a) The assignments of acetoxyl groups may have to be interchanged.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. All reactions were monitored by TLC (Merck silica gel 60F, 0.25 mm) with an appropriate solvent system [(A) AcOEt, (B) 1:1, (C) 2:1 AcOEt–hexane, and (D) 5:3:1 2-propanol–AcOEt–H_2O]; components were detected by spraying the plates with 20% sulfuric acid–ethanol, with subsequent heating. Column chromatography was performed by Wako C-200 silica gel. The ^1H and ^{31}P NMR spectra were measured in $CDCl_3$ with Varian VXR-500 (500 MHz for ^1H) and VXR-200 (81 MHz for ^{31}P) instrument (the SC-NMR Lab., Okayama Univ.) at 21 °C, except for compound **7** [which was measured with Hitachi R600 (60 MHz) instrument]. Chemical shifts are reported as δ values relative to tetramethylsilane (internal standard for ^1H) and 85% phosphoric acid (external standard for ^{31}P). The mass spectra were taken on an A.E.I. MS 50 ultrahigh resolution instrument and were given in terms of m/z (rel intensity) compared with the base peak.

(5*R* and 5*S*)-3-*O*-Acetyl-5,6-dideoxy-1,2-*O*-isopropylidene-5-[(*R* and *S*)-(methoxy)phenylphosphinyl]-6-nitro-α-*xylo*-hexofuranoses (4). TEA (0.10 ml, 0.72 mmol) was added dropwise at 0 °C to a mixture of **3**[5] (464 mg, 1.70 mmol) and methyl hydrogenphenylphosphinate (1.41 g, 9.04 mmol) in benzene (2 ml). The mixture was stirred for 3 h at 25 °C and then poured into saturated aq $NaHCO_3$. The resulting solution was stirred overnight and extracted three times with CH_2Cl_2. The extracts were washed with saturated aq NaCl, dried (Na_2SO_4), and evaporated in vacuo. The residue was purified in a column of silica gel with AcOEt–hexane as an eluant, giving an inseparable mixture [9:9:1:1 (two D-gluco and two L-ido isomers)] of **4** as a colorless syrup, the ratio being determined by ^1H and ^{31}P NMR: 620 mg (85%); R_f=0.28 (B); ^1H NMR (500 MHz) for two D-gluco isomers δ=1.25, 1.28*, 1.45, 1.48* (3H each, 4s, CMe_2), 1.70, 2.09* (3H, 2s, AcO-3), 3.58, 3.61* (1H, 2m, H-5, their splitting patterns uncertain because of overlapping with other proton signals), 3.60, 3.67* (3H, 2d, J_{POMe}=11.1 Hz, POMe), 4.39, 4.48* (1H, 2d, $J_{1,2}$=3.8, 3.6* Hz, H-2), 4.50, 4.59* (1H, 2ddd, $J_{4,5}$=9.7, 9.1*, $J_{4,P}$=5.7, 7.4*, $J_{3,4}$=2.8, 2.9* Hz, H-4), 4.51, 4.87* (1H, 2td, $J_{6',P}$=14.9, 15.2*, $J_{6,6'}$=14.9, 15.0*, $J_{5,6'}$=4.9, 5.4* Hz, H-6'), 4.77, 4.89* (1H, 2ddd, $J_{6,P}$=12.2, 13.7*, $J_{5,6}$=6.4, 7.0* Hz, H-6), 4.99, 5.25* (1H, 2d, H-3), 5.74, 5.78* (1H, 2d, H-1), 7.54, 7.54* [2H, m, Ph(*m*)], 7.63, 7.64* [1H, 2m, Ph(*p*)], 7.74, 7.78* [2H, 2m, Ph(*o*)], * for another diastereomer with regard to the phosphorus atom (the assignment of some of the δ values may have to be interchanged); ^{31}P NMR δ=39.1 and 38.0 (D-gluco), 39.4 and 38.6 (L-ido isomers); MS m/z 430 (M+1; 1.0), 414 (24), 354 (33), 340 (28), 312 (13), 293 (18), 265 (38), 258 (55), 211 (44), 173 (31), 155 (100). Found: m/z 430.1273. Calcd for $C_{18}H_{25}NO_9P$: M+1, 430.1267.

(5*R* and 5*S*)-3-*O*-Acetyl-5-deoxy-1,2-*O*-isopropylidene-5-[(*R* and *S*)-(methoxy)phenylphosphinyl]-α-D-*xylo*-hexofuranoses (6). Compound **4** (585 mg, 1.36 mmol) dissolved in a mixture of ethanol (3 ml) and acetic acid (0.15 ml, 2.6 mmol) was hydrogenolyzed in the presence of 20% $Pd(OH)_2$ on carbon (630 mg, 0.90 mmol) at 20 °C under atmospheric pressure of H_2. After 24 h, the catalyst was filtered off and the filtrate was evaporated in vacuo, giving 6-ammonio-hexofuranose acetate derivatives **5** as a colorless syrup: R_f=0.49 (D).

To a stirred solution of **5** in water (15 ml) was added, at 0 °C, acetic acid (0.20 ml, 3.5 mmol) and then sodium nitrite (384 mg, 3.57 mmol). After 2 h, the mixture was twice extracted with $CHCl_3$. The combined organic layers were washed with aq $NaHCO_3$ and then water, dried (Na_2SO_4), and evaporated in vacuo. The residue was separated by column chromatography (with AcOEt as an eluant), giving two fractions.[#]

The faster-eluting fraction [R_f=0.27 (A)] gave a colorless syrup which was one D-gluco isomer of **6** [but contained a minor amount (<10%) of an L-ido isomer]: 138 mg (25% from **4**): ^1H NMR (500 MHz) δ=1.30, 1.53 (3H each, 2s, CMe_2), 2.08 (3H, s, AcO-3), 2.63 (1H, dddd, $J_{5,P}$=13.9, $J_{4,5}$=10.9, $J_{5,6}$=5.1, $J_{5,6'}$=4.0 Hz, H-5), 3.60 (3H, d, J_{POMe}=11.0 Hz, POMe), 3.90 (1H, ddd, $J_{6',P}$=23.5, $J_{6,6'}$=11.9 Hz, H-6'), 3.91 (1H, ddd, $J_{6,P}$=7.0 Hz, H-6), 4.05 (1H, m, HO-6), 4.50 (1H, d, $J_{1,2}$=3.9, $J_{2,3}\approx$0 Hz, H-2), 4.77 (1H, ddd, $J_{4,P}$=5.0 Hz, $J_{3,4}$=2.8 Hz, H-4), 5.34 (1H, d, H-3), 5.85 (1H, d, H-1), 7.52 [2H, m, $J_{o,m}=J_{m,p}$=7.5, $J_{m,P}$=3.5 Hz, Ph(*m*)], 7.61 [1H, m, $J_{o,p}=J_{p,P}$=1.4 Hz, Ph(*p*)], 7.71 [2H, m, $J_{o,P}$=11.7 Hz, Ph(*o*)]; ^{31}P NMR δ=42.0.

The slower-eluting fraction [R_f=0.20 (A)] gave a colorless syrup which was mainly the other D-gluco isomer **6** [but contained a minor amount (<10%) of another L-ido isomer]: 144 mg (27% from **4**); ^1H NMR (500 MHz) δ=1.26, 1.42 (3H each, 2s, CMe_2), 1.96 (3H, s, AcO-3), 2.75 (1H, ddt, $J_{5,P}$=17.1, $J_{4,5}$=10.8, $J_{5,6}$=5.5, $J_{5,6'}$=5.4 Hz, H-5), 3.64 (3H, d, J_{POMe}=11.2 Hz, POMe), 3.68 (1H, m, HO-6), 4.04 (1H, ddd, $J_{6,6'}$=11.8, $J_{6',P}$=10.7 Hz, H-6'), 4.08 (1H, ddd, $J_{6,P}$=10.2 Hz, H-6), 4.38 (1H, ddd, $J_{4,P}$=6.0, $J_{3,4}$=2.7 Hz, H-4), 4.42 (1H, d, $J_{1,2}$=3.9, $J_{2,3}\approx$0 Hz, H-2), 5.08 (1H, d, H-3), 5.79 (1H, d, H-1), 7.53 [2H, m, Ph(*m*)], 7.61 [1H, m, Ph(*p*)], 7.74 [2H, m, Ph(*o*)]; ^{31}P NMR δ=42.0; MS m/z 401 (M+1; 1.0), 385 (16), 325 (13), 283 (21), 253 (25), 229 (54), 211 (20), 199 (37), 173 (34), 155 (100). Found: m/z 401.1353. Calcd for $C_{18}H_{26}NO_8P$: M+1, 401.1365.

(5*R* and 5*S*)-3-*O*-Acetyl-5-deoxy-1,2-*O*-isopropylidene-5-[(*R* and *S*)-(methoxy)phenylphosphinyl]-6-*O*-(tetrahydro-2-pyranyl)-α-D-*xylo*-hexofuranose (7). A solution of **6**[#] (140 mg, 0.350 mmol) and dihydropyran (0.10 ml, 1.1 mmol) in dry CH_2Cl_2 (1.5 ml) containing PPTS (50 mg, 0.20 mmol) was stirred for 10 h at 20 °C. The solution was diluted with ether, washed with half-saturated brine, dried (Na_2SO_4), and evaporated in vacuo. The residue was purified by column chromatography (with 3:1 AcOEt–hexane), giving **7** (154 mg, 90%) as a colorless syrup: R_f=0.45—0.30 (A); ^1H NMR (60 MHz) δ=1.25—1.65 [6H, m, C-(CH_2)$_3$-C-O-6], 1.28, 1.35, 1.45, 1.48 (6H, 4s, CMe_2), 1.96, 2.01, 2.06, 2.10 (3H, 4s, AcO-3), 2.45—2.85 (1H, m, H-5), 3.47, 3.50, 3.59 (3H, 3d, J_{POMe}=11.0 Hz, POMe), 3.50—4.15 (4H, m, CH_2-O-C-O-6, H_2-6), 4.25—4.65 (2H, m, H-4, CH-O-6), 4.45 (1H, d, $J_{1,2}$=4.0 Hz, H-2), 5.34 (1H, d, $J_{3,4}$=2.8 Hz, H-3), 5.80 (1H, d, H-1), 7.45—7.70, [3H, m, Ph(*m,p*)], 7.70—7.90 [2H, m, Ph(*o*)]; MS m/z 481 (M^+; 0.6), 469 (1.7), 401 (15), 385 (19), 325 (18), 283 (27), 253 (20), 229 (41), 199 (34), 173 (42), 155 (100). Found: m/z 484.1843. Calcd for $C_{23}H_{33}O_9P$: M, 483.1862.

1,2,3,4,6-Penta-*O*-acetyl-5-deoxy-5-phenylphosphino- (12) and 5-Phenylphosphinyl-α,β-D-glucopyranoses (13). To a solution of **7** (264 mg, 0.545 mmol) in dry benzene (5 ml) was added, with stirring, a solution of SDMA (3.4 M toluene

[#] Because the separation of the two fractions of **6** was rather difficult and each fraction was expected to give the same mixture of **8** and/or **9** after the SDMA reduction (Ref. 8), the combined fractions of **6** were used for the practical preparation of **7**.

solution, 0.50 ml, 1.7 mmol) in dry benzene (2 ml) in small portions at 5 °C under an argon atmosphere. The stirring was continued at this temp for 1 h. Then, water (0.5 ml) was added and the mixture was stirred for 30 min. The precipitate was centrifuged and washed with several portions of benzene. The organic layers were combined and evaporated in vacuo, giving the 5-phenylphosphino derivative **8** as a colorless syrup: R_f=0.78—0.70 (A): ^{31}P NMR δ=−53.4, −51.5; besides these strong signals, a weak signal (less than a 5% relative intensity) was observed at δ=30.1 most likely assignable to **9**.

The above syrup (mostly **8**) was immediately treated with a mixture of ethanol (5 ml) and 0.5 M hydrochloric acid (5 ml) at 90 °C for 3 h under an argon atmosphere. After cooling, the reactants were neutralized with weakly basic ion-exchange resin Amberlite IRA-45. The resin was filtered off and washed with water, and the filtrate was evaporated in vacuo to give a mixture of 5-deoxy-5-phenylphosphino- [**10**, R_f=0.74 (D), major] and 5-phenylphosphinyl-D-glucopyranoses [**11**, R_f=0.58 (D), minor] as a colorless syrup.

This was acetylated with acetic anhydride (1 ml) in dry pyridine (2 ml) for 12 h at 20 °C and then the mixture was concentrated in vacuo. The residue was separated by column chromatography with a gradient eluant of 1:1 AcOEt–hexane→AcOEt, into three fractions A—C.

Fraction A [R_f=0.56 (C)] gave a chromatographically inseparable mixture (31.3 mg) consisting of 5-[(*R*)-phenylphosphino]-α-D-glucopyranose **12a** (2.0% from **7**) and its β-isomer **12b** (9.9%). Pure compound **12b** was obtained by recrystallization of the above mixture from 1:1 AcOEt–hexane: colorless prisms, mp 148—149 °C; ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 483 (M+1; 0.8), 440 (4.1), 381 (100), 339 (27), 321 (12), 279 (32), 261 (12), 237 (23), 219 (28), 125 (22). Found: C, 54.35; H, 5.58%; *m/z* 483.1420. Calcd for $C_{22}H_{27}O_{10}P$: C, 54.77; H, 5.64%. Calcd for $C_{22}H_{28}O_{10}P$: (M+1), 483.1420.

Fraction B [R_f=0.20 (C)] gave colorless crystals (26.7 mg) which consisted of 5-[(*S*)-phenylphosphinyl]-α-D-glucopyranose **13a** (4.5% from **7**) and its β-isomer **13b** (5.3%); mp 226—228 °C (1:1 mixture, from AcOEt); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 499 (M+1; 3.8), 456 (5.2), 397 (70), 355 (100), 337 (18), 295 (60), 253 (39), 234 (45), 159 (36), 125 (47). Found: C, 53.22; H, 5.54%; *m/z* 499.1382. Calcd for $C_{22}H_{27}O_{11}P$: C, 53.02; H, 5.46%. Calcd for $C_{22}H_{28}O_{11}P$: (M+1), 499.1369.

Fraction C [R_f=0.15—0.10 (C)] gave an inseparable mixture of products as a colorless syrup (5 mg, ca. 2% from **7**); ^{31}P NMR δ=24.5, 25.8, 26.3; for their structures, see the main text.

Reaction of Thioaldehydes with Amines

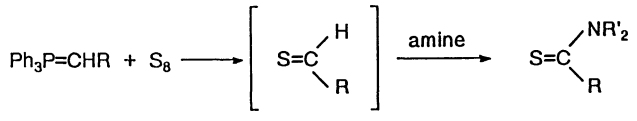
Kentaro OKUMA,* Yasuo KOMIYA, and Hiroshi OHTA
Department of Chemistry, Faculty of Science, Fukuoka University, Jonan-ku, Fukuoka 814-01
(Received May 7, 1991)

The reaction of phosphonium ylides with elemental sulfur gave thioaldehydes, which changed to the corresponding thioamides in good yields when treated with amines. When thioaldehydes containing α-hydrogens were treated with secondary amines, the corresponding enamines or reduction products were obtained.

The chemistry of thiocarbonyl compounds has been of current interest.[1] Several authors have reported the formation of thioaldehydes (**1**). Kirby and Lochead reported the generation of thioaldehydes from S-esters of sodium hydrogenthiosulfate.[1a] Generation of thioaldehydes also occurs from the Norrish cleavage of phenacyl sulfides.[1b] Recently, we also showed that the reaction of phosphonium ylides (**2**) with elemental sulfur or thiiranes gave symmetrical olefins via thiocarbonyl compounds.[2] Reactions of these relatively unstable thioaldehydes are of much interest. However, there are quite a few reports on the reaction of these thioaldehydes with amines. Okazaki has reported that the reaction of 2,4,6-tri-*t*-butylthiobenzaldehyde with primary amines afforded the corresponding imines.[3] Recently, we reported the reaction of **1** with secondary amines (**3**) afforded the corresponding thioamides (**4**) in good yields.[4] In this paper, we would like to give a detailed account on the reaction of thioaldehydes with amines.

Results and Discussion

We first tried the reaction of methoxycarbonylmethylenetriphenylphosphorane (**2a**) with sulfur in the presence of secondary amines, **3**. Treatment of **2a** with elemental sulfur and morpholine in toluene gave the corresponding thioamide (**4a**) in 75% yield. As shown in Table 1, other thioamides, **4**, were obtained in good yields. Since thioaldehyde (**1a**) could be also synthesized by the reaction of the corresponding sulfenyl chloride with triethylamine,[1a] we also carried out the reaction of **1a** starting from methyl mercaptoacetate (methyl thioglycolate) (**5a**) with morpholine. The reaction of thioaldehydes derived from thiols with N-chlorosuccinimide (NCS) with secondary amines also gave the corresponding thioamides, **4**, in good yields. Other reactions were carried out in a similar manner. However, when phenylmethanethiol (**5d**) and methanethiol (**5e**) were used as starting thiols, only the corresponding sulfenamides (**6**) were obtained. Thus, electron-withdrawing groups were required to obtain thioamides in this reaction. (Table 2)



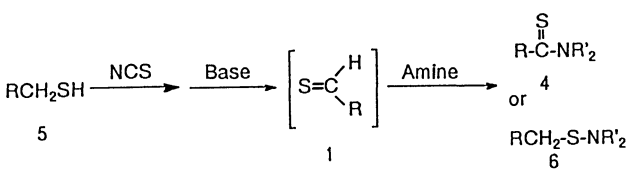
Scheme 1.

Table 1. Reaction of Thioaldehydes with Secondary Amines

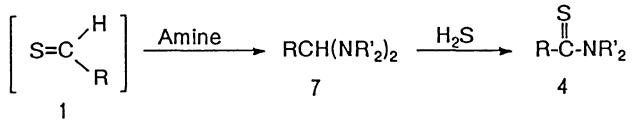
Thioaldehyde 1	R	Amine 3	Thioamide (yield/%) 4	
a	COOMe	Morpholine	**4a**	75
a	COOMe	Dimethylamine	**4b**	76
a	COOMe	Piperidine	**4c**	60
a	COOMe	Pyrrolidine	**4d**	47
b	COOEt	Morpholine	**4e**	73
c	Ph	Morpholine	**4f**	56

Milligan and Swan reported that the reaction of *O*-carbamoylmethyl thiosulphate with primary and secondary amines afforded 2-amino-2-thiooxoacetoamides and disulfides. They suggested that these compounds might be formed in a complex manner from thioaldehyde intermediates.[5] As to the formation of thioamides, **4**, the following mechanism is reasonable: Thioaldehydes, **1**, were converted to the corresponding bis(dialkylamino)alkanes, **7**, (aminal) by treatment with amines in a manner similar to the reaction of amines with aldehydes. The resulting **7** further reacted with the hydrogen sulfide produced to give thioamides, **4**.

The above mechanism was confirmed by the following two reactions. When the reaction of **2c** with sulfur in the presence of morpholine was carried out at 50 °C, **7** was isolated in 70% yield instead of **4f**. Additionally,



Scheme 2.



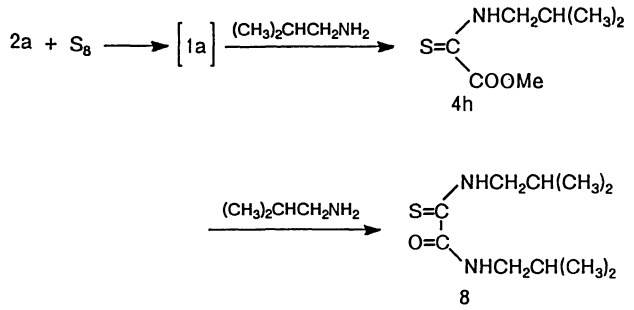
Scheme 3.

Table 2. Reaction of Thiols with NCS Followed by the Addition of Amines

Thiol 5	R	Conditions: Base	Solvent	Temperature/°C	Amine	Products (Yield/%)	
5a	COOMe	DBU	CH_2Cl_2	Reflux	Morpholine	**4a**	55
		DBU	THF	Reflux	Morpholine	**4a**	65
		BuLi	THF	0	Morpholine	**4a**	75
		DBU	CH_2Cl_2	Reflux	Dimethylamine	**4b**	65
		BuLi	THF	0	Dimethylamine	**4b**	75
5b	COOEt	BuLi	THF	0	Morpholine	**4e**	70
5c	4-$NO_2C_6H_4$-	DBU	CH_2Cl_2	Reflux	Morpholine	**4g**	91
5d	Ph	DBU	CH_2Cl_2	Reflux	Morpholine	**6a**	55
		BuLi	THF	0	Morpholine	**6a**	70
5e	H-	BuLi	THF	0	Morpholine	**6b**	70

treatment of **7** with hydrogen sulfide afforded the corresponding thioamide, **4f**, 65% yield. It is well known that thioamides were formed by the reaction of sulfur with aryl alkyl ketones (Willgerodt–Kindler reaction).[6] In this case, the primary step might be the formation of aminals, **7**, resulting from the action of the amine on the ketones, which then changed to thioamides as shown in the present reaction.

We further tried the reaction of **1a** with sulfur in the presence of primary amines. Treatment of **1a** with sulfur in the presence of isobutylamine also gave thioamides, **4h**. The resulting **4h** further reacted with isobutylamine to give *N*,*N*′-diisobutyl-2-amino-2-thiooxoacetamide (**8**) in 64% yield. However, when benzylidenetriphenylphosphorane, **2c**, was treated with elemental sulfur and isobutylamine, the observed products were benzylideneisobutylamine and triphenylphosphine sulfide. The corresponding thioamide could not be obtained. Electron-withdrawing groups on the phosphonium ylides might be necessary for thioamide synthesis.



Scheme 4.

To confirm the formation of thioaldehydes, **1**, in this reaction, we tried the reaction of phosphonium ylides, **2**, with sulfur in the presence of dienes. Treatment of phosphonium ylide, **2a**, with elemental sulfur in the presence of 2,3-dimethyl-1,3-butadiene or cyclopentadiene afforded the corresponding Diels–Alder adduct, **9** or **10**, in 56% or 64% yield, respectively.

We then tried the reaction of thioaldehydes containing α-hydrogens with secondary amines. The results of these reactions were different from previous ones. First, we tried the reaction of phenethyltriphenylphosphonium bromide with elemental sulfur and secondary amines. The obtained products were the corresponding enamine (**11**) and triphenylphosphine

sulfide. This result suggested that these reactions would proceed through thiobenzaldehyde intermediates, which further reacted with amines to give enamines. However, the yields of enamines were very low and other unidentifiable products were obtained. Meyer and Gewald reported that enamines were easily changed to the corresponding thioamides in good yields.[7] However, we could not isolate the corresponding thioamides in the present work. The difference in the reactivity might be due to the difference in the substituents.

We then tried the reaction of other types of thioaldehydes. Treatment of 2-ethoxycarbonylethylidenetriphenylphosphoran (**2e**) with elemental sulfur and morpholine afforded ethyl 3- morpholinopropionate (**12a**) and triphenylphosphine sulfide in 60 and 82% yields, respectively. Asinger et al. reported the reaction of alkyl aryl ketones with sulfur and NH_3.[6] They suggested that these ketones were converted to the corresponding thioketones, the thiocarbonyl group of which was reduced to the methylene group by treatment of hydrogen sulfide. The present reaction might proceed in a similar manner.

Thioamide syntheses from thioaldehydes were previously reported by only one group. Fischer and coworkers reported that the reaction of thioaldehyde-metal complexes with ynamines afforded thioamides by cycloaddition followed by extrusion of metals and the addition of carbon monooxide.[8]

In summary, we found that thioaldehydes show a different reactivity upon treatment with amines depending on whether the aldehydes have α-hydrogens or not. Thioaldehydes with the α-hydrogens gave the reduction products. On the other hand, thioaldehydes without the α-hydrogens afforded thioamides in good yields.

Experimental

General. Melting points are uncorrected. ^1H NMR spectra were determined with a JEOL PMX-60, a FX-90, or a GX-400 spectrometer. Mass spectra were recorded on a JEOL GS 270 spectrometer.

Materials. Stable phosphonium ylides were prepared by a method mentioned in the literature.[9] Methyl thioglycolate, *N*-chlorosuccinimide, 4-nitrobenzyl bromide were purchased from Wako Pure Chem. Compounds **12a** and **12b** were prepared by the reaction of ethyl acrylate with the corresponding amines.[10]

Reaction of 2a with Sulfur in the Presence of Secondary Amines. To a solution of **2a** (1.67 g, 10 mmol) and morpholine (1.74 g, 20 mmol) in toluene (25 ml) was added a solution of sulfur (0.64 g, 20 mmol) in toluene (20 ml). After refluxing for 12 h, the reaction mixture was washed with water and evaporated to give yellow oily crystals. This mixture was extracted with hexane (30 ml×3). The combined extracts were evaporated to give thioamide **4a**. Other reactions were carried out in a similar manner.

4a; 0.71 g (3.7 mmol, 75%), mp 77—79 °C, ^1H NMR ($CDCl_3$) δ=3.56—3.65 (m, 2H), 3.74—3.86 (m, 4H), 3.87 (s, 3H), 4.15—4.24 (m, 2H). Precise mass for $C_7H_{11}NO_3S$: 189.0459 (calcd), 189.0492 (found).

4b; 0.44 g (3.8 mmol, 76%), ^1H NMR($CDCl_3$) δ=3.17 (s, 3H), 3.30 (s, 3H), 3.83 (s, 3H). Precise mass for $C_5H_9NO_2S$: 147.0354 (calcd), 147.0419 (found).

4c; 0.58 g (2.8 mmol, 60%), ^1H NMR ($CDCl_3$) δ=1.88—2.20 (m, 4H), 3.49—3.78 (m, 4H), 3.86 (s, 3H). Precise mass for $C_8H_{13}NO_2S$: 187.0667 (calcd), 187.0631 (found).

4d; 0.41 g (2.4 mmol, 47%), ^1H NMR ($CDCl_3$) δ=1.58—1.85 (m, 4H), 3.40—3.86 (m, 2H), 3.86 (s, 3H), 3.96—4.23 (m, 2H). Precise mass for $C_7H_{11}NO_2S$: 173.0510 (calcd), 173.0473 (found).

4e; 0.68 g (3.6 mmol, 73%), ^1H NMR ($CDCl_3$) δ=1.32 (t, 3H), 3.53—4.11 (m, 8H), 4.29 (q, 2H). Precise mass for $C_8H_3NO_3S$: 203.0616 (calcd), 203.0562 (found).

Reaction of 2c with Sulfur in the Presence of Morpholine. To a solution of benzyltriphenylphosphonium bromide (2.25 g, 5 mmol) in benzene (30 ml) was added a solution of butyllithium (4.5 ml, 10% w/v, 7 mmol) in hexane at room temperature. After stirring for 1 h, morpholine (4.35 g, 50 mmol) and sulfur (0.32 g, 10 mmol) were added and refluxed for 2 h. The resulting mixture was washed with water (20 ml×2) and evaporated to give yellow oily crystals. This mixture was extracted with hexane (30 ml×3). The combined extracts were evaporated to give *N*-thiobenzoylmorpholine **4f** (0.58 g, 2.8 mmol, 56%), mp 134—134.5 °C, (lit,[11] mp 134.5—136 °C). ^1H NMR ($CDCl_3$) δ=3.62 (br s, 4H), 3.89 (m, 2H), 4.48 (m, 2H), 7.27 (m, 5H). Anal. Calcd for $C_{11}H_{13}NOS$: C, 63.74; H, 6.32; N, 6.76%. Found: C,63.95; H, 6.67; N, 6.90%.

Preparation of 4-Nitrophenylmethanethiol, (5c). To a solution of sodium thiosulfate (4.96 g, 20 mmol) in water (50 mL) was added a solution of 4-nitrobenzyl bromide (4.32 g, 20 mmol) in ethanol (20 mL). Afer stirring for 24 h, 5 mL of concd HCl was added to this solution and refluxed for 3 h.

The resulting solution was condensed to 40 mL and extracted with dichloromethane (15 mL) for three times. The combined extract was dried over $MgSO_4$ and evaporated to give the corresponding thiol, **5c** (2.21 g, 65%), mp 56—57 °C, (lit,[132] mp 58 °C).

Reaction of Methyl Thioglycolate with *N*-Chlorosuccinimide Followed by the Addition of DBU and Elemental Sulfur. To a solution of *N*-chlorosuccinimide (0.81 g, 6.0 mmol) in 20 mL of dichloromethane was added a solution of methyl thioglycolate (0.53 g, 5.0 mmmol) in dichloromethane (10 mL). After stirring for 2 h, the resulting suspension was filtered. The yellow filtrate was added to a solution of DBU (1.17 g, 7.0 mml) and morpholine (0.52 g, 6.0 mmol) in dichloromethane (30 mL) After refluxing for 3 h, the reaction mixture was washed with water and extracted with ether (15 mL×3). The combined extracts were dried over sodium sulfate and evaporated to give a pale yellow oil. The resulting oil was chromatographed over silica gel by elution with dichloromethane–ethyl acetate to afford **4a** in 65% yield. Mp 77—79 °C. Thioamides **4b** and **4e** were also prepared in a similar manner.

Reaction of 4-Nitrophenylmethanethiol, (5c), with NCS Followed by the Addition of DBU and Morpholine. To a solution of NCS (0.67 g, 5 mmol) in dichloromethane (20 mL) was added a solution of 4-nitrophenylmethanethiol (0.68 g, 4 mmol) in dichloromethane (10 mL) at room temperature. After stirring for 2 h, the resulting suspension was filtered. The filtrate was added a solution of morpholine (0.35 g, 4 mmol) and DBU (0.76 g, 5 mmol) in dichloromethane (30 mL) and refluxed for 3 h. The reaction mixture was washed with water, dried over $MgSO_4$, and evaporated to give pale yellow crystals. Recrystallization from methanol afforded colorless crystals of thioamide, **4g** (yield 91%). Mp 193—194 °C; Anal. Calcd for $C_{11}H_{12}N_2O_3S$: C, 52.37; H, 4.79; N, 11.10%. Found: C, 52.02; H, 4.86; N, 11.07%.

Reaction of Methanesulfenyl Chloride with Morpholine. To a solution of morpholine (0.87 g, 10 mmol) in 30 ml of THF was added a solution of methanesulfenyl chloride (0.28 g, 3 mmol) in THF at −15 °C. Immediately, white crystals of morpholinium chloride were precipitated. The suspension was stirred for 3 h, washed with water, and extracted with hexane (15 mL×3). The combined extracts were dried over $MgSO_4$ and evaporated to give a pale brown oil, which was subjected to bulb-to-bulb distillation to give a pale yellow oil of methylsulfenylmorpholide (mp 40—50 °C/0.5 mmHg; lit,[13] 48—49 °C/5 mmHg, 1mmHg=133.322 Pa). *N*-benzylsulfenylmorpholine, (**6a**), was obtained in a similar manner. Mp 73—74 °C, (lit,[13]) mp 73.5—74.5 °C.

Reaction of 2c with Morpholine in the Presence of Sulfur at 50 °C (Preparation of 7). To a suspension of benzyltriphenylphosphonium chloride (1.94 g, 5 mmol) in benzene (25 mL) was added butyllithium (10% w/v, 4 mL, 6 mmol) in hexane. To this suspension, morpholine (1.74 g, 20 mmol) and sulfur (0.32 g, 10 mmol) were added portionwise at room temperature. After stirring for 1 h at 50 °C, the reaction mixture was evaporated to give pale yellow oily crystals. Recrystallization from ethanol gave colorless crystals of aminal **7** (0.71 g, 3.25 mmol), mp 100—101 °C, (lit,[14] 100—101.5 °C).

Reaction of 2c with Sulfur in the Presence of Primary Amines. To a solution of benzyltriphenylphosphonium bromide (2.25 g, 5 mmol) in benzene was added a solution of butyllithium (4.5 ml, 10% w/v, 7 mmol) at room temperature. After stirring for 1 h, butylamine (3.60 g, 50 mmol) and sulfur (0.32 g, 10 mmol) were added and refluxed for 2 h. The resulting mixture was washed with water and evaporated to give yellow oily crystals. The mixture was extracted with hexane (30 ml×3). The combined extracts were evaporated to give a yellow oil, which was distilled under reduced pressure (bulb-to-bulb distillation) to give a colorless oil of benzylidenebutylamine. Other reaction was carried out in a similar manner. Benzylidenebutylamine: 0.41g (2.6 mmol, 51%), 50—60 °C/4 mmHg, (lit,[15] 128—131 °C/25 mmHg), ^{1}H NMR ($CDCl_3$) δ=0.70—2.00 (m, 7H), 3.72—3.87 (m, 2H), 7.10—7.93 (m, 5H), 8.17 (s, 1H). Benzylideneisobutylamine; 0.56 g (3.5 mmol, 70%), 50—60 °C/4 mmHg, ^{1}H NMR ($CDCl_3$) δ=0.99 (d, $2CH_2$ J=6.8 Hz), 1.78—2.30 (m, 1H), 3.43 (d, CH_2, J=6.8 Hz), 7.20—7.72 (m, 5H), 8.06 (s, 1H).

Reaction of 2a with Sulfur in the Presence of Diene. To a solution of **2a** (1.68 g, 5.0 mmol) and 2, 3-dimethyl-1,3-butadiene (2 ml, 20 mmol) in toluene (40 ml) was added elemental sulfur (0.64 g, 20 mmol). After refluxing for 20 h, the resulting mixture was evaporated to give reddish-brown oily crystals. This mixture was extracted with methanol(30 ml×2). The combined extracts were evaporated to give a reddish-brown oil, which was chromatographed over silica gel by elution with hexane–dichloromethane (3:1) to give adduct **9** (0.52 g, 2.8 mmol, 56%).[2,16] Adduct **10** was prepared in a similar manner.

10;[2] 0.54 g (3.2 mmol, 64%), ^{1}H NMR ($CDCl_3$) (*Endo*) δ=1.66 (br s, CH_2), 3.56 (s, Me), 3.75 (br s, CH), 4.18 (br CH), 4.44 (d, CH, J=3.0 and 5.1 Hz); (*Exo*) δ=1.84 (br s, CH_2), 3.29 (s, CH), 3.54 (br, CH), 3.86 (s, Me), 4.07 (br, CH), 5.91 (dd, =CH, J=3.2 and 6.2 Hz), 6.36 (dd, =CH, J=3.2 and 4.8 Hz).

Reaction of 2a with Sulfur in the Presence of Primary Amines, To a solution of **2a** (1.67 g, 5 mmol) and isobutylamine (1.82 g, 25 mmol) in benzene (50 mL) was added a solution of sulfur (0.32 g, 10 mmol) in benzene. After refluxing for 5 h, the reaction mixture was washed with water and evaporated to give yellow oily crystals. This mixture was extracted with hexane (30 ml×3). The combined extracts were evaporated to give a yellow oil, which was distilled under reduced pressure (bulb-to-bulb distillation) to give a colorless oil of **8**.

8; 0.66 g (3.1 mmol, 61%), mp 90—100 °C/2.5 mmHg. ^{1}H NMR ($CDCl_3$) δ=0.94 (d, 2 CH_3, J=3.2 Hz), 1.01 (d, 2 CH_3 J=3.4 Hz), 1.65—2.33 (m, 2 H), 3.16 (t, CH_2, J=6.6 Hz), 3.44—3.60 (m, CH_2), 8.59 (br, NH), 10.00 (br, NH). ^{13}C NMR ($CDCl_3$) δ=20.02 (CH_3), 20.28 (CH_3), 27.39 (CH), 28.43 (CH), 48.02 (CH_2), 53.39 (CH_2), 158.71 (C=O), 186.53 (C=S). Precise mass for $C_{11}H_2N_2ON_2OS$: 216.1296 (calcd) , 216.1273 (found).

Reaction of 2d with Sulfur in the Presence of Secondary Amines (Preparation of Enamines). To a solution of phenethyltriphenylphosphonium bromide (2.24 g, 5 mmol) in the benzene was added a solution of butyllithium (4.5 ml, 10% w/v, 7 mmol) in hexane at room temperature. After stirring for 1 h, morpholine (2.18 g, 25 mmol) and sulfur (0.32 g, 10 mmol) were added and stirred for 2 h. The resulting mixture was washed with water and evaporated to give brown oily crystals. This mixture was extracted with hexane (15 mL×3). The combined extracts were evaporated to give a yellow oil, which was distilled under reduced pressure (bulb-to-bulb distillation) to give a colorless oil of **11a**.

11a; 0.095 g (0.5 mmol, 10%), mp 100—110 °C/1.0 mmHg. ^{1}H NMR ($CDCl_3$) δ=2.98 (t, 4H, J=4.63 and 5.13 Hz), 3.73 (t, 4H,J= 4.88 Hz), 5.41 (d, =CH, J=14.16 Hz), 6.59,

(d, =CH, J=14.16 Hz), 7.18 (m, 5H). ^{13}C NMR ($CDCl_3$) δ= 49.03 (CH_2), 66.36 (CH_2), 101.47 (=CH), 124.28, 124.38, 128.50, 138.74 (Ar), 139.66 (=CH). Precise mass for $C_{12}H_{15}NO$: 189.1154 (calcd), 189.1167 (found).

11b; 0.11 g (0.065 mmol, 13%), mp 140—150 °C/1.5 mmHg.[17] ^{1}H NMR ($CDCl_3$ δ=1.90 (m, 4H), 3.21 (m, 4H), 5.08 (d, =CH, J=13.92 Hz), 6.96—7.18 (m, Ar and =CH). ^{13}C NMR ($CDCl_3$) δ=25.25 (CH_2), 48.97 (CH_2, 97.62 (=CH), 122.92, 123.36, 128.50, 140.20 (Ar), 135.82 (=CH).

11c; 0.08 g (0.05 mmol, 10%), mp 90—100 °C/1.0 mmHg. ^{1}H NMR ($CDCl_3$ δ=2.77 (S, 2 CH_3), 5.17 (d, =CH), 6.76 (d, =CH), 7.20 (m, 5 H).

Reaction of 2e with Sulfur in the Presence of Amines. To a suspension of (2-ethoxycarbonylethyl)triphenylphosphonium bromide (2.22 g, 5 mmol) in benzene was added a solution of butyllithium (4.5 ml, 10% w/v, 7.0 mmol) in hexane at room temperature. After stirring for 1 h, morpholine (4.35 g, 50 mmol) and sulfur (0.32 g, 10 mmol) were added and the solution was refluxed for 2 h. The resulting mixture was washed with water and evaporated to give yellow oily crystals. This mixture was extracted with hexane(30 ml×3). The combined extracts were evaporated to give a yellow oil, which was distilled under reduced pressure (bulb-to-bulb distillation) to give a colorless oil of **12a**. Other reactions were carried out in a similar manner.

12a; 0.56 g (3.0 mmol, 60%), mp 80—90 °C/2.0 mmHg. ^{1}H NMR ($CDCl_3$) δ= 1.27 (t, CH_3), 2.32—2.72 (m, 8H), 3.57 (m, 4H), 4.14 (q, 2H). ^{13}C NMR ($CDCl_3$) δ=14.30 (CH_3), 32.29 (CH_2), 53,52 (CH_2), 54.07 (CH_2), 60.35 (CH_2), 66.96 (CH_2).

12b; 0.44 g (3.0 mmol, 60%), 100—110 °C/3.0 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.26 (t, CH_2, J=7.08 Hz), 2.25 (s, 2CH_3), 2.55 (m, 4H), 4.15 (q, 2H, J=7.33 and 7.08 Hz). ^{13}H NMR ($CDCl_3$) δ=14.25 (CH_2), 33.05 (CH_2), 45.24 (2CH_3), 54.93 (CH_2), 60.35 (CH_2), 172.49 (C=O).

Ethyl 3-Butylaminopropionate (12c); 0. 50 g (2.9 mmol, 57%), mp 90—100 °C/2.5 mmHg. ^{1}H NMR ($CDCl_3$) δ= 0.69—1.58 (m, 7H), 1.25 (t, CH_3), 2.25—1.96 (m, 6H), 4.06 (q, 2H). Precise mass for $C_9H_{19}NO_2$; 173.1415 (cald), 173.1396 (found).

This work was partly supported by the Central Research Institute of Fukuoka University and a Grant-in-Aid for Scientific Research No. 02640415 from the Ministry of Education, Science and Culture. We are grateful to Dr. Haruo Matsuyama at Tokyo Metropolitan University for the high-resolution mass spectroscopic analysis.

The Reaction of (Arylthio)trimethylstannanes with 1-Aryl-1-bromoethanes: Effect of Substituent on the Process Shifting from Unimolecular to Bimolecular Substitution

Seizi KOZUKA* and Hisashi NAKAMURA
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3-Chome, Sumiyoshi, Osaka 558
(Received May 8, 1991)

A kinetic study has been conducted on the reaction of (arylthio)trimethylstannanes with 1-aryl-1-bromoethanes. The reaction of the arylbromoethane bearing an electron-donating substituent was found involving unimolecular ionization of the arylbromoethane. The other reactions, however, were found to be second-order reactions. The nature of the second-order reactions was shifted from one involving unimolecular ionization as the minor process, to a clear bimolecular nucleophilic reaction, according to the electron-withdrawing nature of the substituents on the arylbromoethanes.

The mechanisms of the reactions of (arylthio)trimethylgermanes have been known to be dependent on the nature of the substrates regardless of their quite similar aspects in the products. Namely, the reaction with benzoyl chloride was found to proceed by five-coordination of the germanium atom (Eq. 1).[1] The reaction with benzyl bromides, on the other hand, involved nucleophilic attack of the sulfur atom on the benzyl moiety (Eq. 2).[2]

$$(CH_3)_3GeSC_6H_4X + YC_6H_4COCl \xrightarrow{\text{5-Co. of Ge}} (CH_3)_3GeCl + YC_6H_4CO\text{–}SC_6H_4X \quad (1)$$

$$(CH_3)_3GeSC_6H_4X + YC_6H_4CH_2Br \xrightarrow{\text{Nu. attack of S}} (CH_3)_3GeBr + YC_6H_4CO\text{–}SC_6H_4X \quad (2)$$

The difference of those two reactions in their mechanisms has been rationalized in terms of different steric requirements of the individual substrates. The benzyl moiety provides enough room to be attacked by the sulfur atom of the bulky thiogermane. On the other hand, a similar attack of the sulfur of the thiogermane on the carbon atom of benzoyl functional group would be difficult by steric hindrance. Formation of the tetrahedral addition intermediate bearing four heavy atoms, including the sulfur with bulky trimethylgermyl group, would be difficult since they require much space around the central carbon atom. Hence, the reaction proceeds by five-coordination process when forced to proceed.

In this connection, it is quite natural that the analogous thiostannane could attack not only on benzyl[3] but also on benzoyl[4] substrates (Eq. 3). The bulky trimethylstannyl group does not inhibit the nucleophilic attack of the sulfur atom because the stannyl–sulfur bond is long enough providing a room around the reaction center of the sulfur atom.[2]

$$(CH_3)_3SnSC_6H_5X + YC_6H_4COCl \text{ (or } YC_6H_4CH_2Br) \xrightarrow{\text{Nu. attack of S}} (CH_3)_3GeCl \text{ (or Br)} + YC_6H_4CO\text{–}SC_6H_4X \text{ (or } YC_6H_4CH_2\text{–}SC_6H_4X) \quad (3)$$

On the other hand, the sulfur atom in the shorter silyl-sulfur linkage could not act as a nucleophile. The bulky trimethylsilyl group nearby the nucleophile of the sulfur, disturbs the reactivity by steric hindrance. Thus, the reaction of (arylthio)trimethylsilane with a haloalkane, phenacyl bromide, was found to proceed by another process i.e., five-coordination of the silicon atom (Eq. 4)[5]

$$(CH_3)_3SiSC_6H_4X + RBr \xrightarrow{\text{5-Co. of Si}} (CH_3)_3SiBr + RSC_6H_4X \quad (4)$$
(R=PhCOCH$_2$)

Standing on these results, an increment of steric hindrance on benzyl moiety would disturb the bimolecular nucleophilic attack. The reaction of (arylthio)trimethylgermanes with 1-aryl-1-bromoethanes (1-arylethyl bromides) was examined expecting mechanism shift from bimolecular nucleophilic to five-coordination process.

Unexpected unimolecular ionization of 1-aryl-1-bromoethanes was found as the mechanism. The result was also unexpected in view of the reaction conditions used, since the reaction was carried out under typical second order reaction conditions, with nearly equal amount of diluted nucleophile. The solvent was also unusual for the process because the reactions were carried out in aprotic solvents. The unexpected mechanism was undoubtedly due to the nature of the starting arylbromoalkane. The arylbromoalkane was a secondary alkyl bromide bearing an α-phenyl group which gives much stabilized carbenium ion on ionization (Eq. 5).[6]

$$(CH_3)_3GeSC_6H_4X + YC_6H_4CH(CH_3)Br \rightarrow [YC_6H_4C^+HCH_3\ Br^-] \rightarrow (CH_3)_3GeBr + YC_6H_4CH(CH_3)\text{–}SC_6H_4X \quad (5)$$

We have now extended our study to the reaction of (arylthio)trimethylstannane with 1-aryl-1-bromoethanes. The longer stannyl–sulfur bond may provide enough space for a bimolecular nucleophilic attack of the sulfur atom on the particular haloalkane, regardless of its facile unimolecular ionization. Preliminary aspects of

the reaction have been communicated recently.[7]

Results and Discussion

Trimethyl(phenylthio)stannane (1 g) was heated with an equimolar amount of 1-bromo-1-phenylethane at 110 °C for 24 h in a sealed tube. Only phenyl 1-phenylethyl sulfide and bromotrimethylstannane were found by ^{1}H NMR analysis of the resulting mixture. The products were isolated by fractional distillation and identified (Eq. 6).

$$(CH_3)_3SnSC_6H_5 + C_6H_5CH(CH_3)Br \xrightarrow{110\,^\circ C,\ 24\ h} (CH_3)_3SnBr + C_6H_5CH(CH_3)\text{–}SC_6H_5 \quad (6)$$

Rate of the reaction was measured by ^{1}H NMR analysis observing ratio of the trimethyl signals of the starting and the product stannanes at time. There were several limitations on the choice of the kinetic conditions. Some of the target trimethyl signals of the stannanes with certain substituents, could be observed separately under any reaction conditions. While, the signals of the other stannanes usually submerged into one signal by ligand-exchange reaction in common solvents. Pseudo-first-order kinetic conditions in less polar solvent of chloroform were chosen for the present study. Under these reaction conditions, the target signals could be observed separately for all the reactions of the stannanes bearing various substituents. Polar solvents and second-order reaction conditions could not be used for the present study.

A good linear pseudo-first-order kinetic plot was obtained up to 60% completion of the reaction in chloroform with 10-fold excess of 1-aryl-1-bromoethanes. A slight upward deviation of the plot was observed above 60% completion of the reaction. The deviation might due to the acceleration of the reaction by the products. In fact, additions of the products into the reaction solutions resulted noticeable acceleration of the rates of the reactions. Accordingly, rate constants for the reactions were obtained less than 60% completion of the reactions where such acceleration was nearly negligible.

Rate dependency on the concentration of 1-bromo-1-phenylethane was observed employing different concentrations of the arylbromoethane (Table 1, Entries 1, 2, and 3). Plot of the results gave a straight line of slope 1.1. Thus, first-order dependency on the concentration of the arylbromoethane was confirmed within experimental error. The result revealed total second-order reaction, dependent on both the concentrations of trimethyl(phenylthio)stannane and 1-bromo-1-phenyl-

a) First-order dependency on [PhEBr](slope 1.1) for the reactions X=Y=H, (Entry 1, 2, and 3). b) $\Delta H^{\neq}_{400}$=84.8 kJ mol^{-1}, $\Delta S^{\neq}_{400}$=−95.2 J K^{-1} mol^{-1}, correlation coefficient (γ)= 0.9999, (2, 4, and 5). c) Effect of X for the reactions Y=H: $\rho_{X(\sigma)}$=−0.31, γ=0.9991, (4, 6 to 9). d) Estimated value (11, 12, and 13). e) No linear plot for the effect of Y, when X=H, (4, 10, and 14 to 16). f) No dependency on [SnS] for the reaction of Y=*p*-CH_3 (13, 17, and 18). g) First-order dependency on [SnS] (slope 1.1) for the reactions: X=H, Y=*p*-NO_2 (16, 19, and 20). h) Effect of X for the reactions Y=*p*-NO_2: $\rho_{X(\sigma)}$=−1.04, γ=0.999, (16, 21 to 24).

ethane.

Rates were measured for the reactions with (substituted arylthio)trimethylstannanes with 1-bromo-1-phenylethane. A small negative ρ_x value due to the effect of the substituent (X) was thus obtained (Table 1, $\rho_{X(\sigma)}=-0.31$, Entries 4, 6 to 9), with a straight Hammett plot. The second-order kinetic behavior together with the negative Hammett plot, would suggest a bimolecular nucleophilic attack of the sulfur atom on 1-bromo-1-phenylethane. The reaction, however, seems to be not fully consisted by the mechanism. The absolute ρ_x value appeared too small. There would be another contributing process, that might be an unimolecular ionization of 1-bromo-1-phenylethane, in view of the small absolute ρ_x value. The contribution of unimolecular process was confirmed by the reaction of the arylbromoethane having electron-withdrawing substituent. The detailed results of the unimolecular reaction will be described below. The results would suggest the contribution of the unimolecular process for the reaction of the unsubstituted 1-bromo-1-phenylethane at least in some extent.

Definitely, no dependency of the rate of the reaction on the concentration of the thiostannane was observed for the reaction of 1-bromo-1-(*p*-tolyl)ethane (Table 1, Y=*p*-CH_3, Entries 13, 17, and 18). The reaction with the arylbromoethane bearing an electron-donating substituent (Y=*p*-CH_3) would involve an unimolecular ionization of the arylbromoethane as the mechanism. The reaction of another arylbromoethane having more powerful electron-donating substituent (*p*-OCH_3) would proceed by the same manner. The arylbromoethane bearing *p*-OCH_3 as the substituent, Y could not be prepared in pure form due to its instability. The substituents, X effect would not be expected for the reactions when the 1-aryl-1-bromoethanes possesses electron-donating substituents.

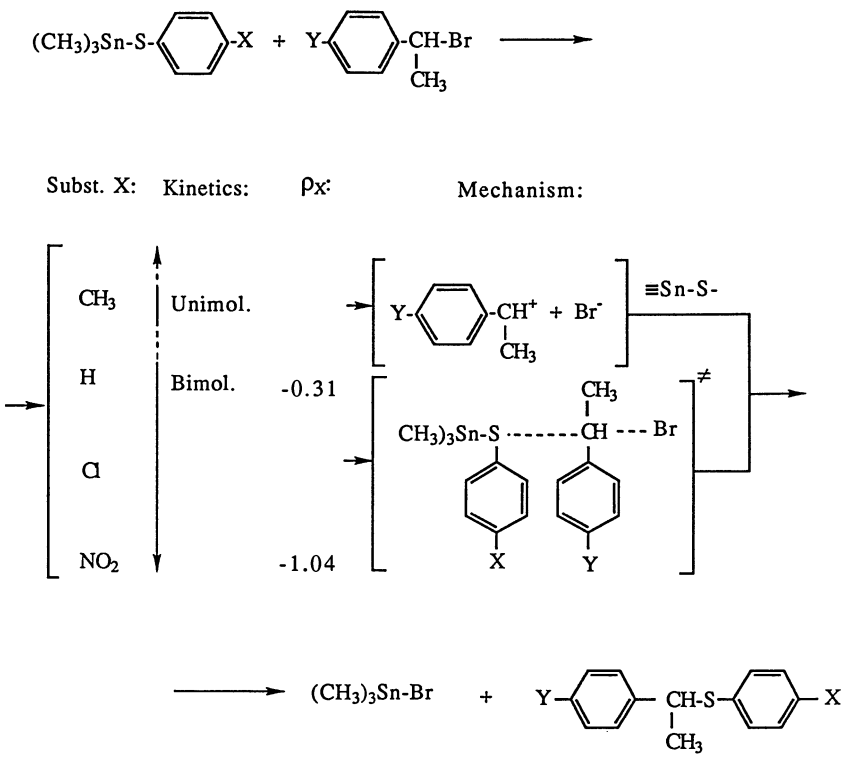
On the contrary, another electronic nature of the 1-aryl-1-bromoethanes, that is the arylbromoethane bearing nitro group on the aryl ring, gave clearly contrasted result in the substituent (X) effect. Appreciable negative ρ_x value was observed for the reactions of the arylbromoethane bearing nitro group as the substituent, Y (Table 1, Y=*p*-NO_2, $\rho_{X(\sigma)}=-1.04$, Entries 16, 21 to 24). Rate dependency on the concentration of the thiostannane was examined for the reaction with the arylbromoethane bearing nitro group. A clear first-order dependency was observed on the concentration of the thiostannane within experimental error (Table 1, Entries 16, 19, and 20, slope=1.1). These results would clearly suggest a bimolecular nucleophilic attack of the sulfur atom as the mechanism for the reaction of 1-bromo-1-(*p*-nitrophenyl)ethane.

The expected mechanism shift from bimolecular nucleophilic to five-coordination, has not been observed. The present study, however, revealed that the nature of the arylbromoethanes effects dramatically on the course of the reaction. The process of the reactions clearly changed from first-order unimolecular ionization to second-order bimolecular nucleophilic attack.

The substituent effect on the benzylic substrates for bimolecular nucleophilic reactions usually gives complicated Hammett plots, although negative tendency appears as a whole.[8] A similar bent plot with a negative tendency was also observed for the analogous reaction of benzyl bromides with (arylthio)trimethylgermanes.[2] A particular electronic effect was discussed by Hudson et.al., explaining the bent plot.[8] On the other hand, slightly bent upwards, but almost linear and clearly large negative Hammett plots have been observed for the unimolecular reactions of benzylic substrates.[9] The upward deviations of Hammett plots for the unimolecular reactions have been rationalized by considering minor contribution of a bimolecular process.[6,9] A bent plot can be drawn in the present study for the effect of the substituent Y. However, the acceleration due to the *p*-methyl group appeared abnormally too much in comparison with that commonly observed for bimolecular reactions of benzylic substrates. Neither σ nor σ^+ constants gave linear correlations (Entries 4, 10, and 14 to 16). The abnormal acceleration due to *p*-methyl group was rationalized, as discussed above, by considering shift of the reaction mechanism.

The shift of the process would undoubtedly be dependent on the nature of the 1-aryl-1-bromoethanes. The easier ionize arylbromoethane, especially bearing electron-donating substituent, exclusively facilitated the unimolecular pathway. The opposite nature of the substituent, on the other hand, brought in exclusive contribution of the bimolecular process, as shown in Scheme 1.

It is interesting to note here, the similarities and differences of the present reactions to those of the analogous thiogermanes with the same substrates.[6] Unimolecular ionization of the arylbromoethanes was found as the mechanism for the reaction of (arylthio)-trimethylgermanes with all the substituted arylbromoethanes. Clear bimolecular nucleophilic substitution was not observed, although minor contribution of the process could not be ruled out for the reaction with the thiogermane.[6] On the contrary, the arylbromoethanes bearing electron-withdrawing substituents (Y=*p*-NO_2) have been found exclusively to accept bimolecular nucleophilic attack of the sulfur atoms of various (arylthio)trimethylstannanes in the present study. Difference in nucleophilicity of the sulfur atoms of the thiogermanes and the thiostannanes may be a factor accounting for the difference in the mechanisms of those two reactions. On the other hand, different bond lengths between germyl–sulfur and stannyl–sulfur bonds would be the important factor controlling the mechanism, in view of the steric control of the mechanisms in analogous reactions, as discussed previously.[2] The longer stannyl–sulfur bond pushes off the bulky trimethylstan-



Scheme 1.

nyl group and provides a room around the sulfur allowing to act it as a nucleophile even toward a secondary carbon atom.

Experimental

Materials. (Arylthio)trimethylstannanes were prepared from bromotrimethylstannane and appropriate arenethiol as described previously.[3] Substituted 1-aryl-1-bromoethanes were prepared by reduction of the corresponding acetophenone followed by bromination.[10] Substituent (Y), yield of the arylbromoethane, and its bp were as follows: *p*-CH_3, 65%, 73 °C/mmHg (1 mmHg=133.322 Pa), *p*-Cl, 70%, 120 °C/28 mmHg, *m*-Cl, 70%, 100 °C/2 mmHg, *p*-NO_2, 76%, 120 °C/2 mmHg. Kinetic solvent, chloroform was dried over magnesium sulfate and simply distilled before use without removal of ethanol of the stabilizer.

Product Analysis. (Phenylthio)trimethylstannane (1.00 g, 3.68 mmol) was heated at 110 °C for 24 h in a sealed tube in the presence of an equimolar amount of 1-bromo-1-phenylethane. ^{1}H NMR Analysis of the resulting mixture showed signals corresponding to bromotrimethylstannane and phenyl 1-phenylethyl sulfide. The products were separated by distillation obtaining bromotrimethylstannane, bp 59 °C/26 mmHg, 50% yield, and the sulfide, bp 120 °C/1 mmHg, 52% yield. The isolated products were characterized by their physical properties and spectra.

Kinetics. The procedure was essentially the same to that reported previously.[3] Concentrations and temperature for the kinetic experiments are recorded in the Table. Addition of 2.3×10^{-2} mol dm^{-3} of either bromotrimethylstannane or phenyl 1-phenylethyl sulfide resulted ca. 5% acceleration of the reaction of trimethyl(phenylthio)stannane with 1-bromo-1-phenylethane.

The Catalysis of Maghemite and Hematite on the Aldol and the Retro-Aldol Condensation of Acetone

Haruo WATANABE* and Jun'etsu SETO
Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240
(Received December 25, 1990)

The catalytic activities of maghemite on the aldol condensation of acetone and on the retro-aldol condensation of diacetone alcohol are found to be higher than those of hematite. Further, the catalytic activity of maghemite on the formation of mesityl oxide is significantly higher than that of hematite. The active sites are considered to be surface hydroxyl groups which behave as a Brønsted base and acid points. Maghemite has more basic surface hydroxyl groups than does hematite, and far more acidic surface hydroxyl groups than does hematite they are sufficiently strong to make its average surface acidity greater than that of hematite. The basic surface hydroxyl groups of maghemite are speculated to be those which bond to the iron ions of the octahedral sites the acidic ones are those of the tetrahedral sites of the spinel lattice of the surface.

Maghemite is a ferrimagnetic inverse-spinel type iron oxide, which is widely used for magnetic recording tapes. Its surface properties have a large influence on its dispersibility in paint and, thus, on the output and noise characteristics of tape. However, there have been relatively few studies on the surface properties of maghemite, compared to these of hematite.

In previous papers,[1-3] the nature of the surface hydroxyl groups of maghemite were examined by identifying either the PZC (Point of Zero Charge) or IEP (Isoelectric Point); the heat of formation of the surface hydroxyl groups was examined through measurements of the heat of immersion, compared with that of hematite. It was clarified that the surface hydroxyl groups of maghemite are more acidic than those of hematite, and that the heat of formation of the surface hydroxyl groups is lower than that for hematite. These differences between maghemite and hematite have been attributed to differences in the bulk crystal structure. However, these properties are related to the averaged parameters of the surface hydroxyl groups; more microscopic differences between maghemite and hematite are expected.

In the present work, the specific acidity and basicity of the surface hydroxyl groups of maghemite compared with those of hematite were studied using the Brønsted acid and base points as well as their effect on the catalysis of the aldol and the retro-aldol condensations of acetone. From the view point of heterogeneous catalysts for aldol or retro-aldol condensations, reports concerning iron oxides[4] have been fewer than those for aluminum oxides[5-8] or alkali earth metal oxides.[9-14]

Experimental

Samples. The maghemite sample used in the present work was prepared from synthetic acicular α-FeOOH (geothite) by sequential dehydration, reduction, and oxidation processes. The hematite sample was prepared by a heat treatment of the above-mentioned maghemite sample in air at 550 °C. In all cases, the samples were purified as follows: first, washing with an alkali solution, then distilled water and, finally, by electrodialysis. The samples were then filtered, dried at 100 °C for 24 h in an oven, and stored in a desiccator. The samples and purification procedure are the same as those reported previously.[1] The specific surface areas of the samples were 19 $m^2 g^{-1}$ for maghemite and 16 $m^2 g^{-1}$ for hematite, measured by using the BET method of nitrogen adsorption at liquid-nitrogen temperature, assuming the cross-sectional area of a nitrogen molecule to be 16.2 $Å^2$. The surface porosity of the samples was checked by a *t*-plot; the existance of surface pores less than 30 Å in diameter was confirmed to be negligible. The surface hydroxyl groups, which could behave as catalytic active sites, had densities of 11.8 groups nm^{-2} for maghemite samples and 12.8 groups nm^{-2} for hematite samples, as determined in a previous study.[2]

Chemicals and Reactions. The acetone used in the present work was of spectral grade, dehydrated with Drierite. Diacetone alcohol (4-hydroxyl-4-methyl-2-pentanone) was obtained from Wako Pure Chem. Ind. Ltd., and purified by vacuum distillation.

One-gram samples were ultrasonically dispersed in 40.0 g of acetone or diacetone alcohol in tightly stoppered 100 ml conical flasks; these were then placed in an incubator with water thermostated to an accuracy of less than ±0.05 °C. The products were analyzed by a gas chromatograph equipped with a 3 m column of PEG-20, and a detector for flame ionization, on the supernatant of the dispersion (sampled after a constant time and filtered by a membrane filter). The reaction times of both reaction systems were 15 h for the condensation of acetone and 10 h for the decomposition of diacetone alcohol.

Results and Discussion

Aldol Condensation of Acetone. The aldol condensation of acetone to form diacetone alcohol (hereafter abbreviated to DAA) is known to be catalyzed by the Brønsted basic point of heterogeneous catalysts.[12] The following dehydration reaction of DAA to form mesityl oxide (4-methyl-3-penten-2-one (hereafter abbreviate MO)) is known to be catalyzed by the Brønsted acid.[15] A series of reactions is as follows:

$$2\,(CH_3)_2CO \underset{\text{base point}}{\rightleftarrows} (CH_3)_2(OH)C\text{–}CH_2CO\text{–}CH_3$$

$$\xrightleftharpoons[\text{acid point}]{-H_2O} (CH_3)_2C{=}CH\text{–}CO\text{–}CH_3$$

In the present work, the catalytic activity of the aldol condensation (the catalytic activity of surface Brønsted base point) was measured on the samples as the conversion of acetone to the total products of DAA plus MO.

In all of these cases, the total conversions in the present reaction systems were less than 1.5%, which is far less than the reaction equilibrium;[16] no products excluding DAA or MO (such as the trimeric condensed product[17-19]) were detected in the present reaction systems. The rate of this reaction, even when it follows second-order kinetics, could be regarded as following zero-order kinetics and can be approximated by the following integrated form of the reaction rate formula:

$$kt = x/a(a-x) \fallingdotseq x/a^2 \ (x \ll a).$$

Here, k is the reaction rate constant, a the initial concentration of the reactant (i.e. acetone), and x the concentration of products (i.e. DAA plus MO after a reaction time of t). Therefore, the conversions x at a constant t are proportional to the rates of reaction k. Figure 1 shows this total conversion per unit surface area of samples after a constant time of 15 h in an Arrhenius plot. These findings show that the catalytic activity of maghemite is slightly higher than that of hematite, and

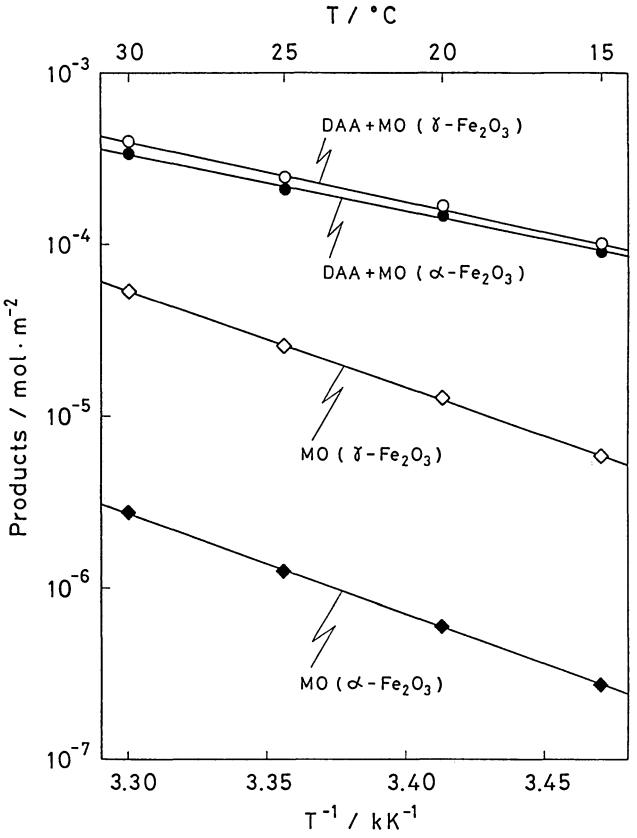

Fig. 1. Temperature dependences of the amounts of the reaction products of acetone after a reaction time of 15 h. Total amount of (DAA+MO) of maghemite (γ-Fe_2O_3): ○; total amount of (DAA+MO) of hematite (α-Fe_2O_3): ●; amount of MO of maghemite (γ-Fe_2O_3): ◇; amount of MO of hematite (α-Fe_2O_3): ◆.

that the activation energies of both samples are of the same value, 70.6±0.5 kJ mol^{-1} for maghemite and 67.3±0.5 kJ mol^{-1} for hematite, respectively. Regarding the similar values for the activation energies of this reactions, it is considered that the rate-determining step does not depend on the activity of the samples. This consideration is well supported by the work of Zhang et al.,[13] which shows that the rate-determining step for C–C bond formation is the coupling of acetone and carbanion.

Conversions to the MO per unit surface area of the samples are also shown in Fig. 1, and have a linear relationship in an Arrhenius-type plot. It is remarkable that the conversions of maghemite to MO are much higher than that of hematite. This is caused by the catalytic activities of the acidic points of the surface (surface hydroxyl groups) and are higher for maghemite compared to hematite.

Regarding the catalytic activity of maghemite, an identical magnitude of activity was confirmed for aldolization and dehydration with a commercially available maghemite sample. The sample has an acicular shape with a length of 0.2—0.4 μm and an acicular ratio of 8—10. The saturation magnetization is 73.0 emu g^{-1} and the specific surface area is 24 m^2 g^{-1}. Purification of this sample was the same as that mentioned in the experimental section.

Retro-Aldol Condensation of Diacetone Alcohol. The retro-aldol condensation of DAA, which forms acetone, is known to be catalyzed by the Brønsted basic points of heterogeneous catalysts.[9,10] The MO is also formed (as mentioned above) in the presence of the Brønsted acid points. In the present work concerning this reaction system the products, except for acetone and MO, were negligibly small. The conversion of the retroaldolisation to acetone was less than 2%, which is also far less than equilibrium;[16] the rate of this reaction was reported to follow either zero-orders[6] or first-order kinetics.[9] The rate of this reaction, even when it follows the first-order kinetics, could be regarded as following zero-order kinetics, and can be approximated by the following integrated form of the reaction rate formula:

$$kt = \ln a/(a-x) \fallingdotseq x/a \ (x \ll a).$$

Then, conversions x at a constant t are proportional to the rates of reaction k. The conversions per unit surface area to acetone after a constant reaction time of 10 h are plotted in an Arrhenius plot in Fig. 2. The catalytic activity of acetone formation for maghemite is higher than that for hematite; this tendency does not change from the viewpoint of activity per hydroxyl group on the surface, considering the surface density of the hydroxyl groups. The activation energies for this reaction are 64.0±0.5 kJ mol^{-1} for maghemite and 66.9±0.5 kJ mol^{-1} for hematite. Both values are compatible with each other, and agree with the values reported in the literature.[9]

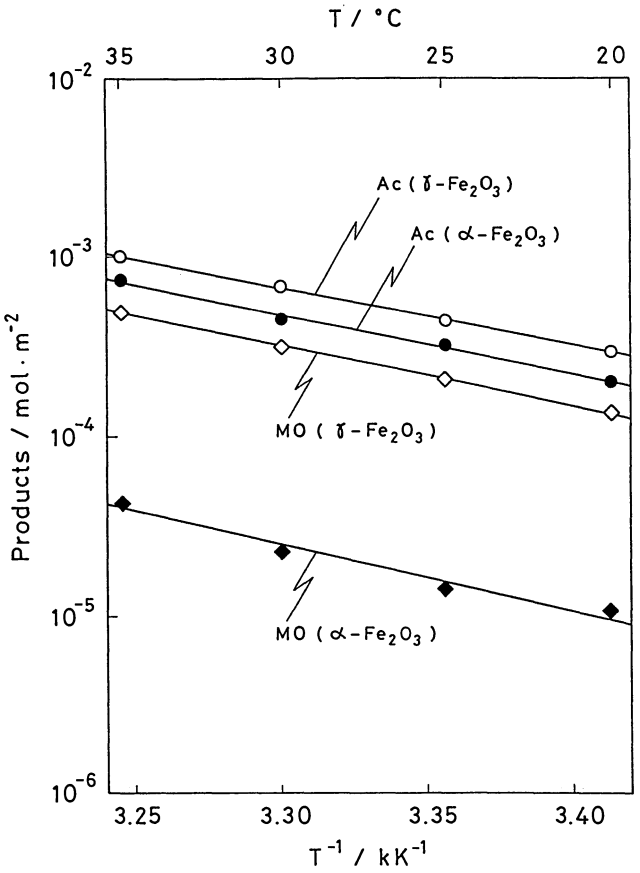

Fig. 2. Temperature dependences of the amounts of the reaction products of DAA after a reaction time of 10 h. Amount of acetone of maghemite (γ-Fe_2O_3): ○; amount of acetone of hematite (α-Fe_2O_3): ●; amount of MO of maghemite (γ-Fe_2O_3): ◇; amount of MO of hematite (α-Fe_2O_3): ◆.

Regarding the dehydration to MO, the conversion was less than 2%, which is far less than equilibrium; the rates of this reaction, reported to follow first-order kinetics,[15] could be approximated as mentioned before to be proportional to the conversions. The conversions per unit surface area of the samples after a constant reaction time of 10 h are plotted in an Arrhenius plot in Fig. 2. The catalytic activity of maghemite for the dehydration of DAA to MO has been found to be much higher than that of hematite. However, the activation energies of this reaction are almost the same (66.5±0.5 kJ mol^{-1} for maghemite and 71.9±0.5 kJ mol^{-1} for hematite), and almost equal to the value reported in the literature.[15]

Acidity and Basicity of the Surface Hydroxyl Groups. The catalysis used in the present work, originated from the acidic or basic nature of the surface hydroxyl groups, and could be explained from the view point of the Brønsted acid and base.

For acidic catalysis (that is, the dehydration reaction of DAA to MO) the catalytic activity of maghemite is higher than that of hematite. The fact that the acidity of maghemite is higher than that of hematite is well supported by the following view points. Concerning the enthalpy of formation of a bulk crystal, of which maghemite is higher than that of hematite,[20] the partial charges of the oxygen atoms of maghemite should be less than those of hematite, causing a higher acidity of maghemite than that of hematite.[21] This is well confirmed by the chemical shift of O(1s) of XPS[3,22] as well as the point of the PZC (Point of Zero Charge), of which the value for maghemite is lower than that for hematite.[1] Regarding for the dissociation and association of the proton of the surface hydroxyl groups, the equilibrium constants were determined in a previous study;[3] the chemical reactions and those values are as follows:

$$FeOH_2^+ \overset{K_{a1}^{int}}{\rightleftarrows} FeOH + H^+, \quad FeOH \overset{K_{a2}^{int}}{\rightleftarrows} FeO^- + H^+.$$

Maghemite: $pK_{a1}^{int} = 2.7$, $pK_{a2}^{int} = 8.3$

Hematite : $pK_{a1}^{int} = 3.2$, $pK_{a2}^{int} = 10.2$

The Brønsted acidity of maghemite is higher by a factor of 2 orders of magnitude than that of hematite, considering the values of pK_{a2}^{int}. According to the above-mentioned points, the results of the present work indicate that the acidic catalytic activity of maghemite is higher than that of hematite, which is reasonable in view of these acidities of the surface hydroxyl groups.

Regarding the basic catalysis (that is, the aldolization or retro-aldolization between acetone and DAA) the catalytic activity of maghemite is higher than that of hematite. This result is in contradiction to the fact that the Brønsted basicity of maghemite is lower than that of hematite, e.g. these values for PZC and the values for pK_{a1}^{int}. Concerning this point, further discussion is necessary, and the average basicity is not available. Especially the surface hydroxyl groups on maghemite are not more uniform than are those of hematite, since the crystal structure of maghemite is an inverse-spinel type which has iron ions in the tetrahedral coordination sites (the coordination number (CN) is 4) and in the octahedral coordination sites (the coordintion number (CN) is 6), whereas the crystal structure of hematite is the corundum type, which only has iron ions at the octahedral coordination sites.

Specific Acidity and Basicity of the Surface Hydroxyl Groups. Regarding the acidity or basicity of the surface hydroxyl groups as as a function of the value of PZC, Parks[23] again showed that the surface hydroxyl groups bonding to the metal ions of the tetrahedral coordination sites show a lower value of 2.4 pH units, compared with those of octahedral coordination sites. For an evaluation of PZC, maghemite can be treated as being a complex oxide comprising iron oxide in the tetrahedral coordination as well as the octahedral coordination. For the PZC of a complex oxide containing n distinct component oxides, Parks[24] also showed that

$$PZC = \sum_{i=1}^{n} f_i \, PZC_i,$$

in which PZC_i is the PZC of the component oxides (i), and f_i is the atomic fraction on the surface. On the other hand, PZC has the following relations with K_{a1}^{int} and K_{a2}^{int}:

$$PZC = 1/2\,(pK_{a1}^{int} + pK_{a2}^{int}).$$

The PZC of a complex oxide can thus be written as

$$PZC = 1/2\left(\sum_{i=1}^{n} f_i\, pK_{a1}^{int}{}_i + \sum_{i=1}^{n} f_i\, pK_{a2}^{int}{}_i\right),$$

where $K_{a1}^{int}{}_i$ and $K_{a2}^{int}{}_i$ are the K_{a1}^{int} and K_{a2}^{int} of the component oxides (i). To examine the specific basicity of the surface hydroxyl groups, the component values of $K_{a1}^{int}{}_i$ as well as those of the fraction of f_i are more important than the average value of K_{a1}^{int}. It is still difficult to evaluate or determine the values of $K_{a1}^{int}{}_i$. The $K_{a1}^{int}{}_i$ are related, as mentioned above, with the PZC_i as follows:

$$PZC_i = 1/2\,(pK_{a1}^{int}{}_i + pK_{a2}^{int}{}_i).$$

The values of PZC_i correspond with those of the $K_{a1}^{int}{}_i$. Yoon et al.[25] have proposed improvements to Parks' semiempirical equation for PZC in the following manner; for a complex oxide, when the correction of the crystal field stabilization energy of the metal ion by the hydroxide ion is not required, as in the case of Fe^{3+} ion with the tetrahedral or octahedral coordination,[26]

$$PZC = \sum_{i=1}^{n} f_i\, PZC_i$$

$$= 18.43 - 53.12 \sum_{i=1}^{n} f_i\,(v/L_s)_i - 0.5 \sum_{i=1}^{n} f_i \log((2-v)/v)_i.$$

Here, v is the bond valence, i.e., the valency of the metal ion per coordination number, and L_s ($=L+r$) is the sum of the mean M–O bond length (L) and the O–H distance (r), taken to be 1.01 Å. According to the above equation, the component values of PZC_i and those of the fraction of f_i are calculated using the parameters of Fe^{3+} ions and the Fe–O bonds, referring to crystallographic data for maghemite[27] and hematite.[28]

These numerical parameters and values are listed in Table 1. The Fe^{3+} ions of maghemite are arranged in a spinel-type crystal lattice, and are divided into 4 classes as Fe^{3+} (1), Fe^{3+} (2), Fe^{3+} (3), and Fe^{3+} (4), respectively. The Fe^{3+} ions of hematite are entirely equivalent to Fe^{3+} (5) in Table 1. These Fe^{3+} ions are arranged in a corundum-type crystal lattice.

The values of the PZC, i.e. the summation of the f_i PZC_i, according to the above equation, are higher than those values determined by measurements carried out in a previous paper,[1] i.e. 5.5 for maghemite and 6.7 for hematite. The semiempirical equations by Parks and Yoon et al., in which the constants are defined using the PZG values of the hydrated samples, show higher values than do those for the unhydrated samples, as used in the present work and the previous paper.[1] The differences between the values of the PZC for maghemite and hematite are 1.2 pH units by measurement and 1.3 pH units by using the above-mentioned calculation, and are almost the same in value. This fact well supports the validity of the application of the above equations to the present work.

The results from the above calculations can be used to understand the catalytic activities of maghemite and hematite, that the PZC_i values of octahedral sites of maghemite are higher than those of hematite. This fact indicates that the values of $pK_{a1}^{int}{}_i$ of the surface hydroxyl groups bonding to the surface iron ions of octahedral sites of maghemite (Fe^{3+} (2), (3), (4)) are higher than those of hematite (Fe^{3+} (5)). In other words, the Brønsted basicity of the surface hydroxyl groups bonding to the iron ions of the octahedral sites of maghemite is higher than that of hematite. This consideration leads to a reasonable explanation that the basic catalytic activity of the aldolization or the retro-aldolization of acetone of maghemite is higher than that of hematite.

It is also worthwhile noting from the above calculations that the value of PZC_i of the tetrahedral sites Fe^{3+} (1) of maghemite is far lower than that of the octahedral sites (Fe^{3+} (2), Fe^{3+} (3), and Fe^{3+} (4)) compared with the

Table 1. Parameters of Fe^{3+} Ions and Fe–O Bonds, and Component Values of PZC_i for Maghemite (γ-Fe_2O_3) and Hematite (α-Fe_2O_3)

	Fe^{3+} ions			Fe–O bonds				PZC_i	PZC $\sum_{i=1}^{n} f_i PZC_i$
		CN[a]	N_m[b]	v	L_s/Å	N_b[c]	f_i		
Maghemite (γ-Fe_2O_3)	Fe^{3+}(1)	4	8	3/4	1.88	32	0.286	4.53	
	Fe^{3+}(2)	6	4	1/2	2.03	24	0.214	9.45	
	Fe^{3+}(3)	6	8	1/2	2.02	48	0.429	9.42	
	Fe^{3+}(4)	6	4/3	1/2	2.13	8	0.071	9.73	
									8.05
Hematite (α-Fe_2O_3)	Fe^{3+}(5)	6	36[d]	1/2	1.99	216	1.000	9.34	
									9.34

a) CN is the coordination number. b) N_m is the number of Fe^{3+} ions per unit cell. c) N_b is the number of Fe–O bonds per unit cell. d) In the hexagonal unit cell.

value given in Parks' review,[23] in which a difference between the values of 2.4 pH units is reported. More than double the value of the difference is derived from a calculation. This also suggests that the value of $pK_{a2}^{int}{}_i$ is far lower than the average value of pK_{a2}^{int} of 8.3 for maghemite. These sites would show strong Brønsted acidity and promote the acidic catalysis of the dehydration reaction to MO.

Conclusion

(1) The catalytic activities of maghemite on the aldol condensation of acetone and the retro-aldol condensation of diacetone alcohol are higher than those of hematite.

(2) The catalytic activity of maghemite for the formation of mesityl oxide is significantly higher than that of hematite.

(3) Maghemite has the more basic surface hydroxyl groups than hematite and far more acidic surface hydroxyl groups than hematite, which are strong enough to make the average surface acidity higher than hematite.

(4) The basic surface hydroxyl groups of maghemite are bonded to the iron ions of the octahedral sites, and the acidic ones are of the tetrahedral sites of the spinel lattice of the surface.

The authors wish to thank Professor Yoshiyuki Nishiyama of the Chemical Research Institute of Non-Aqueous Solutions of Tohoku University, for useful discussions.

Local Structure of Polyethylene Glycol–NaI Solid Polyelectrolyte as Studied by ^{13}C and ^{23}Na NMR

Takahiro UEDA,† Hiroshi OHKI,†† Nobuo NAKAMURA,* and Hideaki CHIHARA†††
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received January 24, 1991)

^{13}C CP/MAS NMR, ^{23}Na powder NMR, and ^{23}Na two dimensional nutation NMR were applied to complexes of NaI with polyethylene glycol (PEG) and tetraethylene glycol (TEG) to study the conformation of the polyethers and local structure around the Na^+. ^{13}C chemical shift data suggest strongly that the polyether chains assume the gauche conformation in the complexes. ^{23}Na NMR spectrum of TEG–NaI complex gave a broad asymmetric line; simulation of the line shape led to e^2Qq/h=590 kHz and η=0.7. No significant temperature dependence of the line shape was observed between 200 K and room temperature. For PEG–NaI complex e^2Qq/h and η were estimated to be about 320 kHz and 0.7, respectively, from the nutation spectrum. On the basis of the above results, new model structures of PEG–NaI complex were presented.

Complexes of polyethylene glycol (PEG) with inorganic salts such as NaI, NaSCN, and KSCN[1,2] exhibit ionic conductivitiy of the order of 10^{-4}—10^{-3} S cm^{-1} and are classified to solid polyelectrolytes. Among them, the complex of PEG with NaI has been extensively studied by conductivity measurements, X-ray diffraction, and various other experimental methods.[3–7] Thus, Fauteux et al.[7] have reported that the ionic conductivity exhibits an Arrhenius behavior, and that the apparent activation energy above 60 °C depends on the salt concentration of the solid electrolyte. As to the structure of PEG–NaI complex, Himba[5] performed an X-ray fiber diffraction experiment and proposed a monoclinic unit cell with cell constants of a=1.701, b=0.8, c=1.688 nm, and β=115.1° in which PEG chains were oriented along the b-axis, but the detailed molecular arrangement was not determined. Also, Chatani and Okamura[6] reported results of their X-ray experiment on the PEG–NaI complex and proposed a model structure that Na^+ and I^- ions alternate with each other to form a zigzag chain around which a helical PEG chain which possesses *tg* conformation forms an envelope.

^{13}C CP/MAS (cross polarization/magic angle sample spinning) NMR is one of the most powerful experimental tools for conformational analysis of polymer molecules in solid state and has been successfully applied to various kinds of polymers.[8–12] In the present work we applied this method to PEG–NaI and its model oligomer complex, tetraethylene glycol (TEG)–NaI, in order to study the conformation of the chain in these complexes. We also measured the ^{23}Na NMR lineshapes[13,14] to deduce some information on the coordination of ethylene oxide units to the sodium ion. This paper describes the results of these experiments and presents possible model structures for PEG and TEG complexes based on the analysis of the experimental data. We also present the results of ^1H and ^{23}Na spin-lattice relaxation time (T_1) measurements and show that, although the sodium ion transport has been believed to govern the high conductivity in PEG–NaI complex, the diffusion rate of Na^+ is very slow in the crystalline state.

Experimental

Polyethylene glycol #4000 (reagent grade: M_w=3000—3700), tetraethylene glycol and NaI (extra pure reagent grade) were purchased from Nakarai Tesque Inc. As PEG and NaI are both sensitive to the atmospheric moisture, they were dried and stored in a desiccator over P_2O_5 and $CaCl_2$. The polymer-salt complex with the molar ratio 4:1 (O:Na) was prepared by the standard method.[3] The stoichiometric mixture of NaI and the ethylene oxide unit of polymer (1:4) was dissolved in dry methanol and stirred for 24 h at room temperature. The solvent was then slowly evaporated at room temperature to dryness and the complex thus deposited as thin-film was stored in a desiccator over P_2O_5 and $CaCl_2$.

The tetraethylene glycol (TEG)–NaI complex was prepared by dissolving the mixture of TEG and NaI with the molar composition of 1:1 in tetrahydrofuran (THF), concentrated to about one-third of its original volume and then being kept at 4 °C; the deposited white polycrystals were collected and recrystallized twice from THF. The complex was dried and stored in a desiccator over P_2O_5 and $CaCl_2$.

For the ^{13}C NMR measurements each specimen was packed into the MAS sample rotor (ZrO_2) under the N_2 atmosphere and dried under vacuum at room temperature for several hours. The specimen for the ^{23}Na and ^1H measurements were sealed into an ampoule with the He heat exchange gas.

^{13}C CP/MAS and ^{23}Na spectra, and ^{23}Na spin-lattice relaxation times, T_1, were measured with the Bruker MSL-200 spectrometer. A home-built pulse NMR spectrometer operating at 17 MHz was used for ^1H relaxation time measurements. The experimental errors in the ^1H and ^{23}Na relaxation measurements were estimated to be within 5% and 10%, respectively. The temperature was controlled within ±1 K with the Bruker VT-1000 unit for the ^{23}Na relaxation measurements. It was measured to within ±0.5 K by Chromel-*p*-Constantan thermocouples for ^1H relaxation measurements.

^{13}C CP/MAS NMR experiments were done at 50 MHz with the sample spinning rate of ca. 3 kHz at room temperature.

^{13}C chemical shifts were determined with the external standard tetramethylsilane.

^{23}Na NMR lineshapes, the spin-lattice relaxation times and 2D nutation spectra[15] for the two complexes were measured at the resonance frequency of 53 MHz. In order to derive the quadrupole coupling constant, e^2Qq/h, and the asymmetry parameter of the electric field gradient tensor, η, we prepared computer program[16] to describe the evolution of the spin system using the Liouville operator formalism[17] and used it to simulate the ^{23}Na nutation spectral data.

Results and Discussion

^{13}C CP/MAS NMR Spectra. Figure 1 shows the ^{13}C CP/MAS NMR spectrum of PEG–NaI complex and the ^{13}C dipolar decouple(DD)/MAS NMR spectrum of PEG at room temperature. The spectrum of PEG sample consists of two sharp peaks due to carbons in the crystalline part and of a broad component which comes from the noncrystalline part.[18] The fact that the intensity of the broad component is rather high indicates that the crystallinity of our PEG specimen is relatively poor.

On the other hand, the spectrum of the PEG–NaI complex gives only a single sharp peak, which shows strongly that the complexation gives rise to almost perfect crystalline material. Moreover, all the carbon atoms in the complex are equivalent and only one kind of conformation can exist with respect to the carbon bonds.

In order to examine the effect of the complexation on the conformation of the $-O-CH_2CH_2-$ chain in more detail we measured the ^{13}C CP/MAS spectrum in the TEG–NaI complex which can be regarded as a model compound for the PEG–NaI complex. The ^{13}C CP/MAS–NMR spectrum of the TEG–NaI complex together with ^{13}C high resolution NMR spectrum of the neat liquid of TEG are shown in Fig. 2.

In the case of liquid TEG the spectrum consists of three peaks with the intensity ratio of 1 : 2 : 1 in the order of decreasing field. These peaks are easily assigned as follows: The terminal carbon bonded to the hydroxyl group gives the peak at the highest field, the one next to the terminal carbon appears at the lowest field and the other four carbons give the central peak.

In contrast to pure TEG, the TEG–NaI complex gave two peaks with the intensity ratio of 1 : 3. The magnitude of the chemical shift at the highest field is the same as that of the terminal carbon in the pure TEG, suggesting strongly that the terminal OH groups of TEG do not participate in the complexation. The strong signal due to inner carbons shows an upfield shift due obviously to the complexation. The fact that the inner carbons give

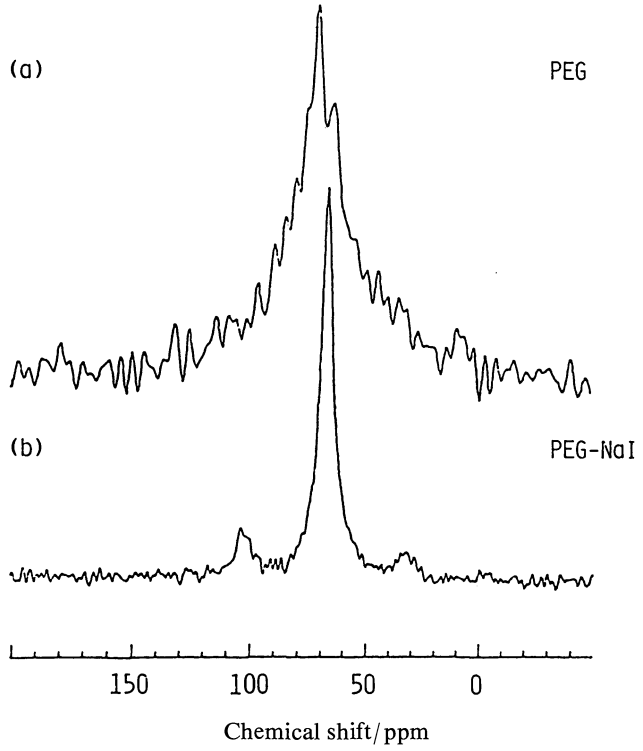

Fig. 1. ^{13}C dipolar decouple (DD)/MAS NMR spectrum of PEG (a) and ^{13}C CP/MAS NMR spectrum of PEG–NaI complex (b) at room temperature. The spinning rates for samples: (a) 3 kHz; (b) 2 kHz. The small peaks in the spectrum (b) are the spinning side bands.

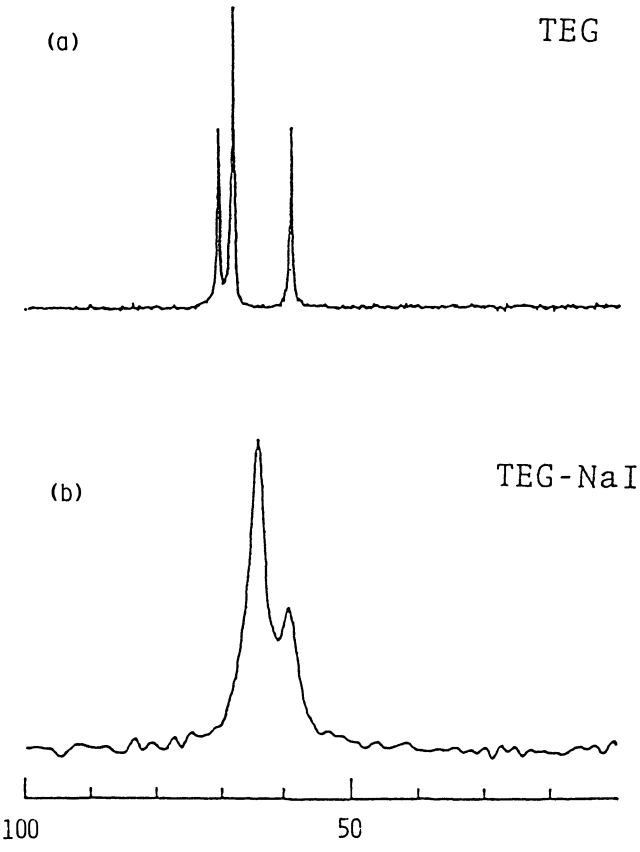

Fig. 2. ^{13}C NMR spectrum of pure TEG (neat liquid) (a) and ^{13}C CP/MAS NMR spectrum of TEG–NaI complex (b) at room temperature. The spinning rate for the TEG–NaI complex is 3.5 kHz.

Table 1. ^{13}C Chemical Shifts of TEG and PEG, and their Complexes with NaI (ppm from TMS)

Sample	I	II	III
PEG (solid)	70.6 64.0	—	—
PEG–NaI	67.2	—	—
PEG (soln)	69.6	72.0	60.6
TEG–NaI	63.7	—	58.8
TEG (liq.)	66.0	70.3	58.8

$$-O-\underset{I}{\underline{CH_2CH_2}}-O-\underset{II}{\underline{CH_2}}-\underset{III}{\underline{CH_2}}-OH$$

altogether only a single peak indicates that all the inner carbon atoms assume the same conformation. The values of the chemical shifts determined in the present ^{13}C CP/MAS-NMR experiments are listed in Table 1. A systematic work on the ^{13}C CP/MAS-NMR spectra of crown ether complexes by Saito et al.[11] showed that the *tg* conformer(–O^g–C^t–C–) gives the ^{13}C signal at about 71 ppm whereas the *gg* conformer(–O^g–C^g–C–) at about 67 ppm. Although the value of the chemical shift, 67.2 ppm, in the present NaI complex does not coincide with these values, it is lower than 69.6 ppm in the pure PEG solution which is the weighted average of the chemical shifts of the *tg* and *gg* conformations. Thus, the peak at 67.2 ppm in the NaI–PEG complex is assigned to the *gg* conformer.

^{23}Na NMR Spectra. The ^{23}Na–NMR spectrum of the TEG–NaI complex is shown in Fig. 3. This spectrum corresponds to the central transition broadened by the second order quadrupolar perturbation. We carried out the simulation for the lineshape by the usual procedure[13,14] and estimated, from comparison with the observed spectrum, the quadrupole coupling constant, e^2Qq/h, and the asymmetry parameter, η, of the electric field gradient tensor, to be 590±10 kHz and 0.7±0.1, respectively. The simulated spectrum with these parameters is given in Fig. 3 by the broken line. Fig. 4(a) shows the projection onto the F_1 axis of the ^{23}Na two dimensional nutation NMR spectrum. The spectrum indicates that all the Na^+ occupy crystallographically equivalent sites. The simulated spectrum with the above values of e^2Qq/h and η is shown by the broken line, reproducing fairly well the experimental result. The large e^2Qq/h and η suggest that the Na^+ is coordinated by the oxygens asymmetrically.

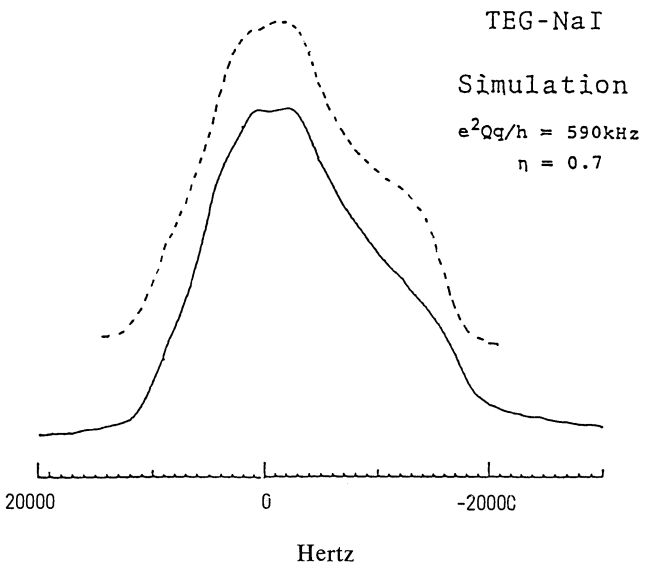

Fig. 3. ^{23}Na NMR spectrum of TEG–NaI complex (solid line) at room temperature and the simulated spectrum (broken line) with e^2Qq/h=590 kHz and η=0.7.

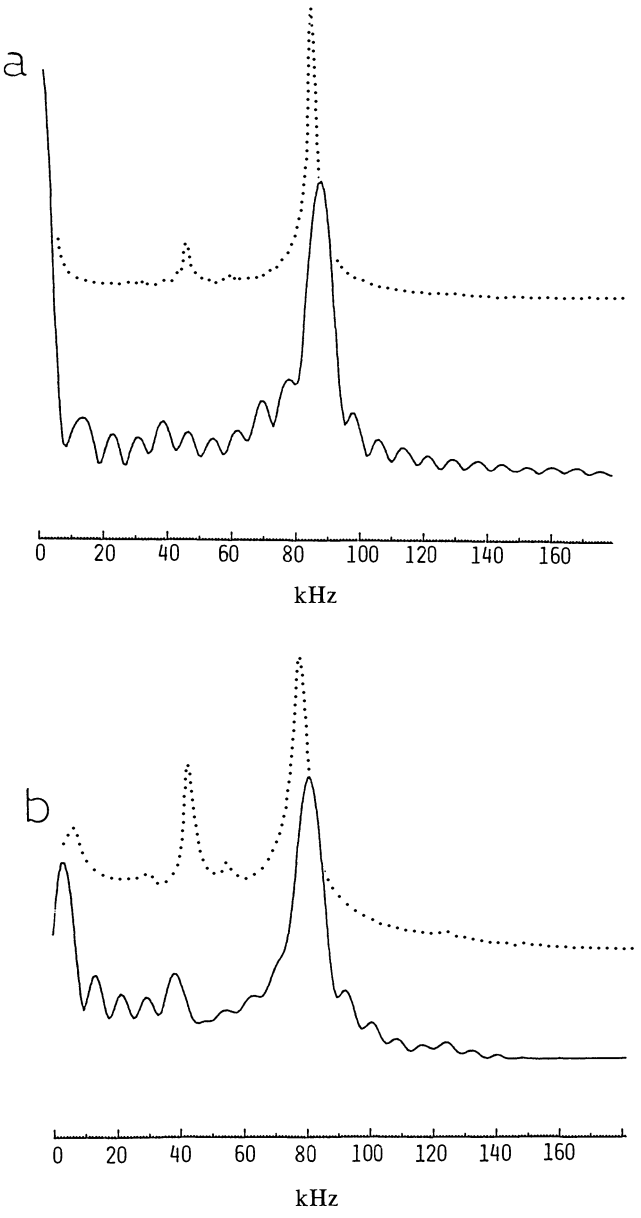

Fig. 4. ^{23}Na 2D nutation NMR spectrum of the TEG–NaI complex (a) and of the PEG–NaI complex (b), and the simulated spectrum (broken line) with e^2Qq/h =590 kHz, η=0.8 and ω_{rf}=39.3 kHz for the TEG–NaI complex and e^2Qq/h=320 kHz, η=0.7 and ω_{rf}=37.5 kHz for the PEG–NaI complex.

In the case of the PEG–NaI complex, the ^{23}Na NMR gives a relatively narrow, symmetric spectrum at room temperature as shown in Fig. 4. A similar spectrum was reported for the PEO–$NaClO_4$ (EO : Na^+=4.5 : 1) by Greenbaum.[19] These results predict a fairly small quadrupole interaction. In order to confirm this point we conducted a 2-dimensional nutation NMR experiment for ^{23}Na in the PEG–NaI complex. The information for quadrupole interaction are involved in the projection of the 2D spectrum onto the F_1 axis as is shown in Fig. 4. From the computer simulation of the nutation spectrum we estimated the quadrupole coupling constant and the asymmetry parameter of ^{23}Na to be about 320±10 kHz and about 0.7±0.1, respectively, for the PEG–NaI complex. As in the TEG–NaI complex all Na^+ occupy crystallographically equivalent sites.

Conductometric studies[20] of PEO–KSCN complex in methanol and experiments[21] on ^{23}Na NMR chemical shift in Na-containing complexes in solutions give some evidence that the cations are probably coordinated tetrahedrally by four ether oxygens. The value of the asymmetry parameter, η, which reflects the site symmetry of the Na^+ ion site, is also similar to the values for the $NaBr \cdot 2(D_2O)$ and $NaCl \cdot 2(D_2O)$ (0.7962 and 0.77, respectively).[23] In these compounds, the Na^+ ions are coordinated by four oxygens of water. Therefore, it is reasonable to consider that each Na^+ in the PEG–NaI complex is also coordinated tetrahedrally in the solid state. But the coordinated tetrahedron is appreciably distorted so as to produce a finite and highly asymmetric electric field gradient at the cation site. Assumption of the distorted tetrahedral coordination under the conditions that the *gg* conformation applies to each carbon–carbon bond and that a unit cell contains two monomer units as shown by a previous X-ray diffraction experiment[5] allows us to build some probable model structures for PEG–NaI complex. Among a few model structures which satisfy the above conditions, two of the most probable models are presented in Fig. 5. In these two model structures each EO segment assumes the *gg* conformation and all ether oxygens coordinate favorably to the cation. The model(a) looks, however, less stable than model(b) because in the former structure the distance between the protons in the $-CH_2-O-CH_2-$ segments is unreasonably short (ca. 1.4 Å) as the van der Waals distance. Therefore we adopt only the model structure(b). The characteristics of our model structure(b) for the PEG–NaI complex is compared with the previous model by Chatani and Okamura (C–O model)[5] as follows:

(1) The molar ratio (EO : Na) is 4 : 1 for our model, whereas the previous one (C–O model) is 3 : 1.

(2) Na^+ ions are arranged so as to make the EO molecule to form a zigzag chain in our model, while Na^+ and I^- ions are arranged alternately to realize a 2/1 helix in the C–O model. Although at present we cannot locate the large anions(I^-), we may presume that the coordination number with respect to the Na^+–I^- coordination is 2.

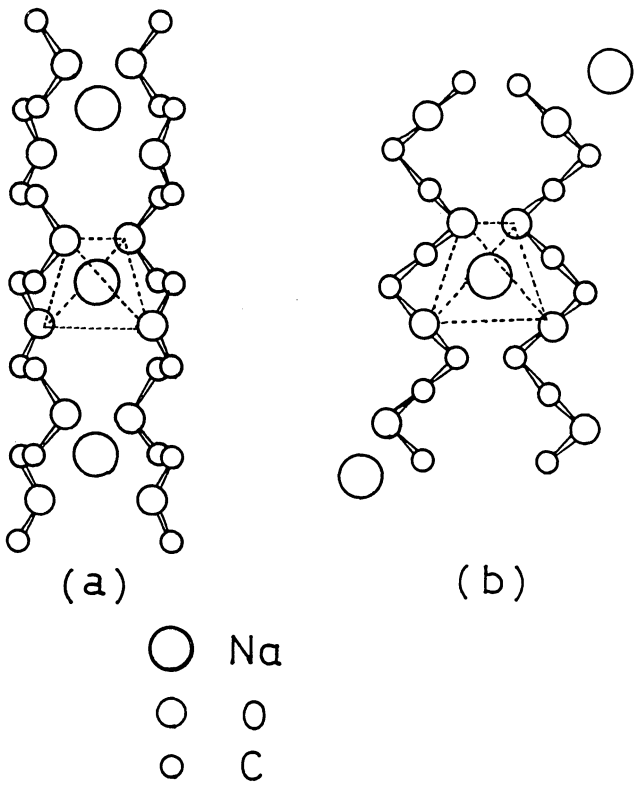

Fig. 5. The model structures of PEG–NaI complex. The conformation of the PEG chain is *gg*. The PEG chain has S-shape in the model (a) and forms helix in the model (b).

(3) The Na^+ and I^- are incorporated into a helical PEG chain that makes a fiber period of 7.98 Å with six EO units in the case of the X-ray experiment, while in our model structure Na^+ are interposed by two helical PEG chains that make the fiber period of 13.8 Å with four EO units. The polymer chain assumes a 4/3 helix and the conformation is *gg* ($-O^g-C^g-C-$) conformer.

(4) Each Na^+ ion is coordinated by four ether oxygens and the Na^+–O distance in our model structure is 2.15 Å. In the C–O model the Na^+ is coordinated by three oxygens and two I^- ions with the Na^+–O distances of 2.28, 2.48, and 2.70 Å which are longer than 2.15 Å in our model.

(5) The *gg* conformation in our model structure can interpret the ^{13}C NMR results but the C–O model which is based on the *tg* conformation predicts the ^{13}C chemical shift of about 71 ppm, conflicting with our experimental results.

A point to be interpreted is why the polymer assumes the *gg* conformation in the complex in spite of reduced stability of this conformation[22] which is obviously less stable than the *tg* or the *tt* conformation observed in other polymers. Energy consideration upon the stability of the whole system will be required.

^{1}H and ^{23}Na Relaxation Times. We measured the ^{1}H

and ^{23}Na spin-lattice relaxation times, T_1, at 17 MHz and 53 MHz, respectively, for PEG–NaI complex for the purpose of examining the possible relation between the ionic motion and the high conductivity in this material. The results are shown in Fig. 6. ^{23}Na relaxation time does not change appreciably below about 200 K; it means that lattice vibrations of only small amplitude govern the relaxation. The monotonous decrease in T_1 above about 200 K indicates that some motion which contributes to the relaxation is excited above 200 K. The slope in Fig. 6 gives the activation energy for that motion 12 kJ mol^{-1}. This value is much smaller than 81 kJ mol^{-1} obtained in the conductivity measurement.[7]

The T_1 for the proton also decreases monotonously on heating, leading to the activation energy of ca. 13 kJ mol^{-1}, which is comparable with that for ^{23}Na. The T_1 for the proton changes discontinuously at the eutectic point (321 K) of the complex.[7] Above this temperature the motion of the polymer chain is rapid compared with the Larmor frequency and its apparent activation energy is 25 kJ mol^{-1}; it is impossible to identify the motion at the present stage. These results show that in the crystalline state of the complex a motion or motions are responsible commonly for the relaxation of both ^{23}Na and ^{1}H and, because the dipolar relaxation of ^{1}H must be governed by some large amplitude motion of the CH_2 segments; this motion of CH_2 groups is ascribed to the result of motion of a polymer chain such as twisting of the ethylene groups. The relaxation of Na^+, on the other hand, is caused by small fluctuation of EFG associated with such chain motion: We could not therefore detect the diffusion nor the hopping of Na^+ by NMR at least up to the eutectic point of complex. The present relaxation measurements suggest that the rate of the Na^+ transport is very low in the crystalline state.

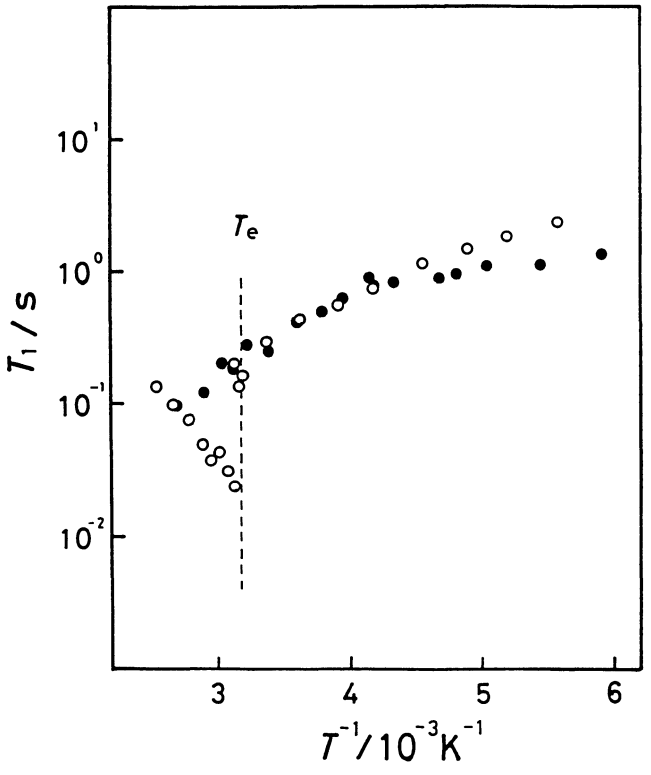

Fig. 6. Temperature dependence of ^{1}H (○) and ^{23}Na (●) spin-lattice relaxation times (T_1) in PEG–NaI complex at 17 MHz and 53 MHz, respectively. The eutectic point (T_e) is 321 K.

Conclusion

The ^{13}C CP/MAS NMR experiments on the PEG–NaI and the TEG–NaI complexes revealed that the bond conformation around each ethylene carbon atom is *gg*. This fact conflicts with model structure for the PEG–NaI complex presented recently on the basis of X-ray fiber diffraction. Quadrupole-perturbed ^{23}Na NMR spectrum together with 2D ^{23}Na nutation NMR showed that the quadrupole coupling constants and the asymmetry parameters are significantly large in both complexes, implying that distorted tetrahedral coordination of oxygens to the cation is realized. Based on the present ^{13}C and ^{23}Na NMR data we proposed a new model for the PEG complex. The results of ^{1}H and ^{23}Na relaxation time measurements indicated that the rate of transport of Na^+ is extremely low at ambient temperature.

Combined Temperature-Programmed Reduction (TPR)-Temperature-Programmed Desorption (TPD) Study of Supported Platinum Catalysts

Kohki EBITANI and Hideshi HATTORI*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 27, 1991)

Successive temperature-programmed desorption (TPD) after temperature-programmed reduction (TPR) (Combined TPR-TPD) was performed in order to characterize supported platinum catalysts (Pt/SiO_2, Pt/Al_2O_3, Pt/ZrO_2 and Pt/TiO_2) as well as to judge the validity of the apparent TPR profiles. In successive H_2-TPD runs obtained after cooling in the absence of hydrogen from 450 °C to room temperature, the hydrogen desorption peak was observed only for the Pt/TiO_2 sample, indicating that the hydrogenic species were kept on Pt/TiO_2 sample, while no hydrogenic species were retained on the other samples after TPR up to 450 °C. For both Pt/Al_2O_3 and Pt/TiO_2 samples, hydrogen spillover seemed to proceed. Hydrogen incorporation during TPR was greater for Pt/TiO_2 than for the others. This hydrogen spillover causes an overestimation of the consumed H_2/Pt value determined by the apparent TPR profile for Pt/TiO_2. For Pt/SiO_2 and Pt/ZrO_2 samples, the apparent TPR profiles were mostly due to a reduction of the supported Pt oxides. For the Pt/TiO_2 sample, the hydrogen incorporation/emission at different temperatures during TPR was investigated. To generate SMSI states, desorption of the spiltover hydrogen is suggested to play a significant role; the role of hydrogen incorporation/emission in the generation of SMSI states is also discussed.

Since Tsuchiya et al. revealed by a temperature-programmed desorption (TPD) method that four types of hydrogen adsorption occurred on platinum surfaces,[1] TPD has been frequently used to characterize the surface properties of catalysts. Temperature-programmed reduction (TPR) is a method similar to TPD, and has especially been developed to characterize supported metal catalysts.[2–4] In principle, a hydrogen-containing stream perfuses over a catalyst sample while the temperature is being raised linearly. By measuring the concentration of hydrogen in an effluent stream as a function of the temperature, the TPR profile is obtained. The direct, useful information provided by TPR profiles is the reducibility of the supported metal precursors. The preparative method, pretreatment temperature, modifications with the other metal components, and morphology were reflected in the reducibility of the metal oxides.[2,5–8]

The "reducibility" of metal oxides has usually been discussed based on the features and areas of the apparent TPR profiles. However, the apparent TPR profiles (hydrogen consumption profiles) are not completely due to a reduction of the metal cations. As suggested by Huang et al.,[9] a reduced metal is capable of adsorbing hydrogen from the gas phase, and the adsorbed hydrogen on metallic sites can desorb into the carrier gas. Also, the migration of adsorbed hydrogen on metallic sites to the support (hydrogen spillover[10,11]) and/or its reverse process (back-spillover[12]) should be taken into consideration regarding an analysis of the apparent TPR profiles. From this point of view, Huang et al. carried out successive TPR experiments while trying to remove any contribution of chemical processes other than reduction to the apparent TPR profiles for monometallic Pt/Al_2O_3, Ir/Al_2O_3, and bimetallic $Pt/Ir/Al_2O_3$. However, only repetitions of TPR runs cannot be used to distinguish hydrogenic species retained on a surface at the end of the 1st run from those formed by a low-temperature adsorption of hydrogen. We wish to report here on the combined TPR-TPD results concerning supported platinum catalysts (Pt/SiO_2, Pt/ZrO_2, Pt/Al_2O_3 Pt/TiO_2) in order to judge the validity of the apparent TPR profiles of these catalysts. Furthermore, we examined the combined TPR-TPD for Pt/TiO_2 by changing the upper temperature of the TPR measurement in order to elucidate the role of H_2 consumption/emission in the generation of the Strong Metal Support Interaction (SMSI) state, which is well known as the temperature-dependent process.[13,14]

Experimental

Catalyst Preparation and Apparatus. The supported Pt catalysts were prepared by impregnation with a H_2PtCl_6 aqueous solution. We prepared 2 wt% Pt/SiO_2 and 0.6 wt% Pt/Al_2O_3 catalysts with Fuji Davison-Type ID SiO_2 and JRC-ALO-4 (Reference catalyst of Catalysis Society of Japan), respectively. The 0.5 wt% Pt/ZrO_2 and 0.6 wt% Pt/TiO_2 catalysts were prepared with $Zr(OH)_4$ and $Ti(OH)_4$, respectively. $Zr(OH)_4$ and $Ti(OH)_4$ were obtained by the hydrolysis of $ZrOCl_2 \cdot 8H_2O$ and $TiCl_4$, respectively, with 25% aqueous ammonia followed by filtration. The obtained hydroxide gel was washed with distilled water until no Cl^- ions could be detected. These catalysts were dried at 110 °C and calcined at 400 °C. Prior to TPR experiment, each sample was calcined at 300 °C for 2 h, and then heated in Ar flow in situ at 300 °C for 2 h.

The TPR apparatus used in this study is shown in Fig. 1. A mixture of 3% H_2 in Ar was used as a reductive gas. This mixture was purified over reduced copper in order to remove any trace oxygen, followed by passing it through 13X molecular sieves to remove water. The change in the concentration of H_2 as a function of the temperature was monitored by a thermal conductivity detector (TCD), yielding the TPR pro-

The heating rates are indicated.
At the end of D), 23 Torr H_2 was introduced over the sample for 1 min.

file. Since water is formed during the reduction process, gas coming from the reactor was dried over 5A molecular sieves before entering the TCD.

The TPD experiment was carried out succesively after the TPR experiment in the same apparatus. As a carrier gas, pure Ar was used. The Ar gas was purified by the same procedures described in the TPR section. The heating rates for TPR and TPD were 10, and 15 $K\,min^{-1}$, respectively. The amounts of consumed hydrogen were calibrated to the amount for reducing of CuO.

Combined TPR-TPD. Although the methodology used in this work was essentially the same as that reported by Huang et al.,[9] we used pure Ar as a carrier gas for the TPD measurement instead of a H_2/Ar mixture in order to avoid any H_2 adsorption during the TPD experiment.

The procedures in this work are illustrated together with a thermoprofile in Fig. 2, and are as follows:

(1) The apparent TPR profile is obtained up to T (T is usually 450 °C).

(2) The sample is cooled to room temperature in a H_2/Ar gas stream.

(3) At room temperature, the H_2/Ar gas mixture switches into pure Ar gas. Then, without H_2 adsorption, the temperature of the sample is raised in an Ar gas stream to 650 °C. The resulting TPD profile is designated the 1st TPD profile.

(4) The sample is cooled to room temperature in an Ar gas stream.

(5) The H_2 gas (3 vol% H_2 in Ar) is then exposed to the sample at ca. 40 °C for 1 min. The temperature of the sample is raised in an Ar gas stream to 650 °C. The resulting TPD profile is designated the 2nd TPD profile.

The difference between the 1st TPD obtained after cooling in the presence of hydrogen and the 2nd TPD reveals the effect of adsorption temperature on the desorption of the hydrogenic species. In some experiments, the sample was cooled to room temperature under a pure Ar stream instead of a H_2/Ar mixed-stream in the procedure (2).

Results and Discussion

Combined TPR-TPD. Figure 3 shows the apparent TPR profiles up to 450 °C of the supported platinum catalysts. Single apparent hydrogen consumption peaks were observed for Pt/ZrO_2, Pt/Al_2O_3, and Pt/TiO_2, appearing at 225, 254, and 145 °C, respectively. These peak temperatures are in good agreement with those reported for Pt/Al_2O_3[5–7] and Pt/TiO_2.[15] On the other hand, two apparent consumption peaks at 130 and 240 °C were observed for the Pt/SiO_2 sample. The appearance of two consumption peaks was reported by Augustine and Sachtler for Pt/Al_2O_3,[16] who suggested that they are due to two-dimensional PtO_2 and three-

dimensional platinum oxide. The apparent consumption peak temperatures are tabulated in Table 1 together with the ratio of the consumed hydrogen during the TPR experiment to the total platinum content in the sample (consumed H_2/Pt). It is clearly shown in Table 1 that the consumed H_2/Pt value for Pt/TiO_2 is larger than those for other samples.

The 1st TPD profiles obtained after cooling in the presence of hydrogen are shown in Fig. 4. These TPD profiles were measured by increasing the sensitivity of the detector. In the 1st TPD, hydrogen desorption was not observable for Pt/ZrO_2. For Pt/Al_2O_3, the desorption peaks were broad and appeared over a wide temperature range (70—600 °C). For Pt/SiO_2, the desorption peak was more clear than that for Pt/Al_2O_3, and appeared at 125 °C. In the case of Pt/TiO_2, at least three desorption peaks appeared at 215, 280, 635 °C. The amount of desorbed hydrogen from Pt/TiO_2 was larger than that for other samples. This means that a large amount of the hydrogenic species was kept over the Pt/TiO_2 sample after cooling down in the presence of hydrogen.

When a sample was cooled in the absence of hydrogen after the 1st TPD, a hydrogen desorption peak was observed only for the Pt/TiO_2 sample. However, the area of the observed TPD profile for Pt/TiO_2 was smaller than that obtained after cooling in the presence of hydrogen (Fig. 5). No desorption of hydrogen was found for Pt/Al_2O_3 or Pt/SiO_2, indicating that the

Table 1. Results for the Apparent TPR Profiles of Supported Platinums

Sample	Peak temp/°C	H_2/Pt[a)]
Pt/ZrO_2	225	1.9
Pt/SiO_2	130 340	0.5
Pt/Al_2O_3	254	1.0
Pt/TiO_2	145	3.4

a) The ratio of the consumed hydrogen determined by the apparent TPR profile up to 450 °C to the platinum.

origin of the desorbed hydrogen in 1st TPD shown in Fig. 4 occurs during cooling to low temperature in the presence of hydrogen; the surfaces of Pt/Al_2O_3 and Pt/SiO_2 were free from any adsorbed hydrogenic species at the end of the TPR measurement up to 450 °C. On the other hand, for Pt/TiO_2, the existence of desorptions in the 1st TPD obtained after cooling in the absence of hydrogen confirmed that hydrogenic species are formed over Pt/TiO_2 during the TPR measurement; these species remained at the end of TPR measurement up to 450 °C.

Judging from the appearence of a peak in the 1st TPD obtained after cooling in the absence of hydrogen and a consumed H_2/Pt value greater than 1 (Table 1), the apparent TPR profile of Pt/TiO_2 shown in Fig. 3 must be due to both a reduction of the supported platinum oxides and hydrogen incorporation over Pt/TiO_2.

Figure 6 shows the 2nd TPD profiles which were measured after hydrogen adsorption (23 Torr, 1 Torr=133.322 Pa) at ca. 40 °C for 1 min. Single desorption peaks were observed for Pt/ZrO_2, Pt/Al_2O_3, and Pt/SiO_2 at 100, 90, and 140 °C, respectively. These desorption temperatures are close to those for the hydrogen species adsorbed at platinum metallic sites.[17] For the Pt/TiO_2 sample, two desorption peaks were observed at 80 and 290 °C. No desorption peak was observed around 600 °C, which is the most prominent difference. The 2nd TPD profiles of Pt/TiO_2 and Pt/Al_2O_3 are different from the 1st TPD profiles obtained after cooling in the presence of hydrogen (Fig. 4-a,c). It should be noted that these desorption temperatures are lower than those at which hydrogen consumption occurs during the apparent TPR measurements shown in Fig. 3.

The difference between the 1st TPD obtained after cooling in the presence of hydrogen and the 2nd TPD is considered to show the effect of the H_2 adsorption temperature on the binding state of the adsorbed hydrogenic species. In other words, the hydrogenic species formed during cooling in the presence of hydrogen can be detected in the 1st TPD profile. It is well-known that the hydrogen adsorption temperature affects the hydrogen adsorption states;[9,11,18–23] high-temperature hydrogen adsorption causes a hydrogen spillover for both Pt/TiO_2[18–23] and Pt/Al_2O_3.[9,11] It is thus postulated that the difference between the 2nd and 1st TPD obtained after cooling in the presence of hydrogen is due to spiltover hydrogens. The concentration of these species for Pt/TiO_2 (Fig. 4-c) is much greater than that for Pt/Al_2O_3 (Fig. 4-a).

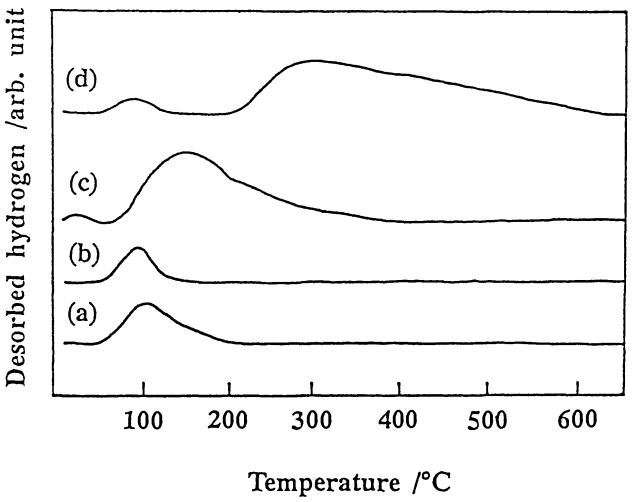

Fig. 6. The 2nd TPD profiles of the supported platinum.
(a) Pt/ZrO_2, (b) Pt/Al_2O_3, (c) Pt/SiO_2, (d) Pt/TiO_2.

The above-mentioned results clearly show that Pt/TiO_2 posesses the hydrogenic species, even at 450 °C, in the TPR measurement and that these hydrogenic species were formed by exposure to hydrogen at high temperatures via a hydrogen spillover process. The formation of these hydrogenic species on Pt/TiO_2 created by exposure to hydrogen at high temperatures causes an overestimation of the consumed H_2/Pt value if determined by the apparent TPR profile. The apparent hydrogen consumption (TPR) profile of Pt/TiO_2 contains the hydrogen adsorption (spillover) process in addition to a reduction of the supported platinum oxides. Chang et al.[24] also reported that the hydrogen consumption peak below 300 °C in the TPR profile for Pd/TiO_2 is due to hydrogen spillover to the TiO_2 support.

For Pt/SiO_2, Pt/ZrO_2, and Pt/Al_2O_3, the apparent TPR profile is mostly due to a reduction of the supported platinum oxides, since the desorption rate is faster (Fig. 6) than the adsorption rate at the temperatures at which hydrogen consumption occurs in TPR measurements (Table 1). The low consumed H_2/Pt value observed for Pt/SiO_2 might indicate the presence of unreduced platinum oxides after a TPR measurement up to 450 °C. An alternative explanation might be that Pt/SiO_2 was not completely oxidized by calcination at 400 °C.

Interaction of Hydrogen with Pt/TiO_2. It is well-known that a high-temperature reduction causes the Strong Metal-Support Interaction (SMSI) state of the supported platinum for Pt/TiO_2.[13,14] The occurrence of SMSI is believed to contain the hydrogen incorporation/emission process, which is temperature dependent.[17–22] We thus examined the effect of the upper temperature of the TPR on the 1st TPD in order to clarify the role of the hydrogen incorporation/emission process in the generation of SMSI states.

The apparent TPR profile of Pt/TiO_2 over a wide range of temperatures is shown in Fig. 7. We chose three temperatures (350, 450, 650 °C) as the upper temperature of the TPR measurement; they are indicated in Fig. 7. The 1st TPD profiles obtained after TPR measurements up to 350, 450, and 650 °C are shown in Fig. 8. These TPD profiles were obtained after cooling in the absence of hydrogen and, thus, reflect only changes in the upper temperatures of the

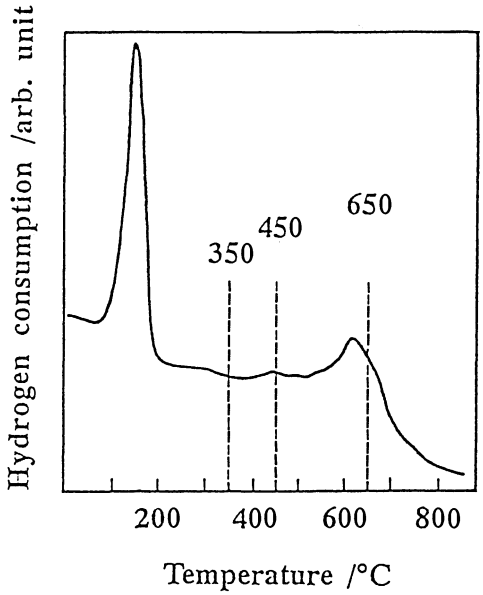

Fig. 7. The apparent TPR profile of Pt/TiO_2 up to 830 °C.

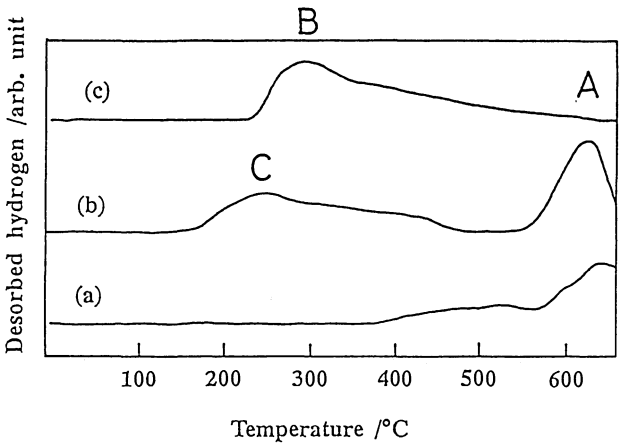

Fig. 8. The 1st TPD profiles of Pt/TiO_2 obtained after the TPR measurement up to (a) 350 °C, (b) 450 °C, (c) 650 °C, and cooling down in the absence of hydrogen.

TPR measurement. In the TPD profile obtained after a TPR measurement up to 350 °C, a single desorption peak above 600 °C was observed. Upon increasing the upper temperature of the TPR measurement to 450 °C, a new desorption peak at around 250 °C appeared in the successive TPD. Following TPR to an upper temperature of 600 °C, the desorption peak became single at 290 °C. At least three hydrogen desorptions were observed. These desorption peaks have been designated as peaks A (above 600 °C), B (around 290 °C), and C (at 250 °C), as indicated in Fig. 8.

The change in the hydrogen exposure temperature changed both the hydrogen adsorption state and the state of Pt/TiO_2. Hongli et al. studied hydrogen TPD from the Pt/TiO_2 related to the SMSI states,[12] and reported that the single desorption peak at 290 °C is a characteristic of the SMSI states. The single desorption peak B at 290 °C, obtained for a sample run up to 650 °C, suggests that a hydrogen treatment up to 650 °C creates SMSI states.

A desorption temparature of 290 °C, obtained for the SMSI state of Pt/TiO_2, is higher than those for the other supported platinum catalysts such as Pt/Al_2O_3 (90 °C), Pt/ZrO_2 (100 °C), and Pt/SiO_2 (140 °C). Raupp and Dumesic studied hydrogen adsorption on titania-deposited Ni polycrystalline, and reported that the adsorption strength of Ni toward hydrogen was enhanced by the presence of titania moieties in the vicinity of Ni metal.[25] The existence of the titania species over metal particles has recently been evidenced by a high-resolution transmittance electron microscopic investigation.[26] It is, therefore, considered that the higher desorption temperature for the SMSI state of Pt/TiO_2 is caused by the presence of titania moieties located in the vicinity of Pt particles.

As seen in Fig. 8, desorption peak A disappeared upon a hydrogen treatment up to 650 °C, indicating that the hydrogenic species producing peak A were desorbed during a TPR measurement between 450 and 650 °C. It is suggested that the desorption of hydrogenic species A plays an important role in the generation of SMSI states.

Hydrogen desorption peak A was observed in the TPD profile after a TPR measurement up to 350 °C. Huizinga and Prins[18] as well as Beck et al.[19] have attributed the hydrogenic species over Pt/TiO_2 formed by hydrogen adsorption below 220—300 °C to represent the spillover state on the TiO_2 support. We therefore consider desorption peak A as being the desorption of spiltover hydrogens on the TiO_2 support. A desorption of these spiltover hydrogens is thought to be necessary to generate SMSI states from this work.

Munuera et al.[22] and Sanz et al.[23] claimed that a further incorporation of hydrogen into the Ti^{3+} cations to form diamagnetic hydride-like species, such as $[Ti-H]^{3+}$, is necessary to generate SMSI states. If their conclusion is correct, hydrogen adsorption would have occurred between 450—650 °C. However, in this work, since hydrogen desorption occurred for the SMSI state, their suggestion is not plausible. A suggestion by Munuera and Sanz[22,23] was made in terms of the ESR result: that the number of Ti^{3+} centers decreases upon reduction at 500 °C, in spite of a continuous incorporation of H_2 into TiO_2 support which occurs under these conditions. The decrease in the Ti^{3+} number during an increase in the reduction temperature seems to be due to both spin pairing and spin–spin relaxation, as interpreted by Bonneviot and Haller.[27]

The role of hydrogen desorption in the generation of the SMSI states has been proposed.[12,18,22] Huizinga and Prins[18] as well as Kunimori et al.[20] have proposed that a dehydration of the support takes place at 500 °C in the neighborhood of the metal particles, thus produc-

ing a reduced form of $TiO_2(Ti_4O_7)$[28] in the vicinity of the Pt particles. They proposed that hydrogen is desorbed in the form of water. On the other hand, Hongli et al.[12] as well as Conesa et al.[21] suggested that any back-spillover of the hydrogen species from the support to the metal (metal-catalyzed hydrogen desorption) plays an important role in producing SMSI behavior. In this case, hydrogen is desorbed in the form of hydrogen molecules.

It was also shown in the present work that the role of the hydrogen desorption at around 450—650 °C in the generation of the SMSI states is significant. Since hydrogen was desorbed in the form of molecular hydrogen within the temperature range 450—650 °C, a desorption of spiltover hydrogens seems to be plausible, even though it is not certain whether dehydration also occurs or not. It is proposed that titania migrates with the adsorbed hydrogen onto platinum particles to create the SMSI state. On platinum particles, hydrogen-containing titanium suboxides release hydrogen atoms which recombine to form molecular hydrogen while leaving the surface.

The acid properties of anatase having different crystalline sizes were estimated by measuring the temperature-programmed desorption (TPD) of ammonia as well as the infrared spectrum of adsorbed pyridine at elevated temperature. The size-controlled anatase was prepared by hydrolysis of the titanium tetraisopropoxide dissolved in propyl alcohol using various amounts of distilled water. The acid properties of the anatase were confirmed to be strongly affected by the crystalline size. Especially, the strength of acid sites was found to remarkably increase with a decrease in the crystalline size. The specific activity and the activation energy for 1-butene isomerization on the anatase also depended on the crystalline size. The generation of strong acid sites on the surface is discussed in terms of the crystalline size.

Acid sites on metal oxides are believed to be ascribed to surface hydroxyl groups or a charge imbalance localized on the surface. Localization of deficient amounts of electrons results from a local imbalance between positive and negative charges of the constituents, and acts as a Lewis acid for catalytic reactions. Since a charge imbalance can be expected by substituting the metal ions with other metal ions possessing different charges, new acid sites could be designed on the surface of doped and/or mixed metal oxides.[1-3] A charge imbalance might emerge, however, even on single-component metal oxides comprising small-sized crystallites, since the electronic properties of tiny metal or metal oxide crystallites have been widely expected to be somewhat different from that of bulk materials.[4] These differences are partially attributed to surface imperfections of crystallographic structures in small-sized crystallites. The typical imperfections in small crystallites are metal or oxygen vacancies, which cause a local charge imbalance.

The idea that new, strong acid sites might be generated on small crystallites has been preliminary demonstrated on TiO_2 by a titration test using several kinds of color indicators.[5] This type titration test, however, sometimes provides us with an ambiguous determination of the acid strength due to a vague change in the color of indicators. The purpose of the present work was to confirm the idea using more reliable methods in measurements of the acid properties, and to understand the generation of strong acid sites in terms of crystalline size.

Experimental

Size-controlled anatase was prepared in the same manner as described elsewhere.[5] In short, 0.025 mol of titanium tetraisopropoxide (Kishida Kagaku Co., 99.9% purity) was dissolved in 50 mL of propyl alcohol, followed by hydrolysis with the desired amounts of distilled water in order to control the size of the resultant TiO_2. The obtained precipitates were dried at 383 K and then calcined at 693 K for 3 h in air. All of the powders, thus produced, were anatase and no trace of rutile was detected by X-ray diffraction measurements, since the phase transformation of anatase to rutile is reported to occur only at temperatures higher than 873 K.[6] The mean sizes of the anatase crystallites were estimated by X-ray line broadening at $2\theta=25.3°$ using the Scherrer equation; 4 kinds of TiO_2 with sizes of around 70, 100, 130, and 170 Å, respectively, were examined. BET surface areas were obtained by N_2 adsorption at 77 K.

The TPD of ammonia on the anatase was carried out using a He purge with a flow rate of 100 mL min^{-1} and a temperature rising rate of 10 K min^{-1}. The sample powder (0.2 g) was first calcined at 693 K in air, and then treated in flowing O_2 at 573 K for 1 h, followed by cooling to room temperature with evacuation. A certain amount of ammonia was iteratively injected into the carrier gas (He), which was introduced over the powder until no more adsorption of ammonia was observed. Pyridine was adsorbed on anatase at 423 K in order to avoid its physical adsorption, followed by evacuation at the desired temperatures. Infrared spectroscopy was employed at room temperature to monitor pyridine still adsorbed on TiO_2, even after evacuation at elevated temperatures.

Isomerization of 1-butene was carried out at temperatures from 413 to 493 K using a closed circulation system made of glass. The sample powder (0.5 g) was first calcined at 693 K in air, and then recalcined at 573 K for 1 h in an O_2 atmosphere, followed by evacuation at room temperature prior to the reaction. The rate constant was estimated, assuming a first-order reaction concerning 1-butene. The initial pressure of 1-butene was always set at 11.8 cmHg (15.72×10^3 Pa) in the present work.

Results

The BET surface areas and the mean crystalline sizes of TiO_2 used in this work are given in Table 1. The highest acid strengths detected by indicators are also given in Table 1. In Fig. 1 are shown the TPD spectra of ammonia on TiO_2 with sizes of about 75, 102, 125, and 162 Å respectively. Three peaks centered around 413, 523, and 663 K are observed in these spectra; the first peak is mainly ascribed to the desorption of ammo-

nia physically adsorbed over TiO_2. Assuming a log-normal distribution for the first peak, the amounts of ammonia chemisorbed were estimated by weighing the other two peaks on the chart. Since ammonia adsorbs on an acid site, the number of acid sites per g and/or m^2 of TiO_2 was calculated (see Fig. 2).

The infrared spectra of pyridine still adsorbed at 423, 523, 623, 673, and 723 K are given in Fig. 3, where the crystalline sizes of TiO_2 used were 82, 125, and 175 Å, respectively. Four absorption peaks were observed at 1610, 1575, 1490, and 1445 cm^{-1} when pyridine was adsorbed on TiO_2 at 423 K. All of the peaks observed

Table 1. BET Surface Areas and the Mean Crystalline Sizes of TiO_2 Studied in This Work.[5] Amounts of Water Employed for the Hydrolysis of $Ti(OC_3H_7)_4$ are Also Given

Sample no.	Water added	Surface area	Crystalline size	Highest Acid strength
	mL	$m^2 g^{-1}$	Å	(H_0)
TiO_2(1)	2000	130	75, 82	−3.0
TiO_2(2)	1000	120	102	−3.0—+1.5
TiO_2(3)	300	105	125	+1.5—+3.3
TiO_2(4)	50	81	162, 175	+3.3—+4.0
TiO_2(5)	Commercial	39	1500—2300	+4.8

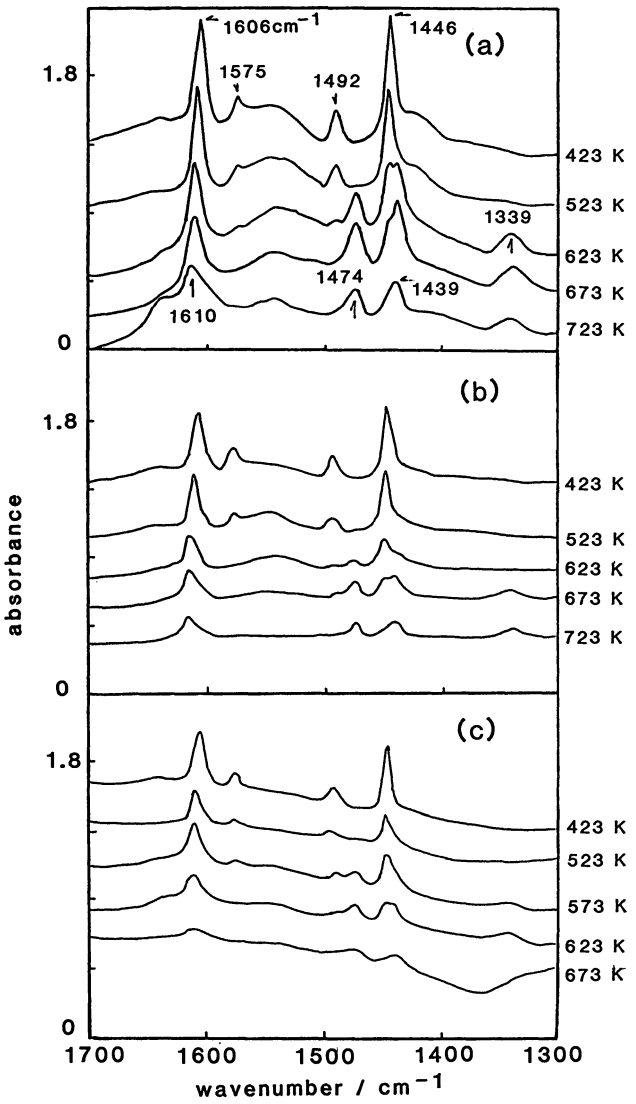

Fig. 3. Infrared spectra of pyridine still adsorbed on TiO_2 at elevated temperatures. TiO_2 studied are sized 82 Å (a), 125 Å (b), and 175 Å (c), respectively.

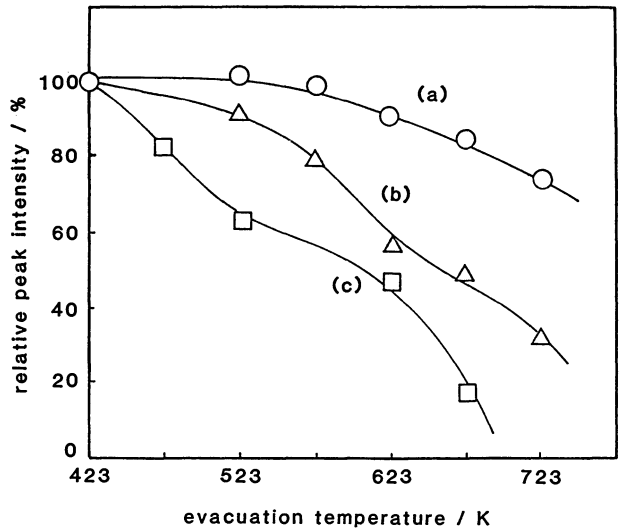

Fig. 4. Decrease in the absorption peak intensity at 1610 cm^{-1} at elevated temperatures. The peak intensities are normalized by the intensity observed after a He purge at 423 K.

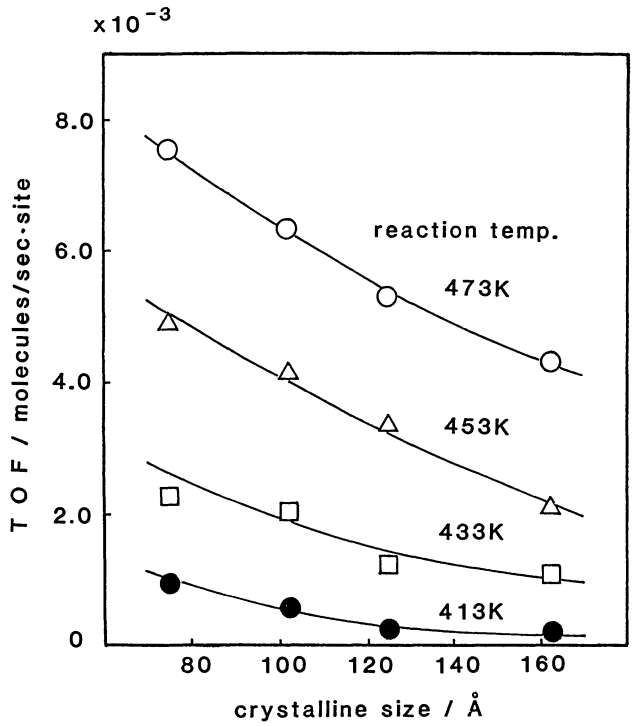

Fig. 5. Change in the turnover frequency of 1-butene isomerization on TiO_2 with the TiO_2 crystalline size.

are ascribed to pyridine adsorbed on the Lewis acid sites,[7] and still remained at temperatures higher than 623 K. Since the area of the absorption peak is proportional to the amounts of pyridine adsorbed, the changes in the peak area at 1610 cm^{-1} with the temperature were monitored for TiO_2 with the crystalline sizes mentioned above. In order to clearly show the difference in these changes, the peak areas were normalized by the peak

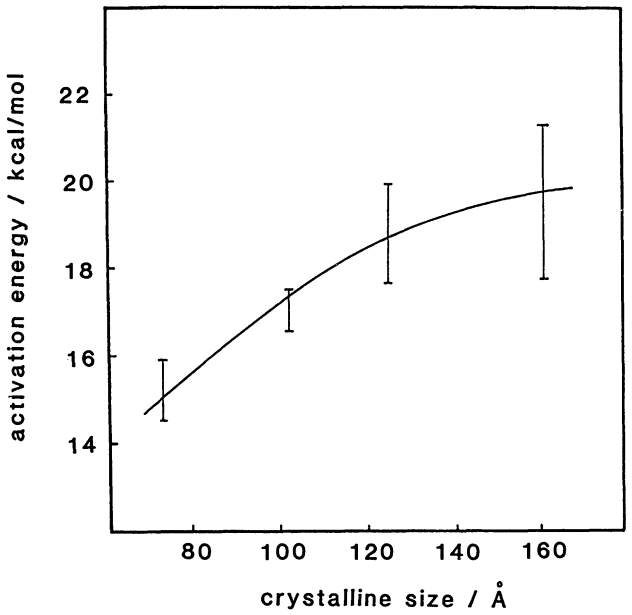

Fig. 6. Change in the activation energy for 1-butene isomerization on TiO_2 with the TiO_2 crystalline size. The activation energies were calculated from the results shown in Fig. 5.

area observed at 423 K for every sample, as shown in Fig. 4.

Since the number of acid sites on TiO_2 was known, the specific activity for 1-butene isomerization on TiO_2 could be expressed in terms of "molecules/sec/site". The obtained results are depicted in Fig. 5 against the crystalline size of TiO_2 used, allowing us to calculate the activation energy on TiO_2 (see Fig. 6).

Discussion

As is obviously shown in Table 1, the crystalline size of TiO_2 decreased as the amount of water used for hydrolysis increased. Although it was not necessarily reproducible to obtain TiO_2 with sizes smaller than 60 Å, which exhibit the highest acid strength of H_0=−5.6, crystallites with sizes of around 70—80 Å with the highest acid strength of H_0=−3.0, could be prepared using more than 2 L of water for hydrolysis. Strong acid sites over the smaller TiO_2 crystallite are also indicated by the TPD of pyridine on TiO_2 with various sizes. In Fig. 3(a) the pyridine adsorbed on TiO_2 with sizes of 82 Å, with H_0(max)=−3.0, is still considerable, even after evacuation at 723 K; on TiO_2 with sizes of around 175 Å (H_0(max)=−8.3), however, only small amounts of pyridine were detected by evacuation at 673 K, as is shown in Fig. 3(c). The fractions of pyridine still adsorbed at various temperatures (drawn in Fig. 4) were determined by monitoring the peak areas at 1610 cm^{-1} and normalizing the areas by the peak areas observed at 423 K. As can clearly be seen in Fig. 4, the fraction of pyridine remaining at elevated temperatures strongly depends on the crystalline size of the

TiO_2 employed; larger amounts of pyridine still remain on smaller TiO_2 crystallites, leading to the conclusion that strong acid sites are created on small-size TiO_2 crystallites. In addition, it would be interesting to discuss the peak shifts which occur in Fig. 3. Although the peak at 1610 cm^{-1} has been reported to shift somewhat toward long wavenumbers with evacuation at elevated temperatures,[8] other peaks observed at 1490 and 1445 cm^{-1} at 423 K were also shown to move to 1475 and 1438 cm^{-1} respectively, after evacuation at 623 K. These shifts could be recognized in all of the samples studied here (see Fig. 3). The new peaks at 1475 and 1438 cm^{-1} were never observed on TiO_2 evacuated at 623 K prior to pyridine adsorption. What happened on the adsorbed pyridine by evacuation at 623 K is yet another problem to be resolved.

The amounts of acid sites over the surface of size-controlled TiO_2 were estimated by measuring the peak areas due to chemisorbed ammonia in ammonia-TPD spectra, assuming one ammonia molecule per one acid site. Although the acid amounts on 1 g of TiO_2 increased with a decrease in the crystalline size, the acid-site density (expressed in terms of "site/m^2") was constant at 1.7×10^{18} sites/m^2 when the crystalline size was larger than 100 Å (see Fig. 2). This indicates that although new acid sites are not created on TiO_2 with sizes larger than 100 Å the acid strength of the sites is modified to be stronger as the crystalline size decreases. Over the surface of TiO_2 with sizes smaller than 100 Å the acid-site densities slightly increased with a decrease in the crystalline size, indicating the generation of new acid sites over the finely divided TiO_2 crystallites. The generation of new acid sites on TiO_2 crystallites with sizes smaller than 100 Å seems to be attributable to metal and/or oxygen ions vacancies which emerged on the surfaces of small TiO_2 crystallites, since these vacancies have been reported to be enhanced in small-size crystallites.[9] In the present work sample powders were reoxidized at 573 K prior to the TPD measurements, suggesting smaller amounts of oxygen ion vacancies on the surface of the TiO_2 used. Consequently, the new acid sites on the finely divided TiO_2 crystallites are tentatively assigned to Ti ion vacancies on the surface.

The strong acid sites over the surface of small TiO_2 crystallites can be elucidated in terms of the electronic properties, which have been widely accepted to be somewhat different from those of bulk-like materials.[4] A blue-shift in the absorption edge of UV-visible spectrum has been reported on tiny TiO_2 particles.[10] This indicates an increase in the bandgap between the conduction and valence band levels of TiO_2 semiconductors. An increase in the bandgap with crystalline size has been estimated by Brus,[11] who calculated the energy of the lowest excited states of various semiconductors. This calculation has been applied to TiO_2 particles,[12] and an increase in the bandgap of small-size TiO_2 has been assigned to an elevation of the conduction band edge. Though the change in the top of the valence band has not been mentioned in this paper, it might be natural to deduce a descent of the valence band edge to expand the bandgap of small TiO_2. A change in the valence band level results in a change in the acid strength of TiO_2 when used as a catalyst, since the positive holes formed in the valence band act as Lewis acid sites during catalysis. Consequently, the descent of the valence band edge in small-sized TiO_2 causes Lewis acid sites with higher acid strengths.

Finally, we tried to relate the acid properties of the finely-divided TiO_2 crystallites to their catalytic performance for the isomerization of 1-butene to *cis*- or *trans*-2-butenes. The product ratio of *cis*/*trans* obtained here was always within the range 1 to 2, suggesting no basic sites, such as Ti^{3+} over TiO_2; this is because the ratio observed on the basic sites has been believed to be much higher than that obtained here.[13] All of the acid sites on the present TiO_2 have been confirmed to be that of the Lewis acid, as discussed above. The isomerization (double bond migration) of 1-butene on Lewis acid sites has been considered to proceed via butenyl cations, which are produced by an elimination of H^- ions from 1-butene adsorbed on the Lewis acid sites.[14] Because the elimination step might be rate-determining regarding doble-bond migration, the catalytic performance of a site strongly depends upon the acid strength. On a stronger acid site, the elimination proceeds faster, leading to a higher turnover frequency on stronger acid sites. The turnover frequencies observed on the present TiO_2 become higher as the crystalline sizes become smaller, as shown in Fig. 5. This coincides well with the results obtained in our preliminary work that strong acid sites emerge on small-size TiO_2 crystallites. From the results shown in Fig. 5, the way in which the activation energies depend upon the size of TiO_2 crystallites is revealed (see Fig. 6).

The generation of both new and strong acid sites on the surfaces of finely-divided TiO_2 crystallites was concluded in the present work; this idea will be extended to the generation of both new and strong acid sites on binary oxides containing tiny TiO_2 crystallites.

Intramolecular Electron Transfer and S_N2 Reactions in the Radical Anions of 1-Benzoyl-ω-haloalkane Studied by Pulse Radiolysis

Norio KIMURA* and Setsuo TAKAMUKU
The Institute of Scientific and Industrial Research, Osaka University, 8-1 Mihogaoka, Ibaraki, Osaka 567
(Received March 6, 1991)

A one-electron reduction of 1-benzoyl-ω-haloalkane (Cl, Br, I) by solvated electrons and a subsequent intramolecular reaction of the radical anions, thus formed, have been investigated by using a pulse radiolysis technique. The reaction mechanism, electron transfer (ET) or S_N2, and the rate constants were found to change as a function of the nature of the halide and the methylene chain length of the substrate. Although the order of reactivity based on leaving halogen atoms was I, Br, and Cl, the ease of the S_N2 reaction was found to be in the order Cl>Br>I. In addition, the reaction rates were also affected by the polarity of the solvent used. On the basis of these results, it is discussed how the ET–S_N2 dichotomy takes place.

Radical anions ($D^{\cdot-}$) are often used as electron-transfer (ET) reagents. They are easily generated by electrochemical and radiation-chemical reactions, as well as by the reaction of aromatic hydrocarbon with an alkali metal. The most widely investigated reaction is a reductive cleavage of a C–X bond in aliphatic halides (RX) (Eq. 1).[1–8] Mechanistic and kinetic information

$$D^{\cdot-} + RX \rightarrow D + R\cdot + X^- \quad (1)$$

is available for this reaction from electrochemical[1–3] and pulse radiolysis[4–6] studies. There is a large variation in the reaction rate, depending on the oxidation potential of the radical anion donor ($D^{\cdot-}$) and the reduction potential of the alkyl halide acceptor (RX).

On the other hand, Lund and Simonet[9] have studied an electrochemical reaction of fluorenone with alkyl halide and confirmed a C–O bond formation at an α-carbon atom of the halide. An S_N2 reaction of the fluorenone radical anion with alkyl halide was proposed in order to explain the results. This reaction mechanism was also supported by the results from pulse radiolysis.[5]

In a previous investigation concerning the intramolecular reaction in the radical anions of 1-(4-biphenylyl)-ω-haloalkane,[10] an S_N2 reaction yielding a spirocyclic radical occurred competitively to an ET reaction, leading to a terminal carbon radical. However, no such a competitive intramolecular reaction was investigated in other reaction systems.

In the present work, we investigated the one electron reduction of 1-benzoyl-ω-haloalkane ($Ph–CO–(CH_2)_n–X$ (BZ_X-n), X=Cl, Br, I; n=2, 3, 4) by solvated electrons and the subsequent intramolecular reaction of the radical anions, thus formed, by using a pulse radiolysis technique. Further, in order to obtain information concerning the reaction mechanism, the solvent effects on the reaction rates were also investigated.

Results and Discussion

Effects of Chain Length, *n*, and Leaving Halogen Atom. Hexamethylphosphoric triamide (HMPA) solutions of BZ_X-n were irradiated with an 8-ns electron pulse at room temperature. The transient absorption spectra of BZ_X-n (X=Cl, Br, I; n=3, 4) recorded at various times after the pulse are presented in Fig. 1. The spectra observed immediately after the pulse exhibit λ_{max} at 330 and 490 nm, and agree very closely with the spectrum of the radical anion of acetophenone (λ_{max}=330 and 490 nm) which was measured in this work under the same

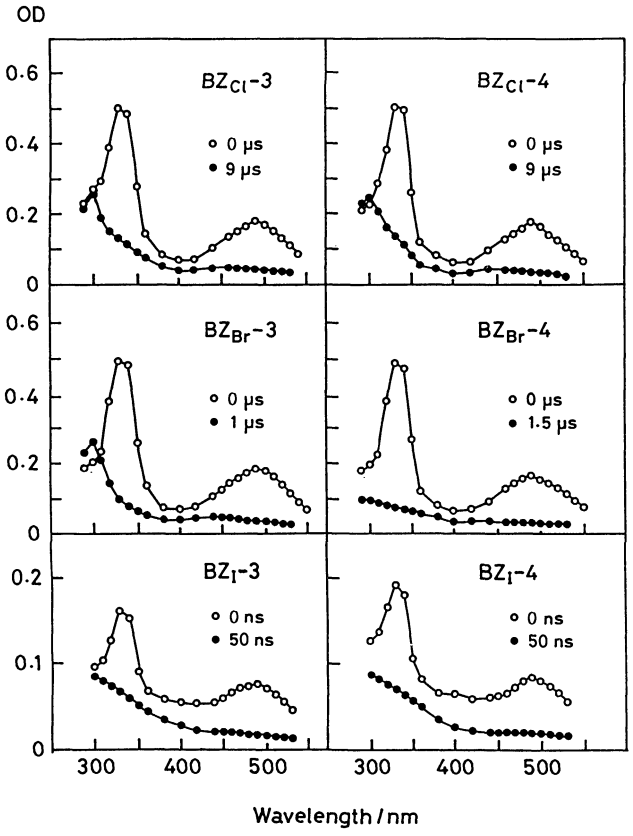

Fig. 1. Transient absorption spectra recorded at various times after the irradiation of an 8-ns electron pulse to HMPA solutions (3×10^{-3} mol dm^{-3}) containing 1-benzoyl-ω-haloalkane (BZ_X-n, X=Cl, Br, I; n=3, 4) at room temperature.

reaction conditions. The initial intensities of these bands observed from BZ_{Cl}-3, BZ_{Cl}-4, BZ_{Br}-3, and BZ_{Br}-4 are almost the same to those of the acetophenone radical anion. However, the initial intensities of the 330 and 490 nm bands observed from BZ_{I}-3 and BZ_{I}-4 are weaker than those of BZ_{Cl}-*n* and BZ_{Br}-*n*, which possess the same chain length (*n*), respectively. This can be explained by the short lifetime of the radical anion (**1** in Scheme 1), as described later. The decay of the 330 and 490 nm bands of all radical anions (**1**) followed first-order kinetics, and the rates were independent of both the solute concentration (1×10^{-2}—1×10^{-3} mol dm^{-3}) and absorption dose. These results indicate that the decay reaction of the radical anion (**1**) proceeds unimolecularly.

On the other hand, in the case of BZ_{Br}-3, the decay of the initial bands are characterized by the formation of a new band with λ_{max} at 300 nm. Further, a similar 300 nm band was also observed in the cases of BZ_{Cl}-3 and BZ_{Cl}-4. This new band coincides with that of an α-methoxybenzyl radical, PhĊH(OMe) (λ_{maxc}=300 nm), formed by a one-electron reduction of benzaldehyde dimethyl acetal. The similarity between both spectra indicates the formation of a similar species, i.e., a cyclic ether radical (**3** in Scheme 1; 2-phenyltetrahydro-2-furyl and 2-phenyltetrahydro-2-pyranyl radicals).

The rate constants (*k*, s^{-1}) measured from the decay of the 490 nm bands are summarized in Table 1, together with the yields of the alkyl phenyl ketone (**4**) by γ-irradiation. In the cases of BZ_{Cl}-2, BZ_{Br}-2, BZ_{Br}-4, BZ_{I}-3, and BZ_{I}-4, the *G*-values (1.8—2.1) of the formation of (**4**) are close to the *G*-value of the solvated electron, i.e., $G(e_s^-)$=2.3 in HMPA.[11] Therefore, in these compounds, it is clear that an intramolecular ET reaction leading to the production of a terminal carbon radical (**2**) preferentially occurs (Scheme 1).

On the other hand, in the cases of BZ_{Cl}-3, BZ_{Cl}-4, and BZ_{Br}-3, the yields of (**4**) were very low ($G<0.1$); the values are quite different from the *G*-values (2.3—2.5) of the substrate disappeared. In these compounds, a formation of the 300 nm bands assigned to a cyclic ether

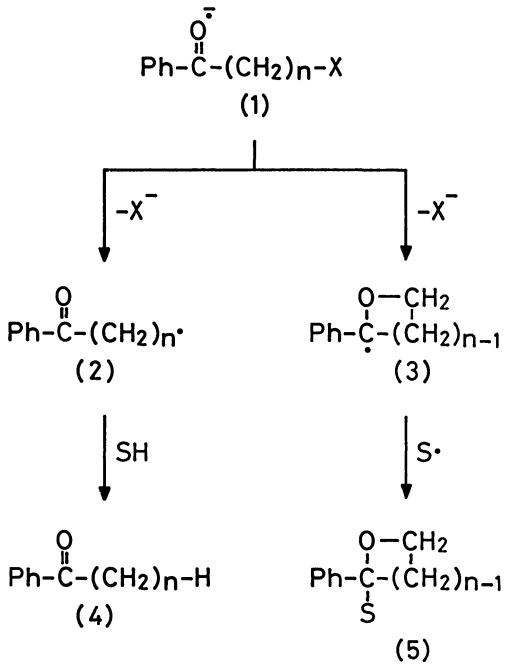


Scheme 1.

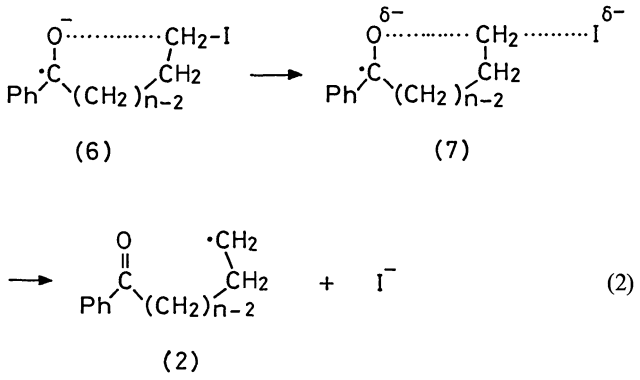
radical (**3**) was observed. Although the final products of this radical have not been confirmed, the mass spectra of the main products showed the formation of an adduct with a solvent radical (S·). These results provide clear evidence which support the idea that an intramolecular nucleophilic substitution (i.e., S_N2) is the main chemical process in these compounds.

As described previously, the reaction mechanism and the decay rate constants of the radical anion (**1**) were found to change by the nature of the halide and the methylene chain length (*n*). The decay rate constants of the radical anion (**1**) with the same chain length are in the order I > Br > Cl, which is consistent with the ease of reducing the alkyl halides.[2] On the other hand, the intramolecular S_N2 reaction occurred predominantly in BZ_{Cl}-3, BZ_{Cl}-4, and BZ_{Br}-3. Thus, the S_N2 reaction seems to require a reaction system in which an efficient release of a halide ion does not occur. Further, in the present reaction system, an important factor for an S_N2 reaction is the contribution of a cyclic structure which assists a favorable conformation for a backside attack onto a terminal carbon atom, i.e. , at least a five- or six-membered ring is required.

On the other hand, Pross and Shaik[12,13] proposed that,at the transition state in nucleophilic substitution reactions, one half of the negative charge on the nucleophile anion is transfered to the substrate, and that a negative charge is localized in the leaving group, regardless of the position of the transition state along the reaction coordinate. However, when the nucleophile or leaving group is modified, so as to make the reaction faster, the product energy level becomes lower, and the transition state occurs earlier, in accord with the

Leffler–Hammond postulate.[14,15]

According to the proposed theory, a negative charge is distributed to the carbonyl oxygen and the leaving halogen atom in equal amounts in the transition state. However, the reaction coordinate hardly progresses in the cases of BZ_I-3 and BZ_I-4, i.e., the transition state geometry (**7**) is close to that of a loose association complex (**6**) produced by an ion–dipole interaction (Eq. 2). Thus, it becomes harder to form a new bond, since the interaction of the two bonding orbitals (O···CH_2) is weak and the O–C–I angle is different from 180° in the transition state. However, in the cases of BZ_{Cl}-3, BZ_{Cl}-4, and BZ_{Br}-3, the reaction coordinate progresses to satisfy the S_N2 conditions, which allow an attack of the central carbon in the axis of the C–X bond and a partial bond formation in the transition state.



(6) (7)

(2)

On the other hand, molecular models indicate that the O–C–X angle in the six-membered-ring transition state slightly differs from 180°, while the O–C–X angle in the five-membered-ring transition state is very close to 180°. It, thus, appears that a six-membered ring is more difficult to form in the S_N2 transition state than a five-membered ring. For this reason, in the case of BZ_{Br}-4, which reacts more rapidly than does BZ_{Cl}-4, a new bond was not formed in the same manner as BZ_I-4. Further, the cyclic transition state of BZ_X-2 (X=Cl, Br) is too strained to form the S_N2 transition state, i.e., the carbonyl oxygen anion hits a terminal carbon from other direction than the axis.

The following conclusion thus emerges from these results. The ET and S_N2 reactions involve a common mechanism in which an electron is transfered from the carbonyl oxygen anion to a terminal carbon accompanied by a simultaneous fission of the C–X bond. Therefore, the S_N2 reaction is considered to be an extreme case in electron-transfer reactions accompanied by a fission of the C–X bond. That is, the S_N2 reaction selectively occurs when the conditions for the S_N2 reaction (described above) are satisfied.

Effeects of Solvent on the Reaction Rates. In order to make the reaction mechanism clear, solvent effects on the reaction rates were investigated using five different solvents such as DMA, DMF, DMSO, HMPA, and NMP (*N*-methyl-2-pyrrolidone). The transient absorption spectra observed immediately after the pulse were similar to that observed in HMPA. However, the decay rate constants of the 330 and 490 nm bands were dependent on the nature of the solvent used. A correlation of the rate constants ($\log k$) with an acceptor number (AN)[16] of the solvent was examined in the same manner as in the case of a unimolecular dissociation of the radical anions of aryl chloride[17] and chloroacetophenone isomers.[18] In these cases, good linear correlations were obtained. Plots of $\log k$ measured from BZ_X-*n* (X=Cl, Br, I; *n*=3, 4) vs. AN are shown in Fig. 2. These plots show a quite different shape, depending on the nature of the leaving halogen atom. Similar correlations were also obtained when the Reichardt–Dimroth polarity parameter, $E_T(30)$,[19] was used.

The extent of the solvation for anions is dependent on the charge density, which differs according to the ion radius and the structure.[20] Such different solvations for anions in the transition state, intermediates, or reactants causes either a retardation or acceleration of the reaction rate.

In the case of BZ_{Cl}-*n* (*n*=2—4), it is apparent that the rate constants increase with increasing AN, namely the solvent polarity. Therefore, stronger solvations are

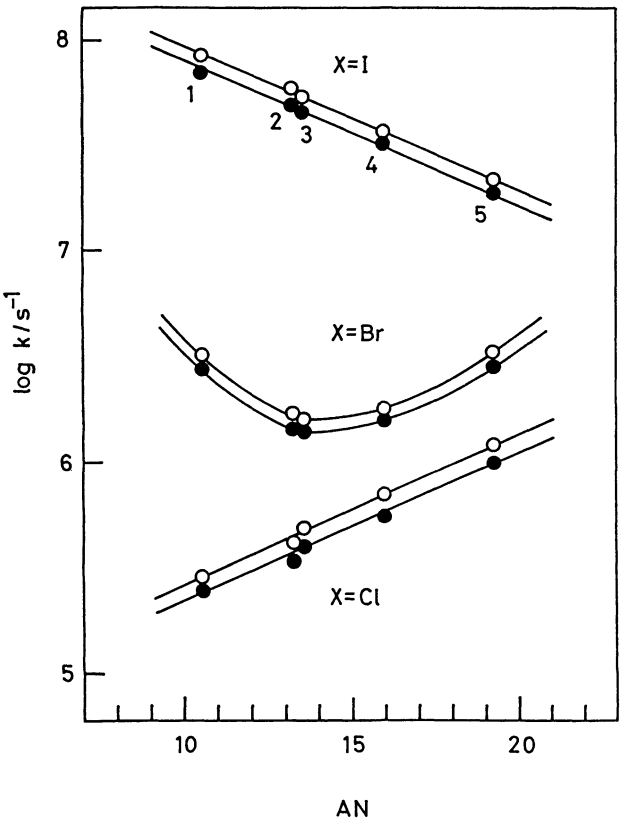


Fig. 2. Relationship between the decay rate constants ($\log k$) of the radical anions of BZx-3 (○; X=Cl, Br, I) and BZx-4 (●; X=Cl, Br, I) and acceptor number (AN) of the solvents: 1, HMPA; 2, NMP; 3, DMA; 4, DMF; 5, DMSO.

expected for the leaving chloride ion than for the ketone radical anion. Thus, an increase in the solvent polarity resulted in an increase in the rate. However, in the case of BZ_I-n (n=3, 4), the correlations are reversed. This means that the degree of solvation is higher for the ketone radical anion than for the iodide ion. Unlike these halides, U-shaped plots were obtained in the case of BZ_{Br}-n (n=2—4). Such a correlation is hardly explained at the moment, but may be the result of a difference in the solvation power for each individual anion of the solvent used.

However, plots of $\log k$ vs. the polarity parameters had the same shape for each halide, though the reaction mechanism is state in different terms (ET and S_N2) with different chain lengths (n). These results suggest that the bond-breaking process, concerted with an electron transfer which is involved in both the ET and S_N2 reactions, occurs as the rate-determining step.

These results strongly support the conclusion described in the preceding section. Accordingly, the fundamental mechanistic difference between the ET and S_N2 reactions is whether a new bond formation synchronized to the concerted electron transfer and bond-breaking processes occurs or not.

Experimental

Materials. 1-Benzoyl-2-chloroethane (BZ_{Cl}-2) from Tokyo Kasei was used without further purification. 1-Benzoyl-3-chloropropane (BZ_{Cl}-3) from Aldrich was purified by distillation under reduced pressure.

1-Benzoyl-4-chlorobutane (BZ_{Cl}-4). To a mixture of 8.0 g (0.06 mol) of $AlCl_3$ in dry benzene (100 ml) was added 7.0 g (0.05 mol) of 5-chlorovaleryl chloride at 0 °C. The mixture was stirred for 2 h at room temperature and then hydrized with ice water. The benzene layer was separated, washed with water, dried over sodium sulfate, and evaporated. The residue was recrystallized from pentane: Mp 49—50 °C (lit,[21] 50 °C) (Found: C, 67.20; H, 6.70; Cl, 18.01%).

1-Benzoyl-2-bromoethane (BZ_{Br}-2), 1-Benzoyl-3-bromopropane (BZ_{Br}-3), and 1-Benzoyl-4-bromobutane (BZ_{Br}-4). These compounds were prepared by using the previously described procedure for 3-bromopropionyl chloride, 4-bromobutyryl chloride, and 5-bromovaleryl chloride. BZ_{Br}-2: Mp 60—61 °C (lit,[22] 60 °C) (Found: C, 50.80; H, 4.30; Br, 37.56%). BZ_{Br}-3: Mp 38—39 °C (lit,[23] 38.5 °C) (Found: C, 52.62; H, 4.82; Br, 35.50%). BZ_{Br}-4: Mp 58—59 °C (lit,[21] 58.5 °C) (Found: C, 54.90; H, 5.55; Br, 32.90%).

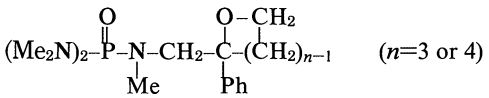
1-Benzoyl-3-iodopropane (BZ_I-3) and 1-Benzoyl-4-iodobutane (BZ_I-4). The corresponding bromides were refluxed in methyl ethyl ketone containing 10-fold excess of KI for 10 h. The organic layer was evaporated and the residue was recrystallized from pentane. BZ_I-3: Mp 51—52 °C (Found: C, 43.95; H, 4.20; I, 46.06%). BZ_I-4: Mp 71—72 °C (lit,[21] 71.5 °C) (Found: C, 46.14; H, 4.46; I, 44.29%).

Apparatus. The samples held in Suprasil quartz cells were irradiated with an 8-ns pulse of 28 MeV electrons from a linear accelerator of Osaka University. The transient species were monitored with a pulsed Xe lamp. The monitoring light was passed through a monochrometer (Nikon G-250) after being passed through the sample cell and monitored with an R928 photomultiplier (Hamamatsu Photonics). The output of the photomultiplier was digitized bya programable transient digitizer (Tektronix 7912AD) interfaced with a microcomputer (Sharp X68000ACE), which was also used to store the data on a disc and to analyze the data.

N,N-Dimethylacetamide (DMA), *N,N*-dimethylformamide (DMF), dimethyl sulfoxide (DMSO), hexamethylphosphoric triamide (HMPA), and *N*-methyl-2-pyrrolidone (NMP) used as a solvent were distilled over CaH_2 under reduced pressure. Solutions were prepared immediately before irradiation and were degassed under high vacuum.

Product analysis was carried out by GLC (Shimazu GC-7A; using 1-m×3-mm glass column packed with 5% Silicone OV-1 on Chromosorb WAW DMCS, 60—80 mesh) and GLC-MS (JEOL JMS-DX300) after extraction by pentane from γ-irradiated HMPA solution.

The mass spectra of the main products (Yields: 60—70% based on the substrate disappeared) from BZ_{Cl}-3, BZ_{Cl}-4, and BZ_{Br}-3 showed the formation of an adduct (**5**) of a cyclic



(n=3 or 4)

(**5**)

ether radical (**3**; see text) with HMPA. Results were as follows: adduct **5** (n=3); m/z 325 ($M^{+\cdot}$), 281 ($M^{+\cdot}-Me_2N$), 178 ($M^{+\cdot}-147$), 147 {[Ph–C–$(CH_2)_3$–O]$^+$}, 135 {$[(Me_2N)_2PO]^+$, major peak}, 105 $[(PhCO)^+]$, 77 (Ph^+), 58 $[(Me_2NCH_2)^+]$, 44 (Me_2N^+); adduct **5** (n=4); m/z 339 ($M^{+\cdot}$), 295 ($M^{+\cdot}-Me_2N$), 178 ($M^{+\cdot}-161$), 161 {[Ph–C–$(CH_2)_4$–O]$^+$}, 135 {$[(Me_2N)_2PO]^+$, major peak}, 105 $[(PhCO)^+]$, 77 (Ph^+), 58 $[(Me_2NCH_2)^+]$, 44 (Me_2N^+).

Effects of Temperature and Pressure on the Charge-Transfer Complex Formation through Hydrogen Bonding and Ionization Reactions between 2,6-Dibromo-4-[(3,5-dibromo-4-hydroxyphenyl)(2-ethoxycarbonylphenyl)-methylene]-2,5-cyclohexadien-1-one and Amines

Norio NISHIMURA,* Yoshihiro OSAWA, Kohji KURAMOTO, and Kazuo SUKEMICHI
Department of Chemistry, Faculty of Science, Okayama University, Okayama 700
(Received April 8, 1991)

The effects of temperature and pressure on the formation of charge-transfer (CT) complexes between 2,6-dibromo-4-[(3,5-dibromo-4-hydroxyphenyl)(2-ethoxycarbonylphenyl)methylene]2,5-cyclohexadien-1-one (TBPE) and amines in nonpolar solvents have been studied, and the thermodynamic parameters estimated. It was found that the heat of formation (ΔH°) as well as the reaction volume (ΔV°) are largely negative, compared with those for ordinary CT complex formation. The electronic spectra in the visible region due to the outer CT complexes are well-characterized for primary and secondary amines in nonpolar solvents that have no proton-donating/-accepting nature. In other cases, the CT spectra are broad. Ionization of TBPE in polar solvents takes place as evidenced by the electronic spectrum of TBPE anion. However, ΔH° as well as ΔV° are unusually small. When Proton Sponge is used in nonpolar solvents, ion pairs are formed. In this case, ΔH° and ΔV° are largely negative as expected.

In 1954, Davis and Hetzer[1] found that when a benzene solution of 2,6-dibromo-4-[(3,5-dibromo-4-hydroxyphenyl)(2-ethoxycarbonylphenyl)methylene]2,5-cyclohexadien-1-one (TBPE) was poured to solid tribenzylamine, the yellow solution of TBPE acquired a slightly pink tinge which disappeared on heating but returned on cooling. Sakai and co-workers have shown that the thermochromic nature of the TBPE–amine systems in 1,2-dichloroethane (DCE) could be applied to the selective determination of antihistamine drugs.[2–6] They suggested that TBPE associates with amines to form a kind of charge-transfer (CT) complex through hydrogen bonding.

In a preliminary paper,[7] we have shown that the complexes formed between TBPE and triethylamine (TEA) and between TBPE and *N,N*-dimethy-2-(diphenylmethoxy)ethylamine (DHA) are of a new type of CT complex as characterized by their strong CT band in the visible region, large equilibrium constant, and large negative values of the heat of reaction and reaction volume.

In this paper, we report the thermodynamic quantities for the CT complex formation between TBPE and primary, secondary, and tertiary aliphatic amines, together with those for the ion-associate formation between TBPE and *N,N,N′,N′*-tetramethyl-1,8-naphthalenediamine (Proton Sponge, PS).

Experimental

Materials. Reagent grade potassium salt of TBPE was dissolved into an H_2O–EtOH mixture. An aqueous solution of oxalic acid was added slowly to the mixture until the blue color of the solution changed to orange red. TBPE as a free phenol, was extracted by chloroform and the solution evaporated to dryness. Recryctallization of TBPE was made by adding hexane dropwise to its chloroform solution, mp 215—217 °C (lit,[8] 210—215 °C). Reagent grade Proton Sponge was recrystallized from a cyclohexane–petroleum ether mixture. Triethylamine (TEA), dipropylamine (DPA), and propylamine (PA) were dried over potassium hydroxide and distilled under a reduced pressure. Solvents were purified in the usual manner.

Procedures. Spectra of the CT complex and the ion-associate at 0.1 MPa were recorded on a Union SM-401 spectrophotometer. The measurement temperature was regulated within ±0.1 °C by circulating thermocontrolled water. A high-pressure vessel with a water jacket for temperature control was used for spectral measurements.[9] It was set in a cell compartment of a Hitachi 100-50 double-beam spectrophotometer. Using available data, the changes of solvent density with temperature and pressure were taken into account. The equilibrium constants for the formation of the CT complex and the ion-associate were determined from the Benesi–Hildebrand (B–H) plot[10] with the base in great excess over TBPE. The enthalpy and entropy of formation were determined from the variation of the equilibrium constants with temperature according to the van't Hoff equation.

The equilibrium constant in logarithmic scale was plotted against external pressures, and the plots were fitted to the following quadratic equation by means of a computer program.

$$\ln K_p/K_0 = ap^2 + bp + c \quad (1)$$

where K_p and K_0 are the equilibrium constants at p and 0.1 MPa, respectively. The volume of reaction extrapolated at atmospheric pressure (ΔV°) was calculated by

$$bRT = -\Delta V^\circ - \Delta n\, \kappa_T RT \quad (2)$$

where κ_T denotes the isothermal compressibility of solvents, and Δn the difference in the number of molecules between products and reactants. The second term arises from the translational energy loss associated with reaction.[11]

Results

The temperature dependence of the absorption spectrum in the visible region is shown in Fig. 1. The

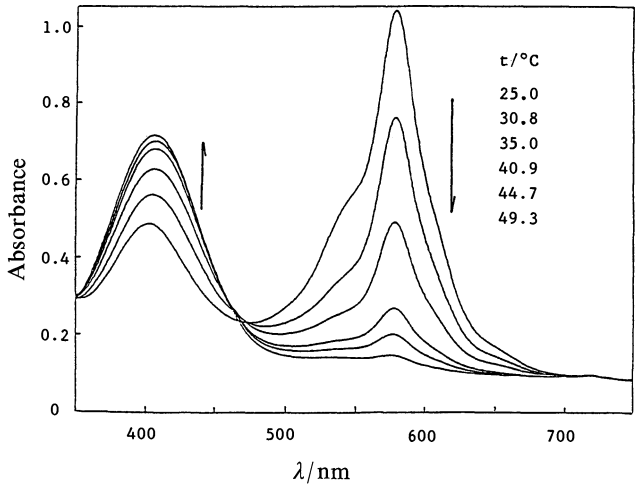

Fig. 1. Temperature dependence of the absorption spectrum in benzene; $[TBPE]_o=6.04\times10^{-5}$ mol dm^{-3}, $[PA]_o=2.08\times10^{-4}$ mol dm^{-3}.

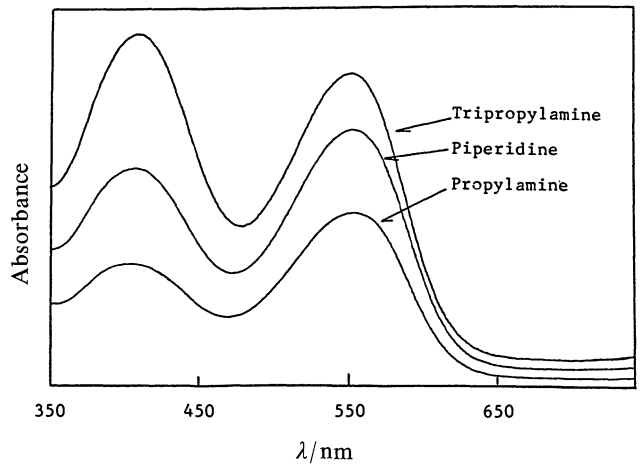

Fig. 2. Absorption bands of TBPE in 1,4-dioxane in the presence of primary, secondary, and tertiary amines.

absorption band at ca. 580 nm can be ascribed to the CT complex and the band at ca. 400 nm to TBPE. As the temperature raises, the CT band decreases, while the TBPE band increases but less rapidly and shifts toward a longer wavelength side. Thus the band at ca. 400 nm must involve some contribution of the CT complex. The B–H plots were performed using the absorbance of the CT band for this reason. The shape and the position of the CT band depend on the combination of amines and solvents. This is shown in Figs. 2 and 3. It was found that each B–H plot for the CT complex formation is linear. Representative B–H plots are shown in Fig. 4. Remarkable pressure effects on the equilibrium were observed. By the aid of Eqs. 1 and 2, the reaction volumes were estimated. The thermodynamic parameters are given in Table 1. When TBPE

was mixed with PS in nonpolar solvents, a band appeared at ca. λ_{max}=620 nm. This band can be assigned to the TBPE anion, since both the position and the spectral pattern agreed with those of the potassium salt of TBPE. Remarkable temperature and pressure dependences on the equilibrium were observed in this case, too. Figure 5 shows the B–H plot. The thermodynamic quantities for the formation of the ion-associate in some nonpolar solvents were estimated and are given in Table 2.

Discussion

Charge-Transfer Complex Formation Reaction. We have reported[7)] that the tertiary amines such as TEA react with TBPE to form a new type of CT complex in nonpolar solvents, and that the system exhibits a remarkable thermochromism as well as piezochromism. We proposed that the origin of the strong CT band could be ascribed to the canonical electronic structures of the following type.

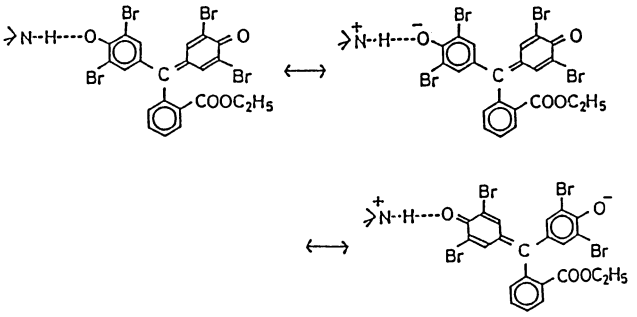

Figure 1 shows a remarkable thermochromic nature for the TBPE–propylamine system, too. From the B–H plot, the equilibrium constants were estimated. By means of the van't Hoff plot, the heat of reaction and the entropy of reaction were estimated (Table 1). The reaction volumes are between −22 and −35 cm^3 mol^{-1}. These (absolute) values are remarkably greater than those for ordinary CT complex formation (0—−15 cm^3 mol^{-1}).[12)] Therefore, due to the predominant contribution of the dative structures (vide supra), the present CT complex must be more "tight" than the ordinary one.

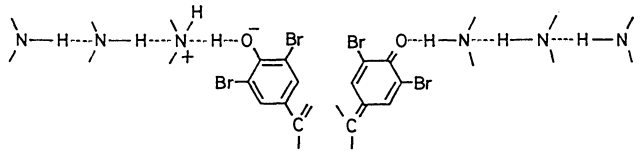
In 1,4-dioxane (DX) and tetrahydrofuran (THF), the spectral pattern of the CT band is very similar to each other, irrespective of primary, secondary and tertiary amines (Fig. 2). The spectral pattern of the TBPE–TEA system in benzene, chloroform, and THF is also the same as that in Fig. 2. On the other hand, when primary or secondary amines are used, the spectral pattern changes remarkably, depending on the nature of solvents (Fig. 3). With auxiliary experiments, it has

been confirmed that the CT spectrum is sharp and exhibits a "structure" (shoulder) only when TBPE and primary or secondary amines are dissolved in nonpolar solvents that have no proton donating/accepting ability.

According to our view, hydrogen bonding is playing an important role. There are some possible combinations of hydrogen bonding. In DX and THF, the hydrogen-bond formation between TBPE and these solvents will disfavor the CT complex formation. The situation will be the same for the hydrogen bonding between primary/secondary amines and DX/THF. The comparatively small values of the equilibrium constants in DX may be ascribed to this reason. Primary and secondary amines can donate as well as accept the hydrogen atom that can form hydrogen bond. In benzene and CCl_4, they will form a kind of (dynamic) cluster through hydrogen bonding. The amine cluster taking part in the formation of CT complex would give rise to its enhanced effective mass, resulting in a less mobile conformation (see type A indicated below). Hydrogen bonding of the type B is also possible.



Type A Type B

It is likely that either or both of the above types of hydrogen bonding are responsible for the well-characterized CT band. Meanwhile, the formation of cluster is disfavored in DX due to the predominant hydrogen bonding between primary/secondary amines and excessively existing DX. It is evident that the cluster formation is impossible for tertiary amines in any kinds of solvents. The above idea would explain the spectral patterns in Figs. 2 and 3.

In order to obtain evidence for supporting the cluster formation, the shift of the CT band with solvent was examined. In Fig. 6, $\bar{\nu}_{max}$ is plotted against the E_T-value, a solvent polarity parameter. For the TBPE–TEA system, a fairly well correlation may be seen (line A). For the TBPE–PA system, solvents that have hydrogen-bonding ability seem to fall on the same line. Judging from the chemical shift of ^{1}H NMR of chloroform (δ=7.25 ppm vs.TMS, 60 MHz ^{1}H NMR), chloroform could, be regarded to this group of solvents. The position of diethyl ether is rather critical. On the other hand, solvents that have no hydrogen-bonding ability seem to constitute an other group (line B). The shift is less remarkable, and this is in harmony with the assumption of cluster formation, proposed in the foregoing paragraph. That is, the formation of amine cluster will disfavor the access of solvent molecules to the CT complex, resulting in the small red shift.

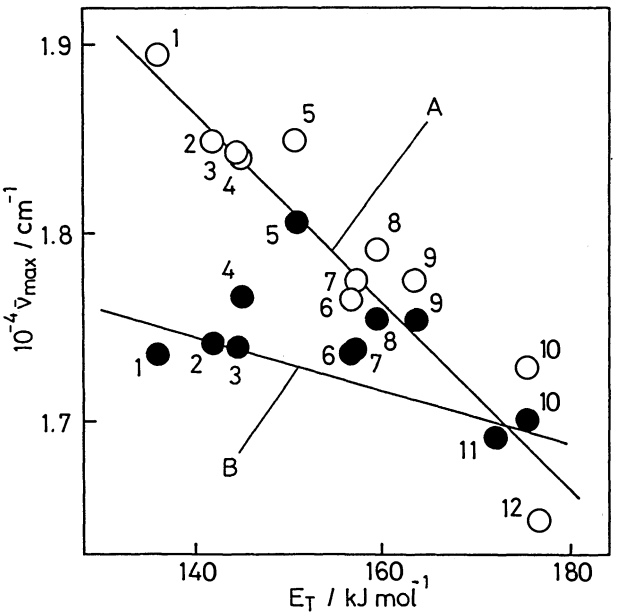


Fig. 6. Relationship between $\bar{\nu}_{max}$ (CT band) and E_T-value for the TBPE–TEA (○) and TBPE–PA (●) systems. Entry number: 1, CCl_4; 2, toluene; 3, benzene; 4, Et_2O; 5, DX; 6, THF; 7, chlorobenzene; 8, ethyl acetate; 9, $CHCl_3$; 10, DE; 11, dichloromethane; 12, acetone.

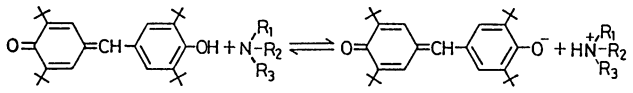
When ordinary aromatic amines of low basicity are used, the formation of CT complex was not observed in the usual conditions. Hence the equilibrium would be related to the amine basicity. The value of pK_a for TEA and PA are 11.01 and 10.71, respectively. Although the value of pK_a for DPA is not available, it would be very near to that of TEA, referring to the pK_a of diisopropylamine (10.96). Although the above pK_a-values are those in water, the equilibrium constants for the TBPE–PA system is, as a whole, smaller than those for the other two; this may be ascribed to the difference in the pK_a value. The solvent effects on the thermodynamic data in Table 1 seem to be entangled, and it is difficult to find a definite trend. Perhaps the complication could be ascribed to the intervention of various types of hydrogen-bond formations, the steric factor, and the amine basicity etc., and further study is neccesary.

Ionization Reaction. It is generally known that ionization is enhanced by temperature and pressure. The observation of considerable volume decrease has been interpreted in terms of electrostriction. The electrostriction becomes pronounced when the ion is small, the charge large and localized, and the solvent nonpolar. Typical ionization of phenols is accompanied by the volume change from −4 to −30 cm^3 mol^{-1}.[13] When TBPE alone or TBPE and small amount of aliphatic amine was dissolved in polar solvents, the formation of TBPE anion was observed. We examined the temperature dependence on the equilibrium and found that the equilibrium scarcely shifts with temperature in acetoni-

trile, acetone, and methanol. This indicates that the heat of ionization is near zero and the entropy change so small. In agreement with our observation, Sakai[2] also reported that the temperature dependence on the equilibrium between TBPE anion/quaternary ammonium ion-associates and its nonionized components in 1,2-dichloroethane is negligibly small. The effect of pressure on the equilibrium was also examined in acetone and methanol. The approximate ΔV°-value estimated by means of Eqs. 1 and 2 was 1.0 ± 1.0 cm^3 mol^{-1} in acetone and negligibly small in methanol. The above findings are unusual in view of normal ionization reactions where remarkable enthalpy, entropy, and volume decreases are observed.

A possible cause might be due to the symmetrical structure of TBPE anion; the electric charge will be delocalized over the molecule, and this might give rise to the small temperature effects. Free phenol corresponding to galvinoxyl (so-called "hydrogalvinoxyl", see below) could be regarded as a model compound for examining the above presumption. We expected that the temperature effects for the following equilibrium



"hydrogalvinoxyl"

will be similar, since the anion has symmetrical electronic structures similar to those of TBPE anion. However, remarkable temperature dependence was observed for this system. The estimated values of the heat of formation were -29 kJ mol^{-1} in acetone and -46 kJ mol^{-1} in acetonitrile.[14] Although the reason is not clear, this temperature/pressure-insensitive nature seems peculiar to the ionization of TBPE in polar solvents.

When TBPE and PS were mixed in nonpolar solvents, the proton from TBPE was trapped by PS to form ion pairs, as evidenced by the appearance of well-characterized spectrum of TBPE anion in the vicinity of 600 nm. In contrast to the case of the CT complex, the pattern of the spectrum does not change with solvent at all. Substantial temperature and pressure effects were observed. The thermodynamic data are given in Table 2. The volumes of reaction for the formation of ion-pair are between -30 and -39 cm^3 mol^{-1} as expected in the ordinary ion-pair formation reactions. The enthalpy and entropy changes are those usually observed. Using the data in Tables 1 and 2, we tentatively plotted ΔH° against ΔS° (Fig. 7). In spite of the intervention of a various types of hydrogen bonding, it seems that the approximate linear free energy relationship[15] holds for both the CT complex and ion-pair formations. Figure 8 shows the relation between $\bar{\nu}_{max}$ and E_T-value. For solvents of smaller E_T-values, a small but clear red-shift trend may be seen, as usually observed for π–π^* transitions. In contrast, a rather blue-shift trend may be seen for solvents of larger E_T-values, indicating that the ground state of the anion is a little more stabilized than the excited state. A good correlation between $\bar{\nu}_{max}$ and E_T-values for a series of alcohols suggests a substantial role of hydrogen bonding. The comparatively small solvatochromic shift over a wide E_T range is in accord with our expectation, since the dipole moment of the ion pair in the ground state will not be so different from that in the excited state.

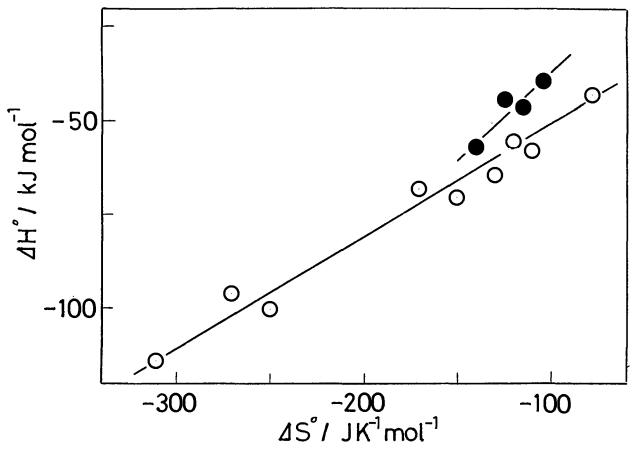


Fig. 7. Linear free energy relationship for CT complex formation (○) and ion-pair formation (●).

The Pitzer Formalism vis-à-vis the Mixture Rule for the Estimation of Apparent Molal Volumes of Aqueous NaCl–KCl, NaCl–KBr, and NaCl–K_2SO_4 Mixtures at 298.15 K

(Received July 30, 1990)

The density data reported by Wirth for aqueous solutions of KCl, KBr, and K_2SO_4 in NaCl solutions of five different fixed concentrations at 298.15 K have been used to calculate the apparent molal volumes of the mixtures; the results have been compared with those calculated by the Pitzer formalism as also the Young and Smith's mixture rule.

Recently, attention has been drawn to the successful extension of the Pitzer formalism[1,2] by Kumar[3–5] for the calculation of volume properties of a number of mixed electrolytes in aqueous solutions. Humffray[6] has also proposed a comparatively simpler treatment by adopting the Young and Smith's "mixture rule"[7] for estimating the densities and apparent molal volumes of mixtures of electrolytes from those of the individual components, and obtained a better agreement for NaCl–KBr mixtures than from Pitzer's equations. Kumar[8a] has however observed that the good agreement obtained by Humffray is due to the fact that the variation of the densities of the mixtures happens to be linear with respect to the component densities. It is the purpose of this investigation to extend such studies to a number of other electrolyte mixtures in order to investigate further the extent of agreement between the experimental values and those calculated from the mixture rule, and the Pitzer's equations.

For this purpose, we have made use of the entire set of precise density data reported by Wirth (for the mixtures: NaCl–KCl, NaCl–KBr, and NaCl–K_2SO_4)[9] by suitable interpolation of the data, without and with proper reformulation of the empirical equations given for the representation of the mixture density, so that the latter could be represented for constant total ionic strengths within the range: 0.25 to 1 mol kg^{-1}.

Calculations and Results

Wirth's reported density data in terms of molarity have been converted to molality for meaningful comparison with the recent data, by means of the following conversion formula deduced in analogy with that for the pure components:[10]

$$\frac{\sum c_i}{\sum m_i} = d_{\mathrm{mix}} - \frac{\sum c_i M_i}{1000}. \qquad (1)$$

The experimental ϕ_v^* values for the mixtures are then calculated with the help of the following equation

$$\phi_v^* = \frac{1000(d_0 - d_{\mathrm{mix}})}{d_{\mathrm{mix}}\, d_0 \sum m_i} + \frac{\sum m_i M_i}{d_{\mathrm{mix}} \sum m_i}. \qquad (2)$$

Here d_{mix} and d_0 are the densities of the mixture and the solvent respectively, m_i is the molality and M_i the molecular weight of the ith component in the mixture.

Wirth[9] reported the density values of KCl, KBr, and K_2SO_4 in NaCl solutions of five fixed concentrations [viz., 0.04, 0.16, 0.35, 0.62, and 0.97 equiv] in which the concentration of the first electrolyte generally varied from 0.04 to 0.64 equiv except in the case of K_2SO_4. All density values of the mixtures of different electrolytes were represented by means of least square equations:[9]

$$(d_3 - d_2)/c_3 = a - b(\mu_v^{1/2} - c_2^{\circ 1/2}). \qquad (3)$$

From the experimental data as reported by Wirth in Tables 2, 3, and 4, Ref. 9, it has been possible to interpolate the experimental densities and apparent molal volumes of the different mixed electrolytes at a number of constant total ionic strengths between 1 and 0.25 mol kg^{-1}. However, such calculations with Wirth's reported equations produce only a set of three to four density values for each ionic strength, which is inadequate for the present purpose. In order to obtain more data for meaningful comparison, we have introduced the following technique. Instead of a fixed concentration of NaCl in the mixtures as reported by Wirth, the concentration of the other electrolyte is now made fixed, so as to vary the concentration of NaCl in the mixtures. All these density values are then represented in the form of equations analogous to Wirth's equation by the computerized least squares method with proper 'a' and 'b' values.

With the help of these reformulated equations it is now possible to calculate the densities or apparent molal volumes at suitable ional fractions other than those calculated directly from Wirth's reported equations. The thus calculated values of densities [or rather, the density differences ($\Delta d = d_3 - d_2$)] and apparent molal volumes, at the total ionic strengths of 1, 0.75, 0.50, and 0.25 mol kg^{-1}, are shown in columns 3 and 4 of Table 1, for the NaCl—KCl mixture only (two 1—1 type electrolytes with common anion). The consistency of the density values obtained from our reformulated equation with those calculated using Wirth's equations, has been tested and found to be excellent.

Table 1. Experimental Δd and ϕ_v^* Values (Wirth's data) together with the Corresponding Estimated ϕ_v^* Values by Young's Rule and Pitzer's Equation for NaCl–KCl Mixtures at 298.15 K

m_{NaCl}	m_{KCl}	$\Delta d \times 10^3$ / g cm^{-3}	ϕ_v^* / cm^3 mol^{-1} (Wirth)	ϕ_v^* / cm^3 mol^{-1} (Pitzer)	ϕ_v^* / cm^3 mol^{-1} (Young's rule)

0.25	1.71	1.01	4.85

Pitzer's Equation. The form of the Pitzer equation[11] which was used by Kumar[5] has also been utilized here. The apparent molal volume of an ith type ion in a mixture can be estimated by the following equation (which is slightly different from that of Kumar[8]):

$$\phi_{v_i}=\phi^\circ_{v_i}+\frac{z_i^2 A_v}{2b}\ln(1+bI^{1/2})+RT\sum_j B^v_{ij}m_j + \frac{BT}{|z_i|^{1/2}}\sum_j C^v_{ij}m_j^2|z_j|^{1/2}, \quad (4)$$

where

$$B^v_{ij}=B^\circ_{ij}+\frac{1}{2I}B^1_{ij}[1-(1+2I^{1/2})\exp(-2I)^{1/2}];$$

$$B^\circ_{ij}=\left(\frac{\partial\beta^{(0)}_{ij}}{\partial P}\right)_T,\ B^1_{ij}=\left(\frac{\partial\beta^{(1)}_{ij}}{\partial P}\right)_T;$$

$$C^v_{ij}=\left(\frac{\partial C^\phi_{ij}}{\partial P}\right)_T/2;\ A_v=1.8743,\ b=1.2.$$

The apparent molal volume of the Jth salt in a mixture can then be obtained by summing over the component ionic values: $\phi_{v_J}=\sum_i \nu_i\phi_{v_i}$ which in turn calculates the theoretical mean apparent molal volumes ϕ^*_v of the mixtures: $\phi^*_{v_{cal}}=(\sum_J m_J\phi_{v_J})/\sum_J m_J$.

In order to calculate the ϕ^*_v values of the different mixtures by the Pitzer formalism the values of the pure electrolyte parameters $(\partial\beta^{(0)}/\partial P)_T$, $(\partial\beta^{(1)}/\partial P)_T$, and $(\partial C^\phi/\partial P)_T$ (as also ϕ°_v) for the different cation–anion pairs such as Na–Cl, K–Cl, Na–Br, Na–SO_4, and K–SO_4 are required. The experimental ϕ_v values at different concentrations over the range 0.01—1.04 M (1 M=1 mol dm^{-3}) were directly calculated for NaCl, KCl, KBr, and K_2SO_4 from Wirth's reported pure electrolyte density values, using 10—15 data points, whereas those for NaBr and Na_2SO_4 were obtained from Isano's data[12] using five data points for each in the concentration range 0.05—4 M. The values of the pressure derivative parameters and ϕ°_v for the individual electrolytes were then calculated with the help of the Pitzer equation by the nonlinear least squares method. The calculated values for the individual electrolytes, together with the standard deviations of fit (σ) are shown in Table 2. The calculated values of ϕ^*_v at the specified ionic strengths for all the systems mentioned have been incorporated in column 5 of Table 1.

In the Pitzer equation (Eq. 4) the contributions arising out of the interactions between like charges were ignored. However, the consideration of such interactions, called the "mixing terms", gives a better representation for the data studied here. The different binary mixing terms $\theta^v[\equiv\theta_{ik}(m_Am_k\nu_i+m_Bm_i\nu_k)+\theta_{jl}(m_Am_l\nu_J+m_Bm_j\nu_l)]$ both for cation–cation and anion–anion types, are calculated from the difference between the experimental and estimated ϕ^*_v values as usual: $\theta^v=[(\phi^*_{v_{exp}}-\phi^*_{v_{cal}})(m_A+m_B)]/RT$, where m_A, m_B are the molalities of the salts whose cations as well as anions are under consideration for interaction, the ν's being the moles of ionic species produced per mole of the salts (assumed that θ^v_{ii} etc.=0). The θ_{ik} and θ_{jl} values for the NaCl–KCl, NaCl–KBr, and NaCl–K_2SO_4 mixtures considered are shown in Table 3. The extended Pitzer equation for calculating ϕ_{v_i} in a mixture with the use of the mixing terms is obtained by simply adding the term $RT\sum_k \theta_{ik}m_k$ to Eq. 4. Also included in Table 1are the various standard deviations of fit without and with the binary mixing terms for the systems studied (σ_1 and σ_2 respectively).

Mixture Rule. For the calculation of the mean apparent molal volume using Young and Smith's mixture rule,[7] the following equation has been used:

$$\phi^*_v=\frac{n_A\phi_A+n_B\phi_B}{n_A+n_B}, \quad (5)$$

where ϕ^*_v, ϕ_A, and ϕ_B are respectively the apparent molal volumes of the mixtures and the components A and B, all at the same ionic strength. The calculated values of ϕ^*_v at different ional fractions of various systems are shown in column 6 of Table 1. For the calculation of the "mixing terms", the excess volumes of mixing ΔV^{ex}_{mix} for the systems mentioned, which are related to interactions of like charged ions, were calculated by using Millero's equation:[13,14]

$$\Delta V^{ex}_{mix}/\sum_J m_J=\phi^*_{v_{exp(mix)}}-\sum_J m_J\phi'_{v_J}/\sum_J m_J,$$

where ϕ'_{v_J} indicates the $\phi_{v_{exp}}$ value of each individual electrolyte in the mixture at the ionic strength of the

Table 4. Friedman Mixing Parameters Obtained by Least Squares Fit of Eq. 6, for the Three Systems NaCl–KCl, NaCl–KBr, and NaCl–K_2SO_4 at 298.15 K

I	NaCl–KCl		NaCl–KBr		NaCl–K_2SO_4	
mol kg^{-1}	ν_0	ν_1	ν_0	ν_1	ν_0	ν_1
1.0	1.1006	−0.1711	1.2670	−0.1354	1.2007	−0.3062
0.75	1.2089	−0.0882	1.1105	−0.0791	1.0278	−0.3438
0.50	1.0011	0.0252	0.5723	−0.2406	1.4368	−0.5413
0.25	0.8618	0.0595	0.8525	0.0747	1.3815	−0.0631

mixture. The ΔV^{ex}_{mix} values thus obtained are fitted to an equation of the form:[15]

$$\Delta V^{ex}_{mix} = I^2 y_B(1-y_B)[\nu_0+\nu_1 I(1-2y_B)], \quad (6)$$

where ν_0 and ν_1 are related to the ionic interaction parameters[16] (ν_0 to θ_{MN}) and their values are shown in Table 4; (y_B=the ionic strength fraction of component B).

The ΔV^{ex}_{mix} values thus obtained are now incorporated in the ϕ^*_v values estimated from the mixture rule; thus:

$$\phi^*_{v_{cal}} = (\sum_J m_J \phi_{vJ})/\sum_J m_J + \Delta V^{ex}_{mix}/\sum_J m_J, \quad (7)$$

and the standard deviations of fit with the $\phi^*_{v_{exp}}$ values, without and with the mixing terms (σ_3 and σ_4 respectively), are also shown in Table 1 for the NaCl–KCl system mentioned.

Discussion

The ϕ°_v values for NaCl, KBr, NaBr, and KCl obtained in this study are slightly higher than those reported by Kumar for the same systems. We have also calculated the ϕ°_v values using the Redlich–Meyer equation:[17] $\phi_v = \phi^\circ_v + S_v\sqrt{c} + hc$, where S_v is the theoretical limiting slope (=1.868 $cm^3\,dm^{3/2}$ for 1—1 electrolytes at 25 °C) and 'h' is an empirical constant. The different ϕ°_v values obtained from the least squares plots of $(\phi_v - S_v\sqrt{c})$ vs. c are also included in Table 2.

The standard deviations of fit for the ϕ^*_v values of the different mixtures without using the mixing parameters (i.e., σ_1 and σ_3) (Table 1) indicate that for all the mixtures, the Pitzer approach gives better agreement with the experimental values than does the "mixture rule" at the higher two ionic strengths, while at the lower two ionic strengths the agreement is evenly balanced. For the NaCl–KBr mixtures, Humffray[6] observed better agreement using Pitzer's equation at I=1—3 m, while at I=4 m the mixture rule gave a better fit. With the addition of the "volume mixing terms" to Young's rule, as also the interaction terms θ to Pitzer equation, the estimated values of ϕ^*_v in both cases have improved considerably, as is evident from the σ_2 and σ_4 values shown in Table 1. We now find that both the "mixture rule" and the "Pitzer approach" are almost equally successful in predicting the ϕ^*_v values for the mixtures considered.

Figure 1 illustrates the variation of $\phi^{\circ,*}_v$ values of NaCl in the three binary electrolyte mixtures, with different fixed concentrations of KCl, KBr, and K_2SO_4 respectively. The different $\phi^{\circ,*}_v$ values of NaCl in the mixtures containing fixed concentration of the other electrolyte were obtained from the intercepts of various reformulated equations representing the density data. It is interesting to note that the extrapolated ϕ°_v values of pure NaCl obtained by the nonlinear least squares method for the above three types of mixtures containing KCl, KBr, or K_2SO_4 all agree excellently well with the experimental ϕ°_v value of pure NaCl solution.

Very recently Connaughton, Millero, and Pitzer[18] have summarized the Pitzer equations for the volume change on mixing any combination of the four sea salts NaCl, Na_2SO_4, $MgSO_4$, $MgCl_2$ at constant ionic strength. They find that the inclusion of mixing terms based on the differences in the interactions of ions of the same sign is of marginal value at 25 °C. At other temperatures the agreement without the mixing terms is good, but significant improvement is obtained by inclusion of some binary mixing terms. Among the three different mixtures considered by us only the NaCl–K_2SO_4 mixture resembles, as regards the charge type, one of the mixtures considered by Connaughton et al.,[18] namely NaCl–Na_2SO_4 (though the former has no common ions while the latter is a common cation mixture); our other two mixtures are of different charge types than the ones considered by the said authors. The $\theta^v_{Cl^-,SO_4^{2-}}$ value found by Millero is approximately equal to 2×10^{-6} at 25 °C. The values found by us for the same vary from -0.6×10^{-6} to 48×10^{-6} over the ionic strength range 1.0—0.25 mol kg^{-1}.

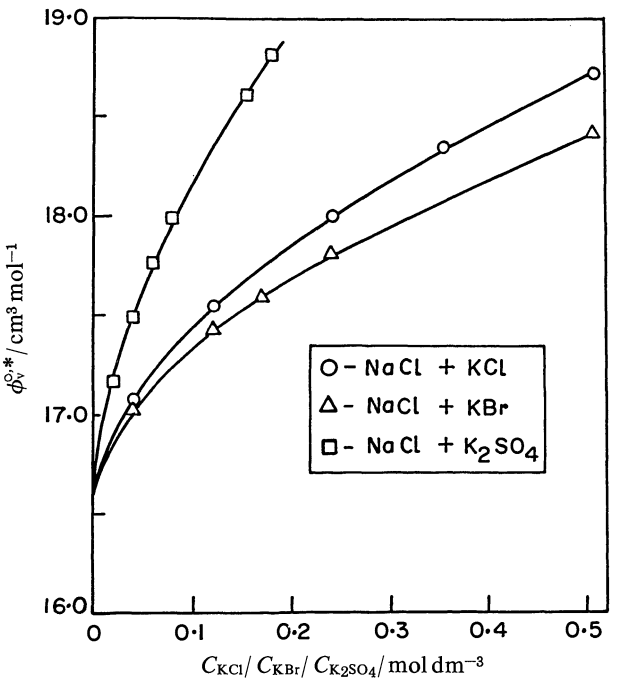

Fig. 1. Variation of $\phi^{\circ,*}_v$ values of NaCl in three binary electrolyte mixtures, with different fixed concentrations of KCl, KBr, and K_2SO_4.

The help received from Swami Satyapriyananda of the R. K. Mission V.C . College, Rahara, in the computer processing of data is thankfully acknowledged.

X-Ray, Electrical and Catalytic Studies of the System $CoFe_2O_4$-Co_2TiO_4

Gulabshankar Ramkhelawan DUBE and Vishnu Shivram DARSHANE*
Institute of Science, 15, Madam Cama Road, Bombay 400032, India
(Received October 18, 1990)

The system $Co_{1+x}Fe_{2-2x}Ti_xO_4$ has been studied with a view to investigating the cation distribution and to correlate the catalytic behavior of spinel with electrical and structural properties. To investigate cation distribution, techniques like X-ray diffraction, electrical conductivity, and thermo emf. have been used. The catalytic evaluation was carried out in the temperature range of 473—673 K using benzyl alcohol as a probe molecule. Our results show $CoFe_2O_4$ to be better catalyst for benzyl alcohol decomposition compared to Co_2TiO_4 or pure oxides of the system.

Oxidic spinels shows interesting electrical, magnetic, and catalytic properties. In these compounds, the properties are controlled by the nature of ions, their charge, and the site distribution amongst tetrahedral and octahedral sites. Several workers[1-3] have reported solid spinel solution of ferrites by substituting ions at tetrahedral and octahedral sites.

Ferrites have been used as efficient catalysts for the decomposition of alkenes,[4,5] hydrogen peroxide,[6,7] and alcohol.[8,9]

We have studied $CoFe_2O_4$–Co_2TiO_4 with a view to investigating the cation distribution and the effect of substitution on the tetrahedral and octahederal sites with reference to catalytic behavior.

Materials and Methods

The different compositions of the system were prepared by coprecipitation techniques.[10] A. R. grade soluble chlorides viz. $CoCl_2 \cdot 6H_2O$, $TiCl_4$ (15% solution), and $FeCl_3 \cdot 6H_2O$ were used to get Co^{2+}, Fe^{3+}, and Ti^{4+} ions in solution.

An aqueous solutions containing these ions in the required molar proportion were prepared by dissolving above salts in distilled water. The corresponding hydroxides were precipitated using 10% NaOH and maintaining the pH between 9.0 and 9.5. The precipitate was heated on water bath at 360 K for 3 h. and was then oxidized by adding calculated amount of 30% H_2O_2 (100% vol) with constant stirring. The precipitate was filtered, washed and dried in vacuum cryostat at 350 K for 2 h.

To measure electrical conductivity and thermoelectric power, pellets were prepared using 2% poly(vinyl acetate) solution as binder. The pellets were heated slowly in air (275 K min^{-1}.) to remove binder and then sintered at 1173 K.

The compositions of the product were checked by chemical analysis and were found to be in agreement with the theoretical values. The particle size was determined from XRD analysis and was found to be approximately 4 μm.

X-Ray powder patterns were recorded on diffractometer (Siemens D-Crystalloflex) using Cu $K\alpha$ radiation with Ni-filter. X-Ray patterns of all the compositions indicated formation of single spinel phase. To measure the intensity, area under different $h\ k\ l$ peaks were determined and the values obtained in relation to the peak area for 311 reflection was taken as 100. To calculate relative integrated intensity, I, of given $h\ k\ l$ reflection, following formula[11] was used where notations have their usual meaning,

$$I_{h\,k\,l} = |F_{h\,k\,l}|^2 \times P \times \frac{1+\cos^2 2\theta}{\sin^2\theta\cos\theta}$$

The atomic scattering power values for various ions were taken from International Table.[12] To determine cation distribution and it's variation with compositions, the intensity ratios I_{200}/I_{400}, I_{220}/I_{440}, I_{422}/I_{400}, I_{400}/I_{422} for different possible models were calculated and compared with the observed intensity ratios.

DC resistivity measurements were carried out using LCR-Markoni bridge. The flat faces of each pellet were coated with thin layer of conducting silver paste and resistivity as well as thermo emf. measurements were carried out from room temperature to 673 K.

Each composition of the system has been investigated for its catalytic activity in the temperature range of 473—673 K. 3.0 g of the powdered catalyst was packed in a 25 cm long quartz

reactor with 10 mm internal diameter. The reactor was equipped with thermocouple to monitor the temperature of the catalyst bed. The vapours of benzyl alcohol were passed over catalyst and the products were condensed using conventional techniques and were analyzed by gas chromatography. The products were further confirmed by GCMS.

Results and Discussion

X-Ray diffractometer patterns of all the compositions showed single spinel phase. The results of X-ray analysis are given in Table 1. From table it is observed that all the compositions of the system possess cubic symmetry. The lattice constant increases linearly from $CoFe_2O_4$ to Co_2TiO_4 obeying Vegard's law. The increase in lattice constant from $CoFe_2O_4$ is due to replacement of Fe^{3+} by slight bigger Co^{2+} and Ti^{4+} ions at octahedral site.

The cation distribution between two sites in the system has been arrived at by X-ray intensity calculations. The observed and calculated intensity ratios for different models for the composition x=0.6 is given in Table 2. From table, it is observed that the model with Ti^{4+} at B-site, Co^{2+} both A- and B-sites while Fe^{3+} distributed equally between A- and B- site shows better agreement. Our results on cation distribution are in close agreement with the values reported earlier on $CoFe_2O_4$ and Co_2TiO_4.[13,14]

Electrical Properties: DC resistivity of the compounds of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$ measured as a function of temperature varied between 10^6 and 10^7 ohm-cm. The plot of $\log\rho$ vs. $10^3/T$ showed a linear nature obeying Wilsen's law.

$$\rho = \rho_o \exp(\Delta E/KT).$$

High values of resistivity indicate that elements with stable oxidation state are present at B-site.

From Table 1, it is observed that with subsequent replacement of Fe^{3+} by Co^{2+} and Ti^{4+} activation energy increases. This is due to the fact that Ti^{4+} (d^0) orbitals have much lower energy i.e. they are very stable and are much more contracted than Fe^{3+} d-orbitals. Also as concentration of Fe^{3+} ion decreases in the lattice, the mobility of charge carriers decreases resulting in the increase in the activation energy.

Thermoelectric coefficient values of the series varied between -40.00 and $+255.00\ \mu V\ K^{-1}$. The compounds with $x \leqslant 0.2$ are n-type while $0.4 \leqslant x \leqslant 1.0$ are p-type (Table 1) semiconductors. p-Type semiconductivity of cobalt rich compounds can be attributed to the formation fo Co^{2+}/Co^{3+} ion pairs but unfortunately the presence of Co^{3+} ions could not be detected from X-ray intensity calculations as the concentration may be very small.

Catalytic Studies: Decomposition of benzyl alcohol has been reported by several workers using pure metal

oxides and various zeolites.[15–18] However literature survey indicates that not much work has been reported where spinels have been used as catalysts for the decomposition of benzyl alcohol.

Decomposition of benzyl alcohol mainly yields benzaldehyde and toluene.

$$C_6H_5CH_2OH \xrightarrow{\text{Catalyst}} C_6H_5CHO + 2H^*$$
$$C_6H_5CH_2OH + 2H^* \longrightarrow C_6H_5CH_3 + H_2O$$

Results of benzyl alcohol decomposition over various compositions of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$ are listed in Table 3. From table it is observed that conversion of benzyl alcohol on $CoFe_2O_4$ is always greater at all the temperatures compared to other catalyst compositions. The conversion of benzyl alcohol vs. temperature for the various compositions of the system is reported in Fig. 1. Further from Fig. 1 it is observed that conversion of benzyl alcohol decreases from $CoFe_2O_4$ to Co_2TiO_4. The decreases in the catalytic activity from cobalt-ferrite to cobalt titanate can be explained on the basis of cation distribution in the spinel.

$CoFe_2O_4$ being an inverse spinel, Fe^{3+} ions are present both, tetrahedral as well as octahedral site. Since Fe^{3+} can hop between +2 and +3 states, provide more active centers for the catalytic reaction. Therefore $CoFe_2O_4$ is more active. Subsequent replacement of Fe^{3+} by Co^{2+} and Ti^{4+} ions, an equivalent amount of Fe^{3+} ion is replaced by Co^{2+} at A-site while at B-site, it is substituted by Ti^{4+} ion. Thus B-site of the spinel system is occupied by the ions with stable oxidation state (Ti^{4+} and Co^{2+}) with increase in concentration of X which favors the formation of benzaldehyde, a dehydrogenation product.

With decrease in the iron(III) concentration in the spinel, toluene selectivity decreases and aldehyde selectivity increases indicating that ions at tetrahedral site are

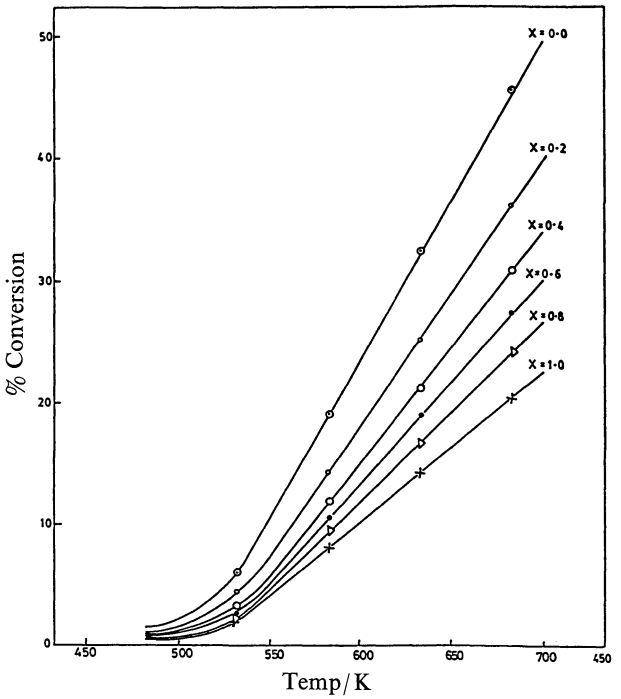

Fig. 1. Plot of % conversion of benzyl alcohol vs. temp over different compositions of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$.

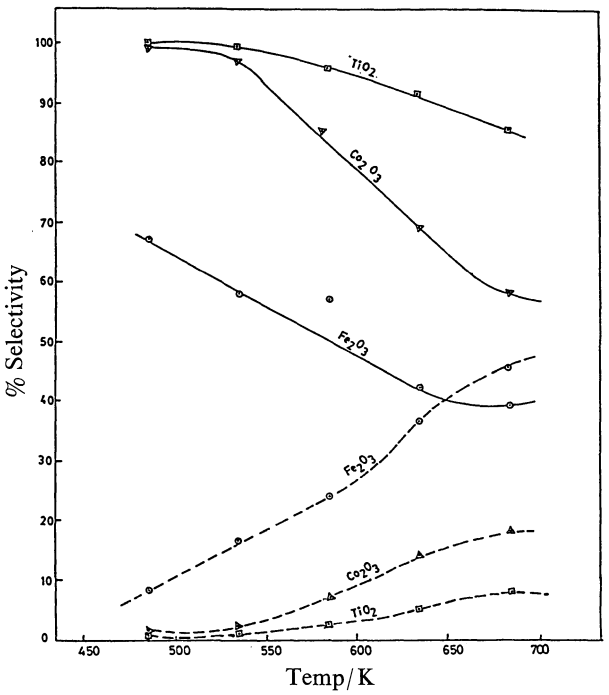

Fig. 2. Plot of aldehyde (——) and toluene (– –) selectivity of pure oxides vs. temp of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$.

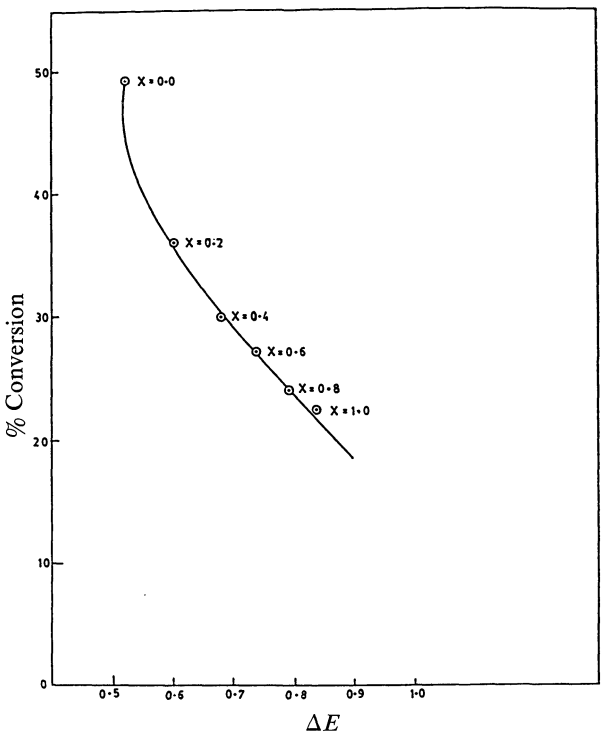

Fig. 3. Plot of % conversion vs. activation energy for the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$ at 673 K.

responsible for the reduction of benzyl alcohol. Similar results have also been reported by Onchuku[19] in the investigation of decomposition of hydrogen peroxide using Cu–Ni–ferrite system.

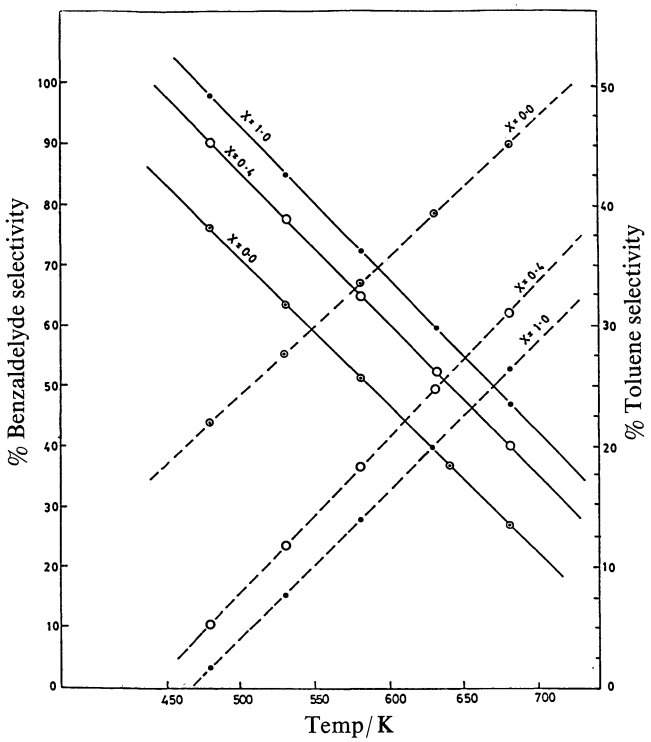

Fig. 4. Plot of % benzaldelyde and toluene selectivity over x=0.0, 0.4, and 1.0 for the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$.

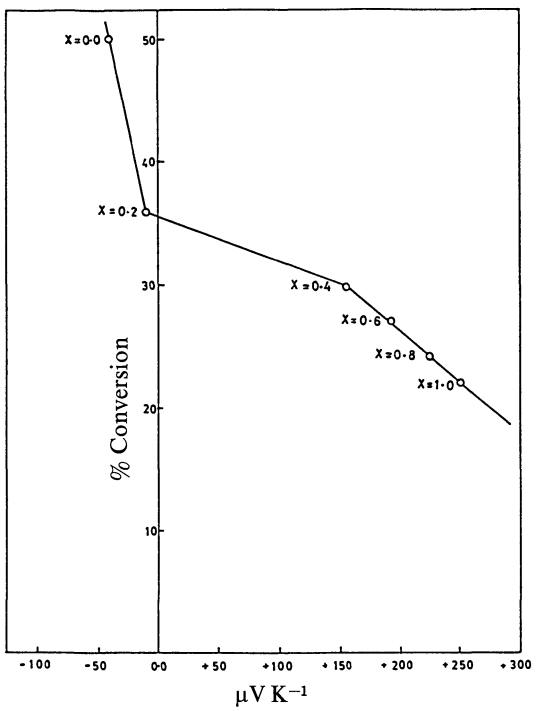

Fig. 5. Plot of % benzyl alcohol conversion vs charge carrier of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$.

The above observation is further supplemented by Fig. 2 which gives toluene selectivity over pure oxides of the system i.e. Fe_2O_3, Co_2O_3, and TiO_2. From Fig. 2 it is observed that Fe_2O_3 and Co_2O_3 yield maximum toluene while TiO_2 gives mainly benzaldehyde.

The substitution of Co^{2+} and Ti^{4+} results in the increase in the activation energy of the system from 0.52 eV ($CoFe_2O_4$) to 0.83 eV (Co_2TiO_4). Further from Fig. 3 it is noted that $CoFe_2O_4$ is the most active catalyst with the highest percentage conversion (49.62%) over any titanium containing compositions. The change in activation energy greatly influences the catalytic activity. The catalytic activity is due to transfer of electrons/holes from catalyst surface to substrate and is reversible. Hence greater the value of activation energy more will be the energy required for electronic transitions resulting in decrease in catalytic activity i.e. decrease in percentage benzyl alcohol decomposition.

From Fig. 4 it is observed that aldehyde selectivity increases and toluene selectivity decreases with increase in value of x. $CoFe_2O_4$ indicated 75.85% benzaldehyde selectivity at 473 K while at the same temperature Co_2TiO_4 showed 97.62% selectivity (Table 3).

It is well known that n-type semiconductors are always more active and selective towards dehydration of alcohols due to rapid migration of electrons while p-type semiconductors are active and selective towards dehydrogenation due to migration of holes.[20] The effect of nature of charge carriers on the catalytic activity of spinels is shown in Fig. 5. $CoFe_2O_4$ (α=40 $\mu V K^{-1}$) is most active for dehydration due to $Fe^{3+} \rightleftarrows Fe^{2+} + e^-$ hopping process (Table 3) where electrons are predominently the charge carriers. As the concentration of iron(III) decreases in the lattice ($x \geqslant 0.4$) the holes become predominent charge carriers result in decrease in overall catalytic activity.

Conclusion

Thus from X-ray intensity, electrical conductivity and thermo emf measurements the probable cation distribution of the system $Co_{1+x}Fe_{2-2x}Ti_xO_4$ is suggested as $Co_x^{2+}Fe_{1-x}^{3+}[Co_{1.0}^{2+}Fe_{1-x}^{3+}Ti_x^{4+}]\ O_4^{2-}$. Further it is observed that $CoFe_2O_4$ is most active catalyst towards benzyl alcohol decomposition while Co_2TiO_4 is most selective dehydrogenation catalyst.

Raman Phonon Spectroscopic Study of Phase Transition in *trans*-Stilbene Crystal

Subhasis CHAKRABARTI and Tridibendra Narayan MISRA*
Department of Spectroscopy, Indian Association for the Cultivation of Science, Calcutta 700032, India
(Received November 19, 1990)

Raman phonon spectroscopy in the 10—170 cm^{-1} range has been used to study phase transition in *trans*-stilbene crystal. At 77 K, eight distinct phonon modes and an internal mode are observed whereas at 300 K the spectrum shows only four phonon bands and an internal mode. The temperature dependence of spectral pattern and some phonon band width suggest that the phase transition in this crystal is quasi-continuous over a small temperature range 215—225 K. The absence of a soft mode and a strong increase of the phonon band width, when approaching the T_c from below, suggest that the phase transition is of order-disorder type. The well established disordered structure of *trans*-stilbene crystal at room temperature attains an ordered structure at low temperature at least through one, possibly two order–disorder transitions.

Raman phonon spectroscopy has been used extensively to investigate phase transition in crystals.[1—4] Phonon spectroscopy is suited for such studies particularly in organic molecular crystals due to the fact that in such crystals the intermolecular forces are 10—100 times weaker than the intramolecular forces and the internal and external motions of molecules in most cases fall in different domain of frequencies. The lattice vibrational frequencies in organic crystals generally lie below 200 cm^{-1}. In *trans*-stilbene crystal, however, some internal modes representing torsion of the phenyl ring also lie in this low frequency range and the Raman active internal modes in this spectral range has been identified by Bree and Edelson.[5] We have used this Raman phonon spectroscopic technique to study phase transition in *trans*-stilbene crystal.

trans-Stilbene is a very flexible molecule in the ground state. The crystal belongs to the monoclinic space group $P2_1/c$ with four molecules in the unit cell.[6,7] At room temperature however the structure is highly disordered, one of the two independent sites shows orientational disorder.[6] In contrast to that at 300 K, at 113 K, the second orientation of the molecule at one of the sites almost disappears and the lattice becomes more ordered.[8] No studies of phase transition in *trans*-stilbene crystal based on standard X-ray or neutron diffraction technique seem to have been reported. Extensive Raman spectroscopic study of this crystal both in external lattice modes and in internal molecular modes by Bree and Edelson[5] did not observe any phase transition in 113—4.2 K range as no significant change in relative intensities of internal modes could be detected by them. However contrary to that observed in first-order structural phase transition, no sharp change in frequency or intensity may occur in second-order phase transition. Also often it is difficult to identify slow and gradual change in Raman band intensity. The study of Bree and Edelson[5] was, however, less extensive at high temperature domain.

Temperature dependence of phonon band width has been shown to be very useful to indicate phase transition in organic crystals.[3] The band width broadening is often related to the progressive setting of disorder when temperature increases.[9,10] When the translational symmetry of the crystal breaks due to disorder, some modes of the whole Brillouin zone can become Raman active. This broadens the phonon bands of the dispersive modes. Phase transition in this crystal at high-temperature domain has recently been reported by Ghoshal et al.[11] by "Photokinematical Approach" which utilized a luminescence intensity change of a dopant as the host crystal goes through a phase transition temperature. They identified two phase transitions in this crystal.

We have undertaken a careful study of Raman phonon spectral pattern and their band widths as a function of temperature. Our studies add further credence to the luminescence technique developed by Ghoshal et al.[11] for phase transition studies and in addition provide information about the nature of phase transition.

Experimental

The compound *trans*-stilbene was obtained from M/S Aldrich Chemical Company Ltd., U.S.A. and purified by repeated crystallization from benzene followed by zone refining with 75 passes. Crystals were grown in a bridgman furnace. Both polycrystalline samples and single crystals were used to obtain the Raman spectra. Unfortunately polarized spectra could not be studied due to lack of facilities.

Raman spectra were obtained using a Spex double monochromator Model 1403 and the 5145 Å line of Spectra Physics Model 2020-5 Argon Ion Laser. Spex Datamate 1B was used for data acquisition and analysis and the band position should be accurate within 1 cm^{-1}. A Superveritemp model 10DT of Janis Research U.S.A. was used to cool the crystal from room temperature down to 77 K. Temperatures were measured and controlled by Lake Shore Model 805 temperature controller. Liquid nitrogen temperature spectrum was run with the crystal immersed in the cryogen.

Results and Discussion

Temperature Dependence of Phonon Spectra. In *trans*-stilbene crystal, the four molecules in the unit cell occupy the inversion centers. Twelve librational phonons are expected to be Raman active. The Raman phonon spectra of *trans*-stilbene crystal at a series of

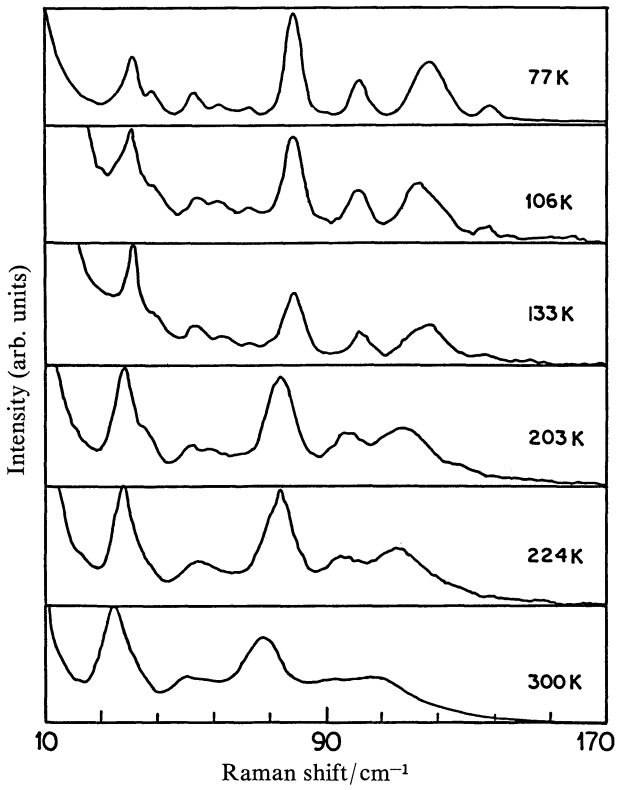

Fig. 1. Raman phonon spectra of *trans*-stilbene crystal at several temperatures. The spectral resolution is 1 cm^{-1}.

temperature are shown in Fig. 1. At 77 K, nine distinct low frequency modes at 34.4, 39.4, 52.2, 60.6, 68.2, 81.0, 99.4, 118.8, and 135.2 cm^{-1} are observed whereas at 300 K, only five broad bands at 29.4, 51.8, 71.8, 92.5, and 101.2 cm^{-1} persist. The 92.5 and 101.2 cm^{-1} bands at 300 K are very broad and are hardly resolved. Our low frequency Raman spectra at 77 K and that reported by Bree and Edelson[5] at 4.2 K can be compared and the bands can be easily correlated. Such correlation is shown in Table 1. Bree and Edelson assigned the quartet at 120.7, 123.4, 127.0, and 131.7 cm^{-1} as factor-group split components of an internal mode. We accordingly assign our 118.8 cm^{-1} band as an internal mode and the remaining eight as lattice modes.

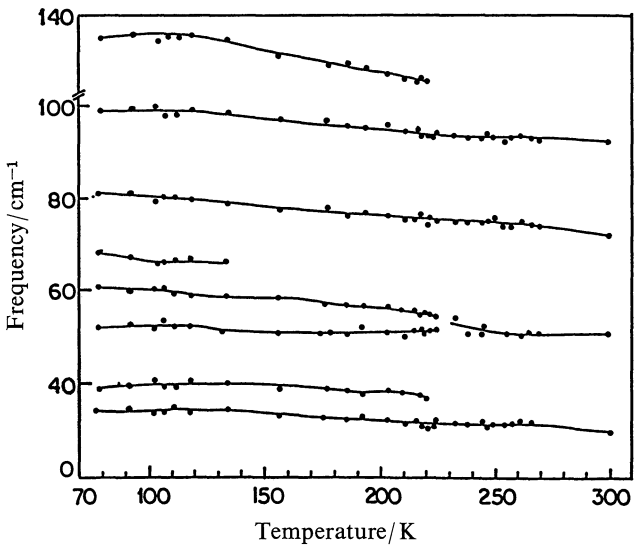

Fig. 2. Temperature dependence of Raman active lattice phonon frequencies in *trans*-stilbene crystal.

A close inspection of the spectra in Fig. 1. reveals that some distinct changes occur in a small temperature range 215—225 K. The medium intense broad phonon band of frequency 51.8 cm^{-1} observed at 300 K flattens out and splits into two bands of frequencies 51.2 and 57.2 cm^{-1} in the 215—225 K temperature range. A third component appears and becomes distinctly observable at 133 K as a phonon band of frequency 66 cm^{-1}. All these three bands intensify and shift to higher frequencies with cooling. At 220 K a third band at 124.8 cm^{-1} appears. These bands intensify and shift to higher frequencies as the temperature is lowered.

The temperature dependence of the Raman active phonon frequencies is shown in Fig. 2. As the temperature is raised, the phonon frequencies shift to lower values. The phonon band around 40 cm^{-1} shows a gradual decrease in intensity with increasing temperature and disappears after 215—225 K. Similar behavior is observed in the 135.2 cm^{-1} phonon band. The triplet structure in the 52—68 cm^{-1} region observed at low temperature fuses into a single broad band in this temperature domain. Further the intensity ratio of 29.4 and 71.8 cm^{-1} bands at 300 K and the corresponding bands at 34.4 and 81.2 cm^{-1} at 77 K are significantly different and this change occurs in the temperature domain 215—225 K.

All these results suggest that there is a continuous phase transition in *trans*-stilbene crystal spread over a small temperature range 215—225 K.

Temperature Dependence of Phonon Band Width. Temperature dependence of phonon band width indicates phase transition in organic crystals.[3] In Fig. 3 we

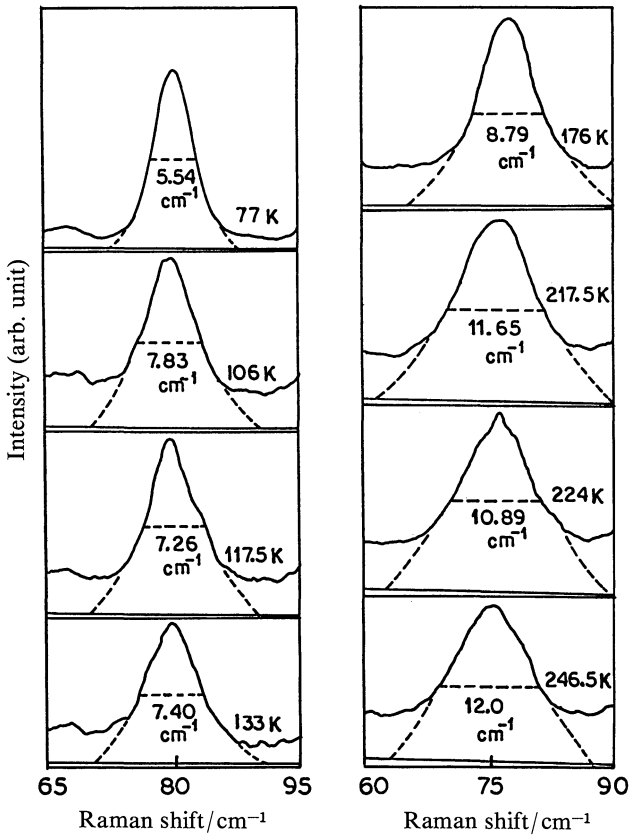

Fig. 3. Band widths (FWHM) of 81 cm^{-1} (at 77 K) band at several temperatures in extended scale. Extrapolation of the bands to the base line is shown by broken lines.

show 81 cm^{-1} (at 77 K) phonon band in extended scale at several temperatures near the transition regions and in Fig. 4. temperature dependence of band widths of 81 and 34.4 cm^{-1} (at 77 K) phonon bands are shown. The variation of width seems to be continuous or very close to be so except at two temperature domains where the continuity pattern is broken and the width shows some small but definite decrement with temperature rise. One of the break points of the curves coincides with the transition temperature region 215—225 K suggested by the temperature dependence of phonon spectral patterns. The other break point in the 105—115 K temperature region is not indicated in the spectral pattern. The change in the band width for this temperature region, however, seems to be within the error bar of the experimental Raman resolution and no definite conclusion about a phase transition at this temperature range can be drawn. The break points in the continuity pattern of the band width-temperature plot is more pronounced in 81 cm^{-1} phonon than in 34.4 cm^{-1} band. This is possibly due to the fact that the 34.4 cm^{-1} phonon band overlaps with other band at 39.4 cm^{-1} and the overlapping becomes significant at higher temperature. For the other modes, the quantitative analysis of their band widths has not been possible owing to their multiple overlapping.

Temperature Dependence of Internal Modes. We have also studied the Raman spectra of the crystal representing internal modes of *trans*-stilbene molecule at various temperatures. There is no significant change in the internal modes except that with lowering of temperature the frequencies change slightly to the higher values. However, the B_g mode at 558 cm^{-1} and the A_g mode at 869 cm^{-1} show distinct intensity reversal in a small temperature range around 110 K. This is shown in Fig. 5. This temperature domain agrees with the low temperature peak in the temperature dependence of band width plot as shown in Fig. 4. Ghoshal et al.[11] suggested a phase transition in the *trans*-stilbene crystal at this temperature from their luminescence studies. The agreements of our two approaches coupled with the photokinematical report of Ghoshal et al.[11] about a second phase transition at 110±5 K is interesting.

