Ligands and Local Symmetry. Atoms, functional groups, and faces are three-dimensional objects to be examined in organic stereochemistry. We use the term "ligand" to comprise these objects. The chemical term "ligand" corresponds to the mathematical term "block". A set of equivalent ligands (or blocks) in a molecule is subject to a coset representation $\mathbf{G}(/\mathbf{G}_i)$, in which **G** is the global symmetry of the molecule and $\mathbf{G}_i$ denotes the local symmetry governing each ligand.[11] In this section, we briefly discuss ligands and local symmetry to obtain a minimum set of mathematical concepts.

When $\mathbf{G}_i$ is a subgroup of **G**, we have a coset decomposition,

$$\mathbf{G} = \mathbf{G}_i t_1 + \cdots + \mathbf{G}_i t_r, \tag{1}$$

where $t_1=I$. This decomposition provides a permutation representation of **G**, which is called a coset representation (CR). We use the symbol $\mathbf{G}(/\mathbf{G}_i)$ to denote the CR. The CR $\mathbf{G}(/\mathbf{G}_i)$ acts on the set of cosets represented by

$$\mathbf{G}/\mathbf{G}_i = \{\mathbf{G}_i t_1, \cdots, \mathbf{G}_i t_r\}. \tag{2}$$

Since we have

$$\mathbf{G}_i t_k (t_k^{-1} \mathbf{G}_i t_k) = \mathbf{G}_i \mathbf{G}_i t_k = \mathbf{G}_i t_k,$$

we obtain the following theorem.

Theorem 2. *The stabilizer of* $\mathbf{G}_i t_k$ *is* $t_k^{-1}\mathbf{G}_i t_k$.

If $\mathbf{G}_i$ and $t_k^{-1}\mathbf{G}_i t_k$ is conjugate within $\mathbf{G}$, then the corresponding CRs ($\mathbf{G}(/\mathbf{G}_i)$ and $\mathbf{G}(/t_k^{-1}\mathbf{G}_i t_k)$) are equivalent,i.e.,

$$\mathbf{G}(/\mathbf{G}_i) \cong \mathbf{G}(/t_k^{-1}\mathbf{G}_i t_k). \tag{3}$$

When an orbit corresponds to the CR $\mathbf{G}(/\mathbf{G}_i)$, we call the orbit a $\mathbf{G}(/\mathbf{G}_i)$ orbit. If we consider a three-dimensional object Ω_1 of $\mathbf{G}_i$ symmetry, we can provide other objects according to $t_k\Omega_1=\Omega_k$ (k=1,2,$\cdots$,r). The set of the r objects, i.e.

$$\Omega = \{\Omega_1,\Omega_2,\cdots,\Omega_r\}$$

is subject to the coset representation $\mathbf{G}(/\mathbf{G}_i)$, when Ω_k corresponds to $\mathbf{G}_i t_k$ in one-to-one fashion. We have reported the correspondence in the light of a regular body.[11] This $\mathbf{G}_i$ of $\mathbf{G}(/\mathbf{G}_i)$ is called the local symmetry that governs each member (block) of Ω.[8] Because the Ω_1 belongs to $\mathbf{G}_i$ symmetry, we have

$$g\Omega_1 = \Omega_1 \text{ (for } \forall g \in \mathbf{G}_i). \tag{4}$$

This equation affords

$$t_k g t_k^{-1}\Omega_k = t_k g t_k^{-1} t_k \Omega_1 = t_k g \Omega_1 = t_k \Omega_1 = \Omega_k \tag{5}$$

for $\forall g \in \mathbf{G}_i$ and k=1,2,$\cdots$,r. Hence, we have the following theorem.

Theorem 3. *Each* $\mathbf{G}_i$*-block* Ω_k(k=1,2,$\cdots$,r) *has stabilizer* $t_k\mathbf{G}_i t_k^{-1}$.

For emphasizing a chemical meaning, we also use the term $\mathbf{G}_i$-ligand in place of the $\mathbf{G}_i$-block. The stabilizer denotes the point group that corresponds to the local symmetry specifying the ligand.

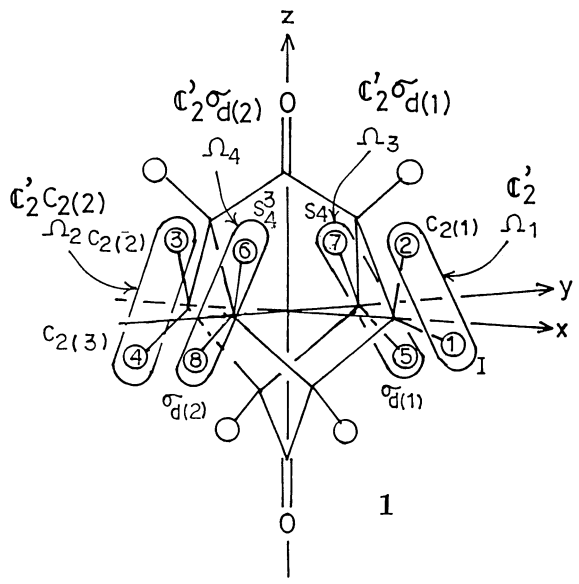

Fig. 1. $\mathbf{C}_2'$-blocks in adamantane-2,6-dione.

Eample **1**. In order to illustrate Theorem 3, let us examine $\mathbf{C}_2'$-blocks in adamantane-2,6-dione (**1**). This molecule belongs to the $\mathbf{D}_{2d}$ group, which is composed of 8 elements (symmetry operations), i.e.,

$$\mathbf{D}_{2d} = \{I,C_{2(1)},C_{2(2)},C_{2(3)},\sigma_{d(1)},S_4^3,S_4,\sigma_{d(2)}\}.$$

Consider the 8 methylene hydrogens in **1** (Fig. 1). We first assign hydrogen no. 1 to the I element. Then, hydrogen no. 2 is assigned to the $C_{2(1)}$ operation, since the action of $C_{2(1)}$ on the hydrogen no. 1 produces the hydrogen no. 2. This treatment is repeated over all of the elements of the $\mathbf{D}_{2d}$ group. As the result, we obtain the following correspondence; $1\leftrightarrow I$, $2\leftrightarrow C_{2(1)}$, $3\leftrightarrow C_{2(2)}$, $4\leftrightarrow C_{2(3)}$, $5\leftrightarrow\sigma_{d(1)}$, $6\leftrightarrow S_4^3$, $7\leftrightarrow S_4$, and $8\leftrightarrow\sigma_{d(2)}$. Let us next consider each methylene. Starting from the above results, we obtain the following correspondence;

$$\Omega_1 = \{1,2\} \leftrightarrow \mathbf{C}_2' = \{I,C_{2(1)}\}$$

$$\Omega_2 = C_{2(2)}\Omega_1 = \{3,4\} \leftrightarrow \mathbf{C}_2'C_{2(2)} = \{C_{2(2)},C_{2(3)}\}$$

$$\Omega_3 = \sigma_{d(1)}\Omega_1 = \{5,7\} \leftrightarrow \mathbf{C}_2'\sigma_{d(1)} = \{\sigma_{d(1)},S_4\}$$

$$\Omega_4 = \sigma_{d(2)}\Omega_1 = \{6,8\} \leftrightarrow \mathbf{C}_2'\sigma_{d(2)} = \{\sigma_{d(2)},S_4^3\}$$

This correspondence is associated with the coset decomposition,

$$\mathbf{D}_{2d} = \mathbf{C}_2' + \mathbf{C}_2'C_{2(2)} + \mathbf{C}_2'\sigma_{d(1)} + \mathbf{C}_2'\sigma_{d(2)}. \tag{6}$$

According to this equation, the coset representation $\mathbf{D}_{2d}(/\mathbf{C}_2')$ governs

$$\mathbf{D}_{2d}/\mathbf{C}_2' = \{\mathbf{C}_2',\mathbf{C}_2'C_{2(2)},\mathbf{C}_2'\sigma_{d(1)},\mathbf{C}_2'\sigma_{d(2)}\}.$$

as well as

$$\Omega = \{\Omega_1,\Omega_2,\Omega_3,\Omega_4\}.$$

We have four $\mathbf{C}_2'$-blocks (Ω_1 to Ω_4), the stabilizers of which are obtained by means of Theorem 3. These results are consistent with their chemical meanings.

Methylene	Stabilizer
Ω_1	$\mathbf{C}_2'=\{I,\ C_{2(1)}\}$
Ω_2	$C_{2(2)}\mathbf{C}_2'C_{2(2)}^{-1}=\mathbf{C}_2'=\{I,\ C_{2(1)}\}$
Ω_3	$\sigma_{d(1)}\mathbf{C}_2'\sigma_{d(1)}^{-1}=\mathbf{C}_2''=\{I,\ C_{2(2)}\}$
Ω_4	$\sigma_{d(2)}\mathbf{C}_2'\sigma_{d(2)}^{-1}=\mathbf{C}_2''=\{I,\ C_{2(2)}\}$

Desymmetrization of Enantiospheric Orbits. When $\mathbf{G}$ is an achiral group and $\mathbf{G}_i$ is its chiral subgroup, the $\mathbf{G}$-($/\mathbf{G}_i$) orbit is defined as an *enantiospheric* orbit.[8] The purpose of this section is to examine the desymmetrization corresponding to the subduction $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max}$, where $\mathbf{G}^{\max}$ is the subgroup that contains all of the proper

rotations of **G**. Although a general discussion on the subduction of coest representations has appeared in our previous papers,[10] the present section provides a more specified discussions concerning enantiospheric orbits.

The corresponding coset decomposition (Eq. 1) contains a transversal $\{t_1,t_2,\cdots,t_r\}$, in which $r/2$ elements are proper rotations and the remaining $r/2$ elements are improper rotations. When we designate the latter half by the symbol $u_k(k=1,2,\cdots,r/2)$, we are able to rewrite the coset decomposition as follows.

$$\mathbf{G} = (\mathbf{G}_i t_1 + \mathbf{G}_i t_2 + \cdots + \mathbf{G}_i t_k + \cdots + \mathbf{G}_i t_q) + (\mathbf{G}_i u_1 + \mathbf{G}_i u_2 + \cdots + \mathbf{G}_i u_k + \cdots + \mathbf{G}_i u_q), \quad (7)$$

where $q=r/2$ and $u_k=t_k u_1$. Note that u_1 can be an arbitrary improper rotation during the discussion in this section. The $\mathbf{G}/\mathbf{G}_i$ set is divided into two parts,

$$\mathbf{G}^+/\mathbf{G}_i = \{\mathbf{G}_i t_1, \mathbf{G}_i t_2, \cdots, \mathbf{G}_i t_q\}, \quad (8)$$

and

$$\mathbf{G}^-/\mathbf{G}_i = \{\mathbf{G}_i u_1, \mathbf{G}_i u_2, \cdots, \mathbf{G}_i u_q\}. \quad (9)$$

Obviously, each coset in $\mathbf{G}^+/\mathbf{G}_i$ contains proper rotation and $\mathbf{G}^-/\mathbf{G}_i$ is concerned with improper rotations. Because we have $\mathbf{G}_i t_k t_l \in \mathbf{G}^+/\mathbf{G}_i$, $\mathbf{G}_i t_k u_l \in \mathbf{G}^-/\mathbf{G}_i$, $\mathbf{G}_i u_k t_l \in \mathbf{G}^-/\mathbf{G}_i$ and $\mathbf{G}_i u_k u_l \in \mathbf{G}^+/\mathbf{G}_i$, the two parts, $\mathbf{G}^+/\mathbf{G}_i$ and $\mathbf{G}^-/\mathbf{G}_i$, are mirror images to each other.

Since $\mathbf{G}^{\max}$ is the subgroup that contains all of the proper rotations of **G**, we have a coset representation by using $\{t_1,t_2,\cdots,t_q\}$, i.e.,

$$\mathbf{G}^{\max} = \mathbf{G}_i t_1 + \mathbf{G}_i t_2 + \cdots + \mathbf{G}_i t_q, \quad (10)$$

because $\mathbf{G}_i$ is also a subgroup of $\mathbf{G}^{\max}$. Obviously, the subgroup $\mathbf{G}^{\max}$ is a normal subgroup of **G**, where $|\mathbf{G}^{\max}|=|\mathbf{G}|/2$.

Since any coset $(\mathbf{G}^{\max}u_k)$ contains all of the improper rotations $(k=1,2,\cdots,q)$, we can select u_1 as a representative without losing generality. Thereby, we have

$$\mathbf{G} = \mathbf{G}^{\max} + \mathbf{G}^{\max}u_1. \quad (11)$$

When Eq. 10 is introduced into Eq. 11, we have $u_k=t_k u_1(k=1,2,\cdots,q)$.

We rewrite the notation of Ω_k as follows: $\Omega_k^+=\Omega_k$ $(1\leqslant k\leqslant q)$ and $\Omega_k^-=\Omega_{q+k}$ $(1\leqslant k\leqslant q)$. Thereby, Ω is divided into two subsets,i.e.,

$$\boldsymbol{\Omega}^+ = \{\Omega_1^+,\Omega_2^+,\cdots,\Omega_q^+\}, \quad (12)$$

$$\boldsymbol{\Omega}^- = \{\Omega_1^-,\Omega_2^-,\cdots,\Omega_q^-\}, \quad (13)$$

We have the following correspondences, $\Omega_k^+ \leftrightarrow \Omega_i t_k$ and $\Omega_k^- \leftrightarrow \Omega_i u_k$, where $k=1,2,\cdots,q$. Obviously, $\boldsymbol{\Omega}^+$ and $\boldsymbol{\Omega}^-$ are mirror images to each other under the action of the **G** group. As for Example 1 (Fig. 1), we construct $\boldsymbol{\Omega}^+=\{\Omega_1,\Omega_2\}$ and $\boldsymbol{\Omega}^-=\{\Omega_3,\Omega_4\}$, which are the mirror images to each other. The two sets coincide with each other under the action of the improper rotations of $\mathbf{D}_{2d}$, but not under the action of the proper rotations of $\mathbf{D}_{2d}$.

Since Theorem 3 holds for any Ω_k^-, $u_k\mathbf{G}_i u_k^{-1}$ is the stabilzer of the Ω_k^-. Consider $u_l \in \mathbf{G}_i u_l$. Since u_l and u_k are improper rotations (i.e., $u_l,u_k\mathbf{G}^{\max}u_1$), Eq. 11 indicates that there exists a proper rotation (t_k) that satisfies $t_k=u_k u_l^{-1}\in\mathbf{G}^{\max}$. Hence, we have $u_k=t_k u_l$. It follows that

$$u_k\mathbf{G}_i u_k^{-1} = t_k u_l \mathbf{G}_i (t_k u_l)^{-1} = t_k(u_l\mathbf{G}_i u_l^{-1})t_k^{-1} \quad (14)$$

Here, we consider two cases:

Case (a) there exists an improper rotation (u_l) that satisfies $u_l\mathbf{G}_i u_l^{-1}=\mathbf{G}_i$ (i.e. $u_l\mathbf{G}_i=\mathbf{G}_i u_l$) and

Case (b) there exists no improper rotation (u_l) that satisfies $u_l\mathbf{G}_i u_l^{-1}\mathbf{G}_i$ (i.e., $u_l\mathbf{G}_i\neq\mathbf{G}_i u_l$ for $\forall u_l\in\mathbf{G}^{\max}u_1$).

In Case (a), Eq. 14 is further converted into

$$u_k\mathbf{G}_i u_k^{-1} = t_k(u_l\mathbf{G}_i u_l^{-1})t_k^{-1} = t_k\mathbf{G}_i t_k^{-1}.$$

This equation means that the stabilizer of Ω_k^- is $t_k\mathbf{G}_i t_k^{-1}$, which is identical with that of Ω_k^+. Because the stabilizer $t_k\mathbf{G}_i t_k^{-1}$ is a chiral subgroup of **G**, it is also a subgroup of $\mathbf{G}^{\max}$. Hence, all of the $t_k\mathbf{G}_i t_k^{-1}$'s are conjugate to $\mathbf{G}_i$ under the action of $\mathbf{G}^{\max}$ as well as that of **G**. Then, we have

$$\mathbf{G}^{\max}(/u_k\mathbf{G}_i u_k^{-1}) \cong \mathbf{G}^{\max}(/t_k\mathbf{G}_i t_k^{-1}) \cong \mathbf{G}^{\max}(/\mathbf{G}_i) \text{ for } \boldsymbol{\Omega}^+$$

and

$$\mathbf{G}^{\max}(/t_k\mathbf{G}_i t_k^{-1}) \cong \mathbf{G}^{\max}(/\mathbf{G}_i) \text{ for } \boldsymbol{\Omega}^-$$

for $k=1,2,\cdots,q$. It follows that the subduction $\mathbf{G}$-$(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max}$ produces two $\mathbf{G}^{\max}(/\mathbf{G}_i)$ orbits (i.e. $\boldsymbol{\Omega}^+$ and $\boldsymbol{\Omega}^-$ as $\mathbf{G}^{\max}$-sets).

In case (b), $\mathbf{G}_i$ is not conjugate to any $u_l\mathbf{G}_i u_l^{-1}$ within $\mathbf{G}^{\max}$. Equation 14 indicates that $u_k\mathbf{G}_i u_k^{-1}$ $(k=1,2,\cdots,q)$ is conjugate to $u_l\mathbf{G}_i u_l^{-1}$ within $\mathbf{G}^{\max}$. Obviously, $t_k\mathbf{G}_i t_k^{-1}$ $(k=1,2,\cdots,q)$ is conjugate to $\mathbf{G}_i$ within $\mathbf{G}^{\max}$. These facts mean that $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max}$ produces two orbits according to the following equation,

$$\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max} = \mathbf{G}^{\max}(/\mathbf{G}_i) + \mathbf{G}^{\max}(/\mathbf{G}_i'),$$

where $\mathbf{G}_i'=u_l\mathbf{G}_i u_l^{-1}$. As a result, $\boldsymbol{\Omega}^+$ and $\boldsymbol{\Omega}^-$ are governed by $\mathbf{G}^{\max}(/\mathbf{G}_i)$ and $\mathbf{G}^{\max}(/\mathbf{G}_i')$, respectively. The above discussions are summarized as follows.

Theorem 4. *Let* **G** *be an achiral point group. Consider an enantiospheric orbit governed by* $\mathbf{G}(/\mathbf{G}_i)$, *where* $\mathbf{G}_i$ is a chiral subgroup of **G**. *Let* $\mathbf{G}^{\max}$ *be a maximal chiral subgroup of* **G**. *Then, there are two possibilities.*

$$\text{Case (a): } \mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max} = 2\mathbf{G}^{\max}(/\mathbf{G}_i) \quad (15)$$

$$\text{Case (b): } \mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max} = \mathbf{G}^{\max}(/\mathbf{G}_i) + \mathbf{G}^{\max}(/\mathbf{G}_i'), \quad (16)$$

a) Forbidden CR.

where $\mathbf{G}_i$ *and* $\mathbf{G}_i'$ *are conjugate in* $\mathbf{G}$ *but not conjugate in* $\mathbf{G}^{max}$

This thorem is the basis of Theorem 1, since it indicates that the enantiospheric $\mathbf{G}(/\mathbf{G}_i)$ orbit behaves differently under $\mathbf{G}$ and $\mathbf{G}^{max}$.

Table 1 is a subduction table for $\mathbf{D}_{2d}$ group, which lists all of the subductions concerning the $\mathbf{D}_{2d}$ group by its subgroups. From the data of this table, we select the following examples that illustrate the two possibilities described in Theorem 4.

Example **2.** Let us consider $\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{D}_2$. Since the $\mathbf{D}_{2d}(/\mathbf{C}_1)$ is a regular representation, each coset consists of each symmetry operation of $\mathbf{D}_{2d}$. All of the eight cosets (symmetry operations) are commutable with $\mathbf{C}_1$; hence, this case is an example of Case (a). We obtain

$$\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{D}_2 = 2\mathbf{D}_2(/\mathbf{C}_1). \tag{17}$$

This equation exemplifies Theorem 4.

In order to illustrate the chemical meaning of this equation, let us consider derivation of adamantane-2,6-dione (**1**). The 8 methylene hydrogen atoms (○) are taken into consideration (Fig. 2). A replacement of four hydrogen atoms (○) with other atoms (●) produces a $\mathbf{D}_2$-molecule (**2a**), in which ○'s and ●'s construct $\mathbf{D}_2(/\mathbf{C}_1)$ orbits (Fig. 2). This is an example of case (a), which is algebraically represented by Eq. 17. If ○ and ● are interchanged, the resulting molecule (**2b**) is enantiomeric to **2a**.

Example **3.** Let us examine $\mathbf{D}_{2d}(/\mathbf{C}_2')\downarrow\mathbf{D}_2$(See Example 1). We have obtained the coset decomposition represented by Eq. 6. Since we have $\mathbf{C}_2'\ \sigma_{d(1)} \neq \sigma_{d(1)}\mathbf{C}_2'$ and $\mathbf{C}_2'\ \sigma_{d(2)} \neq \sigma_{d(2)}\mathbf{C}_2'$, Theorem 4 indicates that this is an

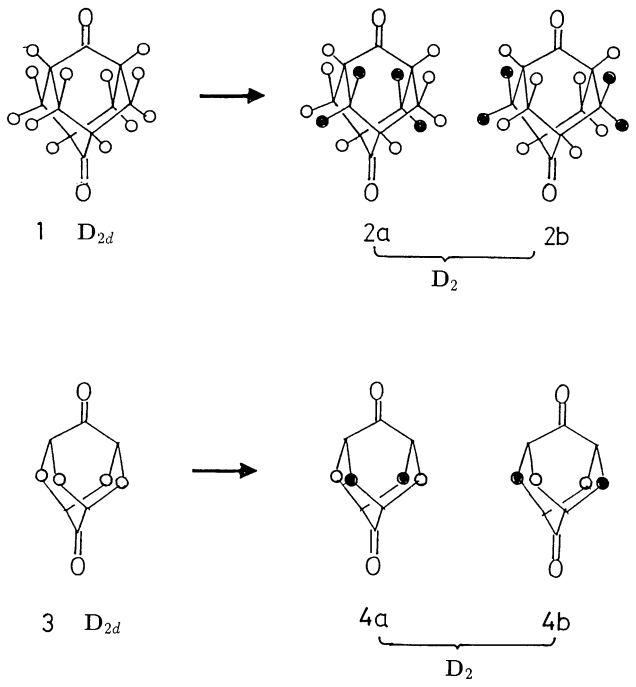

Fig. 2. $\mathbf{D}_2$ molecules derived from a $\mathbf{D}_{2d}$ molecule.

example of Case (b). In fact, we obtain

$$\mathbf{D}_{2d}(/\mathbf{C}_2')\downarrow\mathbf{D}_2 = \mathbf{D}_2(/\mathbf{C}_2') + \mathbf{D}_2(/\mathbf{C}_2''), \tag{18}$$

as shown in the intersection between the $\mathbf{D}_2(/\mathbf{C}_2')$-row and the the $\downarrow\mathbf{D}_2$-column (Table 1).

Chemically speaking, this equation corresponds to such a conversion as the desymmetrization of **3** into **4a** (or **4b**). The four methylene carbons of **3** construct an orbit governed by $\mathbf{D}_{2d}(/\mathbf{C}_2')$. This orbit is divided into a $\mathbf{D}_2(/\mathbf{C}_2')$ orbit and $\mathbf{D}_2(/\mathbf{C}_2'')$ orbit in each of the desymmetrized compounds (**4a** and **4b**).

Example **4**. Let us consider $\mathbf{S}_8(/\mathbf{C}_2)\downarrow\mathbf{C}_4$. We have the following coset decomposition,

$$\mathbf{S}_8 = \mathbf{C}_2 + \mathbf{C}_2\mathbf{C}_4 + \mathbf{C}_2S_8 + \mathbf{C}_2S_8^3. \tag{19}$$

Among the four cosets, the $\mathbf{C}_2S_8$ satisfies the relationship, $\mathbf{C}_2S_8=S_8\mathbf{C}_2$; hence, this case is an example of Case (a). We obtain

$$\mathbf{S}_8(/\mathbf{C}_2)\downarrow\mathbf{C}_4 = 2\mathbf{C}_4(/\mathbf{C}_2). \tag{20}$$

This equation exemplifies Theorem 4. Consider $\mathbf{A}=\mathbf{C}_2+\mathbf{C}_2S_8$. This set is not a group as shown later. Note that $S_8S_8\in\mathbf{C}_2C_4(S_8S_8\notin\mathbf{C}_2)$.

Further Desymmetrization of Enantiospheric Orbits. For Case (a) of Theorem 4, consider the subduced representation (SR) $\mathbf{G}^{max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$, where $\mathbf{G}_j$ is a subgroup of $\mathbf{G}^{max}$. Suppose that we obtain the following equation

$$\mathbf{G}^{max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j = \sum_{k=1}^{\nu_j}\gamma_k^{(ij)}\mathbf{G}_j(/\mathbf{G}_k^{(j)}), \tag{21}$$

where the multiplicities ($\gamma_k^{(ij)}$'s) are non-negative integers.[10] Since both $\mathbf{G}_i$ and $\mathbf{G}_j$ are subgroups of $\mathbf{G}$ as well as those of $\mathbf{G}^{max}$, Eqs. 15 and 21 afford the following theorem. Note that $(\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{max})\downarrow\mathbf{G}_j=\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$.

Theorem 5, *Supose that an enantiospheric orbit follows Case (a) of Theorem 4. Then, any chiral subduction,* $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$, *is represented by*

$$\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j = \sum_{k=1}^{\nu_j}(2\gamma_k^{(ij)})\mathbf{G}_j(/\mathbf{G}_k^{(j)}), \tag{22}$$

wherein $\mathbf{G}$ *contains proper and improper rotations; and its subgroups,* $\mathbf{G}_i$ *and* $\mathbf{G}_j$, *consist of proper rotations only.* As a result, any $\mathbf{G}_k^{(j)}$ is a proper rotation and any $\mathbf{G}_j(/\mathbf{G}_k^{(j)})$ represents a hemispheric orbit.

This theorem is exemplified by the following examples, which are selected from the data of Tables 1 and 2.

Example **5**. We take the equations,

$$\mathbf{D}_2(/\mathbf{C}_1)\downarrow\mathbf{C}_2 = 2\mathbf{C}_2(/\mathbf{C}_1) \text{ and}$$

$$\mathbf{D}_2(/\mathbf{C}_1)\downarrow\mathbf{C}_2' = 2\mathbf{C}_2'(/\mathbf{C}_1),$$

from Table 2. When we introduce these equations into Eq. 17, we have

$$\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{C}_2 = 4\mathbf{C}_2(/\mathbf{C}_1) \text{ and}$$

$$\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{C}_2' = 4\mathbf{C}_2'(/\mathbf{C}_1).$$

As for Case (b) of Theorem 4, consider the SR $\mathbf{G}^{max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ where $\mathbf{G}_j$ is a subgroup of $\mathbf{G}^{max}$. Then, we obtain following equations.

$$\mathbf{G}^{max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j = \sum_{k=1}^{\nu_j}\gamma_k^{(ij)}\mathbf{G}_j(/\mathbf{G}_k^{(j)}), \tag{23}$$

$$\mathbf{G}^{max}(/\mathbf{G}_i')\downarrow\mathbf{G}_j = \sum_{k=1}^{\nu_j}\delta_k^{(ij)}\mathbf{G}_j(/\mathbf{G}_k^{(j)}), \tag{24}$$

where the multiplicities ($\gamma_k^{(ij)}$'s and $\delta_k^{(ij)}$'s) are non-negative integers. Since $\mathbf{G}_i$, $\mathbf{G}_i'$ and $\mathbf{G}_j$ are subgroups of $\mathbf{G}$ and of $\mathbf{G}^{max}$, Eqs. 23 and 24 are combined with Eq. 15 to afford the following theorem.

Theorem 6. *Suppose that an enantiospheric orbit follows Case (b) of Theorem 4. Then, any chiral subduction,* $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$, *is represented by*

$$\mathbf{G}^{max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j = \sum_{k=1}^{\nu_j}(\gamma_k^{(ij)}+\delta_k^{(ij)})\mathbf{G}_j(/\mathbf{G}_k^{(j)}), \tag{25}$$

wherein $\mathbf{G}$ *contains proper and improper rotations; and its subgroups,* $\mathbf{G}_i$ *and* $\mathbf{G}_j$, *consist of proper rotations only.* As a result, any $\mathbf{G}_k^{(j)}$ is a proper rotation and any $\mathbf{G}_j(/\mathbf{G}_k^{(j)})$ represents a hemispheric orbit.

Theorem 6 is verified as follows.

Example **6**. When we introduce

$$\mathbf{D}_2(/\mathbf{C}_2')\downarrow\mathbf{C}_2 = \mathbf{C}_2(/\mathbf{C}_1) \text{ and}$$

$$\mathbf{D}_2(/\mathbf{C}_2'')\downarrow\mathbf{C}_2 = \mathbf{C}_2(/\mathbf{C}_1)$$

Table 2. Subduction Table of $\mathbf{D}_2$ Group

	$\downarrow\mathbf{C}_1$	$\downarrow\mathbf{C}_2$	$\downarrow\mathbf{C}_2'$	$\downarrow\mathbf{C}_2''$	$\downarrow\mathbf{D}_2$
$\mathbf{D}_2(/\mathbf{C}_1)$	$4\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_2(/\mathbf{C}_1)$	$2\mathbf{C}_2'(/\mathbf{C}_1)$	$2\mathbf{C}_2''(/\mathbf{C}_1)$	$\mathbf{D}_2(/\mathbf{C}_1)$
$\mathbf{D}_2(/\mathbf{C}_2)$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$2\mathbf{C}_2(/\mathbf{C}_2)$	$\mathbf{C}_2'(/\mathbf{C}_1)$	$\mathbf{C}_2''(/\mathbf{C}_1)$	$\mathbf{D}_2(/\mathbf{C}_2)$
$\mathbf{D}_2(/\mathbf{C}_2')$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$\mathbf{C}_2(/\mathbf{C}_1)$	$2\mathbf{C}_2'(/\mathbf{C}_2)$	$\mathbf{C}_2''(/\mathbf{C}_1)$	$\mathbf{D}_2(/\mathbf{C}_2')$
$\mathbf{D}_2(/\mathbf{C}_2'')$	$2\mathbf{C}_1(/\mathbf{C}_1)$	$\mathbf{C}_2(/\mathbf{C}_1)$	$\mathbf{C}_2'(/\mathbf{C}_1)$	$2\mathbf{C}_2''(/\mathbf{C}_2)$	$\mathbf{D}_2(/\mathbf{C}_2'')$
$\mathbf{D}_2(/\mathbf{D}_2)$	$\mathbf{C}_1(/\mathbf{C}_1)$	$\mathbf{C}_2(/\mathbf{C}_2)$	$\mathbf{C}_2'(/\mathbf{C}_2)$	$\mathbf{C}_2''(/\mathbf{C}_2)$	$\mathbf{D}_2(/\mathbf{D}_2)$

into Eq. 18, we have

$$\mathbf{D}_{2d}(/\mathbf{C}_2')\downarrow\mathbf{C}_2 = 2\mathbf{C}_2(/\mathbf{C}_1).$$

This result is identical with the equation listed in the intersection between $\mathbf{D}_{2d}(/\mathbf{C}_2')$-row and $\downarrow\mathbf{D}_2$-column of Table 1. This example produces a result similar to Theorem 5, though the process is different. A more typical example is as follows. Since we have

$$\mathbf{D}_2(/\mathbf{C}_2')\downarrow\mathbf{C}_2 = 2\mathbf{C}_2'(/\mathbf{C}_2) \text{ and}$$

$$\mathbf{D}_2(/\mathbf{C}_2'')\downarrow\mathbf{C}_2 = \mathbf{C}_2''(/\mathbf{C}_1)$$

in Table 2, we introduce these equations into Eq. 18 to obtain

$$\mathbf{D}_{2d}(/\mathbf{C}_2')\downarrow\mathbf{C}_2' = 2\mathbf{C}_2'(/\mathbf{C}_2) + \mathbf{C}_2'(/\mathbf{C}_1).$$

Example 7. For illustrating Theorem 6, let us examine an enantiospheric orbit ($\mathbf{T}_h(/\mathbf{C}_3)$) appearing in the compound (**5**) of $\mathbf{T}_h$ symmetry. The subduction of this orbit into **T** is represented by

$$\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{T} = 2\mathbf{T}(/\mathbf{C}_3). \tag{26}$$

This subduction is realized by compounds **6a** and **6b**, which belong to **T** symmetry (Fig. 3). These compounds are enantiomeric to each other. The occupation of the orbit is changed from $\mathbf{T}_h(/\mathbf{C}_3(A_8)]$ to $\mathbf{T}[/\mathbf{C}_3(A_4, B_4)]$.[12]

The subduction of the orbit into $\mathbf{C}_2$ is represented by

$$\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{C}_2 = 4\mathbf{C}_2(/\mathbf{C}_1). \tag{27}$$

This equation is obtained according to Theorem 6 by introducting

$$\mathbf{T}(/\mathbf{C}_3)\downarrow\mathbf{C}_2 = 2\mathbf{C}_2(/\mathbf{C}_1)$$

into Eq. 26.

The chemical meaning of Eq. 27 is illustrated as follows. If we replace appropriate A_2 with B_2 according to this subduction, there appear **7a** and **7b** (Fig. 4). The resulting packing of the divided orbit is expressed by $\mathbf{C}_2[/\mathbf{C}_1(3A_2, B_2)]$.[12]

On the other hand, we introduce the equation,

$$\mathbf{T}(/\mathbf{C}_3)\downarrow\mathbf{C}_3 = \mathbf{C}_3(/\mathbf{C}_1) + \mathbf{C}_3(/\mathbf{C}_3), \tag{28}$$

into Eq. 26. Thereby, we obtain

$$\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{C}_3 = 2\mathbf{C}_3(/\mathbf{C}_1) + 2\mathbf{C}_3(/\mathbf{C}_3). \tag{29}$$

Figure 5 shows examples of the subduction into $\mathbf{C}_3$. The hemispheric orbits in the products (**8a** and **8b**) are filled in a way of $\mathbf{C}_3[/\mathbf{C}_1(2A_3), /\mathbf{C}_3(A,B)]$, which is in agreement with Eq. 29.

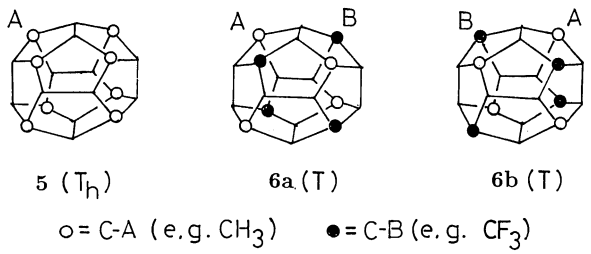

Fig. 3. **T** molecules derived from a $\mathbf{T}_h$ molecule.

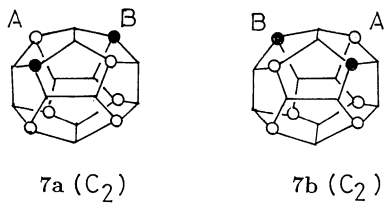

Fig. 4. $\mathbf{C}_2$ molecules derived from a $\mathbf{T}_h$ molecule.

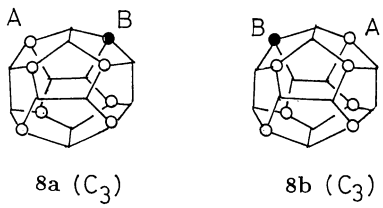

Fig. 5. $\mathbf{C}_3$ molecules derived from a $\mathbf{T}_h$ molecule.

Chirogenic Sites in Direct Chiral Synthesis. We are able to differentiate the two halves (Ω^+ and Ω^-) of an enantiospheric $\mathbf{G}(/\mathbf{G}_i)$ orbit (Ω) under chiral environment. Thereby, we obtain either one of enantiomeric $\mathbf{G}^{max}$-molecules. If we differentiate an appropriate part of the one half from the corresponding mirror image contained in the other half, we can obtain a chiral molecule. However, it is a problem to determine which subsymmetry is realized in this operation. This section deals with this problem. If the differentiation of the parts produces a chiral **H**-molecule, we call the part an **H**-*chirogenic site*. Each chirogenic site is always accompanied with the mirror image counterpart.

To begin with, we examine two extreme cases. The discussions in the preceding section afford the following theorem.

Theorem 7. *Each of the two halves of a* $\mathbf{G}(/\mathbf{G}_i)$ *orbit is a* $\mathbf{G}^{max}$*-chirogenic site.*

When $\mathbf{G}_1=\mathbf{C}_1=\{I\}$, the corresponding $\mathbf{G}(/\mathbf{G}_1)$ is a regular representation of **G**. In this case, we have a simple result as follows.

Theorem 8. *An orbit governed by the regular representation* $\mathbf{G}(/\mathbf{G}_1)$ *has a chirogenic site that corresponds every subgroup.*

Proof. When $\mathbf{G}_1=\mathbf{C}_1$, we have

$$\mathbf{G}(/\mathbf{G}_1)\downarrow\mathbf{G}_i = \frac{|\mathbf{G}|}{|\mathbf{G}_i|}\mathbf{G}_i(\mathbf{G}_1^{(i)}),$$

where $\mathbf{G}_i(/\mathbf{G}_1^{(i)})$ is the regular representation of the $\mathbf{G}_i$ group. This equation indicates that every subduction is accompanied with the division of respective orbits. Hence, the $\mathbf{G}_i(/\mathbf{G}_1^{(i)})$ part in the $\mathbf{G}(/\mathbf{G}_1)$ orbit is $\mathbf{G}_i$-chirogenic.

In order to formulate general cases other than the extreme ones, we should examine division (or conservation) of an orbit through a desymmetrization process. For this purpose, we prove the following theorem.

Theorem 9. *Let $\mathbf{G}_i$ and $\mathbf{G}_j$ be any subgroups of $\mathbf{G}$. If $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ is transitive, then we have $\mathbf{G}_i\mathbf{G}_j=\mathbf{G}$. Conversely, if we have $\mathbf{G}_i\mathbf{G}_j=\mathbf{G}$, then $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ is transitive.*

Proof. (a) Consider a coset $\mathbf{G}_it_\alpha$ appearing in the coset decomposition (Eq. 1). Then, we obtain another coset, $\mathbf{G}_it_\alpha g$, which obviously constructs a double coset, $\mathbf{G}_it_\alpha\mathbf{G}_j$, when g runs over all $g\in\mathbf{G}_j$. Obviously, the double coset corresponds to an orbit produced by the subduction, $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$. If $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ is transitive, all of the double cosets should be identical, i.e. $\mathbf{G}_it_\alpha\mathbf{G}_j=\mathbf{G}_it_\beta\mathbf{G}_j$ for $\forall t_\alpha$ *and* $\forall t_\beta$. Let t_β be equal to I. Then, we have $\mathbf{G}_it_\alpha\mathbf{G}_j=\mathbf{G}_i\mathbf{G}_j$. Hence, we have

$$\bigcup_{\alpha=1}^{r}\mathbf{G}_it_\alpha\mathbf{G}_j = \bigcup_{\alpha=1}^{r}\mathbf{G}_i\mathbf{G}_j. = \mathbf{G}_i\mathbf{G}_j.$$

Since the left-hand side contains all of the elements of $\mathbf{G}$ (i.e., $\mathbf{G}=\bigcup_{\alpha=1}^{r}\mathbf{G}_it_\alpha\mathbf{G}_j$), the equation is converted into

$$\mathbf{G} = \mathbf{G}_i\mathbf{G}_j. \tag{30}$$

(b) Conversely, suppose that $\mathbf{G}_i\mathbf{G}_j=\mathbf{G}$. Then, we have $\mathbf{G}_it_1\mathbf{G}_j=\mathbf{G}$ for $t_1=I$. This equation indicates the double coset $\mathbf{G}_it_1\mathbf{G}_j$ contains all of the elements of $\mathbf{G}$. Hence, there appears one orbit during the subduction, $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$; that is to say, $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}_j$ is transitive.

It should be noted that this thorem holds for any $\mathbf{G}_i$, $\mathbf{G}_j$, and $\mathbf{G}$, no matter whether they are proper or improper. The following examples clarify the scope of the theorem.

Example **8.** (a) For $\mathbf{T}_d(/\mathbf{C}_s)\downarrow\mathbf{T}$, we have $\mathbf{C}_s\mathbf{T}=\mathbf{T}_d$. Hence, Theorem 9 indicates that there emerges no division of the orbit; i.e., $\mathbf{T}_d(/\mathbf{C}_s)\downarrow\mathbf{T}=\mathbf{T}(/\mathbf{C}_1)$.

(b) For $\mathbf{T}_d(/\mathbf{C}_{3v})\downarrow\mathbf{D}_{2d}$, we have $\mathbf{C}_{3v}\mathbf{D}_{2d}=\mathbf{T}_d$. Hence, Theorem 9 indicates that there emerges no division of the orbit; i.e., $\mathbf{T}_d(/\mathbf{C}_{3v})\downarrow\mathbf{D}_{2d}=\mathbf{D}_{2d}(/\mathbf{C}_s)$.

(c) For $\mathbf{T}_d(/\mathbf{C}_{3v})\downarrow\mathbf{D}_{3v}$, we have $\mathbf{C}_{3v}\mathbf{C}_{3v}=\mathbf{C}_{3v}\neq\mathbf{T}_d$. Hence, Theorem 9 indicates that the orbit is divided during the process as follows; $\mathbf{T}_d(/\mathbf{C}_{3v})\downarrow\mathbf{C}_{3v}=\mathbf{C}_{3v}(/\mathbf{C}_s)+\mathbf{C}_{3v}(/\mathbf{C}_{3v})$.

(d) For $\mathbf{T}(/\mathbf{C}_3)\downarrow\mathbf{C}_3$, we have $\mathbf{C}_3\mathbf{C}_3=\mathbf{C}_3\neq\mathbf{T}$. Hence, Theorem 9 indicates that the orbit is divided during the process as follows; $\mathbf{T}(/\mathbf{C}_3)\downarrow\mathbf{C}_3=\mathbf{C}_3(/\mathbf{C}_1)+\mathbf{C}_3(/\mathbf{C}_3)$.

Let $\mathbf{G}(/\mathbf{G}_i)$ be enantiospheric. Then, $\mathbf{G}_i$ and $\mathbf{G}^{\max}$ are chiral subgroups; hence, $\mathbf{G}_i\mathbf{G}^{\max}=\mathbf{G}^{\max}\neq\mathbf{G}$. In this case, Theorem 9 is converted into a corollary.

Corollary 1. *An enantiospheric orbit $\mathbf{G}(/\mathbf{G}_i)$ is divided during $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{G}^{\max}$.*

The concrete form of the division has been given by Theorem 4.

Let $\mathbf{H}$ be a nearest subgroup of $\mathbf{G}_j$. The term "nearest" is used when there is no subgroup of $\mathbf{G}_j$ between $\mathbf{G}_j$ and $\mathbf{H}$. Thus, $\mathbf{H}$ is one of the nearest subgroups of $\mathbf{G}_j$ and $\mathbf{G}_j$ is one of the nearest supergroups of $\mathbf{H}$. Since $\mathbf{G}_j$ is chiral, $\mathbf{H}$ is also chiral. Suppose that each CR in Eq. 21 is subduced by means of

$$\mathbf{G}_j(/\mathbf{G}_k^{(j)})\downarrow\mathbf{H} = \sum_{l=1}^{\nu_l}\zeta_l^{(ij)}\mathbf{H}(/\mathbf{H}_l)$$

We have derived Eq. 21 for Case (a) and Eq. 23 for Case (b). Thereby, we derive the following equation from Eq. 21.

$$\begin{aligned}\mathbf{G}^{\max}(/\mathbf{G}_i)\downarrow\mathbf{H} &= \mathbf{G}^{\max}(/\mathbf{G}_i)\downarrow\mathbf{G}_j\downarrow\mathbf{H}\\ &= \sum_{k=1}^{\nu_j}\gamma_k^{(ij)}\mathbf{G}_j(/\mathbf{G}_k^{(j)})\downarrow\mathbf{H}\\ &= \sum_{k=1}^{\nu_j}\gamma_k^{(ij)}\sum_{l=1}^{\nu_\mathbf{H}}\zeta_l^{(ik)}\mathbf{H}(/\mathbf{H}_l)\\ &= \sum_{l=1}^{\nu_\mathbf{H}}\eta_l^{(ij)}\mathbf{H}(/\mathbf{H}_l),\end{aligned} \tag{32}$$

where

$$\eta_l^{(ij)} = \sum_{k=1}^{\nu_j}\gamma_k^{(ij)}\zeta_l^{(ik)}. \tag{33}$$

We arrive at the following theorem.

Theorem 10. *Let $\mathbf{H}$ be a nearest subgroup of $\mathbf{G}_j$. If there is an appropriate CR $(\mathbf{G}_j(/\mathbf{G}_k^{(j)}))$ that satisfies $\mathbf{G}_k^{(j)}\mathbf{H}\neq\mathbf{G}_j$, then the site governed by $\mathbf{H}(/\mathbf{H}_l)(l=1,2,\cdots,\nu_l)$ is an $\mathbf{H}$-chirogenic site during the desymmetrization process $(\mathbf{G}\rightarrow\mathbf{G}_j\rightarrow\mathbf{H})$.*

Proof. If there is an appropriate CR $(\mathbf{G}_j(/\mathbf{G}_k^{(j)}))$ that satisfies $\mathbf{G}_k^{(j)}\mathbf{H}\neq\mathbf{G}_j$, then the subduction represented by Eq. 31 produces two or more orbits (Theorem 9). This means that the site governed by $\mathbf{H}(/\mathbf{H}_l)(l=1,2,\cdots,\nu_\mathbf{H})$ is an $\mathbf{H}$-chirogenic site.

This theorem also holds for Case (b), since Eqs. 23 and 24 of Case (b) are essentially identical with Eq. 21 of Case (a). It is the next problem to determine whether the $\mathbf{H}(/\mathbf{H}_l)$ part is an $\mathbf{H}$-chirogenic site during all of the desymmetrization processes toward $\mathbf{H}$. For this purpose, we should examine all of the nearest chiral supergroups of $\mathbf{H}$. If there exists such a chiral synthesis, we call the synthesis a $\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{H}$-ligand-differentiating reaction.

Example **9.** Let us consider $\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{C}_2$. We take account of $\mathbf{D}_2$ group as a nearest chiral supergroup of $\mathbf{C}_2$.

$$\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{D}_2 = 2\mathbf{D}_2(/\mathbf{C}_1) \text{ and}$$

$$\mathbf{D}_2(/\mathbf{C}_1)\downarrow\mathbf{C}_2 = 2\mathbf{C}_2(/\mathbf{C}_1)$$

We apply Theorem 10 to $\mathbf{G}_j=\mathbf{D}_2$, $\mathbf{G}_k^{(j)}=\mathbf{C}_1$ and $\mathbf{H}=\mathbf{C}_2$.

Since we have $C_1C_2=C_2\neq D_2$, there emerge two or more orbits during the conversion of D_2 into C_2. Theorem 10 indicates that the resulting $C_2(/C_1)$ parts are C_2-chirogenic. The overall process is represented by

$$T_h(/C_3)\downarrow C_2 = 4C_2(/C_1). \quad (34)$$

This conclusion is illustrated by a potential chiral synthesis (Fig. 6). Consider the attack of a chiral reagent (containing two chiral active sites) onto the molecule (**5**). One of the C_2-chirogenic sites of the T_h-$(/C_3)$ orbit is represented by the symbol (①) in **9a**, which is generated by the attack. The attack of the mirror-image part (①) creates the diastereomeric intermediate (**9b**). If **9a** is energetically preferred, the corresponding C_2-molecule is created preferably.

If all of the CRs in Eq. 21 ($G_j(/G_k^{(j)})$'s) satisfy $G_k^{(j)}H=G_j$, then each subduction represented by Eq. 31 produces one orbit (Theorem 9). This means that there appears no division of each orbit during the process of converting G_j into H_j. Thus, the site governed by G_j-$(/G_k^{(j)})$ is converted, with no division, into the one governed by $H(/H_l)$(for $\exists l$), where $|G_j|/|G_k^{(j)}|=|H|/|H_l|$. Hence, this site is not an **H**-chirogenic site but $\geqslant G_j$-chirogenic site.

The following corollary is practically important, since its chemical meaning is quite concrete.

Corollary 2. *Each G_i-ligand in a $G(/G_i)$ orbit is a G_i-chirogenic site.*

Proof. Let G_i and G_j be chiral subgroups of **G**. Suppose that G_j is an arbitrary nearest supergroup of G_i. We consider a coset representation acting on G_it_1 or $\Omega_1(t_1=I)$. The stabilizer of $G_it_1(\Omega_1)$ is G_i, under the actions of **G**, of G_j and of G_i. Hence, the orbit containing G_it_1 (or Ω_1) is subject to $|G|/|G_i|$-membered $G(/G_i)$ in the case of **G**; to $|G_j|/|G_i|$-membered $G_j(/G_i)$ in the case of G_j; and to one-membered $G_i(/G_i)$ in the case of G_i. If the second step of the desymmetrization ($G\rightarrow G_j\rightarrow G_i$ (i.e. $G_j(/G_i)\downarrow G_i$)) produces no division of the orbit, then Theorem 9 affords $G_iG_i=G_j$. It follows that $G_i=G_j$. Hence, there exists no such G_j.

This corollary indicates that we can produce a G_i molecule by differentiating one of the G_i-ligands in Ω^+ from the counterpart in Ω^+. Although there are $|G|/|G_i|$ ways for selecting such a chirogenic site, they produce homomers that are chemically identical.

It is rather tedeous task to determine chirogenic sites by means of Theorem 10. A desymmetrization lattice[8] is effective to determine such chirogenic sites of an orbits. Figure 7 depicts the desymmetrization lattice of $D_{2d}(/C_2')$. Compare $D_2(/C_2')+D_2(/D_2'')$ and $2C_2(/C_1)$. Thus, the orbits of the D_2 are not divided in the process of converting into the C_2. This fact is equivalent to the fact that Theorem 10 holds for this case. Hence, the $C_2(/C_1)$ part in the $D_{2d}(/C_2')$ orbit is not a C_2-chirogenic site. This means that there is no direct method of generating a C_2-molecule from the $D_{2d}(/C_2')$ orbit.

On the other hand, there is a direct method of generating a C_2'-molecule from the $D_{2d}(/C_2')$ orbit by the inspection of the desymmetrization lattice. This result is alternatively verified by Corollary 2.

Special Cases. In the preceding discussion, the chiral subgroup **H** ($\leqslant G_j$) is examined. The **H** part in Ω^+ can be differentiated from the mirror image in Ω^-, if Theorem 10 holds for all of the nearest supergroups G_j. It should be

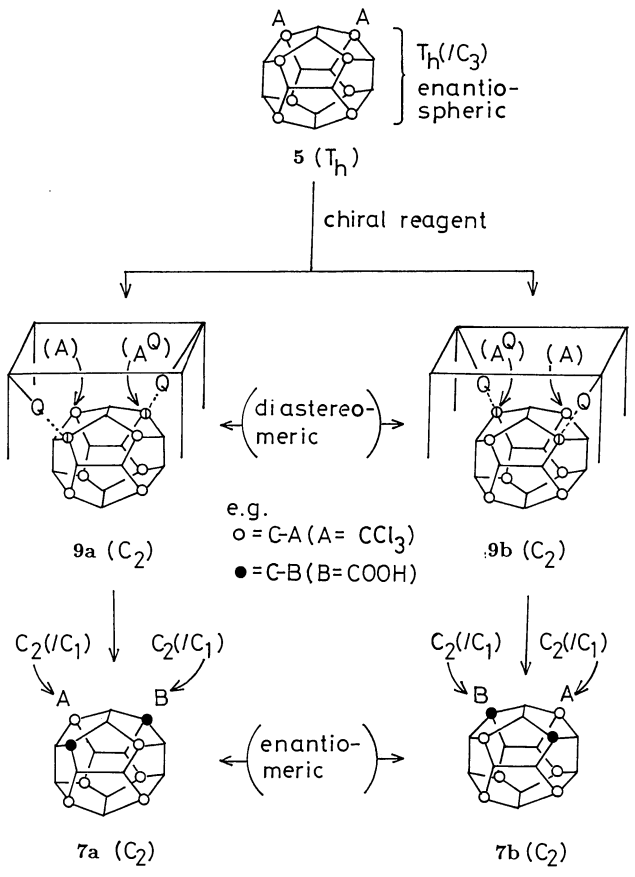

Fig. 6. A potential chiral synthesis generating C_2 molecules from a T_h molecule.

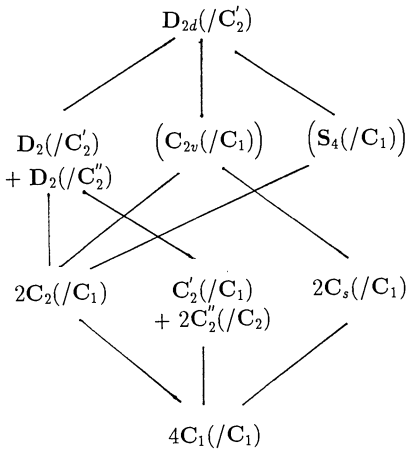

Fig. 7. Desymmetrization lattice of $D_{2d}(/C_2')$.

noted that the combination of the two parts does not always construct a group.

With respect to this point, we have the following theorem in general.

Theorem 11. *Let* $\mathbf{H}$ *be a chiral subgroup of an achiral group* $\mathbf{G}$ *and* u_1 *be an improper rotation contained in* $\mathbf{G}$. *If* $\widetilde{\mathbf{H}}=\mathbf{H}+\mathbf{H}u_1$ *is a subgroup of* $\mathbf{G}$, *then we have* $u_1\mathbf{H}=\mathbf{H}u_1$ *and* $u_1u_1\in\mathbf{H}$. *Conversely, if the relations* $u_1\mathbf{H}=\mathbf{H}u_1$ *and* $u_1u_1\in\mathbf{H}$ *hold, then* $\widetilde{\mathbf{H}}$ *is a subgroup of* $\mathbf{G}$.

Proof. (a) Suppose that $u_1\mathbf{H}=\mathbf{H}u_1$ and $u_1u_1\in\mathbf{H}$. (i) For $\forall a,b\in\mathbf{H}$, we have $ab^{-1}\in\mathbf{H}\subseteq\widetilde{\mathbf{H}}$, since $\mathbf{H}$ is a group. (ii) Consider $\forall a\in\mathbf{H}$ and $\forall b\in\mathbf{H}u_1$. There exists $b'\in\mathbf{H}$ that satisfies $b=b'u_1\in\mathbf{H}u_1$. By means of the above assumption, we have $u_1u_1=c\in\mathbf{H}$ for $\exists c\in\mathbf{H}$, $u_1c^{-1}=c'u_1$ for $\exists c'\in\mathbf{H}$, and $u_1(b')^{-1}=b''u_1$ for $\exists b''\in\mathbf{H}$. It follows that $ab^{-1}au_1^{-1}(b')^{-1}au_1c^{-1}(b')^{-1}=ac'b''u_1\in\mathbf{H}u_1\subseteq\widetilde{\mathbf{H}}$. (iii) If $a\in\mathbf{H}u_1$ and $b\in\mathbf{H}u_1$, then there exist $a',b'\in\mathbf{H}$ that satisfy $a=a'u_1\in\mathbf{H}u_1$ and $b=b'u_1\in\mathbf{H}u_1$. It follows that $ab^{-1}=a'u_1u_1^{-1}(b')^{-1}=a'(b')^{-1}\in\mathbf{H}\subseteq\widetilde{\mathbf{H}}$, On the basis of (i), (ii), and (iii), $\mathbf{H}$ is a group.

(b) Suppose that $\widetilde{\mathbf{H}}=\mathbf{H}+\mathbf{H}u_1$ is a subgroup of $\mathbf{G}$. Since $\mathbf{H}u_1$ is the set of all improper rotations in $\widetilde{\mathbf{H}}$ and $u_1\mathbf{H}$ is also the set of all improper rotations $\widetilde{\mathbf{H}}$, they must be equal. It follows that $\mathbf{H}u_1=u_1\mathbf{H}$. Since u_1 is an improper rotation, we have $u_1^{-1}\in\mathbf{H}u_1$. Since we take $u_1u_1=c$, we have $cu_1^{-1}=u_1\in\mathbf{H}u_1$. This means that $c\in\mathbf{H}$. Hence, we have $u_1u_1=c\in\mathbf{H}$.

In continuation of the preceding section, suppose that $\mathbf{H}$ is the nearest subgroup of $\mathbf{G}_j$ and $\mathbf{H}\leqslant\mathbf{G}_j\leqslant\mathbf{G}^{\max}\leqslant\mathbf{G}$. Suppose that $\mathbf{G}$ contains u_1 satisfying $u_1u_1\in\mathbf{H}$ as an improper rotation and that $\mathbf{H}u_1=u_1\mathbf{H}$. Then, Theorem 11 indicates that we are able to obtain the point group $\widetilde{\mathbf{H}}$ ($\leqslant\mathbf{G}$) that contains $\mathbf{H}$ as the maximum chiral subgroup; i.e., $\widetilde{\mathbf{H}}$ $\{h,hu_1|\forall h\in\mathbf{H}\}=\mathbf{H}+\mathbf{H}u_1$. Let us examine a subduction represented by $\mathbf{G}(/\mathbf{G}_i)\downarrow\widetilde{\mathbf{H}}$, where $\mathbf{G}(/\mathbf{G}_i)$ is enantiospheric. Since the relationship between $\widetilde{\mathbf{H}}(/\mathbf{H}_l)$ and $\mathbf{H}(/\mathbf{H}_l)$ is the same as that between $\mathbf{G}(/\mathbf{G}_i)$ and $\mathbf{G}^{\max}$-$(/\mathbf{G}_i)$, we arrive at the following theorem by means of Eq. 31.

Theorem 12. *Suppose that an enantiospheric orbit* $\mathbf{G}$-$(/\mathbf{G}_i)$ *is in accord with Case* [*a*] *of Theorem 4. If we can construct* $\widetilde{\mathbf{H}}$ *as above, the subduction* $\mathbf{G}(/\mathbf{G}_i)\downarrow\widetilde{\mathbf{H}}$ *is represented by*

$$\mathbf{G}(\mathbf{G}_i)\downarrow\widetilde{\mathbf{H}}=\sum_{l=1}^{{}^{v}\mathbf{H}}\eta_l^{(ij)}\widetilde{\mathbf{H}}(/\mathbf{H}_l), \tag{35}$$

where $\mathbf{H}_l$ *is chiral subgroups.*

The $\widetilde{\mathbf{H}}(/\mathbf{H}_l)$ orbits appearing in the right-hand side of Eq. 35 are enantiospheric. This theorem is exemplified by comparing $\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{C}_{2v}$ with $\mathbf{D}_{2d}(/\mathbf{C}_1)\downarrow\mathbf{C}_2$. Note that the summation in Eq. 35 is concerned with the chiral $\mathbf{H}$, not with $\widetilde{\mathbf{H}}$. In Eq. 35, $\widetilde{\mathbf{H}}(/\mathbf{H}_l)$ may be equivalent to $\widetilde{\mathbf{H}}_j$-$(/\mathbf{H}_l')$ if $\mathbf{H}_l$ is conjugate to $\mathbf{H}_l'$ as subgroups of $\widetilde{\mathbf{H}}$ and if they are not conjugate as subgroups of $\mathbf{H}$. For example, compare the subduction $\mathbf{T}_d(/\mathbf{C}_2)\downarrow\mathbf{D}_{2d}=\mathbf{D}_{2d}(/\mathbf{C}_2)+2\mathbf{D}_{2d}$-$(/\mathbf{C}_2')$ with $\mathbf{T}_d(/\mathbf{C}_2)\downarrow\mathbf{D}_2=\mathbf{D}_2(/\mathbf{C}_2)+\mathbf{D}_2(/\mathbf{C}_2')+\mathbf{D}_2(/\mathbf{C}_2'')$. It should be noted that, if there appears no division during the subduction $\mathbf{G}(/\mathbf{G}_i)\downarrow\widetilde{\mathbf{H}}$ as compared with the subduction to its supergroup(s), this process is not effective in chiral synthesis. For example, Fig. 7 contains such non-effective cases ($\mathbf{C}_{2v}$ and $\mathbf{S}_4$).

By means of Theorem 12, we have the following corollary.

Corollary 3. *a)* Let $\mathbf{G}(/\mathbf{G}_i)$ *be enantiospheric. If* $\mathbf{G}$ *contains* $\mathbf{C}_s$ *(a mirror plane) and* $\mathbf{C}_i$ *(inversion), then we have*

$$\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{C}_s=\frac{|\mathbf{G}|}{2|\mathbf{G}_i|}\mathbf{C}_s(/\mathbf{C}_1), \tag{36}$$

$$\mathbf{G}(/\mathbf{G}_i)\downarrow\mathbf{C}_i=\frac{|\mathbf{G}|}{2|\mathbf{G}_i|}\mathbf{C}_i(/\mathbf{C}_1). \tag{37}$$

Discussion

In preceding section, we have presented the theoretical foundation of asymmetric syntheses. In the light of the resulting logical framework, we reexamine asymmetric syntheses reported so far and propose alternative possibilities of chiral syntheses. Figure 8 illustrates a potential experiment in which an enantiospheric orbit is subject to $\mathbf{C}_s(/\mathbf{C}_1)$. The starting material (**10**) of the $\mathbf{C}_s$ symmetry has two CH_2OH ligands. We regard each ligand as A in the lump. Then the two A's are subject to $\mathbf{C}_s(/\mathbf{C}_1)$, belonging to an enantiospheric orbit. In order to obtain a chiral product, we must differentiate only two ligands belonging to the orbit. Suppose that a chiral reagent (Q) attacks either of ligands. Then, such an interaction as $CH_2OH\cdots Q$ (A^Q) appears; the attack produces a chiral environment. Either one of such possible intermediates (**11a** or **11b**) is energetically predominant and yields a final product of $\mathbf{C}_1$.

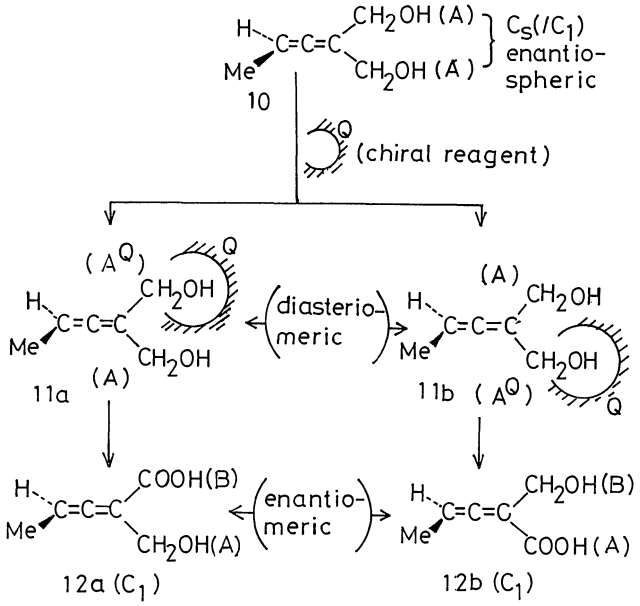

Fig. 8. A potential chiral synthesis generating $\mathbf{C}_1$ molecules from a $\mathbf{C}_s$ molecule.

All of the asymmetric syntheses reported so far[13] are classified to the above-described simple case, in which an enantiospheric orbit is governed by $C_s(/C_1)$. For an example of this type, Fuji[14] reported an asymmetric protonation of a dicarboxylate, in which two carboxylate groups belonging to an enantiospheric orbit are differentiated. These reactions have been classified into enantiotopic-group-differentiating reactions.[15] In the light of the present notation, they are characterized as $C_s(/C_1)\downarrow C_1$-ligand-differentiating reactions. An enantiospheric orbit of the faces of a carbonyl group or of the related functional group, which is subject to the $C_s(/C_1)$ representation, undergoes a chiral synthesis. For example, hydrogen transfers from chiral reducing agents to achiral substrates, asymmetric additions to alkenes, asymmetric syntheses at hetero atoms, and so forth have been reported.[13] Additional examples have been recently reviewed.[16] These reactions have been classified into enantiotopic-face-differentiating reactions.[15] They are characterized more specifically as $C_s(/C_1)\downarrow C_1$-face-differentiating reactions in terms of the present terminology.

The discussions in the previous section indicate that there can exist more general cases, in which an enantiospheric orbit is subject to a coset representation other than $C_s(/C_1)$. Figure 9 shows a potential experiment that produces a C_2 molecule (**15a** or **15b**) from an S_4 molecule (**13**). The two carbonyl groups belong to an enantiospheric orbit subject to $S_4(/C_2)$. The attack of a chiral reducing agent perturbs the carbonyls to belong to disteromeric environments (**14** and **14b**), either of which is energetically preferred. Hence, either one of an enantiomeric pair (**15a** and **15b**) is produced predominantly. This is characterized as an $S_4(/C_2)\downarrow C_2$-group-differentiating reaction. The reaction is a novel type of chiral reaction in the sense that it involves no explicit faces to be differentiated. Thus, the two carbonyl groups in **13** are associated with each other not by a mirror plane, but by S_4 operation. To the best of our knowledge, this type of reactions has never been reported. The mode of the differentiation of **13** (Fig. 9) is different from that of **10** (Fig. 8).

Example 9 (Fig. 6) illustrates a $T_h(/C_3)\downarrow C_2$-group-differentiating reaction. It is to be noted that $T_h(/C_3)\downarrow T$-group-differentiating reactions (e.g. **5**→**6a** or **6b**) and $T_h(/C_3)C_3$-group-differentiating reactions (e.g. **5**→**8a** or **8b**) are also possible. It is challenging problems to realize such novel chiral syntheses. In

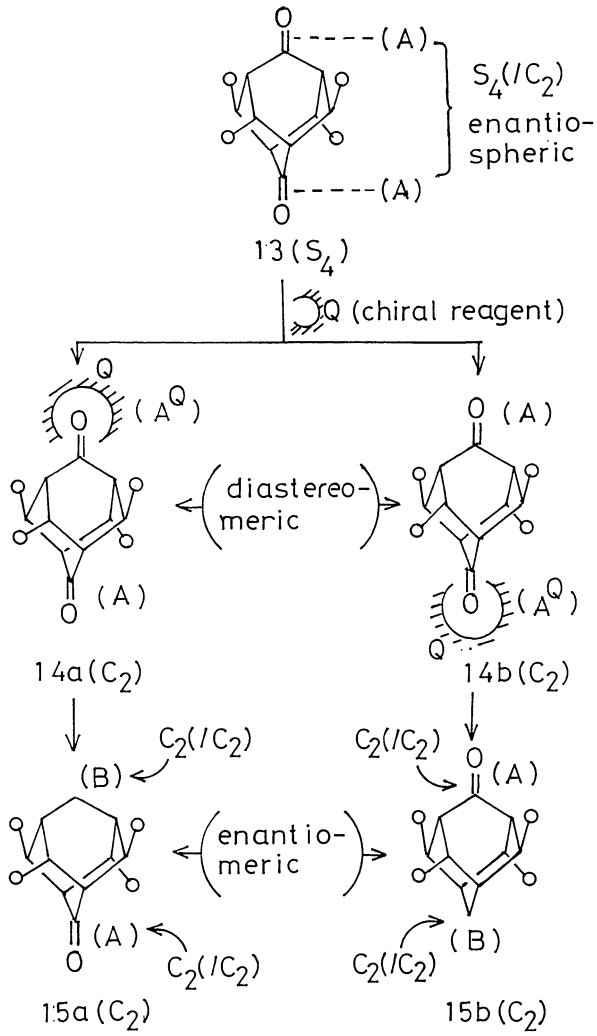

Fig. 9. A potential chiral synthesis generating C_2 molecules from a S_4 molecule.

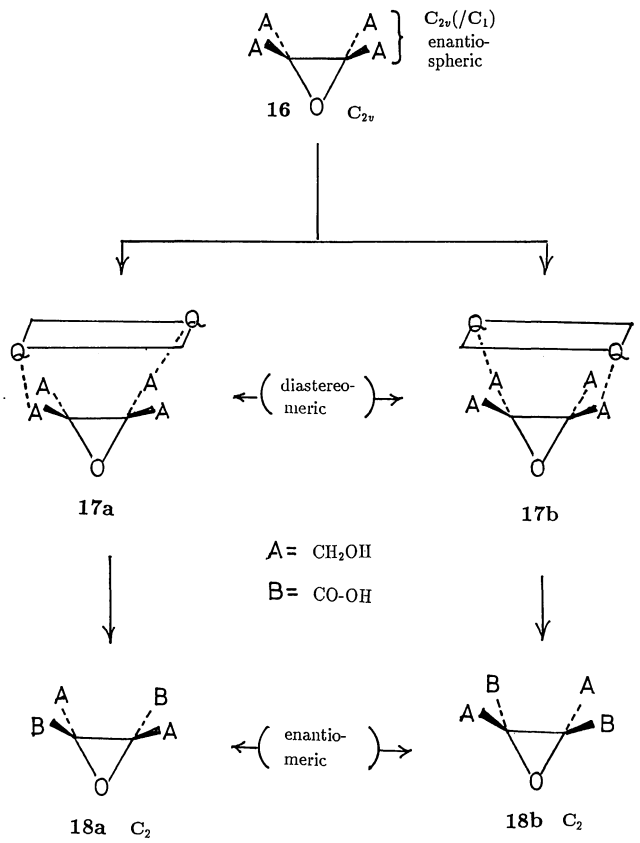

Fig. 10. A potential chiral synthesis generating C_2 molecules from a C_{2v} molecule.

particular, the $\mathbf{T}_h(/\mathbf{C}_3)\downarrow\mathbf{C}_3$-group-differentiating reaction can be accomplished if the reaction is ceased at the point that only one group of the eight functional groups (Fig. 6) has been attacked. Note that this reaction is based on Corollary 2.

Let us examine the $\mathbf{C}_{2v}$-molecule (**16**), in which four CH_2OH ligands construct an orbit subject to $\mathbf{C}_{2v}(/\mathbf{C}_1)$. This orbit is enantiospheric and active to a chiral synthesis. Figure 10 indicates a model of chiral synthesis which produces a $\mathbf{C}_2$-molecule from a $\mathbf{C}_{2v}$-molecule. This process corresponds to the subduction represented by $\mathbf{C}_{2v}(/\mathbf{C}_1)\downarrow\mathbf{C}_2=2\mathbf{C}_2(/\mathbf{C}_1)$. We can consider a potential chiral reagent that has two chiral units (Q) in diagonal positions, which are concerned with a $\mathbf{C}_2$-chirogenic site of the substrate. Since the resulting intermediates (**17a** and **17b**) are diastereomeric, the energetically predominant intermediate yields either of enantiomeric products (**18a** or **18b**). We refer to this reaction as a $\mathbf{C}_{2v}(/\mathbf{C}_1)\downarrow\mathbf{C}_2$-group-differentiating reaction.

Conclusion

Prochirality is defined logically by examining the desymmetrization of an enantiospheric orbit. A chirogenic site in the enantiospheric orbit provides a basis of operating chiral syntheses.

(Received February 27, 1991)

The proton ENDOR spectra of the zinc-doped copper(II) acetate monohydrate single crystal were measured at 20 K. Hyperfine coupling tensors have been determined for the two protons of the water molecule at the axial position of the paramagnetic copper ion and a proton of the water forming the hydrogen bond with carboxylate oxygen at the equatorial plane of the copper ion. The axial water protons have small positive isotropic hyperfine couplings owing to the pseudo-contact interaction, and the equatorial water proton has a small negative one due to the spin polarization effect of the positive spin on the acetate oxygen through the hydrogen bond. The anisotropic hyperfine tensors of the former protons are interpreted by the dipolar interaction with the unpaired spin on the copper $d_{x^2-y^2}$ orbital. The anisotropic interaction of the latter protons indicates that the spin delocalizes onto the oxygen atoms of the acetate bridges. Based on these observed hyperfine interactions, the mechanism of the spin–spin interaction in the dimer complex is discussed.

Magnetic exchange interactions in metal dimer complexes continue to be a subject of much interest among chemists.[1] Copper(II) acetate monohydrate involving an antiferromagnetic coupled dimer has been widely studied, resulting in a long controversy concerning the exchange pathway in the dimer. Figgis and Martin initially proposed that the antiferromagnetic interaction is due to the existence of a δ-bond between the copper(II) ions.[2] Forster and Ballhausen employed a molecular orbital treatment, showing the importance of the copper–copper σ-bond.[3] Later, Hansen and Ballhausen used a weakly coupled chromophore model which included no direct copper–copper interaction to explain the antiferromagnetism.[4] Goodgame et al. considered that the direct metal–metal bond is not important for the antiferromagnetism and that the spin coupling occurs by a superexchange via the carboxylate bridge.[5] Since then, the superexchange mechanism has been favored by most authors. Much current research is being directed toward the development of a more complete understanding of the exchange mechanism; various physical methods (EPR,[6a] NMR,[6b] NQR,[6c] etc.) have been employed.

Revealing the spin distribution in the dimer would be useful in clarifying the mechanism of the antiferromagnetism. Copper(II) acetate monohydrate doped with zinc(II) ions shows paramagnetism with $S=1/2$ of the Cu–Zn dimer at a temperature below 50 K, since the host Cu–Cu dimer becomes completely diamagnetic. An unpaired electron occupies one of the so-called "magnetic orbitals" which is centered on a copper atom. Kokoszka et al. investigated a zinc-doped copper acetate monohydrate single crystal by EPR.[7] They found that the unpaired electron on the copper $d_{x^2-y^2}$ orbital interacts weakly with the zinc ion. Since the superexchange interaction appears to occur through the ligand orbitals, the ligand hyperfine (hf) couplings provide useful information concerning the mechanism of the antiferromagnetic interaction. The EPR spectra show a well-resolved copper hf structure, which lacks resolution of the ligand hf splittings.

In this paper we report on the proton ENDOR of single crystal of zinc-doped copper(II) acetate monohydrate. The observed proton hf coupling tensors are compared to those of the other monomeric copper(II) complexes and the exchange interaction mechanisms are discussed.

Experimental

Single crystals of zinc-doped copper(II) acetate monohydrate were obtained in the same manner as that described in a reference.[7] Isotope-enriched ^{63}Cu acetate (99%) was used to simplify the EPR and ENDOR spectra. A copper acetate monohydrate crystal is monoclinic with a space group $C2/c$, containing four dimeric molecules in a unit cell. There are two independent intermolecular hydrogen bonds between the hydrogen atom of the water and oxygen atom of the acetate bridge, as shown in Fig. 1.[8]

The EPR spectra were recorded on a Varian E112 X-band EPR spectrometer. The magnetic fields and microwave frequencies were measured by an Echo Electronic EFM 2000 NMR field meter and a Takedariken TR 5204 frequency counter, respectively. The ENDOR spectra were recorded on an EPR spectrometer equipped with a Varian E1700 ENDOR unit and an ENI 550L RF power amplifier. These measurements were carried out at 20 K using an Oxford ESR 9 cryostat. At this temperature the host copper-copper dimers became completely diamagnetic ($S=0$) and the only copper–zinc dimers ($S=1/2$) were observed in the EPR spectra.

