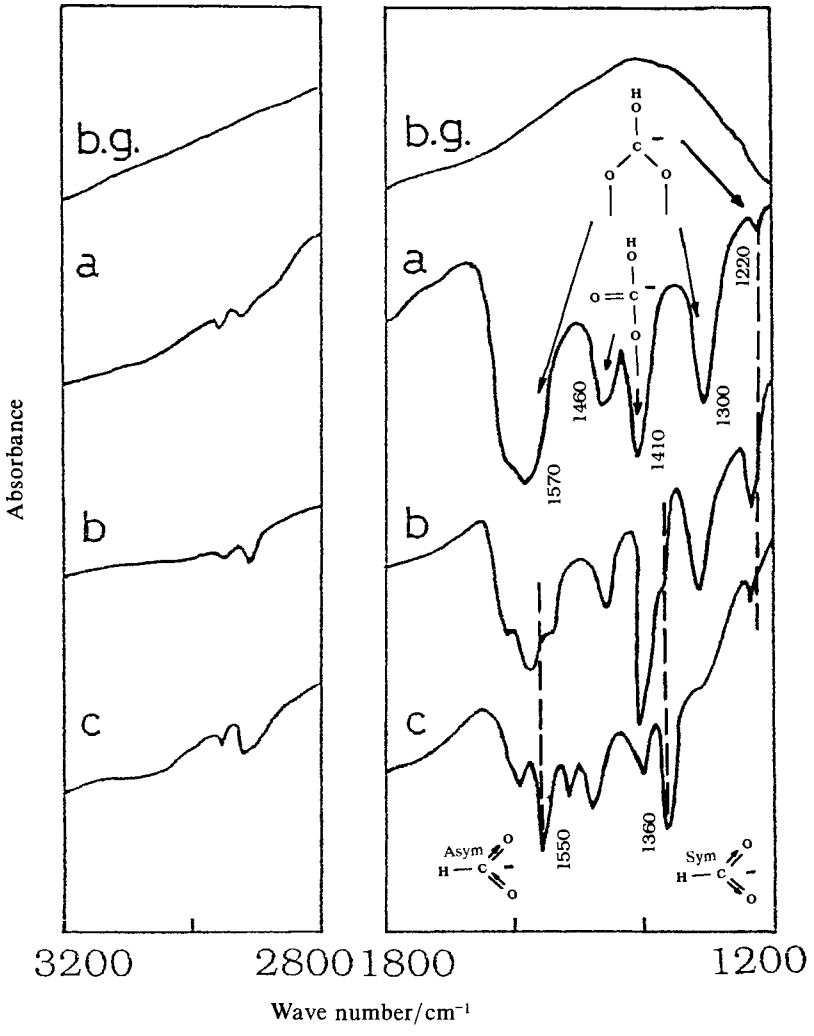

Fig. 7. IR spectra for CO_2/H_2 adsorbed on Re/CeO_2. b.g.: background, a: at room temp, b: at 130 °C, c: at 230 °C.

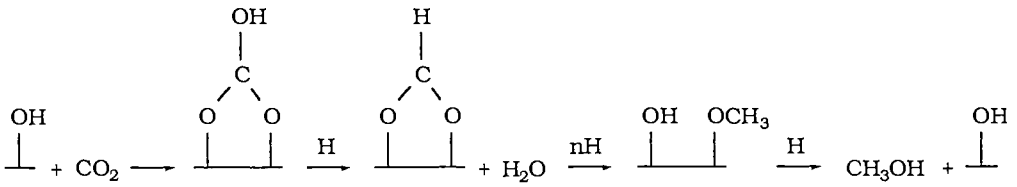

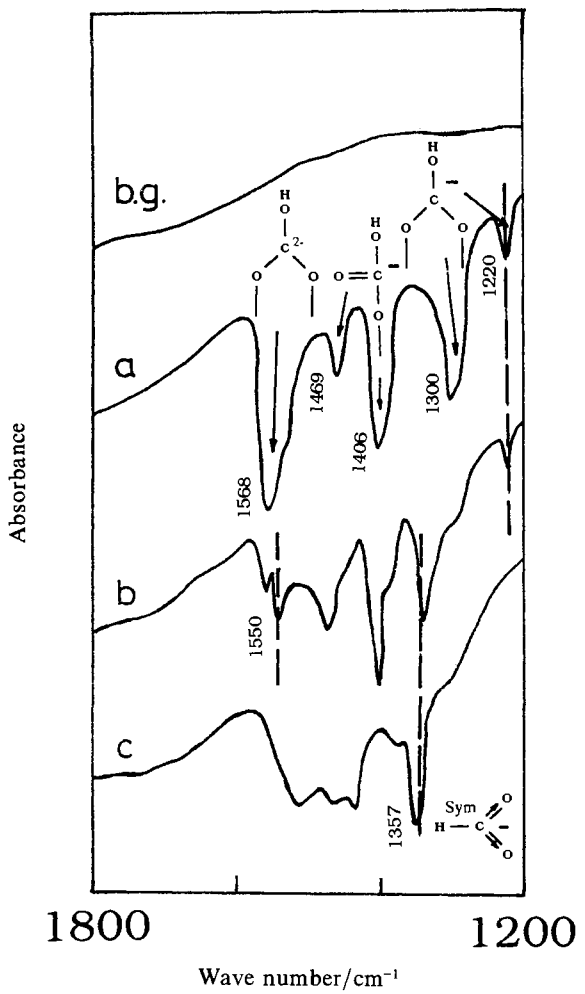

Fig. 8. IR spectra for CO_2 adsorbed on CeO_2. b.g.: background, a: at room temp, b: at 130 °C, c: at 230 °C.

at 1200 and 1610 cm^{-1} disappeared and the intensity of the bands at 1360, 1397, and 1550 cm^{-1} increased when temperature was raised to 230 °C. Since the $HCOO^-$(ad) species, which is evidenced by the bands at 1360 and 1550 cm^{-1}, exists on the surface of Re/CeO_2 at 230 °C under which a high yield of methanol was observed, it is suggested that the $HCOO^-$(ad) species is an active intermediate in the reaction over Re/CeO_2.

As shown in Fig. 8, the bands at 1220, 1300, 1406, 1469, and 1568 cm^{-1} were observed in the IR spectra of CO_2 adsorbed on CeO_2 at room temperature, but that the $HOCO_2^-$(ad) species, which is evidenced by 1220 cm^{-1}, disappeared when the temperature was increased to 230 °C; the 1357 cm^{-1} band was also observed at a higher temperature. This indicates that the $HOCO_2^-$(ad) and $HCOO^-$(ad) species could be formed on the surface of CeO_2 without Re. The XPS spectrum of the reduced Re/CeO_2 showed that an intense peak appeared at 530 eV, which was assigned to O_{1s} of the OH group. This indicates that a large amount of the OH group exists on the surface of Re/CeO_2. Therefore, CO_2 is considered to react with the surface OH (inserted to Ce–OH) to form $HOCO_2^-$(ad), as shown by the shoulder band at 1610 cm^{-1} in Fig. 6, in the first step. Then, $HOCO_2^-$(ad) reacts with H dissociated on Re (H–Re) to form $HCOO^-$(ad) over the surface Ce site on CeO_2 oxide, followed by the formation on CH_3O^- and CH_3OH by successive hydrogenation with hydrogen atoms which was dissociated on Re (H–Re). This can be illustrated by the scheme shown at the top of this page.

Increase of Solvent-Soluble Products of Coal by Repeated Butylation with Zinc and Butyl Iodide under Mild Conditions

Yoshiharu YONEYAMA,* Yutaka YAMAMURA, Kiyoshi HASEGAWA, and Tsutomu KATO
Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received November 29, 1990)

Yubari and Taiheiyo coals were repeatedly butylated with zinc metal powder and butyl iodide under mild conditions. After the benzene-soluble products (BS) from each reaction were combined the mixture was further butylated. The BS and its butylation products (Bu.BS) were fractionated by gel permeation chromatography. At each reaction step, BS with a similar structural character but different degrees of polymerization were solubilized for Taiheiyo coal; for Yubari coal BS with similar characteristics were solubilized. A large portion of these Bu.BS from both coals were solubilized in hexane. The molecular weight of BS decreased after butylation. These results suggest that this procedure brings about depolymerization as well as the introduction of butyl groups, while enhancing solubilization.

We previously developed a new alkylation procedure for coal solubilization,[1] which can effectively convert coal to benzene-soluble products under mild conditions (at 130 °C for 3—5 h under atmospheric pressure). The solvent-solubility of products is very high. Also, because of the ease of treating by the use of zinc metal powder and butyl iodide, this is a simple and safe method for coal solubilization; it is also suitable for examining coal structures.

In a previous paper we showed that the solubilization of low-rank coal in benzene is not increased by this method to a large extent,[1] and that the cleavage of the aliphatic linkage in coal structures increased with increasing number of alkyl groups attached to the aromatic rings.[2] In studies of coal solubilization under mild conditions, repeated reactions usually promoted bond cleavages.[3,4] It is thus expected that repeated butylation causes a high degree of coal solubilization; it is therefore of interest to examine changes in the degree of polymerization and that in the structural characteristics of coal products upon butylation.

The purpose of this study was to determine the solubility of reaction products obtained by repeated butylation, and to examine changes in their structural

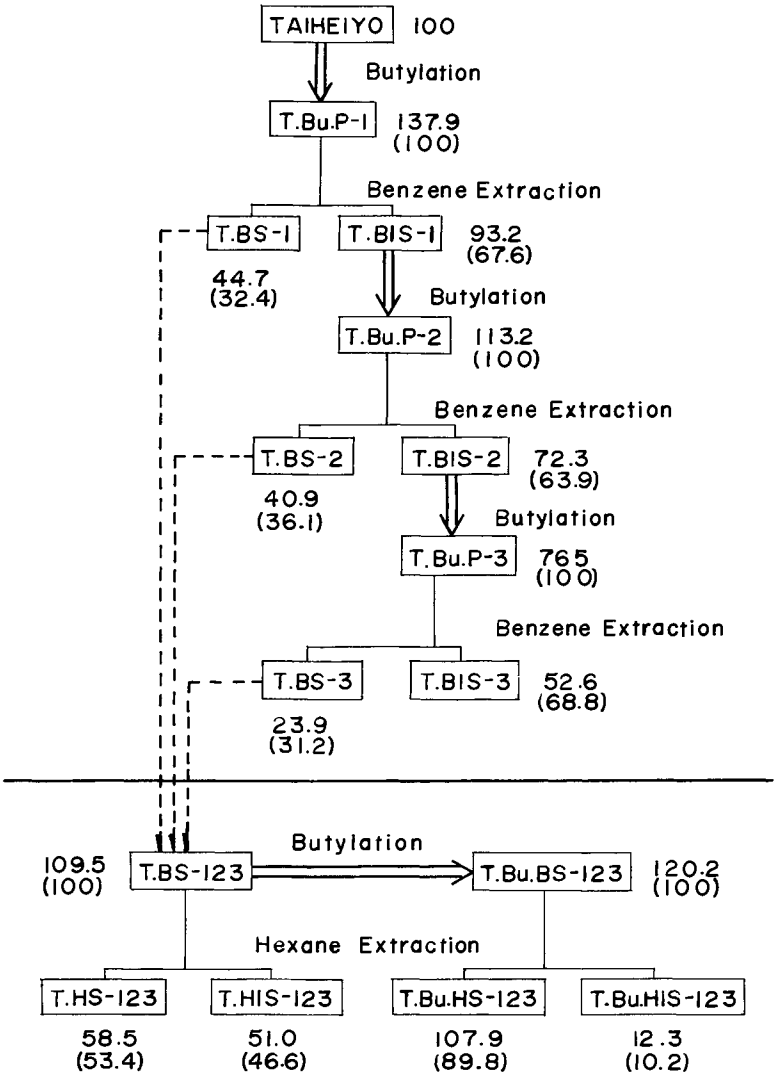
features.

Experimental

Yubari (C, 83.4%; H, 6.1%; N, 2.0%; Odiff, 8.5%; Ash, 5.1%) and Taiheiyo coals (C, 75.4%; H, 6.1%; N, 1.4%; Odiff, 17.1%; Ash, 8.3%) were used. The reaction was carried out in a similar way to that of a previous study:[1] 10 g of a coal sample, 40 g of zinc metal powder, and 100 ml of butyl iodide were placed in a 300 ml three-neck flask, while being agitated, the mixture was heated at 130 °C for 3.5—5 h under nitrogen in an oil bath. Then, unreacted butyl iodide was removed by evaporation and the mixture was washed with dilute hydrochloric acid to remove any unreacted zinc metal. The products were exhaustively extracted with hot benzene. The benzene-insoluble products (BIS) were successively butylated, twice for Yubari coal, and three times for Taiheiyo coal. The butylated products (Bu.P) were extracted with benzene, as described above. The benzene-soluble products (BS) from each reaction were combined, and the combined products further butylated. The BS and butylated BS (Bu.BS) were fractionated into hexane-soluble (HS) and hexane-insoluble products (HIS) by extraction with hexane. Details are given in Schemes 1 and 2. The BS and Bu.BS were separated into 8 and 7 fractions, respectively, by gel permeation chromatography (GPC), using packed columns of Bio-Beads S-X4 and S-X8 (25.4 mm i.d.×100 cm long); benzene was used as the eluent (cut volume, 6 ml). The number-average molecular weight (M_w) of each fraction was determined by VPO at 4—10 g kg^{-1} with a CORONA 114, using benzene as the solvent, and extrapolated to infinite dilution. Since most of the samples contained a small amount of iodine, the content was determined by the Schoeniger's method[5] to correct for analytical data. The FT-IR spectra were measured by a diffuse reflectance procedure using a JASCO FT/IR-3 spectrometer. The samples were ground with KBr prior to measurement. The structural parameters were estimated according to equations proposed by Brown and Ladner[6] and modified by Yokoyama et al.[7] The concerned structural parameters are as follows: The ratio of the number of aromatic carbons to the total number of carbons, f_a; the ratio of the number of peripheral aromatic carbons to total number of aromatic carbons (degree of aromatic ring condensation), H_{au}/C_a; the degree of aromatic ring substitution of the aliphatic chain, σ_{al}; the degree of aromatic



Scheme 2.

ring substitution of groups other than the aliphatic chain, σ_0; and the length of the aliphatic chain, n ($H_0/H_\alpha+1$). ^1H and ^{13} NMR spectra were taken on a JEOL JNM-FX 90Q spectrometer. Samples for measurements of the ^{13}C NMR spectra were prepared by dissolving approximately 100 mg of the coal products in 0.2—0.3 ml of $CDCl_3$; the spectra were measured with proton decoupling at a frequency of 22.49 MHz. The required pulse numbers were approximately 10000.

Results and Discussion

The yields of each fraction are shown in Schemes 1 and 2. The yields (daf) are based on the weights of the original coals and reactants, and are shown out of and within parentheses, respectively. Although the first Bu.P of Yubari coal could be dissolved in benzene to a high extent, the second one was less successful. In contrast, the benzene-solubility of Taiheiyo-Bu.P was almost constant at 30%, irrespective of the number of butylations. Table 1 shows the number of butyl groups introduced per 100 carbon atoms and the values of BS/Butyl calculated by the following equation:

$$\text{BS/Butyl (wt/wt)} = \frac{\text{Bu.P Yield (wt\%)} \times \text{BS Yield (wt\%)}/100}{\text{Bu.P Yield (wt\%)} - 100}.$$

These values, which are hereafter termed "solubilization efficiency (Es)", provide diagnostic criteria for judging coal solubilization. The butyl groups were much more easily introduced into coal during the first reaction than during later reactions; further, the introduction of butyl groups did not increase additional butylations. As can be seen from Figs. 1 and 2, the IR

spectra of the BIS from both coals showed a moderately intense band of apliphatic CH stretching at 2958—2871 cm^{-1}, and an aliphatic CH deformation at 1465 and 1379 cm^{-1}, upon gradually increasing Es; this was opposite to the decrease of the number of butyl groups introduced. From these facts, it is concluded that many butyl groups remained in BIS support of further dissolution of Bu.P during additional reactions. As described above, since the cleavage of aliphatic linkages of coal structures increases with increasing number of alkyl groups attached to aromatic rings, it seems that the linkage-cleavage reactions significantly occur during later butylation.

In the solubilization of coal by alkylation methods it is difficult to determine whether the solvent-soluble products are derived from the coal or the by-products.[8] In this study the values of Es were larger than 1, and no significant absorption peaks due to by-products, which may arise from the reaction with only butyl iodide and zinc, were present in the ^{13}C NMR spectra of all the solvent-soluble products. This allows us to confirm that the solvent-soluble products are derived from coal and that butylation really occurs.

Tables 2 and 3 summarize the ultimate analyses, M_w and the results of structural analyses. For Taiheiyo coal, the M_w of the BS gradually increased upon the repetition of the reaction, while for Yubari coal their M_w were almost the same at each step. For both coals, the results of the structural analyses of BS at each step were similar each other. These results indicate that for Taiheiyo coal products with similar structures and different degrees of polymerization solubilized.

It has been reported that repeated reactions usually promote the reaction on coal solubilization under mild conditions.[3,4] A similar result was obtained in this study; even Taiheiyo coal, a low-lank coal, solubilized in benzene to a high extent.

It has also been reported that the ease of cleavage of the aliphatic linkage in the coal structure increases with increasing the number of alkyl groups on the aromatic rings.[2] In this study, all of the BS obtained during each step was combined, and then further butylated,

structural parameters of these mixture and their butylation products, which were separated by GPC, are given in Tables 2 and 3. The changes of M_w and hexane-solubility are in Scheme 3. Repeated butylation increases the weight of the reactants. Butyl-free M_w of the butylated BS of Yubari (Y.Bu.BS-12) and Taiheiyo coals (T.Bu.BS-123) were 2140 and 2120, respectively. For Yubari coal, M_w of BS decreases after butylation. For Taiheiyo coal, M_w of the butylated BS (T.Bu.BS-123) was slightly higher than that of BS (T.Bu.BS-123). However, because the yields of the hexane-soluble products (HS) increased from 46.6% to 89.8%, it seems that M_w of the BS decreases due to this reaction. These results suggest that some linkages present in coal structures may cleave, as is expected from the results obtained from a study using model compounds.[2]

The GPC elution curves are shown in Figs. 3 and 4, and the M_w and structural parameters of these GPC fractions are listed in Tables 4 and 5. In each GPC separation, the samples which do not contain benzene-insoluble products were well fractionated in order of decreasing M_w; all of them were almost recovered after elution. Larsen et al.[9] have been reported that a larger-

molecular-weight material is strongly associated with one another and significant amounts of low-molecular-weight materials were incorporated into them, consisting of a cross-linked structure found by the GPC separation. It seems that such incorporation can also occur during this reaction.

As can be seen from Tables 4 and 5, there was a downward tendency for f_a, and an upward one for σ_{al} with increasing number of butyl groups introduced. The decrease in the values of σ_o is attributed to a cleavage of the functional oxygen-containing groups, as reported in the results regarding model compound studies.[2]

To obtain a large amount of solvent-soluble products under this mild condition, the resulting sample is suitable for estimating the coal structure. However, the solvent-soluble products are so heavy that high-molecular-weight materials incorporated a significant amount of low-molecular-weight ones. Therefore, to obtain detailed information concerning the coal structure, the pretreatment of coal products (such as hydrogenation under mild conditions and/or chemical-type separation) would be required.

Some portions of the cross-linkage of the coal structure were cleaved into solvent-soluble products, as described above. However, M_w of the HS obtained by this method corresponds to that of a preasphaltene by other methods.[10] Sternberg and Delle Donne[11] have reported that because petroleum asphaltene, in contrast to coal, contained a considerable number of alkyl groups attached to the aromatic clusters, they are largely soluble in benzene, in spite of the fact that they comprise a large number of aromatic rings per cluster, in compari-

son with coal. These facts indicate that the high extractability of butylated BS with hexane can be attained by introducing many butyl groups; the occurrence of some cleavage of the aliphatic linkages was suggested by the model compound study.

UV and DSC Analyses of Suspensions of Mixtures of Phosphatidylcholine and a Fatty Acid Having a Diene Group

Etsuo HASEGAWA, Masanori HATASHITA, Noboru KIMURA, and Eishun TSUCHIDA*
Department of Applied Chemistry, Waseda University, Tokyo 169
(Received December 9, 1990)

Synopsis. The aqueous suspensions of the mixtures of a phosphatidylcholine (1,2-Bis[(2*E*,4*E*)-2,4-octadecadienoyl]-sn-glycero-3-phosphocholine (**1b**) and 1,2-dioctadecanoyl-sn-glycero-3-phosphocholine (**1a**)) with a fatty acid ((2*E*,4*E*)-2,4-octadecadienoic acid and octadecanoic acid), having a diene chromophore were analyzed by DSC and UV measurements. The phase transition was dependent on the composition of the lipid mixtures. The UV spectral change of the diene chromophore of a fatty acid for the **1a** mixtures corresponded well with the phase transition determined by DSC analyses, but not for the **1b** mixtures.

Liposomes composed of phosphatidylcholine and other lipids have been studied as biological membrane models.[1] However, liposomes are often unstable and tend to aggregate and precipitate during storage. To overcome these problems, charged compounds such as fatty acid, phosphatidic acid, dihexadecyl hydrogenphosphate, and octadecylamine, which can control the surface potential of liposomes, are incorporated in phosphatidylcholine bilayers. Among them, fatty acids are interesting because they are one of the components of biological membranes and are present at high concentrations in certain membranes: for example, 8% in rat liver plasma.[2] They control various membrane-mediated cellar functions,[3-6] such as the enzyme activity, membrane fluidity, permeability, and fusion. A mixture of fatty acid and phosphatidylcholine is a simple model membrane used for understanding the roles of fatty acids in biological membranes.

Studies on the mixtures of a fatty acid and a phosphatidylcholine having saturated acyl chains have revealed:[7-10] (1) fatty acids eliminate the pretransition; (2) mixing is good at the 1:2 molar ratio of saturated phosphatidylcholine and fatty acids having the same carbon numbers (1:2 complex formation); (3) the thermal phase transition is a lamellar-to-nonlamellar phase, and (4) the apparent pKa of fatty acid in the lipid bilayer is surprisingly large.

A phase-transition analysis of lipid bilayer membranes is normally carried out by DSC, NMR, and ESR methods. In addition to these types of measurements, a simple method using UV measurements has been reported: for example, on lamellar aggregates of single-chain amphiphiles containing a chromophore, such as an azobenzene residue.[11] The shift of λ_{max} of the chromophore is useful for a phase-transition analysis. A phosphatidylcholine having polymerizable groups (dienes) in acyl chains is also used as a UV probe of bilayer transitions.[12]

We describe here an application of a diene-containing fatty acid to bilayer transition analysis of fatty acid–phosphatidylcholine mixtures by a UV measurement, and compare the results with those of a DSC measurement.

Experimental

Materials. 1,2-Bis[(2*E*,4*E*)-2,4-octadecadienoyl]-sn-glycero-3-phosphocholine (**1b**), (2*E*,4*E*)-2,4-octadecadienoic acid (**2b**), and 1,2-dioctadecanoyl-sn-glycero-3-phosphocholine (**1a**) were purchased from Nippon Oil & Fats Co., Ltd. 1-Hexadecanoyl-(2*E*,4*E*)-2,4-octadecadienoyl-sn-glycero-3-phosphocholine (**1c**) was prepared.[13] The purity was confirmed by thin-layer chromatography on silica gel. Octadecanoic acid was purchased from Kishida Chem. Co., Ltd. **2b** was recrystallized once from hexane. Benzene was distilled from calcium hydride. Phosphatidylcholine and fatty acid mixtures were prepared by freeze-drying from dry benzene.

Lipid suspensions were prepared by adding a prescribed amount of distilled water to the freeze-dried powder. They were suspended with glass beads (diameter: 2—3 mm) on a Vortex mixer at a temperature above the transition temperature under a nitrogen atmosphere for 15 min.

DSC was performed by using DSC 10 (Seiko I&E). Samples were placed into silver microtubes, and measurements were run with temperature scanning at 2 °C min^{-1} under a nitrogen atmosphere.

The temperature-dependence of the absorption maximum corresponding to the diene groups of lipid suspension was analyzed in a quartz cell (path-length: 10 mm) with UV spectrometry (Shimadzu MPS-2000) with a heating rate of 1 °C min^{-1}.

Results and Discussion

A saturated phospholipid (1,2-dioctadecanoyl-sn-glycero-3-phosphocholine (**1a**)) and an unsaturated one (1,2-bis-[(2*E*,4*E*)-2,4-octadecadienoyl]-sn-glycero-3-phosphocholine (**1b**)) were used and mixed with a saturated fatty

acid (octadecanoic acid (**2a**)) or an unsaturated one ((2*E*,4*E*)-2,4-octadecadienoic acid (**2b**)). All of the compounds have acyl chains of the same carbon numbers (18), since it has been reported that mixing strongly depends on a combination of the chain length of a phospholipid acyl chain and the fatty acid.[8] The phase-transition behaviors were analyzed by DSC measurements and by observing the UV spectral change of the diene chromophores upon increasing the temperature at a constant rate.

The DSC analyses were performed on lipid suspensions packed in silver microtubes, but not on aluminum ones, due to the presence of an acid compound. Figure 1 shows DSC curves for various mixtures of the phospholipids and the fatty acids with different molar ratios. As shown in Fig. 1b, the mixture of **1a** and **2b** showed a single peak upon increasing the fraction of the fatty acid component up to 0.67 and the transition temperature increased, as in the case of mixtures of **1a** and **2a** (Fig. 1a). This means that two components mix well under mole fractions of the fatty acid up to 0.67. An increase of the fatty acid component to more than 0.67 causes the formation of a domain of excess fatty acid, in addition to a homogeneously mixed domain of **1a** and **2b** with a molar ratio of 1:2. This can be seen by the appearance of two peaks.

Apart from these two mixtures, those related to unsaturated phospholipid **1b** showed complexed behaviors, as indicated in Figs. 1c and 1d. The mixtures showed three transitions in the DSC curves with increasing the mole fraction of the fatty acid component. This indicates that the good mixing found in mixtures of the saturated phospholipid **1a** with fatty acids did not occur in those of the unsaturated phospholipid **1b** mixtures. Figures 1c and 1d indicate that the phase transitions at lower temperatures change to transitions at higher temperatures with an increase in the fatty acid fraction.

At mole fractions of a fatty acid less than 0.3 the mixture showed two peaks, corresponding to the presence of two blocks: one comprising pure **1b**, and the other comprising **1b** and a fatty acid with a molar ratio of 1.6—2.0:1.0. The molar ratio could be calculated from a decrease in the endothermic heat change, compared to that of a pure **1b** suspension. Upon further increases in the mole fraction of a fatty acid component up to 0.67, the first intermediate mixture changed to the second and third mixtures along with a concomitant decrease of **1b**, itself, and the first intermediate mixture. At a much higher content of a fatty acid, the **1b** mixtures form a block of excess fatty acid; this was confirmed by the appearance of an endothermic peak of pure fatty acid **2a** or **2b**, as in the cases of mixtures of **1a** and a fatty acid. Therefore, the third peak may be responsible for the 1:2 homogeneous mixtures that are normally found in the saturated lipid systems described above.

It has been reported that the UV chromophores of phospholipids and synthetic surfactants can be used to determine the phase-transition temperatures of their molecular assemblies.[11,12] The absorption maxima change sharply at the transition temperature. Here, we tried to use the diene chromophore of fatty acid **2b** to analyze mixtures with phospholipids **1a** or **1b**.

Mixtures of **1a**/**2b** gave a spectral change in the UV region with the temperature. Figure 2 summarizes the changes in the absorption maxima of various mixtures of **1a** and **2b** with increased temperature. The changes were sharp in the mixtures (the mole fraction of **2b** up to 0.67) and the phase-transition temperatures could be calculated. Mixtures of **1b** with a fatty acid had only one transition.

Table 1. Comparison of Transiton Temperatures Determined by DSC and UV Measurements[a)]

Lipid mixture	Transition temperature (T_c)/°C							
	Mole fraction of fatty acid							
	0.0	0.13	0.22	0.30	0.50	0.67	0.83	1.00
1a/2a	55	55	—	61	—	72	66	65
1a/2a (2b)	(54)	(57)	—	(62)	(68)	(69)	—	—
1a/2b	55	54	—	58	61	62	62, 69	68
	(54)	(54)	—	(58)	(63)	(63)	—	—

	(18)	(19)	(22)	(27)	(36)	(35)	—	—
1b/2b	19	21	20, 25	18, 24	16, 26, 47	27, 49	25, 62, 68	68
	(18)	(21)	(21)	(23)	(31)	(27)	—	—

a) The values in the parentheses mean transition temperatures determined by UV measurements.

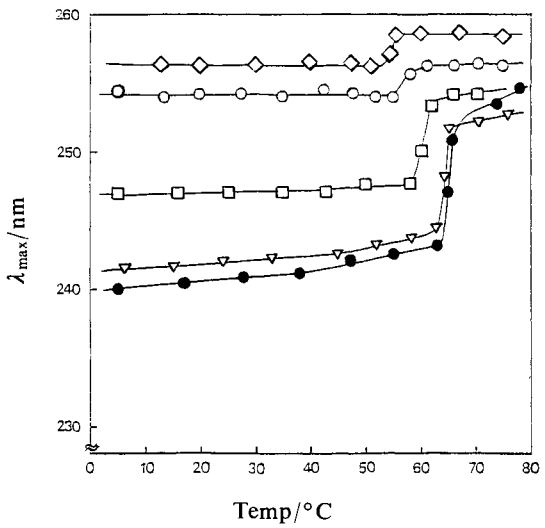

Fig. 2. Temperature dependence of the absorption maxima for diene groups in various mixtures of **1a** and **2b**. Mole fraction of **2b**: 0 (◇), 0.13 (○), 0.30 (□), 0.50 (▽), 0.67 (●).

Table 1 summarizes the transition temperatures (T_c) of various lipid mixtures determined by DSC and UV measurements. For **1a**/**2b** and **1a**/**2a** mixtures, both measurements gave the same transition temperatures, respectively, but not for the mixtures of **1b** with a fatty acid. The results show that care must be taken when using a UV probe for the determination of phase-transition temperatures.

These results indicate for the miscibility of phosphatidyl choline with fatty acid that: (1) the (2*E*,4*E*)-diene group containing a fatty acid is capable of mixing well with saturated phosphatidylcholine as does a saturated fatty acid; (2) the presence of the (2*E*,4*E*)-diene moiety in diacyl chains of phosphatidylcholine interferes with the homogeneous mixing with a fatty acid. In addition to these results, a diene-containing phospholipid, 1-hexadecanoyl-2-[(2*E*,4*E*)-2,4-octadecadienoyl]-sn-glycero-3-phosphocholine (**1c**, T_c: 24 °C),[12)] gave a single transition peak (T_c: 57 °C) when it was mixed with **2a** with a molar ratio of 1:2. This indicates that the (2*E*,4*E*)-2,4-octadecadienoyl group at the 2-position of the glycerol backbone is not responsible for non-homogeneous mixing of **1b** with a fatty acid.

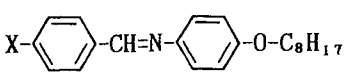
(Received January 5, 1991)

Synopsis. Mesomorphic properties are studied on the title compounds where substituents are F, Cl, Br, I, NO_2, and CN. Besides the known mesophases, nematic and smectic Ad, in CN and NO_2 homologues, stable smectic A and B phases were observed in either of the Cl and Br derivatives. Metastable nematic and smectic A phases were found in F derivative. The effects of terminal polar substituents, stabilization of the smectic A phase by moderately polar substituents, and of the nematic phase by strongly polar substituents, were confirmed.

The liquid crystalline compound, 4-octyloxy-*N*-(4-cyanobenzylidene)aniline (CBOOA) has been studied extensively as one of the typical compounds having smectic A (S_A) and nematic (N) phases. CBOOA is very popular not only because it exhibits stable S_A and N phases at relatively low temperatures but also because of its interesting physical properties. McMillan's early study[1] which suggested the existence of a second order S_A–N phase transition in this compound stimulated a good number of experiments on the nature of this phase transition.[2-7] It is also of particular interest that CBOOA was shown to exhibit a thermotropic reentrant nematic (RN) phase transition at high pressures.[8,9] It has been conceived until now that this peculiar property is attributable to the strong antiferroelectric intermolecular interaction caused by the cyano end group.[10,11] Noting that strong polarity of the terminal substituent is essential, Prasad et al.[12] studied whether RN phase also appeared at high pressures when the cyano group is replaced by nitro group. In this homologue (NBOOA), however, the S_{Ad}/N phase boundary was quite straight in the p–T phase diagram, and the reentrant nematic phase transition did not take place until up to 2 kbar. In this way the kind of terminal substituent delicately affects the liquid crystalline properties. In a recent paper[13] we showed that terminal polar substituents counteracts on the thermodynamical stability of the S_A state, namely, moderately polar substituents stabilize the S_A state whereas strongly polar substituents relatively stabilize the N state. It was also shown that all of the parameters of the Kobayashi–McMillan's pair and mean field potentials were determined experimentally. In order to further study the terminal polar substituent effect, we prepared a series of compounds, 4-octyloxy-*N*-(4-substituted benzylidene)anilines, where X are H,



F, Cl, Br, and I. The liquid crystalline properties are studied and compared among the seven compounds including the known cyano and nitro derivatives, and the substituent effect is compared with the results obtained in the three-ring systems.[13] Although the conventional namings XBOOA may also be used, the symbols [X] are used for short in this paper.

Experimental

The materials were synthesized through dehydration condensation of 4-X-substituted benzaldehyde with 4-octyloxy aniline, the latter of which was prepared from potassium 4-acetamidophenoxide by Williamson's method.[14] Chemical analyses gave good agreement with the formulae.

Dipole moment of the molecule was determined with heterodyne beat method in dilute benzene solutions at 25 °C. The temperatures and the entropies of phase transitions were measured with a Seiko Electronics DSC 20 calorimeter. The temperature was calibrated by the melting of zone-refined biphenyl, and the transition enthalpy was calibrated by the solid–solid phase transition of potassium nitrate and the melting transitions of gallium, indium, tin, and biphenyl. Smectic layer spacings were determined from the first order quasi-Bragg reflection of copper $K\alpha$ radiation. The scattering angle was calibrated by the (001) peak of the monoclinic c-polytype powder of stearic acid. Proton NMR lineshape was recorded in [Cl] and [Br] to assess the molecular alignments in the smectic phases with a laboratory-made Fourier-transform NMR spectrometer. The liquid crystalline phases were identified with the aids of texture observation, X-ray diffraction, proton NMR spectrum, and the DSC experiments.

Results and Discussion

Dipole Moment of the Molecule. Values of the dipole moments, μ, of the molecules are given in Table 1. Since the value of μ in [H], 1.77 D (1 D=1 Debye=3.3356×10^{-30} C m), measures contributions from the linkage groups, –CH=N– and –O–, the larger values for the other six compounds show that a permanent dipole parallel to the long molecular axis is formed by the polar substituent. The halogeno compounds exhibit values in the range of 2.60 ± 0.08 D, and [NO_2] and [CN] have values greater than 5 D.

Identification of the Liquid Crystalline Phases. In the known compound, [CN] and [NO_2],[12,15,16] the reported mesophases, S_A and N, were confirmed from the microscopic texture observations. Differential scanning calorimetry and the texture observation revealed that no liquid crystalline phases appear in [H] and [I]. [F] showed metastable N and S_A phases of only narrow temperature ranges on cooling from the isotropic (I) phase. In either of [Cl] and [Br], two liquid crystalline phases were found, both of which were of smectic type in microscopic appearances. DSC study revealed that the smectic-to-smectic and the smectic-to-isotropic phase transitions were strongly of first order, and the entropy of the former transition was about half in mag-

Table 1. Dipole Moment μ of the Molecule, and the Smectic Layer Spacings, d, in the S_B and S_A Phases

Compound	μ/Debye	d/Å (S_B)	d/Å (S_A)
[H]	1.77	—	—
[F]	2.52	—	—
[Cl]	2.56	25.1	24.7
[Br]	2.68	25.8	25.4
[I]	2.65	—	—
[NO_2]	5.14	—	31.9
[CN]	5.21	—	35.7

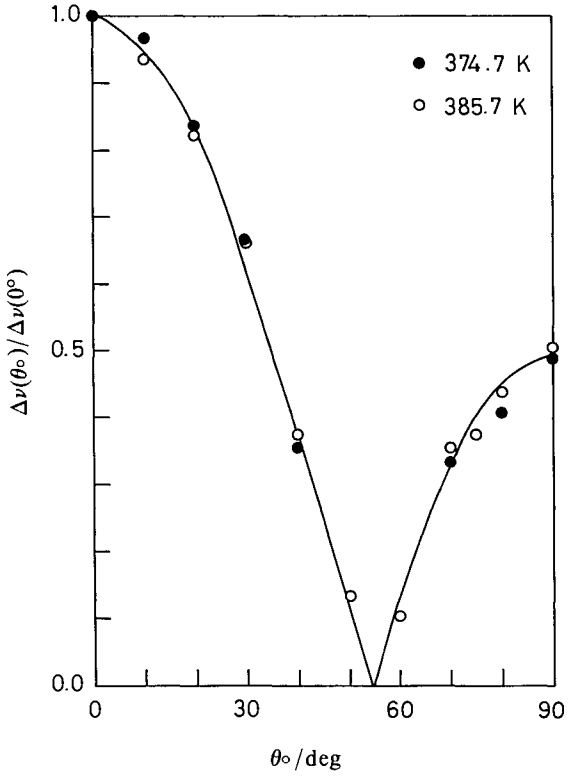


Fig. 1. The angular dependence of the proton NMR splitting frequency normalized to that taken at $\theta_o=0°$ in the high (○) and low (●) temperature smectic phases of [Br]. Each phase is assigned to S_A and S_B in the text. θ_o is the angle between the external magnetic field and the averaged direction of the director. The solid line represents $p_2(\cos\theta_o)$ where p_2 is the Legendre polynomial of rank two.

nitude that of the latter transition. More decisive results in identifying these phases were obtained from the angular dependence studies of the proton NMR lines. Figure 1 shows the angular dependence of the dipolar splitting of the phenyl protons in [Br]. The open and the filled circles show the data taken in the high and low temperature smectic phases, respectively. If the smectic states are of the orthogonal type (in which the averaged direction of the molecular long axis is not tilted from the layer normal), the dipolar splitting frequency is given by the equation,[17]

$$\Delta\nu(\theta_o)/\Delta\nu(0°) = |p_2(\cos\theta_o)|, \quad (1)$$

irrespective of the magnitude of orientational order parameter. Here θ_o is the angle between director and the external magnetic field, and p_2 (x) is the Legendre polynomial of rank two. Figure 1 clearly show that the experimental results follow Eq. 1, and the dipolar splitting vanishes as θ_o approaches the magic angle (54.7°). Both of the smectic phases are thus revealed to be of orthogonal type. The result in [Cl] was quite similar to that of [Br]. Judging also from the textures, DSC, and X-ray results, the high and low temperature mesophases were concluded to be S_A and S_B, respectively. The phase transition behaviors of all the compounds studied are summarized in Table 2.

Layer Spacings in the Smectic Phases. The smectic layer spacings were measured in S_A and S_B phases, and are summarized in Table 1. Judging from the stereochemical molecular model, the molecular length along the long axis is 23—24 Å in this series of compounds. The observed values of d in the S_A phases of [Cl] and [Br] shows that these mesophases are of the monolayer type, whereas those in [NO_2] and [CN] belong to S_{Ad} modification, as has been already reported. The observed d in the low temperature smectic (S_B) phase in [Cl] and [Br] is consistent with the monolayer model, and is also consistent with the NMR result.

Entropies of Phase Transitions. The temperatures and the entropies of phase transitions are summarized in Table 2. The entropies of N–I phase transitions, ΔS_{NI}, observed in [NO_2] and [CN] were 0.249 R and 0.273 R, respectively, where R is the gas constant. These are considerably smaller than the universal value of 0.42 R predicted by the statistical theories of Maier and Saupe[18] and McMillan.[19] On the other hand, the entropies of S_B–S_A transition, ΔS_{BA}, observed in [Cl] and [Br] were 0.908 R and 1.034 R, respectively, both of which are larger than 0.559 R predicted by Meyer and McMillan.[20] The S_{Ad}–N transition entropy was too small to be detected in [CN], while it amounted to 0.165 R in [NO_2]. Details on the difference in nature of the two S_{Ad}–N phase transitions will be described elsewhere.[21] Table 2 also summarizes the total amount of the entropies of phase transitions in each of the compounds. It is of some interest to point out that the accumulated entropies of phase transitions in each of the compounds amount to like values, 116±8 J K^{-1} mol^{-1}, proving that the entropy of the condensed state in such a rod-like compound is acquired mainly at the phase transitions in a stepwise manner until the isotropic symmetry is finally obtained. This fact was first pointed out by Tsuji et al.[22] in the 4-substituted *N*-(4-hexyloxybenzylidene)anilines, analogues to our series having reversed linkage group and shorter alkyl chain, where the accumulated entropy was 93.6±2.5 J K^{-1} mol^{-1}. The latter value is comparable to but a little smaller than our result. The difference (22 J K^{-1} mol^{-1}) is attributable to the difference in chain length because of the following assessment. If three conformations are allowed for each of the methylene group, the conformational entropy shared by the two methylene units is $2R \ln 3$=18.3 J K^{-1} mol^{-1}, which explains the above dif-

Table 2. Temperatures and Entropies of Phase Transitions

Observed stable phases are designated by *. The plain figures represent the temperatures of phase transition in Kelvin, and the parenthesized figures stand for the discontinuities of entropy at the phase transitions in the unit of J K^{-1} mol^{-1}. Accumulated entropy of phase transitions for each compound is shown in the last column.

ference fairly well.

Effect of Terminal Polar Substituents on the Liquid Crystalline Properties. It was shown by the present authors[13] that terminal polar substituents bring about increase in the intermolecular attractive force, and also bring about counteracting contributions to the stability of the S_A phase in the homologous series of 4-substituted *N*-[4-(4-octyloxybenzoyloxy) benzylidene]anilines (OBBX series). In that case, the tendency of liquid crystal formation was strongly enhanced in the homologous compounds with polar end groups compared with the unsubstituted one. It was also shown that moderately polar substituents like halogens significantly stabilized the S_A phase, but extremely polar substituents such as cyano group relatively stabilized the N phase. The general conclusions still hold in the present series: namely, the liquid crystalline nature is enhanced in [Cl], [Br], [NO_2], and [CN] compared with the non-mesogen [H]. It is also recognized that N phase is relatively stabilized in [NO_2] and [CN], whereas destabilized and lost in [Cl] and [Br]. It is the expected tendency that the halogeno compounds favor the S_A state. It should be noted, however, that two-ring compounds generally have less tendency of forming the liquid crystalline phase than three-ring compounds, and it is the major difference in the phase transition behaviors of the present and the OBBX series. The survival of the high temperature crystalline phase up to above 390 K in [I] and the existence of only metastable N and S_A phases in [F] will be attributable to this general tendency.

We thank Dr. Hatsumi Mori for her kind advice and collaboration in DSC measurements.

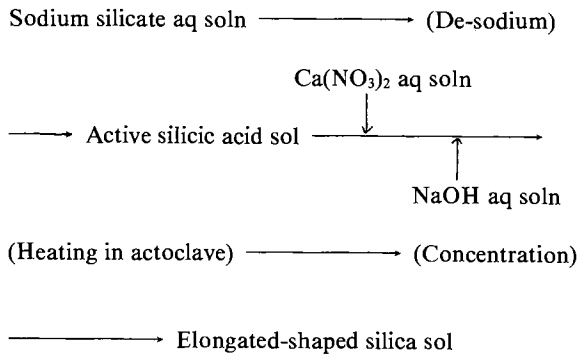
(Received February 6, 1991)

Synopsis. An active silicic acid sol was added to a mixture of a $Ca(NO_3)_2$ aqueous solution and a NaOH aqueous solution, then the mixture was heated for several hours under stirring at 100—150 °C to obtain a silica sol. The silica sol consisted of elongated-shaped colloidal particles desirable for film formation.

Most of the commercially available silica sols have spherical particles[1,2] of 4—150 nm in diameter or cocoon-like nonspherical particles.[3] Iler[4] prepared an amorphous silica sol by heating a wet silica gel in an autoclave.

However, he did not succeed in establishing the conditions to prepare sols with other shapes, such as an elongated shape which is desirable for filmformation.

In this note, we first report the preparation of elongated-shaped silica sols. The method is based on the addition of Ca^{2+} ions to an active silicic acid sol, and is represented by the following scheme:



In this process, several factors such as (1) the amount of Ca^{2+} and Na^+ ions contained in silica sols, (2) the reaction temperature, and (3) silica concentration, significantly influenced on shape of the final silica sol particles.

The experimental findings are qualitatively summarized as follows:

1) The Ca^{2+} ion is strongly adsorbed to the surface of the active silicic acid sol. In the course of heating the sol in an autoclave, the Ca^{2+} ion plays a crucial role in the formation of elongated-shaped particles, namely, the ion controls the directionality of particle growth. Too high a Ca^{2+} ion content leads to rapid gelation of the sol, while too low a Ca^{2+} ion content makes the particle shape spherical.

2) A base such as NaOH is necessary for the particle growth of colloidal silica where the Na^+ ion is strongly adsorbed to the surface of the active silicic acid sol. When the Na^+ ion content is too high, the particle-shape becomes spherical, while the sol is liable to gelate if it is too low.

3) When the silica content is too high, the sol readily gelates during the reaction.

4) A moderately high reaction temperature gives silica sols with a large specific surface area and the elongatedshape. Too high a temperature leads to rapid gelation of the silica sols, and too low a temperature gives spherical particles with a small specific surface area. To obtain the elongated-shaped silica sols it is essential to control these factors strictly. For instance, when a silica sol composed of SiO_2 3.2%, CaO 208 ppm, and Na_2O 550 ppm (SiO_2/Na_2O molar ratio=60) was allowed to react at 130 °C for 6 h and then concentrated up to 20% in silica content, the sol is elongated. A transmission electromicroscope (TEM) photograph of the elongated-shaped silica sol thus obtained is shown in Fig. 1. It is seen that the elongated-shaped sol growing in one direction has an almost uniform size of 10—15 nm in diameter. The average particleslength measured by the dynamic light scattering method (N4,

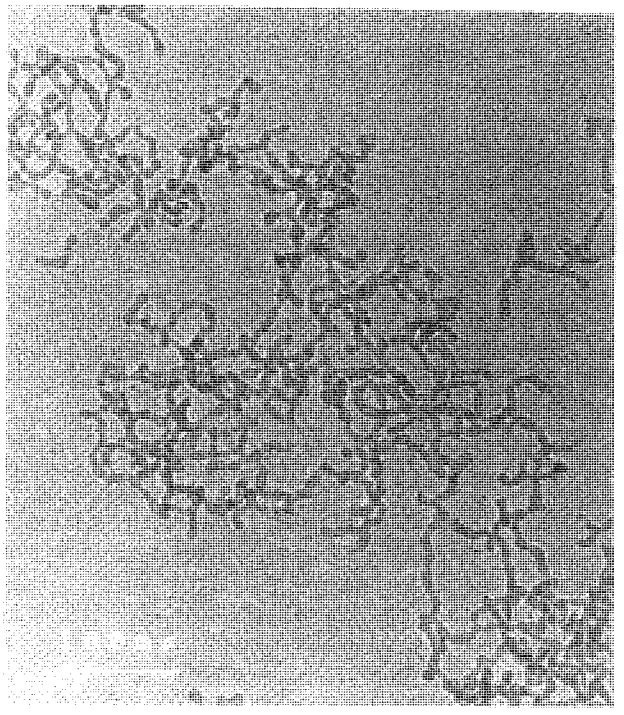


Fig. 1. TEM image of the elongated silica sol.

Table 1. Characteristics of the Elongated Silica Sol

Specific gravity (at 20 °C)	1.130
pH (at 25 °C)	9.65
Viscosity/cP[a] (at 25 °C)	46.3

a) 1 P=10^{-1} Pa s.

D1nm) was 65.8 nm, and the ratio of the particle size measured by this method and by the BET method (D2nm) was 5.4. The characteristics of the sol are given in Table 1.

Under the above-mentioned preparation conditions, the amounts of Ca^{2+} and Na^{+} ions correspond to 0.65 wt% and 1.7 wt% of SiO_2, respectively. Hence, on assumption that the silanol sites on the surface of the elongated-shaped silica particles are exchanged with these ions during the reaction, the fractions of these ions in the total surface silanol sites (i.e., the surface coverages of the ions) are 3.9% for Ca^{2+} and 18.7% for Na^{+}.

XANES Spectra of $Co(ala)_3$ and $Co(acac)_3$ in Solid and Solution

Mitsuru SANO
Department of Chemistry, College of General Education, Nagoya University, Nagoya 464-01
(Received May 28, 1990)

Synopsis. XANES spectra of $[Co(ala)_3]$ and $[Co(acac)_3]$ have been measured in solid and solution. Comparisons of spectra of the species in solid and solution give a basis for the spectral change being attributable to intermolecular interactions.

X-Ray absorption spectra near K-edge have been measured for many years. The relations between XANES features and electronic structures of the absorbing atom have been extensively studied. In spite of some successful studies,[1] full understanding still remains for further systematic studies.

In recent papers,[2,3] the author reported that systematic measurements of Co K-edge XANES for Co(III) complexes showed counter-ion effect for $[Co(NH_3)_6]X_3$ (X=Cl, Br, and I), and that the Co XANES spectra of $[Co(H_2O)_6](ClO_4)_2$, $[Co(H_2O)_6]SO_4$, and $[Co(NH_3)_6]Br_3$ in solid are different from those in solution. These findings suggest that "the counter ion effect" in solid does not originate from a long-range effect as ejected electrons directly interact with counter ions but from a short range effect where XANES is influenced by slight distortion of a local electronic and geometrical structure induced by counter ions. Then, if this suggestion is correct, it is expected that XANES spectra of non-charged compounds without counter ions in solution will differ from those in the crystal in which a strong intermolecular interaction such as hydrogen-bonding exists. In order to make sure this, I measured XANES spectra of (+)mer-$[Co(ala)_3]$ (ala^-=alaninate) which has hydrogen bonds in the crystal and those of $[Co(acac)_3]$ ($acac^-$=4-pentanedionate) which has no strong intermolecular interaction in the solid, and compared them with those in solution.

The cobalt(III) complexes were prepared and recrystalized according to standard methods.[4] Organic solvents were purified by distillation. A solid sample was ground and diluted with boron nitride and contained in a plastic cell. A small volume of each sample solution (0.1 M, 1 M=1 mol dm^{-3}) was contained in a teflon cell with teflon windows. X-Ray absorption measurements were carried out at the BL-10B on the storage ring of Photon Factory (KEK). Synchrotorn radiation (2.5 GeV, 120—280 mA) was monochromatized with a chnnel-cut Si(311) monochromater. Other instrumental details are given in Ref. 5. The absorption spectra were measured in the transmission mode at room temperature. All spectra have been normalized to give an edge jump of 1.0.

Figure 1 shows the XANES spectra and their first

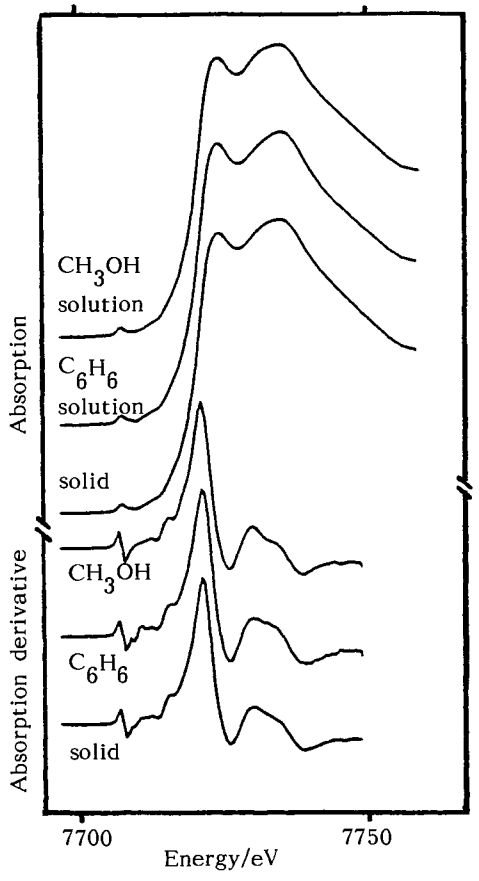

Fig. 1. Co K edge spectra and their derivatives of $[Co(acac)_3]$ in solid and solutions.

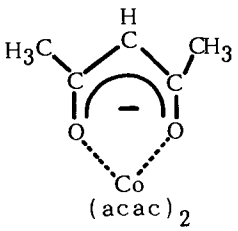
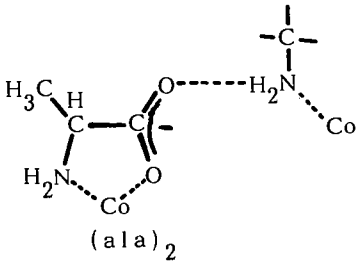


Scheme 1.



Scheme 2.

derivatives of $[Co(acac)_3]$ in crystal and solution, and Fig. 2 the corresponding spectra of $[Co(ala)_3]$. The spectra of $[Co(acac)_3]$ are similar to each other and also similar to those of its acetonitrile and dimethylformamide solutions. Although the XANES spectrum of $[Co(ala)_3]$ in crystal generally resembles that in aqueous solution, some small differences are found in 7725—7750 eV; two absorptions can be observed in solution and three absorptions in solid.

The crystal structures of both complexes have been well studied.[6-7] The coordination form for $[Co(acac)_3]$ is schematically shown by Scheme 1 and six Co–O bond lengths are practically the same (Co–O=1.883—1.892 Å).[5] This suggests the absence of strong intermolecular interactions in solid $[Co(acac)_3]$. This is also supported by the fact that the compound easily sublimes. Since there is no strong intermolecular interaction in solid $[Co(acac)_3]$, it is expected that the conditions of geometrical and electronic structures are the same in solid and in solution. This can be the reason for the XANES spectra being similar to each other. In $[Co(ala)_3]$,[7] the alaninate ions coordinate to a cobalt ion as shown in Scheme 2. Strong hydrogen bonds exist between the complexes in the crystal in Scheme 2. This strong interaction between the molecules causes a change in the geometrical arrangement and charge distribution within the molecule, which will result in a change in the electronic state. The interaction between the complex and water in aqueous solution is much weaker than that between the complexes in solid. The intermolecular interaction in crystal different from that in solution results in a change in a different geometrical and electronic structure and thus a change in the spectra of $[Co(ala)_3]$.

The present result exemplifies that the XANES spectral change is attributable to the intermolecular interaction associated with a geometrical and electronic local change rather than direct interactions of the electron wave with surrounding atoms. It also discloses what is "the counter-ion effect". Yamashita et al.[8] reported a correlation between XANES patterns and crystal packing structures. These findings demonstrate how much change of XANES in solid by intermolecular interaction. It is useful to compare with XANES of solid compounds and theoretical consideration.

The author thank professor Hideo Yamatera at Daido Institute of Technology for his useful discussion and his encouragement. This work has been performed under the approval of the Photon Factory Program Advisory Committee (Proposal No. 86015).

Intercalation of a Triethylenetetramine-Substituted Cyclodextrin by Co(II)- and Ni(II)-Montmorillonites

Tsuyoshi KIJIMA,* Hiromoto NAKAZAWA,† and Satoshi TAKENOUCHI†
Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 889-21
† National Institute for Research in Inorganic Materials, Tukuba, Ibaraki 305
(Received September 26, 1990)

Synopsis. The intercalation of mono[6-[(8-amino-3,6-diazaoctyl)amino]-6-deoxy]-β-cyclodextrin (CDtrien) by Co(II)- and Ni(II)-montmorillonites was examined at 25 °C. At low uptakes, the CDtrien molecules in both minerals form a monolayer, 13—14 Å thick, with their cavity axes perpendicular to the silicate layers. At higher loadings, guest molecules with the same orientation form a bilayer in Co- (21.8 Å thick) and Ni-montmorillonites (17.6 Å). Their thicknesses are larger than those for the Cu-and Zn-analogues, 16.1 Å, i.e. twice the molecular thickness.

New porous solids have been required for the platforms of immobilized enzymes, for improved columns in adsorption and ion-exchange chromatography, and for effecting gas separations.[1] Our attention has been focused on developing microporous inclusion compounds having novel characteristics. An organic and inorganic double host material is an example which can be obtained by the intercalation of host molecules such as cyclodextrins in inorganic hosts.[2-4] We recently studied the intercalation of mono[6-[(8-amino-3,6-diazoctyl)amino]-6-deoxy]-β-cyclodextrin(CDtrien) by Na-, Ca-, Cu-, and Zn-montmorillonites, and revealed the mechanism of the CDtrien intercalation and the arrangement of the guest molecules in the host cavities.[5] This paper reports on the intercalation of CDtrien by Co(II) and Ni(II)-montmorillonites.

In a previous paper,[5] the mode of intercalation by Ca-montmorillonite was explained by the formation of CDtrien$(H_2O)_2$–Ca complexes. However, after this paper was published, it was found by analytical scanning electron microscopy that the uptake of CDtrien by Ca-montmorillonite is accompanied by a remarkable release of Ca, which forms a second phase. A reexamination by X-ray diffraction suggested that the second phase is calcium carbonate. Thus, the previous explanation must be modified as follows: the intercalation by Ca-montmorillonite proceeds by an ion exchange of interlayer Ca^{2+} ions with the divalent cationic forms of CDtrien, as in the case of Na-montmorillonite.

Experimental

The CDtrien and the Na-montmorillonite used as starting minerals were the same as those used in a preceding study.[5] The Co(II)- and Ni(II)- exchanged minerals were prepared by placing the Na-montmorillonite in a 1.25 mol dm^{-3} solution of $CoCl_2$ and $NiCl_2$ at 25°C for 10d, respectively. The exchanged products were fully washed with water, centrifuged, and lyophilized. The Co(II)- and Ni(II)-clays were soaked in an aqueous solution containing 0.25, 1, 1.5, and 3.0 mmol of CDtrien per gram of clay at 25 °C for 10 d, centrifuged, fully washed with water, and air-dried at 40 °C. The CDtrien and water contents in the resulting solids were determined by thermogravimetric analysis. An X-ray diffraction measurement was made using Fe-$K\alpha$ radiation, and 1-tetradecanol having a long d-spacing (39.90 Å) was used as an external standard.

Results and Discussion

The uptakes of CDtrien for Co(II)- and Ni(II)-montmorillonites are plotted against the amount of CDtrien added (Fig. 1). The interlayer spacings of the resulting solids were determined from 001 reflections in the X-ray diffraction patterns. Figure 2 shows the variation of Δ, the thickness of the intercalated layer obtained by subtracting 9.5 Å, the thickness of the silicate layer, from the observed d-spacings. When 0.25 mmol of CDtrien was added per gram of each clay, a phase with a Δ value of 12.9—14.1 Å appeared and coexisted with its parent host phase. With a further addition of CDtrien the solids were converted into a single phase with a Δ value of 21.8 (Co-intercalate) or 17.6 Å (Ni-intercalate). The uptake curves of both intercalates showed saturation. The CDtrien uptakes were accompanied by the release of interlayer metal ions, as shown in Fig. 1.

Table 1 summarizes the Δ values and compositions of intercalates of Co- and Ni-montmorillonites with

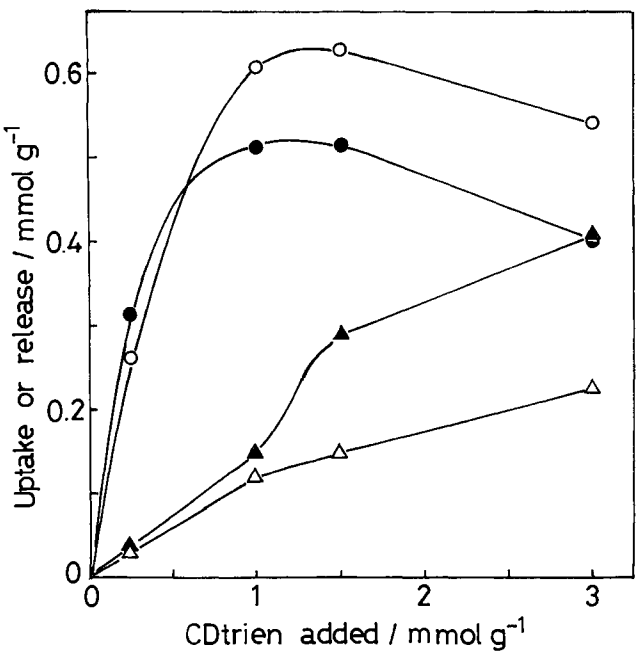

Fig. 1. CDtrien uptake by (○) Co- and (●) Ni-montmorillonites and release of (△) Co^{2+} and (▲) Ni^{2+} ions as a function of CDtrien added.

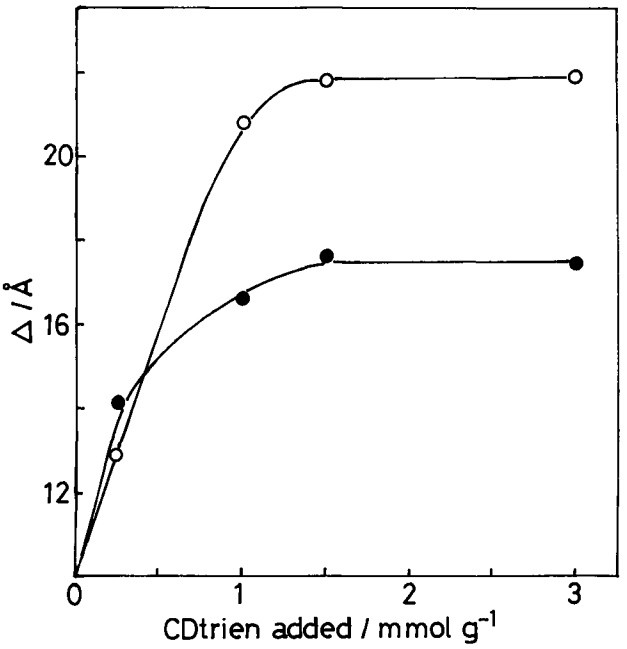

Fig. 2. The thickness of the intercalated layer, Δ (see text), as a function of CDtrien added. Key as in Fig. 1.

CDtrien obtained at an addition level of 1.5 mmol g^{-1}. The initial amounts of the cationic and the neutral forms of interlayer metal ions in Co(II)- and Ni(II)-montmorillonites were evaluated as described previously.[5]

The uptake reaction for Co-and Ni-montmorillonites took place in the pH range of as narrow as 8.3—8.9. Similarly to the previous discussion,[5] the above-mentioned data indicate that the intercalation of CDtrien by Co-and Ni-montmorillonites proceeds by the formation of CDtrien–Co^{2+} or CDtrien–Ni^{2+} complexes at low uptakes and by the combined modes of complexation and an ion exchange of Co^{2+} or Ni^{2+}/CDtrien2H^+ at higher loadings, where CDtrien2H^+ is the divalent form of CDtrien. We can, thus, evaluate the amounts of interlayer metal ions desorbed and those of both neutral and ionized forms of intercalated CDtrien (Table 1). At addition levels of more than 1.5 mmol g^{-1}, the uptake of CDtrien shows a tendency to decrease, in contrast to an increase in the release of interlayer metal ions. This can be explained by assuming that the CDtrien uptake due to ion exchange increases, whereas that due to complexation decreases appreciably, resulting in a decrease in the total uptake of CDtrien.

According to the literature,[6] the stability constants for trien–Cu^{2+}, trien–Ni^{2+}, trien–Zn^{2+}, and trien–Co^{2+} complexes in solution are $10^{20.4}$, $10^{14.0}$, $10^{12.1}$, and $10^{11.0}$, respectively. If stability constants of CDtrien–metal ion complexes in the solid state are assumed to be comparable to those in solution, the complexation tendency would be of the order of $Cu^{2+} \gg Ni^{2+} > Zn^{2+} > Co^{2+}$. In contrast, the experimental result is the order Co^{2}(90.5)$\gg Cu^{2+}$(65.9)$> Ni^{2+}$(56.9)$\gg Zn^{2+}$(23.8), where the amounts of the neutral form of intercalated CDtrien in mol% are given in parentheses. The high degree of complexation for Co^{2+} ion could be explained in terms of the extremely high stability of the structure of interlayer CDtrien complexes, as is discussed later. The relatively high degree of complexation for the Ni^{2+} ion can also probably be attributed to a similar structural effect.

The previous observations[5] showed that Cu(II)- and Zn-montmorillonites intercalate CDtrien to form a bilayer at high uptakes: the bilayered molecules are in a close contact with each other at a van der Waals distance of 16.1 Å, with their cavity axes perpendicular to the silicate layers and with the trien groups pointing both upward and downward in the intramolecular-complexing or divalent cationic forms. On the other hand, the Δ values for the Co(II)- and Ni(II)-intercalates are greater by 5.7 and 1.5 Å than those for the Cu- and Zn-analogues, respectively. This fact suggests that the CDtrien molecules in the former two intercalates are also arranged as a bilayer with the same orientation, but with a looser contact of 5.7 or 1.5 Å between the layers.

Upon heating up to 150 °C, the CDtrien layers of the Co(II)-intercalate contracted in thickness from 21.8 to 19.7 Å, due to the release of interlayer water. No interlayer contraction, on the other hand, was observed for the Cu- and Zn-intercalates. These observations suggest that at least a part of the interlayer water molecules participates as a ligand in the formation of the expanded bilayer in the Co-intercalate. It is thus suggested that the CDtrien molecules in Co(II)-montmorillonite form a 1:1 octahedral aqua complex, CDtrien$(H_2O)_2$–Co^{2+}, and that they are dimerized with a tail-to-tail arrangement, as illustrated in Fig. 3. The intercalated CDtrien$(H_2O)_2$–Co^{2+} complex would be highly stabilized by such a dimerization. A similar dimerized structure was observed for the CDen intercalate of Cu-montmorillonite.[2]

The intercalated layers of the Ni(II)-intercalate is also contracted in thickness from 17.6 to 16.2 Å upon heating up to 150 °C. This fact suggests that a slight expansion

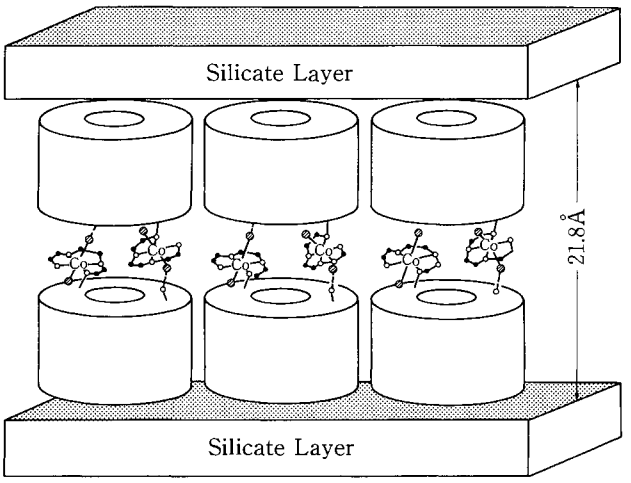

Fig. 3. A tentative model of the arrangement of CDtrien molecules in the interlayer space of Co-montmorillonite. ●, C; ○, N; ◍, water molecule.

of the CDtrien bilayer in the Ni(II)-intercalate also results from the interlayer water molecules and that the anhydrous form of the intercalate may have a structure similar to that of the Cu(II)- and Zn-intercalates. Thus, the CDtrien molecules in Ni(II)-montmorillonite are likely to make an isolated octahedral aqua complex, CDtrien$(H_2O)_2$–Ni^{2+}. The slight increase in the thickness of CDtrien$(H_2O)_2$–Ni^{2+} complex bilayer can be understood by assuming that they are more rigid and more bulky than the square plannar CDtrien–Cu^{2+} or tetrahedral CDtrien–Zn^{2+} complex.

The authors wish to thank Dr. Haruo Ohashi for his helpful discussions.

Determination of Rhodium by Third-Derivative Spectrophotometry with *o*-Hydroxyhydroquinonephthalein in the Presence of *N*-Hexadecylpyridinium Chloride†

Itsuo MORI,* Yoshikazu FUJITA, Minako TOYODA, and Sachi MAEKUBO
Osaka University of Pharmaceutical Sciences, Matsubara-shi, Osaka 580
(Received November 29, 1990)

Synopsis. A third-derivative spectrophotometric determination ($d^3A/d\lambda^3$) of rhodium with *o*-hydroxyhydroquinonephthalein (Qnph) in the presence of *N*-hexadecylyridinium chloride (HPC) was proposed by measuring the distance of $d^3A/d\lambda^3$ on the peak at 530 nm (λ_3) and the troughs at 500 nm (λ_2) and 560 nm (λ_4). Beer's law was valid for the range 0—10 μg rhodium 10^{-1} cm^3; the apparent molar $d^3A/d\lambda^3$ was 7.37×10^5 dm^3 mol^{-1} cm^{-1}.

The most popular spectrophotometric method for the determination of rhodium, one of the platinum metals, is based on reaction between rhodium(III) and tin(II) chloride in hydrochloric acid medium.[1-3] However, this method is not sensitive and lacks reproducibility. On the other hand, the derivative spectrophotometric method has recently been found to be more sensitive, selective, and reversible than classical zero-order derivative spectrophotometries.[4-6] In addition, we have recognized that *o*-hydroxyhydroquinonephthalein (Qnph) used as a xanthene dye is a most useful organic agent.[7-9] Also, the coexisting effect of such surfactants as *N*-hexadecylpyridinium chlorid (HPC) has been reported in various spectro- or fluoro-photometries.[10-12] Accordingly, for the purpose of establishing a sensitive and simple spectrophotometric determination of rhodium, a third-derivative spectrophotometric determination with Qnph was investigated in the surfactant micellar media.

Experimental

Apparatus and Reagents. Absorption and high-derivative spectra were recorded on a Shimadzu UV 160 spectrophotometer with a 1.0-cm matched cell. The third-derivative spectrum was recorded by a fixed third-order differentiation circuit of $\Delta\lambda$=31.5 nm with a scan speed of 1500 nm per min. A Hitachi-Horiba F-7AD glass electrode pH meter was used for pH measurements.

A Qnph solution, 1.0×10^{-3} mol dm^{-3} was prepared by dissolving Qnph in methanol. A 5.0×10^{-4} mol dm^{-3} rhodium(III) solution was diluted by using a standard atomic absorption spectroscopy solution (Wako chemical Co., Ltd.). A 1.0×10^{-2} mol dm^{-3} HPC solution was prepared by dissolving HPC in water; a Sörensen phosphate buffer solution (pH 6.4—7.2) was used for the pH adjustments. Deionized water was used throughout.

Standard Procedure. To a solution containing 0—10 μg rhodium(III) in a 10-cm^3 volumetric flask, 3.0 cm^3 of a 2.0×10^{-2} mol dm^{-3} buffer solution (pH 6.5), 1.0 cm^3 of a 1.0×10^{-2} mol dm^{-3} HPC solution and 0.8 cm^3 of 5.0×10^{-4} mol dm^{-3} Qnph solution were added; the mixture was diluted to volume with water (Solution A), kept at 75 °C for 30 min, then cooled to room temperature (10—25 °C) for 5 min. The $d^3A/d\lambda^3$ distances at 500 nm (trough λ_2), 530 nm (peak λ_3) and 560 nm (trough λ_4) were measured against a reagent blank (Solution B).

Results and Discussion

Absorption Spectra. Figure 1 shows the absorption spectra of the Qnph–rhodium(III) solution (Solution A) and the Qnph solution (Solution B) in the presence of HPC as a cationic surfactant (or absence). The color formation reaction in the presence of HPC was stable and exhibited a large absorbance in comparison with that in the absence of HPC. In addition, the derivative spectrum (third-derivative, $d^3A/d\lambda^3$) of Solution A against Solution B was most sharp and apparent. Figure 2 shows two peaks (λ_1 480 nm, λ_3 530 nm) and three valleys (λ_2 500 nm, λ_4 560 nm, λ_5 610 nm). The analytical response was obtained by measuring the absorbance distance between the peak at 530 nm (λ_3) and the valleys at 500 nm (λ_2) and 560 nm (λ_4); its value was large compared with the zero-order derivative absorption spectrum.

Effect of pH. The maximum and constant $d^3A/d\lambda^3$ was obtained within limited ranges of pH 6.4—7.2,

using 2.0—3.0 cm^3 of a 2.0×10^{-1} mol dm^{-3} phosphate buffer solution. Accordingly, 3.0 cm^3 of a buffer solution (pH 6.5) was used for pH adjustments in all further work.

Effect of Surfactants. The complex formation reactions between Qnph and rhodium(III) were systematically investigated by using the $d^3A/d\lambda^3$-method in the absence or presence of only a surfactant, or its combination; cationic-, anionic, nonionic-, and amphoteric-surfactants—HPC, sodium dodecylsulfate (SDS), Tween 20, sodium *N*-lauroylsarcosine (LS). The coexistence of only the cationic surfactant was most effective, and its color was stable and abundant regarding reproducibility. In tested cationic surfactants such as hexadecyltrimethylammonium chloride (HTAC), benzyldimethyltetradecylammonium chloride (Zephiramine, Zp), benzyltriethylammonium chloride (TBBAC), and HPC, the presence of 5.0×10^{-3} mol dm^{-3} HPC was most effective.

Table 2. Effect of Foreign Ions

Foreign ions	Added		$d^3A/d\lambda^3$	Error
	as	μg/10 cm^3		%
—	—	—	3.80	—
Co(II)	Nitrate	0.30	3.81	+0.3
Ni(II)	Nitrate	4.40	3.83	+0.8
Zn(II)	Nitrate	3.27	3.82	+0.6
Bi(III)	Nitrate	0.52	3.88	+2.1
Th(IV)	Nitrate	1.16	3.81	+0.3
S^{2-}	Sodium	0.80	3.79	−0.3
$S_2O_3^{2-}$	Sodium	0.28	3.80	+0
$C_2O_4^{2-}$	Sodium	6.6	3.79	−0.3
Citrate	Sodium	14.10	3.78	−0.6
F^-	Potassium	144.50	3.80	±0

Rhodium(III) taken, 5.0 μg 10 cm^{-3}; Qnph, 5.0×10^{-4} mol dm^{-3}; HPC, 1.0×10^{-3} mol dm^{-3}; pH, 6.5; Reference, reagent blank (Solution B).

Accordingly, final 1.0×10^{-3} mol dm^{-3} HPC was used for a further investigation.

Effect of Concentration of Qnph. The recommended concentration of Qnph was final 0.4—1.0×10^{-4} mol dm^{-3}, and final 5.0×10^{-5} mol dm^{-3} Qnph was used for subsequent procedures.

Effect of Stability. The effects of the temperature and heating time were examined at 10—80 °C for 2—60 min. The optimum heating condition was at 70 °C for 5—20 min; further work was carried out at 70 °C for 5 min.

Calibration Graph and Reproducibility. Beer's law held at lower than 10 μg of rhodium(III) per 10 cm^3, and apparent molar $d^3A/d\lambda^3$ was 7.37×10^5 dm^3 mol^{-1} cm^{-1}. The reproducibility for 5 μg/10 cm^3 rhodium(III) (5 experiments) was 1.5%.

Interferences. Although nickel(II), zinc(II), bismuth(III), thorium(IV), and other platinum metals, such as palladium, gave a positive error, and citrate, oxalate, thiocyanate ions gave negative errors, the infuluence of foreign ions on the proposed $d^3A/d\lambda^3$-method was reduced to about half, compared with zero-order spectrophotometry. For a mixture of rhodium and other platinum metals, pre-separation by other techniques, such as ion exchange chromatography,[13,14] was necessary.

Composition of Complex. The molar ratio of rhodium(III) to Qnph in a color formation reaction in the presence of HPC was determined by continuous variation (Job's) and molar-ratio methods to be 2:3; the molar ratio of rhodium(III) to HPC, however, was not investigated.

Conclusion. The complex formation reaction between Qnph and rhodium(III) in the presence of a cationic surfactant alone, such as HPC at pH 6.5, was very stable and abundant regarding reproducibility. Accordingly, this Qnph-rhodium(III) complex was newly used for a sensitive and simple third-derivative spectrophotometry of rhodium(III). The $d^3A/d\lambda^3$-method was compared with zero-order spectrophotometry; the calibration graph was linear over the range 0—10 μg rhodium(III) per 10 cm^3. The proposed method was 5-times more sensitive, and the influence of foreign ions

was reduced by half compared with the zero-order method. Also, the method was 10-fold more sensitive than Chromazurol S, and 30-fold more sensitive than the Eriochrome Cyanine R and 4-(2-pyridylazo)resorcinol methods.[15,16]

Synopsis. A new dichlorodimanganese(III) and novel tetrachlorodimanganese(IV) complexes with 1,2,3,4-tetrakis-(salicylideneamino)-2,3-diphenylbutane were prepared and characterized. The obtained dimanganese(IV) complex was rather stable to moisture in the solid state, but readily reduced to the corresponding dimanganese(III) complex in a methanol solution. The complexes can not be electrochemically formed as mixed valence states.

Binuclear manganese(III) and (IV) complexes have been receiving considerable attention as model systems for the photosynthetic oxygen-evolving complex.[1-4] From the viewpoint of these interests, many of the oxygen-bridged (μ-oxo, μ-hydroxo, and/or μ-phenyloxo) type binuclear manganese(III) and some μ-oxo type binuclear manganese(IV) complexes have been prepared and characterized.[5-9] In these complexes, the bridging oxo ligands are considered to play a role in connecting two or more high-valent manganese ions in the molecules. Actually, the binuclear manganese(IV) complexes reported hitherto regarding the above-mentioned interests are almost limited to the μ-oxo type complexes.[6-9]

In this paper we report on the syntheses and properties of a new type of binuclear manganese(III) and (IV) complexes with an octadentate Schiff base ligand, 1,2,3,4-tetrakis(salicylideneamino)-2,3-diphenylbutane (H_4sabzta), which do not contain a bridging oxo ligand. For the sake of a comparative study, the corresponding mononuclear manganese(III) and (IV) complexes with 1,2-bis(salicylideneamino)-1-phenylethane (H_2sabzen) were also prepared.

Experimental

Syntheses. The ligands, H_4sabzta and H_2sabzen, were prepared by a method described in our previous paper.[10]

[Mn_2(sabzta)Cl_2]: Manganese(II) chloride tetrahydrate (3.64 mmol) and tetrabutylammonium permanganate, (TBA)MnO_4, (0.78 mmol) were added to a dry ethanol solution (20 cm^3) containing H_4sabzta (2.21 mmol). This solution was refluxed for 2 h and then cooled to ambient temperature. The dark-brown crystalline powder obtained was collected. The crude product was recrystallized from methanol. The yield was ca. 42%. Found: C, 60.01; H, 4.24; N, 6.14%. Calcd for $C_{44}H_{34}N_4O_4Mn_2Cl_2 \cdot H_2O$: C, 59.95; H, 4.12; N, 6.36%.

[Mn(sabzen)Cl]: This complex was obtained as a dark-brown crystalline powder by reacting manganese(II) chloride tetrahydrate (1.79 mmol), (TBA)MnO_4 (0.60 mmol) and H_2sabzen (2.39 mmol) in dry ethanol (20 cm^3) in a way similar to the method for Mn_2(sabzta)Cl_2. The crude product was recrystallized from methanol. The yield was ca. 45%. Found: C, 59.42; H, 4.34; N, 6.02%. Calcd for $C_{22}H_{18}N_2O_2MnCl \cdot 3/4H_2O$: C, 59.21; H, 4.40; N, 6.28%.

[Mn_2(sabzta)Cl_4]: Mn_2(sabzta)Cl_2 (0.11 mmol) was suspended in dry acetone (20 cm^3); a methanol solution (2 cm^3) containing hydrochloric acid (0.21 mmol) was then added dropwise to the suspension. The obtained deep-green clear solution was filtered and the filtrate was concentrated under reduced pressure. The deep-green crystals obtained were collected and washed with dry acetone. The yield was ca. 23%. Found: C, 57.06; H, 4.22; N, 5.50%. Calcd for $C_{44}H_{34}N_4O_4Mn_2Cl_4 \cdot C_3H_6O$: C, 56.87; H, 4.06; N, 5.64%.

[Mn(sabzen)Cl_2]: This complex was obtained as deep-green crystals by treating Mn(sabzen)Cl (0.11 mmol) with hydrochloric acid in a way similar to that for Mn_2(sabzta)Cl_4. The yield was ca. 30%. Found: C, 56.25; H, 4.00; N, 5.77%. Calcd for $C_{22}H_{18}N_2O_2MnCl_2$: C, 56.43; H, 3.87; N, 5.98%.

Measurements. The IR spectra were recorded on a JASCO A-102 grating spectrometer on a KBr disk. Electronic spectra were recorded on a Hitachi 220A recording spectrophotometer. The electric conductivities were determined by a Horiba Conductivity Meter (Model DS-14). Polarograms were recorded on a Yanagimoto Polarographic Analyzer (Model P-1100) in dichloromethane containing 0.1 mol dm^{-3} tetrabutylammonium perchlorate as the supporting electrolyte, by the use of a three-electrode cell equipped with glassy carbon as a working electrode, a platinum coil as an auxiliary electrode, and a saturated calomel electrode (SCE) as a reference electrode. In practice, all of the potentials were normalized by the use of ferrocene as an internal standard. The magnetic susceptibilities were measured by the Faraday method over the temperature range 85—300 K.

Results and Discussion

[Manganese(III) Complexes]. Since the binucleating ligand H_4sabzta has two "salen-like" donating sites, where H_2salen denotes 1,2-bis(salicylideneamino)ethane, the two manganese(III) ions in Mn_2(sabzta)Cl_2 are expected to hold in each of the above-mentioned donating sites. The IR spectrum of Mn_2(sabzta)Cl_2 is almost similar to that of the corresponding mononuclear complex Mn(sabzen)Cl and Mn(salen)Cl.[11] Further, it does not show any characteristic bands at 700—600 cm^{-1}, due to the presence of the μ-oxo or μ-peroxo structure.[6] The magnetic moments of Mn_2(sabzta)Cl_2 and Mn(sabzen)Cl per one manganese atom at room temperature are 5.08 and 4.90 BM, respectively. These obtained values are consistent with the spin-only value expected for a d^4 high-spin manganese(III) complex. The magnetic moment of the binuclear complex was almost independent of the temperature over the range 85—300 K, indicating the absence of a spin-exchange interaction between the metal ions. This is in contrast with the magnetic properties of the μ-oxo type dimanganese(III) complexes, in which a rather strong antiferromagnetic spin-exchange interaction between the manganese ions via oxo group(s) has been observed.[5-8]

Table 1. Electronic Spectral Data for Manganese(III) and (IV) Complexes

Complex	Solvent	$\tilde{\nu}/10^3$ cm^{-1} (log ε)			
Mn_2(sabzta)Cl_2	CH_2Cl_2	20.3 (3.24)	23.8 (3.67)	31.3 (4.21)	35.7 (4.33)
	CH_3OH		25.0 (3.79)		35.0 (4.33)
Mn(sabzen)Cl	CH_2Cl_2	20.8 (3.24)	23.8 (3.86)	31.7 (4.37)	35.7 (4.50)
	CH_3OH		25.3 (3.37)		35.5 (4.29)
Mn_2(sabzta)Cl_4	CH_2Cl_2	15.9 (3.61)	23.8 (3.83)	32.9 (4.32)	37.0 (4.56)
	CH_3OH		25.4 (3.67)		35.7 (4.19)
Mn(sabzen)Cl_2	CH_2Cl_2	15.9 (3.56)	23.8 (3.80)	33.0 (4.29)	37.2 (4.53)
	CH_3OH		24.9 (3.69)		35.6 (4.22)
Mn(salen)Cl_2[a]	CH_2Cl_2	15.4 (3.60)	23.0 (3.78)		

a) Ref. 15.

The obtained complexes are soluble in both nondonor and donor solvents such as dichloromethane, chloroform, methanol, ethanol, and dimethylformamide. However, the electronic spectra of the complexes are sensitive to a kind of solvent; namely, different spectral features are observed in dichloromethane and in methanol (Table 1). These spectral properties resemble those of the pentacoordinated manganese(III) complexes with a "salen"-type ligand.[11-13] The molar conductivities of Mn_2(sabzta)Cl_2 and Mn(sabzen)Cl in methanol are 163 and 78 S cm^2 mol^{-1} at 25 °C, respectively, which are consistent with the expected values for 1:2 and 1:1 electrolytes, respectively.[14] These results strongly suggest that the chloride ions in the complexes are extensively dissociated and that solvated di- and monocationic complex ions, $[Mn_2(sabzta)]^{2+}$ and $[Mn(sabzen)]^+$, are formed in a methanol solution, respectively. It is concluded that the two manganese(III) sites do not interact intramolecularly, but act independently as the corresponding mononuclear complex.

[Manganese(IV) complexes]. In this study, a synthetic method for the mononuclear manganese(IV) complexes Mn(salen)Cl_2 and its homologues[15] was applied for the preparation of Mn_2(sabzta)Cl_4 and Mn(sabzen)Cl_2. The magnetic moments of these complexes are 3.90 and 3.80 BM per one manganese at room temperature, respectively; their values coincided well with the spin-only moment expected for the d^3 manganese(IV) ion. Matsushita et al. have reported that in manganese complexes with "salen"-type ligands a lower-frequency shift of ν(C–O) at the phenolate moiety was observed upon going from manganese(III) to (IV).[15] An analogous relationship exists in the present complexes; bands are observed at 1290 and 1300 cm^{-1} for the manganese-(IV) and (III) complexes, respectively.

The manganese(IV) complexes obtained are soluble in dichloromethane, chloroform, and dry acetone; a deep-green solution is formed. The electronic spectra of these complexes in dichloromethane exhibit a new intense absorption band around 15900 cm^{-1} (Table 1), which is assignable to the CT transition from the Cl^- to the Mn(IV) ion on the basis of a resemblance to the reported spectra of Mn(salen)Cl_2 and its homologues.[15] From the magnetic and spectral properties of the binuclear manganese(IV) complex, it is concluded that the two manganese(IV) ions in this complex are also held in each of the two "salen-like" donating sites and have an octahedral geometry by coordinating two chloride ions at axial positions as well as the mononuclear complex, Mn(sabzen)Cl_2 and Mn(salen)Cl_2. As described above, it should be emphasized that this complex is the first example of a binuclear manganese(IV) complex lacking a bridging oxo ligand.

Table 2. Electrochemical Data for Manganese(III) and (IV) Complexes

Complex	E_{pc}	E_{pa}	ΔE_p	$E'_{1/2}$[a]	$E_{1/2}$
	V	V	mV	V	V
Mn_2(sabzta)Cl_2	−0.690	−0.590	100	−0.640	−0.650
					0.650
Mn(sabzen)Cl	−0.695	−0.595	100	−0.645	−0.655
					0.615
Mn_2(sabzta)Cl_4	−0.710	−0.600	110	−0.655	−0.655
					0.350
Mn(sabzen)Cl_2	−0.700	−0.590	110	−0.645	−0.645
					0.360

a) $E'_{1/2}=(E_{pc}+E_{pa})/2$.

The methanolic solutions of manganese(IV) complexes do not show a deep-green color, but brown. Their electronic spectra are quite similar to those of the corresponding manganese(III) complexes in methanol (Table 1). The spectral difference of the manganese(IV) complex for dichloromethane and methanol solutions strongly indicates that the manganese(IV) complexes are reduced to the corresponding manganese(III) complexes. Unfortunately, it is ambiguous at present that the manganese(IV) complexes are reduced by either methanol or trace water contained in this solvent. Whereas Mn_2(sabzta)Cl_4 and Mn(sabzen)Cl_2 are rather stable to moisture in the solid state and show no appreciable changes in appearance, their IR spectra are observed when they are exposed to air for several months.

Both the present mononuclear and binuclear complexes exhibit redox waves at nearly the same potentials in dichloromethane (Table 2). Each of these four complexes exhibits only one reduction wave at around −0.65 V, which can be assigned to a quasi-reversible or irreversible one-electron reduction process for Mn(III) to Mn(II) on the basis of the peak separations (ΔE_p=100—110 mV) and their wave shapes in cyclic voltammograms.

However, their peak currents observed for the binuclear complexes are about twice, compared with the current of the corresponding redox waves for the mononuclear complexes, respectively. This electrochemical property is almost similar to that of the dicopper(II) complex with the same ligand, Cu_2(sabzta),[10] and can be interpreted in terms of the fact that binuclear complexes are electrochemically reduced by two simultaneous monoelectronic steps at nearly the same potential as that for the corresponding mononuclear complexes. In other words, the present binuclear manganese complexes can not be electrochemically formed as mixed valence states, such as Mn(III)–Mn(II).

The redox waves observed at the anodic region are also assigned to the irreversible one-electron redox process of Mn(III/IV), since the oxidation waves of the coordinated Schiff base ligands and chloride ion in these four complexes appeared at a more positive potential region. The reduction of Mn(IV) to Mn(III) for the manganese(IV) complexes occurs at about a 300 mV more cathodic region, compared with the corresponding oxidation potentials for the manganese(III) complexes. This shift of the redox potentials should indicate a stabilization of the manganese(IV) state by coordinating two chloride ions to metal centers.

We wish to express our thanks to Professor Sigeo Kida and Associate Professor Hisashi Ōkawa of Kyushu University for help in obtaining the magnetic data.

Synthesis and Characterization of Six-Membered Cyclometallated Complexes of 2-Bezylpyridine with Rhodium(III)

Katsuma HIRAKI,* Masayoshi ONISHI, and Hiroko KISHINO
Department of Industrial Chemistry, Faculty of Engineering, Nagasaki University, Bunkyo-machi, Nagasaki 852
(Received December 25, 1990)

Synopsis. 2-Benzylpyridine (Hpiph) is metallated with $RhCl_3 \cdot 3H_2O$ to give $[\{Rh(piph)Cl_2(Hpiph)\}_2] \cdot H_2O$ [piph=2-(2-picolyl)phenyl] in which piph is coordinated at phenyl-1-C and picolyl-N atoms. This complex reacts with tertiary phosphines (PR_3) such as PEt_3, PEt_2Ph, and PPh_3 to yield $[Rh(piph)Cl_2(PR_3)_2]$.

Considerable interest has developed concerning cyclometallated complexes owing to not only the direct activation of the carbon–hydrogen bonds with transition metal complexes,[1-3] but also the wide range of the utilization for organic synthesis,[4] optical resolution of organic compounds,[5] catalyst precursors,[6] and so on. Several articles have already been published concerning five-members-chelated organorhodium(III) complexes derived from nitrogen-containing ligands, such as 2-phenylpyridine,[7] benzo[*h*]quinoline,[7] azobenzenes,[8] aromatic oximes,[9] 1-phenylpyrazole,[10] and 8-methylquinoline.[11] However, six-membered cyclometallated complexes with rhodium(III) are very scarce.

We have studied six-membered cyclopalladated complexes of 2-benzylpyridine,[12] 2-benzoylpyridine,[13] and 2-neopentylpyridine.[14] Here, we will report the synthesis and characterization of new six-membered cyclometallated complexes of 2-benzylpyridine with rhodium(III).

Results and Discussion

When 2-benzylpyridine was heated with $RhCl_3 \cdot 3H_2O$ in 2-methoxyethanol at 80 °C, a yellow-brown complex, $[\{Rh(piph)Cl_2(Hpiph)\}_2] \cdot H_2O$ [piph=2-(2-picolyl)phenyl] (**1**) was formed in 45% yield. Complex **1** was so poorly soluble in organic solvents that NMR spectra of **1** could not be obtained. However, **1** was tentatively ascribed to a chloro-bridged dimeric structure on the basis of the elemental analysis and the poor solubility. Treatment of **1** with excess amounts of tertiary phosphines in refluxing dichloromethane afforded mononuclear complexes, $[Rh(piph)Cl_2(PR_3)_2]$ (**2a**, R=Et; **2b**, PR_3=PEt_2Ph; **2c**, R=Ph). The elemental analyses of **2a**—**c** were satisfactory. Their IR spectra showed a weak absorption near 1600 cm^{-1} and fairly strong bands near 1430 and 1485 cm^{-1}, ascribable to ν(C=N) of the pyridyl group and phosphine moieties, respectively, supporting the above formulations.

The $^{13}C\{^1H\}$ NMR spectrum of **2a** showed a double triplet at δ=145.4 ($^1J_{CRh}$=29.3 Hz, $^2J_{CP}$=17.6 Hz, RhC), disclosing clearly that direct metallation took place at one aromatic carbon of 2-benzylpyridine and that the metallated carbon was situated cis to the two phosphine ligands (Fig. 1). In general, a pyridyl nitrogen is coordinated easily to a trivalent rhodium atom.[7] Indeed, in the ^1H NMR spectrum of **2a**, pyridyl 6-H of the piph moiety resonates at a considerably lower field (at δ=10.33) than that (δ=8.56) of free 2-benzylpyridine, indicating the coordination of the pyridyl group. Accordingly, it is certain that the rhodium-bonded carbon (1-C), located ortho to the picolyl group, and the pyridyl nitrogen are coordinated together to the rhodium atom, forming a new six-membered chelate structure, piph-C^1, N-Rh, similarly to the cases of $\{Pd(piph)(CH_3CO_2)\}_2$] and its related complexes.[12]

2-Benzylpyridine, in which the phenyl and the 2-pyridyl groups are separated by the methylene group, reacted with $RhCl_3 \cdot 3H_2O$ in the alcohlic solvent at ca. 80 °C to afford the dimeric complex, **1** containing one metallated piph unit per Rh atom. This bears analogy with the cyclometallated rhodium(III) complexes of 8-methyl-quinoline,[11] in which the methyl group was not involved apparently in the conjugate system of the quinoline moiety. It is noted that these are in sharp contrast with the other N-containing ligands, such as 2-phenylpyridine,[7] benzo[*h*]quinoline,[7] azobenzenes,[8] aromatic oximes,[9] and 1-phenylpyrazole,[10] each of which consists of a continuous conjugate system and reacted with $RhCl_3 \cdot 3H_2O$ in refluxing ethanol to give a dimeric complex containing two metallated C,N-chelate units per Rh atom.

In the $^{13}C\{^1H\}$ NMR spectrum of **2a**, the methylene carbons of ethyl groups resonated as a triplet at δ=14.8 owing to virtual coupling with the two phosphorus atoms. Furthermore, the ^1H NMR spectrum of **2a** exhibited a quintet at δ=0.73 ascribable to the methyl protons, and its signal splitting was due to coupling with two vicinal methylene protons and virtual coupling with the two phosphorus atoms ($^3J_{HH}$=$^{3+5}J_{HP}$=7.3 Hz). These data imply unambiguously that the two phosphine

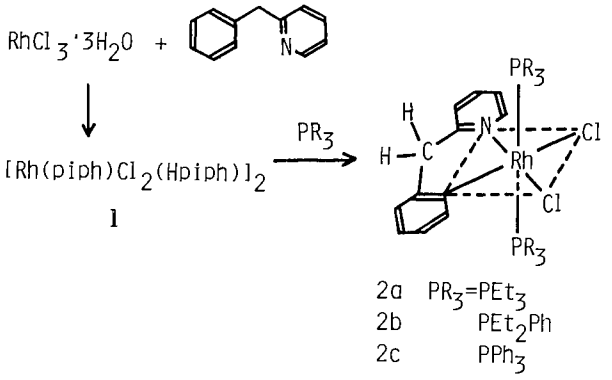

Fig. 1. The 2-(2-picolyl)phenyl-C^1,N-rhodium(III) complexes.

ligands in **2a** are equivalent and located trans to each other, similarly to the case of $[Rh(CH_2\text{–}C_9H_6N)X_2(PBu^n_3)_2]$ (C_9H_6N=8-quinolyl).[11]

In the ^1H NMR spectrum of **2a**, the picolyl methylene protons appeared as a singlet at δ=4.22, which showed no change in the range of +30—−60°C. These facts indicate that the two methylene protons are equivalent and that the piph moiety is plain and situated in the same plane as the $RhCl_2$ moiety forms. In addition, the piph moiety is rigid and shows no inversion motion, in sharp contrast with the piph moiety in $[Pd(piph)Cl\{C_5H_3N(Me)_2\text{-}3.5\}]$.[12] The rigid plain structure of the piph moiety in **2a** is due to steric effect of the two tertiary phosphine ligands, located above and below the central rhodium atom.

In the $^{13}C\{^1H\}$ NMR spectrum of **2b**, the signal patterns of the rhodium-bonded carbon and the methylene carbons of the ethyl groups are quite similar to those of the corresponding carbons in **2a**, indicating that **2b** has an analogous structure to **2a**. This is also supported by the facts that the ipso-carbons of the phosphine phenyl groups exhibited a triplet owing to virtual coupling ($^{1+3}J_{CP}$=7.3 Hz), and that the phosphine ortho-protons showed a quartet due to combination of virtual coupling and H–H coupling ($^{3+5}J_{HP}=^3J_{HH}$=7 Hz). Its ^1H NMR spectrum exhibited two quintets at δ=0.81 and 1.02 (each 6H, $^3J_{HH}=^{3+5}J_{HP}$=7.3 Hz, CH_3), one broad quartet at δ=2.06 (4H, $^3J_{HH}$=ca. 7 Hz, CH_2CH_3), and two multiplets at δ=2.50 and 2.77 (each 2H, $CH_AH_BCH_3$). Irradiation at the quintet at δ=0.81 converted the broad quartet into a broad singlet, whereas that at the quintet at δ=1.02 changed the two multiplets into two broad doublets [each, $^2J(H_AH_B)$=15.6 Hz]. These data imply that two ethyl groups in the PEt_2Ph ligand are unequivalent owing to the restriction of rotation of the PEt_2Ph ligands and that two methylene protons in one of the two ethyl groups are also nonequivalent. Furthermore, it is notable that $^{2+4}J_{HP}$ of the methylene protons in the PEt_2Ph ligands was too small to be detected. In fact, the corresponding $^2J_{HP}$ of methylene prontons in uncoordinated PEt_3 is very small (0.5 Hz).[15] However, the coupling constant of PEt_3 varies depending on the coordination. For example, $[PdBr_2(PEt_3)_2]$ and $[PdBrPh(PEt_3)_2]$ exhibited 4 Hz of $^{2+4}J_{HP}$ of the methylene protons.[16]

Complex **2c** is scarcely soluble in organic solvents and the NMR data could not be obtained.

Experimental

2-Benzylpyridine was available from Tokyo Kasei Kogyo Co., Ltd. General procedures were described previously.[17]

Reaction of 2-Benzylpyridine with $RhCl_3\cdot3H_2O$. A 2-methoxyethanol solution (20 cm^3) containing $RhCl_3\cdot3H_2O$ (300 mg, 1.20 mmol) and 2-benzylpyridine (1.00 g, 6.0 mmol) was heated at 80°C for 0.5 h. After cooling, the resulting products were filtered and the precipitates were washed with diethyl ether to give a pale yellow solid, $[Rh(piph)Cl_2(Hpiph)]_2\cdot H_2O$ (**1**). Yield 280 mg (45%). Mp 242—250°C. IR (KBr) 760 (o-C_6H_4), 1020 (Py ring), 1480 (CH_2), 1560, 1605 (Py), and 3030 cm^{-1} (aromatic CH). Found: C, 55.49; H, 4.11; N, 5.26%. Calcd for $C_{24}H_{23}N_2Cl_2ORh$: C, 55.41; H, 4.26; N, 5.38%.

$[Rh(piph)Cl_2(PEt_3)_2]$ (2a). A dichoromethane suspension (10 cm^3) containing **1** (100 mg, 0.10 mmol) and triethylphosphine (0.08 cm^3, 0.55 mmol) was refluxed for 1 h to afford a yellow solution. The yellow solution was evaporated to dryness under reduced pressure. The resulting solid was recrystallized from dichloromethane and hexane to yield lemon yellow powders, **2a**. Yield 41 mg (86%). Mp 207—212°C, IR (KBr) 755 (o-C_6H_4), 1030 (Py ring), 1420 (PCH_2), 1450 (CH_2), 1570, 1600 (Py), 2890, 2940, 2970 (CH), and 3025 cm^{-1} (aromatic CH); ^1H NMR (CD_2Cl_2) **PEt_3**: δ=0.73 (18H, quintet, $^3J_{HH}=^{3+5}J_{HP}$=7.3 Hz, CH_3), 1.71 (12H, m, PCH_2); **piph:** δ=4.22 (2H, s, $PyCH_2$), 6.92 (1H, t, ^3J=7.3 Hz, CH), 6.95 (1H, d, ^3J=ca. 6.5 Hz, CH), 6.97 (1H, t, ^3J=7.0 Hz, CH), 7.20 (1H, dt, ^3J=7.3 Hz, ^4J=1.5 Hz, CH), 7.39 (1H, d, ^3J=7.0 Hz, CH), 7.75 (1H, dt, ^3J=7.3 Hz, ^4J=1.5 Hz, CH), 8.20 [1H, d, ^3J=7.3 Hz, 3-H(Py)], and 10.33 [1H, d, ^3J=6.0 Hz, 6-H(Py)]; $^{13}C\{^1H\}$ NMR (CD_2Cl_2) **PEt_3**: δ=7.53 (s, CH_3), 14.79 (t, $^{1+3}J_{CP}$=12.7 Hz, PCH_2); **piph:** 49.45 (s, $PyCH_2$), 122.3 (s), 123.7 (s), 125.2 (s), 125.8 (s), 127.2 (s), 135.9 (s), 138.8 (s), 140.5 (s), 145.4 (dt, $^1J_{CRh}$=29.3 Hz, $^2J_{CP}$=17.6 Hz, Rh-C), 157.7 (s, quarternary C), and 161.0 (s, quarternary C). Found: C, 49.58; H, 6.81; N, 2.34%. Calcd for $C_{24}H_{30}NCl_2P_2Rh$: C, 49.84; H, 6.97; N, 2.42%.

$[Rh(piph)Cl_2(PEt_2Ph)_2]CH_2Cl_2$ (2b). A dichloromethane suspension (10 cm^3) containing **1** (100 mg, 0.10 mmol) and diethylphenylphosphine (0.09 cm^3 0.50 mmol) was refluxed for 1.5 h to afford a reddish yellow solution. The solvent was removed under reduced pressure. The resulting solids were recrystallized from dichloromethane and diethyl ether to give a yellow solid, **2b**. Mp 207—214°C; IR (KBr) 735 (o-C_6H_4), 1030 (Py ring), 1435 (PCH_2), 1455 (CH_2), 1490 (PC_6H_5), 1575, 1610 (Py), 2880, 2940, 2970 (CH), and 3050 cm^{-1} (aromatic CH). ^1H NMR (CD_2Cl_2) **PEt_2Ph**: δ=0.81 (6H, quintet, $^3J_{HH}=^{3+5}J_{HP}$=7.3 Hz, CH_3), 1.02 (6H, quintet, $^3J_{HH}=^{3+5}J_{HP}$=7.3 Hz, CH_3), 2.06 (4H, broad quartet, $^3J_{HH}$=ca. 7 Hz, CH_2), 2.50 (2H, m, CH_2), 2.77 (2H, m, CH_2), 6.81 (4H, t, ^3J=7.3 Hz, m-CH), 6.93 (4H, quartet, $^3J_{HH}=^{3+5}J_{HP}$=7 Hz, o-CH), ca. 6.9 (2H, overlapping, p-CH); **piph:** δ=3.55 (2H, s, CH_2), 6.36 (1H, d, ^3J=7.3 Hz, CH), 6.71 (1H, t, ^3J=7.3 Hz, CH), 6.9—7.05 (3H, overlapping, CH), 7.07 (1H, t, ^3J=6.9 Hz, CH), 8.42 [1H, d, ^3J=8.0 Hz, 3-H(Py)], and 9.93 [1H, d, ^3J=6.3 Hz, 6-H(Py)]; $^{13}C\{1H\}$ NMR (CD_2Cl_2) **PEt_2Ph**: δ=7.51 (2C, s, CH_3), 7.7 (2C, s, CH_3), 13.5 (2C, t, $^{1+3}J_{CP}$=13.7 Hz, CH_2), 14.5 (2C, t, $^{1+3}J_{CP}$=13.7 Hz, CH_2), 127.6 (4C, s, m-C), 128.9 (2C, s, p-C), 131.3 (4C, s, o-C), 132.7 (2C, t, $^{1+3}J_{CP}$=7 Hz, ipso-C); **piph:** δ=48.6 (s, CH_2), 122.3 (s), 123.9 (s), 124.8 (s), 127.2 (s), 136.1 (s), 137.3 (s), 140.7 (s), 145.3 (1C, dt, $^1J_{CRh}$=27 Hz, $^2J_{CP}$=15 Hz, RhC), 156.3 (s, quarternary C), and 159.0 (s, quarternary C). (Received December 25, 1990)

Synopsis. When hydrated sodium molybdenum bronze, VD, was heated in air, dehydration as well as both irreversible and reversible phase changes took place as follows:

$$Na_{0.22}(H_2O)_{0.43}H_{0.03}MoO_{3.11} \xrightarrow{442\ K} Na_{0.21}H_{0.03}MoO_{3.14} \xrightarrow{555\ K} Na_2Mo_4O_{13} + MoO_3 \xrightarrow{801\ K} \text{melt.}$$

Interest has been focused on studies of alkali molybdenum bronzes which show low-dimensional electronic properties,[1] such as semiconductor-metal transitions[2,3] and superconductivity.[4] Wold et al.[2] first prepared sodium molybdenum bronze, $Na_{0.9}Mo_6O_{17}$, by fusing the desired molar proportion of a mixture of MoO_3 and Na_2MoO_4 at 823 K for 1 h. However, the authors[5] obtained $Na_{0.9}Mo_6O_{17}$ from the hydrated sodium molybdenum bronze by heating in nitrogen at about 600 K. This is a useful and effective preparation method for the following reasons: (1) The treating temperature is lower by about 200 K than that for the usual fused method. (2) Although the usual preparation method of $Na_{0.9}Mo_6O_{17}$ proceeds in the liquid phase, in our method there is a solid phase without any intermediate products.[5] (3) The hydrated sodium molybdenum bronze already contains Na before any treatment. It is, therefore, important to have detailed information concerning the hydrated sodium molybdenum bronze as a starting material for the preparation of $Na_{0.9}Mo_6O_{17}$. However, no detailed characterization has yet been performed.[6-9] The authors have recently reported[10] on the characterization of hydrated sodium molybdenum bronzes by the use of TG-DTA and NMR. In a series of investigations concerning the hydrated alkali metal molybdenum bronze, we studied both the structural and compositional changes of the hydrated sodium molybdenum bronze by a heat treatment in air; they are described in this paper.

Experimental

The sample was obtained by the method of Thomas and MacCarron.[9] The air-dried sample (named "AD") was unstable. A sample called "VD" was stable and was used for the experiment; it was obtained from AD by vacuum drying at room temperature overnight or by standing in air for more than 30 d. TG-DTA curves were obtained using a MAC SCIENCE TG-DTA 2000 with a heating rate of 10 K min^{-1}. Samples heated at various temperatures were studied using a RIGAKUDENKI GEIGER D-1 FLEX X-ray diffractometer and a JASCO 701G IR spectrophotometer. Changes in surface area were measured using a QUANTACHROME QUNTASORB Jr. The contents of Na and Mo in the samples were measured using a HITACHI 180-80 atomic absorption spectrometer with the 330.23-nm line for Na and the 313.26-nm line for Mo. Mo^{5+} was determined by using the method of Choain and Marion.[11]

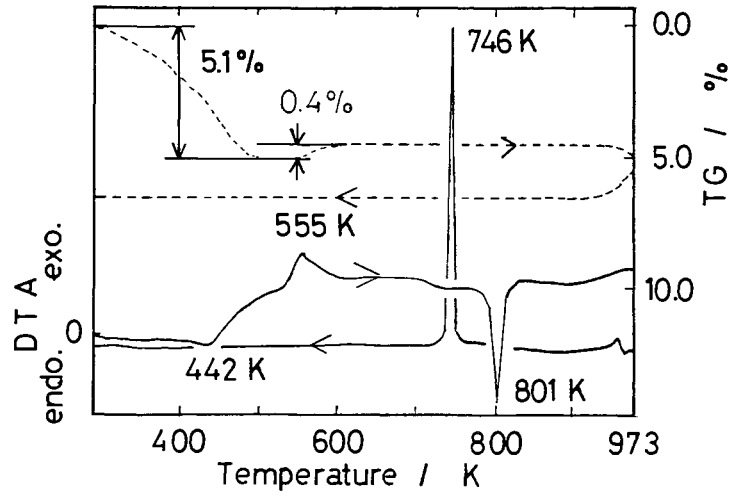

Fig. 1. TG-DTA curves of VD in air. The curves were obtained by heating (—>—) with a heating rate of 10 K min^{-1} and then by cooling (—<—) naturally to room temperature.

Results

Figure 1 shows the TG-DTA curves of hydrated sodium molybdenum bronze, VD, which were obtained by heating to 973 K and then cooling naturally to room temperature. Upon heating, two endothermic peaks at 442 and 801 K and an exothermic peak at 555 K appeared. The endothermic peak at 442 K was accompanied by a weight loss (5.1%) and the exothermic peak at 555 K, by a weight gain (0.4%); the endothermic peak at 801 K showed no weight change. Upon cooling, two exothermic peaks with no weight change appeared at 746 and 937 K. The endothermic peak at 442 K and the exothermic peak at 555 K upon heating gave no corresponding peak upon cooling. It is, therefore, suggested that an irreversible phase transition takes place. On the other hand, the endothermic peak at 801 K upon heating corresponds to the exothermic peak at 746 K upon cooling, and is attributed to a reversible phase transition.

Figure 2 shows the X-ray diffraction patterns of samples heated at various temperatures. The pattern of the sample heated at 498 K is identical with that of VD, although the X-ray peaks are broad. The samples heated at 593 and 828 K show patterns attributed to $Na_2Mo_4O_{13}$ and MoO_3.

The IR spectra of the samples heated at the same temperatures as in the case of X-ray studies were obtained. Although the spectra of samples heated at 423 and 498 K were identical with that of VD, those of the samples heated at 593 and 828 K were very complicated.

The surface areas of the samples heated at the same temperatures as in the case of the X-ray studies are shown in Table 1. Although the surface areas of samples with the VD structure were nearly constant, they decreased steeply when samples with the VD structure were completely transformed to $Na_2Mo_4O_{13}$ and MoO_3. It is clear that the change in the surface area depends on the crystal structure.

The TG results and the results obtained by chemical analyses are given in Table 1. According to these results, samples having the VD structure necessarily contain Mo^{5+}, which is produced by reduction of Mo^{6+}, resulting from an insertion of cations. On the contrary, samples without the VD structure did not contain Mo^{5+}, even though they contained Na.

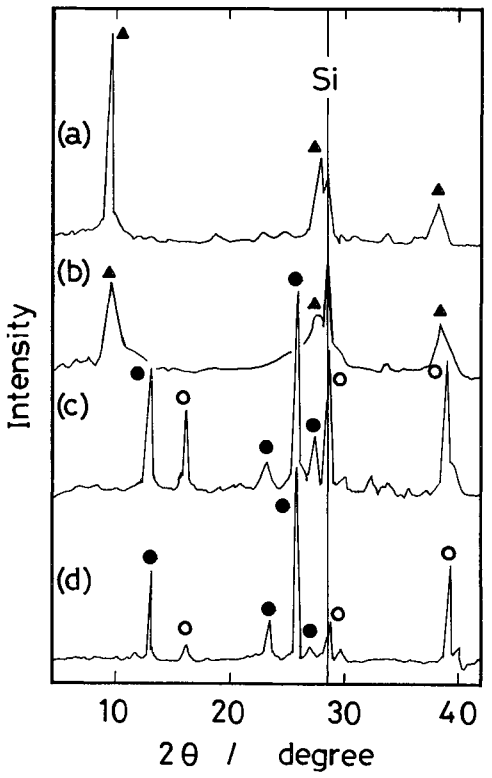

Fig. 2. X-Ray diffraction patterns of the samples heated in air at (a): 423, (b): 498, (c): 593, and (d): 828 K. ▲ represents VD, ●, MoO_3 and ○, $Na_2Mo_4O_{13}$, respectively.

Discussion

According to chemical analyses, VD contains 0.25 mol of Mo^{5+} and 0.22 mol of Na^+, as shown in Table 1. The NMR results[10] have proved that VD contains protons. Considering these results, it is suggested that the concentration of protons is 0.03 (=0.25−0.22) mol. VD is therefore, formulated as $Na_{0.22}(H_2O)_{0.43}H_{0.03}MoO_{3.11}$. The weight gain (0.4%) at around 555 K should be due to a recombination of oxygens in air to make up for the lattice oxygens consumed by the protons. This value corresponds to 0.02 mol of oxygens and to 0.04 mol of protons, which agrees rather well with that of 0.03 mol evaluated from the results of the chemical analysis.

The results obtained by chemical analyses of the samples heated at 498 and 593 K are the same, except that a sample heated at 498 K contains 0.04 mol of Mo^{5+}. This sample has the VD structure. The NMR result also shows the presence of a small number of protons. Protons in a Type-I hydrogen bronze can be kept at a temperature of more than 550 K.[12] Considering these results, 0.03 mol of protons should be maintained in the

a) Molar ratio to Mo.

sample. Therefore, the composition is $Na_{0.21}H_{0.03}MoO_{3.14}$; the sample heated at 593 K has a different structure, and the composition is $Na_{0.21}MoO_{3.14}$. This X-ray result proves that the sample heated at 593 K and then cooled to the room temperature comprises a mixture of $Na_2Mo_4O_{13}$ and MoO_3. The Na_2MoO_4/MoO_3 ratio of the sample is about 1/9, agreeing well with the range of coexistence with $Na_2Mo_4O_{13}$ and MoO_3 according to a Na_2MoO_4–MoO_3 phase diagram.[13-15] The exothermic peak at 555 K is due to an irreversible phase transition from VD to $Na_2Mo_4O_{13}$ and MoO_3.

The sample heated at 828 K and then cooled to room temperature apparently shows a glassy state. The X-ray results prove that it comprises $Na_2Mo_4O_{13}$ and MoO_3. According to the phase diagram, an eutectic temperature of 810 K appears when the $Na_2Mo_4O_{13}/MoO_3$ ratio is between 23/77 and 6/94. In this range, the samples can produce solid solutions at an eutectic temperature such as for $Na_2Mo_4O_{13}\cdot MoO_3$ and $Na_2Mo_4O_{13}\cdot 2MoO_3$.[13] Since the Na_2MoO_4/MoO_3 ratio of 1/9 found in this study just falls within this range and the X-ray results show the presence of $Na_2Mo_4O_{13}$ and MoO_3 (as mentioned above), it can be concluded that the endothermic peak at 801 K upon heating is due to the eutectic point, (which corresponds to the melting point of the solid solution), and the exothermic peak at 746 K upon cooling, to solidification. According to above consideration, we conclude that the hydrated sodium molybdenum bronze, VD, is changed by a heat treatment in air as follows:

$$Na_{0.22}(H_2O)_{0.43}H_{0.03}MoO_{3.11} \xrightarrow{442\ K} Na_{0.21}H_{0.03}MoO_{3.14}$$
$$\xrightarrow{555\ K} Na_2Mo_4O_{13} + MoO_3 \xrightarrow{801\ K} \text{melt.}$$

(Received December 17, 1990)

Synopsis. Rhodium complexes, $Rh(L)(C_2H_4)_2$ {L=$(CH_3C{=}O)_2CH$ (acac), and $(CF_3C{=}O)_2CH$ (hfa)}, catalyze hydrogermylation and hydrosilylation of phenylacetylene with Bu_3GeH and R_3SiH (R=Bu, Et), respectively, to produce $Ph(R_3M)C{=}CH_2$ (M=Ge, Si) selectively. Other rhodium complexes, that is, $[RhCl(C_2H_4)_2]_2$, $Rh_2Cl_2(cod)_2$, $Rh(tmhd)(C_2H_4)_2$ {tmhd=$(t\text{-BuC}{=}O)_2CH$}, and $Rh(dbm)(C_2H_4)_2$ {dbm=$(PhC{=}O)_2CH$}, also catalyze these reactions, but with less regioselectivity.

Hydrosilylation, hydrostannylation, and hydrogermylation of terminal acetylenes under transition metal catalysis have been widely studied[1] because of their potential utility in the synthetic organic chemistry of vinylic organometals with 14(IV B) series elements (Eq. 1).

$$R_3MH + R'\text{-}C{\equiv}CH \xrightarrow{cat.} \underset{\text{1 (}\alpha\text{-adduct)}}{\overset{R'}{\underset{R_3M}{\diagdown\!\!\diagup}}C{=}CH_2} + \underset{\text{2 (}\beta\text{-adducts, }E\text{ and }Z\text{)}}{\overset{R}{\underset{H}{\diagdown\!\!\diagup}}C{=}CH{\sim}MR_3} \quad (1)$$

R,R'=alkyl, phenyl

The selective formation of β-adducts (**2**) has been thoroughly investigated under transition metal catalysis or radical conditions.[1b-e] However, catalysts yielding α-adduct (**1**) selectively have not been well-studied, except for rhodium catalysts used for the hydrostannylation of terminal acetylenes. We report here on a new rhodium catalyst which is effective for the selective formation of an α-adduct in the hydrogermylation and hydrosilylation of phenylacetylene.

Experimental

Materials. The rhodium complexes used in the present study were prepared by using ordinary methods,[2] and were stored at −25 °C. The solvents and other reagents were purified by distillation before use.

General Procedure. All operation were carried out under a nitrogen atmosphere. The typical procedure was as follows. To a mixture of $Rh(hfa)(C_2H_4)_2$ {1.46 mg (4.0×10^{-3} mmol)} and CH_2Cl_2 (10 ml) was added phenylacetylene {0.41 g (4.0 mmol)}, and the mixture was stirred at 40 °C for 10 min. Then, (n-Bu)$_3$GeH {0.098 g (0.4 mmol)} was added rapidly and the reaction was monitored by GLC. The reaction products were isolated by short-pass distillation. The characterization and the product distribution of products were determined by ^{1}H NMR and GLC.

Table 1. Rhodium-Catalyzed Hydrogermylation and Hydrosilylation of PhC≡CH[a]

Run	Catalyst[b]	Temp	Time	PhC≡CH/R_3MH	Yield[c]	Products (% ratio)[d]	
		°C	h	(Molar ratio)	%	**1**	**2** (E/Z)
M=Ge				R=Bu			
1	$RhCl(CO)(PPh_3)_2$	0	6	10	65	7	93 (70/23)
2	$RhCl(CO)(PPh_3)_2$-galvinoxyl	0	2	10	73	1	99 (91/8)
3	$[RhCl(C_2H_4)_2]_2$	0	0.5	1	84	15	85 (36/49)
4	$[RhCl(C_2H_4)_2]_2$	0	1	10	89	61	39 (20/19)

	C_6H_6	40	3	1	80	50	50 (40/10)

a) One mol% of the catalyst was used. b) Isolated yields by short pass distilation based on R_3MH. c) Determined by GLC.

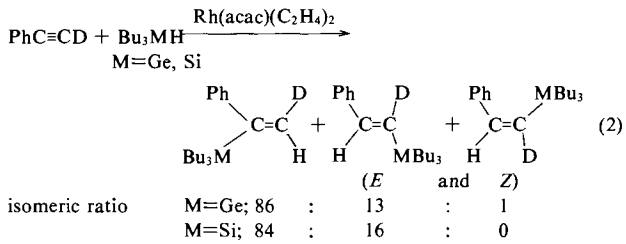
Hydrosilylation was also carried out by the same method mentioned above.

Results and Discussion

Rhodium complexes {$RhClL_3$, $RhCl(CO)L_2$, $[RhCl(cod)]_2$; L=PPh_3} were previously found to catalyze the hydrostannylation of acetylene with Bu_3SnH to produce an α-adduct, $Ph(Bu_3Sn)C=CH_2$ selectively, and a combination of galvinoxyl (radical inhibitor) and $RhCl(CO)(PPh_3)_2$ in the hydrostannylation of phenylacetylene proved to give an α-adduct exclusively in excellent yield.[3] In the hydrogermylation of phenylacetylene, however, these catalysts gave β-adducts (**2**) as the main products, and the presence of the radical inhibitor suppressed the formation of the α-adduct and (*Z*)-β-adduct, as shown in Table 1 (Run 2). When we used a large excess of PhC≡CH to Bu_3GeH (>10), only $[RhCl(C_2H_4)_2]_2$ produced the α-adduct with moderate selectivity (61%), probably because of an effective exchange of the ethylene with PhC≡CH.

Interestingly, $Rh(acac)(C_2H_4)_2$, in which chloride in $[RhCl(C_2H_4)]_2$ is replaced by acetylacetonate, gave the α-adduct in good yields, irrespective of the molar ratio of PhC≡CH/R_3GeH, although the catalytic activity was somewhat less than that of $[RhCl(C_2H_4)_2]_2$. The catalyst also acted as an effective catalyst for the hydrosilylation of PhC≡CH with R_3SiH (R=Bu, Et) under the same conditions as those in hydrogermylation, but not for hydrostannylation. When we used $(CF_3C=O)_2CH$ instead of acac as a β-diketonate ligand, the regioselectivity toward the α-adduct in both reaction systems was greatly improved (select.=ca. 95%). On the other hand, the other complexes with a bulky β-diketonate ligand, that is $Rh(tmhd)(C_2H_4)_2$ and $Rh(dbm)(C_2H_4)_2$, also catalyzed both reactions, but with less selectivity. These results indicate that the regioselectivity in both reaction systems is influenced by both electronic and steric effects of the ligands around the rhodium metal. In this catalyst system, the reaction temperature and solvent also affected the regioselectivity toward the α-adduct. For example, in the $Rh(acac)(C_2H_4)_2$ catalyst system, as shown in Table 2, dichloromethane having a small coordination ability was found to be appropriate as a reaction medium.

Compared with Bu_3GeH, Bu_3SiH required a longer reaction time because of the less reactivity of Bu_3SiH, and the regioselectivity toward the α-adduct was somewhat less than that of Bu_3GeH (Runs 7 and 12). However, with less crowded triethylsilane, Et_3SiH, regioselectivity toward the α-adducct increased, giving almost the same selectivity to that of Bu_3GeH. The solvent effect was almost the same with that in the hydrogermylation as shown in Table 2.



(2)

The $Rh(acac)(C_2H_4)_2$ system proved to give $Ph(Bu_3M)C=CHD$ (M=Ge, Si) stereoselectively in the reaction of PhC≡CD with Bu_3GeH and Bu_3SiH, respectively (Eq. 2).

This result supports the *syn*-addition process in the present α-directive hydrogermylation and hydrosilylation which is generally observed in the transition metal-catalyzed hydrostannylation[4] and hydrosilylation.[5]

The catalytic behaviors of $Rh(acac)(C_2H_4)_2$ and $Rh(hfa)(C_2H_4)_2$ for α-adduct selectivity have not get been clarified. Consequently, $Rh(hfa)(C_2H_4)_2$ is a useful catalyst which provides a simple method for the preparation of $Ph(R_3M)C=CH_2$ (M= Ge, Si; R=Bu, Et) with regard to the starting materials and procedures.

Reactions of 2-Hydrazino- and 8-Hydrazinocyclohepta[*b*]pyrroles with Dimethyl Acetylenedicarboxylate

Noritaka ABE* and Kumiko YATABE
Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753
(Received January 16, 1991)

Synopsis. 2-Hydrazinocyclohepta[*b*]pyrrole reacted with dimethyl acetylenedicarboxylate (DMAD) to give the hydrazones (**2a**), the pyrimidinone-fused cyclohepta[*b*]pyrrole (**3**), 1,2,4-triazinone-fused cyclohepta[*b*]pyrroles, and the 1,2-dihydro-3*H*-pyrazol-3-one derivative. Thermolysis of **2a** gave **3** and tetramethyl pyrrole-2,3,4,5-tetracarboxylate. The reaction of ethyl cyclohepta[*b*]pyrrole-3-carboxylate with DMAD at room temperature gave the hydrazone and the spiro-pyrazoline derivative.

It is known that hydrazino-substituted heterocycles react with dimethyl acetylenedicarboxylate (DMAD) to give the hydrazones, and that subsequent cyclization gives either 1,2,4-triazin-5-ones or 5-pyrazolones.[1] Although cyloadditions of azaazulenes are of interest and some studies have been carried out,[2-7] cycloadditions of hydrazinoazaazulenes have not yet been studied. In this paper we report on the reactions of 2-hydrazino- and 8-hydrazinocyclohepta[*b*]pyrroles with DMAD.

The treatment of 2-hydrazinocyclohepta[*b*]pyrrole (**1a**) with two molar amount of DMAD in benzene at room temperature for 3 h gave dimethyl 2-[1-[(*E*)-1,2-bis(methoxycarbonyl)vinyl]cyclohepta[*b*]pyrrol-2(1*H*)-ylidenehydrazono]succinate (**2a**) (22%), methyl 2-oxo-2*H*-cyclohepta[4,5]pyrrolo[1,2-*a*]pyrimidime-4-carboxylate (**3**)[3] (1%), dimethyl 2-[(cyclohepta[*b*]pyrrol-2-yl)hydrazono]succinate (**4a**) (4%), methyl 3,4-dihydro-4-oxo-2*H*-cyclohepta[4,5]pyrrolo[2,1-*c*][1,2,4]triazin-4-ylideneacetate (**5**) (4.5%), methyl 3,4-dihydro-4-oxo-2*H*-cyclohepta[4,5]pyrrolo[2,1-*c*][1,2,4]triazin-3-ylideneacetate (**6**) (3%), and methyl 1-(cyclohepta[*b*]pyrrol-2-yl)-2,5-dihydro-5-oxo-1*H*-pyrazole-3-carboxylate (**7**) (12%). When **1a** was treated with one molar amount of DMAD in acetonitrile at room temperature, **7** (46%) was obtained as a major product, and **2a** and **3** were not obtained. The treatment of **1a** with three molar amounts of DMAD in acetonitrile at room temperature gave **2a** (43%) as the major product; the yield of **7** was low (2%). For an improvement of the yield of cycloadducts (**5** and **6**), although the reaction was tried under reflux or in the presence of Pd-C, no particular change was observed.

These structures were deduced on the basis of spectral data, especially ^{1}H NMR spectra, as well as elemental analyses.

Compound **3** was considered to be a thermolyzed product of **2a**. Thus, **2a** was heated in *t*-butylbenzene under reflux for 6 h and gave **3** (19%) and **8**[8] (30%).

The reactions of ethyl 2-hydrazinocyclohepta[*b*]pyrrole-3-carboxylate (**1b**) with DMAD somewhat differed from those of **1a**. Thus, a treatment of **1b** with DMAD in acetonitrile at room temperature gave the ethoxycarbonyl **4b** (65%) and 3-ethyl 4',5'-dimethyl 1-[(*Z*)-1,2-bis(methoxycarbonyl)vinyl]-1',2'-dihydrospiro[cyclohepta[*b*]pyrrole-2(1*H*),3'-[3*H*]pyrazole]-3,4'5'-tricarboxylate (**9**) (3%), and a treatment in refluxing xylene gave 1-ethyl 4,5-dimethyl 2-[(*Z*)-1,2-bis(methoxycarbonyl)vinylhydrazono]-2*H*-cyclohepta[*gh*]pyrrolizine-1,4,5-tricarboxylate (**10**) (4%), **4b** (7%), **8** (16%), and 10-ethyl 2,3-dimethyl cyclohepta[4,5]pyrrolo[1,2-*a*]imidazole-2,3,10,-tricarboxylate (**11**)[9] (10%). Compounds **10**, **8**, and **11** would be secondary reaction products. Thus, **4b** was treated with DMAD in refluxing xylene and compounds **10**, **8**, and **11** were obtained.

The formation of the spiro-pyrazoline derivative resembles the reaction of benzophenone phenylhydrazone with DMAD.[10]

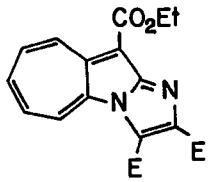
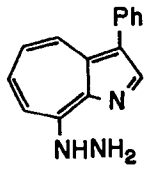
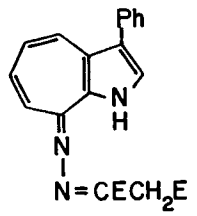
10



11



12



13

The reaction of 8-hydrazino-3-phenylcyclohepta[*b*]-pyrrole (**12**) with DMAD gave dimethyl 2-[3-phenylcyclohepta[*b*]pyrrol-8(1*H*)-ylidenehydrazono]succinate (**13**) in 56% yield. From the expectation of cyclization, compound **13** was treated with acetic anhydride or triethylamine, as previously used;[1] no distinct product was obtained.

Experimental

The melting points are uncorrected. ^{1}H NMR spectra (250 MHz) and ^{13}C NMR spectra (62.87 MHz) were taken on a Hitachi R-250H spectrometer using $CDCl_3$ as a solvent (TMS as an internal standard). IR spectra were recorded for Nujol mulls with a Hitachi 270-50 infrared spectrophotometer. High-resolution mass spectra were determined with a JEOL-01SG-2 spectrometer at 70 eV of ionization energy. Column chromatography was performed on Kieselgel 60.

Reaction of 1a with DMAD. a) A mixture of **1a** (0.500 g) and DMAD (0.893 g) in dry benzene (100 ml) was stirred for 3 h at room temperature and evaporated. The residue was chromatographed with chloroform to give **2a** (0.305 g, 22%), **3**[3] (0.005 g, 1%), **4a** (0.040 g, 4%), **5** (0.038 g, 4.5%), **6** (0.028 g, 3%), and 7 (0.102 g, 12%), successively.

2a: Red prisms; mp 186—187 °C (from hexane); ^{1}H NMR δ=3.65 (3H, s), 3.75 (3H, s), 3.82 (2H, s), 3.87 (3H, s), 3.88 (3H, s), 6.40 (1H, s), 6.65—6.95 (6H, m), and 7.26 (1H, d, J=11.0 Hz); ^{13}C NMR δ=32.55 (t), 51.74 (q), 52.31 (q), 52.50 (q), 52.85 (q), 102.23 (d), 112.62 (d), 128.74 (d), 129.44 (d), 129.66 (d), 131.98 (d), 133.00 (d), 133.97 (s), 145.25 (s), 147.09 (s), 147.24 (s), 147.28 (s), 162.18 (s), 164.05 (s), 165.44 (s), 165.70 (s), and 169.64 (s); IR 1752, 1740, 1726, 1706 (C=O), and 1660 cm^{-1} (C=N). Hydroformylation–Amidocarbonylation of Methylvinylphosphinate. Application to Synthesis of Glufosinate

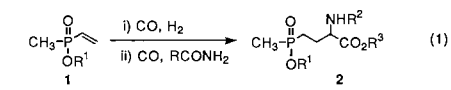
Toshiyasu SAKAKURA, Xin-Yan HUANG, and Masato TANAKA*
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received January 17, 1991)

Synopsis. Glufosinate, 2-amino-4-[(hydroxy)methylphosphinyl]butanoic acid, (**2a**) was synthesized from 2-chloroethyl methylvinylphosphinate (**1a**) via successive hydroformylation–amidocarbonylation. Hydroformylation of **1a** catalyzed by $Co_2(CO)_8$ in methanol gave 2-chloroethyl (3,3-dimethoxypropyl)methylphosphinate (**5**). Crude **5** was subjected to cobalt-catalyzed amidocarbonylation to afford *N*-acylglufosinic acid methyl ester (**2b**). Hydrolysis of **2b** under acidic conditions gave **2a** quantitatively.

Transition metal-catalyzed carbonylations with carbon monoxide are useful methods to synthesize carbonyl compounds from easily accessible starting materials like olefins, halides, etc. Applications of these reactions to functionalized substrates are expected to provide new and facile synthetic routes to multifunctional compounds.[1] Now, we wish to report a convenient synthesis of glufosinate (**2a**) from a methylvinylphosphinate (**1a**) via successive carbonylations catalyzed by transition metal complexes (Eq. 1).

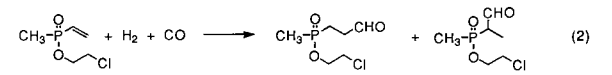


1 2

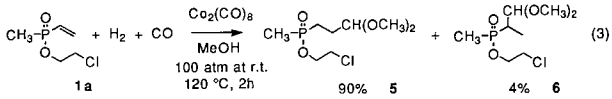
1a: $R^1 = CH_2CH_2Cl$ 2a: $R^1 = R^2 = R^3 = H$
2b: $R^1 = CH_2CH_2Cl$, $R^2 = PhCO$, $R^3 = Me$
2c: $R^1 = CH_2CH_2Cl$, $R^2 = PhCO$, $R^3 = H$

Glufosinate (phosphinothricin) is the first naturally occurring amino acid with a phosphinic acid moiety and shows strong herbicidal and antibiotic activities. There have been a considerable number of precedents about the synthesis of glufosinate.[2,3] The synthetic routes are mainly divided into two categories. One is Strecker reaction of phosphinyl aldehydes.[2b-d] The other is the Michael addition of an amino acid derivative to the methylvinylphosphinate (**1**).[2e-j] The process via carbonylation (Eq. 1) is superior to these reactions in the following aspects. i) Highly toxic cyanide which requires troublesome treatment of aqueous waste is not involved. ii) The amino acid moiety is introduced inexpensively with carbon monoxide and an amide. The starting compound **1a** is easily obtained by the dehydrochlorination of 2-chloroethyl 2-chloroethylmethylphosphinate which is synthesized by the reaction of dichloromethylphosphine and ethylene oxide in a high yield.[4]

Hydroformylation of **1a** (Eq. 2) with cobalt carbonyl took place with high linear-selectivities over 85% irrespective of solvents (Table 1). However, the yield of the aldehyde was low due to the formation of high-boiling by-products. Optimization of various reaction conditions finally resulted in the finding that the reaction in methanol afforded the desired linear aldehyde in a very high yield as a form of dimethyl acetal (Eq. 3). A similar observation was reported by Wakamatsu et al. in the hydroformylation of acrylonitrile with $Co_2(CO)_8$.[5]



1a 3 4



1a 90% 5 4% 6

On the other hand, the problem in rhodium-catalyzed hydroformylation of **1a** using $Rh_4(CO)_{12}$, $Rh_2Cl_2(CO)_4$, or $HRh(CO)(PPh_3)_3$ was low linear selectivity rather than low aldehyde yield (Table 2). It is noteworthy that the high linear- or the branched-selectivities observed in

Table 1. Hydroformylation of **1a** with $Co_2(CO)_8$[a]

Solvent	Conv./%	Yield of aldehyde/%	Linear-sel./%
Benzene	84	42	94
t-BuOH	85	32	89
Et_2O[b]	45	15	86
Acetone[c]	21	15	92
DMF	0	0	—

a) $Co_2(CO)_8$ 0.1 mmol, **1a** 10 mmol, solvent 9 ml, 120°C, $CO/H_2=1/1$, 100 atm at room temperature, 2 h, linear-sel.=100×**3**/(**3**+**4**). b) 150°C. c) 4.5 h.

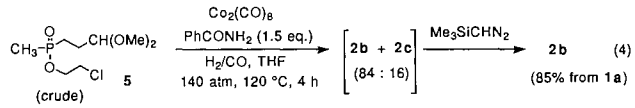
Table 2. Hydroformylation of **1a** with Rhodium Catalysts[a]

Catalyst	Conv./%	Yield/%		Linear-sel./%
		Aldehydes	Hydrogenation	
$Rh_4(CO)_{12}$	100	61	13	11
$Rh_2Cl_2(CO)_4$	100	70	19	22
$HRh(CO)(PPh_3)_3$	100	80	9	9
$Rh(acac)\{P(OPh)_3\}_2$[b]	56	53	1	97

a) Rh 0.01 mg-atom, **1a** 10 mmol, solvent 9 ml, 100°C, $CO/H_2=1/1$, 100 atm at room temperature, 5—19 h, linear-sel.=100×**3**/(**3**+**4**). b) Rh complex 0.05 mmol, **1a** 5.7 mmol, $P(OPh)_3$ 0.13 mmol, benzene 1.4 ml, $CO/H_2=1/1$, 1 atm, 45°C, 2 h. acac: acetylacetonate.

the hydroformylation of **1a** with cobalt or rhodium catalysts, respectively, are similar to those reported for the hydroformylation of an α,β-unsaturated carboxylate with $Co_2(CO)_8$ or $Rh_4(CO)_{12}$.[6] On the other hand, Trzeciak et al. have reported an unusually high linear selectivity in the rhodium-catalyzed hydroformylation of ethyl acrylate with the Rh–$P(OPh)_3$ system.[7] The catalytic system was successfully applied to the hydroformylation of **1a** to achieve a high linear selectivity under mild conditions (Table 2).[8]

Since a high linear selectivity and a high yield have been achieved in the hydroformylation of **1a** with $Co_2(CO)_8$ in MeOH (Eq. 3), we next investigated the amidocarbonylation[9] of the resulting acetal (**5**) (Eq. 4). Although examples of amidocarbonylation of acetals have been rare,[10] the reaction of **5** proceeded smoothly to give a mixture of the methyl ester (**2b**) and presumably the free carboxylic acid (**2c**);[11] the latter could be quantitatively converted to the former via the treatment with trimethylsilyldiazomethane.[12] The amidocarbonylation proceeded in various solvents such as benzene, ethyl acetate, dioxane, and tetrahydrofuran; the last one gave the highest reaction rate. Since the amidocarbonylation is slow in methanol, the solvent should be exchanged after the hydroformylation.



The hydrolysis of **2b** was easily carried out under acidic conditions to give glufosinate quantitatively. Thus, glufosinate can be efficiently synthesized via successive hydroformylation–amidocarbonylation of the methylvinylphosphinate. The resolution of racemic glufosinate and the conversion of the optical isomer to its racemate have already been established.[13]

Experimental

^1H and ^{13}C NMR signals were referred to tetramethylsilane as an internal standard. Chemical shift in ^{31}P NMR was referred to H_3PO_4.