Nature of Phase Transitions. In first-order phase

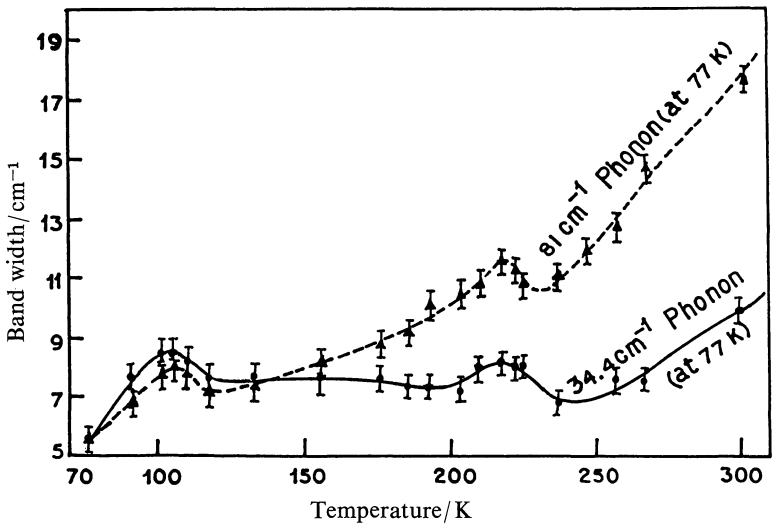

Fig. 4. Temperature dependence of band widths of Raman phonon bands of *trans*-stilbene crystal.

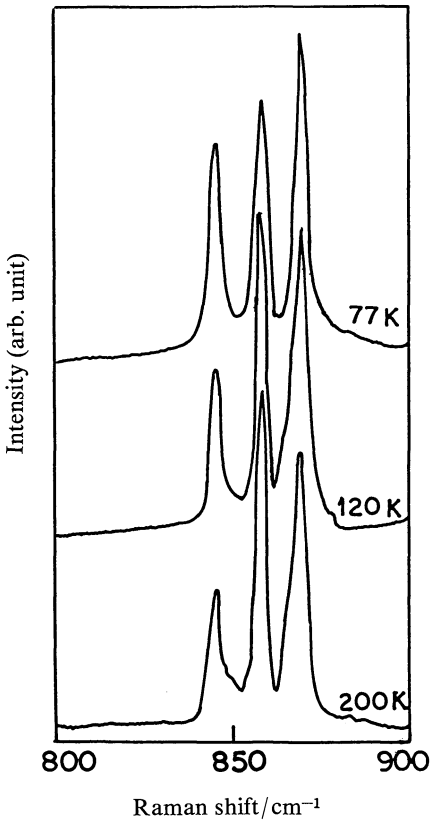

Fig. 5. Raman spectra of *trans*-stilbene crystal in 800—900 cm^{-1} region at several temperatures.

transition, the structural deformation occurs abruptly at one temperature. The second-order phase transition, on the other hand, is continuous and occurs over a temperature range. In *trans*-stilbene we find progressive evolution of phonon spectra as the critical temperature T_c (spread over a range) is approached with no sudden change. The phase transition of this crystal is quasi-continuous (pseudo-second order).

Order–disorder transition is described by a double well potential near T_c. In the phase above T_c there is large amplitude motions from one potential well to another. Below T_c, the molecules lie on the same side of the double well and oscillation occurs in an essentially quadratic well. The system then can be characterized by two characteristic frequencies, one is quasi-harmonic frequency within either side of the double well and a second frequency which describes the relaxational behavior from one well to the other.

In some cases where order–disorder phase transition is established,[12] a large enhancement of Rayleigh intensity is observed as T_c is approached from above. This has been attributed to the relaxational mode describing the jump from one side of the double well to the other. In our experimental result though such enhancement of Rayleigh intensity is not unequivocally established as the first phase transition temperature domain 215—225 K is reached. Such intensity enhancement is, however, observed as 105—115 K is approached. This is evident from Fig. 1. The second order–disorder phase transition at 105—115 K as proposed from "Photokinematical Approach" therefore, seems plausible.

X-Ray analysis shows that at room temperature, the structure of *trans*-stilbene is not highly ordered. One of the two independent sites show orientational disorder.[6] It is, therefore, expected that an ordered structure will be attained at some lower temperature. Indeed at about 113 K, the second orientation of the molecules in the lattice is hardly present.[8] It thus seems that the disordered structure of *trans*-stilbene crystal at 300 K attains the ordered structure at low temperature through at least one order–disorder transition.

Conclusion

We have used Raman phonon spectroscopy to study phase transition in *trans*-stilbene crystal. The temperature dependence of spectral pattern and phonon band width suggest that there is a quasi-continuous phase transition over a small temperature range 215—225 K. The absence of a soft mode and a strong increase of the phonon band width when approaching the T_c from below suggest that the phase transition is of order–disorder type. The disordered structure at room temperatute attains an ordered structure at low temperature through at least one, possibly two order–disorder transitions.

(Received November 13, 1990)

An oxomolybdenum(V) complex with two chelating ligands of alkane- and arenethiolate parts, $(NEt_4)[Mo^VO(\alpha,2\text{-toluenedithiolato})_2]$, was prepared and characterized by visible, ESR, IR, and Raman spectroscopies. Four distinct ligand-to-metal charge transfer absorption bands were observed in visible region. The complex crystallizes in the space group $P2_1$ with a=9.535(2), b=16.582(9), c=8.085(1) Å, β=90.757(4)°, V=1278.3(8) Å^3, Z=2, and d_{calcd}=1.431 g cm^{-3}. The structure was solved and refinement based on 2102 reflections converged at R=0.089 and R_w=0.100. The complex takes an apical oxo and trans bis(α,2-toluenedithiolato) structure with a distorted $MoOS_4$ core from a tetragonal-pyramidal geometry.

The molybdenum center of sulfite oxidase has been considered to be bound to a bidentate dithiolene ligand connecting pterin and phosphate groups.[1,2] Recent EXAFS and ESR results indicate that the molybdenum center has one or more thiolate ligands besides the dithiolene ligand.[3,4] A $(Mo^VO)^{3+}$ complex having an unsymmetrical chelating dithiolato ligand has become of interest because tetrapeptide, Cys–X–Y–Cys (X,Y=amino acid residues), has a possibility to serve as an unsymmetrical dithiolate to activate $(Mo^VO)^{3+}$ ion.[5]

A simple model complex, $[Mo^VO(SPh)_4]^-$,[6] has been studied in detail. Some monooxomolybdenum(V) complexes having symmetrical dithiolate chelates have been reported as the precursor model complexes for the resting species of the active site of molybdoenzyme, e.g. $(Mo^VO(SCH_2CH_2S)_2]^-$,[7] $[Mo^VO(bdt)_2]^-$ (bdt=1,2-benzenedithiolato).[8] Relation between the number of thiolate ligands and the ESR parameter in $(MoOL_{4-x}L'_x)^-$ has been established.[9—11] Monooxomolybdenum(V) complexes have been systematically studied using a tridentate chelating ligand, e.g. hydrotris(3,5-dimethyl-1-pyrazolyl)borate.[12]

Complexation of two dithiolene type ligands and two alkanethiolates to $(MoO)^{3+}$ ion in unsymmetrical dithiolate, α,2-toluenedithiolate, seems to form an appropriate model complex for the active center of sulfite oxidase.

Experimental

All procedures were performed in argon atmosphere by the Schlenk technique. All solvents were dried and distilled under argon gas before use.

$(NEt_4)[Mo^VO(SPh)_4]$ was prepared by the reported method.[6] α,2-Toluenedithiol was synthesized by standard literature methods.[13]

Synthesis of (NEt_4) $[Mo^VO(\alpha\text{-tdt})_2]$ (α-tdt=α,2-toluenedithiolato) (1). The titled complex was synthesized by the following two methods. The crystals for the X-ray analysis were obtained by the method a.

a) From $(NEt_4)[MoO(SPh)_4]$ with Ligand Exchange Method. To a DMF solution (5 ml) of 35.7 mg (0.04 mmol) of $(NEt_4)[Mo^VO(SPh)]$ was added 0.017 ml (0.09 mmol) of α,2-toluenedithiol at room temperature. The solution was stirred overnight at room temperature and concentrated in vacuo to 0.5 ml volume. Addition of 10 ml of diethyl ether gave dark blue powder. The powder was collected with filtration and washed with 5 ml of diethyl ether. Recrystallization from DMF–diethyl ether gave dark blue microcrystals in 70% yield. Found: C, 47.13; H, 5.90; N, 2.75%. Calcd for $C_{22}H_{32}NOS_4Mo$: C, 47.98; H, 5.86; N, 2.54%.

b) From $MoOCl_3(thf)_2$. To an acetonitrile solution (10 ml) of 0.05 ml (0.3 mmol) of α,2-toluenedithiol and 0.09 ml (0.6 mmol) of triethylamine was added dropwise an acetonitrile solution of $MoOCl_3(thf)_2$ (58 mg, 0.16 mmol) at 0 °C. The solution turned dark green and was allowed to stand at room temperature for 5 h, before tetraethylammonium chloride (30 mg, 0.18 mmol) in methanol (6 ml) was added. After filtration the filtrate was concentrated in vacuo to 2 ml. Addition of methanol (30 ml) to the solution gave dark purple powder. The crude product was recrystallized from acetonitrile–methanol. Yield, 53%. Found: C, 47.17; H, 5.71; N, 2.61%. Calcd for $C_{22}H_{32}NOS_4Mo$: C, 47.98; H, 5.86; N, 2.55%.

Physical Measurements. Visible spectra were recorded in a solution of **1** or in a KBr disk on a JASCO Ubest-30 spectrophotometer. Infrared spectrum was taken in 400—200 cm^{-1} region as Nujol mulls and in 1000—400 cm^{-1} region as a KBr disc on a JASCO DS-402G spectrophotometer. Raman spectrum was obtained on a JASCO R-800 spectrophotometer equipped with an HTV-R649 photomultiplier. A powder sample in a capillary was irradiated with a 632.8 nm He–Ne laser excitation line. The frequency calibration of the spectrometer was carried out with indene as a standard. Electrochemical measurements were carried out using a Yanaco P-1100 instrument in acetonitrile solution that contained 0.1 M (1 M=1 mol dm^{-3}) tetrabutylammonium perchlorate as a supporting electrolyte. $E_{1/2}$ value, determined as $(E_{p,a}+E_{p,c})/2$, was referenced to the SCE electrode at room temperature and a value uncorrected with junction potential was obtained. ESR spectra in DMF–acetonitrile (1/4, v/v) were recorded on a JEOL JES-FE1X spectrometer at room temperature and at ca. 80 K.

X-Ray Structure and Determination. Single crystals of **1** grew from acetonitrile–ethanol. The crystal was sealed in a glass capillary under argon atmosphere for the X-ray measure-

ment. The space group and approximate cell dimensions of the crystal were determined from oscillation and Weissenberg photographs. X-ray measurement was performed at 20 °C on a Rigaku AFC-4 diffractometer equipped with a Rotaflex rotating anode X-ray generator. The radiation used was Mo$K\alpha$ monochromatized with graphite (0.71069 Å). No absorption correction was made, although Lorentz and polarization corrections were applied. The basic crystallographic parameters for **1** are listed in Table 1. Unit cell dimensions were refined with 25 reflections. Three standard reflections were chosen and monitored with every 100 reflections and did not show any significant change. The positions of Mo, O, and S atoms were determined by the direct method using MULTAN 80. Subsequent Fourier synthesis based on the phases of Mo, O, and S atoms revealed the positions of the remaining non-hydrogen atoms. The final refinement was carried out using full-matrix least-squares techniques with non-hydrogen atoms. The y coordinate of the molybdenum atom was fixed in the refinement. The refinement with anisotropic thermal parameters is converged at R=0.089. Atom scattering factors and dispersion corrections were taken from the International Table.[14] The absolute configurations of the structure were determined from five Bijvoet pairs of reflections with large differences in $|F_o|$.

EHMO Calculations. In order to simplify extended Hückel MO calculations using an NEC PC-98 EHMO program obtained from Kodansha Sci. Co., $[Mo^VO(SCH{=}CH\text{-}CH_2S)_2]^-$ was employed instead of $[Mo^VO(\alpha\text{-tdt})_2]^-$ as a model complex. Two geometries were examined in the above model complex to evaluate the distortion of the Mo^VOS_4 core in $[Mo^VO(\alpha\text{-tdt})_2]$. One is a C_{4v} $MoOS_4$ core using the crystallographical parameters of $[Mo^VO(SPh)_4]^-$ reported in a literature.[6] Another is an idealized C_2 structure in $[Mo^VO(SCH{=}CH\text{-}CH_2S)_2]^-$ although $[Mo^VO(\alpha\text{-tdt})_2]^-$ as determined in this work has an approximate C_2 structure in Fig. 2. Mo–O, Mo–S, S–C, C–C, and C–H bond distances used are 1.680, 2.403, 1.760, 1.540, and 1.070 Å, respectively. A value, 109.9°, was employed for both Mo–S–C–H(CH_2) and Mo–S–C–H(CH=) torsion angles. A torsion angle, 120°, was adopted for S–C(H)=C–H and S–C(H_2)–C–H. The EHMO atomic parameters for Mo(V) were taken from a literature.[15]

Results and Discussion

Crystal Structure. The complex crystallizes in the space group $P2_1$ and the unit cell contains two $[Mo^VO(\alpha\text{-tdt})_2]^-$ anions and two NEt_4^+ cations. An ORTEP view of the $[Mo^VO(\alpha\text{-tdt})_2]^-$ ion is shown in Fig. 1. Only a trans isomer was obtained by the present synthetic method.

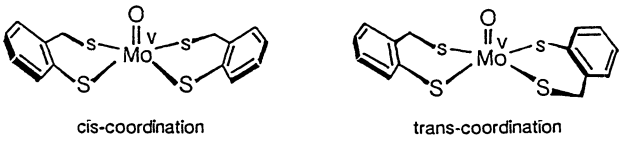

Table 2 lists the atomic coordinates of the non-hydrogen atoms and the estimated standard deviations. Selected bond distances and angles are listed in Table 3.[16] The coordination around the molybdenum atom is a distorted tetragonal-pyramidal geometry with an approximate C_2 symmetry, containing the one terminal oxo, the two alkanethiolato and the two arenethiolato ligands. The Mo=O distance is 1.688(18) Å which is in a range 1.64—1.72 Å observed for various Mo(V)=O

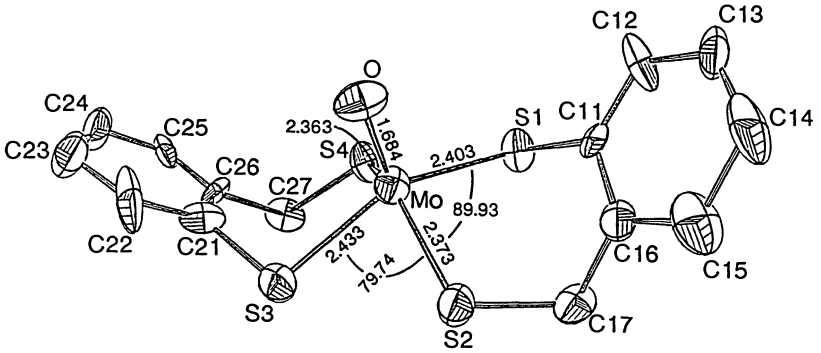

Fig. 1. ORTEP view of $(NEt_4)[Mo^VO(\alpha\text{-tdt})_2]$ (**1**) showing the atom-labeling scheme.

complexes. Two types of Mo–S bonds were found; longer ones (2.40(1) Å and 2.43(1) Å) for the molybdenum-arenethiolate and shorter ones (2.37(1) Å and 3.37(1) Å) for the molybdenum-alkanethiolate bonds. This trend is expected from the difference in the bond lengths between $[Mo^VO(SPh)_4]^-$ and $[Mo^VO(SCH_2CH_2S)_2]^-$.[6,7] The larger S pπ-donation of alkanethiolato ligand to $(MoO)^{3+}$ contributes to increase of the Mo–S bond order. Figure 2 shows the schematic drawing of the distortion in **1**. The two alkanethiolate Mo–S bonds give larger O–Mo–S bond angles (mean 112°) and a smaller trans S–Mo–S angle (136.2(3)°) while the two arenethiolate Mo–S bonds provide smaller O–Mo–S bond angles (mean 105°) and a larger trans S–Mo–S (150.1(3)°). The Mo^VOS_4 core

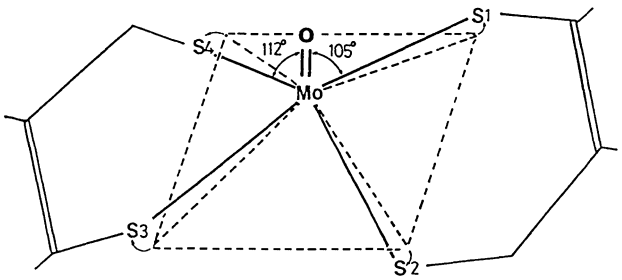

Fig. 2. Schematic drawing of the distortion of $(NEt_4)[Mo^VO(\alpha\text{-tdt})_2]$ (1).

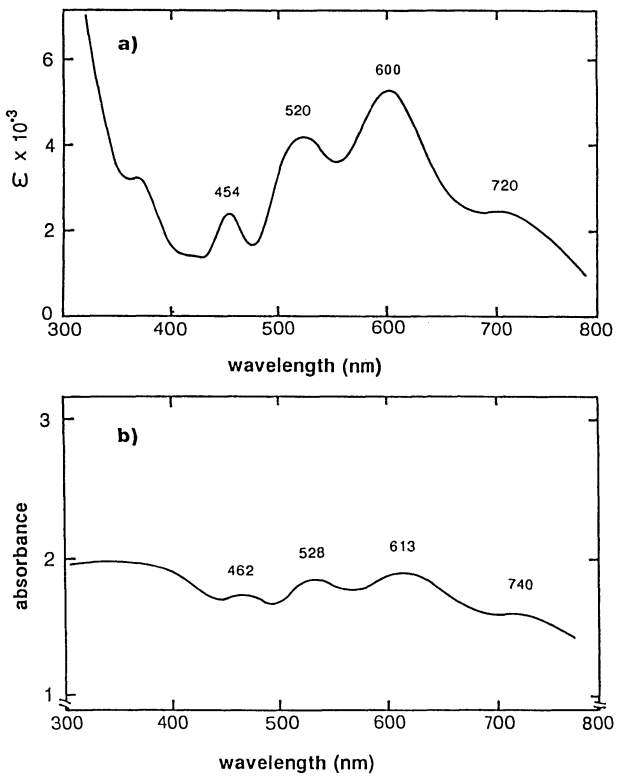

Fig. 3. Visible spectra of $(NEt_4)[Mo^VO(\alpha\text{-tdt})_2]$ (1) a) in acetonitrile solution and b) in the solid state (KBr matrix).

of $[Mo^{V}O(SPh)_4]^-$ was reported to have two O–Mo–S angles, 108.5(3)° and 111.2(3)°. Only one example for similar distortion has been reported for $[Mo^{V}O(SCH_2CH_2CH_2S)_2]^-$ which has two kinds of large trans S–Mo–S angle (149.9(1)° and small trans S–Mo–S angle (138.8(1)°).[17] The presence of two kinds of S–Mo–S bond angles is probably due to the large bite angle ca. 89° of α,2-toluenedithiolate. It is noticeable that the distortion of the $MoOS_4$ core in **1** is the largest among the known ones.

Properties of 1. Figures 3-a and 3-b shows the visible spectra of **1** in solution and in the solid KBr matrix, respectively. Four distinct absorption maxima were observed at 454 nm (ε, 2300 $mol^{-1}cm^{-1}$), 520 nm (4100), 600 nm (5200), and 720 nm (2300) in an acetonitrile solution. Four maxima at 462, 528, 613, and 740 nm were also obtained in the KBr matrix with the same ratio of the absorbance as shown in Fig. 3-b. The spectra of **1** indicate that only the trans isomer exists both in solutions and in the solid state as established by the crystallographic analysis. These intense absorption maxima (ε, 2300—5200 $mol^{-1}cm^{-1}$) could be assigned to ligand-to-metal charge-transfer (LMCT) bands. Actually, the broad absorption maxima due to LMCT in the visible region of approximate C_{4v} Mo(V)=O complexes, e.g. 602 nm (6400 $mol^{-1}cm^{-1}$ in acetonitrile) for $(NEt_4)[Mo^{V}O(SPh)_4]$, have been extensively studied by Ellis et al.[18] They have pointed out that the low energy d-d transition due to Mo(V)=O group is masked by the dominant LMCT bands. For example, only a weak absorption maximum has been reported at 670 nm with 20 $mol^{-1}cm^{-1}$ in this region for $[Mo^{V}OCl_4]^-$ in CH_2Cl_2.[19]

EHMO calculations were carried out to interpret the difference between the ideal square-pyramidal structure (four trans S–Mo–S angles are 140°) and the distorted structure (two trans S–Mo–S angles are 136° and 150°) in $[Mo^{V}O(SCH_2CH{=}CHS)_2]^-$. The distorted structure corresponds to that of **1** analyzed cystallographically. No significant difference was found in the energy levels of d-orbitals between them. This result suggests that the four distinct absorption maxima are ascribed not to d-d transition but to the ligand-to-metal charge transfer from two or more sulfur pπ orbitals to Mo(V) d_{xy} orbital as induced by the lower symmetry of α,2-toluenedithiolate. Figure 4 shows the IR and Raman spectra of **1** in solid state. The Raman and IR spectra in solid state showed a strong ν(Mo=O) mode at 940 and 938 cm^{-1}, respectively. An IR Mo=O band has been reported to appear in the same region at 929 cm^{-1} for $(NEt_4)[Mo^{V}O(SPh)_4]$.[6] The higher-wavenumber shift is ascribed to the less π-donor ability of arenethiolate ligand than alkanethiolate liagnd. Actually, the higher-wavenumber shift has been established in the case of the larger π-donor ability of the thiolate ligands in $[MoO(SR)_4]^-$ (SR=SPh, S-4-$CH_3C_6H_4$, S-4-ClC_6H_4, S-3-ClC_6H_4, S-4-FC_6H_4, S-2,6-$Cl_2C_6H_3$, and SC_6F_5).[18] Intense Raman bands at 444 and 352 cm^{-1} are tentatively assigned to ν(Mo–S). Strong IR bands observed at 385, 361, 344, and 302 cm^{-1} are associated with IR active ν(Mo–S) frequencies. The results reflect decrease in symmetry of **1**.

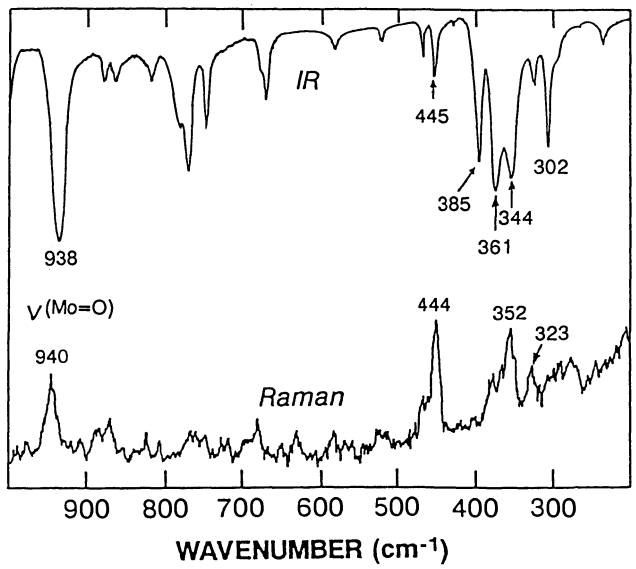

Fig. 4. IR and Raman spectra of $(NEt_4)[Mo^{V}O(\alpha\text{-}tdt)_2]$ (**1**) in solid state.

The electrochemical property of **1** was studied using cyclic voltammetry of a solution in 0.1 M $(n\text{-}Bu)_4NCl$–DMF. A reversible couple was observed at −0.73 V vs. SCE that corresponds to a one-electron reduction of the complex. An irreversible oxidation peak was given at +0.65 V due to the Mo(V)/Mo(VI) couple. The Mo(V)/Mo(IV) redox potential of **1** in DMF is expected to be higher compared with that of $(NEt_4)[Mo^{V}O(SPh)_4]$ (−0.75 V in acetonitrile) because of the larger electron donation from alkanethiolato to $(Mo^{V}O)$ ion than that of arenethiolato. The redox potential is found to become more positive by the electron-withdrawing character of the thiolate ligands as has been pointed for *p*-substituted benzenethiolate molybdenum(V) complexes by Ellis et al.[18] Therefore, **1** would be expected to exhibit a more negative redox potential due to the presence of two alkanethiolate ligands, but it shows a more positive one (−0.73 V vs. SCE in acetonitrile) than that (−0.77 V in acetonitrile) of $[Mo^{V}O(SPh)_4]^-$.[6] We examined the difference in SOMO orbital energies between the regular square-pyramidal and the distorted structures for the simple model complex, $[Mo^{V}O(SCH_2CH{=}CHS)_2]^-$, using EHMO calculations. The SOMO orbital energies for the regular structure and the distorted structure are −10.315 and −10.323 eV, respectively. The results can be explained by the ease of reduction of the distorted **1**. It is likely that this distortion induces the variation of O=Mo–S–C torsion angle accompanied with the change of π-interaction in Mo–S bond.

A DMF–CH_3CN solution (1 : 4) of **1** exhibited an axial ESR signals at room temperature and at ca. 80 K

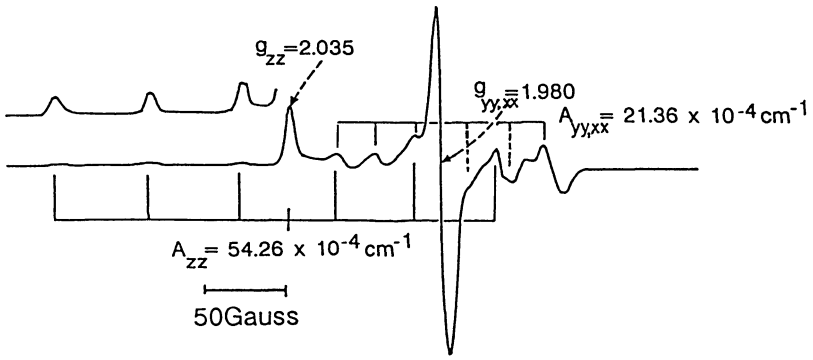

Fig. 5. ESR spectra of $(NEt_4)[Mo^VO(\alpha\text{-tdt})_2]$ (**1**) in DMF–acetonitrile freezing solution at ca. 80 K.

Table 4. ESR Parameters of $(NEt_4)[Mo^VO(\alpha\text{-tdt})_2]$ (**1**) and Various Related Mo(V) Thiolate Complexes

	s	p_x	p_y	p_z	$d_{x^2-y^2}$	d_{z^2}	d_{xy}	d_{xz}	d_{yz}
Regular $MoOS_4$ all O–Mo–S 110°	0.005	0.00	0.00	−0.023	−0.034	0.044	−0.937	0.00	0.00
Distorted $MoOS_4$ O–Mo–S1, O–Mo–S3=113° O–Mo–S2, O–Mo–S4=105°	0.004	0.00	0.00	−0.022	−0.049	0.044	−0.933	0.00	0.00

as shown in Fig. 5. The low-temperature ESR measurement for **1** provided g_{zz}=2.035 at ca. 80 K which is a relatively large value in the synthetic molybdenum(V) thiolate complexes. The ESR parameters are compared with those of various molybdenum(V) thiolate complexes in Table 4. The axial signals for **1** are obtained even in the distortion from a tetragonal-pyramidal to an approximate C_2 structure as revealed by the crystallographic analysis. In the various cases of monooxomolybdenum(V) complexes, g tensor has been determined to coincide with Mo=O direction, e.g. $[Mo^VOCl_4]^-$.[19] The large g_{zz} value should reflect the ligand field equatorial to the Mo=O bond axis because of spin-orbit coupling between Mo and sulfur. Furthermore, the low-energy charge-transfer transition also contributes to the observed g_{zz} value shift in addition to the above ligand field because the SOMO of Mo(V) calculated by the EHMO method shows the contribution from S $p\pi$-orbitals as described later. Therefore, the reported small value of g_{zz} for $[Mo^VO(SCH_2CH_2S)_2]^-$ is in conflict with the tendency of large electron-donating character of the alkanethiolato ligand.

Table 5 lists the MO coefficients of the SOMO in the simple model complex, $[Mo^VO(SCH_2CH{=}CHS)_2]^-$ for **1** to evaluate the influence of the distortion to the ESR signals of **1**. The EHMO calculations were carried out in two geometries which are regular and distorted. The difference between the SOMO electron densities for the two geometries by mixing p_z and d_{z^2} orbitals in the z direction is not so large that the distortion of the $MoOS_4$ core does not influence the MO electron density in SOMO contributing to the shift of the g_{zz} value. The results are coincident with a small change reported in the ESR signals between $[Mo^VOCl_4]^-$ and $[Mo^VOCl_5]^{2-}$.[19] Further study will be required to examine this trend on the ESR parameters.

We thank Professor Mikiharu Kamachi for the ESR measurement. We gratefully acknowledge partial support of this research by a Grant-in-Aid for Scientific Research on Priority Areas of "Macromolecular Com-

plexes" No63612093 from the Ministry of Education, Science and Culture.

(Received January 14, 1991)

Reaction of nickel(II) perchlorate with the title ligand (Hpahqs) in aqueous solution followed by standing for about six months produces a complex having the formulation $[Ni_4(pahqs)_4(H_2O)_4]\cdot 20H_2O$. A single crystal X-ray analysis revealed that the complex contained the four nickel(II) and four ligand molecules and showed a novel structure of oxygen bridged tetranuclear nickel(II) complex. Crystal data: triclinic, space group $P\bar{1}$, a=17.884(7), b=22.071(8), c=12.819(8) Å, α=100.77(4)°, β=92.55(4)°, γ=71.46(4)°, Z=2. Except one N atom in each azo-group, all the other donor atoms in the ligand were fully used in coordination to nickel(II), forming either *N,N,O*- or *N,O*-chelate rings, simultaneously. The geometry around each of the four nickel(II) was distorted octahedron. The bond lengths of Ni–N(N atoms in *N,N,O*-terdentate moieties) were elongated compared with those of the corresponding complex, and the lengths of Ni–N(N atoms in quinoline rings) were kept almost similar values to those of the Ni(II)-8-hydroxyquinoline complex. The bond lengths of Ni–O were elongated compared with those of the nickel(II) complexes with either *N,N,O*- or *N,O*-chelate rings, resulting in the contraction of the angles of N–Ni–N or N–Ni–O. The angles of Ni–O–Ni around four nickel(II) sites were ca. 140°. The antiferromagnetic exchange interaction was operating between the four nickel(II) via bridging oxygen atoms.

The multidentate ligands of ortho-hydroxyazo system containing more than two groups of potentially chelating donor atoms have become of interest in connection with the coordination selectivity for a variety of metal ions.[1] Previously, we prepared the new multidentate ligands, 7-[(3,5-dihalo-2-pyridyl)azo]-8-hydroxyquinoline-5-sulfonic acid (abbr. as Hpahqs), and investigated their coordination behavior toward metal(II) ions in aqueous solution. As a result, Ni(II), Zn(II), and Cd(II) ions, which are classified as soft or medium acids, coordinated selectively to the *N,N,O*-terdentate moiety containing azo-group to form the 1:2 (metal:pahqs) complexes having four five-membered fused chelate rings.[2] On the contrary, VO(IV) (hard acid) bonded selectively to the only *N,O*-skeleton in hydroxyquinoline(HQ) moiety.[3]

The metal complexes of azo system ligands are difficult to isolate as a single crystal. There are only several studies for syntheses and analyses of single crystals of metal(II) complexes with ortho-hydroxyazo ligands, and, in addition, all these complexes have simple mononuclear or dinuclear structures.[4] In the present work,[5] a single crystal of Ni(II) complex with the title ligand having the peculiar composition of Ni(II):pahqs=4:4 was isolated and its structure has been characterized by X-ray crystallography. The most striking aspect of the present results was that, in this complex, except one N atom in each azo-group, all the other donor atoms in pahqs were fully used in coordination to Ni(II), and the four Ni(II) were bridged by O atoms in the HQ moieties, showing a first novel structure of tetranuclear Ni(II) complex. The difference in composition of metal to ligand of the species in solution[2] and of the present solid complex can not be explained so clear at this stage. Furthermore, it was found that an antiferromagnetic interaction was operating between the four Ni(II) via bridging oxygen atoms. These results suggest that this multidentate ligand will be expected to form various tetranuclear metal complexes via bridging oxygen atoms with other metal ions, which will be interested in structural and magnetic chemistry.[6,7]

Experimental

Synthesis of Ligand. The ligand was prepared by the method described in our previous paper.[2)]

Preparation of Crystal of $[Ni_4(pahqs)_4(H_2O)_4]\cdot 20H_2O$. To a solution of the ligand (0.205 g, 0.44 mmol) in 250 cm^3 of water was added $Ni(ClO_4)_2\cdot 6H_2O$ (0.195 g, 0.53 mmol) under stirring. The pH of the solution was adjusted to 2.81 by adding a perchloric acid (60%). The solution was stirred

a) $B_{eq}=(4/3)\sum_i\sum_j\beta_{ij}(\boldsymbol{a}_i\cdot\boldsymbol{a}_j)$, where β_{ij} is the anisotropic temperature factor, and $\boldsymbol{a}_i$ and $\boldsymbol{a}_j$ are lattice parameters.

for ca. 12 h and then allowed to stand for about six months. The violet prismatic crystals (65.4 mg, yield: 28%) were obtained. Found: C, 30.04; H, 2.81; N, 10.00%. Calcd for $C_{56}H_{24}N_{16}O_{16}Cl_8S_4Ni_4 \cdot 24H_2O$: C, 29.82; H, 2.86; N, 9.93%. Thermogravimetric analysis of the complex indicates a weight loss of 18.98% in the region 292—480 K (heating rate 3 K min^{-1}). This is in good agreement with the calculated weight loss (19.17%) for twenty-four water molecules from the complex. All the other chemicals used were of an analytical or equivalent grade and were used as received.

Physical Measurements. Infrared spectra of KBr pellets were recorded on a JASCO-A102 spectrometer. Polarograms were recorded on a Yanaco Polarographic Analyzer P-1100 in an aqueous solution. A three-electrode system comprising a dropping mercury working electrode (DME), a Pt-wire auxiliary electrode, and a saturated calomel reference electrode (SCE) was used for measurements. TG-DTA analyses were performed using Rigakudenki PTC-10A Differential Thermogravimetric Analyzer. Magnetic susceptibilities (χ_A) were measured by the Faraday method in the temperature range from 80 to 300 K. The apparatus was calibrated by the use of $[Ni(en)_3]S_2O_3$.[8] All the susceptibilities were corrected for a diamagnetism of the constituting atoms by the use of Pascal's constants.[9] The effective magnetic moments were calculated by the equation, $\mu_{eff}=2.828[(\chi_A-N_\alpha)T]^{1/2}$. In which, the temperature-independent paramagnetic contribution (N_α) was taken as 230×10^{-6}emu mol^{-1} (1 emu=$4\pi\times10^{-6}$ m^3).

Crystallographic Data Collection and Refinement of the Structure. Three dimensional X-ray diffraction data were collected on an Enraf–Nonius CAD4F-11 diffractometer with graphite monochromated Cu-$K\alpha$ radiation using an ω–2θ scan mode. The data reduction was carried out using the Enraf–Nonius structure determining package.[10] The structure was solved by direction method using MALTAN11/82 program.[11] The positional and thermal parameters of all non-hydrogen atoms were determined and refined by successive block-diagonal least-squares method using BDLS program (UNICS III).[12] The atomic scattering factors for all atoms and the anomalous dispersion corrections for non-hydrogen atoms were taken from Ref. 13. Comparatively large R value (ca. 10%) may be due to the disordered waters of crystallization in the crystal.

Details of the crystal data, intensity measurements, and refinements are given in Table 1, final atomic fractional coordinates in Table 2, and selected bond distances and angles in Table 3, respectively.

Tables of structure factors, anisotropic thermal parameters, mean square displacement tensor of atoms, coordinates of atoms, and complete bond lengths and angles are deposited as Document No. 8954 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

The structure consists of discrete $[Ni_4(pahqs)_4(H_2O)_4]$ molecule. The position of twenty water molecules of crystallization could not be definitely determined. The molecular and chemical structures of the complex are given in Figs. 1 and 2, respectively. The four ligands were differentiated as A, B, C, and D. The atom-numberings for the ligands and nickel(II) sites are shown in Fig. 2. The O atoms in the coordinated water molecules are represented by OW(i) (i=1—4).

nickel(II) sites. Each of the ligands bonded to two nickel(II) by N atom in the pyridine ring, N atom in the azo-group adjacent to the HQ moiety, O atoms of the hydroxyquinolinate and N atom in the quinoline ring to form three five-membered chelate rings (two *N,N,O*- and one *N,O*-chelate rings), where all the nickel(II) were bridged by O atom of the hydroxyquinolinate. In other words, in this complex, except one N atom in each azo-group, all the other donor atoms in pahqs were fully used in coordination to nickel(II), forming either *N,N,O*- or *N,O*-chelate rings, simultaneously. A part of the chelate ring was the same as that expected for Ni(II)-αPAN (2-(2-pyridylazo)-1-naphthol), Ni(II)-βPAN (1-(2-pyridylazo)-2-naphthol), and Ni(II)-HQ complexes in aqueous solution[2,14] and that observed for Cu(II)-βPAN and Ni(II)-HQ complexes by single crystal X-ray analyses.[4b,4c,15,16] The geometry around each of the four nickel(II) was distorted octahedron. As can be seen from Fig. 3, the complex contained three types of nickel(II) sites with respect to their coordination groups: 1) two *N,N,O*-terdentate moieties of the ligands coordinate to nickel(II) with *mer*-configuration (Ni(2) site); 2) two *N,O*-bidentate moieties of the ligands and two water molecules coordinate to nickel(II) with *cis-cis-cis* configuration (Ni(3) site); 3) one *N,N,O*-terdentate moiety and one *N,O*-bidentate moiety of the ligands and one water molecule coordinate to nickel(II) with formation of a mixed chelate system (Ni(1) and Ni(4) sites).

The bond lengths of Ni(1,2,4)-N(N atoms in pyridine rings, 2.067(10)—2.103(10) Å; N atoms in azo-groups, 1.960(10)—2.008(9)Å), and Ni(1,2,4)-O(2.107(7)—2.188(8) Å, O atoms in *N,N,O*-terdentate moietites) were slightly longer than those of Ni-N (1.93(5) Å, N atom in azo-group) , Ni-N (1.97(4) Å, N atom in thiazole ring) , Ni-O (1.98(4) Å of an analogous nickel(II) complex with thiazolylazo dye.[4a] And the angles of N-Ni-N (76.2(4)—76.7(4)°) and N-Ni-O (78.0(4)—80.0(4)°) were smaller than those of N-Ni-N (78(2)°) and N-Ni-O (80(2)°) of the analogous complex, in which a ligand also acted as *N,N,O*-terdentate one.[4a] On the other hand, the bond lengths of Ni(1,3,4)-N (N atoms in quinolinolate, 2.030(11)—2.093(9) Å) were almost similar to that of Ni-N (2.043(2)—2.082(2)°) in Ni(II)-HQ complex,[17] and Ni(1,3,4)-O (O atoms in *N,O*-bidentate moieties, 2.083(7)—2.188(8) Å) were significantly longer than those of Ni-O (2.054(1)—2.058 (1) Å) of the nickel (II) complex with HQ.[17] The average angles of N-Ni-O (80.5(3)°, *N,O*-bidentate moieties) were smaller than those of N-Ni-O (86.50(6)°[17]) of the nickel(II) complex with HQ. In any event, the bond lengths of Ni-N (N atoms in *N,N,O*-terdentate moieties) were elongated compared with those of the corresponding complex,[4a] and the bond lengths of Ni-N (N atoms in quinoline rings) were kept similar values to those of Ni(II)-HQ complex,[17] this may be associated with the electron-rich N atoms in the quinoline rings.[17] The bond lengths of Ni-O were elongated compared with those of the corresponding nickel(II) complexes with either *N,N,O*- or *N,O*-chelate rings, resulting in the contractions of the angles of N-Ni-N or N-Ni-O, since O atoms acted as bridging donor atoms between nickel(II) sites.

Properties of the Complex. The complex exhibits characteristic IR spectra due to ligand vibration modes. The most significant difference of the IR bands between the present complex and those of the pahqs itself was that the $\nu_{(N=N)}/cm^{-1}$ (1367, 1324) in the complex was shifted to lower frequencies compared with that of the free ligand ($\nu_{(N=N)}$, 1375 cm^{-1}), and was split into two bands. This may be resulted from a delocalization of the negative charge on the azo-group by the complexation with nickel(II) which lead to a reduction of the N=N bond order.[18]

The half wave potential of the azo-group in the aqueous solution of the complex (−0.405 V vs. SCE at pH=6.9) at the same pH values was markedly shifted toward the negative side compared with that of the ligand itself (−0.272 V vs. SCE at pH=6.9), showing that the very stable *N,N,O*-chelate rings of the complex were present even in the solution state.[2,19]

The variation of the magnetic susceptibility (χ_A) and effective magnetic moment (μ_{eff}) with temperature for the complex is illustrated in Fig. 4. It can be seen in this fugure that the effective magnetic moment per nickel(II) ion, μ_{eff}/Ni, was 2.95 BM at 296.3 K and gradually decreased with the lowering of temperature. This indicates that antiferromagnetic exchange interaction is operating between the four nickel(II) via bridging oxygen atoms. It is reasonable to suggest that the angles of Ni-O-Ni (ca. 140°) may lead to the antiferromagnetic interaction.[7]

Further study on the magnetic exchange mechanism among the four nickel(II) sites is continuing.

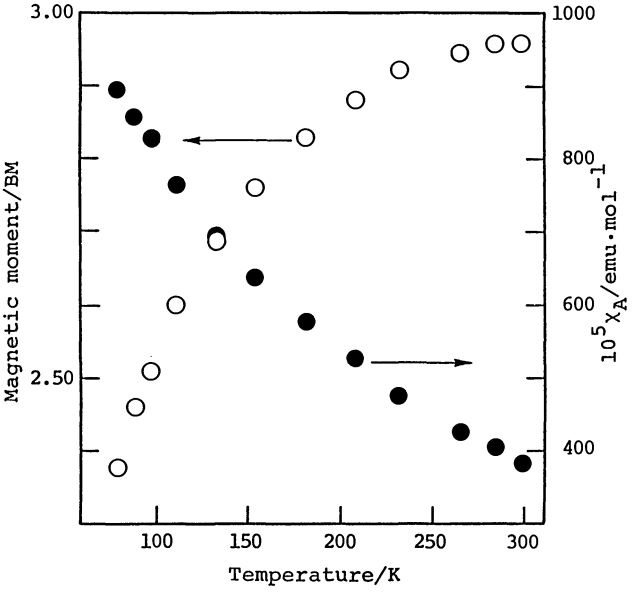

Fig. 4. Temperature dependence of magnetic moments (μ_{eff}/Ni) and magnetic susceptibilities (χ_A).

Association of Tris(acetylacetonato)chromium(III) with Chlorinated Phenols in the Liquid-Liquid Partition System

Shoichi KATSUTA, Hisanori IMURA,† and Nobuo SUZUKI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received March 5, 1991)

The liquid–liquid partition behavior of tris(acetylacetonato)chromium(III) ([Cr(acac)$_3$]) between heptane and 0.10 mol dm^{-3} aqueous sodium perchlorate solutions has been studied in the presence of a series of chlorinated phenols (HA) at 298.2 K. A large enhancement of the partition coefficient of [Cr(acac)$_3$] with HA has been observed, e.g., it rises by about 1000-fold in the presence of 0.02 mol dm^{-3} 3,5-dichlorophenol in the organic phase. This effect is ascribable to the association of [Cr(acac)$_3$] with HA in the organic phase. From a partition-equilibrium analysis, the association complexes have been identified as being [Cr(acac)$_3$]·iHA (i=1,2), and the association constants ($\beta_{ass,i}$) determined. The $\beta_{ass,i}$ value increases with an increase of the acid-dissociation constant of HA in the family of HA with the same combination of substituents at the 2,6-positions, i.e., the association is due to hydrogen bonding of the hydroxyl hydrogen atom of HA to [Cr(acac)$_3$]. A linear free-energy relationship has been found between the $\beta_{ass,i}$ values of [Cr(acac)$_3$] and those of [Co(acac)$_3$] previously reported.

The liquid–liquid partition of electrically neutral metal chelates is the most important process governing the extractability and separation efficiency of metal ions with a chelating agent in both solvent extraction and liquid chromatography. Suzuki and his coworkers have studied the partition coefficients of a large number of metal chelates, and have shown that the solvent effect on the partition coefficient can generally be interpreted in terms of regular solution theory.[1–4] In the case of acetylacetonato (2,4-pentanedionato) complexes, however, even for coordinatively saturated complexes such as tris(acetylacetonato)chromium(III) ([Cr(acac)$_3$]) and -cobalt(III) ([Co(acac)$_3$]), the effect of some solvents, such as chloroform and 1-octanol, could not be interpreted quantitatively.[3] This may be due to a specific interaction, such as hydrogen bonding between the metal acetylacetonates and the solvents. The hydrogen bonding between metal complexes and organic compounds might be very important for not only the partition behavior, but also regarding other chemical properties, such as the solubility and reactivity of metal complexes.[5] There have been a few studies concerning the interaction between metal β-diketonates and proton-donor solvents, such as chloroform and methanol.[1,5,6] However, the interaction observed in their systems was rather weak. The specific interaction between these chelates and chlorinated phenols, which are considered to be strong proton donors, has not yet been studied, except for our previous work, in which it was found that [Co(acac)$_3$] forms highly stable association complexes with chlorinated phenols in heptane.[7] Such the association with the phenols may occur for other metal chelates, such as [Cr(acac)$_3$]. It is necessary to accumulate systematic data concerning the specific interaction in order to quantitatively discuss both the nature and characteristics of the specific interaction between metal chelates and proton donors.

† Present address: Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310.

In this paper, the effect of a series of chlorinated phenols on the partition of [Cr(acac)$_3$] between heptane and 0.1 mol dm^{-3} aqueous sodium perchlorate solutions was investigated in detail. The association constants of [Cr(acac)$_3$] with the phenols in heptane were determined by a partition-equilibrium analysis; they are discussed by comparing them with those of [Co(acac)$_3$].

Theoretical

The partition coefficient of [Cr(acac)$_3$] (P_0) in the absence of chlorinated phenols is defined as the ratio of the equilibrium molar concentration of the complex in the organic phase to that in the aqueous phase,

$$P_0=[[\mathrm{Cr(acac)_3}]]_{org}/[[\mathrm{Cr(acac)_3}]]_{aq}, \quad (1)$$

where the subscripts aq and org denote the aqueous and organic phases, respectively.

When [Cr(acac)$_3$] and chlorinated phenols (HA) form association complexes ([Cr(acac)$_3$]·iHA) in the organic phase, the apparent partition coefficient of [Cr(acac)$_3$] (P') in the presence of HA can be expressed as

$$P'=\frac{[[\mathrm{Cr(acac)_3}]]_{org}+\sum_{i=1}^{n}[[\mathrm{Cr(acac)_3}]\cdot i\mathrm{HA}]_{org}}{[[\mathrm{Cr(acac)_3}]]_{aq}} \quad (2)$$

$$=P_0(1+\sum_{i=1}^{n}\beta_{ass,i}[\mathrm{HA}]_{org}{}^{i}), \quad (3)$$

where $\beta_{ass,i}$ is the association constant in the organic phase corresponding to the following equilibrium:

$$[\mathrm{Cr(acac)_3}]_{org}+i\mathrm{HA}_{org}\rightleftarrows[\mathrm{Cr(acac)_3}]\cdot i\mathrm{HA}_{org},$$

$$\beta_{ass,i}=\frac{[[\mathrm{Cr(acac)_3}]\cdot i\mathrm{HA}]_{org}}{[[\mathrm{Cr(acac)_3}]]_{org}[\mathrm{HA}]_{org}{}^{i}}. \quad (4)$$

Therefore, the following equation can be derived:

$$P'/P_0=1+\sum_{i=1}^{n}\beta_{ass,i}[\mathrm{HA}]_{org}{}^{i}. \quad (5)$$

An enhancement of the partition coefficient of

[Cr(acac)3] in the presence of HA is directly related to the association constant and the equilibrium concentration of HA in the organic phase by Eq. 5.

Experimental

Reagents. [Cr(acac)3] was obtained from Dojin Chem. Lab., recrystallized from hexane, and dried in vacuo. The purity was checked by a melting-point measurement and elemental analysis: Mp, 214 °C (literature value, 216 °C[8]). Found: C, 52.36; H, 6.14%. Calcd for $C_{15}H_{21}O_6Cr$: C, 51.58; H, 6.06%. 3-Chlorophenol (3-CP), 2,3-dichlorophenol (2,3-DCP), 3,5-dichlorophenol (3,5-DCP), 2,3,5-trichlorophenol (2,3,5-TCP), 2,3,6-trichlorophenol (2,3,6-TCP), and 2,4,5-trichlorophenol (2,4,5-TCP), which were of more than 98% purity, were commercially obtained and further purified by recrystallization from hexane or vacuum sublimation. Pentachlorophenol (PCP) (Aldrich, more than 98% purity) was used as obtained. Heptane was purified by ordinary methods. Water was doubly distilled. Other reagents were of analytical reagent grade and used without further purification.

Partition Measurements. An aqueous solution of 1.0×10^{-5}—7.7×10^{-4} (1 M=1 mol dm^{-3}) [Cr(acac)3] was prepared by partitioning [Cr(acac)3] from its heptane solution to water just before use, in order to minimize the dissociation of the complex in aqueous solution. The aqueous solution of [Cr(acac)3] was mechanically shaken with pure heptane or a heptane solution of 3.5×10^{-4}—1.0×10^{-1} M chlorinated phenols for 5—60 min at 350 strokes per min in a thermostated room at 298.2±0.5 K. The two phases were separated by centrifugation at 3000 rpm. The absorbance of [Cr(acac)3] in the aqueous phase before ($A_{i,aq}$) and after (A_{aq}) shaking was measured at 331 nm with a Hitachi U-3200 or JASCO Uvidec-2 spectrophotometer. The phenols had no absorption at this wavelength and did not affect the molar absorption coefficient of [Cr(acac)3] in the aqueous phase. The partition coefficient of [Cr(acac)3] in the absence (P_0) or presence (P') of chlorinated phenols was calculated using

$$P_0 \text{ or } P' = (A_{i,aq} - A_{aq}) V_{aq} A_{aq}^{-1} V_{org}^{-1}, \quad (6)$$

where V_{aq} and V_{org} are the volumes of aqueous and organic phases, respectively; the volume ratio V_{aq}/V_{org} was chosen to be 1—4 according to the magnitude of P' so as to minimize the absorbance-measurement error of the aqueous phase. The proton concentration of the aqueous phase was adjusted to 10^{-2}—10^{-3} M with perchloric acid to suppress any dissociation of the phenols. The ionic strength was adjusted to 0.10 M with sodium perchlorate.

Results

No dissociation of [Cr(acac)3] in the partition experiment was confirmed as follows: The equilibrated aqueous phase was shaken with chloroform to remove [Cr(acac)3] completely from the aqueous phase. Chloroform has a high partition coefficient for [Cr(acac)3], 5.70×10^3.[3] No absorption due to dissociated complexes, such as $[Cr(acac)]^{2+}$, and $[Cr(acac)_2]^+$, was detected in the remaining aqueous phase. All partition equilibria of [Cr(acac)3] were found to be established within 5-min shaking.

It was confirmed that the partition coefficient of [Cr(acac)3] (P_0) in the absence of chlorinated phenols is independent of the [Cr(acac)3] concentration within the range 1.3×10^{-5}—1.3×10^{-4} in the organic phase. The average and standard deviation of the P_0 value of [Cr(acac)3] for 12 measurements were 0.370±0.018, which is in good agreement with a value from the literature, 0.351.[9]

The apparent partition coefficient of [Cr(acac)3] (P') measured in the presence of a series of chlorinated phenols (HA) is shown in Fig. 1 as plots of $\log(P'/P_0)$ against the logarithmic value of the equilibrium concentration of the phenols in the organic phase, $\log[HA]_{org}$. Here, $[HA]_{org}$ is calculated from the initial concentration in the organic phase (C_{HA}) and the partition coefficient (P_{HA}) of those phenols as follows:

$$[HA]_{org} = C_{HA}/(V_{aq} V_{org}^{-1} P_{HA}^{-1} + 1), \quad (7)$$

where the P_{HA} values were quoted from our previous study,[10] i.e., 0.534 for 3-CP, 21.5 for 2,3-DCP, 2.61 for 3,5-DCP, 89.8 for 2,3,5-TCP, 96.6 for 2,3,6-TCP, 62.9 for 2,4,5-TCP, and 980 for PCP. The $[HA]_{org}$ calculated here should be approximately equal to the equilibrium concentration of HA free from association with [Cr(acac)3], since the total concentration of [Cr(acac)3] was always made to be smaller than 3% of C_{HA}. In all of the systems, the apparent partition coefficient of

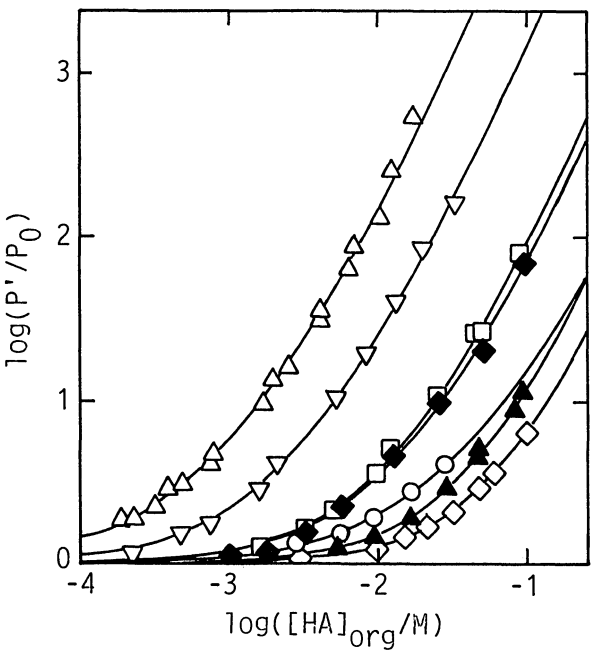

Fig. 1. Enhancement of the partition coefficient of [Cr(acac)3] as a function of the equilibrium concentration of chlorinated phenols (HA) in the organic phase. The solid lines indicate the regression curves by the nonlinear least-squares procedure based on Eq. 5.
▽, 3-CP; ▲, 2,3-PCP; △, 3,5-DCP; ◆, 2,3,5-TCP; ◇, 2,3,6-TCP; □, 2,4,5-TCP; ○, PCP.

$[Cr(acac)_3]$ rapidly increases with an increase in the phenol concentration in the organic phase. The largest effect is found in the 3,5-DCP system: the partition coefficient of $[Cr(acac)_3]$ rises by about 1000-fold in the presence of 0.02 M 3,5-DCP. This enhancement effect is remarkably different among the phenols, and increases according to the following order: 2,3,6-TCP<2,3-DCP<PCP<2,3,5-TCP≈2,4,5-TCP<3-CP<3,5-DCP.

Discussion

The enhancement of the apparent partition coefficient of $[Cr(acac)_3]$ in the presence of the chlorinated phenols can be ascribed to an association of $[Cr(acac)_3]$ with the phenols in the organic phase. According to Eq. 5, the slope of the plot of $\log(P'/P_0)$ vs. $\log[HA]_{org}$ is equal to the mean number of HA molecule associating with one molecule of $[Cr(acac)_3]$. The plots in Fig. 1 for 3-CP, 3,5-DCP, 2,3,5-DCP, and 2,4,5-TCP, which give especially great enhancement of the partition coefficient of $[Cr(acac)_3]$, are close to straight lines with a slope of 2 in the higher concentration region of the phenols. In the case of 2,3-DCP and 2,3,6-TCP, although no such limiting slope can be observed, the slopes of the plots increase to higher than unity at high concentrations of the phenols. These results mean that the maximum association number of the chlorinated phenols is two under these experimental conditions. From the plots given in Fig. 1, the association constants, $\beta_{ass,1}$ and $\beta_{ass,2}$ were computed by a nonlinear least-squares procedure (SALS program, The University of Tokyo) based on Eq. 5, and listed in Table 1. In the case of PCP, the P' measurement was only possible for a limited concentration range of PCP due to its low solubility (ca. 0.03 M in heptane); the slope of the plot is nearly unity, even at higher concentrations. In accordance with the results for other chlorinated phenols, however, the association constants were computed by assuming the formation of 1:1 and 1:2 association complexes. Hence, the $\beta_{ass,2}$ value of PCP may involve a fairly large error. The solid lines in Fig. 1 indicate regression curves by the obtained association constants; they are well fitted to the experimental plots. The largest values of the association constants are found in the 3,5-DCP system. All of these values for the chlorinated phenols are very large compared with the very few data concerning the association constants of $[Cr(acac)_3]$ with other proton donors reported so far, e.g., the $\log \beta_{ass,1}$ values with chloroform and methanol in carbon tetrachloride at 298 K are −0.52 and 0.11, respectively.[5]

Table 1. Association Constants of $[Cr(acac)_3]$ with Chlorinated Phenols (HA) in Heptane at 298.2 K

No.	HA	$\log(\beta_{ass,1}/M^{-1})$	$\log(\beta_{ass,2}/M^{-2})$
1	3-CP	3.02 (0.03)	5.13 (0.03)
2	2,3-DCP	1.63 (0.03)	2.83 (0.03)
3	3,5-DCP	3.56 (0.02)	6.04 (0.03)
4	2,3,5-TCP	2.26 (0.05)	3.72 (0.06)
5	2,3,6-TCP	1.39 (0.03)	2.49 (0.04)
6	2,4,5-TCP	2.27 (0.03)	3.87 (0.03)
7	PCP	1.97 (0.01)	2.71 (0.08)

Numerals in parentheses show the standard deviations calculated by SALS program.

The possibility of a direct coordination of the phenols to the inner sphere of $[Cr(acac)_3]$ was completely denied by the fact that the absorption band at 560 nm of $[Cr(acac)_3]$ in heptane, assigned to the d-d transition,[11] did not change in the presence of 0.05 M 3,5-DCP. If the association is caused by hydrogen bonding, the association constant is expected to correlate with the acid-dissociation constant of the chlorinated phenols.[12] Figure 2 shows the association constant of $[Cr(acac)_3]\cdot HA$ ($\log \beta_{ass,1}$) as a function of the acid-dissociation constant of the chlorinated phenols ($\log K_a = -pK_a$); the pK_a values are cited from the literature, i.e., 8.97 for 3-CP, 7.71 for 2,3-DCP, 8.25 for 3,5-DCP, 6.43 for 2,3,5-TCP, 5.80 for 2,3,6-TCP, 6.72 for 2,4,5-TCP, and 4.74 for PCP.[13] Good correlations are found for three families of phenols with the same combination of substituents at the 2,6-positions: (1) 3-CP and 3,5-DCP, (2) 2,3-DCP, 2,3,5-TCP, and 2,4,5-TCP, and (3) 2,3,6-TCP and PCP. In each family, the association constant increases with an increase in the acid-dissociation constant of the phenols; such relations indicate that the association of $[Cr(acac)_3]$ with the chlorinated phenols is due to hydrogen bonding of the hydroxyl hydrogen atom of the phenols to $[Cr(acac)_3]$. In addition, these three families lie at different regions in Fig. 2, and the

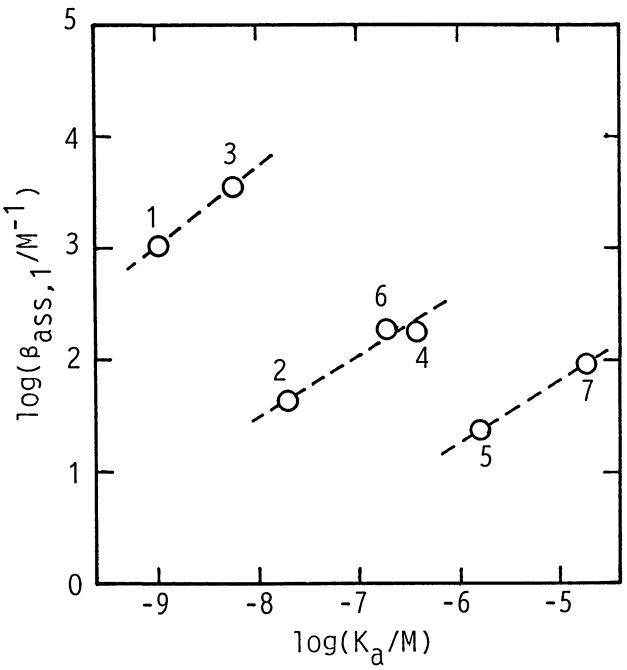

Fig. 2. Correlation between the logarithmic values of the association constant ($\beta_{ass,1}$) and the acid-dissociation constant (K_a) of chlorinated phenols. The numbers in figure correspond to those in Table 1.

association constants decrease as family(1)>family(2) >family(3). This difference among the families can be mainly interpreted in terms of the formation of an intramolecular hydrogen bond between the hydroxyl hydrogen atom and the chlorine atoms at the 2,6-positions, which should reduce the intermolecular association with [Cr(acac)3].[12] The intermolecular association may also be hindered sterically by bulky chlorine atoms at the 2,6-positions. Consequently, 3,5-DCP has the highest association ability among the investigated phenols, since this phenol has no chlorine atoms at the 2,6-positions and its acidity is relatively strong due to the electron-withdrawing nature of chlorine atoms at the 3,5-positions.

The association reaction of [Cr(acac)3] was compared with that of the same type of tris(acetylacetonato) complex, [Co(acac)3], which also forms 1 : 1 and 1 : 2 association complexes with the chlorinated phenols.[7] Figure 3 shows the correlation between the logarithmic value of the association constant of [Cr(acac)3] ($\beta_{ass,i}$(Cr)) with the chlorinated phenols and that of [Co(acac)3] ($\beta_{ass,i}$(Co)) with the corresponding phenols. The same and good linear free-energy relationships are found with respect to both $\beta_{ass,1}$ and $\beta_{ass,2}$:

$$\log(\beta_{ass,i}(\mathrm{Cr})/\mathrm{M}^{-i}) = 0.90 \log(\beta_{ass,i}(\mathrm{Co})/\mathrm{M}^{-i}) + 0.04, \quad (8)$$

with a correlation coefficient of r=0.998. This reveals that these association reactions for [Cr(acac)3] and [Co(acac)3] are the same regarding type. As shown by the slope of 0.90, the association constants of [Cr(acac)3] are always somewhat smaller than those of [Co(acac)3]. That is to say, the proton-acceptor ability of [Cr(acac)3] is a little inferior to that of [Co(acac)3]. In order to discuss the reason for this difference between [Cr(acac)3] and [Co(acac)3] in detail, further investigations concerning other metal acetylacetonates may be necessary.

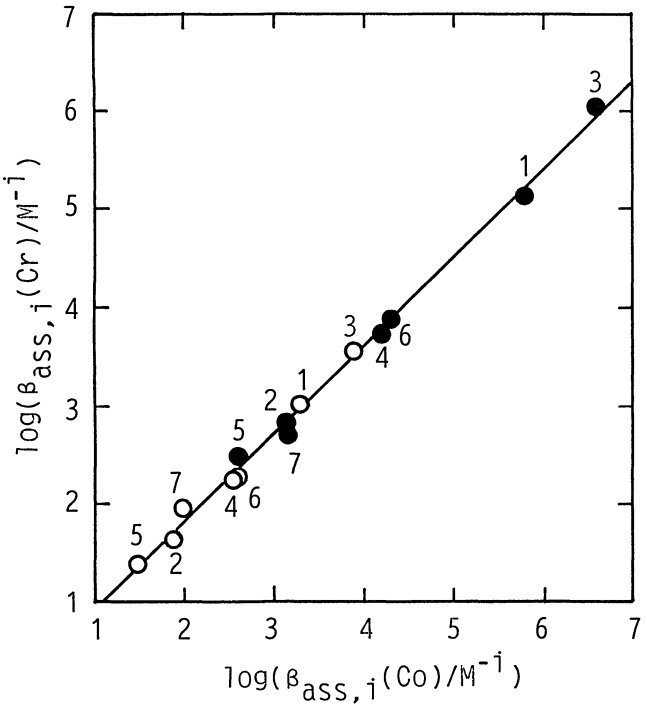

Fig. 3. Correlation between the logarithmic values of the association constants of [Cr(acac)3] ($\beta_{ass,i}$(Cr)) and [Co(acac)3] ($\beta_{ass,i}$(Co)) with chlorinated phenols in heptane. The solid line indicates the regression line by the linear least-squares procedure (Eq. 8). The numbers in figure correspond to those in Table 1. ○, i=1; ●, i=2.

The structure of the association complex may be estimated from the maximum association number of the phenols observed for both tris(acetylacetonato) complexes. The tris(acetylacetonato) complex has an octahedral configration with the ligand oxygen atoms about the central metal atom.[14] In the eight octahedral faces, two faces perpendicular to the C_3 axis of the tris-complex, each of which comprises three closely positioned oxygen atoms from three acetylacetonato ligands, are relatively open to the approach of phenols. The hydroxyl hydrogen of the phenol probably interacts with equal probability with the three oxygens on each of these two faces and, consequently, one molecule of the complex can associate with two molecules of the phenols.

In conclusion, it was found that [Cr(acac)3] forms highly stable 1 : 1 and 1 : 2 association complexes with chlorinated phenols by hydrogen bonding in heptane. This association reaction causes a great enhancement of the partition of the metal acetylacetonate between heptane and aqueous solutions in the presence of the chlorinated phenols. Many other metal chelates can probably associate with the chlorinated phenols and, from an analytical viewpoint, the addition of the chlorinated phenols can be expected to provide a great enhancement for the solvent extraction of various metal chelates or to strongly affect the retention behavior of metal chelates in liquid chromatography.

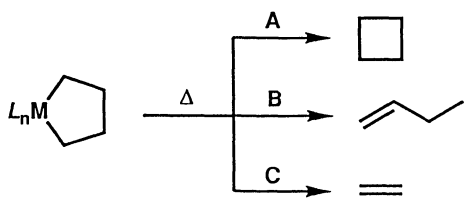
Synthesis, Structure, and Reactions of Stable Titanacyclopentanes

Kazushi MASHIMA, Nozomu SAKAI, and Hidemasa TAKAYA*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606
(Received March 15, 1991)

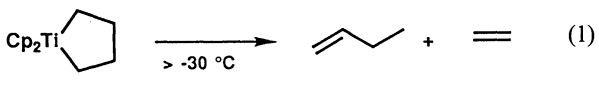
Titanacyclic compounds of the formula $Cp^*_2Ti(CH_2CH_2C(CH_2CHR)CH_2)$ (**5a**; R=H and **5b**; R=C_6H_5, Cp^*=pentamethylcyclopentadienyl), the first stable titanacyclopentanes, have been prepared by the reaction of bis(pentamethylcyclopentadienyl)titanium–ethylene complex (**3**) with methylenecyclopropanes (**4**), and their structures were determined based on both spectroscopic data and X-ray crystallography. Complex **5b** crystallized in space group $P2_1/a$ (Z=4) with cell constants, a=21.832(3), b=8.580(1), c=14.759(2) Å, β=96.81(1)°, U=2744.9(6) Å^3 (4261 reflections, R=0.053). The reaction of **5** with carbon monoxide afforded spiro[2.4]heptan-5-ones in 98% yield. The thermal decomposition of **5** has been investigated, and possible mechanisms of the reactions have been proposed based on deuterium-labeled experiments. A novel formal reductive elimination of organic ligands giving 1-phenylspiro[2.4]hexane has been observed in the thermolysis of **5b**. A structure–reactivity relationship has been discussed.

The chemistry of metallacyclic compounds has been the subject of considerable interest since many synthetically important organic reactions mediated by transition-metal complexes proceed via metallacyclic intermediates.[1] Although numerous metallacyclic compounds have been known, only a limited number of such compounds of the first transition series elements have been isolated and characterized.[2,3] Metallacyclopentanes, when they are heated in solution or in solid state, suffer from several kinds of thermal reactions which can be classified into three modes of reactions (paths A, B, and C), as shown in Scheme 1. A simple reductive elimination produces cyclobutane (mode A), while a β-hydrogen elimination followed by a reductive elimination (mode B) gives rise to 1-butene. The third important reaction is the β-carbon–carbon bond fission (mode C) giving two moles of olefins, which is sometimes reversible; an oxidative coupling of two olefins on a metal gives back metallacyclopentanes. The product distribution varies depending on the nature of metals, ligands, and other experimental conditions. Usually, compounds of the late transition elements suffer from mode A and B reactions, while those of the early transition elements tend to decompose by paths B and C.

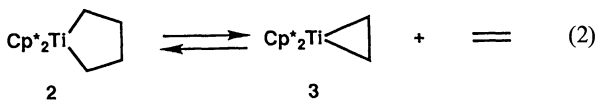
Bis(cyclopentadienyl)titanacyclopentane (**1**) (Cp=cyclopentadienyl) has been known to be unstable in solution, even at −30 °C, and all attempts to isolate **1** have been unsuccessful. A facile β-elimination reaction (mode B reaction) and a β-carbon–carbon bond fission (mode C reaction) giving 1-butene and ethylene, respectively, might be the major reason of its instability (Eq. 1).[3] Isolation of complex **2** (Cp^*=pentamethylcyclopentadienyl) is also very difficult because it is in equilibrium with ethylene complex **3** and free ethylene (Eq. 2). Here, a selective cleavage of the β-C–C bond is the main pathway of decomposition.[3c] We thought that if a strained olefin is used in place of ethylene, this equilibrium will be forced to shift to the left-hand side so that the strain of the olefin would be released. Such an effect would stabilize the titanacyclopentane **2**. For the purpose of carrying out detailed structure–reactivity studies on this class of compounds, we have investigated this subject. We describe here the isolation, structures, and some reactions concerning new stable titanacyclopentanes derived from **3** and methylenecyclopropanes **4**.[4]



Scheme 1.



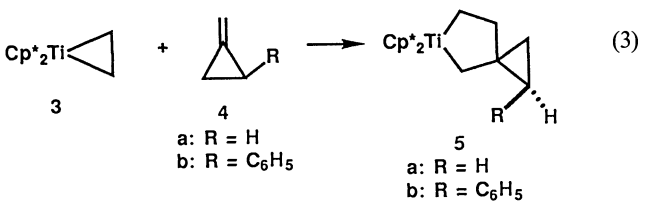
1 (1)



2 3 (2)

Results and Discussion

Synthesis and Characterization of Stable Titanacyclopentanes 5. Decamethyltitanocene–ethylene complex **3** has been conveniently prepared in 43% isolation yield by a reaction of $Cp^*_2TiCl_2$ and two equivalent of butyllithium under atmospheric pressure of ethylene. When a mixture of **3** and an excess amount of methylenecyclopropane (**4a**) in hexane was stirred at −10 °C for 48 h under an argon atmosphere, titanacyclopentane **5a** was obtained as orange needles in 65% yield after recrystallization of the crude product from hexane at



(3)

−80 °C (Eq. 3). Complex **5a** melted at 156—158 °C with decomposition, while slowly decomposing in toluene at 95 °C ($t_{1/2}$=91 min).

The structure of **5a** was supported by its spectral data. The ^{1}H NMR spectrum of **5a** in toluene-d_8 showed that each methylene proton is magnetically equivalent and exhibited no substantial change down to −90 °C; this indicates that the conformational change of the titanacyclopentane ring is rapid, even at −90 °C. Similarly, the phenyl derivative **5b** was prepared as deep-red prisms in 83% yield by treatment of **3** with 2-phenyl-1-methylenecyclopropane (**4b**) at 20 °C for 48 h. The half-life of **5b** in toluene at 95 °C is ca. 3 min. The structure of **5b** was determined by its spectral data and X-ray crystallography.

The molecular structure of **5b** is shown in Fig. 1. Selected bond distances and angles are summarized in Tables 1 and 2. Complex **5b** is monomeric and has the coordination geometry of a distorted tetrahedron defined by two pentamethylcyclopentadienyl ligands and two carbon atoms of the metallacyclopentane ring. The bond lengths of 1.513(5) Å for C(3)–C(4), 1.529(5) Å for C(3)–C(7), and 1.527(4) Å for C(6)–C(7) are comparable, which is in contrast with the fact that the stable metallacyclopentanes of the first transition elements such as Fe,[2g] Co,[2c,5] and Ni[2a,b,6] have a tendency for the bond distances of C_β—C_β' to usually be shorter than those of C_α–C_β. This relatively long C_β–C_β' bond distance in **5b** might be related to an easy cleavage of the C_β–C_β' bond of titanacyclopentanes. The five-membered ring of **5b** is fixed in a puckered form and the C(1)–C(3) bond occupies a pseudoequatorial position. The C(4)–Ti–C(6) angle is 80.6(1)°, showing that this angle is considerably distorted from the ideal value of 110° calculated for Cp_2TiH_2.[7] This deformation of

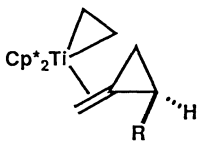
Cp14–Cp15–Cp20	126.3(3)		

a) Cp*1 and Cp*2 are the centroids of two cyclopentadienyl rings, Cp1–Cp5 and Cp11–Cp15, respectively.

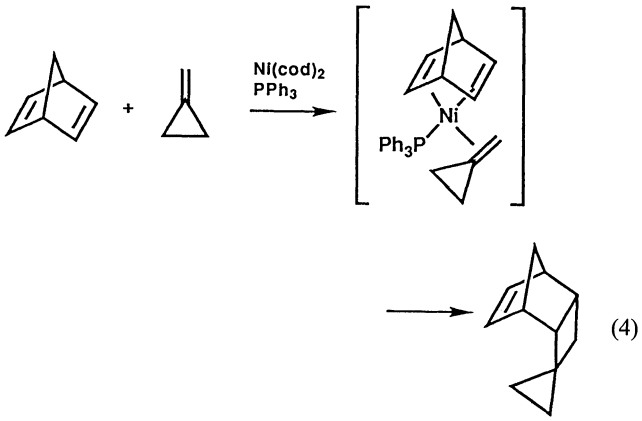
angle C(4)–Ti–C(6), however, is not considered to destabilize the complex very much, since the difference in the total energy of the complex was calculated to be only within 3 kcal mol^{-1} over the range 75—130°.[5]

Complex **5** can be considered to arise from a mixed-ligand complex of type **6** by oxidative coupling of the



6

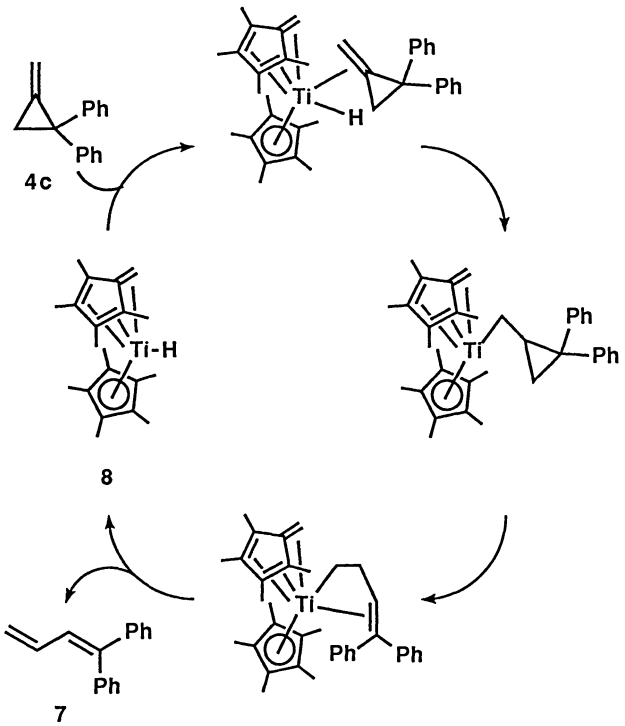
two ligands on titanium or by migratory insertion of the olefin into the Ti–C bond.[8] Selective formation of a related mixed-ligand complex has been proposed for a [2+2] cyclocoupling of norbornadiene and methylenecyclopropane (Eq. 4), in which a subtle balance of the coordination abilities of the two olefins is considered to be an important factor.[9] On the other hand, another possible mechanism is a direct [2+2] suprafacial reaction of the olefinic part of methylenecyclopropane and the strained Ti–C bond of **3**.[8a]



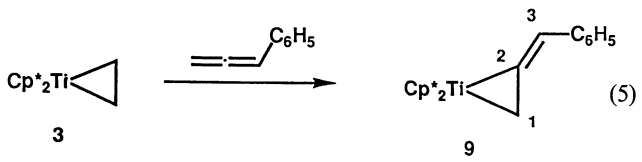
(4)

When 2,2-diphenyl-1-methylenecyclopropane (**4c**) was stirred with **3** in toluene at room temperature, no reaction took place, which can be ascribed to a steric repulsion between bulky pentamethylcyclopentadienyl ligands and two phenyl substituents of **4c**. At an elevated temperature (70 °C), however, **4c** isomerized catalytically to 1,3-butadiene derivative **7** in quantitative yield (Scheme 2). The catalytic conversion of **4c** to **7** can be viewed as proceeding by the mechanism shown in Scheme 2, which involves a cyclopropylmethyl—3-butenyl rearrangement. Titanium hydride **8** is considered to be a catalytically active species.[10,11]

The reaction of **3** with phenylallene has also been investigated; only a ligand-exchange reaction occurred to give a new titanocene–phenylallene complex **9** (Eq. 5). The structure of **9** was determined by a comparison

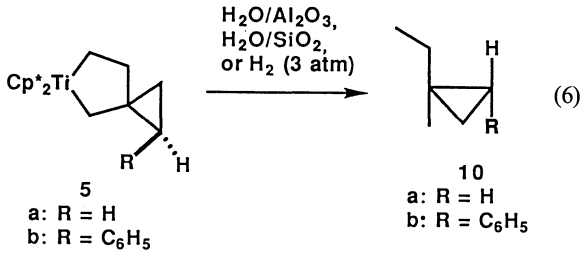


Scheme 2.

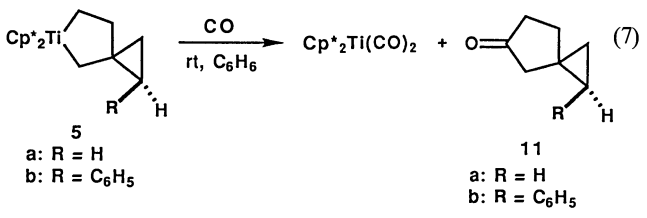


of the ^1H and ^{13}C NMR chemical shift values as well as the C–H coupling constants of **9** and those of free phenylallene.[3c,7] No stereochemical assignment has been performed, though the structure of a sterically less-hindered isomer has been tentatively presented. Phenylallene was released from **9** when it decomposed upon exposure to air.

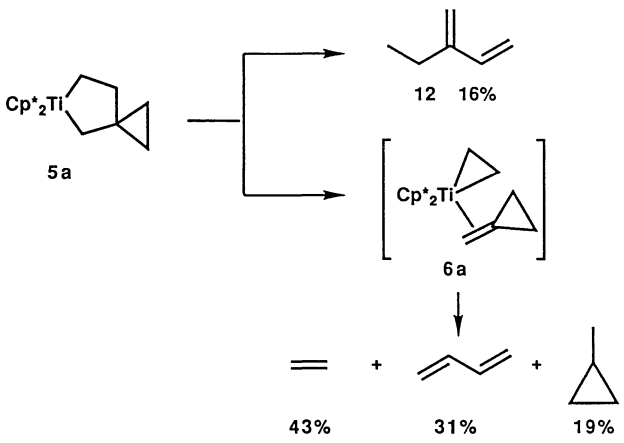
Reactions of 5a and 5b. Complexes **5** are quite stable in dilute hydrochloric acid. However, when a benzene solution of **5a** was treated with silica gel or alumina, a smooth hydrolysis occurred to give 1-ethyl-1-methylcyclopropane (**10a**) in 96% yield (Eq. 6). A similar treatment of **5b** in benzene with silica gel afforded *r*-1-ethyl-1-methyl-*t*-2-phenylcyclopropane (**10b**) in 88% yield. Compounds **10a** and **10b** were also obtained in quantitative yields when **5a** and **5b** were treated with hydrogen (3 atm).



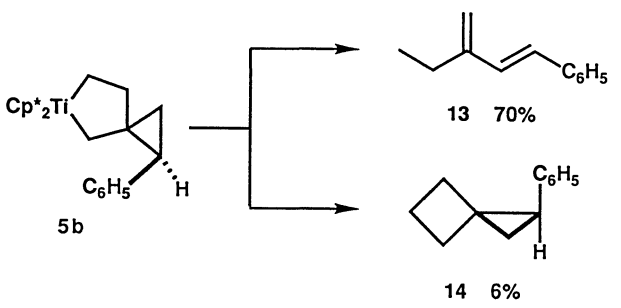
When **5a** or **5b** in hexane was exposed to three atmospheric pressure of carbon monoxide at room temperature, cyclopentanone derivative **11a** or **11b** was obtained in almost quantitative yields, respectively (Eq. 7).[12,13] This is in contrast with the reported fact that the reaction of complex $Cp^*_2\overline{TiCH_2(CH_2)_2CH_2}$ (**2**) with carbon monoxide did not give cyclopentanone, but resulted in the formation of ethylene and $Cp^*_2Ti(CO)_2$.[3c]



Thermal Decompositions of 5a and 5b. Thermal reactions of complexes **5** were carried out by rapidly heating a solid sample at 200 °C under reduced pressure; the resulting organic products were collected and analyzed. The results are summarized in Schemes 3 and 4. Two pathways were observed for **5a**, in which a β-carbon–carbon bond cleavage occurred predominantly to give ethylene (43%), butadiene (31%), and methylcyclopropane (19%) (Scheme 3). 1,3-Diene **12** (16%) was also obtained, which is considered to arise from a cleavage of the C(1)–C(3) bond of the spiro[2.4]heptane ring. No products arising from a simple β-hydrogen elimination were detected. In contrast, the thermolysis of complex **5b** did not undergo via the β-carbon–carbon bond fission, but gave 1,3-diene **13** in 70% yield (Scheme 4). Interestingly, the reductive elimination product, a cyclobutane derivative **14** (6%), was also obtained. To our knowledge, this is the first example of a direct reductive elimination of cycloalkanes from the metallacycles of group-4 transition metals. Recently, an oxidative decomposition of titanacyclobutanes has been reported to give cyclopropanes.[14] The remarkable differences in the reaction modes observed for **5a** and **5b** might be partly attributed to the presence of a weak benzylic carbon–carbon bond in **5b**. Another possible factor is the fact that the bulky phenyl substituent deforms the titanacyclopentane ring so that it occupies a pseudoequatorial position, which might make the β-carbon–carbon bond fission more difficult to occur. A similar structure–reactivity relationship has been discussed for the transition-metal-catalyzed valence isomerization of 1,8-bishomocubane.[15]

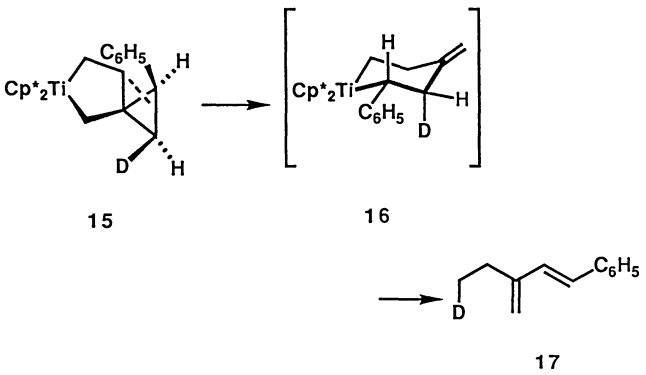


Scheme 3.



Scheme 4.

The formation mechanism of the 1,3-dienes **12** and **13** is worthy of further consideration. Three machanisms, Schemes 5—7, can be considered, a priori, whose stereochemical courses are shown for deuterium-labeled complex **15**. Mechanism A shown in Scheme 5 involves an initial rearrangement of complex **15** to **16**, followed by β-hydrogen elimination and reductive elimination. The formation of six-membered metallacycle **16** can be accounted for by a skeletal rearrangement from a cyclopropylmethyl to a 3-butenyl structure.[16] A number of examples of this type of rearrangements have so far been presented for the transition-metal-catalyzed reactions of methylenecyclopropanes.[17–21] From **16**, in which the bulky phenyl substituent occupies an equatorial position, the 1,3-diene **17** with deuterium at the terminal position will be formed by an elimination of the axial deuterium atom followed by a reductive elimination reaction.

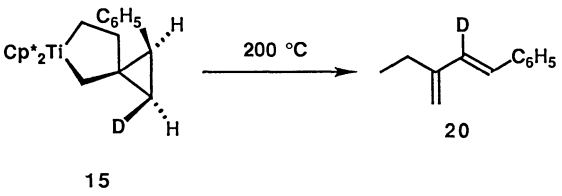


Scheme 5.

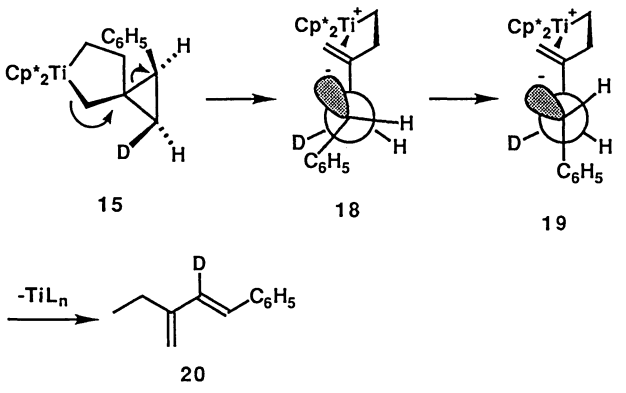
Mechanism B is illustrated in Scheme 6. This reaction is initiated by a heterolytic cleavage of the Ti–C bond, giving zwitterionic species **18**. In the next step, this eclipsed conformer **18** proceeds to a more stable gauche conformer **19** by least motion, so that the phenyl substituent at C(1) comes to the *s*-trans position. Subsequent trans hydride abstraction by titanium gives an alkyltitanium hydride species, and reductive elimination affords the 1,3-diene product **20** with deuterium at the 2-position.

Mechanism C (Scheme 7) involves a direct γ-elimination of one of the two C(2) methylene hydrogens, leading to **17**. Here, deuterium abstraction by titanium is also expected, since the Ti–D distance (4.39 Å) is shorter than that of Ti–H (4.74 Å). This mechanism can not be ruled out, even though such an elimination process seems to be unlikely in view of the long distances between Ti and these hydrogens.

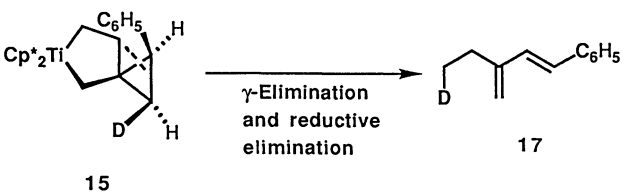
In order to obtain information concerning the reaction mechanism, we studied the stereochemical course of the reaction using deuterium-labeled complex **15**. When isolated complex **15** was heated at 200 °C under vacuum, 1,3-diene **20** was obtained as the major product. Thus, the formation of **20** could be reasonably explained by mechanism B shown in Scheme 6.



(8)



Scheme 6.



Scheme 7.

As a result, all of the three reactions (A—C illustrated in Scheme 1) are possible for titanacyclopentanes **5**, and the product distributions are highly dependent on the substituent on the metallacycles. The difference in the conformation of the five-membered ring of **5** as well as the presence of substituents in the ring may, at least in part, be a factor which controls the reaction modes.

Experimental

General. All manipulations involving air- and moisture-sensitive organometallic compounds were carried out by the use of the standard Schlenk technique under an argon atmosphere purified through a BASF-Catalyst R3-11 column. All solvents were purified by distillation under argon after drying over calcium hydride or sodium benzophenone ketyl. ^{1}H NMR spectra were recorded on a Varian EM-390 (90 MHz), a JEOL EX 270 (270 MHz), or a JEOL GX400 (400 MHz) spectrometer. ^{13}C NMR spectra were measured on a JEOL EX 270 (67.5 MHz) or a JEOL GX400 (100 MHz) spectrometer. Other spectra were recorded by the use of the following instruments: IR, Hitachi 295; low-resolution mass and high-resolution mass spectra, JEOL D300 (70 eV); gas chromatographic (GLC) analyses, Hitachi 263-30 equipped with a flame ionization detector. Elemental analyses were performed by

the Wako Pure Chemical Ind. Ltd. All melting points were measured in sealed tubes and uncorrected. Methylenecyclopropane,[22] 2-phenyl-1-methylenecyclopropane,[23] and 2,2-diphenyl-1-methylenecyclopropane[23] were prepared by the modified literature methods. Cyclobutanone was obtained from Aldrich Chem. Co.

Preparation of Decamethyltitanocene-Ethylene Complex 3. To a solution of $Cp^*_2TiCl_2$ (2.65 g, 6.8 mmol) in toluene (100 mL) was added dropwise a solution of butyllithium (15 mmol) in hexane (10 mL) at −78 °C. The reaction mixture was exposed to an atmospheric pressure of ethylene; the temperature was then allowed to rise to 20 °C. After stirring the mixture for a period of 2 days, all volatiles were removed under reduced pressure. The resulting residue was extracted with hexane (200 mL); the hexane solution was then filtered through a pad of Celite 545. The filtrate was concentrated to ca. 30 mL, and the solution was kept at −20 °C overnight to afford the ethylene complex **3** (1.01 g, 43% yield) as light-green crystals, whose NMR spectral data were superimposable with those reported.[3c]

Preparation of 5a. To a solution of decamethyltitanocene–ethylene complex **3** (0.43 g, 1.24 mmol) in hexane (50 mL) (0.43 g, 1.24 mmol) cooled at −70 °C was added methylenecyclopropane (**4a**) (2 mL, excess) by a trap-to-trap method. When the reaction mixture was slowly warmed up to −20 °C during 2 h, the light-green color changed to orange. This homogeneous solution was further stirred at −20 °C for a period of 48 h. The resulting deep-red solution was concentrated under reduced pressure; crystallization of the residue from hexane at −80 °C gave **5a** (0.32 g, 65% yield) as orange needles, mp 156—158 °C (decomp). ^{1}H NMR (400 MHz, C_6D_6) δ=0.37 (s, $2H_1$ and $2H_2$), 0.62 (s, $2H_4$), 0.63 (t, $2H_6$, $J_{6,7}$=6.8 Hz), 1.79 (t, $2H_7$), and 1.87 (s, C_5Me_5). ^{13}C NMR (100 MHz, C_6D_6) δ=12.32 ($C_5\mathit{Me}_5$, $J_{C\text{-}H}$=126 Hz), 20.48 (C_1 and C_2, 157 Hz), 25.01 (C_3), 41.59 (C_7, 123 Hz), 63.48 (125 Hz) and 65.60 (125 Hz) for C_4 and C_6, and 120.82 (C_5Me_5). IR (KBr) ν 3045 (w), 2960 (s), 2880 (s), 2800 (s), 1492 (w), 1434 (m), 1375 (s), 1314 (w), 1260 (w), 1180 (m), 1017 (m), 992 (m), 827 (w), 801 (w), 626 (w), 587 (w), 532 (w), 479 (w), 440 (w), 400 (m), and 370 (w) cm^{-1}. Mass spectrum m/z, 400 (M^+), 398 ($M^+ - 2$), 318 ($M^+ - C_6H_{10}$, base peak), 181 ($M^+ - 219$). Exact mass spectrum m/z, Calcd for $C_{26}H_{40}{}^{48}$Ti: M, 400.2609. Found: m/z 400.2584. Found: C, 77.56; H, 9.58%. Calcd for $C_{26}H_{40}$Ti: C, 77.98; H, 10.07%.

Preparation of 5b. A light-green solution of **3** (1.68 g, 4.86 mmol) and 2-phenyl-1-methylenecyclopropane (**4b**) (1.0 mL, 6.3 mmol) in hexane (50 mL) was stirred at 20 °C. After 48 h, a deep-red solution was obtained. All volatiles were removed under reduced pressure and the resulting residue was crystallized from hexane at −80 °C to give **5b** (1.92 g, 83% yield) as red plates. An analytical sample of **5b** was obtained by recrystallization from toluene at −80 °C as deep-red prisms, mp 122—124 °C (decomp). ^{1}H NMR (400 MHz, C_6D_6) δ=−0.13 (ddd, H_{6a}, $J_{6a,6b}$=11.0 Hz, $J_{6a,7b}$=5.5 Hz, and $J_{6a,7a}$=5.5 Hz), 0.09 and 0.39 (ABq, $2H_4$, $J_{4a,4b}$=11.9 Hz), 0.88 (dd, H_{2cis}, $J_{1,2cis}$=6.1 Hz and $J_{2cis,2trans}$=4.1 Hz), 0.97 (dd, H_{2trans}, $J_{1,2trans}$=8.6 Hz), 1.33 (ddd, H_{6b}, $J_{6b,7a}$=11.0 Hz, $J_{6b,7b}$=5.8 Hz), 1.53 (ddd, H_{7a}, $J_{7a,7b}$=12.3 Hz), 1.63 (dd, H_1), 1.69 (s, C_5Me_5), 1.87 (s, C_5Me_5), 2.31 (ddd, H_{7b}), 7.10—7.30 (m, C_6H_5). Stereochemical assignments of the ring methylene protons have not been performed. ^{13}C NMR (100 MHz, C_6D_6) δ= 12.08 ($C_5\mathit{Me}_5$, $J_{C\text{-}H}$=127 Hz), 12.33 ($C_5\mathit{Me}_5$, 127 Hz), 28.74 (C_2, 157 Hz), 34.17 (C_1, 154 Hz), 34.85 (C_3), 44.15 (C_7, 122 Hz), 55.36 (C_4, 125 Hz), 64.98 (C_6, 123 Hz), 120.89 (C_5Me_5), 121.02 (C_5Me_5), and aromatic carbons at 124.49, 127.49, 128.38, and 142.52. IR (KBr) ν 3045 (w), 2970 (s), 2900 (s), 2800 (s), 1640 (m), 1601 (m), 1497 (m), 1445 (m), 1378 (s), 1304 (w), 1077 (w), 1063 (w), 1019 (m), 821 (m), 774 (m), 737 (m), 697 (s), 636 (m), 401 (w) cm^{-1}. Mass spectrum m/z, 476 (M^+), 318 ($M^+ - C_{12}H_{14}$), 158 ($M^+ - Cp^*_2Ti$), 129 ($M^+ - 347$, base peak). Exact mass spectrum m/z, Calcd for $C_{32}H_{44}{}^{48}$Ti: M, 476.2921. Found: m/z 476.2900. Found: C, 80.17; H, 9.95%. Calcd for $C_{32}H_{44}$Ti: C, 80.65; H, 9.31%.

X-Ray Structure Determination of 5b. Deep-red crystals of **5b** were grown from a saturated toluene solution at −20 °C overnight. The crystals were mounted in thin-walled glass capillaries under argon and then flame-sealed. Pertinent details concerning the data collection and the final cell dimensions, which were obtained from a least-squares refinement of 2θ values of 50 independent reflections in the range of $19°<2\theta<30°$, are given in Table 3.

The 4261 unique raw intensity data were converted to values of the structure factor by corrections for Lorentz and polarization effects. Inspection of the standard three reflections ((8 0 0), (0 4 0), and (0 0 4)) measured after every 50 reflections showed no systematic variation in the intensity. A systematic absence, (h 0 l) with h=odd and (0 k 0) with k=odd, indicated the space group $P2_1/a$.

The location of the titanium atom was determined by a direct method (MULTAN-78 program).[25] A series of standard block-diagonal least-squares refinements and Fourier syntheses revealed the remaining carbon atoms as an anisotropic temperature factor. The hydrogen atoms were located both by the difference Fourier syntheses and calculations. All non-hydrogen atoms as an anisotropic and hydrogen atoms as an isotropic temperature factor were refined to $R=\sum||F_o|-|F_c||/\sum|F_o|=0.053$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.056$. A weighting scheme, $1/w=\sigma_c{}^2+(0.015|F_o|)^2$, was employed. A final difference Fourier map indicated that no

significant residual peak remained. The selected bond lengths and angles are listed in Tables 1 and 2, respectively.

Catalytic Isomerization of 2,2-Diphenyl-1-methylenecyclopropane (4c). A sealed NMR tube containig complex **3** (2.0 mg, 0.057 mmol) and 2,2-diphenyl-l-methylenecyclopropane (**4c**) (35 mg, 0.17 mmol) in toluene-d_8 (0.5 mL) was heated at 70 °C for a period of 1 h. The light-green color changed to orange. ^{1}H NMR spectrum showed that **4c** was converted to 1,1-diphenyl-1,3-butadiene (**7**),[26] which was isolated by preparative TLC (Merck silica gel 60 F_{254}). **7**: ^{1}H NMR ($CDCl_3$) δ=5.12 (dd, H_3, $J_{2,3}$=10.1 and $J_{3,4}$=1.8 Hz), 5.38 (dd, H_4, $J_{2,4}$=16.8 Hz), 6.44 (ddd, H_2, $J_{1,2}$=11.0 Hz), 6.71 (d, H_1). ^{13}C NMR ($CDCl_3$) δ=118.48 (C_4, J_{C-H}=158 Hz), 127.26 (160 Hz), 127.37 (160 Hz), 127.44 (160 Hz), 128.03 (160 Hz), 128.06 (160 Hz), 130.27 (162 Hz), 128.39 (C_3, 155 Hz), 134.85 (C_2, 156 Hz), 139.53, 141.96, 143.02. Mass spectrum m/z, 206 (M^+, base peak), 191 ($M^+ - 15$), 178 ($M^+ - 28$), 165 ($M^+ - 41$). Exact mass spectrum, m/z, Calcd for $C_{16}H_{14}$: M, 206.1095, Found: m/z 206.1076.

Reaction of 3 with Phenylallene. To a solution of **3** (140 mg, 0.405 mmol) in toluene (10 mL) was added dropwise phenylallene (304 mg, 2.62 mmol) in toluene (5 mL) at −50 °C. This solution was stirred at room temperature overnight. The color of the solution turned from light-green to red. The resulting solution was concentrated in vacuo; the residue was then dissolved in hexane (5 mL). Upon cooling the solution at −20 °C, complex **9** (90 mg, 75% purity, 38% yield) precipitated as a green powder. In spite of repeated recrystallization from hexane, no pure sample of **9** could be obtained. ^{1}H NMR (C_6D_6) δ=1.67 (s, $2C_5Me_5$), 2.60 (d, H_3, $J_{1,3}$=3.3 Hz, H_3), 5.12 (d, H_1), 7.0—7.5 (m, C_6H_5). ^{13}C NMR (C_6D_6) δ=11.60 ($C_5\mathit{Me}_5$, J_{C-H}=126 Hz), 86.54 (C_3, 147 Hz), 119.53 (C_5Me_5), 120.83 (C_1, 156 Hz), 244.15 (C_2), 124.56 (160 Hz), 126.05 (146 Hz), 128.43 (158 Hz), and 142.00 (aromatic carbons).

Oxidation of complex **9** by O_2 in C_6D_6 afforded phenylallene in quantitative yield (by ^{1}H NMR).

Hydrolysis of 5a. A solution of **5a** (24 mg, 0.06 mmol) in octane (5 mL) was treated with Al_2O_3 (0.5 g) at room temperature. The orange-red color changed immediately to pale-yellow. GLC analysis indicated that 1-methyl-1-ethylcyclopropane (**10a**) was formed in 96% yield. An authentic sample of **10a** was prepared by the Simmons–Smith[27] methylenation of 2-methyl-1-butene. ^{1}H NMR ($CDCl_3$) δ=0.22 (m, cyclopropane ring protons, 4H), 0.92 (t, CH_3CH_2, J=7.32 Hz), 1.02 (s, CH_3), 1.25 (q, $CH_3\mathit{CH}_2$). ^{13}C NMR ($CDCl_3$) δ=10.82 ($\mathit{C}H_3CH_2$, J_{C-H}=125 Hz), 12.61 (cyclopropane ring carbons, 158 Hz), 16.30 (C_1), 22.19 (CH_3, 126 Hz), 31.97 ($CH_3\mathit{C}H_2$, 124 Hz). Mass spectrum m/z, 84 (M^+), 69 ($M^+ - CH_3$, base peak).

Hydrolysis of 5b. Complex **5b** (64 mg, 0.13 mmol) in benzene (5 mL) was treated with Al_2O_3 (0.5 g) to give 1-ethyl-1-methyl-2-phenylcyclopropane (**10b**) in 88% yield (determined by ^{1}H NMR). The stereochemistry of **10b** was determined to be the *r*-1-ethyl-*t*-2-phenyl isomer by a comparison of its GLC retention time and the ^{1}H NMR spectrum with those of the authentic sample.

Preparation of (*E*)- and (*Z*)-2-Methyl-1-phenyl-1-butene. The title compounds have been reported as being a mixture of *E* and *Z* isomers.[28] These isomers were separated by preparative GLC (DIDP, 140 °C, 0.6 kg cm^{-1}). *Z*-isomer: ^{1}H NMR ($CDCl_3$) δ=1.09 (t, $CH_2\mathit{CH}_3$, J=7.63 Hz), 1.88 (s, CH_3), 2.24 (q, CH_2CH_3), 6.25 (s, -CH=), 7.18—7.31 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=12.74 (C_4, J_{C-H}=127 Hz), 23.43 (CH_3, 134 Hz), 25.43 (C_3, 124 Hz), 124.73 (C_1, 153 Hz), 125.72 (162 Hz), 127.93 (158 Hz), 128.39 (155 Hz), 138.48, 140.92. *E*-isomer: ^{1}H NMR ($CDCl_3$) δ=1.11 (t, CH_3CH_2, J=7.63 Hz), 1.86 (s, CH_3), 2.18 (q, $CH_3\mathit{CH}_2$), 6.26 (s, olefinic proton), 7.15—7.32 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=12.65 (C_4, J_{C-H} =127 Hz), 17.60 (CH_3, 127 Hz), 33.24 (C_3, 127 Hz), 123.51 (C_1, 151 Hz), 125.63 (160 Hz), 127.88 (160 Hz), 128.72 (157 Hz), 138.69, 140.70. The stereochemistry was determined on the basis of ^{13}C NMR spectrum.[29] Mass spectrum m/z, 146 (M^+), 131 ($M^+ - CH_3$, base peak).

Preparation of *r*-1-Ethyl-1-methyl-*c*-2-phenylcyclopropane and *r*-1-Ethyl-*t*-2-phenyl Isomers.[30] Both isomers of the title compound were prepared by the Simmons–Smith methylenation[27] of (*E*)- and (*Z*)-2-methyl-1-phenyl-1-butene, respectively. *c*-2-Phenyl isomer: ^{1}H NMR ($CDCl_3$) δ=0.74 (dd, H_{3t}, $J_{3t,3c}$=5.89 Hz), 0.79 (t, CH_3CH_2, J=7.48 Hz), 0.84 (dd, H_{3c}), 0.93 and 1.13 (ABX pattern, $CH_3\mathit{CH}_2$), 1.21 (s, CH_3), 1.95 (dd, H_2, $J_{2,3t}$=8.24 and $J_{2,3c}$=5.80 Hz), 7.18—7.35 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=10.60 (CH_3, J_{C-H}=124 Hz), 17.20 (C_3, 157 Hz), 23.89 (CH_3, 125 Hz), 24.04 (C_1), 26.52 (CH_2, 123 Hz), 30.42 (C_2, 158 Hz), 125.30 (162 Hz), 127.66 (160 Hz), 128.81 (160 Hz), and 140.02 for aromatic carbons. *t*-2-Phenyl isomer **10b**: ^{1}H NMR ($CDCl_3$) δ=0.76 (s, CH_3), 0.76—0.80 (m, H_{3t} and H_{3c}), 1.03 (m, $CH_2\mathit{CH}_3$), 1.32 and 1.53 (ABX pattern, CH_2CH_3, J=6.1 and 12.0 Hz), 1.87 (t, H_2, J=6.0 Hz), 7.17—7.30 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=10.93 (CH_3, J_{C-H}=125 Hz), 17.09 (CH_3, 125 Hz), 17.58 (C_3, 157 Hz), 23.91 (C_1), 28.74 (C_2, 158 Hz), 33.84 (CH_2, 123 Hz), 125.30 (160 Hz), 127.69 (160 Hz), 128.87 (160 Hz), 148.15 for aromatic carbons. The mass spectrum of the trans and cis mixture m/z, 160 (M^+), 145 ($M^+ - CH_3$), 131 ($M^+ - C_2H_5$, base peak). Exact mass spectrum m/z, Calcd for $C_{12}H_{16}$: M, 160.1252. Found: m/z 160.1252.

Reaction of 5a with H_2. After placing a solution of **5a** (32 mg, 0.081 mmol) in octane (4 mL) into a glass pressure bottle, hydrogen was introduced up to 3 atm. After 20 h at room temperature, 1-ethyl-1-methylcyclopropane (**10a**) was obtained in 86% yield (GLC). The structure was identified by a comparison of the GLC retention time and the ^{1}H NMR spectrum with those of the authentic sample.

Reaction of 5b with H_2. After placing a solution of **5b** (37 mg, 0.078 mmol) in hexane (10 mL) into a glass pressure bottle, hydrogen was introduced up to 3 atm. Then, after stirring the mixture at room temperature for 40 h, the orange-red solution turned to orange. *r*-1-Ethyl-1-methyl-*t*-2-phenylcyclopropane (**10b**) was obtained in 88% yield (GLC).

Reaction of 5a with CO. An orange solution of **5a** (131 mg, 0.327 mmol) in hexane (10 mL) was placed in a glass pressure bottle (100 mL); carbon monoxide (3 atm) was then pressured. After stirring at room temperature for 45 min, the starting complex was converted to spiro[2.4]heptan-5-one (**11a**) in 98% yield, the structure of which was confirmed by a comparison of the ^{1}H, ^{13}C, mass, and IR spectra with the reported ones.[31]

Reaction of 5b with CO. A solution of complex **5b** (99.3 mg, 0.21 mmol) in toluene (10 mL) was placed in an autoclave. Carbon monoxide was then pressured to 30 atm. After 20 min at room temperature, the decrease in the CO pressure stopped. 1-Phenylspiro[2.4]heptan-5-one (**11b**) was obtained in 98% yield (GLC) which was isolated by preparative GLC (SE-30, 220 °C) separation. **11b**: ^{1}H NMR ($CDCl_3$) δ=1.13 (d, H_2, $J_{1,2}$=7.64 Hz), 1.91 and 2.04 (ABq, H_4), 2.05 (ABX,

$2H_7$), 2.12 (t, H_1), 2.41 (t, $2H_6$, $J_{6,7}$=7.78 Hz), 7.05—7.28 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=16.58 (C_2, J_{C-H}=159 Hz), 27.40 (C_3), 28.61 (C_1, 158 Hz), 33.69 (132 Hz), 39.32 (131 Hz), and 42.05 (131 Hz) for C_4, C_6, and C_7, 125.92 (160 Hz), 127.73 (158 Hz), 128.15 (158 Hz), and 138.69 for aromatic carbons, 217.79 (C_5). IR (neat) ν 1747 cm^{-1} (C=O). Mass spectrum m/z, 186 (M^+), 142 ($M^+ - 44$), 129 ($M^+ - 57$), 91 ($M^+ - 95$, base peak). Exact mass spectrum m/z, Calcd for $C_{13}H_{14}O$: M, 186.1045. Found: m/z 186.1045.

Thermolysis of 5a. The isolated complex **5a** (21 mg, 0.053 mmol) was placed in a Schlenk tube and rapidly heated up to 200 °C under reduced pressure in an oil bath. The products were condensed into an NMR tube, and the tube was sealed. ^{1}H NMR and GLC analysis (Durapak) indicated that methylcyclopropane[32] (19%), butadiene (31%), 2-ethyl-1,3-butadiene **12** (16%), and ethylene (43%) were obtained. These compounds were also analyzed by GC-Mass spectroscopy.

Thermolysis of 5b. Complex **5b** (146 mg, 0.31 mmol) was heated at 200 °C under reduced pressure, and the volatile products were condensed on a liquid-nitrogen cold finger. GLC and ^{1}H NMR analysis indicated that 1-phenyl-3-ethyl-1,3-butadiene (**13**)[33] (70%) and 1-phenylspiro[2.3]hexane (**14**) (6%) were obtained. The structure of **12** was determined by a comparision of the ^{1}H NMR and GLC retention time with those of an authentic sample. **13**: ^{1}H NMR ($CDCl_3$) δ=1.18 (t, CH_2CH_3, J=7.5 Hz), 2.37 (q, CH_2CH_3), 5.09 and 5.14 (=CH_2), 6.60 (d, H_1, J=16.3 Hz), 6.84 (d, H_2), 7.21—7.45 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=12.68, 24.66, 115.03, 126.31, 127.24, 127.66, 128.48, 137.42, 147.64. Mass spectrum m/z, 158 (M^+), 143 ($M^+ - CH_3$), 129 ($M^+ - C_2H_5$, base peak). Exact mass spectrum m/z, Calcd for $C_{16}H_{14}$: M, 158.1095. Found: m/z 158.1089.

Preparation of Benzylidenecyclobutane. In an 80 mL Schlenk tube equipped with a magnetic stirring bar was stirred a solution of cyclobutanone (1.0 g, 14 mmol) dissolved in 20 mL of THF. This was cooled to −60 °C; then a solution of benzylmagnesium chloride (15 mmol) in THF (20 mL) was added dropwise over 0.5 h. When the addition was completed, the homogeneous solution was slowly warmed to room temperature over a period of 2 h. The reaction mixture was poured into ice-water, and the mixture was extracted with three 50-mL portions of ether. The crude alcohol was treated with 6 equiv H_2SO_4 at 70—80 °C for 2 h. The products were extracted with ether (50 mL). The ether layer was washed with aq $NaHCO_3$ and dried over sodium sulfate. Crude benzylidenecyclobutane (0.77 g, 37% yield) was obtained by short-path distillation and used without further purification. ^{1}H NMR ($CDCl_3$) δ=2.09 (m, $CH_2CH_2CH_2$), 2.87 (t, $CH_2CH_2CH_2$, J=7.8 Hz), 3.03 (t, $CH_2CH_2CH_2$, J=7.9 Hz), 6.06 (s, olefinic proton), 7.11—7.31 (m, C_6H_5).

Preparation of 1-Phenylspiro[2.3]hexane (14). A mixture of benzylidenecyclobutane (0.75 g, 5.2 mmol), diiodomethane (3.0 g, 11 mmol), and zinc–copper (2.49 g, 38 mmol) in ether (40 mL) was heated at reflux for 30 h. The solution was filtered and the solid was washed with two 30-mL portions of ether. The filtrate and washings were treated with aq. sodium hydrogencarbonate (30 mL, twice), and then with saturated aq. sodium chloride. The ether layer was dried over sodium sulfate. Short-path distillation yielded a colorless oil (0.46 g). A GLC analysis indicated that the product was contaminated with several impurities. Preparative GLC separation (DIDP column) gave a pure sample of **14**. ^{1}H NMR ($CDCl_3$) δ=0.85 (dd, H_{2trans}, $J_{1,2trans}$=8.85 Hz, $J_{2cis,2trans}$=5.49 Hz), 1.06 (dd, H_{2cis}, $J_{1,2cis}$=5.80 Hz), 1.83 (dd, H_1), 1.89—2.27 (m, cyclobutane methylene protons), 6.95—7.27 (m, C_6H_5). ^{13}C NMR ($CDCl_3$) δ=16.49 (C_5, J_{C-H}=138 Hz), 20.44 (C_2, 160 Hz), 26.38 (132 Hz) and 31.35 (135 Hz) for C_4 and C_6, 28.08 (C_1, 158 Hz), 28.54 (C_3), 124.88 (161 Hz), 126.49 (158 Hz), 127.84 (158 Hz), and 141.28 for aromatic carbons. IR (KBr) ν 3058 (m), 3020 (m), 2978 (m), 2942 (s), 2920 (s), 2848 (m), 1602 (m), 1498 (s), 1452 (m), 1204 (w), 1107 (w), 1086 (w), 1062 (w), 1037 (w), 918 (w), 833 (w), 787 (w), 761 (m), 741 (m), 702 (s) cm^{-1}. Mass spectrum m/z, 158 (M^+), 143 ($M^+ - CH_3$), 130 ($M^+ - C_2H_4$, base peak), 115 ($M^+ - C_3H_7$), 104 ($M^+ - C_4H_6$). Exact mass spectrum m/z, Calcd for $C_{12}H_{14}$: M, 158.1095. Found: m/z 158.1099.

Preparation of *cis*-3-Deuterio-2-phenyl-1-methylenecyclopropane (*cis*-4b-d_1). This compound was prepared by essentially the same method as that described in the literature.[24] Only modification is used for the preparation of *cis*-3-deuterio-1,1-dibromo-2-phenylcyclopropane with a phase-transfer catalyst system.[23a]

Thermolysis of 15. Complex **15** has been thermally decomposed as described for **5b**. 2-Deuterio-1-phenyl-3-ethyl-1,3-butadiene (**20**) was obtained. Within the limit of ^{1}H NMR detection, deuterium was only located at the C(2) position. The deuterium content of **20** was 88%.

Reversed Phase Extraction Chromatographic Separation of Germanium with Aliquat 336S from Citric Acid

Sarat Kumar SAHOO
Department of Metallurgical Engineering, Indian Institute of Technology, Bombay 400076, India
(Received October 18, 1990)

Germanium was extracted from 0.005 mol dm^{-3} citric acid at a pH between 2.5 and 6.5 on a column of silica gel coated with Aliquat 336S as the stationary phase. Germanium was then stripped with 0.5 mol dm^{-3} hydrochloric acid and determined spectrophotometrically as its complex with phenylfluorone. Germanium was separated from alkali and alkaline earths, manganese, iron, cobalt, nickel, copper, and zinc in binary mixtures by the exploitation of difference in pH for formation of citrato complexes. It was separated from antimony, bismuth, tin, gallium, indium, and thallium by taking advantage of stability of chloro and sulfato complexes. This method was applied to the determination of germanium in coal fly ash.

The solvent extraction methods for the separation of germanium with liquid anion exchangers as extractants are limited. Germanium has been separated from tin and lead with Amberlite LA-1.[1] Trioctylamine in kerosine was used for the extraction of germanium from oxalic acid.[2,3] The separation of germanium from cobalt and copper by extraction chromatography was carried out with trioctylamine.[4] However, germanium was not separated from associated elements. In continuation of our work with citric acid[5] as the complexing media, extraction chromatographic studies were extended for the separation of germanium on a column of silica gel coated with Aliquat 336S as the stationary phase. This paper describes the separation of germanium from associated elements.

Experimental

Apparatus and Reagents. Spectrophotometer GS 886C (ECIL, India) with matched corex glass cells and Orion Research Microprocessor Ionalyser 901 (Orion, USA) were used.

A stock solution of germanium (3.976 mg cm^{-3}) was prepared by fusing 0.573 g of germanium oxide (ExcelaR grade, Qualigens, India) with 0.5 g of sodium hydroxide in a platinum crucible, neutralizing the residue with hydrochloric acid and diluting to 100 cm^3 with distilled water, and standardized gravimetrically.[6] A solution containing 15 μg cm^{-3} of germanium was prepared by appropriate dilution.

Aliquat 336S (trialkylmethylammonium chloride) was obtained from Fluka and used without further purification.

The silica gel (100—200 mesh) was dried at 120 °C for 2 h, and then packed in a U-tube. A stream of dry nitrogen was passed for 3 h through a small Drechsel bottle containing 25 cm^3 of dimethyldichlorosilane, and then through U-tube containing the silica gel, to convert the surface silanol groups to silyl ether groups. The silica gel was then washed with anhydrous methanol to form methoxyl groups from the unreacted hydroxyl groups, as well as to remove hydrochloric acid from the silica gel. The treated silica gel was then dried at 100 °C. In routine work 1 cm^3 of dimethyldichlorosilane is adequate to render 10 g of silica gel hydrophobic.

A solution of 1 cm^3 of Aliquat 336S in benzene was prepared and transferred into a flask containing 4 g of the hydrophobic silica gel. The benzene was slowly removed from the suspension, in a rotary vacuum evaporator, until dry silica gel was obtained; a low vacuum was applied to remove air from the micropores and to accelerate evaporation of benzene. The silica gel coated with Aliquat 336S was then slurried with citric acid solution and poured into a column having a bed dimension of 10×0.8 cm, where 4 g of the coated silica gel was sufficient to give a bed height of 8 cm which was used for the column studies. The column is not affected with use of strong acids or alkalies as stripping agents.

General Procedure. An aliquot of solution containing 15 μg of germanium was mixed with 5 cm^3 of 0.005 mol dm^{-3} citric acid and the pH of the resulting solution was adjusted to 4.0 either with 0.005 mol dm^{-3} citric acid or sodium hydroxide. The solution was passed through the column at a flow rate of 1 cm^3 min^{-1} where germanium was extracted as its anionic citrato complex by Aliquat 336S. It was stripped with various mineral acids and alkalies. Eight 5 cm^3 fractions were collected. The amount of germanium from each fraction was determined spectrophotometrically as its complex with phenylfluorone at 530 nm.[7]

Results and Discussion

Germanium can be quantitatively extracted with 0.1 mol dm^{-3} Aliquat 336S in xylene from 0.01 mol dm^{-3} citric acid at a pH between 3.0 and 6.0 employing batch

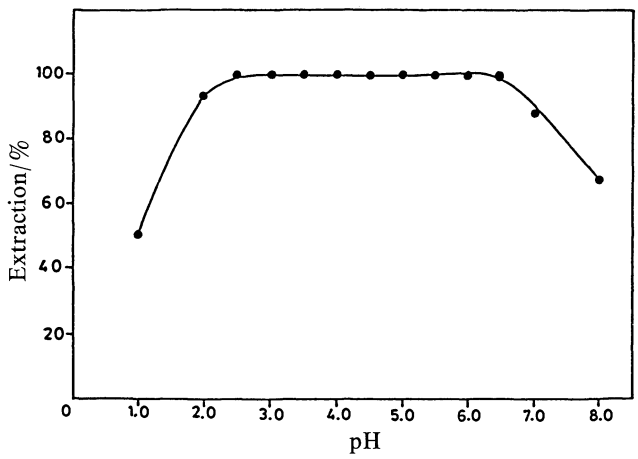

Fig. 1. Effect of pH on extraction of germanium from citric acid.

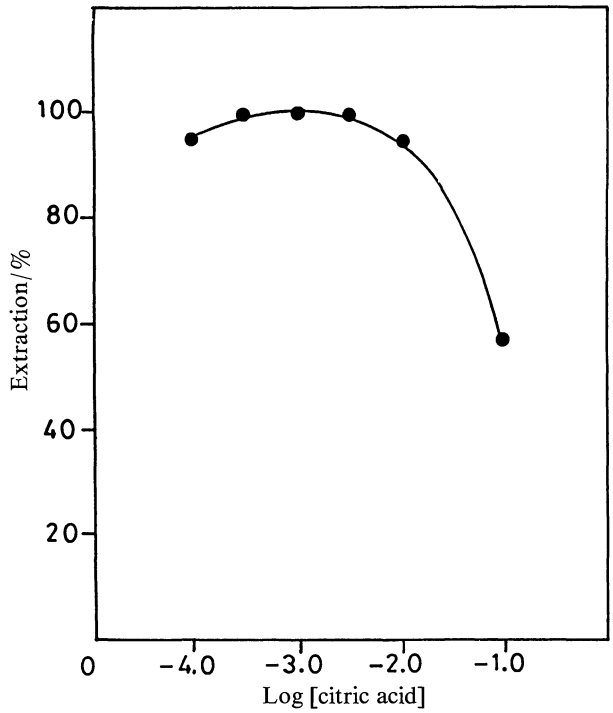

Fig. 2. Effect of citric acid concentration on extraction of germanium.

extraction.[8] However in the extraction chromatographic method, this procedure was modified. The study of extraction of germanium as a function of pH was carried out in the pH range of 1.0 to 8.0. The extraction commenced at pH 1.0 (51.4%) and was quantitative in the pH range of 2.5 to 6.5. Above pH 6.5 (96.2% extracted), the amount of germanium extracted decreased (Fig. 1). The optimum pH for the extraction of germanium used was 4.0 as it is intermediate between 2.5 to 6.0 where extraction was quantitative.

The optimum concentration of citric acid for the complete extraction of germanium was ascertained by extracting from aqueous solution containing 1×10^{-4} to 1×10^{-2} mol dm^{-3} of citric acid. The extraction was incomplete below 1×10^{-4} mol dm^{-3} (Fig. 2). Above 1×10^{-2} mol dm^{-3} citric acid concentration the extraction decreased probably due to presence of competitive equilibria between anionic citrato complex of germanium and citrate anion of Aliquat 336S.

The germanium extracted was stripped from the stationary phase with various mineral acids and alkalies. Hydrochloric acid (0.5—4 mol dm^{-3}), nitric or sulfuric acid (0.25—8 mol dm^{-3}) was capable of stripping of germanium quantitatively. Similarly, 0.25—1.0 mol dm^{-3} of sodium hydroxide or sodium carbonate was also effective for stripping of germanium. At high concentration of hydrochloric acid (>6 mol dm^{-3}) germanium forms negatively charged chloro complex which in turn was reextracted on the column. Hydrochloric acid was selected as a stripping agent considering its use in the spectrophotometric determination of germanium (Table 1).

Separation of Germanium from Other Ions. Germanium was separated from several elements in binary mixtures by utilizing the differences in their capability to form anionic complexes. Thus, since alkali and alkaline earths, manganese, iron, cobalt, nickel, zinc, cadmium, aluminium, and lead can not form anionic citrato complexes they were not extracted and hence were separated from germanium. Some metal ions forming stable complexes with citrate were strongly retained on the column but these were effectively separated from germanium by using suitable stripping agents. Since germanium forms anionic chloro complexes at higher concentration of hydrochloric acid, it was possible to separate it from scandium, titanium, zirconium, hafnium, vanadium, thorium, and palladium as they can not form such complexes and were stripped out with 6 mol dm^{-3} hydrochloric acid. Germanium, which was retained in the form of anionic chloro complex on the liquid anion exchanger, was subsequently stripped with 0.5 mol dm^{-3} hydrochloric acid. Germanium has been separated from gallium, indium, thallium, tin, antimony, and bismuth in binary mixtures by the judicious choice of stripping agents. Germanium was stripped with 3 mol dm^{-3} hydrochloric acid when other elements were reextracted as chloro complexes and later stripped with specific eluents (Table 2). In all these separations, the elements were determined spectrophotometrically by using appropriate chromogenic reagents.[9] Examples of the separation of germanium from multicomponent mixtures are given in Table 3.

Analysis of Germanium in Fly Ash. A 0.5 g of fly ash was dissolved in a mixture (10 cm^3) of aqua regia and hydrofluoric acid (1 : 1) in a Teflon container[10] and evaporated to almost dryness. The residue was dis-

	Tl	1.0 $HClO_4$	150.0	99.9

solved in dilute hydrochloric acid. An aliquot of solution containing germanium was passed through the column as described in General Procedure. Copper, cobalt, zinc, and cadmium were not retained and so they passed through column. Thorium was then stripped with 6 mol dm^{-3} hydrochloric acid and finally germanium with 3 mol dm^{-3} hydrochloric acid. The germanium content found was 18.8 ppm against the standard value of 19.0 ppm.

The advantages of the proposed method over solvent extraction method is that it couples the favorable features of solvent extraction and ion exchange. Multiple extractions are possible in a single column. In batch extractions, 10 cm^3 of 0.1 mol dm^{-3} Aliquat 336S is used for one extraction whereas in extraction chromatography same amount can be used for twenty extractions on a single column.

The proposed method is rapid and reasonably selective. The time required for complete separation and determination is 2 h.

I am thankful to Professor S. M. Khopkar, Depart-

ment of Chemistry for his guidance and encouragement and to Professor T. R. Rama Mohan, Department of Metallurgical Engineering for providing the necessary facilities.

The Design of Amino Hydroxamic Metal Chelates and Their Activity in Biological Systems. Formation Constants between 2-Amino-4-methylpentanehydroxamic Acid with Proton, Copper(II), and Iron(III) in Aqueous Solution

Enrico LEPORATI* and Gianluca NARDI
Istituto di Chimica Generale ed Inorganica, Universita' degli Studi di Parma,
Viale delle Scienze, 78, 43100-PARMA, Italy
(Received November 9, 1990)

The complex-formation equilibria and relative stability constants of species present in aqueous solution of copper(II) and iron(III) with "L-leucinehydroxamic acid" (2-amino-4-methylpentanehydroxamic acid, ahmpe) have heen determined by using potentiometric and spectrophotometric titrations in 0.5 mol dm^{-3} KCl solution at 25 °C. Their acid-base reaction stoicheiometries have heen evaluated and the protonation constants calculated from potentiometric data with the aid of the GAUSS Z and SUPERQUAD programs. The complex formation constants have heen determined by using SQUAD (absorbance data), SUPERQUAD and STBLTY (potentiometric data) programs. The ligand is bound to the metal ions through the coordination of the N atoms of the α-amino group and the deprotonated $-NHO^-$ group in copper(II)–ahmpe system. For iron(III)–ahmpe system the coordination is referred to oxygen atoms of carboxylate and hydroxamate moieties. The UV-visible studies provide important evidence for the formation of several complex species depending on the pH. The experimental curves [$\varepsilon=f(\lambda)$], deduced from refinement of absorbance data with the program SQUAD, have been split up into precisely positioned absorption bands by Gaussian analysis using a nonlinear least-squares computer program NLIN. So the solution electronic spectra have been also employed to estimate the coordination sphere and have let us to suppose a weak tetragonal coordination [$CuL_2(H_2O)_2$] and octahedral for Fe^{3+} complexes. The determination of formation constants and the coordination pattern proposed have a great interest in terms of metal chelate structures and their important role in biological systems.

Several studies have been recently carried out on hydroxamic acids and their metal complexes owing to the possible biological activity connected with these compounds. Some of these have shown to be potent inhibitors of aminopeptidase,[1–3] a zinc metallo-protease, of enzyme 5-Lipoxygenase[4,5] which is associated with a variety of diseases states as asthma and allergy. Besides several peptide–hydroxamic acids have been designed as inhibitors of human skin collagenase[6] (*Z*-Pro–Leu–Gly–NHOH), Enkephalin-Degrading Enzymes[7,8] (Tyr–Gly–Gly–Phe–Leu), Thermolysin[9] and of a Converting Enzyme of Angiotensin I[10] (L-Glu–(NHOH)–L-Pro for example). Because of the interest about peptide–hydroxamic acids, especially tripeptide such as Pro–Leu–Gly–NHOH, recent works[11,12] have pointed out the importance of thermodynamic stabilities of metal transition complexes containing peptide–hydroxamic polydentate ligands. The authors have not found a relationship with the peptide chain indicating there is no significant interaction in solution. A more recent interest in the class of hydroxamic acids has been increasing mainly due to their capabilities of binding Fe^{3+}. The so-called siderophores are iron chelates microbially produced; they can be divided in iron chelates based on hydroxamic moiety and iron chelates based on catechol group, such as Enterobactin.[13] Several tripod-like hydroxamates and dihydroxamic acids have been synthesized[14,15] and, in order to simulate the properties of natural siderophores ferrichrome,[16] tests in vivo have been carried out. In fact an adequate iron supply is necessary to the growth of bacters. Iron is an essential element for almost all living organisms and also in human body (ca. 4 g), but it is very toxic when in excess. The complex Fe^{3+}–glycinehydroxamic acid has been proposed in veterinary terapy against iron anemy and has been proved to react with Apotransferrin, an iron transport protein.[17] Besides certain macrocyclic ligands[18] containing hydroxamate moieties make the reduction potentials Fe(III)/Fe(II) highly negative but also complexes with unusually high oxidation states are stabilized. For example hydroxamic acids form high colored chelates with V(V) or V(IV); these complexes have been employed extensively as analytical reagents for the detection of this metal.[19–21] In the light of potentiometric and spectrophotometric studies some authors[22,23] have discussed the mechanism of complex formation of Fe^{3+}–glycinehydroxamic acid and Ni^{2+}–pyridoxal-glycinehydroxamic acids. Important results have been obtained about the reactive species [$Fe(OH)^{2+}$, $Fe(OH)_2^+$, Ni^{2+}, and $Ni(OH)^+$] implicated in the formation equilibria. It must be emphasized that it's important to investigate the complexing ability of hydroxamic acids not only with iron but also with Cu^{2+}, Zn^{2+}, Ni^{2+}, Mn^{2+}, Co^{2+}, and Cr^{3+}. So the inhibition of urease has been interpreted in terms of reversible binding to the active site nickel ion[24] and other complexes, once considered harmful to organisms, today are regarded necessary in animal nutrition. In continuation of our efforts, potentiometric and spectrophotometric studies have been carried out dealing with transition metal complexes of L-Leucinehydroxamate with iron(III) and copper(II).

Experimental

Reagents. The ligand ahmpe was obtained from Sigma (St. Louis, MO) and its purity was checked through potentiometric titrations. Doubly distilled and deionized water was used in all titrations prepared to have a final volume of 25 cm^3 and thermostatted at 25.0±0.1 °C, with a Paratherm electronic (Julabo) circulating constant temperature water bath. All titrations were carried out under an atmosphere of purified nitrogen. The concentration of stock solution of bivalent metal chloride [$CuCl_2 \cdot 2H_2O$] (AnalaR Products) was determined by using an electrogravimetric method, while standard stock solution for atomic absorption spectrometry has been employed determining iron [$Fe(NO_3)_3$]. The ionic strength was kept at 0.5 mol dm^{-3} with KCl (Merck). Potassium hydroxide (carbonate free) was utilized as titrating solution (0.3840 mol dm^{-3}) and standardized according to Gran's method as previously described.[25,26] Molarity of hydrochloric acid was determined with anhydrous sodium carbonate, using phenolphthalein (solution at 10%) as indicator.

Potentiometric Measurements. Potentiometric titrations were performed using a Metrohm E 636 Titroprocessor and a combined electrode 8102SC ROSS (ORION Research). Quantities of the titrant KOH were added by using a Metrohm Dosimat E 635 autoburet. All titration solutions were prepared with a final volume of 25 cm^3 and kept at constant temperature of 25±0.1 °C. The solution was shaken employing a mechanical stirrer and it was maintained in the vessel a stream of nitrogen presaturated with water vapor, by bubbling over the surface of the solution. The range of concentration of ligand in potentiometric titrations was 0.0077—0.0096 mol dm^{-3} for ahmpe-H^+ (pH range 3.20—11.24; number of titrations 6); 0.0076—0.0082 mol dm^{-3} for ahmpe-Cu^{2+} (pH range 3.02—10.67; number of titrations 6); 0.0104—0.0239 mol dm^{-3} for ahmpe-Fe^{3+} (pH range 1.77—7.58; number of titrations 10). The concentration of metal varied between 0.00164—0.00532 mol dm^{-3} for ahmpe-Cu^{2+} and 0.00153—0.00785 mol dm^{-3} for ahmpe-Fe^{3+} system using as supporting electrolyte potassium chloride (I=0.5 M) (1 M=1 mol dm^{-3}). Periodic titrations (dynamic) of hydrochloric acid were carried out with standard carbonate-free potassium hydroxide solution according to Gran's method.

Spectrophotometric Measurements. Absorption spectra in the ranges 400—820±0.3 nm for Cu^{2+}-ahmpe and 300—700±0.3 nm for Fe^{3+}-ahmpe systems were recorded on Kontron Uvikon 860 spectrophotometer to the fourth decimal place with a stepping of 2 nm. Solution containing ligand and metal ion, prepared and maintained under nitrogen with ionic strength 0.5 mol dm^{-3} (KCl), were analysed at a series of pH from 3.30 to 8.80, using 10 mm cells for Cu^{2+}-ahmpe and from 1.89 to 7.89 pH values using 1 mm cells for Fe^{3+}-ahmpe systems.

Calculations. Great accuracy has been taken in the calculation and critical evaluation of some parameters ($E^{\ominus}$, A_j, B_j, N, K_w) relative to potentiometric calibration curves, using different mathematical procedures as previously described.[27,28] An initial estimate of complex formation constants was achieved by the program GAUSS Z.[29] In this program the function $\bar{n}$ against pH let us to estimate the stoicheiometries of possible complexes in the case of binary systems. Successively the SUPERQUAD program[30] was employed to refine the formation constants which minimize the sum of squared residual between observed and calculated emf values (Eq. 1):

$$U=\sum_{i=1}^{z} w_i (E_i^{obsd} - E_i^{calcd})^2, \quad (1)$$

where z is the total number of potentiometric data and w_i is the weighting factor defined by equation (Eq. 2):

$$w_i = 1/[\sigma_{E_i}^2 + (\partial E_i/\partial v_i)^2 \sigma_{v_i}^2], \quad (2)$$

where σ_E(=0.2) and σ_v(=0.008) are respectively the error in emf and in the volume used in the refinement. Moreover STBLTY was utilized to refine formation constants (K-forms or β-forms). In this program a recent pH titration method (FICS) has been used to calculate free metal ions and free ligand concentrations from experimental data without any hypothesis about species for the system.[31,32] The calculation of stability constants then can be reduced to a linear least-square problem by using any of the mass balance equations. The subprogram NONLINEAR LS REFINE is the most commonly used refinement program in STBLTY. The final choice between different SUPERQUAD analyses was based on graphical comparisons between calculated curves and the corresponding simulated data obtained from the HALTAFALL[33] computer program. Besides a further confirmation of potentiometric data has been performed on spectrophotometric values by means of program SQUAD,[34] in which formation constants are refined on the basis of comparison between observed and calculated absorbance values. All the calculations were carried out on the CRAY Y-MP8/432 and IBM 4341/10 computers of the Consorzio per la Gestione del Centro di Calcolo Elettronico dell' Italia Nord Orientale, Casalecchio di Reno, Bologna, Italy, with financial support coming from the University of Parma. Listing of experimental data and final computations from SUPERQUAD, GAUSS Z, NBAR, and SQUAD are available on request from the authors.

Results and Discussion

Protonation Equilibria. Starting from the set of potentiometric data, first the overall protonation constants and the initial amounts (mmol) of reagents (T_L, T_H) were refined simultaneously by using SUPERQUAD. In this calculation the liquid junction potentials (A_j, B_j) have been neglected because of their littleness (pH interval 3.20—10.54) as shown in already published papers.[27,28] The variances (σ^2) in the quantities T_L and T_H of this refinement were respectively 5.2137×10^{-7} and 1.353×10^{-6} $mmol^2$. It might be pointed out (Fig. 1) the excellent agreement between observed and calculated pH values as a function of volume of added titrating solution. The trend of these curves also reflects the presence of two distinct buffering zones separated between them by a small inflection point. The first buffer zone in the pH range 6.10—8.45 corresponds to deprotonation of the oxygen atom ($\log K_2^H$=7.263); the second zone in the pH range 8.00—10.30 is due to deprotonation of α-amino group ($\log K_1^H$=9.152). Besides two titrations have been stopped at pH 7.7 (Fig. 1a) and 8.2 (Fig. 1b) because of the low solubility of ligand in aqueous solution due to its lipophilic character. The cumulative and stepwise protonation and complex formation constants of ahmpe are quoted in

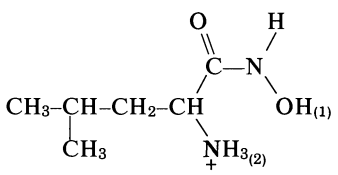
Table 1.

The ligand exhibits two protonation centers: The terminal hydroxamate moiety (H^1; Chart 1) and the α-amino group (H^2; Chart 1). In addition to SUPERQUAD, GAUSS Z and STBLTY programs were employed to refine protonation constants starting from the same experimental data and the results agree closely. Kurzak and collaborators[35] reported values of $\log\beta_{011}$=9.12 and $\log\beta_{021}$=16.26 at 0.1 mol dm^{-3} ($NaClO_4$) at 25 °C. Small differences with our values might be justified (especially for $\log K_2$=7.14) by the influence of the ionic strength on the protonation constants, which we obtain at I=0.5 mol dm^{-3} (KCl). It must be noticed that the presence of the α-amino group in ahmpe increases the acidity of the OH group (-NHOH) in comparison with the corresponding hydroxamic acid $CH_3CH(CH_3)$-CH_2CH_2-CONHOH [$\log K$=9.67(3)[36]]. In the same way the replacement of -NHOH moiety for the OH group lowers considerably the protonation constant of the α-amino group due to the greater electron-withdrawing effect of the -NHOH group.



Hahmpe

Chart 1. H_2L^+ with the two removable protons (1 and 2).

Metal Complex Equilibria. Starting from several sets of potentiometric data, obtained in different ligand to metal ratios, many attempts have been carried out to obtain the best fitting chemical models applying SUPERQUAD program, whereas all the protonation constants were kept constant. The refinement included as fixed contributions (very small) the known metal hydrolysis constants[37,38] for the species $[Fe(OH)]^{2+}$, $[Fe(OH)_2]^{+}$, $[Fe_2(OH)_2]^{4+}$, and $[Fe_3(OH)_4]^{5+}$. All the overall formation constants calculated by both computer methods (SUPERQUAD and STBLTY, see Table 1) agreed closely, even though the standard deviations of the refined quantities calculated by SUPERQUAD program were slightly higher. Equilibria between Co^{2+} and Ni^{2+} ions and ahmpe cannot be studied because

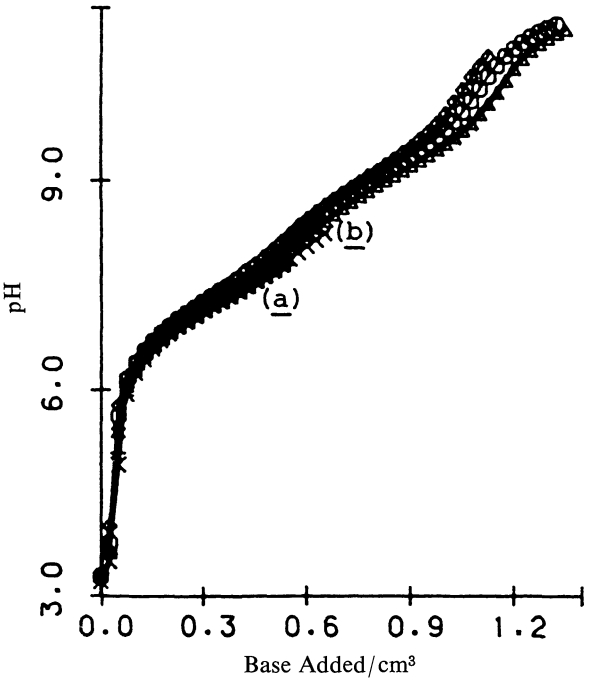


Fig. 1. Experimental and calculated (by SUPERQUAD program) titration curves of pH as a function of volume of KOH added for H^+–ahmpe system, V_o=25 cm³, C_{KOH}=0.38412 mol dm^{-3} [T_L range 0.19365—0.24025, T_H range 0.40614—0.49798]. T_L and T_H are mmol of ahmpe and hydrogen ion in the titration vessel.

precipitation occurs at already acid pH. The refinement converged satisfactorily when only species present for Cu^{2+}–ahmpe system were $[CuL]^+$, $[Cu_2(OH)L_2]^+$, $[CuL_2]$ and $[Cu(OH)L_2]^-$. The most consistent set of complexes found for Fe^{3+}–ahmpe system, together with their respective formation constants shown in Table 1, was $[FeL_2]^+$, $[FeHL]^{3+}$, $[FeH_2L_2]^{3+}$, $[FeHL_2]^{2+}$, $[Fe_2(OH)_2L_2]^{2+}$, $[Fe_2(OH)L_3]^{2+}$, $[FeH_2L_3]^{2+}$, $[FeHL_3]^+$, $[FeL_3]$, and $[Fe(OH)L_2]$. In Fig. 2 species distribution curves are reported. In the case of Cu^{2+}–ahmpe system the complexation begins at pH ca. 3.0 with the formation of $[CuL]^+$ and the dimer $[Cu_2(OH)L_2]^+$ species, which reaches its maximum concentration of 87.0% at pH 4.75. Previous authors[39,40] too have concluded that the dimer is in equilibrium with the mononuclear complex $[CuL]^+$, which is present in small quantity (maximum of 19.99% at pH 3.80). The species $[CuL_2]$ reaches a maximum concentration of 99.8% total copper at pH 7.2 (Fig. 2a)]. Typical absorption spectra for Cu^{2+}–ahmpe are plotted in Fig. 3a, in the pH range 3.75—6.32. At low pH a broad absorption spectrum is present and its maximum shifts towards visible region as the pH increases [maximum, 0.064 A at 724 nm(1); 0.154 A at 654 nm(2); 0.218 A at 644 nm(3); Fig. 3a]. The first maximum of absorbance in the range 586—724 nm occurs at pH 4.66 and λ_{max} of 644 nm and corresponding ca. to the maximum concentration of the hydrolyzed dimeric complex (see Fig. 2a). The increase in absorp-

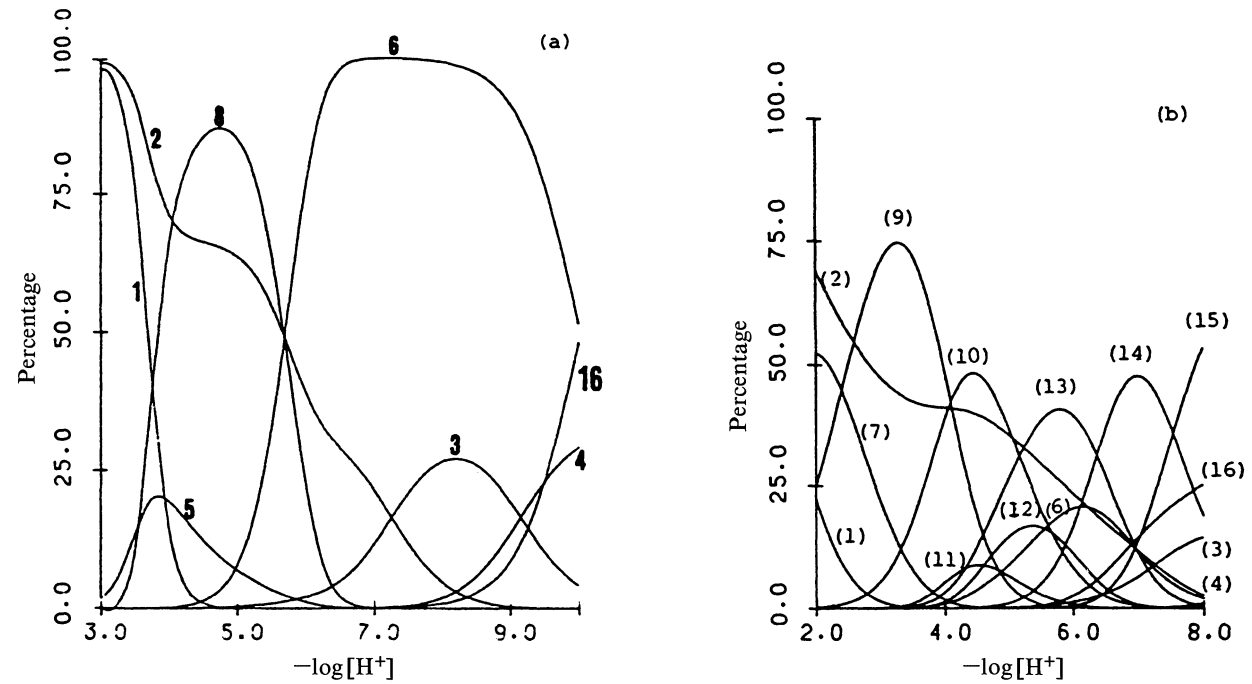

Fig. 2. Typical distribution diagrams for M^{n+}–ahmpe system. The percentage of each species has been calculated from the data of a hypothetical solution of metal ions (0.004 mol dm^{-3} for Cu^{2+} and 0.006 mol dm^{-3} for Fe^{3+}) and ahmpe (0.012 mol dm^{-3} for Cu^{2+} and 0.02 mol dm^{-3} for Fe^{3+}) by the HALTAFALL program (N. Ingri, W. Kakalowicz, L. G. Sillén, and B. Warnqvist, **14**, 1261 (1967)), and using a PLOTTER Calcomp 936. The concentrations of the species not containing metal were calculated as percentages of the total ligand, those containing metal as percentages of the total metal. Fig. 3. Plots of experimental absorbance data versus wavelength for solutions [(a), C_L range 7.592×10^{-3}—7.726×10^{-3} mol dm^{-3}, C_M range 2.469×10^{-3}—2.513×10^{-3} mol dm^{-3}; (1), pH=3.754; (2), pH=4.052; (3), pH=4.660; (4), pH=5.483; (5), pH=5.745; (6), pH=5.875; (7), pH=6.317; (b), C_L range 7.157×10^{-3}—7.219×10^{-3} mol dm^{-3}, C_M range 4.824×10^{-3}—4.866×10^{-3} mol dm^{-3}; (1), pH=3.431; (2), pH=3.783; (3), pH=4.218; (4), pH=4.736] of Cu^{2+}–ahmpe system at 25 °C using the program VISION with the Plotter Calcomp 936.

tion (hyperchromic effect) of the broad spectrum near the IR region and the shift towards smaller wavelengths (hypsochromic effect) of the same band with increasing pH indicates greater complexation, due to the appearance of the hydrolyzed binuclear complex, $[Cu_2(OH)L_2]^+$ (intense green color). When the pH is increased further on from 4.66 to 6.32 (Fig. 3a) small hypochromic and high hypsochromic effects [maximum, 0.218 A at 644 nm(3); 0.182 A at 614 nm(4); 0.175 A at 574 nm(5); Fig. 3a] are observed (change of color from intense green to purple in acid media), while for pH >5.745 a simultaneous increase in the absorption (hyperchromic shift) and a small decrease in the wavelength (hypsochromic effect) [maximum, 0.175 A at 574 nm(5); 0.183 A at 558 nm(6); 0.205 A at 542 nm(7); Fig. 3a] occurs with the formation of the complex $[Cu(OH)L_2]^-$. The color changes from purple to reddish purple. Two distinctive isosbestic points appear at 589 and 483 nm (Fig. 3a). These correspond to an equilibrium between species $[Cu_2(OH)L_2]^+/[CuL_2]$ (each species is present for the 49.0% total copper at pH 5.7, Fig. 2a) and $[CuL_2]/[Cu(OH)L_2]^-$, respectively. It must be noticed that some solutions, several days old, containing Cu^{2+} and ahmpe ligand, both at acid and basic pH values, exhibited a different trend (Fig. 3b). They showed an azure coloring which becomes more intense as the pH increasing (hyperchromic effect), while the maximum shifts slightly towards lower wavelength (hypsochromic shift) [maximum, 0.104 A at 768 nm(1); 0.120 A at 754 nm(2); 0.144 A at 726 nm(3); 0.162 A at 706 nm(4); Fig. 3b]. In order to explain this behavior, we have supposed that the hydroxamate ligand hydrolyzes with the formation

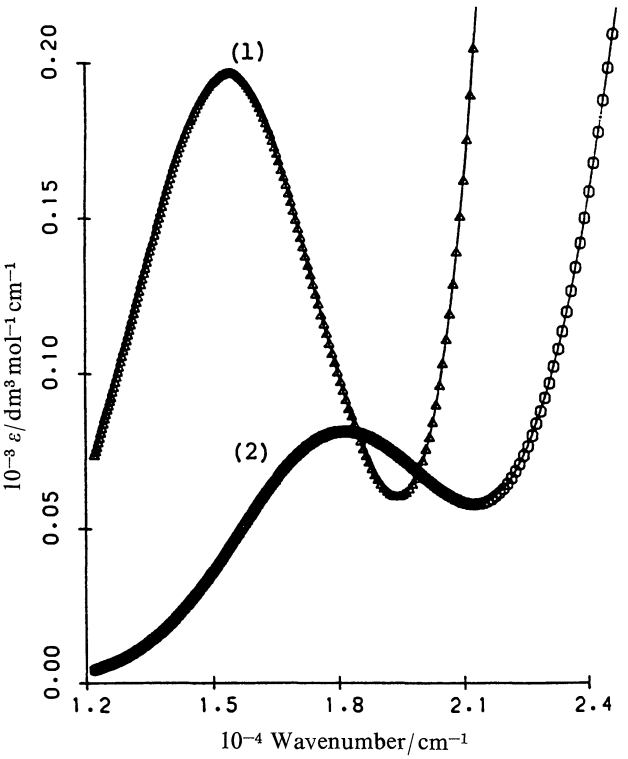

Fig. 4. Plots of molar absorption coefficients (ε) of the two complexed species of Cu^{2+}–ahmpe at 25 °C by program SQUAD: $\varepsilon_{[Cu_2(OH)L_2]^+}$ (1), $\varepsilon_{[CuL_2(H_2O)_2]}$ (2).

of the corresponding amino acid-complexes even in acid solution. In Fig. 4 we have reported molar absorption coefficients (ε) of $[Cu_2(OH)L_2]^+$ and $[CuL_2]$ obtained by use of the program SQUAD in the range 1.2×10^{-4}—2.5×10^{-4} cm^{-1}. The molar absorption coefficients were refined employing 2954 points and obtaining a standard deviation in the absorbance data of 5.9×10^{-2}. By means of the positions of the absorption maxima (Fig. 4), it's possible to check with good precision the ligand-field contribution of ligands about absorbing complexes. According to Billo,[41] the ligand-field contribution of each N (amino) is equal to 4530 cm^{-1}; we can calculate the contribution of each nitrogen of the hydroxamate groups in the $[CuL_2]$ with λ_{max}=18215 cm^{-1} corresponding to: (18215—9060)/2=4577 cm^{-1}. For the hydrolyzed dinuclear complex $[Cu_2(OH)L_2]^+$ with λ_{max}=648 nm, if we suppose coordination of one leucine-hydroxamate residue to each copper ion via the nitrogens of the α-amino and hydroxamate moieties, the global contribution of nitrogen atoms ($-NH_2$ and

$-NHO^-$) is 9107 cm^{-1}, so the two remaining groups would have to contribute ca. 3162 cm^{-1}. This value agrees well with the predicted contribution of OH^- or H_2O groups of 3010 cm^{-1}. The most important details arising from this work are thermodynamic conclusions, which in some case suggest the structures of the complexes present in aqueous solution. Spectral investigations of structures perceive only those aspects of the structure that are involved in electronic transitions. On the other hand, the spectrophotometric characteristics and the numerical interpretation of the most stable complexes (CuL_2 or FeH_2L_2, $FeHL_2$, and FeL_3) reflect all bond strengths, ring strains, the coordination sphere around the metal ions, and configurations. In order to interpret the $[CuL_2(H_2O)_2]$ spectrum, a careful and detailed Gaussian analysis of the experimental spectrum of $[CuL_2(H_2O)_2]$ (Fig. 5, 201 ε data points in the ν interval of 12200—25000 cm^{-1}) was performed by using the NLIN computer program.[42] This procedure is based on the nonlinear Gauss–Newton least-squares method. In these calculations the parameters of the components bands and related maxima positions were carefully determined. As previously described,[43,44] the assignments and calculated maxima positions of the components bands (Fig. 5, Table 2) allowed D_{4h} symmetry (tetragonally distorted) with four short copper–ligand bonds in one plane (xy) and two longer copper–H_2O bonds lying along the z axis above and below this plane. In this case, the B_{1g} term will be the ground state and three spin-allowed transitions from the $^2B_{1g}$ state to the other doublet states are to be expected.

$[CuL_2(H_2O)_2]$

$$\nu_1 = E(B_{1g} \rightarrow A_{1g}) = -4D_s - 5D_t$$
$$\nu_2 = E(B_{1g} \rightarrow B_{2g}) = 10D_q$$
$$\nu_3 = E(B_{1g} \rightarrow E_g) = 10D_q - 3D_s + 5D_t$$
$$D_q = \nu_2/10 = 1820.0 \text{ cm}^{-1}$$
$$D_s = 1/7[\nu_2 - \nu_1 - \nu_3] = -2792.9 \text{ cm}^{-1}$$
$$D_t = 1/35[4(\nu_3 - \nu_2) - 3\nu_1] = -1005.7 \text{ cm}^{-1}$$

In Table 2 the comparison of the spectrophotometric properties of copper(II)–ahmpe complexes ($[Cu_2(OH)L_2]^+$, $[CuL_2(H_2O)_2]$, and $[Cu(OH)L_2]^-$) with others of amino hydroxamic acids[35,39,43–47] already studied is summarized. From the results obtained, it is possible to verify an excellent agreement between the parameters of the components bands (ε, ν, f, $\Delta\nu$) for the different systems, meaning that a similar behavior (thermodynamic stability, structure, configuration, coordination sphere, etc.) takes place through the $[CuL_2(H_2O)_2]$ complex formation. In particular our results concerning this system are in good agreement with those reported earlier for copper (II)–ahmpe.[35] As regards the compositions and stability constants of the complexes, our results are in fairly good agreement with the above mentioned ones. However, the small differences observed in the parameters D_s and D_t for the different systems means that the energies for a tetragonal distortion, commonly given in terms of the radial parameters, are slightly different for $[CuL_2(H_2O)_2]$. The differences observed in the values D_q and ε could be due to various factors: changes in the metal ligand distance, while the increment in the molar absorption intensity (ε) of the components bands involves a change from centrosymmetric coordination sphere to weakly acentric molecules. Typical titration curves (observed and calculated) for Fe(III)–ahmpe mixtures are shown in Figs. 6a, b. The titration curves obtained on variation of iron and ligand concentration (Figs. 6a, b) were processed in addition to SUPERQUAD program by

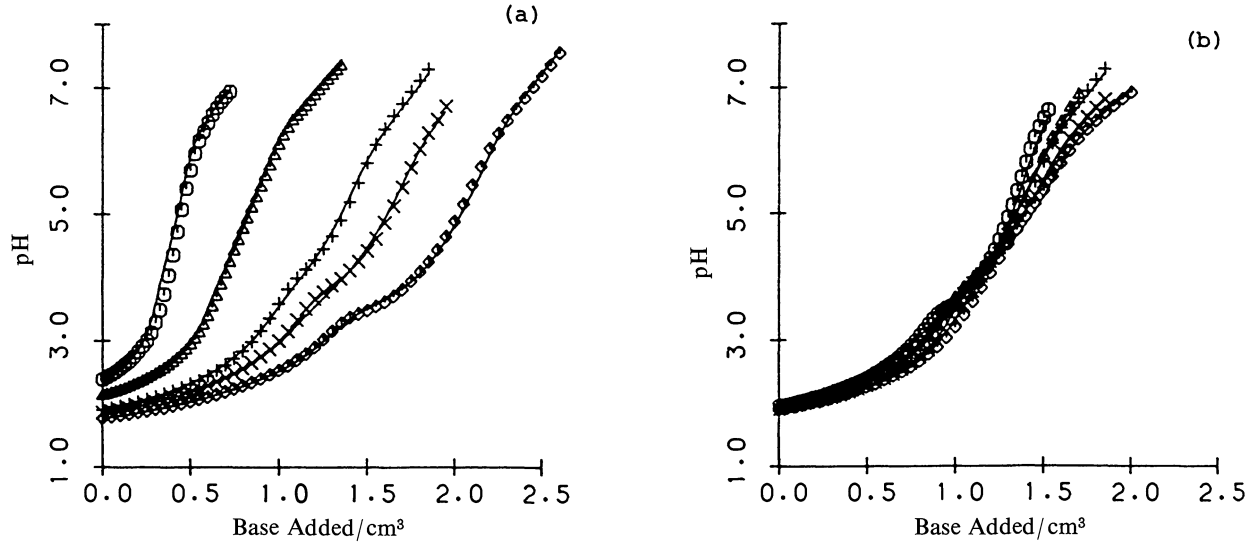

Fig. 6. Experimental and calculated (by SUPERQUAD program) titration curves of pH as a function of volume of KOH added for Fe^{3+}–ahmpe system, V_o=25 cm^3. (a), C_{KOH}=0.46364 mol dm^{-3} [T_L= 0.37732, T_M range 0.03839—0.19628, T_H range 0.81563—1.06633]; (b), C_{KOH}=0.46403 mol dm^{-3}, [T_L range 0.26070—0.59685, T_M=0.12798, T_H range 0.72466—1.39698]. T_L, T_M, and T_H are mmol of ahmpe, iron(III), and hydrogen ion in the titration vessel.

procedures in the FICS method to give $\partial C_H/\partial C_M$ or $\partial C_H/\partial C_L$ respectively, as a function of pH. Finally, the NONLINEAR LS REFINE subprogram of STBLTY[31,32,45,47,48] was applied to select and refine the existing species in the system. From numerous models, the one which yielded the best fit of the titration data (see Figs. 6a, b) is given in Table 1. Our model is only in partial agreement with those given by Brown et al.[17] and El-Ezaby and Hassan[22] for the analogous iron(III)–amino hydroxamate systems. In particular, besides other species of minor importance, the totally deprotonated species $[FeL]^{2+}$ was not found in a quite acid pH range. The relative importance of the various species in each pH range is shown by the typical distribution graph for Fe^{3+}–ahmpe (Fig. 2b). In the presence of Fe^{3+}, the species distribution curves show that complexation begins at low pH values <1.6 for $[Fe(HL)]^{3+}$ species (max. 52.4% total iron at pH 2.0) corresponding to the displacement of one proton. As the pH increases, the proton liberation data shows that complexation proceeds further and at pH 3.3 the predominant species is $[FeH_2L_2]^{3+}$ (74.7%) corresponding to the displacement of two protons. At pH 4.45, the proton displacement value rises to about 3.0 and can be attributed to the formation of the $[FeHL_2]^{2+}$ (48.3%) species when the hydroxamate moiety is about 59.8% ionized. As the pH increases further, the major species present are: $[FeH_2L_3]^{2+}$ (max. 40.9% at pH 5.85), $[FeHL_3]^{+}$ (max. 47.8% at pH 7.05), and $[FeL_3]$ (max. 53.4% at pH 8.0). In these last species three hydroxamate groups can satisfy the octahedral configuration around iron (III), but the $[FeL_3]$ complex formation can be reached only at very high free ligand concentration. Additionally, the formation of protonated, deprotonated and/or mixed hydroxo complexes can be assumed. The spectrophotometric study was carried out on a series of solutions containing ahmpe and iron ions, with concentrations and pH values selected from those employed in the potentiometric titrations. The visible spectra of the Fe^{3+}–ahmpe system as a function of pH are shown in Fig. 7. When the pH is increased from 1.784 to 3.060 [maximum, 0.605 A at 480 nm(1); 0.663 A at 480 nm(2); 0.738 A at 474 nm(3); 0.858 A at 472 nm(4); 1.059 A at 464 nm(5); Fig. 7] small hypsochromic and high hyperchromic effects are observed (intense reddish brown), indicating that complexation at this pH interval presumably gives $[FeHL]^{3+}$, $[FeH_2L_2]^{3+}$, and $[FeHL_2]^{2+}$ (Fig. 2b). A maximum at 464 nm [curve (5), Fig. 7] is reached at pH 3.060, which corresponds to the maximum in the concentration (71.0%) of the protonated complex, $[FeL_2L_2]^{3+}$.

As the pH increases further on a decrease in the wavelength and an increase in the absorption occurs with a maximum at 448 nm [curve (7), Fig. 7]. The color of the solution changes from wine red [intense reddish brown, pH 1.78 to 3.93] to orange red at pH ca. 4.5 and remains this color up to pH 8.0. Componentization of the visible spectra (300—700 nm) data deduced by refinement procedure with program SQUAD indicates at least six colored species are present between 1.784—7.900 pH values. The 13 spectra, each containing 201 absorbance values between 300 and 700 nm, could be presented as linear combinations of six "components"

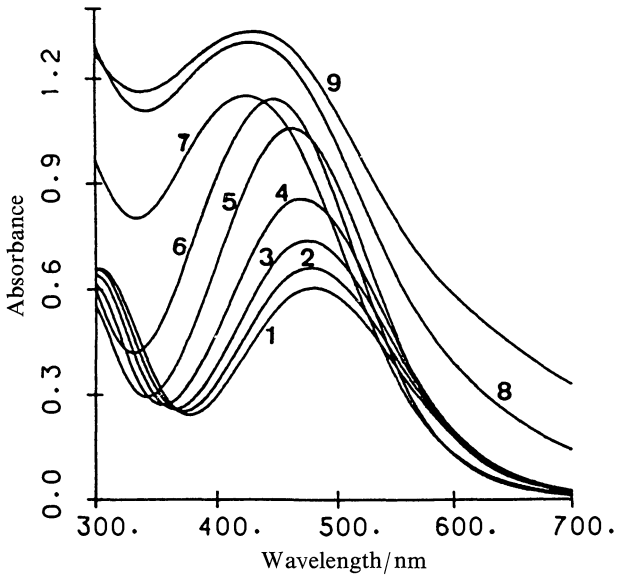

Fig. 7. Plots of experimental data versus wavelength for solutions [C_L range 1.517×10^{-2}—1.647×10^{-2} mol dm^{-3}, C_M range 5.659×10^{-3}—6.143×10^{-3} mol dm^{-3}; (1), pH=1.784; (2), pH=1.930; (3), pH=2.139; (4), pH=2.455; (5), pH=3.060; (6), pH=3.931; (7), pH=5.233; (8), pH=6.592; (9), pH=7.442] of Fe^{3+}–ahmpe system at 25 °C using the program VISION with the Plotter Calcomp 936.

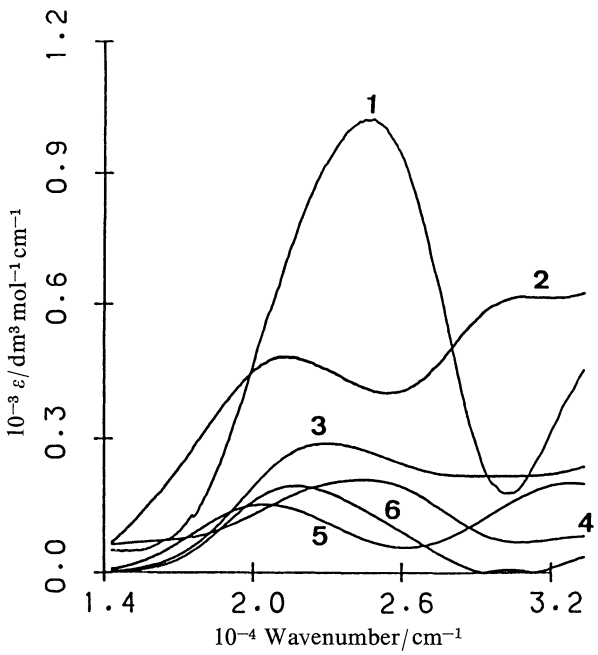

Fig. 8. Plots of molar absorption coefficients (ε) of the six complexed species of Fe^{3+}–ahmpe system: (1) $\varepsilon_{Fe_2(OH)L_3}$, (2) ε_{FeHL_3}, (3) ε_{FeHL_2}, (4) ε_{FeL_3}, (5) $\varepsilon_{FeH_2L_2}$, (6) ε_{FeHL}.

(or molar extinction coefficients, Fig. 8) spectra within standard deviation in absorbance of 0.0201. The least-squares modeling of the spectra included a very small contribution from absorption by Fe^{3+} and its hydrolyzed species (determined from the absorbance of dilute $Fe(NO_3)_3$ solutions at different pH values) in addition to major contributions from six Fe^{3+}–ahmpe complexes. Since iron(III) is a typical hard ion, we presume the coordination of O,O atoms of hydroxamate moiety of ahmpe. Accordingly, the protonated $[FeHL]^{3+}$ $[FeH_2L_2]^{3+}$, $[FeHL_2]^{2+}$, $[FeH_2L_3]^{2+}$, and $[FeHL_3]^{+}$ complexes contain the amino group in its protonated form. This assumption is supported by the spectrophotometric results (see Fig. 7) and those recorded for iron(III)–hydroxamate systems.[45,49–51]

Grateful acknowledgement is made to the Ministero della Pubblica Istruzione (Rome) and National Research Council of Italy (C.N.R.) for generous grants. I am greatly indebted to Professors P. Gans, A. Sabatini, and A. Vacca for their generous support of the program SUPERQUAD.

Oxidation of Sulfite and Thiosulfate by the Cobalt(III) Complex of Dipicolinate in Aqueous Medium

Mahammad Ali, Swapan K. Saha, and Pradyot Banerjee*
Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Jadavpur, Calcutta 700032, India
(Received November 15, 1990)

The oxidation of sulfite and thiosulfate by $Co(dipic)_2^-$ (where H_2dipic=2,6-pyridinedicarboxylic acid) was studied in aqueous medium. The reactions were carried out by varying reagent concentrations, pH, and ionic strength. For thiosulfate oxidation, the rate is zero order in complex and second order in thiosulfate. The reaction rates were found to increase with the acidity and the general rate law is expressed as $k_{obs}=\{k_0'+k_1'[H^+]\}[S_2O_3^{2-}]^2$ where k_0' and k_1' denote the acid independent and dependent paths respectively. The values of rate parameters are $k_0'=(2.87\pm0.20)\times10^{-8}$ mol dm^{-3} s^{-1} and $k_1'=(0.57\pm0.02)$ mol^{-2} dm^6 s^{-1} at 30 °C. A plausible mechanism is suggested by considering the formation of an intermediate active species in the rate-determining step. The sulfite oxidation was, however, first order both in complex and reagent. An inverse dependence on $[H^+]$ was obtained for this reaction indicating a higher reactivity of the anionic species in solution. The general rate law is given by $k_{obs}=2(k_1[SO_2\cdot H_2O]+k_2[HSO_3^-]+k_3[SO_3^{2-}])$ and the evaluated second-order rate constants are: $k_1=(5.60\pm0.04)\times10^{-5}$ mol^{-1} dm^3 s^{-1}, $k_2=(3.02\pm1.21)\times10^{-3}$ mol^{-1} dm^3 s^{-1} and $k_3=(4.91\pm0.05)\times10^{-2}$ mol^{-1} dm^3 s^{-1} at 60 °C. The reactivity order $SO_3^{2-}>HSO_3^->SO_2\cdot H_2O$ has been explained successfully by considering the two isomeric structures for these species in solution. An overall rate law has been derived to interpret these results over the whole range of pH. The theoretical pH rate profile calculated from the different rate parameters shows an excellent agreement with the experimental one suggesting the validity of the proposed mechanism.

Very recently, we reported the oxidation of sulfite[1] and thiosulfate[2] with a substitution inert complex, dodecatungstocobaltate(III), in aqueous acidic solution. In the oxidation of sulfite, a mixed order dependence on sulfite concentration and a variable product distribution in accordance with stoichiometry was obtained. The thiosulfate oxidation was, however, a simple second-order reaction and in both these studies an alkali metal ion catalysis was observed. But these studies were limited to a pH range 1.5—5.5, as the complex was unstable beyond this pH and the reductants were unstable at low pH. Correspondingly, reactivities of the mono- and divalent anionic forms of the sulfite were determined. In the present study we have chosen a complex, $Co(dipic)_2^-$ (where H_2dipic=2,6-pyridinedicarboxylic acid), which is stable both in acidic and alkaline media and only one reactive species exists within the experimental pH range, and it has a standard reduction potential value[3] (E°=0.747 V), little lower than the dodecatungstocobaltate(III)[2] (E°=1.00 V). The choice of the complex is also significant because $Co(dipic)_2^-$ posseses a hydrophobic π-conjugated ligand and is much more reactive with the redox centers in metalloproteins than the redox reagents having hydrophilic electron transfer surfaces.[3-6] The aim of this study is to determine and compare the reactivities of all the species of these reductants available in aqueous solution and also to obtain additional information regarding the mechanistic behavior of the complex towards the reaction.

Experimental

Materials and Reagents. The complex, ammonium salt of bis(dipicolinato)cobaltate(III), $NH_4[Co(dipic)_2]$, was prepared and standardized by the same procedure as reported earlier.[7] Analytical grade reagents were used without further purification. Solutions were prepared in double distilled water and purged with dinitrogen before reaction. The sulfite solution was prepared by dissolving an appropriate amount of sodium sulfite in double distilled water which has been purged with dinitrogen adequately. In a similar fashion thiosulfate solution was prepared and standardized iodimetrically. All solutions were prepared just prior to use. Sodium perchlorate and potassium nitrate used in this study were of analytical grade and also recrystallized thrice before use. Sodium acetate–acetic acid and sodium borate–hydrochloric acid were used as buffers to maintain the pH of the solution as required.

Kinetic Measurements. The reactions were followed in a Pye-Unicam SP8-150 UV/VIS spectrophotometer equipped with thermostated cell compartments. Temperature was controlled using a Haake F3 thermostat. The pH measurements were carried out in a Systronics digital pH meter (model 335, India). Extra precautions were taken to eliminate the loss of sulfurous acid as SO_2 and to prevent air oxidation of thiosulfate. Reactions were carried out in air-tight stoppered quartz cells.

Test for Free Radicals. Both the reactions were tested for free radical generation during the reaction. For this purpose acrylonitrile (5 ml. 20% v/v, degassed with nitrogen) was added to a deaerated reaction mixture. Appearance of a heavy white precipitate within 10 min of reaction confirmed the presence of free radicals in the reaction mixture of sulfite. No polymerization was encountered when acrylonitrile was added to the deaerated solution of complex and reagents separately.

Stoichiometry and Reaction Products. For the thiosulfate oxidation, the reaction stoichiometry was determined iodimetrically by estimating the unreacted thiosulfate in reaction mixtures of thiosulfate and complex in different ratios. The stoichiometry thus obtained is 1:1 ($[Co(dipic)_2^-]$: $[S_2O_3^{2-}]$). The reaction product was tetrathionate and confirmed by the method of Kolthoff and Belcher[8] using the reaction,

$$S_4O_6^{2-} + 3CN^- + H_2O \longrightarrow S_2O_3^{2-} + SO_4^{2-} + SCN^- + 2HCN \quad (1)$$

For the sulfite oxidation, the stoichiometry was determined spectrophotometrically by estimating the excess $[Co(dipic)_2^-]$ in a $Co(dipic)_2^-$–sulfite reaction mixture. With excess sulfite, the stoichiometry was determined by estimating excess sulfite iodimetrically. Under both conditions, a 2:1 $[(Co(dipic)_2^-]$:[S(IV)] stoichiometry was obtained. The corresponding reaction product obtained was sulfate.

Results and Discussion

Oxidation of Thiosulfate by $Co(dipic)_2^-$. The reaction between $Co(dipic)_2^-$ and thiosulfate was followed at 510 nm (ε_{max}=630 $mol^{-1}\,dm^3\,cm^{-1}$) by following the decrease in absorbance of the complex. Na_2edta (1.0×10^{-5} mol dm^{-3}) was used as the masking agent throughout the experiment to avoid any catalysis caused by the presence of foreign metal ions. A 30—35% decrease in rate was observed compared to that in the absence of EDTA. Variation of [EDTA] shows no further effect on the reaction rate. Under pseudo-first-order conditions, the plots of absorbance vs. time are all linear (80 to 90%, of total reaction) indicating a zero-order dependence of rate in complex. The corresponding k_{obs} are calculated from the slope of such plots. A plot of k_{obs} vs. $[S_2O_3^{2-}]$ gives a curvature of increasing slope in the range of $[S_2O_3^{2-}]$=0.005—0.05 mol dm^{-3} at pH 4.5, I=0.60 mol dm^{-3} ($NaClO_4$), and temperature 30 °C. But a plot of k_{obs} vs. $[S_2O_3^{2-}]^2$ is a straight line passing through the origin indicating a second-order dependence of rate on $[S_2O_3^{2-}]$ (Fig. 1). The effect of

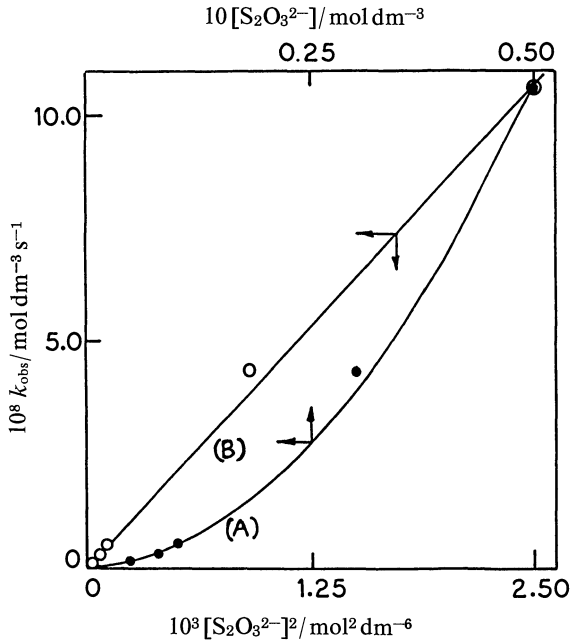

Fig. 1. Different plots showing the dependence of the observed rate on the reductant concentrations (A) k_{obs} vs. $[S_2O_3^{2-}]$, (B) k_{obs} vs. $[S_2O_3^{2-}]^2$. Conditions are; $[Co(dipic)_2^-]=4.0\times10^{-4}$ mol dm^{-3}, I=0.60 mol dm^{-3}, pH=4.5, $[EDTA]=1.0\times10^{-5}$ mol dm^{-3}, and at 30 °C.

Table 1. Dependence of Rate on pH for the Oxidation of Thiosulfate by $Co(dipic)_2^-$ at $[S_2O_3^{2-}]$=0.03 mol dm^{-3}, $[Na^+]$=0.60 mol dm^{-3}, [Complex]=4.0×10^{-4} mol dm^{-3}, [EDTA]=1.0×10^{-5} mol dm^{-3}, and at 30 °C

pH	$10^8\,k_{obs}$ / mol $dm^{-3}\,s^{-1}$
3.90	9.24 (13.2)
4.01	7.90 (11.3)
4.25	6.05 (9.60)
4.50	4.35 (6.50)
4.90	3.45 (5.30)

The parenthetical values represent the k_{obs} in the absence of EDTA added externally. $k_0'=(2.87\pm0.20)\times10^{-8}$ mol $dm^{-3}\,s^{-1}$; $k_1'=(0.57\pm0.02)$ $dm^6\,mol^{-2}\,s^{-1}$.

hydrogen ion concentration on the reaction rates was studied in the pH range 3.90—4.90 at $[S_2O_3^{2-}]$=0.03 mol dm^{-3}, I=0.60 mol dm^{-3} ($NaClO_4$) and temperature 30 °C. The reaction rates increase with the increase in $[H^+]$ and the corresponding results are given in Table 1. A plot of k_{obs} vs. $[H^+]$ gives a straight line with a positive intercept on the rate axis and follows a rate law of the type,

$$\text{rate} = k_0'[S_2O_3^{2-}]^2 + k_1'[H^+][S_2O_3^{2-}]^2 \quad (2)$$

where k_0' represents the acid independent path and k_1', the acid dependent path. The values of k_0' and k_1' are evaluated and summarized in Table 1. Considering the stoichiometry of the reaction and the above rate dependence, the mechanism of the oxidation of thiosulfate by $Co(dipic)_2^-$ may be postulated as,

$$S_2O_3^{2-} + S_2O_3^{2-} \underset{k_{0-}''}{\overset{k_0''}{\rightleftharpoons}} [S_2O_3,S_2O_3]^{4-} \quad (3)$$

$$S_2O_3^{2-} + HS_2O_3^- \underset{k_{1-}''}{\overset{k_1''}{\rightleftharpoons}} [S_2O_3,HS_2O_3]^{3-} \quad (4)$$

$$[S_2O_3,S_2O_3]^{4-} + 2\,Co(dipic)_2^- \xrightarrow{fast} S_4O_6^{2-} + 2\,Co(dipic)_2^{2-} \quad (5)$$

$$[S_2O_3,HS_2O_3]^{3-} + 2\,Co(dipic)_2^- \xrightarrow{fast} S_4O_6^{2-} + 2\,Co(dipic)_2^{2-} + H^+ \quad (6)$$

The above mechanism thus accounts for both the zero-order dependence in complex and the second-order dependence in thiosulfate. Therefore, the rate law may be given as

$$-\text{d[complex]}/dt = k_0''[HS_2O_3^-][S_2O_3^{2-}] + k_1''[S_2O_3^{2-}][S_2O_3^{2-}] \quad (7)$$

Considering the dissociation of $HS_2O_3^-$ as

$$HS_2O_3^- \underset{}{\overset{K_2'}{\rightleftharpoons}} H^+ + S_2O_3^{2-} \quad (8)$$

and $[S_2O_3^{2-}]=[S_2O_3^{2-}]+[HS_2O_3^-]$, the above rate law may be modified as

$$-\frac{\text{d[complex]}}{dt} = 2\cdot\frac{(k_0''K_2'+k_1''[H^+])}{(K_2'+[H^+])^2}\cdot K_2'[S_2O_3^{2-}]^2 \quad (9)$$

The second dissociation constant[9] of sulfurous acid is $K_2'=1.0\times10^{-2}$ mol dm^{-3}. So under the experimental conditions, $K_2' \gg [H^+]$, and the above equation may be reduced to,

$$-d[\text{complex}]/dt = k_1 = 2(k_0''+k_1''K_2'^{-1}[H^+])[S_2O_3^{2-}]^2 \quad (10)$$

The equation (10) simplifies to the observed rate law (2) with $k_0'=2\,k_0''$ and $k_1'=2\,k_1''K_2'^{-1}$.

An attempt has been made to determine the effect of ionic strength on the reaction rate. Under the conditions, $[S_2O_3^{2-}]=0.03$ mol dm^{-3}, pH=4.50, $[Co(dipic)_2^-]=4.0\times10^{-4}$ mol dm^{-3} and at 30 °C, no effect of ionic strength is observed in the range, I=0.2—1.5 mol dm^{-3} ($NaClO_4$).

It is to be noted here that no sulfur deposition was observed in the experimental pH region during the course of reaction. However, at high acid, rapid sulfur deposition occurs and this phenomenon was studied by Dinegar et al.[10] The decomposition rate of thiosulfate thus obtained (k=0.5 mol^{-2} dm^6 s^{-1}) is of the same order as to the oxidation rate (k_1'=0.57±0.02 mol^{-2} dm^6 s^{-1}) in this study. The experimental rate constants for the oxidation of thiosulfate ions by $Fe(CN)_6^{3-}$,[11] (k=0.6 mol^{-2} dm^6 s^{-1}) and $W(CN)_8^{3-}$,[12] (k=0.30 mol^{-2} dm^6 s^{-1}) are also of the same order as that in this study and favors the proposed mechanism. We have also studied the effect of cations and anions on the reaction rate for this system. Neither the charge nor the size of the cations or anions have appreciable effect on the reaction rate. A 30—35% decrease in rate in the presence of added EDTA was observed (Table 1) and may be attributed to the catalytic effect caused by the presence of trace amount of multivalent cations.

Oxidation of S(IV) by $Co(dipic)_2^-$. The stoichiometric equation for the oxidation of S(IV) by $Co(dipic)_2^-$ both in acidic and alkaline medium may be written as

$$2\,Co(dipic)_2^- + S(IV) \longrightarrow 2\,Co(dipic)_2^{2-} + SO_4^{2-} \quad (11)$$

Table 2. Dependence of Rate on the [S(IV)] for the Oxidation of Sulfite by $Co(dipic)_2^-$ at Different pH, Conditions are [Complex]=4.0×10^{-4} mol dm^{-3}, I=0.50 mol dm^{-3}, and at 60 °C

[S(IV)]		$10^3\,k_{obs}/s^{-1}$		
mol dm^{-3}	pH	2.0	4.5	8.0
0.01			0.10	1.00
0.03			0.24	2.50
0.05		0.12	0.36	4.76
0.07		0.16	0.53	5.70
0.10		0.22	0.71	8.90
0.15		0.33		

$k_1=(5.60\pm0.04)\times10^{-5}$ dm^3 mol^{-1} s^{-1}, $k_2=(3.02\pm1.21)\times10^{-3}$ dm^3 mol^{-1} s^{-1}, and $k_3=(4.91\pm0.05)\times10^{-2}$ dm^3 mol^{-1} s^{-1}; $K_1=(5.03\pm0.01)\times10^{-3}$ mol dm^{-3}, and $K_2=(4.26\pm0.10)\times10^{-7}$ mol dm^{-3}.

where S(IV) indicates all type of the reacting sulfite species (e.g. $SO_2\cdot H_2O$, HSO_3^-, and SO_3^{2-}). Sulfate was only the reaction product as confirmed by the usual tests.

The spectral change for the reaction between $Co(dipic)_2^-$ and S(IV) was noted at pH 3.0, 4.5, and 8.0 with I=0.50 mol dm^{-3} ($NaClO_4$) and at 25 °C. All the spectral scannings gave an isosbestic point near 450 nm and indicated the absence of an appreciable amount of stable intermediate formed during the course of reaction. Measurement of the reaction rate was accomplished by monitoring the decrease in optical density at 510 nm (the absorption maximum of $Co(dipic)_2^-$ species). All the experiments were carried out under pseudo-first-order conditions keeping S(IV) concentration at least tenfold in excess over $Co(dipic)_2^-$ concentration. The plots of $-\log(A_t-A_\infty)$ against time (where A_t and A_∞ have their usual significance) are all linear upto 85% of the total reaction and thus ensures a first-order dependence on complex concentration. Dependence of rate on S(IV) is first order and is shown by the linearity of the plot of k_{obs} vs. [S(IV)] at pH 2.0, 4.5, and 8.0 at I=0.50 mol dm^{-3} ($NaClO_4$) and temperature 60 °C. The corresponding data are listed in Table 2.

The effect of hydrogen ion concentration on the oxidation rate was investigated in the pH range 2.0—8.0 at a constant temperature (60 °C) and ionic strength (I=0.50 mol dm^{-3}, $NaClO_4$). The dissociation constants of sulfurous acid[12] are reported to be $K_1=1.05\times10^{-2}$ mol^{-1} dm^3 and $K_2=4.36\times10^{-7}$ mol^{-1} dm^3 at 25 °C. Therefore, all the molecular and both mono- and divalent anionic species of the reductant would be present in

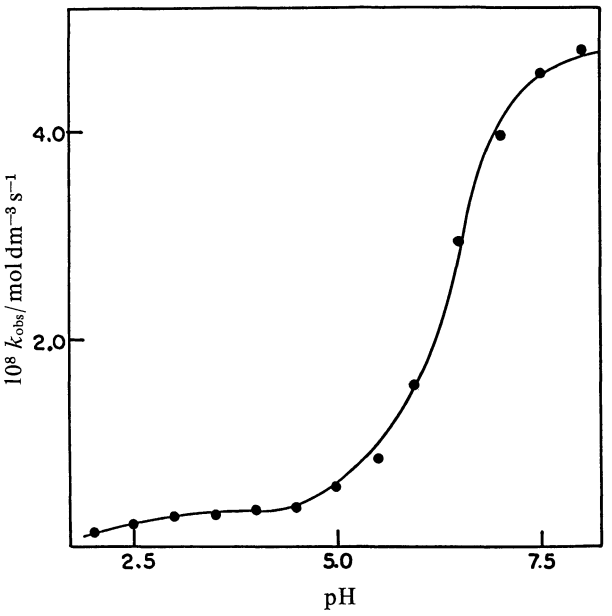

Fig. 2. Plot of k_{obs} vs. pH for the oxidation of sulfite with $Co(dipic)_2^-$ at [complex]=4.0×10^{-4} mol dm^{-3}, [S(IV)]=0.05 mol dm^{-3}, I=0.50 mol dm^{-3} ($NaClO_4$) and at 60 °C. Bold line represents the experimental graph and the theoretical values are shown by ●.

the experimental pH range. We made an attempt to find out the reactivities of individual species separately. For this purpose, we have chosen two different pH regions (i) pH 2.0—5.0, around the pK_1, where only molecular ($SO_2 \cdot H_2O$) and monovalent anionic (HSO_3^-) species are present and (ii) pH 5.5—8.0, around the pK_2, where only monovalent (HSO_3^-) and divalent (SO_3^{2-}) anionic species are only reactive. The corresponding equilibria are described later (in Eqs. 13 and 14). Under both the conditions the plot of k_{ox} vs. $[H^+]^{-1}$ gives the limiting curves of decreasing slope with non-zero intercept on the rate axis. This involves the necessity of three parameters leading to the equation of the form

$$k_{ox}=\frac{a+b[H^+]}{c+[H^+]} \tag{12}$$

where $k_{ox}=k_{obs}/2[S(IV)]$ and 2 is the stoichiometric factor. Data were fit to this equation using a non linear least-squares computer-fit program with each point weighed as k_{ox} and corresponding values of *a, b, c* under the two conditions are given as (i) a=(1.64±0.01)×10^{-5}; *b*=(5.60±0.04)×10^{-5}; *c*=(5.03±0.01)×10^{-3} and (ii) *a*=(2.09±0.04)×10^{-8}; *b*=(3.02±1.21)×10^{-3}; *c*=(4.26±0.09)×10^{-7}.

It is well-known that sulfurous acid exists as hydrated sulfur dioxide in aqueous solution but both HSO_3^- and SO_3^{-2} do exist in aqueous media. The dissociation of sulfurous acid in aqueous solution may be given as[13]

$$SO_2 \cdot H_2O \overset{K_1}{\rightleftharpoons} HSO_3^- + H^+ \tag{13}$$

$$HSO_3^- \overset{K_2}{\rightleftharpoons} SO_3^{2-} + H^+ \tag{14}$$

where K_1 and K_2 are the first and second dissociation constants of sulfurous acid. Considering the stoichiometry and above observations, the possible mechanism corresponding to the oxidation of S(IV) by $Co(dipic)_2^-$ may be proposed as

$$Co(dipic)_2^- + SO_2 \cdot H_2O \xrightarrow{k_1} SO_3^{\cdot-} + Co(dipic)_2^{2-} + 2H^+ \tag{15}$$

$$Co(dipic)_2^- + HSO_3^- \xrightarrow{k_2} SO_3^{\cdot-} + Co(dipic)_2^{2-} + H^+ \tag{16}$$

$$Co(dipic)_2^- + SO_3^{2-} \xrightarrow{k_3} SO_3^{\cdot-} + Co(dipic)_2^{2-} \tag{17}$$

$$S(V)(H\dot{S}O_3 \text{ or } SO_3^{\cdot-}) + Co(dipic)_2^- + H_2O \xrightarrow{\text{fast}} SO_4^{2-} + Co(dipic)_2^{2-} \tag{18}$$

Now considering the pH region 2.0—5.0, as in condition (i), where k_1 and k_2 paths are operative, the corresponding rate law may be given as

$$k_{obs}=2\frac{k_2K_1+k_1[H^+]}{K_1+[H^+]}[S(IV)] \tag{19}$$

$$k_{ox}=\frac{k_2K_1+k_1[H^+]}{K_1+[H^+]} \tag{20}$$

where k_{obs} is the pseudo-first-order rate constant. Similarly in the pH region 5.5—8.0, as in the condition (ii), where the HSO_3^- and SO_3^{2-} are the reactive species, the rate expression can be given as

$$k_{ox}=\frac{k_3K_2+k_2[H^+]}{K_2+[H^+]} \tag{21}$$

and both Eqs. 19 and 20 are consistent to Eq. 11 with a=K_1k_2, *b*=k_1 and *c*=K_1 in Eq. 19 and with *a*=K_2k_3, *b*=k_2 and *c*=K_2 in Eq. 20. The values of k_1, k_2, k_3, and dissociation constants K_1 and K_2 thus obtained are listed in Table 2. There is an excellent agreement between the reported values of K_1 and K_2 and those obtained from the computer-fit program for the experimental data.

Considering the reaction of all the species in the pH range 2.0—8.0, the general rate expression for the reaction between $Co(dipic)_2^-$ and S(IV) can be given as

$$k_{obs}=2\frac{k_1[H^+]^2+K_1k_2[H^+]+K_1K_2k_3}{[H^+]^2+K_1[H^+]+K_1K_2}[S(IV)] \tag{22}$$

Using the above values of k_1, k_2, and k_3 and the values of first and second dissociation constants of sulfurous acid the values of k_{obs} are calculated from the above expression at different $[H^+]$. An excellent agreement between the calculated and observed rate (Fig. 1) provides further support in favor of the proposed mechanism.

A comparison of the reactivities of the different S(IV) species obtained in solution shows the reactivity order $SO_2^{2-}>HSO_3^->SO_2 \cdot H_2O$. In fact SO_3^{2-} is 16 times more reactive than HSO_3^- and HSO_3^- is 53 times more reactive than $SO_2 \cdot H_2O$. This difference in reactivity may be explained by considering the following equilibria,[14]

$$HSO_3^- + H^+ \rightleftharpoons \underset{(A)}{H:SO_3:H} \rightleftharpoons \underset{(B)}{HO\text{–}S\text{–}OH}$$

$$SO_3^{2-} + H^+ \rightleftharpoons \underset{(C)}{H:SO_3} \rightleftharpoons \underset{(D)}{HO:SO_2}$$

In the acidic medium (pH 2.0) an appreciable amount of $SO_2 \cdot H_2O$ is believed to exist in solution. In the (A) form the lone pair is tied up with proton whereas in (B) the electron density will be withdrawn from the sulfur atom by the two OH groups. Similar phenomenon may occur for (C) and (D) also but the electron density will be more on the sulfur atom since the electrons on the sulfur atom are tied up by one proton in (C) or pulled up by one OH group in (D). For SO_3^{2-}, no such consideration occurs and thus electron density will be more available and consequently would show the highest reactivity which actually we found.

The present study provides a systematic approach to the oxidation of sulfur dioxide and thiosulfate in aqueous medium. This study constitutes a rare example where the reactivities of all the species of sulfur dioxide available in aqueous solution have been determined and compared.

The zero-order rate in complex for the thiosulfate oxidation also is one of the very few examples of thiosulfate oxidation where the rate-determining step is

the formation of some active intermediate which in turn reacts with the complex in a fast step. This study has some special importance. Generally in the oxidation reactions of thiosulfate by metal ions and complexes, a zero-order dependence on [complex] is encountered for oxidants having $E^\circ \leqslant 0.54$ V and a first-order dependence for oxidants[2,15-17] having $E^\circ \geqslant 0.80$ V. The present study, therefore, cites a unique example where zero-order rate in complex is obtained though the oxidation potential is sufficiently high ($E^\circ = 0.75$ V). Possibly π-donating character of the dipicolinate ligand makes the metal-center reluctant to electron transfer and thus follows a zero-order rate in complex. Our experimental results are comparable to the reported k_2 values with other oxidants in the presence of added EDTA. But none has reported the acid independent k_0' path which we found significant in the present study.

Mössbauer and Infrared Spectroscopic Studies of Some Alkyl- and Arylamine Coordinated Pentacyanoferrate(II) Complexes

Ratnakar Balkrishna LANJEWAR and Amar Nath GARG*
Department of Chemistry, Nagpur University, Nagpur 440010, India
(Received December 3, 1990)

Mössbauer spectra of alkyl- and arylamine coordinated pentacyanoferrate(II) complexes, $Na_3[Fe(CN)_5L]\cdot xH_2O$ where L=$(CH_3)_3N$, $(CH_3)_2CHNH_2$, $(CH_3)_2CHCH_2NH_2$, $(CH_3)_3C-NH_2$, $C_6H_5NH_2$, $C_6H_5NHCH_3$, $C_6H_5N(CH_3)_2$, $C_6H_5NHC_2H_5$, o-$ClC_6H_4NH_2$, and p-$ClC_6H_4NH_2$ have been studied. All compounds exhibit a well-resolved quadrupole doublet. An unusually high quadrupole splitting is observed for isobutylamine coordinated complex (ΔE_Q=1.75 mm s^{-1}). Other complexes show ΔE_Q=0.67—0.86 mm s^{-1}. A correlation of δ vs. ΔE_Q suggests a positive sign of electric field gradient for isobutylamine coordinated complex and negative for all other complexes. Partial isomer shift (p.i.s.) and δ have been correlated with partial quadrupole splitting (p.q.s.). Also characteristic CN and Fe–N stretching frequencies have been correlated with δ to derive information on σ-donor and π-acceptor properties of the ligands.

Mössbauer spectroscopic studies of coordinated pentacyanoferrate(II) complexes, $[Fe(CN)_5L]^{n-}$ where L= H_2O, NH_3, CO, NO_2, SO_3^{2-}, py, NO^+, DMSO, RNH_2, R_3N etc. have been reported extensively.[1—14] In these studies main emphasis has been to know the extent of deformation in octahedral geometry and correlate isomer shift (δ) with quadrupole splitting (ΔE_Q) to predict the sign of electric field gradient (EFG). Also bonding characteristics with regard to σ-donor and π-acceptor properties of the ligands have been investigated.[8—10] In our earlier studies on mono-, di-, and trialkylamine coordinated pentacyanoferrates(II), it has been observed that though substituted alkylamines, (R_nNH_{3-n}) are primarily σ-donors but in some cases indirect π-interaction is also possible.[11] In the present studies we have synthesized some new pentacyanoferrate(II) complexes, $Na_3[Fe(CN)_5L]\cdot xH_2O$ where L=$(CH_3)_3N$, $(CH_3)_2CHNH_2$, $(CH_3)_2CHCH_2NH_2$, $(CH_3)_3C-NH_2$ $C_6H_5NHCH_3$, $C_6H_5N(CH_3)_2$, $C_6H_5NHC_2H_5$, o-ClC_6H_4-NH_2, and p-$ClC_6H_4NH_2$ and studied their Mössbauer and infrared spectra. We have also attempted to see the validity δ vs. ΔE_Q correlation in predicting the sign of EFG.

Experimental

All reagents used were AR, GR (S. Merck) or of high purity grade (Koch-Light, UK and Fluka, Switzerland). Solvents were distilled and dried before use. The complexes were prepared by slightly modified procedure described in the literature.[15,16]

Preparation of Trimethylamine, Isopropylamine, Isobutylamine, and *t*-Butylamine Coordinated Complexes: Three gram of sodium pentacyanonitrosylferrate(II) (1 mol) and 2 g of sodium acetate were dissolved in 20 ml water and mixed with ice cold solution of the respective amine (20—25 ml) in ethanol. The solution was continuously stirred and additional amount of amine was added till a negative test for pentacyanonitrosylferrate(II) was obtained. The mixture was kept in freezing mixture for 2—4 h during which the complexes separated out.

Preparation of Arylamine Coordinated Complexes: In order to prepare these complexes, sodium amminepentacyanoferrate(II), $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ (SPF) was synthesized[16] which was used for further synthesis of arylamine coordinated complexes. Freshly prepared 3 g SPF (1 mol) was dissolved in 20 ml water, cooled and mixed with an ice cold solution of respective amine (20—25 ml). The solution was continuously stirred for 3—4 h. On addition of cold absolute ethanol

a) Standard deviations are within ±0.03 mm s^{-1}.

complexes were precipitated. These were filtered and dried in vacuo over $CaCl_2$ in a desiccator. The complexes were characterized by the elemental analysis of C, H, N, and Fe. Number of water molecules were matched with the suggested molecular formulae (Table 1).

Mössbauer spectra were recorded on a transducer driven Mössbauer spectrometer in constant acceleration mode (Nucleonix, Hyderabad) at room temperature. A ca. 5 mCi $^{57}Co(Rh)$ source was used. The spectrometer was calibrated using natural iron foil and sodium pentacyanonitrosylferrate(II) dihydrate (SNP) was used as standard. Spectral lines were assumed to have Lorentzian line shape and the Mössbauer parameters were calculated from visual fitting. Errors were estimated from replicate spectral recording. Infrared spectra (4000—200 cm^{-1}) in KBr pellets were recorded on Perkin-Elmer-157 IR spectrophotometer.

Results and Discussion

The Mössbauer spectra of all the complexes exhibit a well-resolved quadrupole doublet at room temperature. The Mössbauer parameters of all the individual complexes are listed in Table 1. Also given in the Table 1 are characteristic infrared frequencies for ν(C≡N), δ(Fe-CN), ν(Fe-C), and ν(Fe-N). Typical Mössbauer spectra of isobutylamine and *t*-butylamine coordinated complexes are shown in Fig. 1.

If one of the cyano ligands in hexacyanoferrate(II), $[Fe(CN)_6]^{4-}$ is replaced by a neutral ligand L to give $[Fe(CN)_5L]^{3-}$, then octahedral geometry remains unaffected but the symmetry is lowered from O_h to approximately C_{4v}.[7] Even though the electronic configuration will be t_{2g}^6 but it will further split into d_{YZ}, d_{ZX}, and d_{XY} (also called e and b_2). All the complexes are expected to be diamagnetic. All amines are essentially σ-donors. The five cyano ligands have vacant π* $2p_y$, $2p_z$ orbitals

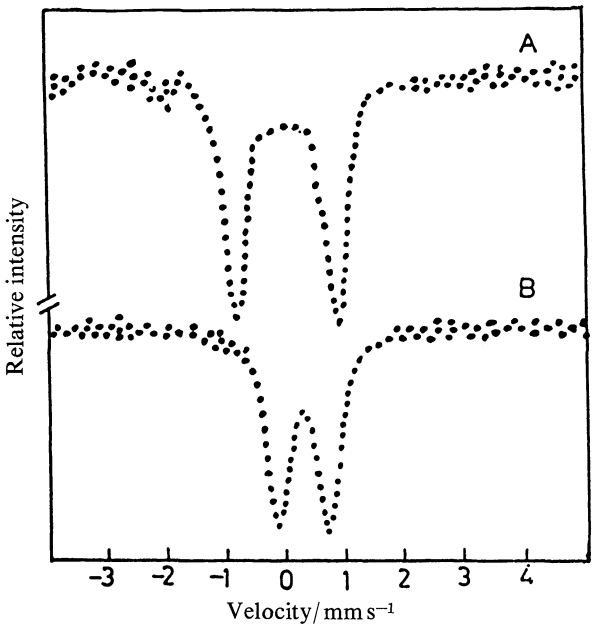

Fig. 1. Mössbauer Spectra of (A) isobutylamine and (B) *t*-butylamine coordinated pentacyanoferrate(II) complexes at room temperature.

available for back bonding, while no such orbitals are available in the case of amines. X-Ray crystal structure determination[17,18] of sodium pentacyanonitrosylferrate(II) has shown that the ligand NO^+ and *trans*-cyano are approximately colinear with central Fe atom slightly displaced in the direction of NO ligand from the plane of four pseudoequivalent CN ligands. Manoharan et al.[19] have studied several hexanitroferrates(II) and confirmed π* $2p_y$, $2p_z$-bonding ability of NO_2^- but found it to be much less than that of CN^- ligands.

(i) Mössbauer Parameters: All compounds show large quadrupole splitting (ΔE_Q) indicating quite significant distortion in octahedral geometry. Since all the six 3d-electrons form a closed shell (t_{2g}^6), no quadrupole splitting is expected due to valence electron contribution. However, due to substitution of sixth cyano with an amine ligand distortion in octahedral geometry is expected. Therefore, ΔE_Q is a direct measure of the distortion due to ligand contribution although small electronic contribution may also be expected due to further lifting of degeneracy in t_{2g} level as suggested by Manoharan and Gray[20] for sodium pentacyanonitrosylferrate(II). All ΔE_Q values fall in the range, 0.67—1.75 mm s^{-1} and can be divided into two subgroups; Gr. I with ΔE_Q=0.67—0.86 mm s^{-1} and Gr. II with ΔE_Q=1.75 mm s^{-1}. Surprisingly isobutylamine coordinated complex exhibits largest ΔE_Q=1.75 mm s^{-1} which is more than double compared to other complexes.

Isomer shift values of all the complexes are in the range −0.04—0.29 mm s^{-1} with respect to SNP as standard. These are well within the typical range for iron(II) low spin complexes.[1-3,10] For all the six aniline coordinated complexes, the isomer shift values are within 0.27±0.02 mm s^{-1} and are comparable with other alkylamine coordinated complexes. It indicates that substitution of alkyl or aryl group or even that of chloro at ortho or para position on phenyl group of aniline ligand does not have any significant effect on s-electron density at the Fe nucleus. It may be further noted that δ value for isobutylamine coordinated complex (−0.04 mm s^{-1}) is very low and it is almost equal to that for dibutylamine and butylamine coordinated complexes studied earlier in our laboratory.[11] It is known that on substitution with bulkier groups in NH_3, its basic character changes resulting in an increase in electron density and hence decrease in δ value is expected. As mentioned δ values for aniline coordinated complexes do not vary significantly indicating that change in basic character of amines may not affect the σ-donor property of the amine ligands.

As already mentioned, a strong asymmetry is generated due to the presence of sixth odd ligand L, resulting in quadrupole splitting. Earlier several workers have observed $\Delta E_Q \approx 0.80$ mm s^{-1} in amine and monoalkylamine coordinated complexes.[4-11] It is suggested that since alkyl- or arylamines are only σ bonded, d_π orbitals of iron remain distributed among five CN^- ligands only. Hence the nature of alkyl or aryl groups should not

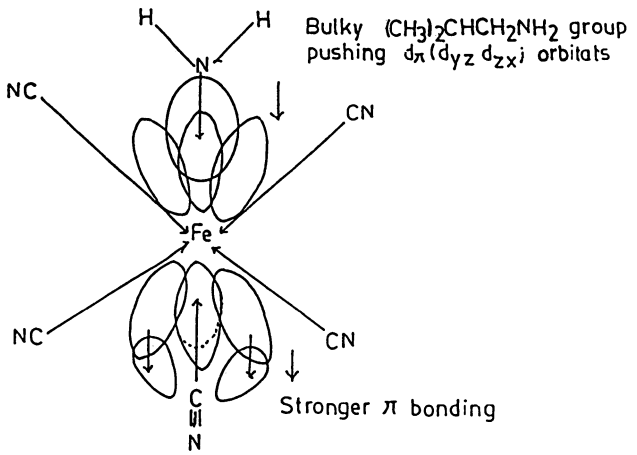

Fig. 2. Diagrammatic representation of isobutylamine ligand pushing π-orbitals (only d_{YZ} and d_{ZX}) of Fe atom which may result in increased π-bonding with trans CN ligand.

cause any significant change in ΔE_Q values. However, for isobutylamine coordinated complex an unusually high ΔE_Q=1.75 mm s^{-1} is observed. It is comparable with sodium pentacyanonitrosylferrate(II) (ΔE_Q=1.71 mm s^{-1}) where it is attributed to excessive π-bonding character of NO.[8] Therefore, in the case of isobutylamine coordinated pentacyanoferrate(II) complex also it may be possible that the central Fe atom is slightly pushed towards trans CN^- by the bulkier isobutyl group and also due to greater π-bonding ability of CN^-. This is schematically illustrated in Fig. 2.

These observations, viz. almost similar values of δ and ΔE_Q for various monoalkyl- and arylamines in these complexes are in accordance with the observation of Ballhausen and Gray.[21]

(ii) Correlation of δ and ΔE_Q: Several workers have attempted to correlate δ and ΔE_Q values and used this correlation in predicting the sign of EFG and bonding characteristics.[22–25] On plotting δ vs. ΔE_Q for all the complexes studied here a linear correlation is observed as shown in Fig. 3. ΔE_Q decreases with increasing δ for all the complexes of the type $[Fe(CN)_5(NH_2R)]^{3-}$ with various alkyl or aryl groups. This is based on the assumption that a positive sign of EFG exists for isobutylamine coordinated complex (similar to SNP) and a negative sign for all other coordinated complexes. However, this sign of EFG needs to be experimentally verified by a crystal orientation or magnetic perturbation method.

(iii) Infrared Spectra: Various vibrational modes of the complexes were assigned by comparison with those for other pentacyanoferrate(II) complexes.[5,8,13] The most important of all vibrational frequencies is the most intense C≡N stretching band which is observed in the region 2140—2040 cm^{-1}. Earlier three modes have been observed for ν(CN) of some di- and trialkylamine coordinated complexes.[11,12] In the present studies, however, we have observed only one band at ca. 2040 cm^{-1} for ν(CN) in all the pentacyanoferrate(II) complexes except for isobutylamine coordinated complex where two intense bands at 2140, 1950 cm^{-1} were observed. Both these bands are either at higher or lower by ca. 100 cm^{-1} compared to normal ν(CN) mode

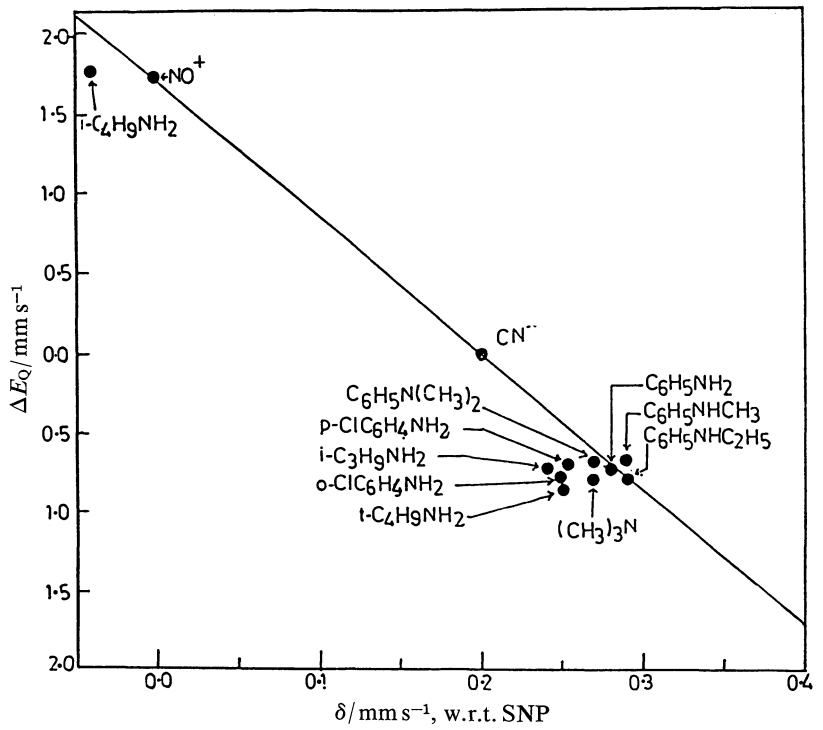

Fig. 3. Correlation of isomer shift (δ) vs. quadrupole splitting (ΔE_Q) values in alkyl- and arylamine coordinated pentacyanoferrate(II) complexes.

observed at ca. 2040 cm^{-1}. Another important characteristic mode of medium intensity is due to Fe–C≡N bending observed in the range 580—540 cm^{-1}. A very weak band observed in the range 450—400 cm^{-1} has been assigned to Fe–C stretching vibrations in acccordance with the assignments of Fluck et al.[8] Another weak band was observed in the range 315—225 cm^{-1} which may be assigned to Fe–N stretching.[8-27] A sharp medium intensity band is also observed at ca. 1600 cm^{-1} and assigned to bending mode of H_2O molecules occupying interstitial position. Interestingly for isobutylamine coordinated complexes ν(CN), δ(Fe–CN) and to some extent ν(Fe–N) are shifted by ca. 100 cm^{-1} in comparison with other complexes. This shift may be a sufficient indication of the difference in bonding characteristics of the isobutylamine coordinated complex compared with others. It may be noted that ν(Fe–C) remains almost unaffected on substitution. Rachlewicz et al.[27] have found ν(Fe–N) to be sensitive to further substitution and changes in bonding characteristics. Therefore, on the basis of ν(Fe–N) and other frequencies, we can conclude that bonding in isobutylamine coordinated complex is certainly different than other complexes.

Since σ-donor and π-acceptor properties of the ligands CN^- and RNH_2 are playing a dominant role, an attempt has been made to correlate ν(CN) and ν(Fe–N) with δ values of the respective complexes as shown in Fig. 4. In both cases straight line correlations have been observed indicating a decrease in δ value with both the stretching modes. Brar and Muzumdar[12] and Inoue et al.[13] have also correlated δ with ν(CN) in pentacyanoferrate(II) complexes. Earlier we have observed a similar trend for ν(CN) and δ(Fe–C≡N) for di- and trialkylamine coordinated complexes.[10] It has been argued that if d_π–p_π back donation from Fe to CN is reduced than Fe–C bond strength should decrease. Following the same argument Fe–N bond strength should also be affected depending on the interaction of ligand orbitals with the metal d_π orbitals. Again a clear trend dividing the ligands into two subgroups is evident. Gr. I complexes exhibiting $\Delta E_Q \approx 0.75$ mm s^{-1} show ν(CN) and ν(Fe–N) at lower frequencies. On the other hand isobutylamine coordinated complex exhibiting unusually high ΔE_Q shows the respective bands at higher frequencies. Almost similar kind of trend is observed for δ(Fe–CN) (Table 1).

(iv) Partial Isomer Shift and Quadrupole Splitting: Several attempts have been made to evaluate partial isomer shift (p.i.s) and partial quadrupole splitting (p.q.s.) values of the ligands in a series of isostructural complexes and correlating them with bonding characteristics.[28,29] These values were calculated using the equations:

$$[L]_{p.i.s.} = \delta - 0.21$$

$$[L]_{p.q.s.} = 1/2(\Delta E_Q - 1.68)$$

where δ and ΔE_Q are observed values. These are listed in Table 1. Plots of p.q.s. vs. δ and p.i.s. show straight line correlations as shown in Fig. 5. In both cases p.q.s. values increase with decreasing δ or p.i.s. values. For distorted octahedral complexes of the type $[Fe(CN)_5L]^{3-}$ it has been observed that δ values are affected depending on whether L is a better σ-donor or

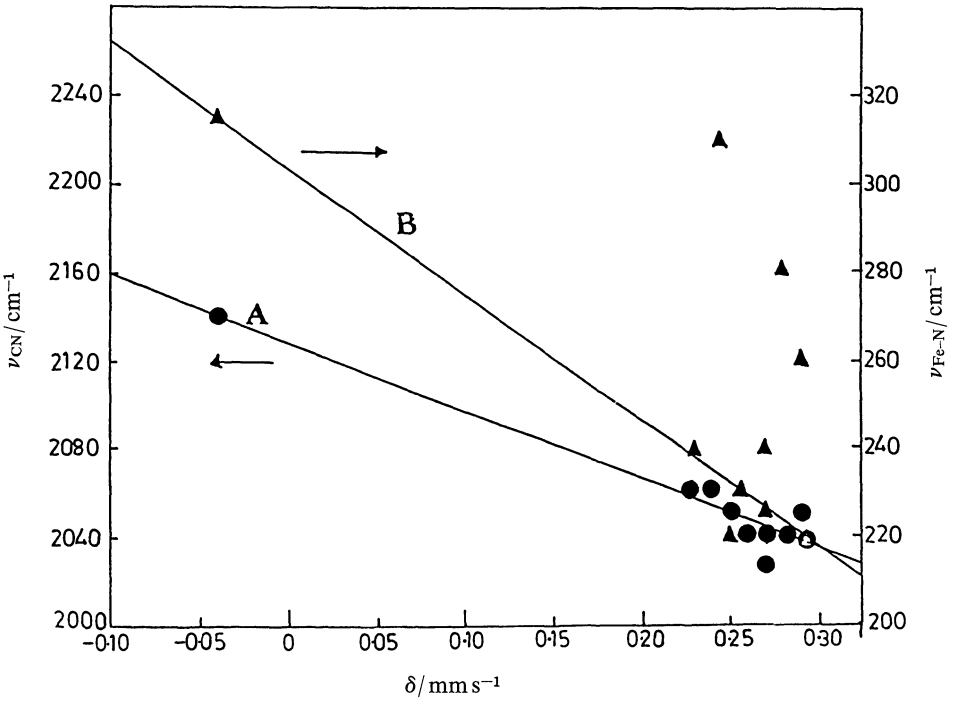

Fig. 4. Variation of isomer shift (δ) with (A) ν(C≡N) and (B) ν(Fe–N) stretching frequencies in $Na_3[Fe(CN)_5(RNH_2)] \cdot xH_2O$ complexes.

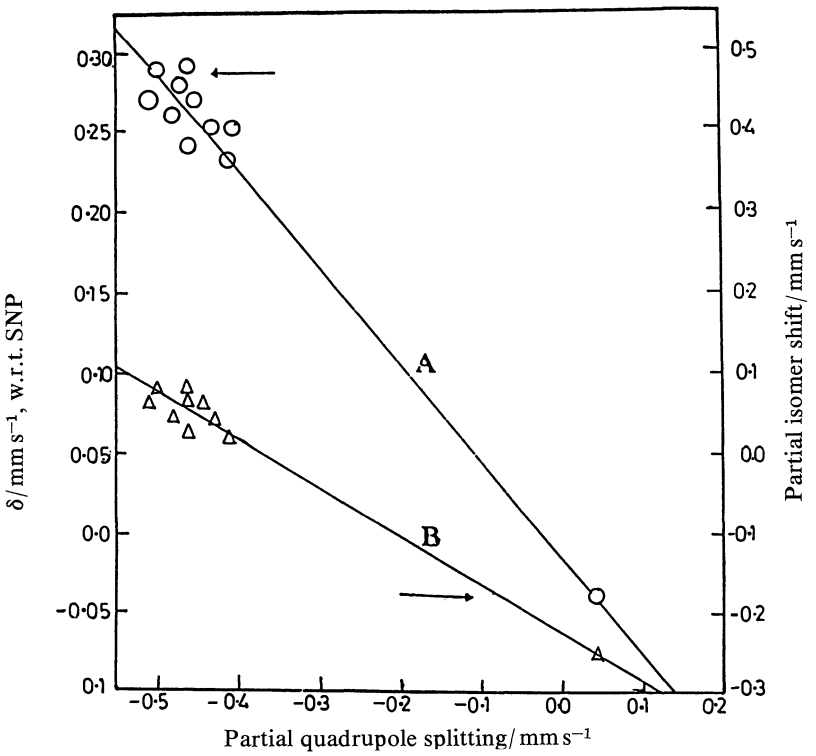

Fig. 5. Correlation of partial quadrupole splitting (p.q.s.) with (A) isomer shift (δ) and (B) partial isomer shift (p.i.s.) in $Na_3[Fe(CN)_5(RNH_2)] \cdot x\ H_2O$ complexes.

π-acceptor than and CN^- ligand.[26] In the present study where all the ligands are alkyl- or aryl-group substituted amines, their σ-donor property is affected by the substitution. It could be correlated with the change in base strength of amines as well. For example alkylamines with bulkier alkyl group are stronger bases and with arylamines are weaker bases than NH_3. However, this does not seem to affect the σ-donor property of the respective amines significantly except in the case of isobutylamine as indicated by its low values of δ and p.i.s. Presumably it is not just the σ-donor property but a combination of σ-donor and π-acceptor characteristics, both of which are operating simultaneously and can not be separated.

Conclusion

Mössbauer spectra of alkylamine and arylamine coordinated pentacyanoferrate(II) complexes exhibit a well resolved quadrupole doublet. Isobutylamine coordinated complex exhibits unusually high ΔE_Q and low δ which are comparable with sodium pentacyanonitrosylferrate(II). Correlation of δ vs. ΔE_Q gives a straight line suggesting a positive sign of EFG for isobutylamine coordinated complex. Stretching modes of CN and Fe–N also correlate well with the isomer shift data suggesting significant differences in its bonding characteristics compared with other alkyl- and arylamine coordinated complexes.

Our grateful thanks are due to Council of Scientific and Industrial Research, New Delhi for financial assistance. Thanks are also due to RSIC, Lucknow for providing C, H, N analysis and IR spectral data.

Regioselective Hydrogenation Using Platinum-Support Zeolite Modified by CVD-Method

Hideyuki KUNO,* Makoto SHIBAGAKI, Kyoko TAKAHASHI, Ichiro HONDA, and Hajime MATSUSHITA
Life Science Research Laboratory, Japan Tobacco Inc., 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227
(Received February 16, 1991)

A platinum-support zeolite coupled with a silica layer was prepared by Chemical Vapor Deposition (CVD) of tetraethoxysilane, and was investigated in order to determine the catalytic characterization in an analysis of the surface. With this catalyst system, it was demonstrated that the terminal carbon–carbon double bond is preferentially hydrogenated in the case of several unsaturated hydrocarbons. Further, it was elucidated that a highly regioselective hydrogenation of compounds which possess plural double bonds was achieved over this catalyst system. As a result, a reaction model regarding this catalyst system has been put forward.

In order to achieve highly regioselective reactions with heterogeneous catalyst systems, it is desirable to have a high efficiency in substrate-recognizing ability. In previous papers,[1,2] we have reported that the regioselective hydrogenation of unsaturated alcohols and acids proceeded efficiently by the use of a platinum–silica or platinum–alumina catalyst modified by a long carbon-chain layer. However, these catalyst systems do not have a wide range of applications, since, for instance, the reactants are restricted to aliphatic alcohols or acids. Further, it is difficult to control the degree of modification of the surfaces on the catalysts in these systems.

It was reported that, using the CVD (Chemical Vapor Deposition)-method, a finely deposited silica layer can be formed on the surface of zeolite and, further, that the diameter of micro pores in zeolite can be controlled.[3–5] It is thought that the silica layer is combined to the silanol group on the zeolite surface by covalent bonds and not combined to any part of the metal. It is also expected that the degree of modification can be controlled by using the CVD-method. Accordingly, it is considered that the reaction field constructed by the CVD-method would be effective in the application of highly regioselective reactions.

A platinum–zeolite catalyst coupled with tetraethoxysilane was prepared by the CVD-method. Hydrogenation of the unsaturated hydrocarbons was carried out over this CVD-modified catalyst; it was elucidated that the differences in the hydrogenation rates were dependent on the positions of the carbon–carbon double bond in the unsaturated hydrocarbons. Compared with the modified catalyst previously reported by us, the following advantages exist: (1) highly regioselective hydrogenation, (2) no restrictions regarding the reactants, (3) high stability under various conditions.

In this paper we report that the regioselective hydrogenation of several compounds with plural double bonds was achieved over a CVD-modified catalyst, and that the terminal double bond is preferentially hydrogenated. The characterization of the CVD-modified catalyst was also investigated.

It was also investigated whether the reactivity and selectivity of the hydrogenation are influenced by the variety of active metals and solid-supports in a CVD-modified catalyst system.

Experimental

Materials. Commercial reagents were used for the reactions without further purification.

Preparation of CVD-Modified Catalyst. Using the ion-exchange method,[6] platinum on zeolite-4A was prepared. The CVD-treatments were performed in a glass-flow reactor in flowing nitrogen gas (60 $cm^3 min^{-1}$). The platinum–zeolite-4A catalyst (4.0 g) was treated at 400 °C for 2 h, at 100 °C for 1 h with diethyl ether (5 $cm^3 h^{-1}$), at 200 °C for 3 h with tetraethoxysilane (1 $mmol h^{-1}$)), at 200 °C for 1 h, and at 300 °C for 1 h with deionized water (hydrolysis treatment of ethoxyl group). This series of treatments was repeated several times and, finally, the catalyst was treated at 200 °C for 1 h without hydrolysis treatment.[7]

Analysis of CVD-Modified Catalyst. After the ion-exchange treatment, the filtrate was subjected to Inductively Coupled Plasma (ICP) analysis in order to determine the metal loading. The CVD-modified catalysts were analyzed by X-ray photoelectron spectroscopy (XPS) to determine the composition of the surface phase.

Hydrogenation of Mixture of Two Alkenes. In a 10 cm^3 round-bottom flask, 150 mg of a CVD-modified catalyst, or 30 mg of a 1.2% platinum–zeolite-4A (control catalyst), was suspended in 5 cm^3 of hexane containing 0.1 mmol of undecane as an internal standard; 5 cm^3 of hexane containing 1-octene (0.1 mmol) and *trans*-4-octene (0.1 mmol) was added with stirring at 25 °C under a hydrogen atmosphere. The reactants and products were analyzed by gas chromatography (a capillary column DB-1 30 m). The compounds were assigned and their concentrations were determined using authentic samples and an internal standard.

Hydrogenation of Alkadienes. In a 10 cm^3 round-bottom flask, 5 cm^3 of hexane containing tetradecane (0.05 mmol) as an internal standard and diene (0.1 mmol) were stirred with 300 mg of CVD-catalyst or 60 mg of the control catalyst at 25 °C under a hydrogen atmosphere. Both the reactants and products were analyzed in a similar manner to that described above. The assignment of the products was performed using gas chromatography and GC-MS.

Results and Discusssion

Characterization of CVD-Modified Catalyst. The

CVD-treatment on the metal-supports was repeated 5 times. The surface of the platinum–zeolite-4A coupled with tetraethoxysilane by 5-cycle CVD-treatment (5cCVD-modified catalyst A) was analyzed by XPS; the results are listed in Table 1. The relative amounts of silicon and oxygen on the CVD-modified catalyst are larger than those in the non-modified catalyst. From these data, it was elucidated that the silica layer was deposited on the surface of the platinum–zeolite-4A.[8] The thickness of the silica layer on zeolite-4A is shown by the following Eq. 1, as reported by Niwa et al.:[9]

$$(\mathrm{Si/Al})_{\mathrm{xps}} = (d+t)/(d-t), \quad (1)$$

where $(\mathrm{Si/Al})_{\mathrm{xps}}$ is the ratio of Si atom to Al atom by XPS analysis, t: the thickness of silica, and d: the releasing depth of the photoelectron (ca. 50).

The value of $(\mathrm{Si/Al})_{\mathrm{xps}}$ was dependent on the Pt loading, which is shown in Fig. 1. As can be seen from the figure, a straight line is obtained. These results suggested that the silica layer was not combined with platinum particles by the CVD-treatment, and that the platinum was highly dispersed. It is reasonable to estimate the value of $(\mathrm{Si/Al})_{\mathrm{xps}}$ in the case of no Pt loading. As being ca. 1.8, and, using this in Eq. 1, the thickness of the silica in 5cCVD-modified catalyst A is estimated to be ca. 14.3 Å. On the basis of the XPS analysis, it was demonstrated that most of the catalyst surface is covered with the 5 layers of the silica except for platinum particles, and that the small holes in the silica layer were formed around these platinum particles.

Table 1. Ratio of Elemental of Surface Phase by XPS

Catalyst	Al	Si	O	Pt
Pt(1.2%)/zeolite (A)	1.00	0.98	3.02	0.08
5cCVD-A	1.00	1.44	3.79	0.07

5cCVD-A: 5cCVD-modified catalyst A.

Competitive Hydrogenation of Two Alkenes. The hydrogenation of a mixture of 1-octene and *trans*-4-octene was carried out over the several CVD-modified catalysts. It was elucidated that R1/R2 (R1: initial rate of 1-octene, R2: initial rate of *trans*-4-octene) is dependent on the number of times of the CVD-treatment and the results are shown in Fig. 2. In the range of 0 to 5, R1/R2 increases with the number of the CVD-treatments. However, R1/R2 does not increase with more than 5 treatments. Consequently, it is considered that 5-cycle CVD treatment is the most effective to attain regioselective hydrogenation.

The hydrogenation of a mixture of 1-octene and other octenes was carried out over 5cCVD-modified catalyst A and platinum–zeolite-4A (control catalyst). As shown in Table 2, selective hydrogenation was observed by the use of 5cCVD-modified catalyst A in all cases. Compared with the hydrogenation over the control catalyst, R1/R2 was dependent on the variety of the other octene in the case of the hydrogenation over 5cCVD-modified catalyst A. In other words, the selectivity with regard to the double bond near the terminal site in the 5cCVD-modified catalyst A system is much higher in comparison with that in the control catalyst system. In the case of a mixture of 1-nonene and *trans*-4-nonene, the result was similar to those for the two-octene system.

In the case of these hydrogenations, it is considered that a catalytic active site mainly exists on the outside

5CVD-A	1-Octene	*cis*-2-Octene	7.20×10^{-4}	2.16×10^{-4}	3.33

a) Conditions: alkene, 0.1 mmol; hexane, 10 cm^3; reaction temperature, 25 °C. b) A, Pt(1.2%)/zeolite-4A (30 mg); 5CVD-A, 5cCVD-modified catalyst A (150 mg).

surface of zeolite. From the XPS data, it is suggested that the small holes are formed around the platinum particles, and the hydrogenation would be exclusively performed in these holes. Therefore regioselectivity would be caused by steric hindrance around the platinum in the holes. The carbon-carbon double bond in 1-octene can more easily approach the platinum than that in the other octenes, for instance *trans*-4-octene, because the conformation of the substrates is regulated by the silica layer on platinum–zeolite. Accordingly, the less hindered carbon–carbon double bond is easily hydrogenated in the 5cCVD-modified catalyst A system (Fig. 3).

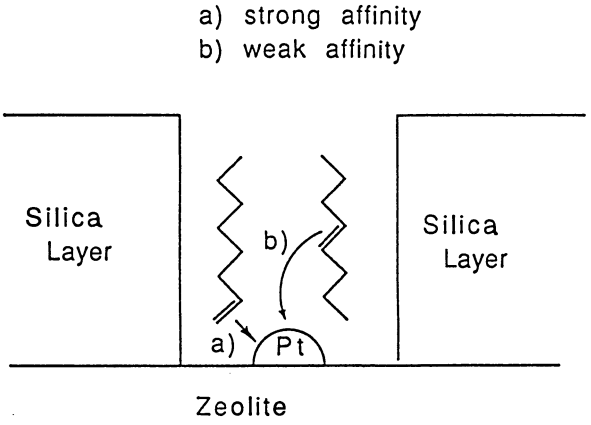

Fig. 3. Reaction Model for Hydrogenation of Octene in 5CVD-catalyst A system.

Dependence on Variety of Metals on Zeolite. In order to elucidate the dependence on the variety of metals in the CVD-modified catalyst, the hydrogenation of the mixture of 1-nonene and *trans*-4-nonene was carried out over several CVD-modified catalysts. These results are listed in Table 3. It was elucidated that the R1/R2 value in the 5cCVD-modified catalyst (5-cycle CVD-modified catalyst) system is much larger than that in the control catalyst in all cases. In the case of using platinum or rhodium-catalyst, isomerization did not occur during the reaction, but 10% of the isomers of nonene, for instance *cis-trans* isomer, were detected in the case of palladium. As the results show in Table 3, the CVD-modification (5-cycle) is effective in construction of a reaction field for the regioselective hydrogenation, regardless of the variety of metals.

Dependence on Variety of Supports. The hydrogenation of the mixture of 1-nonene and *trans*-4-nonene was carried out over a 5cCVD-modified catalyst with a variety of supports. The results are shown in Table 4. The Rl/R2 values in the 5cCVD-modified catalyst system were much larger than those in the control catalyst in the cases of zeolite-4A, zeolite-13X, and silica. However, if titania or hydrous zirconium(IV) oxide is used as a support, the R1/R2 value in the 5cCVD-modified catalyst system is similar to that in the control

catalyst. It was also elucidated that the regioselectivity of the hydrogenation in the 5cCVD-modified catalyst is dependent on the variety of supports. The surface of zeolite was finely covered by a homogeneous silica layer because of the high reactivity between tetraethoxysilane and zeolite, and the reaction field was effectively constructed for the regioselective hydrogenation. On the other hand, the homogeneous silica layer was not finely constructed on titania and hydrous zirconium oxide because of the difference in ion radius between the support and silica layer. Accordingly, it is considered that zeolite is the best support as the binder of the silica layer.

Hydrogenation of Several Alkadienes. It was anticipated that the regioselective hydrogenation of a hydrocarbon possessing a number of carbon–carbon double bonds could be achieved since differences in the hydrogenation rates were found for different positions of the carbon–arbon double bond in octene and nonene. The hydrogenation of 1,5-tridecadiene was investigated over the 5cCVD-modified catalyst A and over the control catalyst. The regioselectivity for the hydrogenation of 1,5-tridecadiene was low over the control catalyst, as shown in Fig. 4a. However, when using 5cCVD-modified catalyst A, the highly regioselective hydrogenation of 1,5-tridecadiene was achieved (Fig. 4b). The hydrogenation of other alkadienes, for instance limonene, 8-cyclohexyl-1,5-octadiene, and 1,5-undecadiene, was carried out in the 5cCVD-modified catalyst A and control catalyst systems, these results are listed in Table 5. From these results, it can be seen that similar tendencies are observed in the hydrogenation of the other compounds as with 1,5-tridecadiene. Further, in the case of the hydrogenation conditions which are shown

Table 5. Regioselective Hydrogenation for Diene-Compounds Catalyzed by 5cCVD-Modified Pt/Zeolite-4A[a]

Catalyst	Substrate	Product	Max. Yield/%
Pt/zeolite-4A(A)[b]	1,5-Tridecadiene	5-Tridecene	20.8

Pt/zeolite-4A(A)[b]	8-Cyclohexyl-1,5-octadiene	1-Cyclohexyl-3-octene	2.4
5cCVD-A[c]	8-Cyclohexyl-1,5-octadiene	1-Cyclohexyl-3-octene	58.9
Pt/chacoal[e]	8-Cyclohexyl-1,5-octadiene	1-Cyclohexyl-3-octene	39.5

a) Conditions: Substrate, 0.1 mmol; hexane(solvent), 5 cm^3; reaction temperature, 25 °C.
b) 60 mg. c) 300 mg. d) 600 mg. e) 10 mg.

in Table 5, it was also elucidated that the 5cCVD-modified catalyst is superior to platinum (5%)-charcoal which is known as an effective catalyst for the regioselective hydrogenation of limonene.[10]

In conclusion, a highly regioselective hydrogenation of the carbon–carbon double bond in unsaturated compounds was achieved with a CVD-modified catalyst.

Aerobic Epoxidation of Olefinic Compounds Catalyzed by Tris(1,3-diketonato)iron(III)

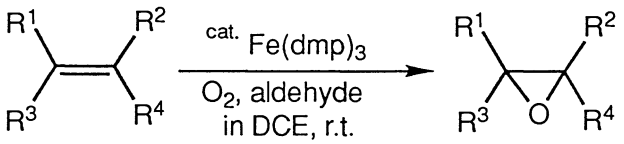
(Received March 30, 1991)

Tris[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]iron(III) ($Fe(dmp)_3$) was found to be an excellent catalyst for oxygenation of a number of olefinic compounds including styrene analogues and olefinic alcohols into the corresponding epoxides in good to quantitative yields with combined use of molecular oxygen and an aldehyde at room temperature.

Iron complexes are considered to be one of the most promising catalysts for oxygenation, because iron is a relatively inexpensive and less poisonous metal compared with other transition metals.[1] Therefore much research works have been made for iron complex-catalyzed epoxidation of olefins with various oxidants, such as iron(III) porphyrins/iodosobenzene[2a] and sodium hypochlorite,[2b] or iron(III) perchlorate/α-siloxyalkyl perbenzoate.[2c] Molecular oxygen can also be used for epoxidation of olefins by employing the following catalysts; iron(III) porphyrins/O_2/H_2 on colloidal platinum,[2d] iron(III) complexes of artificial bleomycin/O_2/2-mercaptoethanol[2e] or (μ_3-oxo)triiron cluster $[Fe_3O(OCOR)_6L_3]$.[2f] In the above epoxidation reactions, however, the limitation of substrates, olefinic compounds, remained as an important problem to be solved.

Through our continued study on the aerobic epoxidation of olefins catalyzed by oxovanadium(IV) complexes[3a] or nickel(II) complexes,[3b–e] it could be pointed out that the behavior of the active oxidant generated from transition metal complexes with combined use of molecular oxygen and reductants is different from that of generally employed epoxidation reagents, such as *m*-chloroperbenzoic acid (*m*CPBA). For example, in the aerobic epoxidation of styrene (**1**) catalyzed by nickel(II) complex,[3f] styrene oxide (**2**) was obtained but in unsatisfactory yield (34%) accompanying C=C bond fission of styrene (**1**) into benzaldehyde (**3**, 31% yield), and similar results were also reported by other researchers.[2e,4] Recently, $Pr(OAc)_3$ was shown as an effective catalyst for the aerobic epoxidation of olefins in the coexistence of an aldehyde.[5] Taking the above results into account, our interests were focused on finding a suitable common transition metal catalyst which might be employed in the oxidation of a wide variety of olefinic compounds. After screening several metal complexes, it was found that tris(1,3-diketonato)-iron(III) has an excellent catalytic activity on aerobic epoxidation far better than bis(1,3-diketonato)iron(II). Of several tris(1,3-diketonato)iron(III) catalysts, tris-[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]iron(III) ($Fe(dmp)_3$) (**11a**) was found to be the most effective catalyst for epoxidation of olefinic compounds with an atmospheric pressure of oxygen and an aldehyde at room temperature. Concerning the similar iron(III) complex, epoxidation of propylene with molecular oxygen and crotonaldehyde catalyzed by tris(acetylacetonato)iron(III) have already been reported to proceed in low conversion (<40%).[6]



Scheme 1.

Results and Discussion

Epoxidation of Styrene Catalyzed by Various Iron Complexes. As mentioned before, styrene (**1**) is highly reactive toward oxygenation and rather difficult to obtain styrene oxide (**2**) selectively due to C=C bond cleavage of styrene (**1**) into benzaldehyde (**3**). Thus, in order to examine the effect of iron complexes for aerobic epoxidation, styrene (**1**) was taken as a model substrate and treated with combination of molecular oxygen and an aldehyde in 1,2-dichloroethane (DCE) at room temperature in the presence of a catalytic amount of bis- or tris(acetylacetonato)iron complexes (see Table 1). Of several iron(II) and iron(III) complexes, the highest yield of styrene oxide (**2**) was achieved when Fe(III)(acac)$_3$ (**6**) was employed as a catalyst (Entry 3).

Thus, various tris(1,3-diketonato)iron(III) type catalysts were prepared and their catalytic activities in aerobic epoxidation of styrene (**1**) were examined. As shown in Table 2, undesired cleavage of C=C bond was

4[b]	H	Ph	H	H	(**17**)	14	*trans*-Stilbene oxide (**18**)	99[e]

a) Reaction conditions; styrene analogues 3.0 mmol, 2-ethylbutyraldehyde 18.0 mmol, $Fe(dmp)_3$ (**11a**) 0.03 mmol (1.0 mol%) in 1,2-dichloroethane (DCE) 10.0 ml, O_2 1 atm, r.t. b) $Fe(acac)_3$ (**6**) 0.03 mmol was used. c) GC yield. d) Mixture of *cis* and *trans* isomers (11/89). e) Isolated yield.

propane (**14**), 2-(*p*-chlorophenyl)oxirane (**16**), or *trans*-stilbene oxide (**18**) were obtained in quantitative yields respectively without any undesirable over-oxidation as cleavage of C=C double bond affording aromatic aldehydes.

Epoxidation of Various Olefinic Compounds Catalyzed by Fe(dmp)$_3$ (11a). The above procedure was also successfully applied to various olefinic compounds. Aliphatic trisubstituted, 1,2-disubstituted or *exo*-terminal olefins afforded the corresponding epoxides in high to quantitative yields (see Entries 1—4 in Table 4). And in the case of cyclohexene (**23**), undesirable allylic oxidation affording 2-cyclohexen-1-ol was suppressed down to 5%. In a similar fashion, the corresponding epoxides were obtained in quantitative yields from acetates of olefinic alcohol, such as citronellyl acetate (**27**) and linalyl acetate (**29**) (Entries 5 and 6). Cholesteryl acetate (**31**) was selectively oxygenated into the corresponding β-epoxide **32** similar to the nickel(II)-catalyzed epoxidation.[3f] In the cases of geranyl acetate (**33**) and neryl acetate (**36**), double bonds at C^6–C^7 position were oxygenated preferentially over allylic double bonds, and the corresponding epoxides were obtained as mixtures of monoepoxides **34**, **37** and diepoxides **35**, **38** (Entries 8 and 9).

Epoxidation of Olefinic Alcohols Catalyzed by Fe(dmp)$_3$ (11a). Since olefinic alcohols were not efficiently oxygenated into the corresponding epoxy alcohols by using nickel(II) complexes, iron(III) complex-catalyzed epoxidation of citronellol (**39**), an olefinic alcohol, was examined. As shown in Table 5, epoxy alcohol **40** was obtained in quantitative yield without any over-oxidation of hydroxyl group by using Fe(dmp)$_3$ (**11a**) as a catalyst (Entry 1), whereas nickel(II) complex-catalyzed epoxidation of citronellol (**39**) stopped half-way and yield of epoxy alcohol **40** was moderate (Entry 2). It was assumed that nickel(II) complex was deactivated due to the undesirable coordination by hydroxyl group of olefinic alcohol, while iron(III) complexes having three 1,3-diketone ligands might not be preferable for

a) Reaction conditions; olefinic alcohol 3.0 mmol, isobutyraldehyde 18.0 mmol, $Fe(dmp)_3$ (**11a**) 0.03 mmol (1.0 mol%) in 1,2-dichloroethane (DCE) 10.0 ml, O_2 1 atm. b) Isolated yield. c) GC yield. d) Mixture of *cis* and *trans* isomers (1/1).

the coordination by hydroxyl function.

Further, several olefinic alcohols, such as homoallylic alcohol **41** and **43**, or allylic alcohol **45** were oxygenated into the corresponding epoxy alcohols in good to quantitative yields (see Entries 2—4 in Table 6).