Results

The angular dependence of the proton ENDOR spectra observed for the magnetic field in the bc^* plane are shown in Fig. 2. A large number of proton ENDOR signals were observed, and some ENDOR signals were split into doublet lines by nuclear spin–spin couplings at

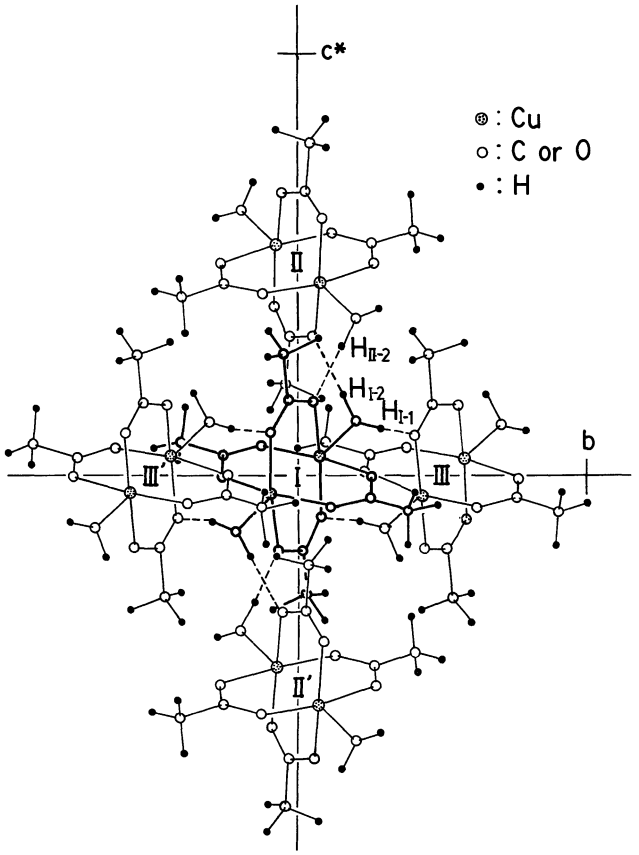

Fig. 1. Crystal structure of copper(II) acetate monohydrate projected onto the *bc** plane.

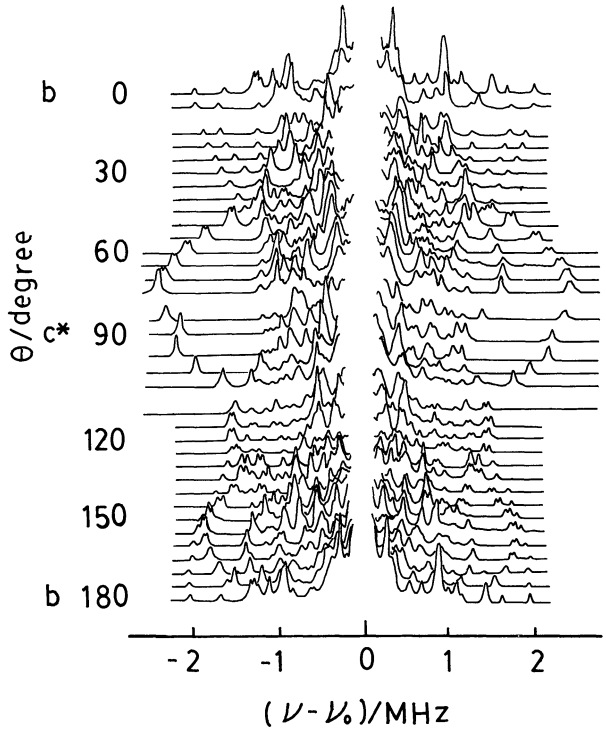

Fig. 2. Angular-dependence of ^{1}H ENDOR signals when the magnetic fields are in the *bc** plane.

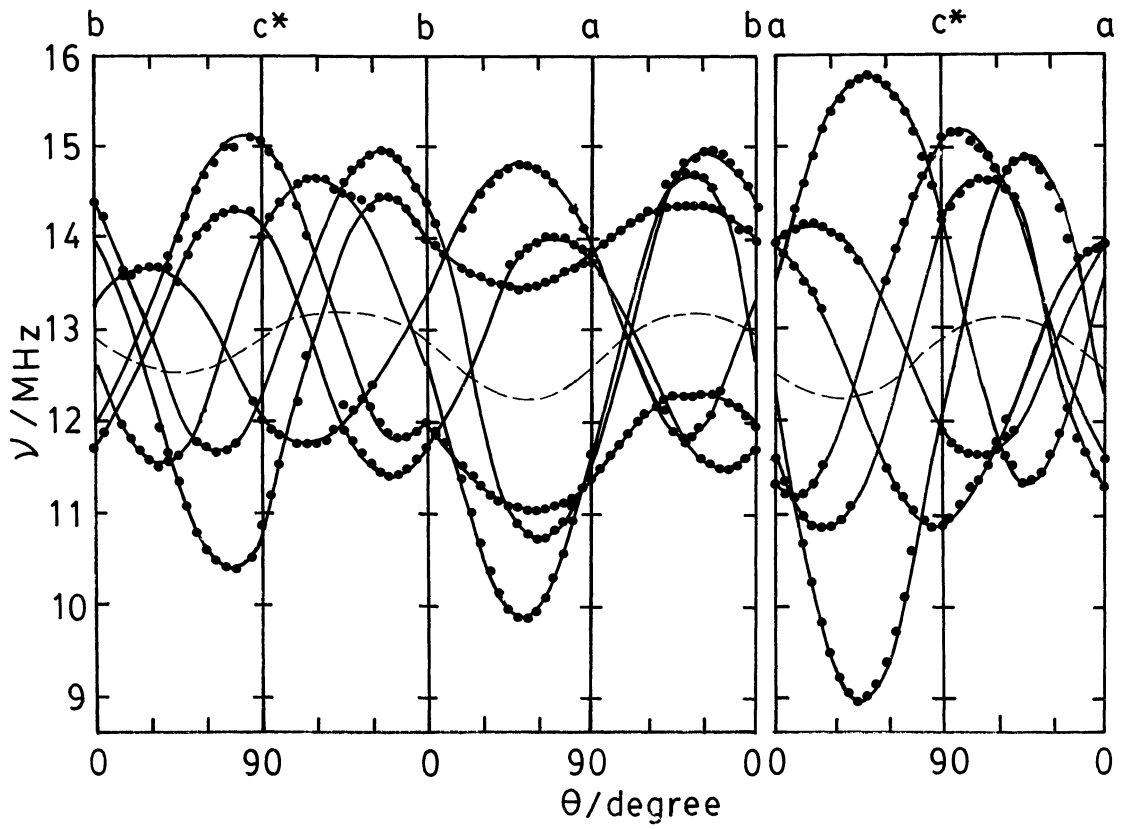

Fig. 3. Angular-dependence of ^{1}H ENDOR frequencies for rotations around the *a*-, *c**-, and *b*-axis. The broken line indicates the free proton frequency; the solid lines were calculated using the tensors of Table 1 and Eq. 1.

some crystal orientations. The ENDOR frequencies are given by

$$h\nu^{H}(M_s)=K^{H}(M_s)+h\nu(\text{2nd})+h\nu(\text{dipole}). \quad (1)$$

Although a full expression of each term was given in our previous paper,[9] it must be noted that $h\nu$(2nd) denotes a second order correction of the ENDOR frequencies due to an indirect coupling with the copper nuclei;[10] the $h\nu$(dipole) is the effect of nuclear spin–spin coupling between protons. This last term was not expressly included in the present analysis for the angular dependence of the ENDOR frequencies; however, the frequency of the center of the doublet splitting by the spin–spin coupling was used. Figure 3 shows the observed ENDOR frequencies for rotation about the *a*-, *c**-, and *b*-axis and the angular-dependent ENDOR frequencies computed by Eq. 1 and the parameters in Table 1. The signs of the hf couplings are not determinable from the conventional ENDOR technique and, hence, an assumption was made that the largest anisotropic hf principal value must be positive, since the anisotropic part of the proton hf coupling would be dominated by the dipole interaction with the spin on the metal ion. The assignment of the observed proton hf couplings to the proton positions was made by comparing their direction cosines with those of the Cu–H vectors calculated from the crystallographic data, since the principal axes of the proton hf couplings are considered to orient along the respective Cu–H directions. Three proton hf couplings could be assigned. Two of them were assigned to the protons of the water molecule coordinated to the copper ion (I-1 and I-2); the other was assigned to the proton of the water molecule which is coordinated to the neighboring complex and is involved in the hydrogen bond with the acetate oxygen (II-2). The agreement between the direction cosines of the hf coupling tensors and the crystallographic Cu–H vectors is satisfactory. The Cu–H distances calculated from the anisotropic dipolar couplings by the use of the point-dipole approximation also agree with those from the crystallographic data.

Discussion

Isotropic hf Coupling. The protons at I-1 and I-2 positions have small positive isotropic hf coupling constants, whereas the II-2 proton has a small negative one (Table 2). Similar results have been reported for $[Cu(H_2O)_6]^{2+}$ in the zinc Tutton salt by Atherton and Horsewill.[10] They found that the protons of the axial waters in $[Cu(H_2O)_6]^{2+}$ have small positive isotropic hf couplings (mean value a_{av}=0.15 MHz), and the protons of the equatorial one have negative couplings (mean value a_{av}= −0.9 MHz).

The observed hf coupling matrix ($\boldsymbol{A}$) is the sum of three contributions,

$$\boldsymbol{A}=a\boldsymbol{E}+\boldsymbol{A}^{\circ}+\boldsymbol{A}^{L}, \quad (2)$$

where the first term is the Fermi contact coupling, the second the anisotropic dipolar interaction between the electron spin and the nucleus and the third the orbital contribution to the hf couplings. Although the anisotropic spin-only coupling matrix ($\boldsymbol{A}^{\circ}$) is traceless, its orbital counterpart ($\boldsymbol{A}^{L}$) is not. The isotropic part of $\boldsymbol{A}^{L}$ is usually called the pseudo-contact interaction. Atherton and Horsewill interpreted the negative hf couplings of the equatorial protons as being the result of

II-2	−0.18	−0.19	0.01

spin polarization through the OH bond by unpaired spin delocalized on the water nonbonding orbital due to an overlap with the copper unpaired spin orbital; the positive coupling of the axial protons was interpreted as arising mainly from a pseudo-contact hf interaction. In the present case the small negative spin density ($\rho_H = -0.00013$) at proton II-2 may be attributed to a spin polarization effect through the hydrogen bond due to the positive spin on the acetate oxygen, which is introduced by an overlap with the singly occupied copper 3d-orbital; this is similar to the case of protons 3 and 3′ in copper-doped zinc(II) acetate dihydrate.[11] On the other hand, the spin densities at the protons in the axial water molecule are nearly zero, indicating that neither spin delocalization nor spin polarization effects exist at the axial water molecule.

Anisotropic Coupling. The anisotropic parts of the hf tensors arise from dipolar interactions between the electron spin centered on the copper ion and the nuclear spin of the protons. However, a conventional point-dipole approximation used to evaluate the anisotropic hf tensor is not suitable for the case in which the metal-ligand distance is less than about 0.3 nm. In such a case, it is necessary to calculate the following matrix element:[12]

$$A_{\text{aniso}} = \langle \psi \mid H_{\text{dipole}} \mid \psi \rangle ; \quad (3)$$

here, H_{dipole} denotes the dipole–dipole interaction Hamiltonian and ψ is the unpaired electron orbital. Taking the $d_{x^2-y^2}$ or d_{z^2} orbital for ψ, three principal values of the tensor can be expressed in a first-order approximation as follows:

$$A_{\xi\xi} = 2PR^{-3}[1 - ((12/7)\cos^2\theta - (6/7)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}]$$

$$A_{\eta\eta} = -PR^{-3}[1 - ((12/7)\cos^2\theta - (9/7)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}] \quad (3)$$

$$A_{\zeta\zeta} = -PR^{-3}[1 - ((12/7)\cos^2\theta - (3/7)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}],$$

for $d_{x^2-y^2}$, and

$$A_{\xi\xi} = 2PR^{-3}[1 + ((6/7)\cos^2\theta - (3/7)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}]$$

$$A_{\eta\eta} = -PR^{-3}[1 + ((6/7)\cos^2\theta - (9/14)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}] \quad (4)$$

$$A_{\zeta\zeta} = -PR^{-3}[1 + ((6/7)\cos^2\theta - (3/14)\sin^2\theta)R^{-2}\langle r^2\rangle_{3d}],$$

for d_{z^2}. The principal axes ($\xi\eta\zeta$) are shown in Fig. 4, $P = g\beta_e g_n \beta_n$, R is the metal-proton distance, and θ is the angle between the z-axis and the metal-proton direction. If $R^2 \gg \langle r^2\rangle_{3d}$, the term $R^{-2}\langle r^2\rangle_{3d}$ may be ignored and Eqs. 3 and 4 are reduced to the point-dipole approximation. The anisotropic hf tensors shown in Table 3 were obtained by using $\langle r^2\rangle_{3d} = 2.88\times10^{-3}$ nm^2 for Cu^{2+} reported by Freeman et al.[13] For the protons of the I-1 and I-2 positions, the agreement between the tensors derived from the $d_{x^2-y^2}$ configuration and the experimentally determinations are satisfactory, but the

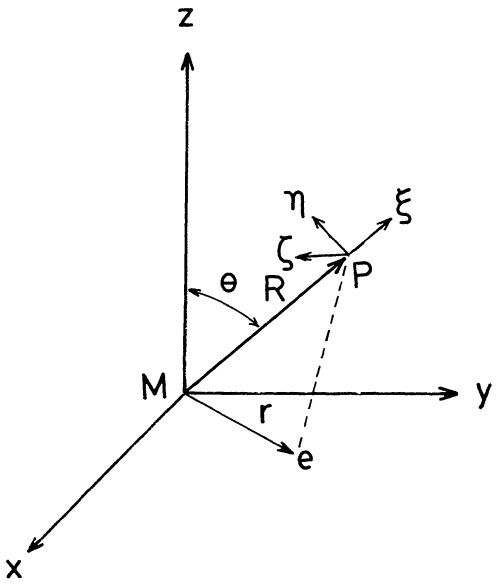

Fig. 4. Coordinate systems used for calculating the dipolar interaction between the electron spin (e) on the metal ion (M) and the nuclear spin of the proton (P). The (xyz) Cartesian coordinate system is the molecular axes of the metal complex. The (ξ, η, ζ) Cartesian coordinate system is the principal axes of the dipolar coupling tensor determined by taking the ξ-axis to be along the M–P direction and η to be in the $z\xi$ plane.

		−2.44	−2.29	−2.24						

a) Observed tensor. b) Calculated for the $d_{x^2-y^2}$ configuration. c) Calculated for the d_{z^2} configuration.

d_{z^2} configuration derives large hf tensors. The calculated hf tensors with both configurations for the proton II-2 are smaller than the observed hf tensor, suggesting the presence of a significant spin delocalization on the acetate oxygen.

Spin Distribution and Exchange Mechanism. In the copper(II) acetate monohydrate, two singly occupied electrons on each Cu atom interact with each other, making the triplet state energy become higher by 284 cm^{-1} than that of the singlet state.[2] In Cu–Zn dimers one unpaired electron centered on the copper atom is present. Since the unpaired electron orbital of the Cu–Zn dimer corresponds to the magnetic orbital of Cu–Cu dimer, the spin distribution of Cu–Zn dimer provides useful information concerning the magnetic orbital. The ground state configuration was initially assigned to $d_{x^2-y^2}$ by Figgis and Martin[2] and Ross;[14] they suggested that the antiferromagnetisum can be ascribed to a Cu–Cu interaction through the δ-bond; in the sustained by Forster and Ballhausen,[3] however, a Cu–Cu interaction through the σ-bond were proposed, based on the d_{z^2} ground state configuration. The isotropic proton hf couplings of the axial water molecule indicate that the spin density on the axial water molecule expected for the d_{z^2} configuration is not substantial, and that the anisotropic hf couplings of the protons are in favor of the $d_{x^2-y^2}$ ground state. Also, the isotropic and anisotropic hf coupling of the proton II-2 indicates the presence of a significant spin delocallization onto the acetate oxygen atoms from the copper $d_{x^2-y^2}$ orbital, and the spin polarization effect of the acetate ligands in the Cu–Zn dimer leads to a double-spin polarization contribution in the Cu–Cu dimer.[15] The results of the proton ENDOR study strongly support a superexchange interaction propagated by acetate bridges.

Equations of State for the Lennard-Jones Mixtures at High Temperatures

Shin-ichi WAKAYAMA, Mitsuo KOSHI,* and Hiroyuki MATSUI
Department of Reaction Chemistry, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113
(Received March 25, 1991)

The virial coefficients for binary mixtures at high temperatures were directly calculated up to the fifth term by use of a Monte-Carlo integration technique and the various empirical mixing rules that have been proposed for estimating mixture virial coefficients were tested. It was found that these empirical mixing rules tend to fail as the molecular size differences increased. Accurate compressibility of the Lennard-Jones binary mixtures were also calculated by adopting Metropolis Monte-Carlo simulations in order to examine validity of the fifth order virial equation of state. At high temperature (T^*=20), the compressibility factors calculated by the fifth order virial equation of state were in good agreement with the results of the simulations in the range of $V/b \geq 0.4$ ($b=2\pi\sigma^3 N_a/3$). It was also found that the van der Waals one fluid theory could provide accurate compressibility factors even for mixtures of molecules with large size differences at high temperatures.

Although detailed knowledge of the equation of state (EOS) for mixtures is required for the calculations of equilibrium properties of high density multi-component systems such as chemical equilibrium behind detonation waves, precise theoretical determination of the EOS for high density mixtures still remains very difficult. Because of this, various types of empirical or semi-empirical EOS have been widely used in many practical applications. Recent progress in Monte-Carlo and molecular dynamics simulations enables the direct calculations of properties of dense mixtures and the validity of empirical EOS has been examined against these simulation results.[1-4] However these examinations are often limited to relatively low temperature region. The accuracy of empirical EOS for dense mixtures at high temperatures still remains unclear. The primary purpose of the present study is to test the applicability of the virial EOS and the van der Waals one fluid theory to the prediction of properties of dense mixtures at high temperatures. Such examinations are especially important in exploring an adequate EOS for the calculations of detonation properties.

The virial EOS,

$$\frac{pV}{RT}=1+\frac{B(T)}{V}+\frac{C(T)}{V^2}+\frac{D(T)}{V^3}+\frac{E(T)}{V^4}+\cdots, \quad (1)$$

has several advantages for many practical applications. Its simple analytical form is well suitable to the determination of complex chemical equilibrium composition by minimizing the Gibbs free energy. In principle, the virial coefficients can be calculated theoretically on the basis of intermolecular potentials. However calculations of virial coefficients for mixtures are rather difficult; specially, exact calculation of the third and higher order virial coefficients for mixtures has not been performed. Although various empirical mixing rules for mixture virial coefficients[5-7] have been used in the past, these mixing rules have weak theoretical basis and therefore their validity has to be tested by comparing with exact mixture virial coefficients.

In the present study, the virial coefficients for binary mixtures of molecules interacting with Lennard-Jones (L-J) 12-6 potentials were calculated numerically up to fifth term. Calculations were performed with a hypothetical Lorentz-Berthelot rule for unlike L-J parameters. Although this rule is very simple, relathionship of mixing rule between the unlike L-J parameters and the virial coefficients is not straightforward. Resulting virial coefficients were compared with those derived from empirical mixing rules over wide ranges of interaction potential parameters. In addition, exact compressibility of binary L-J mixtures were directly calculated by the use of Metropolis Monte-Carlo simulation and results were compared with compressibility factors calculated by the fourth order virial EOS for the binary mixtures.

An effective one component treatment of dense mixtures is generally used in many practical EOS. Among these, the van der Waals one-fluid (vdW1) theory is the most popular and its validity at low temperatures has been investigated by comparing with the results of Monte-Carlo[8] or Molecular Dynamics[9] computer simulations. These investigations suggested that applicability of the vdW1 theory was questionable for systems that contain molecules having quite different intermolecular potential parameters. Although the vdW1 theory has been frequently applied to the calculations of detonation properties,[10] its validity has to be examined. Compressibility factors obtained from the vdW1 theory were also compared with the results of the Metropolis Monte-Carlo simulations in order to clarify the applicability of the vdw1 theory at high temperatures.

1. Virial Coefficients for Binary L-J Mixtures

1-1 Calculation of Virial Coefficients. The virial coefficients for mixtures can be written as,

$$\begin{aligned} B_m &= \sum\sum X_i X_j B_{ij}, \\ C_m &= \sum\sum\sum X_i X_j X_k C_{ijk}, \\ D_m &= \sum\sum\sum\sum X_i X_j X_k X_l D_{ijkl}, \\ E_m &= \sum\sum\sum\sum\sum X_i X_j X_k X_l X_m E_{ijklm}, \end{aligned} \tag{2}$$

here X_i is the mole fraction of component i, and B_{ij}, C_{ijk},$\cdots$ are the virial coefficients which depend on intermolecular potentials for i, j, k,$\cdots\cdots$ molecules. For example, the coefficient D_{ijkl} depends on the potential energy functions between four molecules, i, j, k, and l, and can be expressed as a sum of the cluster integral. By using notations given by Rowlinson[11] for the irreducible cluster integral, the following expression for D_{ijkl} can be derived:

$$D_{ijkl} = -(D_4 + D_5 + D_6)/8. \tag{3}$$

Here, D_4, D_5, and D_6 are the integral of the product of Mayer F-functions. For an example, a term D_4 is expressed as follows,

$$D_4 = D_{4a} + D_{4b} + D_{4c}, \tag{4}$$

$$D_{4a} = \iiint f_{01} f_{12} f_{23} f_{30}\, dR_1 dR_2 dR_3, \tag{5a}$$

$$D_{4b} = \iiint f_{01} f_{13} f_{32} f_{20}\, dR_1 dR_2 dR_3, \tag{5b}$$

$$D_{4c} = \iiint f_{02} f_{21} f_{13} f_{30}\, dR_1 dR_2 dR_3, \tag{5c}$$

$$f_{ij} = \exp\left(-\frac{U_{ij}}{kT}\right) - 1. \tag{6}$$

Here, f_{ij} is a Mayer F-function, U_{ij} is the potential between molecules i and j, and R_i ($i \neq 0$) is the position vector between molecule i and molecule 0. It is noted that the values of D_{4a}, D_{4b}, and D_{4c} are all the same for a pure fluid, but they are different each other for the multi-component system. Similar expressions for other virial coefficients can also be derived by adopting the diagrams for the irreducible cluster integral given by Rowlinson.

Calculations of virial coefficients were performed for the Lennard-Jones (L-J) binary mixtures. Although the L-J potential is known to be inaccurate as a representation of the intermolecular interaction for high energy collisions, the L-J fluid provides a convenient model for testing various mixture theories. In the present calculations, the Lorentz-Berthelot mixing rule was used for unlike intermolecular interactions; i.e., the potential energy between unlike molecules i and j is given by the equation;

$$U_{12} = 4\varepsilon_{12}((\sigma_{12}/r)^{12} - (\varepsilon_{12}/r)^6). \tag{7}$$

The L-J parameters for unlike interaction, ε_{12} and σ_{12} are calculated from the L-J parameters for a pure fluid;

$$\varepsilon_{12} = (\varepsilon_{11}\varepsilon_{22})^{1/2} = \varepsilon_{11}\alpha^{1/2}, \tag{8}$$

$$\sigma_{12} = (\sigma_{11} + \sigma_{22})/2 = \sigma_{11}(1 + \eta)/2, \tag{9}$$

here, $\alpha = \varepsilon_{22}/\varepsilon_{11}$ and $\eta = \sigma_{22}/\sigma_{11}$.

The second virial coefficient for the binary mixture, B_{12}, is directly obtained form the reduced second virial coefficient, $B^*(T^*)$, for the pure fluid;

$$B_{12}(T^*_{12}) = b_{12} B^*(T^*_{12}), \tag{10}$$

here $T^*_{12} = kT/\varepsilon_{12}$ and $b_{12} = 2\pi\sigma_{12}^3 N_a/3$ (N_a is the Avogadro number). In order to obtain higher-order virial coefficients for mixtures, various types of irreducible cluster integrals such as given in Eq. 5 have to be calculated. Although Barker et al.[12] have used the Simpson's formula to integrate these cluster integrals for a pure fluid, it is quite difficult to apply their method to a multi-component system. A numerical integration technique proposed by Conroy[13] was employed in the present calculation. Points are selected at random in space of the integration variables and the integrands are evaluated at these points. It was found that the mean value of the integrands did not converge well to the integral unless large number of points were used. However, the calculations were speeded up by employing a stratified sampling technique. For the calculation of the third virial coefficients, the intermolecular distance in the range of 0.001σ to 10σ was divided into 4 regions. These segments of intermolecular distance construct 4^2 sub-spaces of the integration variables (*strata*). Sampling points in each strata were selected by using quasi-random numbers.[13] In case of fourth and fifth virial coefficients, intermolecular distances were divided into 9 and 10 regions so that 9^3 and 10^4 strata were composed for fourth and fifth virial coefficients, respectively. It was found that total numbers of 1.6×10^6, 7.29×10^6, and 1×10^8 sampling points were required for the calculation of the third, forth, and fifth virial coefficients in order to achieve the relative accuracy within 1%.

The fifth virial coefficient for a pure fluid at $T^*=20$ were also calculated to test the integration scheme. A value of 0.0207 for the normalized fifth virial coefficient, $E_{11111}^* = E_{11111}/b_{11}^4$, is in good agreement with a value of 0.0209 calculated by Barker et al.[12] The normalized virial coefficients for unlike interactions, C^*_{ijk}, D^*_{ijkl}, and E^*_{ijklm}, were calculated at $T^*_{11}=20$ for 'σ-equal' fluid ($\eta=1$) and 'ε-equal' fluid ($\alpha=1$); results are summarized in Tables 1 and 2, respectively. Calculations of the fifth virial coefficient were only performed for parameter sets of $\alpha=1$, $\eta=2$ and $\alpha=3$, $\eta=1$, since these calculations needed very long CPU time (120 min on Cray X-MP/416).

1-2 Comparisons with Empirical Virial Coefficients for Mixtures. Although several empirical virial coefficients for unlike interactions have been proposed in

the past, these have weak theoretical basis and the validity of empirical formulae for the fourth and fifth coefficients has never been tested against results of strict numerical calculations. Among these, following three approximations for mixture virial coefficients were tested.

(i) Based on the statistical mechanical expression of the third virial coefficient, Orentlincher et al.[5] proposed the following expression,

$$C_{ijk}=(C_{ij}C_{jk}C_{ki})^{1/2}. \tag{11}$$

The coefficient C_{ij} is defined by a similar relation to Eq. 10:

$$C_{ij}=b_{ij}^2C^*(T^*_{ij}). \tag{12}$$

Here C^* is the reduced virial coefficient for a pure fluid.

(ii) Rowlinson et al.[6] have examined several scaling approximations for mixture virial coefficients by comparing with exact values of C_{112}. They recommended to use the following expressions:

$$C_{ijk}=(b_{ij}b_{jk}b_{ki})^{2/3}C^*(kT/\varepsilon_{ijk}), \tag{13}$$

$$\varepsilon_{ijk}=(\varepsilon_{ij}\varepsilon_{jk}\varepsilon_{ki})^{1/3}. \tag{14}$$

(iii) McHenry[7] proposed an empirical formula given below:

$$C_{ijk}=b_{ijk}^2C^*(kT/\varepsilon_{ijk}), \tag{15}$$

$$b_{ijk}=2\pi[(\sigma_{ij}+\sigma_{jk}+\sigma_{ki})/3]^3N_a/3. \tag{16}$$

Extension of these mixing rules (i)—(iii) to higher order virial coefficients is straightforward. In the above equations, the reduced virial coefficients for a pure fluid, $B^*(T^*)$, $C^*(T^*)$,$\cdots$, are required to calculate mixture virial coefficients. These values were obtained by a spline interpolation of the pure-component virial coefficients given by Barker et al.[12] Resulting third and fourth virial coefficients based on the approximations (i) and (ii) are compared with the values calculated by the direct numerical integration in Fig. 1 for 'σ-equal' fluid as a function of α. It is noted that the approximations (ii) and (iii) give the same results for σ-equal fluid. As can be seen in the figure, the approximation (ii) generally gives better agreement with the results of direct numerical calculations than the approximation (i). However, errors in approximations (i) and (ii) are within 5% in the range of $\varepsilon\leqslant 4$. Figure 2 shows comparisons of mixture virial coefficients based on the approximations (ii) and (iii) with those obtained by the numerical calculations for 'ε-equal' fluid as a function of the size parameter ratio, η. In this case, the approximation (ii) is also better than (iii), but its error is more than 10% at $\eta=2$ and is rapidly increasing with increasing the difference in molecular size.

At high temperature ($T^*_{11}=20$), it can be concluded that these empirical mixing rules (i)—(iii) for binary L-J mixtures give relatively small errors ($\leqslant 5\%$) for the mixture which contains molecules of similar size even if the L-J energy parameters of these molecules are quite different. However none of these approximations can

provide the precise third and fourth virial coefficients for mixtures containing molecules which have large difference in size.

2. Compressibility Factors at High Temperatures

2-1 Metropolis Monte-Carlo Calculation of Compressibility Factors. The compressibility factors for the L-J fluid of a single component has been widely studied by using Monte-Carlo[14-17] or molecular dynamics[18-22] simulations. Nicolas, Gubbins, Street, and Tildesley (NGST) proposed the EOS for L-J pure fluid which had 33 parameters.[14] These parameters were determined by fitting the compressibility factors to the results of their own molecular dynamics simulations together with many other results of Monte-Carlo and molecular dynamics calculations at $T^*\leqslant 6$ and $V/b\geqslant 0.4$ (V is the specific volume). Although the applicability of these simulations with limited number of molecules to much higher density range is not clear, Wood and Parker[1] showed that the Metropolis Monte-Carlo simulation[23] could be useful for the region of $V/b\geqslant 0.2$ at the temperature of $2T_c$ (T_c=the critical temperature). Since this density region is high enough for the application to many detonation problem, it might be interesting to calculate the high temperature compressibility factors by the Metropolis Monte-Carlo simulation.

In the present study, compressibility factors at high temperatures both for pure and multi-component systems were calculated by using Metropolis Monte-Carlo technique and the results were compared with the compressibility factors calculated by the virial EOS. The results presented here employed 256 particles in a cubic cell with periodic boundary conditions. A chain length of 10^5 was generated to achieve the convergence of the calculated pressures after first 6×10^4 chains were discard in order to ensure the complete relaxation of the system from the fcc initial configuration. A new configuration in the chains was constructed by moving a particle in the cell. A particle to be moved and its displacement were determined by random numbers. The rate of convergence with chain length was governed by a value of the maximum displacement of a particle to construct a new configuration in the chains. Optimum value for this maximum displacement was found to be 0.075σ.

Results of the Metropolis Monte-Carlo simulations for pure L-J fluid at $T^*=2.5$ and 20 are compared with compressibility factors calculated by the fifth order virial EOS in Fig. 3. As can be seen in the figure, the fifth order virial EOS is only valid in very low density region at $T^*=2.5$, whereas the virial series is readily converged at $T^*=20$ in the range of $V/b\leqslant 0.2$. At high temperatures, less terms seem to be needed to achieve the convergence of the virial series. In Fig. 3 compressibility factors calculated by the NGST EOS are also shown for comparison. Although the NGST EOS were derived from simulation data in the range of $0.5\leqslant T^*\leqslant 6$ and $0.4\leqslant V/b\leqslant 1.4$, results of the present Metropolis Monte-Carlo simulations are in good agreement with the NGST EOS in the range of $V/b\geqslant 0.2$ even at $T^*=20$. This indicates that the NGST EOS can be applicable at high temperatures for the calculation of detonation properties.

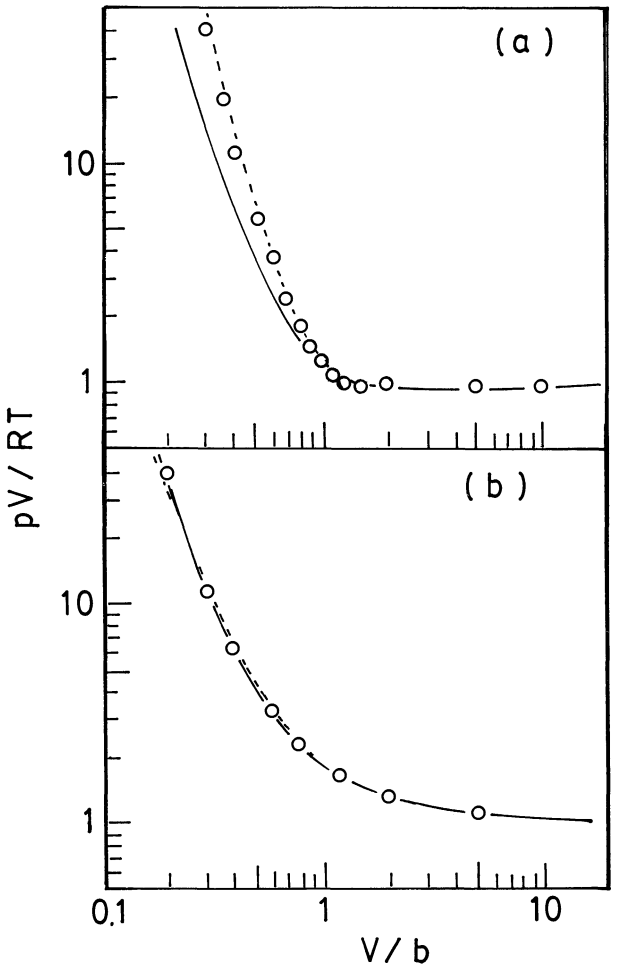

Fig. 3. Compressibility factor of the L-J pure fluid at $T^*=2.5$ (a) and $T^*=20$ (b). Circles: Metropolis Monte-Carlo simulation, solid line: the fifth order virial equation of state, broken line: the NGST equation of state (Ref. 14).

The compressibility factors for the equimolar L-J binary mixture obtained by the present Metropolis Monte-Carlo simulations at $T^*_{11}=20$ are shown in Fig. 4 for the ε-equal mixture with $\eta=2$ and in Fig. 5 for the σ-equal mixture with $\alpha=3$. In both cases the fifth order virial EOS gives excellent agreement with the present simulation results. These results suggest that the virial EOS converges much faster at high temperatures than at low temperatures in the range of $V/b \geqslant 0.2$.

2-2 Effective One Component Treatment of Dense Mixtures. The fifth order virial EOS gives accurate compressibility factors both for a single and multi-component systems at high temperatures, if the density is not too high. However, in many practical applications of the virial EOS such as calculations of chemical equilibrium in Chapman-Jouguet detonation, temperature derivatives of the virial coefficients are required. Since calculation of derivatives of virial coefficients by the Monte-Carlo or other numerical integration method is quite difficult, the analytical expression of the EOS is desirable for dense mixtures. The van der Waals one

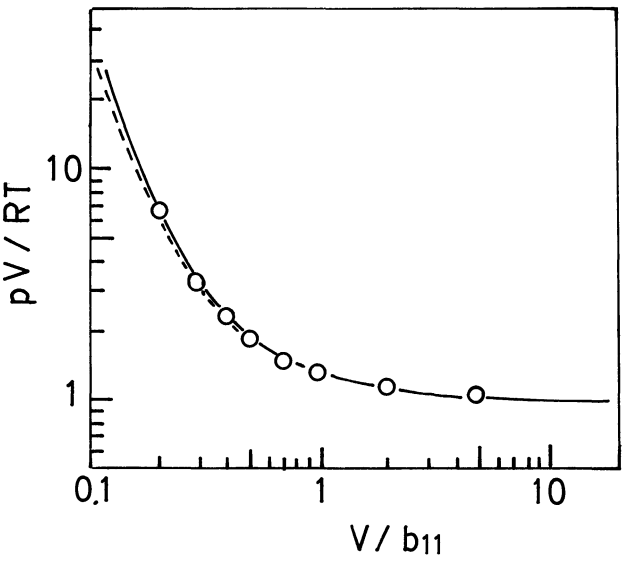

Fig. 4. Compressibility factor of the L-J binary mixture at $T^*_{11}=20$. $\alpha=\varepsilon_{11}/\varepsilon_{22}=1$ and $\eta=\sigma_{11}/\sigma_{22}=2$. Circles: Metropolis Monte-Carlo simulation, solid line: the fifth order virial equation of state, broken line: the vdW1 theory with the NGST equation of state (Ref. 14).

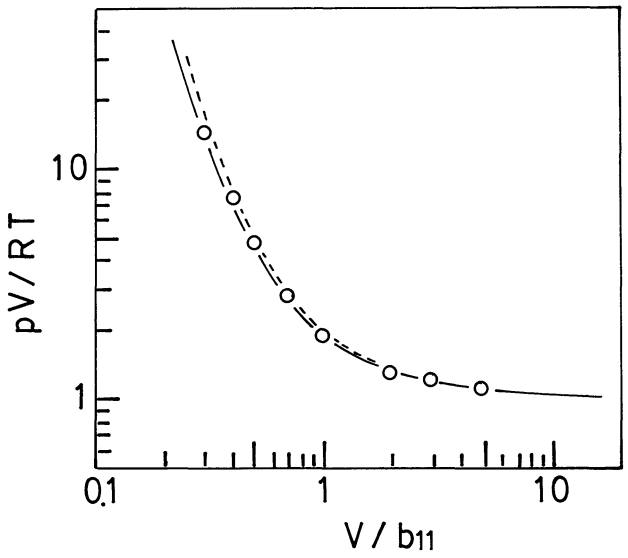

Fig. 5. Compressibility factor of the L-J binary mixture at $T^*_{11}=20$. $\alpha=\varepsilon_{11}/\varepsilon_{22}=3$ and $\eta=\sigma_{11}/\sigma_{22}=1$. Circles: Metropolis Monte-Carlo simulation, solid line: the fifth order virial equation of state, broken line: the vdW1 theory with the NGST equation of state (Ref. 14).

fluid theory is the one of the most widely used analytical expression of the equation of state in which a hypothetical effective one component potential is used for all of the intermolecular interactions. The parameters of this effective one component L-J potential, σ_m and ε_m, is given by following equations:

$$\sigma_m^3=\sum\sum X_i X_j \sigma_{ij}^3, \tag{17}$$

$$\varepsilon_m=\sum\sum X_i X_j \varepsilon_{ij} \sigma_{ij}^3 / \sigma_m^3. \tag{18}$$

By adopting the NGST EOS to define the EOS for this effective one component fluid, the compressibility factors were calculated and results are compared in Figs. 4 and 5. The van der Waals theory gives good agreement with the simulation results for ε-equal fluid and slightly higher values than the simulations for the mixtures of $\alpha=3$ and $\eta=1$. However the disagreement in this case is less than 10% in the range of $V/b \geqslant 0.4$.

It has been shown that the prediction of van der Waals mixture theory deteriorates as the molecular size difference between the species of the mixture increases at low temperatures.[2,4,24] Our results in Figs. 4 and 5 indicate that the accuracy of the van der Waals one fluid theory is considerably improved at high temperatures.

Recently Hamad and Mansoori[24] proposed a new dense fluid theory of mixtures which can be applicable for mixtures of molecules with large size and energy differences. Their theory is based on the effective one component treatment and the L-J parameters for mixtures are obtained by solving the following set of equations:

$$\frac{C^*(kT/\varepsilon_m)}{B^{*2}(kT/\varepsilon_m)} = \frac{\sum\sum\sum X_i X_j X_k C_{ijk}}{(\sum\sum X_i X_j B_{ij})^2}, \tag{19}$$

$$\sigma_m{}^3 = \frac{\sum\sum X_i X_j \sigma_{ij}{}^3 B^*(kT/\varepsilon_{ij})}{B^*(kT/\varepsilon_m)}. \tag{20}$$

The use of Eqs. 19 and 20 in calculating the mixture L-J parameters requires knowledge of the unlike interaction third virial coefficients. They used empirical mixing rules (i)—(iii) for C_{ijk} to solve Eqs. 19 and 20 and found their theory gave accurate values of Henry's constant, pressure, and internal energy of dense mixtures at low temperatures. At high temperatures, empirical mixing rules (i)—(iii) are not accurate, as shown in the previous section. We tried to solve Eqs. 19 and 20 with the exact unlike interaction third virial coefficients calculated by the Monte-Carlo integrations at $T^*{}_{11}=20$. However the attempt was failed because of the numerical instability. It is also noted that a value of σ_m in Eq. 20 is different from $\sigma_{11}=\sigma_{22}$ for the σ-equal mixtures if $\alpha \neq 1$. The applicability of Eqs. 19 and 20 at high temperatures seems to be limited unless the precise analytical expressions for C_{ijk} are available.

3. Conclusions

The virial coefficients for unlike intermolecular interactions were calculated up to the fifth order term by the direct numerical integration of cluster integral. Several empirical mixing rules for the unlike interaction virial coefficients were tested at high temperature against the results of the numerical integration. The accuracy of these approximate virial coefficients were found to be not enough for the mixtures which contained species having different molecular size.

Although the fifth order virial equation of state understimates the compressibility factors at low temperatures, it gives accurate compressibility factors of dense fluid mixtures in the range of $V/b \geqslant 0.4$ at $T^*=20$. It is also found that the van der Waals one fluid theory can provide good approximation for compressibility of mixtures regardless the difference in molecular size at high temperatures. The van der Waals one fluid theory with accurate analytical equation of state for a pure fluid such as the NGST equation of state is promising for predicting properties of high temperature dense mixtures.

The authors are grateful to Dr. T. Saito and Dr. Y. Watanabe (Cray Research Japan Ltd.) for helpful comments and discussions on our Monte-Carlo programs. A part of this work was supported by the 20th Research Grant of the Foundation for the Promotion of the Industrial Explosives Technology.

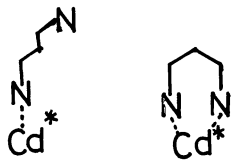
Cadmium (5^3P_1)-Photosensitized Luminescence of Some Aliphatic Diamines

Shunzo YAMAMOTO,* Yoshimi SUEISHI, and Norio NISHIMURA
Department of Chemistry, Faculty of Science, Okayama University, 3-1-1, Tsushima-naka, Okayama 700
(Received May 29, 1991)

The cadmium(5^3P_1)-photosensitized luminescence of some aliphatic diamines was studied by a steady-illumination method at temperatures between 230 and 330 °C. It was found that 1,2-ethylenediamine, *N*,*N*,*N*′,*N*′-tetramethyl-1,2-ethylenediamine, 1,3-propanediamine, and *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine have two emission bands (wavelengths at the peaks of these bands are about 450 and 550 nm), while *N*,*N*,*N*′,*N*′-tetramethylmethanediamine, *N*,*N*′-dimethylpiperazine, and triethylenediamine have only a short-wavelength band. From the temperature and pressure dependences of the emission intensities of the two bands, it had been concluded previously that these bands could be assigned to two kinds of 1 : 1 exciplexes between an excited cadmium atom and a diamine molecule. From the temperature dependence of the equilibrium constants between the two exciplexes which had been obtained from the ratio of the emission intensities of the two bands, the enthalpy and entropy changes of the equilibrium were evaluated. The cyclic exciplexes assigned to the long-wavelength band have smaller enthalpies and entropies than do the noncyclic exciplexes assigned to the short-wavelength band.

It is well known that excited triplet cadmium[1-4] and mercury[5,6] atoms react with the some compounds which contain a nitrogen or an oxygen atom (NH_3, H_2O, aliphatic amines, alcohols, and ethers) to form exciplexes, and that these exciplexes fluoresce. Recently, we have studied the cadmium-photosensitized reactions of some aliphatic diamines.[7] Two emission bands were observed in the blue and green regions for *N*,*N*,*N*′,*N*′-tetramethyl-1,2-ethylenediamine (TMEDA) and *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine (TMPDA), while only a short-wavelength band was observed for *N*,*N*′-dimethylpiperazine (DMP) and triethylenediamine (TEDA). From the temperature and pressure dependences of the emission intensities of these two bands, we have concluded that these bands can be assigned to two kinds of 1:1 exciplexes between an excited cadmium atom and a diamine molecule. The cyclic and noncyclic exciplexes which are shown in Scheme 1 were suggested for the long- and short-wavelength bands respectively. DMP and TEDA can not form cyclic exciplexes because of their rigid structures.



Scheme 1.

In the present study, the equilibrium constants between the two exciplexes were determined over the temperature range 230—330 °C, from which the enthalpy and entropy changes of the equilibrium can be estimated. The present paper reports on details conserning the cadmium-photosensitized luminescence of diamines and the quenching of the 326.1 nm resonance radiation by them.

Experimental

The experimental apparatus and the procedures for the measurements of resonance radiation at 326.1 nm and sensitized luminescence were similar to those used previously.[7,8] A part of the vacuum line was constructed using greaseless stopcocks in order to prevent any adhesion of sample gases to stopcock grease. A cylindrical quartz cell (17 mm in internal diameter and 20 cm in length) was kept in an electric furnace, the temperature of which was varied from 230 to 330 °C. A spiral cadmium discharge lamp made of Pyrex glass was placed in another furnace kept at 250 °C. The 228.8 nm resonance line was completely absorbed by the Pyrex glass. The visible lines from the lamp were removed with a glass band-pass filter (Toshiba, UV-D33S). The 326.1 nm resonance line was used to excite Cd($^3P_1$) atoms from cadmium vapor in the cell. The resonance radiation at 326.1 nm and the sensitized luminescence were monitored with a Hitachi spectrophotometer (Model 139). The wavelength dependence of the sensitivity of the monochromator-photomultiplier combination was determine by using standard fluorescence solutions of quinine sulfate and *N*,*N*-dimethyl-*m*-nitroaniline.[9]

N,*N*,*N*′,*N*′-Tetramethylmethanediamine (TMMDA), 1,2-ethylenediamine (EDA), TMEDA, 1,3-propanediamine (PDA), TMPDA, DMP, and TEDA were obtained from commercial sources (G. R. grade). These diamines were used after drying by potassium hydroxide and repeated trap-to-trap distillation. The cadmium metal used was of high-purity grade (99.9999%).

Results

Figure 1 shows the emission spectra obtained in the cadmium-photosensitized reaction of DMP and PDA at various temperatures between 230 and 300 °C. These spectra were corrected for the wavelength dependence of the sensitivity of the detection system. As is shown in Fig. 1, two emission bands are evident for PDA (broken lines show a separation of two bands for the spectra at 230 °C). The spectra for the PDA obtained at 230, 260, and 300 °C were adjusted to the same total intensity at two peaks. The profiles have an isosbestic point. The intensity of the short-wavelength band (band I) increases and that of the long-wavelength band (band II) decreases with increasing temperature. DMP shows one emission

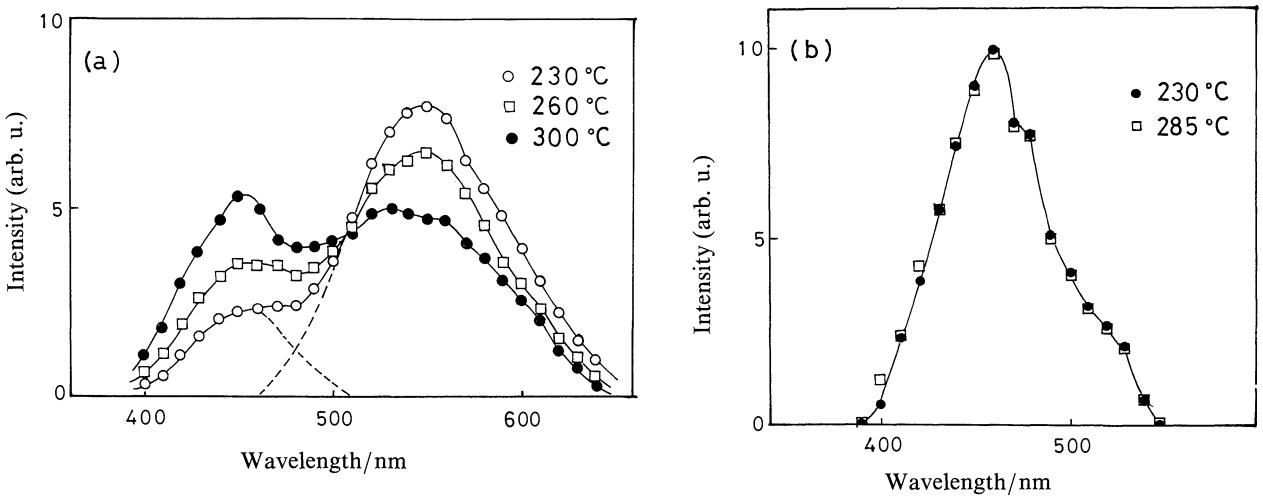


Fig. 1. Emission spectra for cadmium-photosensitized luminescence of PDA (a) and DMP (b).

Table 1. Half-Quenching Pressure for Quenching of 326.1 nm Resonance Radiation, Wavelength at Peak of Emission Bands, and Quantum Yield of Luminescence

Diamine	$P_{1/2}$	λ/nm		Quantum yield	
	Pa	Band I	Band II	Band I	Band II
TMMDA	66.0±2.6	480	—	0.24	—
EDA	8.9±0.1	460	570	0.040	0.27
TMEDA	11.1±0.2	460	550	0.020	0.16
PDA	12.7±0.2	450	550	0.044	0.17
TMPDA	15.5±0.2	452	570	0.040	0.17
DMP	12.0±0.2	460	—	0.060	—
TEDA	10.3±0.2	442	—	0.29	—

band and the spectrum is independent of temperature. EDA, TMEDA, and TMPDA have two emission bands and the temperature dependences of their emission spectra are very similar to that for PDA, while TMMDA and TEDA have only the short-wavelength band and their spectra are also independent of the temperature, like that for DMP. The position and shape of band I of EDA, TMEDA, PDA, and TMPDA are similar to those of the bands of TMMDA, DMP, and TEDA, and of the bands reported for the Cd($^3P_1$)-aliphatic amine systems. Band II has not been reported for other systems.

The quantum yields of the luminescence were determined by comparing the integrated intensity of the emission bands with that for ammonia under the same conditions. The quantum yield of the luminescence for ammonia was reported to be 0.67.[1,2] The quantum yields obtained at 230 °C are listed in Table 1.

In order to estimate the efficiencies of quenching of the 326.1 nm resonance radiation, the emission intensity at 326.1 nm was measured at various pressures of diamines. Stern-Volmer plots for some diamines are shown in Fig. 2. The half-quenching pressures obtained from the slope of the straight lines in Fig. 2 are listed in Table 1. The measurements were carried out in the absence of any

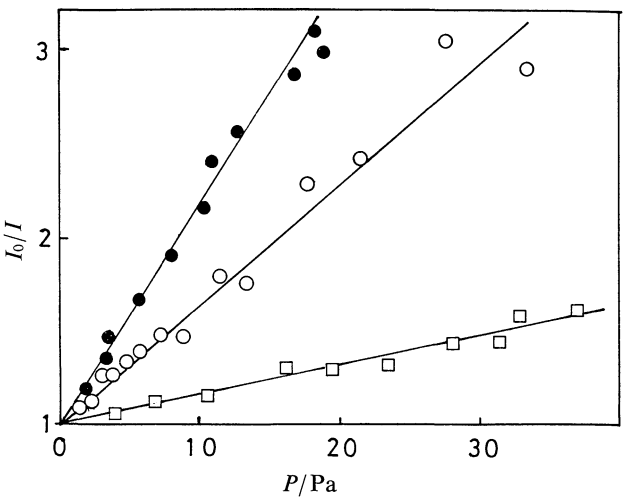

Fig. 2. Stern-Volmer plots for quenching of resonance radiation by EDA (●), TMPDA (○), and TMMDA (□) at 230 °C.

buffer gas. It is not necessary to take into account the effect of pressure broadening, since the pressures of the diamines were very low.

The pressure dependences of the relative intensities at the peaks of the emission bands for PDA are shown in Fig. 3. Slightly different pressure dependence from those presented in a previous letter[7] was obtained by using greaseless stopcocks in this study. As Fig. 3 shows, the intensities increase rapidly with increasing PDA pressure in the low-pressure region, and then leveled off to a constant value. The intensities are constant at higher pressures than 200 Pa (I_{440}/I_{550}=0.28). The pressure dependence of the relative emission intensity at 450 nm is very similar to that at 550 nm. Similar pressure dependences of the emission intensities of the two bands were obtained for EDA, TMEDA, and TMPDA.

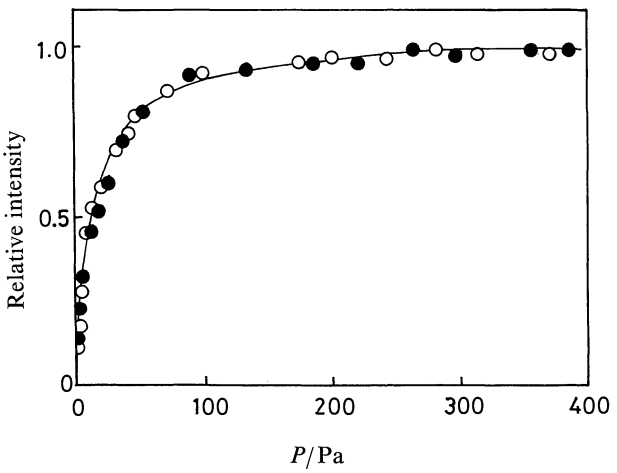

Fig. 3. Pressure dependences of emission intensities at 450 (○) and 550 nm (●) for PDA at 230°C.

Discussion

In a previous letter[7] we concluded that the two emission bands can be assigned to two kinds of 1:1 exciplexes between an excited cadmium atom and a diamine molecule from the pressure and temperature dependences of the emission intensities of the two bands as well as the dependence of the emission intensities on the intensity of the exciting light. From the temporal profiles of the intensities of the two emission bands and that of the 326.1 nm resonance radiation measured for TMPDA under pulsed excitation conditions, it has been suggested that two exciplexes are formed directly from $Cd(^3P_1)$, and that there are collision-induced mixing processes between these exciplexes.[10] The following reaction scheme has been proposed:

$$Cd(^1S_0) + h\nu(326.1\text{ nm}) \longrightarrow Cd(^3P_1) \quad (1)\ I^\circ$$

$$Cd(^3P_1) \longrightarrow Cd(^1S_0) + h\nu(326.1\text{ nm}) \quad (2)\ k_2$$

$$Cd(^3P_1) + DA \longrightarrow CdDA^* \quad (3)\ k_3$$

$$Cd(^3P_1) + DA \longrightarrow CdDA^{**} \quad (4)\ k_4$$

$$Cd(^3P_1) + DA \longrightarrow \text{other reactions} \quad (5)\ k_5$$

$$CdDA^* + DA \rightleftharpoons CdDA^{**} + DA \quad (6)(-6)\ k_6, k_{-6}$$

$$CdDA^* \longrightarrow Cd(^1S_0) + DA + h\nu(450\text{ nm}) \quad (7)\ k_7$$

$$CdDA^{**} \longrightarrow Cd(^1S_0) + DA + h\nu(550\text{ nm}). \quad (8)\ k_8$$

Here, DA represents a diamine, CdDA* stands for an exciplex which fluoresces band I, while CdDA** stands for another exciplex which fluoresces band II. As has been discussed in a previous paper,[10] it was concluded that the production of $Cd(^3P_0)$ is a minor process for the Cd/TMPDA system from the finding that the decay profile of the resonance radiation is consistent with the quenching rate constant determined from the slope of the Stern–Volmer plot. If $Cd(^3P_0)$ is produced and the equilibration between $Cd(^3P_1)$ and $Cd(^3P_0)$ is rapid, as in the Cd/ammonia system,[4] the slope of the Stern–Volmer plot should correspond to the population-weighted sum of the quenching rate constants of the $^3P_1$ and $^3P_0$ states, while the rate constant determined by the decay profiles of the resonance radiation must be equal to the weighted average; there must be a difference by a factor of more than two between the weighted sum and the weighted average at 500 K. The minor production of $Cd(^3P_0)$ in this system can be attributed to the large quenching efficiency of TMPDA. The production of $Cd(^3P_0)$ is not involved in the above-mentioned reaction mechanism, since the other diamines used also had large quenching efficiencies.

A steady-state treatment leads to the following equation:

$$\frac{I_0}{I} = 1 + \frac{k_Q}{k_2}[DA], \quad (9)$$

where I_0 and I represent the intensities of the resonance radiation (defined as k_2 $[Cd(^3P_1)]$) in the absence and presence of diamines, respectively; k_Q is the quenching rate constant: $k_Q = k_3 + k_4 + k_5$. The Stern–Volmer plots given in Fig. 3 are expressed by this equation.

In a previous paper[10] the value of $4.0\times10^5\ s^{-1}$ for k_2 (the effective radiation lifetime of $Cd(^3P_1)$ is somewhat lengthened by radiation imprisonment) was used in a simulation of temporal profile of the resonance radiation in the cadmium–TMPDA system at 230°C. From the half-quenching pressures, the values of k_Q can be estimated; they are listed in Table 1.

The following equations for the intensities of the exciplex emissions are derived by the steady-state treatment based on the assumption that fast equilibrium between two exciplexes is attained:

$$I_s = \alpha k_7[CdDA^*] = \alpha I^\circ \frac{(k_3 + k_4)[DA]}{k_2 + k_Q[DA]} \frac{k_6 k_7}{(k_6 + k_{-6})(k_7 + k_8)}, \quad (10)$$

$$I_I = \beta k_8[CdDA^{**}] = \beta I^\circ \frac{(k_3 + k_4)[DA]}{k_2 + k_Q[DA]} \frac{k_6 k_8}{(k_6 + k_{-6})(k_7 + k_8)}, \quad (11)$$

where I_s and I_I are the emission intensities at the peaks of bands I and II, I° is the intensity of the 326.1 nm resonance radiation absorbed by cadmium atoms, and α and β are proportional factors between the total emission intensities of bands I and II and the intensities at the peaks. As was mentioned above, the emission intensities at the peaks of bands I and II level off to constant values at high pressures. If I_s^∞ and I_I^∞ denote the constant intensities at high pressures, the following equation is

obtained:

$$\frac{I_s}{I_s^\infty}=\frac{I_l}{I_l^\infty}=\frac{k_Q[DA]}{k_2+k_Q[DA]}. \quad (12)$$

The solid line in Fig. 3 shows the values calculated according to Eq. 12 by using the values of k_2 and k_Q shown above. The calculated values are in good agreement with the observed ones within the limits of experimental error. Similar good agreements between the calculated and experimental values were obtained for other diamines. This demonstrates that the above reaction scheme and the assumption mentioned above are reasonable.

The equilibrium constant, K, between two exciplexes is expressed by

$$K=\frac{[CdDA^{**}]}{[CdDA^{*}]}=\frac{\alpha}{\beta}\frac{k_7}{k_8}\frac{I_l}{I_s}. \quad (13)$$

The ratios of α/β were obtained for the four diamines which show the two emission bands at some temperatures by comparing the values of I_l/I_s to the ratios of the integrated intensities of the emission bands (Table 2), and found to be independent of the temperature. Since both k_7 and k_8 are the rate constants for radiation processes, the ratio k_7/k_8 must be independent of the temperature. In a previous paper,[10] it was shown that a simulation of the temporal profiles of the two emission bands gave the results that $k_7=k_8=1.9\times10^5$ s^{-1} for TMPDA. Since we have no information concerning the values of k_7 and k_8 for other diamines, it is assumed that the values of k_7/k_8 for other diamines are also equal to unity as a first approximation. Although the k_7- and k_8-values should depend on the kind of diamine, they may be expected to vary in a somewhat similar manner to one another, since the two exciplexes for EDA, TMEDA, PDA, and TMPDA have similar structures, respectively (as will be shown later, the enthalpy changes between the two exciplexes are very similar for these diamines). The values of K can be obtained by Eq. 13 at various temperatures for EDA, TMEDA, PDA, and TMPDA. The values of ΔH° and ΔS° were obtained from the slopes and the intercepts of the straight lines between $\ln K$ and $1/T$ shown in Fig. 4 and are listed in Table 2, together with the K-values at 230 °C.

In conclusion, the exciplexes for the long-wavelength bands have a smaller enthalpy and entropy than do the exciplexes for the short-wavelength bands. This results seem to give another kind of evidence that the former are cyclic, because of the general tendency that cyclic compounds have smaller entropy than do chain compounds.[11] The energy differences between the two exciplexes obtained above are smaller than the energy differences between the wavelengths of the peaks of the two emission bands (about 48 kJ mol^{-1}). This shows that the potential energy surfaces of the ground state for

a) At 230 °C.

the cyclic exciplexes must be more repulsive than that for the noncyclic exciplexes; this is shown schematically in Fig. 5.

Callear et al.[12,13] observed two emission bands in mercury(6^3P_0)-*t*-butylamine and diethylamine systems. They pointed out that the short-wavelength band is due to the HgA* monomer, and that the long-wavelength band can be assigned to the HgA_2* dimer. Although they did not described the structures of the dimers, two amine molecules may attach directly to an excited mercury atom. If this is the case, the HgA_2 dimers are closely related to the cyclic exciplexes observed in the present study. Indeed, both species have a common feature of having long-wavelength bands. More experimental work is needed to clarify this point.

(Received June 7, 1991)

The effects of the temperature, initial concentration, and chemical quenchers on dual photoreactions of phthalazine were investigated. The results give further supporting evidence for a previously proposed reaction mechanism, i.e., phthalazine in the lowest excited singlet and triplet states affords singlet and triplet radical pairs, respectively, in the initial hydrogen abstraction process from 2-propanol. The singlet radical pair gives a reduction product in a solvent cage, whereas the radicals produced in the triplet state escape from the solvent cage, causing dimerization. On the basis of the reaction mechanism of dual photoreactions, external heavy-atom effects on the radical pairs within a solvent cage have been studied. The results indicate that heavy-atom perturbations bring about an enhancement of the intersystem crossing efficiency from the triplet-state radical pair to the singlet one, including a spin inversion of the radical pair in the solvent cage, rather than $S_1 \rightarrow T_1$ intersystem crossing induced within a single molecule of phthalazine.

The spin multiplicities of a caged radical pair formed during the initial step of photochemical reactions govern the reactivities of the subsequent reactions of the radicals, affecting the product distribution. In general, singlet radical pairs undergo cage reactions efficiently, while triplet ones do so inefficiently.[2)] In the latter case, the triplet radical pairs must undergo a spin inversion to singlet radical pairs prior to cage reactions. Thus, the intersystem crossing of this type concerning radical pairs in a solvent cage competes with the escape of radicals from the cage.[3)] In this connection, the effects of an external magnetic field on caged reactions have been widely investigated.[2,4-6)] However, studies on the internal and external heavy-atom effects on the intersystem crossing process of a radical pair in a solvent cage have scarcely been reported. A 2-propanol solution of phthalazine may serve as a relevant reaction system for studying the above-mentioned effects.[7)]

In a previous paper[7)] we reported that phthalazine (P) simultaneously undergoes dual photoreactions to afford 1,2-dihydrophthalazine (**1**) and 1,1′,2,2′-tetrahydro-1,1′-biphthalazine (**2**) upon ultraviolet light irradiation in a 2-propanol solution. From the observed photochemical behavior and the phosphorescence characteristics under the influence of a quencher, sensitizer, and surfactant, the following reaction mechanism has been proposed. During the initial step of the dual photoreactions, phthalazine (P) abstracts a hydrogen atom from the 2-propanol(RH) used as a solvent to form a radical pair of the 1,2-dihydro-1-phthalazinyl radical (PH·) and the 1-hydroxy-1-methylethyl radical (R·) in a solvent cage. The resulting singlet radical pair (^{1}[PH·+R·]), derived from the lowest excited singlet state (S_1) of the substrate, participates in a subsequent hydrogen abstraction to produce **1** in a solvent cage. On the other hand, the same radical, PH·, derived from the lowest triplet state (T_1) of the substrate, escapes from the solvent cage, causing dimerization to afford product **2** (Scheme 1).

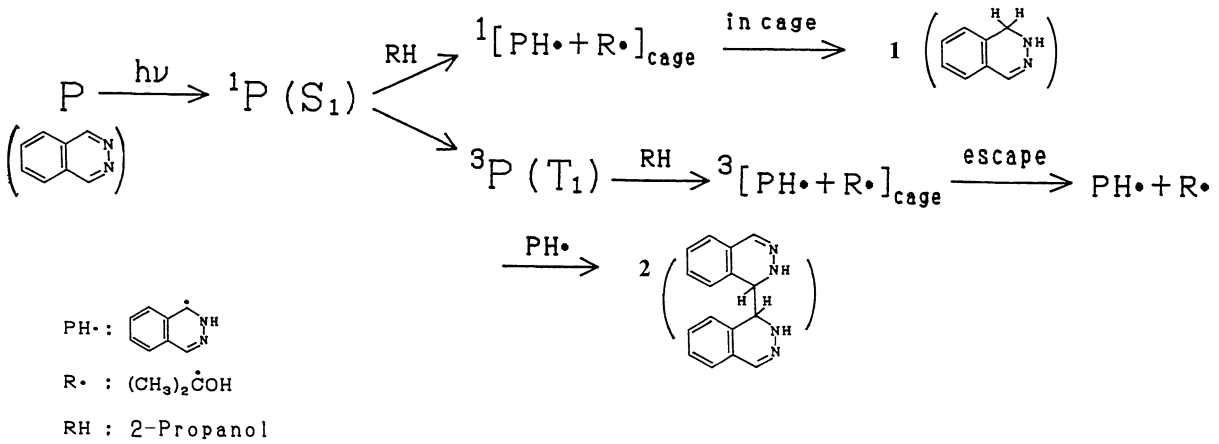
In the current work, studies of the temperature and initial concentration effects on the photochemical reactivities of phthalazine, and chemical quenching in 2-propanol, were carried out in order to obtain further supporting evidence concerning the reaction mechanism. On the basis of the reaction mechanism presented in Scheme 1, the observed external heavy-atom effects on the reactivities and phosphorescence are discussed, and an example of an intersystem crossing process that includes spin inversion from the triplet to the singlet radical pair within a solvent cage is presented.

Experimental

Materials. Phthalazine (Aldrich Chem. Co.) was purified by recrystallization from a mixture of benzene and hexane. 1,2-Dibromoethane and bromoform were purified by repeated fractional crystallizations. 2-Allylphenol and cinnamyl alcohol (Wako Pure Chemical Ind.) were used as received.

Measurements. The phosphorescence spectra were taken with a Shimadzu RF-500 spectrofluorimeter equipped with a cylindrical rotating sector at 77 K. The triplet lifetimes were determined with a previously described method in a mixture of ethanol and methanol (1:1 v/v) at 77 K.[8)]

Light Source and Irradiation. A 450 W high-pressure mercury lamp (Ushio UM-452) and a set of filters comprising a solution (1% K_2CO_3 aqueous solution containing 10^{-2} mol dm^{-3} K_2CrO_4) and a Corning glass filter (CS-7-54) were used for 313-nm light irradiation. A 70 W low-pressure mercury lamp (Ushio UL1-7SQ) and a solution filter ($NiSO_4$ 500 g dm^{-3}) were



Scheme 1.

used for 254-nm light irradiation. 2-Propanol solutions of phthalazine in a 5×10^{-2} dm^3 quartz cylindrical reaction cell were flushed with nitrogen passed through a pyrogallol solution and a silica-gel column both before and during irradiation. The temperatures of the reaction system were controlled by passing temperature-controlled water into a reaction cell with a jacket.

Actinometry and Analysis of Photoproducts. Actinometry was performed by using a potassium trioxalatoferrate(III) solution.[9] The amounts of the photoproducts were spectrophotometrically determined by the same manner described previously.[7]

Results and Discussion

Temperature and Concentration Dependence of the Dual Photoreactions. In addition to the results reported earlier, the effects of the temperature and initial substrate concentrations on the formations of products **1** and **2** have been examined in order to obtain a further confirmation of the mechanism of the dual photoreactions.

In Fig. 1, the concentrations of the produced **1** and **2** are plotted against the irradiation times for reactions at various temperatures. It can be seen from this figure that product **2** is formed in higher yields at higher temperatures, while the yield of **1** is not affected by the temperature.[10] In addition, the dependence of the reactivity on the initial substrate concentrations can be seen from Table 1. The quantum yield for the formation of **1** is not altered with a change in the concentration of phthalazine, while that for **2** increases with increasing concentration.

These observed effects of the initial concentrations and temperature can be considered to give further supporting evidence for the reaction mechanism proposed earlier. That is, because the formation of **1** occurs in a solvent cage, which includes 1,2-dihydro-1-phthalazinyl radical (PH·) and alcohol radical (R·) produced in the initial hydrogen abstraction reaction, the yield of **1** may be influenced inefficiently by both the concentration and

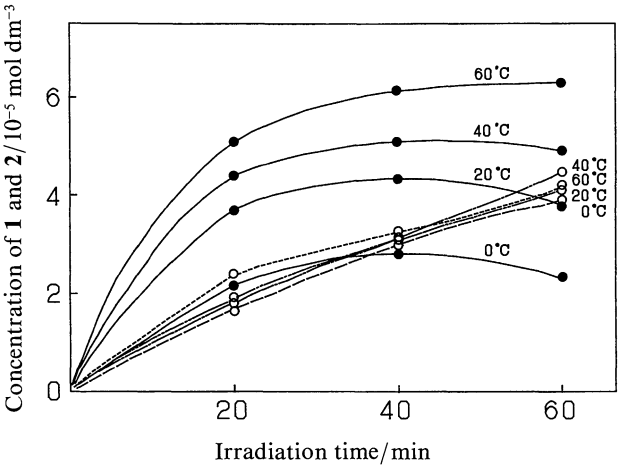


Fig. 1. Temperature dependence of the formations of **1** (○) and **2** (●). [Phthalazine]=4×10^{-4} mol dm^{-3}, Solvent: 2-Propanol, Excitation wavelength: 253.7 nm.

Table 1. Quantum Yield for the Formation of **1** (Φ_1) and **2** (Φ_2) at Room Temperature

5×10^{-3}	0.0095	0.069	7.2

temperature. Moreover, from the temperature dependence, it is demonstrated that the efficiency of the escape process of the radicals from the solvent cage of the present system is not subjected to the effect of temperature in the range 0 to 60 °C.

On the contrary, the formation of **2** is susceptible to concentration and temperature effects, since it takes place in a bulk solution through encounters of 1,2-dihydro-1-phthalazinyl radicals escaping from the solvent cage.

Quenching for the Formation of 2 by Olefins. The in-cage (S_1) and out-of-cage (T_1) reaction mechanisms for

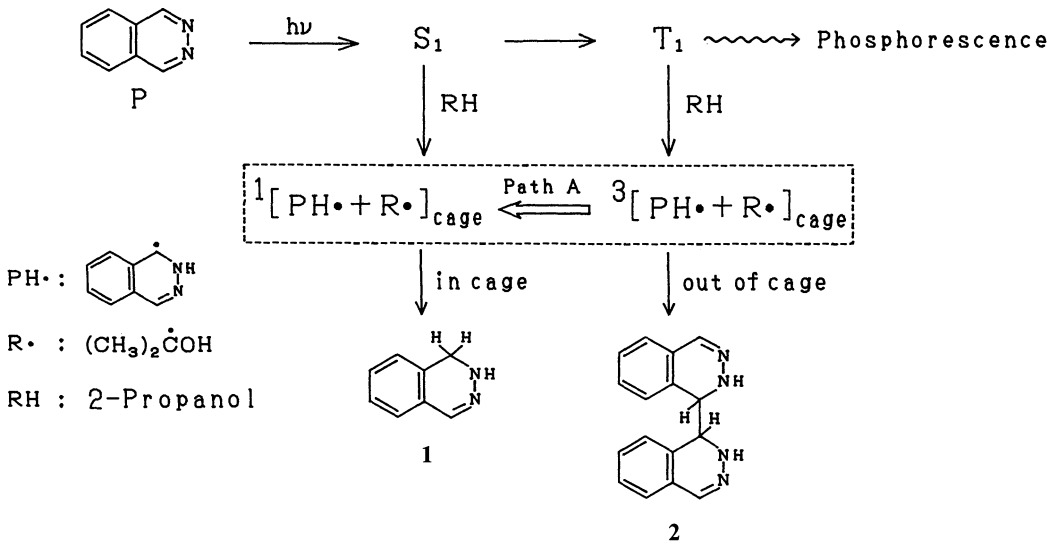
the respective **1** and **2** formations can also be demonstrated by the chemical quenching using olefinic compounds such as 2-allylphenol and cinnamyl alcohol. These compounds quench the formation of **2**, but not the formation of **1**. Stern-Volmer quenching plots are presented in Fig. 2. Since the lowest triplet energies of the above-mentioned compounds are not available, they have been estimated from their phosphorescence spectra as being 289 kJ mol^{-1} (69.2 kcal mol^{-1}) and 303 kJ mol^{-1} (72.4 kcal mol^{-1}) for 2-allylphenol and cinnamyl alcohol, respectively. These values are larger than the lowest triplet energy values of phthalazine (256 kJ mol^{-1}, 61.2 kcal mol^{-1});[11] thus, the observed quenching can not be regarded as being to a triplet–triplet energy transfer from phthalazine to the quenchers. In fact, the intensity of the phthalazine phosphorescence is not affected by these quenchers. Accordingly, the results can be explained as a sort of chemical quenching of the 1,2-dihydro-1-phthalazinyl radical by the olefinic compounds in a bulk solution. The absence of quenching for the formation of **1** is attributed to an in-cage reaction of this radical.

External Heavy Atom Effect. It has been found that the dual photoreactions of phthalazine are affected by added bromine-containing compounds, such as 1,2-dibromoethane and bromoform.[12] The quantum yields for the formations of **1** (Φ_1), **2** (Φ_2), and **1**+**2** ($\Phi_1+\Phi_2$) are plotted as a function of the concentrations of these bromo compounds in Figs. 3 and 4. The addition of bromo compounds brings about an increase in the yield of **1**, together with a decrease in the yield of **2**. This indicates that the efficiency of an intersystem crossing which is associated with the photoreactions is altered through an enhancement of the spin-orbit coupling. Moreover, it has been found that the emission intensity of phthalazine phosphorescence (with a maximum at 482 nm and a lifetime (τ=0.51 s) of the phosphorescent lowest triplet state at 77 K in a 1:1 mixture of ethanol and methanol) is not influenced by the addition of 2×10^{-2} mol dm^{-3} of the bromine compounds (1,2-dibromoethane: 0.49 s, bromoform: 0.56 s).

From the following considerations, the present observations can not be explained in terms of external heavy-atom effects on the $S_1\rightarrow T_1$ and the $T_1\rightarrow S_0$ intersystem crossing processes occurring in a single molecule of phthalazine. First, if the $S_1\rightarrow T_1$ intersystem crossing in an excited phthalazine molecule could be affected by heavy-atom perturbations, the addition of bromine compounds might lead to an increase in the yield of **2**, together with an enhancement of the phosphorescence intensity. This is clearly not the case for the present system. Second, the possible heavy-atom enhanced $T_1\rightarrow S_0$ intersystem crossing decay process of



Scheme 2.

triplet phthalazine can not be responsible for the observed variation in the photoreactivity. That is, although the observed change in Φ_2 may reflect the $T_1 \rightarrow S_0$ mechanism, the observed increase in Φ_1 can not be interpreted from this mechanism, which predicts no change for a reaction occurring prior to the $T_1 \rightarrow S_0$ intersystem crossing. Third, the constancy of the phosphorescence intensity and the lifetime indicates the absence of a heavy-atom induced variation in the efficiencies of the formation and decay of the T_1 species of the phthalazine molecule.