$Co_2(CO)_8$ was recrystallized from toluene at a low temperature. Rh(acac)$[P(OPh)_3]_2$ was synthesized according to the literature.[14] The methylvinylphosphinate (**1a**) was obtained from Nissan Chemical Industries Ltd.

Hydroformylation of 1a. Octacarbonyldicobalt (0.1 mmol), the methylvinylphosphinate (10 mmol), and methanol (9 ml) were added to a 27 ml Hastelloy-C autoclave under nitrogen. Synthesis gas ($H_2/CO=1/1$) was charged up to 100 atm at room temperature. The autoclave was heated in an oil bath at 120°C for 2 h. The reaction mixture was analyzed by capillary GC (OV-1701 and PEG-20M, 25 m) using tridecane as an internal standard. Rhodium catalyzed reactions were conducted similarly; see Table 2 for reaction conditions.

Amidocarbonylation of 5. Hydroformylation of **1a** was carried out in methanol as stated above. The reaction mixture was concentrated. The resulting oil, octacarbonyldicobalt (0.2 mmol), benzamide (15 mmol) and tetrahydrofuran (10 ml) were added to a 27 ml Hastelloy-C autoclave under nitrogen. Synthesis gas ($H_2/CO=1/1$) was charged up to 140 atm. The autoclave was heated in an oil bath at 120°C for 3.8 h. The reaction mixture was analyzed by HPLC (ODS, methanol: $H_2O=1/1$) using benzene as an internal standard after the esterification of the free amino acid with trimethylsilyldiazomethane.[10]

The products were isolated by distillation (Kugelrohr) or preparative thin-layer chromatography (silica gel, $CHCl_3$: MeOH=15:1). Spectral data were listed below.

2-Chloroethyl Methylvinylphosphinate (1a). ^1H NMR[2d] ($CDCl_3$) δ=1.57 (d, J=14 Hz, 3H, CH_3P), 3.70 (t, J=6 Hz, 2H, CH_2Cl), 4.0–4.4 (m, 2H, OCH_2), 6.0–6.5 (m, 3H, $CH=CH_2$); ^{13}C NMR ($CDCl_3$) δ=14.9 (d, J=102 Hz, CH_3P), 43.1 (d, J=7 Hz, CH_2Cl), 63.8 (d, J=6 Hz, OCH_2), 129.6 (d, J=121 Hz, $C\underline{H}=CH_2$), 135.8 (s, $CH=C\underline{H}_2$); MS m/z (%) 171 ($M^+(^{37}Cl)+H$, 0.3), 169 ($M^+(^{35}Cl)+H$, 1.0), 153 ($M^+(^{35}Cl)-Me$, 4), 133 (M^+-Cl, 100), 119 (15), 107 (24), 91 (20). Synopsis. Cycloadditions of the title compounds with dimethyl acetylenedicarboxylate gave 1:2-cycloadducts. The structural assignments of the products were deduced by spectral inspections; the structure for one compound was established by X-ray crystallography.

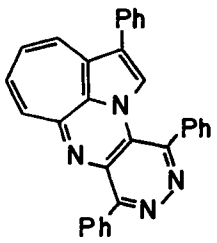
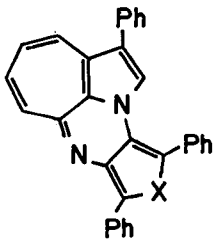
Many investigations have been carried out concerning the reactions of heterocycles with dimethyl acetylenedicarboxylate (DMAD) due to interesting surprises regarding their reactions and usefulness for building heterocyclic rings.[1-3] The reaction of poly-fuzed heterocyclies having multi reaction sites with DMAD is very interesting. One of the authors (NA) has been investigating the syntheses and cycloadditions of azaazulenes, and recently reported the syntheses of pyridazine-, furan-, and thiophene-fused 2a,5-diazabenz[*cd*]azulenes (**1**, **2a**, and **2b**).[4] The cycloaddition of these compounds is attractive, since they comprise different aromatic heterocyclic moieties. The authors have therefore advanced the reaction.

The treatment of **1** with DMAD in refluxing acetonitrile for 70 h gave a 1:2-adduct (**3**) in 78.7% yield. Its structure was elucidated using spectroscopic data as well as elemental analysis. Its ^{1}H NMR spectrum displays four ester-methyl singlets at δ=3.38, 3.64, 3.80, and 3.95; four seven-membered protons at δ=5.47, 5.95, 6.07, and 6.38; 15H phenyl protons at δ=7.0-8.0; and one singlet at δ=6.69. Information concerning chemical shifts of the seven-membered ring protons have suggested that compound **3** retains the 2a,5-diazabenz[*cd*]azulene nuclei.[4] Since the chemical shift of the singlet is comparable to that of **1**, the environments of both singlet protons would be similar. It is therefore considered that the reaction occured at both the N-9 and C-8 positions. In the ^{13}C NMR spectrum of **2**, one sp^3 carbon (s) was observed at δ=63.51; the other signals are in accord with the structure. This reaction is comparable to that of 4-methylphthalazine with DMAD.[5]

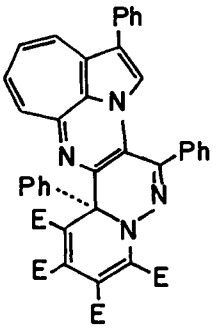
Treatment of **2a** with DMAD in refluxing acetonitrile for 50 h gave the 1:2-adduct (**4**) in 45.8% yield. The structure was assumed by spectroscopic data and established by an X-ray analysis. In its ^{1}H NMR spectrum, four ester-methyl singlets at δ=3.21, 3.48, 3.49, and 3.63; four seven-menbered protons at δ=6.67, 7.11, 7.64, and 7.73; 15H phenyl protons at δ=7.2—7.9; and one singlet at δ=6.41 were observed. The chemical shifts and signal patterns of seven-membered ring protons resemble those of **5**.[6] In the ^{13}C NMR spectrum of **4**, two sp^3 carbons were observed at δ=58.05 (d) and 94.52 (s); these are comparable to dihydrofuran derivatives. The mass spectrum of **4** displays intense peaks at *m*/*z* 384 and 336, which would be attributed to ions of the cyclazine and furan moieties, respectively, produced by fragmentation of the molecular ion; this strongly suggests the structure (the structure of **4** is shown in Fig. 1).



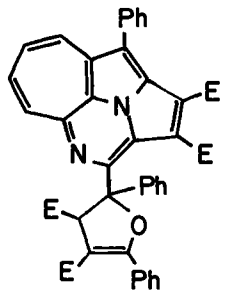
1



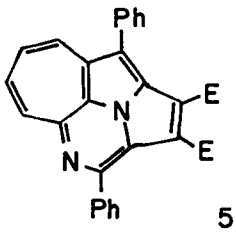
2a: X = O
2b: X = S



3: E = CO_2Me

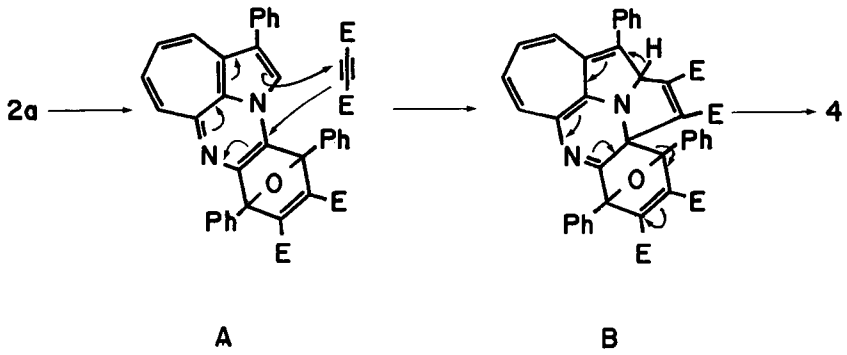


4: E = CO_2Me



5: E = CO_2Me

A plausible mechanism for the formation of **4** is shown in Scheme 1. DMAD initially attacks the furan moiety of **2a** to give intermidiate **A**; a successive attack of a second molar of DMAD on **A** gives **B**. Bond scission attended by aromatization of **B** leads to **4**. The second step followed by aromatization is similar to a reaction in which 1,4-diphenyl-2a,5-diazabenz[*cd*]azulene reacts



Scheme 1.

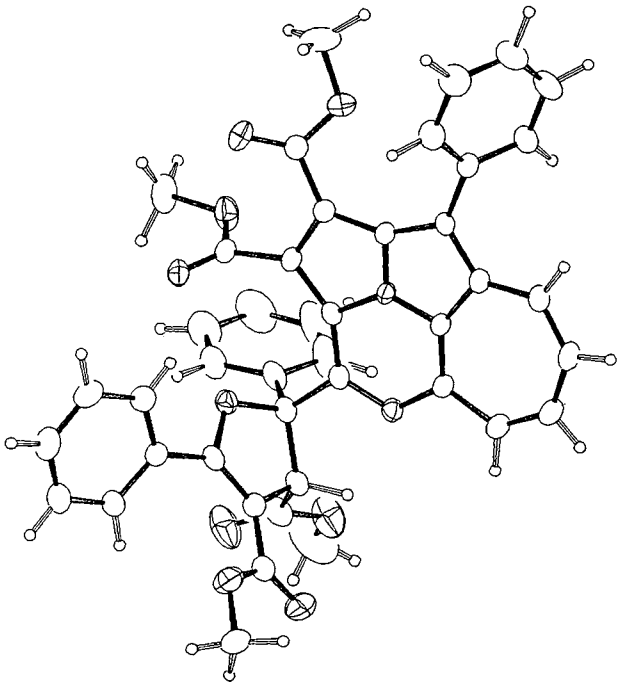


Fig. 1. Molecular structure of **4**.

with DMAD to give **5**.[6]

Compound **2b** did not react with DMAD under the conditions used.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra (250 MHz) and ^{13}C NMR spectra (62.87 MHz) were taken on a Hitachi R-250H spectrometer using $CDCl_3$ as a solvent (TMS as an internal standard). IR spectra were recorded for Nujol mulls with a Hitachi 270-50 infrared spectrophotometer. Mass spectra were determined with a JEOL-01SG-2 spectrometer an ionization energy of 70 eV. Column chromatography was performed on a Kieselgel 60.

Reaction of 1 with DMAD. A mixture of **1** (0.070 g) and DMAD (0.150 g) in dry acetonitrile (50 ml) was refluxed for 70 h and evaporated. Elution with benzene–chloroform (1:1) gave **3** (0.090 g, 78.7%), which was recrystallized from cyclohexane to give reddish-brown needles; mp 283—284 °C; ^{1}H NMR δ=3.38, 3.64, 3.80, 3.95 (each 3H, s, OMe), 5.47 (1H, dd, J=11.6 and 7.9 Hz, H-5), 5.95 (1H, dd, J=12.2 and 7.9 Hz, H-4), 6.07 (1H, d, J=12.2 Hz, H-3), 6.38 (1H, d, J=11.6 Hz, H-6), 6.69 (1H, s, H-2), 7.05 (2H, dd, J=7.9 and 1.8 Hz, H-*o*-phenyl), 7.27—7.45 (9H, m, H-*m*,*p*-phenyl), 7.61 (2H, dd, J=7.9 and 1.8 Hz, H-*o*-phenyl), and 7.90 (2H, dd, J=7.9 and 1.8 Hz, H-*o*-phenyl); ^{13}C NMR δ=52.01 (q), 52.24 (q), 52.83 (q×2), 63.51 (s), 103.23 (s), 103.74 (s), 114.61 (d), 119.10 (s), 123.89 (s+d), 125.44 (s), 127.29 (d×2), 127.34 (d×2), 127.49 (s), 127.52 (d×2), 128.57 (d×2), 128.62 (d×3), 129.33 (d), 129.63 (d), 130.11 (d×2), 130.83 (d), 132.11 (s), 133.28 (s), 135.10 (d), 135.29 (d), 136.06 (s), 136.19 (s), 137.29 (s), 142.73 (s), 147.64 (s), 157.01 (s), 162.40 (s), 163.23 (s), 164.84 (s), and 166.79 (s); IR 1746, 1740, and 1710 (C=O), 780, 764, 736, 707, and 696 cm^{-1} (phenyl). Found: C, 70.44; H, 4.65; N, 7.48%. Calcd for $C_{43}H_{32}N_4O_8$: C, 70.48; H, 4.36; N, 7.64%.

Reaction of 2a with DMAD. A mixture of **2a** (0.140 g) and DMAD (0.30 g) in dry acetonitrile (80 ml) was refluxed for 50 h and then evaporated. The residue was chromatographed. Elution with benzene gave recoverded **2a** (0.038 g, 27.1%). Elution with benzene–chloroform (1:1) gave **4** (0.106 g, 45.8%), which was recrystallized from cyclohexane to give red needles; mp 274—275 °C; ^{1}H NMR δ=3.21, 3.48, 3.49, 3.63 (each 3H, s, OMe), 6.41 (1H, s, H-3'), 6.67 (1H, dd, J=11.0 and 8.6 Hz, H-7), 7.11 (1H, dd, J=11.6 and 8.6 Hz, H-8), 7.25—7.60 (13H, m, H-phenyl), 7.64 (1H, d, J=11.0 Hz, H-6), 7.73 (1H, d, J=11.6 Hz, H-9), and 7.77 (2H, dd, J=7.9 and 1.8 Hz, H-*o*-phenyl); ^{13}C NMR δ=51.15 (q), 51.34 (q), 51.54 (q), 52.46 (q), 58.05 (d), 94.52 (s), 104.05 (s), 115.21 (s), 115.64 (s), 122.43 (s), 124.80 (d), 126.46 (d×2), 126.78 (s), 127.30 (d×4), 127.70 (d), 127.73 (d×2), 127.96 (s), 128.06 (d), 128.79 (s), 129.34 (s), 129.68 (d×2), 130.35 (d), 130.48 (d×2), 131.72 (d), 131.93 (d), 132.72 (s), 132.91 (d), 137.75 (s), 141.71 (s), 151.02 (s), 163.31 (s), 164.28 (s), 166.34 (s), and 171.06 (s); IR 1742, 1724, and 1705 (C=O), 774, 754, and 696 cm^{-1} (phenyl). MS m/z (rel intensity) 721 (0.8, M$^+$+1), 720 (0.6, M$^+$), 719 (6), 384 (6), 336 (14), 105 (30), 81 (42), 69 (70), 32 (100). Found: C, 71.82; H, 4.73; N, 3.78%. Calcd for $C_{43}H_{32}N_2O_9$: C, 71.66; H, 4.48; N, 3.89%.

Single Crystal X-Ray Structure Determination of 4. The crystals of **4** belong to a monoclinic system with cell dimensions of a= 16.513 (3) Å, b= 21.153 (7) Å, c= 10.714 (4) Å, β=107.14 (2)°, and V= 3621.8 (17) Å^3. The space group is $P2_1/n$, and Z= 4. The empirical formula is $C_{43}H_{32}N_2O_9$, the molecular weight is 720.47, and the caluculated density is 1.29 g cm^{-3}. Three-dimensional X-ray data were collected by the use of graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å) on a Syntex R3 automatic four-circle diffractometer up to a maximum 2θ of 50°. The intensity data from 5762 independent reflections were collected and 3513 with $|F_o|>3\sigma|F_o|$ were used in the present X-ray analysis. The structure was solved by a direct method (MULTAN78). All non-hydrogen atoms were located by an initial E synthesis. The remaining hydrogens were located by a difference Fourier map, and were included in additional calculations. Block-diagonal least

squares refinements with anisotropic 54 non-hydrogen atoms and 32 isotropic hydrogens converged to a conventional R factor of 0.066. All of the calculations were carried out on a HITAC M-680H computer of Hiroshima University using a structure analysis program system (UNICS3).[7,8]

We thank Dr. Akira Mori (Kyushu University) for performing mass spectra and elemental analyses.

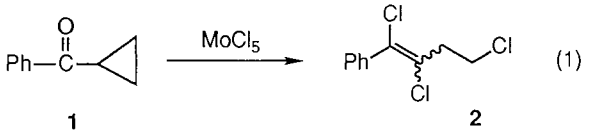
Molybdenum Pentachloride-Induced Reaction of Cyclopropyl-Substituted Carbonyl Compounds

Toshikazu HIRAO,* Shinichiro NAGATA, Makoto YAMAGUCHI, and Yoshiki OHSHIRO*
Department of Applied Chemistry, Faculty of Engineering, Osaka University,
Yamadaoka, Suita, Osaka 565
(Received February 12, 1991)

Synopsis. Molybdenum pentachloride induced the ring-opening reactions of cyclopropyl phenyl ketone or propyl 2-(trimethylsilylmethyl)cyclopropanecarboxylate to give 1-phenyl-1,2,4-trichloro-1-butene or *cis*-2-chloro-4-pentanolide, respectively.

Molybdenum pentachloride is an excellent reagent for *cis*-chlorination of olefins.[1] In our previous papers, molybdenum pentachoride has been disclosed to work well as a Lewis acid to cleave a carbon–oxygen bond of acetals in the reaction with vinylsilanes.[2] This characteristic is expected to be useful in the transformations of carbonyl compounds via molybdenum enolates. Ring-opening reactions of small-ring compounds provide a versatile synthetic method.[3] We herein report the molybdenum pentachloride-induced reactions of cyclopropyl-substituted carbonyl compounds.

Cyclopropyl phenyl ketone (**1**) was treated with molybdenum pentachloride in dichloromethane to give 1-phenyl-1,2,4-trichloro-1-butene (**2**). Ring cleavage[4] and chlorination are achieved by this procedure. An increase in the amount of molybdenum pentachloride raised the yield of **2** as shown in Table 1 (Eq. 1).



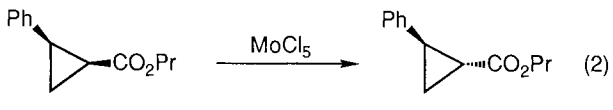
1 2 (1)

Table 1. Synthesis of **2**

$MoCl_5$/equiv	Time/h[a)]	Yield/% **2**
2	45	10
3	45	22
4	24	34

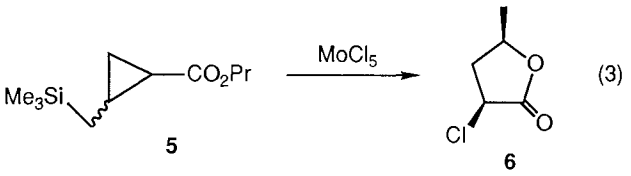
a) Reaction temperature, room temperature.

Propyl *cis*-2-phenylcyclopropanecarboxylate (**3**), however, did not undergo the ring-opening reaction under similar conditions, and was isomerized to the *trans* isomer **4** in 70% yield (Eq. 2). This result indicates that the reactivity of the ester function is lower towards molybdenum pentachloride.



3 4 (2)

On the contrary, it should be noted that the reaction of propyl 2-(trimethylsilylmethyl)cyclopropanecarboxylate (**5**) with molybdenum pentachloride led to desilylation and ring-opening lactonization giving *cis*-2-chloro-4-pentanolide (**6**) stereoselectively in 45% yield (Eq. 3).



5 6 (3)

Such a ring-opening reaction was not observed in the case of propyl 2-butyl-3-(trimethylsilyl)cyclopropanecarboxylate (**7**) even on treatment at 80 °C in DMF. The ester **7** was recovered quantitatively, suggesting that the presence of trimethylsilylmethyl group appears to facilitate ring opening as is the case with 1-[2-(trimethylsilylmethyl)cyclopropylcarbonyl]imidazole.[5]

The reaction scheme is explained by the intervention of an enolate intermediate based on the operation of molybdenum pentachloride as a Lewis acid, which is considered to be supported by the isomerization of **3** to **4**. Desilylative ring cleavage of **5** gives the enolate, which undergoes recyclization and *cis*-chlorination possibly with molybdenum pentachloride.[1] Chlorination seems to take place at the α- and γ-positions of the ketone **1**, being accompanied by the transformation of the ketone function to the corresponding olefinic chloride.

Molybdenum pentachloride is demonstrated to be a versatile Lewis acid with the capability of chlorination.

Experimental

IR and ^{1}H NMR spectra were recorded with Hitachi 270-30 and JEOL JNM-FX90Q spectrometers, respectively. Electron impact mass spectra were recorded with JEOL JMS-DX303 at the Faculty of Engineering, Osaka University.

The cyclopropanecarboxylates **3** and **5** were prepared according to the reported method.[6]

Synthesis of 1,2,4-Trichloro-1-phenyl-1-butene (2). To a solution of molybdenum pentachloride (1.37 g, 5.0 mmol) in dichloromethane (5.0 mL) was dropwise added cyclopropyl phenyl ketone (**1**, 0.183 g, 1.25 mmol) over 30 min at 0 °C. The mixture was warmed to room temperature and was stirred for 24 h. Ether (20 mL) and conc. HCl (2 mL) were added to the resulting mixture, which was extracted with ether (3×20 mL). The combined ethereal solution was washed with 10% aqueous $Na_2S_2O_3$ (10 mL), saturated aqueous NH_4Cl (10 mL), and brine (10 mL), dried ($MgSO_4$), and concentrated. GLC analysis (1.2 m PEG 20M 10% column, 180 °C) of the residue showed the formation of **2** (34%). **2** (*E* and *Z* mixture): IR (neat) 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$ with TMS, 90 MHz) δ=2.82 (t, 1.04H, J=6.9 Hz), 3.21 (t, 0.96H, J=6.9 Hz), 3.71 (t, 1.04H, J=6.9 Hz), 3.81 (t, 0.96H, J=6.9 Hz), 7.3—8.3 (m, 5H); MS m/z 238 (M^++4), 236 (M^++2), 234 (M^+). Anal. ($C_{10}H_9Cl_3$) C, H, Cl.

Synthesis of *cis*-2-Chloro-4-pentanolide (6). To a solution of molybdenum pentachloride (0.137 g, 0.50 mmol) was dropwise added propyl 2-(trimethylsilylmethyl)cyclopropanecarboxylate (**5**, 0.107 g, 0.50 mmol) over 5 min at 0 °C. The mixture was stirred at 0 °C for 5 min and then at room temperature for 20 h. Methanol aqueous solution (50%, 2 mL) was added to the reaction mixture, which was stirred at room temperature for 1 h and was extracted with ether (3×20 mL). The combined ethereal solution was washed with brine, dried (Na_2SO_4), and concentrated. GLC analysis (1.2 m PEG 20M 10% column, 150 °C) of the residue showed the formation of **6** (45% yield). **6:** IR (neat) 1780 cm^{-1}; ^1H NMR ($CDCl_3$ with TMS, 90 MHz) δ=1.46 (d, 3H, J=6.6 Hz), 2.33 (dd, 1H, J=8.5, 6.7 Hz), 2.48 (dd, 1H, J=5.6, 2.9 Hz), 4.43 (dd, 1H, J=6.7, 2.9 Hz), 4.89 (ddq, 1H, J=8.5, 6.6, 5.6 Hz); MS m/z 136 (M^++2), 134 (M^+). Anal. ($C_5H_7O_2Cl$) C, H, Cl.

Isomerization of Propyl *cis*-2-Phenylcyclopropanecarboxylate (3) to the *trans*-Ester 4. The reaction of **3** was carried out in a similar manner as mentioned above. The ester **4** was produced in 70% yield with the recovery (30%) of the starting ester **3**.

Thermal Properties of Liquid-Crystalline Polyitaconates with Paired Mesogens.

Kazuo SUGIYAMA* and Kohei SHIRAISHI
Department of Industrial Chemistry, Faculty of Engineering, Kinki University,
Hirokoshinkai, Kure, Hiroshima 737-01
(Received December 20, 1990)

Synopsis. 2-Methylenesuccinates (Itaconates) (**2**) having two 4-methoxyazobenzene moieties as paired mesogenic groups were prepared. The monomer **2** was radically homopolymerized and copolymerized with non-mesogenic monomer, dioctadecyl itaconate (DOI). Paired mesogenic homopolyitaconate exhibits a nematic phase and the copolymers of the monomer **2** with DOI also show a mesomorphic phase up to 25 mol% of DOI content. The enhancement of mesophase formation by paired mesogens is discussed.

In order to obtain comprehensive knowledge concerning the structure–property relation of thermotropic liquid crystalline side-group polymers (TLCPs), numerous polymers have been prepared and their mesomorphic properties investigated with a variation of the type of mesogen and the spacer in polyacrylates,[1,2] polymethacrylates,[3] polyesters[4,5] and polysiloxanes.[6] The properties of TLCPs are varied by the mesogenic structure and how mesogens are incorporated into the backbones. TLCPs with accentuated liquid-crystalline properties were prepared with paired mesogenic units fixed to a polysiloxane main chain.[7,8]

The concentration of mesogens along the polymer chain could also be achieved by making use of polymethylenesuccinates (polyitaconates).[9] The polymerization reactivity of itaconate monomers with paired mesogens and the mesomorphic properties of the polymers are, however, not obvious concerning detail. In recent papers, the syntheses and thermal behaviors of non-vinyl TLCPs were reported. The polymers considered were polyfumarate[10] or polyitaconate[11] backbones, a methylene spacer and 4-(4-methoxyphenylazo)-phenoxy and 4-(4-cyanophenoxycarbonyl)phenoxy mesogenic groups. In this brief note, we described the enhancement of mesophase formation by pairing the mesogens in polyitaconates, poly[bis[6-[4-(4-methoxyphenylazo)phenoxy]hexyl]itaconate].

Experimental

Preparation of Monomers: Bis[6-[4-(4-methoxyphenylazo)phenoxy]hexyl] itaconate **2** was prepared as follows: a benzene solution of 0.05 mol of itaconic anhydride and a 0.11 mol of 6-[4-(4-methoxyphenylazo)phenoxy]-1-hexanol was refluxed in the presence of a catalytic amount of *p*-toluenesulfonic acid for 3 d. After removing the solvent, the crude product was recrystallized twice from benzene. 83.9% yield; mp 121—122.4 °C; ^{1}H NMR ($CDCl_3$) δ=1.12—1.86 (m, 16H, $-CH_2(CH_2)_4CH_2-$), 3.36 (s, 2H, $-CH_2-$), 3.84—4.33 (m, 8H, $-CH_2(CH_2)_4CH_2-$), 3.91 (s, 6H, $-OCH_3$), 5.72—5.80 (m, 1H, H–CH=), 6.30—6.45 (m, 1H, H–CH=), 6.89—7.93 (m, 16H, Aromatic). Found: C, 68.78; H, 7.01; N, 7.44%. Calcd for $C_{43}H_{50}O_8N_4$ (M, 750.900): C, 68.78; H, 6.71; N, 7.46%.

Dioctadecyl itaconate (DOI) was prepared from the reaction of 0.18 mol of itaconic anhydride and 0.40 mol of 1-octadecanol according to the preparation method of **2**. 83.6% yield; mp 59.4—59.8 °C; ^{1}H NMR ($CDCl_3$) δ=0.77—1.74 (m, 70H, $-CH_2(CH_2)_{16}CH_3$), 3.26 (s, 2H, $-CH_2-$), 3.88—4.18 (m, 4H, $-CH_2(CH_2)_{16}CH_3$), 5.48—5.62 (m, 1H, H–CH=), 6.12—6.24 (s, 1H, H–CH=). Found: C, 77.66; H, 12.25%. Calcd for $C_{41}H_{78}O_4$ (M, 635.076): C, 77.54; H, 12.38%.

6-[4-(4-methoxyphenylazo)phenoxy]hexyl methacrylate was prepared by adding dropwise a slight excess of methacryloyl chloride to 6-[4-(4-methoxyphenylazo)phenoxy]-1-hexanol dissolved in anhydrous THF at 0 °C and in the presence of triethylamine. 66.3% yield; mp 81.2—82 °C; ^{1}H NMR ($CDCl_3$) δ=1.43—2.00 (m, 8H, $-CH_2(CH_2)_4CH_2-$), 2.08 (s, 3H, $-CH_3$), 4.14 (s, 3H, $-OCH_3$), 3.56—4.52 (m, 4H, $-CH_2-(CH_2)_4CH_2-$), 5.76—5.93 (m, 1H, H–CH=), 6.32—6.49 (s, 1H, H–CH=), 7.20—8.41 (m, 8H, Aromatic). Found: C, 69.68; H, 7.12; N, 16.14%, Calcd for $C_{23}H_{28}O_4N_2$ (M, 396.491): C, 69.66; H, 7.08; N, 16.33%.

Polymerization: The polymerization procedure was the same as that described by Sugiyama.[12] Polymers were reprecipitated twice from benzene and methanol. The intrinsic viscosities [η] of the polymer were determined in benzene at 30 °C with an Ubbelohde viscometer. The composition ratios of the copolymers were calculated from the nitrogen content as obtained by elemental analysis.

Results and Discussion

Itaconates with mono- and paired mesogenic units, the monomers **1** and **2**, are shown in Scheme 1. The polymerization of the monomer **2** was carried out using a free-radical initiator. The results given in Table 1 show that monomer **2** polymerizes to give mesomorphic polyitaconates with moderate conversion. As far as the viscosity behavior in benzene is concerned, their intrinsic viscosities are relatively small. The weight-averaged molecular weight was estimated to be 3430 for the polymer of [η]=0.027 dL g^{-1} by means of GPC measure-

ment.[13]

The molecular weight of polyitaconates seems to high sufficient to discuss the liquid crystalline properties. A DSC study showed that all of the paired mesogenic polyitaconates as well as mono-mesogenic polymers[11] turned into mesophase, since they showed two endothermic peaks and an exothermic peak upon heating and cooling cycles, respecctively. The mono-mesogenic polyitaconates showed rather broad melting and clearing peaks,[11] while the paired mesogenic polyitaconates showed sharp transition peaks at higher temperatures than the mono- would be favorable for liquid crystalline alignment and give sharp peaks in thermal analysis. According to polarized optical microscopy (POM), the mesophase of polyitaconates showed a schlieren texture and was confirmed to be nematic phase. The schlieren texture of polyitaconates was retained unchanged up to room temperature. It is suggested from a DSC trace on cooling cycles and POM that the polyitaconates are frozen in the mesophase at room temperature. The phase-transition temperatures determined by means of DSC measurements are tabulated in Table 1. Figure 1

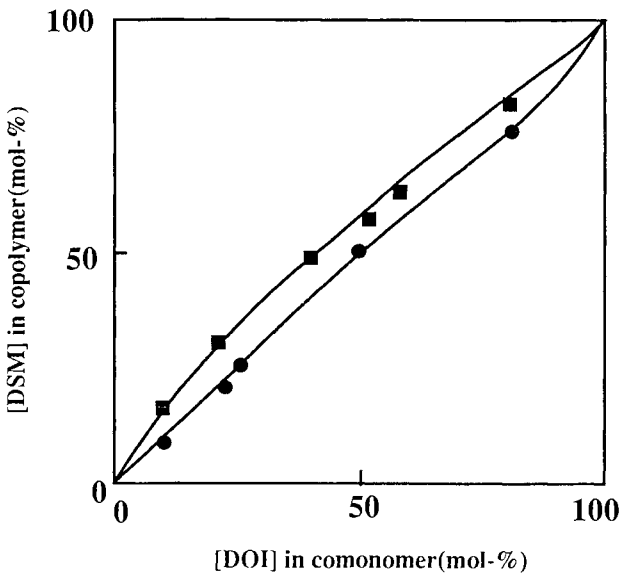

Fig. 2. Composition curve for the polymerization of monomers **1** (■) and **2** (●) with DOI (M_1) initiated with 1,1′-azobis(cyclohexanecarbonitrile) in benzene at 100°C.

shows the relationships between the phase-transition temperature and the intrinsic viscosity for the polyitaconates. The clearing temperature (T_i) of polyitaconates gradually increases with an increase in the intrinsic viscosity values, as observed in liquid crystalline polyacryrates with $[\eta]$ below 0.1 dL g^{-1}.[14] Comparing the two kind of polymers, paired mesogenic polyitaconates show a higher T_i and a wider range of nematic states than do the mono-mesogenic ones. This is explained by concentrating the mesogenic groups along the main chain: paired mesogenic groups favor a lateral interaction between successive pendant groups. It is known that the distance between successive pendent mesogenic groups along the polymer backbone plays an important role for mesophase formation in alternating mesogenic copolymers.[15]

In order to reinforce the enhancement of mesophase formation by paired mesogens, the copolymerization of itaconates (M_2) with non-mesogenic DOI monomer (M_1) was carried out radically with 1 mol% for monomer amounts of ACN in bulk at 100°C. The obtained copolymers were 30—50% in yield with 0.041—0.045 dL g^{-1} intrinsic viscosities. Figure 2 shows the composition curves for copolymerization. Applying the data in Fig. 2 to a curve-fitting method, the monomer reactivity ratios were calculated to be r_1=0.45 and r_2=0.95 for monomer **1** and r_1=1.02 and r_2=0.81 for monomer **2**, respectively. It is suggested that two kinds of polyitaconates radicals are nearly equal in reactivity for the DOI monomer, while the DOI radical decreases reactivity for itaconate with a paired mesogenic group, as is known from the steric effect of the bulky nature of the pendant groups. Thermal analyses of these random copolymers provided information concerning the

b) Polymethacrylate was obtained from the polymerization of 6-[4-(4-methoxyphenylazo)phenoxy]hexyl methacrylate initiated by 1 mol% of 1,1'-azobisisobutyronitrile in the presence of 3.5 mol% of mercaptoacetic acid in benzene at 60°C for 24 h.

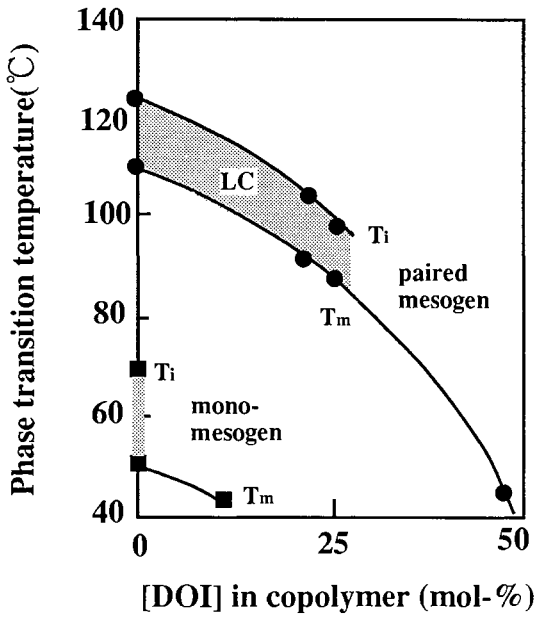

Fig. 3. Relationship between phase transition temperature and DOI content in copolymer of monomers **1** (■) and **2** (●) with DOI.

enhancement of the mesophase by introducing a pairing of the mesogens. Figure 3 exhibits the effect of nonmesogenic component on mesophase formation in a random copolymer. Paired mesogenic polyitaconates showed a nematic phase up to 25 mol% of DOI content, although the dilution lowered the phase-transition temperatures. On the other hand, copolymers of monomesogenic itaconates with nonmesogenic DOI showed no mesophase, even when the polyitaconates were diluted with 10 mol% of DOI content; it showed only the melting point. It is concluded that paired mesogens enhance the interaction of successive pendants in the liquid crystalline state and that the mesophase of copolymers with nonmesogenic DOI can be retained.

It is well known that the variation of substituents at the α-position of mesomorphic vinyl polymers causes a change in the kind of mesophase and transition temperature.[16,17)] Table 2 shows the transition temperature of various polymers bearing methoxyazobenzene moieties as a mesogenic group. In the case of monomesogenic liquid-crystalline polymers, large substituents at the α-position lower the transition temperature, since it accounts for the prevention of the mesogenic units from a liquid crystalline aligning due to their bulky nature. On the other hand, a paired mesogenic polymer shows a higher transition temperature based on a close packing of the mesogenic groups.

Aggregates in Langmuir-Blodgett Films of Spiropyrans Having Hydroxyl or Hydroxymethyl Group

Akio MIYATA,* Yutaka UNUMA, and Yoshiyuki HIGASHIGAKI
Tokyo Research Laboratories, Sharp Corporation, Kashiwa, Chiba 277
(Received November 29, 1990)

The optical properties of monomolecular layers at an air–water interface and also of Langmuir–Blodgett (LB) films of several photochromic spiropyrans with a single hydrophobic long chain and either a hydroxyl or a hydroxymethyl group have been investigated. Changes in the optical spectra of these films were induced by either UV irradiation or heating. UV-visible, and IR absorption spectra showed that spiropyran SP145 formed J-aggregates and SP147 formed H-aggregates. The half-decay period of the J-aggregate to the spiropyran (SP) form was longer than that of the colored monomeric photomerocyanine (PMC) to the SP form. It was concluded that hydrogen bonding between neighboring colored PMC molecules via hydroxyl, hydroxymethyl, and nitro groups stabilizes the aggregate state.

Spiropyran (SP) molecules are converted into the photomerocyanine (PMC) form on UV irradiation, and a reverse change takes place when the colored product is irradiated with visible light of a specific wavelength. This photochromic reaction can be applied to developing high density optical recording information storage media. In view of this, several workers[1–4] have studied the photochromic reactions of spiropyran monomolecular layers and multilayers prepared by the Langmuir–Blodgett (LB) technique.

The LB technique is useful to prepare a well-ordered molecular aggregation state of spiropyran molecules. Under such conditions these molecules often exhibit spectroscopic changes due to aggregate formation, i.e., red-shifted J-aggregates and blue-shifted H-aggregates. Ando et al.[5] reported that SP1822 (Fig. 1) LB films mixed with hexadecane formed J-aggregates after successive UV irradiation and heat treatment procedures at 35—50 °C. The J-aggregate state is featured by its sharper, more intensely colored band at a longer wavelength (λ_{max}=618 nm) than in the PMC state (λ_{max}=583 nm). A small Stokes shift in the fluorescence peak is another characteristic of the J-aggregate. The SP1801 (Fig. 1) LB films, however, formed a J-like aggregate (λ_{max}=600 nm) when either stearic acid or octadecyl alcohol was used as matrix molecules.[6] These films do not form an aggregate without admixing. This J-like aggregate formation was also noted in alternating LB films of SP1801 and stearic acid.

Fig. 1. Chemical structures of spiropyran derivatives used.

Only a few studies have been done on the aggregate formation of amphiliphilic spiropyrans, though the characterization of dye aggregate states in general has been performed by many researchers. Their formation of well-ordered J- and H-aggregate states, and examination of a correlation between the structure and aggregate forming ability of spiropyrans are therefore of interest. Molecules in an aggregate interact through various cohesive forces, i.e., hydrogen, ionic, and covalent bonding. In this paper the importance of hydrogen bonding in aggregation is emphasized.

The present work deals with the photochromic behavior of spiropyran derivatives prepared as monolayers at the air–water interface or as LB films. The spiropyrans used here contain a long alkyl chain and a hydroxyl group. These formed an LB film without matrix molecules such as stearic acid or octadecyl alcohol. The colored PMC form and the J- and H-aggregate forms are highly stable, and the results suggest that these aggregates are formed through hydrogen bonding.

Experimental

Materials. The spiropyrans (Fig. 1) were purchased from the Nippon Kankoh-Shikiso Kenkyusho Co., and were used without further purification. The spreading solvent was spectroscopic grade chloroform.

Procedures. Measurements of surface pressure–area (π–A) isotherms and the deposition of monolayers onto quartz slides were performed by means of a conventional Langmuir trough (Joyce Loebl, Langmuir Trough IV, UK) equipped with a Whilhelmy balance. The substrates for visible spectroscopic measurements were rendered hydrophobic by immersion in a 10% chloroform solution of trimethylchlorosilane. The LB films were deposited at a surface pressure of 20 mN m^{-1} and a dipping speed of 15 mm min^{-1}. The subphase

was maintained at 20 °C, pH 5.8.

The visible absorption spectra of monolayers were measured with a multichannel spectrophotometer (Otsuka Electronics Co., model MCPD-200), whereas a double-beam UV-visible spectrophotometer (Japan Spectroscopic Co., model UVIDEC-610C) was used for multilayers. Infrared spectra of the LB films were measured with an IR spectrophotometer (Japan Spectroscopic Co., model IR-810), and fluorescence spectra were detected by means of a monochromator (Japan Spectroscopic Co., model CT-25C) combined with photomultiplier (Hamamatsu Corp., model R943-02) by excitation at 550 nm. The monochromator had a spectral band width of ca. 0.1 nm. To make proceed photochromic reactions from the SP to the PMC form on the subphase, the monolayer was irradiated with a UV lamp (366 nm, UVP Inc., model UVL-56, USA).

Results

Surface Pressure-Area (π-A) Isotherms. When monolayers of the spiropyran derivatives were compressed after conversion from the SP to the PMC form by UV irradiation, it was possible to deposit them as an LB film onto the substrate. Figure 2 shows the π-A isotherms for the monolayers of SP144, SP145, and SP147 after UV irradiation. The monolayers were stable up to a surface pressure of 40 mN m^{-1}, and the limiting areas are 0.53 nm^2 (SP144), 0.57 nm^2 (SP147), and 0.58 nm^2 (SP145).

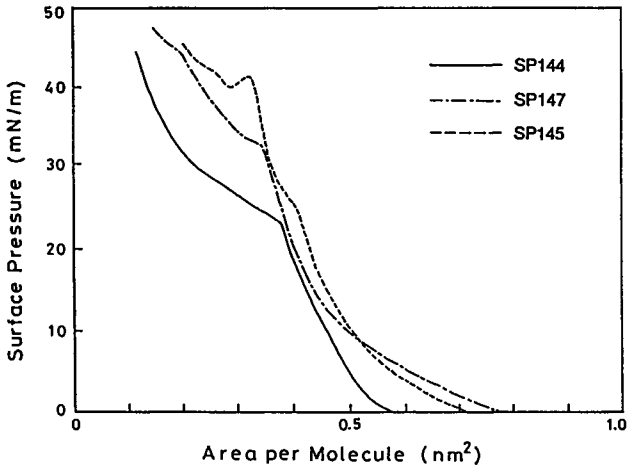

Fig. 2. Surface pressure-area isotherms for monolayers of spiropyran derivatives after UV irradiation.

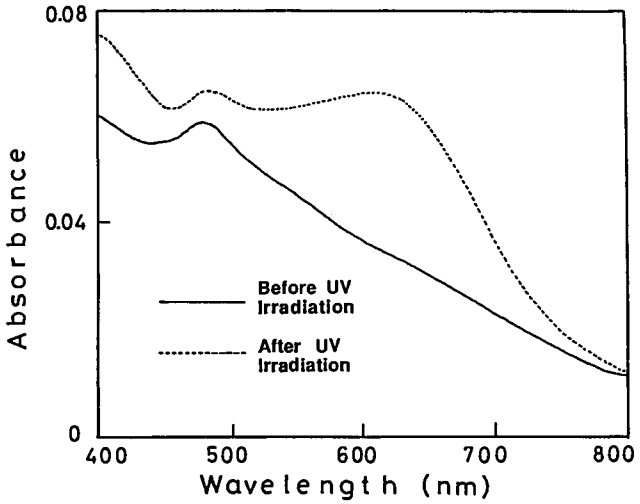

Fig. 3. SP144 LB film absorption spectra.

Photochromic Behavior of SP144. The absorbance of the SP144 monolayer at the air-water interface was negligible because its colored PMC without NO_2 group had a small extinction coefficient. Spectral measurements became possible with ten double multilayers formed on both sides of the substrate. Figure 3 shows the absorption spectra before UV irradiation, where the dye was in the SP form, and after UV irradiation. In the latter case a broad band is seen around 610 nm arising from the PMC form. On visible irradiation, the absorption spectrum returned to the original one, which was obtained also by heating in darkness. This reversible transformation was repeated using UV light and heating, and the change from the PMC to the SP form took place with a half-decay time of 2 min at 25 °C. A small absorption band at 480 nm is probably due to H-aggregates. No further changes were noted in the visible spectrum when the SP144 LB film was irradiated with UV light (366 nm, 1.0 mW cm^{-2}) for more than 10 min. This indicates that new aggregates are not formed after photoisomerization from the SP to the PMC form.

Infrared spectral analysis of the SP144 LB films was performed on a calcium fluoride support. The results

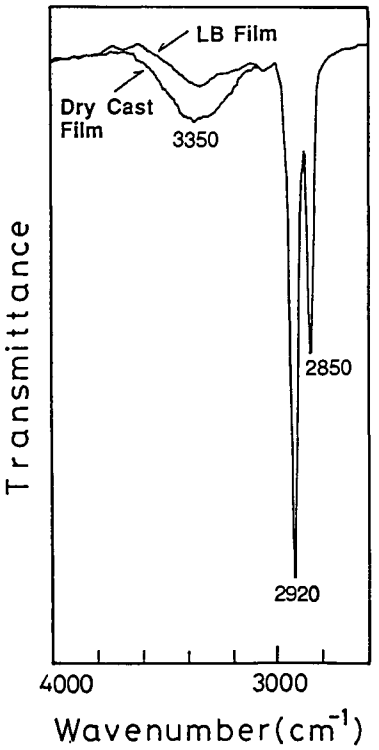

Fig. 4. SP144 IR spectra in the region 4000—2600 cm^{-1}.

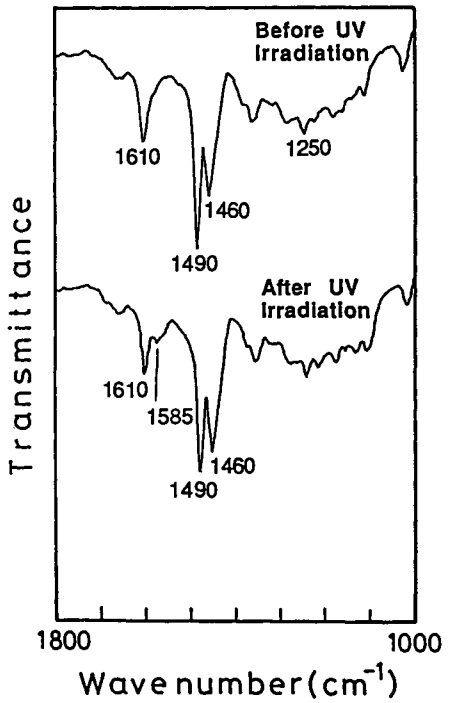

Fig. 5. SP144 LB film IR spectra in the region 1800—1000 cm^{-1}.

are shown in Figs. 4 and 5. In CCl_4 the SP form molecules exhibit a peak at 3620 cm^{-1} reflecting the free O–H stretching. However, in the LB films this free OH-band is absent and instead a broad band peaking at 3350 cm^{-1}, which appeared also in a dry SP144 film cast from a dichloromethane solution, is observed due to the stretching of the hydrogen bonded OH groups (Fig. 4). In the LB films deposited at pH 9.0, the broad band did not exist due possibly to deprotonation of the hydroxyl groups. As seen in Fig. 5, no substantial change took place in the spectral shape over a wavenumber range 1800 to 1000 cm^{-1} in going from the SP to the PMC form in the LB film. The intensity of the 1610 cm^{-1} peak, assignable to the C=C stretching of *trans*-photomerocyanine,[3] did not increase by UV irradiation. Therefore, we conclude that no significant change took place in the molecular skeleton, and the PMC form is an alternatively open form (cisoid) and not a completely open (almost planar) form, or the so called transoid. An IR study by Morinaka et al.[7] demonstrated the occurrence of similar phenomena, namely hydrogen-bond formation and no cisoid-transoid isomerization in vacuum-deposited films of a spiropyran having a hydroxy group but no long alkyl chain. Reportedly they observed a stabilization of the PMC form via intermolecular hydrogen bonding in the vacuum-deposited films, but we were unable to prepare a stable PMC form in the LB films. Presumally the strengths of the hydrogen bonding are different between the two experiments because of a difference in the molecular orientation in the films.

Photochromic Behavior of SP145. A larger extinction coefficient of spiropyrans having nitro groups enabled measurement of their monolayers at the air–water interface. Monolayer absorption spectra after UV irradiation are displayed in Fig. 6. A broad band (555 nm) assigned to the PMC form appeared at a surface pressure of 5 mN m^{-1}, whereas a relatively sharp band (638 nm) reflecting the J-aggregate form appeared at surface pressures of 15—25 mN m^{-1}.

The J-aggregated state was maintained by the transfer of surface monolayers onto the substrate. Figure 7 shows the absorption spectra of the transferred LB films. The J-aggregate (λ_{max}=638 nm) was converted into the colorless SP form with a half-life of 560 min at 25 °C in darkness. Subsequent UV irradiation of the SP form regenerated the PMC form (λ_{max}=585 nm) without J-aggregate formation. The half-decay period for the PMC-to-SP conversion of SP145 is 135 min, being longer than those of the colored PMC forms of SP18 (15 min) and SP1801 (30 min)[6] for which no intermolecular hydrogen bonding was observed by IR

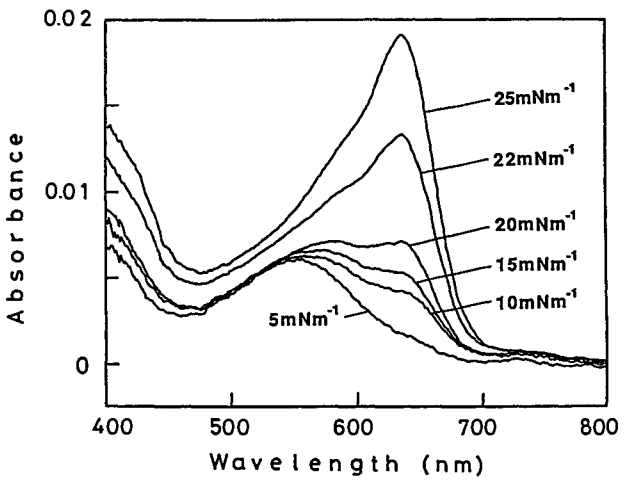

Fig. 6. Absorption spectra of the SP145 monolayer at the air–water interface.

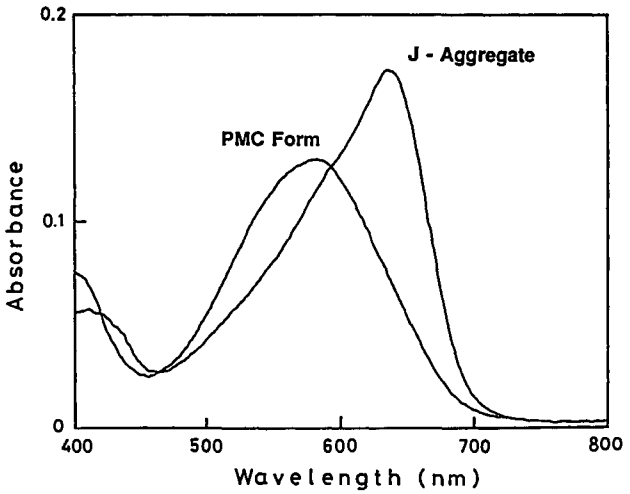

Fig. 7. SP145 LB film absorption spectra.

spectroscopy. A possible reason for the non-reformation of J-aggregates may be that their two-dimensional arrangements were sterically hindered by a molecular structural change during the conversion from the initial J-aggregated state to the SP form. Once such a change has occurred, recovery on the substrate is apparently impossible because an arrangement favorable for the J-aggregate formation may take place only at the air–water interface.

In order to examine whether the absorption band at 638 nm was due to J-aggregates, the fluorescence spectrum of the SP145 LB film was measured. A relatively small Stokes shift (65 nm) suggests that the dye is in a J-aggregated state as shown in Fig. 8. The Stokes shift, however, is larger than that (16 nm) of SP1822 having two long alkyl chains. This may reflect an inhomogeneous arrangement of the SP145 J-aggregate, or suggest that SP1822 J-aggregate is more tightly packed and well-ordered. Figure 9 shows the IR spectra for the J-aggregate, SP, and PMC form of the SP145 LB film. The NO_2 asymmetrical stretching at 1520 cm^{-1} in the SP form is shifted to 1518 cm^{-1} in both the J-aggregate and the PMC form. In contrast, the symmetrical NO_2 stretching mode at 1340 cm^{-1} in the SP form is shifted to 1295 cm^{-1} in the PMC form, and to split peaks at 1280 and 1250 cm^{-1} in the J-aggregate form. Since the colored PMC form has a zwitterion structure, the wavenumber lowering of the symmetrical NO_2 stretching peak may be a result of a resonance effect between the phenoxide ion and *p*-nitro group. The significantly lower frequency and larger intensity of the symmetrical NO_2 stretching bands in J-aggregate may reflect a stronger resonance effect, which promotes an intermolecular charge transfer from the negative oxygen atom of phenoxide ion in the pyran ring to the positive nitrogen atom in the indoline ring of an adjacent PMC molecule. Similarly, in the SP1822 LB film the sysmetrical NO_2 stretching peak was shifted from

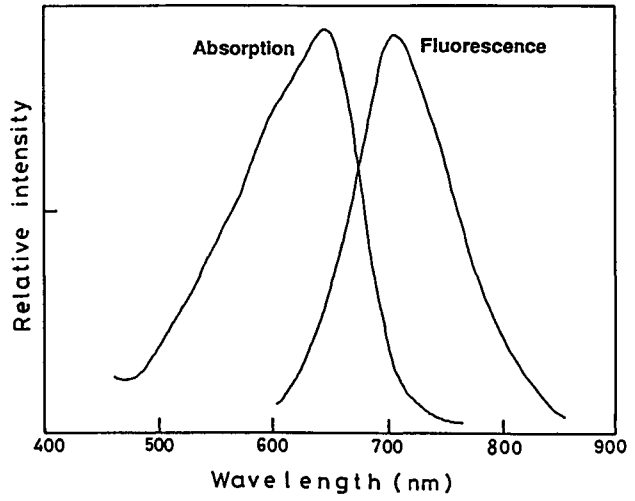

Fig. 8. Absorption and fluorescence spectra of J-aggregates in SP145 LB film.

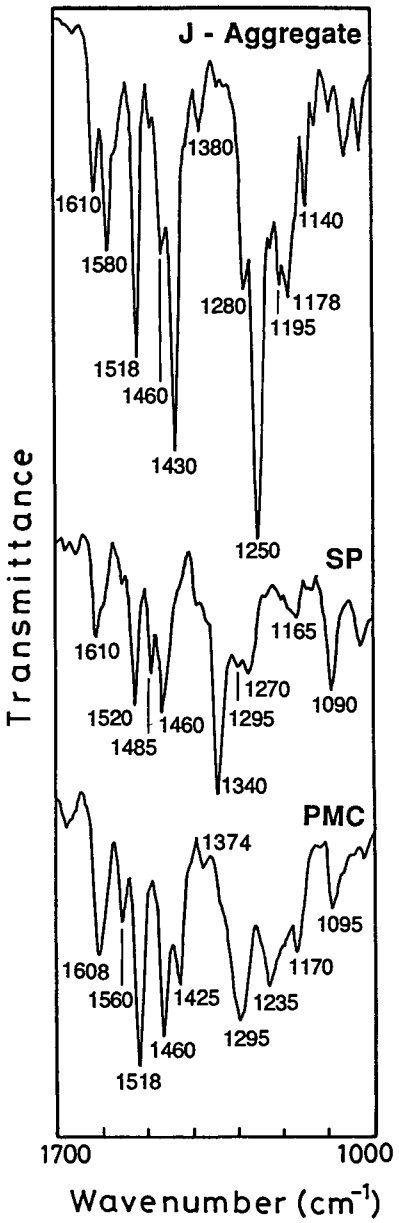

Fig. 9. IR spectra in the region 1700—1000 cm^{-1} for SP145 LB film.

1340 cm^{-1} in the SP form to 1290 cm^{-1} in the PMC and J-aggregate form.[8] To examine the state of the OH group, IR spectra were measured in the region 4000—2400 cm^{-1}. The SP form in CCl_4 showed a free OH-band at 3600 cm^{-1}. In the LB films, a weak band at 3220 cm^{-1} reflecting the O–H stretching in a hydrodgen bonded state was observed in both the PMC and the J-aggregate form, but not in the SP form. This demonstrates the formation of intermolecular hydrogen bonding in the PMC and J-aggregate form. The IR spectra for a SP145 cast film onto a CaF_2 substrate is shown in Fig. 10. By the SP-to-PMC conversion, the intensity of a broad peak at 3350 cm^{-1} increased while that of sharp peak at 3550 cm^{-1} decreased to a shoulder of the former peak. The 3550 cm^{-1} band is assigned to free

O–H streching. Accompanying the ring closure by 580-nm irradiation and by heating, the intensity of the free OH-band (3550 cm^{-1}) was recovered and that of the hydrogen-bonded OH-band decreased. These spectral changes were well reproducible. The intensity of the hydrogen-bonded OH-band in the dry cast films, however, was much larger than that in the LB films.

Photochromic Behavior of SP147. After spiropyan SP147 was spread on water, the colored PMC form (λ_{max}=590 nm) was observed without UV irradiation. The absorption spectra for the monolayer after UV irradiation are shown in Fig. 11. In the LB film a broad band at 590 nm is transformed into a new absorption band at 560 nm due to aggregate formation by heat treating at 35 °C for 120 min (Fig. 12). This peak shift seems the higher dipole interaction energy increased due to formation of either H-dimer or H-aggregate containing three or four molecules. This H-aggregate was stable and did not decay for more than a month.

The IR spectra of the PMC and the H-aggregate form are depicted in Fig. 13. On heating the LB films, the intensities of the hydrogen-bonded O–H stretching (3220 cm^{-1}) and of the symmetric NO_2 stretching (1290 cm^{-1}) increased. This suggests that hydrogen-bond formation among the NO_2 group, phenoxide ion, and OH group is responsible for the formation of the H-aggregate. By heat treatment, the SP147 dry cast film behaved in essentially the same manner as the LB film with regard to these features. Hydrogen bonding is

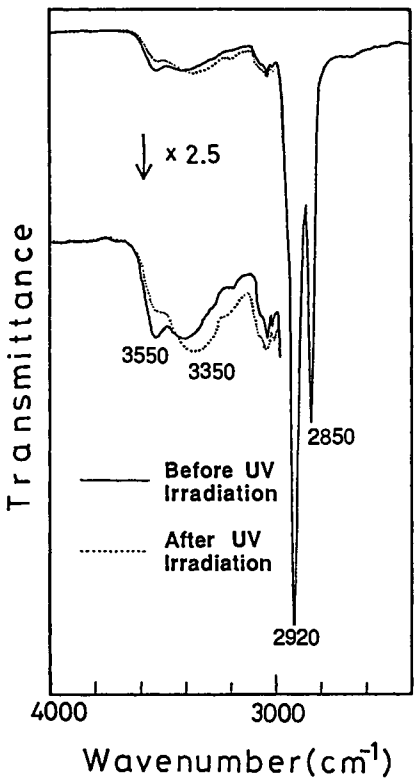

Fig. 10. IR spectra in the region 4000—2400 cm^{-1} for SP145 dry cast film.

one of the key driving forces for aggregate formation. An intramolecular hydrogen bonding may also occur in the PMC molecules, but the IR band reflecting this may have been hidden by the asymmetrical and symmetrical $-CH_2-$ stretching peaks (2910 and 2850 cm^{-1}) of the long alkyl chain.

Discussion

The photochromic behaviors of the spiropyran derivatives studied here are summarized in Table 1. UV-generated PMCs of SP18 (X=H),[9,10] SP145 (X=CH_2OH), and SP1822 (X=$CH_2OCOC_{21}H_{43}$)[11] have a head-to-tail configuration due to dipole–dipole interaction, and form J-aggregates in the monolayer at the air–water interface. Since the PMC form is more polar than the SP form, an electrostatic interaction may occur between neighoring PMCs in the J-aggregate. Previous studies have shown that the SP18 J-aggregate is unstable and readily converted into the PMC form in the LB films.[9,10] As verified in the presented work, the PMC of SP145 formed a J-aggregates which is more stable than the SP18 J-aggregate in the LB films. The stability of J-aggregates is a result of stronger dye–dye interaction and prevents the PMC-to-SP isomerization via formation of microcrystals. In contrast, the UV-generated PMCs of SP1801 (X=OCH_3)[11] and SP147 (X=OH) having the electron donating groups did not form J-aggregate in the monolayer on water. The SP147 PMC form, however, changed to an H-aggregate or an H-dimeric state by heat treatment in the LB film and dry cast film.

Table 1. Aggregate Formation in the Monolayer and LB Film

	Monolayer	LB film

SP147	PMC	H-aggregate
SP18	J-aggregate	J-aggregate
SP1801	PMC	PMC
SP1822	J-aggregate	J-aggregate

a) Signal not measurable.

Based on the blue-shifted visible absorption band and intensity increase of IR OH-band, we propose four types of molecular configuration for a hydrogen-bonded SP147 dimer in Fig. 14. It is generally known that H-dimer and H-aggregate assume a side-by-side arrangement.[12] In the type a and b the hydrogen bonding occurs among the OH group, phenoxide ion, and the NO_2 group. The transition dipole moments of the two molecules are in parallel, and this molecular configuration should exhibit a bule-shifted absorption from the monomer band. In type c the hydrogen bond forms between the OH group and the phenoxide ion, and here

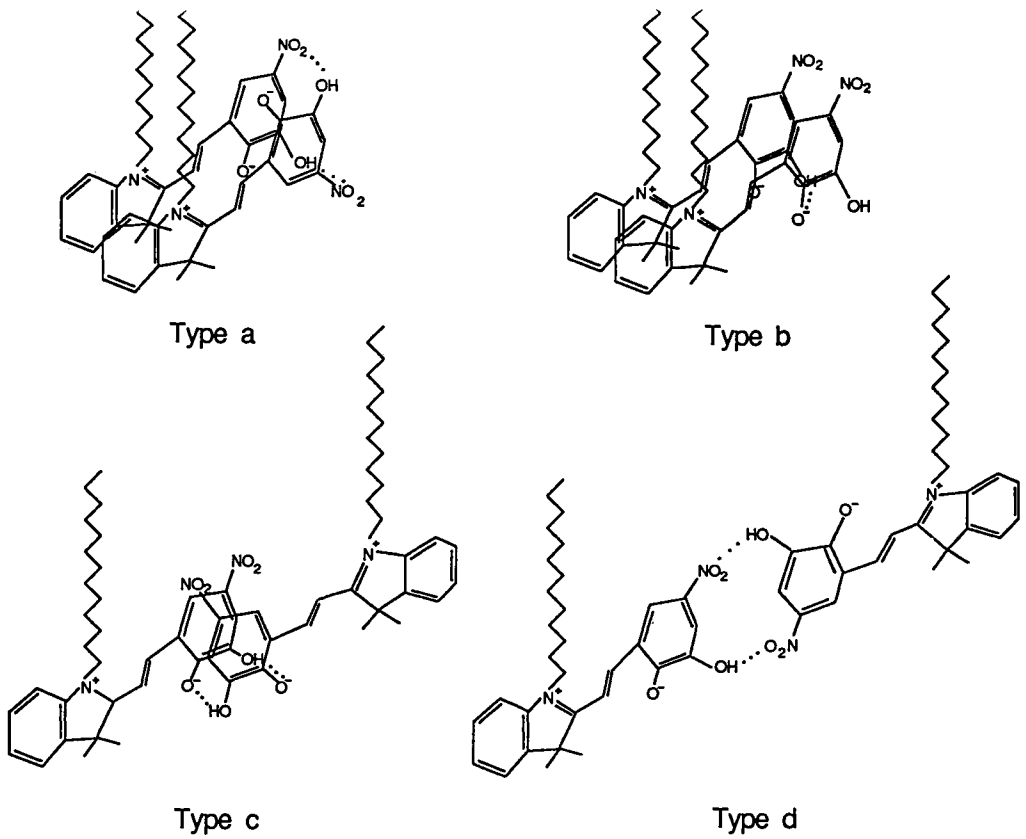

Fig. 14. Molecular configuration models of SP147 dimer.

the two transition moments are oriented anti-parallel. The slip angle between the molecular long axis and the center-to-center line, is small. Thus PMC molecules are essentially in a head-to-head arrangement. In type d, the hydrogen bond forms between the OH group and the NO_2 group. Again, PMC molecules are in a head-to-head arrangement. Both type c and d should hence exhibit a red-shifted absorption. In view of these, type a or b is the most plausible configuration for the reported H-dimer or H-aggregate.

In conclusion, intermolecular hydrogen bonding acts in stabilizing the colored PMC form and in promoting aggregation of spiropyrans having hydrophilic OH and CH_2OH groups, in systems where hydrophilic matrix molecules are absent. Spiropyrans with an NO_2 group and either OH or CH_2OH groups form diffrent types of aggregates depending on the mode of configurations of open-ring PMC molecules in the LB films and the dry cast films.

The authors are grateful to Drs. Mistuyuki Soma and Yuko Soma of the National Institute of Environmental Studies for IR assignments, and to Dr. David Heard of Sharp Corporation and Professsor Akihiko Yamagishi of the University of Tokyo for valuable discussions.

Shock Tube Studies of the H_2-O_2-CO Reaction by Atomic Resonance Absorption Spectroscopy

Tohru KOIKE
Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239
(Received December 20, 1990)

The atomic resonance absorptions of O- and H-atoms in the reaction of shock-heated $H_2/O_2/CO/Ar$(1/1/1/97 and 0.2/1/1/97.8) mixtures were observed over a relatively low temperature range from 1000 to 1400 K. The induction times, determined from the absorptions, were investigated by means of computer modeling which included a sensitivity test. The rate constant for the important initiation reaction, $CO+O_2=CO_2+O$, was evaluated to be $k_{13}=10^{13.1\pm0.6}$ exp $(-196.9\pm14.9$ kJ/$RT)$ cm^3 mol^{-1} s^{-1}, which may supplement the lack of reported rate constants in the low-temperature region.

The reaction

$$CO+O_2=CO_2+O \quad (13)$$

is a radical-producing step which initiates CO oxidation and has drawn the attention of many researchers, where the reaction number is in accordance with that given in Table 1. Recently, Thielen and Roth[1] studied CO oxidation in a shock-heated CO/O_2 system employing atomic resonance absorption spectroscopies (ARAS) of O-atoms. In a CO–O_2 mixture, the overall oxidation reaction is not so fast that it requires a high-temperature environment to observe the progress of the reaction within the restricted observation time of the shock-tube system. They determined the k_{13} value in the high-temperature region of 1700—3500 K.

Gardiner et al.[2] studied the reaction in both H_2/O_2 and $H_2/O_2/CO$ systems by means of UV absorption spectroscopy of the ground-state OH-radicals at temperatures of 1400—2500 K. They compared the induction times of OH absorption in the $H_2/O_2/CO$ system with those in the H_2/O_2 system and obtained k_{13} in the lower temperature region by computer modeling.

Reviews concerning elementary reactions in $H_2/O_2/CO$ system were given in detail by a group at the University of Leeds,[3] and more recently by Warnatz.[4] These two groups proposed the same k_{13} value in the temperature range 1500—3000 K.[3,4]

We have also adopted the $H_2/O_2/CO$ system and have observed the growth rates of O- and H-atoms directly by ARAS and have determined the k_{13} value in a low-temperature region in order to supplement the lack of reported rate constants.

Experimental

Since details concerning the incident shock-tube and the ARAS optical system were given in a previous paper,[5] we discuss them here only briefly.

The ARAS system comprises a light source and a detector. Gas mixtures of H_2 or O_2 diluted in He (by 1% flowing at 2 Torr through a quartz tube, 1 Torr=133.322 Pa) were excited by a microwave generator (Raytheon, PGM10X1); the accompanied emissions were used for the light source. A combination of a vacuum-UV-monochromator (Minuteman, 302-VM dispersion=40 nm/mm), of which wavelength was centered at 121.6 nm of the Lyman-α line by H-atoms or at 130.5 nm of the O-triplet line by O-atoms, and a solar blind photomultiplier (Hamamatsu, R-1459) was used as the detector. The signals of the absorption time profiles were recorded on a digital oscilloscope (Iwatsu, DS-6121) combined with an XY-recorder.

The test section of the shock tube was evacuated to less than 10^{-5} Torr before each run. The leak rate was ca. 10^{-5} Torr min^{-1}, and the shock waves were actuated within 3 min after closing all valves of the shock-tube.

Gases for the test gases ($H_2/O_2/CO/Ar$=1/1/1/97 and 0.2/1/1/97.8) were 99.99999% pure H_2, 99.999% pure O_2, 99.6% pure CO and 99.999% pure Ar and were used without further purification.

Results and Discussion

Figure 1 is a sample oscillogram of the absorption history at 121.6 nm for the 1/1/1 ($H_2/O_2/CO$) mixture; it shows the slight rise at the shock front, a low plateau,

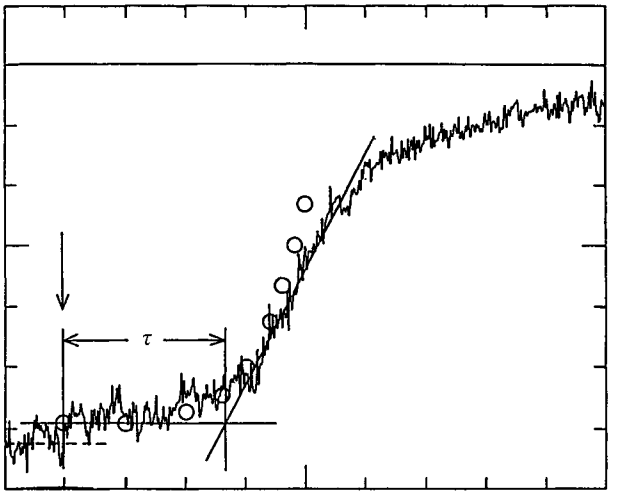

Fig. 1. A sample oscillogram of the absorption profile at 121.6 nm.
Test gas: $H_2/O_2/CO/Ar$=1/1/1/97,
P_1=20 Torr, T_2=1173 K.
The time-scale is 50 μs/div. The upper line shows the zero-level of the incident light intensity. The arrow shows the shock front. The induction time, τ, was evaluated as in the figure. The circles show the results by computer modeling with the reaction mechanism in Table 1.

and an exponential increase. Such a time profile was also obtained for absorption at 130.5 nm. Since the absorption by H_2 for the two light sources are smaller than those by O_2 and CO,[1,5,6] the absorption time profiles are not so different between the two mixtures. From the oscillograms, the induction times, τ, defined as the time interval between the shock arrival at the observation window and the foot of the exponential absorption rise, were evaluated on the laboratory base. As is shown in Fig. 1, the foot is the intersection of the low plateau and the extrapolated line of the absorption increase. The low plateau of the absorption after the shock front can be attributed to absorption by O_2 and CO.[1,5,6] Since the total absorption is the summation of each absorption of the contributing species, this revised

definition of τ must be more reasonable than those adopted in a previous study.[5]

The data points of the experimental τ values obtained from the 121.6 and 130.5 nm absorption profiles are shown in Figs. 2 and 3, respectively. Each line exhibits a least-squares result for the data points. The temperature dependences of both lines are almost equal and the τ values in the 1/1/1 mixture are smaller than those in the 0.2/1/1 mixture.

These results were subjected to interpretation by computer modeling. The induction time for the modeling is defined as being the time interval between shock arrival and the attainment of certain values of the

radical concentrations. These concentrations for H- and O-atoms were assumed to be 8.3×10^{-13} and 1.66×10^{-12} mol cm^{-3}, respectively.[5,6] These are almost in accord with the detection limit of the present ARAS system; the induction times, thus defined, in computer modeling are considered to be compatible with the induction times obtained from an oscillogram of the absorption profile.[5]

The reaction mechanism used in the computer modeling of the present study is shown in Table 1. This mechanism comprises H_2–O_2 reaction steps of Reactions (1)—(11),[4] derived in a former study,[5] and CO steps to form CO_2, Reactions (12)—(14). Excepting the k_1 and k_{13} values, the k values are those recently recommended by Warnatz.[4] He re-evaluated the values by Baulch et al.[3] as well as those by other groups that have appeared after Baulch's review.

In order to comprehend the roles of each reaction in the progress of the H_2–O_2–CO reaction, we carried out a sensitivity test for the reaction mechanism shown in Table 1 by changing each rate constant by factors of five and one-fifth. Figure 4 shows the results of the sensitivity test. The variations of the τ values are dominant for the sensitivity tests for Reactions (1), (4), (5), (6), and (13). A similar tendency of the variations was obtained for the two 1/1/1 and 0.2/1/1 mixtures.

Reaction (1) was found to be an important initiation in the H_2–O_2 reaction; we[5] thus had derived the k_1 value by means of ARAS and computer modeling which included a sensitivity test. The k_1 value in Table 1 is, however, that re-evaluated from the revised τ, as obtained above for the H_2/O_2 mixture. In the present system of the $H_2/O_2/CO$ mixture, Reaction (1) has a smaller effect on the variation of the τ values. Reactions (4)—(6) are bi-molecular reactions which include one radical; they are representative reaction steps in the H_2/O_2 reaction system. The rate constants for those steps had been well established in studies of the H_2/O_2 system. Reaction (13) is a radical-producing step to initiate CO oxidation, as is emphasized in the introduction; it is the most influential reaction on the τ values

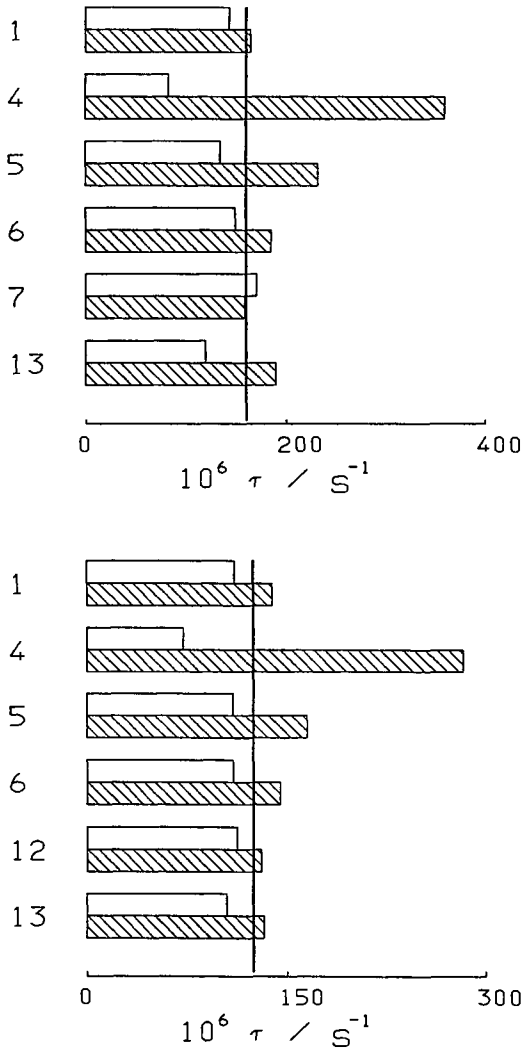

Fig. 4. Sensitivity calculation for τ.
Upper: for the result of Fig. 1 by H-atoms.
The numbers at the left hand side show the elementary reactions in Table 1. The above bar for each number shows the τ value obtained by computer modeling when each rate constant was multiplied by a factor of 5. The lower hatched bar was obtained by using the rate constant divided by the same factor. The elementary reactions giving small variations of τ are not shown in the figure. The vertical line through the bars shows the standard value of τ given by using the reaction parameters in Table 1.
Lower: for the 0.2/1/1 mixture at 1385 K by O-atoms. The numbers, the bars and the vertial line have the same meaning as those above.

among the CO participating reaction steps.

In the present study, we fit the τ values by computer modeling to the experimental τ values given in Figs. 2 and 3 by adjusting the k_{13} value. The k_{13} values, thus determined, are shown vs. $10^4/T$ in Fig. 5. We see no distinctive dependences of the k_{13} values on the test gas mixtures, as well as the species, H- or O-atoms, observed. The line shows the result of least-squares fitting for the k_{13} values and following Arrhenius expression could be derived:

$$k_{13} = 10^{13.1\pm0.6} \exp(-196.9\pm14.9 \text{ kJ}/RT) \text{ cm}^3 \text{ mol}^{-1} \text{ s}^{-1},$$

where the values with $\pm$ exhibit one standard deviation.

Computer modeling with the reaction mechanism given in Table 1 was also carried out for the absorption time profile given in Fig. 1. The absorptivity of H-atoms used in the computer modeling was 5×10^{10} $\text{cm}^2 \text{ mol}^{-1}$, which was determined in a study of the H_2O pyrolysis at temperatures above 2000 K (described later). The agreement of the absorption profile between the experiment and computer modeling is good for the early period of the reaction. At later stages, however, the absorption determined by modeling is larger than that found by experiment. These modeling results are due to the fact that the absorptivity of H-atoms becomes smaller at higher concentrations;[1,6] such effects were not taken into account in the computer modeling.

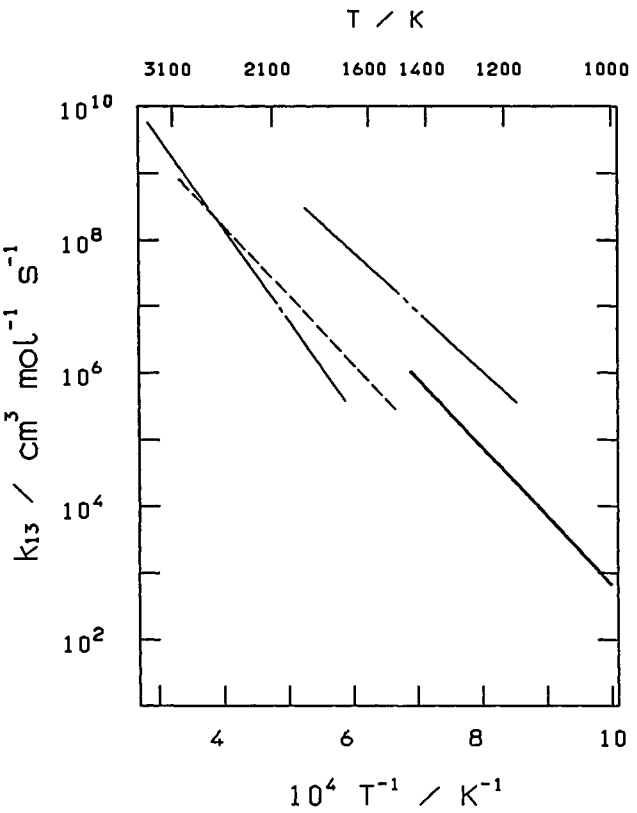

Fig. 6. Arrhenius expression of k_{13}.
Solid line: This work.
Chain line: by Thielen and Roth.[1]
Broken line: by Baulch et al.[3]
Chain-broken line: by Brabbs et al.[7]

Figure 6 shows an Arrhenius expressions for k_{13} from different sources by Thielen and Roth,[1] Baulch et al. (the same one by Warnatz)[3,4] and Brabbs et al.,[7] along with our value. Baulch et al.[3] took into account the expression by Gardiner et al.[2] in recommending their k_{13} value. Thus, the value given by Gardiner et al.[2] can be considered to be the data reviewed by Baulch et al.[3] and is not shown in the figure.

As shown in Fig. 6, most of these reported k_{13} values were obtained at higher temperatures than ours. The value by Brabbs et al.[7] was obtained in a temperature region close to the present study, but is larger than ours. Their value is also larger than the extrapolated values of Thielen and Roth[1] as well as Baulch et al.[3] by almost one order of magnitude. The discrepancies were so large that Gardiner et al.[2] examined the results by Brabbs et al.[7] by taking into account such view points as 1) the purities of the test gas mixtures used, 2) the difference of the vibrational relaxation times of CO depending on the compositions of the test gas mixtures used, and 3) a few uncertainties concerning the emission spectroscopy adopted.

Although Gardiner et al.[2] were not successful in explaining the larger value of k_{13} by Brabbs et al.,[7] their points[2] seem to cover most of the important criterions necessarily to consider the discrepancies.

Our k_{13} value determined in the present study is smaller than the value by Brabbs et al.,[7] but larger than the extrapolated values by Thielen and Roth[1] as well as Baulch et al.;[3] examinations of the present results through any appropriate criterions are thus required. We adopted Gardiner's view points for the examination. His view point concerned with the emission spectroscopy could be excluded in the present case. Gardiner's second view point is based on the vibrational relaxation of CO, which depends on the compositions of test gas mixtures; it could be ignored in the present case, since the present experimental conditions, including the composition of the test gas mixtures, are almost the same as those adopted by Gardiner et al.[2]

The first view point of the Gardiner et al.[2] concerns impurities of the test gas mixtures used; we examined our experiments in terms of this view point. The purities of H_2, O_2 and Ar used for the experiments were above 99.999%; we discarded them for the present from considerations of the impurities. Although the purity of CO was given as 99.6%, we mainly focused our attention on the impurity problem origining from the CO gas used.

A trial experiment for CO/Ar mixtures both with and without O_2 was carried out under the same experimental conditions as the present by using the ARAS. It was observed that only a small absorption, starting at the shock front and continuing with a constant value, appeared. Since no growing absorption was observed during the reaction period, the influence of the impuri-

ties, if any, on the progress of reaction is considered to be negligible within the present temperature range.

With regard to the influence of impurities,[3] a question always arises whether or not a trace amount of H_2O derived from the CO container might accelerate the reaction to be measured. We, therefore, studied the reactivity of H_2O both by computer modeling and experiment. Computer modeling was carried out according to the reaction mechanism given in Table 1 for a test gas mixture of $H_2/O_2/CO/H_2O=1/1/1/0.01$ in Ar. No acceleration of the reaction (estimated from the growth rates of O-atoms and H-atoms) with the presence of H_2O was observed to occur in the modeling. Furthermore, the experimental verifications were done for test gas mixtures of H_2O/Ar and H_2O/O_2/Ar. No absorption under the present experimental conditions was observed for the growth of O- and H-atoms, which could be produced directly or indirectly by the decomposition of H_2O. It has been confirmed that H_2O is very stable within the present temperature range. The influence of H_2O on the reaction progress is thus also negligible. Detailed reports on the reaction of H_2O measured using the present technique may appear elsewhere.

In conclusion, we could establish a reliable k_{13} in the lower temperature region, though we could not elucidate the discrepancies between the present k_{13} value and extrapolations of the reported k_{13} values[1,3,4] to the lower temperature region.

The present author wishes to thank Professor Kihei Morinaga, National Defense Academy, for providing him with many helpful suggestions.

Mechanism of the Reaction of NH($^1\Delta$) with NO in Argon Matrix

Keiichi YOKOYAMA, Hiroshi KITAIKE, and Takayuki FUENO*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received January 28, 1991)

Matrix-isolated hydrazoic acid HN_3 admixed with NO was photolyzed by a low-pressure mercury discharge lamp. Product analysis based on the FTIR spectroscopy has revealed the formations of NH, N_2O, OH, HNO, and HONO as photoproducts. From the comparisons of the amount of HN_3 consumed with that of N_2O produced, we conclude that the reaction of NH($^1\Delta$) with NO proceeds mainly through the process NH($^1\Delta$)+NO→N_2O+H. The quantum yield of N_2O is found to be $\phi_1=0.7\pm0.1$. The conclusion is in line with our previous results of the gas phase experiments at room temperature.

We have previously investigated the gas-phase reaction of NH($^1\Delta$) with NO both theoretically and experimentally.[1] The theoretical studies have shown that the reaction should proceed through an intermediacy of the HNNO adduct and that two channels are open for the unimolecular decomposition of the HNNO adduct:

$$NH(^1\Delta)+NO \longrightarrow [HNNO] \begin{cases} \longrightarrow N_2O+H & (1a) \\ \longrightarrow N_2+OH & (1b) \end{cases}$$

The entire reaction is expected to be essentially collision-controlled, and the HNNO decompositions as the product-determining step have energy barrier heights lower than the heat of the adduct formation, with a marginal advantage of reaction (1a) over reaction (1b). The expectation that the primary product of the reaction should be N_2O was borne out by the experimental determination of the quantum yield of N_2O being ca. 0.7, under the assumption that the quantum yield of NH($^1\Delta$) in the photodissociation is 1.0.

$$HN_3 \xrightarrow{h\nu} NH(^1\Delta)+N_2 \qquad \phi=1 \text{ at } 2537\,\text{Å} \qquad (2)$$

It is feared, however, that in the gas phase N_2O might well be formed by some routes other than the direct process (1a). Hack et al. carried out laser photolysis of HN_3 in the presence of NO in the gas phase at room temperature.[2] On the basis of the laser-induced fluorescence signal intensity of OH, they concluded that the primary product is OH($X^2\Pi$) to be formed by reaction (1b). They suggested the possibility that the formation of N_2O was rather a consequence of subsidiary reactions as follows:

$$NH(^1\Delta)+HN_3 \longrightarrow NH_2+N_3 \qquad (3)$$

$$N_3+NO \longrightarrow N_2O+N_2 \qquad (4)$$

In the present work, we have undertaken studies of the photo-induced reaction of HN_3 with NO in argon matrix. Our principal purpose here is to examine whether our previous gas-phase product determination study has indeed reflected the kinetics of reaction (1a). In a matrix there are not only isolated monomers but also dimers, polymers, and complexes with other molecular species, but generally there are little mobilities for isolated molecules except for the H atom. Thus, photoinduced reactions are thought to be completed within single cages of argon matrix. Contributions of subsidiary processes to the overall reaction could be examined more closely in this study.

Experimental

The cryogenic apparatus used in the matrix experiments is schematically shown in Fig. 1. A Cryomini D310 closed-cycle helium system (Iwatani Cryo-Techno Inc.) was used to refrigerate the deposition target made of CsI of 20 mm in diameter and 2 mm in thickness. An indium gasket was inserted between the CsI disk and the copper sample holder mounted on the cold head. Two Pylex nozzles of 0.5 mm in internal diameter were placed at a distance of 3 cm from the target in the direction orthogonal to each other to spray sample gases onto the target. Only one of these nozzles was used in the present experiments. A thermocouple of Chromel vs. Au–0.07% Fe was embedded on the sample holder. The ordinary operating temperature was measured to be 12 K. A liquid nitrogen trap and an oil diffusion pump were used to evacuate all of these devices placed within a stainless steel envelope.

IR spectra were measured through two KRS-5 windows located on both sides of the target on the envelope. In the direction perpendicular to the IR beam, there were two quartz

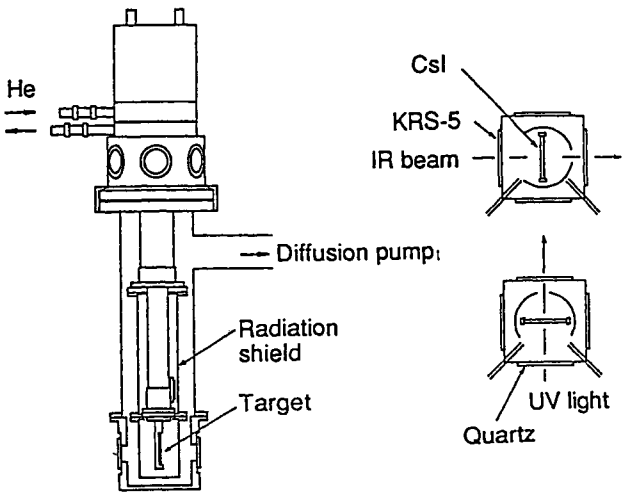

Fig. 1. Schematic drawing of the cryogenic apparatus. Top right, target alignment for IR measurement. Bottom right, that for deposition of the sample gases and UV photolyses.

windows for UV irradiation. The target was rotatable on a horizontal plane for IR measurement and UV irradiation. The UV light source used was a 22W low-pressure mercury discharge lamp (Ultra Violet Prod. Inc.) placed just in front of the quartz window of 2 mm in thickness without lens nor filter. This alignment provided homogeneous exposure of the target to the 2537 Å UV light. It is thought that another mercury line 1849 Å will little influence the measurements because of the absorption by the quartz window (not suprasil) at this wavelength. A Fourier-transform infrared spectrometer FT/IR-5000 (Japan Spectroscopic Co., Ltd.) was operated with a resolution of 4 cm^{-1} and the spectra were calculated from the coaddition of 100 interferograms. The deposition rates of sample gases were controlled with a teflon needle valve and a capacitance manometer CMLB-1000 (Vacuum General Inc.).

HN_3/NO/Ar(=0.1—1/0.08—1/100) gas mixtures were sprayed out through the nozzle at a rate of 2 mmol h^{-1} for ca. 3.5 h. After measurements of IR spectra for deposited samples, UV irradiation was started. Photolyzed matrix spectra were measured at the irradiation times of 0.5, 1, 2, 4, 6, 10, 20, 30, 60, and 120 min. A single measurement took about 4 min. The matrix temperature was monitored to be maintained at 12 K during irradiation. A relative intensity of the N_2O ν_3 (2224 cm^{-1}) to the HN_3 ν_2 (2138 cm^{-1}) band was evaluated on the basis of the matrix spectra of N_2O/HN_3/Ar of known compositions.

HN_3 was synthesized by the reaction of NaN_3 with excess stearic acid at 80—90 °C in a vacuum glass line. After the purification by means of trap-to-trap distillations at −80 °C, HN_3 gas was stored in a 6-l Pyrex bulb. NO (99.99%), Ar (99.9999%), and N_2O (99.999%) (Takachiho Kagaku Inc.) were used without further purification. Gas mixtures diluted in argon were kept in a 6-l Pyrex bulb overnight for mixing.

Results

(A) Assignment of Complexes. The HN_3/NO/Ar matrix spectra have exhibited, in the vicinity of the HN_3 ν_2 band (2138 cm^{-1}), a perturbed ν_2 band at 2150 cm^{-1} due to the hydrogen-bonded HN_3 dimer.[3] More highly aggregated molecules may also contribute to this peak since annealing experiments broadened the ν_2 band. By contrast, the ν_2 band was not resolved by possible complexation of HN_3 with NO, which might reflect a weaker hydrogen bonding between the two components.

A new peak was observed at 1882 cm^{-1} near the isolated NO stretching (1874 cm^{-1}). It is assigned essentially to the HN_3–NO complex on the basis of the following observations. First, this peak is observed in the HN_3/NO/Ar spectra but is absent in either of the HN_3/Ar and NO/Ar matrix spectra. Second, as can be seen in Fig. 2, the relative peak heights of the complexes vs. NO remain constant, irrespective of the molar fraction of NO in the sample gas used. It is possible, however, that the assigned peak is actually overlaped with that of the $(HN_3)_2$–NO complex, as will be considered later.

(B) Photoproducts. Figure 3 shows a difference spectrum of an HN_3/NO/Ar matrix after photolysis for 1 h. The irradiation diminishes HN_3 and the complexes and gives rise to $NH(X^3\Sigma^-)$, N_2O, OH, HNO, HONO, and NO_2. Little change was observed in absorbance of the peak due to the isolated NO monomer

a) Observed in the photolysis of the HN_3/Ar matrix.

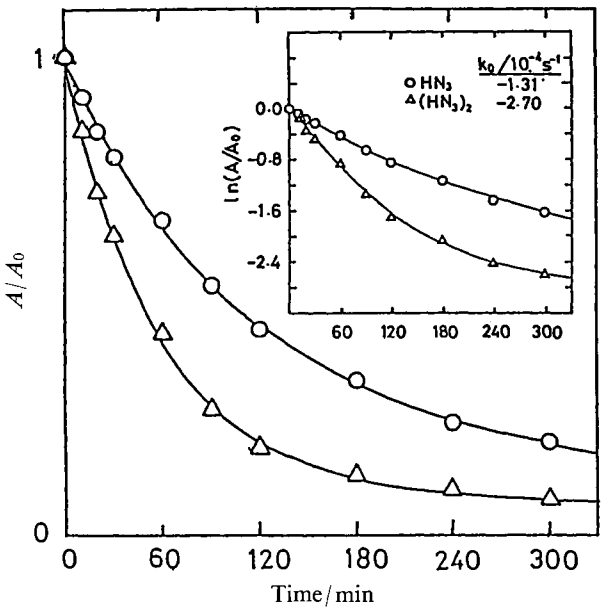

Fig. 4. Differernce between relative decay curves for the HN_3 monomer (2138 cm^{-1}) and dimer (2150 cm^{-1}) in the spectrum of HN_3/NO/Ar=0.5/0.5/100. Solid curve is obtained from biexponential fitting. Insert is log plots of the decays. Note that initial slope ratio is about 1 : 2 (monomer : dimer).

(1874 cm^{-1}). Assignments of the product peaks are listed in Table. 1, together with the literature values. In the vicinity of the NH_2 ν_2 band (1499 cm^{-1}), no significant peak was observed.

Evidently, N_2O is the primary product of the present matrix experiments also. As we believe, it has arisen from reaction (1a) directly, even though the mechanism proposed by Hack et al.,[2] i.e., the succession of reactions (3) and (4), cannot wholly be negated at this stage. Importantly, the concurrent formation of HNO lends strong support to our belief. Namely, the H atom which should have been formed together with N_2O by reaction (1a) could migrate in argon matrix cages to undergo recombination with NO:

$$NO + H + M \longrightarrow HNO + M \quad (5)$$

Reaction (1a) followed by reaction (5) seems to be the only route for the formation of HNO under our experimental conditions.

(C) Time Evolution. The HN_3 ν_2 band absorbances for monomer (2138 cm^{-1}) and dimer (2150 cm^{-1}) are plotted in Fig. 4 as the functions of irradiation time. Two curves have apparently different time constants. Log plots of these decay curves manifest that the dimer is photodecomposed nearly twice as rapidly as is the monomer; the initial slope ratio for dimer to monomer is about 2. The results indicate that the dimerization does not perturb the IR intensity of the ν_2 band nor the UV dissociation cross section of HN_3. In addition, it seems that highly aggregated HN_3 molecules, if any, hardly contribute to the absorption at 2150 cm^{-1}

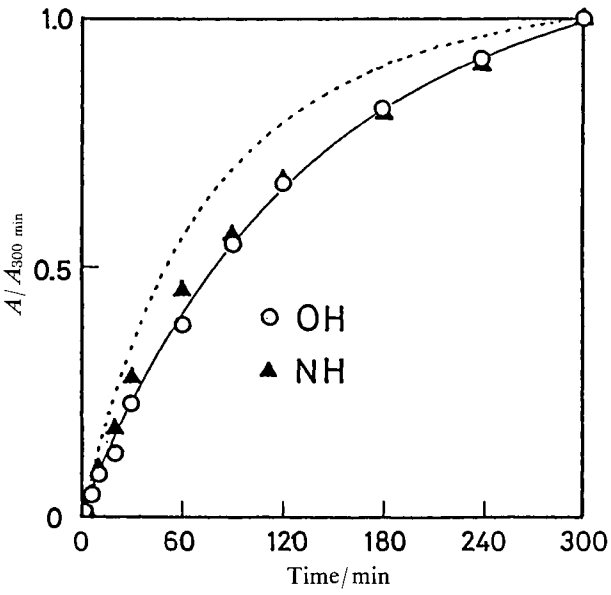

Fig. 5. Comparisons of the OH (3554 cm^{-1}) or the NH (3136 cm^{-1}) production profile with the HN_3 monomer and dimer decay profiles. The solid and dashed curves provide decrements in absorbance at the HN_3 (2138 cm^{-1}) and $(HN_3)_2$ (2150 cm^{-1}) ν_2 bands, respectively. HN_3/NO/Ar=1/1/100.

because they should be photodecomposed further more rapidly.

Figure 5 shows the increases in the OH (3554 cm^{-1}) and NH (3136 cm^{-1}) absorbances with the elapsing irradiation time. For the purpose of comparisons in

shape, measured absorbances have been arbitrarily normalized to a constant value at 300 min. Shown by the solid and dotted curves are the *decrements* in absorbance of HN_3 (2138 cm^{-1}) and $(HN_3)_2$ (2150 cm^{-1}), respectively, as the functions of time (Fig. 4). It can be seen that both the OH and NH increment curves fit the HN_3 monomer decrement curve. The results suggest that NH arises from the photolysis of the HN_3 monomer and that the precursor for OH is the 1 : 1 HN_3–NO complex.

The absorbance of N_2O ν_2 band (2224 cm^{-1}) was also found to increase with time but to be fitted with neither of the HN_3 and $(HN_3)_2$ decay curves. The time profile showed a somewhat faster saturation curve. This is presumably due to a photodecomposition process of N_2O itself.[4]

$$N_2O \xrightarrow{h\nu} N_2 + O(^1\Delta) \qquad \lambda < 2300\ \text{Å} \qquad (6)$$

Under such circumstances, we have decided to examine the initial rate of the formation of N_2O relative to that of the consumption of HN_3 monomer as the function of the molar fraction χ_{HN_3} of HN_3 present in the sample gas deposited. Note that the word "initial" used here means such an early time region that the secondary photodecomposition does not affect $[N_2O]$, normally less than 4 min.

Figure 6 shows the initial production rate of N_2O (2224 cm^{-1}), $d[N_2O]/dt$ (t=0), relative to the initial decay rate of HN_3 monomer (2138 cm^{-1}), i.e., $-d[HN_3]/dt$ (t=0), at the varying initial molar fraction χ_{HN_3}. It can be seen in Fig. 6 that the relative initial rate $-d[N_2O]/d[HN_3]$ (t=0), is constant at 0.52, irrespective of χ_{HN_3}. The results indicate that N_2O is produced from the HN_3 monomer complexes; i.e. HN_3–$(NO)_{1,2}$.

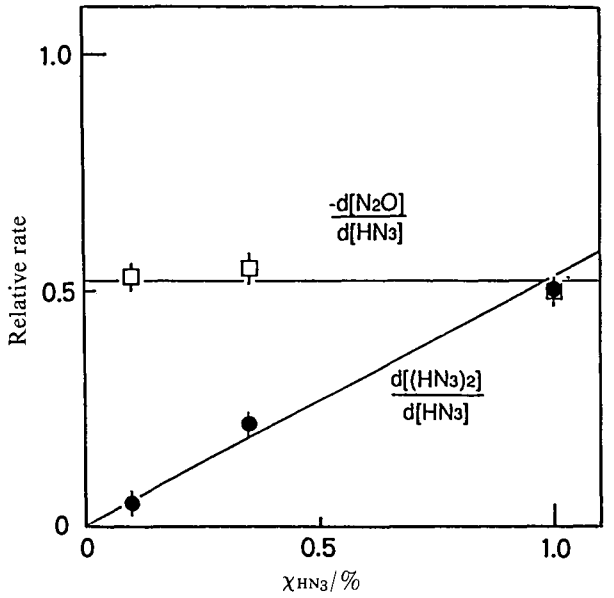

Fig. 6. Dependence of the production of N_2O on the fraction of HN_3. Dependence of the monomer: dimer ratio of HN_3 is also shown.

In addition, the initial rate of the consumption of $(HN_3)_2$ (2150 cm^{-1}) was measured relative to $-d[HN_3]/dt$ (t=0). The relative rate $d[(HN_3)_2]/d[HN_3]$ (t=0) was confirmed to be proportional to χ_{HN_3}. Therefore, if the photolysis of $(HN_3)_2$–$(NO)_{1,2}$ had given rise to N_2O, the plots of $-d[N_2O]/d[HN_3]$ against χ_{HN_3} would have shown a significant positive slope. Constancy of $-d[N_2O]/d[HN_3]$ indicates that the photolysis of the 2 : 1 or 2 : 2 complex $(HN_3)_2$–$(NO)_{1,2}$ has hardly contributed to the N_2O production. The results entirely negate the contribution of the succession of reactions (3) and (4) in the N_2O production under the present conditions.

(D) Yield of N_2O. We have evaluated the yield of N_2O formed by the photolysis of the 1 : 1 complex. In the measurements of the yield, there are two complexities. One is that N_2O may be formed by the photolysis of the 1 : 2 complex as well. The other is that the absorption at 1882 cm^{-1}, which was used to measure the amount of the 1 : 1 complex, may have overlaped with that of the 2 : 1 complex. Therefore, appropriate corrections are needed in evaluating the yield from the rates of the N_2O production and the complex consumption.

Let the yields of N_2O arising from the photolyses of the 1 : 1 and 1 : 2 complexes be denoted as ϕ_1 and ϕ_2, respectively. Since N_2O is assumed to be formed from both complexes, we may write

$$d[N_2O] = -\phi_1\, d[HN_3\text{–}NO] - \phi_2\, d[HN_3\text{–}(NO)_2]. \qquad (I)$$

The apparent overall yield of N_2O, defined as $\Phi \equiv -d[N_2O]/d[HN_3\text{–}NO]$ is then expressed as

$$\Phi = \phi_1 + \phi_2\, d[HN_3\text{–}(NO)_2]/d[HN_3\text{–}NO]. \qquad (II)$$

The second term $d[HN_3\text{–}(NO)_2]/d[HN_3\text{–}NO]$ is expected to be proportional to χ_{NO}, which will be confirmed later. Thus, plots of Φ vs. χ_{NO} should provide the ϕ_1 value as the intercept at $\chi_{NO} \to 0$.

In order to evaluate the Φ value, the initial rate of the consumption of the 1 : 1 complex is needed. The complex peak at 1882 cm^{-1} which is the only peak distinguishable at the present resolution contains both the 1 : 1 and 2 : 1 complexes:

$$-dC/dt = -d[HN_3\text{–}NO]/dt - d[(HN_3)_2\text{–}NO]/dt, \qquad (III)$$

where C is the amount of the complexes absorbing at 1882 cm^{-1}. Dividing both sides by $d[N_2O]/dt$, we can write

$$-dC/d[N_2O] = \Phi^{-1} - d[(HN_3)_2\text{–}NO]/d[N_2O], \qquad (IV)$$

where the second term $d[(HN_3)_2\text{–}NO]/d[N_2O]$ should be proportional to χ_{HN_3} in view of the results illustrated in Fig. 6. Hence, by plotting $-dC/d[N_2O]$ against χ_{HN_3}, we obtain the reciprocal Φ from the intercept.

In practice, the values of dC/dt have been evaluated from the absorbance changes at 1882 cm^{-1} in the initial 4 min period. The initial decreasing rates of C have been divided by the initial production rates of N_2O (2224 cm^{-1}). Plots of the quotients against χ_{HN_3} at a fixed χ_{NO} value of 1.0%, for instance, have indeed proved to

be linear, as is shown in Fig. 7. The intercept 0.48 leads to Φ=2.08 at χ_{NO}=1.0%.

The values of Φ at various χ_{NO} values have been measured in a similar way. Figure 8 shows the plots of Φ vs. χ_{NO}. As has been anticipated in the form of Eq. II, the plots are linear. The intercept gives ϕ_1=0.7± 0.1.

For the absorption peaks of HN_3, N_2O, and $(HN_3)_{1,2}$-NO, proportionalities between the concentrations and the absorbances have been assumed. Relative absorption coefficients are measured to be 1 : 1.15 : 0.225 for HN_3 (2136 cm^{-1}): N_2O (2224 cm^{-1}): $(HN_3)_{1,2}$-NO (1882 cm^{-1}). These values have been obtained from the IR spectra of the matrices made of the sample gases of known compositions. The absorption coefficient of the complex peak (1882 cm^{-1}) has been assumed to be equal to that of isolated NO monomer, because the IR absorption intensity of the N-O stretching would not be perturbed largely by the complexation.

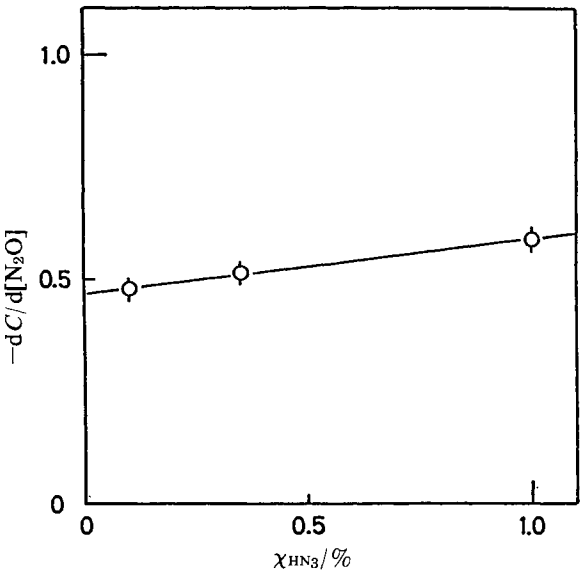

Fig. 7. χ_{HN_3} dependence of reciprocal yield, $-dC/d[N_2O]$, at a fixed χ_{NO} value of 1.0%. The intercept corresponds to the value of Φ^{-1}.

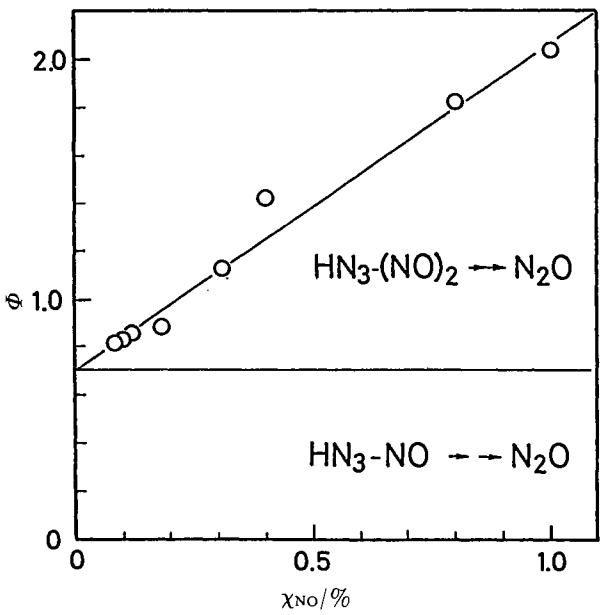

Fig. 8. [NO] dependence of the yield of N_2O from the photolysis of the 1 : 1 and 1 : 2 complexes HN_3-NO and HN_3-$(NO)_2$. The intercept corresponds to the absolute yield ϕ_1 of N_2O in reaction (1).

Discussion

Since NH($a^1\Delta$) formed by the photolysis of HN_3 is metastable, there may exist a physical quenching to NH($X^3\Sigma^-$):

$$NH(^1\Delta) + Ar \longrightarrow NH(^3\Sigma^-) + Ar. \quad (7)$$

Ramsthaler-Sommer et al. measured the lifetime of NH($a^1\Delta$) in argon matrix.[5] Their reported value of ca. 0.7 s at 12 K is long enough to allow the barrierless reaction (1) to complete without an influence of the quenching process (7).

The photoinduced reaction of the 1 : 1 complex can be regarded as reaction (1) in argon matrix cages. The value 0.7±0.1 obtained for ϕ_1 indicates that N_2O arises dominantly from reaction (1a) via the HNNO intermediacy. The result is perfectly compatible with the observation of HNO, whose production is a quite likely event as a fate of the H atom formed in reaction (1).

We have already noted the failure in detecting NH_2. For the purpose of more quantitative discussion, the infrared intensity of the NH_2 ν_2 band 1499 cm^{-1} is needed. Thus, we conducted separate photolysis experiments of NH_3/Ar and NH_3/CO in order to isolate the radical.

$$NH_3 \xrightarrow{h\nu} NH_2 + H. \quad (8)$$

A low-pressure mercury discharge lamp with suprasil window provides 1849 Å UV light which should efficiently photodecompose NH_3. In the case of NH_3/Ar, the NH_2 ν_2 band at 1499 cm^{-1} showed only a slight absorption after an irradiation over a period of five hours, probably because of the recombination between the dissociated NH_2 and the H atom. In the NH_3/CO photolysis, on the other hand, effective productions of NH_2, HCO, and $HCONH_2$ have been observed.[6] Assuming that the amount of NH_2 produced is equal to that of NH_3 consumed, we have estimated a lower limit of the relative intensity of the NH_2 ν_2 band to the N_2O ν_3 band to be $I_{NH_2}/I_{N_2O}>0.1$. Obviously, this value is underestimated owing to the production of a significant amount of $HCONH_2$. By appling this value to a spectrum for HN_3/NO/Ar, in which an absorbance ratio A_{NH_2}/A_{N_2O} is found to be less than 0.01, we estimate an upper limit of the production ratio $d[NH_2]/d[N_2O]$ to be less than 0.1. Therefore, only less than 10% of N_2O might be formed via the succession of reaction (3) and

(4), if any.

We have also been cautious of the possibility that N_2O may be formed directly from NO. Although isolated NO monomer cannot be decomposed by irradiation with a low-pressure mercury discharge lamp, the dimer is susceptible to the photodissociation:[7]

$$ONNO \xrightarrow{h\nu} N_2O + O \qquad \lambda < 2400\,\text{Å} \qquad (9)$$

However, in the present experiments, reaction (9) will not participate significantly, since the intense Hg resonance line at 1849 Å has been attenuated to a large extent through the window used in this study. In fact, the initial production rate $d[N_2O]/dt$ ($t=0$) in the photolysis of NO/Ar (1/100) was found to be less than 2% that in the photolysis of HN_3/NO/Ar (1/1/100). Thus, N_2O formed in the photolysis of HN_3/NO/Ar has no doubt originated nearly exclusively from the photodecomposition of HN_3.

Our original aim of the present work was to detect the HNNO intermediate. This was unsuccessful, however. It is supposed that the nascent vibrationally excited HNNO has an extremely short lifetime compared to a period of time required for stabilization by collisions with Ar. Thus, fragmentation will take place prior to stabilization. Also, the photodecomposition might be so fast that the amount of HNNO could not reach the detection limit.

We have assigned a peak at 3554 cm^{-1} to the OH radical in the spectrum of an HN_3/NO/Ar matrix photolyzed. The infrared absorption of OH in argon matrix has not been established yet. There are some discrepancies among the reported values.[8-10] Acquista et al.[8] and Suzar et al.[9] conducted the photolysis of H_2O at 1218 Å and decomposition of H_2O by means of electron impact in argon matrix, respectively. Both of them assigned two absorptions near 3452 and 3428 cm^{-1} to the OH vibration. On the other hand, Cheng et al.[10] found a new peak at 3548.2 cm^{-1}, which was concluded to be due to the OH radical prepared in solid argon by means of the reactions of atomic H with NO_2, O_3, and atomic O. The shift of 21.4 cm^{-1} from 3569.6 cm^{-1} as the gas-phase fundamental band is within the common range of matrix shifts.[11] They pointed out the possibility that the absorptions at 3452 and 3428 cm^{-1} previously assigned to OH may be due to the hydroxyl radical in complex with either H_2O or one Ar atom. Our observation 3554 cm^{-1} supports the conclusion by Cheng et al. The difference of 6 cm^{-1} between their wavenumber and ours may have been caused by an interaction of OH with N_2, which has been formed simultaneously with OH via reaction (1b). N_2 matrix experiments to isolate OH will be interesting.

The formation of HONO observed in a considerable amount probably stems from the 1:2 complex HN_3–$(NO)_2$. By virtue of weakness of the N–N bonding in $(NO)_2$, its photolysis will be apt to form the same intermediate HNNO as does reaction (1).

$$NH(^1\Delta) + ONNO \longrightarrow [HNNO]^* + NO \qquad (11)$$

If HNNO formed in this reaction has still enough excess energy, reaction (1b) will follow to give OH, which may in turn recombine with the other NO molecule to form HONO.

$$OH + NO + Ar \longrightarrow HONO + Ar \qquad (12)$$

Finally, in addition to the chemical channels (1a) and (1b), a quenching process must be considered.

$$NH(^1\Delta) + NO \longrightarrow NH(^3\Sigma^-) + NO \qquad (1c)$$

Hack et al. measured the rate constant of reaction (1c) in the gas phase, to claim that its branching ratio was as large as 0.4.[2] If so, the reaction of $NH(^1\Delta)$ with NO will inevitably be accompanied by the reaction of $NH(^3\Sigma^-)$ with NO under the present conditions as well. Since N_2O may arise from $NH(^3\Sigma^-)$ as well as $NH(^1\Delta)$, our value of ϕ_1 (=0.7) may not directly correspond to the branching ratio of the singlet reaction (1a) alone. This final point is still open to inquiry. Nevertheless, the conclusion that reaction (1a) is the most dominant channel of the reacion between $NH(^1\Delta)$ and NO will be basically correct.

Conclusions

Product analyses of the photochemical reactions in HN_3/NO/Ar matrices at 12 K were conducted to investigate the microscopic mechanism of the reaction of $NH(^1\Delta)$ with NO. NH, N_2O, OH, HONO, and HNO were identified by the IR spectra. The absolute yield of N_2O from the phtolysis of the 1:1 complex HN_3–NO was found to be $\phi_1=0.7\pm0.1$. Also, a considerable amount of N_2O was confirmed to arise from the 1:2 complex HN_3–$(NO)_2$. The photolysis of the 2:1 or 2:2 complex $(HN_3)_2$–$(NO)_{1,2}$ was found not to contribute to the production of N_2O, indicating that $NH(^1\Delta)$ fragmented from one of two HN_3 would react with the other HN_3 preferentially.

Formations of OH($X^2\Pi$, $A^2\Sigma^+$) in the Reaction of NH($^3\Sigma^-$) with NO in Incident Shock Waves

Keiichi YOKOYAMA, Yasuo SAKANE, and Takayuki FUENO*
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received January 28, 1991)

Gaseous mixtures of HNCO and NO diluted in Ar were heated by incident shock waves to about 3500 K to investigate the bimolecular reaction of NH($^3\Sigma^-$) with NO. Ultraviolet emissions from the excited NH($A^3\Pi$) and OH($A^2\Sigma^+$) were monitored to determine the rate constants for the ground-state reaction NH($^3\Sigma^-$) $+NO\rightarrow N_2+OH(X^2\Pi)$. The branching ratio defined as the rate constant for the formation of OH relative to that for the NH($^3\Sigma^-$) decay was found to be 0.32±0.07 at the shock-wave temperature adopted. An intense spike of chemiluminescence due to $OH(A^2\Sigma^+\rightarrow X^2\Pi)$ was observed, a finding which indicates a possible participation of the channel $NH(^3\Sigma^-)+NO\rightarrow N_2+OH(A^2\Sigma^+)$ at high temperatures.

We have previously studied the reaction of NH($^1\Delta$) with NO in the gas phase at room temperature.[1] The results have been in essence (1) that the reaction should proceed through an intermediacy of an adduct radical HNNO and (2) that the subsequent decomposition of HNNO gives rise to N_2O+H in prevalence over the channel leading to N_2+OH. Ab initio configuration-interaction (CI) calculations of the potential energy profiles[1] rationalized the experimental results.

Gas-phase reaction of NH($^3\Sigma^-$) with NO is intriguing in connection with the above-mentioned chemistry of NH($^1\Delta$) on one hand and with the issue of the process control for fuel combustions on the other. The reaction has already received interest by several groups of workers,[2–7] who unanimously claim that NH($^3\Sigma^-$) decays essentially at the collision-controlled rate, the rate constant being on the order of 10^{13} cm^3 mol^{-1} s^{-1}. However, product identification as the most important phase of chemical kinetics has remained unsettled.

In the present study, we intend to elucidate the kinetic feature of the NH($^3\Sigma^-$)–NO system, paying due attention to the time-dependent behavior of products. For this purpose, we have shock-heated the HNCO/NO/Ar mixtures of varying composition to ca. 3500 K, to let the NH($^3\Sigma^-$) entity generated by the thermal decomposition[8]

$$HNCO + Ar \longrightarrow NH(^3\Sigma^-) + CO + Ar \qquad (1)$$

react with the coexisting NO. In analogy to the case of NH($^1\Delta$), the reaction is expected to proceed in the following manner:

$$NH(^3\Sigma^-) + NO \longrightarrow [HNNO]^* \begin{cases} \longrightarrow N_2O + H & (2a) \\ \longrightarrow N_2 + OH & (2b) \end{cases}$$

Unfortunately, however, N_2O if formed by reaction (2a) is liable to be readily decomposed into N_2+O under the experimental conditions adopted. Thus, monitoring the OH radical to be formed by reaction (2b) will be a central issue of this study.

Experimental

The conventional incident shock tube described in a previous study[8] was used. Only the optical arrangement was altered. Time-resolved emission spectra were observed in the spectral region of 337.0±3.0 nm for NH($A^3\Pi$–$X^3\Sigma^-$) and 309.1±3.0 nm for OH($A^2\Sigma^+$–$X^2\Pi$). A Nikon-P250 grating monochromator with 1200 lines/mm and F=4.5 and a Hamamatsu 1P28 photomultiplier were used without lens or concave mirror. Time resolution arising from the observation volume was about 2 μs. The signals were amplified with an electronic rise time 2.2RC less than 1 μs and stored in a digital storage scope (Kawasaki Electronica KDS-103). Sample gases were shock-heated to about 3500 K in the pressure range of 210—870 Torr (1 Torr=133.322 Pa). The compositions HNCO/NO/Ar of the samples used were 0.021/0.595/99.4 for the NH measurements and 0.048/1.10/98.9 and 0.053/0.616/99.3 for the OH measurements. The OH emission sensitivity was calibrated on the basis of the H_2/O_2/Ar experiments under the same conditions.

HNCO was synthesized by the reaction of potassium cyanate KCNO with excess stearic acid at 90—110 °C in a vacuum glass line. After removal of water using P_2O_5 and purification by means of trap-to-trap distillations at −80 °C, HNCO was stored at −196 °C and vaporized prior to use. NO (99.99%), H_2 (99.999%), O_2 (99.8%), N_2O (99.9%) (Takachiho Kagaku Inc.), and Ar (99.999%) (Seitetsu Kagaku Inc.) were used without further purification. Gas mixtures diluted in argon were stored in a 6-l Pyrex bulb for more than one day.

Results

(A) Decay of NH. The NH emission-time profiles recorded have exhibited a rapid rise within 10 to 20 μs after the arrival of shock and subsequent decay during 40 to 100 μs. From these decay curves we have evaluated the rate constants k_2 of the overall reaction (2), assuming a pseudo first-order decay law in excess of NO. The rate constant was determined to be k_2=(7.1±0.5)×10^{12} cm^3 mol^{-1} s^{-1} at ca. 3500K.

Figure 1 shows the Arrhenius plots of the reported experimental k_2 values at various temperatures including the value obtained in the present study. A negative temperature dependence is evident. The plotted points are best fitted by the Arrhenius equation, $k_2=A\exp(-E_a/RT)$, with A=(7.8±0.6)×10^{12} cm^3 mol^{-1} s^{-1} and E_a=−(3.5±0.3) kJ mol^{-1}. The results indicate that the association step (HNNO formation) involving no

potential energy barrier should be rate-controlling.

(B) Formation of OH. In the OH emission-time profiles, an intense emission was observed during a period of initial 30 μs, as is shown in Fig. 2. We attribute this emission to the OH($A^2\Sigma^+ \rightarrow X^2\Pi$) chemiluminescence, as will be discussed later. After the intense spike, almost steady or slowly increasing emission profiles were observed. These latter emissions are due to OH($A^2\Sigma^+$) which is in thermal equilibration with OH($X^2\Pi$). Thus, the emission intensity of this steady part directly corresponds to the concentration of OH($X^2\Pi$).

In order to determine the rate constant k_{2b} and hence the branching ratio $\beta \equiv k_{2b}/k_2$, we have decided to recourse to the computer simulation technique. Thus, we intend to search for the value of k_{2b} that will best reproduce the time-concentration profiles of OH observed under the varying experimental condition. To this end, we have invoked several elementary reactions to be considered concurrently at high temperatures. The elementary steps chosen for the simulation are listed in Table 1, together with pertinent Arrhenius parameters. For reaction (1), we have chosen the most recent kinetic data obtained by Hanson et al.[9] For

reactions (2a) and (2b) of our present interest, we use the rate constants $(1-\beta)k_2$ and βk_2 respectively, where k_2 is the above-mentioned rate constant for the net decay of NH. Reactions 3 through 6 are those elementary processes which are known to be important in simulating the time-concentration profile of $NH(^3\Sigma^-)$ after its generation by reaction (1).[8] The remaining reactions are all those that are related somehow with the OH radical. Reaction (7) in particular is the key reaction which has turned up to be of importance in the high temperature region above 2300 K.[10] The rate constants for reactions (8) through (13) were all taken from the literature.[11]

An example of the curve-fittings by simulation is shown in Fig. 2. As can be seen in Fig. 2, the calculated OH concentration first tends to increase with the decaying NH concentration. The OH concentration observed in this sample run stays at a nearly constant level of 3×10^{-10} mol cm^{-3} over the time period of 25—125 μs. The curve simulated under the assumption that $\beta=1.0$ definitely overestimates the OH concentration. It appears that the best fit of the calculated curve to the observed is attainable when β is assigned a value of 0.28. Note that the OH concentration approaches the experimentally observed steady level even when reaction (2b) has been assumed to make no contribution at all, i.e., $\beta=0$. This is simply because of the situation that reactions (7) and (12) can make significant contributions in the prolonged time region considered.

Computer simulations as delineated above have been conducted for a total of 9 runs. Results for typical runs are summarized in Table 2, together with the relevant experimental data. The values of β appear to be nearly constant at 0.32 ± 0.07 on the average, the allowance limit attached being the probable error. Taking this branching ratio as granted, the branching ratio for reaction (2a) is estimated to be 0.68 ± 0.07 which is in good agreement with the ratio 0.7 deduced previously for the case of the reaction of $NH(^1\Delta)$ at room temperature.[1]

Discussion

(A) Branching Ratio. The branching ratio depends on the excess energy and temperature. We have calculated the branching ratios at 300 K and 3500 K on the basis of the RRKM theory. Since the reactions to be taken into account are only (2a) and (2b), calculations of only the ratio k_{2a}/k_{2b} suffice.

According to the basic RRKM theory, the ratio of the specific rate constants is given by

$$\frac{k_{2a}(E)}{k_{2b}(E)}=\frac{N_a(E-E_a)}{N_b(E-E_b)} \quad \text{(I)}$$

Here, $k_{2i}(E)$, i being a or b, is the rate constant at a specific energy E, which is measured from the potential energy minimum for HNNO; E_i is the barrier height for reaction (2i); and $N_i(E-E_i)$ is the number of available states for the respective transition states with an energy in excess over E_i. In order to obtain the ratio k_{2a}/k_{2b} Eq. I need be integrated over the energy distribution. We assume that chemically activated HNNO upon its formation by the association of NH with NO would undergo fragmentation before collisional stabilization affects the internal energy distribution. Thus, we may write approximately[12]

$$\frac{k_{2a}}{k_{2b}}=\int_{E_0}^{\infty}\left(\frac{N_a(E-E_a)}{N_b(E-E_b)}\right)F(E)\mathrm{d}E \quad \text{(II)}$$

where E_0 is the reactant potential energy level and where $F(E)$ is the energy distribution function:

$$F(E)=\frac{N(E-E_0)\exp(-E/kT)}{\int_{E_0}^{\infty}N(E-E_0)\exp(-E/kT)\mathrm{d}E} \quad \text{(III)}$$

with $N(E-E_0)$ as the number of available states for HNNO having energy in excess over E_0.

In calculating the ratio k_{2a}/k_{2b} by Eq. II, the energy humps, E_0, E_a and E_b were all taken from the results of our previous CI calculations (Fig. 3).[1] With the vibration zero-point energy corrections, they are 234, 180, and 197 kJ mol^{-1}, respectively. The values of N, N_a, and N_b were all evaluated by the Whitten-Rabinovitch approximation,[13] using the fundamental vibrational frequencies obtained from the ab initio SCF calculations. At 3500 K, k_{2a}/k_{2b} has come out to be 3.2. It follows that $\beta=0.24$, in reasonable agreement with the experimental value of 0.32. The small discrepancy between the calculated and observed values may be due to the uncertainty attached to the calculated potential energies of the transition states as well as the dynamically preferential formation of $OH(X^2\Pi)+N_2$, i.e. the non-statistical behavior of HNNO. Either way, it is confirmed that a sizable amount of OH can arise from reaction (2), although it may not innately be the main product.

6	4.05	2.15	25.0	871	3444	3.68	0.44

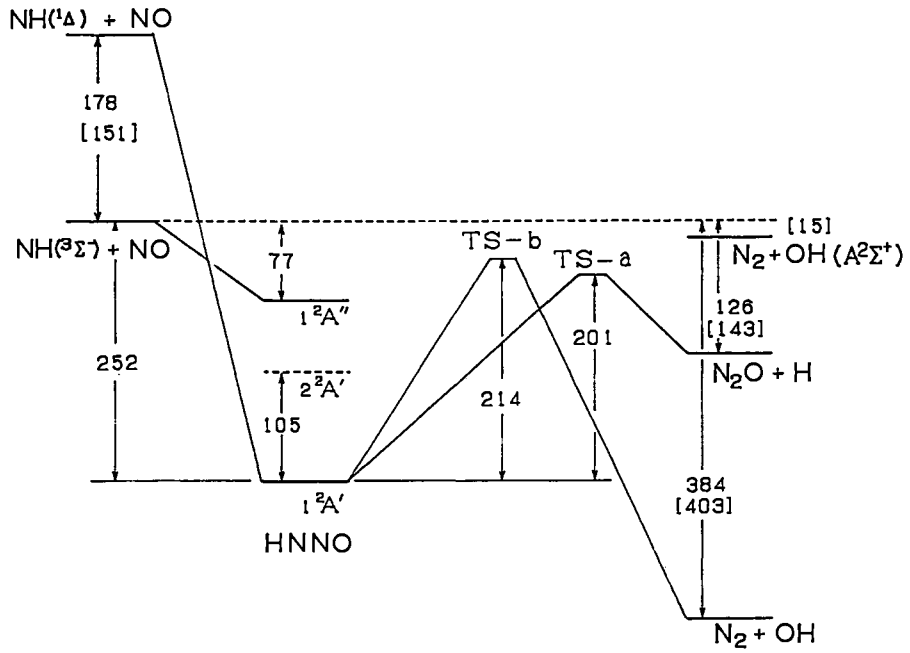

Fig. 3. Potential energy profiles calculated by the MRD-CI(4-31G**//4-31G**) procedure.[1] The energy gaps shown are in units of kJ mol^{-1}. The values given in brackets are those obtained from the relevant thermochemical data.[16] TS-a and TS-b denote the transition states located for the unimolecular steps of reactions (2a) and (2b), respectively.

Further, we have obtained β=0.31 and 0.19 for NH($^1\Delta$)+NO and NH($^3\Sigma^-$)+NO, respectively, both at 300 K. The former value is in good accord with our previous results of the N_2O quantum yield measurements [$\phi_{N_2O}\equiv 1-\beta=0.7$].[1]

Incidentally, the above discussions presume that the HNNO adduct to be formed from NH($^3\Sigma^-$)+NO be in its ground electronic atate (X^2A'), just as in the case of the NH($^1\Delta$)+NO system. The presumption will be acceptable in view of the possibility of an effective "conical" crossing between the two doublet surfaces of the interacting HN ··· NO system.

(B) OH Chemiluminescence. The initial spike in the OH emission profiles is attributed to the OH($A^2\Sigma^+ \rightarrow X^2\Pi$) chemiluminescence on the basis of the following observations. First, the emission was observed in the absorption experiments as well. That is, in order to monitor the OH concentration, we applied also the absorption technique using a He-H_2O microwave-discharge lamp as a light source of the OH absorption. Obtained profiles were of course quite different from the emission profiles, but the initial spike was still an intense emission in contrast to the pattern of the subsequent steady part due to absorption. Second, we confirmed that the peak height of the spike attained a maximum at the wavelength 308 nm, which was consistent with the OH(A-X) emission band. Third, when temperature was raised from 3500 K to 4100 K, the peak height did not increase correspondingly as did the subsequent steady part. Fourth, when $N_2O/H_2/Ar$ gas mixtures were shock-heated, a similar intense spike was observed. In this connection, when O_2 or H_2O, instead of NO, was added to the HNCO/Ar gas mixtures, no emission spike was observed.

A few words will be in order regarding the initial spike which was observed in the reaction system N_2O+H_2. The OH chemiluminescence will be possible in the manner as follows:

$$N_2O + Ar \longrightarrow N_2 + O + Ar \quad (13)$$

$$H_2 + O \longrightarrow OH + H \quad (14)$$

$$N_2O + H \longrightarrow [HNNO]^* \longrightarrow N_2 + OH(A^2\Sigma^+) \quad (15)$$

It should be noted that the initial step of reaction (15) is nothing but the reverse process of the unimolecular step of reaction (2a).

The formation of $OH(A^2\Sigma^+)$ is formally represented as

$$NH(^3\Sigma^-) + NO \longrightarrow [HNNO]^* \longrightarrow N_2 + OH(A^2\Sigma^+) \quad (2c)$$

The branching ratio of reaction (2c) has been estimated from the comparison of the chemiluminescence intensity with the thermal emission intensity. We assume that the relative intensity is equal to the rate of the $OH(A^2\Sigma^+)$ formation through reaction (2c) relative to that through the excitation of $OH(X^2\Pi)$ on collisions with Ar:

$$\frac{I_{chem}}{I_{therm}} = \frac{k_{2c}[NH(^3\Sigma^-)][NO]}{k_{ex}[OH(X^2\Pi)][Ar]} \quad (IV)$$

Here, k_{ex} denotes the rate constant for the collisional

excitation, which may be assumed to be to $k_{quench}K_{ex}$, where k_{quench} is the quenching rate constant[14] and where K_{ex} is the equilibrium constant between $OH(X^2\Pi)$ and $OH(A^2\Sigma^+)$. As a result, we have estimated $k_{2c} \leq 7 \times 10^{10}$ $cm^3\,mol^{-1}\,s^{-1}$. The branching ratio for reaction (2c) is thus less than 0.01. Considering that reaction (2c) is only slightly exothermic, the reaction is expected to have a significantly high barrier.

Hoffmann et al. have already reported on the same chemiluminescence arising from the reaction of N_2O with the H atom having a kinetic energy of ca. 2.5 eV under bulk conditions (single-collision and arrested-relaxation).[15] At lower H-atom kinetic energies (ca. 1.8 eV), however, there was no chemiluminescence. Since the N_2O+H system lies about 1.5 eV below the $NH(^3\Sigma^-)+NO$ system, the threshold energy for the production of $OH(A^2\Sigma^+)+N_2$ from $NH(^3\Sigma^-)+NO$ should lie 0.3 to 1.0 eV above the energy level for $NH(^3\Sigma^-)+NO$.

Previous ab initio MO calculations[1] have revealed that the ground state $HNNO(1^2A')$ surface is correlated to $OH(X^2\Pi)+N_2$ adiabatically. Therefore, it is most likely that for the first excited state $HNNO(2^2A')$ an adiabatic potential energy surface correlates to $OH(A^2\Sigma^+)+N_2$. The virtual excitation energy of the $HNNO(2^2A')$ at the equilibrium geometry of *cis*-$HNNO(1^2A')$ has been calculated by the MRD-CI method to be 105 $kJ\,mol^{-1}$, as is shown in Fig. 3. The excitation energy seems to be low enough for the internal conversion from $1^2A'$ to $2^2A'$ to take place thermally. For clear discussion of the dynamical mechanism of the formation of $OH(A^2\Sigma^+)$, MCSCF calculations on the excited state surface are required.

Conclusions

From the time-concentration profiles of the OH radicals formed in the shock-heated HNCO/NO/Ar mixtures, the branching ratio of the reaction, $NH(^3\Sigma^-)+NO \rightarrow N_2+OH(X^2\Pi)$, was determined to be 0.32 ± 0.07. The experimental result was rationalized by the RRKM treatments of the product-determining step. A new chemiluminescent reaction $NH(^3\Sigma^-)+NO \rightarrow OH(A^2\Sigma^+)+N_2$, was found, although it is a minor channel.

(Received September 10, 1990)

The structure of *cis*-$[CoF_2(NH_3)_4]ClO_4$ has been determined by a single-crystal X-ray diffraction method. Crystals are tetragonal, space group $P4_1$ (or $P4_3$), a=7.2645(6), c=16.260(2) Å, V=858.1(2) Å^3, Z=4, T=297(1) K, final R=0.052 for 970 observed unique reflections. The coordinated F and N atoms could be distinguished unambiguously from each other based on the thermal parameters. The bond distances Co–F and Co–N are 1.828(6)—1.870(5) and 1.924(7)—1.944(7) Å, respectively. The absorption spectra of the single crystals have been examined in the visible and infrared regions with polarized radiation by the use of microspectrophotometers. The 584 nm band (B_1) was considered to borrow intensity from some A_1 bands through vibronic coupling with some B_1 vibrations, and the 504 nm band (A_2 & B_2) through some A_2 and B_2 vibrations. Two of the four ammine groups of this cobalt complex were found to give an NH_3 rocking frequency (860 cm^{-1}) higher by 50 cm^{-1} than the other two (at 810 cm^{-1}). This fact has been attributed to two inter-molecular hydrogen bonds (NH···F=2.85—2.68 Å) in which the former two ammine groups are involved.

In structural chemistry, the idea of combining an optical microscope and spectrophotometer emerged a long time ago, and its actual practice started some forty years ago. An extensive use of this combination, however, has become possible only recently, after a number of technological developments were made regarding both microscopes and spectrophotometers. We are now attempting to adopt this combination as a tool for elucidating the detailed electronic structures of some complex molecules in their single crystals, whose sizes cannot readily be greater than 50 μm (order of magnitude). The present paper deals with one part of our work along this line.

cis-Difluorotetraamminecobalt(III) perchlorate, *cis*-$[CoF_2(NH_3)_4]ClO_4$, is one of the new complexes which have recently been prepared.[1] It gives violet needle crystals. The crystal structure has now been determined, as detailed below. It has been found that all of the complex molecules are oriented with their C_2-axes approximately along the crystalline elongation direction, which is now established to be its tetragonal c-axis. Therefore, this crystal is extremely favorable for spectroscopic analyses of the complex molecule presently in question. By the use of polarized radiation, well characterized bands are expected to be newly resolved, and their transition moment directions determined. Some results of such analyses are reported below.

Experimental

Sample Preparation. Single crystals of *cis*-$[CoF_2(NH_3)_4]ClO_4$ were obtained by evaporating the solvent from an aqueous mixture of *cis*-$[Co(NH_3)_4(H_2O)_2](ClO_4)_3$ and NH_4F, as detailed in a previous paper.[1]

Structure Determination. Crystal data are as follows: $[CoF_2(NH_3)_4]ClO_4$, Formula weight 264.5, tetragonal $P4_1$ (or $P4_3$), a=7.2645 (6), c=16.260 (2) Å, V=858.1 (2) Å^3, Z=4, D_m (CCl_4/CH_3I)=2.04 (1), D_x=2.05 Mg m^{-3}, λ (Mo $K\alpha$)=0.71073 Å, μ=2.33 mm^{-1}, $F(000)$=536, T=297 (1) K. Crystals are purple needles elongated along c. A crystal of dimensions 0.08×0.08×0.5 mm was mounted on a Rigaku AFC-5 four-circle diffractometer with graphite-monochromatized Mo $K\alpha$ radiation. The cell parameters were refined by least squares for 25 2θ values ($20<2\theta<30°$). The intensity measurements were performed using a 2θ=55° (h −9→9, k −9→9, l 0→21) by θ–2θ scan technique. Systematic absences were 0 0 l with $l\neq4n$. The variation of five standard reflections was $0.98<\Sigma(|F_o|/|F_o|_{initial})/5\leq1.00$. 4015 reflections were measured and 2482 reflections were observed with $|F_o|<3\sigma(|F_o|)$. The number of unique reflections was 970, with R_{int}=0.022 after an absorption correction ($0.81<A<0.85$). The Laue group and systematic absences showed that the space group is $P4_1$ (or $P4_3$). The positions of the Co and Cl atoms were deduced from the Patterson function. All of the six coordinating atoms around the Co could be located by Fourier synthesis and tentatively refined using the nitrogen scattering factor. The isotropic thermal parameters of two atoms became smaller (1.2 Å^2) than those of the other four atoms, which ranged from 2.3 to 5.2 Å^2. Thus, these two atoms were assigned to be more electron-rich atoms, F. Then, all of the nonhydrogen atoms were refined anisotropically. Five out of twelve H atoms were located by a difference synthesis; the others were calculated. The coordinates of the H atoms were fixed according to the isotopic thermal parameter, B=4 Å^2. The function $\Sigma w||F_o|-|F_c||^2$ was minimized with $w^{-1}=\sigma^2(|F_o|)+(0.015|F_o|)^2$ by a block-diagonal least-squares method. Final R=0.052, wR=0.053, S=2.04 for 970 unique reflections. The space group of the crystal specimen used for data collection appeared to be $P4_3$. The enantiomeric space group, $P4_1$, was rejected because of larger R factors, R=0.059, wR=0.064. The reflection/parameter ratio was 6.1 ($\Delta/\sigma<0.2$, $-0.8<\Delta\rho<1.2$ e Å^{-3}). Complex neutral-atom scattering factors were used.[2] The calculations were carried out on a FACOM M-380R computer at Keio university using the

UNICS-III computation program system.[3]

Visible Absorption Spectrum. The absorption spectra of a single crystal of the cis cobalt complex now in question were examined in the visible spectral region at two different orientations of the electric vector of the polarized radiation. The procedures for the microscopic spectral measurement and a curve-analysis method were both essentially the same as that described in a previous paper.[4]

Infrared Absorption Spectrum. A Jasco Micro FTIR-100 was used. A single crystal with the dimensions of 15×30 μm was placed under a microscope. Its transmittance spectra were recorded at two different polarizations of the radiation: one with $E//c$ and the other $E\perp c$, where E is the electric vector of the infrared radiation. For producing an infrared interferogram, 100 scans were accumulated with a resolution 4 cm^{-1} and with a cosine apodization function. A liquid-nitrogen-cooled mercury cadmium telluride detector was used.

Results and Discussion

Structure of $[CoF_2(NH_3)_4]ClO_4$. The final atomic parameters of non-hydrogen atoms and interatomic distances and bond angles are presented in Tables 1 and 2.[5] The Co atom is coordinated octahedrally by two F atoms and four NH_3 molecules, the former being in the cis positions. The average bond distance of the Co–F, 1.849 (6) Å, is 0.083 Å shorter than that of the Co–N, 1.932 (8) Å. This fact supports the distinction of F from NH_3 based on their thermal parameters in the refinement. The crystal structure is shown in Fig. 1. The bisector of the F–Co–F bond angle is approximately parallel to c. There exist intermolecular hydrogen bonds, N–H···F (or O), as shown in Table 3.