Conclusion

A wide variety of epoxides were prepared by the aerobic epoxidation of olefinic compounds including styrene analogues or olefinic alcohols in good to quantitative yields by using tris(1,3-diketonato)iron(III) complex, and particularly tris[1,3-bis(*p*-methoxyphenyl-1,3-propanedionato]iron(III) ($Fe(dmp)_3$) (**11a**) was found to be the most excellent catalyst in present oxygenation.

Experimental

General: Melting points were measured on a Mettler FP62 apparatus and uncorrected.

(a) Spectrometers: IR spectra were obtained by using a JASCO Model IR-700 infrared spectrometer on KBr pellets or liquid film on KBr. ^1H NMR spectra were recorded with a JEOL Model FX-270 spectrometer using $CDCl_3$ as solvent and with tetramethylsilane as internal standard.

(b) Chromatography: GC-analysis were performed on a Shimadzu GC-15A using a glass capillary column (Shimadzu CBP-l0, 25 m), and the peak areas were obtained with a Shimadzu chromatopack CR-5A.

Preparation of 1,3-Diketones and Tris(1,3-diketonato)iron-(III) Complexes. Tris(acetylacetonato)iron(III) (**6**, $Fe(acac)_3$) were purchased from Tokyo Kasei Kogyo Co., Ltd. (TCI) Bis(acetylacetonato)iron(II) (**4a**, $Fe(acac)_2$),[7] chlorobis(acetylacetonato)iron(III) (**5**, $Fe(acac)_2Cl$),[8] tris(1,1,1-trifluoro-2,4-pentanedionato)iron(III) (**7a**, $Fe(tfa)_3$),[9] tris(1,1,1,5,5,5-hexafluoro-2,4-pentanedionato)iron(III) (**8a**, $Fe(hfa)_3$),[10] tris-(2-acetylcyclohexanonato)iron(III) (**9a**, $Fe(ach)_3$),[11] and tris(3-methyl-2,4-pentanedionato)iron(III) (**10a**, $Fe(mac)_3$)[12] were prepared according to the reported methods, respectively, and ligands were purchased from TCI Co., Ltd. (**4b, 7b, 8b,** and **9b**) and Aldrich Chemical Company, Inc. (**10b**), respectively.

1,3-Bis(*p*-methoxyphenyl)-1,3-propanedione (11a, Hdmp);[3c,13] A refluxing suspension of sodium hydride (0.39 mol) in cyclohexane (400 ml), a solution of *p*-methoxyacetophenone (0.33 mol) and ethyl *p*-methoxybenzoate (0.33 mol) in cyclohexane (200 ml) was added over 1 h, and reflux was continued for another 2 h. After cooling, reaction mixture was quenched with 1.0 mol dm^{-3} aqueous HCl, then crude product was extracted with THF–Et_2O. The organic extract was washed with brine, and dried over anhydrous sodium sulfate, then solvent was removed in vacuo. Recrystallization from hexane–ethyl acetate gave slightly colored needles (58% yield): Mp 131—138 °C; ^1H NMR ($CDCl_3$) δ=3.90 (6H, s), 6.80 (1H, s), 7.00 (4H, m), 7.95 (4H, m); IR (KBr) 2938, 2840, 1687, 1605, 1507, 1429, 1305, 1263, 1230, 1170 cm^{-1}

Tris[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]iron-(III) (11b, Fe(dmp)$_3$); To a stirred mixture of Hdmp (30.0 mmol) in THF-MeOH (1/1, 100 ml), an aqueous solution of $FeCl_3$ (10.0 mmol, 50 ml) was added over 10 min. Precipitated reddish-brown solid was filtered and washed with MeOH and water. After drying in vacuo (90 °C/0.1 mmHg, 1 mmHg=133.322 Pa), $Fe(dmp)_3$ **11a** was yielded as reddish-purple solid. Found: C, 66.78; H, 5.18%. Calcd for $C_{45}H_{45}O_{12}Fe$: C, 64.83; H, 5.44%.

Melting Points and IR Spectra of Iron Complexes. Bis-(acetylacetonato)iron(II) (4a, Fe(acac)$_2$); Red solid; mp 169.0—169.4 °C; IR (KBr) 2918, 1571, 1562, 1525, 1376, 1270 cm^{-1}.

Chlorobis(acetylacetonato)iron(III) (5, Fe(acac)$_2$Cl); Red solid; mp 180.4—181.0 °C; IR (KBr) 2992, 2918, 1571, 1525, 1364, 1290 cm^{-1}.

Tris(1,1,1-trifluoro-2,4-pentanedionato)iron(III) (7a, Fe(tfa)$_3$); Orange solid; mp 212.4—212.8 °C; IR (KBr) 1615, 1510, 1292, 1147 cm^{-1}.

Tris(1,1,1,5,5-hexafluoro-2,4-pentanedionato)iron(III) (8a,

Fe(hfa)$_3$); Yellowish-orange solid; mp 162.0—162.6 °C; IR (KBr) 1647, 1619, 1565, 1540, 1445, 1255, 1210, 1146 cm^{-1}.

Tris(2-acetylcyclohexanonato)iron(III) (9a, Fe(ach)$_3$); Reddish-purple solid; mp 228.6—229.0 °C; IR (KBr) 2930, 2854, 1573, 1460, 1374, 1331, 1278 cm^{-1}.

Tris(3-methyl-2,4-pentanedionato)iron(III) (10a, Fe(mac)$_3$); Reddish-purple solid; mp 189.6—190.0 °C; IR (KBr) 2998, 2960, 2918, 1876, 1574, 1467, 1424, 1360, 1330, 1292 cm^{-1}.

Tris[1,3-bis(*p*-methoxyphenyl)-1,3-propanedionato]iron-(III) (11a, Fe(dmp)$_3$) Reddish-purple solid; mp 278.0—279.4 °C; IR (KBr) 2930, 2836, 1604, 1587, 1527, 1492, 1377, 1305, 1257, 1228, 1175 cm^{-1}.

Epoxidation of 1,5-Dimethyl-1-vinyl-4-hexenyl Acetate (Linalyl Acetate, 31). (see Entry 6 in Table 5). A mixture of linalyl acetate (**29**) (3.0 mmol), Fe(III)(dmp)$_3$ (**11a**) (0.03 mmol, 1.0 molo%), isobutyraldehyde (9.0 mmol) in 1,2-dichloroethane (10.0 ml) was stirred under an atmospheric pressure of oxygen at room temperature for 12 h. Reaction mixture was washed with saturated aqueous $NaHCO_3$ solution, and, after drying over anhydrous sodium sulfate, solvent was removed in vacuo. Purification of the residue by column chromatography on SiO_2 (hexane–ethyl acetate) afforded 1-(3,4-epoxy-4-methylpentyl)-1-methylallyl acetate (**30**) (639 mg, quantitative yield).

^{1}H NMR and IR Spectra of Epoxides (in Tables 3—6). Styrene Oxide (2), 1,2-Epoxycyclohexane (24). ^{1}H NMR spectra, IR spectra and retention time in GC analysis agreed with those of the authentic samples.

A series of dipeptides with the sequence of H-D-Leu-L-Phe-R, where R denotes 4-phenylpiperidide, 4-phenylpiperazide, and their derivatives, have been synthesized to examine their ability to inhibit chymotrypsin. Dipeptide phenylpiperidide and phenylpiperazide inhibited chymotrypsin fairly strongly (K_i=7.5×10^{-4} M and 1.4×10^{-3} M, respectively) (1 M=1 mol dm^{-3}), while their phenyl-substituted analogs were inactive. In high resolution ^{1}H NMR measurements, it was found that the proton signals of D-Leu γ-CH and β-CH$_2$ shifted considerably to the upfield when compared with those of H-D-Leu-L-Ala-OH, suggesting that these upfield shifts are due to the magnetic anisotropy effect by the benzene ring of the Phe residue. This was confirmed by measuring NOE between D-Leu-isobutyl and L-Phe-phenyl groups. These NMR data indicate that the side chains of both D-Leu and L-Phe are in close proximity, resulting in formation of a hydrophobic complex. It was suggested that, in the inhibitory conformation of dipeptides against chymotrypsin, the phenyl group of phenylpiperidide or phenylpiperazide moiety fits the S_1 site, while the side chain-side chain hydrophobic complexing core fits the S_2 site.

The discovery of various chymotrypsin-like proteases that play crucial roles in pathological lesions has required highly specific and selective inhibitors for depressing these proteases.[1] We have recently reported that dipeptide methyl esters containing 2,3-methanophenylalanine (∇Phe),[2] H-∇Phe-L-Phe(or Leu)-OMe, inhibits chymotrypsin fairly strongly (K_i=1.6—14×10^{-4} M).[3] It was assumed that these dipeptide methyl esters construct an inhibitory conformation with a hydrophobic core between ∇Phe-phenyl and ester-methyl groups.[4,5] Such inhibitory conformation was considered to be compelled by the extremely constrained three-membered ring of ∇Phe, which restricts the ϕ and ψ angles very severely.[5,6] Similar inhibitory conformation was also found for H-D-Phe-L-Phe-OMe, which inhibited chymotrypsin strongly (K_i=9.0×10^{-5} M).[7]

In these inhibitory conformations, the hydrophobic core was assumed to fit the chymotrypsin S_2 site, while the L-Phe or L-Leu residue in the position 2 fits the S_1 site.[3,4,7] The formation of a hydrophobic core appears to be the most important structural requirement for this particular inhibition. If this formation occurs without compulsion, the molecular conformation may stabilize much more strongly. Deber and Joshua[8] reported the synthesis of a series of linear dipeptides of the type H-L-Phe-L- or -D-Xxx-OH, where Xxx represented various amino acid residues, and found the presence of an intramolecular side chain-side chain complexing for H-L-Phe-D-Xxx-OH, but not for H-L-Phe-L-Xxx-OH. In the present study, we noted this side chain-side chain interaction in aromatic dipeptides as one of possible ways to construct a hydrophobic core for chymotrypsin inhibition.

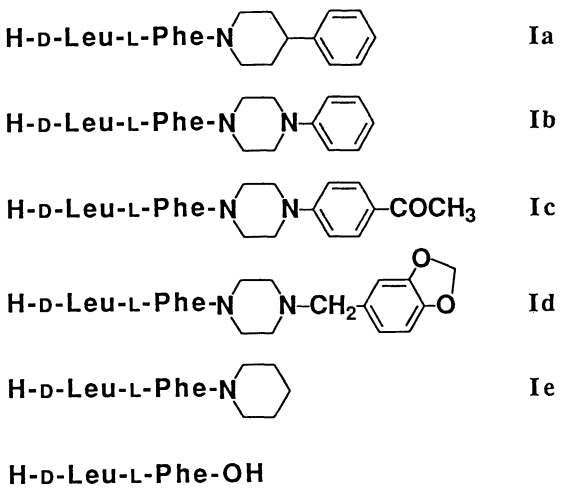

Fig. 1. Structure of dipeptide phenylpiperidide (**Ia**), phenylpiperazide (**Ib**), and their derivatives.

We have designed a series of H-D-Leu-L-Phe-R (**Ia—e**), where R denotes 4-phenylpiperidide, 4-phenylpiperazide, and their derivatives (Fig. 1). In this paper the synthesis of dipeptides and their inhibitory activity for chymotrypsin will be described together with their conformational analysis by ^{1}H NMR.

Results and Discussion

The synthetic scheme is depicted in Fig. 2. A series of Boc-L-Phe amides (**IIa—e**) were prepared by a mixed anhydride coupling method between Boc-L-Phe-OH and amines in yields of 66—95%. The resulting amides were treated with trifluoroacetic acid (TFA) to remove the Boc group, and then coupled with Boc-D-Leu-OH using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) in the presence of 1-hydroxybenzotriazole (HOBt) (43—77% yields). The desired dipeptide amides (**Ia—e**) as hydrochlorides were obtained from Boc-D-Leu-L-Phe amides by treatment with hydrogen chloride in dioxane.

Inhibitory activity for chymotrypsin was analyzed

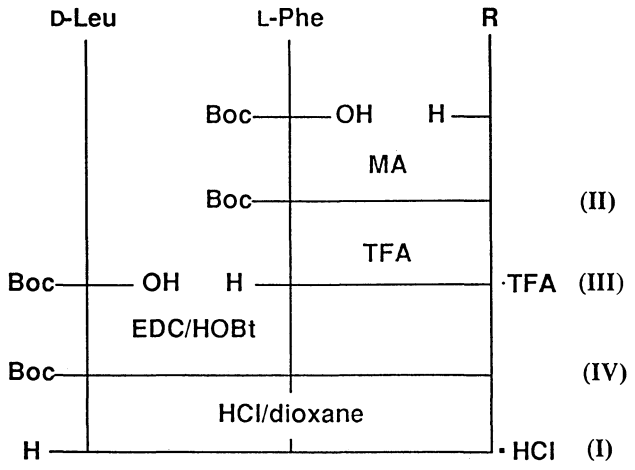

Fig. 2. Synthetic scheme of H-D-Leu-L-Phe-R.
R designates the amide derivatives of 4-phenylpiperidine, 1-phenylpiperazine, 4'-piperazinoacetophenone, 1-piperonylpiperazine, and piperidine.

Table 1. Inhibitory Activities of Dipeptides for Chymotrypin

Peptides	K_i/M
Ia	7.5×10^{-4}
Ib	1.4×10^{-3}
Ic	No inhibition
Id	No inhibition
Ie	No inhibition
H-D-Leu-L-Phe-OH	No inhibition
H-D-Leu-L-Ala-OH	No inhibition

using succinyl-Ala-Ala-Pro-Phe-*p*NA as a substrate,[9] because significant UV absorption due to the inhibitors at wavelengths below 250 nm made the spectroscopic monitor at 237 nm of hydrolysis of another popular substrate Ac-Tyr-OEt difficult. It was found that the dipeptide phenylpiperidide (**Ia**) and phenylpiperazide (**Ib**) inhibit chymotrypsin moderately. Analyses by Dixon plots[10] and Lineweaver-Burk plots[11] indicated the inhibition manner to be competitive. In Fig. 3 the Dixon plot of compound **Ia** is shown. The K_i values of **Ia** and **Ib** were 7.5×10^{-4} and 1.4×10^{-3} M, respectively (Table 1). It should be noted that the inhibitory potencies of these dipeptides are almost equal to those of ▽Phe-containing dipeptides.[3] This suggests that incorporation of a sterically constrained amino acid such as ▽Phe is not necessarily crucial for constructing the inhibitory conformation.

Dipeptides with phenyl-substituted piperazide (**Ic—d**) showed no inhibition. Also, H-D-Leu-L-Phe piperidide (**Ie**) did not inhibit chymotrypsin at all. These results imply that the phenyl group in the R moiety of H-D-Leu-L-Phe-R should not be substituted to elicit an inhibitory activity against chymotrypsin.

In 400-MHz ^{1}H NMR measurements, the signal assignments were carried out by the two-dimensional COSY experiment. The chemical shift values were carefully read off for comparison. When the chemical shifts of D-Leu side chain protons were compared with those of H-D-Leu-L-Ala-OH, considerable upfield shifts became prominent for all dipeptides having the D-Leu-L-Phe sequence: δ=0.13—0.38 for D-Leu β-CH_2; and δ=0.28—0.49 for D-Leu γ-CH. Even protons of δ-methyl groups showed a small upfield shift (δ=0.12—0.15). These results indicate that the side chain of D-Leu is in very close proximity to the phenyl group and undergoes the anisotropy effect of the benzene ring. Since H-D-Leu-L-Phe-OH and H-D-Leu-L-Phe piperidide (**Ie**), which has no phenyl in the *C*-terminal R

Table 2. Chemical Shifts of Leucine Side Chain Protons of Dipeptides

Dipeptide	Chemical shifts (ppm) of leucine residue

portion, also showed such upfield shifts of D-Leu side chain (Table 2), the shielding phenyl group apparently belongs to L-Phe in the position 2.

The presence of side chain interaction between D-Leu-isobutyl and L-Phe-phenyl was confirmed by measurements of the nuclear Overhauser effect (NOE). H-{H} NOE difference spectra of H-D-Leu-L-Phe-piperidide (**Ie**) were obtained by irradiation of each selected proton signal (Fig. 4). When the proton signals of the D-Leu-β-methylene, γ-methine, and δ-methyl groups were irradiated separately, the enhancement as positive NOE was observed for the proton signals of L-Phe-phenyl in the aromatic envelope (Figs. 4B and 4C). Similar enhancement was also observed for the D-Leu β-methylene, γ-methine, and δ-methyl protons by irradiation of L-Phe-phenyl proton signals (Fig. 4D). These NOE observed indicate that the side chains of D-Leu and L-Phe in D-Leu-L-Phe dipeptides are spatially in close proximity to each other.

Deber and Joshua[8] found a similar type of side chain interactions for L-Phe-D-Xxx dipeptides. They observed distinct upfield shifts (0.2—0.7 ppm) for the signals of D-Xxx β- and γ-methylene protons in 100-MHz ^{1}H NMR. Although they suggested that these upfield shifts are due to the shielding effect of L-Phe-phenyl, no direct evidence has been presented. Since the side chain interactions were not observed for L-Phe-L-Xxx dipeptides, it seems that this side chain-side chain interaction in dipeptides is stabilized in the configurational sequences of L-D and D-L. In fact, the building study using the CPK model indicated that a tight side chain complexing is feasible for and L-D and D-L.

The hydrophobic complex formed between the side chains of the adjacent residues in D-Leu-L-Phe dipeptides appears to be too bulky to fit the S_1 hydrophobic pocket of chymotrypsin active center. Since the S_2 site of chymotrypsin is Trp-215,[12] the moiety in hydrophobic complexing seems to interact with this Trp hydrophobic site. In the case, the phenyl group of phenylpiperidide and phenylpiperazide should occupy the S_1 pocket. Inactivity of dipeptides having phenyl-substituted piperidine residues (Table 1) is due probably to their bulkiness that makes the dipeptide incapable to fit the S_1 site, while inactivity of H-D-Leu-L-Phe-OH would be explained by lack of the substituent at the *C*-terminal carboxyl group.

We have previously reported the inhibitory conformation of H-D-Phe-L-Phe-OMe,[7] in which D-Phe-phenyl and ester-methyl groups construct a hydrophobic core responsible for interaction with the chymotrypsin S_2 site. This was demonstrated by NOE experiments. As proven in the present study, it is also likely that a conformer with the side chain-side chain complex exists in the enzyme assay solution, although we could not confirm it by NOE experiments because of overlapping of the proton signals of the two phenyl groups. How-

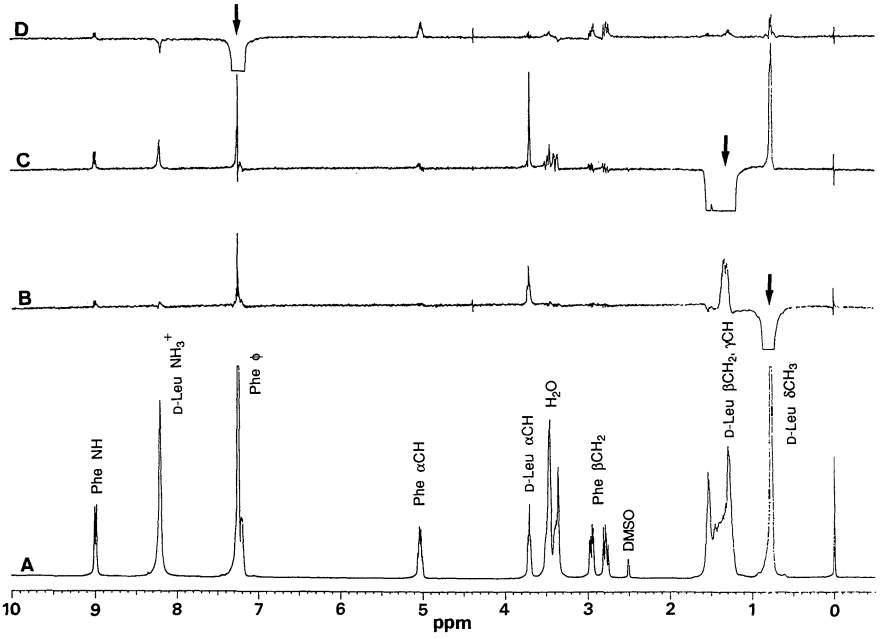

Fig. 4. 400-MHz ^{1}H NMR spectra of H-D-Leu-L-Phe-piperidide (**Ie**) hydrochloride in DMSO-d_6 at 25 °C.
A: The control spectrum acquired with irradiation in a blank region of the spectrum.

ever, this conformation would not cause an inhibition of chymotrypsin, since no group to interact with the S_1 site is present in this conformation. For D-Leu-L-Phe dipeptides, the presence of a conformer with the hydrophobic complex formed between D-Leu-isobutyl and *C*-terminal phenyl groups, a type of complex observed for H-D-Phe-L-Phe-OMe, is also partly feasible. However, the competitive inhibition by this conformer is unlikely due to the undetectable inhibition by dipeptides **Ic** and **Id** (Table 1). Collectively, the conformation to induce the enzyme inhibition, namely the inhibitory conformation, appears to differ between D-Leu-L-Phe and D-Phe-L-Phe dipeptides, while both dipeptide inhibitors seems to resemble each other in the size and spatial arrangement of P_1 and P_2 sites.

In ^{1}H NMR spectrum of H-D-Leu-L-Phe-phenylpiperidide (**Ia**), which is the most potent inhibitor synthesized in this study (Table 1), two sets of proton signals were observed, suggesting the presence of conformers (Table 2). These conformers would be characterized by the difference in either axial or equatorial positioning of the phenyl group on the piperidine ring. Although we could not assign these conformations, it is clear that the conformer in the major conformation (65%) constructs the intramolecular hydrophobic side chain complex as shown by obvious upfield shifts of the D-Leu-isobutyl side chain (Table 2). It is thus suspected that the intrinsic inhibitory activity of this isomer would be much stronger than that observed for the mixture of isomers.

The present study indicates that the side chain-side chain hydrophobic interaction can be constructed in dipeptides with the D-L configurational sequence, and that a hydrophobic core formed has a conformation suitable to fit the active site of chymotrypsin. The hydrophobic interaction between the dipeptide and the enzyme should result in inhibition of the enzyme catalytic action. Analyses of such an inhibitory conformation of dipeptides might lead to elucidation of the subtle structure of the chymotrypsin active center.

Experimental

Synthesis. High performance (HP)-TLC was carried out on Silica Gel G (Merck, Frankfurt) with the following systems (v/v): R_f^1, $CHCl_3$–MeOH (9 : 1), R_f^2, *n*-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2). Optical rotations were measured with a Union high sensitivity polarimeter PM-71. All melting points were uncorrected.

Boc-L-Phe-amides (IIa—e): To a solution of Boc-L-Phe-OH (1.327 g, 5.0 mmol) in tetrahydrofuran was added isobutyl chloroformate (0.65 ml, 5.0 mmol) at −15 °C. After 10 min, amine (4-phenylpiperidine, 1-phenylpiperazine, 4′-piperazinoacetophenone, 1-piperonylpiperazine, or piperidine) (10 mmol) was added. The reaction mixture was stirred for 2 h at 0 °C and overnight at room temperature, and evaporated. The residue was dissolved in EtOAc and the solution was washed successively with 4% $NaHCO_3$, 5% $KHSO_4$, and water, and then dried over Na_2SO_4. Physical properties of each compound are shown in Table 3.

Table 3. Physical Properties of Synthetic Peptides

Boc-D-Leu-L-Phe-amides (IVa—e): Boc-L-Phe-amides (**IIa—e**) (2.0 mmol) were treated with TFA at 0 °C for 30 min. After evaporation and trituration with the aid of dry diethyl ether, the resulting powder (**IIIa—e**) was collected and dried. To a solution of this TFA salt and Et_3N (0.28 ml, 2.0 mmol) in DMF (10 ml) were added Boc-D-Leu-OH·H_2O (530 mg, 2.0 mmol), EDC·HCl (422 mg, 2.2 mmol), and HOBt (324 mg, 2.4 mmol) at 0 °C. The reaction mixture was treated as described above. Physical properties are shown in Table 3.

H-D-Leu-L-Phe-amide (Ia—e) Hydrochlorides: Compounds **IVa—e** (0.5 mmol) were dissolved in 4.6 M HCl in dioxane (2.2 ml, 10 mmol) at 0 °C for 2—5 h. After evaporation, the residue was crystallized from MeOH–diethyl ether. Physical properties are shown in Table 3.

Enzyme Assay. Dipeptides synthesized were tested for their inhibitory activity against bovine chymotrypsin (Worthington Biochemical Co., Freehold, New Jersey). Substrate succinyl-Ala-Ala-Pro-Phe-*p*NA was synthesized by the conventional solution method. For the kinetic analyses of interactions between dipeptides and chymotrypsin, the standard method was carried out. Briefly, substrate was dissolved in 0.1 M Tris-HCl buffer (pH 7.8) with or without inhibitors. The enzyme reaction was initiated by adding an aliquot (30 μl) of the chymotrypsin solution (final concentration, 1.3 μg ml^{-1}) to the solution of substrate and inhibitor (1470 μl). The final concentrations of the substrate and inhibitors varied as 6.25, 12.5, 25 μM and 0, 250, 500, 750, 1000 μM, respectively. The rate of hydrolysis of the substrate was determined in duplicate by the spectroscopic measurement of liberated *p*-nitroanilide at 410 nm using a Hitachi 124 spectrometer. Inhibition constants, K_i, were determined by the Dixon plot analysis[10] and summarized in Table 1.

^{1}H NMR Measurements. Samples were prepared by dissolving 10 mg of the peptide in 0.5 ml of DMSO-d_6 (99.96% *d*, Aldrich, Milwaukee, Wisconsin). All ^{1}H NMR spectra were recorded on a Bruker AM-400 spectrometer operating at 400-MHz ^{1}H frequency at 25 °C. The chemical shifts were determined using tetramethylsilane as an internal standard and the signals were assigned by the two-dimensional COSY. The

COSY spectra were obtained by using the standard method.[13] Two hundreds fifty-six FIDs were acquired with successive t_1 values. The digital resolution was 9.76 Hz/pt. The H–{H} NOE data were recorded by a gated irradiation pulse sequence. The NOE difference spectra were obtained by subtracting the control spectrum from an original NOE spectrum produced by presaturation of selected proton signal with a low decoupling power for 3 s before pulse.

A Novel Catalyst System, Trimethylsilyl Chloride and Indium(III) Chloride, as an Efficient Catalyst in the Sulfide Synthesis

Teruaki MUKAIYAMA, Takashi OHNO, Takashi NISHIMURA, Jeong Sik HAN, and Shū KOBAYASHI
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162
(Received April 12, 1991)

O-Trimethylsilyl monothioacetals, which are generally difficult to activate under acidic conditions due to their rapid disproportionation, smoothly react with triethylsilane in the presence of a novel catalyst system, trimethylsilyl chloride and indium(III) chloride, to afford the corresponding sulfides in good to high yields. One pot synthesis of sulfides from aldehydes is also attained in high yields by successive treatments of aldehydes with trimethylsilyl alkyl (aryl) sulfides and triethylsilane in the presence of the above catalyst system under extremely mild conditions.

Utilities of acetals are widely extended during last few decades, not only as protective groups but also as electrophiles in various coupling reactions, especially carbon–carbon bond forming reactions.[1] *O*-trimethylsilyl monothioacetals are also useful intermediates as masked carbonyl compounds, however, activations of these compounds in the reaction with some nucleophiles are generally difficult because of their readiness to disproportionate under acidic conditions, and hitherto only a few examples of the reactions of *O*-trimethylsilyl monothioacetals with nucleophiles were reported.[2]

A novel method for the preparation of sulfides from carbonyl and related compounds, reduction of *O*-trimethylsilyl monothioacetals, was prelimirarily reported in the previous communication.[3] In this paper, we would like to describe on a novel catalyst system, trimethyisilyl chloride (TMSCl) and indium(III) chloride ($InCl_3$), which effectively catalyzes the reaction of *O*-trimethylsilyl monothioacetals with triethylsilane. Further, one pot synthesis of sulfides just starting from aldehydes using trimethylsilyl alkyl(aryl) sulfide and triethylsilane in the presence of the above catalyst system is described in detail.

Synthesis of Sulfides from *O*-Trimethylsilyl Monothioacetals. An Efficient Activation of *O*-Trimethylsilyl Monothioacetals Using TMSCl and $InCl_3$ as a Catalyst. In the first place, the reaction of 1-ethylthio-1-trimethyisiloxy-3-phenylpropane (**4**) with triethylsilane was chosen as a model and several reaction conditions were examined. When a typical Lewis acid such as $TiCl_4$, $SnCl_4$, BF_3OEt_2 or $ZnCl_2$ etc. was employed, no desired product was obtained after examination of several reaction conditions such as solvent, reaction temperature, amount of promoter, etc (Table 1, Entries 1—3). In these reactions, disproportionation of **4** took place quite readily to result in the formation of dithioacetal, an undesirable by-product. Trimethylsilyl triflate (TMSOTf) or trimethylsilyl iodide (TMSI), which was reported to be an effective catalyst in the reaction of ethylthio(phenyl)trimethylsiloxymethane (**1**) or 1-ethylthio-1-trimethylsiloxycyclohexane with trimethylsilane,[4] did not work well in the case when Et_3SiH was employed as a reducing reagent (Table 1, Entries 4 and 5). These results indicated that, under these reaction conditions of employing the above mentioned Lewis acids, the reaction systems were so acidic that the disproportionation proceeded faster than the desired reduction did. Therefore, milder reaction conditions were supposed to be necessary to accomplish this reaction. We have recently developed quite efficient catalyst system, TMSCl–$SnCl_2$[5] or TrCl–$SnCl_2$,[6] in the aldol or Michael reactions of silyl enol ethers with aldehydes or α,β-unsaturated ketones. These catalysts consist of a neutral molecule and a weak Lewis acid and effectively lead to the completion of the reactions under mild conditions. Bearing in mind these catalyst sys-

tems, we employed TMSCl–$SnCl_2$ as a catalyst in the present reaction. While **1** smoothly reacts with Et_3SiH at rt in the presence of 10 mol% each of TMSCl and $SnCl_2$ give the corresponding sulfide in 63% yield, no desired reduction product was obtained in the reaction of **4** with Et_3SiH (Table 1, Entry 6). We further searched for novel catalyst systems, and after screening several weak Lewis acids other than $SnCl_2$, $InCl_3$ was found to be very effective and the desired sulfide was obtained in 68% yield when a novel catalyst system, TMSCl–$InCl_3$, was employed (Table 1, Entry 7). It should be noted that neither TMSCl nor $InCl_3$ alone is effective in the present reaction and the reaction proceeds only when TMSCl and $InCl_3$ are combined.

Several examples of the present reaction of *O*-trimethylsilyl monothioacetals with triethylsilane are demonstrated in Table 2. In every case, the desired sulfides are obtained in good to high yields.

Concerning the structure of the novel catalyst system, we assumed the following equilibrium and the generation of the cationic species shown in Chart 1 similar to

Chart 1.

that in the case of TMSCl–$SnCl_2$ or TrCl–$SnCl_2$. The most important point is preferential activation of trimethylsiloxy group (Scheme 1, path A) to ethylthio group (path B) using TMSCl–$InCl_3$ catalyst system, which depends on stronger affinity of silicon atom toward oxygen atom than toward sulfur atom.[9] When path A and path B proceed parallelly in the case of using other Lewis acid catalysts such as $TiCl_4$, BF_3OEt_2, $SnCl_4$, etc., a dithioacetal **19** is mainly formed by the reaction of the intermediate **16** (or **17**) with ethylthiotrimethylsilane **18**, which is more reactive than Et_3SiH. It is also notable that $InCl_3$ is a quite mild Lewis acid and do not participate in the direct activation of **15**.

Thus, a novel catalyst system, TMSCl–$InCl_3$, effectively catalyzes the reaction of *O*-trimethylsilyl monothioacetals with triethylsilane. It should be noted that

the undesirable disproportionation of *O*-trimethylsilyl monothioacetal is restricted and effective activation of this mixed acetal in the reaction with Et_3SiH is realized by employing the novel catalyst system under extremely mild reaction conditions.

One-Pot Snythesis of Sulfides from Aldehydes. *O*-trimethylsilyl monothioacetals used in the first section are prepared by the reaction of aldehydes with trimethylsilyl alkyl(aryl) sulfide in the presence of a catalytic amount of TMSOTf or ZnI_2 and imidazole.[2] If this reaction is catalyzed by TMSCl–$InCl_3$, one pot synthesis of sulfides will be successfully achieved; namely aldehydes react with trimethylsilyl alkyl(aryl) sulfide under the influence of TMSCl and $InCl_3$ to generate *O*-trimethylsilyl monothioacetals in situ, which are readily reduced by Et_3SiH to afford the corresponding sulfides.

According to this hypothesis, benzaldehyde was successively treated with trimethylsilyl alkyl(aryl) sulfide and Et_3SiH in the presence of a catalytic amount of TMSCl–$InCl_3$. The reaction smoothly proceeded to give the corresponding sulfide in 87% yield. Similarly, other aldehydes and ketones can be converted to the corresponding sulfides in high yields according to the present procedure (Table 3). It is noteworthy that the yields of the sulfides by this one pot synthesis consisting of two successive reactions are improved in most cases compared with those of the reaction of *O*-trimethylsilyl monothioacetals with Et_3SiH.

Though several methods for the preparation of sulfides have been reported, one pot synthesis from aldehydes is rare.[8] The present reaction provides a convenient route to sulfides from aldehydes under extremely mild reaction conditions. Current work to develop other useful synthetic reactions employing this novel catalyst system is now in progress.

Experimental

IR spectra were recorded on Horiba FT-300 infrared spectrometer. ^1H NMR spectra were recorded on a Hitachi R-1100, R-1200, or JEOL JNR-EX270L spectrometer, and tetramethylsilane (TMS) served as internal standard. Column chromatography was performed on Silica gel 60 (Merck) or Wakogel B5F. All reactions were carried out under argon atmosphere in dried glassware.

Indium(III) chloride ($InCl_3$) was purchased from Soekawa Rika Co., Ltd., and was used without further purification. Trimethylsilyl chloride (TMSCl) was distilled before use and was stored as 0.25 M (1 M=1 mol dm^{-3}) dichloromethane solution.

O-trimethylsilyl monothioacetals **1**—**3** and **7** were prepared from the corresponding aldehydes according to the literature.[2] Similarly, other *O*-trimethylsilyl monothioacetals **4** and **5** were synthesized. In the synthesis of **6**, zinc(II) iodide (ZnI_2) was used instead of trimethylsilyl trifluoromethanesulfonate (TMSOTf).

1-Ethylthio-1-trimethylsiloxy-3-phenylpropane (4). Bp 86—89 °C (0.2 mmHg, 1 mmHg=133.322 Pa); IR (neat) 1100, 840 cm^{-1}; ^1H NMR (CCl_4) δ=0.13 (s, 9H), 1.24 (t, 3H, J=7.2 Hz), 1.82—2.25 (m, 2H), 2.29—2.89 (m,4H), 4.73 (t, 1H, J=6.0 Hz), 7.13—7.33 (m, 5H). Found: C, 62.42; H, 9.11; S, 11.67%. Calcd for $C_{14}H_{24}OSSi$: C, 62.63; H, 9.01; S, 11.94%.

1-Ethylthio-1-trimethylsiloxynonane (5). Bp 76—77 °C (0.15 mmHg); IR (neat) 2960, 1250, 1090, 870 cm^{-1}; ^1H NMR (CCl_4) δ=0.14 (s, 9H), 0.84—1.94 (m, 20H), 2.54 (q, 2H, J=6.0 Hz), 4.67 (t, 1H, J=6.0 Hz). Found: C, 60.50; H, 11.93; S, 11.38%. Calcd for $C_{14}H_{32}OSSi$: C, 60.80; H, 11.66; S, 11.59%.

1-Ethylthio-1-phenyl-1-trimethylsiloxyethane (6). Bp 73—75 °C (0.50 mmHg); IR (neat) 1140, 850 cm^{-1}; ^1H NMR (CCl_4) δ=0.25 (s, 9H), 0.99 (t, 3H, J=6.6 Hz), 1.84 (s, 3H), 2.16 (t, 2H, J=6.6 Hz), 6.80—7.30 (m, 5H). Found: C, 61.21; H, 8.88; S, 12.02%. Calcd for $C_{13}H_{22}OSSi$: C, 61.36; H, 8.71; S, 12.60%.

A Typical Procedure for the Synthesis of Sulfides from *O*-Trimethylsilyl monothioacetal. A typical procedure is described for the reaction of 1-ethylthio-1-phenyl-1-trimethylsiloxyethane (**2**) with Et_3SiH; to a suspension of $InCl_3$ (0.056 mmol) in dichloromethane (1 ml) was added 0.25 M (1 M=1 mol dm^{-3}) dichloromethane solution of TMSCl (0. 14 mmol), and the reaction mixture was stirred for 30 min at room temperature. Then **2** (0.28 mmol) in dichloromethane (1 ml) and triethylsilane (0.34 mmol) in dichloromethane (1 ml) was successively added and the reaction mixture was further stirred for 5 h at room temperature. Then aqueous sodium hydrogen carbonate was added at 0 °C and the aqueous layer was extracted with dichloromethane. The organic layer was washed with brine and dried over $MgSO_4$. After the removal of the solvents under reduced pressure, benzyl ethyl sulfide (**8**)[4] was isolated by thin layer chromatography on silica gel (83% yield). IR (neat) 2950, 1450, 700 cm^{-1}; ^1H NMR

($CDCl_3$) δ=1.22 (t, 3H, J=7.3 Hz), 2.43 (q, 2H, J=7.3 Hz), 3.71 (s, 2H), 7.21—7.38 (m, 5H).

A Typical Procedure of the One Pot Synthesis of Sulfides from Aldehydes. A typical procedure is described for the one pot synthesis of benzyl ethyl sulfide (**8**) from benzaldehyde; to a suspension of $InCl_3$ (0.071 mmol) in dichloromethane was added 0.25 M dichloromethane solution of TMSCl (0.17 mmol) and the reaction mixture was stirred for 30 min at room temperature. The reaction mixture was cooled down to −23 °C, and benzaldehyde (0.35 mmol) in dichloromethane (1 ml), ethylthiotrimethylsilane (**18**, 0.42 mmol) in dichloromethane (1 ml) and Et_3SiH (0.42 mmol) in dichloromethane (1 ml) were successively added. The mixture was further stirred for 5 h at room temperature, then aqueous sodium hydrogen carbonate was added at 0 °C and the aqueous layer was extracted with dichloromethane. The organic layer was washed with brine and dried over $MgSO_4$. After the removal of the solvents under reduced pressure, benzyl ethyl sulfide (**8**) was isolated by thin layer chromatography on silica gel (87% yield).

Other spectral data are presented below.

Benzyl 2-Propyl Sulfide (9). IR (neat) 2950, 1450, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.25 (d, 6H, J=6.6 Hz), 2.72—2.84 (m, 1H), 3.74 (s, 2H), 7.19—7.34 (m, 5H). Found: C, 72.23; H, 8.65; S, 19.43%. Calcd for $C_{10}H_{14}S$: C, 72.23; H, 8.49; S, 19.28%.

Benzyl Phenyl Sulfide (10).[8] IR (neat) 1450, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.10 (s, 2H), 7.15—6.31 (m, 10H).

Ethyl 3-Phenylpropyl Sulfide (11). IR (neat) 2900, 1450, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (t, 3H, J=7.3 Hz), 1.85—1.96 (m, 2H), 2.49—2.57 (m, 4H), 2.72 (t, 2H, J=7.7 Hz), 7.15—7.31 (m, 5H). Found: C, 72.80; H, 8.92; S, 17.70%. Calcd for $C_{11}H_{16}S$: C, 73.27; H, 8.94; S, 17.78%.

Ethyl Nonyl Sulfide (12). IR (neat) 2920 cm^{-1}; ^1H NMR (CCl_4) δ=0.70—1.82 (m, 20H), 2.14—2.65 (m, 4H). Found: C, 70.19; H, 13.01; S, 16.75%. Calcd for $C_{11}H_{24}S$: C, 70.14; H, 12.84; S, 17.02%.

Ethyl 1-Phenylethyl Sulfide (13).[9] IR (neat) 2970, 700 cm^{-1}; ^1H NMR (CCl_4) δ=1.10 (t, 3H, J=7.2 Hz), 1.48 (d, 3H, J=7.8 Hz), 2.22 (q, 2H, J=8.4 Hz), 3.86 (q, 1H, J=8.4 Hz), 7.00—7.35 (m, 5H).

Ethyl Cyclohexyl Sulfide (14).[4] IR (neat) 2930 cm^{-1}; ^1H NMR (CCl_4) δ=1.03—2.13 (m, 13H), 2.25—2.80 (m, 3H).

Mono-, Di-, and Tri-C-Deuteration of 1,5-Anhydro-D-glucitol

Masuo FUNABASHI* and Toshimori HASEGAWA
Chemistry Department, College of Arts and Sciences, Chiba University, Yayoi-cho, Chiba 260
(Received April 23, 1991)

Deuterium was effectively introduced into the title sugar (**1a**) at C-1, C-3, C-5, and C-6 to afford 1,5-anhydro-D-[1-$^2H_1$], -[3-^2H], -[5-^2H], -[1-$^2H_2$], -[6-$^2H_2$], and -[5,6-$^2H_3$]glucitols respectively as primary targets for a basic study of the unknown metabolism of **1a**, which had been suggested to be a candidate of metabolic indexes for insulin-dependent diabetes mellitus.

1,5-Anhydro-D-glucitol (polygalitol: **1a**) which had been known as a component of some plants such as *polygala amara,*[1] *polygala vulgaris,*[2] and *polygala tenuifolia*[3] has been first identified in human cerebrospinal fluid from diabetic uremic patients by pitkänen,[4] and confirmed later by Smith et al.[5]

Yoshioka and his co-workers,[6] on the other hand, have also confirmed the presence of a considerable amount of the sugar alcohol (average: 2.5 mg dl^{-1}) in human plasma from healthy persons of various ages and they observed a gradual recovery of **1a** in the plasma of diabetic patients receiving insulin regularly during several months, in contrast with the fact that the content of **1a** in the plasma from diabetic patients receiving no insulin remained negligibly small.

Though both physiological and metabolic meaning of this minor sugar is still uncertain, some studies concerning feeding suppression in rats,[7] transport inhibition in hamster[8] or inhibitory effects to enzymes such as hexokinase[9] and α-glucosidase[10] have been reported so far.

These phenomena prompted us to prepare both hot and cold labeled derivatives of **1a** in order to elucidate the unknown metabolism of the sugar alcohol.

In a previous communication,[11a] we briefly reported a synthesis of 1,5-anhydro-D-[1-$^2H_1$]glucitol (**1j**) and 1,5-anhydro-D-[1-$^2H_2$]glucitol (**1m**) as preliminary targets.

The present paper comprehensively describes mono-, di-, and tri-C-deuteration of **1a** in detail.

Results and Discussion

For the synthesis of **1a**, there are several useful methods such as direct reduction of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide with lithium aluminum hydride,[12] palladium on carbon[13] or tributylstannane,[14] and reductive desulfurization[15] of phenyl 2,3,4,6-tetra-*O*-acetyl-1-thio-β-D-glucopyranoside with Raney-nickel.

From the standpoint of stereospecificity and work-up, the direct reduction of protected glucosyl halides with lithium aluminum hydride (LAH) or lithium aluminum deuteride (LAD) is our main choice and the respective syntheses are described as follows.

(1) Mono-C-deuteration

(a) (1*R*)-1,5-Anhydro-D-[1-$^2H_1$]glucitol (1j). Two different routes were achieved for the synthesis of **1j**. First, we chose, as a starting material, 1,2,3,4,6-penta-*O*-acetyl-β-D-[1-^{2}H]glucopyranose[11] (**1b**) obtained in two steps from D-gluco-1,5-lactone. The pentaacetate (**1b**) was then converted into 2,3,4,6-tetra-*O*-acetyl-α-D-[1-^{2}H]glucopyranosyl bromide, which was directly treated with excess amount of LAH to afford the desired product (**1j**) having 1*R* configuration. ^{1}H NMR of the acetate (**1e**) showed the disappearence of H_1 axial proton at δ=3.00 and the presence of H_1 equatorial proton at δ=4.15 having $J_{1,2}$=5.6 Hz. ^{13}C NMR of **1e** also revealed the signal of C_1 at δ=66.86 was missing.

Comparison of mass spectra of **1e** with that of the peracetate of **1a** clearly demonstrated the shift of one mass unit in several peaks [97 to 98, 170 to 171, 212 to 213, 273 to 274, and 333 (M^++1) to 334 (M^++1)].

Secondly, we chose 2,3,4,6-tetra-*O*-benzyl-α-D-[1-^{2}H]glucopyranosyl chloride easily obtained by treating 2,3,4,6-tetra-*O*-benzyl-α-D-[1-^{2}H]glucopyranose (**1c**) with methanesulfonyl chloride, and the resulting glucosyl chloride was reduced with an equimolar amount of LAH in dry ether to yield a syrupy (1*R*)-2,3,4,6-tetra-*O*-

benzyl-1,5-anhydro-D-[1-$^2H_1$]glucitol (**1d**) in a 58% yield. The benzyl groups of **1d** were then removed conventionally in the presence of Pd/C (10%) in acetic acid to afford the compound **1j** described above.

The second route requires multi-step reactions, and was less satisfactory as for a scale-up of preparation.

(b) 1,5-Anhydro-D-[3-^{2}H]glucitol (1k). 1,2,3,4,6-Penta-*O*-acetyl-β-D-[3-^{2}H]glucopyranose was first prepared by the reported method[16] in four steps from 1,2;5,6-di-*O*-isopropylidene-α-D-[3-^{2}H]allofuranose,[17] and next converted to the corresponding glucopyranosyl bromide, which was successively reduced with LAH in the same manner described above to give the desired compound **1k** in a total yield of 7% from D-glucose. ^{13}C NMR spectrum of the tetraacetate (**1f**) disclosed complete disappearence of C-2 signal observed at δ=73.79 in the corresponding light compound. Mass spectrum of **1f** also indicated the presence of m/z 334 (M^++1).

(c) 1,5-Anhydro-D-[5-^{2}H]glucitol (1l). 1,2,3,4,6-Penta-*O*-acetyl-β-D-[5-^{2}H]glucopyranose prepared stepwise by the known method[18] from 3-*O*-benzyl-1,2-*O*-isopropylidene-6-*O*-trityl-α-D-xylofurano-5-ulose, was first transformed into the corresponding bromide, which was then similarly treated with LAH to afford the compound (**1l**) in an overall yield of 35% from the 5-ulose. ^{13}C NMR spectrum of the tetraacetate (**1g**) showed the absence of C-5 signal at δ=76.47, and the mass spectrum also indicated the presence of m/z 334 (M^++1) peak.

(2) Di-C-deuteration

(a) 1,5-Anhydro-D-[1-$^2H_2$]glucitol (1m). Direct reduction of 2,3,4,6-tetra-*O*-benzyl-α-D-[1-^{2}H]glucopyranosyl chloride described in the case of **1c** was effected with LAD in dry ether to afford the corrresponding 2,3,4,6-tetra-*O*-benzyl-1,5-anhydro-D-[1-$^1H_2$]glucitol (**1h**) in 63% yield. Removal of benzyl groups in **1h** by means of hydrogenolysis in the presence of Pd/C (10%) gave **1m** as crystals, which was then converted to 2,3,4,6-tetra-*O*-acetyl-1,5-anhydro-D-[1-$^2H_2$]glucitol (**1i**). Double introduction of deuterium into C-1 of was unambiguously confirmed by ^{1}H NMR spectrum of **1i**, in which both H_1 axial proton at δ=3.30 and H_1 equatorial proton at δ=4.15 completely disappeared. ^{13}C NMR spectrum of **1i** disclosed the absence of C-1 signal at δ=66.86, coinciding with the result of ^{1}H NMR.

The presence of m/z 335 (M^++1) peak in the mass spectrum of **1i** clearly indicates two mass unit increase in comparison with that of the light compound.

An alternative route to **1m** was similarly achieved by reducing 2,3,4,6-tetra-*O*-acetyl-α-D-[1-^{1}H]glucopyranosyl bromide with LAD in dry ether. In terms of economy of LAD, which was excessively required in the latter case, the former seems to be better, but the latter is superior from the standpoint of short reaction steps and convenience.

(b) 1,5-Anhydro-D-[6-$^2H_2$]glucitol (1n). 1,2,3,4,6-Penta-*O*-acetyl-β-D-[6-$^2H_2$]glucopyranose,[18] prepared in three steps [(i) reduction with LAD, (ii) hydrolysis with 80% acetic acid, and (iii) acetylation with acetic anhydride/sodium acetate] from 1,2-*O*-isopropylidene-α-D-glucofuranurono-6,3-lactone, was brominated and successively reduced with LAH to afford the desired product (**1n**) in a total yield of 32%. ^{1}H and ^{13}C NMR spectra of the acetate (**1o**) showed the disappearence of H-6 multiplet at δ=4.17 and C-6 signal at δ=62.22 respectively. The octet of H-5 signal at δ=3.59 was definitely changed to doublet ($J_{4,5}$=9.9 Hz). The presence of m/z 335 (M^++1) peak in the mass spectrum of **1o** also supported the double deuteration of **1a**.

(3) Tri-C-deuteration

1,5-Anhydro-D-[5,6-$^2H_3$]glucitol (1q). 1,2-*O*-isopropylidene-α-D-[5,6-$^2H_3$]glucofuranose, obtained by stereoselective reduction[19] of 1,2-*O*-isopropylidene-α-D-xylohexofuranurono-6,3-lactone with sodium borodeuteride, was similarly converted to 2,3,4,6-tetra-*O*-acetyl-α-D-[5,6-$^2H_3$]glucopyranosyl bromide, and the bromide was immediately reduced with LAH to afford the desired compound (**1q**) in a total yield of 19% from the starting lactone. ^{13}C NMR spectrum of the peracetate (**1p**) disclosed both signals at δ=62.22 (C-6) and 76.47 (C-5) were completely disappeared, and the presence of m/z 336 (M^++1) peak in the mass spectrum of **1p** also supported the triple deuteration.

Experimental

Melting points were determined on a YAZAWA micro hotstage and were uncorrected. Solvents were evaporated off in vacuo below 40 °C. Optical rotations were measured with a JASCO DIP-140 digital polarimeter. ^{1}H and ^{13}C NMR spectra were recorded on a JEOL GX-100 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra measured with a Hitachi M-60 mass spectrometer connected with Hitachi data processing system M-003. TLC were carried out on Merck plates (silica gel 60, 0.25 mm). Column chromatography was performed on Wakogel C-200 or C-300.

1,2,3,4,6-Penta-*O*-acetyl-β-D-[1-^{2}H]glucopyranose (1b): To a cooled solution (0 °C) of D-glucono-1,5-lactone (10 g, 0.56 mmol) in a buffer solution (130 ml) of sodium acetate–acetic acid (pH 5.7) was gradually added sodium borodeuteride (Merck 98%, 1 g, 24 mmol) for 10 min and keeping pH at below 6.0 (dropwise addition of acetic acid). The reaction solution was then treated with IR-120 (H^+) and the resin was filtered off. The filtrate was concentrated in vacuo with aid of methanol and ethanol repeatedly. The resulting amorphous residue was dried, and acetylated with acetic anhydride (100 ml) and sodium acetate (5 g). The reaction mixture was then poured into ice-water, and the precipitate was filtered, and recrystallized from ethanol, giving 9.9 g (45%). mp 131—132 °C (lit,[20] 132 °C). ^{1}H NMR: no peak due to H-1 at δ=5.73. Anal. ($C_{16}H_{22}O_{11}$) C, H.

2,3,4,6-Tetra-*O*-benzyl-α-D-[1-^{2}H]glucopyranose (1c): A solution of 2,3,4,6-tetra-*O*-benzyl-D-glucono-1,5-lactone[21] (540 mg, 1 mmol) in dry ether (40 ml) and boron trifluoride

etherate (7.5 ml) was gradually added to a suspension of lithium aluminum deuteride (Merck 98%; 490 mg, 12 mmol) in dry ether (40 ml) under ice-cooling. The reaction mixture was then heated to reflux for 2 h and cooled. Dilute hydrochloric acid (2 M, 5 ml) was carefully added to the mixture, and the precipitate was filtered off. The filtrate was washed with aqueous $NaHCO_3$ and brine. The ethereal layer was dried ($MgSO_4$), concentrated to a crystalline mass, which was recrystallized from ethanol giving 0.49 g (90%); mp 150—151 °C, $[\alpha]_D^{12}$ +14.0° (*c* 1.0, $CHCl_3$); MS (70 eV) *m/z* (rel intensity) 432 (M^+−109; 0.60), 253 (14), 181(19), 92 (100), 79 (12), 65 (13). Anal. ($C_{34}H_{36}O_6$) C, H.

(1*R*)-2,3,4,6-Tetra-*O*-benzyl-1,5-anhydro-D-[1-$^2H_1$]glucitol (1d): To a solution of **1c** (2.2 g, 4.2 mmol) in CH_2Cl_2 (20 ml) was added *s*-collidine (2 g, 16.5 mmol) and methanesulfonyl chloride (0.96 g, 8.4 mmol), and the reaction mixture was kept overnight at room temperature (16 °C). The solution was successively treated with 1 M HCl, aqueous $NaHCO_3$, and water. The organic layer was dried ($CaCl_2$), and concentrated to a syrup, which was directly treated with lithium aluminum hydride (0.5 g, 13 mmol) in dry ether (50 ml). Excess of LAH was then decomposed with ethyl acetate and water, and the precipitate was filtered off. The ethereal layer was concentrated to a pale yellow syrup, which was chromatographed on a silica gel (C-200) with benzene–ethyl acetate (10/1). Evaporation of the eluates gave a pure syrup (1.23 g, 58%), having $[\alpha]_D^{14}$ +7.5° (*c* 0.42, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=7.2—7.4 (20H, aromatic), 4.46—5.00 (8H, m, CH_2Ph), 4.04 (1H, H-1, d, $J_{1,2}$=4.6 Hz), 3.37 (1H, m, H-5). No peak due to H-1 axial (δ=3.21). Anal. ($C_{34}H_{36}O_5$) C, H.

(1*R*)-1,5-Anhydro-D-[1-^{2}H]glucitol (1j): (a) 2,3,4,6-tetra-*O*-acetyl-α-D-[1-^{2}H]glucopyranosyl bromide (1.8 g), prepared by reacting **1b** (2.1 g) with 10 ml of a chilled solution of 25% HBr in acetic acid, was dissolved in dry ether (20 ml). This ethereal solution was gradually added to a stirred suspension of lithium aluminum hydride (1 g) in dry ether (30 ml) with keeping gentle reflux. Excess hydride was then decomposed with ethyl acetate and water. The precipitate was filtered and washed twice with water. The aqueous layer was then deionized with IR-l20 (H^+) and IR-45 (OH^-), and concentrated in vacuo in the presence of benzene and ethanol to a thick syrup, which gradually solidified. Recrystallization from methanol gave crystals (0.42 g, 58%); mp 143—144 °C, $[\alpha]_D^{9}$ +43.2° (*c* 0.74, H_2O) [lit,[12] nondeuterated: Mp 142—143 °C, $[\alpha]_D$ +42.3° (*c* 0.84, H_2O)]. Anal. ($C_6H_{12}O_5$) C, H.

(b) A mixture of **1d** (1.57 g) and palladium on carbon (10%, 1.5 g) in acetic acid (25 ml) was shaken at room temperature with hydrogen until absorption ceased. The catalyst was filtered and washed with water. The combined and washings were concentrated in vacuo to a syrup, which was dried in the presence of ethanol and benzene azeotropically. The solidified mass was recrystallized from methanol to give 0.25 g (52%) of crystals; mp 142—143 °C, $[\alpha]_D^{12}$ +43.0° (*c* 0.5, H_2O).

(1*R*)-2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[1-$^2H_1$]glucitol (1e): A solution of **1j** (0.50 g) dissolved in acetic anhydride (6 ml) and pyridine (6 ml) was kept overnight at room temperature, and poured into ice-water containing $NaHCO_3$.

The resulting mixture was then extracted with $CHCl_3$ (30 ml), and the $CHCl_3$ layer was washed with aqueous $NaHCO_3$ and water, dried ($MgSO_4$), and concentrated to a syrupy residue, which was chromatographed on a silica gel (Wako gel C-300) with benzene–ethyl acetate (5/1) to give a crystalline mass; mp 71—72 °C, $[\alpha]_D^{12}$ +42.0° (*c* 0.87, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=2.028 (9H, s, $COCH_3$), 2.034 (3H, s, $COCH_3$), 3.60 (1H, m, H-5), 4.14 (1H, dd, H-6, $J_{5,6}$=2.3, $J_{6,6}$=12.2 Hz), 4.15 (1H, d, H-1 equatorial, $J_{1,2}$=5.6 Hz), 4.19 (1H, dd, H-6′ *J*=4.6 Hz), 5.01 (1H, dd, H-2, $J_{2,3}$=9.5 Hz), 5.03 (1H, t, H-4, $J_{3,4}=J_{4,5}$=9.5 Hz), 5.20 (1H, t, H-3). Anal. ($C_{14}H_{20}O_9$) C, H.

1,5-Anhydro-D-[3-^{2}H]glucitol (1k): 1,2,3,4,6-Penta-*O*-acetyl-β-D-[3-^{2}H]glucopyranose (1.5 g), obtained by acetylation of D-[3-^{2}H]glucopyranose[16] with acetic anhydride–sodium acetate, was treated with 10 ml of 25% solution of HBr in acetic acid, and the resulting bromide was reduced with lithium aluminum hydride (0.80 g) as menthioned above. After the same work-up, the compound **1k** was obtained as crystals (0.32 g); mp 142—143 °C, $[\alpha]_D^{12}$ +42.5° (*c* 0.65, H_2O).

2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[3-^{2}H]glucitol (1f): The compound **1k** (0.21 g) was acetylated in the same manner as **1j** and chromatographed on silica gel to give a solid mass (0.26 g); mp 71—73 °C, $[\alpha]_D^{12}$ +42.0° (*c* 0.52, $CHCl_3$); ^{13}C NMR ($CDCl_3$) δ=20.59—20.71 ($\underline{C}H_3$×4), 62.24 (t, C-6), 66.85 (t, C-1), 68.39 (d, C-4), 68.91 (d, C-2), 76.47 (d, C-5), 169.49—170.62 ($\underline{C}O$×4).

1,5-Anhydro-D-[5-^{2}H]glucitol (1l): 1,2,3,4,6-Penta-*O*-acetyl-β-D-[5-^{2}H]glucopyranose (1.2 g), prepared from D-[5-^{2}H]-glucopyranose,[19] was treated with 25% solution (10 ml) of HBr in acetic acid, and the resulting bromide was reduced with lithium aluminum hydride (0.6 g) to give crystals after the same work-up; yield 0.24 g, mp 142—143 °C, $[\alpha]_D^{12}$ +42.7° (*c* 0.51, H_2O).

2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[5-^{2}H]glucitol (1g): The compound (0.20 g) was acetylated and chromatographed in the same conditions as **1e** to give a crystalline mass (0.24 g); mp 72—73 °C (ether–petroleum ether), $[\alpha]_D^{13}$ +42.5° (*c* 0.50, $CHCl_3$); ^1H NMR δ=2.028 (9H, s, $COCH_3$), 2.034 (3H, s, $COCH_3$), 3.30 (1H, t, H-1 axial, $J_{1,2}=J_{1,1}$=10.6 Hz), 4.13 (1H, d, H-6, $J_{2,6'}$=12.2 Hz), 4.14 (1H, dd, H-1 equatorial, $J_{1,2}$=5.6 Hz), 4.20 (1H, d, H-6′), 5.01 (1H, m, H-2), 5.03 (1H, d, H-4, $J_{3,4}$=9.5 Hz), 5.20 (1H, t, H-3, $J_{2,3}=J_{3,4}$).

2,3,4,6-Tetra-*O*-benzyl-1,5-anhydro-D-[1-$^2H_2$]glucitol (1h): 2,3,4,6-Tetra-*O*-benzyl-α-D-[1-^{2}H]glucopyranosyl chloride (2.0 g), described in the preparation of **1d**, was reduced with lithium aluminum deuteride (0.6 g) in dry ether. The excess of LAD was then decomposed in the same manner as **1c** to give a crude syrup, which was chromatographed on silica gel (Wako gel C-300). Evaporation of the corresponding fractions gave a clear syrup (1.18 g, 63%); $[\alpha]_D^{15}$ +7.0 (*c* 0.50, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=3.38 (1H, m, H-5), 3.55—3.67 (5H, m, H-2, H-3, H-4, H-6 and H-6′), 4.47—4.99 (8H, m, $\underline{C}H_2Ph$), 7.2—7.4 (20H, aromatics).

1,5-Anhydro-D-[1-$^2H_2$]glucitol (1m): (a) Hydrogenolysis of **1h** (2.1 g) was carried out in the same manner as described in **1d** to give a crystalline residue (0.40 g, 60%), which was recrystallized from methanol; mp 143—144 °C, $[\alpha]_D^{13}$ +43.0° (c 1.0, H_2O).

(b) Lithium aluminum deuteride reduction of 2,3,4,6-tetra-*O*-acetyl-α-D-[1-^{2}H]glucopyranosyl bromide (2.1 g, see experiment **1j**) gave the compound **1m** (0.48 g, 57%).

2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[1-$^2H_2$]glucitol (1i): Acetylation of **1m** (0.30 g) followed by chromatography and recrystallization described in the preparation of **1e** gave a crystalline compound **1i** (0.45 g) having mp 72—73 °C and $[\alpha]_D^{13}$ +43.0° (*c* 0.50, $CHCl_3$); ^{13}C NMR δ=20.59—20.71 ($\underline{C}H_3CO$), 62.22 (t, C-6), 68.47 (d, C-4), 68.99 (d, C-2), 73.74 (d, C-3), 76.47 (d, C-5), 169.5—170.6 ($\underline{C}OCH_3$).

1,5-Anhydro-D-[6-$^2H_2$]glucitol (1n): 1,2,3,4,6-Penta-*O*-acetyl-

β-D-[6-$^2H_2$]glucopyranose[18] (1.0 g) was converted to the corresponding bromide (see experiment **1j**), which was then reduced with LAH (0.30 g) to give crystals (0.72 g); mp 142—143 °C, $[\alpha]_D^{13}$ +42.8° (*c* 1.0, H_2O).

2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[6-$^2H_2$]glucitol (1o): The compound **1n** (0.20 g) was acetylated and chromatographed in the same conditions as **1e** to give a clear syrup (0.26 g), which gradually crystallized; mp 71—73 °C, $[\alpha]_D^{13}$ +42.0° (*c* 0.52, $CHCl_3$); ^{13}C NMR δ=20.60—20.71 ($\underline{C}H_3CO$), 66.88 (t, C-1), 68.47 (d, C-4), 68.98 (d, C-2), 73.74 (d, C-3), 76.38 (d, C-5), 169.5—170.6 ($\underline{C}O\times4$). Anal. ($C_{16}H_{20}O_9$) C, H.

2,3,4,6-Tetra-*O*-acetyl-1,5-anhydro-D-[5,6-$^2H_2$]glucitol (1p): 1,2,3,4,6-Penta-*O*-acetyl-β-D-[5,6-$^2H_3$]glucopyranose[19] (1.56 g) was treated with 30% HBr solution (1.0 ml) in acetic acid, and the resulting bromide was reduced with LAH in the same manner as **1j** to give a syrupy residue, which was then acetylated with acetic anhydride (10 ml)/pyridine (10 ml), and chromatographed on silica gel with benzene–ethyl acetate (5/1). Evaporation of the eluates afforded a clear syrup (1.08 g), which gradually crystallized; mp 72—73 °C, $[\alpha]_D^{13}$ +42.5° (*c* 0.65, $CHCl_3$); ^{13}C NMR ($CDCl_3$) δ=20.59, 20.67 ($\underline{C}H_3CO$), 66.86 (t, C-1), 68.44 (d, C-4), 68.99 (d, C-2), 73.74 (d, C-3), 169.5—170.6 ($\underline{C}O\times4$). Anal. ($C_{14}H_{20}O_9$) C, H.

1,5-Anhydro-D-[5,6-$^2H_3$]glucitol (1q): The tetraacetate **1p** (1.00 g) was deacetylated with sodium methoxide in methanol and deionized with IR-120 (H^+). The aqueous methanol solution was then concentrated in vacuo to a syrupy residue (0.42 g), which was treated with methanol to give crystals (0.26 g); mp 142—143 °C, $[\alpha]_D^{13}$ +43.0° (*c* 0.53, H_2O). Anal. ($C_6H_{12}O_5$) C, H.

The authors are very thankful to the members of Chiba University Analytical Center for the measurements of NMR and Mass spectra as well as for elemental analyses.

Gamma Radiolysis of Flavin Mononucleotide and Flavin-Adenine Dinucleotide in Aqueous Solution

Abhijit SAHA, Parikshit Chandra MANDAL, and Sudhindra Nath BHATTACHARYYA*
Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 1/AF, Bidhannagar, Calcutta 700064, India
(Received July 17, 1990)

Flavin-adenine dinucleotide (FAD) and flavin mononucleotide (FMN) were irradiated with ^{60}Co γ-ray and *G*-values for their decomposition under aerated, argon and nitrous oxide saturated conditions at pH 6.5 were determined by spectrophotometric, fluorescence and HPLC measurements. Among the water-borne radicals the hydroxyl radical (OH) was found to be responsible for causing permanent changes in FAD and FMN. The striking similarity between the difference spectra of irradiated FAD and FMN in N_2O saturated conditions shows that the OH radicals attack at the isoalloxazine moiety. A plausible mechanism for the reaction of the OH radicals with the isoalloxazine moiety has been discussed. The rate constant for the reaction of isoalloxazine moiety of FAD with OH radicals was determined to be 4.7×10^9 dm^3 mol^{-1} s^{-1} by competition kinetic studies using glucose as the reference solute. From the kinetic consideration and *G*-values it is evident that ca. 50% of the OH radicals attack at the AMP (adenosine monophosphate) portion of FAD apart from isoalloxazine moiety. The attack at the AMP portion of FAD is supported by the observed phosphate release in the irradiated FAD solution. Effect of Fe^{3+} ion on the radiolysis of FAD and FMN was also studied.

A large number of dehydrogenase enzymes which are very important in biological functions, e.g., electron transport in mitochondria, biosynthesis of pyrimidine bases, etc. contain flavin mononucleotide (FMN) and flavin-adenine dinucleotide (FAD) as their prosthetic groups. When exposed to ionizing radiation these enzymes lose their activity. But actual mechanism of inactivation of these flavoenzymes is yet to be known. To have an insight on the mechanism of radiation inactivation it is therefore necessary to study the chemical changes produced by radiation on free FMN and FAD molecules.

Winstead and Moss[1] have studied the inactivation of FAD by γ-irradiation in dilute aqueous solution both in presence and absence of air. From the spectral changes owing to varying doses absorbed they have suggested that the inactivation is due to attack by the water-borne free radicals derived from water radiolysis ($H_2O\rightsquigarrow H, OH, e_{aq}^-$)[2] at the isoalloxazine moiety of FAD.

In this paper we present our investigation on the role of the OH radicals in the decomposition of FAD and FMN in terms of *G*-values, the rate constant for the reaction of the OH radicals with isoalloxazine moiety of FAD, the possible sites of attack of OH radicals and the effect of iron(III) ion on the radiolysis of FAD and FMN in dilute aqueous solution.

Experimental

Materials. FAD and FMN were purchased from Sigma Chemical Company. Glucose, ferric ammonium sulfate, and other reagents that were used in the investigation were of 'AnalaR' grade. Triply distilled water was used to prepare the solutions. A phosphate buffer (2×10^{-2} mol dm^{-3}) was used for maintaining the pH at 6.5 of FAD and FMN solutions. Acetonitrile was of HPLC grade (Aldrich). Argon and N_2O gases of high purity were used for flushing the solutions. A ^{60}Co γ-source (dose rate=12 or 3.3 Gy min^{-1}) was used for irradiating the solutions. The dose rate was measured by Fricke dosimetry.

Analysis. The loss of flavin chromophore in FAD and FMN on γ-irradiation was estimated spectrophotometrically by measuring the absorbance of their solutions at 450 nm. The spectra of FAD and FMN were measured on a recording spectrophotometer. In the case of absorbance measurements of FAD and FMN in argon or N_2O saturated solutions a stoppered quartz spectrophotometer cell was used. The loss of FMN was also determined by measuring the loss of fluorescence intensity at 530 nm using an excitation wavelength of 450 nm.

The amount of FMN and FAD in irradiated samples was ascertained by separating them from their radiolysed products by HPLC. The HPLC separation was done by using Waters Liquid Chromatograph with an ODS-C_{18} column. A mobile phase of 1×10^{-2} mol dm^{-3} disodium hydrogenphosphate (adjusted to pH 5.5 with dilute H_3PO_4)–acetonitrile (100 : 12) was filtered, degassed, and used at a flow rate of 1.0 mL min^{-1}. The column eluents were monitored by the UV absorption at 450 nm and 210 nm using a variable wavelength detector.

Inorganic phosphate release from FAD after irradiation was measured by the method of Lowry and Lopez.[3]

Iron(II) ion concentration was measured spectrophotometrically by means of 1,10-phenanthroline reagent.[4]

Results

Figure 1a—c illustrates the effect of γ-irradiation on the spectral properties of 2.5×10^{-5} mol dm^{-3} FAD (pH 6.5) in aerated, N_2O saturated and argon saturated solutions. The spectrum after aeration of the irradiated solution has been shown in each case. It is evident that under argon saturated conditions, the absorbance decreased due to irradiation are partially restored by aeration of the irradiated samples. This suggests that some products formed radiolytically are partially oxidized to regenerate the parent molecule. Similar observations have also been obtained in the case of FMN.

Figure 1d shows that the loss of chromophore in FAD is not linear with the increase of the absorbed dose. The initial *G*-values for flavin chromophore loss in FAD have been determined from the initial slope of the

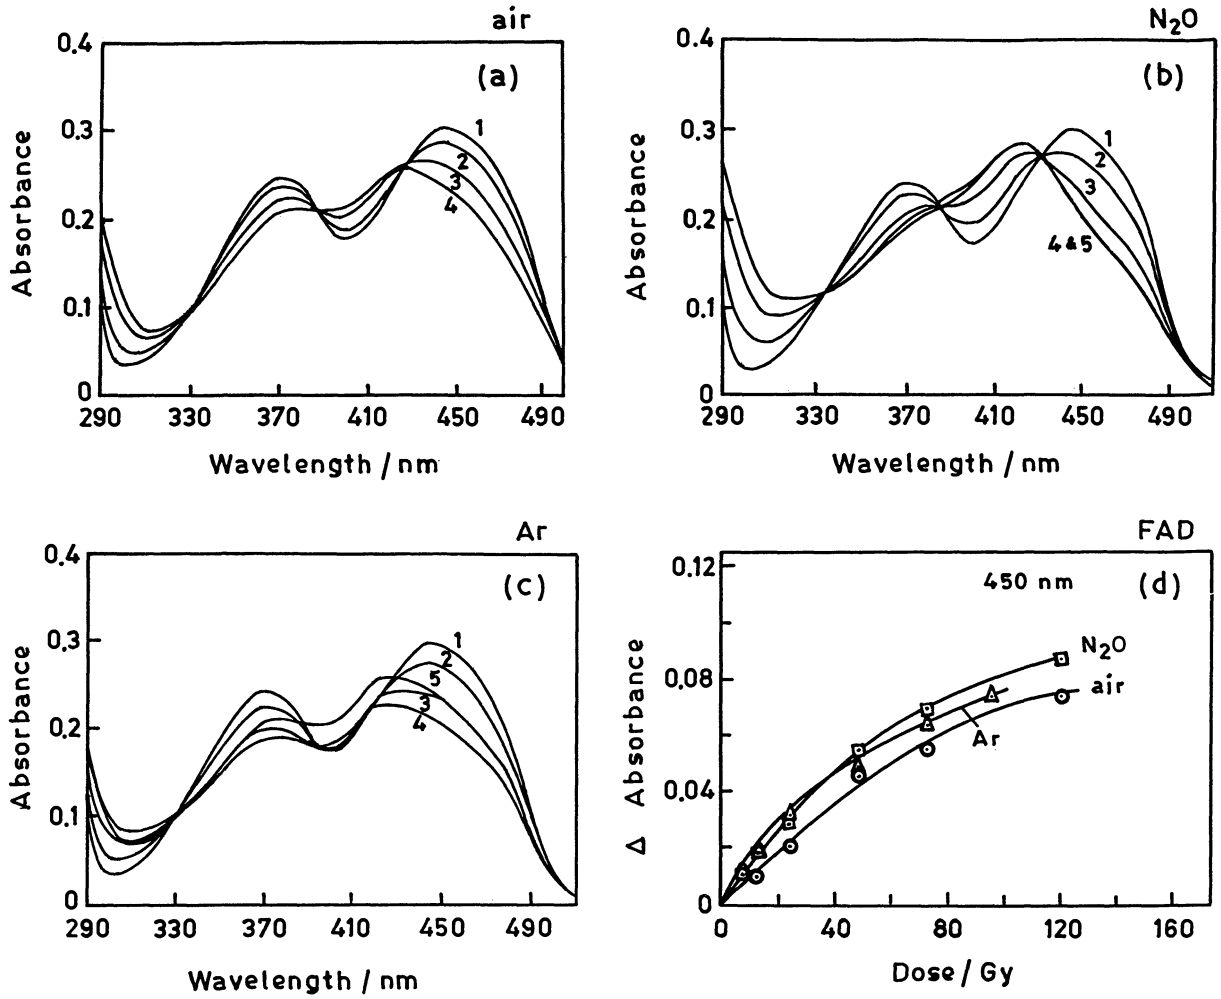

Fig. 1. Absorption spectra of FAD (2.5×10^{-5} mol dm^{-3}) in 2×10^{-2} mol dm^{-3} phosphate buffer irradiated under aerated (a), N_2O-saturated (b), and argon saturated (c), conditions. Absorbed dose: 1: 0.0 Gy; 2: 24 Gy; 3: 72 Gy; 4: 120 Gy 5: spectra obtained after aeration of the FAD solution irradiated with a dose of 120 Gy. (d) Changes of A_{450} for FAD solution with absorbed dose under aerated (⊙), N_2O-saturated (⊡), and argon saturated (△) solutions.

curves. The flavin chromophore loss in FMN was also determined in the same way. The results are presented in Table 1.

The fluorescence spectra of unirradiated and irradiated FMN solutions are shown in Fig. 2. This figure shows that on irradiation the fluorescence intensity decreased but there was no change in spectral shape of irradiated samples from the unirradiated one. The loss in fluorescence intensity was found to be linear with absorbed doses. Hence G(-FMN) values in aerated and N_2O saturated conditions were determined from the slope of the linear plot of loss of fluorescence intensity versus absorbed dose. The G(-FMN) values determined from such fluorescence measurements are in good agreement with those determined from HPLC analysis (Table 1) and from absorbance measurements. Therefore it would appear that the spectrophotometric determination of G-values from the disappearance of FMN absorbance is relatively free from significant error. In the case of FAD, although the spectral shape of the fluorescence remained same, there was increase in the fluorescence intensity at 530 nm after gamma irradiation of low doses. Hence the loss of flavin moiety in FAD on irradiation could not be determined fluorometrically. Further, the loss of FAD measured by HPLC differed markedly from that by loss of absorbances. Hence the decrease of absorbance at 450 nm gives only the extent

Table 1. G-Values for Flavin Loss under Different Conditions, [FAD]=[FMN]=2.5×10^{-5} mol dm^{-3}, pH=6.5

G-Values	Solution saturated with		
	Air	Argon	Nitrous oxide
G(-chromophore)$_{FMN}$[a]	1.23	2.1(1.20)[b]	
G(-chromophore)$_{FAD}$[a]	0.68	1.38(0.70)[b]	1.30
G(-FMN)	1.16(1.10)[c]	—	2.8(2.66)[c]
G(-FAD)	1.30	—	2.50

a) Determined spectrophotometrically. b) Measured after aeration of the radiolysed solution. c) Determined fluorometrically.

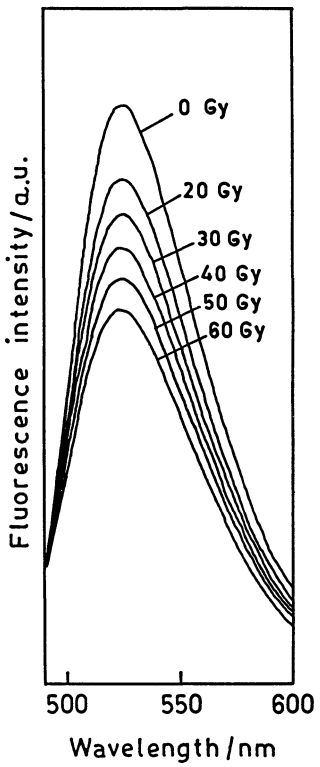

Fig. 2. Changes in the fluorescence emission of FMN (2.5×10^{-5} mol dm^{-3}) solution after γ-irradiation under aerated conditions. Excitation wavelength= 450 nm.

of modification of flavin chromophore in FAD. That is why G-values determined spectrophotometrically and by HPLC are expressed as G(-chromophore) in the former case and by G(-FAD) or G(-FMN) in the latter case.

Since some products generated on irradiation of FAD and FMN under argon are found to be reverted back by aerating the irradiated solution, the G-values in these cases could not be measured by HPLC.

The rate constant for the reaction of isoalloxazine moiety in FAD with the OH radicals has been determined by the competition kinetic technique using glucose as the reference solute. When irradiation was carried out in N_2O-saturated medium, e_{aq}^- reacts exclusively with N_2O to give a stoichiometric equivalent of OH radicals.

$$e_{aq}^- + N_2O \longrightarrow N_2 + OH + OH^-. \quad (1)$$

Therefore, when an aqueous solution of FAD and glucose is irradiated in N_2O saturated conditions, there would be a competition of FAD and glucose (GLH) for the OH radicals. The yields of chromophore loss of FAD should then follow the relationship

$$\frac{G(\text{-chromophore})_0}{G(\text{-chromophore})} = 1 + \frac{k_1}{k_2}\frac{[\text{GLH}]}{[\text{FAD}]}, \quad (2)$$

where G(-chromophore)$_0$ and G(-chromophore) are the yields of chromophore loss of FAD in the absence and

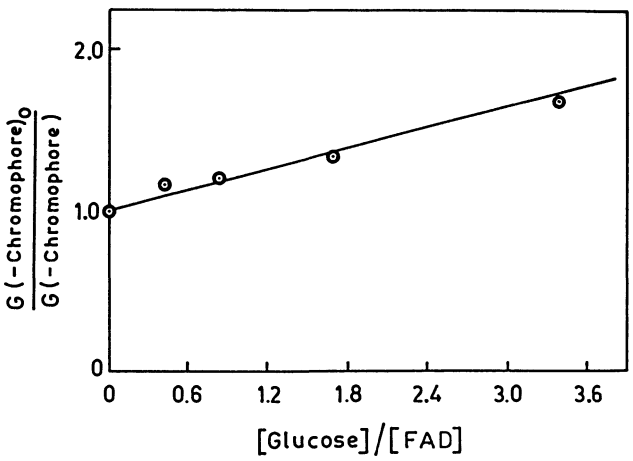

Fig. 3. Kinetic plot for the competition reactions of OH radicals between FAD and glucose. [FAD]= 2.5×10^{-5} mol dm^{-3}.

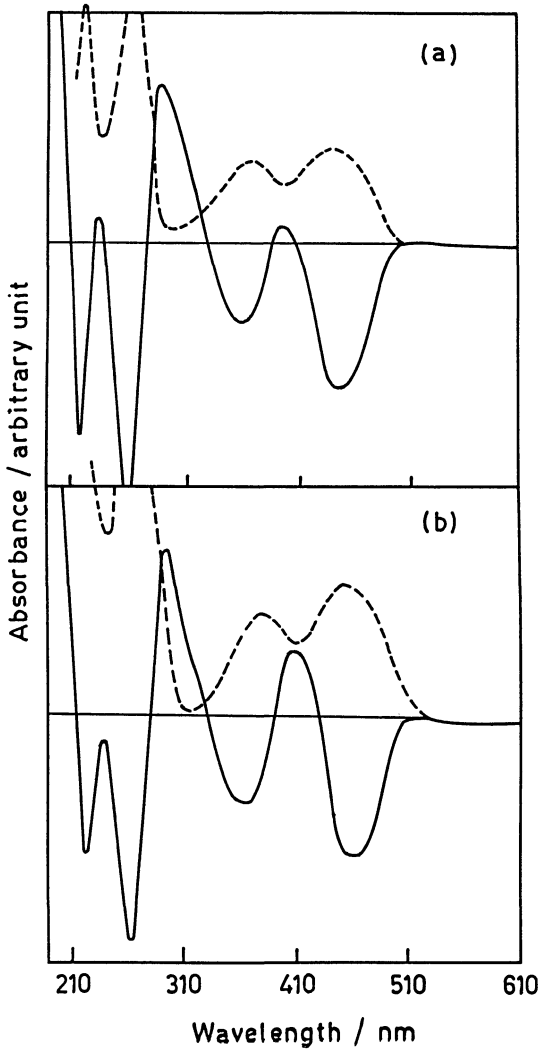

Fig. 4. Difference spectra of the products formed in FAD, (a), and FMN, (b) solutions irradiated with a dose of 120 Gy under N_2O-saturated solutions. Dashed curves are the respective absorption spectra.

presence of glucose, respectively; [GLH] and [FAD] are the molar concentrations of glucose and FAD, k_1 and k_2 being the rate constants for the reactions of OH radicals with glucose and the isoalloxazine moiety in FAD respectively. If G(-chromophore)$_0$/ G(-chromophore) is plotted against [GLH]/[FAD], a straight line with a slope of k_1/k_2 is expected. The observed results are plotted in Fig. 3. From the slope of straight line the value of k_1/k_2 could be determined. Taking the value of k_1 as 1×10^9 dm^3 mol^{-1} s^{-1},[5] the value of k_2, the rate constant for the reaction of isoalloxazine moiety in FAD with the OH radicals, has been estimated to be 4.7×10^9 dm^3 mol^{-1} s^{-1}.

The difference spectra of irradiated FAD and FMN in N_2O saturated medium are shown in Fig. 4a,b. The figure shows that in both cases there are three peaks at nearly identical wavelengths 408, 296, and 240 nm. The similarity of the product peaks obtained under the similar experimental conditions indicates that the same types of products have been formed in both cases.

As some of the flavoenzymes contain iron(III) the role of this metal ion in modification of radiosensitivity of flavins was also studied. Because of the instability of iron(III) ions in aqueous solution at pH 6.5 the study was to be carried out at pH ca. 2. The role of Fe^{3+} ions at pH ca. 2 on isoalloxazine moiety of FAD and FMN could be extrapolated to pH 6.5, since the pK value for $Fl+H^+=FlH^+$ is nearly zero[6] (where Fl represents flavin moiety). Therefore, flavin would remain in a neutral state at both pH 6.5 and ca. 2. Thus, when FAD is irradiated in the presence of iron(III) ion in argon saturated medium at pH ca. 2 the loss of flavin chromophore in FAD has been found to be the same as that obtained in absence of iron(III) ion. But the reduction yield of iron(III) ion $G(Fe^{2+})$ was found to increase with

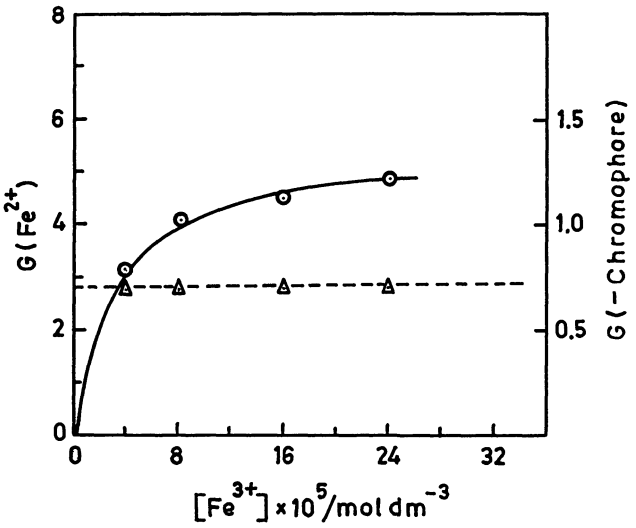

Fig. 5. Dependence of $G(Fe^{2+})$, (⊙) and G(-chromophore) in FAD, (△) on concentration of Fe^{3+} ion in the γ-radiolysis of FAD in the presence of Fe^{3+} ions at pH ca. 2 under argon saturated conditions, [FAD]=2.5×10^{-5} mol dm^{-3}.

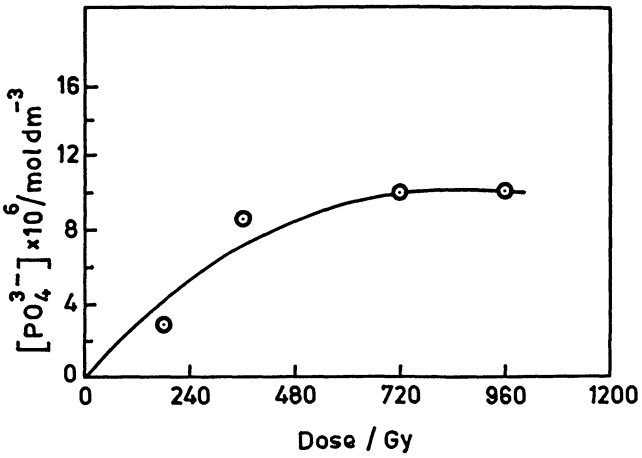

Fig. 6. Extent of phosphate release from FAD on γ-radiolysis under N_2O-saturated conditions, [FAD]= 2.5×10^{-4} mol dm^{-3}.

the increase in its concentration and reached a plateau value of ca. 4.8 at higher $[Fe^{3+}]$ as shown in Fig. 5. The reduction yield of iron(III) ion in the presence of FMN was found to be identical with that observed in the presence of FAD under similar experimental conditions.

In addition to the flavin moiety the FAD molecule also contains a phosphate-sugar linkage. It is well-known that when OH radicals react with the sugar moiety of nucleotides, inorganic phosphates are released.[7] To ascertain whether OH radicals react with FAD at sites other than the isoalloxazine ring, the amount of inorganic phosphate released in irradiated FAD was determined. Figure 6 shows the extent of phosphate release in γ-irradiated FAD in N_2O saturated medium against the absorbed dose. The initial G-value for the phosphate release was estimated to be ca. 0.23. But no detectable amount of phosphate release was observed on γ-irradiation of FMN under the similar conditions.

Discussion

In the aerated medium e_{aq}^- and H radicals are scavenged by oxygen forming the superoxide anion (O_2^-) and hydroperoxyl (HO_2) radicals as given in the Eqs. 3 and 4.

$$e_{aq}^- + O_2 \longrightarrow O_2^- \quad (3)$$

$$H + O_2 \longrightarrow HO_2 \quad (4)$$

Since the redox potential of O_2/O_2^- (E_0=−0.33 V)[8] is lower than those of Fl/Fl^- (E_0=−0.3 V),[9] the superoxide anions could reduce flavins to dihydroflavins. But these dihydroflavins would be oxidized readily by molecular oxygen by a complex mechanism[10] to give back flavins. Hence there would be no net modification of flavins due to reaction with O_2^- in aerated medium.

In N_2O saturated medium G_{OH} is twice than that in aerated medium. From Table 1, it is seen that the

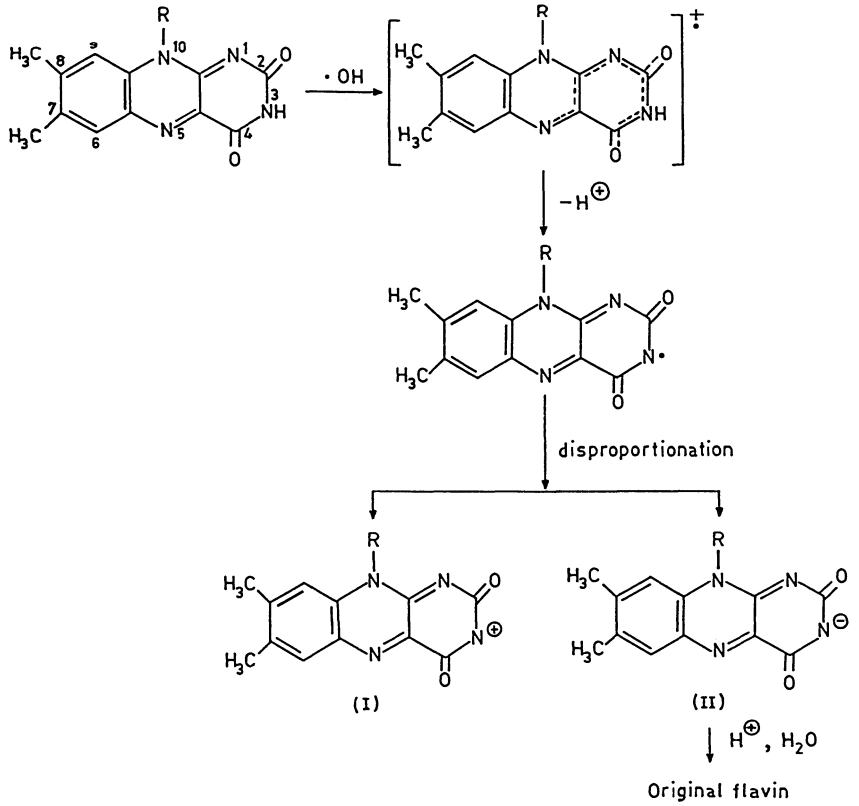
chromophore loss in FAD and FMN in N_2O saturated medium are nearly twice that observed in aerated medium. This result definitely shows that OH radicals have important contribution to the modification of FAD and FMN during the irradiation by γ-rays. The flavin chromophore loss of FAD and FMN under the deaerated conditions was found to be larger than that observed under the aerated conditions (Table 1). This may be attributed to the reactions of FAD with e_{aq}^- and H radicals. Ahmad et al.[11] have shown that FAD and FMN are reduced by e_{aq}^- to form dihydroflavins, FlH_2.

$$Fl + e_{aq}^- + H^+ \longrightarrow FlH \quad (5)$$

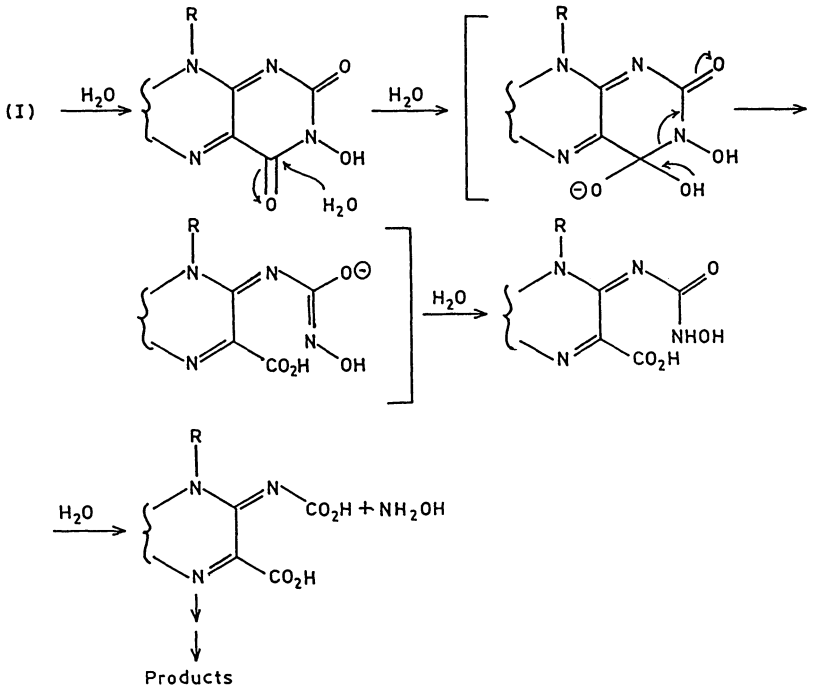
$$2\,FlH \xrightarrow{\text{disproportionation}} Fl + FlH_2 \quad (6)$$

As stated earlier these dihydroflavins are oxidized by molecular oxygen to flavins. This explains the partial recovery of absorbances of irradiated FAD and FMN by aeration as shown in Fig. 1c. But in the case of dinitrogen monoxide saturated condition the absorption spectra of the irradiated sample remained unchanged (Fig. 1b) on aeration. Since the major damaging species in N_2O saturated medium is OH radicals, it could be inferred that OH radicals cause a permanent damage to FAD and FMN. This permanent change in absorption caused by OH radicals might be due to modification of the isoalloxazine moiety of flavins. The absorption behavior of the products formed from such reactions could be studied following the difference spectra of the products formed in the reactions. Figure 4 shows that there are three negative peaks in the difference spectra of the products with minima at those wavelengths (260, 370, and 450 nm) which correspond to the maxima in the absorption spectrum of unirradiated FAD and FMN. These negative peaks indicate the removal of ground-state absorption of FAD and FMN on radiolysis. The absorption peaks of the products have shifted to shorter wavelengths than those of starting flavins. This spectral shift may imply that OH radical reaction causes the loss of π-conjugation of isoalloxazine moiety of flavins.

From Table 1 it is evident that under aerated or N_2O saturated conditions the decomposition yield of flavins, viz. FMN is equal to half the value of G_{OH}. To account for this G-value, a disproportionation reaction of the transient intermediate formed by the reaction of OH radicals with the flavin should take place as was suggested previously.[12] Heelis et al.[13] have suggested that possible oxidation sites at the fiavin moiety are the C-8 methyl group and the extended π-conjugated system. They have shown that $SO_4^{\cdot-}$ radical causes oxidation predominantly by abstracting electron from the π-conjugated system followed by deprotonation from N-3 atom. Kishore et al.[14] have shown by pulse radiolysis studies that OH radical causes oxidation only at π-conjugated system in flavin moiety of lumichrome. To explain the chromophore loss in FAD and FMN an analogous mechanism may be shown as Schemes 1 and



Scheme 1.



Scheme 2.

2.

But the above mechanism cannot account for the observed G(-chromophore) in FAD. Table 1 shows that under N_2O saturated conditions the G(-chromophore) for FAD is only 1.3 which is much less than the value expected from the reaction mechanism. The possible reason for this discrepancy is that apart from the isoalloxazine moiety a significant portion of the total OH radicals attacks at the AMP (adenosine monophosphate) portion of FAD. The rate constant for the reaction of OH radicals with adenosine (ca. 3.7×10^9 $dm^3\,mol^{-1}\,s^{-1}$) is comparable to that with flavin moiety of FAD and calculation shows that ca. 50% of the total OH radicals would react with the AMP moiety of FAD molecule. This is supported from the fact that in both aerated and N_2O saturated media the G(-chromophore) values in FAD are nearly half of that in FMN under identical conditions. However, when the loss of FAD was measured after separating the products by HPLC, G(-FAD) was found to be ca. 2.5, which is much higher than the value obtained from the spectrophotometric measurements. This increased degradation of FAD is due to the modification of AMP moiety in FAD. The attack of OH radicals at the AMP portion is further confirmed from the phosphate release on γ-irradiation of FAD in N_2O saturated medium, because the attack of OH radical on the AMP results in phosphate release from the molecule.

The role of Fe^{3+} in the radiolysis of FAD and FMN has also been studied. In both cases the reduction of Fe^{3+} has been observed. At pH ca. 2 under deaerated conditions, the $G(Fe^{2+})$ value in absence of FAD and FMN was 3.0 which is almost equal to the radiation chemical yield of the H atoms.[2] But in the presence of FAD or FMN the $G(Fe^{2+})$ value was found to be 4.8. This increase of the $G(Fe^{2+})$ value might be due to the reaction of Fe^{3+} with the transient intermediate formed by the reaction of OH radicals with flavins or by other reducing products formed in the reaction. It is interesting to note that the chromophore loss in FAD and FMN were not influenced by the presence of Fe^{3+} during irradiation. Hence the reduction of Fe^{3+} by the transient radical is unlikely. The only possible pathway to account for the formation of reduced iron is the reduction of Fe^{3+} by the product formed in the solvolysis of (I) (Schemes 1 and 2). Hydroxylamine or the hydroxamic acid derivative (III) could reduce two equivalents of Fe^{3+}. Thus according to the aforesaid discussion $G(Fe^{2+})$ is expected to be $G_H+2\times G$(-chromophore)$=3.0+2\times1.2=5.4$ for FMN and $G_H+2\times G$(-chromophore) $=3.0+2\times0.7=4.4$ for FAD. If a small loss of Fe^{2+} ion due to aereal oxidation during measurements is considered, then the observed results are found to be in conformity with that expected in the case of FMN. But for the case of FAD, the observed $G(Fe^{2+})$ is ca. 4.8 (Fig. 5) which is slightly higher than the expected value. It is important to mention here that the attack of OH radicals towards AMP would produce radicals which are easily reduced and oxidized in nature.[15] Thus reducing radicals might react with Fe^{3+} ions giving Fe^{2+}. As a result, the yield of Fe^{2+} could be increased without affecting G(-chromophore) of FAD molecule.

(Received December 25, 1990)

The crystal structures of the inclusion compounds of the 2*c*,4*t*-diphenylcyclobutane-1*r*,3*t*-dicarboxylic acid (α-truxillic acid) host (**1**) with methanol [MeOH] (1:2) and with dimethylacetamide [DMA] (1:2) have been determined by single crystal X-ray diffraction. The substantial difference between the effects of the protic (MeOH) and aprotic (DMA) guests on the molecular packing is discussed. Crystal data: **1**·2MeOH: monoclinic ($P2_1/n$), a=12.528(4), b=5.589(1), c=13.715(4) Å, β=101.16(4)°, Z=2, R=0.064 for 1300 reflections; **1**·2DMA: monoclinic ($P2_1/c$), a=6.151(1), b=26.586(2), c=7.938(1) Å, β=105.32(6)°, Z=2, R=0.056 for 1488 observations. In both clathrates, half of the rigid α-truxillic acid molecule occupies the asymmetric unit together with one guest molecule. The hydrogen bonds between the trans-positioned functional groups of the host acid and the guest molecules in **1**·2MeOH give rise to infinite layers parallel with the crystallographic *ac* diagonal. In contrast, the only one-way hydrogen bond from host to guest in **1**·2DMA leads to discrete 1:2 host–guest aggregates. In this latter case, the hosts and guests are stacked separately, along the *c* axis direction.

Elucidation of new models for molecular recognition is a recent challenge for organic chemistry.[1] In this regard, inclusion compounds in general and lattice inclusions in particular will remain in good standing for a while. Recent crystal structure determinations have revealed a new brand of lattice inclusions in which the guest entities are anchored to the framework formed by the host molecules through hydrogen bonds.[2] This feature is such an eminent characteristic of the crystals that the term coordinatoclathrate has been coined for them.[2,3] Hosts that display this behavior are mainly based on rigid and symmetric dicarboxylic acids.[4] In the compounds studied earlier,[2,4–10] the number of bridging carbon atoms between the –COOH functions is even, and the two –COOH groups are oriented more or less at right angles to one another.[2] Here we report on the structures of two solid coordinatoclathrates of α-truxillic acid (2*c*,4*t*-diphenylcyclobutane-1*r*,3*t*-dicarboxylic acid, **1**), which has an odd number (3) of carbon atoms between two symmetry-related –COOH functions with diametrically opposite orientations. (The synthesis and the inclusion properties of this host have been published elsewhere.[9,10]). The methanol (MeOH) and dimethylacetamide (DMA) guests possess protic and aprotic character, respectively.

Experimental

Sample Preparation. The α-truxillic acid host was prepared as previously described.[9] Crystals of the inclusion compounds were obtained by dissolution of the host in the respective guest solvent, followed by slow solvent evaporation.

X-Ray Data Collection and Processing. The single crystals selected for X-ray measurement were sealed in glass capillaries. The intensitites were collected on a STOE/AED2 diffractometer at room temperature with graphite monochromatized Cu $K\alpha$ radiation (λ=1.5418 Å), using the 2θ–ω scan mode within the range $3<2\theta<140°$. The unit cell parameters were refined against θ values of 30 and 50 reflections for **1**·2MeOH and **1**·2DMA, respectively, within the range $27<2\theta<44°$.

The net intensities were corrected for Lorentz and polarization effects but not for absorption. Crystal data and selected experimental details are summarized in Table 1.

Structure Analysis and Refinement. Reasonable starting models of the structures were derived by direct methods, using MULTAN[11] for **1**·2MeOH and SHELXS[12] for **1**·2DMA. Only structure factors with $F>6\sigma(F)$ were included in the subsequent full-matrix least-squares refinements [SHELX[13]]. The positions of the non-hydrogen atoms were refined together with their anisotropic thermal parameters, whereas isotropic temperature factors were refined for the hydrogen atoms.

The H atoms in **1**·2MeOH, except for the methyl hydrogens of the guest, were located from a difference electron density map, and their positions were kept riding on their 'mother' atoms during the subsequent refinements. The methanol $-CH_3$ group was refined as a rigid group with free rotation

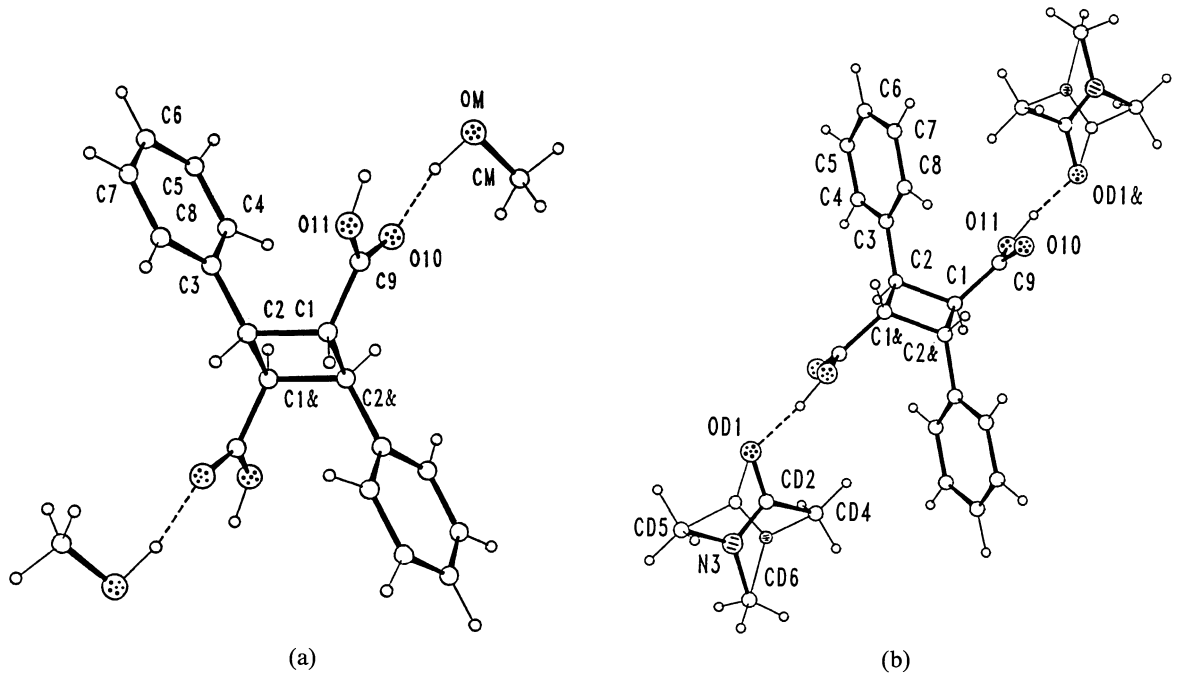
around the O–C bond.

The guest in the **1**·2DMA structure shows positional disorder. The difference electron density map, calculated for the structural model containing C, O, and N atoms, remained blurred in the region of the guest molecule. It was, however, possible to construct a proper model of the disorder with the aid of molecular modelling [CHEM-X 86[14]]. This model consists of two orientations of the DMA molecule, partly overlapping each other (cf. Fig. 1b). Accordingly, the refinement was extended to two additional peaks representing the alternative positions for C(D2) and N(3) atoms, and two sets of hydrogens for the C(D4), C(D5), and C(D6) methyl carbons



(a) (b)

Fig. 1. Perspective views of the formula units of (a) **1**·2MeOH and (b) **1**·2DMA, with atoms labeled as in the text. Solid and dashed lines represent covalent and hydrogen bonds, respectively; O atoms are dotted, N atoms are hatched. In the structure of **1**·2DMA, the guest shows rotational disorder: it assumes two orientations partly overlapping each other.

were included in the structure factor calculations. The hydrogens of the host molecule, except for three H atoms, were assumed to be at geometrically predictable positions. H(1) and H(2) of the *c*-butane ring (Fig. 1b) and the carboxylic H(11) atom were located by difference electron density calculation and were kept riding on their 'mother' atoms. The refinement of the alternative C(D2a)/C(D2b) and N(3a)/N(3b) disorder sites yielded site occupancies of 0.47/0.53, respectively.

Some strong low-θ reflections (26 for **1**·2MeOH and 30 for **1**·2DMA), with considerably higher F_c than F_o, probably due to extinction effects, were excluded from the last refinements, where the final residual indices (R and R_w in Table 1) were reached.

Results and Discussion

Figure 1 shows perspective views of the formula units of the present two inclusion compounds of α-truxillic acid (**1**). The final atomic positional parameters are given in Table 2. Hydrogen bond geometries are listed in Table 3. The helical chain of hydrogen bonds in **1**·2MeOH is illustrated in Fig. 2, whereas the crystal packings are depicted in Figs. 3 and 4.[15]

Molecular Structures. In the two inclusion compounds the geometry of α-truxillic acid (**1**), possessing C_i molecular symmetry, is similar within experimental error (Fig. 1). The cyclobutane ring is planar with somewhat strained bond lenghts and bond angles: C(1)–C(2)=1.581(3) and 1.571(4), C(1)–C(2)&=1.551(1) and 1.539(4) Å, ∠C(1)–C(2)–C(1)&=89.4(2) and 89.8(2), ∠C(2)–C(1)–C(2)&=90.6(2) and 90.7(2)° in **1**·2MeOH and **1**·2DMA, respectively (&=1−x, 1−y, 1−z for **1**·2MeOH and −x, 1−y, 1−z for **1**·2DMA). The C(2)–C(1)–C(9)–C(11) torsion angles[16] [84.2(3) and 82.5(3)°] indicate similar orientations of the carboxyl functions. Even the rotational angles of the phenyl rings about the C(2)–C(3) bond differ by only 14°. The dihedral angles between the least-squares (LS) planes[17] of the cyclobutane and the phenyl rings are 76.9(1) and 82.8(1)°, whereas the COO(H) groups are inclined through 66.8(2) and 63.9(2)° away from the attached phenyl substituents in **1**·2MeOH and **1**·2DMA, respectively.

Two distinct models (termed hereinafter *A* and *B*) can be used to describe the disorder of the DMA with respect to the rotation axis through the oxygen and one of the *N*-methyl carbon [C(D6)] atoms. Thus, the C(4D)/C(5D) atomic pair occupies alternatively the same positions with about 50% probability, whereas C(D2) and N(3) have two disorder sites (Fig. 1b). The

a) The position of the hydrogens involved in hydrogen bonds are taken from difference electron density maps and are not refined.

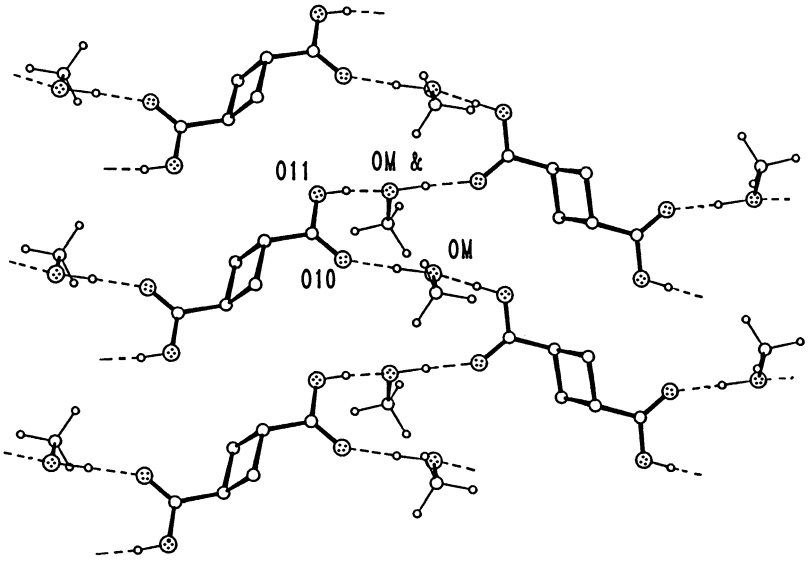

Fig. 2. Diagram of the hydrogen bond network in the crystal structure of **1**·2MeOH. The phenyl substituents and the hydrogens of the host, except H(11), which is involved in H-bonding, are omitted for clarity. Solid and dashed lines represent covalent and hydrogen bonds, respectively.

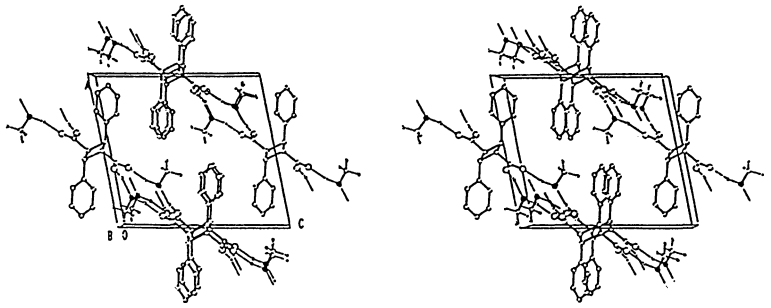

Fig. 3. Stereo packing illustration of the **1**·2MeOH crystal structure. The O atoms of the guest are in bold. The hydrogens of the host, not invloved in hydrogen bonds, are omitted for clarity.

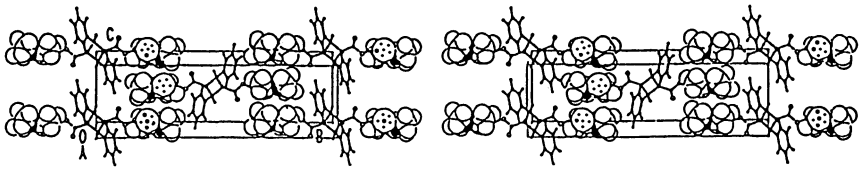

Fig. 4. Stereo packing diagram of the **1**·2DMA crystal structure. The host molecule is shown in ball-and-stick style, the guest molecule is drawn as space filling models with only one disorder site for each C(2D) and N(3). The N and O atoms of the guest are indicated by black filling and dotting, respectively.

non-hydrogen atoms of the DMA molecule are coplanar within 0.040 and 0.072 Å in *A* and *B*, respectively.

Packing Relations and Host-Guest Interactions. The protic MeOH and aprotic DMA arrange the host entities in substantially different ways (Figs. 3 and 4).

In **1**·2MeOH the hydrogen bonding between the host acid and the alcoholic guests results in infinite helices (Fig. 2), similar to those found in the alcoholic inclusions of the related 3,3-diphenyl-*cis*-cyclopropane-1,2-dicarboxylic acid.[9,10,18] Nevertheless, due to the intramolecular hydrogen bond between the *cis*-positioned –COOH groups, the cyclopropane host behaves externally as monofunctional, forming inclusions usually with 1 : 1 stoichiometry. As a consequence, the H-

bonded helices in the EtOH[18] and *t*-BuOH inclusions[9,10] of the *cis*-cyclopropanedicarboxylic acid host are endless in one dimension, and are held together by weaker Van der Waals' forces.

In contrast, the *trans*-truxillic acid (**1**) is a bifunctional host, forming inclusions usually with 1 : 2 host–guest stoichiometry. In its MeOH inclusion the alcoholic guests, helically arranged around the screw axes at 1/4, *y*, 1/4 and 3/4, *y*, 3/4, connect both ends of the hosts via strong OH···O bonds. The divalent host entities, located either at *a*/2 or *c*/2 are linked together by the hydrogen-bonded helices (cf. Fig. 4) into infinite layers. These two-dimensional, infinite 'supramolecules' are then held together by Van der Waals' forces between the hydrophobic phenyl rings.

In **1**·2DMA (Fig. 4) the one-way hydrogen bond interaction between host and guests gives rise to discrete host–guest aggregates. The single OH···O hydrogen bond, from the donor at each end of **1** to the carbonyl group of the DMA molecule, fixes the DMA·**1**·DMA aggregates along the *b* axis. The twofold screw axes translate these aggregates and the two apolar DMA units fit exactly between two other DMA molecules separated by the short [7.937(1)Å] *c* axis. It seems probable that the bulky, closely packed DMA molecules assume alternatively either disorder form *A* or *B* in order to avoid formation of short, (<2.4 Å) unfavorable H···H intermolecular contacts. The infinite columns of the apolar DMA guests completely isolate the host molecules. This particular mode of packing suggests possibilities for future applications in topochemical reactivity[19] and for the development of other crystalline materials properties.[20]

Conductivity of Manganese(II) Sulfate in Aqueous Solution at Various Temperatures

Eiji KUBOTA,* Satoru TAKIZAWA, Wataru KASHIWAGI, and Masatoki YOKOI
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received October 31, 1990)

Synopsis. The molar conductivity of manganese(II) sulfate, $MnSO_4$, in aqueous solution was measured in a temperature range of 10—45 °C. The acquired data were analyzed by the Quint–Viallard equation, and the resulting ion association constant, K_A, was used in the Bjerrum equation to determine the contact ion size, R_B. The limiting ionic molar conductivity λ_0 (1/2 Mn^{2+}) for the manganese ion at 15, 25, 35, and 45 °C are 40.8, 53.1, 65.2, and 79.8 S cm^2 mol^{-1}, respectively. The resulting thermodynamic properties for the ion association reaction are: $\Delta G^\circ_{298}=-13.5$ kJ mol^{-1}, $\Delta H^\circ=7.91$ kJ mol^{-1}, and $\Delta S^\circ_{298}=74.1$ J K^{-1} mol^{-1}.

Though the conductivity of manganese(II) sulfate in aqueous solutions at 25 °C has been the subject of extensive works,[1–4] its molar conductivity in aqueous solutions at other temperatures has never been studied. We previously measured the molar conductivity of iron(II) sulfate at various temperatures.[5] In this paper, the measurement was extended to manganese(II) sulfate in a temperature range of 10—45 °C. The temperature dependence of the ionic molar conductivity of divalent metal ions in aqueous solution is discussed in terms of the ion size.

Experimental

Reagent grade $MnSO_4$ was repeatedly recrystallized and purified in the usual manner. Preparation and purification of $MnSO_4$ were conducted under nitrogen atmosphere. Conductivity water was prepared by distilling water three times, and then allowed to pass very slowly through a mixed bed ion-exchange resin shortly before use.

All the measurements were made under nitrogen atmosphere. Conductivities were measured at a frequency of 1 kHz with a linear type bridge[6] in a temperature range of 10—45 °C, with the temperature controlled to ±0.005 °C. The conductivity cell was equipped with a platinized platinum electrode, and the cell constant was 0.99877±0.00001 cm^{-1} at 25 °C. No detectable change in the cell constant was observed over the temperature range of 10—45 °C.

On starting each run, nitrogen gas was passed gently through the conductivity water in the cell for about 20 min, and the conductivity of water was measured equilibrium value, which was less than 1.1×10^{-7} S cm^{-1}. The concentration of the sample solution was determined gravimetrically by the weight buret technique. A stock solution was poured from the weight buret into the cell without opening the cell to prevent contamination from CO_2 in the air. About 30 min was required for the reading of resistance to reach an equilibrium value. The measured resistance exhibited little drift with time after the thermal equilibration.

Results and Discussion

The molar conductivities, Λ, measured as a function, of concentration, c, in the temperature range 10—45 °C are given in Table 1. Using the successive approximation method, the conductivity data were analyzed in terms of the Quint–Viallard equation, Eq. 1.[17]

a) c/mol dm^{-3}; $\Lambda(1/2MnSO_4)$/S cm^2 mol^{-1}, molar conductivity.

$$\Lambda = \gamma[\Lambda_0 - Sc^{1/2}\gamma^{1/2} + Ec\gamma \log c\gamma + J_1 c\gamma - J_2 c^{3/2}\gamma^{3/2}]. \quad (1)$$

Here

$$K_A = (1-\gamma)/c\gamma^2 f_\pm^2, \quad (2)$$

$$-\log f_\pm = Ac^{1/2}\gamma^{1/2}/(1+B\mathring{a}c^{1/2}\gamma^{1/2}), \quad (3)$$

where c is the concentration, γ the degree of dissociation, K_A the ion association constant, $f_\pm$ the mean ionic activity coefficient given by the Deby-Hückel theory,[8] and $\mathring{a}$ the ion size parameter. The coefficients S, E, J, A, and B contain solvent properties, and J_1 and J_2 are functions of the ion size parameter $\mathring{a}_{J2}$.

In the analysis, the ion size parameters appearing in the J_1 and $f_\pm$ terms were fixed at the Bjerrum's distance, q. The best-fit $\mathring{a}_{J2}$ values for J_2 were calculated by minimizing the value of $\sigma\Lambda$ defined by

$$\sigma\Lambda = [\Sigma(\Lambda_{calcd} - \Lambda_{obsd})^2/(N-3)]^{1/2}, \quad (4)$$

Table 2. Conductivity Parameters for Aqueous $MnSO_4$ Solution at Various Temperatures[a]

35	163.2±0.1	11.8±0.1	307±1	0.03	3.9
40	179.3±0.1	11.8±0.1	324±1	0.03	3.9
45	196.1±0.2	11.9±0.1	337±2	0.04	3.8

a) $\Lambda_0(1/2MnSO_4)$/S cm^2 mol^{-1}, limiting molar conductivity. $\mathring{a}_{J2}$/Å, ion size parameter for J_2 term. K_A/dm^3 mol^{-1}, ion association constant. $\sigma\Lambda$/%, relative standard deviation in Λ. R_B/Å, contact ion size for the Bjerrum's equation.

where N is the number of experimental points.[9] The results are given in Table 2.

When a conductivity equation containing the $c^{3/2}$ term as in Eq. 1 is applied, the fitting of the data is generally better.[5,9] If an ion association is represented by the Bjerrum's equation, Eq. 5, the contact ion size, R_B(Å), can be calculated from the K_A value given by Eq. 2;[5,10]

$$K_A(calcd) = \frac{4\pi N}{1000}\int_{R_B}^{q} r^2 \exp(e^2/r\,DkT)dr. \quad (5)$$

The results for R_B are also given in Table 2.

As can be seen in Table 2, Λ_0 and K_A tend to increase with raising temperature. This is also the case for other sulfates of divalent transition metal ions ($FeSO_4$,[5] $CoSO_4$,[3] $NiSO_4$,[3] and $ZnSO_4$[3]). Among these sulfates, $MnSO_4$ exhibits the smallest Λ_0 value and the largest K_A value while $ZnSO_4$ exhibits the greatest Λ_0 value and the smallest K_A value.

The limiting ionic molar conductivity, $\lambda_o(1/2\ Mn^{2+})$ =53.1 S cm^2 mol^{-1}, for Mn^{2+} at 25 °C is in good agreement with the literature value: 53.1 S cm^2 mol^{-1} by Broadwater and Evans[11] and 53.2 S cm^2 mol^{-1} by Hallada and Atkinson,[12] with the value $\lambda_0(1/2\ SO_4^{2-})$= 80.0 S cm^2 mol^{-1}.[8] Althogh the ion size parameter $\mathring{a}_{J2}$ is relatively large, reflecting the nature of the adjustable parameter, R_B has a reasonable value (the sum of the ionic crystal radii is ≈3.4 Å[13]).

The λ_0's for the Mn^{2+} ion at a series of temperatures are given in Table 3 together with those for other divalent ions; these were calculated using the Λ_0 values for $CaSO_4$[3] and the λ_0 values for the Ca^{2+} ion at 15, 35, and 45 °C.[8] As is evident in Table 3, the limiting molar conductivities for a series of divalent transition metal ions show a similar increase with a rise in the temperature. The value of λ_0^{2+} generally increases from Mn^{2+}

a) This work. b) Ref. 5. c) Ref. 3.

to Zn^{2+} except for Fe^{2+} at 35 °C. In particular, this trend is conspicuous at elevated temperatures of 35 and 45 °C.

From Mn^{2+} to Ni^{2+}, the order of the λ_0^{2+} value is opposite to those of the crystal ionic radii and the size of the first hydration sphere revealed by X-ray diffraction on the aqueous solutions.[15] This may suggest that the ionic mobility is inversely proportional to the crystal ionic radii of divalent transition metal ions and of the hydrated ion size.

The $\log K_A - 1/T$ plot to obtain ΔH^0 or ΔS^0 exhibits a good linearity. The resulting thermodynamic constants for the ion association reaction are given in Table 4 together with those of other sulfates. It is seen that the parameters for $Mn^{2+} \cdot SO_4^{2-}$ are similar in magnitude to those for the sulfate ion pairs compared.

The authors wish to thank the staffs of the Shinshu University Nagoya University, and the University of Tokyo Computation Centers for the use of the computers.

The Excited-State Dipole Moment of Nitrobenzene Estimated from Solvent Spectral Frequency Shifts

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980
(Received March 20, 1991)

Synopsis. The excited-state dipole moment of nitrobenzene has been estimated to be 33.7×10^{-30} C m from solvent spectral frequency shifts. This value agrees well with that ($(31.7\pm3.3)\times10^{-30}$ C m) determined from an electrooptical absorption measurement.

Many theories[1] have previously been proposed regarding solvent spectral frequency shifts of organic molecules. On the basis of some of these, dipole moments and/or polarizabilities have been estimated for the excited states of organic molecules. As mentioned in a previous paper,[2] comparisons of the excited-state dipole moments and/or polarizabilities estimated from the solvent spectral shifts with those determined from electrooptical measurements are necessary, in part, to justify the theoretical expressions for the solvent spectral frequency shifts. Among the theoretical expressions, those expressions that give excited-state dipole moment and polarizability values that are comparable to those of electrooptical measurements will survive. Recently, Sinha and Yates[3] have reported the excited-state dipole moment of nitrobenzene from an electrooptical measurement. Nitrobenzene is one of the typical molecules used for the study of the solvent spectral frequency shifts, because the shifts of nitrobenzene are large. This paper, therefore, applies Abe's improved equation[2,4] to data for nitrobenzene in order to examine the accuracy of this equation by comparing an excited-state dipole moment estimated from the solvent spectral shifts with that obtained from the electrooptical measurement.

Results and Discussion

In a previous paper,[2] Abe's improved expression for the solvent spectral frequency shift of a neutral solute molecule in solution is given by

$$A\times(p_{00}^{A}\cos\theta)p_{ii}^{A}+B\times(p_{ii}^{A})^2+C\times\alpha_{ii}^{A}=\sigma_{0i}^{\circ}-\sigma_{0i}+D, \quad (1)$$

where

$$E=\frac{(d^{S}/M_{r}^{S})^{2/3}}{(r_{A}+r_{S})^4}\times\frac{\pi}{hc}\left(\frac{4\pi L}{3}\right)^{2/3}, \quad (2)$$

$$A=E\times\frac{2(p_{00}^{S})^2}{3(4\pi\varepsilon_0)^2kT}, \quad (3)$$

$$B=E\times\frac{\alpha_{00}^{S}}{4\pi\varepsilon_0}, \quad (4)$$

$$C=E\times\left\{\frac{(p_{00}^{S})^2}{4\pi\varepsilon_0}+\frac{3}{2}\times\frac{I_0^{S}I_0^{A}\alpha_{00}^{S}}{I_0^{S}+I_0^{A}}\right\}, \quad (5)$$

and

$$D=E\times\left[\frac{2(p_{00}^{S})^2(p_{00}^{A})^2}{3(4\pi\varepsilon_0)^2kT}+\frac{1}{4\pi\varepsilon_0}\times\{(p_{00}^{S})^2\alpha_{00}^{A}+\alpha_{00}^{S}(p_{00}^{A})^2\}+\frac{3}{2}\times\frac{I_0^{S}I_0^{A}\alpha_{00}^{S}\alpha_{00}^{A}}{I_0^{S}+I_0^{A}}\right]. \quad (6)$$

Here σ_{0i}° and σ_{0i} are the wave numbers of a transition from the ground state to the ith-excited state of a molecule in the vapor state and in solution, respectively. The A and S superscripts/subscripts denote the solute and solvent molecules, respectively. The subscripts 00 and ii denote the ground and ith-excited states, respectively. The dipole moment and polarizability are denoted by p and α, respectively. The angle between p_{00}^{A} and p_{ii}^{A} is denoted by θ. The symbol c is the speed of light in a vacuum, h is Planck's constant, L is Avogadro's constant, ε_0 is the permittivity of a vacuum, M_r is the relative molecular mass, d is the density, and I_0 is the ionization potential of the ground state. In applying Eq. 1, the method of detailed calculations was the same as that used in Ref 2.

Macovei[5] has investigated in detail the effects of a solvent on the absorption maximum of the 41820 cm^{-1} band[6] of nitrobenzene in the vapor phase. Data for 13 solvents from his spectral data involving 26 solvents were chosen for this study. Data for protic solvents and for solvents lacking information regarding ionization potentials were excluded. Moreover, data for the solvents 1,2-dichloroethane, acetonitrile, and 1,4-dioxane were excluded. 1,2-Dichloroethane is a mixture of rotational isomers having different dipole moments. The aceonitrile molecule has a large dipole moment (3.92 D, where 1 D=3.333×10^{-30} C m). In Abe's theory,[4] the solvent molecule is assumed to have a small enough dipole moment that it is not tightly oriented with nitrobenzene (4.21 D). According to Marcus,[7] 1,4-dioxane has a dipole moment of 0.45 D. Which of 0 and 0.45 D should be used as the dipole moment of dioxane is not clear. Therefore, the datum for 1,4-dioxane was excluded. In applying Eq. 1, the temperature was assumed to be 20 °C. Data used for nitrobenzene were r_A=0.344 nm, $\alpha_{00}^{A}=126.29\times10^{-25}$ cm^3, I_0^{A}=9.88 eV, and $\cos\theta=1$.[3] The values of p_{ii}^{A} and α_{ii}^{A} estimated by means of Calculation 1 in Ref. 2 are 10.1 D and 397×10^{-25} cm^3, respectively. Even if a value of -1 was used for $\cos\theta$, the same excited-state values (i.e., $p_{ii}^{A}=-10.1$ D and $\alpha_{ii}^{A}=397\times10^{-25}$ cm^3) were still obtained. This supports the assumption that p_{00}^{A} and p_{ii}^{A} are collinear. By using the p_{ii}^{A} and α_{ii}^{A} values so estimated, one can calculate the frequencies. The correlation between the experimental frequencies ($\sigma_{0i,\,obsd}$) and the calculated ones ($\sigma_{0i,\,calcd}$) is shown in Fig. 1. On the whole, the correlation is good.

The present estimation of p_{ii}^{A}=10.1 D closely agrees with the experimental values of (9.5 ± 1)[3] and (9 ± 2)[8] D

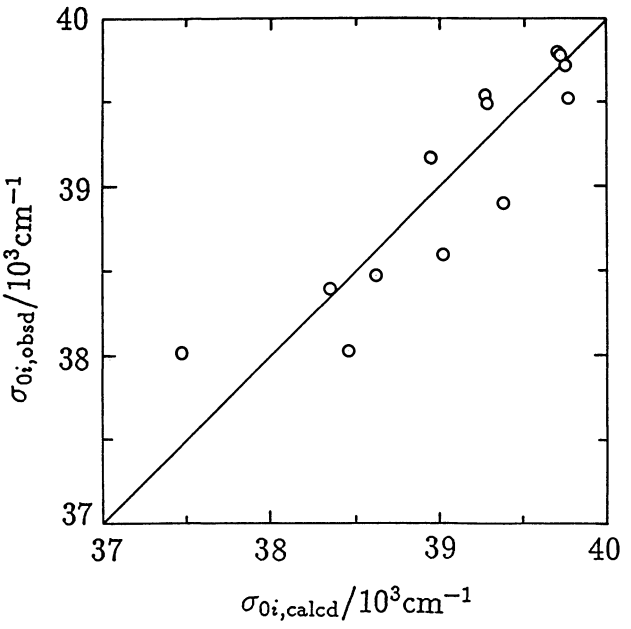

Fig. 1. A plot of $\sigma_{0i,obsd}$ vs. $\sigma_{0i,calcd}$.

determined from the electrooptical measurements. Several values for the excited-state dipole moment of nitrobenzene have hitherto been estimated from the solvent spectral frequency shifts: by applying McRae's equation,[9] Macovei[5] obtained $p_{ii}^{A}=7.19$ D. Using the simple equation based on the Onsager model,[10] Suppan and Ledger[11,12] obtained $p_{ii}^{A}=6.3$ D. Modifying the equation proposed by Amos and Burrows,[13] Millefiori et al.[14] obtained a good result of $p_{ii}^{A}-p_{00}^{A}=4.37$ D. By applying McRae's equation, Prabhumirashi obtained $p_{ii}^{A}=5.84$ D[15] and 7.99 D.[16] A comparable result for nitrobenzene, as determined by the electrooptical measurements and the present analysis, shows that Fq. 1 can be applied for estimating the excited-state dipole moment of a polar solute molecule, as already described in Ref. 2.

(Received January 25, 1991)

Synopsis. Potassium, sodium, and ammonium salts of $[V(cydta)(H_2O)]^-$ complexes were prepared, where cydta denotes *trans*-1,2-cyclohexanediamine-*N,N,N',N'*-tetraacetate. Crystal structure analysis of $Na[V(cydta)(H_2O)]\cdot 5H_2O$ revealed that the vanadium(III) atom adopts a capped trigonal-prism structure, a cydta acting as a sexidentate ligand and an aqua ligand occupying the capping position.

Usually vanadium(III) forms complexes with coordination number six.[1] However, we have recently shown that vanadium(III) forms seven-coordinate complexes with edta and hedtra,[2] the geometries of which are capped-trigonal prisms.[3-5] Our current work investigates whether vanadium(III) adopts the same structure with other edta-type aminopolycarboxylates. Here we report the synthesis and crystal structure of a cydta complex of vanadium(III). In contrast to the well known pentagonal bipyramidal structures of iron(III)-EDTA complexes,[6-8] the iron(III)–CyDTA complex adopts a capped trigonal prismatic structure.[9] This suggests that vanadium(III)–CyDTA might also adopt a capped trigonal prismatic structure. This hypothesis is experimentally confirmed. The structures of capped trigonal-prism complexes with edta-like ligands are compared.

Experimental

General Procedure. The complexes were prepared under a nitrogen atmosphere. A column (10 mmϕ) of Dowex 50W-X8 (50—100 mesh) was used for exchanging cation in vanadium(III)–CyDTA complex.

Synthesis of $K[V(cydta)(H_2O)]\cdot 2H_2O$ (1a). To a suspension of 7.29 g (20 mmol) of H_4cydta in 50 cm^3 of water was added 2.76 g (20 mmol) of potassium carbonate. The addition of VCl_3 (3.15 g, 20 mmol) to the solution results in a dark green gel. Upon addition of 4.00 g of potassium hydrogencarbonate (40 mmol), the gel dissolved and the color of the solution turned to brown. The solution volume was reduced to 20 cm^3 by evaporation, and the pale brown precipitate was collected by filtration and washed with water and ethanol successively. Yield 6.67 g (69%). Found: C, 34.56; H, 4.86; N, 5.77%. Calcd for $C_{14}H_{24}KN_2O_{11}V$: C, 34.57; H, 4.97; N, 5.76%.

Syntheses of $Na[V(cydta)(H_2O)]\cdot 5H_2O$ (1b) and $NH_4[V(cydta)(H_2O)]\cdot 4H_2O$ (1c). An aqueous solution (5 cm^3) of **1a** (1.0 g, 2.0 mmol) was passed through a column packed with 3.8 cm^3 of Na-type cation exchange resin. Brown plate crystals suitable for X-ray diffraction work were obtained by standing the aqueous solution in a methanol vapor. Found: C, 32.74; H, 5.53; N, 4.90%. Calcd for $C_{14}H_{30}N_2NaO_{14}V$: C, 32.07; H, 5.77; N, 5.34%.[10]

1c was obtained by almost the same procedure as the sodium salt. Found: C, 33.57; H, 6.11; N, 8.00%. Calcd for $C_{14}H_{32}N_3O_{13}V$: C, 33.54; H, 6.43; N, 8.38%.

X-Ray Crystal Structure Determination of 1b. General procedures for data collection and analysis are the same as those described in the previous paper.[5] Crystal data are listed in Table 1. As one of the sites of water of crystallization was found to be partially occupied, the occupancy factor was also refined to give the value 0.25. Anisotropic temperature factors were applied for the non-hydrogen atoms except for the partially occupied oxygen atom. The coordinates of hydrogen atoms attached to carbon atoms were calculated and fixed.

Results and Discussion

Bond lengths and angles around the vanadium atom were listed in Table 2.[11] An ORTEP drawing of the $[V(cydta)(H_2O)]^-$ anion is shown in Fig. 1. Cydta acts as a sexidentate ligand and a water molecule occupies the seventh coordination site, thus the geometry is a monocapped twisted trigonal-prism which resembles $[V(hedtra)(H_2O)]$[3] and $[V(edta)(H_2O)]^-$.[4,5] The N(1)–O(1)–O(3) and N(2)–O(5)–O(7) planes are almost parallel, the dihedral angle between the planes being 4.1°. The complex has an approximate 2-fold axis through the vanadium–aqua bond, although it has some tendency to form a 4:3 piano stool structure[12] like edta complexes: planarity of N(1)–N(2)–O(7)–O(1) (deviations from the least-squares plane are 0.15, −0.17, −0.11, and 0.17 Å) is much better than N(1)–N(2)–O(5)–O(3) (0.33, −0.26, −0.28, and 0.27 Å) and the former plane is parallel to O(3)–O(5)–O(W), the dihedral angle between the planes being 3.0°. The cyclohexane ring takes the chair form as expected.

Table 3 compares the torsion angles[13] of edta and

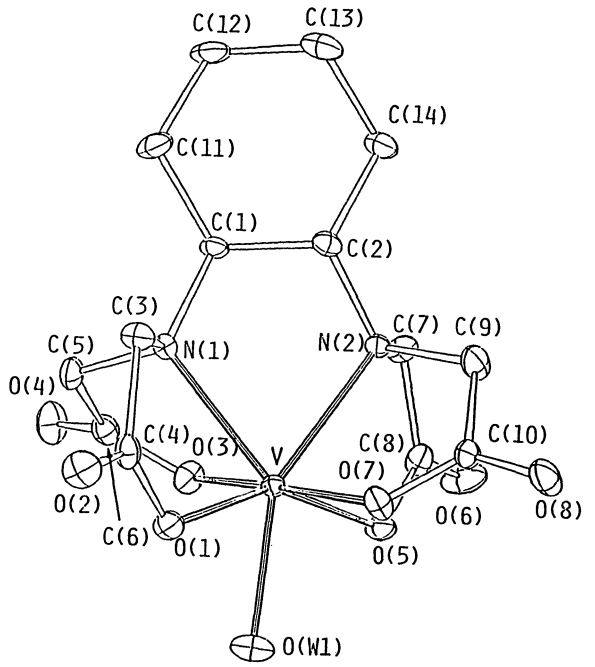

Fig. 1. ORTEP diagram of the [V(cydta)(H_2O)]$^-$ anion in Na[V(cydta)(H_2O)]·5H_2O. Hydrogen atoms are omitted for clarity.

edta-related complexes with capped trigonal prism structures. The range of angles is quite wide but all are less than 27°. In pentagonal bipyramidal structures such as [Fe(edta)(H_2O)]$^-$, the corresponding angles are more than 45°.[6-8] A capped trigonal-prism structure is also reported for [Fe(cydta)(H_2O)]$^-$,[9] but the torsion angles for [Fe(cydta)(H_2O)]$^-$ are much larger than those for [V(cydta)(H_2O)]$^-$. The average bond lengths between metal and donor atoms are 2.127 and 2.113 Å for the iron and vanadium complexes, respectively. This difference is slightly larger than that of Shannon's ionic radii ($r_{Fe^{3+}}$=0.0645 Å vs. $r_{V^{3+}}$=0.0640 Å).[14]

The sodium ion is six-coordinate with crystal water molecules and carboxylato oxygen atoms with Na–O bond lengths in the range 2.331 (6)—2.727 (5) Å. The sodium ions and water molecules form a hydrophilic sheet along the [020] plane, and the complex anions are layered between them. The partially occupied water molecule is not connected to any of the surrounding atoms via hydrogen bonding.

Table 3. Comparison of Torsion Angles of Capped Trigonal-Prismatic Seven-Coordinate Complexes with edta and Related Ligands

Complex	θ_1/deg	θ_2/deg	θ_3/deg
[V(hedtra)(H_2O)][a]	16.25 (6)	11.10 (7)	14.80 (7)

Ca[Fe(cydta)(H_2O)]·8H_2O[d]	26.9 (2)	26.3 (2)	23.4 (2)

a) Ref. 3. b) Ref. 5. c) This work. d) Ref. 9.

Thus, the cydta complex of vanadium(III) also forms a capped trigonal-prismatic seven-coordinate complex as do the edta and hedtra complexes. Although the geometry is more symmetrical than the edta complex, it shows some tendency towards a 4:3 piano stool structure similarly to the edta complex.

Circular Dichroism Spectrum of C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ Containing Chiral Methylene Formed by Stereospecific Deuteration

Tomoharu AMA,* Takaji YASUI, and Jinsai HIDAKA†
Department of Chemistry, Faculty of Science, Kochi University, Akebono-cho, Kochi 780
†Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received March 25, 1991)

Synopsis. C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ was prepared by way of the stereospecific deuteration of the facially coordinated edma (ethylenediamine-*N*-acetate) in $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$. The vicinal CD spectrum due to the C(*S*)-edma-d_1 in the C_i-*trans*(O) complex was investigated in connection with the D→H exchange in the ligands, suggesting a two-step mechanism.

Ethylenediamine-*N*-acetate (edma=$NH_2CH_2CH_2$-$NHCH_2COO^-$) coordinates to cobalt(III) to form various geometrical and optical isomers.[1–5] Of these isomers, the one in which edma coordinated facially to cobalt(III) has been remarked because of the characteristic reactivity of the coordinated edma. In the course of our studies on stereochemistry of Co(III) complexes with edma and its derivatives, it was found that one of the methylene protons in the glycinate moiety (G-ring) of the facially coordinated edma is stereospecifically deuterated in a basic D_2O solution to form an asymmetric center; $NH_2CH_2CH_2NHC^*HDCOO^-$.[2] This note is concerned with the preparation of optically active edma (C(*S*)-edma-d_1) due to the stereospecific deuteration of $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$,[6] and the preparation and CD spectrum of C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$[6] which has only the vicinal CD contribution arising from the asymmetric carbon atoms, -C*HD-, of the ligands.

Experimental

Preparation of Complexes. $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]Cl and C_i-*trans*(O)-[Co(edma)$_2$](ClO$_4$): These complexes were prepared according to the method described in the previous paper[2] and the absolute configuration of $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]Cl has been determined as $\Delta\Delta\Delta$(N_R, N_R).[2]

***C_i*-trans(O)-[Co(C(*S*)-edma-d_1)$_2$](ClO$_4$):** A buffer solution (pH 10.30) was prepared by adding a few drops of 2 mol dm^{-3} DCl–D_2O to a solution containing 1.0 g of Na_2CO_3 in 20 cm^3 of D_2O. About 1.0 g of $(-)^{CD}_{543}$-C_2-*trans*(O) isomer was dissolved into the buffer solution (20 cm^3), and the solution was kept at 40.0 °C for ca. 25 min in order to deuterate one of the two protons in the methylene of G-ring in the facially coordinated edma.[2] The deuteration of the G-ring $-CH_2-$ was confirmed by means of ^{1}H NMR measurements (Fig. 2). The solution was acidified to pH 6 with 2 mol dm^{-3} HCl to stop the reaction. Zinc powder (2 g) was added to the solution to reduce the central cobalt(III) to cobalt(II), and then the mixture was stirred for 5 min at room temperature (about 20 °C). After the excess of zinc was filtered off, lead dioxide (7 g) was added to the solution adjusted to pH 6. The mixture was stirred for 15 min at room temperature to reconstitute the cobalt(III) complex with the deuterated edma. After the reactant solution had been filtered, the filtrate was poured onto a column of SP-Sephadex (Na^+ form, 5.0 cm×60 cm) and then the adsorbed band was eluted with a 0.2 mol dm^{-3} NaCl aqueous solution. Three bands: brown (by-product), red, and another red (other geometrical isomers of deuterated [Co(edma)$_2$]$^+$), were eluted in this order.[1,2] After the earlier red band containing the deuterated C_2-*trans*(O) and C_i-*trans*(O) isomers was eluted out, two drops of 1 mol dm^{-3} acetic acid solution was added to the eluate and then the eluate was concentrated to ca. 50 cm^3 in a rotary evaporator under reduced pressure at 35 °C. Addition of about 1 cm^3 of saturated $NaClO_4$ solution to the concentrated solution gave the crude C_i-*trans*(O) isomer as fine yellowish orange crystals. The ClO_4^- salt of C_i-*trans*(O) is less soluble than that of C_2-*trans*(O) isomer. The crystals were quickly filtered and washed with a few milliliters of cold water. Recrystallization was carried out from a small amount of warm water by addition of five drops of saturated $NaClO_4$ solution. Found: C, 24.42; H, 4.61; N, 14.05%. Calcd for C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$](ClO$_4$) (F.W.=394.65): C, 24.35; H (1.008×18/F.W.), 4.60; N, 14.20%.[8]

Measurements. The absorption and CD spectra were measured by a JASCO UVIDEC 670-type spectrophotometer and JASCO J-22 and J-600 spectropolarimeters, respectively. The ^{1}H NMR spectra were recorded on a Hitachi R-90H Fourier Transform NMR spectrometer, using TSP [3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid sodium salt] as an internal standard.

Results and Discussion

The two geometrical isomers in this report, C_2-*trans*(O)-[Co(edma)$_2$]$^+$ and C_i-*trans*(O)-[Co(edma)$_2$]$^+$ are illustrated in Fig. 1. The ^{1}H NMR spectrum of the starting complex, $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$, right after dissolving in basic D_2O solution shows an AB quartet signal (at δ=ca. 3—4) due to the methylene protons of G-ring (Fig. 2(a)). The two higher-field and two lower-field peaks of this AB quartet have been assigned to the inside methylene proton (H_a in Fig. 3(a)) and the outside one (H_b in Fig. 3(a)), respectively.[2] Moreover, it has been known that one of the G-ring methylene protons in $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$ is stereospecifically deuterated in a basic D_2O solution, namely, the outside proton (H_b) is deuterated faster than the inside one (H_a).[2] In fact, the lower-field peaks (H_b) disappeared and the higher-field ones (H_a) turned out to the singlet one, twenty-five minutes after dissolving in the solution (Fig. 2(b)). This spectral behavior indi-

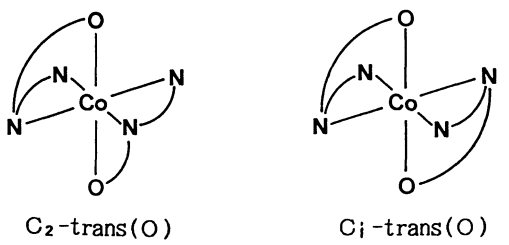

Fig. 1. Two geometrical isomers, C_2-*trans*(O)- and C_i-*trans*(O)-[Co(edma)$_2$]$^+$.

cates that one of the G-ring methylene protons in $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$ was deuterated to form asymmetric centers, –C*HD–. Here, it is to be noted that the G-ring methylene carbons are regulated to C(*S*) configuration, because both the secondary nitrogen atoms of the facially coordinated ligands in $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$ take N(*R*) configuration (Fig. 3(b)). $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ thus obtained was converted into C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ (Fig. 3(c)) as described in experimental section.

The absorption and CD spectra in the d-d transition band region of $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ and the converted complex are shown in Fig. 4. The absorption spectral pattern of the latter differs significantly from that of the former and then, coincides with that of the C_i-*trans*(O)-[Co(edma)$_2$]$^+$,[2] suggesting that the converted complex takes a C_i-*trans*(O) geometry. When the formation of this C_i-*trans*(O) complex proceeded with retention of the configuration of C(*S*)-edma-d_1, the secondary nitrogen atoms of the coordinated ligands should take N(*R*) configuration for C(*S*)edma-d_1 having inside proton and N(*S*) configuration for C(*S*)-edma-d_1 having outside proton, as shown in Fig. 3(c). This is confirmed from the comparison with ^{1}H NMR spectra (Figs. 5(a) and (b)) of C_i-*trans*(O)-[Co(edma)$_2$]$^+$ and the converted C_i-*trans*(O) complex, in line with the assignment of $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(edma)$_2$]$^+$ and the deuterated one. Namely, two singlet peaks (at δ=ca. 4.1 and ca. 3.3) due to two G-ring –C*HD– are observed for the spectrum of the converted C_i-*trans*(O) complex (Fig. 5(b)), and the signal peak at δ=ca. 4.1 is assigned to the outside proton and the peak at δ=ca. 3.3 to the inside one. Thus, the converted C_i-

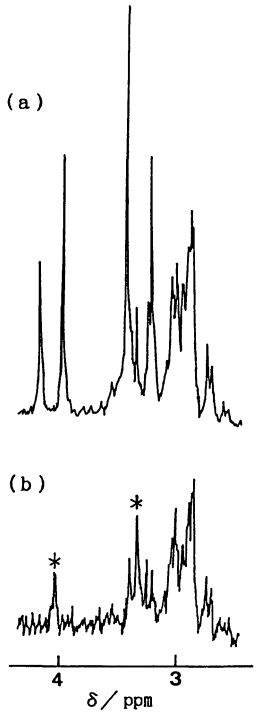

Fig. 5. ^{1}H NMR spectra of C_i-*trans*(O)-[Co(edma)$_2$]$^+$. (a) Undeuterated complex and (b) deuterated complex. Asterisked peaks: G-ring –C*HD–.

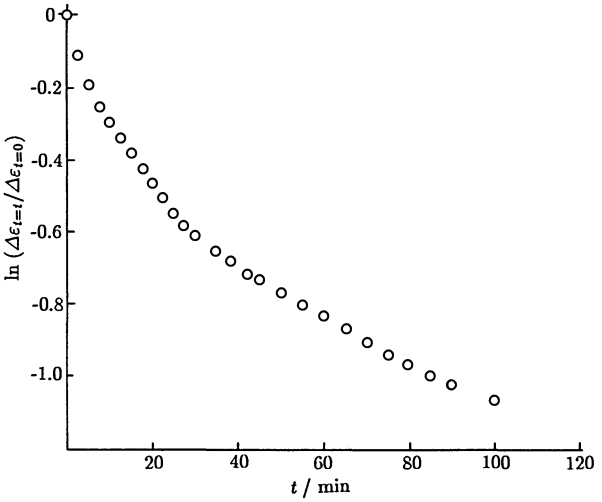

Fig. 6. The time-course change of CD intensity for C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ which was kept in a buffered aqueous solution (pH 10.33) at 40.1 °C.

trans(O) complex is assigned to C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$.

In the d-d transition band region, C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ shows extremely weak CD bands ($\Delta\varepsilon$: +0.0084 at 19000 cm^{-1} and +0.0018 at 27500 cm^{-1}) whose sign pattern differs obviously from that of $(-)^{CD}_{543}$-C_2-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ (Fig. 4). This reflects that the optical activity of the C_i-*trans*(O) complex arises only from the asymmetric carbon atoms, –C*HD–, of the ligands, while that of the $(-)^{CD}_{543}$-C_2-*trans*(O) complex is contributed from the configuration *Δ* of complex and asymmetric nitrogen atoms, N(*R*)N(*R*), besides that from –C*HD– of the ligands. In general, the vicinal CD contribution arising from the asymmetric carbon atom of coordinated ligand is very weak in intensity compared with the CD contribution from the configurational chirality, for example, [Co(L-ala)(NH$_3$)$_4$]$^{2+}$ shows weak CD bands ($\Delta\varepsilon$: ca. −0.02, +0.07, and −0.22 at 18300, 19500, and 20200 cm^{-1}, respectively) in the d-d transition region.[7] In the corresponding region, C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ shows much weaker CD intensity than [Co(L-ala)(NH$_3$)$_4$]$^{2+}$ (Fig. 4). This may be ascribed to the difference between the substituents on the methylene carbon of the ligands, namely, –C*H(CH$_3$)– and –C*HD–.

C_i-*trans*(O)-[Co(C(*S*)-edma-d_1)$_2$]$^+$ loses its optical activity by D→H exchange of the ligands in an aqueous solution and the CD change with time at 525 nm is shown in Fig. 6. The exchange seems to proceed with two steps and the two $t_{1/2}$ values are roughly estimated from the figure as 8.8 and 130 min. Taking into consideration that the outside proton (H$_b$) exchanges more easily than the inside one (H$_a$) in the deuteration,[2] it is probable that the earlier step results from the exchange of outside D with H on C(*S*)-edma-d_1 having N(*R*) configuration and the later step from the exchange of inside D on C(*S*)-edma-d_1 having N(*S*) configuration. The ratio of the exchange rates of the outer and inner D is about 15.

Synopsis. A new tetraaza-macrocyclic complex involving a ten-membered chelate ring, *trans*-[$Co(NO_2)_2(N_410)$]BF_4 (N_410=1,4,7,10-tetraazacycloheptadecane) was prepared and the structure was determined by the X-ray diffraction method. The ten-membered chelate ring takes a distorted boat–chair–boat form with the N–Co–N bite angle of 105.4(1)°.

In previous papers,[1–3] we reported the preparation and characterization of 1,4,7,10-tetraazacyclotetradecane (N_47), -pentadecane (N_48), and -hexadecane (N_49) complexes of Co(III), which involve a seven-, eight-, and nine-membered chelate ring, respectively. In this note, we report the preparation and crystal structure of a new *trans*-dinitrocobalt(III) complex with 1,4,7,10-tetraazacycloheptadecane (N_410) which involves a ten-membered chelate ring.

Experimental

1,4,7,10-Tetrakis(*p*-tolylsulfonyl)-1,4,7,10-tetraazacycloheptadecane (1) and 1,4,7,10-Tetraazacycloheptadecane Trihydrobromide (2). **1** was prepared by a method similar to those for analogous cyclotetradecane, -pentadecane, and -hexadecane.[4] ^{13}C NMR ($CDCl_3$, TMS) δ=21.5(C–Ts–), 25.3, 27.2, 28.0(C–C–C), 48.7, 49.9, 50.2, 50.7(N–C–C), 127.3, 127.4, 129.6, 129.8, 135.1, 135.2, 143.3, 143.6(phenyl). **1** was detosylated by refluxing in a mixture of 47% hydrobromic acid and acetic acid for 2 d to give **2**, which was recrystallized from water and ethanol. Found: C, 32.08; H, 6.89; N, 11.41%. Calcd for $C_{13}H_{33}N_4Br_3$: C, 32.19; H, 6.86; N, 11.55%. ^{13}C NMR (D_2O, dioxane(δ=67.4)) δ=24.9, 26.7(C–C–C), 44.3, 45.3, 46.8, 47.6(N–C–C).

***trans*-[$Co(NO_2)_2(N_410)$]BF_4.** This complex was prepared by oxidizing an aqueous solution containing $CoCl_2\cdot 6H_2O$, $NaNO_2$ and N_410 with air according to a method similar to those for the corresponding N_48 and N_49 complexes.[1] Found: C, 32.67; H, 6.35; N, 17.72%. Calcd for $C_{13}H_{30}N_6O_4Br_4Co$: C, 32.52; H, 6.30; N, 17.50%. ^{13}C NMR (DMSO-d_6, TMS) δ=22.0, 26.1, 27.2(C–C–C), 49.8, 52.4, 54.3, 56.5(N–C–C). Electronic spectra {in CH_3CN, $\tilde{\nu}/10^3$ cm^{-1} ($\log(\varepsilon/mol^{-1}\,dm^3\,cm^{-1})$)}: 21.5(2.53), 28.2(3.59), 38.7(4.36).

^{13}C NMR spectra were obtained on a Hitachi R-90HS spectrometer, and electronic spectra on a Hitachi U-3400 spectrophotometer.

Crystal Structure Determination. Crystals of *trans*-[$Co(NO_2)_2(N_410)$]BF_4 were grown by slow evaporation of an aqueous solution of the complex. An orange crystal of approximate dimensions 0.83×0.43×0.63 mm^3 was used for the measurement.

Crystal Data: *trans*-[$Co(NO_2)_2(C_{13}H_{30}N_4)$]$BF_4$, MW=480.2, monoclinic, $P2_1/n$, a=11.982(1), b=19.340(2), c=9.698(1) Å, β=113.63(1)°, V=2059.0(4) Å^3, Z=4, D_c=1.549 g cm^{-3}, D_m=1.55 g cm^{-3}, μ(Mo$K\alpha$)=8.955 cm^{-1}. Diffraction data were collected on a Rigaku AFC-5R diffractometer with graphite monochromatized Mo$K\alpha$ radiation (λ=0.71069 Å). The ω–2θ scan technique was employed with the scan rate 4/° min^{-1} and the scan range 1.2+0.5tanθ/°. Within the range $2\theta<60°$, 6124 independent reflections were measured. No absorption correction was applied.

The calculations were carried out on a HITAC M-680H computer at the Computer Center of Institute for Molecular Science with the program system UNICS III.[5] The structure was solved by the heavy-atom method using 4831 unique reflections with $|F_o|>3\sigma(|F_o|)$. The function $\sum w(|F_o|-|F_c|)^2$ was minimized by block-diagonal least-squares with anisotropic thermal parameters for non-hydrogen atoms and isotropic for hydrogen atoms. Complex neutral-atom scattering factors were used.[6] The positions of all hydrogen atoms were identified in the difference synthesis. Final R and R_w were 0.057 and 0.061, respectively. The atomic parameters of non-hydogen atoms are listed in Table 1.[7]

Results and Discussion

The $[Co(NO_2)_2(N_410)]^+$ complex shows three signals for C–C–C and four signals for N–C–C groups in the ^{13}C NMR spectrum and can be assigned as the *trans*-isomer with either C_2 or C_s symmetry.[1] In the elec-

tronic spectrum, the complex gives two strong charge-transfer bands at 28200 and 38700 cm^{-1}. The positions and intensities of these bands are similar to those for *trans*-$[Co(NO_2)_2(N_4x)]^+$(x=7, 8, 9).[1] The *cis*-$[Co(NO_2)_2(N_4x)]^+$(x=5, 6, 7) isomers show both of them at higher energy, ca. 30000 and 40000 cm^{-1}.[1] The *trans*-isomer of the present complex was confirmed by the X-ray structure determination described below.

A perspective view of the complex cation is shown in Fig. 1(a). Table 2 lists the selected bond distances and angles together with the short interatomic distances. The complex is a *trans*-dinitro isomer. The four chiral amino nitrogen atoms have an RSSR(SRRS) configuration. The same chiralities of the four nitrogen atoms have been found for analogous N_4x complexes, *trans*-$[NiCl_2(N_47)]$,[10] $[Cu(N_47)]^{2+}$,[11] *trans*-$[CoCl_2(N_48)]^+$,[2] and *trans*-$[NiCl_2(N_49)]$.[10] The two NO_2^- ions coordinate to the Co(III) through the nitrogen atom and are oriented toward the nitrogen atoms of the macrocycle to form short O ··· HN hydrogen bondings (2.02—2.10 Å). The Co–NO_2 bond lengths (1.957(2) and 1.965(2) Å) are a little longer than those found in *trans*-dinitro Co(III) complexes, such as *trans*-$[Co(NO_2)_2(NH_2CH_2CH_2NH_2)_2]^+$ (av. 1.938(2) Å)[12] and *trans*-$[Co(NO_2)_2(NH_2CH_2CH_2CH_2CH_2NH_2)_2]^+$ (av. 1.934(4) Å).[13] The lengthening of the Co–NO_2 bonds may be attributed to the steric repulsion between the NO_2^- ion and the methylene protons as observed short O ··· HC distances (2.45(4)—2.70(4) Å). The bond distances of Co–N(1)(2.040(3) Å) and Co–N(4)(2.005(3) Å) for the ten-membered chelate ring are longer by ca. 0.09 Å than those of Co–N(2)(1.933(4) Å) and Co–N(3) (1.930(3) Å). The N(1)–Co–N(4) bite angle of the ten-membered chelate ring is 105.4(1)°, while those of three five-membered chelate rings are 84.4(1), 85.4(1), and 84.8(1)°. The same elongation of the Co–N bond and widening of the N–Co–N bite angle have been observed for the eight-membered chelate ring in *trans*-$[CoCl_2(N_48)]^+$.[2] The fairly large distortion from the regular octahedron is attributable to the strain arising from the planar arrangement of three five-membered chelate rings and the repulsion among hydrogen atoms of the medium-sized ten-membered chelate ring. The five membered chelate rings involving N(1)–C(1)–C(2)–N(2) and N(3)–C(5)–C(6)–N(4) moieties take a distorted envelope conformation, and that involving a N(2)–C(3)–C(4)–N(3) moiety forms a gauche conformation. The conformation of the ten-membered chelate ring is assigned as a distorted boat–chair–boat (BCB) form as shown in Fig. 1(b). A similar BCB form has been found in 1,6-*cis*-diaminocyclodecane-dihydrochloride.[14] All the bond angles around the nitrogen and carbon atoms of the ten-membered chelate ring are larger than the tetrahedral angle, in particular the Co–N–C angles are large, 124.7(2)° and 119.5(2)°. Trans-annular hydrogen–hydrogen interactions are also observed among the sets of HN(1), HC(7) and HC(11), and of HN(4), HC(9) and HC(12), which are depicted as dashed lines in Fig. 1(b).

(Received November 11, 1990)

Synopsis. An isomer of fusarubin, 2-acetonyl-5,8-dihydroxy-7-hydroxymethyl-3-methoxy-1,4-naphthoquinone, was prepared from 2-hydroxymethyl-7-(2-hydroxypropyl)-1,4,5,6,8-pentamethoxynaphthalene.

Several new antibiotics, such as fusarubin (**1**),[2a)] erythrostominone,[2b)] javanicin,[2c)] bostrycin,[2d)] purpuromycin,[3)] and fredericamycin A,[4)] contain a 2-methoxynaphthazarin moiety; for the antibiotics above, that moiety is 5,8-dihydroxy-2-methoxy-1,4-naphthoquinone. We have already prepared two intermediates of them, **2** and **3**, as shown in Chart 1.[5)]

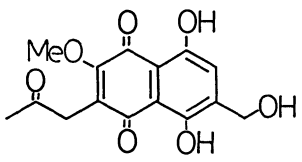
3: R=CH_2OH



4

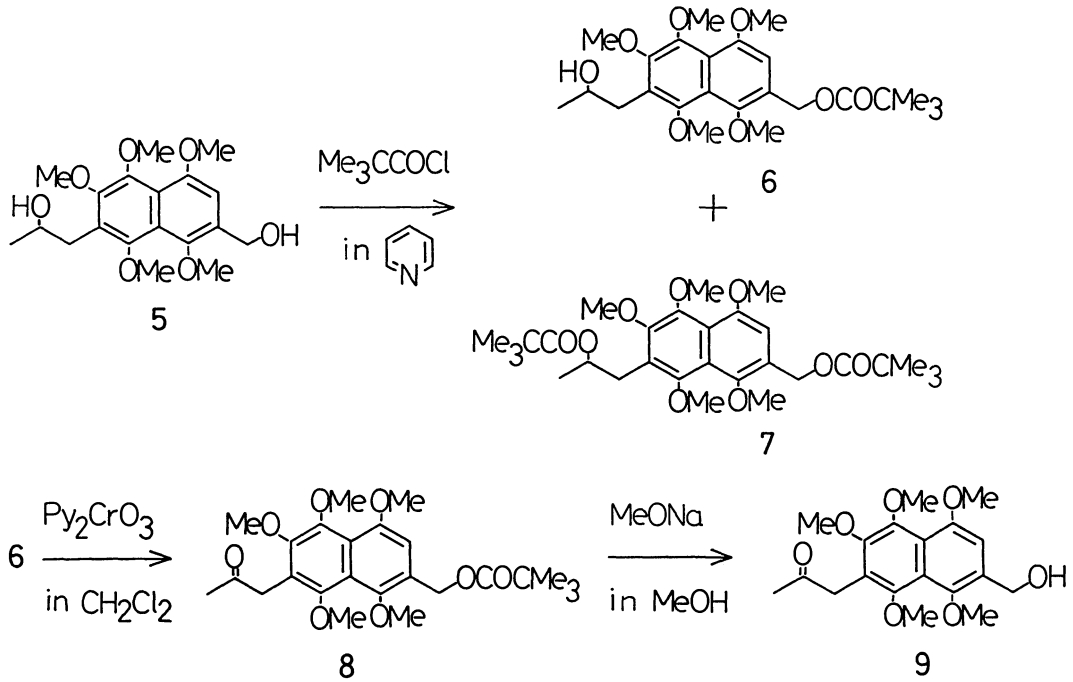
Chart 1.

As a part of our study of synthetic naphthoquinone derivatives, synthesis of fusarubin isomer (**4**) was attempted from 2-hydroxymethyl-7-(2-hydroxypropyl)-1,4,5,6,8-pentamethoxynaphthalene (**5**).

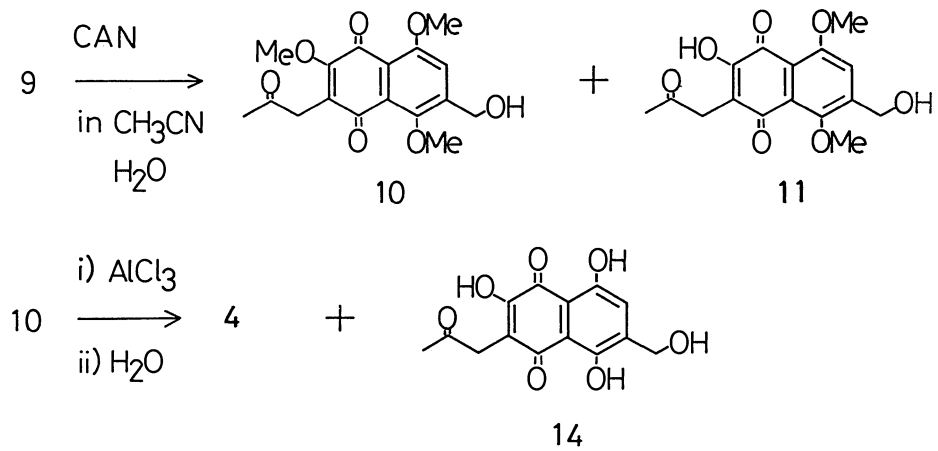
Results and Discussion

To specifically oxidize the 2-hydroxypropyl group of **5**,[6)] selective protection of the hydroxymethyl group in **5** was needed. Treatment of **5** with bulky pivaloyl chloride gave the monoester **6** in 46% yield as the major product, along with the diester **7** (10% yield). Oxidation of the secondary hydroxyl group in **6** with chromium(VI) oxide-pyridine(1/2)[7)] produced the ketone **8** (88% yield), which was reacted with sodium methoxide in methyl alcohol to give the alcohol **9** (91% yield) (Scheme 1).

Two-step demethylations[8)] of pentamethoxynaphthalene **9** were carried out by reaction with cerium(IV) ammonium nitrate (CAN) followed by reaction with aluminum chloride. Oxidative demethylation of **9** with CAN gave two quinones. One of them was presumed to be 3,5,8-trimethoxynaphthoquinone (**10**) (48% yield). Previously, in NMR studies of 1,4-naphthoquinone, it



Scheme 1.



Scheme 2.

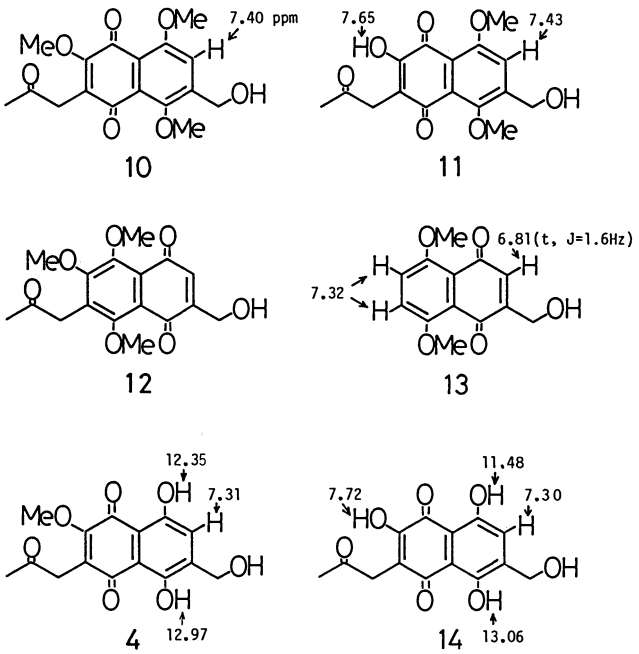


Chart 2.

was shown that the signals attributable to the quinone ring proton were always observed further upfield than the signals of the benzene ring protons and were located at δ=6—7.[9] If the structure of our product was **12**, the quinone ring proton should be observed as a triplet around δ=6.8 (the quinone proton signal of 2-hydroxymethyl-5,8-dimethoxy-1,4-naphthoquinone (**13**) was reported to be at δ=6.81).[10] However, our main product showed a singlet signal at δ=7.40, and it was confirmed that this proton was a benzene ring proton. The major product was therefore shown to be **10**. The minor product was similarly determined to be 5,8-dimethoxynaphthoquinone (**11**) (14% yield).

The second demethylation of **10** with aluminum chloride in dichloromethane gave 2-acetonyl-5,8-dihydroxy-7-hydroxymethyl-3-methoxy-1,4-naphthoquinone (**4**) (46% yield). This is a fusarubin isomer. 2-Acetonyl-3,5,8-trihydroxy-7-hydroxymethyl-1,4-naphthoquinone (**14**) was also produced in the reaction in 14% yield (Scheme 2). Their ^{1}H NMR spectra were assigned as shown in Chart 2.

Experimental

Melting points were determined with a Yanagimoto micro-melting point apparatus and were uncorrected. ^{1}H and ^{13}C NMR spectra were taken on a JEOL JNM-60 in $CDCl_3$ solutions unless otherwise specified, using Me_4Si and $CDCl_3$ as internal standards, respectively. Mass spectra and IR spectra were obtained with a JEOL DX-300 spectrometer, and a Hitachi 260-30 spectrometer, respectively. Column chromatography was carried out on silica gel (Wakogel C-200) eluting with chloroform.

The Reaction of 5 with Pivaloyl Chloride. To a solution of **5** (72 mg, 0.197 mmol) in dried pyridine (2 ml) was added pivaloyl chloride (28 mg, 0.236 mmol) at 0 °C. The reaction mixture was kept in a refrigerator (5 °C) overnight, then quenched with ice water and extracted with chloroform. The chloroform solution was washed sequentially with dil. HCl, aqueous $NaHCO_3$, and brine, then dried over Na_2SO_4 and concentrated. The residue was purified by silica-gel chromatography to give two oily products in the following order: 2-pivaloyloxymethyl-7-[2-(pivaloyloxy)propyl]-1,4,5,6,8-pentamethoxynaphthalene (**7**) (11 mg, 10% yield), 2-(2-hydroxypropyl)-7-pivaloyloxymethyl-1,3,4,5,8-pentamethoxynaphthalene (**6**) (41 mg, 46% yield).

6: IR (neat) 1730 (C=O), 1618, 1600, 1360, 1150, and 1050 cm^{-1}; ^{1}H NMR δ=1.25 (s, 9H, 3×CH_3), 1.30 (m, 4H, CH_3, OH), 3.05 (m, 2H, -C<u>H</u>$_2$CH(OH)-), 3.76 (s, 6H, 2×OCH_3), 3.85, 3.96, 4.00 (each s, 3H, OCH_3), 3.90 (m, 1H, CH), 5.33 (s, 2H, -C<u>H</u>$_2$OCOC$(CH_3)_3$-), and 6.79 (s, 1H, ArH); MS *m/z* 450 (M^+), 403, 349, 333, 289, and 57. HRMS, Found: *m/z* 450.2234. Calcd for $C_{24}H_{34}O_8$: M, 450.2253.

7: IR (neat) 1730 (C=O), 1600, 1360, 1150, and 1050 cm^{-1}; ^{1}H NMR δ=1.10 (s, 9H, 3×CH_3), 1.24 (d, *J*=6.0 Hz, 3H, CH_3), 1.25 (s, 9H, 3×CH_3), 3.07 (m, 2H, -C<u>H</u>$_2$CH(OCOC$(CH_3)_3$)-), 3.75 (s, 6H, 2×OCH_3), 3.82 (s, 3H, OCH_3), 3.88 (m, 1H, CH), 3.95, 4.00 (each s, 3H, OCH_3), 5.33 (s, 2H, -C<u>H</u>$_2$OCOC$(CH_3)_3$-), 6.77 (s, 1H, ArH); MS *m/z* 534 (M^+), 450, 392, 289, and 57. HRMS, Found: *m/z* 534.2884. Calcd for $C_{29}H_{42}O_9$: M, 534.2829.

2-Acetonyl-7-pivaloyloxymethyl-1,3,4,5,8-pentamethoxynaphthalene (8). Anhydrous chromium (VI) oxide (65 mg, 0.65 mmol) was added to a mixture of dried dichloromethane (5 ml) and pyridine (0.11 mml, 1.3 mmol) and stirred for 15 min. The alcohol **6** (49 mg, 0.11 mmol) in dried dichloromethane (2 ml) was added to the solution, stirred at room temperature for 30 min, and filtered. The filtrate was worked

up as usual and the residue was chromatographed on silica gel to give **8** (43 mg, 88% yield) as an oil. IR (neat) 1725 (ester, ketone C=O), 1600, 1355, 1150, and 1050 cm^{-1}; ^1H NMR δ=1.26 (s, 9H, 3×CH_3), 2.27 (s, 3H, $COCH_3$), 3.71 (s, 2H, $-CH_2CO-$), 3.76, 3.84 (each s, 3H, OCH_3), 3.94 (s, 6H, 2× OCH_3), 3.97 (s, 3H, OCH_3), 5.34 (s, 2H, $-CH_2OCOC(CH_3)_3-$), and 6.80 (s, 1H, ArH); MS *m/z* 448 (M^+), 433, 405, 347, 289, and 57. HRMS, Found: *m/z* 448.2115. Calcd for $C_{24}H_{32}O_8$: M, 448.2107.

2-Acetonyl-7-hydroxymethyl-1,3,4,5,8-pentamethoxynaphthalene (9). Sodium methoxide (117 mg, 2.15 mmol) was added to a solution of **8** (194 mg, 0.43 mmol) in methyl alcohol (3 ml) and stirred overnight at room temperature in the dark. The solvent was removed under reduced pressure and the residue was decomposed by the addition of water, and extracted with chloroform. Column chromatography on silica gel gave **9** (143 mg, 91% yield) as an oil. IR (neat) 3450 (broad, OH), 1720 (C=O), 1600, 1360, and 1050 cm^{-1}; ^1H NMR: δ=1.88 (broad, 1H, OH), 2.26 (s, 3H, $COCH_3$), 3.70, 3.76, 3.84, 3.94, 3.99 (each s, 3H, OCH_3), 3.88 (s, 2H, $-CH_2CO-$), 4.86 (s, 2H, $-CH_2OH$), and 6.86 (s, 1H, ArH); ^{13}C NMR δ=29.53 ($CO\underline{C}H_3$), 39.85 ($\underline{C}H_2CO$), 56.57 (CH_2OH), 60.92 (2C, OMe), 61.56, 62.34, and 62.68 (OMe), 106.63 (C-6), 121.20, 122.47, 123.26 (C-2), 129.66 (C-7), 144.92, 146.23, 149.36, 149.81, and 152.59 (C-OMe), and 183.15 (C=O); MS *m/z* 364 (M^+), 334, 301, 259, and 115; HRMS, Found: *m/z* 364.1513. Calcd for $C_{19}H_{24}O_7$: M, 364.1522.

Oxidative Demethylation of 9 with CAN. A solution of CAN (1.72 g, 3.25 mmol) in water (3 ml) was added dropwise to a solution of **9** (457 mg, 1.3 mmol) in acetonitrile (5 ml) and stirred at room temperature for 30 min. The reaction mixture was diluted with water and extracted with chloroform. The usual work-up and chromatographic purification (silica gel) gave two products: 2-acetonyl-7-hydroxymethyl-3,5,8-trimethoxy-1,4-naphthoquinone (**10**) (195 mg, 48% yield) and 2-acetonyl-3-hydroxy-7-hydroxymethyl-5,8-dimethoxy-1,4-naphthoquinone (**11**) (58 mg, 14% yield).

10: Orange crystals (hexane–ethanol (10:1)); mp 130—131 °C; IR (KBr) 1705 (ketone C=O), 1655, 1630 (each quinone C=O), 1580, 1215, and 1030 cm^{-1}; ^1H NMR δ=2.29 (s, 3H, $COCH_3$), 2.50 (broad, 1H, OH), 3.68 (s, 2H, $-CH_2CO-$), 3.76, 3.98, 4.08 (each s, 3H, OCH_3), 4.79 (s, 2H, $-CH_2OH$), and 7.40 (s, 1H, ArH); ^{13}C NMR δ=30.18 (CH_3), 38.41 ($\underline{C}H_2COCH_3$), 56.70 (CH_2OH), 60.18, 61.04, and 61.78 (OMe), 116.99 (C-6), 119.05, 124.60, 126.31 (C-2), 145.17 (C-7), 150.60, 156.43, and 158.49 (C-OMe), 179.93 (C-4), 184.32 (C-1), and 204.73 (C=O); MS *m/z* 334 (M^+), 319, 291, 277, and 231. HRMS, Found: *m/z* 334.1065. Calcd for M, 334.1053. Found: C, 60.80; H, 5.39%. Calcd for $C_{17}H_{18}O_7$: C, 61.07; H, 5.43%.

11: Orange crystals (hexane–ethanol(3:1)); mp 186.5—187.5 °C; IR (KBr) 3420, 3200 (each OH), 1695 (ketone C=O), 1660, 1640 (each quinone C=O), 1360, 1220, 1085, and 1040 cm^{-1}; ^1H NMR δ=2.30 (s, 4H, $COCH_3$, $-CH_2O\underline{H}$), 3.69 (s, 2H, $-CH_2CO-$), 3.79, 4.04 (each s, 3H, OCH_3), 4.85 (d, *J*=5.0 Hz, 2H, $-C\underline{H}_2OH$), 7.44 (s, 1H, ArH), and 7.65 (s, 1H, ArOH); ^{13}C NMR (DMSO-d_6) δ=29.38 (CH_3), 37.84 ($\underline{C}H_2COCH_3$), 56.36 (CH_2OH), 57.90 and 60.93 (OMe), 116.60 (3C: C-2, C-6), 124.14, 147.46 (C-7), 149.80, 155.06, and 156.08 (C-OH, 2× C-OMe), 178.72 (C-4), 183.29 (C-1), and 203.99 (C=O); MS *m/z* 320 (M^+), 305, 278, 260, 245, and 217. Found: C, 59.80; H, 5.11%. Calcd for $C_{16}H_{16}O_7$: C, 60.00; H, 5.03%.

Demethylation of 10 with Aluminum Chloride. Aluminum chloride (730 mg, 5.5 mmol) was added to a solution of **10** (183 mg, 0.55 mmol) in dichloromethane (5 ml) cooled in an ice bath. After stirring at room temperature for 2 h, the reaction mixture was decomposed by the addition of 5 wt% aqueous oxalic acid (100 ml) and extracted with chloroform. The usual work-up and chromatographic purification (silica gel) gave two products, a fusarubin isomer **4** (77 mg, 46% yield) and 2-acetonyl-3,5,8-trihydroxy-7-hydroxymethyl-1,4-naphthoquinone (**14**) (22 mg, 14% yield).

4: Red-brown crystals (hexane–ethanol); mp 173.5—174.5 °C; IR (KBr) 3430 (broad, OH), 1710 (ketone C=O), 1605 (quinone C=O), 1420, 1270, 1170, and 1080 cm^{-1}; ^1H NMR δ=2.31 (s, 3H, $COCH_3$), 3.75 (s, 2H, $-CH_2CO-$), 4.18 (s, 3H, OCH_3), 4.78 (s, 2H, $-C\underline{H}_2OH$), 7.31 (s, 1H, ArH), 12.35 (s, 1H, C-5-OH), and 12.97 (s, 1H, C-8-OH); ^{13}C NMR (DMSO-d_6) δ=29.84 (CH_3), 57.50 (CH_2OH), 61.56 (OMe), 109.74, 110.20, 124.54 (C-6), 128.88 (C-2), 145.92 (C-7), 156.26, 158.72, 159.58 (C-OMe, 2×C-OH), 180.15 (C-4), 185.41 (C-1), and 203.81 (C=O); MS, *m/z* 306 (M^+), 264, 249, 246, and 203. Synthesis of Urushiols with Pentadecatrienyl Side Chain, Two Constituents of the Sap of a Lac Tree, *Rhus Vernicifera*

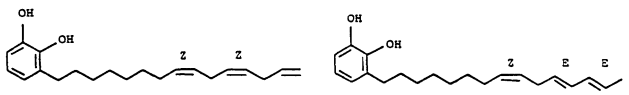
Tetsuo MIYAKOSHI,* Hidenori KOBUCHI, Noriyasu NIIMURA, and Yoshiro YOSHIHIRO
Department of Industrial Chemistry, Meiji University, Higashimita, Tama-ku, Kawasaki-shi 214
(Received January 17, 1991)

Synopsis. Two phenolic lipids, 3-[(8*Z*,11*Z*)-8,11,14- and 3-[(8*Z*,11*E*,13*E*)-8,11,13-pentadecatrienyl]catechol, which are the major constituents of the sap from a Japanese or Chinese lac tree, *Rhus vernicifera*, have been synthesized via the Wittig reaction of ylides derived from 3,6- and 3,5-heptadienylphosphonium salts with 3-(8-oxooctyl)catechol diacetate.

The fluid sap exuded from several kinds of Japanese or Chinese lac trees, *Rhus vernicifera*, dries into a tough and brilliant film and has been used as a naturally occurring coating material for thousands of years in the Orient.[1] It is a latex composed of urushiols (60%), water (30%), plant gum (7%), water-insoluble glycoproteins (2%), and copper glycoproteins (ca. 0.1%).[2–5] The structures of urushiols have been determined to be catechols substituted at position 3 of the aromatic ring with a C_{15}-alkyl or alkenyl side chain.[5] The urushiols with an unsaturated side chain, **1** and **2**, are important contributors to the industrially useful polymerization properties of these natural products.[1,6] The presence of **1** in *poison ivy* and the sap from Japanese laquer was reported by Dawson et al.[7] and Hashimoto et al.[8] In a previous paper we reported the synthesis of 3-[(8*Z*,11*Z*)-8,11,14- and (8*Z*,11*E*,13*E*)-8,11,13-pentadecatrienyl]-veratrole by a Wittig reaction between 3-(8-oxooctyl)-veratrole and the ylide derived from [(*Z*)-3,6- (**3**) and [(3*E*,5*E*)-3,5-heptadienyl]triphenylphosphonium iodide (**4**).[9] In this paper we describe an efficient synthesis of **1** and **2**.



1 **2**

Results and Discussion

Protection of hydroxyl groups of catechol as methyl ethers is now widely used and the protected form is very stable under various basic conditions.[9] However, deprotection cannot be carried out in acid-sensitive molecules such as urushiols having a pentadecatrienyl side chain.[10] Acetylation is also not exempted from some of these disadvantages. Urushiol was synthesized by a stepwise procedure based on repeated protection and deprotection of the hydroxyl group of catechol in good yields.[11]

The synthetic pathways to compounds **1** and **2** are illustrated in Scheme. For the synthesis of 3-(8-oxooctyl)catechol diacetate (**9**), veratrole was subjected to alkylation[12] with 1,8-dibromooctane (84%), demethylation[13] with boron tribromide (92%), and acetylation with acetic anhydride (76%) to give the bromide **7**. This was converted to the iodide **8** (88%) and oxidized with DMSO–$NaHCO_3$ to afford **9** (71%).

10 $R^1=CH{=}CHCH_2CH{=}CHCH_2CH{=}CH_2$, $R^2=Ac$
11 $R^1=CH{=}CHCH_2CH{=}CHCH{=}CHCH_3$, $R^2=Ac$

Scheme. Reagents: a, BBr_3, CH_2Cl_2; b, Ac_2O, C_5H_5N; c, NaI, Me_2CO; d, DMSO, $NaHCO_3$; e, BuLi, C_6H_6, **3** or **4**; f, $LiAlH_4$: *t*-BuOH=3 : 1, THF.

First, the Wittig reaction between **9** and the ylide derived from **3** gave 8,11,14-pentadecatrienyl compounds (45%). The main product **10** was isolated by HPLC. In the infrared spectrum of **10**, intense absorption bands of a monosubstituted olefin were observed at 910 and 990 cm^{-1}, without the characteristic *trans*-double bond absorption at 970 cm^{-1}. The stereochemistry of **10** was confirmed by a 270 MHz ^1H NMR spectrum with extensive decoupling experiments. Furtheremore, the stereochemistry of the olefin formed by the Wittig reaction was determined to be *cis* from the diagnostic shift of the allylic methylene carbon (δ=27.2 $\underline{C}H_2C{=}C$), which is to appear at δ=33—35 if the bond was *trans*.[14,15] The ^{13}C NMR spectrum also demonstrated the 8-*cis*-configuration exhibiting the 8- and 9-olefinic carbon atoms at δ=130.4 and 126.9. The 10- and 13-carbon atoms of **10** occurred at δ=25.6 and 31.5 in the ^{13}C NMR spectrum. These values are typical of such a long-chain dienyl and trienyl compounds.[16–18] Although these reaction conditions were known to result in a *cis*-stereoselective Wittig olefination,[18] the crude product contained 8% of (8*E*)-isomer, as demonstrated by GLC and HPLC.

3-[(8*Z*,11*E*,13*E*)-8,11,13-Pentadecatrienyl]catechol diacetate **11** was synthesized in a similar way from **9** and **4** in 40% yield. The resulting product **11** had an infrared absorption band at 985 cm^{-1} due to disubstituted *trans,trans*- conjugated double bonds. The (8*Z*,11*E*,13*E*)-olefinic configuration was confirmed by ^1H–^1H, ^1H–^{13}C COSY and a J-resolved NMR experiment. The (8*E*)-isomer could not be detected in this reaction product.

When **10** was treated with $LiAlH_4$ in tetrahydrofuran (THF) at room temperature, partial hydrogenation of the double bonds took place. The protecting groups of **10** were removed by treatment with $LiAlH_4$–*t*-butyl alcohol (1 : 3) in THF at −50 °C to give urushiol **1** (61%). The structure of the synthetic **1** was identified

by comparison of IR, ^{1}H NMR and EI-MS spectra with those of the reported data.[5]

3-[(8*Z*,11*E*,13*E*)-8,11,13-Pentadecatrienyl]catechol (**2**) was synthesized from **11** in the same reductive procedure. The structure was identified by comparing the IR and ^{1}H NMR spectra with the reported data.[5]

In conclusion, we have succeeded in the synthesis of urushiols **1** and **2** via the Wittig reaction of ylides derived from the heptadienylphosphonium salts **3** and **4** with di-*O*-acetyl-protected aldehyde **9**, respectively. This synthetic method may be applicable to the preparation of such long-chain polyene-substituted phenols as other urushiol analogues and cardanols.[6]

Experimental

All ^{1}H NMR spectra were taken in chloroform-*d* or carbon tetrachloride with tetramethylsilane as internal standard on a Varian EM 390 spectrometer (90 MHz) and JEOL GSX 270 spectrometer (270 MHz). All ^{13}C NMR spectra were recorded on a JEOL GSX 270 spectrometer operated at 67.9 MHz. Low resolution mass spectra were taken on a JEOL DX-300 mass spectrometer. The spectra were run at 70 eV or with an emission current of 100 μA. High-performance liquid chromatograph (HPLC) was performed on a Gilson liquid chromatography with GPC (TSK gel, G1000H$_8$ 60×2.2 cm×2, eluent: chloroform, flow rate, 4.0 ml min^{-1} and silica gel (Develosil 10 mm×25 cm, 5 μm, eluent: hexane–ethyl acetate=96:4, flow rate, 1.5 ml min^{-1}).

(3*Z*)-3,6-Heptadienyltriphenylphosphonium Iodide (3). To a solution of (*Z*)-7-iodo-1,4-heptadiene (4.0 g, 18 mmol), triphenylphosphine (7.08 g, 27 mmol) in 50 ml of acetonitrile was added under stirring for 24 h at 90 °C. After 18 h the solution was filtered. The solid was washed with THF, and dried to give **3**,[9] 7.67 g (88%).

3-(8-Bromooctyl)veratrol (5). Butyllithium 66.2 ml (1.5 M in hexane, 99.3 mmol, 1 M=1 mol dm^{-3}) was added to a stirred solution of veratrole (41.1 g, 0.298 mol) in 1300 ml of dry THF at 0 °C under nitrogen atmosphere. After stirring for 2 h at room temperature, a solution of 1,8-dibromooctane (27.0 g, 99.3 mmol) in 50 ml of dry THF was added and the mixture was refluxed for 5 h. A saturated NH_4Cl solution was added to the mixture at room temperature. The mixture was poured into a saturated NH_4Cl solution and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried (K_2CO_3), and concentrated in vacuo to give crude products. The remaining veratrole was taken off under reduced pressure (5 Torr, 1 Torr=133.322 Pa) at 70 °C. The residual oil was chromatographed over silica gel eluting with hexane to remove 1,8-dibromooctane then with benzene to give **12**,[9] 27.5 g (84% yield).

3-(8-Bromooctyl)catechol (6). To a stirred solution of boron tribromide (25.0 g, 99.6 mmol) in 50 ml of dichloromethane was added dropwise a solution of **5** (23.1 g, 70.2 mmol) in 150 ml of dichloromethane for 30 min at 0 °C. The mixture was allowed to warm up slowly to room temperature over 12 h. The mixture was treated with water, and the dichloromethane layer was treated with brine, dried ($MgSO_4$), and concentrated in vacuo. The residual oil was chromatographed (benzene–ethyl acetate=1:1 as eluent) to give **6** as an oil (19.4 g, 92%). R_f=0.58 (benzene–ethyl acetate=1:1); IR (neat): 3500, 1600, 1500, 780, 730, 640 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=1.1—2.0 (m, 12H, CH_2), 2.53 (t, *J*=7 Hz, 2H, CH_2Ar), 3.33 (t, *J*=7 Hz, 2H, CH_2Br), 5.22 (br. s, 2H, OH, D_2O exchangeable), 6.62 (br. s, 3H, ArH); EI-MS *m/z* (rel intensity, %) 302 (M^+, 12), 300 (M^+, 12), 180 (21), 179 (25), 136 (7), 124 (89), 123 (100).

3-(8-Bromooctyl)catechol Diacetate (7). A solution of **6** (16.8 g, 55.8 mmol), acetic anhydride (17.1 g, 0.168 mol), and pyridine (0.89 g, 11.3 mmol) was stirred at 100 °C for 4 h, added to water, and extracted with ethyl acetate. The extract was washed with dil aq HCl and then neutralized with dil aq NaOH. The extract was dried (K_2CO_3) and concentrated in vacuo. The residue was chromatographed to afford **7** (16.3 g, 76%) as an oil. R_f=0.37 (benzene–ethyl acetate=9:1); IR (neat) 1780, 1600, 1500, 1220 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=1.1—2.0 (m, 12H, CH_2), 2.27 (s, 3H, CH_3CO), 2.31 (s, 3H, CH_3CO), 2.51 (t, *J*=7 Hz, 2H, CH_2Ar), 3.33 (t, *J*=7 Hz, 2H, CH_2Br), 7.04 (m, 3H, ArH); EI-MS *m/z* (rel intensity, %) 386 (M^+, 3), 384 (M^+, 3), 302 (99), 300 (100), 124 (54), 123 (75).

3-(8-Iodooctyl)catechol Diacetate (8). After a mixture of **7** (5.26 g, 13.7 mmol) and NaI (3.07 g, 20.5 mmol) in 50 ml of acetone was stirred at 60 °C for 3 h, the resulting mixture was poured into a saturated sodium chloride solution and the product was extracted with ethyl acetate. The extract was washed with $Na_2S_2O_3$, dried over $MgSO_4$, and concentrated in vacuo. Purification of the crude oil by column chromatography on silica gel (benzene–ethyl acetate=98:2 as eluent) afforded **8** (5.21 g, 88%) as an oil. R_f=0.40 (benzene–ethyl acetate=98;2); IR (neat) 1780, 1600, 1500, 1220 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=1.1—2.0 (m, 12H, CH_2), 2.27 (s, 3H, CH_3CO), 2.31 (s, 3H, CH_3CO), 2.51 (t, *J*=7 Hz, 2H, CH_2Ar), 3.05 (t, *J*=7 Hz, 2H, CH_2I), 6.92 (m, 3H, ArH); EI-MS *m/z* (rel intensity, %) 432 (M^+, 3), 390 (15), 348 (60), 263 (4), 222 (4), 207 (8), 123 (100).

3-(8-Oxooctyl)catechol Diacetate (9). A mixture of **8** (18.5 g, 42.8 mmol), 200 ml of DMSO, $NaHCO_3$ (7.1 g, 84.5 mmol), and 200 ml of benzene was stirred at 90 °C for 4 h under nitrogen atmosphere. Then the mixture was poured into water and extracted with benzene. The combined extracts were dried over $MgSO_4$, filtered, and evaporated. Column chromatography (gradient elution, benzene–eth l acetate=9:1—3:1) gave **9** as a colorless oil (9.7g, 71% yield). R_f=0.33 (benzen–ethyl acetate=9:1); IR (neat) 2720, 1780, 1730, 1600, 1500, 1220 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=1.1—1.8 (m, 10H, CH_2), 2.27 (s, 3H, CH_3CO), 2.31 (s, 3H, CH_3CO), 2.35 (t, *J*=7 Hz, 2H, CH_2CO), 2.50 (t. *J*=7 Hz, 2H, CH_2Ar), 6.97 (m, 3H, Ar), 9.63 (br. s, 1H, CHO); EI-MS *m/z* (rel intensity, %) 320 (M^+, 2), 278 (14), 236 (100), 218 (9), 124 (31), 123 (44). Found: C, 67.31; H, 7.58%. Calcd for $C_{18}H_{24}O_5$: C, 67.48; H, 7.55%.

3-[(8*Z*,11*Z*)-8,11,14-Pentadecatrienyl]catechol Diacetate (10). To a suspension of **3** (2.31 g, 4.8 mmol) in 80 ml of dry benzene was added butyllithium (3.3 ml, 1.5 M in hexane, 4.8 mmol) at 20 °C under nitrogen and the resulting reddish solution was stirred for 1 h. The upper layer of the phosphorane solution was taken up by a syringe and added to a stirred solution of **9** (1.02 g, 3.18 mmol) in 10 ml of dry benzene over 0.5 h at 25 °C. Stirring was continued for 3 h at 25 °C. The mixture was poured into a saturated aqueous ammonium chloride solution, extracted with benzene, and dried over $MgSO_4$. The solvent was distilled under reduced pressure and the residue was extracted with hexane. Concentration of the hexane solution under reduced pressure gave a crude product. The crude product was chromatographed over silica gel with benzene–ethyl acetate (9:1) as eluent and GPC with chloroform as eluent. The residue was purified by HPLC to give **10** (0.524 g, 42%) as an oil. R_f=0.48 (benzene–ethyl acetate=9:1); IR (neat) 3020, 2920, 1770, 1600, 1465, 1370, 1260, 1205, 1160, 1010, 995, 910, 780, 720 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$) δ=1.13—1.75 (m, 10H, 2,3,4,5,6-CH_2), 2.03 (m, 2H, 7-CH_2), 2.27 (s, 3H, CH_3COO), 2.31 (s, 3H, CH_3COO), 2.50 (t, *J*=7 Hz, 2H, CH_2Ar), 2.82 (m, 4H, C=CCH_2C=CCH_2C=C), 4.80—5.09 (m, 2H, 15-C=CH, $J_{cis\text{-}14,15}$=10.0, $J_{gem\text{-}15,15}$=1.7, $J_{trans\text{-}14,15}$=17.0, $J_{13,15}$=1.6 Hz), 5.27 (m, 4H, 8,9,11,12-C=CH), 5.74—5.89 (m, 1H, 14-C=CH, $J_{trans\text{-}14,15}$=17.0, $J_{cis\text{-}14,15}$=10.0, $J_{13,14}$=6.1 Hz), 6.78—7.25 (m, 3H, ArH), ^{13}C NMR ($CDCl_3$) δ=20.3 (CH_3CO), 20.9 (CH_3CO), 25.6 (C-10), 27.2 (C-7), 31.5

(C-13), 114.6 (C-15), 120.8 (ArC-6), 126.2 (ArC-4), 126.9 (C-9), 127.2 (ArC-5), 127.8 (C-11), 129.4 (C-12), 130.4 (C-8), 136.6 (ArC-3), 136.8 (C-14), 140.5 (ArC-2), 142.4 (ArC-1), 168.2 (C=O), 168.3 (C=O); EI-MS m/z (rel intensity, %) 398 (M^+, 5), 355 (12), 136 (27), 124 (26), 123 (100); Found: C, 75.21; H, 8.55%. Calcd for $C_{25}H_{34}O_4$: C, 75.34; H, 8.60%. The spectral data of (8*E*)-isomer are as follows: IR (neat) 3020, 2920, 1770, 1600, 1465, 1370, 1260, 1205, 1160, 1010, 995, 970, 910, 780, 720 cm^{-1}, EI-MS m/z (rel intensity, %) 398 (M^+, 4), 355 (11), 136 (20), 123 (100).

3-[(8*Z*,11*E*,13*E*)-8,11,13-Pentadecatrienyl]catechol Diacetate (11). Compound **9** and **4** were allowed to react in a similar manner to that described in the preparation of **10** to give **11** as an oil (40%). R_f=0.43 (benzene–ethyl acetate=9 : 1); IR (neat) 3015, 2926, 1770, 1615, 1591, 1469, 1370, 1258, 1210, 1170, 1213, 1013, 985, 909, 789, 725 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.33 (m, 6H, 3,4,5-CH_2), 1.57 (m, 4H, 2,6-CH_2), 1.73 (d, J=7 Hz, 3H, CH_3C=C), 2.03 (m, 2H, 7-CH_2), 2.29 (s, 3H, CH_3COO), 2.33 (s, 3H, CH_3COO), 2.51 (t, J=8 Hz, 2H, CH_2Ar), 2.82 (m, 2H, C=CCH_2C=C), 5.31—5.45 (m, 2H, 8,9-C=CH), 5.45-5.66 (m, 2H, 11,14-C=CH), 5.90—6.10 (m, 2H, 12,13-C=CH), 7.03 (m, 1H, ArH), 7.09—7.21 (m, 2H, Ar). The accurate chemical shifts and coupling constants were determined by the decoupling experiments: 8-CH: 5.43, 9-CH: 5.37, 11-CH: 5.51, 12,13-CH: 6.01, 14-CH: 5.58; $J_{7,8}$=6.2, $J_{8,9}$=11.0, $J_{11,12}$=$J_{13,14}$=14.4, $J_{10,11}$=$J_{14,15}$=6.5 Hz. ^{13}C NMR ($CDCl_3$) δ=18.0 (C-15), 20.3 (CH_3CO), 20.9 (CH_3CO), 27.1 (C-7), 29.1, 29.2, 29.4, 29.5, 29.7 (C-2-6), 30.0 (C-1), 30.2 (C-10), 120.8 (ArC-6), 126.2 (ArC-4), 126.3 (C-9), 127.1 (C-8), 127.2 (ArC-5), 129.8 (C-14), 129.4 (C-12), 130.8 (C-11), 131.5 (C-13), 136.6 (ArC-3), 140.5 (ArC-2), 142.4 (ArC-1), 168.2 (C=O), 168.3 (C=O); EI-MS m/z (rel intensity, %) 398 (M^+, 57), 355 (55), 313 (24), 285 (10), 135 (45), 124 (56) ,123 (100), Found: C, 75.38; H, 8.49%. Calcd for $C_{25}H_{34}O_4$: C, 75.34; H, 8.60%.

3-[(8*Z*,11*Z*)-8,11,14-Pentadecatrienyl]catechol (1). To a solution of $LiAlH_4$ (68 mg, 1.8 mmol) in 5 ml of dry THF was added *tert*-butyl alcohol (400 mg, 5.4 mmol) in dry THF (5 ml) at 0 °C and the mixture was stirred for 10 min. To the resulting mixture, a solution of **10** (78 mg, 0.2 mmol) in 5 ml of dry THF was added at −50 °C, and the mixture was stirred for 50 min. Methanol (1 ml) was added to the mixture at −50 °C. After warming to room temperature, the mixture was poured into an aq saturated NH_4Cl solution and the product was extracted with ethyl acetate. The organic layer was dried over Na_2SO_4 and concentrated in vacuo below 25 °C. The residue was chromatographed over silica gel (benzene–ethyl acetate=9 : 1 as eluent) and by HPLC (silica gel Si 60, 5 μm, 10 mm×25 cm eluting with hexane–ethyl acetate=94 : 6, 1.5 ml min^{-1}) to give **1** (39 mg, 61%) as an oil. R_f=0.34 (benzene–ethyl acetate=9 : 1); IR (neat) 3450, 3030, 2920, 1600, 1500, 1475, 1360, 1275, 990, 910, 720 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.13—1.75 (m, 10H, 2,3,4,5,6-CH_2), 2.03 (m, 2H, 7-CH_2), 2.55 (t, J= 7Hz, 2H, CH_2Ar), 2.82 (m, 4H, C=CCH_2C=CCH_2C=C), 4.80—5.09 (m, 2H, 15-C=CH, $J_{cis\text{-}14,15}$=10.0, $J_{gem\text{-}15,15}$=1.7, $J_{cis\text{-}14,15}$=17.0, $J_{13,15}$=1.6 Hz), 5.1—5.3 (m, 2H, OH, D_2O exchangeable), 5.27—5.49 (m, 4H, 8,9,11,12-C=CH), 5.74—5.89 (m, 1H, 14-C=CH, $J_{trans\text{-}14,15}$ =17.0 Hz), 6.60 (s, 3H, ArH); EI-MS m/z (rel intensity, %) 314 (M^+, 5), 179 (25), 136 (21), 124 (27), 123 (100). Retention time of **1** on GLC (10.40 min; OV-1, 0.32 mm×25 m, programed from 200 to 280 °C at 5 °C min^{-1}).

3-[(8*Z*,11*E*,13*E*)-8,11,13-Pentadecatrienyl]catechol (2). This was prepared from **11** and $LiAlH_4$–*t*-BuOH in THF in a similar manner to that described in the preparation of **1**. **2**: Yield; 65% oil; R_f=0.39 (benzene-ethyl acetate=9 : 1); IR (neat) 3480, 3030, 2940, 2860, 1625, 1600, 1475, 1375, 1270, 1230, 1178, 985, 825, 770, 730 cm^{-1}; ^1H NMR (270 MHz, $CDCl_3$) δ=1.31 (m, 8H, 3,4,5,6-CH_2), 1.57 (m, 2H, 2-CH_2), 2.03 (m, 2H, 7-CH_2), 2.59 (t, J=8 Hz, 2H, CH_2Ar), 2.81 (m, 2H, C=CCH_2C=C), 5.31—5.45 (m, 3H, 8,9-CH_2), 5.45—5.66 (m, 2H, 11,14-C=CH), 5.7 (br. s, 2H, OH, D_2O exchangeable), 5.92—6.09 (m, 2H, 12,13-C=CH), 6.69 (s, 3H, ArH); The accurate chemical shifts and coupling constants were determined by decoupling experiments: 8-CH: 5.43, 9-CH: 5.37, 11-CH: 5.53, 12, 13-CH: 6.02, 14-CH: 5.58; $J_{8,9}$=10.4, $J_{9,10}$=$J_{7,8}$=6.5, $J_{10,11}$=$J_{14,15}$=7.0, $J_{13,14}$=$J_{11,12}$=14.4 Hz; ^{13}C NMR ($CDCl_3$) δ=19.0 (C-15), 27.1 (C-7), 29.1, 29.2, 29.4, 29.5, 29.6 (C-2-6), 29.8 (C-1), 30.3 (C-10), 112.0 (ArC-6), 120.0 (ArC-4), 122.0 (ArC-5), 127.0 (C-9), 127.2 (C-8), 129.4 (C-14), 129.9 (C-12), 130.4 (C-11), 130.7 (C-13), 131.5 (ArC-3), 142.0 (ArC-2), 143.1 (ArC-1); EI-MS m/z (rel intensity, %) 314 (M^+, 9), 179 (5), 136 (11), 124 (27), 113 (100). Compound **2** was identified by comparison of the retention times on GLC (10.25 min; OV-1, 0.32 mm×25 m, programed from 200 °C to 280 °C at 5 °C min^{-1}) and HPLC (11.35 min; silica gel, 10 mm×25 cm, 5 μm, hexane–ethyl acetate=96 : 4, 1.5 ml min^{-1}) with those of the natural sample and by GC-MS analysis.

The present work was partially supported by a Grant-in-Aid for Scientific Reserch No. 62550678 from the Ministry of Education, Science and Culture. The authors are grateful to Dr. Ju Kumanotani and Dr. Ryuichi Oshima for invaluable discussion.

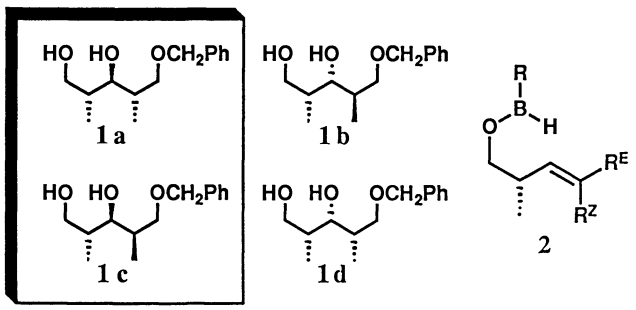
Diastereoselective Synthesis of 2,3-*anti*-5-Benzyloxy-2,4-dimethyl-1,3-pentanediols via Cyclic Hydroboration

Yasushi YOKOYAMA,* Yuji TERADA, and Hideyuki KAWASHIMA
Department of Materials Science, Faculty of Engineering, Yokohama National University, Tokiwadai, Hodogaya-ku, Yokohama 240
(Received February 7, 1991)

Synopsis. The treatment of (2*E*,4*S*)- and (2*Z*,4*S*)-1-benzyloxy-5-ethenyloxy-2,4-dimethyl-2-pentene with borane both with and without a catalytic amount of $Rh(Ph_3P)_3Cl$ gave 2,3-*anti*-3,4-*anti*-(2*R*,3*R*,4*S*)- and 2,3-*anti*-3,4-*syn*-(2*R*,3*R*,4*R*)-5-benzyloxy-2,4-dimethyl-1,3-pentanediols, respectively, with fair to good diastereoselectivity.

The enantioselective preparation of polypropionate antibiotics, particularly macrolides, has attracted the strong attention of a large number of synthetic organic chemists.[1] As the synthon of polypropionates, 2,4-dimethyl-1,3,5-pentanetriol derivatives **1a—d** and the related compounds are very useful, and have been used in the synthesis of biologically important natural compounds.[2–4] An excellent review concerning these compounds has already appeared.[5]

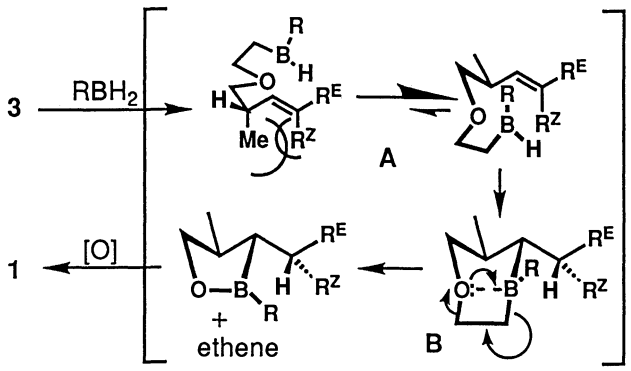
We have recently reported an allylic 1,3-strain-controlled cyclic hydroboration, used to produce acyclic compounds possessing a 1,2-*anti*-2-methyl-1,4-diol unit.[6] In this article we would like to report on the diastereoselective construction of 2,3-*anti*-2,4-dimethyl-1,3,5-pentanetriol derivatives via the cyclic hydroboration method.



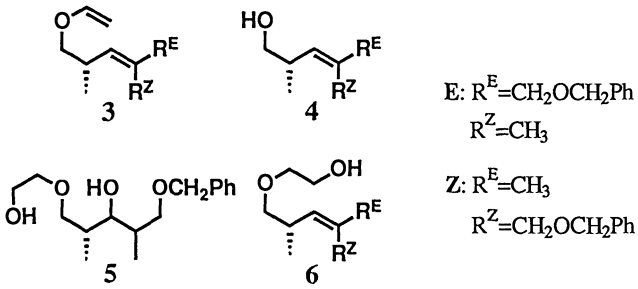
Our target molecules to prepare were **1a** and **1c**. Since species **2** was known not to afford intramolecular hydroboration products (because of its low reactivity toward olefins[7]), we had to find a new reaction system. We chose ethenyl ethers as the intramolecular borane carrier. The advantage of using ethenyl ethers is that this C_2 unit is known to fall off as an ethene molecule during the intramolecular hydroboration reaction;[8] therefore, no ether cleavage reaction, (which is sometimes difficult[9]) was necessary for a further chemical transformation (Scheme 1).

Ethenyl ethers **3E** and **3Z** were prepared from the corresponding optically active alcohols, **4E** and **4Z**, respectively, with almost complete control of the double-bond geometry (>98 : <2)[6b] without any loss of chirality.[2]

The reaction of *E* isomer **3E** with borane in THF at



Scheme 1.



−70 °C to room temperature, followed by an alkaline hydrogen peroxide treatment, gave an inseparable mixture of two triol monobenzyl ethers (**1a** and **1b**, 56%), together with 2-hydroxyethyl ether **5** (15%). The diastereomeric ratio, **1a**/**1b**, was determined to be 80/20 by comparing the ^1H NMR data with that described in the literature.[2,3] In a low-Lewis-basic solvent, CH_2Cl_2, which might accelerate ethene extrusion by avoiding solvent coordination to the boron atom of cyclic intermediate **B** in Scheme 1, no hydroxyethyl ether **5** was detected, though a smaller amount of a mixture of diols (75/25, 36%) was obtained with homoallylic ether **6E** (10%).

It was found that (1,1,2-trimethylpropyl)borane (thexylborane) is not effective in this reaction. The steric bulkiness interfered not only a stereoselective reaction, but even cyclic hydroboration, itself.

Similar results were obtained for ethenyl ether **3Z** (Table 1).

The diastereoselectivity of this reaction was lower than that of 1,4-dienes.[6] Although Harada et al. observed that boranes reacted with the electron-rich, sterically-uncongested ethenyloxy moiety faster than with the trisubstituted double bond,[8] the low reactivity of **A** in Scheme 1 might have allowed a reversely diaster-

Table 1. Cyclic Hydroboration of Ethenyl Ethers **3E** and **3Z**

Substrate	Borane	Solvent	Time/h[a]	**1** Yield/% (*anti*/*syn*)		**5** Yield/%	**6** Yield/%
3E	BH_3	THF	16.5	56	(80/20)	15	0
3E	BH_3	Ether	12.5	60	(75/25)	9	0
3E	BH_3	CH_2Cl_2	20	36	(75/25)	0	10
3E	$ThexBH_2$[b]	THF	14(5)	33	(50/50)	7	25
3Z	BH_3	THF	15	77	(70/30)	17	4
3Z	BH_3	Ether	18	71	(70/30)	8	0
3Z	BH_3	CH_2Cl_2	20.5	53	(70/30)	0	0
3Z	$ThexBH_2$[b]	THF	15(3.5)	44	(75/25)	42	6

a) Reaction time at room temperature. Additional refluxing time before quenching, if done, is in the parenthesis. b) $ThexBH_2$ stands for (1,1,2-trimethylpropyl)borane.

Table 2. Cyclic Hydroboration of Ethenyl Ethers **3E** and **3Z** with Borane in THF in the Presence of $Rh(PPh_3)_3Cl$

Substrate	Rh(I)/mol%	Time/h	**1** Yield/% (*anti*/*syn*)		**5** Yield/%	**6** Yield/%
3E	2.1	18	53	(60/40)	22	0
3Z	4.6	17.5	53	(90/10)	0	10

eoselective *intermolecular* hydroboration of a borane species toward the trisubstituted double bond of **A** to give isomers **1b** or **1d**.

In 1985 Männig and Nöth reported that hydroboration reactions using 1,3,2-benzodioxaborole (catecholborane) were greatly accelerated by a catalytic amount of $Rh(PPh_3)_3Cl$.[10] Recently, further developments and applications of this reaction have been reported.[11–14] Pt-catalyzed hydrosilylation, closely related to Rh-catalyzed hydroboration, was also reported by Tamao et al.[15] Since the intramolecular hydroboration of intermediate **A** in Scheme 1 was not very fast at −78 °C, it would be accelerated by the Rh(I) catalyst. While hoping to improve the *anti*/*syn* selectivity of the diols, we next carried out a reaction (borane, THF, −78 °C to room temperature) with 2—5 mol% of $Rh(PPh_3)_3Cl$. The results are given in Table 2.

Although ethenyl ether **3E** gave a 60/40 mixture of diols **1a** and **1b** in 53%, **3Z** gave a mixture of **1c**/**1d** with a 90/10 ratio in 53% yield. A similar observation, that the selectivity of the Pt-catalyzed hydrosilylation reaction of (*Z*)-olefin was better than that of (*E*)-olefin, has been reported by Tamao et al. According to them, the hydrosilylation-oxidation reaction of **3E** gives **1a** in a 3.5/1 ratio, while **3Z** gives **1c** in >10/1.[15]

Experimental

The IR spectra were measured using a JASCO A-202 IR spectrometer. The ^1H NMR spectra were recorded with a JEOL JNM-FX-90Q or JEOL JNM-PMX-60 spectrometer in $CDCl_3$, unless otherwise noted. The low- and high-resolution mass spectra were taken with a JEOL JMS D-300 mass spectrometer. All reactions were carried out in dry solvents under a nitrogen atmosphere.

(2*E*,4*R*)-1-Benzyloxy-2,4-dimethyl-5-ethenyloxy-2-pentene (3E). To a mixture of mercury(II) acetate (287 mg, 0.90 mmol, 1.53 equiv) and ethenyl ethyl ether (2 ml) at room temperature was added a solution of (2*R*,3*E*)-5-benzyloxy-2,4-dimethyl-3-penten-1-ol (**4E**) (130 mg, 0.59 mmol) in 3.5 ml ethenyl ethyl ether; the resulting mixture was refluxed for 17.5 h. During that period, another 5 ml of ethenyl ethyl ether was added. At the end of the reaction, 5 ml of ether and 6 ml of 5% aqueous potassium hydroxide solution were successively added. Extraction with ether followed by the usual work up and purification with silica gel flash column chromatography (hexane–ethyl acetate, 95:5) gave 131 mg (90%) of ethenyl ether (**3E**). ^1H NMR (CCl_4, 60 MHz) δ=1.03 (3H, d, J=7.0 Hz), 1.69 (3H, s), 2.8 (1H, m), 3.47 (2H, d, J=6.3 Hz), 3.80 (2H, s), 3.88 (1H, dd, J=6.7, 2.0 Hz), 4.31 (1H, dd, J=14.2, 2.0 Hz), 4.39 (2H, s), 5.21 (1H, d, J=9.2 Hz), 6.39 (1H, dd, J=14.2, 6.7 Hz), 7.23 (5H, s); IR (neat) 1630 (sh), 1610, 1200, 700 cm^{-1}; MS *m*/*z* (rel intensity) 246 (M^+; 0.1), 138 (M^+-PhCH_2OH; 100). Found: *m*/*z* 138.1052. Calcd for $C_9H_{14}O$ ($M-PhCH_2OH$): 138.1045.

(2*Z*,4*R*)-1-Benzyloxy-2,4-dimethyl-5-ethenyloxy-2-pentene (3Z). Essentially the same procedure described above using mercury(II) acetate (450 mg, 1.41 mmol, 1.19 equiv), ethenyl ethyl ether (9 ml), and (2*R*,3*Z*)-5-benzyloxy-2,4-dimethyl-3-penten-1-ol (**4Z**) (262 mg, 1.19 mmol) gave 283 mg (97%) of ethenyl ether (**3Z**). ^1H NMR (CCl_4, 60 MHz) δ=0.94 (3H, d, J=7.0 Hz), 1.80 (3H, s), 2.8 (1H, m), 3.46 (2H, d, J=6.3 Hz), 3.93 (1H, dd, J=7.0, 2.0 Hz), 4.01 (2H, s), 4.34 (1H, dd, J=14.1, 2.0 Hz), 4.44 (2H, s), 5.18 (1H, d, J=9.2 Hz), 6.37 (1H, dd, J=14.1, 7.0 Hz), 7.29 (5H, s); IR (neat) 1630 (sh), 1607, 1200, 700 cm^{-1}; MS *m*/*z* (rel intensity) 246 (M^+; 0.1), 138 (M^+-PhCH_2OH; 100). Found: *m*/*z* 138.1046. Calcd for $C_9H_{14}O$ ($M-PhCH_2OH$): 138.1045.

Typical Procedure of Cyclic Hydroboration. Ethenyl ether **3Z** (112 mg, 0.454 mmol) was dissolved in ether (5 ml); the solution was then cooled to −74 °C, to which was added (dropwise over a period of 2 h) a mixture of a 2.0 mol dm^{-3} ethereal solution of borane–dimethyl sulfide complex (1/1) (0.25 ml, 0.5 mmol, 1.1 equiv) and ether (5 ml). After the addition was completed, the cooling bath was removed, and the reaction mixture was stirred for 18 h at room temperature. To it was added 1 ml water, 1 ml 1 mol dm^{-3} aq sodium hydroxide, and 0.3 ml 35% aq hydrogen peroxide successively; the mixture was then stirred at 60 °C for 2 h. Extraction with ethyl acetate followed by the usual work up and silica-gel flash column chromatography (hexane–ethyl acetate, 70:30 to 50:50) gave a mixture of **1c** and **1d** (61 mg, 0.258 mmol, 57%), **1d** (15 mg, 0.063 mmol, 14%), and 2-hydroxyethyl ether **5** (11

Table 3. Selected ^{1}H NMR Data of Diol **1d**[a)]

In C_6D_6

a) Given in δ (ppm) downfield from tetramethylsilane as an internal standard.

mg, 0.037 mmol, 8%). The **1c**/**1d** ratio of the diol mixture was analyzed by ^{1}H NMR to be 90/10.

Typical Procedure of Cyclic Hydroboration with Rh(PPh$_3$)$_3$Cl. Ethenyl ether **3E** (133 mg, 0.538 mmol) was dissolved in THF (6 ml), and the solution was cooled to −74 °C. To it was added (dropwise over a period of 2 h) a mixture of a 2.0 mol dm^{-3} ethereal solution of borane–dimethyl sulfide complex (1/1) (0.30 ml, 0.6 mmol, 1.1 equiv) and THF (6 ml). To this was added (at that temperature) a solution of Rh(PPh$_3$)$_3$Cl (11 mg, 0.011 mmol, 2.1 mol%) in THF (4 ml). After the addition was completed, the cooling bath was removed, and the reaction mixture was stirred for 18 h at room temperature. To it was added 1 ml water, 1 ml 1 mol dm^{-3} aq sodium hydroxide, and 0.6 ml 35% aq hydrogen peroxide, successively; the mixture was then stirred at 60 °C for 2 h. Extraction with ethyl acetate followed by the usual work up and silica-gel flash column chromatography (hexane–ethyl acetate, 70 : 30 to 50 : 50) gave a mixture of **1a** and **1b** (68 mg, 0.285 mmol, 53%) and 2-hydroxyethyl ether **5** (33 mg, 0.116 mmol, 22%). The **1a**/**1b** ratio was analyzed by ^{1}H NMR to be 60/40.

Assignment of the Product Stereochemistry. The product ratio was determined by ^{1}H NMR. Namely, the chemical shift values of two doublet methyls were compared with the values reported in the Refs. 2 and 3; the ratio was calculated from the integration values. It should be noted that the chemical shift values of the diol **1d** in C_6D_6 reported by Nagaoka and Kishi in Ref. 2 are not in good accordance with those of ours. However, ours were identical with the data of **1d** in $CDCl_3$ reported by Oikawa et al. in Ref. 3. The chemical shift data of **1d** are listed in Table 3.

Methyl (*R*)-3-hydroxy-2-methylpropanoate was kindly provided by Kanegafuchi Chemical Industries, Co., and is greatly acknowledged.

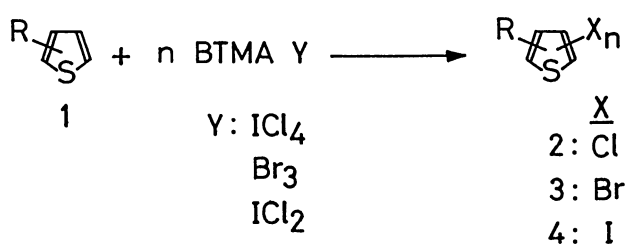
Synopsis. The reactions of thiophene derivatives with benzyltrimethylammonium tetrachloroiodate, benzyltrimethylammonium tribromide, and benzyltrimethylammonium dichloroiodate in acetic acid or in acetic acid–zinc chloride under mild conditions gave chloro-, bromo-, and iodo-substituted thiophene derivatives, respectively, in satisfactory yields.

Since thiophene derivatives (**1**) are sensitive toward the electrophilic substitution reactions, the halogenation of **1** generally gives a mixture of mono-, di-, and other polysubstituted halogenation products. For example, direct chlorination of thiophene (**1a**) with chlorine gave a mixture of 2-chloro-, 2,5-dichloro-, 2,3,4-trichloro-, 2,3,5-trichloro-, and 2,3,4,5-tetrachlorothiophene.[2] Bromination of **1a** with an equimolar amount of bromine gave 2-bromothiophene accompanying 2,5-dibromo- and a smaller amount of tribromothiophene as by-products.[3] Only 2-iodo- and 2,5-diiodothiophene can be synthesized by direct iodination of **1a** with iodine in the presence of mercury(II) oxide,[4] and other iodothiophenes can be prepared indirectly by the reaction of acetoxymercurio derivative with iodine.[5] Direct halogenation of 2-methylthiophene (**1b**) with chlorine[6] and bromine,[7] also gave the mixtures, respectively. By the iodination of **1b** with iodine–mercury(II) oxide, 5-iodo derivative is obtained,[8] and other iodo derivatives have been synthesized by indirect methods.

We have recently shown that benzyltrimethylammonium polyhalides such as benzyltrimethylammonium tetrachloroiodate (BTMA ICl_4),[9] benzyltrimethylammonium tribromide (BTMA Br_3),[10] and benzyltrimethylammonium dichloroiodate (BTMA ICl_2)[11] are useful aromatic chlorinating, brominating, and iodinating agents. In this paper we wish to report on the direct selective halogenation of aromatic heterocyclic compounds, especially **1**, with BTMA ICl_4, BTMA Br_3, and BTMA ICl_2.

Results and Discussion

The reaction of **1** with BTMA ICl_4 in acetic acid gave chloro-substituted thiophene derivatives (**2**). The reaction of **1** with BTMA Br_3 or BTMA ICl_2 in acetic acid in the presence of zinc chloride gave bromo- (**3**) or iodo-substituted thiophene derivatives (**4**), respectively. The results are summarized in Table 1.



As shown in the Table 1, these reactions usually proceeded stoichiometrically. However, in many cases, the reaction of **1** with BTMA ICl_4 gave a mixture of several chloro-substituted thiophene derivatives **2**, which could not be separated from each other.

In the cases of bromination and iodination, used zinc chloride may form complexes with BTMA Br_3 and BTMA ICl_2, producing such active species as $[PhCH_2(CH_3)_3N]^+[ZnCl_2Br_2]^{2-}Br^+$ and $[PhCH_2(CH_3)_3N]^+[ZnCl_4]^{2-}I^+$, respectively.[27]

We believe that the procedure for the direct halogenation of **1** using benzyltrimethylammonium polyhalides (stable solid reagents) is more useful and effective than that using molecular chlorine, bromine, or iodine, because of ease, simplicity and generality. As a limitation to the procedure, attempts at the monochlorination of **1** using an equimolar amount of BTMA ICl_4 were unsuccessful due to contamination of the polychlorinated products.

Experimental

3-Methyl-2,4,5-trichlorothiophene (2c-3); Typical Procedure for the Chlorination: BTMA ICl_4 (6.50 g, 15.5 mmol) was added to a solution of 3-methylthiophene (**1c**) (0.49 g, 5 mmol) in acetic acid (50 ml); the mixture was stirred at 70 °C for 24 h. During this time, the color of the solution turned black, and a yellow precipitate was deposited. After the solution was cooled to room temperature, the yellow precipitate (BTMA ICl_2) was filtered off. The filtrate was concentrated in vacuo and the obtained residue was treated with 5% $NaHSO_3$ (10 ml) and with 5% $NaHCO_3$ (10 ml), and then extracted with dichloromethane (50 ml×3). The black organic layer was separated and dried over $MgSO_4$. Then, a trace amount of acetic acid and black impurities in the solution were removed by column chromatography on alumina. The eluent was concentrated in vacuo to give a colorless oil **2c-3**; yield 0.64g (63%); bp 219 °C/760 mmHg (lit,[20] bp 115—116 °C/23 mmHg, 1 mmHg=133.322 Pa).

3,5,3′,5′-Tetrachloro-2,2′-dithienyl (2f-4): Mp 120—121 °C; ^1H NMR ($CDCl_3$) δ=6.77 (2H, s, 4- and 4′-H). Found: C, 31.42; H, 0.72%. Calcd for $C_8H_2S_2Cl_4$: C, 31.60; H, 0.66%.

2,5-Dibromothiophene (3a-2); Typical Procedure for the Bromination: BTMA Br_3 (3.90 g, 10 mmol) and $ZnCl_2$ (ca. 1 g) were added to a solution of thiophene (**1a**) (0.42 g, 5 mmol) in acetic acid (30 ml); the mixture was then stirred at room temperature for 2 h until the disappearance of the orange color of the reagent. Aqueous $NaHSO_3$ (5%, 10 ml) was added to the mixture; this mixture was extracted with hexane (50 ml×3). The organic layer was dried over $MgSO_4$, and passed through a short alumina-column. The eluent was concentrated in vacuo to give **3a-2** as a colorless oil; yield 0.65 g

a) In the cases of both bromination and iodination, $ZnCl_2$ was used as catalyst. b) Known products were characterized by comparing their ^1HNMR spectra and bp or mp with those of authentic samples or reported data. c) Yield of isolated product. d) Mixture of several chloro-substituted products. e) Mixtrue of several bromo-substituted products. f) Mixture of several iodo-substituted products.

(54%); bp 217—218 °C/760 mmHg (lit,[12] bp 68 °C/2 mmHg).

Ethyl 4,5-Dibromo-2-thiophenecarboxylate (3e-2): Mp 55 °C; ^1HNMR ($CDCl_3$) δ=1.47 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 4.17 (2H, q, J=7 Hz, $C\underline{H}_2CH_3$), and 7.64 (1H, s, 3-H). Found: C, 26.50; H, 1.81%. Calcd for $C_7H_6O_2SBr_2$: C, 26.78; H, 1.93%.

2,5-Diiodo-3-methylthiophene (4c-2); Typical Procedure for the Iodination: BTMA ICl_2 (3.65 g, 10 mmol) and $ZnCl_2$ (ca. 1.5 g) were added to a solution of **1c** (0.49 g, 5 mmol) in acetic acid (30 ml); the mixture was stirred at room temperature for 4 h. During this time, a color of the solution turned black. Aqueous $NaHSO_3$ (5%, 10 ml) was added to the mixture; this mixture was extracted with hexane (50 ml×3). The organic layer was dried over $MgSO_4$, and then passed through a short alumina-column in order to remove any trace amount of acetic acid or black impurities. The eluent was concentrated in vacuo to give a colorless oil **4c-2**; yield 1.61 g (92%); bp 238—240 °C/760 mmHg (lit,[20] bp 120—121 °C/2.5 mmHg).

Ethyl 4,5-Diiodo-2-thiophenecarboxylate (4e-2): Mp 77 °C; ^1HNMR ($CDCl_3$) δ=1.33 (3H, t, J=7 Hz, $CH_2C\underline{H}_3$), 4.30 (2H, q, J=7 Hz, $C\underline{H}_2CH_3$), and 7.48 (1H, s, 3-H). Found: C, 20.58; H, 1.45%. Calcd for $C_7H_6O_2SI_2$: C, 20.61; H, 1.48%.

Synthesis and Properties of Gramicidin S Analogs Consisting of Eight Amino Acid Residues

Makoto TAMAKI* and Sadatoshi AKABORI
Department of Chemistry, Faculty of Science, Toho University,
Miyama, Funabashi-shi, Chiba 274
(Received March 20, 1991)

Synopsis. Three cyclic octapeptides (des-Val$^{1,1'}$-gramicidin S, des-Leu$^{3,3'}$-gramicidin S and des-Val^{1},Leu$^{3'}$-gramicidin S), showed no antibiotic activity. Although their CD spectra resembled each other, they differed from that of gramicidin S. These results indicate that the removal of two of the Val and/or Leu residues at positions 1, 1', 3, and 3' of gramicidin S greately affects both the antibiotic activity and conformation.

Gramicidin S (GS)[1] is an antibiotic cyclodecapeptide, cyclo(-Val-Orn-Leu-D-Phe-Pro-)$_2$,[2] with a rigid β-pleated sheet conformation.[3] In order to investigate the contribution of the ring size to both the antibiotic activity and conformation, many GS analogs with a variety of ring sizes have been synthesized.[4–6] Recently, in synthetic studies of several cyclododeca- and cyclotetradecapeptides related to GS and gratisin (GR), we have reported that the primary structure of GS with ten residues is not always necessary for exhibiting strong activity, and that the CD spectra of these synthetic peptides mainly reflect the amino acid sequence around their β-turn part (-D-Phe-Pro-).[7–9] However, we have not yet evaluated the structure-activity correlation of its analogs with a smaller ring size than that of GS.

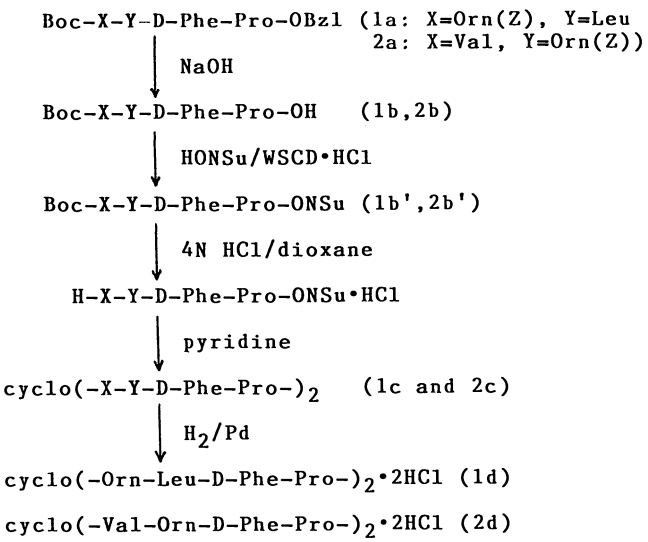

Fig. 1. Synthetic scheme of des-Val$^{1,1'}$- and des-Leu$^{3,3'}$-GS.

In this paper we describe the syntheses, antibiotic activity, and CD spectra of three cyclooctapeptides (cyclo(-Orn-Leu-D-Phe-Pro-)$_2$ (des-Val$^{1,1'}$-GS, **1d**), cyclo(-Val-Orn-D-Phe-Pro-)$_2$ (des-Leu$^{3,3'}$-GS, **2d**), and cyclo(-Orn-Leu-D-Phe-Pro-Val-Orn-D-Phe-Pro-) (des-Val^{1},Leu$^{3'}$-GS, **3d**)) which lack two residues of the Val or Leu residues at positions 1, 1', 3, and 3' of GS. We also discuss the contribution of the ring size to both the antibiotic activity and conformation.

The synthetic routes of these analogs are shown in Figs. 1 and 2. These methods are similar to those described in previous papers of this series.[7,10] In the syntheses of des-Val$^{1,1'}$- and des-Leu$^{3,3'}$-GS, cyclizations of H-Orn(*Z*)-Leu-D-Phe-Pro-ONSu (**1b'**) and H-Val-Orn(*Z*)-D-Phe-Pro-ONSu (**2b'**) were carried out in pyr-

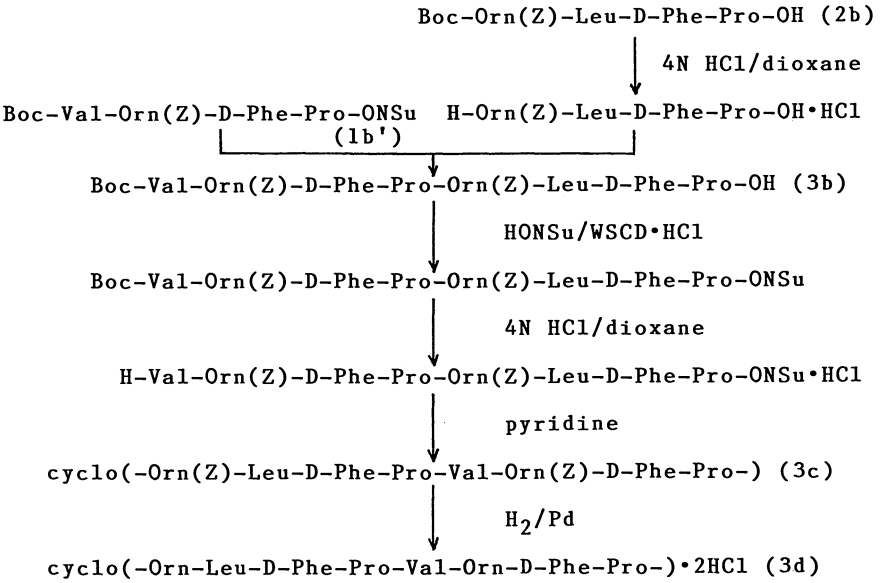

Fig. 2. Synthetic scheme of des-Val^{1}, Leu$^{3'}$-GS.

idine at 25 °C for 1 d. The final concentration of the active esters was 3 mM (1 M=1 mol dm^{-3}). High-performance liquid chromatography (HPLC) profiles of the crude cyclic products are shown in Fig. 3. The molecular weight of each cyclic product isolated by semipreparative HPLC was determined by FAB mass spectrometry. The cyclic products from the tetrapeptide active esters have widely different molecular weights. Compound **1b'** produced the cyclic dimer (30%), trimer (4%), and tetramer (0.5%); Compound **2b'** produced the cyclic dimer (35%), trimer (6%), and tetramer (0.5%). These active esters, however, did not produce a cyclic monomer. The numbers in parentheses are the yields of each cyclic product calculated from **1b** and **2b**. Recently, regarding the cyclization of H-Val-Orn(*Z*)-Leu-D-Phe-Pro-ONSu and H-Tyr(Bzl)-Val-Orn(*Z*)-Leu-D-Phe-Pro-ONSu containing the D-Phe-Pro sequence at the C-terminal, we reported that the former yields exclusively the cyclic dimer, while the latter produces the cyclic monomer and dimer.[10] The present results indicate that the lengths of these active esters greatly affect their mode of cyclization.

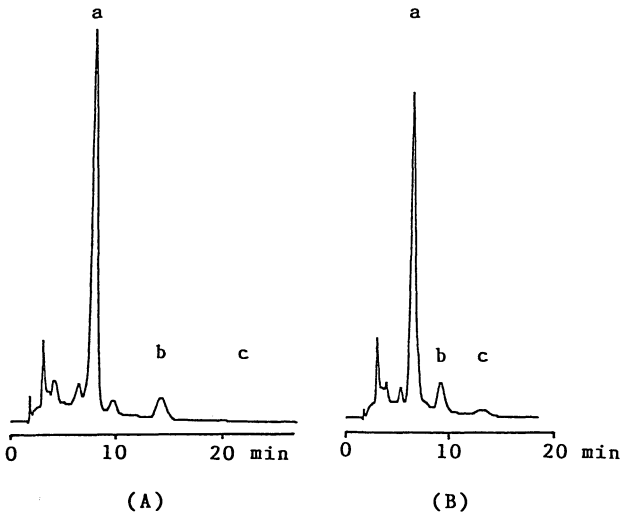

Fig. 3. HPLC profiles[a] of products in cyclization of H-Orn(Z)-Leu-D-Phe-Pro-ONSu (A) and H-Val-Orn(Z)-D-Phe-Pro-ONSu (B).
(a: cyclic dimer, b: cyclic trimer, c: cyclic tetramer)
a) Elution solvent used in these HPLC analysis was MeOH-H_2O (6 : 1).

The yields, physical properties and analytical data of intermediary products and GS analogs are summarized in Tables 1 and 2.

Des-Val$^{1,1'}$-GS, des-Leu$^{3,3'}$-GS and des-Val^{1}, Leu$^{3'}$-GS showed no antibiotic activity against all of the microorganisms tested. We also found that cyclo(-Orn-D-Phe-Pro-)$_2$ shows no activity.[11] On the other hand, we have reported that some cyclododecapeptides related to GR with various seqeunces at the β-turn part show strong activity,[7,8] and that several cyclotetradecapeptides related to GS possess 1/4—1/8 activity of GS.[9] These results indicate that removing either two or four of the Val and/or Leu residues at positions 1, 1', 3, and 3' from GS results in a loss of activity, while the addition of two or four amino acid residues to GS makes it feasible to take a suitable conformation for exhibiting antibiotic activity.

The CD spectra of these synthetic peptides and GS in an aqueous solution are shown in Fig. 4. These CD

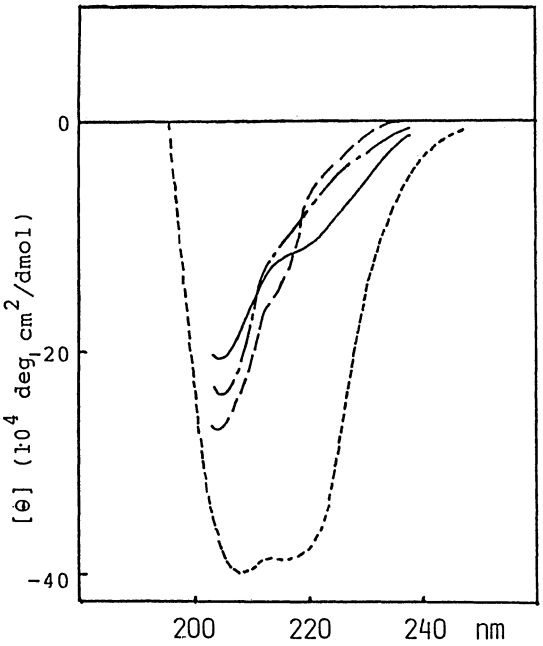

Fig. 4. CD spectra of GS and its analogs in aqueous solution.
des-Val$^{1,1'}$-GS, ——; des-Leu$^{3,3'}$-GS, ——; des-Val^{1}, Leu$^{3'}$-GS, — - —; GS, ------.

spectra resemble each other; although a trough is observed at 204 nm and a shoulder near 217 nm, their CD patterns differ from that of GS, even though these peptides possess the D-Phe–Pro seqeunce. We recently reported that the CD spectra of cyclo(–Val–Orn–Leu–D-Phe–Pro–Tyr–)$_2$ and cyclo(–Val–Orn–Leu–Leu–D-Phe–Pro–Leu–)$_2$ having the D-Phe–Pro sequence are similar to that of GS.[7,9] On the other hand, the CD spectrum of cyclo(–Orn–D-Phe–Pro–)$_2$ resembles those of the synthetic cyclooctapeptides, rather than GS; a trough was observed near 200 nm and a shoulder near 220 nm.[12] Kopple et al. reported from NMR studies that this cyclohexapeptide possesses a β-turn caused by a D-Phe–Pro seqeunce as GS.[13] Further, the same β-turn was also found in cyclo(–Ala–Gly–D-Phe–Pro–)$_2$, which possesses the Ala–Gly sequence in place of the Orn–Leu or Val–Orn sequence of the cyclooctapeptides synthesized in our studies.[14] These facts suggest that the synthetic cyclooctapeptides have a β-turn similar to that of GS, and that the difference between these synthetic cyclooctapeptides and GS in CD spectra may result from removing two of Val and / or Leu residue from GS, in other words, a distinction of the ring size.

Experimental

All melting points are uncorrected. The CD spectra were measured by a JASCO J-500 spectropolarimeter at a concentration of 1.5—2.0×10^{-4} M. The molecular weights of these synthetic peptides were determined by FAB mass spectrometry using a JEOL JMS-D-300 mass spectrometer. Amino acid analyses were carried out using a Hitachi 835 amino acid analyzer after hydrolysis in 6 M HCl at 110 °C for 24 h. HPLC analysis was carried out using an 800 series (JASCO). A Finepak SIL C18 column (10 μm, 250×4.6 mm I.D., or 250×6.7 mm I.D., JASCO) was used: flow rate, 1 ml min^{-1}; solvent, MeOH–H_2O (6:1) or MeOH-5%–$NaClO_4$ (4:1); monitoring wavelength, 220 nm.