Consequently, we have reached the following conclusion on the basis of a spin-correlated reaction mechanism in which **1** is formed from a singlet radical pair within a solvent cage as well as the findings, described above. In the present photoreaction systems including bromine compounds, the observed change in the reactivity and phosphorescence characteristics of phthalazine can be reasonably ascribed to the enhancement of an intersystem crossing process, involving a radical pair within a solvent cage formed during the initial step of the dual photoreactions; no events occurred in a single phthalazine molecule. The spin inversion from the triplet state (^{3}[PH·+R·]) of the radical pair to the singlet one (^{1}[PH·+R·]) in a solvent cage is induced under the influence of a heavy-atom spin-orbit interaction. The proposed reaction pathways are illustrated according to Scheme 2. In this scheme Path A is the proposed spin inversion (intersystem crossing) of the radical pair within the solvent cage; it competes with the escape of radicals and a back reaction to the starting materials, phthalazine (P) and 2-propanol (RH). A similar spin inversion has been revealed in several photoreactions by studies on photoreactions under an external magnetic field.[1,3-5] In this case, however, the inversion of the spin state is dominated by electron-molecular hyperfine interactions. Few descriptions are available concerning the spin inversion resulting from a spin-orbit coupling in a radical pair. Turro et al.[4] reported that the bromine-substituted dibenzyl ketone showed an internal heavy-atom effect on intersystem crossing in its radical pair. Recently, Tanimoto et al.[13] have reported that the photolysis of 2-naphthylphenyldiazomethane involves a spin inversion in a radical pair within a solvent cage under an external magnetic field. Accordingly, the results presented here are examples of photochemical reactions in which heavy-atom perturbed intersystem crossing between the singlet and triplet states of the radical pair in the solvent cage plays an important role in the product distribution and reactivity. It, therefore, seems that in some cases the selective formation of a desired product from dual photochemical reactions involving different spin-correlated radical pairs may be attained by using a heavy-atom containing compound.

Effect of Bromotrifluoromethane on the Ignition in Methane and Ethane-Oxygen-Argon Mixtures behind Shock Waves

Akimichi SUZUKI, Tadaaki INOMATA,* Hiroshi JINNO, and Takao MORIWAKI

(Received April 2, 1991)

The ignition delay times behind shock waves in CH_4–, and C_2H_6–O_2–Ar systems containing CF_3Br were measured for a range of temperatures between 1400 and 2100 K and pressures between 1.5 and 3.5×10^5 Pa. These measurements indicated that CF_3Br promotes the ignition of CH_4 but inhibits the ignition of C_2H_6. Although the inhibition effect for C_2H_6 increases with increasing CF_3Br concentration and decreasing temperature, the promotion effect in CH_4 was independent of both the CF_3Br concentration and the temperature in this experiment. We calculated the induction times for conditions similar to the experiments using a model which included 49 elementary reactions related to CF_3Br. Calculations using this model gave induction times that were in good agreement with the experiments. The calculated values, however, depended on several effective reactions among the 49 reactions.

Ignitions of methane and ethane in shock tubes under various experimental conditions have been investigated since 1959.[1-21] It is well-known that methyl halides accelerate the ignition of CH_4 but retard the ignition of C_2H_6; these effects are due to chemical reasons.[22-23] Methyl bromide was the most effective substance as an ignition promoter for CH_4 and methyl iodide had the greatest effect as an ignition inhibitor for C_2H_6. The different effects in CH_4 and C_2H_6 ignitions have been clarified from the rates of reactions involving halogen species as well as the differences of predominant reactions in both fuels. We have already reported the effect of CH_3Br addition on the ignition of CH_4 and C_2H_6.[22-24]

In this study, in order to examine the influence of the substitution of hydrogen by fluorine, we investigated the effect of CF_3Br addition on the ignition of CH_4 or C_2H_6, compared with the effect of CH_3Br addition. Although this species has received much attention in experimental studies regarding flame inhibition,[25-29] the number of reports concerning its effects on ignition has been extremely small. We therefore provide new experimental information concerning addition effects of CF_3Br in methane- and ethane-oxygen-argon mixtures, as well as a numerical analysis of the mechanism.

Experimental

Measurements. The shock tube used in this experiment was made of 8.0 cm i.d. stainless-steel pipe. The reaction and driver sections were 450 and 80 cm in length, respectively. Thus, dwell times of about 500 microseconds behind a reflected shock wave could be obtained using helium driver gas. A poly(ethylene-terephthalate) diaphragm was ruptured by increasing the driver gas pressure up to a certain value. The reaction gases were mixtures of methane or ethane, bromotrifluoromethane, and oxygen diluted with argon (Table 1). The shock wave velocities were controled by changing the pressure ratio of helium and nitrogen gas in the driver section. The incident shock velocities were measured by PZT-type pressure transducers placed along the reaction section and a digital counter. The state of the test gas behind the shock wave was determined using ideal one-dimensional shock equations with thermodynamic properties. The onsets of ignition were detected by OH radical absorption with a photomultiplier fitted with a 306 nm interference filter on the end of reaction section. A typical oscillograph is shown in Fig. 1. The ignition delay times, defined as the time interval between the pressure rise due to the arrival of a shock wave and the rise of an optical signal by the photomultiplier, were obtained under various conditions.

Calculations: In order to discuss the effect of CF_3Br on the reaction mechanism for methane and ethane oxidations, we calculated the ignition delay times using a model. The model used for methane and ethane oxidations are described in Refs. 30—33. This mechanism consists of 35 species and 113 elementary reactions, including forward and reverse reactions.

9		1.0		0.1	3.5	95.4

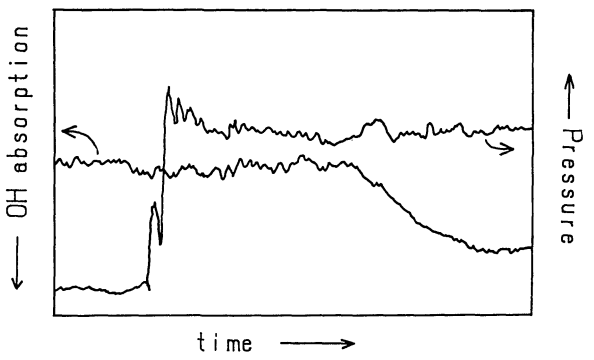

Fig. 1. Typical oscillograms of pressure and OH absorption.

Considering that the pressure is constant within the induction time (Fig. 1), a model calculation was performed that assumed a constant pressure.

We calculated the OH concentration and defined the calculated ignition delay time as being the time interval of a sudden rise in the OH concentration. This gives ignition delay times closer to the observed values.[23] Elementary reactions related to CF_3Br were obtained from the literature.[34] (Table 2)

Results and Discussion

CH_4 System. The ignition delay times of mixtures 2 and 3 including CF_3Br are slightly short compared with those of mixture 1, excluding CF_3Br over the entire temperature region, as shown in Fig. 2. The points are the observed values and the lines are the calculated values. It is obvious that CF_3Br has a promotion effect for methane ignition. The concentration dependence of

a) Rate constants in the form $A=T^n\exp(-E/RT)$, in cm, mol, s, kcal, and K units.

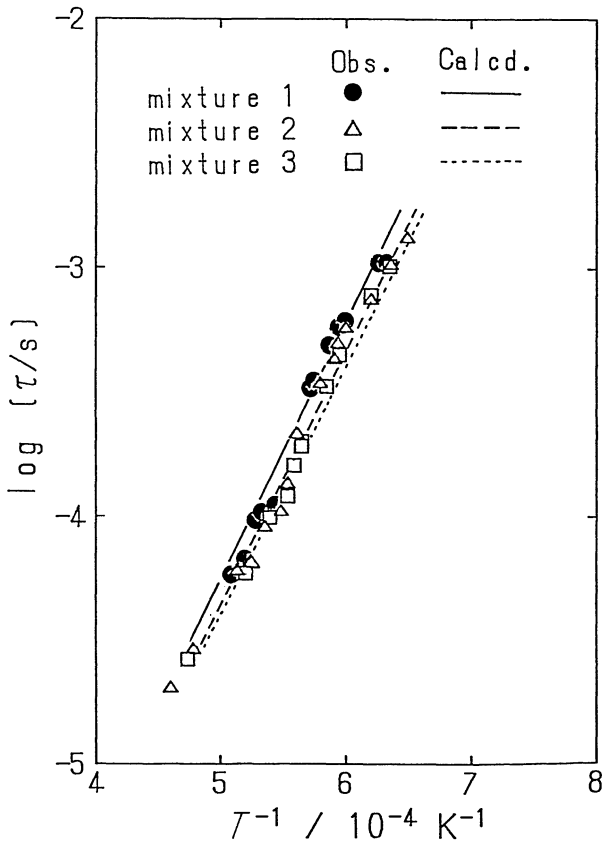

Fig. 2. Comparison of the calculated and observed ignition delay times in CH_4 systems. T is temperature behind shock wave.

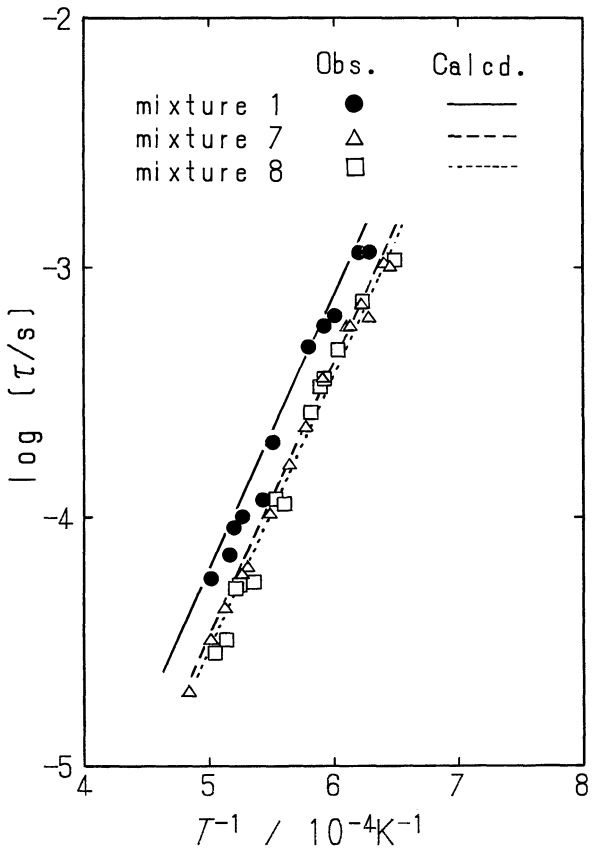

Fig. 3. Comparison of the calculated and observed ignition delay times in CH_4 systems.

CF_3Br, however, is small. These experimental data can be expressed by the least-square method as follows:

$$\log \tau = -9.85 + 1.08\ (10^4/T) \quad \text{for mixture 1,}$$

$$\log \tau = -9.48 + 1.02\ (10^4/T) \quad \text{for mixture 2,}$$

and

$$\log \tau = -9.55 + 1.03\ (10^4/T) \quad \text{for mixture 3.}$$

The slopes of mixtures 1—3 are almost the same, indicating that the promotion effect at high temperature is almost the same as that at low temperature. The ignition delay times of CH_4–O_2–Ar–CH_3Br are shown in Fig. 3 together with those of mixture 1. The tendency was the same for mixtures 7 and 8 including CH_3Br. Accordingly, we try to analyze the kinetics of methane combustion including CF_3Br in comparison with that including CH_3Br.

When comparing the results in Figs. 2 and 3 we considered that the concentration dependence of CF_3Br is smaller than that of CH_3Br.

The reaction mechanism of the CH_4–O_2–Ar system has already been studied. In order to realize a difference in the addition effects between both fuels, we express the consumption route of CH_4 according to the induction time.[35,36] An initiation reaction of this system is a thermal decomposition of fuel, as follows:

$$CH_4 = CH_3 + H. \quad \text{(R1)}$$

Though the time interval during which reaction (R1) effects the ignition delay times is short, this reaction is important, considering the fact that no ignition occurs without reaction (R1). CH_3 produced by the initiation reaction reacts with O or O_2, as follows:

$$CH_3 + O_2 = CH_3O + O \quad \text{(R2)}$$

and

$$CH_3 + O = CH_2 + OH. \quad \text{(R3)}$$

Since O atoms are scarcely produced during the early stage of the induction period, reaction (R2) is dominant. The route in flame, however, is reaction (R3), since O atoms are produced in a region of high temperature. The CH_3O produced by reaction (R2) decomposes immediately, as follows:

$$CH_3O = CH_2O + H. \quad \text{(R4)}$$

Any H atoms produced react with CH_4 and O_2:

$$CH_4 + H = CH_3 + H_2 \quad (R5)$$

and

$$H + O_2 = OH + O. \quad (R6)$$

The reaction with O_2 as a chain-branching reaction produces two radicals. Of the two radicals the O atom reacts with CH_3; on the other hand, the OH radical reacts with CH_4, as follows:

$$CH_4 + OH = CH_3 + H_2O. \quad (R7)$$

As mentioned above, CH_4 is consumed within the early stage of the induction period by a chain mechanism comprising reactions (R2), (R4), (R5) or reactions (R2), (R4), (R6), (R7).

During the ignition CF_3Br effects the chain mechanism. As shown in Figs. 2 and 3, the calculated ignition delay times agree with the observed values for all mixtures at both low and high temperatures. We therefore considered that the assumed scheme is reasonable. To make sure which reactions are effective, we performed sensitivity analysis. These were performed on 49 reactions involving F or Br-containing species by increasing both the forward and reverse rate constants, multiplying them by ten times and by deleting each reaction at 1866 and 1517 K. From this sensitivity test, the reactions which had some effects on the ignition delay times are shown in Table 3. We also performed this sensitivity test at 1517 K, as shown in Table 3. Reactions (A4) and (A15) are very sensitive in deleting, but not sensitive in increasing these rate constants. In this study we considered these reactions to be effective, owing to the high sensitivity in deleting.

Time profiles of the rates of these effective reactions involving Br-containing species at both 1517 and 1866 K

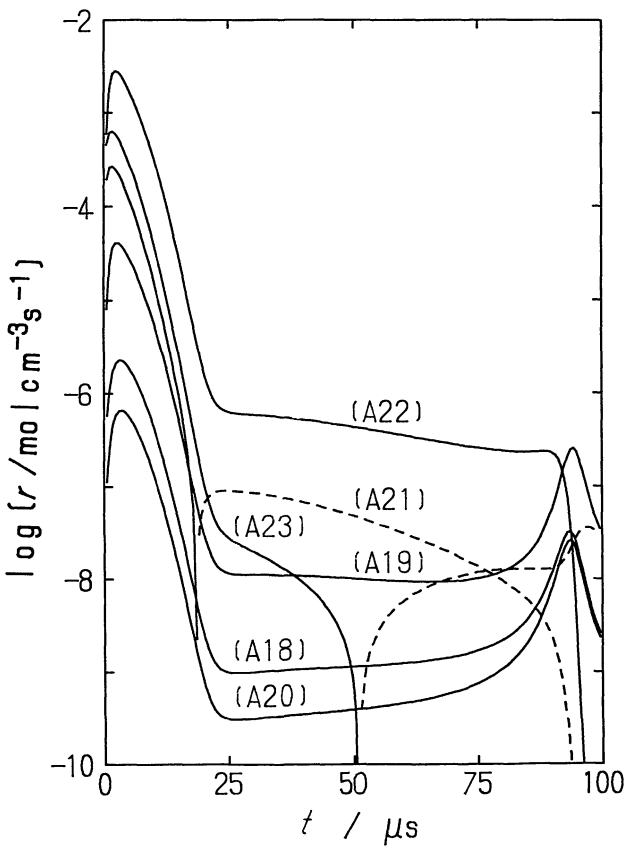

Fig. 7. Net reaction rates at 1866 K in mixture 2.

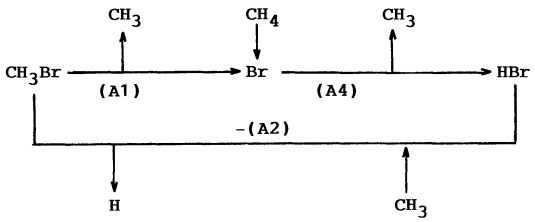
are shown in Figs. 4 and 5. Also, the time profiles of the main species including Br are shown in Fig. 6. During the early stage of the induction period reaction (A15) is the fastest of these five reactions at both 1517 and 1866 K. Further, since reaction (A15) is faster than reaction (R1), the former reaction acts as an initiation reaction. This may be reasonable, considering that the bond energy of C–Br is smaller than those of C–H and C–F.

As time passes, the rate of reaction (A15) becomes smaller. This means that CF_3Br decomposes during an earlier stage of the induction period. From Fig. 6 we realize that CF_3Br changes into CH_3Br within the ignition delay times.

Lifshitz has shown that most oxidation mechanisms for simple molecules involve closed-loop reactions that determine the behavior of the overall oxidation mechanism. In his investigation he identified the reactions that comprise this closed loop by examining the net reaction rates at half the induction time.[37] In the present study, during the induction period reactions (A1), (A2), and (A4) had high reaction rates. These reactions thus form a loop, as follows:



The total reaction of these reactions is

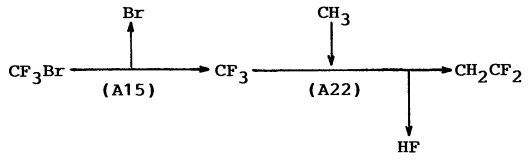
$$CH_4 = CH_3 + H,$$

which provides H atoms that are the active species during combustion. We considered that this loop has a dominant effect on methane ignition. This loop is the same as that obtained in the CH_4–O_2–CH_3Br system.

To make sure how CF_3 produced by the decomposition of CF_3Br effects the ignition delay times, we calculated the time profiles of the reaction rates which had higher values among the reactions involving the F-containing species at 1866 K (Fig. 7). It was found that reactions (A19), (A21), (A22), and (A23) have high reaction rates during the induction period. Especially, reaction (A22) has the fastest rate during the induction period, ten-times larger than other reactions. According to a sensitivity analysis, reaction (A22) has a high inhibition effect on the ignition delay times at both 1517 and 1866 K.

In this system CH_3 is produced from CH_4 by an attack of Br atoms (reaction (A4)), and CH_3 (reaction (A2)) reacts with HBr to produce H atoms, which are the active species during combustion. CH_3 thus plays an important role as a chain carrier in this system. It is further reported that reaction (A22) is also effective in flame.[34] It is therefore reasonable that reaction (A22), which consumes CH_3 as a chain carrier, has a large

inhibition effect in sensitivity analysis. By the reason that the effect suppresses any promotion effect by an attack of Br atoms, we considered that the promotion effect of CF_3Br is smaller than that of CH_3Br. From Fig. 7, the main route of CF_3Br decomposition is as follows:



C_2H_6 System. As shown in Fig. 8, CH_3Br has an inhibition effect on ethane ignition. The lines indicate the calculated results and the points are the observed values. The observed ignition delay times of mixture 4—6 are shown, as follows, by least-squares methods:

$$\log \tau = -9.40 + 0.81\ (10^4/T) \qquad \text{for mixture 4,}$$

$$\log \tau = -9.76 + 0.91\ (10^4/T) \qquad \text{for mixture 5,}$$

and

$$\log \tau = -9.63 + 0.96\ (10^4/T) \qquad \text{for mixture 6.}$$

As the concentration of CF_3Br increases, the slopes of these lines become large. This means that this inhibition effect at high temperature is smaller than that at low temperature. The concentration dependence of CF_3Br was large in comparison with methane ignition. Since this tendency was the same for CH_3Br,[22,23] we analyzed the kinetics of the C_2H_6–O_2–CF_3Br system in comparison with the C_2H_6–O_2–CH_3Br system (already reported).

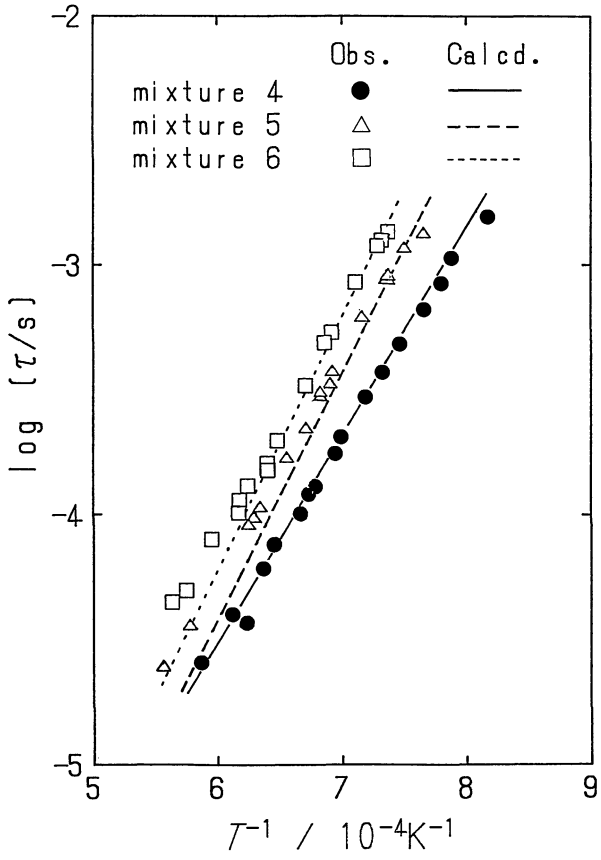


Fig. 8. Comparison of the observed and calculated ignition delay times.

In the C_2H_6–O_2–Ar system we express the consumption route of C_2H_6 during the early stage of the induction period.[35,36] In this system the initiation reaction is a thermal decomposition of C_2H_6,

$$C_2H_6 = CH_3 + CH_3. \qquad \text{(R8)}$$

The gratest part of CH_3 produced reacts with C_2H_6, as follows:

$$C_2H_6 + CH_3 = C_2H_5 + CH_4. \qquad \text{(R9)}$$

The C_2H_5 produced by reaction (R9) decompose immediately,

$$C_2H_5 = C_2H_4 + H, \qquad \text{(R10)}$$

and a part of the H atoms produced react with C_2H_6; some part of the H atoms react with O_2:

$$C_2H_6 + H = C_2H_5 + H_2 \qquad \text{(R11)}$$

and

$$H + O_2 = OH + O. \qquad \text{(R6)}$$

Reaction (R6), which is a chain-branching reaction, produces O atoms and OH radicals. OH radicals react with C_2H_6 and the O atoms react with CH_3:

$$C_2H_6 + OH = C_2H_5 + H_2O. \qquad \text{(R12)}$$

As mentioned above most of the C_2H_6 is consumed by a chain mechanism comprising reactions (R10) and (R11) or ractions (R10), (R6), and (R12).

CF_3Br effects the chain mechanism of C_2H_6 consumption. In this system we also performed a sensitivity analysis at both 1565 and 1717 K in order to realize how CF_3Br effects the mechanism. From this analysis the effective reactions are shown in Table 4. The time profiles of the reaction rates of the effective reactions which contian Br-atom are shown in Figs. 9 and 10. We also show the time profiles of the important reactions in the C_2H_6–CH_3Br system in Fig. 11 (already reported). The reactions which can be considered as an initiation type are reactions (A15) and (R8) in C_2H_6–CF_3Br, and reactions (A1) and (R8) in C_2H_6–CH_3Br. The calculated rate of reaction (R8) during the very early stage is about three times as large as that of reaction (A15) at 1500 K. The calculated rate of reaction (R8) is

Table 4. Percentage Change of the Ignition Delay Times ($\tau_{deleted}$, $\tau_{k\times10}$) to Those (τ) Calculated by Using the Complete Mechanism in Mixture 5

a) $\frac{(\tau_{deleted}-\tau)\times100}{\tau}$, b) $\frac{(\tau_{k\times10}-\tau)\times100}{\tau}$.

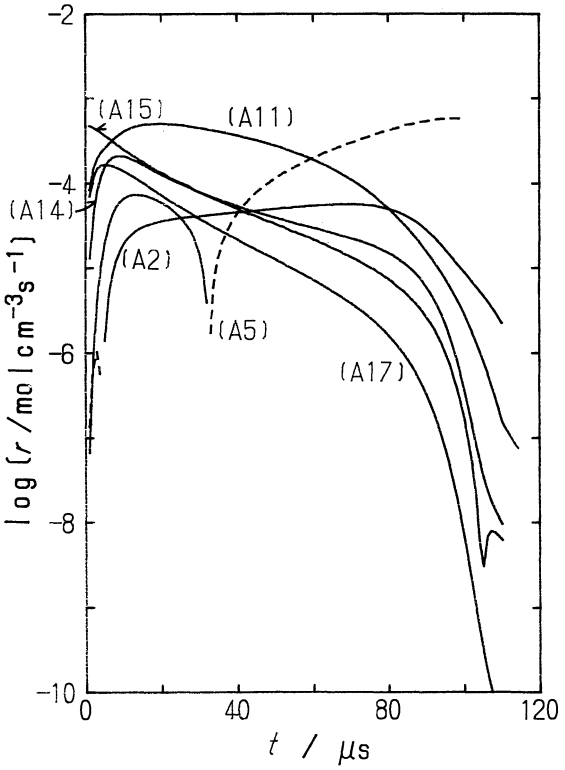

Fig. 9. Net reaction rates at 1565 K in mixture 5. The calculated reactions are those involving Br-containing species.

much faster than that of (A1). Thus, in both systems, reaction (R8) may act as the initiation reaction. However, reaction (A15), which is a thermal decomposition, also has a sufficiently large reaction rate in the C_2H_6–CF_3Br systems.

In C_2H_6–CH_3Br (already reported) CH_3Br reacts with

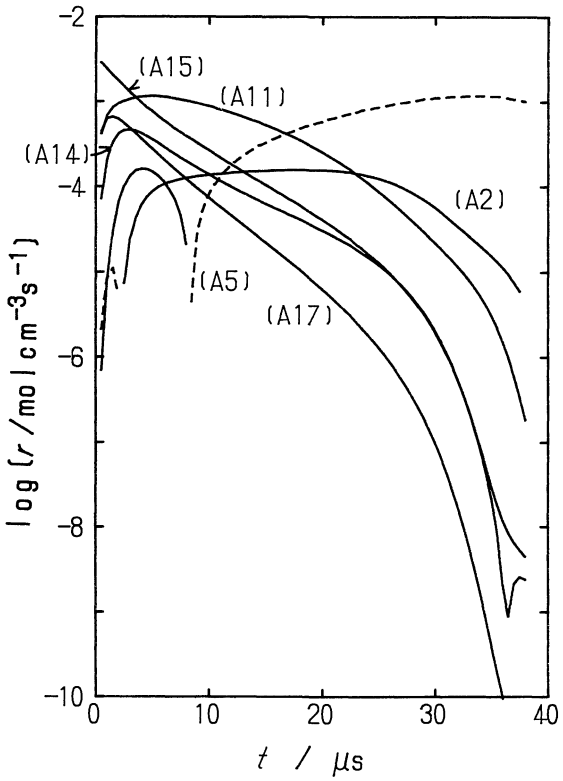

Fig. 10. Net reaction rates at 1717 K in mixture 5. The calculated reactions are those involving Br-containing species.

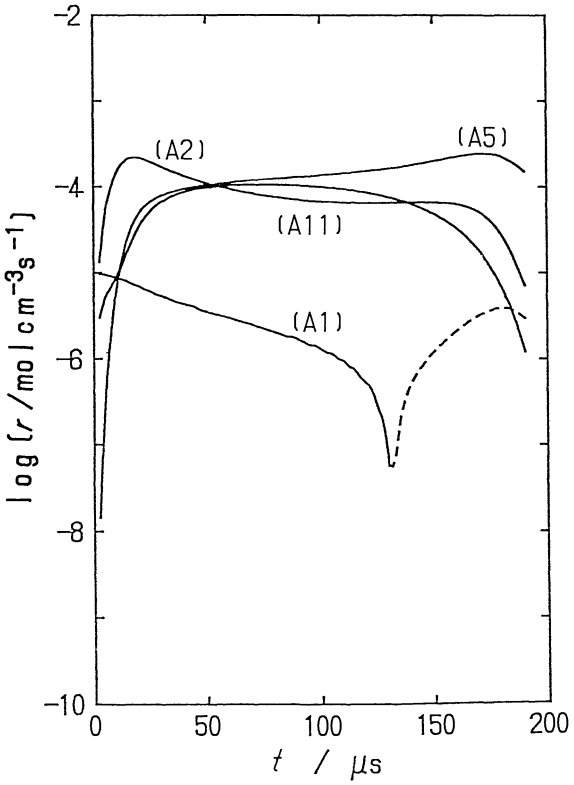

Fig. 11. Net reaction rates at 1500 K in mixture 9. The calculated reactions are those involving Br-containing species.

H produced by ethane decomposition, as follows:

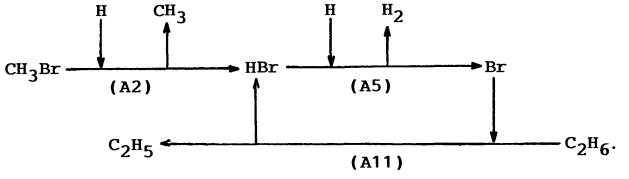
$$CH_3Br + H = CH_3 + HBr, \quad (A2)$$

$$HBr + H = H_2 + Br, \quad (A5)$$

and

$$C_2H_6 + Br = C_2H_5 + HBr. \quad (A11)$$

Most of the CH_3Br is consumed by reaction (A2). This fact is reasonable considering that the ignition temperature in the C_2H_6–O_2 system is lower than that in the CH_4–O_2 system, and that the concentration of H atoms in the C_2H_6 system is larger than that in the CH_4 system. Reaction (A5), which follows reaction (A2), has a large inhibition effect, since the HBr produced by reactions (A2) and (A11) consumes H as the active species. These three reactions can be expressed by the following loop:



In the C_2H_6–CF_3Br system, although reaction (R8) is dominant during the early stage, the rate of reaction (A15) is sufficiently large. Further, since the H and CH_3 concentrations increase in this system, reactions (A14) and (A17) became faster, as shown in Figs. 9 and 10. It is thus considered that reactions (A14), (A15), and (A17) are competitive. Reactions (A14) and (A17) have large inhibition effects and reaction (A15) has a promotion effect according to sensitivity analysis. If CF_3Br is consumed by reaction (A14), the HBr produced by reaction (A14) may react through the same route mentioned above in the C_2H_6–CH_3Br system. However, considering that reaction (A5) has a small promotion effect, this route may not be the main one. It is interesting that reaction (A5), which has a large inhibition effect in C_2H_6–CH_3Br, has a promotion effect in C_2H_6–CF_3Br. This might be caused by a difference in the relative concentration ([HBr]/[Br]), as shown in Figs. 12 and 13. [HBr]/[Br] in a mixture including CH_3Br is much larger than that in a mixture including CF_3Br. This indicates that in a CF_3Br mixture the concentration of Br is larger than that of HBr; in this system the reverse reaction rate thus becomes larger after the middle of induction period, as shown in Figs. 9 and 10.

To summarise our interpretation of the results, we can say that the total inhibition effect in this system depends on a balance of the consumption reactions of CF_3Br (reactions (A14), (A15), and (A17)) during the early stage of the induction period. Thus, in this system the

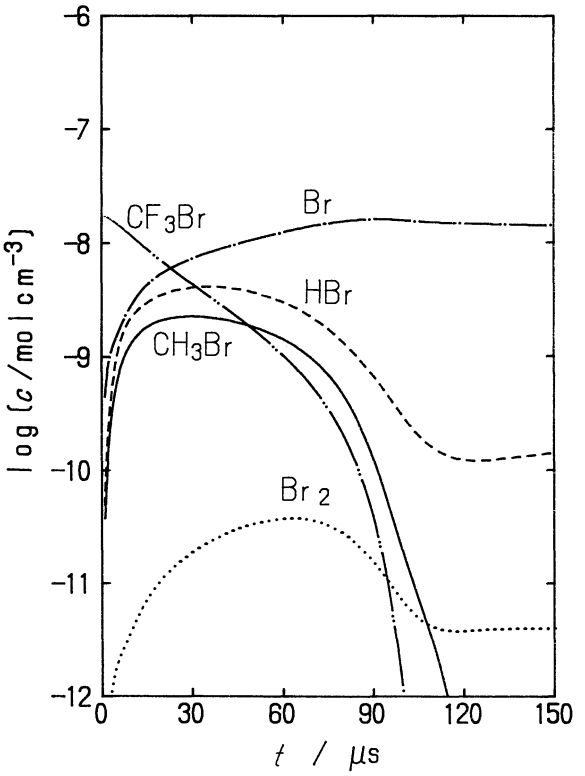


Fig. 12. Calculated concentration profiles of Br-containing species at 1565 K in mixture 5.

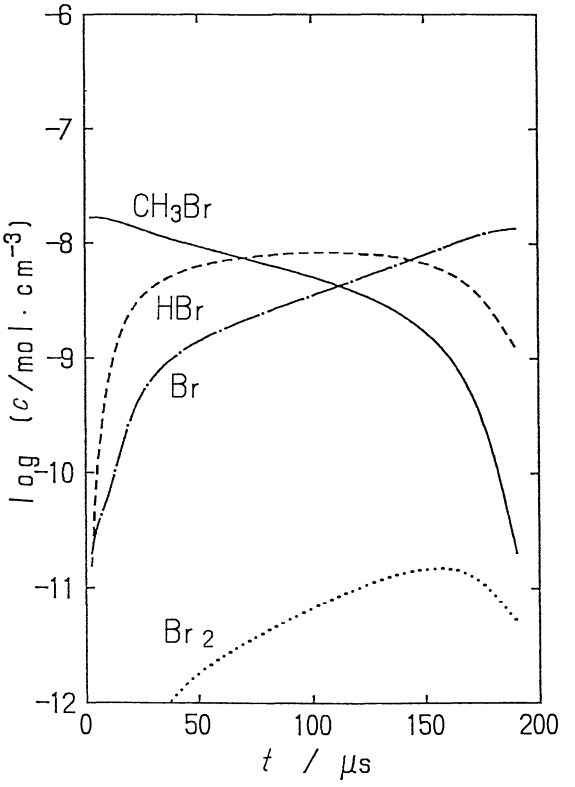

Fig. 13. Calculated concentration profiles of Br-containing species at 1500 K in mixture 9.

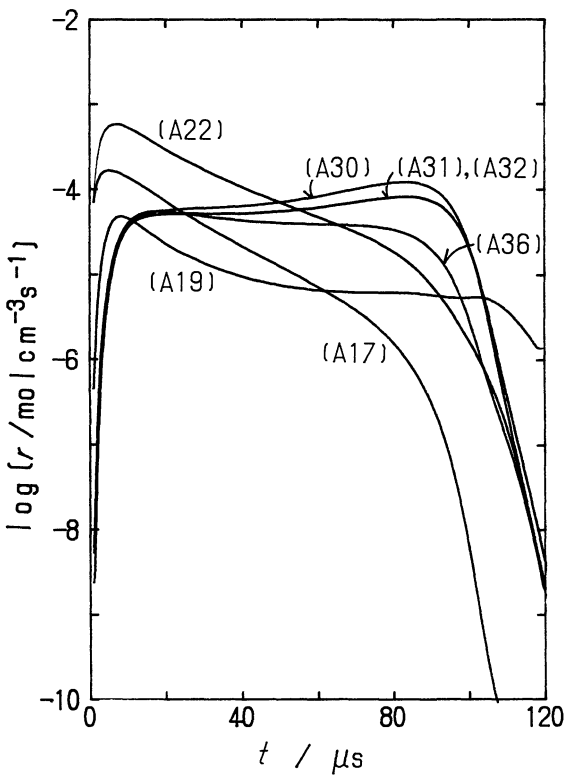

Fig. 14. Net reaction rates at 1565 K in mixture 5. The calculated reaction are the effective reactions involving F-containing species.

inhibition effects of reactions (A14) and (A17) surpass any promotion effect of reaction (A15). To make sure how CF_3 effects ethane ignition and how CF_3 is consumed, the rates of the effective reactions at 1565 K (which involve F-containing species) are shown in Fig. 14. This result indicates that reactions (A22), (A30), and (A36) have large rates during the induction period. During the earlier stage of the induction period, reaction (A22) has the fastest reaction rate.

In this system CH_3 is produced by the decomposition of C_2H_6. CH_3 is the source of active species, H. It is thus reasonable that reaction (A22), which consumes CH_3 radicals as the source of H atoms, has an inhibition effect in sensitivity analysis. This may show that the rate of reaction (A14) in this system is slower than reaction (A2) in the CH_3Br system.

CF_3 is consumed in a similar way as in the CH_4–CF_3Br system, considering that the effective reactions involving F-containing species are almost the same as in the CH_4–CF_3Br system.

Conclusion

In this study the ignition delay times were dependent on the reactions during the earlier stage. This may indicate that during the induction times the decomposition of fuel is important. Therefore, we can think that the effective reactions which formed loops didn't include O-containing reactions in the same reasons. In this study it is especially important to identify the initiation reaction. Although in the CH_4 system CF_3Br decomposition is an initiation reaction, in the C_2H_6 system C_2H_6 decomposition is an initiation reaction. This deference may cause these opposite effects.

In order to make the mechanism clearer, modifications of the used model and the concentration measurements of radicals during the induction time are essential.

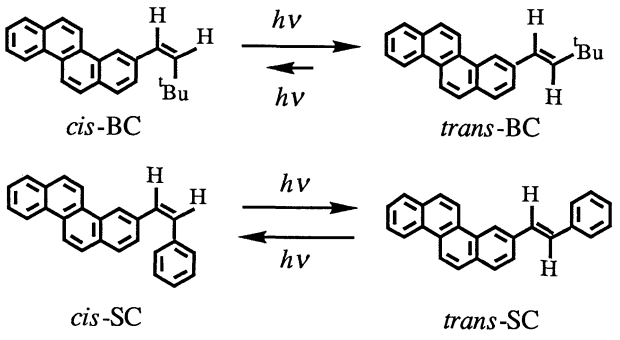
(Received June 24, 1991)

The effect of substitution of 3-chrysenyl group (Ar) on unsaturated double bonds in their triplet sensitized isomerization was investigated for Ar–CH=CH–R, R=^{t}Bu (BC) and Ph (SC) by means of stationary irradiations, laser flash photolyses, and MO calculations. Both olefins undergo mutual isomerization between their cis- and trans-isomers. However, BC has a unique triplet energy surface with two decay funnels at the planar trans (^{3}t*) and twisted (^{3}p*) conformations, which are in equilibrium with each other; ^{3}t* undergoes either unimolecular decay to the ground-state trans isomer or triplet energy transfer to the cis isomer (quantum chain process) and ^{3}p* decays to the ground state to give the cis and trans isomers. $T_n \leftarrow T_1$ absorptions observed for BC and SC are mainly attributed to ^{3}t* and ^{3}p*, respectively, on the basis of semiempirical MO calculations. The populations at ^{3}t* and ^{3}p* are estimated.

Recently, we demonstrated that the mode of photoisomerization, one-way (solely from cis to trans) or two-way (mutually between cis and trans) of aromatic olefins, Ar–CH=CH–R, in the triplet state is governed by the nature of substituents on the double bond, and proposed that the triplet energy of an aromatic group (Ar) and the conjugative property of substituent R (aryl or alkyl) play important roles in determining the mode of their isomerization by affecting the relative location of the trans and twisted triplets on their energy surface.[1-4] The lower the triplet energy of Ar, the more stabilized the trans triplet (^{3}t*) compared to the perpendicularly twisted triplet (^{3}p*) tending to result in one-way isomerization. However, a phenyl group on the β-ethylenic carbon (R=Ph) stabilizes of ^{3}p*, which favors two-way isomerization.[2-4] 2-Anthrylethylenes[5,6] and stilbenes[7,8] are extreme cases undergoing the one-way and two-way isomerizations, respectively.

Substitution of 1-pyrenyl[3] (triplet energy; E_T= 48 kcal mol^{-1}) and 8-fluoranthenyl[4] (52 kcal mol^{-1}) as Ar whose triplet energies are slightly or moderately higher than that of anthracene (42 kcal mol^{-1}) on an ethylenic carbon led to new mode of isomerization when R=Ph. These results in intermediate behavior between typical one-way and two-way isomerizations, whereas, with R=^{t}Bu, one-way isomerization takes place.[3] In the intermediate mode, the triplet states have two minima at ^{3}t* and ^{3}p* in equilibrium, and the deactivation takes place from ^{3}t* and from ^{3}p*.

These findings have led us to investigate the effect of substitution of 3-chrysenyl group on an unsaturated bond, Ar–CH=CH–R, as Ar whose triplet energy (57 kcal mol^{-1}) is slightly lower than that of naphthalene (61 kcal mol^{-1}),[9] with R=^{t}Bu, 3-(3,3-dimethyl-1-butenyl)chrysene (BC), and R=Ph, 3-styrylchrysene (SC).



Experimental

Materials. Sensitizers (thioxanthone, benzophenone, 1- and 2-acetylnaphthalene, anthraquinone, benzil, 9-fluorenone, and biacetyl) were purified by crystallization or distillation. Solvent benzene was distilled over calcium hydride before use.

1-(Bromomethyl)naphthalene. Refluxing a mixture of 1-methylnaphthalene (25.0 g, 0.176 mol) and *N*-bromosuccinimide (30.0 g, 0.169 mol) in CCl_4 in the presence of dibenzoyl peroxide gave 1-(bromomethyl)naphthalene (37.5 g, 96%).[10] ^{1}H NMR ($CDCl_3$) δ=4.64 (s, 2H, CH_2Br), 7.2—8.2 (m, 7H, ArH).

(1-Naphthylmethyl)triphenylphosphonium Bromide. 1-(Bromomethyl)naphthalene (37.5 g, 0.17 mol) was treated with triphenylphosphine (46.0 g, 0.18 mol) in refluxing toluene to give (1-naphthylmethyl)triphenylphosphonium bromide (69.5 g, 85%).

1-(*p*-Methylstyryl)naphthalene. 1-(*p*-Methylstyryl)-naphthalene was synthesized in a similar manners with those reported for 2-styrylnaphthalene.[11] *p*-Methylbenzaldehyde (25.0 g, 0.21 mol) was allowed to react with (1-naphthylmethyl)triphenylphosphonium bromide (38 g, 0.08 mol) in the presence of sodium ethoxide (39.0 g, 0.58 mol) in absolute ethanol under dry nitrogen to give 1-(*p*-methylstyryl)naphthalene (11.9 g, 62%).

3-Methylchrysene. 3-Methylchrysene was prepared by

photochemical cyclization of 1-(*p*-methylstyryl)naphthalene. The procedures were essentially the same as those described for chrysene in the literature.[12] 1-(*p*-Methylstyryl)naphthalene (2.5 g, 0.01 mol) was irradiated by 400 W HPML (3 h) in cyclohexane (1 dm^3) in the presence of iodine (0.13 g, 0.5 mmol) under oxygen atmosphere to give 3-methylchrysene (1.97 g, 79%); mp 171—172 °C; ^1H NMR ($CDCl_3$) δ=2.68 (s, 3H, CH_3), 7.39—8.03 (m, 7H, ArH), 8.57—8.79 (m, 4H, ArH).

3-(Bromomethyl)chrysene. 3-(Bromomethyl)chrysene was prepared by bromination of 3-methylchrysene (5.8 g, 24 mmol) with *N*-bromosuccinimide (4.3 g, 24 mmol) in carbon tetrachloride in the presence of dibenzoyl peroxide. 3-(Bromomethyl)chrysene was purified by crystallization from benzene (3.4 g, 44%); mp 176—177 °C; ^1H NMR ($CDCl_3$) δ=4.81 (s, 2H, CH_2), 7.57—8.07 (m, 7H, ArH), 8.61—8.85 (m, 4H, ArH).

(3-Chrysenylmethyl)triphenylphosphonium Bromide. 3-(Bromomethyl)chrysene (3.4 g, 11 mmol) was treated with triphenylphosphine (3.2 g, 12 mmol) in refluxing toluene to give (3-chrysenylmethyl)triphenylphosphonium bromide (5.0 g, 82%).

3-(3,3-Dimethyl-1-butenyl)chrysene (BC). (3-Chrysenylmethyl)triphenylphosphonium bromide (5.0 g, 8.6 mmol) was suspended in absolute ether (200 ml) with mechanical stirring under dry nitrogen. To this solution was gradually added a solution of butyllithium in hexane (15%, 15 ml). The stirring was continued for 30 min, and then a solution of 2,2-dimethylpropanal in ether (70%, 20 ml) was added to this solution. The reaction mixture was refluxed gently for 30 min. The precipitate was filtered off and the filtrate was washed with water. After drying of extract with anhydrous sodium sulfate, evaporation of the solvent gave an isomeric mixture of 3-(3,3-dimethyl-1-butenyl)chrysene (1.4 g, 54%). The cis isomer was separated by column chromatography (SiO_2) with petroleum ether (bp<69 °C) and the trans isomer was obtained by irradiating a benzene solution of the isomeric mixture with a tungsten-halogen lamp in the presence of iodine under argon.

cis-BC: Mp 166—167 °C; ^1H NMR ($CDCl_3$) δ=1.06 (s, 9H, CMe_3), 5.82 (d, 1H, *J*=12 Hz, C=CH), 6.71 (d, 1H, *J*=12 Hz, C=CH), 7.40—8.05 (m, 7H, ArH), 8.60—8.86 (m, 4H, ArH); UV (cyclohexane) λ_{max} 228 nm (ε 20200), 264 (53100), 273 (86800), 298 (13100), 310.5 (13500), 324.5 (13200), 347 (680), 365 (530). Calcd for $C_{24}H_{22}$: C, 92.85; H, 7.14%. Found: C, 92.74; H, 7.12%.

trans-BC: Mp 158—159 °C; ^1H NMR ($CDCl_3$) δ=1.22 (s, 9H, CMe_3), 6.56 (d, 1H, *J*=16 Hz, C=CH), 6.60 (d, 1H, *J*=16 Hz, C=CH), 7.50—8.07 (m, 7H, ArH), 8.58—8.81 (m, 4H, ArH); UV (cyclohexane) λ_{max} 237 nm (ε 28900), 274 (87500), 283 (79600), 304.5 (16800), 317.5 (23100), 332 (23000), 354 (1100), 374 (730). Calcd for $C_{24}H_{22}$: C, 92.85; H, 7.14%. Found: C, 92.81; H, 7.31%.

3-Styrylchrysene (SC). Benzaldehyde (0.55 g, 5.2 mmol) was allowed to react with (3-chrysenylmethyl)triphenylphosphonium bromide (1.2 g, 2.1 mmol) in the presence of sodium ethoxide (1.4 g, 20.6 mmol) in absolute ethanol under dry nitrogen to give 3-styrylchrysene (0.66 g, 70%). The cis and trans isomers were separated by column chromatography (SiO_2) with benzene:hexane (=1:9) mixture, then purified by crystallization from benzene.

cis-SC: Mp 176—177 °C; ^1H NMR ($CDCl_3$) δ=6.80 (d, 1H, *J*=12 Hz, C=CH), 6.85 (d, 1H, *J*=12 Hz, C=CH), 7.05—8.04 (m, 7H, ArH), 8.32—8.83 (m, 4H, ArH); UV (benzene) λ_{max} 326 nm (ε 21600), 335 (21700). Calcd for $C_{26}H_{18}$: C, 94.55; H, 5.45%. Found: C, 94.83; H, 5.58%.

trans-SC: Mp 225—227.5 °C; ^1H NMR ($CDCl_3$) δ=7.30—8.08 (m, 14H, C=CH and ArH), 8.60—8.83 (m, 4H, ArH); UV (benzene) λ_{max} 294 nm (ε 47000), 306 (45000), 327 (31000), 341 (42000), 355 (35000), 380 (4500). Calcd for $C_{26}H_{18}$: C, 94.55; H, 5.45%. Found: C, 94.64; H, 5.63%.

Stationary Irradiation. Photostationary isomer ratios were measured in degassed benzene solutions (three freeze-pump-thaw cycles) in the presence of a desired concentration of a sensitizer in a 1-cm diameter quartz tube. The irradiation was performed with 366- and 405-nm light isolated through a Toshiba UV-D36B and an L-39 glass filter, respectively, from a 400-W high-pressure mercury lamp. The light intensity was determined using potassium tris(oxalato)ferrate(III) actinometry,[13] and the concentrations of olefins in the reaction mixtures were determined by GLPC or HPLC analysis.

Phosphorescence Measurement. Phosphorescence spectra were measured at 77 K in deaerated 3-methylpentane or EPA (ether:isopentane:ethanol=5:5:2) on Hitachi F-4000 or F-4010 spectrofluorimeter equipped with phosphorescence accessories.

Laser Flash Photolyses. Laser flash photolyses were performed by using an excimer laser (Lambda Physik EMG101, XeCl, 308 nm, 150±7 mJ, 10-ns fwhm) or an excimer laser-pumped dye laser (Lambda Physik FL-3002, 425 nm, 3.5±0.3 mJ, Stilbene 3) and a pulsed xenon arc (Wacom KXL-151, 150 W) as a monitoring light source.[4] Sample solutions (benzene or carbon tetrachloride) were deaerated by three freeze-pump-thaw cycles or argon purging.

Calculation. Oscillator strengths and transition energies of $T_n \leftarrow T_1$ absorptions of chrysene and 3-chrysenylethylenes and $D_n \leftarrow D_1$ absorptions of 3-chrysenylmethyl radicals were calculated by the semiempirical PPP-SCF-SCI method.[14]

Results

Isomerization Behavior on Stationary Irradiation. On triplet sensitization both BC and SC underwent two-way isomerization mutually between their cis- and trans-isomers.

However, in the isomerization of BC sensitized with anthraquinone (1×10^{-2} mol dm^{-3}) in deaerated benzene as Fig. 1 (plot a) shows, the photostationary state isomer ratios $([t]/[c])_s$ increased linearly with increasing concentration of *cis*-BC in $(2.5—10.0)\times10^{-3}$ mol dm^{-3}. As Table 1 indicates, the composition of the trans isomer at the photostationary state [(% trans)$_s$] ([BC]=1.0×10^{-3} mol dm^{-3}) was increased with lowering of the triplet energy of the sensitizers employed.

Moreover, $(\%\text{trans})_s$ decreased with increase of the concentration of the sensitizers. Thus, on 9-fluorenone sensitization, $(\%\text{trans})_s$ decreased from 8.2% at 5×10^{-3} mol dm^{-3} to negligible amounts at higher than 5×10^{-2} mol dm^{-3}, indicating that the isomerization proceeds almost one-way at 5×10^{-2} mol dm^{-3} of the sensitizer.

Addition of azulene in the range of $(3.3—13)\times10^{-4}$ mol dm^{-3} linearly increased $([t]/[c])_s$ as illustrated in Fig. 1 (plot b) on anthraquinone (1×10^{-2} mol dm^{-3}) sensitization.

Table 1. The Effect of Triplet Sensitizers on the Composition of the trans Isomer at the Photostationary State $(\%trans)_s$ of BC (1.0×10^{-3} mol dm^{-3}) in Benzene

a) Ref. 15. b) Wavelengths of light used for irradiation.

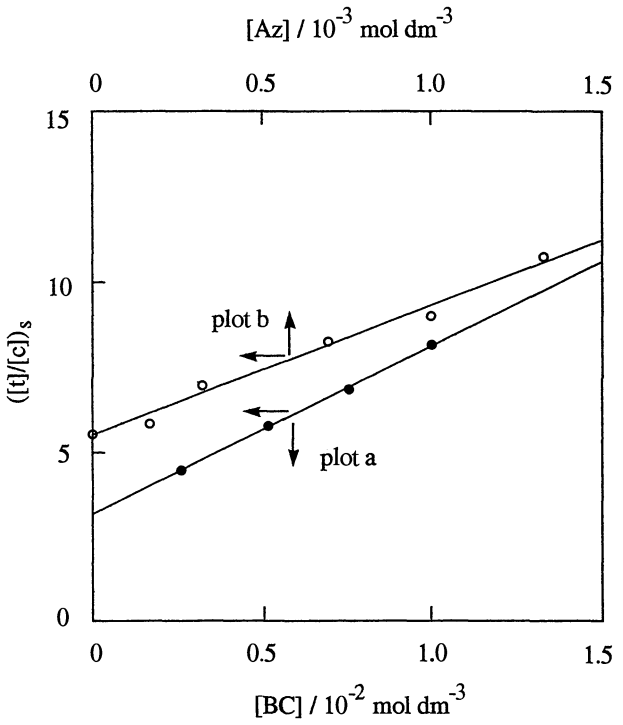

Fig. 1. Plots of the photostationary state isomer ratios against concentration of BC (plot a; closed circles) or azulene (plot b; open circles).

On the other hand, in the isomerization of SC $([t]/[c])_s$ was not changed at all with its concentration in $(0.8—3.3)\times10^{-4}$ mol dm^{-3}, however, $(\%trans)_s$ was varied among the sensitizers; 37.0 and 29.4% on sensitization with biacetyl (E_T=56.3 kcal mol^{-1},[15] 0.1 mol dm^{-3}) and benzil (0.14 mol dm^{-3}), respectively.

Phosphorescence Spectra.

cis-BC, *trans*-BC, and *trans*-SC exhibited phosphorescence in 3-methylpentane and EPA (ether:isopentane: ethanol=5:5:2) at 77 K. However, *cis*-SC did not phosphoresce at all.

As Fig. 2 illustrates, *trans*- (Fig. 2a) and *cis*-BC (Fig. 2b) exhibited different spectra. However, as depicted in Fig. 2b, the spectrum of *cis*-BC was changed very rapidly during the measurement; the weak band at 500 nm decreased and the strong bands at 515 and 560 nm increased in intensity for each scanning of the spectrum,

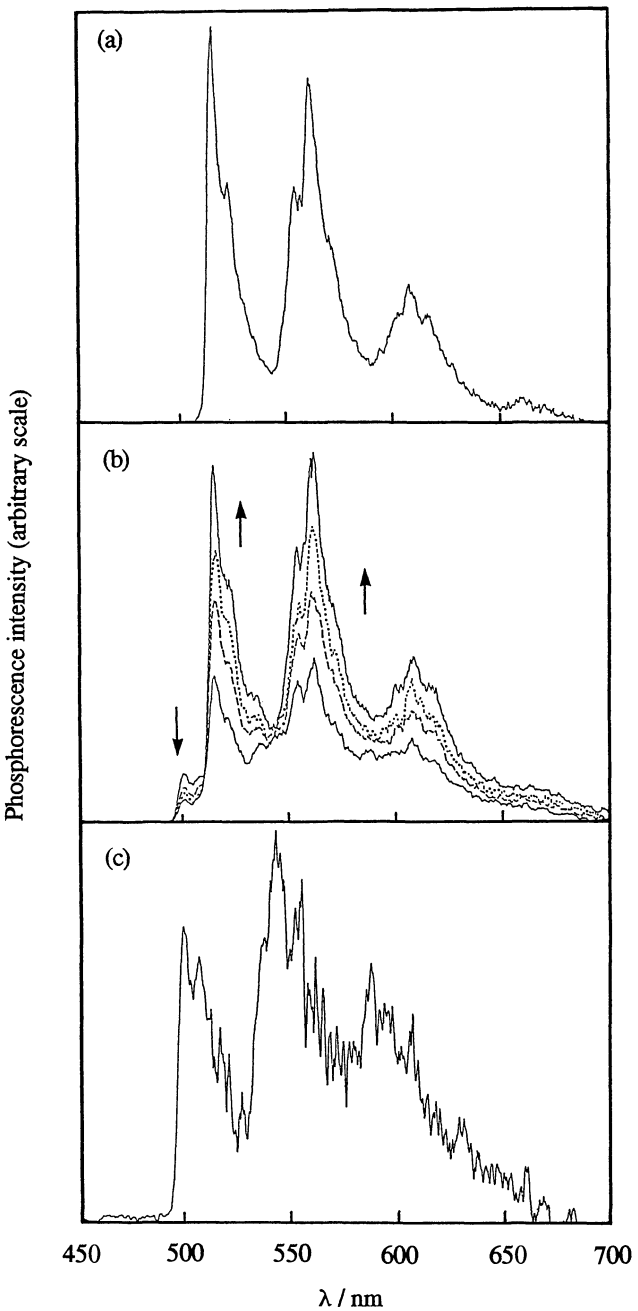

Fig. 2. Phosphorescence spectra obtained on excitation of *trans*-BC (a) and *cis*-BC (b) in 3-methylpentane at 77 K, and a difference spectra (c, subtracted a from b). Solid lines indicate the first and the 4th scans, and dashed and dotted lines indicate the second and the third scans, respectively (see text).

and finally, the spectrum became identical with that of *trans*-BC.

Therefore, the observed phosphorescence spectrum of *cis*-BC is reasonably assigned to a mixture of the cis and trans isomers. The phosphorescence spectrum due to *cis*-BC is obtained by the subtracting the spectrum of the trans isomer from that of the mixture multiplied by an adequate factor (Fig. 2-c). The lifetime measurement was unsuccesful and also it is not clear whether the emission comes from adiabatic isomerization on the triplet energy surface or re-excitation of the trans isomer after diabatic isomerization through $^3p^*$. However it should be noted that the isomerization of BC takes place even in rigid media at 77 K in spite of the presence of two relatively large substituents on both of it's ethylenic carbons. This is a property of it's T_1 potential energy surface.

The phosphorescence excitation spectrum showed the same behavior. The excitation spectrum of *trans*-BC was identical with its absorption spectrum irrespective of the monitoring wavelength either 515 or 560 nm (Fig. 3). On the other hand, the excitation spectrum of *cis*-BC was also identical, when monitored at 500 nm (Fig. 3), but not identical, when monitored at 515 nm, with its absorption spectrum, and the spectral profile was changed during

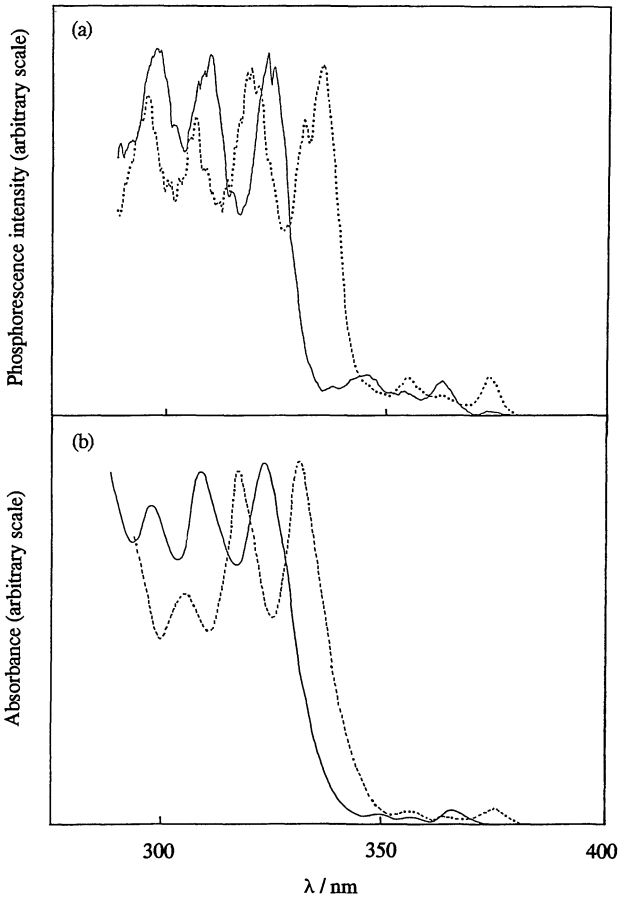

Fig. 3. Phosphorescence excitation spectra of *cis*-BC monitored at 500 nm (—) and *trans*-BC monitored at 520 nm (·····) in EPA at 77 K (a), and absorption spectra of *cis*-BC (—) and *trans*-BC (·····) in benzene at ambient temperature (b).

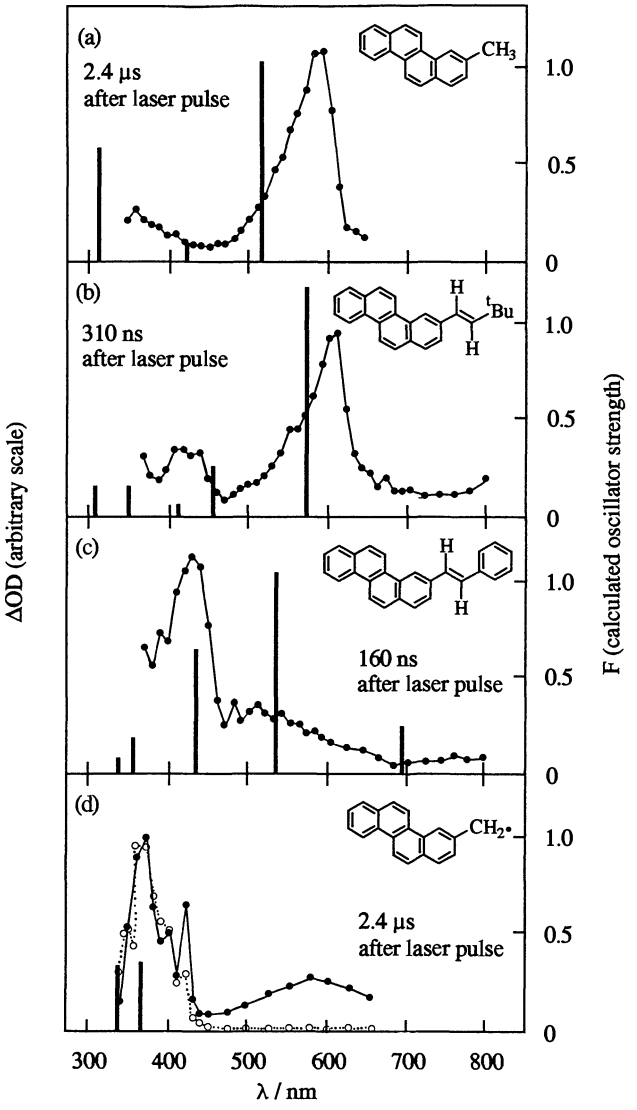

Fig. 4. $T_n \leftarrow T_1$ and $D_n \leftarrow D_1$ absorption spectra and calculated oscillator strengths (see text) of 3-methylchrysene (a), 3-(3,3-dimethyl-1-butenyl)chrysene (b), 3-styrylchrysene (c), and 3-chrysenylmethyl radical (d). Solid line was measured in deaerated benzene and dotted line was measured in deaerated CCl_4. The calculation was made for 3-vinylchrysene instead of BC.

measurement.

Table 2 summarizes the triplet energies of *trans*- and *cis*-BC, *trans*-SC along with chrysene estimated from the 0-0 band of their phosphorescence spectra.

Transient Absorption Spectra. Figure 4 depicts transient absorption spectra of the triplet state of BC, SC and related species. *trans*-BC exhibited two major $T_n \leftarrow T_1$ absorption bands around 430 and 580 nm, and *trans*-SC a strong band at 430 nm and a weak broad band around 500 nm in deaerated benzene (Fig. 4b and 4c) on sensitized excitation with biacetyl or thioxanthone (as a triplet sensitizer) with 425-nm laser pulses. The decay profiles of their absorption bands were essentially independent of wavelength and single-exponential with lifetimes of 810 ns for *trans*-BC and of 210 ns for *trans*-SC. On excitation under similar conditions *cis*-BC and *cis*-SC also exhibited almost the same absorptions with the same lifetimes as the corresponding trans isomers.

3-Methylchrysene showed almost identical $T_n \leftarrow T_1$ absorption around 580 nm with 17 μs lifetime under similar conditions (Fig. 4a) as chrysene[16] (the lifetime was determined to be 30 μs). 3-Chrysenylmethyl radical,[17] a model of the triplet olefins with a twisted conformation, generated by photolysis of 3-(bromomethyl)chrysene with 308-nm laser pulses, showed an absorption around 360 nm (Fig. 4d).

The oscillator strengths and transition energies of $T_n \leftarrow T_1$ or $D_n \leftarrow D_1$ absorptions were calculated for chrysene, 3-vinylchrysene, *trans*-SC and 3-chrysenylmethyl radicals by the semiempirical PPP-SCF-SCI method,[14] and are included in Fig. 4 as bar indications. The length of the bars indicates the relative oscillator strength.

Estimation of Extinction Coefficients of $T_n \leftarrow T_1$ Absorption for $^3t^*$ and $^3p^*$. The molar extinction coefficients (ε_T) of $T_n \leftarrow T_1$ absorption of $^3t^*$ and $^3p^*$ were determined by comparison with that of anthracene triplets (ε_T=46000 dm^3 mol^{-1} cm^{-1} at 430 nm).[18] The triplet states of the chrysenylethylenes were produced by energy transfer from thioxanthone triplets in deaerated benzene. The sensitizer was irradiated at a fixed concentration with laser pulses of a constant intensity with changing concentration of the substrates, anthracene and the chrysene derivatives to measure the optical densities (ΔOD) of their resulting triplet states. The ΔOD values increased with increasing concentration of the substrate and attained a plateau at higher concentrations. By assuming the energy transfer efficiency to be unity, ε_T value of the triplet 3-methylchrysene was determined to be 20000 dm^3 mol^{-1} cm^{-1} at 580 nm. The $T_n \leftarrow T_1$ absorption of BC exhibited ε_T=2900 and 10000 dm^3 mol^{-1} cm^{-1} at 430 and 580 nm, respectively, and that of SC showed ε_T=5900 and 1300 dm^3 mol^{-1} cm^{-1} at 430 and 580 nm, respectively.

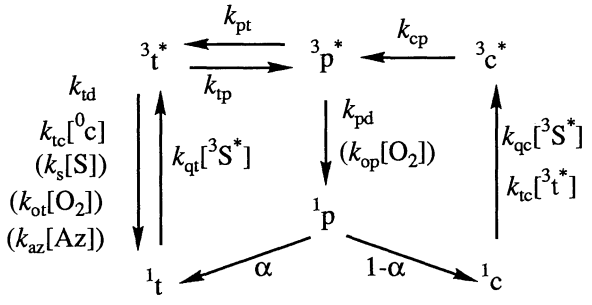
Quenching Rate Constants of Olefin Triplets by Azulene and Oxygen. The $T_n \leftarrow T_1$ absorptions of BC and SC were efficiently quenched in benzene by azulene and oxygen without change of spectral profiles. The decay rate constant, k_d ($=1/\tau_T$) value increased linearly with increasing concentration of azulene or oxygen, and the slope gave a quenching rate constant by azulene (k_{az}^{obsd}) or oxygen (k_{ox}^{obsd}). The k_{az}^{obsd} values were obtained as 9.5×10^9, 6.8×10^9, and 3.5×10^9 mol^{-1} dm^3 s^{-1} for chrysene, BC, and SC, respectively. The k_{ox}^{obsd} values were 2.0×10^9, 3.5×10^9, and 5.6×10^9 mol^{-1} dm^3 s^{-1} for chrysene, BC, and SC, respectively.

Discussion

On anthraquinone sensitization of BC, the observed increase of the photostationary isomer ratio, $([t]/[c])_s$, linearly with BC concentration (Fig. 1) and with lowering of the triplet energies of the sensitizer employed indicates the following two things. The first, trans ($^3t^*$) and twisted triplets ($^3p^*$) are in equilibrium ($K_{tp}=k_{tp}/k_{pt}$), and the second, $^3t^*$ has a sufficient lifetime to transfer its triplet energy to the cis isomer leading to quantum chain process and $^3p^*$ decays to the ground state to give the cis and trans isomers (Scheme 1). Therefore, BC undergoes a mutual isomerization between the cis and trans isomers accompanied by quantum chain isomerization from cis to trans isomers.

In contrast to BC, the lack of concentration effects of the olefin and triplet sensitizer on $([t]/[c])_s$ for the SC isomerization indicates that SC undergoes typical two-way isomerization with a single-decay funnel at $^3p^*$.

In the transient absorption, the band around 580 nm observed for BC can be assigned to the planar trans triplet, $^3t^*$, and those around 430 nm (strong in SC and weak in BC) to $^3p^*$ by comparison with $T_n \leftarrow T_1$ absorptions of the model compounds and based on MO calculations. First, the band around 580 nm is very close in wavelength to the $T_n \leftarrow T_1$ absorptions of chrysene and 3-methylchrysene, and the other band at 430 nm to the absorption of 3-chrysenylmethyl radicals. The long tail observed for SC at longer wavelengths is likely to be due to $^3t^*$ in equilibrium with $^3p^*$. Second the observed absorption wavelengths for BC fit well with the calculated values. For SC, however, the observed spectrum around 500 nm did not fit well with the calculated result for $^3t^*$, and can be ascribed to $^3p^*$. The



Scheme 1. Photoisomerization scheme of BC and SC.

absorption band of ^{3}p* is at longer wavelengths ($\lambda_{max}\approx$430 nm) than that of 3-chrysenylmethyl radicals ($\lambda_{max}\approx$360 nm) and this might imply some kind of interaction between the two chromophores of twisted "1,2-biradicals".

Furthermore when one assumes that the planar triplets (^{3}t*) of the olefins have the same ε_T values as the 3-methylchrysene triplets at the peak wavelength, the observed ΔOD values of these olefin triplets at 580 nm are to be obtained when ^{3}t* is populated in 50% among the triplet state of BC and in 7% for SC. Accordingly, the population of ^{3}p* is to be 50% for BC and 93% for SC in triplet state. Based on these populations, ε_T at 430 nm for ^{3}p* is estimated as 5800 and 6300 for BC and SC, respectively, and these values are in excellent agreement with each other. This is quite reasonable, because ^{3}p*'s of BC and SC may have similar twisted structures.

The observed apparent quenching rate constants of the triplet states with azulene, k_{az}^{obsd}, and by oxygen, k_{ox}^{obsd}, enable one to estimate K_{tp}. The k_{az}^{obsd} and k_{ox}^{obsd} values are related with K_{tp} as expressed by Eqs. 1 and 2,[9] where k_{ot} and k_{op} are the rate constants for quenching of ^{3}t* and ^{3}p* by oxygen, respectively.

$$k_{az}^{obsd} = \frac{k_{az}}{1 + K_{tp}}, \quad (1)$$

$$k_{ox}^{obsd} = \frac{k_{ot} + k_{op}K_{tp}}{1 + K_{tp}}. \quad (2)$$

When we assume that k_{az} for ^{3}t* of BC and SC are the same as that for chrysene, 9.5×10^9 mol^{-1} dm^3 s^{-1}, K_{tp} is estimated as 0.39 (^{3}t* 72%) for BC and 1.7 (^{3}t* 37%) for SC from Eq. 1. Likewise, reasonable assumption of $k_{ot}=2\times10^9$ as for chrysene and $k_{op}=9\times10^9$ dm^3 mol^{-1} s^{-1} as for stilbene ^{3}p*,[8] affords K_{tp} as 0.23 (^{3}t* 81%) and 0.83 (^{3}t* 55%) for BC and SC, respectively. The population of ^{3}t* is estimated here from the quenching rate constants are slightly higher than those estimated from the extinction coefficients (^{3}t* 50% for BC and 7% for SC). The difference in K_{tp} between the methods of estimation may be attributed to difficulty in assumption of the quenching rate constants, k_{az}, k_{op}, k_{ot}, and ε. However, for the convenience of the subsequent discussion, one could assume the average population of ^{3}t* as 68% and 33% for BC and SC, respectively.

Triplet energy of ^{3}t* is estimated for BC and SC from the population of ^{3}t* and ^{3}p* by using an equation $\Delta G=-RT\ln([^3p^*]/[^3t^*])$. ^{3}t* of BC is 0.5 kcal mol^{-1} lower in energy than ^{3}p* for BC ($[^3p^*]/[^3t^*]=32\%/68\%=0.47$) and ^{3}t* of SC is 0.4 kcal mol^{-1} higher in energy than ^{3}p* ($[^3p^*]/[^3t^*]=67\%/33\%=2.0$). These results together with the results of phosphorescence (Table 2) enable us to propose the potential energy surfaces along the twisting of the double bond for BC and SC as depicted in Fig. 5.

According to Scheme 1, the change of $([t]/[c])_s$ with [*cis*-BC] (plot a in Fig. 1) is expressed by Eq. 3,[2] the slope (5.3×10^2 mol^{-1} dm^3) corresponds to $k_{tc}/(1-\alpha)K_{tp}k_{pd}$ and the intercept denotes $([t]/[c])_s$ value (population of 74.8% of the trans isomer) when quantum chain process does

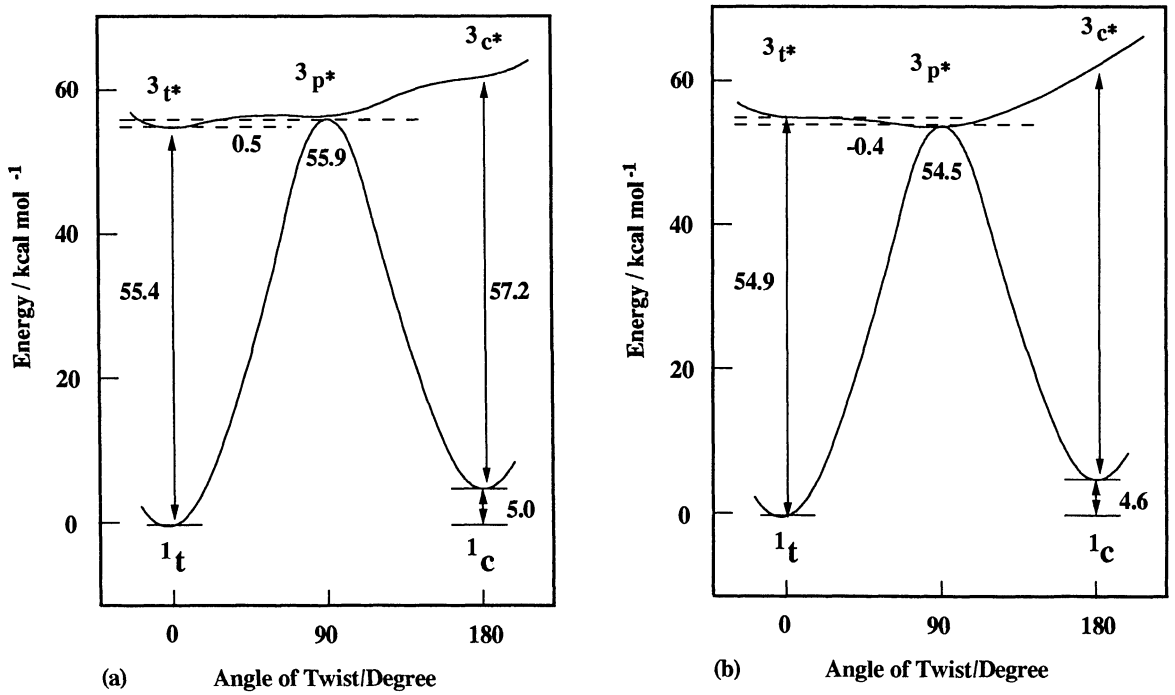


Fig. 5. Estimated potential energy surfaces for BC (a) and SC (b) plotted against rotational angle around the C–C double bond.

not participate at all.

$$([t]/[c])_s = \frac{\alpha K_{tp} k_{pd} + k_{td} + k_{tc}[cis\text{-BC}]}{(1-\alpha) K_{tp} k_{pd}}, \quad (3)$$

where we assume that the equilibrium between $^3t^*$ and $^3p^*$ is accomplished, that is $k_{tp} \gg k_{td}$, $k_{tc}[cis\text{-BC}]$ and $k_{pt} \gg k_{pd}$.