Group Theoretical Predictions. On the basis of the crystal structure just described, the number of optically active vibrations, in which the vibrations in all the

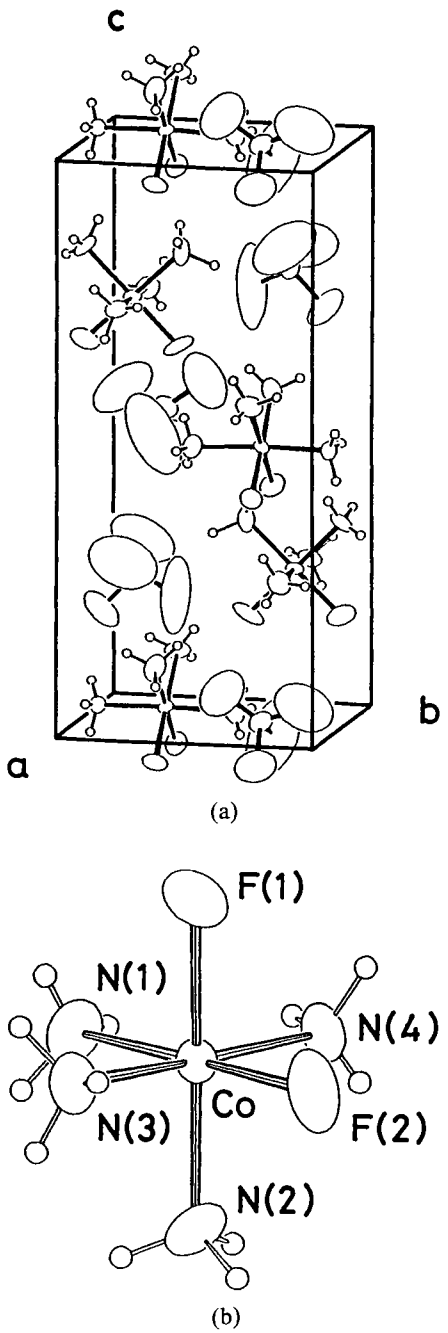

Fig. 1. (a) Crystal structure of *cis*-$[CoF_2(NH_3)_4]ClO_4$ and (b) molecular structure of the complex cation.

Bravais unit cells in the crystal take place in-phase, has been calculated for each type of vibration (Table 4). The $CoF_2(NH_3)_4^+$ ion has $3\times19-6=51$ intramolecular normal vibrations and the ClO_4^- ion has $3\times5-6=9$. Because four $CoF_2(NH_3)_4^+$ ions and four ClO_4^- ions are involved in the Bravais unit cell, $60\times4=240$ optically active intramolecular vibrations are expected for the crystal. Among them, 60 give their transition moments along the *c*-axis, 60 are infrared-inactive, and the remaining 120 are polarized along the perpendicular directions to the *c*-axis.

As long as the strict crystallographic symmetry is concerned, no further characterization is possible for these intramolecular vibrations. In a good approximation, however, every $CoF_2(NH_3)_4^+$ ion here has a pseudo-C_{2v} symmetry. As shown in Fig. 2, the C_2 symmetry axis is oriented along the crystallographic *c*-axis; We designate this the molecular *z*-axis. Two of the four Co–N bonds are in the plane which is formed by the two Co–F bonds; this plane is designated the molecular *xz*-plane, and the two NH_3 groups on the ends of these Co–N bonds are denoted by "NH_3-pair I." The two other Co–N bonds are both along the molecular *y*-axis, and are called "NH_3-pair II." The normal vibrations of the $CoF_2(NH_3)_4^+$ ion are now classified as given in Table 5.

The environment of the *d*-electrons of the Co atom is also considered to have nearly C_{2v} symmetry. The electron configuration of the ground state thus belongs to the A_1 species, and those corresponding to the T_{1g} species for the O_h symmetry turn out into three configu-

rations belonging to the B_1, A_2, and B_2 species. The electronic excited state T_{2g} in the O_h environment, however, splits into three states (A_1, B_2, and A_2) in the C_{2v} environment.

Visible Region Absorption Spectrum. The experimental results are shown in Fig. 3. As can be seen, two bands appear at about 20000 and 27000 cm^{-1}. The first band comprises two components. As was once pointed out by Yamatera,[6] two electronic transitions ($A_2 \leftarrow A_1$ and $B_2 \leftarrow A_1$) in the lower frequency region ($T_{1g} \leftarrow A_{1g}$ for O_h) are expected to have nearly equal frequencies, whereas $B_1 \leftarrow A_1$ should have an appreciably lower frequency than do the other two. Therefore, the lower-frequency component of the lower frequency group of bands is assignable to the $B_1 \leftarrow A_1$ transition ($d_{X^2-Y^2} \leftarrow d_{XY}$ for O_h, see Fig. 2 and its legend) and the other two to $A_2 \leftarrow A_1$ ($d_{X^2-Y^2} \leftarrow d_{YZ+ZX}$ for O_h) and $B_2 \leftarrow A_1$ ($d_{X^2-Y^2} \leftarrow d_{YZ-ZX}$ for O_h). The second group of bands ($T_{2g} \leftarrow A_{1g}$ for O_h) shows no explicit splitting, and is assigned to an overlapping of the following three transitions: $A_1 \leftarrow A_1$ ($d_{Z^2} \leftarrow d_{XY}$ for O_h), $B_2 \leftarrow A_1$ ($d_{Z^2} \leftarrow d_{YZ+ZX}$ for O_h), and $A_2 \leftarrow A_1$ ($d_{Z^2} \leftarrow d_{YZ-ZX}$ for O_h). (Note that the axis system XYZ for O_h is different from the system xyz for C_{2v}, see Fig. 2).

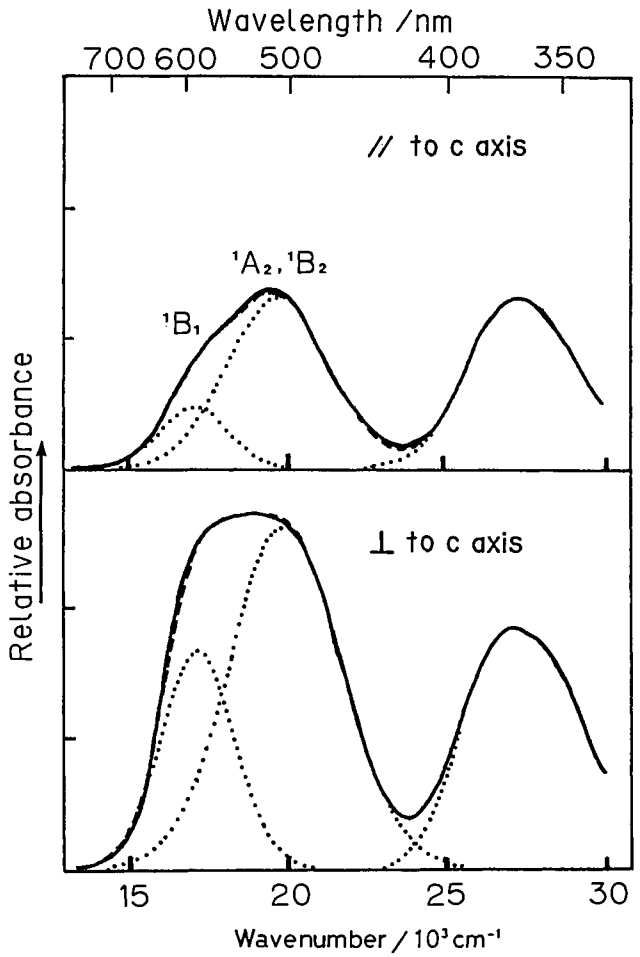

Fig. 3. Dichroic spectrum of a single crystal of *cis*-$[CoF_2(NH_3)_4]ClO_4$. Solid line, observed spectrum; dotted line, calculated Gaussian components; dashed line, sum of the Gaussian components.

We now examine the observed dichroism. Because all of the $CoF_2(NH_3)_4^+$ ions in the crystal are oriented with their C_2-axis along the crystallographic c-axis, only the A_1-type transition is expected to appear in the $E//c$ spectrum, as long as the selection rules of purely electronic transitions are taken into account. Actually, however, appreciable $E//c$ absorption intensities have been found (see Fig. 3) in the spectral regions assigned to the B_1 and A_2 & B_2 transitions. It is therefore quite certain that these intensities should be interpreted while taking vibronic coupling into consideration. The lowest-frequency (at 584 nm) electronic band, B_1, is considered to borrow some intensity from the A_1 band at 366 nm, or, more probably, from stronger A_1 bands somewhere in a higher frequency region through coupling with some of the B_1 vibrations. The higher-frequency components (at 504 nm) of the first band (A_2 and B_2) are considered to borrow some intensities from the A_1 bands through A_2 and B_2 vibrations. As can be seen in Fig. 3, the vibronic couplings are definitely greater for the latter (through A_2 and B_2 vibrations) than for the former (through B_1 vibrations). The number of B_1 normal vibrations is 13; this number is much smaller than the sum (22) of the numbers of the A_2 and B_2 normal vibrations (see the last column of Table 5). Therefore, one might assume that the number of the

vibrations active for intensity borrowing determines the transition intensity. To persue the consequence of this simple assumption, numbers were estimated for every electronic transition (Table 6). As can be seen in the last line of this table, the number of the possible cases of the vibronic couplings turns out to be nearly equal for the $//c$ component to that for the $\perp c$ component in every band now in question. It is therefore rather tempting to attribute the prominent perpendicular dichroisms actually observed for the 584 and 504 nm bands largely to their own electronic properties. It is probable, however, that the vibronic couplings do contribute not only to the $//c$ intensities, but also to the $\perp c$ intensities in these bands. It is also probable that, in every case, some of the possible vibrations and much greater contributions than do some of the other vibrations belonging to the same symmetry species; we must therefore study the nature of such vibronic couplings in more detail in the future.

Infrared Absorption Spectrum. The results of the measurements are given in Fig. 4. Six bands were observed at about 3250, 3180, 1620, 1265, 1090, and 850 cm^{-1}. On the basis of a previous study by Shimanouchi and Nakagawa[7] on $Co(NH_3)_6^{3+}$ and some other ammine complexes, these have been assigned, respectively, to NH_3 degenerate stretching, NH_3 symmetric stretching, NH_3 degenerate deformation, NH_3 symmetric deformation, ClO_4 T_2-type stretching, and NH_3 rocking vibrations (Table 7). Each band is found comprise approximately two components. Although each $CoF_2(NH_3)_4^+$ ion has four NH_3 groups, they are not equivalent to one another regarding the crystallographic symmetry. Practically, however, the two NH_3 groups of pair-I are similar to each other, and two of pair-II are similar (see Table 1 and 2). The two NH_3 groups of pair-I are equivalent if the molecular pseudo-C_{2v} symmetry is taken into account; likewise, the NH_3 groups of pair-II are equivalent. In addition, "inter-pair" vibrational interactions should be very small, based on their geometrical arrangements. For every NH_3 band, therefore, one of the two components is assigned to pair-I and the other to pair-II. These can be distinguished on the basis of the dichroic characters of the components.

An NH_3 symmetric deformation vibration, for example, has its transition moment (p) along the pseudo-C_3 axis. For each of the $NH_3(1)$ and $NH_3(2)$, the transition moment is directed at an angle of 45° to the c-axis. Therefore, the pair-I A_1 vibration causes an absorbance which is proportional to $(2p\cos 45°)^2=2p^2$. The B_1 absorbance should also be $(2p\cos 45°)^2=2p^2$, and no B_2

absorbance should result. From the average of the contributions of the four $CoF_2(NH_3)_4^+$ ions in the Bravais unit cell, the intensity ratio ///⊥ of the pair-I NH_3 symmetric deformation band should be $2p^2/1p^2=2/1$. For each of the $NH_3(3)$ and $NH_3(4)$, on the other hand, the transition moment (p) now in question is directed perpendicularly to the *c*-axis. The pair-II A_1 vibration, therefore, causes no absorbance, whereas the pair-II B_2 vibration causes absorbance that is proportional to $(2p)^2$. Thus, the ///⊥ intensities average out to $0/2p^2=0/2$. As can be seen in Fig. 4, the NH_3 symmetric deformation band comprises two components at 1280 and 1250 cm^{-1}. At 1280 cm^{-1} the dichroic ratio, ///⊥, is found to be nearly 2/1. whereas at 1250 cm^{-1} it is almost 0/2. Therefore, the 1280 cm^{-1} component is assignable to pair-I and the 1250 cm^{-1} component to pair-II.

An NH_3 degenerate deformation vibration is considered to have two transition moments, which are directed perpendicularly to each other in the plane normal to the NH_3 pseudo-C_3 axis. By taking this into account, a similar analysis has revealed that the pair-I NH_3 degenerate deformation vibration causes the relative intensities $///\perp=2p^2/3p^2$ and that of pair-II $///\perp=4p^2/2p^2$.

Thus, the observed peak at 1660 cm^{-1}, which shows a strong parallel dichroism, is assignable to the pair-II NH_3 degenerate deformation vibration, and that at 1620 cm^{-1} to the pair-I NH_3 degenerate deformation vibration.

In a similar manner, assignments of the components of every band have been made, as shown in Table 7. As can be seen, the greatest frequency difference between the components was for the NH_3 rocking band. Here, the pair-II frequency is higher than that of pair-I by 50 cm^{-1}. This is explained by taking intermolecular hydrogen bonds into account. As shown in Table 3, two strong hydrogen bonds (N···F=2.85—2.86 Å) are found at F(1)···H(43)–N(4) and F(2)···H(32)–N(3). Therefore, some of the effective ∠H–N–Co and ∠H–N–H angle bending force constants should be appreciably greater for the pair-II NH_3 groups than the corresponding ones for the pair-I NH_3 groups. As can be seen in Fig. 4 and Table 7, the pair-II NH_3 degenerate deformation frequency (1660 cm^{-1}) is also higher than that of pair-I (1620 cm^{-1}). This fact may also be explained by the two strong intermolecular hydrogen bonds. A hydrogen bond generally causes a lowering of the stretching force constant of the N–H bond in question. The fact that the pair-II NH_3 degenerate stretching frequency (3250 cm^{-1}) is lower than that (3285 cm^{-1}) of pair-I may be interpreted as indicating such an effect of the hydrogen bonds. The fact, however, that the pair-I NH_3 symmetric deformation frequency (1280 cm^{-1}) is higher than that of pair-II (1250 cm^{-1}) is yet to be explained.

We express appreciation to Dr. Masahiro Morita of the Science University of Tokyo for computer programming for the curve analysis. One (Y.M.) of us is indebted to Professor Tetsuroh yoshida in Meisei University for his helpful discussions. The work in Iwaki Meisei University was partly supported by a Grant-in-Aid No. 02670985, from the Ministry of Education, Science and Culture.

Synthesis of [6-(1,4,7,10-Tetraaza-12-cyclotridecyl)-1,4,8,11-tetraazacyclotetradecane]dinickel(II) Perchlorate and Its Electrocatalytic Property for Water Reduction

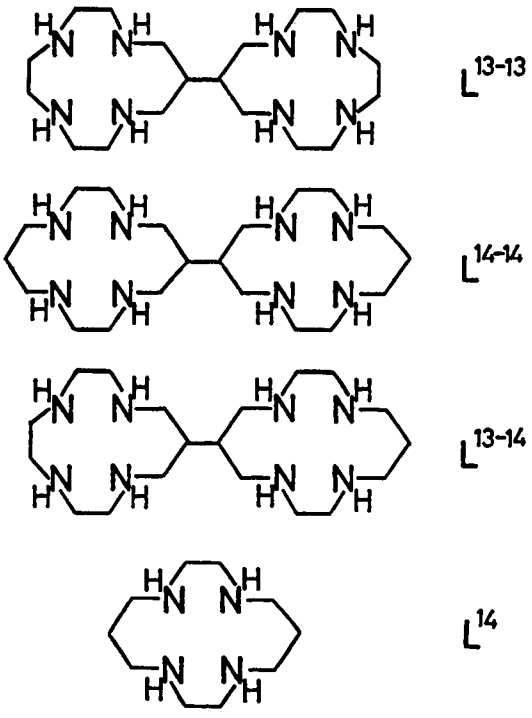
Katsura MOCHIZUKI,* Hajime GOTOH, Masaaki SUWABE, and Tohru SAKAKIBARA
Department of Chemistry, Yokohama City University, Yokohama 236
(Received January 23, 1991)

A new bimacrocyclic ligand, in which 13- and 14-membered rings are linked together by a C–C bond, 6-(1,4,7,10-tetraaza-12-cyclotridecyl)-1,4,8,11-tetraazacyclotetradecane (L^{13-14}), and its dinickel(II) complex, $[Ni^{II}_2L^{13-14}]^{4+}$, were synthesized. The absorption spectra and cyclic voltammograms of $[Ni^{II}_2L^{13-14}]^{4+}$ showed that it has properties of both the 13- and 14-membered rings. Cyclic voltammetry and controlled-potential electrolysis showed that $[Ni^{II}_2L^{13-14}]^{4+}$ can serve as an electrocatalyst for water reduction to produce H_2. The electrocatalytic efficiency for H_2 produclion at −1.5 V was found to be as follows: $[Ni^{II}_2L^{14-14}]^{4+}$ (L^{14-14}: 6,6′-bi(1,4,8,11-tetraazacyclotetradecane)) > $[Ni^{II}_2L^{13-14}]^{4+} \approx [Ni^{II}L^{14}]^{2+}$ (L^{14}: 1,4,8,11-tetraazacyclotetradecane) ≫ $[Ni^{II}_2L^{13-13}]^{4+}$ (L^{13-13}: 12,12′-bi(1,4,7,10-tetraazacyclotridecane)).

The production of hydrogen from water is extremely important, especially for the chemical storage of light or electrical energy. For this purpose, a highly efficient catalytic system generating H_2 (and O_2) from water should be developed. Although the problem of overvoltage must be solved, some Ni(II) complexes with monomacrocyclic ligands are known to have a capability like that of an electrocatalyst.[1] Recently, Sauvage et al. investigated the electrocatalytic properties of a binuclear Ni(II) complex with biscyclam, $[Ni^{II}_2L^{14-14}]^{4+}$, in which two cyclams, L^{14}, are linked together by a C–C bond; they found that the bimacrocyclic complex, $[Ni^{II}_2L^{14-14}]^{4+}$, is a better catalyst than is the corresponding monomacrocyclic, $[Ni^{II}L^{14}]^{2+}$.[2] These findings prompted us to systematically study the electrocatalytic capabilities of this type of bimacrocyclic complexes.

We attempted to clarify how the electrocatalytic property of $[Ni^{II}_2L^{14-14}]^{4+}$ changes upon replacing the 14-membered macrocycles of $[Ni^{II}_2L^{14-14}]^{4+}$ with 13-membered ones. Thus, the dinickel(II) complexes with a bimacrocyclic ligand having two 13-membered rings, L^{13-13}, and with one having 13- and 14-membered rings, L^{13-14}, were required. However, the synthesis of the latter "nonsymmetric" ligand, L^{13-14}, has been unprecedented, to the best of our knowledge.

In this paper we describe the preparation of "nonsymmetric" ligand, L^{13-14}, and its dinickel(II) complex, as well as the electrocatalytic efficiencies of dinickel(II) complexes with L^{13-13}, L^{13-14}, and L^{14-14} for H_2 generation from water.

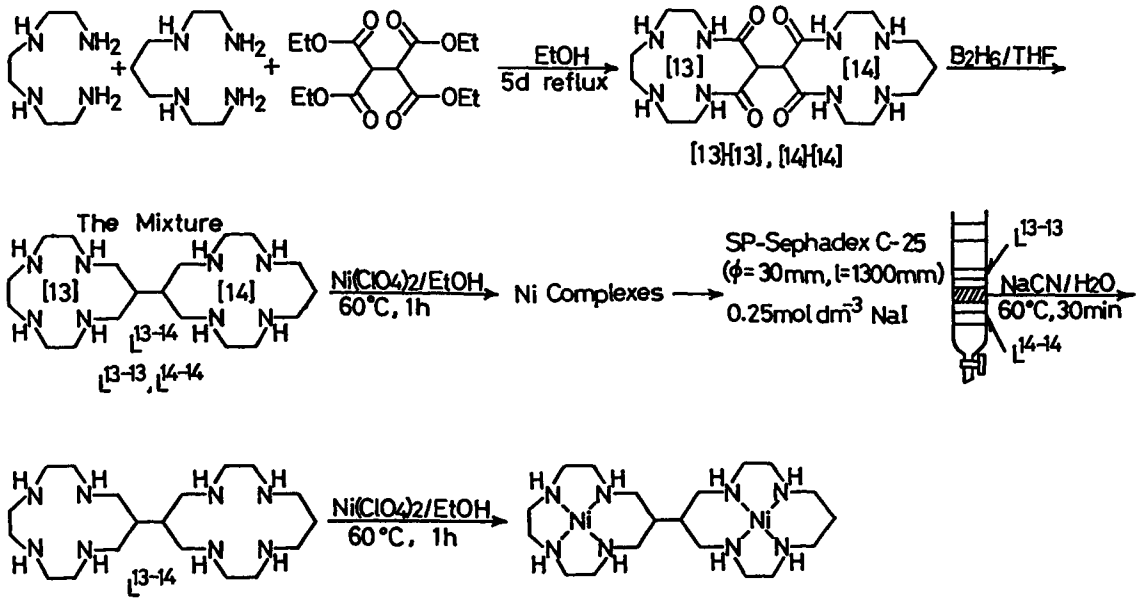


Results and Discussion

Synthesis of L^{13-14} and Its Dinickel(II) Complex. The synthetic route of the intending bimacrocyclic Ni(II) complex is shown in Scheme 1.

Statistic predominance was applied to the preparation of the bimacrocyclic ligand, L^{13-14}. Since the separation of L^{13-14} from the reaction mixture failed, its isolation was performed after conversion of the ligands into dinickel(II) complexes. This idea came from the following speculation based on experimental results.

It is known that in water both $[Ni^{II}L^{14}]^{2+}$ and $[Ni^{II}L^{13}]^{2+}$ (L^{13}: 1,5,8,11-tetraazacyclotridecane) are in equilibrium between square planar and octahedral forms; in the latter two water molecules coordinate to the Ni(II) ion; that the ratio of octahedral forms is slightly higher in $[Ni^{II}L^{14}]^{2+}$ (29%, 25 °C) than in $[Ni^{II}L^{13}]^{2+}$ (13%, 25 °C).[10] This means that the coordination of water to the 14-membered macrocyclic Ni(II) complex predominates slightly over that of the 13-membered one. If a similar relationship holds between the bimacrocyclic Ni(II) complexes and anionic ligands instead of water, $[Ni^{II}_2L^{14-14}]^{4+}$ favors octahedral form than does $[Ni^{II}_2L^{13-13}]^{4+}$. The cationic character of the



Scheme 1.

complex is thus least in $[Ni^{II}_2L^{14-14}]^{4+}$, and most in $[Ni^{II}_2L^{13-13}]^{4+}$. As a result, separation of the mixture by cation exchange chromatography may be possible.

Condensation between tetraethyl 1,1,2,2-ethanetetracarboxylate and a 1 : 1 mixture of 3,6-diazaoctane-1,8-diamine and 3,7-diazanonane-1,9-diamine, followed by reduction with B_2H_6, afforded a mixture of three ligands: L^{13-13}, L^{13-14}, and L^{14-14} (see Experimental). The gas chromatogram of the mixture showed three peaks: the first was assigned to L^{13-13} (28%) and the third to L^{14-14} (16%) respectively, compared with the respective authentic samples (Fig. 1). We assigned the second peak to L^{13-14} (50%). Indeed, a FAB mass spectrum of the mixture showed three peaks at m/z 371, 385, and 399, which corresponded to $[M+H]^+$ for L^{13-13}, L^{13-14}, and L^{14-14}, respectively.

Separation of these three ligands was accomplished, when the ligands were converted into the dinickel(II) complexes and then chromatographed with SP-Sephadex C-25 cation-exchange resin using 0.25 mol dm^{-3} NaI as the eluent. As expected, $[Ni^{II}_2L^{14-14}]^{4+}$ was eluted first, $[Ni^{II}_2L^{13-14}]^{4+}$ second, and $[Ni^{II}_2L^{13-13}]^{4+}$ last. This clear separation of the three bands indicates that the second band is not a mixture of $[Ni^{II}_2L^{14-14}]^{4+}$ and $[Ni^{II}_2L^{13-13}]^{4+}$, but $[Ni^{II}_2L^{13-14}]^{4+}$, itself; this view is supported by the FAB mass spectrum of the free ligand obtained by treatment of the Ni(II) complex with NaCN (m/z 385, $[M+H]^+$ for L^{13-14}). Since a complete exchange of iodide into the perchlorate ion was tedious, an analytical sample of $[Ni^{II}_2L^{13-14}](ClO_4)_4 \cdot H_2O$ was prepared by treatment of L^{13-14} with $Ni(ClO_4)_2 \cdot 6H_2O$.

The ligand, L^{13-14}, and the $[Ni^{II}_2L^{13-14}]^{4+}$ complex, thus isolated, were characterized as follows.

Although the ^{13}C NMR spectrum of L^{13-14} in $CDCl_3$ was very similar to the sum of the spectrum of L^{14-14} and

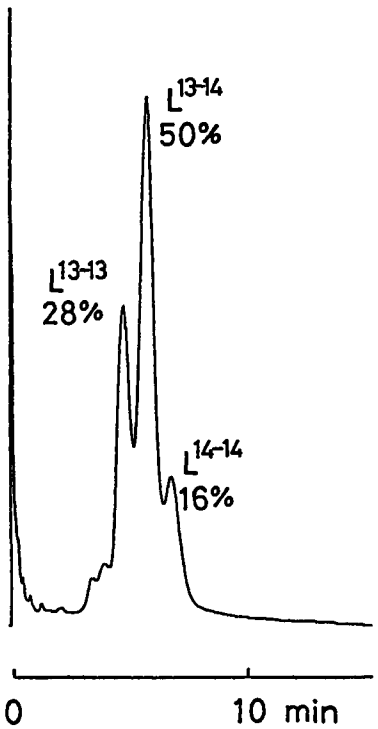


Fig. 1. Gas chromatogram of the mixture of ligands produced by reduction of the condensation product with tetramines (column: 1% OV-1, 0.25 m×2.6 mm; carrier gas: He; column temperature: 220 °C).

that of L^{13-13}, small differences in the chemical shifts around the C–C bridge were observed between, L^{13-14}, L^{13-13}, and L^{14-14}. The 100.614 MHz ^{13}C NMR spectrum of L^{13-14} in D_2O expectedly showed 11 signals (9 triplets and 2 doublets).

Figure 2 shows the absorption spectrum of $[Ni^{II}_2L^{13-14}]^{4+}$ in an aqueous solution; it is almost equal to the

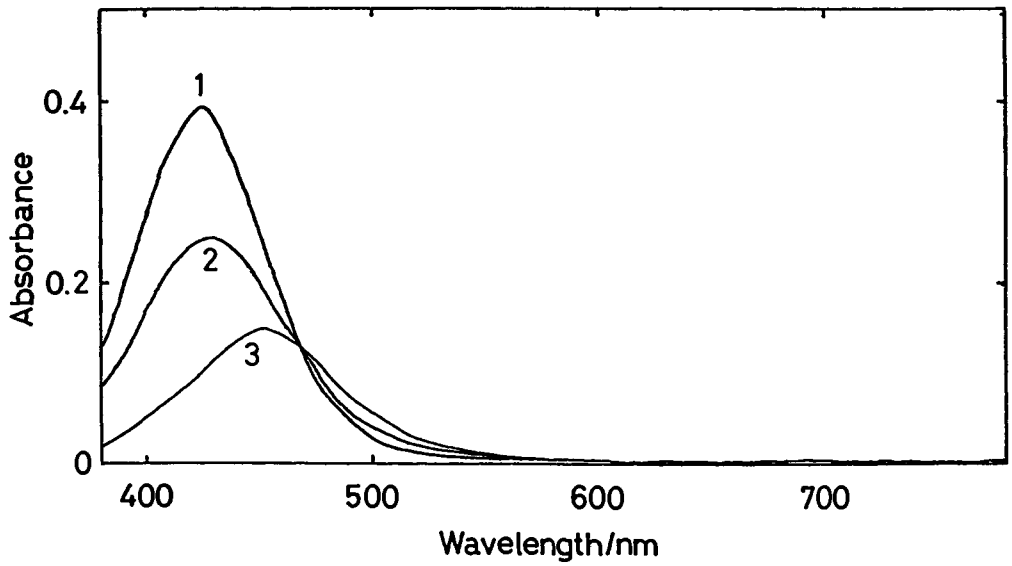

Fig. 2. Absorption spectra of 2×10^{-3} mol dm^{-3} $[Ni_2L^n]^{4+}$ (n=13—13 (1), 13—14 (2), 14—14 (3)) in water at 25 °C.

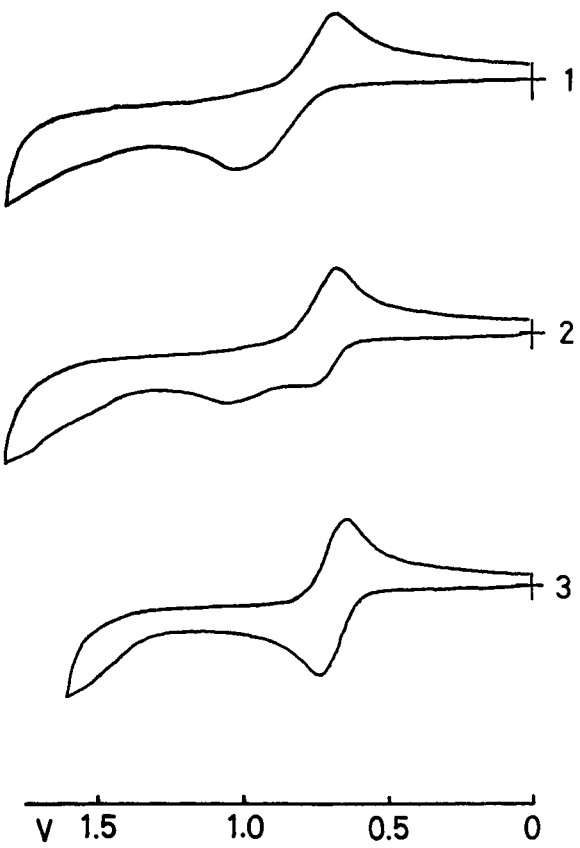

Fig. 3. Cyclic voltammograms of 2×10^{-3} mol dm^{-3} $[Ni_2L^n]^{4+}$ (n=13—13 (1), 13—14 (2), 14—14 (3)) in acetonitrile at 25 °C. Glassy carbon electrode. V vs. Ag-Ag$^+$ (0.01 mol dm^{-3} $AgNO_3$).

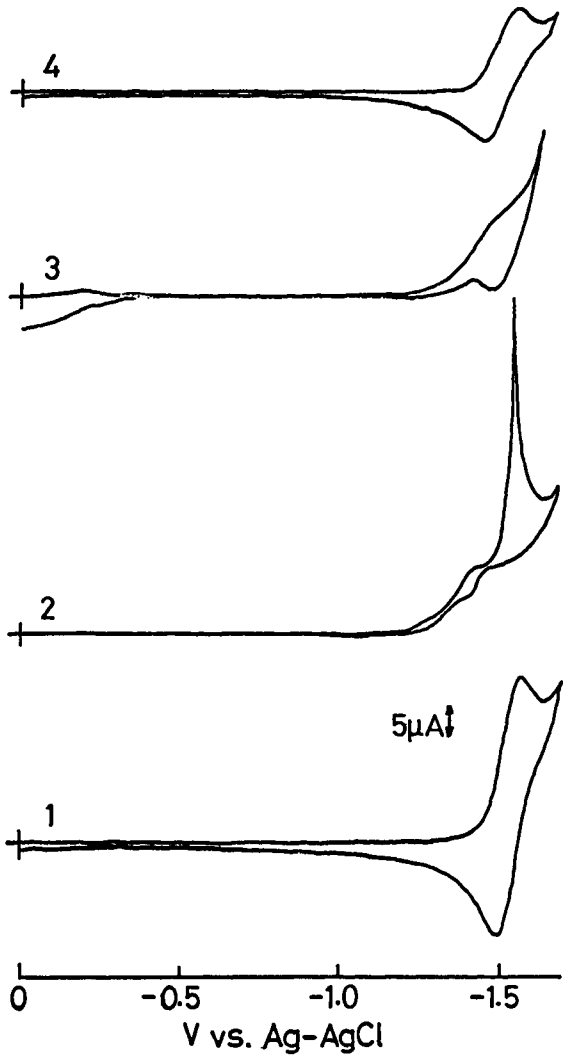

Fig. 4. Cyclic voltammograms of 5×10^{-3} mol dm^{-3} $[NiL^{14}]^{2+}$ (1) and 2×10^{-3} mol dm^{-3} $[Ni_2L^n]^{4+}$ (n= 13—13 (2), 13—14 (3), 14—14 (4)) in 0.1 mol dm^{-3} KCl aqueous solutions at 25 °C. HMDE.

average of the spectrum of $[Ni^{II}_2L^{14-14}]^{4+}$ and that of $[Ni^{II}_2L^{13-13}]^{4+}$. The same conclusion was also obtained by cyclic voltammetry. Figure 3 shows the cyclic voltammograms (CV) observed in the oxidation of $[Ni^{II}_2L^{13-14}]^{4+}$, $[Ni^{II}_2L^{14-14}]^{4+}$, and $[Ni^{II}_2L^{13-13}]^{4+}$,

respectively, in acetonitrile. The CV of $[Ni^{II}_2L^{13-14}]^{4+}$ (E_{pa} 0.80_0; 1.04_5; E_{pc} 0.67_5 V) is again almost equal to the average of the spectrum of $[Ni^{II}_2L^{14-14}]^{4+}$ (E_{pa} 0.74_5; E_{pc} 0.64_5 V) and that of $[Ni^{II}_2L^{13-13}]^{4+}$ (E_{pa} 1.02_5; E_{pc} 0.68_0 V). $[Ni^{II}_2L^{13-14}]^{4+}$ was found to have properties of both the 13- and 14-membered rings.

Thus, a new bimacrocyclic ligand having 13- and 14-membered rings linked bythe C–C bond and its dinickel(II) complex were unequivocally obtained.

Electrocatalytic Properties. Figure 4 shows the CV's for the reduction of Ni(II) complexes in an aqueous solutions containing 0.1 mol dm^{-3} KCl as a supporting electrolyte. Our observations for $[Ni^{II}_2L^{14-14}]^{4+}$ were different from the results previously reported by Sauvage et al.;[2] they did not describe a quasi-reversible wave, but an irreversible wave for Ni^{II}/Ni^{I} couples in a neutral aqueous solution. We observed, here, a quasi-reversible wave at -1.50 V, accompanied by a small adsorption wave at -1.3 V, in a neutral aqueous solution of $[Ni^{II}_2L^{14-14}]^{4+}$ (E_{pc}=-1.55_1 V, E_{pa}=-1.44_9 V, HMDE, scan rate: 100 mV s^{-1}, 0.1 mol dm^{-3} KCl, 25 °C). A couple of cathodic and anodic peaks were observed; they were assignable to the couples of $[Ni^{II}Ni^{II}]/[Ni^{II}Ni^{I}]$ and $[Ni^{II}Ni^{I}]/[Ni^{I}Ni^{I}]$[11] by comparison with the Ni^{II}/Ni^{I} couple of $[Ni^{II}L^{14}]^{2+}$ (E_{pc}=-1.56 V, E_{pa}=-1.48 V), since two Ni(II) in the complex should be reduced at the very close potentials.[12] A similar quasi-reversible wave was observed when 0.1 mol dm^{-3} $NaClO_4$ was used as the supporting electrolyte. On the other hand, the 13-membered ring complex, $[Ni^{II}_2L^{13-13}]^{4+}$, does not show reversible waves, but a cathodic peak at -1.43 and a sharp irreversible peak at -1.54 V; the latter may be caused by strong adsorption of the complex to the Hg electrode. The mixed-ring complex, $[Ni^{II}_2L^{13-14}]^{4+}$, shows a broad wave comprising a broad cathodic peak around -1.47 V assignable to the reduction of two Ni(II) ions in the 13- and 14-membered rings, and an anodic peak around -1.47 V to the oxidation of Ni(I) formed in the 14-membered ring.

Figure 5 shows CV's measured under various conditions. When the solution contained only a supporting electrolyte (0.1 mol dm^{-3} KCl), a supporting electrolyte+phosphate buffer (pH 6.8), or a supporting electrolyte+$[Ni^{II}_2L^{14-14}]^{4+}$ (2×10^{-5} mol dm^{-3}), neither cathodic nor anodic peaks were observed in 0—-1.7 V. Only when both phosphate buffer and $[Ni^{II}_2L^{14-14}]^{4+}$ (2×10^{-5} mol dm^{-3}) was added to 0.1 mol dm^{-3} KCl solution, did a new wave appear at ca. -1.66 V. This was assigned

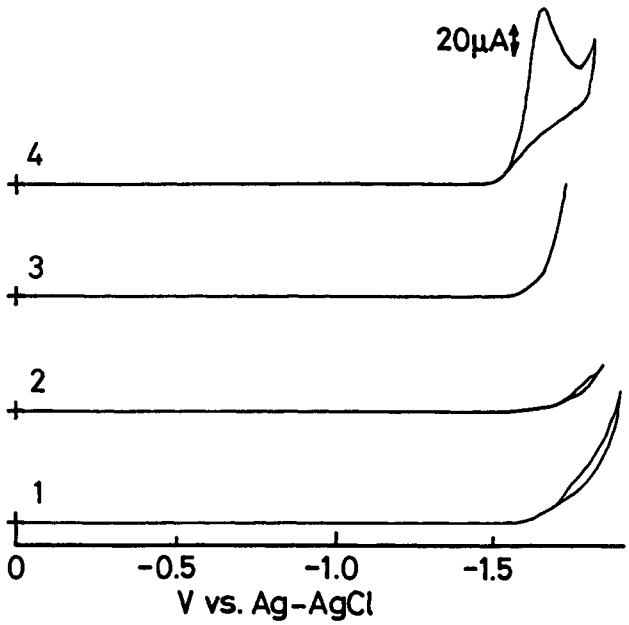

Fig. 5. Cyclic voltammograms of 0.1 mol dm^{-3} KCl aqueous solutions containing no buffers + no catalysts (1), phosphate buffer ($[HPO_4^{2-}]_T$=4×10^{-2} mol dm^{-3}, pH=6.8) (2), 2×10^{-5} mol dm^{-3} $[Ni_2L^{14-14}]^{4+}$ (3), and phosphate buffer ($[HPO_4^{2-}]_T$=4×10^{-2} mol dm^{-3}, pH=6.8)+2×10^{-5} mol dm^{-3} $[Ni_2L^{14-14}]^{4+}$ (4). T= 25 °C. HMDE.

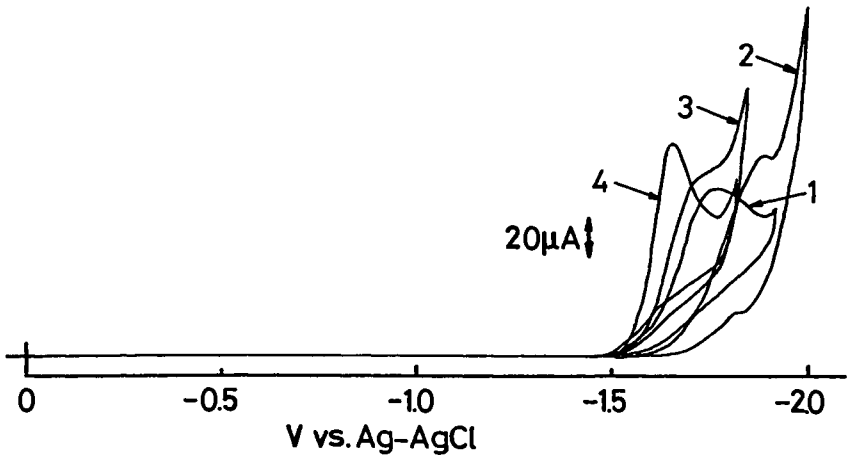

Fig. 6. Cyclic voltammograms of 0,1 mol dm^{-3} KCl aqueous solutions containing phosphate buffer ($[HPO_4^{2-}]_T$=4×10^{-2} mol dm^{-3}, pH=6.8) and 2×10^{-5} mol dm^{-3} Ni(II) complexes: $[NiL^{14}]^{2+}$ (1); $[Ni_2L^n]^{4+}$ (n= 13—13 (2), 13—14 (3), 14—14 (4)). T=25 °C. HMDE.

to the catalytic wave for water reduction, as reported previously.[2] Indeed, the controlled-potential electrolysis at the peak potential produced reasonable amounts of H_2, which was identical with a standard H_2 sample by gas chromatography. Similar catalytic waves were also observed upon the addition of $[Ni^{II}L^{14}]^{2+}$, $[Ni^{II}_2L^{13-14}]^{4+}$, or $[Ni^{II}_2L^{13-13}]^{4+}$.

Figure 6 shows the catalytic waves observed for solutions containing each Ni(II) complex (2×10^{-5} mol dm^{-3}), phosphate buffer, and 0.1 mol dm^{-3} KCl. The peak potentials, $(E_p)_{cata}$, of the catalytic waves are different among these Ni(II) complexes and their peak currents, $(i_p)_{cata}$, lie in 87—110 μA (see Table 1). According to the following order; $[Ni^{II}_2L^{13-13}]^{4+}<[Ni^{II}_2L^{13-14}]^{4+}\approx[Ni^{II}L^{14}]^{2+}<[Ni^{II}_2L^{14-14}]^{4+}$, $(E_p)_{cata}$ shifts toward the positive. As $(E_p)_{cata}$ becomes more positive, the wave begins to rise at a more positive potential; the overvoltage for the water reduction therefore becomes smaller. These results suggest that $[Ni^{II}_2L^{14-14}]^{4+}$ is the most favorable catalyst for H_2 production and that the electrocatalytic capability of $[Ni^{II}_2L^{13-14}]^{4+}$ should lie between those of $[Ni^{II}_2L^{14-14}]^{4+}$ and $[Ni^{II}_2L^{13-13}]^{4+}$, being close to that of mononuclear $[Ni^{II}L^{14}]^{2+}$.

The practical capabilities of the electrocatalysts could be evaluated by measurements of the amount of H_2 evolved by controlled-potential electrolysis: the greater was the amount of H_2, the more effective was the Ni(II) complex. The gas in the flask was analyzed by gas chromatography at an appropriate interval. In all cases, the amount of H_2 that evolved increased linearly with the electrolysis time.

We used a 1×10^{-4} mol dm^{-3} Ni(II) complex, where the concentration of the electrocatalyst has only a minor effect on the efficiency of H_2 production.[2] In the electrolysis at −1.5 V, only a small amount of H_2 is detected on a blank experiment in the absence of the Ni(II) complexes (Fig. 7). The addition of $[Ni^{II}_2L^{13-13}]^{4+}$ to a blank solution does not improve H_2 production, indicating that a Ni(II) complex with only 13-membered rings has a negligible electrocatalytic capability at −1.5 V. On the other hand, when the other Ni(II) complex with a 14-membered ring, $[Ni^{II}L^{14}]^{2+}$, $[Ni^{II}_2L^{13-14}]^{4+}$, or $[Ni^{II}_2L^{14-14}]^{4+}$, is added, a significantly larger amount of H_2 evolves compared with the case of a blank. The efficiency of binuclear $[Ni^{II}_2L^{14-14}]^{4+}$ is higher than that of mononuclear $[Ni^{II}L^{14}]^{2+}$ by about two times; this result, though the efficiency is somewhat lower in our experiments, is similar to that reported by Sauvage et al.[2] The capability of $[Ni^{II}_2L^{13-14}]^{4+}$ is almost equal to that of mononuclear $[Ni^{II}L^{14}]^{2+}$ and lies between those of $[Ni^{II}_2L^{14-14}]^{4+}$ and $[Ni^{II}_2L^{13-13}]^{4+}$. Thus, the order of the electrocatalytic capability derived from the controlled-potential electrolysis well corresponds to that predicted from $(E_p)_{cata}$ in CV experiments.

These data obtained herein undoubtedly show that the electrocatalytic capability strongly depends on the ring sizes of bimacrocyclic Ni(II) complexes, where the capability falls as 14-membered rings are replaced by 13-membered rings, i.e., the "symmetric" bimacrocycle, $[Ni^{II}_2L^{14-14}]^{4+}$, is the most favorable for H_2 generation.

Table 1. Electrochemical Data of Catalytic Waves[a]

Complex	$(E_p)_{cata}$/V	$(i_p)_{cata}$/μA
$[Ni^{II}L^{14}]^{2+}$	−1.77	87
$[Ni^{II}_2L^{14-14}]^{4+}$	−1.66	110
$[Ni^{II}_2L^{13-14}]^{4+}$	−1.75	95
$[Ni^{II}_2L^{13-13}]^{4+}$	−1.89	104

a) Solutions contained 0.1 mol dm^{-3} KCl, phosphate buffer ($[HPO_4^{2-}]_T=4\times10^{-2}$ mol dm^{-3}, pH 6.8), and 2×10^{-5} mol dm^{-3} Ni(II) complex.

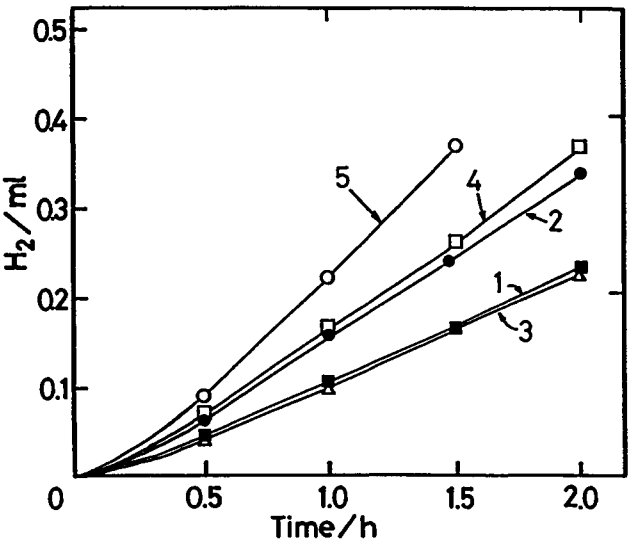

Fig. 7. Amount of H_2 evolved by the electrolysis at −1.5 V vs. Ag–AgCl. Electrolytic solutions contain only phosphate buffer ($[HPO_4^{2-}]_T=0.2$ mol dm^{-3}, pH=6.8) (1) and phosphate buffer+1×10^{-4} mol dm^{-3} Ni(II) complexes: $[NiL^{14}]^{2+}$ (2); $[Ni_2L^n]^{4+}$ (n=13—13 (3), 13—14 (4), 14—14 (5)). Mercury-pool electrode (8 cm^2). T=ca. 23 °C.

Experimental

Materials. The procedures for preparations of the ligand L^{13-14} and of its dinickel(II) complex are as follows.

Tetraoxo Derivatives: Tetraethyl 1,1,2,2-ethanetetracarboxylate (25.5 g, 0.08 mol) was dissolved in dry ethanol (1.6 dm^3) under an N_2 atmosphere, to which was added dropwise in 30 min a mixture of 3,6-diazaoctane-1,8-diamine (11.7 g, 0.08 mol) and 3,7-diazanonane-1,9-diamine (12.8 g, 0.08 mol). The solution was heated under reflux for 5 d. White precipitates which formed were filtered, washed with cold ethanol, and dried over P_2O_5 in a vacuum to give a mixture consisting of three tetraoxo derivatives, 6-(11,13-dioxo-1,4,7,10-tetraaza-12-cyclotridecyl)-1,4,8,11-tetraazacyclotetradecane-5,7-dione), 12,12′-bi[1,4,7,10-tetraazacyclotridecane-11,13-dione], and 6,6′-bi[1,4,8,11-tetraazacyclotetradecane-5,7-dione] in 18% yield. Since several attempts to separate the mixture failed, a crude mixture was subjected to the following procedures.

Reduction of the Mixture of Tetraoxo Derivatives: The mixture (4.0 g) of tetraoxo derivatives was suspended in tetrahydrofuran (300 cm^3) under an N_2 atmosphere, to which

was added B_2H_6 (240 cm^3, 1 mol dm^{-3} in tetrahydrofuran). After the solution was heated under reflux for 6 h, B_2H_6 (160 cm^3) was again added; refluxing was continued for additional 12 h. After the solution was cooled to room temperature, methanol (200 cm^3) was carefully added dropwise (*CAUTION*: this reaction can be explosive) to quench any excess B_2H_6. The resulting solution was evaporated to dryness. To the residue, conc. HCl (30 cm^3), water (60 cm^3), and methanol (160 cm^3) were added; the solution was then evaporated to dryness, this treatment being repeated five times in order to remove boric acid as trimethyl borate. To the residue, thus obtained, was added NaOH (50 cm^3, 1 mol dm^{-3}, pH>13). The reduction products were extracted five times with $CHCl_3$) (100 cm^3). The combined extracts were dried over anhydrous Na_2SO_4 over night and evaporated to dryness to give a white residue, a mixture of three bimacrocyclic ligands: L^{13-13}, L^{13-14}, and L^{14-14}. Yield: 92%.

Separation of the Mixture of Ligands: A mixture (1.5 g) of L^{13-13}, L^{13-14}, and L^{14-14} was dissolved in ethanol (80 cm^3), to which was added nickel(II) perchlorate hexahydrates (2.85 g, 7.8 mmol) in ethanol (160 cm^3). The mixture was stirred at 60 °C for 1 h to give yellow precipitates. The precipitates were suspended in a small amount of water and passed through a column of Cl-form anion-exchange resin (Amberlite IRA-410, ϕ=30 mm, l=300 mm) to exchange the counter ions from perchlorates to chlorides. The resulting clear solution was chromatographed with a cation-exchange column (SP-Sephadex C-25, ϕ=30 mm, l=1300 mm), with a 0.25 mol dm^{-3} sodium iodide solution as the eluent, to give three orange bands. The first and third bands were assigned to $[Ni^{II}_2L^{14-14}]^{4+}$ and $[Ni^{II}_2L^{13-13}]^{4+}$ respectively by comparison with respective authentic samples (see below). The second eluate was concentrated to ca. 200 cm^3, adjusted to pH>13 by adding NaOH, and heated at 60 °C. To the solution was added NaCN (2.4 g, 0.049 mol); the solution was stirred at 60 °C for 30 min. After being cooled to room temperature, the solution was extracted with $CHCl_3$ (100 cm^3) four times. The combined extracts were dried over anhydrous Na_2SO_4 and evaporated to dryness to give a pale-yellow residue of the free ligand, L^{13-14}, in 13 % yield. An analytical sample of hydrochloride was prepared by the following treatment. The residue was dissolved in a small amount of ethanol, to which was added conc. HCl (1 cm^3) to give a white precipitate. The precipitate was washed with dry ethanol and dried over P_2O_5 in a vacuum.

$[Ni^{II}_2L^{13-14}](ClO_4)_4\cdot H_2O$: The free ligand L^{13-14} (0.1 g, 0.26 mmol) was dissolved in ethanol (5 cm^3), to which was added nickel(II) perchlorate hexahydrates (0.19 g, 0.52 mmol) in ethanol (10 cm^3). The mixture was stirred at 60 °C for 1 h, cooled at room temperature, and filtered to give yellow precipitates. The precipitates were recrystallized from a small amount of water to give plate crystals, which were washed with cold water and dried at 80 °C over P_2O_5 in a vacuum. Yield: 42%. Found: C, 24.89; H, 4.91; N, 12.34%. Calcd for $C_{19}H_{44}N_8Ni_2Cl_4O_{16}\cdot H_2O$: C, 24.86; H, 5.05; N, 12.21%. VIS (H_2O) 428 (ε 130), (CH_3NO_2) 431 nm (167 mol dm^3 cm^{-1}).

$[Ni^{II}_2L^{14-14}](ClO_4)_4\cdot H_2O$: L^{14-14} was prepared according to a method described in the literature.[6] The dinickel(II) complex of L^{14-14} was prepared by the analogous method described above. Found: C, 25.66; H, 5.02; N, 11.85%. Calcd for $C_{20}H_{46}N_8Ni_2Cl_4O_{16}\cdot H_2O$: C, 25.78; H, 5.19; N, 12.03%. VIS (H_2O) 450 (ε 77), (CH_3NO_2) 456nm (113 mol^{-1} cm^3 cm^{-1}).

L^{14-14}: ^{13}C NMR ($CDCl_3$, TMS) δ=29.1 (t), 42.7 (d), 49.2 (t), 50.7 (t), and 54.8 (t).

$[Ni^{II}_2L^{13-13}](ClO_4)_4\cdot H_2O$: L^{13-13} and its dinickel(II) complex were prepared by the analogous method as described in the preparation of $[Ni^{II}_2L^{14-14}](ClO_4)_4\cdot H_2O$. Found: C, 24.13; H, 4.72; N, 12.48%. Calcd for $C_{18}H_{42}N_8Ni_2Cl_4O_{16}\cdot H_2O$: C, 23.92; H, 4.91; N, 12.40%. VIS (H_2O) 424 (ε 185), (CH_3NO_2) 427 nm (203 mol dm^3 cm^{-1}).

L^{13-13}: ^{13}C NMR ($CDCl_3$, TMS) δ=42.0 (d), 47.3 (t), 49.0 (t), and 54.1 (t).

Measurements. The visible absorption spectra were measured with a Hitachi 340 spectrophotometer. ^{13}C NMR spectra were recorded with JEOL FX90Q or Brucker AM400 spectrometers. FAB mass spectra were measured with a JEOL DX303 spectrometer.

Cyclic voltammograms for the oxidation of dinickel(II) complexes were measured according to a method described in our previous paper.[9] Cyclic voltammograms for the reduction were carried out by using a Yanagimoto Polarographic Analyzer P-1100. A hanging mercury electrode (Metrohm EA-290 equipped with glass capillary EA-1053) and Pt spiral electrode were used as working electrode and counter electrode respectively.

Controlled-potential electrolyses were performed at room temperature (ca. 23 °C), in a gas-tight electrolysis cell under one atmosphere of N_2 with a Fuso potentiostat 315A. The gas-tight cell was a 100 cm^3, three-necked, round-bottomed flask equipped with two side arms. The working electrode used in all the experiments was mercury (8 cm^2) which had been distilled twice. The counter electrode (Pt) and the reference electrode (Ag/AgCl) were separated from the working electrode compartment by a glass frit. The gases occupied 95 cm^3 of the cell volume. Before electrolysis, the aqueous solution (50 cm^3) was degassed by bubbling N_2 for 30 min, after which the admission tap was turned off, the internal pressure within the electrolysis cell being kept equal to 1 atm by means of an oil valve.

Gas samples (0.5 cm^3), taken at various intervals with a gas-tight syringe through a septum, were analyzed on a Shimadzu GC-14A gas chromatograph with a thermal conductivity detector by using a 2.1 m×3 mm column packed with molecular sieve 5A at 60 °C using argon as carrier gas.

(Received January 28, 1991)

Application limits of the proposed concentration depth profile using laser induced fluorescence spectroscopy based on the reciprocal principle (*Bull. Chem. Soc. Jpn.*, **64**, 755 (1991)) were investigated. Although this method has no limitations regarding film thickness and spatial resolution in the depth direction theoretically, for practical applications, they are limited by the instrumental factors. Effects of uncertainty in the observation angle measurement, which depends on the size of the detector, the mechanical precision of the rotating stage, and experimental errors in the fluorescence intensity measurement on the accuracy of the reconstructed concentration depth profile were discussed in detail. The theoretical results predicted nanometer level depth profiling with our laboratory-constructed instruments. A 29 nm thick model film sample, consisting of long chain molecular bilayers, was used to verify the theoretical analysis results. The concentration depth profile for bilayer level steps of about 5 nm was obtained under our experimental conditions. Possible improvements in this method and monolayer level depth profiling were also considered.

Many problems in thin film chemistry and materials science are concerned with the distribution of chemical species in the depth direction.[1,2] In many situations, vacuum spectroscopic depth profiling methods are undesirable, because they are destructive methods and they need high vacuum conditions which are unsuitable for in situ and in vivo analysis. Optical spectroscopical concentration depth profiling methods such as photoacoustic spectroscopy (PAS) depth profiling,[3] attenuated total reflection (ATR) spectroscopy depth profiling[4] are non-destructive and non-contact methods not requiring high vacuum system.[5,6] Recently, we have reported on the concentration depth profiling technique using laser induced fluorescence spectroscopy under normal incidence conditions based on the reciprocal principle.[7] Using this method, the quantitative concentration depth profile of a 187 nm thick Langmuir–Blodgett (LB) model film sample was obtained by the least square method. This spectroscopic technique is attractive since it has a high spatial resolution in the depth direction and can be used on a film sample thinner than the wavelength of the excitation light. In addition, by using the normal incidence conditions, it is possible to obtain a three dimensional concentration profile by scanning the excitation beam.

However, to function as a basic methodology for practical applications, answers must be got for the following questions: How accurate is the reconstructed concentration depth profile? Is there any limitation to film thickness for this method? What is the spatial resolution in the depth direction? Then it is necessary to investigate the application limits.

In this paper, we investigate application limits, such as film thickness, and accuracy of the reconstructed concentration depth profile by this method. The main instrumental error sources such as the uncertainty in determining observation angle, the mechanical precision of the rotating stage, and the uncertainty in the fluorescence intensity measurement, and their effects on the accuracy of the reconstructed concentration depth profile are discussed. In the experiments, a 29 nm thick LB model film sample where fluorophore is distributed in the form of a nearly linear function is used to verify the theoretical conclusions, and a bilayer level concentration depth profile is obtained.

Theory and Simulation

The basic theory of depth profiling using laser induced fluorescence spectroscopy under normal incidence conditions based on the reciprocal principle has been discussed in our previous paper.[7] Here we summarize it briefly. Figure 1 illustrates the basic optical arrangement. The fluorescence intensity $F(\theta)$ obtained

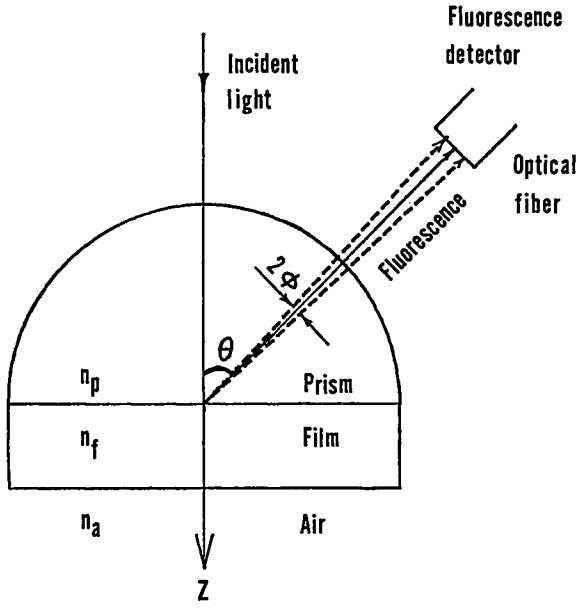

Fig. 1. Measurement principle of the depth profiling method.

at an observation angle θ under normal incidence conditions can be expressed as Eq. 1,

$$F(\theta)=k\int_0^t C(z)T(\theta, z)\mathrm{d}z, \quad (1)$$

where $C(z)$ is the concentration distribution in the depth direction z, t is the thickness of the sample, and k is a constant given by material constants and instrumental factors. The transmission function $T(\theta, z)$ can be obtained by theoretical analysis of multiple reflection of the fluorescence electromagnetic wave between prism/film and film/air interfaces.[8] When θ, z, and t are given, $T(\theta, z)$ can be calculated exactly from the optical parameters such as the fluorescence wavelength and the refractive indices of the prism, film, and air. Thus $C(z)$ can be obtained by resolving the inverse integral of Eq. 1 from a set of fluorescence intensity data. It is well known that resolution of the inverse integral problem is difficult due to the ill-posed problem.[9–11] However, for the present method, if a process leading to the formation of $C(z)$ is estimated beforehand, then $C(z)$ can be easily obtained by the least square method.[7] As shown in the previous experimental reports of this depth profiling method,[7] the experimental errors seriously affect results of the reconstructed concentration profiles. We can discuss the effects of the instrumental error factors on the accuracy and the limitation of the present depth profiling method by a numerical simulation method. Since $C(z)$ is obtained from a set of fluorescence intensities determined at a series of observation angles by the least square method, the following three error sources are considered. First, uncertainty ϕ in observation angle, as shown in Fig. 1, is determined by the size of the detector and the distance between the detector and the illuminated point. Second, the angular error $\Delta\theta$ is determined by the mechanical precision of the rotating stage. Third, the measurement error ΔF in the fluorescence intensity is caused by noise such as electric noise. An influence of base-line drift on ΔF cannot be disregarded, when measurement period is relatively longer than the instrument stability.

Here, three typical concentration distribution cases are discussed. In the first case, $C(z)$ is a linear function form

$$C(z)=Az+B \quad (2)$$

as shown in Fig. 2-A), which was used as a trial function in our previous paper.[7] In the second case, $C(z)$ is an exponential function form

$$C(z)=C_0\exp(-z/l) \quad (3)$$

as shown in Fig. 2-B), which often emerges in chemical kinetics systems. In the third case, $C(z)$ is an error function form

$$C(z)=C_0[1-\mathrm{erf}(-z/l)] \quad (4)$$

as shown in Fig. 2-C), which is usually met in a diffusion limiting process. The parameters A, B, C_0, l can be obtained by the least square method, i. e., by

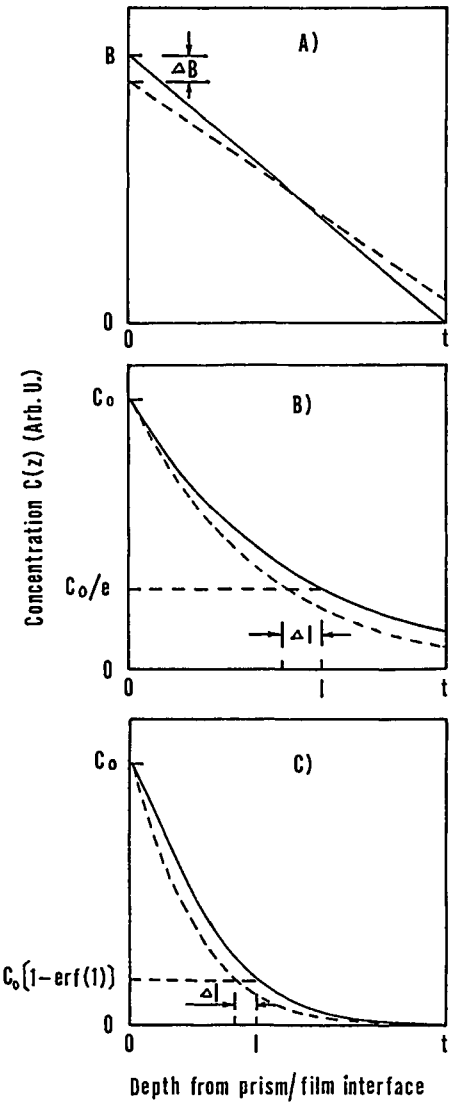

Fig. 2. Model function used in the simulation. The solid and dashed lines represent the original $C(z)$ and reconstructed $C(z)$. A: $C(z)$ is a linear function form. B: $C(z)$ is an exponential function form. C: $C(z)$ is an error function form.

minimizing the following value s,

$$s=\sum_i[F_m(\theta_i)-F_c(\theta_i)]^2/g_{\theta_i}, \quad (5)$$

where i means the i-th measurement data, $F_m(\theta_i)$ and $F_c(\theta_i)$ are the measured and calculated fluorescence intensities, respectively, and g_{θ_i} is a weight factor.

The differences between actual and calculated values of parameters A, B, and l are represented by ΔA, ΔB, and Δl, respectively (Fig. 2). The accuracy of the reconstructed $C(z)$ is evaluated by the relative errors of the parameters in Eqs. 2—4, i. e., $\Delta A/A$ or $\Delta B/B$ for the linear distribution case, and $\Delta l/l$ for the exponential and error function cases.

In this simulation, θ_i is assumed to be varied from 20° to 80° with 1° steps. The calculated fluorescence intensities $F_c(\theta_i)$ in Eq. 5 are obtained according to Eq. 1 for

the above three cases expressed as Eqs. 2—4. The constants in Eqs. 2—4 are normalized as follows: A (% nm^{-1}) and B (%) are $-1(\%)/t(\mathrm{nm})$ and 1(%), respectively, and C_0 (%) and l (nm) are 1(%) and t (nm), respectively. In order to calculate $\Delta A/A$, $\Delta B/B$, and $\Delta l/l$ caused by ϕ, the measured fluorescence intensity $F_m(\theta_i)$ in Eq. 5 is simulated by substituting θ_i with $\theta_i+\phi$. When the effect of $\Delta\theta$ is considered, the observation angle θ_i takes a certain value within the range of $\theta_i\pm\Delta\theta$. In the worst case, θ_i is randomly given by either $\theta_i+\Delta\theta$ or $\theta_i-\Delta\theta$, leading to $F_m(\theta_i+\Delta\theta)$ or $F_m(\theta_i-\Delta\theta)$. Considering ΔF, $F_m(\theta_i)$ in Eq. 5 is within the range of $F_m(\theta_i)\pm\Delta F$, and the value of $F_m(\theta_i)$ in Eq. 5 is also substituted randomly by $F_m(\theta_i)+\Delta F$ or $F_m(\theta_i)-\Delta F$. With these simulated values of $F_m(\theta_i)$, the relative errors of $\Delta A/A$, $\Delta B/B$, and $\Delta l/l$ caused by ϕ, $\Delta\theta$, and ΔF are obtained from Eq. 5. The results are shown in Figs. 5, 6, and 7, respectively.

Experimental

The experimental set up used is the same as reported in our previous paper.[7] An Ar^+ laser (output, 30 mW) provides the excitation light (wavelength, 488 nm). The laser beam was modulated with a chopper. The chopped beam was focused on the focal plane of the hemicylindrical prism (refractive index n, 1.88) which was mounted on two rotating stages. A step index type optical fiber bundle was used to collect the fluorescence transmitted through the prism. The area collecting fluorescence was 0.2 mm×1 mm, and the numerical aperture was 0.57. One end of the optical fiber was fixed at the focal plane of the prism and the other end of the optical fiber was coupled with a monochromator. A film polarizer was placed in front of the optical fiber to restrict the fluorescence collected only to the perpendicularly polarized component. A photomultiplier (Hamamatsu 1P21) was used as a detector. The signal from the photomultiplier was fed into and amplified with a lock-in amplifier. Fluorescence intensity data were obtained at the fluorescence wavelength of 580 nm.

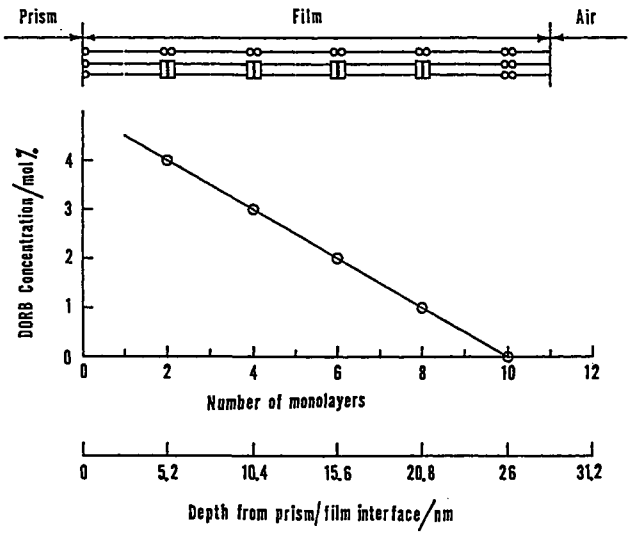

Fig. 3. Concentration depth profile of the model film sample. The upper part is a schematic representation of the model film sample construction. Rectangles represent the head groups of DORB, which are the fluorophores. Circles represent CdC_{20} head groups (nonfluorescent). Long hydrocarbon chains are represented as lines. The lower part is the concentration depth profile represented graphically. The circles and the straight line represent the true and approximate linear function form concentration depth profiles, respectively.

The LB multilayer deposition method was used to prepare a model film sample where $C(z)$ is a nearly linear function form. A model film sample having an exact linear function form or an exponential function form $C(z)$ is difficult to prepare. Details of the preparation procedure were reported previously.[7] The LB multilayers were deposited onto the prism directly. In order to ensure the prism surface was uniform and hydrophobic, a monolayer of CdC_{20} was first deposited. Then a mixture of CdC_{20} and N,N'-dioctadecylrhodamine B (DORB), in which the concentration of DORB varied from 4% to 0%, was deposited in 2 layer steps. The concentration depth profile of the model film sample is shown in Fig. 3, and its $C(z)$ can be precisely expressed as a discrete function with the spacing of a bilayer thickness (5.2 nm) between the values. This concentration depth profile of the model film sample is approximately described as a linear function form in the same manner as the previous report,[7]

$$C(z)(\%) = -0.19(\%\ \mathrm{nm}^{-1})\, z(\mathrm{nm}) + 5(\%). \quad (6)$$

Results and Discussion

In order to obtain $C(z)$ from Eq. 1, the necessary condition is that the partial derivative of $T(\theta, z)$ with respect to z, $\partial T(\theta, Z)/\partial Z$, must not be equal to zero. Otherwise $T(\theta, z)$ is independent of z, that is, $T(\theta, z)$ becomes a constant $T(\theta)$, and Eq. 1 becomes as follows,

$$F(\theta) = kT(\theta)\int_0^t C(z)\mathrm{d}z. \quad (7)$$

It is clear that information on $C(z)$ disappears from the observed $F(\theta)$ expressed in Eq. 7.

Figure 4 shows a calculation example of the relations between $\partial T(\theta, Z)/\partial Z$ and the film thickness at the observation angle of 20°. The calculation results show

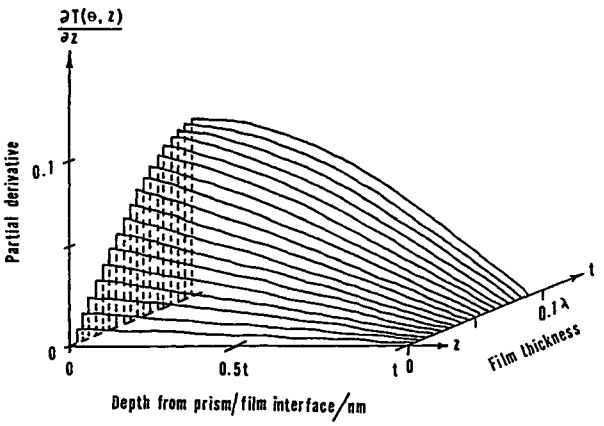

Fig. 4. Calculation results of partial derivative $\partial T(\theta, z)/\partial z$ for different film thicknesses at observation angle 20°. t: film thickness. λ: wavelength of fluorescence.

the partial derivative is not zero, and moreover, $\partial T(\theta, Z)/\partial Z$ has different values at different θ. This means that at different θ_i, $T(\theta_i, z)$ has different function forms. Hence, $C(z)$ can be obtained mathematically from Eq. 1 regardless of t. In other words, theoretically, this method is not limited by the film thickness. It is obvious from Eq. 1 that the measured fluorescence $F(\theta)$ does not involve informations related to concentration distribution $C(z)$ when $\partial T(\theta, Z)/\partial Z$ is zero, even though $T(\theta, z)$ has certain value.

Considering the above theoretical results and the previous experiments,[7] the application limit is considered to depend on instrumental factors and experimental errors. Then, their effects on the accuracy of the reconstructed $C(z)$ were investigated. After that, the application limits of film thickness under our experimental conditions were discussed on the basis of the simulation results.

For the first case in which $C(z)$ is a linear function form, Fig. 5 shows the simulation results of the effects of ϕ, $\Delta\theta$, and ΔF on the accuracy of the reconstructed $C(z)$. The circles and the vertical error bars in Figs. 5-B) and 5-C) represent the average values and variation for ten simulation results taking the values $\theta_i+\Delta\theta$ or $\theta_i-\Delta\theta$, and $F_m(\theta_i)+\Delta F$ or $F_m(\theta_i)-\Delta F$ randomly for Figs. 5-B) and 5-C), respectively. The relative value $\Delta F/F$ in Fig. 5-C) is considered to be the same as the signal to noise ratio (S/N). Since $F_m(\theta)$ takes a value within the range of $F_m(\theta)\pm\Delta F$, the noise is considered as $2\Delta F$. Thus the relation between $\Delta F/F$ and S/N is as follows,

$$\Delta F/F = 1/2(S/N). \tag{8}$$

The vertical axes of Fig. 5 represent the relative error $\Delta B/B$ of the parameter B obtained from Eq. 5 and $\Delta B/B$ decreases with decreasing ϕ. The variation range of

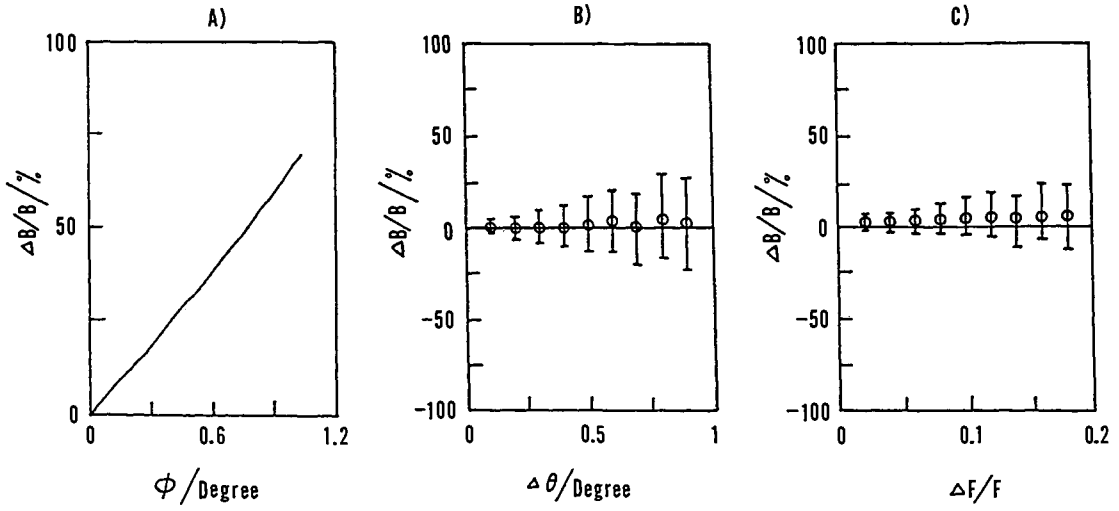

Fig. 5. Effects of instrumental factors on the accuracy of the reconstructed concentration depth profile for the first case. A: effect of ϕ on $\Delta B/B$. B: effect of $\Delta\theta$ on $\Delta B/B$. C: effect of ΔF on $\Delta B/B$.

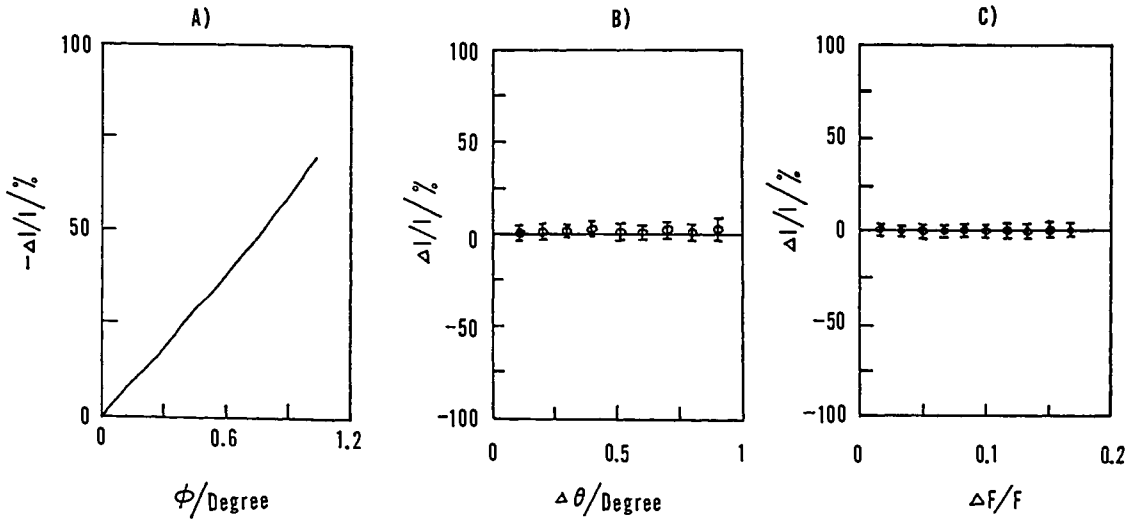

Fig. 6. Effects of instrumental factors on the accuracy of the reconstructed concentration depth profile for the second case. A: effect of ϕ on $\Delta l/l$. B: effect of $\Delta\theta$ on $\Delta l/l$. C: effect of ΔF on $\Delta l/l$.

$\Delta B/B$ also decreases with the decrease of both $\Delta\theta$ and $\Delta F/F$ although the average values of $\Delta B/B$ are nearly equal to zero as shown in Figs 5-B) and 5-C). These results indicate that the accuracy of the reconstructed $C(z)$ depends on the experimental errors. The effects of ϕ, $\Delta\theta$, and ΔF on $\Delta A/A$, which is the relative error of the parameter A of the linear equation function form expressed as Eq. 2, were also simulated and the results are simular to those shown in Fig. 5.

It has been stated that ϕ is determined by the size of the detector, and the distance between the detector and the illuminated point. When using a small sized fiber bundle, ϕ can be decreased, so that accuracy of the reconstructed $C(z)$ can be improved. However, at the same time, S/N decreases which results in a decreased accuracy of the reconstructed $C(z)$. Therefore there is an optimum condition between ϕ and ΔF, which is determined experimentally.

For the second case in which $C(z)$ is an exponential function form, Fig. 6 shows the effects of ϕ, $\Delta\theta$, and ΔF on the accuracy of the reconstructed $C(z)$. It is clear that the relative error $\Delta l/l$ of parameter l in Eq. 3 decreases with decreasing ϕ, but varies hardly at all with $\Delta\theta$ and $\Delta F/F$ in comparison with the first case shown in Fig. 5. For the first and the second cases, Eq. 1 takes the following forms:

$$F(\theta)=k[A\int_0^t zT(\theta, z)\mathrm{d}z+B\int_0^t T(\theta, z)\mathrm{d}z], \quad (9)$$

$$F(\theta)=k\int_0^t c_0 \exp(-z/l)T(\theta, z)\mathrm{d}z. \quad (10)$$

Therefore, the relations between ΔF and ΔA, ΔB and Δl are expressed as Eqs. 11 and 12, respectively.

$$\Delta F=[\Delta A\int_0^t zT(\theta, z)\mathrm{d}z+\Delta B\int_0^t T(\theta, z)\mathrm{d}z], \quad (11)$$

$$\Delta F=k\int_0^t [\exp(-z/(1+\Delta l))-\exp(-z/l)]T(\theta, z)\mathrm{d}z. \quad (12)$$

It can be seen that ΔF has a linear relation with ΔA and ΔB for the first case, but it has an exponential relation with Δl for the second. Thus ΔF has a smaller effect on the exponential distribution than the linear one. When $\Delta\theta$ and $\Delta F/F$ are within the range of 0—1° and 0—0.2, the average values of $\Delta l/l$ in Figs. 6-B) and 6-C) are nearly equal to zero, and the variation range of $\Delta l/l$ is about ±5%. Therefore, in this case, the effects of $\Delta\theta$ and ΔF are small, and ϕ is the main factor affecting the accuracy of reconstructed $C(z)$.

For the third case in which $C(z)$ is an error function form, the effects of ϕ, $\Delta\theta$, and ΔF on the accuracy of reconstructed $C(z)$ were also investigated, and the results are similar with those shown in Fig. 6.

In conclusion, when $C(z)$ is an exponential function form or an error function form, the accuracy of the reconstructed $C(z)$ is mainly determined by the instrumental factor ϕ. When $C(z)$ is a linear function form, the accuracy of the reconstructed $C(z)$ depends on both the instrumental factors ϕ and $\Delta\theta$, and the experimental ΔF. However, if $\Delta\theta$ is smaller than 0.05° and S/N is above 10, $\Delta B/B$ caused by $\Delta\theta$ and ΔF are estimated to be about ±1% and ±4% respectively from Figs. 5-B) and 5-C). Under this situation, ϕ is also the main factor for affecting the linear distribution.

Figure 7 shows the simulation results of the relations between $\Delta B/B$ and film thickness t. The relations between $\Delta l/l$ and the film thickness t for the exponential and error function cases are similar to those shown in Fig. 7. The plotted data indicate that $\Delta B/B$ increases with thinner films. In other words, the accuracy of the reconstructed $C(z)$ becomes worse when the film thickness decreases. For an experimental system, ϕ has a fixed value, thus the applicable limit of film thickness can be obtained according to the required accuracy of the reconstructed $C(z)$, although there is no limitation theoretically. For example, to keep $\Delta B/B$ smaller than ±10%, when ϕ is 0.3°, the limit of film thickness is about 50 nm from Fig. 7.

In our experiment, the accuracy of the rotating stage was 0.05°, and signal to noise ratio was kept above 10. The fiber bundle width was about 0.2 mm, and the distance between the fiber bundle and the illumination point was about 21.4 mm. Thus ϕ is calculated to be 0.13°. The errors of the reconstructed $C(z)$ caused by $\Delta\theta$ and ΔF are estimated to be ±1% and ±4% from Figs. 5-B) and 5-C), respectively. The errors of reconstructed $C(z)$ caused by ϕ, $\Delta\theta$, and ΔF are a cumulative error. Therefore, in order to maintain an accuracy of the reconstructed $C(z)$ of better than 10%, the error of the reconstructed $C(z)$ caused by ϕ must be smaller than ±5%. For this accuracy level and the value of ϕ, the limitation of film thickness is estimated to be about 30 nm from Fig. 7. This theoretical analysis result is verified by the experiments using the 29 nm thick LB model film sample.

Figure 8 shows the experimental and theoretical fluorescence intensity dependence on the observation angle under normal incidence conditions for the model film sample. The theoretical and experimental results are represented by a solid line and circles, respectively. The theoretical values were obtained by substituting

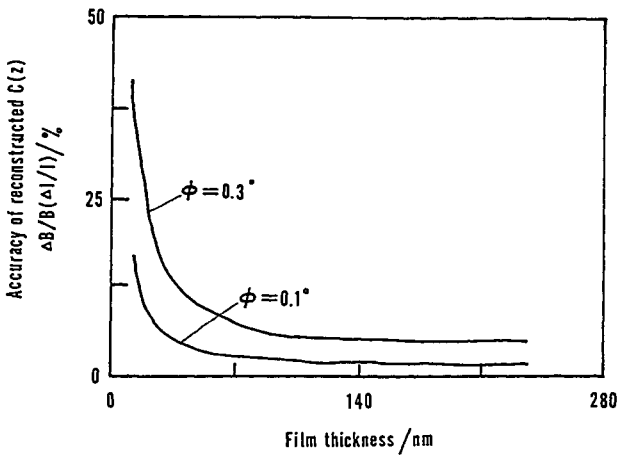

Fig. 7. Dependence of the accuracy of the reconstructed concentration depth profile on film thickness for the case that $C(z)$ is a linear function form.

$C(z)$ expressed as Eq. 6 into Eq. 1. The theoretical values agree well with the experimental ones.

With the fluorescence intensity data presented in Fig. 8, the constants A and B of the linear function form used as the test function were calculated from Eq. 5. Figure 9 shows the results of the reconstructed $C(z)$ with the actual $C(z)$ described in circles. The solid and dotted lines represent the average reconstructed $C(z)$ and its variation range for four times determinations, respectively. The average values calculated for the parameters A and B are -0.21% nm $^{-1}$ and 5.48%, respectively. As shown in Eq. 6, the values of A_0 and B_0 of the model film sample are approximately -0.19 (% nm^{-1}) and 5 (%), respectively (Fig. 3). Hence $\Delta A/A$ and $\Delta B/B$ are got as 10.5% and 9.5%, respectively. Therefore the accuracy of reconstructed $C(z)$ is about 10% which agrees well with the theoretical estimation. The model film sample consists of long chain molecular bilayers, and the concentration changes in each bilayer have been recognized with a reasonable accuracy as shown in Fig. 9. Hence the spatial resolution in the depth direction is estimated to be at least on the order of the bilayer thickness, 5.2 nm.

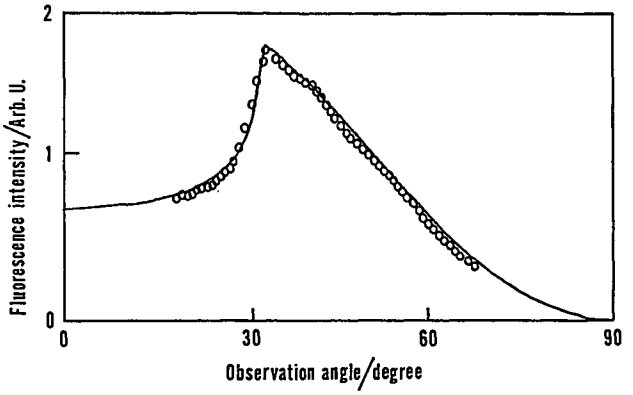

Fig. 8. Theoretical and experimental results of the angular dependency of the fluorescence intensity measured for the model sample. The theoretical values are described by the solid line, and the experimental results are plotted with circles.

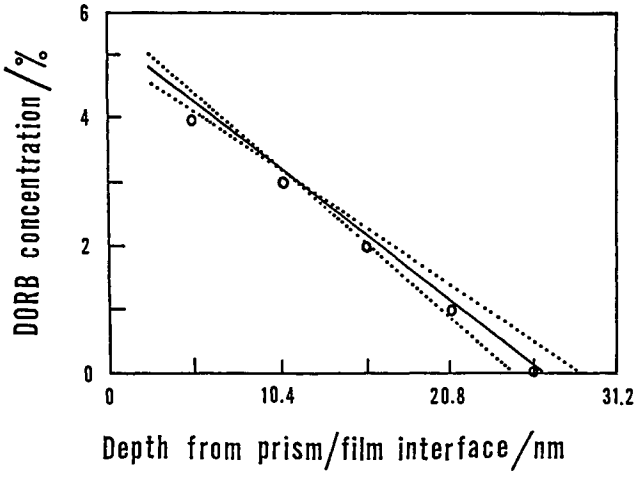

Fig. 9. Reconstructed concentration depth profile for the model film sample. The solid and dotted lines represent the average reconstructed $C(z)$ and the variation range of reconstructed $C(z)$. The circles represent the actual $C(z)$ of the model sample.

The signal to noise ratio can be improved using a more sensitive photomultiplier. For example, a photomultiplier such as Hamamatsu R923 is more sensitive by a factor of 5 than the used one in our experiments (Hamamatsu 1P21). Moreover, it can be improved further by using a photon counting technique. Therefore, the signal to noise ratio can be improved at least by a factor of 10 compared with our present experiments. This means ϕ can be decreased by a factor of 10, then the limitation of the film thickness is estimated to be 5 nm from Fig. 7, and concentration depth profiles on the nm level or molecular level are expected. In fact, Fig. 9 suggests, where the molecule is a long chain molecule, that the concentration depth profile is on the molecular level.

The authors wish to express their thanks to Professor Y. Goshi and Dr. K. Miyamura of the University of Tokyo, for their useful advice in preparation of the model LB film sample.

The Structure of Notoryne, a Halogenated C_{15} Nonterpenoid with a Novel Carbon Skeleton from the Red Alga *Laurencia nipponica* Yamada[1)]

Hajime KIKUCHI,† Teruaki SUZUKI,* Etsuro KUROSAWA, and Minoru SUZUKI*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received November 26, 1990)

A new halogenated C_{15} nonterpenoid with a novel carbon framework, named notoryne, has been isolated from the title alga and its structure was established on the basis of spectroscopic and chemical evidence. In addition, the structure of a rearranged product, whose structure has long remained unsettled, of laurefucin derivative was also determined by spectral and chemical methods. Furthermore, the biogenesis of the halogenated C_{15} nonterpenoids from *L. nipponica* collected at warm current region in Hokkaido is also discussed.

Red algae of the genus *Laurencia* are known to produce halogenated C_{15} nonterpenoid ethers containing different ring systems, which usually have a conjugated enyne or a bromoallene moiety at one end of the molecule.[2,3)] Among the Japanese species of the genus *Laurencia, L. nipponica* displayed a marked variation in the major metabolites, which seems to be mainly dependent upon the growth locality. The major metabolites from this species, collected in the warm current region in Hokkaido, are, with some exception,[4,5)]

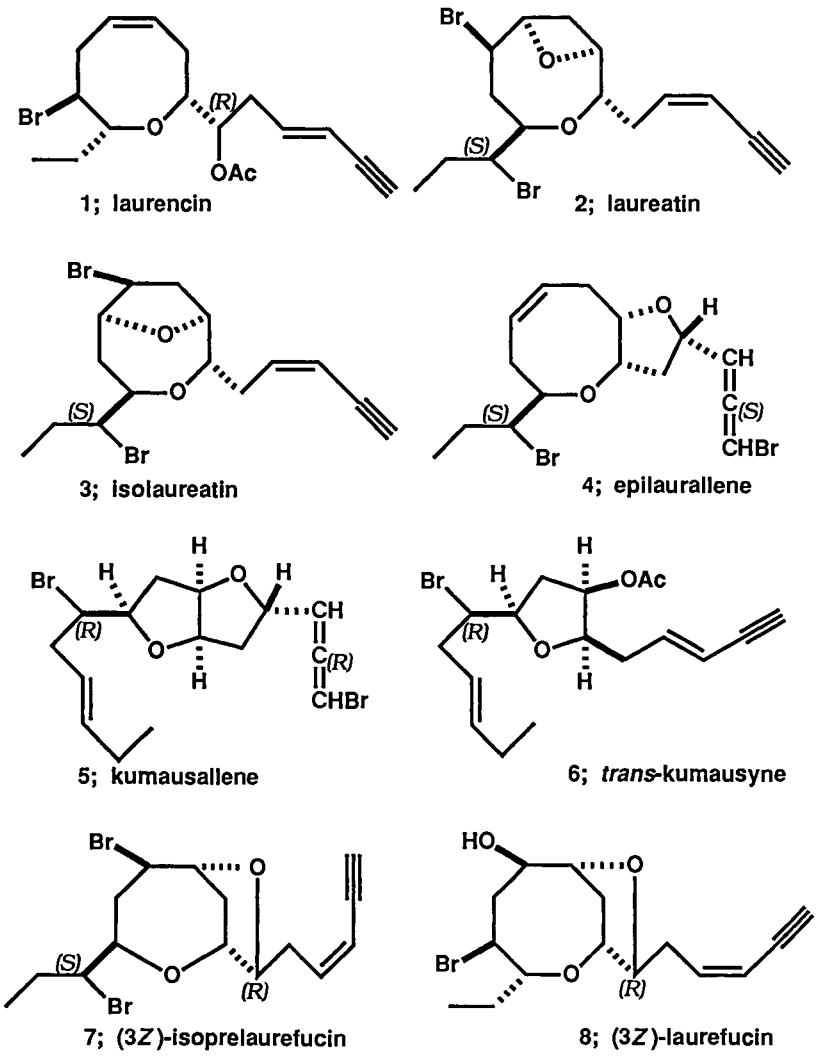

Fig. 1. The main C_{15} nonterpenoids from *Laurencia nipponica* collected in the warm current region in Hokkaido.

† Present address: Tobishi Pharmaceutical Co., Ltd., Ome 198.

composed of C_{15} nonterpenoids, e.g. laurencin (**1**),[6,15] laureatin (**2**),[7,9,15] isolaureatin (**3**),[8,9,15] epilaurallene (**4**),[10,15] kumausallene (**5**),[11,13] *trans*-kumausyne (**6**),[12,13] and (3*Z*)-isoprelaurefucin (**7**)[14] (Fig. 1).

In connection with our studies on this species growing in the warm current region in Hokkaido, we have newly made collection at Notoro Point, near Abashiri, and examined its constituents. This specimen contained (3*Z*)-laurefucin (**8**)[16] as the major metabolite and a new C_{15} nonterpenoid, which we have named notoryne, as a minor one. In this paper we report the isolation and the structure elucidation of notoryne (**9**) as well as the structure of a rearranged product **22**, which has previously been obtained from laurefucin derivative.[17] Furthermore, the biogenesis of C_{15} nonterpenoids from *Laurencia nipponica* collected at warm current region in Hokkaido is also discussed.

Notoryne (**9**), colorless oil, $[\alpha]_D$ +40.3° ($CHCl_3$), had a molecular formula of $C_{15}H_{20}BrClO_2$. The presence of a (*Z*)-2-penten-4-ynyl side chain in **9** was evident from the UV [λ_{max} 223 nm (ε 12500)], IR [ν_{max} 3300 and 2100 cm^{-1}], ^1H NMR [δ=3.13 (1H, dd, *J*=2.4 and 0.8 Hz), 5.60 (1H, dddd, *J*=10.3, 2.4, 1.3, and 1.3 Hz), and 6.08 (1H, dddd, *J*=10.8, 7.3, 7.3, and 0.8 Hz)], and mass [*m/z* 285, 283, and 281 ($M^+-C_5H_5$)] spectra. Furthermore, the ^1H NMR spectrum revealed the presence of a methyl group at δ=1.00 (3H, dd, *J*=7.3 and 7.3 Hz) and six methine groups at δ=3.88 (1H, ddd, *J*=8.3, 7.3, and 6.8 Hz), 3.91 (1H, ddd, *J*=7.3, 7.2, and 3.9 Hz), 3.98 (1H, ddd, *J*=8.3, 6.8, and 5.5 Hz), ca. 4.1 (2H, m), and 4.26 (1H, ddd, *J*=7.3, 7.3, and 5.5 Hz) which are flanked by a bromine, a chlorine, or an oxygen atom. Since the IR spectrum of **9** showed no hydroxyl and carbonyl absorptions, both oxygen atoms in **9** were assumed to be involved in ether links. Moreover, the ^{13}C NMR spectrum of **9** showed no other double bonds other than those of the conjugated enyne moiety, and hence **9** must be composed of two oxide rings.

Extensive spin decoupling experiments in the ^1H NMR spectrum of **9** indicated the presence of the following partial structure (Fig. 2) for **9**. Hydrogenation of **9** with platinum oxide in ethanol gave a hexahydro derivative **10**, $C_{15}H_{26}BrClO_2$. The ^1H NMR spectrum of **10** displayed no signals at δ=3.5—2.9 due to epoxide protons[18] and at near δ=2.7 due to methylene protons on a 1,3-disubstituted oxetane ring.[9,19] Furthermore, the mass spectrum of **10** showed no fragment ions due to a 1-halopropyl or a 1-halohexyl moiety, thus suggesting that the substituents at C-6 and C-13 must not be halogen atoms but oxygen atoms.

The FI mass spectrum of **9** showed significant fragment ions at *m/z* 285, 283, 281 (32:100:80), 179, 177 (45:45), and 171, 169 (3:10). On the other hand, the EI mass spectrum of **9** showed a base peak at *m/z* 133 and significant peaks at *m/z* 97 and 69 along with those at *m/z* 285, 283, 281, 179, and 177. The main fragmentation in both spectra would be explicable as shown in Scheme 1, leading to formula **9** as the most favor-

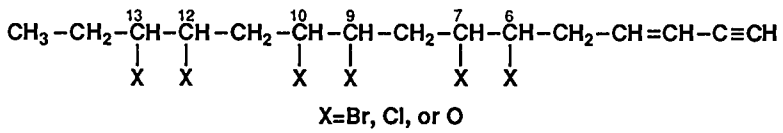

Fig. 2. Partial structure for notoryne (**9**).

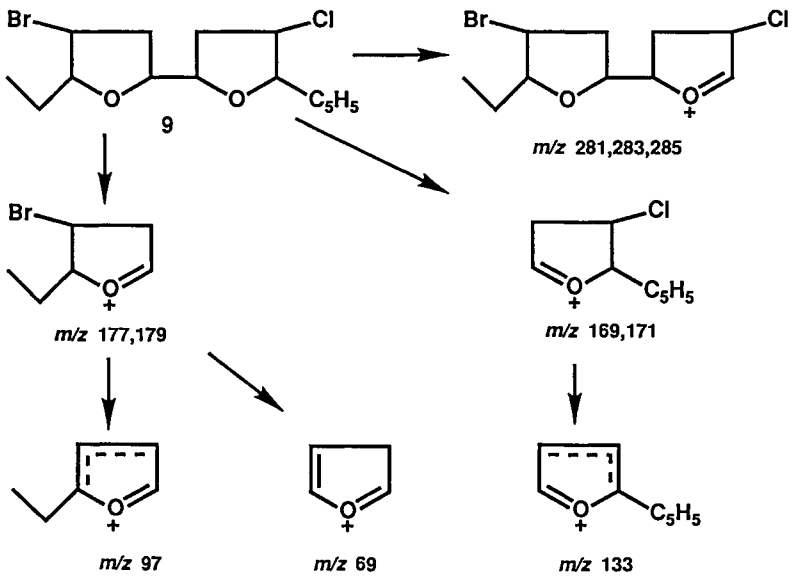
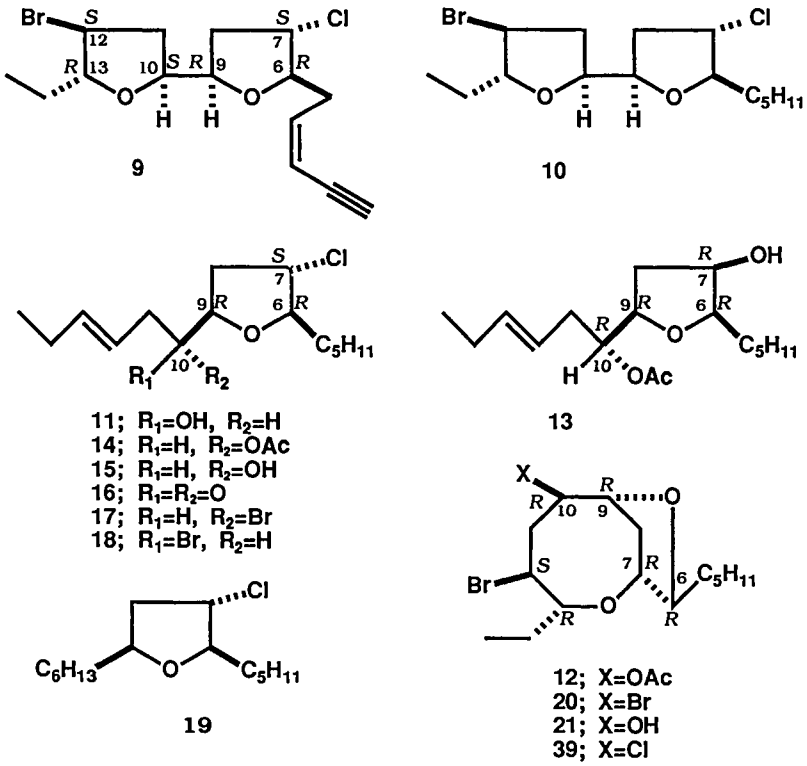
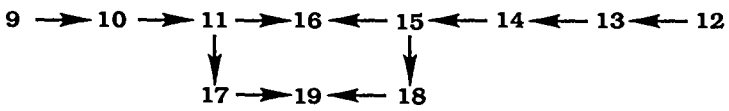


Scheme 1. The main fragmentation in the mass spectra of **9**.





Scheme 2. Chemical correlation of **9**.

able planar structure for notoryne. Confirmation of the structure was obtained by the following chemical correlation with known compound (Scheme 2).

Treatment of **10** with zinc and acetic acid in methanol gave a chloro alcohol **11**, $C_{15}H_{27}ClO_2$, ν_{max} 3550, 3430, 3030, and 970 cm^{-1}. The ^1H NMR spectrum of **11** revealed signals due to a *trans* double bond at δ=5.34 and 5.62 (each 1H, dt, J=15 and 6 Hz). The mass spectrum of **11** showed fragment ions at m/z 207, 205 (3:9; $M^+-C_5H_{11}$) and 177, 175 (4:14; $M^+-C_6H_{11}O$), suggesting **11** possesses an oxolane ring containing a chlorine atom, a C_5-side chain, and a C_6-side chain with a hydroxyl group.

On the other hand, the acetoxy alcohol **13**,[17,20] which was obtained by treatment of hexahydroacetyllaurefucin (**12**)[17,20] with zinc and acetic acid in methanol, was treated with carbon tetrachloride and triphenylphosphine in benzene to give a chloro acetate **14**, $C_{17}H_{29}ClO_3$, whose IR spectrum showed no hydroxyl absorption. This halogenation reaction with carbon tetrahalide and triphenylphosphine usually proceeds in the S_N2 manner with inversion of configuration.[21] Therefore, the configuration at C-7 in **13** must have been inverted from *R* to *S*. Saponification of **14** with potassium carbonate in methanol yielded the corresponding chloro alcohol **15**, $C_{15}H_{27}ClO_2$, whose spectral data showed a close resemblance to those of the chloro alcohol **11** derived from **9**. Collins oxidation of both the chloro alcohols, **11** and **15**, gave the same ketone **16**, $C_{15}H_{25}ClO_2$, thus indicating that the both chloro alcohols are an epimer of the hydroxyl group at C-10. This was confirmed by the following reactions.

On treatment with carbon tetrabromide and triphenylphosphine in benzene, a chloro alcohol **11** gave a bromochloro ether **17**, $C_{15}H_{26}BrClO$. On the other hand, another chloro alcohol **15** also gave a bromochloro ether **18** on bromination with carbon tetrabromide and triphenylphosphine. Both the halo ethers **17** and **18** afforded the same tetrahydrofuran derivative **19**, $C_{15}H_{29}ClO$, by Raney nickel reduction in ethanol, thus proving that the chiral centers at C-6, C-7, C-9, and C-10 of the chloro alcohol **11** should be represented by *R*-, *S*-, *R*-, and *S*-configuration, respectively. Thus the structure of notoryne can be assigned as formula **9** except for the configurations at C-12 and C-13, which are discussed later.

Previously Fukuzawa et al.[17] have observed that a dibromo compound **20**, which was obtained by the bromination of hexahydrolaurefucin (**21**) with thionyl bromide in ether, is converted into a rearranged product

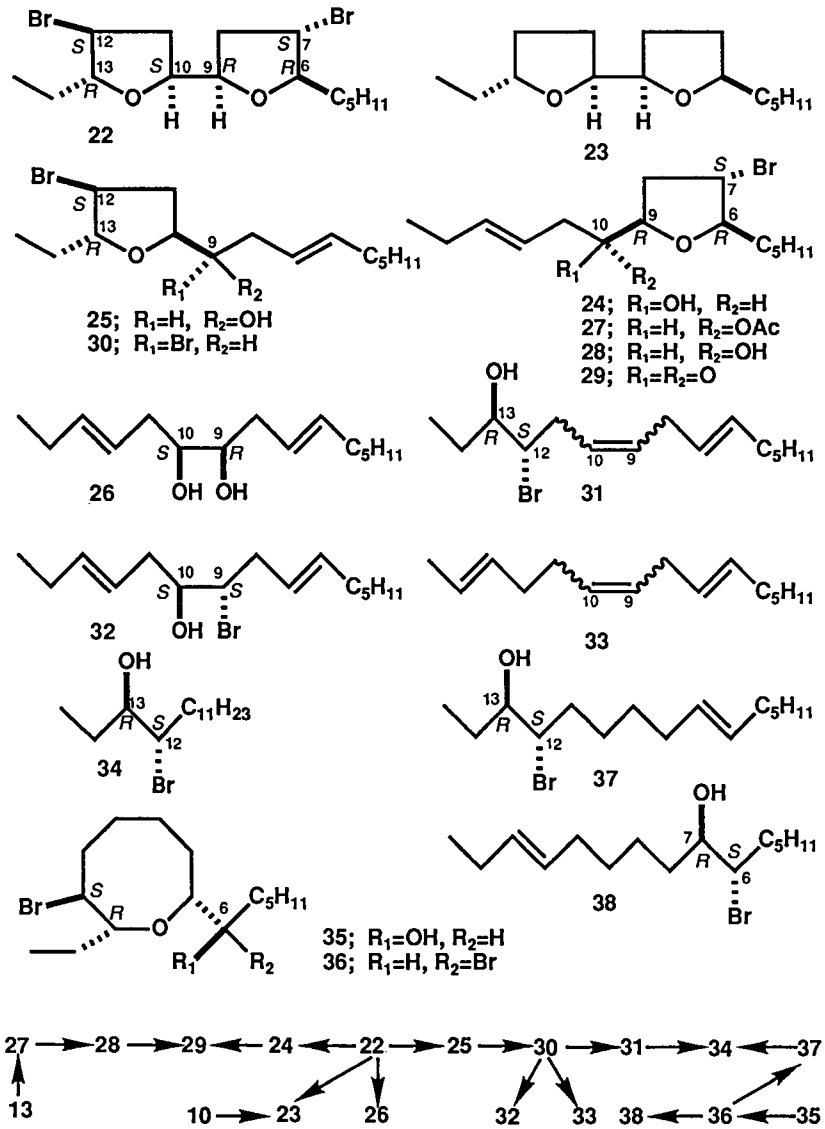
22, which has the same molecular formula of $C_{15}H_{26}Br_2O_2$ as that of **20**, on silica-gel column chromatography. The structure of this rearranged product **22** has long remained unresolved.

The spectral properties of **22** were very similar to those of hexahydronotoryne (**10**), suggesting that **22** possesses the same carbon skeleton, including an ethyl group, a pentyl group, and two bromine atoms, as that of **10**. This was confirmed by the following chemical derivation (Scheme 3).

Treatment of **10** with Raney nickel in refluxing ethanol gave a dehalogenated compound **23**, $C_{15}H_{28}O_2$. On the other hand, the rearranged product **22** was also treated with Raney nickel in ethanol at room temperature to afford a debrominated compound which was found to be identical with **23** in all respects. Above results indicated that the rearranged product **22** possesses the same stereochemistry at C-6, C-9, C-10, and C-13 as that of **10**. The locations of two bromine atoms and their stereochemistry as well as that at C-12 and C-13 were determined as follows.

Treatment of **22** with zinc and acetic acid in methanol gave two unsaturated bromo alcohols, **24** and **25**, which have the same molecular formula of $C_{15}H_{27}BrO_2$, and a glycol **26**[17,20] in 25, 49, and 16% yields, respectively. One of the bromo alcohols, compound **24** showed in its ^1H NMR spectrum the presence of two methyl groups, four methine groups, and a *trans* double bond. The mass spectrum of **24** exhibited significant fragment ions at 221, 219 ($M^+-C_6H_{11}O$) and 99 ($M^+-C_9H_{16}BrO$), arising from the C_9–C_{10} single bond cleavage. As shown in Scheme 3, the assigned structure **24** was confirmed by the correlation with the acetoxy alcohol **13** as in the case of compound **11** derived from hexahydronotoryne (**10**). Collins oxidation of **24** gave a bromo ketone **29**, which was identical with the ketone derived from **13** via a bromo acetate **27** and a bromo alcohol **28**.

Another bromo alcohol **25** also showed in its



Scheme 3. Chemical correlation of the rearranged product **22**.

^{1}H NMR spectrum the presence of two methyl groups, four methine groups, and a *trans* double bond. The mass spectrum of **25** showed significant fragment ions at 179, 177 ($M^+-C_9H_{17}O$) and 141 ($M^+-C_6H_{10}BrO$), which should also be generated by C_9–C_{10} bond cleavage. These data are consistent with the assigned structure **25**, except for the configurations at C-12 and C-13. The absolute configurations at C-12 and C-13 in **25** were established by the chemical correlation to laurencin (**1**).

Treatment of **25** with carbon tetrabromide and triphenylphosphine in benzene afforded a dibromo compound **30**, $C_{15}H_{26}Br_2O$, which was then treated with zinc and acetic acid in methanol to give three products, two of which were unsaturated bromohydrins **31** and **32**, $C_{15}H_{27}BrO$. Another reduction product was an unsaturated hydrocarbon **33**, $C_{15}H_{26}$. One of the unsaturated bromohydrins, compound **31**, which was found to be a mixture of (9*Z*)- and (9*E*)-isomer (ca. 2:3) by the ^{1}H NMR (400 MHz) spectrum, was hydrogenated with PtO_2 in ethanol to yield a saturated bromohydrin **34**, $C_{15}H_{31}BrO$.

On the other hand, octahydrodeacetyllaurencin (**35**)[6] was treated with carbon tetrabromide and triphenylphosphine in benzene to give a dibromide **36**, $C_{15}H_{28}Br_2O$,[22] which was then subjected to the reduction with zinc and acetic acid in methanol to afford two unsaturated bromohydrins **37** and **38**, $C_{15}H_{29}BrO$. One of the bromohydrins, compound **37** was subsequently hydrogenated with PtO_2 in ethanol to yield a saturated bromohydrin which was identical with the bromohydrin **34** in all respects, thus indicating that the absolute configurations at C-12 and C-13 in compound **25** are assigned as *S* and *R*, respectively. Therefore, it is concluded that the structure of the rearranged product must be represented by formula **22**, including the absolute configuration.

As already mentioned above, the configuration at C-13 of hexahydronotoryne (**10**) is the same as that of the rearranged product **22**, and hence the absolute configuration at C-13 of **10** is also assigned as *R*. The configuration at C-12 of **10** was deduced from the following evidence. In the 400 MHz ^{1}H NMR spectra, the signals due to the methine protons at C-12 in compounds **10** and **22** revealed the same chemical shift and splitting pattern at δ=3.86 (ddd, J=8.3, 7.3, and 6.8 Hz). Furthermore, compound **22**, on treatment with zinc and acetic acid in methanol, gave (12*E*)-olefin **24** as a sole product. Similarly, hexahydronotoryne (**10**) also afforded only (12*E*)-olefin **11** under the same reduction conditions as in the case of **22**. Since the degradation proceeds through E2 mechanism under *trans*-periplanar arrangement of the bromine atom at C-12 and the ethereal oxygen atom at C-13, the (12*E*)-double bond in **11** and **24** should arise from *erythro* configuration between C-12 and C-13. These findings strongly indicated that the absolute configuration at C-12 of hexahydronotoryne (**10**) is *S*, the same as that of **22**.

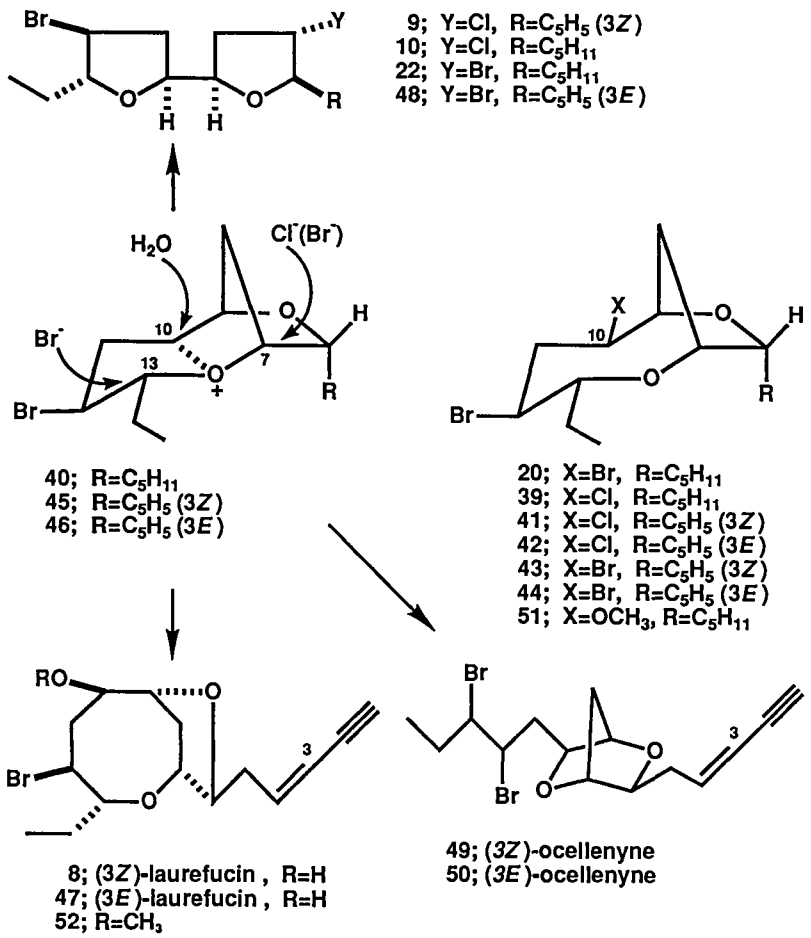
Accordingly, the structure of notoryne, including the absolute configuration, must be shown as formula **9**.

The structural similarity between hexahydronotoryne (**10**) and the rearranged product **22** suggested that a chloro compound **39**, when treated with silica gel, would give hexahydronotoryne (**10**). As anticipated, the chloro compound **39**, prepared from hexahydrolaurefucin (**21**) by chlorination with thionyl chloride in ether, afforded hexahydronotoryne (**10**) in quantitative yield when it was treated with activated silica gel[23] in hexane at room temperature for 24 h. Furthermore, on treatment with aluminum oxide (Merck, activity II-III) or silica gel (Merck, Kieselgel 60), the chloro compound **39** gave hexahydronotoryne (**10**) and hexahydrolaurefucin (**21**) in about 20 and 80% yields, respectively. On the other hand, on treatment with activated silica gel, the dibromo compound **20** gave the rearranged product **22** in almost quantitative yield. Moreover, compound **20** afforded hexahydrolaurefucin (**21**) in quantitative yield on treatment of aluminum oxide and also afforded **22** and **21** in 40 and 60% yields on treatment with silica gel.

The mechanism of the rearrangement reactions of compounds **20** and **39** would be explained by assuming that an oxonium ion may serve as an intermediate as shown in Scheme 4.

The stereochemistry of the bromine atom at C-10 of the dibromo compound **20** was unambiguously established as a β-oriented configuration by X-ray crystallographic analysis.[24] Since the close resemblance of the chemical shifts and multiplicities in the 400 MHz ^{1}H NMR spectra of **20** and **39** indicated that the configurations at C-10 and the ring conformations in **20** and **39** are nearly identical, the configuration at C-10 in **39** must be *R*. In **20** and **39**, the 2p orbital of the lone pair on the oxygen atom of the oxocane ring is situated close to the C–X (X=Br or Cl) bond at C-10 (about 2.81 Å in the crystalline state), the formation of an oxonium ion **40** can be rationalized by transannular participation of the ether oxygen. Reactions of the resulting oxonium ion **40** with bromide ion or chloride ion at C-7 position would lead to the rearranged product **22** or hexahydronotoryne (**10**), respectively. Furthermore, reaction of cation **40** with water at C-10 position would lead to hexahydrolaurefucin (**21**).

The isomerization reactions described above suggested that notoryne (**9**) could be an artifact generated during the course of the isolation procedure, in which aluminum oxide and silica gel have been used as the absorbent for chromatography. Thus the separation was carried out with high performance liquid chromatography (Finepak SIL-C_{18} with CH_3CN–H_2O (70:30)), under whose condition the synthetic **41**, prepared from (3*Z*)-laurefucin (**8**) by chlorination with thionyl chloride in ether, was unchanged. The HPLC of the neutral oil gave notoryne (**9**) and (3*Z*)-laurefucin (**8**) in ca. 5 and 18% yields, respectively. However, compound **41** could not be detected. Furthermore, the possibility that **9** was produced during the extraction procedure can be ruled out on the basis of the following evidence. Both



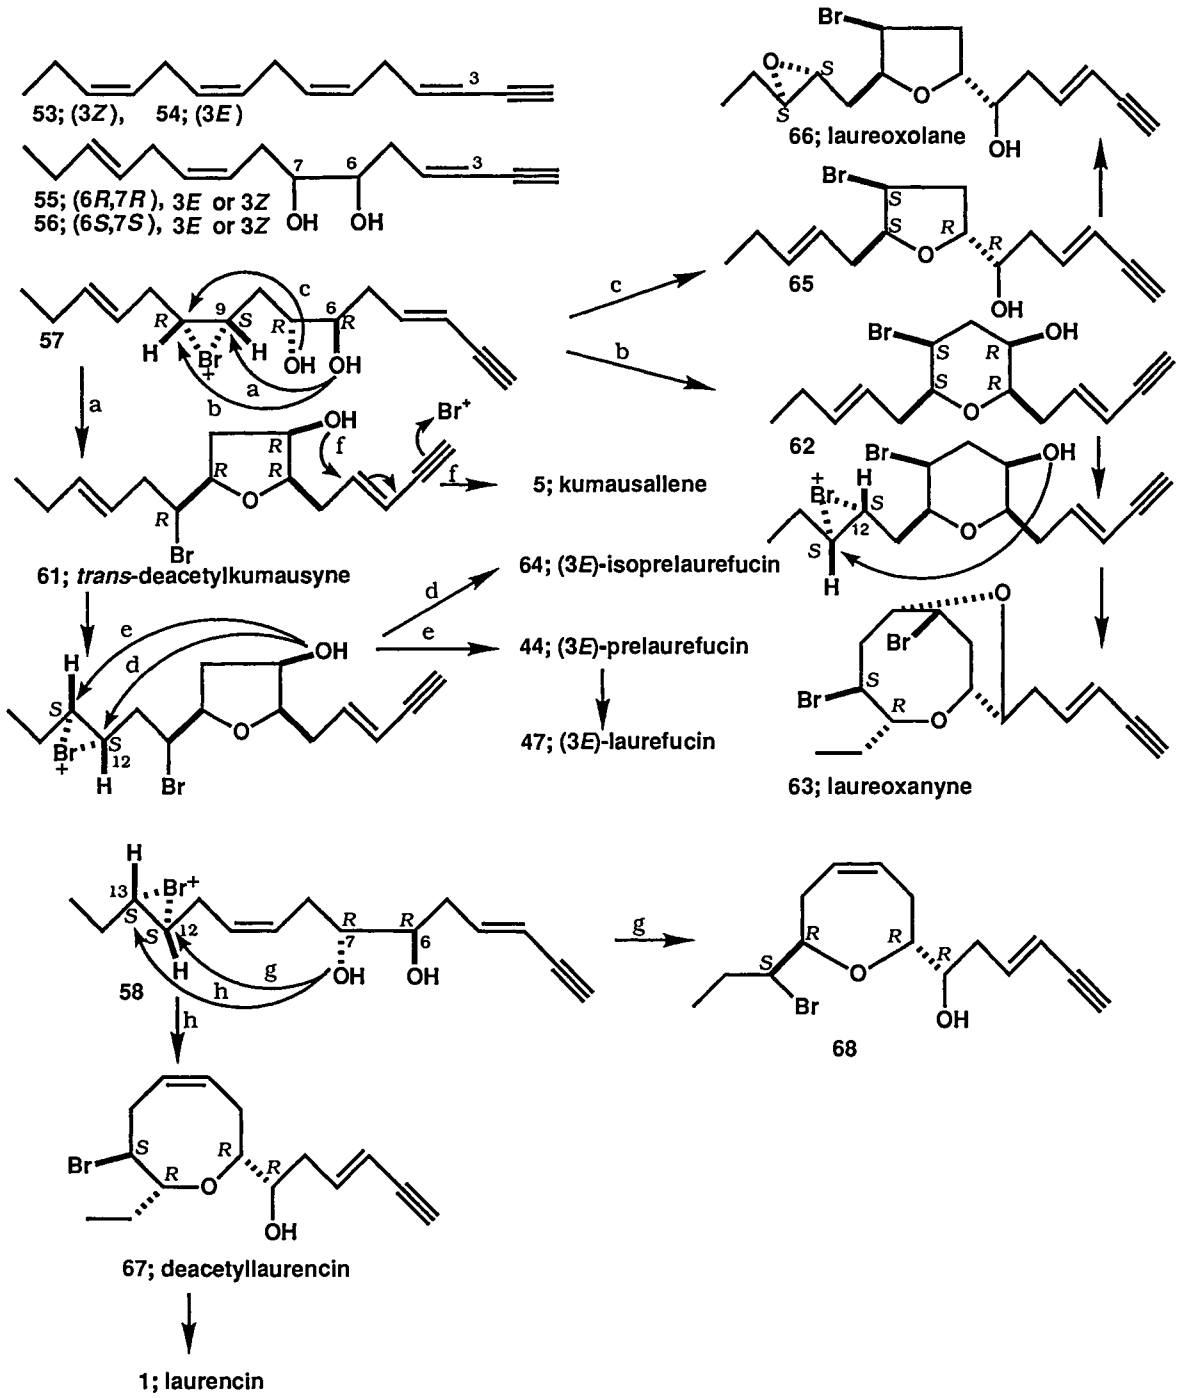
Scheme 4. Mechanism of the rearrangement reaction.

the compounds **20** and **39**, when treated with aqueous methanol, gave an *O*-methyl derivative which was identical with *O*-methylhexahydrolaurefucin (**51**) derived by hydrogenation from *O*-methyllaurefucin (**52**),[25] which has been isolated from the methanol extracts of *Laurencia nipponica* collected at several locations and must be an artifact formed during the extraction procedure. However, the neutral methanol extract of Notoro's specimen displayed the absence of *O*-methyllaurefucin (**52**). These results strongly indicate that notoryne (**9**) is a natural product.

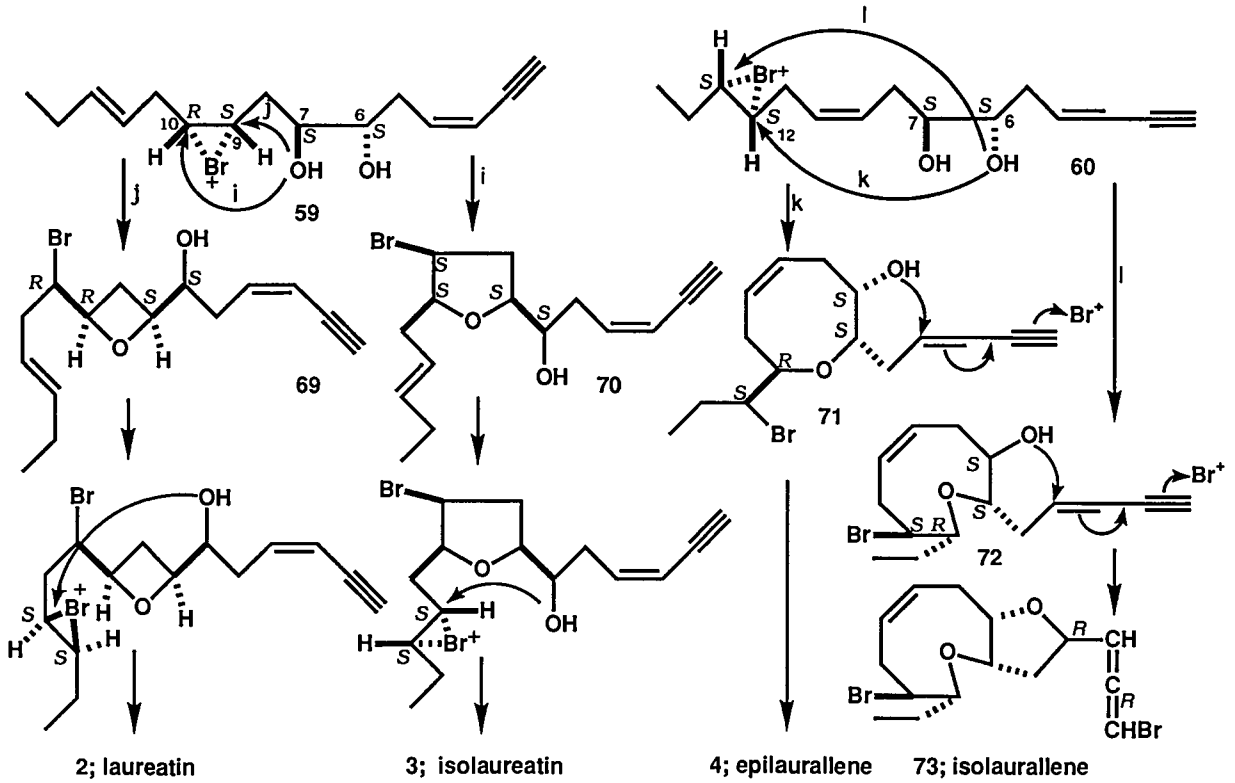
As shown in Scheme 4, notoryne (**9**) would be enzymatically synthesized from compound **41**, designated as (3*Z*)-neoprelaurefucin, via the oxonium ion **45** by attack of chloride ion at C-7. (3*Z*)-Neoprelaurefucin (**41**) and (3*E*)-neoprelaurefucin (**42**) may serve as the precursors of (3*Z*)-laurefucin (**8**) and (3*E*)-laurefucin (**47**), formed via cations **45** and **46** by attack of water at C-10, respectively. Furthermore, compounds **43** and **44**, designated as (3*Z*)-prelaurefucin and (3*E*)-prelaurefucin, could serve also as the precursors of **8** and **47**. *O*-Methyllaurefucin (**52**) (3*E*) would be formed via the oxonium ion **46** by attack of methanol at C-10. Both neoprelaurefucins, **41** and **42**, and prelaurefucins, **43** and **44**, phantasmal metabolites, have not been isolated from natural sources. On the other hand, (3*E*)-prelaurefucin (**44**) would give a dibromide **48**, which has not yet been isolated so far, via the cation **46** by attack of bromide ion at C-7 as in the case of notoryne (**9**). More recently, lauroxolane, which has the same molecular formula and the same carbon skeleton as those of **48**, has been isolated from *Laurencia majuscula* collected off the North Shore of Oahu, Hawaii.[26] A comparison of the spectral data of lauroxolane and those of the rearranged product **22** indicates that the relative stereochemistry of lauroxolane must be different from that of **22**. Furthermore, (3*Z*)-prelaurefucin (**43**) and (3*E*)-prelaurefucin (**44**) also seem to serve as the precursors of (3*Z*)- and (3*E*)-ocellenyne, **49** and **50**, which have previously been isolated from the sea hare *Aplysia oculifera*.[27] Ocellenynes would be formed via the oxonium ion **45** and **46** by attack of bromide ion at C-13.

The C_{15} nonterpenoids isolated from *L. nipponica*, whose major representatives are shown in Fig. 1, may be derived from laurencenyne (**53**)[28,30] or *trans*-laurencenyne (**54**)[29,30,5] via (6*R*,7*R*)- or (6*S*,7*S*)-laurediols, **55** (3*E* or 3*Z*) and **56** (3*E* or 3*Z*),[31] which have also been isolated from the same alga. As illustrated in Schemes 5 and 6, the formation of cyclic ethers with various ring size can be rationalized by the cyclization of the

(9*S*,10*R*)-bromonium ions, **57** and **59**, or (12*S*,13*S*)-bromonium ions, **58** and **60**, derived from laurediols. These bromonium ions may arise from laurediols by the addition of Br^+ generated from Br^- by bromoperoxidase[32,33] to the double bonds at C-9 or C-12. Reaction of the bromonium ion **57** (3*E*) (Scheme 5) with the hydroxyl group at C-6 would lead to the bromo ethers **61** and **62**. The former bromo ether **61** is *trans*-deacetylkumausyne.[12] The latter bromo ether **62**, which has not yet been found so far, may give laureoxanyne (**63**)[34] via (12*S*,13*S*)-bromonium ion. *trans*-Deacetylkumausyne (**61**) may further afford (3*E*)-prelaurefucin (**44**) and (3*E*)-isoprelaurefucin (**64**)[35,14] also via (12*S*,13*S*)-bromonium ion. Kumausallene (**5**) may also arise from *trans*-deacetylkumausyne (**61**) by bromonium ion-catalyzed cyclization. Furthermore, reaction of the bromonium ion **57** with the hydroxyl group at C-7 would give the bromo ether **65**, which must afford laureoxolane (**66**),[36] isolated from this alga as a minor component. Reaction of the bromonium ion **58** (3*E*) with the hydroxyl group at C-7 would lead to the formation of deacetyllaurencin (**67**)[6] and deacetyliso-



Scheme 5. Biogenesis from (6*R*,7*R*)-laurediols.



Scheme 6. Biogenesis from (6*S*,7*S*)-laurediols.

laurencin (**68**).[37]

On the other hand, on reaction with the hydroxyl group at C-7, the bromonium ion **59** (3*Z*) (Scheme 6) would give the bromo ethers **69** and **70**, from which laureatin (**2**)[7,9] and isolaureatin (**3**)[8,9] may be derived also via (12*S*,13*S*)-bromonium ions, respectively. Furthermore, reaction of the bromonium ion **60** with the hydroxyl group at C-6 would give two bromo ethers **71** and **72**. Epilaurallene (**4**)[10] or laurallene[38] may arise from the bromo ether **71** by bromonium ion-catalyzed cyclization. Similarly, the bromo ether **72** may give isolaurallene (**73**),[39] which has been isolated from this alga as a minor component.

Experimental

All the melting points were uncorrected. The IR spectra were measured on a JASCO A-102 spectrophotometer and the UV spectra on a Hitachi 124 or a Shimadzu UV-240 spectrophotometer. The ^{1}H NMR spectra were obtained in $CDCl_3$ as the solvent with TMS as the internal standard by using a JEOL JNM-FX-100, JNM-FX-400, or JNM-PS-100 spectrometer. The ^{13}C NMR spectra were recorded on a JEOL JNM-FX-100 spectrometer in $CDCl_3$ solution. The low and high resolution EI-MS spectra were measured on a JEOL JMS-D300 spectrometer, and the low FI-MS spectrum was taken with a JEOL JMS-OISG-2 spectrometer. Optical rotations were measured on a JASCO DIP-140 polarimeter in $CHCl_3$ solution. Aluminum oxide (Merck, activity II-III) and silica gel (Merck, Kieselgel 60, 70—230 mesh) were used for column chromatography. The high performance liquid chromatography (HPLC) was performed on a JASCO TRI-ROTAR using Finepak SIL-C_{18} column (JASCO).

Isolation. Half-dried alga (8 kg), which was collected at Notoro Point, near Abashiri, Hokkaido, in July 31, 1981, was extracted with MeOH and the neutral MeOH exrtract (59 g) obtained by the conventional methods was fractionated by column chromatography over standard alumina. The fraction eluted with hexane gave a mixture of hydrocarbons, which was repeatedly chromatographed on silica-gel column with hexane to yield isodihydrolaurene (2.5% of the neutral oil),[4] laurene (2.1%),[40] and *trans*-laurencenyne (0.7%).[29] The fraction eluted with benzene were further subjected to repeated column chromatography over silica gel with benzene to give nidificene,[13,41] (3*Z*)-laurediol acetate,[31] and crude notoryne which was purified by silica-gel column chromatography with hexane/benzene (1 : 3) to give pure notoryne (**9**) (5.0%). The fraction eluted with benzene/EtOAc (10 : 1) afforded debromoallolaurinterol (1.0%),[16,42] (3*Z*)-acetyllaurefucin (1.3%),[16] and (3*Z*)-7-acetyllaurediol (2.6%). The fraction eluted with EtOAc was further chromatographed on silica-gel column with benzene–EtOAc (1 : 1) to yield (3*Z*)-laurefucin (18%).[16]

Notoryne (9): Colorless oil; $[\alpha]_D$ +40.3° (*c* 1.03); UV (ethanol), λ_{max} 223 nm (ε 12500) and λ_{inf} 220 (ε 10300) and 231 nm (ε 9400); IR (neat), ν_{max} 3300, 3030, 2100, 1615, 1110, 1070, 1025, 970, 920, and 735 cm^{-1}, ^{1}H NMR (400 MHz) δ=1.00 (3H, t, *J*=7.3 Hz, H_3-15), 1.49 (1H, dqd, *J*=14.3, 7.3, 7.2 Hz, H-14), 1.76 (dqd, *J*=14.3, 7.3, 3.9 Hz, H-14), 2.17 (1H, ddd, *J*=13.2, 8.3, 8.3 Hz, H-11), 2.3 (2H, m, H_2-8), 2.59 (1H, dddd, *J*=14.8, 7.3, 7.0, 1.3 Hz, H-5), 2.66 (1H, ddd, *J*=13.2, 6.8, 6.8 Hz, H-11), 2.67 (1H, m, H-5), 3.13 (1H, dd, *J*=2.4, 0.8 Hz, H-1), 3.88 (1H, ddd, *J*=8.3, 7.3, 6.8 Hz, H-12), 3.91 (1H, ddd,

J=7.3, 7.2, 3.9 Hz, H-13), 3.98 (1H, ddd, J=8.3, 6.8, 5.5 Hz, H-10), 4.1 (2H, m, H-6 and H-7), 4.26 (1H, ddd, J=7.3, 7.3, 5.5 Hz, H-9), 5.60 (1H, dddd, J=10.8, 2.4, 1.3, 1.3 Hz, H-3), and 6.08 (1H, dddd, J=10.8, 7.3, 7.3, 0.8 Hz, H-4); ^{13}C NMR (25.0 MHz) δ=10.0 (q, C-15), 25.4 (t, C-14), 34.3 (t, C-5), 38.0 (t, C-11 or C-8), 39.3 (t, C-8 or C-11), 47.2 (d, C-12), 59.1 (d, C-7), 78.8 (d, C-13 or C-6), 79.8 (s, C-2), 79.9 (d, C-6 or C-13), 82.1 (d, C-1), 85.9 (d, C-9 or C-10), 87.0 (d, C-10 or C-9), 110.8 (d, C-3), and 139.5 (d, C-4); EI-MS (70 eV) m/z (rel intensity) 313, 311 (0.3:0.3; M^+−Cl), 285, 283, 281 (5:21:16; M^+−C_5H_5), 284, 282 (1:1; M^+−Cl−C_2H_5), 201 (3; M^+−HBr−HCl−C_2H_5), 179, 177 (3:3; M^+−$C_9H_{10}ClO$), 135 (16), 133 (100; M^+−$C_6H_{10}BrO$−HCl), 105 (14), 97 (47; M^+−$C_9H_{10}ClO$−HBr), 69 (36; M^+−$C_9H_{10}ClO$−Br−C_2H_5), 55 (8), and 41 (17); FI-MS (70 eV), m/z 350, 348, 346 (27:63:43; M^+), 285, 283, 281 (32:100:84; M^+−C_5H_5), 284, 282 (16:16; M^+−Cl−C_2H_5), 269, 267 (6:13; M^+−Br), 179, 177 (45:45; M^+−$C_9H_{10}ClO$), and 171, 169 (3:10; M^+−$C_6H_{10}BrO$). Found: m/z 282.9923. Calcd for $C_{10}H_{15}{}^{81}Br^{35}ClO_2$: M−$C_5H_5$, 282.9923.

Hydrogenation of Notoryne (9). The hydrogenation of **9** (12 mg) was performed in EtOH over PtO_2-catalyst to give an oily product which was chromatographed on silica-gel column with hexane–benzene (2:1) to afford hexahydronotoryne (**10**) (12 mg); colorless oil; $[\alpha]_D$ +52.6° (c 0.980); IR (neat), ν_{max} 1290, 1120, 1100, 1070, 1030, 970, 925, 790, and 740 cm^{-1}; ^{1}H NMR (400 MHz) δ=0.89 (3H, br t, J=6.8 Hz), 1.00 (3H, t, J=7.3 Hz), 1.2—1.6 (9H, m), 1.75 (1H, dqd, J=15.0, 7.3, 4.4 Hz), 2.13 (1H, ddd, J=13.2, 8.3, 8.3 Hz), 2.23 (2H, dd, J=7.3, 5.9 Hz), 2.65 (1H, ddd, J=13.2, 6.8, 6.8 Hz), 3.86 (1H, ddd, J=8.3, 7.3, 6.8 Hz), 3.8—4.0 (4H, m), and 4.22 (1H, ddd, J=7.3, 7.3, 5.4 Hz); EI-MS (70 eV), m/z 318, 316 (0.2:0.2; M^+−HCl), 274, 272 (0.1:0.3; M^+−HBr), 179, 177 (9:9; M^+−$C_9H_{16}ClO$), 177, 175 (8:25; M^+−$C_6H_{10}BrO$), 139 (37; M^+−HCl−$C_6H_{10}BrO$), 121 (12), 97 (100; M^+−$C_9H_{10}ClO$−HBr), 95 (15), 69 (40; M^+−$C_9H_{16}OCl$−Br−C_2H_5), 55 (14), and 41 (23).

Conversion of Hexahydronotoryne (10) into 11. To a solution of **10** (20 mg) and AcOH (80 μl) in MeOH (1 ml) was added activated Zn-dust (150 mg), and the mixture was stirred for 21 h at room temperature under N_2 atmosphere. After being filtered off and evaporated, the mixture was extracted with ether. The ethereal solution was washed successively with water, 5% aqueous $NaHCO_3$, and water. After drying over Na_2SO_4, the solvent was evaporated to give a residual oil which was purified by column chromatography over silica gel with hexane–benzene (1:3) to yield **11** (15 mg); oil; $[\alpha]_D$ +31.6° (c 0.530); IR (neat), ν_{max} 3550, 3430, 3030, 1280, 1120, 1065, 1045, 1020, and 970 cm^{-1}; ^{1}H NMR (100 MHz) δ=0.89 (3H, br t, J=6 Hz), 0.98 (3H, t, J=7 Hz), 1.1—1.8 (8H, m), 1.99 (1H, d, J=2 Hz, OH), 1.8—2.6 (6H, m), 3.79 (1H, dddd, J=7, 7, 4, 2 Hz), ca. 4.0 (2H, m), 4.11 (1H, ddd, J=8, 6, 4 Hz), 5.34 (1H, dt, J=15, 6 Hz), and 5.62 (1H, dt, J=15, 6 Hz); EI-MS (70 eV), m/z 276, 274 (1:3; M^+), 239 (21; M^+−Cl), 221 (11), 207, 205 (3:9; M^+−C_5H_9), 177, 175 (4:14; M^+−$C_6H_{11}O$), 153 (17), 139 (20; M^+−$C_6H_{11}O$−HCl), 121 (38), 99 (8: M^+−$C_9H_{16}ClO$), 95 (74), 83 (31), 81 (41), 70 (21), 69 (M^+−$C_6H_{11}O$−Cl−C_5H_{11}), 67 (28), 57 (20), 55 (95), 43 (32), and 41 (100).