Microbiological Assays. The microorganisms employed were *Staphylococcus aureus* ATCC 6538, *Streptomyces pyogenes* N.Y.5, *Corynebacterium diphtheriae* P.W.8, *Micrococcus pyogenes* ATCC 10240, *Bacillus subtilis* ATCC 6633, *Escherichia coli* NIHJ-JC2, and *Proteus vulgaris* OX 19. The minimum concentration of compounds necessary to completely inhibit the growth of these microorganisms was determined by an agar dilution method with 10^6 organisms per milliliter.

We thank Professor Ichiro Muramatsu, Rikkyo University, for helpful discussion. We also thank the staff of the Research Laboratories of Toyo Jozo Co. for elemental analyses, microbiological assays, and measurement of FAB mass spectra.

Crystal Structure of the Gold(III) Complex, Trichloro(dibenzyl sulfide)gold(III)

Kazuhiro TAKAHASHI
Department of Chemistry, Faculty of Science, Shimane University,
Nishikawatsu-cho, Matsue 690
(Received February 21, 1991)

Synopsis. The structure of the title complex has been determined. The crystal is orthorhombic, with the space group *Pnma*, Z=4, a=13.331 (2), b=16.130 (3), and c=7.6949 (9) Å. The complex has a square-planar coordination geometry. The Au and the 3Cl1S donor atoms are located on a crystallographic mirror plane. The length of the Au–Cl bond trans to the Au–S bond is slightly longer than those of the other two Au–Cl bonds.

Ever since two complexes consisting of halogen, gold, and dibenzyl sulfide (DBS) were first isolated in 1905,[1] many investigations for gold(I), gold(III), and mixed-valence gold(I)-gold(III) complexes of DBS have been undertaken in the fields of coordination chemistry and physical chemistry.[2–5] However, exact X-ray crystal structure analyses of these complexes, except for gold(I) complexes,[5] were not carried out until quite recently.

The author and collaborators have studied the DBS–gold complexes with interests in the coordination structures and a correlation between structures and physical properties. We have so far reported the structures of [$AuBr_3$(DBS)] and *catena*-[AuCl(DBS)]-[$AuCl_3$(DBS)],[6,7] and the optical properties of DBS–gold complexes.[8] In this study, the structure of the title complex, [$AuCl_3$(DBS)], has been determined by a single crystal X-ray diffraction method in order to reveal details of the coordination structure. Its structural features are compared with those of related gold(III) complexes, mainly focusing on the coordination structure and the trans influence of DBS. Further characterization has been carried out in terms of the electronic spectra.

Experimental

[$AuCl_3$(DBS)] was prepared according to the Ray and Sen's procedure,[2] using $HAuCl_4 \cdot 4H_2O$ as a metal source instead of $AuCl_3$. A yellow prismatic crystal was obtained by recrystallization from a benzene–toluene (95/5 v/v) solution at ca. 5 °C (Found: C, 32.70; H, 2.73%). The electronic spectra were recorded on a Shimadzu MPS-2000 spectrophotometer (280—800 nm). The intensity data were collected at 295±1 K, by use of an Enraf–Nonius CAD4 automated four-circle X-ray diffractometer (graphite monochromated Mo K_α radiation, λ=0.71073 Å). All the computations were carried out on a DEC MicroVAXII, using the programs in CAD4 Structure Determination Package (SDP, 4th ed). The unit cell parameters were determined from 25 reflections with $22<2\theta<31$ °.

Crystal Data: $C_{14}H_{14}SCl_3Au$; M=517.7; orthorhombic; *Pnma*; a=13.331(2), b=16.130(3), and c=7.6949(9) Å; V=1654.6(8) Å^3; D_m=2.1 (by floatation), D_c=2.08 g cm^{-3}; Z=4; μ=94.7 cm^{-1}; crystal size=0.30×0.25×0.28 mm^3.

A total of 2191 reflections were collected (scan type: ω–2θ; scan range: $2 \leqq 2\theta \leqq 55°$; scan width: $\Delta\omega$= (0.8+0.35 tan θ)°; ω scan rates: 2.75° min^{-1} for a preliminary scan, variable (1.18—2.75° min^{-1}, depending on intensity) for the final scan). The intensities of five standard reflections monitored at 90 min intervals showed good stability during data collection. The intensity data were corrected for the Lorentz-polarization effects, and for the absorption based on Ψ scans of the nine reflections ($80<\chi<88°$).[9] The structure was solved by the direct method (MULTAN in SDP) using 1314 independent reflections with $I>3\sigma(I)$, and was then refined by the full-matrix least-squares procedure. Anisotropic thermal parameters were adopted for non-hydrogen atoms. Hydrogen atoms were not included in the structure calculations. The final R values were $R=\sum||F_o|-|F_c||/\sum|F_o|=0.0319$ and $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.0435$, where the weighting scheme is $w=1/\sigma^2(|F_o|)=4|F_o|^2/\{\sigma(I)^2+(0.04|F_o|^2)^2\}$.

Results and Discussion

The final atomic coordinates are given in Table 1.[#] Figure 1 shows the molecular structure of [$AuCl_3$(DBS)]. The complex has a square-planar coordination geometry ordinarily observed in mononuclear four-coordinated Au(III) complexes. The Au and the four donor atoms form a perfectly planar coordination sphere since these atoms lie on the crystallographic mirror plane. The four bond angles subtended at the Au (86—92°) are slightly deviated from the ideal angle of 90°. These slight deviations are suggestive of very weak steric constraints of the bulky ligand, DBS. The lengths of three Au–Cl coordination bonds (2.27—2.29 Å) fall within the range observed for $[AuCl_4]^-$ (2.27—2.30 Å),[4,10] and for Au(III) complexes with 3Cl1L donor atom set (2.27—2.35 Å, L=P of triphenylphosphine,[11] and L=S of thianthrene[12]).

[#] Lists of structure factors, anisotropic thermal parameters, bond distances and angles, and the results of least-squares plane calculations are deposited as Document No. 8951 at the Office of the Editor of Bull. Chem. Soc. Jpn.

The Au–S bond length (2.310(3) Å) falls within the range observed for sulfur-coordinated square-planar Au(III) complexes (2.28—2.36 Å).[12,13] The molecular structure of [$AuCl_3$(DBS)] resembles the tribromo complex, [$AuBr_3$(DBS)].[6] The lengths of the three Au–Cl bonds are shorter than those of the corresponding Au–Br bonds in [$AuBr_3$(DBS)] (2.41—2.43 Å). A difference between Au–Cl and Au–Br distances (average 0.14 Å) is expected from a difference in the effective ionic radius between Cl^- (1.67 Å) and Br^- (1.82 Å), and also from that in the covalent radius between Cl (0.99 Å) and Br (1.14 Å).[14] Figure 2 shows the crystal structure of [$AuCl_3$(DBS)]. A significant intermolecular contact smaller than 3.5 Å is observed only between the phenyl rings of adjacent molecules (C(4)–C(4)' (symmetry code: $1-x,1-y,1-z$), 3.347(6) Å). The crystals of [$AuCl_3$(DBS)] and of [$AuBr_3$(DBS)] (triclinic) are not isomorphous. No close contact among chlorides less than the sum of the van der Waals radii is observed in the present crystal, in contrast to the close Br–Br contact (3.46 Å) observed in the [$AuBr_3$(DBS)] crystal.[6] The shortest Cl–Cl distance is 4.203(5) Å of the Cl(1)–Cl (3)″ ($1/2+x$, $1/2-y$ or $y,1/2-z$).

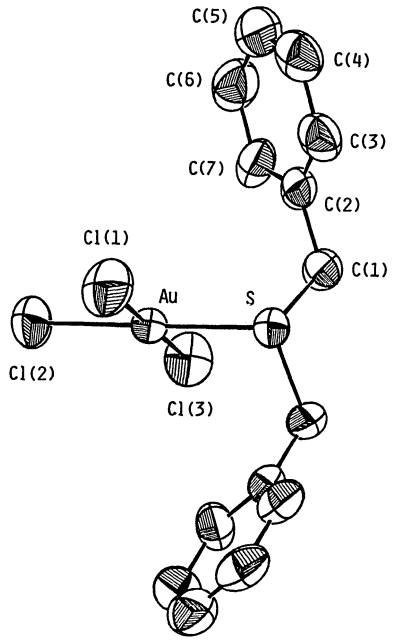

Fig. 1. ORTEP drawing of the [$AuCl_3$(DBS)] molecule with atom numbering scheme (thermal ellipsoids are drawn at 50% probability level). Selected interatomic distances (l/Å) and angles (ϕ/°) around the coordination sphere of the gold(III) ion are: Au–Cl(1) 2.272(3), Au–Cl(2) 2.287(4), Au–Cl(3) 2.272(3), Au–S 2.310(3) Å; Cl(1)–Au–Cl(2) 90.6(1), Cl(1)–Au–Cl(3) 178.8(1), Cl(1)–Au–S 86.7(2), Cl(2)–Au–Cl(3) 90.7(1), Cl(2)–Au–S 177.4(1), Cl(3)–Au–S 92.0(1)°.

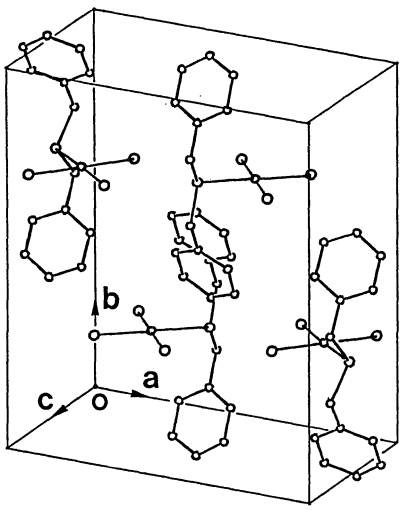

Fig. 2. Perspective view of the molecular arrangement in the unit cell.

In the molecules of square-planar trihalogeno(phosphine)gold(III) complexes, [$AuCl_3(PPh_3)$],[11] and [$AuBr_3\{P(C_2H_5)_3\}$],[15] the Au–halogen bond trans to the Au–P bond is appreciably longer than the other two Au–halogen bonds. This lengthening is attributed to the electrostatic trans influence of phosphines.[11,15,16] A similar pattern is observed in the [$AuCl_3$(DBS)] molecule, i.e., the Au–Cl(2) bond (2.287(4) Å) trans to the Au–S is longer than the other two Au–Cl bonds (both 2.272(3) Å). It should be noted here that no such distinct lengthening is observed in the [$AuBr_3$(DBS)] molecule,[6] and that a difference in the length between the Au–Cl(2) bond and the other two Au–Cl bonds (0.01—0.02 Å, evaluated by considering their standard deviations) is smaller than those of the phosphine complexes (0.05—0.09 Å).[11,15] These facts indicate that the trans influence of DBS is very weak compared with the phosphine ligands in square-planar trihalogenogold(III) complexes. Taking into account the fact that the Au–S bond of the present complex is shorter than that in [$AuBr_3$(DBS)] (2.349(3) Å), the relative strength of the trans influence of ligands seem to be in the order, $Cl^- < Br^- \approx$ DBS, for the trihalogeno(DBS)gold(III) complexes.

The electronic spectra of [$AuCl_3$(DBS)] in $CHCl_3$ and Nujol mull are shown in Fig. 3. The solution and solid spectra show a single broad absorption band, with the absorption maxima at 29600 (ε=4860 $mol^{-1}\,dm^3\,cm^{-1}$)

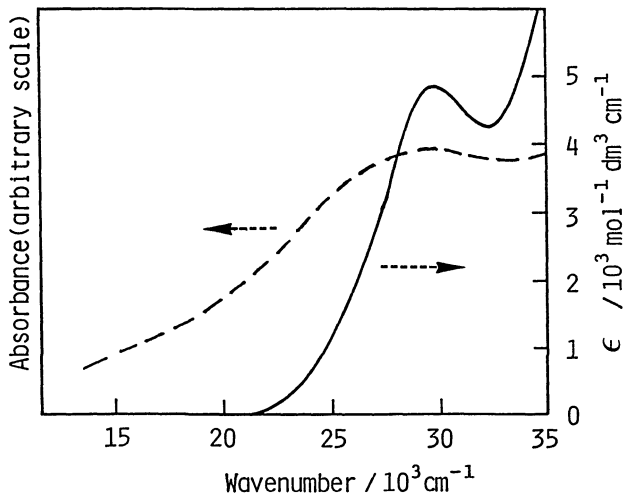

Fig. 3. Electronic spectra of [$AuCl_3$(DBS)].
———: $CHCl_3$ solution (5×10^{-4} mol dm^{-3}),
— — —: Nujol mull.

and 29400 cm^{-1}, respectively. This intense and broad band is attributable to a charge transfer interaction between Au^{3+} and ligands.[17] The d–d bands are presumably hidden in this intense band.

The X-ray experiment was carried out in the Electrotechnical Laboratory (ETL). The author is grateful to Dr. Hiroshi Tanino (ETL), Assoc. Professor Masahiro Mikuriya, Mr. Toshinori Fujii (Kwansei Gakuin Univ.), Dr. Makoto Handa, and Professor Kuninobu Kasuga (Shimane Univ.), for their kind and helpful supports.

A New Calix[6]arene-Based Uranophile with Phosphonate Groups as Ligands

Takeshi NAGASAKI, Takashi ARIMURA, and Seiji SHINKAI*
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received March 1, 1991)

Synopsis. A new calix[6]arene-based uranophile which has six phosphonomethyl groups on the upper rim was synthesized. This compound forms a 1 : 1 complex with uranyl ion (UO_2^{2+}). The stability constant was estimated to be $10^{17.5}$ M^{-1},# which is satisfactorily comparable with those for calix[6]arene-based uranophiles bearing OH or COOH groups on the lower rim.

The selective extraction of uranium from sea water has been of much concern for chemists because of its importance in relation to energy problems. In order to design such a ligand that can selectively extract uranyl ion (UO_2^{2+}), one faces a difficult problem, namely, the ligand must strictly discriminate between UO_2^{2+} and other metal ions which are present in great excess in sea water. A possible unique solution for this difficult problem is to use a cyclic ligand suitably structured to perform the UO_2^{2+} binding. As UO_2^{2+} complexes adopt either a pseudoplanar pentacoordinate or hexacoordinate structure,[1] a macrocyclic ligand with a nearly coplanar arrangement of either five or six donating groups would serve as a specific ligand for UO_2^{2+} (i.e., as a uranophile). This sort of approaches has been reported by a few research groups.[2-5] We recently found that pentasodium 31,32,33,34,35-pentahydroxycalix[5]arene-5,11,17,23,29-pentasulfonate (**1**$_5$) and hexasodium 37,38,39,40,41,42-hexahydroxycalix[6]arene-5,11,17,23,29,35-hexasulfonate (**1**$_6$) have remarkably high stability constants (K_{uranyl}=$10^{18.7-19.2}$ M^{-1}) and selectivity factors (K_{uranyl}/K_{M^+}=10^{10-17}) in water.[6,7] In particular, the "super-uranophile" nature of the calix[6]arene derivatives is of great significance from a practical viewpoint because they can be synthesized from commercially-available calix[6]arene-37,38,39,40,41,42-hexol in good yields.[8,9] The remarkably high selectivity is attributed to the rigid skeleton of calix[5]arene and calix[6]arene which can provide the pre-organized penta- and hexacoordination geometry for the binding of UO_2^{2+} but cannot accommodate a square-planar or tetrahedral coordination geometry appropriate for other metal cations.[6,7,10,11] We here synthesized 37,38,39,40,41,42-hexamethoxy-5,11,17,23,29,35-hexakis(phosphonomethyl)calix[6]arene (**2**) and estimated the stability constant for the complex formation with UO_2^{2+}.

1 M=1 mol dm^{-3}.

Results and Discussion

pH Dependence. It is known that both calix[*n*]arenepolyols and their *O*-carboxymethyl derivatives (**1**$_n$: R=CH_2COOH) are poorly soluble in water.[10,12] To determine the stability constant, the moderate solubility in water is required. To satisfy this requirement we previously introduced sulfonate groups into the *p*-positions to the hydroxyl groups on the lower rim. On the other hand, compound **2** showed sufficient solubility in water.

We first estimated pK_a values of **2** and sodium methoxybenzylphosphonate (**3**). The titration curve for **2** is illustrated in Fig. 1. The pK_a values for **2** were estimated to be 2.91 and 8.86 and those for **3** to be 2.16 and 7.71. The result indicates that the phosphonate group in **2** show the pK_a values higher by 0.75—1.15 pK units than that in **3**. A Henderson-Hasselbach plot (pH=pK_a−n·log [(1−α)/α] where n becomes greater than unity when the dissociation groups interact with each other) for the second acid dissociation of the phosphonate groups in **2** gave n=1.5 whereas that for the second acid dissociation of the phosphonate group in **3** gave n=1.0. The results establish that the pK_a values for **2** are raised because of the intramolecular interactions among the phosphonate groups.

Addition of **2** to uranyl dinitrate ($UO_2(NO_3)_2$) solution at 25 °C increased the UV and visible absorption band over a wide wavelength range (225—600 nm) owing to the competitive association of **2** with UO_2^{2+} (the spectrum is similar to Fig. 1 in Ref. 7). The spectral change after mixing was relatively slow: it usually took 4 to 5 h to reach the equilibrium spectrum. On the other hand, addition of acyclic **3** (used as a

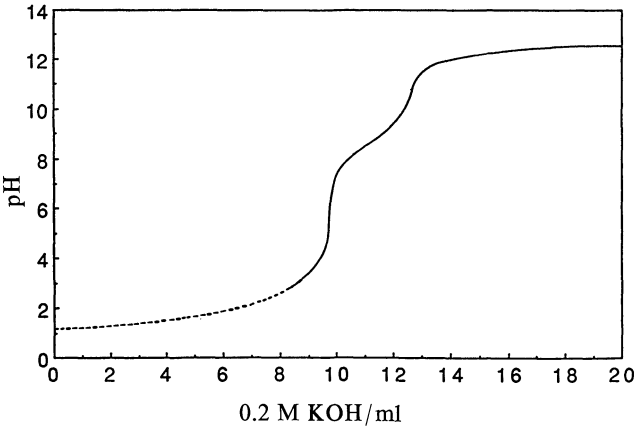

Fig. 1. Potentiometric titration of **2** by an autotitrator: 25±0.5 °C, μ=0.10 with KCl, [**2**]=5.00×10^{-3} M (in 20 ml of 7.00×10^{-2} M HCl). Below pH 2.8, the solution was not clear because of the precipitation of **2** (shown by a dotted line).

reference compound: [3]=6·[2]) to uranyl dinitrate solution did not increase the absorption band. The difference shows that the efficient UO_2^{2+} binding to **2** is based on the ring structure of calix[6]arenehexol.

In Fig. 2, we plotted the absorbance at 449 nm (a shoulder of the spectrum: A_{449}) against pH. It is seen from Fig. 2 that the A_{449} for **2** sharply increases at pH 8—9, forms a plateau at pH 11.4—11.8, and decreases above pH 12. The increase at pH 8—9 is ascribed to the dissociation of the phosphonate groups whereas the decrease above pH 12 is ascribed to the competitive association of UO_2^{2+} with OH^- present in great excess at this pH range. In fact, the precipitation of the hydroxide complex was observed pH 12.5. Judging from the pK_a values determined above, the "active" ligands for the UO_2^{2+}-binding are dianionic phosphonate groups (i .e., $-CH_2P(=O)O_2^{2-}$). Careful examination of Fig. 2 reveals, however, that at around pH 8.86 (average pK_a of **2**) the complex formation scarcely takes place. In other words, the plot of A_{449} versus pH (Fig. 2) shifts to higher pH region than the titration curve (Fig. 1). The discrepancy suggests that the half-dissociated **2** bearing three $-CH_2P(=O)O_2^{2-}$ and three $-CH_2P(=O)O_2H^-$ cannot yet serve as the "active" ligand. We consider that the coordination ability of the $-CH_2P(=O)O_2^{2-}$ groups is suppressed by the intramolecular hydrogen-bonding interaction with the $-CH_2P(=O)O_2H^-$ groups.

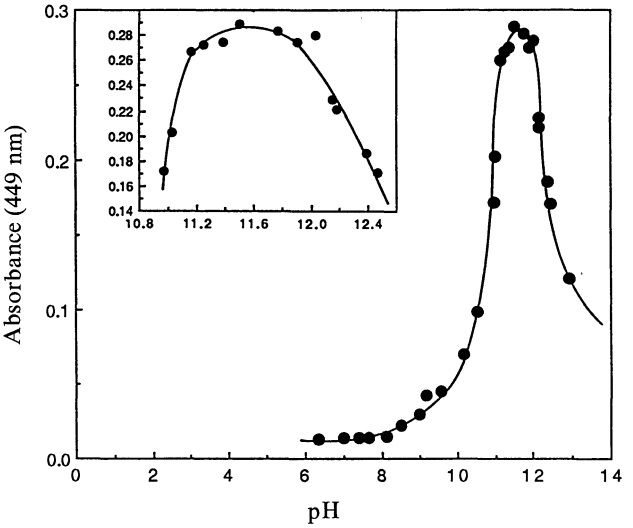

Fig. 2. pH dependence for the formation of the UO_2·**2** complex: $[UO_2(NO_3)_2]$=[**2**]=0.33 mM, μ=0.1 with KCl, 25 °C.

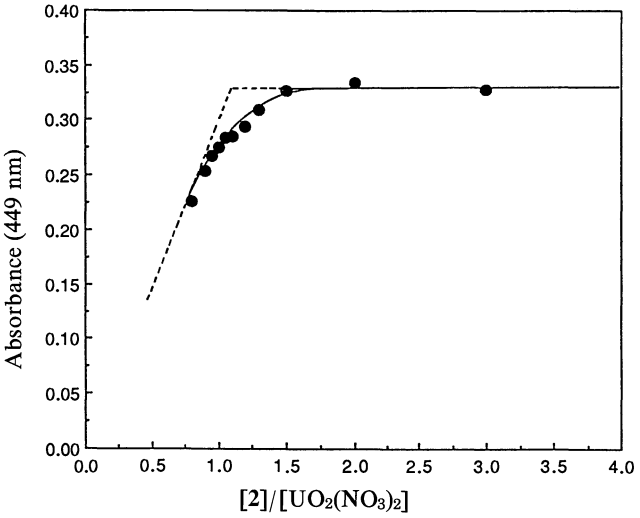

Fig. 3. Molar ratio plot for UO_2·**2** complex: $[UO_2(NO_3)_2]$=0.29 mM (constant), pH 11.5 with KOH, μ=0.1 with KCl, 25 °C.

Stoichiometry and Stability Constants. As a prelude to estimate the stability constant, we determined the stoichiometry of the UO_2·**2** complex. In Fig. 3, the A_{449} was plotted against [**2**]/$[UO_2^{2+}]$. A break-point appeared at [**2**]/$[UO_2^{2+}]$=1.0, supporting the formation of a 1: complex. From the A_{449} value at the plateau one can estimate the ε_{449} to be 1170 $M^{-1}cm^{-1}$ for the UO_2·**2** complex, which is comparable with those (about 1400 $M^{-1}cm^{-1}$) for the UO_2·**1** complexes.[7]

UO_2^{2+} is known to form a stable carbonate complex, $[UO_2(CO_3)_3]^{4-}$ and the stability constant ($K_{carbonate}$=$[UO_2(CO_3)_3^{4-}]/[UO_2^{2+}][CO_3^{2-}]^3$) is estimated to be $10^{12.5}$ M^{-3} at 25 °C and pH 10.4.[13] When **2** is added to the uranyl tricarbonate solution, the competitive displacement of carbonates by **2** takes place and reaches an equilibrium after a few hours. This process is expressed by Eq. 1. One can thus estimate the displacement equilibrium constant (K_e) from the spectral change. Finally, the stability constant for UO_2^{2+} (K_{uranyl}=$[UO_2$·**2**$]/[UO_2^{2+}]$[**2**] can be determined by Eq. 2.[14]

$$[UO_2(CO_3)]^{4-} + 2 \overset{K_e}{\rightleftarrows} UO_2\cdot 2 + 3CO_3^{2-} \quad (1)$$

$$K_{uranyl} = K_e \cdot K_{carbonate} \quad (2)$$

At pH 10.4 (where 91.4% of the phosphonomethyl groups exist as $-CH_2P(=O)O_2^{2+}$. This pH is not the optimum condition for the formation of the UO_2·**2** complex: see Fig. 2) the K_{uranyl} was estimated to be $10^{16.3}$ M^{-1}. This value is smaller by about three orders of magnitude than those for **1**$_5$ and **1**$_6$[7] (Table 1). Assuming that the $K_{carbonate}$ is scarcely affected at pH 10.3—11.6, we can calculate the K_{uranyl} at pH 11.5 (where 98.3% of the phosphonomethyl groups exist as $-CH_2P(=O)O_2^{2-}$. This pH is the optimum condition for the formation of the UO_2·**2** complex) to be $10^{17.5}$ M^{-1}. This value is smaller only by 1.2—1.7 pK units than those for the UO_2·**1** complexes.[7]

In conclusion, the present study demonstrated that the phosphate group serves as an excellent ligand for the complexation with UO_2^{2+}. We are currently devoting our research efforts toword the synthesis of calix[6]arene-based uranophiles bearing phosphonate groups

Table 1. Stability Constants (K_{uranyl}) for Calixarene-Based Uranophiles[a]

Calixarene	pH	log K_{uranyl}

on the lower rim.

Experimental

Materials. The synthesis of **2** was independently reported (as communications) by Almi et al.[15] and by us.[16]

37,38,39,40,41,42-Hexamethoxy-5,11,17,23,29,35-hexakis-(*O,O*-diethylphosphonomethyl)calix[6]arene (4). 37,38,39,40,41,42-Hexamethoxy-5,11,17,23,29,35-hexakis(chloromethyl)-calix[6]arene (910 mg; 0.90 mmol) was refluxed in triethyl phosphite (27 g; 160 mmol) for 14 h. After cooling, unreacted triethyl phosphite was distilled under reduced pressure. The residue was dissolved in chloroform and subjected to column chromatography (stationary phase, silica gel; mobile phase, chloroform–methanol (10 : 1 v/v)). The concentration of the eluent gave **4** in 96% yield; mp 149—151 °C; IR (neat) $\nu_{P=O}$ 1245 cm^{-1}, ν_{P-O-C} 960 and 1055 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (6H, t, C–CH_3), 2.75 (2H, d(J_{PH}=21 Hz), $ArCH_2P$), 3.43 (3H, s, OCH_3), 3.89 (2H, s, $ArCH_2Ar$), 3.94 (4H, dq(J_{PH}=7.3 Hz, J_{HH}=7.3 Hz), $POCH_2C$), 6.79 (2H, s, ArH). Found: C, 55.90; H, 7.60%. Calcd for $(C_{13}H_{19}O_4P)_6 \cdot 3H_2O$: C, 55.91; H, 7.22%.

37,38,39,40,41,42-Hexamethoxy-5,11,17,23,29,35-hexakis-(phosphonomethyl)calix[6]arene (2). Compound **4** (810 mg; 0.50 mmol) was refluxed in dioxane (10 ml)-concd HCl (10 ml) mixed solvent for 12 h. After cooling, the solution was evaporated to dryness under reduced pressure and the residue was recrystallized from ethanol–ether: Colorless powder, mp >300 °C, yield 82%; IR (nujol) ν_{OH} 3600 cm^{-1}, $\nu_{P=O}$ 1240 cm^{-1}, ν_{P-O-C} 1005 cm^{-1}; ^1H NMR (CD_3OD) δ=2.85 (2H, m, $ArCH_2P$), 3.01 (3H, s, OCH_3), 3.93 (2H, s, $ArCH_2Ar$), 6.91 (2H, s, ArH). Found: C, 48.23; H, 5.33%. Calcd for $(C_9H_{11}O_4P)_6 \cdot 3H_2O$: C, 48.44; H, 5.22%.

Determination of the Stability Constants. The stability constants for UO_2^{2+} were evaluated by a displacement method[17] at 25 °C. The details of the method were described previously.[7]

Potentiometric Titration. Potentiometric titration of **2** and **3** ([**2**]=5.00×10^{-3} M and [**3**]=2.00×10^{-2} M in 20 ml of 7.00×10^{-2} M HCl) was carried out at 25±0.5 °C by using an auto-titrator (Kyoto Electronics, Model APB-117). The details of the measurement conditions are described in a caption to Fig. 1.

Synopsis. The oxidation of *l*-2(10)-pinene with lead tetraacetate in glacial acetic acid at 60 °C afforded, besides fifteen known other products, (1*S*,6*S*)-7,7-dimethylbicyclo [4.1.1]octan-3-one (**2**) and (1*R*,6*S*)-2-one isomer (**3**), whose structures were established on the basis of their spectroscopic data. A possible reaction pathway for the formation of these new compounds **2** and **3** involving novel ring-enlargement is described.

One of us (Y. M.) and his co-worker[2)] have studied the lead tetraacetate oxidation of *l*-2(10)-pinene (**1**) by employing trilead tetraoxide in a mixture of acetic acid and acetic anhydride at 60 °C. Hydrolysis of the oily reactant with aqueous potassium hydroxide afforded six major products [mirtenol (**4**), 1-*p*-menthene-7,8-diol (**5**), *trans*- and *cis*-1(7),8-*p*-menthadien-2-ol (**6**,**7**), *trans*- and *cis*-1(7)-*p*-menthene-2,8-diol (**8**,**9**)] and nine minor products [*trans*-pino-carveol (**10**), α-terpineol (**11**), *n*-borneol (**12**), 1(7),4(8)-*p*-menthadien-2-ol (**13**), periryl alcohol (**14**), *p*-cymen-7-ol (**15**), carvacrol (**16**), 1,4(8)-*p*-menthadien-7-ol (**17**), 1,4(8)-*p*-menthadien-9-ol (**18**)]. All of the major products can easily be converted into periryl alcohol which is useful as flavor. Meanwhile, the lead tetraacetate oxidation was performed on other terpene hydrocarbons such as camphene[3)] and longifolene[4)] that have a terminal methylene group between a quaternary carbon and tertiary carbon. The oxidation was found to give ring-enlargement products (*R*-homocamphenilone and longi-homocamphenilone) in good yields.

If the terminal methylene group of *l*-2(10)-pinene (**1**) undergoes a similar ring-enlargement reaction, the corresponding products are expected to become highly important synthetic intermediates for preparation of β- and γ-thujaplicins.[5)] We wish to report herein our detailed reinvestigation on the oxidation of **1** with lead tetraacetate, which enabled us to isolate two unique ring-enlargement compounds.

When the trilead tetraoxide oxidation of *l*-2(10)-pinene (**1**) was carried out in glacial acetic acid alone at 60 °C for 2.5 h and then the reaction mixture was hydrolyzed, we found that two minor compounds (**2** and **3**) were produced beside the fifteen, already identified compounds[2)] **4**—**18** on the evidence of GLC and GC-MS analyses. Yields of these products based on GLC analysis are summarized in Table 1. Compounds **2** and **3** were purified by silica-gel column chromatography, followed by removal of alcoholic compounds by employing phthalic anhydride,[6)] and finally by the use of preparative GLC.

Compound **2** was a colorless oil, and its EI-MS showed the molecular ion peak at *m*/*z* 152. The molecular formula of **2** was found to be $C_{10}H_{16}O$ by HR-MS. The IR spectrum showed the presence of a carbonyl group (1697 cm^{-1}) and methylene group(s) (1470 and 1454 cm^{-1}) in compound **2**. The ^1H NMR spectrum of **2** exhibited two methyl proton signals at δ=0.75 and 1.28, but no signals due to terminal methylene protons. The complex signals at δ=1.75—2.90 in the spectrum were studied by examining the cross peaks of the 2D ^1H NMR (H–H COSY) and 2D ^{13}C NMR (C–H COSY) spectra, as well as by proton–proton decoupling experiments. The assignment of each proton signal was made as follows. First, the interrelations between carbon and proton signals were established by the analysis of the C–H COSY spectrum, thus disclosing that compound **2** consisted of one carbonyl group, one quaternary carbon, two methine groups, and four methylene groups (A, B, C, and D), besides the two methyl groups. Then, one of the methine protons (δ=2.06) was shown to have vicinal couplings with four protons of two methylene groups A (δ=1.79, 2.552) and B (δ=2.42, 2.61). Another methine proton (δ=2.20) had vicinal couplings with four protons of two methylene groups A and C (δ=1.82, 1.84). The latter methylene protons (C) were further coupled with two protons of another methylene group D (δ=2.550, 2.82). Therefore, combination of these NMR spectral data and the mode of the formation pathways (see later) has led to the structure, 7,7-dimethylbicyclo[4.1.1]octan-3-one, for compound **2**. The precise δ and *J* values of all proton signals, which have been confirmed by a computer-assisted simulation analysis, are shown in the Experimental section.

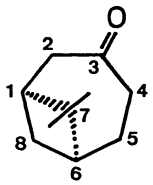
Table 1. Yield/% of the Oxidation Products from **1** with Trilead Tetraacetate[a)]

Product	Yield/%	Product	Yield/%
2	3	**11**	4
3	0.1	**12**	1
4	14	**13**	3
5	25	**14**	9
6	5	**15**	0.3
7	0.2	**16**	0.2
8	15	**17**	0.2
9	0.5	**18**	2
10	11	Others	6

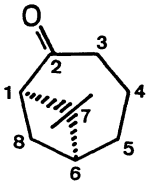
a) Yields (based on GLC analysis) represent the result of several runs of the same experiment.

Compound **3** was also a colorless oil, whose EI-MS showed the molecular ion peak at *m*/*z* 152. The molecular formula of **3** was identical with **2** ($C_{10}H_{16}O$, by HR-MS). The IR spectrum of **3** similarly showed the pres-

ence of a carbonyl (1687 cm^{-1}) and methylene groups (1469, 1455 cm^{-1}). The analysis of ^1H and ^{13}C NMR spectra (including their 2D NMR) of compound **3** was carefully made in a manner similar to the case of **2**. It was noted that the methine proton signal at lower field (δ=2.68) showed vicinal couplings only with two, methylene protons (δ=1.96, 2.46) besides a long-range coupling with another methine proton (δ=2.25); this indicated the position of the carbonyl group adjacent to the former methine group. As a result, the isomeric structure, 7,7-dimethylbicyclo[4.1.1]octan-2-one, is assigned to **3**. The δ and J values of all signals for compound **3** are shown in the Experimental section.



2



3

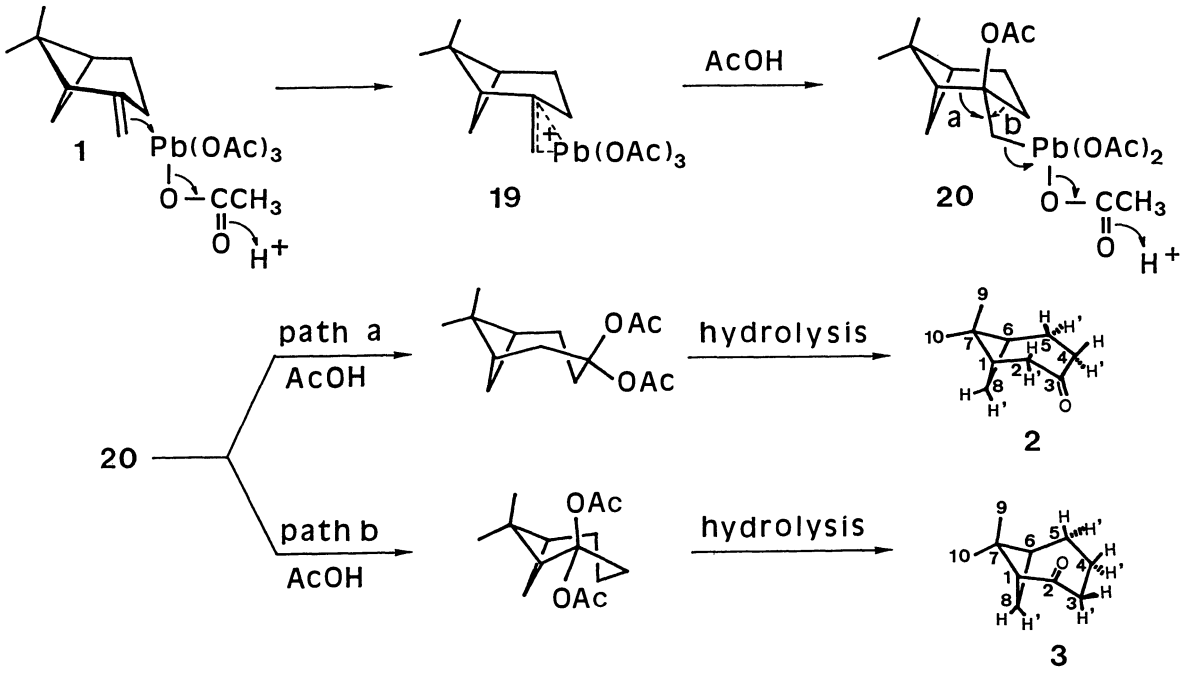
The most likely pathways for the formation of compounds **2** and **3** from **1** are illustrated in Scheme 1. The initial lead intermediate **19** is presumed to undergo a heterolytic cleavage accompanied by two, competitive 1,2-anionotropic shifts (path 'a' and 'b' in **20**).[7] The relative yield between **2** and **3** suggests a predominant migration of the tertiary carbon (C_1) (path 'a') compared with that of the secondary carbon (C_3) (path 'b') of intermediate **20**. Because no inversion of the configuration of the bridge-head carbon (C_1) in **20** is considered to take place, the absolute configuration of compounds **2** and **3** are assigned to be (1*S*,6*S*) and (1*R*,6*S*), respectively, as shown in the formulas.[8]

Experimental

Commercially available *l*-2(10)-pinene (**1**) was washed with dilute aq Na_2CO_3, then with water, and dried (Na_2SO_4). This was distilled through a spinning band precision distillation column under a reduced pressure to provide freshly distilled **1**: Bp 70—75 °C/111 mmHg (1 mmHg=133.322 Pa), n_D^{25}=1.4715, d_4^{25}=0.8722, $[\alpha]_D^{25}$=−18.6° (neat) [lit,[9] $[\alpha]_D$=−22.1° (neat) for (1*S*,5*S*) form].

Column chromatography was performed with Wako C-300 silica-gel. Preparative GLC was carried out with a Yanaco G1800 gas liquid chromatograph system equipped with a TCD (thermal conductivity detector) and PEG 20M steel column (ϕ 3 mm×5 m). GLC analysis was conducted with a Yanaco G2800 gas liquid chromatograph system equipped with a HFID (hydrogen flame ionization detector) and PEG 20M glass capillary column (ϕ 0.28 mm×20 m, column temp. 60—180 °C/2 °C min^{-1}). Optical rotations were measured with a JASCO DIP-140 spectrophotometer. IR spectra were taken on a JASCO IR-A-202 Grating spectrometer. Mass spectra were taken on a JEOL JMS-HX100 (with a JEOL JMA-DA5000 mass data system) high-resolution instrument and are given in terms of m/z (rel intensity) compared with the base peak. NMR spectra were recorded in $CDCl_3$ with a JEOL GX-500 (500 MHz for ^1H and 125 MHz for ^{13}C) at 27 °C. The assigments of all signals were made by employing a first-order analysis with the aid of decoupling, H–H COSY and C–H COSY techniques, and the parameters were confirmed by a computer-assisted simulation analysis.

Oxidation of *l*-2(10)-Pinene (1) with Lead Tetraacetate. A solution of **1** (136 g, 1.0 mol) in glacial acetic acid (1.8 l) was stirred at 60±2 °C. Trilead tetraoxide (690 g, 1.0 mol) was slowly added to the above solution during a period of 90 min and the stirring was continued for further 1 h. The reactant was carefully neutralized with aq Na_2CO_3. The precipitated solid of $PbCO_3$ was removed by filtration and the filtrate was extracted with hexane (3×1 l). The combined extracts were washed with water, dried (Na_2SO_4), and evaporated in vacuo to give an almost colorless oil (145.9 g): n_D^{25}=1.4676, d_4^{25}=1.0012, $[\alpha]_D^{22}$=−47.1° (neat), EV (ester value)=324. Hydroly-



Scheme 1. Possible reaction pathways for the formation of **2** and **3**.

sis of the reactant oil was performed by following a general method,[2] affording hydrolytic products (107.9 g). Their structures were confirmed by comparing the GLC and GC-MS data with those of the authentic samples **4**—**18**.[2] The yields of these compounds based on GLC analysis are summarized in Table 1. The new minor products **2** and **3** were carefully separated by silica-gel column chromatography, followed by removal of alcoholic compounds by employing phthalic anhydride,[6] and then preparative GLC.

Stepwise Reduction of Acetals to the Corresponding Hydrocarbons. A Mild and Effective Transformation via Carbinyl Bromides

Takeshi ORIYAMA,* Yuichi ICHIMURA, and Gen KOGA
Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo, Mito 310
(Received March 15, 1991)

Synopsis. Stepwise reduction of two alkoxyl groups in acetal was effected by the action of triethylsilane along with acetyl bromide and $SnBr_2$ and then of tributyltin hydride (or lithium aluminium hydride) providing methyl or methylene compounds in good yields under very mild conditions.

The dealkoxylation of aldehyde- or ketone-acetals to the corresponding methyl or methylene compounds is one of the reactions of potential usefulness in organic synthesis. Although a methodology similar to this transformation via dithioacetals has been well-established,[1] dealkoxylative reduction of dialkyl acetals usually leads to the mono-dealkoxylated products[2] which are sluggish to further reduction.[3]

Now we wish to report a mild and convenient procedure to effect stepwise reduction of two alkoxyl groups in acetals to give the corresponding methyl or methylene compounds.

Our previous investigation[4] on the halogenative reduction of acetals to corresponding carbinyl halides with triethylsilane promoted by SnX_2/AcX[5] suggested that the subsequent reduction of thus obtained halides to alkanes would provide a two-step conversion of acetals to alkanes, which would constitute a mild and convenient alternative to Wolff-Kizhner[6] or Clemmensen reduction[7] of the parent carbonyl compounds.

In the first place, we undertook to examine the reduction of 1-naphthaldehyde dimethyl acetal to 1-methylnaphthalene. First reduction of acetal to 1-bromomethylnaphthalene was carried out according to the procedure described in the previous paper.[4] Subsequent reduction of the bromide to 1-methylnaphthalene was effected by tributyltin hydride in benzene. The two-step conversion either with or without the purification of the intermediate, 1-bromomethylnaphthalene, invariably afforded 1-methylnaphthalene in 85% overall yield. A one-pot operation with an intermediary manipulation for solvent exchange has proved to be satisfactory enough with a minimal loss of yield (77% overall). While the tin hydride reduction for the second step is most mild and effective, less selective lithium aluminium hydride may also be employed as an alternative reagent of choice in cases where the radical reduction is hampered by undesirable side reactions.

The reaction was conducted with various acetals under the optimum conditions and the results are summarized in Table 1. Higher yields were obtained in the cases of aromatic aldehyde acetals (Entries 1—7). Ketone acetals also gave the corresponding methylene compounds in good yields (Entries 9—14). In the case of aliphatic ketone acetals, a small amount of olefin (9—25%) was obtained as a by-product (Entries 12, 13, and 14). The reaction was also effective to ethylene acetal to result in the corresponding hydrocarbon (Entries 3 and 11).

a) All the products gave satisfactory ^{1}H NMR and IR spectra. b) Isolated yield from acetal. c) $Sn(OTf)_2$ was used in place of $SnBr_2$. d) 1.3-Diphenylpropene was obtained in 9% yield. e) 1-Phenyl-2-butene was obtained in 25% yieid. f) 4-Phenylcyclohexene was obtained in 14% yield.

Experimental

Followings are the typical procedures for the reduction of 1-naphthaldehyde dimethyl acetal.

Method A: To a suspension of tin(II) bromide (6.9 mg, 0.02 mmol) and 1-naphthaldehyde dimethyl acetal (135 mg, 0.67 mmol) in dichloromethane (2 ml) were added triethylsilane (107 mg, 0.92 mmol) in dichloromethane (1.5 ml) and acetyl bromide (187 mg, 1.52 mmol) in dichloromethane (1.5 ml), successively at ice-bath temperature under argon atmosphere. The mixture was stirred for 1.5 h at this temperature and quenched with a phosphate buffer (pH 7). The organic materials were extracted with dichloromethane, dried over Na_2SO_4, and evaporated to leave the crude 1-bromomethylnaphthalene as an oil. The crude bromide was dissolved into benzene (3 ml) and *n*-Bu_3SnH (304 mg, 1.04 mmol) and a catalytic amount of azobisisobutyronitrile was added to it. After the mixture was refluxed for 30 min, the solvent was evaporated and 1-methylnaphthalene (80.7 mg, 85%) was isolated from the residue by thin layer chromatography over silica gel.

Method B: First step reduction was the same as that of Method A. To a suspension of $LiAlH_4$ (36.2 mg, 0.95 mmol) in THF (1 ml) was added a THF (4 ml) solution of the crude bromide from 1-naphthaldehyde dimethyl acetal (128 mg, 0.63 mmol). The mixture was stirred for 2.5 h. The reaction was quenched with a phosphate buffer (pH 7), and the precipitates were removed by Celite filtration. The organic materials were extracted with Et_2O and dried over $MgSO_4$. Filtration and concentration in vacuo gave an oily residue which was purified by thin layer chromatography over silica gel to afford 1-methylnaphthalene (74.9 mg, 84% from acetal).

One-Pot Operation: After completion of first-step reduction of acetals, solvents and volatile materials were removed from reaction flask using water-jet aspirator. The resultant residue was dissolved into benzene and subjected to the second-step reduction as described in the method A procedure.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 02854053 from the Ministry of Education, Science and Culture.

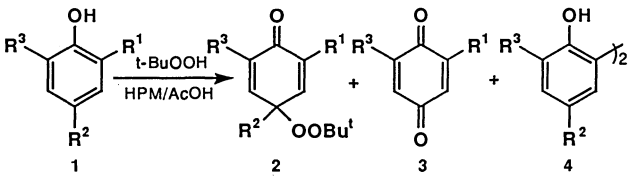
The Oxidation of *p*-Substituted Phenols Using a *t*-Butyl Hydroperoxide–Heteropolyacid System

Masao SHIMIZU,* Hideo ORITA, Takashi HAYAKAWA, Yoshihito WATANABE, and Katsuomi TAKEHIRA*
National Chemical Laboratory for Industry, Tsukuba Research Center, Tsukuba, Ibaraki 305
(Received March 13, 1991)

Synopsis. The oxidation of *p*-substituted phenols with *t*-BuOOH in the presence of heteropolyacids was carried out. 4-*t*-Butylperoxy-2,5-cyclohexadien-1-ones were obtained in good yields by the oxidation of 2,4,6-trialkylsubstituted phenols in this oxidation system.

Heteropolyacids are useful catalysts for the oxidation of hydrocarbons since they possess both oxidizing ability and acid catalyst center.[1] Hydrogen peroxide oxidation of various organic substrates has been done by use of heteropolyacid as catalyst[2] since aqueous hydrogen peroxide is inexpensive, environmentally clean, and easy to handle. Meanwhile, it is well-known that *t*-butyl hydroperoxide is also a convenient oxidizing agent, especially for highly selective oxygenation of olefins and acetylenes.[3] However, there have been few reports on the oxidation with *t*-butyl hydroperoxide catalyzed by heteropolyacids. It was reported that secondary alcohols were selectively oxidized to ketones using a *t*-BuOOH–hexadecylpyridinium molybdophosphate system.[4]

We previously reported that 2,6-di-*t*-butyl-4-hydroperoxy-4-methyl-2,5-cyclohexadien-1-one was determined as an intermediate in the oxidation of 2,6-di-*t*-butyl-4-methylphenol to 2,6-di-*t*-butyl-*p*-benzoquinone with a H_2O_2–heteropolyacid system.[5] Here, we report the oxidation of several *p*-substituted phenols with a *t*-BuOOH–heteropolyacid system.



HPM=$H_3PMo_{12}O_{40}\cdot nH_2O$

Results and Discussion

When 2,6-di-*t*-butyl-4-methylphenol (**1a**) was stirred with 80% *t*-butyl hydroperoxide in the presence of 12-molybdophosphoric acid at 30 °C in acetic acid for 5 h, 2,6-di-*t*-butyl-4-*t*-butylperoxy-4-methyl-2,5-cyclohexadien-1-one (**2a**) was obtained in 44% yield. This product is analogous to the compound obtained in the oxidation of **1a** with the H_2O_2–heteropolyacid system.[5] 2,6-Di-*t*-butyl-*p*-benzoquinone (**3a**) was also obtained in 9% yield as a by-product. The oxidations of **1a** with *t*-butyl hydroperoxide were carried out using other heteropolyacid as catalyst (Table 1). Molybdic compounds showed higher catalytic activities than tungstic ones. Although carboxylic acids such as acetic and propionic acids were employed as a solvent to afford **2a** in good yields, the oxidation did not proceed efficiently in alcohols such as methanol and ethanol; this tendency is similar to that obtained with the H_2O_2–heteropolyacid system.[5]

Table 1. Oxidation of **1a** Using *t*-BuOOH–Heteropolyacid[a]

Catalyst	Conv./%	Yield/%	
		2a	**3a**
$H_3PMo_{12}O_{40}\cdot nH_2O$	99.0	47.9	8.6
$H_3PW_{12}O_{40}\cdot nH_2O$	46.7	26.2	0.8
$H_4SiMo_{12}O_{40}\cdot nH_2O$	99.9	41.6	9.3
$H_4SiW_{12}O_{40}\cdot nH_2O$	58.1	27.4	3.3
H_2MoO_4	17.1	14.1	—
None	17.5	17.1	—

a) Reaction conditions: **1a**, 2 mmol; *t*-BuOOH (80%), 1 ml; catalyst, 100 mg; AcOH, 10 ml; 30 °C, 5 h.

Table 2. Oxidation of Phenols Using *t*-BuOOH–Heteropolyacid[a]

	R^1	R^2	R^3	Yield/%

c	*t*-Bu	Me	Me	33.5	11.5	—
d	H	*t*-Bu	*t*-Bu	—	—	26.3
e	H	Me	*t*-Bu	—	—	3.9
f	*t*-Bu	$AcOCH_2$	*t*-Bu	—	64.9	—
g	*t*-Bu	MeO	*t*-Bu	—	91.2	—

a) Reaction conditions: phenol, 2 mmol; *t*-BuOOH (80%), 1 ml; $H_3PMo_{12}O_{40}\cdot nH_2O$, 100 mg; AcOH, 10 ml; 30 °C, 3 h.

When 2,4,6-trialkylsubstituted phenols were oxidized with the *t*-BuOOH–heteropolyacid system, peroxides were obtained as main products (Table 2). However, the quinone (**3a**) became as a main product when the phenols which have more eliminative substituents than methyl group on the para positions, such as **1f** and **1g**, were treated with *t*-butyl hydroperoxide. In the reactions of 2,4-disubstituted phenols, no peroxide formed but dimerized products at the ortho position of the phenol rings were obtained.

From the above results, the oxidation mechanism is considered as follows. When the 6-unsubstituted phenols were oxidized in the *t*-BuOOH–heteropolyacid system, the corresponding dimers were formed. This result suggests that the oxidations proceed by way of phenoxyl radical intermediates. Although two 6-unsubstituted phenols couple each other at the ortho position of the phenol rings to afford dimers, 2,4,6-trisubstituted phenols are difficult to dimerize due to

sterical hindrance. The radicals generated from the 2,4,6-trisubstituted phenols react with *t*-butyl hydroperoxide at the para position of the phenyl rings to afford the peroxides. *p*-Benzoquinones were formed by decomposition of the peroxides. A similar reaction mechanism from the peroxide to the *p*-benzoquinone under acidic conditions was reported.[6] As previously reported,[5] a 4-hydroperoxy-2,5-cyclohexadien-1-one was obtained as a main product from 2,6-di-*t*-butyl-4-methylphenol with H_2O_2–heteropolyacid oxidation system. It seems that the first step of the phenol oxidation with the H_2O_2–heteropolyacid system is similar to that with the present system.

Consequently, 4-*t*-butylperoxy-2,5-cyclohexadien-1-ones were obtained in good yield by the oxidation of 2,4,6-trialkylsubstituted phenols with the *t*-BuOOH–heteropolyacid system. Cobalt(II) salts have usually been used as catalyst for synthesis of the peroxide. This is one of rare examples of peroxide synthesis with other metal species than cobalt as catalyst.[7]

Experimental

Melting points were determined on a Yanagimoto micro-melting apparatus. ^{1}H NMR spectra were recorded on a Hitachi R-40 High Resolution NMR Spectrometer (90 MHz). IR spectra were recorded on a JASCO FT/IR-7000 Fourier Transfer Infrared Spectrometer. Gas chromatograph analyses were performed on a Shimadzu GC-7A gas chromatograph using a Thermon 3000 column. *t*-Butyl hydroperoxide (about 80% solution in di-*t*-butyl peroxide, Merck-Schuchardt) was used without further purification.

General Procedure for the Oxidation of a Phenol Using a *t*-BuOOH–Heteropolyacid System. *t*-Butyl hydroperoxide (2 ml) was added dropwise to a solution of a phenol (2 mmol) and a catalyst (100 mg) in acetic acid (10 ml). The reaction mixture was stirred at 30 °C under nitrogen atmosphere. Water was added to the solution and products were extracted with dichloromethane three times. The organic layer was washed with water and dried over anhydrous magnesium sulfate. Yields of the products were determined by an internal standard technique using the GC method for **2a**, and by isolation for the others.

2,6-Di-*t*-butyl-4-*t*-butylperoxy-4-methyl-2,5-cyclohexadien-1-one (2a). The crude product was chromatographed on silica gel using benzene–hexane (1 : 3) mixture as eluent. The product was recrystallized from hexane; mp 84—85 °C (lit,[6] mp 85.5—86.5 °C). ^{1}H NMR ($CDCl_3$) δ=1.15 (s, 9H), 1.22 (s, 18H), 1.30 (s, 3H), 6.55 (s, 2H); IR (KBr) 1665, 1644, 1364, 1247, 1199, 1162, 1058, 884, 872 cm^{-1}.

4-*t*-Butylperoxy-2,4,6-trimethyl-2,5-cyclohexadien-1-one (2b). The crude product was chromatographed on silica gel using dichloromethane as eluent. Bp 28 °C (1.33 Pa); ^{1}H NMR ($CDCl_3$) δ=1.17 (s, 9H), 1.33 (s, 3H), 1.86 (s, 6H), 6.57 (s, 2H); IR ($CHCl_3$) 1680, 1640, 1450, 1365, 1065, 909 cm^{-1}. Found: C, 69.96; H, 9.11%. Calcd for $C_{13}H_{20}O_3$: C, 69.64; H, 8.93%.

2-*t*-Butyl-4-*t*-butylperoxy-4,6-dimethyl-2,5-cyclohexadien-1-one (2c). The crude product was chromatographed on silica gel using benzene as eluent. Bp 35 °C (1.33 Pa); ^{1}H NMR ($CDCl_3$) δ=1.17 (s, 9H), 1.22 (s, 9H), 1.32 (s, 3H), 1.83 (s, 3H), 6.60 (m, 2H); IR ($CHCl_3$) 1644, 1458, 1360, 1065, 903 cm^{-1}. Found: C, 72.78; H, 10.04%. Triethylborane Induced Selective 1,4-Reduction of α,β-Unsaturated Carbonyl Compounds with Triphenyltin Hydride or Tributyltin Hydride

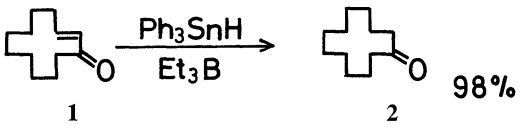
Kyoko NOZAKI, Koichiro OSHIMA,* and Kiitiro UTIMOTO*
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received April 5, 1991)

Synopsis. Reduction of α,β-unsaturated ketones and esters with triphenyltin hydride or tributyltin hydride in the presence of triethylborane has been studied. Whereas the reaction of α,β-unsaturated ketones ($R^1CH=CHCOR^2$) with triphenyltin hydride provided the corresponding saturated ketones ($R^1CH_2CH_2COR^2$), treatment of α,β-unsaturated ester (PhCH=CHCOOMe or $CH_3CH=CHCOO$-n-C_6H_{13}) afforded an adduct ($PhCH_2CH(SnPh_3)COOMe$ or $CH_3CH(SnPh_3)CH_2COO$-n-C_6H_{13}).

1,4-Selective reduction of α,β-unsaturated carbonyl compounds has been achieved by triphenyltin hydride in refluxing toluene.[1] Recently we have reported that triethylborane induced a facile addition of triphenyltin hydride to an acetylenic bond to give alkenylstannane effectively.[2] The reaction proceeded at low temperature compared with the conventional method which uses azobisisobutyronitrile or peroxide as a radical initiator. Taking this advantage, we applied our method to the title reaction and found that selective reduction of α,β-unsaturated carbonyl compounds to saturated carbonyl compounds proceeded efficiently by treatment with triphenyltin hydride or tributyltin hydride in benzene at 25 °C.

Treatment of a benzene solution of 2-cyclododecenone **1** and Ph_3SnH with Et_3B at 25 °C for 6 h



1 **2**

Scheme 1.

provided cyclododecanone **2** in 98% yield (Scheme 1). The other representative results are shown in Table 1.

The reduction of β-ionone (**3**) provided α,β-unsaturated ketone **4** in 88% yield selectively and no 1,6-reduction product was observed in the reaction mixture (Entry 7 in Table 1). α,β-Unsaturated aldehyde was converted into saturated aldehyde in good yield which was exemplified by the reduction of citral (**5**) (Entry 8 in Table 1). Over-reduction of 3,7-dimethyl-6-octenal (**6**) into alcohol (3,7-dimethyl-6-octen-1-ol) was not observed because of the mildness of the reaction conditions.[3] An alkynone such as 3-octyn-2-one was reduced to 2-octanone in 50% yield with 4 equivalents of Ph_3SnH.

The use of less than 2 equivalents of triphenyltin hydride resulted in an incompletion of the reduction. However, the amount of triethylborane could be reduced to catalytic amount without decrease of the

Table 1. 1,4-Reduction of α,β-Unsaturated Ketones with Ph_3SnH[a]

Entry	Unsaturated ketone	Reaction time/h	Product	Yield/%

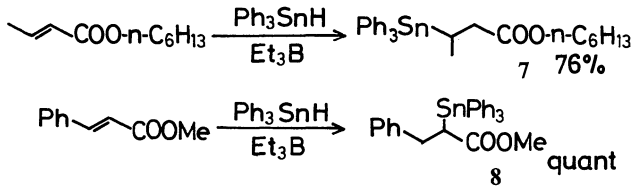
a) Triethylborane (2.2 mol), triphenyltin hydride (2.2 mol), and α,β-unsaturated ketones (1.0 mol) were empolyed. b) GLPC yields. c) Triphenyltin hydride (4.0 mol) was employed.

yield of saturated ketones. For instance, an addition of catalytic amount of triethylborane (0.1 mmol) to a solution of 2-cyclohexenone (1.0 mmol) and triphenyltin hydride (2.2 mmol) provided cyclohexanone in 77% yield after stirring for 3 h at 25 °C. Tributyltin hydride could be used instead of triphenyltin hydride and the reaction of 2-cyclododecenone with tributyltin hydride in the presence of triethylborane gave cyclododecanone in 98% yield after 7 h at 25 °C.

We are tempted to assume following reaction mechanism: (1) Triphenyltin hydride or tributyltin hydride adds to α,β-unsaturated ketones ($R^1CH=CHCOR^2$) in 1,4-fashion to give $R^1CH_2CH=CR^2$ ($OSnR_3$) (R=Ph or *n*-Bu) and (2) subsequent hydrogenolysis with second triphenyltin hydride or tributyltin hydride to provide saturated ketones and $R_3Sn-SnR_3$ (R=Ph or *n*-Bu).

Treatment of α,β-unsaturated ester with triphenyltin hydride in the presence of triethylborane gave β-triphenylstannyl or α-triphenylstannyl carboxylic ester (**7** or **8**) in contrast to the reaction of α,β-unsaturated ketones (Scheme 2). Triphenylstannyl radical attacked β-carbon of hexyl crotonate to give a carbon radical $Ph_3SnCH(Me)\dot{C}HCOO$-*n*-C_6H_{13} which abstracted hydrogen from Ph_3SnH to form the product. In contrast, triphenylstannyl radical attacked α-carbon of methyl cinnamate to provide a carbon radical $Ph\dot{C}HCH(SnPh_3)COOMe$ because phenyl group stabilizes an adjacent carbon radical more effectively than carboalkoxy group.[5] The reaction of tributyltin hydride in place of triphenyltin hydride with α,β-unsaturated ester was sluggish and resulted in an incompletion.[6-8] Treatment of PhCH=CHCOOMe with tributyltin hydride in the presence of triethylborane provided $PhCH_2CH(Sn$-*n*-$Bu_3)COOMe$ in 50% yield along with recovered starting material (10%) and saturated ester, $PhCH_2CH_2COOMe$ (10%). The reaction of $CH_3CH=CHCOO$-*n*-C_6H_{13} with tributyltin hydride gave β-tributylstannylated ester, $CH_3CH(Sn$-*n*-$Bu_3)CH_2COO$-*n*-C_6H_{13} in 15% yield along with starting ester (47%).



Scheme 2.

In conclusion, the coexistence of triethylborane facilitate the reduction of α,β-unsaturated ketones into saturated ketones with triphenyltin hydride or tributyltin hydride. The reduction proceeded under mild conditions (25 °C) compared with the conventional methods which require high reaction temperature (100—150 °C).

Experimental

Analytical gas chromatography (GLPC) was performed with a Shimadzu gas chromatograph, Model GC-8A using thermal conductivity detector and helium as carrier gas. ^1H NMR and ^{13}C NMR spectra were taken on a Varian XL-200 spectrometer, $CDCl_3$ was used as solvent and chemical shifts were given in δ with tetramethylsilane as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer. The elemental analyses were carried out at the Elemental Analysis Center of Kyoto University.

General Procedure for the Reduction of α,β-Unsaturated Ketones with Triphenyltin Hydride. The reduction of 2-cyclododecenone is representative. A hexane solution of triethylborane[4] (1.0 M, 1 M=1 mol dm^{-3}, 2.2 ml, 2.2 mmol) was added to a solution of 2-cyclododecenone (0.18 g, 1.0 mmol) and triphenyltin hydride (0.77 g, 2.2 mmol) in benzene (10 ml) at 25 °C under argon atmosphere. After stirring for 6 h at 25 °C, the reaction mixture was concentrated and the residue was submitted to silica-gel column chromatography using hexane–ethyl acetate (10 : 1) as an eluant to give cyclododecanone (0.18 g) in 98% yield

Reduction of 2-Cyclohexenone with Triphenyltin Hydride. A hexane solution of triethylborane (1.0 M, 2.2 ml, 2.2 mmol) was added to a solution of 2-cyclohexenone (96 mg, 1.0 mmol) and triphenyltin hydride (0.77 g, 2.2 mmol) in benzene (10 ml) at 25 °C under argon atmosphere. After stirring for 3 h at 25 °C, nonane (90 mg, 0.85 mmol) was added to the resulting mixture. The yield of cyclohexanone was determined by GLPC (OV-1 2% on Chromosorb W AW DMCS 60—80 mesh, 2 m, 65 °C, cyclohexanone: t_r=2.54 min, nonane: t_r=3.35 min).

The Reaction of α,β-Unsaturated Ester with Triphenyltin Hydride. The reaction of hexyl crotonate with triphenyltin hydride is a typical example. A hexane solution of triethylborane (1.0 M, 2.2 ml, 2.2 mmol) was added to a solution of hexyl crotonate (0.17 g, 1.0 mmol) and triphenyltin hydride (0.77 g, 2.2 mmol) in benzene (10 ml) at 25 °C under argon atmosphere. The reaction mixture was stirred for 3 h at 25 °C and concentrated in vacuo. The residual oil was submitted to silica-gel column chromatography to give hexyl 3-triphenylstannylbutanoate (**7**, 0.39 g) in 76% yield as a colorless oil: IR (neat) 3062, 2954, 2926, 2856, 1725, 1481, 1459, 1428, 1351, 1294, 1190, 1147, 1074, 909, 727, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.87 (t, *J*=6.6 Hz, 3H), 1.05—1.70 (m, 8H), 1.42 (d, *J*=7.4 Hz, 3H), 2.32 (m, 1H), 2.67 (dd, *J*=12.0, 7.0 Hz, 1H), 2.73 (dd, *J*=16.0, 7.0 Hz, 1H), 3.88 (t, *J*=6.7 Hz, 2H), 7.35—7.56 (m, 9H), 7.56—7.83 (m, 6H); ^{13}C NMR ($CDCl_3$) δ=13.99, 18.27, 19.04, 22.50, 25.50, 28.43, 31.38, 39.97, 64.68, 128.4, 128.7, 137.3, 138.8, 173.9. Found: C, 64.79; H, 6.70%. Calcd for $C_{28}H_{34}O_2Sn$: C; 64.52; H, 6.57%.

Methyl 3-Phenyl-2-triphenylstannylpropanoate (8): Mp 94.5—95.5 °C; IR (KBr) 3055, 2948, 1720, 1425, 1303, 1202, 1145, 1078, 1040, 995, 830, 765, 740, 720, 698 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.03 (dd, *J*=13.8, 4.7 Hz, 1H), 3.27 (s, 3H), 3.31 (dd, *J*=9.8, 4.7 Hz, 1H), 3.49 (dd, *J*=13.8, 9.8 Hz, 1H), 7.05—7.70 (m, 20H); ^{13}C NMR ($CDCl_3$) δ=34.15, 36.33, 50.85, 126.2, 128.4, 128.6, 129.4, 136.7, 137.1, 137.4, 141.6. Found: C, 65.25; H, 5.16%. Calcd for $C_{28}H_{26}O_2Sn$: C, 65.53; H, 5.11%.

Reduction of Methyl Cinnamate with Tributyltin Hydride. A hexane solution of triethylborane (1.0 M, 2.2 ml, 2.2 mmol) was added to a solution of methyl cinnamate (0.16 g, 1.0 mmol) and tributyltin hydride (0.64 g, 2.2 mmol) in benzene (10 ml) at 25 °C under argon atmosphere. After stirring for 15 h at 25 °C, the resulting mixture was concentrated in vacuo. The residual oil was submitted to silica-gel column chromatography using hexane–ethyl acetate (10 : 1) as an eluant to give methyl 3-phenyl-2-tributylstannylpropanoate (0.23 g, 50%) and methyl 3-phenylpropanoate (16 mg, 10%) along with recovered methyl cinnamate (16 mg, 10%). Following the literature,[8] a solution of 3-phenyl-2-tributylstannylpropanoate (0.23 g, 0.5 mmol) and benzoic acid (0.12 g, 1.0 mmol) was heated at reflux for 3 h to give methyl 3-phenylpropanoate (65 mg, 80%).

Reduction of Hexyl Crotonate with Tributyltin Hydride. A hexane solution of triethylborane (1.0 M, 2.2 ml, 2.2 mmol)

was added to a solution of hexyl crotonate (0.17 g, 1.0 mmol) and tributyltin hydride (0.64 g, 2.2 mmol) in benzene (10 ml) at 25 °C under argon atmosphere. After stirring for 15 h at 25 °C, the resulting mixture was concentrated. The residual oil was submitted to silica-gel column chromatography to give hexyl 3-tributylstannylbutanoate (68 mg, 15% yield) along with recovered hexyl crotonate (80 mg, 47%). Hexyl 3-tributylstannylbutanoate: Bp 110—120 °C (2 Torr, 1 Torr=133.322 Pa, bath temp); IR (neat) 2954, 2924, 2854, 1732, 1459, 1377, 1288, 1185, 1134, 1072 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.77—0.91 (m, 18H), 1.16—1.65 (m, 24H), 2.41—2.50 (m, 2H), 4.05 (t, J=6.8 Hz, 2H); ^{13}C NMR ($CDCl_3$) δ=8.33, 13.69, 13.98, 14.95, 18.68, 22.52, 25.60, 27.54, 28.63, 29.23, 31.42, 40.37, 64.43, 174.3. Found: C, 57.14; H, 10.27%. Calcd for $C_{22}H_{46}O_2Sn$: C, 57.28; H, 10.05%.

Acid-Induced Dimerization Reactions of *N*-(Diphenylphosphinyl)-2-propenimines Leading to Pyridine Derivatives

Hidetaka KAKIUCHI, Tomoshige KOBAYASHI,* and Hiroshi KATO*
Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
(Received April 6, 1991)

Synopsis. Treatment of *N*-(diphenylphosphinyl)-3-aryl-1-phenyl-2-propenimines with *p*-toluenesulfonic acid in heated xylene provided 4-aryl-2,6-diphenylpyridines and 4-aryl-3-arylmethyl-2,6-diphenylpyridines via an unprecedented dimerization reaction of the 2-propenimine.

Previously, we described on the reactions of the *N*-phosphinyl-1-azaallyl anions, generated from the corresponding *N*-phosphinyl imine and enamine, with α,β-unsaturated carbonyl compounds[1] or aromatic aldehydes[2] to afford pyridine derivatives. We also reported on the synthesis of *N*-(diphenylphosphinyl)-1,3-diphenyl-2-propenimine (**1a**) and its chemical behavior under basic conditions.[2] In contrast to simple *N*-phosphinyl imines,[3] little is known on the chemical properties of the *N*-phosphinyl-2-propenimines which are supposed to be rather electron-deficient 1-azadienes, except for the aza-Diels–Alder reaction under high pressure.[4] In this note, we describe on the acid-induced reaction of the *N*-phosphinyl-2-propenimines **1a—d** giving pyridine derivatives.

Results and Discussion

The imine **1a** was treated with a catalytic amount of anhydrous *p*-toluenesulfonic acid in refluxing xylene to give 2,4,6-triphenylpyridine (**2a**) and 3-benzyl-2,4,6-triphenylpyridine (**3a**). Similar reactions with the imines **1b** and **1c** provided 3-aryl-2,6-diphenylpyridines (**2b** and **2c**) and 4-aryl-3-arylmethyl-2,6-diphenylpyridines (**3b** and **3c**). In these reactions, the presence

a) Undepressed on admixture with authentic specimens.[2] b) Detected by GLC analyses. c) Isolated as the corresponding 2,4-dinitrophenylhydrazone.

of aromatic aldehydes **4a—c** originating from the 3-aryl substituents of the imines **1a—c** was observed by GLC analysis. The reaction with the *p*-dimethylamino derivative **1d** afforded the pyridine **2d** and *p*-(dimethylamino)benzaldehyde (**4d**), identified as the corresponding 2,4-dinitrophenylhydrazone, but the (arylmethyl)pyridine **3d** was not isolated. The yields of the products are summarized in Table 1.

Some control experiments were conducted to clarify the mechanistic aspect of the present reaction. The use of an acid is essential for the present transformation, because the imine **1a** was quantitatively recovered when heated in xylene in the absence of *p*-toluenesulfonic acid. In the presence of water, the reaction of **1a** with *p*-toluenesulfonic acid gave the pyridine **2a** and the 1,3-diphenyl-2-propenone in 26 and 34% yield, respectively, and the benzylpyridne **3a** was not obtained. Thus, the present transformation can be best explained by the mechanism as shown in Fig. 2. The initial step would be an acid-catalyzed dimerization of the imine **1** giving an intermediate **5**, which would react with a trace amount of water to afford **6**. Elimination of the aldehydes **4** and diphenylphosphinic amide from **6** leads to the pyridines **2** via the dihydropyridines **7**. On the other hand, the formation of the (arylmethyl)pyridines **3** can be ascribed to a sequence of deprotonation, elimination of the phosphorus moieties, and isomerization. Although the reason why the (arylmethyl)pyridine **3d** was not formed in the reaction of **1d** is ambiguous, the *p*-dimethylamino group may stabilize the cationic intermediate **5** and facilitate its reaction with water prior to its deprotonation.

Although two examples of dimerization reactions of 2-propenimines giving pyridines and pyrimidines have been reported,[5,6] the reaction described above seems to be an unprecedented type of dimerization reaction of the 2-propenimines.

Synthesis of Dimethyl 1,2-Cycloalkanedicarboxylates by Electrochemical Cyclization of Dimethyl α,α′-Dibromoalkanedioates Using a Copper Anode

Masao TOKUDA,* Atsushi HAYASHI, and Hiroshi SUGINOME*
Department of Chemical Process Engineering, Faculty of Engineering, Hokkaido University, Sapporo 060
(Received April 6, 1991)

Synopsis. The electrochemical cyclization of dimethyl α,α′-dibromoalkanedioates by making use of a platinum cathode and a copper anode in the presence of sodium iodide gave three- to six-membered dimethyl 1,2-cycloalkanedicarboxylates in good yields.

The electrochemical reductive cyclization of 1,3-dihalides has been proved to be useful for the preparation of cyclopropanes, bicyclobutanes, or spiropentanes.[1,2] The electroreductive cyclization of 1,4-dihalides has also been reported to give cyclobutane rings.[1] The preparation of higher-membered cycloalkanes by the electrochemical reduction of α,ω-dihalides, however, was not successful until we found that the electroreductive cyclization of α,ω-dibromides carrying alkoxycarbonyl groups at their terminal carbons afforded three- to seven-membered cycloalkanes.[3] We have also reported that ten-, twelve-, or fourteen-membered (*E,E*)- and (*Z,Z*)-1,5-cycloalkadienes can be prepared by the electroreductive cyclization of allylic α,ω-dibromides.[4] The preparation of substituted cyclopentanes by similar electroreductive cyclization has recently been reported.[5]

In this paper we report on the results concerning the electrochemical cyclization of α,ω-dibromides carrying alkoxycarbonyl groups at their terminal carbons. The use of a copper metal as an anode in a one-compartment cell was found to be of importance in this cyclization although the cyclization itself proceeds via reductive pathways. By using a copper anode instead of a platinum anode, much higher yields of three- to six-membered cycloalkanes could be obtained. The present work was carried out as part of our efforts to find effective carbon-carbon bond forming reactions by making use of reactive metal anodes.[6—9]

Results and Discussion

We previously reported that the electrochemical reduction of methallyl bromide gave 2,5-dimethyl-1,5-hexadiene in quantitative yield when electrolysis was carried out in the presence of one molar equivalent of sodium iodide while using a copper anode.[6] We found that this electrolysis using a reactive metal anode is also effective for the electrochemical cyclization of dimethyl α,α′-dibromoalkanedioates. The results of electrochemical cyclization of dimethyl 2,6-dibromoheptanedioate (**1c**) under various conditions are summarized in Table 1. Thus, the electrolysis of **1c** using a copper anode instead of a platinum anode gave cyclization product **2c** in 67% yield, while cyclization using a platinum anode gave only 48% yield of **2c**. We found that the addition of two molar equivalents of sodium iodide in this cyclization enhanced the yield to 85%.

Table 1. Electrochemical Cyclization of Dimethyl 2,6-Dibromoheptanedioate (**1c**) under Various Conditions[a]

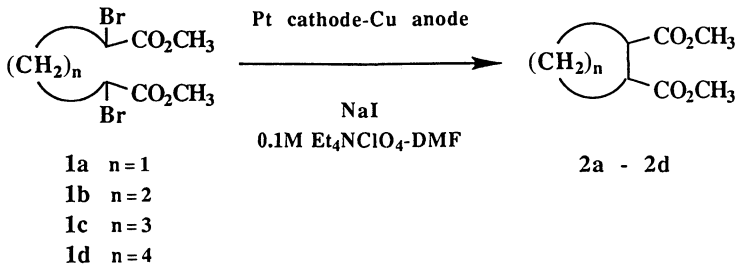
Entry	Cathode	Anode	Additive	Product (**2c**)	
				Yield/%[b]	trans : cis
1	Pt	Pt	—	48	73 : 27
2	Pt	Pt	2 equiv NaI	24	56 : 44
3	Pt	Cu[c]	—	67	75 : 25
4	Pt	Cu[d]	2 equiv NaI	85	65 : 35
5	Pt	Cu–Pt[e]	—	71	72 : 28
6	Pt	Cu–Pt[e]	2 equiv NaI	47	72 : 28

a) Carried out according to the procedure described in the Experimental Section. b) GLC yield. c) A copper anode dissolved: 2.6 mol/mol of **1c**. d) A copper anode dissolved: 3.6 mol/mol of **1c**. e) A copper-modified platinum anode was used. The cathode and anode were alternated at 10-min intervals (0.5 Faraday/mol of **1c**). In total, an electricity of 5 Faradays per mol of **1c** was passed.

Copper equivalent to 2.6—3.6 mol per mol of **1c** was found to be dissolved into the electrolytic solution during the electrolysis using a copper anode (Table 1, Entries 3 and 4). This loss of the copper anode can be appreciably reduced by the following new procedure using a copper-modified platinum anode. This method requires only 0.64 molar equivalent of copper dissolution for the modification of the platinum anode. Furthermore, the modified copper can be recycled between the cathode and anode by alternating their polarities at constant intervals during the electrolysis. The electrolysis of **1c** by using a platinum cathode and a copper-modified platinum anode, and by alternating the polarities at 0.5 Faraday intervals gave **2c** in 71% yield along with 20% of dimethyl heptanedioate (Entry 5).

The electrolysis of dimethyl α,α′-dibromoalkanedioates (**1a—d**) using a platinum cathode and a copper anode in the presence of two molar equivalents of sodium iodide gave the corresponding dimethyl 1,2-cycloalkanedicarboxylates (**2a—d**) (Scheme 1). Table 2 summarizes the yields and isomer ratios of the cyclization products. Dimethyl esters of 1,2-cyclopropane-, cyclopentane-, and cyclohexanedicarboxylates (**2a**, **2c**, and **2d**) were obtained in isolated yields more than 70%. The formation of the four-membered ring was found to be less efficient.

The role of the sodium iodide would be to act as a nucleophile in transforming the starting α-bromo esters into the corresponding iodides, which are more reactive than the starting bromides. It has, in fact, been proved that 33% of the carbon–bromine bonds of **1d** are converted into carbon–iodine bonds when **1d** is stirred for



1a n=1
1b n=2
1c n=3
1d n=4

Table 2. Electrochemical Cyclization of Dimethyl α,α'-Dibromoalkanedioates[a]

Dibromide	n	Product	Yield[b] %	trans : cis
1a	1	**2a**	75 (83)	70 : 30
1a[c]	1	**2a**	— (65)	63 : 37
1b	2	**2b**	30 (58)	70 : 30
1c	3	**2c**	71 (85)	65 : 35
1c[c]	3	**2c**	60 (71)	72 : 28
1d	4	**2d**	77 (86)	36 : 64

a) Carried out according to the procedure described in the Experimental Section. b) Isolated yields. GLC yields are shown in the parentheses. c) Electrolysis was carried out using a platinum cathode and a copper-modified platinum anode; the cathode and anode were alternated at 10-min intervals (0.5 Faraday/mol of **1a**—**d**).

30 min at room temperature in the presence of two molar equivalents of sodium iodide.

In the electrochemical cyclization of **1d**, small amounts of dimethyl octanedioate, dimethyl 2-bromooctanedioate, and dimethyl 2-iodooctanedioate were obtained as by-products along with the major product **2d**. This result indicates that the formation of the observed cycloalkanes (**2**) involves a stabilized carbanion generated by a two-electron reduction of one of the carbon–bromine or the carbon–iodine bonds of the starting dihalides (**1**), followed by an intramolecular nucleophilic displacement of the halogen atom.

It is likely that some organocopper species formed by the electrochemical reaction of organic halides with the copper anode[10] are precursors in the present cyclization or that the copper anode participates in the reaction by anodic dissolution,[9] which effectively captures the halide ions generated by the electrochemical reduction of **1**.

Experimental

N,N-Dimethylforamide (DMF) was dried over molecular sieve 4A and distilled over phosphorus pentaoxide under reduced pressure. Spectral measurements and quantitative GLC analyses were carried out using our standard methods.[4]

Preparation of Dibromo Diesters (1a—d). Starting dimethyl α,α'-dibromoalkanedioates (**1a—d**) were prepared in 70—90% yield from the corresponding alkanedioic acids by the method of Vogel[11] and Shreiner.[12] **1a**: Bp 110—113 °C (0.9 mmHg, 1 mmHg=133.322 Pa); **1b**: Mp 75—77 °C; **1c**: Bp 132—135 °C (0.7 mmHg); **1d**: Bp 149 °C (0.6 mmHg).

General Procedure for Electrolysis. A one-compartment cell (32 mm dia.) was used for the electrolysis.[4] A mixture of dibromides **1a—d** (1.5 mmol) and sodium iodide (3 mmol) in 30 ml of DMF solution containing 0.1 M (1 M=1 mol dm^{-3}) tetrabutylammonium perchlorate (TBAP) was electrolyzed under a nitrogen atmosphere at a constant current of 1 A dm^{-2} using a platinum cathode and a copper anode (0.3×0.4 dm^2). The electricity passed was 5 Faradays per mol of the dibromide.

The copper-modified platinum electrode was easily prepared by the electrolysis of a DMF solution containing 0.1 M TBAP using a platinum cathode and a copper anode. When an electricity of 1 Faraday per mol of the dibromide was passed through the solution, 0.64 molar equivalent of copper were dissolved from the copper anode.

The usual work-up of the electrolyzed solution gave a product mixture which was subjected to preparative TLC (silica gel; benzene–diethyl ether 4 : 1) to give pure products.

Dimethy *trans*-1,2-Cyclopropanedicarboxylate (*trans*-2a): n_D^{25} 1.4438 (lit,[13] n_D^{26} 1.4523); IR (neat) 1736, 1170, 1020 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.45 (m, 2H, J=5.9, 7.3, and 8.8 Hz), 2.18 (m, 2H, J=5.9 and 8.8 Hz), 3.71 (s, 6H); mass spectrum m/z 158 (M^+, 2), 157 (19), 127 (100), 126 (55), 99 (58), 98 (82), 59 (65), 39 (46). Synopsis. The reduction of alkenyl halides with tributyltin hydride in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium has been studied. Alkenyl iodides reacted easily with tributyltin hydride at 25 °C to give the corresponding hydrocarbons stereoselectively. However, the reaction of alkenyl bromides were sluggish at 25 °C and needed heating at 75 °C to complete.

Triethylborane-induced hydrodehalogenation of alkeny halides with tributyltin hydride proceeded non-stereoselectively. For instance, the reduction of (*E*)-1-deuterio-1-iodo-1-dodecene (**1**) or (*Z*)-1-deuterio-1-iodo-1-dodecene with Et_3B–*n*-Bu_3SnH gave a similar isomeric mixture of (*Z*)-1-deuterio-1-dodecene (**2**) and (*E*)-isomer **3** (**2**:**3**=39:61, Scheme 1).[1] Here we report that the reduction of alkenyl iodides with tributyltin hydride in the presence of palladium catalyst proceeds effectively to give the corresponding alkenes with high stereoselectivity.[2]

A number of alkenyl iodides and bromides were reduced with *n*-Bu_3SnH in the presence of $Pd(PPh_3)_4$ catalyst and the results are summarized in Table 1. Whereas (*E*)-1-iodo-1-dodecene reacted easily with *n*-Bu_3SnH at 25 °C to give 1-dodecene in 92% yield after 3 h, (*E*)-1-bromo-1-dodecene was recovered unchanged after treatment with *n*-Bu_3SnH-$Pd(PPh_3)_4$ at 25 °C for 5 h. Heating a benzene solution of (*E*)-1-bromo-1-dodecene, *n*-Bu_3SnH, and $Pd(PPh_3)_4$ at 75 °C for 5 h gave 1-dodecene in 37% yield. The reduction of alkenyl iodides essentially proceeded stereoselectively except for the case of (*E*)-1-deuterio-1-iodo-1-dodecene (**1**). Treatment of **1** (1.0 mmol) with *n*-Bu_3SnH (1.3 mmol) in the presence of $Pd(PPh_3)_4$ (2 mol%) catalyst gave a mixture of (*Z*)-1-deuterio-1-dodecene (**2**) and (*E*)-isomer **3** (**2**:**3**=79:21) in 93% yield. The contamination of (*Z*)-isomer **2** by (*E*)-isomer **3** was attributed to the successive isomerization of (*Z*)-isomer **2**, which was a primary product, by the action of excess *n*-Bu_3SnH under the reaction conditions. In fact, a partial isomerization was observed upon treatment of (*Z*)-1-deuterio-1-dodecene (**2**) with a catalytic amount of *n*-Bu_3SnH and $Pd(PPh_3)_4$. Stirring a benzene solution of **2** (1.0 mmol), *n*-Bu_3SnH (0.2 mmol), and $Pd(PPh_3)_4$ (2 mol%) at 25 °C for 2 h gave a mixture of (*Z*)- and (*E*)-1-deuterio-1-dodecene (**2**:**3**=73:27). The contamination of (*Z*)-isomer **2** by (*E*)-isomer **3** was suppressed by slow addition of an equimolar amount of *n*-Bu_3SnH (1.0 mmol per 1.0 mmol of **1**) to a benzene solution of **1** and Pd catalyst with syringe drive over 1 h (Scheme 2).

As well as (*E*)-1-iodo-1-dodecene, trisubstituted alkenyl iodide such as (*E*)-1-iodo-1-trimethylsilyl-1-dodecene and (*E*)-6-iodo-6-dodecene were easily reduced with *n*-Bu_3SnH–$Pd(PPh_3)_4$ system (Entries 4, 6, 8, and 9 in Table 1). However, (*Z*)-alkenyl iodides such as (*Z*)-1-iodo-1-dodecene and (*Z*)-6-iodo-6-dodecene reacted more slowly than the corresponding (*E*)-iodides because of its steric hindrance. The reaction of (*Z*)-1-iodo-1-dodecene or (*Z*)-6-iodo-6-dodecene took 5 h at 25 °C or 75 °C to complete (Entries 2 or 7 in Table 1).

The method was successfully applied to the reduction of aryl iodides[3] as shown below (Scheme 3). The reduction of 1-iodonaphthalene with *n*-Bu_3SnH in the presence of Pd catalyst proceeded easily at 25 °C. In contrast, the reaction of 1-bromonaphthalene was sluggish at 25 °C. Heating a benzene solution of 1-bromonaphthalene at 75 °C for 5 h gave naphthalene in 72% yield along with recovered 1-bromonaphthalene (11%). Treatment of 1-iodo-2-(3-methyl-3-butenyl)-benzene (**4**) with *n*-Bu_3SnH–$Pd(PPh_3)_4$ gave (3-methyl-3-butenyl)benzene (**5**) in 73% yield. The result showed sharp contrast to the radical reduction of **4** with Et_3B–*n*-Bu_3SnH system. The latter system gave a mixture of 1,1-dimethylindan (18%), 2-methyl-1,2,3,4-tetrahydronaphthalene (33%) and **5** (6%).[1]

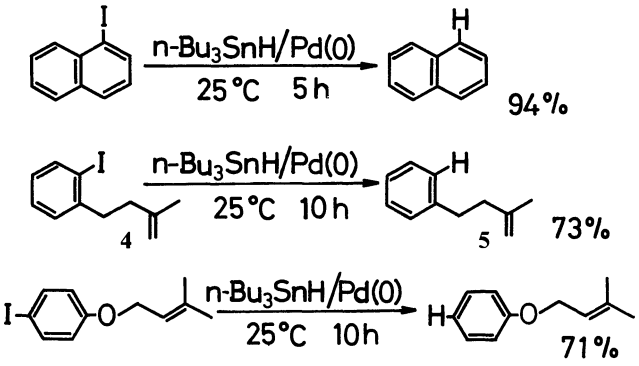

Scheme 3.

Oxidative addition of alkenyl iodides to palladium, (2) reaction of the resulting alkenylpalladium iodides with tributyltin hydride to provide alkenylpalladium hydrides,[4] and (3) reductive elimination from the palladium compounds to give the corresponding alkenes and regenerate the palladium(0) complex.

Experimental

Distillation of the products was performed by use of Kugelrohr (Büchi) and boiling points are indicated by an air-bath temperature without correction. ^{1}HNMR and ^{13}CNMR spectra were taken on a Varian XL-200 spectrometer and $CDCl_3$ was used as solvent unless otherwise noted. Chemical shifts are given in δ with tetramethylsilane as an internal standard. IR spectra were determined on a JASCO IR-810 spectrometer. The analyses were carried out at the Elemental Analysis Center of Kyoto University. Purification of products was performed by silica-gel (Wakogel C-100) column chromatography.

Preparation of Alkenyl Iodides. (*E*)-1-Iodo-1-dodecene and (*E*)-1-bromo-1-dodecene were prepared following the reported procedure.[5] (*E*)-1-Deuterio-1-iodo-1-dodecene was prepared by hydroalumination of 1-deuterio-1-dodecyne with i-Bu_2AlH followed by iodination.[1] (*E*)-1-Iodo-1-trimethylsilyl-1-dodecene and (*E*)-1-bromo-1-dimethylphenylsilyl-1-dodecene were prepared according to the literature.[6] (*E*)-6-Iodo-6-dodecene and (*Z*)-6-iodo-6-dodecene were prepared from 6-dodecyne following the reported procedure for the preparation of (*E*)-3-iodo-3-hexene[7] and (*Z*)-3-iodo-3-

hexene.[8] Hydroalumination of 2,2-dimethyl-3-undecyne with *i*-Bu_2AlH followed by iodination gave a mixture of (*E*)-2,2-dimethyl-4-iodo-3-undecene and (*E*)-2,2-dimethyl-3-iodo-3-undecene (2:1). The former was purified by preparative glpc (OV-1 2% on Chromosorb W 60—80 mesh, 2 m, 150 °C, t_r=6.72 min ((*E*)-2,2-dimethyl-4-iodo-3-undecene) and t_r=8.64 min ((*E*)-2,2-dimethyl-3-iodo-3-undecene). (*E*)-1,1,1,2,2,3,3,4,4,5,5,6,6-Tridecafluoro-8-iodo-7-octadecene was prepared by the reaction of 1-dodecyne with *n*-$C_6F_{13}I$ in the presence of triethylborane.[9]

(*E*)-6-Iodo-6-dodecene: Bp 60—65 °C (bath temp, 1 Torr, 1 Torr=133.322 Pa); IR (neat) 2954, 2924, 2854, 1729, 1630, 1466, 1459, 1379, 1269, 1195, 1136, 1108, 727 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, *J*=6.7 Hz, 3H), 0.90 (t, *J*=6.5 Hz, 3H), 1.20—1.69 (m, 12H), 2.02 (td, *J*=7.3, 7.2 Hz, 2H), 2.36 (t, *J*=7.3 Hz, 2H), 6.18 (t, *J*=7.6 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=14.01, 22.45, 22.52, 28.80, 28.87, 30.55, 30.84, 31.28, 38.37, 103.6, 141.4. Found: C, 48.85; H, 8.06%. Calcd for $C_{12}H_{23}I$: C, 48.99; H, 7.88%.

(*Z*)-6-Iodo-6-dodecene: Bp 60—65 °C (bath temp, 1 Torr); IR (neat) 2954, 2924, 2854, 1729, 1643, 1465, 1459, 1429, 1378, 1274, 1134, 726 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.90 (t, *J*=6.8 Hz, 6H), 1.20—1.69 (m, 12H), 2.10 (td, *J*=6.8, 6.7 Hz, 2H), 2.45 (t, *J*=7.6 Hz, 2H), 5.46 (t, *J*=6.7 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=14.04, 22.42, 22.55, 28.10, 29.03, 30.37, 31.35, 36.35, 45.09, 109.8, 134.8. Found: C, 48.88; H, 8.00%. Calcd for $C_{12}H_{23}I$: C, 48.99; H, 7.88%.

(*E*)-2,2-Dimethyl-4-iodo-3-undecene: Bp 75—80 °C (bath temp, 1 Torr); IR (neat) 2954, 2924, 2854, 1730, 1618, 1465, 1365, 1243, 1202, 1114 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.89 (t, *J*=7.0 Hz, 3H), 1.12 (s, 9H), 1.25—1.45 (m, 8H), 1.50—1.70 (m, 2H), 2.44 (t, *J*=7.6 Hz, 2H), 6.24 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=14.10, 22.64, 23.74, 29.17, 30.32, 30.93, 31.78, 36.84, 40.52, 106.3, 150.7. Found: C, 50.84; H, 8.35%. Calcd for $C_{13}H_{25}I$: C, 50.66; H, 8.17%.

(*E*)-1,1,1,2,2,3,3,4,4,5,5,6,6-Tridecafluoro-8-iodo-7-octadecene: Bp 105—110 °C (bath temp, 1 Torr); IR (neat) 2926, 2854, 1636, 1466, 1365, 1240, 1204, 1146, 1067 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, *J*=5.8 Hz, 3H), 1.15—1.40 (m, 14H), 1.40—1.70 (m, 2H), 2.63 (t, *J*=7.3 Hz, 2H), 6.32 (t, *J*=14.4 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=14.05, 22.71, 28.47, 29.34, 29.48, 29.59, 30.10, 31.94, 41.18, 123.1 (t, *J*=6.5 Hz), 126.5 (t, *J*=24.0 Hz). Found: C, 35.45; H, 3.87%. Calcd for $C_{18}H_{22}F_{13}I$: C, 35.31; H, 3.62%.

2-Iodo-3-phenylthio-1-propene. 3-Bromo-2-iodo-1-propene[10] (2.47 g, 10 mmol) was added to a methanol solution of sodium benzenethiolate, generated from benzenethiol (1.1 g, 10 mmol) and sodium (0.23 g, 10 mg-atom) in methanol under argon atmosphere. After stirring for 1.5 h, the resulting mixture was poured into water. Extractive workup followed by silica-gel column chromatography gave the title compound (1.5 g) in 65% yield: Bp 103—108 °C (bath temp, 1 Torr); IR (neat) 3056, 2954, 2924, 1728, 1619, 1609, 1583, 1480, 1439, 1400, 1273, 1226, 1191, 1088, 1025, 900, 737, 688 cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.83 (s, 2H), 5.73 (bs, 1H), 6.57 (bs, 1H), 7.3—7.5 (m, 5H); ^{13}C NMR ($CDCl_3$) δ=48.96, 105.8, 127.0, 127.7, 128.9, 130.7, 134.6. Found: C, 39.01; H, 3.10%. Calcd for C_9H_9IS: C, 39.15; H, 3.29%.

General Procedure for the Reduction of Alkenyl Iodides and Aryl Iodides. The reduction of (*E*)-1-iodo-1-dodecene was representative. Tributyltin hydride (0.38 g, 1.3 mmol) was added dropwise by syringe drive over 20 min to a solution of (*E*)-1-iodo-1-dodecene (0.29 g, 1.0 mmol) and $Pd(PPh_3)_4$ (23 mg, 2 mol%) at 25 °C under argon atmosphere. After completion of the addition, stirring was continued for another 1 h. The resulting mixture was poured into water and extracted with ethyl acetate (20 ml×3). Combined organic layers were dried over Na_2SO_4 and concentrated in vacuo to give a colorless oil which was submitted to silica-gel column chromatography using hexane as eluant to give 1-dodecene (0.15 g) in 92% yield. In the case of the reduction of (*Z*)-iodoalkenes, an addition of benzene solution of *n*-Bu_3SnH was achieved over 2 h by syringe drive.

Isomerization of (*Z*)-1-Deuterio-1-dodecene. Tributyltin hydride (58 mg, 0.2 mmol) was added to a solution of (*Z*)-1-deuterio-1-dodecene (**2**, 0.17 g, 1.0 mmol) and $Pd(PPh_3)_4$ (23 mg, 2 mol%) at 25 °C under argon atmosphere. After stirring for 2 h, the reaction mixture was poured into water and extracted with ethyl acetate. The examination of the crude product by ^1H NMR showed that (*Z*)-isomer **2** was partially isomerized into (*E*)-isomer **3** (**2**:**3**=73:27).

(*Z*)-2,2-Dimethyl-3-undecene: Bp 88—90 °C (bath temp, 13 Torr); IR (neat) 2954, 2922, 1729, 1466, 1363, 1273 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, *J*=6.7 Hz, 3H), 1.10 (s, 9H), 1.20—1.48 (m,10H), 2.11—2.21 (dt, *J*=7.0, 7.0 Hz, 2H), 5.15 (dt, *J*=12.0, 7.0 Hz, 1H), 5.31 (d, *J*=12.0 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=14.12, 22.67, 28.37, 29.26, 29.37, 30.32, 31.16, 31.86, 33.07, 129.1, 139.5. Found: C, 85.61; H, 14.54%. Calcd for $C_{13}H_{26}$: C, 85.63; H, 14.37%.

(*Z*)-1,1,1,2,2,3,3,4,4,5,5,6,6-Tridecafluoro-7-octadecene: Bp 85—90 °C (bath temp, 1 Torr); IR (neat) 2926, 2856, 1729, 1664, 1466, 1364, 1240, 1203, 1146, 1121, 1102, 1067, 842, 810, 766, 743, 733, 718, 703 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, *J*=6.2 Hz, 3H), 1.20—1.60 (m, 16H), 2.20—2.46 (m, 2H), 5.38—5.68 (m, 1H), 6.05—6.28 (m, 1H); ^{13}C NMR ($CDCl_3$) δ=14.08, 22.69, 28.57, 29.05, 29.13, 29.34, 29.53, 31.90, 115.9 (t, *J*=23.4 Hz), 145.7 (t, *J*=5.9 Hz). Found: C, 44.74; H, 4.66%. Calcd for $C_{18}H_{23}F_{13}$: C, 44.45; H, 4.77%.

Selective Halofluorination Reaction Mediated by Hexafluoropropene-Diethylamine Complex and *N*-Haloimides

Makoto SHIMIZU, Masaya OKAMURA, and Tamotsu FUJISAWA*
Department of Chemistry for Materials, Mie University, Tsu, Mie 514
(Received April 15, 1991)

Synopsis. Olefins were halofluorinated with hexafluoropropene–diethylamine and *N*-haloimides in a highly regio- and stereoselective manner.

Growing interests in organofluorine chemistry prompt us to develop new methodologies for the introduction of a fluorine atom into molecules in highly selective ways.[1] For the introduction of a fluorine atom into molecules, halofluorination of olefins is one of the most straightforward ways.[2] However, there still remain several important problems associated mainly with selectivities of the reaction, the tedious experimental procedures, and the need for the use of special reaction vessels. A non-trivial problem often accompanies halofluorinations, which concerns the use of hydrogen fluoride-a readily available and inexpensive fluoride ion source but the handling holds certain problems,[2a] and in situ generation of a limited amount of hydrogen fluoride in the reaction medium appears to circumvent some of the problems associated with the conventional halofluorination reactions.

We have now found that the use of hexafluoropropene–diethylamine complex (HFP–DA)[3] and *N*-haloimides enables us to carry out halofluorination reactions quite readily with high regio-and stereoselectivities in an ordinary glassware vessel (Scheme 1). Initial survey of the hydrogen fluoride sources involves the use of acid fluorides (CH_3COF or CH_3SO_2F)–water or metal fluorides (CsF, KF, CoF_2, CoF_3, SbF_3 or SbF_5)–water, which resulted in utter failure. However, the combined use of HFP–DA complex and water revealed a ready accessibility of a limited amount of hydrogen fluoride,

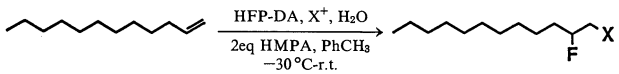
Table 1. Halofluorination of 1-Dodecene[a]



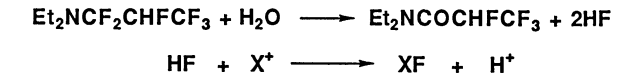
Entry	X^+ source (equiv)	H_2O (equiv)	Yield[b]/%
1	DBH (1.5)[c]	1.5	41
2	DBH (1.5)	1.5	51
3	DBH (1.7)	1.7	58
4	DBH (2.5)	2.5	64
5	DBH (2.5)	0	17
6	DCH (1.7)	1.7	44
7	NIS (1.7)	1.7	61
8	NIS (2.5)	2.5	78

a) The reaction was carried out at −30 °C—room temp for 24 h. b) Isolated yield. c) In 1,4-dioxane.

and the halofluorination of 1- dodecene was successfully performed (see Table 1).

As shown in Table 1, the best result was obtained when the reaction was carried out with HFP–DA (2.0 equiv), *N*-iodosuccinimide (NIS, 2.0—2.5 equiv) or 1,3-dibromo-5,5-dimethylhydantoin (DBH, 2,0—2.5 equiv), H_2O (2.5 equiv) and hexamethylphosphoric triamide (HMPA, 2.0 equiv) in toluene at −30 °C to room temperature, whereas the reaction with 1,3-dichloro-5,5- dimethylhydantoin (DCH) met with moderate success presumably due to the less stable nature of the bridged halonium ion intermediate relative to its iodo or bromo counterpart (see Entries 3, 6, and 7). Under the optimum reaction conditions found for 1 - dodecene a variety of olefins were converted into the corresponding halofluorides in good to excellent yields, and Table 2 shows the results.

Aromatic, aliphatic, and alicyclic olefins all underwent halofluorination with high regio- and stereoselectivities, where iodofluorination in general showed better yield than the bromo analogue. The fluorine atom was always introduced into the more substituted carbons and the trans orientation of fluorine to the other halogen was usually observed. In particular bromofluorination of (*Z*)-1-phenyl-1-propene is noteworthy; (1*R**, 2*R**)-bromofluoride **2** was formed predominantly in the present case (Entry 15), showing a distinct contrast to the methods reported previously[2l] in which (1*R**, 2*S**)-isomer **1** is obtained as a sole product. Close examination of the present halofluorination reveals that the reaction proceeds most probably via generation of a limited amount of hydrogen fluoride from HFP–DA complex and H_2O followed by formation of XF species with NIS or DBH as the following equation shows.



Application of the present halofluorination reaction to the synthesis of a biologically interesting molecule was readily performed via iodofluorination followed by reduction with *n*-Bu_3SnH in good overall yield. Scheme 2 shows the preparation of a fluorine analogue

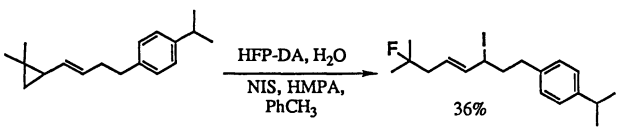

Scheme 3.

of a juvenile hormone MV-678.[4]

Halofluorination reaction exercised in the present study provides a ready procedure for the introduction of fluorine into olefins with high regio- and stereoselectivities under mild conditions using a normal glassware apparatus. With slight modification of the substrate[5] the present halofluorination is further applicable to the synthesis of homologous fluorides, as Scheme 3 illustrates.

Experimental

Infrared spectra of neat liquid film samples (unless otherwise noted) were determined on a JASCO IR-810 spectrometer. ^{1}H NMR spectra were taken on a JEOL JNM-RMX60si spectrometer using tetramethylsilane as an internal standard. ^{19}F NMR spectra were recorded on a Hitachi R-24F spectrometer using $CFCl_3$ as an internal standard. Mass spectra were taken on a Shimadzu QP 1000 spectrometer. Preparative TLC plates were prepared with Merck Kiesel Gel PF_{254}. Column chromatography was carried out with silica gel (Wakogel C-300).

General Procedure for the Halofluorination of Olefins: The following is a typical experimental procedure. In an ordinary glassware vessel to NIS (562 mg, 2.5 mmol) were added toluene (1.5 ml), HFP–DA (0.87 ml, 2.5 mmol), HMPA (0.35 ml, 2.0 mmol), and H_2O (45 ml, 2.5 mmol) successively at −30 °C, and the mixture was stirred at that temperature for 15 min. A solution of 1-dodecene (169 mg, 1.0 mmol) in toluene (1.5 ml) was added and the reaction mixture was allowed to stand at room temperature for 24 h. The normal workup followed by purification by silica-gel column chromatography gave 2-fluoro-1-iodododecane (245 mg, 78%) as a colorless oil. The spectroscopic properties were identical with the reported data.[2d] IR (neat) 2940, 2860, 1470, 1420, 1380, 1195, 995, 800, 730, and 640 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.68—2.20 (21H, m),3.22 (2H, dd, J=6.0, 18.0 Hz), 4.43

(1H, dm, J=48.0 Hz); ^{19}F NMR (CCl_4) δ=−173.0 (m).

1-Bromo-2-fluorododecane:[2d] IR (neat) 2940, 2860, 1475, 1430, 1385, 1020, 830, 730, 695, and 685 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.67—2.10 (21H, m), 3.40 (2H, dd, J=6.0, 18.0 Hz), 4.53(1H, dm, J=48.0 Hz); ^{19}F NMR (CCl_4) δ=−180.0 (m).

Oxidative Cleavage of Chalcones by Electrochemically Generated Superoxide Ion ($O_2^{\cdot-}$)

Manorama SINGH, Krishna Nand SINGH, and Ram Achal MISRA*
Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India
(Received November 26, 1990)

Synopsis. Various chalcones were efficiently cleaved to carboxylic acid(s), in considerably high yield by the reaction with electrochemically generated superoxide ion ($O_2^{\cdot-}$) at mercury cathode and molecular oxygen.

Superoxide ion ($O_2^{\cdot-}$), which is an anion radical and one of the activated oxygen species, plays important roles in biological systems[1-11] and provides impetus to organic chemists to study its chemical reactivity from synthetic considerations.[12-15] It has been recognized that superoxide ion, depending upon the nature of organic substrate, can act as a base, nucleophile, ligand, radical, or an oxidant.[14-22] The electrochemical generation of $O_2^{\cdot-}$ in aprotic medium, in presence of tetraalkylammonium salt by reducing molecular oxygen, is known since 1965[23] and remains a method of choice for preparing and using in situ generated superoxide ion more satisfactorily than using KO_2–crown ether.[24]

The chemistry of superoxide ion with a wide range of simple organic compounds is very little known and needs further investigations. Recently, we have reported the superoxide-initiated oxidation of some secondary alcohols,[25] primary alcohols,[26] and fragmentation of some tosylhydrazones of carbonyl compounds using electrochemically generated superoxide ion.[27] Reactions of electrogenerated $O_2^{\cdot-}$ with chalcones have not been studied so far. A survey of literature reveals that there exists only one report in which Rosenthal and Frimer[28] have studied the reaction of chalcones with KO_2 in 18-crown-6-ether. The reaction of chalcones with electrogenerated superoxide ion has been reinvestigated from following reasons:

a) The best available sample of KO_2 is only 95% pure and is always contaminated with free bases and other impurities.

b) The KO_2 in reaction medium easily results in other activated oxygen species such as hydroxyl ($OH^{\cdot}$) and peroxyl ($OOH^{\cdot}$) radicals thereby delimiting the interpretation of results.

c) The electrogeneration of superoxide ion affords a stable and pure solution of the species in aprotic medium and gives opportunity for in situ reactions with chalcones.

Experimental

Instruments. Melting points were measured with a Buchii melting point apparatus and are uncorrected. IR spectra were recorded on a Perkin–Elmer 783 grating spectrophotometer. ^{1}H NMR spectra were measured at 90 MHz with

a) Measured using copper coulometer.

JEOL FT-NMR spectrometer FX-90 Q, chemical shifts are expressed as δ/ppm, downfield from the internal tetramethylsilane reference. Carbon and hydrogen were analyzed using Perkin–Elmer model 240 C elemental analyzer. GLC was carried out on a Shimadzu Gas Chromatograph, GC-9A in conjuction with Shimadzu C-R 6A chromatopac. Cyclic voltammograms were recorded with an X–Y (t) recorder (Servogor type 733). All measurements were carried out at 25 °C by a three electrode system consisting of a counter (stationary platinum disc: 22 mm in diameter), a platinum rod test electrode, 0.1 M (1 M=1 mol dm^{-3}) TBAP (tetrabutylammonium perchlorate) in DMSO (spectroscopic grade) served as supporting electrolyte. The scan rate of the potential was 200 mV s^{-1}.

Chalcones (**1**—**7**; Table 1) were prepared according to the reported method[29] and were characterized by their physico-chemical and spectral studies. These were subjected to the reaction with electrochemically in situ generated superoxide ion. After electrolysis and work-up, all the products isolated were fully characterized by their physico-chemical and spectroscopic data.

Oxidative Cleavage of Chalcones. Typical Procedure for 4-Methoxychalcone (4): Apparatus. Wenking Potentioscan POS 73 (Bank-Electronik, Germany) is used for constant potential macro electrolysis. The electrochemical cell consists of a double walled glass cell (volume 150 ml) in which a medium porosity glass frit separates the anodic and cathodic chambers. The mercury pool (23.76 cm^2) and platinum foil (3.78 cm^2) served as an anode and a cathode respectively. Saturated Calomel Electrode (SCE) served as a reference electrode.

Electrolysis. A solution of tetrabutylammonium bromide (3.22 g; 0.1 M) in DMF (100 ml) was used as supporting electrolyte. The cathodic chamber containing 50 ml of the electrolyte was purged with nitrogen for 15 min. The electrolytic solution was pre-electrolyzed at −1.9 V vs. SCE until the background current drops to about 2 mA. Now 2 ml of cyclohexene was added to anolyte for absorption of liberated bromine. Catholyte was saturated with oxygen for 30 min. Chalcone (**4**; 0.5 g; 2.1×10^{-4} M) was added to the cathodic chamber and reaction was carried out at constant potential of −1.0 V vs. SCE until the loss of starting material as checked by TLC and current falls appreciably (Table 1).

Work-Up. Upon completion of electrolysis, catholyte was taken in 100 ml of cold water and to it was added 25 ml of saturated solution of $NaHCO_3$. The above mixture was extracted with ether (20 ml×3), dried (Na_2SO_4), filtered and evaporated to yield unreacted chalcone. Now the aqueous layer was acidified with dil aq HCl and extracted with ether (25 ml×4), dried (Na_2SO_4), filtered and solvent was removed to yield mixture of acids. These acids were separated by column chromatography on 70—230 mesh silica gel (Merck Kieselgel 60 Art. No. 7734) using benzene–MeOH–AcOH (05:04:01) as eluent. Yields were established (after their esterification) by GLC. Products were identified by their physico-chemical and spectral data.

Results and Discussion

During present investigation chalcones (**1**—**7**) are made to react with in situ electrochemically generated superoxide ion at −1.0 V vs. SCE in the atmosphere of molecular oxygen in DMF solution. The chalcones under this reducing conditions, owing to the mediation of O_2^-/O_2 are oxidatively cleaved to carboxylic acids (Table 1).

Cyclic Voltammetry. The cyclic voltammogram of superoxide ion formation is shown by dotted line (----) and the CV of oxygen reduction in the presence of chalcone (**2**) by solid line (——) (Fig. 1).

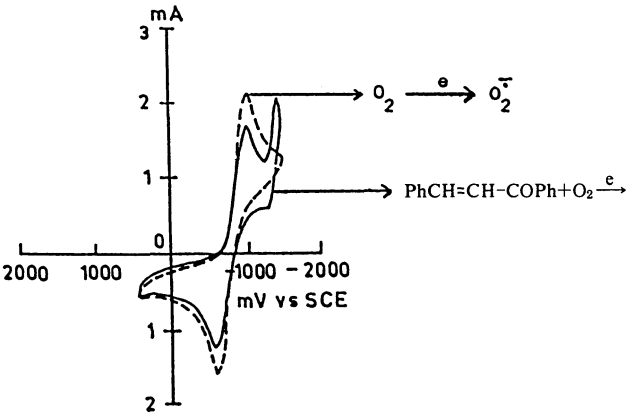

Fig. 1. Cyclic voltammogram for oxygen reduction (----) and in the presence of chalcone (**2**) (——). Solvent: DMSO+0.1 M TBAP; T: 20 °C. Scan rate: 200 mV s^{-1} at Pt.

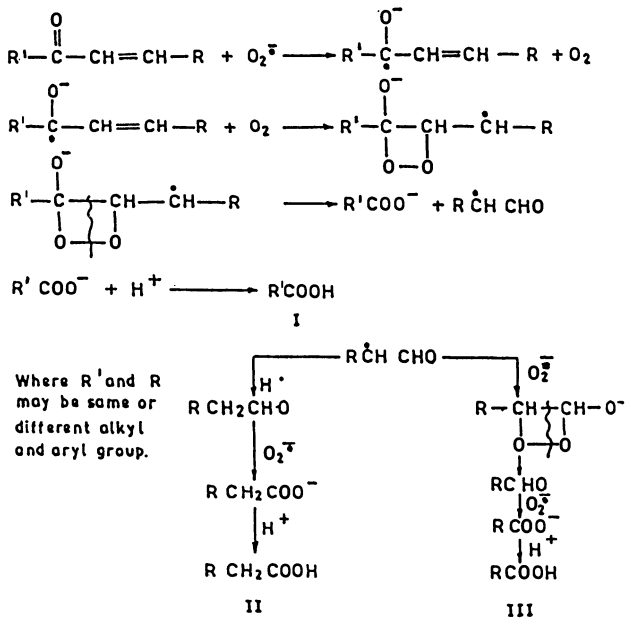
Examination of Fig. 1 reveals that molecular oxygen is reduced at −0.9 V to O_2^-, this species is reoxidized in the reverse sweep of potential at −0.60 V. The value of 0.30 V as ΔE_p shows that the electrode process is quasi-reversible.[30] In the CV of superoxide ion in presence of substrate, in addition to CV peak of O_2^- (−0.9 V) another peak at −1.45 V is observed, attributable to a possible reduction of substrate. The O_2^- oxidation peak at −0.60 V does not disappear as is observed in the CV of superoxide ion reaction with primary alcohols,[26] but its disappearance in the case of tosylhydrazones[27] probably indicates that superoxide ion is destroyed in a fast follow up chemical reaction between the superoxide ion and the substrate. The cathodic peak current (ipc) in absence of chalcone is 2.15 mA and in presence of chalcone is 1.65 mA (decrease 0.5 mA). Similarly the anodic peak current (ipa) in absence and presence of



Scheme 1.

chalcone is 1.6 mA and 1.25 mA respectively (decrease 0.35 mA). Thus the decrease in current ratio is 1.42 (Fig.1).

On the basis of product isolation and CV studies the following mechanism is proposed for the oxidative cleavage of chalcones (Scheme 1).

Thus, superoxide ion reacts with chalcone forming radical anion of the substrate, which reacts with surrounding molecular oxygen to form unstable adduct and is readily cleaved to carboxylate anion ($RCOO^-$) and aldehyde radical ($R\dot{C}HCHO$). The latter, with a sequence of steps involving O_2^- affords the products.

The authors (M.S. and K.N.S.) thank the CSIR, New Delhi for the award of Senior Research Fellowships and (R.A.M.) to Alexander Von Humboldt Foundation, Germany, for the gift of a Wenking Potentioscan POS 73.

EXAFS Investigation of Pentasil-Structured Gallium-Containing Metallosilicates

Kiyomi OKABE, Nobuyuki MATSUBAYASHI,* Kazuhiro SAYAMA, Hironori ARAKAWA, and Akio NISHIJIMA
Surface Chemistry Division, National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received January 28, 1991)

Synopsis. Pentasil-structured bimetallosilicates were prepared by adding Ga and Fe (or Sr) salts simultaneously during the hydrothermal synthesis of a pentasil silicate, and local structures around Ga were directly elucidated by means of EXAFS for the first time. It was found that Fe and Ga independently substituted the silicate framework, and that the local structure around Sr was the same as that in Sr^{2+}-exchanged gallosilicate.

It was reported that tectosilicate frameworks are substituted by such elements as B, Be, Al, Fe, Ga, Ge, Cr, P, and Mg.[1] Among these elements, B, Al, Fe, and Ga are most frequently used for preparing metallosilicate catalysts, since the acidity of the catalysts can be altered by the substitution. Pentasil metallosilicates, thus prepared, have a unique channel structure, and the framework metals are atomically dispersed. These characteristics provide long catalytic life as well as high activity in the conversion of methanol to hydrocarbons.[2] Selectivity is often improved by additives during the hydrothermal synthesis of the silicates.[3] However, interaction between the second metal and the metal in the framework of the silicates is not well-characterized at the present time. It is of great importance to elucidate the interaction, since the interaction may give rise to a change in electronic states of the active sites, improving the catalytic property. The purpose of the present investigation is to clarify the micro-structure around Ga in Ga-containing bimetallosilicates and to show the intermetallic interaction between Ga and the second metal by means of EXAFS. In the present investigation, Fe and Sr were chosen as the second metals, since (a) the former is typical of an isomorphous substitutional element and the latter is non-substitutional, as mentioned above, and (b) both are catalytically important additives and a large amount of data has been accumulated on their ability to modify the acidity of catalysts.[4]

Experimental

Colloidal silica, gallic nitrate (and/or iron(III) nitrate), tetrapropylammonium bromide (TPABr), sodium hydroxide, and distilled water were mixed together to form a metallosilicate (M-silicate; M=Ga, Fe) gel having the following composition; SiO_2/Ga_2O_3 (and/or Fe_2O_3)=200, SiO_2/TPABr=10, SiO_2/OH=10. The gel was crystallized by autoclaving at 433 K. Some of the crystalline metallosilicates were treated with 0.1 mol dm^{-3} aqueous solutions of $SrCl_2$ or $Ga(NO_3)_3$ at 373 K after calcination at 773 K, and the Na^+ of the pentasil silicates was replaced by Sr^{2+} or Ga^{3+}. Sr-containing gallosilicate was prepared by adding strontium acetate (Sr/Ga=10) during the hydrothermal synthesis of gallosilicate. The K-edge EXAFS spectra of Ga, Sr, and Fe were measured at the Photon Factory (BL-10B and BL-7C) of the National Laboratory for High Energy Physics. In Fourier transforms of the EXAFS data, the phase shifts due to an absorbing atom and backscattering atoms were corrected using parameters calculated by Teo and Lee[5] for M–O (M=Ga, Sr, Fe). Furthermore, the distances were corrected using the results for standard samples (Ga_2O_3, SrO, and Fe_2O_3).

Results and Discussion

Figure 1 shows the Fourier transforms of Ga K-edge EXAFS of (a) Ga_2O_3 and (b—e) gallosilicates at the various stages of the hydrothermal reaction. The profile of the gel mixture at an initial stage (b) was quite different from that of Ga_2O_3 (a). The peaks at 1.9 and 3.2 Å of Ga_2O_3 are assigned to Ga–O and Ga–O–Ga, respectively. The latter peak was not found in the spectra of the gallosilicates (b—e). The profiles of the silicates were almost unchanged during the hydrothermal reaction. The peaks at 3.1 and 3.5 Å may correspond to Ga–O–Si distances, as assigned previously.[6] The fact that the second neighboring atoms on Ga are

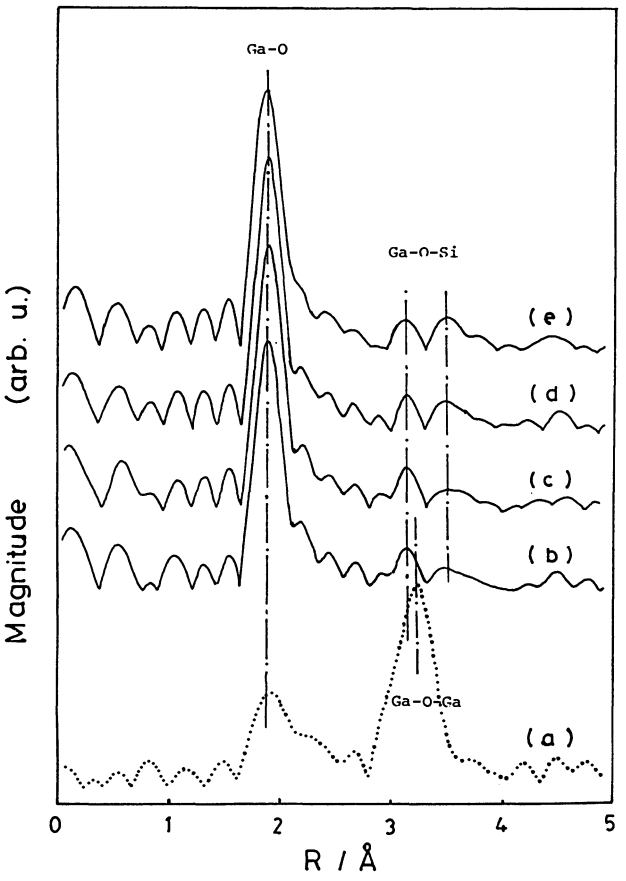

Fig. 1. Fourier transforms of Ga K-edge EXAFS with phase-shift correction of (a) Ga_2O_3, and gallosilicates after hydrothermal reaction of (b) 0 h, (c) 2 h, (d) 2.5 h, and (e) 6 h.

not Ga but Si indicates that Ga is highly dispersed in the silicate, even at the very beginning of the hydrothermal reaction. The atomic isolation of the metal in the silica matrix is different from the previous case of ferrisilicate, where FeO(OH) was formed in the starting gel.[6] The identical peak positions in the EXAFS profiles between the amorphous and crystalline phases strongly suggest that the micro-structure around Ga was formed in a very early stage of the hydrothermal reaction without the formation of an oxide or hydroxide of Ga, and that the local environment around Ga was almost unchanged throughout the hydrothermal reaction.

However, the relative intensity of the peaks at 3.5 Å increased and that at 3.1 Å decreased slightly with hydrothermal reaction time, as illustrated in Fig. 2. The change in XRD intensity at a spacing d(501) of the silicates (△) indicates that the silicate bulk was crystallized during a short period of time after a hydrothermal reaction time of 2 h. These results suggest that the peaks at 3.1 Å correspond to the Ga–O–Si distance in an amorphous silicate and the ones at 3.5 Å to that of the pentasil structure, and that the regularity of the micro-structure around Ga in the pentasil framework increased with time.

Figure 3 shows the Fourier transforms of Ga K-edge EXAFS of (a) Ga_2O_3, (b) Ga^{3+}-exchanged Fe-silicate, (c) Fe, Ga-bimetallosilicate, (d) Sr-containing Ga-silicate, and (e) pentasil structured Sr^{2+}-exchanged Ga-silicate.

The peak positions of (b) are different from those of Ga_2O_3 (a) or Ga-silicate (Fig. 1), implying that most of the Ga of (b) was in the form of counter cations to acid sites caused by the framework Fe. The peak at 3.0 Å of the silicate corresponds to the distance to the second neighboring atoms on Ga. The dissimilarity of the profiles suggests that the peak may correspond to the Ga^{3+}–O–Fe distance, since a peak of the same distance

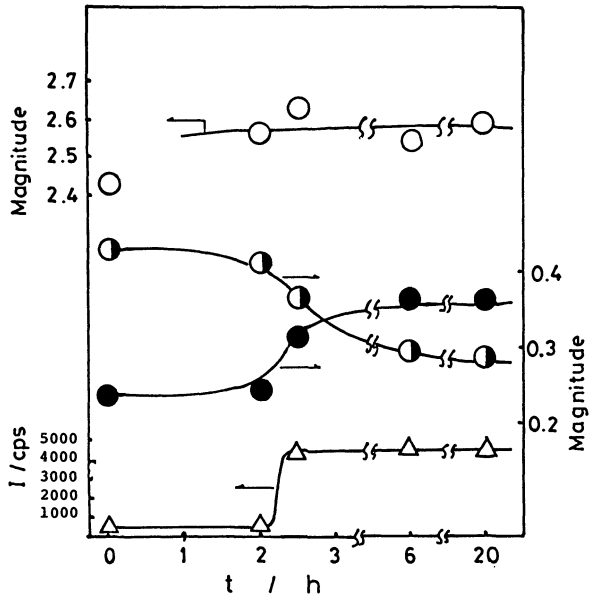

Fig. 2. Changes in peak intensities at 1.9 Å (○), 3.1Å (◑) and 3.5 Å (●) of Fig. 1, and in XRD peak intensities at 2θ=23.2° (△) with hydrothermal reaction time.

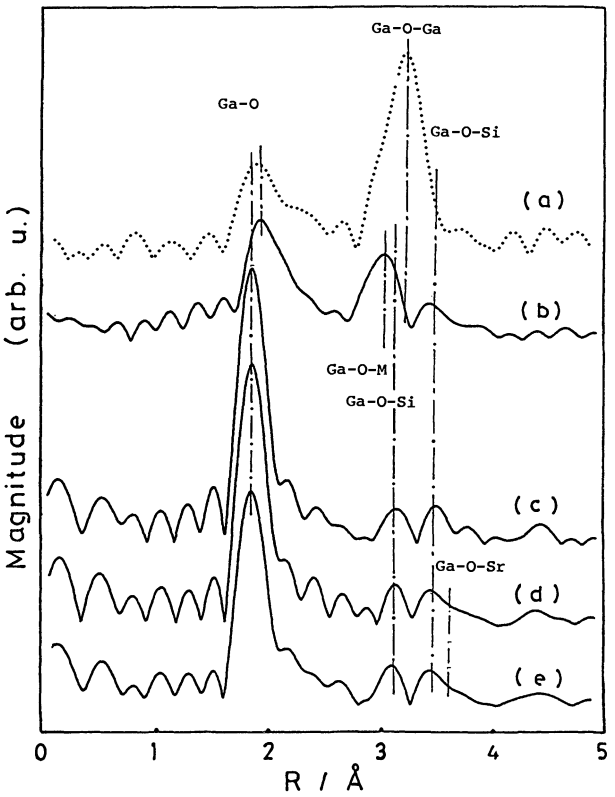

Fig. 3. Fourier transforms of Ga K-edge EXAFS, with phase-shift correction, of (a) Ga_2O_3, (b) Ga^{3+}-exchanged ferrisilicate, (c) Fe,Ga-bimetallosilicate, (d) Sr-containing gallosilicate, and (e) Sr^{2+}-exchanged gallosilicate.

was also found in the Fourier transform of Fe K-edge EXAFS of Ga^{3+}-exchanged Fe-silicate. A weaker peak was found at 3.45 Å in profile (b) in Fig. 3. The relative peak intensity depends on many factors, the atomic weight of the adjacent atoms being one of them. By simply assuming that the atomic weight corresponding to the peak at 3.45 Å is about half that of the peak at 3.0 Å and that the other factors are the same between these two peaks, the weak peak can be explained in terms of the Ga–O–M distance. Si may be the most appropriate candidate for the M element, since the relative atomic weight ratio of Si/Fe is 0.5 and the distance derived from the peak position is similar to the Ga–O–Si distance in crystalline gallosilicate, as mentioned above. Thus, the peaks at 3.0 and 3.45 Å may be assigned to the Ga^{3+}–O–Fe and Ga^{3+}–O–Si distances, respectively.

The Ga–O distance in (c) is 1.9 Å, and is shorter than that in (b) by 0.1 Å. The profile of (c) in the range of 3.0—3.5 Å is also different from that of (b), and exactly the same as that of Ga-silicate. The peaks at 3.1 and 3.5 Å of Ga-silicate were both assigned to Ga–O–Si, as described above. The fact that no other peaks of Ga–O–M (M=Ga, Fe) are found in (c) suggests that Ga and Fe are atomically and independently dispersed in the silicate crystals without mutual interaction.

The profile of (d) is the same as (e), indicating that the local structures around Ga are similar to each other. The profiles are also similar to that of Ga-silicate (Fig.

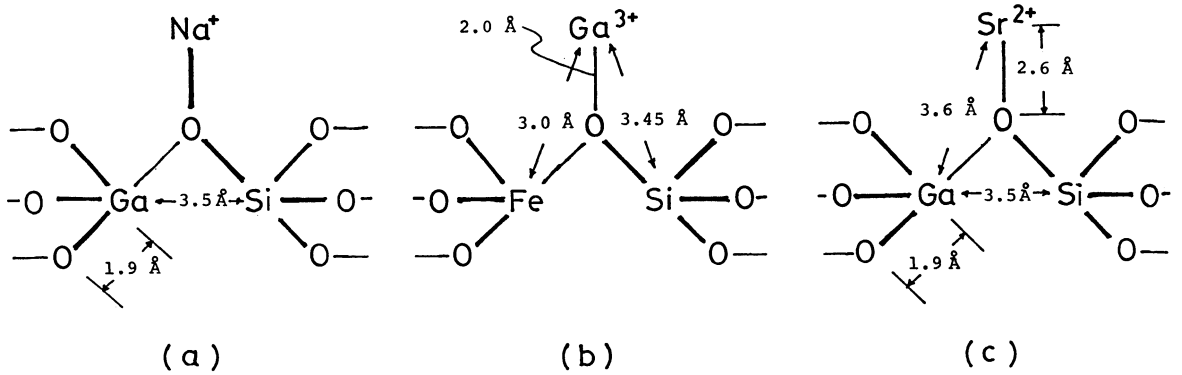

Fig. 5. Intermetallic distances determined by EXAFS of (a) gallosilicate, (b) Ga^{3+}-exchanged ferrisilicate, and (c) pentasil-structured Sr-containing gallosilicate.

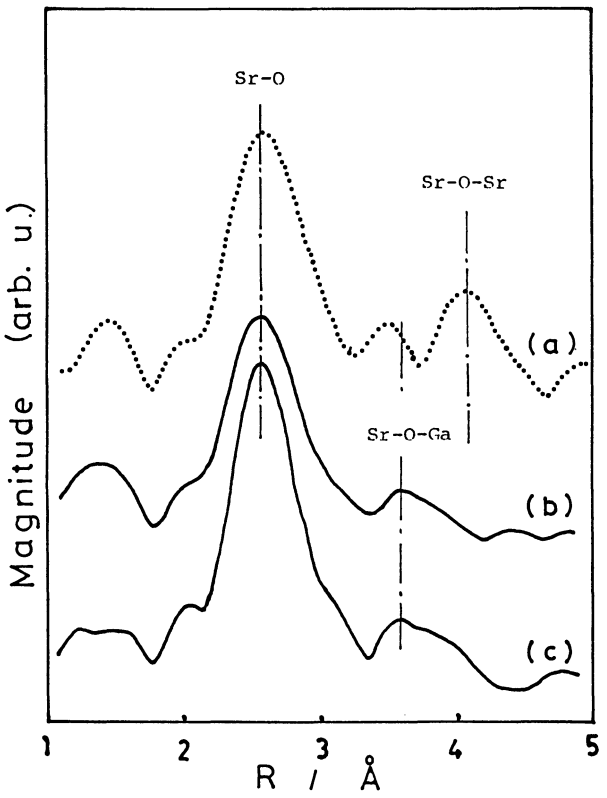

Fig. 4. Fourier transforms of Sr K-edge EXAFS, with phase-shift correction, of (a) SrO, (b) Sr-containing gallosilicate, and (c) Sr^{2+}-exchanged gallosilicate.

1), except for the peak broadening at 3.5—3.6 Å. It is well known that framework Ga gives rise to an acid site, and that Sr of (e) is in the form of an extra-framework cation attached to this site. Therefore, the broadening of the peak suggests that it actually consists of two peaks, Ga–O–Si (3.5 Å) and Ga–O–Sr^{2+} (3.6 Å). The latter peak was also found in the Fourier transforms of Sr K-edge EXAFS of Sr^{2+}-exchanged Ga-silicate and Sr-containing Ga-silicate, as depicted in Fig. 4. The similarity between the profiles of Sr^{2+}-exchanged Ga-silicate and Sr-containing Ga-silicate implies that most of Sr in the latter are not contained in the silica matrix, but are in extra-framework ion-exchanging sites.

In conclusion, intermetallic distances of pentasil-structured bimetallosilicates were directly and precisely determined by means of EXAFS, providing the following information on interactions between the metals:

(1) The micro-structure around Ga of gallosilicate was formed in a very early stage of the hydrothermal reaction, before bulk crystallization, without the formation of an oxide or hydroxide of Ga.

(2) In the crystallization of Fe, Ga-bimetallosilicate, no interactions between Fe and Ga were found structurally, and the silicate framework was substituted by either metal independently.

(3) The micro-structure around Sr in Sr-containing gallosilicate was similar to that of Sr^{2+}-exchanged silicate, and Sr was in an extra-framework ion-exchanging site.

It is believed that precise control of the interactions between metals in metallosilicates is prerequisite for improving the catalytic property. To accomplish this control, a large amount of data on interactions must be accumulated. We have found EXAFS to be a very powerful tool for clarifying the interaction from a structural point of view at the atomic level. More detailed structural data will be produced with further investigations by EXAFS.

Synthesis of *N*-Methylaniline and *N,N*-Dimethylaniline with Methanol over Alumina Catalyst

Hiromi MATSUHASHI* and Kazushi ARATA
Department of Science, Hokkaido University of Education, Hachiman-cho, Hakodate 040
(Received January 28, 1991)

Synopsis. Alumina catalysts prepared by different methods were used for the synthesis of *N*-methylaniline and *N,N*-dimethylaniline from aniline and methanol. Al_2O_3 catalysts prepared from isopropoxide and nitrate showed high activity and JRC-ALO-1 and JRC-ALO-3 supplied by the Catalysis Society of Japan showed low activity. The highest selectivity for *N,N*-dimethylaniline was 82.8% with 90.1% aniline conversion. The catalytic activity of Al_2O_3 was not poisoned by pyridine and CO_2.

N-Alkylation of aniline with methanol was catalyzed by solid acid and base catalysts. Silica gel and ZSM-5 zeolites were applied for this reaction,[1,2] but catalytic activities of these catalysts were not high. In the case of acid catalysts, the activity for this reaction might be suppressed by the adsorption of aniline since aniline, itself, has a strong basic characteristic. It therefore seems that the use of a strong acid catalyst is not suitable for this reaction. Takemiya et al. reported aniline alkylation with methanol over solid base catalysts: MgO[3] and $NaOH/Al_2O_3$.[4] The products consisted exclusively of *N*-methylaniline. Alumina is one of the best catalysts for this reaction.[5] In this study, we report that Al_2O_3 catalysts prepared from isopropoxide and nitrate showed high activity for the *N*-methylation of aniline. We anticipate that Al_2O_3 has an acid-base bifunctional characteristic.

Four kinds of Al_2O_3 were used in this study.

Al_2O_3-1. Aluminum hydroxide was obtained by hydrolyzing $Al[OCH(CH_3)_2]_3$ (Wako Pure Chemicals, Guaranteed Reagent) dissolved in dried ethanol with distilled water. Water and ethanol were evaporated. Then, $Al(OH)_3$ was suspended in distilled water again and boiled for 1 h. Excess water was evaporated.

Al_2O_3-2. Aqueous ammonium was added to an aqueous solution of $Al(NO_3)_3 \cdot 9H_2O$ (Wako Pure Chemicals, Guaranteed Reagent) to precipitate $Al(OH)_3$. The final pH of the suspension was 7—8. The precipitate was washed with distilled water, dried, and heated at 773 K in air.

Al_2O_3-3 and Al_2O_3-4 were JRC-ALO-1 and JRC-ALO-3, supplied by the Catalysis Society of Japan as reference catalysts. MgO was prepared by boiling commercial high-purity MgO (Merck) in water, followed by drying and a thermal treatment at 773 K in a He stream. ZrO_2 was obtained by hydrolyzing $ZrO(NO_3)_2 \cdot 8H_2O$ (Wako Pure Chemicals, Guaranteed Reagent) with aqueous ammonia, washing, drying, and a thermal treatment at 773 K in air. Li^+/Al_2O_3 and Na^+/Al_2O_3 were prepared by an impregnation method. Al_2O_3-1 was suspended in aqueous Li^+ or Na^+ carbonate; the water was evaporated to dryness over a hot plate. The content of alkali ions was 10 mol%.

All catalysts were heated in glass reaction tubes at 773 K for 3 h in a He stream before reaction. The catalytic reaction experiments were carried out with a conventional flow microreactor. After the catalyst (0.2 g) was heat-treated in a reactor in the He stream (20 cm^3 min^{-1}), a vaporized mixture of methanol and aniline (mole ratio=5) was passed through the catalyst bed at a feed rate of 4.09 $cm^3 h^{-1}$. The partial pressure of methanol and aniline was 5.15×10^4 Pa and 1.03×10^4 Pa respectively. The product stream was cooled and condensed at a reservoir attached under the reactor. The liquid product was sampled every 30 min and analyzed by using a G.L.C. column (2 m×3 mm o.d.), packed with SE-30. The products were identified by GC-MS. The conversion is explained as being proportions of *N*-methylaniline and *N,N*-dimethylaniline based on aniline.

The conversion and composition of the products between 60 and 90 min at 623 K are summarized in Table 1. In all cases, even though the catalytic activity

Table 1. *N*-Methylation of Aniline over Various Catalysts at 623 K

Catalyst	Conversion	Selectivity/%	
	%	*N*-Methylaniline	*N,N*-Dimethylaniline
Al_2O_3-1	32.1	78.2	21.8
Al_2O_3-1[a]	66.1	60.4	39.6
Al_2O_3-1[a,b]	81.2	39.0	61.0
Al_2O_3-1[a,c]	90.1	17.2	82.8
Al_2O_3-2	30.5	70.1	29.9
Al_2O_3-3	21.7	69.6	30.4
Al_2O_3-4	17.5	83.3	13.7
ZrO_2	Trace	Trace

Na^+/Al_2O_3	0.8	100	—
MgO	Trace	Trace	

a) Reaction temperature: 673 K. b,c) Methanol/Aniline (mole ratio): b) 10, c) 15.

decreased rapidly during the initial period of the reactions, the catalysts showed almost constant activity after 60 min. Among the tested catalysts, the Al_2O_3 catalysts showed higher activity than did the other acid or base catalysts. In particular, Al_2O_3-1 and Al_2O_3-2 gave 32.1% and 30.5% methylated products, respectively. The selectivity for *N,N*-dimethylaniline was high when the flow rate of the He carrier was low. Table 1 also suggests that higher reaction temperatures and large ratios of methanol to aniline lead to a higher selectivity for *N,N*-dimethylaniline. In this study, the highest selectivity for *N,N*-dimethylaniline was 82.8%, with a 90.1% conversion. No liquid product was obtained when the reaction temperature was 723 K or higher. The activity of MgO, a typical solid base, was very low under the present conditions. ZrO_2, which is known to hold basic sites together with acidic ones on the surface,[6,7] also showed low activity.

Pyridine, CO_2, and H_2O were adsorbed on the Al_2O_3 surface for characterizing the active site. The supplement of the reactant mixture was stopped after a reaction for 120 min, and the adsorbant was introduced into the reaction system. The amount of pyridine or H_2O introduced was 0.5 cm^3 (as liquid); CO_2 was fed for 30 min. The results are shown in Table 2. The addition of pyridine and CO_2 had no (or less) effect on the catalytic activity, suggesting that the reaction did not occur at strong acid sites which were poisoned by pyridine. It was expected that the reaction proceeded on the basic site of Al_2O_3. Because the activity became slightly decreased by the adsorption of CO_2, Li^+/Al_2O_3 and Na^+/Al_2O_3 were applied for the reaction. The basicity of Al_2O_3-1 was enhanced[4] by doping of Li^+ and Na^+. However, as is shown in Table 1, both of these catalysts showed much less activity. It was therefore clear that this reaction did not occur only at the basic sites.

Table 2. Effect of Adsorption of Pyridine, CO_2, and H_2O

Addition	Conversion ratio (after/before)
Pyridine, 0.5 ml	1.0
CO_2, 30 min	0.95
H_2O, 0.5 ml	0.48

Adsorbants were added after the reaction for 2 h.
Reaction condition, see Text.

As is shown in above, the catalytic activity was affected by the doping of Na^+. Since Al_2O_3-3 and -4 contain 0.03% and 0.3% Na_2O, respectively, the reason for the low activity of Al_2O_3-3 and -4 was estimated to be that a small amount of Na^+ was contained as an impurity.

The effect of the addition of H_2O was, however, larger than that of pyridine or CO_2, and the activity was decreased to half before the addition.

Since water molecules poison both acidic and basic sites and the activity of Al_2O_3 or *N*-methylation of aniline, acid-catalyzed dehydration was very high, and even though the catalyst did not have a strong acid character, it could be presumed that the Al_2O_3 catalyst might act as a bifunctional catalyst in this reaction.

Synopsis. Sedimentation potentials and electrical conductivities were measured for NaCl, NaBr, sodium tetraphenylborate Na[BPh4], and tetraphenylphosphonium chloride [Ph4P]Cl in water–acetone systems (up to 50 wt% of acetone). Using the data obtained and the reported values of partial molar volumes V_2^∞, the ionic division of V_2^∞ was carried out. The values of V_2^∞ (Na^+) evaluated for NaCl, NaBr, and Na[BPh4] were self-consistent and they work as references for ionic division of V_2^∞ (MX).

As a continuation of our series of work on the division of the partial molar volume of an electrolyte V_2^∞ (MX) to the cationic and anionic parts,[1–4] we have measured the sedimentation potentials for NaCl, NaBr, Na[BPh4], [Ph4P]Cl, and [Ph4P]Br dissolved in water–acetone mixtures up to 50 wt% of acetone.

We reported earlier[5] that in water–acetone system, the V_2^∞'s of NaCl, KCl, CsCl, NaBr, KBr, and [Ph4P]Cl vary only slightly with solvent composition, while for the salt Na[BPh4], rather abrupt increase in V_2^∞ appears in solvents containing 10 to 30 wt% of acetone. Main purpose of this work is to see whether this increase of V_2^∞ (Na[BPh4]) is attributable to the ion Na^+ or the ion $[BPh_4]^-$.

For the ionic division of V_2^∞ of an electrolyte MX, data of transport number of the electrolyte MX are needed. Thus, conductivities of the sample salts have also been measured.

Experimental

Samples. Commercially available highest grade Na[BPh4] (Dojin Co., Ltd. or Fluka) was used without further purification. The [Ph4P]Cl and [Ph4P]Br used were the products of Fluka or Merck. The solvent acetone was purified for conductivity measurements by refluxing the guaranteed grade sample with molecular sieves but no purification was done for acetone for sedimentation potential measurements.

Sedimentation Potentials. The sedimentation potentials were measured at Kagoshima University. The experimental set-up was principally the same as before,[1] but in the course of this work some modifications were given on the sample cell and the measuring procedures. First, we prepared a new sample cell which is wholly made of teflon, while so far[1–4] part of the cell was made of acrylic resin. The platinum electrodes in the sample cell were directly connected to the outer electric circuit through a coaxial connector. Second, in our previous work[1–4] the electrodynamic vibrator was vibrated at frequency 100 Hz but in this work the frequency was 150 Hz for NaCl, NaBr, and [Ph4P]Cl, and 1000 Hz for Na[BPh4] and [Ph4P]Br. By adopting higher frequencies, we can reduce the effects of the so-call $1/f$ noise and the interference by the commercial AC of 60 Hz. The theory[6] predicts that even at frequency 1000 Hz no relaxation due to the electrophoretic effect of the ionic cloud appears in solutions with solute concentration less than 10^{-3} mol dm^{-3}.

In our sedimentation potential measurements, the amount of acceleration applied externally by the electrodynamic vibrator is expressed as $\omega^2 x$, where ω is the angular frequency and x is the amplitude of oscillation produced in solution. Thus far we have evaluated the magnitude of acceleration by measuring the amplitude x with stroboscope and microscope. We confirmed that change of the frequency from 100 to 150 Hz accompanies the corresponding decrease of the amplitude, the acceleration remaining constant. At frequency 1000 Hz, we monitored the degree of acceleration by an accelerometer, for the amplitude of vibration is too small to observe by microscope. The accelerometer (IMV Co., Ltd.) consists of a piezoelectric acceleration pick-up (IH-02) and a digital charge vibrometer (VM-1970). The acceleration applied to the cell was 7.0 G. Combined use of higher vibration frequencies and aceceleration meter permitted us to reduce the number of run needed to have the reliable sedimentation potential values in solutions.

Sedimentation potentials should be proportional to the externally applied acceleration. As is shown in Fig. 1, excellent linear relations passing through the origin hold for solutions of NaBr dissolved in water and in the solvent containing 30 wt% of acetone. In our apparatus, the vibration at frequency 100 Hz and amplitude 0.062 cm produces the acceleration 17.7 G. Extrapolation of the linear relations of Fig. 1 to the state of 17.7 G gives the identical values obtained at 100 Hz and amplitude 0.062 cm. The sedimentation potentials in aqueous solutions of Na[BPh4] and [Ph4P]Br at 7.0 G also

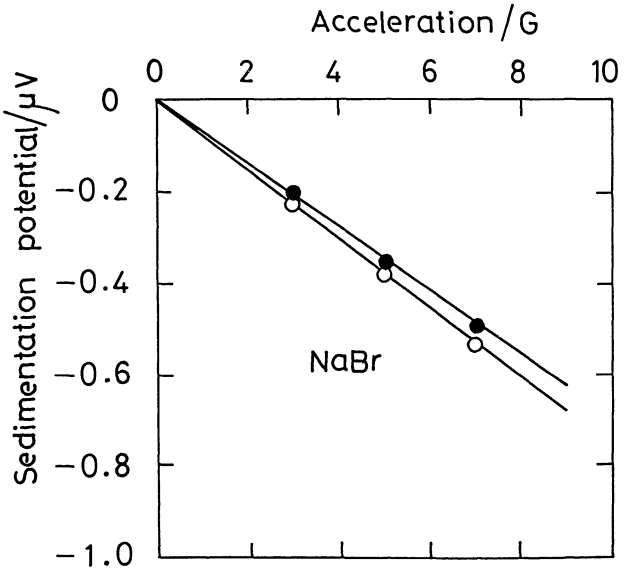

Fig. 1. Relation between the applied acceleration and the sedimentation potentials produced in solutions of NaBr dissolved in water (—○—) and 30 wt% of acetone (—●—).

correspond excellently to the values obtained at 100 Hz and amplitude 0.062 cm.

Electric Conductivities. The conductivities were measured at Shinshu University. The specific conductivities of the conductivity water and acetone were 1.3×10^{-7} and 0.9×10^{-8} S cm^2, respectively. A linear-type bridge and platinum black electrodes (cell constant 0.12305 cm^2) were used for the measurement. The sample solutions were in the ranges 10^{-4}—10^{-3} mol dm^{-3}, and the concentrations were changed in the cell by measuring the weight.

Results and Discussion

Electric Conductivities and Transport Numbers. We used the Fuoss–Onsager equation[7] to analyze the conductivity data:

$$\Lambda=\Lambda^{\infty}-S\,c^{1/2}+Ec\log c+Jc \qquad (1)$$

where c is the solute concentration in mol dm^{-3} and the coefficients S, E, and J are the parameters given by the

a) For NaCl, NaBr, and [Ph$_4$P]Cl, values at 17.7 G. For [Ph$_4$P]Br and Na[BPh$_4$], values at 7.0 G. b) Calculated from the electrical conductivities given in Table 1. c) For [Ph$_4$P]Br, see the text.

theory.[7] Data anaylsis showed that in any case investigated ion association is negligible. The limiting molar conductivities determined are summarized in Table 1. We then estimated the ionic molar conductivities based on the assumption that Λ^∞ ($[Ph_4P]^+$)=Λ^∞ ($[BPh_4]^-$). We have two ways of estimation:

$$\Lambda^\infty([Ph_4P]^+)=\Lambda^\infty([BPh_4]^-)$$
$$=(1/2)\{\Lambda^\infty(Na[BPh_4])+\Lambda^\infty([Ph_4P]Cl)-\Lambda^\infty(NaCl)\}$$
$$=(1/2)\{\Lambda^\infty(Na[BPh_4])+\Lambda^\infty([Ph_4P]Br)-\Lambda^\infty(NaBr)\}.$$

Both estimations lead to practically identical ionic molar conductivities. The worst is the system with 50 wt% of acetone for which the differences amount to three in the first decimal place. Transport numbers for each electrolyte were calculated using the ionic molar conductivities thus estimated. Our transport number for the ion Na^+ 0.418 for NaBr in 20 wt% of acetone is in fair agreement with the literature value 0.425.[8]

Sedimentation Potentials. The limiting sedimentation potentials[1] are given in Table 2 along with the numerical values of the solvent density used in the calculation.

Division of Partial Molar Volume into V_2^∞ into V_+^∞ and V_-^∞. The relation between the sedimentation potential E and the ionic partial molar volumes V_+^∞ and V_-^∞ is expressed as follows:[4]

$$E=(ad/F)\cdot[(t_+/z_+)\cdot(m_+-V_+^\infty\rho) - (t_-/z_-)\cdot(m_--V_-^\infty\rho)], \quad (2)$$

where the symbols are the same as in our previous work.[4] We have divided the partial molar volumes V_2^∞ (MX) of a salt MX into two ionic parts V_+^∞ (M^+) and V_-^∞ (X^-) by combining Eq. 2 and the additivity rule that V_2^∞ (MX)=V_+^∞(M^+) + V_-^∞(X^-). The V_2^∞ (MX) values are available,[5] except for V_2^∞ ([Ph4P]Br), which were estimated from V_2^∞ ([Ph4P]Cl), V_2^∞ (NaCl), and V_2^∞ (NaBr).

Ionic partial molar volumes obtained are included in Table 2. The values of V_+^∞ (Na^+) calculated from V_2^∞'s of NaCl, NaBr, and Na[BPh4] agree each other within experimental errors over the whole solvent composition investigated. On the contrary, the V_-^∞ (Br^-) values calculated from V_2^∞ (NaBr) and V_2^∞ ([Ph4P]Br) differ considerably in solvents containing more than 30 wt% of acetone. As for the ion $[Ph_4P]^+$, the values from ([Ph4P]Cl) are always larger than those from the V_2^∞ ([Ph4P]Br) by 6—11 $cm^3\,mol^{-1}$. For the ion Cl^-, differences in the values of V_-^∞ (Cl^-) from V_2^∞ (NaCl) and V_2^∞ ([Ph4P]Cl) become progressively larger with the amount of acetone in the solvent. The reason for these inconsistent results for the salt [Ph4P]X (X=Cl or Br) is unclear for us at present. According to Perie, Perie, and Chemla,[9] the ion $[Ph_4P]^+$ decomposes at the cathode, although they mentioned nothing about the degree of decomposition. Taking into account all factors we have taken the values of V_+^∞ (Na^+) averaged over those calculated from V_2^∞ (NaCl), V_2^∞ (NaBr), and V_2^∞ (Na[BPh4]) as references for ionic division of V_2^∞ (MX). The values of V_+^∞ (Na^+) are: −3.9, −3.6, −3.6, −3.7, −4.3 (averaged over NaCl and NaBr), and −3.9 $cm^3\,mol^{-1}$ at 0, 10, 20, 30, 40, and 50 wt % of acetone, respectively.

Dielectric constant of water–acetone mixture decreases with wt% of acetone. In spite of the decrease in the dielectric constant, the ionic partial molar volumes of the simple univalent ions Na^+, Cl^-, and Br^-, hence, the V_2^∞ (NaCl) and V_2^∞ (NaBr) remain practically constant. Also the ion $[Ph_4P]^+$ shows the behavior independent of the solvent composition. Through ionic division of V_2^∞, it has become clear that the abrupt increase of V_2^∞ (Na[BPh4]) in the solvent composition ranges 20—30 wt % of acetone as reported earlier[5] is due to the ion $[BPh_4]^-$ and not to the ion Na^+.

Part of this work was reported in the Fourth Asia Pacific Physics Conference held in Seoul in August in 1990. This work was supported by Grant-in-Aid for Scientific Research on Priority Area of "Molecular Approaches to Non-equilibrium Processes in Solutions" No. 02245101 from the Ministry of Education, Science and Culture.

Thermodynamic Study of Brij 35 in Aquo-Polyethylene Glycol Solvents

Leena KOSHY and Animesh Kumar RAKSHIT*
Department of Chemistry, Faculty of Science, M. S. University of Baroda, Baroda 390002, India
(Received September 25, 1990)

Synopsis. The critical micelle concentrations of Brij 35 in aquo PEG 200 solutions were determined by the iodine solubilization method at five different temperatures at various PEG percents. The thermodynamic quantities of micellization as well as the free energies of micellization at infinite dilution were computed and rationalized.

As a part of our interest on the thermodynamics of micellization of nonionic surfactant, Brij 35, in aqueous solution in the presence of various solutes, it was decided to study the effect of polyethylene glycol 200 (PEG 200) on the micellization process of this surfactant in water. Effect of sucrose[1] was studied earlier. PEG 200 is an oligomer and its effect on micellization of Brij 35 was expected to be more chemical than electrochemical in nature. We choose PEG 200 because a literature survey did not show any study with this oligomer. This paper deals with PEG 200 at concentration of 2 to 10% w/v. Due to the importance of nonionic surfactants in industry, e.g., detergency,[2] in the formation of microemulsion[3] which may be useful in tertiary oil recovery and so on, the importance of detailed knowledge of thermodynamics of micellization of nonionic surfactants in presence of other components has become topical. Though there are reasonably large number of studies of the nonionic surfactant Triton X100,[4,5] we have not found detailed systematic study of Brij 35 in literature. Therefore a systematic thermodynamic study of the effect of PEG 200 on the micellization of Brij 35 is reported here.

PEG 200 (Merck, India) was used without any further treatment. Brij 35 (BDH, England) was also used as received. Its chemical formula is $C_mH_{2m+1}(OCH_2CH_2)_nOH$ where m=12 and n=23 with molar mass 1198. Iodine (Sarabhai, India) was sublimed before use and water was doubly distilled from $KMnO_4$. The iodine solubilization method[1,6] was used for determining critical micelle concentration (cmc). The experimental procedure adopted was explained in an earlier publication.[1] There was always a possibility of PEG interacting with iodine and thereby affecting the result. Hence direct surface tension determination by the Wilhelmy plate method was done for a few systems in absence of iodine to determine the critical micelle concentration. The results were comparable with each other as can be seen from Table 1.

Table 1. Critical Micelle Concentration, cmc (μmol dm^{-3}) of Brij 35 in Various Aquo–PEG Solutions at Different Temperatures

Solvent (% PEG 200)	cmc at				
	30 °C	35 °C	40 °C	45 °C	50 °C

6.0	26	29(29)[a]	33	36	38
8.0	25	28	30	35	37
10.0	23	25	28	30	35

a) By direct surface tension determination by Wilhelmy plate method in absence of iodine.

In Table 1 the cmc in water as well as in 2,4,6,8, and 10% PEG 200–water solution at the experimental temperatures of 30,35,40,45, and 50 °C are reported. The maximum error in these values was estimated to be 1.0 μmol from at least three separate measurements and then the standard deviation of the mean was computed. In Fig. 1 we plot the variation of cmc (mole fraction scale) as a function of concentration of PEG at different temperatures. It seems that the effect of increase in temperature and that of increase in PEG amount is similar. It is well known that increase in temperature effects the three dimensional water matrix by breaking it. It seems that the addition of PEG has similar effect. When PEG is added to water, by virtue of its very presence, it breaks the water matrix and then interacts with water to form a different three dimensional structure. The variation of cmc seems to be dependent on the water structure to a very large extent and not to be so much on the water–PEG matrix. Formation of structured solvent should probably have increased the

cmc. Now in Table 1 we find that there is increase in the cmc values at 50 °C with the addition of PEG (2%). That is why we believe that the water–PEG structure has also some effect on cmc values. Two opposing effects are present in the system. These are (1) water structure break down and (2) water–PEG structured matrix formation. The cmc values depend on the effect of these two factors on micelle formation. The quantitative effect of each of these factors is difficult to estimate at this moment. From Fig. 1 it is observed that at about 1% PEG all cmc-concentration of PEG isotherms intersect. This fact indicates that probably at this concentration of PEG the processes of micellization of Brij 35 at all temperatures are similar.

In Table 2 the thermodynamic quantities calculated for these systems are given. The free energy, enthalpy, and entropy of micellization were computed by using the following well known relations

$$\Delta G_m = RT \ln(\text{cmc}),$$
$$\Delta H_m = -RT^2 \, \mathrm{d} \ln(\text{cmc})/\mathrm{d}T,$$
$$\Delta S_m = (\Delta H_m - \Delta G_m)/T,$$

where cmc was taken in mole fraction scale. The transfer process here means the formation of the micelle in the corresponding solvent from solvated free monomer surfactant whose mole fraction was unity. To calculate ΔH_m, ln(cmc) was plotted against T and a linear plot was obtained. The slope of the line was taken as $\mathrm{d} \ln(\text{cmc})/\mathrm{d}T$. This value was found to be positive for all PEG containing systems. Therefore the micellization process was exothermic for all of them. Only for pure aqueous solution the micellization was endothermic in nature. The maximum error in ΔG_m was estimated to be ±0.3%. The error in ΔH_m was ±3.0% which was determined from the standard deviation of the slope of ln(cmc)–T plot by regression analysis. The error in ΔS_m values was ±1.0%.

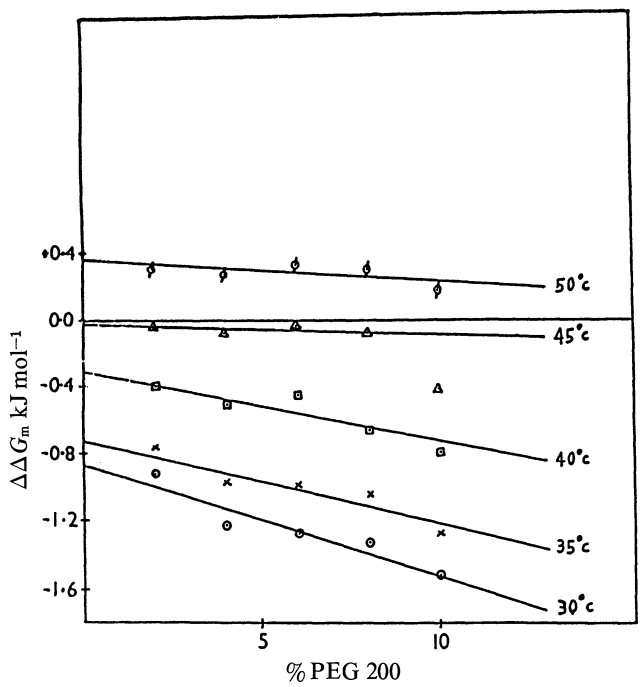

Fig. 2. Plot of $\Delta\Delta G_m$ vs. % PEG 200 at various temperatures.

From Table 2 we find that the ΔS_m is of the order of 70 J mol^{-1} K^{-1}. This type of high entropy change is generally associated with phase changes. Hence it can be assumed that the micelle behaves as a new phase here. It has also been suggested[7] that the positive values of ΔS_m can be attributed to the increase in entropy due to water structure breakdown on micellization as well as due to release of water molecules associated with hydrocarbon chains[8,9] which overshadows the decrease in entropy due to micelle formation. Shaw[10] suggests that it might be due to the freedom of movement of the hydrocarbon chain in the core of the micelle.

It is possible to calculate $\Delta\Delta G_m$ for these systems. This quantity is the free energy of transfer of micelle from pure aqueous environment to PEG containing solution environment plus the medium effect i.e. the free energy of transfer of free monomer surfactant from water to the particular solvent. Pure solvent at atmospheric pressure was taken as the standard state. In Fig. 2 such $\Delta\Delta G_m$ is plotted against % PEG at all temperatures. It is observed that at the highest temperature of study i.e. at 50 °C these processes of transfer together is nonspontaneous one whereas at 45 °C the transfer free energy change is around zero. At other temperatures of 30, 35, and the 40 °C the Brij 35, in monomeric form and also as micelle, prefers the PEG containing solvent rather than the aqueous one (for example at 2% PEG Δcmc in comparison with aqueous solution at 30 °C is 15 units whereas at 50 °C it is −5 units, Table 1). Also

Table 3. $\Delta\Delta G_m$ and $\Delta G_m^{s,0}$ in Aquo–PEG Solvent Systems

Temperature/°C	$\lim_{c\to 0} \Delta\Delta G_m$	$\Delta G_m^{s,0}$
	kJ mol^{-1}	kJ mol^{-1}
30	−0.87	−36.2
35	−0.73	−36.6
40	−0.32	−37.0
45	−0.03	−37.5
50	0.36	−37.9

this linear plot can be extrapolated to $c=0$ where c is the concentration of PEG. On can then write

$$\lim_{c\to 0} \Delta\Delta G_m = \Delta G_m^{s,0} - \Delta G_m^{w}$$

where s is solvent, w is water and 0 indicates that the solvent is infinitely diluted in terms of PEG. This quantity signifies whether the micelle prefers an infinitely dilute PEG containing aqueous environment to a purely aqueous surrounding or not.

The data so calculated for $\Delta G_m^{s,0}$ range between -36.2 to -37.9 kJ mol^{-1} at between 30 and 50 °C respectively which are quite similar to that in a sucrose system[1] suggesting similar effect by these two solutes on overall water matrix.

Spectrophotometric Detection for Flow Injection Analysis of Tertiary Alkylamines in Terms of the Intermolecular Charge-Transfer Interaction with Iodine

Bunji Uno,* Kiho Nakajima, and Satoshi Kawai
Gifu Pharmaceutical University, Mitahora-higashi, Gifu 502
(Received February 25, 1991)

Synopsis. Spectroscopic studies of the intermolecular charge-transfer interaction with iodine have been extended in order to develop a new spectrophotometric detection method for flow injection analysis (FIA). Tertiary alkylamines, as a model compound of spectroscopically inactive species, have been determined with high detection sensitivity by FIA using the present detection method.

Although both spectrophotometric and electrochemical detectors are generally used for flow injection analysis (FIA) or high-performance liquid chromatography (HPLC), it is necessary for compounds inactive to both detectors to be derivatized to active species.[1,2] Some compounds are, however, allowed to be derivatized by a few methods with experimental difficulties.[2,3] It is therefore very significant and important to develop a direct detection method for spectroscopically inactive species without derivatization. On the other hand, the intermolecular charge-transfer (CT) process of organic molecules has been investigated in various fields of chemistry, physics, and biophysics. However, analytical applications using this CT interaction have been quite limited in number. In this paper we have addressed ourselves to the development of a new spectrophotometric detection method for flow systems in terms of intermolecular CT spectra with iodine, adopting an FIA method in order to avoid problems concerning chromatographic separation. The present technique has been examined by the determination of tertiary alkylamines as a model compound possessing no bands in the ultraviolet—visible region, and being extremely difficult to be derivatized to spectroscopically active species.

Experimental

Spectral Measurements. Iodine molecular complexes with alkylamines were studied in heptane and dichloromethane. Their spectral measurements were performed using 1 or 10 cm matched quartz cells equipped with stoppers, regulated to 25 °C by circulating constant temperature water throughout the cell compartment by the use of a Taiyo thermoleader (Model EZL-80).

Flow Injection System. The FIA apparatus is shown schematically in Fig. 1; it comprises Shimadzu LC-6AD and LC-3A HPLC pumps to provide a flow of the dichloromethane carrier and to deliver a dichloromethane solution of iodine; a Rheodyne 7125 injector with a 20-μl loop is used to introduce the analyte. A Gasukuro Kogyo low-dead-volume mixing tee was used to mix the mobile phase carrying the analyte with the iodine solution. A Shimadzu SPD-6A spectrophotometric detector was set at 290 nm. These instruments were connected using a stainless-steel pipe with an inner diameter 0.3 mm (Fig. 1).

Chemicals and Solvents. The samples employed here were triethylamine, tripropylamine, and tributylamine, which were commercially available from Nacalai Tesque, Inc., and were purified by repeated distillation under reduced pressure. Solvents used for spectroscopic observations were heptane and dichloromethane of spectrograde purity, dried over CaH_2 and then carefully rectified. Dichloromethane of special guaranty grade was used as an FIA carrier without any further treatment. The carriers available for the present detection scheme were solvents inactive to iodine, that is, having no electron-donating character such as saturated hydrocarbons or alkyl chlorides. If heptane was used as a carrier, we failed to pump quantitatively throughout the apparatus because of its low viscosity.

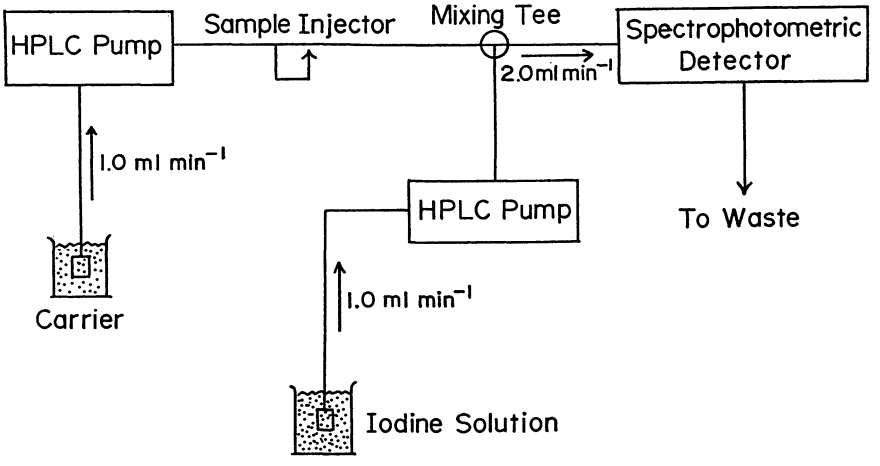

Fig. 1. Schematic diagram of the flow injection apparatus.

Results and Discussion

Formation of the Iodine Complexes with Tertiary Alkylamines. The intermolecular n-σ type CT interaction of alkylamines with strongly electron-accepting iodine has been both theoretically and experimentally investigated in detail.[4-6] The spectral measurements and their analyses gave constants (K) of the iodine CT complex formations of triethylamine, tripropylamine and tributylamine in heptane at 25 °C as 4840, 807 and 1370 mol^{-1} dm, respectively, by the use of Kubota's and Benesi-Hildebrand's equations;[7-9] this value for triethylamine was in fair agreement with that determined by Nagakura.[5] A theoretical analysis using the above equations has made it possible to evaluate the absorption maximum (λ_{max}) and its molecular extinction coefficient (ε_{max}) of the intermolecular CT bands for tertiary alkylamines-iodine-heptane system as ca. 280 nm and 2.5×10^4, respectively. The CT spectra were also recorded in dichloromethane with the addition of alkylamines to an iodine solution, showing an isosbestic point resulting from the 1 : 1 complex formation. Since the concentration ratio of alkylamines to iodine was unsuitable for the above equations, accurate K values in dichloromethane could not be evaluated. However, the absorbance of the CT spectra observed is linearly dependent on the donor concentration, indicating that the CT complexes are considered to form quantitatively in dichloromethane in view of the large K values in heptane.[10] The apparent λ_{max} and ε_{max} of the CT transition were evaluated in dichloromethane as 288 nm and 1.54×10^4 for triethylamine, 291 nm and 1.10×10^4 for tripropylamine, and 291 nm and 1.93×10^4 for tributylamine, respectively. Therefore, these bands seem to be applicable to the determination of tertiary alkylamines with a spectrophotometric detector.

The amines are no sooner added to the iodine solution than the solution apparently changes color, indicating that the CT complexes are formed promptly. The temperature dependence on the K values of the iodine CT complexes were investigated;[5,7] it is thus concluded that the lower is the temperature the easier is formation, since the change in enthalpy is negative for complex formation. However, the 10^{-4} mol dm^{-3} level of iodine was sufficient to quantitatively form CT complexes with the amines under 10^{-5} mol dm^{-3} at room temperature, owing to their large K values.

FIA Determination of Tertiary Alkylamines. Optimum FIA conditions were established as follows on the basis of a series of preliminary investigations. A mode of post-injection was adopted to the present FIA determination, since direct injection to the carrier containing iodine did not give the expected increase in the FIA response. The FIA peak height was practically independent of the period from mixing to detection, indicating that the formation rate of the CT complexes is very fast. A commercial mixing tee without further improvement is capable of mixing the carrier with the iodine solution. The pumps were operated at a flow rate of 1.0 ml min^{-1}, which was adequate to obtain a sharp peak. With regard to the concentration of iodine, the 10^{-4} mol dm^{-3} level is sufficient for a quantitative formation of the CT complexes, as mentioned above. The use of a solution of more than 10^{-3} mol dm^{-3} gave an unstable base line. Detection at 290 nm was selected in consideration of the λ_{max} of the CT

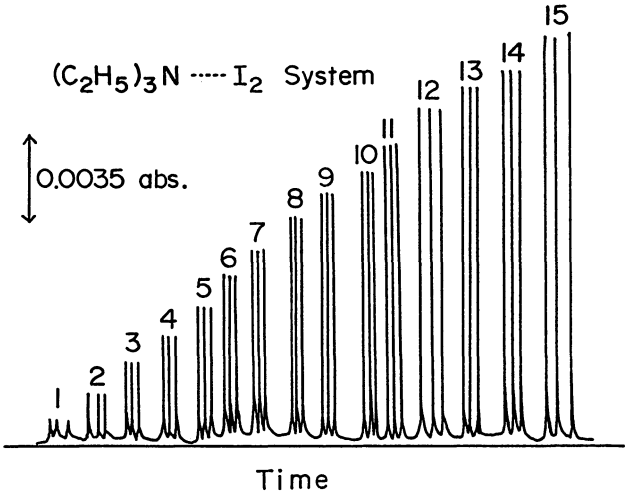

Fig. 2. Flow injection response of triethylamine. The time required for an appearance of the peak is 1.5 min after injection of a sample. Conditions: flow rate of carrier, 1.0 ml min^{-1}; flow rate of iodine solution, 1.0 ml min^{-1}; sample injection, 20 μl; detection wavelength, 290 nm. Concentration of iodine solution is 1.13×10^{-4} mol dm^{-3}. Concentrations of triethylamine are (1) 0.67, (2) 1.34, (3) 2.01, (4) 2.68, (5) 3.35, (6) 4.02, (7) 4.69, (8) 5.36, (9) 6.03, (10) 6.70, (11) 7.37, (12) 8.04, (13) 8.71, (14) 9.38, and (15) 10.1×10^{-6} mol dm^{-3}.

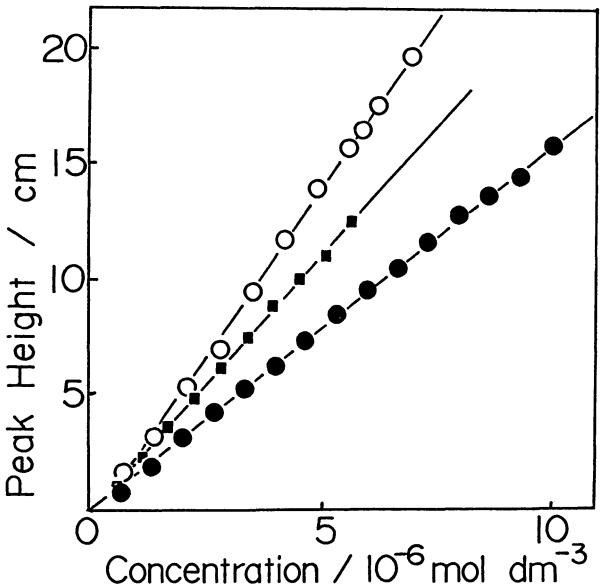

Fig. 3. Concentration (C) dependence of FIA peak height (PH) for triethylamine (●), tripropylamine (■), and tributylamine (○). The regression equations are PH=1.57C−0.137 (sample number (n)=15, standard deviation (s)=0.103, regression coefficient (r)=0.9995) for triethylamine, PH=2.24C−0.320 (n=10, s=0.103, r=0.9997) for tripropylamine, and PH=2.89C+0.867 (n=11, s=0.319, r=0.9988) for tributylamine.

Table 1. Detection Limit for Tertiary Alkylamines by the Present FIA method

Compounds	Detection limit[a]		
	mol dm^{-3}	10^{-9} g	10^{-12} mol
Triethylamine	6.71×10^{-7}	1.36	13.4
Tripropylamine	5.70×10^{-7}	1.63	11.4
Tributylamine	7.11×10^{-7}	2.63	14.2

a) The detection limit was examined with a 20-μl injection.

spectra for iodine-tertiary alkylamines-dichloromethane systems.

A typical response of FIA for the determination of triethylamine is shown in Fig. 2. The FIA response was very good for all of the samples, and the peak height was linearly dependent on the sample concentration (Fig. 3). The detection limit collected in Table 1 was determined as the lower linear range of the calibration lines, since an unavoidable background signal appears with sample injection to an FIA apparatus equipped with a spectrophotometric detector set at high sensitivity. Therefore, good linearity was obtained down to the detection limit determined here, as shown in Fig. 3. It may be allowed to detect more sensitively by adopting the present method to HPLC analysis. However, the detection limit obtained is far superior to the 4×10^{-5} mol dm^{-3} of triethylamine determined by the use of the derivatization method to chemiluminescence based on the oxidation of tertiary amines by benzoyl peroxide.[3] The other methods concerning the derivatization of tertiary amines permit the detection of these analytes at only 2—10×10^{-6} g.[2] Recently, Danielson et al. reported a generation of the chemiluminescent metal complexes of aliphatic amines with tris(2,2′-bipyridine)ruthenium(III).[11] This method can be considered to be very superior and efficient for the determination of aliphatic amines with respect to the detection limits, permitting the limit of these analytes at the 0.04—2×10^{-9} g level. However, the chemiluminescent method upon reaction with tris(2,2′-bipyridine)-ruthenium(III) seems to require the high technique in terms of treating unstable reagents and the construction of a spectroscopic cell to detect the emission of the short lifetime chemiluminescence. Therefore, our CT interaction method can be regarded being both profitable and useful as a simple determination of aliphatic amines in many respects.

As a conclusion, we may safely say that intermolecular CT interactions are applicable for the detection of tertiary alkylamines by FIA with a spectrophotometric detector. The present method appears to be very promising as a HPLC postcolumn detector. Further, since iodine forms CT complexes with many organic substances as a strong σ-electron acceptor, particularly with those having nonbonding electrons,[4-8] this detection scheme might well be adopted for the determination of these compounds possessing no good chromophore.

Extraction-Spectrophotometric Determination of Vanadium(V) with Pyrocatechol and N^1-Hydroxy-N^1,N^2-diphenylbenzamidine

Chandresh AGRAWAL,* Khageshwar Singh PATEL, and Rajendra Kumar MISHRA
Department of Chemistry, Ravishankar University, Raipur 492010, M. P., India
(Received April 12, 1990)

Synopsis. A sensitive procedure for spectrophotometric determination of V(V) with pyrocatechol and N^1-hydroxy-N^1,N^2-diphenylbenzamidine (HDPBA) is described. The value of molar extinction coefficient (ε) of the colored complex in chloroform is 5.60×10^5 dm^3 mol^{-1} cm^{-1} at λ_{max} 410 nm. The optimization of analytical variables, effect of diverse ions and application of the method to environmental samples have been investigated.

Vanadium is reported toxic to human being, animal, and plants .[1-3] Therefore, many sensitive spectrophotometric methods (e.g. xanthene derivative,[4,5] 3,5-dinitrocatechol with brilliant green[6] and rhodamine B,[7] phenylethylenediantipyrinylmethane,[8] diphenylcarbazide,[9] *N*-(*o*-sulphonic benzoyl)-*N*-pyridine (*N*-(2-pyridyl)-2-sulphobenzamide)[10] and hexadecyltrimethyl ammonium[11]) for determination of V(V) in a variety of complex materials are claimed. Most of these methods suffer from interelemental interferences. In the present investigation, another type of new, selective and sensitive method for the spectrophotometric determination of V(V) with pyrocatechol and N^1-hydroxy-N^1,N^2-diphenylbenzamidine is described. The sensitivity of the present method is comparable to other reported methods whereas the selectivity is seen to be superior.

Experimental

Apparatus. A Varian DMS-100 UV-vis spectrophotometer (double beam) matched with 1 cm quartz cells was used for the absorbance measurements. A Systronic pH meter model-335 was employed for measuring the pH values.

Reagents. All chemicals used were of analytical grade. A standard V(V) stock solution (100 μg V/cm^3) was prepared by dissolving the weighed amount of ammonium metavanadate in double distilled water and standardized as in literature.[12] N^1-hydroxyamidine were prepared as described in literature.[12] A pH 6.0 buffer was prepared by dissolving the appropriate amount of sodium hydroxide–potassium hydrogen phosfate.[13] A 0.4% w/v (0.036 mol dm^{-3}) pyrocatechol in water and 0.4% w/v (0.0138 mol dm^{-3}) N^1-hydrory-N^1,N^2-diphenylbenzamidine solution in ethanol was employed.

Procedure. An aliquot of the solution containing upto 1.0 μg V(V) is taken in a 50 cm^3 beaker and heated with 2.0 cm^3 pyrocatechol and 5.0 cm^3 ethanolic solution of N^1-hydroxyamidine. The pH of the solution is adjusted to 6.0 with sodium hydroxide–potassium hydrogen phosfate buffer (1.0 cm^3) in the 10 cm^3 total solution. The solution is heated over boiling water bath till volume of the solution is reduced to nearly half. Then the cold solution is transferred to a 100 cm^3 separatory funnel by maintaining total aqueous volume to 8.0±2.0 cm^3 with distilled water. The aqueous solution is shaken with 8.0 cm^3 chloroform and the organic phase is separated. The aqueous phase is further washed with 1×2 cm^3 fresh chloroform. All the extract is dried over anhydrous sodium sulfate (2 g) in a 25 cm^3 beaker. All the extract after drying is transferred to 10 cm^3 volumetric flask and filled upto the mark with chloroform. The spectra of the complex formed is scanned against the reagent blank.

Table 1. Spectral Characteristics of Different Species Formed with V(V)+Pyrocatechol or V(V)+Pyrocatechol+HDPBA

Analytical characteristics	Solvent	λ_{max} / nm	ε / dm^3 mol^{-1} cm^{-1}
V(V)+Pyrocatechol (9.0×10^{-3} mol dm^{-3})	Water	420	4650
V(V)+Pyrocatechol (1.6×10^{-1} mol dm^{-3})	Water	590	7600
V(V)+Pyrocatechol (9.0×10^{-3} mol dm^{-3}) (upon heating)+ HDPBA in Chloroform	Chloroform	410	15000
V(V)+Pyrocatechol+ 1 ml ethanol (upon heating) +HDPBA in Chloroform	Chloroform	410	18000
V(V)+Pyrocatechol+ HDPBA in ethanol (at room temperature)	Water–ethanol	410	17500
V(V)+Pyrocatechol+ HDPBA in ethanol (upon heating)	Water–ethanol	390	1.37×10^5
V(V)+Pyrocatechol+ HDPBA in ethanol (upon heating)	Chloroform	410	5.6×10^5

Results and Discussion

Spectral characteristics of the colored complexes formed with V(V)+pyrocatechol, V(V)+N^1-hydroxyamidine, and V(V)+pyrocatechol+N^1-hydroxyamidine at different analytical conditions are summarized in Table 1.

Absorption Spectra. The absorption spectra of the colored complex formed among V(V)+pyrocatechol +HDPBA against the reagent blank in chloroform and that of the reagent blank against chloroform are shown in Fig. 1. The absorption maximum of the colored complex formed, lie at 410 nm. At this region, the reagent blank shows some absorption, hence all the measurements were made against the reagent blank.

Effect of Variables on Formation of the Colored Complex: The effect of pH of the aqueous solution before heating is studied. The optimum pH range is found to be 5.5—6.5. A 40—70% (v/v) ethanol concentration is adequate for maximum color development. Removal of excess of ethanol is necessary in order to prevent miscibility of the aqueous and organic phase. At least 0.005 and 0.007 mol dm^{-3} of pyrocatechol and HDPBA is needed for maximum and constant color development and addition of more pyrocatechol and HDPBA upto 0.01 and 0.017 mol dm^{-3}, respectively cause no adverse effect on the color development of the complex. A heating time of at least 8 min (over boiling water bath) is required for the maximum color development of complex formed in aqueous ethanol solution and prolonged heating upto 15 min cause no adverse effect.

Effect of Variables on the Extraction of the Colored Complex: The colored complex formed among V(V)+pyrocatechol+N^1-hydroxyamidine is quantitatively extractable into chloroform, carbon tetrachloride, benzene, and toluene. Of these, toluene gives the most sensitive color reaction (ε=11.0×10^5 dm^3 mol^{-1} cm^{-1}, λ_{max} 420 nm) but after 5 min the organic phase becomes hazy probably due to low solubility of N^1-hydroxyamidine. Hence, chloroform (5.60×10^5 dm^3 mol^{-1} cm^{-1}, λ_{max} 410 nm) has been chosen for the extraction of the complex in the present investigation.

The variation of the temperature of the aqueous phase from 15—40 °C cause no change in the absorbance of the extract. The color of the extract is stable for at least 1 h at room temperature (22±2 °C). The volume ratio of the organic to the aqueous phase from 5 : 2 to 1 : 2 do not affect the color intensity of the extract. A shaking time of 2 min is sufficient for maximum extraction.

The optimum concentration range on the basis of Beer's law is found to be 0—1.0 μg V(V)/10 cm^3 in chloroform with a correlation coefficient of 0.98. The molar absorptivity of the colored complex and the limit for detection of the metal are 5.60×10^5 dm^3 mol^{-1} cm^{-1} and 0.1 μg dm^{-3} (more than the absorbance value of the blank and twice of standard deviation of the blank for 10 replicate measurements) at λ_{max} 410 nm, respectively. The relative standard deviation of 10 replicate measurements at level of 0.4 μg V/10 cm^3 in chloroform is found to be ±2% and the confidence limit at 95% probability is (5.60±0.05)×10^5 dm^3 mol^{-1} cm^{-1}.

Percentage Extraction. A 10 and 20 μg standard solution of V(V) is taken and color is developed as in the

procedure. The colored complex is extracted, the extract is evaporated, digested with acids and determined by 4-(2-pyridylazo)resorcinol as in the literature.[15] The percentage extraction is found to be 98±0.2% in a single extraction.

Stoichiometry of Extraction. The ratio of the metal to pyrocatechol or HDPBA was determined by plotting $\log A/(A_{max}-A)$ versus log molar concentration of pyrocatechol or HDPBA in the organic solution. The slope for pyrocatechol and HDPBA curves are found to be 1.98 and 1.86, respectively, close to integer 2, suggesting the involvement of vanadium : pyrocatechol : HDPBA in 1 : 2 : 2 ratio in the formation of chloroform extractable colored complex. V(V) is reduced to V(IV),[14] by means of pyrocatechol to react further with 2 moles each of pyrocatechol and N^1-hydroxyamidine. The probable reaction mechanism can be written as:

$$VO^{2+} + 2\ PyO_2^{2-} + 2\ HDPBA + n\ EtOH + 2H^+ \rightleftarrows [V(PyO_2)_2]\cdot 2\ HDPBA\cdot n\ EtOH + 2H_2O$$

The complex so formed is extractable into chloroform

$$[V(PyO_2)_2]\cdot 2\ HDPBA\cdot n\ EtOH + 2H_2O \rightleftarrows [V(PyO_2)_2]\cdot 2\ HDPBA\cdot n\ EtOH_o + 2H_2O$$

Where o, PyO_2^{2-}, and HDPBA denote the organic phase, pyrocatechol anion, and N^1-hydroxy-N^1,N^2-diphenylbenzamidine, respectively.

Effect of Diverse Ions: The effect of the diverse ions on the determination of 0.4 μg V(V) was studied as in procedure. No diverse ions were found to interfere in the spectrophotometric determination of the metal. Their tolerance limit are summarized in parenthesis in μgs:
Cu(II) (200), Ag(I) (150), Ba(II) (100), Cd(II) (40), Hg(II) (50), Al(III) (200), La(III) (100), Pb(II) (40), Zr(IV) (200), As(V) (75), Sb(V) (50), Nb(V) (50), Cr(III) (125), W(VI) (50), Fe(III) (50), Co(II) (100), Ni(II) (100), Os(VIII) (25), U(VI) (150), EDTA (400), F^- (150), $C_2O_4^{2-}$ (50), NO_3^- (50), PO_4^{3-} (400).

Application. The validity of this method is tested to environmental samples e.g. cement dust, coal dust, sea water, and industrial waste water. The solid sample is digested with aqua regia and concentrated hydrochloric acid and the dried residue is dissolved in water. In case of 4-(2-pyridylazo)resorcinol method, the metal is prior separated by extraction with N^1-hydroxy-N^1,N^2-diphenylbenzamidine from 6 mol dm^{-3} CH_3COOH as described in the literature.[12] The extract is evaporated, digested by acids treatment, dissolved in water and determined spectrophotometrically by 4-(2-pyridylazo)resorcinol.[15] The metal content analysed by these two procedures are comparable (Table 2).

Reforming of Ethanol —Dehydrogenation to Ethyl Acetate and Steam Reforming to Acetic Acid over Copper-Based Catalysts—

Nobuhiro IWASA* and Nobutsune TAKEZAWA*
Department of Chemical Process Engineering, Hokkaido University, Sapporo 060
(Received February 12, 1991)

The title reactions, $2CH_3CH_2OH \rightarrow CH_3COOC_2H_5+2H_2$ and $CH_3CH_2OH+H_2O \rightarrow CH_3COOH+2H_2$, were carried out over copper-based catalysts (Cu, Cu/SiO_2, Cu/ZrO_2, Cu/Al_2O_3, Cu/MgO, and Cu/ZnO). The selectivities to ethyl acetate and acetic acid markedly depended upon the supports used. Acetaldehyde was formed by the dehydrogenation of ethanol and transformed to either ethyl acetate or acetic acid through steps in which a nucleophilic addition of ethanol (or ethoxide ions) or water (or hydroxide ions) to acetaldehyde occurred. The rates of the transformation steps to ethyl acetate and acetic acid were appreciably affected by the kinds of supports used. The transformation steps proceeded slowly, compared with the dehydrogenation step.

Although alcohols are rapidly dehydrogenated to aldehydes or ketones over copper-based catalysts,[1] the dehydrogenation of higher alcohols is poorly selective. The aldehydes and ketones formed partly undergo an aldol condensation and/or transformation to esters.[2,3] In the dehydrogenation of methanol, methyl formate is produced in high selectivity over copper-based catalysts.[4-6] We have shown that this reaction proceeds consecutively through the dehydrogenation of methanol to formaldehyde and the reaction between the formaldehyde and methanol (or methoxide ions).[7] When water was present along with methanol, steam reforming of methanol ($CH_3OH+H_2O \rightarrow CO_2+3H_2$) occurs selectively.[8,9] The formaldehyde produced reacted rapidly with water to form carbon dioxide and hydrogen via surface formate or formic acid.[10]

Although Kawamoto et al. previously studied the dehydrogenation of various higher alcohols over unsupported copper,[2,3] their experiments were conducted within a restricted range of operating conditions. Regarding the steam reforming of higher alcohols over copper-based catalysts, no paper has been published according to our knowledge.

In the present study, the title reactions were carried out over various copper-based catalysts under a wider range of operating conditions, and differences in the mechanisms of the reactions involving methanol and ethanol were elucidated.

Experimental

The catalysts used in the present experiments were unsupported Cu, Cu/SiO_2 (0.5—90 wt% Cu), Cu/ZrO_2 (0.5—30 wt% Cu). $CuAl_2O_3$ (6.3 and 30 wt% Cu), Cu/MgO (6.2 and 30 wt% Cu), and Cu/ZnO (30 wt% Cu). Support-free Cu was prepared by the decomposition of copper(II) nitrate at 773 K in air for 3 h. The supported catalysts were prepared by impregnation of metal oxides with a solution of copper(II) nitrate and calcined at 773 K in air for 3 h. Prior to the reaction, the catalysts, thus prepared, were reduced in a hydrogen stream of 12 cm^3 min^{-1} at 523 K for 18 h. Experiments were carried out in a manner similar to those in a previous study.[7] A conventional flow reactor was used; the concentrations of the reactants and the products in the effluent were determined by gas chromatography. The selectivities to carbon-containing products were evaluated on the carbon basis.

The valence states of copper were determined by diffuse reflectance UV-vis spectroscopy. The amount of metallic copper exposed on the surface was determined by a reaction with dinitrogen monoxide.[11]

Results and Discussion

Dehydrogenation of Ethanol. 1) Reaction Pathway to Ethyl Acetate: The dehydrogenation of ethanol occurred above 380—420 K, giving acetaldehyde, ethyl acetate and C_4-species (butyraldehyde, 1-butanol, and methyl ethyl ketone). The selectivities to these products depended upon the reaction conditions and the catalysts used. Figure 1 shows the mole fraction of the products against space time over 30 wt% Cu/SiO_2. Both ethyl acetate and butyraldehyde increase with space time. Acetaldehyde increases with an increase in space time,

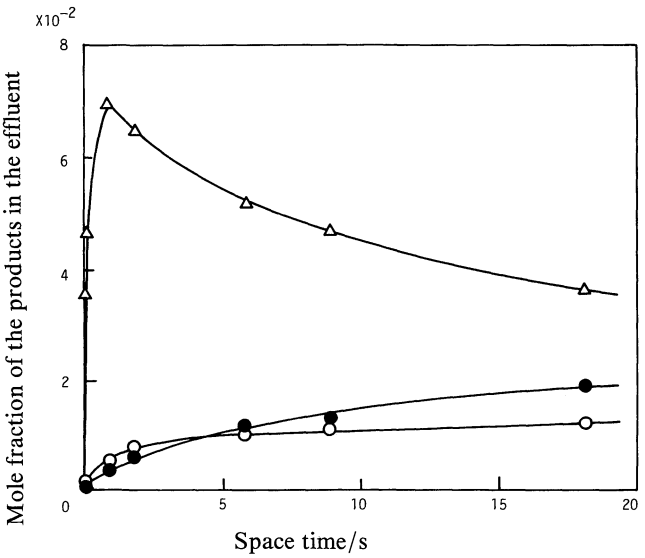

Fig. 1. Mole fraction of the products in the effluent against space time in dehydrogenation of C_2H_5OH over 30 wt% Cu/SiO_2. Temperature: 493 K. Inlet partial pressure $P^0_{C_2H_5OH}$: 20.5 kPa. (△) CH_3CHO, (●) $CH_3COOC_2H_5$, (○) C_3H_7CHO.

passes through a maximum and then decreases. These results strongly suggest that ethyl acetate and butyraldehyde are formed via acetaldehyde. The values of a parameter, $K=P_{CH_3CHO}P_{H_2}/P_{C_2H_5OH}$, which was estimated from the partial pressures of acetaldehyde, hydrogen and ethanol in the effluent, were found to be close to that of the equilibrium constant, K_p,[12,13] of the dehydrogenation of ethanol $C_2H_5OH \rightarrow CH_3CHO+H_2$ at 493 K. Hence, under the reaction conditions the formation of acetaldehyde was much more rapid than those of ethyl acetate and butyraldehyde.

Figure 2 illustrates the selectivity for ethyl acetate formation against conversion of ethanol over 30 wt% Cu/SiO_2 at different temperatures. The selectivity increases considerably with an increase in the conversion of ethanol. At 493 K and an ethanol conversion of 76%, a 56% selectivity was attained. At a given conversion of ethanol, the selectivity increases appreciably with a decrease in the temperature.

To examine the pathway to ethyl acetate, reactions involving acetaldehyde were carried out. In Figs. 3(I) and (II), the mole fraction of various carbon-containing products in the effluent is plotted against time at 433 K. When only acetaldehyde was fed over 30 wt% Cu/SiO_2, crotonaldehyde was exclusively produced. No ethyl acetate was detected in the effluent. However, upon switching acetaldehyde to ethanol, ethyl acetate was

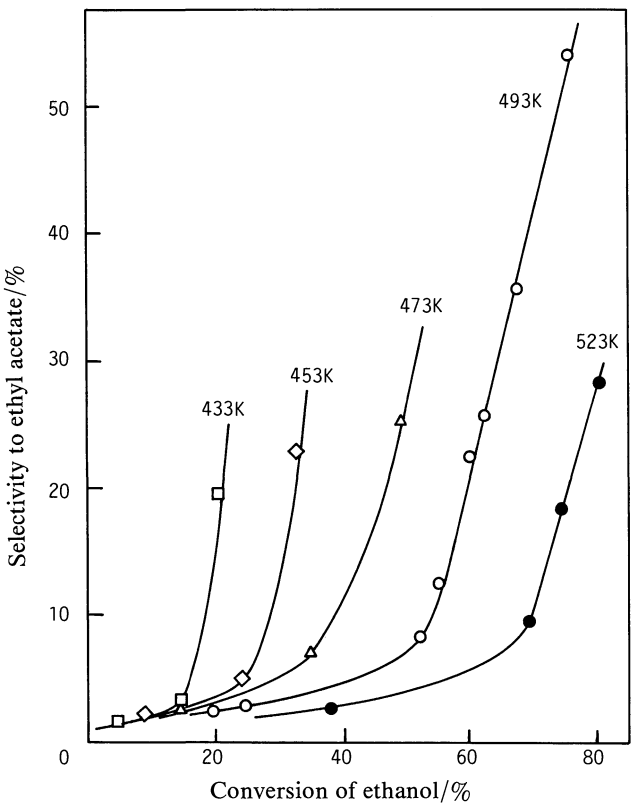

Fig. 2. Selectivity to ethyl acetate against conversion of ethanol over 30 wt% Cu/SiO_2. Inlet partial pressure $P^0_{C_2H_5OH}$: 20.5 kPa.

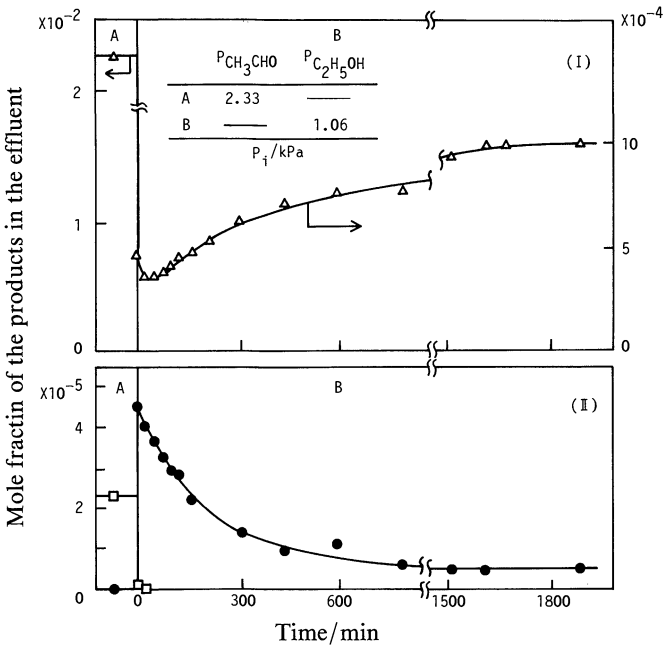

Fig. 3. Carbon-containing products formed in the reactions involving CH_3CHO over 30 wt% Cu/SiO_2: (A) in the absence of C_2H_5OH, (B) in the presence of C_2H_5OH. Temperature: 433 K. (△) CH_3CHO, (●) $CH_3COOC_2H_5$, (□) $CH_3CH=CHCHO$.

formed rapidly, and decreased to a steady value. Crotonaldehyde diminished rapidly. Acetaldehyde in the effluent initially decreased, but then increased with time as the dehydrogenation of ethanol proceeded. When ethanol was fed over the acetaldehyde-free catalyst, ethyl acetate was formed together with acetaldehyde. Since these products increased with time in a monotonic manner, reaching steady values, it was strongly suggested that ester formation occurred appreciably in the presence of adsorbed acetaldehyde. Since methanol was dehydrogenated to methyl formate via reaction between formaldehyde and methanol (or methoxide),[7] we concluded that the acetaldehyde formed by the dehydrogenation of ethanol was subjected to a nucleophilic addition of ethanol (or ethoxide) and transformed to ethyl acetate.

2) Effect of the Supports upon the Reaction: Table 1 lists the selectivity to the carbon-containng products and the product ratio, (C_4/Ester), of C_4-species to ethyl acetate at an ethanol conversion of 50% over various copper-based catalysts. These parameters are greatly affected by the kinds of supports. Cu/ZrO_2 and Cu/ZnO are highly selective for ethyl acetate formation. The C_4-species and diethyl ether are produced appreciably over Cu/Al_2O_3. However, when KOH (1 wt% K) was doped on Cu/Al_2O_3 (not listed in Table 1), the product ratio decreased from 4.3 to 0.4, and the formation of diethyl ether was completely suppressed. These results strongly suggested that C_4-species such as butyraldehyde, methyl ethyl ketone and 1-butanol were

Table 1. Dehydrogenation of Ethanol — Selectivity to Carbon-Containing Products and Product Ratio (C_4/Ester) at 493 K and $P^0_{C_2H_5OH}$=20.5 kPa —

Catalyst[a]	Selectivity[b]/%					C_4/Ester[d]
	Acetaldehyde	Acetone	Diethyl ether	C_4-species[c]	Ethyl acetate

Cu/ZnO	67.3	0.7	0	3.9	28.1	0.1
Cu[e]	70.6	1.7	0	7.4	20.3	0.4

a) Supported Cu catalyst: 30 wt% Cu. b) Selectivity to carbon-containing products at ethanol conversion of 50%. c) Including butyraldehyde, methyl ethyl ketone, and 1-butanol. d) Ratio of mole fraction of C_4-species to ethyl acetate in the effluent at ethanol conversion of 50%. e) Obtained at ethanol conversion of 45%.

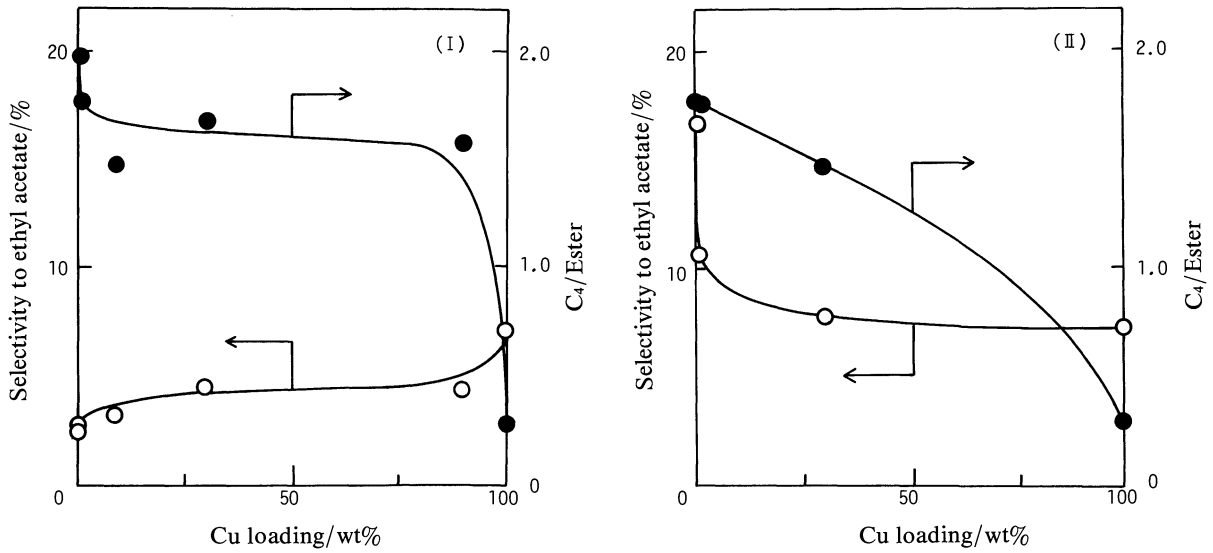

Fig. 4. Selectivity to ethyl acetate and product ratio C_4/Ester obtained at C_2H_5OH conversion of 35%: over Cu/SiO_2, (II) over Cu/ZrO_2. Temperature: 493 K. Inlet partial pressure $P^0_{C_2H_5OH}$: 20.5 kPa.

produced by acid-catalyzed reactions.

Figures 4(I) and (II) illustrate the selectivity to ethyl acetate and the product ratio obtained at an ethanol conversion of 35% over Cu/SiO_2 and Cu/ZrO_2 with various copper loadings. These parameters depend upon the copper loading as well as the kinds of supports. Over Cu/SiO_2, the selectivity for ethyl acetate formation gradually decreases with a decrease in copper loading. On the other hand, the product ratio increases considerably when the copper loading changes from 100 wt% to 90 wt% Cu. This ratio gradually increases with decreasing loading from 90 wt% to 1 wt% Cu; at 0.5 wt% Cu increases considerably. At low copper loadings an appreciable amount of diethyl ether was detected in the effluent. This again suggested that the formation of C_4-species was enhanced in the presence of an acid. Over Cu/ZrO_2 ester formation slowly increases slowly with a decrease in copper loading to 1 wt% Cu. At 0.5 wt% Cu the selectivity to ester increases to a great extent. The product ratio increases with decreases in copper loading.

3) Active Site: When the catalyst was previously reduced to metallic copper, the dehydrogenation of ethanol took place rapidly. No reactions occurred over unreduced catalysts or the supports. The catalysts used for the reaction gave a typical color due to metallic copper. The UV/VIS spectra of the catalysts only exhibited the absorption edge at 560 nm ascribed to metallic copper.[14] This strongly suggested that the dehydrogenation occurred over the metalic copper surface.

Table 2 illustrates the results for the reaction between ethanol and adsorbed acetaldehyde over Cu/SiO_2, Cu/ZrO_2, SiO_2, and ZrO_2. The ethyl acetate formation over 30 wt% Cu/ZrO_2 is about 30 times as fast as that over 30 wt% Cu/SiO_2. The selectivity to this species is 70% over Cu/ZrO_2, whereas that over Cu/SiO_2 is 18%. Over SiO_2 and ZrO_2 supports, no reactions occurred with ethanol alone. However, when acetaldehyde was preadsorbed over the supports, ethyl acetate was produced. Over ZrO_2, ester formation is highly selective and rapid. This reaction proceeds at a rate comparable to that obtained over 30 wt% Cu/ZrO_2. On the other hand,

Table 2. Ethyl Acetate Formation from Adsorbed Acetaldehyde and Ethanol at 433 K

Catalyst[a]	Ethyl acetate formation[b]	
	Rate/cm^3 min^{-1} g-cat^{-1}	Selectivity/%
Cu/ZrO_2	8.4×10^{-2}	70
Cu/SiO_2	0.29×10^{-2}	18
ZrO_2	8.3×10^{-2}	100
SiO_2	0.03×10^{-2}	0.18

a) Cu/ZrO_2, Cu/SiO_2: 30 wt% Cu. b) Obtained at $P^0_{C_2H_5OH}$=1.3 kPa. Acetaldehyde was preadsorbed at P_{CH_3CHO}=2.0 kPa and at 433 K.

over SiO_2 ethyl acetate is produced sluggishly. The selectivity to this species is extremely low compared with that over ZrO_2. The rate of ethyl acetate formation over SiO_2 alone is one-tenth that over 30 wt% Cu/SiO_2. These results strongly suggests that over Cu/SiO_2 this step proceeded practically over copper surface, whereas over Cu/ZrO_2 the support played a role in the formation of ethyl acetate.

Steam Reforming of Ethanol. 1) Reaction Pathway to Acetic Acid: When the mixture of ethanol and water was fed over copper-based catalysts, acetic acid was formed together with products of the dehydrogenation of ethanol. The formation of ethyl acetate and the C_4-species was appreciably retarded by the presence of water. In Fig. 5, the mole fraction of the ethyl acetate and the C_4-species in the effluent is plotted against space time over 30 wt% Cu/SiO_2. Acetaldehyde increases with an increase in space time, and then decreases through a maximum. By contrast, both acetic acid and ethyl acetate increase steadily with increasing space time, suggesting that both of these species are produced through parallel pathways via acetaldehyde. The selectivity to acetic acid increased with an increase in the conversion level of ethanol. At an ethanol conversion of 88%, the selectivity was found to be 43%. At high conversion levels, the dehydrogenation of ethanol to acetaldehyde was found to be practically in equilibrium, suggesting that this step proceeded rapidly, compared with the step for acetic acid formation.

When the mixture of acetaldehyde and water was fed over 30 wt% Cu/SiO_2, acetic acid was formed at a rate comparable to that in the steam reforming of ethanol.

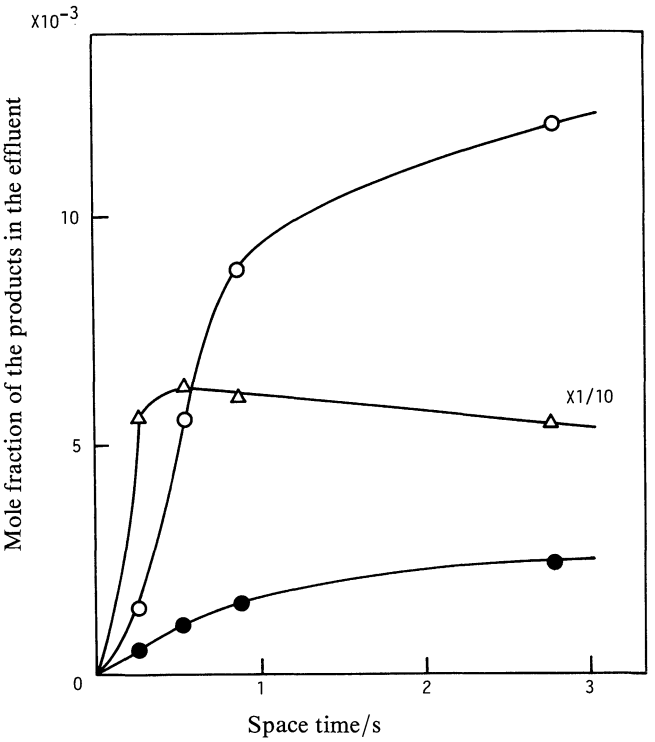

Fig. 5. Mole fraction of carbon-containing products against space time in steam reforming of C_2H_5OH over 30 wt% Cu/SiO_2. Temperature: 523 K. Inlet partial pressure: $P^0_{C_2H_5OH}$: 10.1 kPa, $P^0_{H_2O}$: 20.2 kPa. (○) CH_3COOH, (●) $CH_3COOC_2H_5$, (△) CH_3CHO.

No ethyl acetate was detected in the effluent. These findings were quite similar to those in the reaction between formaldehyde and water.[10] This suggested that adsorbed acetaldehyde underwent a nucleophilic addition of water (or hydroxide ions), giving acetic acid.

Table 3 summarizes the selectivity to the carbon-containing products in the steam reforming over various copper-based catalysts (30 wt% Cu) at an ethanol conversion of 80%. The selectivity to acetic acid is greatly affected by the kinds of supports. Over Cu/ZnO, the selectivity was attained to 38% at this conversion level.

Difference in the Mechanisms of Reforming of Ethanol and Methanol. Reforming of methanol has been studied over various copper-based catalysts.[4-11,15] In

Table 3. Steam Reforming of Ethanol — Selectivity to Carbon-Containing Products at 523 K, $P^0_{C_2H_5OH}$=10.1 kPa and $P^0_{H_2O}$=20.2 kPa —

Catalyst[a]	Selectivity[b]/%					
	Acetaldehyde	Acetone	Diethyl ether	Acetic acid	C_4-species[c]	Ethyl acetate
Cu/Al_2O_3	55.1	0.2	7.0	5.7	16.1	15.9
Cu/SiO_2	53.9	0.3	Trace	24.5	5.9	15.4
Cu/ZrO_2	56.2	4.7	0	0	8.5	30.7
Cu/ZnO	36.4	8.6	0	38.0	0	17.0
Cu[d]	88.0	0.7	0	5.2	0	6.1

a) Supported Cu catalyst: 30 wt% Cu. b) Selectivity to carbon-containing products at ethanol conversion of 80%. c) Including butyraldehyde, and 1-butanol. d) Obtained at ethanol conversion of 64%.

the absence of water, methyl formate and hydrogen were produced, whereas in the presence of water carbon dioxide and hydrogen were produced. These reactions were highly selective. Formaldehyde was produced in the course of the reactions and subsequently transformed to the final products through a reaction with methanol (or methoxide) or water (or hydroxide ions).[7,10] The dehydrogenation to formaldehyde was concluded to be rate-determining in the reforming of methanol.[4-10]

In the reforming of ethanol, ethyl acetate and acetic acid were produced, respectively, in the absence and presence of water. These reactions proceeded in a similar way to those of methanol. The dehydrogenation step to acetaldehyde occurred much more rapidly than the steps to ethyl acetate and acetic acid. The steps to ethyl acetate and acetic acid were strongly affected by the kinds of supports, compared with that to acetaldehyde. Hence, the selectivities for the reforming of ethanol were considerably lower than those for the reforming of methanol and were strongly affected by the kinds of supports. By contrast, since the dehydrogenation step was rate-determining in the reforming of methanol, the effect of the support upon the reaction was not as appreciable as that upon the reforming of ethanol.

Efficient Selective Reduction of Aromatic Nitro Compounds Affording Aromatic Amines under CO/H_2O Conditions Catalyzed by Amine-Added Rhodium-Carbonyl Complexes

Kotohiro NOMURA,* Masaru ISHINO, and Motoo HAZAMA
Organic Synthesis Research Laboratory, Sumitomo Chemical Co., Ltd.,
10-1, Tsukahara 2-Chome, Takatsuki-shi, Osaka 569
(Received April 5, 1991)

Remarkably high catalytic activities for the reduction of aromatic nitro compounds affording aromatic amines using CO (1 atm) and water at room temperature were exhibited by using amine-added rhodium carbonyl complexes ($Rh(CO)_2(acac)$, $Rh_4(CO)_{12}$, and $Rh_6(CO)_{16}$) in 2-methoxyethanol or diglyme (diethylene glycol dimethyl ether) containing a 5 equiv NaOH aqueous solution. The reduction proceeded not only with high catalytic activities, but also with remarkably high nitro-group selectivities, as exhibited in the case of 1-nitroanthraquinone affording 1-aminoanthraquinone, without any other unsaturated groups, such as C=O, being reduced. The T. O. F. (turnovers/time) of 1776 mol-cat^{-1} h^{-1} (296 g-atom Rh^{-1} h^{-1}) was attained for the reduction of *p*-nitroanisole yielding *p*-anisidine using $Rh_6(CO)_{16}$-1,8-bis(dimethylamino)-naphthalene catalyst.

Water-Gas-Shift Reaction (WGSR) has drawn considerable attention from the viewpoint of industrial utilization of carbon monoxide; it is now commercially used as a pure hydrogen source.[1] Many studies have, therefore, already been made concerning this subject

$$H_2O + CO \rightarrow CO_2 + H_2 \quad (1)$$

using both homogeneous and heterogeneous catalysts.[2]

As one of its applications related to WGSR, organic synthesis under CO/H_2O conditions using a homogeneous transition metal complex catalysts, such as hydrogenation, reduction, hydroformylation, hydromethylation, or hydrocarbonylation, are very intriguing subjects,[2] especially the selective reduction of unsaturated compounds has been paid particular attention.[3]

The reduction of aromatic nitro compounds affording aromatic amines using carbon monoxide and water with homogeneous catalysts is an also very attractive subject, and many studies have already been made.[2,3] Alper found that the reduction proceeded under atmospheric

$$ArNO_2 + 3CO + H_2O \rightarrow ArNH_2 + 3CO_2 \quad (2)$$

pressure of CO and room temperature by using $Ru_3(CO)_{12}$ in a benzene–2-methoxyethanol–5 equiv NaOH aqueous solution in the presence of a phase-transfer catalyst ($PhCH_2N(C_2H_5)_3^+Cl^-$)[3a], Kaneda also reported that amine-, diamine-added $Rh_6(CO)_{16}$ showed catalytic activities for the reduction of $PhNO_2$ in 2-ethoxyethanol–H_2O solution at 80 °C,[3b] and Alessio exhibited that $Rh_6(CO)_{16}$–phenanthrolines, especially 3,4,7,8-tetramethyl-1,10-phenanthroline, in ethanol was also effective for this reduction.[3d,e] However, catalytic reduction under mild reaction conditions with high activity has not yet been reported (T. O. F. of 6 g-atom-Ru^{-1} h^{-1} was reported in Ref. 3a).

In the present papers, we describe that amine-, diamine-added rhodium carbonyl complexes shows remarkably high catalytic activities as well as high nitro group selectivities for the reduction of aromatic nitro compounds under extremely mild reaction conditions of room temperature and of 1 atm of CO in 2-methoxyethanol or diglyme containing a 5 equiv NaOH aq solution.[4]

Experimental

General Procedure. All manipulations were carried out under a nitrogen atmosphere, or in vacuo. Water and 2-methoxyethanol, diglyme (diethylene glycol dimethyl ether) and nitrobenzene (Nakarai Tesque Co., Ltd.) were distilled and stored in a Schlenck-type tube under a nitrogen atmosphere. Other aromatic nitro compounds were used as reagent grade (Nakarai Tesque Co., Ltd. or Tokyo Kasei Co., Ltd.). $Rh_4(CO)_{12}$, $Rh(CO)_2(acac)$, and $Rh_6(CO)_{16}$ were also used as reagent grade (N.E. Chem. Cat. Co., Ltd.).

Reduction of Aromatic Nitro Compounds under CO/H_2O. The reaction was typically carried out as follows: a solution with $Rh_6(CO)_{16}$ (0.001 mmol) in 2-methoxyethanol (15 ml) under a nitrogen atmosphere in a Schlenck-type tube was stirred magnetically and the required amount of amine added. Then, the addition of a 5 equiv-NaOH aq solution (5 ml) and aromatic nitro compounds (5 mmol) into the reaction mixture was followed by the introduction of CO (1 atm). The mixture, equipped with CO gas bag, was allowed to react at room temperature (25 °C) for the prescribed time. The reaction product was then determined by GLC using an internal standard, and was identified using GLC by co-injection with an authentic sample (column OV-225, 3 m) and GC-MS (QP-1000, Shimadzu Co., Ltd.).[5,6]

The reduction of 1-nitroanthraquinone (Tokyo Kasei Co., Ltd.) was performed similarly. A certain excess amount of water was added into the reaction medium after the reaction; a red precipitate which was obtained by filteration was dried and redissolved in *N*,*N*-dimethylformamide and was determined by GLC (column OV-210 1 m) using an internal standard.

Results and Discussion

1. Reduction of Nitrobenzene Using CO and Water Catalyzed by Amine-Added $Rh(CO)_2(acac)$ Complexes. The results for the reduction of $PhNO_2$ catalyzed by various amine-added $Rh(CO)_2(acac)$ complexes in a 2-methoxyethanol–5 equiv NaOH aqueous solution under 1 atm of CO and room temperature (25 °C) for 3 h are summarized in Table 1. The reduction proceeded at remarkable rates with the use of a NaOH aqueous solution; a corresponding amount of aniline was obtained as the reaction product (Table 1).[5,6]

It should be noted that the rate markedly increased upon the addition of a small amount of amines; especially, 9,10-diaminophenanthrene and *o*-phenylenediamine were effective for this reaction. As revealed from this table, the catalytic activities shown here (ex. 57 g-atom-Rh^{-1} h^{-1} for $Rh(CO)_2(acac)$–9,10-diaminophenanthrene cat.) are much higher than those previously reported (ex. 6 g-atom-Ru^{-1} h^{-1} from Ref. 3a, it is the highest value so far reported).

Table 2 shows a time-course plot for this reaction using a $Rh(CO)_2(acac)$-9,10-diaminophenanthrene catalyst. It was revealed that the reaction proceeded at a significant rate during the initial stage (72 turnovers for 1 h), but that the rate decreased gradually, because of, perhaps, changes in the NaOH base concentrations (Na_2CO_3 was accompanied, accumlated from NaOH and CO_2 in the reaction mixture) as mentioned below.

The results for the reduction of nitrobenzene under various NaOH concentration conditions are shown in Table 3. The 5 equiv NaOH aqueous solution used was thought to play an important role in this reaction to proceed with a significant rate. 2-methoxyethanol was also favorable as a solvent.

2. Selective Catalytic Reduction of Aromatic Nitro Compounds Using Amine-Added $Rh_4(CO)_{12}$ Complexes.

2-1. Reduction of Aromatic Nitro Compounds Using 9,10-Diaminophenanthrene-Added $Rh_4(CO)_{12}$ Complex. As shown in Table 4, the reaction rate for the reduction of nitrobenzene using a $Rh_4(CO)_{12}$ complex also remarkably increased upon the addition of 9,10-diaminophenanthrene (from 108 to 225 turnovers with a diamine/Rh molar ratio varying from 0 to 2.25, respectively). Turnovers of 610 mol-cat^{-1} (153 g-atom-Rh^{-1}), for 3 h were obtained at low $Rh_4(CO)_{12}$ concentration.

The results for the reduction of various substituted nitrobenzenes using the $Rh_4(CO)_{12}$–9,10-diaminophenanthrene catalyst system for 90 min. are summarized in

Table 1. The Reduction of Nitrobenzene Catalyzed by Amine-Added $Rh(CO)_2(acac)$ Complexes — The Effect of Amine Additives —

Amine	Molar ratio[a]	Turnovers[d]
None[b]	—	<1

Reaction conditions: $Rh(CO)_2(acac)$/9,10-diaminophenanthrene=0.02/0.03 (mmol), $PhNO_2$ 5 mmol, CO 1 atm, 25 °C, 3 h.

Table 4. Reduction of Nitrobenzene Catalyzed by 9,10-Diaminophenanthrene-Added $Rh_4(CO)_{12}$ Complex under CO/H_2O

Molar ratio[a]	Turnovers/mol-cat^{-1}
0	108
1.09	200
2.25	225
1.50	610[b]

Reaction conditions: $Rh_4(CO)_{12}$ 0.02 mmol, 2-Methoxyethanol/5 equiv NaOH aq=15/5 (ml), $PhNO_2$ 5 mmol, CO 1 atm, r.t. (25 °C), 3 h. a) Molar ratio of 9,10-diaminophenanthrene/Rh. b) $Rh_4(CO)_{12}$ 0.005 mmol.

Table 5. It should be noted that these reductions proceeded not only with significant rates but also with high nitro-group selectivities. The order *p*-NH_2 (>250)>*o*-NH_2 (233)>*p*-Cl (218)>*o*-Cl (190)>*p*-Me (178), *p*-OMe (175)>H (158) was obtained for this reaction, which is somewhat different from that previously obtained using $Rh_4(CO)_{12}$–dppe (dppe: $Ph_2P(CH_2)_2PPh_2$) catayst system (*p*-NH_2 (>250)>*o*-Cl (210)>*o*-NH_2 (190)>*p*-Cl (158)>*p*-OMe (140), *p*-Me (128)>H (110 turnovers, mol-cat^{-1} for 90 min)) under the same reaction conditions,[4a] although the high nitro-group selectivities were almost the same as those obtained using Rh–dppe catalyst system.[7] Further, the reduction of aromatic nitro compounds came to completing upon further stirring; *p*-nitrobenzonitrile was converted to afford *p*-aminobenzonitrile almost exclusively without the C=N bond being reduced (Table 6).

2-2. Reduction of 1-Nitroanthraquinone Affording 1-Aminoanthraquinone Catalyzed by Amine-Added $Rh_4(CO)_{12}$ Complexes under CO/H_2O Conditions. Importantly, it was also found that 1-nitroanthraquinone was completely reduced to produce 1-aminoantharquinone (10 h, >99.9% yield, >250 turnovers) using the above-mentioned $Rh_4(CO)_{12}$–diamine catalyst without any other unsaturated groups, such as C=O, being reduced (Table 6). Aminoanthraquinone has been one of the most important key materials used as dyes and their intermediates; although it has been commercially produced by either a stoichiometric or catalytic reduction of nitroanthraquinone or by sulfonating before amination, there are still some problems. We believe that the above-mentioned fact is very important from both industrial and synthetic viewpoints; it may be commercially used in the future as a process for the production of amines by a selective catalytic reduction of aromatic nitro compounds after much further development of this subject.

The results for the reduction of 1-nitroanthraquinone with various amine-added $Rh_4(CO)_{12}$ are summarized in in Table 7. The reduction rate increased upon the addition of only a small amount of amines, especially NEt_3 and 4-dimethylamino) pyridine.[7] The important fact was also found that the effective amines were different between the reduction of $PhNO_2$ using amine-added $Rh(CO)_2(acac)$ and that of 1-nitroanthraquinone

Table 5. Selective Reduction of Aromatic Nitro Compounds Using CO and Water with $Rh_4(CO)_{12}$–9,10-Diaminophenanthrene Catalyst

Reactant	Product	Turnovers/mol-cat^{-1}

$PhCH_2NMe_2$	3	*p*-Nitroanisole	1350 (225)
N^nBu_3	3	*p*-Nitroanisole	1416 (236)
None	—	Nitrobenzene	486 (81)[b)]

Reaction conditions: $Rh_6(CO)_{16}$ 0.001 (mmol), 2-methoxyethanol/5 equiv NaOH aq=15/5 (ml), nitro compounds 5 mmol, CO 1 atm, r.t. (25°C), 1 h. a) Amount of amine or diamine (mmol)/amount of catalyst metal (mmol). b) $Rh_6(CO)_{16}$ 0.001 mmol, 5 h.

using amine-added $Rh_4(CO)_{12}$.

3. Catalytic Reduction of Nitrobenzene under CO/H_2O or H_2 Conditions Catalyzed by 9,10-Diaminophenanthrene-Added $Rh(CO)_2(acac)$ Complex. Particular attention should be paid to Table 8 regarding the different reaction rates obtained for the reduction of nitrobenzene under CO/H_2O and under H_2 conditions. Hydrogen gas was not formed after the reaction mixture under these CO/H_2O conditions;[8)] clearly indicating that reduction under CO/H_2O using this catalyst system did not proceed by the reaction of aromatic nitro compounds and the hydrogen gas that was formed by the Water-Gas-Shift-Reaction. This suggests that a different reaction mechanism can be considered for this reduction under CO/H_2O.[9)]

4. Efficient Catalytic Reduction of Aromatic Nitro Compounds Affording Amines Using Amine-Added $Rh_6(CO)_{16}$ Catalyst Systems under CO/H_2O Conditions. The results show the effects of various amine additives on the reductions of *p*-nitroanisole and *p*-nitrotoluene with $Rh_6(CO)_{16}$ in a 2-methoxyethanol–5 equiv-NaOH aqueous solution under 1 atm of CO at room temperature (25°C) for 1 h (summarized in Table 9).

It should be noted that the rate remarkably increased upon the addition of a very small amount of amines, especially *N*,*N*-dimethylbenzylamine, *N*,*N*,*N*′,*N*′-tetramethyl-1,4-diaminobutane, and tributylamine for the reduction of *p*-nitrotoluene and 1,8-bis(dimethylamino)naphthalene, 2-pyridinol, and tributylamine for the reduction of *p*-nitroanisole. It should be noted that the effective amines are different between these two compounds. The catalytic activity (T. O. F.) of 1776 mol-cat^{-1} h^{-1} (296 g-atom-Rh^{-1} h^{-1}) was attained for the reduction of *p*-nitroanisole, even under these extremely mild reaction conditions. The catalytic activities shown in Table 9 are, as far as we know, much higher than those previously reported.[3)]

The factors affecting these reduction rates and mechanistic studies are now under investigation.

Summary

In conclusion, this paper can be summarized as follows:

(i) Remarkably high catalytic activities for the reduction of aromatic nitro compounds to yield aromatic amines were exhibited by using amine-added rhodium carbonyl complexes under extremely mild reaction conditions: room temperature and atmospheric pressure of carbon monoxide in the presence of a sodium hydroxide aqueous solution.

(ii) The reduction proceeded not only with high catalytic activities, but also with remarkably high nitro-group selectivities, as exhibited in the case of 1-nitroanthraquinone affording 1-aminoanthraquinone and so on.

(iii) Taking into account the above results, a different reaction mechanism will be considered for the selective reduction of aromatic nitro compounds using amine-added rhodium carbonyl complexes under CO/H_2O conditions; this subject is now under investigation.

The authors would like to express grateful acknowledgement to Dr. Gohfu Suzukamo (Organic Synthesis Research Laboratory, Sumitomo Chemical Co., Ltd.) for his helpful discussions and continuous encouragement throughout this research. We also acknowledge Professor Yasukazu Saito (The University of Tokyo) for his helpful comments.

Shinohara, and M. Nomura, *ibid.*, **45**, 151 (1988).

4) We recently have discovered new catalyst systems for selective reduction of aromatic nitro compounds under the mild reaction conditions of room temperature (25 °C) and CO atmosphere: a) K. Nomura, M. Ishino, and M. Hazama, *J. Mol. Catal.*, **65**, L5 (1991); b) *idem., ibid.*, **66**, L1 (1991); c) *idem., ibid.*, **66**, L11 (1991); d) *idem., ibid.*, **66**, L19 (1991).

5) During and after the reaction, sodium carbonate was accompanied which was generated from the reaction of sodium hydroxide and CO_2.

6) The reaction products were only corresponding amines and no other products were observed on this reaction, except that trace amount of other deoxygenated products (azobenzene, azoxybenzene) were sometimes observed on GLC scale in the reduction of nitrobenzene.

7) The rate also increased at higher reaction temperature, or higher CO pressure; K. Nomura, unpublished results.

8) The important fact was also found that a trace amount of dihydrogen (ca. 0.026 mmol) from the reaction mixture was detected after the reduction of $PhNO_2$ (ca. 5 mmol) using $Rh_4(CO)_{12}$ (0.02 mmol) in 2-methoxyethanol (15 ml)–5 equiv NaOH aq solution (5 ml) under CO (1 atm) at 25 °C for 4 h. This result, that the reduction proceeded without by-producing dihydrogen that was formed by Water-Gas-Shift-Reaction, is very important from the industrial viewpoints, and also indicates the above-mentioned assumption.

9) We believe that an original reaction pathway, such as via metal-nitrene intermediate, should be considered for this selective reduction under CO/H_2O conditions; mechanistic studies are now being carried out. For example, R. A. Sheldon, "Chemicals from Synthesis Gas," D. Reidel Publishing Co., Ltd., Dordrecht, Netherland (1981), p. 181; T. Ikariya, *Shokubai*, **5**, 271 (1989).

Syntheses and Crystal Structures of Seven-Coordinate (Ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetato)aquavanadate(III) Complexes

Mamoru SHIMOI, Yoko SAITO, and Hiroshi OGINO*
Department of Chemistry, Faculty of Science, Tohoku University, Aoba-ku, Sendai 980
(Received December 25, 1990)

$K[V(edta)(H_2O)]\cdot 2H_2O$ (**1a**) was prepared by the reaction of VCl_3 with K_4edta. The compound was converted to its sodium and ammonium salts by use of a cation exchange resin. Crystal structure analyses of $Na[V(edta)(H_2O)]\cdot 3H_2O$ (**1b**) and $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (**1c**) revealed that in both compounds the vanadium atom adopts a capped trigonal-prismatic structures with a hexadentate ethylenediaminetetraacetato ligand and an aqua ligand. Crystal data are as follows: **1b**: Monoclinic, $P2_1/a$, a=17.831 (3), b=8.408 (1), c=11.595 (2) Å, β=109.39 (1)°, Z=4, R=0.045 for 6321 reflections; **1c**: Monoclinic, Aa, a=8.552 (1), b=59.948 (6), c=7.226 (1) Å, β=114.95 (1)°, Z=8, R=0.050 for 6087 reflections.

The coordination chemistry of vanadium(III) is attracting attention in connection with its biological importance in tunichromes[1] and vanadium-containing nitrogenase.[2] Vanadium(III) usually forms complexes with coordination number six,[3] but its chemistry has been poorly investigated.

In the course of our research in electron transfer reactions, we found that the kinetics of the electron transfer reactions between $[V^{III}(hedra)(H_2O)]$[4] and halogenopentaamminecobalt(III) complexes obey the zeroth-order rate law when excess V(III) is used.[5] To elucidate the mechanism of this reaction, we analyzed the crystal structures of the reactant $[V^{III}(hedra)(H_2O)]\cdot 2H_2O$ and the final product $K[V^{IV}O(hedra)]\cdot H_2O$. To our surprise, V(III) adopts a capped trigonal-prismatic seven-coordinate structure: The coordinated hedtra ligand is hexadentate and one water molecule occupies the seventh coordination position of vanadium(III).[6] This prompted us to study the structures of vanadium(III) complexes containing edta-related aminopolycarboxylate ligands. Some preliminary results for $Na[V(edta)(H_2O)]\cdot 3H_2O$ have already been reported.[7,8] It was apparent that the edta complex also forms a capped trigonal-prismatic seven-coodinate structure. The geometry of $[V(edta)(H_2O)]^-$ is quite deformed: The coordination sphere was shown to lack an approximate two-fold axis along the V–H_2O bond in contrast to the $[V(hedtra)(H_2O)]$ complex. Many edta complexes with an aqua ligand have also been reported to adopt seven coordination as capped trigonal prisms or pentagonal bipyramids. However, they usually have an exact or approximate two-fold axis along the M–H_2O bond. Furthermore, coordination structures of some seven-coordinate edta complex anions depend on the nature of cation. Thus $[Mg(edta)(H_2O)]^{2-}$ adopts a capped trigonal prismatic structure in the sodium salt,[9] while in the magnesium salt it is pentagonal bipyramidal.[10] The iron(III)–edta complex forms six-coordinate structure in the lithium[11] and guanidinium salts,[12] and pentagonal bipyramidal seven-coodinate structure in many other salts.[13–18] Therefore it would be important to elucidate whether the large deformation observed in the coordination sphere of the $[V(edta)(H_2O)]^-$ anion is intrinsic to a single ion or is due to steric hindrance related to ion packing. In this paper, the crystal structure of the ammonium salt of vanadium(III)–edta complex is analyzed and compared it with those of $[V^{III}(hedtra)(H_2O)]\cdot 2H_2O$[6] and $Na[V(edta)(H_2O)]\cdot 3H_2O$.

Experimental

General Procedure. The complexes were prepared and handled under a nitrogen or argon atmosphere. A column (10 mmϕ) of Dowex 50W-X8(50—100 mesh) was used for exchanging cations in the vanadium(III)–edta complex.

Synthesis of $K[V(edta)(H_2O)]\cdot 2H_2O$ (1a). H_4edta (11.69 g, 40 mmol) was added to 100 cm^3 of water and neutralized with 11.20 g (80 mmol) of potassium carbonate. To the solution was added 6.30 g (40 mmol) of VCl_3 and the solution was stirred for 15 min. Evaporation of the solvent using a rotary evaporator followed by addition of ethanol gave pale brown flocculent crystals, which were collected by filtration and washed with ethanol and ether, successively. Yield 15.5 g (90%). Found: C, 27.55; H, 4.36; N, 6.61%. Calcd for $C_{10}H_{18}KN_2O_{11}V$: C, 27.78; H, 4.20; N, 6.48%.

Synthesis of $Na[V(edta)(H_2O)]\cdot 3H_2O$ (1b). An aqueous solution (6 cm^3) containing 1.0 g (2.3 mmol) of $K[V(edta)(H_2O)]\cdot 2H_2O$ was passed through a column packed with 2.5 cm^3 of Na-type cation exchange resin. The sodium salt was obtained as pale purple crystals almost quantitatively by evaporation of the eluate using a rotary evaporator followed by addition of ethanol. Found: C, 28.43; H, 4.44; N, 6.18%. Calcd for $C_{10}H_2ON_2NaO_{12}V$: C, 27.66; H, 4.64; N, 6.45%. Parallel-piped crystals suitable for X-ray diffractometry were obtained by standing a saturated aqueous solution in a desiccator over phosphorus pentoxide under an argon atmosphere.

Synthesis of $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (1c). The title compound was prepared by the same procedure as the preparation of **1b**, using a requisite amount of NH_4-type cation exchange resin instead of the Na-type one. Yield 88%. Found: C, 28.45; H, 5.78; N, 9.94%. Calcd for $C_{10}H_{23}N_3O_{11.5}V$: C, 28.58; H, 5.52; N, 10.00%. Columnar crystals suitable for X-ray diffractometry were also obtained by the same procedure as for the sodium salt.

X-Ray Crystal Structure Determination of 1b and 1c. Diffraction data were collected on a Rigaku AFC-6A four-

circle diffractometer with graphite-monochromated Mo$K\alpha$ radiation (λ=0.71073 Å). Crystallographic and experimental data for the complexes are listed in Table 1. The reflection data were corrected for Lorentz and polarization factors. No correction was applied for absorption or extinction. All the structures were solved by the conventional heavy-atom method and the parameters were refined by the block-diagonal least-squares method. Anisotropic tempeprature factors were applied for the non-hydrogen atoms. Positions of hydrogen atoms, except for those of water molecules, were deduced from difference Fourier syntheses and refined with isotropic temperature factors. Two hydrogen atom positions for **1b** were fixed at the calculated coordinates. There is ambiguity in the identification of nitrogen atoms of ammonium ions, and oxygen atoms of water of crystallization for **1c**. The atoms with maximum number of hydrogen bonds were assigned as the ammonium nitrogen atoms. This assignment gave a reasonable arrangement of anions and cations in the crystal. The inverse chirality for **1c** gave a larger R value (0.052). Atomic scattering factors for non-hydrogen atoms and hydrogen atoms were taken from Refs. 19 and 20, respectively. The calculations were performed on a Nippon Electric Co. ACOS-2000 computer at the Computer Center of Tohoku University using the Universal Computation Program System UNICS III.[21]

Results and Discussion

Syntheses and Properties of the Vanadium(III) Complexes. The complex was prepared by direct reaction of the potassium salt of edta with vanadium(III) chloride. This method is more convenient than the reduction of the $[VO(edta)]^{2-}$ complex using sodium amalgam.[22] The complexes are reasonably air-stable in

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. B_{ij} is defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})]$.

the solid state, though prolonged exposure of aqueous solutions to air results in oxidation to vanadium(IV) complexes. The crystals of $Na[V(edta)(H_2O)]\cdot 3H_2O$ and $NH_4[V(edta)H_2O)]\cdot 2.5H_2O$ exhibit dichroism and look purple or grayish green depending on the direction.

Structures of $Na[V(edta)(H_2O)]\cdot 3H_2O$ (1b) and $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (1c). Final atomic coordinates and equivalent isotropic temperature factors for $Na[V(edta)(H_2O)]\cdot 3H_2O$ (**1b**) and $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (**1c**) are listed in Tables 2 and 3, respectively. Bond lengths and angles for **1b** and **1c** are given in Table 4.[23] ORTEP drawings of the $[V(edta)(H_2O)]^-$ ions are shown in Fig. 1. Crystals of the ammonium salt are composed of two crystallographically independent complex anions, but the structures of both complexes are almost the same and are also quite similar to that of the sodium salt.

In the complexes, edta acts as a hexadentate ligand forming a twisted trigonal prism, and one water molecule is also coordinated to the vanadium atom in a capping position. Thus the geometry around the vanadium atom is a capped trigonal-prism. The structure of

a) The equivalent isotropic temperature factors for non-hydrogen atoms were computed using the following expression: $B_{eq}=4/3(B_{11}a^2+B_{22}b^2+B_{33}c^2+B_{13}ac\cos\beta)$. B_{ij} is defined by: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+2hkB_{12}+2hlB_{13}+2klB_{23})]$.

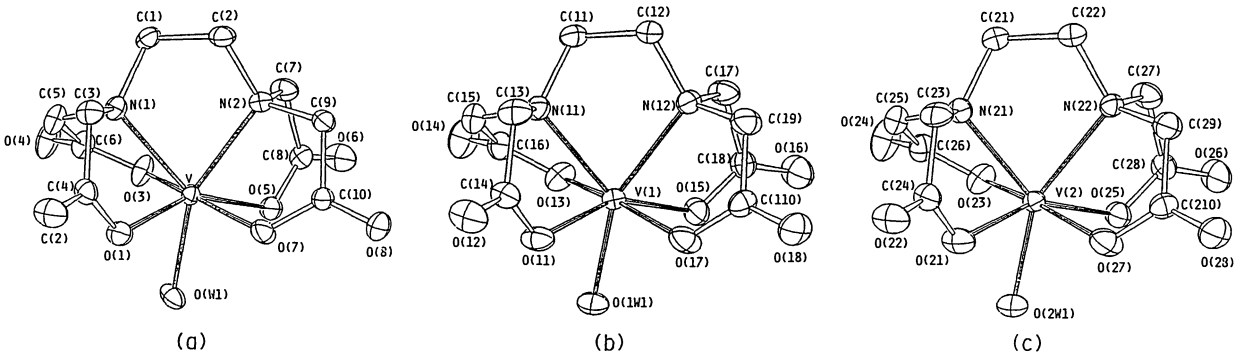

Fig. 1. Molecular structures of $[V(edta)(H_2O)]^-$ with atomic numbering scheme. Hydrogen atoms are omitted for clarity. (a) $Na[V(edta)(H_2O)]\cdot 3H_2O$ (**1b**), (b) complex 1 of $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (**1c**), and (c) complex 2 of **1c**.