The observed triplet lifetime of BC is expressed by Eq. 4.

$$\tau_T = \frac{1 + K_{tp}}{K_{tp} k_{pd} + k_{td}}. \quad (4)$$

The rate constant for deactivation of the trans triplets, k_{td}, can be reasonably assumed to be similar to that for 3-methylchrysene (3.3×10^4 s^{-1}). Substitution of the observed values for K_{tp}(=0.67) and τ_T(=810 ns) into Eq. 4 gives k_{pd} as 3.0×10^6 s^{-1}. This is lower than the deactivation rate constant reported for stilbene (2×10^7 s^{-1}).[8]

Furthermore, Eq. 3 and Fig. 1 (plot a) give two important results. The intercept corresponds to $([t]/[c])_s = \alpha/(1-\alpha)$ when [BC]=0, since $k_{td}/(1-\alpha)K_{tp}k_{pd}$ is negligible, therefore, the observed value, [$([t]/[c])_s$=3] gives α as 0.75. The slope, $k_{tc}/(1-\alpha)K_{tp}\ k_{pd}$, ($5.3\times10^2$ mol^{-1} dm^3) combined with K_{tp} and k_{pd} gives a rate constant, k_{tc}, for the energy transfer from $^3t^*$ to cis isomer (quantum chain process) as $k_{tc}=2.7\times10^8$ mol^{-1} dm^3 s^{-1}. According to the triplet energies of *trans*- and *cis*-BC determined by their phosphorescence, 55.4 and 57.2 kcal mol^{-1}, the energy transfer from $^3t^*$ to *cis*-BC is 1.8 kcal mol^{-1} endothermic. The above value for k_{tc} is in good agreement with a value (2.5×10^8 mol^{-1} dm^3 s^{-1}) estimated for 1.8 kcal mol^{-1} endothermic energy transfer from the following well-accepted equation:[19]

$$k_{tc} = A \exp(-E_a/RT), \quad (5)$$

where, $A=5\times10^9$ mol^{-1} dm^3 s^{-1}, and $-E_a=\Delta E_T=E_T$(*trans*-BC)$-E_T$(*cis*-BC)=1.8 kcal mol^{-1} (Table 2).

In the presence of azulene, $([t]/[c])_s$ is expressed by Eq. 6,[3]

$$([t]/[c])_s = \frac{\alpha K_{tp} k_{pd} + k_{td} + k_{tc}[cis\text{-BC}] + k_{az}[Az]}{(1-\alpha) K_{tp} k_{pd}}, \quad (6)$$

where k_{az} is quenching rate constant of $^3t^*$ by azulene. The slope of plot b in Fig. 1, $k_{az}/(1-\alpha)K_{tp}k_{pd}$, 3.8×10^3 mol^{-1} dm^3, combined with α, K_{tp}, and k_{pd} values gives k_{az} as 1.9×10^9 mol^{-1} dm^3 s^{-1}. This value is quite reasonable since energy transfer from triplet state of *trans*-BC (E_T=55.4 kcal mol^{-1}, Table 2) to azulene (39.8 kcal mol^{-1})[20] is exothermic.

The $([t]/[c])_s$ values for BC depends on the triplet energy (Table 1) and concentration of the sensitizers, and the isomerization is seemingly almost one-way on sensitization with high concentration of 9-fluorenone, 0.05 mol dm^{-3}. This fact is attributed to an equilibrium between $^3t^*$ and the triplet state of the sensitizer employed (S),

$$^3S^* + {}^1t \rightleftarrows S + {}^3t^*, \quad (7)$$

because of their small difference in triplet energy. Therefore, $([t]/[c])_s$ is expressed by Eq. 8, where k_s denotes the rate constant for the energy transfer from $^3t^*$ to S, as previously reported for the isomerization of 2-(3,3-dimethyl-1-butenyl)naphthalene (BN) using sensitizers of low triplet energy.[21]

$$([t]/[c])_s = \frac{\alpha K_{tp} k_{pd} + k_{td} + k_{tc}[cis\text{-BC}] + k_s[S]}{(1-\alpha) K_{tp} k_{pd}}. \quad (8)$$

From the above arguments, triplet and ground state potential energy surfaces for BC and SC are proposed as depicted in Fig. 5.

For BC (Fig. 5-a), the triplet energies of $^3t^*$ and $^3c^*$ were estimated to be 55.4 and 57.2 kcal mol^{-1}, respectively, from their 0-0 bands of phosphorescence spectra. The triplet energy of $^3p^*$ was estimated relatively to $^3t^*$ using an equation $\Delta G=-RT\ \ln([^3p^*]/[^3t^*])$ based on the population of $^3t^*$ and $^3p^*$ ($[^3p^*]/[^3t^*]=0.47$) obtained from ε_T and quenching rate constant by azulene, thus $^3t^*$ of BC is 0.5 kcal mol^{-1} lower in energy than $^3p^*$. Ground state energy difference between cis and trans isomers due to steric hindrance is estimated as 5 kcal mol^{-1}, the same as 2-(3,3-dimethyl-1-butenyl)anthracene.[22]

For SC (Fig. 5-b), the triplet energies of $^3t^*$ (54.9 kcal mol^{-1}) and $^3p^*$ (0.4 kcal mol^{-1} lower in energy than $^3t^*$, $[^3p^*]/[^3t^*]=2.0$) are estimated similarly as for BC. However, the triplet energy of $^3c^*$ is supposed not to be lower than that for $^3t^*$, 54.9 kcal mol^{-1}, and not higher than that of chrysene, 57.4 kcal mol^{-1}, because of its lack of phosphorescence. Ground state energy difference between cis and trans isomers is estimated 4.6 kcal mol^{-1}, the same as reported to stilbene.[7]

The differences of phtochemical behavior and triplet potential energy surfaces between BC and SC may originate from the stabilization of $^3p^*$ of SC due to conjugation with diaryl substituents compared to that of BC.

Conclusion

In the triplet sensitized isomerization of 3-chrysenylethylenes, 3-styrylchrysene (SC) shows the typical two-way mode, whereas 3-(3,3-dimethyl-1-butenyl)chrysene (BC) behaves by intermediate mode with "dual decay funnel". The SC triplet decays only at the twisted geometry. On the other hand, BC triplet decays at both of the twisted and planar trans conformations leading to a quantum chain process from

the latter. Therefore in the (3,3-dimethyl-1-butenyl)-arene series, Ar–CH=CH–^{t}Bu, BC with 3-chrysenyl group (E_T of chrysene=57 kcal mol^{-1}) is located at a boundary position between typical two-way mode with Ar=2-naphthyl (E_T of naphthalene=60 kcal mol^{-1}) and cis→trans one-way mode with Ar=8-fluoranthenyl (E_T of fluoranthene=53 kcal mol^{-1}) derivative.

The present work contributes to revealing that the mode of photoisomerization of aromatic olefins, Ar–CH=CH–R, in the triplet state is controlled by the relative location of the trans and twisted triplets on the energy surface which is defined by the triplet energy of an aromatic group (Ar) and the nature of substituent R (aryl or alkyl).

The authors thank Dr. Shigero Oishi, Kitasato University, for valuable suggestions regarding the transient absorption measurements. Formation of Halide Complexes of Methyl- and Inorganic Germaniun(IV) in Aqueous Hydrohalogenic Acid Solutions

Yoshiki SOHRIN
Institute for Chemical Research, Kyoto University,
Uji, Kyoto 611
(Received May 31, 1991)

The reaction of methyl- and inorganic germanium(IV) hydroxides ($(CH_3)_nGe(OH)_{4-n}$; n=0, 1, 2, or 3) with halide ions (X^-=Cl^-, Br^-, or I^-) to form halide complexes ($(CH_3)_nGeX_{4-n}$) in aqueous acidic solution has been investigated by liquid–liquid extraction, solid–liquid distribution (ion exchange), and ^1H NMR spectrometry. It has been found that methylgermanium moieties are hard Lewis acids similarly to inorganic germanium(IV), because the stability constant of the halide complexes decreases in the order $Cl^->Br^->I^-$. The stability constant for an X^- ion increases as the number of methyl groups attached to the germanium atom increases. The species of inorganic-, monomethyl-, and dimethylgermanium are nonionic and have a tetrahedral structure in HX solution, and OH^- ions attached to the germanium atom are stepwise substituted by X^- ions with an increase in HX activity. Trimethylgermanium alone forms a cation, when the activity of HX is not sufficiently high. These facts suggest that the transfer of a negative charge from methyl groups to the central germanium atom lowers the stability of the bond between the germanium atom (hard acid) and an OH^- ion (hard base).

Organogermanium(IV) compounds generally have a tetrahedral configuration and are expressed as R_nGeL_{4-n} (n=1, 2, 3, or 4), where R is a σ-bonded organic ligand and L is the other ligand bonding to the germanium atom via an atom other than carbon.[1,2] The germanium–carbon (Ge–C) bond is highly inert and stable to water or air, and methylgermanium species ($n\leqslant 3$) have been found in natural waters.[3] The aqueous solution chemistry of organogermanium, however, is only slightly known.

Inorganic germanium(IV) (Ge_i) is an extremely hard and strong Lewis acid. Ge_i of low concentration is thoroughly hydrolyzed and dissolved in water as $Ge(OH)_4$, which is sometimes mentioned as GeO_2. The hydroxide complex is transformed into the halide complex (GeX_4; X=Cl, Br, or I) in hydrohalogenic acid (HX) solution, which is extracted into nonpolar organic solvents.[4,5] Although it is reported that organogermanium compounds also dissolve in water as $R_nGe(OH)_{4-n}$ and form R_nGeX_{4-n} in HX solution,[6-8] there is no quantitative knowledge of the reaction.

While studies on the structure of germanium species in aqueous solution are also rare, it appears that the tetrahedral structure is common not only for the halide complexes but also for the hydroxide complexes. Raman spectra suggested that Ge_i is present as tetrahedral $[O_2Ge(OH)_2]^{2-}$ in nearly saturated aqueous KOH,[9] and that $(CH_3)_2Ge(OH)_2$ has a tetrahedral structure in water.[8]

In order to clarify the effect of methyl groups on the Lewis acid nature of the central germanium atom, a study on halide complexing of methyl- and inorganic germanium in HX solution by liquid–liquid extraction was undertaken. In the present paper, the data of liquid–liquid extraction have been analyzed based on the information on the charge and structure of the germanium species, which is obtained from solid–liquid distribution (ion exchange) and NMR chemical shift of the methyl protons.

Experimental

Reagents. Standard solutions of monomethylgermanium (MeGe), dimethylgermanium (Me_2Ge), and trimethylgermanium (Me_3Ge) (1×10^{-2} M; 1 M=1 mol dm^{-3}) were prepared by alkaline hydrolysis of their chlorides (Alfa or Aldrich) as described previously.[10] (Caution: Although the toxicity of organogermanium compounds is thought to be low,[1] handling of these compounds should be carried out in a hood to avoid inhalation). A standard solution of 1×10^{-2} M Ge_i was prepared from germanium dioxide (Wako) according to Shimomura et al.[11] These standard solutions were stable over a year. Other chemicals were of analytical reagent grade. Distilled water was used throughout.

Resins. The resins used were a strong basic anion-exchange resin, Muromac MSA-1 (100—200 mesh, Cl^- form, Muromachikagakukogyo), a strong acidic cation-exchange resin, Muromac MSC-1 (100—200 mesh, Na^+ form, Muromachikagakukogyo), and a CHP20P resin (200—400 mesh, Mitsubishi Chemicals) that had no ion-exchange groups. These resins were macroreticular styrene–divinylbenzene copolymers. The anion-exchange resin was washed successively with distilled water, methanol, 1 M HCl, and 1 M NaOH, changed into Cl^- form by soaking the resin in ten times volume of 2 M HCl overnight, and washed with distilled water until the effluent was free from Cl^- ions. The cation-exchange resin was washed in the same way, and converted to H^+ form in 4 M HCl. The CHP20P resin was washed successively with methanol, 1 M NaOH, 1 M HCl, and methanol. These resins were dried to a constant weight in a vacuum drying oven and stored in a desiccator.

Procedure. Liquid–Liquid Extraction: An aliquot of aqueous solution containing various concentrations of HX and 5×10^{-5}—1×10^{-3} M of a germanium compound was shaken with an aliquot of CCl_4 for 30 min in a 30 ml centrifuge tube at 25±0.1 °C, using a Taitec bio-shaker BR-30L. After phase separation, the germanium concentration in both the phases was determined with a Japan Jarrel Ash ICAP-500 inductively

coupled argon plasma emission spectrometer. The precise procedure was described previously.[10]

When HI solution was used as the aqueous phase, following precautions were taken to make the solution free from I_3^-. The experiment was done under red light, and aqueous and organic solutions were deaerated with nitrogen. The I_3^- ions were removed from an HI stock solution just before its use by passing the solution through the column in which an I^- form anion-exchange resin was packed. In spite of the above precautions, it was shown by absorbance measurement at 351 nm that I_3^- ions were formed during the extraction experiment. For example, 7.0×10^{-5} M and 2.2×10^{-3} M of I_3^- were found in 0.725 M and 5.90 M HI solutions, respectively. Thus Me_3Ge alone that was extracted into the organic phase in the lowest acid concentration range was examined in the HI–CCl_4 system.

Solid-Liquid Distribution: Nine ml of aqueous solution containing various concentrations of HCl and 0.50 g of a dried ion-exchange resin were placed in a 30 ml centrifuge tube. After the addition of 1 ml of a 1×10^{-2} M germanium standard solution, the tube was shaken gently for 24 h at 25±0.1 °C with the bio-shaker. The resin was separated by filtration, and shaken with 10 ml of 1 M NaOH for 24 h to elute the germanium compound. The germanium compound concentrations in the HCl solution and the eluate were determined with the ICAP-500. From these concentrations, the distribution coefficient

$$K_d = \text{Amount of germanium in resin (mol g}^{-1})/\text{Amount of germanium in HCl solution (mol ml}^{-1}) \quad (1)$$

was calculated.

Since the CHP20P resin is hydrophobic, 0.50 g of the dried resin was first suspended in 5 ml of methanol. After the addition of 10 ml of distilled water, the resin was shaken with the methanol–water mixture for 30 min, and separated by filtration. The resin was shaken with distilled water, and finally with an HCl solution of which HCl concentration was the same as that in the distribution experiment. Then the resin was filtered and immediately used for the experiment. The subsequent procedure was similar to that for ion-exchange resins.

^{1}H NMR Spectra: ^{1}H NMR spectra were obtained in D_2O or $CDCl_3$ at 25±1 °C on a Varian VXR200 spectrometer with a Varian VXR4000 data station. Germanium compound concentrations were 10^{-1}—10^{-3} M. Chemical shifts were measured relative to the resonance of sodium 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid in D_2O and tetramethylsilane in $CDCl_3$.

Mean Activity of HX. The acid concentration in aqueous solution was measured by titration with an NaOH solution, using a Toa Electronics automatic titrator AUT-1 equipped with a glass electrode. The mean activity of HX ($a_\pm$), which was expressed on the molarity scale, was calculated from the measured concentration using a table described by Hamer and Wu[12] and the density data.[13] The initial and equilibrium concentrations of the acid agreed within 1% in solution containing more than 1 M of HX. For more dilute HX solution, however, the equilibrium concentration of the acid was lower than the initial concentration. This decrease was mainly caused by NaOH contained in the added germanium standard solution. Since the change in X^- ion concentration was negligible, the average of $a_\pm$ calculated from the initial and equilibrium concentrations of the acid was adopted as data. The error in log $a_\pm$ brought about by the above treatment is possibly a maximum of 0.2 for 10^{-3} M HX solution.

Results and Discussion

Liquid–Liquid Extraction. The results of liquid–liquid extraction are illustrated in Fig. 1. The distribution ratio of a germanium compound (D) is plotted against $a_\pm$ on log–log scale. The D is defined as

$$D = C_{Ge,o}/C_{Ge} \quad (2)$$

where $C_{Ge,o}$ and C_{Ge} mean the analytical molar

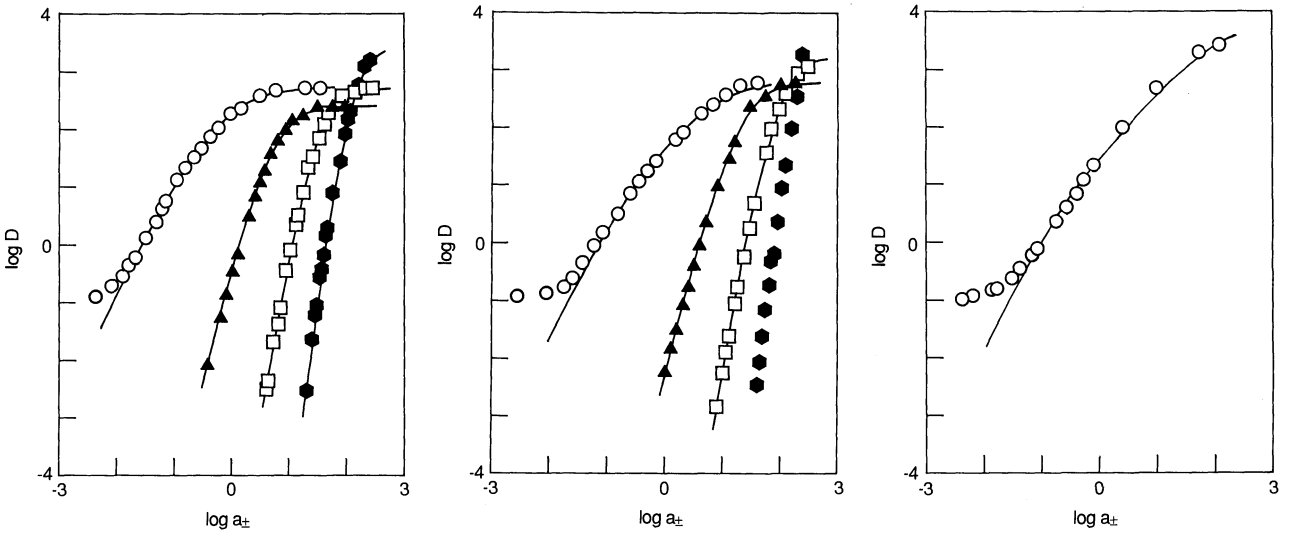

Fig. 1. Plots of log D vs. log $a_\pm$ for 5×10^{-5}—1×10^{-3} M germanium compounds. Solid curves are calculated using the partition constants (Table 1) and stepwise stability constants (Table 2). Only a portion of the experimental points are shown. (a, left) HCl–CCl_4 system; (b, center) HBr–CCl_4 system; (c, right) HI–CCl_4 system; ●, Ge_i; □, MeGe; ▲, Me_2Ge; ○, Me_3Ge.

concentration of the germanium compound in the organic phase and the aqueous phase, respectively. Cleavage of the Ge–C bonds did not occur under the experimental conditions. Distribution equilibrium was reached in a few minutes for all germanium compounds. The recovery was a minimum of 95%.

Log D did not depend on the initial concentration of germanium compounds in the aqueous phase which varied between 5×10^{-5} and 1×10^{-3} M. This fact suggests that germanium species are monomeric in both the aqueous and organic phases. While the log D vs. log $a_{\pm}$ plot of Me_3Ge is sigmoid, the plateau in the lower log $a_{\pm}$ range does not appear for the other germanium compounds. Germanium compounds should exist as nonionic hydroxides ($(CH_3)_nGe(OH)_{4-n}$; hereafter n=0, 1, 2, or 3) in water.[4,7,8] When the formation and distribution of halide complexes ($(CH_3)_nGeX_{4-n}$) are negligible in the low log $a_{\pm}$ range, D is independent of log $a_{\pm}$ and equal to the partition constant of the hydroxide:

$$P_{OH} = [(CH_3)_nGe(OH)_{4-n}]_o/[(CH_3)_nGe(OH)_{4-n}], \quad (3)$$

where brackets signify the molar concentration. Log P_{OH} of Me_3Ge is -0.95. The formation of oligomers of Me_2Ge, MeGe, and Ge_i is unlikely in the low log $a_{\pm}$ range, because log D of these compounds is much lower than the log P_{OH} of Me_3Ge.

Log D increases with the increase in log $a_{\pm}$. This is caused by the formation and distribution of the germanium halide complex. Benoit and Clerc[4] investigated the liquid–liquid extraction of Ge_i in the HCl–CCl_4 system, and found that the analytical ratio of Ge:Cl in the organic phase was 1:4. When log $a_{\pm}$ is sufficiently high, log D does not depend on log $a_{\pm}$, which implies that $(CH_3)_nGeX_{4-n}$ is the dominant species in both the aqueous and organic phases. Then, D agrees with the partition constant of the halide complex:

$$P_x = [(CH_3)_nGeX_{4-n}]_o/[(CH_3)_nGeX_{4-n}]. \quad (4)$$

It is obvious from Fig. 1 that P_x is much higher than P_{OH} for each germanium compound.

The analysis of the data is carried out on the assumption that $(CH_3)_nGeX_{4-n}$ alone is extracted into the organic phase. With regard to Me_3Ge, the D corrected by subtracting P_{OH} from the apparent D is used for the analysis. The log D vs. log $a_{\pm}$ plot is linear in the low log $a_{\pm}$ range for all systems. The slope is almost 2 for Me_3Ge, 4 for Me_2Ge, 6 for MeGe, and 8 for Ge_i (Table 1). The extraction equilibrium, overall stability constant, and extraction constant can be expressed as

$$(CH_3)_nGe(OH)_{4-n} + (4-n)H^+ + (4-n)X^- \rightleftharpoons (CH_3)_nGeX_{4-n} + (4-n)H_2O, \quad (5)$$

$$(CH_3)_nGeX_{4-n} \rightleftharpoons (CH_3)_nGeX_{4-n,o}, \quad (6)$$

$$\beta^0 = ((CH_3)_nGeX_{4-n})(H_2O)^{4-n}/((CH_3)_nGe(OH)_{4-n})(H^+)^{4-n}(X^-)^{4-n}, \quad (7)$$

$$K_{ex}{}^0 = ((CH_3)_nGeX_{4-n})_o(H_2O)^{4-n}/((CH_3)_nGe(OH)_{4-n})(H^+)^{4-n}(X^-)^{4-n} = \beta^0 P_x{}^0, \quad (8)$$

where parentheses represent the activity and superscript 0 denotes the thermodynamic constant. The following are also assumed: (i) the activity coefficients are unity for germanium species in both the aqueous and organic

a) Calculated using points adopted from a linear portion in the low log $a_{\pm}$ range, where the variation in log D is about 2. b) Equation 10 was fitted to the same points which were used to calculate the slope. c) Ref. 10. d) Standard deviation. e) Number of points. f) Evaluated by the curve fitting. g) Estimated from Fig. 2.

phases; (ii) the activity of water is unity; (iii) the activities of H^+ and X^- ions are equal to $a\pm$. Then,

$$D = ((CH_3)_nGeX_{4-n})_o/((CH_3)_nGe(OH)_{4-n}), \quad (9)$$

$$\log D = 2(4-n)\log a\pm + \log K_{ex}^0. \quad (10)$$

The observed slopes can be rationalized by Eq. 10.

When $\log a\pm$ is sufficiently high,

$$\log D = \log P_x^0. \quad (11)$$

Thus, β^0 can be estimated from the extraction data. The values of $\log K_{ex}^0$, $\log P_x^0$, and $\log \beta^0$ obtained by a linear least-squares method are listed on Table 1. The plateau in the higher $\log a\pm$ range was not observed for Ge_i in the HCl and HBr systems, MeGe in the HBr system, and Me_3Ge in the HI system. $\log P_x^0$ of $GeCl_4$, CH_3GeBr_3, and $(CH_3)_3GeI$ is obtained as a parameter in the estimation of stepwise stability constants which is described later. This estimation can not be applied to $GeBr_4$, because the $\log P_x^0$ is very high. Figure 2 shows the relationship between $\log P_x^0$ and van der Waals volumes (V_w) of the germanium halide complexes that are calculated according to Bondi.[14] A fairly good correlation is observed among MeGe, Me_2Ge, and Me_3Ge, and the regression line is

$$\log P_x^0 = 0.100\ V_w - 3.18 \qquad (r = 0.890). \quad (12)$$

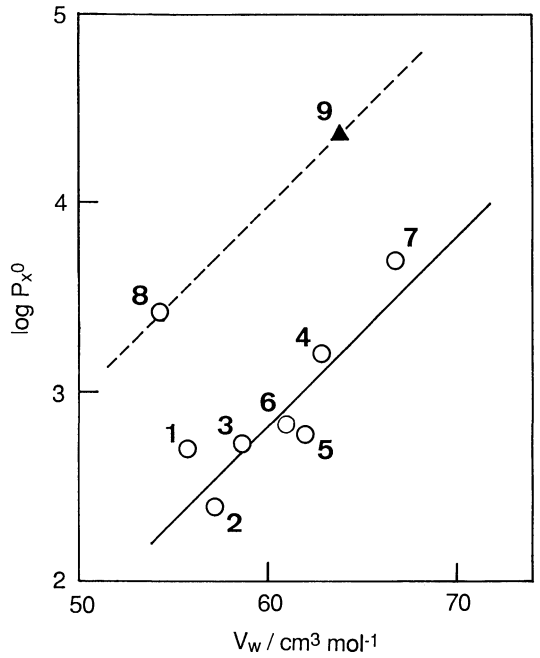

Fig. 2. Plots of $\log P_x^0$ vs. V_w for germanium halides. The solid line shows Eq. 12. ○, determined from the liquid–liquid extraction data; ▲, estimated; 1, CH_3GeCl_3; 2, $(CH_3)_2GeCl_2$; 3, $(CH_3)_3GeCl$; 4, CH_3GeBr_3; 5, $(CH_3)_2GeBr_2$; 6, $(CH_3)_3GeBr$; 7, $(CH_3)_3GeI$; 8, $GeCl_4$; 9, $GeBr_4$.

Log P_x^0 of $GeCl_4$ is higher than that expected from this correlation, which is attributable to that the molecule has no dipole moment and is highly soluble in CCl_4. Assuming that the same extent of departure from the regression line occurs for $GeBr_4$, the log P_x^0 is evaluated to be 4.4. Although application of the regular solution theory[15] was tried, no improvement over the above estimation of log P_x^0 was made because of increased number of unknown parameters.

Solid–Liquid Distribution. The dependence of $\log K_d$ on $\log a\pm$ of HCl is realized in Fig. 3. The recovery of germanium compounds was poorer (minimum 80%) and the experimental error was larger than that in the liquid–liquid extraction.

Although distribution of Ge_i, MeGe and Me_2Ge to the ion-exchange resins is negligible in the low $\log a\pm$ range, that to the CHP20P resin is significant. The value of $\log K_d$ for the CHP20P resin is enhanced in the order Ge_i<MeGe<Me_2Ge<Me_3Ge. These facts support that the germanium compounds are dissolved as the nonionic hydroxides in water. Log K_d for the CHP20P resin rises with increasing $\log a\pm$, which is ascribed to the formation and distribution of the germanium chlorides.

Log K_d of Ge_i, MeGe, and Me_2Ge for the anion- and cation-exchange resins also increases with the increase in $\log a\pm$, while the value of $\log K_d$ is lower than that for the CHP20P resin. It is probable that the distribution of these compounds is caused not by ionic interaction but by hydrophobic adsorption on the resin substrate. Hence, the dominant dissolved species of Ge_i, MeGe, and Me_2Ge are nonionic in HCl solution. The coordination number of the germanium atom in these compounds remains at four, and OH^- ions bonded to the germanium atom are stepwise substituted by Cl^- ions with increasing $\log a\pm$.

It has been supposed that Ge_i forms anionic species, such as $[Ge(OH)_xCl_{5-x}]^-$ or $[Ge(OH)_xCl_{6-x}]^{2-}$, in HCl solution (>5 M; $\log a\pm$>1.2).[4,16–18] Distribution of Ge_i to an anion-exchange resin was given as a piece of the evidence.[16] However, $\log K_d$ of Ge_i for the CHP20P resin is higher than that for the anion-exchange resin, and the distribution to the cation-exchange resin is significant above 6.5 M of HCl ($\log a\pm$>1.6), as shown in Fig. 3. Although it was stated that electrophoresis of the Ge_i anion was observed in 6 M HCl ($\log a\pm$=1.4),[17] the conclusion was based on the concentration difference of less than 5%, of which significance was doubtful from an analytical point of view. Everest and Harrison[18] claimed the presence of Ge_i anion in 6—9 M HCl solution saturated with Ge_i, because solubility of Ge_i and its adsorption on an anion-exchange resin had the maximum in this [HCl] range. They also reported that the solubility maximum did not occur in HBr solution and that no Ge_i bromo complexes were formed. In dilute Ge_i solution, however, the distribution to the anion-exchange resin shows no maximum in 6—9 M HCl (Fig. 3: 1.4—2.2 in $\log a\pm$), and the nature of log D vs.

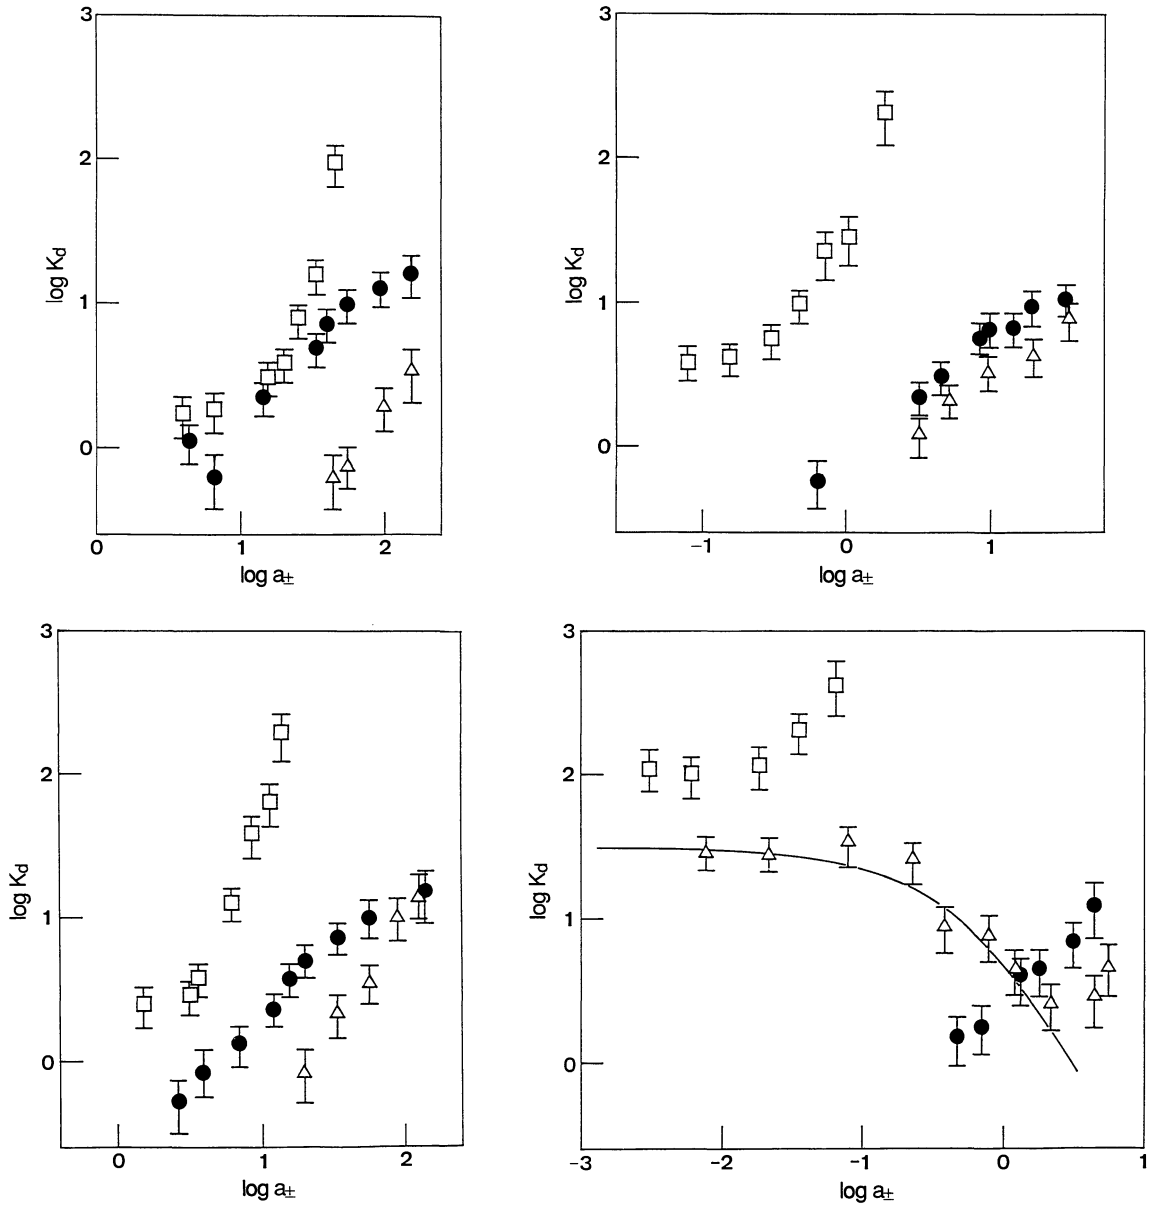

Fig. 3. Plots of log K_d vs. log $a_\pm$ for 1×10^{-3} M germanium compounds in HCl solution. Vertical bars show the 1 standard deviation. The solid curve is calculated from Eq. 20. (a, top left) Ge_i; (b, bottom left) MeGe; (c, top right) Me_2Ge; (d, bottom right) Me_3Ge; ●, anion-exchange resin; △, cation-exchange resin; □, CHP20P resin.

log $a_\pm$ plots for Ge_i in the HCl and HBr systems is identical (Fig. 1). Benoit and Clerc[4] gave the solvent extraction data in evidence of the Ge_i anion. They extracted $GeCl_4$ from aqueous phases which contained a constant total molality of HCl–$HClO_4$ or HCl–LiCl into an organic phase of CCl_4, to investigate the dependence of log D on log (Cl^-) or log (H^+). When the total molality was 12.0 mol kg^{-1} (log $a_\pm$=2.32), d log D/d log (Cl^-)=−0.2 and d log D/d log (H^+)=0.7 were found, and the Ge_i species was thought to be $[GeCl_4(OH)(H_2O)]^-$. However, the activity coefficients of Cl^- and H^+ ions are likely to vary with the change in the solute composition, when the total molality is high. Figure 1 shows that d log D/d log $a_\pm$ is 1.90 for 12.0 mol kg^{-1} HCl, which can not be explained on the presence of $[GeCl_4(OH)(H_2O)]^-$. The previously reported evidence of the Ge_i anion is controvertible as described above. Consequently, it is presumed that Ge_i does not form anionic species and retains a tetrahedral configuration in HX solution similarly to Me_2Ge and MeGe.

A remarkable difference of cation-exchange behavior for Me_3Ge from that for the other germanium compounds appears in Fig. 3. Me_3Ge is highly adsorbed by the cation-exchange resin in the low log $a_\pm$ range, whereas it is not adsorbed by the anion-exchange resin. This indicates that Me_3Ge forms a cation in HCl solution.

^{1}H NMR Spectra. Methyl protons of each germanium compound gave a singlet resonance line in D_2O

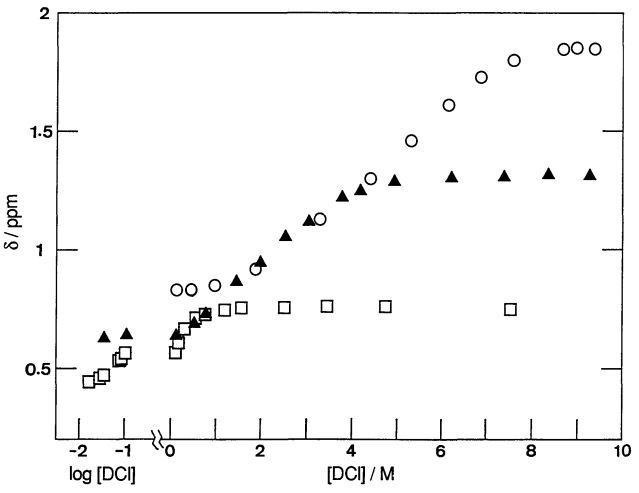

Fig. 4. Chemical shift of the methyl protons of 10^{-3}—10^{-1} M germanium compounds in D_2O as a function of [DCl]. ○, MeGe; ▲, Me_2Ge; □, Me_3Ge.

and $CDCl_3$ except one case that is mentioned later. The chemical shift of the methyl protons in D_2O is plotted against [DCl] in Fig. 4. The chemical shifts remain constant in the low [DCl] range, increase with the increase in [DCl], and reach to maximums. The maximums are the same as the chemical shifts for germanium chlorides in $CDCl_3$, which are 1.68 ppm for CH_3GeCl_3, 1.23 ppm for $(CH_3)_2GeCl_2$, and 0.72 ppm for $(CH_3)_3GeCl$. This supports that the dissolved species of methylgermanium in D_2O containing sufficiently high concentration of DCl are the chloride complexes with a tetrahedral configuration. The slight difference between the chemical shifts in D_2O and $CDCl_3$ is attributable to solvent effect.

The chemical shift of methyl protons for $(CH_3)_3GeOH$ was 0.44 ppm in D_2O and 0.42 ppm in $CDCl_3$, and that for $(CH_3)_3GeCl$ was 0.76 ppm in D_2O and 0.72 ppm in $CDCl_3$. The chemical shift was 1.22 ppm for $(CH_3)_3COH$, 1.60 ppm for $(CH_3)_3CCl$, 0.16 ppm for $(CH_3)_3SiOH$, and 0.42 ppm for $(CH_3)_3SiCl$ in $CDCl_3$. The absolute values of the chemical shift and the chemical shift changes caused by replacement of an OH^- ion bonded to the central atom by a Cl^- ion are similar among these compounds. Since the central carbon and silicon atoms in these compounds are sp^3 hybridized, it is assumed that the germanium atom of $(CH_3)_3GeOH$ and $(CH_3)_3GeCl$ is also sp^3 hybridized in both $CDCl_3$ and D_2O. With regard to the Me_3Ge cation that is suggested by the ion-exchange experiment, an sp^3d hybrid orbital is another possibility. A trimethyltin cation, $[(CH_3)_3Sn(H_2O)_2]^+$ has a bipyramidal sp^3d configuration, of which carbon atoms form a planar triangle.[19] It is difficult to presume the structure of Me_3Ge cation from the present data.

The chemical shift difference between the hydroxide and chloride complexes for Me_2Ge (0.67 ppm) and MeGe (1.02 ppm) in D_2O is twice and three times as great as that for Me_3Ge (0.32 ppm), respectively. This implies that the central germanium atoms of Me_2Ge and MeGe are also sp^3 hybridized, and that the effect of ligand exchange on the chemical shift is an additive property. Since the chemical shift increases monotonously, the formation of chloro complex anions in the intermediate [DCl] range is very unlikely.

When $(CH_3)_3GeOH$ was extracted from aqueous solution into $CDCl_3$, two singlet lines were found at 0.42 and 0.36 ppm in the organic phase. The peak area ratio was dependent on $C_{Me_3Ge,o}$, and the latter peak became large with increasing $C_{Me_3Ge,o}$. These peaks are assigned to $(CH_3)_3GeOH$ and $(CH_3)_3GeOGe(CH_3)_3$, respectively. The dimerization is written as

$$2(CH_3)_3GeOH_{,o} \rightleftharpoons (CH_3)_3GeOGe(CH_3)_{3,o} + H_2O. \quad (13)$$

Since the reaction does not proceed at an appreciable rate after separation of the aqueous and organic phases, the two lines are observed separately. The equilibrium constant for the reaction (13) is estimated at 13 from $C_{Me_3Ge,o}$ and the peak area ratio. This value indicates that the dimer comprises only 2.5% of 10^{-3} M of Me_3Ge in $CDCl_3$ which is equilibrated with water, and that the dimerization is negligible in the analysis of the liquid–liquid extraction data. When Me_2Ge and MeGe were extracted from aqueous solution into $CDCl_3$, no methyl resonance lines other than those for $(CH_3)_2GeCl_2$ and CH_3GeCl_3 were found. Although the formation of Me_2Ge oligomers in CCl_4 has been reported,[20] it is also negligible in the liquid–liquid extraction.

Stepwise Stability Constants. Based on the above discussion, the germanium species in HX solution are presumed as follows. The species of Ge_i, MeGe, and Me_2Ge have a tetrahedral structure and are nonionic. Hydroxide ions attached to the central germanium atom are stepwise substituted by X^- ions with the increase in $\log a_\pm$. Me_3Ge forms a cation when the $\log a_\pm$ is not sufficiently high. Now, stepwise stability constants for these species are estimated from the liquid–liquid extraction data.

For Ge_i, MeGe, and Me_2Ge, the stepwise reaction and stability constant are written as

$$(CH_3)_nGe(OH)_{i+1}X_{j-1} + H^+ + X^- \rightleftharpoons (CH_3)_nGe(OH)_iX_j + H_2O, \quad (14)$$

$$K_j^0 = ((CH_3)_nGe(OH)_iX_j)(H_2O)/((CH_3)_nGe(OH)_{i+1}X_{j-1})(H^+)(X^-), \quad (15)$$

where $n+i+j=4$. For Me_3Ge, the stepwise reaction and stability constant can be defined as

$$(CH_3)_3GeOH + H^+ \rightleftharpoons [(CH_3)_3Ge(H_2O)]^+ \quad (16)$$

Table 2. Stepwise Stability Constants for Methyl- and Inorganic Germanium Species in HX Solution at 25°C

	n[a]	log K_1^0	log K_2^0	log K_3^0	log K_4^0	log β^{0}[b]
			HCl			
Ge_i	21	−3.02±0.29[c]	−3.84±0.31	−4.82±0.51	−5.09±0.56	−16.77±0.87
MeGe	25	−2.31±0.10	−2.95±0.12	−3.81±0.06	—	− 9.07±0.17
Me_2Ge	17	−0.71±0.04	−2.15±0.03	—	—	− 2.86±0.05
			HBr			
MeGe	22	−2.57±0.10	−4.32±0.21	−4.67±0.23	—	−11.56±0.33
Me_2Ge	16	−1.59±0.06	−3.49±0.04	—	—	−5.08±0.07
	n	log K_{1p}^0			log K_{1x}^0	log β^0

a) Number of points. b) Calculated from the stepwise stability constants. c) Standard deviation.

$$K_{1p}^0 = ([(CH_3)_3Ge(H_2O)]^+)/((CH_3)_3GeOH)(H^+) \quad (17)$$

$$[(CH_3)_3Ge(H_2O)]^+ + X^- \rightleftharpoons (CH_3)_3GeX + H_2O \quad (18)$$

$$K_{1x}^0 = ((CH_3)_3GeX)(H_2O)/([(CH_3)_3Ge(H_2O)]^+)(X^-) \quad (19)$$

The assumptions that were made in the evaluation of K_{ex}^0 are adopted in a non-linear least-squares computation, except that the activity of water is calculated from the acid concentration and osmotic coefficient,[12] because wide ranges of [HX] are concerned in the computation. Resulting values are listed on Table 2. Log P_x^0 of $GeCl_4$, CH_3GeBr_3 and $(CH_3)_3GeI$ is also determined as a parameter by the computation (Table 1). The computation is inapplicable to Ge_i in the HBr system, because the bending on the log D vs. log $a\pm$ plot is not observed. The solid curves in Fig. 1 are calculated using the partition and stepwise stability constants.

Values of log β^0 listed on Table 2 are calculated from the stepwise stability constants, and in agreement with those on Table 1. Figure 5 shows the equilibrium composition of the germanium species in aqueous solution as a function of [HCl]. It is apparent from Figs. 4 and 5 that the [DCl] range where the variation in the chemical shift occurs is coincident with the [HCl] range where the composition of the germanium species changes. Moreover, the distribution of Me_3Ge to the cation-exchange resin is reproduced using the stepwise stability constants. When the Me_3Ge cation is the only species that is adsorbed by the cation-exchange resin,

$$K_d = 10^{-3}[[(CH_3)_3Ge(H_2O)]^+]_r/$$
$$\{[(CH_3)_3GeOH] + [[(CH_3)_3Ge(H_2O)]^+] + [(CH_3)_3GeCl]\}$$
$$= 10^{-3}K_H^{Me_3Ge}[H^+]_r/\{1/K_{1P}^0 + a\pm + K_{1X}^0(a\pm)^2/(H_2O)\}, \quad (20)$$

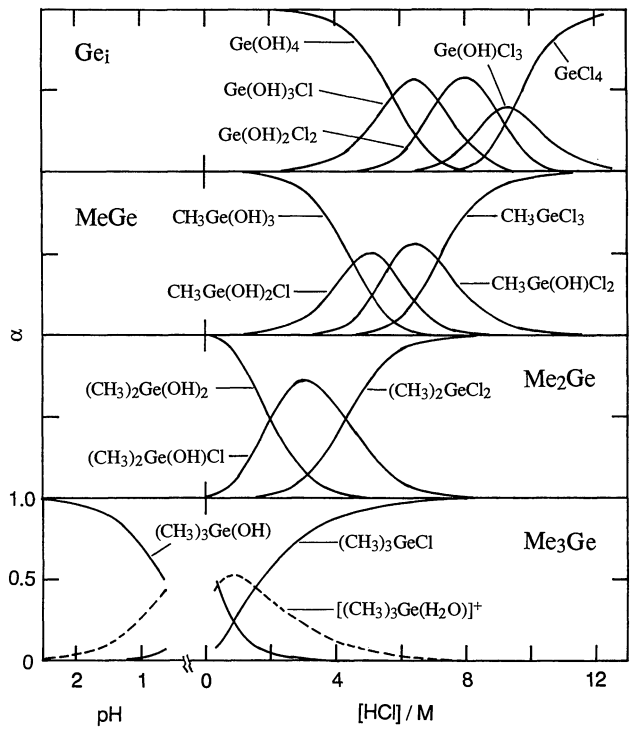

Fig. 5. Equilibrium composition of germanium species in aqueous solution as a function of [HCl].

where subscript r implies the concentration in the resin (mol g^{-1}) and

$$K_H^{Me_3Ge} = (H^+)[[(CH_3)_3Ge(H_2O)]^+]_r/[H^+]_r[[(CH_3)_3Ge(H_2O)]^+]. \quad (21)$$

Assuming that $K_H^{Me_3Ge}=1.7\times10^3$ and $[H]_r=5.0\times10^{-3}$, the solid curve in Fig. 3 is obtained. These results indicate the validity of the stepwise stability constants estimated here.

Effect of Methyl Groups on the Lewis Acid Nature of the Central Atom. Log β^0 for a methylgermanium moiety decreases in the order $Cl^->Br^->I^-$ (Tables 1 and 2). This indicates that the methylgermanium moieties are hard Lewis acids similarly to Ge_i.[8] Log β^0 for an X^- ion increases as the number of methyl groups attached to the germanium atom increases. The same tendency appears in the stepwise stability constants for an equivalent coordination site (Table 2). For chloride complexes, log $K_4^0=-5.09$ for Ge_i, log $K_3^0=-3.81$ for MeGe, log $K_2^0=-2.15$ for Me_2Ge, and log $K_{1p}^0K_{1x}^0=0.37$ for Me_3Ge. Thus an OH^- ion bound to a germanium atom is easily replaced by an X^- ion, when methyl groups are attached to the germanium atom. This feature is clearly shown in Fig. 5. The [HCl] range where the species composition changes shifts to a lower concentration range with the increase in the number of methyl groups.

Since the charge and structure of germanium compounds do not alter in the present reaction, solvent effects are not serious. The tetrahedral configuration around the central germanium atom implies that the steric strain between the ligands bonded to the germanium atom is hardly affected by the size of the ligands investigated in this paper. Consequently, the dominant factor is an inductive effect. The transfer of a negative charge from a soft base CH_3^- to the central germanium atom increases the electron density on the germanium atom, and weakens the ionic interaction between the germanium atom and a hard base, such as an OH^- ion.[21]

The inductive effect is most pronounced for Me_3Ge. The acidity of the central germanium atom of Me_3Ge is remarkably reduced by methylation. The Me_3Ge moiety can not cause hydrolysis in dilute HX solution, and forms a hydrated cation. Such a hydrated cation is not formed by Ge_i, MeGe, and Me_2Ge in HCl and HBr solutions. However, since log P_{1x}^0 of Me_3Ge decreases in the order $Cl^->Br^->I^-$, the Me_3Ge moiety is still a hard acid. Hence, the electron donation from methyl groups that reduces the bond stability between the germanium atom and a hard base does not result in stabilization of the bond between the germanium atom and a soft base, such as an I^- ion.

Cassol et al.[22] reported a similar effect by methylation on complex formation between methyltin(IV) cations, which are also hard, but are weaker Lewis acids, and F^- or Cl^- ions. According to their data, the number of methyl groups bonded to the tin atom hardly affects the tendency to bind Cl^- in equivalent coordination places: as an example, log $K_3=-0.25$ for CH_3Sn^{3+}, log $K_2=-0.23$ for $(CH_3)_2Sn^{2+}$, and log $K_1=-0.17$ for $(CH_3)_3Sn^+$. The tendency to bind F^-, however, decreases with the increase in the number of the methyl groups: log $K_3=4.12$ for CH_3Sn^{3+}, log $K_2=2.87$ for $(CH_3)_2Sn^{2+}$, and log $K_1=2.27$ for $(CH_3)_3Sn^+$. The structure of methyltin cations is different from that of methylgermanium compounds: The dimethyltin cation has an octahedral configuration containing linear C–Sn–C and the trimethyltin cation has a bipyramidal configuration.[19] Accordingly, the inductive effect of methyl groups on the tin atom is similar to that on the germanium atom despite the distinction of hybridization.

Quite a different effect has been reported on a methylmercury(II) cation, of which the central atom has a d^{10} electronic configuration similarly to germanium(IV) and tin(IV) atoms. Since the halide complex stability constant of Hg^{2+} and CH_3Hg^+ decreases in the order $I^->Br^->Cl^->F^-$,[19,23] these cations are soft acids. In this case, methylation reduces stability of the bond between the mercury atom and a soft base. For example, the stability constants of iodides are log $K_1=12.87$, log $K_2=10.95$ for Hg^{2+}, and log $K_1=8.60$ for CH_3Hg^+, whereas those of fluorides are log $K_1=1.03$ for Hg^{2+}, and log $K_1=1.50$ for CH_3Hg^+.[19,23] An explicit and extensive explanation of the effect by methylation on the Lewis acid nature of the various atoms has not been given yet.

The author wishes to thank Professor Masakazu Matsui, Dr. Sorin Kihara, and Dr. Eiichiro Nakayama for helpful discussions.

(Received June 17, 1991)

The kinetics of the oxygen atom transfer reactions between *cis*-$[MoO_2(R_2dtc)_2]$ [R=CH_3, C_2H_5, *i*-C_3H_7, *i*-C_4H_9, $C_6H_5CH_2$ (Bz), C_6H_5 (Ph)] and PPh_3 (coupled reactions 1 and 2) have been investigated.

$$[MoO_2(R_2dtc)_2] + PPh_3 \xrightarrow{k_1} [MoO(R_2dtc)_2] + OPPh_3 \quad (1)$$

$$[MoO_2(R_2dtc)_2] + [MoO(R_2dtc)_2] \overset{K_d}{\rightleftharpoons} [Mo_2O_3(R_2dtc)_4] \quad (2)$$

The rate constants (k_1) of oxygen atom transfer reaction 1 correlate with the formal potentials of $[MoO_2(R_2dtc)_2]^{0/-1}$ except for R=Bz and Ph. The equilibrium constant values (K_d) of dimerization reaction 2 decrease with increase of the electron-donating ability of the substituents on the dithiocarbamate ligands.

Barral et al. reported that the *cis*-dioxobis(dithiocarbamato)molybdenum(VI) complexes $[MoO_2(R^1{}_2dtc)_2]$ (R^1=Et, *n*-Pr, and *i*-Bu)[1] undergo an oxygen atom transfer reaction to tertiary phosphine ($PR^2{}_3$; R^2=*n*-Bu and Ph) giving Mo(IV) complexes $[MoO(R^1{}_2dtc)_2]$ and $OPR^2{}_3$.[2] However, the reaction is complicated by the intervention of an Mo(V) dinuclear complex according to the following equations:

$$[MoO_2(R^1{}_2dtc)_2] + PR^2{}_3 \xrightarrow{k_1} [MoO(R^1{}_2dtc)_2] + OPR^2{}_3 \quad (1)$$

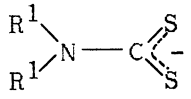
$$[MoO_2(R^1{}_2dtc)_2] + [MoO(R^1{}_2dtc)_2] \overset{K_d}{\rightleftharpoons} [Mo_2O_3(R^1{}_2dtc)_4] \quad (2)$$

Among these molybdenum complexes, only the Mo(V) dinuclear complexes have large extinction coefficients in the vicinity of 510 nm.[3,4] Thus, if the reaction is followed at this wavelength, biphasic kinetic behavior may be observed.

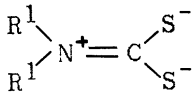
This oxygen atom transfer reaction has attracted much attention, especially as models of enzymic reactions.[5] Kinetic invesitgations have been made by several reseachers.[2,6-8] Barral et al.[2] reported kinetic studies of the $[MoO_2(n\text{-}Pr_2dtc)_2]/PPh_3$ system in *o*-dichlorobenzene at 41 °C; McDonald et al.[6] studied the kinetics of the $[MoO_2(Et_2dtc)_2]/PPh_3$ system in benzene at 24 °C, and Durant et al.[7] investigated the kinetics of $[MoO_2(Et_2dtc)_2]/PPh_3$ system in acetonitrile solution by the stopped-flow technique at temperatures between 15 and 45 °C. However, the kinetic results of these investigations were contradictory.

Holm et al.[8] extensively investigated the kinetics of reactions between $[MoO_2(Et_2dtc)_2]$ and $PPh_n(Et)_{3-n}$ (n=0—3) in 1,2-dichloroethane and developed a general treatment of the kinetics which provided a satisfactory explanation for the biphasic kinetic behavior. The rate constant k_1 was found to increase with increasing nucleophilicity of $PPh_n(Et)_{3-n}$.

Chemical properties of dithiocarbamate complexes are sensitive to the nature of the substituent on the dithiocarbamate ligand because of the existence of two resonance forms.[9]



(I)



(II)

An increase of the electron-donating ability of the R^1 group favors resonance form II and hence leads to the increase of the electron density on the sulfur atoms bound to the metal atom.

Hitherto, the effect of the substituents on the dithiocarbamate ligands on the kinetics of the oxygen atom transfer reactions has not been investigated. This is the motive of this work in which the kinetics of the reactions between *cis*-$[MoO_2(R^1{}_2dtc)_2]$ (R^1=Me, Et, *i*-Pr, *i*-Bu, Bz, and Ph) and PPh_3 are dealt with. Kinetic traces were analyzed by essentially the same procedure that developed by Holm et al.[8]

Experimental

Materials. 1,2-Dichloroethane ($1,2\text{-}C_2H_4Cl_2$), obtained from Wako Pure Chemicals Industries, was purified by fractional distillation over P_2O_5. Triphenylphosphine (Nacalai Tesque Inc.) was purified twice by recrystallization from ethanol–water. Sodium salts of dithiocarbamates $R^1{}_2dtc^-$

(R^1=*i*-Pr, *i*-Bu, Bz, Ph) were prepared by literature methods.[10,11] Sodium salts of dimethyldithiocarbamate and diethyldithiocarbamate were purchased from Nacalai Tesque Inc. The complexes $[MoO_2(R^1{}_2dtc)_2]$ were prepared according to literature methods.[12,13]

Apparatus and Procedures. Procedures for kinetic measurements were almost identical with those reported previously.[8] The change of absorbance vs. time was measured with a UV-160 spectrophotometer (Shimadzu Co.).

Calculations in the kinetic analysis were performed by an ACOS 630/10 computer. For the nonlinear least-squares fitting between experimental data and theoretical values, the SALS (Statistical Analysis with Least Squares fitting) program developed by Nakagawa and Oyanagi[14] was used.

Results and Discussion

Biphasic kinetic behavior was observed for all $[MoO_2(R^1{}_2dtc)_2]/PPh_3$ systems, and is due to the formation and decay of $[Mo_2O_3(R^1{}_2dtc)_4]$ (Fig. 1). The kinetic traces are also found to be sensitive to the nature of substituents on the dithiocarbamate ligands.

The kinetic analysis of coupled reactions 1 and 2 was developed by Holm et al.[8] The absorbance of the reaction solution is expressed by equation 3 ($L=R^1{}_2dtc_2^-$).

$$A = l\left(\varepsilon_4 \frac{(C-[MoO_2L_2])}{1+2K_d[MoO_2L_2]} + \varepsilon_5 \frac{K_d[MoO_2L_2]\,(C-[MoO_2L_2])}{1+2K_d[MoO_2L_2]} + \varepsilon_6[MoO_2L_2]\right) \quad (3)$$

where l and C denote the optical path length and the initial concentration of $[MoO_2L_2]$, respectively. Symbols ε_4, ε_5, and ε_6 are the molar extinction coefficients of $[MoOL_2]$, $[Mo_2O_3L_4]$, and $[MoO_2L_2]$, respectively, the lattermost of which can be determined independently by spectroscopic measurement of $[MoO_2L_2]$. The time dependence of $[MoO_2L_2]$ is given by

$$-k_1t = \frac{1+K_dC}{P-C}\ln\left(\frac{[MoO_2L_2]}{C}\right) + 2K_d\ln\left(\frac{2K_d[MoO_2L_2]+1}{2K_dC+1}\right) - \frac{1+K_d(2P-C+Q^{1/2})}{2(P-C)}\times \ln\left(\frac{1+K_d(2[MoO_2L_2]+2P-C-Q^{1/2})}{1+K_d(2P+C-Q^{1/2})}\right) - \frac{1+K_d(2P-C-Q^{1/2})}{2(P-C)}\times \ln\left(\frac{1+K_d(2[MoO_2L_2]+2P-C+Q^{1/2})}{1+K_d(2P+C+Q^{1/2})}\right), \quad (4)$$

where $P \neq C$ and $Q=K_d^{-2}+4P^2+C^2+2K_d^{-1}C-4PC$. Here, k_1 is the rate constant for the forward reaction of reaction 1 and P is the initial concentration of PPh_3. The time dependence of $[MoO_2L_2]$ was numerically obtained from equation 4 by the Newton–Raphson method, and the absorbance vs. time curve was calculated from equation 3. The kinetic parameters are obtained by the nonlinear least-sqaures fitting between the observed data and the values calculated from equation 3. The fitting parameters are k_1, K_d, ε_4, and ε_5 in this study.

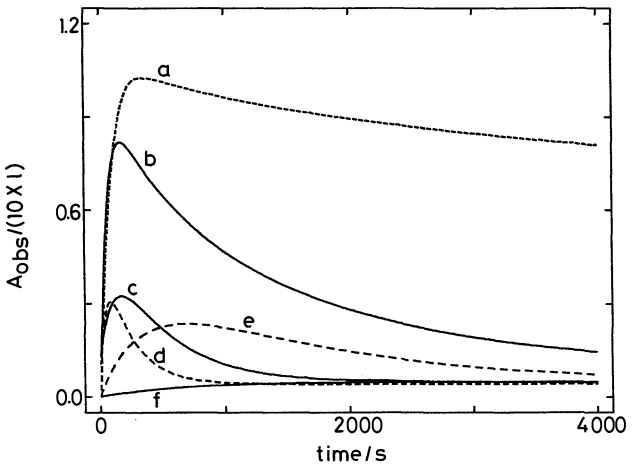


Fig. 1. Change of absorbance as a function of time for the reaction between 1.0 mM $[MoO_2(R^1{}_2dtc)_2]$ and 50.0 mM PPh_3 in 1,2-dichloroethane at 25°C. (a) R^1=Ph, (b) R^1=Bz, (c) R^1=Et, (d) R^1=Me, (e) R^1=*i*-Bu, (f) R^1=*i*-Pr. Absorbance (A_{obs}) was measured in a quartz cell with optical path length (l)=0.1 cm for (a)—(e) and 1 cm for (f).

The results of kinetic analysis are summarized in Table 1. Most of the kinetic runs were obtained under the conditions $[MoO_2(R^1{}_2dtc)_2]_0$=1.0 mM and $[PPh_3]_0$=50.0 mM (1 M=1 mol dm^{-3}). However, in the $[MoO_2(Bz_2dtc)_2]/PPh_3$ system, the initial concentrations of $[MoO_2(Bz_2dtc)_2]$ and PPh_3 were varied to confirm the validity of the kinetic analysis. The agreements among the parameters obtained are satisfactory. Furthermore, the parameters k_1, K_d, ε_4, and ε_5 determined for the system $[MoO_2(Et_2dtc)_2]/PPh_3$ in this study are in fair agreement with the values reported by Holm et al.[8]

The rate constant for oxygen atom transfer reaction 1 is influenced by the nature of the substituents on the dithiocarbamate ligands. As shown in Fig. 2, the log k_1 values correlate linearly with the formal potentials for the one-electron reduction of $[MoO_2(R^1{}_2dtc)_2]$,[15] except for R^1=Bz and Ph. This suggests that one-electron transfer from PPh_3 to $[MoO_2(R^1{}_2dtc)_2]$ plays an important role in the rate determining step of the oxygen atom transfer reactions. The values of log k_1 for the systems $[MoO_2(Bz_2dtc)_2]/PPh_3$ and $[MoO_2(Ph_2dtc)_2]/PPh_3$ deviate from the correlation line between log k_1 and the formal potentials. This may be due to the electron-withdrawing effect of the benzyl and phenyl groups; in these cases, the contribution of resonance form I becomes more important than that of form II.

Table 1. Kinetic Data for the Oxygen Atom Transfer Reaction between $[MoO_2(R^1{}_2dtc)_2]$ and PPh_3 in 1,2-$C_2H_4Cl_2$ at 25 °C[a)]

R^1	$k_1/M^{-1}\,s^{-1}$	K_d/M^{-1}	$\varepsilon_4/M^{-1}\,cm^{-1}$	$\varepsilon_5/M^{-1}\,cm^{-1}$	$\varepsilon_6/M^{-1}\,cm^{-1}$[b)]
i-Pr[c)]	0.0120(1)	$5(3)\times10^1$	$4.60(2)\times10^2$	$1.7(8)\times10^4$	30
i-Bu	0.0241(5)	$5.0(8)\times10^2$	$5.2(5)\times10^2$	$2.4(3)\times10^4$	17
Et	0.085(3)	$7.9(4)\times10^2$	$4.8(2)\times10^2$	$2.44(6)\times10^4$	17
Et[d)]	0.071(3)	$5.9(10)\times10^2$	4.3×10^2[b)]	$2.80(25)\times10^4$	18
Me	0.203(7)	$1.18(6)\times10^3$	$4.7(2)\times10^2$	$2.12(9)\times10^4$	12

Ph	0.113(9)	$4(2)\times10^5$	$4.7(2)\times10^2$	$2.2(2)\times10^4$	57

a) Each value is the average of four determinations, unless otherwise stated. Standard deviations are given in parentheses. Initial concentrations of $[MoO_2(R^1{}_2dtc)_2]$ and PPh_3 are 1.0 and 50.0 mM, respectively, unless otherwise stated. The symbols ε_4, ε_5, and ε_6 denote molar extinction coefficients at 512 nm of $[MoO(R^1{}_2dtc)_2]$, $[Mo_2O_3(R^1{}_2dtc)_4]$, and $[MoO_2(R^1{}_2dtc)_2]$, respectively. b) The extinction coefficient values were determined by independent spectroscopic measurements. c) Average of two determinations. d) From Ref. 8. e) $[MoO_2(Bz_2dtc)_2]$= 0.5 mM; $[PPh_3]$=50 mM. f) $[MoO_2(Bz_2dtc)_2]$=1.0 mM; $[PPh_3]$=100 mM.

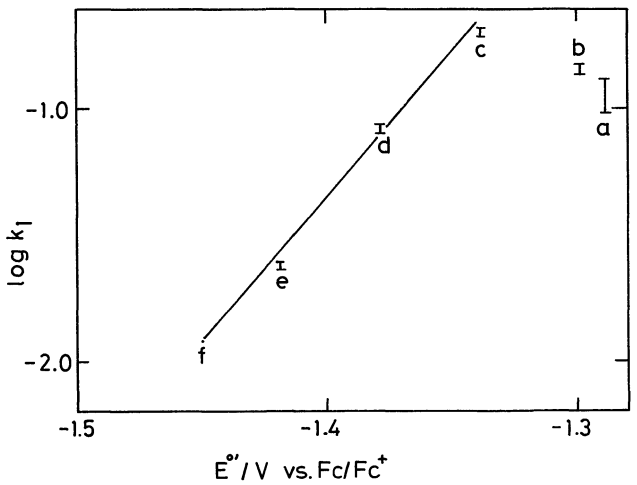

Fig. 2. Correlation between $\log k_1$ and the formal potentials for the one-electron reduction of $[MoO_2(R^1{}_2dtc)_2]$.[15] (a) R^1=Ph, (b) R^1=Bz, (c) R^1=Me, (d) R^1=Et, (e) R^1=*i*-Bu, (f) R^1=*i*-Pr.

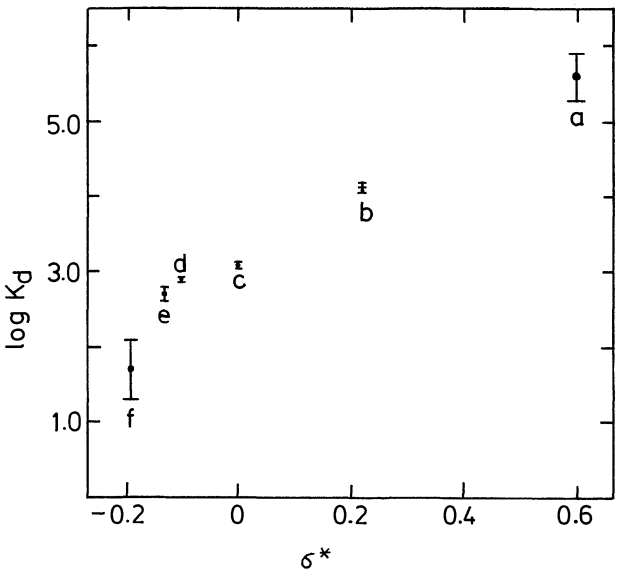

Fig. 3. Plots of $\log K_d$ vs. Taft's polar substituent constant of the substituents on dithiocarbamate ligands. (a) R^1=Ph, (b) R^1=Bz, (c) R^1=Me, (d) R^1=Et, (e) R^1=*i*-Bu, (f) R^1=*i*-Pr.

The equilibrium constant of reaction 2, K_d, also varies with the nature of the substituents on the dithiocarbamate ligands. The $\log K_d$ value correlates well with Taft's polar substituent constant (σ^*)[16] as shown in Fig. 3: The $\log K_d$ value decreases with increase of the electron-donating ability of substituents.

The $[Mo_2O_3]^{4+}$ moiety in $[Mo_2O_3(n\text{-}Pr_2dtc)_4]$ has a nearly linear Mo–O–Mo linkage and the two terminal-oxygen atoms are in the cis-positions.[17] The electronic structure of the $[Mo_2O_3]^{4+}$ moiety was described by Cotton et at.[18] Two electrons from oxygen and one electron from each molybdenum atom fill bonding and nonbonding orbitals derived by the interaction between the d_{xz} orbitals of each Mo atom and the p_x orbital of bridging oxygen to form a three-center π-bond over the Mo–O–Mo linkage. The energy level of the bonding orbital of the three-center π-bond rises with the increase of electron-donating ability of the substituents on the dithiocarbamate ligands. Censequently, $[Mo_2O_3(R^1{}_2dtc)_4]$ becomes less stable with increasing electron-donating ability of the substituents.

(Received June 18, 1991)

Reaction of $NiI_2(RNC)_2$ (**1**) (**a**: R=2,6-$Me_2C_6H_3$; **b**; 4-Br-2,6-$Me_2C_6H_2$; c: 2,4-*t*-Bu_2-6-MeC_6H_2: d: 2,4,6-*t*-$Bu_3C_6H_2$ with RNC or PPh_3 gave $NiI_2(RNC)_3$ (2) or $NiI_2(PPh_3)(RNC)_2$ (**3**) (a: R=2,6-$Me_2C_6H_3$; b: 2,6-Me_2-4-BrC_6H_2). An X-ray analysis of (**3a**) showed that the complex has a trigonal bipyramidal structure; crystal data: Space group $Pna2_1$; a=21.577(2), b=9.440(1), c=17.075(1) Å, $\alpha=\beta=\gamma=90.0°$, V=3477.7(6) Å^3, R=0.0444. The bromide and chloride complexes, $NiX_2(2,6\text{-}Me_2C_6H_3NC)_2$ (**1e**: X=Cl; **1f**: X=Br) did not produce five-coordinated species. When complexes (**1a**, **1b**, **1e**, or **1f**) were treated with Hg in the presence of isocyanide, the donor-acceptor complexes $[Ni(RNC)_4HgX_2]_2$ (X=I, Br, or Cl) (**4**) were formed. An X-ray analysis of (**4b**) (R=4-Br-2,6-$Me_2C_6H_2$) was undertaken; crystal data: Space group: $P\bar{1}$ (triclinic); a=12.709(3), b=16.145(3), c=12.614(3) Å, α=96.11(2), β=107.67(2), γ=73.11(2)°, V=2359.5(10) Å^3, R=0.0686. The complex is a donor-acceptor complex containing the Ni–Hg bond and has a dimeric structure bridged by two I atoms. The configuration around Ni is the trigonal bipyramid and around Hg, distorted tetrahedron.

The low-valent metal complexes often show an instability that is related to the electron-releasing capability of ligands. This instability can be improved by the release of the excess electron density from the metal center. One possibe way to reduce the electron density on the metal atom without changing its oxidation state is formation of a donor–acceptor complex. A general preparation of donor–acceptor complexes is arising from interaction of zerovalent complexes with Group 2 metal dihalides.[1] Dixneuf et al have reported that carbene–iron derivatives which were easily oxidized were stabilized by formation of carbene–Fe(O) Hg(II) donor–acceptor complexes on treatment with HgX_2.[2]

When $NiX_2(RNC)_2$ were treated with mercury metal in the presence of isocyanide, an initial electron transfer from Hg^0 to Ni^{2+} occurred, and finally the Ni–Hg donor–acceptor complex was formed. Here we reported preparation and characterization of donor–acceptor complexes and related ones.

Experimental

Isocyanides[3] and $NiI_2(RNC)_2$[4] were prepared by literature methods, some with modification. Electronic and infrared spectra were recorded on Hitachi 330 and JASCO 442 spectrometers, respectively. ^{1}H NMR spectra were recorded on a JEOL FX100 instrument. Electric conductivities were measured by the Ando Electronic Co. LCR-10 impedance bridge.

Preparation of *trans*-NiI_2(2,4,6-*t*-$Bu_3C_6H_2NC)_2$ (1d). A mixture of NiI_2 (0.57 g, 1 mmol) and 2,4,6-*t*-$Bu_3C_6H_2NC$ (0.12 g, 0.44 mmol) in CH_2Cl_2 (5 ml) was stirred at room temperature. After 1 h, the mixture was filtered and the solvent was removed in vacuo. The residue was crystallized from CH_2Cl_2–hexane to give the title complex (0.16 g, 86%). Found: C, 53.45; H, 6.82; N, 3.25%. Calcd for $C_{38}H_{58}N_2I_2Ni$: C, 53.36; H, 6.83; N, 3.27%. IR (KBr): 2174 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.31 (s, *p*-*t*-Bu), 1.58 (s, *o*-*t*-Bu), and 7.33 (s, aromatic protons).

Other nickel(II) complexes were prepared by a similar procedure mentioned above.

trans-$NiI_2(2,6\text{-}Me_2C_6H_3NC)_2$ (**1a**) (88%): Found: C, 37.59; H, 3.25; N, 4.89%. Calcd for $C_{18}H_{18}N_2I_2Ni$: C, 37.61; H, 3.16; N, 4.87%. IR (KBr) 2163 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.52 (s, Me), and ca. 7.2 (m, aromatic protons). ^{1}H NMR (a mixture of **1a** and RNC)($CDCl_3$) δ=2.45 (s, *o*-Me), and ca. 7.2 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 387 (5500 dm^3 mol^{-1} cm^{-1}), 342 (3700), 296 (36700), and 237 (23500) nm.

trans-NiI_2(2,4-*t*-Bu_2-6-$MeC_6H_2NC)_2$ (**1c**) (73%): Found: C, 49.84; H, 6.01; N, 3.63%. Calcd for $C_{32}H_{46}N_2I_2Ni$: C, 50.07; H, 6.12; N, 3.67%. IR (nujol) 2168 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.30 (s, *p*-*t*-Bu), 1.50 (s, *m*-*t*-Bu); 2.49 (s, *m*-Me), and ca. 7.2 (aromatic protons). ^{1}H NMR ($CDCl_3$) (a mixture of **1c** and RNC) δ=1.30 (s, *p*-*t*-Bu), 1.50 (s, *m*-*t*-Bu), 2.45 (s, *m*-Me), and ca. 7 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 453 (1700), 388 (10900), 340 sh (8000), 290 (65700), 262 (40000), and 247.5 (49200) nm.

trans-NiI_2(4-Br-2,6-$Me_2C_6H_2NC)_2$ (**1b**) (90%): Found: C, 29.66; H, 2.17; N, 3.73%. Calcd for $C_{18}H_{16}N_2Br_2I_2Ni$: C, 29.51; H, 2.20; N. 3.82%. IR (nujol) 2171 cm^{-1}. Electronic spectrum (CH_2Cl_2) λ_{max} 450 (900), 389 (5900), 346 (4700), 304 (43700), 296 (42800), and 248 (24400) nm.

Preparation of *cis*-$NiCl_2(2,6\text{-}Me_2C_6H_3NC)_2$ (1e). To a solution of $NiCl_2(PPh_3)_2$ (0.16 g, 0.25 mmol) in CH_2Cl_2 (10 ml) was added 2,6-xylyl isocyanide (0.075 g, 0.57 mmol) at room temperature. After 1 h, the solution was filtered and the solvent was removed in vacuo. Crystallization of the residue from CH_2Cl_2 and hexane gave orange yellow crystals (0.064 g, 65%). Found: C, 55.05; H, 4.59; N, 7.11%. Calcd for $C_{18}H_{18}N_2Cl_2Ni$: C, 55.16; H, 4.63; N, 7.15%. IR (nujol) 2208, and 2195 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.42 (s, *o*-Me), and ca. 7.0 (aromatic protons). ^{1}H NMR ($CDCl_3$) (a mixture of **3a** and RNC) δ=2.41 (s, *o*-Me), and ca. 7 (aromatic protons).

trans-$NiBr_2$ (2,6-$Me_2C_6H_3NC)_2$ (**1f**), was prepared from a metathesis of (**1e**) with KBr. Found: C, 44.88; H, 3.89; N, 5.77%. Calcd for $C_{18}H_{18}N_2Br_2Ni$: C, 44.96; H, 3.77; N, 5.83%.