Chlorination of 13 into 14. A solution of **13**[17,20] (73 mg) in dry carbon tetrachloride (1 ml) was refluxed with triphenylphosphine (81 mg) for 23 h in N_2 atmosphere and then cooled. The subsequent removal of the solvent gave an oily substance which was chromatographed over silica gel with hexane–benzene (1:1) to afford **14** (46 mg); oil; $[\alpha]_D$ +23.2° (c 0.860); IR (neat), ν_{max} 3030, 1740, 1240, 1095, 1065, 1035, 970, 945, and 710 cm^{-1}; ^{1}H NMR (100 MHz) δ=0.89 (3H, br t, J=7 Hz), 0.95 (3H, t, J=7 Hz), 1.1—1.7 (8H, m), 1.7—2.7 (6H, m), 2.07 (3H, s), 3.95 (2H, m, W_H=13 Hz), 4.24 (1H, ddd, J=8, 8, 5 Hz), 4.86 (1H, ddd, J=7, 6, 5 Hz), 5.32 (1H, dt, J=16, 7 Hz), and 5.57 (1H, dt, J=16, 6 Hz); EI-MS (70 eV), m/z 318, 316 (0.1:0.3; M^+), 281 (0.7; M^+−Cl), 258, 256 (1:3; M^+−CH_3COOH), 229 (3), 221 (50; M^+−Cl−CH_3COOH), 177, 175 (1:3; M^+−$C_8H_{13}O_2$), 153 (66), 139 (4; M^+−HCl−$C_8H_{13}O_2$), 121 (14), 95 (19), 83 (7), 82 (9), 81 (17), 69 (15; M^+−$C_8H_{13}O_2$−Cl−C_5H_{11}), 67 (8), 55 (17), 43 (100), and 41 (19).

Saponification of 14 into 15. A solution of **14** (18 mg) and K_2CO_3 (50 mg) in MeOH (0.5 ml) was stirred for 1.5 h at room temperature under N_2 atmosphere, then water was added, and most of MeOH was evaporated in vacuo. The mixture was then extracted with ether and the ethereal solution was washed with saturated brine and dried over Na_2SO_4. After removal of the solvent, the residual oil was chromatographed over silica gel with hexane–benzene (1:3) to yield **15** (15 mg); oil; $[\alpha]_D$ +28.9° (c 0.830); IR (neat), ν_{max} 3550, 3430, 3030, 1280, 1120, 1090, 1060, 1040, 970, and 720 cm^{-1}; ^{1}H NMR (100 MHz) δ=0.89 (3H, br t, J=6 Hz), 0.98 (3H, t, J=7Hz), 1.1—1.8 (8H, m), 2.10 (1H, d, J=6 Hz, OH), 1.8—2.5 (6H, m), 3.47 (1H, dddd, J=6, 6, 6, 6 Hz), 3.98 (2H, m), 4.09 (1H, ddd, J=9, 7, 5 Hz), 5.40 (1H, dt, J=16, 6 Hz), and 5.45 (1H, dt, J=16, 6 Hz); EI-MS (70 eV), m/z 276, 274 (1:3; M^+), 239 (5; M^+−Cl), 221 (4; M^+−H_2O−Cl), 207, 205 (12:37; M^+−C_5H_9), 177, 175 (2:6; M^+−$C_6H_{11}O$), 169 (4; M^+−C_5H_9−HCl), 139 (8; M^+−HCl−$C_6H_{11}O$), 121 (28), 95 (68), 93 (14), 82 (24), 80 (46), 70 (31), 69 (67; M^+−$C_6H_{11}O$−Cl−C_5H_{11}), 67 (26), 57 (16), 55 (100), 42 (26), and 41 (68).

Collins Oxidation of 11 into the Chloro Ketone 16. Collins oxidation of **11** (12 mg) was carried out with dry chromium trioxide (30 mg) in dry pyridine (46 μl) and dry CH_2Cl_2 (1 ml) by the usual method to give an oily substance which was chromatographed over silica gel with hexane–benzene (1:3) to give **16** (9 mg); oil; $[\alpha]_D$ +85.0° (c 0.367); IR (neat), ν_{max} 3030, 1715, 1305, 1300, 1115, 1075, 1045, and 970 cm^{-1}; ^{1}H NMR (100 MHz) δ=0.90 (3H, br t, J=6 Hz), 0.99 (3H, t, J=7 Hz), 1.1—1.8 (8H, m), 2.1 (2H, m), 2.40 (2H, m), 3.30 (2H, br d, J=5 Hz), 3.8—4.2 (2H, m), 4.58 (1H, t, J=8 Hz), and 5.3—5.8 (2H, m); EI-MS (70 eV), m/z 274, 272 (0.7:2; M^+), 237 (1; M^+−Cl), 210 (7), 177, 175 (20:91; M^+−C_6H_9O), 139 (36; M^+−C_6H_9O−HCl), 121 (90), 95 (100), 93 (26), 80 (13), 78 (18), 69 (70; M^+−C_6H_9O−Cl−C_5H_{11}), 67 (20), 55 (74), 43 (22), and 41 (74).

Collins Oxidation of 15 into the Chloro Ketone 16. Collins oxidation of **15** (15 mg) was carried out in the same conditions as that in the case of the oxidation of **11** to afford, after the purification by means of silica-gel chromatography, a ketone (12 mg) which was identical with the chloro ketone **16** in all respects (IR, ^{1}H NMR, MS, and specific rotation).

Bromination of 11 into 17. A solution of **11** (20 mg) in dry benzene (2 ml) was refluxed with triphenylphosphine (40 mg) and carbon tetrabromide (50 mg) for 30 min in N_2 atmosphere. The subsequent removal of the solvent gave a residual substance which was subjected to column chromatography over silica gel with hexane to yield **17** (11 mg); mp 122—123 °C (diisopropyl ether); $[\alpha]_D$ +27.6° (c 0.808); IR ($CHCl_3$), ν_{max} 3030, 1665, 1120, 1095, 1070, 1040, 1020, 970, and 925 cm^{-1}; ^{1}H NMR (100 MHz) δ=0.89 (3H, br t, J=6 Hz), 0.98 (3H, t, J=7 Hz), 1.1—1.8 (8H, m), 2.0—2.8 (6H, m), 3.8—4.1 (3H, m), 4.27 (1H, ddd, J=7, 7, 4 Hz), 5.42 (1H, dt, J=15, 6 Hz),

and 5.63 (1H, dt, J=15, 5 Hz); EI-MS (70 eV), m/z 340, 338, 336 (1:3:3; M^+), 303, 301 (12:12; M^+-Cl), 270, 268, 266 (1:3:3; $M^+-C_5H_9-H$), 259, 257 (3:9; M^+-Br), 221 (9: $M^+-Cl-Br-H$), 177, 175 (3:10; $M^+-C_6H_{10}Br$), 139 (7; $M^+-C_6H_{10}Br-HCl$), 121 (23), 111 (18), 107 (22), 95 (74), 83 (39), 81 (21), 79 (22), 69 (78; $M^+-C_6H_{10}Br-Cl-C_5H_{11}$), 67 (39), 55 (100), and 41 (97).

Bromination of 15 into 18. A solution of **15** (16 mg) in dry benzene (3 ml) was refluxed with triphenylphosphine (32 mg) and carbon tetrabromide (40 mg) for 30 min in N_2 atmosphere. After removal of the solvent, a residual oil was subjected to a column chromatography over silica gel with hexane to afford **18** (18 mg); oil; $[\alpha]_D$ +26.9° (c 1.77); IR (neat), ν_{max} 3030, 1660, 1120, 1080, 1065, 1030, 970, 920, 720, and 705 cm^{-1}; ^1H NMR (100 MHz) δ=0.89 (3H, br t, J=6 Hz), 0.99 (3H, t, J=7 Hz), 1.1—2.8 (14H, m), 3.7—4.1 (3H, m), 4.22 (1H, ddd, J=7, 7, 7 Hz), 5.41 (1H, dt, J=15, 6 Hz), and 5.62 (1H, dt, J=15, 5 Hz); EI-MS (70 eV), m/z 340, 338, 336 (1:3:3; M^+), 303, 301 (15:15; M^+-Cl), 259, 257 (3:9; M^+-Br), 258, 256 (1:3; M^+-HBr), 221 (11; $M^+-Cl-Br-H$), 177, 175 (3:10; $M^+-C_6H_{10}Br$), 151 (25), 139 (7; $M^+-C_6H_{10}Br-HCl$), 121 (22), 107 (23), 95 (59), 83 (26), 81 (23), 79 (22), 69 (55; $M^+-C_6H_{10}Br-Cl-C_5H_{11}$), 55 (100), and 41 (94).

Conversion of 17 into 19. To a solution of **17** (10 mg) in EtOH (1 ml) was added W-7 Raney nickel freshly prepared from Al-Ni alloy (2 g), and the mixture was stirred for 17 h at room temperature. After removal of the Ni, the solvent was evaporated to leave a residual oil which was chromatographed on column chromatography over silica gel with hexane-benzene (4:1) to give a chrolo ether **19** (5 mg); oil; $[\alpha]_D$ +21.6° (c 0.190); IR (neat), ν_{max} 1280, 1245, 1120, 1090, 1070, 925, and 720 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, J=6 Hz), 0.89 (3H, br t, J=6 Hz), 1.1—1.8 (18H, m), 1.7—2.3 (2H, m), and 3.7—4.2 (3H, m); EI-MS (70 eV), m/z 262, 260 (0.1:0.3; M^+), 191, 189 (3:9; $M^+-C_5H_{11}$), 177, 175 (30:100; $M^+-C_6H_{13}$), 139 (14; $M^+-C_6H_{13}-HCl$), 135 (23), 121 (24), 95 (36), 83 (30), 69 (54; $M^+-C_5H_{11}-C_6H_{13}-Cl$), 55 (75), 43 (42), and 41 (38).

Conversion of 18 into 19. To a solution of **18** (21 mg) in EtOH (1 ml) was added W-7 Raney nickel freshly prepared from Al-Ni alloy (2 g), and the mixture was stirred for 17 h at room temperature. After worked up as usual, the resulting oil was purified by silica-gel column chromatography with hexane-benzene (4:1) to yield an ether (10 mg) which was identical with the chloro ether **19** in all respects.

Rearranged Product 22: Oil; $[\alpha]_D$ +49.6° (c 1.02); IR (neat), ν_{max} 1290, 1205, 1200, 1115, 1095, 1065, 1030, 1000, 970, 920, 780, and 740 cm^{-1}; ^1H NMR (400 MHz) δ=0.89 (3H, br t, J=6.8 Hz), 1.00 (3H, t, J=7.3 Hz), 1.2—1.7 (9H, m), 1.75 (1H, dqd, J=15.1, 7.3, 3.9 Hz), 2.18 (1H, ddd, J=13.2, 8.3, 8.3 Hz), 2.33 (2H, dd, J=6.8, 6.8 Hz), 2.65 (1H, ddd, δ=13.2, 6.8, 6.8 Hz), 3.86 (1H, ddd, J=8.3, 7.3, 6.8 Hz), 3.8—4.0 (3H, m), 4.06 (1H, ddd, J=7.3, 4.9, 4.9 Hz), and 4.21 (1H, ddd, J=6.8, 6.8, 5.7 Hz); EI-MS (70 eV), m/z 371, 369, 367 (0.3:0.6:0.3; $M^+-C_2H_5$), 329, 327, 325 (0.7:1.4:0.7; $M^+-C_5H_{11}$), 319, 317 (1:1; M^+-Br), 318, 316 (1:1; M^+-HBr), 247, 245 (1:1; $M^+-C_5H_{11}-HBr$), 221, 219 (10:10; $M^+-C_6H_{10}BrO$), 179, 177 (14:14; $M^+-C_9H_{16}BrO$), 139 (95; $M^+-C_6H_{10}BrO-HBr$), 121 (25), 97 (100; $M^+-C_9H_{16}BrO-HBr$), 95 (26), 69 (60; $M^+-C_9H_{16}BrO-Br-C_5H_{11}$), 55 (20), and 41 (31). Found: m/z 370.9845. Calcd for $C_{13}H_{21}{}^{81}Br_2O_2$: $M-C_2H_5$, 370.9867.

Conversion of 10 into 23. To a solution of **10** (18 mg) in EtOH (3 ml) was added W-7 Raney nickel freshly prepared from Al-Ni alloy (2 g), and the mixture was refluxed for 3.5 h. After worked up as usual, the resulting oil was purified by silica-gel column chromatography with hexane-benzene (1:3) to yield a dehalogenated ether **23** (10 mg); oil; $[\alpha]_D$ −14.5° (c 0.518); IR (neat), ν_{max} 1090, 1070, 1040, and 930 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, J=7 Hz), 0.90 (3H, t, J=7 Hz), 1.1—2.0 (16H, m), 1.9—2.1 (2H, m), and 3.7—4.0 (4H, m); EI-MS (70 eV), m/z 240 (0.2; M^+), 211 (1; $M^+-C_2H_5$), 169 (1; $M^+-C_5H_{11}$), 141 (43; $M^+-C_6H_{11}O$), 140 (11; $M^+-C_2H_5-C_5H_{11}$), 123 (46), 99 (79; $M^+-C_9H_{17}O$), 98 (23), 81 (100), 67 (14), and 55 (37).

Conversion of 22 into 23. To a solution of **22** (18 mg) in EtOH (2 ml) was added W-7 Raney nickel freshly prepared from Al-Ni alloy (2 g), and the mixture was stirred for 1.5 h at room temperature. After worked up as usual, the residual oil was purified by silica-gel column chromatography with hexane-benzene (1:3) to give a debrominated ether (11 mg) which was identical with the ether **23** in all respects.

Partial Degradation of 22. To a solution of **22** (257 mg) and AcOH (400 μl) in MeOH (5 ml) was gradually added activated zinc dust (800 mg) with stirring for 2.5 h at room temperature under N_2 atmosphere. After the usual work-up, the resulting oil was subjected to column chromatography over silica gel with hexane-benzene (2:1) to afford three products, **24** (52 mg), **25** (101 mg), and **26** (24 mg).

24: Oil; $[\alpha]_D$ +28.5° (c 1.12); IR (neat), ν_{max} 3560, 3430, 3030, 1280, 1120, 1080, 1065, 1045, 1025, 970, and 925 cm^{-1}; ^1H NMR (100 MHz) δ=0.89 (3H, br t, J=6 Hz), 0.98 (3H, t, J=7 Hz), 1.1—1.8 (8H, m), 2.01 (1H, d, J=3 Hz; OH), 2.0—2.3 (5H, m), 2.50 (1H, ddd, J=14, 8, 8 Hz), 3.80 (1H, dddd, J=7, 7, 4, 3 Hz), 3.8—4.2 (3H, m), 5.38 (1H, dt, J=15, 6 Hz), and 5.62 (1H, dt, J=15, 5 Hz); EI-MS (70 eV), m/z 320, 318 (1:1; M^+), 302, 300 (0.5:0.5; M^+-H_2O), 251, 249 (2:2; $M^+-C_5H_9$), 250, 248 (2:2; $M^+-C_5H_9-H$), 239 (12; M^+-Br), 221 (12; M^+-H_2O-Br), 221, 219 (3:3; $M^+-C_6H_{11}O$), 169 (5; $M^+-C_5H_9-HBr$), 151 (25), 139 (37; $M^+-C_6H_{11}O-HBr$), 121 (32), 99 (9; $M^+-C_9H_{16}BrO$), 95 (52), 83 (21), 81 (44; $M^+-C_9H_{16}BrO-H_2O$), 69 (66; $M^+-C_6H_{11}O-Br-C_5H_{11}$), 67 (23), 57 (14), 55 (100), 43 (23), and 41 (70).

25: Mp 36—37 °C (hexane); $[\alpha]_D$ +6.50° (c 1.00); IR (Nujol), ν_{max} 3560, 3440, 3030, 1320, 1300, 1290, 1110, 1080, 1070, 1020, 980, 970, 935, and 920 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, J=7 Hz), 1.00 (3H, t, J=7 Hz), 1.1—1.9 (8H, m), 2.04 (1H, d, J=2 Hz; OH), 1.9—2.7 (6H, m), 3.7—4.1 (4H, m), 5.36 (1H, dt, J=15, 6 Hz), and 5.57 (1H, dt, J=15, 6 Hz); EI-MS (70 eV), m/z 320, 318 (1:1; M^+), 302, 300 (1:1; M^+-H_2O), 263, 261 (0.3:0.3; $M^+-C_4H_9$), 245, 243 (0.3:0.3; $M^+-H_2O-C_4H_9$), 239 (3; M^+-Br), 221 (8; M^+-Br-H_2O), 209, 207 (3:3; $M^+-C_8H_{15}$), 181 (2; $M^+-HBr-C_4H_9$), 179, 177 (4:4; $M^+-C_9H_{17}O$), 149, 147 (2:2; $M^+-C_9H_{17}O-C_2H_5-H$), 141 (2; $M^+-C_6H_{10}BrO$), 97 (65; $M^+-C_9H_{17}O-HBr$), 81 (17), 69 (100; $M^+-C_9H_{17}O-Br-C_2H_5$), 55 (16), and 41 (27).

26: Mp 95—96 °C (diisopropyl ether); $[\alpha]_D$ −3.90° (c 1.04); IR (Nujol), ν_{max} 3300, 3200, 3030, 1045, 970, and 965 cm^{-1}; ^1H NMR (100 MHz) δ=0.89 (3H, br t, J=7 Hz), 0.99 (3H, t, J=7 Hz), 1.1—1.6 (6H, m), 2.2 (2H, br d, J=3 Hz; OH×2), 1.7—2.4 (8H, m), 3.63 (2H, m), 5.40 (2H, dt, J=15, 6 Hz), 5.61 (1H, dt, J=15, 6 Hz), and 5.65 (1H, dt, J=15, 5 Hz); EI-MS (70 eV), m/z 240 (1; M^+), 222 (2; M^+-H_2O), 204 (1; $M^+-H_2O\times2$), 171 (4; $M^+-C_5H_9$), 165 (1; $M^+-C_4H_9-H_2O$), 153 (8; $M^+-C_5H_9-H_2O$), 129 (5; $M^+-C_8H_{15}$), 111 (16; $M^+-C_7H_{13}O_2$), 93 (12), 81 (23), 79 (29), 70 (19; $M^+-C_6H_{11}O-C_5H_{11}$), 69 (96; $M^+-C_{10}H_{19}O_2$), 67 (19), 57 (19), 55 (100), 43 (19), and 41 (39).

Bromination of 13 into 27. A solution of **13** (88 mg) in dry

benzene (5 ml) was refluxed with triphenylphosphine (155 mg) and carbon tetrabromide (196 mg) for 1 h in N_2 atmosphere. After removal of the solvent, the residual oily substance was subjected to column chromatography on silica gel with hexane–benzene (1 : 1) to afford **27** (106 mg); oil; $[\alpha]_D$ +26.1° (*c* 1.21); IR (neat), ν_{max} 3030, 1740, 1235, 1120, 1090, 1035, 970, and 945 cm^{-1}; ^1H NMR (100 MHz) δ=0.89 (3H, br t, *J*=6 Hz), 0.95 (3H, t, *J*=7 Hz), 1.1—2.5 (14H, m), 2.06 (3H, s), 3.96 (2H, m), 4.24 (1H, ddd, *J*=8, 8, 5 Hz), 4.87 (1H, ddd, *J*=7, 6, 5 Hz), 5.32 (1H, dt, *J*=15, 6 Hz), and 5.58 (1H, dt, *J*=15, 5 Hz); EI-MS (70 eV), *m/z* 362, 360 (0.2 : 0.2; M^+), 302, 300 (2 : 2; M^+-CH_3COOH), 221 (64; $M^+-CH_3COOH-Br$), 153 (29), 139 (14; $M^+-C_8H_{13}O_2-HBr$), 121 (13), 111 (22), 95 (16), 81 (13), 80 (13), 69 (28; $M^+-C_8H_{13}O_2-Br-C_5H_{11}$), 55 (22), 43 (100), and 41 (17).

Saponification of 27 into 28. A solution of **27** (31 mg) and K_2CO_3 (100 mg) in MeOH (1 ml) was stirred for 1.5 h at room temperature under N_2 atmosphere. After the usual work-up, the resulting oily substance was chromatographed on silica-gel column with hexane–benzene (1 : 3) to yield **28** (25 mg); oil; $[\alpha]_D$ +32.4° (*c* 1.14); IR (neat), ν_{max} 3540, 3430, 3030, 1120, 1090, 1055, 1035, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.90 (3H, br t, *J*=6 Hz), 0.98 (3H, t, *J*=7 Hz), 1.1—2.6 (14H, m), 2.12 (1H, d, *J*=6 Hz; OH), 3.48 (1H, dddd, *J*=6, 6, 6, 6 Hz), 3.7—4.2 (3H, m), 5.42 (1H, dt, *J*=15, 6 Hz), and 5.62 (1H, dt, *J*=15, 5 Hz); EI-MS (70 eV), *m/z* 320, 318 (1 : 1; M^+), 251, 249 (26 : 26; $M^+-C_5H_9$), 239 (13; M^+-Br), 221 (15; M^+-H_2O-Br), 169 (27; $M^+-C_5H_9-HBr$), 151 (16), 139 (31; $M^+-C_6H_{11}O-HBr$), 133 (10), 123 (13), 121 (31), 95 (71), 83 (27), 81 (58; $M^+-C_9H_{16}BrO$), 70 (34), 69 (87; $M^+-C_6H_{11}O-Br-C_5H_{11}$), 67 (32), 57 (27), 55 (100), 43 (37), and 41 (85).

Collins Oxidation of 24 into the Bromo Ketone 29. Collins oxidation of **24** (12 mg) was carried out with dry chromium trioxide (31 mg) and dry pyridine (50 μl) in dry CH_2Cl_2 (1.2 ml) under the same conditions as that in the case of the oxidation of **11** to give an oily substance which was purified by silica-gel column chromatography with hexane–benzene (3 : 1) to yield **29** (10 mg); oil; $[\alpha]_D$ +66.3° (*c* 0.563); IR (neat), ν_{max} 3030, 1720, 1300, 1115, 1070, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.90 (3H, br t, *J*=6 Hz), 0.99 (3H, t, *J*=7 Hz), 1.2—1.7 (8H, m), 2.2 (2H, m), 2.49 (2H, m), 3.30 (2H, br d, *J*=5 Hz), 3.92 (1H, ddd, *J*=6, 5, 5 Hz), 4.15 (1H, m), 4.58 (1H, dd, *J*=8, 8 Hz), and 5.3—5.8 (2H, m); EI-MS (70 eV), *m/z* 318, 316 (2 : 2; M^+), 221, 219 (16 : 16; $M^+-C_6H_9O$), 203, 201 (5 : 5), 139 (68; $M^+-C_6H_9O-HBr$), 121 (94), 95 (97), 69 (91; $M^+-C_6H_9O-Br-C_5H_{11}$), 67 (16), 55 (70), 43 (19), and 41 (100).

Collins Oxidation of 28 into the Bromo Ketone 29. Collins oxidation of **28** (12 mg) was carried out under the same conditions as that in the case of the oxidation of **24** to afford a ketone (10 mg) which was identical with the bromo ketone **29** in all respects.

Bromination of 25 into 30. Bromination of **25** (130 mg) was performed with triphenylphosphine (210 mg) and carbon tetrabromide (270 mg) in dry benzene (20 ml) to give an oily substance, which was chromatographed over silica gel with hexane to yield a dibromide **30** (80 mg); oil; $[\alpha]_D$ +26.5° (*c* 1.23); IR (neat), ν_{max} 3020, 1295, 1110, 1070, 1060, 1010, 970, and 930 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, *J*=6 Hz), 1.00 (3H, t, *J*=7 Hz), 1.1—2.8 (14H, m), 3.86 (1H, ddd, *J*=8, 8, 7 Hz), 3.8—4.3 (3H, m), 5.41 (1H, dt, *J*=15, 6 Hz), and 5.60 (1H, dt, *J*=15, 6 Hz); EI-MS (70 eV), *m/z* 384, 382, 380 (0.2 : 0.4 : 0.2; M^+), 327, 325, 323 (0.3 : 0.6 : 0.3; $M^+-C_4H_9$), 303, 301 (5 : 5; M^+-Br), 221 (5; $M^+-HBr-Br$), 205, 203 (1 : 1; $M^+-C_6H_{10}BrO$), 179, 177 (5 : 5; $M^+-C_9H_{16}Br$), 97 (79; $M^+-C_9H_{16}Br-HBr$), 81 (11), 79 (11), 69 (100; $M^+-C_9H_{16}Br-Br-C_2H_5$), 67 (23), 57 (20), 55 (31), 43 (10), and 41 (64).

Partial Degradation of 30. To a solution of **30** (82 mg) and AcOH (400 μl) in MeOH (5 ml) was gradually added activated zinc dust (1.5 g) with stirring for 2 h at room temperature under N_2 atmosphere. After the usual work-up, the resulting oil was chromatographed on silica gel with hexane–benzene (3 : 1) to afford three products **31** (22 mg), **32** (21 mg), and **33** (12 mg).

31: Oil; $[\alpha]_D$ −18.0° (*c* 1.68); IR (neat), ν_{max} 3530, 3380, 3020, 1100, 1055, and 970 cm^{-1}. ^1H NMR (100 MHz) δ=0.88 (3H, br t, *J*=7 Hz), 1.01 (3H, t, *J*=7 Hz), 1.1—2.2 (10H, m), 1.94 (1H, d, *J*=3 Hz; OH), 2.4—2.9 (4H, m), 3.64 (1H, m), 4.14 (1H, ddd, *J*=7, 7, 4 Hz), and 5.1—5.8 (4H, m); EI-MS (70 eV), *m/z* 304, 302 (0.1 : 0.1; M^+), 286, 284 (0.1 : 0.1; M^+-H_2O), 275, 273 (0.1 : 0.1; $M^+-C_2H_5$), 223 (3; M^+-Br), 205 (4; M^+-H_2O-Br), 165 (1; $M^+-C_4H_9-HBr$), 153, 151 (1 : 1; $M^+-C_{11}H_{19}$), 95 (15), 93 (14), 85 (15), 81 (20), 79 (29), 69 (40), 67 (38), 59 (16; $M^+-C_{12}H_{20}Br$), 57 (100; $M^+-C_{11}H_{18}BrO$), 55 (42), 43 (26), and 41 (58).

32: Oil; $[\alpha]_D$ −10.8° (*c* 1.68); IR (neat), ν_{max} 3530, 3400, 3020, 1665, 1080, 1060, 1035, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, *J*=7 Hz), 0.98 (3H, t, *J*=7 Hz), 1.1—1.5 (6H, m), 1.91 (1H, d, *J*=8 Hz; OH), 1.7—2.2 (4H, m), 2.31 (2H, dd, *J*=6, 6 Hz), 2.66 (2H, dd, *J*=6, 6 Hz), 3.53 (1H, dtd, *J*=8, 7, 3 Hz), 4.06 (1H, ddd, *J*=8, 7, 3 Hz), 5.36 (1H, dt, *J*=15, 7 Hz), 5.39 (1H, dt, *J*=15, 5 Hz), 5.52 (1H, dt, *J*=15, 6 Hz), and 5.65 (1H, dt, *J*=15, 6 Hz); EI-MS (70 eV) *m/z* 304, 302 (0.4 : 0.4; M^+), 286, 284 (0.2 : 0.2; M^+-H_2O), 235, 233 (2 : 2; $M^+-C_5H_9$), 223 (2; M^+-Br), 222 (1; M^+-HBr), 206 (2; $M^+-Br-OH$), 205 (8; M^+-Br-H_2O), 153 (13; $M^+-C_5H_9-HBr$), 135 (14), 83 (12), 81 (14), 70 (61; $M^+-C_9H_{16}Br-C_2H_5$), 69 (100; $M^+-C_{10}H_{18}BrO$), 67 (26), 57 (14), 55 (85), and 41 (81).

33: Oil; IR (neat), ν_{max} 3020, 1075, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, t, *J*=7 Hz), 0.97 (3H, br t, *J*=7 Hz), 1.1—1.5 (6H, m), 1.7—2.2 (4H, m), 2.5—2.9 (4H, m), and 5.44 (6H, m); EI-MS (70 eV), *m/z* 206 (1; M^+), 177 (1; $M^+-C_2H_5$), 150 (2), 149 (1; $M^+-C_4H_9$), 121 (3), 108 (14), 95 (64), 93 (29), 81 (33), 80 (32), 79 (82), 69 (17), 67 (100), 57 (13), 55 (42), 43 (32), and 41 (86).

Hydrogenation of 31. Hydrogenation of **31** (14 mg) was performed in EtOH over PtO_2-catalyst. After removal of the catalyst and the solvent, the residual oil was chromatographed over silica gel with hexane–benzene (3 : 1) to give a saturated bromohydrin **34** (11 mg); oil; $[\alpha]_D$ −26.7° (*c* 0.890); IR (neat), ν_{max} 3530, 3400, 1295, 1220, 1105, 1095, 1050, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.88 (3H, br t, *J*=6 Hz), 1.02 (3H, t, *J*=7 Hz), 1.1—2.0 (22H, m), 1.97 (1H, d, *J*=6 Hz; OH), 3.61 (1H, dddd, *J*=7, 6, 5, 3 Hz), and 4.18 (1H, ddd, *J*=9, 5, 3 Hz); EI-MS (70 eV), *m/z* 279, 277 (0.2 : 0.2; $M^+-C_2H_5$), 227 (0.2; M^+-Br), 226 (0.1; M^+-Br), 197 (1; $M^+-C_2H_5-HBr$), 149 (2), 71 (6), 59 (100; $M^+-C_{12}H_{24}Br$), 58 (5), 57 (24), 55 (5), 43 (21), and 41 (7).

Bromination of Octahydrodeacetyllaurencin (35)[6] into 36. Bromination of **35** (400 mg) was performed with triphenylphosphine (655 mg) and carbon tetrabromide (830 mg) in dry benzene (15 ml) to give an oily substance which was chromatographed over silica gel with hexane to yield a dibromide **36** (406 mg); oil; $[\alpha]_D$ −2.50° (*c* 1.08); IR (neat), ν_{max} 1185, 1115, 1090, 1070, and 1050 cm^{-1}; ^1H NMR (100 MHz) δ=0.90 (3H, br t, *J*=6 Hz), 0.99 (3H, t, *J*=7 Hz), 1.1—2.2 (18H, m), 3.4—3.8 (2H, m), and 3.8—4.2 (2H, m); EI-MS (70 eV), *m/z* 386, 384, 382 (0.1 : 0.2 : 0.1; M^+), 305, 303 (0.6 : 0.6; M^+-Br), 304,

302 (0.3 : 0.3; M^+-HBr), 247, 245 (9 : 9; $M^+-HBr-C_4H_9$), 221, 219 (4 : 4; $M^+-C_6H_{12}Br$), 165 (38), 139 (34; $M^+-C_6H_{12}Br-HBr$), 111 (12; $M^+-C_6H_{12}Br-Br-C_2H_5$), 109 (50), 97 (32), 95 (86), 81 (60), 79 (50), 69 (100), 67 (65), 55 (83), and 41 (66).

Partial Degradation of 36. To a solution of **36** (264 mg) and AcOH (800 μl) in MeOH (10 ml) was gradually added activated zinc dust (1.5 g) with stirring for 4 h at room temperature under N_2 atmosphere. After the usual work-up, the resulting oily substance was subjected to repeated silica-gel column chromatography with hexane–benzene (3 : 1) to yield **37** (40 mg) and **38** (125 mg).

37: Oil; $[\alpha]_D$ −28.9° (*c* 1.50); IR (neat), ν_{max} 3400, 3020, 1655, 1295, 1230, 1100, 1070, 1050, and 970 cm^{-1}; ^1H NMR (100 MHz) δ=0.89 (3H, br t, *J*=6 Hz), 1.02 (3H, t, *J*=7 Hz), 1.1—2.2 (19H, m), 3.60 (1H, m), 4.17 (1H, ddd, *J*=8, 6, 4 Hz), and 5.37 (2H, m); EI-MS (70 eV), *m/z* 306, 304 (1 : 1; M^+), 288, 286 (2 : 2; M^+-H_2O), 277, 275 (0.3 : 0.3; $M^+-C_2H_5$), 249, 247 (0.3 : 0.3; $M^+-C_4H_9$), 225 (1; M^+-Br), 207 (19; M^+-H_2O-Br), 151 (5; $M^+-OH-Br-C_4H_9$), 123 (35), 111 (10; $M^+-C_7H_{14}BrO$), 109 (60), 97 (16), 95 (100), 83 (19), 81 (65), 69 (83), 67 (55), 59 (79; $M^+-C_{12}H_{22}Br$), 57 (19), 55 (82), and 41 (60).

38: Oil; $[\alpha]_D$ −23.8° (*c* 0.608); IR (neat), ν_{max} 3400, 3020, 1650, 1305, 1280, 1260, 1115, 1070, 1040, 1010, and 965 cm^{-1}; ^1H NMR (100 MHz) δ=0.90 (3H, br t, *J*=6 Hz), 0.96 (3H, t, *J*=7 Hz), 1.1—2.2 (18H, m), 3.69 (1H, m), 4.18 (1H, ddd, *J*=8, 5, 3 Hz), and 5.4 (2H, m); EI-MS (70 eV), *m/z* 306, 304 (0.6 : 0.6; M^+), 288, 286 (0.3 : 0.3; M^+-H_2O), 225 (3; M^+-Br), 207 (6; M^+-Br-H_2O), 141 (7; $M^+-C_6H_{12}Br$), 123 (57), 109 (12), 95 (56), 82 (15), 81 (100), 69 (41; $M^+-C_{10}H_{20}BrO$), 67 (62), 57 (11), 55 (71), 43 (13), and 41 (61).

Hydrogenation of 37. Hydrogenation of **37** (18 mg) was performed in EtOH over PtO_2-catalyst. After removal of the catalyst and the solvent, the resulting oily substance was purified by silica-gel column chromatography with hexane–benzene (3 : 1) to give a saturated bromohydrin (18 mg) which was identical with the bromohydrin **34** in all respects.

Treatment of 39 with Activated Silica Gel. A mixture of **39** (31 mg) and silica gel (Merck, Kieselgel 60, 70—230 mesh) (1.5 g), which was activated at 140 °C for 3 h, in hexane was stirred at room temperature for 24 h. After the silica gel was filtered off and washed with ethyl acetate, the combined solvents were evaporated to leave an oily substance which was chromatographed on silica-gel column with hexane–benzene (1 : 1) to yield hexahydronotoryne (**10**) (31 mg).

Treatment of 39 with Silica Gel. A solution of **39** (20 mg) and silica gel (Merck, Kieselgel 60, 70—230 mesh) (1 g) in hexane (10 ml) was stirred at room temperature for 24 h. After being worked up as described above, the residual oily substance was chromatographed on silica-gel column with hexane–benzene (1 : 1) to give hexahydronotoryne (**10**) (4 mg) and hexahydrolaurefucin (**21**) (16 mg).

Treatment of 39 with Aluminum Oxide. A solution of **39** (19 mg) and aluminum oxide (Merck, activity II-III) (1 g) in hexane (10 ml) was stirred at room temperature for 20 h. After the aluminum oxide was filtered off and then washed with ethyl acetate, the combined solvents were evaporated to give an oily substance which was chromatographed on silica-gel column with hexane–benzene (1 : 1) to yield hexahydronotoryne (**10**) (4 mg) and hexahydrolaurefucin (**21**) (15 mg).

Amination of Carboxylic Acids by Reductive Fixation of Molecular Nitrogen by Glow Discharge Against Aqueous Solution

Kaoru HARADA,* Shun-ichiro IGARI, Toratane MUNEGUMI,†
Michiaki TAKASAKI, and Akira SHIMOYAMA
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received November 29, 1990)

Amination of several carboxylic acids by reductive fixation of molecular nitrogen was achieved by glow discharge against aqueous solution of these carboxylic acids. The yield of the aminated product is the highest in the case of maleic acid among carboxylic acids used. The addition of hydrochloric acid to the reaction mixture enhances the yields of aminated products. This may be caused by the fact that chloride anion is oxidized by hydroxyl radicals to chlorate ion, and the fixation of molecular nitrogen proceeds under relatively reducing conditions.

Numerous experimental studies on the formation of bioorganic compounds under possible prebiotic conditions have been reported in the past three decades.[1] Most of the studies were carried out under reducing conditions, using hydrocarbon, ammonia, hydrogen, and carbon monoxide etc. However, if the temperature on the primitive earth was high (1000 °C), the chemical equilibrium of the atmosphere would have shifted to the non-reducing side as shown in Eq. 1. The resulting hydrogen gas would have escaped from the gravitational field of the earth, and the primitive atmosphere would be a mixture of nitrogen, carbon dioxide and water. This is an extreme case of the non-reducing atmosphere of the primitive earth.

$$\begin{aligned} &H_2 + 1/2O_2 \longrightarrow H_2O \\ &CO + 1/2O_2 \longrightarrow CO_2 \\ &CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2 \\ &2NH_3 \longrightarrow N_2 + 3H_2 \end{aligned} \quad (1)$$

Ammonia is one of the important starting materials for the formation of nitrogen-containing bioorganic compounds under prebiotic conditions. If ammonia did not exist on the primitive earth, abiotic formation of nitrogen-containing bioorganic compounds would strongly restricted. The formation of ammonia from molecular nitrogen is thermodynamically favored when hydrogen is present at relatively low temperature (Harber–Bosch methods). However ammonia is difficult to be produced without hydrogen. And ammonia is unstable both thermally and photochemically.

Molecular nitrogen is one of the most inert diatomic molecules, and the reductive fixation of molecular nitrogen with water is thermodynamically difficult because of the large positive ΔG° value as shown in Eq. 2.

$$\begin{aligned} &4/5N_2 + 9/5H_2O \longrightarrow NH_3 + 3/5HNO_3 \\ &\Delta G^\circ = +86.2 \text{ kcal mol}^{-1} \end{aligned} \quad (2)$$

Photochemical conversion of molecular nitrogen in the presence of catalyst[2,3] and hydrolysis of nitrogen–metal complexes[4] are known as reductive fixation of molecular nitrogen, while little study has been carried out on the molecular fixation of notrogen in the absence of a catalyst.[5,6]

In our previous investigation, we reported that direct amination of carboxylic acids in aqueous ammoniacal solution by using glow discharge.[5] It was found that the reductive fixation of molecular nitrogen with water by using glow discharge yields ammonia and nitrate ion.[6] When aqueous acetic acid was added to this system, it was found that aminated product (glycine) was identified.[7]

In this paper, details of the experimental results of the amination reactions of various carboxylic acids using molecular nitrogen and water induced by glow discharge are described. And some of the additive effects on the reductive fixation of nitrogen gas was studied. Under these reactions it was found that a) ammonia and nitrate

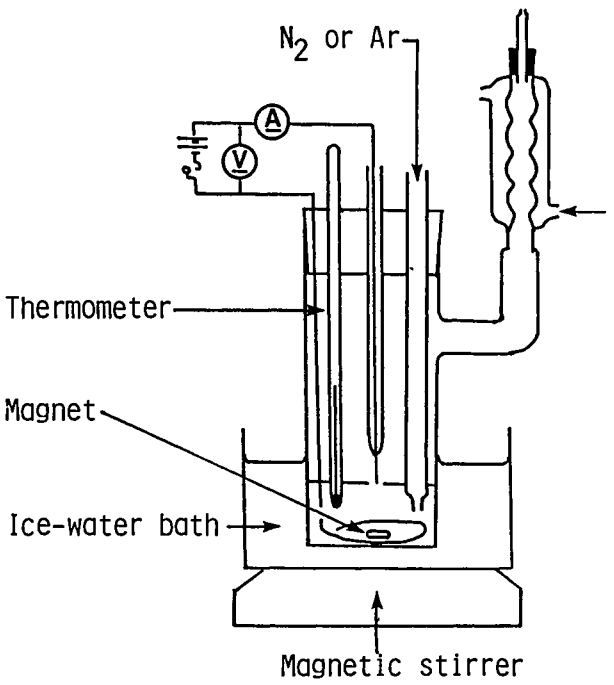

Fig. 1. Apparatus for nitrogen fixation by CGDE.

† Present address: Oyama National College of Technology, Oyama, Tochigi 323.

ions were simultaneously formed in the aqueous solution, and that b) various amino acids and aminated degradation products were formed. Formation of amino acid was chosen because of the ease of identification and also as a model for the formation of the bioorganic compounds under non-reducing conditions.

Experimental

Glow discharge was applied on the surface of water (20 ml) containing a small amount of sulfuric acid (0.025 mmol) under nitrogen atmosphere. The applied electric current was 20—50 mA at 500—600 V. The reaction temperature was kept at 25—40 °C by cooling the reaction mixture in an ice-water bath. The reaction tube for the glow discharge reaction is shown in Fig. 1. A small amount of reaction mixture was withdrawn at intervals and each sample was analyzed with an amino acid analyzer for amino acid and ammonia, and also by ion chromatography for nitrate and nitrite ions.

Results and Discussion

The experimental results of reductive fixation of molecular nitrogen are summarized in Figs. 2 and 3. As shown in Fig. 2, the amount of ammonia and nitrate ion found in the reaction mixture increased as the reaction proceeded and the concentrations of ammonia and nitrate ion were 0.45 mmol/20 ml and 0.38 mmol/20 ml, respectively, after 24 h. As a control reaction, the glow discharge was carried out in a similar way under argon atmosphere. Neither ammonia nor nitrate ion was found in the reaction mixture (Fig. 3). This whole process was also carried out without glow discharge, and ammonia or nitrate ion was not detected. Nitrite ion was not found in the reaction mixture,

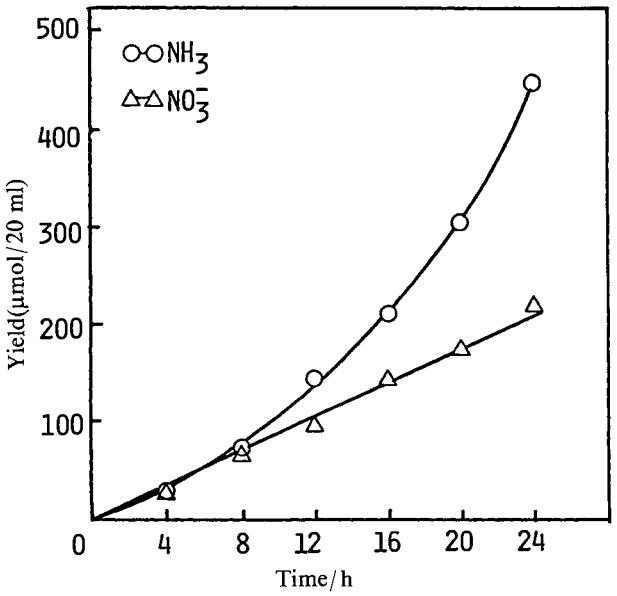

Fig. 2. Formation of NH_3 and NO_3^- from N_2 and H_2O by CGDE.
Reaction conditions: 520—600 V, 50 mA, 35—45 °C.
Substrate: H_2SO_4 0.025 mmol/20 ml H_2O–N_2.

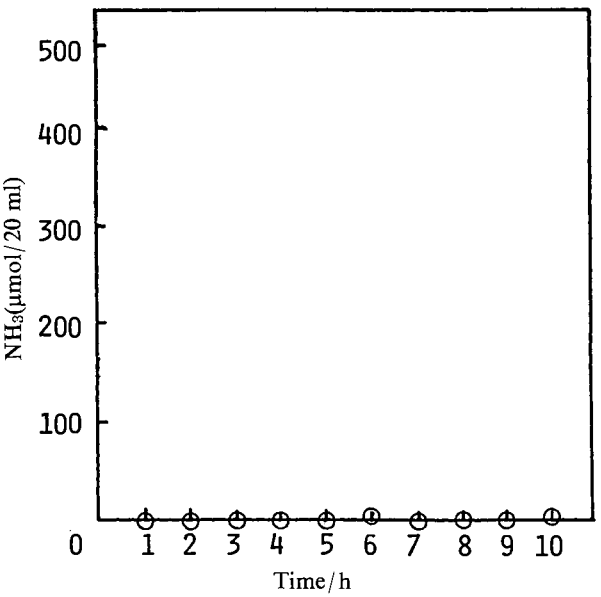

Fig. 3. Ammonia found in the reaction mixture of H_2O–Ar system by CGDE.
Reaction conditions: 720—800 V, 50—60 mA, 40—50 °C.
Substrate: H_2SO_4 0.1 mmol/20 ml H_2O–Ar.

probably because of the rapid oxidation to nitrate ion. A possible pathway for the formation of ammonia and nitrate ion could be shown as follows:

$$N_2 \longrightarrow 2N$$
$$H_2O \longrightarrow OH + H$$
$$N + H_2O \longrightarrow N + H + OH$$
$$N + nH \longrightarrow NH \longrightarrow NH_2 \longrightarrow NH_3$$
$$N + OH \longrightarrow NO_2^- \longrightarrow NO_3^-$$
$$N_2 + H_2O \longrightarrow NH_3 + NO_3^- \quad (3)$$

The nitrogen atom generated under high energy conditions is reduced with hydrogen to form NH and NH_2 radicals, and finally NH_3. Therefore, if some suitable organic amino acceptor is present in the reaction mixture, the glow discharge reaction could result in the formation of several amino compounds. In this study, several aliphatic carboxylic acids were used and the time course of the resulting amino compounds was shown in Figs. 4—9. Carboxylic acids used were acetic acid, propionic acid, succinic acid, acrylic acid and maleic acid in the glow discharge reaction using molecular nitrogen and water. The effect of added sodium chloride and hydrochloric acid on the reductive amination of molecular nitrogen was also studied (Figs. 10—12).

Figure 4 shows the time course of the amination reaction of aqueous acetic acid (10%, 20 ml) by glow discharge under nitrogen atmosphere. The aminated product, glycine, and the aminated degradation product, methylamine, were confirmed. The yields of these aminated products are smaller than those from the reaction of other carboxylic acids.

Figure 5 shows the time course of the amination

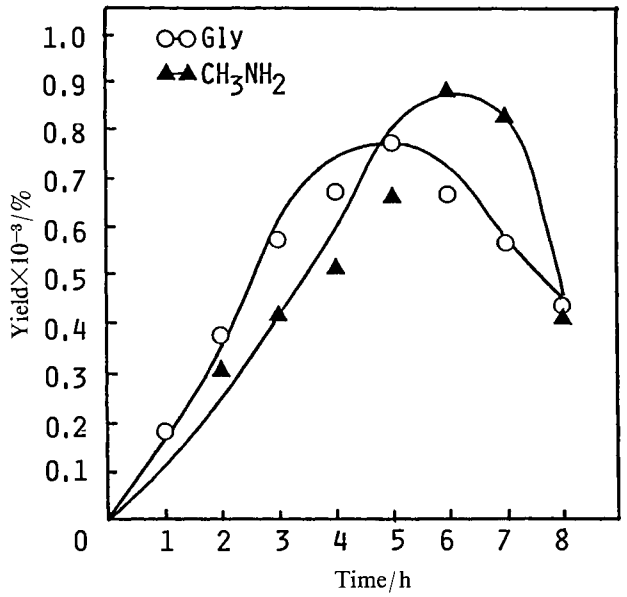

Fig. 4. The amination of acetic acid by CGDE.
Reaction conditions: 540—640 V, 40—50 mA, 30—40 °C.
Substrate: acetic acid 33 mmol/H_2O(total 20 ml) -N_2.

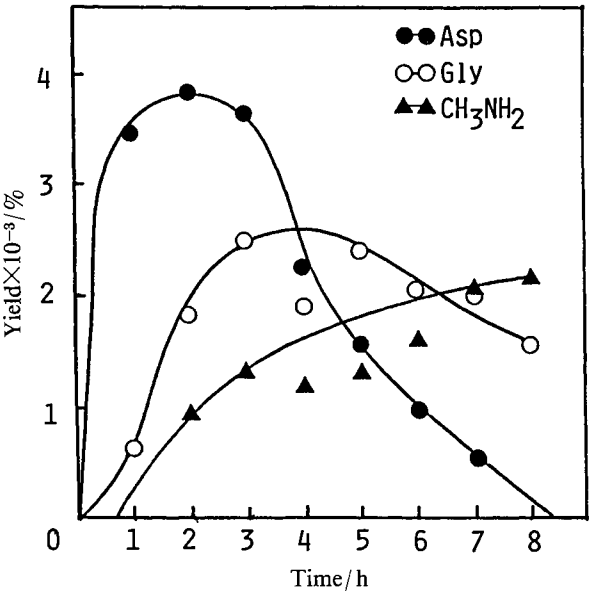

Fig. 6. The amination of succinic acid by CGDE.
Reaction conditions: 560—620 V, 50 mA, 35—45 °C.
Substrate: succinic acid 10 mmol/H_2O(total 20 ml) -N_2.

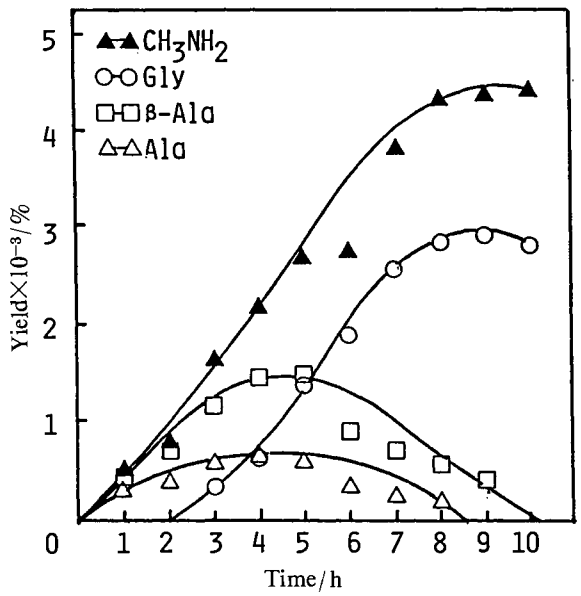

Fig. 5. The amination of propionic acid by CGDE.
Reaction conditions: 560—680 V, 40—60 mA, 35—45 °C.
Substrate: propionic acid 27 mmol/H_2O(total 20 ml) -N_2.

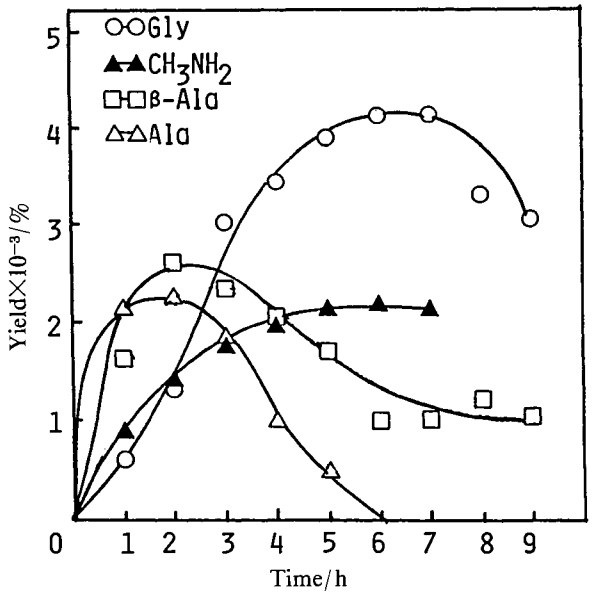

Fig. 7. The amination of acrylic acid by CGDE.
Reaction conditions: 560—600 V, 40—60 mA, 35—45 °C.
Substrate: acrylic acid 8.3 mmol, H_2O(total 20 ml) -N_2.

reaction of propionic acid (10%, 20 ml). β-Alanine and alanine were confirmed as aminated products. The ratio of β-ala : ala after 1 h was roughly 1.5 : 1. Methylamine and glycine, which are the aminated degradation products, were also confirmed. This indicates that the C–C bond could easily be cleaved under the conditions used.

Figure 6 shows the amination of succinic acid (10 mmol/20 ml). The directly aminated product, aspartic acid, formed first, and the aminated degradation products, glycine and methylamine, increased with time. The yields were similar to the case of propionic acid.

Figure 7 shows the time course of amination of acrylic acid (3%, 20 ml) with nitrogen. In this case the concen-

tration of acrylic acid was reduced in order to avoid radical polymerization of the unsaturated carboxylic acid. The direct amination product, β-alanine and alanine, were formed first and the yields of aminated degradation products, glycine and methylamine, increased with the reaction time. The yield of alanine reached almost zero after 6 h in the reaction, while the yield of β-alanine remained at the higher level at that time. This suggests that β-alanine might be formed from the degradation products, for example, by the coupling of methylamine and acetic acid.

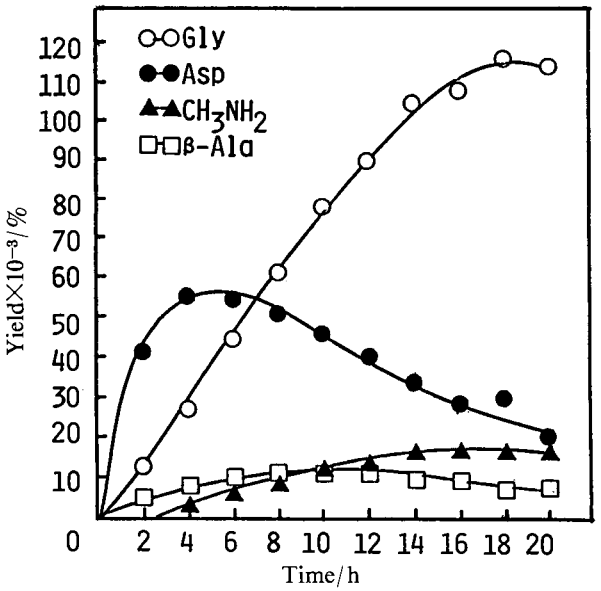

Fig. 8. The amination of maleic acid by CGDE.
Reaction conditions: 460—500 V, 20 mA, 10—20 °C.
Substrate: maleic acid 10 mmol/H_2O(total 20 ml) -N_2.

Figure 8 shows the amination of maleic acid by glow discharge under nitrogen atmosphere. Direct amination product, aspartic acid, was synthesized first, and the aminated degradation products, glycine, methylamine, and β-alanine, were formed with the reaction proceeded. The yields of aminated products in this reaction were much higher (>50×) than those of the other carboxylic acids.

As was described earlier, the direct amination of aliphatic carboxylic acids by using electric discharge was possible in relatively high concentration of aqueous ammonia.[5] In this reductive fixation of nitrogen by using electric discharge, a small amount of ammonia was formed in aqueous solution. Therefore, it is worthwhile to investigate whether the direct amination of carboxylic acid in such a low ammonia concentration proceeds or not under the high energy conditions. When glow discharge was applied to the N_2–H_2O system for 24 h, 450 mol/20 ml of ammonia was produced. The concentration of ammonia is equivalent to about 0.03% aqueous ammonia. Therefore, glow discharge was applied to 10% acetic acid (20 ml) containing 0.03% ammonia. The time course of the reaction is shown in Fig. 9. The highest yield of glycine and methylamine reach 3×10^{-3} and 2×10^{-3}%, and the formation of β-alanine and aspartic acid was confirmed. The yields are higher than those obtained by using molecular nitrogen.

In the following investigation, the effect of additives

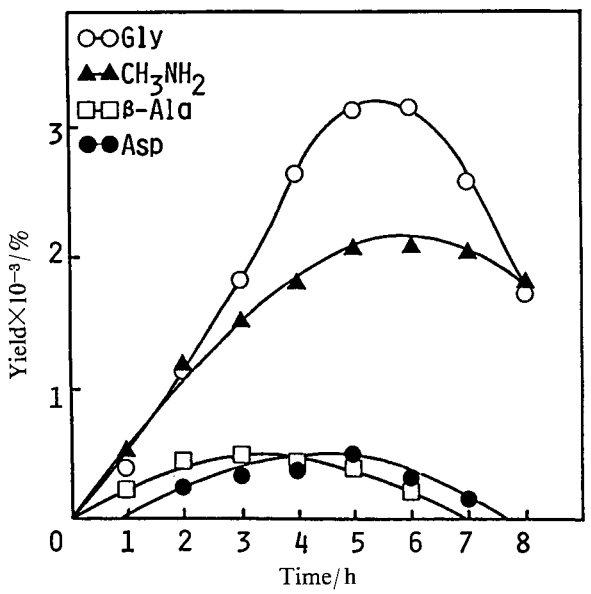

Fig. 9. The amination of acetic acid by CGDE.
Reaction conditions: 540—640 V, 40—60 mA, 35—45 °C.
Substrate: ammonia 17 mmol+acetic acid 33 mmol/H_2O(total 20 ml) -N_2.

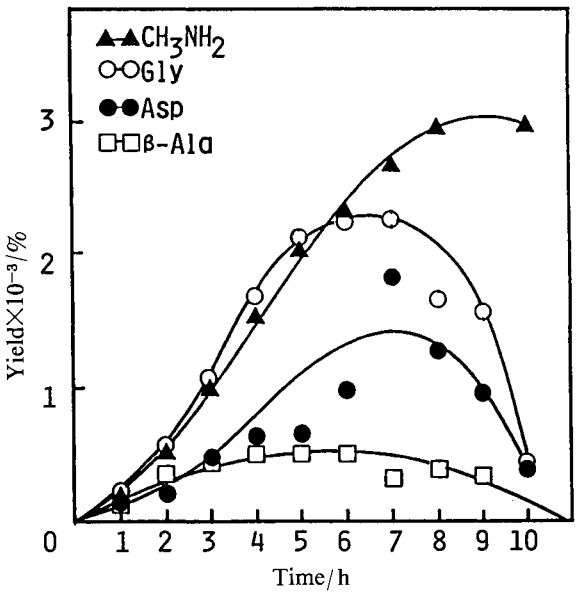

Fig. 10. The amination of acetic acid by CGDE in the presence of NaCl.
Reaction conditions: 520—560 V, 20—40 mA, 20—30 °C.
Substrate: acetic acid 33 mmol, 0.09M-NaCl/H_2O(total 20 ml) -N_2.

(NaCl and HCl) in the reductive amination of carboxylic acids is described. Because chloride anion could be oxidized under the reaction conditions, this might enhance the yields in the reductive amination of nitrogen molecule. The effect of sodium chloride in the amination reaction of acetic acid is shown in Fig. 10. The yield of glycine increased about three times compared with that of reactions without sodium chloride. The yields of other aminated secondary products, methylamine, glycine, β-alanine, and aspartic acid, were also higher than the case without sodium chloride.

The effect of hydrogen chloride addition was investigated in the reaction with acetic acid. The time course of the formation of aminated products using 0.1 M HCl (1 M=1 mol dm^{-3}) is shown in Fig. 11. In addition to the direct amination product, glycine, aminated secondary products, methylamine, β-alanine, and aspartic acid, were synthesized in higher yields. The yield of glycine is much higher (×30) compared with the yields without hydrogen chloride. When the concentration of hydrogen chloride was reduced to 0.01 M, the yield of glycine decreased, but, the yield was still four times higher than that without hydrogen chloride (Fig. 12). Therefore, the effect of hydrogen chloride in the reductive amination by glow discharge in aqueous solution is significant. Similarly, the effect of hydrogen chloride in the reductive amination of maleic acid is shown in Fig. 13. When the concentration of hydrochloric acid was 0.01 M, the yield of aspartic acid is similar to that obtained without hydrochloric acid. However, when the concentration of HCl was increased to 0.1 M, the yields of aspartic acid and glycine increased roughly twice. The formation of chlorate ion (ClO_3^-) was confirmed in the reaction mixture by ion chromatography. This indicates that chloride ion (Cl^-) was oxidized to chlorate ion by hydroxyl radicals ($Cl^- \rightarrow [ClO^-]$

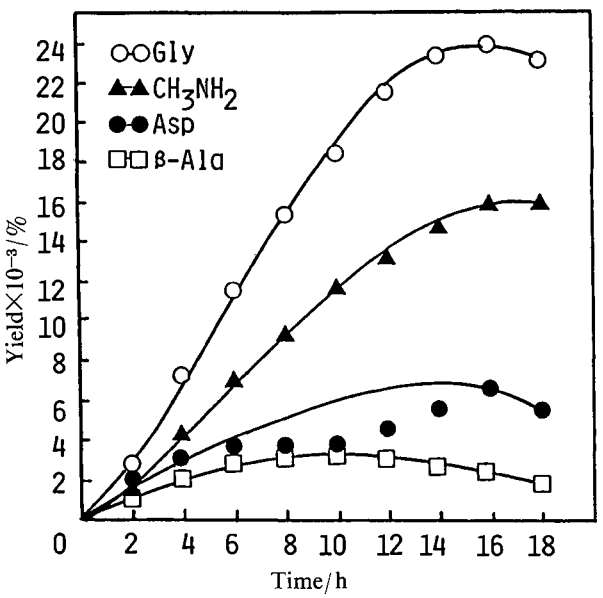

Fig. 11. The amination of acetic acid by CGDE in the presence of HCl.
Reaction conditions: 480—500 V, 20 mA, 10—20 °C.
Substrate: acetic acid 33 mmol, 0.09M-HCl/H_2O(total 20 ml) -N_2.

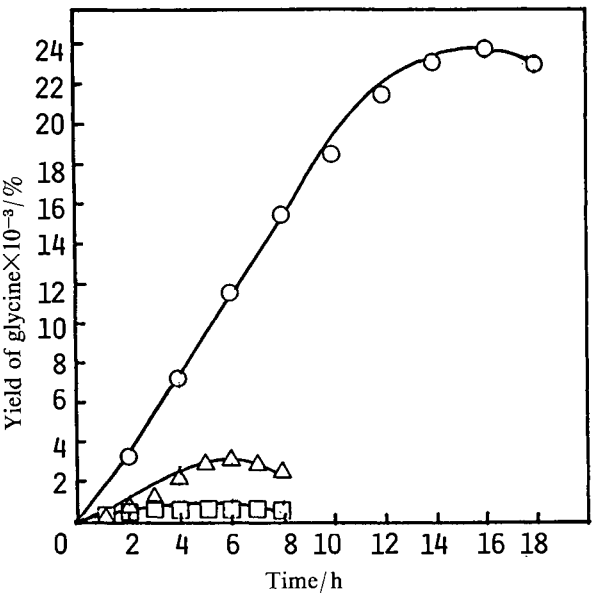

Fig. 12. The amination of acetic acid by CGDE in the presence of HCl.
Reaction conditions: ○—○ 480—500 V, 20 mA, 10—20 °C. △—△ 520—600 V, 40 mA, 30—40 °C. □—□ 540—640 V, 40—50 mA, 35—45 °C.

Reaction conditions: 440—460 V, 20 mA, 10—20 °C.
Substrate: △—△, ○—○ maleic acid 10 mmol/0.01M-HCl(total 20 ml)-N_2; ■—■, ●—● maleic acid 10 mmol/0.1M-HCl(total 20 ml)-N_2.

$\rightarrow ClO_3^-$). When the Cl^- concentration decreased to 55% of the initial concentration of hydrogen chloride (0.1 M), the yield of ClO_3^- reached 45% after glow discharge for 12 h. This suggests that Cl^- serves as a scavenger for hydroxyl radicals, therefore forming relatively reducing reaction conditions, and increasing the yields of reductive amination products.

The formation of ammonia and nitrate ion from molecular nitrogen and water is a new type of chemical reaction that could be regarded as a disproportionation reaction under high energy conditions. The reaction is not controlled thermodynamically. The simultaneous formation of reduced (ammonia) and oxidized (nitrate ion) compounds could be explained by the decomposition of nitrogen and water molecules under high energy conditions and the recombination of the resulting radicals. The active species in the ammination reaction could be NH or NH_2 radicals formed by the coupling reaction of nitrogen and hydrogen atoms generated by glow discharge. The ratio of ala : β-ala produced from propionic acid (1 : 1.5) was similar to that obtained in NH radical reaction to propionic acid (1 : 1.6).[7,8] This indicates that the amination of carboxylic acid by reductive fixation of molecular nitrogen under high energy conditions may proceed via a radical mechanism.

The reductive fixation reaction of molecular nitrogen with water is not only interesting chemically, but also interesting from the point of view of chemical evolution. This type of reaction could be regarded as a model experiment to examine the effect of lightning struck on the hydrosphere in a non-reducing atmosphere (composed mainly of H_2O, N_2, and CO_2) on the primitive earth. The lightning may induce various chemical reactions under aqueous conditions, which could produce various bioorganic compounds that cannot arise thermodynamically.

Some Unusual Properties of Tris(2,6-dimethoxyphenyl)phosphine Sulfide and the Related Compounds

Masanori WADA,* Mitsuyuki KANZAKI, Masanobu FUJIWARA, Kazuhisa KAJIHARA, and Tatsuo ERABI
Department of Materials Science, Faculty of Engineering, Tottori University, Koyama, Tottori 680
(Received December 11, 1990)

The title sulfide {2,6-$(MeO)_2C_6H_3$}$_3$P=S [abbr. $(2,6)_3$P=S] reacted with acids to form a novel mercaptophosphonium salt [$(2,6)_3$P–SH]X, solution thermolysis of which in the absence or presence of triphenylphosphine resulted in the unusual desulfurization to give the tertiary phosphonium salts [$(2,6)_3$P–OH]X. $(2,6)_3$P=S also reacted with alkyl iodides or bromides under mild conditions to give stable (alkylthio)phosphonium salts [$(2,6)_3$P–SR]X (R=Me, Et, n-Bu), which reacted with thiols at room temperature in the presence of a catalytic amount of the tertiary phosphine $(2,6)_3$P to give [$(2,6)_3$P–H]X and unsymmetrical disulfides.

Triphenylphosphines bearing methoxyl substituents at 2,6-positions of the phenyl groups, such as {2,6-$(MeO)_2C_6H_3$}$_3$P [abbr. $(2,6)_3$P, see Fig. 1], exhibit high basicities and nucleophilicities.[1–3] In our previous paper, we reported some unusual physical and chemical properties of the oxide $(2,6)_3$P=O.[4] In the present paper, we report the details of some unusual properties of its sulfide $(2,6)_3$P=S towards acids and alkyl halides. The preliminary results have been reported elsewhere.[5,6]

Results and Discussion

Preparation and Desulfurization of Mercaptophosphonium Salts. The tertiary phosphine $(2,6)_3$P reacted easily with elemental sulfur in toluene at room temperature to give its sulfide $(2,6)_3$P=S [step (1) of Scheme 1].

In contrast to triphenylphosphine sulfide Ph_3P=S, an addition of 60% $HClO_4$ to a solution of $(2,6)_3$P=S in acetone resulted in immediate precipitation of a novel mercaptophosphonium salt [$(2,6)_3$P–SH]ClO_4 [step (2)]. To our further surprise, when [$(2,6)_3$P–SH]ClO_4 was heated in 2-propanol, it was partly desulfurized to give an equilibrated mixture of [$(2,6)_3$P–H]ClO_4 and [$(2,6)_3$P–SH]ClO_4 in a ratio of 71 : 29 [step (3)]. Heating a solution of $(2,6)_3$P=S in ethyl methyl ketone (MEK) containing aqueous HCl also gave [$(2,6)_3$P–H]$^+$ salt (55% yield). Analogous results were obtained using methanol or 2-propanol as the solvent. The reversibility [step (3')] was confirmed by treating [$(2,6)_3$P–H]Cl·2.5H_2O with sulfur in acetone.

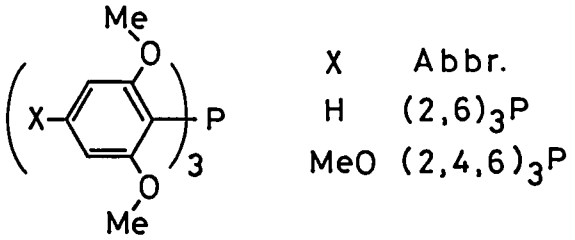

Fig. 1.

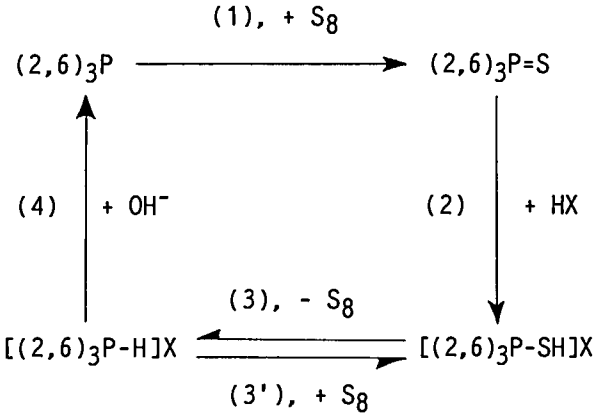


Scheme 1.

Since [$(2,6)_3$P–H]$^+$ salts are easily deprotonated by aqueous sodium hydroxide to give $(2,6)_3$P in quantitative yields [step (4)], the combination of these reactions [steps (2)–(4)] may be used to reduce $(2,6)_3$P=S to $(2,6)_3$P *without using any reducing reagent.*

Although other sulfides $(2,6)_2$PhP=S, $(2,6)Ph_2$P=S, and $(2\text{-}MeOC_6H_4)_3$P=S were prepared from the corresponding tertiary phosphine and elemental sulfur, we had no evidence for the formation of their mercaptophosphonium salts. These sulfides, as well as Ph_3P=S, were stable against the desulfurization in solutions containing HCl or $HClO_4$ even at 70 °C for 8 h. Tris(2,4,6-trimethoxyphenyl)phosphine sulfide $(2,4,6)_3$P=S [(2,4,6)= 2,4,6-$(MeO)_3C_6H_2$], on the other hand, gave a complex mixture containing 1,3,5-trimethoxybenzene, the protonation product at C(–P).

When $(2,6)_3$P=S was treated with Ph_3P in acetone containing HCl at 50 °C for 3 h, a mixture of [$(2,6)_3$P–H]Cl·2.5H_2O and Ph_3P=S was obtained both in quantitative yields. $(2,6)_2$PhP=S also reacted with Ph_3P in the presence of acid to give [$(2,6)_2$PhP–H]$^+$ salt[1] and Ph_3P=S, but $(2,6)Ph_2$P=S and $(2\text{-}MeOC_6H_4)_3$P=S were recovered almost unreacted.

Reactions of Triarylphosphine Sulfides with Alkyl Halides. Although an (alkylthio)phosphonium salt is a key intermediate in the reactions or formation of organodisulfides,[7] its isolation from these reaction mixtures is generally very difficult.[8] We found that $(2,6)_3$P=S reacted very easily with alkyl iodide (RI=MeI, EtI, *n*-BuI) in benzene at room temperature to give imme-

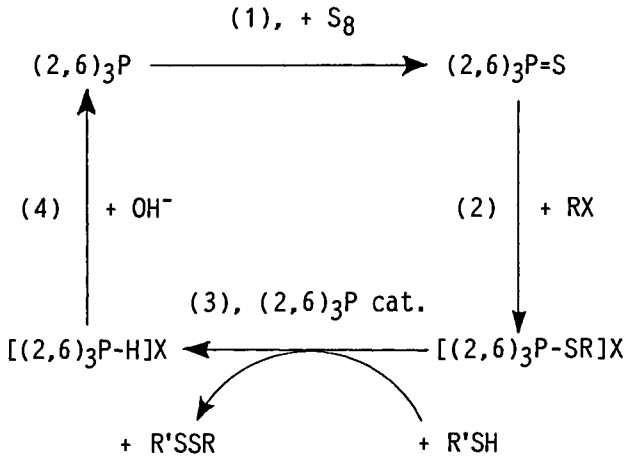
diately precipitates of $[(2,6)_3P–SR]I$ [step (2) of Scheme 2]. The reactions with alkyl bromides were slower under analogous conditions, but $(2,6)_3P=S$ reacted both with EtBr and BuBr in ethanol on heating at 60 °C for 2 h. $(2,6)_2PhP=S$ also reacted with methyl iodide at room temperature to give $[(2,6)_2PhP–SMe]I$, but neither $(2,6)Ph_2P=S$ nor $Ph_3P=S$ reacted with these alkyl halides under these conditions.

The bromides $[(2,6)_3P–SR]Br$ are soluble and stable in water, and an addition of 60% aqueous perchloric acid to the aqueous solution gave the precipitates of $[(2,6)_3P–SR]ClO_4$. These (alkylthio)phosphonium salts are thermally stable even in the presense of base. Thus, they were recovered almost unchanged after heating at 80 °C for 24 h in ethanol containing triethylamine.

The inertness of the P–SR bond to hydrolysis or to alcoholysis can readily be explained by both the steric and electronic effects of the 2,6-dimethoxyl substituents. However, the most attractive explanation involves the interaction between the phosphorus atom and one or more of the oxygen atoms on 2,6-positions in the phosphonium species. The presence of such interactions may interfere both sterically and electronically with additional coordination by oxide anions, a key step for P–SR bond cleavage. An analogous explanation has been cited for the unusual thermal reactions of (2-hydroxyalkyl)phosphonium salts $[(2,6)_3P–CH_2CRR'OH]X$.[2]

Reactions of (Alkylthio)phosphonium Salts with Thiols. Omelańczuk and Mikołajczyk prepared some (methylthio)phosphonium salts by treating the phosphine sulfides with methyl triflate.[9] They also found that reaction of $[Ph_3P–SMe]^+$ salt with NaSEt gave exclusively triphenylphosphine and a mixture of dimethyl, diethyl, and methyl ethyl disulfides. Masui et al. reported that a variety of phosphonium salts $[Ph_3P–SR]ClO_4$ could be prepared electrochemically from Ph_3P and dialkyl (or diaryl) disulfide and that their reaction with thiols in the presence of triethylamine gave Ph_3P and unsymmetrical diorganodisulfides.[10] We also found that $[(2,6)_3P–SR]I$ (R=Me, Et, Bu) reacted with thiols R'SH (R'=Ph, 4-MeC_6H_4, n-C_8H_{17}), in methanol containing a catalytic amount of $(2,6)_3P$ [step (3)]. The mixture was stirred at room temperature for 24 h under argon, and it was worked up to give the tertiary phosphonium salt $[(2,6)_3P–H]I$ and the unsymmetrical disulfides selectively. 2,6-Dimethoxybenzenethiol[11] reacted with $[(2,6)_3P–SR]I$ much slower than the other thiols, due probably to the bulkiness. We expected that in these reactions the catalyst $(2,6)_3P$ (pK_a 9.33)[1,12] worked as a base toward R'SH to form $[(2,6)_3P–H]SR'$, and that the anion $R'S^-$ thus formed reacted with the cation $[(2,6)_3P–SR]^+$ to form RSSR' and to reproduce $(2,6)_3P$. In fact, triethylamine (pK_a 10.75) could be used in place of $(2,6)_3P$ to give triethylammonium iodide and $(2,6)_3P$, as well as RSSR'. The lack of formation of symmetrical disulfides at lower temperatures is astonishing, and it can be best explained as that the exchange of alkylthio group at phosphorus by $R'S^-$ anion[9] is sterically precluded in our compounds. However, the formation of symmetrical disulfides was observed when the reactions were performed at elevated temperatures or when the base was used in larger amounts. We observed no formation of monosulfide RSR' even under these conditions. In the absence of base, the reaction was very slow even at elevated temperatures, and it gave equilibrium mixtures of $[(2,6)_3P–SR]I$, $[(2,6)_3P–H]I$, R'SH, and RSSR'. The reversibility of the reaction could be used for the preparation of (phenylthio)phosphonium salt $[(2,6)_3P–SPh]ClO_4$ by the reaction of $[(2,6)_3P–H]Cl$ and PhSSPh, although the yield was poor.

Since $[(2,6)_3P–H]I$ can easily be deprotonated by aqueous alkali hydroxide, we now obtained a reaction cycle as shown in Scheme 2. This indicates that unsymmetrical disulfides can be prepared under mild conditions from elemental sulfur, alkyl halide, thiol, and aqueous alkali hydroxide using $(2,6)_3P$ as a reproducible reagent.



Scheme 2.

Experimental

Physical Measurements. ^1H and ^{13}C NMR spectra were recorded for solutions in $CDCl_3$ using a JEOL model JNM-GX-270 spectrometer operating at 270 and 67 MHz, respectively. IR spectra were recorded for Nujol mull using a Simadzu FTIR-4200 spectrophotometer. Gas–liquid chromatography was recorded on a Hitachi 263-30 gas chromatograph by means of a one m. Silicone gum rubber SE 30 column at 60—250 °C.

The ^1H NMR and ^{13}C NMR spectral data of new compounds are shown in Tables 1 and 2, respectively.

Triarylphosphines. Tris(2,6-dimethoxyphenyl)phosphine, $(2,6)_3P$, was obtained from the K. I. Kasei Co., Ltd. It was purified by washing with water followed by recrystallization from 2-propanol. Other tertiary phosphines, tris(2,4,6-trimethoxyphenyl)phosphine, $(2,4,6)_3P$, bis(2,6-dimethoxyphenyl)phenylphosphine, $(2,6)_2PhP$, (2,6-dimethoxyphenyl)diphenylphosphine, $(2,6)Ph_2P$, and tris(2-methoxyphenyl)phosphine, $(2\text{-}MeOC_6H_4)_3P$, were prepared as described previously.[1,12]

a) In the order of C-1, C-2,6, C-3,5, C-4, MeO-2,6, C-1′, C-2′, and others; s=singlet, d=doublet; J_P (in Hz) given in square brackets. b) The C-1 resonance could not be observed.

Preparation of Triarylphosphine Sulfides. $(2,6)_3P{=}S$. To a solution of $(2,6)_3P$ (4.425 g, 10 mmol) in toluene (100 ml) was added elemental sulfur (0.353 g, 11 mmol). The mixture was stirred at room temperature for 4 h. Unreacted sulfur was filtered off, and the filtrate was cooled to −30 °C to give crystals, which were dried at 120 °C for 2 h to give $(2,6)_3P{=}S$ in 88% yield. It can be purified by recrystallization from toluene, ethanol or acetone, followed by drying at 120 °C. Mp 206—208 °C. Anal. ($C_{24}H_{27}O_6PS$) C, H, S.

$(2,4,6)_3P{=}S$. To a solution of $(2,4,6)_3P$ (0.533 g, 1 mmol) in toluene (20 ml) was added elemental sulfur (0.032 g, 1 mmol) to give a clear solution in a few minutes. The mixture was stirred at room temperature for 1 h and was cooled to −30 °C to aid precipitation of the crystals of $(2,4,6)_3P{=}S$ in 70% yield. Mp 221 °C. Anal. ($C_{27}H_{33}O_9PS$) C, H, S.

$(2\text{-}MeOC_6H_4)_3P{=}S$. To a suspension of $(2\text{-}MeOC_6H_4)_3P$ (0.352 g, 1 mmol) in acetone (10 ml) was added elemental sulfur (0.032 g, 1mmol), and the mixture was stirred at room temperature for 3 h to afford the crystals of $(2\text{-}MeOC_6H_4)_3P{=}S$ in 87% yield, which were recrystallized from tetrahydrofuran to give the analytical sample. The melting point was not observed below 230 °C. Anal. ($C_{21}H_{21}O_3PS$) C, H.

$(2,6)_2PhP{=}S$ and $(2,6)Ph_2P{=}S$. Analogous treatments of $(2,6)_2PhP$ or $(2,6)Ph_2P$ as described above resulted in the formation of $(2,6)_2PhP{=}S$ (mp 170 °C) or $(2,6)Ph_2P{=}S$ (mp 159—160 °C) in 80—90% yields. Anal. ($C_{22}H_{23}O_4PS$) C, H, S and ($C_{20}H_{19}O_2PS$) C, H.

Preparation of Mercaptophosphonium Salt. To a solution of $(2,6)_3P{=}S$ (0.485 g, 1 mmol) in acetone (10 ml) was added with stirring 60% aqueous perchloric acid (0.4 ml). The resultant precipitates were filtered, washed with cold acetone, and dried in air to give $[(2,6)_3P{-}SH]ClO_4$ in 95% yield. Mp

181—182 °C. Anal. ($C_{24}H_{28}O_{10}ClPS$) C, H.

Desulfurization of $[(2.6)_3P\text{-}SH]^+$ Salts A suspension of $[(2,6)_3P\text{-}SH]ClO_4$ (0.338 g, 0.6 mmol) in 2-propanol (30 ml) was heated at 70 °C. Aliquots were taken at 1, 4, and 8 h of heating. The solvent was removed under reduced pressure, and the ^1H NMR spectra of the residue showed the presence of $[(2,6)_3P\text{-}SH]ClO_4$ and $[(2,6)_3P\text{-}H]ClO_4$[1] in 32 : 68, 29 : 71, and 29 : 71 ratios, respectively.

To a solution of $(2,6)_3P$=S (0. 2 mmol) in MEK (15 ml) was added 6M HCl (2 ml) (1 M=1 mol dm^{-3}). The resultant suspension was heated at 70 °C for 4 h to give new crystals, which were found to be identical with those of $[(2,6)_3P\text{-}H]Cl \cdot 2.5H_2O$ (55% yield, see below).

Preparation of $[(2.6)_3P\text{-}H]Cl \cdot 2.5H_2O$. To a solution of $(2,6)_3P$ (2.212 g, 5 mmol) in MEK (50 ml) was added 12M HCl (1 ml) dissolved in MEK (4 ml). The resultant precipitates were recrystallized from acetone (120 ml) to give $[(2,6)_3P\text{-}H]Cl \cdot 2.5H_2O$ in 95% yield. Mp 170—187 °C, decomposed. Anal. ($C_{24}H_{33}O_{8.5}ClP$) C, H, Cl.

Reactions of Triarylphosphine Sulfides with Triphenylphosphine in the Presence of Acid. A mixture of $(2,6)_3P$=S (3 mmol) and Ph_3P (0.800 g, 3.05 mmol) in acetone (30 ml) containing 6M HCl (1 ml) was heated at 50 °C for 3 h. The solvent was removed under reduced pressure, and the residual solid was treated with water (100 ml) to leave the crystals of Ph_3P=S (92% yield). To the aqueous filtrate was added 60% aqueous perchloric acid (1 ml) to precipitate the crystals of $[(2,6)_3P\text{-}H]ClO_4$[1] in 99% yield.

$(2,6)_2PhP$=S reacted with Ph_3P in analogous manner to give $[(2,6)_2PhP\text{-}H]ClO_4$[1] in 77% yield.

Preparations of (Alkylthio)phosphonium Salts. $[(2,6)_3P\text{-}SR]I$ (R=Me, Et, *n*-Bu) and $[(2,6)_2PhP\text{-}SMe]I$. To a solution of $(2,6)_3P$=S (1 mmol) in benzene (10 ml) was added MeI (0.2 ml) to give immediately the precipitates of $[(2,6)_3P\text{-}SMe]I$ in quantitative yield. Mp 220 °C, decomposed. Anal. ($C_{25}H_{30}O_6IPS$) C, H.

Analogous treatments of $(2,6)_3P$=S with RI (R=Et, Bu) resulted in the formations of $[(2,6)_3P\text{-}SEt]I$ (mp 206 °C) and $[(2,6)_3P\text{-}SBu]I$ (mp 175 °C) in 80 and 88% yields, respectively. Anal. ($C_{26}H_{32}O_6IPS$) C, H and ($C_{28}H_{36}O_6IPS$) C, H.

An analogous treatment of $(2,6)_2PhP$ with MeI resulted in the formation of $[(2,6)_2PhP\text{-}SMe]I$ in 84% yield. Mp 168—170 °C, decomposed. Anal. ($C_{23}H_{26}O_4IPS$) C, H.

$[(2,6)_3P\text{-}SR]Br$ and $[(2,6)_3P\text{-}SR]ClO_4$ (R=Et, Bu). To a solution of $(2,6)_3P$=S (1 mmol) in ethanol (20 ml) was added EtBr (0.5 ml). The mixture was heated at 55 °C for 2 h. The volatile materials were removed under reduced pressure, and the residual solid was washed with benzene to give $[(2,6)_3P\text{-}SEt]Br$ in 91% yield; mp 194 °C. It was dissolved in water (0.100 g 10 ml) by heating, and 60% aqueous perchloric acid (0.1 ml) was added at room temperature to give the precipitates of $[(2,6)_3P\text{-}SEt]ClO_4$ in 82% yield. The perchlorate salt was served for the elemental analysis. The melting point was not observed below 230 °C. Anal. ($C_{26}H_{32}O_{10}ClPS$) C, H

An analogous treatment of $(2,6)_3P$=S with BuBr resulted in the formation of $[(2,6)_3P\text{-}SBu]Br$ (74% yield, mp 174 °C) and $[(2,6)_3P\text{-}SBu]ClO_4$ (86%, the melting point was not observed below 230 °C. Anal. ($C_{28}H_{36}O_{10}ClPS$) C, H.

Reactions of $[(2,6)_3P\text{-}SR]I$ (R=Me, Et, *n*-Bu) with Thiols. A mixture of $[(2,6)_3P\text{-}SMe]I$ (0.308 g, 0.5 mmol), PhSH (0.1 ml, 0.55 mmol), and $(2,6)_3P$ (0.022 g, 0.05 mmol) in methanol (10 ml) was stirred under argon at room temperature for 24 h. An aliquot was analyzed by GLC to confirm the selective formation of MeSSPh. The mixture was acidified by addition of 1 M HCl (0.1 ml), the volatile materials were removed under reduced pressure, and the residue was treated with benzene (10 ml) to separate the excess PhSH and MeSSPh. The ^1H NMR and the IR spectra of the residue were identical with those for $[(2,6)_3P\text{-}H]I$ (94% yield). The GLC retention time of MeSSPh was measured separately with the sample obtained by exchange reaction[13] of two symmetrical disulfides catalyzed by Ph_3P or $(2,6)_3P$. When $[(2,6)_3P\text{-}SMe]I$ was reacted with 4-MeC_6H_4SH or *n*-$C_8H_{17}SH$ in analogous manners, the ^1H NMR spectrum showed that the residues contained mainly $[(2,6)_3P\text{-}H]I$ (95% yield) and small amounts (<2%) of unreacted $[(2,6)_3P\text{-}SMe]I$. The yields (>90%) of MeSSR were estimated by ^1H NMR or GLC.

Analogous results were obtained for $[(2,6)_3P\text{-}SEt]I$ and $[(2,6)_3P\text{-}SBu]I$, and they reacted with PhSH, 4-MeC_6H_4SH, and $C_8H_{17}SH$ under the same conditions to give $[(2,6)_3P\text{-}H]I$ (>85% yields) and unsymmetrical disulfides (^1H NMR or GLC, >85% yields).

Preparation of $[(2,6)_3P\text{-}H]I$. $(2,6)_3P$ (3 mmol) was dissolved in water (150 ml) containing HCl (7 mmol). Addition of KI (0.548 g, 3.3 mmol) solution in water (3 ml) resulted in the precipitation of crystals, which were recrystallized from water to give $[(2,6)_3P\text{-}H]I$ in 80% yield. Mp 215—217 °C. Anal. ($C_{24}H_{28}O_6PI$) C, H, I.

Preparation of (Phenylthio)phosphonium Salt. A mixture of $[(2,6)_3P\text{-}H]Cl \cdot 2.5H_2O$ (1.572 g, 3 mmol) and PhSSPh (0.218 g, 1 mmol) in methanol (10 ml) was heated in a sealed glass tube at 80 °C for 24 h. The solvent was removed under reduced pressure, and the residue was extracted with benzene (10 ml)-water (45 ml). Addition of 1 M sodium hydroxide (3.5 ml) to the water layer resulted in the precipitation of $(2,6)_3P$ (2.36 mmol). To the filtrate was added 60% percloric acid to result in the precipitation of $[(2,6)_3P\text{-}SPh]ClO_4$ (0.3 mmol). The melting point was not observed below 230 °C. Anal. ($C_{30}H_{32}O_{10}ClPS$) C, H.

Reaction of $[(2,6)_3P\text{-}H]I$ with Base. To a methanol (4 ml) solution of $[(2,6)_3P\text{-}H]I$ (0.570 g, 1 mmol) was added 1 M sodium hydroxide (1.1 ml) to give light yellow precipitates, which were washed well with water and filtered to give $(2,6)_3P$ in 95% yield.

This work was partially supported by the Grant-in-Aid for Scientific Research on Priority Area of Organic Unusual Valency No. 02247215 from the Ministry of Education, Science and Culture, and partly by the Asahi Glass Foundation for Industrial Technology.

Titanium(III) Chloride Mediated Reduction of 1-Nitro-2-phenylethenes

Akira SERA,* Shoji FUKUMOTO, Masako TAMURA, Kiyoshi TAKABATAKE, Hiroaki YAMADA, and Kuniaki ITOH
Department of Chemistry, Faculty of Science, Kobe University, Kobe 657
(Received December 14, 1990)

The reaction of 1-nitro-2-phenylethenes (β-nitrostyrenes) with aqueous titanium(III) chloride afforded substituted pyrroles in addition to the expected reduction products, oximes and carbonyl compounds. 2-Substituted 1-nitro-2-phenylethenes yielded divinylamine derivatives instead of pyrroles. The reaction mechanism has been rationalized by taking account of the electron transfer from titanium(III) species to the nitro olefins, followed by protonation, dimerization, cyclization, and/or hydrolysis.

Much attention has been paid to the role of conjugated nitroalkenes as versatile intermediates in organic synthesis, since they may be transformed into legions with diverse functionalities.[1,2] The conversion of nitroalkenes to alkylamines has been accomplished through the use of catalytic hydrogenation, lithium aluminum hydride, or sodium borohydride–boron trifluoride.[3] Carbonyl compounds and their oximes have been prepared from nitroalkenes by means of titanium(III) chloride,[4] Raney nickel/sodium phosphinate,[5] chromium(II) chloride,[6] lithium trialkylhydroborate,[7] zinc/acetic acid,[8] lead/acetic acid,[9] sodium stannite,[10] tin(II) chloride,[11,12] and electrochemical means.[13,14] In addition, nitriles are synthesized by reactions of nitroalkenes with iodotrimethylsilane[15] or by a cathodic reduction in the presence of titanium(IV) chloride.[16]

We previously reported that the reaction of 1-nitro-2-phenylethenes **1** with titanium(III) chloride yields divinylamine derivatives **4** and pyrroles **5**, in addition to the expected oximes **2** and carbonyl compounds **3**.[17] This paper is concerned with the synthetic utility and the mechanistic features of the titanium(III) chloride-mediated reduction of several 1-nitro-2-phenylethenes (**1**, substituted β-nitrostyrenes).

Results and Discussion

A report by McMurry and Melton[4] indicates that 1-nitrocyclooctene is readily reduced with aqueous titanium(III) chloride in tetrahydrofuran at pH <1 to give cyclooctanone in 55% yield. However, we found that the reaction of **1a—d** with titanium(III) chloride under almost neutral conditions (pH=6.5, an ammonium acetate buffer) results in dimerized and/or cyclized products in addition to the expected carbonyl compounds or oximes. The product distribution was dependent on the structural features of the starting 1-nitro-2-phenylethenes (Table 1). The reaction of **1a** with titanium(III) chloride (6 mole equiv) afforded a small amount of 3,4-diphenylpyrrole (**5a**) along with 1,4-dinitro-2,3-diphenylbutane (**6a**). The formation of **5** and **6** is the first example of the reductive dimerization of nitro olefins by chemical means. Since **6a** was thought to be a possible intermediate for pyrrole forma-

a) Taken in part from Ref. 17. b) In aqueous tetrahydrofuran at pH 6.5. Molar $TiCl_3$/**1** ratio was 6. c) Isolated yields. d) Molar $TiCl_3$/**1** ratio was 12. e) Molar $TiCl_3$/**1** ratio was 18. f) In acetonitrile.

tion, the reaction was conducted with 12-fold molar titanium(III) chloride at an elevated temperature. Expectedly, **5a** was obtained in an improved yield (32%). The reaction conditions were then examined to improve the yields of **5a**. As shown in Table 2, the reaction with 12 molar titanium(III) chloride in neutral aqueous 1,4-dioxane at 35 °C gave **5a** in a satisfactory yield (50%). Phenylacetaldehyde (**3a**) could not be isolated because of its instability under the reaction conditions employed.[18] Similar results were obtained for a series of substituted 1-nitro-2-phenylethenes (**1b—d**) possessing a hydrogen atom at the β-position to the nitro group (R^2=H). In all cases, pyrroles **5b—d** as well as carbonyl compounds **3b—d** were obtained. Although many procedures have been documented for pyrrole synthesis,[19] the present reaction may be taken as a new entry into symmetrically substituted pyrroles. The major advantages of the present method are that the operation is simple and the starting compounds are easily prepared from the corresponding aldehydes and nitroalkanes.

	12 (pH=4.4)	23
	12 (pH<1)	0

a) At 35 °C for 24 h, pH=6.5. b) Isolated yields. c) At 65 °C.

The reaction of **1a** with an insufficient amount (3 mole equiv) of titanium(III) chloride yielded **6a** (15%), **7a** (3%), and 2,3-diphenyl-4-nitrobutanal oxime (**11**, 23%). These partially reduced products were supposed to be the intermediates leading to pyrrole **5a**. Accordingly, **6a** was synthesized by the Michael reaction of **1a** with 1-nitro-2-phenylethane, and the product was separated to the *meso*- and *dl*-**6a**. Titanium(III) chloride reduction of these two isomers did not afford **5a** at all; however, the disodium salt of **6a** could be reduced under the present reduction conditions to produce **5a**. Thus, the dinitronate anion (**B**) of **6a** should be the actual intermediate, and the formation of pyrroles is rationalized by taking account of the stepwise electron transfer-protonation process (Scheme 2).[4] Electron transfer from the titanium(III) species to **1** gives rise to an anion radical (**A**) stabilized by the 2-phenyl substituent. This anion radical is further reduced to give an oxime **2**, which is readily reduced by aqueous titanium(III) chloride to give an imine (overall six-electron transfer).[20,21] Upon hydrolysis this imine gives rise to a carbonyl compound **3**. The formation of a carbonyl compound by direct hydrolysis of oxime is unlikely under the present conditions. The anion radical (**A**) would dimerize to give an intermediate (**B**) which is further reduced by titanium(III) chloride to a diimine through the dioxime **7**. Elimination of ammonia from the imine–enamine tautomeric form (**C**) of the diimine intermediate finally affords the pyrrole derivative **5**. In the reductions of 1-nitro-1-alkenes by known methods,[4–14] no dimeric products were reported. The formation of the dimeric products is therefore characteristic of the reaction with titanium(III) chloride. Chelation of two anion radical intermediates with titanium(III or IV) species would hold both radical centers sufficiently close

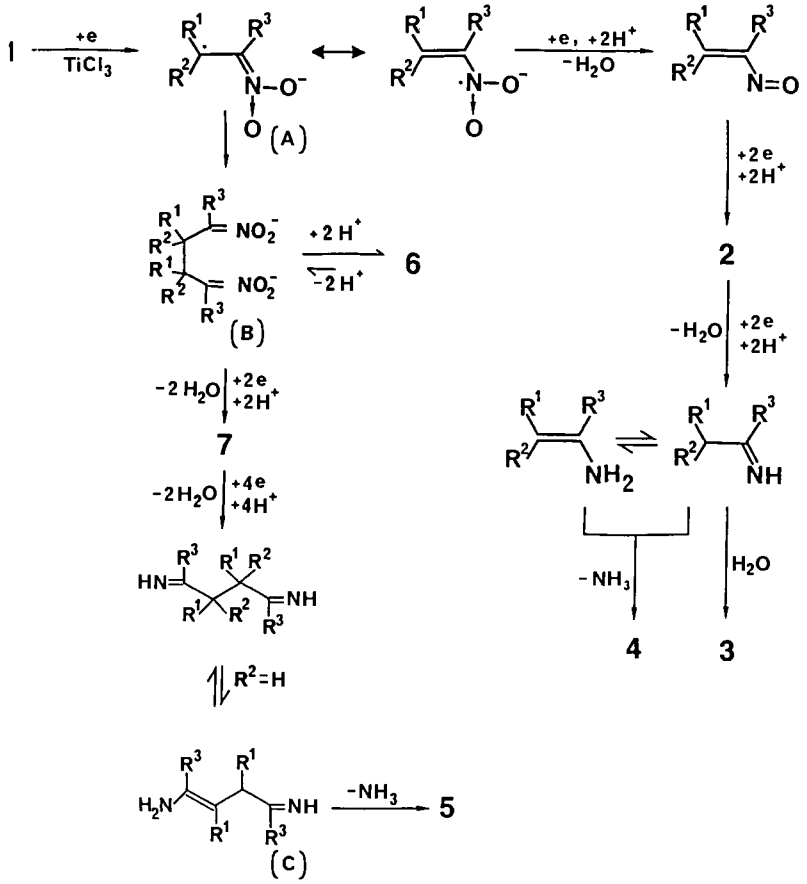
to achieve radical coupling, just as was proposed for the electrochemical hydrodimerization of cinnamate esters.[22]

On the other hand, the reaction of nitroolefins possessing no β-hydrogen atom **1f,g** with titanium(III) chloride yielded divinylamine derivatives **4f,g**. In these cases carbonyl compounds **3f,g** and oximes **2f,g** were produced, but no pyrrole was detected. The yield of **4f** increased at the expense of that of **2f** with excess titanium(III) chloride at higher temperature. The divinylamines **4f,g** may be regarded as forms of cross-conjugated dienamines (an open chain version of pyrrole). Many cross-conjugated dienamines have been described in the literature.[23] However, those dienamines which possess a structural feature of C=C–N–C=C, like **4f,g**, have been only little documented,[24,25] although many of those possessing the C=C–C=C–N and C=C(N)–C=C functionalities have been synthesized and their characteristics are thoroughly elucidated.[23] The mechanism of divinylamine formation can be considered to be as follows. The intermediate radical anions (**A**) from **1f,g** are highly stabilized and have no tendency to dimerize to (**B**), due to the presence of two bulky phenyl groups on the radical center. The electron transfer-protonation process thus gives rise to oximes **2f,g**, which are reduced further to give imine intermediates. These imines yield carbonyl compounds by hydrolysis or tautomerize to enamines. Spectroscopic studies[24,26] have shown that the equilibrium is usually almost completely in favor of the imine form for simple nonconjugated aldimines and ketimines. Nevertheless, imine–enamine tautomerism has been clearly demonstrated for reactions in which the enamine tautomer reacts with a variety of electrophiles.[27] In the present case the primary enamines are stabilized by conjugation with the two phenyl groups. Intervention of the imine–enamine tautomerism was further confirmed by trapping these species. In the presence of aniline, the titanium(III) chloride reduction of **1f** yielded *N*-(2,2-diphenylethylidene)aniline, produced by the addition of aniline to an imine (2,2-diphenylethanimine) followed by elimination of ammonia. On the other hand, addition of *N*-benzylidene butylamine afforded *N*-benzylidene-2,2-diphenylvinylamine, produced by the addition of an enamine (2,2-diphenylvinylamine) to the Schiff base followed by the elimination of butylamine. From these observations, it is clear that the nucleophilic addition of the enamine to the imine followed by the elimination of ammonia afforded divinylamine **4f**[28] as the final product. The product selectivity is thus governed by both the nature and number of substituents at C_2 of the starting 1-



Scheme 2.

nitroethenes.

As expected, 1-nitro-2-(2-nitrophenyl)ethene (**1h**) yielded indole (**8**). 3,3′-Bi-1*H*-indole (**9**) was also produced by dimerization of the intermediate radical anion (**A**) followed by cyclization. The absence of 3,4-bis-(2-aminophenyl)pyrrole, another possible cyclization product from the dimerized intermediate, indicates a predominance of the imine tautomer in the imine–enamine tautomerism of the dimerized intermediate. The titanium(III) chloride reduction of 1,2-dinitro-1,2-diphenylethene (**1i**) and 1,1-dinitro-2,2-diphenylethene (**1j**) resulted only in the formation of benzil dioxime and benzophenone (hydrolysis product), respectively.

Experimental

All melting points were determined on a micro hot-plate melting-point apparatus and are not corrected. IR spectra were measured on a JASCO IRA-3 spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded on JEOL FX-90Q and PS-100 spectrometers. Chemical shifts are given in ppm downfield from internal tetramethylsilane. Mass spectra were recorded on an ESCO EMD-05A spectrometer.

Substituted nitroethenes were prepared according to methods described in the literatures.[29] Solvents were purified as usual. Aqueous titanium(III) chloride solution was purchased from Wako Chemical Ind., and titrated before use.

General Procedure of Titanium(III) Chloride Reduction. A buffered titanium(III) chloride solution was prepared by adding ammonium acetate (5.5 g, 71 mmol) in 25 ml of water to a 1.76 M aqueous titanium(III) chloride solution (11 ml) under nitrogen (1 M=1 mol dm^{-3}). Adjustment of the pH was achieved by adding 10% (w/v) aqueous ammonia to the solution. A solution of 1-nitro-2-phenylethene (**1**, 3 mmol) in 14 ml of tetrahydrofuran was rapidly added to the buffered titanium (III) chloride solution; the solution was stirred at 0 °C under nitrogen. The reaction was monitored by TLC. After the substrate was completely consumed, the reaction mixture was extracted several times with diethyl ether. The combined extracts were washed successively with aqueous sodium hydrogencarbonate and sodium chloride solutions, and dried over magnesium sulfate. The solvent was removed under reduced pressure and the residue was subjected to silica gel chromatography. The results are given in the Tables.

Representative Products of the Titanium(III) Chloride Reduction. 3,4-Diphenylpyrrole (5a):[30] Oil, IR (neat) 3400, 1720, 1600, and 1560 cm^{-1}; ^{1}H NMR (CCl_4) δ=6.7 (2H, d, J=2.6 Hz), 7.1 (10H, m), and 8.0 (1H, br); MS m/z 219 (M^+), 218, 190, 188, and 164.

1,4-Dinitro-2,3-diphenylbutane (6a): A *meso*–*dl* mixture; mp 178—180 °C; IR (KBr) 1550 and 1380 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.5—5.2 (6H, m) and 7.3 (10H, m); MS m/z 300 (M^+), 254, 223, 208, and 194. Found: C, 63.79; H, 5.50%. Calcd for $C_{16}H_{16}N_2O_4$: C, 63.99; K, 5.37%.

meso and *dl*-**6a**[31] were prepared.

meso-**6a:** Mp 101—102 °C; IR (KBr) 1554, 1380, 790, and 696 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.7—4.1 (2H, br. t), 4.8—5.3 (4H, br), and 6.8—7.4 (10H, s); ^{13}C NMR ($CDCl_3$) δ=45.7, 77.3, 128.6, 128.7, 129.1, and 134.3; MS m/z 300 (M^+), 254, 223, 208, and 194. dl-**6a:** Mp 240—243 °C; IR (KBr) 1554, 1382, 790, and 700 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.7—3.9 (2H, br. t), 4.1—4.3 (2H, br. dd), 4.7—5.1 (2H, br. t), and 7.2—7.7 (10H, m); ^{13}C NMR (DMSO-d_6) δ=46.8, 78.7, 127.9, 128.0, 128.8, and 137.5; MS m/z 300 (M^+), 254, 223, 208, and 194.

2,5-Dimethyl-3,4-diphenylpyrrole (5b):[32] Mp 145—148 °C; IR (KBr) 3350, 1600, 1500, 1450, and 770 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.2 (6H, s), 7.0 (10H, m), and 7.3 (1H, br); MS m/z 247 (M^+), 246, 202, 179, and 77.

3,4-Diphenyl-2,5-hexanedione Dioxime (7b):[32] Mp 370 °C (decomp); IR (KBr) 3240 and 1500 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=1.5 (6H, s), 4.2 (2H, s), 7.2 (10H, m), and 9.7 (2H, s); MS m/z 296 (M^+), 279, 262, 247, and 188.

2,5-Diethyl-3,4-diphenylpyrrole (5c):[33] Mp 149—150 °C; ^{1}H NMR ($CDCl_3$) δ=1.2 (6H, t), 2.6 (4H, q), 7.1 (10H, m), and 7.5 (1H, br); MS m/z 275 (M^+), 274, 260, 246, 231, and 230.

Benzyl Phenyl Ketone Oxime (2d):[34] Mp 86—89 °C; IR (KBr) 3200, 1605, 1495, and 1450 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.1 (2H, s), 6.5—7.7 (10H, m), and 9.3 (1H, br); MS m/z 211 (M^+), 193, 164, 119, 103, and 91.

2,3,4,5-Tetraphenylpyrrole (5d):[35] Mp 213.5—214 °C; ^{1}H NMR ($CDCl_3$) δ=6.8—7.4 (20H, m) and 8.2 (1H, br); MS m/z 371 (M^+), 370, 293, 265, and 216.

Diphenylacetaldehyde Oxime (2f):[36] Mp 117—118.5 °C; IR (KBr) 3260, 1600, 1450, 1250, 960, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.9 (1H, d, J=7 Hz), 7.1—7.5 (10 H, s), 7.8 (1H, d, J=7 Hz), and 8.0 (1H, s); ^{13}C NMR ($CDCl_3$) δ=51.3, 127.2, 128.6, 128.8, 140.3, and 153.1; MS m/z 211 (M^+), 194, 180, 167, and 115.

Bis(2,2-diphenylvinyl)amine (4f):[24] Pale yellow needles (benzen–hexane), mp 143.5—144.5 °C; IR (KBr) 3360 and 3200 cm^{-1}; UV (MeCN) λ_{max} 360 nm (ε_{max}=25600); ^{1}H NMR ($CDCl_3$) δ=6.6 (2H, s) and 7.0 (20H, m, Ph and NH); ^{13}C NMR ($CDCl_3$), geminal two phenyl rings are not equivalent, δ=117.5 ($Ph_2\underline{C}$=), 126.7, 127.3, 128.2, 129.4 (C=$\underline{C}$HN–), 129.7, 130.3, 131.2, 139.4, and 142.6; MS m/z 373 (M^+), 372, 296, 206, and 179. Found: C, 89.86, H, 6.28, N, 3.77%. Calcd for $C_{28}H_{23}N$: C, 90.04, H, 6.21, N, 3.75%.

1,1-Diphenyl-2-propanone Oxime (2g):[37] Mp 160—162 °C; IR (KBr) 3420, 1605, 1495, and 1455 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.8 (3H, s), 4.9 (1H, s), 7.1 (10H, m), and 8.5 (1H, s); MS m/z 225 (M^+), 208, 193, 167, 165, and 152. Found: C, 80.03, H, 6.83%. Calcd for $C_{15}H_{15}NO$: C, 79.97, H, 6.71%.

Bis(1-methyl-2,2-diphenylvinyl)amine (4g): Oil, IR ($CHCl_3$) 3400 and 1610 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.2 (6H, s), and 6.8—7.7 (21H, m, Ph and NH); MS m/z 207 (M^+-Ph_2C=CHMe), 206, 178, 165, and 130.

3,3′-Bi-1*H*-indole (9):[38] Mp 280 °C (decomp); IR (KBr) 3380 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=6.7—7.8 (10H, m) and 10.9 (2H, br); MS m/z 232 (M^+), 231, and 203.

Reduction of 1a with 3 Molar Equivalents of Titanium(III) Chloride. Reaction of **1a** (4.47 g, 30 mmol) with 90 mmol of titanium(III) chloride under the standard conditions for 45 h yielded, after usual work-up, **6a** (15%), **7a** (3%), and 2,3-diphenyl-4-nitrobutanal oxime (**11**, 23%).

2,3-Diphenyl-4-nitrobutanal Oxime (11): An isomer mixture; mp 205—210 °C; IR (KBr) 3400, 1555, 1460, 1385, and 705 cm^{-1}; ^{1}H NMR (DMSO-d_6) δ=3.5—5.0 (8H, m), 6.8 (1H, d, J=8 Hz), 7.2 (1H, d, J=8 Hz), 7,1—7.7 (20H, m), 10.3 (1H, s), and 10.7 (1H, s); ^{13}C NMR (acetone-d_6) δ=44.5 and 49.2, 49.5 and 50.8, 80.3, 128.6 and 129.6, 129.0 and 128.0, 129.8 and 129.7, 129.8 and 129.9, 130.2 and 130.4, 130.2 and 130.5, 139.5, 140.5, 151.1 and 151.4; MS m/z 284 (M^+), 283, 253, 207, and 205. Found: C, 67.34; H, 5.95; N, 9.78%. Calcd for

$C_{16}H_{16}N_2O_3$: C, 67.51; H, 5.67; N, 9.85%.

Reduction of Disodium Salt of 6a with Titanium(III) Chloride. A solution of disodium salt (173 mg, 0.5 mmol) of **6a** in methanol (8 ml) was added to a buffered solution (pH=6.5) of titanium(III) chloride; the mixture was stirred for 24 h at room temperature. After the usual work-up, 20 mg (18%) of **5a** was obtained.

Titanium(III) Chloride Reduction of 1f in the Presence of Aniline or *N*-Benzylidenebutylamine. 1,1-Diphenyl-2-nitroethene (**1f**, 3 mmol) was reduced in a buffered aqueous tetrahydrofuran solution (pH 6.5) containing titanium(III) chloride (18 mmol) and aniline (3 mmol) at 30 °C for 2 h. After the usual work-up, the product was chromatographed on silica gel to give *N*-(2,2-diphenylethylidene)aniline (62%). This compound was easily oxidized by air to give benzophenone (57%) and *N*-formylaniline (47%). A similar reaction carried out in the presence of *N*-benzylidenebutylamine (15 mmol) yielded *N*-benzylidene-2,2-diphenylvinylamine (40%) as yellow crystals: Mp 131.5—133.5 °C; IR (KBr) 1620, 1590, 1550, 1480, and 1440 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.0—7.7 (16H, m, PhX3 and C=C<u>H</u>–N) and 8.3 (1H, s, –N=C<u>H</u>Ph); MS *m/z* 283 (M^+), 206, 178, and 165. Found: C, 89.20; H, 6.21; N, 4.89%. Calcd for $C_{21}H_{17}N$: C, 89.05, H, 6.01; N, 4.95%.

A new attempt of utilizing solid acids and bases for ring opening of epoxides with Me_3SiCN was investigated. Solid strong bases such as calcium oxide and magnesium oxide catalyzed the regio- and chemoselective ring opening of epoxides with Me_3SiCN much more effectively than homogeneous catalysts. On CaO and MgO, the reactions of unsymmetrical epoxides with Me_3SiCN afforded 3-trimethylsiloxyalkanenitriles in high yields through regio- and stereoselective attack of cyanide ion on the less substituted epoxycarbon. Additionally, on CaO, 2,3-epoxy-1-alkanol derivatives were selectively converted to the corresponding C-3 opened products by the attack of cyanide ion. In these cases no isocyanides were formed. It was suggested that CaO acted as a bifunctional catalyst; the lattice oxide anions of CaO activated Me_3SiCN, and simultaneously calcium ions promoted the ring opening of epoxyalkanol as Lewis acid sites.

Cyanotrimethylsilane (Me_3SiCN), which is considered as stabilized hydrogen cyanide, has been widely applied to organic synthesis.[1] Recently Me_3SiCN has been reported to react with epoxyalkanes in the presence of various Lewis acids to give 3-trimethylsiloxyalkanenitriles or 2-trimethylsiloxyalkyl isocyanides.[2] "Hard" acids such as $AlCl_3$,[3,4] Et_2AlCl,[3,5] $Al(O^iPr)_3$,[5] $LuCl_3$,[6] and $Ti(O^iPr)_4$[7] promote the reaction of epoxides with Me_3SiCN to afford 3-trimethylsiloxyalkanenitriles. In contrast, 2-trimethylsiloxyalkyl isocyanides are predominantly produced in the presence of "Soft" acids such as $ZnCl_2$,[8] ZnI_2,[8] $Pd(CN)_2$,[5] and $SnCl_2$.[5] In acid-promoted nitrile formation via ring openings of unsymmetrical epoxides, however, the problems of low regioselectivity and contamination of isocyanides are often encountered.[5]

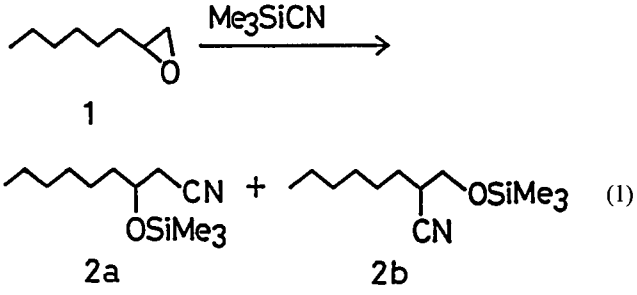
We have attempted to utilize inorganic solid acids and bases such as zeolites[9] and clay montmorillonite[10] for several types of liquid-phase organic reactions. These heterogeneous organic reactions on inorganic solids are becoming very useful for the following reasons:[11] (1) They are operationally simple, with product isolation involving only filtration and solvent evaporation, (2) they are often more selective and milder than the corresponding homogeneous reactions, (3) a synergistic reaction-promoting effect by acid and base sites is expected because both acid and base sites can exist independently on the surface of solid.

Recently we found that inorganic solid bases could efficiently activate Me_3SiCN to react with carbonyl compounds to afford 3-trimethylsiloxyalkanenitriles.[12] On the basis of this finding, we applied several types of solid bases as promoters to ring openings of unsymmetrical epoxides and 2,3-epoxy-1-alkanol derivatives with Me_3SiCN, and reported in a rapid communication that certain solid bases such as CaO and MgO greatly activated the ring opening of epoxides to produce exclusively 3-trimethylsiloxyalkanenitriles in a highly regioselective manner.[13] Regioselective ring opening of 2,3-epoxy-1-alkanol derivatives with nucleophiles is an intriguing synthetic subject since easily available, optically pure 2,3-epoxy-1-alkanols are important building blocks for synthesis of natural products.[14] In this context, we have previously demonstrated a highly regioselective ring opening of 2,3-epoxy-1-alkanols with several inorganic nucleophiles supported on a solid acid of calcium ion-exchanged Y-typed zeolite, in which the calcium ions bound in zeolite regulated the ring opening by forming a five-membered chelate complex with 2,3-epoxy-1-alkanol.[9b,9c]

In this paper, we describe the details of ring opening of epoxides promoted by inorganic solid bases such as CaO and MgO, comparing with the effects by other soluble promoters of $Al(O^iPr)_3$ and $^nBu_4NF$. In addition, we discuss the role of the metal cations of solid bases in regioselective ring opening of 2,3-epoxy-1-alkanol, based on a spectroscopic evidence for the formation of a five-membered chelate complex of Eu^{3+} with 2,3-epoxy-1-alkanol.

Results and Discussion

1) Reactions of Unsymmetrical Epoxides with Me_3SiCN. The reaction of 1,2-epoxyoctane (**1**) with Me_3SiCN was examined in the presence of various solid catalysts in heptane, and the results are listed in Table 1 (Eq. 1). On solid bases such as CaO, MgO, hydroxy-



(1)

apatite (HAp, $Ca_{10}(PO_4)_6(OH)_2$),[15] and CaF_2, the ring opening of the epoxide was accelerated to produce 3-(trimethylsiloxy)nonanenitrile (**2a**) in over 97% regiose-

Table 1. Ring Opening of 1,2-Epoxyoctane (**1**) with Me_3SiCN

Run	Solid catalyst	Solvent	Condition Temp/°C (Time/h)	Yield %	**2a : 2b**
1	CaO[a]	Heptane	R.T. (0.5)	98	97 : 3
2	MgO[a]	Heptane	R.T. (0.5)	97	98 : 2
3	HAp[a,b]	Heptane	R.T. (1.5)	97	98 : 2

SiO_2	585	$+3.3 \geqslant H_o \geq +1.5$
Fe-Mont	37	$-8.2 \geqslant H_o$

a) Specific surface area. b) Maximum acid or base strength were measured by use of Hammett indicators in benzene. c) H_- of CaF_2 could not be determined.

lectivity (Run 1—4). The catalytic activity of solid base decreased in the order of $CaO \fallingdotseq MgO > HAp \gg CaF_2$, correlating to their intrinsic base strengths (Table 2). In contrast to the solid bases, strongly acidic montmorillonite (Fe-Mont), as well as weakly acidic silica (SiO_2), showed no catalytic activity for the ring opening (Run 5, 6). When Me_3SiCN and a soluble Lewis acid such as $Al(O^iPr)_3$ or $^nBu_4NF$ were treated with **1**, reaction rates were largely reduced compared with the cases of CaO and MgO (Run 7, 8).

Since silicon has strong affinities for fluoride ion and oxide ion, when combined with fluoride ion or oxide ion, silicon can expand its coordination number from the normal value of four to five or six to form penta- or hexacoordinated compounds.[16] These penta- and hexacoordinate silicon compounds have higher reactivities than the ordinary tetracoordinate silicon compounds. On the other hand, the basic sites on CaO and MgO were reported to be the surface lattice oxygen (O^{2-}) species.[17] It can be, therefore, presumed that a strongly basic site of O^{2-} on the surface of CaO or MgO coordinates to Me_3SiCN to release a cyanide ion, resulting in nucleophilic ring opening of epoxides (Chart 1).[18]

Next, the reaction of **1** with Me_3SiCN on MgO was examined with respect to the influence of the reaction solvent (Table 3). The reaction rate was remarkably decreased when dimethoxyethane (DME) was used. A polar solvent such as DME may strongly adsorb on the surface of MgO to weaken the interaction between Me_3SiCN and MgO.

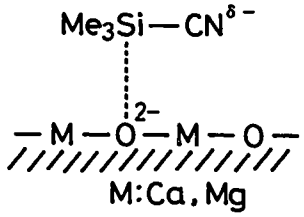

Chart 1.

Table 3. Effects of Solvent in the Reaction of **1** with Me_3SiCN on MgO[a]

Run	Solvent	Time/h[b]	Yield/%	**2a : 2b**

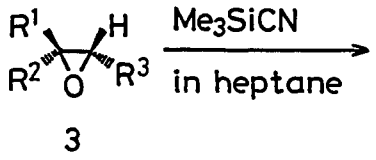
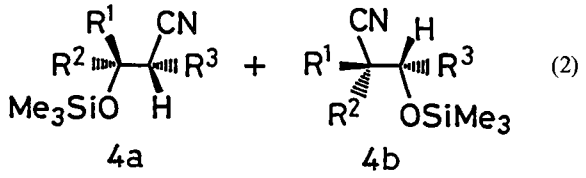
a) Epoxide (1 mmol), Me_3SiCN (2 mmol), and solid catalyst (0.2 g) in heptane, at room temperature. b) Epoxide (1 mmol), Me_3SiCN (1.5 mmol), and $Al(O^iPr)_3$ (1.5 mmol), in heptane, at room temperature.

The synthetic potential of the present method was demonstrated by the successful employment of other epoxides (Eq. 2). Table 4 shows the ring openings of



3

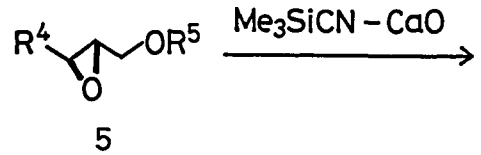


4a 4b (2)

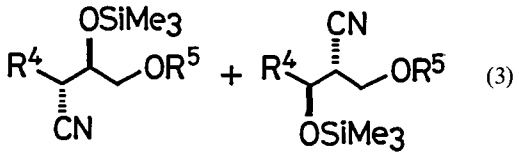
various unsymmetrical epoxides (**3**) with Me_3SiCN on CaO and MgO. All the epoxides investigated quantitatively afforded 3-trimethylsiloxyalkanenitriles by highly regioselective ($\geqslant$94%) attack of cyanide on the less substituted epoxycarbon without the formation of isocyanides. The ring opening in Run 3—5 occurred completely in an S_N2 fashion. Previously it was reported that a soluble strong base such as lithium diethylamide induced the rearrangement of epoxides to the corresponding allylic alcohols.[19] However, CaO and MgO never induced this type of rearrangement.

When Me_3SiCN and a soluble Lewis acid $Al(O^iPr)_3$ were treated with epoxides (**3**), regioselectivity was reduced (Run 5, 8). Consequently, solid bases of CaO and MgO were ascertained to be very effective in the regioselective ring-opening of epoxides with Me_3SiCN.

2) Base Induced Regioselective Ring Openings of 2,3-Epoxy-1-alkanol Derivatives with Me_3SiCN. On CaO, the ring opening of trans-2,3-epoxy-1-hexanol (**5**)[20] with Me_3SiCN (Eq. 3) smoothly took place at



5



6a 6b (3)

room temperature to afford **6a** and **6b** in good total yield (86%) and good regioselectivity (89 : 11). We assume that such high regioselection is attributed to the formation of a five-membered chelate complex between two oxygen atoms of the epoxyalkanol and a calcium ion of CaO. This chelate formation directs the ring-opening site of epoxide.[9b,9c] When 2,3-epoxy-1-alkanol was acetylated beforehand and then treated with

Table 5. CaO-Directed Reactions of *trans*-2,3-epoxy-1-alkanol and Its Derivative with Me_3SiCN[a]

Run	R^4	R^5	Condition Temp/°C (Time/h)	Yield %	**6a : 6b**
1	^{n}Pr	H	R.T. (4)	86	89 : 11
2	^{n}Pr	Ac	R.T. (4)	91	96 : 4
3	^{i}Pr	Ac	60 °C (1)	75	96 : 4
4	Cyclohexyl	Ac	60 °C (2)	84	97 : 3

a) CaO (0.5 g), epoxides (0.5 mmol), Me_3SiCN (1 mmol), in heptane.

Me_3SiCN on CaO, more regioselective ring opening at the C-3 carbon ($\geqslant$90) was realized as shown in Table 5. This higher regioselectivity would be caused by the inductive effect of the acetyl group in addition to the above-mentioned chelate formation between Ca^{2+} and 2,3-epoxy-1-acetate. In Runs 1—4 the ring openings proceeded with inversion of configuration, and no isocyanides were formed. MgO, HAp, and CaF_2 showed lower activities than CaO.

Compared with heptane, benzene and CH_2Cl_2 induced not only lower rates but lower regioselectivities. Benzene and CH_2Cl_2 may restrain the chelate formation between an epoxyalkanol molecule and a calcium ion. Furthermore, no ring-opening reaction occurred in DME. This strongly negative effect of DME is probably due to chelation of a calcium ion on CaO, so that DME may prevent a calcium ion from electrophilic activation of oxirane ring toward nucleophilic attack. Thus a less polar solvent is preferable in order to increase reaction rate and regioselectivity.

Reportedly, $Ti(O^iPr)_4$ promotes the reaction of *trans*-2,3-epoxy-1-hexanol with Me_3SiCN under DME reflux conditions to give C-3 and C-2 opening products in 83 : 17 regioselectivity and 32% yield.[21] In another control experiment, no reaction occurred when the *trans*-2,3-epoxy-1-hexanol was refluxed in THF with Me_3SiCN (3 equiv) in the presence of $^nBu_4NF$ (3 equiv). CaO thus catalyzed the ring opening of epoxyalkanols much more efficiently and selectively than $Ti(O^iPr)_3$ and $^nBu_4NF$.

3) Investigation on Chelate Complex Formation between 2,3-Epoxy-1-alkanol and Ca^{2+}. In order to clarify the role of Ca^{2+} ions of CaO in the nucleophilic ring opening of 2,3-epoxy-1-alkanol, we tried to confirm a putative intermediate complex formed from Ca^{2+} and 2,3-epoxy-1-alkanol in solution by means of ^1H NMR spectroscopy.[22] Unfortunately, most of calcium salts were sparingly soluble in nonpolar organic solvents suitable for ^1H NMR spectroscopy (e.g. $CDCl_3$). Here we chose $Eu(fod)_3$ instead of Ca^{2+} salts based on the following three reasons. First, Eu^{3+} (0.98 Å) is almost the same as Ca^{2+} (0.99 Å) with respect to ionic radius. Second, the coordination properties of Eu^{3+} have been recognized to be very similar to those of Ca^{2+}: Eu^{3+}, as well as Ca^{2+}, has a strong affinity for oxygen ion.[23]

Third, $Eu(fod)_3$ is freely soluble in organic solvents such as $CDCl_3$.

$Eu(fod)_3$ has been used as a typical NMR shift reagent.[24] Paramagnetic ions such as Lu^{3+} exert stronger magnetic fields on NMR spectra and afford greater spectral spreading properties, when coordinated by organic compounds which possess Lewis base sites. Therefore, the influence of magnetic fields by Lu^{3+} falls away sharply with the distance from Lu^{3+}, and the induced shifts will be significant only if a nucleus is in close average proximity to Lu^{3+}.

Figure 1 demonstrates the changes of chemical shifts in the ^1H NMR spectra (200 MHz) of 1-hexanol and *trans*-2,3-epoxy-1-hexanol with the amount of $Eu(fod)_3$ in $CDCl_3$. As expected, the shift of each proton of 1-hexanol induced by $Eu(fod)_3$ attenuated along the following series: $H_1>H_2>H_3>H_4>H_5>H_6$. However, the shifts observed in the case of *trans*-2,3-epoxy-1-hexanol decreased in the order of $H_3>H_1>H_2>H_4>H_5>H_6$. An anormalous larger shift of H_3 suggests that H_3 of *trans*-2,3-epoxy-1-hexanol is located closer to Eu^{3+}. By the molecular model examination of a bidentate complex of $Eu(fod)_3$ with *trans*-2,3-epoxy-1-hexanol, we could ascertain that the proton at C-3 and Eu^{3+} became so closely spaced each other as to interact strongly (Chart 2). Consequently it is obvious that the epoxyalkanol forms a bidentate complex with Eu^{3+}.

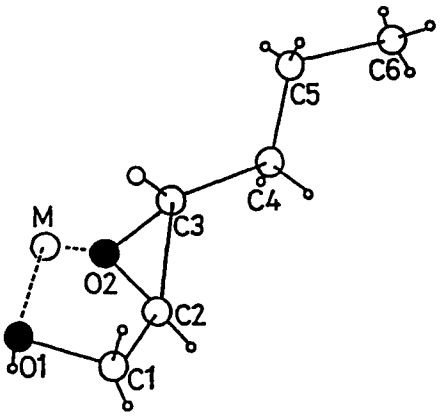


Chart 2.

The reaction of *trans*-2,3-epoxy-1-hexanol with Me_3SiCN in the presence of $Eu(fod)_3$[25] was rather slower and took about 20 h at 98 °C for completion. However, a good regioselectivity (88 : 12) and a good total yield of 80% were obtained as expected from the above mentioned complex formation. This regioselectivity was almost the same as that of the reaction on CaO.

$Ca(OTf)_2$ is easily prepared by adding triflic acid to a suspension of calcium carbonate in dry methanol.[26] $Ca(OTf)_2$ though not soluble in $CHCl_3$ is freely soluble in methanol and DMSO. By using $Ca(OTf)_2$ dissolved

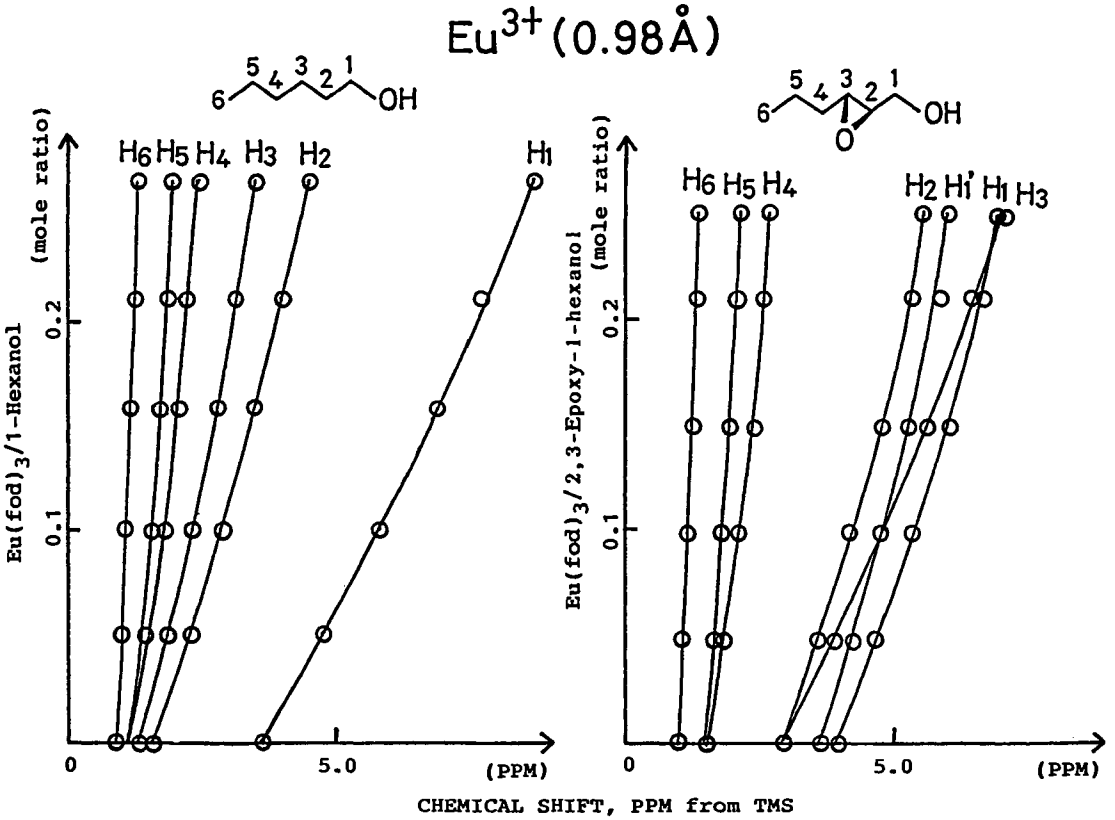

Fig. 1. Chemical shifts as a function of added $Eu(fod)_3$ to 1-Hexanol or 2,3-Epoxy-1-hexanol in 0.55 ml $CDCl_3$. 200 MHz spectra of 1-Hexanol or 2,3-Epoxy-1-hexanol with $Eu(fod)_3$ was measured at room temperature.

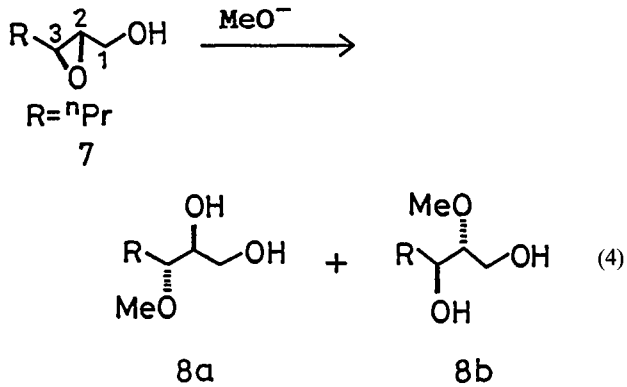
Table 6. Reactions of *trans*-2,3-Epoxy-1-hexanol (7) with MeO^-

Run	Promoter	Nucleophile	Condition	Yield %	8a : 8b
1	$Ca(OTf)_2$	MeOH[a]	$CHCl_3$, 50 °C, 3 h	82	79 : 21
2		MeONa[b]	THF, 50 °C, 18 h	36	64 : 36

a) 7 (1 mmol), MeOH (5 mmol), and $Ca(OTf)_2$ (1 mmol), in $CHCl_3$. b) 7 (1 mmol), and MeONa (3 mmol), in THF.

in MeOH–$CHCl_3$ (1 : 30), we could examine homogeneous ring opening of epoxyalkanol (Eq. 4). When



(4)

MeOH and $Ca(OTf)_2$ were treated with *trans*-2,3-epoxy-1-hexanol (7) in $CHCl_3$, a C-3 : C-2 ratio was as high as 79 : 21 (Table 6). On the other hand, when 7 and MeONa were vigorously mixed in THF in the absence of any calcium salt, a lower C-3 : C-2 ratio of 64 : 36 (**8a : 8b**) was obtained (Table 6). Evidently calcium ions could enhance the regioselectivity at C-3 acting as homogeneous Lewis acids.

On the basis of the spectroscopic study using $Eu(fod)_3$ and a comparative experiment using $Ca(OTf)_2$, it is concluded that the calcium ions on the surface of CaO regulate the ring-opening site, probably by forming bidentate chelate complexes with 2,3-epoxy-1-alkanol molecules.

Additionally, compared with the homogeneous Lewis acid-promoted reactions (e.g. $Al(O^iPr)_3$, $Ti(O^iPr)_4$ and $Eu(fod)_3$), CaO-promoted ring openings proceeded more efficiently and regioselectively because CaO served as a bifunctional catalyst; the oxide anions on CaO activated Me_3SiCN, and simultaneously the calcium ions on CaO activated epoxyalkanol as Lewis acids regulating the ring-opening site.

Conclusion

The present synthetic method using inorganic solid base catalysts provides a convenient and simple procedure for the regioselective ring opening of epoxides with Me_3SiCN. Especially the strong base solids such as CaO and MgO enable milder reaction conditions (room temperature, neutral reaction medium), higher regiospecific transformation, and easier product isolation than Lewis acids ever used in the corresponding homogeneous reactions. Further studies are underway to utilize base solids in various types of liquid-phase organic reactions which involve organosilicon reagents.

Experimental

Measurement. Infrared (IR) spectra were measured in $CDCl_3$ or CCl_4 with a JASCO IR-810 spectrometer. The ^1H NMR spectra were measured in $CDCl_3$ with Hitachi R-600 (60 MHz) and Varian GEMINI 200 (200 MHz) spectrometers. Tetramethylsilane (TMS) was used as an internal standard. The chemical shifts are given in δ (ppm) downfield from TMS, and the coupling constants are in hertz. Gas chromatographic analyses were carried out with a Shimadzu GC-8A instrument with a flame ionization detector and a capillary column (OV-1 bonded, 25 m and PEG-HT bonded, 25m).

Materials. MgO and CaO were prepared by calcining their hydroxide (Kishida Chemical Co.) at 500 °C/0.5 Torr (1 Torr=133.322 Pa), for 2 h. Hydroxyapatite[15] (HAp, $Ca_{10}(PO_4)_6(OH)_2$, Nacalai Tesque, Inc.) was dried at 500 °C/0.5 Torr for 2 h. CaF_2 (Kishida Chemical Co.) and Silica (Fuji-Davison B-Type) were dried at 200 °C/0.5 Torr for 2 h. Iron (III) ion-exchanged montmorillonite (Fe-Mont) was prepared from sodium ion exchanged montmorillonite (Kunipia-F, Kunimine Co.) by ion exchange.[10b] Fe-Mont was dried at 120 °C/0.5 Torr for 3 h.

Organic solvents were dried over molecular sieves 3A.

(2*S*,3*S*)-2,3-Epoxy-1-alkanols were prepared from trans allylic alcohols by Sharpless asymmetric epoxidation process.[27]

$Ca(CF_3SO_3)_2$. Trifluoromethanesulfonic acid (5 ml, 0.06 mol) was slowly added to a suspension of calcium carbonate (2 g, 0.02 mol) in dry methanol (20 ml) at room temperature. The reaction mixture was stirred at room temperature for 20 min, then at reflux for 2 h. It was concentrated under reduced pressure, and then the resulting white cake was dried at 130 °C/1 Torr for 3 h to give 6.6 g of calcium triflate (98% yield).

Acid and Base Strength Measurements of Solids. The method of measurement corresponded to Walling's method.[28] The following Hammett indicators (pK_a value) were employed; 4-nitroaniline (+18.4), 2,4-dinitroaniline (+15.0), phenolphthalein (+9.3), bromothymol blue (+7.2), 4-(dimethylamino)azobenzene (butter yellow) (+3.3), 4′-amino-2,3′-dimethylazobenzene (+2.0), 4-(phenylazo)-*N*-phenylaniline (+1.5), crystal violet (+0.8), and anthraquinone (− 8.2).

The color of the indicator adsorbed on the solid was visually observed after the addition of about 5 ml of dry benzene and one drop of a 0.1% solution of the indicator in benzene to 0.1 g of a solid.

Reactions of Unsymmetrical Epoxides with Me_3SiCN and Inorganic Solids. To a suspended mixture of the solid catalyst (0.2 g) and heptane (2 ml) were added a heptane solution

(3 ml) of epoxide (1 mmol), and Me_3SiCN (2 mmol), successively. The mixture was stirred under the conditions listed in Tables 1, 3, and 4. As work-up, ether (5 ml) was added, the solid catalyst was filtered off through a Celite pad and washed with ether. The filtrate was distilled on a Kugelrohr apparatus to yield the products. The regioisomeric ratios of the products were determined by ^1H NMR (200 MHz) and capillary GC (OV-1, 25 m).

Reaction of 1,2-Epoxyoctane with Me_3SiCN and $^nBu_4NF$. A solution of $^nBu_4NF$ in THF (1.1 M, 1 M=1mol dm^{-3}) was stored over activated 3A molecular sieves powders. (Activation of powdered 3A molecular sieves involved heating at 200 °C and 0.5 Torr pressure for at least 3 h.) Under a nitrogen atmosphere, the solution of $^nBu_4NF$ (3 mmol) was added to a solution of a 1,2-epoxyoctane (1 mmol) and Me_3SiCN (3 mmol) in THF (5 ml) at room temperature. The mixture was stirred at 60 °C for 4 h. The THF was removed by evaporation, and the residue was diluted with Et_2O. The reaction mixture was washed with water and the organic layer was dried over anhydrous Na_2SO_4. The organic layer was evaporated and distilled by a Kugelrohr apparatus to yield the products.