$[V(edta)(H_2O)]^-$ is quite similar to that of $[V(hedtra)(H_2O)]\cdot 2H_2O$ (**2**).[6] The averaged V–O(carboxylato) bond lengths are 2.052 (23) Å for **1b** and 2.051 (16) for **1c**, these values being almost equal to that in **2** (2.048(13) Å).[6] However, the bond lengths in $[V(edta)(H_2O)]^-$ range more widely than those in $[V(hedtra)(H_2O)]$. This difference is reflected in the difference of configurations of both complexes. Figure 2 shows the projections of coordination spheres for $[V(edta)(H_2O)]^-$ and $[V(hedtra)(H_2O)]$ along the axis passing through the centers of gravity, CE1 and CE2, of the N(*n*1)–O(*n*1)–O(*n*3) and N(*n*2)–O(*n*5)–O(*n*7) triangular faces, where *n* is zero for **1b** and **2**, respectively, and is the first digit of atomic numbering, 1 or 2, for **1c**. In each complex these triangles are almost parallel to each other (dihedral angles between the planes are 4.90 for **1b**, 3.28 and 3.11 for **1c**, and 2.20° for **2**, respectively), but they are twisted with respect to each other. As parameters for the degree of twist between the two trianglular surfaces, we can define the twist angles as θ_1: N(*n*1)–CE1–CE2–N(*n*2), θ_2: O(*n*1)–CE1–CE2–O(*n*5), and θ_3: O(*n*3)–CE1–CE2–O(*n*7). These angles are also given in Fig. 2. Although $[V(hedtra)(H_2O)]$ has an approximate C_2 axis along the V–H_2O bond, $[V(edta)(H_2O)]^-$ has no such symmetry. On the other hand, the O(*n*1), O(*n*7), N(*n*1), and N(*n*2) atoms for $[V(edta)(H_2O)]^-$ are almost coplanar; they deviate from the least-squares plane by only −0.028, +0.026, +0.029, and −0.027 Å for **1b**, +0.013, −0.012, −0.013, and +0.013 Å for the complex 1 of **1c**, and +0.12, −0.12, −0.12, and +0.12 Å for the complex 2 of **1c**, respectively. These planes are almost parallel to the O(*n*3)–O(*n*5)–O(*n*W) plane. The dihedral angles between the planes are 4.96° for **1b** and 4.93° for complexes 1 and 2 of **1c**, respectively. Thus the geometry of $[V(edta)(H_2O)]^-$ may also be described as a 4:3 piano stool[24] or tetragonal base-trigonal base.[25] It is of interest to note that the edta ligand, which has higher symmetry than the hedtra ligand, adopts a coordination structure of lower symmetry than the latter ligand. In the previous communication we mentioned that this low symmetry for $[V(edta)(H_2O)]^-$ is peculiar among the various seven coordinate structures with edta and aqua ligands. Table 5 shows the twist angles, θ_1, θ_2, and θ_3, of the capped trigonal-prismatic complexes with edta-like ligands. All complexes except for $[V(edta)(H_2O)]^-$ have an approximate or crystallographic two-fold axis along the M–H_2O bond as is shown by the equivalence of θ_2 with θ_3. The lack of symmetry in $[V(edta)(H_2O)]^-$ is also reflected in the large difference in the angles, O(*n*1)–N(*n*1)–O(*n*3) and O(*n*5)–N(*n*2)–O(*n*7): 84.1 (1) vs. 62.31 (7)° for **1b**, 81.9(1) vs. 62.2(1) and 81.7(1) vs. 61.5(2) for **1c**. The corresponding angles for **2** are much less different: 75.41 (6) vs. 70.67 (6)°.

Figure 3 shows the packing diagram of $Na[V(edta)(H_2O)]\cdot 3H_2O$. Two O(8) atoms of neighboring anions bridge two sodium ions around the center of symmetry (Na···Na=3.628 (3) Å), and the sodium ions are coordinated tetrahedrally with crystal water molecules (O(W2) and O(W3)) and two O(8) atoms, with bond distances ranging from 2.312(3) to 2.381 (3) Å. In

Table 4. Interatomic Distances and Angles for $Na[V(edta)(H_2O)]\cdot 3H_2O$ (**1b**) and $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (**1c**)

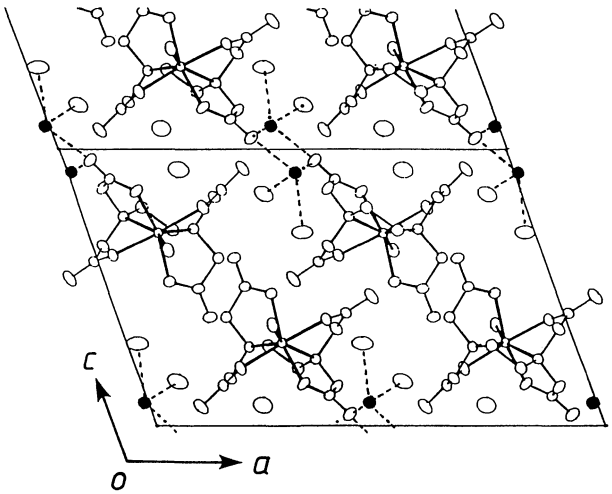

Fig. 3. Cell projection for $Na[V(edta)(H_2O)]\cdot 3H_2O$ (**1b**) along *b*. Sodium ions are depicted by solid elipsoids. Coordination bonds between sodium and oxygen atoms are shown with dotted lines.

the ammonium salt (Fig. 4), the cations are hydrogen-bonded to O(*n*8) atoms: N(3)···O(28^{i})=2.961 (4), N(4)···O(18^{ii})=2.958 (7) Å, where i and ii denote the symmetry operations x, y, $1+z$, and $1+x$, y, z, respectively. However, these hydrogen bonds are weak compared to the other hydrogen bonds found between the ammonium cations and water molecules (the hydrogen bond distances range from 2.822 (5) to 2.898 (5) Å). Thus the distortion of the complex anions found in the sodium and ammonium salts may be due to the interaction between

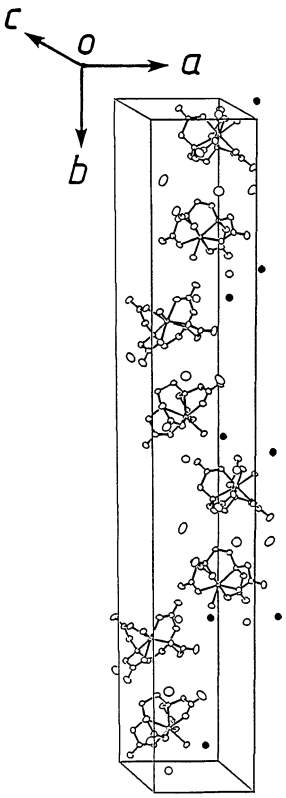

Fig. 4. Perspective of the unit cell for $NH_4[V(edta)(H_2O)]\cdot 2.5H_2O$ (**1c**). Ammonium nitrogen atoms are depicted by solid elipsoids.

the O(*n*8) atom and the cation; rather, the large deformation may be intrinsic to the $[V(edta)(H_2O)]^-$ anion and due to the d^2 configuration of vanadium(III) ion. For $[V(hedtra)(H_2O)]$, this distortion may be compensated by the rather weak bond between vanadium and the hydroxyethyl group.

The capped trigonal-prismatic structure of $[V^{III}(edta)(H_2O)]^-$ is in contrast to the pentagonal-bipyramidal structure of $[Fe^{III}(edta)(H_2O)]^-$,[13-18] although the ionic radii of Fe(III) and V(III) are almost the same ($r_{Fe^{3+}}$=0.645 vs. $r_{V^{3+}}$=0.640 Å).[30] This may be due to the difference of electronic configurations between iron(III) and vanadium(III): d^5 and d^2, respectively.

Preparation and Characterization of *N,N*-Bridged and/or *S,S*-Bridged Sexidentate-N_2,O_2,S_2 Cobalt(III) Complexes. Crystal Structure of {(3*S*, 8*S*)-2,2,9,9-Tetramethyl-1,10-dithia-4,7-diazacyclotetradecane-3,8-dicarboxylato}cobalt(III) Bromide

Ken-ichi Okamoto,* Norio Fushimi, Takumi Konno, and Jinsai Hidaka
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received March 27, 1991)

Four kinds of cobalt(III) complexes with *N,N*-bridged, *S,S*-bridged, or *N,N*- and *S,S*-bridged (cyclo type) sexidentate-N_2,O_2,S_2 ligand containing two D-penicillaminate moieties were newly synthesized. Of these complexes, the crystal structure of the title complex was determined by the X-ray diffraction method. The crystal was orthorhombic, space group $P2_12_12_1$, a=16.935(5), b=23.506(7), c=13.057(6) Å, V=5198(3) Å^3, Z=8, and the final R value was 0.0685. The ligand coordinates to the cobalt atom as the *N,N*- and *S,S*-bridged sexidentate-N_2,O_2,S_2. The absolute configurations of the nitrogen and sulfur donor atoms are *S*(N),*S*(N) and *R*(S),*R*(S) respectively. The *N,N*-bridged five-membered ring is the gauche form with the δ conformation and the *S,S*-bridged seven-membered ring is the twist-chair form with the λ conformation. The other three complexes were characterized by their electronic absorption, ^{13}C NMR, and circular dichroism (CD) spectra. The *N,N*- and/or *S,S*-bridged complexes showed the characteristic absorption and CD spectral behavior in the region of 16—24×10^3 cm^{-1}.

Cobalt(III) complexes with an *N,N*- or *S,S*-bridged sexidentate-N_2,O_2,S_2 thioether type ligand containing two *S*-methyl-L-cysteinate (L-smc) or L-cysteinate (L-cys) moieties have been investigated for the stereochemical and spectrochemical interests.[1,2] For example, the cobalt(III) complexes with *S,S'*-ethylenebis(L-cysteinate), *S,S'*-trimethylenebis(L-cysteinate), *N,N'*-ethylenebis(*S*-methyl-L-cysteinate), and *N,N'*-trimethylenebis(*S*-methyl-L-cysteinate) exhibited an extreme trans(O) selectivity concerning the formation of the geometrical isomers, where the expectant isomers are trans(O) and trans(N) for the *S,S*-bridged complexes, and trans(O) and trans(S) for the *N,N*-bridged ones.[1,2] This stereochemical characteristic seems to reveal that the cobalt(III) complexes with an *N,N*- and *S,S*-bridged (cyclo type) sexidentate-N_2,O_2,S_2 ligand are possibly formed.

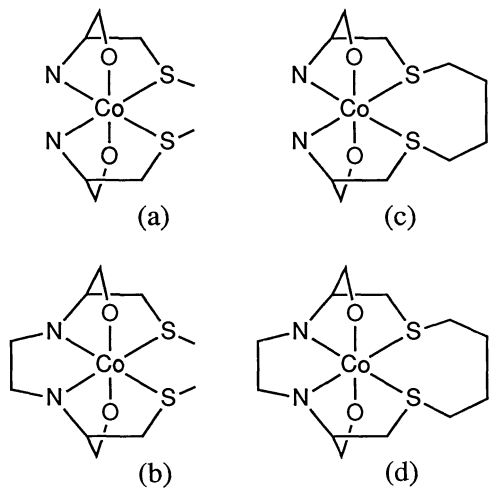

Fig. 1. Structure of (a) *trans*-(O)-[Co(D-smp)$_2$]$^+$, (b) *trans*-(O)-[Co(*N,N*-ebsmp)]$^+$, (*N,N*-bridged complex), (c) *trans*-(O)-[Co(*S,S*-tmbp)]$^+$, (*S,S*-bridged one), and (d) [Co(cyc-etmbp)]$^+$ (cyclo type one).[3]

The cyclo type complex is of interest not only in preparative work, but also in spectrochemistry. In the present work, D-penicillaminate (D-pen), which has the same framework as L-cysteinate, was used as the two terminals of the sexidentate-N_2,O_2,S_2 ligand. The trans(O) cobalt(III) complexes with the *N,N*-bridged, *S,S*-bridged, or cyclo type ligand[3] were synthesized by the alkylation reaction of the thiolato complex[4] containing two D-penicillaminate moieties with dimethyl sulfate, 1,2-dibromoethane, or 1,4-dibromobutane (Fig. 1). This paper reports the isolation of the four kinds of cobalt(III) complexes with the sexidentate-N_2,O_2,S_2 ligand, and their stereochemical and spectrochemical behavior. Of these complexes, the crystal structure of the cyclo type complex, [Co(*cyc*-etmbp)]$^+$ (Fig. 1), was determined by X-ray diffraction method.

Experimental

Materials. All reagents were purchased from the Wako Pure Chemical Ind. Co., Ltd., or Tokyo Chemical Ind. Co., Ltd. in Japan. All chemicals were of reagent grade and were used without further purification.

Preparation of Ligands. 1) *N,N'*-Ethylenebis(D-penicillamine): *N,N*-H$_4$ebp. This ligand was prepared by a procedure similar to that used for *N,N'*-ethylenebis(*S*-benzyl-L-cysteine).[5] The reaction solution was adjusted to pH 5 with hydrochloric acid and allowed to stand at 0 °C for 2 h. The deposited precipitate was collected by filtration, washed with deaerated cold water and methanol, and then dried in a vacuum desiccator. Found: C, 42.50; H, 7.31; N, 8.15%. Calcd for $H_4ebp\cdot 3/4H_2O=C_{12}H_{24}N_2O_4S_2\cdot 3/4H_2O$: C, 42.65; H, 7.60; N, 8.29%. ^{1}H NMR[100 MHz; solvent D_2O; standard DSS δ=2.99 (2H, S, CH), 2.65 (4H, broad, CH_2), 1.47 (6H, s, CH_3), 1.35 (6H, s, CH_3)]. ^{13}C NMR δ: see Table 4.

Preparation of Complexes. 2) *trans*(O)-Bis(*S*-methyl-D-penicillaminato)cobalt(III) Perchlorate: *trans*(O)-[Co(D-smp)$_2$]ClO$_4$. This complex was prepared by the procedure described in the literature,[4] and obtained as the perchlorate salt

by using a column of QAE-Sephadex A-25 (ClO_4^- form, 3 cm×35 cm). Found: C, 28.60; H, 5.37; N, 5.52%. Calcd for $[Co(D\text{-}smp)_2]ClO_4\cdot 3/2H_2O = C_{12}H_{24}N_2O_4S_2CoClO_4\cdot 3/2H_2O$: C, 28.27; H, 5.34; N, 5.49%.

3) *trans*(O)-*N*,*N*′-Ethylenebis(*S*-methyl-D-penicillaminato)cobalt(III) Hexafluorophosphate: *trans*(O)-[Co(*N*,*N*-ebsmp)]PF_6. To a solution containing 1 g of $[Co(NH_3)_6]Cl_3$[6] in 30 cm^3 of hot water (ca. 60 °C) were added 2 g of *N*,*N*′-ethylenebis(D-penicillamine) described in (1) and 0.5 g of activated charcoal. The mixture was stirred at 60 °C for 15 min, cooled to room temperature, and then filtered to remove insoluble materials. From the absorption spectral measurements and the column chromatographic behavior, it was found that the reaction mixture contained only *trans*(O)-[Co(*N*,*N*-ebp)]$^-$.[3] To the filtrate was added ca. 10 cm^3 of a 2.0 mol dm^{-3} aqueous solution of $NaClO_4$. This solution was concentrated to a small volume with a rotary evaporator and the deposited NaCl was filtered off. To the filtrate was added an appropriate amount of acetone and it was kept in a refrigerator for 6 h. The resulting brown precipitate was collected by filtration, washed with acetone, and then dried in a vacuum desiccator. Found: C, 29.81; H, 5.48; N, 5.82%. Calcd for $Na[Co(N,N\text{-ebp})]\cdot 3H_2O\cdot 1/2NaCl = C_{12}H_{20}N_2O_4S_2CoNa\cdot 3H_2O\cdot 1/2NaCl$: C, 29.68; H, 5.40; N, 5.77 %.

About 10 cm^3 of dimethyl sulfate was added to the reaction solution containing *trans*(O)-[Co(*N*,*N*-ebp)]$^-$ and the mixture was stirred for a few minutes. After being allowed to stand at room temperature overnight, the solution separated into two layers. The upper reddish layer was poured onto a column of SP-Sephadex C-25 (Na^+ form, 4.5 cm×45 cm). After sweeping the column with water, the adsorbed band was eluted with a 0.02 mol dm^{-3} aqueous solution of Na_2SO_4. Only deep red band was eluted and fractionated. From the absorption spectral measurements, it was found that each eluate contained only *trans*(O)-[Co(*N*,*N*-ebsmp)]$^+$. The eluates were combined and concentrated to a small volume with a rotary evaporator. The deposited Na_2SO_4 was filtered off. To the filtrate was added an appropriate amount of saturated NH_4PF_6 aqueous solution. The solution was concentrated to a small volume again and kept in a refrigerator overnight. The resulting deep red crystals were collected by filtration, washed with ethanol and ether, and then dried in a vacuum desiccator. Found: C, 28.38; H, 5.26; N, 4.77 %. Calcd for $[Co(N,N\text{-ebsmp})]PF_6\cdot 2H_2O = C_{14}H_{26}N_2O_4S_2PF_6Co\cdot 2H_2O$: C, 28.48; H, 5.12; N, 4.74 %.

4) *trans*(O)-*S*,*S*′-Tetramethylenebis(D-penicillaminato)cobalt(III) Perchlorate: *trans*(O)-[Co(*S*,*S*-tmbp)]ClO_4. *trans*(O)-[Co(D-pen)$_2$]$^-$ was prepared by the same procedure as that used for *trans*(O)-[Co(*N*,*N*-ebp)]$^-$ described in (3), using D-penicillamine (2 g) instead of *N*,*N*-H_4ebp. The greenish brown filtrate was concentrated to a small volume with a rotary evaporator, and to this was added to 10 cm^3 of 1,4-dibromobutane in 50 cm^3 of dimethyl sulfoxide. After being allowed to stand at room temperature for 1 d, unreacted 1,4-dibromobutane and dimethyl sulfoxide were extracted into diethyl ether. The leaving deep purple solution was poured onto a column of SP-Sephadex C-25 (Na^+ form, 4.5 cm×45 cm). After sweeping the column with water, the adsorbed band was eluted with a 0.05 mol dm^{-3} aqueous solution of NaCl. The five bands, dark red, reddish purple, purple, dark purple, and purple, were eluted in this order. The faster moving dark red band was transferred to another column of SP-Sephadex C-25 (Na^+ form, 4 cm×90 cm) and eluted with a 0.05 mol dm^{-3} aqueous solution of NaCl, because the other four bands were decomposed or disappeared during elution. The dark red band was separated into the three bands, dark red, reddish purple, and purple, in this order. From the absorption and ^{13}C NMR spectral measurements, it was found that the faster moving band contained the desired complex but the other two eluates were by-products whose sulfur atoms were not spanned by tetramethylene bridge. Then, the first moving dark red band was concentrated to a small volume with a rotary evaporator. The deposited NaCl was filtered off. The filtrate was passed through a column of QAE-Sephadex A-25 (ClO_4^- form, 3 cm×35 cm) eluting with water. After the eluate had been concentrated again, an appropriate amount of ethanol was added to it. The resulting red precipitate was collected by filtration, washed with ethanol and ether, and then dried in a vacuum desiccator. Found: C, 31.46; H, 5.61; N, 5.06%. Calcd for $[Co(S,S\text{-tmbp})]ClO_4\cdot 3/2H_2O = C_{14}H_{26}N_2O_4S_2CoClO_4\cdot 3/2H_2O$: C, 31.38; H, 5.45; N, 5.22%.

5) *trans*(O)-*S*,*S*′-Ethylenebis(D-penicillaminato)cobalt(III) Chloride: *trans*(O)-[Co(*S*,*S*-ebp)]Cl. This complex was prepared and chromatographed by a procedure similar to that used in (4), using 1,2-dibromoethane instead of 1,4-dibromobutane. The only purple band was eluted. From the absorption spectral measurements, it was found that the eluate contained only *trans*(O)-[Co(*S*,*S*-ebp)]$^+$. The eluate was concentrated to a small volume with a rotary evaporator. The deposited NaCl was filtered off. The filtrate was poured onto a column of Sephadex G-10 (3 cm×70 cm) eluting with water. After the eluate had been concentrated to a small volume again, an appropriate amount of ethanol was added to it. The solution was kept in a refrigerator for 5 h. The resulting purple crystals were collected by filtration, washed with ethanol and ether, and then dried in a vacuum desiccator. Found: C, 32.97; H, 5.53; N, 6.42 %. Calcd for $[Co(S,S\text{-ebp})]Cl\cdot H_2O = C_{12}H_{22}N_2S_2O_4ClCo\cdot H_2O$: C, 33.15; H, 5.56; N, 6.44 %.

6) {(3*S*,8*S*)-2,2,9,9-tetramethyl-1,10-dithia-4,7-diazacyclotetradecane-3,8-dicarboxylato}cobalt(III) Nitrate: [Co(*cyc*-etmbp)]NO_3. To a solution containing 1.5 g of *trans*(O)-$Na[Co(N,N\text{-ebp})]\cdot 3H_2O\cdot 1/2NaCl$ (described in (3)) in 30 cm^3 of dimethyl sulfoxide was added about 10 cm^3 of 1,4-dibromobutane. After being allowed to stand at room temperature for 18 h, the reaction mixture turned to deep red. Dimethyl sulfoxide and unreacted 1,4-dibromobutane were extracted into diethyl ether. The leaving dark red oil was poured onto a column of SP-Sephadex C-25 (Na^+ form, 4 cm×65 cm). After sweeping the column with water, the adsorbed band was eluted with a 0.05 mol dm^{-3} aqueous solution of NaCl. Two bands, orange red and red, were eluted in this order. Since the faster moving band seemed to contain two isomers, it was transferred to another column of SP-Sephadex C-25 (Na^+ form, 4.5 cm×45 cm). By developing the band with a 0.05 mol dm^{-3} aqueous solution of NaCl, two bands, orange red and red, were eluted in this order. From the absorption and CD spectral measurements, it was found that the orange red band contained the desired complex and the two red bands were by-products whose sulfur atoms were not spanned by tetramethylene bridge. The faster moving band was concentrated to a small volume with a rotary evaporator. The deposited NaCl was filtered off. The filtrate was passed through a column of QAE-Sephadex A-25 (NO_3^- form,

3 cm×35 cm) eluting with water. The eluate was concentrated to a small volume again and kept in a refrigerator for 6 h. The resulting dark red crystals were collected by filtration, washed with ethanol and ether, and then dried in a vacuum desiccator. Found: C, 36.63; H, 5.96; N, 7.97%. [Co(*cyc*-etmbp)]NO_3·3/2H_2O=$C_{16}H_{28}N_3O_7S_2Co$·3/2H_2O: C, 36.64; H, 5.95; N, 7.97%.

The nitrate salt of the complex was dissolved with the appropriate amount of water and it was passed through a column of QAE-Sephadex A-25 (Br^- form) eluting with water. The eluate was concentrated to a small volume and kept in a refrigerator. The resulting crystals, [Co(*cyc*-etmbp)]Br·5.5H_2O, were suitable for X-ray structure analysis and could be collected by filtration.

Measurements. The electronic absorption spectra were recorded with a JASCO UVIDEC-610C or UVIDEC-505 spectrophotometer, and the CD spectra with a JASCO J-20 or J-600 spectropolarimeter. All the measurements were carried out in aqueous solutions at room temperature. The ^1H and ^{13}C NMR spectra were recorded with a JEOL JNM-FX-100 or -FX-90Q NMR spectrometer in a deuterium oxide (D_2O) or acetonitrile-d_3 (CD_3CN) solvent at the probe temperature. Sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) or tetramethylsilane (TMS) was employed as the internal reference.

Crystallography. X-Ray Data Collection. Unit cell parameters and intensity data for the single orange-red crystal (ca. 0.55×0.55×0.35 mm^3) were measured on an Enraf Nonius CAD4 diffractometer with graphite-monochromated Mo $K\alpha$ radiation (λ 0.71069 Å, 50 kV and 26 mA). Unit cell parameters were determined by least-squares refinement from 25 reflections with $20°<2\theta<24°$. Crystal data: [$CoC_{16}H_{28}N_2O_4S_2$]Br·5.5H_2O, M=614.47, orthorhombic, space group $P2_12_12_1$, a=16.935(5), b=23.506(7), c=13.057(6) Å, U=5198(3) $Å^3$, Z=8, D_C=1.57 g cm^{-3}, $F(000)$=2536, μ=23.2 cm^{-1}, and room temperature.

The intensity data were collected by the ω–2θ scan mode up to $2<2\theta<56°$ ($0\leqq h\leqq 23$, $0\leqq k\leqq 33$, $0\leqq l\leqq 18$) with scan width $(0.8+0.350\tan\theta)°$ and scan rate varied from 1 to 5° min^{-1} (on ω). The intensities were corrected for Lorentz and polarization, and not for absorption. A total of 5929 independent reflections with $|F_o|>3\sigma(|F_o|)$ of the measured 8286 reflection were considered as "observed" and used for structure determination.

Determination of Crystal Structure. The cobalt and four coordinated atoms were located by the direct methods of the crystallographic program package SDP/VAN.[7] The remaining non-hydrogen atoms were found by conventional difference Fourier techniques to give a trial structure. The structure was refined by the full-matrix least-squares technique using SHELX76[8] on the FACOM M780/20 computer at the Computer Center of the University of Tsukuba. Anisotropic temperature factors were applied to all non-hydrogen atoms. Hydrogen atoms were fixed by geometrical constrains (C–H=0.95 Å) and isotropic thermal parameters (U=0.05 $Å^2$). The water hydrogen atoms were not included in the calculation. The final refinement gave R=0.0685 and R_w=0.0708 with the weighting scheme $w=1.5254/\{\sigma^2(F_o)+0.002334F_o^2\}$. The final difference Fourier synthesis indicated no significant peaks larger than 1.0 eA^{-3}. Atomic positional parameters are given in Table 1 and selected bond distances and angles within the cations are summarized in Table 2.[9]

Results and Discussion

Crystal Structure of [Co(*cyc*-etmbp)]$^+$. A perspective drawing of the typical complex cation (A species) is shown in Fig. 2, together with its atomic numbering scheme. There are two crystallographically independent complex cations in an asymmetric unit, through their shapes and sizes remarkably resemble each other. In the both complex cations, the cobalt atom is octahedrally surrounded by two cis N, two trans O, and two cis S atoms, that is, the ligand coordinates to cobalt

atom as a sexidentate to take the trans(O) configuration. Two D-penicillaminate moieties are spanned by ethylene and tetramethylene to form the *N,N*-bridged five-membered and *S,S*-bridged seven-membered rings. As the result of bridging, the complex cations acquire two kinds of additionally optically active sources with regard to the chiral configuration of nitrogen donor atom (*R*(N) and *S*(N)) and sulfur donor one (*R*(S) and *S*(S)). The absolute configurations of these donor atoms and the chelate ring conformations in the complex cations can be confirmed on the basis of the asymmetric carbon atoms, *S*(C), in the two D-penicillaminate moieties.[10] Both of the chiral nitrogen donor atoms take selectively the *S*(N) configuration and the *N,N*-bridged five-membered ring has a gauche form with a δ conformation (Fig. 3(b)). Further, the two sulfur donor atoms take the *R*(S) configuration and the *S,S*-bridged seven-membered ring has a twist-chair form with a λ conformation (Fig. 3(a)), which is quite similar to those of the *N;N*-bridged seven-membered ring in *cis*-$[Co(NO_2)_2(tmd)_2]^+$ (tmd=1,4-butanediamine).[11]

The bond distances and angles are similar to those for the cobalt(III) complexes with thioether or thiolate ligands containing the cys, pen, or their derivatives (Table 3).[1,10,12-14] Especially, [Co(*cyc*-etmbp)]$^+$ shows quite similar bond distances and angles to *trans*(O)-[Co(*N,N*-ebsmc)]$^+$, except for the Co–S and S–C distances. The Co–S (2.214—2.230(2) Å; av. 2.224 Å) and S–C (1.852—1.892(10) Å; av. 1.877 Å) distances of the cyc-etmbp complex coincide with those of the *S,S*-bridged complex, $(+)^{CD}_{560}$-[Co{(2*R*,9*S*)-2,9-diamino-3,3,8,8-tetramethyl-4,7-dithia-1,10-decanedioato}]$^+$ (Co–S: 2.199(7) and 2.221(8) Å; S–C: 1.89(2) and 1.91(2) Å),[13] but differ from those of *trans*(O)-[Co(*N,N*-ebsmc)]$^+$ (Co–S: av. 2.261(4) Å; S–C; av. 1.843(14) Å)[1,3] and *trans*(S)-[Co(L-smc)$_2$]$^+$ (Co–S: 2.270(2) and 2.273(2) Å; S–C: 1.835(10) and 1.838(10) Å).[3,12] It is noteworthy that the bond angles of S–Co–S (98.2(1) and 99.1(1)°) are larger than those of N–Co–N of the *N,N*-bridged chelate rings, *cis*-$[Co(NO_2)_2(tmd)_2]^+$ (92.0—93.4(1)°; av. 92.4°).[11]

Characterization. The absorption and CD spectra of the present [Co(sexidentate-N_2,O_2,S_2)]$^+$ type complexes are shown in Figs. 4 and 5, and their data are summarized in Table 3. For the thioether type complexes such as [Co(L-smc)$_2$]$^+$, [Co(D-smp)$_2$]$^+$, and [Co(L-met)$_2$]$^+$, it has been known that the cis(S) isomer exhibits the intense broad absorption band at ca. 34×10^3 cm^{-1} and the trans(S) isomer the intense sharp one at ca. 28×10^3 cm^{-1}, arising from the sulfur-to-metal charge-transfer (SMCT) transition.[1,2,4,15] Taking these facts into consideration,

all the present complexes, which exhibit the intense broad SMCT band at ca. 34×10^3 cm^{-1}, are assigned to take the cis(S) configuration, that is, the trans(O) or trans(N) isomer. Of the present three complexes except for the cyc-etmbp complex, the *N,N*-ebsmp complex is assignable to *trans*(O)-[Co(*N,N*-ebsmp)]$^+$ (Fig. 1), because the two cis nitrogen donor atoms are spanned by ethylene to form the five-membered ring. This assignment is supported by the fact that the *N,N*-ebsmp complex exhibits quite similar absorption and CD spectral patterns to *trans*(O)-[Co(*N,N*-ebsmc)]$^+$ over the whole region (Fig. 4 and Table 3), which has a quite similar framework to the *N,N*-ebsmp complex and its configuration has been determined by the X-ray structure analysis.[1] The absorption and CD spectral patterns of the *S,S*-tmbp complex, which was prepared by the reaction of *trans*(O)-[Co(D-pen)$_2$]$^-$ with 1,4-dibromobutane, coincides well with those of [Co(*cyc*-etmbp)]$^+$ over the whole region (Fig. 5 and Table 3). Accordingly, the *S,S*-tmbp complex is probably assigned to *trans*(O)-[Co(*S,S*-tmbp)]$^+$ (Fig. 1). The *S,S*-ebp complex, which was prepared by a similar reaction to the *S,S*-tmbp complex using *trans*(O)-[Co(D-pen)$_2$]$^-$ and 1,2-dibromoethane, exhibits quite similar absorption spectrum

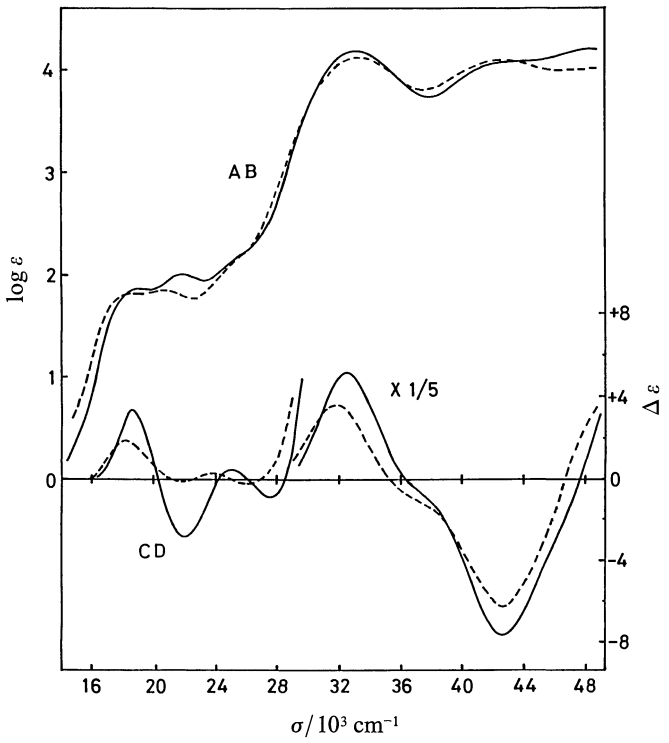

Fig. 5. Absorption and CD spectra of [Co(*cyc*-etmbp)]$^+$ (——) and *trans*-(O)-[Co(*S*,*S*-tmbp)]$^+$ (-----).

and CD pattern to those of *trans*(O)-[Co(*S*,*S*-ebc)]$^+$ over the whole region (Table 3).[2] These similarities suggest that the *S*,*S*-ebp complex takes a trans(O) configuration, *trans*(O)-[Co(*S*,*S*-ebp)]$^+$. These assignments based on their absorption and CD spectra are supported by their ^{13}C NMR spectral measurements.

The ^{13}C NMR chemical shift data for the four cobalt(III) complexes and *S*,*S*-H$_4$ebp are summarized in Table 4. Each signal was assigned on the basis of the insensitive nuclei enhanced by polarization transfer (INEPT) method and of the comparison with the chemical shift data for the related complexes.[1,2] [Co(*cyc*-etmbp)]$^+$ exhibits the eight resonance lines for the sixteen carbon atoms, indicating a C_2 symmetry of the complex. This reveals that the *cyc*-etmbp complex in solution retains the same conformation as in crystal. *trans*(O)-[Co(*S*,*S*-tmbp)]$^+$ exhibits a similar ^{13}C NMR spectral behavior to the *cyc*-etmbp complex, except that the resonance line (δ=75.47) due to the methine carbon atom appears significantly higher field than that (δ=81.42) of [Co(*cyc*-etmbp)]$^+$ whose two nitrogen donor atoms were spanned by ethylene. This suggests that the *S*,*S*-bridged seven-membered ring of the *S*,*S*-tmbp complex takes the twist-chair form with the λ conformation as in the *cyc*-etmbp complex. The ^{13}C NMR spectrum of *trans*(O)-[Co(*S*,*S*-ebp)]$^+$ exhibits six resonance lines due to the twelve carbon atoms, suggesting that the complex also has a C_2 symmetry, that is, the *S*,*S*-bridged five-membered ring takes a gauche form with a λ conformation and the chiral sulfur donor atoms takes the *S*(S), *S*(S) configuration. These regulations are probably ascribed to the rigid framework of the two D-terdentate terminal moieties.

In contrast with the three *S*,*S*-bridged complexes, the ^{13}C NMR spectrum of *trans*(O)-[Co(*N*,*N*-ebsmp)]$^+$ exhibits three resonance lines for each carbon atom of the two D-terdentate terminal moieties and of the *N*,*N*-bridged five-membered ring (Table 4). This suggests that the *N*,*N*-ebsmp complex is a mixture of the isomers (*R*(S),*R*(S), *R*(S),*S*(S) and/or *S*(S),*S*(S)) with regard to the chiral sulfur donor atoms. The *R*(S),*S*(S) isomer of *trans*(O)-[Co(*N*,*N*-ebsmp)]$^+$ being a C_1 symmetry is expected to show two sets of the resonance lines for each carbon atom, while one set of resonance lines is expected for the *R*(S),*R*(S) or *S*(S),*S*(S) isomer because of a C_2 symmetry of the complex cation. Accordingly, the *N*,*N*-ebsmp complex is assumed to be a mixture of either the *R*(S),*R*(S) and *R*(S),*S*(S) isomers or the *S*(S),*S*(S) and *R*(S),*S*(S) ones. *trans*(O)-[Co(*N*,*N*-ebsmc)]$^+$, which has the same framework as the present *N*,*N*-ebsmp complex, consists of the two isomers, *S*(S),*S*(S) and *R*(S),*S*(S), in crystal, although the *N*,*N*-ebsmc complex was proportionated to three isomers, *R*(S),*R*(S), *R*(S),*S*(S), and *S*(S),*S*(S), in solution.[1] Taking the structure of the *N*,*N*-ebsmc complex in crystal into consideration, it is probable that *trans*(O)-[Co(*N*,*N*-ebsmp)]$^+$ consists of the *R*(S),*R*(S) and *R*(S),*S*(S) isomers even in solution.

In the region of 16—24×10^3 cm^{-1}, the present trans(O) complexes with the *N*,*N*-bridged, *S*,*S*-bridged, or cyclo type sexidentate-N$_2$,O$_2$,S$_2$ ligand show the characteristic absorption spectral behavior in connection with the bridging type of the ligands. In comparison with the

Table 4. ^{13}C NMR Chemical Shifts[a]

Compound	COO	N–CH	S–C	N–CH$_2$	S–CH$_2$–CH$_2$	CH$_3$(pen)	S–CH$_3$

[Co(*cyc*-etmbp)]$^+$[b]	181.65	81.42	60.24	55.80	36.84 30.61	30.88 24.97	
trans(O)-[Co(*N*,*N*-ebsmp)]$^+$[b]	177.26	79.42	57.05	54.28		28.93 24.11	15.33
	176.23	78.88	56.88	54.01		28.50 23.67	15.01
	176.07	78.66	55.69			28.28 22.43	

a) ppm from DSS in D_2O. b) ppm from TMS in CD_3CN.

broad absorption band of *trans*(O)-[Co(D-smp)$_2$]$^+$ in this region, *trans*(O)-[Co(*S,S*-ebp)]$^+$ intensifies markedly the lower energy absorption component of the corresponding band, while *trans*(O)-[Co(*N,N*-ebsmp)]$^+$ intensifies the higher energy component (Fig. 4 and Table 3). On the other hand, *trans*(O)-[Co(*S,S*-tmbp)]$^+$ shows a similar absorption spectral pattern to [Co(*cyc*-etmbp)]$^+$, and furthermore, their intensities are similar to that of *trans*(O)-[Co(D-smp)$_2$]$^+$ (Figs. 4 and 5, and Table 3). These facts suggest that the strain due to the *S,S*-bridging contributes more dominantly to the absorption spectral behavior in the d-d transition region than that due to the *N,N*-bridging.

The CD spectral behavior of *trans*(O)-[Co(*S,S*-ebp)]$^+$ differs significantly from that of *trans*(O)-[Co(D-smp)$_2$]$^+$. This is attributed to the difference in steric regulation between the chiral sulfur donor atoms in the complexes. The CD contribution due to the chiral sulfur donor atoms in *trans*(O)-[Co(D-smp)$_2$]$^+$ is probably canceled, because the D-smp complex is a mixture of three isomers (*R*(S),*R*(S), *R*(S),*S*(S), and *S*(S),*S*(S)).[4] While, the *S,S*-bridged five-membered ring of *trans*(O)-[Co(*S,S*-ebp)]$^+$ takes a gauche form with the λ conformation, and accordingly, the two sulfur donor atoms are regulated to the *S*(S),*S*(S) configuration. In contrast with the *S,S*-ebp complex, *trans*(O)-[Co(*N,N*-ebsmp)]$^+$ shows a similar CD spectral pattern to *trans*(O)-[Co(D-smp)$_2$]$^+$ over the whole region (Fig. 4 and Table 3).[4] This similarity suggests that the *N,N*-ebsmp complex consists of two isomers, *R*(S),*R*(S) and *R*(S),*S*(S), in solution as mentioned above. Here, it takes notice that the *N,N*-bridged five-membered ring of the *N,N*-ebsmp complex takes a gauche form with the δ conformation, that is, *S*(N),*S*(N) with regard to the bridged nitrogen donor atoms. However, the contribution to the CD spectral pattern will be minor in this case, because the chiral sulfur donor atoms contribute to the CD spectral pattern much larger than the chiral nitrogen atoms do.[16,17] The similar consideration is applicable to the similarity in CD spectral behavior between [Co(*cyc*-etmbp)]$^+$ and *trans*(O)-[Co(*S,S*-tmbp)]$^+$ over the whole region (Fig. 5 and Table 3). Namely, each of the chiral sulfur donor atoms of both complexes are fixed to the *R*(S) configuration because of the twist chair form with the λ conformation of the *S,S*-bridged seven-membered ring.

Stereoselectivity in Diastereomeric Tetrahedral Metal(II) Complexes of Chiral Salicylideneamines: Crystal Structure and Molecular Mechanics Calculation of Bis[*N*-(*l*-menthyl)salicylideneaminato]cobalt(II)

Hiroshi SAKIYAMA,* Hisashi ŌKAWA,* Naohide MATSUMOTO, and Sigeo KIDA†
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashiku, Fukuoka 812
(Received April 11, 1991)

Stereoselectivity of bis[*N*-(*l*-menthyl)salicylideneaminato]cobalt(II) [Co(sal-ment)$_2$] has been studied by single crystal X-ray analysis and molecular mechanics calculations. The X-ray analysis has revealed a nearly tetrahedral surrounding (dihedral angle of 82.5°) and *Δ* configuration about the metal ion. Molecular mechanics calculations were made based on MM2 program, assuming a tetrahedral surrounding about the metal ion and fixing the four donor atoms and six atoms adjacent to the donor atoms at the positions as determined by the single crystal X-ray analysis. The most stable structure obtained from the MM2 calculation coincides well with that from the crystal structure analysis. Together with the X-ray structural results for [Cu(sal-ment)$_2$] and bis[*N*-[(*R*)-1-phenylethyl]salicylideneaminato]cobalt(II) [Co(sal-Rmb)$_2$] studied in this study and for related [Zn(sal-Rmb)$_2$] and [Cu(sal-Rmb)$_2$] studied previously, the factors responsible for the stereoselectivities of those bis(salicylideneaminato)metal(II) complexes have been discussed.

Studies of enantiomeric and diastereomeric metal complexes have been stimulated by the interests to elucidate the correlation between circular dichroism induced in the visible region and the absolute configuration about the metal ion and to explore the factors responsible for the stereoselective behavior found for those complexes.[1] Tetrahedral or pseudo-tetrahedral bis-chelate complexes of the general type [M(A–B)$_2$] are enantiomeric and can in principle exist in two absolute configurations, *Δ* and *Λ*[2] (see Fig. 1). The resolution of the enantiomers has been hardly attained with a very few exceptions[3] because of the lability of tetrahedral complexes. The stereoselectivities of diastereomeric tetrahedral or pseudo-tetrahedral complexes of bidentate salicylideneamines or related Schiff bases have been investigated by ^{1}H NMR[2,4–8] and circular dichroism[8,9] spectroscopies and single crystal X-ray structural analysis.[9,10] It is generally accepted that interligand non-covalent interactions plays an important role in the predominant formation of one of the diastereomers.[11] A direct evidence for the operation of such interligand noncovalent interactions was obtained for tetrahedral bis[*N*-[(*R*)-1-phenylethyl]salicylideneaminato]zinc(II) [Zn(sal-Rmb)$_2$][9] where the chiral *N*-substituent of one ligand is in a close contact with the adjacent chelate ring of the other ligand, affording *Δ* configuration about the zinc(II) ion. In bis[*N*-[(*R*)-1-phenylethyl]salicylideneaminato]copper(II) [Cu(sal-Rmb)$_2$][10] the preferred configuration about the copper is pseudo-tetrahedral and of *Δ*. In this complex an interligand interaction occurs between the hydrogen attached to the asymmetric carbon in the *N*-substituent and the phenolic oxygen of the adjacent chelate ring. As seen in the above examples, the factors contributing to the stereoselectivity of diastereomeric tetrahedral complexes of salicylideneamines are not straightforward.

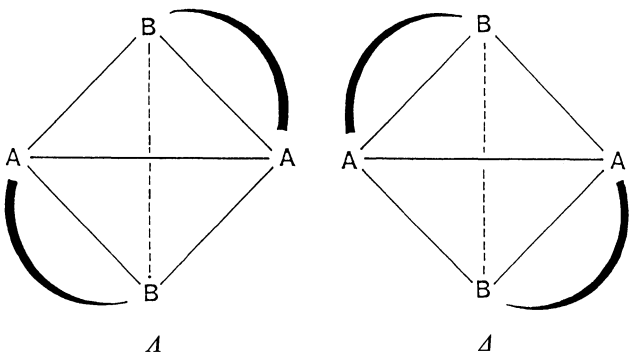

Fig. 1. Two absolute configurations (*Δ* and *Λ*) for tetrahedral complexes.

In this study the stereoselectivity of bis[*N*-(*l*-menthyl)salicylideneaminato]cobalt(II) [Co(sal-ment)$_2$] has been studied by single-crystal X-ray method and molecular mechanics calculations by MM2 program. Further, we have examined the crystal structures of bis[*N*-(*l*-menthyl)salicylideneaminato]copper(II) [Cu(sal-ment)$_2$] and bis[*N*-[(*R*)-1-phenylethyl]salicylideneaminato]cobalt(II) [Co(sal-Ramb)$_2$] and found that the former is isomorphous to [Co(sal-ment)$_2$] and the latter to [Zn(sal-Rmb)$_2$].[9] From the inspection of both the X-ray analytical results for those complexes and the molecular mechanics calculations for [Co(sal-ment)$_2$] it is aimed to elucidate the main factors responsible for stereoselectivities of the tetrahedral or pseudo-tetrahedral complexes of salicylideneamines.

Experimental

Preparations. [Co(sal-ment)$_2$] and [Cu(sal-ment)$_2$] were prepared by the literature methods.[8]

[Co(sal-Rmb)$_2$]. An ethanolic solution of (*R*)-1-phenylethylamine purchased from Tokyokasei Chemical Co. (0.48 g, 4 mmol) and salicylaldehyde (0.48 g, 4 mmol) was refluxed for 2 h. To this were added powdered NaHCO$_3$

† Present address: Kumamoto Institute of Technology, Ikeda 4-22-1, Kumamoto 860

(0.34 g, 4 mmol) and cobalt(II) acetate tetrahydrate (0.49 g, 2 mmol), and the mixture was stirred at 60 °C for 2 h and allowed to stand overnight at ambient temperature. The resulted red crystals were recrystallized from ethanol.

Found: C, 70.84; H, 5.51; N, 5.54%. Calcd for $C_{30}H_{28}CoN_2O_2$: C, 71.00; H, 5.52; N, 5.56%.

Single-Crystal X-Ray Analyses. Single crystals of [Co(sal-ment)$_2$] were grown by the slow crystallization from a chloroform–ethanol (3 : 1 in volume) mixture, and a crystal with approximate dimensions of 0.4×0.4×0.2 mm was used for the study. Intensities and lattice parameters were obtained on a Rigaku AFC-5 automated four-circle diffractometer, using graphite-monochromated Mo $K\alpha$ radiation (λ=0.71073 Å) at 20±1 °C. Lattice parameters and their estimated standard deviations were obtained from a least-squares fit to 25 2θ values in the range 15°<2θ<30°. For the intensity data collections, the ω–2θ scan mode was used at a scan rate of 6° min^{-1}. The octant measured was $+h$, $+k$, $+l$. Three standard reflections were monitored every 100 reflections and their intensities showed a good stability. The intensity data were corrected for Lorentz-polarization effects but not for absorption. The crystal data of [Co(sal-ment)$_2$] are summarized in Table 1.

The structures were solved by the heavy-atom method and refined by the block-diagonal least-squares method. Atomic scattering factors were taken from Ref. 12. Hydrogen atoms were included in their calculated positions and held fixed. All the calculations were carried out on a FACOM M-780 computer in the Computer Center of Kyushu University by the use of local version of the UNICS-III and ORTEP programs.[13,14] The final positional parameters for [Co(sal-ment)$_2$] are given in Table 2. The F_o–F_c tables, thermal parameters, H-atom parameters, and full bond distances and angles are deposited as Document No. 8958 at the Office of the Editor of Bull. Chem. Soc. Jpn.

[Cu(sal-ment)$_2$] was found to be isomorphous to [Co(sal-ment)$_2$]: Formula=$CuO_2N_2C_{34}H_{48}$, F.W.=580.31, trigonal, space group=$P3_1$, a=8.874(3), c=34.645(9) Å, V=2365(2) Å^3, Z=3, D_x=1.22 g cm^{-3}.

[Co(sal-Rmb)$_2$] was also found to be isostructural with [Zn(sal-Rmb)$_2$]: Formula=$Co_2O_4N_4C_{60}H_{54}$, F.W.=1012.98, space group=$P2_12_12_1$, orthorhombic, a=17.771(3), b=29.681(9), c=9.892(6) Å, V=5218(3) Å^3, Z=4, D_x=1.28 g cm^{-3}.

Molecular Mechanics Calculations. The molecular mechanics calculations were carried out by the use of the MM2 program.[15] The most stable structure of [Co(sal-ment)$_2$] was obtained by the procedures as described as follows. As the first step the complex was divided into two parts, the *l*-menthyl part and the rest, and their most stable structures were calculated for imaginal "*l*-menthylmethane" (1-isopropyl-2,4-dimethylcyclohexane) and tetrahedral bis(salicylideneaminato)cobalt(II) [Co(sal-ment)$_2$], respectively. As the second step the initial steric energy of [Co(sal-ment)$_2$] was calculated for both Δ and Λ forms every 30° by rotating the *l*-menthyl groups with respect to the N–C(menthyl) bond, while maintaining the most stable structures of the constituents obtained in the first step. Finally, the conformer with the lowest steric energy was used in the energy minimization to obtain the most stable structure of the whole complex molecule. Since the parameters of sp^2 nitrogen atom and cobalt atom are lacking, the parameters of sp^2 carbon atom were used for the sp^2 nitrogen and the four donor atoms and the six atoms attached to the donor atoms were fixed at the positions determined from the crystal structure analysis. In other words, the cobalt atom was not included in the energy minimization. The MM2 calculational data are deposited as supplementary materials (Table S5—S10).

Table 2. Atomic Parameters of [Co(sal-ment)$_2$]

Results and Discussion

Crystal Structures of [Co(sal-ment)$_2$] and [Cu(sal-ment)$_2$]. These complexes are isomorphous (see Table 1). The crystal structure of the cobalt complex is described here. Its perspective view is given in Fig. 2, together with the numbering system. Relevant bond lengths and angles are listed in Table 3.

The deprotonated form of the Schiff base functions as a bidentate ligand to form a nearly tetrahedral surrounding about the cobalt ion. The dihedral angle between the plane defined by Co, N(1), and O(1) and the plane defined by Co, N(2), and O(2) is 82.5°. We analyzed the molecular structure by taking into account the established configuration of the *l*-menthyl group and found the dextral disposition of two ligands along the C_2 axis, i.e. *Δ* configuration.

The cyclohexane ring of the *l*-menthyl group assumes a chair form and the salicylideneamine moiety is equatorially bonded to the cyclohexane ring. The conformation with respect to the N(1)–C(8) bond is such that the hydrogen attached to C(8) is eclipsed to the hydrogen attached to C(7). This conformation must be the most preferred one. In any other conformations a large interligand steric repulsions is expected between the azomethine hydrogen and *l*-menthyl group.

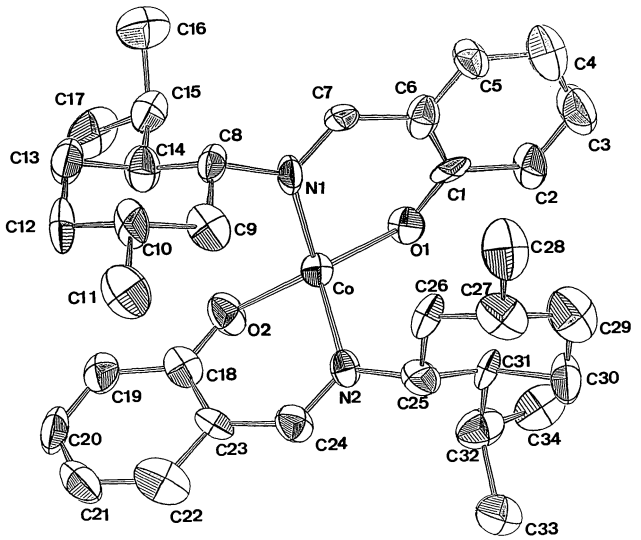

Fig. 2. ORTEP view of [Co(sal-ment)$_2$] with numbering system.

Table 3. Relevant Bond Distances and Angles of [Co(sal-ment)$_2$]

Bond distances (Å)	
Co-O1	1.91(1)
Co-O2	1.90(1)
Co–N1	1.98(1)
Co–N2	2.02(1)
Bond angles (deg)	
O1–Co–O2	125.0(3)
O1–Co-N1	95.5(5)
O1-Co–N2	112.3(4)
O2–Co–N1	112.5(4)
O2–Co–N2	94.9(5)
N1–Co–N2	118.6(4)
Distances between non-bonded atoms (Å)	
O1–C31	3.26(2)
O2–C14	3.31(2)

In the crystal the C(14) of the *l*-menthyl group is in a close proximity of the phenolic oxygen O(2) of the adjacent chelate ring with the interatomic distance of 3.31(2) Å. Similarly the C(31)–O(1) interatomic distance is 3.26(2) Å. Even taking the C–H–O angles into consideration, those short distances suggest the presence of the hydrogen bonding between these atoms.

[Co(sal-Rmb)$_2$]. The X-ray study has shown that the crystal of this complex is isomorphous to that of [Zn(sal-Rmb)$_2$]. This zinc complex assumes a nearly tetrahedral environment about the metal ion and the absolute configuration is *Λ*. The detailed structure of this complex has been reported in our recent paper.[9]

Molecular Mechanics Results. *l*-Menthylmethane. This molecule assumes a chair structure.[16] In our calculations only the rotation of the isopropyl group with respect to C(cyclohexane)–C(isopropyl) bond was considered. The result indicates that the isopropyl group is subjected to a severe steric effect from the adjacent methyl group. The most preferred conformation is such that the isopropyl hydrogen (–C<u>H</u>(CH$_3$)$_2$) is eclipsed to the adjacent methyl group and the two methyl groups of the isopropyl moiety are thrust away to the opposite side.

[Co(sal-ment)$_2$]. The most stable structure of [Co(sal-ment)$_2$] obtained by molecular mechanics calculations is shown in Fig. 3. This structure is essentially the same as the molecular structure determined by the single crystal X-ray method (see Fig. 2). The bond distances and bond angles determined by the two methods agree within 0.1 Å and 4°, respectively, except for those of the aromatic part.

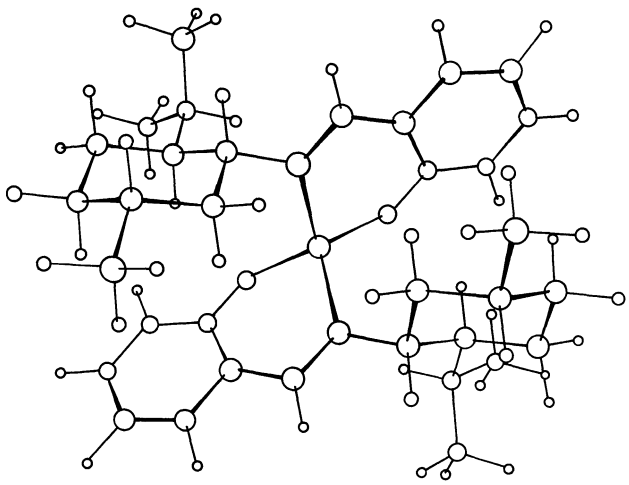

Fig. 3. The most stable structure of [Co(sal-ment)$_2$] obtained by the molecular mechanics calculation.

The ligand moiety in the complex molecule retains the most stable structure of free (sal-ment)$^-$, in which the conformation about the N–C(menthyl) bond is such that the hydrogen on the asymmetric carbon attached to the nitrilo nitrogen is eclipsed to the azomethine carbon so as to reduce the steric repulsion between the *l*-menthyl group and the aromatic part. A large rotational barrier about the N–C(menthyl) bond is probably the cause to retain this conformation even in the complex molecule. The *Λ* form is possible if the *l*-menthyl group is rotated by ca. 180° about the N–C(menthyl) bond from the most stable conformation of the free ligand, but this form is unfavorable because of a steric repulsion between the aromatic ring and *l*-menthyl group.

Factors Responsible for Stereoselectivity. Though the structurally well-characterized, tetrahedral or pseudo-tetrahedral complexes of salicylideneamines with a chiral N-substituent are still limited, their stereochemistries are significantly diversed, depending upon the nature of the central metal ion and the Schiff base ligand. In this study we have aimed to deduce dominant factors responsible for the stereochemistry in each complex. Four factors can be considered here: (A) the preferred configuration of the central metal ion, (B) the preferred conformation of salicylideneamines mainly due to the intraligand steric repulsion, (C) an interligand steric repulsion between ligands, and (D) an interligand noncovalent attracting interaction.

The preferred configurations for four-coordinate cobalt(II) and zinc(II) ions are tetrahedral whereas that for copper(II) ion is planar.[17,18] The most stable structures of (sal-ment)$^-$ and (sal-Rmb)$^-$ are such that the N-substituent and the aromatic part are disposed as far as possible because of the steric repulsion. With respect to the rotational barrier due to the steric repulsion, (sal-Rmb)$^-$ is more flexible than (sal-ment)$^-$.

(1) [M(sal-ment)$_2$] (M=Co, Cu). The tetrahedral surrounding has been proved for both complexes. Because of the interligand steric repulsion tetrahedral configuration is preferable rather than square planar configuration. This configuration is also preferable to cobalt(II) but not to copper(II). The ligand moiety retains the most stable conformation in the complexes because of the rotational barrier due to the intraligand steric repulsion. If two (sal-ment)$^-$ ligands maintaining the most stable conformation were disposed planarly about a metal ion, a severe interligand steric hinderance would occur. Thus, such a steric effect is the cause for the tetrahedral distortion of the copper complex. The stereoselectivity to afford *Δ* configuration about the central metal may also be attributed to an interligand steric repulsion between the two chiral ligands.

(2) [Cu(sal-Rmb)$_2$]. In this complex the dihedral angle around the metal ion is rather small (39.5°).[10] This is because the steric requirement of the copper(II) to prefer a planar configuration is larger than the intraligand steric repulsion in each ligands. The ligand conformation is significantly altered from the most stable free-ligand conformation so as to reduce the interligand steric repulsion. It is also obvious that the hydrogen bonding between the asymmetric carbon and the phenolic oxygen of the neighboring chelate ring is cotributing to the stabilization. The difference of the steric hindrance between the methyl group and the phenyl group gives rise to the stereoselectivity to afford the *Δ* configuration.

(3) [M(sal-ment)$_2$] (M=Co, Cu). (3) [M(sal-Rmb)$_2$ (M=Co, Zn). Both the cobalt(II) and zinc(II) complexes assume a tetradedral structure which is preferable to both metal ions. Since this configuration causes little interligand steric hindrance, the ligand retains essentially its most stable form of the free ligand. The stereoselectivity of those complexes to afford *Λ* configuration about the metal ion should be attributed to the intramolecular interligand interaction between the N-substituent and the chelate ring of another ligand of the complex.

Reactions of Leuco Bindschedler's Green with Some *p*-Benzoquinones in Acetone

Yoshihiro OSAWA, Norio NISHIMURA,* and Shunzo YAMAMOTO
Department of Chemistry, Faculty of Science, Okayama University,
Tsushima, Okayama 700
(Received September 10, 1990)

The rate of reaction between Leuco Bindschedler's Green (BGH) and some *p*-benzoquinone derivatives (Q's) in acetone was followed spectrophotometrically by means of the stopped-flow technique. The reaction was found to proceed reversibly. The rate data and the activation parameters for the forward and backward reactions were estimated. The rates were susceptible to the oxidation–reduction potentials of the Q's. The absorption spectra observed at low temperatures indicated that three kinds of intermediates were involved. Radicals formed during the reaction were detected by the ESR method. The results have been discussed in relation to those previously obtained for systems involving Leuco Crystal Violet (LCV) and Leuco Malachite Green (LMG).

Hydride-transfer reactions have been an attractive research subject together with proton-transfer reactions in vivo as well as in vitro. In hydride-transfer reactions, *N*-benzyl-1,4-dihydronicotinamide (BNAH) and related compounds have been regarded as model compounds of dihydronicotinamide coenzymes. Westheimer and co-workers[1,2] suggested that the oxidation–reduction reactions involved direct hydride transfers, and this idea was believed for a long time. However, Steffens and Chipman[3] suggested first that the so-called hydride-transfer reactions involved an intermediate with the character of a charge-transfer (CT) complex. Ohno and Kito,[4] and Fukuzumi and Tanaka[5] demonstrated that a CT complex as an intermediate is really involved in such reaction systems. The oxidations of 9,10-dihydro-10-methylacridine and its derivatives to the corresponding acridinium ions by π-acceptors were investigated by Colter and co-workers.[6,7] They obtained spectroscopic and kinetic evidence for CT complexing between the reactants. The involvement of quantum-mechanical tunneling in the "hydride-transfer" reaction between LCV and chloranil (CA) was advocated by Isaacs and co-workers.[8,9] We have observed the formation of CT complexes in the same system and in the LMG/CA system.[10,11] Thus, the one-step hydride-transfer mechanism is debatable. It was found in this work that the hydrogen atom on the nitrogen in BGH is abstracted in the form of a hydride ion much more easily than the hydrogen atom on the central carbon atom in LCV and LMG. We were interested in knowing how situations would change if LCV and LMG were replaced by BGH. In a preliminary study,[12] we briefly reported the reaction of BGH with tetracyanoethylene and found the reaction proceeded reversibly. The present paper reports an investigation of the reactions of BGH with a series of *p*-benzoquinones.

Experimental

Materials. Reagent-grade BGH manufactured by Dojin Chemicals Ltd. was used as received, since this compound is very difficult to purify in the usual manner; mp 119—120.5 °C. Reagent-grade tetrachloro-*p*-benzoquinone (chloranil, CA), 2,6-dichloro-*p*-benzoquinone (2,6-DCQ), 2,5-dichloro-*p*-benzoquinone (2,5-DCQ), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), *p*-benzoquinone (BQ), and tetramethyl-*p*-benzoquinone (TMQ) were purchased from Tokyo Kasei Kogyo and recrystalized twice from benzene. $BGH^{+\cdot}$ perchlorate (Würster's Blue) was prepared according to the method of Michaelis and Granick;[13] dark purple, mp 147—148 °C. Reagent-grade solvents were dried on Molecular Sieves 4A-1/16, and distilled before use.

Kinetic Measurements. When the acetone solution of BGH was mixed with that of benzoquinones, a characteristic band due to Bindschedler's Green cations (BG^+) appeared at λ_{max}=725 nm. All the runs were performed with excess quinone concentrations, i.e., $[BGH]_0$: $(4—5)\times10^{-5}$ mol dm^{-3}, and $[Quinones]_0$: $(0.5—8)\times10^{-3}$ mol dm^{-3}. Separately-prepared reactant solutions were deaerated by nitrogen gas bubbling and were charged in drive syringes which were thermostatically regulated within ±0.1 °C. The mixing was performed within 1 ms by means of nitrogen gas pressure. After mixing, the change in the absorbance at 725 nm was monitored by using a Unisoku USP-519 spectrophotometer. The runs were repeated 10 to 30 times and curve smoothing was performed by means of an attached computer.

Electronic Spectra at Low Temperatures. A specially designed cryostat with optical windows was set in a Union SM-401 spectrophotometer, and spectra in the visible region at various low temperatures were recorded. In order to prevent the deposition of dew on the windows, dry nitrogen gas was blown onto the windows during the measurements.

ESR Measurements. Reactant solutions of BGH and Q were introduced separately into an H-shaped tube with a side tube (i.d. 1 mm) for ESR measurements. After the solutions were degassed by freezing and thawing under vacuum, the solutions were mixed and transferred into the side tube. A JEOL JES-FE3XG spectrometer equipped with a 100 kHz field modulator and a TE 011 cavity was used for ESR measurements. The temperature in the cavity was controlled by a JEOL variable temperature regulator.

Results

A representative spectrum in the initial stage of reaction between BGH and CA is shown in Fig. 1. The absorption band at λ_{max}=725 nm can be attributed to

a) 17.5°C for 2,6-DCQ, and 18.0°C for 2,5-DCQ.

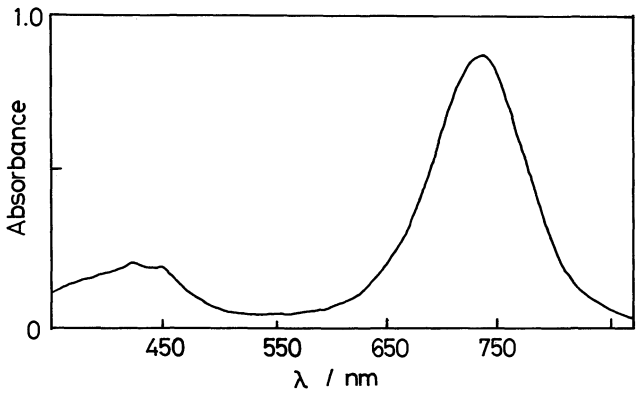

Fig. 1. Electronic spectrum of the BGH/CA system in excess of CA after the initial stage of reaction in acetone at 25°C.

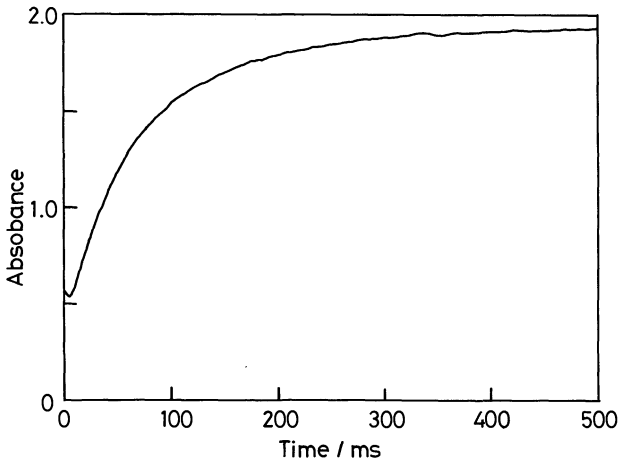

Fig. 2. Initial rise of absorbance at 725 nm as a function of time (20 cycles) in the reaction of BGH (6.92×10^{-5} mol dm^{-3}) with CA (1.53×10^{-3} mol dm^{-3}) at 25°C.

BG^+, and the peculiarly-shaped absorption band in the vicinity of 450 nm is due to semiquinone anion radicals.[10,14] A time-dependent curve in the initial stage of the absorbance at 725 nm after averaging the repeated runs is shown in Fig. 2. After a pseudo-equilibrium had been attained in this time scale, the absorbance at 725 nm increased gradually when the observation time scale was changed by a factor of 10^3. By setting an appropriate time region in the initial stage, the curve was analyzed by the Damping Gauses–Newton method combined with the aid of an attached computer program. The estimated rate data (k_{obsd}) are given in Table 1.

In Fig. 3, the apparent first-order rate constants for the BGH/CA system at various temperatures are plotted as a function of initial CA concentrations. This figure shows that the rate is first-order with respect to CA at each temperature and that the reaction involves a reverse process. The same type of plots were obtained for other quinones.

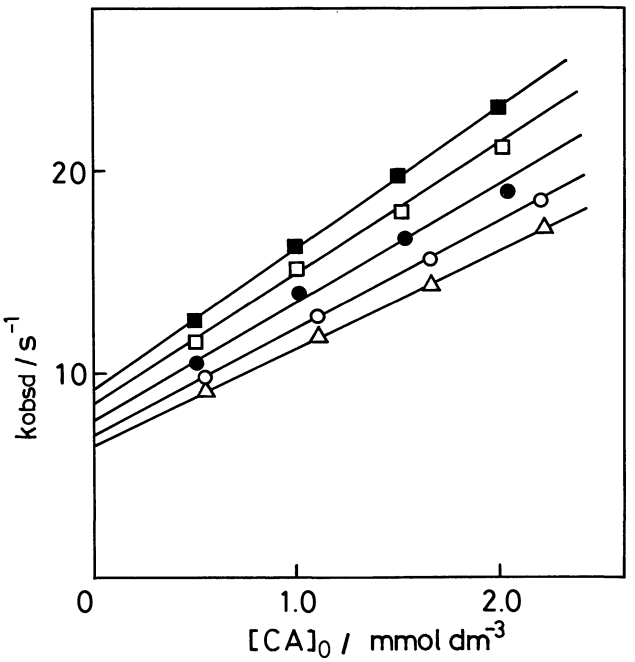

Fig. 3. Plots of k_{obsd} against the initial concentration of CA at temperatures (°C): 13.5 (Δ), 18.5 (○), 25.0 (●), 32.0 (□), and 40.0 (■).

In Fig. 4, the electronic spectra for the BGH/CA system in an EPA solution at various temperatures are shown. For comparison, the change in the electronic spectrum of a mixture of *N*-methyldiphenylamine (MDA) and CA in EPA is shown in Fig. 5. It is noted that the pattern of the spectrum in Fig. 4 and its temperature dependence are very different from those in Fig. 5. The pattern and the band position of the spectrum in Fig. 5 are rather similar to those of the LCV/CA and LMG/CA systems.[10,11]

For the BGH/CA and BGH/DDQ systems, ESR spectra assignable to the corresponding semiquinone anion radicals were observed at room temperature. For both the BGH/2,5-DCQ and BGH/2,6-DCQ systems, a very broad signal appeared at 25 °C. However, when the temperature was lowered below −45 °C, the signal pattern changed to an expected 1 : 2 : 1 triplet.

Discussion

Rate Equations and Reaction Mechanism. From the above results, the rate of BG^+ formation in the initial stage, under the condition $[BGH]_o \ll [Quinones]_o$, can be given by:

$$d[BG^+]/dt = k_{obsd}([BG^+]_e - [BG^+]) \quad (1)$$

where $[BG^+]$ and $[BG^+]_e$ denote the concentrations of BG^+ at time t and at the pseudo-equilibrium, respectively. Fukuzumi and co-workers[15] studied a hydride-transfer reaction between BNAH and the Q's. They found that a CT complex was first formed between BNAH and Q as evidenced by the appearance of a CT complex spectrum

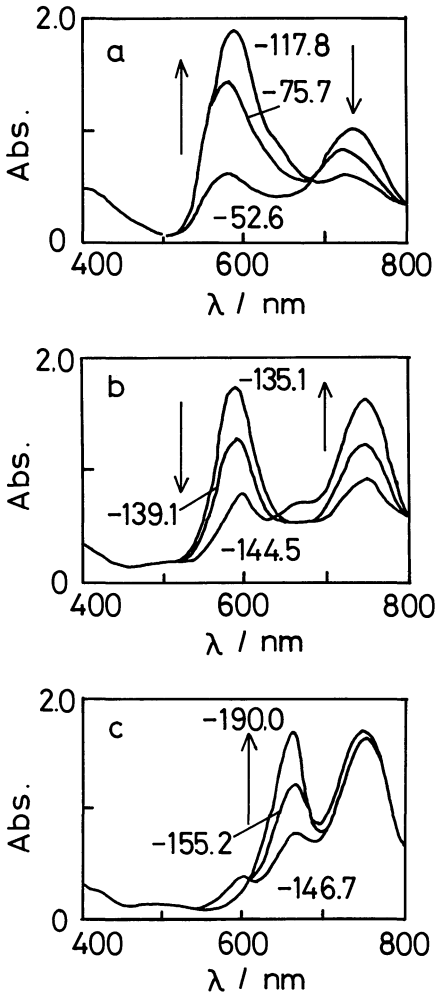

Fig. 4a—c. Spectral change as a function of temperature for the BGH/CA system in EPA. Arrows show the direction of decreasing temperature, and numerical values in the figure denote measurement temperatures in °C; $[BGH]_o$, $[CA]_o \approx 10^{-5}$ mol dm^{-3}.

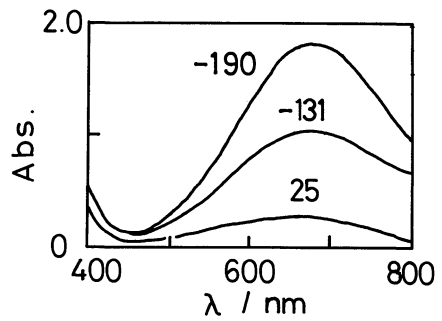

Fig. 5. Temperature dependence of a CT band that appeared in the CA/MDA system. Numerical values in the figure denote measurement temperatures in °C.

in the visible region at room temperature. They proposed that, the CT complex was in rapid equilibrium with the radical ion pair ($BNAH^{+\cdot}Q^{-\cdot}$). Thereafter, irreversible proton transfer takes place to form the radical pair

(BNA$^{\cdot}$ QH$^{\cdot}$). Subsequently, electron transfer yielding BNA^+ and QH^- takes place.

If we accept their proposed mechanism as a whole and take into account the reverse reaction and the gradual increase in BG^+ after the pseudo-equilibrium is reached, a plausible reaction mechanism in harmony with the above empirical equation may be as follows:

$$BGH + Q \underset{}{\overset{K_1}{\rightleftharpoons}} CTC \overset{K_2}{\rightleftharpoons} (BGH^{+\cdot}\ Q^{-\cdot}) \underset{k_b}{\overset{k_f}{\rightleftharpoons}} (BG^{\cdot}\ QH^{\cdot}) \overset{K_3}{\rightleftharpoons} (BG^+\ QH^-)$$

$$(BG^+\ QH^-) + Q \longrightarrow BG^+ + Q^{-\cdot} + QH^{\cdot}$$

$$2QH^{\cdot} \longrightarrow \text{Dimerization},$$

where Q denotes benzoquinones, and parentheses denote cages. Hydride-transfer reactions usually show large kinetic isotope effects (k_H/k_D).[3,6,8,10] Therefore, if the rate-determining step involves a proton transfer and the other steps are in rapid equilibrium in the initial stage, k_{obsd} can be given by:

$$k_{obsd} = k_b/K_3 + K_1K_2k_f[Q]_o \quad (2)$$

From the plots of k_{obsd} against the initial concentration of quinones (Fig. 3), the values of $K_1K_2k_f$ and k_b/K_3 were estimated and are given in Table 2. The activation parameters are given in Table 3. The overall pseudo-equilibrium constant K is given by:

$$K = K_1K_2(k_f/k_b)K_3 \quad (3)$$

By utilizing the kinetic data, K can be calculated. For example, K at 25 °C for the BGH/CA system is 713 dm^3 mol^{-1}. Under the condition $[BGH]_o \ll [CA]_o$, K is given by:

$$K = [BG^+\ QH^-]_e/[BGH]_e[CA] = \frac{A_e/\varepsilon}{([BGH]_o - A_e/\varepsilon)[CA]_o} \quad (4)$$

where A_e denotes the absorbance at 725 nm after the pseudo-equilibrium has been attained, and ε the molar absorptivity at this wavelength. Unfortunately, the ε-value is not known. However, if we assume ε as

74000 $dm^3\ mol^{-1}\ cm^{-1}$, and use the A_e-values obtained for various initial CA concentrations, the average K-value was found to agree well with the one obtained from the kinetic data.

When we compare the kinetic data for the BGH/CA system with those for the LCV/CA and LMG/CA systems, we can notice two distinctive points: the rate is faster in the order of 10^3—10^5 and the activation energy is remarkably smaller (Table 3) than those for the LCV/CA and LMG/CA systems. Secondly, the reaction involves a reversible process in the rate-determining step. Moreover, the electronic spectra which appeared in the visible region are remarkably different from those observed in the LCV/CA and LMG/CA systems.

Substituent Effects. The values of $K_1K_2k_f$ as well as k_b/K_3 decrease in the order DDQ≫CA>2,6-DCQ>2,5-DCQ≫BQ, TMQ (Table 2). In the hydride-transfer reaction of BNAH with the Q's, Fukuzumi et al.[15] found that the rate varies significantly with the redox potentials $E°(Q/Q^{-\cdot})$. In our case, if one-electron transfer takes place prior to the hydrogen transfer (or successive proton and electron transfer), the rate of the forward reaction will also be correlated to $E°(Q/Q^{-\cdot})$. In Fig. 6, the $K_1K_2k_f$ values in logarithmic scale are plotted as a function of $E°$. Since there are no available data for $E°$ in acetone, we used the values of $E°$ in acetonitrile.[16] It can be seen that the plot of $\log K_1K_2k_f$ vs. $E°$ is approximately parallel to that of the BNAH/Q system. This fact suggests that the mechanisms for both systems are similar. It was found that the linear free energy relationship holds well for both the forward and backward reactions, suggesting that these reactions proceed by the single interaction mechanism.[17] However, it is hard to explain the remarkably large negative values of $\Delta S^{\neq}$ for the backward process. We propose the following reason: according to the absolute rate theory, the rate constant is given by:

$$k = (e\,\kappa k_B T/h)e^{\Delta S^{\neq}/R}\cdot e^{-Ea/RT} \quad (5)$$

where κ denotes the transmission coefficient. We usually calculate $\Delta S^{\neq}$ on the assumption of $\kappa=1$. However, if the formation of (BG· QH·) takes place via a triplet transition state, the value of κ must be much smaller than unity due to intersystem crossing. In this case, the assumption of $\kappa=1$ gives rise to an apparent small $\Delta S^{\neq}$ value. The activation energies for the forward and backward processes are similar (Table 3). This means that the heat of reaction is nearly equal to zero. As ion-pair formation reactions from neutral species are generally exothermic, this is another curious point. At present, the cause is not obvious.

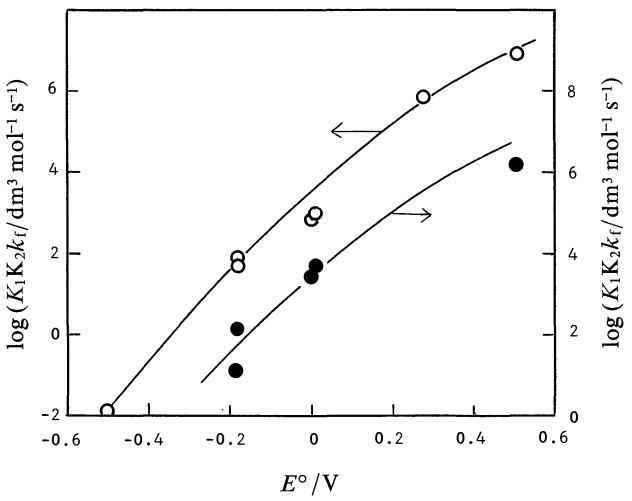

Fig. 6. Correlation between $\log(K_1K_2k_f)$ and the redox potential of p-benzoquinones $E°$; ●: this work, ○: data cited from Ref. 15.

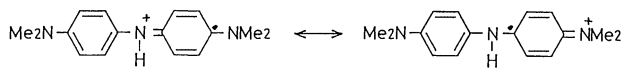
Electronic Spectra at Low Temperatures. The electronic spectra of a mixture of BGH and CA in EPA solution were taken at low temperatures (Fig. 4a—c). In the figure, the band due to the semiquinone radical (Fig. 1) is obscure. This was found to be caused by an instrumental problem, not by the absence of the radical. It is notable that these spectral changes, as shown in Fig. 4, have not been reported so far for similar hydride-transfer systems. Due to experimental limitations, we were forced to start the spectral measurements after the pseudo-equilibrium had been attained. At −52.6 °C, we can see two distinct bands at λ_{max}=730 nm (referred to as band A) and at λ_{max}=590 nm (band B). Since λ_{max} for BG^+ is known to be 725 nm at room temperature, it is obvious that BG^+ is responsible for the band A. A small red shift upon cooling may be due to solvent effects. As the temperature was lowered, the intensity of the band B increased at the expense of the band A (Fig. 4a). This provides direct evidence of the reverse process. At lower temperatures, new bands appeared at λ_{max}=750 nm (band C) and λ_{max}=660 nm (band D) (Fig. 4b, c).

It is very difficult to assign these spectra unambiguously. From the viewpoint of the canonical electronic structures of BG·, it would not be responsible for any of the bands in Fig. 4. On the other hand, the electronic structures of the moiety $BGH^{+\cdot}$ can be described as follows:



Therefore, it is likely that one of these bands may be assigned to $BGH^{+\cdot}$. Foster and Thomson[18] observed the electronic spectrum of the cation radicals of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in the vicinity of 600 nm. Nakayama and Suzuki[19] examined the temperature dependence of the spectra of Würster's cation radicals including $TMPD^{+\cdot}$, and found that at lower temperatures the absorption band of their dimers appears on the longer wavelength side. If these situations are taken into account, the band B could be assigned to $BGH^{+\cdot}$ and the band D to its dimer.

In order to confirm this, $BGH^{+\cdot}ClO_4^-$ was prepared and dissolved in ethanol-rich EPA. The solution was cooled rapidly to −188.5 °C. We observed two distinct bands (λ_{max} at 660 and 750 nm). As the temperature was increased (−155 °C), the intensity of the band at λ_{max}= 660 nm decreased, and at the same time, a shoulder appeared in the vicinity of 600 nm. Above −100 °C, the band at 660 nm and the shoulder disappeared and only the band on the longer wavelength side assignable to BG^+ survived; the process of BG^+ formation from $BGH^{+\cdot}$ is not clear. It is noted that in this system the formation of a CT complex is impossible. Accordingly, the band D observed in the BGH/CA system could be assigned to the dimer of $BGH^{+\cdot}$, and the shoulder to $BGH^{+\cdot}$. Temperature dependence of the intensity of the band B relative to D, and the band positions are somewhat different from those for the BGH/CA system in usual EPA. This is probably due to solvent effects.

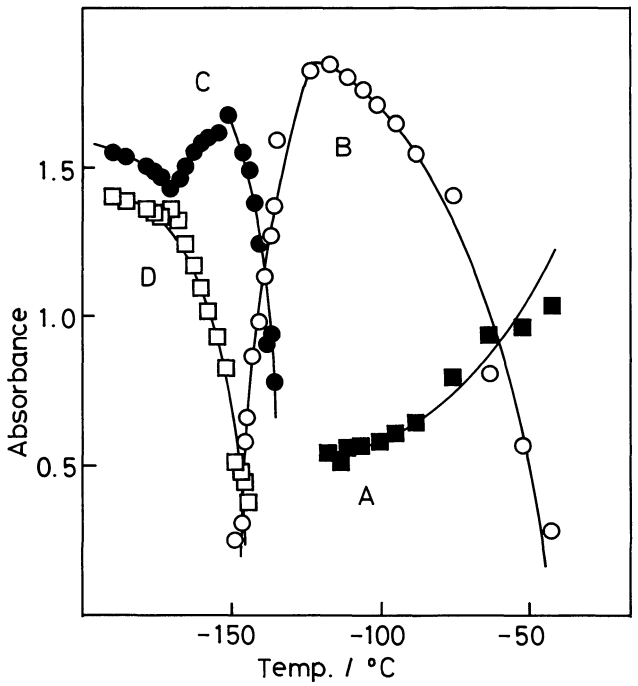


Fig. 7. The change in absorbances at λ_{max}/nm: 730 (band A), 590 (band B), 750 (band C), and 660 (band D) as a function of temperature.

It is recognized that the absorption band due to outer CT complexes between CA and aromatic amines appears in the range of 500—800 nm. For example, the λ_{max}-values are 616 nm for *N*,*N*-dimethylaniline, 660 nm for MDA (Fig. 5), 680 nm for LCV,[10] 670 nm for LMG,[11] and 800 nm for TMPD.[18] In the light of these situations, we can expect the formation of an outer CT complex in the present system, too. Judging from the temperature dependence of the band C, this band could be assigned to an outer CT complex if the assignments of the bands, A, B, and D are correct.

Temperature dependence of the intensities of the above bands is shown in Fig. 7. It was confirmed that the spectral change with temperature took place reversibly. Similar absorption bands and the temperature dependence of their intensities were observed for the BGH/2,5-DCQ system, too. Using the data in Fig. 7, together with the Arrhenius parameters (Table 2), and assuming dimer formation, we constructed an approximate energy diagram as shown in Fig. 8. The heat of formation of the dimer agrees with those reported for similar systems (ca. 35 kJ mol^{-1}).[19] The energy levels of usual outer CT complexes are known to be at most 20 kJ mol^{-1} lower than that of the reactants, while the energy level of the proposed CT complex in this study is too low. Therefore, a different character of CT complex seems to be formed in our system. Indeed, the band C is well-characterized (Fig. 4), while the outer CT band is generally very broad (Fig. 5). Recently, we

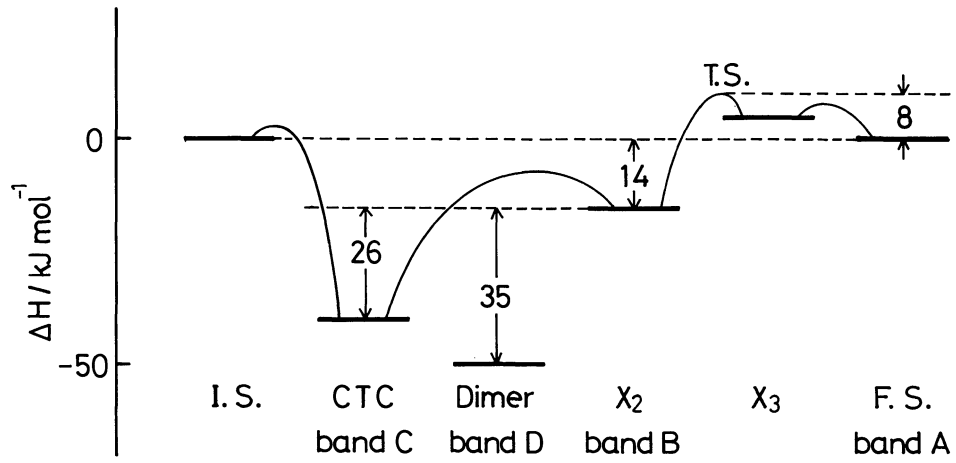

Fig. 8. Approximate energy diagram for the reaction between BGH and CA. X_2 denotes ($BGH^{+\cdot}$ $Q^{-\cdot}$) and X_3 denotes ($BG^{\cdot}QH^{\cdot}$).

reported that a CT complex was formed between TBPE* and aliphatic amines through hydrogen bonding.[20] This CT complex exhibited a well-characterized absorption at ca. λ_{max}=550 nm. It has been accepted that hydrogen bonding involves a CT character.[21,22] Because of the large electronegative nature of nitrogen atom, the formation of such a type of CT complex is likely. In this CT complex, electron transfer will take place easily through hydrogen bonding followed by the forward and backward H-atom (or proton + electron) oscillations. The heat of hydrogen bond formation may be ca. 20 kJ mol^{-1}. If this value is taken into account for the formation of the above type of CT complex, the energy diagram in Fig. 8 may not be so surprising. The well-characterized structure of band C suggests that this CT complex is "tight".

ESR Spectra. For the BGH/CA system, a singlet ESR spectrum with g=2.0058 was obtained in acetone at 25 °C. This can be assigned to the corresponding semiquinone anion radical ($Q^{-\cdot}$).[10] This radical is comparatively stable, but it decays according to the strict first-order kinetics with $k_{decay}=1.29\times10^{-4}$ s^{-1} (25 °C). For the BGH/DDQ system, a quintet ESR spectrum with intensity ratios of 1 : 2 : 3 : 2 : 1 was obtained. The signal is assignable to the corresponding semiquinone anion radicals.[23] Spin trapping is known to be a powerful method for detecting unstable neutral radicals. 2-Methyl-2-nitrosopropane (MNP) is known as a radical trap. In order to obtain further information for radicals occurring in our systems, we added MNP to the BGH/DDQ system. Figure 9a is the resulting ESR signal. We can easily see that the signal is composed of three kinds of radical species. A quintet near the center is obviously due to the semi-quinone. A triplet with a hyperfine coupling constant (hfcc) of 1.56 mT and g=2.0057 can be ascribed to a spin adduct.

Lai and Colter[23] reported that *N*-methyl-acridanyl radical was trapped by MNP in the oxidation reaction of *N*-methylacridan by 2,3-dicyano-1,4-benzoquinone. Since our system is similar to theirs, the trapped radical may be BG$^{\cdot}$ rather than QH$^{\cdot}$.

The remaining wavy signal spreading over a wide range of the magnetic field (>3 mT) is very weak, but shows a remarkably small hfcc. The g-value was estimated to be about 2.003. The authentic ESR signal of $BGH^{+\cdot}$ obtained by dissolving $BGH^{+\cdot}$ perchlorate in acetone at 25 °C is shown in Fig. 9b. The g-value was calculated to be 2.0030. If these situations and the proposed mechanism are taken into account, the wavy weak signal could be attributed to $BGH^{+\cdot}$. Kolodny and Bowers[24] reported that when acetonitrile solutions of *p*-phenylenediamine (PPD) and DDQ were mixed in a flow system, superimposed ESR signals attributable to $PPD^{+\cdot}$ and $DDQ^{-\cdot}$ were obtained. They found that the intensity of the $PPD^{+\cdot}$ signal was much weaker and decayed rapidly. Although the reason is not clear, the weak signal in our case is in line with their observation.

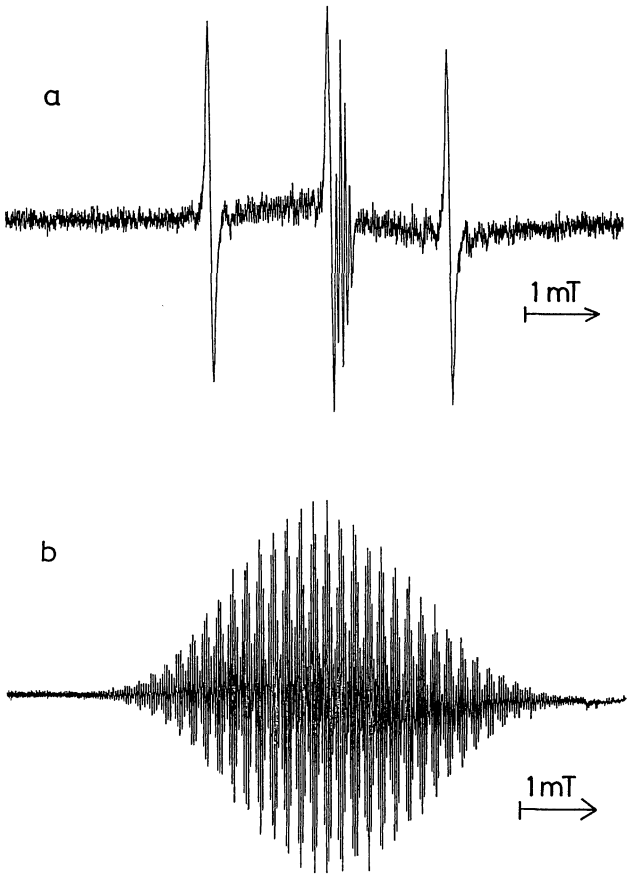

Fig. 9. (a) ESR spectra for the BGH/DDQ system in the presence of MNP in acetonitrile, $[BGH]_o$=1.08, $[DDQ]_o$=0.27, $[MNP]_o$=12.9 mmol dm^{-3}. (b) ESR signal of $BGH^{+\cdot}$.

The above findings, together with the spectrophotometric observations, provide direct evidence for the existence of the intermediates, assumed to be formed during the stepwise pathway for the present reaction systems.

* 2,6-Dibromo-4-[3,5-dibromo-4-hydroxyphenyl)(2-ethoxycarbonylphenyl)methylene]-2,5-cyclohexadien-1-one.

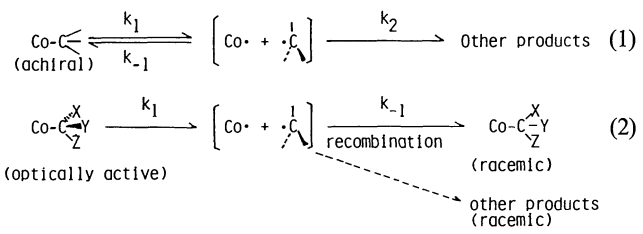
Preparation of Optically Active [1-(Methoxycarbonyl)ethyl]cobaloximes Coordinated with Various Axial Ligands and Their Photoracemization. Remarkable Steric Effect of Axial Ligand on the Co-C Bond Homolysis[1)]

Yoshiaki OHGO,* Hideki WADA, Chiyako OHTERA, Makoto IKARASHI, Shoe BABA, and Seiji TAKEUCHI
Niigata College of Pharmacy, Kamishin'ei-cho, Niigata 950-21
(Received November 28, 1990)

Optically active [1-(methoxycarbonyl)ethyl]cobaloximes coordinated with various axial bases were prepared and their photoracemization rates were measured in a solution state. It was found that although the electronic effect of the axial ligand was negligible on the rate of photochemical Co–C bond homolysis, the steric bulkines accelerated the rate remarkably. These results had a similar tendency to those observed in a previously reported reaction wtih 1-cyanoethyl cobaloximes, though the degree of rate enhancement due to the steric bulkiness of the axial ligand was extremely enlarged. The reason is also discussed.

Extensive investigations concerning the reactions of alkyl cobalt complexes have been carried out by spectrophotometric methods using achiral complexes. However, these methods include inherent possibilities for underestimating the rate of Co–C bond homolysis (k_1) (Eq. 1), when accompanied by a rapid backward reaction (recombination of alkyl radical and Co(II) species).



On the other hand, a chiroptical measurement using optically active alkylmetal complexes provides a more simple and precise evaluation of the forward rate (k_1). Since the alkyl radicals formed by bond homolysis are either planar or a rapidly inverting pyramid, the recombination of these species with Co(II) and other subsequent reactions (such as radical coupling and beta-elimination) should give substantially racemic or achiral products (Eq. 2). Thus, the Co–C bond homolysis rate constant of alkyl cobalt complexes (k_1) can be directly evaluated from the optical rotational change. We have shown that optically active alkylcobalt complexes are useful for the elucidation of both solution-state[2-4)] and solid-state[5-13)] reactions involving cobalt–carbon bond formation and cleavage, especially for the case of a system accompanied by an extremely rapid backward reaction.

In a previous paper[2a)] we reported on the photoracemization of 1-cyanoethyl cobaloxime complexes. Here, we wish to describe the preparation of new optically active [1-(methoxycarbonyl)ethyl]bis(dimethylglyoximato)cobalt(III) complexes which have chirality at the carbon bound directly to the cobalt atom; we also describe the effect of the axial ligand on the rate of photochemical Co–C bond homolysis.

Results and Discussion

Preparation of Optically Active [1-(Methoxycarbonyl)ethyl]cobaloxime Complexes. Bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl][(*S*)-1-phenylethylamine]cobalt(III), (***S,S***)-**1**, was prepared according to almost the same procedure as that described in a previous paper in which the preparation of the enantiomer, (***R,R***)-**1**, was reported.[2b)] Five recrystallizations gave a constant optical rotation ($[\alpha]_{589}$ −205.6, $[\alpha]_{578}$ −226.7, $[\alpha]_{546}$ −253.3(*c* 0.180, chloroform)). 4-Substituted pyridine complexes of bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl]cobalt(III) were easily prepared by a ligand exchange of (*S*)-1-phenylethylamine [(*S*)-1-PEA] with the corresponding pyridine derivatives in methanol in the presence of dilute hydrochloric acid. Tributylphosphine, ethyldiphenylphosphine, and diethylphenylphosphine complexes of bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl]cobalt(III) were also prepared by an axial ligand exchange of (***R,R***)-**1** with the corresponding phosphines in methanol in the presence of dilute hydrochloric acid. The newly prepared complexes were characterized by IR, NMR, and elemental analyses (see experimental part); the structures are shown in Fig. 1. Triphenylphosphine and tricyclohexylphosphine-coordinated complexes can not be isolated in their pure form, probably due to partial ligand dissociation. These complexes were, accordingly, prepared in situ by an addition of the corresponding axial ligand to a solution of aqua complex:

$$(CH_3CHCOOCH_3)Co(Hdmg)_2(H_2O)+B \longrightarrow (CH_3CHCOOCH_3)Co(Hdmg)_2B+H_2O.$$

The addition of 50-fold free phosphine was found to be sufficient to complete the ligand-exchange reaction, even in the case of the most bulky tricyclohexylphosphine (Fig. 2). The (*RS*)-1-phenylethylamine-coordinated complex was also prepared in situ by the addition of

(*RS*)-1-phenylethylamine to a solution of the aqua complex. The structures of the substrates prepared in situ are also shown (bracketed) in Fig. 1.

Photoracemization. The optical rotation of a chloroform solution of optically active 1-(methoxycarbonyl)ethyl cobaloxime complexes which were coordinated with various axial ligands(shown in Fig. 1) gradually decreased due to Co–C bond homolysis upon visible-light irradiation. Kinetic studies were performed by measuring the decrease in the optical rotation of a 3.79×10^{-3} mol dm^{-3} chloroform solution of each complex (containing a 100-fold excess of a corresponding ligand, which is sufficient to prevent ligand dissociation) under either a nitrogen or argon atmosphere at room temperature (23±2 °C). The first-order rate plots ($\ln\alpha$ vs. time) exhibited excellent linearity and yielded the photoracemization rate constants (summarized in Table 1). In the cases of triphenylphosphine and tricyclohexylphosphine-coordinated complexes, racemization occurred even in the dark. The rates were therefore corrected for the corresponding thermal racemization under the same conditions. The reaction rate of a series of amine-coordinated complexes remained almost unaltered, in spite of the rather wide range of pK_a change. On the other hand, the rate in a series of phosphine-coordinated complexes (Entry 6—10) changed remarkably, and although the order was independent of the pK_a value of the axial ligand, the rates increased with increasing cone angle.[14a,b] A similar tendency was previously observed in the photoracemization of a series of 1-cyanoethyl cobaloximes; this tendency was remarkably enlarged in the present series (Fig. 3). The acute dihedral angle (θ) between the planes of the two dimethylglyoximato groups, the displacement (d) of the Co atom toward the axial ligand from the mean plane (composed of four nitrogen atoms in the equatorial ligand), and the Co–P bond length of a series of 1-cyanoethyl cobaloximes[2a,10,11] have been shown to increase with an increase in the cone angle of the phosphine ligand, in order to avoid repulsion due to the short contacts between the substituent of phosphine ligand and dimethylglyoxime

a) 1-PEA: 1-Phenylethylamine; the pK_a of 1-phenylethylamine was not reported, but is expected to be about 9—10 from those of $PhCH_2NH_2$ (9.35) and $PhC(Me)_2NH_2$ (10.27). b) Experimental cone angle (see Ref. 14b). c) Tolman's cone angle (see Ref. 14a). d) The rate constants are corrected for the thermal racemization at 23°C under the same conditions: the rate constants in parenthesis are net observed values in which the contribution from the thermal racemization is involved. e) See Ref. 19 for those of pyridine derivative, and Ref. 20 for phosphines.

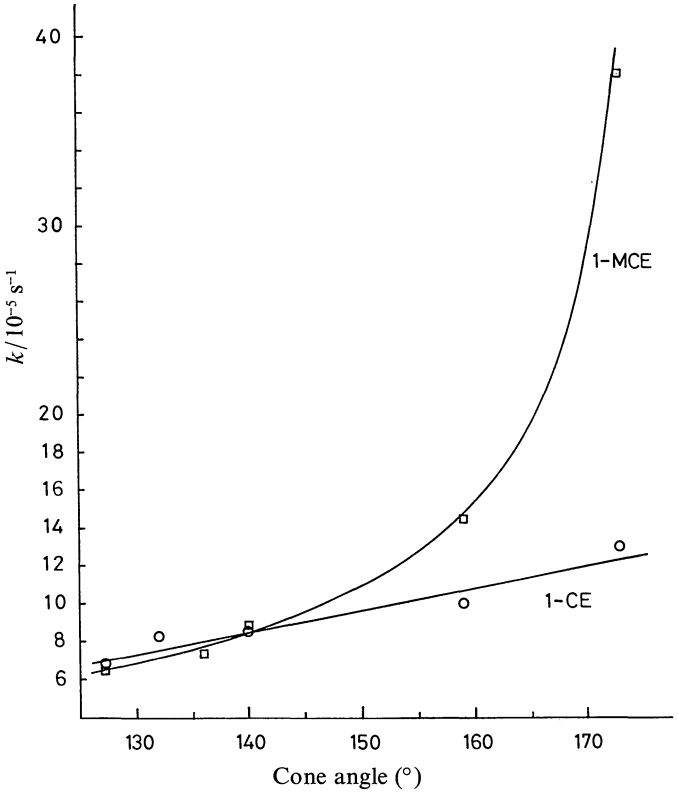

Fig. 3. The correlation between racemization rates of 1-(methoxycarbonyl)ethyl cobaloximes (1-MCE) and the cone angles of the coordinated phosphines, in comparison with that of 1-cyanoethyl cobaloximes (1-CE).

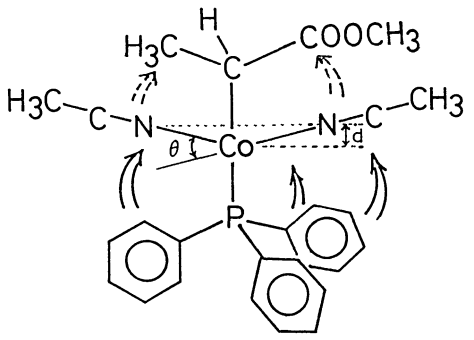

Fig. 4. Repulsive interaction in the phosphine-coordinated cobaloximes.

moiety. Although we do not have X-ray crystallographic data for a series of 1-(methoxycarbonyl)ethyl cobaloximes, a similar situation may be expected to occur for the series as well (Fig. 4). Since the Co–C bond lengths in 1-(methoxycarbonyl)ethyl cobaloximes[12,13,17] are not so much lengthened, compared with those in 1-cyanoethyl derivatives,[2a,7,15,16] and the bond lengths are almost unaltered with a change in the axial phosphine ligand,[2a,10,11] a steric repulsion between the larger alkyl (1-(methoxycarbonyl)ethyl) and the in-plane dimethylglyoximato ligand are much more serious than that between 1-cyanoethyl group and the in-plane ligands. Consequently, the Co–C bonds in 1-(methoxycarbonyl)ethyl cobaloximes are more highly strained than those in 1-cyanoethyl cobaloximes with increasing bulkiness of the axial ligand, being more susceptible to photochemical Co–C bond homolysis. In conclusion, it follows that the electronic effect of the axial ligand is negligible and that the steric effect is overwhelmingly dominant in determining the rate of photochemical Co–C bond homolysis in the solution state: the steric bulkiness of both the axial base and the axial alkyl group accelerates the rate (k_1) both remarkably and cooperatively.

Experimental

The IR spectra were recorded on a JASCO A-3 spectrometer. The NMR spectra were obtained on a JEOL FX-200 spectrometer, using TMS as the internal standard. The optical rotations were measured on a Perkin–Elmer 241 polarimeter.

Photoracemization. All of the operations, except for photoreactions, were carried out in the dark. Each sample (3.79 mmol dm^{-3}) and 100-fold excess of the corresponding axial ligand were dissolved in degassed chloroform under an Ar atmosphere. In the cases of Entries 5, 9 and 10, 3.79 mmol dm^{-3} of (*R*)-aqua[1-(methoxycarbonyl)ethyl]cobaloxime and 100 fold of (*RS*)-1-phenylethylamine, triphenylphosphine or tricyclohexylphosphine were dissolved in degassed chloroform under an Ar atmosphere. Each solution was transferred to a glass (Pyrex) cell in order to measure the optical rotation. The cell was placed at a distance of ca.3.0 m from the light source [four 40 W fluorecent lamps "white" (Matsushita Electric Ind. Co.)], at that distance, the flux density was 0.009 mW cm^{-2}. The optical rotation, which gradually decreased upon irradiation, was measured at regular time intervals.

Materials. Bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl][(*S*)-1-phenylethylamine]cobalt(III) [(*S,S*)-1] was prepared by almost the same procedure as the enantiomer, except for using (*S*)-1-phenylethylamine (Aldrich, $[\alpha]_D$ −39) as the axial ligand. Five recrystallizations from methanol–water gave a constant optical rotation: $[\alpha]_{589}$ −205.6, $[\alpha]_{578}$ −226.7, $[\alpha]_{546}$ −253.3 (*c* 0.180, chloroform). Found: C, 48.40; H, 6.46; N, 13.93%. Calcd for $C_{20}H_{32}N_5O_6Co$: C, 48.29; H, 6.48; N, 14.08%.

Bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl](pyridine)cobalt(III). To a methanol (10 cm^3) solution of 1 g of **(*S,S*)-1** was added 2 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.32 cm^3 of pyridine with stirring. After standing for 15—20 min at room temperature, the reaction mixture was extracted with dichloromethane and washed with water. The dichloromethane layer was dried over anhydrous sodium sulfate, and concentrated in vacuo to give 0.72 g of a crude product (79%). The crude product (0.4 g) was recrystallized from methanol (4.5 cm^3) and water (5.5 cm^3) to give leaflets (0.32 g), $[\alpha]_{589}$ −172.2, $[\alpha]_{578}$ −189.3, $[\alpha]_{546}$ −227.8 (*c* 0.170, chloroform). The IR and NMR spectra were identical with those of the (*R*)-isomer.

(4-Cyanopyridine)bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl]cobalt(III). To a methanol (10 cm^3) solution of 1 g of **(*S,S*)-1** was added 2 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.48 g of 4-cyanopyridine with stirring. After 5 min small amounts of crystals were deposited. After 20 min the reaction mixture was extracted with dichloromethane and washed with water. The dichloromethane layer was dried over anhydrous sodium sulfate and concentrated in vacuo to give 0.76 g (79%). The crude product (0.4 g) was recrystallized from methanol (7 cm^3) and water (9 cm^3) to give dark-red crystals (0.31 g). ^{1}H NMR ($CDCl_3$) δ=0.375 (d, 3H, $C\underline{H}_3CH(Co)COOCH_3$), 2.199 and 2.216 ($CH_3$ of dmgH, in the same region the signal of $CH_3C\underline{H}(Co)COOCH_3$ is overlapped), 3.487 (s, 3H, $COOCH_3$), 7.54 (d, 2H, cyanopyridine), 8.76 (d, 2H, cyanopyridine). $[\alpha]_{589}$ −150.6, $[\alpha]_{578}$ −165.9, $[\alpha]_{546}$ −194.5 (*c* 0.132, chloroform). Found: C, 45.08; H, 5.22; N, 17.46%. Calcd for $C_{18}H_{25}N_6O_6Co$: C, 45.01; H, 5.25; N, 17.50%.

Bis(dimethylglyoximato)[(*S*)-1-(methoxycarbonyl)ethyl](4-methylpyridine)cobalt(III). To a methanol (10 cm^3) solution of 1 g of **(*S,S*)-1** was added 2 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.36 cm^3 of 4-methylpyridine with stirring. After 7 min the crystals began to deposit (0.2 g). After standing for about 20 min at room temperature the reaction mixture was extracted with dichloromethane and washed with water. The dichloromethane layer was dried over anhydrous sodium sulfate, and concentrated in vacuo to give 0.7 g of a crude product. The combined yield was 0.9 g (95%). The crude product (0.4 g) was recrystallized from methanol (18 cm^3) and water (22 cm^3) to give plates (0.28 g). ^{1}H NMR ($CDCl_3$) δ=0.404 (d, 3H, $C\underline{H}_3CH(Co)COOCH_3$), 2.190 and 2.207 ($CH_3$ of dmgH, and in the same region the signal of $CH_3C\underline{H}(Co)COOCH_3$ is overlapped), 2.317 (s, 3H, CH_3 of 4-methylpyridine), 3.484 (s, 3H, $COOCH_3$), 7.06 (d, 2H, arom-H of 4-methylpyridine), 8.32 (d, 2H, arom-H of 4-methylpyridine). $[\alpha]_{589}$ −152.9, $[\alpha]_{578}$ −171.2, $[\alpha]_{546}$ −211.8 (*c* 0.170, chloroform). Found: C, 45.58; H, 5.93; N, 14.63%. Calcd for $C_{18}H_{28}N_5O_6Co$: C, 46.06; H, 6.01; N, 14.92%.

(Tributylphosphine)bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl]cobalt(III). To a methanol (13 cm^3) solution of 1 g of **(*R,R*)-1** ($[\alpha]_{578}$ +223.0, *c* 0.145, chloroform) was added 1.5 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.5 cm^3 of tributylphosphine with stirring. The reaction was monitored by TLC. After completion of a ligand exchange, 9 cm^3 of water was added to the reaction mixture. The solution was left standing overnight in a refrigerator. Crude crystals (0.43 g) were deposited. Another crop of crystals (0.11 g) was obtained from the filtrate. The combined yield was 0.54 g (46%). The crude product was recrystallized twice from methanol–water (2/1) to give light-yellow crystals. ^{1}H NMR ($CDCl_3$) δ=0.560 (t, 3H, $C\underline{H}_3CH(Co)COOCH_3$), 0.884 (t, 9H, 3×$CH_3$ of Bu_3P), 1.1—1.4 (m, 18H, methylene of Bu_3P), 1.649 (s, 2H, 2×OH of dmgH). $[\alpha]_{589}$ +143.1, $[\alpha]_{578}$ +156.6, $[\alpha]_{546}$ +207.1 (*c* 0.139, chloroform). Found: C, 49.62; H, 8.75; N, 9.66%. Calcd for $C_{24}H_{48}N_4O_6PCo$: C, 49.82; H, 8.36; N, 9.68%.

(Ethyldiphenylphosphine)bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl]cobalt(III). To a methanol (19 cm^3) solution of 2 g of **(*R,R*)-1** ($[\alpha]_{578}$ +212.6, *c* 0.180, chloroform) was added 3 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.9 cm^3 of ethyldiphenylphosphine with stirring. The reaction was monitored by TLC. After completion of a ligand exchange, water (14.5 cm^3) was added to the reaction mixture. The solution was left standing overnight in a refrigerator. Crude crystals (1.92 g, 81% yield) deposited, which was recrystallized twice from methanol–water (10/8—10/9) to give dark-red crystals. ^{1}H NMR ($CDCl_3$) δ=0.502 (t, 3H, $C\underline{H}_3CH(Co)COOCH_3$), 0.805 (quint, methyl of $EtPh_2P$), 1.947, 1.962, 1.972, 1.986 (12H, methyl of dmgH), 2.094 (quint, 1H, $CH_3C\underline{H}(Co)COOCH_3$), 2.31 (m, 2H, methylene of $EtPh_2P$), 3.405 (s, 3H, $COOCH_3$), 7.38 (m, 10H, Ph). $[\alpha]_{589}$ +153.4, $[\alpha]_{578}$ +167.5, $[\alpha]_{546}$ +218.9 (*c* 0.121, chloroform). Found: C, 52.84; H, 6.32; N, 9.49%. Calcd for $C_{26}H_{36}N_4O_6PCo$: C, 52.89; H, 6.15; N, 9.49%.

(Diethylphenylphosphine)bis(dimethylglyoximato)[(*R*)-1-(methoxycarbonyl)ethyl]cobalt(III). To a methanol (15 cm^3) solution of 1.6 g of **(*R,R*)-1** ($[\alpha]_{578}$ +212.6, *c* 0.180, chloroform) was added 3 cm^3 of 2 mol dm^{-3} hydrochloric acid and 0.701 cm^3 of diethylphenylphosphine with stirring. The reaction was monitored by TLC. After completion of a ligand exchange, water (4 cm^3) was added to the reaction mixture. The solution

was left standing overnight in a refrigerator. Crystals (0.48 g) deposited. ^{1}H NMR ($CDCl_3$) δ=0.556 (t, 3H, $C\underline{H}_3CH(Co)COOCH_3$), 0.935 (quint, 6H, $(C\underline{H}_3CH_2)_2P$), 1.947, 1.962, 1.972, 1.986 (12H, CH_3 of dmgH), 1.9—2.2 (m, signals of $(CH_3C\underline{H}_2)_2PhP$ and $CH_3C\underline{H}(Co)COOCH_3$ were overlapped in this region), 3.418 (s, 3H, $COOCH_3$), 7.04 (m, 2H, arom), 7.36 (m, 3H, arom). $[\alpha]_{589}$ +168.0, $[\alpha]_{578}$ +184.1, $[\alpha]_{546}$ +247.3 (*c* 0.260, chloroform). Found: C, 48.52; H, 6.95; N, 10.31%. Calcd for $C_{22}H_{36}N_4O_6PCo$: C, 48.71; H, 6.69; N, 10.33%. Another crop of crystals (0.63 g) was obtained from the filtrate. The combined yield was 1.11 g (64%).

Selective Formation of α-Cleavage Cycloadduct of Oxirane with Heterocumulene Promoted by High-Coordinated Trialkyltin Complexes

Katsunori YANO, Nobuyoshi AMISHIRO, Akio BABA,* and Haruo MATSUDA
Department of Applied Chemistry, Faculty of Engineering, Osaka University,
2-1 Yamada-Oka, Suita, Osaka 565
(Received March 14, 1991)

In the reaction of monosubstituted oxiranes and heterocumulenes, trialkyltin iodides coordinated by phosphine oxides effectively catalyzed the formation of heterocycles via cleavage at the substituted site in the oxirane ring, while other types of organotin complexes or noncomplexed organotin iodides promoted selective cleavage at the opposite site. A mechanistic investigation demonstrated that the coordination of phosphine oxide promotes the reverse reaction of the oxirane-ring cleavage leading to the predominant formation of α-cleavage cycloadducts.

Although the cycloaddition of monosubstituted oxiranes with heterocumulenes has been a useful method for the synthesis of five-membered heterocycles,[1-6] most reactions were reported to proceed via the cleavage of oxiranes at their nonsubstituted site (β-cleavage).[7,8] The change of the regioselectivity of oxirane-ring cleavage from β-cleavage to α-cleavage (cleavage at the substituted site) is a simple and useful tool to increase the scope of cycloaddition of oxiranes with heterocumulenes. Although many regioselective cleavages were reported in the reaction of oxiranes with nucleophiles, the effective change in cycloaddition reactions with nucleophiles has rarely been reported.[9,10] We recently reported that tetraphenylstibonium iodide was a versatile catalyst for the selective α-cleavage cycloaddition of general monosubstituted oxiranes.[11] However, the activity of this catalyst is highly dependent on the substrates used; for example, 1,2-epoxy-3-chloropropane and sulfur-containing heterocumulenes were not reactive at all. On the other hand, although some organotin halide complexes were briefly reported to catalyze β-cleavage cycloaddition, their activity and structures vary in accordance with the combination of tin halides with ligands.[12-19] These results and the high affinity of tin for sulfur compounds[20-24] prompted us to investigate a selective α-cleavage cycloaddition of oxiranes to heterocumulenes including isothiocyanates by means of complexation of organotin iodides.[25]

In this paper, we wish to report the regio-controlled cycloaddition of monosubstituted oxiranes with heterocumulenes such as isocyanates, carbodiimides and isothiocyanates. The direction of oxirane-ring cleavage is strongly dependent on the complexation mode. Trialkyltin iodides coordinated by phosphine oxides promoted α-cleavage cycloaddition, yielding 3,4-disubstituted five-membered heterocycles. On the other hand, the complex of Bu_2SnI_2 and noncomplexed organotin iodide resulted in a selective β-cleavage cycloaddition. A plausible reaction path is explainable in terms of an equilibrium in the oxirane cleavage step. The effect of complexation was demonstrated by using an intermediary adduct, while no such adduct could be detected in the Ph_4SbI catalyst system though a similar reaction path has been proposed.[26]

Results and Discussion

Cycloaddition with Isocyanates and Carbodiimides. Table 1 lists the results of cycloadditions of monosubstituted oxiranes with carbodiimides or isocyanates, noncomplexed Bu_3SnI catalyzed the selective β-cleavage addition (Entry 1). For α-cleavage addition, the addition of bases was indispensable, and the complexes

investigated were the combination of tributyltin iodide and phosphine oxides such as tributylphosphine oxide and hexamethylphosphoric triamide (HMPA). These complexes predominantly gave 3,4-disubstituted oxazolidines **1** which have been obtained in small amounts by the action of conventional catalysts such as Lewis bases (triethylamine[27] and sodium ethoxide[10]), -acids ($AlCl_3$[10] and LiCl[28]) and tetraalkylammonium halides.[29,30] Moreover, the use of excess amounts of phosphine oxides gave a higher selectivity of **1** (91%), although a longer reaction time was required (Entry 9). This problem was overcome by the use of Me_3SnI (which is more active due to its high acidity) instead of Bu_3SnI (89% selectivity, Entry 10). However, the α-cleavage ability enhanced by the addition of bases, could not be explained in terms of Lewis acidity since a stronger Lewis acid, noncomplexed Bu_3SnI, is considered to cleave an oxirane ring more easily at the substituted site.[10] The formation of **1** in the case of (chloromethyl)oxirane (Entry 14) is particularly noteworthy since even the versatile catalyst Ph_4SbI could not produce it at all.

The above results strongly suggest that the complexation mode and the stability of the resulting complexes are responsible for the regio-control of oxazolidine formation. It was reported that phosphine oxides coordinate to tributyltin iodide to form five-coordinated complexes, while they form six-coordinated complexes with dibutyltin diiodide.[31-34] It is interesting that the former showed the opposite regioselectivity of the latter. The stability of the complexes also seems to be important for α-cleavage cycloaddition, since if the complexes dissociate to the original tributyltin iodide and ligands, the resulting free tributyltin iodide would promote the β-cleavage of oxiranes. Tributylphosphine oxide and HMPA are superior to either tributylphospine or triethylamine due to the higher coordination ability toward tin atoms.[35] Moreover, excess amounts of phosphine oxides disturb the dissociation of complexes, although the interaction between oxiranes and tin complexes would be weakened to reduce reactivity.

The addition of isocyanates to oxiranes was less selective than carbodiimides and suffered from the requirement of an equimolar amount of tributyltin iodide (Entries 17—19). Isocyanates perhaps were so active that catalytic control could not be enhanced.

Cycloaddition of Oxirane with Isothiocyanate. The lower electrophilicity and high affinity for tin atoms prompted us to use isothiocyanates instead of carbodiimides in the cycloaddition reactions. Results are shown in Table 2. The catalyst, an Me_3SnI–HMPA system, effected a regioselective cycloaddition to give 4-substituted 2-imino-1,3-oxathiolane **3** and 3,4-disubstituted 1,3-oxazolidine-2-thione **4**. This result was very interesting since other organotin halide complexes gave β-cleavage cycloadducts, as previously reported.[7] Moreover, a large excess of HMPA was not required as was the case with the carbodiimides.

The fact that no consumption of **3** was observed under

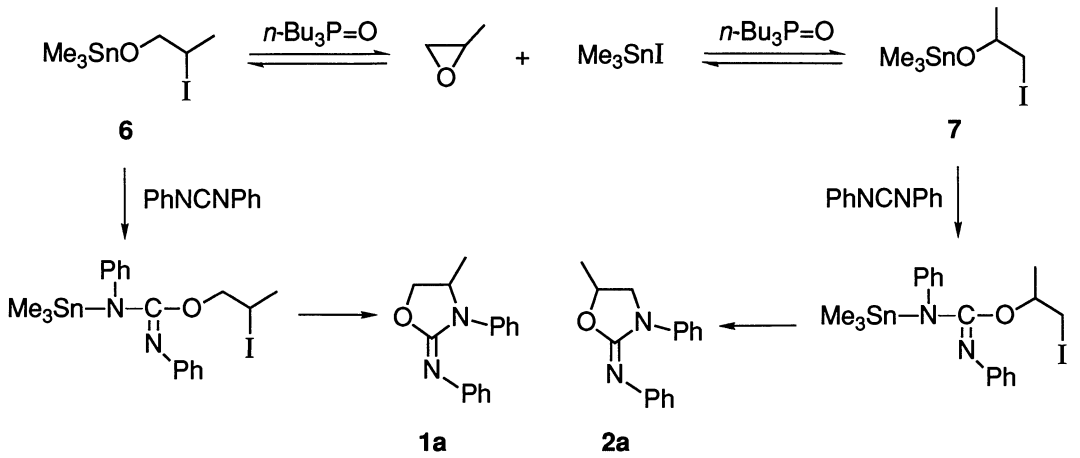
the same conditions as those used for the cycloaddition showed that there was no rearrangement of **3** to **4**.

In this type of cycloaddition, a desulfurization has often been reported,[7] which is assumed to be caused by the addition of oxirane to **3**, producing oxazolidinones **5** as depicted in Scheme 3. Consequently, the 3,5-disubstituted oxazolidinones **5** would probably not be produced via a β-cleavage of the oxirane ring. This type of rearrangement was confirmed as follows. Strong Lewis acids such as $AlCl_3$ readily caused this transformation in an 86% yield, while no oxazolidinone formation was promoted by the Me_3SnI complex. This result may be ascribed to the low acidity of Me_3SnI coordinated by HMPA. Although methyl isothiocyanate gave **5** in a 51% yield, this side reaction was observed only minimally with the addition of phenyl isothiocyanate.

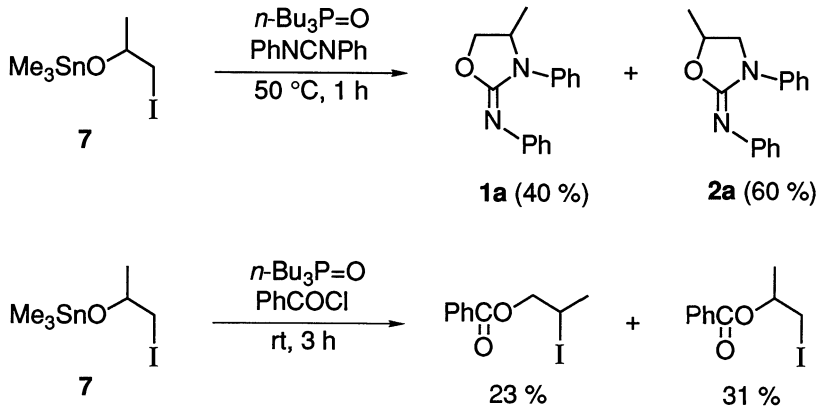
Reaction Mechanism. The reaction path way to 3,4- and 3,5-disubstituted five-membered heterocycles is illustrated in Scheme 4 and is exemplified by the addition of methyloxirane to diphenylcarbodiimide.

The first step, cleavage of the oxirane ring, appears to be a key step for regio-control of this addition. The cleavage of methyloxirane by trimethyltin iodide (Me_3SnI) in the presence of $Bu_3P{=}O$ proceeded readily at room temperature. However, the identification of the resulting adducts and the ratio of **6** and **7** could not be determined by NMR, though the predominant formation of **7** was indicated. This result suggested that the predominant formation of the α-cleavage adduct was not due to the selective α-cleavage of oxiranes at the first step. On the other hand, in the absence of $Bu_3P{=}O$, the addition of Me_3SnI to methyloxirane was exothermic and resulted in the quantitative formation of a distillable trimethyltin 2-iodopropoxide, and the resulting propoxide was added to diphenylcarbodiimide, forming **2a** quantitatively when reacted at 50 °C for 1 h. This selective formation of **2a** indicates that methyloxirane would be cleaved at the β-site to give **7**. On the other hand, surprisingly, in the presence of $Bu_3P{=}O$, this propoxide **7** gave **1a** in a 40% yield together with **2a** (60%) as shown in Scheme 5. This result seemed to suppose the transformation of the 3,5-disubstituted product by the complex $Bu_3P{=}O$ and Me_3SnI, but this idea was proved false by the fact that no consumption of **2a** by the complex was observed even under far more drastic conditions (80 °C, 3 h). A similar result was observed in the reaction with benzoyl chloride (Scheme 5).

Next, the transformation of 2-iodoisopropoxide **7** to 2-iodoisopropoxide **6** will be considered. The isolation of **6** from the mixture of **7** and $Bu_3P{=}O$ was attempted. The distillation of the adduct, however, was failed, and methyloxirane was regenerated in a 78% yield. The methyloxirane was thought to be generated from **7** by the



Scheme 4.



Scheme 5.

action of $Bu_3P{=}O$ during distillation. This result strongly suggested that facile equilibrium between **7** and the starting substrates was promoted by $Bu_3P{=}O$. Moreover, although the oxirane ring is subject to cleavage at the β-site even in the presence of $Bu_3P{=}O$, the participation of **6** is apparently plausible from the results shown in Scheme 5 in spite of the lack of visual evidence such as NMR spectra.

On the basis of the above results, the reaction mechanism for the predominant formation of 3,4-disubstituted cycloadducts can be explainable in terms of the equilibrium of the addition of oxirane and Me_3SnI as shown in Scheme 4. At first, the cleavage of oxirane results in the formation of **6** and **7**. Diphenylcarbodiimide adds electrophilically to both tin iodoalkoxides, where the alkoxide **6** would preferentially react because of the higher reactivity of a primary alkoxide over a secondary one (**7**). The addition is followed by the cyclization into 3,4-disubstituted oxazolidine **1a**. In the presence of $Bu_3P{=}O$, a facile transformation of **7** to **6** leads to the predominant formation of **1a**. The coordination of bases accelerates the addition of heterocumulenes to tin ω-haloalkoxides as already reported.[7,16,36-39] On the other hand, an isocyanate, a higher reactive heterocumulene, can readily react even with the secondary alkoxide **7**, and the selective formation of 3,4-disubstituted oxazolidinones is difficult. The lower electrophilicity of isothiocyanate, of course, results in a selective α-cleavage cycloaddition.

Conclusion

The complexes of organotin iodides with Lewis bases controlled the regiospecific addition of monosubstituted oxirane to heterocumulenes. The coordination of appropriate bases has some notable potentials: Activation of the addition, specification of the regioselectivity, and limitation of side reactions.

Experimental

Apparatus and Materials. Melting points are uncorrected. IR spectra were recorded on a Hitachi 260-30 spectrophotometer. ^1H NMR and ^{13}C NMR spectra were measured on a Hitachi R-90H or a JEOL JNM-GSX-400 spectrometer. Mass spectra were obtained with a JEOL JMS-DS303

spectrometer. Microanalyses were recorded on a JEOL JMS-DX303 spectrometer (data software processing, JMS-DA 5000). Analytical GLC was performed on a Shimadzu GC-8A using a 2 m×3 mm glass column packed with Silicone OV-1 on Uniport HP (5%, 60—80 mesh). Short-path distillations of products were carried out in a Kugelrohr apparatus.

All oxiranes were freshly distilled from CaH_2. All Lewis bases were purified by general procedures. Isothiocyanates and PhNCO were obtained from commercial sources and used without further purification. PhNCNPh,[40] BuNCNPh,[41] and organotin iodides[42,43] were prepared according to the described methods.

Reaction of Oxirane with Carbodiimide. Diphenylcarbodiimide (2 mmol) was added to a solution of Me_3SnI (2 mmol) and Bu_3PO (2 mmol) in ethyloxirane (20 mmol) under dry nitrogen. The mixture was stirred at 50 °C until the infrared absorption of N=C=N (2150 cm^{-1}) disappeared, and the yields of **1b** (82%) and **2b** (18%) were determined by GLC. The products were isolated by column chromatography on silica gel, giving **1b** (eluted by chloroform; 399 mg, 75%) and **2b** (eluted by benzene; 69 mg, 13%).

Reaction of Oxirane with Isocyanate. As a typical procedure, phenyl isocyanate (2 mmol) was added dropwise to a solution of Bu_3SnI (2 mmol) and Bu_3PO (2 mmol) in methyloxirane (20 mmol) for 1 h with stirring at 50 °C under dry nitrogen. Following addition, the formation and the yields of two products, α-cleavage cycloadduct **1g** (43%) and β-cleavage cycloadduct **2g** (50%), were monitored by GLC. The excess oxirane was removed in vacuo, and the mixture was subjected to isolation by column chromatography on silica gel, giving viscous **1g** (eluted by chloroform; 135 mg, 38%) and crystalline **2g** (eluted by benzene; 152 mg, 43%).

4-Methyl-3-phenyl-1,3-oxazolidin-2-one (1g):[11] Mp 51 °C; IR (KBr) 1740 cm^{-1} (C=O).

5-Methyl-3-phenyl-1,3-oxazolidin-2-one (2g):[5] Mp 81 °C; IR (KBr) 1740 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=1.52 (3H, d, J=6.0 Hz), 3.60 (1H, t, J=7.5 Hz), 4.10 (1H, t, J=8.0 Hz), 4.62—4.96 (1H, m), and 7.00—7.60 (5H, m); MS m/z 177 (M^+).

The following compounds were obtained in a similar manner.

4-Ethyl-3-phenyl-1,3-oxazolidin-2-one (1h):[11] Bp 120 °C/

0.1 mmHg; IR 1750 cm^{-1} (C=O).

Reaction of Methyloxirane with Me_3SnI. The mixture of Me_3SnI (10 mmol) and methyloxirane (4 ml) was stirred for 1 h at room temperature under dry nitrogen. The excess oxirane was removed in vacuo, and **7** was isolated by distillation (bp 53 °C/0.1 mmHg; 2.13 *g*, 61%). ^1H NMR ($CDCl_3$) δ=0.47 (9H, s), 1.27 (3H, d, J=6.0 Hz), 3.18 (2H, d, J=5.3 Hz), 3.60—3.98 (1H, m); ^{13}C NMR ($CDCl_3$) δ=−2.44 (q), 21.22 (q), 51.59 (t), 69.21 (d).

Transformation of 3b to 5b (=2b). **3b** (1 mmol) was added to a solution of $AlCl_3$ (0.1 mmol) and ethyloxirane (5 mmol), and the mixture was stirred at 40 °C under dry nitrogen (0.3 h). The formation and the yield of **5b** (86%) was determined by GLC. **5b** (292 mg, 77%) was isolated by silica gel column treatment (eluted by benzene). The spectrum data of **5b** were the same as those of **2b**.

This study was financially supported by a Grant-in-Aid for Scientific Research No. 02650609 from the Ministry of Education, Science and Culture, and Nagase Science and Technology Foundation.

Benzo[*b*]cyclohepta[*e*][1,4]thiazines and Their Diazine Analogues. III.[1] π-Electronic Structures of 5*H*, 11*H*$^+$-Cyclohepta[*b*]quinoxalinium Ions and Their O- and S-Analogues

(Received March 20, 1991)

π-Electronic structures of 5*H*,11*H*$^+$-cyclohepta[*b*]quinoxalinium ions and their O- and S-analogues were elucidated by means of ^{1}H and ^{13}C NMR spectra, electronic spectra, and theoretical calculations. Consequently, it was shown that these compounds had very stable aromatic characters with positive resonance energies and that the 6π-tropylium-6π-benzonoid form plays an important role for the π-conjugation structure.

On of the authors (T.N.) and his co-workers[2] reported more than thirty years ago that the reaction of 2-chloro- and 2-methoxytropone (**1a,b**) with *o*-phenylenediamine (**2a**) gave 5*H*-cyclohepta[*b*]quinoxaline (**3a**), which they named "benzo[*b*]tropazine".

4

In 1971, Fukunaga[3a] reported that the reaction of ethoxytropylium tetrafluoroborate (**4**) with **2a** and its dimethyl derivative (**2b**) gave greenish-black crystals of **5a** and **5b**, which upon basification produced free compounds **6a** and **6b** that reverted to **5a,b** quantitatively

upon acidification. He proposed that the structure of **6** was the quinoxaline form (namely an isomer of **3a**), and that the salt **5** existed as a resonance-stabilized, peripheral anti-Hückel 16π-electron system based on the evidence of detailed NMR studies of **3a** and its related compounds.[3b] He also suspected that our colorless compound[2] reported as "purified" benzotropazine should have been a dimer of his 6*H*-cyclohepta[*b*]quinoxaline **6a**, but he did not study the structure of the dimer any further. On the other hand, according to our study, benzo[*b*]cyclohept[*e*][1,4]oxazine **3c** and its S-analogue **3d**[5,6] gave the red-colored cations **7c** and **7d**, respectively, under acidic conditions. Later, we also confirmed[1] that compound **3a** existed as a tautomeric form **6a**, and on acidification **6a** was converted into a dark-green salt **7a** which showed intense long-wavelength absorption bands at 500—800 nm; no such bands were observed in the spectra of **7c** and **7d** in acid.

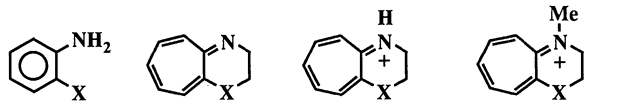
From the standpoint of synthetic and theoretical interest, we recently started the re-investigation of the electronic structures and reactivities of various troponoids and azulenoid compounds. In a previous paper, we reported[7] that the fundamental skeleton of the tropones possessing a unique heptagonal structure may be predicted to be aromatic with positive resonance energies[8] conforming to Gimarc's topological charge stabilization rule (TCS rule).[9] We also found that naturally occurring tropolones nicely fit the theory that conformity to the TCS rule provides a stable molecular system.

In order to clarify the π-electronic structures of the neutral species **3a**—**d** and their cationic species **7a**—**d**, we now wish to describe here a detailed study of their NMR spectra, electronic spectra, and theoretical considerations. Resonance energies, circuits resonance energies, and ring currents of these compounds were also estimated by the use of Aihara's method.[8] The HMO theory is assumed to be in its simplest form. Streitwieser evaluated the heteroatom parameters for the amine nitrogen, the imine nitrogen, the ether oxygen, and the ketone oxygen.[10] In this paper, we adopted these values with some other heteroatom parameters.[11,12]

Results and Discussion

NMR Spectra. The ^{1}H NMR spectra of **3b** and its O- and S-analogues were compared with the spectra of some related compounds such as aromatic amines **2a,c** and **8a,b**, 1*H*-2,3-dihydrocycloheptapyrazines **9a,b** and their thiazine analogue **9c**, and their cations **10a**—**c**,[13] *N*-methylated cations **11a,b**[13] and **12a**—**c**,[1,6,14] quinoxaline (**13**) and phenazine (**14**).

The average chemical shift (δ_{av}) values of protons on the seven-membered and benzene rings and the differences ($\Delta\delta_{av}$) of the average chemical shift values be-

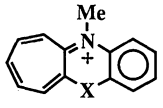


8a X=OH **b** X=SH

9a X=NH **b** X=NMe **c** X=S

10a X=NH **b** X=NMe **c** X=S

11a X=NMe **b** X=S



12a X=NMe **b** X=O **c** X=S

14

tween the neutral species and the corresponding cationic species are listed in Table 1.

Noting the differences of the average chemical shifts of the rings between solvents, the signals in CD_3CN shifted slightly to a lower field compared with those in $CDCl_3$, but this difference was smaller than 0.1 ppm. Under acidic conditions, the chemical shifts moved with the acid concentration, but this change in 20% CF_3COOD nearly agreed with those in CF_3COOD, and its difference as compared with that of the BF_4^- salt in CD_3CN was smaller than 0.1 ppm, suggesting that there were no problems in discussing $\Delta\delta_{av}$.[15]

In order to clarify the relationship between the NMR chemical shifts and π-electron distributions, the π-electron densities of **3a**—**d** and the related compounds were calculated by the MNDO method.[16] There is a quantitative relationship between NMR chemical shifts and electron distributions in aromatic molecules, as reported by many authors.[17] The suggested equations for protons (1) and for carbons (2) seem to have gathered the most support, where the $\Delta\delta$ values are the chemical shift changes and ρ_π is the change in charge.

$$\Delta\delta_H = 10.7\,\rho_\pi \quad (1)$$

$$\Delta\delta_C = 160\,\rho_\pi \quad (2)$$

The $\Delta\delta_{av}$ values of aromatic diamines **2a**—**c** were shown to be larger than those of **8a,b**. The relative values were related to the basicity of these amines.[18] In the NMR spectra of 1*H*-2,3-dihydrocyclohepta[*b*]-pyrazines (**9a,b**)[13] and their S-analogue **9c**,[13] the δ_{av} values of the protons on the seven-membered ring became slightly smaller compared with those of the benzene ring of the aromatic amines **2a**—**c** and **8a,b**. The $\Delta\delta_{av}$ value of **9c** was slightly larger than those of diamines **9a,b** which have higher basicity. The $\Delta\delta_{av}$ values of *N,N'*-dimethyl (**11a**)[13] and *N*-methyl cation (**11b**)[13] are nearly equal to those of the cationic species **10a** and **10c**. The π-electron densities of compounds **9**—**11** are shown in Fig. 1.

The π-electron distributions of the troponeimine part of **9** and **11** were similar to each other, whereas the π-electron densities on the nitrogen atom at position 1 of **10** were more negative than those of **9** and **11**. The sum of the π-electron densities of the seven-membered ring carbons of the cationic species were smaller than those of the neutral species. Though the δ_{av} values of the benzene ring of free compound **6a** were similar to those of quinoxaline **13** and phenazine **14**, these values were demonstrated to be shifted to a lower magnetic field compared with those of *N*-methyldiazine **3b** and its O-(**3c**) and S-analogues (**3d**). These results suggested that, as the π-conjugated system of **6a** differed from those of

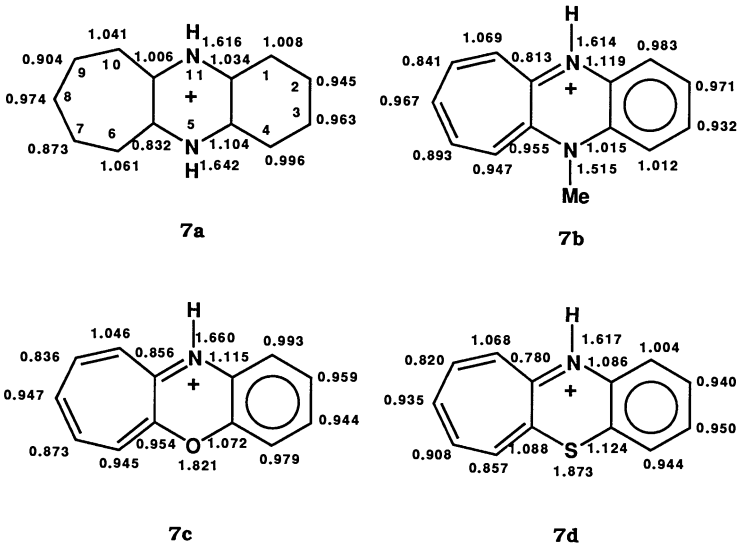

Fig. 2. π-Electron densities of **7** by the MNDO method.

3b—**d**, compound **6a** be removed from discussion of the π-electronic systems of **3a**—**d** and **7a**—**d**. The δ_{av} values of the protons on the benzene and seven-membered rings of $5H,11H^{+}$-cyclohepta[*b*]quinoxalinium ion (**7a**) appeared upfield by 0.5—0.6 and 1.0 ppm, respectively, compared with those of the O-(**7c**) and S-analogues (**7d**). The latter values were approximately proportional to differences in their π-electron density (Fig. 2). Although it was not possible to interpret their chemical shift changes in terms of the change in charge, the π-electron density of **7a** was larger than those of **7c** and **7d**. The $\Delta\delta_{av}$ between **7a** and **7c** or **7d** were calculated to be 0.36 ppm from Eq. 1. The δ_{av} values of **3b** and **7b** were smaller than those of **3c,d** and **7c,d**.

The $\Delta\delta_{av}$ values of the protons on the benzene ring of **3b**—**d** were much smaller than those of the aromatic amines **2a**—**c**, whereas the $\Delta\delta_{av}$ values of the seven-membered protons of **3b**—**d** were larger than those of **2a**—**c** and were similar to those of dihydropyrazines **9a,b**. In the NMR spectra of **3b**—**d**, the signals of the protons

on the benzene ring shifted slightly to a lower field, whereas the signals of the seven-membered ring protons shifted largely to a lower field under acidic conditions. The π-electron densities of **6a,3**, and **12** are shown in Fig. 3. The correlation coefficients between the calculated $\Delta\delta_H$ values and the observed $\Delta\delta_{av}$ values of the seven-membered rings in the N-, O-, and S-analogues were 0.92, 0.99, and 0.97, respectively.

The δ_{av} and $\Delta\delta_{av}$ values of the ^{13}C chemical shifts of **3b—d**, **7a—d**, and **12a** are listed in Table 2, where the $\Delta\delta_{av}$

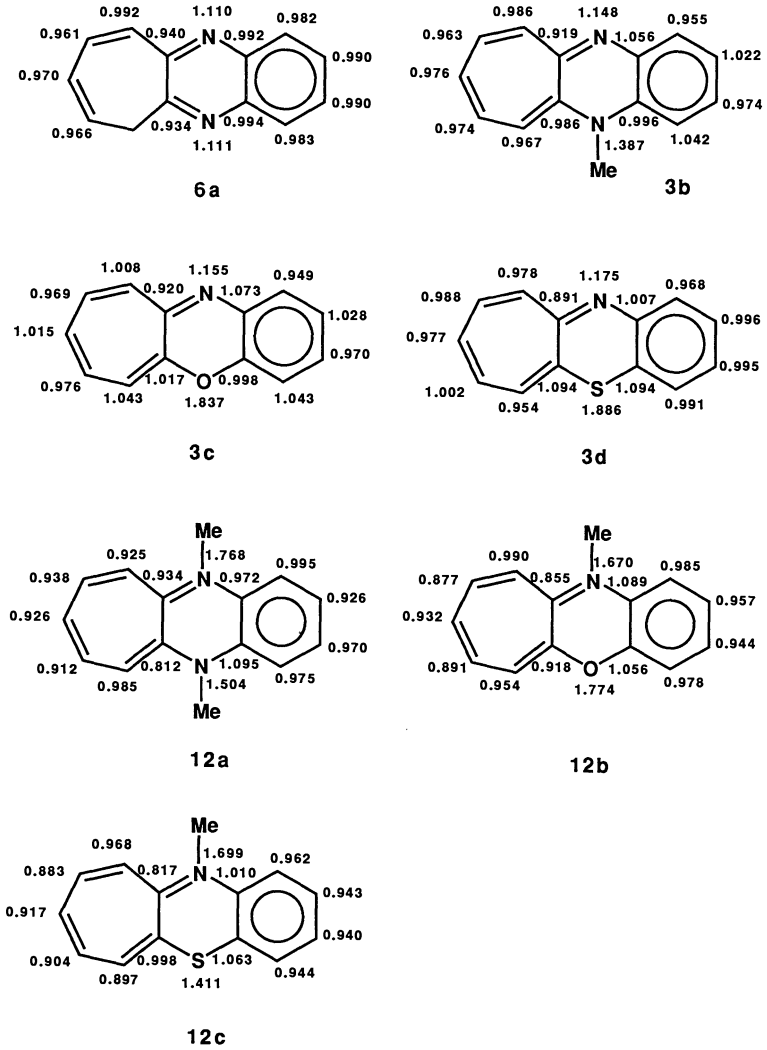

Fig. 3. π-Electron densities of **6**, **3**, and **12** by the MNDO method.

3b	129.1	136.8	7.7	6.6
3c	130.0	138.8	8.8	2.8
3d	129.0	138.8	9.8	4.2

$\Delta\delta_C^{calcd}$ values were calculated from Eq. 2.

values were the differences between the δ_{av} of the seven-membered and benzene ring carbons. The $\Delta\delta_{av}$ of **7a,b** and **12a** were similar in magnitude to their O- and S-analogues. The cationic species had larger $\Delta\delta_{av}$ values than the neutral species.

From the above-cited NMR spectral data, the heteroatoms of **3b—d** and related compounds were closely related to the seven-membered ring rather than the benzene ring. The cationic species had the smallest values for π-electron densities compared with their neutral species. The change in charge seemed to be one of the reasons for its lower field shifts.

Resonance Energies and Circuit Currents. Resonance energies, circuit resonance energies, and circuit currents of **3**, **7**, and **12** were calculated by Aihara's graph theory of aromaticity.[8] Geometrically unidentical π-electron circuits are shown and numbered in Fig. 4. The results are listed in Table 3. Compounds **3**, **7**, and **12** could be regarded as aromatics with positive resonance energies. The cationic species possessed larger resonance energies than the neutral species. From the calculated circuit resonance energies of each ring, the circuit resonance energies of r_1 and r_3 showed positive values, while the values of r_2, r_4, r_5, and r_6 were very small or negative. Consequently, compounds **3a,b** and **7a,b** were stabilized as the 6π-tropylium-6π-benzenoid form similar to the O- and S-analogues, but not as a 16π-peripheral system as was suggested by Fukunaga.[3]

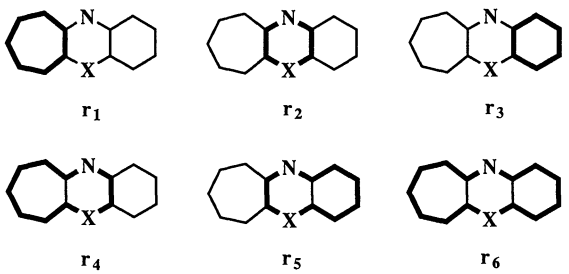

Fig. 4. Geometrically unidentical π-electron circuits.

The calculated circuit currents are also shown in units of I_0 in Table 3. The plus and minus signs in the Table indicate diatropism and paratropism, respectively. Large diatropism was predicted to arise from r_1 and r_3, while large paratropism was predicted to arise from r_4 and r_6. As for compound **3b**, the diatropism effect due to the 6π-tropylium structure (i.e., structure r_1: $0.997I_0$) and the 6π-benzenoid part (i.e., structure r_3: $0.881I_0$) was the main contributor to the magnetic effect, although a small contribution came from the diatropism effect of the heterocyclic part (i.e., structure r_2: $0.094I_0$, r_5: $0.175I_0$) and the paratropism effect due to the peripheral 16π-structure (i.e., structure r_6: $-0.155I_0$). Such a tendency was also found for the O- and S-analogues. Thus, theoretical considerations suggested that the 6π-tropylium-6π-benzenoid form played a crucial role in the stabilization of 5*H*,11*H*$^+$-cyclohepta[*b*]quinoxalinium ions and their O- and S-analogues, and the downfield shifts of the seven-membered ring protons were due to its large diatropism.

Electronic Spectra of 3 and 7. In the electronic spectra of **7a—d**, the bands in the visible region showed large red shifts with increased intensities compared with those of the corresponding neutral species **3a—d**, as mentioned previously.[1,4,6] Compounds **3b** and **3c** showed four electronic absorption bands in the long wavelength region (500—800 nm). It is interesting to note that the cationic species, **7a**, **7b**, and the free *N*-methyl compound **3b**, had almost the same deep green color and very similar absorption bands. For example, **7b** showed long wavelength absorption bands at 564, 616, 670, and 752 nm (log ε 3.01, 2.91, 2.83, and 2.34). On the other hand, compounds without a benzene ring, such as **9a—c**, **10a—c**, and **11a,b**, did not show these absorption bands in the same region.[13] These absorption bands were thus closely related to the π-electronic structure of the benzene ring.

We have also calculated the electronic transition of these compounds by the CNDO/S-CI method.[19] The coefficient distribution of the three highest occupied and the three lowest unoccupied π orbitals are shown in Fig.

a) E (eV) is the energy of the transitions; f (dimensionless) is the oscillator strength.

5. They were similar to each other. Therefore, the calculated electronic transitions were predicted to have very similar absorption bands. The electronic transitions calculated for **3b**, **7a**, and **7b** are collected in Table 4. The free *N*-methyl compound **3d** showed two $\pi \rightarrow \pi^*$ electronic transitions at 2.58 and 3.09 eV, corresponding to $\pi_1 \rightarrow \pi_1^*$ and $\pi_1 \rightarrow \pi_2^*$, whereas its cation **7b** showed corresponding transitions at 2.05 and 2.26 eV, respectively.

From the coefficient distribution as shown in Fig. 5, these bands could be attributed to an intramolecular charge-transfer transition from the benzene ring part to the seven-membered ring part. CNDO/S calculations satisfactorily reproduced the red shift observed in the long wavelength region of the neutral spcies and their cationic species **7a**—**d**.

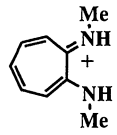
Molecular Geometries. The geometry optimizations of **3**, **6**, **7**, and **9**—**12** were carried out with optimization of all geometrical parameters with no assumptions whatsoever. In **3b**—**d** and related compounds, the C–C bonds of the benzene ring were 1.40—1.43 Å, the formular double bonds of the seven-membered ring were 1.35—1.39 Å, the C–C single bonds were 1.40—1.47 Å, except for the C-5a–C-10a bonds which were 1.45—1.49 Å. The C-10a–N-11 bonds were 1.31—1.37 Å, the C-11a–N-11 bonds were 1.40—1.44 Å. In the oxazines,

the C–O bonds were 1.35—1.38 Å.

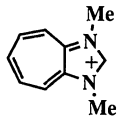
In the thiazines, the C–S bonds were 1.68—1.70 Å. CNDO/S calculations adopted these optimized values.

Concluding Remarks

Fukunaga[3b] compared the NMR and electronic spectra of compounds **6a—b**, **15**, and **16** with the reference compounds **5a,b**.

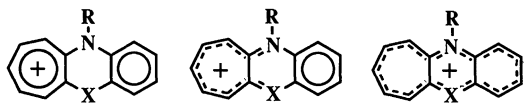


15



16

The ^{1}H NMR spectra of **5a—b** indicated large upfield shifts of the ring-proton signals compared with those of the benzene ring of **6** and the seven-membered ring protons of **15** by 1.2—1.9 ppm. Such a large upfield shift arose from the paramagnetic ring current effect. He believed that **5a,b** existed as a resonance-stabilized, peripheral 4nπ-electron system. We assumed three models (I—III) for the π-electronic structures of **7a—d**.



I II III

From the above-cited spectral data and theoretical calculations, we propose that the heteroatoms of **7a—d** are closely related to the seven-membered ring rather than the benzene ring. The positive charge is delocalized over the seven-membered ring (Type I). This suggests that contributions of the 10π-2-aminotroponiminium structure (Type II) and 16π-peripheral conjugation structure (Type III) are negligible. The electronic structures of **7a—d** can not be elucidated solely by II, because the electronic spectra of **10** and **11** do not show absorption bands in the long wavelength region. In view of these absorption bands that can be attributed to an intramolecular charge-transfer transition, the π-conjugation system of 5*H*,11*H*$^+$-cyclohepta[*b*]quinoxalinium ions and their O- and S-analogues are shown by the contribution of I. Therefore, we conclude that the title compounds are stabilized as a 6π-tropylium–6π-benzenoid system (I) and the appearance of their color is due to the intramolecular charge-transfer transition.

Experimental

General. NMR spectra were re-measured as CD_3CN and $CDCl_3$ solutions on JEOL JNM PS100 (100 MHz), GX 270 (270 MHz) and GX 400 (400 MHz) spectrometers with TMS as the internal standard. The UV-vis spectra were recorded with Shimadzu UV-202 or Hitachi 557 spectrometers.

Materials. Aromatic amines were purchased from Wako Pure Chemicals Ind. Benzo[*b*]cyclohepta[*e*][1,4]thiazines and the related compounds were prepared according to the reported methods.[1,4,6,13]

***o*-Phenylenediamine (2a):** ^{1}H NMR (CD_3CN) δ=6.54 (4H, s, ar-H) and 3.60 (4H, br, NH_2); (20% CF_3COOD–CD_3CN) δ=7.28 (4H, ar-H).

4,5-Dimethyl-*o*-phenylenediamine (2b): ^{1}H NMR (CD_3CN) δ=2.04 (6H, s, CH_3), 3.40 (4H, br, NH_2), and 6.37 (2H, s, ar-H); (20% CF_3COOD–CD_3CN) δ=2.27 (6H, s, CH_3) and 7.23 (2H, s, ar-H).

***N,N'*-Dimethyl-*o*-phenylenediamine (2c):** ^{1}H NMR ($CDCl_3$) δ=2.82 (6H, s, CH_3), 3.15 (2H, br, NH), and 6.70 (4H, s, ar-H); (10% CF_3COOD-$CDCl_3$) δ=3.40 (6H, s, CH_3) and 7.75 (4H, s, ar-H).

5-Methyl-5*H*-cyclohepta[*b*]quinoxaline (3b): ^{1}H NMR (400 MHz) (CD_3CN) δ=2.64 (3H, s, CH_3), 4.46 (1H, d, *J*=10 Hz, H-6), 5.21 (1H, t, *J*=10.7 Hz, H-8), 5.39 (1H, d, *J*=12 Hz, H-10), 5.80 (2H, m, H-7,9), 6.23 (1H, d, *J*=8 Hz, H-4), 6.47 (1H, d, *J*=8 Hz, H-1), 6.52 (1H, t, *J*=8 Hz, H-2), and 6.67 (1H, t, *J*=8 Hz, H-3); ^{13}C NMR (100 MHz) (CD_3CN) δ=34.8 (CH_3), 109.8 (C-6), 114.0 (C-4), 123.6 (C-8), 123.8 (C-2), 126.6 (C-1), 127.9 (C-3), 134.0 (C-10), 138.0 (C-7 or 9), 138.1 (C-9 or 7), 140.8 (C-4a), 141.3 (C-11a), 151.3 (C-5a), and 163.8 (C-10a).

Benzo[*b*]cyclohept[*e*][1,4]oxazine (3c): ^{1}H NMR (270 MHz) ($CDCl_3$) δ=5.37 (1H, d, *J*=9.5 Hz, H-6), 5.75 (1H, dd, *J*=10.5 and 8 Hz, H-8), 5.94 (1H, t, *J*=10.5 and 9.5 Hz, H-7), 5.97 (1H, d, *J*=12 Hz, H-10), 6.11 (1H, dd, *J*=12 and 8 Hz, H-9), 6.35 (1H, d, *J*=7.9 Hz, H-4), and 6.69 (3H, m, H-1,2,3); ^{13}C NMR (67.8 MHz) (CD_3CN) δ=114.1 (C-6), 115.1 (C-4), 125.5 (C-1), 126.6 (C-2), 128.2 (C-3), 129.2 (C-8), 134.7 (C-7 or 9), 136.8 (C-4a), 137.0 (C-10), 137.3 (C-9 or 7), 147.9 (C-11a), 158.1 (C-5a), and 161.2 (C-10a).

Benzo[*b*]cyclohept[*e*][1,4]thiazine (3d): ^{1}H NMR (400 MHz) (CD_3CN) δ=6.10 (1H, d, *J*=8 Hz, H-6), 6.13 (1H, d, *J*=12 Hz, H-10), 6.19 (1H, ddt, *J*=11, 7, and 1 Hz, H-8), 6.31 (1H, ddt, *J*=11, 8, and 1 Hz, H-7), 6.37 (1H, ddd, *J*=12, 7, and 1 Hz, H-9), 6.85 (1H, dd, *J*=7 and 1.5 Hz, H-4), 6.95 (1H, td, *J*=7 and 1.8 Hz, H-3), 7.00 (1H, dd, *J*=7 and 1.8 Hz, H-1), and 7.04 (1H, ddd, *J*=7 and 1.5 Hz, H-2); ^{13}C NMR (100 MHz) (CD_3CN) δ=126.6 (C-4), 127.6 (C-3), 128.2 (C-4a), 128.3 (C-1), 128.6 (C-2), 130.0 (C-10), 132.6 (C-8), 134.5 (C-6), 134.6 (C-11a), 134.7 (C-9), 135.3 (C-7), 144.4 (C-5a), and 160.3 (C-10a).

2,3-Dimethyl-5*H*,11*H*$^+$-cyclohepta[*b*]quinoxalinium Tetrafluoroborate (5b): ^{1}H NMR (270 MHz) (CD_3CN) δ=1.90 (6H, s, CH3), 5.55 (2H, d, *J*=11.0 Hz, H-10), 5.92 (1H, t, *J*=9.3 Hz, H-8), 5.94 (2H, s, H-1,4), and 6.50 (2H, dd, *J*=11.0 and 9.3 Hz, H-7,9).

2,3-Dimethyl-6*H*-cyclohepta[*b*]quinoxaline (6b): ^{1}H NMR (270 MHz) ($CDCl_3$) δ=2.48 (6H, s, CH3), 3.55 (2H, d, *J*=6.6 Hz, H-6,6), 6.06 (1H, dt, *J*=10.0 and 6.6 Hz, H-7), 6.25 (1H, dd, *J*=10.0 and 5.5 Hz, H-8), 6.77 (1H, dd, *J*=12.1 and 5.5 Hz, H-9), and 7.24 (1H, d, *J*=12.1 Hz, H-10).

5*H*,11*H*$^+$-Cyclohepta[*b*]quinoxalinium Tetrafluoroborate (7a): ^{1}H NMR (400 MHz) (CD_3CN) δ=5.65 (2H, d, *J*=11 Hz, H-6,11), 6.04 (1H, t, *J*=9.5 Hz, H-8), 6.11 (2H, m, H-1,4), 6.52 (2H, m, H-2,3), 6.60 (2H, dd, *J*=11 and 9.5 Hz, H-7,9), and 7.83 (2H, br, NH); ^{13}C NMR (100 MHz) (CD_3CN) δ=116.9 (C-1,4), 124.0 (C-6,10), 128.2 (C-2,3), 131.4 (C-8), 132.2 (C-4a,11a), 147.9 (C-7,9), and 157.7 (C-5a, 10a).

11*H*$^+$-5-Methylcyclohepta[*b*]quinoxalinium Tetrafluorobo-

rate (7b): ^{1}H NMR (400 MHz) (CD_3CN) δ=2.85 (3H, s, CH_3), 5.88 (1H, d, *J*=11 Hz, H-6 or 10), 5.93 (1H, d, *J*=11 Hz, H-10 or 6), 6.26 (1H, t, *J*=9.5 Hz, H-8), 6.39 (1H, dd, *J*=7.5 and 1.5 Hz, H-1 or 4), 6.43 (1H, d, *J*=8 Hz, H-4 or 1), 6.69 (1H, td, *J*=7.5 and 1.5 Hz, H-2 or 3), 6.77 (1H, td, *J*=7.5 and 1.5 Hz, H-3 or 2), 6.90 (1H, ddd, *J*=11, 9.5, and 1.5 Hz, H-7 or 9), 6.93 (1H, ddd, *J*=11, 9.5, and 1.5 Hz, H-9 or 7), and 8.48 (1H, br, NH); ^{13}C NMR (100 MHz) (CD_3CN) δ=37.0 (CH_3), 117.5 (C-1 or 4), 117.6 (C-4 or 1), 123.9 (C-6 or 10), 125.1 (C-10 or 6), 127.6 (C-2 or 3), 128.8 (C-3 or 2), 131.3 (C-8), 132.1 (C-4a), 136.7 (C-11a), 147.5 (C-7 or 9), 148.2 (C-9 or 7), 156.0 (C-5a), and 159.0 (C-10a).

11*H*$^+$-Benzo[*b*]cyclohept[*e*][1,4]oxazinium Tetrafluoroborate (7c): ^{1}H NMR (400 NHz) (CD_3CN) δ=6.67 (1H, dd, *J*=8 and 1.5 Hz, H-1 or 4), 6.70 (1H, dd, *J*=7.5 and 1.5 Hz, H-4 or 1), 6.85 (1H, d, *J*=11.5 Hz, H-6 or 10), 6.89 (1H, td, *J*=7.5 and 1.5 Hz, H-2 or 3), 6.92 (1H, dd, *J*=10.3 and 1 Hz, H-10 or 6), 6.95 (1H, td, *J*=8 and 1.5 Hz, H-3 or 2), 7.09 (1H, ddd, *J*=10.3, 9, and 1Hz, H-8), 7.34 (1H, td, *J*=10.3 and 1.5 Hz, H-7 or 9), 7.49 (1H, dd, *J*=11.5, 9, and 1 Hz, H-9), and 9.40 (1H, br, NH); ^{13}C NMR (100 MHz) (CD_3CN) δ=117.4 (C-1 or 4), 118.5 (C-4 or 1), 126.4 (C-11a), 128.0 (C-2 or 3), 129.8 (C-6 or 10), 130.0 (C-10 or 6), 131.1 (C-3 or 2), 138.2 (C-8), 145.1 (C-7 or 9), 145.6 (C-4a), 149.0 (C-9 or 7), 157.6 (C-10a), and 161.5 (C-5a).

11*H*$^+$-Benzo[*b*]cyclohepta[*e*][1,4]thiazinium Tetrafluoroborate (7d): ^{1}H NMR (400 MHz) (CD_3CN) δ=6.76 (1H, d, *J*=11.5 Hz, H-6 or 10), 6.82 (2H, m, H-1,4), 7.07 (3H, m, H-2,3,8), 7.18 (1H, d, *J*=9 Hz, H-10 or 6), 7.22 (1H, td, *J*=9 and 1.5 Hz, H-7 or 9), 7.41 (1H, ddd, *J*=11.5, 9, and 1.5 Hz, H-9 or 7), and 9.55 (1H, br, NH); ^{13}C NMR (100 MHz) (CD_3CN) δ=120.4 (C-4), 121.2 (C-4a), 127.6 (C-1), 129.4 (C-6), 130.6 (C-2 or 3), 130.9 (C-3 or 2), 134.4 (C-11a), 140.5 (C-10), 142.2 (C-8 or 9), 144.2 (C-9 or 8), 145.7 (C-5a), 148.1 (C-7), and 162.9 (C-10a).

***o*-Aminophenol (8a):** ^{1}H NMR (50% $CDCl_3$-CD_3CN) δ=6.60 (s, ar-H); (1:2:2, CF_3COOD-$CDCl_3$-CD_3CN) δ=6.75—7.45 (m, ar-H).

2-Aminobenzenethiol (8b): ^{1}H NMR (CD_3CN) δ=4.0 (3H, br, NH and SH) and 6.50—7.40 (4H, m, ar-H); (20% CF_3COOD-CD_3CN) δ=7.20—7.70 (m, ar-H).

2,3-Dihydro-1*H*-cyclohepta[*b*]pyrazine (9a): ^{1}H NMR (270 MHz) (CD_3CN) δ=3.40 (4H, s, CH_2), 6.00 (1H, t, *J*=9.3 Hz, H-7), 6.15 (2H, d, *J*=11.5 Hz, H-5,9), and 6.46 (2H, dd, *J*=11.5 and 9.3 Hz, H-6,8); (20% CF_3COOD-CD_3CN) δ=3.59 (4H, s, CH_2), 7.13 (1H, t, *J*=10 Hz, H-7), 7.26 (2H, d, *J*=11 Hz, H-5,9), and 7.51 (2H, dd, *J*=11 and 10 Hz, H-6,8).

2,3-Dihydro-1-methyl-1*H*-cyclohepta[*b*]pyrazine (9b): ^{1}H NMR (270 MHz) (20% CF_3COOD+CD_3CN) δ=3.35 (3H, s, CH_3), 3.68 (2H, t, *J*=5.0 Hz, CH_2), 3.78 (2H, t, *J*=5.0 Hz, CH_2), 7.08 (1H, t, *J*=9.3 Hz, H-7), 7.21 (2H, d, *J*=11.0 Hz, H-5,9), 7.50 (1H, dd, *J*=11.0 and 9.3 Hz, H-8), and 7.58 (1H, dd, *J*=11.0 and 9.3 Hz, H-6).

5,11-Dimethyl-5*H*-cyclohepta[*b*]quinoxalinium Tetrafluoroborate (12a): ^{1}H NMR (400 MHz) (CD_3CN) δ=3.08 (6H, s, CH_3), 6.27 (2H, d, *J*=12 Hz, H-6,10), 6.56 (1H, t, *J*=9.5 Hz, H-8), 6.70 (2H, m, H-1,4), 6.93 (2H, m, H-2,3), and 7.22 (2H, dd, *J*=12 and 9.5 Hz, H-7,9); ^{13}C NMR (100 MHz) (CD_3CN) δ=37.6 (CH_3), 118.0 (C-1,4), 124.7 (C-6,10), 128.0 (C-2,3), 131.5 (C-8), 133.2 (C-4a, 11a), 147.9 (C-7,9), and 158.3 (C-5a, 10a).

We wish to thank Professor Jun-ichi Aihara (Shizuoka Univ.) for helpul discussions on the resonance energy and ring currents. We are gratefull to Dr. Tadamichi Fukunaga (E. I. du Pont de Nemours and Co.) for sending unpublished NMR and other experimental data[3b] and to Professor Hiroshi Yamamoto (Okayama Univ.) for some advice. We also wish to thank Dr. Hiroshi Naganawa (Inst. Bio-org. Chem., Shinagawa) for the NMR measurements.

Molecular Orbital Approach to Antioxidant Mechanisms of Phenols by an Ab Initio Study

Kazunori TANAKA, Shogo SAKAI,† Shogo TOMIYAMA, Tomihiro NISHIYAMA, and Fukiko YAMADA*
Department of Applied Chemistry, Faculty of Engineering, Kansai University,
Yamatecho, Suita, Osaka 564
(Received February 4, 1991)

An ab initio molecular orbital theory has been applied to a study of the hydrogen abstractions of phenolic antioxidants in the chain process of autoxidation. The optimum structures of phenols, of peroxides, and of those compounds in the transition states were obtained with a Hartree–Fock/STO-3G basis set. From the values of enthalpy (ΔH) and activation energy (E_a) obtained, it was found that the rates of the reaction of peroxyl radical with phenolic antioxidant were faster than those with organic substrate in the propagation, and that the effect of the aromatic ring of the antioxidants not only stabilized a product state but also decreased an energy level in the transition state. The para-substituent effect that an electron-releasing substituent increased the antioxidant activity, whereas an electron-withdrawing one decreased it, was recognized. The relationship between ΔH and E_a values followed the Evans–Polanyi rule. The transition states in the hydrogen abstractions with lower E_a values prefer reactant-like structures, whereas those with higher E_a values prefer product-like ones.

Antioxidants have commonly been used to prevent deterioration due to the autoxidation of organic substrates. Autoxidations at various temperatures have been well characterized as radical chain reactions. Such antioxidants as phenol and aromatic amine derivatives react as chain-breaking inhibitors of the peroxyl radical:[1)]

$$ROO\cdot + ArOH \rightarrow ROOH + ArO\cdot, \quad (a)$$

where ROO· denotes the peroxyl radical and ArOH represents antioxidant phenols. Another possible reaction is the direct attack on the alkyl radical:

$$R\cdot + ArOH \rightarrow RH + ArO\cdot \quad (b)$$

In the absence of the antioxidant, the following propagation reactions proceed:

$$R\cdot + {}^3O_2 \rightarrow ROO\cdot \quad (c)$$
$$ROO\cdot + RH \rightarrow ROOH + R\cdot, \quad (d)$$

where RH is the organic substrate. It is assumed that reaction (c) proceeds with zero activation energy.[1)] The main reactions can be represented by reactions (a) and (d) and thus, reaction (a) occurs easily in comparison with reaction (d). The radical ArO· from the antioxidant is less reactive and consequently it is difficult for a new chain reaction to become initiated (e), as was first reported by Bolland and Ten Have.[2)]

$$ArO\cdot + RH \rightarrow ArOH + R\cdot \quad (e)$$

The ArO· radical would be expected to act as the ideal radical to capture other ROO· radicals. Namely, the reactivity of ArO· is attributed to its resonance structure to fulfill the ideal conditions.

† Present address: Osaka Sangyo University, Daito-shi, Osaka 574.

In 1988, Scott described in his review[3)] that electron-releasing groups in the aromatic ring increase antioxidant activity, whereas electron-attracting groups decrease it, and substituents delocalizing the electron in the aryloxyl or arylaminyl radicals increase the antioxidant activity. These facts can be rationalized on the basis of the transition state involved in hydrogen abstraction by alkylperoxyl radical. There is both partial separation of charge between the alkylperoxyl and the aromatic ring and partial delocalization of the electron in the π-bond system. Consequently, substituents which release electrons or delocalize the unpaired electron decrease the transition state energy.

In this paper, further examinations of the reactivities of elementary reactions in autoxidations in the absence or presence of the antioxidants are described on the following model reactions:

Reaction between R· and triplet oxygen

$$C_6H_5\cdot + {}^3O_2 \rightarrow C_6H_5OO\cdot \quad (1)$$

Reaction between R· and an antioxidant

$$C_6H_5\cdot + ArOH \rightarrow C_6H_6 + ArO\cdot \quad (2)$$

Propagation reaction

$$CH_4 + \cdot OOH \rightarrow CH_3\cdot + HOOH \quad (3)$$
$$C_6H_6 + \cdot OOH \rightarrow C_6H_5\cdot + HOOH \quad (4)$$

Chain-breaking reaction

$$HOH + \cdot OOH \rightarrow HO\cdot + HOOH \quad (5)$$
$$ArOH + \cdot OOH \rightarrow ArO\cdot + HOOH \quad (6)$$

Reaction between methoxyl or phenoxyl radical and a substrate

$$CH_3O\cdot + CH_4 \rightarrow CH_3OH + CH_3\cdot \quad (7)$$
$$ArO\cdot + CH_4 \rightarrow ArOH + CH_3\cdot \quad (8)$$

Subsequently, the para-substituent effects of phenol antioxidants in the hydrogen abstraction by ROO· radicals are investigated in detail.

Structure I depicts the hydrogen abstraction in the transition state and the various substituents, R and X, are shown below.

a) R-C_6H_4OH+·OOX→R-C_6H_4O·+HOOX.

Experimental

Determination of Antioxidant Activity. Measurements of oxygen-absorption rates were performed with an isobaric gas-absorption apparatus under a closed-flow system (2.0±0.1 L oxygen h^{-1}) provided with an electrolyser using 50 cm^3 of tetralin containing an antioxidant (0.001 mol dm^{-3}) and azobis(isobutyronitrile) as the initiator (0.01 mol dm^{-3}). The oxidation temperature was kept at 60±0.1 °C and oxygen absorption was periodically measured in a constant-pressure closed system. The induction period (IP) was determined in the usual way.[4]

Computation

Ab initio molecular orbital calculations were carried out for the reactions, Eqs. 1—18, corresponding to the elementary reactions, (a)—(e), with the GAUSSIAN 80 programs.[5] Geometries for all the structures were optimized at the HF level with the STO-3G basis set[6] by using the energy gradient method.[7] The energies and structures of the transition states were also calculated in the same way mentioned above, but the aromatic ring involved in reactions 4, 6, and 8—18, was only fixed with that of optimized phenol geometry. Concerning reactions 3, 5, and 7, these values were calculated with the HF/3-21G basis set.[8,9] Thus, the electronic correlation energies in these three reactions were computed by means of Møller-Plesset (MP) pertubation up to the third order.[10] The ΔH and E_a values were obtained from the total energies for the optimum structures of both systems and the energy of the transition state (E_{ts}), as follows:

$$\Delta H(\text{kJ mol}^{-1}) = -2625.460[E_{total}(\text{reactants}) - E_{total}(\text{products})]$$

$$E_a(\text{kJ mol}^{-1}) = -2625.460[E_{total}(\text{reactants}) - E_{ts}]$$

$$1 \text{ A.U.} = 2625.460 \text{ kJ mol}^{-1}$$

The activation parameters obtained are shown in Tables 1—4.

Results and Discussion

The Initial Channel of the Chain-Breaking Inhibition. Table 1 shows the calculated ΔH values of Eqs. 1 and 2, along with the energy profiles of both exothermic reactions. The difference between the ΔH values in Eqs. 1 and 2 is 33.48 kJ mol^{-1}. Therefore, the C_6H_5OO· radical is stable in comparison with the product of Eq. 2. In Eq. 1, the direct interaction between the radical and triplet oxygen having the feature of a biradical proceeds with no barriers, whereas the reaction of Eq. 2 reaches the product state through the transition state.

In the autoxidation of organic substrates, an alkyl radical is formed by addition of an initiator such as azobis(isobutyronitrile) and is further transformed into the ROO· radical after interaction with triplet oxygen (Eq. c). Bolland and ten Have[2] determined the initial rates of the autoxidations under several conditions: The variations of antioxidants or substrates, concentration, and oxygen pressure. Thus, they concluded that antioxidants react with ROO· radicals and not with R· radicals. This conclusion agrees with the results of our calculations supporting the idea that the initial channel of the chain-breaking inhibition by antioxidants is the

2	−127.86	−54.06

reaction with the ROO· radical.

Reactivity of the HOO· Radical. Concerning Eq. 3 in Table 2, the values of ΔH and E_a at the MP3/3-21G level are 119.62 and 130.88 kJ mol^{-1}, and in Eq. 5 these values are 69.50 and 97.86 kJ mol^{-1}, respectively. The differences in the ΔH and E_a values between Eqs. 3 and 5 are 50.12 and 33.02 kJ mol^{-1}, respectively. The rate of hydrogen abstraction from the O–H bond was much faster than that from the C–H bond. In other words, the methyl radical is unstable compared with the hydroxyl radical and Eq. 3 has the feature of reversible reaction.

Subsequently, the influence of an aromatic ring was considered at the STO-3G level (see Table 2). The differences in the ΔH and E_a values between Eqs. 3 and 4 are 97.36 and 67.66 kJ mol^{-1}, respectively, while those between Eqs. 5 and 6 are 79.88 and 43.68 kJ mol^{-1}, respectively. Consequently, by introducing an aromatic ring to the reaction system, their reactivities are increased. The E_a value of Eq. 4, which is the model of the propagation reaction (d), was exceedingly large in comparison with that of Eq. 6 which is the model of the chain-breaking reaction (a).

From these results, it was confirmed that the rate of the chain-breaking reaction was much faster than the propagation reaction and that the aromatic ring in the antioxidant molecules tends to decrease the activation energy of the chain-breaking reaction and to stabilize the energy of the phenoxyl radical produced after the hydrogen abstraction.

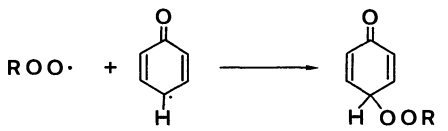
Reactivity of the Phenoxyl Radical. It is known that one molecule of simple phenol captures two molecules of ROO· radicals; one is captured by the hydrogen abstraction of the phenolic OH group, and the other by the coupling reaction with the 4-oxo-2,5-cyclohexadienyl radical produced from the phenoxyl radical by the rearrangement of the π-electron (see reactions a and f).[1]



(f)

The data from Eqs. 7 and 8 in Table 2 indicate the closeness of both energy levels of the transition and product states, and the E_a values of Eq. 8 is larger than that of Eq. 7 at the STO-3G level. Both Eqs. 7 and 8 are the model system of the reaction (e). It was noted that the system returns readily from the transition state to the reaction state. From these results, it can be concluded that the reaction between the phenoxyl radical and a substrate cannot proceed readily, whereas the 4-oxo-2,5-cyclohexadienyl radical reacts with the peroxyl radical smoothly to terminate chain reactions.

Substituent Effect of Phenolic Antioxidant. The calculated ΔH and E_a values in the cases of Eq. 6 and Eqs. 9—18, of the reactions of *p*-substituted phenols with two kinds of peroxyl radicals (see Structure I, X=H and CH_3), are shown in Table 3. By using the values in Eqs. 6 (R=H) and 14(R=H), the $\Delta(\Delta H)$ and ΔE_a were evaluated. An approximately linear relationship between both values is shown in Fig. 1. The slope value (α), $\Delta E_a/\Delta(\Delta H)$, is 0.395 except for the value in Eq. 17. This fact indicates that the hydrogen abstraction in the chain-breaking reaction follows the Polanyi–Evans rule.[11]

Table 3. *p*-Substituent Effects of Phenols with Activities as Antioxidants

a) The n value was obtained by the induction period method in Ref. 12 (cumene was used as the substrate). b) The data in Ref. 13 (cracked gasoline). c) The data in Ref. 14 (Pennsylvania gasoline). d) This work (tetralin).

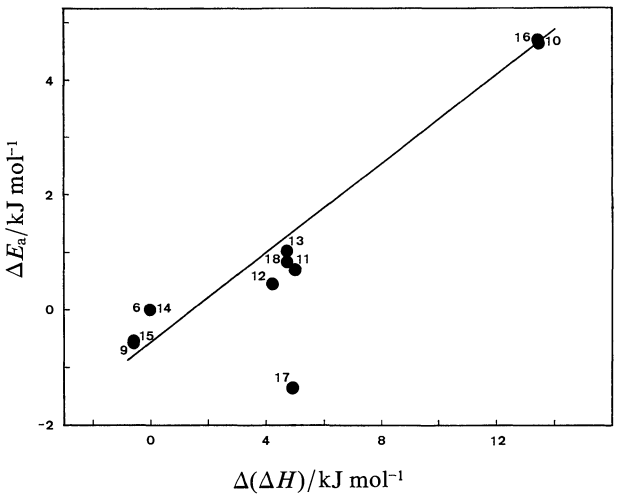

Fig. 1. Plot of ΔE_a vs. $\Delta(\Delta H)$ values.

Ingold et al.[12] reported on the stoichiometric coefficient, n, for substituted phenols using cumene as a substrate at 65 °C by the induction period method. The n values in Table 3, change inversely with the ΔH and E_a values except for those in Eq. 10. This indicates that the electron-releasing substituent in phenol decreases the ΔH and E_a values and increases the antioxidant activity, whereas the electron-attracting substituent increases both values and decreases the activity. The relationship between the E_a and induction period (IP) values indicates an antioxidant activity, by the uses of two kinds of gasolines[13,14] and tetralin as substrates, and confirms the result mentioned above, as can be seen in Table 3.

Geometry of the Transition State. The geometry of the molecular model of the hydrogen abstraction in the transition state was defined by both distance and angle parameters, as shown in Table 4. These values indicate linear binding between the hydrogen atom of the OH substituent of the phenol and the oxygen atom of the peroxyl radical. Figure 2 shows the relation between the E_a and r_1 values, except for Eqs. 10, 11, 16, and 17, in the cases of the substituents OCH_3 and NH_2. The E_a values increase with increasing r_1 values. It was, therefore, thought that the structures of the transition states in the reactions which have lower E_a values are reactant-like, whereas those which have higher values are product-like. This result agrees with the postulation by Hammond.[15]

(Received March 1, 1991)

The gas-phase hydration of propene over proton-exchanged or metal ion-exchanged zeolites with various Si/Al ratios and structures (such as ZSM-5, mordenite, ferrierite, and Y-type) has been studied. It was found that the catalytic activity of proton-exchanged zeolites for the conversion of propene to 2-propanol did not depend on their framework structure, but showed a volcano-shaped dependence on the Al content, as was observed in the hydration of ethene. On the basis of temperature-programmed desorption experiments of NH_3 adsorbed on the zeolites, it was confirmed that the activity is controlled by the acidity of the catalysts. The catalytic activity of metal ion-exchanged Y zeolites increased with an increase in the electronegativity of the metal ion.

Hydration of lower olefins over proton-exchanged zeolites has been investigated at atmospheric and high pressures in the gas[1-5] and liquid[6] phases. Although efforts have been made to clarify the factors controlling the activity for hydration, they have been ambiguous because the conditions are complex and the activity of the catalyst depends on several factors.

We have previously reported that in the hydration of ethene over proton-exchanged zeolites at atmospheric pressure the catalytic activity of the zeolites is independent on the framework structure, showing a volcano-shaped dependence on the Al content or a SiO_2/Al_2O_3 molar ratio; a linear correlation between the activity and the number of acid sites on the zeolite was observed.[1] Further, it was suggested that the Brønsted acid site is the active site, since the temperature dependency of the activity is similar to that of a number of Brønsted acid sites. Eguchi et al.[4] as well as Kikuchi et al.[5] have, indeed, reported high catalytic activities of zeolites for the reaction. The former group has also claimed that no correlation was observed between the catalytic activity of zeolites for the hydration of propene and the number of acidic sites.[4] These results are not consistent with the correlation concerning the activity of zeolites for ethene hydration with the acid amount reported by the present group[1,3] and by Kikuchi et al.[5] This may be due to the high partial pressure of water vapor in their experiment, caused by a decrease in the number of acidic sites, owing to too much water being observed on mordenite by Kikuchi et al.[7]

In this work, therefore, catalytic hydration of propene was carried out over various zeolites including metal ion-exchanged Y zeolites in a simpler system, at both a low partial pressure of water vapor and at atmospheric pressure. We investigated how the activity for the hydration of lower olefins can be recognized by the amounts of acidic sites and tried to make the effects of the metal ion clearer on the basis of such recognition. This paper clarifies the primary factors controlling the activity for the hydration of propene over proton-exchanged and metal ion-exchanged zeolite catalysts, and summarizes catalytic hydration over zeolites together with the previously reported results for ethene, 2-methylpropene, and 1-butene. It may be important to reveal the primary factors controlling the activity for hydration in order to design zeolite catalysts, since ion-exchange resins have disadvantages in that they decrease in catalytic activity with time and display thermal instability; alternative effective catalysts have been desired, although they are used preferentially as solid catalysts for the hydration of lower olefins.

Experimental

The parent zeolites (ZSM-5 (denoted as MFI), ferrierite (FER), and ultrastable Y-type (Y-12 and 40)) were supplied by Tosoh Corporation. Mordenite (MOR-15) and Y-type (Y-5.6) corresponding to JRC-Z-HM-15 and JRC-Z-HY-5.6, respectively, were obtained from the Catalysis Society of Japan. The number in the sample name represents the SiO_2/Al_2O_3 molar ratio in the zeolite framework, which was confirmed by ^{29}Si MASNMR (Brucker PC-250, 49.66 MHz). Proton-exchanged zeolites were prepared by the calcination (723 K, 2 h) of NH_4^+-exchanged zeolites which were supplied or prepared by three repetitions of an ion exchange of the parent Na^+-exchanged zeolites with a 2 wt% aqueous NH_4NO_3 solution at room temperature overnight. Metal ion-exchanged Y zeolites were prepared as follows: 10 g of proton-exchanged ultrastable Y zeolite (SiO_2/Al_2O_3=12.3) was ion-exchanged in 500 cm^3 of an aqueous solution of metal nitrates or chlorides with 10 mmol cm^{-3}.# The obtained solid was then

#As shown in Table 2, the exchange level of Co^{2+} or Ni^{2+} was very low, indicating that the ion exchange of Co^{2+} or Ni^{2+} with H^+ is more difficult than those of the other metal ions. Similar phenomena have been reported for the ion exchange of Co^{2+} or Ni^{2+} with Na^+ in various zeolites (W. Romanowski and J. M. Jablonski, "Catalysis on Zeolites," ed by D. Kallo and K. M. Minachev, Akademiai Kiado, Budapest (1988), p. 277).

dried in air at 393 K. The ion exchange levels were determined by using atomic absorption spectroscopy after the samples were dissolved in a HF solution.

The catalytic reaction was carried out in a continuous flow reactor at atmospheric pressure using 1 g of catalysts. The reactants and products were analyzed by gas chromatography connected directly to the reaction apparatus. The flow rates of propene and water vapor were 2.6 and 5.2 $cm^3\ min^{-1}$, or 5.2 and 10.4 $cm^3\ min^{-1}$, respectively. The total flow rate was 30 $cm^3\ min^{-1}$ (N_2 balance).

Results and Discussion

Catalytic Activities of Various Proton-Exchanged Zeolites. An approximately steady formation of 2-propanol was attained within 1 h, and the conversion of propene into 2-propanol changed little with the reaction time. 2-Propanol was the main product during the steady state of all experiments; small amounts of acetone, acetaldehyde, methanol, ethyl methyl ketone, 1-propanol, and 1,5-hexadiene were observed as by-products above 413 K. Hereafter, the conversion to 2-propanol per gram of the catalyst was used as a measure of the catalytic activity. The catalytic activities of various proton-exchanged zeolites for the hydration of propene are summarized in Table 1. All of the proton-exchanged zeolites used were active for a 2-propanol synthesis. The temperature dependence of the activities of HFER-16 is shown in Fig. 1 as an example. At first, the activity increased with an increase in the reaction temperature. The reason for the decline in activities at higher temperature involves a reduction in the equilibrium conversion, indicated by the broken line in Fig. 1. The maximum yield of 2-propanol was achieved at 383—403 K. The best yield (2.2%) was obtained at 383 K upon the HFER-16 zeolite.

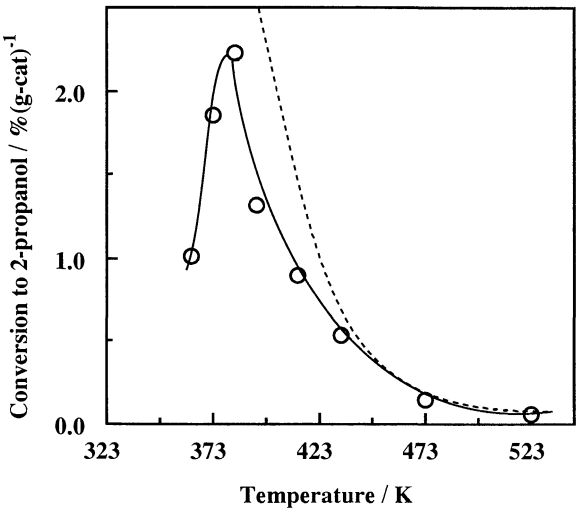

Fig. 1. Temperature dependence of the catalytic activity of HFER-16 for the hydration of propene. Reaction conditions were the same as those in Table 1. The broken line corresponds to the equilibrium conversion.

Figure 2a shows the effect of the Al content on the conversion of propene. Here, conversions at 393 K are plotted, since conversions above 403 K were too close to the equilibrium conversions to compare the activities. A similar tendency was observed when conversions at 373 K were plotted against the Al constents. The optimum SiO_2/Al_2O_3 molar ratio for 2-propanol formation is about 15—16, as shown in Fig. 2a. This value is in agreement with those reported by Fajula et al.[6] as well as ours[3] for the catalytic hydration of 1-butene in an aqueous solution and a gas phase, respectively. It should be noted that the activities of the HY zeolites with

a) Reaction conditions: C_3H_6, 2.6 $cm^3\ min^{-1}$; H_2O, 5.2 $cm^3\ min^{-1}$; N_2, 22.2 $cm^3\ min^{-1}$; catalyst=1.0 g; pressure=1 atm. b) Cited from Ref. 8. c) Cited from G. T. Kokotairo, "Proceedings of the NATO Advanced Study Institute on Zeolites: Sciences and Technology," ed by F. R. Ribeiro, A. E. Rodrigues, L. D. Rollmann, and C. Naccache, Martinus Nijhoff Publishers, Hague (1984), p. 83. The value indicated correspond to the diameter of larger pores if the zeolite has pores with different size. d) Exchange level of H^+. e) Obtained from profiles of temperature programmed desorption of ammonia. The amount and its peak temperature of β-NH_3, which well reflect the number of acid sites and its strength, respectively, as was described previously,[8] were shown. f) Prepared with HNO_3 solution. g) These values are uncertain owing to overlap of α- and β-NH_3 peaks. h) Equilibrium conversion (%).

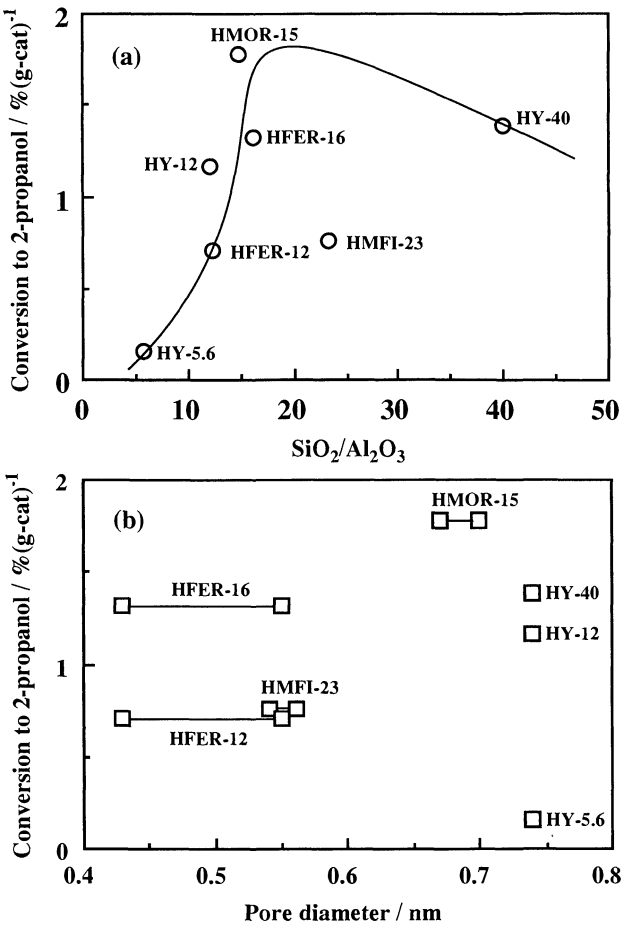

Fig. 2. Effect of Al content (SiO_2/Al_2O_3) (a) and framework (b) of zeolites on the conversion of propene to 2-propanol at 393 K. Reaction conditions were the same as those in Table 1.

various Al contents were much different from one another, as is shown in Fig. 2b. These figures indicate that the activity of the zeolites for the hydration of propene is dependent on their Al contents, not on their framework structure or pore diameter.

Taking into consideration that the hydration of olefins is an acid-catalyzed reaction, a more fruitful approach would be to compare the activity of the zeolites with the number or strength of their acid sites. The correlation between the number of acid sites of proton-exchanged zeolites and the relative catalytic activity for the hydration of propene is depicted in Fig. 3b. The conversion to 2-propanol increased with an increase in the number of acid sites, which is represented in Table 1 by the amount of desorbed β-NH_3. This correlation is in good agreement with those observed in the hydration of ethene[1] (Fig. 3a), 2-methylpropene[3] (Fig. 3c), and 1-butene[3] (Fig. 3d). Although the number and strength of the acid sites on HMFI-23 zeolite have also been measured by the t.p.d method (Table 1), the results for HMFI-23 are not plotted in the figures, since it has been reported that the β-peak temperature is close to the α-peak temperature and that separation is very difficult and ambiguous.

Next, the correlation between the acid strength and the catalytic activity is discussed. As shown in Table 1, the peak temperature of β-NH_3 varied with the zeolites, generally indicating a change in the acid strength of protons, though it has been pointed out that the peak temperature of NH_3 desorption does not always correspond to the true acid strength, but varies with the experimental conditions as well as the amount of NH_3 adsorbed.[9] Fair correlations between the activities for the hydration of propene and the peak temperature of β-NH_3 have been recognized, while a poor correlation was observed in the hydration of ethene; no conclusion was obtained with 2-methylpropene or 1-butene because of the very few plots obtained. No appearance of universality among the correlations suggests that the acid strength is not the primary factor in the hydration of olefins. It follows from Fig. 3 that the acid sites with an acid strength above a certain level would all be effective for the reaction, and that the more important factor for the hydration reaction would be the number of acid sites, compared to the acid strength. This idea is supported by a report that the acidic sites giving a β-peak well correspond to the active sites on proton-exchanged ferrierite in the hydration of ethene.[5]

Propene hydration in this work was carried out at a lower partial pressure of water vapor than those used by Eguchi et al.[4] as well as by Kikuchi et al.[5] If one takes into account that the water vapor decreases the number of strong acid sites (probably due to a decrease in the acid strength[7] or the fact that the adsorption of water inhibits the chemisorption of propene on the acidic site) the higher activity of mordenite over those reported by Eguchi et al.[4] as well as by Kikuchi et al.[5] can be readily understood; further, the hydrophobic properties of the zeolites would not much affect the present conclusion. If hydration is carried out at a higher partial pressure of water vapor, it is probable that the maximum activity is obtained at a higher SiO_2/Al_2O_3 ratio than that given in Fig. 2a, since the hydrophobic properties[10] and strong acid sites[6] of catalysts would be necessary.

Unfortunately, it was very difficult to directly compare the reactivities of olefins over the zeolites, since the equilibrium conversion and the most reactive temperature of each olefin or the most active catalyst for each olefin could not be specified.

Catalytic Activities of Metal Ion-Exchanged Zeolites. It has been reported that the activity for the hydration of ethene was increased by a metal ion exchange,[11] and it may be important to clarify the effect of metal ions on the basis of the recognition of the number of acidic sites as a primary factor which controls the activity under the present experimental conditions. The catalytic activities of metal ion-exchanged zeolites were therefore investigated on an ultrastable Y zeolite (HY-12). The change in the conversion with time was similar to that of

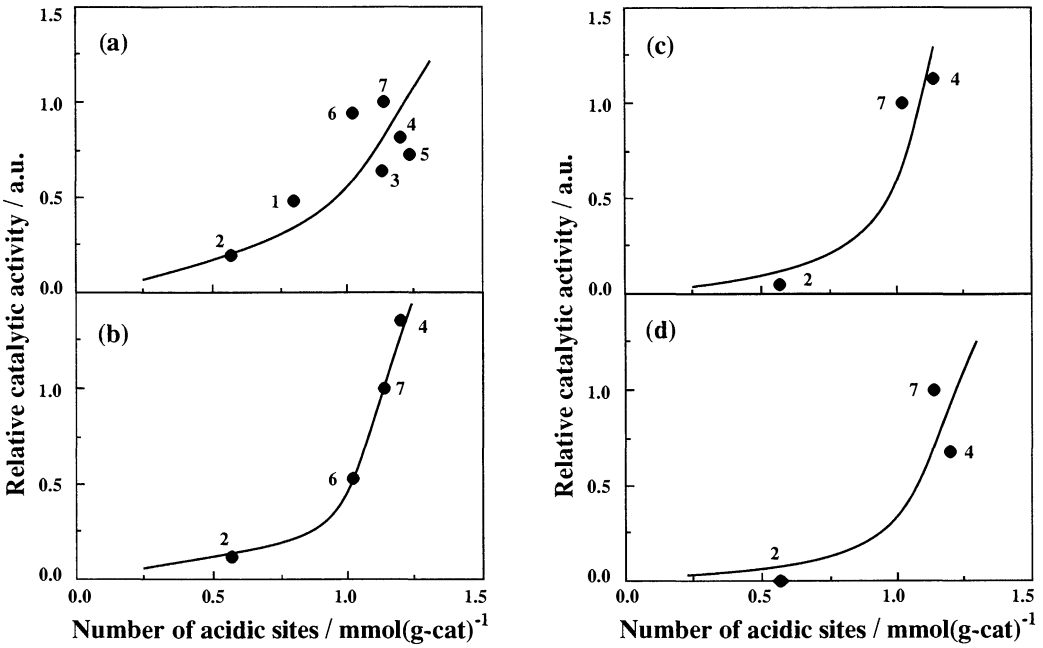

Fig. 3. Correlations between the number of acid sites of proton-exchanged zeolites and the relative catalytic activities for the hydration of ethene (a), propene (b), 2-methylpropene (c), and 1-butene (d). The catalytic activities for the hydration of ethene, 2-methylpropene, and 1-butene are cited from Refs. 1, 3, and 3, respectively. The catalytic activity of HFER-16 was taken as unity. The notations of 1, 2, 3, 4, 5, 6, and 7 in Figs. (a)—(d) correspond to the catalysts of HY-4.8, HY-5.6, HMOR-10, HMOR-15, HMOR-20, HFER-12, and HFER-16, respectively.

Table 2. Conversion of Propene to 2-Propanol over Metal Ion-Exchanged Zeolites at 393 K[a)]

Co^{2+}Y-12	21.7	0.27
Ni^{2+}Y-12	17.5	0.17
Cu^{2+}Y-12	43.0	0.61
Equi. conv./%[b)]		4.44

a) Reaction conditions: C_3H_6, 5.2 cm^3 min^{-1}; H_2O, 10.4 cm^3 min^{-1}; N_2, 11.8 cm^3 min^{-1}; O_2, 2.6 cm^3 min^{-1}; catalyst=1.0 g; pressure=1 atm. b) See Table 1.

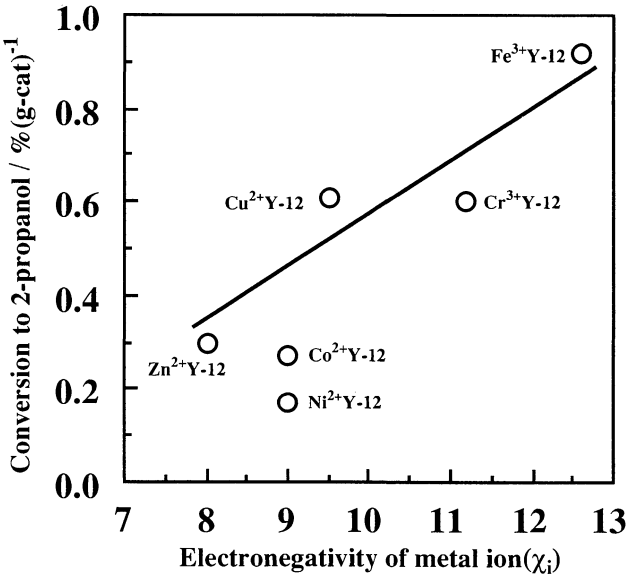

Fig. 4. Correlation between catalytic activities of metal ion-exchanged zeolites and the electronegativities of metal ions (χ_i). χ_i reported by Tanaka et al. (Ref. 12) was used. Reaction conditions were the same as those in Table 2.

the proton-type. The rates and selectivities were little changed by the addition of oxygen to the reactant gas. The results are summarized in Table 2. The conversion was increased by the exchange of transition metal ions at 393 K, but was very low (less than one quarter of equilibrium conversion).

Figure 4 shows the correlation between the conversion to 2-propanol and the electronegativity of metal ions.[13)] The conversion on Fe^{3+}, Cr^{3+}, Zn^{2+} and Cu^{2+} were in the range of 0.28—0.49 mmol g^{-1} while those on Co^{2+} (0.18 mmol g^{-1}) and Ni^{2+} (0.15 mmol g^{-1}) were much lower. A fair correlation was observed and the conversion increased with an increase in the electronegativity. The deviation of the conversions on Co^{2+}Y-12 and Ni^{2+}Y-12 to a lower extent from a linear line is probably due to the lower amounts of metal ions (or lower ion exchange levels) than those of the others. As

discussed in the previous section, the number of active centers is one of the factors which control the activity for the hydration of propene. The linear dependence in Fig. 4 shows that not only the number of acidic sites, but also the electronegativity of metal ions, controls the activity. The role of electronegativity in hydration can be explained as follows. Metal ions with a higher electronegativity would show a greater ability to coordinate olefin and/or water molecules, as has been reported for an A-type zeolite by Tanabe at al.[11] This ability may result in the higher catalytic activity.

Thus, all findings in the present work lead to the conclusion that the hydration of propene over proton-exchanged zeolites proceeds on a Brønsted acid site, and that the catalytic activity of zeolites is not influenced by the framework structure, but shows a volcano-shaped dependence on the Al content. Further, the activity of the Y-type zeolite was increased by a transition metal ion exchange.

Entropy Change Associated with the Charge Transfer Reation of Various Quinones in Aprotic Solvents

Kenji KOMAGUCHI, Yasuhiro HATSUSEGAWA, Akira KITANI, and Kazuo SASAKI*
Department of Applied Chemistry, Hiroshima University, Kagamiyama, Higashi-Hiroshima 724
(Received March 18, 1991)

Temperature dependence of the cathodic reduction potentials of various *p*-benzoquinone derivatives have been determined in five aprotic solvents, benzonitrile, acetonitrile, propylene carbonate, *N*,*N*-dimethylformamide, and dimethyl sulfoxide. As for the first electron transfer reactions, the free energy of transfer between any two of solvents has been found to be less than 1.0 kcal mol^{-1}, which is much smaller than the solvation enthalpy of ordinary anions. As a result, the transfer entropy is compensated almost perfectly by the transfer enthalpy. The compensation effect also appears in the transfer energies of the second electron transfer reaction though not perfect.

In the previous paper,[1] we have stated that the free energy of transfer of quinone/quinone anion radical systems in several aprotic solvents is negligibly small. This statement was derived from the experimental fact that the first electrode potential ($E_1°$) of various quinones determined in a solvent M, aligns on a straight line of unit slope when they are plotted against those determined in another solvent N.

The fact is expressed as the following equation,

$$E_1°(\mathrm{i,M}) = E_1°(\mathrm{i,N}) + \mathrm{const.} \quad (1)$$

where i expresses individual substrate and M and N specify two different solvents. Eq. 1 is of course an empirical equation and $E°$ values are apparent ones. Formally speaking, however, the equation should also hold for the absolute potentials though their numerical values are unknown.

$$E_1°(\mathrm{i,M})_{abs} = E_1°(\mathrm{i,N})_{abs} + K \quad (2)$$

Our conclusion was that K appearing in Eq. 2 is very small and is within the experimental uncertainty. In this paper, we will add a quantitative base for the above conclusion by analyzing the entropy change in the redox reaction of various quinone derivatives.

The entropy change associated with the electrode reactions of aromatic compounds has been studied extensively by Svaan and Parker[2] and more recently by Jaworsky[3,4] and also by Nagaoka et al.[5] Entropy change of various quinone derivatives in the gas phase electron attachment is discussed by Heinis et al.[6]

Experimental

A nonisothermal cell arrangement[2,3] was used for determining the temperature coefficient of electrode potentials. In one compartment of the cell, the temperature of which was varied in the range of 10—50 °C at a step of 10 °C, a set of test electrodes were placed. The other compartment, in which a reference electrode was placed, was kept at a fixed temperature (25±0.1 °C) and the temperature gradient was set up over the length of a liquid bridge connecting the two compartments. Potential sweep technique (sweep rate : 0.1 V s^{-1}) was employed for the potential determination at various temperatures. The potential values were determined as the mean of cathodic peak potential and its anodic counterpart. Test solutions contained 0.1 mol dm^{-3} Et_4NClO_4 and 5×10^{-3} mol dm^{-3} of a given substrate. The working electrode was a Pt wire (0.5 mm in diameter and 0.5 cm in length) and the counter electrodes was a Pt plate. The reference electrodes used were low-chloride calomel electrodes whose potentials are dependent on the perchlorate concentration.[7] These electrodes were prepared individually for each solvent system using the respective solvent.

Since all solvents studied are hygroscopic in nature and moistening of the test solution affected strongly the measurement, a special caution was necessary for avoiding the moistening. All the solvents used were dehydrated with CaH_2 or molecular sieves overnight and distilled just before use. Water content was checked by gas chromatography to be less than the limit of detection (8×10^{-4} mol dm^{-3}). The measurements carried out in the course of ascending temperature were repeated in the reverse course of descending temperature so as to confirm the agreement of the two values. The temperature coefficient thus determined has an uncertainty of ±0.02 mV K^{-1}.

Results and Discussion

The temperature coefficients of electrode potentials as well as derived values of entropy change for both the first and second electron transfer reactions of 13 quinones in 5 aprotic solvents are compiled in Table 1. Jaworski's data[4] are also listed for reference. It is evident that our data are always smaller than his by a factor of 2 to 4. We cannont understand why such big differences appeared. Thermal diffusion of silver ion, which was used by him as the potential reference, might be the source of the discrepancy. Enthalpy data were calculated by assuming zero free energy change for the reaction of *p*-benzoquinone **1** in every solvent studied.[8]

Before discussing the nature of the present data, it will be worthwhile to check the reliability of our measurements. Svaan and Parker,[2] who studied the problem with various types of compounds, reported that $\Delta S_1°$ values of dinitrobenzenes ranged from −5.05 (1,4-dinitrobenzene, $T\Delta S_1° = -1.50$ kcal mol^{-1}; 1 cal=4.184 J) to −9.41 e.u. (2,5-dimethyl-1,3-dinitrobenzene, $T\Delta S_1° = -2.80$ kcal mol^{-1}). Our values for various

quinones are very close to those of dinitrobenzenes. On the other hand, Jaworski's values are very large and almost near our $\Delta S_2°$ vlaues.

The entropy change associated with the charge transfer reaction is mostly determined from the potential difference in a nonisothermal cell. It should be noted that such a measurement unavoidably involves irreversible entropy production intrinsic to the transport phenomena, heat flow and Soret effect.[9] Fortunately, de Bethune[10] showed that, if the potential determining electrode reactions are regarded as reversible, the irreversible entropy productions can be ignored and the standard entropy change can be safely determined. Actually, however, it is also true that many organic compounds do not behave reversibly at electrodes. Quinones are no exception. This is particularly true for the second electron transfer reaction between anion radicals and their dianions as has been described in the previous paper. Accordingly, our attention will mainly be focused on the first electron transfer reactions.

As are seen in Table 1, the variation of $-T\Delta S_1°$ of each individual substrate makes it rather complicated to find some systematic correlation with their molecular characteristics. A notable thing appearing in this table is that there are some compounds which have a positive entropy value. The entropy change for gaseous electron attachment reaction of various quinones have been reported by Heinis et al.[6] According to them, the values are all negative irrespective of the nature of substituents. It is interesting to note that the positive values in Table 1 always appear in the reaction of chlorinated compounds.[11] We have mentioned[1] that there is a significant contrast between the solvation behavior of chlorinated and nonchlorinated compounds. Heinis et al. also noticed a similar substituent effect of Cl in the correlation between electron affinity and electrode potential.[6] To the extension that the solvent is considered as a dielectric continuum, the entropy change should have a negative value. Since the reaction

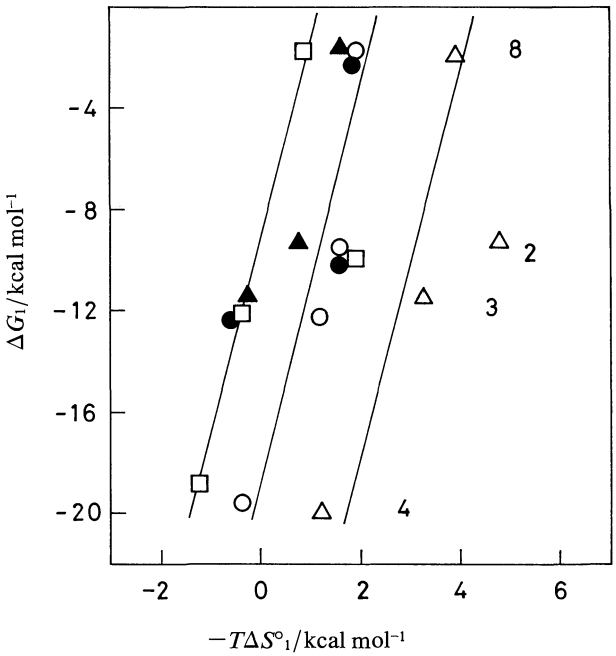

Fig. 1. Entropy change in the first electron transfer reaction of chlorinated compounds. ΔG_1's are relative values referred to 1,4-benzoquinone. Numerical figures indicate compound number given on the margin of Table 1. Symbols specify solvents used. △: BN, □: PC, ○: AN, ●: DMF, ▲: DMSO.

entropy reflects the difference in the structure ordering around the product and reactant, a positive entropy change will indicate that the degree of order is higher with the neutral reactant molecule than that of the charged product. This point is worthy of a more detailed analysis in future studies. Regarding this, there is another point to be noted, though qualitative, that variation of $T\Delta S_1°$ of chlorinated compounds in a given solvent seems to be discriminated from other nonchlorinated compounds. As is seen in Fig. 1, $-T\Delta S_1°$ of chlorinated compounds in a given solvent (solvent is

specified by different symbols), increases with decreasing number of chlorine (or cyano group) substitution; **4>3>2>8**. In addition, if we ignore the point for **4** in DMF, which has an anomalously large positive value and is omitted from the figure, $T\Delta S_1°$ seems to be roughly proportional to ΔG_1.[8] On the other hand, no such simple correlation seems to exist in nonchlorinated compounds. Qualitatively, irrespective of the nature of substrates, $-T\Delta S_1°$ in DMF (●) and DMSO (▲) exhibit smaller values than those in other solvents, particularly in BN (△). Regarding this, it will be worth noting the work of Hupp and Weaver,[12] who studied the entropy change in the redox system of some coordinated transition metal compounds. They showed that, in accordance with the simple Born equation, the reaction entropy changes linearly with the reciprocal of ionic radius. In the present case, however, no such a simple correlation was observed and the entropy change seems to be insensitive to the size of substrate studied.[13] The

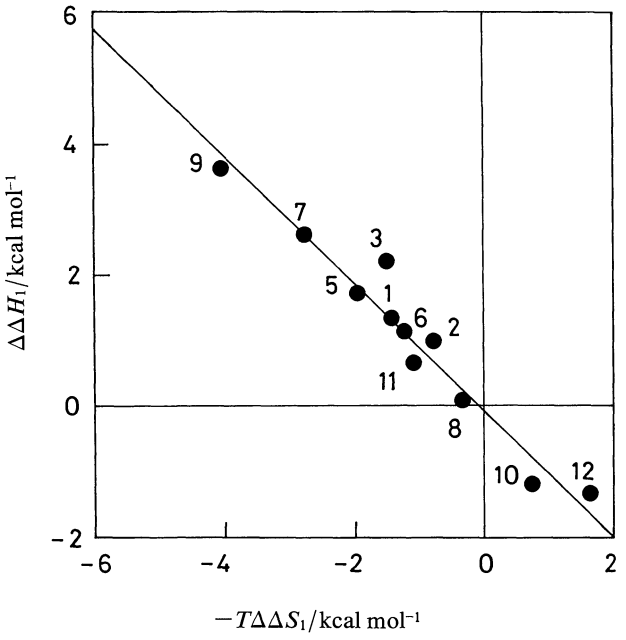

Fig. 2. Correlation between two transfer energies of the first electron transfer reaction transferred from AN to DMSO.

different size dependence appeared in transition metals and quinone systems may be attributed to the difference in the surrounding conditions of charge in molecule. In case of metal complexes, the charge of the central metal ion is separated by ligands from the surrounding solvent molecules and the polarizing force will be directly affected by the size of ligands. On the other hand, in the case of quinone anion radical, most of the negative charge is localized on carbonyl oxygen and the charge density at oxygen will be independent of the size of aromatic ring. The solvation at carbonyl oxygen mainly contributes to entropy change and relatively small size effect would be expected for quinone systems. The spherical symmetry of the metal complexes and planer structure of the quinones should also be accounted for.

Although individual values of $T\Delta S_1°$ vary in a rather complicated fashion, we can find a very simple rule for the transfer entropies, i.e., the difference in two different solvents. A typical example is shown in Fig. 2, where the transfer entropy, $-T\Delta\Delta S_1°$ from AN to DMSO is plotted against the corresponding transfer enthalpy, $\Delta\Delta H_1$.[8] One can readily see that a compensation effect exists between two energies, $T\Delta\Delta S_1°$ and $\Delta\Delta H_1$, for the transfer process concerned. More or less similar correlations were found for every combination of two solvents. Since the compensation between $T\Delta\Delta S_1°$ and $\Delta\Delta H_1$ arises when the free energy of transfer is almost null, the results obtained here provide a strong support to our previous conclusion.

The compensation effect can be analyzed in a little more detail. Table 2, which lists the least square parameters in the following equation, was prepared for this purpose.

$$T\Delta\Delta S_1° = a\Delta\Delta H_1 + b$$

Generally speaking, when the compensation is perfect and the potential of the reference electrode is invariable throughout the different solvents studied, the slope "a" should be unity and the intersect "b" must be zero. If, on the other hand, the transfer free energy is not zero but is a constant, b will have a finite value. Of course, the potential of the reference electrode cannot be regarded to be invariable because the perchlorate activity will vary slightly from solvent to solvent. According to Parker,[14]

Table 2. Parameters Appearing in the Compensation Equation,[8] $T\Delta\Delta S_1° = a\Delta\Delta H_1 + b$

Solvent couple from	Solvent couple to	a/kcal mol^{-1}	b/kcal mol^{-1}	Correlation coefficient
AN	BN	0.94±0.09	0.54±0.15	0.954
PC	BN	0.83±0.10	0.72±0.23	0.943

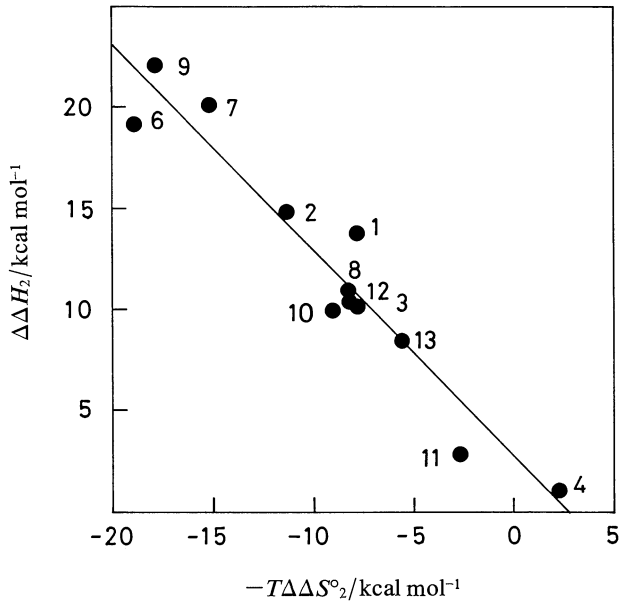

Fig. 3. Correlation between two transfer energies of the second electron transfer reaction transferred from BN to DMF.

the activity coefficient of perchlorate anion changes from −0.3 in DMSO to −0.4 in DMF. The resultant variation of the electrode potential is less than 1 mV(0.02 kcal mol^{-1}). The largest value of b in Table 2 is 1.01±0.3 kcal mol^{-1} for the transfer process from DMSO to BN. It should be noted in the first place that an enthalpy change of 1.0 kcal mol^{-1} is much smaller than the solvation enthalpy of typical anions (65 to 115 kcal mol^{-1} for I^- to F^-)[15] and is still of the order of the experimental uncertainty, which is estimated to be less than 0.3 kcal mol^{-1}.

It is interesting to note that, however, the b values seem to vary rather systematically according to the order of solvation energies observed previously for the second electrode potential, ($E_2°$): DMSO-DMF>PC>AN>BN. Final conclusions on this matter can thus be summarized as follows.

1. The free energy of transfer of the quinone/quinone anion radical system among several aprotic solvents studied here does not exceed 1.01±0.3 kcal mol^{-1} and is almost negligible.

2. There is a possibility that a very small solvent effect yet exists, however, within the limit of 1.0 kcal mol^{-1}.

A similar compensation effect can also be found in the second electron transfer reactions as is shown in Fig. 3. Except for the solvent combination of PC and DMF, we can find a fairly good linear correlation between $\Delta\Delta H_2$ and $T\Delta\Delta S_2°$ suggesting that the two transfer energies, $T\Delta\Delta S_2°$ and $\Delta\Delta H_2$, are largely though not perfectly compensating each other. As for the second electron transfer reactions, scattering of data is enhanced and it seems difficult to draw meaningful correlations.

The authors are grateful to Mr. Yasushi Ohsaki, Mr. Masahiro Ohura, and Mr. Tomoyuki Kashimura for their preliminary work of this research.

8) It should be noted that the entropy values here discussing are the absolute ones while those of ΔG and ΔH are relative values determined on the arbitrary assumption : ΔG_1 for the reaction of *p*-benzoquinone is always zero irrespective of solvent. As a result, ΔH values in Table 1 involve a constant difference from the absolute values. The assumption, however, does not contain any drawback since we are discussing the difference of two ΔH values ($\Delta\Delta H$).

Mixed Adsorbed Film and Micelles of Sodium Taurocholate and Sodium Taurodeoxycholate

Atsunori WADA, Norihiro MATUBAYASI,* and Kinsi MOTOMURA†
Faculty of Fisheries, Nagasaki University, 1-14 bunkyoumachi, Nagasaki 852
† Department of Chemistry, Faculty of Science, Kyushu University 33, Fukuoka 812
(Received April 8, 1991)

The surface tension of an aqueous mixture of sodium taurocholate (NaTC) and sodium taurodeoxycholate (NaTDC) in the presence of 0.1 mol kg^{-1} sodium chloride was measured as a function of the total concentration and composition of the bile salts at 25 °C. The result, processed by a thermodynamic treatment based on excess thermodynamic quantities, showed that NaTC and NaTDC are freely miscible in an adsorbed film, while mixing in a limited composition region of the micelle.

The sterol nucleus constitutes a hydrophobic group of a variety of surfactants having a biological origin. In our previous papers we have shown the strong lateral attractive force of the sterol nucleus and how it mixes with a hydrocarbon chain in a mixed adsorbed film.[1-3] Sodium taurocholate (NaTC) and sodium taurodeoxycholate (NaTDC) are typical surfactants which have the sterol nucleus as a hydrophobic group, and in which the hydrophobic property is changed accounting to the number of hydroxyl groups. For NaTDC, dihydoxy bile salt, the characteristic behavior (such as their small aggregation number and unusual shapes of the micelle) have been shown.[4-6] For NaTC, trihydoxy bile salt, the critical formation of a micelle has been questioned because of its broad critical concentration region.[4-8]

In order to understand the properties of bile salts better, such as micelle formation and lateral interaction arising from the difference in the number of hydroxyl groups, we have chosen an NaTC–NaTDC mixed system in an aqueous solution with 0.1 mol kg^{-1} sodium chloride added. This mixed system is suitable for differentiating between trihydoxy and dihydoxy bile salts, since NaTC and NaTDC have chemically the same structure, except for their 7 position. We have measured the surface tension of the aqueous mixtures as a function of the concentration and composition of bile salts at 25 °C. It has been shown that the thermodynamic properties of synthetic surfactants in micelles are quite similar to that in an adsorbed film.[9-11] A thermodynamic treatment seems to be applicable to the NaTC–NaTDC system, although the micelle structure of the bile salts is very different from that of synthetic surfactants. Special interest is put on the relation of the compositions between the bulk, the adsorbed film, and the micelle. We hope to demonstrate some of the characteristics of the lateral interaction of bile salts in the micelle and the adsorbed film using thermodynamic analysis.

Materials and Method

Sodium taurocholate (NaTC) and sodium taurodeoxycholate (NaTDC) were purchased from Sigma Chem. Co. and used without purification. As shown in the result section, the measured surface tension vs. concentration curves for NaTDC and their mixtures show no minimum around their critical micell concentration (cmc). Aqueous solutions of bile salts were prepared with a 0.1 mol kg^{-1} sodium chloride solution. Sodium chloride was used as received, and water was twice distilled from an alkaline permanganate solution. The surface tension was measured by a drop volume technique, described elsewhere.[12] The drop was permitted to stand for 15 min in order to confirm the adsorption equilibrium.

Result

Mixed Adsorbed Film of NaTC and NaTDC. In order to analyze the mixed adsorbed film of NaTC and NaTDC, we measured the surface tension of aqueous solutions of the mixture as a function of the total concentration of bile salts (m_t) in a molality scale defined by

$$m_t = m_1 + m_2. \tag{1}$$

The composition of the bile salts (X_2^W) was defined as

$$X_2^W = m_2/m_t \tag{2}$$

at constant pressure and temperature, 25 °C.[13] Here, subscripts 1 and 2 refer to NaTC and NaTDC, respectively, and superscript W refer the aqueous phase. The results are shown in Fig. 1. The surface tension decreases steeply with increasing total concentration, representing the high surface activity of bile salts.

In the solution measured, the ith salts completely dissociated into $\nu_{i,k}$ k-ions. Then, the variation of the surface tension (γ) at constant temperature and pressure is given as[9-14]

$$d\gamma = -\sum_k \sum_i \nu_{i,k} \Gamma_k^H d\mu_k, \tag{3}$$

where Γ_k^H and μ_k refer to the surface densities and chemical potential of the kth ions. Subscript i counts for NaTC, NaTDC, and NaCl, respectively, and k counts for taurocholate anion (TC), taurodeoxycholate anion (TDC), Cl^-, and Na^+, respectively. In the present system all ions behave almost ideally up to the cmc,[6] the chemical potential of ion k is thus given as

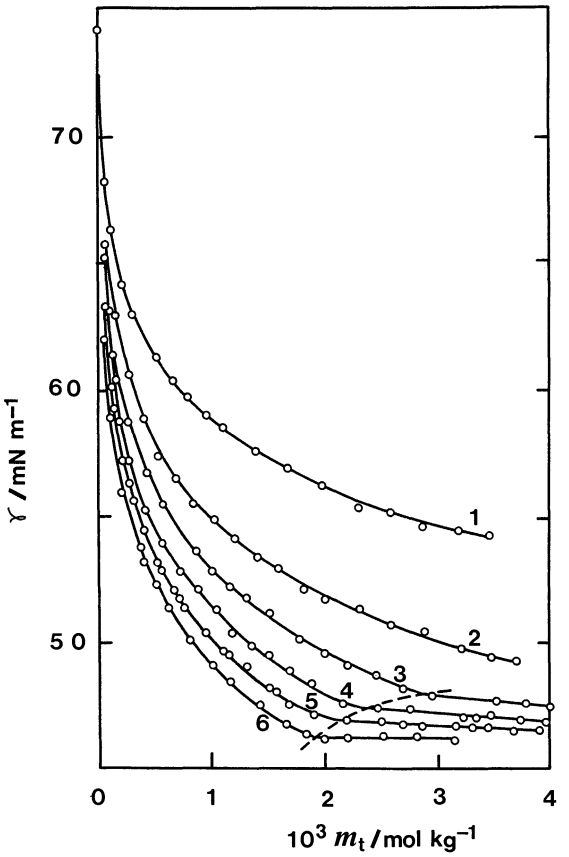

Fig. 1. Surface tension vs. concentration curves of NaTC–NaTDC mixed system in 0.1 mol kg^{-1} sodium chloride aqueous solution at constant composition: (1) X_2^W=0.0; (2) 0.2; (3) 0.4; (4) 0.6; (5) 0.8; (6) 1.0. The dotted line connects the cmc.

$$\mu_k = \mu_k^\circ(T,p) + RT\ln\sum_i \nu_{i,k}\, m_i. \tag{4}$$

Rearranging of Eq. 3 using Eqs. 1, 2, and 4 leads to

$$d\gamma = -RT\left(\frac{\Gamma_t^H}{m_t} + \frac{\Gamma_t^H}{m_t+m_3} + \frac{\Gamma_{Cl}^H}{m_t+m_3}\right) dm_t - RT\left(\frac{\Gamma_2^H}{X_2^W} - \frac{\Gamma_1^H}{X_1^W}\right) dX_2^W, \tag{5}$$

where subscript 3 refers the added NaCl and Γ_t^H refers to the total interfacial density defined as

$$\Gamma_t^H = \Gamma_1^H + \Gamma_2^H. \tag{6}$$

Taking into account the fact that Γ_{Cl}^H is smaller than Γ_t^H as well as the high concentration of NaCl, the third term within the first brackets in Eq. 5 is negligible compared to the other terms. Then, the Γ_t^H and the composition of the adsorbed film (X_2^H) are evaluated, respectively, using the relations

$$\Gamma_t^H = -\frac{m_t(m_t+m_3)}{RT(2m_t+m_3)}\left(\frac{\partial\gamma}{\partial m_t}\right)_{T,p,X_2^W}, \tag{7}$$

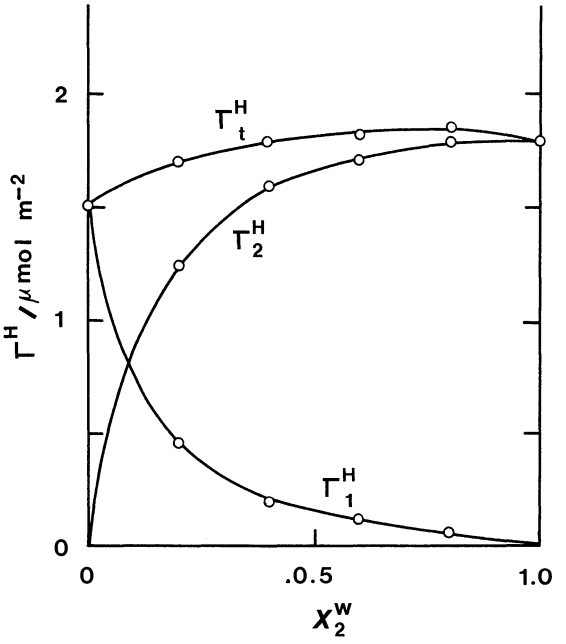

Fig. 2. Surface density vs. composition curves at constant total concentration of 1.0×10^{-3} mol kg^{-1}.

$$X_2^H = X_2^W - (X_1^W X_2^W/RT\Gamma_t^H)(\partial\gamma/\partial X_2^W)_{T,p,m_t}, \tag{8}$$

and

$$X_2^H = X_2^W - [1/m_t + 1/(m_t+m_3)]X_1^W X_2^W \times (\partial m_t/\partial X_2^W)_{T,p,\gamma}. \tag{9}$$

The adsorption isotherms for both bile salts rise sharply at low concentrations and almost reach a plateau over a total concentration of about 0.5×10^{-3} mol kg^{-1}. In Fig. 2, the evaluated total surface density is plotted against the bulk composition at a total concentration of 1×10^{-3} mol kg^{-1}. Here, the total surface density shows increases in going from pure TC and a plateau in going to pure TDC over an X_2^W of about 0.4. Applying Eqs. 8 and 9 for graphs of m_t vs. X_2^W at constant γ and γ vs. X_2^W at constant m_t (obtained from the Fig. 1), the values of the composition in a mixed adsorbed film were calculated and plotted against the bulk composition at a constant surface tension value of 55 mN m^{-1} (Fig. 3). It can be seen that the composition in the adsorbed film lies close to TDC compared with that of a bulk solution. Using this value, the surface densities of TC and TDC are also plotted in Fig. 2. The surface density of TC drops steeply, while that of TDC increases rapidly with increasing X_2^W. These results agree well with previous work in that the adsorbed mixed film is enriched by the component which shows a stronger cohesive interaction in the film.[2,3,12,13]

The interaction in the mixed film can easily be seen in a plot of the mean area per molecule (A) (A=1/$N_A\Gamma_t^H$, where N_A is the Avogadro's number) against the com-

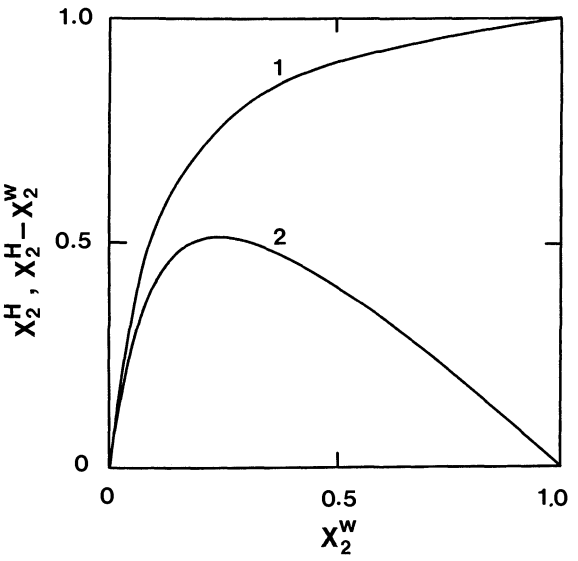

Fig. 3. Relation between compositions in the adsorbed film and aqueous solution in equilibrium at constant surface tension of 55 mN m^{-1}: (1) X_2^H vs. X_2^W; (2) $X_2^H - X_2^W$ vs. X_2^W.

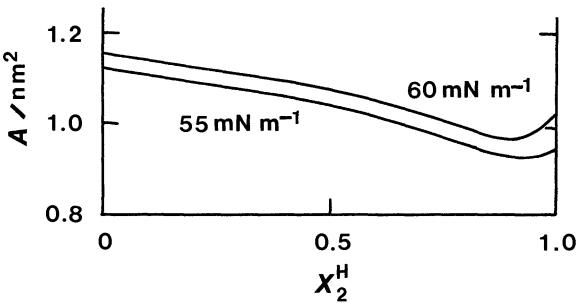

Fig. 4. Mean area occupied per molecule vs. composition in the adsorbed film curves at constant surface tension values.

position of the mixed film, as shown in Fig. 4. In the TC-rich region the mean area shows almost ideal mixing, while a slight attractive interaction in the TDC-rich region can be seen.

Mixed Micelle of NaTC and NaTDC. In order to obtain the cmc of a mixture of NaTC and NaTDC, the surface tension of the aqueous mixtures was measured at a high total concentration under a fixed NaCl concentration of 0.1 mol kg^{-1} at 25 °C. For NaTDC the slope of the plot changes markedly at 1.89×10^{-3} mol kg^{-1}. Above this concentration the surface tension remains constant, giving evidence that the aggregation number is sufficiently large to determine the cmc by surface tension measurements. The value of the cmc agrees well with the interpolated value from emf measurements in several added NaCl concentrations reported by Ryu et al.[6] For NaTC the surface tension gradually decreases with m_t over the entire concentration range measured. For mixtures, there are sharp breaks

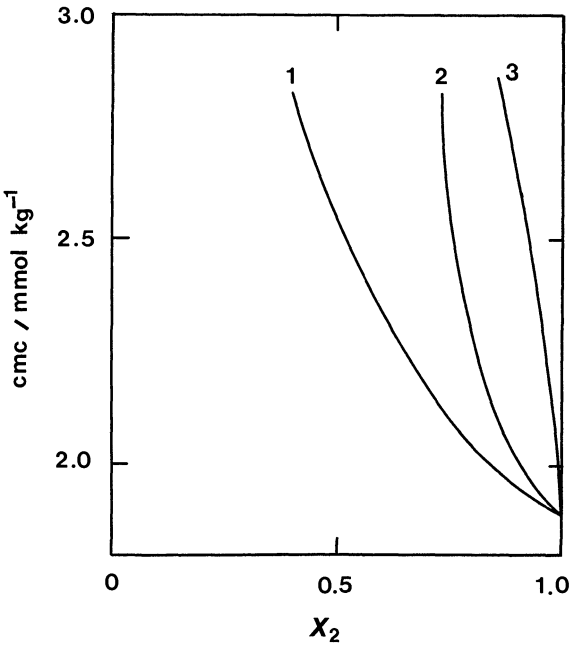

Fig. 5. Critical micelle concentration vs. composition curves. (1) cmc vs. X_2^W; (2) cmc vs. X_2^M; (3) cmc vs. $X_2^{H,cmc}$.

in the plots, except for X_2^W=0.2. However, the changes of the slopes at the break points become less sharp in going to pure TC, and at concentrations above the break point the surface tension gradually decreases with increasing concentration. We can assume that the aggregations which can be designated as micellization occur at these break points, since the curve connecting these break points is monotonous. The cmc's, thus obtained, are plotted against X_2^W in Fig. 5. It is important to note that the cmc depends strongly on the bulk composition and is difficult to extrapolate to the pure NaTC axis, indicating that a pure NaTC micelle can not be formed in a moderate concentration region.

By a thermodynamic treatment based on the excess thermodynamic quantities, similar to those used for the adsorbed film, the Gibbs–Duhem equation of the mixed micelle is given as[15]

$$\sum_k \sum_i \nu_{i,k} N_k^M d\mu_k = 0. \quad (10)$$

Denoting the composition of a mixed micelle by X_2^M ($X_2^M = N_1 + N_2$, where N is the number of k-ions in a mixed micelle) and using Eqs. 4 and 10 yields

$$X_2^M = X_2^W - X_1^W X_2^W [1/\text{cmc} + 1/(\text{cmc} + m_3)] \times (\partial \text{cmc}/\partial X_2^W)_{T,p}, \quad (11)$$

where assumptions that the condition of electroneutrality holds for a micelle, the solution can be treated ideally, and N_{Cl^-}/N_t smaller than unity are achieved.[15] Applying this relation to the curve in Fig. 5, the composition of a micelle at the cmc is shown as cmc vs.

X_2^M plots in Fig. 5. The composition in an adsorbed mixed film at cmc is calculated by the following equation[11] (and plotted in Fig. 5):

$$X_2^{H,cmc} = X_2^M - (X_1^W X_2^W / RT\Gamma_t^{H,cmc})(\partial\gamma^{cmc}/\partial X_2^W)_{T,p}. \quad (12)$$

If the aggregation numbers of bile salts are as small as dimers or trimers, a thermodynamic treatment for micelles based on excess thermodynamic quantities is not applicable. The experimental result is that the surface tension vs. concentration curve of pure NaTDC gives constant values after cmc. This confirms an aggregation number which is sufficiently large for a thermodynamic treatment. Furthermore, the evaluated values of the composition in the adsorbed film at the cmc's using Eq. 12 agree well with the values obtained from Eq. 7. These results demonstrate that micelles composed of bile salts can be adequately treated by the thermodynamic treatment employed here, although the treatment assumes a hypothetical dividing surface in the micelle.

Discussion

TC and TDC have the same chemical structure, except for a hydroxyl group in the TC 7 position of the cholanic acid residue. The number of hydroxyl groups results in the difference in their aggregation behavior. It has been shown that TDC forms a micelle while TC does not in a moderate concentration region.[4-6] This behavior is clearly shown in the cmc vs. X_2^W graph shown in Fig. 5. For mixtures, the cmc's were observed above about X_2^W=0.2. Even at such a low composition of TDC in solution the calculated composition in the mixed micelles shows a value of nearly 0.8; the cmc vs. X_2^M curve shows an almost vertical change at that composition, indicating a solubility limit of TC in the TDC micelle.

For synthetic surfactants it has been shown that the molecular interaction in a micelle is quite similar to that in an adsorbed film.[11] For bile salts we can also assume that the molecular interaction in micelles is basically the same as that in the adsorbed film, even though the size and structure of bile salt micelles are unlike that of synthetic surfactants.[15] In the adsorbed film TC and TDC shows a slight attractive interaction, as shown in the A vs. X_2^H relations. This result indicates that TC and TDC will attract each other and mix freely in their micelles. However, there is a significant difference in the compositions of the adsorbed film and micelle. A deviation of the compositions from that of a bulk solution is a useful indication of the geometrical packing factor in the micelle, since the interactions between monomeric bile salts in a bulk solution are negligible. In studies of a series of alkyl ammonium salt mixtures,[11,17,18] differences have been clearly shown among compositions of the solution, the adsorbed film, and the micelle arising from the chemical structure of the surfactants and the micelle. For the decylammonium bromide–decylammonium chloride (DeAC) system,[17] in which the difference is their counter ions, both salts mix ideally and the X_2^W, $X_2^{H,cmc}$, and X_2^M have almost the same values, even though they differ significantly due to differences in their cmc's and in the surface tension values at the cmc of pure salts. For the dodecylammonium chloride (DAC)–DeAC system,[11] the $X_2^{H,cmc}$ and X_2^M lie close to TDC and $X_2^{H,cmc}$ is slightly larger than the X_2^M, indicating that the stronger cohesive interaction is weakened at the curved interface. On the other hand, the cone-shaped dodecyltrimethylammonium chloride (DTAC) aggregates into a micelle rather than into an adsored film. For the DeAC–DTAC system,[18] X_2^M shows a remarkably larger value than does $X_2^{H,cmc}$.

Together with these findings, the relation among the compositions of the NaTC–NaTDC system indicates that the structure of the bile salt micelle is very different from that of the plane interface; the stronger cohesive force of NaTDC is weakened appreciably in the micelle due to the geometry of the mixed micelle.

Solvatochromic Shift of Aromatic Ketyl Anions due to Hydrogen Bonding

Tsuneki ICHIKAWA,* Ken-ichi UEDA, and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Sapporo 060
(Received April 20, 1991)

The electronic spectra of fluorenone radical anions generated by γ-irradiation at 77 K in glassy matrices of ethanol and ethanol–2-methyltetrahydrofuran mixtures have been measured for elucidating the mechanism of the spectral change due to solvation of the radical anions by alcohols. Three kinds of the radical anions are generated in the mixed solvent: the radical anions without hydrogen bond ($\varepsilon = 1.05\times10^4$ dm^3 mol^{-1} cm^{-1} at λ_{max}=568 nm), with one ethanol molecule ($\varepsilon = 0.67\times10^4$ dm^3 mol^{-1} cm^{-1} at λ_{max}=529 nm) and two ethanol molecules ($\varepsilon = 0.37\times10^4$ dm^3 mol^{-1} cm^{-1} at λ_{max}=448 nm) hydrogen-bonded through the π electron on the carbonyl oxygen. The spectral shift and the decrease of the molar extinction coefficient of aromatic ketyl radical anions are explained as due to the stabilization of a carbonyl antibonding π orbital by hydrogen bonding.

One of the powerful methods for studying solvation dynamics is the pulse radiolysis technique. In this method solute molecules are first generated by irradiation of a solution with a pulsed ionizing radiation, and the spectral change of the solute due to solvation are detected using a fast optical detection system.[1] However the technique is not always suitable for studying the solvation structure, because the spectral resolution of the detection system is not necessarily high enough for discriminating the solutes with different solvation structures.

The solvation dynamics of benzophenone radical anions in alcohols have been extensively studied by using the pulse radiolysis technique,[2-6] since solvation of the radical anions entails exceptionally large spectral shift. In these studies the spectral shift was attributed to electrostatic effects induced by the reorientation of solvent dipoles. On the other hand, Shida et al. attributed the spectral shift to hydrogen bonding between the anion radical and alcohol. They measured absorption spectra of benzophenone radical anions in γ-irradiated matrices at 77 K, and found the absorption maximum at 630 nm in ethanol matrix but at 800 nm in aprotic matrices.[7,8] Hoshino et al. measured transient absorption spectra of several aromatic ketyl radical anions in alcohols and found a gradual blue shift of the absorption maxima except for the fluorenone radical anion.[9] They claimed that the spectral shift was not due to hydrogen bonding but to reorientation of solvent dipoles. They considered that the neutral aromatic ketones had already been hydrogen-bonded to alcohols.[10] However, it was suggested later that the hydrogen bond could be formed through the out-of-plane π electron of the radical anion.[11,12] We recently studied in detail the solvation of benzophenone radical anion in γ-irradiated ethanol–2-methyltetrahydrofuran mixtures at cryogenic temperatures and concluded that the spectral shift is due to hydrogen bonding between the radical anion and ethanol.[13] The out-of-plane π electron localized mainly on the carbonyl oxygen is invoked for the bond. The preexisting in-plane hydrogen bond between the neutral aromatic ketone and alcohol is considered not to affect the absorption spectrum due to π–π transitions.

Although the molecular structure of fluorenone is similar to that of benzophenone, Hoshino et al. failed to detect the spectral shift of the former radical anion by solvation. On the other hand, Shida et al. observed the solvent dependency of the absorption spectrum and proposed that the hydrogen bonding with one and two alcohol molecules is responsible for the apparently complex spectra of the fluorenone radical anion in alcoholic matrices.[11,12,14]

In the present study the electronic spectra of the fluorenone radical anion in γ-irradiated ethanol–2-methyltetrahydrofuran mixtures have been measured at 77 K to elucidate the nature of the solvation process. A molecular orbital explanation is given for the spectra change of aromatic ketyl radical anions due to the formation of hydrogen bond.

Experimental

Ethanol (Wako Pure Chemical Co.; >99.5%) was used without further purification. 2-Methyltetrahydrofuran (MTHF) was used after purification with usual procedures.[3] The volume fractions of ethanol in the ethanol–MTHF mixture were 0, 0.25, 0.5, and 1 at 293 K. The solutions containing 0.04 mol dm^{-3} of fluorenone were degassed by several freeze-pump-thaw cycles and then sealed in high-purity quartz cells with an optical path length of 0.2 cm. The samples were then immersed in liquid nitrogen to produce crack-free glass matrices.