†† Studies on the Interaction of Transition-Metal Complexes 34. For Part 33, see Y. Yamamoto and H. Yamazaki, *J. Chem. Soc., Dalton Trans.*, **1989**, 2161.

^{1}H NMR ($CDCl_3$) δ=2.45 (s, *o*-Me), ca. 7 (aromatic protons). ^{1}H NMR ($CDCl_3$) (**2a** and RNC) δ=2.40 (s, *o*-Me), ca. 7 (aromatic protons). IR (nujol) 2194 cm^{-1}.

Preparation of $NiI_2(2,6\text{-}Me_2C_6H_3NC)_3$ (2a). 2,6-Xylyl isocyanide (0.07 g, 0.53 mmol) was added to a brown solution of *trans*-$NiI_2(2,6\text{-}Me_2C_6H_3NC)_2$ (0.20 g, 0.35 mmol) in CH_2Cl_2 (5 ml) at room temperature. The solution color turned blue. Addition of hexane to the solution gave blue crystals (0.21 g, 85.0%) of the title complex. Found: C, 45.63; H, 3.76; N, 5.94%. Calcd for $C_{27}H_{27}N_3I_2Ni$: C, 45.93; H, 3.85; N, 5.95%. IR (nujol) 2162 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.50 (s, Me), and ca. 7.13 (c, aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 450 sh (680), 386 (5900), 343 (4200), and 295 (37700) nm.

$NiI_2(4\text{-Br-}2,6\text{-}Me_2C_6H_2NC)_3$ (**2b**) (75%). Found: C, 34.77; H, 2.43; N, 4.61%. Calcd for $C_{27}H_{24}N_3Br_3I_2Ni$: C, 34.40; H, 2.57; N, 4.46%. IR (nujol) 2160 cm^{-1}.

Preparation of $NiI_2(PPh_3)(2,6\text{-}Me_2C_6H_3NC)_2\cdot 1/3CH_2Cl_2$ (3a). To an orange solution of *cis*-$NiCl_2(PPh_3)_2$ (0.3 g, 0.46 mmol) and 2,6-xylyl isocyanide (0.13 g, 1.0 mmol) in CH_2Cl_2 (10 ml) was added an excess of KI in H_2O (5 ml) at room temperature and the mixture was stirred for 1 h. Organic layer was dried over Na_2SO_4. Removal of the solvent and crystallization of the residue from CH_2Cl_2 and hexane gave blue crystals (0.26 g, 67.5%). Found: C, 50.25; H, 3.95; N, 3.21%. Calcd for $C_{36+(1/3)}H_{33+(2/3)}N_2PCl_{(2/3)}I_2Ni$: C, 50.42; H, 3.92; N, 3.24%. IR (nujol) 2160 and 2187 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.20 (s, Me), 5.29 (s, CH_2), and ca. 7.6 (c, aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 570 (1700), 384 (5100), ca. 340 (7500), and 291 (38000) nm.

4-Bromo-2,6-dimethylphenyl isocyanide complex was also prepared by a similar procedure.

$NiI_2(PPh_3)$ (4-Br-2,6-$Me_2C_6H_2NC)_2$ (**3b**) (75%): Found: C, 43.44; H, 3.31; N, 2.84%. Calcd for $C_{36}H_{31}N_2Br_2I_2PNi$: C, 43.46; H, 3.14; N, 2.82%. IR (nujol) 2160 cm^{-1}.

Preparation of $[Ni(2,6\text{-}Me_2C_6H_3NC)_4][PF_6]\cdot CH_2Cl_2$. When $[NH_4][PF_6]$ was added to a brown solution of $NiBr_2$ (0.32 g, 1.47 mmol) and 2,6-xylyl isocyanide (0.393 g, 3.0 mmol) in THF (15 ml), the solution turned wine red. After the mixture was heated at 60 °C for 2 h, the solvent was removed in vacuo and the residue was extracted with CH_2Cl_2. The solvent was removed to ca. 5 ml and hexane was added, giving brown crystals (0.38 g, 53%) containing one molecule of CH_2Cl_2 as a solvated molecule. Found: C, 46.87; H, 4.02; N, 5.93%. Calcd for $C_{37}H_{38}N_4P_2F_{12}Cl_2Ni$: C, 46.38; H, 4.00; N, 5.85%. IR (nujol) 2176 and 2192 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.53 (s, Me), 5.30 (s, CH_2), and ca. 7.1 (aromatic protons).

Preparation of $[Ni(2,6\text{-}Me_2C_6H_3NC)_4HgI_2]_2$ (4a). (a) Reaction of *trans*-$NiI_2(2,6\text{-}Me_2C_6H_3NC)_2$ with mercury in the presence of 2,6-xylyl isocyanide. A mixture of *trans*-$NiI_2(2,6\text{-}Me_2C_6H_3NC)_2$ (0.11 g, 0.19 mmol), 2,6-xylyl isocyanide (0.03 g, 0.23 mmol) and Hg (ca. 2 ml) in CH_3CN (10 ml) was stirred for 2.5 h at room temperature, forming the dark yellow precipitate. The organic layer was dried and the residue was extracted with benzene. The solvent was dried to ca. 3 ml and hexane was added, giving brown crystals (0.14 g, 71%) of the title complex. Found: C, 41.58; H, 3.44; N, 5.27%. Calcd for $C_{72}H_{72}N_8I_4Hg_2Ni_2$: C, 41.66; H, 3.50; N, 5.40%. IR (nujol) 2139 and 2081 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.50 (s, Me), ca. 7 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} ca. 360 sh (10400), 305 (20700), 237 sh (27700), and 231 (29400) nm.

(b) Reaction of $Ni(2,6\text{-}Me_2C_6H_3NC)_4$ with HgI_2. 2,6-Xylyl isocyanide. To a suspension of $Ni(2,6\text{-}Me_2C_6H_3NC)_4$ (0.26 g, 0.45 mmol) in CH_3CN (15 ml) was added HgI_2 (0.2 g, 0.44 mmol). After stirring for 5 h at room temperature, the mixture was filtered and the solvent was removed in vacuo. Recrystallization of the residue from CH_2Cl_2–hexane gave brown crystals.

The following complexes were prepared by the procedure (a).

4-Bromo-2,6-dimethyl isocyanide complex, $[Ni(4\text{-Br-}2,6\text{-}Me_2C_6H_3NC)_4HgI_2]_2$ $(C_6H_6)_2$ (**4b**) (87%), was also prepared from the reaction of *trans*-$NiI_2(4\text{-Br-}2,6\text{-}Me_2C_6H_3NC)_2$ with mercury in the presence of 4-bromo-2,6-dimethylphenyl isocyanide. Found: C, 35.15; H, 2.69; N, 3.91%. Calcd for $C_{84}H_{76}N_8Br_8I_4Hg_2Ni_2$: C, 35.24; H, 2.68; N, 3.91% . IR (nujol) 2141 and 2082 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=1.55 (s, 6H, Me), 2.44 (s, 18H, Me), and 7.37 (benzene and aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} ca. 360 sh (11300) and 313 (20300) nm.

$[Ni(2,6\text{-}Me_2C_6H_3NC)_4HgCl_2]_2$ (**4e**) (65%). Found: C, 50.05; H, 4.21; N, 6.47%. Calcd for $C_{36}H_{36}N_4Cl_2HgNi$: C, 50.58; H, 4.24; N, 6.55%. IR (nujol) 2165 and 2104 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.49 (s, Me), and ca. 7.0 (aromatic protons). Electronic spectrum (CH_2Cl_2): λ_{max} 330 sh (9500) and 280 (15000) nm.

$[Ni(2,6\text{-}Me_2C_6H_3NC)_4HgBr_2]_2$ (**4f**) (68%). Found: C, 45.83; H, 3.85; N, 5.76%. Calcd for $C_{36}H_{36}N_4Br_2HgNi$: C, 45.80; H, 3.84; N, 5.94%. IR (nujol) 2165 and 2101 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.58 (s, Me), ca. 7.0 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 312 sh (19000).

Preparation of $[Ni(PPh_3)(4\text{-Br-}2,6\text{-}Me_2C_6H_2NC)_3HgI_2]_2$ (5b). Mercury was added to a blue solution of $NiI_2(PPh_3)$ (4-Br-2,6-$Me_2C_6H_3NC)_2$ (0.14 g, 0.14 mmol) and 4-bromo-2,6-dimethylphenyl isocyanide (0.03 g, 0.14 mmol) in benzene (10 ml) and the mixture was stirred for 0.5 h at room temperature, changing an orange solution. The mixture was filtered and the solvent was removed to ca. 3 ml. Hexane was added, giving orange crystals (0.134 g, 68%) of the title complex. Found: C, 38.51; H, 2.77; N, 3.01%. Calcd for $C_{90}H_{78}N_6Br_6I_4P_2Hg_2Ni_2$: C, 38.45; H, 2.80; N, 2.99%. IR (nujol) 2075 and 2085 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.14 (s, Me), and ca. 7.3 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 396 (15500), 323 (27400), and 260 sh (37800) nm.

$[Ni(PPh_3)(2,6\text{-}Me_2C_6H_3NC)_3HgI_2]_2(CH_2Cl_2)_3$ (**5a**) was recrystallized from CH_2Cl_2 and hexane. Found: C, 43.33; H, 3.44; N, 3.14%. Calcd for $C_{93}H_{90}N_6Cl_6P_2I_4Hg_2Ni_2$: C, 43.08; H, 3.50; N, 3.24%. IR (nujol) 2082 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=2.23 (s, Me), 5.29 (s, CH_2), and ca. 7.3 (aromatic protons). Electronic spectrum (CH_2Cl_2) λ_{max} 394 (10000), 314 (18600), and 260 (46800) nm.

Data Collection and Solution of the Structure. Complex (**3a**) was recrystallized from CH_2Cl_2–benzene, and **4b**, from benzene–hexane, respectively. Weissenberg photographs indicated that the crystals of **3a** were orthorhombic with space group $Pna2_1$ and those of **4b**, triclinic with the space group $P\bar{1}$. Cell constatns of **3a** were determined from 18 reflections ($11°<2\theta<22°$), and those of **4b** from 20 reflections ($12°<2\theta<25°$) on a Rigaku automated diffractometer. Details of the crystal parameters along with data collection are summarized in Table 1. Intensities were corrected for Lorentz and polarization effects. No absorption corrections were made; the absorption coefficient of **4b** is large, but the crystal used for data collection was not well-shaped one to make correction. The positions of the heacy atoms were determined by a Patterson map using the UNICS III program system.[5]

The remaining atoms were located in succeeding different Fourier syntheses. The positions of all atoms for **3a**, and of Hg, Ni, and Br atoms for **4b** were refined anisotropically by using block-diagonal least-squares methods. Final difference Fourier maps of **3a** and **4b** showed smaller residual peaks than 0.6 e A^{-3}. No attempts were made to locate the hydrogen atoms. The positional parameters are given in Tables 2 and 3. Anomalous dispersion effects and atomic scattering factors

a) Positional parameters are multiplied by 10^4 (from Hg to Br40) and by 10^3 (from C10 to C6). The atoms from Hg to Br40 were anisotropically defined and other atoms were isotropically defined. The equivalent temperature factors, $B_{eq}=(4/3)\Sigma\Sigma\beta_{ij}(a_ia_j)$ are multiplied by 10^2.

were taken from the usual tabulation.[6]

Results and Discussion

Preparation of *trans*- and *cis*-$NiX_2(RNC)_2$ and Related Complexes. Organge or brown complexes, $NiI_2(RNC)_2$ (**1a**: R=2,6-$Me_2C_6H_3$; **1b**: R=4-Br-2,6-$Me_2C_6H_2$; **1c**: R=2,4-*t*-Bu_2-6-MeC_6H_2; **1d**: 2,4,6-*t*-$Bu_3C_6H_2$) were prepared from reactions of NiI_2 with isocyanides, according to literature methods.[4] The chloride complex, $NiCl_2(RNC)_2$ (R=2,6-$Me_2C_6H_3$) (**1e**) was preparated by a substitution reaction of dichlorobis(triphenylphosphine)nickel(II) with isocyanide. The bromide, $NiBr_2(RNC)_2$ (R=2,6-$Me_2C_6H_3$) (**1f**) was obtained by a metathesis of the chloride complex with KBr. The infrared spectra showed only one sharp band at ca. 2100 cm^{-1} (ν(N≡C)) for iodide and bromide complexes, and two peaks for the chloride one. The iodide and bromide complexes have a trans-configuration and the latter, a cis-one.

The reaction of **1a** or **1b** with an appropriate isocyanide or PPh_3 gave blue complexes formulated as $NiI_2(RNC)_3$ (**2a**: R=2,6-$Me_2C_6H_3$; **2b**; R=4-Br-2,6-$Me_2C_6H_2$) and $NiI_2(PPh_3)(RNC)_2$ (**3a**: R=2,6-$Me_2C_6H_3$, **3b**: R=4-Br-2,6-$Me_2C_6H_2$), respectivley. It was supported by an X-ray analysis of **3a** that complexes **2** and **3** have the trigonal bipyramidal structure (Fig. 1).

The basal plane has been occupied by two I's and a phosphine, and two isocyanide ligands have been in the apical positions. The ^1H NMR spectrum of **2a** showed only one singlet at δ=2.50 for *o*-methyl protons, suggesting an intramolecular exchange between apical and basal isocyanide ligands. In the ^1H NMR spectrum of a mixture of **2a** and 2,6-xylyl isocyanide only one singlet due to *o*-methyl groups appeared at δ=2.45, and the electric conductivity of the mixture showed to be a nonelectrolyte. This behavior is due to an inter- and intramolecular ligand exchange.

Brown solution of **1f** changed blue reminiscent of a five-coordinated species, when 2,6-xylyl isocyanide was added to **1f** in CH_2Cl_2. Some attempts to isolate a blue species were unsuccessful with recovery of **1f**. A similar reaction was carried out for the chloride complex **1e**. Color change has not been observed and the electronic spectrum of the mixture is similar to that of **1e**, showing that a five-coordinate species does not exist. Five-coordinated species with I are more stable than those with Br and Cl, probably due to higher coordination ability than the other halogens.

In the reaction of **1c** or **1d** containing bulky isocyanide, no assignment responsible for the formation of five-coordinated species was observed, and the starting complex was recovered, due to steric bulkiness.

Donor–Acceptor Complexes. When mercury was added to a solution of **1b** in CH_3CN, brown crystals

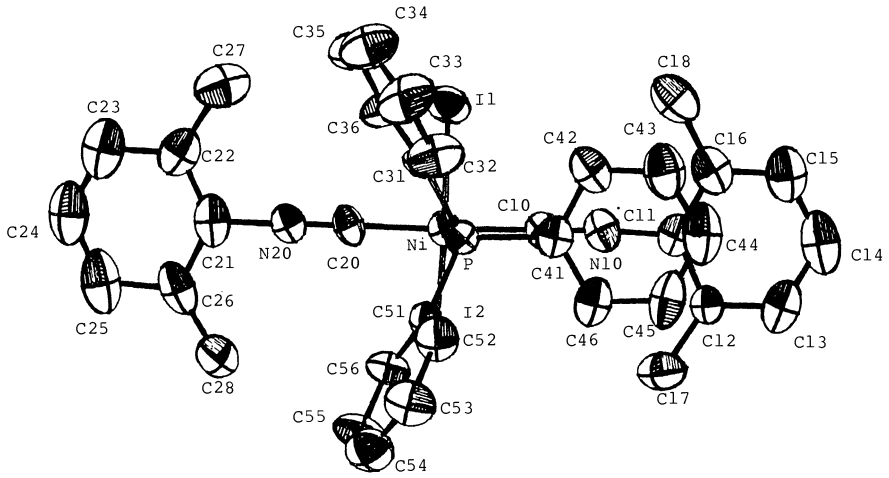

Fig. 1. Molecular structure of $[NiI_2(PPh_3)(2,6\text{-}Me_2c_6H_3NC)_2]$ (**3a**).

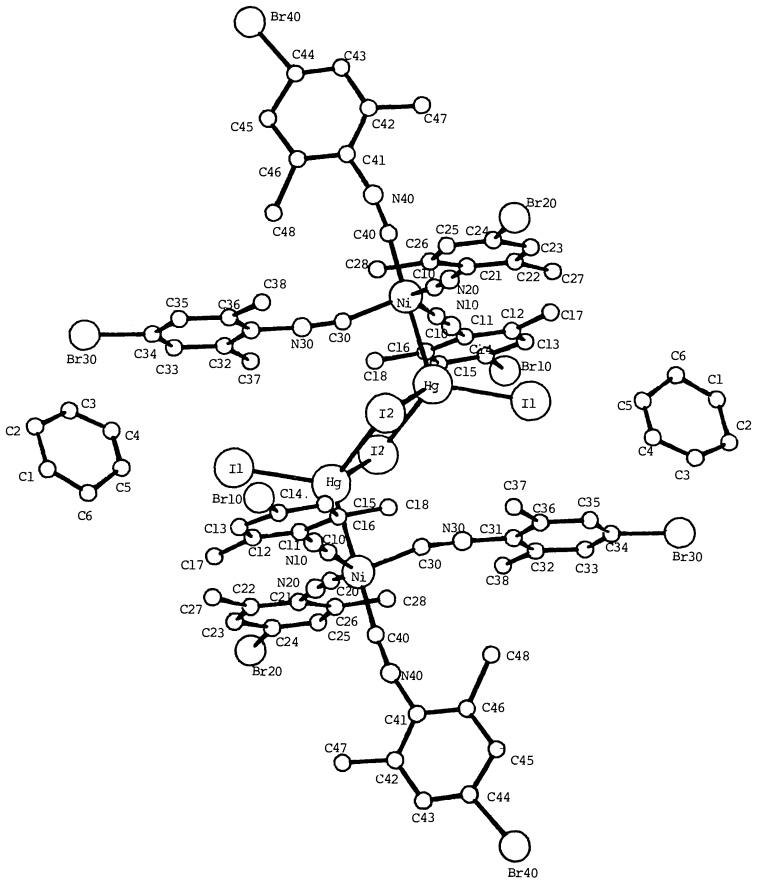

Fig. 2. Molecular structure of $[Ni(4\text{-Br-}2,6\text{-}Me_2C_6H_2NC)_4HgI_2]_2$ (**4b**).

formulated as $[Ni(4\text{-Br-}2,6\text{-}Me_2C_6H_2NC)_4HgI_2]_2$ (**4b**) were obtained. A similar reaction

$$2NiX_2(RNC)_2 + 4RNC + 2Hg \longrightarrow [Ni(RNC)_4HgX_2]_2 \quad (1)$$

occurred in the presence of 4-bromo-2,6-dimethylphenyl isocyanide to give **4b** quantitatively. The structure was determined by an X-ray analysis (Fig. 2).

The spectroscopic studies of **4b** were in good agreement with the crystal structure. The infrared sepctrum showed two ν (N≡C) peaks at 2050—2150 cm^{-1}, being in higher energy region than those of the parent zerovalent complexes and in lower energy than those of divalent complexes, suggesting partical charge transfer from nickel to mercury. Similar infrared behaviors have been noted in the molybdenum–mercury bonded

complexes.[7]

The ^{1}H NMR spectrum showed two characteristic peaks at δ=1.55 and 2.44 consisting of a 1:3 intensity ratio, assigned to the apical and basal isocyanide ligands, respectively. The ^{1}H NMR spectrum of a mixture of **4b** and 4-bromo-2,6-dimethylphenyl isocyanide showed two singlets at δ=1.56 and 2.44 for *o*-methyl protons. The former intensity increased with added isocyanide, showing that ligand exchange between the apical and free isocyanide ligands has occurred. The ligand in a trans-position to a Ni–Hg bond is more labile than the basal ones. It has been known that isocyanide ligands in a trans position to M–M bond were preferentially replaced by PPh_3 in the reactions of $[L_3M-ML_3]^{2+}$ (M=Pd, Pt; L=RNC) with triphenylphosphine.[8] Similar donor–acceptor complexes $[Ni(2,6\text{-}Me_2C_6H_3NC)_4HgX_2]_2$ (**4a**: X=I; **4e**: X=Cl; **4f**: X=Br) were prepared from **1a**, **1e**, or **1f** with mercury in the presence of 2,6-xylyl isocyanide. The ^{1}H NMR spectra of these complexes showed only one singlet at ca. δ=2.50 for *o*-methyl protons, suggesting an intermolecular ligand exchange. 2,6-Xylyl isocyanide ligand is more labile than 4-bromo-2,6-dimethylphenyl isocyanide, related with an electron-acceptor ability. These donor–acceptor complexes were also obtianed by the usual treatment of $Ni(RNC)_4$ with HgI_2.

$$2\,Ni(RNC)_4 + 2\,HgI_2 \longrightarrow [Ni(RNC)_4HgI_2]_2. \quad (2)$$

The phosphine complexes, $[Ni(PPh_3)(RNC)_3HgI_2]_2$ (**5a**: R=2.6-$Me_2C_6H_3$; **5b** R=4-Br-2,6-$Me_2C_6H_2$) were prepared by the reaction of $NiI_2(PPh_3)(RNC)_2$ with mercury in the presence of isocyanide. The infrared spectrum showed two N≡C stretching frequencies at 2070 and 2090 cm^{-1}, in lower energy region than those of the parent complex, due to greater σ-donor ability of triphenylphosphine than isocyanide. The ^{1}H NMR spectrum showed a singlet at δ=ca. 2.17 for *o*-methyl protons. We tentatively assumed that the apical isocyanide was replaced by triphenylphosphine, because of labile property of the apical ligand as shown in the ^{1}H NMR spectrum of **4b**.

Rossi and Hoffmann have concluded from a molecular orbital treatment of five-coordinated d^8 complexes that good σ-donor ligands will prefer axial site, while good π-acceptor will prefer the equatorial sites.[9] The configuration of these complexes is in agreement with the proposal.

Electronic Spectra. The electronic spectrum of a 1.25×10^{-4} M (M=mol dm^{-3}) solution of **3a** in CH_2Cl_2 showed two peaks at 569 and 367 nm, and two shoulder peaks at ca. 455 and 340 nm. With decrease of the solution concentration (2.51×10^{-5} M), the peak at 569 nm disappeared and the shoulder at ca. 340 nm decreased. Finally the spectrum consisted with that of **1a**, suggesting that triphenylphosphine in the basal plane is more labile than isocyanide ligands in the apical plane. Similar spectroscopic changes have been observed in **2a**. When RNC or PPh_3 (ca. 20 times per the complex) was added to a ca. 10^{-5} M solution of $NiI_2(RNC)_2$ or $NiI_2(RNC)_3$ in CH_2Cl_2, a new peak appeared at ca. 570 nm. The similar behavior was observed in a mixture of **1f** and 2,6-xylyl isocyanide (1: ca. 100 ratio), but the complex (**1e**) did not showed formation of a five-coordinated species even in the presence of a large excess of 2,6-xylyl isocyanide. These results showed the presence of the following equilibrium (trigonal bipyramidal⇌square planar), where L is RNC or PPh_3.

$$NiI_2(RNC)_2(L) \rightleftharpoons NiI_2(RNC)_2 + L. \quad (3)$$

The equilibrium of **2** or **3** lies far to the left in a high concentration or in the presence of an appropriate ligand. The electronic spectrum of **4** showed two peaks at ca. 250 and 310 nm, shifted to shorter wavelength than that of the parent zerovalent complex, probably accompanied with Ni→π*(CNR). The λ_{max} values of **4** red-shifted with Cl, Br, and I. Bathochromic shift was observed in the triphenylphosphine derivative **5**. These are related with the electron acceptor ability.

Structures of $NiI_2(PPh_3)(2,6\text{-}Me_2C_6H_3NC)_2$ (3a) and $[Ni(4\text{-}Br\text{-}2,6\text{-}Me_2C_6H_2NC)_4HgI_2]_2$ (4b). Sructure of 3a. The blue complex (**3a**) has a distorted trigonal bipyramidal structure, in which two isocyanide ligands occupied apical positions, and two I atoms and a phosphine, a basal plane. This structure is in disagreement with Rossi and Hoffmann's result.[9] The average bond angle of I–Ni–P is 124°, wider than a theoretical angle and the I–Ni–I angle is 110°, narrower than an ideal angle. The bond angle of C(10)–Ni–C(20) is 174°, bent away from triphenylphosphine. These are responsible for steric influence of bulky phosphine. The average Ni–I bond is 2.645 Å, comparable with usual Ni–I bond distance. The Ni–C(10) bond length of 1.85(1) Å is longer than 1.81(1) Å of the Ni–C(20) bond. Phenyl rings of apical isocyanide ligands are almost parallel to one phenyl ring of triphenylphosphine (C41–C46) [172.4(6) and 164.1(6)°]. These likely minimized steric interaction between aromatic rings of isocyanide and triphenylphosphine. Diherdal angles between the NiI_2P plane and phenyl rings of apical ligands (C11–C16 and C21–C26) are 92.1(4) and 78.4(5)°, respectively, again due to releasing of steric interaction.

Structure of 4b. The geometry around nickel atom is a distorted trigonal bipyramid. The Hg–Ni–C(40) bond is linear. The nickel atom is occupied upward by 0.33 Å from the triangular C(10)C(20)C(30) plane (a mean angle of C(40)–Ni–C: 100.0°), and the average C–Ni–C angle associated with the triangle C(10)C(20)C(30) are ca. 117°. The plane [C(10)C(20)C(30)] is almost parallel to phenyl rings of isocyanide ligands in the apical sites, minimizing repulsive interaction with axial ligands. The geometry around mercury atom was essentially tetrahedral with the main distortion. The Ni–Hg–I and

I–Hg–I bond angles except the I(2)–Hg–I(2′) bond angle of 92.1(5)° containing a bridged ligands, is in the range 108.8—116.6°. The bond length of Hg–Ni is 2.619 (3) Å, being comparable with the sum (2.59 Å) of the covalent radii. The Hg–I (bridged) distances (2.954(1) and 2.900(2) Å) are longer than that of Hg–I (terminal) bond (2.734(2) Å). They were shorter than the terminal and bridged Hg–I distances (2.681(1) (terminal) and 2.982(1) and 2.937(1) (bridged) in $[(Ph_3PC_5H_4)Hg(\mu\text{-}I)I]_2$.[10] The C–N triple bond length are usual. The Ni–C–N and C–N–C bond angles are similar to those found in usual isocyanide complexes. The Hg–I(2)–Hg bond angle is 87.9°, comparable with that in $[(Ph_3PC_5H_4)Hg(\mu\text{-}I)I]_2$.[10]

Supplemental Materials.

Thermal parameters (Tables 1 and 3), bond distances and angles (Tables 2 and 4), and Tables of F_o-F_c are available. The tables of thermal parameters, all the bond distances and angles, and observed and calculated structural factors are deposited as Document No. 8969 at the Office of the Editor of Bull. Chem. Soc. Jpn.

The Reaction of 2-Substituted Cycloalkanones with Aldehydes under Acidic Conditions

Tadashi SATO* and Kengo HAYASE
Department of Applied Chemistry, Waseda University, Ookubo 3, Shinjuku-ku, Tokyo 169
(Received May 27, 1991)

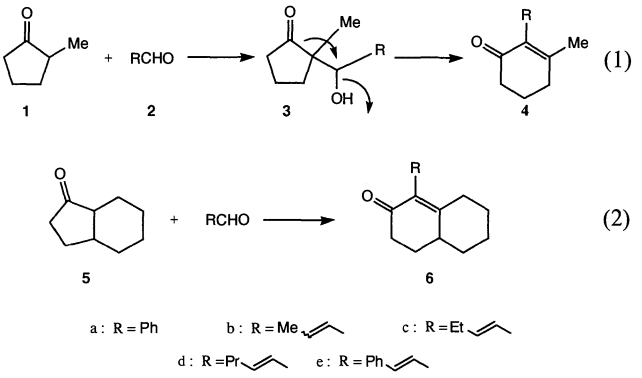
The title reaction proceeded with either ring enlargement or bicyclic compound formation, as well as the aldol reaction, depending upon the types of the reactants and reaction conditions.

The aldol reaction between ketones and aldehydes generally affords a mixture of many products, due to the involvement of self-condensation, reverse reaction, dehydration followed by Michael addition, among others. Therefore, the cross aldol reaction is usually carried out using some derivatives equivalent to the substrates, such as enol ethers for ketones, and acetals for aldehydes.[1)]

During our studies on the chemistry of β-stannyl ketones with Lewis acids, we noticed that 2-methylcyclopentanone reacted with benzaldehyde cleanly to undergo a ring enlargement under a Lewis acid treatment. Inspired by the results, we investigated the reactions of 2-substituted cycloalkanones with aldehydes under various conditions without any prior derivatization. It was found that the reaction proceeded fairly cleanly, affording several types of products depending upon the kinds of Lewis acids and aldehydes.

Results

When 2-methylcyclopentanone (**1**) was reacted with benzaldehyde **2a** or unsaturated aldehydes **2b**—**2e** under Lewis acid treatment, cyclohexenones **4a**—**4e** were obtained as major products (Eq. 1). The ring enlargement was also effected from **5** by the reaction with **2a** and **2b** (Eq. 2). The results are summarized in Table 1 (Runs a—j).



The reaction could be schemed as initiated by the aldol reaction producing **3**, followed by the elimination of the hydroxyl group and acyl migration. Expectedly the aldol **3a**, prepared according to the reported method,[2)] gave **4a** when treated with trimethylsilyl trifluoromethanesulfonate (TMSOTf) treatment (Run k).

Although the acyl migration was exclusive in Runs a, f,

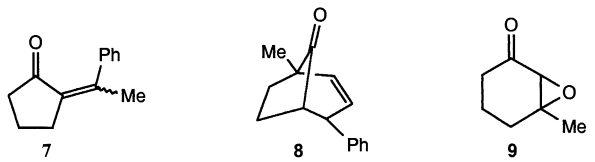
a) Yields are on the cycloalkanone basis. b) Using two equivalents of **13**.

g, i, and j, the methyl migration also occurred in Runs b and c, producing **7** as a minor product. An aldol condensation at the 5-position was also observed as a side reaction in Runs c and d, producing **16f** (Eq. 4). A small amount of by-product was isolated in Run h, to which the structure **8** was assigned in view of the spectroscopic data.[3] Presumably **8** was formed through an intramolecular S_N2' type reaction on the side chain of **3e** with C5 of the cyclopentanone ring. No products involving methyl migration, nor methylene migration were identified in the reactions with the unsaturated aldehydes. The minor product in Run e was assigned as a cis isomer, since it showed exactly the same mass spectrum as that of the major product, while it lacked the IR peak for the trans double bond at 969 cm^{-1} found in the major product.



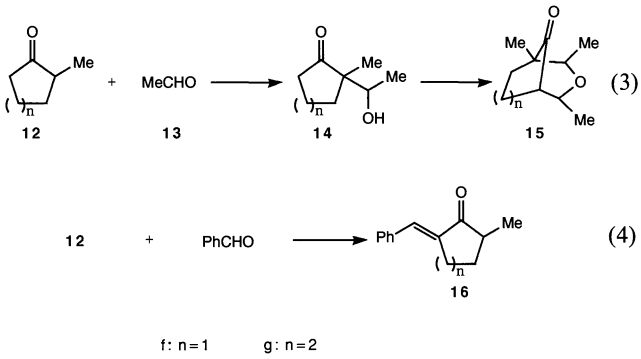
7 **8** **9**

10 **11**

The structure of **4a** was confirmed by comparing with the authentic sample, prepared from **9** according to the reported method.[4] The structure of **7** (*trans–cis* mixture) was confirmed by the catalytic hydrogenation to afford **10** (diastereomer mixture), which indicated the IR absorption at 1736 cm^{-1}, suggesting the presence of five-membered ketone system. The attempted dehydration of **11**, obtained in small amount from the corresponding silyl enol ether and acetophenone,[5] resulted only in retro-aldol reaction to give acetophenone, without affording any amount of **7**.

The reaction terminated at the stage of aldol formation **3a**, when a mixture of **1** and **2a** was treated with $TiCl_4$ (Run l). However, no reaction proceeded with AgOTf, Et_3B, $SnCl_4$, or $FeCl_3 \cdot 6H_2O$. Characteristically $AlCl_3$ and BF_3–etherate did not induce the reaction of the unsaturated aldehydes **2b** and **2d** with **1**, contrary to the cases of benzaldehyde (Runs a and d).

In contrast to the ring enlargement with the aromatic or unsaturated aldehydes described above, the reaction type changed entirely when acetaldehyde **13** was used. The TMSOTf-induced reaction of **12f** (=**1**) with **13** afforded a bicyclic compound **15f** (Eq. 3), even with the use of only one equivalent of the aldehyde. The involvement of two molecules of the aldehyde was evident in view of the mass spectroscopic data. Presumably the reaction proceeded through a double aldol reaction at 2 and 5-positions of **12f**, followed by



(3)

(4)

f: n=1 g: n=2

cyclization. Expectedly, the yield was improved by using two equivalents of **13** (Run m). The same type of the reaction occurred with **12g** upon treatment with TMSOTf, affording **15g** (Run p). Notably, **15f** was a single diastereomer as revealed from ^1H NMR (400 MHz) and ^{13}C NMR spectra, while **15g** was evidently a mixture of diastereomers in view of ^1H NMR analysis. Presumably, the whole reaction is controlled thermodynamically to afford the products as the most stable form. The bicyclic compounds **15f** and **15g** were also obtained from the respective mono-aldols **14f** and **14g** upon treatment with TMSOTf, irrespective of whether acetaldehyde was added or not (Runs r—t). Apparently the reactions in Runs r and t involved the retro-aldol reaction. The aldols **14f** and **14g** (diastereomer mixture) were prepared from the corresponding silyl enol ethers with **13** under the $TiCl_4$ treatment.[2]

Unlike the cases of the five-membered ketone described above, no ring enlargement was observed in case of the six-membered ring system even with benzaldehyde. When **12g** was treated with **2a** in the presence of TMSOTf, the product was an α,β-enone **16g**, identical with the authenic sample prepared by the reported method.[7] (Eq. 4, Run o).

The reaction terminated at the stage of mono-aldols **14f** and **14g**, when the reactions of **12f** and **12g**, respectively, were induced with $AlCl_3$ (Runs n and q). The diastereoselectivity in these cases was a little higher than that obtained in the $TiCl_4$-induced aldol reaction of the corresponding silyl enol ethers.[2]

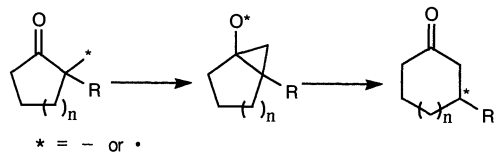
Discussion

It appears that all the reactions described in the present paper proceed through the initial aldol reaction at the more substituted α-position (2-position) of the cycloalkanones. It has been known that the reactions of 2-methylcyclohexanone and 2-methylcyclopentanone with some aldehydes in protic solvents proceed at the unsubstituted position (5- or 6-position) of the cycloalkanones followed by dehydration under both acidic and basic conditions.[6,7] Generally the benzylidene derivatives (*exo*-enones) are obtained under basic conditions, while benzyl derivatives (*endo*-enones)

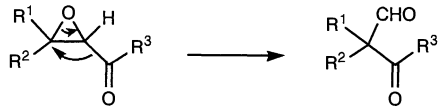
are obtained under acidic conditions.[8] It has been well documented that the aldol reaction is reversible and accompanied by a facile dehydration in protic solvents. Thus the thermodynamically most stable compounds might be the product under these conditions. On the other hand, the kinetic aldols can be isolated without being dehydrated, by starting from the corresponding derivatives of the substrates in aprotic solvents under mild conditions. Under these conditions, the reaction site is controlled by the regiochemistry of the enolates. The regioselective aldol reaction at the substituted position of the 2-substituted cycloalkanones has been elaborated by starting from the more substituted silyl enol ethers.[1] The silyl enol ethers or other metal enolates derived therefrom react with aldehydes to produce regiospecific aldols. The aldol reaction of the persubstituted enolates prepared in this way has been extensively studied, particularly from view point of the stereochemistry.[9] The formation of the persubstituted enolates has also been achieved from 2-bromo-2-methylcyclohexanone by treating with Zn-Et_2AlCl.[10]

The regiochemistry of the aldol reaction of the unsymmetrical cycloalkanones in aprotic solvents has received less attention. It is known that the aldol reaction of 2-methylcycloalkanones with benzaldehyde proceeds at the less hindered site, when promoted by tetraalkoxysilane/fluoride anion in dimethylformamide or without solvent.[11] The diethylaluminum tetramethylpiperidide-induced aldol reaction of 2-methylcyclohexanone in tetrahydrofuran is also known to react at the 6-position,[12] indicating that the enolization proceeds to afford the less substituted enolate. Therefore it is remarkable that the present reaction proceeded at the more hindered position. Although the aldols **3** and **14** were actually isolated in Runs 1, n, and q, the aldols underwent further reaction to result in either ring enlargement or retro-aldol reaction in other cases. Conceivably the ring enlargement reaction proceeded through (1) elimination of the hydroxyl group from the aldol, (2) concomitant 1,2-acyl migration, and (3) deprotonation, as shown in Eq. 1. Probably the series of the steps proceed only when elimination of the hydroxyl group (step 1) is facilitated through the cation-stabilizing effect by phenyl or alkenyl group, and the ring enlargement (step 2) does not give rise to the unfavorable strain, as would possibly be encountered in the *trans*-formation from six- to seven-membered ring system. Unless these requirements are fulfilled, the retro-aldol reaction proceeds to produce either **15** or **16**, depending upon whether the aldehyde is acetaldehyde or benzaldehyde, respectively. The γ-pyrone formation from 2,6-dialkylcyclohexanones under acidic conditions has been reported.[13]

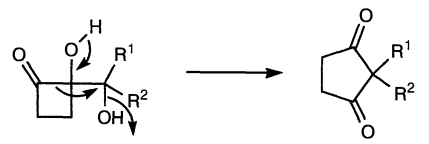
The 1,2-acyl migration will be discussed next. A reaction scheme involving cyclopropoxyl radical or anion, resulted from the intramolecular addition of alkyl radical or anion to the carbonyl group is a well-



(5)



(6)



(7)

documented process of 1,2-acyl migration (Eq. 5).[14] It seems likely, however, that the present ring enlargement involves a direct 1,2-acyl migration to the electron deficient carbon terminus rather than through the cyclopropoxy intermediates. This type of the acyl migration was first studied by House in the Lewis acid-induced reactions of α,β-epoxy ketones, and has been a target of many researchers (Eq. 6).[15] The unusually high migratory aptitude of the acyl group, as compared with that of methylene or hydride, has been established.[16] The 1,2-acyl migration proceeds concertedly with inversion of configuration at the migration terminus. Another instance of the Lewis acid-induced 1,2-acyl migration has been observed with pinacol–aldol system (Eq. 7).[17] Since the epoxy ketone could be looked as an equivalent to the aldol in a sense that the β-position of the carbonyl group has an oxygen leaving group, these examples could be assigned as precedence for the 1,2-acyl migration in the aldol system. However, it is highly likely that the acyl migration in these systems is effectively drived by the opening of oxirane or cyclobutanone ring, and also by the presence of a carbocation-stabilizing oxygen substituent at the migration origin carbon. Thus the present reaction is notable in that the 1,2-acyl migration is induced only with the participation of the alkenyl and aryl groups in stabilizing the cationic intermediates.

The base-induced reaction of the tosylate of **14g** has been reported to afford a mixture of cyclobutanone derivatives as well as a ring-opened product. However, neither acyl migration nor retro-aldol reaction has been observed.[18]

Remarkably the products from the unsaturated aldehydes have a unique system of 2-acyl-1,3-diene unit. To our best knowledge, only two cases have been reported for the preparation of this cross-conjugated electron-deficient diene system: the vinylation at α-position of α,β-epoxy ketones,[4] and the Robinson annulation of cycloalkanones with divinyl ketone.[19]

The phenylation at the α-position of α,β-epoxy ketones affording **6a** has been demonstrated as an example of α-alkylation and α-arylation of α,β-enones.[20,21]

Experimental

General Procedure and Instrumentation. GLC experiments were carried out on a 2.5 m×3 mm stainless steel column packed with Silicone SE 30 or Carbowax 20 M on silanized Chromosorb W. Column chromatography was carried out on Kieselgel 60, Art. 7734 (70—230 mesh ASTM). All the spectroscopic data were determined on a pure sample obtained by column chromatography. ^{1}H NMR spectra (60 MHz) were recorded on a Hitachi R-24 or JEOL PMX60 SI spectrometer. ^{1}H NMR (90 MHz) and ^{13}C NMR (22.5 MHz) spectra were measured on a Hitachi JNM-PMX 60 S R-90 H spectrometer, and 400 MHz ^{1}H NMR spectra on a JEOL GSX-400 spectrometer. GC-MS spectra were taken on a Shimadzu QP-1000 mass spectrometer, and high-resolution mass spectra on a JEOL DX-300 mass spectrometer. IR spectra were recorded on a Shimadzu IR-400 spectrometer. Unless otherwise stated, CH_2Cl_2 was used as a solvent for the column chromatography, CCl_4 solutions for ^{1}H NMR (60 MHz), $CDCl_3$ solutions for ^{1}H NMR (400 MHz) and ^{13}C NMR, and liquid film for IR measurement.

Reaction of 1 with 2a in the Presence of $AlCl_3$ (Run a). To a suspension of $AlCl_3$ (0.333 g, 2.5 mmol) in CH_2Cl_2 (10 ml) was added dropwise a CH_2Cl_2 solution (20 ml) of **1** (0.245 g, 2.5 mmol) and **2a** (0.265 g, 2.5 mmol) at room temperature during a period of 20 min. After stirred for additional 3 h at this temperature, aqueous $NaHCO_3$ was added and the products were extracted with CH_2Cl_2. The extract was dried over Na_2SO_4, and the solvent was removed in vacuo. The product was purified on a column chromatography to afford **4a** (0.287 g, 62%). IR 1665 and 1622 cm^{-1}. ^{1}H NMR δ=1.7—2.65 (m, 6H), 1.87 (s, 3H), and 6.8—7.45 (m, 5H). The compound **4a** was identical with the authentic sample prepared according to the reported method.[4]

Reaction of 1 with 2a in the Presence of TMSOTf (Run b). To a solution of **1** (0.245 g, 2.5 mmol) and **2a** (0.265 g, 2.5 mmol) in CH_2Cl_2 (20 ml) was added dropwise a CH_2Cl_2 solution (10 ml) of TMSOTf (0.555 g, 2.5 mmol) at room temperature during a period of 20 min. After stirred for additional 3 h, the reaction mixture was worked-up in the same way as described above. The column chromatography afforded **4a** (0.311 g, 67%) and **7** (0.102 g, 9%). In view of the ^{13}C NMR spectrum, **7** was a *trans-cis* mixture. For **7**, MS *m/z* 186 (M$^+$, base), 171, 153, 143, 128, 115, 91, 77, and 65. IR 1698, 1636, and 701 cm^{-1}. ^{1}H NMR δ=1.5—3.5 (m, 6H), 1.67 (d, *J*=2 Hz, 3H), and 7.11 (s, 5H). ^{13}C NMR[22] δ=[9.97*, 16.02], [31.17, 32.36*], [35.23, 36.77*], [39.68, 46.07*], 125.80, 127.93, 128.38, 139.09, 140.56, 156.56, and [210.24,* 210.74], (1:4). Found: *m/z* 186.1015. Calcd for $C_{13}H_{14}O$: M, 186.1044.

Upon catalytic hydrogenation (5% Pd-C/1 atm H_2/AcOEt, 35 h), **7** gave **10** in almost pure state as a diastereomer mixture (77% yield), as evident from ^{13}C NMR analysis. For **10**, MS *m/z* 188 (M$^+$), 173, 145, 117, 110, 97, 91 (base), and 65. IR 1736, 1453, and 699 cm^{-1}. ^{1}H NMR δ=0.96 and 1.20 (two doublets, *J*=8 Hz, 3H), 1.3—3.3 (m, 8H), and 7.10 (s, 5H). ^{13}C NMR[22] δ=[14.45*, 14.91], [25.67, 27.15*], [28.75, 29.74*], 36.01, [42.84, 44.35*], [49.62. 50.60], 125.94, 128.16, 128.75, and 139.68, (1:2). Found: *m/z* 188.1171. Calcd for $C_{13}H_{16}O$: M, 188.1201.

Reaction of 1 with 2a in the Presence of (*n*-Bu)$_2$BOTf, BF_3·OEt_2 (Runs c, d). The reactions were carried out in the same way as described for the TMSOTf-induced reaction (Run b). The respective produts and yields are shown in the Table 1. For **16f**,[11] ^{1}H NMR δ=1.13 (d, *J*=6 Hz, 3H), 1.3—3.5 (m, 6H), and 6.8—7.7 (m, 6H).

Reaction of 3a in the Presence of TMSOTf (Run k). The aldol **3a** was prepared according to the reported method.[2] ^{1}H NMR (diastereomer mixture) δ=0.67 (s, 1/4H), 0.98 (s, 3/4H), 1.15—2.20 (m 6H), 4.10 (br. s, 1H), 4.62 (s, 1H) 7.16 (s, 5H).

To a CH_2Cl_2 solution (45 ml) of **3a** (1.169 g, 5.73 mmol) was added dropwise a CH_2Cl_2 solution (23 ml) of TMSOTf (1.273 g, 5.73 mmol) in the ssme way as described for Run b. The products were **4a** (0.278 g, 26%) and **7** (trace).

Reaction of 1 with 2a in the Presence of $TiCl_4$ (Run 1). The reaction was carried out in the same way as in Run b, from **1** (0.245 g, 2.5 mmol) and **2a** (0.265 g, 2.5 mmol) with $TiCl_4$ (0.480 g, 2.5 mmol). The product was indentical with the authentic **3a** prepared above, with the diastereomer showing at δ=0.67 as the major product.

Reaction of 1 with 2b, 2c, 2d, or 2e in the Presence of TMSOTf (Runs e, f, g, h). To a solution of **1** (0.245 g, 2.5 mmol) in CH_2Cl_2 (5 ml) was added dropwise a CH_2Cl_2 solution (5 ml) of TMSOTf (0.555 g, 2.5 mmol) at room temperature during a period of 15 min. After 15 min, a solution of **2b** (*trans*+*cis*), **2c** (*trans*), **2d** (*trans*), or **2e** (*trans*) (3 mmol) in CH_2Cl_2 (30 ml) was added during a period of 3.5 h. After stirred for additional 45 min at this temperature, the reaction mixture was worked-up in the same way as in Run a. While the products **4c**, **4d**, and **4e** were obtained as single isomers, **4b** was a mixture of *trans* and *cis* isomers, which were separated into each fraction on the column chromatography in yields as specified in the Table 1.

For *trans*-**4b**, MS *m/z* 150 (M$^+$), 135, 117, 107, 91, 79 (base), and 77. IR 1666, 1613, 1375, and 969 cm^{-1}. ^{1}H NMR δ=1.76 (d, *J*=6 Hz, 3H), 1.97 (s, 3H), 2.15—2.55 (m, 6H), and 5.9—6.1 (m, 2H). Found: *m/z* 150.1059. Calcd for $C_{10}H_{14}O$: M, 150.1045.

For *cis*-**4b**, MS same as that for the trans isomer. IR 1666, 1616, 1375, and 787 cm^{-1}. ^{1}H NMR δ=1.45 (d, *J*=6 Hz, 3H), 1.80 (s, 3H), 1.95—2.5 (m, 4H), and 5.4—6.0 (m, 2H). Found: *m/z* 150.1073. Calcd for $C_{10}H_{14}O$: M, 150.1045.

For **4c**, MS *m/z* 164 (M$^+$), 149, 135 (base), 131, 121, 107, 93, 91, 79, and 77. IR 1670, 1375, and 970 cm^{-1}. ^{1}H NMR δ=1.03 (t, *J*=6 Hz, 3H), 1.7—2.6 (m, 6H), 1.97 (s, 3H), and 5.8—6.1 (m, 2H). Found: *m/z* 164.1182. Calcd for $C_{11}H_{16}O$: M, 164.1201.

For **4d**, MS *m/z* 178 (M$^+$), 163, 149, 135 (base), 121, 107, 91, and 80. IR 1670, 1611, and 970 cm^{-1}. ^{1}H NMR δ=0.92 (dist. t, *J*=6 Hz, 3H), 1.1—2.7 (m, 10H), 1.97 (s, 3H), and 5.7—6.1 (m, 2H). Found: *m/z* 178.1361. Calcd for $C_{12}H_{18}O$: M, 178.1357.

For **4e**, MS *m/z* 212 (M$^+$), 197 (base), 179, 169, 155, 141, 115, 91, 77, and 65. IR 1668, 1626, 1375, and 970 cm^{-1}. ^{1}H NMR δ=1.97 (s, 3H), 1.5—2.5 (m, 6H), 6.77 and 6.93 (ABq, *J*=17 Hz, 2H), and 7.0—7.5 (m, 5H). Found: *m/z* 212.1175. Calcd for $C_{15}H_{16}O$: M, 212.1201.

For **8**,[3] MS *m/z* 212 (M$^+$, base), 197, 183, 155, 141, 128, 115, 91, and 77. IR 1732, 1236, and 1053 cm^{-1}. ^{1}H NMR δ=1.33 (s, 3H), 1.4—2.5 (m, 5H), 2.48 (d, *J*=6 Hz, 1H), 6.11 and 6.33

(ABq, J=15 Hz, 2H; upper halves further split to doublets with J=6 Hz), and 6.9—7.6 (m, 5H). ^{13}C NMR δ=16.54, 26.40, 29.22, 31.61, 45.28, 83.68, 123.58, 125.97, 127.24, 128.31, 134.06, 136.78, and 170.63. Found: m/z 1212.1216. Calcd for $C_{15}H_{16}O$: M, 212.1201.

Reaction of 5 with 2a in the Presence of TMSOTf (Run i). To a solution of **5**[23] (0.298 g, 2.16 mmol) and **2a** (0.229 g, 2.16 mmol) in CH_2Cl_2 (20 ml) was added dropwise a CH_2Cl_2 solution (10 ml) of TMSOTf (0.480 g, 2.16 mmol) at room temperature during a period of 20 min. After stirred for additional 3 h, the reaction mixture was worked-up and purified as in Run a, to afford **6a**[20] (0.243 g, 50%). MS m/z 226 (M^+, base), 198, 169, 153, 141, 129, 104, 91, and 77. IR 1671 cm^{-1}. ^{1}H NMR δ=0.60—2.83 (m, 13H) and 6.63—7.53 (m, 5H). ^{13}C NMR[24] δ=24.99†, 26.78†, 28.01†, 32.11†, 34.59†, 36.06†, 38.18, 126.10, 127.07, 129.28, 134.88†, 135.45†, 160.73†, and 196.72†. Found: m/z 226.1366. Calcd for $C_{16}H_{18}O$: M, 226.1358.

Reaction of 5 with 2b in the Presence of TMSOTf (Run j). To a solution of **5** (0.204 g, 1.48 mmol) in CH_2Cl_2 (5 ml) was added dropwise a CH_2Cl_2 solution (5 ml) of TMSOTf (0.329 g, 1.48 mmol) at room temperature during a period of 15 min. After 15 min, a solution of **2b** (0.124 g, 1.78 mmol) in CH_2Cl_2 (30 ml) was added during a period of 3.5 h. After stirred for additional 45 min at this temperature, the reaction mixture was worked-up and purified as above, to afford **6b** (0.197 g, 70%). MS m/z 190 (M^+, base), 175, 161, 147, 119, 105, 91, and 79. IR 1670, 1612, 1488, and 967 cm^{-1}. ^{1}H NMR δ=1.20—2.50 (m, 13H), 1.78 (d, J=5.2 Hz, 3H), and 5.40—6.17 (m, 2H). ^{13}C NMR[24] δ=18.09, 24.95†, 26.67†, 27.64†, 31.19†, 34.50†, 35.99†, 38.49, 123.27, 129.94, 130.53†, 159.16†, and 197.48†. Found: m/z 190.1352. Calcd for $C_{13}H_{18}O$: M, 190.1358.

Reaction of 12f with 13 in the Presence of TMSOTf (Run m). To a solution of **12f** (0.245 g, 2.5 mmol) in CH_2Cl_2 (10 ml) was added dropwise a CH_2Cl_2 solution (10 ml) of TMSOTf (0.278 g, 1.25 mmol) at room temperature during a period of 10 min. After 15 min, a solution of **13** (0.110 g, 2.5 mmol) in CH_2Cl_2 (10 ml) was added during a period of 30 min, and stirred for additional 1.2 h at this temperature. The same work-up as above afforded **15f** (0.109 g, 26%). MS m/z 168 (M^+), 124, 96, 71, 69 (base), and 55. IR 1745, 1379, and 1082 cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ=0.93 (s, 3H), 1.20 (d, J=6.2 Hz, 3H), 1.26 (d, J=6.2 Hz, 3H), 1.39—1.48 (m, 1H), 1.69—1.79 (m, 1H), 1.95—2.40 (m, 1H), 2.15—2.24 (m, 2H), 3.55 (q, J=6.2 Hz, 1H), and 3.93 (q, J=6.2 Hz, 1H). ^{13}C NMR δ=13.87, 15.27, 16.55, 18.66, 24.60, 51.00, 52.39, 78.88, 82.93, and 218.49. Found: m/z 168.1158. Calcd for $C_{10}H_{16}O_2$: M, 168.1150.

The yield was improved to 40%, when 5.0 mmol (2 equiv) of **13** was used.

In the same way, **12g** afforded **15g**, in yields shown in the Table 1 (Run p). MS m/z 182 (M^+), 138, 123, 110, 95, 82 (base), 81, 69, 68, and 67. IR 1718, 1380, and 1124 cm^{-1}. ^{1}H NMR δ=0.83 (s, 3H), 1.21 (d, J=6 Hz, 3H), 1.23 (d, J=6 Hz, 3H), 1.4—2.9 (m, 7H), 3.44 (q, J=6 Hz, 1H), and 3.82 (q, J=6 Hz, 1H). Found: m/z 182.1321. Calcd for $C_{11}H_{18}O_2$: M, 182.1307.

Reaction of 12f with 13 in the Presence of $AlCl_3$ (Run n). To a suspension of $AlCl_3$ (0.333 g, 2.5 mmol) in CH_2Cl_2 (10 ml) was added dropwise a CH_2Cl_2 solution (10 ml) of **12f** (0.246 g, 2.5 mmol) at room temperature during a period of 10 min. After 15 min, a CH_2Cl_2 solution (10 ml) of **13** (0.110 g, 2.5 mmol) was added during a period of 20 min. After stirred for additional 3.5 h at this temperature, the reaction mixture was worked-up in the same way as above to afford **14f** (0.298 g, 75%). The product was identical with that prepared according to the reported method,[2] which was separated into two diastereomers on a column chromatography (silica gel, hexane–ether=3/1). For diastereomer-I, IR 3446, 1731, and 1059 cm^{-1}. ^{1}H NMR δ=1.00 (s, 3H), 1.06 (d, J=6 Hz, 3H), 1.2—2.5 (m, 6H), 3.68 (q, J=6 Hz, 1H), and 3.67 (s, 1H). For diastereomer-II, ^{1}H NMR δ=0.83 (s, 3H), 1.09 (d, J=6 Hz, 3H), 1.2—2.5 (m, 6H), 3.55 (br. s, 1H), and 3.82 (q, J=6 Hz, 1H).

In the same way, **12g** (0.140 g, 1.25 mmol) gave **14g** (0.746 g, 74%)[18] as a diastereomer mixture (Run q), which was identical with that prepared according to the reported method.[2] ^{1}H NMR δ=0.9—1.15 (a couple of singlets and doublets, 6H), 1.5—2.7 (m, 8H), 3.47 (bs. s, 1H), and 3.9—4.3 (m, 1H).

Reaction of 12g with 2a in the Presence of TMSOTf (Run o). Using **12g** (0.280 g, 2.5 mmol), the reaction was carried out in the same way as in Run b, to afford **16g** (0.324 g, 65%). The product was identical with that prepared by the reported method.[7] ^{1}H NMR, δ=1.12 (d, J=7 Hz, 3H), 1.3—3.2 (m, 7H), 7.25 (s, 6H).

Reaction of 14f in the Presence of TMSOTf (Run r). To a CH_2Cl_2 solution (20 ml) of **14f** (0.336 g, 2.36 mmol) was added dropwise a CH_2Cl_2 solution (10 ml) of TMSOTf (0.524 g, 2.36 mmol) at room temperature during a period of 30 min. The mixture was worked-up in the same way as above to give **15f** (0.061 g, 16%). The yield was improved when the reaction was carried out in the otherwise same way with **13** added (Run s).

In the same way, **14g** (0.390 g, 2.5 mmol) gave **15g** (0.224 g, 49%) (Run t).

Financial support from The Asahi Glass Foundation is greatly acknowledged. We also would like to thank Shin-Etsu Chemical Co., Ltd. and Toray Silicone Co., Ltd. for generous gift of silyl reagents.

Determination of the Absolute Configuration and Enantiomeric Purity of Allylic and Acetylenic Alcohols

Fujiko YASUHARA,*†† Shozo YAMAGUCHI,††† Masayuki TAKEDA,†

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Aoba-ku, Sendai 980

† Department of Biochemistry and Engineering, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Aoba-ku, Sendai 980

(Received June 10, 1991)

The relative magnitude of steric bulk of saturated vs. unsaturated substituents in the title compounds has been estimated by a lanthanoid induced shift (LIS) study of these (*R*)-(+)-α-methoxy-α-(trifluoromethyl)phenylacetate esters [(*R*)-(+)-MTPA esters] by ^{1}H NMR spectroscopy:

CH_2=C(Me)–>Pentyl>*n*-Pr>Et≃CH_2=CH–>Me>CH≡C–; Ph>Cyclohexyl

These results allow the assignment of the absolute configurations of both cyclic and acyclic unsaturated alcohols. Furthermore, the relative intensity of well-separated OMe signals for those diastereomeric MTPA esters can be used for the determination of the %ee of the original alcohols.

The phenomenon of the chemical shift nonequivalence of diastereomeric esters and amides has been widely used for determinations of the absolute configuration and enantiomeric purity of alcohols and amines. The method using α-methoxy-α-(trifluoromethyl)phenylacetic acid (MTPA; Mosher acid) is especially useful and has been most widely employed for this purpose.[1a] This procedure, however, is not applicable when the ^{1}H NMR signals of the respective diastereomers are not sufficiently separated, or when the crucial signals overlap with other resonances. In such cases, the use of a lanthanoid shift reagent, such as Eu(fod)$_3$ (fod=6,6,7,7,8,8,8-heptafluoro-2,2-dimethyl-3,5-octanedione), with MTPA derivatives (MTPA/LSR method[1b]) often enhances the substancial separation of signals from the OMe and phenyl groups in the MTPA moiety and the methine proton in the alcohol moiety so that useful analyses can be performed.

In the course of continuing LIS studies,[2] we have become interested in extending the MTPA/LSR method to the title compounds, since these chiral unsaturated alcohols (**1** and **2**) and their related compounds are widely distributed in natural products as well as key intermediates for the synthesis of various biological active substances. In order to obtain an NMR configurational correlation scheme (Fig. 2) for predicting the absolute configuration of these alcohols by the MTPA/LSR method, it is essential to clarify the effective steric bulk of saturated vs. unsaturated substituents (R_1 vs. R_2) of the alcohol moiety in the MTPA esters for the coordinating Eu(fod)$_3$.

R_1: Alkyl, R_2: –C≡CR (2)

Results and Discussion

The partially active alcohols employed in this study were prepared by an asymmetric reduction of the corresponding ketones with the Darvon/$LiAlH_4$ complex[3] in good enantioselectivity (e.g., 68% ee for 3-butyn-2-ol). The alcohols, thus obtained, were purified by preparative GLC, if necessary. It is worthwhile noting that the Darvon/LAH complex reduction of α,β-unsaturated carbonyl compound affords an excellent regioselectivity, giving a 1,2-addition product similar to that with $NaBH_4$/$CeCl_3$.[4] Some of them were obtained by the hydride reduction of the corresponding homochiral ketones with $NaBH_4$/$CeCl_3$ or by the optical resolution of racemic alcohols via (*S*)-1-phenylethylamine salts of phthalic acid half esters. *cis*- and *trans*-4-*p*-Menthen-3-ols (Entries 20 and 21) were separated by preparative GLC from a mixture (*cis*/*trans*=88/12) obtained by an LAH reduction of (−)-4-*p*-menthen-3-one ($[\alpha]_D^{20}$ −62.5°, neat).

Shift studies were carried out on diastereomeric mixture of the MTPA esters, as previously reported.[5] Generally, the signal due to the OMe group in the diastereomeric MTPA esters appears as a single peak, thus giving no stereochemical information about the chiral center in question. The signal, however, gave a sufficient separation by the progressive addition of Eu(fod)$_3$. Figure 1 shows a typical example of an LIS study of the (*R*)-MTPA ester of (+)-2-cyclohexen-1-ol. The results are summarised in Table 1.

It is well-known that the order of the steric requirement of the alkyl, alkenyl and alkynyl groups varies appreciably with the reaction mode; for instance, the magnitude of the conformational free energy of the substituent on the cyclohexane ring is of the order of

†† Present adress: Sendai National College of Technology, Kami-ayashi, Aoba-ku, Sendai 989-31.

Et>Me>CH_2=CH–>CH≡C–; *t*-Bu>Ph.[6]

On the other hand, a partly reversed order,

Ph>*t*-Bu; CH≡C–>CH_2=CH–>Et>Me,[7]

has been observed for the chiral hydride reduction of carbonyl compounds by modified $LiAlH_4$ complexes, probably because of an electronic effect which plays a more important role than does the van der Waals repulsion. However, it has been reported that the relative magnitude of the steric requirement of several substituents in the MTPA/LSR study is of the order of

Ph>*t*-Bu>*i*-Pr>Et>Me;[5] COOMe>Ph>Alkyl;[8]

a) Determined by LIS value of the ethynyl proton. b) Configurations not previously reported. These configurations agrees with those predicted from the sense of asymmetric induction by Darvon/LAH complex.[3] c) The assignment is consistent with that presumed from the steric course of asymmetric reduction via hydrosilylation (T. Kogure and I. Ojima, *J. Organomet. Chem.*, **234**, 249 (1982)). d) The result was obtained by repeated run (Ref. 5).

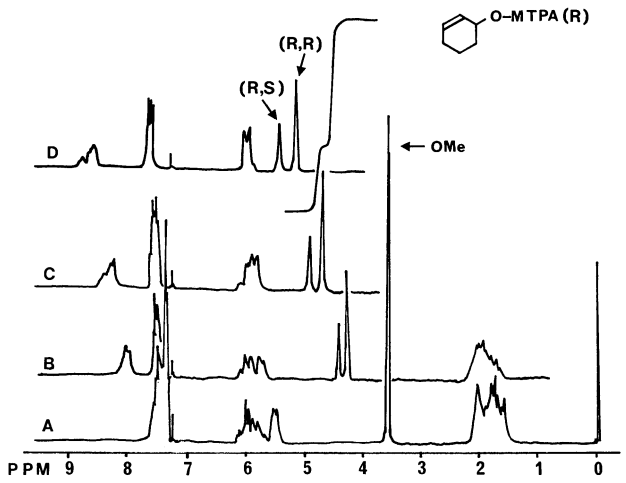

Fig. 1. ^{1}H NMR spectra of the (*R*)-(+)-MTPA ester of 2-cyclohexen-1-ol [(*R*)-(+), 27% ee] in the presence of a specified molar ratio of Eu(fod)$_3$ to the MTPA ester in $CDCl_3$. A, 0; B, 0.1; C, 0.16; D, 0.22.

no systematic investigation has been carried out for those of unsaturated substituents.

The results given in Table 1 clearly indicate that, in contrast to the above two cases,[6,7] the order of effective steric bulk of the substituents in coordination with Eu(fod)$_3$ is as follows:

(a) acyclic alcohols

CH_2=C(Me)->Pentyl>*n*-Pr>Et≃CH_2=CH->Me>CH≡C-; CH_2=$CHCH_2$->Et, Me; Ph>Cyclohexyl

(b) cyclic alcohols

···CH=C(*i*-Pr)->···CH=C(Me)->···CH(Me)-CH_2-, CH_2-CH_2-; ···CH_2-CH(Me)->···CH_2-CH_2->···CH=CH-

These observations strongly suggest that the electronic interaction between the unsaturated substituent and the three heptafluoropropyl groups in Eu(fod)$_3$ is not a dominant factor, but that an extension effect[9] of the substituents is effective (e.g the ethynyl and vinyl groups vs. the methyl group; Entries 1 and 3).

As reported previously,[5] since Eu(fod)$_3$ approaches to the *si*-face side of the ester carbonyl group, the LIS_{OMe} due to compounds (**A**) is consistently larger than that of the compounds (**B**). This correlation scheme enables the determination of the absolute configuration of original alcohols by considering the relative magnitude of the substituents.

Furthermore, the relative intensity of well-separated OMe signals for the diastereomeric MTPA esters can be used to determine the diastereomeric ratio of MTPA esters and, hence, the enantiomeric purity of the original alcohols. The experimental deviations from those obtained by measurements of specific rotation were within ±2%.

Previously,[5] we have observed that substrates with a quasi-axial hydroxyl group, such as *trans*-carveol (Entry 19), do not follow the correlation scheme and that the steric bulk of the substituent on the carbinyl carbon atom of the original alcohol is of the order of

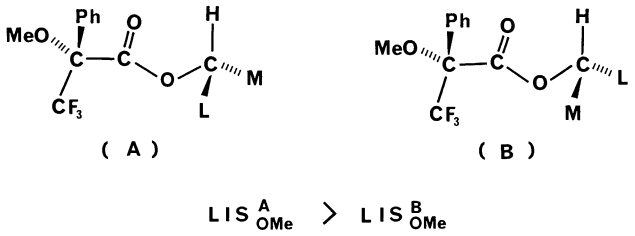

Fig. 2. NMR configurational correlation scheme.

···(*i*-Pr*)CH-CH_2->···CH=C(Me)-,

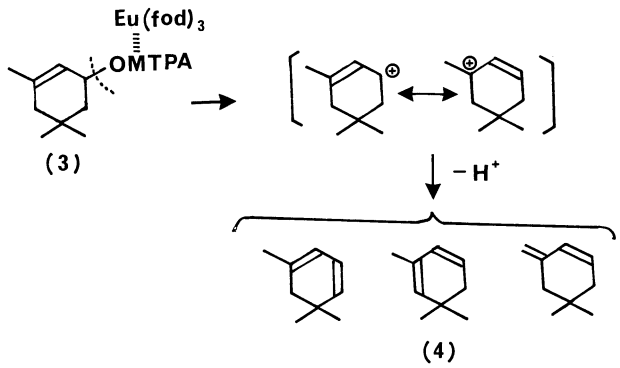
contrary to the usual order. As can be seen in the case of *trans*-4-*p*-menthen-3-ol (Entry 21), however, this irregularity disappeared when the methyl group was substituted by a more bulky isopropyl group.

In cases where only one enantiomer of the concerned alcohol is available (as is often the case with natural products) two diastereomeric MTPA esters can be generated from the same alcohol using both (*R*)-(+)- and (*S*)-(−)-MTPA. Since the NMR spectra of (*R*,*S*) and (*S*,*R*) or (*R*,*R*) and (*S*,*S*) enantiomers are indistinguishable, an application of symmetry principles should provide the necessary information.

Entries 23 and 24 are clear exceptions to this correlation scheme. Although the preferred conformation of these substrates seems to be responsible for this irregularity,[10] a further detailed study would be necessary for an elucidation of this problem.

An MTPA ester of 3,5,5-trimethyl-2-cyclohexen-1-ol (**3**) decomposed immediately upon the addition of a catalytic amount of Eu(fod)$_3$ to a $CDCl_3$ solution, giving three elimination products [one of which was separated (GLC), and identified as 2,6,6-trimethyl-1,3-cyclohexadiene (**4**)[11]] under ordinary NMR measurement conditions ($CDCl_3$, at ambient temperature).

A similar phenomenon was also observed for the MTPA esters of 3-methyl-2-cyclohexen-1-ol, *cis*- and *trans*-piperitols, β-ionol, 2,3,4,4a,5,6,7,8-octahydro-4a-



methyl-2-naphthol, and 4-methyl-3-penten-2-ol. Although this mild elimination reaction caused by the Lewis acid character of $Eu(fod)_3$ is strictly a characteristic of the compounds which afford a tertiary carbocation intermediate, the reaction seems to be inhibited by the adjacent alkyl group on the sp^2 carbon atom (Entry 22), which prevents access[12] of $Eu(fod)_3$. A further investigation of this unique elimination reaction is in progress.

Experimental

Instruments. NMR spectra were taken on a Hitachi R-90H FT spectrometer in $CDCl_3$ with TMS as an internal standard. Optical rotations were determined on Perkin-Elmer 241 electronic polarimeter using 1-dm and 0.1-dm thermostated microcells. GLC analyses were made on Shimadzu GC-7A using PEG 20M column (3 mm×2.0 m). Preparative GLC was carried out on a Varian Aerograph (model 700) using the same stationary phase (column: 4 mm×2.0 m).

Solvents and Reagents. Ether was distilled over $LiAlH_4$. Pyridine was dried over BaO and distilled. All of the solvents were stored over a Linde molecular sieve 4A. A stock $LiAlH_4$ solution in ether was passed through a glass filter under nitrogen and stored in a flask closed with a rubber septum. It was analyzed by iodometry immediately prior to use.[13] Aliquots were removed by a syringe, as needed.

Synthesis of Substrate (Representative Example). Optically active (+)-(1*R*,4*S*)- and (+)-(1*R*,4*R*)-4-*t*-butyl-2-cyclohexen-1-ols (a) 2-Bromo-4-*t*-butylcyclohexanones (**5**). To a stirred solution of 15.4 g of 4-*t*-butylcyclohexanone in 50 ml of CCl_4 was added dropwise 15.1 g of bromine in 15 ml CCl_4. The reaction flask was cooled to 15—30 °C and the rate of addition was adjusted so as to maintain a faint coloration of bromine at all times (ca. 2 h). The reaction product was washed with water, sodium carbonate solution, and saturated brine, successively, and dried over magnesium sulfate. The solvent was evaporated to give 20.5 g of crude (**5**) as a yellow oil.

(b) dl-4-*t*-Butyl-2-cyclohexen-1-one (**6**). The dehydrobromination was carried out as described by Miyano.[14] Under a nitrogen atmosphere, to a hot stirred suspension (140 °C) of 1.6 g of magnesium oxide in 45 ml *N*,*N*-dimethylformamide was added 7.0 g of (**5**) in 5 ml of *N*,*N*-dimethylformamide; the reaction mixture was stirred for 1 h. After it was cooled with an ice-bath, the magnesium oxide was dissolved by adding 100 ml of dil. hydrochloric acid and extracted several times with ether. The combined ether extract was washed with brine, sodium carbonate, and saturated brine, successively, and the solution was dried over magnesium sulfate. After the solvent was evaporated, the residue was distilled under reduced pressure to give 3.7 g of crude product as a colorless oil (bp 80—83 °C/8 Torr, 1 Torr=133.322 Pa). GLC analysis showed that the product contains 11% of 4-*t*-butylcyclohexanone and 89% of (**6**); it was purified by liquid chromatography (silica gel; hexane–ethyl acetate=10/2) to give (**6**). Compound (**6**): Colorless oil, ^1H NMR ($CDCl_3$) δ=0.98 (s, 9H), 6.02 (d of d, J=10 and 2 Hz, 1H), 7.00 (d of t, J=10 and 2 Hz, 1H). These spectra data were consistent with the literature.[15]

(c) (+)-(1*R*,4*S*)-(**7**) and (+)-(1*R*,4*R*)-4-*t*-Butyl-2-cyclohexen-1-ol(**8**). These alcohols were obtained by an asymmetric reduction of (**6**) with a Darvon/LAH complex according to the procedure reported previously.[3] GLC analysis indicated that the product contains sole 1,2-addition products [**7**: 15%, **8**: 85%]; and no other isomer was detected. The separation of *cis* and *trans* mixture was performed by preparative GLC.{(**7**): $[\alpha]_D^{25}$ +31.7° (*c* 0.68 methanol), mp 54.5 °C. Found: C, 77.36: H, 11.85%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%. ^1H NMR ($CDCl_3$) δ=0.91 (s, 9H), 4.02—4.19 (m, 1H), 5.91 (s, 2H); (**8**): $[\alpha]_D^{25}$ +5.14° (*c* 1.07 methanol) mp 38 °C. Found: C, 77.57; H, 11.91%. Calcd for $C_{10}H_{18}O$: C, 77.86; H, 11.76%. ^1H NMR ($CDCl_3$) δ=0.87 (s, 9H), 4.02—4.31 (m, 1H), 5.74 (s, 2H)].

MTPA Esters. 0.1 mmol of partially active unsaturated alcohols were converted to a diastereomeric mixture of (*R*)-(+)-MTPA esters with excess MTPA chloride made from (*R*)-(+)-MTPA according to the usual method.[1]

NMR Shift Studies (Representative Example). NMR spectra of the (*R*)-(+)-MTPA ester of partially active 2-cyclohexen-1-ol ($[\alpha]_D^{25}$ +40.3° (*c* 1.11, $CHCl_3$) 27% ee) were taken with a molar ratio of $Eu(fod)_3$ to the MTPA ester ranging over 0.1—0.3 in $CDCl_3$ (Fig. 1); the magnitudes of the induced chemical shift of the OMe signals were plotted vs. the molar ratio [$Eu(fod)_3$/MTPA ester]. In this range the induced shifts were essentially linear with respect to the molar ratio of the reagent. The ratio of the peak areas of well-separated OMe signals with larger and smaller LIS values was (36/64). From the results of Table 1, (-CH=CH-<-CH_2-CH_2-), (+)-2-cyclohexen-1-ol has the *R*-configuration.[16]

The authors express their sincere thanks to Dr. Masayoshi Ando for his generous gift of valuable samples (Entry 22 and 2,3,4,4a,5,6,7,8-octahydro-4a-methyl-2-naphthol).

Effect of Alkylammonium Ions on the Photochemical Behaviors of γ-Stilbazolium Aggregates in Clay Interlayers

Hisanao USAMI, Katsuhiko TAKAGI, and Yasuhiko SAWAKI*
Department of Applied Chemistry, Faculty of Engineering, Nagoya University,
Chikusa-ku, Nagoya 464-01
(Received June 10, 1991)

Effect of alkylammonium ions (C_n^+) has been studied on the clusterization and photochemical behaviors of γ-stilbazolium (4-(2-phenylvinyl)pyridinium) ion (**1**) adsorbed on clay interlayers. The aggregates of **1** were shown to be dissociated by the coadsorption of C_n^+ with molecular length longer than that of **1**. The major photoreaction was changed from cyclodimerization to *E–Z* isomerization on coadsorbing C_n^+'s longer than **1**. The efficient excimer emission from intercalated **1** was dramatically reduced by coadsorbing alkylammonium ions. The resulting concentration dependence of excimer emission intensity is nicely simulated by a Monte Carlo method for two-dimensional lattice site models.