Reactions of Unsymmetrical Epoxides with Me_3SiCN and $Al(O^iPr)_3$. Under a nitrogen atmosphere, a mixture of $Al(O^iPr)_3$ (1.5 mmol) and Me_3SiCN (1.5 mmol) in hexane (5 ml) was stirred for 2 h at room temperature. An epoxide (1 mmol) was added and the mixture was stirred at room temperature. Then Me_3SiCN (8 mmol) was added and the mixture was stirred at room temperature for 20 h. As work-up, a mixture of ice and 3M NaOH was added, and the mixture was extracted with ether. The ethereal solution was washed with brine and dried over anhydrous Na_2SO_4. The organic layer was evaporated and distilled by a Kugelrohr apparatus to yield the products.

3-(Trimethylsiloxy)nonanenitrile. Bp 110 °C (bath temperature)/0.5 Torr; IR (CCl_4) 1253, 2251 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.15 (s, 9H, CH_3Si), 0.88 (t, 3H, J=7.7 Hz, CH_3), 1.10—1.44 (br, 8H, $(CH_2)_4$), 1.44—1.64 (m, 2H, CH_2COSi), 2.44 (d, 2H, J=7.7 Hz, CH_2CN), 3.9 (dddd, 1H, J=5.1, 5.1, 5.1 Hz, CHOSi); ^{13}C NMR δ=—0.1, 13.8, 22.4, 25.0, 26.1, 28.9, 31.5, 37.0, 68.4, 118.0. Found: C, 63.54; H, 11.33; N, 6.15%. Calcd for $C_{12}H_{25}NOSi$: C, 63.38; H, 11.08; N, 6.16%.

***c*-2-Methyl-2-(trimethylsiloxy)-*r*-1-cyclohexanecarbonitrile:** Bp 135 °C (bath temperature)/20 Torr; IR (CCl_4) 1253, 2249 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.14 (s, 9H, CH_3Si), 1.42 (s, 3H, CH_3), 1.35—1.80 (m, 7H, -(CH_2)-), 1.88—2.06 (m, 1H), 2.60 (dd, 1H, J=7.0, 4.0 Hz, CHCN); ^{13}C NMR ($CDCL_3$) δ=2.1, 21.5, 22.4, 25.8, 26.2, 37.7, 41.0, 73.0, 121.3. Found: C, 62.77; H, 10.21; N, 6.62%. Calcd for $C_{11}H_{12}NOSi$: C, 62.50; H, 10.01; N, 663%.

2,3-Dimethyl-3-(trimethylsiloxy)butanenitrile. Bp 130 °C (bath temperature)/30 Torr; IR (CCl_4) 1253, 2251 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.12 (s, 9H, CH_3Si), 1.28 (d, 3H, J=7.1 Hz, CH_3CCN), 1.38 (s, 6H, CH_3COSi), 2.69 (q, 1H, J=7.1 Hz, CHCN); ^{13}C NMR ($CDCl_3$) δ=2.0, 12.8, 26.7, 27.6, 39.1, 73.7, 122.0. Found: C, 58.17; H, 10.31; N, 7.64%. Calcd for $C_9H_{19}NOSi$: C, 58.32; H, 10.33; N, 7.56%.

3-Methyl-3-(trimethylsiloxy)butanenitrile. Bp 120 °C (bath temperature)/30 Torr; IR (CCl_4) 1253, 2251 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.14 (s, 9H, CH_3Si), 1.38 (s, 6H, CH_3COSi), 2.45 (s, 2H, CH_2CN); ^{13}C NMR ($CDCl_3$) δ=2.0, 29.3, 33.8, 71.7, 118.0. Found: C, 56.08; H, 10.10; N, 8.11%. Calcd for $C_8H_{17}NOSi$: C, 56.09; H, 10.00; N, 8.18%

Reactions of (2*S*,3*S*)-2,3-Epoxy-1-alkanol Derivatives with Me_3SiCN and Inorganic Solids. To a suspended mixture of an inorganic solid (0.5 g) and heptane (2 ml) was added a heptane (3 ml) solution of (2*S*,3*S*)-2,3-epoxy-1-alkanol (0.5 mmol) and the mixture was stirred under the conditions listed in Table 5. As work-up, ether (3 ml) was added, the inorganic solid was filtered off through a Celite pad and washed with ether. After organic solvents were evaporated, the reaction mixture was diluted with methanol (3 ml), and 5 equivalents of potassium fluoride was added. The mixture was stirred at 25 °C for 14 h in order to desilylate the organic products. The regioselectivity of the reaction was based on GC (OV-1; 25 m) and ^1H NMR (200 MHz) analysis of the unpurified reaction mixture after acetylation. The hydroxy carbonitriles were treated with Ac_2O (0.5 ml) and pyridine (0.5 ml) in CH_2Cl_2 (1 ml) in the presence of catalytic 4-(*N*,*N*-dimethylamino)pyridine. After the reaction was complete, the reaction mixture was washed with 1 M HCl solution (3 ml) and brine (3 ml), dried over anhydrous Na_2SO_4, and distilled with a Kugelrohr apparatus to yield dihydroxy carbonitriles.

The two regioisomers of dihydroxy carbonitriles were identical with those obtained from the reactions of epoxyalkanols with Me_3SiCN-$Ti(O^iPr)_4$ by GC (OV-1; 25 m) and ^1H NMR (200 MHz) analyses.

Reaction of (2*S*,3*S*)-2,3-Epoxy-1-alkanol with Me_3SiCN and $Ti(O^iPr)_4$. Under a nitrogen atmosphere, $Ti(O^iPr)_4$ (1.5 mmol) was added to solution of an epoxyalkanol (1 mmol) and Me_3SiCN (3 mmol) in DME (5 ml) at room temperature. The mixture was stirred at 80 °C until the epoxyalkanol was consumed. After 5% H_2SO_4 (5 ml) was added, the two phase mixture was stirred vigorously until two clear layers formed. The dihydroxy carbonitriles were extracted with AcOEt and dried over anhydrous Na_2SO_4. The regioselectivity of the reaction was based on GC (OV-1; 25 m) and ^1H NMR (200 MHz) analysis of the unpurified reaction mixture after acetylation.

Reaction of (2*S*,3*S*)-2,3-Epoxy-1-hexanol with Me_3SiCN and $Eu(fod)_3$. Under a nitrogen atmosphere, $Eu(fod)_3$ (1 mmol) was added to solution of a 2,3-epoxy-1-hexanol (1 mmol) and Me_3SiCN (3 mmol) in heptane (4 ml) at room temperature. The reaction mixture was stirred at 98 °C for 20 h. After 5% H_2SO_4 (5 ml) was added, the two phase mixture was stirred vigorously for 1 h at room temperature. The dihydroxy carbonitriles were extracted with AcOEt, and then dried over anhydrous Na_2SO_4. The regioselectivity was determined as described above.

(2*R*,3*R*)-3-Cyano-1,2-hexanediol. Bp 170 °C (bath temperature)/1 Torr; IR (CCl_4) 2250, 3400 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.98 (br t, 3H, CH_3), 1.10—2.00 (br, 4H, $(CH_2)_2$), 2.50—3.05 (m, 1H, CHCN), 3.30—4.20 (br m, 5H, CH_2OH, CHOH); ^{13}C NMR ($CDCl_3$) δ=13.3, 20.3, 29.7, 35.0, 63.8, 71.1, 120.5. Found: C, 58.52; H, 9.05; N, 9.73%. Calcd for $C_7H_{13}O_2N$: C, 58.72; H, 9.15; N, 9.78%.

(2*R*,3*R*)-3-Cyano-1,2-hexanediol Diacetate. This product was obtained from (2*R*,3*R*)-3-cyano-1,2-hexanediol by acetylation. Bp 150 °C (bath temperature)/1 Torr; IR (CCl_4) 1760, 2250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.94 (t, 3H, J=6.8 Hz, CH_3), 1.25—1.80 (br, 4H, $(CH_2)_2$), 2.06 (s, 3H, Ac), 2.08 (s, 3H, Ac), 2.85—3.00 (m, 1H, CHCN), 4.17 (dd, 1H, J=12.5, 5.2 Hz, C(H)HOAc), 4.44 (dd, 1H, J=12.5, Hz, 3.3 Hz, C(H)HOAc), 5.05 (ddd, 1H, J=5.2, 5.2, 3.3 Hz, CHOAc); ^{13}C NMR ($CDCl_3$), δ=13.1, 20.1, 20.4, 20.5, 30.1, 33.2, 62.2, 69.7, 118.6, 170.0, 170.6.

(2*R*,3*R*)-3-Cyano-3-cyclohexyl-1,2-propanediol Diacetate. Bp 190 °C (bath temperature)/0.5 Torr; IR (CCl_4) 1758, 2249 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.00—2.00 (br, 11H, cyclohexyl), 2.10 (s, 3H, Ac), 2.12 (s, 3H, Ac), 2.84 (dd, 1H, *J*=7.9, 6.0 Hz, CHCN), 4.18 (dd, 1H, *J*=12.4, 5.6 Hz, C(H)HOAc), 4.55 (dd, 1H, *J*=12.4, 2.6 Hz, C(H)HOAc), 5.23 (ddd, 1H, *J*=7.9, 5.6, 2.6 Hz, CHOAc); ^{13}C NMR ($CDCl_3$) δ=20.4, 20.5, 25.4, 25.5, 25.6, 29.2, 31.1, 35.8, 39.8, 62.8, 67.7, 117.7, 170.0, 170.6. Found: C, 63.13; H, 8.14; N, 5.51%. Calcd for $C_{14}H_{21}O_4N$: C, 62.90; H, 7.92; N, 5.24%.

(2*R*,3*R*)-3-Cyano-4-methyl-1,2-pentanediol Diacetate. Bp 130 °C (bath temperature)/0.5 Torr; IR (CCl_4) 1760, 2250 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.09 (d, 3H, *J*=7.2 Hz CH_3), 1.13 (d, 3H, *J*=7.2 Hz, CH_3), 2.12 (s, 6H, Ac), 2.86 (dd, 1H, *J*=8.4, 5.5 Hz, CHCN), 4.18 (dd, 1H, *J*=12.2, 4.8 Hz, C(H)HOAc), 4.57 (dd, 1H, *J*=12.2, 3.0 Hz, C(H)HOAc), 5.21 (ddd, 1H, *J*=8.4, 4.8, 3.0 Hz, CHOAc); ^{13}C NMR ($CDCl_3$) δ=18.3, 20.4, 20.5, 20.8, 26.6, 40.5, 62.9, 68.2, 117.4, 170.0, 170.6. Found: C, 57.96; H, 7.69; N, 6.25%. Calcd for $C_{11}H_{17}O_4N$: C, 58.14; H, 7.54; N, 6.16%.

Reaction of (2*S*,3*S*)-2,3-Epoxy-1-hexanol with MeOH and $Ca(OTf)_2$. Under a nitrogen atmosphere, $Ca(OTf)_2$ (1 mmol) was added to solution of a 2,3-epoxy-1-hexanol (1 mmol) and CH_3OH (5 mmol) in $CHCl_3$. The reaction mixture was stirred at 50 °C for 3 h. It was diluted with Et_2O (5 ml), washed with H_2O (3 ml), and the organic phase was dried over anhydrous Na_2SO_4. The regioselectivity was based on GC (PEG-HT, 25 m) and ^1H NMR (200 Hz) analysis of the unpurified reaction mixture after acetylation.

Reaction of (2*S*,3*S*)-2,3-Epoxy-1-hexanol with MeONa. Under a nitrogen atmosphere, sodium hydride (3 mmol) was slowly added to solution of MeOH (3 mmol) in THF (2 ml). The solution was stirred for 0.5 h and solution of an epoxyalkanol (1 mmol) in THF was added to it. The reaction mixture was stirred at 60 °C for 18 h. It was then diluted with AcOEt (3 ml) and washed with water (3 ml), and the organic phase was dried over anhydrous Na_2SO_4. The regioselectivity was determined as described above.

(2*R*,3*R*)-3-Methoxy-1,2-hexanediol. 140 °C (bath temperature)/0.6 Torr; IR (CCl_4) 2830, 3450 (br), 3630 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.70—1.16 (br t, 3H, CH_3), 1.16—1.80 (br m, 4H, $(CH_2)_2$), 2.57 (s, 2H, OH), 3.42 (s, 3H, OCH_3), 3.60—4.10 (m, 4H, CHOMe, CH_2OH, CHOH); ^{13}C NMR ($CDCl_3$) δ=14.0, 18.5, 32.1 , 58.4, 63.2, 72.3, 83.4. Found: C, 56.52; H, 10.80%. Calcd for $C_7H_{16}O_3$: C, 56.73; H, 10.88%.

(2*R*,3*R*)-3-Methoxy-1,2-hexanediol Diacetate. This product was obtained from (2*R*,3*R*)-3-methoxy-1,2-hexanediol by acetylation. 140 °C (bath temperature)/1 Torr; IR (CCl_4) 1750, 2830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (tr, 3H, *J*=6.6 Hz, CH_3), 1.20—1.65 (br m, 4H, $(CH_2)_2$), 2.03 (s, 3H, Ac), 2.07 (s, 3H, Ac), 3.25—3.45 (m, 1H, CHOMe), 3.38 (s, 3H, OCH_3), 4.11 (dd, 1H, *J*=12.1, 7.6 Hz, C(H)HOAc), 4.34 (dd, 1H, *J*=12.1, 3.0 Hz, C(H)HOAc), 5.12 (ddd, 1H, *J*=7.6, 4.2, 3.0 Hz, CHOAc); ^{13}C NMR ($CDCl_3$) δ=13.8 18.4, 20.6, 20.8, 32.7, 58.4, 62.6, 72.7, 80.2, 170.6, 171.0.

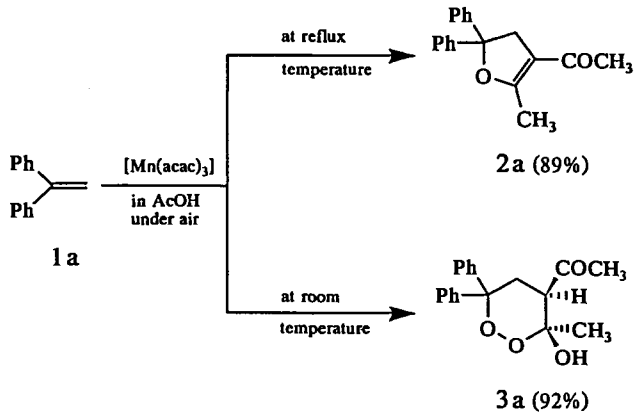
(Received January 25, 1991)

The reactions of 1,1-diphenylethene, 1,1-bis(4-chlorophenyl)ethene, 1,1-bis(4-methoxyphenyl)ethene, 1,1-bis(4-methylphenyl)ethene, 1,1-bis(4-fluorophenyl)ethene, styrene, 1-octene, cyclohexene, and cyclooctene with tris(2,4-pentanedionato)manganese(III) ([Mn(acac)$_3$]) in acetic acid at room temperature give 4-acetyl-3-methyl-1,2-dioxan-3-ol in 8—92% yields, together with 3-acetyl-4-hydroxy-3-hexene-2,5-dione. The similar reactions of 1,1-diphenylethene with 2,4-pentanedione, 3-methyl-2,4-pentanedione, 3-ethyl-2,4-pentanedione, 1-phenyl-1,3-butanedione, acetoacetanilide, and 1,3-cyclohexanedione in the presence of manganese(III) acetate also give the corresponding cyclic peroxide in good to moderate yields. The mechanisms of manganese(III)-induced 1,2-dioxane ring formation and concomitant radical side reaction are discussed.

A unique synthetic methodology utilizing manganese(III)-mediated radical inter- or intra-molecular cyclization reactions has been recently and extensively investigated and modified.[1-3] Particularly, manganese(III) acetate and tris(2,4-pentanedionato)manganese(III) ([Mn(acac)$_3$]) are well-known reagents, which perform a very interesting role in acetic acid. That is, two types of reaction occur simultaneously: (1) a one-electron-transfer from an electron-rich organic substrate (donor) to a manganese(III) complex (acceptor) and (2) a radical reaction for ligands which are formed from the thermolysis of a manganese(III) complex or ligand-exchange reaction.[4] These reactions are also influenced by reaction temperature or additives such as acetate ions and water. In the course of a study on the reactions of [Mn(acac)$_3$] with various organic substrates, one of the present authors found that the reaction product from alkenes using this reagent at room temperature differed dramatically from that at the elevated temperature.[5] When 1,1-diphenylethene (**1a**) was treated with [Mn(acac)$_3$] in acetic acid under air *at the reflux temperature*, it gave 3-acetyl-2-methyl-5,5-diphenyl-4,5-dihydrofuran (**2a**), together with a small amount of benzophenone (**4a**). When the reaction was carried out under air *at room temperature* for 12 h, it gave 4-acetyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (**3a**) (the structure was erroneously assigned as 3-acetyl-2-hydroperoxy-2-methyl-5,5-diphenyltetrahydrofuran in the previous paper[5]) along with small amounts of **4a**, 4,4-diphenyl-4-butanolide (**5a**), and 3-acetyl-4-hydroxy-3-hexene-2,5-dione (**8**). Although a lot of cyclic peroxides were synthesized using photosensitized oxygenation[6] and electrochemical cycloaddition,[7] the present reaction is the first example that molecular oxygen is trapped during the manganese(III)-induced radical intermolecular cyclization.[8] We also found that the reaction of **1a** with a 1,3-dicarbonyl compound in the presence of manganese(III) acetate in acetic acid at room temperature gave a similar cyclic peroxide.[8] Therefore, we have been intrigued by these reaction mechanisms and in the possibility of their application to organic synthesis. Herein we report the results of our study.



Scheme 1.

Results

Reaction of Alkenes with [Mn(acac)$_3$]. We scrutinized the reaction products from **1a** and found that 4,4-diphenyl-4-butanolide (**5a**), 2,2-diphenyl-2-hydroxyethyl acetate (**6a**), 1-phenyl-1,4-pentanedione (**7a**), and 3-acetyl-4-hydroxy-3-hexene-2,5-dione (**8**) were obtained together with **2a** and **3a** after separation by TLC (Table 1). The structures of these products were determined by analyzing their ^{1}H NMR, IR, and mass spectra as well as by comparing their spectra and melting points with the authentic specimen. The reaction of **3a** with triphenylphosphine gave **2a** (32%), 3-acetyl-2-methyl-5,5-diphenyltetrahydrofuran-2-ol (**9**) (49%), 4-oxo-1,1-diphenylpentyl acetate (**10**) (13%), and triphenylphosphine oxide (83%).[6b,e,9] The structure of **3a** was finally confirmed by an X-ray crystallography. A single crystal of **3a** was successfully grown from ethanol in the orthorhombic space group $P2_12_12_1$ with cell constants a=7.856, b=12.823, and c=15.820 Å. The X-ray structure was solved using the SHELXTL direct

a) **1a**: $[Mn(acac)_3]$. b) Isolated yield based on the amount of **1a** used. c) Isolated yield based on the amount of $[Mn(acac)_3]$ used. d) Reaction under an oxygen atmosphere.

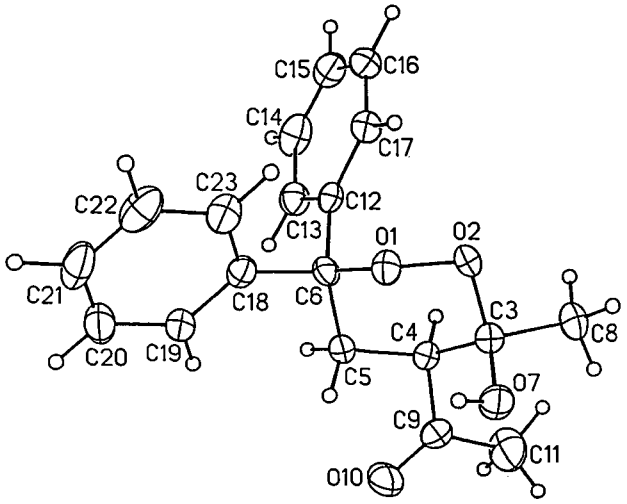

Fig. 1. ORTEP diagram of **3a**. The thermal ellipsoids are 40% equiprobability envelopes, with hydrogens as spheres of arbitrary diameter.

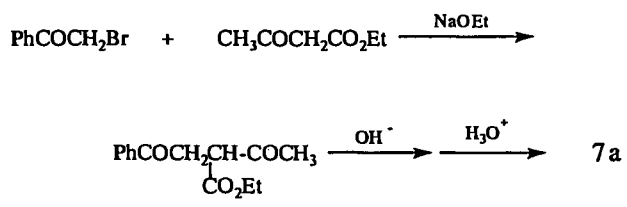
methods program, TREF, which revealed the positions of all of the nonhydrogen atoms. The ORTEP diagram of **3a** is presented in Fig. 1. The O(1)–O(2) bond length is 1.470 Å, the bond angles at O(1) and O(2) are 108.1° and 109.6°, respectively, and the peroxide torsional angle (C(6)–O(1)–O(2)–C(3)) is −74.0°.[10] Unfortunately, we could not determine the absolute configuration because of the lack of a significant anomalous scatterer in the crystal, although **3a** crystallized in a chiral space group (see Experimental Section). However, it should be noted that the cyclic peroxide (**3a**) in the solid state was obtained as the *c*-4-acetyl-3-methyl-1,2-dioxan-*r*-3-ol based on the X-ray analysis. The structure of **7a** was also confirmed by synthesis: the condensation of 2-bromoacetophenone with ethyl 3-oxobutanoate, followed by hydrolysis and acidification, gave **7a** (Scheme 2).



Scheme 2.

The reaction of **1a** with $[Mn(acac)_3]$ in AcOH at 23 °C under air was then carried out at various molar ratios. The best yield of **3a** was attained when the molar ratio was 1 : 1 (Table 1, Entry 2). The reaction under an oxygen atmosphere gave a decreased yield of **3a** with an increase in the yield of **8** (Entry 3). The yield of **3a** decreased at higher molar ratios (Entries 4 and 5).

The reactions were examined for 1,1-bis(4-chlorophenyl)ethene (**1b**), 1,1-bis(4-methoxyphenyl)ethene (**1c**), 1,1-bis(4-methylphenyl)ethene (**1d**), 1,1-bis(4-fluorophenyl)ethene (**1e**), styrene (**1f**), 1-octene (**1g**), cyclohexene (**1h**), and cyclooctene (**1i**) in AcOH to yield the corresponding 1,2-dioxane derivatives (**3b**—**i**) (Scheme 3). It was observed that the molar ratio at which the maximum yield was attained depended on the substrate as shown in Table 2. The alkenes having no aromatic substituents are poor substrates for the 1,2-dioxane formation (Entries 12—14).

Similar reactions of **1a** with (2,4-pentanedionato)-metals such as $[Cr(acac)_3]$, $[Co(acac)_3]$, $[Fe(acac)_3]$, and $[Cu(acac)_2]$ were also carried out, but either **1a** was recovered unchanged or a complex mixture resulted.

Reaction of 1a with 1,3-Diketones in the Presence of Manganese(III) Acetate. When the reaction of **1a** with 2,4-pentanedione in the presence of manganese(III) acetate was carried out at a molar ratio of 1 : 3 : 1, the major product was again **3a**, along with small amounts of **5a**, **7a**, and **8** (Table 3). When 3-methyl-2,4-pentanedione in place of 2,4-pentanedione was added during the oxidation of **1a** with manganese(III) acetate, the products were 4-acetyl-3,4-dimethyl-6,6-diphenyl-1,2-dioxan-3-ol (**11a**), 3-acetyl-2-ethoxy-2,3-dimethyl-5,5-diphenyltetrahydrofuran (**12a**), and **4a**. The reaction of 3-ethyl-2,4-pentanedione also yielded the corresponding 1,2-dioxan-3-ol derivative (**11b**) and 2-ethoxytetrahydrofuran (**12b**). The similar reactions of **1a** using 1-phenyl-1,3-butanedione, acetoacetanilide, and 1,3-cyclohexanedione gave the corresponding cyclic peroxides (**11c**—**e**) (Fig. 2).

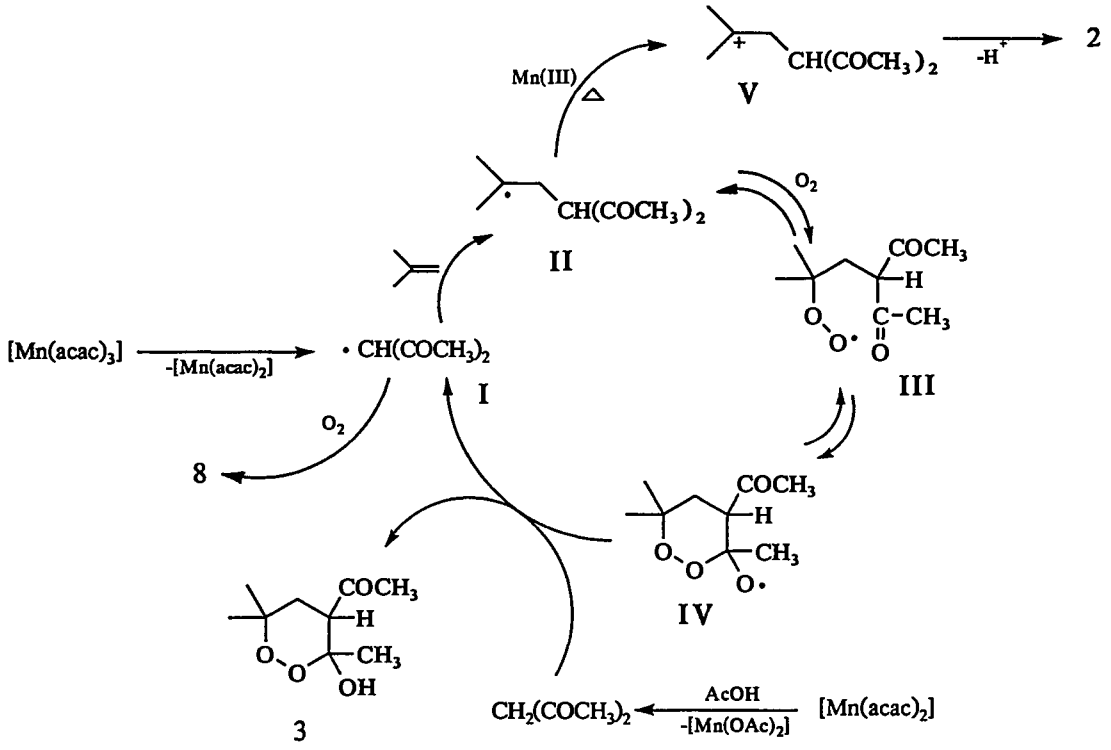
a) **1a**: 1,3-Dicarbonyl compound: Manganese(III) acetate. b) Isolated yield based on the amount of **1a** used.
c) Isolated yield based on the amount of 2,4-pentanedione used.

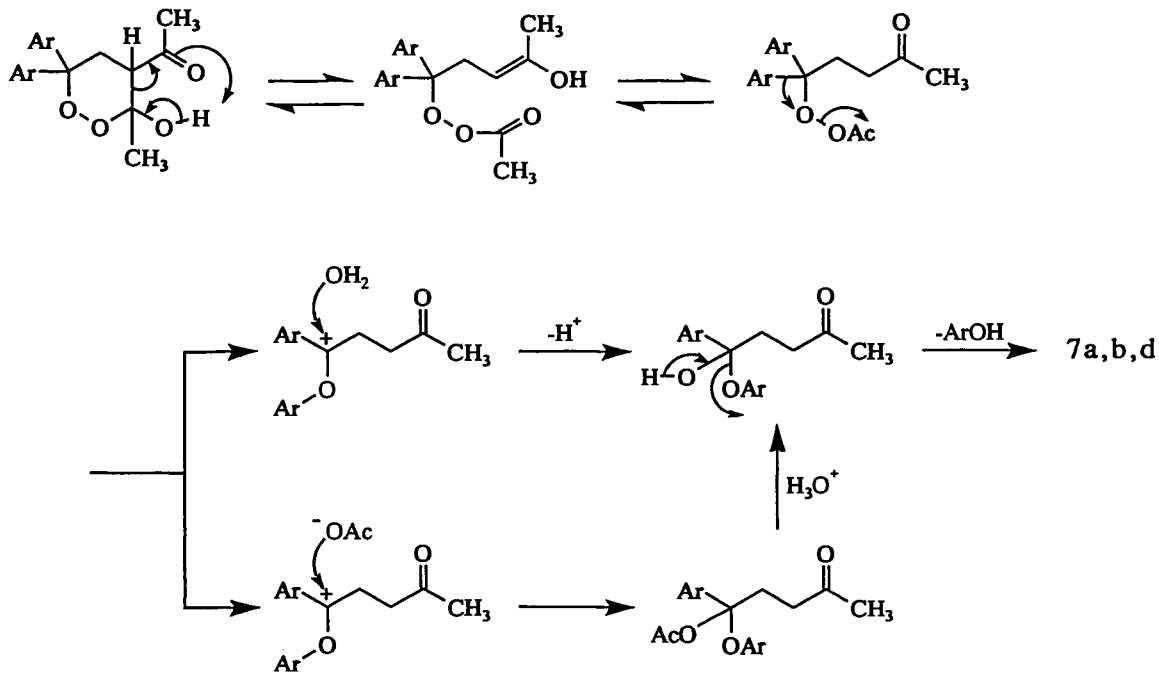
Discussion

The mechanism for the formation of 1,2-dioxanes in the [Mn(acac)3] system can be depicted as the following. The decomposition of [Mn(acac)3] would produce diacetylmethyl radicals (**I**) which attack the double bond in alkenes, resulting in tertiary radicals (**II**).[4d,5] The radicals (**II**) then react with oxygen to give radicals (**III**),[7a,b] which are cyclized to alkoxyl radicals (**IV**) and could give 1,2-dioxanes (**3**) after abstraction of hydro-

gen from the solvent and/or 2,4-pentanedione which results from the ligand-exchange reaction of $[Mn(acac)_2]$. The radicals (**II**), on the other hand, can be oxidized to carbocations (**V**) with Mn(III) at elevated temperatures since concentration of dissolved oxygen in AcOH is probably small at high temperatures, which eventually give rise to dihydrofuran derivatives (**2**) (Scheme 4). When the reaction of **1b** with $[Mn(acac)_3]$ (1 : 2 molar ratio) was carried out at 23 °C for 12 h under an argon atmosphere, **1b** (38%) was recovered and **2b** (57%) was obtained (see Experimental Section). Any existence of **3b** was not detected. This indicates that the oxygens in the 1,2-dioxane ring did come from molecular oxygen in the air. Unexpectedly, the reac-



Scheme 4.

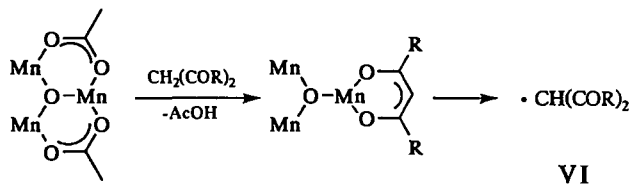


Scheme 5.

tion under an atmosphere of pure oxygen decreased the yield of **3a** and increased the yield of **8**. This may suggest that diacetylmethyl radicals (**I**) formed by the decomposition of [Mn(acac)$_3$] are consumed during dimerization followed by the oxidation with oxygen and the rearrangement, eventually giving **8**. It is worth noting that **3a** was obtained as the *c*-4-acetyl-3-methyl-1,2-dioxan-*r*-3-ol based on the X-ray analysis. This means that the cyclization of peroxyl radical (**III**) is reversible and leads to a thermodynamically stable configuration, that is to say, the *c*-4-acetyl-1,2-dioxan-*r*-3-ol form.[7b]

The formations of 2,2-diaryl-2-hydroxyethyl acetates (**6b**, **d**, **e**) and benzophenones (**4a**, **b**, **d**, **e**) have been well accounted for by the electron-transfer mechanism in the oxidation of **1a** and subsequent cleavage of the resulting diol monoacetate by Mn(III).[11] 4,4-Diaryl-4-butanolides (**5a**, **d**, **e**) are the products of the reaction of alkenes with carboxymethyl radicals, $\cdot CH_2COOH$.[4a–c,12] The formation of 1-aryl-1,4-pentanediones (**7a**, **b**, **d**) showed another feature of the reaction. Probably, they might be formed by retro-Claisen type reaction, followed by Criegee type peroxy ester rearrangement of the corresponding 1,2-dioxanes,[6e] although its mechanism is not yet clarified at present (Scheme 5).

In the case of the manganese(III) acetate system, the ligand-exchange reaction of acetate ligands on manganese(III) acetate and 1,3-dicarbonyl compounds must occur first, because manganese(III) acetate, which is insoluble in AcOH at ambient temperature, does dissolve in the solution of 1,3-diketone–AcOH at room temperature. Although no isolated manganese(III) acetate–1,3-diketone complexes have been reported, it is known that bis(2,4-pentanedionato)manganese(III) carboxylate complexes can be prepared by the ligand-exchange reaction from [Mn(acac)$_3$] and the corresponding carboxylic acids.[13] Slow decomposition of the diketone–Mn(III) complex then yields the corresponding 1,3-diketo radicals(**VI**). This is consistent



VI

Scheme 6.

with previously proposed mechanism by us[2f,4d,h,14] and others.[2c,4g,15] The radicals **VI** attack the alkene in a similar manner as shown in Scheme 4 to give the cyclic peroxides (**3a**, and **11a**—**e**). The ethoxyl groups in **12a** and **12b** probably come from ethanol which was used as the recrystallizing solvent.

Electrochemical oxidation of 2-alkyl-1,3-diketones in the presence of alkenes under an oxygen atmosphere has been reported and this also gave the substituted 1,2-dioxane ring system.[7] The structure of the cyclic

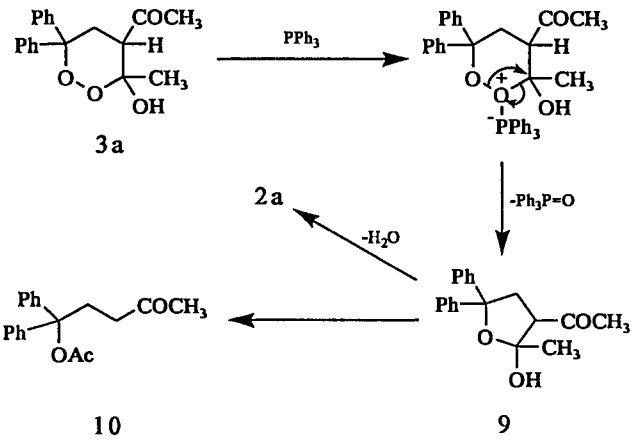
Fig. 2.

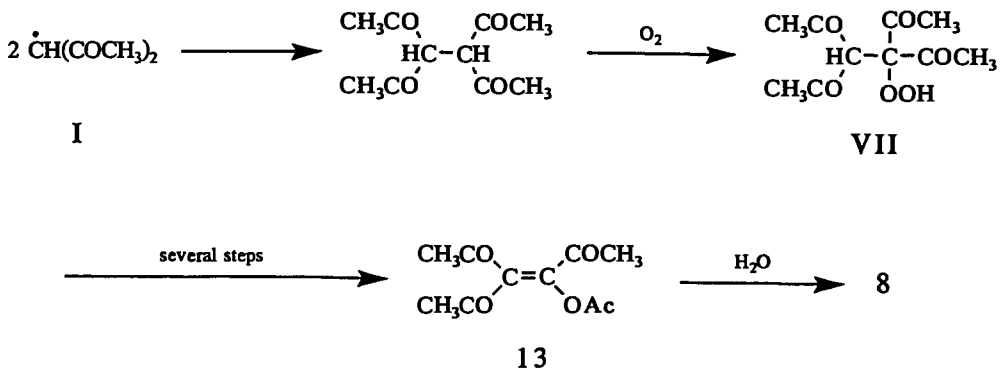
peroxide derivative was determined by X-ray analysis. The reaction is also affected by adding azobis(isobutyronitrile) (AIBN) as a radical initiator.[7b] However, the reactions seem to be limited to the 1,3-diketones which produce tertiary radicals during electrochemical oxidation.

The reduction of **3a** with triphenylphosphine deserves comments. The cyclic peroxide (**3a**) can be coordinated to triphenylphosphine with using one of the oxygens in the 1,2-dioxane ring and subsequent rearrangement would give **9** and then **2a**. The formation of **10** would be explained as the result of retro-Claisen reaction of **9** such as the formation of **7** from **3**. These reactions are shown in Scheme 7.



Scheme 7.

We also looked into the mechanisms in which **8** was formed. The hexanedione **8** was formed irrespective of the substrate used. When oxygen was passed through the reaction mixture, the reaction time was decreased by half and the maximum yield of **8** was attained. During the anhydrous work-up of the reaction of [Mn(acac)$_3$] it afforded 3-acetoxy-4-acetyl-3-hexene-2,5-dione (**13**). Therefore, the mechanism can be visualized as shown in Scheme 8. The diacetylmethyl radicals (**I**) dimerize and are then oxidized to a hydroperoxide (**VII**). The hydroperoxide (**VII**) rearranges to **13** and is finally hydrolyzed to give **8** that was formed during the work-up. The acyl migration of this type is probably the first example that occurs in a polyketonic



I VII 13

Scheme 8.

compound.

This 1,2-dioxane framework reminds us of bioactive natural occurring cyclic peroxides such as root-growth inhibitor.[16a,b] Therefore, we examined the biological activities for insecticide, bactericide, and herbicide of the 1,2-dioxanes (**3a—e**). Contrary to our expectation, no activity was observed for these compounds.[17] However, we believe that this synthetic method can be used as one of the preparative techniques for natural occurring cyclic peroxides.

Conclusions

The reactions of 1,1-diarylethenes, arylethenes, and alkenes, though to limited extent, with tris(2,4-pentanedionato)manganese(III) or with 1,3-diketones in the presence of manganese(III) acetate at room temperature gave 1,2-dioxane derivatives in moderate to good yields. They may provide a useful tool for the synthesis of a new type peroxide, i.e. 1,2-dioxane derivatives.

Experimental

Instrumentation. Infrared spectra were recorded in chloroform except for **12a** on either a JASCO A-102 or a JASCO FT/IR-7000 infrared spectrometer. The IR spectral data are expressed in cm^{-1}. ^1H NMR spectra were measured in chloroform-*d*, DMSO-d_6, or carbon tetrachloride on either a JEOL JNM-PMX60SI or a Nicolet 300MHz NMR spectrometer at room temperature. Chemical shifts are reported in ppm downfield from an internal TMS standard. Mass spectra were measured on either a JEOL JMS-DX303HF or a Finnigan 6000 GC/MS mass spectrometer at an ionizing voltage of 70 eV. All melting points were determined with a Yanaco MP-J3 micromelting point apparatus (Yanagimoto) and were uncorrected. Elemental analyses were performed by Elemental Analysis Center, Faculty of Science, Kyushu University.

Materials. Tris(2,4-pentanedionato)manganese(III)[18] and manganese(III) acetate[4a] were prepared according to the method previously described. 1,1-Diarylethenes (**1a—e**) were prepared by dehydration of the corresponding alcohols which were synthesized from substituted acetophenones and arylmagnesium bromides.[5] Styrene (Wako), 1-octene (Wako), cyclohexene (Wako), cyclooctene (Wako), and acetic acid (Kanto) were used as received.

Oxidation of Alkenes with Tris(2,4-pentanedionato)-manganese(III) ([Mn(acac)$_3$]). A typical procedure for the oxidation of alkenes with [Mn(acac)$_3$] was as follows. An alkene (1 mmol) was dissolved in acetic acid (25 mL) in a 100 mL round-bottomed flask equipped with a calcium chloride drying tube followed by addition of [Mn(acac)$_3$] (1 mmol) to the mixture. The mixture was stirred at 23 °C under air until the brown color of the Mn(III) species turned a transparent pale yellow. The reaction time is shown in Tables 1 and 2. The solvent was removed in vacuo, and the residue was triturated with 2 M (1 M=1 mol dm^{-3}) hydrochloric acid and then extracted with chloroform. The products were separated on TLC (Wakogel B-10) with chloroform as the developing solvent.

Oxidation Products. 3-Acetyl-2-methyl-5,5-diphenyl-4,5-dihydrofuran (2a): Yellow liquid; (lit,[5] bp 180—185 °C/133 Pa).

4-Acetyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3a): Colorless prisms (EtOH); mp 165—166 °C (lit,[5] mp 161—162 °C).

Benzophenone (4a): Colorless needles (EtOH); mp 48 °C.[19]

4,4-Diphenyl-4-butanolide (5a): Colorless prisms (EtOH); mp 90—91 °C (lit,[20] mp 87—90 °C).

2,2-Diphenyl-2-hydroxyethyl Acetate (6a): Colorless prisms (EtOH); mp 92.0—92.5 °C (lit,[21] mp 93—93.5 °C).

1-Phenyl-1,4-pentanedione (7a): Pale yellow liquid; bp 116 °C/66.7 Pa (lit,[22] bp 93—94 °C/13.3 Pa).

3-Acetyl-4-hydroxy-3-hexene-2,5-dione (8): Colorless prisms (benzene); mp 116.0—116.3 °C (lit,[4d] mp 115—116 °C).

3-Acetyl-5,5-bis(4-chlorophenyl)-2-methyl-4,5-dihydrofuran (2b): Colorless cubes; mp 95—96 °C (petroleum ether). IR ($CHCl_3$) ν=1670 (COMe). ^1H NMR ($CDCl_3$) δ=2.20 (3H, s, COMe), 2.33 (3H, t, J=1.6 Hz, Me), 3.56 (2H, q, J=1.6 Hz, $-CH_2-$), 7.28 (8H, s, arom.H). MS m/z (rel intensity) 346 (M^+) (91), 303 (67), 275 (26), 225 (26). Found: m/z 346.0526. Calcd for $C_{19}H_{16}O_2{}^{35}Cl_2$: M, 346.0527.

4-Acetyl-6,6-bis(4-chlorophenyl)-3-methyl-1,2-dioxan-3-ol (3b): Colorless needles (EtOH); mp 164—165 °C. IR ($CHCl_3$) ν=3592—3600 (OH), 1699 (COMe). ^1H NMR ($CDCl_3$) δ=1.28 (3H, s, Me), 2.29 (3H, s, COMe), 2.27 (3H, m, $-CH_2-CH<$), 4.12 (1H, br, OH), 7.00—7.50 (8H, m, arom.H). MS m/z (rel intensity) 380 (M^+) (1), 347 (23), 305 (60), 250 (47), 139 (100). Found: C, 59.81; H, 4.79%. Calcd for $C_{19}H_{18}O_4Cl_2$: C, 59.86; H, 4.76%.

4,4′-Dichlorobenzophenone (4b): Colorless needles (benzene–hexane); mp 144.3—145.3 °C (lit,[23] mp 146.5 °C).

2,2-Bis(4-chlorophenyl)-2-hydroxyethyl Acetate (6b):

Colorless prisms (EtOH); mp 95.5—96.2 °C. IR ($CHCl_3$) ν=3604—3200 (OH), 1743 (OAc). ^1H NMR ($CDCl_3$) δ=2.00 (3H, s, OAc), 3.30 (1H, br, OH), 4.62 (2H, s, $-CH_2-$), 7.32 (8H, s, arom.H). Found: C, 59.11; H, 4.30%. Calcd for $C_{16}H_{14}O_3Cl_2$: C, 59.08; H, 4.33%.

1-(4-Chlorophenyl)-1,4-penanedione (7b): Colorless needles (EtOH); mp 74.5—75.0 °C (lit,[22] mp 76 °C).

3-Acetyl-5,5-bis(4-methoxyphenyl)-2-methyl-4,5-dihydrofuran (2c): Colorless needles (benzene–petroleum ether); mp 96—97 °C (lit,[5] mp 96.0—96.5 °C).

4-Acetyl-6,6-bis(4-methoxyphenyl)-3-methyl-1,2-dioxan-3-ol (3c): Pale yellow liquid. IR ($CHCl_3$) ν=3584—3200 (OH), 1700 (COMe). ^1H NMR ($CDCl_3$) δ=1.27 (3H, s, Me), 2.25 (3H, s, COMe), 2.75 (3H, m, $-CH_2-CH\langle$), 3.75 (6H, s, 2×OMe), 4.43 (1H, br, OH), 6.50—7.50 (8H, m, arom.H). MS m/z (rel intensity) 372 (M^+) (1), 312 (9), 242 (52), 211 (21), 188 (33). Found: m/z 372.1570. Calcd for $C_{21}H_{24}O_6$: M, 372.1571.

3-Acetyl-2-methyl-5,5-bis(4-methylphenyl)-4,5-dihydrofuran (2d): Pale yellow liquid. IR ($CHCl_3$) ν=1664 (COMe). ^1H NMR (CCl_4) δ=2.11 (3H, s, COMe), 2.22 (6H, s, 2×Me), 2.27 (3H, t, J=1.6 Hz, Me), 3.35 (2H, q, J=1.6 Hz, $-CH_2-$), 6.90—7.33 (8H, m, arom.H). MS m/z (rel intensity) 306 (M^+) (1), 211 (10), 175 (9), 119 (100). Found: m/z 306.1604. Calcd for $C_{21}H_{22}O_2$: M, 306.1620.

4-Acetyl-3-methyl-6,6-bis(4-methylphenyl)-1,2-dioxan-3-ol (3d): Colorless needles (EtOH); mp 138—139 °C. IR ($CHCl_3$) ν=3580—3200 (OH), 1669 (COMe). ^1H NMR ($CDCl_3$) δ=1.27 (3H, s, Me), 2.25 (6H, s, 2×Me), 2.34 (3H, s, COMe), 2.76 (3H, s, $-CH_2-CH\langle$), 4.40 (1H, br, OH), 7.06—7.50 (8H, m, arom.H). MS m/z (rel intensity), 340 (M^+) (1), 307 (23), 265 (7), 210 (47), 119 (100). Found: C, 73.87; H, 7.14%. Calcd for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11%.

4,4'-Dimethylbenzophenone (4d): Colorless needles; mp 92—94 °C.[24]

4,4-Bis(4-methylphenyl)-4-butanolide (5d): Colorless liquid; (lit,[25] bp 183 °C/67 Pa).

2,2-Bis(4-methylphenyl)-2-hydroxyethyl Acetate (6d): Colorless prisms (benzene–hexane); mp 71.0 °C. IR ($CHCl_3$) ν=3610 (OH), 1742 (OAc). ^1H NMR ($CDCl_3$) δ=1.97 (3H, s, OAc), 2.28 (6H, s, 2×Me), 3.57 (1H, br, OH), 4.60 (2H, s, $-CH_2-$), 7.00—7.33 (8H, m, arom.H). MS m/z (rel intensity) 284 (M^+) (1), 224 (2), 211 (100), 119 (50), 91 (18). Found: C, 76.09; H, 7.08%. Calcd for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%.

1-(4-Methylphenyl)-1,4-pentanedione (7d): Colorless liquid; (lit,[26] mp 53 °C).

4-Acetyl-6,6-bis(4-fluorophenyl)-3-methyl-1,2-dioxan-3-ol (3e): Colorless prisms (EtOH); mp 142—144 °C. IR ($CHCl_3$) ν=3550—3200 (OH), 1702 (COMe). ^1H NMR ($CDCl_3$) δ=1.30 (3H, s, Me), 2.28 (3H, s, COMe), 2.75 (3H, m, $-CH_2-CH\langle$), 4.23 (1H, br, OH), 7.10—8.00 (8H, m, arom.H). Found: C, 65.53; H, 5.23%. Calcd for $C_{19}H_{18}O_4F_2$: C, 65.51; H, 5.21%.

4,4'-Difluorobenzophenone (4e): Colorless needles; mp 103—105 °C.[27]

4,4-Bis(4-fluorophenyl)-4-butanolide (5e): Yellow liquid. IR ($CHCl_3$) ν=1778 (–O–CO–). ^1H NMR (CCl_4) δ=2.25—3.02 (4H, m, $-CH_2-CH_2-$), 6.83—7.87 (8H, m, arom.H). MS m/z (rel intensity) 274 (M^+) (45), 219 (100), 123 (58). Found: m/z 274.0813. Calcd for $C_{16}H_{12}O_2F_2$: M, 274.0805.

2,2-Bis(4-fluorophenyl)-2-hydroxyethyl Acetate (6e): Colorless needles (petroleum ether); mp 71—72 °C. IR ($CHCl_3$) ν=3596—3200 (OH), 1741 (OAc). ^1H NMR ($CDCl_3$) δ=2.01 (3H, s, OAc), 4.00 (1H, br, OH), 4.63 (2H, s, $-CH_2-$), 7.10—7.60 (8H, m, arom.H). Found: C, 65.86; H, 4.92%. Calcd for $C_{16}H_{14}O_3F_2$: C, 65.75; H, 4.83%.

4-Acetyl-3-methyl-6-phenyl-1,2-dioxan-3-ol (3f): Colorless prisms (EtOH); mp 110—111 °C. IR ($CHCl_3$) ν=3592—3200 (OH), 1698 (COMe). ^1H NMR ($CDCl_3$) δ=1.45 (3H, s, Me), 2.28 (3H, s, COMe), 1.77—3.27 (3H, m, $-CH_2-CH\langle$), 4.10 (1H, s, OH), 5.06 (1H, m, H-5), 7.32 (5H, m, Ph). MS m/z (rel intensity) 237 (M+1) (6), 219 (49), 203 (74), 161 (47). Found: C, 66.00; H, 6.76%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

4-Acetyl-6-hexyl-3-methyl-1,2-dioxan-3-ol (3g). Pale yellow liquid. IR ($CHCl_3$) ν=3580—3200 (OH), 1691 (COMe). ^1H NMR (CCl_4) δ=1.06—2.00 (13H, m, C_6H_{13}), 1.39 (3H, s, Me), 2.24 (3H, s, COMe), 2.33—3.20 (3H, m, $-CH_2-CH\langle$), 4.00 (1H, br, H-5), 4.33 (1H, br, OH). MS m/z (rel intensity), 244 (M^+) (1), 185 (9), 113 (100), 71 (100), 43 (96). Found: m/z 244.1671. Calcd for $C_{13}H_{24}O_4$: M, 244.1674.

5-Acetyl-4-methyl-2,3-dioxabicyclo[4.4.0]decan-4-ol (3h): Pale yellow liquid. IR ($CHCl_3$) ν=3576—3150 (OH), 1692 (COMe). ^1H NMR (CCl_4) δ=0.66—4.00 (11H, m, C_6H_{10}, H-5), 1.26 (3H, s, Me), 2.19 (3H, s, COMe), 5.57 (1H, br, OH). MS m/z (rel intensity) 214 (M^+) (1), 197 (7), 155 (22), 111 (33), 97 (100). Found: m/z 214.1138. Calcd for $C_{11}H_{18}O_4$: M, 214.1204.

12-Acetyl-11-methyl-9,10-dioxabicyclo[6.4.0]dodecan-11-ol (3i): Pale yellow liquid. IR ($CHCl_3$) ν=3600—3200 (OH), 1699 (COMe). ^1H NMR ($CDCl_3$) δ=1.07—3.33 (15H, m, C_8H_{14}, H-12), 1.27 (3H, s, Me), 2.22 (3H, s, COMe), 3.83 (1H, br, OH). MS m/z (rel intensity), 225 (M^+ −17) (20), 183 (8), 167 (13), 121 (17), 97 (50), 71 (55), 43 (100).

Reaction of 1,1-Diphenylethene (1a) with 1,3-Diketones in the Presence of Manganese(III) Acetate.[28] To a mixture of **1a** (1 mmol) and 1,3-diketone (3 or 4 mmol) in acetic acid (25 mL), manganese(III) acetate (1 equivalent) was added. The solution was stirred at 23 °C under air until the brown color of manganese(III) acetate turned colorless. The reaction mixture was then worked-up by the procedure previously described.

Oxidation Products. 4-Acetyl-3,4-dimethyl-6,6-diphenyl-1,2-dioxan-3-ol (11a): Colorless prisms (EtOH); mp 147.8 °C. IR ($CHCl_3$) ν=3596—3200 (OH), 1696 (COMe). ^1H NMR ($CDCl_3$) δ=0.93 (3H, s, Me), 1.40 (3H, s, Me), 2.18 (3H, s, COMe), 2.73 (1H, d, J=14.2 Hz, H-4), 3.22 (1H, d, J=14.2 Hz, H-4), 4.33 (1H, br, OH), 7.06—7.66 (10H, m, 2×Ph). MS m/z (rel intensity) 326 (M^+) (1), 293 (74), 251 (18), 105 (100). Found: C, 73.73; H, 6.84%. Calcd for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%.

3-Acetyl-2-ethoxy-2,3-dimethyl-5,5-diphenyltetrahydrofuran (12a): Colorless prisms (EtOH); mp 123.5—124.5 °C. IR (KBr) ν=1711 (COMe). ^1H NMR ($CDCl_3$) δ=0.55 (3H, t, J=7.2 Hz, $-OCH_2\underline{CH_3}$), 0.97 (3H, s, Me), 1.62 (3H, s, Me), 2.17 (3H, s, COMe), 2.62 (1H, d, J=13.0 Hz, H-4), 3.34 (2H, q, J=7.2 Hz, $-O\underline{CH_2}CH_3$), 3.82 (1H, d, J=13.0 Hz, H-4), 7.00—7.67 (10H, m, 2×Ph). MS m/z (rel intensity) 338 (M^+) (1), 293 (100), 250 (32). Found: C, 78.13; H, 7.74%. Calcd for $C_{22}H_{26}O_3$: C, 78.07; H, 7.74%.

4-Acetyl-4-ethyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (11b): Colorless prisms (EtOH); mp 144.2 °C. IR ($CHCl_3$) ν=3632—3200 (OH), 1693 (COMe). ^1H NMR ($CDCl_3$) δ=0.33—1.91 (5H, m, Et), 1.51 (3H, s, Me), 1.98 (3H, s, COMe), 2.83 (1H, d, J=14.2 Hz, H-4), 3.20 (1H, d, J=14.2 Hz, H-4), 5.20 (1H, br, OH), 7.13—7.67 (10H, m, 2×Ph). MS

m/z (rel intensity) 340 (M^+) (2), 265 (15), 180 (78), 105 (100). Found: C, 74.19; H, 7.05%. Calcd for $C_{21}H_{24}O_4$: C, 74.09; H, 7.11%.

3-Acetyl-2-ethoxy-3-ethyl-2-methyl-5,5-diphenyltetrahydrofuran (12b): Colorless liquid. IR ($CHCl_3$) ν=1706 (COMe). ^{1}H NMR (CCl_4) δ=0.28—2.00 (5H, m, Et), 0.37 (3H, t, J=7.0 Hz, $-OCH_2\underline{CH_3}$), 1.55 (3H, s, Me), 2.05 (3H, s, COMe), 2.27 (1H, d, J=12.0 Hz, H-4), 3.31 (2H, q, J=7.0 Hz, $-O\underline{CH_2}CH_3$), 3.58 (1H, d, J=12.0 Hz, H-4), 6.97—7.54 (10H, m, 2×Ph). MS *m/z* (rel intensity) 352 (M^+) (2), 307 (30), 264 (100). Found: *m/z* 352.2055. Calcd for $C_{23}H_{28}O_3$: M, 352.2037.

4-Benzoyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (11c): Colorless needles (EtOH); mp 139—141 °C. IR (KBr) ν=3420 (OH), 1659 (C=O). ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, s, Me), 2.70—4.17 (3H, m, $-CH_2CH\langle$), 7.12 (1H, s, OH), 7.17—8.13 (15H, m, 3×Ph). Found: C, 76.80; H, 5.99%. Calcd for $C_{24}H_{22}O_4$: C, 76.98; H, 5.92%.

4-*N*-Phenylcarbamoyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (11d): Colorless microcrystals (EtOH); mp 191 °C. IR ($CHCl_3$) ν=3600—3100 (NH and OH), 1670 (C=O). ^{1}H NMR ($CDCl_3$) δ=1.33 (3H, s, Me), 2.53—3.50 (3H, m, $-CH_2-CH\langle$), 4.90 (1H, br, OH), 6.93—7.63 (15H, m, 3×Ph), 8.87 (1H, s, NH). Found: C, 73.71; H, 5.97; N, 3.55%. Calcd for $C_{24}H_{23}O_4N$: C, 74.02; H, 5.95; N, 3.60%.

1-Hydroxy-4,4-diphenyl-2,3-dioxabicyclo[4.4.0]decan-7-one (11e): Colorless microcrystals (EtOH); mp 184—186 °C. IR (KBr) ν=3600—3200 (OH), 1705 (C=O). ^{1}H NMR (DMSO-d_6) δ=1.36—2.97 (9H, m, C_5H_9), 6.67 (1H, s, OH), 7.06—7.70 (10H, m, 2×Ph). Found: C, 73.92; H, 6.26%. Calcd for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22%.

In the reaction of **1a** with 3-methyl-2,4-pentanedione or 1,3-cyclohexanedione in the presence of manganese(III) acetate, a small amount of benzophenone (**4a**) was also obtained.

Reaction of 1,1-Bis(4-chlorophenyl)ethene (1b) with [Mn(acac)$_3$] under Argon Atmosphere. [Mn(acac)$_3$] was recrystallized from benzene/petroleum ether[29] and stored under argon. The [Mn(acac)$_3$] (454.2 mg) and **1b** (167.5 mg) were put in a 100 mL Schlenk flask under argon. Acetic acid (25 mL), which was purified by distillation from acetic anhydride–chromium trioxide and stored under argon, was added to the flask by a syringe. The mixture was stirred at 23 °C under argon for 12 h. The solvent was removed under high vacuum and the residue was triturated with 2M HCl (25 mL). The aqueous solution was extracted with chloroform. The crude products were separated on TLC using chloroform as the developing solvent to give **1b** (63.6 mg; 38% recovered) and **2b** (132.9 mg; 57%).

Reduction of 3a with Triphenylphosphine. A mixture of **3a** (0.5 mmol) and Ph_3P (0.5 mmol) in anhydrous diethyl ether (30 mL) was stirred at room temperature overnight. The solvent was removed and the residue was triturated with 2 M hydrochloric acid. The mixture was then extracted with chloroform. The following products were obtained after the separation on a silica-gel column.

3-Acetyl-2-methyl-5,5-diphenyltetrahydrofuran-2-ol (9): Colorless liquid. IR ($CHCl_3$) ν=3610—3200 (OH), 1706 (COMe). ^{1}H NMR (CCl_4) δ=1.73 (3H,s, Me), 2.18 (3H, s, COMe), 2.63—3.18 (3H, m, $-CH_2CH\langle$), 3.27 (1H, br, OH), 7.07—7.73 (10H, m, 2×Ph). MS *m/z* (rel intensity) 296 (M^+) (7), 254 (4), 196 (60), 183 (100), 105 (65). Found: *m/z* 296.1385. Calcd for $C_{19}H_{20}O_3$: M, 296.1411.

4-Oxo-1,1-diphenylpentyl Acetate (10): Liquid. IR ($CHCl_3$) ν=1737 (O-$\underline{CO}$Me), 1716 (COMe), 1243 ($\underline{O-CO}$Me). ^{1}H NMR ($CDCl_3$) δ=2.01 (3H, s, Me), 2.12 (3H, s, COMe), 2.17—3.33 (4H, m, $-CH_2-CH_2-$), 7.00—7.56 (10H, m, 2×Ph). FAB MS (solvent: $CHCl_3$; matrix: G+T, G+0.5M-NaI), *m/z* (rel intensity) 319 (M+Na) (21), 279 (26), 259 (56), 237 (100). Found: *m/z* 296.1412. Calcd for $C_{19}H_{20}O_3$: M 296.1394.

Triphenylphosphine Oxide: Colorless prisms (EtOH); mp 152—153 °C (lit,[30] mp 154—155 °C).

Synthesis of 1-Phenyl-1,4-pentanedione (7a). The pentanedione (**7a**) was prepared as follows. To a heated solution of ethyl 3-oxobutanoate (0.06 mol) and metallic sodium (0.05 mol) in anhydrous ethanol, 2-bromoacetophenone (0.05 mol) in anhydrous ethanol was added dropwise. After a few hours reflux, the solvent was removed. The residue was triturated with 2 M sulfuric acid and extracted with benzene. After the removal of the solvent, the reaction mixture was added to a 2 M aqueous sodium hydroxide and stirred at room temperature overnight. The reaction mixture was extracted with benzene, the aqueous solution was acidified with 2 M sulfuric acid and then extracted with diethyl ether. The ethereal solution was dried over anhydrous sodium sulfate. 1-Phenyl-1,4-pentanedione (**7a**, 39%), 3-phenyl-2-cyclopentenone (2%), and 4-oxo-4-phenylbutanoic acid (2%) were obtained after the separation on a silica-gel column.

3-Phenyl-2-cyclopentenone: Colorless prisms (diethyl ether); mp 77.5—78.0 °C (lit,[31] mp 83—84 °C).

4-Oxo-4-phenylbutanoic Acid: Colorless prisms (EtOH); mp 112—113 °C (lit,[32] mp 116.5 °C).

Formation of 13 by Anhydrous Work-up. [Mn(acac)$_3$] (8 mmol) in acetic acid (100 mL) was stirred at 23 °C under air until the brown color of Mn(III) turned yellow. The solvent was removed in vacuo and benzene (150 mL) was added to the residue. After separation of [Mn(OAc)$_2$] by filtration, the solvent was removed under reduced pressure. The residue obtained was purified on TLC to afford a trace amount of **13** and **8**. The product, **13**, was prepared by acetylation of **8** with acetyl chloride: A mixture of **8** and acetyl chloride was heated under reflux for 3 h and then concentrated to dryness. It gave **13**.

3-Acetoxy-4-acetyl-3-hexene-2,5-dione (13): Pale yellow liquid. IR ($CHCl_3$) ν=1687, 1723 (COMe), 1768 (OAc). ^{1}H NMR ($CDCl_3$) δ=1.54 (3H, s, COMe), 2.12 (3H, s, OAc), 2.43 (3H, s, COMe), 2.57 (3H, s, COMe). MS *m/z* (rel intensity) 212 (M^+) (2), 170 (12), 127 (63), 43 (100). Found: *m/z* 212.0685. Calcd for $C_{10}H_{12}O_5$: M, 212.0688.

X-Ray Crystallography of 3a.[33] A clear colorless thin plate of **3a** having the approximate dimensions 0.56×0.44×0.13 mm was mounted in a random orientation on a Nicolet R3m/v automatic diffractometer. The radiation used was Mo $K\alpha$ monochromatized by a highly ordered graphite crystal. Final cell constants, as well as other information pertinent to data collection and refinement, are listed in Table 4. The Laue symmetry was determined to be *mmm*, and from the systematic absences noted, the space group was shown unambiguously to be $P2_12_12_1$. Intensities were measured using the omega scan technique with the scan rate depending on the count obtained in rapid pre-scans of each reflection. Two standard reflections were monitored after every two hours or after every 100 data points collected. These showed no significant variation. In reducing the data, Lorentz and polarization corrections were applied, however, no correction for absorption was made due to the small absorption coefficient.

Table 4. Data Collection and Processing Parameters

Space group	$P2_12_12_1$, orthorhombic
Cell constants	a=7.856(3) Å
	b=12.823(6) Å
	c=15.820(8) Å
	V=1594 Å^3
Molecular formula	$C_{19}H_{20}O_4$
Formula weight	312.39
Formula units per cell	Z=4
Density	ρ=1.30 g cm^{-3}
Absorption coefficient	μ=0.85 cm^{-1}
Radiation (Mo $K\alpha$)	λ=0.71073 Å
Collection range	$4°<2\theta<55°$
Scan width	$\Delta\theta=1.30+(K\alpha_2-K\alpha_1)_o$
Scan speed range	1.5 to 15.0° min^{-1}

Weights	$w=\sigma(F)^{-2}$

The structure was solved by use of the SHELXTL direct methods program TREF, which revealed the positions of all of the nonhydrogen atoms. The usual sequence of isotropic and anisotropic refinement was followed, after which all hydrogens were entered in ideal calculated positions and constrained to riding motion with a single variable isotropic temperature factor. In the final cycles of the least squares the hydroxyl hydrogen H7 was freely refined in order to get accurate hydrogen bonding parameters. The C11 methyl group was treated as a separate rigid body and allowed to rotate freely. Although **3a** crystallizes in a chiral space group, the lack of a significant anomalous scatterer makes determination of the absolute configuration impossible. Therefore, a random choice was made to refine the model having an R configuration at C3. After all nonhydrogen shift/esd ratios were less than 0.3, convergence was reached at the agreement factors listed in Table 4. No unusually high correlations were noted between any of the variables in the last cycle of the full-matrix least squares refinement, and the final difference density map showed a maximum peak of about 0.2 e Å^{-3}. All calculations were made using Nicolet's SHELXTL PLUS (1987) series of crystallographic programs.

We are grateful for financial suport of this work by a Grant-in-Aid for Encouragement of Young Scientists No. 62740301 from the Ministry of Education, Science and Culture. We wish to thank Dr. Teruyoshi Marunaka of the Taiho Pharmaceutical Co., Inc., Tokushima, Japan, for his arrangement of the measurements of the mass spectra. H. N. acknowledges Dr. Abdallah Cherif, Department of Medicinal Chemistry, University of Houston, Houston, Texas, U.S.A. for obtaining the H,C COSY spectrum of **3a** and also thanks Dr. Jean-Luc Lim and Mr. Serge Perrier, Department of Chemistry, University of Houston, for their helpful discussion.

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received February 5, 1991)

The reaction of 1-lithio-1-alkynes with oxiranes under the catalytic action of trimethylgallium afforded the corresponding β-hydroxy acetylenic compounds in good yields with excellent regioselectivities. No isomerization of oxiranes was observed during the reactions because of low Lewis acidity of trimethylgallium. The mechanism including activation of an oxirane by the coordination to trimethylgallium was proposed.

The ring-opening reactions of oxiranes with metal acetylides have been used as the most important tool for preparation of β-hydroxy acetylenic compounds,[1-5] which are versatile intermediates in organic syntheses.[6-8] Although several methods have appeared for the reaction, they usually require severe reaction conditions and/or resulted in low yields of the expected products. Recently Yamaguchi et al. reported alkynylation of oxiranes with lithium acetylides by the action of $BF_3 \cdot OEt_2$, and prepared varieties of β-hydroxy acetylenic compounds in good yields.[9] Although the utilities of the BF_3-catalyzed reaction has been proved by several successful applications,[10,11] this reaction requires stoichiometric amount of $BF_3 \cdot OEt_2$. On the other hand, lithium acetylides attack oxiranes under the action of catalytic amount of trimethylgallium to give β-hydroxy acetylenic compounds in good to excellent yields.[12] This paper describes in detail the regioselective reaction of lithium acetylides and oxiranes under trimethylgallium catalysis.

Ring-Opening Reaction of Oxirane with Lithium Acetylides. The reaction of lithium acetylides with oxiranes was tried in the presence of catalytic amount of trimethylgallium; treatment of a THF (tetrahydrofuran) solution of a 1-lithio-1-alkyne with catalytic amount of Me_3Ga and an oxirane was examined. The expected β-hydroxy acetylenic product was obtained in good yield by regioselective attack of acetylide to the less substituted carbon (Scheme 1). In the absence of trimethyl-

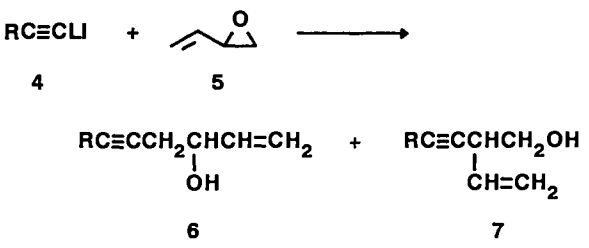
† On leave from Kyowa Yuka Co., Ltd., Yokkaichi, Mie.

gallium, the reaction proceeded sluggishly. Reaction conditions and results are summarized in Table 1.

As shown in Table 1, alkynylation of cyclohexene oxide or cyclopentene oxide gave *trans*-2-alkynylcyclohexanol or -cyclopentanol in good yield under THF reflux. This result is in contrast to that of the reaction with alkynylmagnesium bromide; the reaction of cyclohexene oxide with 1-octynylmagnesium bromide did not gave 2-(1-octynyl)cyclohexanol but afforded a mixture of 2-bromocyclohexanol (58%) and 1-cyclopentyl-2-nonyn-1-ol (31%), indicating the isomerization of cyclohexene oxide into cyclopentanecarbaldehyde under the reaction conditions. It should be noted that no isomerization of oxiranes was observed in the case of trimethylgallium-catalyzed alkynylation of oxiranes. The reaction of epichlorohydrin at 0 °C gave corresponding chlorohydrin **3g**; The reaction at room temperature afforded 1,2-epoxy-4-undecyne **3h**, which was derived from initially produced lithium alkoxide by intramolecular reaction. Among various oxiranes shown in Table 1, reaction with styrene oxide showed relatively good regioselectivity by predominant attack of lithium acetylides on less substituted carbons, whereas BF_3-catalyzed reaction of styrene oxide with 1-lithio-1-heptyne showed non-regioselectivity to give a 1 : 1 mixture of possible two products. These results are shown in Table 1.

In the case of butadiene monoepoxide, Me_3Ga-catalyzed reaction with lithium acetylides showed considerable regioselectivity; the reaction of 1-lithio-1-octyne (**4a**) with butadiene monoepoxide (**5**) gave 1-dodecen-5-yn-3-ol (**6a**) and 2-vinyl-3-decyn-1-ol (**7a**) in the ratio of 71 : 29 without other by-products. The reaction with 1-lithio-2-trimethylsilylethyne (**4b**) gave 6-trimethylsilyl-1-hexen-5-yn-3-ol (**6b**) with high regioselectivity. Above two examples show that alkynyl group was introduced mainly from less substituted carbon of oxirane in the case of trimethylgallium catalyzed alkynylation. On the contrary, in the case of $BF_3 \cdot OEt_2$ mediated alkynylation of butadiene monoepoxide (**5**), the regioselectivity to give **6** is low and several by-products were formed besides regioisomer **7**. Results are summarized in



Scheme 2.

Table 2. Alkynylation of Butadiene Monoepoxide

Entry	R	Method[a]	Yield/%	Ratio (6 : 7)
1	C_6H_{13}	A	76	71 : 29
2		B	44[b]	43 : 57
3	Me_3Si	A	78	92 : 8
4		B	35[b]	54 : 46

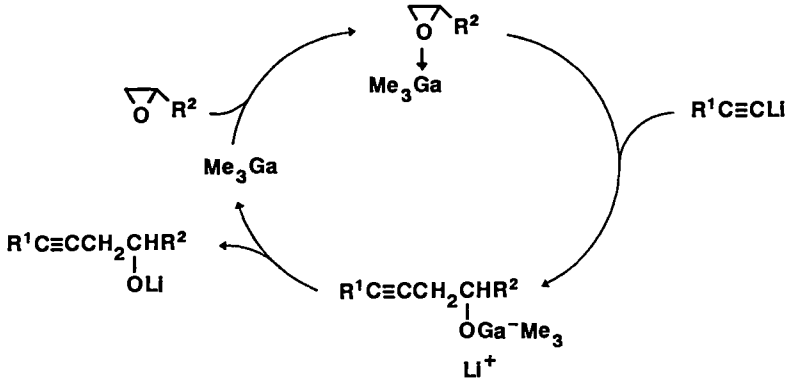
a) A: in th presence of Me_3Ga (0.2 equiv), 50 °C, 4 h. B: in the presence of $BF_3 \cdot OEt_2$ (1.0 equiv), −78 °C, 30 min. b) Isolated yield after column chromatography.

Table 2.

These results as well as relatively regioselective reaction of styrene oxide indicated that Lewis acidity of trimethylgallium is not so strong to induce the isomerization of oxirane or to produce allylic or benzylic cation species but sufficient to catalyze regioselective reaction of oxirane with lithium acetylides.

Mechanistic Considerations

NMR analyses of the mixtures of oxirane, lithium acetylides, and Me_3Ga were informative to the mechanistic considerations. The peak of oxirane protons of cyclohexene oxide was observed at δ=3.12 in $CDCl_3$–hexane. When slightly excess Me_3Ga (hexane solution) was added to a $CDCl_3$ solution of cyclohexene oxide, that of oxirane protons moved to δ=3.33 with broadening. This result indicates that Me_3Ga affected as a Lewis acid by coordinating to the oxygen of cyclohexene oxide and thus activated for the alkynylation. Lewis acidic activation of oxiranes by trimethylgallium



Scheme 3. Catalytic cycle for trimethylgallium-catalyzed alkynylation of oxirane with 1-lithio-1-alkyne.

was also reported in the isonitrile formation by the reaction with cyanotrimethylsilane.[13]

Although exothermic interaction was observed when hexane solution of trimethylgallium was added to THF solution of 1-lithio-1-octyne (1 : 1), any positive evidence could not be obtained for the formation of an ate complex from trimethylgallium and 1-lithio-1-alkyne at this moment.

On the basis of the above discussion, the trimethylgallium catalyzed alkynylation of oxiranes is explained as shown in Scheme 3.

Conclusion

The above described trimethylgallium catalyzed reaction of oxiranes with lithium acetylides to give β-hydroxy acetylenic compounds possesses the following respects: (1) acetylides attacked regioselectively on less substituted carbon with respect to the applied oxiranes, even with styrene oxide and butadiene monoepoxide, (2) relative low Lewis acidity of Me_3Ga did not induce any isomerization of oxiranes before the coupling reaction, (3) catalytic amount of Me_3Ga was sufficient in contrast to the stoichiometric use of $BF_3 \cdot OEt_2$ in reported case, and (4) the expected β-hydroxy acetylenic compounds were obtained in high yields under mild reaction conditions.

Experimental

IR spectra were obtained on a JASCO IR-810 spectrometer. ^1H NMR (200 MHz) were measured on a Varian XL-200. Elemental analyses were performed at Elemental Analysis Center of Kyoto University.

Alkynylation of Oxirane (2) with Lithium Acetylide (1) under the Catalysis of Trimethylgallium (General Procedure): To a THF solution of 1-lithio-1-alkyne (**1**) prepared from 1-alkyne (10 mmol) and butyllithium (1.86 M in hexane, 5.6 ml, 10 mmol, 1 M=1 mol dm^{-3}) 10 ml of THF, trimethylgallium (0.8 M in hexane, 1.0 ml, 0.8 mmol) was added at 0 °C. To the reaction mixture, an oxirane (**2**, 12 mmol, 1.2 eguiv) was added and the whole was stirred for 40 min to 6 h at 0—50 °C or at reflux. The reaction mixture was worked up with brine and extracted with ether. The ethereal solution was washed with brine, dried over anhydrous Na_2SO_4 and concentrated. Chromatographical purification (Silica gel) of the residue gave the product.

4-Undecyn-2-ol (3b): ^1H NMR ($CDCl_3$) δ=0.89 (3H, t, *J*=6.7 Hz), 1.24 (3H, d, *J*=6.2 Hz), 1.20—1.60 (8H, m), 2.15 (2H, dt, *J*=6.7, 2.4 Hz), 2.20 (1H, br-s), 2.32 (2H, tt, *J*=2.4, 6.6 Hz), 3.90 (1H, tq, *J*=5.8, 6.2 Hz); IR (neat) 3600—3000, 1150, 1080, 940 cm^{-1}. Found: C, 78.91; H, 12.07%. Calcd for $C_{12}H_{22}O$: C, 79.06; H, 12.16%.

2-(1-Octynyl)cyclohexanol (3e): ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, *J*=6.5 Hz), 1.08—1.85 (15H, m), 1.99 (2H, m), 2.17 (2H, br-t, *J*=6.2 Hz), 2.36 (1H, d, *J*=2.0 Hz), 3.37 (1H, ddt, *J*=2.0, 3.0, 9.5 Hz); IR (neat) 3600—3100, 1285, 1085 cm^{-1}. Found: C, 80.54; H, 11.84%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

2-(1-Octynyl)cyclopentanol (3f): ^1H NMR ($CDCl_3$) δ=0.88 (3H, t, *J*=6.5 Hz), 1.12—2.03 (14H, m), 1.92 (1H, s), 2.13 (2H, dt, *J*=2.0, 7.0 Hz), 2.50 (1H, ddt, *J*=2.0, 6.0, 6.0 Hz), 4.09 (1H, dt, *J*=6.0, 6.0 Hz); IR (neat) 3600—3100, 1292, 1122, 1073, 1029, 992, 721 cm^{-1}. Found: C, 80.43; H, 11.68%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

1-Chloro-4-undecyn-2-ol (3g): ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, *J*=6.0 Hz), 1.20—1.65 (8H, m), 2.27 (2H, tt, *J*=2.1, 6.9 Hz), 2.35 (1H, d, *J*=6.0 Hz), 2.48 (1H, tt, *J*=2.1, 7.0 Hz), 2.60 (1H, dq, *J*=7.0, 2.1 Hz), 3.62 (1H, dd, *J*=6.1, 11.0 Hz), 3.74 (1H, dd, *J*=4.6, 11.0 Hz), 3.95 (1H, m); IR (neat) 3600—3050, 1090, 1050, 710, 700 cm^{-1}. Found: C, 65.26; H, 9.72%. Calcd for $C_{11}H_{19}OCl$: C, 65.17; H, 9.45%.

1,2-Epoxy-4-undecyne (3h): ^1H NMR ($CDCl_3$) δ=0.89 (3H, t, *J*=6.0 Hz), 1.15—1.62 (9H, m), 2.15 (2H, tt, *J*=2.3, 7.2 Hz), 2.43 (1H, ddt, *J*=5.0, 17.7, 2.3 Hz), 2.60 (1H, ddt, *J*=4.6, 17.7, 2.3 Hz), 2.65 (1H, dd, *J*=2.5, 4.8 Hz), 2.79 (1H, dd, *J*=3.6, 4.8 Hz), 3.08 (1H, ddd, *J*=2.5, 3.6, 5.0 Hz); IR (neat) 960, 930, 840, 830 cm^{-1}. Found: C, 79.36; H, 11.02%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

4-Decyn-2-ol (3i): ^1H NMR ($CDCl_3$) δ=0.91 (3H, t, *J*=6.9 Hz), 1.25 (3H, d, *J*=6.4 Hz), 1.20—4.58 (6H, m), 2.06 (1H, d, *J*=4.9 Hz), 2.19 (2H, tt, *J*= 2.3, 7.0 Hz), 2.28 (1H, ddt, *J*=6.8, 16.0, 2.3 Hz), 2.40 (1H, ddt, *J*=5.0, 16.0, 2.3 Hz), 3.90 (1H, dddq, *J*=4.9, 5.0, 6.8, 6.9 Hz); IR (neat) 3650—3100, 1116, 1085, 940 cm^{-1}. Found: C, 77.56; H, 11.95%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%.

2-Methyl-4-decyn-2-ol (3j): ^1H NMR ($CDCl_3$) δ=0.92 (3H, t, *J*=6.9 Hz), 1.21—1.59 (6H, m), 1.30 (6H, s), 2.01 (1H, s), 2.19 (2H, tt, *J*=2.5, 7.0 Hz), 2.34 (2H, t, *J*=2.5 Hz); IR (neat) 3600—3100, 1266, 1210, 1146, 975, 906, 762 cm^{-1}. Found: C, 78.49; H, 12.12%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

2-(1-Butynyl)cyclohexanol (3m): ^1H NMR ($CDCl_3$) δ=1.16 (3H, t, *J*=7.5 Hz), 1.20—2.10 (9H, m), 2.20 (1H, m), 2.21 (2H, dq, *J*=2.0, 7.5 Hz), 3.41 (1H, ddd, *J*=2.5, 9.5, 9.5 Hz); IR (neat) 3650—3100, 1310, 1275, 1075 cm^{-1}. Found: C, 78.60; H, 10.85%. Calcd for $C_{10}H_{16}O$: C, 78.90; H, 10.59%.

1-Trimethylsilyl-1-octyn-4-ol (3p): ^1H NMR ($CDCl_3$) δ=0.16 (9H, s), 0.88 (3H, t, *J*=6.9 Hz), 1.17—1.57 (6H, m), 1.95 (1H, d, *J*=5.0 Hz), 2.29 (1H, dd, *J*=7.0, 16.7 Hz), 2.45 (1H, dd, *J*=5.0, 16.7 Hz), 3.67 (1H, m); IR (neat) 3600—3100, 2174, 1250, 1125, 1082, 1045, 1017, 841, 758, 697 cm^{-1}. Found: C, 66.55; H, 11.36%. Calcd for $C_{11}H_{22}OSi$: C, 66.60; H, 11.18%.

1-Dodecen-5-yn-3-ol (6a): ^1H NMR ($CDCl_3$) δ=0.90 (3H, t, *J*=6.5 Hz), 1.19—1.69 (8H, m), 2.07 (1H, d, *J*=6.0 Hz), 2.18 (2H, tt, *J*=2.5, 6.0 Hz), 2.40 (1H, ddt, *J*=6.5, 16.1, 2.3 Hz), 2.50 (1H, ddt, *J*=6.5, 16.1, 2.7 Hz), 4.17 (1H, m), 5.18 (1H, ddd, *J*=1.1, 1.1, 10.5 Hz), 5.31 (1H, ddd, *J*=1.1, 1.1, 17.0 Hz), 5.91 (1H, ddd, *J*=6.0, 10.5, 17.0 Hz); IR (neat) 3630—3100, 3080, 1379, 1330, 1122, 1034, 992, 923 cm^{-1}. Found: C, 79.69; H, 11.31%. Calcd for $C_{11}H_{20}O$: C, 79.94; H, 11.18%.

2-Vinyl-3-decyn-1-ol (7a): ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=6.3 Hz), 1.20—1.64 (8H, m), 1.83 (1H, dd, J=6.1, 6.5 Hz), 2.23 (2H, dt, J=2.1, 7.1 Hz), 3.29 (1H, m), 3.55 (1H, ddd, J=6.1, 6.9, 16.0 Hz), 3.69 (1H, ddd, J=6.5, 6.9, 16.0 Hz), 5.21 (1H, ddd, J=1.6, 1.6, 10.0 Hz), 5.40 (1H, ddd, J=1.6, 1.6, 17.0 Hz), 5.75 (1H, ddd, J=6.9, 10.0, 17.0 Hz); IR (neat) 3650—3100, 3082, 1632, 1379, 1331, 1053, 991, 920, 721 cm^{-1}. Found: C, 79.98; H, 11.31%. Calcd for $C_{12}H_{20}O$: C, 79.94; H, 11.18%.

6-Trimethylsilyl-1-hexen-5-yn-3-ol (6b): ^{1}H NMR ($CDCl_3$) δ=0.18 (9H, s), 2.07 (1H, d, J=5.7 Hz), 2.46 (1H, dd, J=6.7, 17.0 Hz), 2.56 (1H, dd, J=5.9, 17.0 Hz), 4.27 (1H, ddddt, J=5.7, 5.9, 6.0, 6.7, 1.5 Hz), 5.17 (1H, ddd, J=1.5, 1.5, 10.0 Hz), 5.29 (1H, ddd, J=1.5, 1.5, 17.5 Hz), 5.89 (1H, ddd, J=6.0, 10.0, 17.5 Hz); IR (neat) 3700—3100, 3082, 3005, 2176, 1250, 1123, 1044, 1001, 926, 842, 759, 697 cm^{-1}. Found: C, 64.21; H, 9.70%. Calcd for $C_9H_{16}OSi$: C, 64.23; H, 9.58%.

4-Trimethylsilyl-2-vinyl-3-butyn-1-ol (7b): ^{1}H NMR ($CDCl_3$) δ=0.15 (9H, s), 1.81 (1H, t, J=6.6 Hz), 3.34 (1H, dtt, J=6.6, 1.2, 6.6 Hz), 3.61 (1H, ddd, J=3.4, 6.6, 6.6 Hz), 3.65 (1H, ddd, J=3.4, 6.6, 6.6 Hz), 5.25 (1H, ddd, J=1.2, 1.2, 10.5 Hz), 5.42 (1H, ddd, J=1.2, 1.2, 17.0 Hz), 5.81 (1H, ddd, J=6.6, 10.5, 17.0 Hz); IR (neat) 3700—3100, 3084, 3010, 2170, 1642, 1299, 1250, 1049, 991, 925, 883, 842, 759, 697, 635 cm^{-1}. Found: 64.23; H, 9.76%. Calcd for $C_9H_{16}OSi$: C, 64.23; H, 9.58%.

Alkynylation of Butadiene Monoepoxide: The alkynylations of butadiene monoepoxide catalyzed by trimethylgallium were carried out along the procedure described above using 0.2 equiv of trimethylgallium. The $BF_3 \cdot OEt_2$ mediated alkynylations were accomplished by the procedure reported in the literature. Thus, $BF_3 \cdot OEt_2$ (2 mmol) was added at −78 °C to THF-hexane solution of 1-lithio-1-alkyne (2 mmol), which was prepared from the reaction of 1-alkyne (2 mmol) with hexane solution of butyllithium (2 mmol). After the whole was stirred at −78 °C for 10 min, butadiene monoepoxide (2 mmol) was added to the solution and the whole was stirred at −78 °C for additional 30 min. The reaction mixture was worked up with sat NH_4Cl and extracted with ether. The ethereal solution was dried (Na_2SO_4) and concentrated to give the crude product, which was purified by column chromatography (silica gel).

This work was financially supported by the Japan Society for the Promotion of Science by a Grant-in-Aid for an International Joint Research Project. The authors are indebted to Tosoh Akzo Co. Ltd. by the kind supply of trimethylgallium.

Complex Formation of Gelatin and Chondroitin Sulfate and the Effects on H^+ Ion Binding

Masakatsu YONESE,* Mikio YANO, and Hiroshi KISHIMOTO
Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467
(Received November 14, 1990)

Soluble and insoluble complex formations of gelatin and chondroitin 6-sulfate (Chs-C) were studied by measuring their viscosities and transmittances; the effects of complex formations on H^+ ion binding were studied by pH titrations. Soluble complexes were formed electrostatically with low ionic strengths; the compositions of the complexes varied with pH from those of solutions. The weight fraction of Chs-C of the saturated soluble complex was found to be 0.294 at pH=5.1. The composition of the insoluble complexes increased in the fraction of Chs-C with decreasing pH. The compositions were found to agree with the theoretical predictions obtained from the condition of electroneutrality. Furthermore, from pH titrations of mixed solutions comprising gelatin and Chs-C, the apparent dissociation constants, pK_a of the carboxylic groups of both polymers were obtained. They were found to increase due to soluble complex formation; soluble complex formation depresses the dissociation of H^+ ions due to a shielding of the positively charged amino groups of gelatin.

Chondroitin sulfates (Chs) are important components of mammalian connective tissues found in vivo as proteoglycans that bind with proteins, such as a collagen. They contribute to tissue elasticity and to the control of bone formation, due to their binding properties with Ca^{2+} and other ions.[1,2] Several kinds of Chs are found in vivo. Chondroitin 4-sulfate (Chs-A) and 6-sulfate (Chs-C), which are typical Chs, are *N*-acetyl-D-galactosamine 4- and 6-sulfate, together with D-glucuronic acids. Their thermodynamic properties, such as counterion binding properties,[3] osmotic coefficients,[4] partial molar volumes,[5] and dilution enthalpies,[6–8] could be explained by the Manning theory based on a line-charge model.[9] One of the characteristics resulting from the alternate arrangement of carboxylic and sulfuric groups in Chs contributes to maintaining the activity of Ca^{2+} ions constant when any pH changes.[3] Furthermore, no differences in these properties were found between Chs-C and -A.[4]

Chs interacts electrostatically with proteins to form complexes. These properties have been studied by light scattering,[10] electrophoresis,[11] and chromatograph methods.[12] In the regions of more acidic pH than the isoionic points of a protein, insoluble complexes were reported to be formed.[13] In gel membranes comprising gelatin and Chs, complex formation affects the membrane characteristics: the membranes shrink, and their water contents and permeabilities decrease due to complex formation.[14–18]

We studied the complex formation of gelatin and Chs-C in solutions and its effects on H^+ ion binding.

Experimental

Materials. Gelatin (Lot. No. P-1710) was offered by Nitta Gelatin Co., Ltd. By passing the gelatin solution through a mixed ion exchange column comprising cation exchange resins (Amberlite IR-120-B) and anion exchange resins (Amberlite IRA-410) an isoionic gelatin was obtained according to Jenus;[19] the isoionic pH was 4.8 (concentration: C_{ge}=1 w/v%). The isoionic gelatin solution was stored under refrigeration. The amino acid composition is shown in Table 1. Sodium salt of chondroitin sulfate C Chs-C was of commercial origin (Seikagaku Kougyou Co., Ltd., Tokyo, Japan) and was used without any purification. All other reagents were special grade from Katayama Co., Ltd. (Nagoya, Japan). Distilled and deionized water was used for the preparation of all solutions.

Viscosity Measurements. The viscosities of the mixed solutions comprising gelatin and Chs-C were measured at 25.0 °C by an Ostwald-type viscometer in which the falling time of water was 92 s.

pH Titration. The pH values of the solutions were measured by using a digital ion meter (Orion, Type 701A) connected to glass and reference electrodes (Orion, Type 91-01 and 90-02). pH titrations of the mixed solutions comprising isoionic gelatin and Chs-C were carried out at 25.0 °C by adding HCl (1.0 mol dm^{-3}) and NaOH (1.0 mol dm^{-3}) under an atmosphere of nitrogen.

From pH titration curves of the mixed solutions, the binding amounts ν of H^+ and OH^- ions were obtained as follows. Equal volumes of the polymer solution and solvent (V dm^3) were titrated by HCl and NaOH solutions (C mol dm^{-3}). When the titrants are added to the polymer and the solvent by ν and ν_0 dm^3, respectively, to attain the same pH, the value ν (mol g^{-1}) is obtained by the following equation[20]

$$\nu=(\nu-\nu_0)\,C/n_p, \tag{1}$$

where n_p (g) is the polymer weight in the sample solution. Since the binding amounts of the OH^- ion are equivalent to

Table 1. Amino Acid Composition of Gelatin

	mmol g^{-1}		mmol g^{-1}
Glycine	3.28	Tyrosine	0.0085
Alanine	1.09	Serine	0.296
Valine	0.195	Threonine	0.155
Leucine	0.226	Methionine	0.025
Isoleucine	0.115	Tryptophan	0
Proline	1.04	Cysteine	0
Hydroxyproline	1.21	Arginine	0.459
Phenylalanine	0.115	Histidine	0.046
Aspartic Acid	0.403	Lysine	0.279
Glutamic Acid	0.671	Hydroxylysine	0.050

the dissociated amounts of H^+ ions, they were defined as negative values.[21]

Composition of Insoluble Complex. The compositions of the insoluble complexes formed under various acidic pH conditions were studied by following two methods: (1) In the transmittance method, mixed solutions comprising gelatin and Chs-C were adjusted at 25 °C to an acidic pH in the region pH=5.6—2.5; after 15 min their transmittances were measured at λ=420 nm. According to A. Nakajima,[22] from compositions showing the transmittance maximum, those of the complexes were determined. (2) In the nitrogen analysis method, from the nitrogen contents of the insoluble complex $(W_N)_{ic}$, gelatin $(W_N)_{ge}$ and Chs-C $(W_N)_{chs}$, the weight fraction of Chs-C of the insoluble complex $(W_{chs})_{ic}$ was obtained by the following relation:

$$(W_{chs})_{ic}=((W_N)_{ge}-(W_N)_{ic})/((W_N)_{ge}-(W_N)_{chs}). \quad (2)$$

After adjusting the pH of the mixed solutions to the acidic region, they were allowed to stand for 15 min. Precipitated bulky insoluble complexes were dried in vacuo (at 80 °C), and their nitrogen contents $(W_N)_{ic}$ were analyzed. The nitrogen contents of gelatin, $(W_N)_{ge}$, and Chs-C, $(W_N)_{chs}$, were 0.178 and 0.267, respectively.

Results

Viscosities of Mixed Solutions Composed of Gelatin and Chondroitin Sulfate. The relative viscosities, η_{rel}, of mixed solutions comprising isoionic gelatin and Chs-C are shown in Fig. 1 as a function of the weight fraction of Chs-C W_{chs}. The total polymer concentrations of the mixed solutions were 0.3 g/100 cm^3, and the added ionic strengths of NaCl J were 0.0, 0.01, and 0.4 mol dm^{-3}. The results of the gelatin solutions did not significantly depend on J, but those of Chs-C solutions did. For J=0.4, the results of the mixed solutions increased linearly with increasing W_{chs}. However, in the cases of J=0.01 and 0, the results deviated from a linear relation; especially in the case of J=0 the deviation became significant. The deviations result from the formation of soluble complexes due to an electrostatic interaction between the gelatin and Chs-C. The ionic strengths resulting from the Na^+ counterion of Chs-C increased from 0 to 0.012 mol dm^{-3} with increasing W_{chs}. Therefore, the total ionic strengths of the mixed solutions varied with W_{chs} and in the region of total ionic strengths smaller than 0.022 mol dm^{-3} soluble complexes were found to be formed.

Chs-C was added to the isoionic gelatin solutions (the concentration C_{ge}=0.3 g/100 cm^3) under various conditions. The specific viscosities of mixed solutions, η_{sp}, defined by Eq. 3 are shown in Fig. 2 as a function of the concentration of Chs-C, C_{chs}:

$$\eta_{sp}=(\eta_{rel}/(\eta_{rel})_0-1), \quad (3)$$

where $(\eta_{rel})_0$ is the relative viscosity of the gelatin solution. In the case of J=0.005 mol dm^{-3} and pH=8.0, the results of η_{sp} increased linearly with increasing C_{chs} and were equal to those of Chs-C solutions (C_{ge}=0). In cases satisfying linearity, no complexes were formed. However, in the case of C_{ge}=0.3 g/100 cm^3 and J=0.005 mol dm^{-3}, the results of η_{sp} showed a steeper increase with C_{chs} and deviated at C_{chs}=0.125 g/100 cm^3 (=$(C_{chs})_c$)

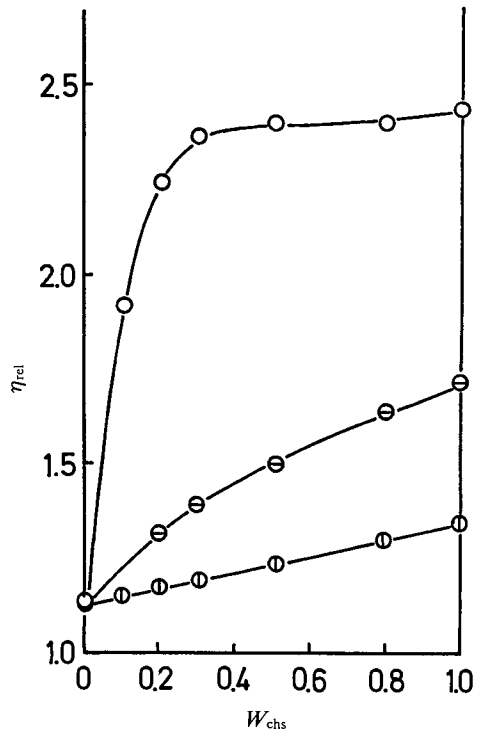

Fig. 1. Relative viscosity of mixed solution composed of gelatin and chondroitin sulfate C in various ionic strengths.
Ionic strength J: ○; 0.0, ⊖; 0.01, ⊙; 0.40 mol dm^{-3}
Total polymer concentrations of the mixed solutions were 0.3 g/100 cm^3, and the ionic strengths were adjusted by adding NaCl.

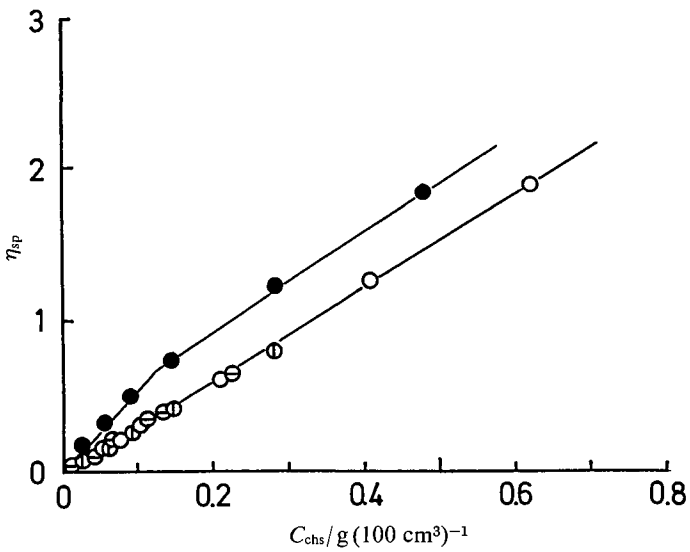

Fig. 2. Effects of adding chondroitin sulfate C to gelatin solutions on specific viscosities.
○: C_{ge}=0 g/100 cm^3, J=0.005 mol dm^{-3}, pH=4.8—5.6, ●: C_{ge}=0.3, J=0.005, pH=4.8—5.4, ⊖; C_{ge}=0.15, J=0.1, pH=4.8—5.4, ⊙; C_{ge}=0.3, J=0.005, pH=8.0.

from linearity. This results from the formation of the soluble complexes. In the region $C_{chs}>(C_{chs})_c$ complexes were formed, and their compositions seemed to vary with C_{chs}, i.e. the fraction of Chs-C in the complexes increased with increasing C_{chs}. At $C_{chs}=(C_{chs})_c$, saturated complexes were formed. In the region $C_{chs}>(C_{chs})_c$, the saturated complex and the free Chs-C present in the solution and the latter increased with increasing C_{chs}. Nakagaki et al. have reported that for soluble complexes formed by a bovine serum albumin (BSA) and Chs-C, BSA molecules bind strongly with Chs-C in a manner like the Langmuir type.[10] By assuming that all of the gelatin and Chs-C contribute to form complexes at $(C_{chs})_c$, the weight fraction of Chs-C in the saturated soluble complex $(W_{chs})_{ssc}$ was estimated to be 0.294.

pH Titrations of Mixed Solutions. The pH values of mixed solutions comprising isoionic gelatin and Chs-C solutions are shown in Fig. 3 as a function of W_{chs} for J=0 and 0.1 mol dm^{-3}. Their total concentrations were 1 g/100 cm^3 and the added ionic strengths J were adjusted by NaCl. The solid curves indicate the pH values calculated by assuming an ideal mixture. In the case of J=0.1 mol dm^{-3}, the results agreed with the calculated values. However, in the case of J=0, the experimental results were more alkaline than the calculated ones in the region $W_{chs}<0.3$; upon increasing W_{chs}, both of the results approached each other. The increments of pH in the region $W_{chs}<0.3$ are considered to result from the formation of soluble complexes.

The binding amounts of H^+ ion on isoionic gelatin and Chs-C, ν mol g^{-1}, were obtained from their pH titration curves by using Eq. 1. The values of ν are shown in Fig. 4 as a function of pH. The saturated binding amount of the isoionic gelatin, ν_{ge}^{∞}, was 0.85×10^{-3}, mol g^{-1}. This is equivalent to the total amount of the basic amino acids of the gelatin,[21] which was 0.83×10^{-3} mol g^{-1} (Table 1). The saturated binding amount of Chs-C, ν_{chs}^{∞}, was 1.60×10^{-3} mol g^{-1}, equal to the concentration of glucuronic acid in Chs-C (1.67×10^{-3} mol g^{-1}), as determined by the carbazole-sulfuric acid method.[23] Figure 4 also shows the results for ν using mixed solutions (W_{chs}=0.177, 0.334, and

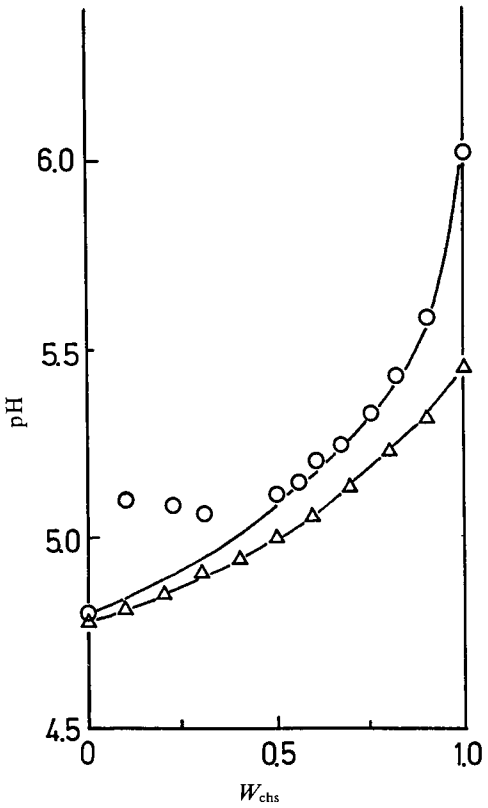

Fig. 3. pH of mixed solutions vs. weight fraction of chondroitin sulfate C.
J: ○; 0.0, △; 0.10 mol dm^{-3}. Solid curves are the calculated values obtained by assuming an ideal mixtures.

0461); these are the binding amounts of H^+ ions per 1 g of polymers. The results were found to be close to that for a Chs-C solution in the pH region 4.5—6. Upon decreasing the pH of mixed solutions, they became opaque due to the formation of insoluble complexes. The arrows in Fig .4 indicate the pH values at which insoluble complexes start to be formed (=$(pH)_{ic}$). Since the insoluble complexes were deposited onto the glass electrode in the region pH<$(pH)_{ic}$, the experimental results might not be very exact in these regions.

When there was no interaction between the gelatin and Chs-C, the ideal binding amounts of H^+ ions, ν^{ideal}, could be expressed by summing up the binding amounts of the gelatin and Chs-C, ν_{ge} and ν_{chs},

$$\nu^{ideal} = (1-W_{chs})\,\nu_{ge} + W_{chs}\,\nu_{chs}. \quad (4)$$

The calculated values are shown in Fig. 4 with broken lines. In the region of pH greater than about 6, the experimental and calculated results were almost equal. However, in the region of smaller pH, the former were more than the latter. An enhancement of H^+ ion binding is expected from the results shown in Fig. 3, and is considered to result from the formation of complexes.

Compositions of Insoluble Complexes. Upon decreasing the pH of mixed solutions comprising gelatin and Chs-C, a phase separation occurred. The transmittances of the mixed solutions of various compositions were measured at various times after adjusting to acidic pH in the range pH=2.5—5.0. During the initial stage a milky turbidity appeared, but with an elapse of time the bulky insoluble complexes precipitated, even under stirring conditions. The results mesured 15 min after adjusting the pH showed the clearest peaks as a function of W_{chs} (Fig. 5). The values of W_{chs} showing the transmittance maximum at arbitrary acidic pHs, $(W_{chs})_{ic}$, are considered to represent the compositions of insoluble complexes.[22] The $(W_{chs})_{ic}$ results are shown in Fig. 6 as a function of the pH of the solutions. $(W_{chs})_{ic}$ decreased with increasing pH of the solutions.

From the nitrogen contents, $(W_N)_{ic}$, of the insoluble complexes at pH=3, 3.5, and 4.4, the results of $(W_{chs})_{ic}$ were obtained using Eq. 2. They did not depend on the compositions of the mixed solutions, but on the pHs. The mean values of the results are shown in Fig. 6. Taking the errors of the nitrogen analysis into consideration, the results were found to agree fairly well with those from the transmittance method.

The compositions of saturated soluble complexes can vary with the pH of mixed solutions. However, the composition of saturated soluble complexes at only pH=5.1 was estimated to be $(W_{chs})_{ssc}$=0.294 from viscosity measurements. As shown in Fig. 6, $(W_{chs})_{ic}$ and pH.

Discussion

Apparent Dissociation Constant of Carboxylic Groups in Mixed Solutions. The degree of dissociation, α, of the carboxylic group of weak acidic polymers is related to the pH of the solutions by Eq. 5 in the range where α is not close to 0 or 1:[24]

$$pH = pK_a + n \log(\alpha/(1-\alpha)), \quad (5)$$

where pK_a is an apparent dissociation constant and n is a constant. Since the sulfuric groups of Chs-C can be approximated to be fully dissociated in mixed solutions of gelatin and Chs-C,[25,26] their carboxylic groups are responsible for the binding of H^+ ions. Eq. 5 can, thus, be applied to mixed solutions. In mixed solutions the mean value of the degree of dissociation of their carboxylic groups is obtained by

$$\alpha = \frac{(1-W_{chs})\nu_{ge}^{\infty} + W_{chs}\,\nu_{chs}^{\infty} - \nu}{(1-W_{chs})(n_{car})_{ge} + W_{chs}(n_{car})_{chs}}, \quad (6)$$

where $(n_{car})_{ge}$ and $(n_{car})_{chs}$ mol g^{-1} are the contents of the carboxylic groups of the gelatin and Chs-C. $(n_{car})_{ge}$ is 1.074×10^{-3} mol g^{-1}, which is the total content of the acidic amino groups obtained from Table 1; $(n_{car})_{chs}$ is 1.67×10^{-3} mol g^{-1}, which is the content of the glucuronic acid of Chs-C. The relations between pH and $\log(\alpha/(1-\alpha))$ were found to be linear, even for mixed solutions (Fig. 7). The values of pK_a and n obtained from these linearities are the mean values of the carboxylic groups of both polymers. Although the n values were almost constant (the mean value=1.24), the values of pK_a were found to have a maximum at about W_{chs}=0.25 (Fig. 8).

By using the mean value of n, the values of pK_a of the mixed solutions over the full range of W_{chs} can be obtained from the pH results for the mixed solutions shown in Fig. 3. The pK_a values, thus obtained, are

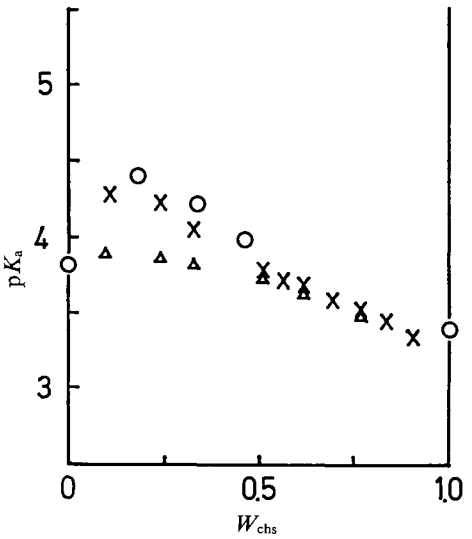

Fig. 8. pK_a values of carboxylic groups in mixed solutions.

also shown in Fig. 8, and are found to be in good agreements with the results mentioned above. The theoretical values of pK_a obtained by assuming ideal mixtures of Chs-C and gelatin are also shown in Fig. 8. The experimental results of pK_a were found to be greater than the theoretical values in the region $0<W_{chs}<0.4$, and the maximum to be around $W_{chs}=0.25$, which is very near to $(W_{chs})_{ssc}$ (=0.29). The carboxylic groups of the gelatin and Chs-C are responsible for the association of H^+ ions. The latter can be considered to be depressed in the association of H^+ ions for the following reasons: (1) competitive binding with H^+ ions and the amino groups of the gelatin, and (2) electrostatic shielding of the neighboring sulfuric groups due to interaction with the gelatin. The latter reason is expected from the fact that pK_a of chondroitin is less than that of Chs-C.[27] Chondroitin is the same structure as Chs-C except for the lack of sulfuric groups. Therefore, the enhancement of the H^+ ion association due to soluble complex formation is ascribed to that of the carboxylic groups of the gelatin due to a shielding of neighboring positively charged amino groups.

Complex Formations and Charge Densities of Gelatin and Chs-C. The saturated binding amounts of H^+ ions on isoionic gelatin molecules ν_{ge}^{∞} was 0.85×10^{-3} mol g^{-1}, as shown in Fig. 4. The charge amounts of the gelatin at the isoionic pH, $(Z_{ge})_{iip}$, is obtained by

$$(Z_{ge})_{iip}=(C_{OH}-C_H)/C_{ge}, \tag{7}$$

where C_{ge} is the concentration of gelatin (g dm^{-3}); C_{OH} and C_H are those of OH^- and H^+ ions (mol dm^{-3}) at the isoionic pH. From the isoionic pH of the gelatin (=4.8), $(Z_{ge})_{iip}$ was determined to be -1.585×10^{-6} mol g^{-1}, which can be negligible. The isoionic pH can thus be approximated to be equal to the isoelectric point, and the maximum charge amount of the gelatin Z_{ge}^{∞} to be ν_{ge}^{∞}. The charge amounts, Z_{ge}, vary with pH, due to a dissociation of H^+ ions, and can be obtained by subtracting the dissociated amounts of H^+ ions, r_{ge}, from Z_{ge}^{∞},

$$Z_{ge}=Z_{ge}^{\infty}-r_{ge}. \tag{8}$$

Cl^- or Na^+ ions come from the HCl or NaOH present in the solutions. However, the concentrations of these ions were so small that their binding amounts might be negligible. The charge of Chs-C Z_{chs} is the summation of the contributions of the sulfuric and the carboxylic groups ($(Z_{sul})_{chs}$ and $(Z_{car})_{chs}$),

$$Z_{chs}=(Z_{sul})_{chs}+(Z_{car})_{chs}=(Z_{sul})_{chs}-r_{chs}, \tag{9}$$

where r_{chs} is the dissociated amounts of H^+ ions from chondroitin sulfuric acid. The values of Z_{ge} and Z_{chs} in the solutions can be related to the formation of both soluble and insoluble complexes. The pHs which start to form the soluble complexes were almost pH=6, at which Z_{ge} was negative (=−0.026 mol dm^{-3}). Soluble complex formation was, thus, found to occur even between both the negatively charged gelatin and Chs-C, being considered to result from an electrostatic interaction between the positively charged amino groups of the gelatin and the charged groups of Chs-C. As the pH decreases, Z_{ge} increases and the insoluble complexes come to be formed; a phase separation thus occurs.

Composition of Complexes. When the complexes formed by electrostatic interactions satisfy electroneutrality, the weight fraction of the Chs-C of the complex $(W_{chs})_{co}$ are related to Z_{chs} and Z_{ge} by the following equation:

$$(W_{chs})_{co}=-Z_{ge}/(Z_{chs}-Z_{ge}). \tag{10}$$

Using Z_{ge} and Z_{chs}, the values of $(W_{chs})_{co}$ were calculated. They are shown in Fig. 6 together with the experimental results for insoluble complexes $(W_{chs})_{ic}$, and a saturated soluble complex at pH=5.1 $(W_{chs})_{ssc}$. The results for the insoluble complexes $(W_{chs})_{ic}$ agreed with the calculated values. Therefore, the formation of insoluble complexes is found to be due to electrostatic interactions between the negative charge of Chs-C and the effective positive charge of the gelatin. However, when the pH value approaches the isoionic point of the gelatin, the experimental results, $(W_{chs})_{ic}$, became greater than the calculated values.

The weight fraction of Chs-C of the saturated soluble complex $(W_{chs})_{ssc}$ was 0.294 at pH=5.1. However, it can not be estimated from Eq. 10 since Z_{ge} (=−0.05 mol dm^{-3})<0. The soluble complexes are thus considered to be formed by an interaction between Chs-C and the positively charged amino groups of the gelatin. Although the theoretical value of $(W_{chs})_{ssc}$ is difficult to estimate from our results, as an extreame estimation, $(W_{chs})_{ssc}$ was calculated from the electroneutrality between Chs-C and all of the positively charged amino groups at pH=5.1: 0.217, and less than the experimental result. This difference might be explained as follows. Near the isoionic point of gelatin, since it is in a shrinking random coil state, parts of the positively charged amino groups are considered to take part in complex formation. Furthermore, parts of the negatively charged groups of Chs-C are also considered to take part in it, and the residual parts are free states in solutions.

Conclusion

(1) The apparent dissociation constants of carboxylic groups of Chs-C and gelatin decrease due to complex formation; thus, the dissociation of H^+ ions of the carboxylic groups of gelatin was depressed by a shielding of the positively charged amino groups due to an interaction with Chs-C.

(2) Along with decreasing pH of the solutions, insoluble complexes were formed due to the electrostatical interactions between Chs-C and the effective positive charges of gelatin; the composition agrees with the values calculated according to electroneutrality.

Electronic Spectra of Phenanthrolinediones, Phenanthrolinones, Bipyridinediones, and Amino-Substituted Phenanthrolines

Masaki YAMADA,* Miki KIMURA, Mineyasu NISHIZAWA, Shigeyasu KURODA, and Ichiro SHIMAO
Department of Materials Science and Engineering, Faculty of Engineering,
Toyama University, 3190 Gofuku, Toyama 930
(Received January 16, 1991)

The electronic spectra of three types of 1,10-phenanthroline derivatives having different π-conjugated systems, phenanthrolinedione, phenanthrolinone, and the parent phenanthroline, showed characteristic patterns easily distinguished from each other. Analogous spectral patterns were noted in amino-substituted 1,10-phenanthrolines, and the protonated structures of these compounds were characterized on the basis of such spectral features.

Recently we reported on the preparation of *N,N'*-annelated phenanthrolinedione **1a** and **1b**, and bipyridinedione **2a** and **2b**, as potential precursors of the corresponding dichloro derivatives of 1,10-phenanthroline (phen) and 2,2'-bipyridine (bpy), respectively.[1] These diones seem to be also attractive compounds as "extended" α-pyridinones. From these viewpoints, we investigated in detail the electronic spectra of **1a**, **1b**, **2a**, **2b**, well-known phenanthrolinone **3a**,[2] **3b**,[3] and nonannelated bipyridinedione **2c**.[4] The electronic spectra of **1a,b** and **3a,b** were largely different from that of the parent phen and from each other, whereas there were small differences in spectral patterns between **2a**—**c** and the parent bpy. It was suggested that the characteristic of spectral patterns should be a good means in identifying the formal π-conjugated systems in phen derivatives regardless of the shifts in absorption maxima.[5] Further, spectral patterns analogous to those of **1** and **3** were observed in the spectra of protonated forms of amino-substituted phens, 1,10-phenanthroline-2,9-diamine (**4**)[3] and 1,10-phenanthrolin-2-amine (**5**).[6] The protonated structures of **4** and **5** were characterized by examining the spectral patterns.

Results and Discussion

Electronic Spectra of Phenanthrolinones and Bipyridinones. The electronic spectra of phen, a phenanthrotinone **3a**, and a phenanthrolinedione **1a** in 250—450 nm region are shown in Fig. 1. A strong π-π^* transition band (β'-band) and two additional bands of

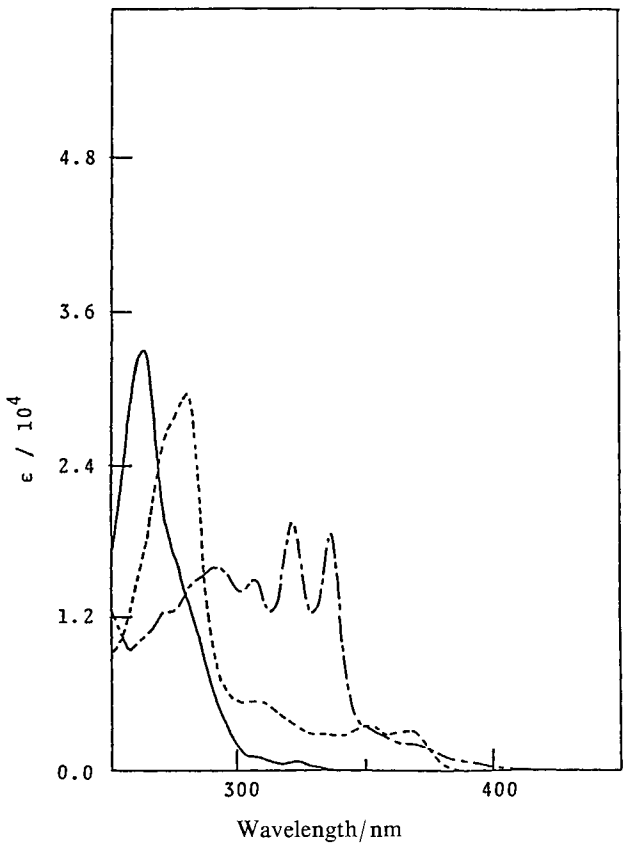

Fig. 1. Electronic spectra of (——): phen, (------): **3a**, and (— - —): **1a** in methanol.

much lower intensity at longer wavelengths (p-band and α-band) appeared in the spectrum of phen.[7] Noticeable differences are observed between the spectrum of **3a** and that of phen, i.e., three clear peaks of much higher intensity than that of p- and α-bands (λ_{max}=308, 352, and 369 nm, with $\log\varepsilon_{max}$=3.74, 3.55, and 3.50, respectively) appeared in the spectrum of **3a**. The spectrum of **1a** is quite different from those of both phen and **3a**, i.e., four peaks of similar intensities (λ_{max}=271, 291, 307, 322, and 337 nm, with $\log\varepsilon_{max}$=4.10, 4.21, 4.18, 4.29, and 4.27, respectively) are observed instead of the β'-band.

The spectral patterns of the parent phen are not affected by simple substituents such as amino,[3,6] chloro,[2,3] and methoxy groups[8,9] at 2- and 9-positions. The only noticeable influences caused by substituents were the red shifts according to the nature and number of substituents and appearances of sub-peaks in β'-bands of disubstituted derivatives, **7** and **9** (Table 1).

The electronic spectra of another phenanthrolinone **3b**[3] and another phenanthrolinedione **1b** along with **3a** and **1a** are depicted in Fig. 2. The chloro substituent in **3b** caused a small red shift compared with **3a**, in a similar manner to the chloro substituent in **6**. Exchange of the ethano-bridge in **1a** by a propano-bridge in **1b** also resulted in a small red shlft.[1,10] Nevertheless, the spectral patterns of **3b** and **1b** are quite similar to those of the corresponding compounds having the same formal π-conjugated systems, **3a** and **1a**, respectively. These results indicate that the characteristic spectral patterns of phen, **3a**, and **1a** reflect the individual π-conjugated systems rather than the substituent effects.

This speculation was supported further by spectral measurement of **1a** in strong acidic media. In concentrated sulfuric acid, the absorbances at wavelengths shorter than 300 nm were increased to a level of the β'-bands (Fig. 3). Since two different sets of isosbestic points appeared successively during spectrometric titration with sulfuric acid (Fig. 3-A and -B), stepwise protonation to the two oxygen atoms in **1a** should take place in strong acidic media, forming **1'a** and **1''a** (Scheme 1). The diprotonated form **1''a** may exist in resonance with **1'''a**, whose π-conjugated system is the same as that of phen.

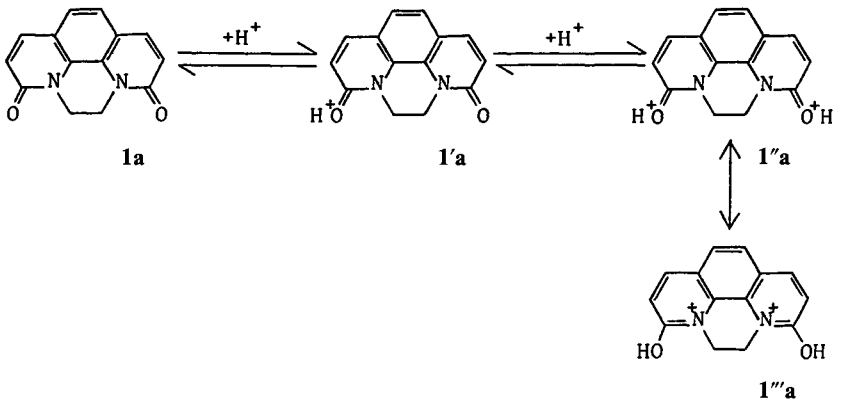

Scheme 1.

The electronic spectra of bipyridinediones **2a**—**c** in 250—450 nm region are displayed in Fig. 4. It is well-known that a strong π–π^* transition band of the parent bpy (β'-band,[11] λ_{max}=280 nm[12]) appears in this region. Analogous bands indeed appear in the spectra of **2a**—**c**. The large red shifts of absorption maxima from that of the parent bpy (93, 63, and 36 nm for **2a**, **2b**, and **2c**, respectively) are noted, which should be attributed to changes in the π-conjugated systems.[5] Large shifts of absorption maxima can take place also by rotation of the interannular bond,[1,13,14] i.e., large blue shifts occur in the spectra of twisted bipyridinediones, **2b** and **2c** (30 and 57 nm, respectively), compared with the planar one, **2a**. Thus we should be careful in identifying the π-conjugated systems of bpy derivatives in terms of the shifts of absorption bands.[5,13]

Amino-Substituted Phen's and Their Protonated Structures. Though the amino substituents at 2- and 9-positions in **4** and **5** do not affect the spectral pattern of phen (see above), protonation to these compounds effected large changes in the spectral pattern. The electronic spectra of amino-substituted phen's, **5** and **4**, and their protonated forms are shown in Fig. 5. A one-step protonation was detected by spectrometric titration of **5** within a pH range of 10 to 0 (pK_a=6.9[15]). A large change in the spectral pattern took place by the protonation, i.e., several prominent peaks appeared at longer wavelengths (Fig. 5-A). In the case of **4**, two-step protonations were observed within a pH range of 10 to 0 (pK_a=7.9 and 2.1[16]). Though the change in the spectral pattern was marginal by the first protonation, it was fairly drastic by the second protonation (Fig. 5-B). In

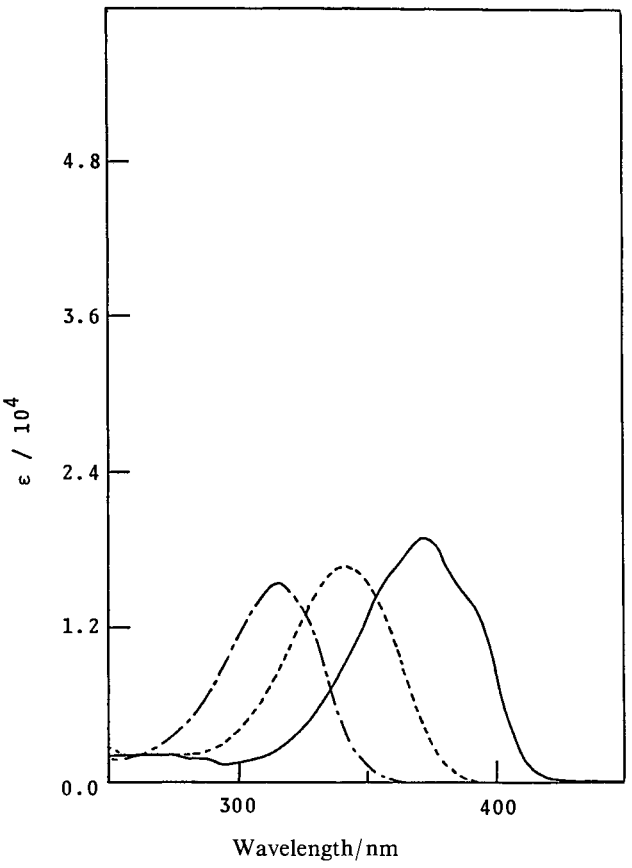

Fig. 4. Electronic spectra of (——): **2a**, (– – –): **2b**, and (— - —): **2c** in methanol.

contrast, only the shifts of the β'-band were noted by the protonation to phen.[17] Since the spectral changes of **4** and **5** are reversible, these changes do not reflect degradation reactions. A comparison between these spectra and some spectra discussed above (Fig. 6) shows that the spectral pattern of the monoprotonated **5** is quite similar to that of **3a** (Fig. 6-A), and that the spectral patterns of diprotonated form of **4** resemble that of phenanthrolinedione **1a**, though the sharpness of each peak is reduced to some extent (Fig. 6-B).

Analogous spectral similarity was observed between simpler heteroaromatic compounds, 2-quinolinamine **10** and 1-methyl-2(1*H*)-quinolinone **11**. A one-step protonation took place in **10** within a pH range of 10 to 0 (pK_a=7.3).[18] The electronic spectra of **10** in free and monoprotonated forms and **11** in a 250—450 nm region are illustrated in Fig. 7. The single peak appearing in

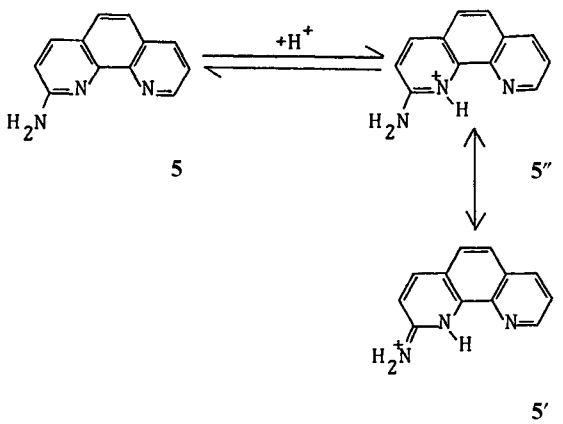
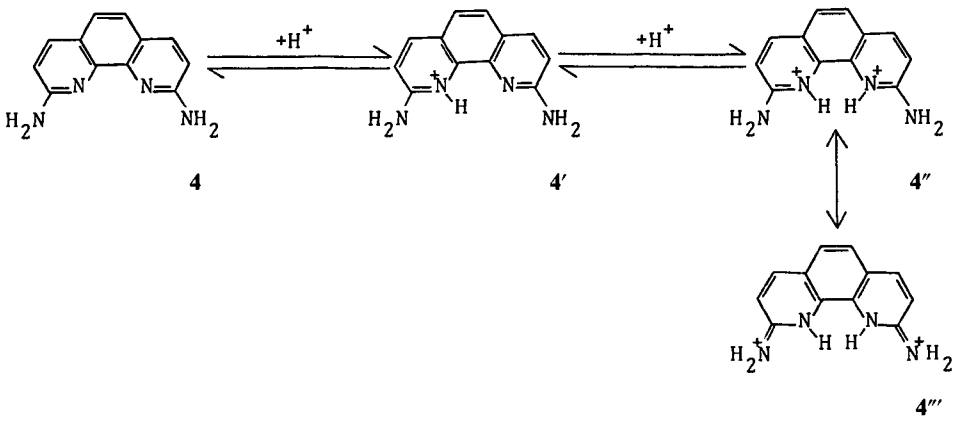
the spectrum of the free form of **10** splitted into two major peaks by protonation. The spectral pattern of monoprotonated **10** was similar to that of **11**. Protonation to **10** took place on the ring nitrogen to form **10′**, because the ring nitrogen of amino-substituted pyridines has much higher basicity than the amino nitrogen.[12,19] There is a large contribution of the resonance structure **10″** in **10′**.[18,20] The spectral similarity of monoprotonated **10** and **11** should be attributed to the similarity of the π-conjugated systems between **10″** and **11** (Scheme 2).

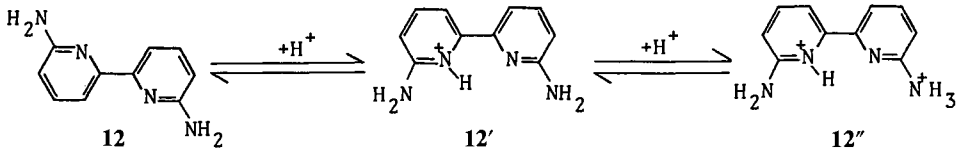
The spectral similarity between monoprotonated **5** and **3a**, and between diprotonated **4** and **1a**, can be rationalized by the same argument. The initial proton-



Scheme 3.



Scheme 4.



Scheme 5.

ation to **5** takes place on the nitrogen in 1-position rather than in 10-position[6] forming **5'**, because the amino substituent at α-position of the pyridine ring significantly increases the basicity of the neighboring ring nitrogen.[12,18–20] There would be a large contribution of the resonance structure **5''**, which is a conjugated system quite similar to that of **3a** (Scheme 3). For the same reason, the initial protonation to **4** should take place at one of the ring nitrogens, forming **4'**. The second protonation should take place at the other ring nitrogen to form **4''**, which has a resonance structure **4'''**. The formal π-conjugated system of **4'''** is quite similar to that of **1a** (Scheme 4). If the second protonation should take place on one of the amino nitrogens, one cannot draw a π-conjugated system similar to that of **1a**. On the other hand, the spectral pattern of monoprotonated form **4'** resembles that of phen rather than that of **3a**. This suggests that the positive charge in **4'** is delocalized not only over the neighboring amino nitrogen but also over the other pyridine ring and its amino substituent, thereby lowering the contribution of the π-conjugated system similar to that of **5''**.

As discussed above, at least judging from the spectral features of phenanthroline derivatives, both the first and second protonation to **4** appear to take place on the ring nitrogens. It is well-known that the second protonation to the ring nitrogens of phen and bpy occurs only in such strong acidic media as concentrated sulfuric acid because of a repulsion between the neighboring protons in diprotonated forms.[17,21] In the present case, however, the second protonation to the ring nitrogen of **4** is apparantly completed at pH 1. Incidentally, the acid-base properties of 2,2'-bipyridine-6,6'-diamine **12**, a bpy analogue of **4**, have been studied by electronic and ^{1}H NMR spectroscopies,[22] and it has been concluded that the second protonation to **12** takes place at the amino nitrogen rather than the ring nitrogen (Scheme 5). Since there were only minor changes in the spectral patterns by protonation to **12**, there should be some uncertainty as to the actual forms for reasons given above with respect to **2a—c**.

shifts for **4** and **12** are summarized in Table 2 together with those of the parent phen and bpy. At least in acid-free forms, the electron donating effects of amino substituents seem to be very similar in the two compounds, as judged from the red shifts in the electronic spectra and the ^{1}H NMR high field shifts.[23] The second protonation to **12** (pK_a=2.2[22]) might also take place at the ring nitrogen in a similar manner to that of **4** (pK_a=2.1). Systematic investigations are needed, however, to settle this problem.

In conclusion, we demonstrated that the electronic spectra of the three types of phen derivatives, **1a,b**, **3a,b**, and the parent phen, show neatly different spectral pattern distinguished from each other by visual inspection. This may reflect the differences in the individual π-conjugated systems. Such a feature could be a good means to elucidate the electronic structure and related properties of phen and the corresponding bpy derivatives.

Experimental

Materials. Preparation of 5,6-dihydropyrazino[1,2,3,4-*lmn*][1,10]phenanthroline-3,8-dione (**1a**), 6,7-dihydro-5*H*-[1,4]diazepino[1,2,3,4-*lmn*][1,10]phenanthroline-3,9-dione (**1b**), 6,7-dihydrodipyrido[1,2-*a*:2′,1′-c]pyrazine-4,9-dione (**2a**), 7,8-dihydrodipyrido[1,2-*a*:2′,1′-c][1,4]diazepine-4,10-dione (**2b**), and 2,9-dichloro-1,10-phenanthroline (**7**) was reported elsewhere.[1] The following materials were prepared by literature procedures: 1-Methyl-1,10-phenanthrolin-2(1*H*)-one (**3a**), mp 123—124 °C (lit,[2] 123—124 °C), 9-chloro-1-methyl-1,10-phenanthrolin-2(1*H*)-one (**3b**), mp 153—154 °C (lit,[3] 154—155 °C), 1,10-phenanthroline-2,9-diamine (**4**), mp 296—298 °C (lit, 1[3] 273—275 °C, lit, 2[9] 296—298 °C), 1,10-phenanthrolin-2-amine (**5**), mp 188—192 °C (lit,[6] 187—190 °C), 2-chloro-1,10-phenanthroline (**6**), mp 129—130 °C (lit,[2] 129—130 °C), 2-methoxy-1,10-phenanthroline (**8**), mp 78—80 °C (lit,[8] 74—76 °C), 2,9-dimethoxy-1,10-phenanthroline (**9**), mp 111—113 °C (lit,[9] 110—111 °C), 1,1′-dimethyl-2,2′-bipyridine-6,6′-(1*H*,1′*H*)-dione (**2c**), mp 224—225 °C (lit,[4] 210—211 °C). 1,10-Phenanthroline (phen) and 2-quinolinamine (**10**) were commercially obtained. 1-Methyl-2(1*H*)-quinolinone (**11**) was prepared by a procedure analogous to that for 3a:[2] recrystallyzed from petroleum ether (bp 30—70 °C), mp 71—72 °C (lit, 1[24] 68—69 °C, lit, 2[25] 73—74 °C).

Spectral Measurements. Electronic spectra were recorded on a Shimadzu UV-265FS Spectrophotometer at 20 °C. ^{1}H NMR spectra were measured with a JEOL JNM-FX90Q Spectrometer at room temperature. The buffer solutions used for spectrometric titrations were as follows:[26] weakly basic area, potassium borate buffer; weakly acidic area, acetic acid-sodium acetate buffer; acidic area, HCl–KCl buffer.

Temperature Distribution in Tubular Solid Oxide Fuel Cell

Kiyoshi KANAMURA,* Shoji YOSHIOKA, and Zen-ichiro TAKEHARA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University,
Yoshida-Honmachi, Sakyo-ku, Kyoto 606
(Received February 7, 1991)

The temperature distribution in the tubular solid oxide fuel cell (SOFC) was calculated by using a finite element method. In this study, specially, the heat generation and consumption caused by the entropy changes at anode and cathode were taken into account for the calculation of temperature distribution in SOFC. In order to estimate the tendency of temperature distribution, the current distribution and the partial pressure distributions of hydrogen, steam, and oxygen were obtained from the calculation by using the simple mathematical model. From the temperature distribution in the tubular SOFC, it can be seen that the temperature difference is largest in the region of porous cathode material. This indicates that the heat generation from the entropy change of cathode reaction has the significant effect for the temperature distribution in tubular solid oxide fuel cell.

Solid oxide fuel cell (SOFC) has been investigated and developed, because of the high energy conversion efficiency. These researches have been concentrated on the development of the electrode materials, the electrolyte materials, and the construction of the cell.[1] Recently the excellent design of SOFC has been achieved by using Electrochemical Vapor Deposition (EVD).[2] The thin electrolyte was deposited on the conductive oxide cathode which was deposited on the porous calcia stabilized zirconia. The tubular SOFC is suitable for EVD process. In this study, the temperature distribution in the tubular SOFC was calculated by a finite element method in order to offer the fundamental knowledge for the development of the high energy conversion SOFC.

The maximum electric energy generated in SOFC corresponds to ΔG of the hydrogen combustion which is the total reaction in SOFC when oxygen and hydrogen are used. ΔH of this reaction, however, is the total energy which can be utilized in SOFC. The energy of $T\Delta S$ cannot be utilized as an electric energy. Since SOFC is operated at high temperature (around 1273 K), the energy of $T\Delta S$ is lost as a heat which amount is much larger than those from other fuel cells operated at low temperature (around 450 K). Moreover, the energy loss is also caused by both overpotentials of hydrogen and oxygen electrodes and the ohmic loss of the electrolyte. These irreversible factors generate the heat in SOFC. In order to minimize the energy loss caused by the overpotential and ohmic resistance, the thickness of electrolyte has to be decreased and the excellent oxygen and hydrogen electrodes have to be developed. The energy loss caused by the entropy change, however, can not be improved, because of the thermodynamic limiting. From this fact, it can be concluded that the temperature distribution caused by the heat generated or consumed by the entropy change of electrode reactions is more important.

The heat management of SOFC is the most important problem for the construction of the SOFC and the determination of the practical operating conditions. Therefore, the calculation of the temperature distribution was conducted by using a finite element method.

Experimental

Yttria stabilized zirconia was prepared by the sintering of the mixture of Y_2O_3 8 mol% and ZrO_2 92 mol% (Toyo Soda Corp.). Its oxygen ion conductance was measured by using AC impedance method at 1273 K. The entropy changes at oxygen and hydrogen electrodes were determined by the measurement of Seebeck coefficients according to the reference.[3]

The temperature distribution in the tubular SOFC was calculated by using the program for a finite element method.[4] From our calculation, the tendency of the temperature distribution can be obtained. The electrochemical parameters of oxygen and hydrogen electrodes reported in reference[5] were used for the estimation of heat generated from oxygen and hydrogen overpotentials. For the simple calculation, some assumptions were adopted.

Results and Discussion

Heat Generation Factors. The heat is generated by the irreversible processes taking place in SOFC and thermodynamic factors in an electrochemical system. In SOFC, the heat is generated or absorbed by the following factors;

(1) Overpotentials of hydrogen and oxygen electrodes.

(2) Ohmic resistance of yttria stabilized zirconia.

(3) Entropy changes at hydrogen and oxygen electrodes.

The overpotentials of hydrogen and oxygen electrodes are dependent on the current. The relationships between the overpotentials and the current for oxygen and hydrogen electrodes have been examined and suggested by many researchers.[5–7] The electrochemical parameters depend on the kind of electrode. In this study, the model cell is constructed by $LaCoO_3$ as a cathode, Ni cermet as an anode, yttria stabilized zirconia as an electrolyte and porous yttria stabilized zirconia as a support. The following equations were adopted in the calculation of the heat generation caused by the

Table 1. Electrochemical Parameters Used in the Calculation of the Current Distribution

Electrochemical parameters	
I_0	9.8 A m^{-2}
K	0.0609 V[a)]
σ[b)]	0.1 S cm^{-1}

a) $K=RT/4\alpha F$ from Ref. 5, α: transfer coefficient, R: gas constant, F: Faraday constant. b) $R=(1/\sigma)(L/S)$; L: thickness of YSZ of element, S: surface area of YSZ of element.

overpotentials in order to simplify the calculation. Table 1 shows the electrochemical parameters which have been suggested in the reference.[5)]

For hydrogen electrode

$$\eta_a = K \ln\left(\frac{I}{I_0}\right) \tag{1}$$

For oxygen electrode

$$\eta_c = 0 \tag{2}$$

where η_a and η_c are overpotentials of anode and cathode, respectively, I_0 is exchange current, I is current, and K is the constant listed in Table 1. The heat generation from the ohmic resistance of yttria stabilized zirconia is also dependent on the current. The relationship between the voltage loss in the electrolyte (ΔV) and the current (I) obeys Ohm's law.

$$\Delta V = IR \tag{3}$$

where R is the resistance of the electrolyte in the tubular SOFC, which is estimated from the conductivity of yttria stabilized zirconia (YSZ). The conductivity of YSZ can be measured by using the impedance method.[8)]

The heat generation caused by the entropy change becomes larger with increasing temperature. The heat caused by the entropy changes at hydrogen and oxygen electrodes has to be taken into account for the calculation of the temperature distribution. The total reaction in SOFC is the hydrogen combustion. The total entropy change (ΔS) is easily estimated from the thermodynamic consideration. The total reaction, however, is separated to cathode and anode reactions in an electrochemical cell. The entropy change is also separated to cathode and anode reactions. In other words, an entropy change of single electrode ($\Delta S_{cathode}$ for the entropy change of cathode reaction, ΔS_{anode} for the entropy change of anode reaction) have to be estimated.

$$\Delta S = \Delta S_{cathode} + \Delta S_{anode} \tag{4}$$

The entropy changes of cathode and anode can be estimated from Seebeck coefficients of oxygen and hydrogen electrodes, as reported in reference.[3)] The entropy change of oxygen electrode reaction was estimated to be -81.6 J K^{-1} mol^{-1} per two electrons under 0.21×10^5 Pa oxygen partial pressure at 1273 K. From Eq. 4, the entropy change of hydrogen electrode can be calculated. These values are dependent on the partial pressure. The dependence can be represented by the following equations.