The samples were irradiated at 77 K with ^{60}Co γ-rays to a dose of 2.2 kGy to generate the fluorenone radical anion by the following reactions,

$$S\wwwwwr S^+ + e^-,\quad e^- + Fl \longrightarrow Fl^-,$$

where S and Fl denote the solvent and fluorenone molecules, respectively. The absorption spectra were measured at 77 K on a Shimadzu MPS-5000 spectrophotometer equipped with a cryostat for optical measurements. The concentration of the radical anion was calculated from the absorbed dose using the yields of 2.35 and 2.55 scavengeable electrons per 100 eV absorbed by ethanol and MTHF, respectively.[8] The yield for the mixed matrices was assumed to be proportional to the composition of the solvent molecules.

Results

Figure 1 shows the absorption spectra of fluorenone radical anion in neat MTHF, neat ethanol, and in the equivolume mixture of MTHF and ethanol. The radical anion in neat MTHF showed an absorption maximum at 568 nm with the molar extinction coefficient of 1.05×10^4 dm^3 mol^{-1} cm^{-1}. In neat ethanol, the absorption maximum was shifted to 448 nm. The hatched part of the spectrum in Fig. 1 is due to the neutral fluorenone ketyl radical generated by proton transfer to the radical anion.[8,14] The yield of the ketyl radical was estimated to be 16% of the electron yield. After the correction for the conversion into the neutral radical, the extinction coefficient of the radical anion in ethanol was determined to be 0.37×10^4 dm^3 mol^{-1} cm^{-1}. The radical anion in the mixed matrix showed a new peak in addition to the peaks corresponding to those in neat MTHF and ethanol. The appearance of the three peaks clearly indicates that the radical anion exists in three forms, i.e., without and with one and two ethanol molecules hydrogen-bonded to the radical anion.

The absorption spectrum of the radical anion with one hydrogen-bonded ethanol molecule was obtained by substracting the spectra for neat MTHF and ethanol from the spectrum for the mixed matrix. The absorption of the overlapping neutral ketyl radical was corrected by assuming that the ratio of the radical against the radical anion with two hydrogen-bonded ethanols is independent of the composition of the mixed solvent. Fig. 2 shows the normalized spectra of the three components, $I_0(\lambda)$, $I_1(\lambda)$, and $I_2(\lambda)$, corresponding to the fluorenone radical anion with zero, one, and two

hydrogen-bonded ethanol molecules, respectively. The absorption spectrum, $S(\lambda)$, for the mixed matrix of volume fraction x of ethanol is expressed as a sum of the three spectral components,

$$S(\lambda)=[W_0(x)I_0(\lambda)+W_1(x)I_1(\lambda)+W_2(x)I_2(\lambda)]C(x), \quad (1)$$

where $W_i(x)$ is the mole fraction of the three types of the radical anion with respect to the total radical anions, and $C(x)$ is the yield of the scavengeable electrons. Figs. 3 and 4 compare the observed and calculated spectra for the mixed matrices of x=0.25 and 0.75, respectively. The value of $W_i(x)$ was determined by best-fitting the calculated spectrum with the observed one. The fair agreement of the spectra indicates that only three types of the radical anion exist in the mixed matrices. The mole fractions determined from the observed spectra are shown in Fig. 5.

Discussion

Since the observed absorption spectra of the fluorenone radical anion in the mixed matrices of ethanol and MTHF can be reconstructed from the three components, the solvation process for the fluorenone radical anion is considered to be essentially the same as that for benzophenone and other aromatic ketyl radical anions; the radical anion is viewed as hydrogen-bonded with one and two ethanol molecules through the out-of-plane π electron on the carbonyl oxygen.

If there is no specific interaction between the neutral fluorenone and ethanol, and if the ethanol molecules are randomly distributed around fluorenone, the probability that a fluorenone radical anion finds an ethanol molecule at the site for hydrogen bonding is given by x. The probability of the hydrogen bond formation is then given by

$$W_0(x)=(1-x)^2,\ W_1(x)=2x(1-x),\ W_2(x)=x^2. \quad (2)$$

The shapes of $W_i(x)$ in Eq. 2 are also shown with thinner curves in Fig. 5. Although $W_0(x)$ is close to the observed curve, $W_1(x)$ is much higher while $W_2(x)$ is lower than the observed $W_i(x)$. This suggests that a considerable part of the radical anion with one hydrogen-bonded ethanol molecule is converted into the radical anion with two hydrogen-bonded ethanol molecules. A candidate for the second hydrogen bond might be an in-plane ethanol molecule which has been hydrogen-bonded to neutral fluorenone.

Now the reason why Hoshino et al. failed to detect the spectral shift of the fluorenone radical anion is clear. The absorption of the radical anion with one hydrogen-bonded alcohol molecule is very weak due to the first conversion of the radical anion into that with two hydrogen-bonded alcohol molecules. The absorption of the latter radical anion is also weak due to the small extinction coefficient. The low spectral resolution in their pulse radiolysis study allowed them to detect only the wavelength-independent decrease of the absorption band of the radical anion without hydrogen bond.

The characteristic features of the spectral change of aromatic ketone radical anions due to formation of the new hydrogen bond are the blue shift and the decrease in the molar extinction coefficients. These features can be qualitatively understood by a simple molecular orbital consideration. Shida et al. made molecular orbital calculations on the radical anions of aromatic ketones and found that the excess charge is located mainly on the carbonyl group in the ground state and on the aromatic group in the excited states.[8] They also assigned the visible absorption bands to intramolecular charge transfer bands. The ground and the excited states of the radical anion are therefore given by a linear combination of two structures; one is ψ_a with an excess negative charge on the carbonyl group (carbonyl antibonding π orbital) and the energy E_a, and the other is ψ_b with a negative charge on the benzene rings and the energy E_b. Neglecting the overlap integral between ψ_b and ψ_b, the transition energy $h\nu$ and the transition moment μ_{EG} for the charge transfer band are approximately given by

$$h\nu \simeq (E_b-E_a)[1+4H_{ab}^2/(E_b-E_a)^2]^{1/2}, \quad (3)$$
$$\mu_{EG} \simeq -H_{ab}(\mu_{aa}-\mu_{bb})/h\nu-[(E_b-E_a)/h\nu]\mu_{ab}, \quad (4)$$

where H_{ab} is the resonance integral between ψ_a and ψ_b, and μ_{jk} is a transition or an electric moment. The absolute value of μ_{ab} is much smaller than that of $\mu_{aa}-\mu_{bb}$. The value of (E_b-E_a) is close to $h\nu$. Therefore, the

transition moment, square root of the transition probability, linearly decreases with increasing transition wavelength. The decrease in the transition probability arises from the decrease in the mixing of the ψ_a and ψ_b states due to the incease in the energy gap, $E_b - E_a$.

Due to the negative charge on the carbonyl oxygen, the radical anion in the ground state easily forms a hydrogen bond, which stabilizes the ψ_a and hence the ground states. Since the contribution of the ψ_a state is very low in the excited state, the excited state is not stabilized by hydrogen-bonding. The formation of the hydrogen bond therefore causes a blue shift of the absorption spectrum and the decrease in the transition probability. Since the transition probability is proportional to the product of the transition wavelength and the molar extinction coefficient, formation of the hydrogen bond also causes a decrease in the extinction coefficient. Figure 6 shows the relation between the wavelength at the absorption maximum, λ_{max}, and the extinction coefficient at λ_{max} for the fluorenone and the benzophenone radical anions. The extinction coefficient decreases with decreasing λ_{max}, which supports the validity of the above consideration. The extinction coefficient would increase with decreasing λ_{max}, if the transition probability were not decreased by formation of the hydrogen bond.

Provided the energy of the excited state is scarcely influenced by the formation of the hydrogen bond, the stabilization energy by hydrogen bonding is approximately the same as the energy of the spectral shift. The values of the stabilization energy are −0.22 and −0.20 eV for the first and the second hydrogen bonding to the benzophenone radical anion, respectively. For the fluorenone radical anion, the values are −0.16 and −0.42 eV, respectively. The large stabilization energy of −0.42 eV suggests that the formation of the second hydrogen bond is accelerated by the first hydrogen bond. The relative concentration of the fluorenone radical anion with one hydrogen-bonded ethanol is thus lower than the statistical one.

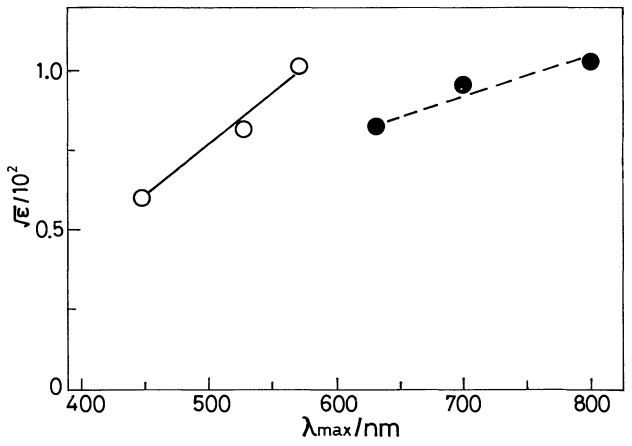

Fig. 6. Plot of the square root of molar extinction coefficients of (○) fluorenone and (●) benzophenone radical anions versus the wavelength at absorption maxima.

Very recently Murai et al. made a pulse radiolysis study on the spectral shift of benzophenone and fluorenone radical anions in MTHF due to ionic association with sodium cations.[15] They found stepwise shifts of the absorption spectra: 800 nm→720 nm→630 nm for the benzophenone radical anion and 570 nm→530 nm→450 nm for the fluorenone radical anion. The spectral shift is quite similar to that due to hydrogen bonding. They attributed the spectral shift to stepwise association of the ions: free ketyl anions→ketyl anion-sodium cation ion pairs→higher ion aggregates (dimer of the ion pair or the ketyl anion coordinating two sodium cations). The fair agreement of the absorption spectra between the higher ion aggregates and the radical anions with two hydrogen-bonded ethanol molecules strongly suggests that the higher ion aggregate corresponds to the radical anion coordinating two sodium cations instead of two alcohol molecules. The reaction rate for the formation of the higher ion aggregate was approximately the same as that for the ion pair formation, which also suggests that the higher ion aggregate corresponds to the ketyl anion coordinating two sodium cations. The reaction would be much slower if the aggregate were formed by a second-order reaction with the ion pairs. Luckhurst and Orgel measured ESR spectra of chemically-prepared fluorenone radical anions in the mixed solvent of *N,N*-dimethylformamide and methanol or ethanol.[16] They attributed the spectral shift by the alcohols to the formation of hydrogen bond between the fluorenone radical anion and the alcohol molecule. The ESR spectrum of the radical anion in pure alcohol was very similar to the spectrum of the radical anion coordinating a divalent metal cation,[17] this suggests that the electronic structure of the aromatic ketyl radical anion with two hydrogen-bonded alcohol molecules is very similar to that coordinating two monovalent cations or one divalent cation.

† Department of Chemistry, Faculty of General Education, Kobe University, Tsurukabuto, Nada-ku, Kobe 657
(Received March 13, 1991)

Ammonium amidotriphosphate $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ was heated at 5 K min^{-1} up to 100, 145, 180, and 240 °C in four different atmospheres : in a stream of dry air, humid air, ammonia, and dry hydrogen chloride. The products were analyzed by HPLC-FIA, X-ray diffractometry, and IR spectrophotometry. A new phase of ammonium *cyclo*-triphosphate was observed at lower temperatures, except for in the ammonia atmosphere. Oligophosphates (chain length=4—12) were more abundant in samples heated to 145 and 180 °C in hydrogen chloride. The *cyclo*-tri- and oligophosphates were most probably formed via a zwitterion form. When heated to 240 °C, the samples were changed to ammonium polyphosphates. Elemental analyses for the sample heated to 240 °C in dry air showed that the ammonium polyphosphates formed contained some phosphorus–nitrogen bonds. Isothermal experiments at 180 °C in dry air indicated that the new phase of ammonium *cyclo*-triphosphate was converted completely to ammonium polyphosphates.

Inorganic phosphates with phosphorus–nitrogen bonds are potential candidates as a new class of fertilizer. They attracted our attention also as flame-proofing materials, and probably in view of this several reports have been published regarding their thermal decomposition.[1-11] Especially, amidophosphates have been studied by many workers.[2-11]

Amidotriphosphate ion has such a structure that the terminal oxygen atom of triphosphate ion is replaced with an amino group. It is well known that amidotriphosphates are prepared by ammonolyses of *cyclo*-triphosphate in aqueous solutions.[12-14] Quimby and Flautt,[12] and Feldmann and Thilo[13] also reported that amidotriphophate ions cyclized again to *cyclo*-triphosphate ions in acidic solutions. We have been interested in whether the cyclization also takes place or not in solid state. Whether phosphorus–nitrogen phosphates are produced or not in such a solid-state reaction is also of interest.

In general, thermal decomposition of inorganic phosphates depends on temperature and time of heating, cooling of the melts, and atmosphere of heating.[15]

We studied the thermal decomposition of some inorganic phosphates with regard to the effect of atmosphere, especially of humidity.[16,17] As an extension thermal decomposition of ammonium amidotriphosphate $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ was studied in the present work in four different atmospheres: dry air, humid air (relative humidity 90% at 25 °C), ammonia, and dry HCl. The products were analyzed by HPLC-FIA, X-ray diffractometry, and IR spectrophotometry as in the preceding work.[16,17]

Experimental

Preparation of Ammonium Amidotriphosphate $(NH_4)_4P_3O_9NH_2 \cdot H_2O$. Ammonium amidotriphosphate was prepared by ammonolysis of ammonium *cyclo*-triphosphate.[13] The latter was obtained according to Ref. 18, but the X-ray diffraction data were different from those in Ref. 18. The present data are listed in Table 1. Analyses of the new ammonium *cyclo*-triphosphate clarified that it was an anhydrous form and was pure. After allowing the sample to stand for about six months below room temperature, the X-ray diffraction lines changed to those reported in Ref. 18 while several of the original lines remained. The *cyclo*-triphosphate ions were not decomposed. The ammonium *cyclo*-triphosphate thus formed was heated again at 5 K min^{-1} to 300 °C in a stream of ammonia. Its *cyclo*-triphosphate ions were not decomposed and the X-ray diffraction data agreed completely with those of the new ammonium *cyclo*-triphosphate. These indicate that the new phase of ammonium *cyclo*-triphosphate, in line with the data in Table 1, is its high-temperature phase.

HPLC-FIA data for several $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ samples thus prepared showed that more than 95.0% of the phosphorus atoms exist as amidotriphosphate ions. Found: P, 26.93; $N(NH_4^+)$, 16.02; $N(NH_2^-)$, 3.89%. Calcd for $(NH_4)_4P_3O_9NH_2 \cdot$

H_2O: P, 27.07; $N(NH_4^+)$, 16.33; $N(NH_2^-)$, 4.08%. The ammonium amidotriphosphate sample used throughout thermal decomposition experiments was pure.

Thermal Decomposition. Thermal decomposition experiments were carried out in a cylindrical electric furnace, by means of dynamic heating methods (heating rate: 5 K min^{-1}) or isothermal methods. The effect of atmosphere on the decomposition was examined by the use of a stream of dry air (50 cm^3 min^{-1}) and humid air (50 cm^3 min^{-1}). The former was obtained by passing air through molecular sieves, and the latter with a humidity generator give 90% of relative humidity at 25 °C.[17] A stream of ammonia (purity: 99.9%) was also used by introducing it directly from a cylinder. Hydrogen chloride was prepared by adding concentrated sulfuric acid to ammonium chloride, then dried with concentrated sulfuric acid. Before heating, the cylindrical furnace was purged with these gases of about twice its volume.

Analyses. Total nitrogen was determined by the Kjeldahl method. Nitrogen present as ammonium ions, $N(NH_4^+)$, was determined by an ammonia-distillation method without decomposition by use of concentrated sulfuric acid. Nitrogen present as amino or imino groups, $N(NH_2^-)$, was calculated by subtracting the $N(NH_4^+)$ from the total nitrogen.[13] Thermal analyses (TG-DTA) were carried out in stationary air at a heating rate of 5 K min^{-1}. The composition of phosphates was determined by an HPLC-FIA method. A 10 mg portion of a sample was dissolved in 2 cm^3 of a 0.1 mol dm^{-3} sodium hydroxide aqueous solution to prevent the cyclization of amidotriphosphate ions to *cyclo*-triphosphate ions, that readily occurs in acidic solutions.[12-14] The solution was diluted to 500 cm^3 with distilled water, and was immediately analyzed with an HPLC-FIA system. Total phosphorus was determined colorimetrically with the HPLC-FIA system.[16] IR spectra were recorded on a JASCO IR spectrophotometer IR-700 by a KBr disc method. Other procedures were essentially the same as those described previously.[16,17]

Results and Discussion

Thermal Decomposition in Stationary Air. Figure 1 shows a result of thermal analyses (TG-DTA) in stationary air. Four endothermic peaks are seen at about 140, 155, 210, and 300 °C. The peak at 300 °C reflects the melting of sample.

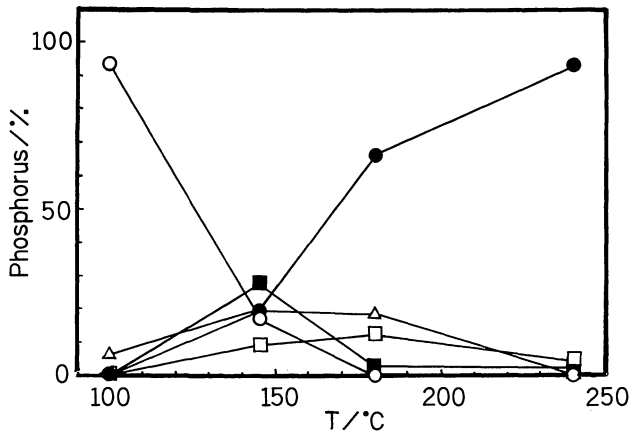

Fig. 2. Changes in amounts of phosphates in the products decomposed at 5 K min^{-1} in stationary air. ○: amidotri-, ●: poly-, □: mono-, di-, and tri-, ■: oligo- (chain length=4—11), △: *cyclo*-tri-.

Figure 2 depicts the percentage of phosphorus atoms existing as amidotri-, mono- to tri-, oligo- (chain length n=4—11), poly-, and *cyclo*-triphosphates in the products obtained by heating to the temperatures indicated on the DTA curve in Fig. 1. Peaks not assignable to these phosphate ions were occasionally detected on the HPLC-FIA chromatograms. In view of the short retention time, they are probably short-chain phosphate ions with one or several phosphorus–nitrogen bonds, and are denoted as "other" phosphates in Table 2. Since these amount to only less than ca. 4% as phosphorus atoms, they are neglected in Fig. 2.

Release of the water of crystallization from $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ would give 5.25% of weight loss. The weight loss at 145 °C was significantly larger, ca. 12.1%. Therefore, the endothermic peak at about 140 °C may reflect elimination of ammonia as well as the water of crystallization.

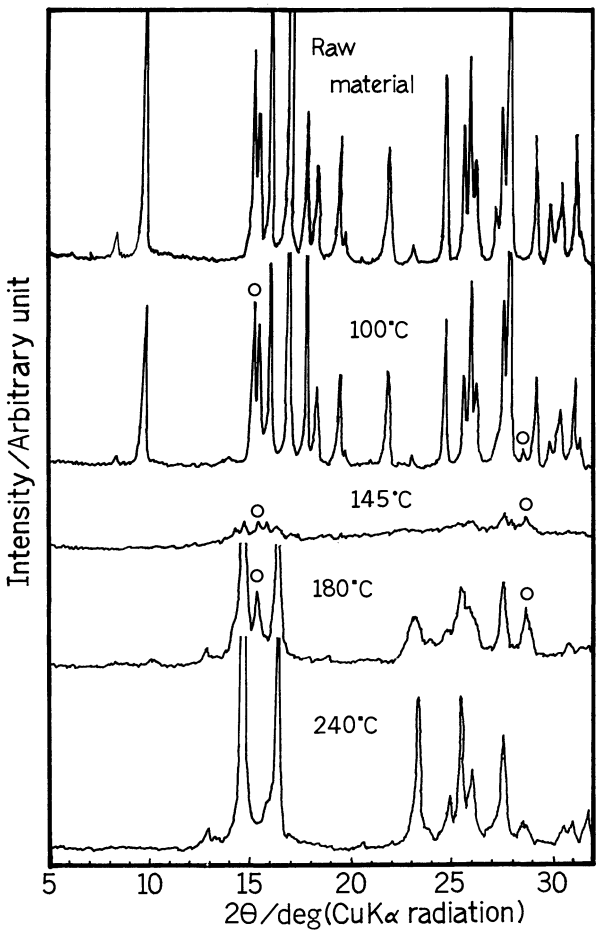

Fig. 3. X-Ray diffraction patterns of the samples decomposed in stationary air. Heating rate: 5 K min^{-1}. O: the lines were attributable to the ammonium *cyclo*-triphosphate indicated in Table 1.

The X-ray diffraction pattern of the sample heated to 180 °C showed the lines for ammonium polyphosphate (I-form)[19] and those for ammonium *cyclo*-triphosphate given in Table 1 (Fig. 3). The lines at 15.4 and 28.8° (2θ) are attributable to the *cyclo*-triphosphate. The sample heated to 240 °C was mostly ammonium polyphosphate as judged from Figs. 2 and 3. The weight loss on the TG curve at 240 °C was ca. 15.4%, which is close to that calculated according to the following equation (15.18%):

$$(NH_4)_4P_3O_9NH_2 \cdot H_2O \rightarrow 3(NH_4)PO_3 + 2NH_3 + H_2O$$

The weight loss at temperatures above 240 °C might be due to the release of ammonia, water, or phosphorus pentoxide from the sample.

Effect of Atmosphere on the Thermal Decomposition. Samples of ammonium amidotriphosphate were heated at 5 K min^{-1} to 100, 145, 180, and 240 °C, in streams of four different gases. Table 2 shows the composition of phosphates of the products. At 100 and 145 °C in dry air, dehydration of $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ induced rapid decomposition of the amidotriphosphate ions. As water vapor suppresses the dehydration and consequently the decomposition of amidotriphosphate ions, the latter reaction is expected to proceed slowly in a humid atmosphere. Indeed at 100 and 145 °C, there remain markedly more amidotriphosphate ions undecomposed when heated in humid air than in dry air. Amidotriphosphate ions were stable up to 180 °C in a stream of ammonia; this implies that amidotriphosphates also were cleaved by elimination of ammonia.

It was reported that amidotriphosphate ions cyclized again to *cyclo*-triphosphate ions in acidic solutions.[12-14] As seen in Table 2, the products occasionally contained *cyclo*-triphosphates. Such samples exhibited necessari-

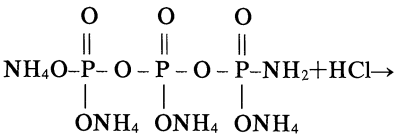
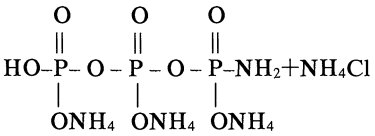
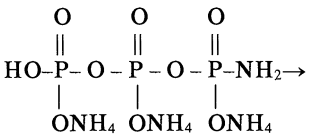
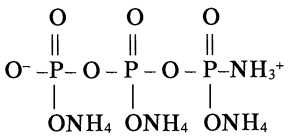
ly two diffraction lines at 15.4 and 28.8° (2θ), which agreed with those listed in Table 1. Quimby and Flautt,[12] and Feldmann and Thilo[13] described that a zwitterion was formed as an intermediate in the course of the cyclization of amidotriphosphate ion. Table 2 shows that *cyclo*-triphosphate ions exist most abundantly in samples heated to 100 °C in hydrogen chloride. This is probably due to the formation and subsequent cyclization of the zwitterion expressed by the following equations:



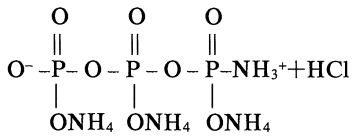


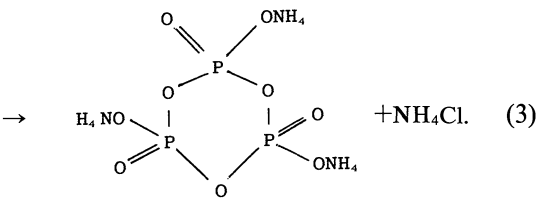
(1)





(2)





(3)

Oligophosphates (n=4—12) were formed more in samples heated to 145 and 180 °C in dry HCl than in the other atmospheres. Sato et al. reported that polyphosphates were produced by condensation of the zwitterions resulting from a reaction of amidophosphates with hydrogen chloride.[20,21] Therefore, the oligophosphates may also be formed by condensation of the zwitterions indicated on the right-hand side of Eq. 2. The zwitterions must be also resulted from a reaction of amidotriphosphate ions with water. Sato et al. suggested the occurrence of such a reaction.[20,21]

The IR spectrum of $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ showed a large peak of ammonium ions at 1400—1500 cm^{-1}[22] and a small peak of amino groups at 1630 cm^{-1}.[23] The sample heated to 100 °C in HCl showed a peak at 1400—1500 cm^{-1}, and a faint peak at 1670 cm^{-1}. The shift from 1630 to 1670 cm^{-1} might be due to the formation of hydrogen bonds. Although Corbridge and Lowe reported that the zwitterions of amidophosphates all exhibited absorption at 1618—1615 cm^{-1} and at 1470—1468 cm^{-1},[22] we were unable to identify the zwitterions of the amidotriphosphates by the IR spectra.

Hydrogen chloride and water are expected to act as hydrolytic agents at higher temperatures. As a result of hydrolysis of the amidotriphosphates, mono- to triphosphates were indeed formed more in samples heated to 145 and 180 °C in HCl and in those heated to 180 and 240 °C in humid air (Table 2). Table 2 shows that there were no *cyclo*-triphosphates in samples heated in ammonia, which may indicate that the zwitterions are not formed in the presence of ammonia molecules.

The products heated to 240 °C entirely consisted of polyphosphate ions, and showed an X-ray diffraction pattern of I-form of ammonium polyphosphate.[19] The sample heated to 240 °C in dry air was analyzed: P, 31.17; N(NH_4^+), 12.86; N(NH_2^-), 0.69%. The result reveals the presence of some phosphorus–nitrogen bonds in the ammonium polyphosphate.

Isothermal Decomposition in a Stream of Dry Air. Ammonium amidotriphosphate $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ thermally produced a new phase of ammonium *cyclo*-triphosphate. The *cyclo*-triphosphate disappeared at higher temperatures. In order to investigate the process in more detail, isothermal runs were carried out in a stream of dry air. The essential features of the results obtained are displayed in Figs. 4 and 5. Mono- to triphosphates were hardly observed (less than 1%) in

samples heated at 100 °C. Tetra- and pentaphosphates were the only species among oligophosphates in samples heated at 180 °C. However, since their total quantity was less than 1.6%, they are neglected in Fig. 5. The chromatograms of samples heated at 100 and 180 °C both showed no peaks of "other" phosphates.

At 100 °C the amount of *cyclo*-triphosphate ions did not change with reaction time, and that of oligophosphates was also constant after 20 min (Fig. 4). These ions were probably formed via the zwitterions. *cyclo*-Triphosphate ions were detected clearly at 10 min at 180 °C (Fig. 5). They decreased with the passage of time to disappear completely in 30 min. X-Ray diffraction analyses gave the same results. Therefore, at higher temperatures, the *cyclo*-triphosphates were converted to ammonium polyphosphates (I-form).

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 03750588 from the Ministry of Education, Science and Culture.

Association of Cycloalkanes with Cyclodextrins in Aqueous Medium

Tomonori OSAJIMA, Toshio DEGUCHI, and Isao SANEMASA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1,Kumamoto 860
(Received April 15, 1991)

The complex formation of α-, β-, and γ-cyclodextrins (CyDs, hosts) with five cycloalkanes (guests), cyclo(pentane, hexane, heptane, octane, and decane), has been studied in aqueous media at 25 °C by making use of the volatilization rate of guest molecules from the aqueous into gas phase. In the excess of the host, α-CyD forms both 1 : 1 and 2 : 1 (host : guest) complexes, while β- and γ-CyDs form 1 : 1 complexes with an exception that β-CyD forms a 2 : 1 complex with cylodecane. The 2 : 1 complex formation constants of α-CyD with cyclo(hexane, heptane, octane, and decane), particularly with cyclooctane, are extremely large compared with their 1 : 1 formation constants. The host–guest spatial fitting models are proposed.

We studied host–guest associations using α-, β-, and γ-cyclodextrins (CyDs) as hosts and C_5—C_9 normal alkanes as guests.[1] The results are summarized as follows.

With an increase in the chain length of alkane, both 1 : 1 and 2 : 1 (host–guest) formation constants for three CyDs increase; in the case of α-CyD, the 1 : 1 formation constant is saturated at C_8. The cross section diameter of an alkane molecule being close to that of α-CyD cavity (5 Å), the guest molecule is assumed to be included in α-CyD along the fully extended alkyl chain. Relatively large formation constants of β-CyD indicate that the cavity diameter of β-CyD (6.9 Å) is sufficiently large to allow a conformational change of the guest alkyl chain so that the guest molecule contacts favorable with the cavity wall. In view of the large cavity diameter (8.5 Å), γ-CyD might form much weaker complexes with alkanes. Contrary to this expectation, however, the formation constants with shorter-chain alkanes are comparable to α-CyD complexations and those with longer-chain alkanes are comparable to β-CyD complexations. In order to rationalize these observations, we made two hypotheses: (1) a flexible conformation of alkyl chain to get contact as widely as possible with the γ-CyD cavity wall and (2) γ-CyD accepts a guest molecule without releasing water molecules originally present in the cavity.

In the present work, cycloalkanes of C_5 to C_8 and C_{10} have been used as guests. These guest molecules, compared to normal alkanes, are more bulky and more rigid. The cavity of α-CyD is too small to include even a cyclopentane molecule as a whole, while, if the guest takes a suitable puckered ring conformation, β-, and γ-CyDs can accept a cycloalkane molecule of fairly large ring. The object of this study is to elucidate the relationship between the guest size and the stability of CyD complexes.

In analytical chemistry, CyDs have been recently used to modify the partition of hydrophobic solutes between organic and aqueous phase.[2] In the field of organic syntheses, water-insoluble CyD derivatives are used in organic solvents.[3] Since cycloalkanes are of common choise as organic solvents, the knowledge of their associations with CyDs is required. There are, nevertheless, few data available concerning the host–guest systems. Cyclohexane–α-, and –β-CyD systems have been so far studied by solubility measurements.[4] The method used in this work to determine the association constant is the same as that employed in our previous works.[1,5]

Experimental

Deionized distilled water was used throughout the experiments. An appropriate amount of α-, β-, and γ-CyDs of guaranteed grade (Nacalai Chemical Co.), dried over phosphorus pentoxide under vacuum, was weighed and dissolved in water to prepare CyD stock solutions of desired concentrations. Five guest substances were used as received; cyclopentane (Nacalai Chemical Co., 98%), cyclohexane (Wako Pure Chemical Co., 99.5%), cycloheptane (Tokyo Kasei Kogyo Co., 98%), cyclooctane (Nacalai Chemical Co., 99%), and cyclodecane (Aldrich, the purity is not specified).

The same device described in the previous paper,[1] was used to prepare aqueous solutions saturated with cycloalkane and to vaporize the guest with a nitrogen gas stream. Depending on the volatility of the guest, the N_2 gas flow rate was adjusted constant at 20 (cyclopentane) to 100 $cm^3\ min^{-1}$ (cyclodecane). As was described previously,[1] the vaporized guest was collected with Tenax GC resin, determined by gas chromatography, and the ammount of guest vaporized during a definite time, ΔQ_ϕ, was calculated.

The concentration of cycloalkane in the saturated aqueous solution was not determined in this work; the data were taken from the literature.[6] The concentrations of hosts and guests employed in the present study are given in Table 1.

Results and Discussion

Association Constants. The 1 : 1 and 2 : 1 (host : guest) association constants, K_1 and K_2, were estimated using an equation derived in the previous paper:[5]

$$\ln(C_\phi - Q_\phi V^{-1}) = -kt/(1+K_1C_{CyD}+K_1K_2C^2_{CyD}) + \ln C_\phi = -k't + \ln C_\phi, \quad (1)$$

where C_{CyD} and C_ϕ refer to the total concentration of host and that of guest, respectively, Q_ϕ is the sum of ΔQ_ϕ from time 0 to t, V is the volume of the aqueous solution,

k is the rate constant for transfer of guest molecules from the aqueous to gas phase, and

$$k'=k/(1+K_1C_{CyD}+K_1K_2C^2_{CyD}). \quad (2)$$

Rearrangement of Eq. 2 yields

$$1/k'=K_1K_2C^2_{CyD}/k+K_1C_{CyD}/k+1/k. \quad (3)$$

The plots according to Eq. 1 for all the cycloalkane–CyD systems examined in this work gave straight lines over the whole aeration time, during which ca. 50 to 70% of the guest molecules present initially in the sample solutions were purged. The slopes of the resulting straight lines, k' (and k), were evaluated by the least-squares method. Typical $1/k'$ vs. C_{CyD} plots are shown in Figs. 1 through 3. The plots exhibit upward curvatures for α-CyD complexations with the cycloalkanes studied here and for the β-CyD–cyclodecane system, indicating the formation of both 1 : 1 and 2 : 1 (host–guest) complexes. The plots for the other host–guest systems are linear, supporting the formation of 1 : 1 complexes. The K_1 and K_2 values were determined by the curve-fitting method and are summarized in Table 1.

Wishnia and Lappi reported K_1 of 4.2×10^2 M^{-1} (1 M=1 mol dm^{-3}) and K of 5.3×10^3 M^{-1} at 25 °C for cyclohexane–α- and β-CyDs, respectively.[4] The cavity of α-CyD is too small to include completely any cycloalkane molecule studied in this work; even cyclopentane has a diameter of ca. 6 Å. In this view, the literature K_1 value of cyclohexane seems too large. Matsui and Mochida studied associations of various alcohols with α- and β-CyDs.[7] Their 1 : 1 association constants of cyclopentanol, cyclohexanol, cycloheptan-

a)Total concentration of cyclodextrin. b) Dash sign indicates that K_2 was not evaluated, because $1/k'$ vs. C_{CyD} plots gave a nearly straight line. c) Initial concentration of guest after being mixed with CyD aqueous solution.

ol, and cyclooctanol are 45.7, 64.6, 79.4, and 178 M^{-1} with α-CyD, 120, 501, 1700, and 2000 M^{-1} with β-CyD, respectively. The literature values of cycloalkanols are considerably larger than the present cycloalkane–α-CyD data, but well comparable to the cycloalkane–β-CyD data. The hydroxyl group of alcohols has a potential ability to bind through hydrogen bonding with primary or secondary OH groups on the rims of CyD molecule or with glycosidic oxygens that constitute the cavity.

Association Model. It is difficult to explain our extraordinarily large K_1 value observed for the cyclodecane–α-CyD system. A plausible explanation is that the high flexibility of the large ring allows the molecule to take such a conformation that a part of the ring, which can be inserted more deeply into the α-CyD cavity, is formed more easily. While the K_1 values of cyclohexane, cycloheptane, and cyclooctane are small, their K_2 values are extremely large. Cromwell et al. suggested that if K_2 is larger than K_1, the cross-section of secondary hydroxyl group sides of two CyDs are situated parallel to each other in a suitable distance to form hydrogen bond.[8] Taking cyclohexane as an example, the 2 : 1 (host : guest) association model is depicted in Fig. 4(A). Two α-CyDs, including in their cavities a part of the cycloalkane ring, (–CH_2–CH_2–), attach to the guest molecule from the oposite side. The magnitude of K_2 depends on the distance between the two CyDs to cooperate with each other to form hydrogen bonds; the distance may be too short for cyclopentane and may be a little long for cyclodecane (the K_2 of cyclodecane is larger than its K_1, but smaller than the K_2 of cyclooctane, cycloheptane, or cyclohexane). It is noteworthy that

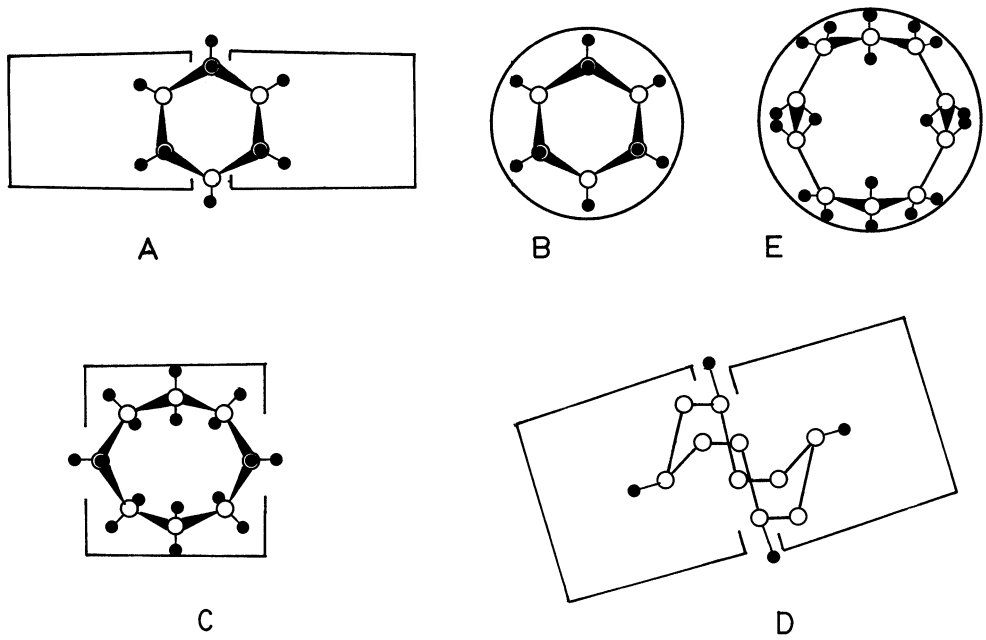

Fig. 4. Inclusion model. A: α-Cyclohexane; B: β-cyclohexane (cross section); C: β-cyclooctane; D: β-cyclodecane; E: γ-cyclodecane (cross section).

the K_2 of cyclooctane is larger by about two orders of magnitude than that of C_6, C_7, or C_{10} cycloalkane; the distance between the two α-CyDs sandwiching a cyclooctane molecule may be most suitable among the cycloalkanes studied to form hydrogen bonds.

Wishnia and Lappi presented a model of association of chair cyclohexane, which has a diameter of 7.0 Å and a thickness of 4.7 Å, with β-CyD.[4] Their model is shown in Fig. 4(B); the guest is best fitted by its periphery with the inner wall of the host cavity. This association mode, however, cannot be applied to the guests of ring size larger than cyclohexane. For these guests, we speculate that the guest enters the host cavity with the ring-planes of both host and guest perpendicular to each other. The association model considered to be reasonable for cyclooctane is shown in Fig. 4(C). The oblate ellipsoid of this guest has a diameter of 7.3 and 8 Å. The diameter of 7.3 Å is a little larger than that of β-CyD cavity employed in this study, but the cavity size itself is still uncertain; ranging from 4.5 to 6.0 Å (α-CyD), from 6.0 to 8.0 Å (β-CyD), and from 8.0 to 10.0 Å (γ-CyD).[9] Cyclodecane has a diameter of 7.6 (the minor axis) and 8.3 Å (the major axis), that is a little larger than the corresponding value of cyclooctane. Cyclodecane can also enter fully the β-CyD cavity, if we employ the larger cavity size, along the longer axis of the guest molecule. It is noteworthy that cyclodecane forms a 2:1 complex. This observation cannot be explained by a simple consideration that the length of the longer axis of cyclodecane exceeds the cavity depth (the cavity is 7 Å deep irrespectively of the type of CyD), because this is also the case for cyclooctane. We speculate, therefore, that the diameter of the shorter axis of cyclodecane is a littile larger than that of β-CyD so that a complete inclusion by the host is inhibited. The 2:1 (β-CyD : cyclodecane) association model is depicted in Fig. 4(D).

The cavity diameter of γ-CyD is sufficiently large to accept any cycloalkane studied in this work. If we adopt 8.5 Å for the host diameter, a cyclodecane molecule is snugly fitted in the host cavity with the ring-planes of both host and guest parallel to each other, as illustrated in Fig. 4(E).

The Volume of Guest and the Association Constant. In preceding studies on associations of CyDs with polynuclear aromatic hydrocarbons,[10] halogenated benzenes,[11] normal alkanes,[1] we pointed out that there is a linear relationship between the total surface area of guest and log K_1. In the case of cycloalkane, the volume of a guest molecule is a better parameter to judge the host–guest fitness, because the part inside the ring of the guest molecule does not take part in the contact with the host cavity wall. Taking the molar volume of cycloalkane from the literature,[12] the plots are shown in Fig. 5. There is no linear relationship for α-CyD, indicating that a cycloalkane molecule is not included as a whole in this host cavity. For β- and γ-CyDs, on the other hand, good linear relationships are observed. In the case of β-CyD, the inclusion is saturated at cyclooctane. The volume inside the host cavity is 150 (α), 270 (β), and 400 Å^3 (γ).[8] In this view, the saturation phenomenon should occur at cyclodecane. Cyclodecane, however, due to the steric hindrance, does not seem to be fully included in the cavity of β-CyD; this is a reasonable explanation why the cylodecane–β-CyD system forms a 2:1 complex. In Fig. 5 are also plotted association constants of cycloalkanol–β-CyD systems taken from the literature,[7] against the molar volume of cycloalkane on the assumption that β-CyD includes only the ring part of a cycloalkanol molecule. It is noteworthy that the plot is almost paralell to that of the cycloalkane –β-CyD system. A slight stabilization observed for cycloalkanols is probably due to their hydrogen bonding with the periphery of β-CyD.

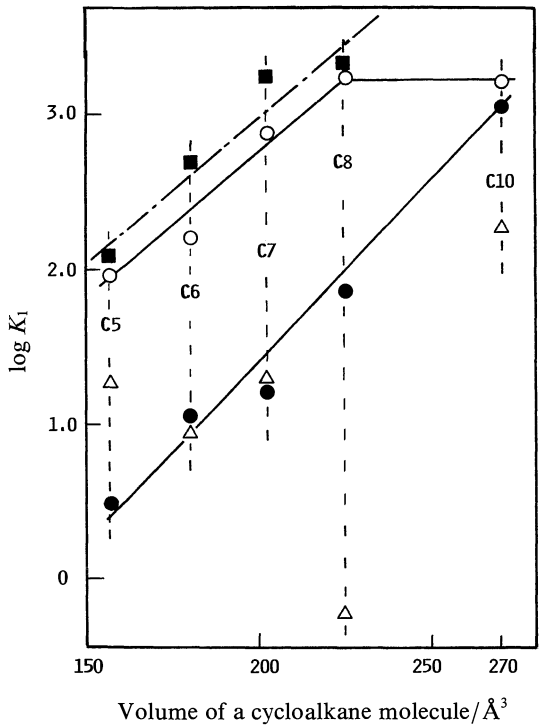

Fig. 5. Dependence of association constant on the volume of a cycloalkane molecule. Cycloalkane–α-CyD (△), –β-CyD (○), –γ-CyD (●), Cycloalkanol–β-CyD (■) (Ref. 7).

Normal and Cycloalkanes. It is interesting to note that, in the complex formation with γ-CyD, the K of a cycloalkane is almost comparable to that of a normal alkane of the same carbon number. This supports one of the hypotheses proposed in our preceding paper.[1] Namely, an alkyl chain takes a herix-coil conformation in the cavity of γ-CyD to get contact as widely as possible with the cavity wall; the cross section of the helix-coil conformation resembles a cycloalkane molecule., With the present study, we reject another hypothesis that takes into account the presence of water in the host cavity. As

for β-CyD, the space inside the cavity is not so large as to allow for an alkyl chain to take a cycloalkane-like arrangement.

Laser induced fluorescence spectroscopy under normal incidence conditions has been applied to a thick film sample, and identification of surface and subsurface fluorescent components was demonstrated. A model film sample adsorbing different fluorescent compounds on its two sides was prepared. Fluorescence spectra from the surface and subsurface regions were separately obtained for observation angles larger and smaller than the critical angle, and it was shown that the same information as the conventional attenuated total reflection method can be obtained with the normal incidence conditions, which is anticipated by the reciprocal principle. Dependence of fluorescence intensity on observation angle agreed well with theoretical calculation results based on the reciprocal principle, which supports the methodology propriety.

Fluorescence spectroscopy has been applied to spectrochemical surface measurement and characterization of various materials, such as organic solids,[1] surface dynamics of biomolecules,[2] and adsorption behavior of proteins at a solid/liquid interface.[3-6] However, in these works, the attenuated total reflection (ATR) conditions has been used to obtain surface fluorescence, in which an excitation beam is incident on the prism/sample interface at an angle larger than the critical angle and fluorescence is measured from the normal direction to the prism. Recently, we have verified that laser induced fluorescence spectroscopy under normal incidence conditions can be used to determine the monolayer level concentration depth profile of an ultrathin film sample,[7,8] by the method based on the reciprocal theory.[9] From an instrumentational viewpoint, normal incidence excitation can obtain the fluorescence angular distribution without changing the irradiation area, and the excitation beam can be easily scanned. These merits are more suitable than the conventional ATR configuration for the local analyses, future dynamic measurements, and three dimensional analyses.[7-9] Therefore, this method is expected to be developed for various applications.

In this paper, we apply this method to surface and subsurface analysis of a thick film sample. According to the reciprocal theory, this fluorescence method using the normal incidence excitation configuration can obtain the same information as with the conventional ATR configuration. Two kinds of fluorescent dyes are adsorbed on different sides of the model film sample surface, and we demonstrate that fluorescence spectra from a dye distributed in the surface and subsurface regions of the film can be detected separately by changing observation angles. Moreover, the measured dependence of the fluorescence intensity on observation angle is compared with theoretical calculation results which are obtained according to the reciprocal principle.

Theoretical Background

Figure 1 shows a schematic illustration of laser induced fluorescence spectroscopy under normal incidence conditions based on the reciprocal principle. Fluorescence intensity $F(\theta)$ determined at the observation angle θ in the prism side can be expressed as the convolution of the concentration depth profile $C(z)$ of a fluorophore and a transmission function $T(\theta, z)$:[7,10]

$$F(\theta) = k\int_0^t C(z)T(\theta, z)\mathrm{d}z, \quad (1)$$

where t is the film thickness, k is a constant. In the case where the sample is an ultrathin film sample, $T(\theta, z)$ can be obtained by the theoretical analysis of the multiple reflection of fluorescence electromagnetic waves between prism/film and film/air interfaces.[9] On the other hand, in the case when the sample is a bulk or a thick film sample, $T(\theta, z)$ can be obtained by considering the

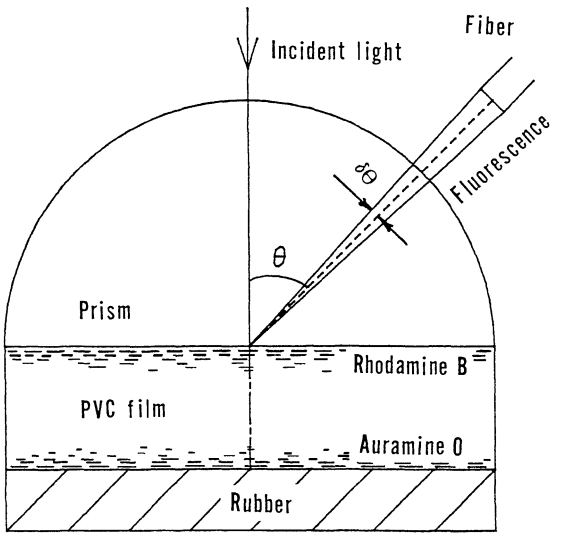

Fig. 1. Schematic illustration of central part of the experimental set up and the model film sample.

reflection and refraction effects of fluorescence occurring at the prism/sample interface. Snell's law and basic electromagnetic theory state that light incident from the prism to the prism/sample interface at an angle larger or smaller than the critical angle θ_c will create an evanescent wave or a transmitted wave in the sample, respectively. The transmitted wave propagates through the whole sample and its intensity is homogeneous over the whole sample. On the other hand, the evanescent wave exists only in the surface region of the sample with a depth on the order of the excitation light wavelength from the prism/film interface, and its intensity decreases exponentially with the distance z. According to the reciprocal theory, fluorescence observed in the prism side at $\theta>\theta_c$ and $\theta<\theta_c$ are an evanescent component and a propagating component, respectively.[11-13] Moreover, the reciprocal theory predicts that the evanescent fluorescence component observed must be from a surface region with a depth on the order of the fluorescence wavelength from the prism/film interface, and the propagating fluorescence component observed is from the whole sample including the surface and subsurface regions. The transmission factors $T(\theta, z)$ of the evanescent and propagating fluorescence components are given by the Fresnel transmission factor $T_f(\theta)$ and the attenuation factor $\exp(-2z/dp)$ as Eq. 2a, and the square of the Fresnel transmission factor $T_f(\theta)$ as Eq. 2b, respectively.[10-13]

$$T(\theta, z)=|T_f(\theta)|^2\exp(-2z/dp), \qquad \theta>\theta_c \tag{2a}$$

$$T(\theta, z)=|T_f(\theta)|^2. \qquad \theta<\theta_c \tag{2b}$$

In Eq. 2a, dp is the penetration depth of the fluorescence which can be obtained from the fluorescence wavelength λ and the refractive indices of prism (n_p) and film (n_f),

$$dp=\lambda/2\pi n_p[\sin^2\theta-(n_f/n_p)^2]^{1/2}. \tag{3}$$

The Fresnel transmission factor $T_f(\theta)$ and the critical angle θ_c can be obtained from n_p and n_f.[11-13] The fluorescence intensity $F(\theta)$ of the evanescent and propagating components can be expressed as follows by substituting Eqs. 2a and 2b into Eq. 1,

$$F(\theta)=k|T_f(\theta)|^2\int_0^t C(z)\exp(-2z/dp)\mathrm{d}z, \qquad \theta>\theta_c \tag{4a}$$

$$F(\theta)=k\int_0^t C(z)|T_f(\theta)|^2\mathrm{d}z=K|T_f(\theta)|^2, \qquad \theta<\theta_c \tag{4b}$$

where the constants K in Eq. 4b can be expressed as Eq. 5,

$$K=k\int_0^t C(z)\mathrm{d}z. \tag{5}$$

Therefore, using the normal incidence excitation configuration shown as Fig. 1, surface and subsurface fluorescence information can be obtained separately at $\theta>\theta_c$ and $\theta<\theta_c$, respectively. This is demonstrated in the following experiement.

Experimental

The experimental set up has been described elsewhere in detail.[7] Figure 1 shows the central part of the set up and the model film sample. An Ar^+ ion laser provided the excitation light (output power, 10 mW), the wavelength of which was selected as 457.9 nm because both the fluorescence compounds Rhodamine B and Auramine O in model film sample can be excited by this laser line. The maximum absorption wavelengths of plasticized poly(vinyl chloride) (PVC) film samples adsorbing Rhodamine B and Auramine O were determined to be about 550 and 440 nm, respectively, by a spectrophotometer and their maximum fluorescence wavelengths were determined to be about 575 and 500 nm, respectively, by a spectrofluorometer. The excitation light was focused on the focal plane of a hemicylindrical prism (n_p, 1.88) which was mounted on the two rotating stages. In order to ensure the model sample made direct contact with the prism, a piece of rubber was used and pressure was applied to the rubber. The side with adsorbed Rhodamine B was in direct contact with the prism. A step index type optical fiber bundle was used to collect the fluorescence. Its diameter was 0.11 cm and the numerical aperture was 0.57. One end of the fiber bundle was fixed at the focal plane of the prism. The other end was coupled with a monochromator. A photomultiplier (Hamamatsu R928) was used as a detector.

The model sample was prepared by an adsorption of fluorescent dyes onto a PVC film (n_f, 1.53) obtained from Okamoto Industry Corporation. The preparation procedure was based on the method proposed by Kaneko et al.[14] in which 1 ml 1×10^{-4} mol dm^{-3} Rhodamine B solution was dropped onto the PVC film sheet (thickness, 0.20 mm). The droplet of Rhodamine B solution remained on the PVC film sheet due to surface tension and the dye molecules diffused into the PVC film, adsorbing in it. After 20 min, the droplet was removed and the PVC film sheet was rinsed with water twice. In the same way, 1 ml 1×10^{-4} mol dm^{-3} Auramine O (with 1×10^{-2} mol dm^{-3} NaOH) solution was dropped onto the other side of PVC film sheet and dye were adsorbed.

Fluorescence microscopic measurements of a cross section of a PVC film sample immersed in 1×10^{-4} mol dm^{-3} Rhodamine B solution for 20 min indicated that the adsorbed fluorescent dye distributed from the surface to a depth of about 40 μm in the PVC film. Similar results were also obtained by the photoacoustic depth profiling method.[15]

Results and Discussion

It has been stated that fluorescence measured at $\theta>\theta_c$ is surface fluorescence which comes from the surface regions with a depth on the order of the fluorescence wavelength from the prism/sample interface, and fluorescence measured at $\theta<\theta_c$ is from the whole sample, including the surface and subsurface regions. The fiber bundle has a finite size, it collects fluorescence from a finite range of observation angles, from $\theta-\delta\theta$ to $\theta+\delta\theta$ as shown in Fig. 1. Therefore the surface fluorescence is

obtained practically at $\theta>\theta_c+\delta\theta$. For the prism/PVC film interface, the calculated θ_c from n_p and n_f is 54.5 °C, and $\delta\theta$ is calculated to be 1.5 °C from the fiber diameter (1.1 mm) and the distance (2.14 cm) between the illumination point and fiber bundle. Therefore, in our experiments, surface fluorescence should be obtained at $\theta>56$ °C.

The fluorescence spectra of the model sample was determined at different observation angles under normal incidence conditions, and two kinds of fluorescence spectra were obtained. They are shown in Fig. 2. The fluorescence spectrum obtained at an observation angle=50 °C ($<\theta_c$) is shown by the the solid line, where two peaks appear at about 575 and 500 nm, respectively. They correspond to the fluorescence of Rhodamine B and Auramine O, respectively. The fluorescence spectrum obtained at observation angle=60 °C ($>\theta_c+\delta\theta$) is shown by the dashed line, where only one peak at about 575 nm corresponding to the fluorescence of Rhodamine B is observed. The chain line is the blank fluorescence spectrum, i.e., the fluorescence spectrum of PVC film without adsorption of fluorescent dye.

As shown in Fig. 1, the side of the PVC film surface adsorbing Rhodamine B is in direct contact with the prism, therefore in the prism/film interface region only Rhodamine B is present. On the other hand, apparently Auramine O distributes in the region away from the interface of the prism/film. Therefore, the results of Fig. 2 demonstrate that surface and subsurface fluorescence information can be obtained by changing the observation angle using the normal incidence excitation configuration, which is anticipated in the theoretical section. Although the reciprocity in the angular distribution of fluorescence has been pointed out,[9,11-13] this work is the first spectroscopical demonstration that surface and subsurface information can be separately obtained by the normal incidence excitation configuration.

Figure 3-A shows the theoretical and measured dependence of fluorescence intensity on the observation angle for $\theta<\theta_c$. The theoretical results were obtained from Eq. 4b, and are represented by a solid line. The measured data were obtained at fluorescence wavelength=575 nm, and are shown by circles. The measured fluorescence intensities agree well with the calculated ones. Figure 3-B shows the theoretical and measured dependence of fluorescence intensity on observation angle for $\theta>\theta_c$. The theoretical and measured fluorescence intensities are represented by a solid line and circles, respectively. The measured fluorescence intensities were obtained at fluorescence wavelength=575 nm. The theoretical results were obtained from Eq. 4a assuming $C(z)$ is a constant. As stated above, at $\theta>\theta_c$, the measured fluorescence is from the surface region with a depth on the order of the

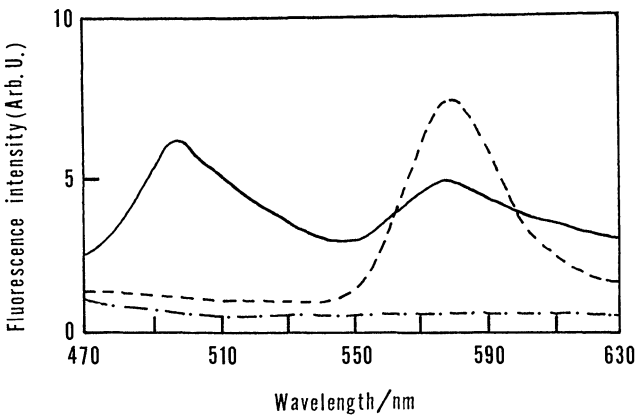

Fig. 2. Fluorescence spectra of the model film sample under normal incidence conditions at different observation angles. The solid and dashed lines represent the fluorescence spectra obtained at 50° and 60°, respectively. The blank fluorescence spectrum is represented by the chain line.

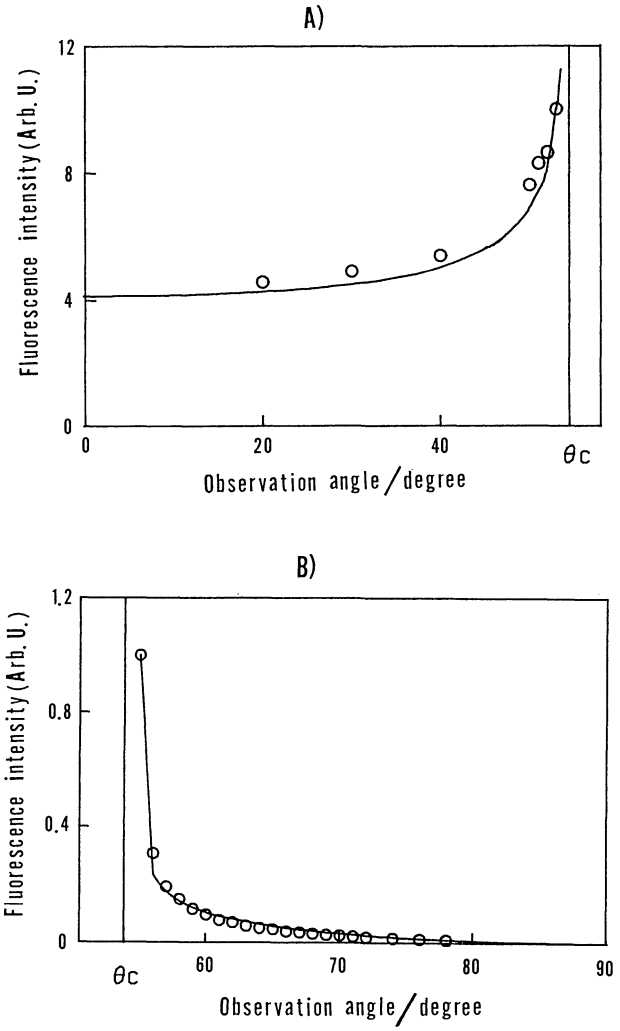

Fig. 3. Theoretical and determined dependence of fluorescence intensity on the observation angles. A: the observation angle is smaller than the critical angle. B: the observation angle is larger than the critical angle.

fluorescence wavelength from the prism/film interface, while adsorbed Rhodamine B is distributed from the surface to a depth of about 40 μm. Therefore the concentration distribution $C(z)$ of Rhodamine B from the surface to a depth on the order of the fluorescence wavelength can be considered as a constant. The results of Fig. 3 indicate that the dependence of fluorescence intensity on observation angle can be quantitatively described by Eqs. 4a and 4b, which confirms propriety of this method, obtained on the basis of the reciprocal principle.[10-13]

In our previous reports, the validity of laser induced fluorescence spectroscopy under normal incidence conditions to an ultrathin film sample was proved.[7,8] In the present work, it was demonstrated that this fluorescence method can also be applied to a bulk or a thick film sample. As a result, the surface fluorescence of these samples can be distinguished from the subsurface fluorescence by this method. The present method provides the possibility to determine the surface fluorescence and subsurface fluorescence simultaneously with two detectors.

Enantioselective Extraction of Di-*O*-benzoyltartrate Anion by Ion-Pair Extractant Having Binaphthyl-Unit

Akira OHKI,* Ryo MIYASHITA, Kensuke NAKA, and Shigeru MAEDA
Department of Applied Chemistry, Faculty of Engineering, Kagoshima University, 1-21-40, Korimoto, Kagoshima 890
(Received April 22, 1991)

A lipophilic diphosphonium salt **1** having binaphtyl-type axial chirality was developed as a novel ion-pair extractant. By use of (*R*)-**1**, (−)-di-*O*-benzoyltartrate ((−)-DBT) was extracted more effectively than (+)-DBT. The enantioselectivity ($\alpha = D_{(-)}/D_{(+)}$; D: distribution ratio) was 1.3—1.4. When monophosphonium-type extractants (**2** and **3**) having structures similar to that of **1** were used, the enantioselectivity was heavily lowered. Equilibrium studies revealed that the extraction occurs *via* formation of a 1 : 1 ion-pair complex between **1** and DBT at pH 7.5—8.0. The effects of pH, ionic strength, and temperature on the extractability and the enantioselectivity were investigated. The enantioselectivity decreased with lowering pH, and was higher at lower temperatures. The optical purity of DBT in the aqueous phase was gradually enhanced by multistage extraction. From an NMR analysis of the **1**·DBT complex, the resonances of methylene-protons adjacent to phosphonium in the more extractable complexes ((*R*)-**1**·(−)-DBT and (*S*)-**1**·(+)-DBT) shifted to a higher field compared to those of the less extractable complexes ((*R*)-**1**·(+)-DBT and (*S*)-**1**·(−)-DBT).

Resolution of enantiomers has been discussed mainly in crystallization systems and in chromatography systems. In the field of solvent extraction, optical resolution (chirality recognition) has so far been scarcely studied, except for the works with Cram's chiral crown ethers.[1-6]

Crown ethers interact only with cationic species such as amino acids and amines. To extract anionic species, the use of ion-pair extraction is essential. However, in the framework of ion-pair extraction there are few reports on the chirality recognition.[7,8] Ion-pair complexes are generally outer sphere complexes between cations and anions; these ions frequently combine with each other through mediation by several water molecules within the complexes. Therefore, it is generally believed that the specificity is not appreciably expected in ion-pair formation itself, whereas a selectivity could be attained via i) a difference in the solubility to aqueous phase, ii) that to organic phase, iii) acid-base reaction, and iv) complex formation in aqueous media. However, two enantiomers in ion-pair extraction systems would behave quite similarly regarding the factors i)—iv).

In order to separate enantiomers by ion-pair extraction, a specificity should exist in the ion-pair formation itself; a difference in the steric hindrance between the enantiomers can result in a specificity when they form ion-pair complexes with chiral ion-pair extractants. However, such a difference hardly reflects the difference in distribution ratios of each enantiomer. This may be a main reason for the scarcity of reports on the chirality recognition in ion-pair extractions.

Recently, we studied ion-pair extractions of organic anions from the viewpoint of molecular recognition.[9-16] In a previous communication,[17] we briefly reported a new type of ion-pair extractant having an axial chirality (binaphthyl unit), which exhibited the ability of chirality recognition in the ion-pair extraction of an organic dicarboxylate anion, di-*O*-benzoyltartrate (DBT). This demonstrates a possibility of chirality recognition by proper design of the extractant molecule. However, the extractant reported has a low lipophilicity and hence is not of practical use as an anion-exchange extractant.

In the present study, we synthesized a chiral extractant of high lipophilicity, (*R*)-(−)- or (*S*)-(+)-1,1′-binaphthyl-2,2′-diylbis[(*p*-octylbenzyl)diphenylphosphonium] dibromide (abbreviated as (*R*)-**1** or (*S*)-**1**; Fig. 1). By using this as an ion-pair extractant (anion-exchange extractant), we examined factors affecting the chirality recognition and extractability. Further, the ion-pair complexes of optical isomer were investigated by NMR. The potential of optical resolution by use of the chiral ion-pair extractant is discussed.

In the field of chromatography, it is known that optical resolution of ionic enantiomers in aqueous media is considerably difficult. Ion-pair extraction is the basis of ion-pair chromatography, and thus, the study of chiral ion-pair extraction is important from such a point of view, as well.

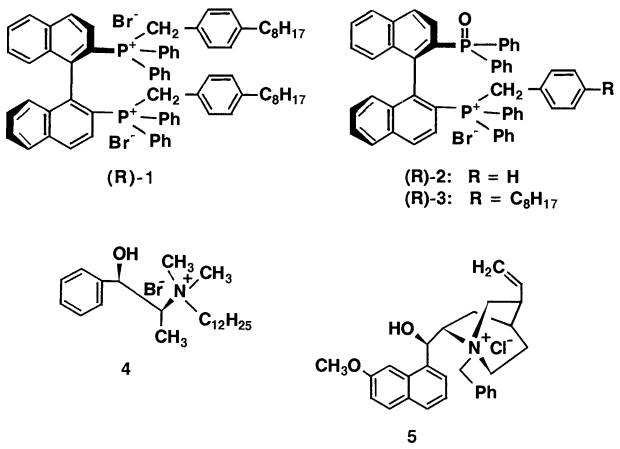

Fig. 1. Ion-pair extractants having chirality.

Experimental

Synthesis of (*R*)-1. *p*-Octylbenzyl bromide was obtained from *p*-octylbenzonic acid via methylation, $LiAlH_4$-reduction, and bromination by phosphorus tribromide. The bromide (4.5 g, 16 mmol), (*R*)-(+)-2,2′-bis(diphenylphosphino)-1,1′-binaphthyl ((*R*)-BINAP; 2.0 g, 3.2 mmol), and *N*,*N*-dimethylformamide (DMF, 10 mL) were charged in a grass tube, which was then sealed along with a stirring magnet under vacuum after several freeze-pump-thaw cycles. The sealed tube was heated at 130 °C for 3 h with internal stirring. After removal of DMF and unreacted *p*-octylbenzyl bromide from the reaction mixture by evaporation with a rotary pump, white crude crystals were obtained. The crystals were purified by column chromatography on silica gel. The column with the crude product was washed with 1,2-dichloroethane and the product was eluted with ethanol. Colorless crystals were obtained. Yield (3.1 g, 81%), mp 214—216 °C. Found: C, 74.58; H, 6.50%. Calcd for $C_{74}H_{78}P_2Br_2$: C, 74.74; H, 6.61%. $[\alpha]_D^{25}$ −142°, $[\alpha]_{546}^{25}$ −186°, $[\alpha]_{435}^{25}$ −487° (*c* 1.0, ethanol). ^1H NMR ($CDCl_3$) δ=0.87 (6H, t; CH_3), 1.15—1.5 (24H, br; CCH_2C), 2.42 (4H, t; CH_2Ph), 4.72 and 4.75 (2H, two d, $J_{PCH}\approx J_{HCH}\approx$12 Hz; $PhCH_2P$), 5.26 and 5.29 (2H, two d, $J_{PCH}\approx J_{HCH}\approx$12 Hz; $PhCH_2P$), and 6.6—8.3 (40H, m; aromatic). ^{31}P NMR ($CDCl_3$) δ^P (from H_3PO_4)=20.9 (s). (*S*)-**1** was similarly prepared from (*S*)-BINAP (Yield; 2.9 g, 76%). Its physicochemical properties were identical with those of the enantiomer except in the sign of rotation. Found: C, 74.48; H, 6.71%.

Synthesis of (*R*)-2. (*R*)-BINAP (2.0 g, 3.2 mmol), benzyl bromide (0.55 g, 3.2 mmol), and DMF (18 mL) were charged in a grass tube and treated in a manner similar to that for (*R*)-**1** synthesis (130 °C, 20 h). Then, 1.1 g of hydrogen peroxide solution (30%) was added to the reaction mixture, and this was heated at 100 °C for 3 h. Yield (1.4 g, 54%), mp 175—179 °C. Found: C, 75.53; H, 4.95%. Calcd for $C_{51}H_{39}OP_2Br$: C, 75.65; H, 4.85%. $[\alpha]_D^{25}$ −49° (*c* 1.0, ethanol). ^1H NMR ($CDCl_3$) δ=3.81 and 3.84 (1H, two d, $J_{PCH}\approx J_{HCH}\approx$12 Hz; $PhCH_2P$), 5.52 and 5.57 (1H, two d, $J_{PCH}\approx J_{HCH}\approx$12 Hz; $PhCH_2P$), and 6.4—8.0 (36H, m; aromatic). (*R*)-**3** was similarly prepared from (*R*)-BINAP and *p*-octylbenzyl bromide. The product was identified by elemental analysis and ^1H NMR.

Reagents. (−)-*N*-Dodecyl-*N*-methylephedrinium bromide (**4**) and (−)-*N*-benzylquininium chloride (**5**) were purchased from Merck and used after recrystallization. Other chemicals were of reagent grade and used without further purification.

Extraction Procedure. An aqueous solution containing the chiral anion (DBT) was shaken with an organic solution containing an extractant in a stoppered centrifuge tube for 3 h in a thermostated bath (±0.1 °C). As extracting solvent, a mixture of 1,2-dichloroethane and carbon tetrachloride (1 : 1) was mainly used. After a phase-separation procedure was rapidly carried out, the concentration of the anion in the aqueous phase was determined by HPLC with a Shimadzu LC-6A liquid chromatograph equipped with a UV detector SPD-6A (275 nm). A column packed with octadecylsilyl (ODS) silica (150 mm×4.6 mm, Wakosil 5C18-200) was used. The eluent was a mixed solution (water–methanol 3 : 2) containing 2 mM (1 M=1 mol dm^{-3}) Na_2HPO_4–KH_2PO_4 buffer. Enantioselectivity (α), the ratio between the distribution ratios of both enantiomers, was obtained as an average of more than three runs.

Multistage Extraction. An aqueous solution (10 mL) containing 5 mM racemic DBT, 15 mM NaBr, and 0.1 M Na_2HPO_4–KH_2PO_4 buffer (pH 7.5) was shaken with an organic solution (1,2-dichloroethane, 10 mL) containing 10 mM (*R*)-**1** for 3 h at 2 °C. After phase separation, the concentration of DBT in the aqueous phase was determined, and the optical rotation of the solution was measured by a polarimeter (JASCO DIP-370 with Hg lamp (435 nm); 10 cm cell) (first-step extraction).

A 9.6 mL aliquot of the aqueous phase after the extraction was taken up, in which 0.1 mL of 0.5 M NaBr solution was added. The resulting solution was shaken with 4 mL of the fresh organic solution containing 10 mM (*R*)-**1** in a similar manner. After phase separation, the concentration and the optical rotation were measured (second-step extraction). Then, 9.2 mL of the aqueous phase after the second-step extraction was taken up, and the solution was treated in a similar manner, except that 0.05 mL of 0.5 M NaBr solution was added (third-step extraction).

In the case of (*S*)-**1** extractant, the extraction procedure was similarly carried out except that 9.4 mL of the aqueous phase was used in the second-step extraction and 9.0 mL, the third-step extraction.

NMR Analysis of Ion-Pair Complex. An aqueous solution (20 mL) containing 50 mM (−)- or (+)-DBT and 0.5 M Na_2HPO_4–KH_2PO_4 buffer (pH 7.5) was shaken with a 1,2-dichloroethane solution (20 mL) containing 5 mM (*R*)- or (*S*)-**1** for 2 h at room temperature. The organic phase was separated. After removal of the solvent by evaporation, the ion-pair complex was obtained (yield: 93%). A portion of it was dissolved in $CDCl_3$ and analyzed by NMR with a JEOL JNM-GSX 400 instrument.

Results and Discussion

Extraction of Enantiomeric DBT. Table 1 summarizes the extraction of enantiomeric DBT by use of various extractants having chirality. When (*R*)-**1** was used, which is a dicationic diphosphonium salt having an axially chiral unit (binaphtyl unit), (−)-DBT was more effectively extracted than (+)-DBT. In contrast, (+)-DBT was more efficiently extracted than (−)-DBT by use of (*S*)-**1** as extractant. Thus, "enantioselective" extraction took place by use of **1** as an ion-pair extractant. The enantioselectivity α was 1.36. When the extraction using (*R*)-**1** was performed at 20 °C, the enantioselectivity was lower than 1.36. When pure 1,2-dichloroethane was used as extracting solvent instead of the mixture solvent (1,2-dichloroethane+carbon tetrachloride) under otherwise identical conditions, the enantioselectivity somewhat decreased.

Compounds **2** and **3** have structures similar to that of **1** but are monocationic phosphonium salts (Fig. 1). When they were used as extractants, the enantioselectivity was considerably lower. Compounds **4** and **5** are commercial phase-transfer catalysts having asymmetric carbons. These did not exhibit chirality recognition as ion-pair extractants.

In the extraction of mandelate by (*R*)-**1**, the (−)-isomer was somewhat more extracted than the (+)-isomer

Table 1. Extraction of Enantiomeric DBT by Chiral Extractant[a]

Extractant	Buffer mM	pH	[NaBr] mM	Temp °C	(+) or (−)[b]	Distribution ratio[c] D_A	D_B	$\alpha=D_A/D_B$
(*R*)-**1**	5	7.5	0.4	2	(−)	0.400	0.294	1.36
(*S*)-**1**	5	7.5	0.4	2	(+)	0.392	0.290	1.35
(*R*)-**1**	2	7.0	0.3	2	(−)	1.10	0.818	1.34
(*R*)-**1**	2	7.0	0	20	(−)	1.08	0.911	1.18
(*R*)-**2**	2	7.0	0	20	(−)	1.93	1.84	1.05
(*R*)-**3**	2	7.0	0	20	−	3.68		d)
4	2	7.0	0	20	−	1.58		d)
5[e]	2	6.1	0	20	−	0.74		d)

a) The aqueous phase initially contained 0.1 mM DBT, NaBr, and Na_2HPO_4–KH_2PO_4 buffer, while the organic phase (1,2-dichloroethane+carbon tetrachloride, 1:1) contained 0.2 mM extractant. b) More extractable enantiomeric DBT. c) D_A and D_B denote the distribution ratios of more and less extractable enantiomeric DBTs, respectively. d) The α value could not be evaluated ($\alpha<1.02$). e) 5 mM of the extractant was added.

(α=1.1). However, in the extraction of dansyl-amino acids such as dansyl-phenylalanine and dansyl-serine by **1** and **3**, the enantioselective extraction was hardly attained under relevant conditions.

Extraction Equilibrium. The extraction of DBT by **1** was investigated in detail. We assume that extraction of the dianion (DBT) by the dicationic extractant (**1**) involves the formation of a 1:1 ion-pair complex between **1** and DBT. The reaction and the extraction constant (K_{ex}) are defined as follows:

$$(Q{\cdot}Br_2)_o + (A^{2-})_w \rightleftharpoons (Q{\cdot}A)_o + 2(Br^-)_w, \quad (1)$$

and

$$K_{ex} = [Q{\cdot}A]_o[Br^-]_w^2/[Q{\cdot}Br_2]_o[A^{2-}]_w, \quad (2)$$

where Q^{2+} and A^{2-} denote **1** and DBT, respectively, and subscripts w and o denote the aqueous and organic phases, respectively. Eq. 2 is converted into a logarithmic form:

$$\log [Q{\cdot}A]_o/[Q{\cdot}Br_2]_o[A^{2-}]_w = \log K_{ex} - 2\log [Br^-]_w. \quad (3)$$

The $Q{\cdot}Br_2$ and the complex, Q·A, are highly lipophilic and do not appreciably dissolve in the aqueous phase. The distribution ratio of $Q{\cdot}Br_2$ was larger than 100 in 1,2-dichloroethane/water system. Thus, the values of $\log [Q{\cdot}A]_o/[Q{\cdot}Br_2]_o[A^{2-}]_w$ and $\log [Br^-]_w$ in Eq. 3 can be easily obtained experimentally.

Figure 2 shows the plots of $\log [Q{\cdot}A]_o/[Q{\cdot}Br_2]_o[A^{2-}]_w$ against $\log [Br^-]_w$ in the extraction of DBT by (*R*)-**1** at pH 7.5 and 8.0. The plot is a straight line with a slope of 2. This indicates that the extraction reaction (1) occurs via the formation of a 1:1 ion-pair complex between **1** and DBT under the relevant pH conditions. The ratio, K_{ex} ((−)-DBT)/K_{ex}((+)-DBT)=1.47, was obtained at pH 7.5.

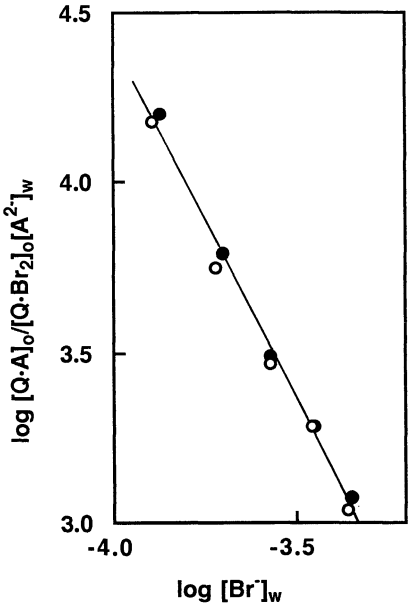

Fig. 2. Extraction of (−)-DBT by (*R*)-**1** at pH 7.5 (●) and at pH 8.0 (○). The aqueous phase initially contained 0.1 mM (−)-DBT, 0—0.4 mM NaBr, and 5 mM Na_2HPO_4–KH_2PO_4 buffer, while the organic phase (1,2-dichloroethane+carbon tetrachloride, 1:1) contained 0.2 mM (*R*)-**1** (2°C).

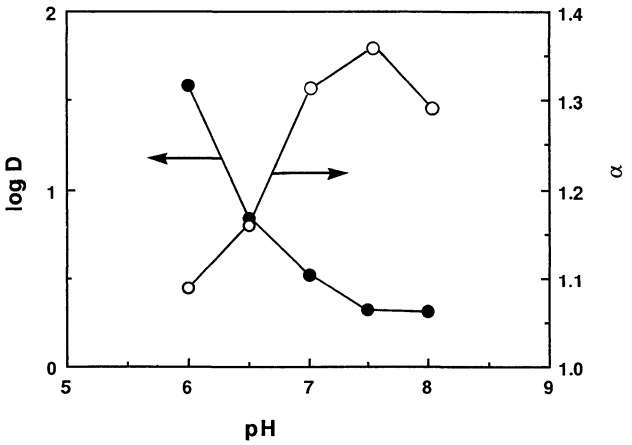

Fig. 3. Effect of pH on the extractability of (−)-DBT and the enantioselectivity (α). Conditions were the same as those in Fig. 2 except that pH was varied (NaBr: 0 mM).

Effect of pH and Ionic Strength. Figure 3 shows the plot of log D (D: distribution ratio of DBT) against pH in the aqueous phase. The extractability of DBT was decreased with increasing pH in the range 6.0—7.5, and is almost constant at pH above 7.5. This suggests that by lowering pH, the protonated DBT is involved to a higher degree in the extraction reaction ($Q^{2+}\cdot Br^-\cdot AH^-$ complex is extracted) and thus the extractability is raised. As mentioned above, the 1 : 1 ion-pair complex ($Q^{2+}\cdot A^{2-}$) is only extracted via Eq. 1 at pH above 7.5.

The enantioselectivity was enhanced with an increase in pH (Fig. 3). A two-point ion-pair formation within the complex between **1** and DBT may play an important role in the enantioselectivity, as will be discussed later.

Figure 4 depicts the effect of ionic strength in the aqueous phase. The extractability is nearly independent of the ionic strength, while the enantioselectivity decreases slightly, as the ionic strength increases.

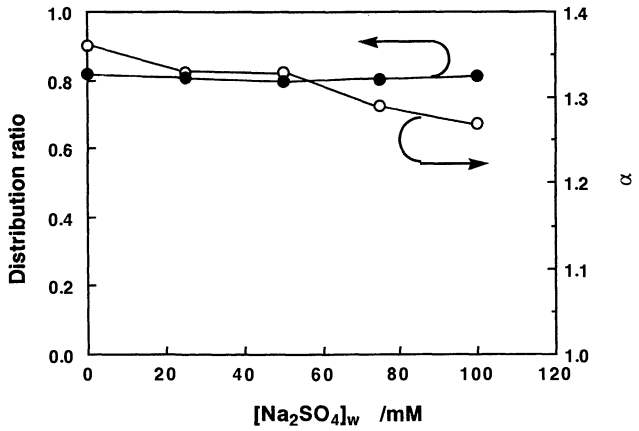

Fig. 4. Effect of ionic strength on the extractability of (−)-DBT and the enantioselectivity (α). Conditions were the same as those in Fig. 2 except that a prescribed amount of Na_2SO_4 was added and 2 mM buffer was used (pH: 7.5; NaBr: 0.2 mM).

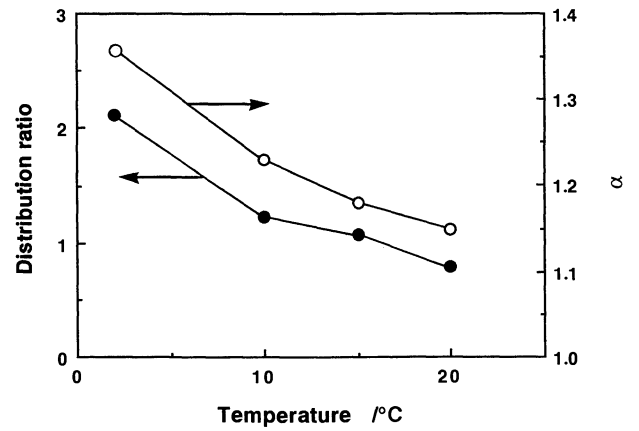

Fig. 5. Effect of temperature on the extractability of (−)-DBT and the enantioselectivity (α). Conditions were the same as those in Fig. 2 except that the temperature was varied (NaBr: 0 mM; pH: 7.5).

Effect of Temperature. The effect of temperature is given in Fig. 5. Both the extractability and the enantioselectivity decrease with an increase in the temperature. The chirality recognition of **1** may come from a difference between the steric hindraces of binaphtyl unit for both enantiomers. As the temperature is lowered, the rigidity of binaphtyl unit increases, resulting in the enantioselectivity enhancement. A similar situation was reported in the studies of Cram's crown ether.[3]

Multistage Extraction. Table 2 summarizes the results of multistage extraction. In each extraction step, the conditions were adjusted to give the % extraction of roughly 50%. As the extraction step went up in the case of (*R*)-**1** extractant, the optical purity of (+)-DBT in the aqueous phase was gradually enhanced; however, the concentration of DBT in the aqueous phase was inevitably decreased. Conversely, when (*S*)-**1** was used, the optical purity of (−)-DBT was increased. The conditions of multistage extraction in the cases of (*R*)-**1** and (*S*)-**1** were somewhat different from each other. Therefore, as seen in Table 2, the optical purities obtained in both cases were a little different.

The enantioselectivity (α) calculated from the optical purity in the first step was 1.42, which is comparable to the values obtained from the separate-mode extraction experiments ((+)- and (−)-DBTs were separately extracted) shown in Table 1 etc. Table 2 shows that the optical purity is improved as the extraction step is repeated. By designing a sophisticated device such as a counter-current extraction system, complete resolution of racemic DBT could be attained.

NMR Analysis of Ion-Pair Complex. Table 3 summarizes the chemical shifts of ^1H and ^{31}P within the ion-pair complex, **1**·DBT, in $CDCl_3$. The chemical shifts of the two methylene-protons adjacent to the phosphonium phosphorus atom in **1** (H^a and H^b) are different from each other. Free rotation of the methylene-carbon is limited because of a steric hindrance around the phosphorus atom. A similar situation was observed in the case of the methylene-protons within **2**

Table 2. Multistage Extraction[a)]

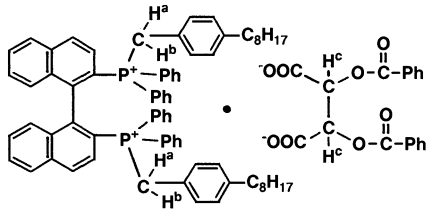
Extractant **1**	Extraction step	$[DBT]_w$[b)] mM	O.R.[c)] °	O.P.[d)] %
(*R*)	1	2.42	+0.027	9.2
	2	1.40	+0.030	18
	3	0.555	+0.024	36
(*S*)	1	2.39	−0.027	9.3
	2	1.33	−0.029	18
	3	0.522	−0.022	34

a) Extraction conditions are described in text. b) The concentration of DBT remained in the aqueous phase after each extraction step. c) Optical rotation of the aqueous phase (λ=435 nm). d) Optical purity of DBT in the aqueous phase.

Table 3. Chemical Shifts of H and P within the Ion-Pair Complex **1**·DBT in $CDCl_3$[a]

Complex[b]	**1**[c]			DBT
	H^a	H^b	P	H^c
(*R*)·Br_2	5.27	4.73	20.9	—
(*S*)·Br_2	5.29	4.75	20.9	—
(*R*)·(−)	5.05	4.41	21.1	5.87
(*R*)·(+)	5.15	4.56	21.1	5.89
(*S*)·(−)	5.14	4.58	21.1	5.88
(*S*)·(+)	5.07	4.40	21.1	5.88

a) $\delta(^1H)$ from tetramethylsilane; $\delta(^{31}P)$ from H_3PO_4. b) For example, (*R*)·(−) denotes the complex between (*R*)-**1** and (−)-DBT. c) For H^a and H^b, the top of apparent triplet peak (two doublet peaks are overlapped) is indicated.



1-DBT ion-pair complex

and **3** (see experimental section).

The couple of the ion-pair complexes enantiomeric to each other, (*R*)·(−)-(*S*)·(+) couple and (*R*)·(+)-(*S*)·(−) couple, naturally exhibited almost the same chemical shifts for the methylene-protons (H^a and H^b); e.g., (*R*)·(−) denotes the complex between (*R*)-**1** and (−)-DBT. However, the chemical shifts for the former couple ((*R*)·(−) and (*S*)·(+)) were shifted to higher field by 40—70 Hz compared to those in the latter couple ((*R*)·(+) and (*S*)·(−)).

As previously described, the extractabilities of (*R*)·(−) and (*S*)·(+) were higher than those of (*R*)·(+) and (*S*)·(−) (Table 1). It is considered that the extractability is enhanced when the ion-pair is more tightly formed. In this case, the electron-withdrawing property of phosphonium decreases, so that the methylene-protons (H^a and H^b) are shifted to higher field.

The chemical shifts of phosphonium phosphorus atom itself and the methine-proton in DBT are nearly common among the four optical isomers (Table 3).

Chirality Recognition in Ion-Pair Extraction. It is found that the enantioselective extraction of DBT is possible by use of **1** as ion-pair extractant. To our knowledge, there has been only one report dealing with the chirality recognition of ionic species in ion-pair extraction system.[7] An enantioselective extraction of mandelate anion is studied, in which a chiral ammonium salt, a derivative of α-methylbenzylamine, is used as extractant. So far, ion-pair extractants having axial chirality have not been studied.

The concept of "three-point interaction" has often been used to explain the mechanism of chirality recognition in chromatographic studies.[18] This concept is applicable to the present system of ion-pair extraction. There is a three-point interaction between **1** and DBT, two ion-pair interactions and one steric interaction (or π–π interaction) of aromatic rings.

When the monocationic extractants **2** and ***3*** were used, the enantioselectivity was heavily decreased (Table 1). These extractants cannot perform such a three-point interaction. Moreover, as shown in Fig. 3, the enantioselectivity was decreased with lowering pH in the aqueous phase. As the pH is lowered, the involvement of protonated DBT to the extraction reaction rises. Thus, the three-point interaction hardly works between **1** and DBT. Consequently, the three-point interaction can be favorably at work, only when the extraction reaction involves both the dicationic **1** and dianionic DBT, leading to high chirality recognition.

The chiral ion-pair extractant **1** possesses a high chirality recognition ability and a high extraction ability resulting from its high lipophilicity. The chirality recognition by ion-pair extraction may open a new realm of optical resolution for ionic species in aqueous media.

The authors wish to express their thanks to Professor M. Takagi of Kyushu University for his helpful suggestions and discussions.

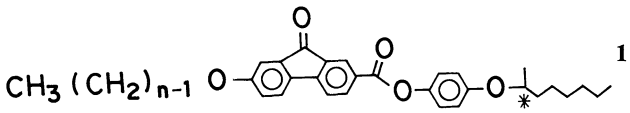
Formation and Properties of Ferroelectric Liquid Crystalline Compound Containing -C(O)-S-O- Linkage

Kohki TAKATOH* and Masanori SAKAMOTO
Chemical Lab., Toshiba R&D Center, Komukai Toshiba-cho, Saiwai-ku Kawasaki 210
(Received February 7, 1991)

During our investigations of the synthesis of ferroelectric liquid crystal compounds containing a fluorenone nucleus, the formation of a novel compound having a -C(O)-S-O- linkage was discovered as a by-product when a derivative of fluorenone carboxylic acid was treated with thionyl chloride and a phenol. This compound also exhibited ferroelectric liquid crystal properties. Compounds with a -C(O)-S-O- linkage have been little reported; this is the first report concerning a liquid crystalline compound with this type linkage. The thermal stability of the mesophase is reduced upon changing from the -C(O)-O- linkage to the -C(O)-S-O- linkage. The synthesis and properties of this compound are discussed in detail.

The authors previously reported the properties of ferroelectric liquid crystals containing fluorene and fluorenone structures.[2,3] During the synthesis of some fluorenone compounds **1**, small amounts of by-products (compounds **2**) appeared during



1

the esterification step. After isolation and purification, compound **2** (n=10) was found to show a liquid crystal phase over a wide range of temperatures under a polarized microscope. For a novel molecular structure of liquid crystalline material and a new reaction, the molecular structure was identified and the properties as a ferroelectric liquid crystal were investigated.

Experimental

Measurements. Measurements of transition temperature and observations of the microscopic texture of the mesophases were carried out using an Olympus polarizing microscope in conjunction with a Mettler FP82 heating stage, a FP80 control unit and a Seikohdenshi differential scanning calorimeter (model DSC 200). ^{1}H NMR spectra were measured using a JEOL JNM-GSX-270 NMR spectrometer for a solution in $CDCl_3$, with tetramethylsilane used as the internal standard. The IR spectra were recorded on a KBr disc with a JASCO Report-100 infrared spectrometer. The purity of each sample was checked by HPLC JASCO TWINCLE and element analysis.

The Synthesis and Purification of Compound 1 (n=10) and Compound 2. 7-Decyloxy-9-oxo-2-fluorenecarboxylic acid (3.00 g, 7.89 mmol) in 35 ml of thionyl chloride was warmed at 70 °C for 2 h. After evaporating the thionyl chloride, 25 ml of dry pyridine was added. Then 4-((*S*)-1-methylheptyloxy)-phenol (2.21 g, 9.95 mmol) in 10 ml of dry pyridine solution was added and the mixture was warmed at 80 °C for 3 h. It was then poured into ice water. After acidification, the precipitate was collected and purified by column chromatography. By recrystallizing the first fraction product from petroleum ether and an ethanol solution, 1.02 g (1.75 mmol, 22%) of yellowish needles were obtained. By recrystallizing the second fraction product from petroleum ether and toluene, 0.84 g (1.29 mmol, 16%) of yellowish needles were obtained.

The molecular structures of these compounds were confirmed using ^{1}H NMR, IR, UV-spectra, and elemental analyses.

Results and Discussion

Formation. The formation of this by-product (compound **2**) has only been confirmed in a few cases. However, in the case of the synthesis of compound **1** (n=10), for example, a good amount of compound **2** (n=10) was obtained. The authors discuss this particular case here and give a detailed description of the conditions in the experimental section.

Molecular Structure. The molecular structure of compound **2** (n=10) was determined by the ^{1}H NMR, IR, UV-spectra, as well as elemental analysis. All of the data are consistent with the molecular structure **2** (n=10), shown below.

Fluorenone H-6	8.31 J_{3-4}=8.1 Hz J_{1-3}=2.7 Hz	8.26 J_{3-4}=8.1 Hz J_{1-3}=2.7 Hz	dd (1H)
Fluorenone H-8	8.40	8.33	d (1H)

Table 2. IR and UV-Spectra and Elemental Analysis of Compound **1** and Compound **2**

Compound **1**	IR/cm^{-1} (KBr)	2930, 2860, 1740 (CO), 1720 (CO), 1600, 1510, 1470, 1300, 1270, 1240, 1200, 1090
	λ_{max}/nm (CH_2Cl_2)	435, 339, 325, 283, 252, 231
Compound **2**	IR/cm^{-1} (KBr)	2930, 2860, 1740 (CO), 1720 (CO), 1610, 1490, 1470, 1300, 1260, 1200, 1100
	λ_{max}/nm (CH_2Cl_2)	439, 340, 326, 283, 231
	Elemental analysis/%	C 74.28 (73.99)
	(Calcd for $C_{38}H_{48}O_5S$)	H 7.96 (7.84)
		S 5.44 (5.20)

The ^{1}H NMR spectra of compound **1** (n=10) and **2** (n=10) are shown in Table 1. The assignment of each peak was carried out by a comparison with the data for other fluorenone derivatives.[2,3] The chemical shifts and splitting patterns of compounds **1** (n=10) and **2** (n=10) were almost identical.

IR, UV-spectra, and elemental analyses of compound **1** (n=10) and **2** (n=10) are shown in Table 2. The IR spectrum of compound **2** (n=10) is very similar to that of compound **1** (n=10), except that a strong characteristic peak at 1260 cm^{-1} appears and the peak at 1510 cm^{-1} of compound **1** (n=10) disappears. The UV-spectra of the two fluorenone derivatives are essentially the same in the region above 260 nm. These spectral properties imply that the main structures comprising compound **1** (n=10), such as the fluorenone moiety as well as the phenyl and alkyl groups, remain in compound **2** (n=10).

Compound **2** (n=10) was purified by triple recrystallization, and elemental analysis was carried out at each stage. All of the analytical results were coincident within experimental error with the calculated values for the formula $C_{38}H_{48}O_5S$.

Judging from all of these results, compound **2** (n=10) was determined to have chemical formula of **2** (n=10).

One possible structure which could explain these data is one with the -C(O)-O-S- linkage. Nevertheless, there seems to be no possibility to form this structure, considering the reaction mechanism.

Compounds containing the -C(O)-S-O- linkage structure have been little reported. The author has found those compounds mentioned in only 10 papers among the literature published since 1962.

For example, Haas et al.[4] reported on the formation of $FC(O)SOC(O)CF_3$ by a reaction of fluorocarbonylsulfenic acid chloride (FC(O)SCl) and silver trifluoroacetate ($F_3CC(O)OAg$). Schuphan and Casida[5] showed the formation of $(R)_2NC(O)SOCH_2CCl{=}CH_2$ through a [2,3]sigmatropic rearrangement of *S*-(3-chloroallyl) thiocarbamate sulfoxide ($(R)_2NC(O)S(O)CH_2CCl{=}CH_2$).

Moon and Oh,[6] Islam and Kwart,[7] and U. Hildebrand et al.[8] reported the formation of a compound containing the -C(O)-S-O- linkage by the reaction of acylsulfenyl chloride derivatives with appropriate alcohol derivatives.

There has been no report concerning a compound with the -C(O)-S-O- linkage, which is formed through a reaction of alcohols or phenols with products formed from carboxylic acids and thionyl chloride.

Phase Transition Behavior. The phase transition behavior of compound **2** was observed using a polarized microscope in conjunction with a heating stage and differential scanning calorimeter.

The phase transition behavior of compound **2** (n=10) is shown below, along with that of compound **1** (n=10) for a comparison.

$$\text{Cr} \xrightarrow{93\,^\circ\text{C}} \text{S}_{c^*} \xrightarrow{102\,^\circ\text{C}} \text{ISO} \quad \text{compound } \mathbf{2}\ (n=10)$$

$$\text{Cr} \xrightarrow{81\,^\circ\text{C}} \text{S}_{c^*} \xrightarrow{118\,^\circ\text{C}} \text{S}_A \xrightarrow{127\,^\circ\text{C}} \text{ISO} \quad \text{compound } \mathbf{1}\ (n=10)$$

Compound **2** (n=10) shows no tendency to decompose when heated to 200 °C in air. A phase determination was possible, since it showed the broken fan texture characteristic of the smectic C phase under a polarized microscope. Miscibility tests were carried out with liquid crystalline materials of which the phase transition behavior was already known. The material exhibits a direct transition from isotropic liquid into the chiral smectic C phase. It has a higher melting point and a lower isotropic liquid–liquid crystal transition temperature than does compound **1** (n=10).

The decrease in the mesophase thermal stability (the transition temperature from the liquid crystal phase to the isotropic liquid phase) of compound **2** (n=10), compared with compound **1** (n=10), can be attributed to the fact that the change from the –C(O)–O– linkage to the –C(O)–S–O– linkage increases the molecular width, decreases the linearity of the molecule and increases the flexibility of the linkage. Especially, the disappearance of the smectic A phase in the case of compound **2** (n=10) means a decrease in the lateral attractive intermolecular interaction, due to the factors mentioned above.

After purification by triple recrystallization and checking the purity using elemental analysis and HPLC each time, the sample was sufficiently pure; however, the isotropic and chiral smectic C phases coexisted in equilibrium over several degrees. The authors experienced this phenomenon in liquid crystalline materials which have a direct transition from an isotropic liquid to the smectic C phase.[3)]

Tilt Angle and Spontaneous Polarization. The temperature dependence of the tilt angle and spontaneous polarization for the compound were measured. These measurements were carried out by a previously reported method.[3)] Liquid crystal cells having a 1×1 cm^2 electrode area were used. Alignment was achieved by coating the glass surfaces with polyimide and buffing the surface in one direction. The cell spacing was 2.0 μm, which was obtained using fiber spacers. In Fig. 1, the temperature dependence of the tilt angle for compounds **1** (n=10) and **2** (n=10) are shown.

The tilt angle of compound **1** (n=10) gradually increases with decreasing temperature, a characteristic of a second-order transition. On the other hand, the tilt angle of compound **2** (n=10) increases abruptly to 29 degrees just below the transition from an isotropic liquid to the chiral smectic C phase; no significant change was observed. These are characteristic of a first-order transition.

The temperature dependence of spontaneous polarization of compounds **1** (n=10) and **2** (n=10) are shown in Fig. 2.

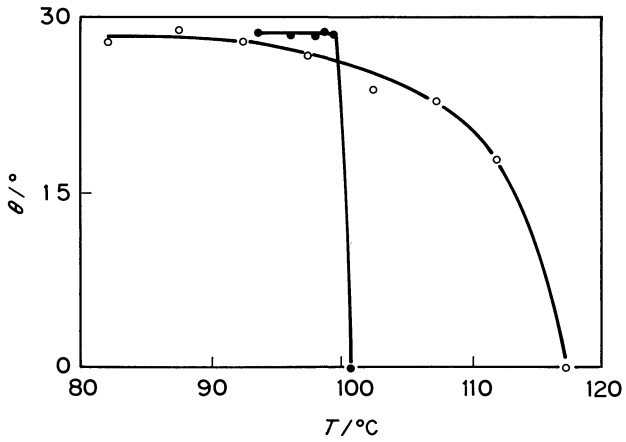

Fig. 1. Tilt angle (θ) temperature dependences of compound (**1**) and compound (**2**). ○ and ● denote compound (**1**) and compound (**2**), respectively.

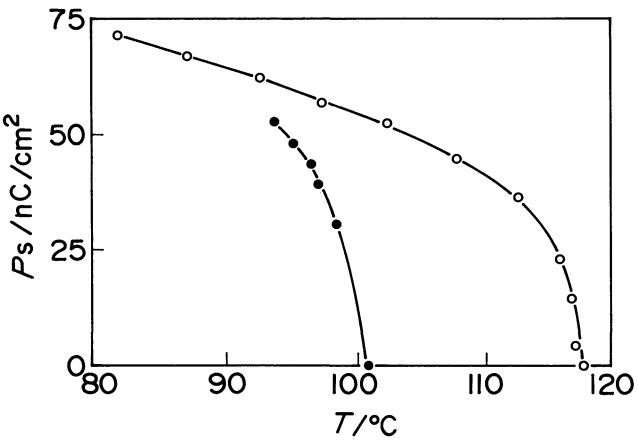

Fig. 2. Spontaneous polarizations (Ps) temperature dependences of compound (**1**) and compound (**2**). ○ and ● denote compound (**1**) and compound (**2**), respectively.

Over the entire temperature range, compound **2** (n=10) shows a lower spontaneous polarization than does compound **1** (n=10). Just below the transition temperature, ths slope of compound **2** (n=10) is steeper than that of compound **1** (n=10) for the ISO-S_{c^*} type first-order transition. However, spontaneous polarization gradually increases with decreasing temperature, in spite of the first-order transition. This could be ascribed to the fact that, in the case of compound **2** (n=10), the transition between the isotropic liquid phase and the chiral smectic C phase is ambiguous and both phases coexist until about 95 °C. From these results, it can be said that the change from the –C(O)–O– linkage to the –C(O)–S–O– linkage does not greatly influence the magnitudes of the tilt angle and spontaneous polarization.

(Received March 22, 1991)

Photoreactions of 4-methoxystyrene (**1**) sensitized with dyes such as Acriflavine, Rhodamine 6G, and Methylene Blue in methanol under oxygen afforded 4-methoxybenzaldehyde, its dimethyl acetal, and 2-methoxy-2-(4-methoxyphenyl)ethanol as oxidation products together with the corresponding dimers, *cis*- and *trans*-cyclobutanes in a ratio of cis/trans ca. 5/95. On the basis of quenching studies of fluorescence and T–T absorption of the dyes, the oxygenation and dimerization are proposed to proceed through an electron transfer from **1** to excited singlet dyes but not to involve generation of singlet oxygen.

Dye-sensitized oxygenation of olefins has been investigated and in most cases singlet oxygen has been proposed as an oxygenating intermediate;[1] however, some oxygenations have recently been proposed to take place through an electron transfer from olefins to excited dyes to give olefin radical cations followed by their reactions.[2,3] This paper now reports, based on quenching studies of fluorescence and T–T absorption of the sensitizers, that the dye-sensitized oxygenation of 4-methoxystyrene (**1**) in methanol proceeds in the singlet state through the cation radical of **1** to afford oxidation products together with dimerization products, and that singlet oxygen usually resulting from sensitization with dye triplets plays no role in this reaction.

Experimental

^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL FX-90Q spectrometer. Fluorescence spectra were obtained on a Hitachi F-4000 fluorescence spectrophotometer. Fluorescence lifetimes were measured using a single photon counting apparatus, Horiba NAES 1100.

Materials. Acriflavine, Methylene Blue (Nakalai Tesque), Eosin Y, Rose Bengal (Wako), and Rhodamine 6G (Tokyo Kasei) were used without further purification in dye-sensitized oxygenation and dimerization reactions of **1**. The dyes were purified by recrystallization from ethanol/benzene for measurements of fluorescence spectra and lifetimes, and for laser flash photolyses.

4-Methoxystyrene (**1**),[4] *cis*- (**2**),[5] and *trans*-1,2-bis(4-methoxyphenyl)cyclobutane (**3**)[5] were prepared as described previously.

4-Methoxybenzaldehyde dimethyl acetal (**5**)[6] was prepared from 4-methoxybenzaldehyde (**4**) by refluxing with methyl orthoformate in the presence of a catalytic amount of ammonium chloride in methanol; bp 102 °C/5 Torr (1 Torr=133.322 Pa); ^{13}C NMR ($CDCl_3$) δ=159.7 (s), 130.5 (s), 127.8 (d), 113.5 (d), 103.1 (d), 55.0 (q), 52.4 (q); ^{1}H NMR ($CDCl_3$) δ=7.40—6.81 (q, 4H, aromatic H), 5.33 (s, 1H, CH), 3.75 (s, 3H, OCH_3), 3.28 (s, 6H, OCH_3). Calcd for $C_{10}H_{14}O_3$: C, 65.92; H, 7.74%. Found: C, 66.05; H, 7.56%.

(4-Methoxyphenyl)oxirane (**7**)[7,8] was prepared from 4-methoxybenzaldehyde with dimethyloxosulfonium methylide;[9] yield 18%, bp 80 °C/2 Torr (lit,[7] bp 76 °C/0.037 Torr).

2-Methoxy-2-(4-methoxyphenyl)ethanol (**6**)[10] was prepared by stirring the oxirane, **7**, in methanol with a few drops of conc. HCl for 17 h; yield 55%, bp 140 °C/3 Torr (lit,[10] bp 137—139 °C/5.5 Torr); ^{13}C NMR ($CDCl_3$) δ=159.5 (s), 130.5 (s), 128.1 (d), 114.0 (d), 84.3 (d), 67.2 (t), 56.5 (q), 55.2 (q); ^{1}H NMR ($CDCl_3$) δ=7.28—6.84 (q, 4H, aromatic H), 4.34—4.18 (m, 1H, CH), 3.78 (s, 3H, OCH_3), 3.78—3.59 (m, 2H, CH_2), 3.30 (s, 3H, OCH_3), 2.86 (broad, 1H, OH).

Irradiation of 4-Methoxystyrene with Dye under Oxygen. 4-Methoxystyrene (**1**, 0.6 M, M=mol dm^{-3}) was irradiated in the presence of dyes (2—3×10^{-3} M) in methanol under oxygen in a uranium glass tube ($\geqslant$340 nm) with a 400-W high-pressure mercury lamp (Riko UVL-400HA) through a filter solution [K_2CrO_4 0.27 g and Na_2CO_3 1 g in 1 dm^3 of H_2O (optical path length, 1 cm)]. The yields of products were determined with a Shimadzu GC-8A gas chromatograph equipped with a flame ionization detector.

Quantum Yields. Quantum yields for the formation of *trans*-1,2-bis(4-methoxyphenyl)cyclobutane (**3**) and 4-methoxy benzaldehyde (**4**) were determined by using potassium tris(oxalato)ferrate(III) actinometry.[11] Irradiation was performed with 436-nm light from a 400-W high-pressure mercury lamp through a cut filter (Shibata Harzlas FS, $\geqslant$400 nm) and a filter solution [$CuSO_4 \cdot 5H_2O$ in H_2O (4.4 g dm^{-3})+2.7 M NH_4OH]. The solutions were quantitatively analyzed on the gas chromatograph and a JASCO 800 series high-performance liquid chromatograph.

Laser Flash Photolyses. Laser flash photolyses were performed with 460-nm laser pulses (Coumarin 47, 10-ns fwhm) from a XeCl (308 nm) excimer laser(Lambda Physik EMG-101)-pumped dye laser (Lambda Physik FL-3002) and with a pulsed xenon arc (Wacom KXL-151, 150 W) as a monitoring light source. The monitoring light coming from a monochromator (JASCO CT-25C) was amplified by a photomultiplier (Hamamatsu Photonics R928) and stored in a storage scope (Iwatsu TS-8123), and the signals were transferred to a personal computer (NEC PC-9801VX21) and accumulated for 3—5 times to be averaged. The system was computer-controlled and the decay curves were analyzed by this computer system. Sample solutions containing Acriflavine (5.0×10^{-4} M) and **1** (0—4.8×10^{-2} M) were deaerated by bubbling with nitrogen for 30 min.

Redox Potentials. Redox potentials were measured by cyclic voltammetry with a potentiostat-galvanostat (Nikko Keisoku NPGS-501) and a function generator (Nikko Keisoku

NFG-3). The measurements were carried out in acetonitrile using a three-electrode cyclic voltammetric cell. A platinum disk and a platinum wire were used as the working and counter electrodes, respectively, and the reference electrode was a Ag/AgCl or an SCE. Tetraethylammonium perchlorate (0.1 M) was used as a supporting electrolyte.

Results and Discussion

Dye-Sensitized Oxygenation and Dimerization of 4-Methoxystyrene. Acriflavine (AF), Rhodamine 6G (R6G), Methylene Blue (MB), Eosin Y (EY), and Rose Bengal (RB) were used as sensitizer. Although these sensitizers exhibit fairly different absorption spectra in the visible region, they have an intense band with a molar extinction coefficient of $\approx 10^5$ at the absorption maximum (Table 1).

Irradiation of a methanol solution of **1** (0.6 M) in the presence of AF (2×10^{-3} M) under oxygen with visible light (>400 nm) gave *cis*- (**2**) and *trans*-1,2-bis(4-methoxyphenyl)cyclobutane (**3**), the corresponding cyclobutane dimers (yield 19% based on **1** consumed at 31% conversion, with an isomer ratio of **2**/**3**=3/97), 4-methoxybenzaldehyde (**4**, 23%), its dimethyl acetal (**5**, 15%), and 2-methoxy-2-(4-methoxyphenyl)ethanol (**6**, 8%), as shown in Scheme 1.

Table 1. Absorption Spectrum Data for Dyes in Methanol

Dye	λ_{max}/nm	ε_{max}	ε_{436}
AF	461	67100	35600
R6G	527	108000	1960
MB	653	96200	730
EY	523	96300	1730
RB	557	110000	2000

The dimers, **2** and **3** (10% at 8% conversion), were also formed under nitrogen together with polymers on AF sensitization in methanol. In this case, however, AF was bleached completely during irradiation.

The photooxygenation and photodimerization of **1** proceeded similarly on sensitization with R6G, MB, RB, and EY to afford, with lower efficiencies, the same products as those from the AF sensitization (Table 2). The isomer ratio **2**/**3** (=3/97—7/93) under oxygen is independent of the dye employed except MB (12/88), and **3** was produced somewhat selectively compared to the reaction under nitrogen (**2**/**3**=23/77—11/89).

In control experiments, aldehyde **4** and (4-methoxyphenyl)oxirane (**7**) were methoxylated in methanol in the presence of a catalytic amount of benzoic or hydrochloric acid to give **5** and **6**,[10] respectively. These results indicate that **5** and **6** are the secondary products derived from the oxygenation products **4** and **7**, respectively, under the reaction conditions.[14]

Effects of Singlet Oxygen Quenchers and Solvents on Photooxidation of 4-Methoxystyrene. Oxygenation of olefins gives generally carbonyl compounds and epoxides in various pathways. 4-Methoxybenzaldehyde, **4**, might be afforded by a reaction of **1** with singlet oxygen possibly generated from dye sensitization.[12] Also, *N*-vinylcalbazole has been reported to dimerize in the

presence of singlet oxygen.[13]

On AF-sensitized irradiation under oxygen the conversion of **1** was scarcely changed (within 3%) even in the presence of 2,3-dimethyl-2-butene (TME, 0.2 or 0.6 M in methanol) as an efficient singlet oxygen trap; the product distribution was similar to that in the absence of TME (Table 3). This observation indicates that singlet oxygen plays no role in the AF-sensitized oxygenation of **1**.

As shown in Table 3, 1,4-diazabicyclo[2.2.2]octane (Dabco) quenched more efficiently the AF-sensitized oxygenation of **1** than the dimerization of **1**. Although Dabco is an effective singlet oxygen quencher, it also inhibits autoxidation[14] and quenches radical cations of organic substrates as an electron donor;[15] in fact, Dabco has a much lower oxidation potential (0.68 V vs. SCE) than **1** (1.31 V). These results together with the above observation that TME exerts no effects on the efficiency of reaction and the distribution of products suggest that Dabco quenches the reaction not only as a radical inhibitor but also an electron donor, but not as a singlet oxygen quencher; the oxygenation proceeds through electron transfer and autoxidation, but not through singlet oxygen oxidation.

In an acetonitrile–methanol (4:1 by volume) mixed solvent the conversion of **1** was analogous to that in methanol, but the yield of dimers was higher (33%) than in methanol. The use of Freon 113–methanol (4:1) decreased both of the conversion of **1** and the yield (8%) of dimers. These results show that the efficiency of dimerization of **1** is affected by the polarity of solvents but is not correlated with the reported lifetime of singlet oxygen.[16,17]

Quantum Yields for Oxygenation and Dimerization. The quantum yields for formation of dimer **3** and aldehyde **4** were determined by irradiating methanol solutions of **1** (0.6 M) and dyes (ca. 5×10^{-3} M) at 436 nm under bubbling with oxygen, and are summarized in Table 4. At first glance the product distributions mentioned above seem to be inconsistent with these results; however, the discrepancy might be explained by photolability of **4** under oxygen. The high ϕ_4 values may be attributed to efficient formation of **4** through radical chain reactions as described below. It is noticeable that the AF- and R6G-sensitized reactions proceed with much higher efficiencies compared to those with EY and RB as sensitizer. According to Rehm–Weller's equation (Eq. 1),[18] the changes of Gibbs' free energy (ΔG) associated with the electron transfer from ground-state **1** to excited singlet AF and R6G are estimated to be exothermic in acetonitrile ($\Delta G=-3.9$ kcal mol^{-1} for AF and -2.4 kcal mol^{-1} for R6G), while those to excited singlet EY and RB are largely endothermic. The calculated ΔG values are listed in Table 5, where E_{ox}^{D} and E_{red}^{A} are the oxidation potential of a donor and the reduction potential of an acceptor, respectively, and E^* is the singlet or triplet excitation energy of the donor (or the acceptor). The efficiencies of the dye-sensitized reactions are consistent with the calculated ΔG values. AF is most effective among the sensitizers employed to give the dimers (**2** and **3**) and the oxidation products (**4**—**6**).

$$\Delta G = E_{ox}^{D} - E_{red}^{A} - E^* - 0.06 \text{ eV} \quad (1)$$

Quenching of Dye Fluorescence by 4-Methoxystyrene and Oxygen. The fluorescence lifetime of AF (τ_f=5.34 ns in MeCN under argon) was quenched at nearly and completely diffusion-controlled rate constants by **1** and oxygen, respectively, as shown in Tables 5 and 6. However, the concentration of **1** (0.6 M) used in the present reaction was much higher than that of oxygen (8.1×10^{-3} M). Therefore, it is reasonable to consider that the excited singlet state of AF interacts with ground-state **1** to generate the cation radical of **1** and the anion radical of AF, but does not practically interact with oxygen. The estimation of the quenching rate, $k_q[Q]$, shows that **1** quenches the excited singlet AF at the rate of 2.5×10^{9} s^{-1} (Table 6), which is larger by a factor of ca. 20 than that for oxygen ($k_q[O_2]=1.1\times10^{8}$ s^{-1}). This shows that 90% of the AF excited singlets interact with **1**, and under these conditions the quantum yield for AF triplet formation is estimated to be less than 0.06, even if oxygen quenching led to a complete formation of the AF triplets. Thus, singlet oxygen could not be efficiently generated in the present system.

Contrary to the cases of AF, R6G, and MB, fluorescence quenching by **1** was much less efficient for EY and RB; the rate constants (k_q) are 4.0×10^{8} and

Table 6. Rate Constants for Quenching of Fluorescence Lifetime of AF by **1** and Oxygen[a]

Quencher	$k_q/10^9\ M^{-1}\ s^{-1}$[b]	$k_q[Q]/10^9\ s^{-1}$[c]
1	4.1	2.5
O_2	14	0.11

a) $[AF]=5\times10^{-5}$ M. b) The lifetime of the excited singlet AF is 5.34 ns in MeCN under argon. c) [Q]= 0.6 M for **1** and 0.0081 M for oxygen.

$3.7\times10^8\ M^{-1}\ s^{-1}$ for EY and RB, respectively. This might be due to the positive ΔG values (Table 5).

Laser Flash Photolysis. On laser flash photolysis of AF (5×10^{-5} M) with 460-nm pulses in deaerated acetonitrile a transient absorption spectrum was obtained in the region of 300—800 nm (λ_{max} 550 and 650 nm), the lifetime being 4.6 μs as monitored at 550 nm (Fig. 1). This spectrum can be attributed to AF triplets.[19] The initial intensity (ΔOD) and lifetime of the absorption decreased with increasing concentration of **1** added ($1.6—4.8\times10^{-2}$ M). A Stern–Volmer plot of $\Delta OD_0/\Delta OD$ ($=\phi_{isc}^0/\phi_{isc}$) against [**1**] gives a good linear relationship (Eq. 2); the slope ($=k_q\tau_f$) is 47.2 M^{-1} (Fig. 2), where ΔOD_0 and ΔOD are the initial optical densities at 550 nm, and ϕ_{isc}^0 and ϕ_{isc} are the quantum yields for intersystem crossing, in the absence and presence of **1**, respectively. The reduced formation of AF triplet with **1** can be attributed to the quenching of the excited singlet AF by **1**. By using τ_f=5.34 ns, k_q is estimated to be $8.8\times10^9\ M^{-1}\ s^{-1}$, which is in agreement with the rate constants obtained from quenching of the fluorescence spectrum and lifetime of AF by **1**, 5.8×10^9 and $4.1\times10^9\ M^{-1}\ s^{-1}$, respectively.

$$\Delta OD_0/\Delta OD = \phi_{isc}^0/\phi_{isc} = 1 + k_q\tau_f[\mathbf{1}] \quad (2)$$

The decay rate of T–T absorption of AF was accelerated on addition of **1**; however, the quenching rate constant was as small as ca. $10^6\ M^{-1}\ s^{-1}$. The ΔG value for electron transfer from the ground-state **1** to the excited triplet AF is largely endothermic. Therefore, it is reasonably concluded that olefin **1** interacts efficiently with the excited singlet state of AF, but much less efficiently with its excited triplet state.

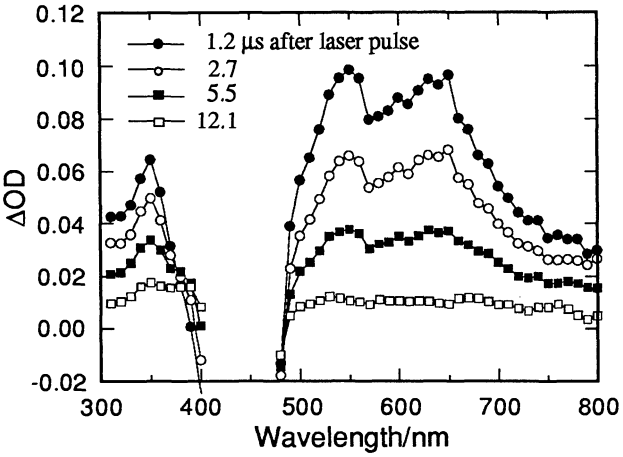

Fig. 1. T–T Absorption spectra of AF in acetonitrile.

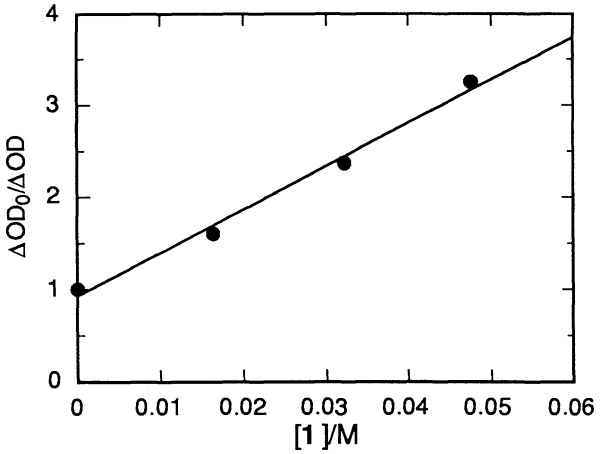

Fig. 2. Quenching of T–T absorption of AF by **1**.

Mechanism. We reported previously that the photodimerization of **1** to give **2** and **3** with a ratio of **2**/**3**=3/97 under oxygen in acetonitrile proceeds through the cation radical of **1** generated on excitation of the

contact charge transfer paor (UV absorption: 320—370 nm) between **1** and molecular oxygen.[5] Moreover, Yamamoto et al. have also reported that the photodimerization of **1** in the presence of 1,4-dicyanobenzene proceeds through the same intermediate.[20] A similar dominant formation of **3** over **2** in the present dye-sensitized cases indicates the intermediacy of $\mathbf{1}^{+\cdot}$ as the key intermediate.

The fluorescence quenching and laser flash photolyses together with the energetic considerations show that the excited singlet state of the dyes undergoes electron transfer with **1**. Also, the aforementioned AF-sensitized reactions of **1** in the presence of TME or Dabco rule out the possibilities of dimerization of **1** catalyzed by singlet oxygen and of electron transfer from **1** to singlet oxygen to generate superoxide anion, though *N*-vinylcalbazole has been reported to dimerize in the presence of singlet oxygen.[12]

As shown in Scheme 2, an electron transfer from the ground-state **1** to the excited singlet dye generates the radical ion pair of $\mathbf{1}^{+\cdot}$ and $Dye^{-\cdot}$ The monomer cation radical ($\mathbf{1}^{+\cdot}$) reacts with another neutral **1** to afford the dimer cation radical of **1** (**8**), which finally collapses to the trans cyclobutane dimer **3** with high selectivity, or reacts with methanol to give a neutral radical (**9**), initiating autoxidation of **1** to afford the aldehyde, **4**, and the oxirane, **7**, through chain processes similar to those reported already.[14,21] The cation radical $\mathbf{1}^{+\cdot}$ would react with oxygen species ($O_2^{-\cdot}$ or O_2) or methanol to generate radical intermediates (**10** and **11**[22]), which also would be able to initiate autoxidation of **1**. The back electron transfer process from $Dye^{-\cdot}$ to $\mathbf{1}^{+\cdot}$ to produce the excited triplet of **1** ($^3\mathbf{1}^*$, $E_T \approx 60$ kcal mol^{-1})[23] is safely ruled out, based on the consideration of the free energy change in the process [$\Delta G = E(\text{Dye}/\text{Dye}^{-\cdot}) - E(\mathbf{1}^{+\cdot}/\mathbf{1}) \approx -57$ kcal mol^{-1} (for AF)].

The free-energy change [$\Delta G = E(\text{Dye}/\text{Dye}^{-\cdot}) - E(O_2/O_2^{-\cdot})$] for the secondary electron-transfer process from the anion radical of dyes to molecular oxygen would be an important factor for reproducing neutral dyes [Process (4) in Scheme 2].[24] It has been reported that the electron transfer from the anion radical of MB ($MB^{-\cdot}$) to O_2 is endothermic;[3] actually, in the present reaction MB was rapidly bleached under oxygen compared to AF.

Another factor affecting the reaction efficiency seems to be the singlet lifetime of the dye employed, but the quantum yield of intersystem crossing (ϕ_{isc} in Table 5) is not such a factor; actually, AF, the most effective sensitizer, has the longest fluorescence lifetime, but its ϕ_{isc} is much larger than ϕ_{isc} of R6G.

Conclusion

By use of high concentrations of the olefin, the dye singlets are almost quenched by the olefin under oxygen atmosphere. Under these conditions the yield of the dye triplets are nearly negligible, and therefore singlet oxygen plays no role in oxidation of the olefin. The oxygenation of the olefin proceeds in methanol mainly through electron-transfer induced autoxidation to give the carbonyl and oxirane compounds (and/or their methanol adduct) together with the dimerization products.

A New Reduction of Some Carboxylic Esters with Sodium Borohydride and Zinc Chloride in the Presence of a Tertiary Amine

(Received April 2, 1991)

In the presence of a tertiary amine, sodium borohydride ($NaBH_4$) combined with zinc chloride ($ZnCl_2$) showed powerful reducing properties and carboxylic esters were smoothly reduced to their corresponding alcohols which were not obtained by reduction with $NaBH_4$ and $ZnCl_2$ alone. Tetrahydrofuran (THF) was an efficient solvent, and the effective molar ratio of the reducing agents, $NaBH_4$: $ZnCl_2$: tertiary amine, was 2 : 1 : 1. In particular, aminobenzoates such as anthranilic esters, were reduced to aminobenzyl alcohols with high yields without the addition of a tertiary amine. Further, it was also found that this combination reduced nitro, cyano, and amido groups to their corresponding amino groups.

It is known that $NaBH_4$ does not usually reduce carboxylic esters. However, several reports have suggested the possibility of $NaBH_4$ reduction of ester groups. The esters were reported to be reduced by using a large excess (20 equiv) of $NaBH_4$ in methanol,[1] and esters having complex-forming neighboring functional groups, such as oxo[2] or hydroxy esters[3] can be reduced. Soai et al. reported an efficient reducing system with $NaBH_4$–*t*-butyl alcohol–methanol for esters,[4] and Kitsuki and Fujikura reported the reduction with $NaBH_4$–2-(2-ethoxyethoxy)ethanol–xylene.[5]

On the other hand, Kollonitsch et al. reported briefly that carboxylic esters are reduced with $NaBH_4$ in the presence of a metal halide such as lithium, magnesium or calcium halide.[6] Further, Brown et al. reported the utility of aluminium chloride ($AlCl_3$) as a metal halide to be used in combination with $NaBH_4$.[7]

In this paper, a new reduction system, a combination of $NaBH_4$ and $ZnCl_2$ in the presence of a tertiary amine, by which carboxylic esters can be reduced smoothly to their corresponding alcohols with high yields, is reported.

Results and Discussion

Methyl benzoate was reduced successfully with 2.0 equiv of $NaBH_4$ and 1.0 equiv of $ZnCl_2$ in the presence of 1.0 equiv of *N,N*-dimethylaniline in THF under reflux conditions to produce an 82% isolated yield of benzyl alcohol as shown in Scheme 1. Triethylamine was similarly proved to be a very effective tertiary amine. Only 8% yield of benzyl alcohol was obtained in the absence of the tertiary amine. *N,N*-Dimethylaniline was preferable as a tertiary amine to triethylamine, because the latter formed a complex with BH_3 in the reaction mixture, which led to difficulty in separation and purification of the product.

Reduction of benzoates with bromo, alkylthio, nitro, and hydroxy moieties was carried out under the same conditions. The results are shown in Table 1.

A bromo or benzylthio group on the benzene ring had little or no influence on the reduction of the ester function. Reduction of methyl 4-nitrobenzoate gave 4-nitrobenzyl alcohol in a rather low yield probably owing to the competitive reduction of the nitro group. In the case of methyl 4-hydroxybenzoate, *p*-cresol was obtained in a 52% isolated yield possibly owing to further reduction of the 4-hydroxybenzyl alcohol initially produced. Similar reduction was reported by Brewster et al. in which 4-methoxybenzyl alcohol was reduced to 4-methylanisole with $LiAlH_4$–$AlCl_3$.[8]

As shown in Table 2, various other esters could also be reduced to their corresponding alcohols with satisfactory isolated yields. However, the reduction of ethyl

cinnamate gave a 46% yield of cinnamyl alcohol together with the double bond-reduced product.

Our reaction conditions were applied to reduction of a few esters with tertiary amino groups, and the reduction was expected to proceed smoothly in the absence of the tertiary amine. Thus, methyl *N,N*-dimethylanthranilate (**1**) could be reduced with 1.5 equiv of $NaBH_4$ and 0.75 equiv of $ZnCl_2$ without the addition of *N,N*-dimethylaniline to give 2-dimethylaminobenzyl alcohol (**2**) as shown in Scheme 2.

Furthermore, the reductions of other aminobenzoates with this reducing system were investigated. These results are summarized in Table 3.

Dialkylamino benzoates were reduced to their corresponding benzyl alcohols with high yields, but the yields were somewhat low in the cases of *N*-unsubstituted or *N*-monoalkyl-substituted derivatives.

Various metal halides were investigated in place of $ZnCl_2$ in the reduction of methyl *N,N*-dimethylanthranilate (**1**). The yield of 2-dimethylaminobenzyl alcohol (**2**) was determined by gas chromatographic (GC) analysis. The results are summarized in Table 4. Lithium and magnesium halide did not enhance the reducing ability of $NaBH_4$, in spite of Kollonitsch's

report mentioned above. However, $AlCl_3$ showed a good effect as reported by Brown et al.,[7] and the reduction proceeded at room temperature but was accompanied by the formation of some decomposition products possibly owing to the strong Lewis acidity of $AlCl_3$.

Solvent effects were investigated in the reduction of methyl *N,N*-dimethylanthranilate (**1**) with $NaBH_4$ and $ZnCl_2$ under refluxing for 2 h. As shown in Table 5, no reduction product was obtained in ethers such as diethyl ether, diisopropyl ether (IPE), and dioxane, but the reduction product was obtained in a low yield in dimethyl ether of diethylene glycol (diglyme). The reduction in ethanol produced only a small amount of ester-exchanged product without the reduction product. THF was the most suitable solvent for this reduction possibly owing to the solubility of the reagents.

The mechanism of the present reduction might be

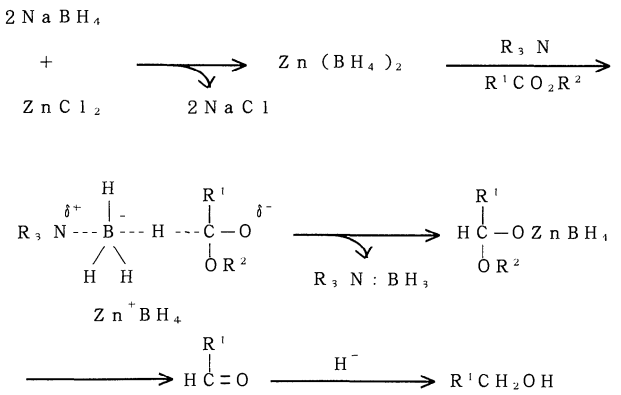
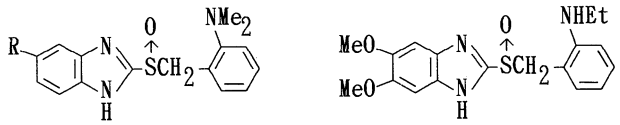
explained by the initial formation of $Zn(BH_4)_2$ followed by the reduction of esters with $Zn(BH_4)_2$ which is activated by a tertiary amine. In order to clarify this, the reduction was studied by varying the molar ratio of $NaBH_4$ and $ZnCl_2$ as shown in Table 6.

When the molar ratio of $NaBH_4$ and $ZnCl_2$ was 2:1, the corresponding 2-dimethylaminobenzyl alcohol (**2**) was produced quantitatively after 1 h. Use of less $ZnCl_2$ served to slow down the rate of the reaction, while use of more $ZnCl_2$ gave a small amount of decomposition product after 1 h owing to the Lewis acidity of $ZnCl_2$, and no appreciable increase of reduction product was observed even after a prolonged reaction time. These results also suggested the formation of $Zn(BH_4)_2$. The formation of $Zn(BH_4)_2$ from $NaBH_4$ and $ZnCl_2$ has been reported by Gensler et al.[9]

Furthermore, the optimum molar ratio of $NaBH_4$ to **1** was proved to be 1.5:1, while the reduction with an equimolar amount of $NaBH_4$ to **1** afforded ca. an 80% yield of **2** after 4 h. The curve of reaction yield showed



Scheme 3.



NC-1300 : R=H
NC-1300-B : R=OMe

S-3337

Scheme 4.

that the reaction would be completed only after a prolonged reaction time. These results revealed that only one hydride on $NaBH_4$ was effective for the reduction of an ester group to an aldehyde. A possible mechanism is shown in Scheme 3.

This reduction technique using $NaBH_4$–$ZnCl_2$–tertiary amine seems very useful because of the possibility of industrial applications in place of reductions with $LiAlH_4$ which is flammable and expensive. For example, the reduction of anthranilates is necessary for producing 2-aminobenzyl alcohols which are key intermediates of new H^+/K^+-ATPase inhibitors[10] as shown in Scheme 4. The reduction of anthranilate has been performed successfully only by using $LiAlH_4$.[11]

Further, the applicability of this reduction system to the reduction of other functional groups, such as amide, nitro, and cyano groups, was studied. The results are shown in Table 7. *N,N*-Dimethylbenzamide and 4-methylbenzonitrile were reduced to the corresponding benzylamine in good yields. However, the yield of the product in the reduction of 2-dimethylaminonitrobenzene without a tertiary amine was relatively low; the addition of *N,N*-dimethylaniline increased the yield. It seemed that the electron-withdrawing nitro group in the molecule decreased the basicity of the tertiary amino group.

Experimental

Nuclear magnetic resonance (NMR) spectra were recorded on a JEOL JNM-FX90Q NMR spectrometer with

Table 7. Reduction of Other Functional Groups[a)]

	$PhNMe_2$		85

a) A mixture of a substrate (1.0 mmol), $NaBH_4$ (2.0 mmol), and $ZnCl_2$ (1.0 mmol) in the presence or absence of *N,N*-dimethylaniline (1.0 mmol) was refluxed in THF for 2 h, and the structure of all products isolated was determined by ^1H NMR and elemental analysis (C, H, N±0.3).

tetramethylsilane as the internal standard. GC analyses were performed on a 1.0 m column of 1% SE-30 on a JEOL JGC-20K gas chromatograph, operating at 30—200 °C. Elemental analyses (C,H,N) were performed on a Heraus C,H,N-Rapid instrument.

Materials. Sodium borohydride and metal halides (lithium chloride, lithium bromide, calcium chloride, magnesium chloride, iron(III) chloride, zinc chloride, zinc bromide, boron trifluoride–diethylether (1/1), tin(IV) chloride, and aluminum chloride) were commercially available. Tetrahydrofuran was purified through aluminum oxide. Commercial diglyme was distilled over calcium hydride and then redistilled under reduced pressure from a small quantity of lithium aluminum hydride. Other etheric solvents, such as diethyl ether, diisopropyl ether, and dioxane, were purified by standard methods followed by a distillation from lithium aluminum hydride. Commercial ethanol (95%) was utilized without further purification. *N,N*-Dimethylaniline, triethylamine, methyl benzoate, methyl 4-nitrobenzoate, methyl 4-hydroxybenzoate, ethyl phenylacetate, ethyl 2-thiopheneacetate, methyl stearate, phthalide, ethyl cinnamate, methyl *N,N*-dimethylanthranilate (**1**), methyl *N*-methylanthranilate, methyl anthranilate, *N,N*-dimethylbenzamide, and 4-methybenzonitrile were commercially available. Ethyl *N,N*-diethylanthranilate was prepared by ethylation of ethyl anthranilate with diethyl sulfate. Ethyl 2-benzylthiobenzoate was prepared by esterification of 2-mercaptobenzoic acid followed by alkylation with benzyl bromide. Methyl 3-dimethylaminobenzoate, ethyl 2-naphthalenecarboxylate, and methyl 2-bromobenzoate were prepared by esterification of the corresponding carboxylic acids. *N,N*-Dimethyl-2-nitroaniline was prepared by the standard method.[12)]

Reduction of Methyl Benzoate. A mixture of methyl benzoate (13.6 g, 100 mmol), $NaBH_4$ (7.60 g, 200 mmol), $ZnCl_2$ (13.6 g, 100 mmol), and *N,N*-dimethylaniline (12.1 g, 100 mmol) was refluxed with stirring in THF (200 ml) for 2 h. The reaction mixture was cooled with ice-cold water, and 10% NH_4Cl solution and chloroform were added. The organic layer was separated, washed with water and saturated NaCl solution, and dried over anhydrous Na_2SO_4. The solvent was evaporated and distilled to give 8.86 g (82% yield) of benzyl alcohol as a colorless oil. Reduction of substituted benzoates and other aromatic and aliphatic esters was carried out by a similar procedure. The results are summarized in Tables 1 and 2.

Reduction of Methyl *N,N*-Dimethylanthranilate (1). A mixture of **1** (1.79 g, 10.0 mmol), $NaBH_4$ (570 mg, 15.0 mmol), and $ZnCl_2$ (1.02 g, 7.5 mmol) was refluxed in THF (50 ml) for 2 h. The reaction mixture was cooled with ice-cold water, and 10% NH_4Cl solution and chloroform were added. The organic layer was separated, washed with water and saturated NaCl solution, and dried over Na_2SO_4. The solvent was evaporated and the residue was purified on a silica-gel column (chloroform) to produce 1.43 g (95% yield) of 2-dimethylaminobenzyl alcohol (**2**) as a colorless oil. ^1H NMR ($CDCl_3$) δ=2.68 (s, 6H), 4.78 (s, 2H), 6.9—7.3 (m, 4H). Other aminobenzoate derivatives were reduced by a procedure similar to that described for **1**. The results are summarized in Table 3.

General Procedure for the Study on the Effect of Metal Halides. A mixture of **1** (1.0 mmol), $NaBH_4$ (1.5 mmol), and an appropriate metal halide (0.5—1.5 mmol) was refluxed with stirring in THF (5 ml) for 2 h. The yield of 2-dimethylaminobenzyl alcohol (**2**) was determined by GC analysis with benzyl alcohol as an internal standard. The results are summarized in Table 4.

General Procedure for the Study of Solvent Effects. A mixture of **1** (1.0 mmol), $NaBH_4$ (1.5 mmol), and $ZnCl_2$ (0.75 mmol) in a solvent (5 ml) was refluxed with stirring for 2 h. The yield of **2** was determined by GC analysis with benzyl alcohol as an internal standard. The results are summarized in Table 5.

General Procedure for the Study of the Effect of the Molar Ratio of $NaBH_4$ and $ZnCl_2$. A mixture of **1** (1.0 mmol), $NaBH_4$ (1.5 mmol), and $ZnCl_2$ (0, 0.5, 0.75, 1.5 mmol) in THF (5 ml) was refluxed with stirring for 2 h. The yield of **2** was determined by GC analysis with benzyl alcohol as an internal standard. The results are shown in Table 6.

General Procedure for the Reduction of Other Functional Groups. A mixture of an amide, nitro or cyano compound (1.0 mmol), $NaBH_4$ (2.0 mmol), and $ZnCl_2$ (1.0 mmol) in the presence or absence of *N,N*-dimethylaniline (1.0 mmol) in THF (5 ml) was refluxed with stirring for 2 h. The reaction was quenched with 20% NH_4Cl solution and the reaction mixture was extracted with $CHCl_3$. The organic layer was washed with saturated NaCl, dried over anhydrous Na_2SO_4, and the solvent was evaporated in vacuo. The residue was purified on a silica-gel column (ether–hexane) to give the corresponding reduced compound. The yields are summarized in Table 7.

Four new silicon compounds, dimethoxysilanediyl bis(5*H*-octafluoropentanoate), $(CH_3O)_2Si[OCO(CF_2)_4H]_2$, dimethoxysilanediyl bis(7*H*-dodecafluoroheptanoate), $(CH_3O)_2Si[OCO(CF_2)_6H]_2$, dimethoxysilanediyl bis(9*H*-hexadecafluorononanoate), $(CH_3O)_2Si[OCO(CF_2)_8H]_2$, and dimethoxysilanediyl bis(pentadecafluorooctanoate), $(CH_3O)_2Si[OCO(CF_2)_6CF_3]_2$, were prepared by the reaction of dichlorodimethoxysilane with sodium salts of fluoro-substituted carboxylic acid. The ^1H NMR, ^{13}C NMR, and ^{19}F NMR and IR spectral data of these silicon compounds were obtained. In the course of a study of the stability of the silicon compounds against hydrolysis by using ^1H NMR spectral measurements, it was found that the ease of hydrolysis of the SiOCOR and the $SiOCH_3$ moieties was exactly same.

Metal alkoxides have been the subject of extensive research owing to their potential as precursor materials for several applications, such as new ceramics, adhesives, and coupling agents, which are molecular bridges between the interface of an inorganic filler and an organic polymer. Many alkyl or aryl orthosilicates and their halogenated derivatives have been prepared[1] and the reactivities of these orthosilicates towards various types of electron donors such as amides and amines have been reported.[2]

In recent years, dramatic developments have been made in the utilization of organofluoro compounds, resulting in new high-performance materials. However, only a few research reports concerning fluoro-substituted alkoxides of metals have appeared in the literature.[3-7] In previous papers we reported on the syntheses of fluoroalkyl and fluoroaryl titanates[8] as well as the syntheses of fluoroalkyl silicates.[9] Although these alkoxides were expected to be stable against moisture, since many of the compounds having the fluorinated carbon structure possess water repellency, all of the products were very sensitive to water and were easy to decompose.

In our last paper, we reported the results of the syntheses and characterizations of new titanium compounds having three fluoro-substituted alkanoyloxyl groups and one butoxyl group.[10] An application for the surface modification against calcium carbonate was also reported. These compounds were found to be an effective substance for a new-type coupling agent, which increases the affinity between organofluoro polymers and some inorganic substances.

In this paper, the results of the syntheses and characterizations of new silicon compounds having two fluoro-substituted alkanoyloxyl groups and two methoxyl groups per molecule are reported.

The stability of these products against hydrolysis is also discussed.

Experimental

Special precautions were adopted to avoid any hydrolysis of the starting materials and products, and all experiments were carried out under an atmosphere of purified nitrogen to preclude oxygen and moisture.

Materials. Silicon tetrachloride (bp 57.5—58.0 °C) was obtained from Kanto Chemical Co., Inc. and purified by distillation. Dichlorodimethoxysilane (bp 100—102 °C) was prepared by the reaction of silicon tetrachloride with methanol; Found: Si, 17.3; Cl, 44.1; OCH_3, 38.3%, Calcd for $C_2H_6Cl_2O_2Si$: Si, 17.4; Cl, 44.0; OCH_3, 38.5%. 5*H*-Octafluoropentanoic acid (bp 40—42 °C/120 Pa), 7*H*-dodecafluoroheptanoic acid (bp 60—61 °C/106 Pa), 9*H*-hexadecafluorononanoic acid (bp 92—93 °C/53 Pa) and perfluorooctanoic acid (bp 89—90 °C/4000 Pa) were received as gifts[11] from Daikin Industries, Ltd. and purified by distillation. The purity of these acids was checked by the use of ^{19}F NMR spectra and gas chromatography (GLC), and no impurities were detected. Sodium salts of these acids were synthesized by the reaction of fluoro-substituted carboxylic acid with excess sodium hydrogencarbonate in tetrahydrofuran (THF). The solvents used were purified by the usual method.

Measurements and Instruments. The FT-IR spectra were measured in a liquid film or by a KBr method with a JEOL JIR-5300 spectrophotometer. Each spectrum was recorded at a resolution of 4 cm^{-1} with a total of 30 scans. Pulsed Fourier Transform 100-MHz ^1H NMR and 25-MHz ^{13}C NMR spectra were run in THF-d_8 with TMS as an internal standard using a JEOL JNR-PX-100 spectrometer at room temperature: ^1H NMR spectra (pulse repetition time, 5 s; number of accumulations, 20) and ^{13}C NMR spectra (pulse repetition time, 2.0 s; number of accumulations, 40000). The FT mode 90-MHz ^{19}F NMR spectra were recorded at 27 °C on a JEOL JNM-FX-90Q in THF with fluorobenzene (−113.6 ppm[12] from $CFCl_3$ in $CDCl_3$) as an external standard: pulse repetition time, 0.5 s; number of accumulation, 20. The assignments of the ^{19}F NMR spectra were referred to in the data book.[12] Gas chromatography was performed with a Hitachi 063 (PEG-6000 supported Chromosorb A NAW 30/60 mesh 5 m packed column, TCD) or Hitachi G-3000 gas chromatograph (OV-1 25 m Fused capillary column, FID) and these intensities were

measured with a Hitachi 834 chromato processor or a Hitachi D-2500 chromato integrator.

Analytical Methods. Silicon was determined gravimetrically as silicon dioxide after the hydrolysis of silicon compounds by adding aqueous ammonia and burned in a quartz crucible. Chlorine was quantified by the Mohr method. Methoxyl groups were measured quantitatively as methanol by GLC after the hydrolysis of the products by adding a sodium hydroxide solution. The contents of the fluorinated alkanoyloxyl group having hydrogen at the end of the chain were estimated indirectly from the intensities against methoxyl protons by ^{1}H NMR spectra.

Syntheses of Dimethoxysilanediyl Bis(polyfluoroalkanoate). Synthesis of Dimethoxysilanediyl Bis(5*H*-octafluoropentanoate), $Si(OCH_3)_2[OCO(CF_2)_4H]_2$: Sodium 5*H*-octafluoropentanoate (6.18 g (23.1 mmol)) was added to a stirred solution of dichlorodimethoxysilane (1.69 g (10.5 mmol)) in 80 ml 1,1,2-trichloro-1,2,2-trifluoroethane at room temperature in a two-necked 200-ml flask connected with a reflux condenser and a three-way stop cock. The heterogeneous mixture was refluxed with stirring for 15 h. Completion of the reaction was checked by adding a silver nitrate solution to a portion of the clear upper solution. Sodium chloride produced and excess sodium 5*H*-octafluoropentanoate were removed by filtration. A transparent, slightly yellow, liquid was obtained after removing the solvent under reduced pressure (yield 5.08 g, 83.5%): IR 2965, 2855, 1782, 1462, 1402, 1340, 1270, 1198, 1162, 1080, 1049, 955, 928, 905, 855, 805, 775, 742, and 708 cm^{-1}; ^{1}H NMR δ=3.64(CH_3, s(singlet), 4.31H), 3.68(CH_3, s, 0.46H), 3.78(CH_3, s, 0.98H), 3.95(CH_3, s, 0.25H), and 5.98(CF_2H, t(t)(triplet(triplet)), J=51.6 (5.0) Hz, 2.0H); ^{13}C NMR δ=52.3(f, s), 52.5(f, s), 53.6(f, s), 55.1(f, s), 109.2(a, t(t), J=253.5(30.8) Hz), 109.3(b, t(m(multiplet)), J=265.6 Hz), 110.3(c, t(m), J=266.7 Hz), 111.6(d, t(t), J=266.7(31.5) Hz), 157.3(e, t, J=30.0 Hz), and 159.5(e, t, J=29.3 Hz) for $(HC^aF_2C^bF_2C^cF_2C^dF_2C^eOO)_2Si(OC^fH_3)_2$; ^{19}F NMR δ=−25.4 (a, d(doublet), J=51.3 Hz, 4F), −17.3(b, s, 4F), −12.3(c, s, 4F), and −6.6(d, s, 4F) for $(HCF_2^aCF_2^bCF_2^cCF_2^dCOO)_2Si(OCH_3)_2$. Found: Si, 5.00; CH_3O, 10.8; $H(CF_2)_4COO$, 49.9 %. Calcd for $C_{12}H_8F_{16}O_6Si$: Si, 4.84; CH_3O, 10.7; $H(CF_2)_4COO$, 50.0 %.

Synthesis of Dimethoxysilanediyl Bis(7*H*-dodecafluoroheptanoate), $Si(OCH_3)_2[OCO(CF_2)_6H]_2$, Dimethoxysilanediyl Bis(9*H*-hexadecafluorononanoate), $Si(OCH_3)_2[OCO(CF_2)_8H]_2$, and Dimethoxysilanediyl Bis(pentadecafluorooctanoate), $Si(OCH_3)_2[OCO(CF_2)_6CF_3]_2$: The procedures and purification techniques were almost the same as those for the preparation of dimethoxysilanediyl bis(5*H*-octafluoropentanoate).

Dimethoxysilanediyl bis(7*H*-dodecafluoroheptanoate) was a slightly brown liquid (yield 81.9%): IR 2970, 2870, 1786, 1465, 1408, 1348, 1300, 1195, 1135, 1080, 1060, 940, 865, 835, 800, 775, 728, and 673 cm^{-1}; ^{1}H NMR δ=3.64(CH_3, s, 4.93H), 3.67(CH_3, s, 0.31H), 3.78(CH_3, s, 0.65H), 3.95(CH_3, s, 0.11H), and 6.0(CF_2H, t(t), J=51.6(5.0) Hz, 2.0H); ^{13}C NMR=52.3(h, s), 52.5(h, s), 53.6(h, s), 55.1(h, s), 109.3(a, t(t), J=253.5(31.5) Hz), 110.8—113.1 (b—f), 156.8(g, t, J=30.0 Hz), 156.1(g, t, J=31.5 Hz), 156.8(g, t, J=30.0 Hz), and 159.3(g, t, J=29.3 Hz) for $(HC^aF_2C^bF_2C^cF_2C^dF_2C^eF_2C^fF_2C^gOO)_2Si(OC^hH_3)_2$; ^{19}F NMR δ=−25.4 (a, d, J=51.3 Hz, 4F), −17.3(b, s, 4F), −11.1(c, s, 4F), −10.4(d, s, 4F), −9.2(e, s, 4F), and −6.2(f, s, 4F) for $(HCF_2^aCF_2^bCF_2^cCF_2^dCF_2^eCF_2^fCOO)_2Si(OCH_3)_2$. Found: Si, 3.52; CH_3O, 7.78; $H(CF_2)_6COO$, 62.6 %. Calcd for $C_{16}H_8F_{24}O_6Si$: Si, 3.60; CH_3O, 7.95; $H(CF_2)_6COO$, 62.8 %.

Dimethoxysilanediyl bis(9*H*-hexadecafluorononanoate) was a slightly brown liquid (yield 70.5%): IR 2966, 2863, 1790, 1464, 1402, 1354, 1323, 1211, 1147, 1063, 997, 953, 854, 806, 769, 730, and 665 cm^{-1}; ^{1}H NMR δ=3.68(CH_3, s, 3.88H), 3.78(CH_3, s, 1.90H), 3.97(CH_3, s, 0.22H), and 5.9(CF_2H, t(t), J=51.1(5.0) Hz, 2.0H); ^{13}C NMR δ=52.4(j, s), 53.3(j, s), 54.8(j, s), 108.0(a, t(t), J=255.0(32.2) Hz), 108.3—112.5 (b—h), 155.5(i, t, J=30.8 Hz), and 156.4(i, t, J=30.8 Hz) for $(HC^aF_2C^bF_2C^cF_2C^dF_2C^eF_2C^fF_2C^gF_2C^hF_2C^iOO)_2Si(OC^jH_3)_2$; ^{19}F NMR δ=−24.2(a, d, J=51.3 Hz, 4F), −16.4(b, s, 4F), −10.3(c, s, 4F), −8.7(d—g, br(broad), 16F), and −5.4(h, s, 4F) for $(HCF_2^aCF_2^bCF_2^cCF_2^dCF_2^eCF_2^fCF_2^gCF_2^hCOO)_2Si(OCH_3)_2$. Found: Si, 3.15; CH_3O, 6.30; $H(CF_2)_8COO$, 70.2%. Calcd for $C_{20}H_8F_{32}O_6Si$: Si, 3.07; CH_3O, 6.33; $H(CF_2)_8COO$, 70.4%.

Dimethoxysilanediyl bis(pentadecafluorooctanoate) was a slightly brown liquid (yield 82.8%): IR 2952, 2849, 1780, 1480, 1440, 1402, 1330, 1240, 1202, 1148, 1100, 1080, 1018, 883, 838, 820, 812, 803, 778, 745, 735, 720, 698, and 660 cm^{-1}; ^{1}H NMR δ=3.64(CH_3, s, 1.65H), 3.67(CH_3, s, 3.05H), 3.79(CH_3, s, 0.14H), and 3.96(CH_3, s, 1.16H); ^{13}C NMR δ=52.4(i, s), 52.5(i, s), 52.7(i, s), 53.0(i, s), 111.6—118.7(a—g), and 156.8(h, t, J=30.8 Hz) for $(C^aF_3C^bF_2C^cF_2C^dF_2C^eF_2C^fF_2C^gF_2C^hOO)_2Si(OC^iH_3)_2$; ^{19}F NMR δ=−13.9(b, s, 4F), −11.3 (c, s, 4F), −10.4(d, s, 4F), −9.2(e and f, br, 8F), −2.0(g, s, 4F), and 31.0 (a, t, J=12.2 Hz, 6F) for $(CF_3^aCF_2^bCF_2^cCF_2^dCF_2^eCF_2^fCF_2^gCOO)_2Si(OCH_3)_2$. Found: Si, 2.95; CH_3O, 6.85%. Calcd for $C_{18}H_6F_{30}O_6Si$: Si, 2.87; CH_3O, 6.77 %.

Results and Discussion

The reaction of the synthesis of dimethoxysilanediyl bis(polyfluoroalkanoate) was heterogeneous in every cases, the same as the preparation of titanium butoxide tris(polyfluoroalkanoate).[10] However, the time to complete the reaction was comparably shorter than that of the titanium butoxide tris(polyfluoroalkanoate) synthesis, even in the reaction with the sodium fluoro-substituted alkanoate having a longer chain.

The NMR spectra of dimethoxysilanediyl bis(5*H*-ctafluoropentanoate), $Si(OCH_3)_2[OCO(CF_2)_4H]_2$, are shown in Figs. 1—3. In the ^{1}H NMR spectrum, three small signal peaks (δ=3.68(0.46H), 3.78(0.98H), and 3.95(0.25H)) were detected along with the main signal peak which originated from methyl protons at δ=3.64(4.31H). This fact shows that a part of the silicon compound was disproportionated to methoxysilanetriyl tris(5*H*-octafluoropentanoate), trimethoxysilyl 5*H*-octafluoropentanoate and tetramethoxysilane. The same observations were detected two kinds of carbons ($\underline{C}H_3$– and –$\underline{C}OO$–) in the ^{13}C NMR spectrum. On the other hand, the effect of the disproportionation on the chemical shift against the $\underline{H}CF_2$– proton signal was very slight and only a broadening was observed in the ^{1}H NMR spectrum. The effect of the disproportionation on the chemical shift of the ^{19}F NMR spectrum was not observed. The ^{13}C NMR spectrum was relatively complicated especially for the –$\underline{C}F_2$– signals (see Fig. 2). The resonance peaks of a carbon atom were coupled magnetically with the geminal and vicinal fluorine atoms.

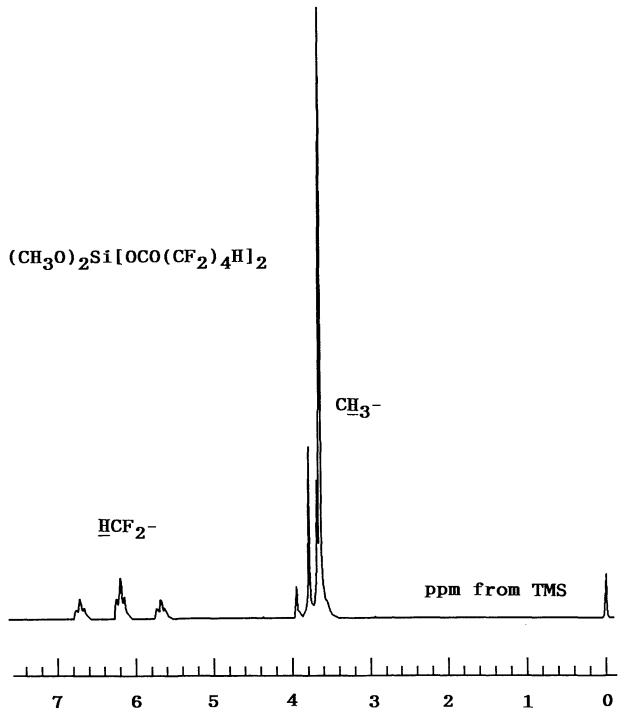

Fig. 1. Pulsed fourier transform 100 MHz ^{1}H NMR spectrum of $(CH_3O)_2Si[OCO(CF_2)_4H]_2$ in THF-d_8.

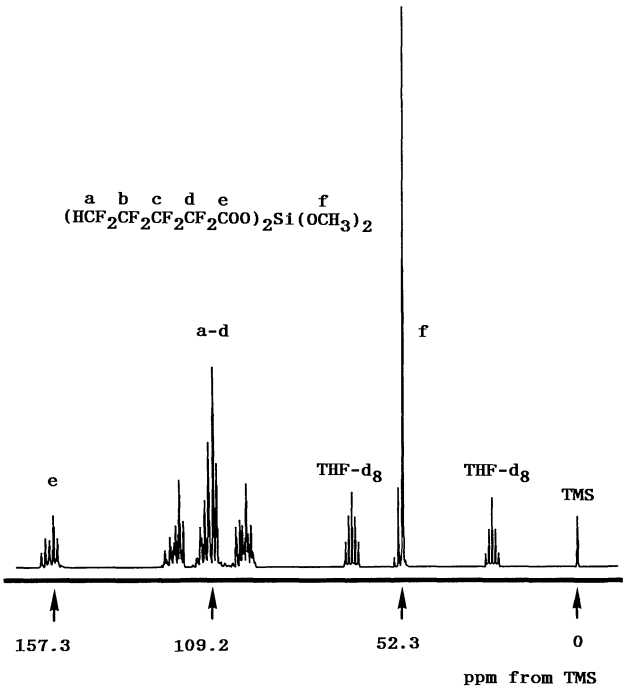

Fig. 2. Pulsed fourier transform 25 MHz ^{13}C NMR spectrum of $(CH_3O)_2Si[OCO(CF_2)_4H]_2$ in THF-d_8.

A group of stronger intensity peaks from the terminal HCF_2– (triplet(triplet)) was observed at 109.2 ppm from TMS in THF-d_8, and the other $-CF_2-$ peaks were weaker.

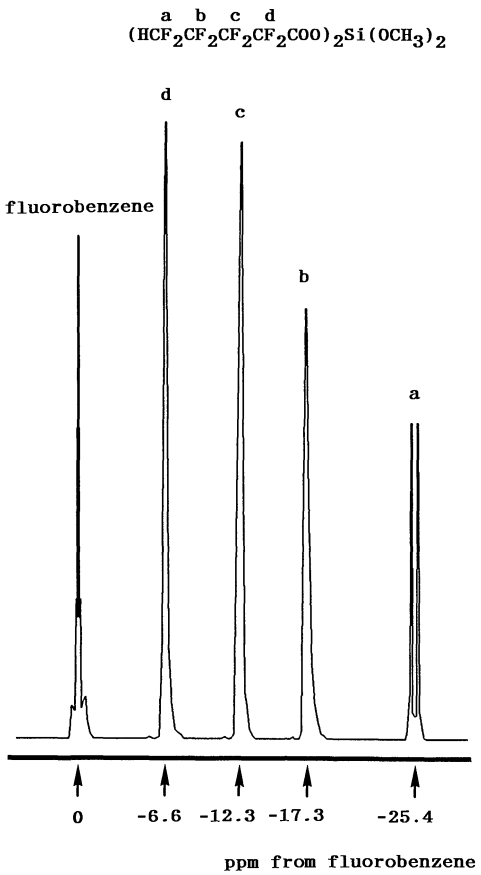

Fig. 3. Pulsed fourier transform 90 MHz ^{19}F NMR spectrum of $(CH_3O)_2Si[OCO(CF_2)_4H]_2$ in THF.

In the case of the ^{13}C NMR spectra, it is well known that for fluorinated carbon atoms, the peak intensities of a carbon bonded to a hydrogen atom, such as HCF_2–, H_2CF–, or –HCF–, are stronger than those of a carbon bonded only to fluorine atoms, such as CF_3– or $-CF_2-$. In the ^{13}C NMR spectra, it was very difficult to make assignments against $-CF_2-$ of almost all the silicon compounds prepared. Only for the simplest one, dimethoxysilanediyl bis(5*H*-octafluoropentanoate), were we able to make an assignment.

These silicon compounds possessed a structure essentially similar to that of the titanate-type coupling agents having fluorocarbon chains.[10] In the titanate-type coupling agents, the TiOCOR moiety was stable in water, although the TiOR' was only moderately stable against water. Therefore, the stability of the silicon compounds to hydrolysis was investigated. From the ^{1}H NMR spectrum of the reaction mixture of dimethoxysilanediyl bis(7*H*-dodecafluoroheptanoate) and water (molar ratio 10:1) in THF-d_8 (internal standard TMS), the intensity ratio of the produced acid COOH (13.9 ppm) and the produced methanol OH (4.0 ppm) was precisely 1:1. This means that the ease of hydrolysis of the SiOCOR and the $SiOCH_3$ moieties was exactly same. The same observation was obtained from

the other prepared silicon compounds.

Moreover, the instabilities to hydrolysis of these silicon compounds were proved as follows. In a 100-ml beaker, 1 g of dimethoxysilanediyl bis(7*H*-dodecafluoroheptanoate) in 50 cm^3 methanol was stirred exposed to the atmosphere at room temperature for 24 h. A white precipitate formed. A white powder was obtained after filtration, washing with 1,1,2-trichloro-1,2,2-trifluoroethane and vacuum drying. The FT-IR spectrum of this powder was the same as that of silica gel. The same observation was obtained from the other silicon compounds.

In conclusion, these dimethoxysilanediyl bis(polyfluoroalkanoate)s were very sensitive to water and decomposed easily, although they had the fluorinated carbon structure which exhibits the property of water repellency.

The present work was partially supported by a Grant-in-Aid for Scientific Research No.62550618 from the Ministry of Education, Science and Culture, to which the authors are grateful.

Asymmetric Michael Addition of the *N*-Alkylidene Derivative of an α-Amino Ester to Methyl (*E*)-3-[(3*R*,7a*S*)-2-Phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate

(Received April 25, 1991)

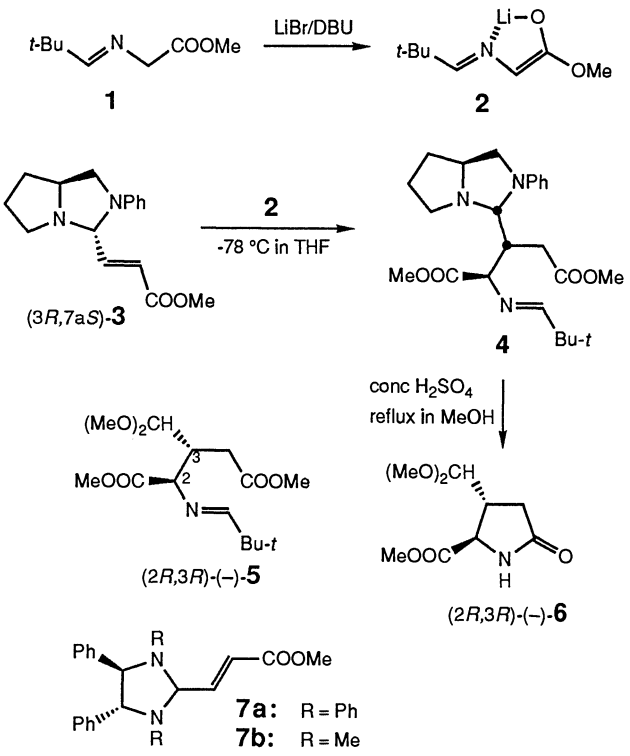
The exclusively diastereoselective asymmetric Michael addition of the lithiated methyl *N*-(2,2-dimethylpropylidene)glycinate to methyl (*E*)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate is described. The synperiplanar conformer of the acceptor propenoate participated in the reaction where the *re*-face of the acceptor molecule was attacked by the *re*(β)-face of the lithiated intermediate.

It has been reported that *N*-alkylidene-substituted α-amino esters can be lithiated with a variety of lithiating reagents including lithium bromide/triethylamine or lithium bromide/1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to generate reactive nucleophiles, *N*-lithiated azomethine ylides or lithium enolates.[1] The lithiated intermediates of *N*-alkylidene-substituted α-amino esters so generated undergo stereoselective cycloaddition to α,β-unsaturated carbonyl compounds leading to 2-pyrrolidinecarboxylates. It is now accepted that the chelation as well as the frontier orbital interaction operating in the transition state is responsible for the observed high selectivities.[1] When the *N*-alkylidene-substituted α-amino esters are derived from bulky aldehydes or ketones, such as 2,2-dimethylpropanal or 2-bornanone, the lithiated intermediates generated from them undergo Michael addition to α,β-unsaturated carbonyl compounds, instead of dipolar cycloaddition, again in a highly stereoselective fashion.[1c,2]

Dipolar cycloaddition reaction of *N*-alkylidene-substituted α-amino esters has been developed to the asymmetric version by utilizing the α,β-unsaturated carbonyl compounds bearing a gem-diamino type chiral controller at the β-position[3a,b,d] or utilizing the *N*-alkylidene-substituted α-amino ester derived from an optically pure alcohol.[3c] On the other hand, the *N*-bornanylidene-substituted α-amino esters[4] or the *N*-pinanylidene-substituted α-amino esters[5] were found to function as excellent Michael donors in the asymmetric Michael reaction. However, no application has been so far reported on the asymmetric Michael addition using a chiral α,β-unsaturated carbonyl compound and achiral *N*-alkylidene-substituted α-amino esters. In this report, we present the exclusively diastereoselective asymmetric Michael addition of the lithium derivative of an *N*-alkylideneglycine methyl ester to a chiral α,β-unsaturated ester, methyl (*E*)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate.[6]

Results and Discussion

Treatment of methyl *N*-(2,2-dimethylpropylidene)-glycinate (**1**) with lithium bromide (2 equiv) and DBU (1.2 equiv) gave the lithiated *N*-alkylideneglycinate **2**, which was allowed to react with methyl (*E*)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate (**3**) in tetrahydrofuran (THF) at −78 °C for 6.5 h to produce the Michael adduct **4** in 98% yield as the sole product (confirmed by ^{1}H NMR of the crude product, Scheme 1).[7] The Michael adducts produced from lithiated *N*-alkylideneglycinates bear a remaining acidic hydrogen adjacent to the imine nitrogen (α-position of the *N*-alkyl group) and the ready epimerization usually occurs at this position under basic conditions.[2] However, no sign of occurrence of epimerization was detected in this reaction. Presumably this is because the



Scheme 1.

deprotonation at the α-position of the *N*-alkyl group was sterically hindered by the bulky chiral controller substituent just as previously observed in the case of bornanimines.[4] When the reaction was carried out at room temperature, formation of two side products resulted (1 h, 6% and 5% by ^{1}H NMR). One of the side products was temporarily assigned as the epimer with respect to the position adjacent to the imine nitrogen because its ratio increased with the prolonged reaction time (57 h at room temperature, 18% and 5% by ^{1}H NMR).[8] The other product produced in 5% yield in the reaction at room temperature may be the diastereomer of **4** resulting from the different diastereoselection. As a result, the diastereoselectivity in the reaction at room temperature was calculated to be 95 : 5.

Although α,β-unsaturated esters **7a,b** bearing a C_2-symmetric imidazolidine chiral controller at the β-position[3d] were applied to carry through the same purpose, they were found to be much less reactive than **3**. Thus, no addition product was obtained under various reaction conditions (both at −78 °C and at room temperature). Even when the lithium derivative of *N*-alkylidene-substituted glycine methyl ester **2** was irreversibly generated from **1** and lithium diisopropylamide (LDA), no formation of the Michael adduct was observed. Such unsuccess of reaction is certainly due to the steric hindrance around the β-position of **7a,b** as well as the decreased reactivity of the lithiated intermediate of methyl *N*-(2,2-dimethylpropylidene)glycinate (**1**) compared with that of the lithiated intermediate of methyl *N*-benzylideneglycinate.[2] However, such difference of reactivities, especially that of **7b**, was much more than our anticipation.

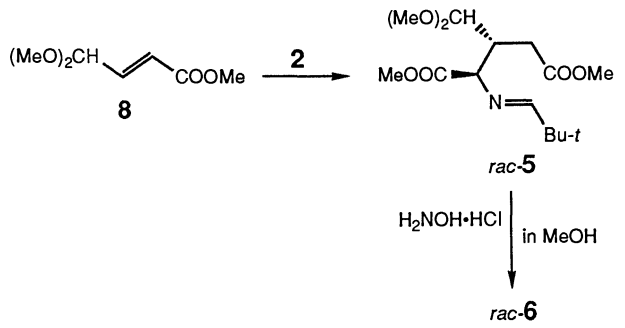
High susceptibility of the Michael adduct **4** to hydrosis at the C=N linkage let us abandon the attempt of purification by column chromatography.[9] Therefore, **4** was converted without further purification to (2*R*,3*R*)-(−)-**6** by refluxing in MeOH in the presence of concentrated sulfuric acid.[10] The processes involved in this conversion are acetal exchange to dimethyl acetal (2*R*,3*R*)-(−)-**5**, hydrolysis of the C=N moiety, and cyclization. Assignment of the absolute configurations of (2*R*,3*R*)-**5** and (2*R*,3*R*)-**6** will be discussed below.

The authentic sample of the racemate of (2*R*,3*R*)-**5**, *rac*-**5**, was prepared in quantitative yield from a similar reaction of methyl (*E*)-4,4-dimethoxy-2-butenoate (**8**) with **2** (−78 °C, 3 h)(Scheme 2). Treatment of *rac*-**5** so prepared with hydroxylamine hydrochloride in methanol at room temperature gave *rac*-**6** in quantitative yield. Structure of *rac*-**6** was confirmed by spectral data and analytical data.

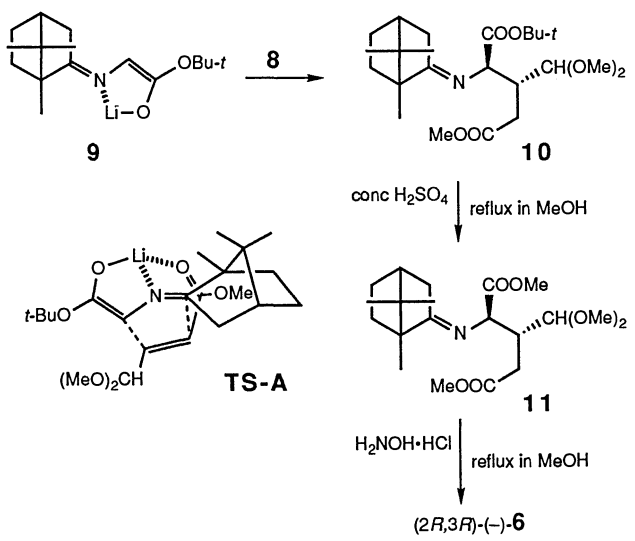
According to the transition state[3b] proposed for the diastereoselective cycloaddition of the lithiated methyl *N*-benzylideneglycinate to (3*R*,7a*S*)-**3**, the *re*(β)-face of the synperiplanar conformer of (3*R*,7a*S*)-**3** should be attacked by the *re*-face of **2**. Therefore, it was expected that the Michael addition of **2** to (3*R*,7a*S*)-**3** would produce dimethyl (2*R*,3*R*)-*N*-(2,2-dimethylpropylidene)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]-imidazol-3-yl]glutamate (**4**), and hence further (2*R*,3*R*)-**5** and (2*R*,3*R*)-**6**.

On the other hand, it has been reported that the *N*-bornanylideneglycinates derived from natural (1*R*)-(+)-2-bornanone react, after lithiation, with α,β-unsaturated esters to give 2-substituted glycinates with the unnatural configuration, the 2*R*-configuration, through the chelated transition state **TS-A** (Scheme 3).[4b] Therefore, the Michael addition of the lithiated intermediate of bornanimine **9** would be successfully applied to prepare the authentic sample of (2*R*,3*R*)-**6**. Thus, the reaction of **8** with **9** was performed under the conditions of reversible lithiation (−78 °C, butyllithium/*t*-butyl alcohol in THF, 1 h) to produce **10** as the sole product.

The Michael adduct **10** was converted to methyl ester **11** by treatment with methanol in the presence of concentrated sulfuric acid, and then the 2-bornanylidene chiral controller of **11** was removed off by heating it with hydroxylamine hydrochloride in methanol to give cyclized product **6**. The sign of its optical rotation ($[\alpha]_D^{24}$ =−40.8° (*c* 0.51, $CHCl_3$)) was found to be the same as that of (2*R*,3*R*)-(−)-**6**, indicating the (2*R*,3*R*)-absolute configuration of **4**.



Scheme 2.



Scheme 3.

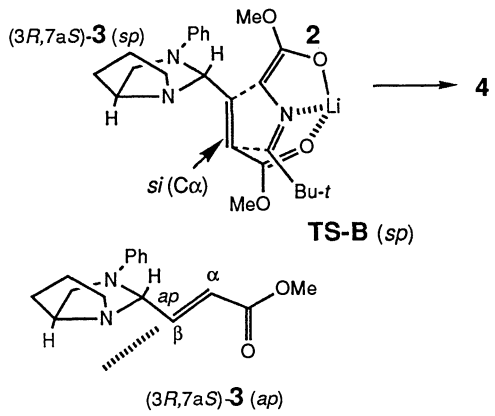


Fig. 1. Proposed transition state for the asymmetric Michael addition of *N*-lithiated azomethine ylide **2** to (3*R*,7a*S*)-**3**.

As previously discussed,[3a,b] the attack of a 1,3-dipole to the α,β-unsaturated ester moiety of (3*R*,7a*S*)-**3** took place from the direction opposite to the bulky *N*-phenyl substituent. Since the Michael adduct **4** was assigned to have (2*R*,3*R*)-configuration in the present work, it is clear that the synperiplanar conformation of (3*R*,7a*S*)-**3** was exclusively involved in the transition state. The transition state **TS-B**(*sp*) is the case (Fig. 1). The participation of the less stable synperiplanar conformation was previously observed in the dipolar cycloaddition of *N*-metalated azomethine ylides with the α,β-unsaturated esters bearing a gem-diamino type chiral controller at the β-position.[3a,b,d] In the transition state involving the thermodynamically more favored antiperiplanar conformer (3*R*,7a*S*)-**3** (*ap*), some more steric hindrance may be caused between the framework of the (3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]-imidazol-3-yl chiral controller and the methoxy group of **2** along the hashed line directing from the α-carbon to the β-carbon of **3**.

In conclusion, the lithium derivative of *N*-(2,2-dimethylpropylidene)glycine methyl ester underwent exclusively diastereoselective asymmetric Michael addition to methyl (*E*)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate. The synperiplanar conformer of the acceptor molecule participated in the reaction in which the *re*-face of the acceptor molecule was attacked by the *re*(β)-face of the lithiated intermediate of the *N*-alkylidene-substituted α-amino ester.

Experimental

General. Melting points were recorded on a Yanagimoto melting point apparatus and are uncorrected. IR spectra were taken with JASCO IRA-1 and A-702 spectrometers. ^{1}H and ^{13}C NMR spectra were recorded with Hitachi R-40 (^{1}H NMR; 90 MHz) and GSX-270 (270 MHz for ^{1}H NMR and 67.94 MHz for ^{13}C NMR) instruments. Chemical shifts are reported in parts per million downfield (δ) from internal tetramethylsilane. Mass spectra and high resolution mass spectra (HRMS) were recorded with a JEOL-01SG-2 spectrometer operating at an ionization energy of 70 eV. Elemental analyses were performed with a Hitachi 026 CHN analyzer. Optical rotations were recorded with a Horiba SEPA-200 polarimeter. For preparative column chromatography, Wakogel C-200, Wako C-300, and Merck Silica gel 60 were employed. Flash chromatography was performed with an Eyera EF-10 apparatus on a 20×180 mm column packed with 0.04—0.063 mm silica gel 60.

Materials. Methyl *N*-(2,2-dimethylpropylidene)glycinate (**1**),[2] methyl (*E*)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazol-3-yl]propenoate (**3**),[3b] methyl (*E*)-4,4-dimethoxy-2-butenoate (**8**),[3b] and *t*-butyl (1*R*,4*R*)-*N*-(2-bornylidene)glycinate[4b] were prepared according to the reported procedures.

Michael Addition of 2 to (3*R*,7a*S*)-3 Leading to 4. To a solution of LiBr (0.521 g, 6 mmol) in dry THF (8 ml) were added, at −78 °C under nitrogen, a solution of **1** (0.474 g, 3 mmol) in THF (4 ml), DBU (0.548 g, 3.6 mmol), and a solution of (3*R*,7a*S*)-**3** (0.545 g, 2 mmol) in THF (4 ml) in that order. The mixture was stirred at −78 °C for 6.5 h. Saturated aqueous NH_4Cl (20 ml) was added to the mixture which was then extracted with Et_2O (30 ml×3). The combined extracts were dried ($MgSO_4$) and then evaporated in vacuo to give dimethyl (2*R*,3*R*)-*N*-(2,2-dimethylpropylidene)-3-[(3*R*,7a*S*)-2-phenylperhydropyrrolo[1,2-*c*]imidazo-3-yl]-glutamate (**4**, 0.841 g, 98%) as pale yellow oil. This compound **4** was so liable to hydrolysis that its purification by column chromatography was unsuccessful. Only ^{1}H and ^{13}C NMR spectra were recorded. Pale yellow liquid; ^{1}H NMR ($CDCl_3$) δ=1.10 (9H, s, *t*-Bu), 1.69—1.84 (3H, m, H-6′ and one of H-7′), 2.04—2.18 (1H, m, the other of H-7′), 2.35 (1H, dd, J_{gem}=10.3 and J_{4-3}=8.1 Hz, one of H-4), 2.44 (1H, dd, J_{gem}=10.3 and J_{4-3}=5.1 Hz, the other of H-4), 2.43—2.52 (1H, m, one of H-5′), 2.84 (1H, t, J_{gem}=$J_{1'-7a}$=8.8 Hz, one of H-1′), 3.05—3.12 (1H, m, the other of H-5′), 3.18 (1H, dddd, J_{3-4}=8.1, 5.1, J_{3-2}=7.7, and $J_{3-3'}$=4.8 Hz, H-3), 3.33 (3H, s, COOMe), 3.53 (1H, dd, J_{gem}=8.8 and $J_{1'-7a}$=7.3 Hz, the other of H-1′), 3.70 (3H, s, COOMe), 3.91 (1H, m, H-7a′), 3.99 (1H, d, J_{2-3}=7.7 Hz, H-2), 4.67 (1H, d, $J_{3'-3}$=4.8 Hz, H-3′), 6.65—6.74 and 7.16—7.27 (5H, m, Ph), and 7.62 (1H, d, *J*=0.7 Hz, CH=N); ^{13}C NMR ($CDCl_3$) δ=24.54 (C-6′), 26.71 (*t*-Bu), 29.85, 32.35 (C-3 and C-7′), 36.73 (*t*-Bu), 43.81 (C-4), 50.93 (C-5′), 51.75 (C-1′), 54.70, 55.06 (2×COOMe), 62.19 (C-7a′), 72.74 (C-2), 82.33 (C-3′), 112.87, 116.73, 128.94, 147.17 (each Ph), 171.92, 173.01 (each COOMe), and 176.84 (C=N).

Conversion of the Michael Adduct 4 to (2*R*,3*R*)-(−)-6. To a solution of **4** (0.128 g, 0.3 mmol) in MeOH (5 ml) was added concentrated H_2SO_4(0.1 ml). The mixture was refluxed for 7.5 h and then poured into saturated aqueous NaCl(2 ml). After neutralized with solid Na_2CO_3, the mixture was concentrated to dryness under a reduced pressure. The residual solid was triturated with CH_2Cl_2 (50 ml) and the inorganic substances were filtered off. The filtrate was evaporated under a reduced pressure to give a deep red oil (0.096 g). This oil was chromatographed on silica gel (EtOAc) to give methyl (2*R*,3*R*)-(−)-3-(dimethoxymethyl)-5-oxo-2-pyrrolidinecarboxylate [(2*R*,3*R*)-(−)-**6**] (0.048 g, 75%): Pale yellow liquid; $[\alpha]_D^{24}$=−41.3 (*c* 0.53, $CHCl_3$); IR (neat) 3200, 2890, 1664, 1416, 1352, 1184, 1048, and 900 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.34 (1H, dd, J_{gem}=17.6 and J_{4-3}=4.8 Hz, one of H-

4), 2.48 (1H, dd, J_{gem}=17.6 and J_{4-3}=9.5 Hz, the other of H-4), 2.85 (1H, dddd, J_{3-4}=9.5, 4.8, J_{3-2}=6.2, and J_{3-CH}=2.9 Hz, H-3), 3.40 (6H, s, 2×OMe), 3.79 (3H, s, COOMe), 4.20 (1H, d, J_{CH-3} =2.9 Hz, 3-CH), 4.35(1H, d, J_{2-3}=6.2 Hz, H-2), and 7.12 (1H, br s, NH); ^{13}C NMR ($CDCl_3$) δ=30.88 (C-3), 40.55 (C-4), 52.74 (COOMe), 54.15, 54.66 (2×OMe), 56.80 (C-2), 104.75 (3-CH), 172.41 (C-5), and 177.39 (COOMe); MS (20 eV) *m/z* (rel intensity, %) 217 (M^+, 0.2), 186 (18), 185 (54), 170 (10), 158 (25), and 75 (base peak). Found: C, 49.86; H, 6.91; N, 6.59%. Calcd for $C_9H_{15}NO_5$: C, 49.76; H, 6.96; N, 6.45%.

Michael Addition of 2 to 8 Leading to *rac*-5 and Further to *rac*-6. To a solution of LiBr (0.49 g, 5.62 mmol) in dry THF (4 ml) were added, at −78 °C under nitrogen, a solution of **1** (0.59 g, 3.75 mmol) in THF (2 ml), DBU (0.684 g, 4.5 mmol, in THF (2 ml), and **8** (0.4 g, 2.5 mmol, in THF (2 ml)) in that order. After stirring at −78 °C for 3 h, the mixture was treated with saturated aqueous NH_4Cl (10 ml), and then extracted with Et_2O (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo to give a pale yellow oil of *rac*-**5** (0.807 g) [^{1}H NMR ($CDCl_3$) δ=1.07 (9H, s, *t*-Bu), 2.42 (1H, dd, J_{gem}=16.5 and J_{4-3}=6.6 Hz, one of H-4), 2.55 (1H, dd, J_{gem}=16.5 and J_{4-3}=5.5 Hz, the other of H-4), 3.01 (1H, m, H-3), 3.31, 3.32 (each 3H, each s, MeO), 3.66, 3.71 (each 3H, each s, COOMe), 3.97 (1H, d, J_{2-3}=5.9 Hz, H-2), 4.22 (1H, d, J_{CH-3} =7.0 Hz, 3-CH), and 7.55 (1H, s, CH=N)]. To a solution of this crude product *rac*-**5** (0.32 g, 1 mmol) in MeOH (5 ml) was added NH_2OH·HCl (0.14 g, 2 mmol). The mixture was stirred at room temperature for 1 h and was then evaporated in vacuo. The residual colorless oil was triturated with CH_2Cl_2 (50 ml) and the colorless solid precipitated was filtered off. The filtrate was evaporated in vacuo. The residual oil (0.285 g) was chromatographed on silica gel (EtOAc–EtOH, 5:1 v/v) to give methyl *rac*-3-(dimethoxymethyl)-5-oxo-2-pyrrolidinecarboxylate (*rac*-**6**, 0.216 g, 99% based on **8**): Colorless solid; mp 80.5—81.0 °C.

Michael Addition of the Lithiated *t*-Butyl (1*R*,4*R*)-*N*-(2-Bornanylidene)glycinate with 8 Leading to 10. To a solution of **9** (0.398 g, 1.5 mmol) in dry THF (5 ml) were added, at −78 °C under nitrogen, *n*-BuLi (1.59 M in hexane, 0.94 ml, 1.8 mmol), *t*-BuOH (0.133 g, 1.8 mmol, in THF (2.5 ml)), and **8** (0.202 g, 1.26 mmol, in THF (2.5 ml)) in that order. After stirring at −78 °C for 24 h, the mixture was treated with saturated aqueous NH_4Cl (10 ml) and then extracted with Et_2O (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residue (0.584 g) was chromatographed on silica gel (hexane–EtOAc, 6:1 v/v) to yield 1-*t*-butyl methyl (2*R*,3*R*)-*N*-[(1*R*,4*R*)-2-bornanylidene]-3-(dimethoxymethyl)glutamate **10** (0.376 g, 70%): Colorless liquid; $[\alpha]_D^{23.5}$=+69.28° (*c* 1.6, $CHCl_3$); IR (neat) 2919, 1716, 1672, 1428, 1360, 1240, 1144, 1064, and 840 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.80, 0.92, 0.95 (each 3H, each s, 3×Me), 1.14—1.35 (2H, m, 2-bornanylidene), 1.43 (9H, s, *t*-Bu), 1.63—1.72 (1H, m, 2-bornanylidene), 1.80—1.95 (3H, m, 2-bornanylidene), 2.32—2.42 (1H, m, 2-bornanylidene), 2.51 (2H, d, J_{4-3}=5.9 Hz, H-4), 3.03 (1H, dq, J_{3-CH}=7.0 and J_{3-2}=J_{3-4}=5.9 Hz, H-3), 3.32, 3.33 (each 3H, each s, 2×OMe), 3.65 (3H, s, COOMe), 4.07 (1H, d, J_{2-3}=5.9 Hz, H-2), and 4.28 (1H, d, J_{CH-3}=7.0 Hz, 3-CH); MS (75 eV) *m/z* (rel intensity, %) 425 (M^+, 10), 411 (14), 410 (54), 355 (12), 354 (57), 352 (14), 338 (33), 337 (20), 336 (16), 324 (32), 308 (12), 294 (12), 265 (28), 264 (18), 250 (13), 209 (39), 208 (10), 89 (10), and 75 (base peak). Found: C, 64.92; H, 9.02; N, 3.22%. Calcd for $C_{23}H_{39}NO_6$: C, 64.91; H, 9.23; N, 3.29%.

Conversion of 10 to 11. Concentrated H_2SO_4 (0.75 ml) was added at 0 °C to a solution of **10** (0.463 g, 1.1 mmol) in MeOH (15 ml). After stirring at 0 °C for 0.5 h and refluxing for 24 h, the mixture was poured into CH_2Cl_2–ice water (60 ml/10 ml). After neutralized with solid $NaHCO_3$ to pH 7, the mixture was extracted with CH_2Cl_2 (30 ml×3). The combined extracts were dried ($MgSO_4$) and evaporated in vacuo. The residual oil (0.419 g) was chromatographed on silica gel (hexane–EtOAc, 4:1 v/v) to give dimethyl (2*R*,3*R*)-*N*-[(1*R*,4*R*)-2-bornanylidene]-3-(dimethoxymethyl)glutamate (**11**, 0.233 g, 56%): Colorless liquid; $[\alpha]_D^{22}$ =+70.13° (*c* 1.21, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ=0.76, 0.92, 0.96 (each 3H, each s, Me), 1.15—1.33 (2H, m, 2-bornanylidene), 1.64—1.73 (1H, m, 2-bornanylidene), 1.77—1.93 (3H, m, 2-bornanylidene), 2.30—2.39 (1H, m, 2-bornanylidene), 2.52 (1H, dd, J_{gem}=16.1 and J_{4-3}=6.6 Hz, one of H-4), 2.56 (1H, dd, J_{gem}=16.1 and J_{4-3}=5.5 Hz, the other of H-4), 3.05 (1H, m, H-3), 4.20 (1H, J_{2-3}=5.5 Hz, H-2), and 4.27 (1H, d, J_{CH-3}=7.3 Hz, 3-CH); ^{13}C NMR ($CDCl_3$) δ=11.39 (C-10′), 19.02 (C-8′), 19.40 (C-9′), 27.52 (C-5′), 31.22 (C-6′), 32.24 (C-3), 36.10, 40.65, 43.84 (C-3′, C-4, and C-4′), 47.47 (C-7′), 51.46, 51.83 (COOMe), 53.63 (C-1′), 54.22, 54.35 (each OMe), 63.38 (C-2), 105.04 (3-CH), 171.84, 173.51 (each COOMe), and 186.76 (C-2′); MS (75 eV) *m/z* (rel intensity, %) 383 (M^+, 10), 369 (20), 368 (base peak), 352 (28), 351 (24), 308 (33), 223 (54), 222 (20), and 75 (64). Found: C, 62.89; H, 8.36; N, 3.89%. Calcd for $C_{20}H_{33}NO_6$: C, 62.64; H, 8.67; N, 3.65%.

Conversion of 11 to (2*R*,3*R*)-(−)-6. To a solution of **11** (0.229 g, 0.6 mmol) in MeOH (20 ml) was added NH_2OH·HCl (0.166 g, 2.39 mmol). After refluxing for 24 h, another portion of NH_2OH·HCl (0.166 g, 2.39 mmol) was added and the mixture was refluxed for additional 24 h. The mixture was condensed to dryness in vacuo and the residual oil was triturated with CH_2Cl_2 (100 ml). The solid precipitated was filtered off and the filtrate was evaporated in vacuo. The residue (0.218 g) was chromatographed on silica gel (EtOAc–EtOH, 10:3 v/v) to give (2*R*,3*R*)-(−)-**6** (0.049 g, 38%). $[\alpha]_D^{24}$ =−40.8° (*c* 0.51, $CHCl_3$).

6) Michael reaction of this acceptor molecule to Grignard reagents was previously reported (M. Asami and T. Mukaiyama, *Chem. Lett.,* **1979**, 569.

7) The crude mixture showed only one imine proton at δ=7.62 (^{1}H NMR).

8) Formation of three products was observed in the reaction at room temperature (**4**: δ=4.67 (H-3′), 7.62 (CH=N); side product **A**: 4.61 (H-3′), 7.65 (CH=N); side product **B**: 4.72 (H-3′), 7.69 (CH=N)). At −78 °C for 6.5 h, **4** was the only product. At −78 °C for 48 h, **4** was accompanied by a trace amount (less than 1%) of **A**. At room temperature for 1 h, **4**:**A**:**B** was 89:6:5 (by ^{1}H NMR). At room temperature for 57 h, **4**:**A**:**B** was 77:18:5 (by ^{1}H NMR).

9) Chromatographic purification of **4** through silica gel column resulted in the partial decomposition by hydrolysis of the C=N moiety.

10) Similar conversion of the perhydropyrrolo[1,2-*c*]imidazole chiral controller to a dimethoxymethyl group was reported in our previous papers (See Ref. 3b).

Catalytic Functions of Artificial Enzyme Composed of Simple Vitamin B_{12} Model and Synthetic Bilayer Membrane†

An artificial enzyme was constructed with a combination of the single-walled vesicle of *N*,*N*-dihexadecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^{+}C_5Ala2C_{16}$) and a simple vitamin B_{12} model; (11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt, [Co(C_2C_3)(DO)(DOH)pn], or [*N*-(2-hydroxyiminocyclohexylidene)-*N'*-(cyclohexyliden-2-one oximato)-1,3-diaminopropane]cobalt, [Co(ch)(DO)(DOH)pn]. Carbon-skeleton rearrangement reactions of alkyl ligands bound to the cobalt complex were markedly favored in the single-walled vesicle, relative to the reactions in methanol and benzene, under anaerobic photolysis conditions at ordinary temperatures. The cobalt complex incorporated into the intramembrane domain is subjected to significant repression of its molecular motion and to desolvation as confirmed by fluorescence and fluorescence polarization measurements. The 1,2-migration of cyano and carboxylic ester groups involved in the alkyl ligands is plausibly enhanced by such effects.

It is well known that metal ions play important roles as essential trace elements in biological systems. Metallocoenzymes involved in holoenzymes exhibit efficient catalyses only under specific micro-environments provided by the corresponding apoproteins. Vitamin B_{12}-dependent enzymes catalyze various isomerization reactions as formally given by Eq. 1.[1] The catalysis includes four carbon-skeleton rearrangements of reversible nature as follows;[2,3] methylmalonyl-SCoA⇌succinyl-SCoA, isobutyryl-SCoA⇌butyryl-SCoA, β-methylaspartate⇌glutamate, and methylitaconate⇌α-methyleneglutarate, as shown by Eqs. 2—5, respectively.

The naturally occurring apoproteins, which provide relevant reaction sites for vitamin B_{12}, are considered to play crucial roles in the molecular rearrangements.[4,5] In this regard, we have been interested in the catalytic activity of vitamin B_{12} in hydrophobic micro-environments to simulate the catalytic functions of the holoenzymes concerned. We have succeeded in constructing holoenzyme models,[6-8] as composed of a synthetic bilayer membrane and a hydrophobic vitamin B_{12} which has ester groups in place of the peripheral amide moieties of the naturally occurring vitamin B_{12}.[9-16] This finding prompted us to develop simple model complexes which are capable of catalyzing the carbon-skeleton rearrangements in similar bilayer membranes. We adopted Costa-type complexes with some modifications of the original one, [Co^{III}\{(C_2C_3)-

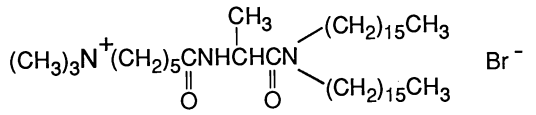
(DO)(DOH)pn}(XY)] and $\{Co^{III}\{(ch)(DO)(DOH)pn\}$-(XY)] (refer to **1**—**6**), since these complexes show redox behavior analogous to that of vitamin B_{12} with respect to the nuclear cobalt.[17-19] A single-walled bilayer membrane composed of a synthetic peptide lipid is quite effective as an apoprotein model.[20-23] On these grounds, we report here the carbon-skeleton rearrangements of alkyl ligands coordinated to the vitamin B_{12} model complexes in the $N^+C_5Ala2C_{16}$ vesicle.



$N^+C_5Ala2C_{16}$

Experimental

General Analyses and Measurements. Elemental analyses were performed at the Microanalysis Center of Kyushu University. IR spectra were taken on a JASCO IR-810 infrared spectrophotometer, while electronic absorption spectra were recorded on a Hitachi 220A or a Hitachi 340 spectrophotometer. ^1H NMR spectra were taken on a Hitachi R-24B, a Bruker AC-250P, and a Bruker AMX-500 spectrometer installed at the Advanced Instrumental Analysis Center of Kyushu University. Assignments of NMR signals for the cobalt complexes were performed by means of the 2D-NMR technique (H–H COSY). Fluorescence spectra were obtained with a Hitachi 650-60 spectrophotometer, and fluorescence polarization measurements were performed with a Union Giken FS-501A fluorescence polarization spectrophotometer equipped with a Union Giken System-77 computer; emission at 530 nm was monitored upon excitation at 340 nm with a slit width of 3.5 nm for both excitation and emission sides. Fluorescence polarization (*P*) was calculated according to a previous method.[24,25] GLC analyses were carried out on a Shimadzu GC-9A apparatus equipped with a Shimadzu C-R3A-FFC chromatopac for data processing.

Materials. Diiodo(11-hydroxyimino-4,10-dipropyl-5,9-diazatrideca-4,9-dien-3-one oximato)cobalt(III), $[Co^{III}\{(C_2C_3)(DO)(DOH)pn\}I_2]$ (**1**), and its alkylated complexes (**2** and **3**), were prepared by methods identical with those reported previously.[26] *N*,*N*-Bis(2-hydroxyiminocyclohexylidene)propane-1,3-diamine, $(ch)(DOH)_2pn$, and its cobalt complexes with various axial ligands (**4**, **5**, and **6**) were prepared by referring to reported procedures[18,27-29] along with some modifications as shown in Scheme 1. An artificial lipid, *N*,*N*-dihexadecyl-N^{α}-[6-(trimethylammonio)hexanoyl]-L-alaninamide bromide ($N^+C_5Ala2C_{16}$), was prepared after a reported procedure.[20,21] Preparation of a fluorescent probe, *N*-[5-(dimethylamino)-1-naphthylsulfonyl]-2-(4-imidazolyl)-ethylamine (dansylhistamine), was described elsewhere.[14] Alkyl

halides, diethyl 2-bromomethyl-2-methylmalonate and ethyl 3-bromo-2-cyano-2-methylpropanoate, and authentic samples of the corresponding products such as diethyl 2,2-dimethylmalonate (**A**), diethyl 2-methylsuccinate (**B**), ethyl 2-cyano-2-methylpropanoate (**C**), ethyl 3-cyanobutyrate (**D**), and ethyl 3-cyano-2-methylpropanoate (**E**) were prepared according to literature methods[13] and confirmed to be sufficiently pure by ^{1}H NMR and GLC.

***N*,*N*′-Bis(2-hydroxyiminocyclohexylidene)propane-1,3-diamine, (ch)(DOH)$_2$pn.** This ligand was synthesized by the condensation of 1,2-cyclohexanedione monooxime (15.8 g, 0.12 mol), which was prepared from ethyl 2-oxocyclohexanecarboxylate and sodium nitrite,[30] with 1,3-diaminopropane (5.20 g, 0.07 mol): Yield 12.5 g (71.0%), mp 50—51 °C; IR (KBr) 3300 (OH), 1640 (C=N), 970 (N–O) cm^{-1}; 60 MHz ^{1}H NMR ($CDCl_3$, TMS) δ=1.75 (8H, m, $ONCCH_2C\underline{H_2}C\underline{H_2}$-$CH_2$), 2.10 (2H, m, $NCH_2C\underline{H_2}CH_2N$), 2.55 (4H, t, J=6.1 Hz, $ONCCH_2CH_2CH_2C\underline{H_2}$), 2.92 (4H, t, J=6.1 Hz, $ONCC\underline{H_2}$-$CH_2CH_2CH_2$), 4.91 (4H, t, J=4.5 Hz, $NC\underline{H_2}CH_2C\underline{H_2}N$), 7.20 (2H, br s, OH). Found: C, 59.51; H, 8.24; N, 19.28%. Calcd for $C_{15}H_{24}N_4O_2$: C, 59.62; H, 8.27; N, 19.17%.

Dibromo[*N*-(2-hydroxyiminocyclohexylidene)-*N*′-(cyclohexyliden-2-one oximato)-1,3-diaminopropane]cobalt(III), [Co^{III}{(ch)(DO)(DOH)pn}Br$_2$] (4). An acetone solution (5 mL) of (ch)(DOH)$_2$pn (1.46 g, 5.0×10^{-3} mol) was added dropwise to an aqueous solution (150 ml) of cobalt dibromide hexahydrate (2.0 g, 6.0×10^{-3} mol) while air was bubbled through the latter aqueous solution. After the reaction mixture was stirred for 4 h, precipitates were recovered by filtration and washed with water. The resulting cobalt complex was recrystallized from acetone–water (1:1 v/v) to afford green needles: yield 1.66 g (65%), mp 251—252 °C; IR (KBr) 720 (Co–N) cm^{-1}; 500 MHz ^{1}H NMR ($CDCl_3$, TMS) δ=1.86 (4H, m, $ONCCH_2C\underline{H_2}CH_2CH_2$), 1.90 (4H, m, $ONCCH_2CH_2C\underline{H_2}CH_2$), 2.59 (2H, m, $NCH_2C\underline{H_2}CH_2N$), 3.01 (4H, t, J=6.16 Hz, $ONCCH_2CH_2CH_2C\underline{H_2}$), 3.21 (4H, t, J=6.46 Hz, $ONCC\underline{H_2}CH_2CH_2CH_2$), 4.07 (4H, t, J=4.52 Hz, $NC\underline{H_2}CH_2C\underline{H_2}N$), 19.0 (1H, s, OH). Found: C, 35.36; H, 4.54; N, 10.92%. Calcd for $C_{15}H_{23}Br_2CoN_4O_2$: C, 35.32; H, 4.54; N, 10.99%.

Diiodo[*N*-(2-hydroxyiminocyclohexylidene)-*N*′-(cyclohexyliden-2-one oximato)-1,3-diaminopropane]cobalt(III), [Co^{III}{(ch)(DO)(DOH)pn}I$_2$] (5). This complex was prepared in the presence of a large excess of potassium iodide by the method employed for the preparation of **4**. The crude product was purified by column chromatography on silica gel (Wakogel C-100) with benzene–acetone (4:1 v/v) as eluant to give dark green powder: Yield 61%, mp 262—263 °C; λ_{max} (CH_2Cl_2) 340 (ϵ 1.15×10^4), 462 nm (6.27×10^3); IR (KBr) 720 (Co–N) cm^{-1}; 500 MHz ^{1}H NMR ($CDCl_3$, TMS) δ=1.83 (4H, m, $ONCCH_2C\underline{H_2}CH_2CH_2$), 1.85 (4H, m, $ONCCH_2CH_2$-$C\underline{H_2}CH_2$), 2.63 (2H, br s, $NCH_2C\underline{H_2}CH_2N$), 2.94 (4H, t, J=6.09 Hz, $ONCCH_2CH_2CH_2C\underline{H_2}$), 3.18 (4H, t, J=6.45 Hz, $ONCC\underline{H_2}CH_2CH_2CH_2$), 4.10 (4H, br s, $NC\underline{H_2}CH_2C\underline{H_2}N$), 19.0 (1H, s, OH). Found: C, 29.94; H, 3.93; N, 9.50%. Calcd for $C_{15}H_{23}I_2CoN_4O_2$: C, 29.82; H, 3.85; N, 9.28%.

Bromo{2,2-bis(ethoxycarbonyl)propyl}[*N*-(2-hydroxyiminocyclohexylidene)-*N*′-(cyclohexyliden-2-one oximato)-1,3-diaminopropane]cobalt(III), [Co^{III}{(ch)(DO)(DOH)pn}-{$CH_2C(CO_2C_2H_5)_2CH_3$}Br] (6). A methanol solution (300 mL) containg **4** (400 mg, 7.8×10^{-4} mol) and diethyl 2-bromomethyl-2-methylmalonate (800 mg, 3.0×10^{-3} mol) was stirred while carbon monoxide was introduced into it until saturation was attained. After being stirred for 1 h, the solution turned pale yellow, indicating formation of the Co^{II} complex. Sodium tetrahydroborate in methanol was added dropwise to the resulting solution until the solution turned deep blue under carbon monoxide atmosphere. The solution changed its color to reddish orange, after it was refluxed for 4 h in the dark. The solution was evaporated to dryness, a solid material insoluble in dichloromethane (15 mL) was removed by filtration, and then the dichloromethane solution was concentrated to ca. 3 mL. Hexane (50 mL) was added to the resulting solution, and precipitates were recovered by filtration and purified by gel-filtration chromatography on a column of Sephadex LH-20 with methanol as eluant to give reddish brown powder: Yield 262 mg (55%); IR (KBr) 1725 (C=O) cm^{-1}; λ_{max} (CH_3OH) 475 nm. Found: C, 46.03; H, 6.23; N, 8.91%. Calcd for $C_{24}H_{38}BrCoN_4O_6\cdot1/2H_2O$: C, 46.02; H, 6.28; N, 8.94%.

Equilibrium Measurements for Incorporation of Vitamin B$_{12}$ Model Complexes into Single-Compartment Vesicles. A dichloromethane solution (1 mL) containing $N^+C_5Ala2C_{16}$ (1.0×10^{-5} mol) and a cobalt complex (2.0×10^{-7} mol), [Co^{III}-{(C_2C_3)(DO)(DOH)pn}I$_2$] or [Co^{III}{(ch)(DO)(DOH)pn}I$_2$], was evaporated in vacuo to remove the solvent completely, and an aqueous potassium iodide solution (1 mL, 5.0×10^{-4} mol dm^{-3}) was added to the residue. The resulting mixture was sonicated for 30 s with a probe-type sonicator at 30 W to give a clear solution. An extent of incorporation of the cobalt complex into the single-walled vesicle was examined by gel-filtration chromatography on a column of Sephadex G-50 with an aqueous potassium iodide solution (5.0×10^{-4} mol dm^{-3}) as eluant. The bound complex was eluted first in the column void volume, and the free complex was followed as the second fraction with a retention time close to the bed volume. An amount of the incorporated complex was determined by electronic spectroscopy. As for complexes with the cobalt–carbon bond, [Co^{III}{(C_2C_3)(DO)(DOH)pn}{$CH_2C(CO_2C_2H_5)_2$-CH_3}Br] and [Co^{III}{(ch)(DO)(DOH)pn}{$CH_2C(CO_2C_2H_5)_2$-CH_3}Br], a methanol solution (10 μL) of each complex was injected into the vesicular solution which was prepared in a manner as stated above, so that any cleavage of the cobalt–carbon bond caused by sonication was avoided.

Photolysis and Product Analyses. $N^+C_5Ala2C_{16}$ (5.0×10^{-5} mol) was dispersed in aqueous potassium bromide (10 mL, 5.0×10^{-4} mol dm^{-3}) by Vortex mixing, and the dispersion sample was then sonicated for 2 min with a probe-type sonicator at 30 W to give a clear solution of single-walled vesicles. A methanol solution (10 μL) of the alkylated complex (5.0×10^{-7} mol), [Co^{III}{(C_2C_3)(DO)(DOH)pn}RBr] or [Co^{III}{(ch)(DO)(DOH)pn}RBr], was added to the vesicular solution. Then, the resulting solution was irradiated with a 500 W tungsten lamp at a distance of 30 cm and at an appropriate temperature. After the alkylated complex was

completely decomposed as confirmed by electronic spectroscopy, the products were extracted with dichloromethane (10 mL×3) and analyzed by GLC. Reaction products were identified by coinjection of the corresponding authentic samples into columns of Silicone DC-550 (Shimadzu Co.) and Silicone SE-30 (Gasukuro Kogyo Inc.) as described previously in detail.[8] A capillary column of Polyethylene Glycol-20M (Gasukuro Kogyo) was used for identification of isomers having similar structures. Each product separated by preparative GLC on Silicone DC-550 was identified by means of ^{1}H NMR spectroscopy. As for reactions in methanol and benzene, a reaction mixture was evaporated to dryness in vacuo before dichloromethane was added. Total yields listed in Tables 1—3 are less than 100% owing to losses during extraction and evaporation treatments in vacuo. However, we confirmed that no other by-productus were obtained.

Results and Discussion

Incorporation of Vitamin B_{12} Model Complexes into Single-Compartment Vesicles. Complexes **1**, **2**, **5**, and **6** were incorporated into the $N^+C_5Ala2C_{16}$ vesicle to the extents of 82—90, 55—60, 16—20, and 54—56% of their total amounts in molar fraction, respectively.[31] The amounts of the complexes incorporated into the vesicle were little affected by temperature change in the range of 5—50 °C. The extents of solubility of these complexes in water were found as follows: **1**, 1.1×10^{-4} mol dm^{-3}; **2**, 2.0×10^{-4} mol dm^{-3}; **5**, 3.1×10^{-4} mol dm^{-3}; **6**, 8.1×10^{-4} mol dm^{-3}. We have already found that the extent of incorporation of hydrophobic vitamin B_{12} derivatives into the $N^+C_5Ala2C_{16}$ vesicle is primarily controlled by the hydrophobicity of the complexes.[8] In other words, the incorporation of those complexes into the vesicle becomes increasingly favored as those become less soluble in aqueous media. However, the solubility parameter alone can not provide a reasonable explanation for the incorporation behavior of the present complexes. The incorporation behavior seems to depend on various factors, such as size, dipolar property, and hydrophobicity of the complex, which give out different modes of interactions with the membrane.

Product Analyses for Photolysis of Alkylated Complexes in Various Media. The cobalt–carbon bond involved in alkylated complexes **2** and **6** was cleaved in the vesicular solution upon irradiation with visible light as reported previously.[31] Likewise, **3** underwent the photolytic cleavage. After the alkylated complex was completely decomposed as confirmed by electronic spectroscopy, the products were analyzed by GLC. Product analyses for the photolysis of alkylated complexes **2** and **3** in various media are summarized in Tables 1 and 2. We identified the products, which were obtained by the photolysis reaction of complex **2**, as diethyl 2,2-dimethylmalonate (**A**, the simple hydrogenated product without rearrangement) and diethyl 2-methylsuccinate (**B**, the rearrangement product) (refer to Eq. 6). As for complex **3**, ethyl 2-cyano-2-methylpropanoate (**C**, the simple hydrogenated product), ethyl 3-cyanobutyrate (**D**, the ester-migrated product), and ethyl 3-cyano-2-methylpropanoate (**E**, the cyano-migrated product) were confirmed to be obtained (refer to Eq. 7).

The following findings are based on the product analyses. (i) The major products are the unrearranged ones in benzene and methanol, but the rearrangement products are largely obtained in the vesicular solution. Consequently, the carbon-skeleton rearrangement is

D E (7)

much enhanced in the vesicle relative to the reaction in homogeneous solutions. (ii) The product ratio **B**/**A** for complex **2** in the vesicular solution is quite large as compared with the one for the corresponding hydrophobic vitamin B_{12} (**B**/**A**=0.12).[8] The photolysis must cause the homolytic cleavage of the cobalt–carbon bond in the initial stage.[32] The radical mechanism was assigned to the carbon-skeleton rearrangement of hydrophobic vitamin B_{12} derivatives which do not hold an anionic ligand trans to the substituted alkyl moiety. However, the ester group migrates more readily via formation of an anionic intermediate relative to the reaction via formation of a radical intermediate even in the vesicle.[33] Therefore, the bromide ion coordinated to the cobalt atom at the axial site seems to take a role in inducing the heterolytic cleavage of the cobalt–carbon bond involved in the model complex so that an anionic intermediate is produced, as caused by one-electron transfer immediately after the homolytic cobalt–carbon cleavage. (iii) The product ratios of the rearranged ones, **B**/**A** and (**D**+**E**)/**C**, increase in the vesicle along with temperature decrease as shown in Tables 1 and 2. Since the single-walled $N^+C_5Ala2C_{16}$ vesicle was found to show a broad phase transition from the gel to the liquid-crystalline state at 20±5 °C by differential scanning calorimetry,[21] the synthetic bilayer membrane favors formation of the rearrangement product in the gel state. A similar result was obtained for complex **6** bearing cyclohexane moieties in the ligand portion, as is apparent from the data in Table 3.

Microenvironment around Vitamin B_{12} Model Complexes in Single-Compartment Vesicle. In order to understand microenvironmental properties experienced by the vitamin B_{12} model complexes in the vesicle, the cobalt complex coordinated at the axial site with dansylhistamine as a fluorescent probe was adopted. The axial ligation constants (K) for [Co^{III}\{(C_2C_3)(DO)(DOH)pn\}Br_2] and [Co^{III}\{(ch)(DO)(DOH)pn\}I_2] with dansylhistamine were determined by electronic spectroscopy after a reported procedure:[9] log K=5.2 and 5.0 in methanol, and 5.3 and 5.2 in benzene, respectively. These data indicate that the metal complexes are largely coordinated with dansylhistamine under the present experimental conditions. The microscopic polarity experienced by the dansyl moiety bound to the vitamin B_{12} model complex is reflected in its fluorescence maximum.[34] In order to obtain the reference data, the fluorescence maxima of dansylhistamine coordinated to the vitamin B_{12} model complexes were measured in various mixtures of water and dioxane as shown in Fig. 1. The fluorescence maximum is shifted to lower wavelength as the solvent polarity decreases. It is clear that the single-walled vesicle of $N^+C_5Ala2C_{16}$ provides a microenvironment for the dansyl moiety that is equivalent to a medium polarity between those of methanol and ethanol. These values are comparable to that obtained for a hydrophobic vitamin B_{12}.[8] The result leads us to conclude that an axial ligand bound to the complex is significantly desolvated in the vesicle.

The microscopic viscosity experienced by the dansyl moiety bound to the vitamin B_{12} model was examined by means of fluorescence polarization (P) measurements. P values for the dansylhistamine-coordinated vitamin B_{12} models in methanol and benzene are 0.004—0.005 and 0.009—0.02, respectively, in the temperature

range 5—50 °C. On the other hand, the identical complexes gave large *P* values in the vesicular solution as shown in Fig. 2. This apparently indicates that the molecular motion of the guest molecules in the vesicle is markedly suppressed.[35] Thus, the microenvironmental effect provided by the vesicle is quite different from those given by simple organic solvents which solubilize the vitamin B_{12} models homogeneously.

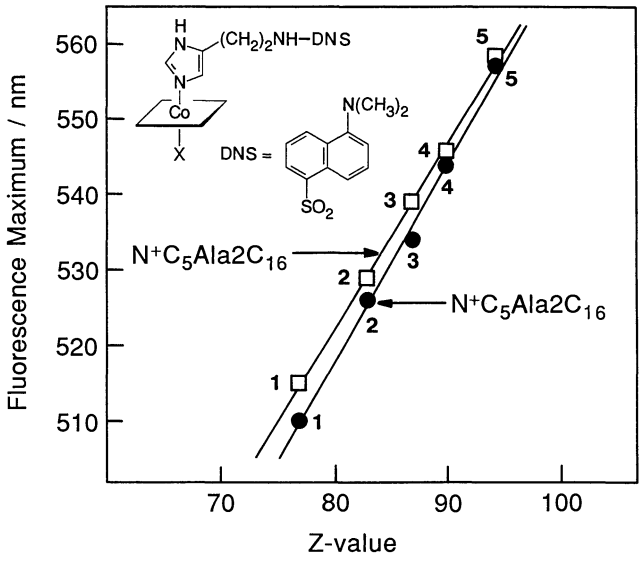

Fig. 1. Medium effect on fluorescence of dansylhistamine (1.0×10^{-5} mol dm^{-3}) coordinated to [Co^{III}{(ch)(DO)(DOH)pn}I] (□, X=I; 1.0×10^{-5} mol dm^{-3}) and [Co^{III}{(C_2C_3)(DO)pn}Br] (●, X=Br; 1.0×10^{-5} mol dm^{-3}), both complexes being incorporated into the $N^+C_5Ala2C_{16}$ (5.0×10^{-3} mol dm^{-3}) vesicle in phosphate–borate buffer (0.05 mol dm^{-3}; pH 9.2) at 20.0±0.1°C. Reference data obtained in water-dioxane at the following ratios (v/v): 1, 1:9; 2, 3:7; 3, 1:1; 4, 7:3; 5, 1:0. The Z-value refers to Kosower's parameter.

The present study demonstrates that a vitamin B_{12}-dependent artificial holoenzyme can be prepared by utilizing a synthetic bilayer membrane and a simple vitamin B_{12} model complex. It is clear that the carbon-skeleton rearrangement of an alkyl ligand coordinated to the simple vitamin B_{12} model takes place much favorably in the vesicular phase. This 1,2-migration must arise from both repression of molecular motion and desolvation effects operating on the alkylated complex in the vesicle, in a manner as observed by utilizing a hydrophobic vitamin B_{12}.[8]

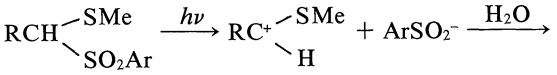
Flash Photolytic Generation of a Dithio Carbocation from 1,3-Dithiolane Derivatives and Its Reaction with Nucleophiles[1)]

Tadashi OKUYAMA,* Naoki HAGA, Shin-ya TAKANE, Kenji UENO, and Takayuki FUENO
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received May 15, 1991)

2-Phenyl-1,3-dithiolanylium ion is generated as a transient intermediate by flash photolysis of aqueous ethanol and acetonitrile solutions of 2-methoxy and other dithiolane derivatives with a xenon lamp. Decay of the absorption (342 nm) of the cation generated from the 2-methoxy derivative follows pseudo-first-order kinetics. Rate constants were measured for the reaction of the cation with various nucleophiles. Decay curves for the cations generated from 2-arylthio and 2-sulfonyl derivatives are steep and show second-order kinetic character owing to the recombination of the cation with the counter anions (thiolate and sulfinate).

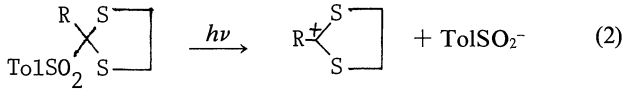
Sulfur-stabilized carbocations are intermediates for acid-catalyzed reactions of ortho thioesters and thioacetals and their stability and reactivity have attracted considerable interest in relation to those of oxygen analogs.[2)] Dithio carbocations are stable enough to be isolated as salts.[3-7)] Chemistry of the isolated salts has been examined.[2,8)]

Ogura[9)] found that 1-(methylthio)alkyl aryl sulfones are easily hydrolyzed by photoirradiation of the aqueous solution. Thio carbocations are assumed as intermediates for this photosolvolysis.



$$RCH(SMe)(SO_2Ar) \xrightarrow{h\nu} RC^+(SMe)(H) + ArSO_2^- \xrightarrow{H_2O} RCHO + MeSH + ArSO_2H \quad (1)$$

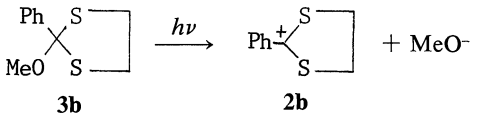
This report suggested us that thio carbocations can be photochemically generated from appropriate precursors. This may provide us good means for examination of rapid reactions of the cations in ground state by using a flash-photolytic technique. We thus considered that, if a nucleofugal group of the precursor sould be a main chromophore for the photolysis, the excited nucleofuge could be efficiently released to leave a ground-state carbocation. For such precursors for dithio carbocations, we have first chosen 2-(*p*-tolylsulfonyl)-1,3-dithiolanes, **1a** and **1b**.



1a, R=H
1b, R=Ph
Tol=*p*-$CH_3C_6H_4$

Irradiation of alcoholic solutions of the sulfone derivatives **1** with a low-pressure Hg lamp gave 2-alkoxy derivatives in high yields. Flash photolysis of aqueous solutions of **1** showed formation of the dithiolanylium ion **2**. However, because of high nucleophilicity of the accompanying sulfinate ion, kinetics of decay of the cation **2** was complicated. A 2-arylthio derivative also behaved similarly.

A 2-alkoxy derivative **3b** was later found to give the carbocation **2b** on irradiation in spite of the non-light-absorbing nucleofugal group.[1,10)]



3b **2b**

Triarylcarbenium ions can be generated by photolysis of various precursors with a nucleofuge such as cyanide,[11,12)] hydroxide,[11,13-16)] acetate,[17,18)] and phenoxide ion.[17,18)] Nonabsorbing nucleofuges can be liberated by photolysis of suitable precursors. McClelland and co-workers[14,17-19)] have extensively studied reactivities of these carbocations by flash photolysis. Reaction of 2-phenyl-1,3-dithiolan-2-ylium ion **2b** generated from **3b** with some nucleophiles is a main subject in the present paper but photolysis of other precursors **1** is also presented.

Results and Discussion

Photolysis was carried out with a xenon lamp usually in 1:1 (v/v) ethanol–water and 1:1 (v/v) acetonitrile–water solutions. On flash irradiation of **3b**, the spectrum with a maximum absorption at 342 nm develops instantaneously and disappears slowly. The spectra of the transient intermediate were recorded with

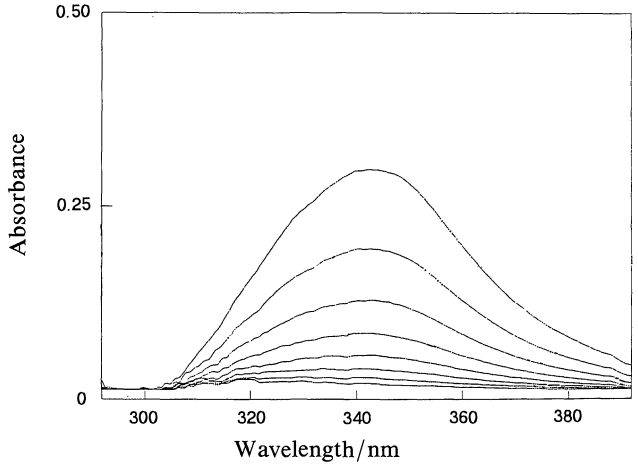


Fig. 1. Transient spectra observed on photolysis of **3b** in 1:1 (v/v) EtOH–H_2O at [HCl]=10^{-3} M. The time interval of the spectra was 120 ms.

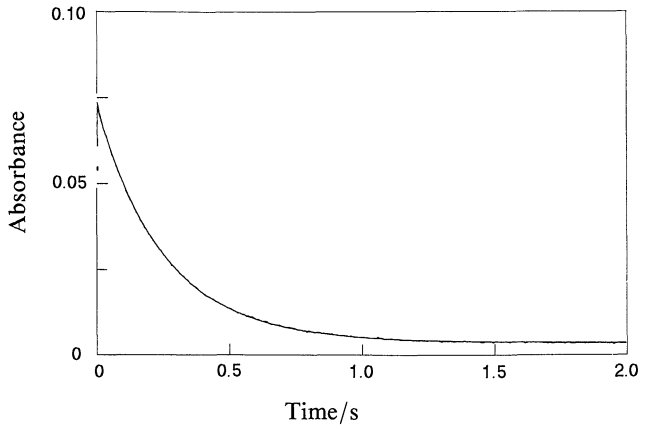

Fig. 2. A trace of the absorption at 342 nm on photolysis of **3b** in 1:1 (v/v) EtOH–H_2O at [HCl]=10^{-3} M. A theoretical pseudo-first-order curve is also drawn.

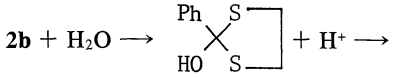
Table 1. Observed Rate Constants for Decay of **2b** in Aqueous Solutions[a)]

[HCl]/M	k_{obsd}/s^{-1}	
	1:1 EtOH–H_2O	1:1 MeCN–H_2O
0	3.98	0.62
10^{-6}	3.75	0.57
10^{-5}	3.92	0.53
10^{-4}	3.78	0.53
10^{-3}	3.72	
Average	3.83	0.56

a) Measured at 25°C and an ionic strength of 0.10 (KCl).

an MCPD detector in time intervals of order of milliseconds as shown in Fig. 1. The absorption maximum agrees with that observed for the cation **2b** in strong acid.[4)] Time-dependent absorbance changes at 342 nm follow a pseudo-first-order ceday curve as shown in Fig. 2. Bubbling of the solution with oxygen or argon did not affect the transient absorption spectrum or decay curve. The decay was not influenced by addition of acid but accelerated with added nucleophiles as will be presented below. From these observations the transient is identified as the free dithiolanylium ion **2b**. Further support for this intermediate was obtained by photosolvolysis that **3b** undergoes upon stationary irradiation with a low-pressure Hg lamp.[10)]

From a decay curve like that shown in Fig. 2, pseudo-first order rate constants k_{obsd} were obtained by the nonlinear least-squares curve fitting. In aqueous solutions, k_{obsd} is not affected with acid (Table 1). This decay of **2b** must be due to reaction with nucleophilic solvent. The k_{solv} in aqueous ethanol and acetonitrile solutions are 3.83 and 0.56 s^{-1}, respectively. Formation of a thioester was confirmed as a final product by stationary photolysis.[10)]



$$PhCOSCH_2CH_2SH + H^+ \quad (4)$$

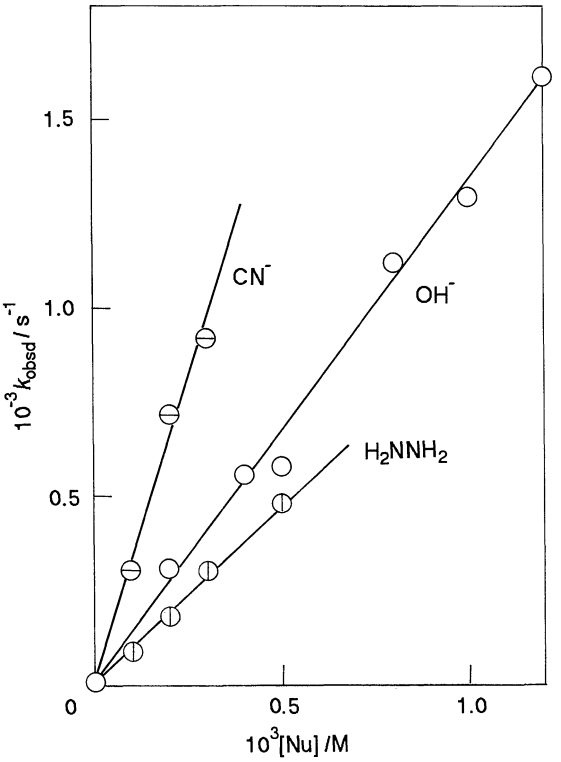


Fig. 3. Plots of k_{obsd} against concentrations of added nucleophiles for OH^- (○), CN^- (⊖), and hydrazine (◑). Data for the latter two were taken in the presence of NaOH at [OH^-]=10^{-4} M.

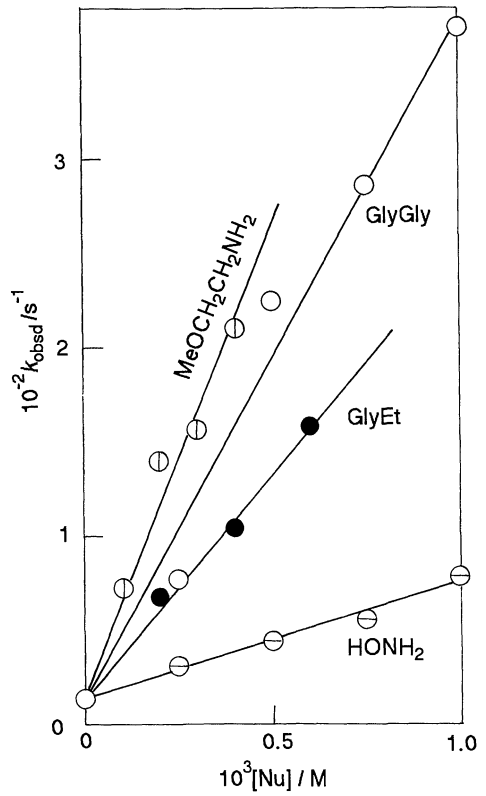

Fig. 4. Plots of k_{obsd} vs. concentrations of nucleophiles for 2-methoxyethylamine (◑), glycylglycine (○), ethyl glycinate (●), and hydroxylamine (⊖). Rates were measured at [OH^-]=10^{-4} M.

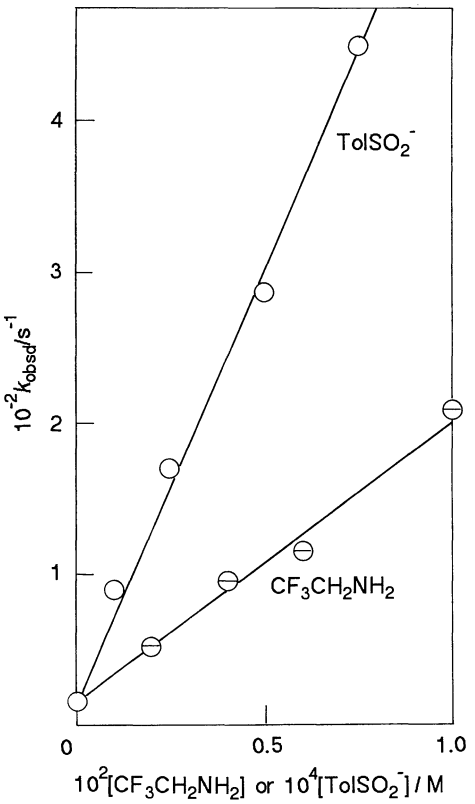

Fig. 5. Plots of k_{obsd} vs. concentrations of nucleophiles for *p*-toluenesulfinate (○) and 2,2,2-trifluoroethylamine (⊖). Rates were measured at $[OH^-]=10^{-4}$ M.

Addition of sodium hydroxide greatly increases the decay rate as is seen in Fig. 3. The k_{obsd} increases linearly with $[OH^-]$. Contamination of carbon dioxide retards the reaction at $[OH^-] < 10^{-4}$M (M=mol dm^{-3}). Other nucleophiles also accelerate the decay of the cation **2b**, following Eq. 5 (Figs. 3-5). The primary reaction involved is the addition of the nucleophile to **2b** (Eq. 6).

$$k_{obsd} = k_0 + k_{Nu}[Nu] \quad (5)$$

$$\mathbf{2b} + Nu^- \xrightarrow{k_{Nu}} \text{Ph(S)(Nu)S} \quad (6)$$

The nucleophilic reactions were mostly examined in the presence of hydroxide ion at $[OH^-]=10^{-4}$ M to avoid formation of the conjugate acid of the nucleophile but contamination of CO_2 was not completely precluded. The rate constants obtained are summarized in Table 2.

Reaction of *p*-toluenesulfinate was also carried out in acidic aqueous acetonitrile solutions. The apparent second-order rate constants k_2, where $k_{obsd}=k_0+k_2[TolSO_2H]_t$, change sigmoidally with pH in the range 1—4 as shown in Fig. 6. This shows that only the sulfinate ion is a nucleophile but conjugate acid is unreactive. Since the fraction of the conjugate base is given by $K_a/(K_a+[H^+])$, the observed k_2 can be expressed

Table 2. Rate Constants for the Nucleophilic Reactions of **2b** in 1:1 (v/v) Aqueous Ethanol

Nucleophile	pK_a[a]	N_+[b]	k_{Nu}/M^{-1} s^{-1}
H_2O/EtOH	(−1.7)	0.73	3.83[c]
OH^-	15.7	4.75	1.3×10^6
$(CF_3)_2CHO^-$	9.3		2.4×10^6
$CF_3CH_2NH_2$	5.7	3.45	1.8×10^4
$EtOCOCH_2NH_2$	7.75	4.40	2.4×10^5
$^-OCOCH_2NHCOCH_2NH_2$	8.13	4.69	3.6×10^5
$MeOCH_2CH_2NH_2$	9.20	5.07	4.6×10^5
$HONH_2$	5.97	5.05	6.4×10^4
H_2NNH_2	8.10	6.01	9.3×10^5
CN^-	9.40	4.12	3.2×10^6
$TolSO_2^-$	1.99		5.8×10^6
p-$ClC_6H_4S^-$	6.14[d]	9.10[e]	4.5×10^8[f]

a) pK_a of the conjugate acid. Taken from "Handbook of Biochemistry," ed by H. A. Sober, CRC Press, Cleveland, Ohio (1968). b) Nucleophilicity parameter.[22] c) In s^{-1}. d) Taken from P. DeMaria, A. Fini, and F. M. Hall, *J. Chem. Soc., Perkin Trans. 2,* **1973**, 1969. e) A value for benzenethiolate. f) Evaluated in 1:1 (v/v) MeCN–H_2O.

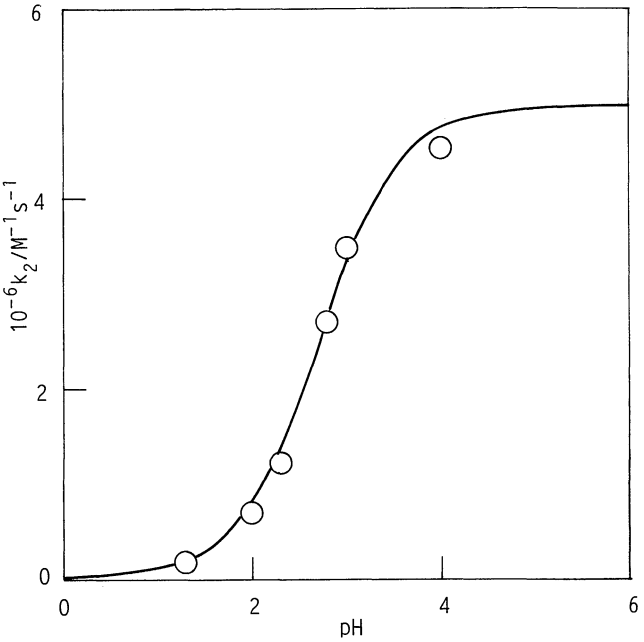

Fig. 6. Plots of apparent second-order rate constants against pH for the reaction of **2b** with *p*-toluenesulfinate in 1:1 (v/v) MeCN–H_2O. Acidity was controlled with HCl. The solid curve is a sigmoid with pK_a=2.7, k_{min}=0, and $k_{max}=5\times10^6$ M^{-1} s^{-1}.

by Eq. 7 The theoretical curve in Fig. 6 is drawn with pK_a=2.7 obtained spectrophotometrically for the sulfinic acid and limiting k_2 at lower and higher pH being 0 and 5.0×10^6 M^{-1} s^{-1}(k_{Nu}). The k_{Nu} agrees reasonably well with that obtained in an alkaline aqueous ethanol solution.

$$k_2 = k_{Nu}K_a/(K_a + [H^+]) \quad (7)$$

Reaction of *p*-chlorobnzenethiol was examined in acidic aqueous acetonitrile solutions. The observed

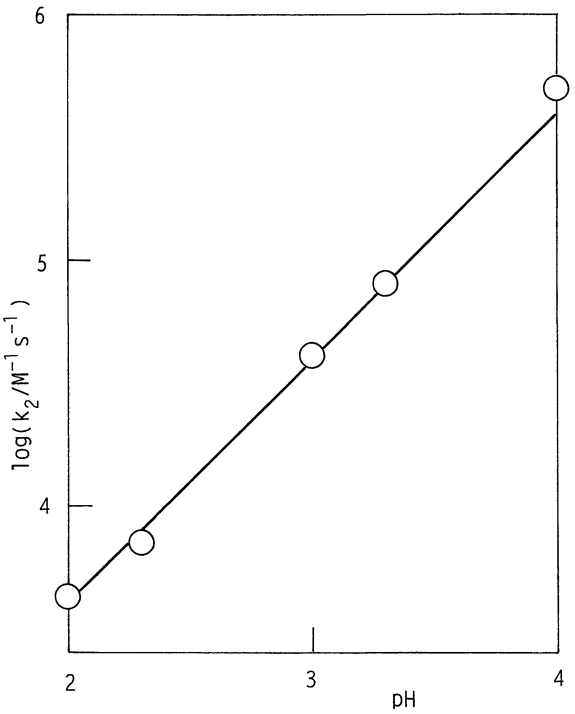

Fig. 7. Logarithmic plots of apparent second-order rate constants against pH for the reaction of **2b** with *p*-chlorobenzenethiol in 1:1 (v/v) MeCN–H_2O. Acidity was controlled with HCl.

second-order rate constants k_2 are dependent on acid concentration (Fig. 7). In this case, both the neutral thiol ArSH and thiolate ArS^- can be good nucleophiles, and the k_2 should obey Eq. 8.

$$k_2 = (k_{ArS^-}K_a + k_{ArSH}[H^+])/(K_a + [H^+]) \quad (8)$$

In the pH region where $[H^+] \gg K_a$, Eq. 8 is reduced to Eq. 9 or 10.

$$k_2 = k_{ArS^-}K_a/[H^+] + k_{ArSH} \quad (9)$$

$$\log k_2 = -\log[H^+] + \log(k_{ArS^-}K_a + k_{ArSH}[H^+]) \quad (10)$$

The logarithmic plots of k_2 against pH ($-\log[H^+]$) fall on a straight line of a unit slope as is seen in Fig. 7. That is, $k_{ArSH}[H^+]$ is negligibly small at $[H^+] = 10^{-4}$—10^{-2} M as compared with $k_{ArS^-}K_a$ in Eq. 10. The reactive species of the thiol reaction is thiolate ion ArS^- even in the acidic media where most of the thiol is present in a conjugate acid form ArSH ($[H^+] \gg K_a$). The k_{ArS^-} for the thiolate ion was evaluated to be 4.5×10^8 M^{-1} s^{-1} using pK_a=7.06 for *p*-chlorobenzenethiol in 49:51 (v/v) ethanol–water solution.[20]

Flash photolysis of aqueous solutions of 2-(*p*-chlorophenylthio)-2-phenyl-1,3-dithiolane (**1c**) and the 2-sulfonyl derivative **1b** showed also formation of the cation **2b**. However, the decay curves of **2b** monitored at 342 nm in this photolysis are different from that observed with **3b** and do not follow psedo-first-order kinetics. The decay of **2b** generated from **1c** fitted the second-order kinetics while the decay observed with **1b** was usually a mixed first- and second-order reaction. These observations must be due to the recombination of **2b** with the accompanying counter anions in a free form. Both of the thiolate and sulfinate ions are very effective nucleophiles and recombination reaction can be a main reaction (in the thiolate case) or an appreciable one (in the sulfinate case) even at very low concentrations in the order of 10^{-6} M as generated by photolysis.

The unsubstituted dithiolanylium ion **2a** (λ_{max}=333 nm) can be generated from the sulfonyl precursor **1a**. The decay curve was also that of mixed first- and second-order reaction. Similar photolysis of 2-methoxy-1,3-dithiolane was also examined but no appreciable cation formation was observed, probably owing to the low efficiency of light absorption.

Photochemical bond cleavage can occur even if the chromophore of the molecule is not directly bonded to the atom involved in the bond breaking. The excess energy of the electronically excited molecule may be transferred to the vibrational states and cleavage of a weaker bond may lead to heterolysis in the present case. All the physical and chemical events in excited states take place in solution within a time scale of nanoseconds and the reactions we observed here are those of photochemical reaction intermediates in the ground state. The main chromophore of the present reaction must be the phenyl group. Although the C–S bondings have a weak absorption around 250 nm, they cannot be

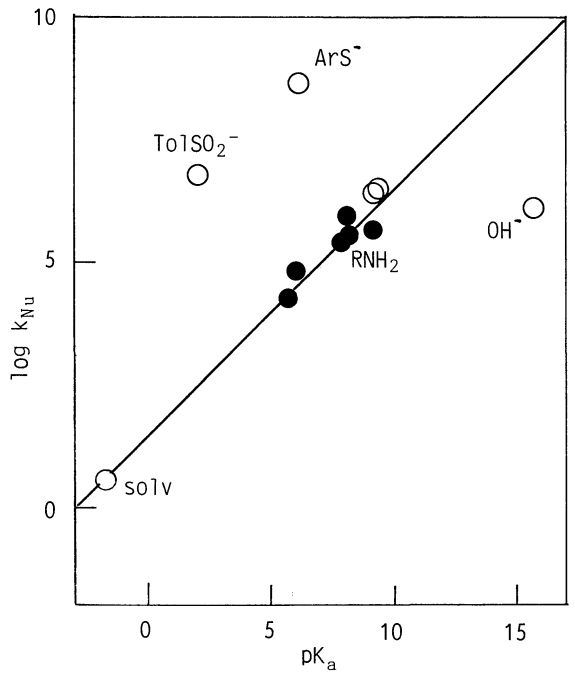

Fig. 8. Correlation of the rate constants with pK_a for the nucleophilic reactions of **2b**. A point for k_{solv} is placed at pK_a of H_3O^+.

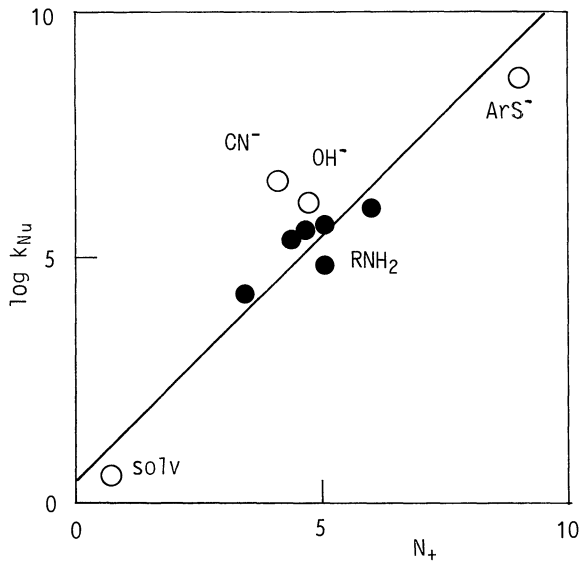

Fig. 9. Correlation of the rate constants with N_+ for the nucleophilic reactions of **2b**. The k_{solv} is plotted against N_+ of H_2O.

satisfactory light absorbers. The unsubstituted dithiolanylium ion **2a** cannot be generated by photolysis of the 2-methoxy derivative.