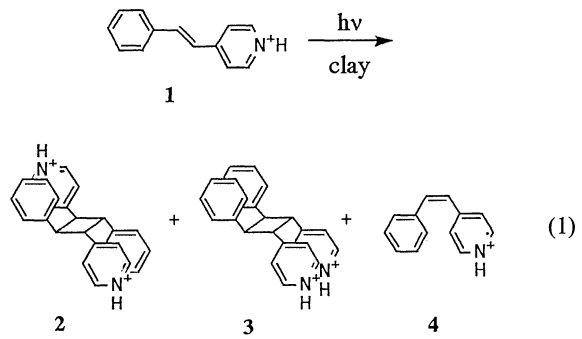
A marked interest has been focused on the photochemistry and photophysics of molecules in heterogeneous systems including micelles, vesicles, and so on.[1,2] On the other hand, only a little has been studied for photochemistry in heterogeneous systems such as silica gel,[3] zeolites,[4] and layered clay minerals.

Smecite clays consist of planar polyanionic sheets and exchangeable sodium ions, providing a stable electrostatic field. An interesting point to be noted is such that the restricted space, i.e., clearance space, in clay layers is variable depending on the size of organic cations to be intercalated.[5] In clay systems, a unique absorption behavior has been reported where different guest molecules are adsorbed separately from each other.[6] It is also reported that the coadsorption of alkylammonium ions induces a significant conformational change of adsorbents.[7]

However, little is known about a possibility, scope, and limitation of photoreaction in clay interlayers. We have been interested in applying the interlayer space of clay as a unique reaction field for spatially controlled photoreactions. We have recently reported that a clay-intercalated stilbazolium ion (**1**) undergoes a selective photodimerization to give *syn* head-to-tail type cyclodimer.[8] It has been also shown that the intercalation is quite efficient and the molecules are relatively immobile.[9] The present paper discloses an interesting effect of alkylammonium ions (C_n^+) on the photochemical behaviors of intercalated aggregates, which are adequately simulated by a Monte Carlo method for a two-dimensional lattice model.

Results and Discussion

In the previous report,[8] the intercalation of γ-stilbazolium (4-(2-phenylvinyl)pyridinium) ion (**1**) on clay interlayers was shown to result in a quite efficient photochemical dimerization affording *syn* head-to-tail (Eq. 1). The selective cyclodimerization was discussed on the basis of antiparallel packing of intercalated molecules.



(1)

Effect of Alkylammonium Ions (C_n^+) on the Photoreaction of Intercalated 1. The effect of alkylammonium ions (C_n^+) on the photochemical behaviors of intercalated **1** was determined in order to examine the formation and dissociation of molecular aggregates in clay interlayers. Irradiations of **1** intercalated on Saponite clay were carried out in the presence of various amounts of C_n^+. The photochemical reaction of **1** was found to be remarkably affected by certain kinds of C_n^+. As shown in Fig. 1, octylammonium ion (C_8^+) heavily retarded the dimerization, while butyl homolog (C_4^+) was practically of no effect. For the case of C_8^+, the *E–Z* isomerization became the predominant photoreaction.

Two possibilities are conceivable as an origin for the inefficient cyclodimerization in the presence of longer chain ammonium ions. One is such that stibazolium ions in the clay layers are substituted by ammonium ions and extracted into the bulk solution, resulting in the efficient *E–Z* photoisomerization. The other one is that coadsorbed C_n^+ ions may cause a significant change in the packing mode of **1** favorable for the isomerization. In order to differentiate the two possibilities, the effect of chain length of ammonium ions on the adsorption of **1** was examined as described in the followings.

Substitution of Intercalated 1 with C_n^+. Adsorption equilibrium and its constant, K_{ad}, for the adsorption of C_n^+ on clay interlayers are expressed as Eqs. 2 and 3, respectively. The K_{ad} values have been shown to increase

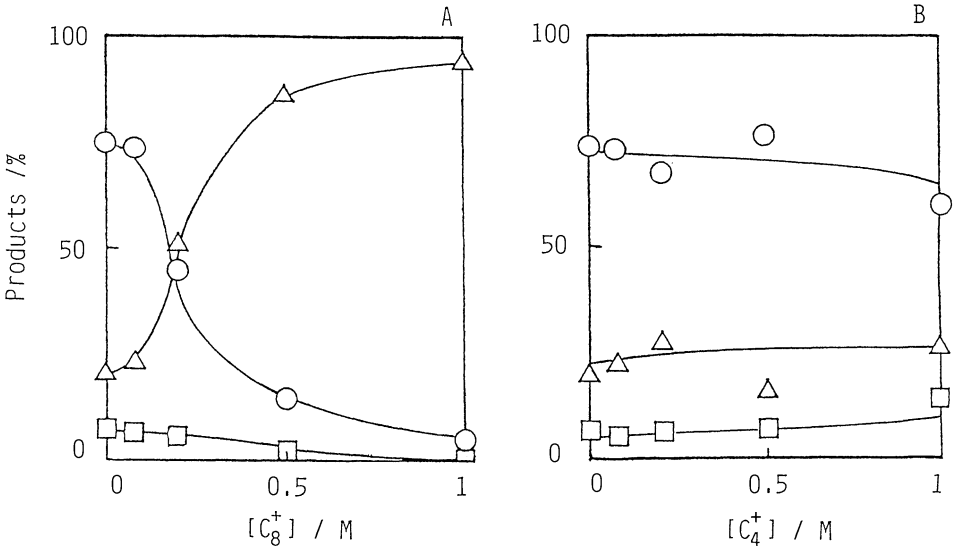


Fig. 1. Effect of alkyl ammonium ions on photoreactivity of pre-intercalated **1** on clay; —○—, *syn* head-to-tail dimer (**2**); —□—, *syn* head-to-head dimer (**3**); —△—, *Z*-**1** (**4**). Intercalated **1**-clay complex (40 mg or 6.8 mM based on CEC; i.e., 100% adsorption) was suspended in 5 ml of aqueous solution of alkylammonium ions; A, octylammonium (C_8^+); B, butylammonium (C_4^+). After stirring overnight, irradiation was carried out for 30 min with a 300 WHg lamp through a Pyrex filter.

Table 1. Substitution of Stilbazolium Ions (**1**) by Alkylammonium Ions (C_n^+) in Clay Interlayer[a]

Alkylammonium ions		K_{ad}[c]	Substituted stilbazolium ions[d]/%
Alkyl group	Molecular length[b]/Å		
—[e]	—	—	1
Butyl (C_4^+)	6.7	0.72	1
Pentyl (C_5^+)	7.9	0.96	2
Hexyl (C_6^+)	9.2	1.99	4
Heptyl (C_7^+)	10.4	3.92	87
Octyl (C_8^+)	11.7	9.2	86
Decyl (C_{10}^+)	14.2	35.7	—

a) In aqueous solution of C_n^+ (0.5 M and 0.6 M HCl, 5 ml) 40 mg of **1**-clay complex was dispersed and stirred overnight. The ratio of $[C_n^+]/[\mathbf{1}]$ was 74. b) Calculated for the all staggered conformers using the following bond lengths: 1.54 Å (C–C), 1.47 Å (C–N), 1.09 Å (C–H), 1.01 Å (N–H). All of the bond angles were assumed to be 109.5°. The molecular length of **1** is 10.4 Å. c) Equilibrium constants of adsorption of C_n^+ on clay.[10] d) Estimated from uv absorption of filtrate through a membrane filter. See experimental section for details. e) No additives.

with increasing chain lengths of C_n^+;[10] e.g., K_{ad}=0.7 for C_4^+ and 9.2 for C_8^+ as listed in Table 1.

$$C_n^+ + Na^+\text{-clay}^- \overset{K_{ad}}{\rightleftharpoons} C_n^+\text{-clay}^- + Na^+ \quad (2)$$

$$K_{ad} = [C_n^+\text{-clay}^-][Na^+]/[C_n^+][Na^+\text{-clay}^-] \quad (3)$$

Stilbazolium ion (**1**) was shown to be effectively intercalated with K_{ad}=ca. 490.[9] Attempted substitution of intercalated **1** by excess amount of C_n^+ added was carried out. As shown in the last column of Table 1, the substitution with C_n^+ where $n \leqslant 6$ was practically negligible, but that with C_7^+ or C_8^+ was quite effective. The expelling effect of C_7^+ and C_8^+ is not explicable in terms of the K_{ad} value of C_n^+ itself, since the increase of one methylene in C_n^+ results in an increase of K_{ad} values only by a factor of two, despite of discontinuous increase of substitution efficiencies at n=6 and 7 (see the third column in Table 1). It is interesting to note that the substitution is most effective when the molecular length of C_n^+ ions is close to that of **1** (i.e., 10.4 Å). The origin of the dramatic effect is unclear at present and remains to be explored. However, the apparent retardation of photodimerization by adding octylammonium ion, as shown in Fig. 1, is mainly due to the effective substitution of **1** by C_8^+.

Effect of C_n^+ on Aggregation Mode of 1. Effect of alkylammonium ions on the photoreaction of intercalated **1** was studied and the results are summarized in Table 2. Hereafter, the amounts of C_n^+ ions were adjusted not to exceed the clay CEC in order to assure the coadsorption of **1** and C_n^+ on clay interlayers. The cyclodimer formation was decreased and the *E*–Z isomerization became predominant by increasing chain length in C_n^+. These features are more apparent in Fig. 2, which demonstrates an alteration of photoproduct distributions by changing the chain lengths. Notable here is that the critical length of C_n^+ is again comparable

Table 2. Effect of Coadsorbed Alkylammonium Ions on the Photoreaction of **1**

$C_n^{+a)}$	Conversion/%	Products/%		
		2	**3**	**4**

a) Mixed solutions of **1** (0.16 mM, 4% adsorption), C_n^+ (3.2 mM, 80% adsorption), and Saponite clay (4 mM, vs. CEC) were stirred for two hours and irradiated.

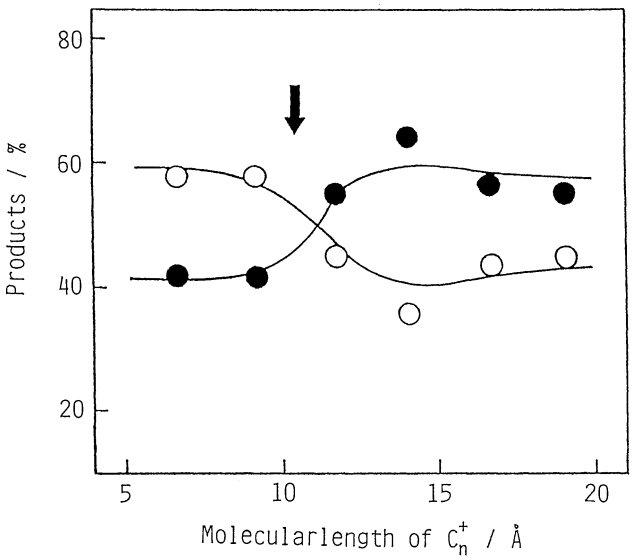

Fig. 2. Effect of molecular lengths of C_n^+ on the photoreaction of intercalated **1**; —○—, cyclodimer (**2**+**3**); —●—, *Z*-**1** (**4**). Suspended solution of **1** (0.16 mM; 4% adsorption) and C_n^+ (3.2 mM; 80% adsorption) intercalated on clay (4 mM) were irradiated by a 300 WHg lamp through a Pyrex filter. The bold arrow represents the molecular length of **1**.

to that of **1** (10.4 Å) as shown by an arrow in Fig. 2.

It is known that the anionic sites of Saponite clay interlayers are scattered on every five angstroms as an average distance.[8,12] The stereochemistry of cyclodimers and emissions from **1** suggested the intercalation of **1** in an alternative antiparallel fashion.[8] The present effect of alkylammonium ions suggests that clusters of **1** are homogenized by the C_n^+ ions of molecular length similar to that of **1** to yield isolated stilbazolium ions responsible for *E*–*Z* isomerization. This fact could be interpreted by a phase separation affected by molecular size, shape and the polar functional groups as known in the case of micelles, microemulsions[11] and clay interlayers.[6] It is tentatively proposed that the present photodimerization is significantly affected by the degree of homogenization of **1** and C_n^+. The addition of

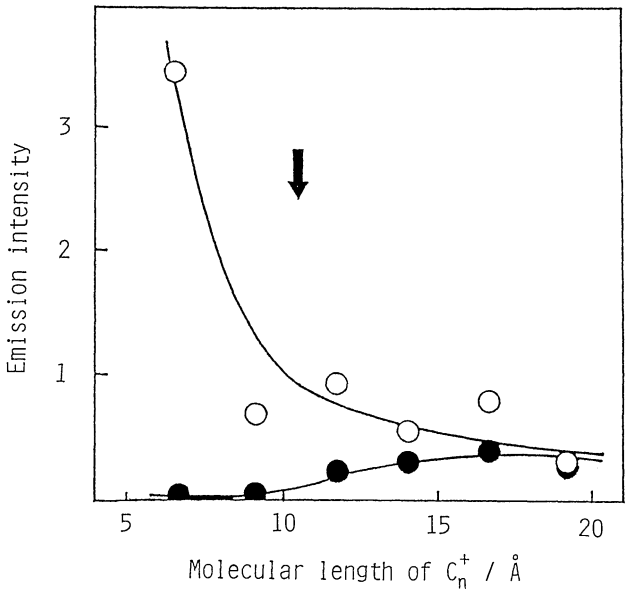

Fig. 3. Effect of molecular lengths of C_n^+ on the emission of **1** intercalated on clay; (a) —○—, excimer fluorescence monitored at 495 nm; (b) —●—, monomer fluorescence monitored at 423 nm. Colloidal suspensions of **1** (5 μM; 5% adsorption) and C_n^+ (95 μM, 95% adsorption) intercalated on clay (100 μM) were excited at 330 nm under Ar. The bold arrow represents the molecular length of **1**.

octylammonium ion would decompose a cluster of **1** by homogenized coadsorption.

Effect of C_n^+ on Monomer and Excimer Fluorescence of 1. In order to get a further insight in the molecular aggregates of **1**, the effect of alkylammonium ions was examined from the monomer and excimer fluorescence of intercalated **1**. Fig. 3 shows the effect of chain lengths of C_n^+ on the fluorescences from **1** in clay layers. The excimer fluorescence was efficiently inhibited by C_n^+'s with longer chain length, and the monomer fluorescence increased with the increasing length. These facts indicate that C_n^+ ions higher than octylammonium ion effectively dissociate the molecular aggregates of **1**. The resulting relative intensity of monomer and excimer fluorescence may be a probe for the aggregation and dissociation of adsorbents.

As shown in Fig. 4, the excimer fluorescence from intercalated **1** is nearly constant in a wide range of 0.1 to 20% adsorption, which indicates an efficient cluster formation or a heterogeneous adsorption of stilbazolium ions.[8] Then, it is interesting to examine the effect of alkylammonium ions on the concentration dependence of fluorescences from **1**. The results with C_8^+ are quite interesting as shown in Fig. 4B. That is, the excimer fluorescence was effectively reduced by coadsorption of C_8^+ and was practically negligible in case of the adsorption of **1** below 5%. This fact suggests that the molecular cluster of **1** was dissociated by C_8^+ and that the two adsorbents of **1** and C_8^+ were homogeneously

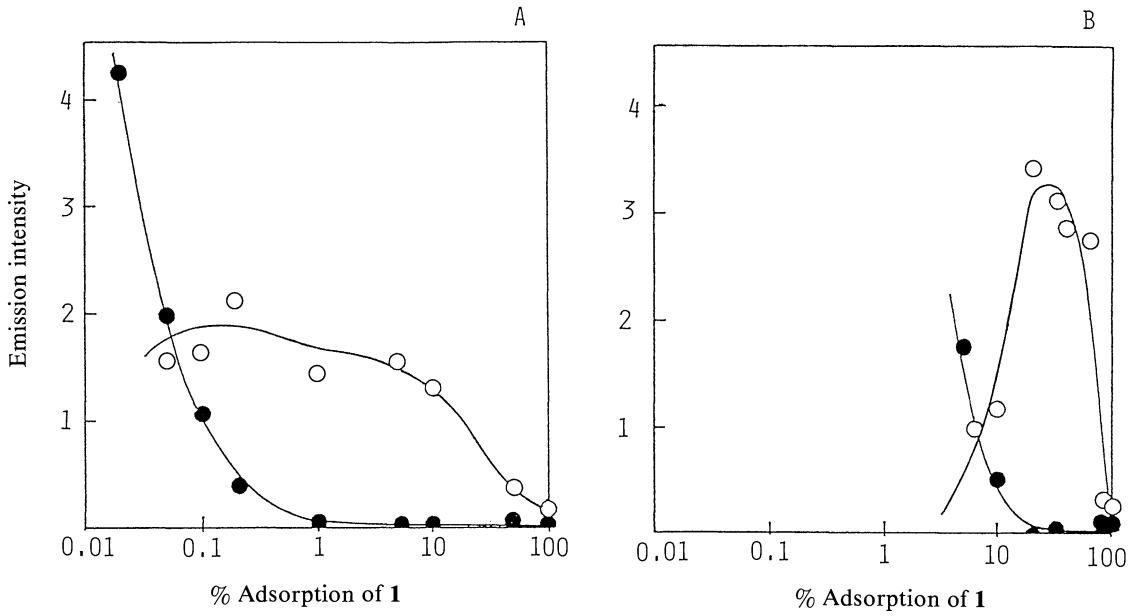

Fig. 4. Effect of C_8^+ on the fraction dependence of fluorescence intensity from **1**; (a) —○—, excimer fluorescence monitored at 495 nm; (b) —●—, monomer fluorescence monitored at 423 nm on the excitation at 330 nm. A: Colloidal suspension of **1** (5 μM and 6 μM of aqueous HCl) intercalated on clay.[8] B: Colloidal suspension of **1** (5 μM and 6 μM aqueous HCl) intercalated on clay, where the remaining sodium ions were completely exchanged by C_8^+.

adsorbed on the clay interlayer.

Simulation of Intercalation on Two-Dimensional Lattice. The effective cluster formation even with 0.1% adsorption of **1** and its dissociation by coadsorbed C_8^+ may be understood more quantitatively by the following simulation behavior for intercalation. It is established that cationic species are adsorbed electrostatically on anionic sites of clay interlayers. The adsorbed species may scramble among any available sites on clay layers. Thus, the adsorbed species aggregate with guest molecules to form clusters depending on their strength of interaction.

A Monte Carlo simulation can treat a mutual interaction of adsorbent on homogeneously dispersed sites. Put n particles of adsorbent (S_1) on a flat surface with a two-dimensional lattice, assuming that the S_1 particles are free to change their adsorbing sites but confined within the lattice. In this model, S_1 can associate with S_n to form an aggregate S_{n+1} with an equilibrium constant K_n, as expressed in case of micelles, in Eqs. 4—6.[2] Here, S_2, S_3, and S_n denote dimer, trimer, and n-mer of S_1, respectively.

$$S_1 + S_1 \overset{K_1}{\rightleftharpoons} S_2 \tag{4}$$

$$S_1 + S_2 \overset{K_2}{\rightleftharpoons} S_3 \tag{5}$$

$$S_1 + S_n \overset{K_n}{\rightleftharpoons} S_{n+1} \tag{6}$$

For the simplicity, K_1, K_2, and K_n could be assumed to be equal to K as the case of the association of surfactant molecules, where the total concentration of S_1 is put

$$[S_1] + 2[S_2] + 3[S_3] + \cdots + n[S_n] + \cdots = 1 \tag{7}$$

unity as Eq. 7. Here, $[S_1]$, $[S_2]$, ···, and $[S_n]$ indicate the fractions of S_1, S_2, ···, and S_n, respectively.

When the two-dimensional lattice possesses a large number of sites, the fractions of n-mers with $n \geqslant 4$ are negligibly small, and Eq. 7 is reduced to Eq. 8.

$$[S_1] + 2[S_2] + 3[S_3] = 1 \tag{8}$$

The fractions of $[S_1]$, $[S_2]$, and $[S_3]$ are calculated as a function of K on the basis of Eqs. 4—6, according to Eq. 9 (See experimental section for details). For example, $[S_1]:[S_2]:[S_3]=1.0:0:0$, $0.56:0.16:0.04$, and $0.42:0.18:0.07$ when $K=0$, 0.5, and 1.0, respectively.

When the number of lattice sites is not of large excess, a more complicated treatment is needed. Suppose that n particles of S_1 are scattered over the two-dimensional lattice. The extent of attractive interaction between the particles could be estimated by means of a probability for an added S_1 particle to be settled on a site without neighboring S_1 particles; the details are described in Experimental section.

In case of 10% intercalation, typical distribution patterns are shown with $K=0$, 0.5, 2, and 20 in Figs. 5A—D. As apparent from these Figures, adsorbent clusters appear and grow with increasing K values. Fig. 6 shows simulation curves for a relationship between %-adsorp-

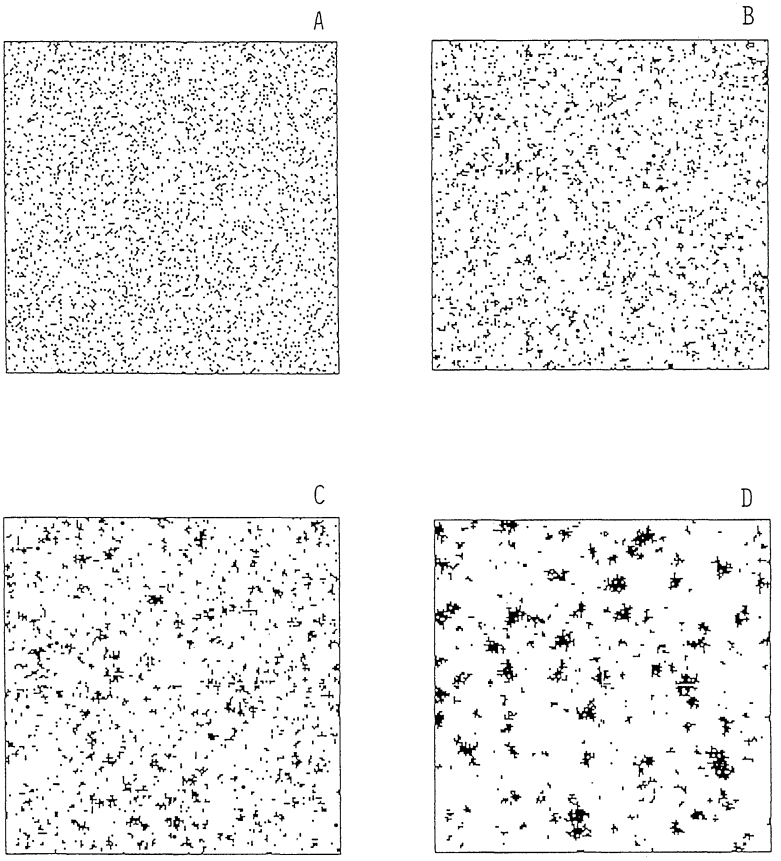

Fig. 5. Adsorption model of S_n on two-dimensional lattice as simulated by a Monte Carlo method; (A) K=0; (B) K=0.5; (C) K=2; (D) K=20. See text for details.

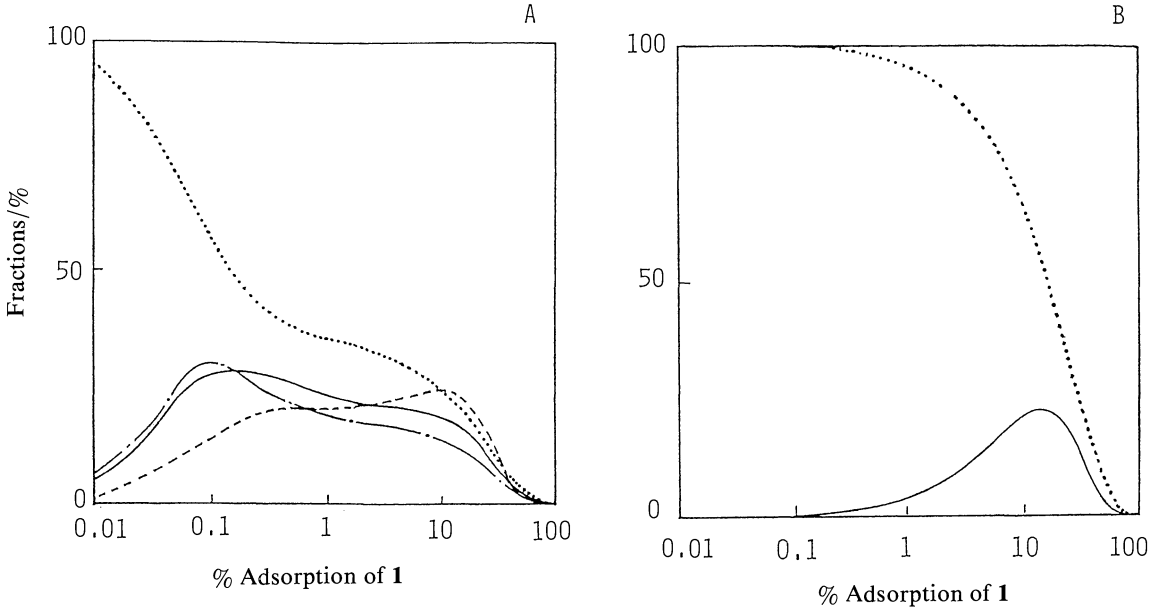

Fig. 6. Computer simulation of fractions of monomer and dimeric aggregates depending on the %-adsorption. A: [S_2] with K=0.1 (----), K=0.5 (—), and K=1.0 (—·—). [S_1] with K=0.5 (·····). B: [S_2] (—) and [S_1] (·····) with K=0.

tion and fractions of S_1 and S_2 in case of K=0 and 0.5. The resulting profiles of S_1 and S_2 fractions in Fig. 6A are quite comparable with the observed monomer and excimer fluorescence intensities in Fig. 4A. The adequate simulation with K=0.5 was confirmed by comparing with the S_2 fraction curves in case of K=0.1 and 1 in Fig. 6A. The coincidence between the two Figures implies a moderate interaction between stilbazolium ions, i.e., K=0.5.

As shown in Fig. 6B, profiles of $[S_1]$ and $[S_2]$ against %-adsorption with K=0 are very close to the features of Fig. 4B for the relative intensities of the monomer and excimer emissions of **1**, where C_8^+ is coadsorbed with **1**. This definitely suggests that specific interaction between the stilbazolium ions is canceled by the coadsorption of C_8^+.

Conclusion. The efficient formation of clusters of stilbazolium ions in clay interlayer is retarded or inhibited by adding alkylammonium ions, C_n^+, with comparable chain length. This is evidenced by an effect of C_n^+ upon the photochemical cyclodimerization and fluorescence intensities. The formation of dimer or cluster of adsorbent is adequately simulated by a Monte Carlo method for a two-dimensional lattice site model.

Experimental

Emission spectra were measured using a Hitachi 650-10S spectrophotometer. Product analyses were carried out with a JASCO UVIDEC-100-III HPLC instrument. Fractions were monitored at 250 nm using a Sil-NH_2 column (30 cm) and the mixed solvent of hexane, ethanol, and 25% aqueous ammonium hydroxide (450 : 50 : 1, v/v) as an eluent flowed at 1 cm^3 min^{-1}.

Materials. A synthetic Saponite clay, Sumecton SA (>110 mesh), was kindly gifted by Kunimine Ind. Co.; the cation-exchange capacity (CEC) is 99.68 mequiv/100 g. Synthesis of stilbazolium (**1**) and the identification of products, *syn* head-to-tail (**2**) and head-to-head (**3**) dimers, and *Z*-stilbazolium ion (**4**), were carried out as reported previously.[8,13] Alkylamines of extra pure grade were used as received from Tokyo Kasei Co.

Irradiations. The irradiation of **1** intercalated on clay layers in the presence of akylammonium ion (C_n^+) was carried out according to following two procedures.

I) Suspended System: The **1**-adsorbed sample were prepared by stirring for 2 h the mixed solutions of **1** (5 mM and 6 mM HCl aq, 100 ml) (1 M=1 mol dm^{-3}) and Saponite clay (10 mM aq, 50 ml). The resulting pale yellow precipitates were filtered out using a membrane filter (Advantech, pore size: 0.45 μm), dried overnight in vacuo, and were ground up with a mortar. From the absorbance of the filtrate, the %-adsorption of **1** on the clay was easily determined. Forty milligrams of the powdered clay-intercalated **1** were dispersed in 5 ml of alkylamine solution (0—1 M and 1.2 equivalents of HCl aq) and were stirred overnight. The irradiation was carried out with a 300 W high-pressure mercury lamp through a Pyrex filter for 30 minutes under Ar. The resulting reaction mixtures were added to concd HCl (10 ml), kept overnight, neutralized with NaOH aq, extracted by CH_2Cl_2, and analyzer by HPLC.

II) Colloidal System: The aqueous solution of **1** (2 mM and 2.4 mM HCl aq, 2 ml) was added to the mixture of aqueous clay (10 mM, 10 ml) and an alkylamine (40 mM and 48 mM HCl aq, 2 ml); the mixed solution was made 25 ml by volume by adding water. After the similar irradiation for 30 min, the products were analyzed as described above.

Emission Spectra. Aqueous solutions of **1** (50 μM and 60 μM HCl aq, 1 ml) and the clay (1000 μM, 1 ml) and/or alkylamines (950 μM, 1 ml) were mixed, made 10 ml by adding water, and stirred overnight. The mixed solution was taken in 1 cm cell, purged with Ar for five minutes. The emission spectra of intercalated **1** were measured by exciting at 330 nm and monitoring at 423 and 495 nm for the monomer and excimer emissions, respectively.

Simulation of Adsorption Modes on Clay Layers. The aggregation modes of **1** on clay layers were simulated on the basis of algorithm noted in the text using a Monte Carlo method. The random numbers for the method were generated using the subroutine of BASIC language program for a NEC PC-9801 microcomputer.

In order to estimate an extent of the attractive interaction between the particles, the Monte Carlo simulation was carried out under the following restrictions. A probability for an added S_1 particle to be settled on a site without neighboring S_1 particles is adjusted so as to be coincident with the fraction, $[S_1]$, obtained from Eq. 9 derived from Eq. 8, when K is fixed on 0 to 20. If not, the S_1 particle is again

$$[S_1] + 2K[S_1]^2 + 3K[S_1]^3 = 1 \quad (9)$$

resettled, until it is adsorbed as an isolated one, with maximum limit of 20 times retrials. This treatment means that the $[S_1]$ is equal to that in the presence of large number of sites.

This work was partly supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Laser Photolysis Studies on [2+2]-Photocycloreversion and Photoisomerization Reactions of *trans*- and *cis*-1,2-Di(1-pyrenyl)cyclobutane Dimers through Radical Ion Intermediates

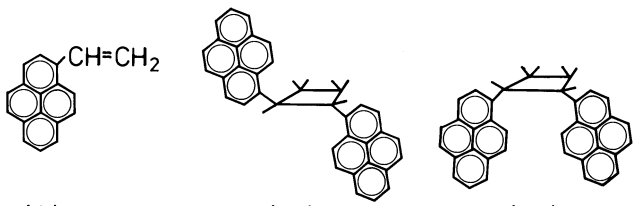
Akira TSUCHIDA, Masahide YAMAMOTO,* and Yasunori NISHIJIMA
Department of Polymer Chemistry, Faculty of Engineering, Kyoto University,
Yoshida, Sakyo-ku, Kyoto 606
(Received June 10, 1991)

Transient radical ion intermediates of [2+2]-photocycloreversion and photoisomerization reactions of the 1-vinylpyrene (**1**) cyclobutane dimers, *trans*- and *cis*-1,2-di(1-pyrenyl)cyclobutanes (**2t** and **2c**, respectively), were studied by nanosecond laser photolysis measurements; the reaction quantum yields were determined by photoproduct analysis. The excited singlet state of dimers **2t** and **2c** was quenched by an electron acceptor, 1,4-dicyanobenzene, with a diffusion-controlled rate in a polar acetonitrile solvent. The transient absorption spectra of the dimers in the system showed the formation of a dimer radical cation of pyrene chromophores, whose positive charge was delocalized in the two pyrene rings. The dimers were cleaved to form **1** through the dimer radical cation. By contrast, the formation of a dimer radical anion could not be observed in quenching by an electron donor, *N*,*N*-dimethyl-*p*-toluidine. The cleavage yield of the dimers from the anionic species was low. The decrease in the electron density in the cyclobutane bond in the cationic state promotes the cycloreversion reaction of dimers. In the absence of an electron donor or acceptor in the nonpolar benzene solvent, the direct photocleavage of **2t** and **2c** to **1** through the singlet excited state occurred efficiently, whereas in polar acetonitrile the cleavage was reduced to half by solvation of the excited states. A photocleavage of dimers also occurred in their triplet states.

The fragmentation reactions of cyclobutane compounds into two olefins, and of oxetane into a carbonyl group and an olefin, have been considered to be good prototypes of [2+2]-cycloreversion reactions.[1-17] If two bonds of the cyclobutane ring are broken simultaneously according to the Woodward–Hoffmann rule, the cleavage reaction proceeds in one step without any transient intermediate.[2] In this case, the stereoselective cycloreversion of cyclobutanes, similar to the case of cycloaddition of olefins, is allowed in their photoexcited states. A photoinduced [2+2]-cycloreversion reaction of cyclobutanes has occasionally been used as the simplest case for theoretical studies of the principle of orbital symmetry conservation.[3,4]

Recently, many reports concerning photocycloreversion reaction have been devoted to two fields. The photocleavage of pyrimidine dimers of DNA is of biological interest.[1,14] UV-Irradiation of DNA produces pyrimidine dimers; this damaged DNA is photoreactivated by the cycloreversion of the dimers caused by a photoreactivating enzyme. Secondly, chemically stored energy in the strained molecules is important from the standpoint of solar-energy storage.[10-13] For this purpose, the valence isomerizations of norbornadiene to quadricyclene and cage compounds have been extensively studied in this field.

As for the recent mechanistic studies concerning the photocycloreversion of the cyclobutane ring, many transient intermediates have been reported to exist.[1,7-17] 1,4-Diradical intermediates are occasionally found in the pyrolysis or photocleavage via the excited triplet state of cyclobutanes.[7-9,11,15,18] Photochemically produced excited complexes, such as excimers and exciplexes, are also reported to initiate cleavage.[11-17] The cycloreversions via the radical cation or anions are mainly studied by using gamma-ray irradiation and pulse radiolysis.[15] The behavior of the cyclobutane radical cations in the cycloreversion reaction has also been studied by theoretical calculations as well as by chemically induced magnetic polarization (CIDNP) experiments.[19,20]



(1) (2t) (2c)

In the present work, we studied the radical cation and anion formation of cyclobutane compounds by nanosecond laser photolysis, and tried to understand the transient intermediates which participate in the cleavage and isomerization reactions via the ionic states. The two isomers of the 1-vinylpyrene (**1**) dimers, *trans*- and *cis*-1,2-di(1-pyrenyl)cyclobutanes (**2t** and **2c**, respectively), have two pyrenyl (Py) groups in the vicinal position of a cyclobutane ring. The chromophore Py is well-known for excimer and dimer radical cation formations:[21-23] In this report, the term "dimer radical ion" is used for the dimeric radical ion whose positive or negative charge delocalizes between two chromophores, whereas the term "radical ion of dimer" is used for the radical ion of one chromophore in cyclobutanes.[23-29] By the measurement of laser photolysis, the "dimer radical ions" and "radical ion of dimers" of **2t** and **2c** were well distinguishable with the transient absorption spectra. Besides the laser photolysis measurements, the reaction quantum yields of photoinduced cycloreversion and isomerization were determined by product analysis,

and are discussed with regard to the transient intermediates observed in the transient absorption spectra.

Experimental

Chemicals. 1-Vinylpyrene **1** was synthesized from 1-pyrenecarbaldehyde by a Wittig reaction. Purification was made by recrystallization and silica-gel column chromatography with hexane–dichloromethane (5:1, v/v) as the eluent. Care was taken to eliminate pyrene, which was an impurity in 1-pyrenecarbaldehyde. Pyrene (Py, Tokyo Kasei Kogyo Co.) was purified twice by recrystallization and once by column chromatography. 1,4-Dicyanobenzene (DCNB, Wako Pure Chem. Ind.) and benzophenone (BP, Wako) were purified three times by recrystallization. *N*,*N*-Dimethyl-*p*-toluidine (DMT, Wako) was purified by distillation under reduced pressure prior to use.

Benzene (Wako) and 2-chlorobutane (Tokyo Kasei) were dried over $CaCl_2$ and purified by distillation. Acetonitrile (MeCN, Wako) was dried by refluxing over P_2O_5 several times and was fractionally distilled. 2-Methyltetrahydrofuran (MTHF, Tokyo Kasei) was filtered using an Al_2O_3 column and then dried. Purification was achieved by distillation under N_2 and subsequent vacuum distillation.

1-Vinylpyrene **1** cyclobutane dimers, **2t** and **2c**, were photochemically produced: The photodimerization of **1** in a MeCN solution produces *trans*- and *cis*-cyclobutane dimers.[30] Photoirradiation of a degassed MeCN solution of **1** (0.027 mol dm^{-3}) in a Pyrex tube by a 300-W high-pressure mercury lamp (Toshiba) for 3 h at room temperature gave both dimers. The products were fractionated by liquid chromatography (Waters, 3000 type) on a silica-gel column (Micro PORASIL) by eluting with CH_2Cl_2–hexane (4:100, v/v). The cis dimer has a larger retention time than the trans dimer. The conformation of **2t** and **2c** was determined by NMR chemical shifts.[31,32]

***trans*-1,2-Di(1-pyrenyl)cyclobutane 2t:** Mp 162—164 °C; ^{1}H NMR (90 MHz; C_6D_6; Me_4Si) δ=2.00—2.49 (4H, m, CH_2), 4.68—5.03 (2H, m, CH), and 7.58—8.37 (18H, m, aromatic); MS *m*/*z* 456 (10 %, M^+), 428 (2, $M^+-C_2H_4$), and 228 [100, **1**$^+$].

***cis*-1,2-Di(1-pyrenyl)cyclobutane 2c:** Mp 81—83 °C; IR (KBr) 3050 m, 2930 m, 2850 w, 1600 m, 1580 w, 1490 w, 1430 w, 1410 w, 1180 s, 840 vs, 750 s, 710 s, 695 s, 675 m, and 495 m cm^{-1}; ^{1}H NMR (90 MHz; C_6D_6; Me_4Si) δ=2.48—2.90 (4H, m, CH_2), 4.98—5.24 (2H, m, CH), and 7.38—8.22 (18H, m, aromatic); MS *m*/*z* 456 (0.5%, M^+), 428 (0.1, $M^+-C_2H_4$), and 228 [100, **1**$^+$].

Cyclobutane dimers were purified by liquid chromatography prior to use; the purity of both dimer was found to be more than 99%. Care was taken to prevent the dimers from thermal or photochemical decomposition.

Quantum Yield Measurements of Photoreactions. The quantum yields of the cycloreversion and isomerization of dimers were determined by photoirradiation under the monochromatic light of a spectrofluorophotometer. A 5-cm^3 sample solution of the dimers (5.0×10^{-5} mol dm^{-3}) in a 1-cm quartz cell was freed from oxygen by N_2 bubbling for 15 min. The samples were photoexcited in a temperature-controlled (297 K) sample chamber of an RF-501 spectrofluorophotometer (Shimadzu). The number of photons of the monochromatic Xe lamp measured by potassium ferrioxalate actinometry[33,34] was 2.0×10^{-9} E s^{-1} at 330 nm (slit width: 19 nm). The Py chromophore was selectively photoexcited at 330 nm, and the system with a DMT additive was photoexcited at 350 nm, since DMT has an absorption tail at 330 nm. For a system of triplet photosensitization, BP was selectively excited at 375 nm. After photoirradiation, the samples were analyzed immediately by liquid chromatography. In all measurements, the photoreaction yield was limited to less than 30% and the absorption of the exciting light by the products was corrected. For all systems, the contribution of thermal reactions, which was practically negligible, was corrected for by a blank experiment. The values of the determined reaction quantum yield were reproducible within ±5%.

Optical Measurements. All sample for the absorption and emission measurements were degassed ($<10^{-5}$ mmHg, 1 mmHg=133.322 Pa) by repeated freeze-pump-thaw cycles in a Pyrex ampoule fitted with a 1-cm quartz cell. The absorption spectra were measured by a UV-200S spectrophotometer (Shimadzu) at a 2-nm slit width. The emission spectra were obtained with an RF-501 spectrofluorophotometer (Shimadzu), whose spectral response was calibrated using a standard tungsten lamp. The quantum yield of emission was determined relative to that of quinine sulfate in sulfuric acid.[35]

The transient absorption was obtained by a nanosecond ruby laser photolysis apparatus, as described elsewhere.[36] The measurements were made at 297 K. The exciting laser light pulse at 347.1 nm has a 10-mJ pulse energy and a 14-ns pulse duration. Samples for the laser photolysis were freed from oxygen by N_2 bubbling for 15 min. The optical density of all samples at 347.1 nm was adjusted to be nearly the same (ca. 1.0) in order to attain homogeneous excitation.

The reference absorption spectra of the radical ions were measured by gamma-ray irradiation from a ^{60}Co source (2×10^6 rad h^{-1}) using a degassed 1-mm quartz cell in glass matrices at 77 K. Radical cations and radical anions were produced in glass matrices of 2-chlorobutane and MTHF, respectively.[37]

Results

Absorption and Emission of Dimers. The absorption-band shape of the chromophore Py is sensitive to the environmental conditions.[38] The cyclobutane dimers, **2t** and **2c**, have the Py groups in the vicinal position of the cyclobutane ring. The absorption spectra thus reflect the degree of the ground-state interaction between two neighboring Py chromophores.

Figure 1 shows the absorption spectra of dimers obtained in the MeCN solvent at 297 K and normalized at 290 nm. The absorption bands at around 290—360 nm are ascribed to the S_2—S_0 transition of the Py chromophore.[22] In Fig. 1, *trans*-dimer **2t** shows practically the same band shape as does that of reference 1-ethylpyrene (EPy); that is, two neighboring Py chromophores at the trans position of cyclobutane ring show no evidence of interaction in the shape of the absorption bands. However, the spectrum of *cis*-dimer **2c** is different from that of **2t**, indicating the existence of an interaction between two Py groups. In the spectrum of **2c**, the vibrational structure becomes less clear: The ratios of the absorption peak to valley for **2c** were smaller than those of **2t**. The molar extinction coefficient of **2t** at the 348.0 nm peak was ca. 8×10^4, whereas that of **2c**

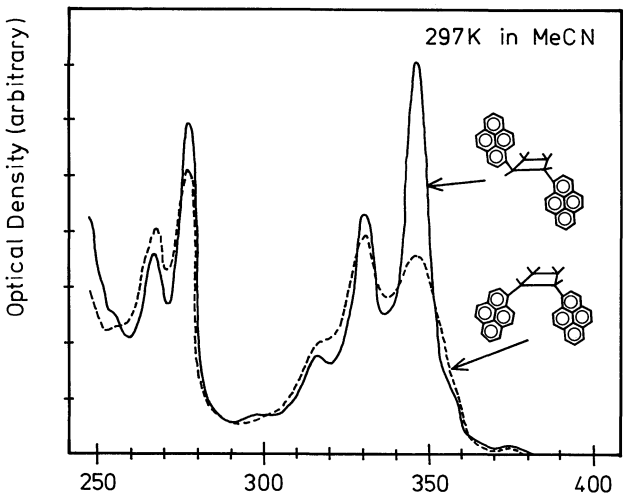


Fig. 1. Absorption spectra of 1-vinylpyrene **1** cyclobutane dimers (**2t**: solid line, and **2c**: broken line) measured in MeCN solvent at 297 K. The spectra were normalized at 290 nm.

was decreased to ca. 3×10^4. This shows that the distance of two Py chromophores of **2t** is too far to interact in the ground state, while for **2c** two Py groups take a sandwich-like conformation and interact with each other. This interaction of chromophores induced broadening of the absorption band with no peak shift, but with a slight hypochromicity.

As for the emission of the dimers, it was very weak due to intramolecular quenching in solution: The emission quantum yield of the intramolecular excimer of **2c** was less than 0.002 at 297 K in benzene solvent; the clear excimer emission of **2t** could not be observed, as has been reported for the emission of tetraphenylcyclobutanes.[11] The pure emission spectra of dimers in solution were difficult to measure due to the contamination of **1**, which shows strong fluorescence and was easily produced by photocleavage, even under the weak exciting light of a spectrofluorophotometer.[16,30] The excited state of the dimers is deactivated by the cleavage reaction and the emission is considerably quenched.

Photoreaction Quantum Yield of Dimers. Table 1 shows the absolute reaction quantum yields of the photoinduced cycloreversion and isomerization of dimers **2t** and **2c**, in several conditions. The O_2-freed sample solutions in the temperature-controlled sample chamber of a spectrofluorophotometer at 297 K were photoirradiated by monochromatic Xe light for a few minutes; the products were then analyzed immediately by liquid chromatography. The Py chromophore was selectively excited by 330 nm light and 1-vinylpyrene **1** was exclusively produced by the [2+2]-cycloreversion of the dimers. Together with the photocleavage reaction, the photoisomerization reaction from *cis*- to *trans*- and *trans* to *cis*-cyclobutane also occurred. Table 1 shows the values of the quantum yields of the cycloreversion and isomerization in nonpolar benzene and polar MeCN solvents. An electron donor, *N*,*N*-dimethyl-*p*-toluidine (DMT), as an additive produces radical anions of **2t** and **2c**, whereas the additive electron acceptor, 1,4-dicyanobenzene (DCNB), produces radical cations of the dimers.[39,40] The concentrations of DMT (1.0×10^{-2} mol dm^{-3}) and DCNB (1.0×10^{-2} mol dm^{-3}) were enough to quench the excited state of Py within 10 ns. An additive, benzophenone (BP, 2.5×10^{-2} mol dm^{-3}), was used as a triplet sensitizer; in this case, BP was selectively photoexcited at 375 nm. The triplet energies of Py and BP are 201 kJ mol^{-1},[33] and 290 kJ mol^{-1},[33] respectively. In this energy relationship, the triplet energy transfer from ^{3}BP* to Py is expected to be diffusion-controlled. In this sensitized system, the reaction quantum yields include both the intersystem crossing efficiency of ^{1}BP* to ^{3}BP* and the triplet energy transfer quantum efficiency from ^{3}BP* to Py. However, both efficiencies are expected to be quantitative at this concentration of Py and, therefore, the values in Table 1 are equivalent to the reaction quantum yields of ^{3}**2t*** and ^{3}**2c***.

Reference Absorption Spectra. For an interpretation of the transient spectra in laser photolysis, reference absorption spectra were obtained by gamma-ray ionization[37] at 77 K in rigid matrices (2-chlorobutane and MTHF) and by laser photolysis at 297 K in solution.

Figure 2 shows two T–T ([I] and [II]) and six radical ion ([III]—[VIII]) absorption spectra with their peak wavelengths. The three spectra obtained at 297 K ([I]—[III]) were measured by the laser photolysis in liquid solvents, whereas five radical ion spectra obtained at

Table 1. Photocycloreversion and Photoisomerization Quantum Yields of Cyclobutane Dimers

Solvent/Additive	Photocycloreversion		Photoisomerization	
	2t	**2c**	**2t**	**2c**
MeCN/DMT[a]	0.033	0.046	0.005	0.033
MeCN/DCNB[b]	0.073	0.061	<0.001	0.071
Benzene	0.15	0.17	0.025	0.080
MeCN	0.093	0.077	0.007	0.033
MeCN/BP[c]	0.060	0.12	0.007	0.099

a) *N*,*N*-Dimethyl-*p*-toluidine (DMT, 1.0×10^{-2} mol dm^{-3}) was added as an electron donor. b) 1,4-Dicyanobenzene (DCNB, 1.0×10^{-2} mol dm^{-3}) was added as an electron acceptor. c) Benzophenone (BP, 2.5×10^{-2} mol dm^{-3}) was added as a triplet sensitizer, and was selectively photoexcited.

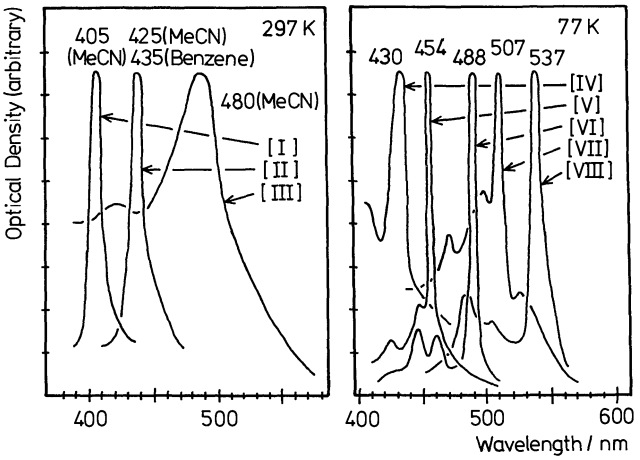

Fig. 2. Absorption spectra of triplet states and radical ions with the peak wavelengths. Spectra [I]—[III] were measured by the laser photolysis at 297 K. Spectra [IV]—[VIII] were obtained by the gamma-ray irradiation in rigid matrices at 77 K. [I]: ^{3}Py*, [II]: ^{3}**1***, [III]: DMT‡, [IV]: DCNB$^{\cdot-}$, [V]: Py‡, [VI]: Py$^{\cdot-}$, [VII]: **1**‡, and [VIII]: **1**$^{\cdot-}$.

77 K ([IV]—[VIII]) were measured by gamma-ray irradiation in rigid matrices. The radical ions and triplet states of the Py chromophore had sharp absorption bands at both temperatures, and the substitution by a vinyl group appreciably induced the red-shift of the peaks. For example, ^{3}Py* has an absorption peak at 405 nm, whereas ^{3}**1*** has a peak at 425 nm in the MeCN solvent. Hence, we can distinguish the Py triplet state (405 nm) formed in the cyclobutanes from the triplet state of **1** (425 nm) which is the product of photocleavage.

Figure 3 shows the absorption spectra of the radical ions of **2t** and **2c** produced by gamma-ray irradiation in rigid matrices at 77 K. The irradiation in the 2-chlorobutane matrix produces the radical cation of the solute, whereas in the MTHF matrix the radical anion is formed. Figures 3 [A] and [C] show the absorption spectra of **2t**‡ and **2c**‡, respectively. They show almost the same characteristics: Both have a broad peak at around 480 nm, which is quite different from that of Py‡ (454 nm). The absorption band shown in spectra [A] and [C] resembles that of intramolecular Py$_2^{\ddagger}$ in shape as well as in position. Such an absorption band

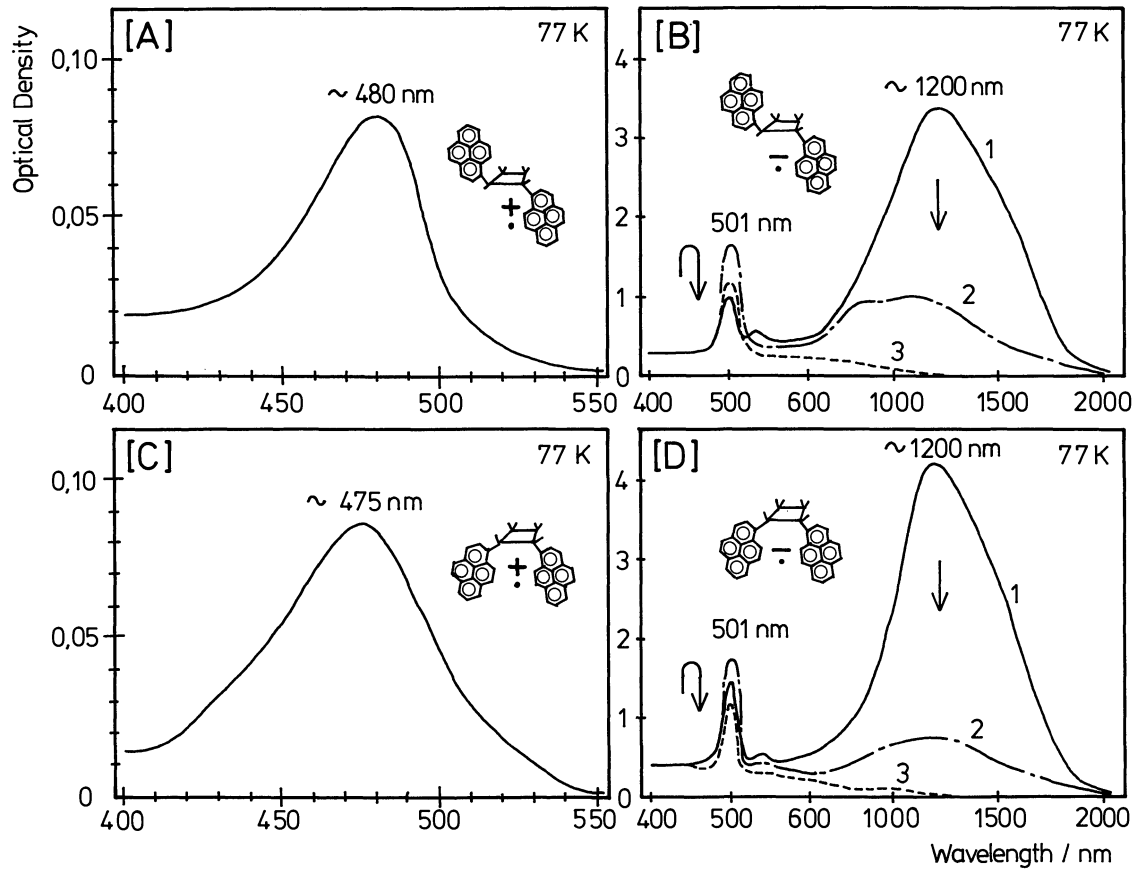

Fig. 3. Absorption spectra of radical ions of 1-vinylpyrene **1** cyclobutane dimers (**2t**: [A] and [B], and **2c**: [C] and [D]) with the peak wavelengths. Spectra were obtained by the gamma-ray irradiation in rigid matrices at 77 K. Immediately after irradiation (spectra No. 1), after warming (spectra No. 2), and after further warming (spectra No. 3). [A]: **2t**‡, [C]: **2c**‡, [B]: **2t**$^{\cdot-}$, and [D]: **2c**$^{\cdot-}$.

was observed for poly(1-vinylpyrene) or for the dimer models.[41] Therefore, these spectra are ascribed to the dimer radical cation of the intramolecular Py ($Py_2^{+\cdot}$) whose positive charge is delocalized between two py rings. The absorption spectrum of intramolecular $Py_2^{+\cdot}$ is less clear in vibrational structure compared to that of the dimer radical cation formed intermolecularly from pyrene.[23]

Radical anions of **2t** and **2c** were produced in MTHF at 77 K and the absorption spectra are shown in Fig. 3 [B] and [D], respectively. Both spectra are almost identical and the curves numbered 1 were taken immediately after gamma-ray irradiation. Two absorption bands are recognized in the spectra: The band at 501 nm is ascribed to the radical anion of Py ($Py^{-\cdot}$) formed in the dimers, and the band at around 1200 nm is assigned to the absorption of trapped electrons.[42] A slight warming of the MTHF matrix increased the band intensity at 501 nm, as shown in spectra No. 2; further warming decreased the absorption (spectra No. 3). The initial increase of this band is explained by a recapturing of trapped electrons to Py chromophores. This absorption band at 501 nm is very sharp compared with that of broad $Py_2^{+\cdot}$, and is similar to $Py^{-\cdot}$ (488 nm) in Fig. 2. The small spectral shift and the sharp band shape show the weaker interaction of Py chromophores in the anionic states of **2t** and **2c** than do those in the cationic states.[28,29]

Laser Photolysis Measurements. Nanosecond ruby-laser photolysis was carried out in order to study the transient intermediates of photocleavage reactions. Figure 4 shows the transient absorption spectra of dimers in benzene and MeCN solutions at 297 K. As shown in spectra [A] and [B], only ^{3}**1*** can be recognized by the photolysis of dimers in the benzene solvent. The transient absorption immediately after laser excitation (<50 ns) was hardly measured due to the overlap of the emission and the absorption of Py excimer could not be observed.[43] In the polar solvent MeCN, the spectra were the same as those in benzene, except for the shift of the absosrption maximum of ^{3}**1*** from 435 nm to 425 nm, which is due to the solvent effect as shown in the reference absorption spectra of Fig. 2. As shown in Fig. 4 [C] and [D], the addition of DMT as an electron donor to the dimers in MeCN solvent produced several transient species, which are ascribed to ^{3}**1*** (425 nm), $DMT^{+\cdot}$ (470 nm), $\mathbf{1}^{-\cdot}$ (500 nm), and $Py^{-\cdot}$ (530 nm). Since DMT has an absorption tail at 347.1 nm, the concentration of DMT in these systems was lowered to 1.0×10^{-3} mol dm^{-3}, which was a tenth of the concentration for the steady-state measurements of Table 1. Next, the effect of an electron acceptor DCNB was examined; the results are shown in spectra [E] and [F], where a strong absorption band of $Py_2^{+\cdot}$ was found at around 480 nm. The concentration of DCNB in these systems was the same as that for the steady-state experiment of Table 1, and the absorption of $DCNB^{-\cdot}$ appeared at 430 nm, overlapping with that of ^{3}**1***. In the figures, the dimer radical cations of **2t** and **2c** gave almost the same spectra.

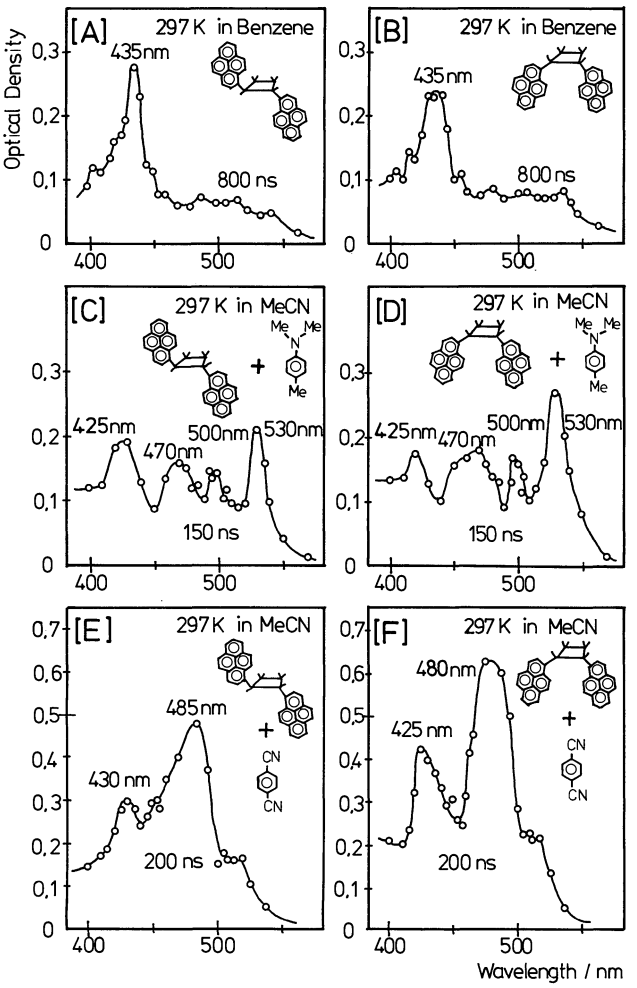

Fig. 4. Transient absorption spectra of 1-vinylpyrene **1** cyclobutane dimers **2t** ([A], [C], and [E]) and **2c** ([B], [D], and [F]) measured by the laser photolysis in benzene ([A] and [B]) or MeCN ([C], [D], [E], and [F]) solvent at 297 K. [A]: **2t** obtained at 800 ns after excitation, [C]: **2t** with DMT at 150 ns, [E]: **2t** with DCNB at 200 ns, [B]: **2c** at 800 ns, [D]: **2c** with DMT at 150 ns, and [F]: **2c** with DCNB at 200 ns. [DMT]= 1.0×10^{-3} mol dm^{-3}, and [DCNB]=1.0×10^{-2} mol dm^{-3}.

Table 2. Observed Transient Intermediates by Laser Photolysis Measurements

Solvent/Additive	2t	2c
MeCN/DMT[a]	^{3}**1***, $Py^{-\cdot}$, $\mathbf{1}^{-\cdot}$, $DMT^{+\cdot}$	^{3}**1***, $Py^{-\cdot}$, $\mathbf{1}^{-\cdot}$, $DMT^{+\cdot}$
MeCN/DCNB[b]	(^{3}**1***)[c], $Py_2^{+\cdot}$, $DCNB^{-\cdot}$	(^{3}**1***)[c], $Py^{+\cdot}$, $DCNB^{-\cdot}$
Benzene	^{3}**1***	^{3}**1***

a) *N*,*N*-Dimethyl-*p*-toluidine (DMT, 1.0×10^{-3} mol dm^{-3}) was added. b) 1,4-Dicyanobenzene (DCNB, 1.0×10^{-2} mol dm^{-3}) was added. c) Absorption band of ^{3}**1*** overlapps with that of $DCNB^{-\cdot}$.

Table 2 summarizes the transient species observed in Fig. 4. In every system, the formation of ^{3}**1*** was

recognized but ^{3}Py* could not be found in the time range of our measurements. In a system with an additive, DCNB, the absorption of the dimer radical cation ($Py_2^{+\cdot}$) was observed, whereas in the system with DMT, there was no noticeable evidence of dimer radical anion ($Py_2^{-\cdot}$) formation.

Discussion

Figure 1 shows a broader absorption band shape of **2c** than that of **2t**, indicating that two neighboring Py chromophores interact in the cis position of the cyclobutane ring. This interaction in the ground state was not found for the cyclobutanes having naphthyl groups. The absorption spectra of *trans*- and *cis*-1,2-di(2-naphthyl)cyclobutanes resemble those of 2-ethylnaphthalene.[44] The Py ring seems to be large enough to interact in the cis position of cyclobutane. The trans dimer **2t** showed almost the same absorption spectrum as that of EPy; that is, the Py chromophores in the trans position of cyclobutane are too far to interact. By contrast, as for the cyclobutane which has an electron donor and an acceptor in the trans position, a chromophore interaction was found in the absorption spectrum; the absorption bands of the Py chromophore for the *trans*-cycloadduct of *trans*-1-(4-dimethylaminophenyl)-2-(1-pyrenyl)cyclobutane were slightly different from that of EPy.[16] The interaction distance of the electron donor–acceptor pair seems to be long enough to reach in the trans position of the cyclobutane ring in the ground state.

Photocycloreversion of Dimers via Ionic Intermediates. The cycloreversion and isomerization of dimers, **2t** and **2c**, via the ionic intermediates were examined by the addition of an electron donor DMT or an electron acceptor DCNB to the solution. The chromophore pairs of DMT–Py and of Py–DCNB are known to form exciplexes in nonpolar solvents; their photophysical characteristics have been extensively studied.[39,40] In such polar solvents as MeCN, an electron transfer from a donor to an acceptor is followed by photodissociation into solvated free radical ions; in this case, electron transfer from DMT to Py produces $DMT^{+\cdot}$ and $Py^{-\cdot}$ and that from Py to DCNB produce $Py^{+\cdot}$ and $DCNB^{-\cdot}$.

Spectra [C] and [D] of Fig. 4 show the transient absorption obtained 150 ns after excitation in an MeCN solvent at 297 K. Photoexcited **2t** and **2c** were quenched by DMT to give the four transient absorption bands. As shown in the figures, the two dimers show similar spectra. In these systems, the concentration of DMT was lowered to one tenth of that in the quantum yield measurements, as mentioned before. By dilution, the electron-transfer quenching of dimers by DMT becomes slightly insufficient. The formations of ^{3}**1*** (425 nm) and $\mathbf{1}^{-\cdot}$ (500 nm), as shown in the spectra, are considered to be caused by this low DMT concentration. The quenching by DMT cannot effectively compete with the direct photocleavage which produces **1**. Then, successive photoabsorption of the same exciting laser pulse tail by product **1** forms ^{1}**1***, which is converted to ^{3}**1*** by intersystem crossing; and $\mathbf{1}^{-\cdot}$ was produced by an electron transfer from DMT to ^{1}**1***. The fact that the lifetime of ^{3}**1*** did not change with the concentration of DMT indicates that the quenching of ^{3}**1*** by DMT is negligible.

The $Py^{-\cdot}$ can be recognized at 530 nm in transient spectra [C] and [D]. The absorption band shape and the peak wavelength of the $Py^{-\cdot}$ are in accord with those obtained by gamma-ray irradiation, as shown in Figs. 3 [B] and [D]. This $Py^{-\cdot}$, whose charge is localized to one Py ring, is produced by electron transfer quenching of ^{1}**2t*** and ^{1}**2c*** with DMT. In the present study, no absorption band which can be ascribed to $Py_2^{-\cdot}$ could be found. As for the formation of the aromatic dimer radical anion, there has been no report,[25] except for a special case.[26] The charge resonance energy in the dimer radical anion seems to be weaker than that of the dimer radical cation. The results that the lifetime of the $Py^{-\cdot}$ is in the microsecond order and that it decays mostly by the recombination with $DMT^{+\cdot}$ (470 nm) indicate that the fraction of the cleavage of dimers through the $Py^{-\cdot}$ is not so large.

Table 1 shows that the quantum yields of photocleavage of dimers through the quenching by DMT are low (0.033 for **2t** and 0.046 for **2c**). This is because $\mathbf{2t}^{-\cdot}$ and $\mathbf{2c}^{-\cdot}$ are deactivated by the recombination with $DMT^{+\cdot}$ and their cleavage is not a major process. On the other hand, the cleavage quantum yields of dimers quenched by DCNB are higher (0.073 for **2t** and 0.061 for **2c**) than the systems of the DMT additive. In the transient absorption spectra as shown in Figs. 4 [E] and [F], the strong absorption of $Py_2^{+\cdot}$ (ca. 480 nm), which was identified by the reference spectra of Figs. 3 [A] and [C], was found as a main band, and this $Py_2^{+\cdot}$ seems to be cleaved. In Figs. 4 [E] and [F], the small absorption band of ^{3}**1*** can also be recognized through it overlaps with that of $DCNB^{-\cdot}$ (430 nm), but it is not a major product.

It is interesting that the photocleavage via $\mathbf{2t}^{+\cdot}$ and $\mathbf{2c}^{+\cdot}$, whose positive charge is delocalized to $Py_2^{+\cdot}$, is more efficient than that via $\mathbf{2t}^{-\cdot}$ and $\mathbf{2c}^{-\cdot}$, whose negative charge is localized to $Py^{-\cdot}$. Ledwith et al. proposed that an open-chain type radical cation of *trans*-1,2-di(9-carbazolyl)cyclobutane (DCzB) participates in the cycloaddition reaction.[45] The laser photolysis experiments of the DCzB showed that the two carbazole (Cz) chromophores in the trans position of the cyclobutane ring give the absorption of the dimer radical cation ($Cz_2^{+\cdot}$).[27] In our system of $\mathbf{2t}^{+\cdot}$, the formation of the dimer radical cation has been confirmed, as mentioned above. Recently, a theoretical calculation and experiments concerning CIDNP have suggested the existence of a "long-bonded cyclobutane" structure:[19,20] The one bond of a radical cation cyclobutane ring becomes long by the deficiency of the electron density.

The finding that the cleavage quantum yields of $\mathbf{2t}^{\pm\cdot}$ and $\mathbf{2c}^{\pm\cdot}$ are larger than those of $\mathbf{2t}^{-\cdot}$ and $\mathbf{2c}^{-\cdot}$ is in agreement with the reactivity tendency of the "long-bonded cyclobutane" structure. The decrease in the electron density in the cyclobutane bond is considered to promote the cleavage reaction.

As for the isomerization reactions of dimers via ionic intermediates, the isomerization from **2c** to **2t** was found to be favorable. This is considered to be caused by the steric factor of the cyclobutane ring.

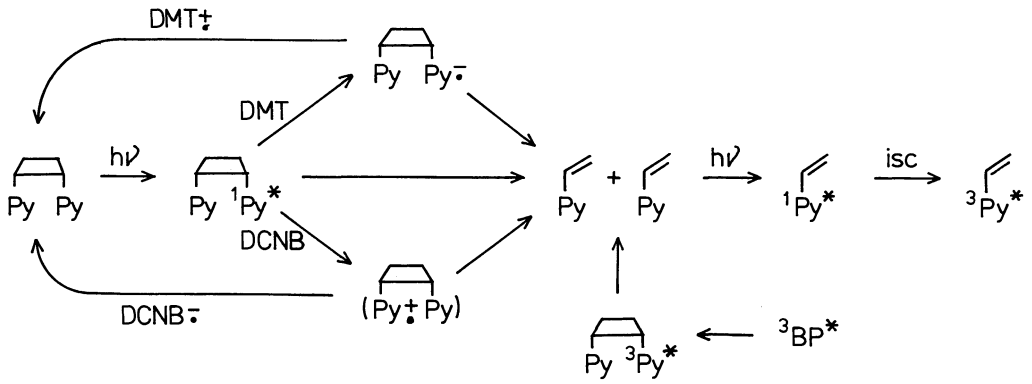
Photocycloreversion of Dimers from Singlet and Triplet Excited States. As shown in Table 1, the reaction quantum yields of cycloreversion and isomerization of **2t** and **2c** without an additive in the nonpolar benzene solvent are larger than those in the polar MeCN solvent. The polar excited singlet state of cyclobutanes seems to be stabilized in a polar MeCN solvent by solvation, and deactivation processes become dominant. Similar solvent effects could also be seen in our previous study.[16] As for the effects of different configurations of **2t** and **2c**, the quantum yields of cycloreversion of both dimers were nearly the same, whereas those of isomerization were larger for **2c** than for **2t**. The latter seems to be due to the "cis effect" of the Py chromophores.[1,8] The "cis effect" occurs due to a strain of the cyclobutane ring when the cyclobutane ring is substituted by large chromophores, or when the cyclobutane ring is a part of a bi- or polycycle. The photocleavage reaction in the latter case has often been reported to proceed by a chain mechanism.[13,14] In the present system, however, the effect is not so large. Furthermore, the quantum yields of cycloreversion for **2t** and **2c** are nearly the same. It seems that a cycloreversion in the excited state is effective for the large Py chromophore in the trans position of cyclobutane, as well as in the cis position.

The cycloreversion and isomerization from the excited triplet state of dimers, **2t** and **2c**, were observed by the use of triplet sensitizer of benzophenone (BP) as shown in Table 1. As mentioned before, these quantum yields in Table 1 are regarded as being the quantum yield of cleavage or isomerization of the dimers from their triplet state. They show that the dimer **2c** has a higher reactivity of cycloreversion and isomerization compared with that for **2t**. In triplet sensitized photocycloreversion, a diradical intermediate is most popular.[9,15] Probably, this is also ascribed to the cis effect.

In laser photolysis measurements, the transient absorption spectra of [A] and [B] in Fig. 4 gave only the band of $^3\mathbf{1}^*$. This formation of $^3\mathbf{1}^*$ was recognized in all transient spectra as shown in Table 2, and further the system which gave a large cleavage quantum yield showed stronger absorption of $^3\mathbf{1}^*$. These facts suggest that $^3\mathbf{1}^*$ is formed through a two step photo-excitation process.[16] The exciting laser light of our laser photolysis has a pulse duration of 14 ns. If the rate of cycloreversion is fast enough, the photoproduct **1** can be excited again by the same exciting light pulse tail, and then the produced $^1\mathbf{1}^*$ converts to $^3\mathbf{1}^*$. Overlapping of the fluorescence in the short time region (<50 ns) after the excitation hindered the observation of short-lived transient species, such as an excimer or zwitterion in the systems of Figs. 4 [A] and [B]. As for the anthracene dimer, the excimer was proposed as the transient intermediate of the cycloreversion.[11] Similarly, the excimer intermediate may participate in the cycloreversion of **2t** and **2c** in consideration of the fact that the chromophore Py easily forms the excimer.[21,22] As for the cyclobutane compounds, the most stable conformation of a cis cyclobutane ring is considered to be in a puckered form. The planar form, where two aromatic rings take the nearest conformation, has a slightly higher energy state, ca. 6.3 kJ mol^{-1} than the puckered form.[46] Furthermore, two aromatic rings cannot take a parallel-sandwich arrangement, even in the planar form of cyclobutane by the framework of cyclobutane ring.[44] Therefore, the excimer formed in cyclobutane compounds is unstable, and this is probably one of the reasons for the weak excimer emission and short lifetime.

Conclusion

The transient states of photocycloreversion and isomerization reactions of 1-vinylpyrene **1** cyclobutane



Scheme 1.

dimers, **2t** and **2c**, were discussed from the absorption spectra of laser photolysis and by the reaction quantum yields under the steady-state photoirradiation. The results are summarized in the Scheme. An efficient cycloreversion of dimers was found from their singlet and triplet states, though the solvation of the excited state by a polar solvent decreased the cycloreversion yields. The intramolecular dimer radical cation formation was observed for the dimers and the $\mathbf{2t}^{\cdot+}$ and $\mathbf{2c}^{\cdot+}$ were found to cleave in a yield comparable to that of direct photocleavage. An electron deficiency in the dimers is considered to be responsible for the cleavage. No formation of the dimer radical anion was observed. The cleavage of $\mathbf{2t}^{\cdot-}$ and $\mathbf{2c}^{\cdot-}$ to **1** was inefficient.

We thank Professor Hitoshi Yamaoka of the Research Reactor Institute, Kyoto University, for his help in determining the reference absorption spectra of the ion radicals.

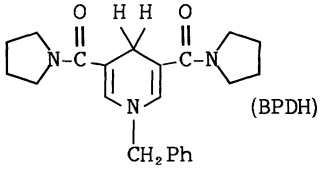
Acid-Promoted Oxidations of an NAD(P)H Model with Hydrogen Peroxide and Molecular Oxygen

Seizo TAMAGAKI, Takashi MIMURA, and Waichiro TAGAKI*
Department of Bioapplied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto 3-3-138, Sumiyoshi-ku, Osaka 558
(Received June 24, 1991)

The $HClO_4$-catalyzed H_2O_2- and O_2-oxidations of a dihyropyridine in acetonitrile were mechanistically investigated; the H_2O_2-oxidation under nitrogen followed a heterolytic course to yield the corresponding pyridinium salt along with a monooxygenated product, while the O_2-oxidation produced the pyridinium salt and H_2O_2 via a radical-chain pathway in which H_2O_2 is not only merely the product but also an initiator.