Total reaction

$$H_2 + \frac{1}{2} O_2 \rightarrow H_2O \tag{5}$$

For hydrogen electrode,

$$\Delta S_{anode} = (S_{H_2O} - R\int_1^{P_{H_2O}} d\ln P) - (S_{H_2} - R\int_1^{P_{H_2}} d\ln P) - S_{O^{2-}}{}^* \tag{6}$$

For oxygen electrode,

$$\Delta S_{cathode} = S_{O^{2-}}{}^* - \frac{1}{2}(S_{O_2} - R\int_1^{P_{H_2O}} d\ln P) \tag{7}$$

where $S_{O^{2-}}{}^*$ is the transported entropy of O^{2-} ion in yttria stabilized zirconia. The entropy changes of hydrogen and oxygen electrodes under various partial pressures can be calculated from Eqs. 6 and 7. $\Delta S_{cathode}$ changes with the partial pressure of oxygen and ΔS_{anode} changes with the partial pressures of hydrogen and steam in SOFC. Therefore, the partial pressure distribution has to be estimated in order to calculate the temperature distribution in the tubular SOFC. The entropy change of single electrode reaction is represented by the function of temperature. In this study, however, it was assumed that the dependence of entropy change on temperature in narrow temperature region was too small to influence the temperature distribution.

Calculation of Current and Partial Pressure Distributions. The current and partial pressure distribution in solid oxide fuel cell have been reported in some references.[9,10)] In this study, the current distribution was calculated by using the model, as shown in Fig. 1. This is the typical tubular SOFC which has metal oxide

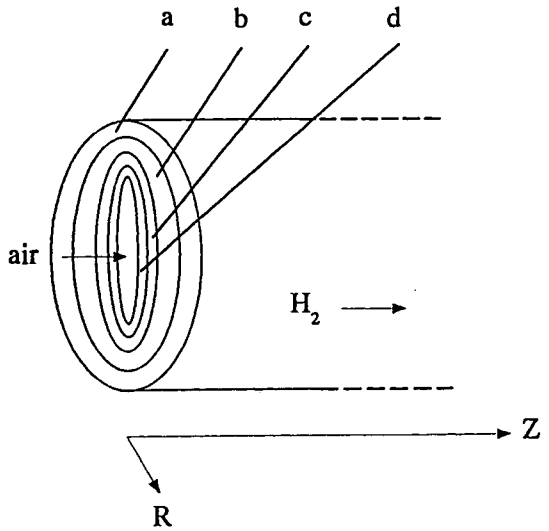

Fig. 1. Schematic illustration of tubular SOFC constructed by electrolyte (yttria stabilized zirconia), anode (Ni zirconia cermet electrode), cathode ($LaCoO_3$), and porous zirconia substrate.

cathode, Ni–ZrO_2 cermet anode, yttria stabilized zirconia electrolyte, and porous yttria stabilized zirconia support. Hydrogen is flown through the outside of cell and oxygen through the inside of cell. The dimension of the cell is summarized in Table 2. In order to calculate the current distribution in this SOFC, the cell is divided to n elements, as shown in Fig. 2. The simple mathematical procedure was used for the calculation of the current and partial pressure distributions in the tubular SOFC. The equivalent circuit for this model is shown in Fig. 3. The current passed through each element is represented by I_i. R_i indicates the resistance of yttria stabilized zirconia electrolyte in i th element. Z_i is the sum of both impedances of oxygen and hydrogen electrodes. The total current (I) is given by the sum of each elementary current (I_i).

$$I = I_1 + I_2 + \cdots + I_i + \cdots + I_n \tag{8}$$

If both electrodes have high electric conductivity, the cell voltage of each element is equal to the cell voltage (V).

$$V = V_1 = V_2 = \cdots = V_i = \cdots = V_n \tag{9}$$

Table 2. Dimension of the Tubular SOFC

Length (L)	20 cm
Diameter inside	10 mm
outside (D)	17 mm
Thickness of cathode	0.5 mm
Thickness of anode	0.5 mm
Thickness of electrolyte	0.5 mm
Thickness of porous substrate	2 mm

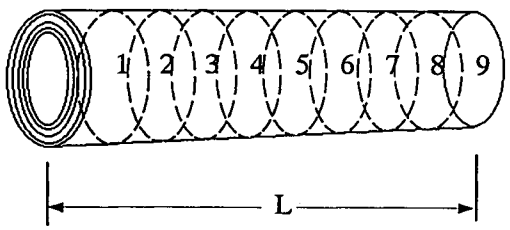

Fig. 2. Model for calculation of current and partial pressure distribution.

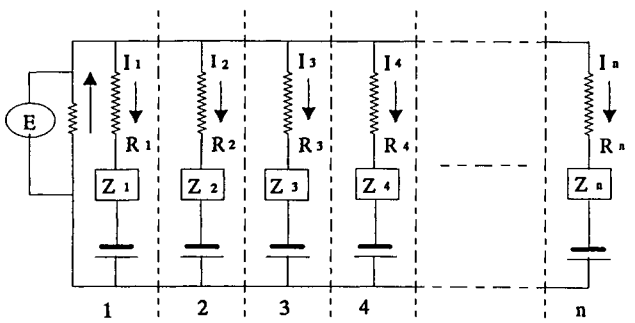

Fig. 3. Equivalent circuit for the model in Fig.2.

For element 1, the relationship between V_1 and I_1 is represented by the following equation,

$$V_1 = E_e - \eta_1 - R_1 I_1 \tag{10}$$

where η_1 is the total overpotential of element 1 and is given by the Eqs. 1, 2, and 11. η_i is given by the sum of both overpotentials of hydrogen and oxygen electrodes.

$$\eta_i = \eta_{ia} + \eta_{ic} \tag{11}$$

where η_{ia} and η_{ic} are the overpotential of hydrogen electrode of element i and that of oxygen electrode of element i, respectively. E_e is the equilibrium voltage of solid oxide fuel cell and is determined from the partial pressures of hydrogen, steam, and oxygen according to Nernst equation.

$$E_e = E_0 - (RT/2F)\ln(P_{H_2O}/P_{O_2}^{1/2} P_{H_2}) \tag{12}$$

For the other elements, the same relationship can be established. The hydrogen and oxygen flow horizontally through the chambers in the cell at constant rate. The partial pressures of oxygen and hydrogen at the entrance of chamber are higher than those at the exit, because oxygen and hydrogen are consumed by the electrode reactions at each element. The partial pressure of steam at the entrance of fuel chamber is lower than that at the exit. The hydrogen partial pressure in element 2 is given by the following equation,

$$P_{H_2,2} = \frac{U_{H_2,1} - \dfrac{I_1}{2F}}{\left(U_{H_2,1} - \dfrac{I_1}{2F}\right) + \left(U_{H_2O,1} + \dfrac{I_1}{2F}\right)} \tag{13}$$

The air and steam partial pressures are given by the similar equations.

$$P_{air,2} = \frac{0.21\,U_{air,1} - \dfrac{I_1}{4F}}{U_{air,1} - \dfrac{I_1}{4F}} \tag{14}$$

$$P_{H_2O,2} = \frac{U_{H_2O,1} + \dfrac{I_1}{2F}}{\left(U_{H_2O,1} + \dfrac{I_1}{2F}\right) + \left(U_{H_2,1} - \dfrac{I_1}{2F}\right)} \tag{15}$$

where $U_{i,1}$ is the flow rate of gas i at the entrance of SOFC (mol s^{-1}). In this way, the partial pressure in element 2 can be obtained. As a result, E_e can be also determined. The elementary current in element 2, I_2, can be calculated from E_e and V by using Eq. 10. Such a procedure is repeated n times. Finally, the current distribution and the partial pressure distribution can be calculated.

Figure 4 shows the equilibrium voltage and the total overpotential distributions along Z-axis in the tubular SOFC calculated from above simple mathematical model, where the total current and gas flow rate are

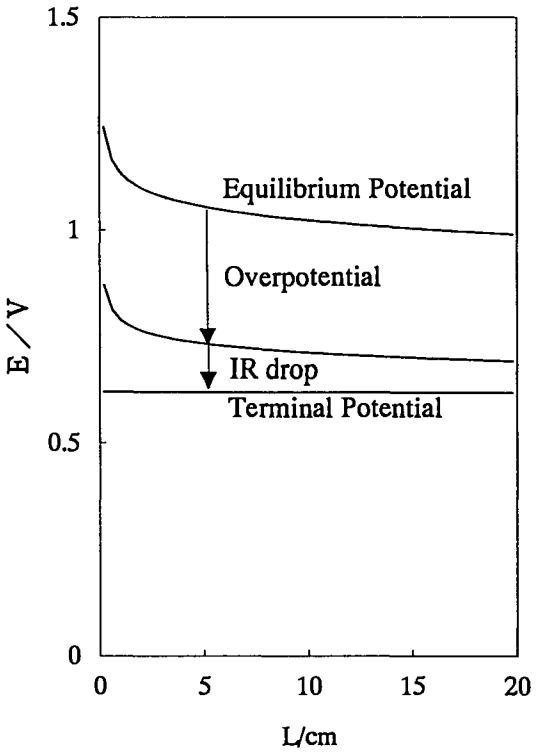

Fig. 4. Distributions of the equilibrium potential and IR drop in the tubular SOFC, discharge current: 200 mA cm^{-2}, flow rate: 5 cm s^{-1}.

assumed to be 200 mA cm^{-2} and 5 cm s^{-1}, respectively. The utilization of hydrogen depends on the flow rate. The flow rate was assumed to be 5 cm s^{-1}, in order to obtain the fuel utilization to be about 10%. These distributions result in the current distribution in the tubular SOFC.

Figure 5 shows the current distribution in SOFC at two flow rates of hydrogen. The average current density is 200 mA cm^{-2}. The partial current near the entrance of SOFC is larger than that near the exit according to the potential distribution in Fig. 4. The current distribution depends on the flow rate and become larger with decreasing of the flow rate. The heat generation caused by the ohmic resistance of electrolyte is seemed to be much larger at the entrance of cell compared with the heat generation at the exit, as expected from the relationship between the heat generation at the electrolyte and the current.

Figure 6 shows the partial pressure distributions of oxygen, hydrogen, and steam in SOFC at 5 cm s^{-1} (0.0376 mol s^{-1}) flow rate. The hydrogen partial pressure gradually decreases along the Z axis from the entrance to the exit. Under these conditions, 10% of hydrogen induced in SOFC is consumed by the electrode reaction. The oxygen partial pressure also decreases. The partial pressure distribution of hydrogen is larger than that of oxygen, because 4 electron per 1 mole oxygen is consumed at the oxygen electrode and 2 electron per 1 mole hydrogen is consumed at the

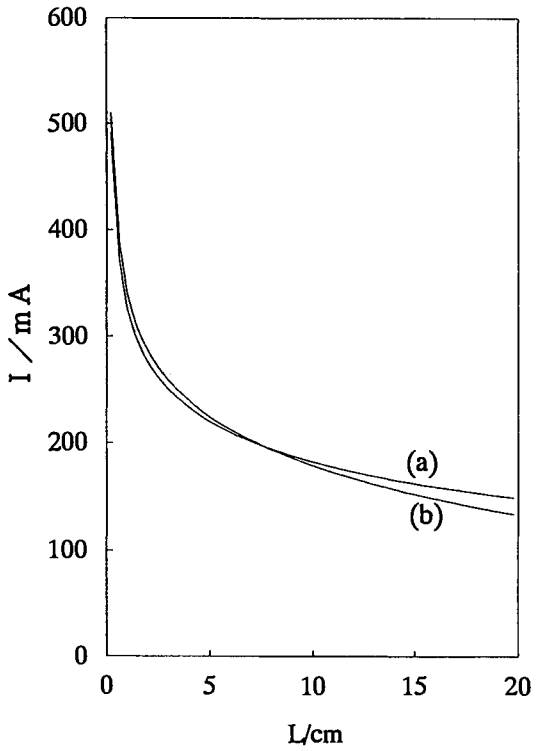

Fig. 5. Current distribution in the tubular SOFC, discharge current: 200 mA cm^{-2}, flow rate: 5 cm s^{-1} (a) and 20 cm s^{-1} (b).

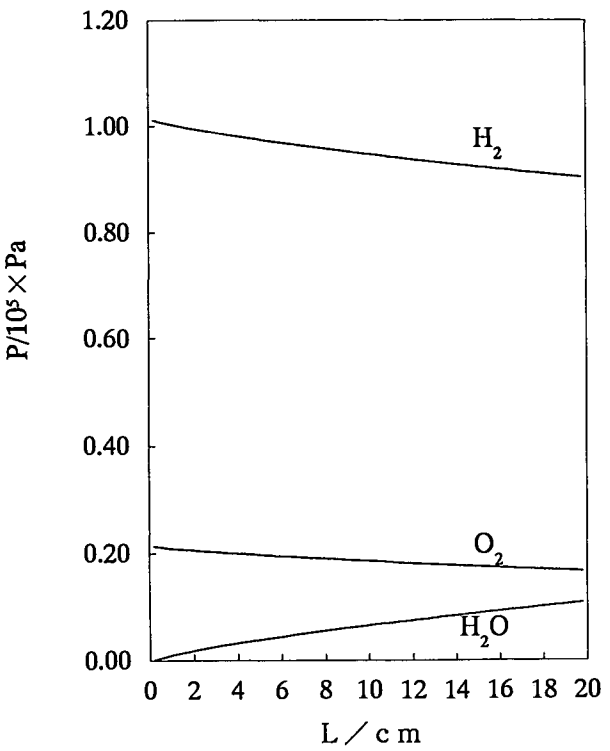

Fig. 6. Partial pressure distributions in the tubular SOFC, discharge current; 200 mA cm^{-2}, flow rate; 5 cm s^{-1}.

hydrogen electrode. The partial pressure distributions of hydrogen and steam are larger than that of oxygen. The heat caused by the entropy change of oxygen and hydrogen electrodes can be estimated from the partial pressure distributions of gasses according to Eqs. 13, 14, and 15.

In this way, the partial pressure distributions of hydrogen, oxygen, and steam and the current distribution in SOFC were obtained. From these results, the heat generation at each element can be estimated. The temperature distribution in SOFC can be calculated by using a finite element method.

Temperature Distribution in Tubular SOFC. Figure 7 shows the model of the tubular SOFC and the initial and boundary conditions for the calculation of a finite element method. The gas temperature was assumed to be 1273 K to simplify the calculation. The temperature distribution at steady state was estimated in this study. The heat conductivities of yttria stabilized zirconia, porous yttria stabilized zirconia support, $LaCoO_3$, and Ni cermet are summarized in Table 3. At the interface between the oxygen chamber and the porous yttria stabilized zirconia, the thermal boundary is assumed. The heat transfer coefficients of the thermal boundary between air and yttria stabilized zirconia support (h_{in}) can be written by

$$h_{in} = Nu\ \kappa / D \tag{16}$$

where Nu (Nusselt constant) is calculated from physicochemical properties of air by using the following equations.

$$Nu = 2.43\ (Re\ Pr\ D/L)^{1/3} \tag{17}$$

$$Pr = C_p\ \mu / \kappa \tag{18}$$

$$Re = Du\ \rho / \mu \tag{19}$$

ρ is the density of gas, μ the viscosity of gas, C_p the heat capacity of gas, κ the heat conductivity, u the flow rate of gas, D the diameter of the cell, L the length of the cell, Pr Prandtl constant, and Re Reynolds number. These parameters are summarized in Table 2 and 4. On the other hand, the heat transfer coefficient of thermal boundary between hydrogen chamber and anode (h_{out}) can be given by the following equation

$$h_{out} = 0.664\ (\kappa / L)\ Re^{1/2}\ Pr^{1/3} \tag{20}$$

In this way, the heat transfer coefficients at the interfaces are easily calculated from these equations. The heat generation at oxygen electrode can be estimated by

$$\frac{dQ}{dt} = IT\Delta S_c + I\eta_c \tag{21}$$

and at hydrogen electrode

$$\frac{dQ}{dt} = IT\Delta S_a + I\eta_a \tag{22}$$

The heat generation from electrolyte is given by

$$\frac{dQ}{dt} = I^2R \tag{23}$$

The hydrogen and oxygen flows along Z-axis from the entrance to the exit. The hydrogen electrode is made from nickel cermet and its thickness is 500 μm. The oxygen electrode is made from $LaCoO_3$ and its thickness is 500 μm. The electrolyte is the yttria stabilized zirconia and its thickness is 500 μm. The thickness of each element is related to the mechanical strength of the cell. The thick element gives the high reliability of the cell. In this study, the thickness of each element was assumed from the point of view of the stability of the cell.

Thus, all parameters used in the calculation of the temperature distribution in the tubular SOFC can be estimated. The calculation by using a finite element method was carried out. Figure 8 shows the temperature distribution in the electrolyte along Z-axis. The temperature at the entrance is lower than that at the exit. From the current distribution, it is expected that the heat energy generated at the entrance is larger than

that at the exit. The temperature distribution in Fig. 8, however, is inconsistent with such an expectation. This fact indicates that the heat generated near the entrance of SOFC is transported to hydrogen gas and oxygen gas. At the exit of the tubular SOFC, the heat is transported form hydrogen gas and oxygen gas to the electrolyte during the initial period of the discharge. Therefore the temperature in electrolyte near the exit is higher than that at the entrance. The temperature distribution in SOFC strongly depends on the flow rate. The uniform temperature distribution can be obtained at 30 cm s^{-1} flow rate. The utilization of fuel, however, decreased with increasing of flow rate.

Figure 9 shows the temperature distribution along R-axis near the entrance of SOFC. The highest temperature is observed at the electrolyte region. The temperatures at porous yttria stabilized zirconia and the nickel cermet electrode are lower than that at the electrolyte. The heat is transported from the electrolyte to hydrogen and oxygen gasses. The temperature gradient is largest at the electrolyte region. This result indicates that the thermal stress at the electrolyte region is the most important factor for the decomposition of SOFC. The heat absorbed by hydrogen gas is comparable to that by oxygen gas. The half of heat energy generated in SOFC is transported to the hydrogen gas chamber near the entrance region of the tubular SOFC.

Conclusion

The simulation of the temperature distribution in solid oxide fuel cell was demonstrated. The heat energy produced by the entropy change of electrode reactions was taken into account for the calculation. The calculation under various conditions will give the guideline for the design of solid oxide fuel cell. For the calculation of the temperature distribution in solid oxide fuel cell, the heat produced from the entropy change of electrode reaction will become larger than those by overpotentials and ohmic resistances with the development of the excellent materials and processes.

In this study, the dependencies of thermal and electrochemical parameters on temperature were not taken into account for the calculation of the temperature distribution. However, the deviation from the true temperature distribution in the model cell, which cannot be measured, may not be significant, because the dependencies of parameters on temperature may be negligible small for the temperature distribution in SOFC. The tendency of the temperature distribution calculated in this study might be similar to that of true temperature distribution in the model cell. The calculation under various conditions will provide the useful information for the selection of materials and the construction of SOFC.

Syntheses, Crystal Structures, and Antitumor Activities of Dinuclear Platinum(II) Complexes, Di-μ-sulfoacetato-bis[(diamine)platinum(II)] Trihydrate

T. Ken MIYAMOTO* and Hikaru ICHIDA
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received December 15, 1990)

A series of new dinuclear platinum(II) complexes have been prepared from the reaction of $[PtL_2(OH)_2]$ with sulfoacetic acid: $[PtL_2(slac)]_2 \cdot 3H_2O$, where slac=sulfoacetate dianion; L_2=1,2-diaminocyclohexane (**1a**—**1c**) or 1,2-diaminoethane (**2**) and L=isopropylamine (**3**) or ammine (**4**). They have di-μ-carboxylato bridged dinuclear zwitterionic structures in crystals. Among them, complexes (**1a**—**1c**) show significant antitumor activities against mice ieukemia L1210.

Since the discovery of broad-spectrum activities of *cis*-dichlorodiammineplatinum(II) (trade name *cis-platin*), a large number of platinum complexes have been synthesized as antitumor agents. Among them there are promising compounds such as (1,2-diaminocyclohexane)platinum(II) derivatives.[1] Many of these compounds are, however, mononuclear complexes; few oligonuclear platinum complexes have shown antitumor activity.[2]

In recent years, the formation of hydroxo-bridged di-,[3] or tri-nuclear[4] complexes has been reported in the hydrolysis reaction of *cis-platin*. Other platinum oligomers, such as "platinum blue",[5] have also received much attention. These studies emphasized a structural diversity of oligonuclear species in the platinum chemistry; antitumor activities have not been reported concerning these oligomers, except a few examples.

We describe here the syntheses, crystal structures, and antitumor activities of a series of new dinuclear platinum complexes, di-μ-sulfoacetato-bis[(diamine)-platinum(II)] trihydrate, $[Pt(diamine)(slac)]_2 \cdot 3H_2O$. Preliminary accounts of the synthesis and structural work have appeared.[6,7]

Experimental

The Three Isomers of Di-μ-sulfoacetato-bis[(1,2-diamino-cyclohexane)platinum(II)], Compounds 1a—c. The compounds were synthesized by modified methods from those described in a previous publication.[8] Dinitrato[(1*R*,2*R*)-1,2-diaminocyclohexane]platinum(II), [Pt(*RR*-dach)$(NO_3)_2$] (4.30 g, 10 mmol), was dissolved in water (100 cm^3) with heating. The solution was passed through a column packed with an anion-exchange resin (Diaion SA10AOH); and additional amount of water was then passed through the column. To the combined eluate, 1.40 g of sulfoacetic acid (10 mmol) was dissolved. The reaction mixture was evaporated to ca. 30 ml

at ca. 60 °C under reduced pressures to give the precipitate of the product, [Pt(*RR*-dach)(slac)]$_2\cdot 3H_2O$ (**1a**). Yield: 3.2 g (3.4 mmol, 67%). A crystal suitable for X-ray crystal analysis was obtained by recrystallization from water as a pale-yellow plate. In a similar manner, two other isomers of di-μ-sulfoacetato-bis[(1,2-diaminocyclohexane)platinum(II)] were synthesized. Found: **1a**: C, 20.05; H, 3.93; N, 5.99; S, 6.76%; **1b**: C, 20.04; H, 4.02; N, 5.97; S, 6.57%; **1c**: C, 20.42; H, 3.94; N, 5.84; S, 6.76%. Calcd for $C_{16}H_{38}N_4O_{13}S_2Pt_2$: C, 20.25, H, 4.04; N, 5.91; S, 6.76%.

Di-μ-sulfoacetato-bis[(1,2-diaminoethane)platinum(II)][Pt(en)(slac)]$_2\cdot 3H_2O$, Compound 2: In a similar way, the title complex was prepared from a 12.0 g (31.6 mmol) portion of dinitrato(1,2-diaminoethane)platinum(II) and 4.5 g (32.1 mmol) of sulfoacetic acid. Yield: 9.0 g (10.7 mmol, 68%). Found: C, 11.13; H, 2.95; N, 6.52; S, 7.28%. Calcd for $C_8H_{26}N_4O_{13}S_2Pt_2$: C, 11.43; H, 3.12; N, 6.67; S, 7.63%. The sample for X-ray crystallography was recrystallized from water as a yellow needle.

Di-μ-sulfoacetato-bis[bis(isopropylamine)platinum(II)][Pt(ipr)$_2$(slac)]$_2\cdot 3H_2O$, Compounds 3: This complex was similarly prepared as a pale yellow powder. Found: C, 19.89; H, 4.72; N, 5.83; S, 6.53%. Calcd for $C_{16}H_{46}N_4O_{13}S_2Pt_2$; C, 20.08; H, 4.85; N, 5.86; S, 6.70%. A crystal for X-ray crystallographic analysis was obtained as a orange-yellow plate by leaving the aqueous solution in a desiccator (desiccant: $CaCl_2$) for 2 months.

Di-μ-sulfoacetato-bis[diammineplatinum(II)][Pt(NH$_3$)$_2$(slac)]$_2\cdot 3H_2O$, Compound 4: A white crystalline solid containing a small amount of green material was obtained. A green impurity could not be removed by recrystallization. Found: C, 5.87; H, 2.77; N, 7.10; S, 7.56%. Calcd for $C_4H_{22}N_4O_{13}S_2Pt_2$: C, 6.09; H, 2.81; N, 7.11; S, 8.13%.

Solubility Test. Solubility (mg cm^{-3}) in H_2O at 26 °C: **1a**:

5; **1b**: 5; **1c**: 50; **2**: 18.

X-Ray Diffraction Measurements and Structure Determination. Among a series of new complexes, three compounds, $[Pt(RR\text{-dach})(slac)]_2 \cdot 3H_2O$ (**1a**), $[Pt(en)(slac)]_2 \cdot 3H_2O$ (**2**), and $[Pt(ipr)_2(slac)]_2 \cdot 3H_2O$ (**3**), were applied to X-ray crystal structure analysis.

The X-ray diffraction intensities were collected on a Rigaku AFC-5R goniometer with graphite-monochromatized Mo $K\alpha$ (λ=0.71069 Å) radiation (40 kV, 120 mA). Details of the X-ray structure analysis on $[Pt(RR\text{-dach})(slac)]_2 \cdot 3H_2O$ were described in a previous report.[7] Crystallographic data are summarized in Table 1 and positional parameters and B(eq) for **2** or **3** are given in Table 2 or 3, respectively. The complete F_o-F_c data are deposited as document No. 9114 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Antitumor Assay in vivo. A preliminary animal test against mice leukemia L1210 was carried out at The Cancer Chemotherapy Center, J. C. R., through the courtesy of Dr. Tazuko TASHIRO. There, 10^5 cells/mouse were transplanted i.p. into CDF_1 mice (6 mice/group), and the samples administered i.p. on days 1,5, and 9. From the mean survival times of treated (T) and control (C) mice, the T/C values were calculated as indicators of activity. Compounds **3** and **4** were not suitable for the animal test because of their instability in saline solution. Thus, comounds **1a**—**c** and **2** were subjected to the primary screening.

Results and Discussion

Syntheses. A series of complexes were synthesized by a neutralization reaction of dihydroxoplatinum(II) complexes with the equivalent mole of sulfoacetic acid (Scheme 1). Compounds **1a**—**c** and **2** were recrystallized from hot water. However, an attempt to recrystallize **3** from a hot aqueous solution led to an immediate decomposition, precipitating a black solid. The

$$cis\text{-}[PtL_2(NO_3)_2] \xrightarrow[\text{exchange}]{\text{anion}} \{cis\text{-}[PtL_2(OH)_2]\} \xrightarrow[\text{acid}]{\text{sulfoacetic}} [PtL_2(slac)_2]_2 \cdot 3H_2O$$

Scheme 1. Synthetic procedure to dinuclear sulfoacetatoplatinum(II).

crystalline product **3** was, therefore, prepared by long standing of a dilute solution at room temperature in a desiccator (see Experimental). An attempt to recrystallize **4** was also unsuccessful: the colorless solution soon turned to green, presumably forming an oligomeric species.

At the beginning we planned to make mononuclear chelate compounds (Fig. 1(A)). Subsequent X-ray crystal analyses, on the contrary, revealed their dinuclear structures (Fig. 1(B)).

Molecular Structures of 1a, 2, and 3. The molecular structure of **1a** was reported in a previous paper.[7]

The molecular structures of **2** and **3** are shown in Figs. 2 and 3, respectively. The bond lengths and angles are listed in Tables 4 and 5.

As a whole, the molecular structures of **1a**, and **3** resemble each other. They are dinuclear complexes having di-μ-bridged carboxylate ligands. Because of a weak coordination of the sulfonate ligand, a mononuclear structure with six-membered chelation of the sulfoacetate ligand (Fig. 1(A)) might be less stable than the dinuclear structur (Fig. 1(B)).

The local positive charge on Pt atoms(+1) and the negative charge of SO_3 groups(−1), in a formal sense, give a zwitterionic character to the dinuclear complexes. Although the geometric requirement imposed by the bridging carboxyl group causes a relatively short Pt–Pt distances (ca. 3.0 Å), they are slightly too long to be regarded as being metal–metal bonds. The two coordination planes around Pt in a dimeric structure are not parallel to each other. The steric repulsion between the amine ligands may cause such a tilt. The Pt–Pt distances and the dihedral angles(°) between the coordination planes are summarized in Table 6 together with other dinuclear platinum(II) which have been reported so far.[9,10] As a general trend, the steric bulk of amine

Kinetic Studies of Electron-Transfer Reactions Induced by the Reductive Quenching of Tris(2,2′-bipyrazine)ruthenium(II)

Suzuko YAMAZAKI-NISHIDA and Masaru KIMURA*
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received January 14, 1991)

The oxidation reaction of the oxalate ion ($C_2O_4^{2-}$) by the peroxodisulfate ion ($S_2O_8^{2-}$) is greatly accelerated by irradiation with visible light in an aqueous solution containing tris(2,2′-bipyrazine)ruthenium(II) ($[Ru(bpz)_3]^{2+}$). The mechanism constitutes a chain reaction initiated by a reductive quenching of photoexcited $[Ru(bpz)_3]^{2+}$ with $C_2O_4^{2-}$. The rate of reaction increases with an increase of the $[Ru(bpz)_3]^{2+}$ concentration or incident light intensity. On the other hand, the reaction rate hardly depends not only on the concentrations of $C_2O_4^{2-}$ and $S_2O_8^{2-}$, but also on the ionic strength and temperature. The $[Ru(bpz)_3]^{2+}$ acts as a photo-catalyst, although the absorption spectra of the reaction solution are slightly changed during the photoreaction. An analysis of the absorption spectra by a graphic method indicates that another absorbing species than $[Ru(bpz)_3]^{2+}$ is formed in the reaction solution. Such a complex has no photocatalytic effect for the redox reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$. The concentration of the produced complex is always coincident with ca. 0.7% of that of the $S_2O_8^{2-}$ reacted. The reaction mechanism and rate law are clarified to account for the results obtained.

Tris(2,2′-bipyridine)ruthenium(II)($[Ru(bpy)_3]^{2+}$) and its derivatives have been extensively investigated from the viewpoint of the solar energy conversion.[1–9] Recently, the analogous tris(2,2′-bipyrazine)ruthenium(II) ion ($[Ru(bpz)_3]^{2+}$) has attracted the attention of many researchers.[10–15] The photochemical properties of $[Ru(bpz)_3]^{2+}$ are similar to those of the $[Ru(bpy)_3]^{2+}$. A salient feature of the former is that the excited state lifetime is longer than that of the latter and that the standard redox potentials are more positive by ca. 0.5 V than those of the corresponding couples for ($[Ru(bpy)_3]^{2+}$), respectively.[16–19] As a result, the photo-excited ruthenium(II) complex ($[Ru(bpz)_3]^{2+*}$) is a stronger oxidant, but poorer reductant, than $[Ru(bpy)_3]^{2+*}$. The $[Ru(bpz)_3]^{2+*}$ has been reported to be reductively quenched with an oxalate ion and ethylenediaminetetraacetic acid (EDTA) in an aqueous solution; the anodic photocurrent obtained in the photoelectrochemical system was attributable to the oxidation of $[Ru(bpz)_3]^{+}$ produced by the quenching reaction.[20–22] As far as the $[Ru(bpy)_3]^{2+}$ is concerned, only a few reductive quenchers, such as Eu^{2+} and ascorbate ion, are known in aqueous solutions.

Various photo-induced electron-transfer reactions with $[Ru(bpy)_3]^{2+}$ as a photocatalyst have been studied kinetically in order to clarify the reaction mechanisms. On the other hand, there have been few kinetic studies on photoreactions with $[Ru(bpz)_3]^{2+}$, except for a reaction system consisting of methylviologen (MV^{2+}), a sacrificial donor (such as EDTA and triethanolamine (TEOA)) and colloidal metal redox catalysts.[12,16,17] In such a system, the $[Ru(bpz)_3]^{2+*}$ is quenched reductively by EDTA or TEOA; the resulting $[Ru(bpz)_3]^{+}$ reacts with MV^{2+} to produce MV^{+} and, subsequently, MV^{+} reduces water in the presence of a catalyst. The quantum yield of the MV^{+} formation by $[Ru(bpz)_3]^{2+}$ is reported to be nearly 100%, while that by $[Ru(bpy)_3]^{2+}$ is only 20% under similar photochemical conditions.

We previously studied the electron-transfer reaction between oxalate and peroxodisulfate induced by photo-excited $[Ru(bpy)_3]^{2+}$.[23] This reaction was initiated by the oxidative quenching of $[Ru(bpy)_3]^{2+*}$ by $S_2O_8^{2-}$.

In this paper we present a kinetic study of the photo-induced electron-transfer reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$ by using $[Ru(bpz)_3]^{2+}$ as a photocatalyst. Several remarkable differences between the $[Ru(bpy)_3]^{2+}$ and $[Ru(bpz)_3]^{2+}$ systems are: (1) the photo-induced reaction is initiated by the oxidative quenching reaction of $[Ru(bpy)_3]^{2+*}$ by the $S_2O_8^{2-}$, while by the reductive quenching of $[Ru(bpz)_3]^{2+*}$ by the $C_2O_4^{2-}$; (2) the ligand-substitution reaction for $[Ru(bpy)_3]^{2+}$ does not occur at all, but that for $[Ru(bpz)_3]^{2+}$ occurs to produce the bis(2,2′-bipyrazine)ruthenium(II) complex. The photochemical stability of the ruthenium(II) complex is an important problem concerning utilization as a photosensitizer and -catalyst. This paper also proposes that the ligand-substitution product of $[Ru(bpz)_3]^{2+}$ is inactive for a photo-catalyzed reaction between $C_2O_4^{2-}$ and $S_2O_8^{2-}$.

Experimental

$[Ru(bpz)_3]Cl_3 \cdot 3.5H_2O$ was prepared and purified as described in the literature.[24,25] Ruthenium trichloride and 2,2′-bipyrazine were purchased from Wako Pure Chemical Co. and Aldrich, respectively. The other chemicals used were of guaranteed reagent grade and were used without further purification. Unless otherwise stated, each sample solution was irradiated with visible light from two 100-W tungsten lamps placed 3 dm to the right- and left-hand sides from the center of the reaction vessel. Oxygen dissolved in the solutions was removed by bubbling through pure nitrogen gas. The concentration of $S_2O_8^{2-}$ remaining in the solution was determined as reported previously,[23] except that the amount of cation exchange resin (Dowex 50W-X8, 200—400 mesh, hydrogen form, washed well with distilled water) to remove the $[Ru(bpz)_3]^{2+}$ was twice as much as that for $[Ru(bpy)_3]^{2+}$. The measurement of the spectral changes in a deaerated solution was carried out by using a Shimadzu digital double beam spectrophotometer (UV-200S).

Results

Dependence of the Reaction Rate on the Concentrations of $S_2O_8^{2-}$, $C_2O_4^{2-}$, and $[Ru(bpz)_3]^{2+}$, Light Intensity, Ionic Strength, and Temperature. Plots of the $S_2O_8^{2-}$ concentration against the reaction time are shown in Fig. 1 under the conditions of 5×10^{-5} mol dm^{-3} $[Ru(bpz)_3]Cl_2$, 0.04 mol dm^{-3} $Na_2C_2O_4$, 30 °C, and an ionic strength of 0.4 mol dm^{-3}. The decomposition rate of $S_2O_8^{2-}$ is almost independent of the $S_2O_8^{2-}$ concentration, and decreases gradually with an increase of the reaction time. Such a time-profile is attributable to the concentration change of $[Ru(bpz)_3]^{2+}$ as a photocatalyst (mentioned later). The plots of $[S_2O_8^{2-}]$ vs. t are also independent of the $C_2O_4^{2-}$ concentrations over the range 0.04—0.055 mol dm^{-3}. On the other hand, the decomposition rate of $S_2O_8^{2-}$ increases with an increase of $[Ru(bpz)_3]^{2+}$ concentration or intensity of the incident light as shown in Figs. 2 and 3. The electron-transfer reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$ hardly proceeds without either of $[Ru(bpz)_3]^{2+}$ or visible light. The dependences of the reaction rate on the ionic strength and temperature were also examined over the range 0.2—0.5 mol dm^{-3} and 20—40 °C, respectively. It is found that the ionic strength as well as temperature of the reaction solution have little effect on the reaction rate. The kinetic studies were carried out in a neutral solution, although the pH of the solution increases after $S_2O_8^{2-}$ is completely exhausted by the photoreaction. This fact is attributed to water reduction with $[Ru(bpz)_3]^{+}$ (see Eq. 10).

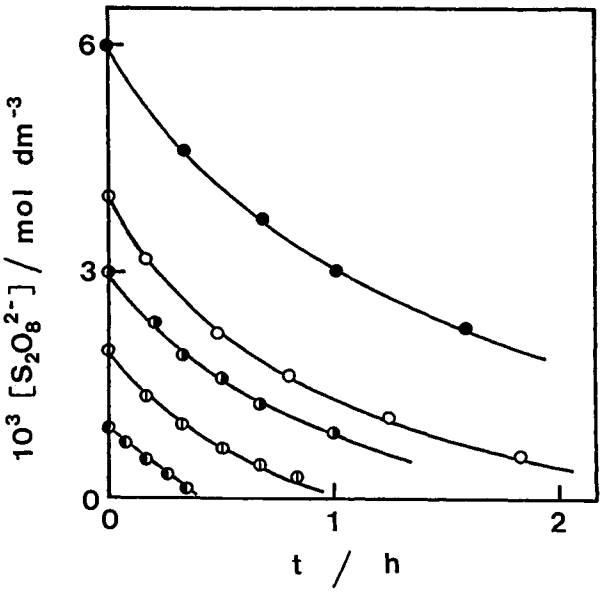

Fig. 1. Plots of $[S_2O_8^{2-}]$ vs. t obtained in the deaerated solution containing 4×10^{-2} mol dm^{-3} $Na_2C_2O_4$ and 5×10^{-5} mol dm^{-3} $[Ru(bpz)_3]Cl_2$ at an ionic strength of 0.4 mol dm^{-3} and 30 °C. Irradiation was done with two lamps. Initial concentrations of $S_2O_8^{2-}$ are (●) 6×10^{-3}, (○) 4×10^{-3}, (◑) 3×10^{-3}, (◔) 2×10^{-3}, and (◐) 1×10^{-3} mol dm^{-3}.

Spectral Change of the Reaction. The typical spectral changes obtained by the irradiation of the reaction solution are presented in Fig. 4. The absorption spectrum at t=0 coincides with that of $[Ru(bpz)_3]^{2+}$. The absorption band of $[Ru(bpz)_3]^{2+}$ at 442 nm decreased with the irradiation time, while new bands appeared at around 380 and 480 nm. Two isosbestic points were

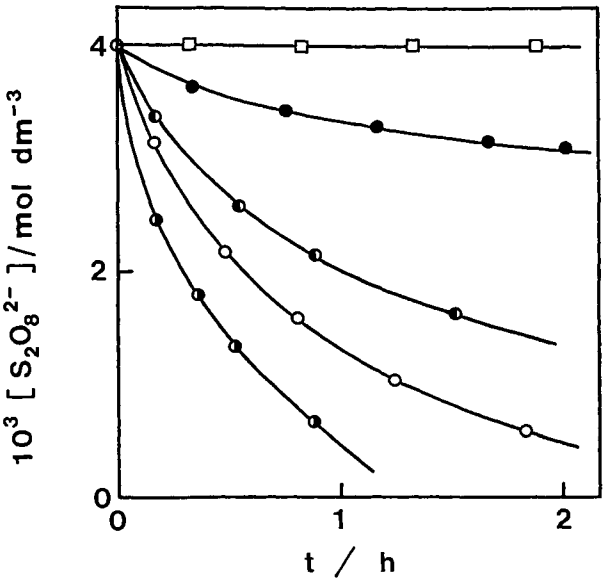

Fig. 2. Effect of the $[Ru(bpz)_3]^{2+}$ ion concentration. Initial concentrations of $[Ru(bpz)_3]Cl_2$ are (□) 0, (●) 1.1×10^{-5}, (◐) 3.1×10^{-5}, (○) 5×10^{-5}, and (◑) 7.7×10^{-5} mol dm^{-3}. Other conditions are the same as in the plots ○ in Fig. 1.

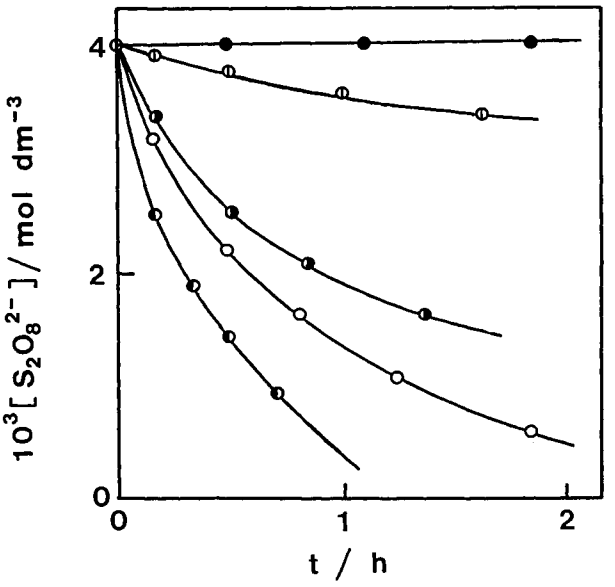

Fig. 3. Effect of the incident light intensity. Conditions:(●) dark, (◔) room light, (◑) 1 lamp, (○) 2 lamps, and (◐) 4 lamps. Other conditions are the same as in the plots ○ in Fig. 1.

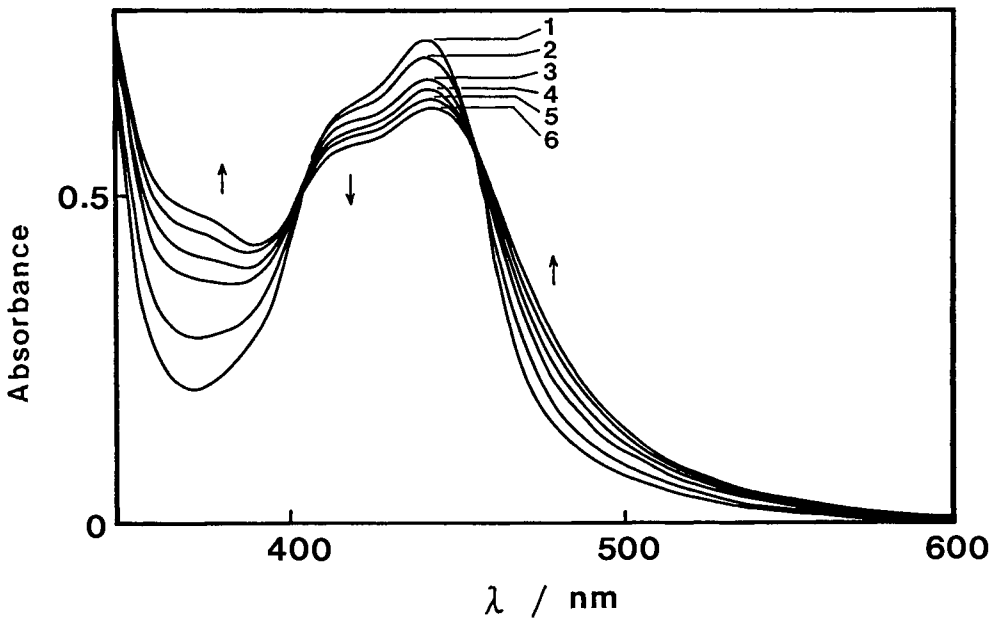

Fig. 4. Spectral change of the solution. Conditions are the same as in the plots O in Fig. 1. Reaction time: (1) 0, (2) 10 min, (3) 28 min, (4) 48 min, (5) 72 min, and (6) 108 min.

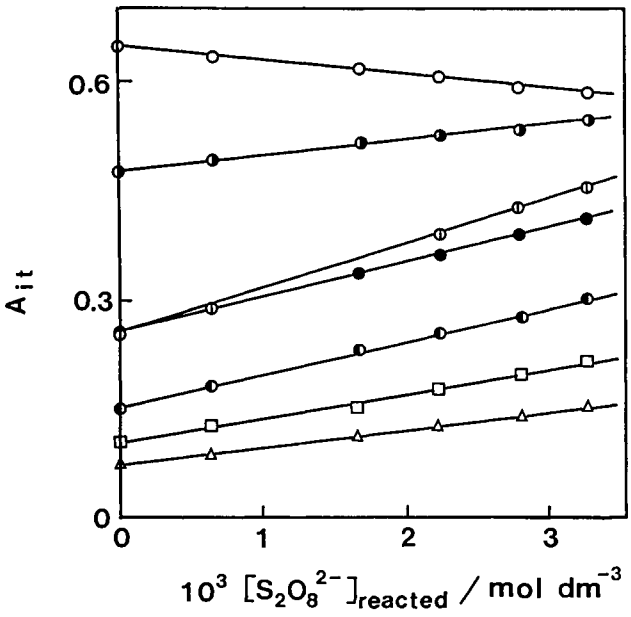

Fig. 5. Plots of A_{it} vs. $[S_2O_8^{2-}]_{reacted}$. Conditions are the same as in Fig. 4. The data are taken at wavelength of (⊙) 380 nm, (○) 420 nm, (◑) 460 nm, (●) 470 nm, (◐) 480 nm, (□) 490 nm, and (△) 500 nm.

observed at 407 and 456 nm. The absorption spectra of $[Ru(bpz)_3]^{2+}$ were not recovered, even if the solution was saturated with air. Figure 5 indicates that plots of A_{it} vs. $[S_2O_8^{2-}]_{reacted}$ are rectilinear; an intercept where A_{it} indicates absorbance at a given wavelength, i, and reaction time, t; $[S_2O_8^{2-}]_{reacted}$ represents the concentration of $S_2O_8^{2-}$ consumed up to $t=t$.

$$A_{it} = a_i + b_i[S_2O_8^{2-}]_{reacted} \quad (1)$$

The intercept, a_i, is the absorbance at a wavelength i and $t=0$. The b_i value varies with the wavelength, whereas it is independent of other experimental factors, such as the initial concentrations of $S_2O_8^{2-}$, $C_2O_4^{2-}$,, and $[Ru(bpz)_3]^{2+}$, light intensity, ionic strength, and temperature. The b_i values are estimated to be 67.9±6.3, −21.8±2.2, 19.9±3.3, 46.3±3.2, 44.7±2.4, 33.8±2.0, and 24.4±1.9, at 380 nm, 420 nm, 460 nm, 470 nm, 480 nm, 490 nm, and 500 nm, respectively.

Quenching Reaction of $[Ru(bpz)_3]^{2+*}$ with $C_2O_4^{2-}$ and $S_2O_8^{2-}$. The quenching rate constants (k_q) of $[Ru(bpz)_3]^{2+*}$ with $C_2O_4^{2-}$ or $S_2O_8^{2-}$ were evaluated from quenching experiments using an unbuffered neutral solution. The Stern–Volmer plots are linear and the k_q values, respectively, 7.2×10^6 and 3.3×10^6 dm^3 mol^{-1} s^{-1} for $C_2O_4^{2-}$ and $S_2O_8^{2-}$ at an ionic strength of 0.4 mol dm^{-3}. Figure 6 depicts the spectral change of a deaerated $[Ru(bpz)_3]^{2+}$ solution containing $C_2O_4^{2-}$ under continuous irradiation. An absorbance at 442 nm decreases the new bands at 420 and 470 nm. The observed absorption spectra did not change along with air saturation in the solution. A similar absorption spectrum has been reported from a flash photolysis of a deaerated solution containing $[Ru(bpz)_3]^{2+}$ and EDTA.[26]

Discussion

The photoexcited $[Ru(bpz)_3]^{2+}$ is quenched reductively by $C_2O_4^{2-}$ and oxidatively by $S_2O_8^{2-}$ with quenching-rate constants of 7.2×10^6 and 3.3×10^6 dm^3 mol^{-1} s^{-1}, respectively. Under the experimental conditions investigated, the concentrations of $C_2O_4^{2-}$ are always ten-

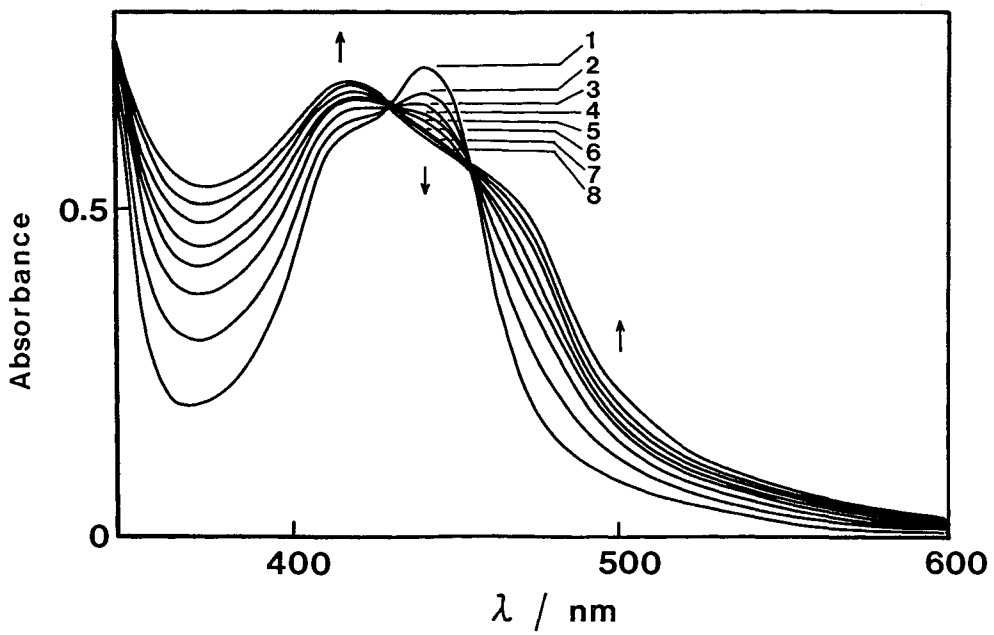

Fig. 6. Spectral change in the reductive quenching reaction of $[Ru(bpz)_3]^{2+*}$ with $C_2O_4^{2-}$. Conditions are the same as in Fig. 1 without an addition of $S_2O_8^{2-}$. Reaction time: (1) 0, (2) 5 min, (3) 10 min, (4) 15 min, (5) 21 min, (6) 30 min, (7) 40 min, and (8) 60 min.

times as much as those of $S_2O_8^{2-}$. Thus, it is most likely that reductive quenching proceeds predominantly in the present system.

The following reaction mechanism is assumed to account for the results obtained:

$$[Ru(bpz)_3]^{2+} + h\nu \longrightarrow [Ru(bpz)_3]^{2+*}, \quad (2)$$

$$[Ru(bpz)_3]^{2+*} \xrightarrow{k_0} [Ru(bpz)_3]^{2+} + h\nu' \text{ or } \Delta \text{ (thermal energy)}, \quad (3)$$

$$[Ru(bpz)_3]^{2+*} + C_2O_4^{2-} \xrightarrow{k_q} [Ru(bpz)_3]^{+} + CO_2^{-} + CO_2, \quad (4)$$

$$[Ru(bpz)_3]^{2+*} + CO_2^{-} \longrightarrow [Ru(bpz)_3]^{+} + CO_2, \quad (5)$$

$$S_2O_8^{2-} + [Ru(bpz)_3]^{+} \longrightarrow SO_4^{-} + SO_4^{2-} + [Ru(bpz)_3]^{2+}, \quad (6)$$

and

$$SO_4^{-} + [Ru(bpz)_3]^{+} \longrightarrow SO_4^{2-} + [Ru(bpz)_3]^{2+}. \quad (7)$$

Assuming a steady state concentration for $[Ru(bpz)_3]^{+}$, SO_4^{-}, and CO_4^{-} radicals, the following reaction rate is obtained:

$$-d[S_2O_8^{2-}]/dt = \frac{k_q I_a \Phi [C_2O_4^{2-}]}{k_0 + k_q [C_2O_4^{2-}]}, \quad (8)$$

Here, I_a is the amount of light absorbed, Φ the quantum yield for the formation of $[Ru(bpz)_3]^{2+*}$ and $I_a\Phi$ corresponds to the formation rate of $[Ru(bpz)_3]^{2+*}$. The I_a can be rewritten as Eq. 9 with an incident light intensity of I_0, and an empirical constant, γ, comprising the molar absorption coefficient of $[Ru(bpz)_3]^{2+}$ and the length of the light path:

$$I_a = I_0(1-\exp(-\gamma[[Ru(bpz)_3]^{2+}])). \quad (9)$$

The rate law (Eq. 8) suggests that the reaction rate is independent of the $S_2O_8^{2-}$ concentration and is dependent on the incident light intensity and the $[Ru(bpz)_3]^{2+}$ concentration. This is coincident with all of the experimental results. Equation 8 also indicates that the reaction rate should depend on the $C_2O_4^{2-}$ concentration. However, the reaction rate observed was almost independent of the $C_2O_4^{2-}$ concentration within the range 0.04—0.055 mol dm^{-3}. The value of $k_q[C_2O_4^{2-}]$ is comparable within such a concentration range to that of k_0 which is estimated to be 9.6×10^5 s^{-1} from the lifetime of $[Ru(bpz)_3]^{2+*}$. The right-hand side of Eq. 8 is rewritten as $I_a\Phi\{1-k_0/(k_0+k_q[C_2O_4^{2-}])\}$; the value of $k_0/(k_0+k_q[C_2O_4^{2-}])$ changes little when the concentration varies by at most 1.5 times as much. Thus, if we were to examine the dependence of the reaction rate on the $C_2O_4^{2-}$ concentration over a wider concentration range, a dependence like that shown in Eq. 8 might be obtained. In fact, however, in the lower concentrations of $C_2O_4^{2-}$, the oxidative quenching of $S_2O_8^{2-}$ for $[Ru(bpz)_3]^{2+*}$ should be considered in the reaction mechanism, while at higher concentrations of $C_2O_4^{2-}$, the dark redox reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$ proceeds considerably. According to Eq. 8, the $S_2O_8^{2-}$ decreases linearly with the reaction time under excess concentrations of $C_2O_4^{2-}$. However, as described later, some $[Ru(bpz)_3]^{2+}$ are transformed to an inert complex for the photoreaction, causing a decrease in the reaction rate with the reaction time. The reaction rate was independent of both the ionic strength and temperature of the solution. This finding is attributed to the fact

that the k_q- and k_0-paths have a similar dependence on the ionic strength and temperature. The latter means that the activation energies for both reaction paths are almost the same. The $[Ru(bpz)_3]^+$ is capable of reducing water when all the $S_2O_8^{2-}$ ions are exhausted by the reaction, which is responsible for an increase in the solution pH.

$$[Ru(bpz)_3]^+ + H_2O \longrightarrow [Ru(bpz)_3]^{2+} + 1/2\,H_2O + OH^- \quad (10)$$

Since the $SO_4^{\cdot-}$ radical is a strong oxidant, the following reactions can be considered:

$$SO_4^{\cdot-} + C_2O_4^{2-} \longrightarrow SO_4^{2-} + CO_4^{\cdot-} + CO_2, \quad (11)$$

$$SO_4^{\cdot-} + [Ru(bpz)_3]^{2+} \longrightarrow SO_4^{2-} + [Ru(bpz)_3]^{3+}, \quad (12)$$

and

$$[Ru(bpz)_3]^{3+} + C_2O_4^{2-} \longrightarrow [Ru(bpz)_3]^{2+} + CO^{\cdot-} + CO_2, \quad (13)$$

The $CO_2^{\cdot-}$ radicals produced by reactions 11 and 13 react with $[Ru(bpz)_3]^{2+}$ to form $[Ru(bpz)_3]^+$, which is subsequently oxidized by $S_2O_8^{2-}$ (see Eqs. 5 and 6). When reactions 11—13 could occur, the reaction rate should be dependent on the $S_2O_8^{2-}$ concentration; but being quite different from the obtained results, these reactions have been ruled out.

A graphical analysis has been developed regarding the change in the absorption spectra (Fig. 4) in order to determine the number of species in the solution. A plot of $A_{it}-A_{it'}$ vs. $A_{i't}-A_{i't'}$ gives a straight line through the origin only when two absorbing species exist in the solution.[27,28] From the results given in Fig. 7, we can conclude that another absorbing species (RuL) as well as $[Ru(bpz)_3]^{2+}$ is present in the solution. The following relationship is derived from Eq. 1:

$$\frac{[[Ru(bpz)_3]^{2+}]_{decreased}}{[S_2O_8^{2-}]_{reacted}} = \frac{[RuL]_{produced}}{[S_2O_8^{2-}]_{reacted}} = \frac{b_i}{\varepsilon_i' - \varepsilon_i}, \quad (14)$$

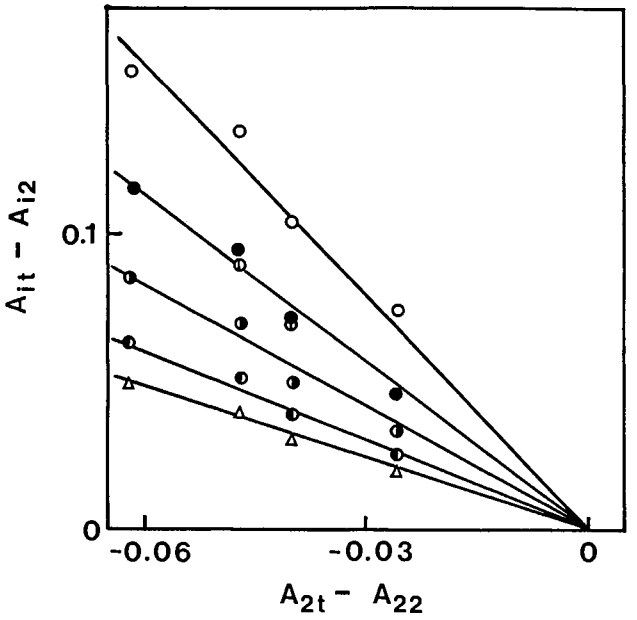

Fig. 7. A graphic method for two absorbing species. The data are taken from Fig. 4. The values of i and t correspond to the wavelength and reaction time, respectively. i=2:420 nm, t=2:10 min. (○) 380 nm, (△) 460 nm, (●) 470 nm, (①) 480 nm, (◑) 490 nm, (◐) 500 nm.

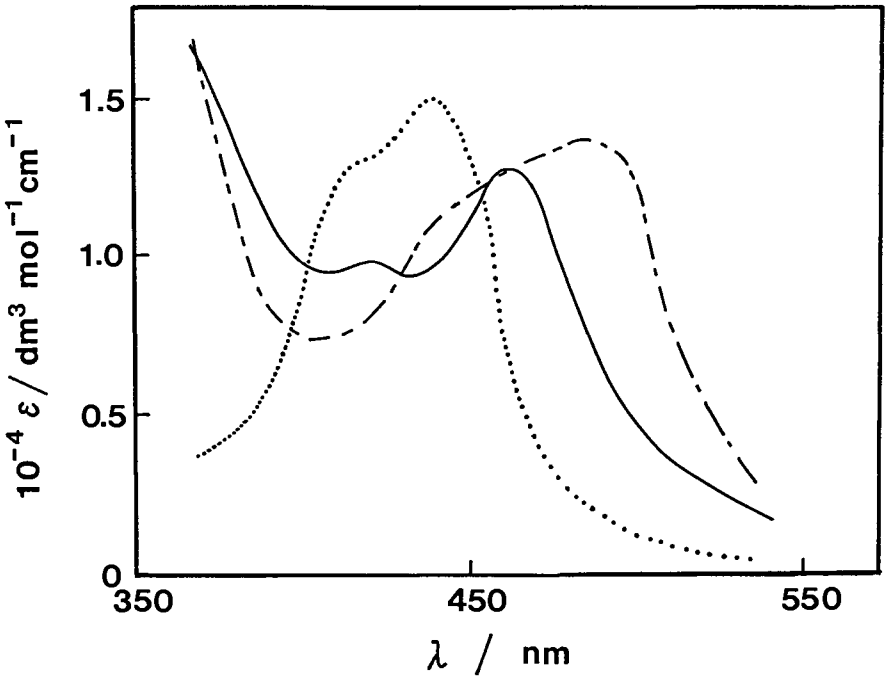

Fig. 8. Absorption spectra of $[Ru(bpz)_3]^{2+}$ (·····), $[Ru(bpz)_3]^+$ (—·—),[17] and RuL (——). The absorption spectra of RuL are calculated from the spectral data in Fig. 4.

where ε_i' indicates the molar absorption coefficient for RuL at wavelength i. Since the value of $b_i/(\varepsilon_i'-\varepsilon_i)$ must be constant for all observed wavelengths, the absorption spectra for RuL is represented in Fig. 8 from the spectral data in Fig. 4 and the b_i values obtained from the plots A_{it} vs. $[S_2O_8^{2-}]_{reacted}$ (Fig. 5). The b_i value was independent of any experimental conditions investigated and the $b_i/(\varepsilon_i'-\varepsilon_i)$ value was estimated to be 7×10^{-3}. Therefore, in the present reaction system, the amount of RuL formed always corresponds to ca. 0.7% of the $S_2O_8^{2-}$ reacted, suggesting that RuL has little photocatalytic effect on the photo-induced redox reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$. This causes a decrease in the reaction rate with an increase in the reaction time (as described in Fig. 1). The RuL might be a bis(bipyrazine)ruthenium(II) complex, such as $[Ru(bpz)_2(C_2O_4)]$, $[Ru(bpz)_2(CO_2)(H_2O)]^+$, or $[Ru(bpz)_2(SO_4)(H_2O)]^+$. The former two species are not likely to be formed, since the absorption spectra observed in the reaction solution are different from those obtained in the quenching reaction of $[Ru(bpz)_3]^{2+*}$ with $C_2O_4^{2-}$ (Fig. 6).

In conclusion, $[Ru(bpz)_3]^{2+}$ acts as a photocatalyst in a way similar to $[Ru(bpy)_3]^{2+}$ for a redox reaction between $S_2O_8^{2-}$ and $C_2O_4^{2-}$. The reaction rate law is apparently similar with respect to the concentration of the quencher. However, the reaction mechanism is quite different, i.e., the initial step is the reductive quenching of $[Ru(bpz)_3]^{2+*}$ by $C_2O_4^{2-}$ for $[Ru(bpz)_3]^{2+}$ as a photocatalyst. Some $[Ru(bpz)_3]^{2+}$ is transformed to an inactive species for the photo-induced electron-transfer reactions. The stability of the ruthenium(II) complex during the photoreaction is a serious problem for the utilization of $[Ru(bpz)_3]^{2+}$, although $[Ru(bpz)_3]^{2+}$ has been described as a new photo-catalyst.

(Received January 14, 1991)

The intercalation of *n*-alkylamines (carbon number 1—18) into γ-titanium phosphate and γ-zirconium phosphate was examined in aqueous, methanol, and benzene solutions. The interlayer spacings increased with an increase in the carbon number of alkylamines, showing the formation of bilayers of alkylamines in a similar manner to that in previous reports. The intercalation reaction depended on the solvents used to dissolve the alkylamines. For example, an anomaly was observed regarding intercalation in ethanol solutions. The interlayer spacings decreased when the carbon number exceeded 14—16, indicating a distortion or the monolayer formation of alkylamines. The rate of intercalation was also seriously affected by the kind of solvents. Intercalation occurred almost instantaneously in aqueous solutions. The rate of the intercalation reaction was generally faster in benzene solutions than that in ethanol solutions. The formation of bilayers was also more perfect in benzene solutions, and resulting interlayer spacings were slightly larger than those prepared in ethanol solutions. The anomaly in ethanol was attributed to a disturbance due to the cointercalation of methanol molecules. The solvent effect was also accountable due to the dielectric constant, or dipole moment, of solvents.

γ-Titanium phosphate ($Ti(HPO_4)_2 \cdot 2H_2O$: γ-TiP) and γ-zirconium phosphate ($Zr(HPO_4)_2 \cdot 2H_2O$: γ-ZrP) are known to have a layered structure with interlayer spacings of around 1.2 nm.[1,2] They can be compared with the corresponding α-phosphates, the interlayer spacings of which are about 0.76 nm.[3] These layerd compounds are insoluble acid salts and are known to be typical inorganic ion exchangers.[4] They can also intercalate various alkylamines or organic bases as host materials; their interlayer spacing increases corresponding to the geometric size of the guest intercalants. Among them, the intercalation of *n*-alkylamines has been examined extensively for intercalated alkylamine molecules forming well-established bilayers within the layered compond[5] similar to those of biological cell membranes.[6]

The procedure for the intercalation of alkylamines seems to have been definitely established according to previous studies.[5,7] However, such studies reported so far have treated the intercalation reaction too much ideally, and structural considerations of the final products have been of major interest. The detailed mechanisms for the intercalation reaction of alkylamines have not yet been clarified. For example, the roles of the acid-base reaction, ion exchange, and van der Waals forces acting on the Langmuir-type monolayer, etc. have not been treated properly. This paper mainly deals with the solvent effect on the intercalation reaction of *n*-alkylamines into γ-type transition metal phosphates, while discussing the mechanisms of the intercalation reaction in detail.

Experimental

Layered Materials. γ-TiP was prepared according to a procedure reported by Kobayashi et al.[1] Amorphous titanium phosphate prepared from phosphoric acid and titanium(IV) chloride was heated hydrothermally in 10 M phosphoric acid (1 M=1 mol dm^{-3}) for 24 h at 280 °C; a well crystallized H^+ form of γ-TiP was thus obtained (Fig. 1a). The crystal was carefully washed with de-ionized water and stored in a saturated NaCl desiccator. Two types of γ-ZrP (sodium ion form) were used in this study. One was obtained from Dai-ichi Kigenso Kogyo Co. Ltd., which was prepared under atmospheric pressure. The other was prepared hydrothermally at about 190 °C for 1 week according to a procedure by Yamanaka et al.[2] The H^+ form γ-ZrP was prepared by treating the Na^+ form of γ-ZrP with 1 M HCl untill free of sodium ions. After drying, the H^+ form of γ-ZrP was stored in a saturated NaCl desiccator. The empirical formula of the H^+ form of γ-TiP could be represented by $Ti(HPO_4)_2 \cdot 1.7—1.8H_2O$. γ-ZrP also had a similar content of the water of crystallization.

Intercalation of Alkylamines. *n*-Alkylamines with carbon numbers (C_n) from 1 to 18 were dissolved in water, methanol, benzene, etc. and were used for intercalation. The concentrations of *n*-alkylamines were 0.1 M (M=mol dm^{-3}) for C_n=1 to 10 and 0.05 M for C_n=14 to 18. Intercalation was carried out by immersing 3.6×10^{-4} moles of phosphates (0.1 g for γ-TiP and 0.117 g for γ-ZrP) in 20 ml of each *n*-alkylamine solution. The reaction time was varied from 0.5 h to 4 d (96 h) and the temperature was kept at 30±0.1 °C unless otherwise stated. The amount of intercalated amines was determined by acid-base titration with 0.1 M HCl methanol solution. The indicator used was a (bromocresol green+methyl red) mixture.

X-Ray Diffraction. The intercalation compounds were characterized using X-ray diffractometer with Mn filtered Fe-*Kα* radiation. *d*-Values of up to 7 nm (λ=0.193736 nm, 2-$\theta \geqq 1.5°$) were successfully measured with sufficient accuracy. The interlayer spacings (*d*-spacings) were determined by averaging the *d*-values of the integral sequence of hexagonally approximated (00*n*) planes.

Results

the phosphates used. The appearances of the crystals are quite different from each other, even though they are classified as a monoclinic lattice with similar geometric dimensions. The X-ray diffraction pattern of hydrothermal γ-ZrP was quite similar to that of γ-ZrP prepared under atmospheric pressure, though they look quite different from each other. The γ-ZrP prepared under atmospheric pressure was mainly used for the hydrothermal γ-ZrP sometimes gave X-ray diffraction patterns which indicated the presence of mixed phases.

Solvent Effect on Butylamine Intercalation. Figures 2a and 2b show the time dependence of the uptake of butylamine in three different solvents. Intercalation into γ-TiP occurred almost instantaneously in aqueous and benzene solutions. On the other hand, it took three to four days to reach equilibrium in a methanol solution. The maximum uptake was in the order aqueous>benzene>methanol (Molality of protons in solid γ-TiP: 7.25 mmol g^{-1} and γ-ZrP: 6.27 mmol g^{-1}). The reaction was relatively slow in γ-ZrP, though the apparent solvent effect was similar to that in γ-TiP. The speed of the reaction rate in aqueous solution may be attributed to the (strong) basic property of butylamine in the solvent, which results in a neutralization reaction with strong solid acid γ-TiP.

A similar experiment was carried out for the alkylamines with C_n=1 to 18 in methanol solutions. The

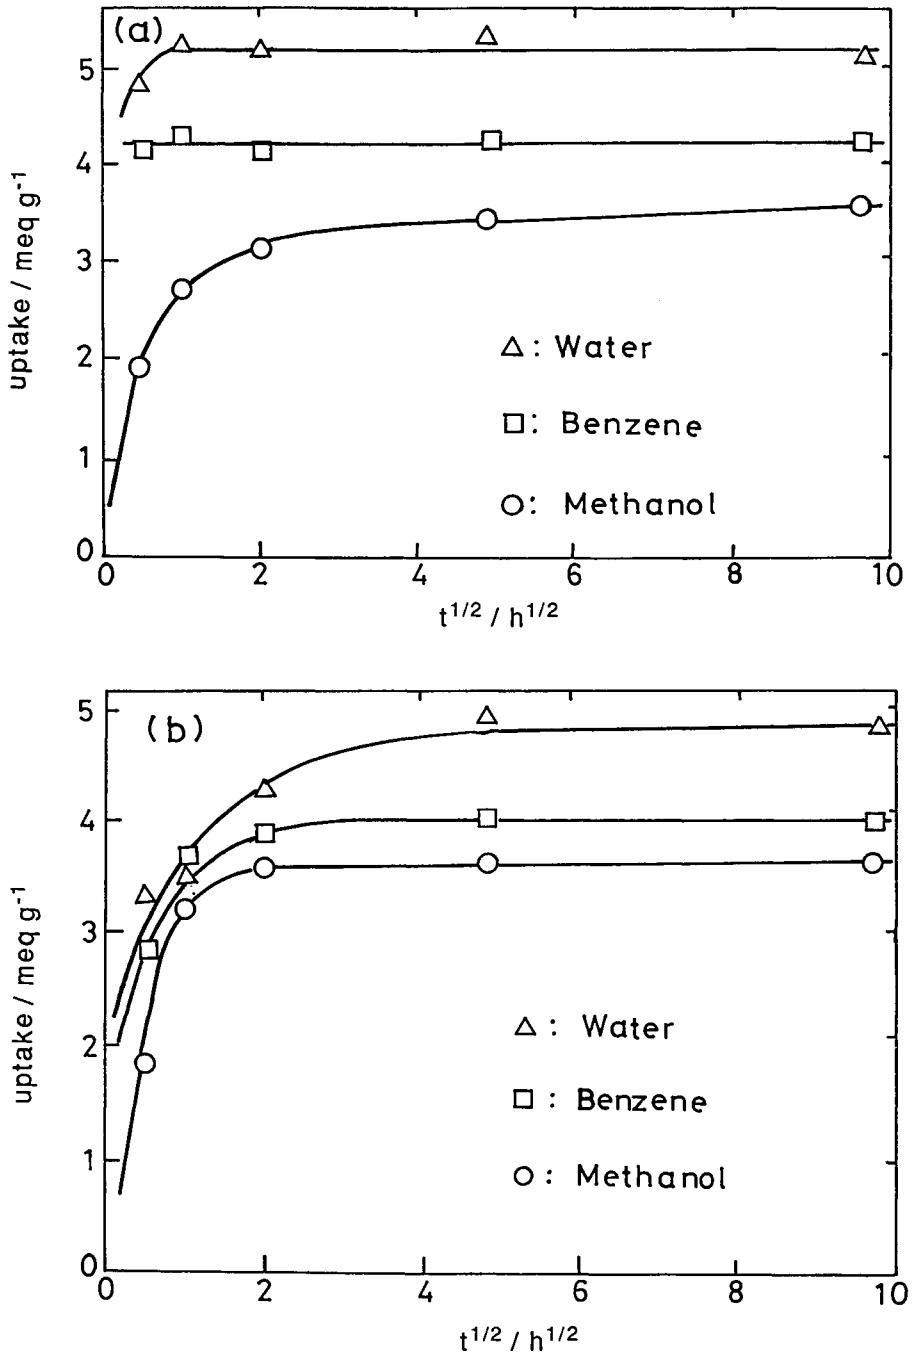

Fig. 2. Uptake of butylamine vs. reaction time in various solvents. (a) γ-TiP, (b) γ-ZrP. Absissa $t^{1/2}$ was taken for convenience and has no chemical significance (same as below).

results are shown in Figs. 3a and 3b. Generally speaking the rate of intercalation became slower as the alkyl-chain of the amines become longer. The intercalation of octadecylamine did not reach the equilibrium point, even after 4 d. The maximum uptake depends considerably on the length of the alkylamines and no easy finding regularity was observed. This fact may suggest a disturbance due to cointercalated methanol molecules. Figure 4 shows the uptake of butylamine into γ-TiP, which was pretreated (immersed) by pure methanol. It was found that the uptake decreased with increasing pretreatment time with methanol. This result suggested the co-intercalation of methanol[5] and, therefore, a disturbance due to the co-intercalated methanol. Figures 5a and 5b shows the results obtained in each benzene solution. The intercalation reached equilibrium points within two days, even in octadecylamine for either γ-TiP or γ-ZrP. The maximum uptakes were almost independent of alkylamines, suggesting a smaller disturbance due to the solvent molecules, unlike

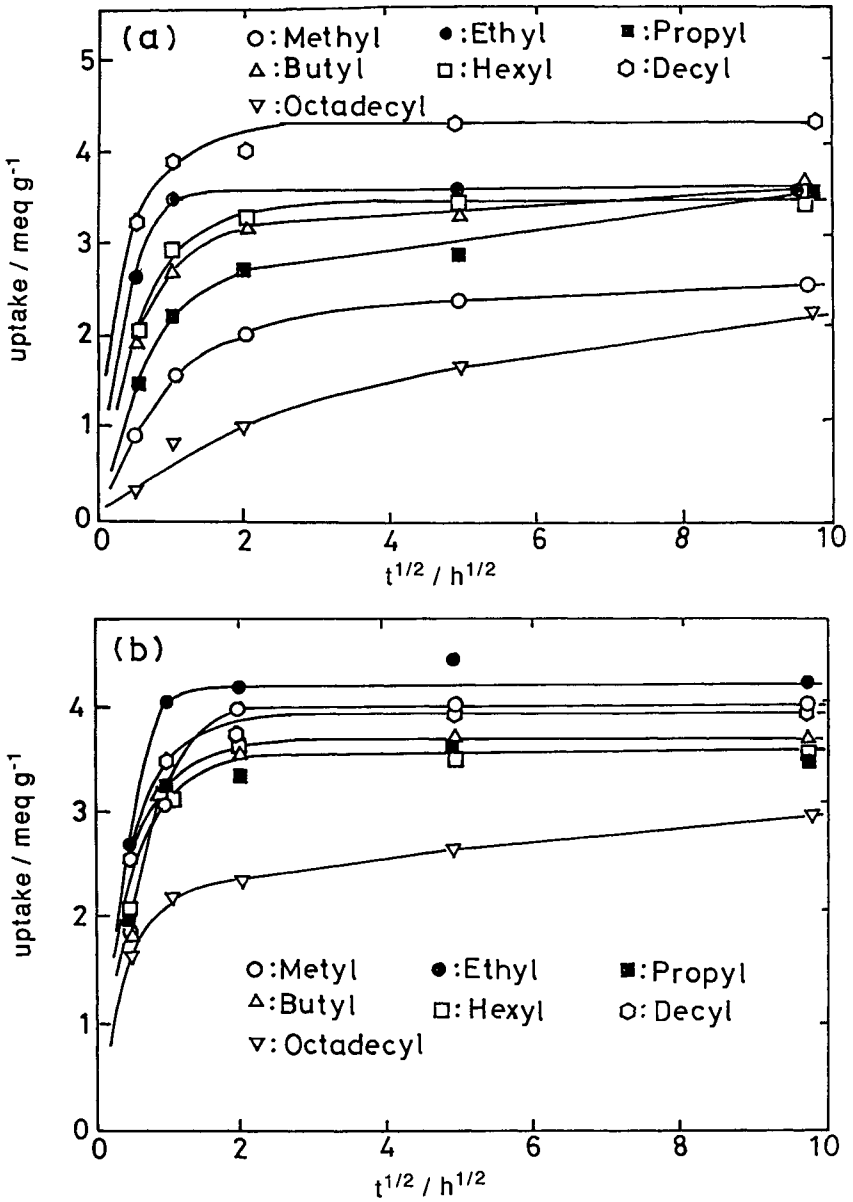

Fig. 3. Uptake of various amines vs. reaction time measured in methanol solutions. (a) γ-TiP, (b) γ-ZrP.

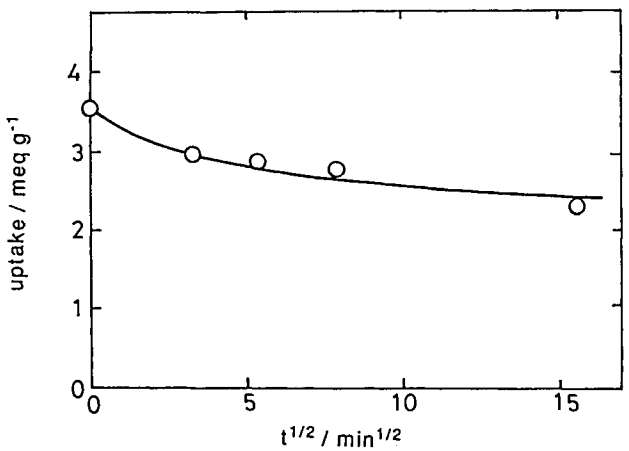

Fig. 4. Uptake of butylamine vs. suspension time in methanol.

those in methanol solutions.

Table 2 shows the amount of intercalated alkylamines [(mole of amine)/(mole of phosphate)] in the products for a reaction time of 4 d. Roughly speaking, the alkylamines intercalated in these phosphates amounted to about 1/2 of the active (or exchangable) protons in the host phosphates. The data obtained by Costantino[5] are listed in the same table for comparison. Our data are in good agreement with those reported by Costantino, except for some combinations (underlined). Small differences between the two data may be attributable to the difference in the preparation procedures of the γ-phosphates. The maximum uptakes were larger in the intercalates prepared in benzene solution than those in methanol solution, corresponding to the reaction rates in both solvents (Figs. 3a, 3b, 5a, 5b).

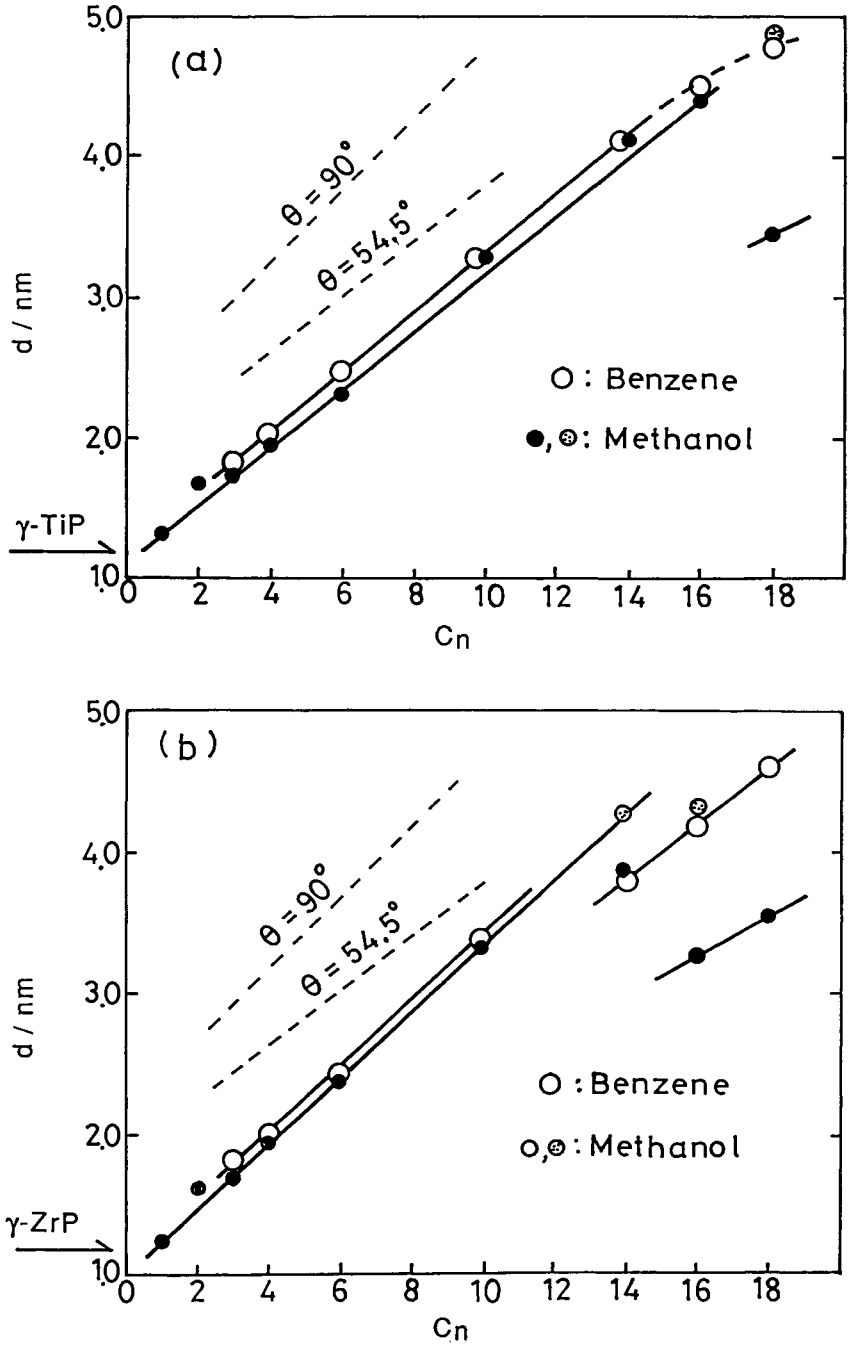

Fig. 6. *d*-Spacing (*d*) vs. number of carbon atom in *n*-alkyl chain (C_n).
(a) γ-TiP, (b) γ-ZrP.

Figures 6a and 6b show the *d*-spacings of the alkylamine intercalates corresponding to those in Table 2. The slope vs. number of carbon atoms (C_n) seems to be almost parallel to the theoretical slope (2×0.127 nm per carbon atom[5]) which was estimated by assuming that the alkyl-chains were intercalated in a bilayer just perpendicular to the basal planes, for C_n lower than 10 (γ-ZrP in both solutions) and lower than 16 (γ-TiP, methanol) or 18 (γ-TiP, benzene). Above these carbon numbers, some distortion might have occurred, such as irregular bilayer formation, inclination, and kink-block distortions.[7] The *d*-spacings for the intercalates of γ-ZrP for C_n=16 and 18 prepared in methanol solution may indicate the formation of monolayer of these amines.

The temperature effect of the intercalation of alkylamines with carbon numbers 14, 16, and 18 was examined in order to clarify the cause of the above mentioned distortion. The combinations of γ-TiP with benzene and γ-ZrP with methanol were selected as to be ideal (no distortion) and non-ideal (much distorted) (Fig. 7), respectively. The bilayer products of γ-TiP were obtained in benzene solutions for temperatures ranging

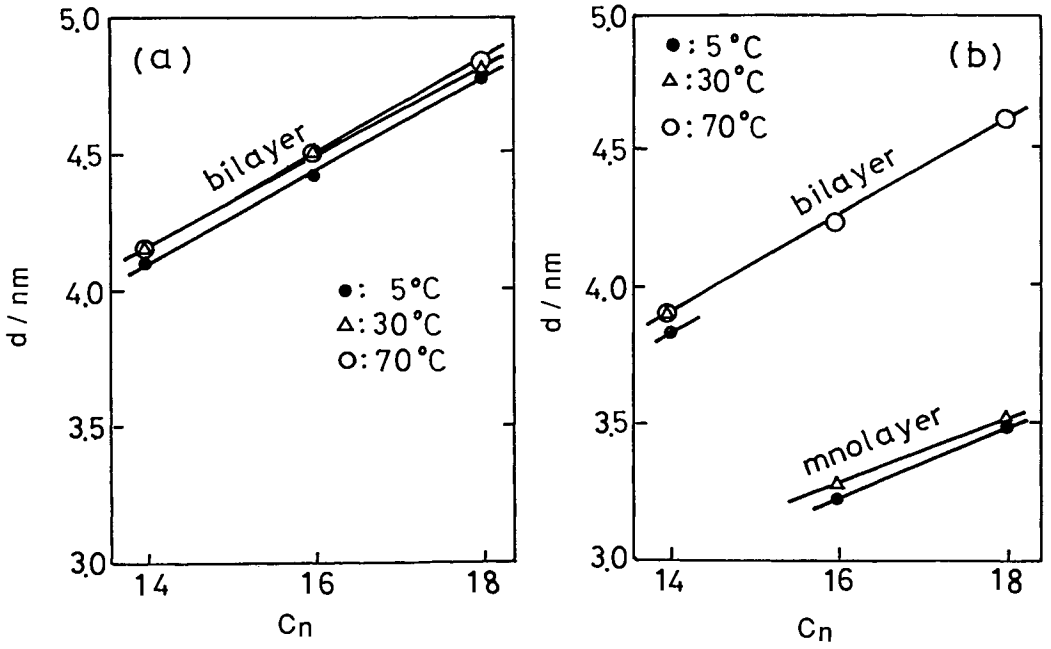

Fig. 7. Temperature dependence of *d*-spacing vs. number of carbon atom in alkyl-chain (C_n). (a) in benzene, (b) in methanol.

between 5 and 70 °C. On the other hand, bilayer products of γ-ZrP for carbon numbers 16 and 18 were obtained in methanol only for a sample prepared at 70 °C. Monolayer products were obtained at lower temperatures. It has been reported that the temperature rise up to this range caused an increase in kink-block distortion, resulting in a decrease in the *d*-spacings.[7] In the present study, however, it was found that the rise in temperature assisted in the formation of more perfect bilayers, presumably due to vibrational motion.

Comparison with Other Solvents. The facility of bilayer formation in the intercalation corresponding to the study illustrated in Fig. 7 (the rate and *d*-spacings) was examined in other solvents, xylene and propanol. Xylene and propanol showed intermediate properties between Figs. 7a and 7b. Thus, the order of facility for the intercalation of *n*-alkylamines was estimated to be as follows:

Benzene > Xylene > Propanol > Methanol

These results may suggest an effect of the dielectric constant of the solvent or the dipole moment of the solvent molecule in addition to the cointercalation of solvent molecules. The slow, imperfect intercalation reaction observed in methanol solutions suggests a strong solvation of the alkyl chain with polar methanol molecules, which may cause a slow desolvation on the occasion of the intercalation process, in addition to the co-intercalation effect stated above.

Ion Exchange and Acid-Base Reactions. The intercalation reaction of *n*-alkylamines into γ-phosphates is fundamentally an acid-base reaction. The ion-exchange reaction of decylammonium cations was examined in both methanol and aqueous solutions (Table 3). No ion-exchange reaction of decylammonium cations occurred in ethanol solution. This result suggests a poor dissociation of decylammonium chloride in the solvent. The *d*-values for the product by ion-exchange reactions of γ-TiP in aqueous solution were similar to that of decylamine intercalates in methanol, and showed the formation of a bilayer compound. On the other hand, the combination of γ-ZrP with decylammonium cations gave a monolayer inter-

Table 3. Interlayer Spacings of *n*-Decylamine and *n*-Decylammonium Ion Intercalates

Solvent	γ-TiP/nm		γ-ZrP/nm	
	Decylamine	Decylammonium	Decylamine	Decylammonium
Methanol	3.58 (Bilayer)	n.i.[a]	3.53 (Bilayer)	n.i.
Water	—[b] (Insoluble)	3.67 (Bilayer)	— (Insoluble)	2.80 (Monolayer)

a) Not intercalated. b) Intercalant was insoluble.

calate. These results indicate that the intercalation of *n*-alkylamines occurred more easily than did that of *n*-alkylammonium ions with a similar alkyl-chain; the intercalation of alkyl-chain was more accelerated by the acid-base reaction than that in an ordinary ion-exchange reaction.

Discussion

This study was designed to reveal that the intercalation of *n*-alkylamines should not be interpreted as being due solely to crystallographic, or visible, considerations regarding intercalated alkylamines, such as packing sequence, inclination of alkyl chain, and kink-block property. It was found from the present study that the crystallographic properties of *n*-alkylamines intercalated in layered compounds depend strongly on the conditions under which the intercalation reaction is carried out. This means that the crystallographic properties of intercalated alkylamines should not be interpreted only in terms of the final products. The crystallographic considerations reported so far should be reexamined by taking into account how they were prepared.

Packing Sequence. It has been proposed that alkyl chains in γ-phosphates are intercalated with an angle of 54.5°.[5] This study suggests, however, that alkyl-chains are intercalated almost perpendicular to the basal plane in γ-ZrP from carbon number 1 to 10 if the length of the carbon chain is assumed to be 0.127 nm/carbon and alkyl chains are closely packed without any distortion. Above that number, alkyl chains do undergo some distortion and, in some cases, intercalation occurs by forming monolayers. Alkylamines are to some extent inclinated in γ-TiP, though the angle is larger than 54.5°. However, it seems insignificant to determine the angle in detail only from the C_n vs. *d*-spacing curve, since the reproducibility of the *d*-value is rather poor and the error in determining the inclination would be large at high angles (near 90°).

Packing Density. It has been estimated that the free areas of the active site (exchangeable proton) are 0.166 and 0.178 nm² for γ-TiP and γ-ZrP, respectively (Table 1). The maximum uptake of alkylamines can not be estimated from the data obtained in ethanol solutions, but can be reasonably be estimated from the data obtained in benzene solutions. The number of alkyl-chains, thus estimated, are 1.22 and 1.33 chains per two active protons for γ-TiP and γ-ZrP, respectively (Table 2). This means that the packing density of the alkyl chains is 0.27 nm² (3.7 alkyl-chains per 1 nm²) in both γ-TiP and γ-ZrP, which approaches the corresponding value 4.17 observed in α-ZrP.[7] It can be concluded, therefore, that the packing density is determined mainly by the cross section of the alkyl chain. The length of the alkyl chain and the free area of the active protons are less important. The kink-block distortion would also be less important if intercalation procedures were settled properly.

The authors wish to thank Mr. K. Ito in Dai-ichi Kigenso Kogyo Co. Ltd., who kindly supplied us γ-ZrP and α-ZrP.

Spectrophotometric Determination of Tetrathionate by Its Oxidation with Iodate

Tomozo KOH* and Masako YAJIMA
Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka, Kanagawa 259-12
(Received January 25, 1991)

The conditions under which tetrathionate is oxidized stoichiometrically to sulfate by iodate have been established by investigating the reaction rate of tetrathionate with iodate in a medium containing varying amounts of sulfuric acid at room temperature and 40 °C. Tetrathionate reacted with iodate with a tetrathionate : iodate mole ratio of 3 : 7 under the conditions of the usual procedure. After a complete reaction, the iodine, formed from excess iodate by the addition of iodide, was spectrophotometrically measured as triiodide. A 14-fold chemical amplification was achieved for the determination of tetrathionate by using the proposed method, compared with the conventional methods via the sulfitolysis and cyanolysis of tetrathionate. A linear calibration graph with a negative slope was obtained over the concentration range 2.5×10^{-7}—2.5×10^{-5} mol dm^{-3} tetrathionate (0.56—56 μg of $S_4O_6^{2-}$ in 10 cm^3); the relative standard deviation was 0.42% at the 1.5×10^{-5} mol dm^{-3} tetrathionate level.

The identification and determination of polythionates in their mixtures are difficult owing to similarities in their chemical and physical properties.[1] Hence, various reactions of individual polythionates, such as cyanolysis,[2–7] sulfitolysis[8–10] and sulfidolysis,[11,12] have been investigated in detail in order to determine a specific polythionate in the presence of other polythionates. These reactions have played an important role in the development of methods for the analysis of mixtures of polythionates.[13–17] All of these methods have been based on the formation of thiosulfate and/or thiocyanate equivalent to the polythionates, and on the spectrophotometric measurements of the reaction products.

It has been stated that iodate can be used as an excellent analytical reagent for standard iodine,[1] because a mixture solution of iodate and the excess amount of iodide is extremely stable and produces quantitatively iodine equivalent to the iodate, by the addition of acid, according to the following equation:

$$IO_3^- + 8I^- + 6H^+ \longrightarrow 3I_3^- + 3H_2O. \quad (1)$$

Further, the molar absorptivity of triiodide at 350 nm is much higher than that of iodine in carbon tetrachloride at 515 nm.[18] With regard to reactions involving oxoacid ions, such as the iodate ion, the potential for its reduction to the iodide ion is expected to increase with an increase in the hydrogen-ion concentration. In a previous paper[19] it was mentioned that thiosulfate can be oxidized by iodate to sulfate in a strong acidic medium, and that a simple, precise method has been developed for the determination of thiosulfate. In this study we attempted to oxidize tetrathionate with iodate in a strong acid medium, and established the conditions under which tetrathionate can be stoichiometrically oxidized to sulfate according to the following equation:

$$3S_4O_6^{2-} + 7IO_3^- + 9H_2O \longrightarrow 12SO_4^{2-} + 7I^- + 18H^+. \quad (2)$$

The proposed method for the determination of tetrathionate, in which the formed iodine equivalent to the excess iodate is measured spectrophotometrically, is very simple and is 14-fold more sensitive than previous methods for tetrathionate by its cyanolysis[15] and sulfitolysis.[8]

Experimental

Apparatus and Reagents. A Shimadzu Model UV-240 recording spectrophotometer with 10-mm quartz cells was used for all of the absorbance measurements. The desired temperatures were controlled by a Taiyo Model M-1 incubator.

All of the chemicals used, except for tetrathionate, were of analytical-reagent grade and were used without further purification. The water used in these experiments was redistilled.

Standard Tetrathionate Solution: Potassium tetrathionate was prepared according to a procedure described by Stamm and Goehring.[20] The obtained tetrathionate was recrystallized with water at temperatures below 60 °C and then dried at room temperature before storage at -10 ± 2 °C. A standard tetrathionate solution (1×10^{-3} mol dm^{-3}) was prepared by dissolving 151.3 mg of the potassium tetrathionate (water content: 0.07%) in water and diluting it to 500 cm^3; it was then stored at 5 ± 2 °C. Working standards were prepared by suitable dilultion.

Standard Iodate Solution: A 0.100/6 mol dm^{-3} iodate solution was prepared by dissolving 3.567 g of potassium iodate (99.98%) in water and diluting to 1000 cm^3. Working standard iodate solutions were prepared by appropriate dilution.

Standard Thiosulfate Solution: An approximately 0.1 mol dm^{-3} solution was prepared by dissolving a known amount of sodium thiosulfate pentahydrate in oxygen-free water containing a small amount of sodium carbonate (0.01% w/v) as a stabilizer. This solution was standardized by iodimetry 1 week after preparation. Working standard thiosulfate solutions (0.01% w/v Na_2CO_3) were prepared by suitable dilution of the standard with oxygen-free water.

Procedure. Pipette 10 cm^3 of a sample solution of up to 2.86×10^{-5}mol dm^{-3} tetrathionate into a 50-cm^3 calibrated flask, and add 3 cm^3 of 5 mol dm^{-3} sulfuric acid and 4.2 cm^3 of $1\times10^{-3}/6$ mol dm^{-3} standard iodate solution. Allow the flask to stand in a thermostat at 40 °C for 30 min in order to oxidize the tetrathionate completely to sulfate according to Eq. 2. Then add 5 cm^3 of 5 mol dm^{-3} acetic acid, 5 cm^3 of 6 mol dm^{-3} sodium hydroxide and 5 cm^3 of 1 mol dm^{-3} potassium iodide, whereupon the iodine equivalent to the excess iodate is quantitatively formed. After diluting to the mark

with water, mix the contents well and measure the absorbance of a solution of the triiodide against water at 350 nm.

Prepare an iodate-free reagent blank by adding 4.2 cm^3 of water in place of 4.2 cm^3 of $1\times10^{-3}/6$ mol dm^{-3} standard iodate solution and treating it exactly the same, and correct it for all the absorbances measured in this study.

Results and Discussion

Calibration Graphs. A series of standard solutions (10 cm^3) of tetrathionate were treated as described in the Procedure section. After the complete reaction of tetrathionate with iodate, the iodine which formed from the excess iodate was spectrophotometrically measured as triiodide. Hence, the proposed method gave a linear calibration graph with a negative slope for an increase in the concentration of tetrathionate. In previous methods, the thiosulfate formed by the sulfitolysis[8] and cyanolysis[15] of tetrathionate was measured by the consumption of iodine according to the following equation:

$$2S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2I^-, \quad (3)$$

in which 1 mol of thiosulfate furnishes 1 mol of electrons. On the other hand, according to Eq. 2, tetrathionate is oxidized to sulfate by iodate; 1 mol of tetrathionate furnishes 14 mol of electrons. Therefore, when the amount of liberated iodine equivalent to the excess iodate for tetrathionate is measured, a 14-fold chemical amplification can be achieved for the determination of tetrathionate. The calibration graph for tetrathionate obtained by the proposed method is shown, together with the calibration graph obtained for thiosulfate using iodine,[21] in Fig. 1, in which the molar concentration scale for tetrathionate was drawn to 14-times the scale for the thiosulfate concentration. The calibration graph for tetrathionate and that for thiosulfate were parallel to each other; the lower reagent blank obtained by the proposed method can be probably attributed to the oxidation of trace amounts of impurities in the reagents by the iodate and to the higher temperatures caused by the heat of neutralization of a strong acid; at higher temperatures the absorbance of triiodide decreases owing to its dissociation. When the reagent blank obtained for thiosulfate was normalized to that for tetrathionate, both the calibration graphs coincided completely with each other. This confirms that tetrathionate is quantitatively oxidized to sulfate by iodate according to Eq. 2 under the conditions described in the Procedure section.

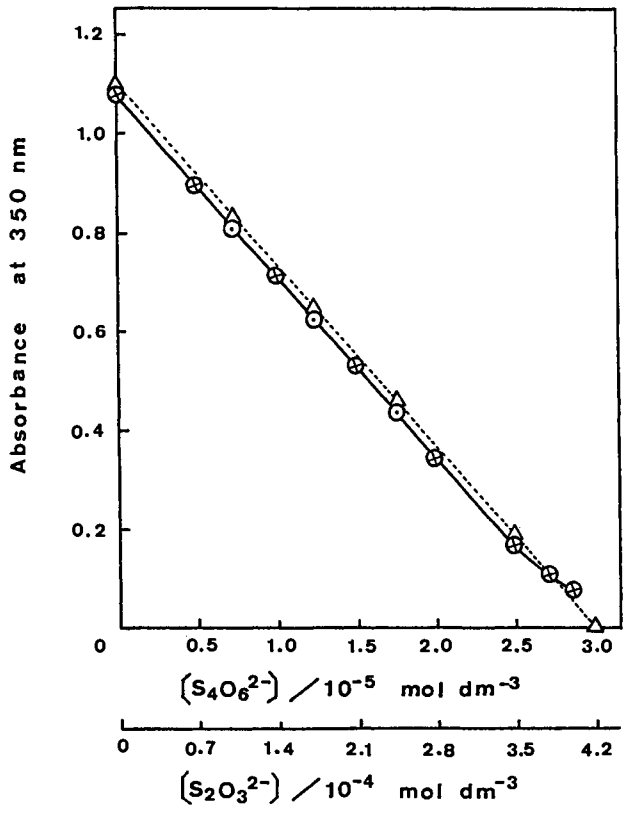

Fig. 1. Calibration graphs for tetrathionate and thiosulfate. ⊗, Tetrathionate by the proposed method; △, thiosulfate by iodine method;[21] ⊙, expected graph (the reagent blank obtained by the iodine method was normalized to that by the proposed method).

The proposed method can be applied to the determination of tetrathionate in the concentration range 2.5×10^{-7}—2.5×10^{-5} mol dm^{-3} (0.056—5.6 ppm). The precision of the method was based on 11 replicate analyses of a 10-cm^3 aliquot of a 1.5×10^{-5} mol dm^{-3} standard tetrathionate solution (33.6 μg of $S_4O_6^{2-}$ in 10 cm^3); the mean value of tetrathionate was found to be 33.5 μg, with a standard deviation of 0.14 μg of $S_4O_6^{2-}$ and a relative standard deviation of 0.42%.

Reaction Rate of Tetrathionate with Iodate. It is normally known that the potential for the redox couples, which involve a large number of hydrogen ions, is strongly dependent on the hydrogen-ion concentration. We therefore made an attempt to oxidize tetrathionate with iodate in an acidic medium of various strong acids: hydrochloric, nitric, perchloric, and sulfuric. Among these acids, only sulfuric acid proved suitable as a medium for the reaction of tetrathionate with iodate.[19] Therefore, the reaction rate was investigated in a medium containing varying amounts of sulfuric acid at 21 °C (i.e., room temparature); tetrathionate was allowed to react with iodate for various periods of time; the amount of iodine liberated from the excess of the iodate by the addition of iodide was then measured. The resulting graphs are shown in Fig. 2. Here, all of the absorbances obtained were normalized to those obtained using 3 cm^3 of 5 mol dm^{-3} sulfuric acid (i.e., all the reagent blanks were normalized to that obtained under the Procedure section). The reaction did not go to completion, even within 2 h in a 0.52 mol dm^{-3} sulfuric acid medium (3-cm^3 addition of 3 mol dm^{-3} H_2SO_4). Still, the reaction rate was accelerated by an increase in the amount of sulfuric acid; the reaction proceeded to stoichiometric completion according to Eq. 2 within 80 min in a 0.70 mol dm^{-3} sulfuric acid

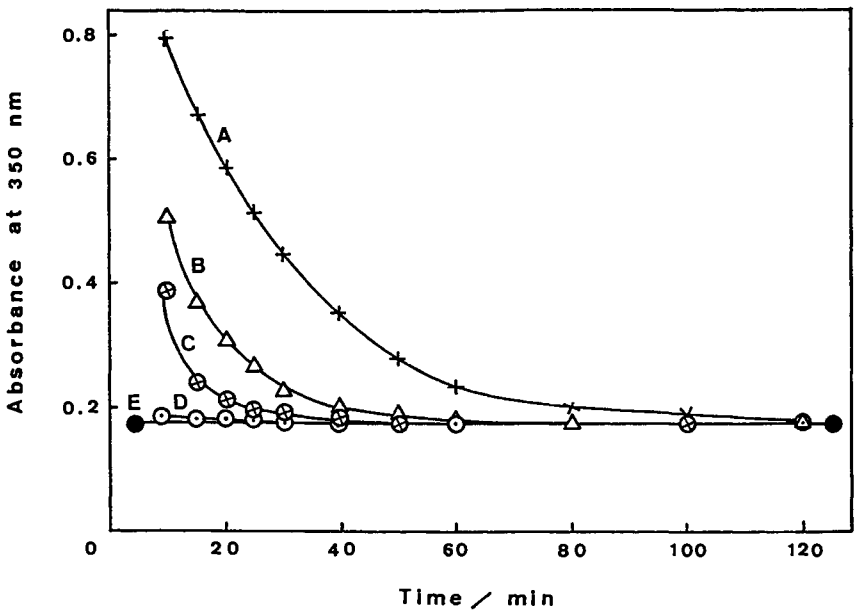

Fig. 2. Reaction rate of tetrathionate with iodate in a medium containing varying amounts of sulfuric acid at 21 °C (i. e., room temperature). A 10-cm^3 solution of 2.5×10^{-5} mol dm^{-3} tetrathionate was used. A, 3-cm^3 addition of 3 mol dm^{-3} H_2SO_4; B, 3-cm^3 addition of 4 mol dm^{-3} H_2SO_4; C, 3-cm^3 addition of 5 mol dm^{-3} H_2SO_4; D, 3-cm^3 addition of 8 mol dm^{-3} H_2SO_4; E, expected value obtained for 3.5×10^{-4} mol dm^{-3} $S_2O_3^{2-}$ using iodine method.[21]

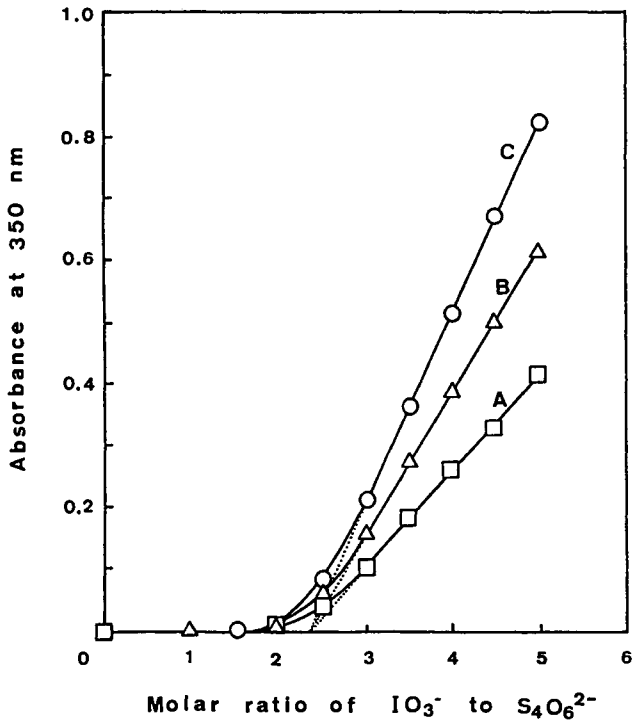

Fig. 3. Molar ratio graphs for the reaction of tetrathionate with iodate. A 10-cm^3 tetrathionate solution with various concentrations was used. A, 1×10^{-5} mol dm^{-3} $S_4O_6^{2-}$; B, 1.5×10^{-5} mol dm^{-3} $S_4O_6^{2-}$; C, 2×10^{-5} mol dm^{-3} $S_4O_6^{2-}$.

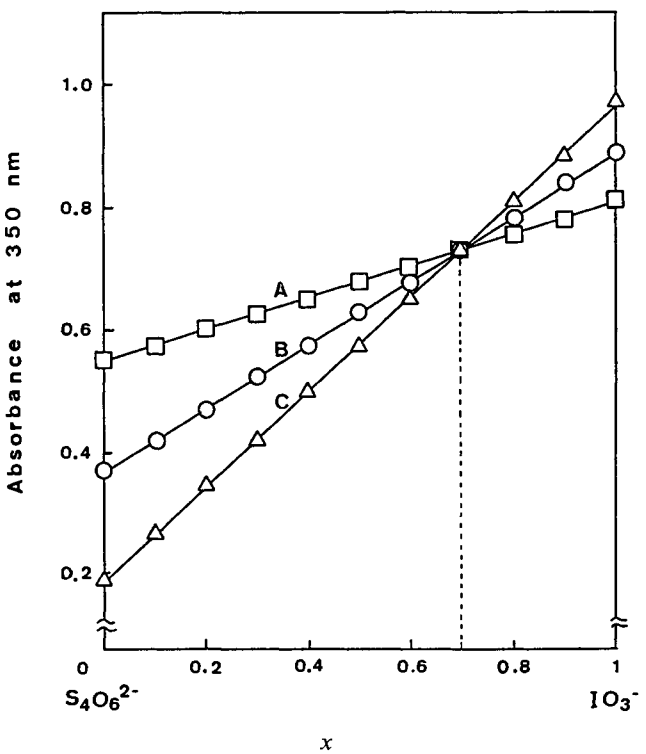

Fig. 4. Continuous variation graphs for the reaction of tetrathionate with iodate. A, $[IO_3^-]+[S_4O_6^{2-}]=5\times10^{-6}$ mol dm^{-3}; B, $[IO_3^-]+[S_4O_6^{2-}]=1\times10^{-5}$ mol dm^{-3}; C, $[IO_3^-]+[S_4O_6^{2-}]=1.5\times10^{-5}$ mol dm^{-3}. A 2.8-cm^3 solution of $1\times10^{-3}/6$ mol dm^{-3} iodate was additionally used.

Table 1. Effect of Foreign Ions on the Determination of 33.6 μg of Tetrathionate in 10 cm^3 of Sample Solution

Ion	Added as[a]	Amount	Amount of $S_4O_6^{2-}$ found	Error
		μg	μg	%
None			33.6	
Na^+	Na_2SO_4	10000	33.6	0

		10	34.5[d]	2.7

a) Water of crystallization is omitted for brevity. b) Iron(III) was masked by adding 1 cm^3 of 0.2 mol dm^{-3} sodium fluoride. c) Nitrite was decomposed by adding 1 cm^3 of 0.5 mol dm^{-3} amidosulfuric acid. d) The nitrogen gas at a flow-rate of 400 cm^3 min^{-1} was bubbled for 30 min.

medium (3-cm^3 addition of 4 mol dm^{-3} H_2SO_4), within 50 min in a 0.87 mol dm^{-3} sulfuric acid medium (3-cm^3 addition of 5 mol dm^{-3} H_2SO_4) and within 30 min in a 1.4 mol dm^{-3} sulfuric acid medium (3-cm^3 addition of 8 mol dm^{-3} H_2SO_4); the absorbances remained constant. At 40 °C, the reaction rate was accelerated much more and the reaction went to completion within 40 min in a 0.52 mol dm^{-3} sulfuric acid medium, within 30 min in a 0.70 mol dm^{-3} sulfuric acid medium and within 20 min in both 0.87 and 1.4 mol dm^{-3} sulfuric acid media. Hence, for the usual procedure, 3 cm^3 of 5 mol dm^{-3} sulfuric acid was employed and tetrathionate was allowed to react with iodate in the 0.87 mol dm^{-3} sulfuric acid medium for 30 min at 40 °C.

The sulfuric acid used had to be neutralized with a strong base; otherwise, the absorbance of triiodide increased greatly and rapidly with time owing to the formation of iodine in a strong acid medium, as the result of air-oxidation of the iodide added for the liberation of iodine from the excess iodate. Accordingly, each amount of the sulfuric acid used was neutralized with a strong base equivalent to the amount of the sulfuric acid. Further, 5 cm^3 of 5 mol dm^{-3} acetic acid was added to make the solution weakly acidic. However, it was desirable to measure the absorbance of the triiodide as soon as possible after its formation. A 4—8 cm^3 volume of 1 mol dm^{-3} potassium iodide solution proved to be sufficient for the complete liberation of iodine; in the Procedure section, a 5-cm^3 volume of 1 mol dm^{-3} potassium iodide solution was employed.

Stoichiometric Relationship for the Reaction of Tetrathionate with Iodate. An attempt was made to determine the stoichiometric relationship for the reaction of tetrathionate with iodate in a medium of sulfuric acid using both the molar ratio method and the continuous variation method. For applying the molar ratio

method, 10 cm^3 each of 1×10^{-5}, 1.5×10^{-5}, and 2×10^{-5} mol dm^{-3} tetrathionate solutions, and 4.2 cm^3 of each of iodate solutions (with varying concentrations) were used with a varying mole ratios of iodate to tetrathionate. After the addition of 3 cm^3 of 5 mol dm^{-3} sulfuric acid to each mixture, the mixture was allowed to stand for 30 min at 40 °C. The absorbance of the series of the solutions obtained was then measured according to the Procedure section. The resulting graphs are shown in Fig. 3. In order to determine the stoichiometric relationship of iodate to tetrathionate involved in the determination of tetrathionate, straight portions of each graph were extrapolated to the abscissa, since the proposed method gave a straight calibration graph over the concentration range of up to 2.5×10^{-5} mol dm^{-3} tetrathionate. Each dotted line intersected the abscissa at the point 2.3 (7/3). This proves that 3 mol of tetrathionate reacted with 7 mol of iodate under the conditions of the usual procedure.

For the method of continuous variations, each $10x$ (x=mole fraction of iodate) cm^3 of 5×10^{-6}, 1×10^{-5}, and 1.5×10^{-5} mol dm^{-3} iodate solutions, and each $10(1-x)$ cm^3 of 5×10^{-6}, 1×10^{-5}, and 1.5×10^{-5} mol dm^{-3} tetrathionate solutions were used to prepare a series of 10-cm^3 solutions with a varying iodate–tetrathionate mole ratio. To each mixture, 2.8 cm^3 of $1\times10^{-3}/6$ mol dm^{-3} iodate solution was added in order to obtain the absorbance of iodine (as triiodide), even in the region of the excess of tetrathionate ($x<0.7$). Then, 3 cm^3 of 5 mol dm^{-3} sulfuric acid and 1.4 cm^3 of water were added; the resulting volume of the solution was 17.2 cm^3 (as described in the Procedure section). The mixture was allowed to stand for 30 min at 40 °C; then, the absorbance of a series of the solutions was measured at 350 nm against water. Figure 4 shows the resulting plots of absorbance vs. mole fraction of iodate; all three graphs intersected at the point indicating a 0.7 [7/(7+3)] mole fraction of iodate. Further, this point appeared just on the absorbance obtained for the amount of the iodate used additionally. These results signify that tetrathionate reacted with iodate stoichiometrically with a tetrathionate : iodate mole ratio of 3 : 7 under the conditions described in the Procedure section, according with the results obtained by the method of molar ratios.

Effect of Foreign Ions. A 10-cm^3 solution containing 33.6 μg of tetrathionate (1.5×10^{-5} mol dm^{-3} tetrathionate) and various amounts of foreign ions was treated as described in the Procedure Section. The results are given in Table 1. The proposed method is based on the oxidation of tetrathionate with iodate in a strong acid medium, followed by spectrophotometric measurements of the iodine (as triiodide) formed (by the addition of iodide) from the excess iodate. Hence, the ions which oxidize iodide or reduce iodate are thought to interfere with the determination of tetrathionate. Copper(II), iron(III), and nitrite (which oxidize iodide), and sulfite and sulfide (which reduce iodate) gave serious errors when present in small amounts. Still, the nitrite was tolerated in amounts of up to 10000 μg by decomposing it by the addition of 1 cm^3 of 0.5 mol dm^{-3} amidosulfuric acid solution.

Structural Study of Optical Resolution. XVI. The Crystal Structures of a Pair of Diastereomeric Salts of the *lel*$_3$-Tris(*trans*-1,2-cyclohexanediamine)nickel(II) Complex with *d*-Tartrate Dianion

Tsutomu MIZUTA and Katsuhiko MIYOSHI*
Department of Chemistry, Faculty of Science, Hiroshima University,
1-1-89 Higashi-senda-machi, Naka-ku, Hiroshima 730
(Received November 30, 1990)

The crystal structures of the diastereomeric salt pair, *Λ-lel*$_3$-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O (**1**) and *Δ-lel*$_3$-[Ni(*R,R*-chxn)$_3$](*d*-tart)·5H$_2$O (**2**) (chxn=*trans*-1,2-cyclohexanediamine and *d*-tart=(+)-(*R,R*)-tartrate dianion), have been determined by single-crystal X-ray diffraction techniques. Crystal **1** is orthorhombic with the space group $P2_12_12_1$, a=10.093(2), b=13.589(4), c=22.011(4) Å, and Z=4. Crystal **2** is also orthorhombic with the same space group, a=11.197(2), b=13.102(2), c=22.402(2) Å, and Z=4. In **1**, the *d*-tart ion makes a familiar face-to-face contact with the *Λ* complex, in which the two alcoholic and one carboxylic O atoms of the *d*-tart ion are involved in the multiple hydrogen bonds to the three H–N groups on the triangular face of the complex. This contact mode resembles the one found earlier in the chloride *d*-tart salt of the corresponding *Λ* Co(III) complex, *Λ-lel*$_3$-[Co(*S,S*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O (**3**). On the other hand, no such face-to-face contact is present in **2**, though it has been found in the corresponding *Δ* Co(III) complex salt, *Δ-lel*$_3$-[Co(*R,R*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O (**4**) in which the *d*-tart ion is obliged to rotate the distal carboxylato group so as to avoid the steric repulsion otherwise imposed on it by one of the bulky chxn ligands. Detailed comparison of the above four crystal structures revealed that the packing modes of the respective complex cations and counterions are surprisingly similar to one another, indicating that the absence of such a face-to-face contact in **2** is attributed to the weaker affinity of the *d*-tart ion for the divalent *Δ* Ni(II) complex, rather than to the steric demands of the crystal packing in **2**. In **2** are found two deformed contact modes similar to each other, in which the *d*-tart ion directs its three O atoms to the triangular face, but only one of them is hydrogen-bonded to one or two of the three H–N groups on the triangular face. The *d*-tart ion thereby avoids the steric repulsion that would be imposed on it if it should make a usual face-to-face contact with the *Δ* complex.

(+)-(*R,R*)-Tartrate dianion (abbreviated as *d*-tart ion hereafter) is known as an effective resolving agent not only for chiral amines but also for metal–amine complexes.[1,2] To elucidate how this simple chiral anion recognizes the chirality of these complexes, we and other groups have analyzed several crystal structures of *d*-tart salts with some tris(diamine)cobalt(III) complex cations.[3–10] They found a common face-to-face contact mode in which the two alcoholic and one carboxylic O atoms of the *d*-tart ion are hydrogen-bonded to the three H–N groups on the triangular face of the complex along the C_3 axis. When the complex has a *Λ* configuration, the above-mentioned multiple hydrogen bonds are favorably formed without any steric repulsion. On the other hand, the *Δ* complex imposes a steric repulsion on the distal carboxylato group of the *d*-tart ion if it should make a similar face-to-face contact with the triangular face. As a result, either the *d*-tart ion rotates its distal carboxylato group to maintain the face-to-face contact,[9] or the multiple hydrogen bonds to the triangular face are more or less damaged in number and/or in strength.[10] In this way, chiral discrimination with *d*-tart ion is effectively attained, particularly for those metal–amine complexes which have bulky substituents on their chelate rings, such as *lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ or *fac*- and *mer*-[Co(*cis*-chxn)$_3$]$^{3+}$ (chxn=1,2-cyclohexanediamine), because the bulkier the substituents, the more severe the steric repulsion that *Δ* enantiomers of these complexes impose on the distal carboxylato group.[9,10] However, most of the diastereomeric salts investigated are those of trivalent Co(III) complex cations, and only two divalent Ni(II) complex salts, i.e., *Λ,Λ*-[Ni(en)$_3$](*dl*-tart)·H$_2$O[11] and *Δ*-[Ni(en)$_3$]$_3$(*d*-tart)$_3$·4H$_2$O[11] (en=1,2-ethanediamine) having no substituent on each chelate, have been so far examined. In the present study, the crystal structures have been determined for a pair of diastereomeric salts of the divalent *lel*$_3$-[Ni(*trans*-chxn)$_3$]$^{2+}$ complex with *d*-tart ion, with the aim of elucidating how the valency of the complex cation affects the contact modes with the *d*-tart ion when the complex carries bulky substituents on the diamine chelates.

Experimental

Preparation of *Λ*-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O (1). To an aqueous solution of (1*S*,2*S*)-cyclohexanediamine[9] (2.9 g) in 20 ml of water, was added 1.5 g of nickel *d*-tartrate prepared by mixing sodium *d*-tartrate with an equivalent amount of NiCl$_2$·6H$_2$O in water. The violet solution thus obtained was left standing at room temperature for several days. Violet crystals were deposited and a crystal of suitable size was selected for the structure analysis. Anal. Found: C, 44.07; H, 8.98; N, 13.80%. Calcd for *Λ*-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O (**1**): C, 43.79; H, 8.69; N, 13.93%.

Preparation of *Δ*-[Ni(*R,R*-chxn)$_3$](*d*-tart)·5H$_2$O (2). **2** was prepared in a similar manner using (1*R*,2*R*)-cyclohexanediamine.[9] Anal. Found: C, 41.27; H, 8.72; N, 13.01%. Calcd for *Δ*-[Ni(*R,R*-chxn)$_3$](*d*-tart)·5H$_2$O (**2**): C, 41.33; H,

X-Ray Structure Analysis. Cell dimensions were determined and refined on a Syntex R3 single-crystal diffractometer. The results are given in Table 1. The intensity data were collected by the ω-scan technique with graphite-monochromated Mo $K\alpha$ radiation (λ=0.71069 Å). Three check reflections monitored after every 197 reflections showed no decrease in intensity during the data collection. Corrections for Lorentz and polarization effects were applied to the intensities, but no absorption and extinction corrections were made.

Each structure was solved by the well-established heavy-atom methods described in the previous work.[9,12,13] The anomalous dispersion coefficient was used for the Ni atom only,[14] and the absolute configuration of the complex cation was confirmed to be Λ for **1** and Δ for **2**.[15] The final R and R_w values are given in Table 1 together with the crystallographic data on **1** and **2**. Final positional parameters for non-hydrogen atoms are given in Tables 2 and 3 for **1** and **2**,

respectively. Tables of the full listing of the crystallographic data, hydrogen atom coordinates, anisotropic thermal parameters for non-hydrogen atoms, bond distances and angles, hydrogen bond distances and angles, and a list of observed and calculated structure factors are deposited as Document No. 9119 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Contact Modes in 1 and 2. There has been found a familiar face-to-face contact in the *Λ*-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O (**1**), which is depicted in Fig. 1 with the numbering schemes adopted for the respective atoms. The geometries of the complex cation in **1** are in complete agreement with those reported previously.[16] The *d*-tart ion takes a normal conformation and directs its four O atoms (O2, O3, O4, and O5) to the triangular face of the complex along the C_3 axis. Of the four, two alcoholic and one carboxylic O atoms (O3, O4, and O5) are triply hydrogen-bonded to the three H–N groups (H2–N2, H2–N6, and H2–N4) on the triangular face without any steric repulsion. The two O atoms (O1 and O2) of the distal carboxylato group are far from any of the bulky chxn ligands, but they are hydrogen-bonded to the H1–N5 and H1–N4 groups of another neighboring complex, which are directed along the C_2 axis. Thus, the above contact mode resembles those so far found in some diastereomeric salts of trivalent *Λ* Co(III) complexes such as *Λ*-*lel*$_3$-[Co(en)$_3$]X(*d*-tart)·5H$_2$O[3,5,6] (X=Cl or Br), *Λ*-[Co(sen)]Cl(*d*-tart)·6H$_2$O[4,6] (sen=*N,N'*-bis(2-aminoethyl)-2-[[(2-aminoethyl)-amino]methyl]-2-methyl-1,3-propanediamine), and *Λ*-*lel*$_3$-[Co(*S,S*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O (**3**).[9] It is then confirmed that a familiar face-to-face contact is maintained even in the divalent Ni(II) complex salt with bulky diamine chelates, provided that the complex has a *Λ* configuration. Actually, a similar face-to-face contact mode has been found in the *Λ,Λ*-[Ni(en)$_3$](*dl*-tart)·H$_2$O[11] as well, where the *d*-tart ion makes such a contact with the *Λ* enantiomer only and the *l*-tart ion does with the *Δ* enantiomer only, as expected. The hydrogen bonds pertinent to these face-to-face contact modes are numerically compared in Table 4.

In contrast, no such face-to-face contact mode is present in the *Λ*-[Ni(*R,R*-chxn)$_3$](*d*-tart)·5H$_2$O (**2**). Instead, each *d*-tart ion is sandwiched between the two triangular faces and connects them through the two "deformed" contact modes in **2**, as seen in Fig. 2. One of them is depicted down to the C_3 axis in Fig. 3 together with the atom numbering schemes, where the *d*-tart ion with a usual conformation directs the three O atoms (O1, O2, and O4) to the triangular face, but only the O1 atom is disposed close enough to form a bifurcated hydrogen bond to the H1–N1 and H1–N3 groups on the triangular face. The O2 atom is hydrogen-bonded to the two H–N groups (H2–N1 and H2–N6) directed along the C_2 axis of another neighboring complex and the O4 atom is to a water molecule.

The other "deformed" contact mode is the one in which the remaining three O atoms (O3, O5, and O6) of the *d*-tart ion are directed to the triangular face of another complex cation in the above layer and similar hydrogen bonds are formed without any steric repulsion; O6 to H1–N4 on the triangular face and to H–OW3 (water molecule), O5 to H2–N4 and H2–N5 directed along the C_2 axis of the neighboring complex in the same layer, and O5 to H–OW1 (water molecule). Consequently, it is evident that the overall hydrogen-bonding interaction of the *d*-tart ion with the triangular face of the complex is by far weaker in **2** than in **1** or **3**,

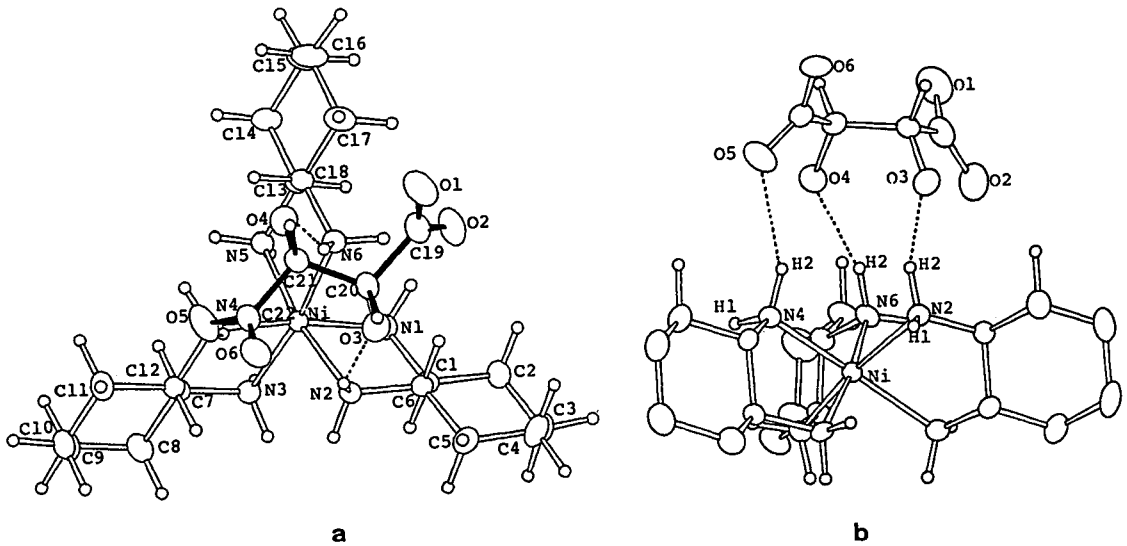

Fig. 1. Drawing of the face-to-face contact mode found in *Λ*-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O (**1**), as viewed down (a) and normal to (b) the C_3 axis of the complex. Possible hydrogen bonds are shown by broken lines and most of the CH protons are omitted for clarity in (b).

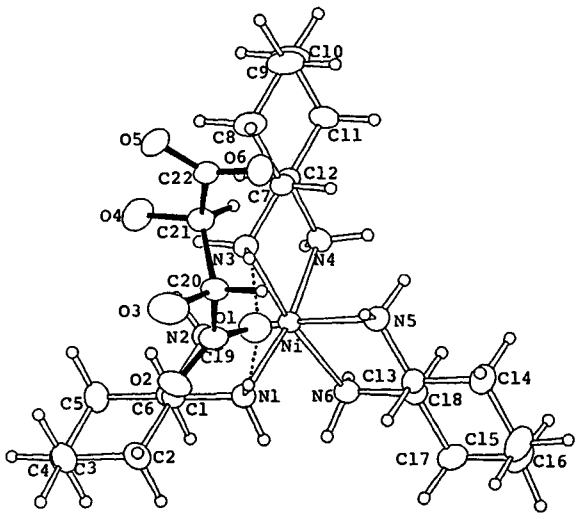

Fig. 3. Drawing of one of the "deformed" contact modes found in *Δ*-$[Ni(R,R\text{-chxn})_3](d\text{-tart})\cdot 5H_2O$ (**2**). Possible hydrogen bonds are shown by the broken lines.

but the *d*-tart ion experiences no steric repulsion from the bulky chxn ligands of the *Δ* complex in **2**.

On the other hand, the familiar face-to-face contact mode has been found in the corresponding *Δ* Co(III) complex, *Δ*-*lel*$_3$-$[Co(R,R\text{-chxn})_3]Cl(d\text{-tart})\cdot 2H_2O$ (**4**),[9] in which the *d*-tart ion is obliged to rotate its distal carboxylato group greatly so as to avoid the steric repulsion that would be otherwise imposed on it by one of the chxn ligands. That is, the *d*-tart ion maintains

1: *Λ*-[Ni(*S,S*-chxn)$_3$](*d*-tart)·3H$_2$O, **2**: *Λ*-[Ni(*R,R*-chxn)$_3$](*d*-tart)·5H$_2$O, **3**: *Λ*-[Co(*S,S*-chxn)$_3$]-Cl(*d*-tart)·2H$_2$O, **4**: *Λ*-[Co(*R,R*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O, and **5**: *Λ*-[Co(*S,S*-chxn)$_3$]Cl$_3$·5H$_2$O.

the face-to-face contact even with the *Λ* complex at the expense of the conformational energy. This is because the accompanying conformational destabilization is compensated for the most part in **4** by the intimate hydrogen bonds to the neighboring complex cations,[9] and also because the face-to-face contact with the trivalent Co(III) complex cation leads to a substantial stabilization. Then, the absence of the face-to-face contact in **2** implies that the neighboring complexes are not appropriately disposed in **2** to assist the conformational change, and/or that the attractive force of the divalent Ni(II) complex is not strong enough for the *d*-tart ion to make a face-to-face contact with its *Λ* enantiomer against the accompanying steric repulsion. So, the packing modes of the composite ions in **2** need to examine and compare with those of the relevant diastereomeric salts before we proceed to settle the above problem.

Comparison of Packing Modes. Now, the packing modes in the present crystals **1** and **2** are compared with those in the relevant diastereomeric salts of the Co(III) complex cations, *Λ-lel*$_3$-[Co(*R,R*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O (**3**) and *Δ-lel*$_3$-[Co(*R,R*-chxn)$_3$]Cl(*d*-tart)·2H$_2$O (**4**).[9] The space groups and the cell dimensions of the four crystals are listed in Table 5 together with those of *Λ-lel*$_3$-[Co(*S,S*-chxn)$_3$]Cl$_3$·5H$_2$O (**5**).[17] The structures of these five crystals are depicted in Fig. 4, where each structure is projected along the *a*-axis for **1**, **2**, and **4**, and along the *c*-axis for **3** and **5**. The range projected is 0—1/2 for the former three, −1/4—1/4 for **3**, and −1/12—1/12 for **5**, and each range (layer) has a thickness of ca. 5 Å. To each of these structures, one complex is added in black to demonstrate that the complex is disposed at that position both above and below the layer.

It is evident in Fig. 4 that quite similar arrangements of the complex cations are found not only in **1**, **2**, and **4**, but also in **5**; each complex cation is arranged in a similar manner in the layer of ca. 5 Å thickness with its C_3 axis directed parallel to the projection axis and with the counterion(s) and water molecules packed in a cavity thus formed. In this respect, crystal **3** has also similar arrangements of the complex cations as well as the counterions and water molecules, though the C_3 axis of each complex is directed not exactly parallel to the projection axis in **3**. Furthermore, since each layer is related to the upper and lower layers by the two- and six-fold screw axes in **1**—**4** and in **5**, respectively, it follows that the counterion(s) is packed in a cavity surrounded by the five complex cations in all of the five crystal structures. Therefore, it can be said that the five crystals bear a close resemblance to one another with respect to the spatial arrangements of the complex cations as well as the counterions, and that their packing modes are governed primarily by the bulky complex cations.

The discussions presented above indicate that the face-to-face contact mode might be adopted in **2** on the spatial grounds mentioned above. However, no such mode is present in **2**, suggesting that the divalent Ni(II) complex is not attractive enough for the *d*-tart ion to make such a contact with its *Λ* enantiomer against the accompanying steric repulsion imposed on the distal carboxylato group. In fact, the acidity of the amino protons should be much lower in the Ni(II) complex, because the central metal ion is divalent and the donation of the lone-pair electrons on the amino groups is less pronounced in the Ni(II) complex than in the low-spin Co(III) complex. Consequently, it is concluded that the contact modes with the *d*-tart ion are readily subjected to the steric demands of the composite ions in the Ni(II) complex salts, while the face-to-face contact is maintained at all costs in the Co(III) complex salts[7—10] where it leads to a substantial stabilization.

Finally, it seems noteworthy that the two "deformed" contact modes found in **2** are quite similar to those found earlier in the *Λ*-[Ni(en)$_3$]$_3$(*d*-tart)$_3$·4H$_2$O (**6**),[11] where each *d*-tart ion is sandwiched between the two triangular faces of the two *Λ* complex cations and it directs to the respective faces the two O atoms of one carboxylato group and one alcoholic O atom on the asymmetric carbon atom to which the other carboxylato group is attached, like in **2**, forming intimate hydrogen bonds to the H–N groups on them. In addition, each *d*-tart ion adopting these "deformed" contact modes in **2** also serves to connect directly the two complex cations in the same layer as it is in, through the two bifurcated hydrogen bonds (N1–H2··O2··H2–N6 and N4–H2··O5··H2–N5), as seen in II shown in Fig. 4, and similar roles are played by each *d*-tart ion in **6**. Consequently, it is fairly reasonable that the "deformed" contact modes are adopted in the Ni(II) complex salts when the face-to-face contact is prohibited by the steric repulsion, i.e., when the complex carries bulky substituents on the chelate rings and has a *Λ* configuration.

Kinetic Studies on the Quenching Reaction of the Photo-Excited $[Ru(bpy)_3]^{2+}$ with $[Co(edta)]^-$ in the Presence of EDTA, CDTA, and $C_2O_4^{2-}$

Suzuko YAMAZAKI-NISHIDA, Aiko NAGAI, Noriko MOURI, Satoko KAWASHIMA, and Masaru KIMURA*
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received February 5, 1991)

In the presence of a sacrificial donor (such as ethylenediaminetetraacetic acid, *trans*-1,2-cyclohexanediaminetetraacetic acid or oxalic acid in a deaerated aqueous solution) $[Co(edta)]^-$ is reduced to $[Co(edta)]^{2-}$ by quenching oxidatively the photo-excited $[Ru(bpy)_3]^{2+}$ ($[Ru(bpy)_3]^{2+*}$). The reduction rate for the $[Co(edta)]^-$ increases with an increase in the concentration of the sacrificial donor, and is kept constant at $[EDTA] \geqslant 0.03$ mol dm^{-3}, $[CDTA] \geqslant 0.01$ mol dm^{-3}, or $[C_2O_4^{2-}] \geqslant 0.07$ mol dm^{-3} at pH 4.6. The ratio $[[Co(edta)]^-]_{reacted}$: $[EDTA]_{reacted}$: $[[Co(edta)]^{2-}]_{formed} = 2:1:2$ is obtained at pH 5.2. The reaction rates were examined as a function of the concentrations of $[Co(edta)]^-$ and $[Ru(bpy)_3]^{2+}$ as well as the pH, ionic strength, and temperature of the solution, and the intensity of the incident light. In the presence of oxygen, the decrease of $[Co(edta)]^-$ is greatly suppressed and the formation of the hydrogen peroxide is appreciable. The reaction mechanism is presented in order to account for the obtained results.

Various redox reactions induced by $[Ru(bpy)_3]^{2+}$ (bpy= 2,2′-bipyridine) or $[Ru(bpz)_3]^{2+}$ (bpz=2,2-bipyrazine) as a photocatalyst, i.e., hydrogen evolution from water decomposition[1-8] or the reduction of carbon dioxide to methane,[9,10] have been studied from the viewpoint of the photochemical conversion of solar energy. One of the major problems in the utilization of these complexes is that the energy-saving electron-transfer reactions are accompanied by very efficient reverse electron-transfer steps which regenerate the starting materials. A simple technique most often used to prevent a reverse electron-transfer reaction is the addition of a sacrificial donor, such as ethylenediaminetetraacetic acid or triethanolamine, into the reaction system. In this paper, the effects of such sacrificial donors as EDTA,[11] CDTA,[11] and $C_2O_4^{2-}$ are discussed concerning the oxidative quenching of $[Ru(bpy)_3]^{2+*}$ with $[Co(edta)]^-$ in a deaerated aqueous solution.

Experimental

Chemicals. $[Ru(bpy)_3]Cl_2 \cdot 6H_2O$ and $K[Co(edta)] \cdot 2H_2O$ were prepared and purified as described in the literature.[12] Disodiumdihydrogenethylenediaminetetraacetate ($Na_2[H_2edta]$) and other chemicals were of guaranteed reagent grade and were used without further purification. A solution containing CDTA was prepared by dissolving in a sodium hydroxide solution. The pH of the solution was continuously adjusted with acetic acid and sodium acetate. Deionized water was further distilled both with and without the addition of permanganate in a glass still.