Rate constants for the nucleophilic reactions of **2b** are correlated with pK_a of the conjugate acid of nucleophiles in aqueous solution (Fig. 8). Although the points for the thiolate and sulfinate ions derivate greatly upward, the points for amines closely fall on the line of a slope β=0.5. The "α-effect" amines,[21] hydroxylamine or hydrazine, do not show appreciable deviations, indicating lack of enhanced reactivity. The thiolate and sulfinate deviations are additional examples of enhanced nucleophilicity of these sulfur nucleophiles.

The k_{Nu} are logarithmically plotted against Ritchie's N_+ nucleophilicity parameters[22] in Fig. 9. Although considerable scatterings are evident, the points fall in the vicinity of a line of a unit slope. The slope of a similar correlation for a less stable triphenylmethylium ion (pK_R=−6.63) was found to be much smaller than unity.[17] The reactivity of the cation **2b** (pK_R=2.5)[2] seems to be in the range of category of the simple Ritchie relationship of a unit slope which was found for reactions of stable carbocations (pK_R>1) with nucleophiles.[22]

Experimental

Materials. Hydroxylamine hydrochloride, hydrazine hydrochloride, potassium cyanide, and potassium chloride were obtained from Wako Pure Chemical. Glycylglycine, ethyl glycinate, and 2,2,2-trifluoroethylamine hydrochloride were from Sigma Chemical. 2-Methoxyethylamine, 1,1,1,3,3,3-hexafluoro-2-propanol, and *p*-chlorobenzenethiol obtained from Aldrich were distilled. Sodium *p*-toluenesulfinate (Wako) was dried at 130 °C for 6 h. Ethanol and acetonitrile were distilled from activated magnesium and calcium hydride, respectively.

A carbon dioxide-free solution of sodium hydroxide was prepared by dissolving metallic sodium in dry ethanol and dilution with freshly boiled water and titrated with a standard hydrochloric acid.

2-Methoxy-2-phenyl-1,3-dithiolane (**3b**) was prepared from the dithiolanylium perchlorate as described previously.[4,10]

2-(*p*-Tolylsulfonyl)-1,3-dithiolane (1a). To a solution of 1,3-dithiolan-2-ylium perchlorate, prepared from 1,2-bis(1,3-dithiolan-2-ylthio)ethane (5.6 mmol),[4] in acetonitrile (30 cm³) was added dry sodium *p*-toluenesulfinate (11.4 mmol) and stirred for 3 h at room temperature. After removal of most of the solvent in vacuo, the residues were dissolved in chloroform, washed with aqueous potassium carbonate, and dried over $MgSO_4$. Removal of the chloroform gave crude solids. Recrystallizations from benzene afforded **1a** in 17% yield. Mp 142—143 °C. Anal. Calcd for $C_{10}H_{12}O_2S_3$: C, 46.12; H, 4.65; S, 36.94%. Found: C, 46.04; H, 4.56; S, 36.48%. ^{1}H NMR ($CDCl_3$) δ=2.45 (s, 3H), 3.40 (s, 4H), 5.35 (s, 1H), 7.23—8.0 (m, 4H). UV (heptane): λ_{max}=226 nm (ε 12000).

2-Phenyl-2-(*p*-tolylsulfonyl)-1,3-dithiolane (1b). Reaction of 2-phenyl-1,3-dithiolan-2-ylium perchlorate obtained from benzoyl chloride and 1,2-ethanedithiol[4] with sodium *p*-toluenesulfinate in the same way as **1a** gave crystalline **1b** in 35% yield (based on benzoyl chloride). Mp 131—132 °C (benzene–ethanol). Anal Calcd for $C_{16}H_{16}O_2S_3$: C, 57.11; H, 4.79; S, 28.59%. Found: C, 56.94; H, 4.73; S, 28.12%. ^{1}H NMR ($CDCl_3$) δ=2.36 (s, 3H), 3.28—3.75 (m, 4H), 6.29—7.50 (m, 9H). UV (heptane): λ_{sh} 250 nm (ε 10000).

2-(*p*-Chlorophenylthio)-2-phenyl-1,3-dithiolane (1c). To a solution of the dithiolanylium perchlorate, prepared from 25 mmol of benzoyl chloride and 1,2-ethanedithiol,[4] in acetonitrile (30 cm³) was added an acetonitrile solution of *p*-chlorobenzenethiol (25 mmol) and excess triethylamine under stirring. After standing for 4 h at room temperature, the solvent was mostly removed by vacuum evaporation. The residues were dissolved in ether, washed with sodium bicarbonate, and dried over $MgSO_4$. The remaining solids after removal of the ether were recrystallized from benzene–hexane to give white plates in an overall yield of ca. 30%. Mp 106—107 °C. Anal. Calcd for $C_{15}H_{13}ClS_3$: C, 55.45; H, 4.03; S, 29.60%. Found: C, 55.27; H, 4.03; S, 29.03%. ^{1}H NMR ($CDCl_3$) δ=3.53 (m, 4H), 7.1—7.5 (m, 9H).

Flash Photolysis. A flash-photolytic apparatus Union RA-412 equipped with a xenon flash lamp (half-height width, ca. 10 s) was used for photolysis. A tungsten lamp was employed with a Pyrex filter for a source of detection light (stationary). Data were fed to and processed with a Union RA-401 processor linked through a photomultiplier or an MCPD (multichannel photodiode array) detector. Rate constants are obtained by nonlinenar least-squares curve fittings (the damping Gauss–Newton method) of the decay curves.

Reactions were carried out in 1:1 (v/v) ethanol–water or 1:1 (v/v) acetonitrile–water usually at an ionic strength of 0.10 maintained with KCl and at 25 °C kept constant with circulating water. The initial substrate concentration was usually 5×10^{-4} M and a stock solution in ethanol or acetonitrile was prepared by weighing. Solutions of nucleophiles were also prepared by weighing. A necessary amount of the substrate stock solution was added with a microsyringe to the reaction solution in a cuvette immediately before photolysis.

We thank Professor S. Otsuka for use of a data processor Union RA-401. This work was in part supported by Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

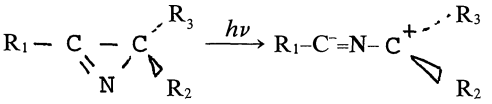
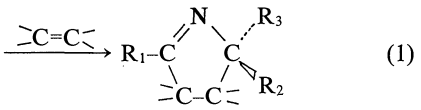
(Received January 14, 1991)

Laser flash photolysis of 3-(4-biphenylyl)-2*H*-azirine (AZ) was carried out in cyclohexane for the direct detection of a nitrile ylide (NY). Two kinds of transient species, triplet AZ (T_1) and NY, have been measured. Decay rates of these species were determined to be 6.7×10^5 s^{-1} (T_1) and 8×10 s^{-1} (NY). The rate constants for the reactions of NY toward acetone and acrylonitrile were determined to be 2.5×10^3 dm^3 mol^{-1} s^{-1} and 2.3×10^6 dm^3 mol^{-1} s^{-1}, respectively. These results were supported by the results of pulse radiolysis of AZ in benzene and stational irradiations of AZ.

Nitrile ylide (NY) is an important reaction intermediate for the synthesis of heterocyclic compounds. This species is one of a group of 1,3-dipoles and is highly reactive toward a wide variety of dipolarophiles such as olefins, ketones, and esters. Various dehydrohalogenation reactions of imidoyl chloride deviatives to yield this species have initially been investigated by Husgen.[1] Padwa[2] and Schmid[3] have independently shown that 2*H*-azirine undergoes facile ring opening on photoirradiation to give NY which reacts with olefins to give 3,4-dihydropyrrole (Eq. 1).



(2*H*—Azirine) (Nitrile Ylide)



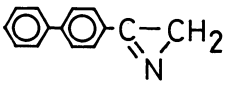
(2*H*-Pyrrole) (1)

The NY thus formed was originally detected by the photoirradiation of arylazirine in a rigid matrix at 77 K by Schmid and coworkers.[4] However, the reaction dynamics of NY were not clarified because of the experimental limitations of stational photoirradiation at low temperature.

Recently, NY produced by the addition reaction of carbenes with nitriles was studied throughly by using a laser flash technique.[5] Scaiano and co-workers reported that the reaction rate constants of the intermediate, which was produced by the addition reaction of 1-naphtylcarbene and acetonitrile with acrylonitrile and diethylfumalate were similar to the values obtained for the 1,3-dipolar addition of NY.[6]

Currently the laser flash photolysis of 2*H*-azirine is the most powerful method to study the charactristics and reactivities of NY. Padwa and co-workers carried out the laser flash photolysis of 2,2- and 2,3-diphenyl-2*H*-azirine.[7] They reported the absorption spectra of NY and the existence of a new complex in the 1,3-dipolar addition reaction. Unfortunately, the profiles of the 2*H*-azirine photoreactions have not been clarified.

Biphenyl compounds are activated by 308 nm irradiation. The transient species formed to excite is expected to be stabilized by the large chromophor and also to be assigned easily. In this study, we carried out the 308 nm laser flash photolysis and a pulse radiolysis of a 2*H*-azirine derivatives substituted at the 3-position with a biphenyl group, 3-(4-biphenylyl)-2*H*-azirine (AZ, R_1=4-biphenylyl, R_2=R_3=H), to elucidate the reaction mechanism for the formation of NY. The stational photoirradiation of AZ was also carried out in order to obtain further experimental support of the mechanism.



[3-(4-Biphenylyl)-2*H*-azirine, AZ]

Results and Discussion

1. Transient Species. Laser flash photolysis of AZ was carried out in argon-saturated cyclohexane ([AZ]=1.0×10^{-3} mol dm^{-3}). Figure 1 shows the transient absorption spectra recored at various times after the flash and decay traces monitored at 410 nm. The traces indicate the presence of two kinds of transient species with different lifetimes which are indicated as **A** (short-lived) and **B** (long-lived) in Fig. 1 (Eq. 2) in the laser flash photolysis of 2,2-diphenyl-3-methyl-2*H*-azirine reported by Padwa and co-workers.[7] The decay

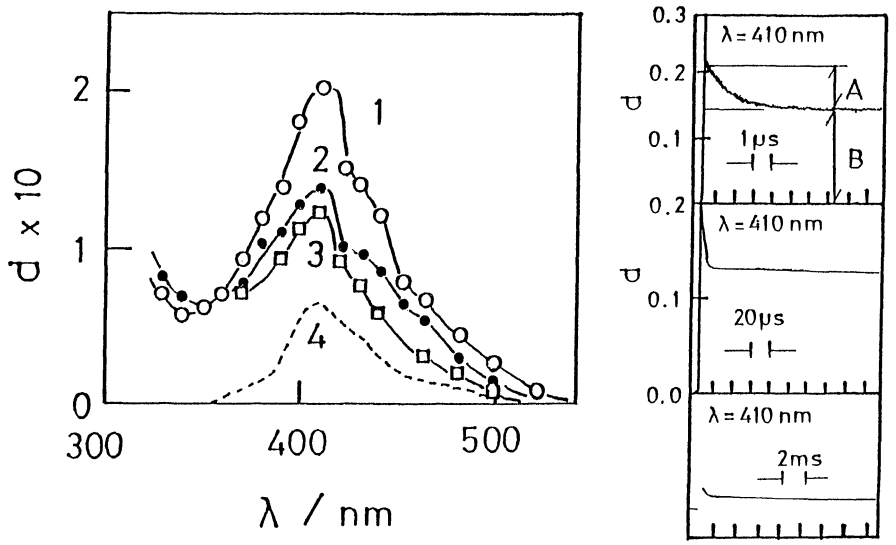


Fig. 1. Transient absorption spectra and the decay traces. Recorded at 0.1 (1), 6 (2), and 160 μs (3) after the flash. Dotted line shows the difference spectrum (1—2). [AZ]=1.0×10^{-3} mol dm^{-3} in cyclohexane.

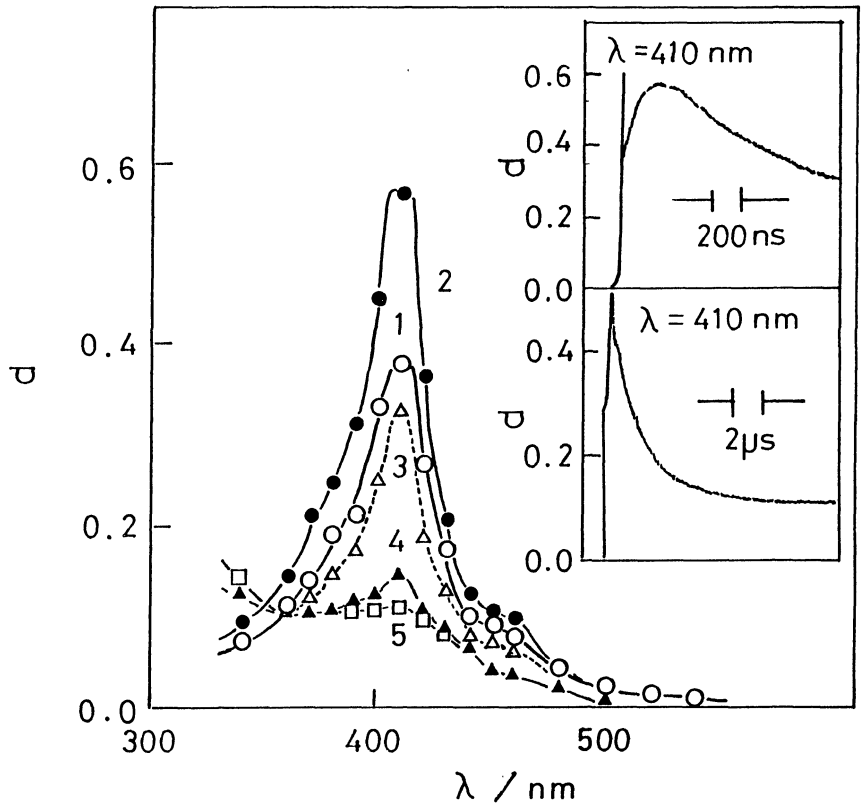

Fig. 2. Transient absorption spectra and digitizer traces measured in the laser flash photolysis of AZ in the presence of acetone. Recorded at 0.1 (1), 0.35 (2), 1.64 (3), and 6 μs (4) after the flash. [AZ]=1.0×10^{-3} mol dm^{-3}, [Acetone]=0.5 mol dm^{-3} in cyclohexane.

of these species follows first-order kinetics and the rate constants for **A** and **B** are 6.7×10^5 s^{-1} and 8×10 s^{-1}, respectively. The absorption spectrum of **A** is exhibited by the difference spectrum as shown by a dotted line in Fig. 1 and is similar to that of **B** (spectra 2 and 3). Both have an absorption maximum around 410 nm. In the presence of oxygen, **A** was quenched whereas **B** was not affected. Thus, it was obvious that **A** was not a precursor of **B** and they were produced simultaneously.

$$\text{AZ} \xrightarrow[\text{Ar-saturated cyclohexane}]{h\nu} \text{Short-lived Species (A)} + \text{Long-lived Species (B)} \quad (2)$$

2. Effect of Acetone. The laser flash photolysis of AZ was also carried out in the presence of acetone as a triplet sensitizer in cyclohexane. The result are shown in Figs. 2 and 3. Since triplet acetone does not absorb light with wavelengths longer than λ=320 nm,[8] the signals measured are due to the transient species of AZ or the reaction intermediates. The rise of the transient species with a λ_{max} at 410 nm was observed at acetone concentrations higher than 0.2 mol dm^{-3}. The yield of **A** increased with increasing acetone concentration (Fig. 3a). On the other hand, the decay rate of **A** (k=7.3×10^5 s^{-1}) was independent of the acetone concentration and was identical to the value obtained by the direct photolysis of AZ. The decay rate of **B** increased with increasing acetone concentration. Based on the linear plots in Fig. 3b, the rate constant for the reaction between **B** and acetone was calculated to be 2.5×10^3 dm^3 mol^{-1} s^{-1}. Since NY reacts with acetone to give 3-oxazoline,[9] species **B** was believed to be NY (Eq. 3).

$$\text{B} + \text{acetone} \longrightarrow \text{Adducts (3-Oxazoline ?)} \quad (3)$$

3. Effect of Acrylonitrile. NY was reported to react with an electron-deficient olefin such as acrylonitrile (AN).[10] The laser flash photolysis of AZ was, therefore, carried out in the presence of AN and oxygen. The initial absorbance of **B** was not affected by the AN. The decay rate of **B** increased with increasing AN concentration, as shown in Fig. 4. The rate constant was determined to be 2.3×10^6 dm^3 mol^{-1} s^{-1}. The stational irradiation of AZ in the presence of AN gave 5-(4-biphenylyl)-3-cyano-3,4-dihydro-2*H*-pyrrole quantitatively. As a result, it was concluded that **B** can be assigned to NY.

4. Pulse Radiolysis of AZ. Pulse radiolysis in bensene is an excellent method to give the triplet state of the solute.[11] The pulse radiolysis of AZ was carried out in benzene to study triplet AZ and its reactivity ([AZ]=1.0×10^{-2} mol dm^{-3}). The transient species measured immediately after the pulse had a λ_{max} around 415 nm. This band decayed exponentially to zero with a decay rate constant of 6.7×10^5 s^{-1} which was consistent with that of species **A** in the direct photolysis reaction. This species was quenched by oxygen; k=6×10^9 dm^3 mol^{-1} s^{-1}.[12] From these results, **A** was concluded to be triplet AZ, although there were a few possibilities that other species, e. g. a radical anion, were formed by the electron pulse.

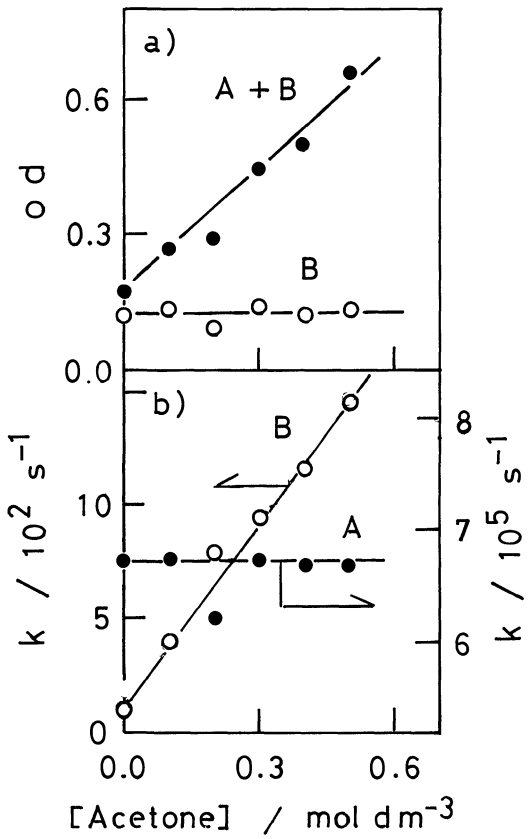

Fig. 3. Effect of acetone on the transient species absorbance (a) and decay rate (b) of the short-lived species (**A**) and the long-lived species (**B**).

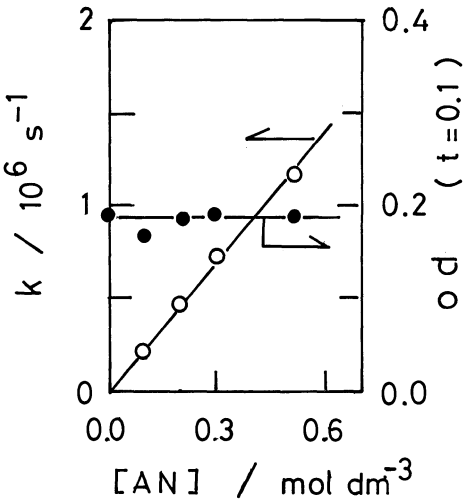

Fig. 4. Effect of AN on the long-lived species [decay rate and absorbance at 0.1 μs after the flash]. The laser flash photolyses were carried out in the presence of oxygen in cyclohexane.

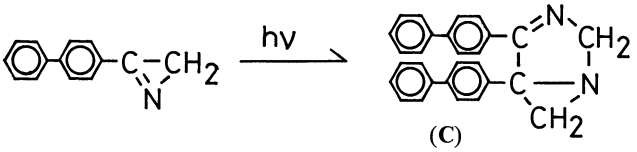
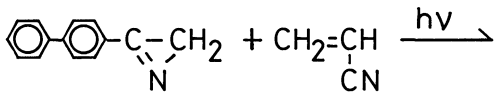
In order to confirm the formation of triplet AZ, the pulse radiolysis of AZ was carried out in the presence of benzophenone (BP) ([AZ]=1.0×10^{-3} mol dm^{-3}, [BP]=2.0×10^{-2} mol dm^{-3} in benzene). Figure 5 shows the time-resolved absorption spectra obtained in this reaction. Immediately after the pulse, an absorption band with a λ_{max} at 530 nm, which was assigned to triplet BP,[13] was measured. The 530 nm band according to pseudo first-order kinetics (3.3×10^{6} s^{-1}) with the simultaneous formation of a 420 nm band. The spectra measured at 460 ns after the pulse (spectrum 5 in Fig. 4), is similar to A. The rate of the latter band formation (4×10^{6} s^{-1}) agrees well with that of the decay of the 530 nm band. Therefore, it was concluded that species A was the triplet state of AZ and was formed by energy transfer from triplet BP (Eq. 4). An ε_{max} value of triplet AZ was estimated to be 3.8×10^{5} dm^{2} mol^{-1} by means of the ε_{max} value of triplet BP.[13]

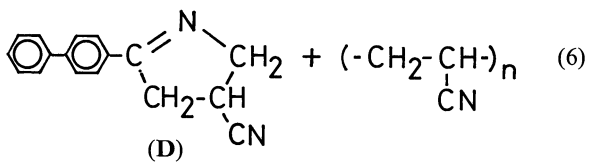
$$^{3}BP^{*} + AZ \longrightarrow BP + {}^{3}AZ^{*} \quad (4)$$

5. Stational Photoirradiation. In order to obtain information on the reaction products, the stational photoirradiation of AZ was carried out in cyclohexane. A dimer, 4,5-di(4-biphenylyl)-1,3-diazabicyclo[3,1,0]-hex-3-ene (**C**) was obtained in a good yield (83%, Eq. 5). In the presence of AN (0.5 mol), 5-(4-biphenylyl)-3-cyano-3,4-dihydro-2*H*-pyrrole (**D**) was formed almost quantitatively (89%) along with an AN-polymer (Eq. 6). These compounds were produced by the 1,3-dipolar addition of NY with AZ or AN as reported by Padwa and co-workers.[10]

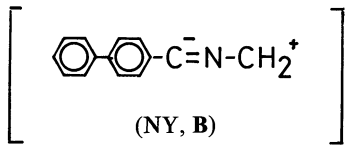


+ Other Products (5)



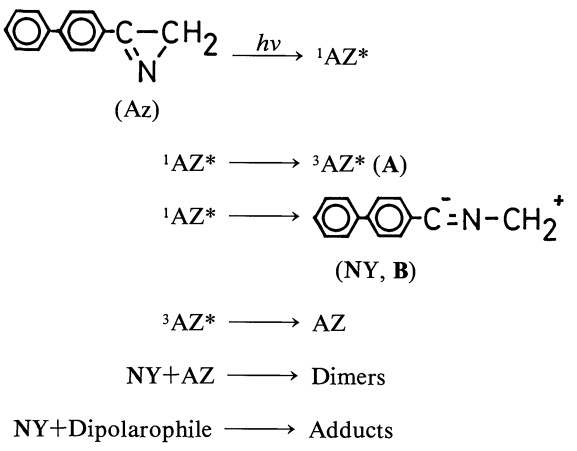


(6)



Upon irradiation with 360 nm light in the presence of BP, an adduct such as 3-oxazidine was not obtained and AZ was mainly recovered. BP was activated to the triplet state by the irradiation. The triplet state of AZ must then have been produced by energy transfer from triplet BP, as shown in Eq. 4. Triplet AZ was unreactive and was deactivated to the ground state.

6. Reaction Mechanism. In the laser flash photolysis of AZ, two kinds of transient species, triplet AZ and NY, were detected. It seemed that the excited singlet state



$^{1}AZ^{*} \longrightarrow {}^{3}AZ^{*}$ (**A**)

$^{3}AZ^{*} \longrightarrow AZ$

NY+AZ ⟶ Dimers

NY+Dipolarophile ⟶ Adducts

Scheme 1.

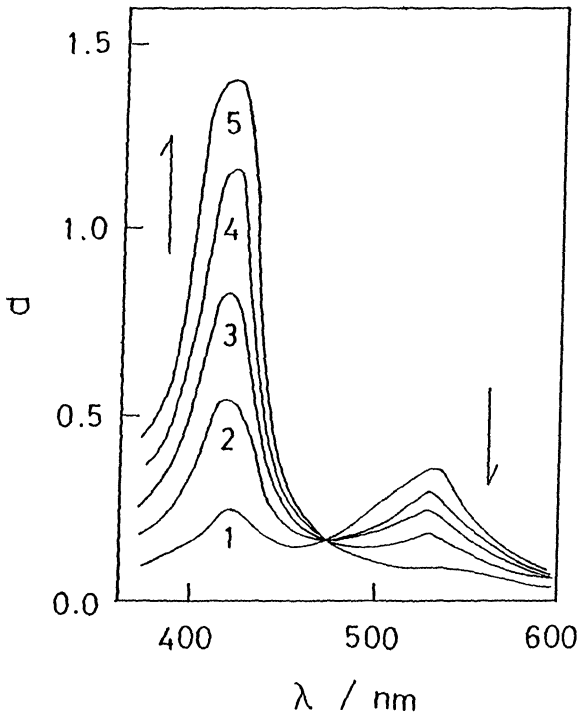


Fig. 5. Time-resolved absorption spectra measured in the pulse radiolysis of AZ in the presence of BP in benzene. Recorded at 10 (1), 50 (2), 100 (3), 200 (4), and 460 ns (5) after the pulse. [AZ]=1.0×10^{-3} mol dm^{-3}, [BP]=2.0×10^{-2} mol dm^{-3} in benzene.

decayed very rapidly to triplet AZ and/or NY. The quenching rate constant of oxygen toward triplet AZ (6×10^9 dm^3 mol^{-1} s^{-1}) also supported the above assigment of the transient species. Since the stational photoirradiation of AZ in the presence of BP didn't give any adducts, the structure of triplet AZ was the closed form and decayed to the ground state. NY was assigned by the reactions with acetone and AN. NY was relatively stable in the absence of the dipolarphile, with a decay rate of 8×10 s^{-1}. It seemed that the rate was the value of the dimer (**C**) formation. The present results support the following mechanism (Scheme 1).

Experimental

AZ was synthesized from 4-vinylbiphenyl by way of 4-(1-azidoethyl)-biphenyl as reported by Hortmann and coworkers.[14] AZ was purified by column chromatography (Florisil) and several recrystallizations from hexane. The yield of AZ for starting olefin was 80.8%. Pale yellow crystals; mp 73.5—74.2 °C; *m*/*z* 193 (M^+); Elementary analysis, Found: C, 86.87; H, 5.74; N, 7.21%; Calcd for $C_{14}H_{11}N$: C, 87.01; H, 5.84; N, 7.15%. ^{1}H NMR ($CDCl_3$, TMS) δ=1.81 (s, 2H) and 7—8 (m, biphenyl); IR (KBr) $\nu_{C=N}$=1742 cm^{-1}, δ_{CH_2}=1442 cm^{-1}, and ν_{C-N}=986 cm^{-1}; UV (cyclohexane) λ_{max}=268.8 nm (1.99×10^5 dm^2 mol^{-1}).

Spectroscopic grade benzene, cyclohexane, and acetone were used without further purification.

Benzophenone (BP) was purified by two recrystallizations from ethanol.

Acrylonitrile (AN) was washed three times with a 5% NaOH aqueous solution, then three times with distilled water. After drying on sodium carbonate, the monomer was distilled twice under a N_2 stream.

Apparatus. The laser flash photolyses were carried out with the aid of a Lambda Phisik EMG 501 lamp with Xe and Cl_2 gases. This apparatus generates a λ=308 nm light pulse (pulse width: 15 ns, ca. 0.1 J).

The pulse radiolyses were carried out with the aid of the L-band electron beam linear accelator at Osaka University (pulse width: 8 ns, ca. 1 kGy).[15]

Stational Photoirradiations. The photoirradiations were carried out by using a 300 W high-pressure Hg lamp and a pyrex filter (thickness: 2 mm). Since AZ absorbs light of wavelengths shorter than 340 nm, an excitation wavelength of 313 nm was used. AZ (0.300 g) was irradiated in cyclohexane (0.5 dm^3) at room temperature for two hours. After several recrystallizations of the products from hexane, 0.249 g 4,5-di(4-biphenylyl)-1,3-diazabicyclo-[3.1.0]hex-3-ene (**C**) was obtained (yield: 83%). White crystals; mp 214—215.2 °C; *m*/*z*=386 (M^+); Elementary analysis, Found: C, 86.78; H, 5.77; N, 7.11%. Calcd for $C_{28}H_{22}N_2$: C, 87.01; H, 5.84; N, 7.15%. ^{1}H NMR ($CDCl_3$, TMS) δ=2.05 (s, $-CH_2-$N), 3.04 (s, N$-CH_2-$N=), and 7.3—8.0 (m, biphenyl); IR (KBr) $\nu_{C=N}$=612 cm^{-1} and ν_{C-N}=1332 cm^{-1}.

AZ (0.135 g) was irradiated with 0.50 mol of AN at 4 °C for three hours in cyclohexane (0.5 dm^3). The products were the adduct, 5-(4-biphenylyl)-3-cyano-3,4-dihydro-2*H*-pyrrole (0.154 g, **D**) and polyacrylonitrile (0.84 g). The adduct was isolated from the polymer by reprecipitations. White crystals; mp 170.2—170.6 °C; *m*/*z*=246 (M^+); Elementary analysis, Found: C, 82.89; H, 5.80; N, 11.21%. Calcd for $C_{17}H_{14}N_2$: C, 82.90; H, 5.73; N, 11.37%. ^{1}H NMR ($CDCl_3$, TMS) δ=2.05 (m, -CHCN-), 3.43 (dd, $-C-CH_2-$), 4.43 (dd, $-N-CH_2-$), and 7.3—8.0 (m, biphenyl); IR (KBr) ν_{CN}=2240 cm^{-1}, $\nu_{C=N}$=1618 cm^{-1}, δ_{CH_2}=1450, 1428 cm^{-1}, and ν_{C-N}=1364 cm^{-1}.

The irradiation of AZ (0.097 g) was carried out in the presence of BP (1.92 g) in cyclohexane (0.1 dm^{-3}) by using a 500 W Xe lamp and an interference filter (λ_{max}=360 nm, T_{max}=21%, $\Delta_{1/2}$=10 nm) for 20 h. AZ was mainly recovered and a small amount of diphenylmethanol was also obtained.

†† Suzugamine Women's College, Inokuchi, Nishi-ku, Hiroshima 733
(Received March 27, 1991)

In order to elucidate the absolute configuration of C-15 in natural hyptol, methyl (15*S*)-12,16-dihydroxy-8,11,13-abietatrien-18-oate and its (15*R*)-epimer were transformed into (15*S*)-12,16-epoxy-11,14-dihydroxy-8,11,13-abietatrien-7-one (**1a**) and its (15*R*)-epimer (**1b**), respectively. The synthetic **1a** was identical to natural hyptol. Thus, the stereochemistry of C-15 in the natural compound was conclusively assigned as *S*-configuration.

Hyptol, a rare abietane-type diterpene possessing a dihydrofuran moiety, has been isolated from the roots of *Hyptis fructicosa* (Labiatae) by Monache et al.[1] On the basis of chemical and spectroscopic studies, they deduced the structure of hyptol to be 12,16-epoxy-11,14-dihydroxy-8,11,13-abietatrien-7-one (**1**). However, the absolute configuration of the C-15 position in the natural compound remained unsolved. In order to elucidate the unknown stereochemistry at the C-15 position, we have attempted the syntheses of (15*S*)-12,16-epoxy-11,14-dihydroxy-8,11,13-abietatrien-7-one (**1a**) and its (15*R*)-epimer (**1b**). For this purpose, methyl (15*S*)-12,16-dihydroxy-8,11,13-abietatrien-18-oate (**2a**)[2] and its (15*R*)-epimer (**2b**)[2] were chosen as convenient relay intermediates, because these compounds have recently been synthesized in our laboratory starting from (+)-dehydroabietic acid.

To introduce an oxygen function at the C-11 position, the (15*S*)-12,16-dihydroxy compound (**2a**) was refluxed with benzoyl peroxide in chloroform to give a mixture of methyl 11-benzoyloxy-12,16-dihydroxy-8,11,13-abietatrien-18-oate (**3a**) and its 12-benzoyloxy-11,16-dihydroxy isomer (**4a**) (ca. 1:1 ratio) in a 36% yield. The mixture of **3a** and **4a** was further transformed into a dihydrobenzofuran compound (**5a**: 70% yield) by a series of reactions: mesylation with methanesulfonyl chloride in pyridine, refluxing with sodium iodide in ethyl methyl ketone, and treatment with aqueous sodium hydroxide in refluxing methanol. Reduction of **5a** with lithium aluminum hydride in ether followed by mesylation of the resulting alcohol (**6a**) with methanesulfonyl chloride in pyridine afforded a mesylate (**7a**). This was treated with sodium iodide and zinc powder in *N*,*N*-dimethylformamide at 120—125 °C to give a 4,4-dimethyl compound (**8a**) in a 56% yield from **5a**. Oxidation of **8a** with Fremy's salt and potassium dihydrogenphosphate in aqueous *N*,*N*-dimethylformamide afforded a para-quinone (**9a**) in an 80% yield. This was submitted to reductive acetylation with zinc powder and acetic anhydride in pyridine to give a diacetate (**10a**: 94% yield), which was further oxidized with chromium trioxide in acetic acid to give a ketone (**11a**: 72% yield). Hydrolysis of **11a** with dilute hydrochloric acid in refluxing ethanol afforded the desired (15*S*)-hyptol (**1a**: 98% yield), the physical and spectral data of which were identical to those of natural hyptol.

For direct comparison with **1a**, the synthesis of (15*R*)-hyptol (**1b**) was also carried out in the same manner as that described for the preparation of **1a**. Oxidation of the (15*R*)-12,16-dihydroxy compound[2] (**2b**) with benzoyl peroxide in refluxing chloroform produced a mixture of methyl 11-benzoyloxy-12,16-dihydroxy-8,11,13-abietatrien-18-oate (**3b**) and its 12-benzoyloxy-11,16-dihydroxy isomer (**4b**) (ca. 1:1 ratio, 38% yield). This mixture was converted into a dihydrobenzofuran compound (**5b**), which was further transformed into a para-quinone (**9b**) via an alcohol (**6b**), a mesylate (**7b**), and a 4,4-dimethyl compound (**8b**). Reductive

acetylation of **9b** followed by oxidation of the resulting diacetate (**10b**) afforded a ketone (**11b**). This was hydrolyzed with dilute hydrochloric acid in refluxing ethanol to give (15*R*)-hyptol (**1b**). The physical and spectral data of the synthetic **1b** were not identical to those of natural hyprol.

From the present study, the stereochemistry of the C-15 position in natural hyptol was conclusively assigned as *S*-configuration.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform, and the ^{1}H NMR spectra in deuteriochloroform at 90 MHz with tetramethylsilane as an internal standard, unless otherwise stated; s: singlet, bs: broad singlet, d: doublet, bd: broad doublet, dd: double doublet, t: triplet, m: multiplet. The column chromatography was performed using Merck silica gel (0.063 mm).

Oxidation of Methyl (15*S*)-12,16-Dihydroxy-8,11,13-abietatrien-18-oate (2a) and Its (15*R*)-Epimer (2b) with Benzoyl Peroxide. a): A solution of **2a**[2] (1.852 g) and benzoyl peroxide (1.944 g) in chloroform (21 ml) was gently refluxed for 3.5 h. After the addition of ether (30 ml) acetic acid (14 ml), and aqueous potassium iodide (20%, 60 ml), the mixture was stirred at room temperature for 2 h and then washed successively with water, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (25 g), using ether–benzene (5:95) as an eluent, to give a mixture of methyl 11-benzoyloxy-12,16-dihydroxy-8,11,13-abietatrien-18-oate (**3a**) and its 12-benzoyloxy-11,16-dihydroxy isomer (**4a**) (902 mg: 36.1% yield). IR 3575, 3300, 1737 sh, and 1723 cm^{-1}. ^{1}H NMR of **3a** (60 MHz) δ=1.19 and 1.28 (each 3H and s, 4-CH_3 and 10-CH_3), 3.64 (3H, s, -CO_2CH_3), 6.63 (1H, s, 14-H), and 7.3—7.7 (3H, m) and 8.18 (2H, bd, J=7 Hz) (-C_6H_5). ^{1}H NMR of **4a** (60 MHz) δ=1.24 and 1.30 (each 3H and s, 4-CH_3 and 10-CH_3), 3.64 (3H, s, -CO_2CH_3), 6.50 (1H, s, 14-H), and 7.3—7.7 (3H, m) and 8.18 (2H, bd, J=7 Hz) (-C_6H_5). Found: C, 72.37; H, 7.08%. Calcd for $C_{28}H_{34}O_6$: C, 72.08; H, 7.35%.

b): A solution of **2b**[2] (2.532 g) and benzoyl peroxide (2.657 g) in chloroform (28 ml) was gently refluxed for 3.5 h. After the work-up as described in a), the crude product was chromatographed on silica gel (25 g), using ether–benzene (5:95) as an eluent, to give a mixture of methyl 11-benzoyloxy-12,16-dihydroxy-8,11,13-abietatrien-18-oate (**3b**) and its 12-benzoyloxy-11,16-dihydroxy isomer (**4b**) (1.310 g: 38.4% yield). IR 3575, 3435, 1735 sh, and 1720 cm^{-1}. ^{1}H NMR of **3b** δ=1.21 and 1.30 (each 3H and s, 4-CH_3 and 10-CH_3), 3.63 (3H, s, -CO_2CH_3), 6.64 (1H, s, 14-H), and 7.4—7.7 (3H, m) and 8.18 (2H, dd, J=8 and 2 Hz) (-C_6H_5). ^{1}H NMR of **4b** δ=1.26 and 1.33 (each 3H and s, 4-CH_3 and 10-CH_3), 3.65 (3H, s, -CO_2CH_3), 6.53 (1H, s, 14-H), and 7.4—7.7 (3H, m) and 8.18 (2H, dd, J=8 and 2 Hz) (-C_6H_5). Found: C, 72.22; H, 7.57%. Calcd for $C_{28}H_{34}O_6$: C, 72.08; H, 7.35%.

Methyl (15*S*)-12,16-Epoxy-11-hydroxy-8,11,13-abietatrien-18-oate (5a) and Its (15*R*)-Epimer (5b). a): Methanesulfonyl chloride (0.19 ml) was added to a stirred solution of a mixture of **3a** and **4a** (ca. 1:1 ratio, 955 mg) in pyridine (2.0 ml) at 0—5 °C. The mixture was stirred at this temperature for 30 min and then at room temperature for 3 h, then poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo to give a mixture of mesylates (1.111 g).

A stirred mixture of the above crude mesylates (1.111 g) and sodium iodide (612 mg) in ethyl methyl ketone (22 ml) was refluxed for 4 h. The mixture was cooled, diluted with ether, and washed successively with water, aqueous sodium thiosulfate, and brine. The dried solution was evaporated in vacuo to give a mixture of iodides (1.160 g).

A mixture of the above crude iodides (1.160 g) and aqueous sodium hydroxide (20%, 2.9 ml) in methanol (14 ml) was refluxed for 1 h. After removal of the methanol in vacuo, the residue was acidified with dilute hydrochloric acid and extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (25 g), using hexane–benzene (3:7) as an eluent, to give **5a** (478 mg: 69.5% yield), mp 155.5—157 °C (from hexane), $[\alpha]_D$+65.9 ° (c 0.41), IR 3560, 3375, and 1720 cm^{-1}; ^{1}H NMR δ=1.25 and 1.32 (each 3H and s, 4-CH_3 and 10-CH_3), 1.27 (3H, d, J=7 Hz, 15-CH_3) 3.66 (3H, s, -CO_2CH_3), 4.03 (1H, t, J=8 Hz) and 4.68 (1H, t, J=8 Hz) (15-CH_2O-), 4.87 (1H, s, 11-OH), and 6.40 (1H, s, 14-H). Found: C, 73.49; H, 8.38%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

b): A solution of a mixture of **3b** and **4b** (ca. 1:1 ratio, 1.120 g) in pyridine (4.0 ml) was mesylated with methanesulfonyl chloride (0.23 ml) as described in a). The crude mesylates (1.295 g) were treated with sodium iodide (713 mg) in refluxing ethyl methyl ketone (25 ml) to give a mixture of iodides (1.286 g). This was further refluxed with aqueous sodium hydroxide (20%, 3.2 ml) in methanol (16 ml) for 1 h. The crude product was chromatographed on silica gel (25 g), using hexane–benzene (3:7) as an eluent, to give **5b** (520 mg, 60.7% yield), mp 167.5—169 °C (from hexane), $[\alpha]_D$+33.0 ° (c 0.58), IR 3560, 3375, and 1718 cm^{-1}; ^{1}H NMR δ=1.25 and 1.32 (each 3H and s, 4-CH_3 and 10-CH_3), 1.27 (3H, d, J=7 Hz, 15-CH_3), 3.66 (3H, s, -CO_2CH_3), 4.04 (1H, dd, J=8 and 7 Hz) and 4.68 (1H, t, J=8 Hz) (15-CH_2O-), 4.87 (1H, s, 11-OH), and 6.42 (1H, s, 14-H). Found: C, 73.04; H, 8.45%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

(15*S*)-12,16-Epoxy-8,11,13-abietatriene-11,18-diol (6a) and Its (15*R*)-Epimer (6b). a): A mixture of **5a** (794 mg) and lithium aluminum hydride (149 mg) in dry ether (7.0 ml) was stirred at room temperature for 1 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo to give a crude **6a** (740 mg). This was recrystallized from acetone–hexane, mp 159—160.5 °C, $[\alpha]_D$+78.9 ° (*c* 1.47), IR 3630, 3565, and 3450 cm^{-1}; ^{1}H NMR (60 MHz) δ=0.89 (3H, s, 4-CH_3), 1.27 (3H, d, *J*=7 Hz, 15-CH_3), 1.39 (3H, s, 10-CH_3), 3.16 (1H, d, *J*=11 Hz) and 3.50 (1H, d, *J*=11 Hz) (-C$\underline{H_2}$OH), 4.01 (1H, t, *J*=8 Hz) and 4.67 (1H, t, *J*=8 Hz) (15-CH_2O-), 5.12 (1H, bs, 11-OH), and 6.40 (1H, s, 14-H). Found: C, 75.92; H, 9.21%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

b): A mixture of **5b** (1.006 g) and lithium aluminum hydride (189 mg) in dry ether (15 ml) was stirred at room temperature for 1 h. The mixture was treated as described in a) to give a crude **6b** (1.001 g). This was recrystallized from acetone–hexane, mp 183.5—185.5 °C, $[\alpha]_D$+66.7 ° (*c* 2.03), IR 3625, 3565, and 3450 cm^{-1}; ^{1}H NMR (60 MHz) δ=0.88 (3H, s, 4-CH_3), 1.28 (3H, d, *J*=7 Hz, 15-CH_3), 1.39 (3H, s, 10-CH_3), 3.16 (1H, d, *J*=10 Hz) and 3.50 (1H, d, *J*=10 Hz) (-C$\underline{H_2}$OH), 4.04 (1H, t, *J*=8 Hz) and 4.65 (1H, t, *J*=8 Hz) (15-CH_2O-), 5.20 (1H, s, 11-OH), and 6.43 (1H, s, 14-H). Found: C, 76.08; H, 9.14%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

(15*S*)-12,16-Epoxy-8,11,13-abietatrien-11-ol (8a) and Its (15*R*)-Epimer (8b). a): A mixture of the crude **6a** (730 mg) and methanesulfonyl chloride (0.26 ml) in pyridine (7.0 ml) was stirred at 0—5 °C for 30 min and then at room temperature for 2.5 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo to give a crude mesylate (**7a**) (1.025 g), ^{1}H NMR (60 MHz) δ=0.98 (3H, s, 4-CH_3), 1.30 (3H, d, *J*=7 Hz, 15-CH_3), 1.40 (3H, s, 10-CH_3), 3.01 (3H, s, -$CH_2OSO_2C\underline{H_3}$), 3.75 (1H, d, *J*=9 Hz) and 4.10 (1H, d, *J*=9 Hz) (-C$\underline{H_2}$OMs), 4.02 (1H, t, *J*=8 Hz) and 4.67 (1H, t, *J*=8 Hz) (15-CH_2O-), and 6.42 (1H, s, 14-H).

A stirred mixture of the above crude **7a** (1.010 g), sodium iodide (1.95 g), and zinc powder (1.68 g) in *N*,*N*-dimethylformamide (24 ml) was heated at 120—125 °C for 10 h. The mixture was cooled, diluted with ether, and then filtered. The filtrate was washed successively with aqueous sodium thiosulfate and brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (30 g), using hexane–benzene (3:2) as an eluent, to give **8a** (389 mg: 56.2% yield from **5a**). IR 3575 cm^{-1}, $[\alpha]_D$+76.3 ° (*c* 0.93); ^{1}H NMR (60 MHz) δ=0.95 (6H, s, -$\underset{|}{C}(CH_3)_2$), 1.28 (3H, d, *J*=7 Hz, 15-CH_3), 1.35 (3H, s, 10-CH_3), 4.01 (1H, t, *J*=8.5 Hz) and 4.65 (1H, t, *J*=8.5 Hz) (15-CH_2O-), 4.91 (1H, s, 11-OH), and 6.40 (1H, s, 14-H). Found: C, 79.75; H, 9.58%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

b): A solution of the crude **6b** (1.050 g) in pyridine (10 ml) was treated with methanesulfonyl chloride (0.37 ml) as described in a) to give a crude mesylate (**7b**) (1.239 g). ^{1}H NMR (60 MHz) δ=0.99 (3H, s, 4-CH_3), 1.29 (3H, d, *J*=7 Hz, 15-CH_3), 1.38 (3H, s, 10-CH_3), 3.01 (3H, s, -$CH_2OSO_2C\underline{H_3}$), 3.72 (1H, d, *J*=9 Hz) and 4.08 (1H, d, *J*=9Hz) (-C$\underline{H_2}$OMs), 4.03 (1H, dd, *J*=9 and 6 Hz) and 4.68 (1H, t, *J*=9 Hz) (15-CH_2O-), 5.02 (1H, s, 11-OH), and 6.42 (1H, s, 14-H).

A stirred mixture of the above crude **7b** (1.239 g), sodium iodide (2.36 g), and zinc powder (2.05 g) in *N*,*N*-dimethylformamide (20 ml) was heated at 120—125 °C for 10 h. After the work-up as described in a), the crude product was chromatographed on silica gel (30 g), using hexane–benzene (3:2) as an eluent, to give **8b** (469 mg: 53.4% yield from **5b**). IR 3565 cm^{-1}; ^{1}H NMR (60 MHz) δ=0.93 (6H, s, -$\underset{|}{C}(CH_3)_2$), 1.27 (3H, d, *J*=7 Hz, 15-CH_3), 1.33 (3H, s, 10-CH_3), 4.00 (1H, dd, *J*=8 and 7 Hz) and 4.63 (1H, t, *J*=8 Hz) (15-CH_2O-), 4.96 (1H, s, 11-OH), and 6.40 (1H, s, 14-H). Found: C, 79.82; H, 9.63%. Calcd for $C_{20}H_{28}O_2$: C, 79.95; H, 9.39%.

(15*S*)-12,16-Epoxy-8,12-abietadiene-11,14-dione (9a) and Its (15*R*)-Epimer (9b). a): A stirred solution of **8a** (33.2 mg) in *N*,*N*-dimethylformamide (4.0 ml) was protected from light with aluminum foil. After the addition of a solution of Fremy's salt (potassium nitrosodisulfonate) (149 mg) and potassium dihydrogenphosphate (58 mg) in water (6.0 ml), the mixture was stirred at room temperature under a stream of nitrogen for 2 h. The mixture was then extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (5 g), using hexane–chloroform (1:1) as an eluent, to give recovered **8a** (3.8 mg: 11.4% yield). Further elution afforded **9a** (28.0 mg: 80.2% yield), mp 143.5—144.5 °C (from methanol), $[\alpha]_D$+11.6 ° (*c* 1.73), IR 1670, 1650, and 1640 cm^{-1}; ^{1}H NMR δ=0.88 and 0.91 (each 3H and s, -$\underset{|}{C}(CH_3)_2$), 1.25 (3H, s, 10-CH_3), 1.28 (3H, d, *J*=7 Hz, 15-CH_3), 3.50 (1H, m, 15-H), and 4.18 (1H, dd, *J*=9 and 6 Hz) and 4.71 (1H, t, *J*=9 Hz) (15-CH_2O-). Found: C, 76.08; H, 8.52%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

b): A stirred solution of **8b**(180.0 mg) in *N*,*N*-dimethylformamide (21.6 ml) was protected from light with aluminum foil. After the addition of a solution of Fremy's salt (804 mg) and potassium dihydrogenphosphate (310 mg) in water (32.4 ml), the mixture was stirred at room temperature under a stream of nitrogen for 2 h. After the work-up as described in a), the crude product was chromatographed on silica gel (15 g), using hexane–chloroform (1:1) as an eluent, to give recovered **8b** (14.9 mg: 8.3% yield) and **9b** (155.7 mg: 82.6% yield), mp 154—155 °C (from methanol), $[\alpha]_D$+128 ° (*c* 0.85), IR 1670, 1650, and 1640 cm^{-1}; ^{1}H NMR δ=0.89 and 0.92 (each 3H and s, -$\underset{|}{C}(CH_3)_2$), 1.25 (3H, s, 10-CH_3), 1.30 (3H, d, *J*=7 Hz, 15-CH_3), 3.50 (1H, m, 15-H), and 4.18 (1H, dd, *J*=9 and 6 Hz) and 4.72 (1H, t, *J*=9 Hz) (15-CH_2O-). Found: C, 76.33; H, 8.54%. Calcd for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34%.

(15*S*)-11,14-Diacetoxy-12,16-epoxy-8,11,13-abietatriene (10a) and Its (15*R*)-Epimer (10b). a): A mixture of **9a** (73.4 mg), acetic anhydride (0.5 ml), and zinc powder (50 mg) in pyridine (1.0 ml) was stirred at 0—5 °C for 10 min and then at room temperature for 2.5 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed successively with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:99) as an eluent, to give **10a** (88.0 mg: 94.1% yield), mp 161—162 °C (from hexane), $[\alpha]_D$+47.2 ° (*c* 1.63), IR 1758 cm^{-1}; ^{1}H NMR δ=0.88 and 0.91 (each 3H and s, -$\underset{|}{C}(CH_3)_2$), 1.23 (3H, s, 10-CH_3), 1.23 (3H, d, *J*=7 Hz, 15-CH_3), 2.27 (6H, s, 2-$OCOCH_3$), 3.52 (1H, m, 15-H), and 4.08 (1H, dd, *J*=9 and 6 Hz) and 4.63 (1H, t, *J*=9 Hz)

(15-CH_2O-). Found: C, 72.20; H, 8.26%. Calcd for $C_{24}H_{32}O_5$: C, 71.97; H, 8.05%.

b): A mixture of **9b** (53.0 mg), acetic anhydride (0.3 ml), and zinc powder (30 mg) in pyridine (0.5 ml) was stirred at 0—5 °C for 10 min and then at room temperature for 2.5 h. After the work-up as described in a), the crude product was recrystallized from hexane to give **10b** (48.2 mg: 71.4% yield), mp 168—170 °C, $[\alpha]_D$+87.5 ° (*c* 0.96), IR 1760 cm^{-1}; ^1H NMR δ=0.89 and 0.91 (each 3H and s, $-C(CH_3)_2$), 1.20 (3H, d, *J*=7 Hz, 15-CH_3), 1.23 (3H, s, 10-CH_3), 2.27 (6H, s, 2-$OCOCH_3$), 3.51 (1H, m, 15-H), and 4.08 (1H, dd, *J*=9 and 6 Hz) and 4.62 (1H, t, *J*=9 Hz) (15-CH_2O-). Found: C, 72.08; H, 8.17%. Calcd for $C_{24}H_{32}O_5$: C, 71.97; H, 8.05%. The mother liquor of recrystallization was evaporated in vacuo. The residue was chromatographed on silica gel (5 g), using ether–benzene (1:99) as an eluent, to give additional **10b** (16.5 mg: 24.4% yield).

(15*S*)-11,14-Diacetoxy-12,16-epoxy-8,11,13-abietatrien-7-one (11a) and Its (15*R*)-Epimer (11b). a): A mixture of **10a** (72.3 mg) and chromium trioxide (54.1 mg) in acetic acid (0.7 ml) was stirred at 0—5 °C for 5 min and then at room temperature for 1 h. The mixture was diluted with water and extracted with ether. The ether extract was washed successively with water, aqueous sodium hydrogencarbonate, and brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (10 g), using ether–benzene (1:99) as an eluent, to give **11a** (53.8 mg: 71.9% yield), $[\alpha]_D$+63.2 ° (*c* 0.87) (natural hyptol diacetate, $[\alpha]_D$+63.8 ° (*c* 0.24)[3]), IR 1765 and 1670 cm^{-1}; ^1H NMR δ=0.92 and 0.94 (each 3H and s, $-C(CH_3)_2$), 1.32 (3H, d, *J*=7 Hz, 15-CH_3), 1.33 (3H, s, 10-CH_3), 2.30 and 2.36 (each 3H and s, 2-$OCOCH_3$), 3.60 (1H, m, 15-H), and 4.19 (1H, dd, *J*=9 and 6 Hz) and 4.73 (1H, t, *J*=9 Hz) (15-CH_2O-). Found: C, 69.77; H, 7.48%. Calcd for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30%.

b): A mixture of **10b** (120.1 mg) and chromium trioxide (90 mg) in acetic acid (1.2 ml) was stirred at 0—5 °C for 5 min and then at room temperature for 1 h. After the work-up as described in a), the crude product was chromatographed on silica gel (10 g), using ehter-benzene (5:95) as an eluent, to give **11b** (91.9 mg: 72.4% yield), mp 178—179 °C (from hexane), $[\alpha]_D$+119 ° (*c* 2.39), IR 1765 and 1670 cm^{-1}; ^1H NMR δ=0.91 and 0.94 (each 3H and s, $-C(CH_3)_2$), 1.27 (3H, d, *J*=6 Hz, 15-CH_3), 1.30 (3H, s, 10-CH_3), 2.29 and 2.35 (each 3H and s, 2-$OCOCH_3$), 3.57 (1H, m, 15-H), and 4.21 (1H, dd, *J*=9 and 6 Hz) and 4.72 (1H, t, *J*=9 Hz) (15-CH_2O-). Found: C, 69.50; H, 7.40%. Calcd for $C_{24}H_{30}O_6$: C, 69.54; H, 7.30%.

(15*S*)-12,16-Epoxy-11,14-dihydroxy-8,11,13-abietatrien-7-one (Hyptol) (1a) and Its (15*R*)-Epimer (1b). a): A mixture of **11a** (19.1 mg) and dilute hydrochloric acid (15%, 0.2 ml) in ethanol (1.0 ml) was refluxed for 24 h. After removal of the ethanol in vacuo, the residue was extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (5 g), using hexane–chloroform (1:2) as an eluent, to give **1a** (14.9 mg: 98.0% yield), mp 200—203 °C (from hexane), $[\alpha]_D$+52.5 ° (*c* 0.20), IR 3570, 3325, and 1620 cm^{-1}; ^1H NMR δ=0.95 (6H, s, $-C(CH_3)_2$), 1.36 (3H, s, 10-CH_3), 1.39 (3H, d, *J*=7 Hz, 15-CH_3), 3.68 (1H, m, 15-H), 4.26 (1H, dd, *J*=9 and 6 Hz) and 4.77 (1H, t, *J*=9 Hz) (15-CH_2O-), 4.63 (1H, s, 11-OH), and 13.39 (1H, s, 14-OH). Found: C, 72.81; H, 7.76%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%. The physical and spectral data of the synthetic **1a** were identical to those of natural hyptol, mp 202—203 °C,[1] $[\alpha]_D$+56 °;[1] ^1H NMR[3] δ=0.95 (6H, s, $-C(CH_3)_2$), 1.36 (3H, s, 10-CH_3), 1.39 (3H, d, *J*=7 Hz, 15-CH_3), 3.68 (1H, m, 15-H), 4.26 (1H, dd, *J*=9 and 6 Hz) and 4.77 (1H, t, *J*=9 Hz) (15-CH_2O-), 4.62 (1H, s, 11-OH), and 13.39 (1H, s, 14-OH).

b): A mixture of **11b** (52.6 mg) and dilute hydrochloric acid (15%, 0.3 ml) in ethanol (2.0 ml) was refluxed for 23 h. After the work-up as described in a), the crude product was chromatographed on silica gel (5 g), using hexane–chloroform (1:2) as an eluent, to give **1b** (30.0 mg: 71.6% yield), mp 210—211 °C (from hexane), $[\alpha]_D$+127 ° (*c* 0.46), IR 3575, 3350, and 1620 cm^{-1}; ^1H NMR δ=0.95 (6H, s, $-C(CH_3)_2$), 1.34 (3H, s, 10-CH_3), 1.38 (3H, d, *J*=6 Hz, 15-CH_3), 3.70 (1H, m, 15-H), 4.25 (1H, dd, *J*=9 and 6 Hz) and 4.79 (1H, t, *J*=9 Hz) (15-CH_2O-), 4.63 (1H, s, 11-OH), and 13.39 (1H, s, 14-OH). Found: C, 72.57; H, 8.14%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

The authors are grateful to Professor F. D. Monache, Universita Cattolica S. Cuore, for kindly supplying the samples and spectral date of natural hyptol and its diacetate.

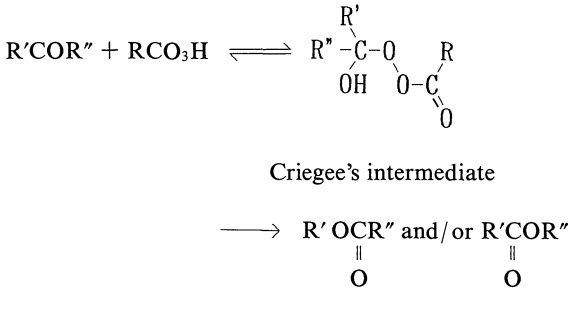
(Received March 29, 1991)

The Baeyer–Villiger reaction of *m*- and *p*-substituted acetophenones (substituents: H, *p*-MeO, *p*-*t*-Bu, *p*-*i*-Pr, *p*-Et, *p*-Me, *p*-Cl, *p*-Br, *m*-MeO, *m*-Me, *m*-Cl) with *o*-nitroperbenzoic acid was studied in chloroform at 30 °C. The rate constants for the general acid catalysis were measured at several concentrations of *o*-nitrobenzoic acid which acted as an acid catalyst. The uncatalyzed and acid-catalyzed rate constants obtained afforded ρ values of −2.16 and −4.11 with σ, respectively. The results indicated that the rate-determining step is the migration of the phenyl group in the peroxy acid-carbonyl adduct for all the substituents studied, whether the reaction is acid-catalyzed or not, and that the acid catalyst intervenes only in the formation of the acid-ketone adduct in the initial state and not in the migration step. The variation of the leaving group abilities required the variation of the substituent constants applied, whereas the acid intervention in the addition step was reflected only in the variation of the ρ value, not in the substituent constants to be applied. The smaller resonance demand for *o*-nitroperbenzoic acid indicated that the structure of the transition state in the migration step was looser and that the position of the transition state was earlier than those for *m*-chloroperbenzoic acid.

It is generally accepted that the Baeyer–Villiger reaction[1a-d] is subject to general acid catalysis and the rate-determining step is the migration in the peroxy acid-carbonyl adduct[2] as depicted in Scheme 1, although



Scheme 1.

there is a possibility that the addition step is rate-determing if the migrating group has a strong electron-releasing moiety.[3] The substituent effect on the Baeyer–Villiger reaction has been studied by many investigators, although reliable data are few because of small numbers of data sets with large experimental errors. Most studies have been done either under conditions where an uncatalyzed "spontaneous" process prevails or under conditions where an acid-catalyzed process prevails. The uncatalyzed reaction of *p*-substituted acetophenones with *m*-chloroperbenzoic acid in chloroform has afforded a ρ value of −1.36 with σ^+,[4] while the acid-catalyzed reactions of *m*- and *p*-substituted acetophenones with trifluoroperacetic acid in the presence of trifluoroacetic acid in ethylene chloride and in acetonitrile have afforded ρ values of −1.10 and −1.45 with σ, respectively.[2] This implies that the substituent constant employed as well as the magnitude of the reaction constant obtained vary with the peroxy acid employed and with the reaction conditions employed, although both reaction systems seem to accompany the other suppressed process to some extent. As to the above acid-catalyzed reaction, the measurements of UV spectra have clearly indicated the presence of a complex of trifluoroacetic acid with acetophenone in ethylene chloride,[2] implying the intervention of the catalyst in the addition step, but no evidence was obtained about whether the migration step is also acid-catalyzed. If the migration step proceeds by a concerted mechanism between the migrating group and the leaving group, the variation of the leaving group abilities is expected to cause some variations in the parameters. Comparisons between the parameters for both processes may give information about whether the catalyst operates in the migration step or not. A similar line of argument is applicable to the addition step. Thus, a correct interpretation of the difference between the parameters is only possible by eliminating the differences in experimental conditions except for the catalyst. With the above goals in mind, we studied the reaction of *o*-nitroperbenzoic acid with *m*- and *p*-substituted acetophenones in chloroform under conditions where both the uncatalyzed and the acid-catalyzed processes proceeded simultaneously.

Results and Discussion

Determination of the Kinetic Law. In order to obtain the kinetic law, an equimolar (5×10^{-2} M) (1 M= 1 mol dm^{-3}) reaction of *p*-methylacetophenone with *o*-nitroperbenzoic acid in chloroform at 30 °C was carried out as a typical example. It was followed by iodometric titration of the residual peroxy acid. Even when the reaction was allowed to start without the acid catalyst, the reaction did not follow any definite kinetic law due to autocatalysis. However, when a certain amount of *o*-nitrobenzoic acid, e.g., 1.5×10^{-2} M, was initially present in the above chloroform solution, the reaction proceeded with an adequate rate and the initial reaction rate strictly

obeyed first-order kinetics (corr coeff: more than 0.999) with respect to the ketone or the peroxy acid concentration to ca. 30% completion of the reaction, although the reaction conditions did not satisfy those of pseudo-first-order kinetics:

$$v = k_{obs}[K], \quad (1)$$

where [K] is the ketone concentration.[5] The influence of the product ester on the reaction rate was not observed at least to 20% completion of the reaction.[6] Equation 1 was followed over the initial ketone concentrations from 2×10^{-2} M to 1.5×10^{-1} M with the invariable observed rate constant so far as the initial concentrations of the other two reactants remained unaltered. To elucidate the apparent simplicity of the kinetics in spite of a lack of pseudo-first-order conditions, it was necessary to examine the relationships between the observed rate constant and the concentration of the other two reactants. The observed rate constant was proportional to the initial peroxy acid concentration over a range of 2.5×10^{-2} to 7.5×10^{-2} M, with the initial concentration of the ketone and the acid kept at 5×10^{-2} and 1.5×10^{-2} M, respectively:

$$k_{obs} = k'_{obs}[PA]_0, \quad (2)$$

where $[PA]_0$ is the initial peroxy acid concentration and k'_{obs} is a constant that depends on the initial acid concentration. With increasing concentrations of the initial acid catalyst over a range of 7.5×10^{-4} to 2.4×10^{-2} M, the value of $k_{obs}/[PA]_0$ linearly increased as shown in Fig. 1, and was expressed as Eq. 3:

$$k_{obs}/[PA]_0 = k_0 + k_{HA}[HA]_0, \quad (3)$$

where $[HA]_0$ is the initial acid concentration, and k_0 and k_{HA} are the rate constants for the uncatalyzed and the acid-catalyzed processes, respectively. The values of these constants were evaluated from the intercept and slope, respectively, by plotting $k_{obs}/[PA]_0$ against $[HA]_0$. The reproducibility of the k_{obs} value was within ±2% on repeated runs, and was considered to be sufficient to calculate k_0 and k_{HA} values. The values obtained are summarized in Table 1. Hammett plots for k_0 and k_{HA} are shown in Figs. 2 and 3, giving ρ values of −2.16 (corr coeff: 0.995) and −4.11 (corr coeff: 0.992) with σ, respectively. Data for m-MeO, p-Cl, and p-Br, which considerably deviated upward from the correlation lines, were not employed for these calculations. Examination of the product(s) by gas chromatography and ^{1}H NMR indicated that the product ester was derived from the exclusive migration of the phenyl group, i.e., p-substituted phenyl acetate in p-methoxy-, p-methyl-, p-chloro-, and unsubstituted acetophenones. Another product anticipated from the methyl migration was not detected at all.

Rate-Determining Step and Dependence of Substituent Constant on the Leaving Group. The ρ values obtained in the two plots (see Figs. 2 and 3) were negative, indicating that the migration step played a decisive role for the overall energy of the reaction and therefore was rate-determining for both the uncatalyzed (k_0 process) and the acid-catalyzed (k_{HA} process) processes. With reference to Palmer and Fry's work[4] on the ^{14}C-kinetic isotope effect and substituent effect on m-chloroperbenzoic acid oxidation of a series of p-substituted acetophenones-1′-^{14}C in chloroform, Ogata and Sawaki[3] pointed out that strong electron-releasing substituents such as p-MeO changed the rate-determining step from the migration step to the addition step on the grounds that the p-MeO showed no kinetic isotope effect and a downward deviation by ca. 0.5 log unit[7] in Hammett

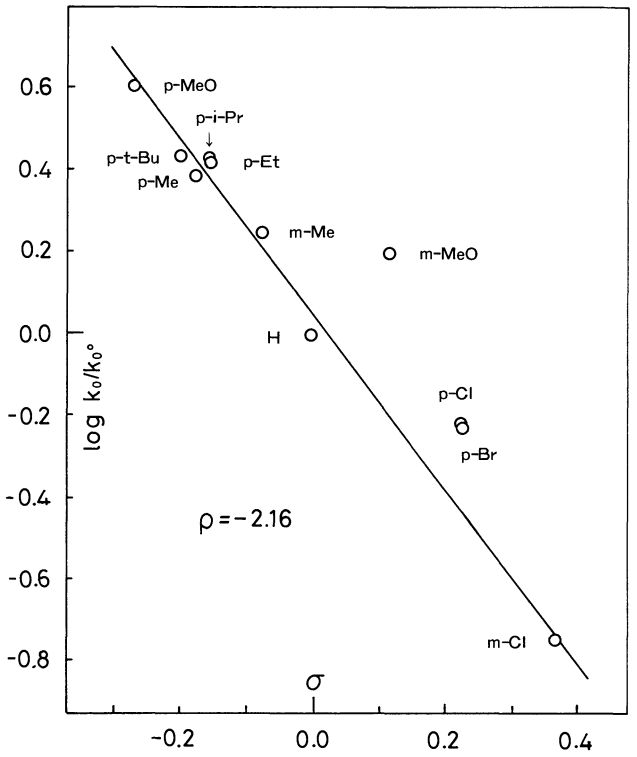

Fig. 2. Hammett plot for the k_0 process.

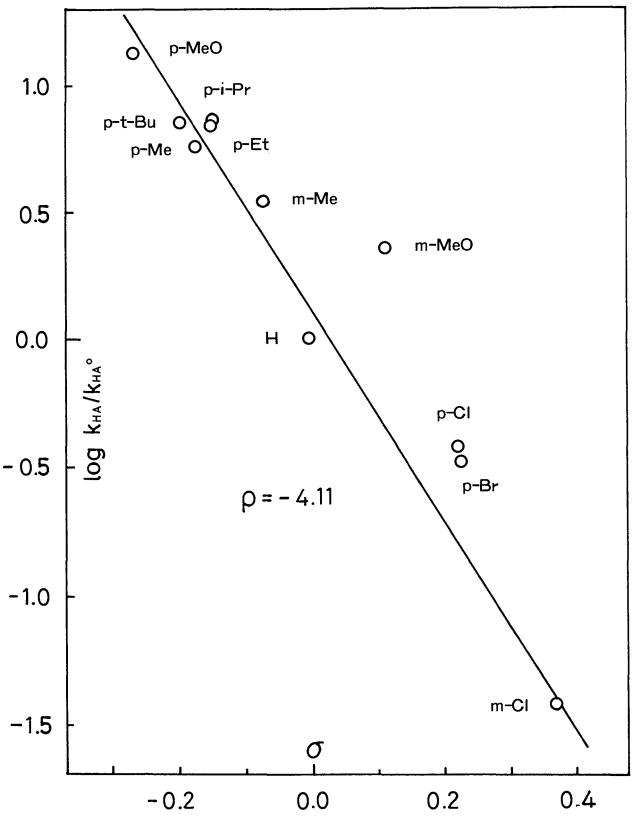

Fig. 3. Hammett plot for the k_{HA} process.

plots with σ^+. The substituent on the peroxy acid may have had little effect on the addition step, because the attack of the peroxy acid on the carbonyl carbon of the acetophenone occurs at its terminal oxygen conjugatively insulated from the rest of the peroxy acid. The substituent on the phenyl group of the acetophenone should have a normal effect expected from the ordinary carbonyl addition reactions in this step. On the other hand, in the migration step, the benzoyloxyl group, which originates from part of the peroxy acid, acts as a leaving group. A substituent on the group is expected to influence the reaction, as is described below. The substituent effect due to the migrating phenyl group should largely depend on the degree of the participation of the migrating phenyl on the migration-terminus oxygen. The degree of the phenyl participation, in turn, depends on the ability of the leaving group to depart from the oxygen, as long as the migration proceeds synchronously. As a whole, the difference in the substituent effects observed between the case for *m*-chloroperbenzoic acid and that for *o*-nitroperbenzoic acid is exclusively attributable to the difference in the leaving abilities of the benzoyloxyl groups between the peroxy acids in the migration step, and is not ascribed to the difference in the substituent effects between the peroxy acids in the addition step, since the electrophiles employed were the same for both reaction systems. If the leaving group ability is closely related to the acidity of the carboxylic acid from which the leaving group is derived, the leaving ability of the *m*-chlorobenzoyloxyl group is lower than that of the *o*-nitrobenzoyloxyl group. A better leaving group decreases the energy of the transition state more in the migration step. The rate-determining step in our case was the migration step for all the substituents studied, including the *p*-MeO group. The case for *m*-chloroperbenzoic acid should have been in the same category as that for *o*-nitroperbenzoic acid, since, in the former case, the reaction required more energy of the transition state in the migration step and therefore later transition state[8] and stronger π-interaction between the migrating phenyl π-system and the migration-terminus oxygen than those for *o*-nitroperbenzoic acid. Since the reported rate constants to which the Brown $\rho^+\sigma^+$ equation was applied were of second order (first order in ketone and first order in peroxy acid), it seemed to imply that the reaction had been carried out under the condition $k_0 \gg k_{HA}[HA]$ for *m*-chloroperbenzoic acid. Even if the rate constants observed corresponded to the k_0 values, it was still better to apply the data set to the Yukawa–Tsuno equation than the Brown $\rho^+\sigma^+$ equation used by Palmer and Fry,[4] and by Ogata and Sawaki.[3] The former equation gave a ρ value of -1.62 and a corr coeff of 0.993 when an r value of 0.54 was adopted.[9] Thus, the variation of the leaving group abilities required the variation of the substituent constants applied. The variation of the resonance demand suggested that the structure of the transition

state in the migration step was tighter for *m*-chloroperbenzoic acid than for *o*-nitroperbenzoic acid and therefore the position of the transition state was relatively late for the former, and vice versa. This was in good agreement with theoretical predictions for the transition-state geometry of the Baeyer–Villiger reaction.[10]

Acid Catalysis in the k_{HA} Process. The k_0 process gave a ρ value of -2.16 with σ as a result of opposite substituent effects between the addition step and the migration step. In the k_{HA} process, a ρ value of -4.11 was obtained with σ. The magnitude of the $|\rho|$ value for the k_{HA} process was almost twice as large as that for the k_0 process. This large difference in magnitude could be rationalized by examining the influence of the acid intervention on the individual steps in the k_{HA} process. If the acid catalyst acts only on the carbonyl or acyloxy oxygen of the leaving group in the migration step, the leaving group departs much more easily from the rest of the Criegee's intermediate. The better leaving group induced by the acid catalyst would thus decrease the energy of the transition state more in this step, promoting the earlier transition state and making it more reactant-like,[8] viz., more Criegee's intermediate-like. The substituent effect on the migration step would therefore decrease due to the less effective participation of the phenyl group on the migration-terminus oxygen in the k_{HA} process than that in the k_0 process. Thus, the overall substituent effect on the k_{HA} process was expected to become much smaller in magnitude than that on the k_0 process. The relative magnitude of the observed ρ values, however, showd the reverse, which indicated that the contribution of the acid catalyst to the migration step of the k_{HA} process should have been negligibly small or ruled out. On the other hand, if the acid catalyst operates only on the carbonyl group of the acetophenone in the initial state, the polarization of the carbonyl group is enhanced even by weak hydrogen bonding,[11] making the ketone more reactive to the nucleophile. It has been shown that acid-catalyzed carbonyl addition reactions are relatively insensitive to the substituent effect.[2,12] The acid-catalyzed addition step in this reaction would therefore be facilitated with a smaller contribution of the substituent effect. Consequently, the overall substituent effect would be mainly governed by the substituent effect on the migration step. A larger $|\rho|$ value was expected in the k_{HA} process than in the k_0 process. This was in good accordance with the relative magnitude of the $|\rho|$ values obtained in both processes. Since the substituent effect on the migration step was nearly the same for the k_0 process and the k_{HA} process in this case, the difference (1.95) in the observed ρ values between the two processes should refer to the intervention of the acid catalyst in the addition step of the k_{HA} process. The last possibility is that the acid catalyzes both the addition step and the migration step successively. As discussed above separately, the intervention of the acid catalyst decreases the substituent effect on each step. Neither of the influences of the decreases in the individual steps on the ρ value is therefore predominant, and the decrease in the rate-determining migration step would probably be a little larger than that in the addition step. The ρ value in the k_{HA} process was therefore expected to become one between the ρ values for the two extreme cases mentioned above, and to be comparable to that in the k_0 process. As for the trifluoroperacetic acid oxidation of *m*- and *p*-substituted acetophenones in the presence of trifluoroacetic acid,[2] the acid-catalyzed process seemed to predominte ($k_0 \ll k_{HA}[HA]$). The low nucleophilicity and the low basicity of the leaving group were coincident with the applicability of the σ value. Although the ρ value for the k_0 process was not available for trifluoroperacetic acid, the fact that the magnitude of the ρ value for trifluoroperacetic acid was ca. a third of that for *o*-nitroperbenzoic acid in the k_{HA} process seemed to imply the acid intervention in the migration step as well as in the addition step.

Similarity Between the k_0 Process and the k_{HA} Process. In Fig. 4 the logarithmic rates for the k_{HA} process are plotted against those for the k_0 process, giving a linear correlation with a corr coeff of 0.999 including *m*-MeO, *p*-Cl, and *p*-Br which deviated upward from the lines of Hammett plots (Figs. 2 and 3). This indicated that these two processes proceeded essentially by the same mechanism, although there was pre-equilibrium for the formation of the acid-ketone adduct in the k_{HA} process.

Abnormality for Some Substituents. *m*-Methoxyacetophenone deviated upward from the Hammett lines (Figs. 2 and 3) by ca. 0.4 and 0.7 log unit for the k_0 process and for the k_{HA} process, respectively, while *p*-methoxyacetophenone showed normal behavior on the lines. The basicity of the substituent, *p*-MeO, is decreased due to its conjugation with the carbonyl of the

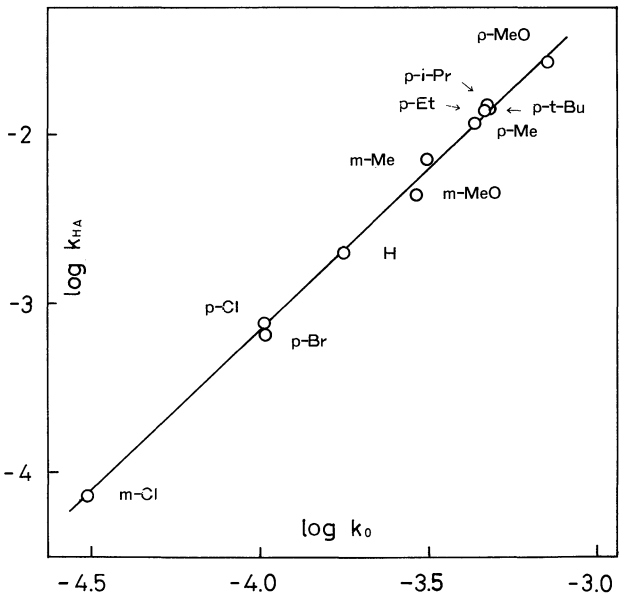

Fig. 4. Linear free energy relationship of k_{HA} vs. k_0.

ketone, whereas *m*-MeO is conjugatively insulated from the carbonyl. It is conceivable that *m*-MeO maintains its basicity enough to form a hydrogen bond with the solvent (specific solvation effect) in the initial state, making the substituent more electron-attractive and therefore making the ketone more reactive in the addition step. Similar enhancement has been observed for *m*-MeO by Friess and Soloway[13] in the reaction of *m*- and *p*-substituted acetophenones with perbenzoic acid in chloroform. The substituents *p*-Cl and *p*-Br also showed upward deviations from the Hammett lines by ca. 0.23—0.24 and 0.34—0.38 log unit for the k_0 process and for the k_{HA} process, respectively. These deviations are a little too large to be regarded as experimental errors. Considering that *m*-Cl behaved well, it might be conceivable that a free radical path (homolytic fission of the -O-O- bond in the Criegee's intermediate)[14] for *p*-Cl and *p*-Br was accompanied in the migration step. The radical reaction may have been accelerated by *p*-halophenyl participation on the migration-terminus oxygen.

Experimental

The boiling points are uncorrected. ^{1}H NMR spectra were obtained on a JEOL JNM-MH 60 spectrometer in δ values relative to the internal TMS. Gas chromatographic analyses were carried out on a Hitachi K 53 with a 30-m golay column of apiezon L high vacuum grease and FID.

***o*-Nitroperbenzoic Acid.** The title compound was prepared by the reaction of *o*-nitrobenzoic acid with 90% hydrogen peroxide in methanesulfonic acid, according to the procedure described by Silbert et al.[15] Further treatment was necessary for its use in the kinetic experiments. The compound obtained was dissolved in purified chloroform at room temperature, washed with distilled water four times in order to remove a trace of methanesulfonic acid, and then dried over anhydrous sodium sulfate for a few minutes. After the sodium sulfate was removed by filtration, the filtrate was concentrated under reduced pressure at 30 °C until a certain amount of the compound had precipitated. This precipitate was redissolved at a temperature not above 40—45 °C within ten minutes. After filtration, the solution was cooled to −20 °C to give light yellow needles. The amount of active oxygen was estimated to be 100±1% by iodometric titration. The compound was kept in a refrigerator.

***p*-Substituted Acetophenones.** *p*-Methyl-, *p*-chloro-, and *p*-bromoacetophenones were prepared by Friedel–Crafts reactions following the usual procedure in carbon disulfide.[16] *p*-Methoxy-, *p*-*t*-butyl-, *p*-isopropyl-, and *p*-ethylacetophenones were prepared by the Perrier modification[17] of the Friedel–Crafts reaction in carbon tetrachloride. The compounds were purified through the recrystallization of their semicarbazones except for *p*-methoxyacetophenones, followed by repeated distillations of regenerated ketones using concd HCl. *p*-Methoxyacetophenone was purified by fractional recrystallization, followed by distillation. Commercially-obtained acetophenone was purified by repeated distillations. The compounds thus obtained were all pure according to gas chromatography. Substituents and boiling points for these compounds were as follows: *p*-MeO, 142.0—142.5 °C/18 mmHg (lit,[18] 139 °C/15 mmHg) (1 mmHg=133.32 Pa); *p*-*t*-Bu, 140—140.5 °C/18 mmHg (lit,[17] 137—138 °C/16 mmHg); *p*-*i*-Pr, 123.0—123.5/14.5 mmHg (lit,[19] 115 °C/10 mmHg); *p*-Et, 127 °C/22 mmHg (lit,[17] 116—117 °C/13 mmHg); *p*-Me, 105 °C/18.5 mmHg (lit,[18] 93.5 °C/7 mmHg); *p*-Cl, 118 °C/20 mmHg (lit,[18] 99.0 °C/7 mmHg); *p*-Br, 133.5—134.0 °C/19.5 mmHg (lit,[18] 117.0 °C/7 mmHg); H, 84.5—85.0 °C/17 mmHg (lit,[18] 88.5 °C/16 mmHg).

***m*-Substituted Acetophenones.** *m*-Methoxy-, *m*-methyl-, and *m*-chloroacetophenones were prepared by the usual procedures from *m*-hydroxyacetophenone, *m*-methylbenzoic acid and *m*-aminoacetophenone, respectively, and were purified by the same manner as described in the preparation of the *p*-substituted acetophenones. The compounds obtained were all pure according to gas chromatography. Substituents and boiling points for these compounds were as follows: *m*-MeO, 132 °C/20 mmHg (lit,[20] 125—126 °C/12 mmHg); *m*-Me, 109 °C/22 mmHg (lit,[21] 65—71 °C/0.2 mmHg); *m*-Cl, 110.5—111.5 °C/17 mmHg (lit,[22] 80 °C/2.5 mmHg).

Solvent. Chloroform used for the kinetics as a solvent was purified by washing with concd sulfuric acid as described in the literature[23] just prior to use.

Product Analyses. The reaction products were analyzed by use of ^{1}H NMR and gas chromatography. The analytical procedures in the case of acetophenone described below were also applied to the other cases of *p*-methoxy-, *p*-methyl-, and *p*-chloroacetophenones. At the end of a kinetic run, the residual solution was examined by ^{1}H NMR, which showed no signal (δ=3.94) for the methyl group of the methyl ester but showed a signal (δ=2.28) for that of the acetate and a signal (δ=2.62) for that of the unreacted ketone. Blank tests proved that the detection of the methyl ester was possible when the molar ratio of methyl ester to acetate was higher than 3/100. Another portion of the residual solution was washed successively with cold 5% potassium iodide aq once, with cold 3% sodium thiosulfate aq twice, with cold 6% sodium hydrogencarbonate aq three times, and finally with cold water twice. After the solution was dried on a small amount of sodium sulfate, the solvent was evaporated under reduced pressure. Gas chromatographic analysis of the liquid residue showed the complete absence of the methyl ester. Blank tests proved that neither the methyl ester nor the acetate was hydrolyzed throughout the above treatment, and that the detection of the methyl ester was possible when the molar ratio of methyl ester to acetate was higher than 1/100, except for *p*-chloroacetophenone where the retention times were the same for the unreacted ketone and the methyl ester. As for the other ketones listed above, the results obtained were similar to those of acetophenone.

Kinetic Measurements. The reaction rates were determined by iodometry of unreacted peroxy acid using the usual ampule technique. In a 100-ml glass-stoppered flask ca. 5×10^{-3} moles of ketone and ca. 1.5×10^{-3} moles of *o*-nitrobenzoic acid were weighed accurately and were dissolved in 50-ml of chloroform. In another 100-ml glass-stoppered flask ca. 5×10^{-3} moles of *o*-nitroperbenzoic acid were weighed accurately and were likewise dissolved in 50-ml of chloroform. After the flasks and the contents were cooled to 0—5 °C in an ice-bath, the *o*-nitroperbenzoic acid solution was added to the solution of the ketone and the acid. The combined solution was swirled quickly and 7—8-ml samples of the solution were sealed in

twelve ampules for each kinetic run. They were immersed into a bath thermostated at 30.00±0.02 °C at the same time. The ampules were withdrawn at adequate intervals and quenched with ice. A 5-ml portion of the solution was pipetted out and transferred into 30-ml of a 2.5% aqueous solution of potassium iodide to which 10-ml of 1 equiv HCl solution had been added immediately before pipetting. The iodine thus liberated was titrated with a 0.1 equiv $Na_2S_2O_3$ solution. All kinetic measurements satisfied the first-order kinetic equation with a correlation coefficient $R>0.999$ to ca. 30% completion of the reaction.

The authors are grateful to Professor Kiyoyasu Kawai of Toyama University for his encouragement during this work.

4) B. W. Palmer and A. Fry, *J. Am. Chem. Soc.*, **92**, 2580 (1970). Recalculation based on the reported data gave a ρ^+ value of −1.37 (corr coeff: 0.987) with σ^+.

5) The empirical Eq. 1 can be paraphrased by

$$v = k_{obs}[PA], \quad (1')$$

where [PA] is the peroxy acid concentration. We can not distinguish Eq. 1 from Eq. 1′ in practice, because the behavior of the ketone and the peroxy acid is the same in terms of the stoichiometry.

6) When the reaction was allowed to start with the same initial concentration ratio of each reactant as the composition ratio at 20% completion of the reaction excluding product ester, the reaction-rate constant observed was still the same as the rate constant at the standard conditions employed in this study.

7) Ogata and Sawaki also regarded *p*-CN as an improper substituent because of a possibility of methyl migration for *p*-cyanoacetophenone. Thus, they used three substituents, i.e., H, *p*-Me, and *p*-Cl among five substituents reported by Palmer and Fry to correlate with σ^+. The downward deviation by ca. 0.5 log unit for the *p*-MeO is that from the correlation line.

8) G. S. Hammond, *J. Am. Chem. Soc.*, **77**, 334 (1955).

9) We included here *p*-CN and *p*-MeO to calculate the correlation line by use of the equation $\log k/k_0=\rho[\sigma+r(\sigma^+-\sigma)]$ for a wider coverage (the notation k_0 in this equation means the rate constant for the unsubstituted compound). There is no distinct evidence for the methyl migration in the case of *p*-cyanoacetophenone.

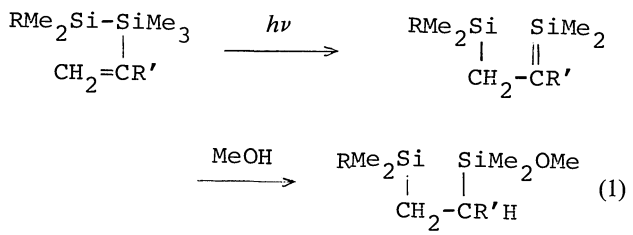
Chofu, Tokyo 182
(Received April 16, 1991)

Photochemical reactions of vinyl-, styryl-, and benzyl-substituted digermanes were investigated by chemical trapping experiments. Photolysis of vinylpentamethyldigermane afforded 1-trimethyl-2-(pentamethyldigermyl)-ethane as a major product, and styrylpentamethyldigermanes gave mainly styryltrimethylgermane. On the other hand, photolysis of benzyl-substituted digermanes (benzylpentamethyldigermane and 1,2-dibenzyltetramethyldigermane) gave hydrogermanes and hydrodigermanes as main products, respectively. These products were derived from germyl radicals generated by photoinduced homolysis of the germanium–germanium bond. In carbon tetrachloride (CCl_4), these germyl radicals were converted to the corresponding chlorogermanes by abstraction of a chlorine atom. Germylene species were also to be evolved from such photolyses.

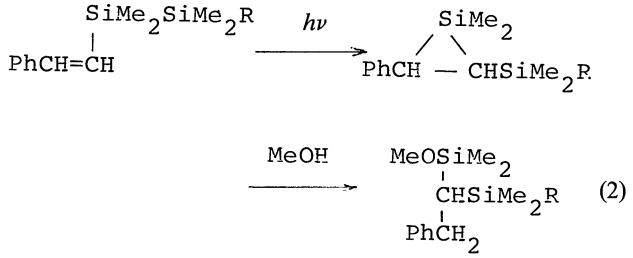
Recently, the photochemistry of organosilicon compounds having σ(Si–Si)–π(C–C) conjugated systems has been investigated extensively. However, the photochemical behavior of germanium analogues is particularly intriguing from the view of group 14 element chemistry.[1] Previously, we reported the generation of germyl radicals on photolysis of phenyl-substituted digermanes.[2,3] We herein describe the photoreactions of σ(Ge–Ge)–π(C–C) conjugated vinyl- and styryl-substituted digermanes, and benzyl-substituted digermanes as a further extension of our studies.

The photolyses of vinyldisilanes have been reported to induce 1,3-silyl migration to give the corresponding silaethenes as highly reactive intermediates, which were proved by trapping experiments with methanol (Eq. 1).[4]



(1)

Similarly, styryldisilanes undergo 1,2-silyl migration to give the corresponding silacyclopropanes as reactive intermediates, which were also evidenced by trapping experiments (Eq. 2).[5]



(2)

On the other hand, the irradiation of benzyldisilanes gives a pair of organosilyl radicals by homolysis of the silicon-silicon σ bond (Eq. 3).[6]

$$PhCH_2Me_2Si\text{–}SiMe_3 \xrightarrow{h\nu} PhCH_2Me_2Si\cdot + \cdot SiMe_3 \quad (3)$$

The purpose of the studies described here is to clarify the photochemical behavior of digermanes and to compare their reactivities with thoes of the analogous vinyl-, styryl-, and benzyl-substituted disilanes.

Results and Discussion

Photochemical Reactions of Vinylpentamethyldigermane. Vinylpentamethyldigermane, CH_2=$CHMe_2Ge$-$GeMe_3$ (**1**) in cyclohexane (ca. 0.2 M, 1 M=1 mol dm^{-3}) was irradiated with a 110 W low-pressure Hg arc lamp (a spiral type) at room temperature under argon for 10 h. In addition to a large excess of an unidentified high-boiling product, 1-trimethylgermyl-2-(pentamethyldigermyl)ethane ($Me_3GeCH_2CH_2Ge_2Me_5$, 8% yield) was obtained as a main product together with trace amounts of trimethylgermane (Me_3GeH), vinyldimethylgermane (CH_2=$CHGeMe_2H$), pentamethyldigermane (Me_5Ge_2H), vinyltrimethylgermane (CH_2=$CHGeMe_3$), hexamethyldigermane (Me_6Ge_2), and 1,2-bis(pentamethyldigermyl)ethane ($Me_5Ge_2CH_2$-$CH_2Ge_2Me_5$). Along with hydrogermanes (Me_3GeH and CH_2=$CHMe_2GeH$), formation of digermane (Me_6-Ge_2) indicated the intermediacy of germyl radicals. Since organogermyl radicals abstract a chlorine atom from CCl_4 effectively and rapidly to trap these germyl radical intermediates,[7] the photolysis of compound **1** was carried out in cyclohexane containing CCl_4. As expected, the corresponding chlorogermanes (CH_2=CH-Me_2GeCl and Me_3GeCl) and hexachloroethane were obtained along with (2-chloroethyl)pentamethyldigermane ($ClCH_2CH_2Ge_2Me_5$), pentamethylchlorodigermane (Me_5Ge_2Cl), and CH_2=$CHGeMe_3$. The forma-

tion of Me_5Ge_2H also implied that digermyl radicals and vinyl radicals were generated by homolysis of the carbon–germanium bond along with the germanium–germanium bond. This was further substantiated by the formation of Me_5Ge_2Cl from the photolysis of **1** in the presence of CCl_4. The expected $CH_2=CH_2$ and $CH_2=CHCl$ were not detected with and without CCl_4, respectively, due to their high degree of volatility. The formation of $ClCH_2CH_2Ge_2Me_5$ could be explained as follows. Addition of a chlorine radical generated by photolysis of CCl_4 to gave the 1-(pentamethyldigermyl)-2-chloroethyl radical ($ClCH_2\dot{C}HGe_2Me_5$), followed by abstraction a hydrogen atom from solvents to produce $ClCH_2CH_2Ge_2Me_5$.

A trace amount of dimethyldichlorogermane (Me_2GeCl_2) was detected in the photolysate. The formation of Me_2GeCl_2 may be accounted for by thermal decomposition of (trichloromethyl)dimethylchlorogermane (CCl_3Me_2GeCl), which is produced by insertion of photochemically generated dimethylgermylene into the C–Cl bond of CCl_4,[8] or chlorine abstraction from CCl_4 stepwise by dimethylgermylene as shown in the silicon cases.[9]

The material balance and yields of the chlorogermanes were poor.

Radical Pair Processes (Main Path).

$$(CH_2=CH)Me_2Ge\text{–}GeMe_3 \xrightarrow{h\nu} \begin{cases} \xrightarrow{CCl_4} (CH_2=CH)Me_2GeCl + Me_3GeCl \\ \xrightarrow{CCl_4} CH_2=CHCl + ClMe_2GeGeMe_3 \end{cases} \quad (4)$$

On the other hand, the presence of $CH_2=CHGeMe_3$ in the photolysate implied that dimethylgermylene was generated on the photolysis of **1** under a variety of irradiation conditions. This was supported by the following trapping experiments. In cyclohexane containing a large excess of 2,3-dimethyl-1,3-butadiene as a germylene trapping agent,[10] the photolysis of **1** gave 1,1-dimethylgermacyclopent-3-ene (3% yield).

Germylene Formation Process (Minor Path).

$$(CH_2=CH)Me_2Ge\text{–}GeMe_3 \xrightarrow{h\nu} CH_2=CHGeMe_3 + [:GeMe_2] \quad (5)$$

$$[:GeMe_2] + \text{  } \longrightarrow Me_2Ge \quad (6)$$

In the photolysis of vinyldisilanes, 1,2-disilylethenes were formed as important intermediates.[4] The germanium–carbon double-bonded species (germenes) are known to react quite effectively with methanol to give the corresponding methoxygermanes.[11] Hence, to confirm the formation of germenes, the photolysis of **1** was examined in cyclohexane containing a large excess of methanol. As a result, no methoxygermanes were detected in the photolysate. Thus, this meant that no germanium–carbon double-bonded species (germenes) were formed as reactive intermediates in the photolysis of vinyl-substituted digermanes (**1**).

These photochemical results are summarized in Table 1.

Photochemical Reactions of Styrylpentamethyldigermane. Styrylpentamethyldigermane ($PhCH=CHMe_2GeGeMe_3$) (**2**) in cyclohexane (ca. 0.1 M) was similarly irradiated with a 110 W low-pressure Hg arc lamp at room temperature under argon for 6 h. Together with a large amount of unidentified polymeric compounds containing germanium atoms, styryltrimethylgermane ($PhCH=CHGeMe_3$, 15% yield) as a major product and trace amounts of Me_3GeH and Me_5Ge_2H were obtained. The presence of $PhCH=CHGeMe_3$ in the photolysate implied the generation of dimethylgermylene under these reaction conditions. To trap this dimethylgermylene, the photolysis of **2** in cyclohexane solution containing a large excess of 2,3-dimethyl-1,3-butadiene[10] was carried out. As expected, 1,1-dimethylgermacyclopent-3-ene (5% yield) was produced. These trapping results suggested that 2,3-dimethyl-1,3-butadiene did not effectively trap photoinduced dimethylgermylene.[12] Dimethylgermylene may have similarly arisen from a simple extrusion process as observed in the vinyldigermane.

$$PhCH=CHGeMe_2GeMe_3 \xrightarrow{h\nu} PhCH=CHGeMe_3 + [:GeMe_2] \quad (7)$$

Formation of trace amounts of hydrogermanes (Me_3GeH and Me_5Ge_2H) indicated the intermediate involvement of germyl radicals. This was confirmed by the formation of the corresponding chlorogermanes ($PhCH=CHMe_2GeCl$ and Me_3GeCl) in the presence of CCl_4.[7] Me_5Ge_2Cl and $PhCH=CHCl$ were also detected in the photolysate. These chlorides indicated the presence of digermyl radicals and styryl radicals, which were generated by homolysis of the germanium–carbon bond. Under these conditions, neither digermanes nor hydrogermanes were detected in the photolysate.

Interestingly, in the photolysis of **2**, a small amount of styrylheptamethyltrigermane ($PhCH=CHMe_2GeMe_2GeGeMe_3$) was detected. This implied that dimethylgermylene is able to insert into a germanium–germanium bond under these reaction conditions.[3]

In the photolysis of styryldisilanes, silacyclopropanes have been reported to be key reactive species.[5] Germacyclopropanes were effectively trapped with methanol to give 1,1-digermyl-2-phenylethanes.[13] Therefore, to examine the possibility of germacyclopropanes as reactive intermediates, the photolysis of **2** in cyclohexane with methanol was carried out. However,

Table 1. Photoproducts and Yields from the Photolysis of the Vinyl-, Styryl-, and Benzyl-Substituted Digermanes **1**—**4** in Cyclohexane

Dimetal	Trapping agent	Photoproducts[a] (yield/%)
$CH_2=CHGe_2Me_5$ **1**	None	Me_3GeH (20), $Me_3GeCH_2CH_2Ge_2Me_5$ (8), $Me_5Ge_2CH_2CH_2Ge_2Me_5$ (1), $(c\text{-}C_6H_{11})_2$ (1)
	CCl_4	$CH_2=CHMe_2GeCl$ (9), Me_5Ge_2Cl (13), $ClCH_2CH_2Ge_2Me_5$ (60), C_2Cl_6 (61), Me_3GeCl (trace), $CH_2=CHGeMe_3$ (trace)
	MeOH	$Me_3GeCH_2CH_2Ge_2Me_5$ (2), $Me_5Ge_2CH_2CH_2Ge_2Me_5$ (1)
	Diene	Me_3GeH (6), (3)
$PhCH=CHGe_2Me_5$ **2**	None	$PhCH=CHGeMe_3$ (15), $(c\text{-}C_6H_{11})_2$ (8)
	CCl_4	Me_5Ge_2Cl (51), $PhCH=CHGeMe_3$ (3), C_2Cl_6 (54)
	Diene	$PhCH=CHGeMe_3$ (25),  (5)
$PhCH_2Ge_2Me_5$ **3**	None	Me_3GeH (12), Me_5Ge_2H (5), $(PhCH_2Me_2Ge)_2O$ (1), Me_8Ge_3 (2), $PhCH_2Ge_3Me_7$ (1), $(PhCH_2)_2$ (5)
	CCl_4	$PhCH_2Me_2GeCl$ (21), Me_5Ge_2Cl (29), C_2Cl_6 (50)
	MeOH	$(PhCH_2Me_2Ge)_2O$ (1), $(PhCH_2)_2$ (11)
	Diene	Me_5Ge_2H (1),  (3)
$(PhCH_2Me_2Ge)_2$ **4**	None	$PhCH_2Me_2GeH$ (7), $(PhCH_2)_2GeMe_2$ (2), $PhCH_2Me_2GeMe_2GeH$ (7), $(PhCH_2)_2$ (7)
	CCl_4	$PhCH_2Me_2GeCl$ (39), $PhCH_2Me_2GeMe_2GeCl$ (23), C_2Cl_6 (45)
	MeOH	$PhCH_2Me_2GeMe_2GeH$ (10), $(PhCH_2)_2$ (10)
	Diene	$(PhCH_2)_2GeMe_2$ (1), $PhCh_2Me_2GeMe_2GeH$ (1), $(PhCH_2)_2$ (3)

a) Ttace amounts of other products were obtained.

no methoxy-substituted compounds were detected in the photolysate. Thus, this result strongly indicated either no formation of germacyclopropanes as reactive intermediates in the photochemical reaction of **2** or that the life time of the germacyclopropane was too fast to be trapped chemically under these conditions.

The results of these photochemical reactions of **2** are also included in Table 1.

Photochemical Reactions of Benzyl-Substituted Digermanes. Benzylpentamethyldigermane ($PhCH_2Me_2GeGeMe_3$) (**3**) and 1,2-dibenzyltetramethyldigermane ($PhCH_2Me_2GeGeMe_2CH_2Ph$) (**4**) in cyclohexane (each 0.1 M) were irradiated with a 110 W low-pressure Hg arc lamp at room temperature under argon for 3—4 h. Many photoproducts were formed in low yields. Among with a large amount of polymeric materials, photolysis of **3** in cyclohexane gave Me_3GeH (12% yield), Me_5Ge_2H (5% yield), and bibenzyl (5% yield) as major products and trace amounts of benzyldimethylgermane ($PhCH_2Me_2GeH$), benzyltrimethylgermane ($PhCH_2GeMe_3$), Me_6Ge_2, dibenzyldigermanoxane ($(PhCH_2Me_2Ge)_2O$), bis(pentamethyldigermyl)oxide ($(Me_5Ge_2)_2O$), octamethyltrigermane (Me_8Ge_3), and 1-benzylheptamethyltrigermane ($PhCH_2Me_7Ge_3$) were also detected. On the other hand, photolysis of **4** in cyclohexane afforded $PhCH_2Me_2GeH$ (7% yield), dibenzyldimethylgermane ($(PhCH_2)_2GeMe_2$) (2% yield), $PhCH_2Me_2GeGeMe_2H$ (7% yield), and $(PhCH_2)_2$ (7% yield).

The origin of the oxygen atom involved in the digermanoxanes is not certain at this stage. In spite of efforts to minimize moisture and air, the digermanoxanes were still obtained in appreciable amounts.

Along with hydrogermanes (Me_3GeH and $PhCH_2GeMe_2H$ for **3** and $PhCH_2GeMe_2H$ for **4**, respectively), formation of digermanes (Me_6Ge_2 for **3** and $(PhCH_2Me_2Ge)_2$ for **4**, respectively) indicated intermediary germyl radicals. To trap such germyl radical intermediates as the corresponding chlorides, the photolyses of **3** and **4** were carried out in cyclohexane containing CCl_4.[8] The corresponding chlorogermanes were obtained and neither digermanes nor hydrogermanes were detected as shown in Table 1. The formation of benzyldimethylchlorogermane ($PhCH_2Me_2GeCl$) and Me_5Ge_2Cl for **3**, and benzyltetramethyldigermyl chloride ($PhCH_2Me_2GeMe_2GeCl$) for **4**, also implied that homolysis of the germanium-carbon bond of benzyl-substituted digermanes **3** and **4** occured along with the homolysis of the germanium-germanium bond.

Radical Pair Processes (Main Path).

$$PhCH_2\text{–}Me_2Ge\text{–}GeMe_2R \xrightarrow{h\nu} \begin{cases} \xrightarrow{CCl_4} PhCH_2Me_2GeCl + RMe_2GeCl \\ \xrightarrow{CCl_4} PhCH_2Cl + ClMe_2GeGeMe_2R \end{cases} \quad (8)$$

R=Me, $PhCH_2$

On the other hand, the formation of $PhCH_2GeMe_3$ for **3** and $(PhCH_2)_2GeMe_2$ for **4**, respectively, with and without CCl_4 implied that dimethylgermylene was generated under a variety of irradiation conditions. 1,1-Dimethylgermacyclopent-3-ene (3% yield and trace amounts for **3** and **4**, respectively) was formed in the photolysis of **3** and **4** in cyclohexane with a large excess of 2,3-dimethyl-1,3-butadiene.[10]

Germylene Formation Process (Minor Path).

$$PhCH_2Me_2GeGeMe_2R \xrightarrow{h\nu} PhCH_2GeMe_2R + [:GeMe_2] \quad (9)$$
$$R=Me,\ PhCH_2$$

The photochemical behavior of benzyl-substituted digermanes was similar to that of the silicon analogues. However, no formation of silylenes has been reported so far.[6]

The photochemical results of benzyl-substituted digermanes (**3** and **4**) are also summarized in Table 1.

Mechanism of Photochemical Reactions of Vinyl-, Styryl-, and Benzyl-Substituted Digermanes. The results obtained from the analysis of the photoproducts were best rationalized on basis of a pair of radicals generated from the photoinduced homolysis of the germaium–germanium and germanium–carbon bonds (Eqs. 4 and 8) as a main path, and of simple extrusion of dimethylgermylene (Eqs. 5, 7, and 9) as a minor path.

Photolysis of digermanes **1**—**4** caused germanium–germanium and germanium–carbon bond cleavage to yield the corresponding pairs of radicals. In CCl_4 the photogenerated germyl-centered radicals and carbon-centered radicals abstracted a chlorine atom effectively to give the corresponding chlorides.[8,14] Thus, in contrast to the silicon analogues, both germyl radicals and carbon radicals appeared to act as reactive intermediates in these photoreactions.

In addition to the homolysis, the extrusion of dimethylgermylene to yield the corresponding monogermanes also occured. Dimethylgermylene arising from a simple extrusion process was also a reactive intermediate independent of the homolytic process.

Thus, the photoproducts isolated here were rationalized to arise from either the radical pair generated from photoinduced homolytic fission of the germanium–germanium and germanium–carbon bonds or extrusion of dimethylgermylene from the starting digermanes. We obtained no evidence for the formation of a germanium–carbon double-bonded species (germene) or germacyclopropane derived from 1,3- and 1,2-germyl migration. On irradiation, however, the silicon analogues underwent 1,3- and/or 1-2-silyl migration to give the corresponding silicon–carbon double-bonded species (silene) and/or silacyclopropane; these could be rationalized also to have arisen by way of the radical pair generated from the photoinduced homolysis of the silicon–silicon bond.

These differences in the photoreactions between the two 14 group metal compounds may be attributed to the difference in the energy of the bond cleaved, namely, germanium–germanium and germanium–carbon bonds are weaker than those of the corresponding silicon–silicon and silicon–carbon bonds. The difference in the thermodynamic stability of germyl and silyl radicals may also contribute to prefential formation of radical products in the photolysis of the digermanes. The strong radical nature of the reaction intermediates may suffer some deterioration of product yields and the material balance of the photolysis.

Experimental

^1H NMR spectra were recorded on a JEOL GX270 using tetramethylsilane as the internal standard. GC-MS spectra were obtained with a JEOL JMS-DX 303 mass spectrometer, and only major peaks are shown. Infrared spectra were recorded on a Shimadzu FT IR 4200 spectrometer. UV and visible spectra were recorded on a JASCO Ubest 50 spectrometer. Gas chromatography was performed on a Shimadzu GC-6A and 8A with 2 m 20% SE30 and 1 m 20% Apiezon L columns.

Materials. 2,3-Dimethyl-1,3-butadiene, CCl_4, and MeOH were commerically available and distilled prior to use. $CH_2=CHMe_2Ge-GeMe_3$,[15] Me_3GeH,[16] $CH_2=CHGeMe_3$,[17] Me_5Ge_2Cl,[15] 1,1-dimethylgermacyclopent-3-ene,[18] Me_5Ge_2H,[19] $PhCH_2Me_2GeCl$,[20] Me_8Ge_3,[21] Me_6Ge_2,[22] and Me_2GeCl_2[16] were prepared as described in the cited references.

Solvent. Cyclohexane was distilled from benzophenone/sodium under argon.

Preparation of Styrylpentamethyldigermane ($PhCH=CHGe_2Me_5$). Styrylmagnesium bromide was prepared from 4.8 g (26 mmol) of styryl bromide and 0.63 g (26 mmol) of magnesium in 40 ml of THF. To this Grignard reagent, 3.4 g (13 mmol) of pentamethylchlorodigermane dissolved in 40 ml of THF was added and refluxed gently for 4 h. After hydrolysis with water, reaction mixtures were extracted with ether, and the organic layer was dried over anhydrous sodium sulfate. After the solvent was removed, fractional distillation gave styrylpentamethyldigermane (3.6 g, 85% yield), bp 119—131 °C/31 mmHg (1 mmHg=133.322 Pa). Pure digermane was isolated by preparative GLC (SE30 20% 2 m column). ^1H NMR (CCl_4) δ=0.25 (s, 9H), 0.35 (s, 6H), 6.65 (m, 2H), and 7.22 (m, 5H); MS (70 eV) *m/z* 324 (6), 207 (100), 119 (26), and 105 (48); UV (in cyclohexane) λ_{max} 266.3 nm (ε 19000); IR (neat) 795m 825, 1665, 1703, 2930, and 2980 cm^{-1}. Found: C, 48.50; H, 6.56%. Calcd for $C_{13}H_{22}Ge_2$: C, 48.27; H, 6.86%.

Preparation of Benzylpentamethyldigermane ($PhCH_2Ge_2Me_5$). Benzylmagnesium chloride was prepared from 2.5 g (20 mmol) of benzyl chloride and 0.5 g (21 mmol) of magnesium in dry ether (30 ml). To this Grignard reagent, 2.0 g (7.8 mmol) of pentamethylchlorodigermane dissolved in dry ether (30 ml) was added. The reaction mixture was stirred with refluxing for 1 h. After hydrolysis with dilute HCl, the reaction mixture was extracted with ether and the organic layer was washed with water. The organic layer was dried over calcium chloride. After removal of the solvent,

fractional distillation gave benzylpentamethyldigermane (1.8 g, 75% yield). The digermane was purified by preparative GLC. ^{1}H NMR (CCl_4) δ=0.17 (s, 15H), 2.27 (s, 2H), and 6.89—6.97 (m, 5H); MS (70 eV) *m/z* 312 (9), 221 (52), 119 (100), and 91 (60); UV (in cyclohexane) λ_{max} 288.8 (ε 12500); IR (neat) 690, 744, 1490, 1595, 2900, 2960, and 3070 cm^{-1}. Found: C, 46.42; H, 7.36%. Calcd for $C_{12}H_{22}Ge_2$: C, 46.27; H, 7.12%.

Preparation of 1,2-Dibenzyltetramethyldigermane ((Ph-$CH_2Me_2Ge)_2$). Dibenzyltetramethyldigermane was prepared from lithium metal (0.21 g, 30 mmol) and benzyldimethylchlorogermane (6.8 g, 30 mmol) in THF (15 nl). The reaction mixture was gently refluxed for 8 h. After completion of this reaction, the reaction mixture was hydrolyzed with diute HCl and extracted with ether. The organic layer was washed with water and dried over sodium sulfate. After removal of the solvent, fractional distillation gave digermane (1.8 g, 31% yield), bp 129—138 °C/3 mmHg. The digermane was purified by preparative GLC. ^{1}H NMR (CCl_4) δ=0.10 (s, 12H), 2.17 (s, 4H), and 6.67—6.90 (m, 10H); MS (70 eV) *m/z* 373 (1), 297 (34), 195 (34), and 91 (100); UV (in cyclohexane) λ_{max} 238.4 nm (ε 14000); IR (neat) 695, 746, 790, 1490, 1605, 2920, 2970, and 3030 cm^{-1}. Found: C, 55.80; H, 7.90%. Calcd for $C_{18}H_{26}Ge_2$: C, 55.78; H, 6.76%.

Identification of the Photoproducts. These compounds were separated by preparative GLC and the structures were assigned by comparing the NMR and GC data of similar compounds reported.

1-Trimethyl-2-(pentamethyldigermyl)ethane: MS (70 eV) *m/z* 366 (15), 323 (25), 247 (20), 221 (95), 207 (14), 119 (100), 104 (7), and 89 (18); ^{1}H NMR ($CDCl_3$) δ=0.10 (s, 9H), 0.17 (s, 6H), 0.22 (s, 9H), 0.64—0.73 (m, 2H), and 0.70—0.90 (m, 2H).

Chloroethylpentamethyldigermane: MS (70 eV) *m/z* 288; ^{1}H NMR ($CDCl_3$) δ=0.26 (s, 6H), 0.27 (s, 9H), 1.23—1.29 (m, 2H), and 2.60—2.66 (m, 2H).

Trace amounts of photoproducts were very carefully identified by comparing the GC data of similar compounds reported.

Vinyldimethylchlorogermane: MS (70 eV) *m/z* 166 (100), 129 (78), 94 (31), and 59 (9).

Vinyldimethylgermane: MS (70 eV) *m/z* 131 (100), 113 (5), 105 (40), 97 (8), 89 (10), and 70 (8).

Bis(pentamethyldigermyl)ethane: MS (70 eV) *m/z* 470 (6), 425 (9), 323 (19), 221 (100), 206 (19), 119 (97), and 89 (9).

Styryltrimethylgermane: MS (70 eV) *m/z* 222 (9), 207 (100), 191 (14), 151 (10), 117 (10), 105 (73), 89 (23), 77 (5).

1-Styrylheptamethyltrigermane: MS (70 eV) *m/z* 428 (1), 413 (8), 325 (36), 293 (12), 221 (64), 207 (40), 119 (100), 105 (16), and 89 (12).

Benzyldimethyldigermanoxane: MS (70 eV) *m/z* 402 (6), 387 (6), 285 (100), 219 (6), 194 (15), and 119 (19).

1-Benzyltetramethylchlorodigermane: MS (70 eV) *m/z* 332 (9), 297 (9), 241 (59), 195 (86), 119 (6), 195 (100).

Dibenzyldimethylgermane: MS (70 eV) *m/z* 286 (6), 195 (100), 165 (9), and 91 (90).

1-Benzyl-1,1,2,2-tetramethyldigermane: MS (70 eV) *m/z* 283 (8), 207 (82), 195 (40), 165 (38), 119 (100), 105 (20), and 91 (80).

Photochemical Reactions of Vinyl-, Styryl-, and Benzyl-Substituted Digermanes. A typical photochemical experiment was as follows: The digermane (ca. 200 mg) was dissolved in dry cyclohexane (6 ml) in a quartz tube. The tube was degassed under vacuum and the atmosphere was replaced with argon. The sample was irradiated with a 110 W low-pressure Hg arc lamp (Sen Tokushu Kogen Co. Ltd.) at room temperature. After irradiation, the photoproducts were identified by comparing the retention times and GC-MS with those of authentic samples.

This research was supported in part by Grant-in-Aid for Scientific Research on Priority Nos. 0164518, 02231227, and 02640387 from the Ministry of Education, Science and Culture.

(Received April 30, 1991)

The high-pressure Diels–Alder reaction of tropones with 2-cyclopenten-1-one afforded isomeric mixtures of adducts. Upon UV irradiation, these adducts isomerized to hexahydro-*as*-indacene, via [1,3] acyl migration, and tetracyclo[7.3.0.0^{3,7}.0^{6,8}]undecene derivatives through a ketene intermediate via a di-π-methane rearrangement. The former tricyclic system corresponds to the carbon skeleton of ikarugamycin. An "*exo* [6+4] adduct" of tropone and 1,4-cyclopentadien-1-ol, an enol form of 2-cyclopentenone, was obtained as a by-product.

Tropones, electron-deficient cyclic trienones, are known to form Diels–Alder adducts with various electron-deficient dienophiles such as maleic anhydride,[2] *N*-phenylmaleimide,[3] and acrylonitrile.[4] Application of a high-pressure technique made even less-reactive dienophiles feasible; recently we examined the reaction of tropones with *p*-benzoquinones.[5] This prompted us to investigate further cycloaddition with an enone such as 2-cyclopenten-1-one, which afforded no product under 1 bar (1 bar=10^5 Pa.).

Since the photoisomerization of dihydrohomobarrelenones to dihydroindenones is well-known,[6] Diels–Alder adducts from a cyclic enone and tropone were expected to form tricyclic analogs.

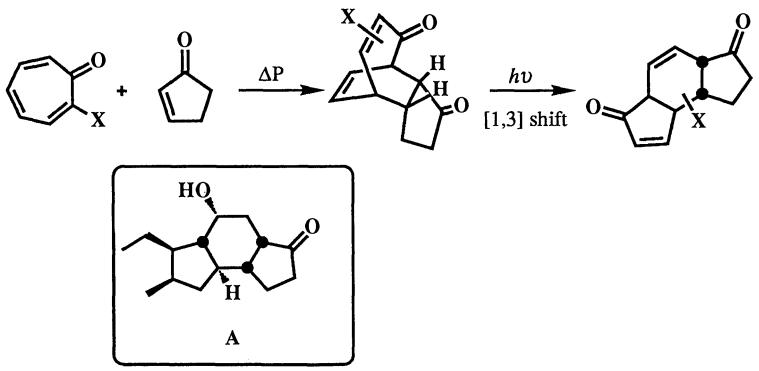
In this paper, we report high-pressure Diels–Alder reactions between tropones and 2-cyclopenten-1-one and the subsequent photoconversion to a tricyclic compound, which has a framework similar to the decahydro-*as*-indacene subunit (**A**) of ikarugamycin.[7]

Results and Discussion

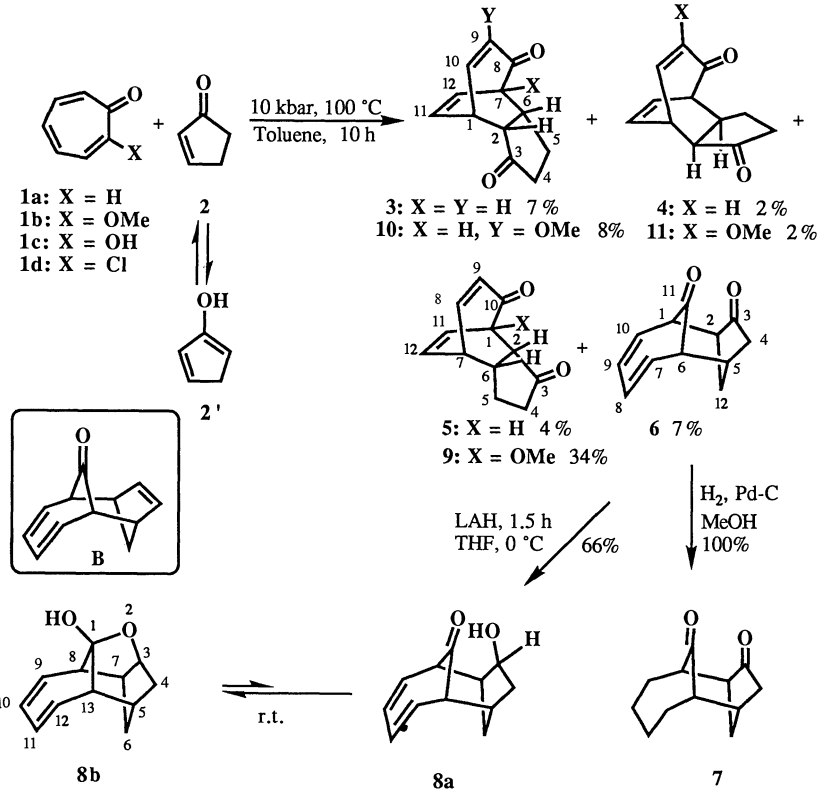
Cycloaddition Reaction. When a toluene solution of tropone (**1**) and 2-cyclopenten-1-one (**2**) was heated at 100 °C for 10 h under 10 kbar, four 1:1-adducts (**3**—**6**) were obtained. The dihydrohomobarrelenone framework for **3**, **4**, and **5** was evident from NMR spectra; e.g., the ^{1}H NMR spectrum of **3** showed the signal of the doublet of doublets at δ=7.12 (J=11.0, 8.4 Hz), ascribable to the β-proton of the α,β-unsaturated ketone. The stereochemistry of the methine protons H-2 and H-6 was determined to be exo by the value ($J_{1,2}$=0 Hz) of the coupling constant. The position of the carbonyl group was found to be at C-3 by analysis of the 2D COSY spectrum, where H-6 showed a correlation with H-12. Therefore, **3** was shown to be tricyclo[5.3.2.0^{2,6}]dodeca-9,11-diene-3,8-dione.

The second product, **4**, was determined to be an *exo* [4+2] adduct from the magnitudes ($J_{1,2}$=5.5 Hz and $J_{6,7}$=8.1 Hz) of the coupling constants of H-1 at δ=3.77 and H-7 at δ=3.71. The third product **5** was another *endo* [4+2] adduct as shown by the coupling constant ($J_{6,7}$=0 Hz), and the position of the carbonyl group was determined to be on C-3.

The spectral data of the remaining product, **6**, was quite different from those of the [4+2] adducts (**3**—**5**); showing no signal lower than δ=6.1 eliminated a [4+2]



Scheme 1.



Scheme 2.

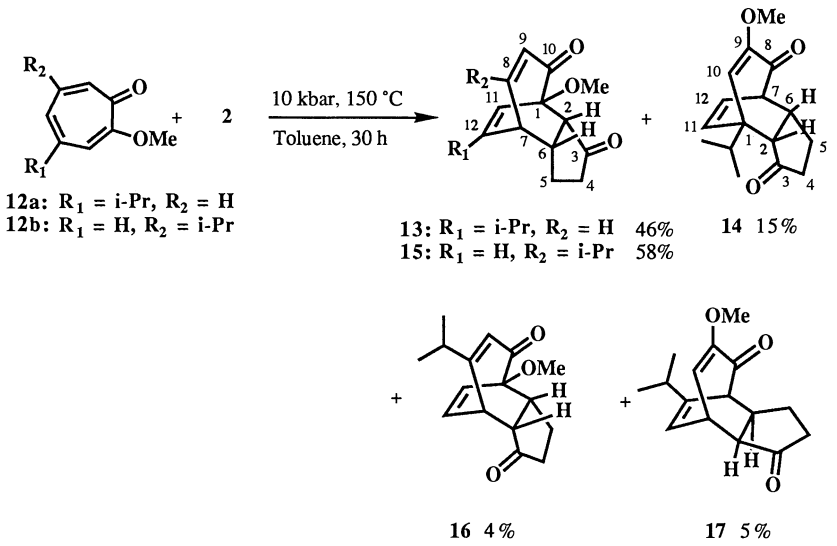
structure. In addition, the ^{1}H NMR spectrum of **6** exhibited four olefinic protons, which also eliminated an [8+2] structure. Its IR spectrum showed two carbonyl absorptions at 1736 and 1713 cm^{-1}; the latter is similar to the absorption (1715 cm^{-1}) of the [6+4] adduct (**B**) between **1a** and cyclopentadiene.[8] The UV spectrum of **6** also resembled that of **B**. These observations are consistent with those of tricyclo[4.4.1.1^{2,5}]dodeca-7,9-diene-3,11-dione, which can be derived from **1a** and 1,4-cyclopentadien-1-ol, an enol form of **2**. One of the two sets of methylene proton pairs [δ=1.84 (dt, J=13.0, 4.8 Hz) and 2.66 (dd, J=13.0, 4.0 Hz), and 2.37 (dd, J=19.1, 4.0 Hz) and 2.58 (dd, J=19.1, 7.1 Hz)] revealed a large *gem*-spin coupling constant which indicated the presence of a CO–CH$_2$ group.

In order to determine the stereochemistry, **6** was hydrogenated to a tetrahydro derivative (**7**). However, the signals of the methylene protons overlapped each other in the ^{1}H NMR spectrum. This indicated that the methylene protons at δ=1.84 and 2.26 and the diene part of **6** are in proximity. Furthermore, upon lithium aluminum hydride (LAH) reduction, **6** gave a dihydro derivative, which showed broad signals, indicating an equilibration between the ketol form (**8a**) and the hemiacetal form (**8b**) at room temperature. Thus, **6** was shown to be an *exo*-adduct. We also observed a temperature-dependent equilibrium, i.e., a 14:86 mixture of **8a** and **8b** at 0 °C, while only **8b** was detected at -50 °C. The ^{1}H NMR spectral coupling sequence of **8b** was analyzed by means of decoupled NMR experiments at 0 °C. Two allylic protons signals (H-7 and H-12) appeared at δ=2.94 (dd, J=6.6, 4.0 Hz) and 2.70 (dd, J=7.7, 3.0 Hz), which were coupled with olefinic protons at δ=5.59 (H-8, dd, J=11.7, 7.3 Hz) and 5.61 (H-11, dd, J=11.7, 6.6 Hz), respectively. The absence of spin coupling of these two allylic protons with H-2 at δ=4.59 (m), the proton on the etheral carbon, led us to the conclusion that the structure of **8b** was 2-oxatetracyclo[6.5.0^{3,7}.0^{5,13}]trideca-9,11-dien-1-ol.

The reason why the five-membered carbonyl group was predominantly reduced was speculated as follows: since a five-membered ring has a larger bond-angle strain than a seven-membered ring, the change from an sp^2 carbon to an sp^3 carbon of the five-membered carbonyl group would be accelerated to release the strain.[9] Alternatively, the preferential reduction of the five-membered cabonyl group was explained by the Cieplak stereoelectronic effect,[10] since the five-membered carbonyl group had a C–H bond antiperiplanar to the incipient σ* orbital.

Similar explanations would apply to the predominant acetal formation with the confronted hydroxyl group in **8** since the seven-membered carbonyl group in a fused system was more hindered than a monocyclic moiety.

The reaction between 2-methoxytropone (**1b**) and **2** under 10 kbar gave three products (**9**—**11**). The



Scheme 3.

structures were determined by the ^{1}H NMR spectral comparison with those of the [4+2] adducts (**3**—**5**). In this case, no [6+4] adduct was detected. Attempted reactions between tropolone (**1c**) and 2-chlorotropone (**1d**) with **2** were unsuccessful; from **1d**, only a resinous material was obtained, and from **1c**, no product other than the starting material was recovered in 80% yield.

Furthermore, reactions between 4-isopropyl- and 6-isopropyl-2-methoxytropones (**12a** and **12b**) and **2** afforded two adducts (**13** and **14**) from **12a** and three adducts (**15**—**17**) from **12b**, respectively.

The ^{1}H NMR spectrum of the main product **13** from **12a** showed the typical doublet of doublets of a [4+2] adduct at δ=7.11 (J=11.0, 8.4 Hz) and a doublet at δ=3.00 (J=9.2 Hz). Since the latter was assigned to the α-methine proton of the carbonyl group, **13** was deduced to be an *endo* [4+2] adduct. The position of the carbonyl group was deduced from the structure of the photorearrangement product as will be discussed later.

One of the olefinic protons of **14** appeared as a singlet at δ=5.77 and two remaining protons coupled with each other, whose coupling constant (J=8.4 Hz) implied that a methoxyl group was located at C-9 of the bridge and an isopropyl group was at the bridgehead, C-1. Since the α-methine proton of the carbonyl group appeared as a doublet (J=8.8 Hz) at δ=2.90, **14** was another *endo* [4+2] adduct.

From the ^{1}H NMR spectrum, the main product **15** from **12b** was deduced to have an isopropyl group at C-8 from the coupling constants of the olefinic protons, two of which coupled with each other (J=9.2 Hz). Since the bridgehead proton H-7 appeared as a doublet (J=7.3 Hz), being coupled with the olefinic proton at C-12, **15** was an *endo* [4+2] adduct. However, the position of the carbonyl group was not unambiguously determined at this stage.

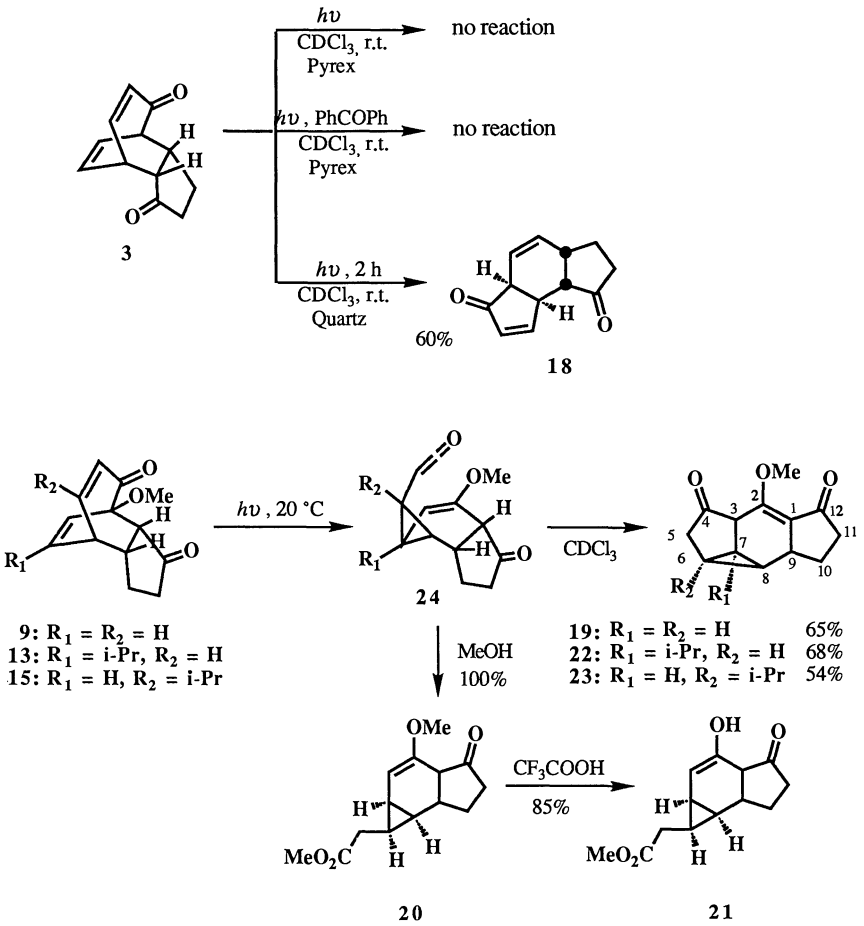
The patterns of three olefinic protons of **16** were similar to those of **15**, indicating a similar type of reaction. Since the signal of H-2 at δ=2.73 was a doublet, which meant $J_{1,2}$=0 Hz, **16** was an *endo* [4+2] adduct. Therefore, **16** was a regioisomer of **15**.

The positions of the methoxyl and isopropyl groups of **17** were deduced by the observation of only two olefinic proton signals in the ^{1}H NMR spectrum. The bridgehead proton, H-1, appeared as a doublet of doublets of doublets (J=9.2, 7.3, 5.5 Hz), which meant that H-1 coupled with the methine proton, H-2, with a coupling constant of 5.5 Hz. Therefore, **17** was an *exo* [4+2] adduct. Since the splitting pattern of H-2, a doublet of doublets, indicated two adjacent protons, the position of the carbonyl group was at C-3.

Thus, tropones reacted with **2** mostly as a 4π-cycloaddend. The regioselectivity of **1b** was parallel to those previously reported.[11] It is quite interesting that **2** behaved as a 4π-component in the reaction with **1a**.[12]

Photochemical Reaction. Upon UV-light irradiation by means of a 400-W high-pressure mercury lamp through a quartz filter in deuteriochloroform ($CDCl_3$), **3** gave a single product, **18**, in 60% yield while no reaction occurred upon irradiation through a Pyrex filter with or without benzophenone, a triplet sensitizer. The ^{1}H NMR spectrum of **18** showed four olefinic protons, in which the signals at δ=7.59 (dd, J=5.6, 2.6 Hz) and 6.19 (dd, J=5.6, 2.4 Hz) indicated the generation of a cyclopentenone moiety. The sequential alignment of four methine protons was determined by the values of the coupling constants. Since the doublet signal (J=7.2 Hz) at δ=2.56 was assigned to be an H-3a proton at the terminal position of the alignment, this indicated the structure of **18** was *cis-transoid-cis*-2,3,3a,5a,8a,8b-hexahydro-*as*-indacene-1,6-dione.

The irradiation of **9** in $CDCl_3$ through a Pyrex filter



Scheme 4.

gave a single product **19**, whose ^{13}C NMR spectrum showed two carbonyl groups at δ=201.8 and 212.8 and two olefinic carbons at δ=114.2 and 160.7, assignable to a vinyl ether. Since no C=C double bonds were observed, **19** was a tetracyclic enedione. A pair of methylene protons at δ=2.03 and 2.78 was assigned to be H-5α and H-5β since the proton at δ=2.78 coupled with H-3 at δ=3.74. Therefore, the double bond was located between C-1 and C-2. Furthermore, H-3 coupled with H-7 at δ=2.00, which further split to a doublet of doublets (J=8.1 and 7.7 Hz) to indicate the presence of a cyclopropane ring. Therefore, **19** was 2-methoxytetracyclo[7.3.0.0^{3,7}.0^{6,8}]undec-1-ene-4,12-dione.

When **9** was irradiated in methanol, a methyl ester, **20**, was obtained. The olefinic proton appeared at δ=4.64 as a doublet (J=4.0 Hz), which coupled with one of three cyclopropane ring protons at δ=1.57 (td, J=8.4 and 4.0 Hz). The coupling constants among protons on the cyclopropane ring showed *cis*-geometry.

Photoproduct **20** gave a demethylated product, **21**, in 85% yield in trifluoroacetic acid.

Similarly, irradiations of **13** and **15** gave tetracyclic derivatives **22** and **23**, respectively. Their ^1H and ^{13}C NMR spectra as well as UV data were similar to those of **19**. Therefore, the positions of the carbonyl groups in the five-membered rings of **13**, **15**, and **16** were determined as shown.

A substituent at the bridgehead affected the photoisomerization course of the [4+2] cycloadducts. Photoreactions of **9**, **13**, and **15**, all of which have a methoxyl group at the bridgehead position, gave tetracyclic derivatives, whereas photoreaction of **3** gave the tricyclic compound **18**. The formation of tetracyclic derivatives was due to the electron-releasing nature of the methoxyl group at the bridgehead.

The formation of a methyl ester, **20**, constitued an intermediacy of a ketene, **24**. In $CDCl_3$, **24** was trapped as **23** via an intramolecular path.

In the photoreaction of **3**, no product formed from either direct irradiation in a Pyrex tube or sensitized irradiation with benzophenone in a Pyrex tube. These data clearly indicate that **3** isomerized to **18** via a π, π^* singlet state, a [1,3] acyl shift. The predominant [1,3] acyl migrations of **3** were similar to those of the dihydrohomobarrelenones[6] and benzohomobarrelenone.[13]

Experimental

Elemental analyses were performed by Miss S. Hirashima and Miss T. Mizoguchi, of Institute of Advanced Material Study, Kyushu University. NMR spectra were measured by JEOL FX 100 Model, JEOL GSX 270 H Model, and GSX-500 Model spectrometers in a $CDCl_3$ solution (unless otherwise specified); chemical shifts were expressed in the unit δ. Mass spectra were measured with a JEOL O1SG-2 spectrometer. IR spectra were taken as KBr disks or as a liquid film inserted between NaCl plates using a JASCO IR-A 102 spectrometer. UV spectra were measured by a Hitachi U-3200 spectrophotometer. HPLC separation was performed on a Waters Type 510 system with a UV-detecter and a Microporasil column.

Cycloaddition Reaction of 1a and 2. A toluene solution (4 cm³) of **1a** (424 mg) and **2** (640 mg) was heated at 100 °C for 10 h under 10000 bar. The solvent was removed under reduced pressure and the residue was purified by SiO_2 column chromatography and HPLC (AcOEt:hexane=1:1) to give 53 mg (7%) of **3**, 14 mg (2%) of **4**, 27 mg (4%) of **5**, and 55 mg (7%) of **6**.

3: Colorless crystals, mp 73—74 °C; ^{1}H NMR δ=1.6—1.8 (1H, m), 2.2—2.4 (2H, m), 2.94 (1H, br d, J=10.3 Hz), 3.0—3.1 (1H, m), 3.49 (1H, dm, J=7.3 Hz), 3.67 (1H, ddd, J=8.4, 7.3, 1.8 Hz), 5.77 (1H, ddd, J=11.0, 1.8, 0.7 Hz), 6.14 (1H, ddm, J=8.4, 7.3 Hz), 6.47 (1H, dd, J=8.4, 7.3 Hz), and 7.12 (1H, dd, J=11.0, 8.4 Hz); ^{13}C NMR δ=27.0, 36.8, 37.9, 39.8, 53.7, 59.3, 127.0, 130.4, 138.0, 151.9, 196.3, and 217.0; IR (KBr) 3048, 2956, 1726, 1656, 1626, 1387, 1269, 1248, 1178, 801, and 706 cm^{-1}; UV (MeOH) 224 (ε 5200) and 242 nm (3900 sh); MS m/z (%) 188 (M$^+$, 40), 160 (68), 131 (58), 118 (61), 104 (76), 103 (51), 78 (74), 77 (41), 56 (41), 55 (50), 51 (75), 39 (87), 28 (100), and 26 (89).

Found: m/z 188.0835 (M$^+$). Calcd for $C_{12}H_{12}O_2$: M, 188.0836.

4: A colorless oil; ^{1}H NMR δ=1.5—1.7 (1H, m), 2.1—2.3 (2H, m), 2.45 (1H, dddd, J=19.1, 11.4, 9.9, 1.5 Hz), 2.86 (1H, ddd, J=11.4, 5.5, 0.7 Hz), 3.10 (1H, ddd, J=11.4, 8.4, 8.1 Hz), 3.71 (1H, ddm, J=8.4, 8.1 Hz), 3.77 (1H, dddm, J=8.4, 8.1, 5.5 Hz), 5.79 (1H, ddd, J=11.0, 1.8, 1.1 Hz), 6.22 (1H, ddd, J=8.4, 7.3, 0.7 Hz), 6.56 (1H, ddd, J=8.1, 7.3, 0.7 Hz), and 7.04 (1H, dd, J=11.0, 8.4 Hz); ^{13}C NMR δ=24.2, 37.7, 38.0, 40.1, 53.8, 58.0, 129.3, 131.2, 137.5, 153.0, 197.4, and 218.0; IR (oil) 3046, 2950, 1738, 1701, 1659, 1628, 1387, 1326, 1240, 1170, 1015, 809, 711, and 675 cm^{-1}; UV (MeOH) 223 nm (ε 3400); MS m/z (%) 188 (M$^+$, 52), 160 (87), 132 (40), 131 (87), 118 (44), 117 (55), 104 (100), 103 (47), 91 (47), 78 (8), 77 (60), 51 (68), 39 (59), 28 (53), and 26 (78).

Found: m/z 188.0835 (M$^+$). Calcd for $C_{12}H_{12}O_2$: M, 188.0836.

5: A colorless oil; ^{1}H NMR δ=1.50 (1H, m), 2.2—2.5 (3H, m), 2.75 (1H, d, J=10.7 Hz), 3.21 (1H, br t, J=8.6 Hz), 3.28 (1H, br t, J=8.4 Hz), 3.84 (1H, dm, J=8.1 Hz), 5.73 (1H, ddd, J=11.1, 2.1, 1.6 Hz), 6.12 (1H, ddm, J=8.1, 7.2 Hz), 6.50 (1H, ddm, J=8.4, 7.2 Hz), and 7.15 (1H, dd, J=11.1, 8.4 Hz); ^{13}C NMR δ=26.9, 40.2, 41.6, 42.6, 47.9, 54.1, 127.8, 129.7, 137.5, 152.8, 195.3, and 215.9; IR (oil) 3046, 2960, 1737, 1668, 1629, 1391, 1265, 1116, 797, and 705 cm^{-1}; UV (MeOH) 229 nm (ε 5200); MS m/z (%) 188 (M$^+$, 100), 164 (57), 131 (63), 117 (28), 104 (34), 91 (44), 78 (39), 55 (42), 39 (42), and 27 (33).

Found: m/z 188.0836 (M$^+$). Calcd for $C_{12}H_{12}O_2$: M, 188.0836.

6: Colorless crystals, mp 163—164 °C; ^{1}H NMR δ=1.84 (1H, dt, J=13.0, 4.8 Hz), 2.37 (1H, dd, J=19.1, 4.0 Hz), 2.58 (1H, dd, J=19.1, 7.1 Hz), 2.66 (1H, dd, J=13.0, 4.0 Hz), 2.8—2.9 (1H, m), 3.23 (1H, dt, J=7.5, 4.0 Hz), 3.32 (1H, dt, J=7.5, 4.0 Hz), 5.60 (1H, dd, J=11.5, 7.5 Hz), 5.73 (1H, ddd, J=11.5, 7.5, 4.8 Hz), and 6.0—6.05 (2H, m); ^{13}C NMR δ=26.7, 40.1, 47.2, 54.8, 57.6, 59.6, 125.1, 126.5, 127.1, 127.7, 207.0, and 215.4; IR (KBr) 3038, 2956, 1736, 1713, 1397, 1195, 1161, 1021, 862, and 709 cm^{-1}; UV (MeOH) 213 (ε 3100), 222 (2600, sh), 262 (3200), 269 (3100), and 300 nm (260, sh); MS m/z (%) 188 (M$^+$, 100), 129 (24), 117 (44), 91 (32), 81 (30), 69 (58), 55 (22), 43 (20), 41 (38), 39 (27), 28 (99), and 26 (23).

Found: C, 76.71; H, 6.43%. Calcd for $C_{12}H_{12}O_2$: C, 76.57; H, 6.43%.

Catalytic Hydrogenation of 6. A MeOH solution (5 cm³) of **6** (40 mg) was stirred under H_2 atmosphere for 30 min in the presence of Pd/C (10 mg). The catalyst was filtered and the solvent was removed under reduced pressure. The residue was chromatographed on a SiO_2 column (AcOEt:hexane=1:1) to give 40.9 mg (100%) of **7**.

7: A colorless oil; ^{1}H NMR δ=1.6—1.7 (4H, m), 1.75—2.0 (5H, m), 2.07 (1H, dd, J=19.1, 3.6 Hz), 2.23 (1H, ddd, J=19.1, 6.6, 0.7 Hz), 2.54 (1H, m), 2.65 (1H, m), and 2.7—2.8 (3H, m); ^{13}C NMR δ=26.6, 26.8, 27.7, 28.0, 28.3, 38.2, 44.2, 53.1, 53.4, 55.1, 212.3, and 216.7; IR (oil) 2930, 2866, 1741, 1707, 1478, 1453, 1405, 1208, 1154, 1100, 1017, and 983 cm^{-1}; MS m/z (%) 192 (M$^+$, 100), 164 (31), 119 (23), 93 (28), 81 (23), 80 (28), 79 (38), 67 (34), 41 (29), 39 (26), and 26 (23).

Found: m/z 192.1150 (M$^+$). Calcd for $C_{12}H_{16}O_2$: M, 192.1151.

Lithium Aluminum Hydride Reduction of 6. A dry THF solution (3 cm³) of **6** (30 mg) was stirred with LAH (1.7 mg) at 0 °C for 1.5 h. A small portion of sat. NaCl solution was then added. The THF solution was concentrated and the residue was chromatographed on PTLC (20 cm×10 cm,

AcOEt:hexane=1:1) to give 20 mg (66%) of **8**.

8: Colorless crystals, mp 103—103.5 °C; ^{1}H NMR at −50 °C, δ=1.25 (1H, ddd, J=12.5, 6.6, 3.3 Hz), 1.53 (1H, dt, J=12.1, 4.7 Hz), 2.02 (1H, dd, J=12.5, 2.9 Hz), 2.10 (1H, dd, J=12.1, 2.9 Hz), 2.45 (1H, br s), 2.70 (1H, dd, J=7.7, 3.0 Hz), 2.81 (1H, dd, J=6.6, 5.5 Hz), 2.94 (1H, dd, J=6.6, 4.0 Hz), 4.59 (1H, m), 5.36 (1H, br s), 5.59 (1H, dd, J=11.7, 7.3 Hz), 5.61 (1H, dd, J=11.7, 6.6 Hz), 5.90 (1H, dd, J=11.7, 7.0 Hz), and 6.03 (1H, dd, J=11.7, 7.3 Hz); ^{13}C NMR δ=30.4, 44.0, 44.2, 44.6, 50.7, 55.7, 78.1, 99.6, 126.2, 128.2, 128.8, and 130.6; IR (KBr) 3318, 3010, 2942, 1373, 1268, 1158, 1057, 981, 972, 961, 850, and 700 cm^{-1}; MS m/z (%) 190 (M^+, 100), 145 (40), 130 (86), 129 (46), 128 (53), 124 (44), 117 (55), 107 (65), 105 (59), 91 (83), 79 (99), 78 (49), 77 (63), 67 (44), and 39 (61).

Found: C, 75.77; H, 7.37% and m/z 190.0994 (M^+). Calcd for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42% and 190.0993 (M).

Cycloaddition Reaction of 1b and 2. A toluene solution (2 cm^3) of **1b** (136 mg) and **2** (160 mg) was heated at 120 °C for 12 h under 10000 bar. The solvent was removed under reduced pressure and the residue was purified by SiO_2 column chromatography and HPLC (AcOEt:hexane=1:1) to give 74 mg (34%) of **9**, 18 mg (8%) of **10**, and 5 mg (2%) of **11**.

9: A colorless oil; ^{1}H NMR δ=1.6—1.7 (1H, m), 2.1—2.5 (3H, m), 3.02 (1H, d, J=9.5 Hz), 3.05—3.15 (1H, m), 3.36 (1H, ddd, J=8.4, 7.3, 1.1 Hz), 3.64 (3H, s), 5.78 (1H, dd, J=11.0, 0.7 Hz), 6.11 (1H, dd, J=9.2, 0.7 Hz), 6.59 (1H, dd, J=9.2, 7.3 Hz), and 7.10 (1H, dd, J=11.0, 8.4 Hz); ^{13}C NMR δ=27.0, 40.1, 40.7, 43.2, 50.5, 54.3, 88.5, 128.2, 131.6, 134.9, 151.9, 193.7, and 212.8; IR (oil) 3030, 2944, 1743, 1677, 1638, 1380, 1211, 1153, 1110, 987, 697, and 681 cm^{-1}; MS m/z (%) 218 (M^+, 70), 189 (22), 161 (25), 147 (95), 121 (43), 108 (100), 91 (45), 78 (40), 65 (61), 56 (39), 51 (33), 44 (39), 40 (76), and 27 (54).

Found: C, 71.23; H, 6.43% and m/z 218.0941 (M^+). Calcd for $C_{13}H_{12}O_3$: C, 71.54; H, 6.47% and 218.0942 (M).

10: Colorless crystals, mp 87—89 °C; ^{1}H NMR δ=1.65—1.8 (1H, m), 2.2—2.4 (3H, m), 2.89 (1H, dm, J=10.3 Hz), 3.0—3.1 (1H, m), 3.55 (3H, s), 3.65 (1H, dm, J=7.3 Hz), 3.72 (1H, ddm, J=9.5, 7.3 Hz), 6.11 (1H, d, J=9.5 Hz), 6.12 (1H, dd, J=8.4, 7.3 Hz), and 6.54 (1H, ddd, J=8.4, 7.3, 1.1 Hz); ^{13}C NMR δ=26.8, 35.2, 36.6, 39.6, 54.3, 54.9, 58.4, 118.7, 126.5, 139.4, 151.4, 192.0, and 217.4; IR (KBr) 3058, 2950, 1736, 1672, 1631, 1615, 1372, 1228, 1128, 1098, 835, 820, and 772 cm^{-1}; UV (MeOH) 232 (ε 2600) and 278 nm (2300); MS m/z (%) 218 (M^+, 100), 164 (28), 147 (24), 131 (28), 108 (56), 91 (49), 78 (29), 65 (26), 39 (31), and 26 (24).

Found: m/z 218.0942 (M^+). Calcd for $C_{13}H_{14}O_3$: M, 218.0942.

11: Colorless crystals, mp 104—105 °C; ^{1}H NMR δ=1.5—1.65 (1H, m), 2.1—2.25 (2H, m), 2.3—2.5 (1H, m), 2.77 (1H, ddd, J=11.7, 5.5, 1.1 Hz), 3.0—3.15 (1H, m), 3.50 (3H, s), 3.79 (1H, dddd, J=9.2, 7.3, 5.5, 1.1 Hz), 3.87 (1H, dd, J=7.3, 6.6 Hz), 5.99 (1H, d, J=9.2 Hz), 6.20 (1H, dd, J=8.4, 7.3 Hz), and 6.64 (1H, dd, J=8.4, 7.3 Hz); ^{13}C NMR δ=24.1, 34.7, 37.8, 40.1, 52.9, 55.1, 56.6, 118.3, 128.5, 139.1, 152.3, 192.8, and 218.2; IR (KBr) 3044, 2924, 1736, 1672, 1616, 1372, 1225, 1118, 824, and 764 cm^{-1}; UV (MeOH) 226 (ε 2400) and 280 nm (3100); MS m/z (%) 218 (M^+, 100), 175 (20), 174 (35), 131 (31), 130 (46), 105 (22), 91 (40), and 78 (25).

Found: C, 71.49; H, 6.76%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%.

Cycloaddition Reaction of 1c and 2. A toluene solution (2 cm^3) of **1c** (143 mg) and **2** (160 mg) was heated at 100 °C for 10 h under 10000 bar. The solvent was removed under reduced pressure to leave a polymerized material.

Cycloaddition Reaction of 1d and 2. A toluene solution (2 cm^3) of **1d** (122 mg) and **2** (160 mg) was heated at 120 °C for 12 h under 10000 bar. The solvent was removed under reduced pressure and 98 mg (80%) of **1d** was recovered after SiO_2 chromatography (AcOEt:hexane=1:1).

Cycloaddition Reaction of 12a and 2. A toluene solution (4 cm^3) of **12a** (360 mg) and **2** (320 mg) was heated at 120 °C for 50 h under 10000 bar. The solvent was removed under reduced pressure and the residue was purified by SiO_2 column chromatography and HPLC (AcOEt:hexane=1:2) to give 180 mg (46%) of **13**, 60 mg (15%) of **14**, and 87 mg (24%) of **12a**.

13: A colorless oil; ^{1}H NMR δ=1.05 (3H, d, J=7.3 Hz), 1.08 (3H, d, J=7.3 Hz), 1.5—1.6 (1H, m), 2.0—2.4 (4H, m), 3.00 (1H, d, J=9.2 Hz), 3.07 (1H, m), 3.15 (1H, d, J=8.4 Hz), 3.65 (3H, s), 5.62 (1H, s), 5.77 (1H, d, J=11.0 Hz), and 7.11 (1H, dd, J=11.0, 8.4 Hz); ^{13}C NMR δ=20.0, 20.7, 26.5, 34.9, 40.2, 40.4, 46.5, 49.8, 54.3, 88.0, 121.1, 128.6, 151.7, 154.8, 194.1, and 213.1; IR (oil) 2960, 2872, 1744, 1678, 1604, 1463, 1410, 1384, 1229, 1209, 1159, 1107, and 978 cm^{-1}; UV (MeOH) 228 (ε 5600), 281 (2200), 302 (1500), and 313 nm (1200); MS m/z (%) 261 (M^+ +1, 8), 260 (M^+, 39), 218 (23), 217 (100), 189 (8), 151 (15), and 83 (6).

Found: m/z 260.1412 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

14: A colorless oil; ^{1}H NMR δ=1.07 (3H, d, J=6.6 Hz), 1.18 (3H, d, J=6.6 Hz), 1.8—1.9 (1H, m), 2.2—2.25 (3H, m), 2.58 (1H, sept, J=6.6 Hz), 2.90 (1H, d, J=8.8 Hz), 3.03 (1H, ddm, J=8.8, 7.4 Hz), 3.54 (1H, d, J=7.3 Hz), 3.58 (3H, s), 5.77 (1H, s), 6.14 (1H, ddd, J=8.4, 7.3, 0.7 Hz), and 6.35 (1H, d, J=8.4 Hz); ^{13}C NMR δ=17.5, 18.4, 28.1, 31.4, 38.4, 40.6, 49.2, 53.6, 54.9, 58.7, 119.0, 124.9, 143.6, 150.2, 191.8, and 216.7; IR (oil) 3008, 2962, 2876, 1734, 1689, 1635, 1613, 1462, 1373, 1243, 1208, 1153, 1125, and 754 cm^{-1}; UV (MeOH) 228 (ε 2500) and 278 nm (2500); MS m/z (%) 261 (M^++1, 19), 260 (M^+, 100), 232 (34), 217 (49), 204 (19), 189 (20), 178 (49), 161 (20), 150 (40), 137 (19), and 135 (40).

Found: m/z 260.1411 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

Cycloaddition Reaction of 12b and 2. A toluene solution (2 cm^3) of **12b** (180 mg) and **2** (160 mg) was heated at 150 °C for 12 h under 10000 bar. The solvent was removed under reduced pressure and the residue was purified by SiO_2 column chromatography and HPLC (AcOEt:hexane=1:2) to give 153 mg (58%) of **15**, 11 mg (4%) of **16**, 13 mg (5%) of **17**, and 22 mg (12%) of **12b**.

15: A colorless oil; ^{1}H NMR δ=1.13 (3H, d, J=7.0 Hz), 1.14 (3H, d, J=7.0 Hz), 2.2—2.4 (4H, m), 2.52 (1H, sept, J=7.0 Hz), 2.9—3.0 (2H, m), 3.22 (1H, d, J=7.3 Hz), 3.63 (3H, s), 5.55 (1H, d, J=1.1 Hz), 6.10 (1H, d, J=9.2 Hz), and 6.51 (1H, dd, J=9.2, 7.3 Hz); ^{13}C NMR δ=20.1, 20.2, 27.6, 37.0, 40.1, 41.4, 47.2, 50.8, 54.1, 87.9, 121.0, 132.3, 134.0, 172.9, 194.1, and 213.1; IR (oil) 2960, 1743, 1669, 1463, 1411, 1385, 1211, 1167, 1113, and 663 cm^{-1}; UV (MeOH) 230 (ε 5900), 258 (3500), and 310 nm (700); MS m/z (%) 261 (M^++1, 21), 260 (M^+, 100), 217 (31), and 137 (14).

Found: m/z 260.1412 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

16: A colorless oil; ^{1}H NMR δ=1.13 (6H, d, J=6.6 Hz), 2.1—2.4 (4H, m), 2.52 (1H, sept, J=6.6 Hz), 2.73 (1H, dm, J=10.6 Hz), 3.14 (1H, dddd, J=10.6, 8.4, 7.0, 1.5 Hz), 3.57 (3H,

s), 3.59 (1H, dm, J=7.0 Hz), 5.63 (1H, t, J=1.5 Hz), 6.11 (1H, ddd, J=9.2, 1.5, 0.7 Hz), and 6.31 (1H, dd, J=9.2, 7.0 Hz); ^{13}C NMR δ=20.0, 20.2, 22.8, 37.1, 38.9, 41.1, 41.5, 53.0, 53.4, 89.0, 122.2, 131.8, 134.0, 172.4, 195.6, and 216.5; IR (oil) 2962, 2874, 1741, 1669, 1629, 1463, 1408, 1385, 1173, 1113, and 665 cm^{-1}; UV (MeOH) 228 (ε 5500), 259 (3400, sh), and 270 nm (2500, sh); MS m/z (%) 260 (M^+, 100), 217 (85), 204 (30), 203 (25), 189 (55), 173 (26), 161 (52), 108 (27), 91 (32), 77 (25), 41 (29), and 26 (30).

Found: m/z 260.1414 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

17: Colorless crystals, mp 96—98 °C; ^{1}H NMR δ=1.01 (6H, d, J=6.2 Hz), 1.6—1.65 (1H, m), 2.1—2.25 (2H, m), 2.3—2.4 (2H, m), 2.75 (1H, dd, J=11.3, 5.5 Hz), 3.00 (1H, ddt, J=11.3, 8.8, 6.2 Hz), 3.50 (3H, s), 3.72 (1H, ddd, J=9.2, 7.3, 5.5 Hz), 3.82 (1H, dd, J=6.2, 1.5 Hz), 6.02 (1H, d, J=9.2 Hz), and 6.18 (1H, dd, J=7.3, 1.5 Hz); ^{13}C NMR δ=20.7, 20.8, 24.0, 33.8, 34.5, 38.5, 40.1, 53.5, 55.0, 60.2, 119.3, 128.4, 147.8, 152.1, 193.5, and 218.6; IR (KBr) 3052, 2956, 2870, 1738, 1670, 1653, 1614, 1449, 1379, 1246, 1232, 1132, 999, and 881 cm^{-1}; UV (MeOH) 251 (ε 3300) and 277 nm (2400); MS m/z (%) 261 (M^++1, 18), 260 (M^+, 100), 232 (11), 217 (14), 178 (11), 164 (30), and 150 (41).

Found: m/z 260.1412 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

Irradiation of 3. a) A $CDCl_3$ solution (1 cm^3) of **3** (40 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 2 h at room temperature. The solvent was removed under reduced pressure and 38 mg (98%) of **3** was recovered.

b) A $CDCl_3$ solution (1 cm^3) of **3** (32 mg) and benzophenone (31 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 3 h at room temperature. The solvent was removed under reduced pressure and 27 mg (84%) of **3** was recovered after SiO_2 chromatography (AcOEt:hexane=1:1).

c) A $CDCl_3$ solution (1 cm^3) of **3** (25 mg) was purged with N_2 gas in a quartz NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 2 h at room temperature. The solvent was removed under reduced pressure and the residue was chromatographed on PTLC (20 cm×10 cm, AcOEt:hexane=1:2) to give 15 mg (60%) of **18**.

18: A colorless oil; ^{1}H NMR δ=1.94 (1H, dd, J=12.7, 9.1 Hz), 2.07 (1H, dddd, J=12.7, 11.5, 9.1, 6.4 Hz), 2.16 (1H, ddd, J=19.1, 11.5, 9.1 Hz), 2.28 (1H, dd, J=19.1, 9.1 Hz), 2.56 (1H, br d, J=7.2 Hz), 2.81 (1H, br s, $h_{1/2}$=16 Hz), 2.98 (1H, ddd, J=8.3, 4.8, 2.4 Hz), 3.74 (1H, ddd, J=7.2, 4.8, 2.6 Hz), 5.57 (1H, d, J=9.9 Hz), 5.77 (1H, ddd, J=9.9, 4.4, 2.4 Hz), 6.19 (1H, dd, J=5.6, 2.4 Hz), and 7.59 (1H, dd, J=5.6, 2.6 Hz); ^{13}C NMR δ=26.6, 33.0, 34.0, 39.1, 44.4, 50.2, 126.9, 129.9, 133.7, 166.2, 206.9, and 216.9; MS m/z (%) 188 (M^+, 76), 164 (65), 160 (100), 146 (40), 131 (40), 118 (80), 117 (48), 104 (62), and 91 (94).

Found: m/z 188.0834 (M^+). Calcd for $C_{12}H_{12}O_2$: M, 188.0836.

Irradiation of 9. a) A $CDCl_3$ solution (1 cm^3) of **9** (100 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 120 min at 20 °C. The solvent was removed under reduced pressure and the residue was purified by PTLC (20 cm×10 cm, AcOEt:hexane=1:1) to give 65 mg (65%) of **19**.

19: Colorless crystals, mp 104—104.5 °C; ^{1}H NMR δ=1.30 (1H, td, J=7.7, 1.7 Hz), 1.7—1.8 (2H, m), 2.00 (1H, ddd, J=8.1, 7.7, 6.4 Hz), 2.03 (1H, d, J=20.3 Hz), 2.31 (1H, dd, J=12.2, 5.0 Hz), 2.33 (1H, dd, J=9.0, 2.8 Hz), 2.35—2.45 (2H, m), 2.78 (1H, ddd, J=20.3, 6.5, 2.4 Hz), 3.74 (1H, dd, J=6.4, 2.4 Hz), and 4.04 (3H, s); ^{13}C NMR δ=15.6, 19.4, 21.5, 30.2, 33.8, 37.3, 39.1, 48.4, 59.8, 114.2, 160.7, 201.8, and 212.8; IR (KBr) 2950, 1735, 1708, 1613, 1409, 1291, 1194, and 756 cm^{-1}; UV (MeOH) 282 (ε 9400), 302 (6300), and 310 nm (5500); MS m/z (%) 218 (M^+, 100), 190 (34), 175 (48), 158 (43), 147 (27), 116 (36), 109 (84), 91 (40), 77 (31), 44 (25), 41 (31), 39 (30), and 28 (32).

Found: C, 71.81; H, 6.48% and m/z 218.0944 (M^+). Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47% and 218.0942 (M).

b) A MeOH solution (1 cm^3) of **9** (60 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 40 min at room temperature. The solvent was removed under reduced pressure and the residue was purified by means of PTLC (20 cm×10 cm, AcOEt:hexane=1:1) to give 64.2 mg (100%) of **20** and 4 mg of **9**.

20: A colorless oil; ^{1}H NMR δ=0.99 (1H, td, J=8.4, 2.6 Hz), 1.32 (1H, tt, J=8.4, 7.3 Hz), 1.57 (1H, td, J=8.4, 4.0 Hz), 1.9—2.5 (6H, m), 2.52 (1H, d, J=7.7 Hz), 2.60 (1H, m), 3.59 (3H, s), 3.69 (3H, s), and 4.64 (1H, d, J=4.0 Hz); ^{13}C NMR δ=15.0, 16.2, 19.7, 29.0, 29.3, 33.6, 35.7, 51.7, 52.3, 54.8, 90.1, 153.9, 173.9, and 215.9; IR (oil) 3000, 2950, 1733, 1660, 1438, 1377, 1353, 1313, 1270, 1208, 1173, 1129, 1038, 1009, and 810 cm^{-1}; MS m/z (%) 251 (M^++1, 8), 250 (M^+, 37), 163 (49), 149 (23), 121 (100), and 91 (19).

Found: C, 66.90; H, 7.04% and m/z 250.1199 (M^+). Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25% and 250.1204 (M).

Demethylation of 20 with CF_3COOH. A $CDCl_3$ solution (1 cm^3) of **20** (25 mg) and CF_3COOH (1 drop) was kept in an NMR tube overnight at room temperature. The solvent was removed under reduced pressure and the residue was chromatographed on a SiO_2 column (AcOEt:hexane=1:1) to give 20 mg (85%) of **21**.

21: Colorless crystals, mp 87—88 °C; ^{1}H NMR δ=1.09 (1H, br t, J=8.4 Hz), 1.3—1.35 (2H, m), 1.68 (1H, m), 2.0—2.1 (3H, m), 2.3—2.65 (5H, m), and 3.17 (3H, s); ^{13}C NMR δ=12.2, 14.6, 16.5, 23.4, 29.4, 31.4, 32.3, 37.5, 51.8, 112.0, 168.1, 173.3, and 207.0; IR (KBr) 3244, 2950, 2836, 1735, 1687, 1631, 1439, 1315, 1199, 1170, 1107, 1007, 841, and 753 cm^{-1}; UV (MeOH) 222 nm (ε 8400); MS m/z (%) 236 (M^+, 22), 205 (19), 186 (21), 177 (27), 163 (100), 162 (47), 161 (25), 158 (30), 149 (40), 123 (58), 121 (35), 109 (26), 91 (28), 82 (19), and 77 (26).

Found: C, 66.23; H, 6.82%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

Irradiation of 13. A $CDCl_3$ solution (1 cm^3) of **13** (50 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 2 h at room temperature. The solvent was removed under reduced pressure and the residue was chromatographed by PTLC (20 cm×10 cm, AcOEt:hexane=1:1) to give 34 mg (68%) of **22**.

22: A colorless oil; ^{1}H NMR δ=0.87 (3H, d, J=6.6 Hz), 0.99 (3H, d, J=6.6 Hz), 1.10 (1H, br d, J=8.1 Hz), 1.5—1.8 (3H, m), 2.12 (1H, d, J=20.5 Hz), 2.3—2.5 (4H, m), 2.80 (1H, ddd, J=20.5, 6.2, 2.2 Hz), 3.52 (1H, s), and 4.06 (3H, s); ^{13}C NMR δ=20.2 (2C) 20.6 (2C), 27.0, 30.5, 33.0, 34.4, 38.7, 39.3, 51.5, 59.4, 114.5, 161.7, 201.7, and 212.5; IR (oil) 2956, 2870, 1741, 1700, 1604, 1462, 1410, 1386, 1305, 1196, 1169, 1147, 1005, 841, and 621 cm^{-1}; UV (MeOH) 282 (ε 7300), 302 (4500), and 311 nm (3600); MS m/z (%) 261 (M^++1, 17), 260 (M^+, 100), 232

(7), 218 (31), 189 (13), and 151 (57).

Found: m/z 260.1412 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 260.1412.

Irradiation of 15. A $CDCl_3$ solution (1 cm^3) of **15** (100 mg) was purged with N_2 gas in a Pyrex NMR tube and the solution was irradiated by a 400-W high-pressure mercury lamp for 110 min at room temperature. The solvent was removed under reduced pressure and the residue was purified by SiO_2 chromatography and HPLC (AcOEt:hexane=1:1) to give 38 mg (54%) of **23** and 30 mg (30%) of **15**.

23: A colorless oil; ^1H NMR δ=0.95 (3H, d, J=6.6 Hz), 1.01 (3H, d, J=6.6 Hz), 1.11 (1H, d, J=8.8 Hz), 1.39 (1H, sept, J=6.6 Hz), 1.74 (1H, m), 1.75 (1H, dd, J=8.8, 6.6 Hz), 1.99 (1H, d, J=20.1 Hz), 2.38 (4H, m), 2.63 (1H, d, J=20.1 Hz), 3.75 (1H, d, J=6.6 Hz), and 4.02 (3H, s); ^{13}C NMR δ=19.5, 19.9, 24.8 (2C), 27.7, 30.5, 33.5, 34.0, 34.6, 39.0, 39.1, 49.6, 58.9, 114.1, 161.1, 201.8, and 211.9; IR (oil) 2956, 2872, 1742, 1702, 1611, 1462, 1416, 1387, 1366, 1199, 1167, 1147, 1004, and 842 cm^{-1}; UV (MeOH) 282 (ε 6200), 302 (4500), and 311 nm (3600); MS m/z (%) 261 (M^++1, 19), 260 (M^+, 93), 232 (46), 217 (47), 201 (19), 200 (100), 189 (20), 185 (32), 164 (28), 85 (32), and 83 (51).

Found: m/z 260.1413 (M^+). Calcd for $C_{16}H_{20}O_3$: M, 160.1412.

H-Aggregate of a Long-Chain Crystal Violet Dye in Langmuir-Blodgett Films[1)]

Akio MIYATA,* Yutaka UNUMA, and Yoshiyuki HIGASHIGAKI
Tokyo Research Laboratories, Sharp Corporation, Kashiwa, Chiba 277
(Received February 22, 1991)

The molecular orientation and aggregate formation in Crystal Violet (CV) dye monomolecular layers have been investigated by means of polarized reflection and absorption spectral measurements at an incident angle of 60°. A relatively sharp absorption band at 2.04 eV and a broad band around 2.23 eV assignable to the J-dimer and the H-dimer, respectively, were observed in the optical measurement geometry with polarized light either parallel(p) or perpendicular(s) to the incident plane. A sharp band at 2.61 eV, assigned to the H-aggregate (tetramer), was detected by p-polarized spectral measurement, but not s-polarized measurement. The J- and H-dimers have horizontal transition moments and the H-aggregate has a vertical transition moment. The H-aggregate peak shifted from 2.53 eV (10 mN m^{-1}) to 2.61 eV (40 mN m^{-1}) with increasing surface pressure. This is due to an increase in the slip angle between the transition dipole moments and their center-to-center lines because the chromophoric planes become to be gradually oriented normal to the water surface. The behavior of these aggregates is interpreted in terms of the extended dipole model.

Dye aggregates can easily be obtained in well-ordered layer structures using the Langumir–Blodgett (LB) method. Merocyanine,[2)] cyanine,[3)] and squarylium[4)] dyes form J- and H-aggregates and this has attracted much attention on account of their optical and electrical functions as photosensitizers. It is desirable to control the orientation and aggregation of the chromophores in layered structures with functions such as energy and electron transfer. Sugi et al. reported that J-aggregates in the merocyanine LB films show a high photoelectric conversion efficiency.[2)] In order to attain higher efficiency, several photoelectrical LB heterojunctions have been prepared.[5)] For example, the electrical and photoelectrical characteristics of organic p-n junction diodes consisting of an n-type Crystal Violet (CV) dye and a p-type merocyanine dye have been studied in comparison with homogeneous merocyanine LB films. Nakahara et al. reported that energy transfer occurred from the merocyanine J-aggregates to the CV dye in hetero-type LB films.[6)]

It is necessary to control the orientation and structure of dye aggregate in the monolayers for developing functional organic thin films with high quality and good structure. The molecular orientations in monolayers on water are determined by cohesive forces of chromophores, by hydrophobic interactions between long alkyl chains, and by adsorptive interactions between chromophores and the water surface. Möbius et al. reported that the orientation of chromophores and aggregates, i.e., dimer, J- and H-aggregates can be investigated by measurements of reflection spectra with linearly polarized light.[7-9)] The transition moments for a porphyrin, a cyanine dye, and an azo dye are oriented within the monolayer plane, with the exception of an azo dye H-aggregate which is oriented normal to the monolayer plane. In this paper we report the optical properties of the CV dye aggregates in the monolayer on water at various surface pressures and the LB films. The configuration of the dye aggregates are discussed in terms of Kuhn's extended dipole model.[10)]

Experimental

Materials. The Crystal Violet dye with a long alkyl chain was purchased from Nippon Kankoh-Shikiso Kenkyusho Co. and was used without further purificaiton. The chemical structure is shown in Fig. 1. Chloroform of spectroscopic grade was used for spreading the monolayers.

Procedures. The subphase was water containing $NaHCO_3$ at pH 6.7—6.8 and at 20—21 °C. Monolayers were spread on the subphase from a 4×10^{-4} M (1 M=1 mol dm^{-3}) chloroform solution of the dye. The measurements of surface pressure-area (π–A) isotherms and preparations of monolayers for absorption spectra were carried out by means of a conventional Langmuir trough (Joyce Loebl Ltd., model IV) equipped with a Wilhelmy balance. The absorption spectra of monolayers at incident angles of 0° and 60° were measured using a multichannel spectrophotometer (Otsuka Electronics Co., model MCPD-200) as illustrated in Fig. 2. The incident plane was perpendicular to the direction of compression. For absorption spectra measurements, the photodetector was positioned to detect only the beam reflected from the mirror and not that from the water surface. After spreading the solution, the monolayer was compressed to a predetermined surface pressure and maintained there for 5 min before starting spectral measurements. The substrates for visible

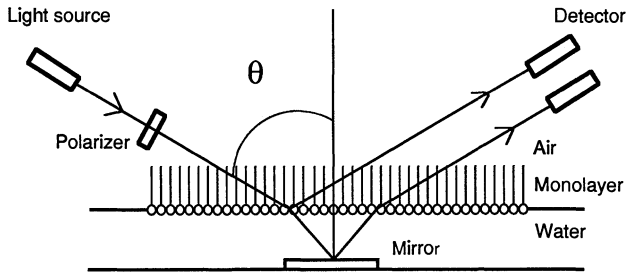

Fig. 2. Schematic diagram of polarized reflection and absorption measurements at an incident angle of 60°.

spectroscopic measurements were made fully hydrophilic by immersion in a 0.5 M KOH–ethanol solution. The monomolecular film was deposited onto a hydrophilic glass substrate by the vertical lifting method.

Results and Discussion

π–A Isotherm. Figure 3 shows a π–A isotherm for the monolayer of CV dye at the air–water interface. The CV dye gives a stable monolayer upto 50 mN m^{-1}. Various conformations of this dye can arise from free rotations of the phenylene rings and amino groups. The chromophore dimensions are about 13Å×14Å×5Å, and a planar close packed arrangement of the molecules on the water surface gives an area of about 120 Å^2 per molecule. The limiting area obtained by extrapolation of the linear portion in the π–A curve to π=0 is 50 Å^2 molecule^{-1}. This area is much too small to be consistent with the molecule lying flat on the water. Judging from this molecular area, the orientation of the chromophoric plane corresponds to lying horizontal on the water surface at 0—5 mN m^{-1}, and the molecules gradually overlap as the pressure increases and produces an upright structure at high surface pressures. For the mixed monolayer of the CV dye and cadmium arachidate, the π–A isotherms clearly gave two-step phase transitions from the expanded to condensed monolayers.[11] The marked two-step phase transitions are probably due to molecular reorientations, which did not depend on mixing ratios, but only on the change of surface pressures. It is possible that similar reorientation occurs in a neat dye monolayer.

Absorption Spectroscopy for Monolayer on Water. Figure 4 shows the normal incident absorption spectra at various surface pressures. An absorption band was observed at 2.04 eV at low surface pressures (0—5 mN m^{-1}). This 2.04 eV band is red-shifted from the monomer band (2.10 eV) in chloroform. The dye within the monolayer does not exist as isolated molecules but as a linear aggregate. The intensity of the 2.04 eV peak decreased with an increase in surface pressures from 10 to 40 mN m^{-1}, while that of the 2.24 eV peak increased. The 2.24 eV band is blue-shifted from the monomer band and assigned to an H-dimer. Its configuration is of a face-to-face structure consisting of two molecules

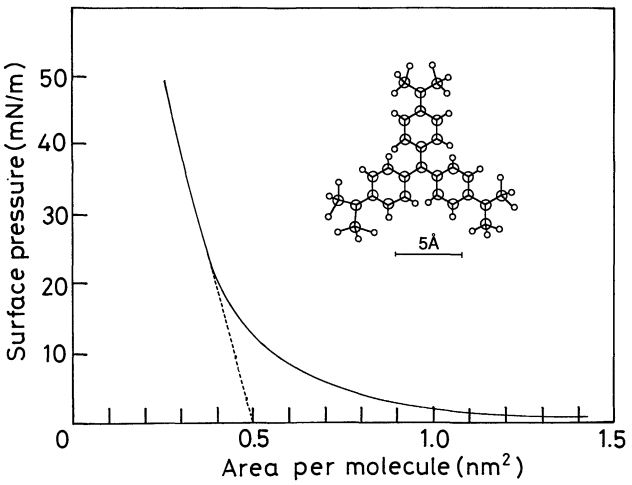

Fig. 3. Surface pressure-area isotherm for the monolayer of the CV dye.

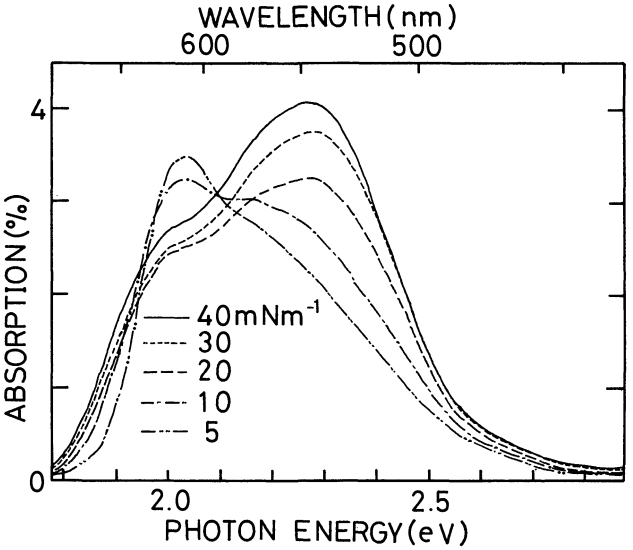

Fig. 4. Absorption spectra under normal incidence for the monolayer on water at various surface pressures.

oriented parallel to the water surface.

The molecular orientation and arrangement were further studied by measuring the polarized absorption spectra with an incident angle of 60°. The broad band around 2.23 eV was observed with polarized light either parallel(p) or perpendicular(s) to the incident plane as shown in Figure 5(a) and (b). On the contrary, the isotropic and sharp absorption band at 2.61 eV, which can be assigned to an H-aggregate, was observed in the p-polarized spectra between 20 and 40 mN m^{-1}, but not in the s-polarized spectra. Figure 6 shows the H-aggregate band detected with p-polarized light after substraction of H-dimer absorption spectra. The peak shifted from 2.53 eV at 10 mN m^{-1} to 2.61 eV at 40 mN m^{-1}. This blue-shift is due to an increase in the slip angle between the transition dipole moments and their center-to-center

lines with increasing surface pressures.

Reflection Spectroscopy. In order to confirm whether the chromophore lies flat or edge-on, reflection spectra were measured with an incident angle of 60°. Figure 7 shows the polarized reflection spectra of the monolayer on water at 40 mN m^{-1}. According to the Möbius' theory,[9] when the transition moment of the dye molecule lies within the surface water, s-polarized reflection (ΔR_s) with an incident angle of 60° should always be positive, and p-polarized reflection (ΔR_p) should be negative. If the transition moment is oriented normal to the water surface, ΔR_s is positive and ΔR_p cannot be observed. In the ΔR_s spectra (Fig. 7), a broad band around 2.15 eV, which is likely assigned to the H-dimer, is positive, while a sharp band assigned to the H-aggregate is almost absent. In the ΔR_p spectra, the broad H-dimer band is negative, while the H-aggregate band at 2.59 eV is positive. This result therefore supports our view that the transition moment for the H-dimer is oriented parallel to the surface plane, while that for the H-aggregate lies normal to the water surface.

Absorption Spectroscopy for Monomolecular Films on Substrate. Polarized absorption spectra were measured in order to examine whether the H-aggregates form in the LB film. The monomolecular LB film was

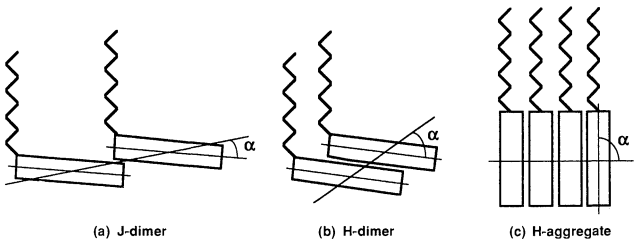

Fig. 9. Model of molecular configurations.

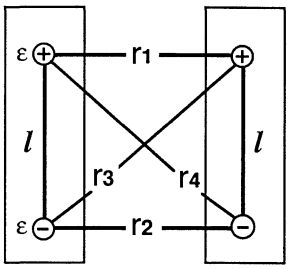

Fig. 10. An arrangement of two extended dipoles of charge ε and length l for calculation of the energy shift $\Delta E'$.

deposited at a surface pressure of 40 mN m^{-1} and a dipping speed of 6 mm min^{-1} under the same conditions for forming H-aggregate in monolayer on water. Figure 8 shows typical polarized absorption spectra of the LB film. The polarized absorption spectra of the LB film is similar to those of the monolayer on water. The H-aggregate band was observed at 2.55 eV. The red-shift from 2.61 eV (monolayer on water) to 2.55 eV indicates that the LB is in a more disordered state than the monolayer on water, and some fluctuations of the chromophores occurred during deposition process.

The Molecular Configuration Model. Figure 9 shows the models for molecular configuration to account for the present observations. Because the charged amino groups linked with three phenyl rings are anchored to the water surface, the dyes tend to assume a flat orientation at low surface pressures (0—5 mN m^{-1}). In view of the red-shifted absorption from the monomer band, dyes form a linear aggregate structure in model **a**. α is the slip angle between the transition dipole moments and their center-to-center lines. In this case the slip angle is small. At intermediate surface pressures (10—30 mN m^{-1}) the chromophores lie flat on the water surface or have an orientation with a relatively small angle between the chromophoric plane and the water surface. The dye molecule slips on the top of another adjacent molecule during film compression. The chromophoric planes are oriented parallel to each other and the dyes have a tace-to-face structure in model **b**. At high surface pressures (20—40 mN m^{-1}) the chromophoric planes are forced into an edge-on position and stack next to each other. In this case α is close to a right angle. The H-aggregate is indicated in model **c**. The appearance of this stacking structure is due to the strong dye–dye interaction between chromophoric planes with an edge-on position.

The Extended Dipole Model. Kuhn and associates proposed an extended dipole model to account for molecular arrangements in the blue- and red-shifted aggregates.[10] The interaction integrals between dye molecules in the aggregation are given by varying a series of parameters, i.e., the number of aggregate molecules, the dipole length, the slip angle α and the distance between the centers of dipoles. In Fig. 10, the molecules are replaced by extended dipoles of length l between two charges $+\varepsilon$ and $-\varepsilon$. The energy shift ($\Delta E'$) of two molecules is obtained by

$$\Delta E' = \frac{2\varepsilon^2}{D}\left(\frac{1}{r_1}+\frac{1}{r_2}-\frac{1}{r_3}-\frac{1}{r_4}\right),$$

where D is the dielectric constant of the medium (D=2.5 for hydrocarbons) and r_i is the distance between two charges. The charge ε and the length l are assumed to be related to the transition moment μ by $\mu=\varepsilon\times l$.

Thus, the transition energy ΔE_{agg} of a dye aggregate is represented with the excitation energy of the dye monomer, ΔE_m, and the interaction integral $\Delta E'$ approximated by

$$\Delta E_{agg} = \Delta E_m \pm \Delta E'.$$

In the case of an aggregate containing n molecules, the intensity of the dipole–dipole interaction between ith and jth molecules is expressed as follows:

$$\Delta E' = \frac{2\varepsilon^2}{D} \sum_{i \neq j}^{n} \left(\frac{1}{|r_i^+ - r_j^+|} + \frac{1}{|r_i^- - r_j^-|} - \frac{1}{|r_i^+ - r_j^-|} - \frac{1}{|r_i^- - r_j^+|} \right),$$

where $|r_i^+ - r_j^+|$ and $|r_i^- - r_j^-|$ are the distance between positive charges and both negative charges of ith and jth molecule, respectively. $|r_i^+ - r_j^-|$ and $|r_i^- - r_j^+|$ are the distance between opposite charges of ith and jth molecule.

The transition dipole moment μ used in our calculation is indicated in the inset of Fig. 11. The positive charge of nitrogen N_1 of the octadecylmethylamino group is assumed as $+\varepsilon$ and each of negative charges of N_2 and N_3 atom as $-0.5\,\varepsilon$. The dipole length is l=8.4 Å. The values of $\Delta E'$ can be calculated by the dipole length and also by estimating the distance between the adjacent transition moments to be about 5 Å, which corresponds to the molecular model and the transition moment μ=9.98 Debye from the chroloform solution spectrum. In correspondence to the face-to-face arrangement, the blue-shift value of the H-aggregate band is considered to be most significant. The calculated values $\Delta E'$ for various arrangements are indicated in Fig. 11. The observed shift −0.06 eV of the J-dimer was fitted to the calculated value $\Delta E'$ of −0.05 eV with n=2 and a minimum slip angle α of 26°. For the observed value between 0.12 and 0.14 eV for the H-dimer, it was calculated to be 0.12 and 0.14 eV with n=2 and slip angles between 72° and 90°. The broadness of the H-dimer band is probably due to containing the coexistence of several kinds of dimers with various slip angles. For the red shift value of 0.43 eV (10 mN m^{-1}) and 0.51 eV (40 mN m^{-1}) of the H-aggregate, it was calculated to be 0.43 eV (α=72°) and 0.49 eV (α=90°) with n=4.

In conclusion, it was found that an H-aggregate assignable to a tetramer of CV dye forms in a close-packed monomolecular layer at high surface pressures. Since the H-aggregate band is present in the p-polarized spectra and absent in the normal incident and s-polarized spectra, its chromophoric planes must be oriented normal to the monolayer. The results of polarized absorption spectral measurements indicated that a well-ordered arrangement of H-aggregate was indeed present in the monolayer on water rather than in the LB film. The H-aggregates having a vertical transition moment observed here are of much significance as optical information storage media that work with a linearly polarized light at an oblique incidence.

Theoretical Studies on the Potential Energy Surfaces of SO_2: Electronic States for Photodissociation from the $\tilde{C}^1B_2$ State

Kenshu KAMIYA*,† and Hiroyuki MATSUI
Department of Reaction Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 14, 1991)

The potential energy surfaces of electronically excited states of SO_2 have been investigated with ab initio molecular orbital method: Especially, the two-dimensional potential energy surface for the $\tilde{C}^1B_2$ ($2^1A'$) state as a function of both the bond angle and bond distance has been carefully analyzed, including the spin-orbit interaction. Energetically, $2^3A'$ (1^3A_1 in C_{2v}) was found to be the most probable state which concerns the reaction mechanism for the photodissociation pathway from the $\tilde{C}$ state (SO_2 ($\tilde{C}^1B_2$) $\rightarrow$ $SO(^3\Sigma^-)+O(^3P)$); however, other pathway may also be possible to go over the avoided crossing on a singlet potential surface.

Sulfur dioxide (SO_2) is well known as an important species concerning atmospheric chemistry and numerous studies have been carried out. Despite its importance, theoretical studies on SO_2, except for the ground state structure and properties, are relatively limited, especially regarding the structures of the potential energy surfaces in excited states.[1-5]

SO_2 is known to photodissociate under ultraviolet radiation at wavelengths shorter than about 220 nm;[6,7] and recent experimental studies using mainly the 193 nm line of an ArF laser have focused on its dissociation dynamics:[8-13] the photodissociation reaction has been recognized to be a predissociation from the $\tilde{C}^1B_2$ state producing the ground state product $SO(X^3\Sigma^-)$ and $O(^3P)$. The excited product ($SO(a^1\Delta)+O(^3P)$) has not been observed, even though it is energetically possible. Freedman et al.[8] first observed the time-of-flight spectrum of the dissociation product. Subsequently, the spectrum of the product SO has been measured by Kawasaki et al.[10] as well as by Felder et al.,[13] and the SO molecule has been found to be vibrationally excited with a maximum peak at $v=2$. Kanamori et al.[11] also observed a similar structure for both the vibrational and rotational distributions using a tunable diode laser. They also observed the spin polarization effect of the SO product, from which they concluded that most of the reaction proceeded via a triplet state. Moreover, they observed a minor peak of $SO(X^3\Sigma^-)$ at $v=5$, for which they suggested the mechanism via a singlet state. Ebata et al.[12] observed the rovibrational dependence of the predissociation rate and supported the mechanism via a triplet state.

In the present study we investigated the potential energy surfaces of SO_2 in excited states with ab initio CI method to clarify some aspects concerning SO_2 photochemistry, especially the possible photodissociation reaction pathways from the excited $\tilde{C}$ state and to the responsible electronic states for the reaction.

Method

Potential energies were calculated using the configuration interaction (CI) method. Except for some preliminary search using the STO-3G basis set, the double zeta basis set augmented with polarization d-functions (DZP) were adopted for most of the calculations: the Dunning [4s, 2p][14] contraction of Huzinaga's (9s, 5p)[15] primitive set with a d-type function (exponent $\alpha=0.85$) was placed on oxygen, and the [6s, 4p][16] contraction of Huzinaga's (11s, 7p)[17] primitive set with a d-type function ($\alpha=0.6$) on sulfur. We also tried the extended basis set augmented with diffuse orbitals (DZP+d) in order to check the importance of Rydberg states. The molecular orbital sets used to construct CI expansion were calculated for the electronic ground state within the approximation of the restricted Hartree–Fock (RHF) theory and the improved virtual orbital (IVO)[18] technique. In order to refine the virtual orbitals using IVO, an electron was removed from the highest occupied $8a_1$ ($13a'$ in C_s structure) orbital to make a hole. For several calculations along the dissociation path of SO_2, the natural orbitals based on the unrestricted Hartree–Fock theory (UHFNO) were also used.

Two types of CI calculations were tried at the experimental equilibrium structure of the ground state.

1) V-SDTQ CI (valence- single, double, triple, and quadruple CI) with the DZP Basis Set: We considered all configurations up to 4 electron excitation from the ground-state configuration in the active space comprising of 10 valence orbitals (1s and 2sp orbitals of S and 1s and 2s of O were fixed as the core) with 14 electrons. The differences in energy spacing with the valence full CI, which included 6-electron excitation, were small. The numbers of configurations were between 729 and 1059 in C_{2v} symmetry.

2) MRSD CI (multi references single and double CI) with the Extended DZP+d Basis Set: s-, p-, and d-types of diffuse orbitals were placed on an S atom, and their exponents were optimized separately using RHF calculations for several Rydberg states. All of the virtual orbitals (except for several with extremely high energies) were considered to generate excitation configurations. For each spin and spatial symmetry in the C_{2v} point group, several tens of configurations were used as references; these were selected by considering preliminary small CI calculations. After perturbation selection with a 50 μhartree threshold in all of the single and double excitations from reference configurations, the dimensions of the matrices actually diagonalized were within

the range from 3000 to 15000.

The second MRSD CI calculations were mainly intended to test the reliability of more tractable V-SDTQ CI calculations. After a comparison of the two types of calculations (Table 1), we found that the order in energy of the important low-lying states was identical in these two types of calculations, although the differences of the energy levels were several tenths of an eV. Despite the differences in energy, the results with V-SDTQ CI were used in this study for qualitative discussions concerning the reaction mechanism. In the MRSD CI calculations, Rydberg states did not appear in the region less than 10 eV, indicating a minor importance of such states in photochemical events concerning the $\tilde{C}$ state. Thus, most of the calculations were carried out with V-SDTQ CI using the DZP basis set without diffuse orbitals.

Results

1. The Equilibrium Structures and Energies. The optimum structures for the ground state $\tilde{X}^1A_1$ and the singlet excited state $\tilde{C}^1B_2(2^1A')$ were searched for using the V-SDTQ CI calculation. The excited $\tilde{C}$ state has been known to have an asymmetric structure.[19] The bond distance and angle for the ground state for the optimized structure in this calculation are R=2.775 Bohr (1.468 Å) and θ=122 degrees, respectively; they roughly agree with experimentally determined values, R=2.706 (1.432 Å) and θ=119.5.[20] Those for the $\tilde{C}$ state are R_1=2.869 Bohr (1.518 Å), R_2=3.467 Bohr (1.835 Å) and θ=108.3 degrees (experimental values are: R_1=2.818 (1.491 Å), R_2=3.097 (1.639 Å) and θ=103.75[19]). The adiabatic excitation energy, $\tilde{C}^1A'\leftarrow\tilde{X}^1A_1$, without a zero-point energy correction was calculated to be 5.00 eV, while the experimental value with zero-point energy is 5.28 eV.[19]

2. Angular Dependence of the Potential Energy. Figure 2 shows the potential energy surfaces of each electronic state as functions of the bond angle calculated in this study. Qualitatively, the shapes of the potential curves and the features of crossings are in good agreement with other theoretical results (SCF[4] or the local density functional theory[1]) although small discrepancies have been found, which may be partly due to differences in the geometries. We will discuss the features on each electronic state separately.

^{1}A′ States ($^1A_1$, $^1B_2$). The electronic configuration of the ground state is (see Fig. 1)

$\tilde{X}^1A_1$:……$(2b_1)^2(5b_2)^2(1a_2)^2(8a_1)^2$.

$\tilde{C}^1B_2(1a_2\rightarrow 3b_1)$ is the second singlet A′ state when its geometry is close to the equilibrium structure of the ground state. The state which is usually denoted 2^1A_1 shows a minimum at the angular region 40—60 degrees, and comprises the electronic state $(5b_2)^2\rightarrow(3b_1)^2$, which has 6 electrons in out-of-plane π orbitals. The corresponding state of O_3 is known to have a ring structure(D_{3h}). This state rapidly increases in energy as the angle becomes larger, and then crosses with $\tilde{X}^1A_1$. We did not attempt more detailed calculations for the coupling of the two states ($\tilde{X}^1A_1$ and 2^1A_1). At nearly 70 degrees, the state (2^1A_1), which no longer has the ring state character, crosses with 1^1B_2. Above 120 degrees the energy of 2^1A_1, whose dominant configuration is now $8a_1\rightarrow 9a_1$, decreases as the angle increases; the state crosses again with 1^1B_2 at nearly 145 degrees, and correlates adiabatically to $^1\Pi_u$ at 180 degrees, degenerating with 1^1B_1 state.

There seems to be no large contamination of the 1^1A_1 and 1^1B_2 states. In the equilibrium structure, 1^1A_1 has 6 electrons in the in-plane π orbitals (n orbitals) and 4 electrons in the out-of-plane π orbitals. This electronic configuration might be expected to correlate to a Δ state when in a linear structure as the in-plane and out-of-plane π orbitals degenerate, as reported for the O_3 molecule. In fact, the ground state correlates to the $^1\Sigma_g^+$ state when in a linear structure. We will discuss the electronic states later. The 1^1B_2 state degenerates with 2^1A_2 and correlates to $^1\Delta$.

^{1,3}A″ (B_1, A_2) State. The shapes of the potential curves are almost parallel to the corresponding singlet and triplet states, and the triplet states are slightly lower in energy than the singlets. For both spin states, the potential surfaces of the first B_1 ($8a_1\rightarrow 3b_1$) and the first A_2 ($5b_2\rightarrow 3b_1$) closely approach; the minimum of the former is at ca. 125 degrees, and that for the latter is at ca. 100 degrees, consequently giving a conical crossing between them. The $^1B_1$ and $^3B_1$ states degenerate when in a linear structure with 2^1A_1 and 1^3A_1, respectively, and correlate to Π_u states.

^{3}A′ State ($^3A_1$, $^3B_2$). Similarly to the case of A″, the

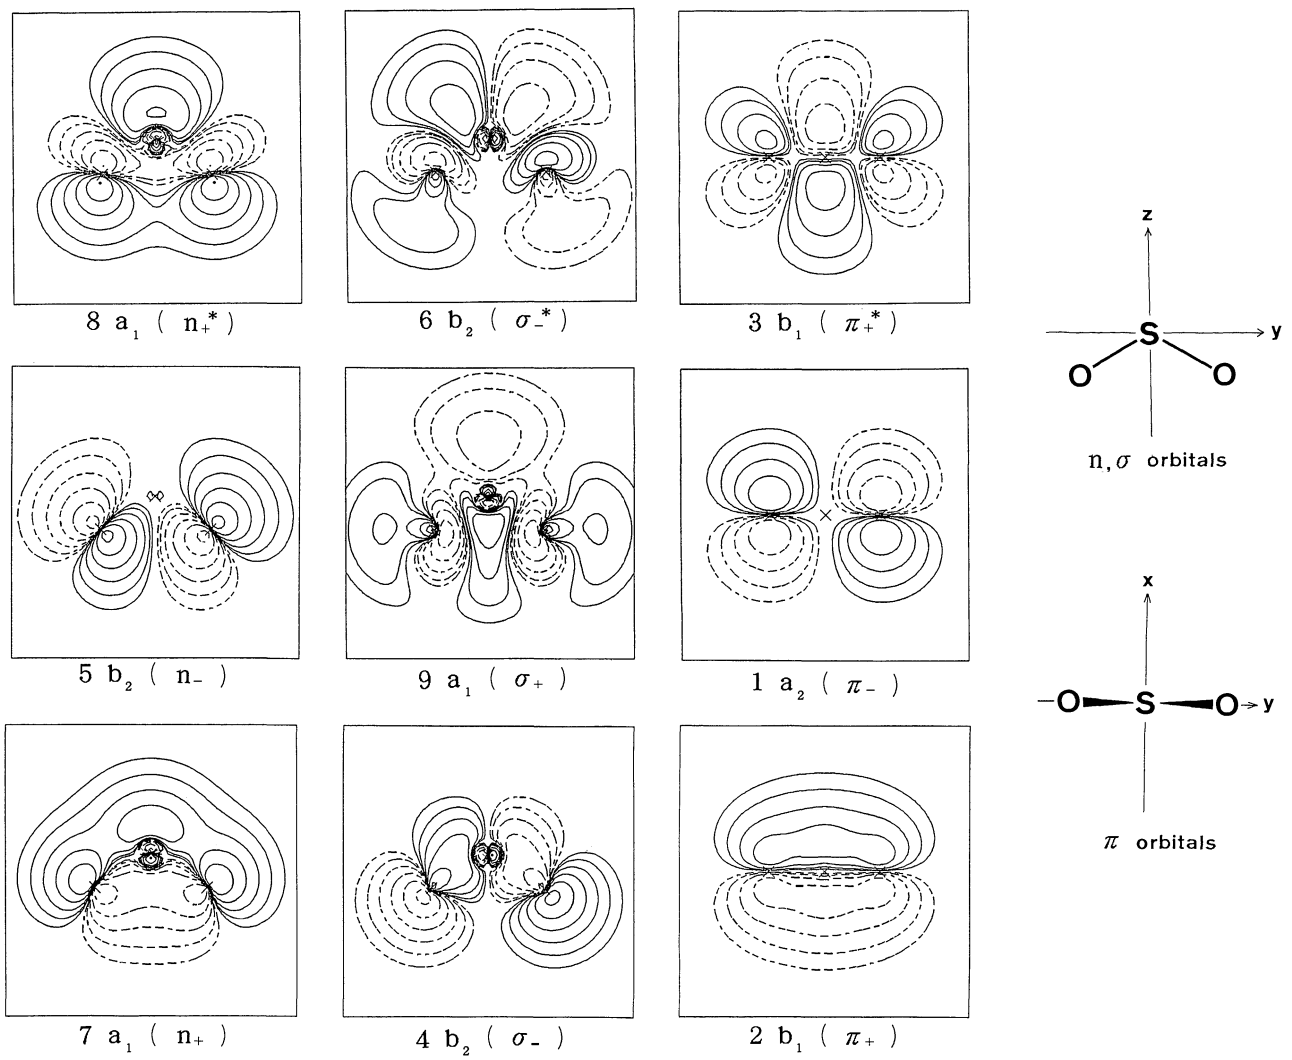

Fig. 1. The typical valence orbitals calculated with RHF/DZP for the ground state at the experimental equilibrium structure. Contour maps are drawn at the intersections with YZ- and XY-planes for n, σ, and π orbitals, respectively.

potential curves of the lower electronic states (1^3A_1 and 1^3B_2) have similar shapes as those of the corresponding singlet states (2^1A_1 and 1^1B_2). At nearly 150 degrees 1^3A_1 and 1^3B_2 cross, just as for the singlet states. 1^3A_1 correlates to $^3\Pi_u$, and degenerates with 1^3B_1.

3. Electronic States at Linear Structure. As shown in Fig. 2, the ground and low-lying excited states have energy minima with the bond angles of 90—130 degrees, except for 1^3A_1 and 2^1A_1, which are both Renner-Teller coupling pairs with 1^3B_1 and 1^1B_1, respectively. In order to resolve spectroscopic problems and photochemical processes, it is important to investigate the electronic states in a linear structure.

As described above, the electronic ground state 1^1A_1 correlates to $^1\Sigma_g^+$ in a linear structure, not $^1\Delta_g$, a degenerate state, which is reported to be the case for O_3.[21] It is 2^1A_1 that degenerates with 1^1B_1 and correlates to the $^1\Pi_u$ state. The reason why the ground state does not degenerate when in a linear structure is that the highest occupied $8a_1$ orbital (a π orbital in the molecular plane (n_+*)) couples with the $9a_1$ orbital and adiabatically correlates to σ_g^+ of a linear molecule.

Table 2 shows the energies for linear structures of O_3 and SO_2 in several electronic states, calculated with the open-shell restricted Hartree–Fock approximation. Two electrons occupying three orbitals (π_u and σ_g^+, noted above) make six independent electronic states corresponding to three electronic configurations: $(\pi_u)^2$, $(\pi_u)^1(\sigma_g)^1$, $(\sigma_g)^2$. ($^1\Delta_g$, $^3\Sigma_g^-$, $^1\Sigma_g^+$ states are from $(\pi_u)^2$, $^1\Pi_u$, $^3\Pi_u$ from $(\pi_u)^1(\sigma_g)^1$, and another $^1\Sigma_g^+$ from $(\sigma_g)^2$.) For both SO_2 and O_3, the orders in energies of the three states within $(\pi_u)^2$ and the two states within $(\pi_u)^1(\sigma_g)^1$ obey Hund's rule. The energies of the three configurations, however, were reverse in order for SO_2 and O_3 with the DZP basis set. This may reflect the difference in the order of the two orbitals, σ_g and π_u, for SO_2 and O_3. The

effect of basis sets was important for calculating the order of the states in SO_2. The results with STO-3G showed a reverse order from those with DZP, while the two basis sets gave the same results for O_3.

A mechanism based on a Renner–Teller coupling of $^1A_1$ and $^1B_1$ into $^1\Delta_g$ for the ground state has been postulated[22] in order to interpret the UV absorption of SO_2 in the range from 340 to 250 nm. However the present calculation shows that the state from the Renner–Teller coupling of 2^1A_1 and 1^1B_1 is $^1\Pi_u(\sigma_g^+ \rightarrow \pi_u)$, and not the ground state, $^1A_1$.

We also checked the energy changes of each state with an asymmetric deformation. Calculations were performed while constraining one SO bond to be fixed, with the bond angle at 180 degrees. While most of the states were unstable and/or dissociative under such an asymmetric deformation, the potential curve of the ground state and the lowest triplet state, $^3\Pi_u$, showed a minimum at the point where the two SO bond distances were the same. The $^3\Pi_u$ was the only state which was lower in energy when in a $D_{\infty h}$ structure than the dissociation energy of the ground states. The $^3\Pi_u$ caused a Renner–Teller splitting under a deformation of the bond angle (as noted above), and the upper state of the pair, $^3A_1$, showed a minimum when in the $D_{\infty h}$ structure. The corresponding singlet Renner–Teller state, $^1\Pi_u$, was higher in energy than the dissociation limit of the ground state, and the upper state $^1A_1$ at $D_{\infty h}$ structure was unstable regarding both a deformation of the bond angle and the bond distance.

4. Potential Energies along the Dissociation $SO_2 \rightarrow SO + O$. In order to discuss the qualitative features of the potential energy surfaces along its dissociation path, some results of preliminary calculations using the STO-3G, V-SDTQ CI based on UHF natural orbitals are shown in Fig. 3. The UHF orbitals can approximately connect the electronic states continuously to the dissociation limit. Note that the calculated energies using STO-3G are less reliable than those using DZP basis sets. All of the degrees of freedom of the molecule were fixed to the experimental equilibrium structure of the $\tilde{C}$ state, except for the dissociative SO bond length, which was varied over a wide range. The lowest four states for each symmetry of $^1A'$, $^3A'$, and $^3A''$ are shown in this figure in order to demonstrate the relationship between the $\tilde{C}$ state and the

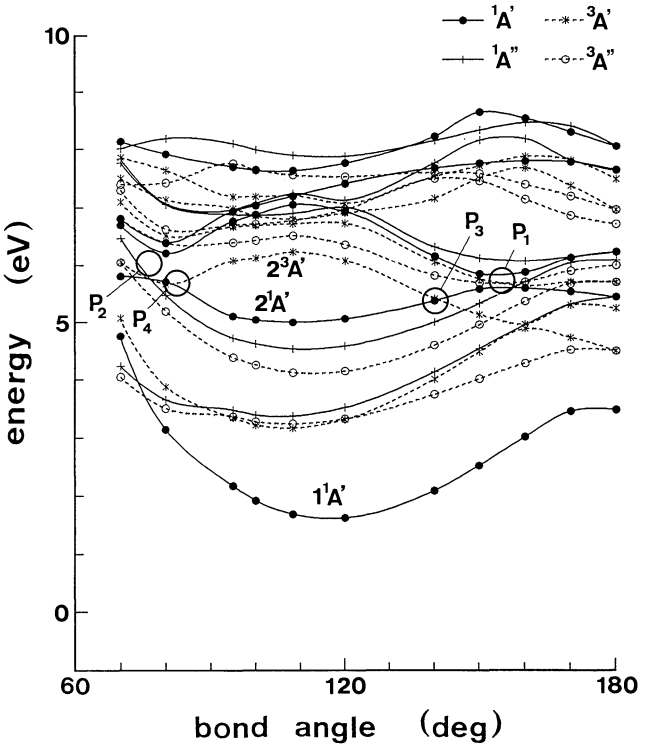

Fig. 4. The potential energies of the low lying states of SO_2 as a function of bond angle at (R_1, R_2)=(2.869 Bohr, 3.467 Bohr) (calculated equilibrium S–O distances for the $\tilde{C}$ state). Zero of energy is for the equilibrium of the ground state. Symbols P_1—P_4 are the crossing points between the $\tilde{C}$ state and $3^1A'$ or $2^3A'$ states.

other triplet states. As shown in the figures, the second $^1A'$ state (corresponds to the $\tilde{C}$ state) correlates to the excited state of products $SO(^1\Sigma^-)+O(^1D)$. The state encounters crossings and/or avoided crossings with another state which correlates to the excited-state product or with the repulsive state which correlates to the ground-state product. It should be noted that a similar structure to that of the singlet surfaces is found in the O_3 system.[23] The $\tilde{C}$ state crosses with several triplet states: 2-4$^3A'$ and 3,4$^3A''$. Although the crossing between $2^1A'$ and $2^3A'$ is not shown in the figure, the crossing appeared in more sophisticated calculations using the DZP basis set.

5. Potential Energy Surface of the Photodissociation from the $\tilde{C}$ State. As noted above, the potential energy surface of the $\tilde{C}^1B_2$ state crosses with another repulsive singlet state and with several triplet states as one of the bond distances is changed. It also crosses with the $^1A_1$ and $^3A_1$ states as the bond angle is changed. In order to examine the features of the potential energy surface crossings, we calculated the potential surfaces as a function of two parameters (one SO bond length (R) and the bond angle (θ)) with the other SO bond length fixed to 2.869 Bohr (the calculated equilibrium bond distance of the shorter SO bond of the $\tilde{C}$ state). Such constraint seems adequate for a qualitative description of the reaction system, since the bond distance of the dissociation product, $SO(^3\Sigma^-)$, calculated to be 2.909 Bohr, was not much different from that of the shorter SO bond of the equilibrium structure of the $\tilde{C}$ state.

Figure 4 shows the cross section of the potential surfaces at R=3.467 Bohr, the calculated equilibrium distance of the longer SO bond of the $\tilde{C}^1A'$ state. Although we do not show any detailed assignments for the uppper states, one can recognize the manifold of the electronic states above 6 eV from the equilibrium of the ground state. The potential curves of the $\tilde{C}^1A'$ and $3^1A'$ states (1^1B_2 and 2^1A_1 in C_{2v} structure, respectively) cross at two points (P_1 and P_2), as shown in the figure. Although the crossing should be avoided, since the two states belong to the same symmetry A' in the C_s point group, the coupling of the states was found to be weak. At crossing point P_1, which is placed at a larger bond angle and lower in energy, the dominant configurations of $2^1A'(\tilde{C}$ state) and $3^1A'$ are $\pi_-\rightarrow\pi_+^*$ and $n_+^*\rightarrow\sigma_+$, respectively. As the bond distance (R) becomes larger, the two states become strongly mixed to give a larger separation. The state which corresponds to $n_+^*\rightarrow\sigma_+$ degenerates with $1^1A''$ (1^1B_1 in C_{2v}) when in a linear

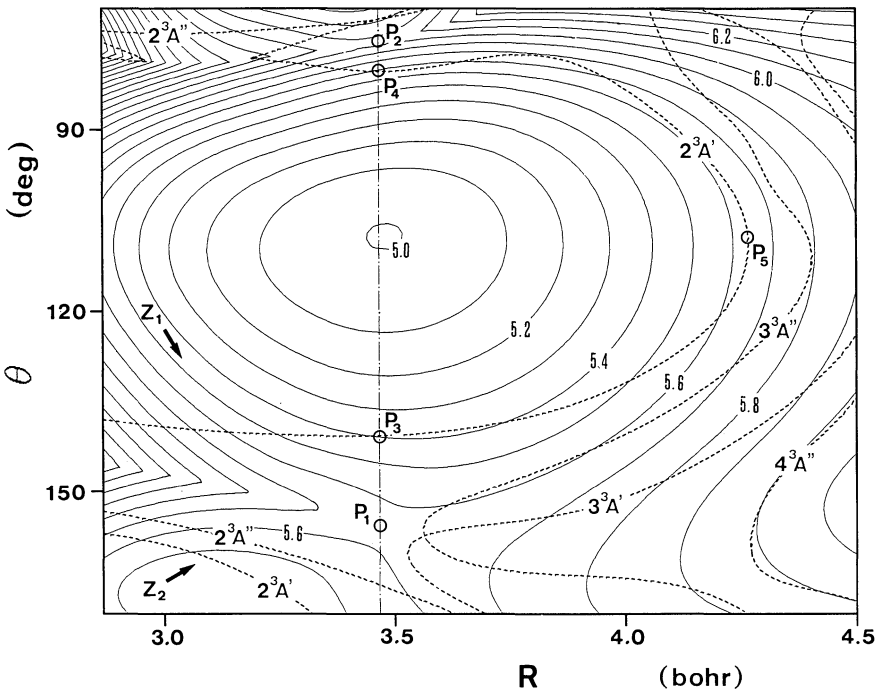

Fig. 5. The potential energy of the $\tilde{C}(2^1A')$ state as a function of the bond angle θ and one of the bond distances R with another bond distance being fixed to 2.869 Bohr. The contour energies are in eV (relative energy from the calculated ground state at equilibrium). The dashed curves are crossing seams with the triplet states ($2^3A'$, $3^3A'$, $2^3A''$, $3^3A''$, and $4^3A''$). Symbols P_3, P_4, and P_5 are the points on the crossing seams between $2^1A'$ and $2^3A'$ where magnitude of the transition probabilities were estimated (see text). The dash-dot line corresponds to the position of the cross section shown in Fig. 4. The arrows Z_1 and Z_2 are shown to indicate the approximate direction of view for (1) and (2) of Fig. 6, respectively.

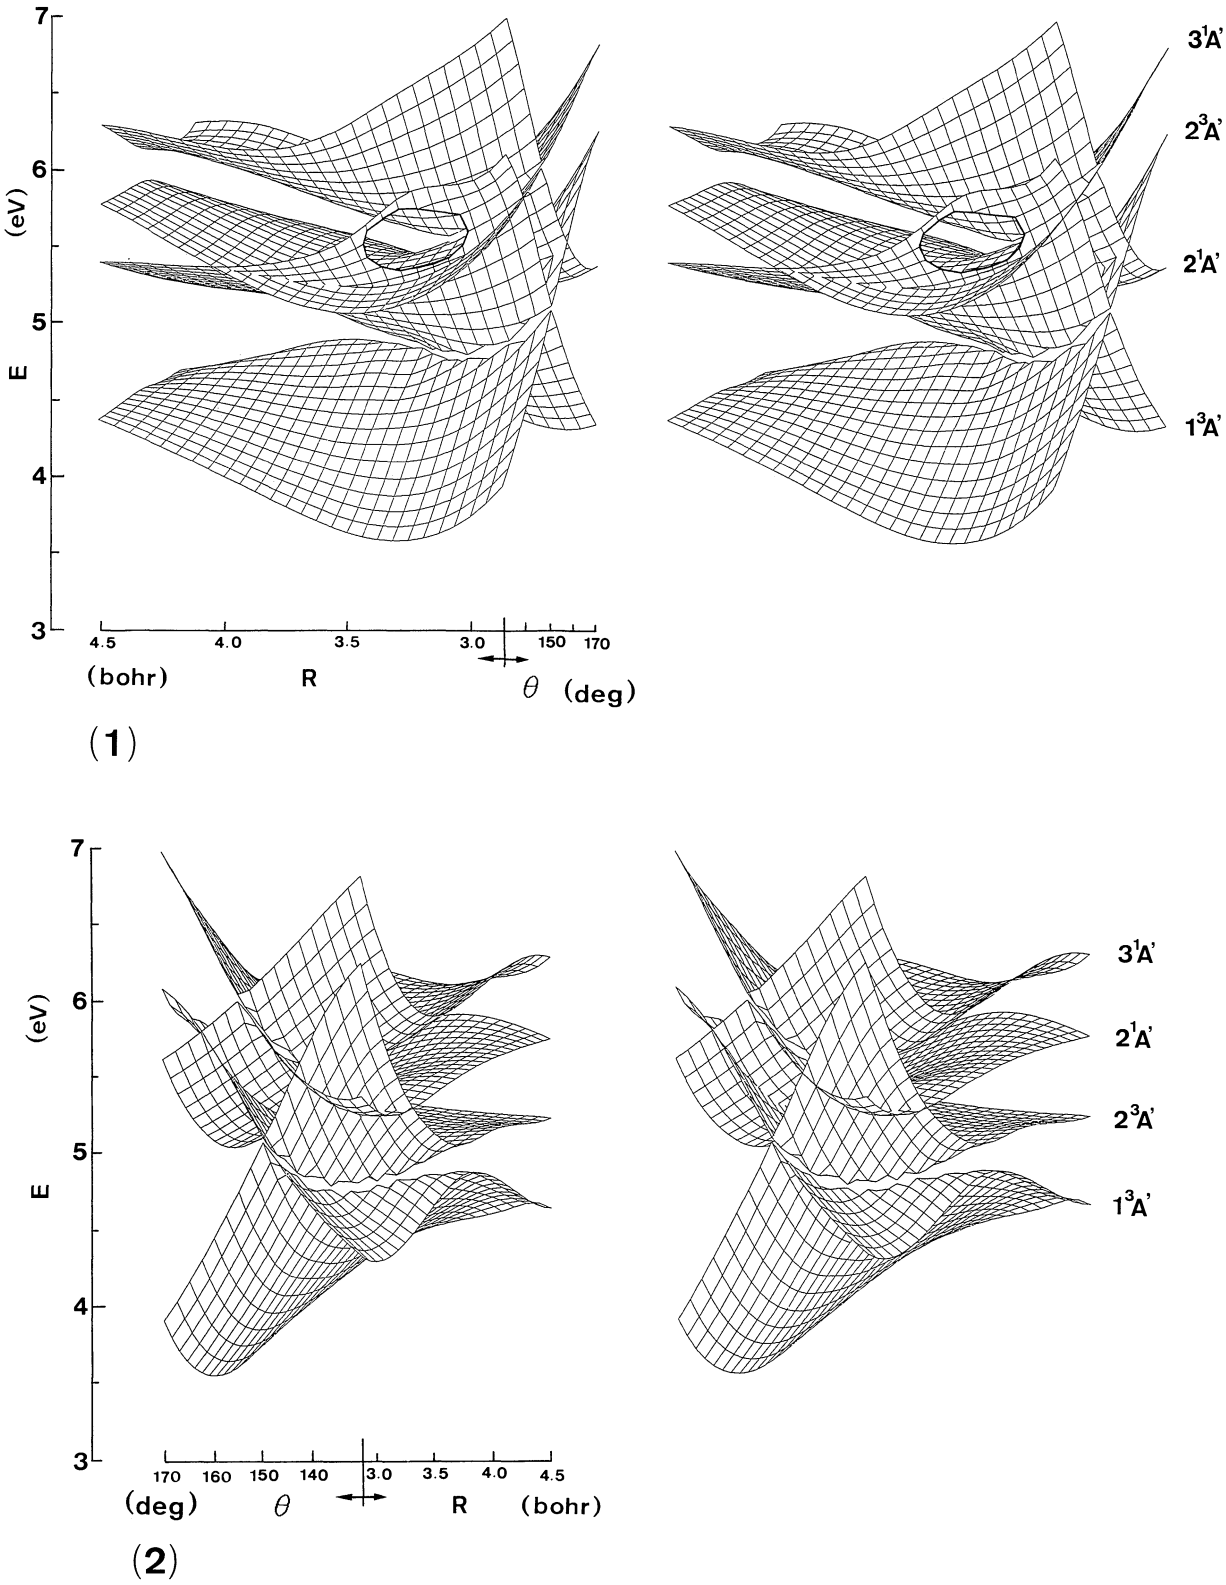

Fig. 6. Stereoscopic view of the potential energy surfaces at the region of crossing or avoided crossing including $2^1A'$ ($\tilde{C}$), $3^1A'$, $1^3A'$, and $2^3A'$ states. The potential surfaces within rectangular region (θ=130—170 degree and R=2.875—4.500 Bohr) are shown, and each approximate directions of view for (1) and (2) are shown in Fig. 5 by the arrows Z_1 and Z_2, respectively. A part of the $2^3A'$ surface in (1) is cut off to show the saddle point on the $2^1A'$ surface.

structure, giving $^1\Pi$, which correlates to the ground state of the product at infinite R.

Figure 4 also shows the crossing points between the $\tilde{C}$ state and $2^3A'(1^3A_1$ in $C_{2v})$: P_3 and P_4. They are slightly lower in energy than those between the $\tilde{C}$ state and $3^1A'$. This reflects that $2^3A'$ is lower in energy than $3^1A'$, originating from a difference in the exchange interaction of each spin state.

Figure 5 shows a potential map of the $\tilde{C}$ state as a function of R and θ. It is drawn adiabatically along the second root of CI for the $^1A'$ states. The dashed curves in the figure indicate the seams of the crossing between the $\tilde{C}$ state and other triplet states; P_3, P_4 (already shown in Fig. 4) and P_5 are the representative points on the crossing between the $\tilde{C}$ state and $2^3A'$ (discussed later). At θ=150—160 degrees, there exists a saddle due to the avoided crossing with the $3^1A'$ state. Also shown in the figure are the several triplet states crossing with the $\tilde{C}$ state surface at regions which are lower in energy than the singlet saddle point. Of these triplets, $2^3A'$ (1^3A_1 in C_{2v}), whose crossing is the lowest, is the only state to correlate to the ground-state product. Note that both the saddle point on the singlet surface and the minimum point on the crossing seam with $2^3A'$ are placed at a region of larger angle θ that the minimum of the potential.

Figure 6 shows schemata of the potential energy surfaces as functions of R and θ at the avoided crossing region of $2^1A'$ and $3^1A'$ (upper two surfaces in the figure), which is mentioned above. Although the energy spacing of the avoided crossing between the two states is not accurate, the avoided crossing region corresponds to that of the saddle point of the $^1A'$ surface. The saddle on the singlet surface is the lowest point on the crossing seam and corresponds to the possible transition point of the dissociation reaction from the $\tilde{C}$ state to the ground-state product if the reaction proceeds on a singlet adiabatic potential surface. The $2^3A'$ and $1^3A'$ states are also shown in the figure (lower two surfaces) in order to show the features of the crossings and the minimum crossing point of the $2^3A'$ and $\tilde{C}$ states. The two triplet states show crossing or avoided crossing features similar to those of the singlets, originating from the same dominant configurations, except for the spin states. The $2^3A'$ (1^3A_1 in C_{2v}) state crosses with $\tilde{C}^3B_2$ in C_{2v} symmetry and correlates to the lowest triplet state, $^3\Pi_u$, which has a minimum when in a linear structure. Although the crossing should be avoided with asymmetric deformation, both of the triplet states correlate to the ground-state product when R is infinity.

Discussion on the Reaction Pathways of the Photodissociation from the $\tilde{C}$ State

One of the experimental findings concerning the UV photodissociation on O_3 is that the excitation of the antisymmetric stretching mode enhances the reaction from the $\tilde{C}$ state.[24] SO_2 has also been reported to show a similar trend, that the excitation of the antisymmetric mode is important rather than the bending mode.[25] Because of the difference in the equilibrium structures of the ground state and the $\tilde{C}$ state, the electronically excited SO_2 is also vibrationally excited. The molecule is also expected to experience considerable vibrations within its longer lifetime than the rotational period before its predissociation.[9]

Based on our calculated results, we can discuss the highest energy point (transition state) along the minimum-energy path from the minimum of the $\tilde{C}$ state to the product ground state. If we assume that the reaction proceeds on a singlet adiabatic surface (called the singlet mechanism), the transition state should be a saddle on the barrier arising from the avoided crossing between $\tilde{C}$ state and $3^1A'$ (2^1A_1 in C_{2v}, $1^1\Pi_u$ in $D_{\infty h}$). In contrast, if the reaction is allowed one singlet-triplet transition (namely, the triplet mechanism), the most probable transition state (the lowest in energy and not requiring further crossing to reach ground state product) is the minimum point on the crossing seam between the $\tilde{C}$ states and the $2^3A'$ (1^3A_1 in C_{2v}, $1^3\Pi_u$ in $D_{\infty h}$) state. As described above, the triplet transition point was lower in energy: thus, the triplet mechanism may be advantageous from an energetical point of view. However, both transition points are placed at the larger bond-angle side of the minimum of the $\tilde{C}$ state. Thid seems to contradict the experimental result that the bending vibration is not important. However, the following comments and discussions may be possible, especially regarding the triplet mechanism.

The photon energy of the ArF laser (193 nm, 6.42 eV) is about 1.1 eV higher than the minimum energy of the $\tilde{C}$ state. According to our results, for the singlet mechanism the saddle point region is the only exit to the dissociation product with a threshold energy of 1.1 eV, meaning that bending motion is necessary for the reaction. For the triplet mechanism, however, the singlet–triplet crossing seams are located over a wide region on the surfaces, which is energetically accessible, including the larger bond distance side of the minimum of the $\tilde{C}$ state. Moreover, the crossing seam runs nearly parallel to the equipotential curves of the singlet surface, meaning that the energy change along the seam is not very drastic. That is, the singlet–triplet transition may not be so concentrated only near the minimum transition point.

It may be possible to roughly estimate the transition probabilities from the potential and the wave function. We estimated the matrix elements for a singlet–triplet spin orbit interaction in the following semiempirical way. In the usual spin orbit coupling Hamiltonian, the second term (spin-other-orbit-interaction) was neglected:

$$H_{so}=\frac{\alpha^2}{2}\sum_i\sum_A\frac{Z_A}{r_{iA}^3}(\boldsymbol{l}_{iA}\cdot\boldsymbol{s}_i)-\frac{\alpha^2}{2}\sum_{i,j}\left(\frac{\boldsymbol{r}_{ij}}{r_{ij}^3}\times\boldsymbol{p}_i\right)\cdot(\boldsymbol{s}_i+2\boldsymbol{s}_j). \quad (1)$$

Further, the multi-center integrals in the first term were neglected, and the effective nuclear charges (Z_A) were

treated as being adjustable parameters and were determined so as to fit the fine structures of the atomic spectrum. We adopted values of $Z_{sulfur}=13.698$ and $Z_{oxygen}=5.304$ using the results of SCF calculations for S and O atoms. If we consider that the velocity component which is perpendicular to the singlet-triplet crossing, determines the transition, the Landau–Zener transition probability can be expressed as follows:

$$\chi(\boldsymbol{p},\boldsymbol{q})=1-\exp(-\zeta), \tag{2}$$

where

$$\zeta=\frac{2\pi V(\boldsymbol{q})^2}{\hbar v|\boldsymbol{G}(\boldsymbol{q})|}.$$

Here, $V(\boldsymbol{q})$ denotes the absolute value of the elecronic singlet–triplet coupling, $|\langle S|H_{el}|T\rangle|$, and $\boldsymbol{G}(\boldsymbol{q})$ denotes the difference in the gradients of the singlet and triplet,

$$\boldsymbol{G}(\boldsymbol{q})=\frac{d}{d\boldsymbol{q}}({}^1E(\boldsymbol{q})-{}^3E(\boldsymbol{q})).$$

Further, v represents the velocity component perpendicular to the crossing seam

$$v=\frac{\boldsymbol{p}\cdot\boldsymbol{G}(\boldsymbol{q})}{m|\boldsymbol{G}(\boldsymbol{q})|}.$$

Here, we define $F(\boldsymbol{q})$ as being a factor which is not dependent on velocity,

$$F(\boldsymbol{q})=\frac{V(\boldsymbol{q})^2}{|\boldsymbol{G}(\boldsymbol{q})|}. \tag{3}$$

$F(\boldsymbol{q})$ can be considered to be a simple index which shows the reference value of the amount of the transition probability.

The F value was calculated at the points P_3, P_4, and P_5 on the two-dimensional potential surface of Fig. 5. P_3 and P_4 are the points where the normal of the seam corresponds to the bending (larger and smaller side of the minimum, respectively), and P_5 the point where the normal corresponds to antisymmetric stretching. As shown in Table 3, F at P_5 was 1.8-times larger than at P_3. It is thus possible that point P_5 is more important than point P_3, although the energy of the former is 8 m hartree (0.22 eV) higher than the latter.

It is apparent, however, the present calculation does not have sufficient quality to discuss further either the energetics or the quality of the wave functions, as one can find after a comparison with the larger CI calculations given in Table 1. Ebata et al.[12] observed the threshold energy of the predissociation to be about 0.35 eV higher than E_0 of the $\tilde{C}$ state; the zero point energy is about 0.1 eV. The calculated energies of points P_3 and P_5 are 0.40 and 0.62 eV higher than the minimum of the $\tilde{C}$ state, respectively. Considering that the structures of the crossing points are not fully optimized, the discussion given above is only qualitatively meaningful.

The effect of the other bond length, which was frozen at the fixed value throughout this study, may also be significant. Although the bond distances of the shorter bond of the molecule in the $\tilde{C}$ state is similar to that of the product, SO, it may be possible that the shorter bond of SO_2 is also vibrationally excited by 193 nm excitation; such an effect can be important in producing a vibrationally excited product, SO, as was observed in some experiments.

Another mechanism may be possible to interpret the minor importance of the bending mode. The bending vibration may cause multiple crossing of the seams while antisymmetric stretching motion is directly connected to dissociative motion. There is no potential structure to enhance the dissociation after the singlet–triplet transition with bending motion, since the $^3\Pi_u$ state is a bound state and has a minimum when in a linear structure.

There exist some experimental evidence that most of the reaction proceeds via a triplet state.[9-12] We have shown the advantage of the triplet mechanism regarding energy, although it is not conclusive because of difficulties in comparing the two different mechanisms.

Kanamori et al.[11] observed two types of product SO fragments; the major one, which had vibrational quantum numbers $v=1$ and $v=2$, showed a spin polarization effect; the minor one, which was in $v=5$, did not. They suggested that this result is a combination of two mechanisms: the major is via a triplet and the minor via a singlet; the possibility of the two pathways, which we suggest here, may correspond to those of Kanamori's results.

Conlcusion

The excited state potential energy surface of SO_2 was calculated using the CI method. The angular dependence of the energy level of each state was presented, showing a qualitatively similar structure as that in previous theoretical calculations.

The structure of the potential energy surfaces and their crossing with the $\tilde{C}$ state were examined in order to obtain insight into the UV photodissociation mechanism and to identify the responsible electronic states for the reaction. It was found that several triplet states did cross with the $\tilde{C}$ state in an energetically accessible region. The most probable state was $2^3A'$ (1^3A_1 in C_{2v}, $^3\Pi_u$ in $D_{\infty h}$), which became the upper state of the Renner–Teller coupling pair when in a nearly linear structure, and had an equilibrium structure with a $D_{\infty h}$ symmetry. The reaction path on the singlet adiabatic surface was also energetically possible through the avoided crossing between the $\tilde{C}$ state and other singlet excited state (2^1A_1 in C_{2v}, $1^1\Pi_u$ in $D_{\infty h}$), but energetically less favorable than the triplet mechanism.

However, the results suggested by the present work should be accepted only qualitatively. We could not give any conclusive discussion concerning the two kind of possible pathways, the singlet and the triplet mechanisms. More quantitative and sophisticated calculations are necessary for any further discussion.

The authors gratefully acknowledge to Professor K. Morokuma (Institute for Molecular Science) and Professor E. R. Davidson (Indiana University) for thier guidance and helpful discussions. All the numerical calculations were carried out at the Computer Center of Institute for Molecular Science using the program MELD.[26]

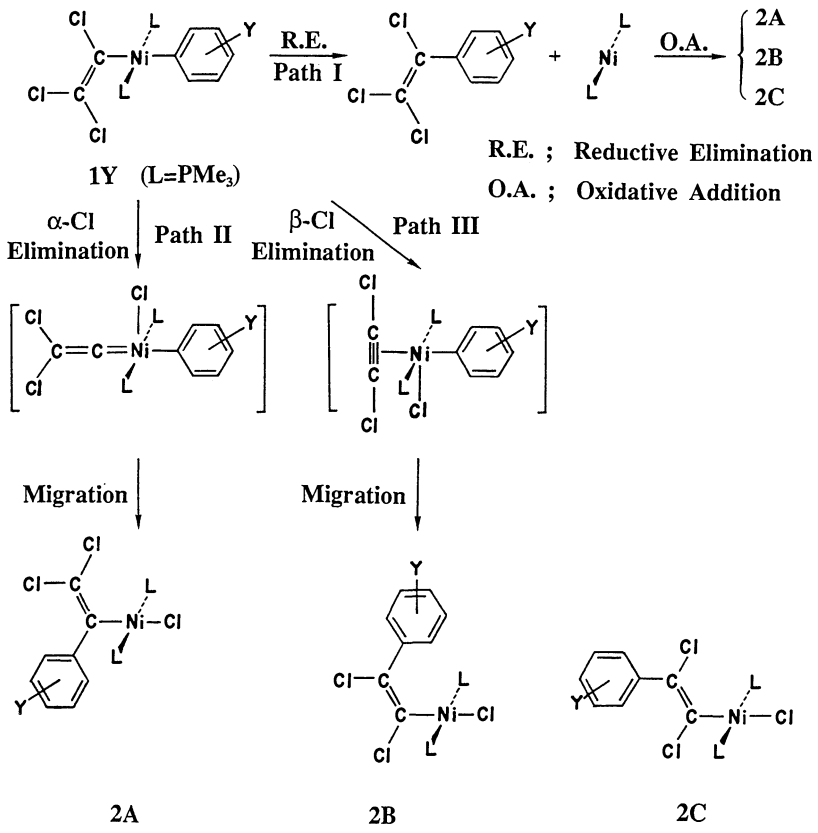
Molecular Structures of Trichlorovinyl(*p*-tolyl)nickel(II) Complex, and Its Thermal and Photo Isomerization Products

Jie CHEN, Yasushi KAI,* Nobutami KASAI, Masanori WADA,*,† and Makoto KUMAZOE
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565
† Department of Materials Science, Faculty of Engineering, Tottori University, Koyama, Tottori 680
(Received April 19, 1991)

The molecular structure of the trichlorovinyl(*p*-tolyl)nickel(II) complex (*trans*-[Ni(CCl=CCl$_2$)(C$_6$H$_4$Me-4)-(PMe$_3$)$_2$] (**1**)), its thermal isomerization product (*trans*-[NiCl{C(C$_6$H$_4$Me-4)=CCl$_2$}(PMe$_3$)$_2$] (**2**)) and one of its photolysis products (*trans*-[NiCl{CCl=CCl(C$_6$H$_4$Me-4)}(PMe$_3$)$_2$] (**3**)) have been determined by an X-ray diffraction method. Crystal data: **1**; triclinic, space group $P\bar{1}$, a=8.768(1), b=9.347(1), c=13.029(2) Å, α=103.79(2), β=96.23(2), γ=86.90(3)°, V=1030.4(3) Å^3, Z=2, D_c=1.393 g cm^{-3}, **2**; orthorhombic, space group $P2_12_12_1$, a=13.884(2), b=14.505(3), c=10.272(2) Å, V=2068.6(6) Å^3, Z=4, D_c=1.388 g cm^{-3}, **3**; triclinic, space group $P\bar{1}$, a=11.628(4), b=8.975(3), c=10.437(4) Å, α=102.91(3), β=99.45(3), γ=89.91(4)°, V=1046.6(7) Å^3, Z=2, D_c=1.377 g cm^{-3}. Molecules **2** and **3** were found to contain *p*-tolyl group on the α-carbon and β-carbon atoms of the vinyl ligand, respectively. Intersting structural deformations were found in **1**.

Reductive elimination and oxidative addition are unit reactions used to obtain new substances through either the fission or formation of bonds using organometallic complexes as catalysts.[1] The combined use of these reactions has been applied in the various fields of organic synthesis. One of the practical applications of these reactions is the formation of a monoorganometal complex from a diorganometal type. The thermolysis of a newly synthesized trichlorovinyl(aryl)nickel(II) complex (**1Y**), *trans*-[Ni(CCl=CCl$_2$)(C$_6$H$_4$Y)(PMe$_3$)$_2$] (Y=OMe-2, Me-2, NMe$_2$-4, Me-4, Me-3, or Cl-4), resulted in the formation of isomeric monoorganonickel(II) complexes.[2]

Three molecular structures (**2A**, **2B**, and **2C**) are possible for the thermal isomerization product of the trichlorovinyl(aryl)nickel(II) complex (**1Y**). A plausible reductive elimination of the trichlorovinyl and aryl groups, followed by an oxidative addition onto the nickel atom, may produce all of three possible isomers (Path I in Scheme 1). An α-chloro elimination of the tri-



Scheme 1.

chlorovinyl ligand followed by its coordination onto a nickel atom may give a vinylidene(chloro)(aryl)nickel intermediate (Path II). The migration of the aryl ligand onto the α-carbon atom of the vinylidene ligand may give an isomer, **2A**. β-Chloro elimination in a similar manner may give an acetylene(chloro)(aryl)nickel intermediate (Path III). The migration of the aryl ligand onto the acetylene carbon atom may give an isomer, **2B**. Isomer **2C** cannot be expected through α- or β-chloro elimination pathways. In order to obtain exact structural information concerning thermal isomerization in this system, X-ray crystal structure analyses of trichlorovinyl(*p*-tolyl)nickel(II) complex, *trans*-[Ni(CCl=CCl_2)(C_6H_4Me-4)(PMe_3)$_2$] (**1**) and its thermal isomerization product, *trans*-[NiCl{C(C_6H_4Me-4)=CCl_2}(PMe_3)$_2$] (**2**) have been carried out.

The photolysis of **1Y** (Y=Me-4, Cl-4) has been studied in order to obtain little-known photochemical properties concenrning square-planar organonickel(II) complexes.[3] Two isomers were obtained in a mixture by irradiation, one of which was identical to the thermolysis product of **1Y**. The molecular structure of another Photolysis product of **1Y**, *trans*-[NiCl{CCl=CCl(C_6H_4-Me-4)}(PMe_3)$_2$] (**3**), was also determined in order to compare the stuctural characteristics with **1** and **2**.

Experimental

Crystal Data. Complexes **1**, **2**, and **3** were prepared by a procedure described previously.[2] Single crystals were obtained by recrystallization from ethanol. Crystals of **1**, **2**, and **3** are pale-yellow, brown, and dark-brown in color with regular prismatic shapes, respectively. Preliminary oscillation and Weissenberg photographs taken with Cu $K\alpha$ radiation showed that crystals **1** and **3** are triclinic, whereas **2** is orthorhombic. Unit-cell parameters were determined at room temperature by a least-squares fit of the 2θ values of 25 strong, higher-angle reflections for three complexes observed on a four-circle diffractometer. Crystal data are summarized in Table 1.

Collection and Reduction of Intensity Data. The integrated intensities were measured on a Rigaku four-circle diffractometer with graphite monochromatized Mo $K\alpha$ (λ=0.71069 Å) radiation. The θ–2θ scan technique was used at a 2θ scan rate of 4° min^{-1} with a scan width of $\Delta 2\theta$=(2.0+0.70 tan θ)°. The background intensities were measured for 7.5 s at both ends of each scan. Three standard reflections were measured after every 61 reflections in order to monitor the radiation damage and any change in the crystal orientation. No significant intensity decay of the standard reflections was observed for all crystals studied. The number of reflection intensities collected up to 2θ=55° for **1** ($\sin\theta_{max}/\lambda$=0.650), 2θ=60° for **2** ($\sin\theta_{max}/\lambda$=0.704), and 2θ=55° for **3** were 4327, 3387, and 4792, among which the observed reflections [$|F_o|>3\sigma(F_o)$] were 3482, 2745, and 3276, respectively. Although the usual Lorentz and polarization effects were

corrected for the intensity data, no absorption correction was applied.

Determination and Refinement of the Structure. The three structures were all solved using the heavy-atom method. Successive Fourier syntheses phased by the nickel atoms found in Patterson maps clearly revealed the remaining nonhydrogen atoms. The structures were refined anisotropically by a full-matrix least-squares method (XRAY SYSTEM),[4] the function minimized being $\sum w(\Delta F)^2$. All of the hydrogen atoms were located on difference Fourier maps and were included in the refinement with isotropic temperature factors. The applied weighting function was $w=[\sigma_{cs}^2(F_o)+0.003\,(F_o)^2]^{-1}$, where σ_{cs} is the standard deviation estimated from the counting statistics. The final discrepancy factors, R (R_w), are 0.064 (0.094) for **1**, 0.043 (0.062) for **2**, and 0.062 (0.084) for **3**, respectively. The refinement parameters are summarized in Table 1.

The atomic scattering factors were taken from the International Tables for X-Ray Crystallography.[5] The final atomic coordinates of complexes (**1**, **2**, and **3**) together with the equivalent isotropic temperature factors (B_{eq}[6]) for nonhydrogen atoms are listed in Table 2.[#] All of the computations were processed on an ACOS 850 computer at the Research Center for Protein Engineering, Institute for Protein Research, Osaka University.

Results and Discussion

Molecular and Crystal Structures. The molecular structures of complexes **1**, **2**, and **3** are shown in Figs. 1—3 by ORTEP drawings,[7] together with the atomic numberings. X-Ray structure analyses of complexes **1**, **2**, and **3** revealed that the thermolysis of complex **1** resulted in isomerization product **2A** (Scheme 1) through a displacement between the *p*-tolyl and *α*-chloro; photolysis gave **2B** through a displacement between the *p*-tolyl and *β*-chloro in the vinyl group. Postulated complex **2C** was not identified in the thermolysis and photolysis of **1Y**.

[#] Tables of anisotropic temperature factors, coordinates of hydrogen atoms, and observed and calculated structure factors are kept as Document No. 8959 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Coordination Geometry of Nickel Atom: Selected structural parameters around the nickel atoms in complexes **1**, **2**, and **3** are given in Table 3. The first structural feature observed commonly in these molecules is that the nickel atom takes a square-planar coordination with either two phosphine ligands and two carbon ligands or one carbon and one chlorine ligand at *trans*-positions; this is similar to those in a series of *trans*-[Ni(aryl)$_2$(PR$_3$)$_2$] and *trans*-[Ni(C$_6$Cl$_5$)(PMe$_3$)$_2${C-(OMe)Me}BF$_4$ complexes.[8-10] In the complexes **1**, **2**, and **3**, five atoms defining the coordination plane of the nickel atom are nearly coplanar. The deviations from a mean plane defined by the inner co-coordination sphere, NiC$_2$P$_2$ or NiCClP$_2$, are: Ni, 0.025; P(1), −0.020; P(2), −0.020; C(1), 0.007; and C(31), 0.009 Å for **1**, Ni, 0.027; P(1), 0.037; P(2), 0.031; C(1), −0.050; and Cl(1),

C(1)–Ni–Cl(2)	—	—	175.9(2)
θ[a] (*Ni, Vinyl*)	88.2°	82.5°	88.7°
θ (*Ni, Tolyl*)	86.5	78.8	86.2
θ (*Vinyl, Tolyl*)	2.3	43.0	2.5

a) θ: Dihedral angle between the least-squares planes (*Ni, Vinyl, Tolyl*) composed of; *Ni*: Ni, P(1), P(2), C(1), and C(31) or Cl(1) or Cl(2). *Vinyl*: C(1), C(2), Cl(1), Cl(2), and Cl(3) in **1**. C(1), C(2), Cl(2), Cl(3), and C(31) in **2**. C(1), C(2), Cl(1), Cl(3), and C(31) in **3**. *Tolyl*: C(31)–C(36).