NAD(P)H pyridine coenzyme is used as a versatile reductant in a living cell,[1] and numerous examples exist of reductions of many organic functional groups such as C=O, C=C, and N=O bonds with NAD(P)H and its model compounds.[2] Meanwhile, peroxides occur in a living body in connection with production or removal of peroxidic compounds and activation of oxygen.[3] Although the oxidations of NAD(P)H by peroxides are potentially important in biology, model studies on the oxidation of NAD(P)H with peroxidic compounds have been only a few. For examle, 1-methyl-1,4-dihydro-3,5-bis(ethoxycarbonyl)-2,6-lutidine was oxidized at high temperatures with diacyl peroxides by a free-radical chain mechanism to the corresponding pyridinium cation.[4] Thus, noncatalytic reactions are generally very slow despite the inherent reducing ability of an NAD(P)H ring itself. Recently, we have reported on the rate-enhancing effect of some bivalent metals in the O_2- and H_2O_2-oxidations of an NAD(P)H model (1-benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-1,4-dihydropyridine (BPDH)); these reactions were found to proceed via a radical chain mechanism.[5]

In continuing our study of oxidations of a dihydropyridine ring, acid-catalyzed oxidation of BPDH with H_2O_2 under N_2 or O_2 has been thoroughly investigated in this work and we have found that, unlike bivalent metal-facilitated oxidations, the acid-catalyzed H_2O_2-oxidation proceeds via different courses depending on the reaction atmosphere. The acid-catalyzed oxidations of a closely-related NADH model with oxygen were previously studied under special conditions,[6] and by using an acid-stable NADH model (BPDH), where H_2O_2 is a final product.[7]



(BPDH)

Experimental

Materials. BPDH was prepared by reducing 1-benzyl-3,5-bis(1-pyrrolidinylcarbonyl)pyridinium chloride with $Na_2S_2O_4$ in a two-phase aqueous Na_2CO_3–CH_2Cl_2 system in a blanket of nitrogen as described in the preceding paper.[8] Acetonitrile was distilled from P_2O_{10}. H_2O_2 (30%) and $HClO_4$ (70%) were obtained from Wako Pure Chemical Industry and used as received.

Kinetics. The acid-catalyzed oxidations have been studied at 25 °C in CH_3CN in the presence of $HClO_4$ as the catalyst by monitoring the variation of the absorbance at 355 nm due to BPDH with time. Unless otherwise stated, the concentrations of BPDH, $HClO_4$, and H_2O_2 were 0.1 mM, 0.1—20 mM, and 0.5—15 mM, respectively. (mM=10^{-3} M, 1M=1 mol dm^{-3}). An $HClO_4$- and an H_2O_2-stock solution were prepared by diluting commercially available 70 and 30% aqueous solutions, respectively, with MeCN.

H_2O_2-Oxidation of BPDH. Product Analysis. BPDH (0.55 g, 1.5 mmol) was dissolved in 20 ml of CH_3CN. To this solution 2.0 mmol of H_2O_2 (30%) and 2.0 mmol of $HClO_4$ (70%) were added under nitrogen. After stirring for 24 h at room temperature, hydrochloric acid (1 equiv, 20 ml) was added. The acetonitrile was evaporated under reduced pressure, the resulting mixture was extracted with $CHCl_3$, and then the solvent was evaporated. The residue was subjected to preparative TLC on a silica plate eluting with 10:1 $CHCl_3$–MeOH to give the oxidized form of BPDH (BPD^+Cl^-) (50%) and 1-Benzyl-3,5-bis(1-pyrrolidinylcarbonyl)-3,4-dihydro-2(1*H*)-pyridinone (47%): Mp 188—192 °C; UV (MeCN) 274 (ε 8800); ^1H NMR ($CDCl_3$) δ=1.85 (8H, m, $N(CH_2)_2(C\underline{H}_2)_2$), 2.87 (2H, m(ABX), 4-$C\underline{H}_2$), 3.47 (8H, m, $N(C\underline{H}_2)_2(CH_2)_2$), 3.77 (1H, q(ABX), 3-H), 4.68 (2H, dd, Ph-$C\underline{H}_2$), 6.52 (1H, s, 6-H), and 7.18 (5H, s, Ph); MS (70 eV) *m/z* (rel intensity) 381 (M^+; 0.7), 311 (1.1), 283 (73), and 91 (100). Elemental Anal: Found: C, 69.11; H, 7.10; N, 10.72 %. Calcd for $C_{22}H_{27}N_3O_3$: C, 69.27; H, 7.13; N, 11.02 %.

O_2-Oxidation of BPDH. Product Analysis. The reaction with O_2 was performed with 0.50 mmol BPDH and 0.5—50 mmol $HClO_4$ in pure oxygen-saturated MeCN (50 ml) for 24 h. To evaluate the yield of the H_2O_2 produced, excess PPh_3 and AcOH was added and the reaction mixture was kept standing at room temperature for another 24 h. An excess of hydrochloric acid was added, the solvent was evaporated, and the residue was subjected to preparative TLC eluting with 5:1 $CHCl_3$–MeOH, giving $Ph_3P=O$ and the corresponding pyridinium chloride (BPD^+Cl^-, I). The results are collected in Table 1.

BPDH–$HClO_4$ 1:1 Adduct. Addition of an approximate excess of aqueous 70 % $HClO_4$ to a solution of BPDH (0.5 mmol) in 25 mL of CH_3CN gave immediate precipitation of a yellow solid; decompn. 153—155 °C; its ^1H NMR spectrum

Table 1. O_2-Oxidation of BPDH in the Presence of Perchloric Acid

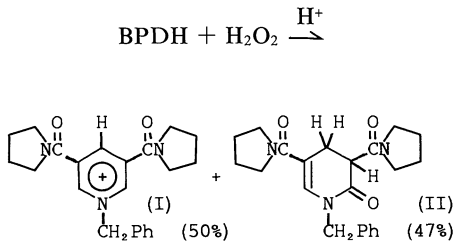
Catalyst	M	Isolated yield/%	
		H_2O_2[a)]	BPD^+Cl^-
$HClO_4$	0.01	70.8	95.0
$HClO_4$	0.20	67.7	96.0
$HClO_4$	1.00	50.5	86.9
$Ca(ClO_4)_2$[5)]	0.05	89.4	94.9

Conditions: [BPDH]=1.0×10^{-2} M; in O_2-saturated MeCN (50 mL) at 25°C. a) The amount of produced H_2O_2 was determined as $Ph_3P=O$.

in DMSO-d_6 indicated that the adduct dissociated into the original components, $HClO_4$ and BPDH, in a molar ratio of 1:1. The resonance due to the liberated $HClO_4$ appeared at δ=10.0.

Results and Discussion

The oxidation of BPDH by H_2O_2 under nitrogen in $HClO_4$-containing acetonitrile afforded the monooxygenated (II) as well as dehydrogenated (I) products being isolated in a 1:1 ratio. In order to disclose the reaction mechanism, the reaction was kinetically examined in



detail. The progress of reaction was followed spectroscopically by monitoring the disappearance of BPDH. The BPDH oxidation of an equiv of H_2O_2 under nitrogen was so much slow that a 100-fold excess of H_2O_2 was employed to retain the practical reaction rate. The reaction followed the first-order kinetics in each [BPDH] and [H_2O_2] (Fig. 1). The rate variation with changing [$HClO_4$] (<10 mM) was complicated but interesting; the rate was linear with regard to [$HClO_4$] in the region of less than 1.5 mM and, after passing through the maximum, the rate seems to approach slowly zero (Fig. 2); such a characteristic feature of acid-dependency of the rate can not be accounted for in terms of a decreasing activity of $HClO_4$ with its increasing concentrations because dissociation of $HClO_4$ to H^+ and ClO_4^- in acetonitrile is almost complete in such a low [$HClO_4$] region (pK_a<2 in MeCN).[9)] Another explanation might be possible by considering participation of water inevitably involved in 70% $HClO_4$, but it also seems unlikely, because no substantial influence was observed by addition of up to a 100-fold excess of water over $HClO_4$. Similarly, the abnormal rate-[$HClO_4$] profile can not be interpreted, of course, by a mechanism, involving a protonation

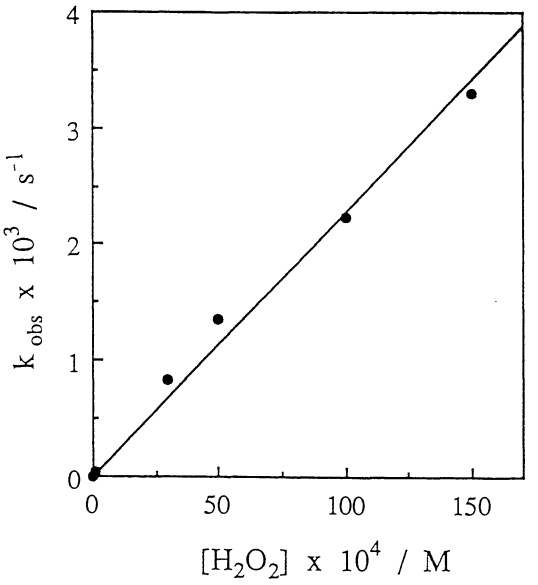


Fig. 1. Dependence of k_{obs} upon H_2O_2 concentration for H_2O_2-oxidation of BPDH under nitrogen in MeCN at 25°C; $[BPDH]_0$=0.1 mM; [$HClO_4$]=2.0 mM.

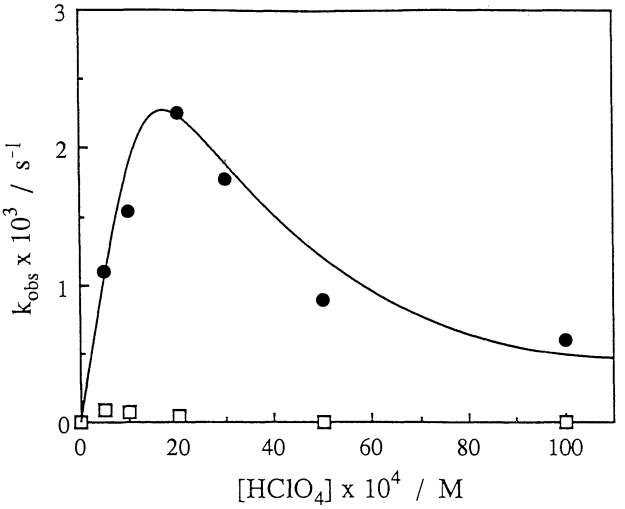

Fig. 2. H_2O_2-oxidation of BPDH in the presence of changing $HClO_4$ concentrations under nitrogen; $[BPDH]_0$=0.1 mM; ●: $[H_2O_2]_0$=10 mM, □: $[H_2O_2]_0$=0.1 mM.

equilibrium between free BPDH and monoprotonated BPDH, where H^+ activates H_2O_2 and only the free BPDH is active for oxidation. Such a mechanism leads to yielding merely a saturation curve.

Meanwhile, the UV-absorption maximum for BPDH (355 nm) shifted stepwise to higher wavelengths when [$HClO_4$] was increased (Figs. 3a and 3b); the first shift to 390 nm occurring around [$HClO_4$]=1 mM is attributed to the formation of the BPDH-$HClO_4$ 1:1 adduct and the second shift to 410 nm around [$HClO_4$]=3.5 mM is attributed to that of the 1:2 adduct. The former adduct

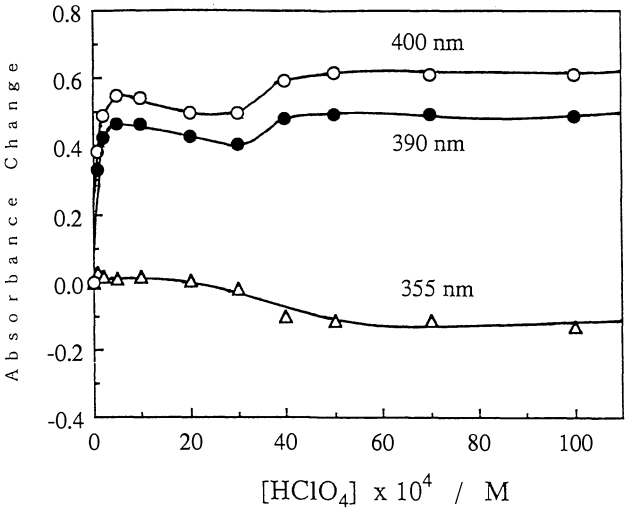

Fig. 3b. Change of absorbance due to BPDH with increasing $HClO_4$ concentrations at various wavelengths under nitrogen.

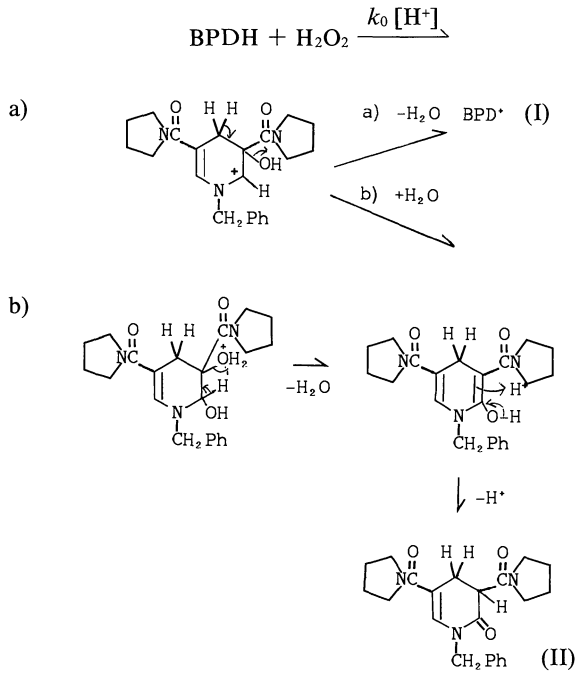
itself could be isolated quantitatively as a yellow precipitate from the acetonitrile solution of a mixture of BPDH and $HClO_4$. The complex exhibits two carbonyl stretching vibration frequencies with almost equal intensities at 1660 and 1690 cm^{-1} which are due to the protonated and the not protonated carbonyl groups in a BPDH molecule, respectively. The absorption due to BPDH itself appears at 1670 cm^{-1}. Thus, the overall protonation events may be expressed as equation 1.

$$\text{BPDH} \underset{\text{HClO}_4}{\overset{K_{a1}}{\rightleftharpoons}} \text{BPDH}\cdot\text{H}^+\text{ClO}_4^- \underset{\text{HClO}_4}{\overset{K_{a2}}{\rightleftharpoons}} \text{(III)} \quad (1)$$

The site of the second protonation is not yet defined. However, we tentatively propose the structure III which bears a proton on each carbonyl oxygen in solution. We can safely say, therefore, that the singly and doubly protonated BPDHs have to coexist, both being virtually inactive toward this oxidation. Furthermore, no influence was observed by a 100-fold addition of a well-known radical chain inhibitor, 2,6-di-*t*-butyl-4-methylphenol (BHT). All these findings allow us to conclude that the oxidation proceeds through an ionic pathway (Scheme 1); namely, the reaction is initiated by rate-determining electrophilic attack of a protonated H_2O_2 at the 3-position of the BPDH ring with the highest



Scheme 1.

HOMO coefficient, followed by partition either to the pyridinium cation (I) via dehydration (path a) or to the monooxygenated compound (II) via hydration followed by dehydration (Path b).

Upon taking the acid-equilibria (1) into consideration explicitly, we obtain the rate equation (2) as a function of [$HClO_4$] well-accounting for the experimental data. From a set of data given in Fig. 2, K_{a1}, K_{a2}, and k' values were estimated by a nonlinear curve-fitting program to be 800 M^{-1}, 300 M^{-1}, and 4 $M^{-1}\,s^{-1}$, respectively. The rate constant k' means $k_0[H_2O_2]$, and is treated as a valuable independent of [H^+].

$$V = -\,d[BPDH]/dt = k_o[H_2O_2][BPDH]_T[H^+]/(1 + K_{a1}[H^+] + K_{a1}K_{a2}[H^+]^2) = k_{obs}[BPDH]_T \quad (2)$$

$$k_{obs} = k'[H^+]/(1 + K_{a1}[H^+] + K_{a1}K_{a2}[H^+]^2)$$

In contrast to the slow oxidation between BPDH and an equiv of H_2O_2 under nitrogen, the same quantity of H_2O_2 under oxygen was found to remarkably enhance the BPDH oxidation. In order to disclose the reaction mechanism, the progress of the O_2-oxidation was followed spectroscopically by monitoring the disappearance of BPDH and the effect of H_2O_2 on rate was examined at first; the results thus obtained are given in Fig. 4, which shows that the rate increased with increasing added H_2O_2 but the addition of H_2O_2 was not necessarily required for the smooth oxidation to occur. Table 1 reveals also that the oxidation of BPDH under an oxygen atmosphere in $HClO_4$-containing acetonitrile afforded BPD^+ (I) and H_2O_2 in quantitative and good yields, respectively. Thus, from now on, we will discuss on the results of the reactions performed under oxygen with no H_2O_2 added. In Fig. 5 is shown a typical ln (A–A_∞) vs. time plot, where a short lag period appeared, indicative of occurrence of a radical chain reaction; in fact, addition of a radical scavenger BHT strongly retarded the overall rate (Fig. 6). A following rapid BPDH consumption was first-order in BPDH; the linearity of the rate vs. $[BPDH]_0$ plot also confirmed this conclusion (data not shown). For simplifying rate evaluation, the rate constant (k_{obs}) for the BPDH-consuming phase was calculated by assuming pseudo-first-order kinetics with respect to BPDH throughout this work. As addition of a trace of H_2O_2 eliminated the lag period, one of the tasks of the H_2O_2 appears to be in enhancing the rate of the initiation step through its homolytic O–O cleavage at the start of the reaction.

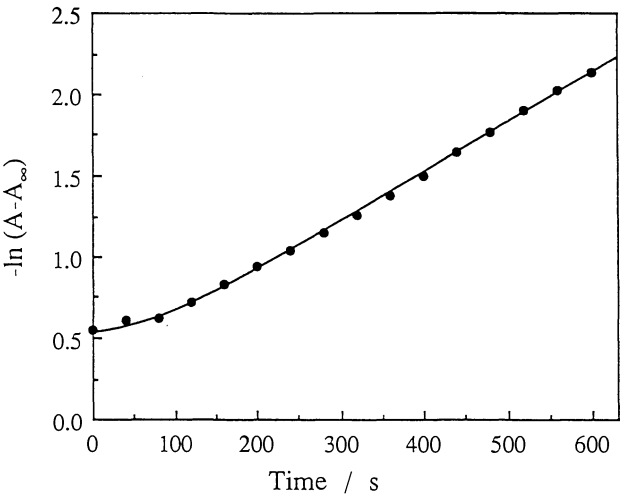


Fig. 5. ln ($A-A_\infty$) vs. time plot for pure O_2-oxidation of BPDH in the presence of $HClO_4$ in MeCN at 25 °C; [$HClO_4$]=5.0 mM; $[BPDH]_0$=0.1 mM.

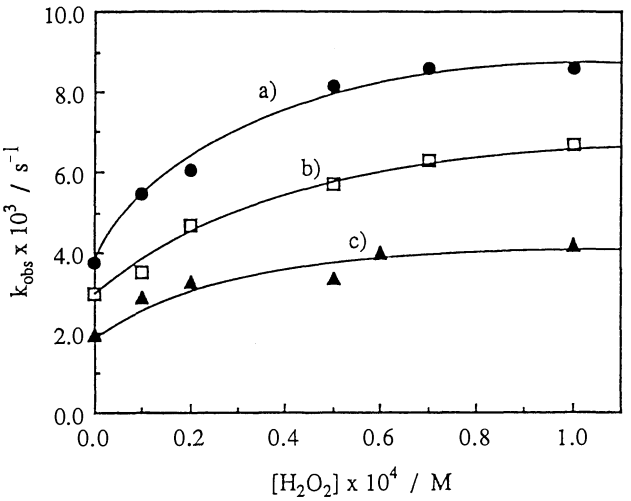

Fig. 4. Effect of H_2O_2 concentrations on the BPDH oxidation in oxygen-saturated MeCN at 25 °C; [$HClO_4$]=2.0 mM (a), 1.0 mM (b), 10 mM (c); $[BPDH]_0$=0.1 mM.

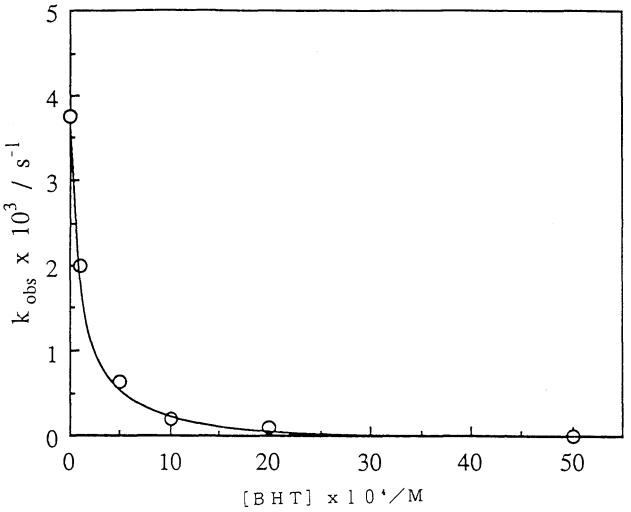

Fig. 6. Effect of altering concentrations of BHT on the rate of pure O_2-oxidation of BPDH; [$HClO_4$]= 2.0 mM; the other conditions were the same as those of Fig. 1.

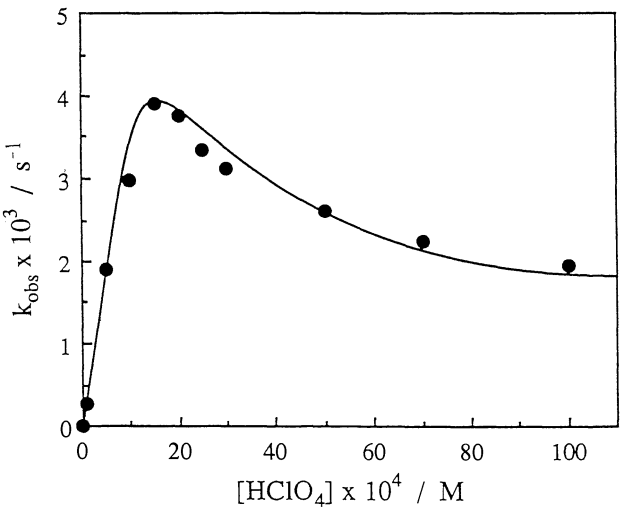

Fig. 7. Pure O_2-Oxidation of BPDH in the presence of various concentrations of $HClO_4$.

The effect of changing amounts of $HClO_4$ on rate exhibited the same characteristic feature as in the H_2O_2-oxidation under N_2 (Fig. 7), indicating that the virtually inactive singly- and doubly-protonated BPDHs are involved here also. When the rate constants were plotted as a function of the percent oxygen content ($\eta = P_{O_2}/(P_{O_2}+P_{N_2})$) of the O_2–N_2 mixture used to saturate the solution, a downward curvature was obtained; the rate was essentially independent of the concentration of the dissolved oxygen in solution at $\eta > 0.2$. Recently, Fukuzumi et al have kinetically studied closely related O_2-oxidation for an acid-stable NADH model, 10-methyl-9,10-dihydroacridine, in the presence of concentrated $HClO_4$; the reaction was first-order in each [$AcrH_2$] and [O_2]. They proposed a mechanism involving the rate-determining acid-catalyzed electron-transfer from $AcrH_2$ to O_2 followed by direct hydrogen transfer from $AcrH_2^{\cdot+}$ to $HO_2\cdot$ in the solvent cage to yield $AcrH^+$ and H_2O_2.[7] In contrast with $AcrH_2$, BPDH undergoes an autoxidation. In order to explain the observed effects of concentrations of BPDH and O_2 on the rate, therefore, we will propose the following Scheme 2 consisting of a set of reactions (3),(4),(5),(6),(7),(8), and (9); H_2O_2-producing reaction (3) is taken into consideration to explain the appearence of the induction period in the absence of added H_2O_2. As for the initiation in the radical chain sequence, we are forced to assume a set of reactions (4), (5), and (6) being the only reactions of importance to be compatible with the experimental data. Solvents and reagents have been reported to be inevitably contaminated with adventitiuos metal ions,[10] therefore, a reactive radical species capable of triggering the chain reaction might be produced according to the Fenton-like reaction. "M" here is used to denote an adventituous metal ion, maybe Fe^{2+}, which undergoes the Fenton reaction to give an $HO\cdot$ radical. This inference would be supported by the fact that addition of an 0.1 equiv of $Fe(ClO_4)_2$ to an O_2-saturated MeCN solution of BPDH removed the induction phase and accerelated the reaction by 1.5-fold.

At high O_2 concentrations ($\eta > 0.2$) the most important termination process must be the disproportionation of $HOO\cdot$ to H_2O_2 and O_2 since reaction (7) would become faster than reaction (8) under such conditions.

During the induction period:

$$\mathrm{BPDH} + O_2 \xrightarrow[\text{slow}]{H^+} \mathrm{BPD^+} + H_2O_2 \qquad (3)$$

Chain-initiating reaction:

$$H_2O_2 + \mathrm{M} \xrightarrow{k_1[H^+]\ (\sim 10^2)} \mathrm{HO\cdot} + \mathrm{M^+} \qquad (4)^{11}$$

$$2\mathrm{M^+} + \mathrm{BPDH} \xrightarrow{(>10^5)} 2\mathrm{M} + \mathrm{BPD^+} + H^+ \qquad (5)^{12}$$

$$\mathrm{HO\cdot} + \mathrm{BPDH} \xrightarrow{k_2\ (\sim 10^{10})} \mathrm{BPD\cdot} + H_2O \qquad (6)^{13}$$

Chain-propagating reaction:

$$\mathrm{BPD\cdot} + O_2 + H^+ \xrightarrow{k_3\ (\sim 10^9)} \mathrm{BPD^+} + \mathrm{HO_2\cdot} \qquad (7)^{14}$$

$$\mathrm{HO_2\cdot} + \mathrm{BPDH} \xrightarrow{k_4\ (\sim 10^9)} H_2O_2\cdot + \mathrm{BPD\cdot} \qquad (8)^{15}$$

Chain-terminating reaction:

$$2\,\mathrm{HO_2\cdot} \xrightarrow{k_5\ (8\times 10^5)} H_2O_2\cdot + O_2 \qquad (9)^{16}$$

Scheme 2. The figures in parentheses are presumed second-order-rate constants ($M^{-1}\,s^{-1}$) in water.

The combination of the individual steps, with assuming a long chain length for the major propagation process, affords the net reaction (Eq. 10):

$$\mathrm{BPDH} + O_2 \xrightarrow{H^+} \mathrm{BPD^+} + H_2O_2 \qquad (10)$$

According to the steady state treatment for intermediates $HO\cdot$, $BPD\cdot$, and $HO_2\cdot$, we arrive at the following equation (11) for the overall rate at given time t (the protonation equilibria (Eq. 1) are not taken into account):

$$V = k_{obs}[\mathrm{BPDH}]$$

$$k_{obs} = k_4\{(k_1/k_5)[H_2O_2][Fe^{2+}][H^+]\}^{1/2} \qquad (11)$$

The proposed mechanism satisfactorily explains the

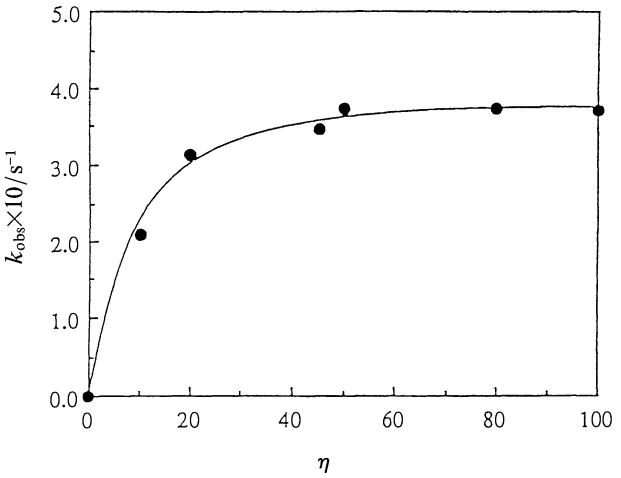

Fig. 8. Effect of partial pressures of oxygen (η) on k_{obs} for oxidation of BPDH; [$HClO_4$]=2.0 mM.

influence of changing O_2-concentrations; namely, the rate is independent of the percent O_2 content when the concentration of dissolved O_2 in solution is significantly high as compared with that of BPDH (Fig. 8). Furthermore, the equation (11) shows that the rate should increase with the square root of H_2O_2 concentrations. Actually, as Fig. 4 reveals, the plot of the observed rate constant (k_{obs}) vs. H_2O_2 concentrations affords a downward curvature.

Meanwhile, H_2O_2 not only caused the induction time to decrease but also H_2O_2 would be employed to initiate another series of chain reactions involving HO· radical as a chain-carrying species, which resulted in depression of the H_2O_2 yield (equations (12) and (13)).

$$BPD\cdot + H_2O_2 \xrightarrow{H^+} BPD^+ + HO\cdot \quad (12)$$

$$HO\cdot + BPDH \longrightarrow H_2O + BPD\cdot \quad (13)$$

The real overall mechanism might become so complicated accordingly that no quantitative evaluation of the rate constant for each step was not attempted.

In conclusion, 1-benzyl-3,5-bis(1-pyrrolydinylcarbonyl)-1,4-dihydropyridine (BPDH) underwent H_2O_2-oxidation in the presence of $HClO_4$ to give BPD^+ and the monooxygenated product in a 1 : 1 ratio through an ionic process, while the O_2-oxidation of the same substrate afforded the BPD^+ and H_2O_2 through a radical-chain pathway including HOO· and BPD· radicals as the chain carriers.

Synthesis of Naphth[1,2,3-*cd*]indol-6(2*H*)-one Derivatives and Their Fluorescence Properties

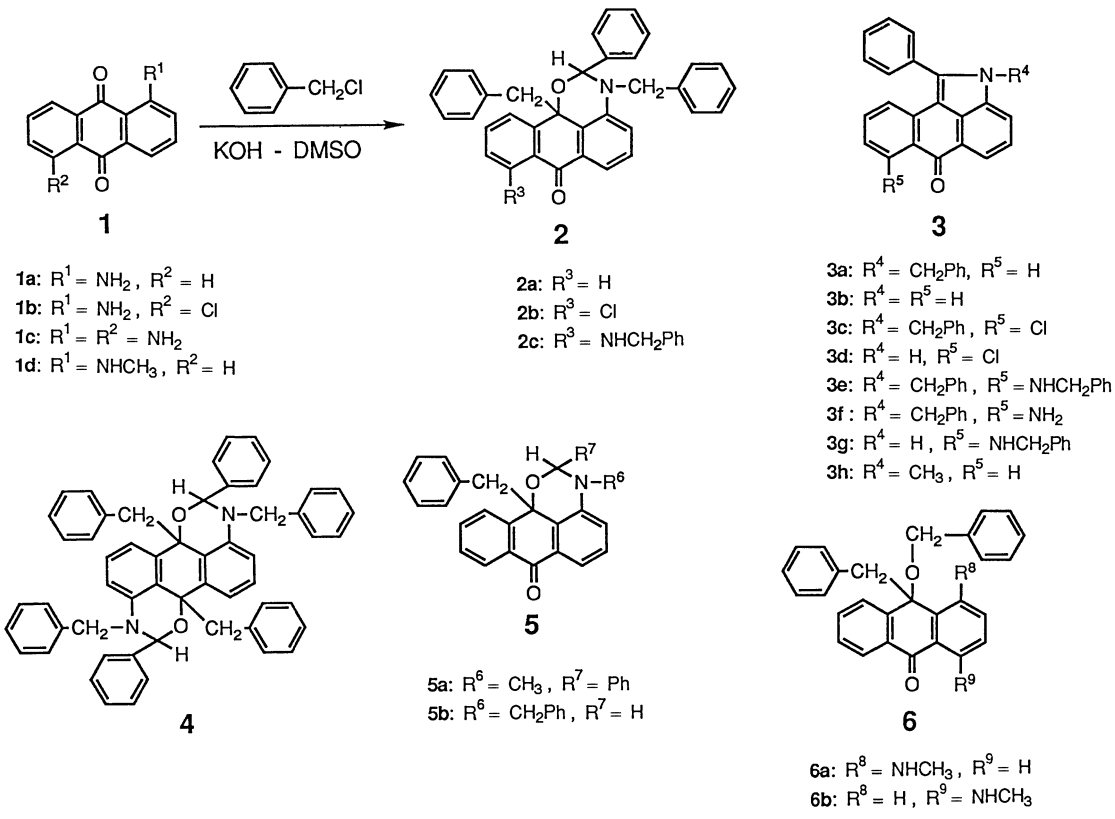
Sadao ARAI,* Shigeaki YAMAUCHI, Yuriko MORIYA, Tei-ichi TANAKA, Yoko YAMAZAKI, Haruo INOUE, Takamichi YAMAGISHI, and Mitsuhiko HIDA*
Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, 1-1 Minami-osawa, Hachioji, Tokyo 192-03
(Received June 29, 1991)

Highly fluorescent 1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (**3b**) and its 7-chloro and 7-amino derivatives were synthesized by reaction of 1-aminoanthraquinones with benzyl chloride in KOH–DMSO system, followed by treatment with aluminium chloride. The compound **3b** was easily *N*-alkylated with various alkyl halides in KOH–DMSO system. The fluorescence quantum yields (Q_f) of naphth[1,2,3-*cd*]indol-6(2*H*)-one derivatives **3** were high (0.5—0.7), except for 7-amino derivatives which did not fluoresce. The Q_f of 7-chloro derivative (**3d**) was strongly dependent on solvent: 0.37 in ethanol; 0.02 in acetonitrile; 0 in benzene. The compounds **3** were demonstrated to be efficient laser dyes for 500—550 nm region.

Fluorescent dyes attract continuous attention because of their application in various field.[1] Especially dye laser applications are growing. In our previous paper we reported a new synthetic method of highly fluorescent naphthindolone derivatives.[2] Thus the reaction of 1-aminoanthraquinone (**1a**) with benzyl chloride in the presence of powdered potassium hydroxide (KOH) in dimethyl sulfoxide (DMSO) afforded 3,11b-dibenzyl-2-phenyl-3,11b-dihydroanthra[1,9-*de*]-1,3-oxazin-7(2*H*)-one (**2a**). Then, the compound **2a** was treated with concd hydrochloric acid in ethanol or aluminium chloride in benzene to give 2-benzyl-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (**3a**) or 1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one(**3b**), respectively. Although naphth[1,2,3-*cd*]indol-6(2*H*)-one derivatives have been known to be good fluorophores,[3] little has been reported concerning their properties so far. We report herein the synthesis of new naphth[1,2,3-*cd*]indol-6(2*H*)-one derivatives and their fluorescence properties and lasing behavior.

Results and Discussion

Synthesis of Naphth[1,2,3-*cd*]indol-6(2*H*)-one Derivatives. In order to synthesize new substituted 1-



Scheme 1.

phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one derivatives, 1-amino-5-chloroanthraquinone (**1b**), 1,5-diaminoanthraquinone (**1c**), and 1-methylaminoanthraquinone (**1d**) were used as starting compounds. The aminoanthraquinone was first treated with powdered KOH in DMSO to yield green solution of the corresponding amide ion. Then excess benzyl chloride was added to the amide ion solution. In the reaction of **1b**, 3,6-dihydro-2*H*-1,3-oxazine compound (**2b**) was obtained in 53% yield. The reaction of **1c** also gave 3,6-dihydro-2*H*-1,3-oxazine compound (**2c**) in 16% yield, and compound **4**, which would be derived from **2c** by the further reaction, was not observed. In the case of the reaction of **1d**, mass spectrum of the isolated product does not show the signals of expected 3,6-dihydro-2*H*-1,3-oxazine compound (**5a** or **5b**: M 417) but does *m*/*z* 419. Its IR spectrum shows the presence of N–H group at 3400 cm^{-1}. ^1H NMR also suggests the presence of N–H group at around 6.3 ppm: By the addition of CD_3OD, the peak of *N*-methyl group (doublet at 2.90 ppm) was changed to singlet and the peaks at around 6.3 ppm was disappeared. ^1H NMR also shows two sets of benzylic protons, which had different chemical shifts with doublet at 4.10 ppm and AB quartet at 3.57 ppm. These results and analytical data suggest that the product is not the expected 3,6-dihydro-2*H*-1,3-oxazine compound (**5a** or **5b**) but benzyl ether-type compound: 10-benzyl-10-benzyloxy-4-methylamino-9(10*H*)-anthracenone (**6a**). Treatment of compound **6a** with concd hydrochloric acid gave compound **3h** (*vide infra*). This fact excludes the possibility of the isomeric structure, 10-benzyl-10-benzyloxy-1-methylamino-9(10*H*)-anthracenone (**6b**).

The 3,6-dihydro-2*H*-1,3-oxazine compound (**2b**) was treated with concd HCl in ethanol to afford 2-benzyl-7-chloro-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (**3c**) in 36% yield. In the reaction of **2b** with aluminium chloride in refluxing benzene the debenzylated product (**3d**) was obtained in 53% yield together with **3c** (12% yield). The reaction of **2c** with $AlCl_3$ in refluxing benzene gave the 7-amino derivatives **3e**, **3f**, and **3g** in 41, 18, and 22% yields, respectively. Treatment of **2c** with $AlCl_3$ or $FeCl_3$ at room temperature afforded only **3e** in 24 and 39% yields, respectively. The 7-benzylamino derivative **3g** was also obtained by the nucleophilic reaction of **3d** with benzylamine in 8% yield. It is noteworthy that reaction of benzyl ether-type compound **6a** with concd HCl in ethanol afforded 1-phenyl-2-methylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (**3h**) in 66% yield, which was identical with *N*-methylation product of **3b** in KOH–DMSO system (see Table 1).

The *N*-alkylation in KOH–DMSO system[4] was applied to **3b** using various alkyl halides in order to examine the properties of the *N*-alkylated compounds as fluorophore, and the alkyl substituent affected largely the lasing behavior (vide infra). After the compound **3b** was deprotonated by KOH in DMSO, alkyl halide was added. Table 1 shows that the *N*-alkylation of **3b** in KOH–DMSO system afforded the corresponding *N*-alkyl derivatives in good yields. The reaction of **3b** with 2-bromoethanol, protected with tetrahydropyranyl group, afforded the corresponding *N*-alkyl derivative (**3l**), which was easily converted to the alcohol (**3m**) by the treatment with *p*-toluenesulfonic acid.

Table 1. *N*-Alkylation of **3b** in KOH–DMSO System

a) Absorption maximum. b) Fluorescence maximum. c) Fluorescence quantum yield.

Fluorescence Properties. Table 2 shows the wavelength of absorption and fluorescence maxima of the compounds **3** in ethanol. Varying the substituent in the 2-position does not result in large shifts in both absorption and fluorescence: The compounds **3** have their absorption maxima (λ_a) at around 430 nm and fluorescence maxima (λ_f) at around 500 nm. In the cases of 7-amino derivatives (**3e**, **3f**, and **3g**) the absorption maxima appeared at the longer wavelength region of 477—493 nm which could be assigned as an intramolecular charge-transfer band between the amino group in the 7-position and the carbonyl group. The fluorescence quantum yield (Q_f) of **3a** was found to be 0.65±0.05, 0.68±0.02, and 0.62 by using three different fluorescence standard of quinine sulfate, fluorescein, and 9,10-diphenylanthracene, respectively. Hence, in Table 2 the Q_f of compounds **3** in ethanol was compared using quinine sulfate as a standard. The Q_f are generally high (0.51—0.70). The substitution of chlorine for H at 7-position resulted in a decrease in Q_f, suggesting

Table 3. Solvent Effect on Absorption and Fluorescence Maxima and Fluorescence Quantum Yields

appreciable deactivation from lowest excited singlet (S_1) state due to internal heavy atom effect. The 7-amino derivatives (**3e—g**) were almost nonfluorescent. This result could be ascribable to the intramolecular CT nature of the S_1 state.[5] As shown in Table 3, the absorption spectra of 2-alkyl derivatives (**3a**, **3h**, and **3i**) showed no significant solvent dependence, while in the cases of the derivatives (**3b**, **3d**, and **3e**) bathochromic shift was observed with increasing solvent polarity. Fluorescence emissions also underwent bathochromic shifts with increasing solvent polarity. Larger Stokes shifts were observed in polar solvents than in nonpolar solvents. These results indicate the excited states of compounds **3** are more stabilized by polar solvents. Fluorescence quantum yield of the 7-chloro derivative (**3d**) was largely dependent on solvent polarity: It has a diminished Q_f in acetonitrile and was almost non-fluorescent in benzene. Hence **3d** would be a useful probe for examining the polarity of the environment around the fluorescent species.

Lasing Behavior. Highly fluorescent compounds **3** were examined for application to laser dyes. The excimer laser operating on XeCl at 308 nm was used as an excitation source. By using this pump laser radiation with 13 ns pulse width, the lasing pulse of **3b** at 506 nm with 7.8 ns was observed, indicating a pulse compressing effect by lasing phenomena. The methanol solution of **3l** and **3m** also exhibited intense laser radiation by XeCl pumping. The tuning curves for **3b**, **3l**, and **3m** in methanol are shown in Fig. 1. The lasing maxima of compound **3b**, **3l**, and **3m** were 506, 508, and 512 nm, respectively. The compound **3m** exhibits a lasing action over a wide range of a 50 nm (500—550 nm). The compound **3l**, which shows a similar tunability to **3b**, has relatively good efficiency of energy conversion from the pump source.

Experimental

Materials. 1-Amino-5-chloroanthraquinone was prepared as follows: The mixture of sodium anthraquinone-1-sulfonate (4.68 g, 15.4 mmol), 95% H_2SO_4 (16 cm^3), and nitric acid (Sp. Gr. about 1.38; 2 cm^3) was heated at 95 °C for 5 h to afford 5-

nitroanthraquinone-1-sulfonic acid, which was treated with sodium chlorate (0.28 g) in hydrochloric acid to give 1-chloro-5-nitroanthraquinone. The reduction of the crude 1-chloro-5-nitroanthraquinone was carried out with sodium sulfide (11 g) in aqueous NaOH solution at 80 °C for 10 h. The product was purified by silica-gel column chromatography with benzene as eluent, followed by recrystallization from benzene to afford 1-amino-5-chloroanthraquinone as red crystals (1.428 g, 36% from sodium anthraquinone-1-sulfonate): Mp 217—219 °C (lit,[6] 219 °C); Found: C, 65.22; H, 2.97; N, 4.94%. 1,5-Diaminoanthraquinone and 1-methylaminoanthraquinone (Sumitomo Chemical Co.) were purified by recrystallization from toluene. Dimethyl sulfoxide was distilled twice under reduced pressure and stored under a nitrogen atmosphere. Benzyl chloride was distilled under a nitrogen atmosphere.

The solvents used in all spectroscopic and lasing measurements were spectrograde or purified according to the literature procedure.[7]

Instruments. Melting points obtained on a Mitamura melting point apparatus are uncorrected. UV and visible spectra were recorded with a Hitachi 220A spectrometer. ^{1}H NMR data were recorded on a Hitachi R-24 (60 MHz) and JEOL FX90Q (90 MHz) spectrometers with Me_4Si as an internal standard. IR spectra were measured on a JASCO IRA-1 spectrometer. Mass spectra were recorded with a JEOL JMS-DX 300 spectrometer by the electron impact (EI) ionizing technique at 70 eV and by the fast-atom bombardment (FAB) with *m*-nitrobenzyl alcohol as a matrix. Elemental analyses were performed on a Yanaco MT2 CHN corder. Fluorescence spectra were measured on a Hitachi MPF-4 spectrofluorometer. Quinine sulfate (Q_f=0.55 in 0.5 mol dm^{-3} sulfuric acid aqueous solution),[8] fluorescein (Q_f=0.79 in 0.1 M NaOH aqueous solution),[9] or 9,10-diphenylanthracene (Q_f=1.0 in cyclohexane)[10] was used as a standard for the determination of fluorescence quantum yields.

Lasing experiments were performed using excimer laser (Lumonics Hyper EX-400) operating on XeCl at 308 nm as excitation source. The dye laser (Lumonics HyperDye-300) output was measured using a joule meter (Scientech model 38-0101).

The compounds **2** and **3** were obtained by the two-step method described previously.[2]

8-Chloro-3,11b-dibenzyl-2-phenyl-3,11b-dihydroanthra[1,9-*de*]-1,3-oxazin-7(2*H*)-one (2b). 1-Amino-5-chloroanthraquinone (**1b**: 513 mg, 1.99 mmol) was reacted with benzyl chloride (2.69 g, 21.2 mmol) in the presence of powdered KOH (1.03g, 18.4 mmol) in DMSO (60 cm^3) at 30 °C for 1 h. The reaction mixture was poured into water (1000 cm^3) and extracted with benzene. After the benzene extract was concentrated, the residue was purified by silica-gel column chromatography with benzene as eluent, followed by recrystallization from ethanol to afford **2b** (316 mg, 53%) as yellow crystals: Mp 194—195 °C; IR (KBr) 1670, 1595, 1580, 1480, 1447, 1295, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.1—4.8 (4H, m, CH_2) and 6.1—7.9 (22H, m, ArH); MS *m*/*z* 527 and 529 (M^+); Found: C, 79.48; H, 4.71; N, 2.53%. Calcd for $C_{35}H_{26}NO_2Cl$: C, 79.61; H, 4.96; N, 2.65%.

8-Benzylamino-3,11b-dibenzyl-2-phenyl-3,11b-dihydroanthra[1,9-*de*]-1,3-oxazin-7(2*H*)-one (2c). After the mixture of 1,5-diaminoanthraquinone (477 mg, 2 mmol) and KOH (1.12 g, 20 mmol) in DMSO (60 cm^3) was stirred for 30 min, benzyl chloride (5.06 g, 40 mmol) was added to the mixture. The solution was stirred overnight at RT. The reaction mixture was poured into water (1000 cm^3) and the organic materials were extracted with benzene. The benzene extract was evaporated. The residue showed 5 spots on TLC (SiO_2, benzene). The largest spot (R_f=0.70) was separated by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford **2c** (192 mg, 16%) as orange crystals: Mp 174.4 °C; UV (C_2H_5OH) 417 (log ε 3.96) and 244 nm (4.41); IR (KBr) 1630, 1590, 1520, 1493, 1282, 792, and 698 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.47 (2H, ABq, *J*=12 Hz, CH_2), 4.39 (2H, ABq, *J*=16 Hz, NCH_2), 4.46 (2H, d, *J*=6 Hz, $NHC\underline{H}_2$), 6.2—7.2 (27H, m, ArH), and 9.63 (1H, t, *J*=6 Hz, NH); MS *m*/*z* 598 (M^+); Found: C, 84.06; H, 5.62; N, 4.31%. Calcd for $C_{42}H_{34}N_2O_2$; C, 84.25; H, 5.73; N, 4.68%.

2-Benzyl-7-chloro-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3c). A mixture of **2b** (211 mg, 0.4 mmol) and concd HCl (5 cm^3) in ethanol (35 cm^3) was refluxed for 3 h. The mixture was concentrated and the residue was purified by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford **3c** (47 mg, 36%) as pale orange crystals: Mp 245—246 °C; UV (C_2H_5OH) 430 (log ε 4.13), 352 (3.61), 310 (sh), and 279 nm (4.24); IR (KBr) 1640, 1606, 1588, 1330, 1192, and 708 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.2 (2H, s, CH_2) and 6.5—8.2 (16H, m, ArH); MS *m*/*z* 419 and 421 (M^+); Found: C, 80.22; H, 4.51; N, 3.46%. Calcd for $C_{28}H_{18}NOCl$: C, 80.09; H, 4.32; N, 3.34%.

7-Chloro-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3d). A mixture of **2b** (517 mg, 0.98 mmol) and $AlCl_3$ (932 mg, 7 mmol) in benzene (180 cm^3) was refluxed for 1 h. The mixture was poured into ice-water. The benzene extract was evaporated and the residue was purified by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford **3d** (171 mg, 53%) as yellow crystals: Mp 330.5—331.5 °C; UV (C_2H_5OH) 433 (log ε 4.13), 357 (sh), 313 (3.88), 280 (4.15), and 248 nm (4.45); IR (KBr) 3200, 1640, 1610, 1590, 1382, 1293, 1042, and 793 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.3—8.0 (11H, m, ArH) and 12.3 (1H, br s, NH); MS *m*/*z* 329 and 331 (M^+); Found: C, 76.23; H, 3.51; N, 4.40%. Calcd for $C_{21}H_{12}NOCl$: C, 76.48; H, 3.67; N, 4.25%.

2-Benzyl-7-benzylamino-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3e). A mixture of **2c** (261 mg, 0.44 mmol) and $AlCl_3$ (382 mg, 2.9 mmol) in benzene (75 cm^3) was refluxed for 35 min. The mixture was poured into ice-water. The benzene extract was evaporated. The residue showed 3 spots (R_f=0.20, 0.10, and 0.05) on TLC (SiO_2, benzene). These products were separated by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford compounds **3e** (87 mg, 41%), **3f** (31 mg, 18%), and **3g** (39 mg, 22%). **3e** (R_f=0.20) as orange crystals: Mp 230.0—230.5 °C (decomp); UV (C_2H_5OH) 491 (log ε 4.13), 383 (sh), 350 (3.87), and 317 nm (3.70); IR (KBr) 3200, 1637, 1575, 1375, 1244, 790, and 700 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.51 (2H, d, *J*=6 Hz, NCH_2), 5.17 (2H, s, CH_2), 6.3—8.2 (21H, m, ArH), and 11.96 (1H, t, *J*=6 Hz, NH); MS *m*/*z* 490 (M^+); Found: C, 85.41; H, 5.20; N, 5.66%. Calcd for $C_{35}H_{26}N_2O$: C, 85.68; H, 5.34; N, 5.71%.

7-Amino-2-benzyl-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3f). (R_f=0.05) as orange crystals: UV (C_2H_5OH) 477 (log ε 3.99), 347 (3.83), and 289 nm (4.04); IR (KBr) 3440, 3030, 1630, 1592, 1268, and 710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=5.22 (2H, s, CH_2) and 6.1—8.2 (18H, m, ArH and NH_2); MS *m*/*z* 400 (M^+); Found: C, 83.69; H, 4.80; N, 7.15%. Calcd for $C_{28}H_{20}N_2O$: C, 83.97; H, 5.03; N, 7.00%.

7-Benzylamino-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one

(3g). A mixture of **3d** (345 mg, 1.05 mmol) and benzylamine (10 cm^3) was heated at 100 °C for 130 h. The mixture was evaporated and the residue was purified by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford **3g** as red crystals (34 mg, 8%): Mp 244.0—245.0 °C; UV (C_2H_5OH) 493 (log ε 3.66), 367 (3.52), 288 (4.16), and 264 nm (4.21); IR (KBr) 3200, 2930, 2850, 1600, 1570, 1388, 1200, and 700 cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=4.55 (2H, d, *J*=4.8 Hz, CH_2), 6.2—8.8 (17H, m, ArH and NH), and 10.8 (1H, t, *J*=4.8 Hz, $NHCH_2$); MS *m/z* 400 (M^+); Found: C, 83.71; H, 5.22; N, 6.91%. Calcd for $C_{28}H_{20}N_2O$: C, 83.97; H, 5.03; N, 7.00%.

10-Benzyl-10-benzyloxy-4-methylamino-9(10*H*)-anthracenone (6a). 1-Methylaminoanthraquinone (**1d**: 475 mg, 2 mmol) was reacted with benzyl chloride (3.2 g, 25 mmol) in the presence of powdered KOH (1.1 g, 20 mmol) in DMSO (60 cm^3) at 30 °C for 1 h. The reaction mixture was poured into water (1000 cm^3) and extracted with benzene. After the benzene extract was concentrated, the residue was purified by silica-gel column chromatography with benzene as eluent, followed by recrystallization from ethanol to afford **6a** (344 mg, 41%) as pale orange crystals: Mp 162.1—163.2 °C (decomp); UV (C_2H_5OH) 397 nm (log ε 3.32); IR (KBr) 3390 (NH) and 1660 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.90 (3H, d, *J*=5 Hz, CH_2), 3.57 (2H, ABq, *J*=13 Hz, CH_2), 4.10 (2H, d, *J*=2 Hz, CH_2), and 5.9—8.1 (18H, m, ArH and NH); MS *m/z* 419 (M^+); Found: C, 83.16; H, 5.90; N, 3.47%. Calcd for $C_{29}H_{25}NO_2$: C, 83.03; H, 6.01; N, 3.34%.

2-Methyl-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3h). A mixture of **6a** (195 mg, 0.46 mmol) and concd HCl (10 cm^3) in ethanol (50 cm^3) was refluxed for 3 h. The mixture was concentrated and the residue was purified by column chromatography (SiO_2, benzene), followed by recrystallization from ethanol to afford **3h** (94 mg, 66%): UV (C_2H_5OH) 431 nm (log ε 4.10); IR (KBr) 3060, 1628, 1590, 1480, 1292, 992, 762, and 700 cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.58 (3H, s, CH_3) and 6.8—8.5 (12H, m, ArH); MS *m/z* 309 (M^+); Found: C, 85.29; H, 4.78; N, 4.49%. Calcd for $C_{22}H_{15}NO$, C, 85.41; H, 4.89; N, 4.53%.

***N*-Alkylation of 3b.** A typical procedure is described for the reaction of **3b** with butyl iodide. The compound **3b** (295 mg, 1 mmol) was stirred with powdered KOH (561 mg, 10 mmol) in DMSO (30 cm^3) for 30 min at 30 °C. Then butyl iodide (1.84 g, 10 mmol) was added to the mixture and the solution was stirred for 1 h at 30 °C. The reaction was quenched with water (700 cm^3). The mixture was extracted with benzene, washed with water, and evaporated. The residue was submitted to column chromatography on silica gel using benzene as eluent. The yellow fractions (R_f=0.08) were concentrated and recrystallized from ethanol to afford **2-butyl-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3i)** (323 mg, 92%) as yellow needles; mp 179.5—180.0 °C; UV (C_2H_5OH) 242 (log ε 4.42), 275 (4.24), 304 (4.07), 355 (3.61), and 430 nm (4.09); IR (KBr) 3070, 2980, 2950, 2880, 1635, 1595, 1290, 772, and 707 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.5—1.9 [m, 7H, $-(CH_2)_2CH_3$], 3.97 (t, 2H, N-CH_2), and 7.0—8.6 (m, 12H, ArH); MS *m/z* 351 (M^+); Found: C, 85.68; H, 6.00; N, 3.89%. Calcd for $C_{25}H_{21}NO_2$: C, 85.44; H, 6.02; N, 3.99%.

2-(8-Bromooctyl)-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3j): Yellow needles from ethanol; mp 88.0—88.5 °C; UV (C_2H_5OH) 242 (sh, log ε 4.47), 275 (4.27), 303 (4.10), 354 (3.65), and 431nm (4.10); IR (KBr) 3060, 2940, 2860, 1630, 1595, 1335, 1278, 770, and 702 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.8—2.0 [m, 12H, $-(CH_2)_6$], 3.38 (t, 2H, Br-CH_2), 4.18 (t, 2H, N-CH_2), and 7.0—8.7 (m, 12H, ArH); MS *m/z* 485 and 487 (M^+); Found: C, 72.16; H, 5.90; N, 2.86%; Calcd for $C_{29}H_{28}NO_2Br$: C, 71.90; H, 5.80; N, 2.88%.

2-Hexadecyl-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3k): Yellow crystals from ethanol; mp 82.5—83.0 °C; UV (C_2H_5OH) 243 (log ε 4.45), 275 (4.26), 304 (4.09), 354 (3.64), and 431 nm (4.10); IR (KBr) 3070, 2930, 2860, 1630, 1598, 1480, 1290, and 708 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.4—1.9 [m, 31H, $-(CH_2)_{14}CH_3$], 4.05 (t, 2H, N-CH_2), and 7.2—8.7 (m, 12H, ArH); MS *m/z* 519 (M^+); Found: C, 85.84; H, 8.67; N, 2.71%. Calcd for $C_{37}H_{45}NO_2$: C, 85.50; H, 8.73; N, 2.69%.

1-Phenyl-2-[2-(tetrahydropyranyloxy)ethyl]naphth[1,2,3-*cd*]indol-6(2*H*)-one (3l): The reaction of **3b** with 1-bromo-2-tetrahydropyranyloxyethane, which was obtained by the reaction of 2-bromoethanol with dihydropyrane in the presence of *p*-toluenesulfonic acid, afforded **3l** as pale brown oil (47%): UV (C_2H_5OH) 425 nm (log ε 4.05); IR (KBr) 2940, 1635, 1288, 1122, 1033, and 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.1—1.6 (6H, m), 3.1—4.5 (m, 7H), and 7.1—8.4 (H, m, ArH); FABMS *m/z* 424 $(M+1)^+$; Found: C, 79.26; H, 5.79; N, 3.19%. Calcd for $C_{28}H_{25}NO_3$: C, 79.41; H, 5.95; N, 3.31%.

2-(2-Hydroxyethyl)-1-phenylnaphth[1,2,3-*cd*]indol-6(2*H*)-one (3m). A methanol (10 cm^3) solution of **3l** (111 mg, 0.26 mmol) and *p*-toluenesulfonic acid (53.2 mg, 0.27 mmol) was stirred for 16 h at RT. After the mixture was dried, the residue was recrystallized from methanol to afford **3m** as yellow needles (61.8 mg, 69%); mp 216—217 °C; UV (C_2H_5OH) 428 nm (log ε 3.97); IR (KBr) 3400, 1610, 1580, 1474, 1275, 1080, and 702 cm^{-1}; ^1H NMR ($CDCl_3$+CD_3OD) δ=3.84 (2H, t, *J*=5.6 Hz, NCH_2), 4.21 (2H, t, *J*=5.6 Hz, CH_2O), and 7.1—8.5 (12H, m, ArH); FAB-MS *m/z* 340 $(M+1)^+$; Found: C, 81.20; H, 5.11; N, 4.17%. Calcd for $C_{23}H_{19}NO_2$: C, 81.39; H, 5.05; N, 4.13 %.

We wish to express our thanks to Messrs. Masao Usui and Tsutomu Shinoda of Tokyo Metropolitan Industrial Technology Center for mass spectral measurements (EI).

Structures of Diterpenoid Tropolones, Salviolone and Miltipolone, from the Root of *Salvia miltiorrhiza* Bunge

Ginda HARO, Masahito MORI, Midori O. ISHITSUKA, Takenori KUSUMI, Yoshinobu INOUYE, and Hiroshi KAKISAWA*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received July 8, 1991)

New types of a bisnorditerpenoid and a norditerpenoid possessing a benzotropolonoid and a tropolonoid moieties, salviolone (**8**) and miltipolone (**15**), respectively, have been isolated and their structures were determined by spectroscopic methods. The structure of salviolone was confirmed by a total synthesis. These compounds exhibit cytotoxic activities against cultured cells.

The dried roots of *Salvia miltiorrhiza* Bunge (Labiatae), known as "Tanjin" in Japanese or "Danshen" in Chinese, have been used in these countries as a folk medicine to treat a wide variety of diseases.[1] Chemical constituents of this root were extensively investigated since 1934,[2] and surveys of minor metabolites were further continued in order to identify more potently active constituents, for the activity of the crude extract often exceeds that of the identified constituents. This Chinese drug is colored reddish-orange and many coloring constituents, mainly quinones[3] with abietane skeleton, as represented by transhione-I (**1**)[4] and isocryptotanshinone (**2**),[5] have been identified. Some of these compounds seemed to be the artifacts produced during drug preparation. We studied on pharmaceutically active compounds in the fresh roots of *S. miltiorrhiza* and found colorless new compounds, designated salviolone (**8**)[6] and miltipolone **15**)[9] besides norsalvioxide (**3**),[6] secodialdehyde (**4**),[7] abietatriene (**5**),[7] cryptoacetalide (**6**),[8] and isomanool (**7**).[7] The new compounds, salviolone and miltipolone, were found to possess unique diterpenoid benzotropolone and tropolone chromophores, respectively. Although many tropolonoid terpenes possessing mono- and sesquiterpenoid skeletons have been known, to the best our knowledge, these are the first diterpenoid tropolones found from the nature. Present report deals with structure elucidation of these compounds.[9]

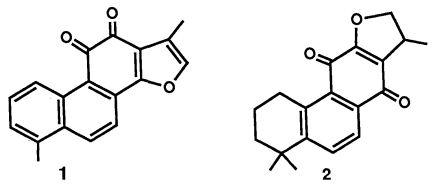

Chart 1.

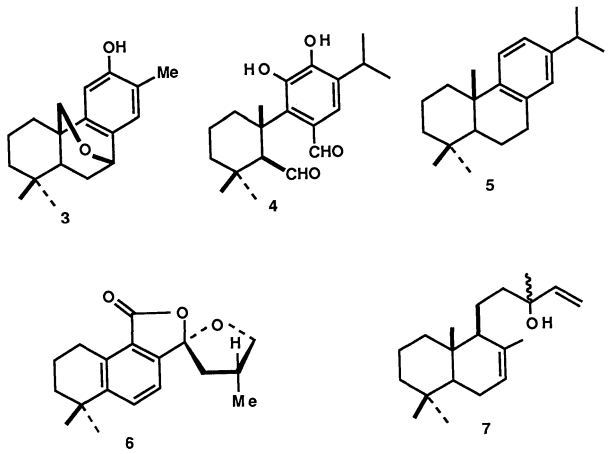

Chart 2.

The fresh roots were soaked in methanol just after the collection and the methanol extract was repeatedly separated by chromatographies to afford new compounds, salviolone (**8**) and miltipolone (**15**), as pale yellow and colorless crystals, respectively.

The molecular composition of salviolone (**8**) was determined to be $C_{18}H_{20}O_2$ from the high resolution mass spectrum. The ^1H NMR spectrum showed a rather downfield aliphatic triplet at δ=3.10 (2H, t, J=7 Hz), which was assignable to a benzylic methylene group and was found to couple with a perturbed quintet at δ=1.95 (2H). This quintet is further coupled with a deformed triplet at δ=1.72 (2H). A singlet at δ=1.36 (6H), possibly due to a *gem*-dimethyl group, exhibits an NOE cross peak in the NOESY spectrum to the methylene signal at δ=1.72, implicating the presence of Ar-CH_2-CH_2-CH_2-CMe_2-group. The IR spectrum shows the bands ascribable to a phenolic OH at 3270 and 1240 cm^{-1}. An intense absorption at 1630 cm^{-1} and an upfield carbonyl signal (δ=179.9) in the ^{13}C NMR spectrum indicated the presence of a carbonyl group involved in a highly conjugated system. Appearance of eleven downfield signals at δ=127.1—179.9 in the ^{13}C NMR spectrum and four downfield proton signals at δ=7.53 (1H, d, J=8.5 Hz), 7.58 (1H, d, J=8.5 Hz), 7.95 (1H, s), and 8.05 (1H, s) as well as the downfield methyl singlet at δ=2.49, and deep blue coloration by iron(III) chloride suggested the existence of some particular phenolic moiety such as an acetylnaphthol or a methylbenzotropolonoid structure. The benzotropolonoid structure seemed to be more probable because of the presence of the cross peak (long-range coupling) between the methyl protons at δ=2.49 and an aromatic proton δ=7.95 in the COSY

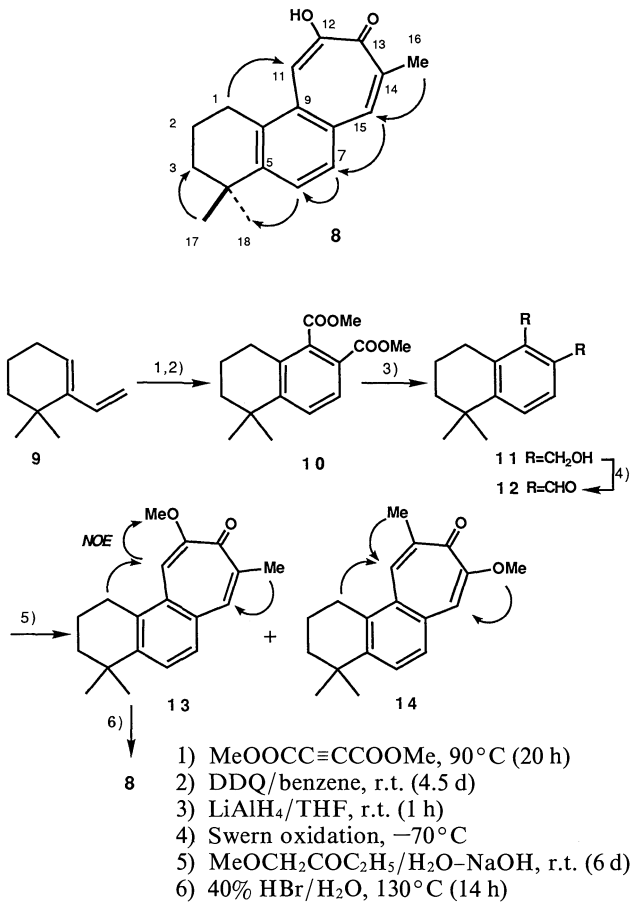

Chart 3.

spectrum. This was further supported by the UV spectrum; the absorption maxima of salviolone [λ_{max} 388 (log ε 3.23), 368 (3.28), 312 (3.60), 285 (4.42), 249 (4.20), 242 nm (4.18)] were quite similar to those of 2-methyl-4,5-benzotropolone.[10] Structure **8** was deduced from these properties and biogenetic considerations. This structure was supported by finding the NOE's in the NOE difference and NOESY spectra (indicated on the structure by arrows). Finally this structure was unequivocally confirmed by a total synthesis.

The Diels–Alder reaction between 3,3-dimethyl-2-vinylcyclohexene (**9**)[11] and methyl acetylenedicarboxylate proceeded smoothly by heating the mixture to give an adduct, which without isolation was treated with DDQ to afford a phthalic ester **10**. The ester **10** was reduced to a diol **11**, which was then subjected to the Swern oxidation at −70 °C to give a dialdehyde **12**. As the dialdehyde was unstable, the crude **12** was immediately used in the following step. The suspension of the dialdehyde **12** and 1-methoxy-2-butanone[12] in an aqueous sodium hydroxide solution[13] was stirred for six days to afford a mixture of salviolone methyl ether **13** and its regioisomer **14** (**13**:**14**=2:1) in 28% yield from the diol **11**. Both products were separated, and characterized by the ^{1}H NMR spectra and NOE experiments (indicated by arrows on the structures). The reactions of the dialdehyde and methoxybutanone did not proceed at all in aqueous alcoholic media.[13,14] The major isomer **13** was heated in aqueous hydrobromic acid to give salviolone (**8**). The spectroscopic properties (^{1}H and ^{13}C NMR, IR, and UV spectra) of synthetic and natural salviolone were identical in all respects.[9]

Miltipolone (**15**) was found to have the molecular formula $C_{19}H_{24}O_3$ from the high resolution FAB mass peak (MH^+). Spectral properties of this compound were partially very close to those of norsalvioxide (**3**)[6] and salviolone (**8**).[6] The IR spectrum showed the band ascribable to a hydrogen bonded OH group at 3000—3300 cm^{-1}. An intense absorption at 1620 cm^{-1} and a rather upfield signal at δ=171.97 in the ^{13}C NMR spectrum indicated the presence of a carbonyl group involved in a conjugated system similar to that of salviolone (**8**). Appearance of six olefinic carbon signals at δ=120.0—166.37 in the ^{13}C NMR spectrum and two downfield proton signals at δ=7.28 and 7.40 as well as very downfield methyl signal at δ=2.42 in the ^{1}H NMR spectrum and deep violet coloration by ferric chloride suggested the existence of some particular phenolic moiety such as an *o*-hydroxyacetophenone or a tropolonoid group. The tropolonoid chromophore was reinforced by the presence of the cross peak between the methyl protons at δ=2.42 and an aromatic proton at δ=7.28 in the COSY spectrum as well as the UV absorption maxima characteristic for the tropolone.[15] The presence of the methyltropolone moiety was confirmed by determining the connectivity of six aromatic carbon atoms and one upfield carbonyl carbon by the COLOC spectrum (Table 1); for example the proton at δ=7.28 on C-15 (δ=136.37) was correlated with C-7 (δ=74.38), C-9 (δ=155.99), C-13 (δ=166.37), and C-19 (δ=21.3), and the proton at δ=7.40 on C-11 (δ=120.02) to C-8 (δ=138.67), C-12 (δ=171.97) and C-13 (δ=166.37).

Two of three oxygen atoms in miltipolone are involved in the tropolonoid moiety and the remaining one oxygen atom was supposed to be included in an ether linkage from the ^{13}C NMR signal at δ=74.38 (d, C-7) and 67.35 (t, 16-C), and the ^{1}H NMR signals on the oxymethylene

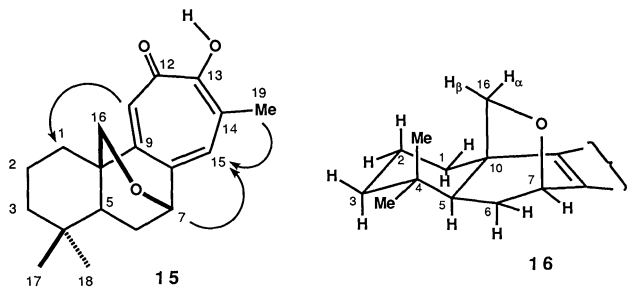

Chart 4.

Table 1. The ^1H and ^{13}C NMR Data (δ; $CDCl_3$) for **15**

No. of carbon	^{13}C NMR (125 MHz)	^1H NMR (500 MHz, J in Hz)	δ ^1H coupling with J^3 (COLOC)

14	131.31		2.42
15	136.37 (d)	7.28 (s)	2.42, 4.68
16	67.35 (t)	α-H 2.99 (dd 2.0, 9.1)	
		β-H 4.36 (d 9.1)	
17	21.3 (q)	3H 1.16 (s)	0.86, 1.23
18	32.7 (q)	3H 0.86 (s)	1.16
19	21.3 (q)	3H 2.42 (s)	7.28

protons (16-CH_2) appearing at δ=2.99 and 4.36 as well as the oxymethine proton at δ=4.68 (7-H). Except for the two aromatic proton chemical shifts, the ^1H NMR patterns of miltipolone were almost superimposable to those of norsalvioxide **3**. This similarity inferred the presence of the partial structure **16** in miltipolone, and the structure was firmly established by the extensive analyses of two dimensional and double resonance NMR spectra. The existence of *geminal* dimethyl group was confirmed by the detections of a *J*-cross peak in the COSY and an NOE cross peak in the NOESY spectra between the two aliphatic methyl signals at δ=0.86 and 1.16. The COLOC spectrum showed the ^3J cross peaks between 5-C (δ=41.47) and 1-H (δ=1.72), 3-H (δ=1.60), 7-H (δ=4.68), 17-H_3 (δ=1.16), and 18-H_3 (δ=0.86). A W-type coupling between 16-H_α and 5-H indicated their anticoplanar orientation. Noteworthy is the fact that the chemical shifts of methylene protons (δ=2.99 and 4.36) at 16-C are considerably different each other due to an anisotropic effect of the tropolonoid group. The presence of *J*-coupling of the proton at δ=4.68 (7-H) to the aromatic proton signal at δ=7.28 (15-H) suggested the connectivity of the partial structure **16** to the tropolonoid moiety. This was further confirmed by observing the NOE's in the NOESY spectrum as indicated in the structure.

Biogenetically,[16] miltipolone (**15**) seems to be a precursor of norsalvioxide (**3**) and salviolone (**8**); oxidative decarbonylation would give the phenolic norsalvioxide (**3**) as in the case that the mild oxidation of a tropolonoid alkaloid, colchicein, produces a corresponding phenolic compound, colchinol:[17] Oxidative deoxymethylenation from miltipolone (**15**) would afford salviolone (**8**).

Salviolone exhibited a cytotoxic activity (TD_{50}) against Vero cells at 3.3 μg ml^{-1}, while miltipolone was active against murine melanoma cell (B16F10) and human colon carcinoma (HCT-116) with TD_{50} 0.16 and 0.003 μg ml^{-1}, respectively.

Experimental

Infrared spectra were recorded on a Hitachi 360 spectrophotometer and ultraviolet spectra were recorded on a Hitachi 340 spectrophotometer. Optical rotation was recorded on a JASCO DIP-181 polarimeter using a 10 cm microcell. ^1H and ^{13}C NMR spectra were taken on JEOL JNM-FX-90Q or Bruker AM-500 spectrometers. Proton chemical shifts are reported in ppm relative to internal TMS and carbon shifts relative to the center peak of $CDCl_3$ (δ=77.1).

Extraction and Isolation. The roots of *Salvia miltiorrhiza* Bunge were collected in June 1984 at Dalian, China. The roots were soaked in MeOH immediately after collection and allowed to stand for 2 weeks. The MeOH extract was concentrated and the residue washed with CH_2Cl_2. The CH_2Cl_2 solution was dried over Na_2SO_4 and concentrated to give a dark brown residue and this material was repeatedly separated by column chromatography on silica gel (Merck, Kieselgel 60 and Wako, Wakogel C-300). Further separations by preparative TLC (Merck GF 254, 0.5 mm) afforded norsalvioxide (**3**), salviolone (**8**), miltipolone (**15**), cryptoacetalide (**6**), and secodialdehyde (**4**).

Salviolone (8): Pale yellow solid, high resolution MS, Found: m/z 268.1490. Calcd for $C_{18}H_{20}O_2$: M, 268.1464. IR (KBr) ν_{max} 3270, 1630, 1566, 1240 cm^{-1}. UV λ_{max} (hexane) 388

(log ε 3.23), 368 (3.28), 312 (3.60), 285 (4.42), 249 (4.20), 242 nm (4.18). ^{1}H NMR δ=1.36 (6H, s, 17,18-Me$_2$), 1.72 (2H, m, 3-H$_2$), 1.95 (2H, quint, J=7 Hz, 2-H$_2$), 2.49 (3H, bs, 16-Me), 3.10 (2H, t, J=7 Hz, 1-H$_2$), 7.53 (1H, d, J=8.5 Hz, 6-H), 7.58 (1H, d, J=8.5 Hz, 7-H), 7.95 (1H, brs, 15-H), 8.05 (1H, s, 11-H), 8.45 (1H, brs, OH); ^{13}C NMR δ=19.7, 22.3, 28.9, 31.7 (×2), 35.0, 38.1, 113.2, 127.1, 131.3, 132.4, 134.0, 134.1, 136.0, 144.1, 148.8, 153.9, 179.9.

Miltipolone (15): Colorless crystals, mp 132 °C, high resolution MS, Found: m/z 301.1837. Calcd or $C_{19}H_{25}O_3$, MH$^+$: m/z 301.1803, $[\alpha]_D^{25}$ −77.8° (c 0.20, $CHCl_3$). UV λ_{max} (EtOH) 244 (log ε 4.52), 324 (3.89), 350 (3.89), 368 nm (3.80).