Procedures. The procedures are essentially the same as those described in a previous paper.[13] The $[Co(edta)]^-$ concentration was determined spectrophotometrically after removing the $[Ru(bpy)_3]^{2+}$ by adding a cation-exchange resine (1 g) (Dowex 50W-X8, 200-400 mesh, hydrogen form, washed well with distilled water) into the solution. The total concentration of the EDTA remaining and the $[Co(edta)]^{2-}$ formed in the sample solution was determined by polarography at +0.3 V vs. SCE in a solution comprised 0.05 mol dm^{-3} acetic acid, 0.05 mol dm^{-3} sodium acetate, and 0.01% gelatin at 25 °C under a nitrogen atmosphere. Polarography was performed in the dark without removing the $[Ru(bpy)_3]^{2+}$, since the cation-exchange resin adsorbs some part of the EDTA. The amount of carbon dioxide formed during the reaction was measured by a method reported previously.[14] The rate constant of the redox reaction between $[Ru(bpy)_3]^{3+}$ and EDTA, CDTA, or $C_2O_4^{2-}$ was determined with a Union RA-401 stopped-flow spectrophotometer. A solution of $[Ru(bpy)_3]^{3+}$ was prepared by oxidizing $[Ru(bpy)_3]^{2+}$ with lead dioxide (PbO_2) in 0.5 mol dm^{-3} sulfuric acid. After removing PbO_2 and $PbSO_4$ by filtration, the $[Ru(bpy)_3]^{3+}$ solution was used for the experiments.

Results and Discussion

Dependence of the Concentration of Sacrificial Donors. No appreciable formation of $[Co(edta)]^{2-}$ was observed in the quenching of $[Ru(bpy)_3]^{2+*}$ with $[Co(edta)]^-$ in the absence of sacrificial agents. However, $[Co(edta)]^-$ decreased remarkably to produce $[Co(edta)]^{2-}$ upon the addition of sacrificial donors in a deaerated aqueous solution. As Fig. 1 shows, the initial rates for a decrease in the $[Co(edta)]^-$ concentration (V_i) increase with an increase in the concentration of the sacrificial donors and are kept constant at $[EDTA] \geqslant 0.03$ mol dm^{-3}, $[CDTA] \geqslant 0.01$ mol dm^{-3}, or $[C_2O_4^{2-}] \geqslant 0.07$ mol dm^{-3}. This indicates that a reverse electron-transfer reaction between $[Ru(bpy)_3]^{3+}$ and $[Co(edta)]^{2-}$ competes with the reaction between $[Ru(bpy)_3]^{3+}$ and the sacrificial donor. It is noteworthy that the limiting rate with the excess EDTA is almost the same as that with CDTA, whereas is about 2 times as large as that with $C_2O_4^{2-}$. Otherwise (noted hereafter), the kinetic results observed with EDTA are presented in detail.

Stoichiometry. The stoichiometry of the reaction was examined in aqueous solutions containing 2×10^{-3} mol dm^{-3} $K[Co(edta)]$ and 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$ at pH 5.2 and 25 °C. The ratio of $[[Co(edta)]^-]_{reacted}$: $[EDTA]_{reacted}$: $[[Co(edta)]^{2-}]_{formed} = 2:1:2$ was always obtained, being independent of the initial EDTA con-

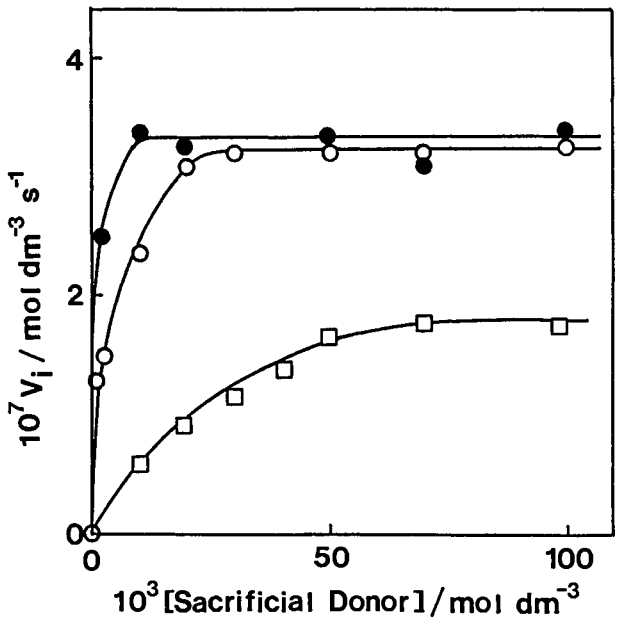

Fig. 1. Dependence of the V_i on the concentration of the EDTA (O), CDTA (●), or $C_2O_4^{2-}$ (□) in deaerated aqueous solutions containing 2×10^{-3} mol dm^{-3} K[Co(edta)] and 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$ at pH 4.6 and 25 °C. Irradiation was done with four lamps.

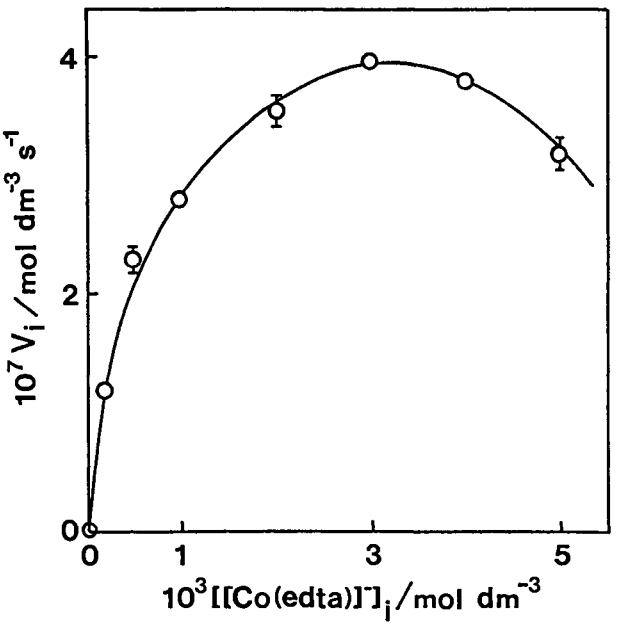

Fig. 2. Dependence of the V_i on the initial concentration of the $[Co(edta)]^-$. Conditions are the same as in Fig. 1 except for 0.05 mol dm^{-3} EDTA.

centration. Carbon dioxide was also formed in the solution; the amount produced per EDTA reacted was estimated to be 1.3—2.1. The concentration of $[Ru(bpy)_3]^{2+}$ was kept constant throughout the reaction. Thus, the stoichiometry of the photo-induced reaction can be expressed by

$$2[Co(edta)]^- + EDTA \rightarrow 2[Co(edta)]^{2-} + \text{products}(CO_2 \cdots). \quad (1)$$

Dependence of the $[Co(edta)]^-$ Concentration. Figure 2 indicates that V_i in the presence of 0.05 mol dm^{-3} EDTA increases with an increase in the initial concentrations of the $[Co(edta)]^-$ ($[[Co(edta)]^-]_i$), and has a maximum value at a $[Co(edta)]^-$ concentration of 3×10^{-3} mol dm^{-3}. A similar result was obtained with 0.05 mol dm^{-3} CDTA. Thus, the decrease of V_i at $[[Co(edta)]^-]_i > 3\times10^{-3}$ mol dm^{-3} is ascribed to an inner filter effect of $[Co(edta)]^-$ on the photoexcitation of $[Ru(bpy)_3]^{2+}$.

Effect of Light Intensity and the $[Ru(bpy)_3]^{2+}$ Concentration. The dependence of V_i on the incident light intensity was examined in an aqueous solution containing 0.05 mol dm^{-3} EDTA, 2×10^{-3} mol dm^{-3} K[Co(edta)], 5×10^{-5} mol dm^{-3} $[Ru(bpy)_3]Cl_2$, 0.05 mol dm^{-3} acetic acid and 0.05 mol dm^{-3} sodium acetate at 25 °C and pH 4.6. It was found that no appreciable formation of $[Co(edta)]^{2-}$ was observed in the dark and that V_i increased in proportion to the number of the lamps irradiated. The dependence of V_i on the $[Ru(bpy)_3]^{2+}$ concentration is presented in Fig. 3. With an increase

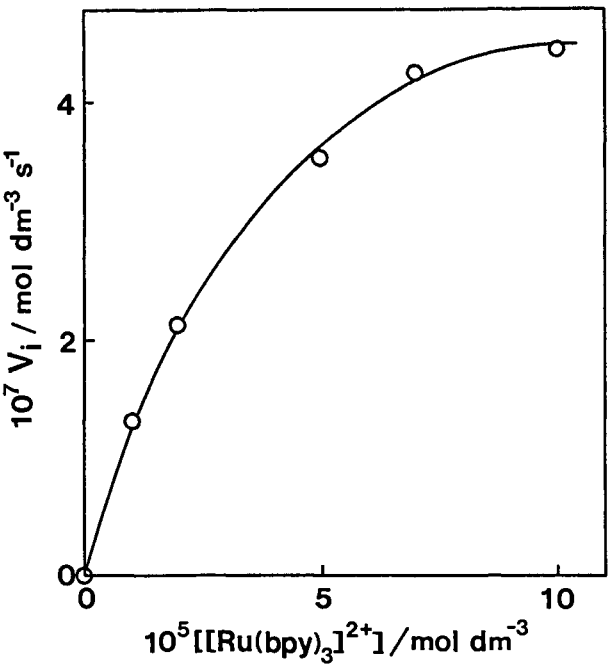

Fig. 3. Effect of the $[Ru(bpy)_3]^{2+}$ concentration. Conditions are the same as in Fig. 1 except for 0.02 mol dm^{-3} EDTA and pH 5.2.

in the $[Ru(bpy)_3]^{2+}$ concentration, V_i increases while approaching a limiting value. This finding as well as the linear relation between V_i and the incident light intensity suggests that V_i is proportional to the amount of light absorbed by $[Ru(bpy)_3]^{2+}$ (I_a), which is described by the Lambert-Beer equation:

$$I_a = I_0\{1 - \exp(-\alpha[[Ru(bpy)_3]^{2+}])\}. \quad (2)$$

Here, I_0 is the intensity of the incident light and α is a constant comprising an absorption coefficient and an optical path length.

Effect of pH. Figure 4 represents the pH effect on V_i, where the pH of the solution was adjusted with various concentrations of acetic acid and 0.05 mol dm^{-3} sodium acetate. In this paper, the term "EDTA" is used to designate all of the forms of that substance, irrespective of the protonation states.[11] As the pH increases, smaller amounts of EDTA were required for a limiting rate. It is worth noting that the V_i values under excess EDTA decrease with a decrease in pH.

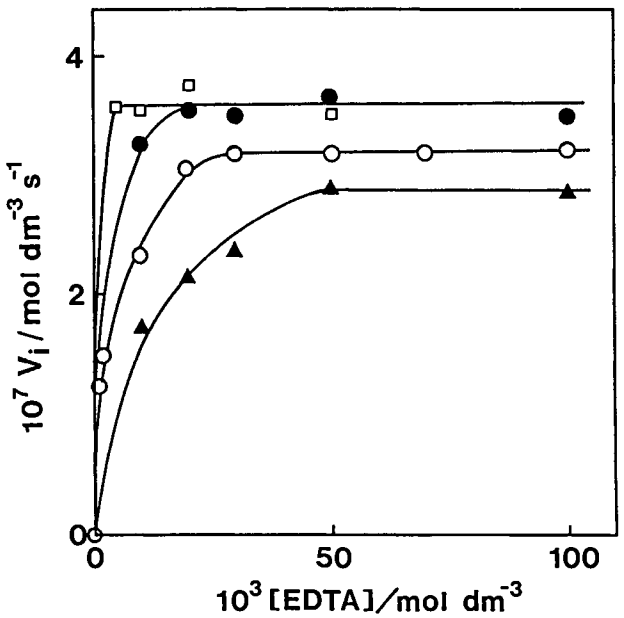

Fig. 4. Dependence of the V_i on the concentration of the EDTA at pH 6.0 (□), 5.2 (●), 4.6 (○), and 4.0 (▲). Other conditions are the same as in Fig. 1.

Effect of Ionic Strength and Temperature. The effect of the ionic strength or solution temperature is shown in Figs. 5 and 6. It was found that the reaction rate for the reduction of $[Co(edta)]^-$ decreased as the ionic strength of the solution increased. This is explainable in terms of a reaction between oppositly charged ions (Eq. 5). The rate of the reaction also increases slightly with an increase in the solution temperature.

Mechanism of Reaction. It has been reported that oxidized EDTA ($EDTA_{OX}^+$) is rapidly deprotonated to form a reducing radical (EDTA').[15–19] The stability of the EDTA' is dependent on the solution pH. In an acidic medium, EDTA' decomposes due to acid-catalyzed decarboxylation.[18,19] Glyoxylic acid, formaldehyde, and carbon dioxide were identified as being the final products for the oxidation of EDTA.[20,21] Based on the above, the following reaction mechanism is proposed to account for the obtained results:

$$[Ru(bpy)_3]^{2+} + h\nu \longrightarrow [Ru(bpy)_3]^{2+*} \quad (3)$$

$$[Ru(bpy)_3]^{2+*} \xrightarrow{k_0} [Ru(bpy)_3]^{2+} + h\nu' \text{ or } \Delta \text{ (thermal energy)} \quad (4)$$

$$[Ru(bpy)_3]^{2+*} + [Co(edta)]^- \xrightarrow{k_q} [Ru(bpy)_3]^{3+} + [Co(edta)]^{2-} \quad (5)$$

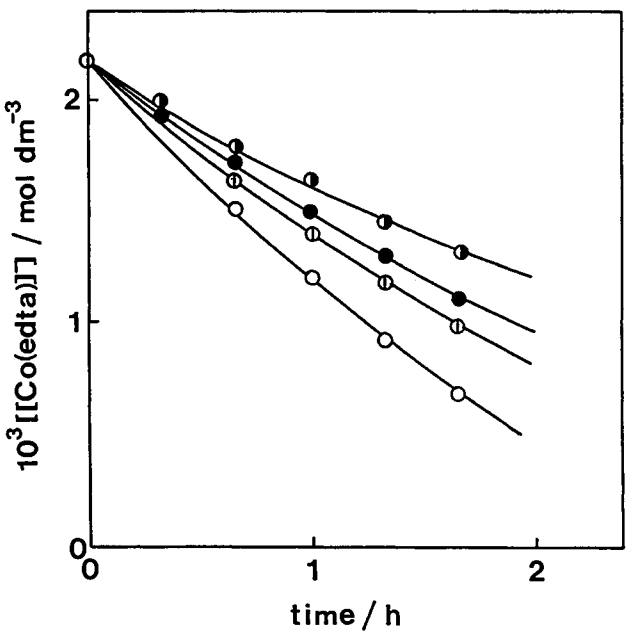

Fig. 5. Effect of the ionic strength. Conditions are the same as in Fig. 1 except for 0.02 mol dm^{-3} EDTA and various ionic strength of 0.2 (○), 0.4 (◑), 0.6 (●), and 1.0 mol dm^{-3} (◑).

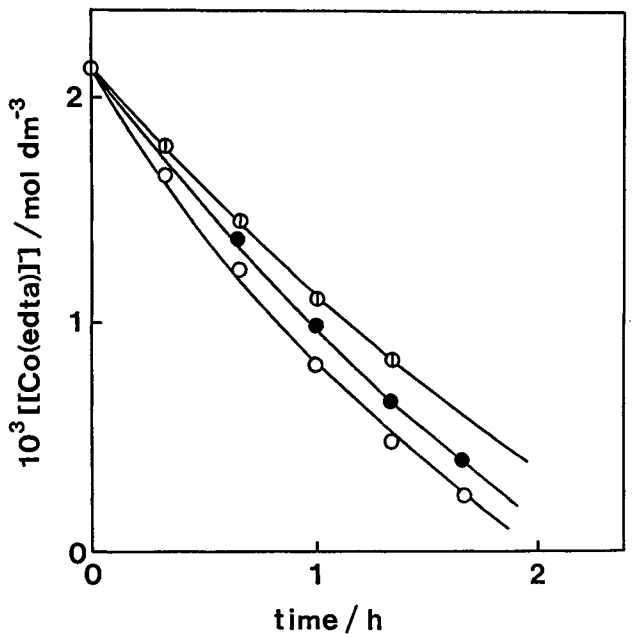

Fig. 6. Effect of temperature. Conditions are the same as in Fig. 1 except for 0.05 mol dm^{-3} EDTA, pH 5.2 and temperature of 5 °C (◑), 15 °C (●), or 25 °C (○).

$$[Ru(bpy)_3]^{3+} + [Co(edta)]^{2-} \xrightarrow{k_1} [Ru(bpy)_3]^{2+} + [Co(edta)]^{-} \quad (6)$$

$$[Ru(bpy)_3]^{3+} + EDTA \xrightarrow{k_2} [Ru(bpy)_3]^{2+} + EDTA_{ox}^{+} \quad (7)$$

$$EDTA_{ox}^{+} \xrightarrow{k_3} EDTA' + H^{+} \text{ (deprotonation)} \quad (8)$$

$$EDTA' + [Co(edta)]^{-} \xrightarrow{k_4} [Co(edta)]^{2-} + \text{products } (CO_2 \cdots) \quad (9)$$

$$EDTA' \xrightarrow{k_5} \text{products (acid-catalyzed decarboxylation).} \quad (10)$$

Assuming a steady state concentration of the $[Ru(bpy)_3]^{2+*}$, $[Ru(bpy)_3]^{3+}$, $EDTA_{ox}^{+}$ and EDTA', the reaction rate is expressed by

$$-\frac{d[[Co(edta)]^{-}]}{dt} = \frac{k_q I_a \Phi [[Co(edta)]^{-}]}{k_0 + k_q [[Co(edta)]^{-}]} \times \frac{(1+\gamma)k_2[EDTA]}{k_1[[Co(edta)]^{2-}] + k_2[EDTA]}, \quad (11)$$

where Φ is the quantum yield for the excited species $[Ru(bpy)_3]^{2+*}$; thus, $I_a\Phi$ corresponds to the formation rate of $[Ru(bpy)_3]^{2+*}$, and the γ value is defined as $k_4[EDTA'][[Co(edta)]^{-}]/\{k_4[EDTA'][[Co(edta)]^{-}] + k_5[EDTA']\}$ and is equal to unity if all of the EDTA' formed by reaction 8 reacts with $[Co(edta)]^{-}$. The second-order rate constant for reaction 6 has been estimated to be larger than $10^4\,dm^3\,mol^{-1}\,s^{-1}$. However, the reverse electron-transfer reaction between $[Ru(bpy)_3]^{3+}$ and $[Co(edta)]^{2-}$ in the solvent cage could take place quite rapidly, since no formation of $[Co(edta)]^{2-}$ was observed without adding a sacrificial donor.

In the presence of the excess EDTA, the relation $k_2[EDTA] \gg k_1[[Co(edta)]^{2-}]$ holds, and the reaction rate reduces to

$$-\frac{d[[Co(edta)]^{-}]}{dt} = \frac{(1+\gamma)k_q I_a \Phi [[Co(edta)]^{-}]}{k_0 + k_q [[Co(edta)]^{-}]}. \quad (12)$$

The obtained stoichiometry suggests that γ is equal to unity and that the decomposition of the EDTA' (Eq. 10) does not occur at pH 5.2. With a decrease in pH, γ decreases owing to reaction 10, and then the limiting rate observed at the excess EDTA decreases. Rate constant k_2 decreases with decreasing pH because of the protonation of EDTA. This is the reason why greater amounts of EDTA were required for the limiting rate at lower pH. Equation 12 indicates that the plot of V_i^{-1} vs. $[[Co(edta)]^{-}]_i^{-1}$ should be a straight line with an intercept of $1/\{(1+\gamma)I_a\Phi\}$ and an intercept/slope ratio of k_q/k_0. Figure 7 shows such a treatment of the data at $[[Co(edta)]^{-}]_i \leq 3\times10^{-3}$ mol dm^{-3} in Fig. 2. The values of $I_a\Phi$ and k_q/k_0 are calculated to be 2.4×10^{-7} mol dm^{-3} s^{-1} and 1.38×10^3 dm^3 mol^{-1}, respectively. The latter value is almost the same as that estimated separately from the Stern-Volmer plot in the quenching experiment under the same conditions. This fact indicates the validity of the reaction mechanism and the proposed rate law. The k_q value is estimated to be 2.1×10^9 dm^3 mol^{-1} s^{-1} using a k_0 value of 1.52×10^6 s^{-1}.[13] The small dependences of the reaction rate on the ionic strength and temperature suggest that both k_q and k_0 have a similar dependence on them.

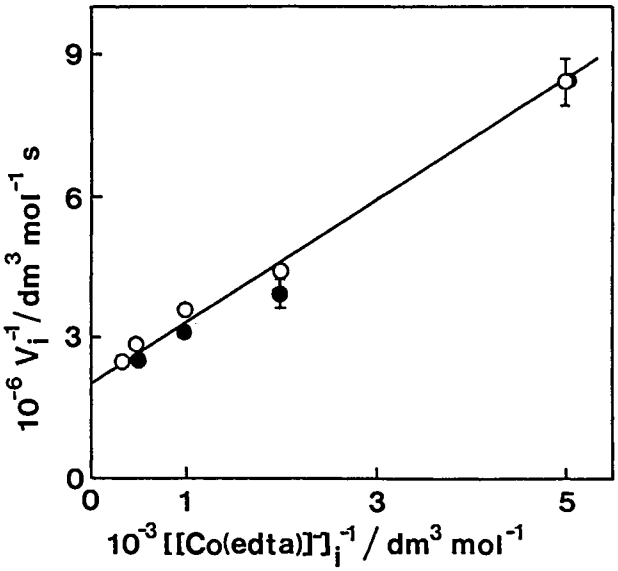

Fig. 7. Plots of V_i^{-1} vs. $[[Co(edta)]^{-}]_i^{-1}$. Conditions are the same as in Fig. 1 except for 0.05 mol dm^{-3} EDTA (○) or CDTA (●).

In the case of the CDTA or $C_2O_4^{2-}$ as a sacrificial donor, $[Ru(bpy)_3]^{3+}$ was reduced to $[Ru(bpy)_3]^{2+}$ according to the following reactions:

$$[Ru(bpy)_3]^{3+} + CDTA \xrightarrow{k_6} [Ru(bpy)_3]^{2+} + CDTA_{ox}^{+} \quad (13)$$

and

$$[Ru(bpy)_3]^{3+} + C_2O_4^{2-} \xrightarrow{k_7} [Ru(bpy)_3]^{2+} + C_2O_4^{-\cdot}. \quad (14)$$

The k_2, k_6, and k_7 were determined at pH 4.7 and 25 °C by the stopped-flow method to be 8.9×10^3, 1.7×10^4, and 1.7×10^5 dm^3 mol^{-1} s^{-1}, respectively. The reaction mechanism in the case of CDTA is supposed to be similar to that with EDTA, since the results obtained in the both systems were almost the same (Fig. 7). Smaller amounts of CDTA were required to be a limiting rate. This finding can be reasonably explained in terms of the k_2 and k_6 values. On the contrary, the dependence of V_i on the $C_2O_4^{2-}$ concentration is different from that with EDTA or CDTA, as shown in Fig. 1. This might be due to a difference in the reactivity of the reducing radicals like EDTA' and $CO_2^{-\cdot}$, since the oxidized form of $C_2O_4^{2-}$ is known to decompose promptly to $CO_2^{-\cdot}$ and CO_2. If the $CO_2^{-\cdot}$ radical is consumed by a reaction with $[Ru(bpy)_3]^{3+}$ (E°=1.26 V vs. NHE[1]), being not with $[Co(edta)]^{-}$ (E°=0.37 V vs. NHE[22]), the reaction rate is derived as Eq. 16.

$$[Ru(bpy)_3]^{3+} + CO_2^{-\cdot} \longrightarrow [Ru(bpy)_3]^{2+} + CO_2 \quad (15)$$

$$-\frac{d[[Co(edta)]^-]}{dt}=\frac{k_q I_a \Phi[[Co(edta)]^-]}{k_0+k_q[[Co(edta)]^-]}\times\frac{2k_7[C_2O_4^{2-}]}{k_1[[Co(edta)]^{2-}]+2k_7[C_2O_4^{2-}]}. \quad (16)$$

A comparison of Eq. 16 to Eq. 11 at $\gamma=1$ indicates that the limiting rate in the case of excess $C_2O_4^{2-}$ is about half that with EDTA. This is consistent with the result shown in Fig. 1. The analogous reaction to Eq. 15, i.e., the reaction between EDTA' and $[Ru(bpy)_3]^{3+}$ is also supposed to proceed. However, $[Ru(bpy)_3]^{3+}$ is reduced predominantly by EDTA since the EDTA' radical reacts with $[Co(edta)]^-$ (Eq. 9). The finding that a $C_2O_4^{2-}$ concentration greater than 0.07 mol dm^{-3} is needed to reach a limiting rate is not understandable, since the k_7 value is much greater than k_2 and k_6. This might be attributable to an interaction between $[Ru(bpy)_3]^{3+}$ and EDTA or CDTA. The equilibrium constant between $[Ru(bpy)_3]^{3+}$ and EDTA ions has been reported to be greater than 78 dm^3 mol^{-1}.[18]

The decrease rate of $[Co(edta)]^-$ is remarkably reduced in the presence of oxygen, with hydrogen peroxide being formed. The results obtained with EDTA as a sacrificial donor are presented in Fig. 8. The oxidative quenching of $[Ru(bpy)_3]^{2+*}$ with oxygen has been reported to be 5.5×10^9 dm^3 mol^{-1} s^{-1}.[23] This indicates that the quenching rate with oxygen is comparable to that with $[Co(edta)]^-$ in aqueous solutions saturated with oxygen. Therefore, the $[Co(edta)]^{2-}$ produced by the quenching reaction is supposed to be reoxidized to $[Co(edta)]^-$ (Eq. 21). In fact, the formation of $[Co(edta)]^-$ was observed upon the addition of $[Co(edta)]^{2-}$, instead of $[Co(edta)]^-$, into the solution.

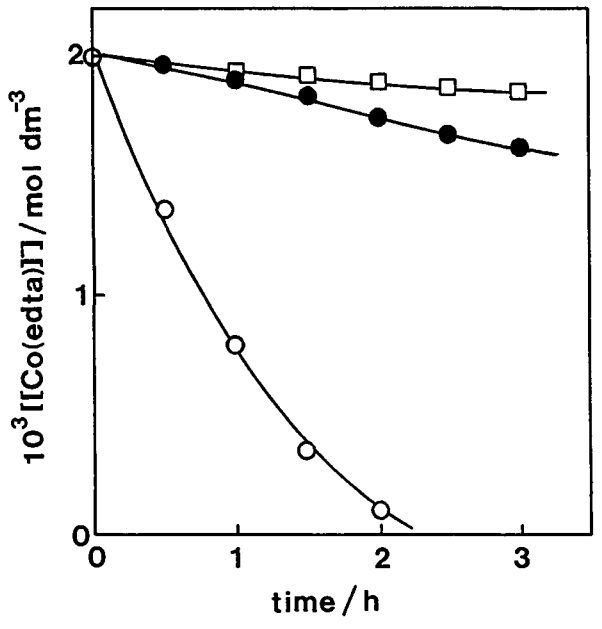

Fig. 8. Effect of oxygen. Conditions are the same as in Fig. 1 except for 0.01 mol dm^{-3} EDTA at pH 5.2 in an aqueous solution saturated with O_2 (□), air (●), or N_2 (○).

$$[Ru(bpy)_3]^{2+*}+O_2\longrightarrow[Ru(bpy)_3]^{3+}+O_2^{\cdot-} \quad (17)$$

$$O_2^{\cdot-}+H^+\rightleftarrows HO_2^{\cdot} \quad (18)$$

$$[Ru(bpy)_3]^{3+}+HO_2^{\cdot}\longrightarrow[Ru(bpy)_3]^{2+}+O_2+H^+ \quad (19)$$

$$HO_2^{\cdot}+EDTA'+H^+\longrightarrow H_2O_2+\text{products} \quad (20)$$

$$[Co(edta)]^{2-}+HO_2^{\cdot}+H^+\longrightarrow[Co(edta)]^-+H_2O_2. \quad (21)$$

The drastic retardation effect of oxygen is obviously due to reactions 19—21.

Kinetics and Mechanisms of Photo-Induced Reduction of Iodine by Diamine-*N*-polycarboxylate Ions in an Aqueous Solution

Masaru KIMURA,* Akiko OHOMURA, Fumiko NAKAZAWA, and Keiichi TSUKAHARA*
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received February 5, 1991)

Although the reduction of iodine by diamine-*N*-polycarboxylate ions such as ethylenediaminetetraacetic acid, *trans*-1,2-cyclohexanediaminetetraacetic acid, *N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetic acid, and ethylenediamine-*N,N'*-diacetic acid was negligible in the dark, it occurred greatly upon irradiation with visible light of an aqueous solution over the pH range 4—8. The rate of the photo-sensitized reaction was of half-order regarding both the light intensity irradiated and the concentrations of iodine, which correspond to those of the triiodide ion in the presence of excess iodide ions, and was proportional to the concentration of the diamine-*N*-polycarboxylate ion. Further, the rate was of half-order for concentrations of I^- below 3×10^{-4} mol dm^{-3} and was of inversely half-order for concentrations of I^- above 6×10^{-4} mol dm^{-3}. The reaction was inhibited by radical scavengers of acrylonitrile, acrylamide, and hexaamminecobalt(III) ions. Both hydrogen ion and complex-forming metal ions, such as copper(II) and zinc(II), are also strong inhibitors of the reaction. The reaction mechanism, where initiation reaction is a photo-dissociation of iodine and the reactive species is a $I_2^{\cdot-}$ radical anion, is proposed to account for the obtained results.

Previously, the photo-chemical reaction between ethylenediaminetetraacetic acid (H_4edta) and iodine (I_2) was used for the analytical chemistry determination of trace amounts of the nitrite ion.[1] The photoreduction mechanism of iodine by amine-*N*-polycarboxylic acid has been proposed based on an initial photodissociation of iodine to iodine atoms followed by chain propagation.[2] In the absence of iodide ions an induction period is present in the photoreduction of iodine by ethylenediaminetetraacetic acid; the reaction occurs with the production of I^- ions.[1,2] When high concentrations of I^- ions were used, the reduction of iodine by oxalate ions was inhibited by I^- ions.[3] Such an effect of the I^- ions on the reduction of iodine cannot be explained by the above proposed mechanism. We have reported that, under the condition that $[I_2]\ll[I^-]$, a full kinetic treatment is possible for a photo-induced reduction of iodine by oxalate ions by monitoring the decay of I_3^-.[3] To clarify the mechanisms of the oxidation of amine-*N*-polycarboxylate ions and of the reduction of iodine, we report in this study on the photo-induced reduction of iodine by amine-*N*-polycarboxylate ions in the presence of the I^- ion.

Experimental

Chemicals. Iodine, potassium iodide, Na_2H_2edta,[4] H_4cdta (=*trans*-1,2-cyclohexanediaminetetraacetic acid),[4] H_3hedta (=*N*-(2-hydroxyethyl)ethylenediamine-*N,N',N'*-triacetic acid),[4] H_2edda (=ethylenediamine-*N,N'*-diacetic acid),[4] and the other chemicals used were of guaranteed reagent grade from Wako Pure Chemical Industries, Ltd. All of the solutions were prepared from redistilled water. The pH's of the solutions were adjusted with an acetate buffer (pH 3.5—6.5), a phosphate buffer (pH 6.5—8), and sulfuric acid (below pH 3.5). No effect of anions in the buffers was observed on the kinetic results.

Procedure. The kinetic measurements employed were the same as those in the method reported previously.[3] Each sample solution was continuously irradiated with visible light from two 100-W tungsten lamps. Aliquot samples were withdrawn at appropriate time intervals after starting the reaction; the absorbance at 350 nm due to I_3^- (ε 2.5×10^4 dm^3 mol^{-1} cm^{-1})[3] was measured by Shimadzu UV-200S and UV-150-02 spectrophotometers. All of the kinetic runs were followed under the condition that the iodide ions had at least a 50-fold excess over iodine. When solutions prepared from nitrogen-saturated water were used, the kinetic results were the same as those in air-saturated solutions. Thus, all of the kinetic measurements were carried out in air-saturated solutions. The temperature was controlled within 0.1 °C. The light intensity was determined using potassium tris(oxalato)ferrate(III) trihydrate as an actinometer.[5] The iron(II) content was determined spectrophotometrically in the form of tris(1,10-phenanthroline)iron(II) ions at 510 nm with a molar absorption coefficient of 1.1×10^4 dm^3 mol^{-1} cm^{-1}.

Results and Discussion

Although the redox reaction between iodine and diamine-*N*-polycarboxylic acid was practically negligible in the dark, it occurred greatly upon irradiation with visible light of the aqueous solutions over the pH range 4—8. Iodine was rapidly converted to I_3^- in the presence of I^-:[6,7]

$$I_2 + I^- \rightleftarrows I_3^-, \quad (1)$$

where $k_f=5.6\times10^9$ dm^3 mol^{-1} s^{-1} and $K_1=7.1\times10^2$ dm^3 mol^{-1}. The absorbance of I_3^- at 350 nm, where the absorbance due to I_2 was quite negligible, was used as a monitor for the kinetic measurements in the present study. A half-order plot for the reaction based on Eq. 2 was linear up to almost completion of the reaction (Fig. 1):

$$A_t^{1/2} - A_0^{1/2} = -(1/2)(\varepsilon l)^{1/2} k_{obsd} t, \quad (2)$$

where A_0 and A_t represent the absorbance at zero time and t, respectively, ε is the molar absorption coefficient of I_3^- at 350 nm, and l is the optical path length to be 1

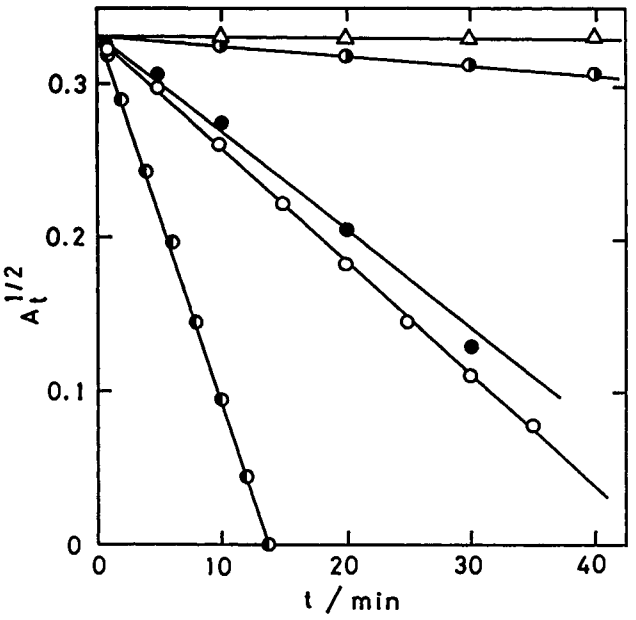

Fig. 1. The half-order plots of $A_t^{1/2}$ vs. t for the photoreaction of iodine with diamine-*N*-polycarboxylate ions and ethylenediamine. $[I_2]=1.0\times10^{-5}$ mol dm^{-3}, $[I^-]_0=1.0\times10^{-3}$, mol dm^{-3}, [diamine-*N*-polycarboxylate]$_0=1.0\times10^{-4}$ mol dm^{-3}, and $I_0=1.41\times10^{-7}$ mol dm^{-3} s^{-1} at 25 °C and pH 4.62 (a 0.1 mol dm^{-3} acetate buffer). ○: EDTA, ●: CDTA, ◐; HEDTA, ◑: EDDA, and △: ethylenediamine.

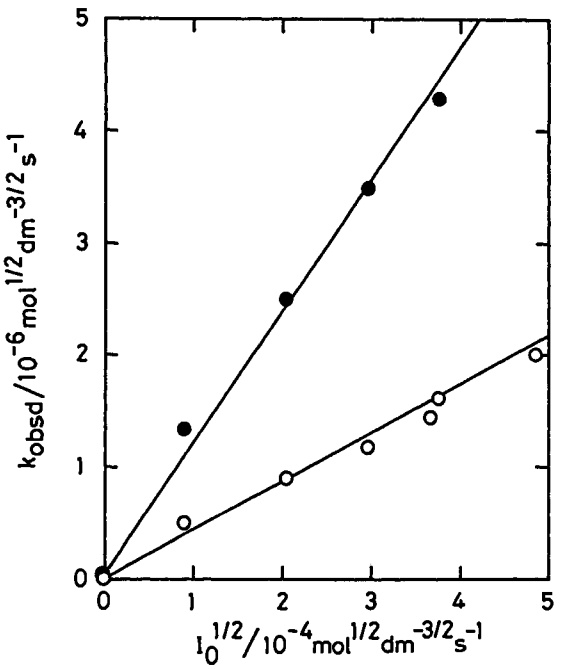

Fig. 2. Plots of k_{obsd} vs. $I_0^{1/2}$ for the photoreaction of iodine with EDTA. ○: $[EDTA]_0=1.0\times10^{-4}$ mol dm^{-3} at pH 4.62 (a 0.1 mol dm^{-3} acetate buffer) and ●: $[EDTA]_0=1.0\times10^{-5}$ mol dm^{-3} at pH 8.6 (a 0.1 mol dm^{-3} phosphate buffer). Other conditions are the same as in Fig. 1.

cm in the present study. Thus, the rate law is described as in Eq. 3:

$$-d[I_3^-]/dt = k_{obsd}[I_3^-]^{1/2}. \quad (3)$$

Effect of Light Intensity. The observed rate constant (k_{obsd}) increased with an increase in the light intensity irradiated (I_0) and plots of k_{obsd} vs. $I_0^{1/2}$ were rectilinear with zero intercept (Fig. 2). These results show that the reacting species is either I· or/and $I_2^{\cdot-}$ dissociated by light irradiation of the I_2 molecule.[3] The latter species is produced successively by a reaction between I· and I^-:

$$I_2 \overset{h\nu}{\rightleftarrows} 2I\cdot \quad [k_{-4}=8\times10^9 \text{ dm}^3\text{ mol}^{-1}\text{ s}^{-1}],^{8)} \quad (4)$$

$$I\cdot + I^- \rightleftarrows I_2^{\cdot-} \quad [K_5=1.1\times10^4 \text{ dm}^3\text{ mol}^{-1}].^{9,10)} \quad (5)$$

Concentration Dependence of Diamine-*N*-polycarboxylate. The rate of photoreduction of iodine increased proportionally to the concentrations of the diamine-*N*-polycarboxylate ions. Plots of k_{obsd} vs. the initial concentrations of EDTA ([EDTA]$_0$) are shown in Fig. 3. This fact indicates that the reaction of I· or $I_2^{\cdot-}$ with EDTA is rate determining.

Effect of the Iodide Ion Concentration. The rate of the reaction increased with increasing the concentrations of I^- ions up to about 4×10^{-4} mol dm^{-3} and then decreased (Fig. 4). This fact, together with the observation of a half-order dependence of $[I_3^-]$ on the rate, shows that the reaction of I· is negligible and that the reactive species is $I_2^{\cdot-}$, since the reaction in the absence of

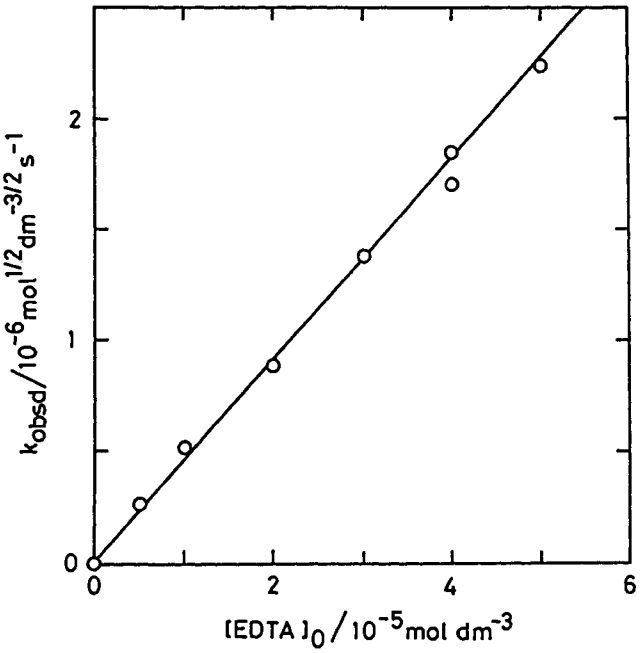

Fig. 3. Plots of k_{obsd} vs. $[EDTA]_0$ for the photoreaction of iodine with EDTA at 35 °C. Other conditions are the same as in Fig. 1.

I^- is very slow.

pH Dependence. The photoreduction of iodine by diamine-*N*-polycarboxylate ions was very slow at any pH less than 2. The reaction rate increased markedly

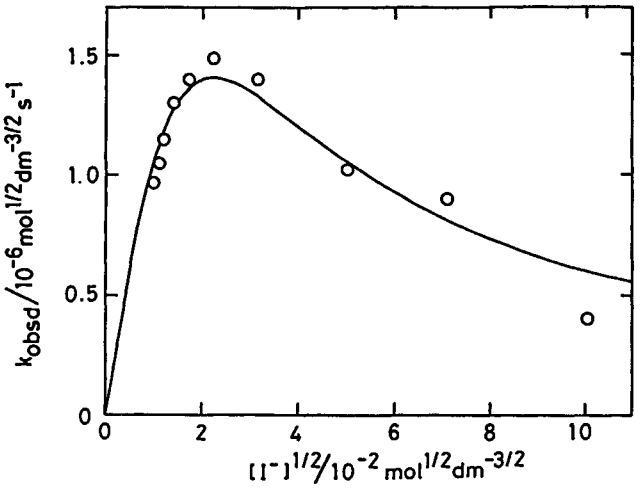

Fig. 4. Plots of k_{obsd} vs. $[I^-]_0^{1/2}$ for the photoreaction of iodine with EDTA. Conditions are the same as in Fig. 1.

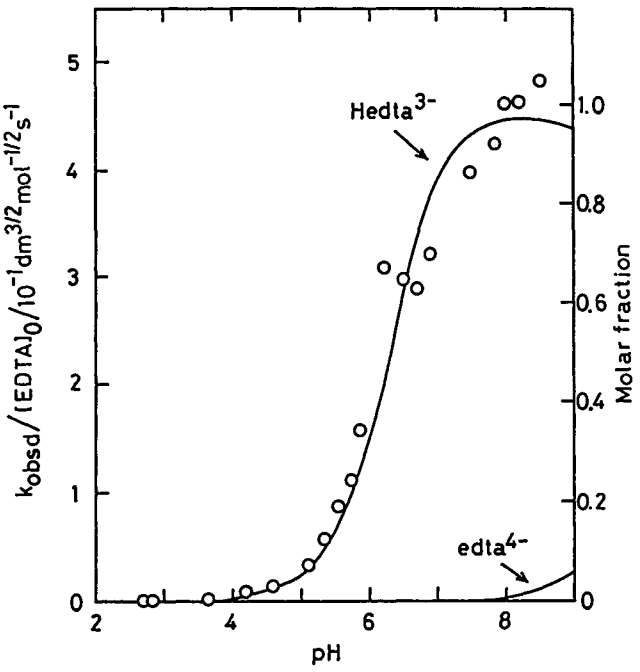

Fig. 5. Plots of k_{obsd} vs. pH for the photoreaction of iodine with EDTA and the molar fraction curve (the solid lines) for $Hedta^{3-}$ and $edta^{4-}$ against pH as indicated. Conditions are the same as in Fig. 1.

with increasing pH at 5—8. Such a pH-dependent curve for the reaction rate superimposes the molar fraction curve for the species $Hedta^{3-}$ (Fig. 5). Thus, the species of $Hedta^{3-}$ could be a main reductant for the radical $I_2^{\cdot-}$ and the other protonated species H_2edta^{2-}, H_3edta^-, and H_4edta would be quite inactive. The species of $edta^{4-}$ may be more reactive than the $Hedta^{3-}$ ion, but the $edta^{4-}$ ion is negligible below pH 8 (see Fig. 5). Consequently, the following equation can be assumed:

Table 1. Effect of Radical Scavengers for the Photoreaction of Iodine with EDTA at 1.0×10^{-4} mol dm^{-3}. Other Conditions are the Same as in Fig. 1

[Scavenger]/mol dm^{-3}	$k_{obsd}/10^{-6}$ mol$^{1/2}$ dm$^{-3/2}$ s^{-1}

2.0×10^{-4}	0.89
5.0×10^{-4}	0.64
1.0×10^{-3}	0.52

$$k_{obsd} = k[Hedta^{3-}] = k[EDTA]_0/\alpha_{HY}, \quad (6)$$

where α_{HY} is a side reaction coefficient $(1+K_{a4}/[H^+]+[H^+]/K_{a3}+[H^+]^2/K_{a2}K_{a3}+[H^+]^3/K_{a1}K_{a2}K_{a3})$ and K_{a1}, K_{a2}, K_{a3}, and K_{a4} are stepwise acid-dissociation constants of H_4edta ($pK_{a1}=2.07$, $pK_{a2}=2.75$, $pK_{a3}=6.24$, and $pK_{a4}=10.34$ at 25 °C and $I=0.1$ mol dm^{-3}).[11]

For the EDDA system the values of $k_{obsd}/[EDDA]_0$ at pH 4.62, 5.60, 6.49, and 7.20 were 1.35×10^{-3}, 6.11×10^{-3}, 2.13×10^{-2}, and 1.00×10^{-1} dm$^{3/2}$ mol$^{-1/2}$ s^{-1}, respectively. These data did not fit to the molar fraction curve for the only $Hedda^-$ species at higher pH, being different from the EDTA system. The reason is discussed later.

Effect of Radical Scavenger. The addition of a radical scavenger, acrylonitrile or acrylamide, into the reaction solution decreased the photoreduction rate of iodine. The value of k_{obsd} in the presence of 1.0—1.5% of the radical scavenger reached about half value in the absence of a radical scavenger (Table 1). In the presence of a radical scavenger and in the absence of EDTA, the absorbance of I_3^- did not decrease appreciably. Thus, it is assumed that the acrylonitrile or acrylamide monomer does not react with I_3^-, I_2, $I^{\cdot}$, and $I_2^{\cdot-}$, but reacts with the photo-oxidizing products of EDTA. Considering that the decrease in k_{obsd} is dependent on the amounts of the radical scavenger, it is also likely that the photo-oxidizing products of EDTA are able to reduce I_2 and/or I_3^-, competing with the radical scavenger.

It is found that a hexaamminecobalt(III) ion ($[Co(NH_3)_6]^{3+}$) also decreases the rate of the reaction, and that the value of k_{obsd} reaches about half in the absence of $[Co(NH_3)_6]^{3+}$ ions (Table 1). Without amine-*N*-polycarboxylate ions the photoreaction did not occur at pH 4—8, suggesting that the $[Co(NH_3)_6]^{3+}$ ions are quite inactive to the reducing radical anion $I_2^{\cdot-}$. This is reasonable on the basis of the redox potentials for these species:[12,13] $E^0([Co(NH_3)_6]^{3+/2+})=0.06$ V and $E^0(I_2/I_2^{\cdot-})=0.21$ V.

Temperature Dependence. The temperature dependence on the rate was examined under the same condi-

Table 2. Temperature Dependence on the Observed Rate Constant (k_{obsd}) for the Photoreaction of Iodine with EDTA at 4.0×10^{-5} mol dm^{-3}. Other Conditions are the Same as in Fig. 1

Temp/°C	k_{obsd}/ 10^{-6} mol$^{1/2}$ dm$^{-3/2}$ s^{-1}
10.0	0.14
15.0	0.25
25.0	0.72
30.0	1.10
35.0	1.77

tions as are shown in Fig. 1, except for $[EDTA]_0=4.0\times10^{-5}$ mol dm^{-3} with various temperatures over 10—35 °C. The results are given in Table 2. The enthalpy and entropy changes of activation were determined from the plots of $\log(k_{obsd}/T)$ vs. T^{-1} ($\Delta H^{\ddagger}=72.1\pm3.6$ kJ mol^{-1} and $\Delta S^{\ddagger}=-121\pm10$ J K^{-1} mol^{-1}).

Mechanism of Reaction. The obtained results are well accounted for by the following mechanism after Reactions 1, 4, and 5 occurred:

$$I_2^{\cdot-}+Y\xrightarrow{k_7}2I^-+Y^{\ddagger} \quad (7)$$

and

$$I_2\ (\text{or } I_3^-)+Y^{\ddagger}\xrightarrow{\text{fast}}\text{products}, \quad (8)$$

where Y represents the amine-*N*-polycarboxylate ions. Assuming a steady-state concentration for I·,

$$I_a\phi+k_{-5}[I_2^{\cdot-}]-k_{-4}[I^{\cdot}]^2-k_5[I^{\cdot}][I^-]=0, \quad (9)$$

where I_a and ϕ are the light intensity absorbed and quantum yield, respectively. Under equilibrium conditions of $k_{-5}[I_2^{\cdot-}]=k_5[I^-][I^{\cdot}]$,

$$[I^{\cdot}]=(I_a\phi/k_{-4})^{1/2}. \quad (10)$$

Under an excess concentration of I^-, $[I^{\cdot}]=[I_2^{\cdot-}]$, where

$$[I_2^{\cdot-}]=(I_a\phi/k_{-4})^{1/2}. \quad (11)$$

Under the condition $[I^{\cdot}]_{total}=[I^{\cdot}]+[I_2^{\cdot-}]$,

$$[I_2^{\cdot-}]=\frac{[I^{\cdot}]_{total}K_5[I^-]}{1+K_5[I^-]} \quad (12)$$

and

$$[I_2^{\cdot-}]=\left(\frac{I_a\phi}{k_{-4}}\right)^{1/2}\left(\frac{K_5[I^-]}{1+K_5[I^-]}\right). \quad (13)$$

Therefore, the following rate law can be derived:

$$-\frac{d[I_3^-]}{dt}=\frac{k_7}{2}\left(\frac{I_a\phi}{k_{-4}}\right)^{1/2}\left(\frac{K_5[I^-]}{1+K_5[I^-]}\right)[Y]. \quad (14)$$

From Lambert-Beer's law I_a correlates to an incident light intensity (I_0) with iodine concentrations of

$$I_a=I_0[1-\exp(-\alpha[I_2])], \quad (15)$$

where α is a constant containing an absorption coefficient and an optical path length. Under the condition $\alpha[I_2]<0.1$ employed in this study, Eq. 15 can be simplified to

$$I_a=I_0\alpha[I_2]. \quad (16)$$

Therefore, Eq. 14 can be represented as

$$-\frac{d[I_3^-]}{dt}=\frac{k_7}{2}\left(\frac{I_0\alpha\phi}{k_{-4}K_1}\right)^{1/2}\left(\frac{[I_3^-]}{[I^-]}\right)^{1/2}\left(\frac{K_5[I^-]}{1+K_5[I^-]}\right)[Y], \quad (17)$$

$$k_{obsd}=\frac{k_7}{2}\left(\frac{I_0\alpha\phi}{k_{-4}K_1}\right)^{1/2}\left(\frac{K_5[I^-]^{1/2}}{1+K_5[I^-]}\right)[Y], \quad (18)$$

The values of α and k_7 could not be obtained in this work, although the values of ϕ and k_{-4} are known ($\phi=0.11$—0.83 and $k_{-4}=8\times10^9$ dm^3 mol^{-1} s^{-1}).

The following reaction for the initial photoreaction is also possible:[9]

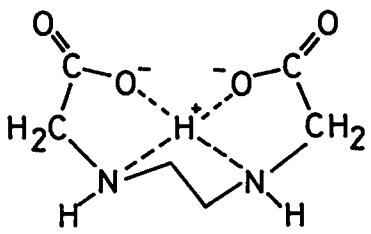
$$I_3^-\overset{h\nu}{\rightleftharpoons}I_2^{\cdot-}+I^{\cdot}. \quad (19)$$

The results at low concentrations of I^-, where the rate is dependent on $[I^-]^{1/2}$, could be well accounted for by Reaction 19. The solid curve in Fig. 4 was calculated by using $K_5=2\times10^3$ dm^3 mol^{-1} and $k_7(\alpha\phi)^{1/2}=8.0\times10^6$ dm$^{9/2}$ mol$^{-3/2}$ s^{-1}. The estimated value for K_5 is smaller than that reported previously.[9,10] This may be attributable to the different experimental conditions or to the contribution of the bimolecular decay of the $I_2^{\cdot-}$ ions:

$$2I_2^{\cdot-}\longrightarrow I_3^-+I^- \quad [k_{20}=4.5\times10^9\ \text{dm}^3\ \text{mol}^{-1}\ \text{s}^{-1}].[15] \quad (20)$$

The reaction of I· with EDTA and other diamine-*N*-polycarboxylate ions must be neglected on the basis of the $[I^-]$ dependence.

Effect of Diamine-*N*-polycarboxylate. The pH dependence on the reaction rate of EDTA indicates that at least one proton-free nitrogen in the molecule is required for the reduction of the radical species, $I_2^{\cdot-}$, and that the lone electron-pair on the nitrogen atom is available for electron transfer to the $I_2^{\cdot-}$ radical anion. The rate constants ($k_{obsd}/[\text{amine-}N\text{-polycarboxylate}]_0$) under completely same conditions were 1.35×10^{-3}, 1.30×10^{-2}, 1.45×10^{-2}, and 4.90×10^{-2} dm$^{3/2}$ mol$^{-1/2}$ s^{-1} at pH 4.62 for EDDA, CDTA, EDTA, and HEDTA, respectively. The trend in reactivity, EDDA$\ll$CDTA$\approx$EDTA$<$HEDTA, is the same as that for the acid-dissociation constants of these amine-*N*-polycarboxylate ions,[11] H_2edda ($pK_{a1}=6.48$)$<H_4$cdta ($pK_{a3}=6.20$)$\approx H_4$edta ($pK_{a3}=6.24$)$<H_3$hedta ($pK_{a2}=5.41$), respectively; it is noted that the EDDA system is exceptionally slow. Under the same conditions as in Fig. 1 (but at pH 7.2), the rate for EDDA increased to 70-fold in $k_{obsd}/[EDDA]_0$ (1.00×10^{-1} dm$^{3/2}$ mol$^{-1/2}$ s^{-1}). This suggests that edda^{2-} is more reactive than Hedda$^-$, the latter being less reactive than Hedta^{3-}. Chapman et al.[16] demonstrated from IR and NMR studies of Hedta^{3-} in an aqueous solution that two of the carboxylate groups of Hedta^{3-} are hydrogen-bonded to one N^+H and that the other two are free. Therefore, the free nitrogen may be reactive with $I_2^{\cdot-}$ in the Hedta^{3-} ion. The inactivity of the species, Hedda$^-$, may arise from the fact that both carboxylate groups of Hedda$^-$ are possible to be hydrogen-bonded to N^+H in solutions.



Hedda^{-}

Effect of Metal Ion. In order to confirm the importance of the lone electron-pair on the amino groups in amine-*N*-polycarboxylate ions mentioned above, we examined the effect of metal ions and found that those which were able to form chelate compounds with the diamine-*N*-polycarboxylate ions, greatly inhibited the photoreduction of iodine. The rate law of Eq. 3 was always satisfied for the coexistence of any metal ions employed. Plots of k_{obsd} vs. $[M^{2+}]_0/[EDTA]_0$ are given in Fig. 6. Strong complex-forming ions, such as copper(II) and zinc(II), inhibit quantitatively, while relatively weak complex-forming ions, such as magnesium(II) and calcium(II), can not greatly inhibit the photoreduction of iodine at pH 4.62. For example, even in a 10^3-fold excess of magnesium over EDTA, the decrease in k_{obsd} was only 20% of that in the absence of the metal ion. The trend regarding the inhibitory effect on the rate at pH 4.62 is $Mg^{2+}<Ca^{2+}\ll Zn^{2+}\approx Cu^{2+}$, the order of which is the same as that of the stability constants of the chelate complex $[M(edta)]^{2-}$; the values of $\log K_{M(edta)}$ at 25 °C and I=0.1 mol dm^{-3} are 8.7, 10.6, 16.4, and 18.7 for Mg^{2+}, Ca^{2+}, Zn^{2+}, and Cu^{2+}, respectively.[10] The results in Fig. 6 indicate that the chelated metal(II) ions cannot reduce any radicals of $I_2^{\cdot-}$ and I$^{\cdot}$ in the case of Cu(II) and Zn(II) ions. Lati and Meyerstein[17] have reported that $[Cu(edta)]^{2-}$ did not react with the $I_2^{\cdot-}$ produced by electron pulse radiolysis. Therefore, the lone electron pair on the nitrogen atom must play an important role in the oxidation and fragmentation of any amine-*N*-polycarboxylate ions.

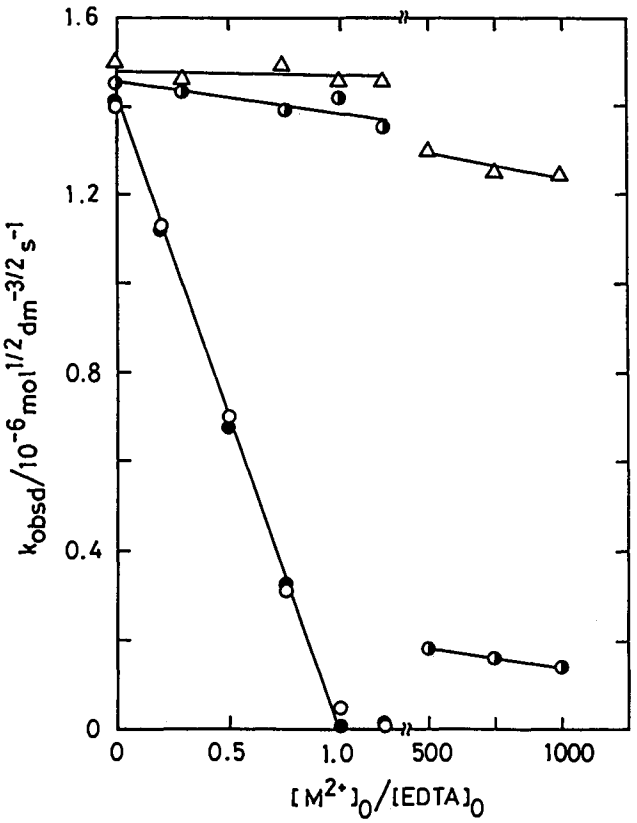


Fig. 6. Plots of k_{obsd} vs. $[M^{2+}]_0/[EDTA]_0$ for the photoreaction of iodine with EDTA. Conditions are the same as in Fig. 1. ○: Cu^{2+}, ●: Zn^{2+}, ◑; Ca^{2+}, and △: Mg^{2+} for M^{2+} ions.

The fragmentation of EDTA in thermal reactions is complicated and the reaction mechanism is still unclear. It has been reported that CO_2 and HCHO are detected as products.[18] We found CO_2 as one of the products in the photoreduction of iodine by EDTA, and also examined the stoichiometry of the reaction. Under the condition $[I_2]\gg[EDTA]_0$, the stoichiometry was not 1 : 1; more than one mole of I_2 was consumed against EDTA. An accurate stoichiometric number could not be determined, but seemed to certainly be dependent on the pH of the reacting solution. Since ethylenediamine was completely inactive under the present experimental conditions (see Fig. 1), fragmentation must occur at acetate arms of EDTA. An ESR study by Poupko et al.[19] has shown that the hydrogen abstraction from EDTA occurs at the acetate carbon atom adjacent to nitrogen atom. Under the condition $[EDTA]_0\gg[I_2]$, which was employed in the present study, fragmentation might have occurred at one acetate group. The effect of radical scavengers of acrylonitrile or $[Co(NH_3)_6]^{3+}$ for the photooxidation of EDTA is completely different from that for the oxalate system studied previously,[3] the latter having a $CO_2^{\cdot-}$ radical anion as an intermediate. This fact suggests that the intermediate radical species is not a free $CO_2^{\cdot-}$ in Reaction 7, but that the radical ion $Y^{\dagger}$ still holds the $-CO_2$ fragment.

In conclusion, we demonstrated that the photoreduction of iodine with diamine-*N*-polycarboxylate ions in an aqueous solution occurs in the order of the reaction rate, HEDTA>EDTA≈CDTA≫EDDA, and that the lone electron-pair of the nitrogen atom plays an important role in the oxidation and fragmentation of amine-*N*-polycarboxylate ions.

Disposition of Ferrocenes in β- or γ-Cyclodextrin Cavity and Consideration on the Absorption Bands of Ferrocene

Nagao KOBAYASHI* and Tetsuo OSA*
Pharmaceutical Institute, Tohoku University, Aobayama, Aoba-ku, Sendai 980
(Received June 30, 1990)

By comparing the induced circular dichroism (ICD) spectrum of 1,4,7,10,13-pentaoxa[13](1,1')-ferrocenophane, **I**, in the presence of β-cyclodextrin (β-CDx) with that of ferrocenes (Fcs) in β-CDx or γ-CDx cavity, the disposition of Fcs in the CDxs is determined. Thus, the orientation of Fc in the Fc:β-CDx 1:1 complex and ferrocenecarboxylic acid (FcMA) in β-CDx at pH 2 is considered to be nearly parallel to the molecular axis of β-CDx, while that of Fc in the Fc: γ-CDx 1:1 complex, FcMA in β-CDx cavity at pH 9, and FcMA and ferrocenedicarboxylic acid (FcDA) in γ-CDx cavity appears to be close to normal to the molecular axis of the CDx. In addition, based on the ICD spectra, an intense band of Fcs at around 200 nm is assigned as a charge-transfer (CT) transition between the cyclopentadienyl (Cp) rings and iron(II). The advantage of using CDxs for the determination of the polarization direction of absorption bands of chromophore molecules is mentioned in comparison with previous methods.

Induced circular dichroism (ICD) studies on inclusion complexes between aromatic guest molecules and cyclodextrins (CDxs) have developed over the past decade.[1,2] In particular, concerning the ICD of CDx–chromophore 1:1 inclusion complexes, the following have been substantiated or shown[1] with high accuracy on the basis of the Kirkwood–Tinoco coupled oscillator expression.[3] (i) Electronic transitions parallel to the molecular axis of CDxs produce positive ICD, while those normal to the axis show negative ICD. (ii) The sign of the calculated rotational strength does not change by the movement of guest molecules along the X-, Y-, and Z-axis, although their magnitude is affected[1g] (the origin of the axes is set at the center of CDx and the Z-axis is parallel to the molecular axis of CDx). (iii) Rotation of the guest molecule in the X–Y plane has no influence on the calculated rotational strength, while that in the X–Z plane does have a great influence on it.[1g] Figure 1,

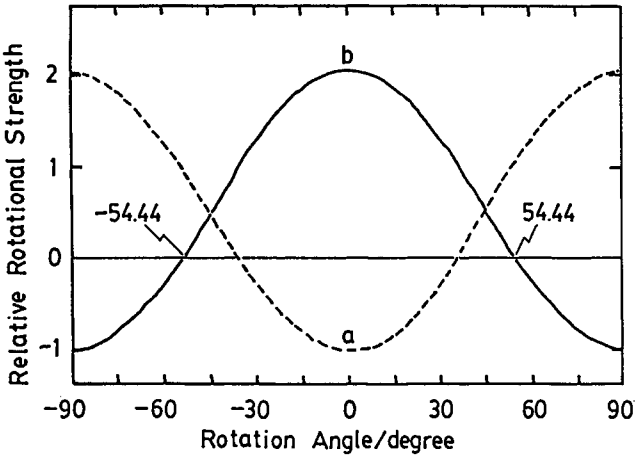

Fig. 1. The dependence of the calculated rotational strength of a CDx–chromophore complex on the rotation angle in the X–Z plane. Curves a and b are the transitions normal and parallel to the molecular axis of CDxs, respectively.

obtained by the procedure shown in Ref. 1h, depicts this dependence of calculated rotational strength on the rotation of the electric transition moment in the X–Z plane. As can be judged from curve b in this figure, electronic transitions whose directions are within 54.44 degrees from the axis of CDxs produce positive ICD sign while those more than 54.44 degrees yield negative ICD sign. Accordingly, it is now possible to determine the polarization direction of the absorption band of chromophore molecules from the sign of the ICD spectra of the chromophore: CDx 1:1 complex. Conversely, the orientation of guest molecules trapped in CDxs cavity can be inferred from the sign of the ICD spectra, if the polarization directions of the bands of the guest molecules are known. This method is valid in particular for molecules which have clear long- and short-axes, because their orientation in CDxs is likely to be fixed. However, if relatively round or square molecules are used as guest molecules, determination of the polarization direction of bands or elucidation of the orientation of guest molecules in CDxs becomes difficult, because more than one kind of orientation may exist. Typical examples are ferrocene (Fc) and its derivatives. Ferrocene is a relatively round molecule, with H atoms displaced towards the Fe atom.[4] As indicated recently by calculation,[5] Fc can bind to β-CDx in both an axial and equatorial orientation. Since the energy difference is too small to be significant (calculated value is 0.5 kcal mol^{-1}),[5] packing forces in a crystal, solvation effects in solution, or even a slight change in Fc structure and the size of the CDxs could well determine the preferred binding mode in real systems. In fact, the disposition of ferrocenecarboxylic acid (FcMA) in β-CDx cavity is altered by dissociation of its carboxyl group,[6] and the orientation of Fc in β-CDx cavity differs markedly from that in γ-CDx cavity.[7] Despite the publication of over 20 articles on Fc derivative–CDx complexes,[5–8] the orientation of Fc in CDxs cavity has not been determined to date. This difficulty is due to

the uncertainty of the assignment of the electronic absorption band of Fc and its derivatives.[9] By preparing a Fc derivative which can bind to CDxs cavity in only one binding mode, we can infer the orientation of other Fc derivatives in CDx cavity by comparing their ICD spectra. In addition, it may be possible to conjecture the polarization direction of UV bands of Fc derivatives. For these reasons we have prepared compound **I** (Fig. 2 inset) and measured its ICD spectra in the presence of β-CDx. For this molecule, only an equatorial inclusion is possible because of size limitations. As will be shown below, the orientation of other Fc derivatives in β- or γ-CDxs was conjectured based on the ICD spectrum of **I** in β-CDx.

Experimental

Measurements. UV-visible absorption and ICD spectra were recorded at 20 °C on a Shimadzu UV-250 spectrophotometer and JASCO J400X spectrodichrometer, respectively. Cells of pathlength 0.5, 1, 2, 5, 10, and 20 mm were used.

Materials. Fc, FcMA, and 1,1'-ferrocenedicarboxylic acid (FcDA) were commercially available reagents and were recrystallized from ethyl acetate, hexane, and ethanol, respectively. β-CDx and γ-CDx were donated by Japan Maize Product Co., and recrystallized from water. Fc–β-CDx and Fc–γ-CDx 1 : 1 complexes were prepared accodrding to the method reported in the literature.[7,8f] Anal. For Fc–β-CDx complex, Found: C, 45.96; H, 6.49; Fe, 4.0%. Calcd for $C_{52}H_{80}O_{35}Fe \cdot 1.5H_2O$: C, 46.26; H, 6.35; Fe, 4.14%. For Fc–γ-CDx complex, Found: C, 45.57; H, 6.45; Fe, 3.5%. Calcd for $C_{58}H_{90}O_{40}Fe \cdot 2H_2O$: C, 45.85; H, 6.24; Fe, 3.68%. Compound **I** was synthesized from 1,1'-ferrocenediol and 1,11-dichloro-3,6,9-trioxaundecane according to the literature.[10] Anal. Found: C, 57.23; H, 6.37; Fe, 14.6%. Calcd for $C_{18}H_{24}O_5Fe$: C, 57.46; H, 6.43; Fe, 14.84%. Mp 59.5—60 °C (lit, 59—61 °C).[10a]

Results

Figure 2 shows the UV-visible absorption and ICD spectra of **I** in the presence of β-CDx in ethylene glycol. The shape of the absorption spectrum is similar to that of Fc (Fig. 3), indicating that the attached crown unit does not significantly affect the electronic structure of the Fc chromophore. Corresponding to the absorption peaks at approximately 430 and 220 nm, a negative and positive ICD peak appeared, respectively. Continuous variation experiments for the determination of complex stoichiometry were not carried out through Figs. 2 to 5,

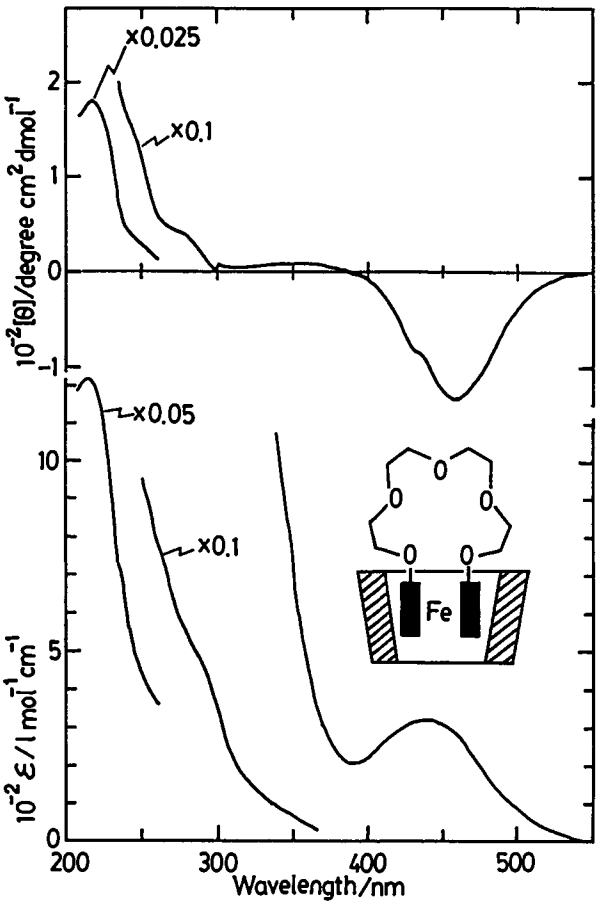

Fig. 2. ICD (top) and UV-visible (bottom) spectra of **I** in the presence of β-CDx in ethylene glycol. [**I**]/M=9.98×10^{-4} and [β-CDx]/M=0.020.

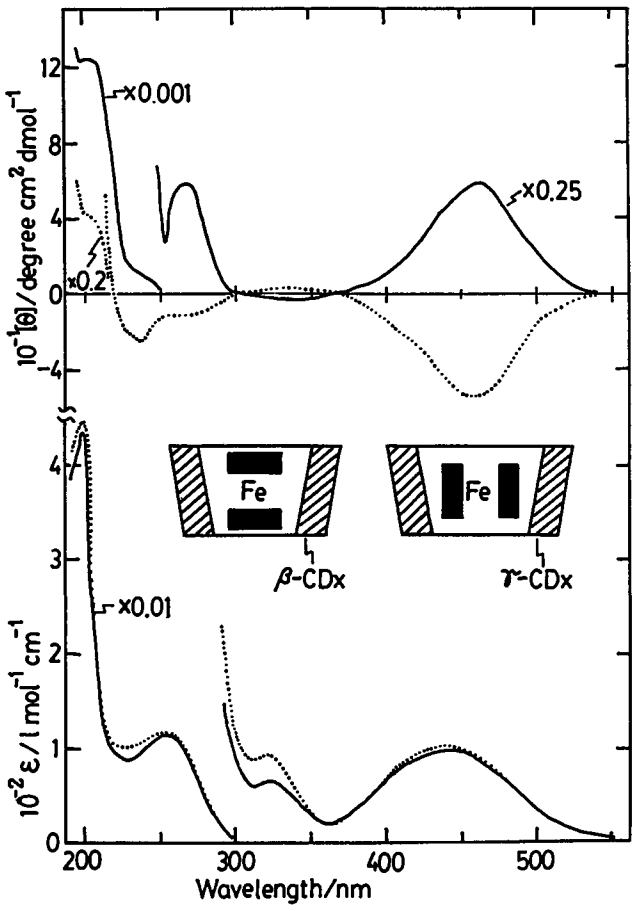

Fig. 3. ICD (top) and UV-visible (bottom) spectra of Fc–β-CDx (solid lines) and Fc–γ-CDx (dotted lines) in ethylene glycol. [Fc–β-CDx]/M=[Fc–γ-CDx]/M=0.001.

since 1 : 1 complex formation between β- or γ-CDx and Fcs has been established by many studies.[5-8]

Figure 3 shows spectra of Fc–β-CDx and Fc–γ-CDx 1 : 1 complexes in ethylene glycol. In the absorption spectra, peaks appear at around 200, 250—260, 330 and 440 nm. ICD spectra of Fc–β-CDx and Fc–γ-CDx complexes are interesting in that their signals are opposite over a wide range of wavelengths.[8p,r] Except at 300—370 nm, Fc–β-CDx complex produced positive ICD peaks or shoulders associated with each absorption peak, while Fc–γ-CDx complex showed negative ICD over a wide range of wavelengths. Note, however, that both complexes produced a positive ICD signal corresponding to the transition at approximately 200 nm.

Absorption and ICD spectra of FcMA in the presence of β-CDx or γ-CDx at pH 2 and 9 are shown in Fig. 4. The general features of the absorption spectra are similar to the spectrum of Fc (Fig. 3) but some differences occur, suggesting that the carboxyl group affects the Fc chromophore to some extent. In the presence of β-CDx at pH 9, i.e. where the carboxyl group is dissociated, the sign of the ICD spectrum is negative, except at <220 nm. On the other hand, it is positive in all regions when it is not dissociated (pH 2). The wavelengths of the absorption maxima and ICD peaks or troughs are in relatively good agreement. In the presence of γ-CDx, ICD was negative except at ca. 290—380 nm. Three troughs were observed at ca. 200—220, 270, and 470—480 nm at both pH 2 and 9.

Figure 5 shows the spectra of FcDA in the presence of β-CDx or γ-CDx at pH 2 and 9. The shape and intensity of the absorption spectrum change with dissociation of the carboxyl groups. However, the shape of the absorption spectra of FcDA is roughly similar to that of Fc without substituent groups (Fig. 3). An absorption band at around 220—230 nm is a band which lie on the tail of the higher transition band, since the absorption coefficient increases dramatically in the wavelength shorter than 200 nm (not shown). The ICD spectra in the presence of β-CDx are complex at

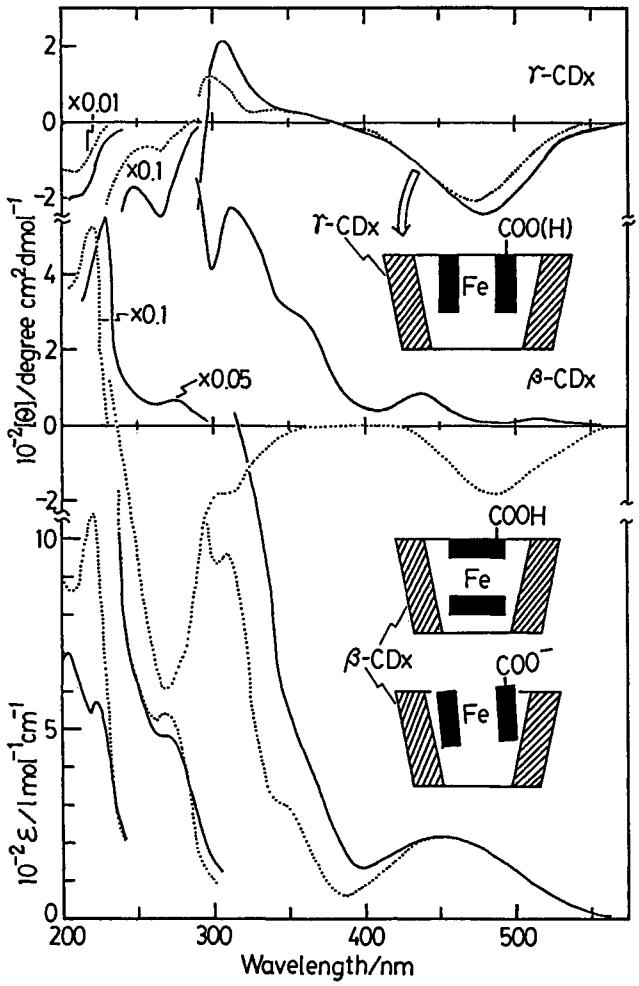

Fig. 4. ICD (middle and top) and UV-visible (bottom) spectra of FcMA in the presence of β-CDx (middle and bottom) or γ-CDx (top) at pH 2 (solid lines) and 9 (dotted lines). [β-CDx]/M=[γ-CDx]/M=0.010 and [FcMA]/M=0.001.

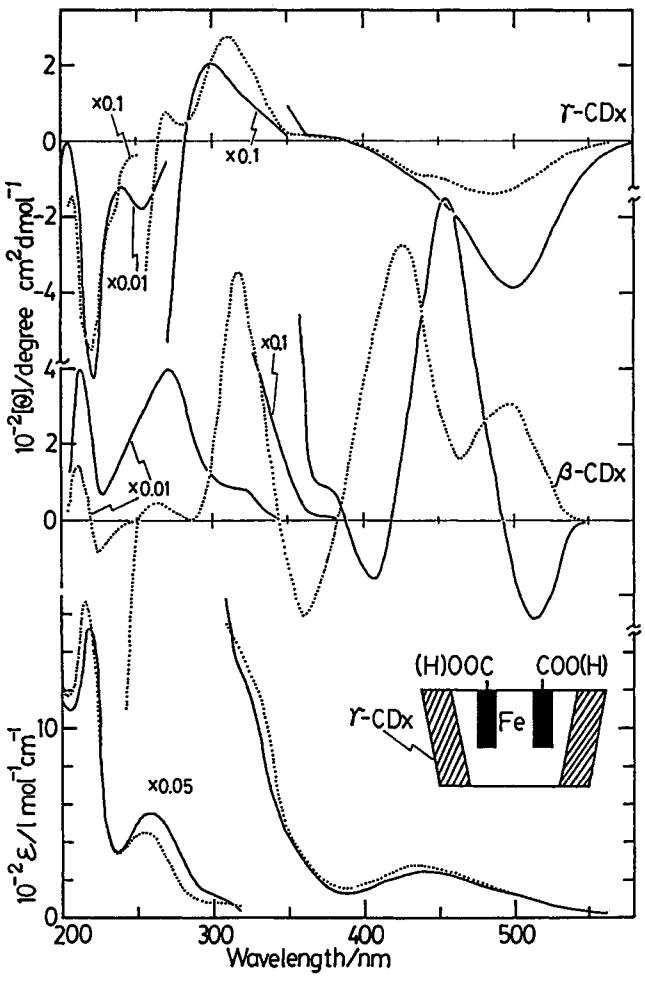

Fig. 5. ICD (middle and top) and UV-visible (bottom) spectra of FcDA in the presence of β-CDx (middle and bottom) or γ-CDx (top) at pH 2 (solid lines) and 9 (dotted lines). [β-CDx]/M=[γ-CDx]/M=0.010 and [FcDA]/M=0.001.

both pH 2 and 9, although the ICD pattern in the region <370 nm at pH 2 is relatively similar to that of FcMA at pH 2. Corresponding to an absorption maximum at around 220 nm, a positive ICD peak was observed at both pH 2 and 9. In contrast, ICD spectra in the presence of γ-CDx is relatively simple, showing negative signs in a wide range of wavelengths. The shape of the ICD curves is similar to each other at both pH 2 and 9, and resembles that of FcMA in the presence of γ-CDx (Fig. 4).

Discussion

From its shape and size, **I** can be trapped in β-CDx cavity only as an equatorial inclusion, as shown in the inset of Fig. 2. Based on the arguments (i) and (ii) mentioned in the introduction, the polarization direction of the band at the longest wavelength is not parallel to the β-CDx axis. Judging from Fig. 1 curve b, it is inclined by more than 54.44 degrees from the molecular axis of β-CDx. By argument (iii) and from the intensity change on rotation in the X–Z plane (Fig. 1), the Fc in Fc–γ-CDx complex (Fig. 3) appears to have a similar disposition to that of **I** in β-CDx cavity (equatorial inclusion), while that in Fc–β-CDx complex is completely different. In addition, since the positions of an ICD trough of Fc–γ-CDx complex and ICD peak of Fc–β-CDx complex coincide almost exactly at 460 nm, they seem to be almost normal to each other. Accordingly, the inclusion of Fc in Fc–β-CDx complex is considered to be close to axial. These results on the disposition of Fc in β- or γ-CDx cavity accord essentially with those obtained by NMR technique for solid samples. Namely, according to what one of the reviewers taught us, the Cp–Fe–Cp axis of Fc molecule declines from the axis of β-CDx by 6.5 degrees but by 72 degrees from that of γ-CDx.[11] Since the ICD pattern of FcMA in the presence of β-CDx at pH 9 (Fig. 4) is quite similar to that of Fc in Fc–γ-CDx complex (Fig. 3), the inclusion of FcMA by β-CDx also appears almost equatorial at pH 9. Although a clear ICD peak was not observed in the region >400 nm, the arrangement of this molecule at pH 2 appears to be close to axial in β-CDx cavity, since the ICD spectroscopic pattern of FcMA in the 200—400 nm region at this pH is similar to that of Fc–β-CDx complex (Fig. 3). The stoichiometry and inclusion type of CDx–chromophore host–guest complexes are determined by many factors. In the case of FcMA–β-CDx system, the pH value of the solution affects the type of inclusion. In alkaline solution, the carboxyl group dissociates and the resultant highly hydrophilic carboxylate anion may resist to be deeply accommodated into β-CDx cavity. As a result, an equatorial inclusion occurs, although FcMA may be deeply trapped by an axial inclusion when the carboxyl group is not dissociated in acidic solution, i.e. when it is less hydrophilic than carboxylate anion. Judging from the spectroscopic pattern of ICD, the inclusion of FcMA and FcDA in γ-CDx is similar at both pH 2 and 9, and it appears to be equatorial from the presence of a trough at ca. 380—550 nm. On the other hand, a zig-zag pattern in the wavelength longer than 380 nm (Fig. 5) indicates that the orientation of FcDA in β-CDx cavity is obscure both when the carboxyl groups are dissociated and undissociated. Because of steric hindrance by the two carboxyl groups, FcDA may be trapped in β-CDx cavity obliquely. In this respect, the results in FcDA–γ-CDx system suggest the possibility that the mutual positions of the two carboxyl groups may change on inclusion. That is, the two carboxyl groups would take many conformations to each other with respect to Cp–Fe–Cp axis in solution. Especially, there is no particular requirement that the two carboxyl groups of FcDA must stay in the same side of Fe atom in the absence of γ-CDx. And, if FcDA molecule is accommodated to γ-CDx cavity in the same conformations as it is in solution, it is conceivable from the consideration using the CPK molecular model that a zig-zag ICD pattern appears in >380 nm because of steric hindrance, although the cavity of γ-CDx is larger than that of β-CDx. However, no such pattern was observed in reality as shown in Fig. 5. Now that the Cp rings are much more hydrophobic than carboxyl groups, it would be most natural to think that the two Cp moieties are trapped in γ-CDx first, leaving the carboxyl groups behind (see the inset in Fig. 5).

The absorption peak in the longest wavelength region has been proposed to contain two components with absorption maxima at around 420—430 and 460—470 nm, and both are assigned as d-d transitions.[9] Interestingly, an ICD peak in the axial inclusion system (Fig. 3, Fc–β-CDx system) and ICD troughs in the equatorial inclusion system (Fig. 2, Fc–γ-CDx system in Fig. 3, FcMA–γ-CDx system in Fig. 4, and FcMA–β-CDx system at pH 9 in Fig. 4) always appear at around 460—470 nm. Hence, out of two components included in this band, the one to the red is deemed to have a polarization direction along the Cp–Fe–Cp axis, as has been found for crystals of Fc.[9f] This result appears to be in agreement with low temperature studies[9b] which indicate that the band is a symmetry-forbidden d-d transition containing charge-transfer (CT) character.

The ICD intensity of Fc–γ-CDx complex is much weaker than that of Fc–β-CDx complex. Two reasons are conceivable for this phenomenon. The first one is attributed to a difference in polarization direction. As shown in Fig. 1 curve b, when the transition dipole which is parallel to the molecular axis of CDx rotates by ca. 90 degrees in the X–Z plane, the calculated rotational strength lessens to ca. half of the original value, together with a change of ICD sign. Accordingly, for example, if a transition dipole at 460 nm which has its polarization direction along the Cp–Fe–Cp axis rotates 90 degrees in the X–Z plane (this corresponds to a change from an axial to an equatorial inclusion), its intensity becomes ca. one-half of the original value.

However, since the observed ICD intensity of Fc–γ-CDx complex is about 25% of that of Fc–β-CDx complex at 460 nm, another factor must be taken into account in order to explain the intensity difference between Fc–β-CDx and Fc–γ-CDx complexes. This factor is the distance between the Fc unit and CDx. The rotational strength is known to be proportional to the inverse of the cube of the distance.[12] Since the radius of β-CDx cavity (4.7—5.2 Å) is about 80% of that of γ-CDx cavity (6.0—6.4 Å),[13] the rotational strength in γ-CDx is estimated to be about half ($0.8^3 \fallingdotseq 0.5$) of that in β-CDx. Thus, the smaller ICD intensity at 460 nm in Fc–γ-CDx complex is quantitatively ($0.5 \times 0.5 = 0.25$, 25%) rationalized by taking the above two factors into account. If, however, the orientation of Fc in Fc–β-CDx complex is equatorial and that in Fc–γ-CDx complex is axial, the ICD intensity at 460 nm would be almost comparable by the same argument, although the sign of ICD is opposite to each other (negative and positive for Fc–β-CDx and Fc–γ-CDx systems, respectively). Thus the observed ICD sign and intensity relationship between Fc–β-CDx and Fc–γ-CDx systems can be interpreted reasonably only when the inclusion of Fc in Fc–β-CDx complex is axial while that of Fc–γ-CDx complex is equatorial. In this way, these considerations also lend support to our conclusion about the disposition of Fc in Fc–β-CDx and Fc–γ-CDx complexes.

Based on the knowledge obtained above, we are now able to resolve a question which has been disputed for a long time,[9] i.e. the assignment of an intense band of Fcs at around 200nm. Two opinions exist concerning the assignment of this band. Some[9a] groups have assigned this band as a π–π^* transition of the Cp rings, while others[9b,c] have interpreted this as a CT transition between the Cp rings and iron(II). As shown in Figs. 2 and 3, Fcs produce a positive ICD peak corresponding to this band when they are included by CDxs as both an axial and equatorial inclusion. If this band is a π–π^* transition, the sign of the ICD should be positive for an equatorial inclusion and negative for an axial inclusion based on the arguments (i)—(iii) above (note that an equatorial inclusion of Fc is equivalent to an axial inclusion of the Cp rings). Thus, the results do not agree with assignment as a "pure" π–π^* transition. Can, then, the observed ICD be reasonably interpreted as a CT transition? As depicted in Fig. 1, transitions whose polarization directions are within 54.44 degrees from the molecular axis of CDxs produce positive ICD whenever Fc is in the CDx cavity (criterion (ii)). On the other hand, the d_{xz} and d_{yz} orbitals of iron decline theoretically 45 degrees from the Cp–Fe–Cp axis of Fc. Hence, whether or not Fcs are included in CDxs cavity by an axial or equatorial inclusion, these orbitals are still declining 45 degrees from the molecular axis of CDxs. This means that if these orbitals are used in CT between the Cp rings and iron, then the sign of the ICD signal becomes positive. In this way, an intense band of Fcs at around 200 nm is reasonably assigned to a CT transition. Although negative ICD is observed at ca. 220—230 nm in FcDA–γ-CDx system, this may be due to the strong electron-withdrawing effect of the carboxyl groups attached to the Cp rings.

Previous reports[9] also discuss the polarization direction of other bands. Using crystals of Fc,[9f] the bands at ca. 260 and 320 nm are proposed to possess polarization along the Z (Cp–Fe–Cp) axis mixed with some polarization along the X or Y axis. Figures 2 and 3 indicate that the present results do not contradict this proposal concerning the 260 nm band, since the sign of ICD of this band is the same as that of the 440 nm band which is polarized along the Z (Cp–Fe–Cp) axis. The sign of ICD between 300 and 370 nm suggests that the band at ca. 320 nm is polarized more strongly along the X or Y direction rather than the Z direction. Otherwise, negative ICD is not produced in this region.

Conclusion

The proposed orientations of Fcs in CDxs are presented in each Figure. Based on the ICD spectra of **I** in β-CDx cavity, the orientations of Fcs in CDxs cavity are determined, and an answer is given for the assignment of a band of Fc which has been in dispute. We would like to stress here the importance of using CDxs for determination of the polarization direction of bands of aromatic compounds. In order to determine the polarization direction of the electronic absorption of non-crystalline compounds experimentally, measurements of dichroic spectra in stretched polymer sheet,[14] and of ICD in mesophases have been of great use.[15] However, there are limitations to these methods. Firstly, since the most essential factor is the alignment of solute molecules, it is difficult to apply these methods to relatively round or square molecules. Round molecules are, of course, not easily studied even in CDx systems. However, as shown in this paper, the orientation of round guest molecules in CDxs cavity can be regulated by modifying their structure. ICD spectra of such guest-oriented inclusion complexes then enable the polarization direction to be determined. Secondly, due to the absorption of polymers or mesophases, only a few polymers can be used for bands lying shorter than ca. 220 nm. In this respect, the CDx system appears to be superior, since water and alcohols are generally used. If water is used, this method is applicable to bands as short as ca. 190 nm.

Selective Ring-Opening Reaction of Epoxides with Sodium Borohydride in the Presence of Cyclodextrins in Aqueous Media[1)]

Ying HU, Mitsunari UNO, Akira HARADA,† and Shigetoshi TAKAHASHI*
The Institute of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567
(Received November 26, 1990)

In the presence of cyclodextrins (CDs), the ring-opening reaction of styrene oxide with $NaBH_4$ in aqueous media proceeded smoothly to give 1-phenylethanol with high selectivity of up to 94%, and kinetic resolution of the racemic epoxide was observed. Kinetic studies suggest the resolution based on the different reaction rates between two enantiomers included in the CD's cavity. The reaction of epoxides such as 1,2-epoxyindan and 1,2-epoxy-3-phenylpropane are also affected by the addition of CDs to proceed smoothly with high regioselectivities.

Inclusion phenomenon or "host and guest chemistry" has attracted growing attention and many efforts have been done to control chemical reactions by means of inclusion phenomenon. Cyclodextrins (CDs), macrocyclic compounds consisting of α-1,4-linked D-glucopyranose, are well-known naturally-occurring host molecules characterized by definite shape and size, chirarity, and solubility in water.[2)]

We have been interested in effects of CDs on organic reactions, and attempted to utilize CDs in organic synthesis. In previous studies, we have applied CDs as inverse phase-transfer catalysts to the oxidation reactions of olefins[3)] and benzylic alcohols,[4)] and as asymmetric reaction vessels to epoxidation of olefins.[5)]

As molecular reaction vessels, CDs are expected to exert microenvironmental effects leading to acceleration of reactions, and conformational effects resulting in selectivities of reactions. Such effects of CDs have been observed in many reaction systems. Breslow reported that CDs greatly accelerated the chlorination of anisole by hypochlorous acid, and that the reaction exhibited remarkable para-selectivity in the presence of CD.[6)] Komiyama used CDs and their derivatives in the formylation, carbonylation, dihalomethylation, and allylation of phenols for rate and regioselectivity enhancement.[7)] Moreover, the effects of CDs in some photoreactions and pyrolysis have been studied in detail by Eaton and Ramamurthy,[8)] and Abelt.[9)] Recently, some efforts have been done for using CDs in asymmetric synthesis. Asymmetric epoxidation of olefins,[5,10)] asymmetric halogenation and hydrohalogenation of styrene,[11)] and asymmetric reduction of ketones[12)] have been reported. Here, we wish to report the effects of CDs on the ring-opening reaction of epoxides with $NaBH_4$ in aqueous medium.

Many methods are known about the ring opening of epoxides, including the reaction with hydrides.[13)] Although $NaBH_4$ is a readily available and mild hydride source, it has long been considered inapplicable to the ring-opening reaction of epoxides to corresponding alcohols due to slow reaction rate. It was recently reported that the reaction of epoxides with $NaBH_4$ can be carried out in alcoholic solvents, but the method seems to be inconvenient for separating products.[14)] In the present study, we have found that in the presence of cyclodextrins, the ring-opening reaction of epoxides with $NaBH_4$ in aqueous media proceeds smoothly with high regioselectivity, and racemic epoxides are kinetically resolved during the reaction.

Results and Discussion

Ring-Opening Reaction of Styrene Oxide. Styrene oxide reacted with $NaBH_4$ in aqueous solution at room temperature very slowly, and gave 1- and 2-phenylethanol with predominance of 2-phenylethanol. When CDs were applied to the reaction, the effects of CDs were found in three respects (Table 1).

Firstly, the reaction was significantly accelerated by the addition of CDs. When the reaction was carried out in the presence of 20 mol% of α-, β-, or γ-CD without changes in other conditions, the conversion of styrene oxide increased from 17% to 54, 83, and 77%, respectively.

Secondly, the regioselectivity of ring opening was changed, i.e. the product ratio of 1-phenylethanol **2a** to 2-phenyl isomer **2b** was reversed as compared with that in the absence of CDs, and the main product of the reaction involving CDs was 1-phenylethanol. When the molar ratio between β-CD and styrene oxide was 2 : 1, 1-phenylethanol reached 94% selectivity.

Thirdly, when β- or γ-CD was used, 1-phenylethanol was obtained with a majority of (*S*)-(−)-1-phenylethanol, and recovered styrene oxide was rich in (*S*)-(−)-styrene oxide. Enantiomer excesses of produced 1-phenylethanol and of recovered styrene oxide were 46 and 31%, respectively, when styrene oxide racemate and β-CD were used in the molar ratio of 1 : 2.

The good effects of CDs on the reaction may be interpreted by formation of water-soluble inclusion complexes between styrene oxide and CDs. The low solubility of styrene oxide in water prevents it from ring-opening reaction with $NaBH_4$. When CD is absent, the molecules of styrene oxide aggregate together and are difficult to come into direct contact with a reagent

E.e. of styrene oxide and 1-phenylethanol were determined by HPLC and specific rotatory power.

dissolved in water. In the presence of CD, a styrene oxide molecule will be included into CD's cavity and move into water. The resulting inclusion complex will encounter easily a reagent, BH_4^-, in water. Instead of CDs, we applied methyl α-D-glucoside and dextrin, which are a sub-unit of CD and open-chain oligomers of glucopyranose, to the ring-opening reaction of styrene oxide. No effects could be observed with these compounds. This fact indicates that the effects of CDs on the reaction are inseparable from the property of inclusion complex formation. In addition, among the three kinds of CDs, β-CD showed the best effects on the reaction, also indicating that inclusion complex formation was involved, and that the shape of styrene oxide molecule is fittest to the cavity of β-CD.

Kinetic Resolution of Styrene Oxide. We confirmed that (*R*)-(+)-styrene oxide gave only (*S*)-(−)-1-phenylethanol; and (*S*)-(−)-styrene oxide gave only (*R*)-(+)-1-phenylethanol. Because the conformation of the asymmetric center should be retained during the ring-opening reaction, it is clear that the origin of the formation of the optically active products is due to kinetic resolution.

By examining the reaction of the two enantiomers, it was found that in comparison with (*R*)-(+)-styrene oxide, the reaction of (*S*)-(−)-styrene oxide was accelerated in a smaller extent and gave a lower selectivity of 1-phenylethanol (Table 2).

In which step did the the kinetic resolution occur? Two possibilities can be considered: One is that CD includes one of the enantiomers selectively. Another is that in CD's cavity the reaction rates of the two enantiomers are different. In order to answer the question, we measured dissociation constants of two enantiomers with β-CD in aqueons solution. The dissociation constants obtained are 8.3×10^{-3} M (1 M=1 mol dm^{-3}) for the inclusion complex of β-CD with (*R*)-(+)-styrene oxide and 9.8×10^{-3} M for the inclusion complex of β-CD with (*S*)-(−)-styrene oxide. The difference between the dissociation constants of two enantiomers seems too small to result in kinetic resolution. Furthermore, we isolated an inclusion complex of β-CD with styrene oxide and proved that the kinetic resolution does not

1-*S*	1 mmol	35	~99(*S*)	48	~99(*R*)	18	72

occur in the step of inclusion complex formation. Thus, the inclusion complex was prepared by stirring an excessive amount of racemic styrene oxide with a saturated aqueous solution of β-CD at room temperature. The inclusion complex produced was collected by filtration from the mixture. By extraction with diethyl ether, the excessive styrene oxide was recovered. Styrene oxide included by β-CD was recovered by suspending the inclusion complex in water, and then extracting with diethyl ether. We found that both styrene oxide included by CD and excessive styrene oxide remained freely were racemates as measuring optical rotation of the recovered styrene oxide.

The reason of kinetic resolution therefore must rest on the different reaction rates of two enantiomers included in the cavity of CD. That is to say, both enantiomers can be included easily by CD to almost the same extent, but exhibit a different reaction rate in the cavity of CD. To confirm this, we attempted to do kinetic study on the reactions of two enantiomers. Unfortunately, the attempt has falled off success due to the complexity of the reaction.

Ring-Opening Reaction of Other Epoxides. Besides styrene oxide, the ring-opening reaction of other epoxides involving CDs was also investigated. As shown in Table 3, the accelerating effect of CDs on the ring-opening reaction of epoxides are remarkable, and the ring-opening reaction is regioselective in the presence of CDs. Especially, racemic 1,2-epoxyindan and 1,2-epoxy-3-phenylpropane were optically resolved to some extent during the reaction involving CD.

1,2-Epoxyindan reacted with $NaBH_4$ in aqueous solution and gave 2-indanol as the sole product. After the reaction involving CDs, recovered 1,2-epoxyindan showed optical rotation, indicating that 1,2-epoxyindan was kinetically resolved during the reaction. When the molar ratio of 1,2-epoxyindan to α-CD was 1 : 1, recovered 1,2-epoxyindan showed specific rotatory power of 12° corresponding to 20% enantiomer excess which was determined by ^1H NMR spectrum using $Eu(hfc)_3$ as a chiral shift reagent.

1,2-Epoxy-3-phenylpropane was another interesting substrate. In the absence of CD, 1,2-epoxy-3-phenylpropane almost did not react with $NaBH_4$ in aqueous solution. All CDs uniformly accelerated the reaction remarkablely. 1-Phenyl-2-propanol was the sole ring-opening product. Among the three kinds of CDs, the effect of α-CD was outstanding. The reaction of 1,2-epoxy-3-phenylpropane required only a catalytic amount of α-CD (Table 4). It was found that during the reaction involving α-CD, 1,2-epoxy-3-phenylpropane racemate was resolved. One thing worthy to be noted is that the effects of CDs were not modified simply by raising the amount of α-CD added. The best efficiency for optical resolution was observed when about 10 mol% of α-CD was used. Then both the reaction rate and the efficiency for optical resolution tended downwards as the increasing amount of α-CD.

By examining the inclusion mode with CPK molecular models, it seems that the decrease in the reaction rate and effeciency in optical resolution can be explained considering the formation of a 2 : 1 CD-epoxide inclusion complex (Figure 1), as the amount of α-CD is

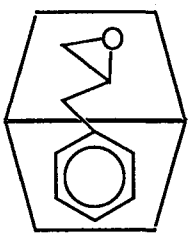

Fig. 1. 2 : 1 CD-1,2-epoxy-3-phenylpropane complexes.

α-CD(5)	72	24	<1	—

a) E.e. of 1,2-epoxy-3-phenylpropane was determined by HPLC. b) $[\alpha]_D^{23}$ was measured in $CHCl_3$. c) $[\alpha]_D^{23}=-9.9°$ corresponds to 24% e.e. as determined by ^1H NMR spectroscopy. According to the report of Bell, the sample was rich in (*R*)-(−)-1-phenyl-2-propanol.[16]

increased. It is clear that the inclusion mode shown in Fig. 1 would undoubtedly interrupt the reaction of the epoxide.

Conclusion

It has been demonstrated by the results presented here that CDs affect the ring-opening reaction of epoxides dramatically. In comparison with the known processes for the ring-opening reaction of epoxides using organic solvents and sensitive hydrides such as lithium aluminum hydride and diborane, the present method has the advantages of easy procedure, high regioselectivity, and high yield of ring-opening product, and provides a practical method applicable for organic synthesis. In addition, although the efficiency of kinetic resolution by CDs is not satisfied at present, it has been suggested that CDs may be used to asymmetric syntheses based on the formation of inclusion complexes.

Experimental

Instruments. GLC analyses were performed on a Shimadzu GC-12A chromatograph equipped with a 3-m Thermon-1000 column. HPLC analyses of asymmetric compounds were carried out on a Shimadzu LC-6A chromatograph equipped with a 25-cm Chiralcel OF column. Optical rotations were measured on a Jasco DIP 370 polarimeter. ^1H NMR spectra were recorded on a Bruker AM 360 instrument. UV spectra were recorded with a Hitachi U-3400 spectrophotometer.

Materials. CDs, $NaBH_4$, (±)-styrene oxide, (*R*)-(+)-styrene oxide, (*S*)-(−)-styrene oxide, cyclohexene oxide, and 1,2-epoxydecane were commercially available. 1,2-Epoxyindan, 1,2-epoxy-3-phenylpropane and *p*-tolyloxirane were prepareded by KOH treatment of corresponding bromohydrins[16] which were obtained from corresponding olefins by the Guss method.[17] The chemical purities of all epoxides were checked by gas chromatography and confirmed to be higher than 98%. The optical purities of (*R*)-(+)-styrene oxide and (*S*)-(−)-styrene oxide were higher than 99% according to HPLC analysis.

Ring-Opening Reaction of Epoxides. The ring-opening reaction of all epoxides was carried out by stirring a mixture of epoxide, $NaBH_4$ and CD in water at room temperature. In the reactions involving CD, 2 ml of water per 1 mmol of CD was used, and 2 ml for all reactions in the absence of CD. The reaction mixture was extracted with ether, and crude products were analyzed by GLC and HPLC. The crude products were purified by silica gel column chromatography with hexane–ethyl acetate. All products of the reactions were identified by ^1H NMR and IR spectroscopy.

Optical purities of styrene oxide, 1-phenylethanol, 1,2-epoxy-3-phenylpropane, and *p*-tolyloxirane were determined by HPLC analysis.

Optical purities of recovered 1,2-epoxyindan and 1-phenyl-2-propanol were determined by ^1H NMR spectroscopy using $Eu(hfc)_3$ as a chiral shift reagent.

Dissociation Constants of β-CD-Styrene Oxide Inclusion Complex. Since the ultraviolet spectrum of styrene oxide is modified by binding into CD's cavity, a UV spectroscopic method was used to determine the dissociation constant K_d.[17]

To each of several 50 ml volumetric flasks containing accurately measured quantity of β-CD, 5 ml of 5.3×10^{-3} M solution of (*R*)- or (*S*)-styrene oxide in water was added. The solutions were diluted to the marks with water. The absorption at 257 nm of each of these solutions was measured at 25 °C. The reference compartment contained a solution of β-CD of identical concentration.

For the calculation of dissociation constants, following equation was used:

$$C_0S_0/\Delta Abs = K_d/\Delta\varepsilon + (C_0+S_0)/\Delta\varepsilon$$

where C_0 is the initial concentration of β-CD, S_0 is the initial concentration of styrene oxide, ΔAbs is the change in absorbance at a particular wavelength from the absorbance of styrene oxide alone at this concentration, and $\Delta\varepsilon$ is the difference in molar extinction coefficient for the complex and the pure styrene oxide. Thus, a plot of $C_0S_0/\Delta Abs$ vs. C_0+S_0 yields a straight line with intercept/slope=K_d.

Caution. (*R*)-(+)-Styrene oxide and (*S*)-(−)-styrene oxide showed plus and minus optical rotation in neat state, respectively. However, the signs of optical rotation of these two isomers reversed when the optical rotation was measured in $CHCl_3$ or CH_2Cl_2 solution at low concentrations, and the specific rotatory power significantly varied with the concentration of the solution. Calibration curves of specific rotatory power must be made for analysis.

Photochemical Reactions of Aryl-Substituted Digermanes through a Pair of Organogermyl Radicals[1)]

Kunio MOCHIDA,* Masanobu WAKASA, Yoshio SAKAGUCHI,† and Hisaharu HAYASHI*,†
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Tokyo 171
†The Institute of Physical and Chemical Research, Wako, Saitama 351-01
(Received January 11, 1991)

The photochemical reactions of aryl-substituted digermanes were investigated by trapping experiments and a laser flash photolysis technique. The photolysis of phenylated digermanes resulted in germanium–germanium bond homolysis to give a pair of two germyl radicals. The germyl radicals abstracted a chlorine atom from carbon tetrachloride to give chlorogermanes. The pair of germyl radicals also underwent ipso-substitution, which was a precursor of the germylenes. The mechanism for the photochemistry of phenylated digermanes is discussed.

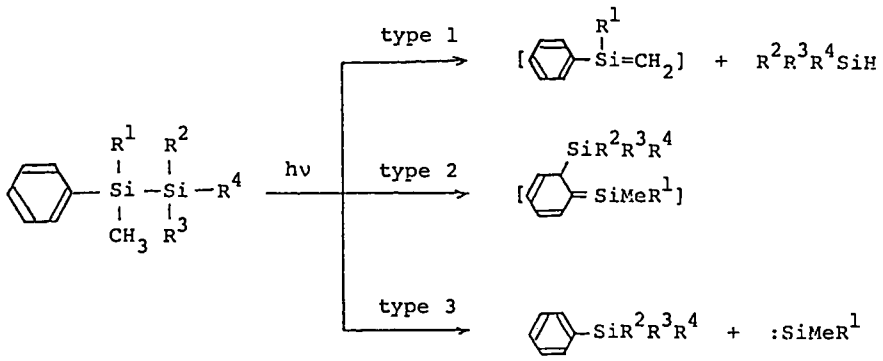
The photochemistry of organopolysilanes having a σ(Si–Si)–π(C=C) conjugated system has been the subject of considerable attention because of their unexpected reactivities as well as in the resulting products.[2–4)]

The photolysis of an aryldisilane was first reported by Boudjouk, Roberts, Golino, and Sommer[5)] for pentaphenylmethyldisilane. The generation of a silicon–carbon double-bonded species is the characteristic feature of the reaction (type 1 in Scheme 1). Later, Ishikawa, Fuchigami, Sugaya, and Kumada[6)] have reported on another type of reaction in which a rather unusual silicon–carbon double-bonded species is postulated as a key intermediate (type 2). The generation of a silylene has also been noted (type 3). Recently, Sakurai, Nakadaira, Kira, Sugiyama, Yoshida, and Takiguchi have presented a free radical mechanism for the photolysis of aryldisilanes. Okinoshima and Weber[8)] have also reported the formation of silicon–oxygen double-bonded species by the photolysis of aryldisilanes in dimethyl sulfoxide (DMSO).

However, there has been few papers on photochemical studies of the germanium analogues.[9)] We previously reported on the photolysis of phenylpentamethyldigermane, in which the generation of a pair of germyl radicals was indicated.[10)] In this paper, we described the photoreactions of phenylated digermanes studied via trapping experiments and a laser flash photolysis technique.

Results and Discussion

Photoreaction of the Phenylated Digermanes. Four kinds of phenyl-substituted digermanes, $(Ph_nMe_{3-n}Ge)_2$ (**1**—**3**, n=1—3, respectively) and $Me_3GeGePh_3$ (**4**), in cyclohexane or in tetrahydrofuran (THF) were investigated with a 110-W low-pressure Hg arc lamp at room temperature under an argon atmosphere for 1—2 h. The photolysis of **1** and **2** in cyclohexane gave $PhMe_2GeH$ (11%), Ph_2GeMe_2 (17%), and $(Me_2Ge)_4$ (4%) for **1**, and Ph_2MeGeH (20%) and Ph_3GeMe (17%) for **2**, as main products. The photolysis of **4** in cyclohexane mainly afforded Me_3GeH (15%), Ph_3GeH (32%), and $PhGeMe_3$ (19%). High-boiling unidentified products containing germanium were also formed in the photoreactions of **1**, **2**, and **4**. The formation of octamethylcyclotetragermane $(Me_2Ge)_4$ for **1** strongly suggests the intermediacy of a dimethylgermylene.[11)] In order to detect possible reaction intermediates, cyclohexane solutions of **1**, **2**, and **4** containing a large excess of 2,3-dimethylbutadiene, a germylene trapping agent,[12)] were similarly irradiated for 1—2 h. Monogermanes ($PhMe_2GeH$ and Ph_2GeMe_2) and $(Me_2Ge)_4$ were produced for **1**, regardless of the presence of 2,3-dimethylbutadiene. No 1,1-dimethylgermacyclopent-3-ene was formed. The rate of cycloaddition of 1,1,2,2-tetramethyldigermene ($Me_2Ge{=}GeMe_2$) formed by a



Scheme 1.

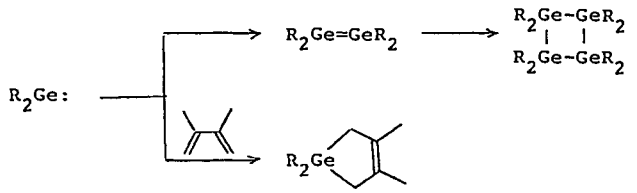
a) The yield of products could not be determined by GLC.

dimethylgermylene may be much faster than that of the dimethylgermylene with 2,3-diemthylbutadiene under these reaction conditions. On the other hand, 1-methyl-1-phenylgermacyclopent-3-ene (1%) was formed together with mongermanes (Ph_2MeGeH and Ph_3GeMe) in the photolysis of **2** and 2,3-dimethylbutadiene. 3-Butenylgermyl derivatives were also detected by means of CC-MS in the photolysis of **1** and **2**.



No 1,1-diphenylgermacyclopent-3-ene and octaphenylcyclotetragermane $(Ph_2Ge)_4$ derived from diphenylgermylene were formed in the photolysis of **4**.

In the presence of carbon tetrachloride, the photolysis of **1**, **2**, and **4** in cyclohexane afforded chlorogermanes quantatively, together with hexachloroethane. The formation of chlorogermanes seems to indicate the intermediacy of the germyl radicals produced by germanium–germanium bond homolysis of the phenylated digermanes. The germyl radicals are known to abstract a chlorine atom from carbon tetrachloride to give the corresponding chlorogermanes and a trichloromethyl radical:[13]

$$R_3Ge\cdot + CCl_4 \longrightarrow R_3GeCl + \cdot CCl_3.$$

The germyl radicals add to 2,3-dimethylbutadiene to produce 3-butenylgermyl derivatives.

Hydrogermanes were formed in the absence of trapping agents. Germyl radicals do not abstract a hydrogen atom from solvents, such as THF or cyclohexane. This was confirmed by the fact that THF-d_8 or cyclohexane-d_{12} solutions containing **1** upon being irradiated gave no $PhMe_2GeD$ but $PhMe_2GeH$. It is unlikely that they can abstract a hydrogen atom from precursor C–H bonds, which are even stronger. Another route to the formation of hydrogermanes may be via a disproportionation of germyl radicals.[14] Germenes are also expected to form by the disproportionation of germyl radicals. The germenes are known to react with methanol to give methoxygermanes.[15] No methoxygermanes were formed in the photolysis of cyclohexane solutions of phenylated digermanes, **1**, **2**, **4** with methanol. At present, the formation processes of hydrogermanes are unclear.

The photolysis of **3** did not proceed since **3** was very difficult to dissolve in cyclohexane or in THF. The results of photochemical reactions of **1**, **2**, and **4** in cyclohexane are summarized in Table 1. Similar results regarding the photochemical reactions of **1**, **2**, and **4** in THF were obtained.

In order to obtain more information concerning the reaction intermediates and primary photochemical processes, laser flash photolysis at 293 K studies of phenylated **1**—**3** were also carried out.

Laser Flash photolysis Studies. Nanosecond transient absorption spectra measurements were performed on degassed solutions containing **1**—**3** at 293 K using the fourth-harmonic pulse of a Nd:YAG laser as the exciting light source.[16]

The time dependence of the transient absorbance, $A(t)$, was measured using each of the THF solutions containing **1**—**3**. The $A(t)$ curves were measured in the wavelength region 300—700 nm. Appreciable signals of two well-separated transient bands were obtained, as shown in Fig. 1. The signals show a fast rise and a following slow decay. The rise time was about 10 ns, the time resolution of the present apparatus. As a typical example, the $A(t)$ curve and the $\log A(t)$ curve observed with **2** at 320 nm for kinetic studies are shown in Fig. 2. Such a curve can be computer analyzed regarding composition of two components through the decay of pseudo first-order kinetics. The $A(t)$ curve

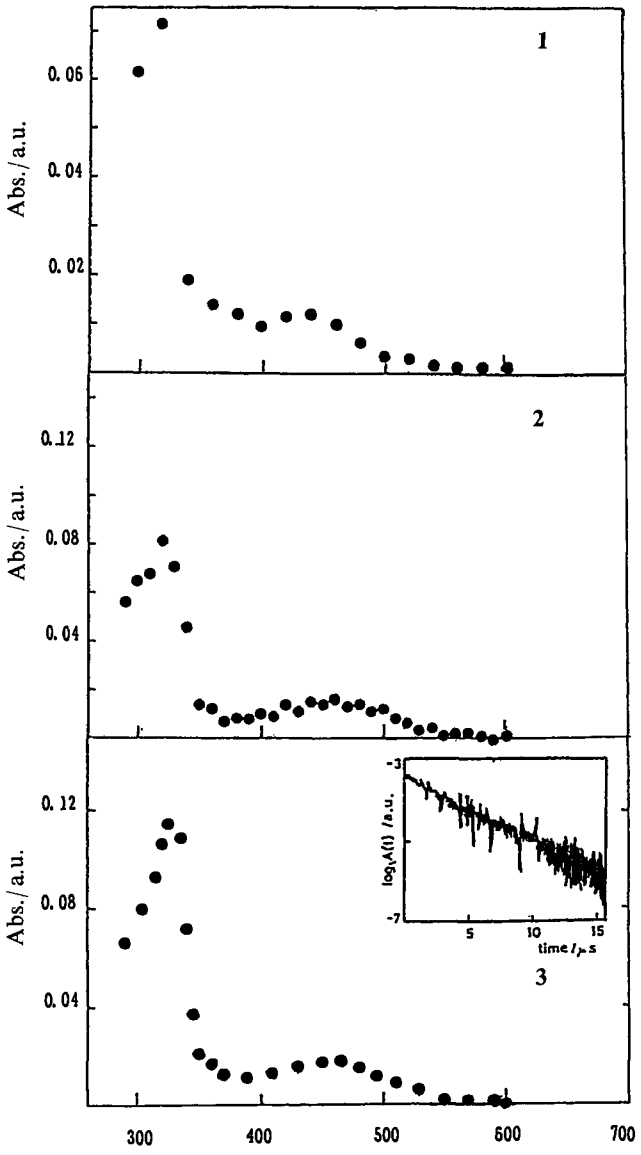


Fig. 1. Transient absorption spectra at 50 ns after photoexcitation of $(Ph_nMe_{3-n}Ge)_2$, **1**—**3** (n=1—3) (10^{-3} M) in degassed THF solutions. Insert (3): a first-order plot for decay of the absorption at 320 nm.

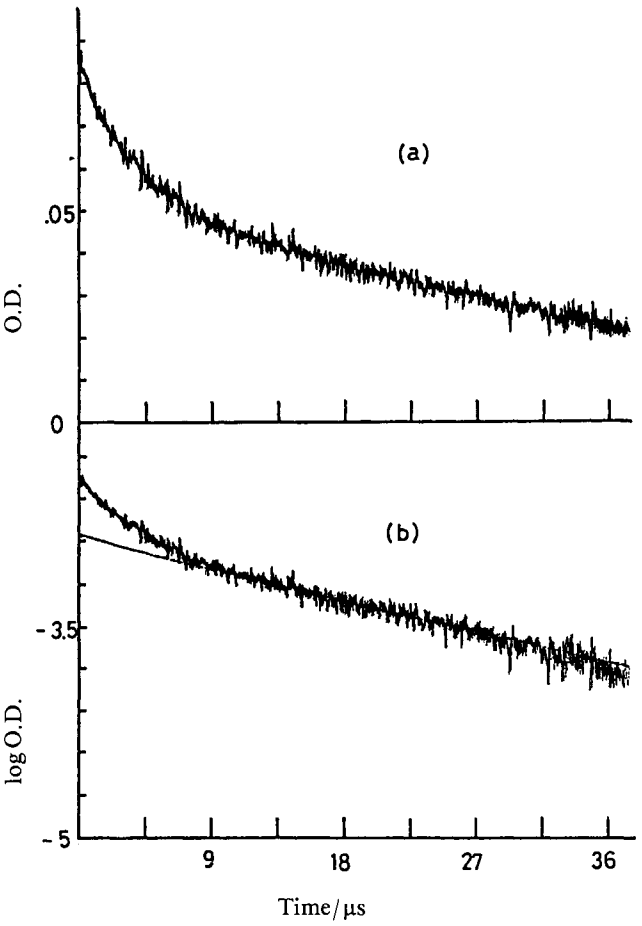

Fig. 2. Representative data displays from laser flash photolysis kinetic spectroscopy experiments: (a) absorbance at 320 nm as a function of time upon irradiation of $(Ph_2MeGe)_2$ (**2**) (2.6 mM) in degassed THF solution, (b) log absorbance at 320 nm as a function of time upon irradiation of **2** (the slope of linear plot is first-order rate constant).

and the $\log A(t)$ curve of the short-lived component, excluding those of the longer-lived one, is shown in Fig. 3. Thus, a careful examination of the transient peak at shorter wavelengths shows that it comprises two components (half lifetimes, $t_{1/2}$<5 μs and $t_{1/2}$>20 μs, respectively, for **1** and **2** in THF and hydrocarbon media). On the other hand, the transient peak at shorter wave-

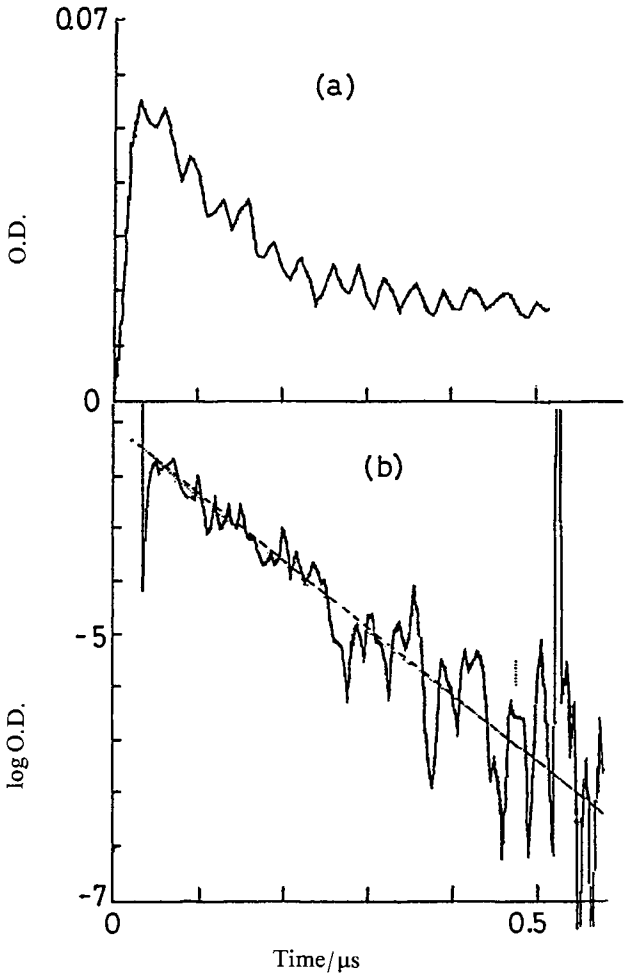

Fig. 4. Representative data displays from laser flash photolysis-kinetic spectroscopy experiments: (a) absorbance of short-lived component at 320 nm as a function of time upon irradiation of $(PhMe_2Ge)_2$ (**1**) (2.6 mM) in degassed THF solution containing CCl_4 (10 mM), (b) log absorbance of short-lived component at 320 nm as a function of time upon irradiation of **1** containing CCl_4.

lengths arising from **3** has only the short-lived component. This component has been reasonably assigned to that of the phenyl-substituted germyl radicals, $Ph_nMe_{3-n}Ge\cdot$ (n=1—3), from a comparison of the spectral characteristics with those reported for germyl radicals.[17] The experimentally determined decay constants of these transient species are summarized in Table 2. The transient arising from **1**—**3** decayed under pseudo first-order kinetics and are dependent on the concentrations of the employed phenylated digermanes. Such kinetics can be explained by the addition of the generated germyl radical to the aromatic ring on a germanium atom. This is very different from the situation reported regarding the addition of germyl radicals to aromatic compounds in solutions.[18] The assignment of a shorter-lived transient has been further substantiated by quenching experiments with carbon tetrachloride, oxygen, and 2,3-dimethylbutadiene. The addition of carbon tetrachloride, an effective germyl radical scavenger, quenched the transient absorption (Table 2). The quenching-rate constants observed nicely agree with the values reported for germyl radicals.[17] Similarly, oxygen quenched the shorter-lived transient very quickly (Table 2). Representative data displays from laser flash photolysis-kinetic spectroscopy experiments are shown in Fig. 4.

What is the latter carrier of the longer-lived transient at shorter wavelengths? The concentration of this species appeared to be correlated with that of the shorter-lived species assigned to the germyl radicals as well as that of the longer-wavelength transient arising from the

germylene described below. Furthermore, the change in the intensity of the transient was examined in isooctane as well as in more viscous solvents, such as dodecane. Figure 5 shows the intensity of the longer-lived transient in isooctane tends to increase in dodecane. This implies that this transient species may be a product of a radical which had escaped from the cage. Accordingly, the longer-lived species may be tentatively assigned to a coupling product of the germyl radicals at the ipso-position, as described in Scheme 2. The possibility of germenes and digermenes, suggested as another species, is excluded the UV data of germenes and digermenes are below 300 nm[19] and above 370 nm[20] respectively.

The experimentally determined decay constants of longer-lived transients are summarized in Table 3.

On the other hand, the transient at the longer wavelength (Fig. 1) could be assigned to that of a germylene by comparing its chemical and spectral properties with those reported.[21-23] These transients arising from **2** and **3** in THF decayed with first-order kinetics. However, the transient arising from **1** in THF is too weak to observe its decay constant. This kinetic behavior implies that the germylene reacts with THF in a similar as do the silylenes.[24] In contrast, in inert solvents, such as isooctane, the transient due to the germylene decayed with second-order kinetics, suggesting the formation of digermenes. This was further substantiated by quenching experiments with a germylene trapping agent, 2,3-dimethylbutadiene, which gives the corresponding germacyclopentenes. The transient from **2** and **3** in THF in the presence of large excess amounts of the diene decayed with pseudo first-order kinetics; the obtained rate constants are summarized in Table 4. The fact that these transients were not quenched by ethanol is in accord with the observed chemical property.

Photoreaction Mechanism of Phenylated Digermanes. The results of photochemical reactions and laser flash photolysis studies of **1**—**4** are best rationalized as a pair of germyl radicals according to the path described in Scheme 2. The photolysis of aryldigermanes cleaves the germanium–germanium bond to give a pair of germyl radicals. The generated germyl radicals readily abstract a chlorine atom from carbon

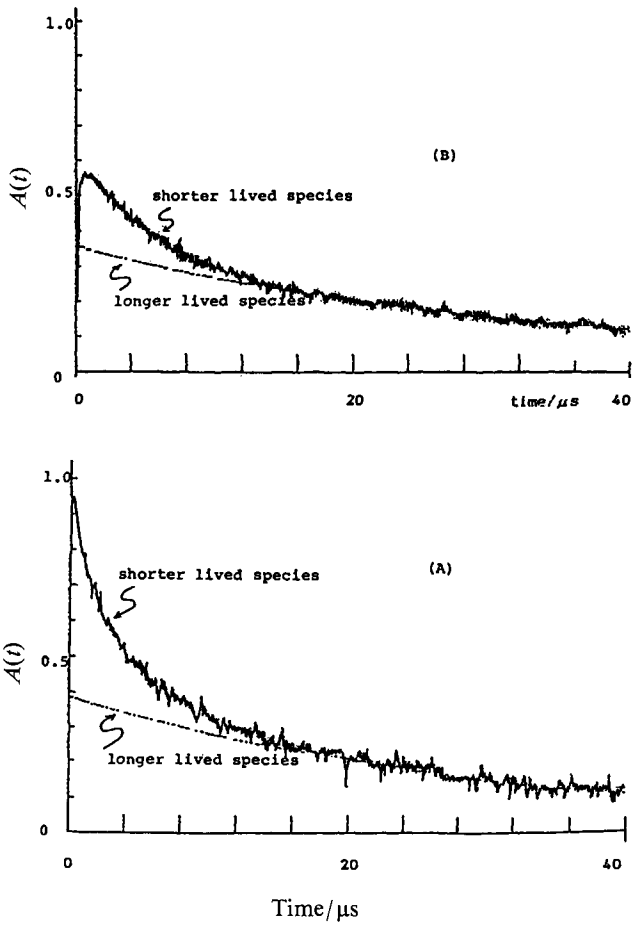

Fig. 5. Plots of the absorbance at 320 nm against t observed with the isooctane (A) and dodecane (B) of **1**.

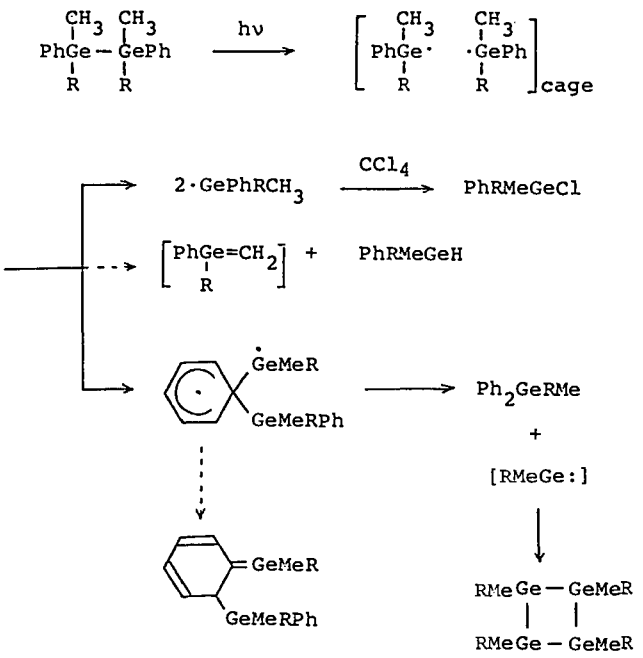

Scheme 2.

tetrachloride to give the corresponding chlorogermanes and trichloromethyl radical. The formation mechanism of hydrogermanes are unclear.

The germyl radicals couple at the ipso-position to give germyl-substituted cyclohexadienyl type radicals. The germyl-substituted cyclohexadienyl type radicals undergo further elimination to produce a gemylene and arylgermanes. The photo-generated germylene dimerize to give digermenes or react with 2,3-dimethylbutadiene to give germacyclopentenes. The arylgermanes produced by elimination processes are Ph_2GeMe_2 for **1**, Ph_3GeMe for **2**, and $PhGeMe_3$ for **4**. In contrast to the case of the aryldisilane, we have no concrete evidence for the presence of formal 1,3-germyl migration products in the photolysis of **1**, **2**, and **4**. This difference in the photochemical behavior between an arydigermane and an aryldisilane may be accounted for in terms of the following reasons. The bond dissociation energy of a germanium–carbon bond (318 kJ mol^{-1}) is less than that of a silicon–carbon bond (343 kJ mol^{-1}), and π-bonding of carbon must be formed more effectively with a silicon atom than with a germanium atom.[18]

In addition, organogermylene is more thermodynamically stable than is silylene. All of those factors favor the formation of germylene and germylene elimination products from the coupling products of germyl radicals at the ipso-position over the formation of germyl migration products.

The formation of germylenes and arylgermanes cannot necessarily be explained by a 1,2-phenyl shift of the phenylated digermanes, since the transient signal of the germylenes was observed with that of the germyl radicals immediately after photoexcitation of the phenylated digermanes. Taking the results of the trapping experiments with carbon tetrachloride, the 1,2-phenyl shift proceeds as a minor path.

Experimental

^1H NMR spectra were recorded on a Varian FT 80A, with tetramethylsilane as an internal standard. GC-MS spectra were obtained with a JEOL JMX-DX 303 mass spectrometer. Infrared spectra were recorded on a Hitachi 260-10 spectrometer. Gas chromatography was performed on a Shimadzu GC-6A and 8A with 2 m 20% SE30 and 1 m 10% SE columns.

Materials. 2,3-Dimethylbutadiene, CCl_4, and ethanol were commercially available. $PhMe_2GeGeMe_2Ph$, bp 170—174 °C/4 mmHg (1 mmHg=133,322 Pa),[25] $Ph_2MeGeGeMePh_2$, mp 132—133 °C,[25] $Ph_3GeGePh_3$, mp 335—340 °C,[25] $Me_3GeGePh_3$, mp 108—109 °C,[26] $PhMe_2GeH$, bp 65—66 °C/20 mmHg,[27] Me_3GeH, bp 26 °C,[28] Ph_2MeGeH, bp 105—106 °C/6 mmHg,[29] Ph_3GeH, mp 39.5 °C,[30] Me_3GeCl, bp 98 °C,[28] $PhMe_2GeCl$, bp 90 °C/10 mmHg,[31] $Ph_2MeGeCl$, bp 140 °C/14 mmHg,[32] Ph_3GeCl, mp 145 °C,[33] Ph_2GeMe_2, bp 145 °C/14 mmHg,[34] Ph_3GeMe, mp 71 °C,[35] $PhGeMe_3$, bp 80 °C/20 mmHg,[36] 1-methyl-1-phenylgermacyclopent-3-ene,[37] and $(Me_2Ge)_4$[11] were prepared as described in the cited references.

Solvents. Cyclohexane, isooctane, dodecane, and THF were distilled from sodium–benzophenone under an argon atmosphere.

Photochemical Reactions of the Phenylated Digermanes. The digermanes (ca. 200 mg) were dissolved in dry cyclohexane (6 cm^3) in a quartz tube. The tube was degassed in a vacuum and charged with argon. The sample was irradiated with a 110-W low-pressure Hg arc lamp at room temperature for 2 h. After irradiation, the photoproducts were verified by comparing the retention times on GLC and GC-MS with those of authentic samples.

Photochemical Reactions of the Phenylated Digermanes with Various Trapping Agents. As a representative example, photolysis of a cyclohexane solution containing 1,1-diphenyltetramethyldigermane with CCl_4 is described. Compound **1** (200 mg, 0.56 mmol) and CCl_4 (0.45 g, 30 mmol) were dissolved in dry cyclohexane (6 m^3) in a quartz tube. The sample tube was degassed in a vacuum and charged with argon. The sample was irradiated at room temperature for 20 min. After irradiation, the photoproducts were verified by comparing the retention time on GLC and GC-MS with those of authentic samples.

Time-Resolved Optical Absorption. Samples in quartz cells with an optical length of 5 mm were degassed by four freeze-pump-thaw cycles. The concentrations of the phenylated digermanes were ca. 10^{-3} M (1 M=1 mol dm^{-3}). Laser flash photolysis experiments were performed at room temperature (293 K) by using the fourth-harmonic (266 nm) of a Quanta-Ray DCR-1 Nd:YAG laser as the exciting light source. The laser pulse was about 5 ns. Details concerning the laser flash photolysis apparatus have been published elsewhere.[16] The signals were monitored by a Tektronix 485 oscilloscope (350 MHz) and recorded by an Iwatsu DM-901 digital memory (10 ns/point, 8 bit) controlled by an NEC PC 8801 microcomputer.

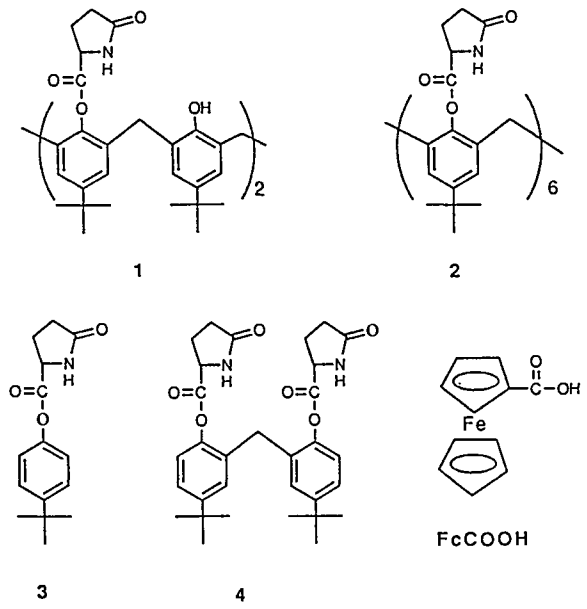
Formation of Molecular Complexes with Calixarenes as Detected by Induced Circular Dichroism

Takashi ARIMURA and Seiji SHINKAI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received February 2, 1991)

Calix[*n*]arenes (*n*=4 and 6) bearing (*S*)-5-oxo-2-pyrrolidinylcarbonyloxyl groups on the lower rim were synthesized. In chloroform, the hexamer bearing six (*S*)-5-oxo-2-pyrrolidinylcarbonyloxyl groups could "bind" ferrocenecarboxylic acid through hydrogen-bonding interactions, the complexation being conveniently detected by induced circular dichroism (ICD) spectroscopy (λ_{max} 445 nm). On the basis of the examination of acyclic reference compounds, the appearance of the ICD band was explained as such that one pyrrolidone unit acts as a binding site and the chiral center in the neighboring pyrrolidone unit affects the transition moments in the ferrocene π-system. The association constant for the 1 : 1 complex was estimated to be 680 M^{-1}. This is a new, convenient method for detecting the formation of molecular complexes with calixarenes in organic media.

Calixarenes are cyclic oligomers which are composed of phenol units. Because of their cavity-shaped architecture, they would be expected to be useful building-blocks in the design of novel host molecules.[1—4] Although calixarenes can include several small molecules in the solid state,[1,2] there exist only a few examples for inclusion of guest molecules in solution.[5] This is because host–guest-type complexation in organic media always competes with solvation of guests by solvent molecules. Exceptional is the aqueous system: For instance, water-soluble calixarenes can associate with organic guest molecules owing to a hydrophobic force, a driving force for association specifically operating in water.[6] Thus, the host–guest chemistry of calixarenes has been studied in aqueous solutions.[3,4,7] Only one example reported so far for complexation in organic media is the binding of *t*-butylamine to 5,11,17,23-tetraallylcalix[4]arene-25,26,27,28-tetrol.[5] However, the main driving force for this complex is supposed to be acid-base neutralization between amine and phenol.[5]

In conformity with the foregoing view, we reached a conclusion that one should adopt a new concept to effect inclusion of guest molecules in organic media. Also, some new strategies should be developed to efficiently detect host–guest interactions occurring in organic media. We noticed hydrogen-bonding interactions which have frequently been used in molecular recognition may be useful.[8—11] To detect the interactions between hosts and guests we chose induced circular dichroism (ICD) which sensitively reports the interaction with chiral centers. Thus, we synthesized calix[*n*]arenes (*n*=4 and 6) as host molecules bearing (*S*)-2-pyrrolidone units which have hydrogen-bonding sites as well as a chiral center. As guest molecules, we chose ferrocene derivatives because they have a characteristic absorption band at around 450 nm.



Experimental

Materials. 5,11,17,23-Tetra-*t*-butylcalix[4]arene-25,26,27,28-tetrol and 5,11,17,23,29,35-hexa-*t*-butylcalix[6]arene-37,38,39,40,41,42-hexol were prepared according to Gutsche's method.[12]# (*S*)-5-Oxo-2-pyrrolidinecarbonyl chloride was prepared from (*S*)-5-oxo-2-pyrrolidinecarboxylic acid (Aldrich, 97% purity) according to the literature.[13]

25,27-Bis[(*S*)-5-oxo-2-pyrrolidinylcarbonyloxy]-5,11,17,23-tetra-*t*-butylcalix[4]arene-26,28-diol (1). Oil-dispersed NaH (152 mg; 3.8 mmol) was added to 40 ml of THF containing tetra-*t*-butylcalix[4]arenetetrol (350 mg; 0.54 mmol). The mixture was stirred for 4 h at room temperature under a nitrogen stream. (*S*)-5-Oxo-2-pyrrolidinecarbonyl chloride (0.53 g; 4.0 mmol) was added dropwise. The reaction was continued at room temperature for 15 h. After addition of a small amount of ethanol, the mixture was concentrated to dryness under reduced pressure. The residue was dissolved in dichloromethane, the solution being washed with water and dried over Na_2SO_4. After concentration to dryness, the residue was recrystallized from hexane–toluene: White powder, mp 280—284 °C, yield 57%; ^{1}H NMR ($CDCl_3$) δ=0.92 and 1.20 (18H each, s each, *t*-Bu), 2.20—2.60 (8H, m,

The nomenclature for calix[*n*]arene is a little confused now. In this paper, we named the [1$_n$]metacyclophane structure [$\overline{(\text{CH}_2\text{-}m\text{-}\text{C}_6\text{H}_4)_n}$] "calix[*n*]arene".

CH_2CH_2 in pyrrolidone), 3.40 and 3.90 (4H each, d each (J=13 Hz), $ArCH_2Ar$), 4.28—4.32 (2H, m, CH in pyrrolidone), 6.20 (2H, broad s, NH), 6.90 and 7.15 (4H each, s each, ArH). Found: C, 74.03; H, 7.70; N, 2.94%. Calcd for $C_{54}H_{66}O_8N_2$: C, 74.45; H, 7.64; N, 3.22%. The ^{1}H NMR spectrum and elemental analysis indicate that the recovered product is 25,27-disubstituted-26,28-dihydroxy-5,11,17,23-tetra-*t*-butylcalix[4]arene. The split pattern for the $ArCH_2Ar$ protons shows that this calix[4]arene adopts a cone conformation.