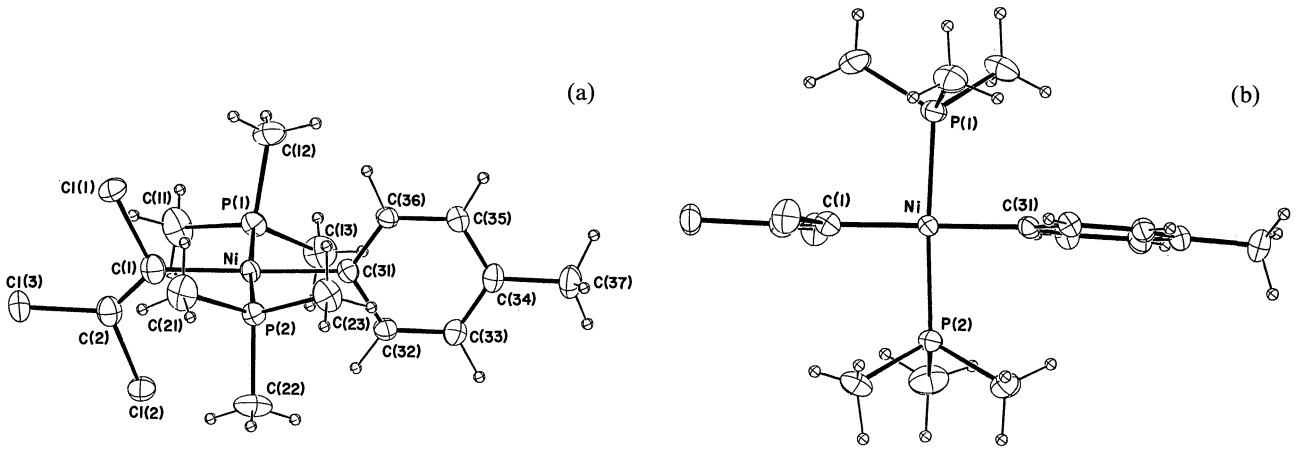

Fig. 1. Molecular structure of [Ni(CCl=Cl$_2$)(C$_6$H$_4$Me-4)(PMe$_3$)$_2$] (**1**) according to an ORTEP drawing with thermal ellipsoids at a 20% probability level; (a) top view, and (b) side view.

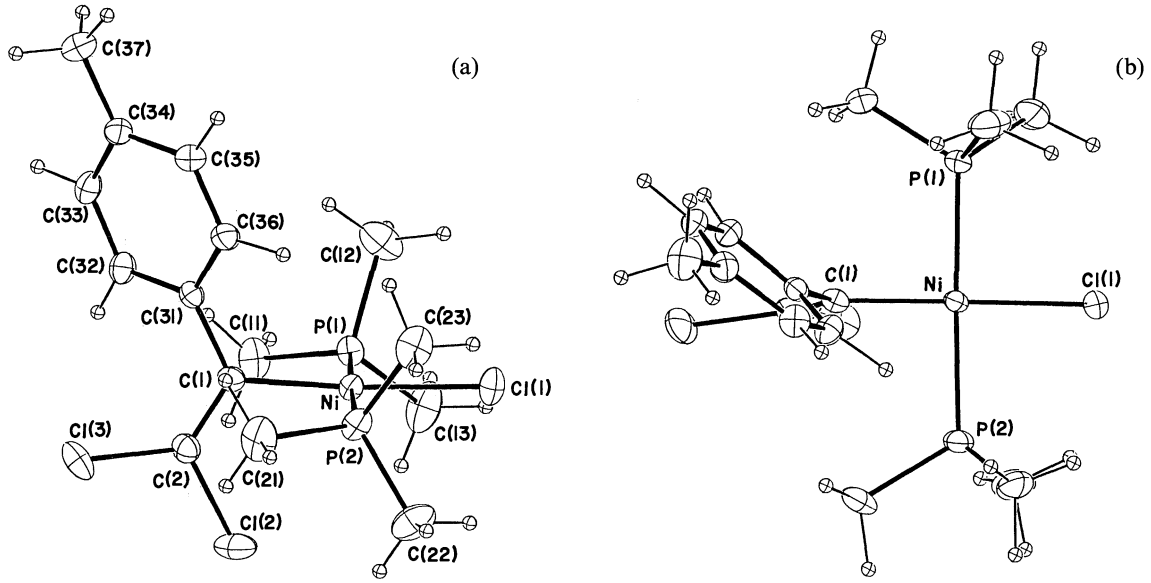

Fig. 2. Molecular structure of [NiCl{C(C$_6$H$_4$Me-4)=CCl$_2$}(PMe$_3$)$_2$] (**2**) according to an ORTEP drawing with thermal ellipsoids at a 20% probability level; (a) top view, and (b) side view.

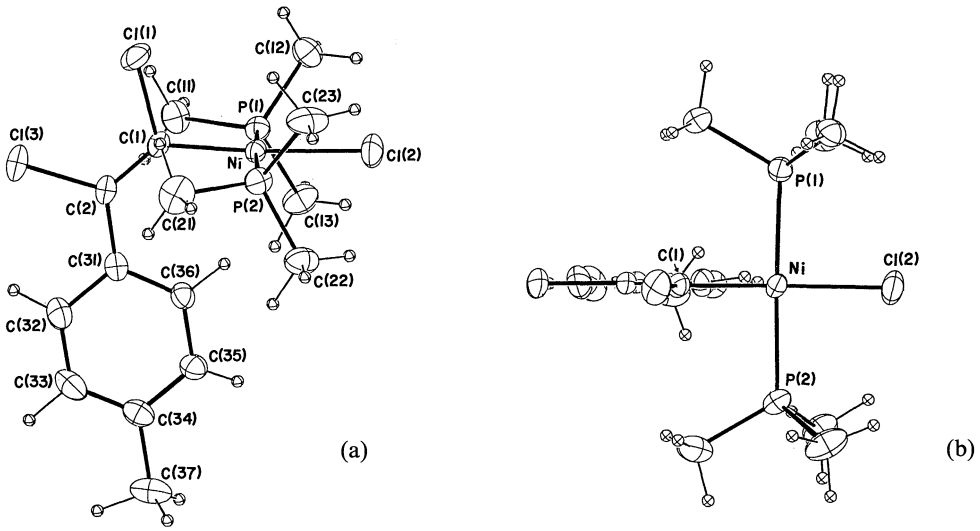

Fig. 3. Molecular structure of [NiCl{CCl=CCl(C$_6$H$_4$Me-4)}(PMe$_3$)$_2$] (**3**) according to an ORTEP drawing with thermal ellipsoids at a 20% probability level; (a) top view, and (b) side view.

−0.044 Å for **2**, Ni, 0.009; P(1), −0.091; P(2), −0.043; C(1), 0.107; and Cl(2), 0.049 Å for **3**, respectively. It is noteworthy that the P(1)–Ni–P(2) bond angles are 175.6(1)° and 175.5(1)° in complexes **1** and **3**, which show angular deviations of 4.4° and 4.5° from exact *trans* coordination; the bond angle in **2** [178.2(1)°] takes a value near to 180°. The bond angles C(1)–Ni–C(31) [178.9(3)°], C(1)–Ni–Cl(1) [175.8(2)°] and C(1)–Ni–Cl(2) [175.9(2)°] also deviate from the expected 180°, probably due to steric effects between the C or Cl and P atoms [mean C(1)···P 2.943 Å, 2.942 Å, 2.914 Å, and C(31)···P 2.850 Å, Cl(1)···P 3.100 Å, Cl(2)···P 3.088 Å for complexes **1**, **2**, and **3**, respectively]. The second feature is that the vinyl planes are approximately perpendicular to the Ni-coordination planes; the corresponding dihedral angles (θ) are 88.2° and 88.7° in complexes **1** and **3**, while that in complex **2** [82.5°] is slightly smaller. The *p*-tolyl plane in complexes **1** and **3** are also approximately perpendicular to the nickel coordination planes; the corresponding dihedral angles are 86.5° and 86.2°, respectively. The vinyl and *p*-tolyl planes in complex **2** are not coplanar with each other (dihedral angle; 43.0°) because of a nonbonded repulsion between the Cl(3) and H(32) atoms [Cl(3)···H(32); 2.82(6) Å, Cl(3)···C(32); 3.213(6) Å].

Conformation of Phosphine Ligand: Table 4 shows

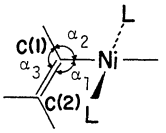
α_3	111.2(6)	122.5(5)	118.1(4)



the coordination geometries of the trimethylphosphine ligands in complexes **1**, **2**, and **3**. The ϕ's shows the torsional angles around the Ni–P bonds (taking the clockwise rotation as their positive direction). The ϕ's for the Ni–P(1) and Ni–P(2) bonds are −19.1°, −17.9°, −2.0°, and −28.7°, 3.1°, 5.0°, respectively. These values indicate that the first phosphine ligand [P(1), C(11), C(12), and C(13)] in complex **1** takes a similar conformation as that in complex **2**, while the second phosphine [P(2), C(21), C(22), and C(23)] in complex **2** has the similar conformation as that in complex **3**. In complex **1**, the two phosphine ligands are mutually related by nickel atom as an approximate center of symmetry. On the other hand, in complexes **2** and **3**, the phosphine ligands are related by an approximate mirror symmetry defined by a plane passing through the C(1), Ni, Cl(1) or Cl(2) atoms, which is normal to the coordination plane. The nonbonded intramolecular atomic distances between the C(1), C(31), or Cl(1), Cl(2) and nearby methyl groups in phosphine ligands are much shorter than the sum of Pauling's van der Waals radii [3.7 Å for C···C contact, and 3.8 Å for Cl···C]. Therefore, the conformations of these phosphine ligands are delicately modified by balancing the nonbonded atomic repulsions between the bulky methyl groups and the neighboring ligands.

Bonding Structure of Vinyl and *p*-Tolyl Ligands: Table 5 summarizes the selected structural parameters to describe the bonding geometries of the vinyl and *p*-tolyl ligands to the nickel atom. Almost the same Ni–P distances for the two phosphorus atoms of each molecule are observed [2.180(2) and 2.180(2) Å] for **1**, [2.201(2) and 2.212(2) Å] for **2**, and [2.212(2) and 2.205 Å] for **3**; the distances for three compounds, however, are slightly different from each other. The bond distance between the nickel and C(31) atoms in complex **1** [1.908(5) Å] has similar value as those between the nickel and vinyl α-carbon [C(1)], 1.907(5), 1.911(5), and 1.855(6) Å for complexes **1**, **2**, and **3**, respectively. These Ni–C distances are comparable with those reported in many organonickel complexes including C(sp^2)–Ni bonds.[11-14]

A remarkable structural feature is the unique structural deformations found in the vinyl ligand in complex **1**. First, the C(1)–C(2) bond distance of 1.258(10) Å is significantly shorter than the standard value for the C=C distance of 1.337 Å, while the corresponding distance in complex **2** [1.315(8) Å] and in complex **3** [1.337(8) Å] are equal to the standard C=C distance. Second, the C(1)–Cl(1) bond distance [1.840(7) Å] in complex **1** is longer than the C–Cl standard distance [1.72 Å in CH$_2$=CHCl, 1.767 Å in CH$_3$Cl or CH$_2$Cl$_2$], whereas the C(2)–Cl distances in **1**, **2**, and **3** complexes are in the range from 1.736 to 1.763 Å. A similar structural behavior has been observed for the vinyl ligand in [Ni(CCl=CCl$_2$)$_2$(PMe$_2$Ph)$_2$].[15] Third, the Ni–C(1)–C(2) bond angles (α_1) in complex **1** [132.5(6)°] and in complex **3** [134.1(5)°] are much larger than α_2 [**1**: 116.3(4), **3**: 107.8(3)°] and α_3 [**1**: 111.2(6), **3**: 118.1(4)°], while no angular deformation was found around the α-carbon atom of the vinyl ligand in complex **2**. The molecular structure of **1** shows an interesting trend toward linearity of the trichlorovinyl group.

Crystal Structure: No intermolecular distance shorter than the normal van der Waals contacts is found in the crystal structures of **1**, **2**, and **3**.

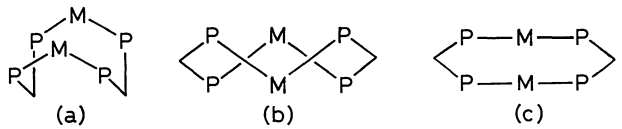
(Received February 8, 1991)

The bis(diphenylphosphino)methane(dppm) compounds of copper(I), $[Cu_2(\mu\text{-dppm})_2(biL)_2](PF_6)_2$ (biL=1,10-phenanthroline and its derivatives), have been synthesized and characterized by ^1H and ^{31}P NMR spectroscopy and X-ray crystallography. The molecules are found to contain a $[Cu_2(dppm)_2]^{2+}$ framework with the two copper atoms bridged by two dppm ligands to give eight-membered $Cu_2P_4C_2$ rings. This framework shows a staggered conformation subject to the coordination of additional ligands, biL. The coordination ^1H and ^{31}P shifts of the dppm are well-correlated with the basicity of the nitrogen donor atom of biL, sensitive to variations in the copper-ligand binding as well as their metal-to-ligand charge-transfer band. Crystallographic data of $[Cu_2(dppm)_2(phen)_2]$ are as follows. monoclinic space group $P2_1/c$, a=11.515(2) Å, b=27.922(4) Å, c=12.493(2) Å, β=107.68(1)°, U=3827(1) Å^3, and Z=2.

Bis(diphenylphosphino)methane (dppm) has served to afford an eight-membered ring dimer, $M_2P_4C_2$ of $M_2(\mu\text{-dppm})_2$. This stable framework adopts the three conformations shown below. The group IB metal monocation (Cu^+, Ag^+, and Au^+) gives this framework with an eclipsed (a) and (c), and a staggered (b) conformation; type (a) is found in $[Cu_2(\mu\text{-dppm})_2L_n]$ (L=CH_3CN (n=4),[1] S_2ct (n=2)[2]) and $[Ag_2(\mu\text{-dppm})_2(NO_3)_2]$;[3] type (b) is found in $[Au_2(\mu\text{-dppm})_2Cl_2]$.[4] These metal ions require additional monodentate or bidentate ligands, since each metal ion in the $M_2(dppm)_2$ framework is coordinatively unsaturated. The additional ligand not only influences the geometry around a metal ion, but also the structure of the framework including the conformation of $M_2(dppm)_2$. There are sparse literature data concerning investigations of the structure and properties of the $Cu_2(dppm)_2$ framework in relation to the additional ligand. In the present work, 1,10-phenanthroline (phen) and its derivatives were used as an additional ligand (biL), from which copper(I) complexes of $[Cu_2(\mu\text{-dppm})_2(biL)_2]^{2+}$ were synthesized. Their geometrical and electronic structures have been characterized by NMR spectroscopy and X-ray crystallography.



Experimental

Materials. $[Cu(CH_3CN)_4]PF_6$ was synthesized according to a method described in the literature.[5] Bis(diphenylphosphino)methane (dppm), 1,10-phenanthroline (phen) and its derivatives were obtained from Aldrich Co.

All operations were carried out under dry and purified argon by using the standard Schlenk or vacuum-line technique.

Preparation of $[Cu_2(\mu\text{-dppm})_2(phen)_2](PF_6)_2$. A 10 cm^3 acetone solution of phen (0.180 g, 1.0 mmol) and dppm (0.384 g, 1.0 mmol) was added to $[Cu(CH_3CN)_4]PF_6$ (0.373 g, 1.0 mmol), and the mixture stirred for 1 h. The resultant pale-yellow clear solution was transferred into a glass tube (7 mm inner diameter). The pale-yellow crystals were obtained after standing for 24 h at room temperature. Although most of the crystals were not suitable for X-ray crystallographic measurements, a few crystals were used.

Other phen derivatives, $[Cu_2(\mu\text{-dppm})_2(phen)_2](PF_6)_2$, were also prepared in a similar way.

Physical Measurements. The electronic absorption spectra were obtained with a Hitachi 200-10 spectrophotometer for an acetone solution in 1-cm quartz cells.

The ^1H NMR spectra were obtained on a JEOL FX200 NMR spectrometer operating in the Fourier-transform mode (16 K data points transform of 2500 Hz spectral width after 200—500 puleses) at 23 °C. ^{31}P NMR spectra were measured at 23 °C without ^1H irradiation. Between 20—50 K transients were accumulated using a 18.0 μs pulse (90°): 16 K data points were collected over a band width of 4 kHz. H_3PO_4 (85%) was used as an external standarad.

Crystallography. Crystal Data. $C_{80}H_{72}Cu_2N_4O_2F_{12}P_6$, monoclinic, space group $P2_1/c$, a=11.515(2), b=27.922(4), c=12.493(2) Å, β=107.68(1)°, U=3827(1) Å^3, Z=2, D_c=1.442 g cm^{-3}, $F(000)$=1704, λ(Mo$K\alpha$)=0.71069 Å, μ=7.56 cm^{-1}, T=23 °C.

X-Ray Data Collection. A single crystal (0.5×0.4×0.4 mm) of the compound was glued on top of a glass fiber and then studied on a Rigaku AFC5R automatic diffractometer. Unit-cell constants and an orientation matrix for data collection, obtained from a least squares refinement using the setting angles of 25 carefully centered reflections over the range $20° < 2\theta < 32°$, corresponded to a monoclinic cell.

The space group $P2_1/c$ was chosen on the basis of the observed systematic absences ($h0l$: $l=2n$; $0k0$: $k=2n$) and a successful determination of the structure.

Solution and Refinement of the Structure of $[Cu_2(\mu\text{-dppm})_2(phen)_2](PF_6)_2\cdot 2(CH_3)_2CO$. A total of 5121 reflections having $I>3\sigma(I)$ were used. The structure was solved by a direct method,[6] and refined by full-matrix least-squares calculations with anisotropic thermal parameters, including

isotropic H atoms located by a difference Fourier synthesis. Finally, a two-cycle refinement led to a convergence at $R=\sum[||F_o|-|F_c||]/\sum|F_o|=0.082$, $R_w=[\sum w(|F_o|-|F_c|)^2/\sum w|F_o|^2]^{1/2}=0.127$, $w=4F_o^2/\sigma^2(F_o^2)$, $\Delta e=0.79$ Å^{-3}, and the largest shift estimated standard deviation at the final cycle (0.13). The atomic parameters of non-hydrogen atoms are given in Table 1.[7]

Results and Discussion

Description of Molecular Structure. The crystal structure comprises of dimeric complex molecules $[(phen)Cu(\mu\text{-dppm})_2Cu(phen)]^{2+}$ (**1**); a perspective view of the inner skeleton is given in Fig. 1. The important bond lengths and angles are summarized in Table 2. This cation has an inversion center. The two copper atoms are doubly bridged by two dppm ligands to form an eight-membered $Cu_2P_4C_2$ ring. Each copper atom displays a four-coordinate form having P_2N_2 donors. The dihedral angle between the (N(1)–Cu–N(2)) and (P(1)–Cu–P(2)) planes is 84.5°, indicating a slightly distorted tetrahedral geometry around the copper atom.

In each copper moiety, all of the distances between the copper and donor atoms are different: both Cu–N(1) and Cu–N(2) are longer by 0.065—0.087 Å than the usual distaces (2.049(9) Å for $[Cu(phen)_2]ClO_4$),[8] and the gap in the two Cu–N distances is 0.022 Å. Similarly, the two Cu–P distances, 2.286(3) and 2.234(3) Å, are also different (0.052 Å), falling within the usual range for copper–dppm compounds so far synthesized: 2.296(8) Å in $[Cu_4(dppm)_4(CS_3)_2]$,[9] 2.22 Å in $[(CuI)_2(dppm)]_2$,[10]

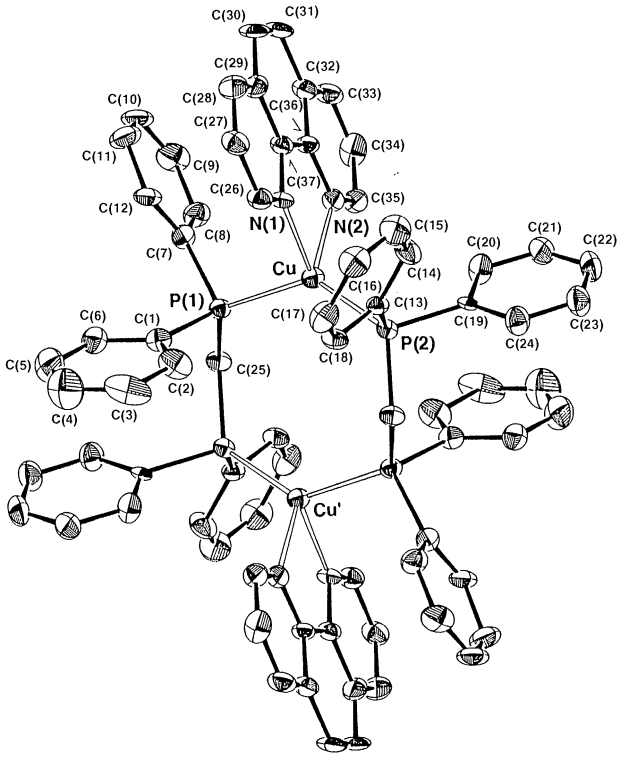

Fig. 1. View of $[Cu_2(\mu\text{-dppm})_2(phen)_2]^{2+}$ with the atomic numbering scheme. Only half the atoms are labeled, the others are related by a center of inversion at the midpoint of the Cu···Cu′ vector.

and 2.231(3) Å in $[Cu_3(OH)(dppm)_3](BF_4)_2$.[11]

The angle of N(1)–Cu–N(2), 79.8(3)°, is close to that of $[Cu(phen)_2]ClO_4$ (81.4(3)°)[8] and $[Cu(dppe)(phen)]PF_6$ (80.7(3)°),[12] where dppe is 1,2-bis(diphenylphosphino)-ethane. On the other hand, a P(1)–Cu–P(2) angle of 134.34(9)°C in **1** is quite large. $[Cu(dppe)(phen)]PF_6$ displays an P–Cu–P angle of 91.3(1)°. Generally, the P–Cu–P angles in monomeric copper(I) compounds of dppe fall within 88—110°.[12,13] This smaller angle is not necessarily due to restraint by chelate coordination of dppe, since monodentate phosphines also give similar values:[14] P–Cu–P=109.3°, 115.9(1)°, and 125.4(1)° for $[Cu(Pph_3)_4]ClO_4$, $[Cu(Pph_3)_2(py)_2]ClO_4$, and $[Cu(Pph_3)_2(bpy)]ClO_4$, respectively. On the other hand the large P–Cu–P angle of 134.34(9)° is not simply ascribed to a restriction by the bridged form of dppm, since $[Cu(\mu\text{-dppm})(CH_3CN)_2]_2(ClO_4)_2$ (119.9(1)°)[1] and $[Cu(S_2ct)(\mu\text{-dppm})]_2$ (114.2°)[2] have normal P–Cu–P angles. Among the various $M_2(dppm)_2$ (M=Cu, Ag, and Au) frameworks, as illustrated in the inserted figures (a), (b), and (c), the staggered conformation (b) tends to open the P–M–P angle rather than the eclipsed one (non-planar type, (a)). The P–Ag–P angle of 138.3(1)° in eclipsed $[Ag_2(dppm)_2(NO_3)_2]$[3] is smaller than that of 155.9(1)° in staggered $[Au_2(dppm)_2Cl_2]$.[4] Hence, the P–Cu–P angle is greatly associated with the conformation of the $M_2(dppm)_2$ framework. Complex **1**, indeed, has a rare staggered framework, while both $[Cu(\mu\text{-dppm})(CH_3CN)_2]_2(ClO_4)_2$[1] and $[Cu(S_2ct)(\mu\text{-dppm})]_2$[2] show an eclipsed framework.

In spite of the significant degree in the opening of the P–Cu–P angle in **1**, the Cu···Cu separation of **1** is 4.742(2) Å, much greater than that of $[Cu_2(dppm)_2(CH_3CN)_2]^{2+}$ (**2**) (3.757(3) Å) and $[Cu_2(dppm)_2(S_2ct)_2]$ (**3**) (3.426(3) Å). This is because a conformation occurs in order to avoid close contact between the two coordinated bulky phen ligands, resulting in a large separation of the copper pair. Hence, each copper(I) moiety in **1** seems to be monomer-like, more than in **2** and **3**.

NMR Chemical Shifts and Metal-Ligand Binding. $[Cu(\mu\text{-dppm})(biL)]_2(PF_6)_2$ gave well-resolved ^1H NMR signals of coordinated biL and dppm, of which chemical shifts are listed in Table 3. For all of the complexes given in Table 3, large coordination shifts ($\delta_{coord}=\delta_{complex}-\delta_{metal\text{-}free}$) were obtained. In the case of phen derivative, for instance, the δ_{coord} of 2,9-H, phenyl-H, and CH_2 protons are −0.59, −0.32, and 1.11, respectively. These are clearly illustrated in Fig. 2. An inspection of Table 3 shows that δ_{coord} (2,9-H) of the dimers is much greater than that in monomeric $[Cu(dppe)(phen)]^+$. This large upfield shift can be accounted for by an anisotropic magnetic effect (ring current effect) of the coordinated dppm. Figure 1 reveals that one of the four phenyl groups of a dppm sits over the nearest-neighbor phen plane in a face-to-face fashion: the phenyl ring of C(7)–C(8)–C(9)–C(10)–C(11)–C(12) and the phen plane of N(1), N(2), and C(26)—C(35). The dihedral angle between the two

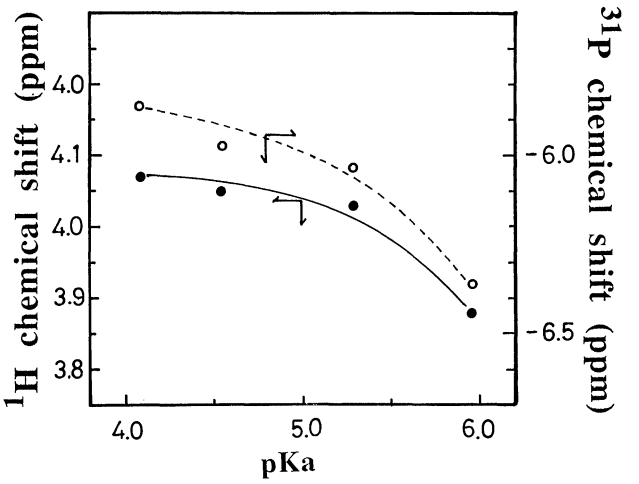

Fig. 3. Plots of the observed ^{1}H and ^{31}P NMR chemical shifts of coordinated dppm vs. pK_a of biL in $[Cu_2(\mu\text{-dppm})_2(biL)_2](PF_6)_2$. The plotted data are listed in Table 3.

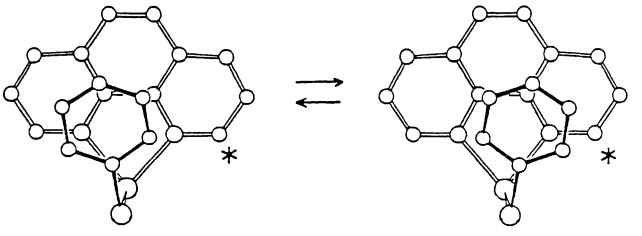
mean planes of the phenyl group and phen is 19.02°, indicating that protons on both planes experience an up-field shift. The distance between the nearest-neighbor atoms on the two plane is ca. 3.4 Å, sufficiently close to cause ring a current shift. Accordingly, the phenyl protons also undergo a ring current effect due to the phen ring. This intramolecular magnetic interaction is characteristic of the dimeric structure of $[Cu(\mu\text{-dppm})(phen)]_2^{2+}$.

The molecular structure shown in Fig. 1 also indicates a magnetic inequivalence of 2- and 9-H of phen (similarly 3- to 8-H) concerning the ring current effect of a phenyl group. However, their signals are not separated. This reveals that a low-energy fluxional process is present in solution because of the flexibility of the $Cu_2C_2P_4$ framework. The phenyl ring moves around above a phen plane, depending on the ring motion, as illustrated below.



All of the biL derivatives of $[Cu(\mu\text{-dppm})(biL)]_2^{2+}$ also provided specific large shifts of these proton signals in question. Hence, all of the complexes studied here afford the dimeric form, even in solution, as well as in the solid state.

The ^{31}P spectra showed a single signal, which is ascribed to $[Cu_2(\mu\text{-dppm})_2(biL)_2]^{2+}$. The observed ^{31}P chemical shifts are plotted against the pK_a values of biL, together with the ^{1}H chemical shifts of the CH_2 of dppm (Fig. 3). Figure 3 indicates that since biL has a higher basicity, this causes up-field shifts of both the ^{1}H and ^{31}P NMR signals. It has been demonstrated[14,15] that the higher is the basicity of biL the stronger is the copper–biL bonding. The upfield ^{1}H and ^{31}P shifts indicate that Cu–P bonding is weakened. Thus, the relationship shown in Fig. 3 well demonstrates the competition between Cu–P and Cu–N bonding. Consequently, the Cu–P bonding tends to be weak when the Cu–biL bonding becomes strong.

The electronic absorption spectra of these solutions also give information concerning copper–ligand binding. A strong absorption band is observed for each solution in the region 360—370 nm, as shown in Table 3. There is no band in the case of binary systems, such as Cu/dppm and Cu/biL (biL=phen derivatives). The latter system affords a metal-to-ligand charge transfer (MLCT) band in the region greater than 400 nm.[15-17] On this basis, the band in Table 3 has been assigned to the metal-to-ligand charge-transfer bands between Cu and biL in ternary complexes. For instance, the band for $[Cu_2(\mu\text{-dppm})_2(phen)_2]^{2+}$ appears at 355 nm, while $[Cu(phen)_2]^+$ provides a band at 440 nm.[17] This remarkable blue shift (by 85 nm) shows that Cu–phen bonding is weaker in $[Cu_2(\mu\text{-dppm})_2(phen)_2]^{2+}$ than in $[Cu(phen)_2]^+$. This is consistent with the fact that the Cu–N bond distance in **1** is greater than that in $[Cu(phen)_2]^+$,[8] as mentioned above. This trend has been found for all of the complexes studied here.

Co-Intercalation of Tetrahydrofuran and Propylene Carbonate with Alkali Metals in β-ZrNCl Layer Structured Crystal

Masao OHASHI,* Koji UYEOKA, Shoji YAMANAKA, and Makoto HATTORI†
Department of Applied Chemistry, Faculty of Engineering, Hiroshima University, Higashi-Hiroshima 724
(Received April 6, 1991)

Alkali metal intercalation compounds of β-ZrNCl were prepared by both chemical and electrochemical processes in tetrahydrofuran (THF) and propylene carbonate (PC), used as solvents. Among the six combinations of alkali metals (Li, Na, and K) with THF and PC, only the Na–THF system did not form a co-intercalation phase. In the other systems, the solvent molecules co-intercalated with alkali metals in mono- and double layer arrangements between the chloride layers of β-ZrNCl, the structures of which were estimated from one-dimensional electron distribution maps along the direction normal to the basal plane. The electrochemical characteristics of β-ZrNCl, used as the cathode of a lithium battery, were greatly influenced by the electrolyte solvent used. The co-intercalation mechanisms are discussed in terms of the energetics of the solvation of alkali metal ions with polar molecules and an expansion of the β-ZrNCl interlayers.

Lithium intercalations in layer-structured crystals have been extensively studied, since such crystals are promising candidates for the electrodes of secondary lithium batteries and electrochromic display (ECD) devices.[1,2] It is well-known that intercalated lithium atoms are ionized in interlayer spaces, and are often solvated with the polar organic solvents used in the preparation,[3]

$$[L] + x\mathrm{Li} + y(\mathrm{Solv}) \rightarrow \mathrm{Li}_x^+(\mathrm{Solv})_y[L]^{x-},$$

where [L] stands for layer-structured crystals such as transition metal dichalcogenides, iron chloride oxide, and graphite; Solv represents solvent molecules. Solvent molecules co-intercalated with lithium expand the basal spacing of the host layers. The degree of this expansion depends on the type of arrangement as well as the size of the molecules. Such an expansion of the interlayer spacing is considered to seriously influence the reversibility of lithium cells, since it may cause a mechanical disintegration of the electrode.[4]

β-ZrNCl is a layer-structured crystal. Each layer comprises a zirconium nitride double layer sandwiched between two close-packed chlorine layers. Such layered sequences (Cl–Zr–N–N–Zr–Cl) are stacked with each other by van der Waals interactions.[5] In a series of previous papers[6,7] we showed that β-ZrNCl is an interesting layered host for lithium intercalation, and could be used as a cathode material for the lithium battery and electrochromic devices, although the electrochemical characteristics of the electrodes are not yet satisfactory for practical use.[8] We also showed that β-ZrNCl readily forms co-intercalation phases with a variety of solvents such as THF, PC, acetonitrile, formamide, *N*,*N*-dimethylformamide, dimethyl sulfoxide, and pyridine.[7] It was considered that the formation of co-intercalation phases would have a bad influence on the performance of batteries.[9] A better understanding concerning the formation mechanism of the co-intercalation phases is indispensable for developing secondary batteries with high performance.

In this study we attempted to elucidate the formation mechanism of the co-intercalation phases of β-ZrNCl with THF and PC. The co-intercalation phases are prepared by both chemical and electrochemical processes by changing combinations of the alkali metals and solvents. The mechanisms are discussed in terms of the energetics of the solvation of alkali ions with the polar molecules and the expansion of the interlayer spacing of β-ZrNCl.

Experimental

Materials. β-ZrNCl was prepared by a reaction of ZrH_2 with ammonium chloride in a stream of dry ammonia according to a method reported elsewhere.[10] Highly crystalline β-ZrNCl was prepared by a chemical transport method;[10,11] it was then ground and sieved through a 200 mesh screen.

THF was purified by refluxing with benzophenone and sodium followed by distillation, and then stored with a molecular sieve (4A). Three kinds of 0.1 M alkali dihydronaphthylide solutions (A–Naph, A=Li, Na, and K; 1 M=1 mol dm^{-3}) were prepared by dissolving equimolar amounts of naphthalene and the respective alkali metals into THF. After 20 h, each solution was filtered through a sintered glass filter in order to remove any insoluble impurities. PC was vacuum distilled and then dried with a molecular sieve (4A). The butyllithium (BuLi) used was a 15 wt% solution from Katayama Chemical. Anhydrous alkali perchlorates were dried by evacuation at 393 K for 12 h.

Chemical Intercalation. Lithium intercalation was carried out by reactions with BuLi and Li–Naph. In the case of the former reaction, only a lithium intercalated sample was obtained,[8] which was then soaked in THF and PC in order to convert it to the respective co-intercalation phases. Varying amounts (or volumes) of Li–Naph were added to β-ZrNCl. After being allowed to stand for 24 h at room temperatures, the lithiated samples were separated by filtration in an Ar-filled glove box (Vacuum Atmosphere Co.). Sodium and potassium intercalated samples were prepared by reactions with

† Present address: Yonago National College of Technology, Hikona-cho, Yonago, Tottori 683.

Na- and K-Naph in a similar manner.

Electrochemical Intercalation. The β-ZrNCl powder sample was pressed onto a stainless-steel mesh of about 8 mm in diameter. Electrochemical cells were constructed by using the pressed sample as the cathode, an alkali metal foil as the anode and a glass filter separator soaked with 1 M Li and Na perchlorate solutions in THF and PC. A $KClO_4$/PC saturated solution was also used for the K/β-ZrNCl cell. The cells were galvanometrically discharged at a rate of 0.2 mA cm^{-2}, and the electrodes were taken out at different stages of discharge to measure the change in the basal spacing of β-ZrNCl.

Analyses. The X-ray powder diffraction (XRD) patterns of all the intercalated samples were measured under an argon atmosphere in a cylindrical cover having thin polyethylene windows by using nickel-filtered Cu $K\alpha$ radiation. The amounts of co-intercalated THF were determined from the weight loss before and after evacuation at 453 K. The amounts of alkali metals intercalated were determined by flame analysis after extraction by a procedure reported elsewhere.[8]

Results

Chemical Intercalation. The basal spacings (d) and some interlayer compositions of the chemical intercalation products are listed in Table 1. The lithium intercalate with a composition of $Li_{0.16}ZrNCl$ and a basal spacing of 0.93 nm was obtained by a reaction with a BuLi solution in hexane.[8] The nonpolar hexane molecules did not co-intercalate with lithium and, thus, the basal spacing is almost unchanged from that of the initial β-ZrNCl (d=0.92 nm). However, when the lithiated sample was dispersed in THF and PC, the basal spacing increased to 1.49 and 2.22 nm, respectively, although β-ZrNCl without lithium did not swell in these solvents. Li-Naph is a stronger reducing agent than BuLi[12] and, as shown in the table, larger amount of lithium can be intercalated by using an appropriate amount of Li-Naph. The amount of lithium intercalated increases with the amount of Li-Naph used.[9] Single-basal-spacing phases were obtained at x=0.18 and 0.20 (x in Li_xZrNCl), the amount of THF co-intercalated (y) being determined to be 0.25 and 0.35, respectively. Although the other products were mixtures of two or three phases with different basal spacing, the spacing appears to vary in the following order with increasing x:

$$0.92 \rightarrow 1.45 \rightarrow 1.85 \rightarrow 2.00 \rightarrow 1.08\ \text{nm}$$
$$\beta\text{-ZrNCl} \quad x=0.18 \quad x=0.20 \quad x=0.5 \quad x>1.0$$

It is interesting to note that the spacing increases up to 2.00 nm with the amount of lithium intercalated and then collapses to 1.08 nm when the amount of lithium (x) exceeds about 1.0.

In reactions with Na-Naph, no co-intercalation phases were obtained; a sample with a small amount of Na showed a basal spacing of 0.99 nm. As the amount of intercalated Na increases, the 0.99 nm phase changes to a 1.08 nm phase. A sample $Na_{0.40}ZrNCl$ with a basal spacing of 0.99 nm swelled in PC and the spacing increased to 2.06 nm, though it did not form any co-intercalation phase with THF.

In the interlayer spaces between the chloride layers of β-ZrNCl, there are 1/2 octahedrally co-ordinated sites and one tetrahderally co-ordinated vacant site on the ZrNCl formula basis. The stoichiometry shown in Table 1 indicates the formation of intercalation phases with $x>0.5$ (x in A_xZrNCl; A=Li and Na); this suggests that alkali metals occupy the tetrahedral as well as the octahedral vacant sites.

K-Naph forms co-intercalation phases with basal spacings of 1.47 and 1.30 nm. If a much larger amount of K-Naph was used, the layer structured phase disappeared and the formation of KCl was observed by XRD analysis. After washing out the KCl with water, the residue was calcined at 1273 K in a vacuum. The resulting compound was found to be ZrN. This finding suggests that K-Naph is a stronger reducing agent than Li- and Na-Naph, so that β-ZrNCl is reduced to ZrN by the following equation:

$$\beta\text{-ZrNCl} + \text{K-Naph} \rightarrow \text{ZrN} + \text{KCl} + \text{Naph}.$$

solvents are shown in Figs. 1 and 2, respectively. The discharges were stopped at different stages of current flow (Q) on separate samples, and the basal spacings of the β-ZrNCl cathodes were measured by an XRD analysis. The spacings listed in Table 2 are coincident with those of the samples obtained by the chemical intercalations up to the same intercalation level. It should be noted that in a battery system with Na–THF, no intercalation of THF occurred, even during the electrochemical process, as found in the chemical intercalation.

In a previous paper[8] it was revealed that in a battery of Li|$LiClO_4$/PC|β-ZrNCl, lithium could not intercalate over the stage of $x \approx 0.16$. The current discharged over this stage was used for the decomposition of PC, rather than for Li intercalation; the discharge curve showed a plateau at about 1.0 V vs. Li/Li^+. Similar decompositions accompanied by plateaus in the discharge curves were observed for Na- and K–PC systems (Fig. 2). All of the β-ZrNCl cathodes taken out at a discharge level of $x=0.10$ had very large basal spacings of 2.00—2.22 nm, indicating that PC could co-intercalate with these three kinds of alkali metals in β-ZrNCl.

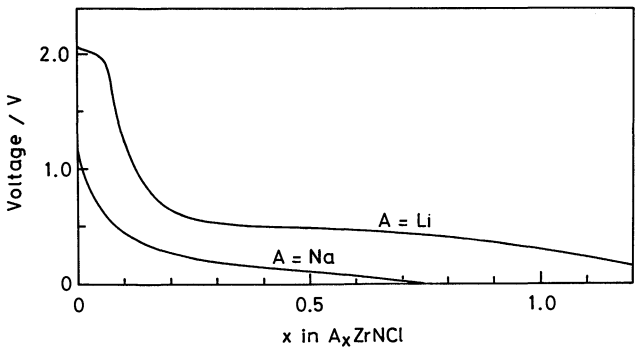

Fig. 1. Discharge curves for A|$AClO_4$/THF|β-ZrNCl cells (A=Li and Na) at a current density of 0.2 mA cm^{-2}.

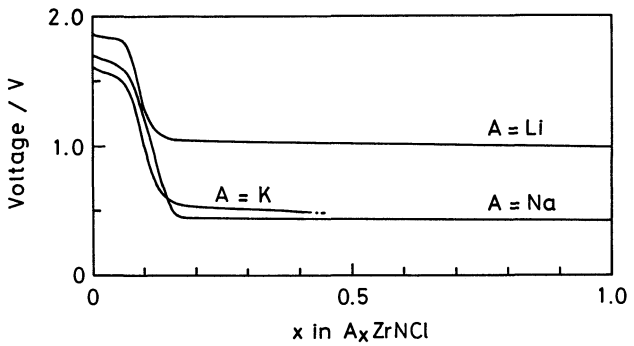

Fig. 2. Discharge curves for A|$AClO_4$/PC|β-ZrNCl cells (A=Li, Na, and K) at a current density of 0.2 mA cm^{-2}.

Interlayer Molecular Arrangements. Most of the co-intercalation phases are highly crystalline and basal reflections up to 12 orders were measured in each XRD pattern. One-dimensional electron-density distribution maps along a direction perpendicular to the basal plane were synthesized on the basis of the corrected reflection intensities on the following three samples; $Li_{0.18}(THF)_{0.28}ZrNCl$ (d=1.49 nm), $Li_{0.20}(THF)_{0.35}ZrNCl$ (d=1.85 nm), and $Li_{0.16}(PC)_{0.64}ZrNCl$ (d=2.22 nm). The presence of a mirror plane was assumed, and the signs of the structural factors were determined on the basis of the β-ZrNCl host structure expanded along the c-axis. The synthesized electron distribution maps are shown in Figs. 3 and 4. The R factors were calculated to be within the range 0.18 to 0.23. The distributions of the figures clearly show that the co-intercalated molecules are located in the Cl···Cl interlayer spaces. In the co-intercalation phase with a smaller basal spacing of 1.49 nm, the THF molecules are oriented with the molecular planes almost perpendicular to the β-ZrNCl layers and in a monolayer arrangement; in the co-intercalation phases with basal spacings of about 2.0 nm, however, the THF and PC molecules are arranged in double layers. It is very likely that the lithium ions seem to be solvated by these molecules through the oxygen atoms.

Discussion

We have examined the intercalations of three kinds of alkali metals coupled with two kinds of solvents for each metal and found that the co-intercalation behaviors are very different, depending on the combinations. In electrochemical intercalations in systems with PC, intercalation compounds $A_x(PC)_yZrNCl$ with $x>0.16$

Table 2. Basal Spacings of the Electrochemical Intercalation Products of β-ZrNCl Separated at Different Stages of Discharge

Anode	Electrolyte	Amount discharged (Q) Q/e/ZrNCl	Basal spacing (d) d/nm
Li	1M $LiClO_4$/THF	0.18	1.49
		0.20	1.85
		1.20	2.00
Na	1M $NaClO_4$/THF	0.40	0.99
K	$KClO_4$ (Satd.)/PC	0.10	2.18
Li	1M $LiClO_4$/PC	0.10	2.22
Na	1M $NaClO_4$/PC	0.10	2.00

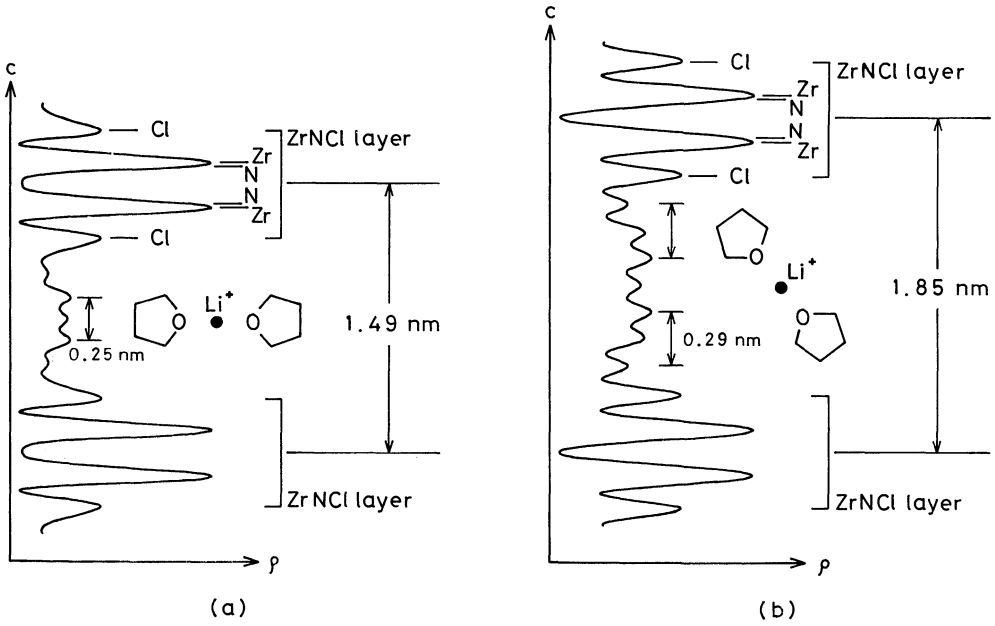

Fig. 3. One-demensional electron-density maps along the direction normal to the β-ZrNCl layers together with the estimated intrlayer molecular arrangements: (a) $Li_{0.18}(THF)_{0.28}ZrNCl$, (b) $Li_{0.20}(THF)_{0.35}ZrNCl$.

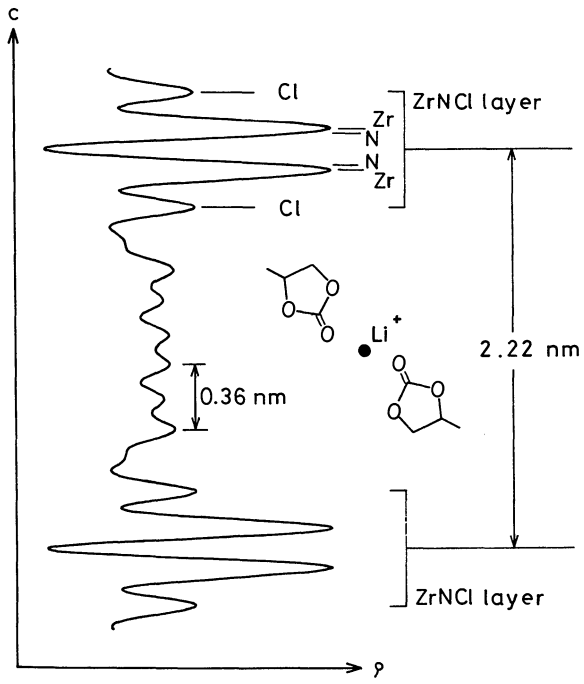

Fig. 4. One-dimensional electron-density map along the direction normal to the ZrNCl layers and the interlayer moleculer arrangement of $Li_{0.16}(PC)_{0.64}ZrNCl$.

were not formed; the current discharged over this point was used for the decomposition of PC rather than for a further intercalation of alkali metals. On the other hand, in electrochemical systems with THF, almost all of the current discharged was used for alkali metal intercalations without being accompanied by a decomposition of THF. In a previous study[8] concerning the characteristics of a $Li|LiClO_4/PC|\beta$-ZrNCl cell, it was expected that the presence of co-intercalated PC molecules in the interlayer spaces might prevent any further intercalation of Li into the interlayer spaces. However, from the comparison of the two electrochemical systems with PC and THF, it is evident that alkali metals can intercalate into the interlayer spaces of β-ZrNCl, even if the spaces are occupied by co-intercalated molecules. An electrochemical system containing PC seems to be rather a special case, in which the surface of the alkali intercalated β-ZrNCl catalyzes the decomposition of PC at relatively high voltages vs. Li^+/Li as seen in Fig. 2. In the case of the Na–THF–ZrNCl system, the intercalation compound Na_xZrNCl did not form any co-intercalation phase. Nevertheless, the cell $Na|NaClO_4/THF|\beta$-ZrNCl experienced a partial polarization for the discharge at the rate same as that used in the cell $Li|LiClO_4/THF|\beta$-ZrNCl, and showed low discharge voltages (Fig. 1). This finding also supports the above conclusion that the co-intercalated molecules do not necessarily hinder the diffusion of alkali metals into the interlayer spaces.

Among the combinations of three kinds of alkali metals (Li, Na, and K) with two kinds of polar solvents (THF and PC), only the Na–THF system does not form co-intercalation phases. In addition, in the Li–THF system, if a larger amount of Li was intercalated, the co-intercalation phase collapsed, releasing solvated THF molecules out of the interlayer spaces. The formation of co-intercalation or collapsed phases seems to be interpreted in terms of the energetics of the solvation of

alkali ions with the polar molecules and an expansion of the interlayer spacing as follows:

In the course of intercalation, work must be done by the solvent molecules to make room in the interlayer spaces. The driving force for the intercalation is mainly due to dipole-cation interactions similar to those involved in the solvation of cations in an electrolyte solution. The co-intercalation occurs if such interactions between the polar solvent molecules and the ionized alkali metals in the interlayer spaces are sufficiently strong to compensate for the energy required for expanding the interlayers. The solvation energy or the work of ion dipole interaction ($W_{I\text{-}D}$) is given by the following equation:[13]

$$W_{I\text{-}D} = \frac{Nnz_ie}{(r_i+r_s)^2}\mu_s,$$

where N is Avogadro's number, n is the co-ordination number of the solvent, z_ie is the ionic charge, r_i and r_s are the ionic radius of alkali metals and the radius of the polar solvent, respectively, and μ_s is the dipole moment of solvent molecules. The finding that PC molecules can form co-intercalation phases with all kinds of alkali-intercalated ZrNCl can be interpreted in terms of its exceptionally large dipole moment (μ_s=4.94 D; D=3.3356×10^{-30} C m). THF has a much smaller dipole moment (μ_s=1.75 D), and the systems have a smaller $W_{I\text{-}D}$ than that of the corresponding PC systems. The $W_{I\text{-}D}$ decreases with an increase in the radius of interlayer cations. In THF-containing systems, although the $W_{I\text{-}D}$ decreases in the order Li>Na>K containing systems, only the Na intercalated β-ZrNCl does not form the co-intercalation phase. This suggests that the $W_{I\text{-}D}$ of the Na–THF system would not be large enough to overcome the energy required for the THF molecules to intercalate. The $W_{I\text{-}D}$ in the K–THF system is much smaller than that of Na–THF. However, the K ions are co-intercalated with THF molecules in β-ZrNCl. This can be explained by the large ionic size of K^+ as follows: the cation radius of K^+ is larger than that of Na^+ and the interlayer spacing supported by the K ions is correspondingly larger. Therefore, only a smaller amount of energy would be required for the THF molecules to expand the interlayer spaces in the K–THF system; the K ions can be regarded as acting as pillars.

The degree of interlayer space expansion due to co-intercalation would also be determined energetically. During the early stages of intercalation, the number of co-intercalated THF molecules increases with an increase in the number of intercalated lithium ions. During this procedure, even a small increase in the number of lithium ions causes a large change in the way the intercalated THF molecules are arranged, consequently, resulting in different expansions of the interlayer spacing (Fig. 3). However, if a much larger amount of lithium is intercalated, the electrostatic interactions between the negatively ionized layers and the lithium cations may exceed the solvation energy in the Li–THF system; even if lithium ions are present between the layers, the THF molecules are released out of the interlayer spaces.

This study was partly defrayed by the Grant-in-aid for Scientific Research on Priority Area of the Ministry of Education, Science and Culture.

Five- and six-coordinated nitrosyl iron(II) complexes of a series of tetrakis(*p*-substituted phenyl)porphyrins have been prepared. Their EPR and IR spectra have been measured and analyzed in order to elucidate the cis-effect of substituents on the axial nitrosyl ligand. As the first redox potentials of the free base porphyrins in the complexes became positive, the NO stretching frequencies increased in both five-coordinated and six-coordinated nitrosyl(porphyrinato)iron(II) complexes with a nitrogenous base at an axial site trans to the NO group. The positive shift of the redox potentials led to an increase in the EPR *g* values and hyperfine coupling constants at room temperature and at 77 K for the five-coordinated complexes, while it led to a decrease in *g* values and to a slight increase in hyperfine coupling constants for the six-coordinated complexes. These results are rationalized by invoking that, as the electron-withdrawing power of porphyrin peripheral substituents is enhanced, the iron-to-NO bond in both the five- and six-coordinated complexes is weakened and the iron-to-nitrogenous base bond in the six-coordinated complexes is strengthened. The difference in the cis- and trans-effects on the EPR parameters and NO stretching frequencies is also discussed.

The electronic properties of the heme at active centers of various hemoproteins and the biological functions of these proteins are markedly influenced by the electronic states of the equatorial porphyrinato and axial ligands. The porphyrin peripheral substituents and axial ligands serve as intermediaries of the electronic and steric interactions between the heme group(s) in hemoprotein and amino acid residues surrounding the heme group. From this point of view, the cis and trans effects on various properties of metalloporphyrins have been extensively investigated.[1-5]

Nitrogen monoxide (nitric oxide) is formed as an intermediate in the biological denitrification process[6] and is the most probable candidate for an endothelium-derived relaxing factor.[7] Further, nitrogen monoxide has been known as a biological ligand of nitrite reductases[8] and guanylate cyclase.[9] Thus, an increasing interest is placed on the physiological significance of nitrogen monoxide.

Because the nitrogen monoxide molecule has an unpaired electron and is coordinated as sixth ligand to the heme iron in hemoproteins, it has so far been employed as a useful electronic probe for elucidating the heme environments and the heme group.[10-13] For understanding the properties of these nitrosylhemoproteins, studies on a model complex, nitrosyl(porphyrinato)iron(II), under various conditions have yielded useful information.[14-20] In a preceding paper, we reported EPR, IR, magnetic circular dichroism (MCD), and electronic absorption spectral studies on the five-coordinated nitrosyl(porphyrinato)iron(II) complex and its six-coordinated complexes with N-, O-, and S-donor ligands under various conditions.[20] These studies on the model nitrosyl(porphyrinato)iron(II) complexes have dealt almost exclusively with elucidating the effects on the properties of an axial ligand trans to a nitrosyl group, because the identification of the axial ligand(s) is critical for hemoproteins. However, differences among the natural hemes (e. g., hemes a, b, and c) in porphyrin peripheral substituents have been demonstrated to cause pronounced changes in the spectral properties of hemoproteins.[1] In an attempt to elucidate a cis-effect on the axial nitrosyl ligand, we investigated the EPR and IR spectra of five- and six-coordinated nitrosyl iron(II) complexes of a series of tetrakis(*p*-substituted phenyl)porphyrins. The studies yielded more systematic information for the cis-effect than the electronic absorption and MCD studies.[21]

Experimental

Materials and Methods. Para-substituted tetraphenylporphyrins, H_2(*p*-X)tpp, where X=NMe_2, OCH_3, F, CO_2CH_3, and NO_2, were purchased from Midcentury Chemicals and their iron(III) chlorides were synthesized as described previously.[22] Fe(tpp)Cl and Fe[(F_5)tpp]Cl [where (F_5)tpp is the dianion of tetrakis(pentafluorophenyl)porphyrin] were purchased from Aldrich Chemical Co. In the synthesis of Fe[(*p*-NO_2)tpp]Cl, the compound was not obtained in a spectroscopically pure form as described previously.[3c] Hence a crude material was prepared as follows. After H_2(*p*-NO_2)tpp and $FeCl_2$ were refluxed in DMF, H_2O and CH_2Cl_2 were added, the CH_2Cl_2 layer was washed three times with water, dried over Na_2SO_4, and then the solvent was evaporated. The solid was redissolved in CH_2Cl_2 and heptane was added. The crude product thus obtained was dried in vacuo and used as an iron(III) complex of (*p*-NO_2)tpp for Sample Preparation.

1-Methylimidazole (*N*-MeIm) and pyridine (Py) were stored over KOH and distilled under an N_2 atmosphere. Nitrogen monoxide (99.5% minimum) purchased from Seitetsu Kagaku Co. was passed through a KOH column to remove higher nitrogen oxides. Gaseous ^{15}NO was generated by the reaction of $Na^{15}NO_2$ (99.2% enrichment, Amersham) with an ascorbic acid aqueous solution and was passed through a cold trap (about −90 °C) and a KOH column. All other chemicals were

of the highest available grade and were used without further purification.

EPR measurements at X-band frequency were carried out on a JES-ME-3X or a JES-RE-2X spectrometer with 100-kHz field modulation at room temperature (ca. 23 °C) and at 77 K. For accurate measurements of the EPR parameters, the microwave frequencies were measured with a digital frequency counter (Advantest, Model TR-5211A), and the magnetic field was calibrated with an NMR field meter (Echo Electronics, EMF 2000A).

The IR absorption spectra of chloroform or 1-methylimidazole solutions of the complexes were measured in a region 1550—1750 cm^{-1}, using CaF_2 windows with pathlength of 0.1 mm. They were recorded on a JASCO A-302 apparatus attached with a DP-A300 data processor for data accumulation and manipulation. In the IR spectrum of the complex with (p-CO_2CH_3)tpp, since the bands of the CO bond at the side chain and the NO bond partially overlapped, the frequencies of the NO band were determined from the difference spectrum of Fe(P)(NO) minus Fe(P)Cl with the same concentration.

Sample Preparation. Nitrosyl(porphyrinato)iron(II) complexes were prepared by a modified method of Kon and Kataoka.[14b,c] The reaction with NO was carried out in a Thunberg-type tube with a side arm on a vacuum line. Five-coordinated complexes were prepared as follows. Pyridine–toluene (1:1, v/v) solution of Fe(P)Cl (P=porphyrin dianion) was degassed by three successive freeze-pump-thaw cycles. Then the solution was equilibrated with NO gas; a tube containing the solution was shaken gently for about 1 h until the solution changed from dark brown to red; the solution was freed of excess NO, pyridine, and solvent in vacuo. The solid thus obtained was dissolved in degassed toluene and the solvent was evaporated. This dissolution–evaporation cycle was repeated and then the product was dried in vacuo for a week in order to completely remove the pyridine ligand. In EPR sample preparations, the product was again dissolved in degassed toluene; the solution was transferred into an EPR tube and sealed on a vacuum line. In IR sample preparations, it was dissolved in chloroform; the solution was transferred into an IR cell under an N_2 atmosphere.

The six-coordinated complexes as EPR or IR samples were prepared by the following methods. (a)EPR samples were prepared by reductive nitrosylation of iron(III) porphyrins with NO. The solution containing Fe(P)Cl and nitrogenous base in toluene was carefully degassed by freeze-pump-thaw cycles. Then the solution was equilibrated with NO gas at a pressure slightly below 1 atm, followed by standing for 1—2 h, transferred into an EPR tube, and sealed. (b)IR samples were prepared by dissolving the five-coordinated nitrosyl iron(II) complexes, obtained by the above-mentioned method, into 1-methylimidazole. The solution was transferred into an IR cell under an N_2 atmosphere.

The concentrations of Fe(P)(NO), N-MeIm, and Py in EPR samples were 2—3 mM, ca. 4 M, and ca. 4 M, respectively (1 M=1 mol dm^{-3}); those of Fe(P)(NO) in IR samples were 5—7 mM.

Results

EPR Spectra of Five-Coordinated Nitrosyl(porphyrinato)iron(II) Complexes. The EPR spectra of five-coordinated nitrosyl(porphyrinato)iron(II) complexes in toluene exhibited a well-resolved triplet for ^{14}NO complexes or a doublet for ^{15}NO complexes (Fig. 1), originated from an ^{14}N (I=1) or ^{15}N (I=1/2) of the NO ligand, respectively. Table 1 lists the g values (g_{iso}) at the central position of the triplet or doublet and the average hyperfine coupling constants (A_{iso}) in the second-derivative curve, together with the first redox potentials of free base porphyrin.

EPR spectral results of five-coordinated Fe(P)(NO) complexes at low temperatures have been utilized in elucidating the stereochemistry of the heme environment for nitrosylhemoproteins such as the NO adducts of

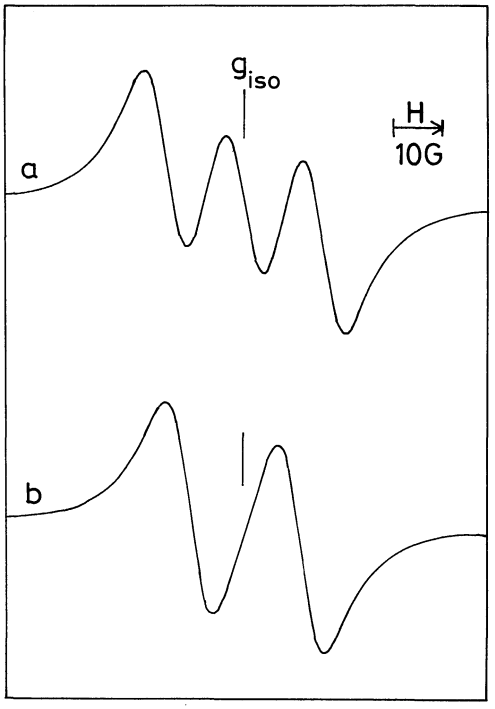

Fig. 1. EPR spectra of (a) Fe(tpp)(^{14}NO) and (b) Fe(tpp)(^{15}NO) in toluene at room temperature. Instrument settings: modulation frequency and amplitude, 100 kHz and 2G; microwave frequency and power, (a) 9.4419 GHz, (b) 9.4481 GHz and 5 mW.

hemoglobins in the presence of inositol hexaphosphate (IHP)[23] or sodium dodecyl sulfate,[14a] those of mutant hemoglobin M,[24] and those of cytochrome c',[13] which contain five-coordinated nitrosylheme. Five-coordinated Fe(P)(NO) complexes in nondonor solvents at low temperatures exhibit characteristic EPR spectra with an intense triplet in the g_3 (or g_z) absorption.[14c,15,20a,l]

The EPR spectra of Fe(tpp)(^{14}NO) and Fe(tpp)(^{15}NO) in glassy toluene at 77 K (Fig. 2) indicate the existence of three g values (g_1, g_2, and g_3). The higher field part of the g_2 absorption is hidden in the intense g_3, absorption. The g_1, g_2, and g_3 absorptions split into a triplet for ^{14}NO complexes or a doublet for ^{15}NO complexes. Thus, the g_2' absorption in Fig. 2 can be identified as a lowest field line of the triplet or doublet of the g_2 absorption. The absorption between g_1 and g_2 which is called an unidentified $g_?$ absorption[20m] is probably related to the coordinated NO group because it splits into a triplet or a doublet depending on the nuclear spin of the NO nitrogen. The EPR spectra of six-coordinated complexes at low temperatures also have such a $g_?$ absorption (vide infra). These $g_?$ absorptions most probably arise from another species.[10,20b,25,26] It is known that the intensity of these absorptions depends on the nature of the porphyrinato ligand, medium or solvent, temperature, and other factors.[10,14c,20b,20l,25-27] Because of the presence of small amounts of another species, there is not a good agreement between the experimental and simulated EPR spectra of nitrosylheme.

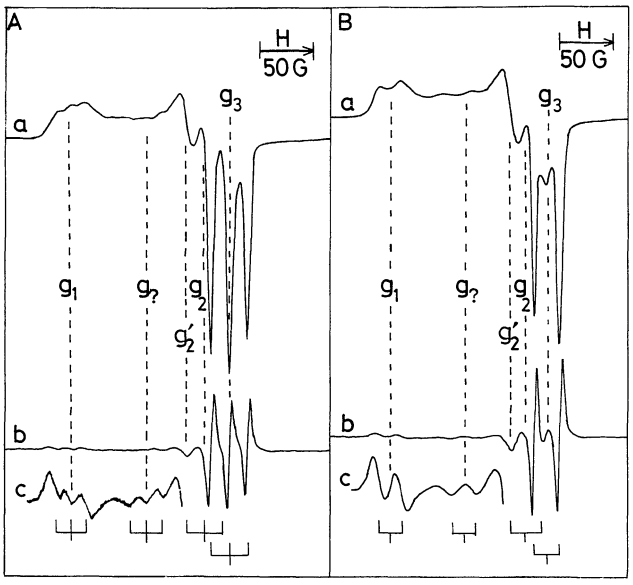

Fig. 2. EPR spectra of (A) Fe(tpp)(^{14}NO) and (B) Fe(tpp)(^{15}NO) in frozen toluene glass at 77 K; (a) first- and (b, c) second-derivative display, where (c) is the expansion of the ordinate of (b). Instrument settings: modulation frequency and amplitude, 100 kHz and 2 G; microwave frequency and power, (A) 9.1811 GHz, (B) 9.1871 GHz and 10 mW.

Table 2 lists the EPR parameters of five-coordinated nitrosyl(porphyrinato)iron(II) complexes at 77 K. The g_3 value was determined from the central line position of triplet or the center of doublet in the first-derivative display, while the g_1, g_2, g_2', and $g_?$ values were determined from those in the second derivative because of the poor resolution in the first derivative. Similarly, the A_3 value was obtained as an average of intervals in the first derivative, while the A_1, A_2, and $A_?$ values were obtained from those in the second derivative. However, the A_2 value for ^{14}NO complexes can not be determined because the two lines at the higher field side of the g_2 absorption were hidden into the g_3 absorption. Thus, the A_2 values of Fe(tpp)(NO) and Fe[(F_5)tpp](NO) were estimated from the equation $A_2(^{14}NO)=A_2(^{15}NO)-[A_3(^{14}NO)/A_3(^{15}NO)]$.

EPR Spectra of Six-Coordinated Nitrosyl(porphyrinato)iron(II) Complxes. Figure 3 shows the first- and second-derivative spectra of the Fe[(F_5)tpp](^{14}NO) complex with *N*-MeIm in toluene at room temperature; the spectra of the complexes with ^{15}NO and with the other porphyrinato ligands were virtually identical with Fig. 3 in the line shape. The first-derivative curve was slightly asymmetric and its second-derivative curve indicated overlapping of two components. These spectral features resemble those of the nitrosyl iron(II) complex of protoporphyrin IX dimethyl ester (Fe(ppixdme)(NO)) with *N*-MeIm.[20b] In contrast with the *N*-MeIm complexes, the Py complexes exhibited EPR spectra with a well-resolved triplet for ^{14}NO complexes, being similar to those of the five-coordinated complexes.

a) See footnote a of Table 1.

The g values at the zero-crossing in the first-derivative spectra of N-MeIm complexes and those at the central peak of the triplet in the second derivative spectra of Py complexes at room temperature are listed in Table 3, together with the first redox potentials of free base porphyrin.

The nitrosyl derivatives of many hemoproteins at low temperatures exhibited EPR spectra similar to those of six-coordinated nitrosyl(porhyrinato)iron(II) complexes with a nitrogenous base. These results have been utilized in identifying the fifth heme ligand of which the most probable candidate is an imidazolyl group of the histidine residue.[10-12] The EPR spectra of six-coordinated nitrosyl(porphyrinato)iron(II) complexes with nitrogenous bases at low temperatures exhibit a line shape characteristic of randomly oriented systems with a rhombic symmetry and its central g_2 (or g_z) absorption has mostly nine hyperfine lines or a triplet of triplets, originating from the hyperfine interaction of an unpaired electron of the NO ligand with two axial ^{14}N nuclei.[14,15,20]

The EPR spectra of Fe[(F_5)tpp](NO) complexes with N-MeIm (Fig. 4) and with Py (Fig. 5) in glassy toluene at 77 K exhibited distinct three g_1, g_2, and g_3 absorptions and an additional g_{II-1} absorption. The g_{II-1} absorption which was called the $g_?$ absorption[10] has been observed in the EPR spectra of various nitrosylhemoproteins and their model complexes.[10,11,15,20] This absorption was interpreted as a part of signal originating from another species (II), which is different in the structure of Fe–N–O unit from the dominant species (I) showing g_1, g_2, and g_3 absorptions.[20b,25,26] Another part of the g_{II} absorption which is hidden into the g_2 and g_3 absorptions could be resolved in the spectrum at a Q-band frequency.[20b] As shown in the second derivative, the g_2 absorption was highly resolved into a triplet of triplets for ^{14}NO

complexes and a doublet of triplets for ^{15}NO complexes, while the g_1 and g_3 absorptions were poorly resolved into four lines for ^{14}NO complexes and three lines for ^{15}NO complexes. Thus, although the line shapes of g_1, g_2, and g_3 absorptions were affected by the isotopic substitution, the determination of hyperfine coupling constants in the g_1 and g_3 absorptions was not possible because of the poor resolution and complicated patterns. It has been demonstrated that the lack of resolved hyperfine splittings in the in-plane g_1 and g_3 absorptions results from both the inhomogeneous broadening based on unresolved hyperfine interaction with pyrrole nitrogens and the poor resolution derived from weak hyperfine interaction with two axial nitrogens.[10] Although nitrosyl cytochrome P-450 contains a six-coordinated nitrosyl iron(II) complex, the resolved hyperfine structure derived from an NO nitrogen has been detected on the in-plane absorptions because the axial site trans to NO is occupied by a thiolate sulfur (I=0).[28,29]

Tables 4 and 5 list the EPR parameters of six-coordinated nitrosyl(porphyrinato)iron(II) complexes with 1-methylimidazole and pyridine at 77 K, respectively, together with the first redox potential of free base porphyrins. The g_2 value was determined from the central line position of nine hyperfine lines for ^{14}NO

complexes or the center of six hyperfine lines for ^{15}NO complexes in the second derivative. The g_3 value was also determined from the center of the g_3 absorption in the second derivative. On the other hand, the g_1 and g_3' values were determined from the extreme position of corresponding absorptions in the first derivative. Because the g_3 absorption overlapped significantly with that of g_2 appearing to be a slight hump or a shoulder, the second-derivative center may be preferable, for the determination of *g*-value, to the extreme position of the first derivative. The hyperfine coupling constants A_2 and a_2 correspond to hyperfine splittings due to the nitrogen nucleus of the NO ligand and the trans axial nitrogenous base, respectively. Both values were obtained from averaged intervals in the second derivative.

NO Stretching Frequencies. It has been demonstrated that the NO stretching frequencies in the IR spectra for five-coordinated Fe(ppixdme)(NO) and the six-coordinated complexes are comparable to those for NO-hemoglobin A in the presence of IHP and in the absence of IHP, respectively, and the binding of IHP to the protein results in cleavage of the proximal histidine to iron bonds in two of four subunits.[16] The NO stretching frequencies of the complexes vary linearly with the solvent polarity[20g] and the basicity of the axial ligand trans to NO.[20h] Thus, the NO stretching frequencies in the IR spectra of nitrosylhemoproteins and those model complexes are a useful measure of the iron-to-NO bond strength and the polarity of heme environments.

Table 6 lists the NO stretching frequencies of three nitrosyl(porphyrinato)iron(II) complexes in chloroform and in 1-methylimidazole. The IR spectra of the complexes in 1-methylimidazole showed a single NO band assigned to that of six-coordinated complexes, though those in neat liquid bases such as pyridine derivatives sometimes show both NO bands of five- and six-coordinated complexes which coexist at equilibrium.[20g] The NO stretching frequencies of five- and six-coordinated complexes with tpp agreed closely with those in KBr pellets (1670 and 1625 cm^{-1})[17] and were slightly higher than those with ppixdme (1675 and 1618 cm^{-1}, respectively).[20g]

Discussion

Introduction of electron-withdrawing or -donating groups at the periphery of a porphyrin results in the shift to positive or negative side, respectively, of the redox potentials of the porphyrin and the corresponding metalloporphyrins.[1,4,30,31] In what follows, the first redox potentials of the free base porphyrin [$E_{1/2}(I)$][31] are used as a measure of the electron-withdrawing or -donating power of the porphyrin peripheral substituents.

Alben and Caughey investigated the cis-effect of porphyrin peripheral substituents on the axial carbonyl ligand in carbonyl(2,4-substituted deuteroporphyrin IX dimethyl esterato)iron(II) complexes with pyridine.[32] They demonstrated that the CO stretching frequency increases with an increase in electron-withdrawing character of the 2,4-substituents. Similarly, the NO stretching frequencies of both five- and six-coordinated complexes in Table 6 markedly and linearly increase as the electron-withdrawing power of the substituents becomes greater. This cis-effect can be explained as follows, in the same manner as that on carbonyl complexes. An increse in the electron-withdrawing power of the porphyrin periphery results in weakening in iron-to-NO π back bonding, followed by a decrease in the electron density of iron d_π and NO π^* orbitals. Consequently, the decreased antibonding character of the NO bond induces the observed increase in the NO stretching frequencies. It is reasonable to predict that this weakening or lengthening of the iron-to-NO bond decreases the displacement of iron from the porphyrin plane toward the NO group, as is generally found in the molecular structure of nitrosyl(porphyrinato)iron(II) complexes.[17]

The changes ($\Delta\nu$) in these stretching frequencies per unit volt in the redox potential of free base porphyrins were estimated by a least-squares method from the linear relation of the NO stretching frequencies in Table 6 and the CO stretching frequencies of carbonyl(2,4-substituted deuteroporphyrin IX dimethyl esterato)iron(II) complexes[32] to $E_{1/2}(I)$ values.[31] The $\Delta\nu$ values thus obtained were 71 cm^{-1} in the five-coordinated NO complexes, 70 cm^{-1} in the six-coordinated NO complexes, and 31 cm^{-1} in the CO complexes. The $\Delta\nu$ values for the NO complexes are about twice that for the CO complexes, suggesting that the π back-bonding of the iron-to-NO ligand is more sensitive to the substitution at porphyrin peripheral side chains than that of the iron-to-

CO ligand.

On the basis of the interpretations for NO stretching frequencies of nitrosyl iron(II) porphyrin complexes, the EPR spectral results of the five- and six-coordinated complexes are analyzed as follows.

Five-Coordinated Complexes. Figures 6 and 7 illustrate the $E_{1/2}$(I) dependence of g_{iso} and A_{iso} values at room temperature and g_3 (or g_z) values at 77 K of five-coordinated nitrosyl(porphyrinato)iron(II) complexes. These g and A_{iso} values increase as $E_{1/2}$(I) becomes positive. (Other g values in Table 2 also exhibit similar tendencies).

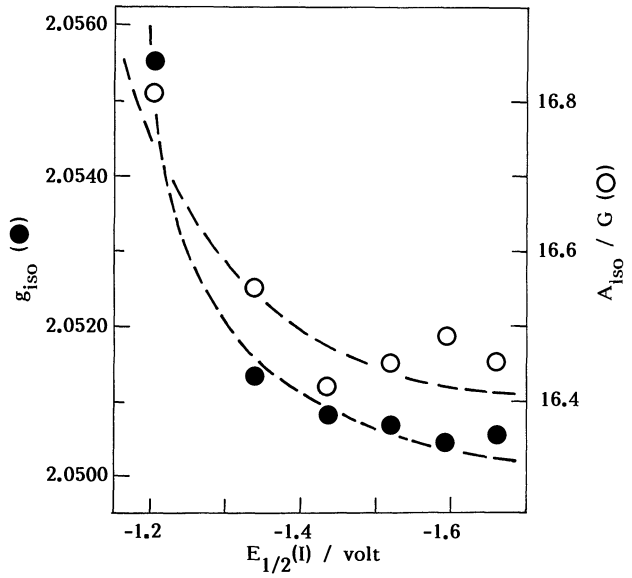

Fig. 6. Relationship between the g_{iso} values of five-coordinated Fe[(p-X)tpp](NO) complexes at room temperature and the $E_{1/2}$(I) values of (p-X)tpp. The trend in the data is indicated by the dashed lines.

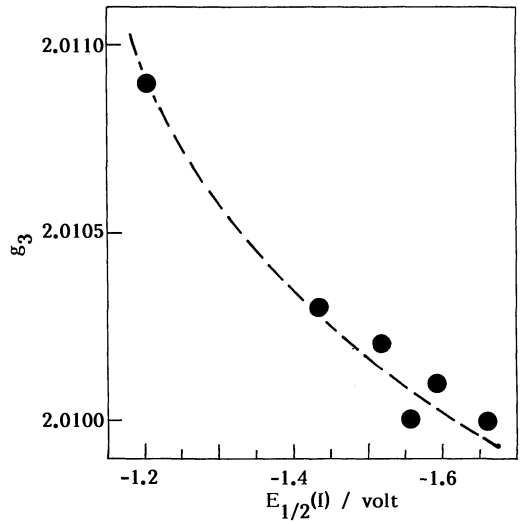

Fig. 7. Relationship between the g_3 values of five-coordinated Fe[(p-X)tpp](NO) complexes at 77 K and the $E_{1/2}$(I) values of (p-X)tpp. The trend in the data is indicated by the dashed line.

The spin density on the nitrogen of NO was estimated to be 2—3% from three hyperfine coupling constants at 77 K according to the method of McNeil et al.[33] Thus, the unpaired electron of an NO group can considerably delocalize to an iron d orbital through the d_{z^2} orbital; the spin-orbit coupling between the iron d orbitals is responsible for the deviation of the g value from a free spin value.[14b,15,34-36]

When the electron density on the iron d_π and NO π^* orbitals decreases with increasing electron-withdrawing character of peripheral substituents as described above, the unpaired electron on d_{z^2} orbital can shift toward the NO nitrogen. This slight increase of the spin density on the NO nitrogen can cause an increase in the hyperfine coupling constants, A_{iso} (Table 1 and Fig. 6) and A_3 (Table 2).

The decrease of the unpaired electron density in the d_{z^2} orbital would be accompanied by a stabilization of the d_{z^2} orbital. The consequent decrease in the separation between the d_{z^2} and d_{xy} levels leads to further spin-orbit coupling,[35] as reflected by an increase in the g values (Figs. 6 and 7).

Six-Coordinated Complexes. Figures 8 and 9 illustrate the $E_{1/2}$(I) dependence of the g_{iso} (at room temperature) and g_2 (at 77 K) values of six-coordinated

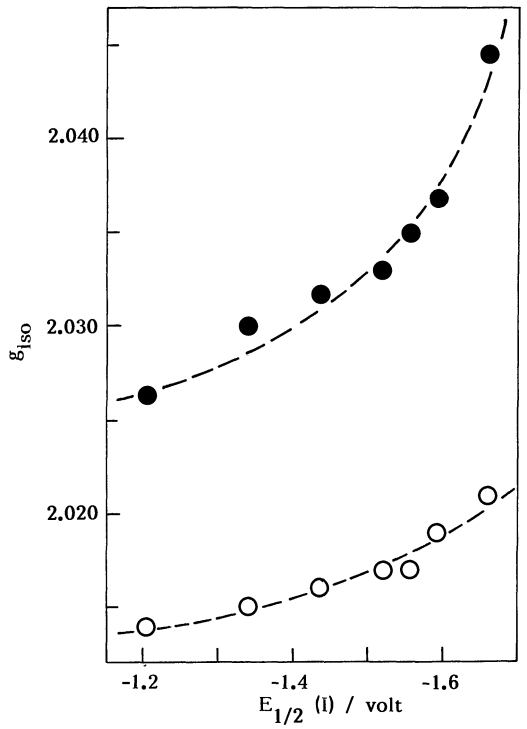

Fig. 8. Relationship between the g_{iso} values of six-coordinated Fe[(p-X)tpp](NO)(Base) complexes at room temperature and the $E_{1/2}$(I) values of (p-X)tpp. Base: ●, pyridine; ○, 1-methylimidazole. The trend in the data is indicated by the dashed lines.

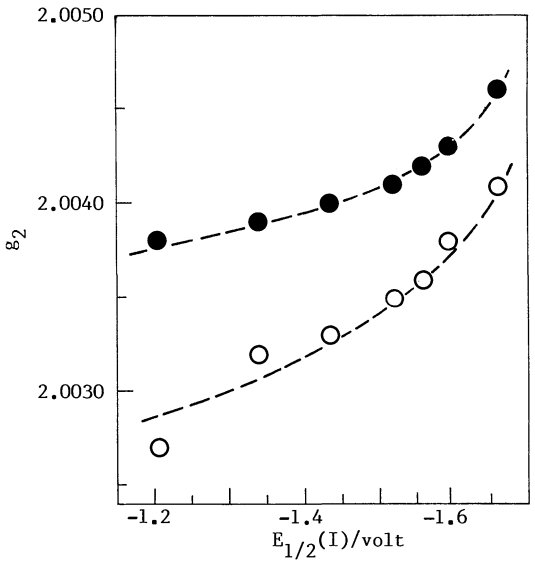

Fig. 9. Relationship between the g_2 values of six-coordinated Fe[(*p*-X)tpp](NO)(Base) complexes at 77 K and the $E_{1/2}$(I) values of (*p*-X)tpp. Base: ●, pyridine; ○, 1-methylimidazole. The trend in the data is indicated by the dashed lines.

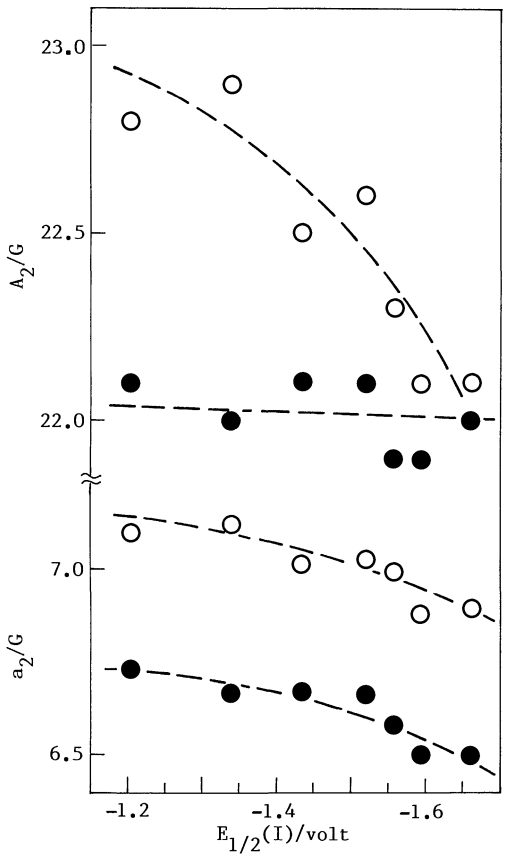

Fig. 10. Relationship between the A_2 and a_2 values of six-coordinated Fe[(*p*-X)tpp](NO)(Base) complexes at 77 K and the $E_{1/2}$(I) values of (*p*-X)tpp. Base: ●, pyridine; ○, 1-methylimidazole. The trend in the data is indicated by the dashed lines.

nitrosyl(porphyrinato)iron(II) complexes with 1-methylimidazole and pyridine. (Other g values in Table 4 also exhibit similar tendencies). As $E_{1/2}$(I) becomes positive, these g values decrease in the complexes with 1-methylimidazole and pyridine, and at the same time, both the g_{iso} value at room temperature and the $(g_1+g_2+g_3)/3$ values at 77 K approach the free spin value. As shown in Fig. 10, the hyperfine coupling constants, A_2 and a_2, increase with a shift of the $E_{1/2}$(I) to the positive side, though the A_2 values of the complexes with pyridine lie within 22.0±0.1 G. Thus, the dependencies of these EPR parameters on $E_{1/2}$(I) for the six-coordinated nitrosyl complexes are in contrast to those for the five-coordinated complexes.

In the six-coordinated nitrosyl complexes as well as the five-coordinated complexes, an enhancement in the electron-withdrawing power of porphyrin peripheral substituents results in a decrease in the electron density on the iron d_π and NO π^* orbitals and the concomitant shift of unpaired electron population on d_{z^2} orbital toward the NO nitrogen. The increase in the unpaired electron population at the NO nitrogen leads to an increase in hyperfine coupling constants. An axial position trans to NO group in the six-coordinated complexes is occupied by 1-methylimidazole or pyridine, which is primarily a σ-donor ligand.[20h,j] Therefore, the above-mentioned decrease in the electron density on iron(II) can be compensated by electron donation from the nitrogenous bases through the d_{z^2} orbital. This donation results in destabilizing the d_{z^2} orbital, which can induce the observed decrease in the g_{iso} (at room temperature) and $(g_1+g_2+g_3)/3$ (at 77 K) values toward the free spin value.

The g_{iso} (at room temperature) and g_2 values (at 77 K) for Fe[(F_5)tpp](NO) complex with 1-methylimidazole are very close to those for the Fe(ppixdme)(NO) complex with imidazolate, which is formed by deprotonation of imidazole and has greater σ-donor ability than the imidazole.[20j] This suggests that the 1-methylimidazole ligand with no dissociable proton in the former complex profoundly donates the σ electron toward iron(II) in a manner similar to the imidazolate in the latter complex.

Consequently, as the electron-withdrawing power of the substituents becomes greater, the Fe–N(nitrogenous base) bond can be strengthened (or shortened) in the six-coordinated complexes, accompanying an increase in NO stretching frequencies as described above. This is inconsistent with the result obtained by the X-ray structural and IR spectral study for six-coordinated nitrosyl(tetraphenylporphyrinato)iron(II) complexes with nitrogenous base that the Fe–N(nitrogenous base) bond lengths decrease with a decrease in the NO stretching frequencies.[17d] Further, when the trans axial ligand in the six-coordinated nitrosyl(porphyrinato)-iron(II) complexes is successively substituted, the g

values increased with an increase in the NO stretching frequencies.[20g] On the other hand, when the side chains of porphyrin periphery in the complexes are also successively substituted, the g values increased with a decrease in the NO stretching frequencies. Such reverse relations between the EPR g values and NO stretching frequencies present a striking contrast between the cis- and trans-effects. This inconsistency or contrast would arise from the fact that the cis-effect on the axial nitrosyl ligand in nitrosyl(porphyrinato)iron(II) complexes is transferred primarily through the porphyrin π and iron d_π orbitals, while the trans-effect is transferred primarily through the iron d_{z^2} orbital.

These findings provide a clue to evaluate the extent of contribution of the cis- and trans-effects to the EPR and IR parmeters in nitrosylhemoproteins and would improve the availability of a nitrosyl ligand as an electronic probe for clarifying the electronic structure and the stereochemistry around the heme.

Studies of Zone Melting. VII. Distribution Coefficients of the *p*-Nitrophenol-Naphthalene Eutectic System

Hidemoto NOJIMA
Department of Industrial Chemistry, School of Science and Technology, Meiji University, Higashimita, Tama-ku, Kawasaki 214
(Received March 29, 1991)

Synopsis. In a zone-melting experiment the effective and equilibrium distribution coefficients of *p*-nitrophenol in naphthalene have been determined by a method based on a determination of the solute concentration in the terminal one zone length after a single zone pass. The effective distribution coefficient (K_e) is determined by

$$K_e=\frac{2}{Z^*+1}\left\{1-\frac{1}{Z^*-1}\left(\frac{C_s^*}{C_0}-1\right)\right\},$$

where C_0 is the initial solute concentration; C_s^* is the solute concentration described above and $Z^*=L/l-1/2$; L and l denote the specimen and zone lengths, respectively. Further, the equilibrium distribution coefficient (K_o) is obtained as

$$K_o=\frac{2(Z^*-B)}{Z^{*2}-1}.$$

The constant (B) is related to the equation $C_s^*/C_0=-AV+B$, where V is the zone travel rate and A is also a constant. The obtained values of K_e and K_o agree with those determined by a method reported previously by the author.

In zone-melting experiments an effective distribution coefficient is generally determined from either the slope or the intercept of a straight line expressing the relationship between the solute concentration and the distance from the starting end of the zone. In many systems, however, a disagreement between the values obtained from the two procedures described above is found for some reason.[1] In addition, for a eutectic system, it is difficult to exactly determine the effective distribution coefficient; it has a comparatively small value compared to that of a mixed crystal system as well as an equilibrium distribution coefficient. In a previous paper[2] the author reported on a method for determining the effective distribution coefficient of a eutectic mixture by a zone-melting process. Even upon using this method, however, disagreement between the two values described above was inevitable.

In the present work the effective distribution coefficient of *p*-nitrophenol in a naphthalene forming eutectic system was determined by a new method. The obtained result agrees with that determined from the slope of the linear equation reported previously.[2] Also, the equilibrium distribution coefficient derived from the above-mentioned result agrees with the value obtained by the previous method.[2]

Theoretical

Determination of the Effective Distribution Coefficient. Consider a rod-shaped specimen with a length L and a constant cross section comprising a uniform eutectic binary mixture;the solute distribution profile after a single zone pass for such a specimen is shown by Fig. 1,[2] from which it is obvious (from the standpoint of material balance) that areas S_1 and S_2 are the same. The line $\overline{C_1C_2}$ is expressed by Eq. 1,[2]

$$C_s=C_0\left(K_e+K_e\frac{x}{l}\right), \tag{1}$$

where C_0 is the initial uniform concentration of the solute; C_s is the solute concentration at a distance x from the top of the specimen after a single zone pass; l is the zone length and K_e is the effective distribution coefficient. Equation 1 is valid for all but the last one zone length. From the conservation of material and refering to Fig. 1,

$$(Z'-1)C_0-\int_0^{Z'-1}C_0(K_e+K_eZ)\mathrm{d}Z=C_s^*-C_0. \tag{2}$$

In Eq. 2, x/l is replaced by Z, i.e. $Z\equiv x/l$; $Z'\equiv L/l$ and C_s^* is the solute concentration in the terminal one zone length after a single zone pass. The effective distribution coefficient is obtained from Eq. 2 as

$$K_e=\frac{2}{Z^*+1}\left\{1-\frac{1}{Z^*-1}\left(\frac{C_s^*}{C_0}-1\right)\right\}. \tag{3}$$

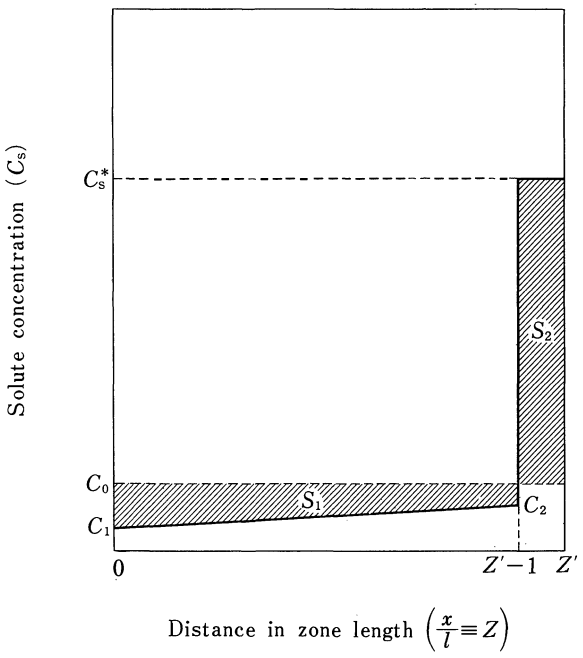

Fig. 1. Schematic diagram representing the material balance after a single zone pass for a eutectic mixture.

Since the solute concentration is determined experimentally as the average value in one zone length, Z' in Eq. 2 can be replaced by $Z^*=L/l-1/2$ in Eq. 3.

Determination of the Equilibrium Distribution Coefficient. In order to find the equilibrium distribution coefficient (K_o) on the basis of Eq. 3, it is necessary for K_e to be expressed as a function of the zone travel rate or freezing rate (V). It is well known for many systems that the relationship among K_e, K_o and V can be expressed by the following Burton–Prim–Slichter's equation:[3]

$$\ln\left(\frac{1}{K_e}-1\right)=\ln\left(\frac{1}{K_o}-1\right)-\frac{\delta}{D}V, \tag{4}$$

where D and δ are the diffusion coefficient of the solute and the diffusion layer thichness, respectively. Equation 4 is rewritten as

$$\frac{(1-K_o)K_e}{(1-K_e)K_o}=\exp\left(\frac{\delta}{D}V\right). \tag{5}$$

The conditions that $K_o \ll 1$ and $K_e \ll 1$ are valid for a eutectic system.[2] Equation 5 can thus be rewritten as

$$\frac{K_e}{K_o}=\exp\left(\frac{\delta}{D}V\right), \tag{6}$$

which, if $\delta V \ll D$, reduces to[#]

$$K_e=K_o+aV, \tag{7}$$

where $a \equiv K_o\delta/D$. From Eqs. 3 and 7, the following equation is obtained:

$$\frac{C_s^*}{C_0}=-AV+B, \tag{8}$$

where

$$A=\frac{a(Z^{*2}-1)}{2} \tag{9}$$

and

$$B=-\frac{K_o(Z^{*2}-1)}{2}+Z^*. \tag{10}$$

Constants A and B are the slope and intercept of Eq. 8 respectively, expressing the dependence of C_s^*/C_0 on the zone travel rate (V). The equilibrium distribution coefficient (K_o) can be given from Eq. 10 as

$$K_o=\frac{2(Z^*-B)}{Z^{*2}-1}. \tag{11}$$

Experimental

Materials. Commercial p-nitrophenol was purified by zone refining for 50 passes and commercial naphthalene was purified by one recrystallization from a benzene solution. Two naphthalene mixtures containing 0.5 and 1.0 wt% of p-nitrophenol were charged in a 30 cm long in Pyrex tubes with an inner diameter of 0.7 cm and outer diameter of 0.9 cm. The tubes were then sealed off under a dry nitrogen atmosphere of about 0.9 atm.

Procedures. The zone-melting experiments were carried out under the following conditions: zone travel rates of 2.47, 2.96, 5.43, 9.21, and 12.80 mm h^{-1}; 1 zone pass; a zone length of 3 cm and a zone temperature of 90±1 °C. The samples after a zone pass were cut into ten fractions, each 3 cm long and equal to the zone length. The samples from each fraction were dissolved in ethanol; color was then developed by adding a small amount of aqueous sodium hydroxide solution. The concentration of p-nitrophenol was determined spectrophotometrically by using a Hitachi 100-01 spectrophotometer at a wavelength of 400 nm.

Results and Discussion

Determination of the Effective Distribution Coefficient. As an example, the distribution of p-nitrophenol along a sample initially containing 1.0 wt% of this compound after a single zone pass at 2.96 mm h^{-1} is shown in Fig. 2; it represents the same profile as in Fig. 1, except that the ordinate is indicated by C_s/C_0 instead of C_s. The effective distribution coefficient was obtained by substituting the observed value of C_s^*/C_0 into Eq. 3. The relationship between the effective distribution coefficient and zone travel rate is shown in Fig. 3, together with the values obtained by a previously reported method,[2] i.e. values from the slope of Eq. 1. The values obtained by these two methods agreed with

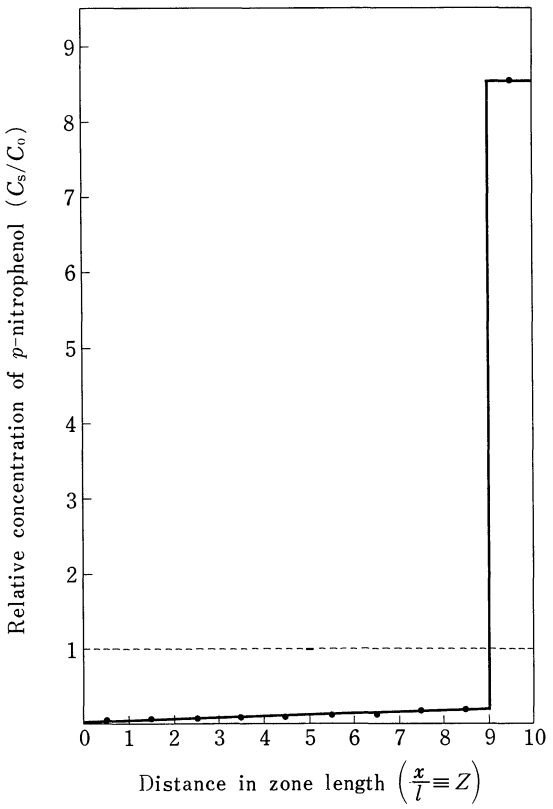

Fig. 2. Distribution of p-nitrophenol after a single zone pass at 2.96 mm h^{-1}; 1.0 wt% of p-nitrophenol.

[#] $\exp(x)=1+x+\frac{x^2}{2!}+\cdots\cdots$, $x \equiv \delta V/D$ and the squares and higher power of x can be neglected for the present case.

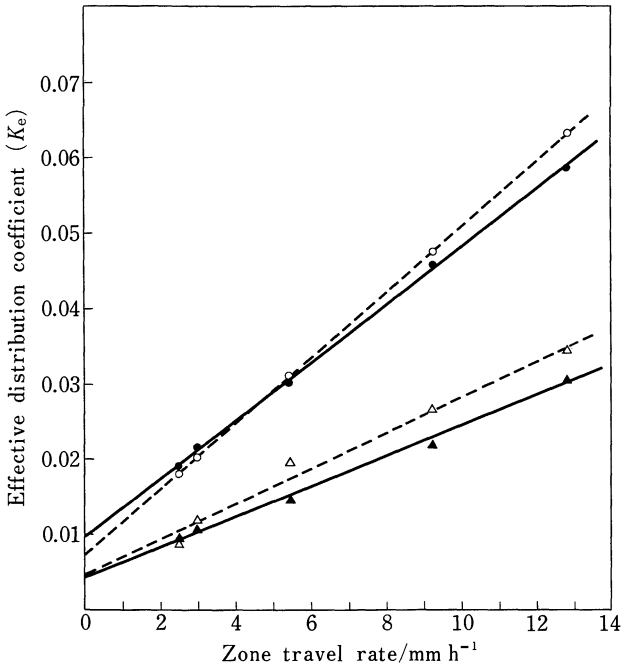

Fig. 3. Relationship between the effective distribution coefficient and the zone travel rate. ●: values for 1.0 wt% of *p*-nitrophenol determined by Eq. 3. ○: values for 1.0 wt% of *p*-nitrophenol determined from the slope of Eq. 1. ▲: values for 0.5 wt% of *p*-nitrophenol determined by Eq. 3. △: values for 0.5 wt% of *p*-nitrophenol determined from the slope of Eq. 1.

Table 1. Equilibrium Distribution Coefficients Determined by Three Methods

Methods employed	Equilibrium distribution coefficient, 0.5 wt% of *p*-nitrophenol	Equilibrium distribution coefficient, 1.0 wt% of *p*-nitrophenol
From Eqs. 8 and 11	4.26×10^{-3}	7.39×10^{-3}
From the intercepts of solid lines in Fig 3	4.23×10^{-3}	9.73×10^{-3}
From the intercepts of dotted lines in Fig. 3	4.51×10^{-3}	7.46×10^{-3}

each other, as is shown in Fig. 3; it is thus obvious that Eq. 7 is valid for this experiment.

Determination of the Equilibrium Distribution Coefficient. It is evident that Eq. 8 is valid for this experiment, as is shown in Fig. 4. By substituting the values of the intercepts of the straight lines in Fig. 4 into Eq. 11, the equilibrium distribution coefficients were evaluated. The obtained values are shown in Table 1 together with those obtained from the intercepts of the straight lines in Fig. 3, as described in a previous paper;[2] these values agree with each other.

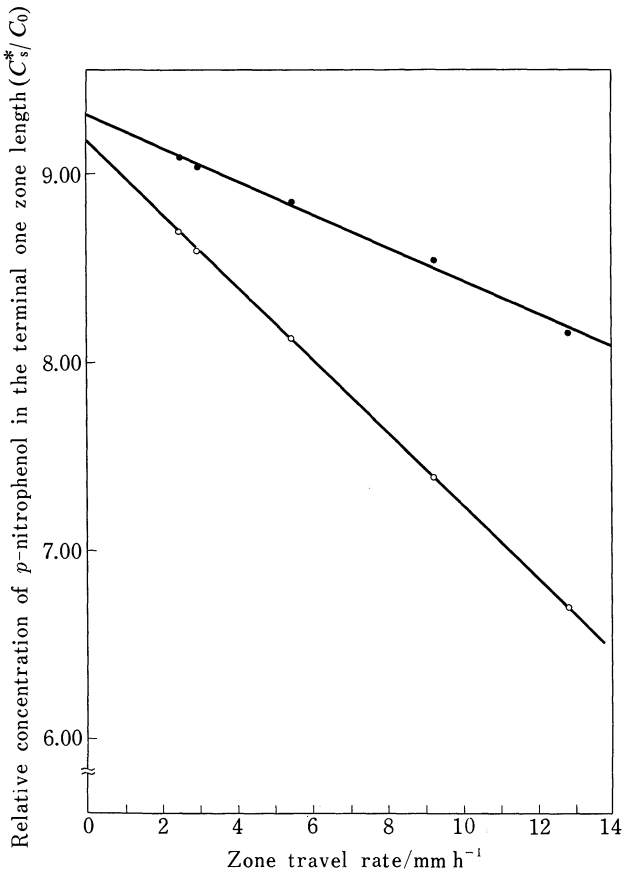

Fig. 4. Relationship between the relative concentration of *p*-nitrophenol in the terminal one zone length and the zone travel rate. ○: 1.0 wt% of *p*-nitrophenol. ●: 0.5 wt% of *p*-nitrophenol.

Conclusion

The effective distribution coefficient of *p*-nitrophenol in naphthalene could be determined by the present method, which agrees with that determined from the slope of Eq. 1. Also, the equilibrium distribution coefficient agrees with the value obtained by a previously reported method.[2] In the present method, both the effective and equilibrium distribution coefficients are determined from the solute concentration in the terminal one zone length, in which the enrichment of the solute is so large that the concentration can be accurately determined even for a specimen with a low solute concentration, in contrast with conventional methods.

The author wishes to thank the Institute of Science and Technology Meiji University for financial support.

Dielectric Properties of Poly(methylphenylsilylene) under Humidity in the Kilohertz Range[1)]

Hiroshi AWANO,* Takayoshi IWAI,† and Hiroji OHIGASHI
Department of Materials Science and Engineering, Yamagata University, Jonan, Yonezawa 992
† Consumer Products Engineering Laboratory, Toshiba Corporation, Shinsugita-cho, Isogo-ku, Yokohama 235
(Received April 11, 1991)

Synopsis. The capacitance and dielectric loss tangent of poly(methylphenylsilylene) thin films were measured under various humidities over the frequency range 0.1—1000 kHz. In the high-humidity range, both the quantities increase with decreasing frequency. The existence of an anomalously low-frequency relaxation (lower than 0.1 kHz) is suggested in which the adsorbed water molecules are involved.

Although the electrical properties of organopolysilanes have become of great interest,[2)] few studies have been carried out on the dielectric properties. In the present work, thin films of poly(methylphenylsilylene) (PMPS) were prepared and their dielectric properties measured under various humidities. An anomalous relaxation of the adsorbed water molecules has been found.

PMPS was prepared by condensation polymerization of dichloromethylphenylsilane based on the Wurtz–Fittig reaction, and purified by reprecipitation from toluene with hexane. A toluene solution of the precipitate was washed several times. Gel permeation chromatography in THF resulted in $\overline{M}_n=9.07\times10^3$ and $\overline{M}_w/\overline{M}_n=1.75$ (reduced to polystyrene). The specimen used had a sandwich structure with a gas-permeating upper electrode. A PMPS thin film with a thickness of 2—3 μm was formed by casting on a glass substrate having a couple of Cr–Au thin-film lower electrodes with a thickness of ca. 100 nm. A gas-permeating Au thin film with a thickness of 30—40 nm was formed on the PMPS film by dc sputtering. Both the capacitance and dielectric loss tangent of the film were measured with a Yokogawa Hewlett-Packard 4192A LF impedance analyzer. The relative humidity was controlled using a Shin-ei SRH-1M humidity generator. Each measurement was carried out after the specimen had been kept standing under the desired temperature and humidity for at least 20 min.

Figure 1 shows the humidity dependence of the capacitance of PMPS at 25 °C. The humidity dependence varies remarkably with the frequency. When the humidity is increased from 10 to 90%, the capacitance doubles at 1 kHz, but it increases by a maximum of 2% at 100 kHz. Moreover, the hysteresis observed at low frequencies is not ignorable, suggesting that the adsorption and desorption of water molecules are somewhat slow. Figure 2 shows the humidity dependences of both the capacitance and the loss tangent of PMPS at 10 kHz. The extent to which these quantities vary with the relative humidity becomes greater as the temperature is raised.

In order to discuss the mechanism through which these dielectric properties vary with the humidity, it may be

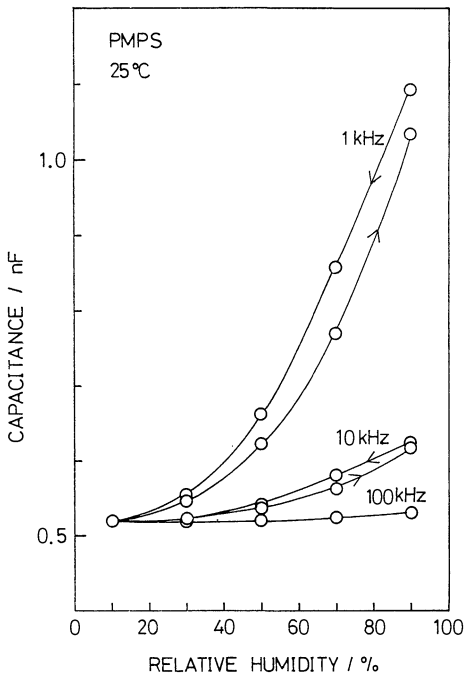

Fig. 1. Humidity dependence of the capacitance of a PMPS film at 25 °C.

convenient to use the absolute humidity or water vapor pressure rather than the relative humidity. Figure 3 shows plots of the capacitance and loss tangent against the logarithm of the water vapor pressure. Thus, as shown in the figure, all of the curves have almost the same shape, and the curves shift to the right with increasing temperature. If we regard these curves as being some kind of adsorption isotherm, the equilibrium constants of adsorption at 10 and 25 °C are greater by factors of 1.9 and 3.7, respectively, than at 40 °C. From these data, the enthalpy change of the adsorption of water has been estimated to be -32 kJ mol^{-1}. This value is near to the energy of hydrogen bonding of water ca. 40 kJ mol^{-1} (per water molecule).[3)] This suggests that the adsorption of water on a PMPS surface might involve the formation of small clusters, each of which comprises several water molecules.

Figure 4 shows the frequency dependence of both the capacitance and the loss tangent of PMPS at 25 °C in the humidity range 10 to 70%. Neither of the quantities vary with the frequency at low humidities, indicating that no relaxation exists in the kilohertz range, since the PMPS is in a glass state. At high humidities, on the

other hand, both the capacitance and loss tangent significantly increase with decreasing frequency, indicating the existence of relaxation in the lower frequency range.

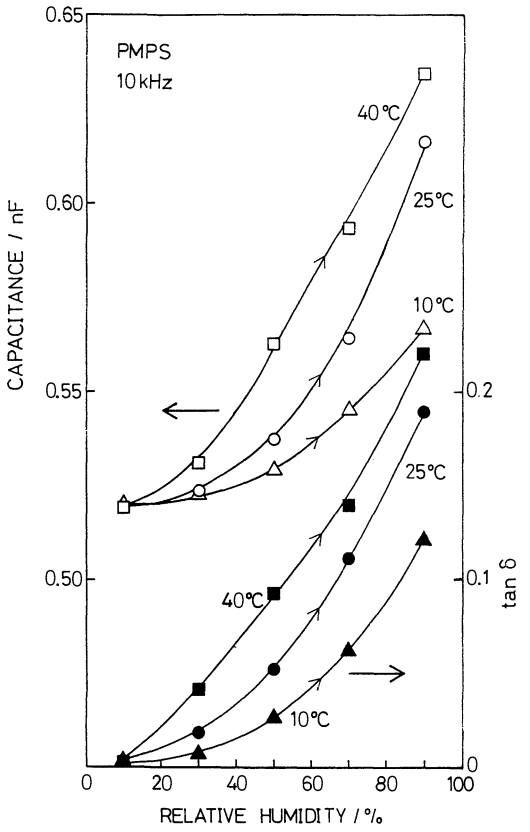

Fig. 2. Humidity dependence of both the capacitance and the dielectric loss tangent of a PMPS film at 10 kHz.

Relaxation in a range lower than kilohertz seems quite anomalous. It seems to be difficult to explain this phenomenon in terms of the usual state of water molecules. For example:

(a) Regarding ice, the relaxation time of Ice I has been reported to be about 0.2 ms.[4]

(b) Regarding the hydration of biopolymers, the rotational correlation time of water in hydrated collagen, from NMR studies, is 10^{-7} s at 25 °C.[5] From dielectric measurements, the fraction of water molecules is strongly bound to collagen with residence times on the order of 10^{-6} s.[6]

(c) In contrast to PMPS, polyimide has a capacitance that is almost invariant in the kilohertz range and a loss tangent that increases with increasing frequency above 10^5 Hz. The latter tendency becomes important as the humidity is increased.[7] This suggests that the relaxation time of the water molecules adsorbed on the polyimide is far shorter than 10^{-5} s.

Thus, a relaxation time of adsorbed water longer than 10^{-2} s is so anomalous. We can thus attribute such a long-term relaxation to hydrogen bonding between adsorbed water and the terminal hydroxyl groups of PMPS: the formation of hydrogen bonding would induce a large polarization in the glassy polymer, which can be related to long-term relaxation. The induction of polarization might involve sigma-conjugation in the silicon backbone of PMPS. We have obtained the following experimental result: the dielectric properties are almost independent of how many times the toluene solution containing PMPS has been washed with water after the synthesis of PMPS. The above result suggests that the contribution of some hydrophilic or ionic impurities to the dielectric properties must be minor. The long-range relaxation under humidity can therefore

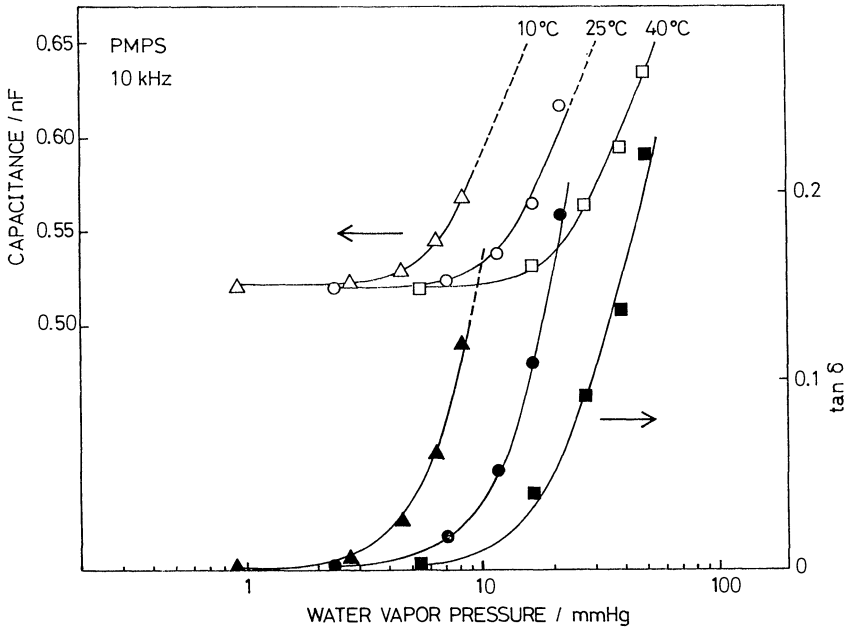

Fig. 3. Plots of the capacitance and the dielectric loss tangent of a PMPS film against the logarithm of water vapor pressure.

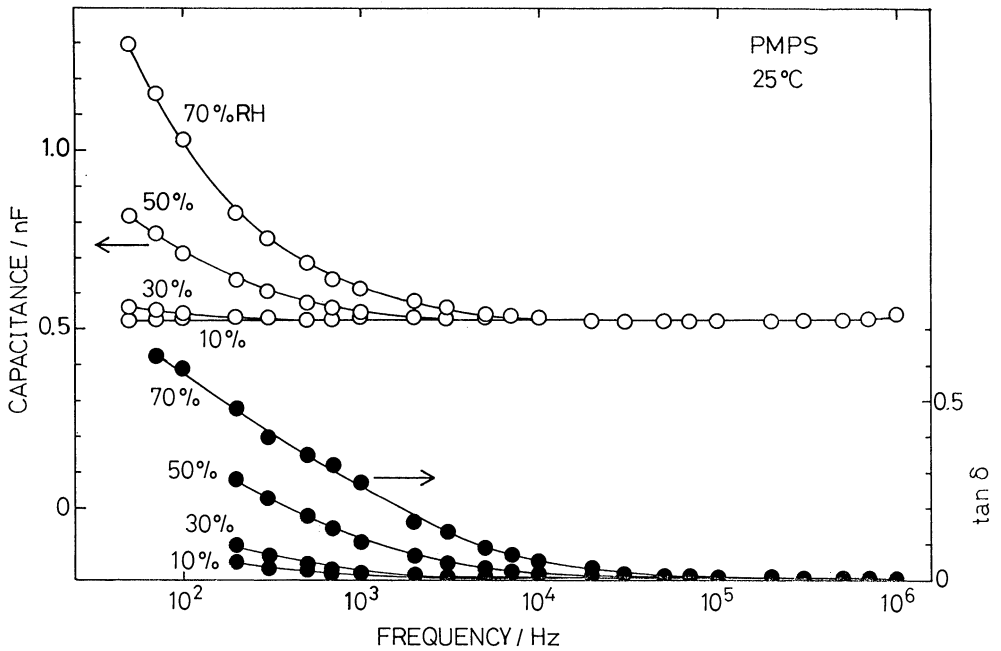

Fig. 4. Frequency dependence of both the capacitance and the dielectric loss tangent of a PMPS film at 25°C.

be attributed to hydrogen bonding between water and the terminal hydroxyl groups of PMPS, rather than to hydrophilic or ionic impurities.

The authors are grateful to Professor K. Ono of Tohoku University for valuable discussions.

(Received March 7, 1991)

Synopsis. Heterometal complexes, $[CuLn(fsadien)(NO_3)(H_2O)_n]\cdot(H_2O)_{5-n}$ (Ln=La, Gd, or Lu), have been synthesized and characterized, where H_4fsadien denotes bis[2-(3-carboxysalicylidene)aminoethyl]amine. Based on electronic absorption and CD spectra, it was suggested that amino alcohols were specifically bound to the Cu(II)-Ln(III) heterometal center, through the nitrogen to the copper(II) ion and through the oxygen to the rare earth(III) ion.

Recently we have reported that the copper(II)–rare earth(III) and cobalt(II)–rare earth(III) heterometal complexes of *N*,*N*′-bis(3-carboxysalicylidene)ethylenediamine (H_4fsaen, Fig. 1a)[1,2] show a unique "selective solvations" associated with copper or rare earth ion, depending upon the the nature of the solvent. That is, in pyridine the solvation occurs at the copper site, whereas in dimethyl sulfoxide or *N*,*N*-dimethylformamide the solvation occurs exclusively at the rare earth site. This selective solvation has been extended to specific binding of amino alcohols on the copper(II)–rare earth(III) or the cobalt(II)–rare earth(III) heterometal center.[2,3]

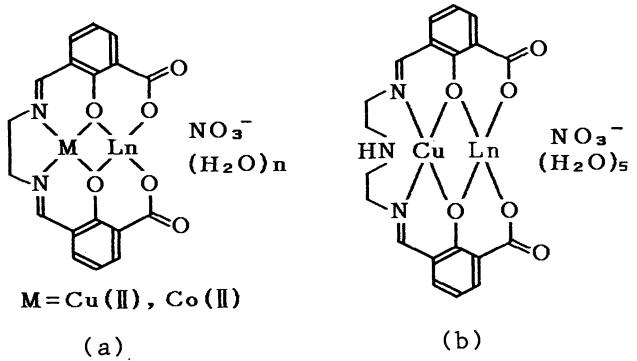

Fig. 1. Chemical structures of copper(II)- or cobalt(II)–rare earth(III) complexes of H_4fsaen (a) and copper(II)–rare earth(III) complexes of H_4fsadien (b).

In this work we have synthesized and characterized copper(II)–rare earth(III) complexes of bis[2-(3-carboxysalicylidene)aminoethyl]amine (H_4fsadien, Fig. 1b), in which copper(II) and rare earth(III) ions are bound at the inside coordination site (N_3O_2-site) and the outside coordination site (O_4-site), respectively. The specific binding of amino alcohols on the Cu(II)–Ln(III) center has been investigated on the basis of electronic absorption and CD spectra.

Experimental

Syntheses. 3-Formylsalicylic acid was prepared after the method of Duff and Bills.[4] Mononuclear copper(II) complex, $[Cu(H_2\ fsadien)]\cdot H_2O$ was synthesized according to the method reported by Casellato et al.[5]

Binuclear Complexes, $[CuLn(fsadien)(NO_3)(H_2O)_n]\cdot(H_2O)_{5-n}$(Ln=La, Gd, or Lu): A methanol solution (10 cm³) of lithium hydroxide monohydrate (2 mmol) was added to a suspension of the mononuclear copper(II) complex, $[Cu(H_2\ fsadien)]\cdot H_2O$ (1 mmol), in methanol (50 cm³). Further addition of methanol (240 cm³) and heating gave a clear solution. To the resulting solution was added a methanol solution (5 cm³) of a rare earth(III) nitrate hydrate (1 mmol), and the mixture was refluxed under stirring for 3 h. After the solution was concentrated to 50 cm³ under reduced pressure, resulted greenish crystals were collected on a glass filter, washed with methanol and then diethyl ether, and dried in the open air. the yield was about 60 %.

Analytical results are given in Table 1.

Measurements. Elemental analyses of carbon, hydrogen, and nitrogen were obtained at the Advanced Instrumentation Center for Chemical Analysis of Ehime University. Metal contents were determined by the EDTA titration of mixed nitrates, which were prepared by dissolving the ignition residue

Table 1. Elemental Analyses of Complexes

Complex	Found/% (Calcd/%)				
	C	H	N	Cu	Ln
$CuLa(fsadien)(NO_3)(H_2O)_5$	31.90 (32.03)	3.17 (3.63)	7.49 (7.47)	8.45 (8.47)	18.38 (18.52)
$CuGd(fsadien)(NO_3)(H_2O)_5$	31.29 (31.27)	3.22 (3.54)	7.38 (7.29)	8.28 (8.27)	21.30 (20.47)
$CuLu(fsadien)(NO_3)(H_2O)_5$	29.88 (30.46)	3.20 (3.45)	7.30 (7,10)	8.66 (8.06)	23.31 (22.19)

(mixed oxides) of the complex in HNO_3. Infrared spectra were measured with a JASCO IR-G Spectrometer on KBr disks, nujol mulls, or hexachlorobutadiene mulls. Absorption and reflectance spectra were obtained with a Hewlett-Packard 8452A Spectrophotometer and an Otsuka Electronics MCPD 1000 Spectrophotometer, respectively. The CD spectra were recorded on a JASCO J-20 Automatic Recording Spectropolarimeter.

Results and Discussion

Infrared spectra of the Cu(II)–Ln(III) complexes are similar to each other. The ν (C=O) vibration (ca. 1670 cm^{-1}) and ν (O–H) vibration (3000—2000 cm^{-1}) of the chelated carboxyl groups are observed for H_4fsadien and [Cu(H_2fsadien)]·H_2O, but those bands disappear on the Cu(II)–Ln(III) complex formation. Instead, the Cu(II)–Ln(III) complexes show the carboxylate vibration at 1535—1550 cm^{-1}. These observations suggest the incorporation of a rare earth(III) ion at the O_4-site. The vibrations due to the nitrate ion are observed as split bands at ca. 1430 and 1380 cm^{-1}, suggesting the bidentate coordination of the nitrate ion.[6] The ν (O–H) vibration of the water molecules appears as a broad band at 3300—3400 cm^{-1} when measured on nujol mulls or hexachlorobutadiene mulls. It is presumed that the water molecules coordinate to the rare earth ion to afford a coordination number larger than six.

Reflectance spectra are shown in Fig. 2. The spectrum of [Cu(H_2fsadien)]·H_2O exhibits a band maximum at ca. 14.3×10^3 cm^{-1} and a shoulder at ca. 17.5×10^3 cm^{-1}, suggesting a trigonal-bipyramidal surrounding about the copper(II) ion[7] with the three nitrogen atoms of the diethylenetriamine moiety and the two phenolic oxygen atoms. On the other hand, the Cu(II)–La(III), Cu(II)–Gd(III), and Cu(II)–Lu(III) complexes show an unresolved broad band at ca. 17.1×10^3, ca. 16.7×10^3, and ca. 16.5×10^3 cm^{-1}, respectively, suggesting no coordination of the central nitrogen of the lateral bridge to the copper(II) to give a square planar configuration around the copper. The model considerations support that the coordination of central nitrogen of the lateral bridge to the copper is difficult when the two carboxylate groups coordinate to a rare earth ion.

The interaction of substrates on the heteronuclear center has been studied spectroscopically by adding various substrates to a DMF solution of the Cu(II)–La(III) complex. Typical absorption spectra are given in Fig. 3 and the numerical data are summarized in Table 2.

In general, the axial coordination of a substrate to planar copper(II) results in a red shift of the d–d band

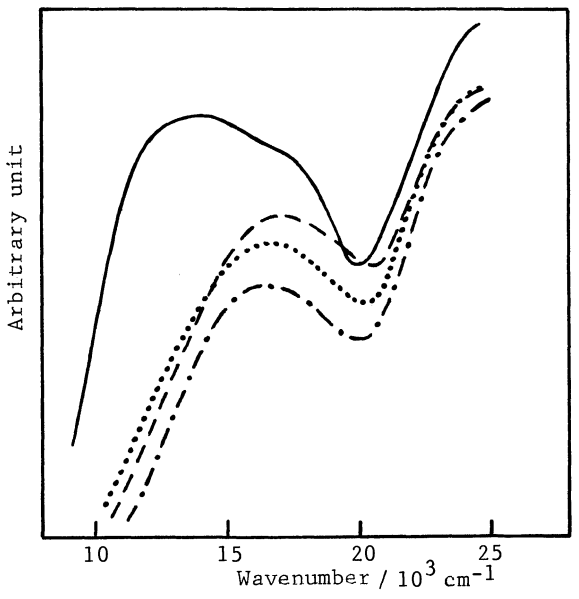

Fig. 2. Electronic spectra in solid state. (——): [Cu(H_2fsadien)]·H_2O; (———): [CuLa(fsadien)(NO_3)(H_2O)$_n$]·(H_2O)$_{5-n}$; (·····): [CuGd(fsadien)(NO_3)(H_2O)$_n$]·(H_2O)$_{5-n}$; (—·—): [CuLu(fsadien)(NO_3)(H_2O)$_n$]·(H_2O)$_{5-n}$.

1-Aminopropane[c]	16.08

a) Concentration of the Cu(II)–La(III) complex is 5×10^{-3} mol dm^{-3}. b) Concentration is 5 mol dm^{-3}. c) Concentration is 1 mol dm^{-3}.

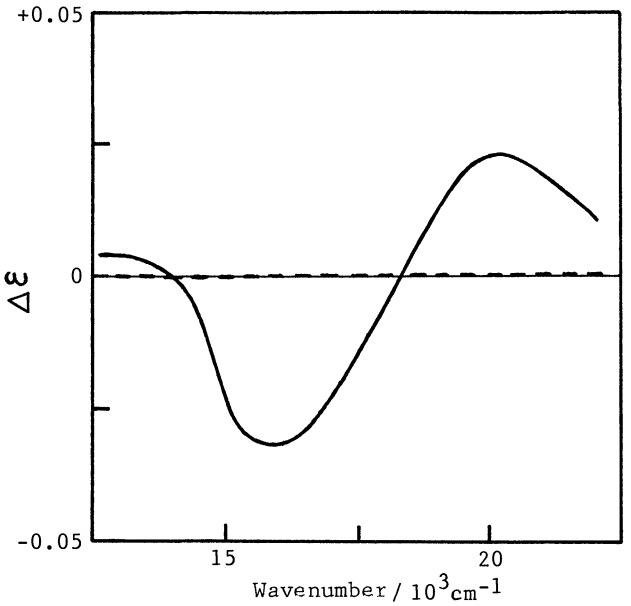

Fig. 4. The CD spectra in DMF. Concentration of the Cu(II)–La(III) binuclear complex is 5×10^{-3} mol dm^{-3}. (——): with (*R*)-(−)-1-amino-2-propanol (1 mol dm^{-3}); (———): with (*S*)-(+)-1,2-propanediol (1 mol dm^{-3}).

maximum. This is indeed the case when 1-aminopropane is added to a DMF solution of the Cu(II)–La(III) complex. A similar red shift of the d–d band was observed when 2-aminoethanol or 3-amino-1-propanol was added as the substrate. On the other hand, such a spectral change was not seen when alcohols (methanol, ethanol, or 1,2-ethanediol) were added as substrates. Obviously amines coordinate to the axial site of the copper(II) center whereas alcohols do not.

It is unclear from the above results if alcohols are bound at the lanthanum(III) center or not, but our CD spectral investigations using a chiral amino alcohol as the substrate has revealed the ligating interaction of alcohols with the lanthanum(III) center. Figure 4 shows the CD spectrum of the Cu(II)–La(III) complex when (*R*)-(−)-1-amino-2-propanol was added as the substrate. The significant circular dichroism induced at the d–d band of the copper(II) clearly demonstrates that the free rotation of the amino alcohol is hindered with respect to the Cu–N bond owing to the following reasons; (i)the hydroxyl group of the amino alcohol may be directly bound to the lanthanum(III) ion or (ii)the hydroxyl group may be involved in hydrogen bonding with DMF or H_2O molecules coordinated to the lanthanum(III) ion discussed previously.[2] Such a CD activity was not observed in the visible region when (*S*)-(+)-1,2-propanediol was added as the substrate (see Fig. 4). This is quite understandable since the chiral diol is captured on the lanthanum(III) center probably as a bidentate ligand. Thus, the present work is another illustration of specific binding of amino alcohols on d–f heterodinuclear center.

A Pd(II)-Cu(II) Catalyst for the Kjeldahl Analysis of Nitrogen in Pyridines

Shigero OISHI* and Hiroshi KOMATSUZAKI
Department of Chemistry, School of Hygienic Sciences, Kitasato University,
Kitasato, Sagamihara, Kanagawa 228
(Received April 1, 1991)

Synopsis. A serious drawback of the Kjeldahl analysis of organic nitrogen, that pyridine derivatives were difficult to degrade to ammonia, was overcome by use of a Pd(II)–Cu(II) catalyst. Three hours of digestion at approximately 320 °C using the catalyst were found to be sufficient for quantitative liberation of ammonia from pyridines.

Nitrogen determination with the Kjeldahl method does not require expensive devices nor specialized techniques, and is precise and accurate.[1] Nevertheless, it has been almost ignored as a means of organic elemental analysis. One reason for this may be because of difficult degradation of pyridine derivatives to ammonia. Mixtures of mercury and selenium were used as catalysts for the degradation.[2-6] These required a long digestion period and were not widely used because of environmental concerns. Recently, the use of hydrogen peroxide as an oxidizing reagent was reported to greatly shorten the digestion period.[6-8] However, it does not seem easy nor safe to handle 50% hydrogen peroxide at high temperatures.

By analogy to the high reactivity of palladium(II) in organometallic chemistry such as the metallation of a phenyl ring,[9] we expected that Pd(II) could provide a means to break down an inert pyridine nucleus.

Experimental

Reagents. Amidosulfuric acid of standard grade for volumetric analysis, acetanilide of standard grade for elemental analysis, and other inorganic reagents of superior grade were purchased from Wako Pure Chemical Ind. 4,4′-Dimethyl-2,2′-bipyridine and other reagent grade organic materials were purchased from Aldrich Chemical Co. and Tokyo Kasei Kogyo Co., respectively. All chemicals were used as received.

Procedure. A standard procedure for a general micro-Kjeldahl method[1] was followed with some modifications. A 10—11 mg portion of sample was weighed into a digestion flask using a small glass boat. Five hundred milligrams of potassium sulfate, catalyst, and 2 ml of concentrated sulfuric acid were added to the flask. The digestion using an electric furnace (Model ME-6, Shibata Co.) was carried out with gentle refluxing of sulfuric acid at approximately 320 °C. After 6 min of distillation of ammonia from the alkalinized mixture into 5 ml of 2% aqueous boric acid containing Methyl Red-Bromocresol Green indicator, the green solution obtained was titrated with 0.01 mol dm^{-3} aqueous amidosulfuric acid to a blue color, which was the same color as a blank run.

Results and Discussion

Figure 1 shows the dependence of nitrogen content found in 4,4′-dimethyl-2,2′-bipyridine upon the degradation time in the case of 2 mg of $PdCl_2$ as a catalyst. Diverse results at 4 h of digestion seemed to depend on the sample position on the furnace; efficiencies of heating were slightly different from place to place among six locations for digestion flasks. Six hours of digestion assured a good reproducibility, but were too long considering the period needed for preparation, distillation, and titration; 3 h may be a practical time. We tried to use a second catalyst to activate palladium to shorten the period of digestion.

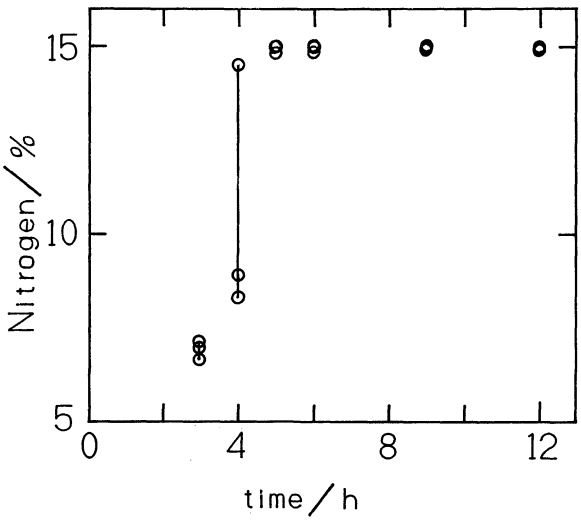

Fig. 1. Dependence of nitrogen content found for 4,4′-dimethyl-2,2′-bipyridine on the digestion time using 2 mg of $PdCl_2$ as a catalyst.

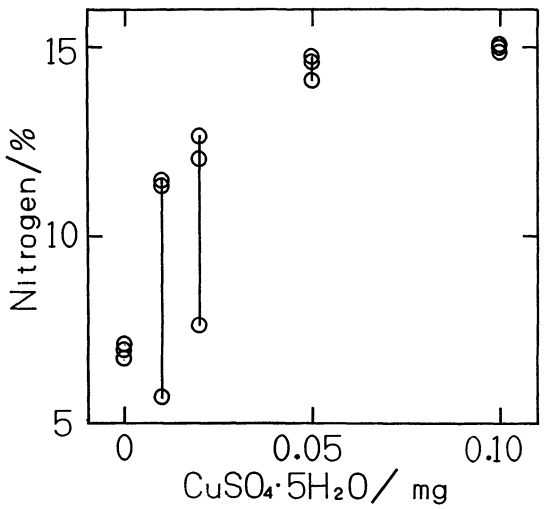

Fig. 2. Nitrogen content found for 4,4′-dimethyl-2,2′-bipyridine by digestion with 2 mg of $PdCl_2$ for 3 h using various amounts of $CuSO_4 \cdot 5H_2O$.

In the Wacker process, Pd(0), formed by the reaction of Pd(II) with ethylene to produce acetaldehyde, is oxidized to Pd(II) by oxygen with the mediation of a Cu(I)–Cu(II) redox pair.[10] By analogy to this, the effects of $CuSO_4 \cdot 5H_2O$ were examined by digesting for 3 h using 2 mg of $PdCl_2$. A very small amount of Cu(II) was found to be effective as shown in Fig. 2.

Figure 3 shows the dependence of nitrogen content found at 3 h of digestion in the presence of 30 mg of $CuSO_4 \cdot 5H_2O$ upon the amount of $PdCl_2$. Even when a large amount of $CuSO_4 \cdot 5H_2O$ was used, a quantity of $PdCl_2$ larger than 1.5 mg was found to be necessary to attain complete liberation of ammonia.

As shown in Fig. 4, the 3 h digestion time could not be shortened even by using both 2 mg of $PdCl_2$ and 30 mg of $CuSO_4 \cdot 5H_2O$.

Several pyridine derivatives, tris(2,2′-bipyridine)iron-(II) diperchlorate, and tris(2,2′-bipyridine)ruthenium(II) diperchlorate were analyzed for nitrogen under the conditions optimized above, namely, 3 h of digestion using 500 mg of K_2SO_4, 2 ml of H_2SO_4, and 30 mg of the Pd–Cu catalyst prepared previously by mixing 2 parts by weight of $PdCl_2$ with 30 parts by weight of $CuSO_4 \cdot 5H_2O$ using an agate mortar. In these experiments, three positions on the furnace were used for samples and the other three were used for reference acetanilide. Two flasks for blank runs were heated during the distillation of ammonia from the sample and reference. For reference acetanilide, we obtained 98.84±0.26% of ammonia, with a 95% confidence limit in 32 experiments, using the Pd–Cu catalyst. The difference from 100% was due to losses by manipulation. Values in Table 1 have been corrected for these losses by using values obtained in the reference runs which were carried out simultaneously. The effect of the Pd–Cu catalyst can be seen as significant. In the absence of the catalyst, no ammonia was liberated from pyridine ring. Interestingly, this appeared even in the cases of nicotinamide and cinchonine, where half of the nitrogen content could be detected, corresponding to the nitrogen of the carbamoyl group and the quinuclidine structure, respectively. In the presence of the catalyst, however, a quantitative amount of ammonia was generated, idicating complete degradation of the pyridine ring.

Although $[Ru(bpy)_3]^{2+}$ appeared to degrade by the appearance of digestion, no nitrogen was detected. The fact that the digestion of ammonium sulfate as a substrate in the presence of $RuCl_3 \cdot H_2O$ gave no ammonia in the distillate indicated that oxidation of ammonia to some volatile species was catalyzed by Ru. Platinum was also

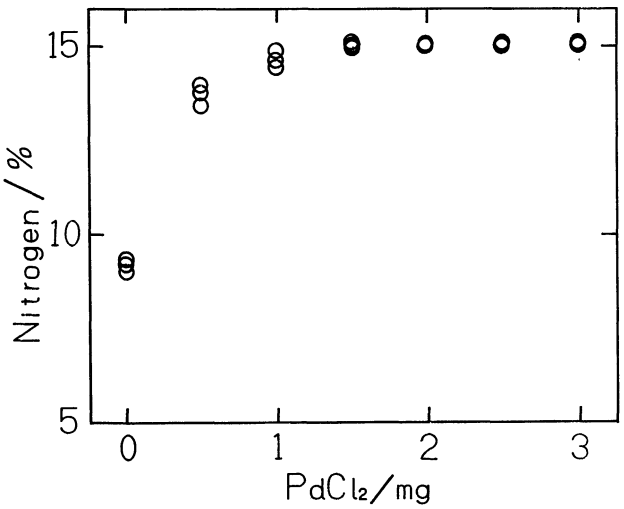

Fig. 3. Nitrogen content found for 4,4′-dimethyl-2,2′-bipyridine by digestion with 30 mg of $CuSO_4 \cdot 5H_2O$ for 3 h using various amounts of $PdCl_2$.

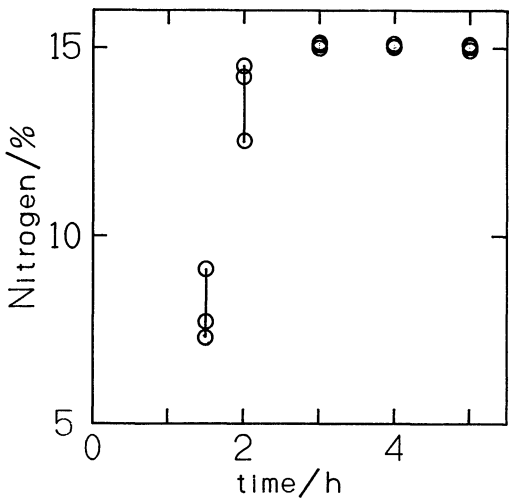

Fig. 4. Dependence of nitrogen content found for 4,4′-dimethyl-2,2′-bipyridine on the digestion time using 2 mg of $PdCl_2$ and 30 mg of $CuSO_4 \cdot 5H_2O$.

Table 1. Kjeldahl Analysis of Nitrogen in Pyridines with and without Use of the Pd–Cu Catalyst

Pyridine derivative	Formula	Nitrogen content/%		
		Calcd	Found	
			without	with
4,4′-Dimethyl-2,2′-bipyridine	$C_{12}H_{12}N_2$	15.20	0.80	15.16
2,2′-Bipyridine (bpy)	$C_{10}H_8N_2$	17.94	0.89	17.97
Acridine	$C_{13}H_9N$	7.82	0.67	7.86
Nicotinamide	$C_6H_6N_2O$	22.94	11.83	22.96
Cinchonine	$C_{19}H_{22}N_2O$	9.52	4.58	9.51
$Fe(bpy)_3(ClO_4)_2$	$FeC_{30}H_{24}N_6Cl_2O_8$	11.62	3.45	11.65
$Ru(bpy)_3(ClO_4)_2$	$RuC_{30}H_{24}N_6Cl_2O_8$	10.94	0.06	0

found to have this catalytic effect. Palladium selectively attacked a pyridine ring to liberate ammonia and did not oxidize ammonia further.

The authors thank Professor Shozo Masuda, Tokyo Science University, for valuable discussions and suggestions.

(Received April 15, 1991)

Synopsis. Barium amidotriphosphate ($Ba_2P_3O_9NH_2 \cdot 3.5H_2O$) was heated at 5 K min^{-1} in streams of dried air, humid air, and dried hydrogen chloride. *cyclo*-Triphosphates were not observed in any products, unlike in the pyrolysis of $(NH_4)_4P_3O_9NH_2 \cdot H_2O$. Water vapor or hydrogen chloride hydrolyzed phosphorus–nitrogen and phosphorus–oxygen bonds of the products.

As a new type of fertilizer and as flame-proofing materials, interest has been focused on inorganic phosphates with phosphorus–nitrogen bonds.[1] Of all the phosphorus–nitrogen phosphates, amidotriphosphates are known to be formed by ammonolyses of *cyclo*-triphosphates in aqueous solution.[2-4]

In the preceding work, we studied the thermal decomposition of ammonium amidotriphosphate $(NH_4)_4P_3O_9NH_2 \cdot H_2O$.[5] The amidotriphosphate cyclized again to form a kind of ammonium *cyclo*-triphosphate.

Although the thermal products of inorganic phosphates partially depend on their constituent cation,[6] it was not clear whether amidotriphosphates other than $(NH_4)_4P_3O_9NH_2 \cdot H_2O$ were thermally changed to *cyclo*-triphosphates or not. As barium amidotriphosphate ($Ba_2P_3O_9NH_2 \cdot 3.5H_2O$) could be obtained easily from $(NH_4)_4P_3O_9NH_2 \cdot H_2O$, we have studied the thermal decomposition of $Ba_2P_3O_9NH_2 \cdot 3.5H_2O$ in the present work, especially with interest in the formation of *cyclo*-triphosphates. Since hydrogen chloride acted as an accelerating agent for the cyclization of $(NH_4)_4P_3O_9NH_2 \cdot H_2O$,[5] $Ba_2P_3O_9NH_2 \cdot 3.5H_2O$ was also heated in a stream of dried hydrogen chloride as well as streams of dried air and humid air.

Experimental

Eight mmol (2.617 g) of ammonium amidotriphosphate ($(NH_4)_4P_3O_9NH_2 \cdot H_2O$)[3] was dissolved in 30 cm^3 of distilled water. This solution was mixed with 7 cm^3 of a 0.5 mol dm^{-3} barium chloride aqueous solution. The precipitate was removed by filtration. A 25-cm^3 portion of the barium chloride solution was added to the filtrate. The product was filtered off and washed sequentially with water, acetone, and ether, and then air-dried. The product was characterized by HPLC-FIA and by determinations of nitrogen,[5] barium,[7] and phosphorus.[8] Ammonium nitrogen[5] was not detected in the product. Found: P, 15.17; Ba, 43.78; N, 2.24%. Calcd for $Ba_2P_3O_9NH_2 \cdot 3.5H_2O$: P, 15.73; Ba, 46.50; N, 2.37%. Fifteen mg of the product was dissolved in 20 cm^3 of a 0.1 mol dm^{-3} aqueous tetrasodium ethylenediaminetetraacetate solution. As soon as it was diluted to 500 cm^3 with distilled water, the solution was analyzed with an HPLC-FIA system.

About 13 mg of the product was placed in a platinum pan. Thermal analyses (TG-DTA) were carried out at 5 K min^{-1} in stationary air and in a stream of dried air at 50 cm^3 min^{-1}. The dried air used was prepared by the passage of air through molecular sieves.[5]

A 0.1-g portion of the product was heated in a cylindrical electric furnace at the same rate of 5 K min^{-1} as that used in TG-DTA. A stream of humid air (relative humidity 90% at 25 °C) at 50 cm^3 min^{-1} and a stream of dried hydrogen chloride were prepared as reported in Ref. 5. Before heating, the electric furnace was purged with a volume of these gases about twice the volume of the furnace. As soon as the sample reached the required temperature, it was taken out and cooled to room temperature in a desiccator, and immediately analyzed by HPLC-FIA, X-ray diffractometry, and IR spectrophotometry. HPLC-FIA was performed as mentioned above. X-Ray diffraction patterns were obtained by the use of nickel-filtered Cu $K\alpha$ radiation. IR spectra were measured with a KBr disc method.

Results and Discussion

Thermal Decomposition in Stationary Air. Figure 1 shows thermal analysis (TG-DTA) measured in stationary air and the DTA measured in a stream of dried air at 50 cm^3 min^{-1}. The endothermic peaks at 60 °C and at 90 °C in stationary air overlapped to appear as one peak at about 70 °C in a stream of dried atmosphere, which implied that the endothermic peaks were caused by the elimination of bound water (the water of crystallization).

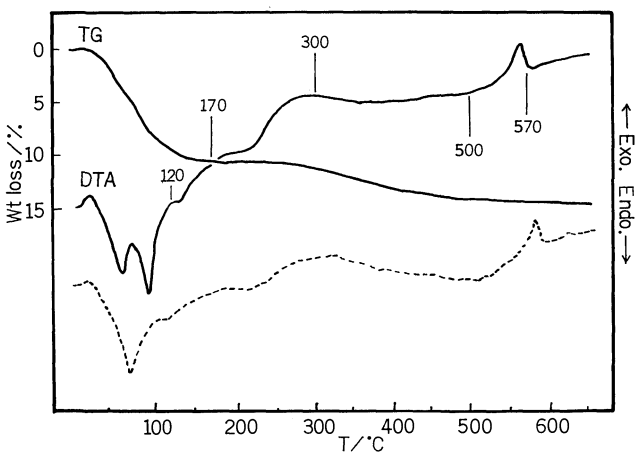

Fig. 1. Thermal analyses of $Ba_2P_3O_9NH_2 \cdot 3.5H_2O$ measured at a heating rate of 5 K min^{-1}. Solid line (—): TG and DTA measured in stationary air, dashed line (---): DTA measured in a stream of dried air.

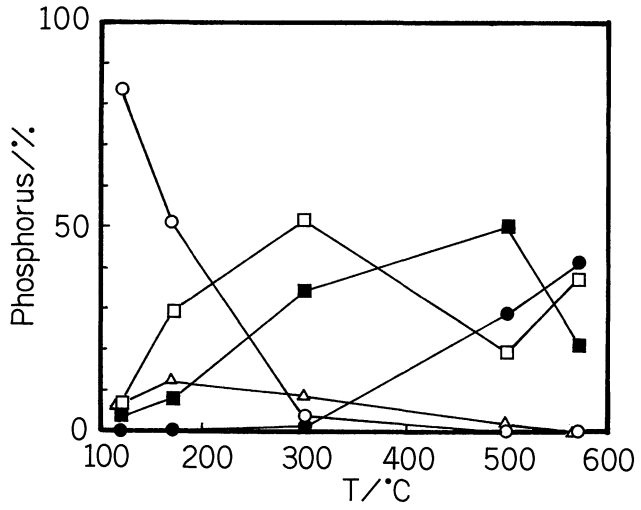

Fig. 2. Changes in amounts of phosphates in the samples heated at 5 K min^{-1} in stationary air. ○: amidotri-, ●: poly-, □: mono-, di-, and tri-, ■: oligo- (chain length=4—11), △: other (the phosphates were thought to have short or middle chain structures with one or several phosphorus-nitrogen bonds).

Figure 2 presents the percentage of phosphorus atoms present as amidotri-, from mono- to tri-, oligo- (chain length=4—12), and polyphosphates in the products obtained by heating to the temperatures indicated on the DTA curve of Fig. 1. Several peaks other than those of the above phosphate ions appeared before the peak of octaphosphate on the HPLC-FIA chromatograms. On the basis of their retention times, they were thought to be short or middle chain phosphates with one or several phosphorus–nitrogen bonds. They are also plotted in a group in Fig. 2 and expressed as "other".

Figure 3 shows the X-ray diffraction patterns of the products. The sample heated to 570 °C contained a crystalline material. The sample mainly consisted of poly- and triphosphates. Its X-ray diffraction data did not agree with any data of barium polyphosphates reported on the JCPDS cards. Therefore, perhaps, the crystalline material might have been a kind of triphosphate.

Figure 4 shows that absorptions at 1475 and at 1428 cm^{-1} appeared on the IR spectrum of the sample heated to 170 °C. Corbridge and Lowe suggested that two absorptions near 1400 cm^{-1} could be ascribed to the ammonium ion.[9] Therefore, the product heated to

	Dried HCl	—	88.5	5.1	6.4	—
300	Dried air	6.4	38.7	29.1	4.7	21.0
	Humid air	—	55.1	36.8	4.0	4.1
500	Dried air	—	24.5	47.2	17.7	10.6
	Humid air	—	18.6	52.1	25.3	4.0
570	Dried air	—	19.5	38.6	36.3	5.6
	Humid air	—	37.5	24.9	35.2	2.4

a) The chain length was from four to twelve. b) These anions were thought to have short or middle chain structures with one or several phosphorus-nitrogen bonds.

170 °C contained ammonium ions, which must have been formed from amino groups. The spectrum of $Ba_2P_3O_9NH_2 \cdot 3.5H_2O$ showed a small absorption at 1602 cm^{-1}. The absorption probably arose from amino groups.[9,10] It disappeared in the IR spectrum of the sample heated to 300 °C, which agreed with the result that amidotriphosphate ions were almost cleaved below 300 °C (Fig. 2).

Effect of Atmosphere on the Thermal Decomposition. The samples were heated at 5 K min^{-1} to the respective temperatures in three different atmospheres. Table 1 shows the percentage of phosphorus atoms present as the respective phosphates in the thermal products. *cyclo*-Triphosphates were observed in the thermal decomposition of ammonium amidotriphosphate ($(NH_4)_4P_3O_9NH_2 \cdot H_2O$), as reported in the preceding paper.[5] Hydrogen chloride accelerated the cyclization of the amidotriphosphate to the *cyclo*-triphosphate at lower temperatures. However, in the present work, *cyclo*-triphosphate ions could not be detected in any products. It might be attributed to the lack of formation of zwitterions reported in Ref. 5.

Table 1 shows that the above-mentioned "other" phosphates were not present and mono-, di-, and triphosphates were abundant in the samples heated in dried hydrogen chloride, which revealed that the hydrogen chloride did not act as an accelerating agent for the cyclization, but as a hydrolyzing agent for the phosphorus–nitrogen and the phosphorus–oxygen bonds. Water vapor in the atmosphere also hydrolyzed the phosphorus–nitrogen and the phosphorus–oxygen bonds present in the products.

The present work was partially supported by a Grand-in-Aid for Scientific Research No. 03750588 from the Ministry of Education, Science and Culture.

Theoretical Estimation of the Entropies of Solvation of Univalent Ions

Takehiro ABE
College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980
(Received April 18, 1991)

Synopsis. A simple theoretical expression for the entropies of solvation of univalent ions has been derived by using a modified Born equation and has been successfully applied to several ions in water and to the typical ions Rb^+ and Cl^- in various solvents.

Abraham and Liszi[1,2] have succeeded in calculating the entropies of solvation of univalent ions in nonaqueous solvents, using a one-layer solvation model in which an ion is surrounded by a local solvent layer, immersed in the bulk solvent. They obtained excellent agreement between the calculated and observed entropy changes. However, their model contains parameters such as the thickness of the local solvent layer and the variation of the dielectric constant with temperature. An attempt has been made, therefore, to present a simple expression which contains no adjustable parameters and roughly reproduces experimental ionic solvation entropies. Recently, Abe[3] presented the following equation for the free energy of solvation of an ion of charge Ze (where Z is the formal charge and e the charge of a proton) embedded in a continuous dielectric medium of solvent:

$$\Delta G^\circ_{\mathrm{Abe}}=\frac{e^2LZ^2}{2a}\times\left(\frac{1}{\ln\varepsilon_r}-\frac{1}{\varepsilon_r\ln\varepsilon_r}-1\right), \qquad (1)$$

where ΔG° is the increase of the standard molar Gibbs function, L the Avogadro constant, ε_r the bulk relative permittivity of the solvent, and a the radius of a spherical cavity in whose center the ion is placed. Equation 1 was derived by considering a distance-dependent relative permittivity of the solvent on the assumption that only the electrostatic free energy is predominant in the case of monoatomic and small ions. The equation reproduced experimental free energies of ions better than the Born equation[4] did.[3] Ehrenson[5] showed that the solvent parameter $\{1/\ln\varepsilon_r-1/(\varepsilon_r\ln\varepsilon_r)-1\}$ in Eq. 1 was the best in the inverse exponential radial dielectric function family of the modified Born equations for the correlation of the free energies of solvation. Moreover, Abe[6] showed that Eq. 1 can be successfully applied to the estimation of the solubilities of sparingly soluble lanthanoid iodates in dimethyl sulfoxide (DMSO)–water. Accordingly, in this paper, Eq. 1 has been applied in order to obtain a simple expression for the solvation entropies of ions. The results of calculations have been compared to those calculated by using the Born equation.

Theoretical Calculations and Discussion

On the assumptions that only the electrostatic contribution is dominant and that a does not depend on the temperature T(K), one can easily derive the following increase of standard molar entropy from Eq. 1 according to $\Delta S^\circ=-(\partial\Delta G^\circ/\partial T)_p$ (where the suffix p denotes constant pressure):

$$\Delta S^\circ_{\mathrm{Abe}}=\frac{e^2LZ^2}{2a}\times\frac{(\varepsilon_r-\ln\varepsilon_r-1)}{\varepsilon_r^2(\ln\varepsilon_r)^2}\times\frac{\mathrm{d}\varepsilon_r}{\mathrm{d}T}, \qquad (2)$$

where $e^2L/2=69.5$ nm kJ mol^{-1} (=16.6 nm kcal mol^{-1}, where 1 cal=4.184 J). On the other hand, ΔS° is easily given similarly from the Born equation by

$$\Delta S^\circ_{\mathrm{Born}}=\frac{e^2LZ^2}{2a}\times\frac{1}{\varepsilon_r^2}\times\frac{\mathrm{d}\varepsilon_r}{\mathrm{d}T}. \qquad (3)$$

Equations 2 and 3 do not contain adjustable parameters and are much simpler than the equation given by Abraham and Liszi.[1] In the present study, Eqs. 2 and 3 were applied to 10 univalent ions in water and to the typical ions Rb^+ and Cl^- in various solvents. The results of calculations were compared with experimental values[1] ($\Delta S^\circ_{\mathrm{obsd}}$) for the 12 ions, as shown in Figs. 1, 2, and 3. In applying Eqs. 2 and 3, all the values for a, ε_r, and $\mathrm{d}\varepsilon_r/\mathrm{d}T$ were taken from Ref. 7 except for the ε_r value of ammonia, for which 16.9[8] (25 °C) was adopted.

All the figures show that Eq. 2 reproduces the $\Delta S^\circ_{\mathrm{obsd}}$ values much better than does Eq. 3 and that Eq. 3 overestimates the ΔS° values as a whole. The experimental values for ΔS° have also been tabulated by Criss

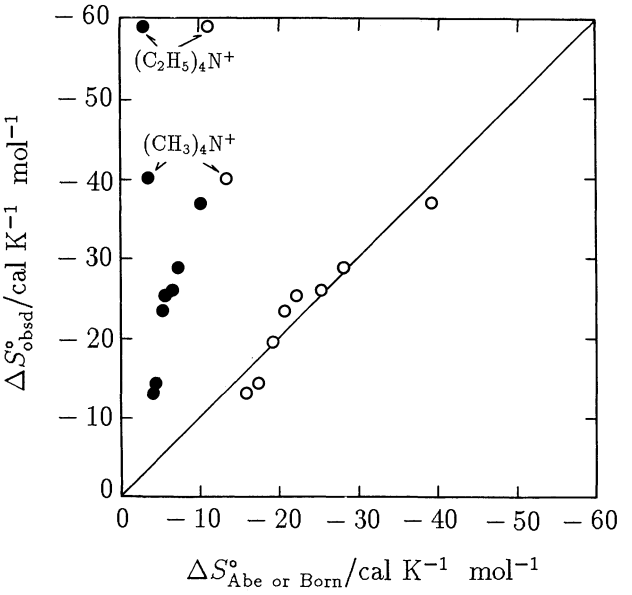

Fig. 1. Plots of observed entropies of solvation of 10 univalent ions (Na^+, K^+, Rb^+, Cs^+, $(CH_3)_4N^+$, $(C_2H_5)_4N^+$, Cl^-, Br^-, I^-, and ClO_4^-) in water (298 K) vs. $\Delta S^\circ_{\mathrm{Abe}}$ (○) and $\Delta S^\circ_{\mathrm{Born}}$ (●).

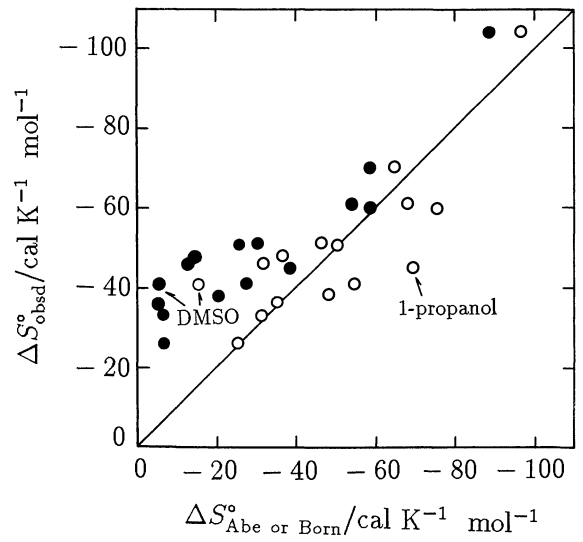

Fig. 2. Plots of observed entropies of solvation of Rb^+ in various solvents (298 K) vs. ΔS°_{Abe} (○) and ΔS°_{Born} (●).

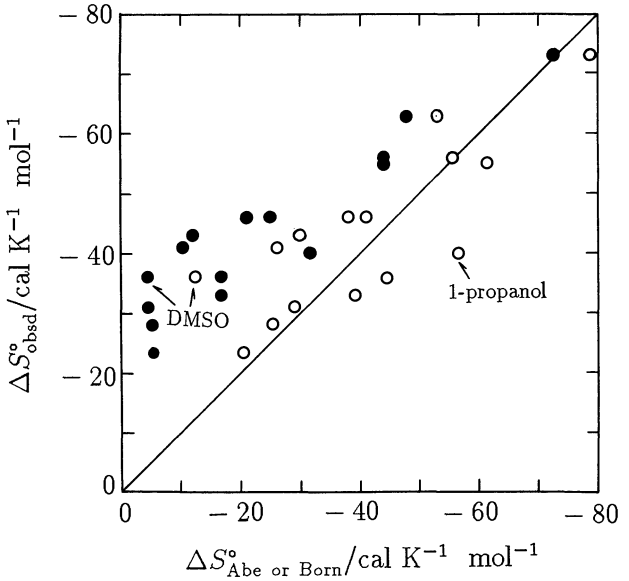

Fig. 3. Plots of observed entropies of solvation of Cl^- in various solvents (298 K) vs. ΔS°_{Abe} (○) and ΔS°_{Born} (●).

and Salomon.[9] Comparison of the values reported by Abraham and Liszi[1] and by Criss and Salomon led to the suggestion that errors in experimintal entropies of solvation are at least several calories K^{-1} mol^{-1}. It was, therefore, not surprising that there was only poor agreemont between the calculated and observed values. Abraham and Liszi[1,2] have combined the calculated electrostatic-entropy value with a nonelectrostatic contribution as the total entropy of solvation. According to them, the nonelectrostatic entropy values are quite small for solvents other than water. As shown in Figs. 1—3, however, Eq. 2, which was derived by considering only the electrostatic-entropic contribution, gave roughly the corresponding experimental values except for the cations $(CH_3)_4N^+$ and $(C_2H_5)_4N^+$ (Fig. 1). From this result, the nonelectrostatic-entropic contribution may be neglected in the case of atomic and small molecular ions. In the case of the large ions $(CH_3)_4N^+$ and $(C_2H_5)_4N^+$, the nonelectrostatic-entropic contribution may not be ignored, since the methyl and ethyl groups obviously interact nonelectrostatically with the water molecules. In Figs. 2 and 3, the plots for the DMSO solvent deviated quite a bit from the lines. Cations are strongly solvated in DMSO, whose molecule has a negative charge localized on an oxygen atom.[10] For this reason, the value of $|\Delta S^\circ_{obsd}|$ for Rb^+ in DMSO is probably larger than that of $|\Delta S^\circ_{Abe}|$ which is due only to the electrostatic-entropic contribuiton. On the other hand, anions are poorly solvated in DMSO.[10] However, this fact cannot account for the large deviation of the plot for Cl^- in DMSO from the line. The deviation suggests a special interaction between Cl^- and DMSO. This special interaction seems to be the interaction between Cl^- and a hydrogen atom of the DMSO molecule, because methylsulfinylmethanide is simply genetated from DMSO[11] and DMSO is a very weak acid.[12] For hydrogen-bonded solvents, Abraham and Liszi[1] found substantial differences between the calculated and observed ΔS° values. In Figs. 2 and 3, however, only the Eq. 2 plot of 1-propanol deviated greatly from the lines. Thus, Eq. 2 may be applied to the approximate estimation of the entropies of solvation of small univalent ions.

Redox Properties for Pentacoordinated Manganese(III) Complexes with Bis(salicylideneamino)alkanes

Masaaki NAKAMURA,* Yuri MIYANAKA, Yasuhiro OHMURA, Satoko SEKINE, Hu HUANG,† and Fumiaki KAI†
Department of Chemistry, Faculty of Science, Kumamoto University, Kumamoto 860

Synopsis. The oxidation potentials of Mn(III/IV) for pentacoordinated chloromanganese(III) complexes with bis(salicylideneamino)alkanes shifted cathodically in the presence of excess chloride ions in their solution. The formation of dichloromanganese(IV) complexes with Schiff bases was spectrophotometrically detected by addition of chloride and hydrogen ions to acetonitrile solutions of the corresponding chloromanganese(III) complexes under aerobic conditions.

The chemistry of manganese(III) and (IV) complexes has been of interest in relation to the catalytic activity of manganese enzymes, such as the oxygen evolution process of photosystem II.[1-3] Previously, Matsushita et al. described a unique synthetic method for manganese(IV) complexes, in which dichloromanganese(IV) complexes with tetradentate or bidentate Schiff bases were prepared by treating the corresponding chloromanganese(III) complexes with hydrochloric acid.[4,5] We have also prepared a tetrachlorodimanganese(IV) complex with an octadentate binucleating Schiff base from the corresponding dichlorodimanganese(III) complex by applying the same synthetic method.[6] This is of interest because hydrochloric acid is not able to oxidize manganese(III) to (IV) as an oxidizing agent.

In this study, the electrochemical properties of pentacoordinated manganese(III) complexes with tetradentate Schiff base, 1,2-bis(salicylideneamino)ethane (H_2salen) and 1,3-bis(salicylideneamino)propane (H_2saltn), were investigated; the role of hydrochloric acid is discussed here.

Experimental

Syntheses. All of the pentacoordinated manganese(III) complexes were prepared in an identical manner, employing a modified method from the literature.[7-9] This may be illustrated for Mn(saltn)Cl.

Mn(saltn)Cl: 1,3-Propanediamine (10 mmol) and salicylaldehyde (20 mmol) were dissolved in ethanol (30 cm^3) and then refluxed for 3 h. Manganese(II) chloride tetrahydrate (10 mmol) was added to the reaction mixture; it was then refluxed for 1 h under aerobic conditions. The obtained dark-green solution was filtered and the filtrate was allowed to stand over night. Dark-green fine crystals were deposited; they were then filtered off, washed with ethanol, and dried in vacuo. The yield was ca. 55%. Found: C, 54.38; H, 5.21; N, 6.65%. Calcd for $C_{17}H_{16}N_2O_2MnCl\cdot C_2H_5OH$: C, 54.75, H, 5.32, N, 6.72%.

[Mn(saltn)H_2O]ClO_4: Found: C, 44.87; H, 4.08; N, 6.13%. Calcd for $C_{17}H_{18}N_2O_7MnCl$: C, 45.10; H, 4.00; N, 6.19%.

Mn(salen)Cl: Found: C, 48.81; H, 4.60; N, 7.14%. Calcd for $C_{16}H_{14}N_2O_2MnCl\cdot 2H_2O$: C, 48.93; H, 4.62; N, 7.13%.

[Mn(salen)H_2O]ClO_4: Found: C, 43.63; H, 3.69; N, 6.36%. Calcd for $C_{16}H_{16}N_2O_7MnCl$: C, 43.81; H, 3.68; N, 6.39%.

Measurements. The electronic spectra were obtained using a Hitachi 220A or U3210 recording spectrophotometer. The electric conductivities were determined by a Horiba Conductivity Meter (Model DS-14). Polarograms were recorded on a Yanagimoto Polarographic Analyzer (Model P-1100) by the use of a three-electrode cell equipped with glassy carbon as a working electrode, a platinum coil as a auxiliary electrode, and a saturated calomel electrode (SCE) as a reference electrode. In practice, all of the potentials were normalized by using ferrocene as an internal standard.

Results and Discussion

In methanol solutions, all of the perchlorate and chloro complexes, [Mn(SB)H_2O]ClO_4 and Mn(SB)Cl (where SB is $salen^{2-}$ or $saltn^{2-}$) showed almost identical spectral features, indicating the formation of a solvated complex, such as $[Mn(SB)(CH_3OH)_2]^+$. This result is supported by their molar conductivities in methanol at 25 °C (Table 1), whose values are consistent with a 1:1 electrolyte.[10] When tetrabutylammonium chloride (TBACl) was added to the methanol solutions up to a molar ratio of [TBACl]/[complex]=200, the electronic spectra of the complexes were little affected and the specific conductivity was linearly increased with an increase in the concentration of TABCl. It is concluded that monocationic complexes can exist in a methanol solution even with excess chloride ions.

On the other hand, molar conductivity data for the chloro complexes demonstrate essentially nonelectrolyte in acetonitrile (Table 1).[10] Each of the observed spectra of the four complexes in acetonitrile and of the two chloro complexes in dichloromethane can be interpreted as being the spectrum of a pentacoordinated manganese(III) complex.[8,9,11] From optical measurements, the perchlorate complexes are changed to the corresponding chloro complexes by the addition of excess TBACl in acetonitrile, respectively. The absorption spectra of Mn(saltn)Cl and [Mn(saltn)H_2O]ClO_4 are shown in Fig. 1 as an example. A plot of the specific conductivity of the perchlorate complex vs. [TBACl]/[complex] in acetonitrile is almost constant within the TBACl concentration range below 1 in molar ratio. The above-mentioned results suggest that an apical ligand substitution occurs in the presence of the chloride ion as follow:

$$[Mn(SB)H_2O]^+ + ClO_4^- + TBA^+ + Cl^- \longrightarrow Mn(SB)Cl + H_2O + TBA^+ + ClO_4^-.$$

Each of the four manganese(III) complexes exihibits

a) Measured at 25°C. The concentration of the complexes was 5.0×10^{-4} mol dm^{-3}. b)TBAX means tetrabutylammonium salts used as a supporting electrolyte. c) $E'_{1/2}=(E_{pc}+E_{pa})/2$.

two redox waves attributable to the manganese center, since the ligands do not show any redox waves at these potential region (Table 1). The oxidation potentials observed are dependent on the charge of the manganese(III) complexes in solution. Namely, the monocationic complexes show irreversible oxidation waves at 0.74—0.78 V in methanol and 1.1 V in acetonitrile. The neutral chloro complexes, however, are oxidized at 0.47—0.64 V in acetonitrile and dichloromethane. When excess chloride ions exist in the solution, the oxidation potentials of the chloro complexes shift negatively to 0.26—0.30 V (Table 1). Furthermore, in the case of the acetonitrile solutions of Mn(salen)Cl and $[Mn(salen)H_2O]ClO_4$, a cathodic peak is detected in the reverse scan by the addition of excess chloride ions, in which the peak-to-peak separation (ΔE_p) is 90—103 mV and the peak ratio (i_{pc}/i_{pa}) is almost equal to unity. Under the same experimental conditions, the normally reversible one-electron oxidation of ferrocene displays rather large ΔE_p values of ca. 60 mV. Accordingly, we have tentatively assigned the oxidation waves to an irreversible one-electron transfer process for Mn(III/IV).

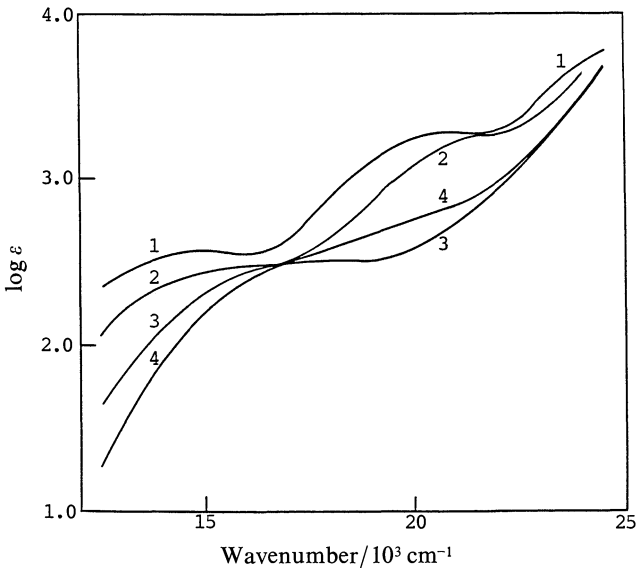

Fig. 1. Electronic spectra of Mn(saltn)Cl in dichloromethane (1), in acetonitrile (2), in methanol (3) and $[Mn(saltn)H_2O]ClO_4$ in acetonitrile (4).

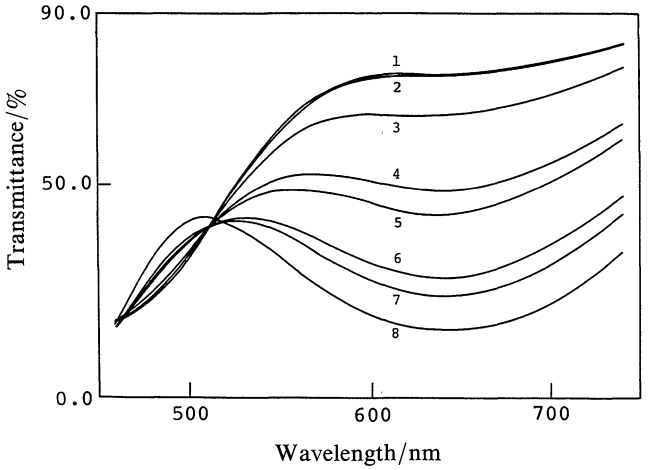

Fig. 2. Spectral changes on addition of perchloric acid to an acetonitrile solution of 5.0×10^{-4} mol dm^{-3} Mn(saltn)Cl in different molar ratios. 1: $[HClO_4]$/[complex]=0.00, 2: 0.02, 3: 0.10, 4: 0.30, 5: 0.40, 6: 0.80, 7: 1.00, 8: 2.00.

It is noted that those oxidation potentials (0.26—0.30 V) appear at a more negative region than does the reduction potential of Mn(IV/III) (0.36 V) for the dichloromanganese(IV) complex with 1,2-bis(salicylideneamino)-1-phenylethane.[6] This significant cathodic shift of the potentials is interpreted as meaning that the manganese(IV) state formed electrochemically is stabilized by a further participation of chloride ions to the manganese(IV) coordination sphere. However, only an addition of excess chloride ions to the manganese(III) complex solution is not sufficient to obtain the manganese(IV) complex.

When perchloric acid was added to the acetonitrile solution of the chloro complexes, Mn(salen)Cl and Mn(saltn)Cl, a new absorption band appeared around 640 nm. Figure 2 shows the spectral changes of Mn(saltn)Cl as an example. This band can be assigned to the CT band of the Cl^- to Mn(IV).[4] Accordingly, this spectral change suggests the formation of dichloromanganese(IV) complexes. The intensity of the CT band is increased with an increase in the concentrations of chloride and hydrogen ions. However, rapid decolorization occurs upon adding these excess ions, indicating a decomposition of the complexes. The most intense absorption band was obtained with an acetonitrile solution containing TBACl and perchloric acid at a molar ratio of [complex]:[TBACl]:$[HClO_4]$=1:3:2, in which [complex]=5.0×10^{-4} mol dm^{-3}. The yield of $Mn(salen)Cl_2$ under the above-mentioned conditions is about 42%, which is determined spectrophotometrically based on literature data for its CT band.[4]

The CT band was observed by using sulfuric acid instead of perchloric acid as a hydrogen ion source, but was not detected by using acetic acid, whose dissociation constant in acetonitrile is $10^{-22.3}$.[12] Furthermore, the presence of oxygen is necessary for the above reaction, since the CT band can not be obtained under anaerobic conditions. In a methanol solution, only the decomposition of the complexes is observed for any concentration ratios of TBACl and $HClO_4$ under aerobic conditions. These results imply that the dichloromanganese(IV) complex is formed by the addition of chloride and hydrogen ions to a solution containing the corresponding pentacoordinated chloromanganese(III) complexes under aerobic conditions.

Synopsis. An amperometric glucose-sensing electrode is constructed by the use of a carbon paste containing 1,1′-dimethylferrocene and a polyethylene glycol-modified glucose oxidase. The polymer-modified enzyme is soluble in organic solvents (e. g., hexane) as well as in water, and exhibits a much higher activity than native enzyme does on the surface of a hydrophobic carbon paste eletrode. The higher enzyme activity results in an enhanced electrode response: the current response to glucose on the modified enzyme-based electrode is several times as large as that obtained on a native enzyme-based electrode.

Much effort has been directed to devise an amperometric enzyme electrode for measuring glucose by combining immobilized glucose oxidase (GOD) with an immobilized electroactive species which mediates an electron transfer between the enzyme and the electrode.[1-3] Recently, a novel method for constructing such a mediated glucose-sensing electrode has been developed: a GOD/mediator-containing carbon paste electrode (CPE) has been prepared by doping the carbon paste with the enzyme and a mediator.[4-6] The GOD/mediator-doped CPE is of particular interest, since it can easily be prepared; it also has a close proximity of the enzymatic, mediating and sensing sites, thus providing a rapid current response to glucose. However, hydrophilic GOD molecules are not expected to exhibit high activity in a hydrophobic carbon paste matrix.

Inada et al.[7-9] have reported that enzymes (e.g., catalase and peroxidase) modified with polyethylene glycol (PEG) dissolve in various organic solvents as well as in water. Further, the PEG-modified enzymes have been reported to show catalytic activities, even in organic solvents. Such a PEG-modified enzyme would exhibit a higher activity than the native enzyme in the carbon paste matrix.

We have prepared a glucose-sensing CPE by the use of 1,1′-dimethylferrocene and a PEG-modified GOD. The effect of the modification of GOD on the electrode response is reported in the present paper.

Experimental

GOD (E.C. 1.1.3.4, from *Aspergillus* sp., Grade II) and peroxidase (E.C. 1.11.1.7, from horseradish, Grade I-C) were purchased from Toyobo. α-(4,6-Dichloro-1,3,5-triazin-2-yl)-ω-methoxypoly(oxyethylene) (activated PEG; molecular weight, 5×10^3)[10] was obtained from Sigma, and 1,1′-dimethylferrocene, from Aldrich. The other reagents used were of analytical-reagent grade. Deionized, doubly-distilled water was used throughout.

The GOD, as received (native GOD, 14 mg), and the activated PEG (140 mg) were added into 2 ml of 0.1 mol dm^{-3} borate–KOH buffer (pH 10); this GOD/PEG mixture was then incubated at 37 °C for 2 h, after which the reaction was stopped by adding acetic acid into the solution to make its pH 6. Unattached PEG was removed in an ultrafiltration cell (Millipore) using a PTTK membrane (Millipore; cut off molecular weight, 3×10^4) and 0.05 mol dm^{-3} $(NH_4)HCO_3$ as a dialyzing solution. Finally, a light-yellow-colored powder of PEG-modified GOD (22 mg) was obtained by lyophilization.

The molecular weight of the PEG-modified GOD was estimated by sodium dodecyl sulfate (SDS)–polyacrylamide (4—20%) gel electrophoresis; the molecular marker proteins were myoglobin (1.7×10^4), carbonic anhydrase (3.0×10^4), ovalbumin (4.5×10^4), bovine serum albumin (6.6×10^4), β-galactosidase (1.2×10^5) and myosin (2.0×10^5). The content of FAD (flavin-adenine dinucleotide) in the modified GOD was estimated by measuring the visible absorption of an aqueous solution of the modified enzyme (at 450 nm). The enzyme activities of the modified and native enzymes in solutions and on CPE's were measured by using the *o*-dianisidine/peroxidase-color-producing system.[11]

Two kinds of glucose-sensing CPE's, CPE I and II, were prepared by using the PEG-modified GOD and the native GOD, respectively. The modified or native GOD, 1,1′-dimethylferrocene and carbon paste (BAS CP-O), 10:10:80 by weight, were thoroughly mixed together. A portion of the mixture was placed in a hole (3.2 mm diameter, 4 mm deep) at the end of an electrode body (BAS 11-2010). CPE I or II thus prepared, an Ag/AgCl electrode and a platinum wire served as working, reference and auxiliary electrodes, respectively. The test solution used was a 0.1 mol dm^{-3} potassium acetate buffer solution (20 ml, pH 5, 25 °C). The solution was stirred with a magnetic bar. Oxygen was expelled from the solution by bubbling argon. CPE I and II were stored in the acetate buffer solution at 0 °C when not in use.

Results and Discussion

Figure 1 shows the result of the SDS-polyacrylamide gel electrophoresis. The native GOD gave a single band on the gel at a molecular weight of ca. 7×10^4. This value agrees fairly well with the molecular weight of the subunit in GOD, 7.5×10^4; the native GOD (molecular weight, 1.5×10^5) consists of two identical subunits. On the other hand, the modified GOD gave a broad electrophoretic pattern, indicating that the molecular weight of the subunit increased to be more than 1×10^5 upon attaching activated PEG onto the GOD molecule. The PEG-modified GOD was soluble in organic solvents as well as in aqueous media. For example, the modified enzyme (1 mg) was instantaneously dissolved in hexane (1 ml).

The acetate buffer solution containing the native GOD (5 mg ml^{-1}) and that containing the modified GOD

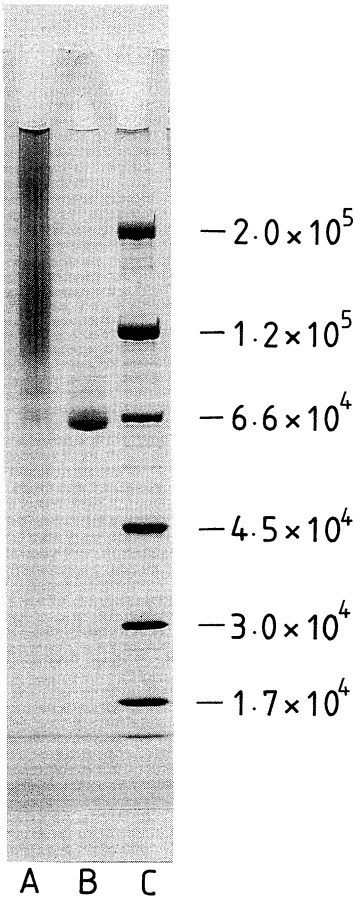

Fig. 1. Electrophoretic patterns of the modified GOD (A), native GOD (B), and marker proteins (C).

(5 mg ml^{-1}) showed optical densities of 0.52 and 0.28, respectively, at 450 nm: the content of FAD in the modified GOD is about a half that in native GOD. When native GOD was incubated in a borate–KOH buffer in the absence of activated PEG, the release of FAD from GOD molecules was not observed. It is therefore indicated that the modified GOD consists of native GOD and the modifier in a weight ratio of ca. 1:1.

The activity of modified GOD in an acetate buffer solution at 25 °C was determined to be 15 U mg^{-1}, whereas that of native GOD under the same conditions was 105 U mg^{-1}. This indicates that the enzyme activity is considerably reduced during the modification process. When the modified GOD was doped into carbon paste, on the other hand, it exhibited a mcuh higher activity than native enzyme. The GOD activities on the surfaces of CPE-I and II were ca. 0.1 and 0.02 U cm^{-2}, respectively. The higher activity of modified GOD in the carbon paste matrix may be attributable to its enhanced effinity for the hydrophobic matrix, which can be proven by the high solubility of the modified enzyme in organic solvents such as hexane.

The increase in the GOD activity in the carbon paste by a modification of the enzyme with PEG resulted in an enhanced response for glucose on CPE I, as compared to

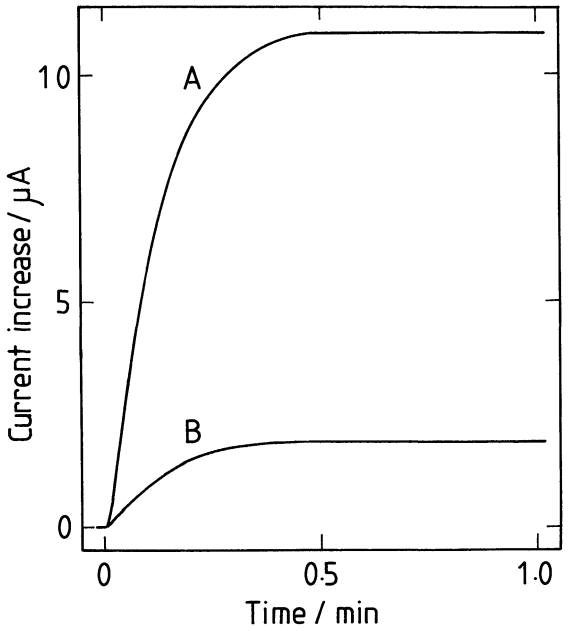

Fig. 2. Response/time curves on CPE I (A) and II (B) for 25 mmol dm^{-3} glucose.

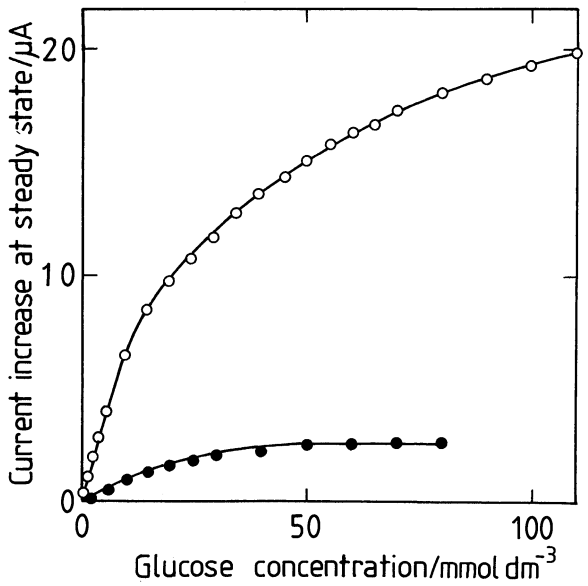

Fig. 3. Relationships between current increase and glucose concentration on CPE I (—○—) and II (—●—).

the case of CPE II. Curves A and B in Fig. 2 show the electrode responses to glucose (25 mmol dm^{-3}) on CPE I and II, respectively. The electrode potential, 0.4 V vs. Ag/AgCl, was sufficient for the oxidation of 1,1′-dimethylferrocene to produce ferricinium ion, and for obtaining ferrocene-mediated current responses to glucose.[4,12] The glucose response on CPE I was about five times as large as that on CPE II.

Figure 3 shows the calibration curves of CPE I and II. CPE I gave a linear current response up to 10 mmol dm^{-3} of glucose, and a siginificant increase in the

response with an increase in the glucose concentration within the range 10—100 mmol dm^{-3}. The detection limit of CPE I was 0.1 mmol dm^{-3} (S/N=5). On the other hand, the detection limit of CPE II was 0.5 mmol dm^{-3} (S/N=5); the electrode response reached a plateau when the glucose concentration was higher than 50 mmol dm^{-3}. These results indicate that the modification of GOD with PEG is effective for widening the dynamic range of the glucose-sensing electrode.

The effect of storage (in the acetate buffer at 0 °C) of CPE I and II was then examined. On each electrode, the response to glucose (25 mmol dm^{-3}) gradually decreased during storage and became ca. 80% of the initial value after 10 d; the long-term stability was, unfortunately, not improved by a modification of enzyme. The decrease in the electrode response was considered to be caused by a leaching of the (modified or native) enzyme out of the carbon paste matrix, since the solution used for storing CPE I or II showed significant GOD activity. Another kind of modification method, to introduce hydrophobic groups onto the surface of GOD molecule, would be required for obtaining enzyme/carbon paste systems with high stability. On the other hand, our preliminary experiments demonstrate that the coating on the surface of CPE I (and that of CPE II) with an anionic polymer (AQ-29D, Eastman)[4] is effective for preventing the enzyme from leaking out of the carbon paste, as well as for diminishing electrochemical interference with such anionic species as ascorbate.

Photoinduced Cyclization of 2-Acetonyl-3-alkoxy-1,4-naphthoquinones: Formation of 2-Alkyl-Substituted 4-Methyl-naphtho[2,3-*d*]-1,3-dioxepin-6,11-diones

Katsuhiko NAKAGAWA

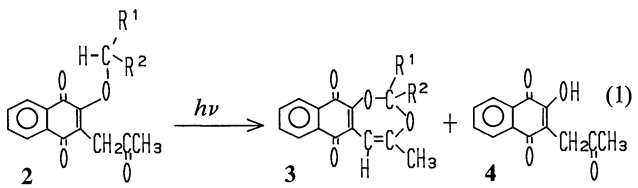
(Received December 25, 1990)

Synopsis. Irradiation of 2-acetonyl-3-alkoxy-1,4-naphthoquinones in benzene gave 2-alkyl-substituted 4-methyl-naphtho[2,3-*d*]-1,3-dioxepin-6,11-dione and 2-acetonyl-3-hydroxy-1,4-naphthoquinone via intramolecular hydrogen-abstraction reaction. Irradiation of quinones in methanol, however, gave the latter product exclusively.

Photochemical reaction of 2-alkoxy-1,4-naphthoquinones usually leads to the formation of quinone dimers[1] and oxetanols[2] in high yields, via intramolecular hydrogen abstraction from the 2′-position of the side chain. This reaction is similar to the Norrish type II photoreaction of aromatic ketones.[3] Recently, we developed the convenient synthesis of 2-acetonyl-3-alkoxy-1,4-naphthoquinones (**2**) by the photochemical reaction of 2-alkoxy-1,4-naphthoquinones (**1**) with 2-methoxy-1-propene.[4] Interestingly, the photochemical reaction of **2** is quite different from those of 2-alkoxy-1,4-naphthoquinones with regard to the mechanistic points.[5] In this paper, the details of the novel photo-induced cyclization of **2** is described.

Results and Discussion

When a solution of 2-acetonyl-3-alkoxy-1,4-naphthoquinones (**2**) in benzene (0.0028 mol dm^{-3}) were irradiated with a high-pressure mercury arc lamp (300 W) through Pyrex filter for 15 min, the heterocyclic 1,4-naphthoquinones **3** as a major products, accompanying with 2-acetonyl-3-hydroxy-1,4-naphthoquinone (**4**), were obtained and the results are summarized in Table 1. The structures of **3** were assigned on the basis of their spectroscopic and elemental analyses, and that of **4** was confirmed by comparison with the authentic sample.[6] The yields of the cyclized products **3** increased in the order of **2a**<**2b**<**2c**, reflecting the γ C–H bond strength.[7] In order to confirm the existence of the hydroquinones derived from **2**, **3**, and **4**, the following two experiments were done. After irradiation of **2c** in benzene for 15 min, the reaction mixture was treated with acetic anhydride and pyridine to give a mixture of diacetate **7c**



a: R^1=R^2=H, **b**: R^1=H, R^2=CH_3, **c**: R^1=R^2=CH_3

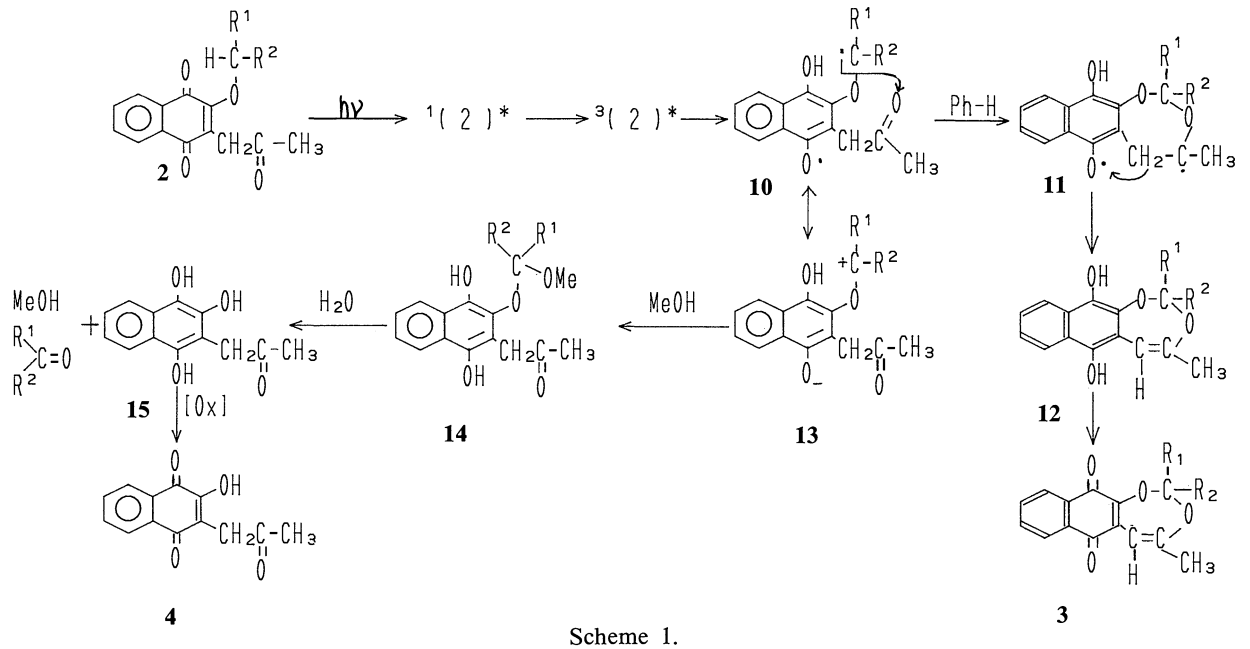

Scheme 1.

(37%) and **9c** (20%), and triacetate **8** (5%) at 90% conversion. The structures of these acetates were confirmed by comparison with the authentic samples synthesized by the reductive acetylation of the corresponding quinones (**2c**, **3c**, and **4**).[8] (Experiment 1) These results indicate that hydroquinones derived from **2**, **3**, and **4** are initial photoproducts, but they are oxidized to the corresponding quinones during work-up procedure involving chromatography over silica gel. In addition, after irradiation of **2c** in benzene-d_6 for 5 min (40% conversion), the 400 MHz ^{1}H NMR spectrum of the reaction mixture revealed the peaks assignable to the hydroquinone **5c** at δ=0.97 (d, J=6.11 Hz, 6H), 1.75 (s, 3H), 3.58 (s, 2H), and 3.74 (sept, J=6.41 Hz, 1H) which were in agreement with those of the hydroquinone **5c** obtained by the reduction of **2c** with dithionite, in addition to the peaks due to **3c** and **4**. The peaks due to **5c** disappeared after adding chloranil to the reaction mixture (Experiment 2). This novel photoinduced cyclization of **2** was sensitized by xanthone and quenched by anthracene, indicating that the reaction occurred from the triplet excited state of **2**. From these results, a plausible mechanism for the formation of **3** is given in Scheme 1. Photocylization may begin with intramolecular γ-H-abstraction by the ^{3}(n, π^*) of **2** to give biradical **10**, which intramoleculary attacks the carbonyl oxygen in the oxoalkyl side chain and cyclizes to **11**.

Intramolecular disproportionation of the biradical **11** produces hydroquinone **12**, which is oxidized by the unreacted **2** or air, to give **3**.

On the other hand, irradiation of **2a**—**c** in methanol gave preferentially **4** (41—70% yield) as shown in Table 1. In the case of the reaction of **2c** the alkoxyl group lost in the course of the photochemical reaction in methanol was detected as acetone by gas chromatography, ^{1}H NMR, and ^{13}C NMR. The yield of acetone increased with increasing irradiation time. From these results, a plausible mechanism for the formation of **4** is given in Scheme 1. The photoinduced C–O bond cleavage may begin with intramolecular γ-H-abstraction as well as the formation of **3**. In methanol the biradical **10** is stabilized by an adjacent heteroatom[9] such as oxygen to produce a zwitterionic intermediate **13**, which reacts with methanol to give the acetal **14**. Hydrolysis of **14** produces ketone (R^1R^2C=O), methanol, and hydroquinone **15**, which is oxidized by the unreacted **2** or air to give **4**.

Experimental

Apparatus. Melting points were measured on Yanagimoto micro-melting points apparatus and are uncorrected. Infrared spectra were taken on a JASCO FT-IR 5000 spectrometer. ^{1}H NMR spectra were recorded on a JEOL GX-400 (400 MHz), a JEOL GX-270 (270 MHz) and a JEOL FX-90Q (90 MHz) spectrometer with use of tetramethylsilane as an internal standard and the chemical shifts are expressed in δ values. UV spectra were taken by using a JASCO Ubest-35 spectrometer. Elemental analyses were performed at the Advanced Instrumentation Center for Chemical Analysis, Ehime University. Mass spectra were recorded on a Hitachi M-2000 spectrometer. GC analyses were performed on a Hitachi Model 163, using a 3 mm i.d., ×2 m stainless steel column packed with 10% SE-30 on celite 545 AW. Preparative separations were performed by column chromatography over silica gel (Wakogel C-200). UV irradiations were carried out in a Pyrex vessel (Fuji glass) under a nitrogen atmosphere with a Fuji glass 300W high-pressure mercury arc lamp.

Materials. 2-Acetonyl-3-alkoxy-1,4-naphthoquinones **2** were prepared by the photochemical reaction of 2-alkoxy-1,4-naphthoquinones with 2-methoxy-1-propene in benzene.[4]

General Procedure for the Photochemical Reaction of 2-Acetonyl-3-alkoxy-1,4-naphthoquinones 2. A degassed solution of 2-acetonyl-3-alkoxy-1,4-naphthoquinones **2** (0.5 mmol) in 180 cm^3 of benzene or methanol in a Pyrex vessel, using a 300 W high-pressure mercury lamp from inside. The progress of the reaction was followed by thin-layer chromatography (TLC), NMR, or GC. After removal of solvent, the residual oil was separated by chromatography on

silica gel with dichloromethane-hexane as an eluant. Final purification was usually accomplished by preparative TLC and recrystallization.

Physical Properties of Photoproducts. 4-Methylnaphtho-[2,3-*d*]-1,3-dioxepin-6,11-dione (3a): Mp 197—198°C; ^{1}H NMR (270 MHz, $CDCl_3$) δ=2.13 (3H, s), 5.51 (2H, s), 6.00 (1H, s), 7.53—7.76 (2H, m), 7.83—8.13 (2H, m); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=22.38 (q), 93.78 (t), 95.14 (d), 124.23 (s), 126.29 (d), 126.72 (d), 131.11 (s), 131.59 (s), 133.71 (d), 155.70 (s), 165.18 (s), 178.18 (s, C=O), 183.76 (s, C=O); IR (KBr) 1660, 1650, 1625, 1595, 1260 cm^{-1}; MS (20 eV), *m/z* 242 (M^+); UV (λ_{max}, nm (log ε), CH_2Cl_2) 248 (4.30), 280 (4.27), 337 (3.54), 442 (3.30); Found: C, 69.40; H, 4.10%. Calcd for $C_{14}H_{10}O_4$: C, 69.42; H, 4.16%.

2,4-Dimethylnaphtho[2,3-*d*]-1,3-dioxepin-6,11-dione (3b): Mp 188—190°C; ^{1}H NMR (270 MHz, $CDCl_3$), δ=1.79 (3H, d, *J*=7.1 Hz), 2.09 (3H, s), 5.29 (1H, q, *J*=7.1 Hz), 5.94 (1H, s), 7.67—7.70 (2H, m), 8.07—8.10 (2H, m); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=20.81 (q), 22.60 (q), 94.81 (d), 101.15 (d), 124.66 (s), 126.34 (d), 126.66 (d), 131.76 (s), 133.71 (d), 154.55 (s), 163.45 (s), 170.63 (s, C=O), 183.93 (s, C=O); IR (KBr) 1676, 1659, 1638, 1597, 1576 cm^{-1}; MS (20 eV), *m/z* 256 (M^+); UV (λ_{max}, nm (log ε), CH_2Cl_2) 278 (4.31), 452 (3.50); Found: C, 70.42; H, 4.70%. Calcd for $C_{15}H_{12}O_4$: C, 70.31; H, 4.72%.

2,2-Dimethylnaphtho[2,3-*d*]-1,3-dioxepin-6,11-dione (3c): Mp 90—91°C; ^{1}H NMR (270 MHz, $CDCl_3$), δ=1.64 (6H, s), 2.11 (3H, s), 6.04 (1H, s), 7.55—7.75 (2H, m), 7.95—8.15 (2H, m); ^{13}C NMR (22.5 MHz, $CDCl_3$) δ=23.68 (q), 25.74 (q), 95.51 (d), 104.56 (s), 126.23 (d), 126.61 (d), 131.76 (s), 133.49 (d), 133.60 (d), 150.66 (s), 160.31 (s), 179.16 (s, C=O), 183.98 (s, C=O); IR (KBr) 1650, 1620, 1590, and 1260 cm^{-1}; MS (20 eV), *m/z* 270 (M^+); UV (λ_{max}, nm (log ε), CH_2Cl_2) 273 (4.44), 446 (3.62); Found: C, 71.15; H, 5.18%. Calcd for $C_{16}H_{14}O_4$: C, 71.10; H, 5.22%.

Reductive Acetylation of the Quinones. Quinones (0.1 mmol), an excess amount of zinc powder (200 mg), and sodium acetate (30 mg) were added to acetic anhydride (3 cm^3). Then, the mixture was refluxed for 30 min. After the yellow color due to the quinone disappeared completely, the reaction mixture was hydrolyzed and neutralized with sodium carbonate. The acetate was extracted with dichloromethane from the reaction mixture and purified further by p-TLC.

Physical Properties of the Diacetate. 6,11-Diacetoxy-4-methylnaphtho[2,3-*d*]-1,3-dioxepin (7a): Mp 169—170°C; ^{1}H NMR (270 MHz, $CDCl_3$) δ=2.05 (3H, s), 2.43 (3H, s), 2.46 (3H, s), 5.43 (2H, s), 7.25—7.50 (2H, m), 7.55—7.85 (2H, m); IR (KBr) 1760, 1655, 1603, 1185, 1082 cm^{-1}; MS (20 eV), *m/z* 328 (M^+).

6,11-Diacetoxy-2,4-dimethylnaphtho[2,3-*d*]-1,3-dioxepin (7b): Mp 158—160°C; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.63 (3H, d, *J*=5.1 Hz), 2.05 (3H, s), 2.43 (3H, s), 2.49 (3H, s), 5.38 (1H, q, *J*=5.1 Hz), 5.49 (1H, s), 7.28—7.50 (2H, m), 7.55—7.90 (2H, m); IR (KBr) 1756, 1647, 1605, 1183, 1087 cm^{-1}; MS (20 eV), *m/z* 342 (M^+).

6,11-Diacetoxy-2,2,4-trimethylnaphtho[2,3-*d*]-1,3-dioxepin (7c): Mp 205—206°C; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.58 (6H, s), 2.03 (3H, s), 2.48 (3H, s), 5.50 (1H, s), 7.24—7.51 (2H, m), 7.53—7.80 (2H, m); IR (KBr) 1760, 1655, 1603, 1185, 1086 cm^{-1}; MS (20 eV), *m/z* 356 (M^+).

2-Acetonyl-1,4-diacetoxy-3-methoxynaphthalene (9a): Mp 118—120°C; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.97 (3H, s), 2.43 (3H, s), 2.47 (3H, s), 3.75 (2H, s), 3.88 (3H, s), 7.30—7.57 (2H, m), 7.60—7.90 (2H, m); IR (KBr) 1760, 1715, 1603, 1210, 1178 cm^{-1}; MS (20 eV), *m/z* 328 (M^+).

2-Acetonyl-1,4-diacetoxy-3-ethoxynaphthalene (9b): Mp 98—100°C; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.37 (3H, t, *J*=7.0 Hz), 2.11 (3H, s), 2.43 (3H, s), 2.45 (3H, s), 3.74 (2H, s), 4.08 (2H, q, *J*=7.0 Hz), 7.30—7.58 (2H, m), 7.60—7.88 (2H, m); IR (KBr) 1763, 1718, 1606, 1206, 1181 cm^{-1}; MS (20 eV), *m/z* 344 (M^+).

2-Acetonyl-1,4-diacetoxy-3-isopropoxynaphthalene (9c): Oil; ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.28 (6H, d, *J*=6.1 Hz), 2.06 (3H, s), 2.40 (3H, s), 2.42 (3H, s), 3.74 (2H, s), 4.44 (1H, sept, *J*=6.1 Hz), 7.30—7.55 (2H, m), 7.57—7.82 (2H, m); IR (KBr) 1774, 1709, 1603, 1178 cm^{-1}; MS (20 eV), *m/z* 358 (M^+).

2-Acetonyl-1,3,4-triacetoxynaphthalene (8): Mp 165—167°C; ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.06 (3H, s), 2.34 (3H, s), 2.44 (3H, s), 2.47 (3H, s), 3.60 (2H, s), 7.30—7.90 (4H, m); IR (KBr) 1779, 1726, 1606, 1178 cm^{-1}; MS (20 eV), *m/z* 358 (M^+).

Reduction of 2-Acetonyl-3-isopropoxy-1,4-naphthoquinone 2c: A degassed solution of **2c** (0.1 mmol) in ether (5 cm^3) was added to a degassed solution of sodium hydrosulfite (0.23 mmol) in water (4 cm^3) and stirred vigorously under a nitrogen. The solution became pale yellow in 30 min. The reaction mixture was poured into a separatory funnel. After removing the aqueous layer, the etheral solution was washed with saturated brine and dried over anhydrous sodium sulfate. The filtrate was evaporated under reduced pressure to give the hydroquinone **5c** with a small amount of **2c** which was produced by the oxidation of **5c** in the usual work up. From ^{1}H NMR spectrum of the reaction mixture in benzene-d_6, the presence of **2c** was confirmed by direct comparison with ^{1}H NMR spectrum of an anthentic sample in benzene-d_6 and the structure of **5c** was determined by the follow ^{1}H NMR spectral deta: Isopropoxy substituent at δ=0.97 (d, *J*=6.1 Hz, 6H, -OCH($\underline{CH_3}$)$_2$), and 3.74 (sept, *J*=6.4 Hz, 1H, -O$\underline{CH}$-(CH$_3$)$_2$) and acetonyl substituent at δ=1.75 (s, 3H, -$\underline{CH_2}$-COCH$_3$), and 3.58 (s, 2H, -CH$_2$CO$\underline{CH_3}$), and aromatic hydrogen at δ=7.18—7.38 (m, 2H), and 8.25—8.45 (m, 2H).

In this investigation I am particularly indebted to Professor K. Maruyama of Kyoto University for his valuable suggestions and encouragement and to Dr. A. Osuka of Kyoto University for his helpful discussions. Helps given by Dr. H. Uno at Advanced Instrumentation Center for Chemical Analysis, Ehime University is greatly appreciated.

(Received April 15, 1991)

Synopsis. (+)-8,11,13-Abietatriene was converted into (15*R*)-16-hydroxyferruginol (**1a**) and its (15*S*)-epimer (**1b**) by the introduction of hydroxyl groups at the C-12 and C-16 positions.

16-Hydroxyferruginol has been isolated from the seed of *Thujopsis dolabrata* Sieb. et Zucc. var *dolabrata* by Hasegawa and Hirose.[1] In a previous paper,[2] we reported the total syntheses of (15*R*)-16-hydroxyferruginol (**1a**) and its (15*S*)-epimer (**1b**), and determined the absolute configuration of the C-15 position in the natural compound to be the *R*-configuration. These C-15 epimeric 16-hydroxyferruginols (**1a** and **1b**) are also useful intermediates for the syntheses of highly-oxygenated abietane-type diterpenes possessing an asymmetric center at the C-15 position such as (15*R*)-coleon C (**2a**),[3,4] (15*S*)-coleon C (**2b**),[3,4] lycoxanthol (**3**),[5,6] nellionol,[7] hyptol,[8] and so on. As an extension of our previous work, we describe here the syntheses of **1a** and **1b**, starting from natural (+)-8,11,13-abietatriene (**4**) as an optically-active relay compound.

Dehydrogenation of **4** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in refluxing 1,4-dioxane afforded the corresponding isopropenyl compound (**5**) which was immediately submitted to hydroboration–oxidation and the resulting C-15 epimeric mixture of 8,11,13-abietatrien-16-ols (**6**: 33% yield from **4**) was further converted into 4-nitrobenzoates (**7**: 93% yield) by heating with 4-nitrobenzoyl chloride in pyridine. The Friedel-Crafts acylation of **7** with acetyl chloride and anhydrous aluminium chloride in nitrobenzene afforded a C-15 epimeric mixture (*ca.* 1:1 ratio) of 12-acetyl compounds (**8a,b**) in a 63% yield. This mixture of **8a,b** was carefully separated by repeated column chromatography and recrystallization to give pure crystalline (15*R*)-12-acetyl-16-(4-nitrobenzoyloxy)-8,11,13-abietatriene (**8a**), mp 139—142 °C, and its (15*S*)-epimer (**8b**), mp 166—167 °C. The Baeyer–Villiger oxidations of **8a** and **8b** with *m*-chloroperbenzoic acid and *p*-toluenesulfonic acid in refluxing 1,2-dichloroethane, followed by reductions of the resulting acetates, **9a** (59% yield) and **9b** (70% yield), with lithium aluminium hydride in dry ether afforded the desired **1a** (90% yield) and **1b** (97% yield), respectively. The physical and spectral data of the synthetic **1a** and **1b** were identical with those of authentic (15*R*)-16-hydroxyferruginol and its (15*S*)-epimer,[2] respectively.

Experimental

All melting points are uncorrected. The IR spectra and optical rotations were measured in chloroform. The column chromatography was performed using Merck silica gel (0.063 mm).

16-(4-Nitrobenzoyloxy)-8,11,13-abietatriene (7). A mixture of (+)-8,11,13-abietatriene (**4**) (26.00 g) and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (96%: 26.20 g) in 1,4-dioxane (260 ml) was refluxed for 4 h. The mixture was passed through an alumina (Merck Act. II-III, 220 g) column and the column was washed with benzene (800 ml). The eluate was evaporated in vacuo to give a crude 8,11,13,15-abietatetraene

(**5**) (23.358 g), ^{1}H NMR (60 MHz, CCl_4) δ=0.93 (6H, s, $-C(CH_3)_2$), 1.14 (3H, s, 10-CH_3), 2.07 (3H, bs, 15-CH_3), 4.87 (1H, bs) and 5.17 (1H, bs) ($-C(CH_3)=CH_2$).

A solution of tetrahydrofuran–borane (1/1) addition compound (1 mol dm^{-3}: 43.5 ml) was added to a stirred solution of the crude **5** (23.358 g) in dry tetrahydrofuran (200 ml) at −15 to −10 °C for 30 min under a stream of nitrogen. After the mixture was stirred at 0—5 °C for 3 h, the following compounds were added successively: aqueous tetrahydrofuran (50%: 15.5 ml), aqueous sodium hydroxide (12%: 15.5 ml), and hydrogen peroxide (30%: 15.5 ml) at −15 to −5 °C. The mixture was stirred at −5—0 °C for 30 min and then at room temperature for 1.5 h, diluted with brine, and extracted with ether. The ether extract was washed with brine, dried over sodium sulfate, and evaporated in vacuo. The residue was chromatographed on silica gel (0.063—0.200 mm, 250 g), using benzene as an eluent, to give mainly recovered **4** (11.91 g). Further elution with benzene afforded a mixture of the C-15 epimeric 8,11,13-abietatrien-16-ols (**6**) (9.116 g: 33.1% yield from **4**), IR 3580 and 3425 cm^{-1}, ^{1}H NMR (60 MHz, CCl_4) δ=0.95 (6H, s, $-C(CH_3)_2$), 1.15 (3H, s, 10-CH_3), 1.18 (3H, d, J=7 Hz, 15-CH_3), 3.45 (2H, d, J=7 Hz, $-CH_2OH$), 6.72 (1H, bs, 14-H), 6.80 (1H, bd, J=8 Hz, 12-H), and 7.05 (1H, d, J=8 Hz, 11-H).

A mixture of compound **6** (2.755 g) and 4-nitrobenzoyl chloride (2.678 g) in pyridine (14 ml) was heated at 80—85 °C for 2.5 h. After the usual work-up, the crude product was recrystallized from hexane to give a C-15 epimeric mixture of **7** (1.936 g: 46.2% yield), mp 97—98 °C, IR 1720 cm^{-1}. Found: C, 74.48; H. 7.84; N, 2.94%. Calcd for $C_{27}H_{33}O_4N$: C, 74.45; H, 7.64; N, 3.22%. The mother liquor of recrystallization was evaporated in vacuo. The residue was chromatographed on silica gel (20 g), using hexane–benzene (1:1) as an eluent, to give additional **7** (1.956 g: 46.7% yield).

(15R)-12-Acetyl-16-(4-nitrobenzoyloxy)-8,11,13-abietatriene (8a) and Its (15*S*)-Epimer (8b). Anhydrous aluminium chloride (2.370 g) was added at 0—5 °C to a stirred solution of **7** (1.936 g) and acetyl chloride (1.30 ml) in nitrobenzene (12 ml). The mixture was stirred at this temperature for 30 min and then at room temperature for 1.5 h, then poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with aqueous sodium hydrogencarbonate and brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (100 g), using hexane–benzene (3:7) as an eluent, to give a mixture (ca. 1:1 ratio) of **8a** and **8b** (1.331 g: 62.7% yield). This mixture was separated into pure **8a** and **8b** by repeated column chromatography and recrystallization.

8a: Mp 139—142 °C (from acetone–hexane), $[\alpha]_D$+42.7° (*c* 1.34), IR 1722 and 1675 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=0.93 (6H, s, $-C(CH_3)_2$), 1.18 (3H, s, 10-CH_3), 1.32 (3H, d, J=7 Hz, 15-CH_3), 2.50 (3H, s, $-COCH_3$), 3.97 (1H, m, 15-H), 4.36 (2H, d, J=7 Hz, 15-CH_2O–), 7.00 (1H, s, 14-H), 7.43 (1H, s, 11-H), 8.07 (2H, d, J=10 Hz) and 8.21 (2H, d, J=10 Hz) ($-C_6H_4NO_2$). Found: C, 72.74; H, 7.60; N, 2.65%. Calcd for $C_{29}H_{35}O_5N$: C, 72.93; H, 7.39; N, 2.93%.

8b: Mp 166—167 °C (from acetone–hexane), $[\alpha]_D$+35.0° (*c* 2.86), IR 1725 and 1680 cm^{-1}; ^{1}H NMR (90 MHz, CCl_4) δ=0.93 (3H, s) and 0.95 (3H, s) ($-C(CH_3)_2$), 1.18 (3H, s, 10-CH_3), 1.30 (3H, d, J=7 Hz, 15-CH_3), 2.49 (3H, s, $-COCH_3$), 3.97 (1H, m, 15-H), 4.40 (2H, d, J=7 Hz, 15-CH_2O–), 7.00 (1H, s, 14-H), 7.43 (1H, s, 11-H), 8.08 (2H, d, J=10 Hz) and 8.22 (2H, d, J=10 Hz) ($-C_6H_4NO_2$). Found: C, 72.70; H, 7.61; N, 2.79%. Calcd for $C_{29}H_{35}O_5N$: C, 72.93; H, 7.39; N, 2.93%.

(15*R*)-12-Acetoxy-16-(4-nitrobenzoyloxy)-8,11,13-abietatriene (9a) and Its (15*S*)-Epimer (9b). a): A mixture of **8a** (110.0 mg), *m*-chloroperbenzoic acid (80%: 99.4 mg), and *p*-toluenesulfonic acid (10.0 mg) in 1,2-dichloroethane (1.5 ml) was refluxed for 3 h. The mixture was cooled, diluted with ether, and the ether solution was washed successively with aqueous potassium iodide, aqueous sodium thiosulfate, aqueous sodium hydrogencarbonate, and brine. The dried solution was evaporated in vacuo. The residue was chromatographed on silica gel (5 g), using benzene as an eluent, to give **9a** (67.4 mg: 59.3% yield) which was recrystallized from methanol, mp 110—113 °C, $[\alpha]_D$+67.4° (*c* 1.41), IR 1758 and 1725 cm^{-1}. Found: C, 70.26; H, 7.33; N, 2.54%. Calcd for $C_{29}H_{35}O_6N$: C, 70.56; H, 7.15; N, 2.84%.

b): A mixture of **8b** (358.0 mg), *m*-chloroperbenzoic acid (80%: 324.0 mg), and *p*-toluenesulfonic acid (20.0 mg) in 1,2-dichloroethane (3.5 ml) was treated as described in a). The crude product was chromatographed on silica gel (15 g), using benzene as an eluent, to give **9b** (259.6 mg: 70.2% yield) which was recrystallized from acetone–methanol, mp 114—116 °C, $[\alpha]_D$+11.8° (*c* 2.64), IR 1755 and 1725 cm^{-1}. Found: C, 70.70; H, 7.35; N, 2.65%. Calcd for $C_{29}H_{35}O_6N$: C, 70.56; H, 7.15; N, 2.84%.

(15*R*)-16-Hydroxyferruginol (1a) and Its (15*S*)-Epimer (1b). a): A mixture of **9a** (51.0 mg) and lithium aluminium hydride (20.0 mg) in dry ether (1.5 ml) was stirred at room temperature for 1.5 h. The mixture was poured into ice-dilute hydrochloric acid and extracted with ether. The ether extract was washed with brine, dried, and evaporated in vacuo. The residue was chromatographed on silica gel (5 g), using ether–benzene (8:92) as an eluent, to give **1a** (28.1 mg: 90.1% yield) which was recrystallized from acetone–hexane, mp 138—139 °C, $[\alpha]_D$+64.9° (*c* 0.96), IR 3600 and 3325 cm^{-1}, ^{1}H NMR (90 MHz, $CDCl_3$) δ=0.89 (3H, s), and 0.91 (3H, s), ($-C(CH_3)_2$), 1.13 (3H, s, 10-CH_3), 1.24 (3H, d, J=7 Hz, 15-CH_3), 3.15 (1H, m, 15-H), 3.64 (1H, dd, J=10 and 7.5 Hz) and 3.88 (1H, dd, J=10 and 4 Hz) (15-CH_2OH), and 6.72 (2H, s, 11-H and 14-H). Found: C, 79.31; H, 10.28%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

b): A mixture of **9b** (179.9 mg) and lithium aluminium hydride (70.0 mg) in dry ether (4.0 ml) was treated as described in a). The crude product was chromatographed on silica gel (5 g), using ether-benzene (8:92) as an eluent, to give **1b** (107.0 mg: 97.1% yield) which was recrystallized from acetone–hexane, mp 179—180 °C, $[\alpha]_D$+ 46.0° (*c* 1.37), IR (KBr) 3550 and 3270 cm^{-1}, ^{1}H NMR (90 MHz, $CDCl_3$) δ=0.91 (6H, s, $-C(CH_3)_2$), 1.16 (3H, s, 10-CH_3), 1.26 (3H, d, J=7 Hz, 15-CH_3), 3.15 (1H, m, 15-H), 3.64 (1H, dd, J=10 and 7 Hz) and 3.88 (1H, dd, J=10 and 4 Hz) (15-CH_2OH), and 6.74 (2H, s, 11-H and 14-H). Found: C, 79.28; H, 10.23%. Calcd for $C_{20}H_{30}O_2$: C, 79.42; H, 10.00%.

A Convenient Preparation of Ketones by the Oxidation of Secondary Alcohols with Chromium(VI) Trioxide in Aprotic Solvent in the Presence of "Wet"-Aluminum Oxide

Masao HIRANO, Sonoko NAGASAWA, and Takashi MORIMOTO*

(Received April 22, 1991)

Synopsis. The oxidation of aliphatic and alicyclic secondary alcohols with chromium(VI) trioxide in the presence of "wet"-aluminum oxide in hexane gave the corresponding ketones in excellent yields under mild conditions.

Recently, supported reagents, consisting of a large number of combinations of agents and such inorganic solid materials as silica gel, aluminum oxide (hereafter referred as alumina), graphite, polymers, zeolites, and clay minerals, etc., have been given considerable attention because of their improved selectivity and reactivity as well as manipulative simplicity. Thus, supported reagents have been recommended for many catalytic and stoichiometric processes, including oxidation, reduction, substitution, elimination, rearrangement, hydrogenation, polymerization, etc., and especially for organic syntheses.[1,2]

In recent communications, we have reported facile and convenient oxidations of alcohols with sodium bromite ($NaBrO_2$),[3] chromium(VI) trioxide,[4] and "Oxone",[5,6] and a novel Baeyer–Villiger-type lactonization of alicyclic ketones with Oxone[7] in aprotic solvents in the presence of commercial chromatographic alumina. The oxidizing milieu of these processes are intimately analogous to a supported reagent system, but the reaction can be immediately started only by mixing alumina, a solvent, and an oxidant with a substrate without the preparation of a supported reagent. In this article, we wish to describe some observations on the facile oxidation of various aliphatic and alicyclic secondary alcohols with chromium(VI) trioxide in aprotic solvents in the presence of "wet"-alumina, since the reaction offers a convenient and selective synthesis of ketones under neutral and mild conditions.

Results and Discussion

The reaction was carried out by mixing finely-ground chromium(VI) trioxide, an alcohol, and an aprotic solvent in the presence or absence of alumina and by magnetic stirring of the heterogeneous mixture under an inert atmosphere in order to avoid autoxidation. It should be noted that efficient stirring was indispensable throughout a given period to ensure a smooth reaction and to attain a reproducible result (±5%<). A small amount of the supernatant was withdrawn at intervals and analyzed by GLC in order to follow the progress of the reaction. After a given reaction period, filtration of an insoluble material and washing of the residue with ether, followed by evaporation of the combined solvent in vacuo, left a ketone.

In the absence or presence of commercial "dry"-alumina, the reaction was rather slow. Indeed, in the oxidation of 4-methylcyclohexanol (**1**) in hexane at room temperature for 15 h ([CrO_3]/[**1**]=1.5; mole ratio), almost all or a considerable amount of **1** (98 or 71%, respectively; by GLC) was recovered, resulting only in the poor formation of 4-methylcyclohexanone (**2**) (trace or 12%, respectively). In addition, the extensive formation of an unknown by-product (16%; GLC selectivity) was observed in the latter case. On the other hand, when the reaction was conducted in the presence of "wet"-alumina (see the Experimental section), 95% of **1** was consumed under the same conditions as above, resulting in the selective formation of **2**. In view of the reactivity of CrO_3 and selectivity of the ketone, "wet"-alumina was clearly proven to play a decisive role in the oxidation. The atomic absorption analyses showed that no detectable amount of a chromium species was involved in the solvent at any time during the reaction, indicating clearly that the reaction occurred exclusively on the alumina surface. The mechanistic details of the present system are regrettably still obscure, although there have been some suggestions of a probable functional role of a support[8] and water adsorbed on a support surface.[9]

The oxidation was also performed in various aprotic solvents (carbon tetrachloride, chloroform, dichloromethane, benzene, and ethyl acetate). In carbon tetrachloride, chromium(VI) trioxide exhibited comparable reactivity to that in hexane, and similar selectivity of a ketone was observed. However, the reaction was rather slow in the other solvents. For example, when cyclododecanol (**3**) was oxidized with a CrO_3-"wet"-alumina system at 303 K for 15 h ([CrO_3]/[**3**]=1.5), the conversions of **3** were 98, 94, 15, 49, 58, and 58% in hexane, carbon tetrachloride, chloroform, dichloromethane, benzene, and ethyl acetate, respectively. Using acetone and 1,4-dioxane as a solvent should be avoided; it was proved that contact of a mixture of chromium(VI) trioxide and "wet"-alumina with these solvents caused immediate ignition. Thus, hexane was our solvent of choice based on the experimentally determined reasonable reactivity of chromium(VI) trioxide in the solvent as well as its low cost and toxicity as compared with chlorinated hydrocarbons, which are frequently used in conventional oxidations with chromium(VI)-based reagents;[10] additionally, its high volatility leads to a facile product isolation.

The oxidation of a variety of alicyclic and aliphatic secondary alcohols with chromium(VI) trioxide was examined in hexane. The alcohols underwent smooth oxidation under mild conditions in the presence of "wet"-alumina. Reaction conditions were chosen on the basis

Table 1. Oxidation of Aliphatic and Alicyclic Secondary Alcohols with Chromium(VI) Trioxide in Hexane in the Presence of "Wet"-Alumina[a)]

a) Under argon for 15 h; 0.5 g of alcohol, 10 cm^3 of hexane, and 2.4 g of "wet"-alumina were used in every run.
b) Isolated yield.

of reactivity of the alcohols and selectivity of the ketones. When equimolar with an alcohol or a slightly larger amount of CrO_3 was used, the ketones were contaminated with the parent alcohols in some cases; e.g., upon oxidation of 2-ethylcyclohexanol (**4**) at 323 K for 15 h ($[CrO_3]/[\mathbf{4}]=1.2$), 21% of **4** was unreacted, whereas **4** was completely consumed under the conditions of Entry 13 in Table 1. Consequently, the oxidations were carried out by using 1.5—2.0 moles of chromium(VI) trioxide per mole of an alcohol in order to complete the reaction. The results are summarized in Table 1. The influence of carbon-chain length of 2-alkanols (Entries 1—4), ring size of simple cycloalkanols (Entries 5—9), and bulkiness or position of an alkyl substituent on the cyclohexane ring (Entries 10—19) was investigated; interestingly, however, there was no appreciable difference in the yield of the ketones. Thus, the CrO_3–"wet"-alumina system was proven to be applicable to a wide variety of secondary alcohols.

Oxidation of 1-alkanols, hexanol (**5a**), heptanol (**5b**), and octanol (**5c**), was also examined, giving a mixture of the corresponding aldehydes (**6a—c**) and the esters (**7a—c**). The selectivity of **6** and **7** was found to be dependent on the concentration of chromium(VI) trioxide.

$$\underset{\mathbf{5}}{3\,RCH_2OH} \longrightarrow \underset{\mathbf{6}}{RCHO} + \underset{\mathbf{7}}{RCOOCH_2R}$$

For instance, the oxidation of hexanol at room temperature for 15 h ($[CrO_3]/[\mathbf{5a}]=1.2$, 2.0, and 3.0) gave 42, 45, and 43% of **6a** and 11, 19, and 53% of **7a**, respectively (by GLC); in the former two cases, 36 and 9% of **5a** was recovered, respectively. The oxidation of **5b,c** at room temperature for 15 h ($[CrO_3]/[\mathbf{5}]=3.0$) gave **6b,c** in 47 and 61% yields, and **7b,c** in 48 and 33% yields, respectively. It was found that there was no remarkable difference in the reactivity of 1-alkanols and the 2-analogs. For example, the conversions of **5a** and 2-hexanol, and **5c** and 2-octanol were 98, 100, 98, and 100%, respectively, at 323 K for 15 h ($[CrO_3]/[Alcohol]=1.5$).

It was of considerable interest to extend the scope of the reaction to a chemoselective oxidation of the hydroxy group in a multifunctional substrate. Thus, the oxidation of the allylic alcohols was investigated. The oxidation of geraniol and its *cis*-isomer, nerol, at room temperature for 15 h ($[CrO_3]/[Alcohol]=3.0$) gave the corresponding aldehydes in 73 and 74% isolated yields, respectively. It is worth noting that the oxidation proceeded without an appreciable loss of the double bond stereochemistry. However, we felt that the results were not adequate enough to deserve a term of "synthetically useful tool" for the allylic oxidation. In addition, oxidation of cinnamyl alcohol was complicated by concurrent double bond cleavage, giving cinnamaldehyde and benzaldehyde both in only moderate yields. Accordingly, a further study is now being undertaken to determine favorable conditions for the chemoselective oxidation of various multifunctional alcohols.

Summing up, oxidation of aliphatic and alicyclic secondary alcohols by means of a combination of chromium(VI) trioxide and "wet"-alumina in hexane gave the corresponding ketones in excellent to almost-quantitative yields. It should be emphasized that the present reaction is fairly clean, and is performable not only instantly, but readily without suffering from the formation of the intractably tarry precipitate of a reduced chromium salt, which allows easy removal of the salt and also easy isolation of a ketone from the reaction mixture as exemplified by the procedures using alumina-

supported chromium(VI) reagents. Thus, this system can be added to a list of efficient and mild oxidants, owing to its easy accessibility, manipulative simplicity, and versatility.

Experimental

^{1}H NMR spectra were measured with a JEOL PMX-60 model spectrometer for solutions in deuteriochloroform or carbon tetrachloride. IR spectra were recorded for thin films or KBr disks on a JASCO A-100 spectrophotometer. GLC was performed on a Shimadzu GC-6A instrument with a 2 m column packed with 5% PEG-20M on Chromosorb GAW-DMCS, with temperature programming. Atomic absorption analyses were carried out on a Hitachi 170-30 model apparatus.

Starting Materials. Commercial chromium(VI) trioxide was dried in vacuo and finely ground. All of the alcohols were also commercially available and were purified by distillation or recrystallization just before use. Solvents were rigorously dried and distilled. "Wet"-alumina was prepared by adding distilled water (2 g) to commercial chromatographic super-dried alumina (ICN BIOMEDICALS, Super I; 10 g) in portions, followed by vigorous shaking of the mixture for a few minutes until a free-flowing powder was obtained.

General Oxidation Procedures. The following procedures are representative. To a heterogeneous mixture of "wet"-alumina (2.4 g) and hexane (10 cm^3) in a round-bottomed flask was added chromium(VI) trioxide (1.5 moles of an alcohol) in portions with magnetic stirring; the stirring was continued for 10 min and 2-hexanol (0.5 g) was then added in a portion. After flushing with dry argon, the flask was sealed with a glass stopper or a silicon-rubber septum, through which the supernatant was withdrawn by a microsyringe in the course of the reaction. After magnetic stirring at 313 K for 15 h, the whole reaction mixture was transferred onto a Pyrex Buchner funnel with a fritted glass disk, and the residue was thoroughly washed with dry ether. Removing the combined solvent by rotary evaporation in vacuo left 2-hexanone, which had adequate purity (nearly 100% by GLC).

All ketones thus obtained were identified by a comparison of the NMR and IR spectra and GLC retention times with those of authentic samples.

The partial financial support for the present research from Nippon Silica Industrial Co., Ltd. and Daicel Chemical Industries, Ltd. is gratefully acknowledged.

Further Chemical Studies on Anisatin, a Neurotoxic Sesquiterpenoid Having a β-Lactone

Haruki NIWA,* Itaru TSUKADA, Masanori NISIWAKI, and Kiyoyuki YAMADA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received April 30, 1991)

Synopsis. By a series of chemical reactions, anisatin was efficiently converted into the key intermediate employed in the synthesis of anisatin.

Anisatin (**1**) is a convulsant sesquiterpenoid isolated from the seeds of Japanese star anise (*Illicium anisatum* L.; shikimi in Japanese).[1,2] The structure of anisatin (**1**) was based on extensive chemical and spectroscopic studies.[2] The unique structure particularly characterized by a novel spiro β-lactone has made anisatin (**1**) a challenging synthetic target. Recently we have achieved the first total synthesis of anisatin (**1**) in the stereocontrolled manner.[3] In the course of synthetic studies of anisatin (**1**), we further investigated the reactivity of the uniquely arranged functional groups in anisatin (**1**) and the derivatives.[4] Described herein is the successful transformation of anisatin (**1**) into lactone **2**, the key intermediate employed in our recent synthesis of anisatin (**1**).[3]

First, we converted anisatin (**1**) into noranisatin acetonide (**4**). Thus, reaction of anisatin (**1**) with 2-methoxypropene in the presence of (+)-10-camphorsulfonic acid in *N,N*-dimethylformamide furnished anisatin acetonide (**3**) in 91% yield. Subsequent oxidation of **3** with $KMnO_4$ in AcOH–H_2O provided noranisatin acetonide (**4**) in 89% yield.

Next, we performed reduction of **4** with $LiAlH_4$ under various conditions and the results are summarized in Table 1. Reduction of **4** in tetrahydrofuran (THF) at reflux temperature yielded pentol **5** and acetal **6** in 30% and 25% yield, respectively. Reduction of **4** in THF at 0°C gave carboxylic acid **7** in 29% yield (isolated and characterized as methyl ester **8**). On reduction of **4** in ether at reflux temperature, **5** and **6** were obtained in 44% and 32% yield, respectively, together with a small amount of hemiacetal **9**[5] (13%). When reduction of **4** was performed in ether at −20°C, **9** was obtained as the major product (60%) along with lactone **10** (21%) and **7** (10%).

Oxidation of **9** wtih I_2–$CaCO_3$ in H_2O–MeOH furnished **10** in 78% yield. Finally, reaction of **10** with 2-methoxypropene in the presence of (+)-10-camphorsulfonic acid in benzene afforded rearranged lactone **2** in 90% yield. Spectral and chiroptical properties of **2** [$[\alpha]_D^{21}$ +14.5° (*c* 0.444, $CHCl_3$)] derived from natural anisatin (**1**) were identical with those of **2** [$[\alpha]_D^{21}$ +14.8° (*c* 0.446, $CHCl_3$)] synthesized from (*R*)-(+)-pulegone.[3]

Experimental

Melting points are uncorrected. Optical rotations were measured on a JASCO DIP-181 polarimeter. Infrared (IR) spectra were obtained on a JASCO Model IR-810 spectrophotometer. Proton nuclear magnetic resonance (^1H NMR) spectra were recorded on a JEOL JNM-C675 (270 MHz) spectrometer in $CDCl_3$ using tetramethylsilane (TMS) as an internal standard. Chemical shifts are expressed in parts per million (ppm) downfield from TMS (δ=0.0) and coupling constants in Hz. The low-resolution (CIMS and EIMS) and high-resolution (HRCIMS and HREIMS) mass spectra were recorded on a JEOL JMS-LG2000 instrument using methane as the reagent gas for CIMS. Fuji-Davison silica gel BW-820MH was used for column chromatography. Merck precoated silica gel 60 F_{254} plates, 0.25 mm thickness, were used for analytical thin-layer chromatography. Benzene was distilled from Na under nitrogen. Tetrahydrofuran (THF) and ether were distilled from Na-benzophenone ketyl under

nitrogen. *N,N*-Dimethylformamide and pyridine were distilled from CaH_2 under nitrogen. Unless otherwise stated, organic solutions obtained by extractive workup were washed with saturated brine, dried over anhydrous Na_2SO_4, and concentrated under reduced pressure by a rotary evaporator.

Anisatin Acetonide (3). To a solution of anisatin (**1**) (515 mg, 1.6 mmol) in *N,N*-dimethylformamide (8 ml) were added 2-methoxypropene (0.22 ml, 2.4 ml) and (+)-10-camphorsulfonic acid (19 mg, 0.080 mmol). The reaction mixture was stirred at room temperature for 1.5 h. Pyridine (ca. 0.1 ml) was added for quenching the reaction and the mixture was concentrated in vacuo. The residue was purified by column chromatography on silica gel [30 g, benzene–acetone (5:1)] to give **3** (527 mg, 91%) as colorless needles; mp 206—208 °C (benzene); $[\alpha]_D^{23}$ +6.6° (*c* 0.14, $CHCl_3$); IR ($CHCl_3$) 3500, 3420, 1830, 1735, 1370, and 1100 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.03 (3H, d, *J*=6.6 Hz), 1.54 (3H, s), 1.56 (3H, s), 1.75 (3H, s), 1.87 (1H, ddd, *J*=14.5, 8.2, 1.0 Hz), 2.02 (1H, dd, *J*=14.8, 3.6 Hz), 2.29 (1H, ddd, *J*=14.5, 11.9, 8.6 Hz), 2.44—2.53 (1H, m), 2.57 (1H, dd, *J*=14.8, 2.3 Hz), 3.26 (1H, s, –OH), 4.03 (1H, d, *J*=6.6 Hz), 4.12 (1H, br s), 4.33 (1H, dd, *J*=3.6, 2.3 Hz), 4.52 (1H, d, *J*=6.6 Hz), 4.90 (1H, dd, *J*=8.6, 1.0 Hz), and 5.44 (1H, d, *J*=1.0 Hz, –OH); CIMS *m/z* (rel intensity) 369 [$(M+H)^+$, 90], 353 (67), 339 (30), 323 (39), and 311 (100). Calcd for $C_{18}H_{24}O_8$: C, 58.69; H, 6.57%. Found: C, 58.51; H, 6.54%.

Noranisatin Acetonide (4). To a solution of **3** (1.1 g, 3.0 mmol) in acetic acid (25 ml) was added a solution of $KMnO_4$ (1.0 g, 6.6 mmol) in H_2O (25 ml). The reaction mixture was stirred at room temperature for 4 h. The reaction was quenched by the addition of saturated $Na_2S_2O_3$ solution (5 ml) and the mixture was extracted with ethyl acetate (3×5 ml). The combined organic layers were washed with saturated NaCl solution (50 ml), dried, and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel [50 g, hexane–ether (6:1→4:1)] to give **4** (0.90 g, 89%) as colorless needles; mp 125.5—126.5 °C (benzene–hexane); $[\alpha]_D^{18}$ +55° (*c* 0.16, $CHCl_3$); IR ($CHCl_3$) 3480, 1830, 1775, 1385, 1375, and 1140 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.09 (3H, d, *J*=6.6 Hz), 1.51 (3H, s), 1.54 (3H, s), 1.59 (3H, s), 2.02 (1H, dd, *J*=13.5, 5.9 Hz), 2.29—2.52 (3H, m), 2.75 (1H, d, *J*=12.5 Hz), 3.99 (1H, d, *J*=7.1 Hz), 4.27 (1H, br s, –OH), 4.28 (1H, d, *J*=7.1 Hz), 4.38 (1H, d, *J*=5.9 Hz), and 4.89 (1H, d, *J*=7.1 Hz); EIMS *m/z* (rel intensity) 338 (M^+, 10), 323 (100), 281 (15), and 263 (31). Calcd for $C_{17}H_{22}O_7$: C, 60.35; H, 6.55%. Found: C, 59.99; H, 6.51%.

$LiAlH_4$ Reduction of Noranisatin Acetonide (4) (Table 1).

(a) Reduction in THF at Reflux Temperature (Entry 1). To a solution of **4** (19 mg, 0.056 mmol) in THF (1 ml) was added a 1M (1M=1 mol dm^{-3}) solution of $LiAlH_4$ in THF (0.12 ml, 0.12 mmol). The reaction mixture was heated under reflux for 2 h. After the reaction mixture was cooled to room temperature, NaF (104 mg, 2.48 mmol) was added and the mixture was vigorously stirred for a while. To the ice-cooled mixture was added dropwise 10% H_2O–THF (1.5 ml). The mixture was stirred for 30 min at room temperature and filtered through a pad of Celite. The filter cake was washed thoroughly with THF. The combined organic solutions were concentrated under reduced pressure. The residue was subjected to column chromatography on silica gel [4 g, benzene–acetone (4:1→1:10→0:1)] to give pentol **5** (5.7 mg, 30%) and acetal **6** (4.1 mg, 25%) as a colorless oil, respectively.

5: $[\alpha]_D^{21}$ +1.2° (*c* 0.50, $CHCl_3$); IR ($CHCl_3$) 3450, 1390, 1150, and 1050 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.02 (3H, d, *J*=6.6 Hz), 1.21 (3H, s), 1.50—1.60 (1H, m), 1.62 (3H, s), 1.68 (3H, s), 1.78 (1H, dd, *J*=14.0, 8.0 Hz), 2.08 (1H, dd, *J*=14.8, 4.0 Hz), 2.20—2.38 (1H, m), 2.49 (1H, ddd, *J*=14.0, 10.8, 8.0 Hz), 3.57—3.65 (1H, m, –OH), 3.63 (1H, d, *J*=14.0 Hz), 3.69 (1H, dd, *J*=4.0, 2.0 Hz), 3.88 (1H, d, *J*=12.0 Hz), 3.90—4.00 (1H, m, –OH), 4.18 (1H, d, *J*=13.0 Hz), 4.60—4.98 (2H, m), 4.83 (1H, d, *J*=14.0 Hz), 5.23 (1H, br s, –OH), and 5.25 (1H, d, *J*=8.0 Hz); EIMS *m/z* (rel intensity) 328 [$(M-H_2O)^+$, 43], 310 (38), 292 (21), and 55 (100). HREIMS. Found: *m/z* 310.1776. Calcd for $C_{17}H_{26}O_5$: $M-2\times H_2O$, 310.1780.

6: $[\alpha]_D^{21}$ −31.2° (*c* 0.511, $CHCl_3$); IR ($CHCl_3$) 3500, 1385, 1160, and 1035 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.01 (3H, d, *J*=6.9 Hz), 1.27 (3H, s), 1.52 (3H, s), 1.56 (3H, s), 1.80 (1H, ddd, *J*=14.8, 12.8, 8.4 Hz), 1.89 (1H, dd, *J*=12.4, 5.0 Hz), 1.96 (1H, ddd, *J*=14.8, 8.4, 2.0 Hz), 2.28 (1H, d, *J*=12.4 Hz), 2.35—2.46 (1H, m), 2.46—2.55 (1H, m, –OH), 3.48 (1H, dd, *J*=12.9, 10.9 Hz), 3.64 (1H, br s, –OH), 3.82 (1H, d, *J*=5.0 Hz), 3.87 (1H, d, *J*=11.4 Hz), 4.10—4.16 (1H, m), 4.14 (1H, d, *J*=11.4 Hz), 4.98 (1H, dd, *J*=8.4, 2.0 Hz), and 5.31 (1H, s); EIMS *m/z* (rel intensity) 326 (M^+, 0.5), 311 (20), 308 (18), and 265 (100). HREIMS. Found: *m/z* 326.1709. Calcd for $C_{17}H_{26}O_6$: M, 326.1729.

(b) Reduction in THF at 0 °C (Entry 2). Reduction of **4** (19 mg, 0.056 mmol) with $LiAlH_4$ (0.12 mmol) was performed in THF at 0 °C for 20 min. After workup as described above, the crude product containing acid **7** was treated with ethereal CH_2N_2 and subjected to column chromatography on silica gel [3 g, benzene–acetone (10:1→5:1→1:1)] to give methyl ester **8** (5.5 mg, 29%) as a colorless oil: $[\alpha]_D^{21}$ −27.3° (*c* 0.134, $CHCl_3$); IR ($CHCl_3$) 3500, 1715, 1435, 1380, 1240, and 1140 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.00 (3H, d, *J*=6.9 Hz), 1.24 (3H, s), 1.45 (3H, s), 1.48 (3H, s), 1.79 (1H, dd, *J*=11.8, 5.0 Hz), 1.82—1.92 (2H, m), 2.34—2.50 (1H, m), 2.56 (1H, d, *J*=11.8 Hz), 3.79 (3H, s), 3.90 (1H, d, *J*=5.0 Hz), 3.99 (1H, d, *J*=11.2 Hz), 4.45 (1H, d, *J*=11.2 Hz), 4.68 (1H, s, –OH), 5.09 (1H, dd, *J*=8.1, 1.0 Hz), and 5.29 (3H, s); EIMS *m/z* (rel intensity) 354 (M^+, 62), 339 (100), 311 (71), and 295 (63). HREIMS. Found: *m/z* 354.1675. Calcd for $C_{18}H_{26}O_7$: M, 354.1678.