37,38,39,40,41,42-Hexakis[(*S*)-5-oxo-2-pyrrolidinylcarbonyloxy]-5,11,17,23,29,35-hexa-*t*-butylcalix[6]arene (2). This compound was synthesized in a manner similar to that described for **1**: Colorless powder, mp 215—217 °C, yield 28%; ^{1}H NMR ($CDCl_3$) δ=1.20 (54H, s, *t*-Bu), 2.22—2.58 (24H, m, CH_2CH_2 in pyrrolidone), 3.80 (12H, broad s, $ArCH_2Ar$), 4.29—4.32 (6H, m, CH in pyrrolidone), 6.17 (6H, broad s, NH), 7.15 (12H, s, ArH). Found: C, 69.85; H, 6.93; N, 4.61%. Calcd for $C_{96}H_{114}O_{18}N_6$: C, 70.31; H, 7.01; N, 5.12%. The ^{1}H NMR spectrum and elemental analysis indicate that six OH groups are substituted.

***p*-*t*-Butylphenyl (*S*)-5-Oxo-2-pyrrolidinecarboxylate (3).** This compound was also synthesized from (*S*)-5-oxo-2-pyrrolidinecarbonyl chloride and *p*-*t*-butylphenol in the presence of NaH: Colorless prisms (recrystallized from acetonitrile), mp 124—127 °C, yield 60%; ^{1}H NMR ($CDCl_3$) δ=1.16 (9H, s, *t*-Bu), 2.04—2.38 (4H, m, CH_2CH_2), 4.02—4.38 (1H, m, CH), 6.12 (1H, broad s, NH), 5.73 and 7.24 (2H each, d each, (J=9 Hz), ArH). Found: C, 69.44; H, 7.70; N, 5.12%. Calcd for $C_{15}H_{19}NO_3$: C, 68.94; H, 7.33; N, 5.36%.

Bis[2-((*S*)-5-oxo-2-pyrrolidinylcarbonyloxy)-5-*t*-butylphenyl]methane (4). This compound was synthesized from (*S*)-5-oxo-2-pyrrolidinecarbonyl chloride and 4,4′-di-*t*-butyl-2,2′-methylenediphenol in the presence of NaH: Colorless prisms (recrystallized from hexane), mp 126—129 °C, yield 43%; ^{1}H NMR ($CDCl_3$) δ=1.25 (18H, s, *t*-Bu), 2.20—2.60 (8H, m, CH_2CH_2), 3.90 (2H, s, $ArCH_2Ar$), 4.30—4.35 (2H, m, CH), 6.15 (2H, broad s, NH), 6.76 and 7.10 (2H each, d each (J=8 Hz), ArH), 7.30 (2H, s, ArH). Found: C, 70.05; H, 7.20; H, 5.12%. Calcd for $C_{31}H_{38}N_2O_6$: C, 69.64; H, 7.16; H, 5.24%.

Results and Discussion

In O-acylation of 25,26,27,28-tetrahydroxy-5,11,17,23-tetra-*t*-butylcalix[4]arene with (*S*)-5-oxo-2-pyrrolidinecarbonyl chloride we found that only two OH groups can be substituted. The similar result was observed for O-alkylation of 25,26,27,28-tetrahydroxy-5,11,17,23-tetra-*t*-butylcalix[4]arene with 2-chloromethylpyridine.[14] In contrast, six OH groups in 37,38,39,40,41,42-hexahydroxy-5,11,17,23,29,35-hexa-*t*-butylcalix[6]arene are all substituted. The difference is attributed to the difference in the ring size: that is, the space on the narrow calix[4]arene ring readily becomes sterically-crowded by O-substitution.

When **2** was mixed with ferrocenecarboxylic acid (FcCOOH) in chloroform, a negative ICD band appeared at 445 nm (Fig. 1). This CD maximum is equal to the absorption maximum of FcCOOH. This band was weakened by the addition of methanol. In contrast, this band was not detected at all in DMSO under the same measurement conditions. These results indicate that FcCOOH "interacts" with **2** and the interaction is based on the formation of hydrogen-bonds.

To confirm the importance of the hydrogen-bonding interaction, we used ferrocene (Fc) and methyl ferrocenecarboxylate (FcCOOMe) as reference guest molecules. The ICD band for these compounds was not detected even in chloroform. Here, one can visualize that attraction between **2** and FcCOOH is ascribed to the hydrogen-bonding interaction between the COCHNHCO moiety in **2** and the COOH moiety in FcCOOH. Between two possible binding modes, (A) includes a seven-membered ring whereas (B) includes a six-membered ring (hydrogen atoms are not counted). We consider that binding mode (B) is more likely.

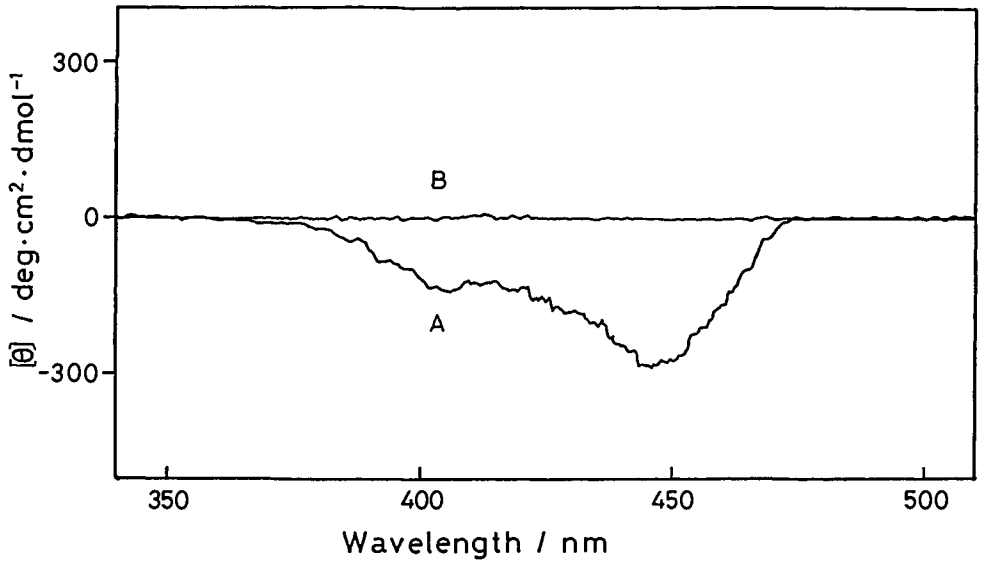


Fig. 1. ICD spectra of FcCOOH in the presence of **2**: 20 °C, [**2**]=1.00×10^{-2} M, [FcCOOH]=5.00×10^{-3} M: (A) chloroform, (B) DMSO.

Table 1. Absorption and ICD Spectra of Ferrocene Derivatives[a)]

Guest	Solvent	λ_{max} in absorption spectrum	$\lambda_{max}(\theta)$ in ICD spectrum			
		nm	Host=1	2	3	4

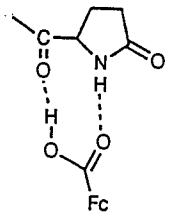
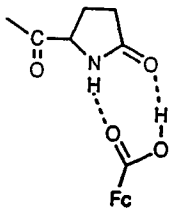
FcCOOH	DMSO	443	nd	nd	nd	nd
FcCOOMe	$CHCl_3$	446	nd	nd	nd	nd
FcCOOMe	DMSO	446	nd	nd	nd	nd

a) 20 °C, chloroform: [1]=[2]=1.00×10^{-2} M, [3]=8.00×10^{-2} M, [4]=4.00×10^{-2} M, [ferrocene derivative]=5.00×10^{-3} M. Nd denotes that the ICD band is not detected.



(A)



(B)

Here, we discuss how the interaction between **2** and FcCOOH becomes CD-active. Compound **1**, having two pyrrolidone units at 1,3-position, should interact with FcCOOH through the hydrogen-bonds in chloroform. Actually, however, the perceptible ICD band was not recognized. The difference suggests that two neighboring pyrrolidone units would be essential for the ICD-activity. To estimate this hypothesis, we synthesized acyclic analogs **3** and **4**. As summarized in Table 1, the ICD band of FcCOOH did not appear in the presence of monomeric **3**. In the presence of dimeric **4**, on the other hand, the weak but perceptible ICD band appeared at 445 nm. This supports the view that two neighboring pyrrolidone units act cooperatively to make the bound FcCOOH CD-active; conceivably, one pyrrolidone unit acts as a binding site and the chiral center in the neighboring pyrrolidone unit affects the transition moments in the ferrocene π-system. With this cooperative action of two neighboring units the ICD-activity is observed for the **2**·FcCOOH complex.

We determined the stoichiometry for complexation between **2** and FcCOOH on the basis of a continuous variation plot (Fig. 2). It is seen from Fig. 2 that **2** and FcCOOH form a 1 : 1 complex. Why do they form a 1 : 1 complex although **2** has six pyrrolidone units on the lower rim? The result implies that the binding of FcCOOH to one pyrrolidone unit strongly suppresses the binding to other remaining pyrrolidone units. Previously, Aoyama et al.[15)] synthesized lipophilic calix[6]arenes bearing amide groups on the lower rim. These compounds provide a polar (DMF-like) microenvironment composed of the amide linkages. Possibly, the lower rim in **2** has such a polar microenvironment.

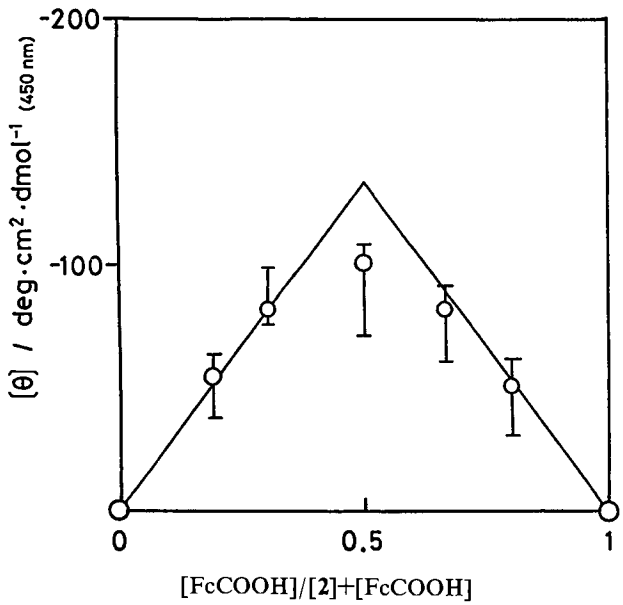


Fig. 2. Continuous variation plot for complexation of **2** and FcCOOH: 20 °C, chloroform, [2]+[FcCOOH]=5.00×10^{-3} M.

This suggests that when FcCOOH is bound to **2** through the hydrogen-bonding interaction, the ferrocene moiety is trapped in the cavity through the dipole–dipole interaction. In this binding model the lower rim is wholly occupied by the first FcCOOH, so that the binding of the second FcCOOH becomes sterically difficult. To prove this association mode, we measured the ^{1}H NMR spectrum of the **2**·FcCOOH complex ($CDCl_3$, 25 °C, [2]=5.00×10^{-2} M, ## [FcCOOH]=7.50×10^{-3} M). FcCOOH in the absence of **2** gave three peaks at 4.25 (5H), 4.45 (2H), and 4.48 (2H) ppm, which were assigned to the cyclopentadiene ring protons without COOH, C<u>H</u>(CHCCOOH), and C<u>H</u>(CCOOH) protons in the cyclopentadiene ring with COOH, respectively. In the presence of **2** the C<u>H</u>(CHCOOH) protons specially shifted to 4.81 ppm whereas the chemical shifts for other protons were scarcely affected. This result means that these protons are placed in the plane of the benzene

1 M=1 mol dm^{-3}.

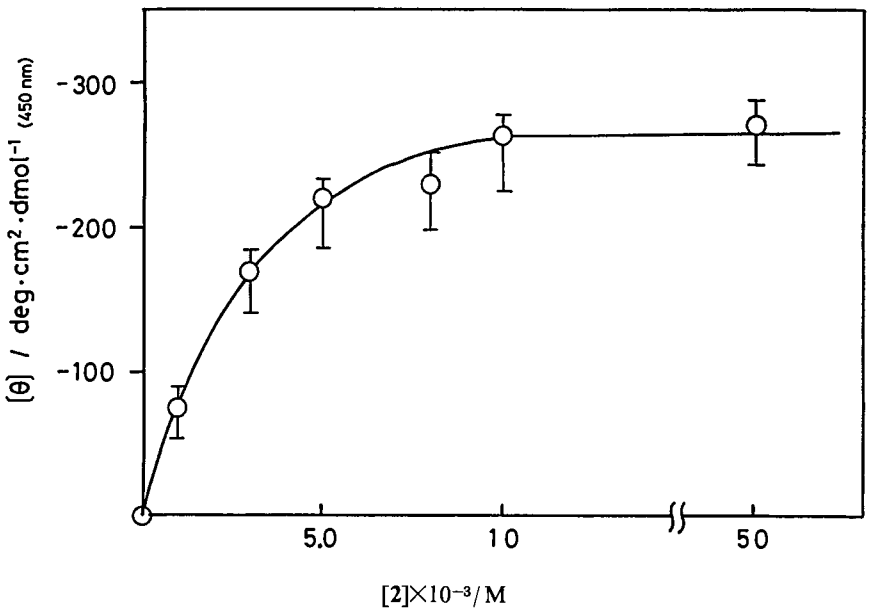

Fig. 3. Plot of θ vs. [2] in chloroform at 20 °C: [FcCOOH]=5.00×10^{-3} M.

rings in **2**; that is, the part of the ferrocene moiety is trapped in the lower rim of the calix[4]arene ring.

We measured θ as a function of [2] (Fig. 3). The plot showed a typical saturation curve. By the analysis of this plot by the Benesi-Hildebrand equation for a 1 : 1 complex, we estimated the association constant to be 680 M^{-1} (correlation coefficient 0.997). This value is comparable with those for complexes formed through two-to-three hydrogen bonds.[16]

Since the complexation between **2** and FcCOOH is based on the hydrogen-bonding interaction, FcCOOH should be substituted by other additives bearing a carboxyl group. This process is similar to the action of "competitive inhibition" in enzyme chemistry. We used trifluoroacetic acid (pK_a in water 0.23), benzoic acid (pK_a in water 4.19), adamantane-1-carboxylic acid (pK_a in water 4.50), and acetic acid (pK_a in water 4.76) as "inhibitors". To a chloroform solution containing **2** (1.00×10^{-3} M) and FcCOOH (2.00×10^{-2} M) was injected a chloroform solution containing concentrated "inhibitors". The final concentration of "inhibitors" was adjusted to 2.00×10^{-2} M. On the addition of adamantane-1-carboxylic acid and acetic acid, the ICD band on the basis of the **2**–FcCOOH interaction was scarcely affected. On the addition of trifluoroacetic acid, in contrast, the ICD band disappeared completely. Benzoic acid moderately competed with FcCOOH, the CD band being decreased with increasing benzoic acid concentration. These results support the view that the association on the basis of hydrogen-bonding interaction is primarily governed by the "acidity" of protons.

The association constant for FcCOOH (K_{FcCOOH}) is defined by Eq. 1. The substitution with benzoic acid (BA) occurring on the lower rim is expressed by Eq. 2. This gives Eq. 3 for the equilibrium constant (K_e). Thus, the association constant for BA (K_{BA}) is expressed, assuming the 1 : 1 substitution between FcCOOH and BA, by Eq. 4.

$$K_{FcCOOH}=\frac{[2\cdot FcCOOH]}{[2][FcCOOH]}, \quad (1)$$

$$2\cdot FcCOOH+BA \rightleftarrows 2\cdot BA+FcCOOH, \quad (2)$$

$$K_e=\frac{[2\cdot BA][FcCOOH]}{[2\cdot FcCOOH][BA]}, \quad (3)$$

$$K_{BA}=K_{FcCOOH}\cdot K_e. \quad (4)$$

We obtained K_e=0.22 from Eq. 3. This allows the estimation of K_{BA}=150 M^{-1}.

In conclusion, the present paper demonstrated the guest complexation through hydrogen-bonding interactions occurring in organic media. In the past, it was difficult to detect the formation of molecular complexes with calixarenes in organic media. In fact, NMR spectroscopy was the sole method.[5] It is shown here that CD spectroscopy serves as an efficent and convenient technique to detect how the guest interacts with the host calixarenes. We plan to extend this concept to chiral recognition of guest molecules.

Synthesis of 7-Substituted 6,7-Dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones. Reaction of 7-Hydroxy Derivatives with Nucleophiles

Takehiko Goto,* Shin Utsunomiya, Hiroshi Aiba, Hirotaka Hayasaka, Mikihiro Endo, Reo Watanabe, Takeshi Ishizaki, Ryu Sato, and Minoru Saito†
Department of Resource Chemistry, Faculty of Engineering, University of Iwate, Morioka 020
(Received February 25, 1991)

Various 7-substituted 6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones are synthesized by the reaction of the corresponding 7-hydroxy derivatives with nucleophiles involving active methylene compounds, aromatics, alcohols, *p*-toluenethiol, benzenesulfinic acid, triethyl phosphite, ammonia, and amines under acidic or basic conditions. Some synthetic applications of the products obtained are demonstrated to give a 7-methylene derivative and fused tricyclic derivatives.

Much effort has been devoted to the investigation of 6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones and their derivatives as cyclic nicotinamide analogs or aza-analogs of phthalimidines,[1-6] some of which are known to be biologically active compounds such as antidiabetic agents,[2] central nervous agents,[3,4] and herbicides.[5] In connection with our studies of novel functionalized isoindoles,[7] we planned the synthesis of their aza-analogs and concentrated our attention on 7-substituted 6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones. Though some 7-substituted derivatives are known to be interesting pharmacologically active compounds such as non-benzodiazepine anxiolytic agents,[3,4] there have been few studies on general synthetic approach to 7-substituted derivatives in the literature, partially because unsymmetrically substituted cyclic compounds pose the problem of regiochemistry. Recently, we have performed the efficient regioselective synthesis of 7-hydroxy derivative[8a] and preliminarily reported some transformations of the hydroxyl group to other substituents.[8b,c] In this paper, we describe the synthesis of a wide variety of 7-substituted derivatives **2**—**8** from 7-hydroxy derivative **1** in detail and discuss the scope and limitation of the present methodology.

Results and Discussion

In principle, hydroxylactam **1** can be considered as (a) a source of acyliminium cation which is well known to react with various types of nucleophiles[9] and (b) a masked aldehyde which is expected to react with anionic species[4,10,11] as depicted in Scheme 1. On the basis of such viewpoints, we examined the reaction of **1** with nucleophiles under various reaction conditions and

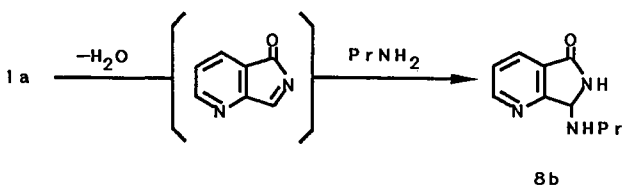
representative results are shown in Tables 1 and 2.

Acyliminium cations generated from **1a**—**c** in boiling trifluoroacetic acid (Method A) smoothly reacted with active methylene compounds such as a keto ester and diketones to yield the corresponding 7-substituted derivatives **2a**—**e** quantitatively. In the case of the keto ester (ethyl acetoacetate), the ^{1}H NMR of the crude product indicated existence of two diastereomers, but only one diastereomer was obtained after recrystallization and characterized. In contrast with the diketone and keto ester, diethyl malonate was inactive under the reaction condition, probably due to the lower concentration of the enol-form compared to the keto ester and diketone. Unfortunately, our further attempts to cause the substitution reaction under severer acidic conditions with sulfuric acid[9] or aluminum trichloride[9] and a basic condition with the enolate anion[10] of diethyl malonate resulted in the formation of a complex mixture.

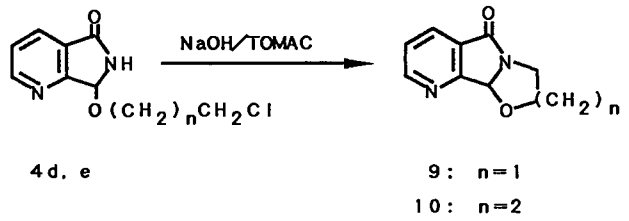
Although our effort to introduce a 7-alkenyl substituent by the reaction of alkenes with the acyliminium cation resulted in the formation of a complex mixture, aromatic compounds cleanly underwent an electrophilic substitution reaction with the acyliminium cation to furnish the corresponding 7-aryl substituted product **3**. Thus, when dimethoxybenzenes and anisole which are activated for the electrophilic substitution reaction were treated with **1a**—**c** under the reaction condition of Method A, the corresponding products **3a**—**f** were obtained in reasonable to excellent yields. On the other hand, a deactivated aromatics, bromobenzene required a strong acid such as concd sulfuric acid (Method B) for the preparation of products **3g**—**j** as well as the case of benzene itself.[8c] In contrast to the completely regioselective formation of the 3,4-isomer with 1,2-dimethoxybenzene, anisole, and bromobenzene afforded a mixture of ortho and para isomers. These isomers were separated by recrystallization and column chromatography and their regiochemistries were determined by ^{1}H NMR.[12]

The reaction of **1** with primary and secondary alcohols in the presence of a catalytic amount of *p*-toluenesulfonic acid (Method C) gave the corresponding 7-alkoxy products **4a**—**g** in quantitative yields. In the case of an optically active alcohol, *l*-menthol, a mixture of the corresponding diastereomers (**4h** and **4i**, diastereomeric excess=0), which was separable by column chromatography, was produced in a high chemical yield. Some 7-sulfur-atom-substituted derivatives were also prepared by the acid-catalyzed reaction in good yields. Thus, the reaction of **1** with *p*-toluenethiol in the presence of catalytic amount of *p*-toluenesulfonic acid in boiling acetonitrile (Method D) gave **5a**. Furthermore, a similar treatment with benzenesulfinic acid which was generated with sodium benzenesulfinate and *p*-toluenesulfonic acid (Method E) led to the formation of **6a,b**. However, the acid-catalyzed reaction with *t*-butyl alcohol gave only a low yield (20%) of the corresponding product because of the equilibrium between the substrate and the product in the presence of water. We could overcome this problem by the conversion of the hydroxyl group of the lactam to an excellent leaving group such as trifluoroacetate in the absence of water. Thus, the treatment of **1a**—**c** with trifluoroacetic anhydride followed by the addition of *t*-butyl alcohol (Method F) led to the formation of **4j**—**l** in high yields. This improved method was also effective for an Arbuzov type of reaction of **1a,b** with triethyl phosphite (Method G) to give the corresponding products **7a,b** which could not be obtained by the *p*-toluenesulfonic acid-catalyzed or non-catalyzed reaction. Even though the trifluoroacetylated intermediate could not be isolated due to its lability, the trifluoroacetylation procedure complements existing methods for the generation of the acyliminium cation.

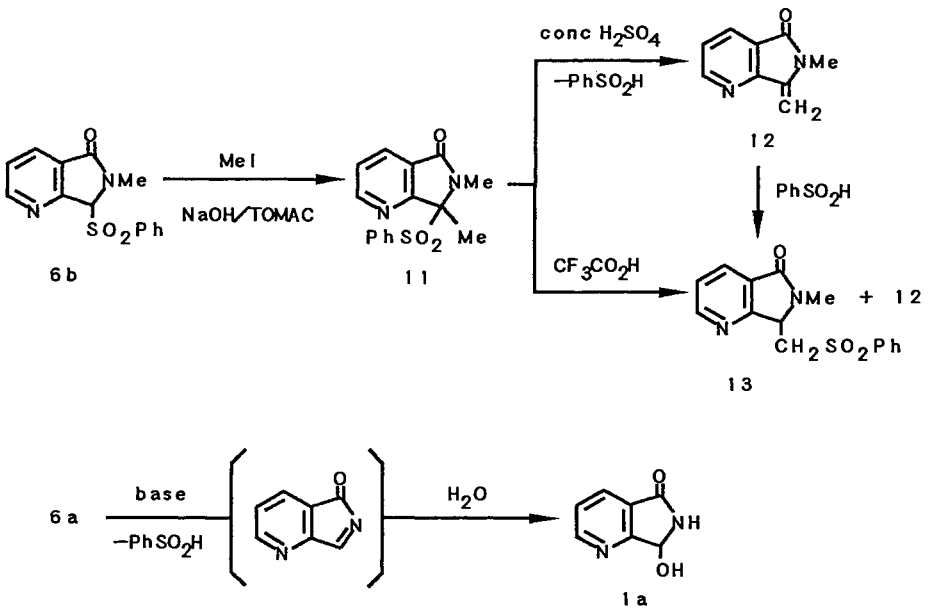
N-Phenylated lactam **1c** was cleanly aminated to **8a** by heating in liquid ammonia (Method H) as shown in the previous report with *N*-unsubstituted **1a**,[8b] while *N*-methylated **1b** gave only a trace amount of the corresponding product under the same reaction conditions. Similarly, treatment of **1a**—**c** with propylamine in boiling dioxane (Method I) led to **8b**—**d** but almost all amount of **1b** was again recovered under these reaction conditions. This remarkable substituent effect suggests that an electron-donating group such as methyl group at N-6 position precludes the ring opening of the hydroxylactam depicted in Scheme 1 (Path b). The electronic effect of substituents (H, Me, and Ph) at N-6 position is consistent with chemical shifts of H-7 of **1a**—**c**; in DMSO-d_6 δ=5.72 (**1b**), 5.82 (**1a**), and 6.44 (**1c**). However, the present data can not exclude a possibility that *N*-unsubstituted lactam **1a** undergoes the elimination of water instead of the ring opening, followed by the addition of an amine (Scheme 2). As also expected from the reaction mechanism in Path b which would involve the formation of a Schiff base, secondary amines



Scheme 2.



Scheme 3.



Scheme 4.

were inactive for the hydroxylactam under the basic reaction condition of Method I. Interestingly, the addition of a catalytic amount of *p*-toluenesulfonic acid in the reaction system (Method J) remarkably accelerated the rate of the reaction with primary and secondary amines to give **8b**—**f** in excellent yields, probably due to the generation of the acyliminium cation. As far as we know, it is the first example of acid-catalyzed amination of hydroxylactams. However, Method J was unsatisfactory for bulky amines such as diethylamine and *t*-butylamine resulting in low yields of the products (<36%). After examining reaction conditions, we found an effective way similar to Method G, that is the treatment of the bulky amine with the solution of **1b** in trifluoroacetic anhydride (Method K) affording **8g**,**h**, quantitatively. It is noteworthy that Methods J and K might be the fruitful methods for the preparation of alkylaminolactam **8** from hydroxylactam **1**.

Since various types of novel 7-substituted derivatives **2**—**8** have become available, we are now attracted to the synthetic application of these compounds. Previously, we reported a convenient alkylation of the 7-phenyl derivative at the 7-position in a phase transfer system, which involved synthesis of some fused cyclic derivatives, to demonstrate a synthetic utility of the 7-substituted derivative.[8b] Thus, we preliminarily tried to expand this methodology as follows: Compounds **4d** and **4e** having a terminal electrophilic carbon cleanly cyclized intramolecularly in the presence of NaOH-powder and trioctylmethylammonium chloride (TOMAC) to tricyclic products **9** and **10**, respectively (Scheme 3). 7-Sulfonylated **6b** having an active methine proton (H-7) was smoothly reacted with methyl iodide in the liquid–solid phase transfer system to give the 7-methylated product **11** in a good yield. Interestingly, compound **11** underwent the elimination of sulfinic acid in concd sulfuric acid to produce 7-methylene derivative **12** (Scheme 4). Recently, a similar elimination reaction has been observed by Hitching and Vernon with a 7-benzyl-7-hydroxy derivative.[6] Although this unstable and strongly fluorescent product could not be purified for the elemental analysis, spectroscopic data support the structure **12** and this method seems to be a useful way for the synthesis of 7-alkylidene derivatives. When compound **11** was treated with trifluoroacetic acid, 7-sulfonylmethyl derivative **13** was isolated (42%) along with **12** (36%) (Scheme 4). It is easily envisaged that this rearrangement product **13** was produced via elimination product **12**. In fact, **12** underwent the addition reaction with benzenesulfinic acid in trifluoroacetic acid to provide **13**. In contrast with 6-substituted **6b**, 6-unsubstituted **6a** could not be alkylated due to the elimination of sulfinic acid in the presence of NaOH followed by the addition of water resulting the 7-hydroxy derivative **1a** (Scheme 4).

In summary, novel 7-substituted derivatives **2**—**8** were obtained from 7-hydroxy derivative **1** by Methods A—K and some synthetic applications of the products were demonstrated.

Experimental

Measurements. Melting points are uncorrected. ^1H NMR spectra at 90 MHz were recorded with Hitachi R-22. IR spectra were recorded with Hitachi 295. Mass spectra were recorded with Hitachi M-2000. Optical rotations were measured with JASCO DPI-181. Elemental analysis were determined with Yanagimoto MT-3.

Materials. All reagents were obtained from Nacalai Tesque, Inc., Wako Pure Chemical Industries Ltd., Tokyo Kasei Co., Ltd., or Aldrich Chemical Co. The reagents were

used without further purification.

6-Substituted and Unsubstituted 6,7-Dihydro-7-hydroxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones (1a—c). These compounds were prepared according to an earlier reported procedure.[8a]

Ethyl 2-(6-Substituted and Unsubstituted 6,7-Dihydro-5-oxo-5*H*-pyrrolo[3,4-*b*]pyridin-7-yl)-3-oxobutanoates (2a—b), 3-(6,7-Dihydro-6-methyl-5-oxo-5*H*-pyrrolo[3,4-*b*]pyridin-7-yl)-2,4-pentanedione (2c), 2-(6-Substituted 6,7-Dihydro-5-oxo-5*H*-pyrrolo[3,4-*b*]pyridin-7-yl)-1,3-diphenyl-1,3-propanediones (2d—f), and 6-Substituted and Unsubstituted 7-Aryl-6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones (3a—f). General Procedure, Method A: A solution of **1** (1 mmol) and an active methylene compound or an aromatic compound (20 mmol) in trifluoroacetic acid (1 ml) was refluxed with stirring for 0.5—6 h. The reaction mixture was poured into ice-water, neutralized with solid Na_2CO_3 to pH 8 and extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water, dried over Na_2SO_4, and evaporated. The residue was further purified over a silica-gel column (Wako-gel C-200, $CHCl_3$ as eluent) to afford the product which was purified by recrystallization (Table 1). Recrystallization of a mixture of ortho and para isomers obtained by using anisole gave the pure para isomer **3f**. The ortho isomer was not isolated.

3g—3j General Procedure, Method B: To a solution of **1** (1 mmol) in concd sulfuric acid (1 ml), bromobenzene (20 mmol) was added under argon. The heterogeneous mixture was vigorously stirred at r. t. for 1—3 h. After a work-up similar to that in Method A, the mixture of the corresponding para and ortho isomer was separated by column chromatography (Wako-Gel C-200, AcOEt as eluent) to isomerically pure product which was further purified by recrystallization (Table 1).

6-Substituted and Unsbstituted 6,7-Dihydro-7-alkoxy-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones (4a—i). General Procedure, Method C: A mixture of **1** (1 mmol), *p*-toluenesulfonic acid monohydrate (0.1 mmol), and an alcohol (20 mmol) was heated at 65—110 °C, if necessary under reflux, for 0.2—8 h. After evaporation of the excess alcohol under reduced pressure, water (10 ml) was added to the residue. The resulting mixture was basified with solid $NaHCO_3$ to pH 9 and extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water, dried over Na_2SO_4 and evaporated to give the product which was purified by recrystallization (Table 1). Optically pure diastereomers were obtained from the mixture of diastereomers, which were produced by the reaction with *l*-menthol, by column chromatography [Wako-gel C-200, hexane–AcOEt (5 : 4 v/v) as eluent] and recrystallization.

4j—l. General Procedure, Method F: A mixture of **1** (1 mmol) and trifluoroacetic anhydride (0.5 ml) was stirred for 20 min under nitrogen. The excess trifluoroacetic anhydride and the resulting trifluoroacetic acid were removed under reduced pressure, followed by addition of *t*-butyl alcohol (2 ml). After 5 min, the mixture was quenched with aqueous $NaHCO_3$ (saturated, 5 ml) and extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water, dried over Na_2SO_4, and evaporated to give the product which was purified by recrystallization (Table 1).

6,7-Dihydro-7-(*p*-tolythio)-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (5a). Method D: A solution of **1a** (1 mmol), *p*-toluenethiol (1.1 mmol) and *p*-toluenesulfonic acid (0.05 mmol) in CH_3CN (10 ml) was refluxed for 3.5 h. After $NaHCO_3$ (0.5 g) had been added to the reaction mixture, the solvent was evaporated. The residue was treated with water (10 ml) and extracted with $CHCl_3$ (10 ml×3). The organic layer was dried over Na_2SO_4 and evaporated. The residue was chromatographed (Wako-gel C-200, $CHCl_3$ as eluent) to give the product which was purified by recrystallization (Table 1).

6-Substituted and Unsubstituted 6,7-Dihydro-7-phenylsulfonyl-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones (6a,b). General Procedure, Method E: Hydroxylactam **1** (1 mmol) was added to benzenesulfinic acid generated from sodium benzenesulfinate (1 mmol) and *p*-toluenesulfonic acid (1 mmol) in acetonitrile (10 ml). The resulting mixture was heated under reflux in the reaction flask connected with a dehydration column involving Na_2SO_4. After 2 h, an additional amount of benzenesulfinic acid (0.5 mmol) was supplied and further heating was continued for 3 h. After cooling to r. t., the reaction mixture was basified with $NaHCO_3$ (0.2 g) and evaporated. The residue was treated with water (10 ml) and extracted with $CHCl_3$ (10 ml×3). The combined extract was washed with water, dried (Ns_2SO_4), and evaporated. The residue was chromatographed (Wako-gel C-200, AcOEt) to give the product which was purified by recrystallization (Table 1).

6-Substituted and Unsubstituted Diethyl 6,7-Dihydro-5-oxo-5*H*-pyrrolo[3,4-*b*]pyridin-7-ylphosphonate (7a,b). General Procedure, Method G: A mixture of **1** (1 mmol) and trifluoroacetic anhydride (2 ml) was stirred for 20 min under nitrogen. After the excess trifluoroacetic anhydride and the resulting trifluoroacetic acid were removed under reduced pressure, triethyl phosphite (2 mmol) in $CHCl_3$ (3 ml) was added to the residue and the resulting mixture was stirred for 4 h. The reaction mixture was quenched with aqueous $NaHCO_3$ (saturated, 20 ml) and extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water, dried over Na_2SO_4, and evaporated. The residue obtained was chromatographed (Wako-gel C-200, AcOEt as eluent) to give the product which was purified by recrystallization (Table 1).

7-Amino-6,7-dihydro-6-phenyl-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (8a). Method H: A solution of **1c** (1 mmol) in liquid ammonia (20 ml) was heated in an autoclave at 110 °C for 12 h. After the evaporation of ammonia at r. t., the residue was chromatographed (Wako-gel C-200, $CHCl_3$ as eluent) to give the product which was purified by recrystallization (Table 1).

6-Substituted and Unsubstituted 7-Alkylamino-6,7-dihydro-5*H*-pyrrolo[3,4-*b*]pyridin-5-ones (8b—f). General Procedure, Methods I and J: A solution of **1** (1 mmol), an amine (1.5 ml), and *p*-toluenesulfonic acid [none (Method I) or 0.2 mmol (Method J)] in dioxane (3 ml) was refluxed for 3—24 h. After addition of water (5 ml), the resulting mixture was extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water and dried over Na_2SO_4. Evaporation of organic solvent from the extract gave the product which was purified by recrystallization (Table 1).

8g—h. General Procedure, Method K: To a solution of **1b** (1 mmol) in trifluoroacetic anhydride (1 ml), an amine (2 ml) was added at 0 °C under nitrogen. A work-up similar to that in Method I afforded the product which was purified by recrystallization (Table 1).

2,3,5,9b-Tetrahydro[1,3]oxazolo[3′,2′:1,2]pyrrolo[3,4-*b*]-pyridin-5-one (9) and 3,4,6,10b-Tetrahydro-2*H*-pyrido[2′,3′:3,4]pyrrolo[2,1-*b*][1,3]oxazin-6-one (10). A mixture of **4d** (0.5 mmol), trioctylmethylammonium chloride (0.05 mmol), and NaOH-powder (0.25 g) in benzene (10 ml) was stirred under nitrogen at r. t. for 40 min. After addition of dichloromethane (10 ml) and filtration, the organic layer was dried over Na_2SO_4 and evaporated to yield **9** (96%) as colorless crystals. Similar

reaction with **4e** for 5 h gave **10** (90%) as colorless crystals.

9: Mp 102 °C (from EtOH); ^{1}H NMR ($CDCl_3$) δ=3.3—4.5 (4H, m, CH_2CH_2), 5.81 (1H, s, H-7), 7.45 (1H, dd, J=8 and 5 Hz, H-3), 8.08 (1H, dd, J=8 and 2 Hz, H-4), 8.80 (1H, dd, J=5 and 2 Hz, H-2); IR (KBr) 1720 cm^{-1} (C=O); MS (70 eV) m/z 176(M^+). Found: C, 61.30; H, 4.55; N, 16.14%. Calcd for $C_9H_8N_2O_2$: C, 61.36; H, 4.57; N, 15.90%.

10: Mp 104—105 °C (from AcOEt); ^{1}H NMR ($CDCl_3$) δ=1.5—2.2 (2H, m, CH_2), 3.1—4.7 (4H, m, CH_2×2), 5.60 (1H, s, H-7), 7.48 (1H, dd, J=8 and 5 Hz, H-3), 8.17 (1H, dd, J=8 and 2 Hz, H-4), 8.80 (1H, dd, J=5 and 2 Hz, H-2); IR (KBr) 1690 cm^{-1} (C=O); MS (20 eV) m/z 176 (M^+−14). Found: C, 63.01; H, 5.35; N, 14.79%. Calcd for $C_{10}H_{10}N_2O_2$: C, 63.14; H, 5.31; N, 14.73%.

6,7-Dihydro-6,7-dimethyl-7-phenylsulfonyl-5*H*-pyrrolo[3,4-*b*]pyridin-5-one (11). Into a mixture of **6b** (2 mmol), trioctylmethylammonium chloride (3 mmol), and benzene (10 ml, saturated with argon) was added NaOH-powder (1 g) under argon with vigorous stirring. When MeI (10 mmol) was added to the resulting dark red suspension, the color disappeared and the stirring was continued for 30 min. After addition of dichloromethane (20 ml), the reaction mixture was filtered and evaporated. The residue was recrystallized from AcOEt to yield **11** (89%) as colorless crystals: Mp 145—146 °C (from AcOEt); ^{1}H NMR ($CDCl_3$) δ=2.13 (3H, s, CH_3), 3.32 (3H, s, CH_3), 7.1—7.5 (6H, m, arom+H-3), 7.70 (1H, dd, J=8 and 2 Hz, H-4), 8.80 (1H, dd, J=5 and 2 Hz, H-2); IR (KBr) 1150 (S=O), 1300 (S=O), and 1720 cm^{-1} (C=O); MS (70 eV) m/z 161 (M^+−141). Found: C, 59.69; H, 4.66; N, 9.05%. Calcd for $C_{15}H_{14}N_2O_3S$: C, 59.59; H, 4.67; N, 9.27%.

6,7-Dihydro-6-methyl-7-methylene-5*H*-pyrrolo[3,4-*b*]-pyridin-5-one (12). A mixture of **11** (1 mmol) and concd sulfuric acid was stirred at r. t. for 30 min. The reaction mixture was poured into ice-water, neutralized with solid Na_2CO_3 to pH 9, and extracted with $CHCl_3$ (10 ml×3). The extracts were washed with water, dried over Na_2SO_4 and evaporated. The residue obtained was chromatographed (Wako-gel C-200, AcOEt as eluent) to give the product **12** (86%): Mp 77 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=3.31 (3H, s, CH_3), 4.94 and 5.67 (2H, d+d, J=2 Hz, =CH_2), 7.39 (1H, dd, J=8 and 5 Hz, H-3), 8.08 (1H, dd, J=8 and 2 Hz, H-4), 8.73 (1H, dd, J=5 and 2 Hz, H-2); IR (KBr) 1650 (C=C) and 1720 cm^{-1} (C=O); MS (70 eV) m/z 160 (M^+).

6,7-Dihydro-6-methyl-7-phenylsulfonyl-5*H*-pyrrolo[3,4-*b*]-pyridin-5-one (13). A solution of **1b** (0.5 mmol) in trifluoroacetic acid (2 ml) was stirred at r. t. for 1 d. The reaction mixture was quenched with ice-water, neutralized with solid Na_2CO_3, and extracted with $CHCl_3$ (10 ml×3). The organic layer was washed with water, dried over Na_2SO_4 and evaporated. The residue obtained was chromatographed (Wako-gel C-200, AcOEt as eluent) to give **12** (36%) and **13** (42%) as colorless crystals. Alternatively, into a solution of **12** (0.5 mmol) in trifluoroacetic acid (2 ml) was added sodium benzenesulfinate (4 mmol). After 4 h, a similar work-up gave **13** (62%) as colorless crystals: Mp 132—133 °C; ^{1}H NMR ($CDCl_3$) δ=3.19 (3H, s, CH_3), 3.66 (1H, dd, J=16 and 6 Hz, SO_2CH), 4.02 (1H, dd, J=16 and 5 Hz, SO_2CH), 5.93 (1H, dd, J=6 and 5 Hz, H-7), 7.5—7.9 (6H, m, H-3+arom), 8.02 (1H, dd, J=8 and 2 Hz, H-4), 8.60 (1H, dd, J=5 and 2 Hz, H-2); IR (KBr) 1140 (S=O), 1300 (S=O), and 1700 cm^{-1} (C=O); MS (20 eV) m/z 225 (M^+−77). Found: C, 59.55; H, 4.64; N, 9.35%. Calcd for $C_{15}H_{14}N_2O_3S$: C, 59.59; H, 4.67; N, 9.27%.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 63740271 from the Ministry of Education, Science and Culture.

Prediction of Product-Selectivity in an Electroorganic Process by Mathematical Modeling of Reaction Mechanism. A Rotating Cylinder Electrode System

Po-Chung CHENG, Tsutomu NONAKA,* and Tse-Chuan CHOU†
Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 227
†Department of Chemical Engineering, National Cheng-Kung University, Tainan, Taiwan, Republic of China
(Received January 27, 1991)

A mathematical mechanism model is developed for the electroreduction of carbonyl compounds in an acidic solution and shows that the formation ratio of hydrodimeric to hydromonomeric products, i.e. the product-selectivity, depends on substrate concentration, mass transfer coefficient and current density. Model calculations are in agreement with experimental results from the electroreduction of *p*-methylbenzaldehyde using a rotating cylinder cathode and explain a drastic effect of mass transport on the product-selectivity.

Product-selectivity control has been a significant subject in electroorganic synthesis. Saveant and coworkers[1-8] extensively studied modes of product distribution in preparative scale electrolysis from a theoretical aspect, but only few experimetal approaches were insufficiently made.[4-6] Wendt[9] also suggested an importance of mass transport in the product distribution of electroorganic processes with few experimental data. On the other hand, some other workers[10-13] reported experimental results that product-selectivity and/or yield were influenced by mass transport, without any theoretical considerations. For purposively designing practical electroorganic processes on the basis of prediction of product-selectivity, it is recommended that studies are harmoniously made from both theoretical and experimental aspects.

Recently we also reported that the ratio of hydrodimeric to hydromonomeric products in the electroreduction of carbonyl compounds, e.g. benzaldehyde and acetophenone, could be varied drastically by controlling mass transport conditions, such as substrate concentration, flow rate in a parallel plate flow cell and rotating speed of a rotating cylinder electrode.[14] Thus, it is aimed in this work to evaluate the product-selectivity by mathematical modeling and demonstrate how the product-selectivity can be controlled.

However, considerable hydrogen evolution[15] and formation of hydroquinonoid-dimers[16-18] in the reduction of acetophenone and benzaldehyde, respectively, might make very difficult the mathematical analysis of reaction model. In this work, therefore, *p*-methylbenzaldehyde was used as a starting compound which has an adequately low reduction potential and is blocked by a methyl group at the *p*-position to be prevented from the formation of the hydroquinonoid-type dimers.[16] In fact, using *p*-methylbenzaldehyde, current efficiencies and material balances are high enough (>90%) for mathematical analysis.

In general, mass transport conditions can be controlled using either a rotating electrode batch cell or a parallel plate flow cell. Although the availability of the latter for industrial processes, of course, is much greater than the former, in this work the former was preferably used because of easier and more accurate mathematical treatment of mass transport phenomena. Furthermore, because quantitative analysis of products was required in this work, a rotating cylinder electrode with a large area was chosen instead of a rotating disc one used commonly for voltammetric studies.

Experimental

Materials. The method of Grimshaw and Ramsey[19] was employed for preparation of the hydrodimer samples: *dl*-(mp 159—160 °C, from ethanol–water) and *meso*-1,2-bis(*p*-methylphenyl)-1,2-ethanediol(mp 143—144 °C, from benzene). All other reagents used were analytical GR grade without further purification.

Electrolytic Cell. The cathode was a Pb solid cylinder, 5 cm in length and 0.5 cm in diameter. The cylindrical Pb sheet anode, 6.5 cm in depth and 5.6 cm in diameter, was separated from the cathode by a ceramic diaphragm in a beaker type batch cell. The rotating cathode was rotated at 250 to 1500 rpm by a variable speed motor (Yanagimoto RP-3).

Procedure. The electrolyte was 0.25 M H_2SO_4 solution containing 50% v/v ethanol, unless stated otherwise. A saturated calomel electrode was used as reference electrode and the electrolyte was deaerated with nitrogen prior to the measurement of polarization curves. For preparative electrolysis, pre-electrolysis was carried out for ca. 15 min. All the electrolyses were carried out at 25±2 °C. Throughout this paper 1 M=1 mol dm^{-3}.

Analysis. The products were routinely analysed using HPLC. The mobile phase was a mixture of acetonitrile and 0.1% aqueous phosphoric acid with a volume ratio of 30:70. The column was a Utron S-C 18 reversed-phase column (Chromato Packings Center) and peaks for the products were detected by UV absorbance at 254 nm.

Results and Discussion

The reaction mechanism for the electroreduction of aromatic carbonyl compounds depends on pH, and the generally accepted scheme in acidic media is as follows:[20]

$$\mathrm{ArCOR} + \mathrm{H^+} \rightleftarrows \mathrm{Ar\overset{+}{C}(OH)R} \qquad \text{(I)}$$

$$\mathrm{Ar\overset{+}{C}(OH)R} + e \xrightarrow{k_1} \mathrm{Ar\dot{C}(OH)R} \quad \text{(II)}$$

$$\mathrm{Ar\dot{C}(OH)R} + e \xrightarrow{k_2} \mathrm{Ar\overline{C}(OH)R} \quad \text{(III)}$$

$$\mathrm{Ar\overline{C}(OH)R} + H^+ \xrightarrow{\text{fast}} \mathrm{ArCH(OH)R} \quad \text{(IV)}$$

$$2\mathrm{Ar\dot{C}(OH)R} \xrightarrow{k_D} \mathrm{ArRC(OH)C(OH)RAr} \quad \text{(V)}$$

In order to theoretically calculate the product-selectivity, a general relationship between k_2 and k_D must be mathematically written. Thus, it is our first goal to obtain Eq. 21 along with Eqs. 10 and 22. At the second stage, for a special case Eq. 27 is obtained along with Eqs. 31 and 32.

Let X_b and X_s represent substrate X in bulk solution and at electrode surface, respectively. Thus, the mass-transfer process of ArCOR(S) and $\mathrm{Ar\overset{+}{C}(OH)R(S^*)}$ from bulk solution to electrode surface can be expressed as follows:

$$S_b \xrightarrow{k_m} S_s \quad \text{(VI)}$$

$$H^+_b \rightleftarrows H^+_s \quad \text{(VII)}$$

$$S_s + H^+_s \overset{K_s}{\rightleftarrows} S^*_s \quad \text{(VIII)}$$

$$S_b + H^+_b \overset{K_b}{\rightleftarrows} S^*_b \quad \text{(IX)}$$

$$S^*_b \xrightarrow{k_m^*} S^*_s \quad \text{(X)}$$

Recognizing that reactions VIII and IX are essentially at equilibrium, we can write

$$[S^*_b] = K_b[S_b][H^+_b], \quad (1)$$

$$[S^*_s] = K_s[S_s][H^+_s], \quad (2)$$

where K_b and K_s are the equilibrium constants between ArCOR(S) and $\mathrm{Ar\overset{+}{C}(OH)R(S^*)}$ in bulk solution and at electrode surface, respectively. In strong acidic solution, $[H^+_s]$ and $[H^+_b]$ are assumed to be constant.

The steady-state material balance for S and S* is given by

$$k_1[S^*_s] = k_m([S_b]-[S_s]) + k_m^*([S^*_b]-[S^*_s]) = i_1/F, \quad (3)$$

where k_m and k_m^* are the mass transfer coefficients of S and S*, respectively, k_1 is the rate constant for the formation of radical $\mathrm{Ar\dot{C}(OH)R}$ (R_s), i_1 is the partial current density for the primary electron-transfer reaction (Eq. II), and F is the Faraday constant.

Suppose that k_m is equal to k_m^*, Eq. 3 becomes

$$k_1^*[C_s] = k_m([C_b]-[C_s]) = i_1/F \quad (4)$$

where

$$[C_b] = [S_b] + [S^*_b],$$
$$[C_s] = [S_s] + [S^*_s],$$
$$k_1^* = k_1K_s[H^+_s]/(1+K_s[H^+_s]) = k^0_1 \exp(-b_1E).$$

b_1 and k^0_1 are the characteristic constants on the assumption of Tafel relationship, and E is electrode potential. It should be noted that $[C_b]$, substrate concentration before protonation, is readily measurable rather than $[S^*_b]$.

The radical(R) formed in the primary electron-transfer reaction then undergoes the second electron-transfer reaction (Eq. III) to form the hydromonomer ArCH(OH)R(HM) or is dimerized (Eq. V) to give the hydrodimer ArRC(OH)C(OH)RAr(HD).

$$V\mathrm{d[HM]}/A\mathrm{d}t = k_2[R_s] = i_2/F, \quad (5)$$

$$k_2 = k^0_2 \exp(-b_2E), \quad (6)$$

$$2V\mathrm{d[HD]}/A\mathrm{d}t = -D_R(\mathrm{d[R]}/\mathrm{d}x)_{x=0}, \quad (7)$$

$$D_R(\mathrm{d}^2[R]/\mathrm{d}^2x) - v_x(\mathrm{d[R]}/\mathrm{d}x) - k_D[R]^2 = 0, \quad (8\text{-a})$$

$$[R] = [R_s] \quad \text{at } x = 0, \quad (8\text{-b})$$

$$[R] = 0 \quad \text{as } x \to \infty, \quad (8\text{-c})$$

where i_2 and k_2 are the partial current density and the rate constant for the second electron transfer reaction, respectively, k_D is the rate constant for the dimerization step, A is the cathode area, V is the volume of catholyte, D_R is diffusion coefficient of R, x is the distance from electrode, and v_x is the x-component of the fluid velocity vector.

Let us neglect the second term in Eq. 8-a, then we obtain Eq. 9 after satisfying the boundary conditions.[21]

$$[R] = \frac{6D_R/k_D}{(\sqrt{6D_R/(k_D[R_s])}+x)^2}. \quad (9)$$

Substituting Eq. 9 into Eq. 7, one finds

$$2V\mathrm{d[HD]}/A\mathrm{d}t = k_3[R_s]^{3/2}, \quad (10)$$

where

$$k_3 = (2k_DD_R/3)^{1/2}.$$

Since hydrogen evolution and other side reactions are negligible, we can write

$$i = i_1 + i_2, \quad (11)$$

$$k_1^*[C_s] = k_2[R_s] + k_3[R_s]^{3/2}, \quad (12)$$

where i is the total current density of electrolysis.

From these equations a simulation for predicting the product-selectivity may be accomplished if all the rate constants are available. The product-selectivity (ζ) is herein defined by

$$\zeta = \mathrm{d[HD]}/\mathrm{d[HM]} = k_3[R_s]^{1/2}/2k_2. \quad (13)$$

The Determination of k^0_1 and b_1. Equation 4 can be rearranged as

$$i_1 = k_1^*k_m[C_b]F/(k_m+k_1^*), \quad (14)$$

or

$$1/i_k = 1/i_1 - 1/i_L,$$

where the limiting current density (i_L) and kinetic current density (i_k) are defined as

$$i_L = k_m[C_b]F, \quad (15)$$

$$i_k = k^0_1 \exp(-b_1E)[C_b]F, \quad (16)$$

or

$$\ln(i_k) = \ln(k^0_1[C_b]F) - b_1E.$$

Potentiostatic electrolysis of *p*-methylbenzaldehyde at

a potential where $i<i_L$, the hydromonomer (HM) is not found and the hydrodimer is a sole product, i.e. $i \fallingdotseq i_1$. Using experimental data from polarization curves (Fig. 1), i_k can be calculated from Eq. 14. A plot of Eq. 16 is presented in Fig. 2. The slope gives a value for b_1 of 26 V^{-1} and the intercept leads to a value for k^0_1 of 5.4×10^{-14} cm s^{-1}.

Values of k^0_2, b_2 and k_3. When the total current density is larger than i_L, i_1, and i_2 can be expressed as

$$i_1 = k_1^*[C_s]F \fallingdotseq i_L, \quad (17)$$

$$i_2 \fallingdotseq i - i_L, \quad (18)$$

Substitution of Eq. 18 into Eq. 5 gives

$$k_2[R_s] = (i-i_L)/F. \quad (19)$$

Then from Eqs. 17, 19, and 12 we obtain

$$k_3[R_s]^{3/2} = (2i_L - i)/F. \quad (20)$$

Combination of Eqs. 19 and 20 leads to

$$z = k_2^3/k_3^2 = (i-i_L)^3/F(2i_L-i)^2. \quad (21)$$

From a plot of Eq. 22 (Fig. 3) b_2 is found to be 26 V^{-1} and k^0_2 can be determined from an intercept, provided k_D and D_R are known.

$$\ln(z) = \ln(k^{0}{}_2{}^3/k_3^2) - 3b_2E. \quad (22)$$

However, any rate constant (k_D) for the dimerization in electroreduction of carbonyl compounds in acidic solutions has not been reported, while k_D in hydroxide solution is known to be in a range of 10^7—10^9 mol^{-1} s^{-1} cm^3.[21,22] Here, 10^8 mol^{-1} s^{-1} cm^3 is tentatively taken as k_D.

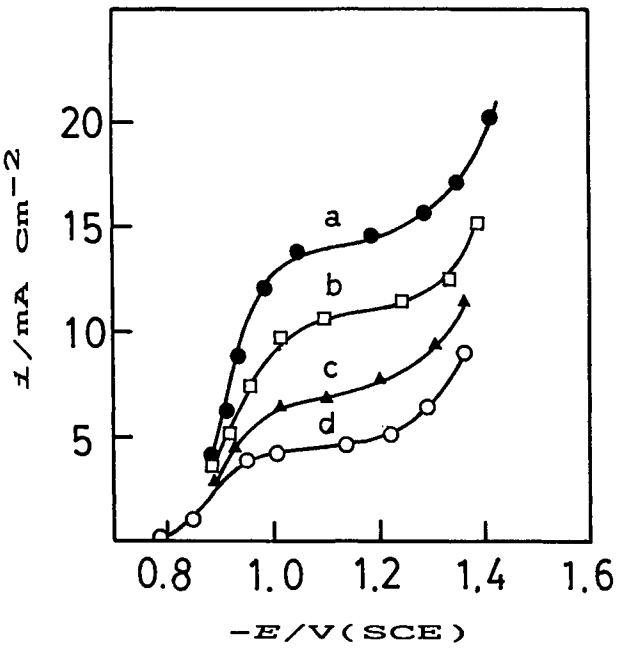

Fig. 1. Polarization curves for the reduction of *p*-methylbenzaldehyde (80 mM) at a rotating cylinder electrode in 0.25 M H_2SO_4/50% EtOH. Rotating speed, a: 1500, b: 1000, c: 500, d: 250 rpm.

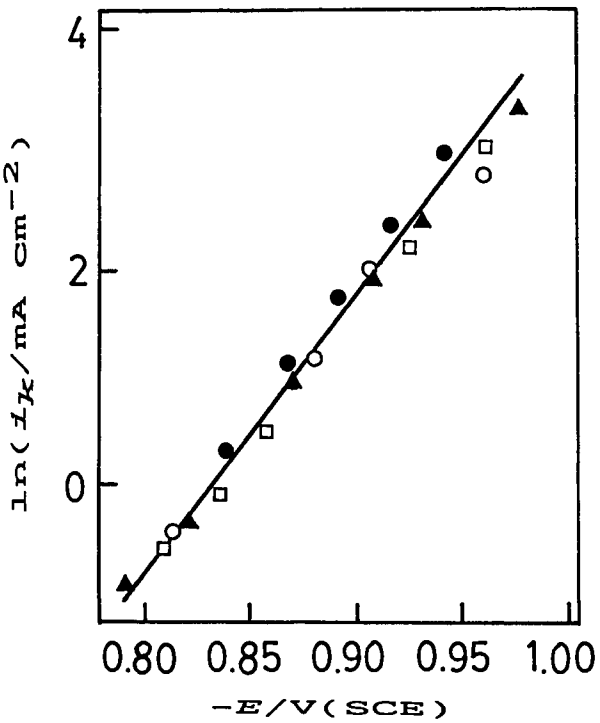

Fig. 2. The relation between i_k and E. Data from polarization curves at various rotating speed: 1500 (●), 1000 (□), 500 (△), and 250 rpm (○).

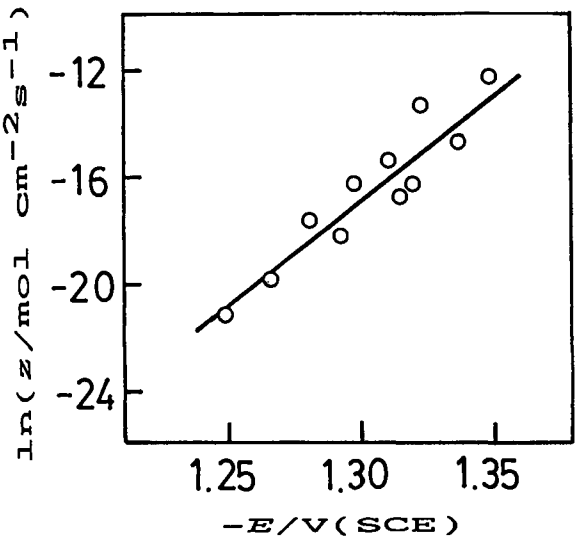

Fig. 3. The relation between $z(=k_2^3/k_3^2)$ and E. Data from polarization curves at 250 rpm.

Using Newton's method, E for a constant current operation can be solved for a set of k_m, $[C_b]$ and i, then ζ is calculated from Eqs. 4—13. Curve a in Fig. 4 shows the prediction of product-selectivity (ζ) for the galvanostatic reduction of *p*-methylbenzaldehyde at a rotating cylinder Pb electrode, using 10^{-3} cm s^{-1} as k_m, 80 mM as $[C_b]$, 10^{-5} cm^2 s^{-1} as D_R, 1.1×10^{-16} cm s^{-1} as k^0_2 and 10^8 mol^{-1} s^{-1} cm^3 as k_D. When either 10^7 or 10^9 mol^{-1}

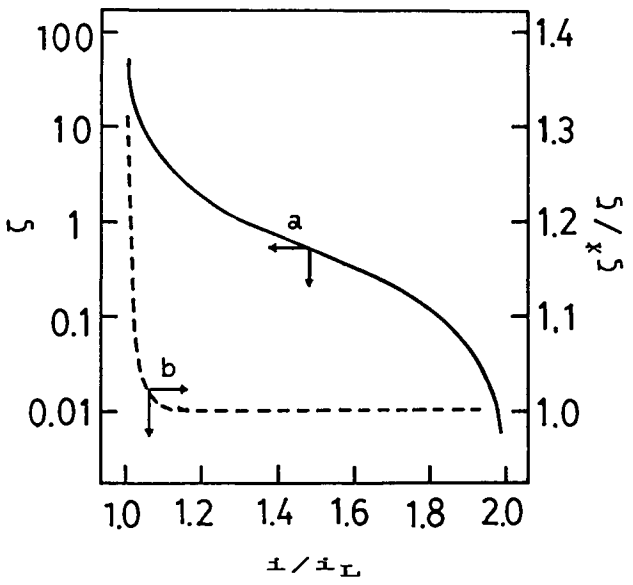

Fig. 4. Prediction of product-selectivity as a function of i/i_L. Curve a: Product-selectivity (ζ) calculated according to Eq. 4—13, using $k_1^0=5.4\times10^{-14}$ cm s^{-1}, $b_1=26$ V^{-1}, $k_2^0=1.1\times10^{-16}$ cm s^{-1}, $b_2=26$ V^{-1}, $k_D=10^8$ mol^{-1} s^{-1} cm^3, $D_R=10^{-5}$ cm^2 s^{-1}, $k_m=10^{-3}$ cm s^{-1}, $[C_b]=80$ mM. Curve b: Comparison between ζ and ζ^*.

s^{-1} cm^3 is taken as k_D, the difference of ζ from curve a is not regarded as significant for $i/i_L>1.04$.

Curve a suggests that the product-selectivity (ζ) can be drastically (ca. 10^4 times) changed by slightly (two times) varying the parameter i/i_L relating directly to mass transport. This should be noticeable from an aspect of product-selectivity control in synthetic electroorganic processes. However, an ambiguity might remain in calculation of curve a using k_D assumed. Therefore, another method, which is simpler and more convenient for predicting ζ, is developed to avoid this kind of problem. Two facts must be emphasized here: (1) When the total current density (i) is smaller than the limiting current density (i_L) of the primary electron-transfer reaction, the hydromonomer (HM) is not found and the the hydrodimer (HD) is the sole product. (2) When i exceeds the limiting current density ($2i_L$) for the two-electron reaction, the formation of HM and hydrogen evolution occur exclusively and HD is almost not formed. Hence, a mathematical evaluation for the product-selectivity is only necessary when i is between i_L and $2i_L$. In such a situation, i_1 is almost equal to i_L (Eq. 17) and Eqs. 19 and 20 are rewritten as follows:

$$V\mathrm{d[HM]}/A\mathrm{d}t=i_2/F=(i-i_L)/F, \tag{23}$$

$$V\mathrm{d[HD]}/A\mathrm{d}t=(2i_L-i)/2F. \tag{24}$$

Since i_L is a function of k_m and $[C_b]$ as presented by Eq. 15, the product-selectivity can be expressed as a function depending on the bulk concentration ($[C_b]$), total current density (i) and mass transfer coefficient (k_m),

$$\zeta^*=\mathrm{d[HD]}/\mathrm{d[HM]}=(2-i/i_L)/2(i/i_L-1)=f(k_m, [C_b], i). \tag{25}$$

Here ζ^* is used to distinguish from ζ, the product-selectivity calculated from Eq. 4—13. Curve b in Fig. 4 shows the comparison between ζ^* is and ζ. Although ζ^* is considerably larger than ζ when i/i_L is in the vicinity of unity, the difference is so small that ζ^* is almost equal to ζ when $i/i_L>1.1$. This implies that Eq. 25 can be used for predicting product-selectivity (ζ^*) in the electroreduction of carbonyl compounds, if k_m, $[C_b]$ and i are known.

For a batch electrolysis, $[C_b]$ and i_L decrease with the electrolysis time in the following ways.

$$-V\mathrm{d}[C_b]/A\mathrm{d}t=i/F \quad \text{when } i_L>i, \tag{26-a}$$

$$-V\mathrm{d}[C_b]/A\mathrm{d}t=k_m[C_b]=i_L/F \quad \text{when } i_L\leqq i. \tag{26-b}$$

Hence a relation between product-selectivity and time must be considered.

In stead of d[HD]/d[HM], the product-selectivity defined by Eq. 27 is used in the following discussion.

$$\zeta=[\mathrm{HD}]/[\mathrm{HM}]. \tag{27}$$

When $i_L>i$ at $t=0$: Let t_0 be the time that is required to decrease i_L to i, then we have

$$[C_{b,0}]=i/k_mF, \tag{28}$$

$$t_0=([C_{b,i}]-[C_{b,0}])VF/iA \tag{29}$$

where $[C_{b,i}]$ and $[C_{b,0}]$ are the substrate concentrations at $t=0$ and $t=t_0$, respectively.

Integration of Eq. 26-b gives

$$[C_b]=[C_{b,0}]\exp[-k_mA(t-t_0)/V]. \tag{30}$$

Then integration of Eq. 23 and 24, after substitution of Eq. 30 for $[C_b]$, yields:

$$[\mathrm{HM}]=iA(t-t_0)/VF-[C_{b,0}]\{1-\exp[-k_mA(t-t_0)/V]\}, \tag{31}$$

$$[\mathrm{HD}]=[C_{b,0}]\{1-\exp[-k_mA(t-t_0)/V]\}+iA(2t_0-t)/2VF. \tag{32}$$

When $i_L\leqq i$ at $t=0$: Let $t_0=0$, $[C_{b,0}]=[C_{b,i}]$, then Eqs. 31 and 32 can be applied to calculate ζ.

Prediction of ζ: Table 1 shows experimental values of the product-selectivity obtained in the galvanostatic electrolysis of *p*-methylbenzaldehyde at a rotating Pb cylinder electrode, compared with those predicted from Eqs. 27,31, and 32. Here, a dimensionless parameter, q, is used in stead of time. $q=1$ means that the charge

Table 1. Product-Selectivity (ξ) for the Reduction of *p*-Methylbenzaldehyde (Initial Concentration: 80 mM) at a Rotating Cylinder Pb Cathode

Run	ω/rpm	i/mA cm^{-2}	q[a)]	ξ_{exp}	ξ_{calcd}
1	250	5	0.2	0.9	1.0
2	250	5	0.3	0.7	0.8
3	250	5	0.4	0.6	0.7
4	500	10	0.2	0.5	0.4

6	1000	10	0.4	1.9	2.1

a) $q=iAt/[C_{b,i}]VF$.

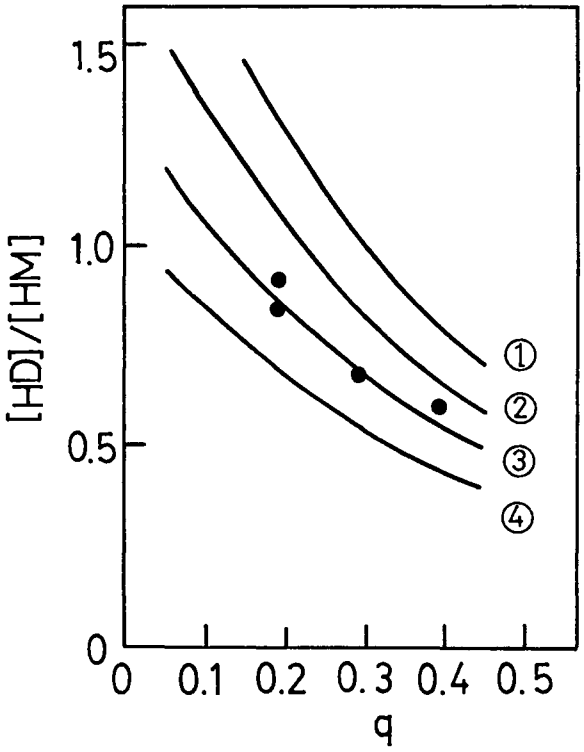

Fig. 5. Effect of charge passed ($q=iAt/[C_{b,i}]VF$) and mass transfer on product-selectivity at 5.0 mA cm^{-2} and 250 rpm. Mass transfer coefficients: ① 0.00055, ② 0.00053 (average mass transfer coefficient), ③ 0.00051, ④ 0.00049 cm s^{-1}.

passed for 1 mole of substrate is 96485 C. The relation between time and q is given by

$$t = q[C_{b,i}]VF/iA \quad (33)$$

Values of k_m's used in this model are determined from Fig. 1 at various rotating speeds. In general, both the two ζ 's are in good agreement. Bearing in mind that the model calculation is based on many assumptions, the result is encouraging. The prediction, of course, may become more accurate if we take hydrogen evolution into account.

Combination of Eqs. 27 and 31—33 gives theoretical curves of ζ vs. q as shown in Fig. 5. The mean mass transfer coefficient at 250 rpm is 0.00053 cm s^{-1} with a deviation of 5%. The theoretical curve is expected to be curve 2. Nevertheless, the measured values of ζ 's are very near to curve 3, calculated by using 0.00051 cm s^{-1} as k_m. The difference between the two k_m 's is rather small, therefore, the validity of this model is proved. It should also be noted that a slight change (5%) in mass transfer rate could lead to a considerable variation (20%) in ζ for the case in Fig. 5. Hence, this model is shown to be applicable to the electroreduction of *p*-methylbenzaldehyde and can explain why the ratio of hydrodimeric to hydromonomeric products in the electroreduction of benzaldehyde increases 20 times as the rotating speed increases from 250 to 1000 rpm.[14]

It is interesting that this model could be used in estimating k_m as implied in Fig. 5. The evaluation of mass transfer coefficient is important in designing a practical electrolytic cell, and the application of this model in a flow cell system is in progress. Finally, it must be emphasized again that the product-selectivity is itself an index of mass transport for some electrolytic systems.

(Received July 3, 1990)

Raman phonon spectroscopy in the 10—170 cm^{-1} range has been used to study phase transition in 4-cyanopyridine crystal. At 77 K, ten distinct phonon modes and an internal mode are observed whereas at 300 K the spectrum shows only six phonon bands and an internal mode. The temperature dependence of spectral pattern and phonon band width suggest that the crystal goes through a phase transition around 120 K. Experimental result suggests that the phase transition is discontinuous with a small structural change.

Raman phonon spectroscopy is a useful technique to investigate phase transition in organic crystals.[1-4] Phonon spectroscopy is particularly suited for the purpose due to the fact that in such crystals the intermolecular forces are 10—100 times weaker than the intramolecular forces and internal and external motions of molecules fall in different domain of frequencies. The lattice vibrational frequencies in organic crystals generally lie below 200 cm^{-1}, however, some out of plane deformation and torsional mode may be active in this region. Infrared and Raman spectroscopic study and vibrational analysis of 4-cyanopyridine has been reported by Green and Harrison[5] and they have assigned the internal vibrations below 200 cm^{-1}. Medhi and Sarma[6] have reassigned some of the internal modes.

At room temperature 4-cyanopyridine crystallizes in the orthorhombic form and belongs to the space group *Pccn* with four molecules in the unit cell.[7] No studies of phase transition in 4-cyanopyridine crystal based on standard X-ray or neutron diffraction technique seem to have been reported. Recently Wong[8] has reported pressure induced phase transition in this crystal by Raman phonon spectroscopic technique. We have investigated temperature dependent phase transition in 4-cyanopyridine crystal using the same technique. In addition we have shown that temperature dependence of phonon band width study is very useful to indicate phase transition in organic crystals. Temperature dependence of some molecular internal vibrational frequencies also often indicates phase transition in organic crystals. In this paper we report the result of our studies which show that indeed there is a temperature dependent phase transition in this crystal and this transition may be structural as in the pressure induced transition.

Experimental

The compound 4-cyanopyridine was obtained from M/S Aldrich Chemical Company Ltd., U.S.A. and purified by zone refining with 200 passes. Crystals were grown in a Bridgeman furnace. Both polycrystalline samples and single crystals were used to obtain Raman spectra.

The Raman spectra were recorded using a Spex double monochromator Model 1403 equipped with a cooled photomultiplier tube and photon counting unit and the 5145 Å line of Spectra Physics Model 2020-5 Ar^+ laser was used as the excitation source. Datamate 1B was used for data acquisition and analysis. The band position measurement should be accurate within 1 cm^{-1}. A Janis research cryostat Superveritemp Model 10DT was used to cool the crystal from room temperature down to 77 K. Temperature was measured and controlled by Lake Shore Model 805 temperature controller. Some uncertainty is given to the temperature measurement. Local laser heating is expected to create a temperature gradient between the crystal and the sensor.

Results and Discussion

Temperature Dependence of Phonon Spectra. With four molecules in the unit cell of the crystal there are total 24 lattice phonon modes. Twelve zone-center phonons are Raman active. The Raman phonon spectra of 4-cyanopyridine crystal in 10—170 cm^{-1} range at a series of temperature are shown in Fig. 1. At 77 K, ten distinct low frequency modes at 20.6, 33.2, 45.0, 58.6, 71.8, 79.0, 86.2, 94.4, 114.2 and 120.6 cm^{-1} represent lattice modes and the mode at 148.0 cm^{-1} has been assigned as internal mode γ (CN) by Green and Harrison.[5] At 300 K only six phonon bands at 16.8, 29.2, 40.8, 62.0, 70.8, and 95.2 cm^{-1} persist. A close examination of these spectra reveal that some distinct changes occur at 120±1 K which can not be attributed simply to temperature change. As temperature is raised from 118 to 122 K, the 78.6 cm^{-1} (79.0 cm^{-1} at 77 K) phonon band disappears and the intensity of the band at 57.4 cm^{-1} (58.6 cm^{-1} at 77 K) increases. Intensity of this band decreases above and below 120 K. The 85.0 cm^{-1} (86.2 cm^{-1} at 77 K) phonon shows appreciable frequency shift. The 71.0 cm^{-1} (71.8 cm^{-1} at 77 K) phonon band also shows a frequency lowering by 4.4 cm^{-1} at this temperature. The 20.6 cm^{-1} frequency increases by 2.4 cm^{-1} at this temperature and then decreases gradually as temperature is raised. Much less sharp but definite shift is also observed with 120.6, 114.2, 94.2, 45.0, and 32.2 cm^{-1} phonon at this temperature. In Fig. 2 we show temperature dependence of some selected phonon frequencies. Many of the lattice

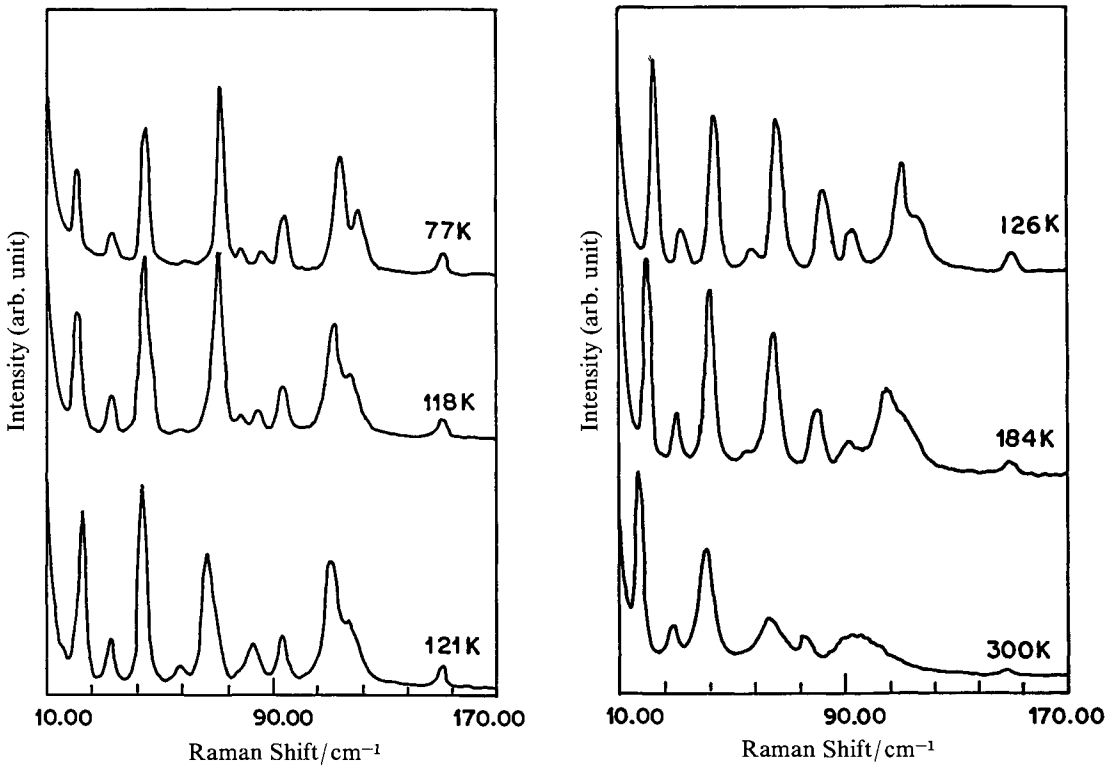

Fig. 1. Raman spectra of 4-cyanopyridine crystal in 10—170 cm^{-1} range at different temperatures.

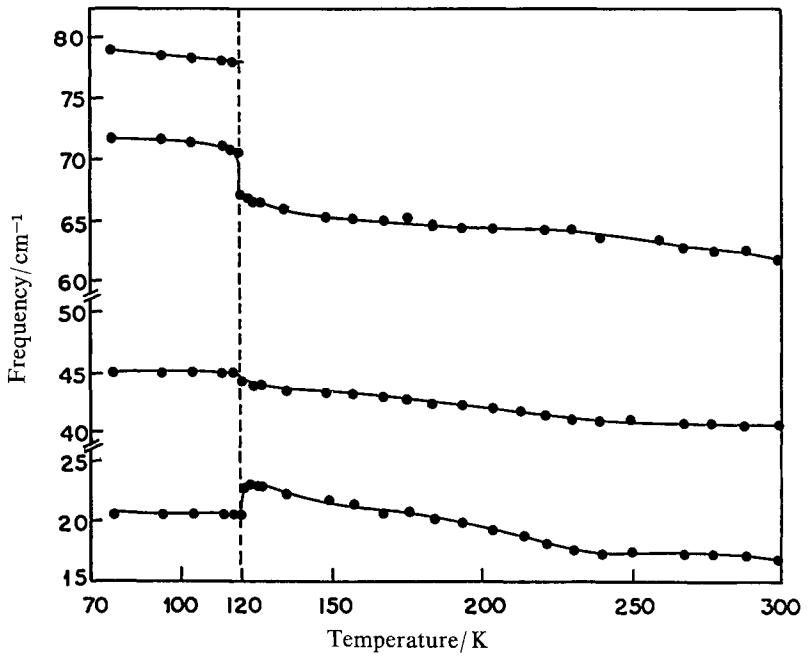

Fig. 2. Temperature dependence of some selected Raman active lattice phonon frequencies in 4-cyanopyridine crystal.

modes show discontinuous change in wavenumber as the crystal temperature is changed from 118 K to 122 K. Raman intensity decreases as the crystal is heated. This is a general observation. Around phase transition temperature there is decrease in frequency in most of the phonon modes but 20.6 cm^{-1} phonon shows reverse behavior. The frequency increases significantly during transition and then shows usual decrement with temperature.

All these results suggest that there is a definite discontinuous phase transition in 4-cyanopyridine crystal at 120±1 K.

Temperature Dependence of Internal Vibrations. We have studied the temperature dependence of internal

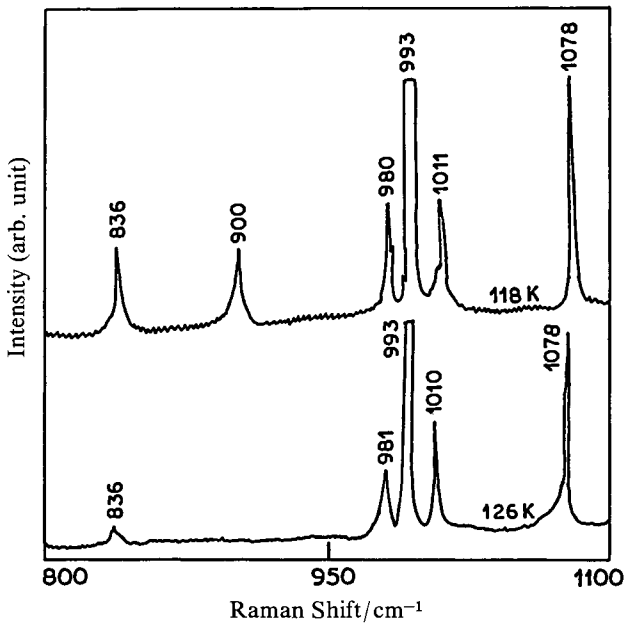

Fig. 3. Raman spectra of 4-cyanopyridine crystal in the 800—1100 cm^{-1} range below and above phase transition temperature.

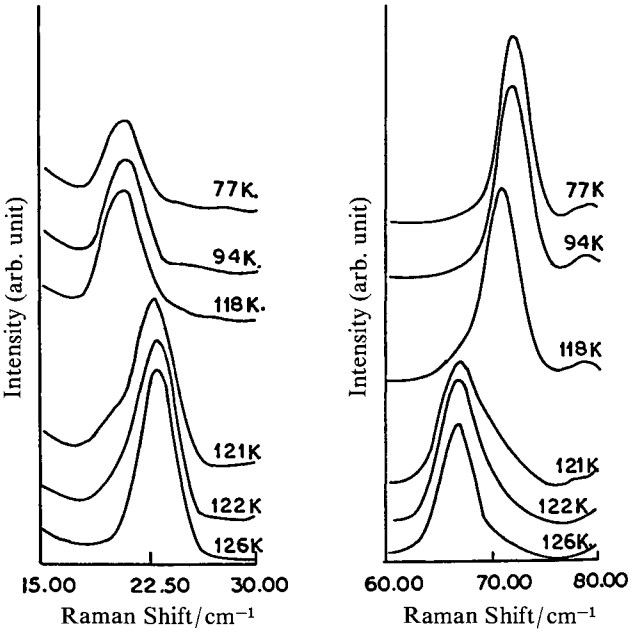

Fig. 4. 71.8 and 20.6 cm^{-1} (at 77 K) phonon bands in extended scale at several temperatures near transition region.

modes also. Though most of the spectral patterns remain unchanged below and above 120±1 K, some definite change is observed. Raman spectra in the 800 to 1100 cm^{-1} range in two phases are shown in Fig. 3. In the low temperature phase a band at 900 cm^{-1} appears. This vibration is of b_1 species and is only infrared active at room temperature.[6] Due to the structural change this vibration becomes Raman active in low temperature phase. Other changes observed are the changes in the intensity ratio of 993 and 1011 cm^{-1} bands and decreament of intensity of a band at 836 cm^{-1} in the high temperature phase.

Temperature Dependence of Phonon Bandwidth. Temperature dependence of phonon band width indicates phase transition in organic crystals.[3] In Fig. 4 we show 71.8 cm^{-1} (at 77 K) and 20.6 cm^{-1} (at 77 K) phonon bands in extended scale at several temperatures near the transition region. Indeed there is indication that new bands appear near the bands observed in one phase when the sample changes into another phase and this is shown as shoulders. Inspite of this, we have been able to measure the FWHM of these two bands. The spec-

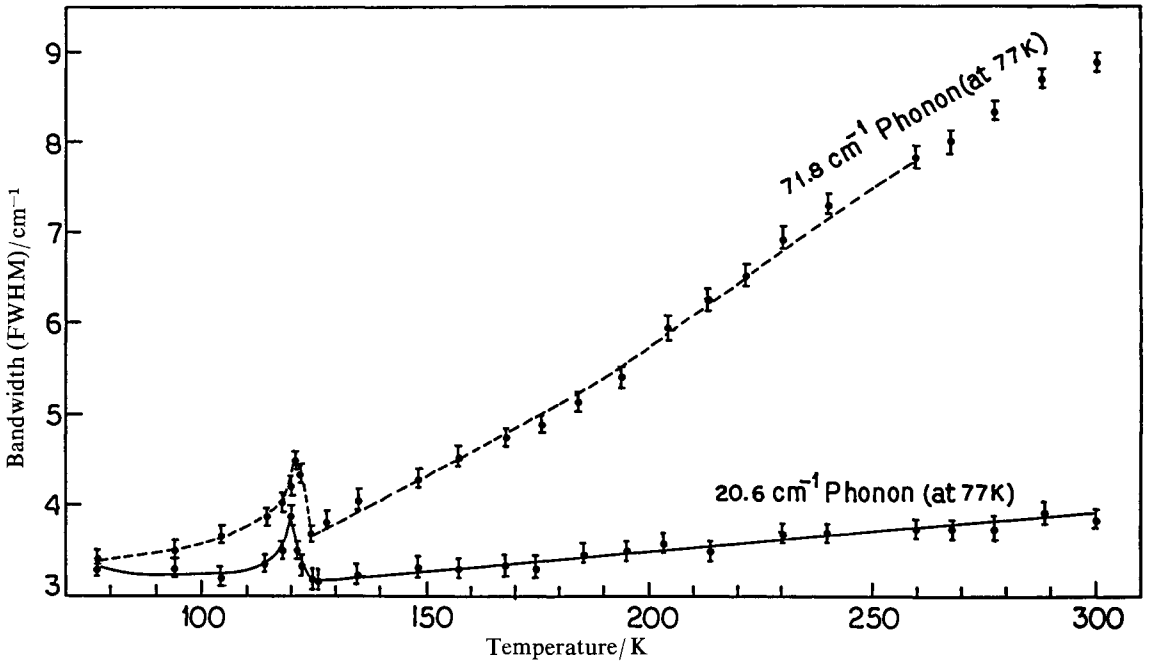

Fig. 5. Temperature dependence of band widths of Raman phonon bands of 4-cyanopyridine cryctal.

tra of Fig. 4 are considered to have been obtained because the phase transition is discontinuous and there is some temperature gradient in the sample. In Fig. 5 temperature dependence of band widths of these two bands are shown. The increase in the band widths of these two bands is large enough to be beyond the error of measurement. At 120±1 K the continuity pattern is broken and the width show some small but definite decrement with temperature rise. The temperature indeed is same as that observed in the temperature versus phonon frequency plot.

Nature of Phase Transition. Temperature dependence of phonon frequencies and band widths suggests that phase transition occurs in a small temperature interval 120±1 K. Raman study indicates that 79.0 cm^{-1} phonon disappears at these temperatures and for some other bands discontinuity as large as 4.4 cm^{-1} is also observed. Internal vibrational spectra in both the phases reveal that there is some small structural change which leads to the appearance of 900 cm^{-1} band at low temperature phase. Phase transition of 4-cyanopyridine is, therefore, a first order transition with small strutural change. The greatest change is observed in 71.8 cm^{-1} phonon band (at 77 K). The crystal lattice at low temperature phase seems to be distorted along the eigen vector of this phonon mode. This observation is similar to that reported by Wong[8] in pressure induced phase transition. However the 71.8 cm^{-1} phonon behaves differently in temperature and pressure induced phase transition. Whereas we have observed large discontinuous jumping in frequency on phase transition, Wong[8] reported only sharp discontinuity in frequency pressure plot at 10 kbar without any appreciable change in phonon frequency at higher pressure. Inspite of this, it seems probable that the phase transition we have observed at 120±1 K is the same as observed by Wong[8] at room temperature at a pressure 10 kbar.

Conclusion

We have used Raman phonon spectroscopy to study phase transition in 4-cyanopyridine crystal. The temperature dependence of spectral pattern and phonon band width suggest that there is a discontinuous phase transiton around 120 K. The lattice mode at 71.8 cm^{-1} (at 77 K) shows the greatest change (62 cm^{-1} at 300 K) while most of the other vibrations remains continuous in both the phases. The structural change is, therefore, considered small.

A Comparative Study on the Acidic Properties and Catalytic Activities of TiO_2, SiO_2, Al_2O_3, SiO_2-Al_2O_3, SiO_2-TiO_2, Al_2O_3-TiO_2, and TiO_2-SiO_2-Al_2O_3

Investigations are carried out to have a systematic comparison of the acidic properties and catalytic activities of single oxide TiO_2, SiO_2, Al_2O_3, their binary oxides and the ternary oxide TiO_2–SiO_2–Al_2O_3. The acidity distributions are measured by using butylamine titration technique and the test reactions selected for the catalytic activity measurements are alkylation of toluene with 2-propanol and the dehydration of 2-propanol. The single oxides have only low acid strength and are not at all active in catalyzing the alkylation reaction, but are marginally active in the dehydration of 2-propanol. However the binary oxides SiO_2–TiO_2 and Al_2O_3–TiO_2 of 10% by weight of TiO_2 are found to contain very strong acid sites $H_o \leqslant -8.2$ and are highly active catalysts in both the test reactions. But TiO_2–SiO_2–Al_2O_3 of 10% by weight of TiO_2 showed the highest acid amount and the highest activity in the aikylation and dehydration reactions compared to the binary oxides. The acid amount and the catalytic activity of the ternary oxide increased with the increase of TiO_2 content upto 50 mol% of TiO_2 and then decreased. The ternary oxide containing 80 mol% of TiO_2 is rich in weak acid sites. The increase of TiO_2 content does not affect the selectivity.

The utility of supported transition metal oxide catalysts like Cr_2O_3–SiO_2, MoO_3–SiO_2–Al_2O_3, and TiO_2–SiO_2–Al_2O_3 in certain acid-catalyzed oligomerization, polymerization, and a wide range of alkylation reactions are known.[1–8] The incorporation of transition metal oxides into SiO_2–Al_2O_3 is expected to alter the acidity distribution of the latter and hence its activity in various acid-catalyzed reactions. For instance, recently it has been found that TiO_2–SiO_2–Al_2O_3 is a highly active and regenerable alkylation catalyst.[8] Further investigations undertaken to study the effect of the pH of the coprecipitating solution on the acidic and catalytic properties of the ternary oxide revealed that the ternary oxide coprecipitated from a solution of pH 4 has optimum acid amount and acid strength and it even contains nearly double the acid amount of SiO_2–Al_2O_3[9].

The acidic properties of single oxides TiO_2, SiO_2, Al_2O_3, and their binary oxides are well studied.[10–16] However a systematic comparative study on the acidic properties and catalytic activities of these single oxides, the binary oxides SiO_2–Al_2O_3, SiO_2–TiO_2, Al_2O_3–TiO_2, and the ternary oxide TiO_2–SiO_2–Al_2O_3 in the isopropylation of toluene (a reaction catalyzed by solid acids with moderately strong acid sites) and the dehydration of 2-propanol (a reaction catalyzed by solid acids with relatively weak acid sites) are not previously attempted. Hence in the present paper we discuss the results of such a study. Besides we have prepared TiO_2–SiO_2–Al_2O_3 of varying TiO_2 content and almost the same silica to alumina molar ratio and studied the effect of titania content on the acidic and catalytic properties of the ternary oxide, the results of which are also included in this paper.

Experimental

Materials: The materials used are sodium silicate (Scientific Chemicals), aluminium sulfate (A. R. grade), titanium tetrachloride (KMML Chavara), 2-propanol (BDH), toluene (BDH), butylamine (SD Chemicals), nitric acid, and ammonia of chemically pure quality. The indicators used are Neutral Red (pK_a=+6.8), Methyl Red (pK_a=+4.8), Dimethyl Yellow (pK_a=+3.3), phenylazodiphenylamine (pK_a=+1.5), Crystal Violet (pK_a=+0.8), dicinnamylideneacetone (pK_a=+3.0), benzylideneacetophenone (pK_a=−5.6), and anthraquinone (pK_a=−8.2).

Preparation of Metal Oxides: (a) Single Oxides: Single oxides such as Al_2O_3 and TiO_2 were prepared by the thermal decomposition of the respective hydroxides at 600 °C in air for 6 h. The hydroxides are precipitated from aqueous solutions of aluminium sulfate and titanium tetrachloride using 1 : 1 ammonia solution. The single oxide SiO_2 was prepared by precipitation from an aqueous solution of sodium silicate with dilute nitric acid followed by aging at 80 °C for 3 h and calcining at 600 °C for 6 h.

(b) Binary Oxides: The binary oxides SiO_2–Al_2O_3, SiO_2–TiO_2, and Al_2O_3–TiO_2 are obtained by the thermal decomposition of their hydroxides. The hydroxides were coprecipitated by adding 1 : 1 ammonia water to the mixed aqueous solutions of the metal salts, sodium silicate and aluminium sulfate for SiO_2–Al_2O_3, sodium silicate and titanium tetrachloride for SiO_2–TiO_2, and aluminium sulfate and titanium tetrachloride for Al_2O_3–TiO_2 till the pH of the final gel became 4. The precipitates were washed thoroughly to remove adhering anions such as chlorides and sulfates, extruded, dried (120 °C for 12 h) and calcined (600 °C for 6 h).

(c) TiO_2-SiO_2-Al_2O_3: The coprecipitation technique employed for the preparation of TiO_2–SiO_2–Al_2O_3 is referred elsewhere.[8] The coprecipitation was done by adding 1 : 1 ammonia water to the mixed aqueous solutions of sodium silicate, aluminium sulfate, and titanium tetrachloride till the pH of the final gel became 4. Six different samples of TiO_2–

Table 1. Amounts of Starting Materials Used for the Synthesis of Tisial with Different TiO_2 Contents and Their Physicochemical Characteristics (Calcined at 600 °C)

Sample	Amount of materials used			Composition		Surface area	Pore volume
	Sodium silicate	Titanium tetrachloride	Aluminum sulfate	SiO_2/Al_2O_3	TiO_2	$m^2 g^{-1}$	$cm^3 g^{-1}$
	g	ml	g	(mole ratio)	mol%		
Tisial-4A	270	5	105	16	2.3	120	1.05
Tisial-4B	265	10	102	15	4.3	108	0.87
Tisial-4C	260	20	100	16.4	8.4	100	0.71
Tisial-4D	220	50	85	17.3	19.8	90	0.60
Tisial-4E	175	120	70	17.4	50.0	66	0.42
Tisial-4F	120	200	40	17.0	80.0	41	0.28
SiO_2–Al_2O_3	260	—	100	16.4	—	135	1.20

SiO_2–Al_2O_3 of varying compositions viz.; Tisial-4A, Tisial-4B, Tisial-4C, Tisial-4D, Tisial-4E, and Tisial-4F were prepared by changing the starting quantities of sodium silicate, aluminium sulfate, and titanium tetrachloride as shown in Table 1. The precipitates were washed thoroughly to remove anions such as chlorides and sulfates, extruded, dried (120 °C for 12 h) and calcined (600 °C for 6 h). Tisial-4D, Tisial-4E, and Tisial-4F samples were also calcined at temperatures 150, 300, and 450 °C.

The physical characteristics such as surface area (for all the samples) and porosity (for binary oxides and ternary oxides) were measured and the chemical compositions were determined by chemical analysis.

Measurement of Acidity: The acidity distribution of different samples were measured by titrating the 100—200 mesh powder suspended in dry benzene with butylamine solution in dry benzene using the above mentioned indicators.[17]

Measurement of Catalytic Activity: The alkylation of toluene with 2-propanol was done in a fixed bed tubular reactor (LHSV 0.5 h^{-1}, toluene/2-propanol mole ratio 3, total reaction time 7 h). The dehydration of 2-propanol was also done in the same reactor (LHSV 0.5 h^{-1}, total reaction time 7 h). The reactor, experimental and analytical procedures, and the method of calculation of percentage yields of alkylaromatics were the same as those employed in the previous work.[8,9]

The products of alkylation were found to be *o*-cymene (*o*-isopropyltoluene), *p*-cymene (*p*-isopropyltoluene), and three isomers of diisopropyltoluenes (DIT).

Results and Discussion

Acidic Properties of Various Mixed Oxide Catalysts: As the TiO_2 content increased, the physical parameters such as surface area and porosity of the ternary oxide TiO_2–SiO_2–Al_2O_3 decreased considerably (Table 1).

Single oxides TiO_2, SiO_2,and Al_2O_3 showed negligible amounts of acid sites stronger than acid strength H_o= +3.3. Also they possess very low value of total acid amount (Table 2). However, the binary oxide SiO_2–Al_2O_3 is a well-known solid acid of very high acid strength ($H_o \leqslant -8.2$) and hence is used as useful catalysts for various acid-catalyzed reactions in the field of petroleum chemistry.[17-21] In good agreement with this, SiO_2–Al_2O_3 coprecipitated from a solution of pH 4 and which contains about 10% (by weight) of alumina was found to possess only strong acid sites (Table 3). Table 3 also shows that the binary oxides SiO_2–TiO_2 and Al_2O_3–TiO_2, both of which contain about 10% by weight of TiO_2 are rich in moderately strong acid sites (H_o

between +1.5 and −5.6) and they even contain very strong acid sites ($H_o \leqslant -8.2$). Even though binary oxides containing TiO_2 are known to posses strong acid sites due to which they serve as effective catalysts in the synthesis of aniline from phenol and ammonia, acid sites of strength $H_o=-8.2$ is never observed previously in the case of Al_2O_3–TiO_2.[21] Hence it may be concluded that the pH of coprecipitation governs the acidity distribution of these binary metal oxides similar to that reported in the case of ternary oxide containing SiO_2, Al_2O_3, and TiO_2. But the total acid amount value of TiO_2–SiO_2–Al_2O_3 containing about 10% by weight each of TiO_2 and Al_2O_3 is large compared with SiO_2–TiO_2 and Al_2O_3–TiO_2 (Table 4). Si–O–Si and Al–O–Al bond formation may occur in SiO_2–TiO_2 (when SiO_2 is the major component) and Al_2O_3–TiO_2 (when Al_2O_3 is the major component) respectively and could be a probable reason for the decreased acid amount values of these binary oxides in comparison with the ternary oxide TiO_2–SiO_2–Al_2O_3. That is, the number of bonds which can generate acid sites per unit surface area may be the highest in the case of TiO_2–SiO_2–Al_2O_3. However, the acid strength of a mixed metal oxide system depends on the averaged electronegativity values of the component metal ions.[10]

The Effect of TiO_2 Content on the Acidity Distribution of TiO_2–SiO_2–Al_2O_3: The acidity distribution of TiO_2–SiO_2–Al_2O_3 of varying TiO_2 content shows that the total acid amount increased with the increase of TiO_2 content and the maximum acid amount is shown by the sample containing 50 mol% of TiO_2 (Tables 3 and 4). Further increase in TiO_2 content decreased both the acid amount and acid strength. TiO_2–SiO_2–Al_2O_3 containing 80 mol% of TiO_2 (Tisial-4F) is rich in very weak acid sites. As the silica to alumina molar ratio is the same in all these Tisial samples, it may be assumed that the probability for the formation of Si–O–Al type bonds are the same, but the probabilities for the formation of Si–O–Ti and Al–O–Ti type bonds are different. The highest acid amount shown by Tisial-4E is due to the maximum number of Si–O–Ti and Al–O–Ti bonds on the surface of the ternary oxide, which are known to generate acidic sites. But the titania rich Tisial-4F may be rich in Ti–O–Ti bonds as substantiated by the existence of acid sites with low acid strength on the surface of this sample, which is the characteristic of TiO_2. Also Fig. 1 shows that with the increase in calcination temperature, the strong acid sites do not appear in Tisial-4F whatever be the calcination temperature, as in the case of TiO_2.[11]

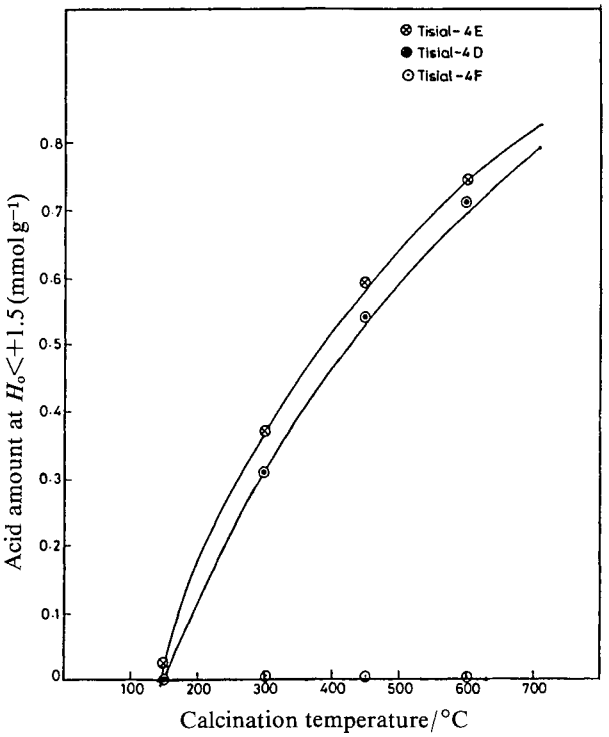

Fig. 1. The effect of calcination temperature on the acidity distribution of Tisial-4D, Tisial-4E, and Tisial-4F.

Catalytic Activity. i) Alkylation of Toluene with 2-Propanol: The single oxides SiO_2, TiO_2, and Al_2O_3 are not effective in demanding the alkylation of toluene. However, the catalytic activity in the conversion of 2-propanol to alkylaromatics is fairly high for the binary oxides SiO_2–Al_2O_3, SiO_2–TiO_2, and Al_2O_3–TiO_2 (Fig. 2). Among them, SiO_2–TiO_2 showed the highest activity and SiO_2–Al_2O_3 showed the least activity. But TiO_2–SiO_2–Al_2O_3 is more active for the conversion of 2-propanol to alkylaromatics than any of these binary oxides. The enhanced activity of TiO_2–SiO_2–Al_2O_3 catalysts could be attributed to the very large acid amount at a suitable acid strength ($H_o \leqslant +1.5$) for the alkylation.[22] This is evident from the linear activity to acidity correlation obtained by plotting the acidity at $H_o \leqslant +1.5$ of different binary oxides and the ternary oxide against their isopropylating activity (Fig. 3).

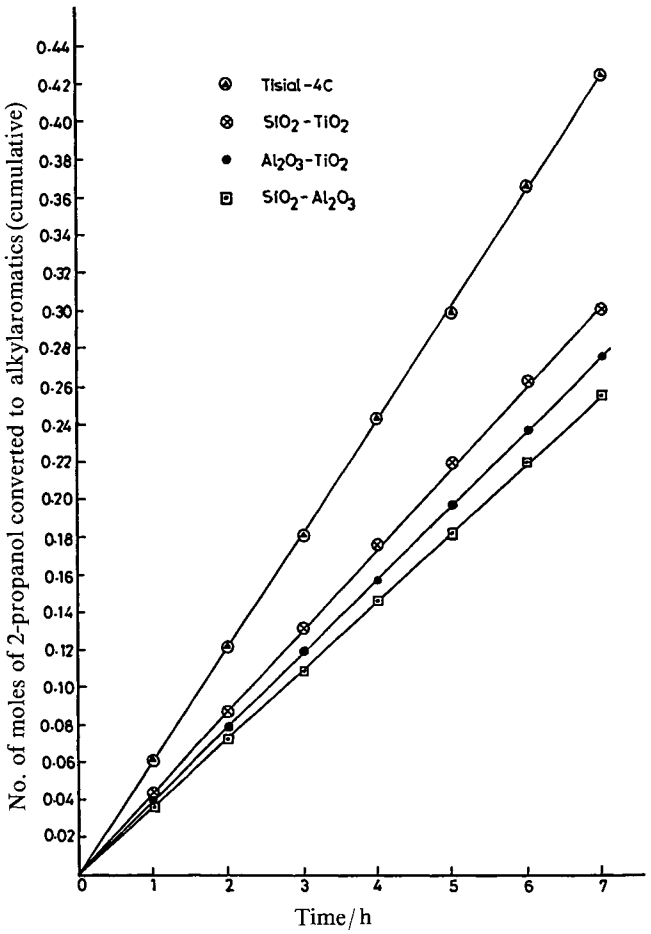

Fig. 2. Comparison of the catalytic activity of TiO_2–SiO_2–Al_2O_3 (Tisial) with that of binary oxides in the alkylation of toluene with 2-propanol. Reaction conditions; reaction temperature: 200 °C; LHSV: 0.5; toluene/2-propanol (mole ratio): 3.

With the increase in TiO_2 content, the alkylating activity of the ternary oxide system also increased (Fig. 4). But the Tisial-4F which is rich in weak acid sites are ineffective in catalyzing the alkylation of toluene.

The product mixtures obtained are rich in *p*-cymene

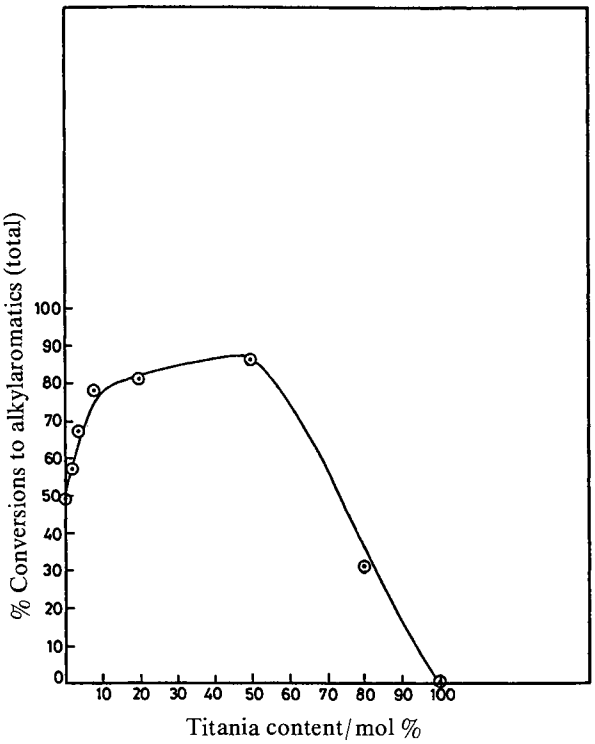

Fig. 4. Effect of titania content of Tisial on the conversion of 2-propanol to alkylaromatics. Reaction conditions; reaction temperature: 200 °C; LHSV: 0.5; toluene/2-propanol (mole ratio): 3.

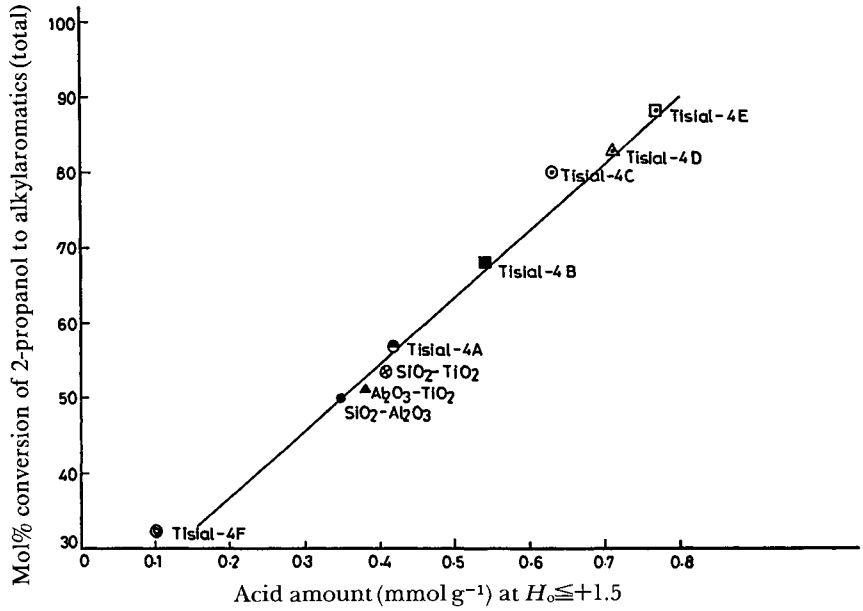

Fig. 3. Effect of acidity distribution on the conversion of 2-propanol to alkylaromatics. Reaction conditions; reaction temperature: 200 °C; LHSV: 0.5; toluene/2-propanol (mole ratio): 3.

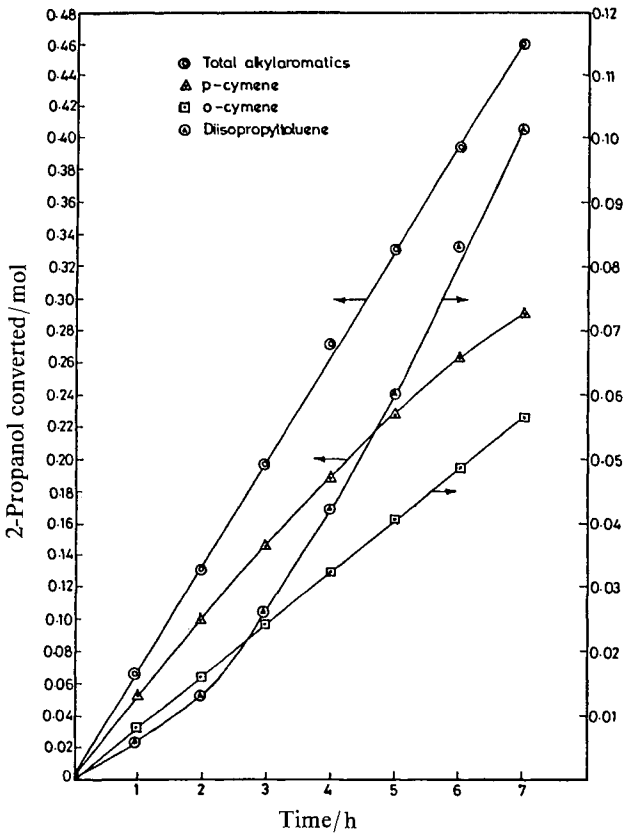

Fig. 5. Cumulative formation of *p*-cymene, *o*-cymene, and diisopropyltoluenes with reaction time over Tisial-4E. Reaction conditions; reaction temperature: 200 °C; LHSV: 0.5; toluene/2-propanol (mole ratio): 3.

content for all the catalysts studied, as illustrated in Fig. 5 for Tisial-4E, which is found to be the most active alkylation catalyst included in the present study. The conversion to *p*-cymene decreased and a corresponding increase in the formation of diisopropyltoluenes is observed with the passing of reaction time. However, the conversion to *p*-cymene remained constant throughout the reaction time.

Even though the alkylating activity of TiO_2–SiO_2–Al_2O_3 increased considerably with increase in TiO_2 content (upto 50 mol% of TiO_2), the selectivity to different products is not altered. This is evidenced from the product patterns obtained at different reaction times, (Table 5) when Tisial-4C of 8.5 mole% of TiO_2 and Tisial-4E of 50 mol% of TiO_2 are used as catalysts.

ii) Dehydration of 2-Propanol: In the dehydration of 2-propanol to propylene, the single oxides TiO_2, SiO_2, and Al_2O_3 showed marginal activity (Fig. 6), whereas the binary oxides are found to show better catalytic activity. However, the ternary oxide system is the most active catalyst for the dehydration and the enhanced activity can be due to the large acid amount values. On plotting the total acidity at $H_o \leqslant +6.8$, of single oxides, binary oxides, and ternary oxide against their dehydrating activity, a linear correlation is obtained (Fig. 7). This suggests that even the weakest acid sites are efficient in demanding the dehydration of 2-propanol.

Conclusion

The binary oxides SiO_2–TiO_2 and Al_2O_3–TiO_2 copre-

cipitated from a solution of pH 4 exhibited acid strength of H_o=−8.2 and are found to be highly active catalysts in the alkylation of toluene with 2-propanol and the dehydration of 2-propanol, even though the single oxides are ineffective catalysts due to their low acid strength. However, the corresponding activity of TiO_2–SiO_2–Al_2O_3 is the highest. The acid amount of the ternary oxide system TiO_2–SiO_2–Al_2O_3 increased with the increase of TiO_2 content upto 50 mol% of TiO_2 and then decreased, without altering the selectivity.

The Acidic Property and Catalytic Activity of MoO_3-SiO_2-Al_2O_3

Kuzhunellil Raghavan Pillai SABU,* Kalur Vijayachandra C. RAO, and Chandrathil Govindan Ramachandran NAIR†
Inter Disciplinary Research Group, Vikram Sarabhai Space Centre, Trivandrum 695022, India
†Department of Chemistry, University of Kerala, Trivandrum 695034, India
(Received July 23, 1990)

The ternary oxide system MoO_3–SiO_2–Al_2O_3 was prepared by coprecipitation method. The pH of coprecipitation has been varied from pH=2 to pH=8 and its effect on the acidic properties of the ternary oxide acidic system was studied by butylamine titration. The MoO_3–SiO_2–Al_2O_3 prepared from highly acidic solution has low acid strength. The total acid amount of the ternary oxide decreased considerably at higher pH (>6) of coprecipitation. It was found that the total acid amount of MoO_3–SiO_2–Al_2O_3 containing 9.7% (by weight) of MoO_3 and silica to alumina molar ratio 16.6 is very high compared with that of SiO_2–Al_2O_3 of the same silica to alumina molar ratio. The acid strength of SiO_2–Al_2O_3 is reduced by the incorporation of MoO_3. Increase in calcination temperature increased the acid strength. The catalytic activity of MoO_3–SiO_2–Al_2O_3 was found to be very high for the alkylation of toluene with 2-propanol. The products are found to be *o*-cymene, *p*-cymene, and three isomers of diisopropyltoluenes. Reaction temperature >200 °C, higher liquid hourly space velocity, and higher alcohol content in the feed decreased the total conversion of 2-propanol to isopropyltoluenes. The acidic property and catalytic activity of MoO_3–SiO_2–Al_2O_3 are not considerably reduced up to four successive regeneration cycles.

Transition metal oxides as such are impractical acid catalysts due to their low acid strength and low value of acid amount. But binary oxides containing transition metal oxides and silica or alumina serve effective catalysts in various acid-catalyzed reactions.[1–5] Similarly many combinations of transition metal oxides viz. TiO_2–ZnO,[6] TiO_2–MoO_3,[7,8] TiO_2–V_2O_5,[8,9] ZnO–Fe_2O_3,[10] and WO_3–TiO_2[11] also have been found to show remarkable acidic properties and catalytic activities. The recent studies by K.V.C. Rao et al. on the ternary oxide sytem TiO_2–SiO_2–Al_2O_3 indicated their utility as acid catalysts in a wide range of alkylation reactions.[12] Also it has been found that the acidity distribution of this ternary oxide system depends on various parameters which include the pH of the solution from which the hydroxides of the component metals of the ternary oxides are coprecipitated, transition metal oxide content and calcination temperature.[13]

Even though MoO_3 supported on SiO_2–Al_2O_3 (Mosial) is also known to catalyze effectively certain oligomerization and polymerization reactions,[14–16] a systematic study on the synthesis of Mosial catalysts and their acidity distributions are not previously attempted. Thus in the present paper, we report the acidic and catalytic properties of a series of Mosial catalysts synthesized by changing the pH of the coprecipitating solution. The acidity distributions are evaluated using butylamine titration technique[17] and the alkylation of toluene with 2-propanol has been selected as the test reaction for comparing the activities of different Mosial catalysts. The effect of calcination temperature on the acidic and catalytic properties, and the effect of process parameters such as temperature and liquid hourly space velocity (LHSV) on the catalytic activity of alkylation are also studied. The regeneration studies on the catalyst have also been included.

Experimental

Materials: The materials used are sodium silicate (Scientific Chemicals), aluminium sulfate (A.R. grade), ammonium molybdate (BDH), 2-propanol (BDH), butylamine (SD Chemicals), nitric acid, and ammonia of chemically pure quality. The indicators used are Neutral Red (pK_a=+6.8), Methyl Red (pK_a=+4.8), Dimethyl Yellow (pK_a=+3.3), phenylazodiphenylamine (pK_a=+1.5), Crystal Violet (pK_a=+0.8), dicinnamylideneacetone (pK_a=−3.0), benzylideneacetophenone (pK_a=−5.6), and anthraquinone (pK_a=−8.2).

Preparation of MoO_3-SiO_2-Al_2O_3: To an aqueous solution of sodium silicate (260 g dm^{-3} of water), dilute nitric acid (1 : 1) is added at 90 °C under constant agitation, till the pH of

Table 1. Physicochemical Characteristics of Different Mosial Catalysts Calcined at 600 °C

Sample	pH of co-ppt	SiO_2/Al_2O_3 molar ratio	% MoO_3 (by weight)	Pore vol	Surface area
				$cm^3\ g^{-1}$	$m^2\ g^{-1}$

Mosial-3	3	40.5	10.3	0.63	61.5
Mosial-4	4	16.6	9.7	0.67	83
Mosial-5	5	9.3	9.2	0.57	57
Mosial-6	6	8.8	6.4	0.36	38
Mosial-7	7	8.4	5.5	0.28	33
Mosial-8	8	8.1	5.3	0.04	8
SiO_2–Al_2O_3	4	16.3	—	1.20	135

the solution is reduced to one. Hot aluminium sulfate solution (100 g in 300 dm^3 of water) is added followed by the addition of ammonium molybdate solution (15 g in 100 dm^3 of water). Ammonia solution is added slowly, till the required pH is attained. The precipitations are carried out at different pH's (2,3,4,5,6,7,8, and 9) and are designated as Mosial-2, Mosial-3 and so on. A SiO_2–Al_2O_3 catalyst is also synthesized at pH 4 without molybdenum oxide. The precipitates are washed with distilled water till free from sulfate ion and are extruded as pellets. These are dried at 120 °C for 12 h and sintered at 600 °C. The Mosial-4 samples were also calcined at different temperatures viz. 150, 300, and 1000 °C.

The physical parameters such as surface area (BET) and pore volume, the silica to alumina molar ratio as well as molybdenum oxide contents of different Mosial catalyst (calcined at 600 °C) determined by chemical analysis are shown in Table 1.

Measurement of Acidity: The acid amounts and acid strength of samples were measured by titrating the 100—200 mesh powder, suspended in dry benzene with butylamine solution in dry benzene using the above mentioned indicators.

Measurement of Catalytic Activity: The isopropylation of toluene with 2-propanol were carried out in a fixed bed tubular reactor at 200 °C (LHSV 0.5 h^{-1}; toluene/2-propanol mole ratio 3; total reaction time 7 h) using all the catalysts synthesized. The effect of temperature on the alkylating activity of Mosial-4 catalyst has been studied at five different temperatures viz. 160, 180, 200, 220, and 240 °C (LHSV 0.5 h^{-1}; toluene/2-propanol mole ratio 3; total reaction time 3 h). Similarly the effect of LHSV on the alkylating activity of Mosial-4 is also studied at three different LHSV viz. 0.5, 1, and 2 (temperature 200 °C, toluene/2-propanol mole ratio 3; total reaction time 7 h). The reactor was fed under gravitational flow. The amount of catalyst used was 25 g which corresponds to 60 ml in volume. The reactor, experimental and analytical procedures of the product mixtures, and method of calculation of percentage yields of isopropyltoluene were the same as those employed in the previous work.[18]

To estimate the catalyst life for alkylation, the same catalyst (Mosial-4 calcined at 600 °C) is subjected to nine successive regenerations by passing air at 600 °C for 5 h, at the end of each alkylation experiment of 7 h.

The products are found to be *o*-cymene, *p*-cymene, and three isomers of diisopropyltoluenes (DIT).

Results and Discussion

The physical characteristics such as surface area and porosity are found to be optimum for the ternary oxide system coprecipitated from solution of pH 4 whereas these two parameters have been considerably reduced by the coprecipitation of the ternary oxide from highly acidic and highly alkaline solutions (Table 1). But the surface area of SiO_2–Al_2O_3 is comparatively high. The percentage of MoO_3 content decreased marginally and the silica to alumina ratio decreased drastically with the increase in the pH of coprecipitation.

Even though activated Al_2O_3 has moderately strong Lewis acid centers,[14] pure silica gel is inactive in demanding acid-catalyzed reactions as the acid strength value of surface SiOH groups is very low.[20] But several combinations of metal oxides each of which contains either SiO_2 or Al_2O_3 have been extensively used as useful catalysts in various acid-catalyzed reactions. Similarly transition metal oxides viz. TiO_2, MoO_3, etc. are impractical acid catalysts due to their low acid strength values, but serve as effective acid catalysts on combination with either SiO_2 or Al_2O_3.[1,3,4] The enhancement in the catalytic properties is attributed to increase in the acid strength and acid amount values of these binary oxides compared with the component single oxides. As reported recently, the incorporation of 10% (by weight) of TiO_2 into a SiO_2–Al_2O_3 support greately changed the acidity distribution of the latter.[13] Table 2 shows the acidity distribution of a series of MoO_3–SiO_2–Al_2O_3 samples calcined at 600 °C. The acidity distributions of all the Mosial samples differ greatly from that of SiO_2–Al_2O_3 as the latter possesses

only too strong acid sites. Also it is well-known that MoO_3 is devoid of acid sites of strength $H_o<+4.8$.[5] Hence it is clear that new acidic sites which differ from those of MoO_3, SiO_2, Al_2O_3, and SiO_2–Al_2O_3 are created on the surface of the ternary oxide MoO_3–SiO_2–Al_2O_3.

However, the acidity distribution of MoO_3–SiO_2–Al_2O_3 system depends mainly on the pH of the final gel during coprecipitation. The Mosials prepared from highly acidic solutions contain mainly weak acid sites ($H_o>+1.5$) whereas a pH of 4 appears optimum in producing acid sites of fairly high acid strength and large acid amount. But further increase in pH decreased the total acid amount values even though the acid strength is not affected. The pH of the coprecipitating solution is shown to have pronounced effect on the compositions of ternary oxides prepared (Table 1). This change in composition, especially the drastic change in silica to alumina mole ratio can be a probable factor governing the acidity distribution.[13]

The acid strength of MoO_3–SiO_2–Al_2O_3 ($H_o \geqslant -3.0$) (Table 2) is comparatively lower than that of TiO_2–SiO_2–Al_2O_3 which is around $H_o=-5.6$.[13] The latter possesses even few acid sites of strength $H_o=-8.2$.[13] This can be probably due to the difference in the averaged electronegativity values of the component metal ions of these two ternary oxide systems.[21]

Effect of Calcination Temperature on Acidity Distribution: Table 3 shows that the Mosial-4 sample calcined at 150 °C is rich in weak acid site ($H_o \geqslant +3.3$) and does not contain any strong acid site. But on increasing the calcination temperature to 300 °C, moderately strong acid site appeared, which may be due to the conversion of weak acid sites to stronger Lewis sites, caused by the loss of water molecules. Mosial-4 sample calcined at 600 °C contains only moderately strong acid sites whereas further increase in calcination temperature to 1000 °C caused almost a complete destruction of acid sites.

Catalytic Activity: The enhancement in the catalytic activity of Mosial-4 and Mosial-5 compared with SiO_2–Al_2O_3 in the alkylation of toluene with 2-propanol (Fig. 1) can be due to the increased acid amount of the ternary oxide system (Table 2). Our earlier studies on TiO_2–SiO_2–Al_2O_3 have also shown that the transition metal oxide exerts a synergistic effect up on the alkylating activity of SiO_2–Al_2O_3.[18] When transition metal

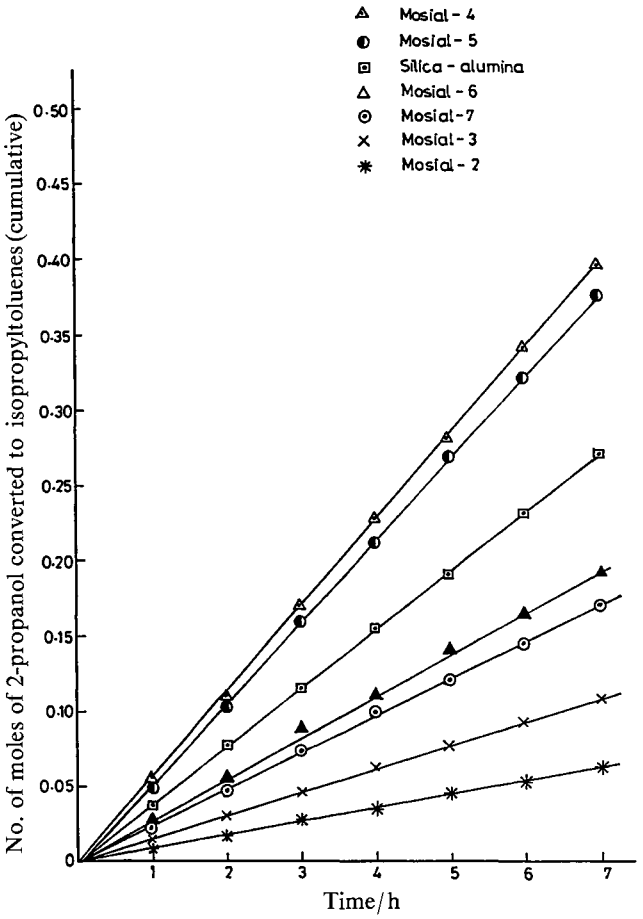

Fig. 1. Cumulative number of moles of 2-propanol converted to isopropyl toluenes over various Mosial catalysts. Reaction conditions: Reaction temperature: 200 °C; Liquid hourly space velocity: 0.5 h^{-1}; Toluene/2-propanol mole ratio: 3.

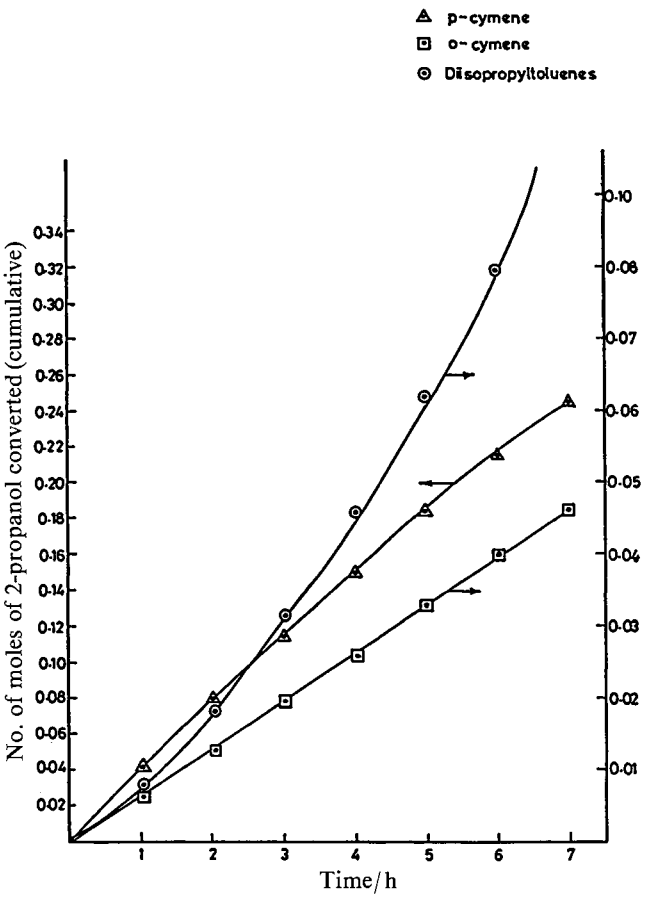

Fig. 2. Cumulative number of moles of 2-propanol converted to *o*-cymene, *p*-cymene, and diisopropyltoluenes over Mosial-4 catalyst. Reaction conditions: Reaction temperature: 200 °C; Liquid hourly space velocity: 0.5 h^{-1}; Toluene/2-propanol mole ratio: 3.

oxides are supported on SiO_2–Al_2O_3, $\overset{+}{M}$–H species are formed where M is the transition metal atom and these species are of suitable acid strength to initiate the alkylation reaction.[18] The $\overset{+}{M}$–H species interacts with the 2-propanol to produce $\overset{+}{M}$–$CH(CH_3)_2$ as shown in Scheme 1 which in turn forms a π-complex with the aromatic substrate, due to the low lying unoccupied d orbitals of the transition metal atom.[18] This π-complex on a π–σ rearrangement gives isopropyltoluenes.[18]

However Mosial-2, Mosial-3, Mosial-6, and Mosial-7 samples exhibited less alkylating activity (Fig. 1) which may be due to the low acid strength and low acid amount values respectively of the former and latter pairs (Table 2). But the rate of formation of isopropyltoluenes remained constant throughout the reaction time for all the catalysts studied (Fig. 1). Even though the product mixture is rich in *p*-cymene content which could be due to steric factors arising when the reacting species are adsorbed on adjoining sites,[22] the extent of formation of *p*-cymene decreased and a corresponding increase in the formation of diisopropyltoluenes was observed with the passing of reaction time (Fig. 2). Hence it could be depicted that the adsorbed *p*-cymene molecules are more prone to get further alkylated to produce diisopropyltoluenes.[18] However the rate of formation of *o*-cymene is unaffected by reaction time. These observations are in good agreement with the results obtained in the alkylation studies of toluene with 2-propanol over TiO_2–SiO_2–Al_2O_3.[18]

Effect of Temperature: The conversion of 2-propanol to isopropyltoluenes increased as the reaction temperature increased from 160 to 200 °C (Fig. 3). Further increase in temperature decreased the conversion. But the unreacted alcohol in the product mixtures is practically nil, irrespective of the reaction temperature (Fig. 3). This shows that the dehydration of 2-propanol is possible over Mosial-4 even at lower temperatures. As shown in Scheme 1, both the dehydrated product (propylene) as well as the alkylated product (isopropyltoluenes) may be formed from the same intermediate, $\overset{+}{M}$–isopropyl.[23] The increase in the reaction temperature from 160 °C to 200 °C may enhance the interaction between the entity $\overset{+}{M}$–isopropyl and the toluene molecule due to the effective diffusion of the latter molecules into the interior surfaces of the catalysts pellet.[23]

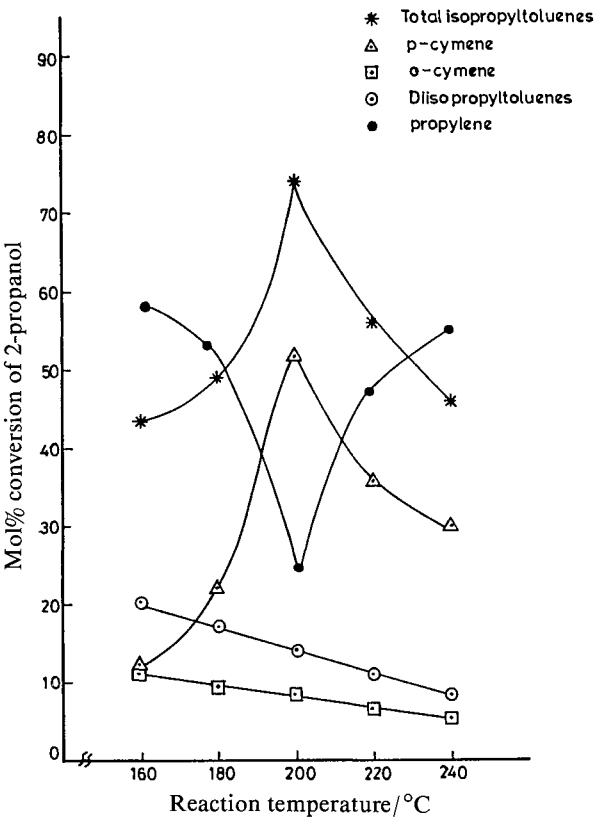

Fig. 3. Effect of reaction temperature on the conversion of 2-propanol to isopropyltoluenes over Mosial-4 catalyst. Reaction conditions: Liquid hourly space velocity: 0.5 h^{-1}; Toluene/2-propanol mole ratio: 3.

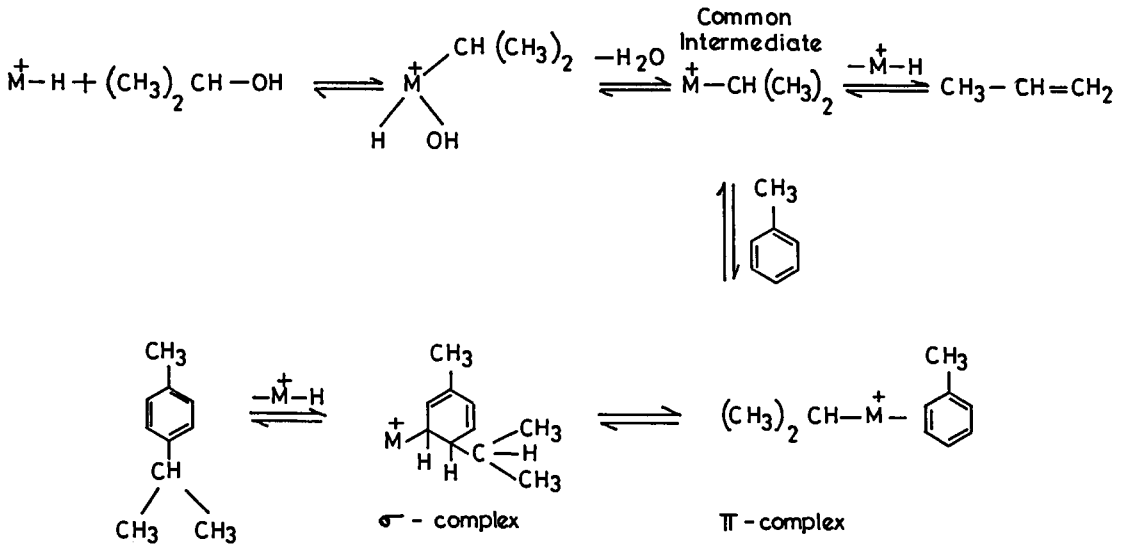

Scheme 1. The mechanism of alkylation of toluene with 2-propanol over MoO_3–SiO_2–Al_2O_3 catalyst.

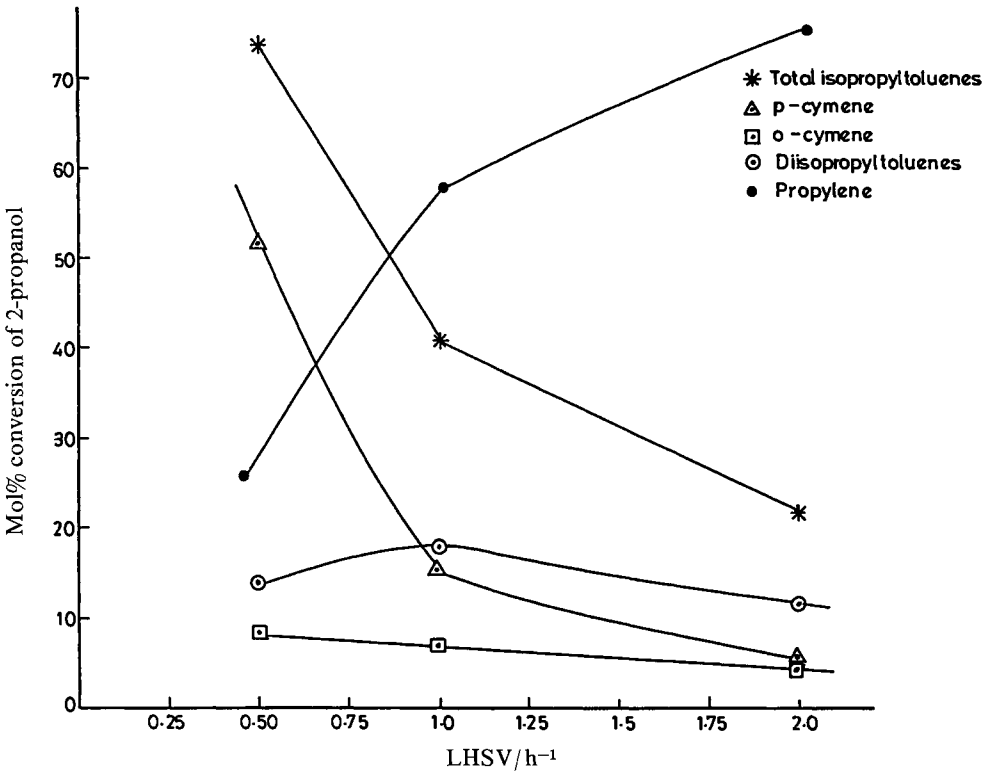

Fig. 4. Effect of liquid hourly space velocity on the conversion of 2-propanol to isopropyltoluenes over Mosial-4 catalyst. Reaction conditions: Reaction temperatures: 200 °C; Toluene/2-propanol mole ratio: 3.

However, at very high reaction temperatures (>200 °C), the formed isopropyltoluene molecules may undergo dealkylation to toluene which could be a probable reason for the decreased conversions. Similarly, the dealkylation of formed cymene molecules at reaction temperatures >200 °C has been observed by us earlier over TiO_2–SiO_2–Al_2O_3 catalyst in the alkylation of toluene with 2-propanol.[18] The *o*-cymene formation decreased marginally with the increase in reaction temperature whereas the optimum formation of *p*-cymene is observed at 200 °C. However in the product mixture, the para-isomer content is more irrespective of the reaction temperature studied, which could be due to the steric factors arising between the reacting species as discussed previously.[22] Hence it may be presumed that the interaction between an adsorbed toluene molecule and the adsorbed alkylating moiety leads to the formation of the para-isomer whereas the interaction of the latter with a free unadsorbed toluene in the gaseous state results in the formation of ortho-isomer.[18] Also it could be depicted that the formation of cymene molecules via the former route take place on the interior surface of the catalyst pellet, the rate of which is enhanced by the effective diffusion of the toluene molecules into the pores of the catalyst pellet.[23] Hence the marginal decrease in the formation of *o*-cymene and increase in the formation of *p*-cymene with increase in reaction temperature. These observations are also in line with those of alkylation reactions carried out over ion-exchanged zeolites.[24]

Increased formation of diisopropyltoluene is observed at lower reaction temperatures. This may be due to the high residence time of cymene molecules formed at lower temperatures, resulting in further alkylation.[18] Multialkylations are generally favored at lower reaction temperature.[25]

Effect of LHSV: As the LHSV increased from 0.5 to 2, the conversion of 2-propanol to isopropyltoluenes decreased drastically (Fig. 4). However unreacted 2-propanol has not been observed in the product mixture in all cases. It may be assumed that at higher LHSV, because of the less effective diffusion of the toluene molecules into the interior surface of the catalyst pellet, the $\overset{+}{M}$–isopropyl species formed there leads to propylene formation and hence the decreased conversions to *p*-cymene and marginal increase in the formation of *o*-cymene.[23] Also at higher LHSV, the formed cymene molecules may get further alkylated by $\overset{+}{M}$–isopropyl species, even before desorbing out from the reaction site, causing increase in the formation of diisopropyltoluenes.

Effect of Toluene/2-Propanol Mole Ratio in the Feed: The conversion of 2-propanol to isopropyltoluenes decreased considerably with the increase in the alcohol content in the feed (Fig. 5). However at these conditions, the dehydration of 2-propanol to propylene predominated, which suggests that large excess of toluene in the feed suppresses the formation of propyl-