Methyl 5,5-Dimethyl-5,6,7,8-tetrahydro-1,2-naphthalenedicarboxylate (10). A mixture of 341 mg (2.50 mmol) of 6,6-dimethyl-1-vinylcyclohexene (**9**)[11] and 382 mg (2.69 mmol) of methyl acetylenedicarboxylate was heated at 90 °C for 20 h under an argon atmosphere. The crude product, ^{1}H NMR ($CDCl_3$) δ=5.38 (t, 1H), 3.79 (s, 3H), 3.74 (s, 3H), 3.1—2.9 (m, 2H), 1.7—1.2 (m, 4H), 1.09 (s, 3H), and 1.03 (s, 3H), was dissolved in 20 ml of benzene and 571 mg (2.52 mmol) of DDQ was added and the whole was stirred at room temperature for 4.5 d. The mixture was filtered through an alumina column eluted by benzene and pure **10** was obtained by Kugelrohr distillation (bath temp: 180—190 °C/0.3 mmHg, 1 mmHg=133.322 Pa) in 37% yield. **10**: ^{1}H NMR ($CDCl_3$) δ=1.32 (s, 6H), 2.6—2.8 (m, 2H), 3.81 (s, 6H), 7.34 (d, 1H, J=8.6 Hz), and 7.71 (d, 1H, J=8.6 Hz). Found: C, 69.24; H, 7.38%. Calcd for $C_{16}H_{20}O_4$: C, 69.55; H, 7.30%.

5,5-Dimethyl-5,6,7,8-tetrahydro-1,2-naphthalenebis(methanol) (11). To an ice-cooled solution of 205 mg (0.74 mmol) of the diester **10** in 12 ml of dry THF was added 840 mg of lithium aluminium hydride and the mixture was stirred at room temperature for 1 h. A usual work-up gave crude products, which were purified by flash chromatography with dichloromethane–methanol (24 : 1) to give 139 mg (85%) of **11**; mp 83.5—85.0 °C (from benzene); ^{1}H NMR ($CDCl_3$) δ=1.28 (s, 6H), 1.5—2.0 (m, 4H), 2.8—3.0 (m, 2H), 4.78 (s, 2H), 4.82 (s, 2H), 7.10 (d, 1H, J=8 Hz), and 7.30 (d, 1H, J=8 Hz). Found: C, 76.27; H, 9.14%. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

Salviolone Methyl Ether (13) and Its Isomeric Methyl Ether (14). To a 112 μg (1.27 mmol) of oxalyl dichloride in 1.86 ml of dichloromethane was added a solution of 185 μl (2.60 mmol) of DMSO in 0.56 ml of dichloromethane at −78 °C drop by drop. After 5 min, 100 mg (0.45 mmol) of the diol **11** in 0.82 ml of dichloromethane was added and the mixture was stirred at that temperature for 45 min. After triethylamine (700 μg, 5.02 mmol) had been added, the whole was stirred for 10 min and then warmed to room temperature. After 1 h, ethyl ether was added to the solution and the whole was filtered through a magnesium sulfate-layer and the filtrate was evaporated to give a crude dialdehyde **12**; ^{1}H NMR ($CDCl_3$) δ=1.1 (s, 6H), 1.2—1.7 (m, 4H), 2.4—2.7 (m, 2H), 7.2 (d, 1H, J=10 Hz), 7.4 (d, 1H, J=10 Hz), 10.0 (s, 1H), and 10.4 (s, 1H). As the aldehyde **12** was unstable, the crude one was used immediately in a subsequent step without further purification. A mixture of the crude dialdehyde **12** and 71 mg (0.70 mmol) of 1-methoxy-2-butanone[12] in 0.3 ml of 2 M NaOH (1 M=1 mol dm^{-3}) and 11.7 ml of distilled water was stirred at room temperature for 6 d;[13] the flask was occasionally ultrasonicated to disperse the syrup produced. The products were taken in diethyl ether and then dichloromethane, and the extracts were washed with saline and dried over anhyd Na_2SO_4. The crude materials were purified by flash chromatography with hexane–ethyl acetate (7 : 3) followed by a preparative TLC (hexane : AcOEt=8 : 2, 14 times development) to afford 28.5 mg of **13** and 18.7 mg of **14**. Total yield from the diol **11** was 28%. **13**; mp 177—178 °C (from benzene); ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.34 (s, 6H), 1.71 (m, 2H), 1.94 (m, 2H), 2.37 (s, 3H), 3.04 (t, 2H, J=6.4 Hz), 3.93 (s, 3H), 7.34 (s, 1H), 7.47 (d, 1H, J=8.5 Hz), 7.50 (d, 1H, J=8.5 Hz), and 7.71 (s, 1H); NOE 2.37 vs. 7.71, 3.93 vs. 7.34, and 3.04 vs. 7.34; ^{13}C NMR (125 MHz, $CDCl_3$) δ=19.8, 22.9, 29.0, 31.8, 34.9, 38.2, 56.0, 111.2, 127.0, 131.1, 131.5, 134.1, 138.9, 140.8, 148.2, 156.3, and 181.6. Found: C, 80.61; H, 7.83%. Calcd for $C_{19}H_{22}O_2$: C, 80.93; H, 7.85%. **14**: Oil; ^{1}H NMR ($CDCl_3$) δ=1.33 (s, 6H), 1.69 (m, 2H), 1.92 (m, 2H), 2.43 (s, 3H), 3.07 (t, 2H, J=6.4 Hz), 3.93 (s, 3H), 7.01 (s, 1H), 7.48 (d, 1H, J=8.5 Hz), 7.54 (d, 1H, J=8.5 Hz), and 8.14 (s, 1H); NOE: δ=8.14 vs. 3.07, δ=2.43 vs. 8.14, and δ=3.93 vs. 7.01.

Synthesis of Salviolone (15). A mixture of 5.9 mg of **13** and 0.75 ml of 40% aqueous HBr was heated at 130 °C for 14 h. The products were taken in chloroform and purified by preparative TLC (dichloromethane : hexane=4 : 1, 3 times development) to give 2.4 mg of **15** in 43% yield.

The authors are grateful to Dr. Guo Yong Tian, Dalian Institute of Medical and Pharmaceutical Science, Dalian, China, for the collection of fresh roots of the plant used in this study. We also thank Bristol-Myers Squibb Research Institute for bioassay.

High Thermodynamic Diastereoselection in the Equilibration of Acyclic γ-Alkoxy α-Amino Nitriles

Takashi INABA,† Makoto FUJITA, and Katsuyuki OGURA*

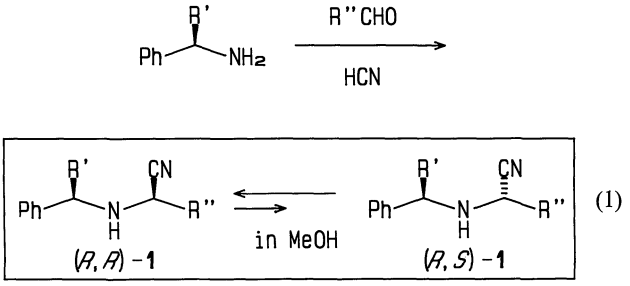
(Received July 24, 1991)

An equilibrium between two diastereomers of an acyclic γ-alkoxy α-amino nitrile was attained in chloroform, and the major component is always its (*R**, *S**)-isomer with high diastereoselectivity.

In acyclic systems, there have been many reports on kinetically controlled 1,3-asymmetric induction, where high stereoselectivity can be realized with aid of metal chelation.[1] On the contrary, high stereoselectivity is unlikely under thermodynamic conditions. Recently we reported a highly selective thermodynamic 1,3-stereocontrol in α-amino nitriles (**1**) derived from α-alkylbenzylamines and aldehydes.[2] In this system, the chiral center of the parent α-alkylbenzylamines controls the stereochemical structure of the α-amino nitrile.

Here we wish to report the second example of high 1,3-asymmetric induction in an acyclic system, i.e., the equilibration between two diastereomeric isomers of an acyclic γ-alkoxy α-amino nitrile (**3**) which, on treatment with an acid, produces a synthetic precursor of the corresponding γ-hydroxy α-amino acid, i.e. α-methyl α-amino γ-lactone (**4**).

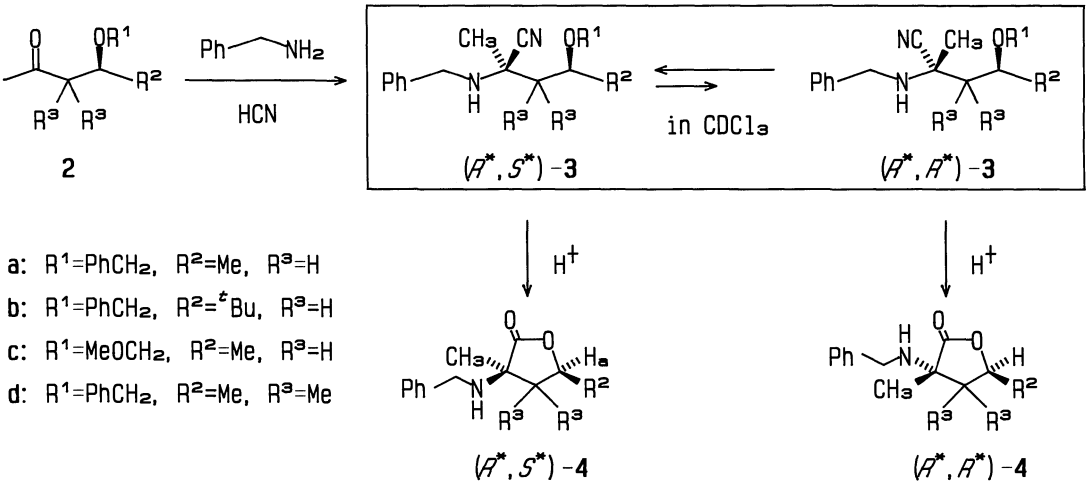


(1)

Results and Discussion

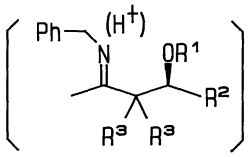
The α-amino nitriles **3a** and **3c** were prepared by the Strecker-type reaction of the corresponding **2** with benzylamine (10 mol equiv), KCN (10 equiv), $NaHSO_3$ (15 equiv) in water or methanol–water (1:3) at room temperature for ca. 20 h. By the reaction of **2b** with benzylamine hydrochloride (1.0 mol equiv) and KCN (1.1 mol equiv) in water, **3b** was obtained. Under these conditions, insoluble **3** separated out as an oil. Yields of **3a**, **3b**, and **3c** were 64%, 63%, and 76%, respectively. The compound (**3d**) which has two methyl groups at its β-position was synthesized in 55% yield by silylcyanation of the Schiff base derived from **2d** and benzylamine and subsequent hydrolytic desilylation. The product (**3**), which consists of two diastereomers, is so labile that we cannot isolate it in pure form except for a major isomer of **3a**. In chromatographic separation on silica gel or Florisil, **3** decomposed. Recycling high-performance gel permeation chromatography made it possible to isolate **3** in a nearly pure form. Recrystallization of **3a** from hexane afforded (*R**, *S**)-**3a** as colorless crystals.

Equilibration between (*R**,*S**)-**3** and (*R**,*R**)-**3**



Scheme 1.

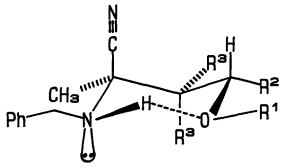
occurred in chloroform, probably via the corresponding Schiff base (**5**) or its protonated form. In methanol, **3** decomposed slowly because **5** reacts with methanol.



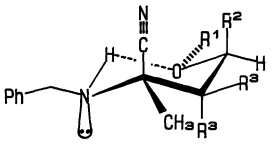
5

This behavior is in contrast with that of **1**, which does not undergo epimerization in chloroform, but in methanol. When the $CDCl_3$ solution of pure (*R**,*S**)-**3a** was allowed to stand at room temperature, epimerization took place. After about 1 d, the ratio of (*R**,*S**)-**3a** and (*R**, *R**)-**3a** was 84:16 (^{1}H NMR). Since this value remained unchanged by elongation of the reaction time, the value of 84:16 was concluded to be the equilibrium ratio of **3a**. The equilibrium ratios of **3b**—**d** were determined after the freshly prepared diastereomeric mixtures were allowed to stand in $CDCl_3$ for 1 d.[3] As summarized in Scheme 2, (*R**, *S**)-**3** is a major component in all cases. Considering that the present 1,3-asymmetric induction is thermodynamically controlled in an acyclic system, the observed concentrations of (*R**, *S**)-**3** are high.

In the IR spectrum of (*R**,*S**)-**3a**, intramolecular hydrogen bonding was observed between the amino hydrogen and the ethereal oxygen. Thus, a dilute $CHCl_3$ solution (0.013 M, 1 M=1 mol dm^{-3}) of (*R**,*S**)-**3a** exhibited an IR absorption at 3340 cm^{-1}. Further the lone pair of the amino nitrogen of an α-amino nitrile is widely recognized to be placed antiperiplanar to its cyano group (stereoelectronic effect).[2,4,5] Therefore the favorable conformers of (*R**,*S**)-**3** and (*R**,*R**)-**3** are assumed to be **[A]** and **[B]**, respectively. Since R^2 group is located at equatorial position in **[A]** and **[B]** has an axial R^2 group, (*R**, *S**)-**3** is more stable than the corresponding (*R**, *R**)-**3**. The important role of the intramolecular hydrogen bonding in high diastereoselection of **3** is supported by a low equilibrium ratio of (*R**, *S**)-**3a** and (*R**, *R**)-**3a** (66:34) in DMSO. The lower



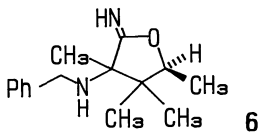
[A] ≡ (*R**, *S**)-**3**



[B] ≡ (*R**, *R**)-**3**

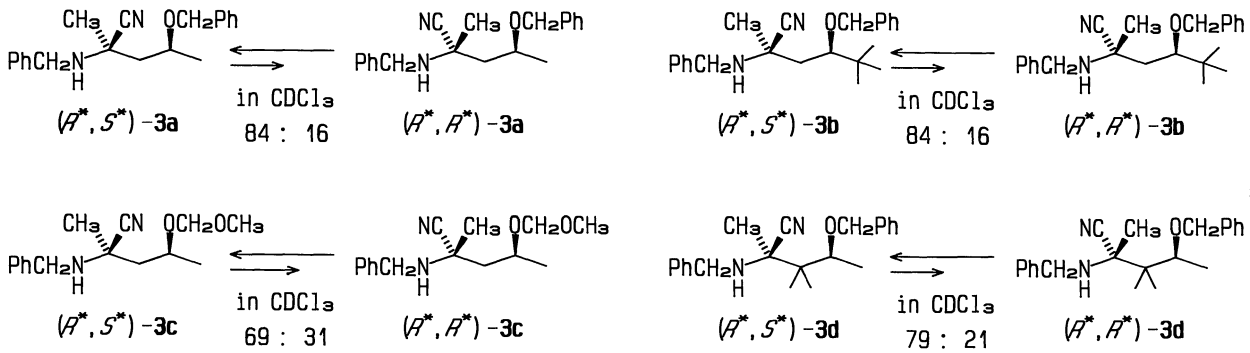
stereoselectivity (69:31) in the equilibration of **3c** is consistent with the decreased electron density of the OR^1 group (R^1=CH_2OCH_3) to make the hydrogen bonding weak.

Finally we describe an acid-catalyzed conversion of **3** into the coresponding α-methyl-α-benzylamino-γ-butyrolactone (**4**) which is brought about by the protonation of the cyano group, the attack of the resulting cation ($-\overset{+}{C}$=NH) on the ethereal oxygen, and the subsequent cleavage of the R^1–O bond. The mechanistic consideration indicates that this reaction is stereospecific. Indeed, (*R**,*S**)-**4a** was given as a single isomer in 65% yield when pure (*R**,*S**)-**3a** was treated with 95% sulfuric acid at room temperature for 15 h. On similar treatment of a diastereomeric mixture of **3a** (84:16), the diastereomeric ratio of **4a** was almost unchanged (82:18). Analogously, **3b** (its diastereomeric ratio=84:16) and **3c** (69:31) also afforded **4b** (75:25) and **4a** (67:33), respectively. In the case of **3d** (79:21), an initial product was 4,5-dihydro-2(3*H*)-furanimine (**6**) (68% yield; 74:26) which was transformed into a 74:26 mixture (96% yield) of (*R**,*S**)-**4d** and (*R**,*R**)-**4d** with *p*-toluenesulfonic acid (PTS) in wet THF. In ^{1}H NMR spectrum of



6

(*R**,*S**)-**4**, strong NOE was observed between methine proton (H_a) and α-methyl protons (**4a** ca. 4%; **4b** 4.8%; **4d** 3.6%), whereas no NOE was detected in those of (*R**,*R**)-



Scheme 2.

4. These facts did not determine only the configurations of **4**, but also those of **3**.

In conclusion, thermodynamically controlled acyclic 1,3-asymmetric induction with high efficiency was realized in the equilibration between two diastereomers of **3**. The conversion of **3** to **4** shows that the present asymmetric induction provides a tool for preparing optically active α-amino acids bearing γ-hydroxy and α-methyl groups from easily available optically active 4-alkoxy-2-alkanones.[6,7]

Experimental

General Procedures. Melting points were determined on a hot-stage microscope apparatus (Yanagimoto) and are uncorrected. ^{1}H NMR spectra were obtained on Hitachi R-600 (60 MHz), JEOL JNM-FX 270 (270 MHz) and JEOL JNM-GSX 500 (500 MHz) spectrometers. Chemical shifts are reported in ppm down field from TMS as the internal standard (δ scale). Infrared spectra were determined with a JASCO A-200 spectrometer and data are presented in cm^{-1} for important diagnostic absorptions. Mass spectra (MS) were determined on a Hitachi RMU-7M spectrometer at 70 eV. Microanalytical data were provided by the Analysis Center of Chiba University.

Preparation of β-Alkoxy Ketones (2). 4-Benzyloxy-2-pentanone (**2a**) and 4-benzyloxy-5,5-dimethyl-2-hexanone (**2b**) were prepared by the "Moffatt–Pfitzner" oxidation[8] of the corresponding alcohols with pyridine, trifluoroacetic acid, and dicyclohexylcarbodiimide in dimethyl sulfoxide.

2a: A colorless oil; bp 103—105°C/133 Pa; ^{1}H NMR ($CDCl_3$; 60 MHz) δ=7.31 (s, 5H), 4.60 (d, 1H, *J*=12 Hz), 4.45 (d, 1H, *J*=12 Hz), 4.06 (m, 1H), 2.72 (dd, 1H, *J*=16, 7 Hz), 2.47 (dd, 1H, *J*=16, 6 Hz), 2.12 (s, 3H), and 1.25 (d, 3H, *J*=6 Hz); IR (neat) 1715 cm^{-1}. Found: *m/z* 192.1160. Calcd for $C_{12}H_{16}O_2$: M, 192.1150.

2b: A colorless oil; bp 117°C/200 Pa; ^{1}H NMR ($CDCl_3$, 270 MHz) δ=7.35—7.21 (m, 5H), 4.58 (d, 1H, *J*=11.2 Hz), 4.52 (d, 1H, *J*=11.2 Hz), 3.71 (dd, 1H, *J*=3.3, 7.9 Hz), 2.69 (dd, 1H, *J*=7.9, 16.5 Hz), 2.57 (dd, 1H, *J*=3.3, 16.5 Hz), 2.17 (s, 3H), and 0.94 (s, 9H); IR (neat) 1720 cm^{-1}. Found: C, 77.05; H, 9.47%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%. Found: *m/z* 234.1623. Calcd for $C_{15}H_{22}O_2$: M, 234.1618.

4-Methyoxymethyl-2-pentanone (**2c**) was prepared by methoxymethylation of 4-hydroxy-2-pentanone with chloromethyl methyl ether and *i*-Pr_2NEt.[9]

Hydrolysis of 2-(1,1-dimethyl-2-benzyloxypropyl)-2-methyl-1,3-dioxolane, which was prepared by addition of methyllithium to 2-(1-formyl-1-methylethyl)-2-methyl-1,3-dioxolane[10] and subsequent benzylation with benzyl bromide and NaH, gave 4-benzyloxy-3,3-dimethyl-2-pentanone (**2d**): A colorless liquid; ^{1}H NMR ($CDCl_3$, 270 MHz) δ=7.36—7.23 (m, 5H), 4.61 (d, 1H, *J*=11.5 Hz), 4.36 (d, 1H, *J*=11.5 Hz), 3.76 (q, 1H, *J*=6.3 Hz), 2.12 (s, 3H), 1.16 (s, 3H), 1.13 (d, 3H, *J*=6.3 Hz), and 1.07 (s, 3H); IR (neat) 1700 cm^{-1}. Found: C, 76.50; H, 9.19%. Anal. Calcd for $C_{14}H_{20}O_2$: C, 76.33; H, 9.15%.

Preparation of 2-Benzylamino-4-benzyloxy-2-methylpentanenitrile (3a) and Its Lactonization. A Typical Procedure: To a suspension of **2a** (384 mg, 2.00 mmol) in water (30 ml) were added $NaHSO_3$ (3.12 g, 30.0 mmol), KCN (1.30 g, 20.0 mmol) and a solution of benzylamine (2.12 g, 20.0 mmol) in MeOH (10 ml) under cooling with ice. After the reaction mixture was stirred at room temperature for 20 h, a deposited oil was extracted with CH_2Cl_2 (30 ml×1, 10 ml×2). The combined organic layers were dried ($MgSO_4$) and evaporated in vacuo. After quick chromatography (within 10 min) on silica gel [hexane–ethyl acetate (5:1)], HPLC separation[11] afforded a colorless oil (393 mg, 64%) which was shown by ^{1}H NMR to consist of (*R**,*S**)-**3a** (84%), (*R**,*R**)-**3a** (16%), and **2a** (trace). The major diastereomer was isolated in a pure form by recrystallization from hexane.

(*R**,*S**)-**3a**: Colorless crystals; mp 35.5°C (hexane); ^{1}H NMR ($CDCl_3$, 270 MHz) δ=7.36—7.07 (m, 10H), 4.61 (d, 1H, *J*=10.6 Hz), 4.40 (d, 1H, *J*=10.9 Hz), 4.18 (m, 1H). 3.80 (d, 1H, *J*=12.0 Hz), 3.73 (d, 1H, *J*=12.0 Hz), 3.11 (br s, 1H, NH), 2.03 (dd, 1H, *J*=14.5, 10.6 Hz), 1.81 (dd, 1H, *J*=14.5, 2.6 Hz), 1.48 (s, 3H), and 1.27 (d, 3H, *J*=5.9 Hz); IR (KBr) 3350 and 2220 cm^{-1}. Found: C, 77.85; H, 7.98; N, 9.10%. Calcd for $C_{20}H_{24}N_2O$: C, 77.98; H, 7.84; N, 9.08%.

^{1}H NMR of (*R**,*R**)-**3a** ($CDCl_3$–D_2O, 270 MHz), which was assigned from spectra of the diastereomeric mixture: δ=7.36—7.07 (m, 5H), 4.61 (d, 1H, *J*=11.2 Hz), 4.43 (d, 1H, *J*=11.2 Hz), 3.88 (m, 1H), 3.86 (s, 2H), 2.08 (dd, 1H, *J*=9.2, 14.5 Hz), 1.85 (dd, 1H, *J*=3.3, 14.5 Hz), 1.55 (s, 3H), and 1.30 (d, 3H, *J*=6.3 Hz).

A diastereomeric mixture (84:16) of **3a** (376 mg, 1.22 mmol) was added to concd sulfuric acid (95%, 5.0 ml) under cooling with ice. After being stirred for 15 h at room temperature, the resulting mixture was poured onto ice containing aqueous NH_3 (28% concn; 15 ml). After extraction with CH_2Cl_2 (30 ml×1, 10 ml×2), the combined organic layers were dried ($MgSO_4$), evaporated in vacuo, and subjected to flash chromatography on silica gel [hexane–ethyl acetate (7:2—2:1)] to give (*R**,*S**)-**4a** (101 mg, 38%) and (*R**,*R**)-**4a** (22.0 mg, 8.2%).

(*R**,*S**)-**4a**: A colorless oil; ^{1}H NMR (500 MHz, $CDCl_3$) δ=7.37—7.24 (m, 5H), 4.53 (qt, 1H, *J*=5.9, 10.1 Hz), 3.80 (d, 1H, *J*=12.1 Hz), 3.68 (d, 1H, *J*=12.1 Hz), 2.19 (dd, 1H, *J*=5.9, 13.0 Hz), 2.06 (dd, 1H, *J*=10.1, 13.0 Hz), 1.72 (br s, 1H, NH), 1.45 (d, 3H, *J*=6.0 Hz), and 1.43 (s, 3H); IR (neat) 3340 and 1770 cm^{-1}. Found: C, 71.16; H, 7.84; N, 6.39%. Calcd for $C_{13}H_{17}NO_2$: C, 71.21; H, 7.81; N, 6.39%.

(*R**,*R**)-**4a:** Colorless crystals; mp 39—40°C (hexane–Et_2O); ^{1}H NMR ($CDCl_3$, 500 MHz) δ=7.33—7.24 (m, 5H), 4.70 (qt, 1H, *J*=6.3, 8.5 Hz). 3.89 (d, 1H, *J*=12.1 Hz), 3.74 (d, 1H, *J*=12.1 Hz), 2.47 (dd, 1H, *J*=6.6, 13.5 Hz), 1.80 (dd, 1H, *J*=8.5, 13.5 Hz), 1.49 (br s, 1H, NH), 1.47 (s, 3H), and 1.42 (d, 3H, *J*=6.3 Hz); IR (KBr) 3290 and 1750 cm^{-1}. Found: C, 71.26; H, 7.85; N, 6.36%. Calcd for $C_{13}H_{17}NO_2$: C, 71.21; H, 7.81; N, 6.39%.

Similarly, treatment of pure (*R**,*S**)-**3a** (110 mg, 0.357 mmol) with sulfuric acid gave (*R**,*S**)-**4a** (51.1 mg, 65%). In this reaction mixture, we could not detect (*R**,*S**)-**4a**.

2-Benzylamino-4-methoxymethoxy-2-methylbutanenitrile (3c) and Its Lactonization: In a similar manner, **3c** (418 mg, 76%) was obtaind from **2c** (292 mg, 2.00 mmol) as a colorless oil, which was shown by ^{1}H NMR to consist of (*R**,*S**)-**3c** (66%), (*R**,*R**)-**3c** (30%), and **2c** (4%): ^{1}H NMR ($CDCl_3$, 270 MHz) δ=7.41—7.23 (m, 5H), 4.71 (d, 0.30×1H, *J*=7.3 Hz), 4.70 (d, 0.66×1H, *J*=6.9 Hz), 4.65 (d, 0.30×1H, *J*=7.3 Hz), 4.63 (d, 0.66×1H, *J*=6.9 Hz), 4.20 (m, 0.66×1H), 4.01 (m, 0.30×1H), 3.88 (br m, 0.96×2H), 3.352 (s, 0.30×3H), 3.345 (s, 0.04×3H), 3.32 (s, 0.66×3H), 2.83 (br s, 0.96×1H, NH), 2.18 (s, 0.04×3H), 2.06 (dd, 0.30×1H, *J*=5.3, 14.8 Hz), 2.00 (dd, 0.66×1H, *J*=7.9,

14.5 Hz), 1.82 (dd, 0.30×1H, J=3.6, 14.5 Hz), 1.78 (dd, 0.66×1H, J=2.7, 14.5 Hz), 1.57 (s, 0.30×3H), 1.50 (s, 0.66×3H), 1.26 (d, 0.30×3H, J=6.3 Hz), 1.24 (d, 0.66×3H, J=5.9 Hz), and 1.22 (d, 0.04×3H, J=6.3 Hz); IR (neat) 3350 and 2220 cm^{-1}.

When a 69:31 mixture of (*R**,*S**)- and (*R**,*R**)-**3c** was treated with sulfuric acid, a 67:33 mixture of (*R**,*S**)- and (*R**,*R**)-**4a** was given in 37% yield.

2-Benzylamino-4-benzyloxy-2,5,5-trimethylhexanenitrile (3b) and 2-Benzylamino-4-(*t*-butyl)-2-methyl-γ-butyrolactone (4b): To a stirring suspension of **2b** (234 mg, 1.00 mmol) in water (0.50 ml) were added benzylamine hydrochloride (145 mg, 1.01 mmol) and KCN (72.0 mg, 1.11 mmol) at room temperature. After the reaction mixture was stirred at the same temperature for 20 h, CH_2Cl_2 (20 ml) and anhydrous $MgSO_4$ to remove the water were added, and the solvent was evaporated in vacuo. A short-column chromatography on silica gel (eluent: ethyl acetate) followed by HPLC separation[11] afforded a colorless oil (229 mg, 63%) which was shown by ^1H NMR to consist of (*R**,*S**)-**3b** (84%) and (*R**,*R**)-**3b** (16%); ^1H NMR ($CDCl_3$, 270 MHz) δ=7.37—7.03 (m, 10H, ArH), 4.82 (d, 0.84×1H, J=11.2 Hz, $OC\underline{H}_2Ph$), 4.78 (d, 0.84×1H, J=11.5 Hz, $OC\underline{H}_2Ph$), 3.91 (d, 0.16×1H, J=9.6 Hz, $NC\underline{H}_2Ph$), 3.90 (d, 0.16×1H, J=9.6 Hz, $NC\underline{H}_2Ph$), 3.74 (br s, 0.84×2H, $NC\underline{H}_2Ph$), 3.68 (dd, 0.84×1H, J=3.3, 10.2 Hz, $OC\underline{H}CH_2$), 3.37 (dd, 0.16×1H, J=3.6, 6.9 Hz, $OC\underline{H}CH_2$), 1.98 (dd, 0.84×1H, J=10.2, 14.5 Hz, $OCHC\underline{H}_2$), 1.88 (dd, 0.84×1H, J=3.3, 14.5 Hz), 1.57 (s, 0.16×3H, $C\underline{H}_3CCN$), 1.50 (s, 0.84×3H, $C\underline{H}_3CCN$), 0.99 (s, 0.84×9H, $C(C\underline{H}_3)_3$), and 0.98 (s, 0.84×9H, $C(C\underline{H}_3)_3$); IR (neat) 3340 cm^{-1}.

Treatment of thus obtained **3b** with sulfuric acid resulted in formation of **4b** with a diastereomeric ratio of 75:25 in 51% yield.

(*R**,*S**)-**4b:** Colorless crystals; mp 74°C (hexane); ^1H NMR ($CDCl_3$, 500 MHz) δ=7.38—7.24 (m, 5H), 4.10 (dd, 1H, J=6.1, 11.0 Hz), 3.78 (d, 1H, J=12.1 Hz), 3.68 (d, 1H, J=12.1 Hz), 2.24 (dd, 1H, J=11.0, 12.9 Hz), 1.92 (dd, 1H, J=6.1 Hz, 12.9 Hz), 1.76 (br s, 1H, $N\underline{H}$), 1.44 (s, 3H), 0.97 (s, 9H); IR (KBr) 3340, 1760 cm^{-1}. Found: C, 73.75; H, 8.94; N, 5.23%. Calcd for $C_{16}H_{23}NO_2$: C, 73.53; H, 8.87; N, 5.36%. Found: m/z 217.1837. Calcd for $C_{15}H_{23}N$: M−CO_2, 217.1829.

(*R**,*R**)-**4b:** Colorless crystals; mp 78°C (hexane); ^1H NMR ($CDCl_3$, 500 MHz) δ=7.35—7.24 (m, 5H), 4.28 (dd, 1H, J=6.6, 9.9 Hz), 3.80 (d, 1H, J=12.1 Hz), 3.76 (d, 1H, J=12.1 Hz), 2.18 (dd, H, J=6.6, 13.8 Hz), 1.95 (dd, 1H, J=9.9, 13.8 Hz), 1.55 (br s, 1H, $N\underline{H}$), 1.45 (s, 3H) and 0.94 (s, 9H); IR (KBr) 3340 and 1740 cm^{-1}. Found: C, 73.46; H, 8.93; N, 5.17%. Calcd for $C_{16}H_{23}NO_2$: C, 73.53; H, 8.87; N, 5.36%. Found: m/z 217.1837. Calcd for $C_{15}H_{23}N$: M−CO_2, 217.1829.

2-Benzylamino-4-benzyloxy-2,3,3-trimethylpentanenitrile (3d): The mixture of **2d** (440 mg, 2.00 mmol), benzylamine (856 mg, 8.00 mmol), and $BF_3{\cdot}OEt_2$ (20 mg) was stirred at 80°C for 16 h under an atmosphere of nitrogen. After removal of the unreacted benzylamine under reduced pressure (100°C/67 Pa), the residue was dissolved in CH_2Cl_2 (6.0 ml) and then trimethylsilyl cyanide (0.40 ml, 3.0 mmol) and $ZnCl_2$ (20 mg) were added at room temperature. After being stirred at the same temperature for 4 h, the reaction mixture was passed through a short column on silica gel (5 g) using Et_2O as an eluent. Purification by recycling HPLC[11] gave a colorless oil (504 mg) which was shown by ^1H NMR to comprise (*R**,*S**)-**3d** (63%), (*R**,*R**)-**3d** (17%), and the Schiff base (**5**; R^1=$PhCH_2$, R^2=R^3=Me) (20%) which might be produced from **3d** by elimination of a HCN moiety during workup. The yield of **3d** was calculated to be 55%. ^1H NMR of **3d** ($CDCl_3$, 270 MHz): δ=7.36—7.03 (m, 10H), 4.623 (d, 0.20×1H, J=11.9 Hz), 4.617 (d, 0.17×1H, J=11.5 Hz), 4.60 (d, 0.63×1H, J=10.6 Hz), 4.51 (br s, 0.20×2H, $NC\underline{H}_2Ph$), 4.42 (d, 0.63×1H, J=10.5 Hz, $OC\underline{H}_2Ph$), 4.37 (d, 0.20×1H, J=11.9 Hz, $OC\underline{H}_2Ph$), 4.29 (d, 0.17×1H, J=11.5 Hz, $OC\underline{H}_2Ph$), 3.98 (q, 0.63×1H, J=6.3 Hz, $OC\underline{H}CH_3$), 3.82 (br s, 0.17×2H, $NC\underline{H}_2Ph$), 3.74 (d, 0.63×2H, J=6.3 Hz, $NC\underline{H}_2Ph$), 3.74 (q, 0.20×1H, J=6.3 Hz, $OC\underline{H}CH_3$), 3.57 (q, 0.17×1H, J=6.3 Hz, $OC\underline{H}CH_3$), 3.32 (br t, 0.80×1H, J=6.6 Hz, $N\underline{H}$), 1.84 (s, 0.20×3H), 1.46 (s, 0.17×3H), 1.39 (s, 0.63×3H), 1.30 (d, 0.17×3H, J=6.3 Hz), 1.25 (d, 0.63×3H, J=6.3 Hz), 1.21 (s, 0.17×3H), 1.19 (s, 0.17×3H), 1.13 (s, 0.20×6H), 1.12 (d, 0.20×3H, J=6.3 Hz), 1.03 (s, 0.63×3H), and 1.00 (s, 0.63×3H); IR (neat) 3350 and 2220 cm^{-1}.

3-Benzylamino-3,4,4,5-tetramethyl-4,5-dihydro-2(3*H*)-furanimine (6): The similar procedure gave 3-benzylamino-3,4,4,5-tetramethyl-4,5-dihydro-2(3*H*)-furanimine (**6**) as a diastereomeric mixture (200 mg, 68%; (*R**,*S**):(*R**,*R**)=79:21) from the equilibrium mixture of (*R**,*S**)-**3d** and (*R**,*R**)-**3d** (504 mg, 80% purity, 1.20 mmol). **6** was colorless crystals; mp 67—71°C; ^1H NMR ($CDCl_3$, 270 MHz) δ=7.41—7.21 (m, 5H, ArH), 4.63 (q, 0.26×1H, J=6.6 Hz, $OC\underline{H}CH_3$), 4.14 (q, 0.74×1H, J=6.3 Hz, $OC\underline{H}CH_3$), 4.04 (d, 0.74×1H, J=12.5 Hz, $NC\underline{H}_2Ph$), 3.85 (d, 0.74×1H, J=12.2 Hz, $NC\underline{H}_2Ph$), 3.83 (s, 0.26×2H, $NC\underline{H}_2Ph$), 1.40 (s, 0.74×3H, $NCC\underline{H}_3$), 1.27 (s, 0.26×3H, $NCC\underline{H}_3$), 1.24 (d, 0.74×3H, J=6.6 Hz, $OCHC\underline{H}_3$), 1.20 (d, 0.26×3H, J=6.6 Hz, $OCHC\underline{H}_3$), 1.10 (s, 0.74×3H, $C(C\underline{H}_3)_2$), 0.95 (s, 0.74×3H, $C(C\underline{H}_3)_2$), 0.94 (s, 0.26×3H, $C(C\underline{H}_3)_2$), and 0.85 (s, 0.26×3H, $C(C\underline{H}_3)_2$); IR (KBr) 3340, 3290, and 1675 cm^{-1}. Found: C, 73.26; H, 9.02; N, 11.36%. Calcd for $C_{15}H_{22}N_2O$: C, 73.13; H, 9.00; N, 11.37%.

2-Benzylamino-2,3,3,4-tetramethyl-γ-butyrolactone (4d): To the solution of **6** (269 mg, 1.09 mmol) in THF (8 ml) were added *p*-toluenesulfonic acid monohydrate (560 mg, 2.95 mmol) and H_2O (0.8 ml). After reflux for 16 h, the reaction mixture was neutralized with saturated aqueous $NaHCO_3$ and extracted with Et_2O (40 ml). The organic layer was washed with brine, dried ($MgSO_4$), and evaporated in vacuo. Flash chromatography on silica gel [hexane–ethyl acetate (5:1)] afforded a 74:26 mixture (*R**,*S**)-**4d** and (*R**,*R**)-**4d** (258 mg, 96% yield), which was separated by recycling HPLC[12] [eluent: hexane–ethyl acetate (2:1)].

(*R**,*S**)-**4d:** Colorless crystals; mp 60—61°C; ^1H NMR ($CDCl_3$, 500 MHz) δ=7.40—7.23 (m, 5H), 4.25 (q, 1H, J=6.4 Hz), 4.13 (d, 1H, J=12.3 Hz), 3.82 (br d, 1H, J=11.5 Hz), 1.40 (s, 3H), 1.29 (d, 3H, J=6.6 Hz), 1.05 (s, 3H), and 0.99 (s, 3H); IR (KBr) 3320 and 1760 cm^{-1}. Found: C, 72.96; H, 8.62; N, 5.58%. Calcd for $C_{15}H_{21}N_2O_2$: C, 72.84; H, 8.56; N, 5.66%.

(*R**,*R**)-**4d:** Colorless crystals; mp 49—50°C; ^1H NMR ($CDCl_3$, 500 MHz) δ=7.33—7.22 (m, 5H), 4.71 (q, 1H, J=6.4 Hz), 3.87 (d, 1H, J=12.6 Hz), 3.71 (d, 1H, J=12.6 Hz), 1.26 (d, J=6.4 Hz, 3H), 1.25 (s, 3H), 0.97 (s, 3H), and 0.89 (s, 3H); IR (KBr) 3330 and 1760 cm^{-1}. Found: C, 72.83; H, 8.64; N, 5.54%. Calcd for $C_{15}H_{21}N_2O_2$: C, 72.84; H, 8.56; N, 5.66%.

Mechanistic Study of the Hydrogenation of Carbon Dioxide to Methanol over Supported Rhenium and Copper-Zinc Catalysts

Zheng Xu,† Zaihu Qian,† and Hideshi Hattori*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
† Department of Chemistry, Jilin University, Changchun, China
(Received March 1, 1991)

The reaction of a mixture containing ^{13}CO, CO_2, and H_2 was carried out in order to elucidate the reaction mechanisms of carbon dioxide hydrogenation to methanol over supported Re catalysts as well as Cu–Zn oxide catalysts. The reactions of formic acid and formaldehyde with hydrogen were also examined. From the incorporation of ^{13}C in the product methanol, it could be distinguised whether the carbon dioxide hydrogenation to methanol proceeds through formation and successive hydrogenation of CO or by direct hydrogenation of CO_2. Methanol is formed almost exclusively by direct hydrogenation of CO_2 over CuO–ZnO based catalysts. However, the two reaction routes operate over Re/ZrO_2 and Re/CeO_2, the contribution of route via CO being higher over Re/ZrO_2 than over Re/CeO_2. The reactions of formic acid and formaldehyde with hydrogen suggest that the surface formate and the adsorbed formaldehyde are involved in the methanol formation, and that the conversion of the formate to the adsorbed formaldehyde is a key step.

In sharp contrast to the extensive studies involving hydrogenation of CO to methanol, hydrogenation of CO_2 to methanol has left some uncertainties regarding the mechanisms. One of the discussion points concerning the mechanism of methanol synthesis is the reaction intermediates. The other point to be discussed is the source of carbon for the product methanol. One candidate is CO_2 and the other is CO resulting from a reverse water–gas shift reaction of CO_2 and H_2.

Two kinds of catalysts used for the methanol synthesis from CO_2 and H_2 are supported transition metals and CuO–ZnO based catalysts. The mechanisms of methanol synthesis seem to be dependent upon the type of catalyst.

As the intermediate of methanol synthesis, surface formate species has been proposed for both supported transition metal catalysts and Cu–Zn oxide catalysts. Ramaroson et al. studied the mechanisms of the formation of C_1 products from CO_2 and H_2 over Pd/SiO_2 and Pd/Al_2O_3 by a chemical trapping method.[1] They proposed that the first step involves the formation of formate by CO_2 insertion into a hydroxide site. Solymosi et al. confirmed by IR spectroscopy the formation of formate in the hydrogenation of CO_2 over supported Rh catalysts.[2] They proposed that hydrogen activated on the Rh migrates onto the support and reacts with hydrocarbonate to yield the formate ion.

Over CuO–ZnO based catalysts, Kieffer et al.[3] and Ramaroson et al.[4] have reported that the formation of formate as an intermediate for the methanol synthesis from CO_2 and H_2 was observed by a chemical trapping method. Amenomiya et al. observed the formation of formate during CO_2 hydrogenation.[5] They proposed that the formate is formed by the insertion of CO_2 into a hydroxide site, and that the formate species is a common intermediate to methanol synthesis as well as to CO formation by a reverse water–gas shift.

To clarify whether methanol is formed directly from CO_2 or through the formation of CO followed by hydrogenation, isotope-labeling studies were performed. Chinchen et al. used $^{14}CO_2$ or ^{14}CO in a mixture of $CO_2/CO/H_2$, and found that CO_2 is the major reactant for methanol synthesis over $CuO–ZnO–Al_2O_3$ under industrial conditions.[6] Liu et al. used ^{18}O-labeled CO_2 for methanol synthesis over a Cu–Zn oxide catalyst.[7] Their results have indicated that there are at least four parallel reactions: $CO–CO_2$ exchange, CO hydrogenation, CO_2 hydrogenation, and a water–gas shift.

Erdoeheloyi et al. studied the hydrogenation of CO_2 over supported Pd.[8] The results failed to suppoort the idea that methanol is produced in a direct reaction of CO_2 and not through the formation of CO and its consecutive hydrogenation.

It seems that over CuO–ZnO based catalysts, methanol is formed directly from CO_2. However, it is not certain whether the same conclusion can be made regarding methanol synthesis over supported transition metal catalysts.

In our previous papers, methanol syntheses from CO_2 and H_2 were carried out over supported Re catalysts and Cu–Zn oxide supported on various metal oxides in order to examine the support effects.[9,10] The activity and selectivity depend on the type of support for both the Re and Cu–Zn oxide catalysts. It is also suggested that different mechanisms are operating in methanol formation over Re/ZrO_2 and Re/CeO_2. In the present study, the mechanisms of hydrogenation of CO_2 were studied regarding both supported Re and Cu–Zn oxide catalysts by the use of ^{13}C-labeled CO in order to clarify the origin of carbon in the products. The reaction of formic acid or formaldehyde with hydrogen was carried out in order to examine the intermediates for methanol.

Experimental

Preparation of Catalysts. Supported Re catalysts were prepared by impregnating CeO_2 and ZrO_2 (20—40 mesh) with an NH_4ReO_4 solution (1 M, 1 M=1 mol dm^{-3}), followed by drying in a vacuum and successively reducing with hydrogen first at 200°C for 2 h, then 400°C for 4 h, and finally at a reaction temperature of 200°C for 2 h before use. The content of Re was adjusted to be 1.5 wt% for both catalysts.

The Cu–Zn oxide catalyst was prepared by the hydrolysis of a mixed solution containing 1 M $Cu(NO_3)_2$ and 1 M $Zn(NO_3)_2$ with 1 M aqueous solution, followed by washing and drying. The dried catalyst was calcined in air at 350°C for 3 h and then at 500°C for 1 h. The mole percents of CuO was adjusted to be 50%.

The Cu–Zn oxide catalysts supported on ZrO_2, MgO, Al_2O_3, and Cr_2O_3 were prepared by the direct addition of $Zr(OH)_4$, $Mg(OH)_2$, $Al(OH)_3$, and $Cr(OH)_3$, respectively, to the $Cu(OH)_2$–$Zn(OH)_2$ coprecipitates obtained as above; this was followed by drying and calcining also in a manner similar to the above. The mole percents of CuO, ZnO, and support metal oxides were adjusted to be 42, 47, and 11% for CuO–ZnO–ZrO_2, 47, 47, and 6% for CuO–ZnO–MgO and CuO–ZnO–Al_2O_3, 34.5, 34.5, and 11% for CuO–ZnO–Cr_2O_3.

Isotope Labeling Reaction. A mixture containing CO_2 (140 Torr, 1 Torr=133.322 Pa), H_2 (420 Torr) and ^{13}CO (10 Torr) was used as a reactant. The ^{13}CO was purchased from Cambridge Isotope Laboratories; its isotopic purity was 99%. Hydrogen was purified by passage through 13X molecular sieves. The CO_2 was purified by freeze-thaw cycles. A recirculation reactor having a volume of 267 cm^3 was employed. A catalyst sample (0.30 g) was placed in the reactor and reduced with hydrogen flow at 300°C for 6 h. After evacuating the hydrogen for 30 min, the reactant was introduced into the reaction system. All reactions were carried out at 200°C. During the reaction, a trap placed in the loop of the recirculation reactor was kept at −78.5°C, so that the formed methanol could be trapped so as to keep the vapor pressure of methanol negligibly low in order to avoid a reverse reaction. For product analysis, the catalyst bed was closed from the recirculation loop and the trap was heated to room temperature. The reaction mixture was then withdrawn. A part of the withdrawn reaction mixture was analyzed by gas chromatography. The other part was subjected to mass spectrometric analysis.

Reaction of Formic Acid or Formaldehyde with Hydrogen. For the reaction of formic acid or formaldehyde with hydrogen, the same recirculation reactor was employed. After pretreatment, the catalyst was exposed to 12 Torr formic acid or formaldehyde at room temperature for 30 min. Then, 420 Torr hydrogen was introduced, and the catalyst was heated to a reaction temperature of 200°C. The products were analyzed by a gas chromatograph using Porapak-Q column.

XPS Measurements. XPS were measured by using an Escalab MK II spectrometer equipped with an in situ reaction cell inside the pretreatment chamber. Mg $K\alpha$ was used as a radiation source. A plate sample was evacuated at room temperature in the pretreatment chamber, then transferred to a small reactor where the reduction with hydrogen stream was carried out at 300°C for 2 h. After the prereduced sample was transferred to the pretreatment chamber, evacuated, and transferred to the analyzing chamber, the Cu2p spectra were measured.

Results and Discussion

Regarding the reaction of the mixture containing CO_2, ^{13}CO and H_2, the experimental results are shown in Table 1. Over Re catalysts, methane was produced as well as methanol. In particular, the formation of methane exceeded to a considerable extent over Re/ZrO_2. In contrast to the case of the Re catalysts, methane was not formed over Cu–Zn oxide catalysts. Practically no reaction was appreciable over CuO–ZnO–Cr_2O_3.

The percentages of the ^{13}C content in each product are plotted against the reaction time in Figs. 1 and 2 for Re/ZrO_2 and Re/CeO_2, respectively. If the product is formed directly from CO_2, the ^{13}C content in the product will be 0% at a conversion of 0%. On the contrary, the

a) Reaction conditions: Reactant: H_2 (420 Torr)+CO_2 (140 Torr)+^{13}CO (10 Torr), Catalyst: 300 mg, Reaction temperature: 200°C.

^{13}C content will be 100% if the product is formed from CO. Although the values obtained by extrapolation to 0 conversion have some uncertainties, these are useful for determining the reaction route. Over a Re/ZrO_2 catalyst, the ^{13}C content in CH_4 was about 60—70% at a conversion of 0%, while that of CH_3OH was in the range of more than 25%. It is thus suggested that CH_4 is formed predominantly via CO, while CH_3OH is formed predominantly by a direct reaction of CO_2.

Over a Re/CeO_2 catalyst, the ^{13}C contents in both CH_4 and CH_3OH were low, compared to those produced over Re/ZrO_2. The percentages of the ^{13}C contents in CH_4 and CH_3OH at a conversion of 0% were about 50% and 10%, respectively. It is, therefore, suggested that the contributions of the routes via CO and via CO_2 are almost equivalent for CH_4 formation, and that CH_3OH is predominantly formed from CO_2. This indicates that the catalytic behavior is different over Re/ZrO_2 and Re/CeO_2 in CO_2 hydrogenation.

One more difference between Re/ZrO_2 and Re/CeO_2 was observed regarding the rate of a CO–CO_2 carbon exchange. Over both catalysts, the rate of incorporation of ^{12}C into CO was fast compared to the formation rates of CH_4 and CH_3OH. The rate of CO–CO_2 carbon exchange was much faster for Re/ZrO_2 than for Re/CeO_2.

The distribution of ^{13}C in the products produced over Cu–Zn oxide catalysts were quite different from those observed over the supported Re catalysts, such as CuO–ZnO–ZrO_2, as shown in Fig. 3. The ^{13}C contents in CH_3OH produced over Cu–Zn oxide catalysts were close to 0%. This demonstrates that product methanol is directly formed from CO_2. The contribution from the route via CO is negligible. This coincides with the conclusion reported by Chinchen et al. for Cu–Zn/Al_2O_3 catalyst.[6)]

Although the incorporation of ^{13}C into methanol was negligible, a CO–CO_2 carbon exchange occurred to a considerable extent. Two possibilities which account for the fast CO–CO_2 exchange against a negligible incorporation of ^{13}C into methanol are as follows. One possibility is that the intermediates for the formation of

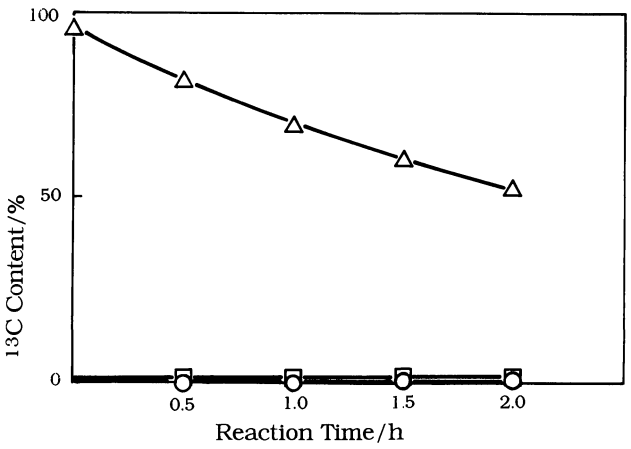

Fig. 3. Variations in the ^{13}C contents of each product in the reaction of $H_2+CO_2+^{13}CO$ over CuO–ZnO–ZrO_2 as a function of the reaction time. △: CO, ○: CO_2, □: CH_3OH.

methanol from CO_2 are not common to those for a CO–CO_2 carbon exchange. The other possibility is that the intermediates are common, but that the slow step in the formation of methanol is a conversion of the intermediates, leading to methanol.

Reactions of Formic Acid and Formaldehyde with Hydrogen. Formic acid is supposed to be adsorbed on the surface in the form of formate. The purpose of the reactions was to determine how the formate and the adsorbed formaldehyde are involved in the hydrogenation of carbon dioxide by a comparison of the product distribution with those obtained in the hydrogenation of carbon dioxide. In the reactions of formic acid and formaldehyde with hydrogen, all of the formic acid and formaldehyde were completely consumed within 1 h; the conversions were 100%. The product distributions in the reactions of formic acid and formaldehyde with hydrogen are given in Tables 2 and 3, respectively.

Over the Re/CeO_2 catalyst, the products in the reaction of adsorbed formic acid with H_2 comprised of CO_2, CH_4, and CO. No methanol formation was observed. Over the Re/ZrO_2 catalyst, however, the products comprised of CH_4 and CO, neither CO_2 nor methanol was observed. It should be noted that CO_2 was not formed over Re/ZrO_2 at all, though CO_2 was the main product over Re/CeO_2.

Over Cu–Zn oxide catalysts, CO, CO_2, and methanol were produced; no methanol was formed over CuO–ZnO–Cr_2O_3. The production of methanol was the highest for CuO–ZnO–ZrO_2.

For all of the catalysts examined, the product distributions in the reaction of formic acid with hydrogen and in the hydrogenation of CO_2 show common features regarding the following three points: (1) The amount of methane greatly exceeded that of methanol over Re catalysts. (2) Over Cu–Zn oxide catalysts, methanol was formed; no methane was formed. (3) Over CuO–ZnO–Cr_2O_3, neither methanol nor methane were formed.

The reaction of formaldehyde with hydrogen gave product distribution quite different from that of formic acid with hydrogen. Over Re/ZrO_2 and Re/CeO_2 catalyst, methanol was formed considerably. In addition, the formation of CO_2, which was the main product in the reaction of formic acid with hydrogen on Re/CeO_2, was not observed.

Over Cu–Zn oxide catalysts, the products comprised mostly of methanol. Only small amounts of CO_2 and CO were formed in the reaction of formaldehyde with hydrogen. It is to be noted that with Cu–Zn oxide

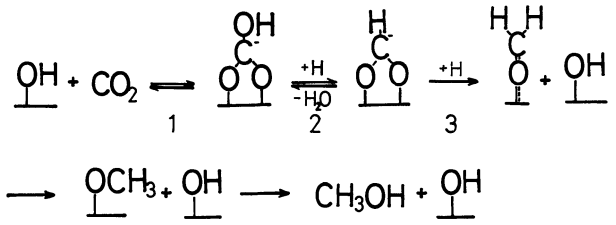
catalysts methanol was formed, even over CuO–ZnO–Cr_2O_3, over which no methanol was formed from formic acid. This indicates that the conversion of adsorbed formic acid to adsorbed formaldehyde is very slow over CuO–ZnO–Cr_2O_3 catalysts.

Some common features between CO_2 hydrogenation and the reaction of formic acid with hydrogen and the predominant formation of methanol in the reaction of formaldehyde suggest the following reaction route. At first, formate is formed from CO_2 and hydrogen; the formate converts into the adsorbed formaldehyde. The adsorbed formaldehyde is hydrogenated to yield methanol. The formation of formate may proceed by the insertion of CO_2 into the hydroxide site, as suggested by Amenomiya et al.[5)] A scheme for methanol formation may be as shown below:



Scheme 1.

Since CO–CO_2 carbon exchange is fast, and essentially no incorporation of ^{13}C into methanol was observed in the reaction of ^{13}CO, CO_2, and H_2, a CO–CO_2 carbon exchange proceeds by intermediates which are different from the formate shown above.

The conversion of the formate into the adsorbed formaldehyde (step 3) is the key step in methanol synthesis. Once the adsorbed formaldehyde is formed, methanol is easily yielded, as is evidenced by the selective formation of methanol in the reaction of formaldehyde with hydrogen.

Over a CuO–ZnO–Cr_2O_3 catalyst, methanol was not formed, neither in CO_2 hydrogenation nor in the reaction of formic acid with hydrogen; methanol, however, was selectively formed in the reaction of formaldehyde with

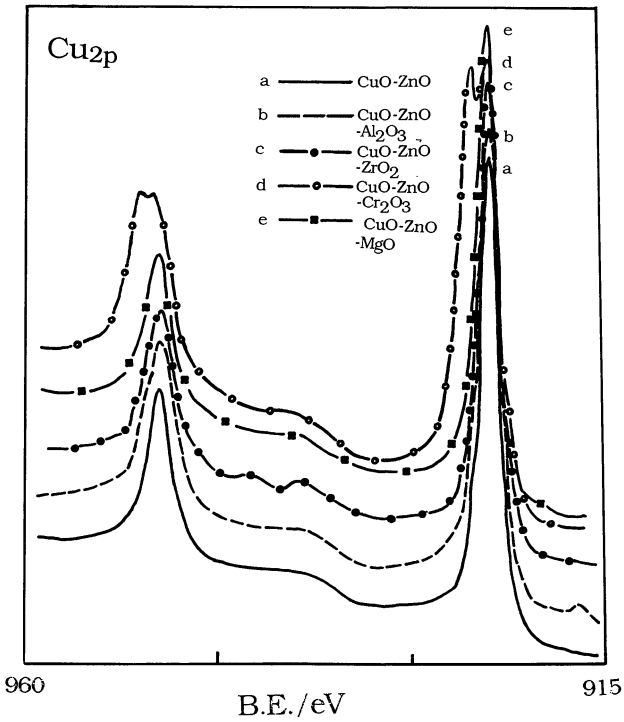


Fig. 4. XPS spectra of various Cu–Zn oxide catalysts after reduction with H_2 at 300°C.

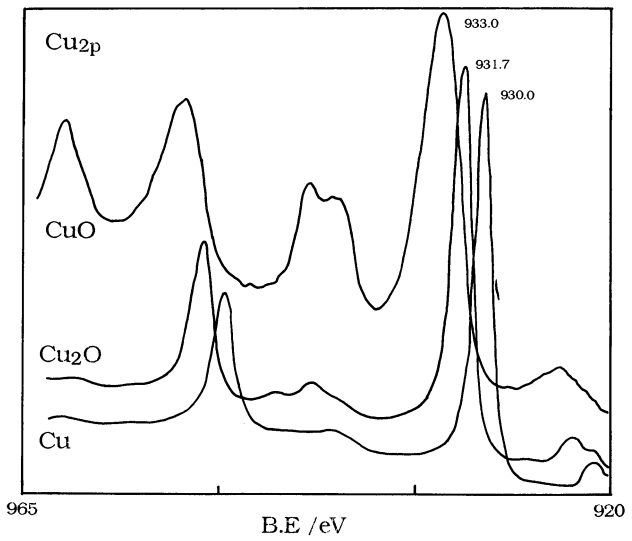

Fig. 5. XPS spectra of standard oxides of Cu.

hydrogen. The conversion of formate into the adsorbed formaldehyde is very slow over $CuO–ZnO–Cr_2O_3$. The state of Cu on $CuO–ZnO–Cr_2O_3$ should be different from those on the other supported CuO–ZnO catalysts. To examine the states of Cu, XPS was measured with $CuO–ZnO–Cr_2O_3$ together with the other Cu–Zn oxide catalysts. As shown in Fig. 4, $CuO–ZnO–Cr_2O_3$ showed two peaks in the Cu_{2p} region, while the other Cu–Zn oxide catalysts showed a single peak. The peaks are assigned to Cu^+, compared with the peaks for CuO, Cu_2O, and Cu^0, as shown in Fig. 5. The peak at 932.7 eV is positioned between those for Cu^{2+} and Cu^+. It is not certain why $CuO–ZnO–Cr_2O_3$ showed two peaks, but it can be said that Cu in the $CuO–ZnO–Cr_2O_3$ tends to stay at a higher oxidation state, compared with the other Cu–Zn oxide catalysts.

In our previous paper,[10] we proposed that Cu^+ in a Cu–Zn oxide solid solution is an active site for methanol formation from CO_2 and H_2.[10] The state of Cu in $CuO–ZnO–Cr_2O_3$ may be either partly oxidized Cu^+ or partly reduced Cu^{2+}. This causes the conversion of the formate to the adsorbed formaldehyde difficult.

With the Re/ZrO_2 catalyst, most of the methanol is formed through the reaction of CO with H_2, though the selectivity to methanol is very low under the reaction condition of subatomospheric pressure. With the Re/CeO_2 catalyst, one of the routes to methanol is considered to proceed by a direct hydrogenation of CO_2 in a similar manner to that shown in Scheme 1.

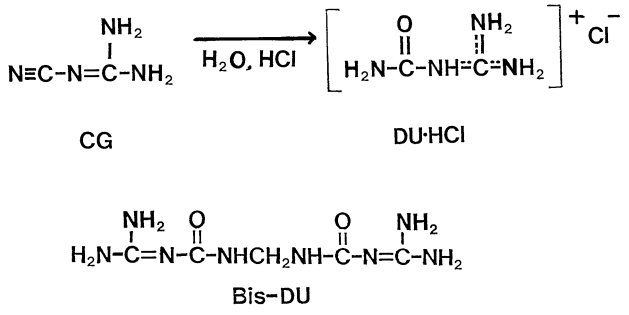
(Received March 7, 1991)

The coagulation of anionic colloidal particles by the cyanoguanidine (CG)–formaldehyde resin has been reported to be caused by an electrostatic interaction of the (diaminomethylene)urea (DU) cation with an anionic surface charge of particles. Our results show that neither DU·HCl nor di-hydrochlorides of *N*,*N*'-methylenebis [*N*'-(diaminomethylene)urea] (Bis-DU·2HCl), itself, nor the resinous products of DU·HCl or Bis-DU·2HCl with formaldehyde, are such effective coagulating agents as the CG–formaldehyde resin and are not explicable only in terms of the electrostatic interaction. Gel-permeation chromatograms of the resins have revealed that the coagulation efficiency increased in proportion to the increase of the fraction of components having higher molecular weight, suggesting that components having higher molecular weight play an important role in coagulation due to the CG–formaldehyde resin.

The resinous products of cyanoguanidine (CG) with formaldehyde under acidic conditions are useful as commercial coagulating agents.[1] The reaction of CG with formaldehyde under acidic conditions is complicated, since the transform of CG into (diaminomethylene)urea (DU) is simultaneously accompanied by the hydroxymethylation and codensation of CG with formaldehyde, as well as the hydroxymethylation and condensation of DU with formaldehyde.[2-6] The coagulation of anionic colloidal particles by CG–formaldehyde resin (CG-resin) has since been explained to be due caused by neutralization of surface charge with cationic DU.[7] However, the detailed mechanism of coagulation has not yet been solved.

In order to elucidate the coagulation mechanism, the composition of the CG-resin was analyzed by gel-permeation chromatography under various conditions, together with those resinous products of DU·HCl and di-hydrochlorides of *N*,*N*'-methylenebis [*N*'-(diaminomethylene)urea] (Bis-DU·2HCl) with formaldehyde, which are hereafter referred to as the DU·HCl-resin and Bis-DU·2HCl-resin. The amounts of formaldehyde bound to DUs or released from the CG-resin by acid-hydrolysis were quantitatively measured, as well as the viscosity change, in order to confirm the reactions. The relationship between the distribution of the molecular weight of these resins and the coagulation efficiency was analyzed.



Scheme 1.

Results and Discussion

Since CG was easily converted into DU·HCl by reacting it with equimolar H_2O and HCl, the CG-resin was considerd to have an analogous structure to that of the DU·HCl-resin. However, the reaction patterns of CG+HCl and DU·HCl with formaldehyde were different from each other. Figure 1 shows the time courses of the reaction of formaldehyde with CG- and DU·HCl-resins, respectively. A linkage of $-CH_2-O-CH_2-$ was scarcely formed in both resins. The amont of formaldehyde reacted tended to be underestimated when determined through iodometry, due to the formation of an insoluble product. More formaldehyde reacted with CG than with DU·HCl, and was incorporated to the methylene moiety of resious products. The amounts of the bound formaldehyde in the CG-resin increased for 2—3 h and were nearly saturated at 3 h. Gel-permeation chromatograms of CG- and DU·HCl-resins, as shown in Fig. 2, revealed that the CG-resin was enriched with components having higher molecular weight, compared with that of other resins. This was supported by the fact that the solution of the CG-resin is more viscous than that of the DU·HCl-resin. The distribution of molecular weight ranges from 200 to 1200 for the CG-resin which is wider than 150—400 for the DU·HCl resin. A similar result was also obtained when a Shodex Q801 column was used instead of TSK gel columns.

The results concerning the coagulation measurement

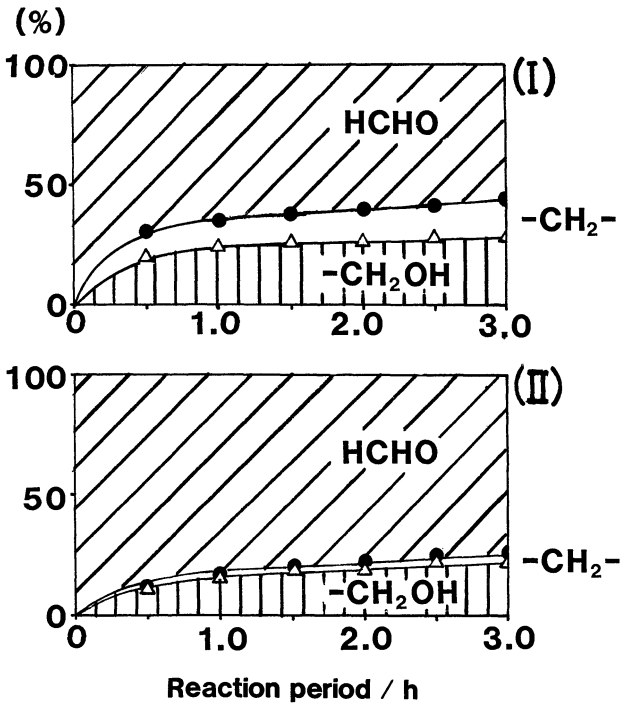


Fig. 1. Time courses of the reactions of cyanoguanidine (CG) and hydrochloride of (diaminomethylene)-urea (DU·HCl) with formaldehyde at 70°C. (I) CG+Formaldehyde+HCl=(1/2/1), (II) DU·HCl+Formaldehyde=(1/2). At 30-min intervals, aliquots of the reaction solutions were withdrawn, and the amounts of several types of formaldehyde were analysed by the Na_2SO_3 method (A) and the iodometry (B). ▨: HCHO=(A), ▥: $-CH_2OH$=(B)−(A), □: $-CH_2-$= (initial amount of formaldehyde)-(B).

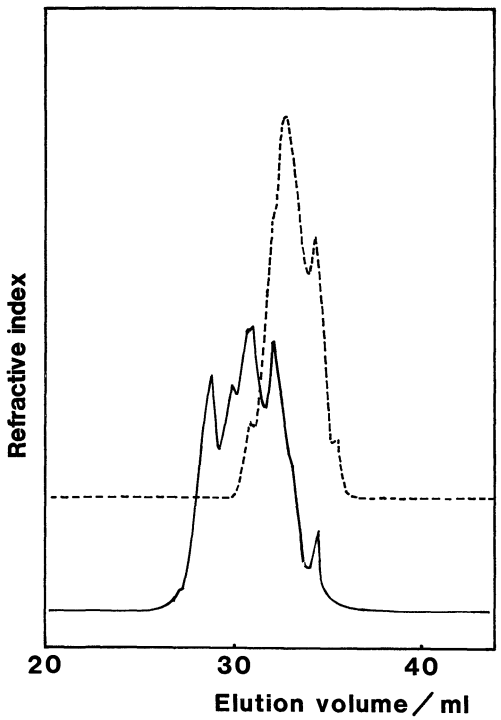

Fig. 2. Gel-permeation chromatograms of the CG- and DU·HCl-resins on combination columns comprising TSK gel $G2500PW_{XL}$ and $G3000PW_{XL}$. The resinous products of CG+Formaldehyde+HCl=(1/2/1)(—) and DU·HCl+Formaldehyde=(1/2)(----), were eluted by a mixed solution of 0.5 mol dm^{-3} acetic acid and 0.5 mol dm^{-3} sodium acetate (1:1) at 40°C.

are summarized in Fig. 3. Neither DU·HCl nor Bis-DU·2HCl, itself, nor the DU·HCl- or Bis-DU·2HCl-resin was such an effective coagulating agent as the CG-resin. Particles of Kaolin having anionic charges were also coagulated by these resins, which were virtually idnetical to polystyrene latex. These results were not explicable in terms of only the mechanisms hitherto presented, that the DU and/or Bis-DU cations should play decisive roles in the coagulation process of latex particles by the CG-resin. This suggests that the components having higher molecular weight in the CG-resin play an important role in the coagulation (flocculation) of latex particles. This was supported by the fact that the flocculation efficiency is improved with an increase of the fraction of components having higher molecular weight, that is, the flocculation efficiency of the CG-2.0F-HCl resin is superior to that of the CG-1.0F-HCl or CG-0.5F-HCl resin.

In order to obtain a clue for elucidating the structure of the CG-resin, its absorption spectrum in the UV region and ^{13}C NMR spectrum were measured. The CG-resin was acid-hydrolyzed under the same conditions as described in the experimental section. While the spectrum of the solution of CG was not affected by the pH, that of DU·HCl was different between acidic and alkaline pH. The spectrum of a solution of the CG-resin resembled that of DU (Fig. 4), suggesting that CG might be transformed into DU during the early stage of resinification. The ^{13}C NMR spectrum of the CG-resin also elucidated an early transformation of CG into DU, since the signal of δ=115.9 (-CN) disappeared and a new signal of δ=150.9 ($-CO-NH_2$) appeared during the early stage of resinification.

As shown in Fig. 5, the released formaldehyde molecules were classified into three categories, as described in the experimental section. The CG-resin has three types of methylene moieties, such as =C(NHR)-NH-CH_2-NH-C(NHR)=, -CO-NH-CH_2-NH-CO-, and =C(NHR)-NH-CH_2-NH-CO-.

These results suggested that the CG-resin has the structure of DU as the mother structure, and comprises a mixture of various condensates having three types of the methylene moieties. Our results suggest that the coagulation of anionic colloidal particles by the CG-formaldehyde resin is not explicable only in terms of its cationic charge, and that the components of the CG-formaldehyde resin having higher molecular weight are considered to play an important role in coagulation (fluocculation).

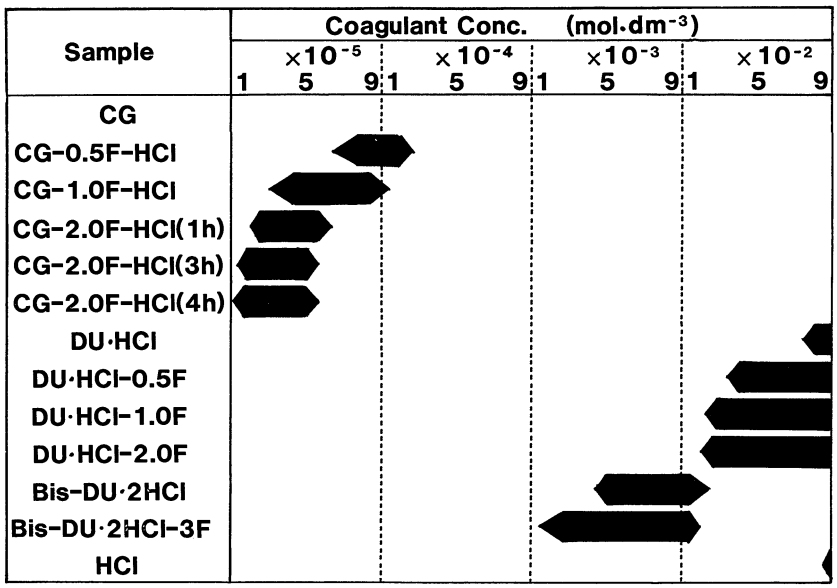

Fig. 3. Coagulation of polystyrene latex by CG, DU·HCl, Bis-DU·2HCl, and their resinous products with formaldehyde. Polystyrene latex: radius, 0.8—1.0 μm; final concentration 0.1%. The length and width of the band simultaneously represent the range of the concentration and the strength of the coagulating activity. CG-0.5F-HCl, CG-1.0F-HCl and CG-2.0F-HCl represent the resinous products of CG with formaldehyde (F) under acidic conditions (the feed mole ratios: CG/F/HCl=1/0.5/1, 1/1/1 and 1/2/1, respectively). DU·HCl-0.5F, DU·HCl-1.0F, DU·HCl-2.0F, and Bis-DU·2HCl-3.0F are the resinous products of DU·HCl/F=0.5, 1/1, and 1/2 and Bis-DU·2HCl/F=1/3, respectively. These products were obtained from the reactions for 4 h, unless otherwise noted.

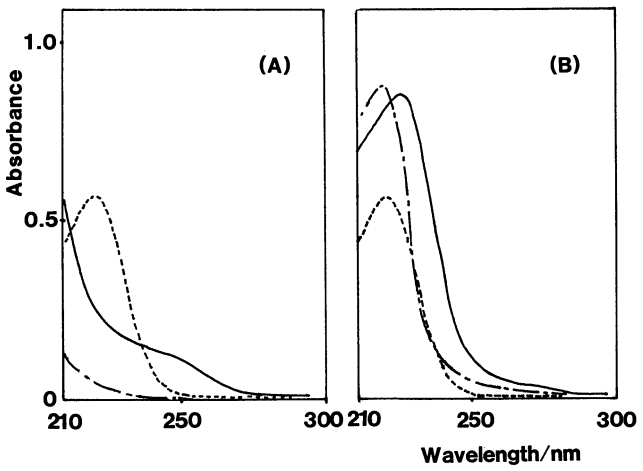

Fig. 4. UV spectra of CG, DU·HCl and the CG-resin under acidic and alkaline conditions. (A) Acidic: in 0.1 mol dm^{-3} HCl soln. (B) Alkaline: in 0.1 mol dm^{-3} aq NaOH soln. CG, ----: DU·HCl, —·—·: the CG-resin, ——. The CG-resin was prepared from CG and formaldehyde (CG/F/HCl=1/2/1) at 70°C for 4 h.

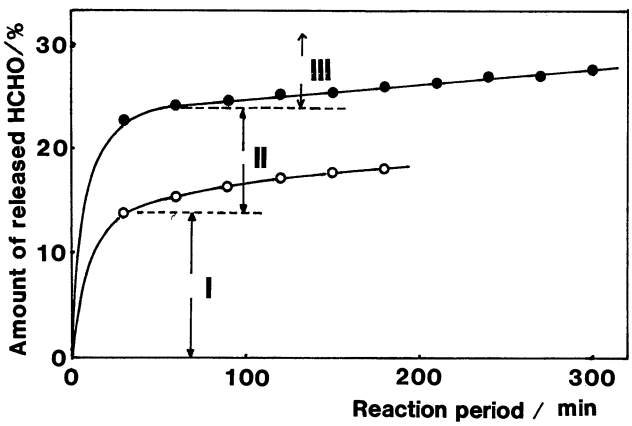

Fig. 5. Acid-hydrolysis of the CG-resin. The CG-resin used was the same as described in Fig. 4. The amounts of the released formaldehyde molecules were determined colorimetrically by the use of acetylacetone. The aq 1% solution of the CG-resin was hydrolyzed in 1.0 mol dm^{-3} HCl at 50°C (—○—) and in 1.0 mol dm^{-3} H_2SO_4 at 90°C (—●—). The numerals, I, II, and III each represents the type of released formaldehyde. I, the hydroxymethyl group: II, the methylene moiety in =C(NHR)-NH-CH_2-NH-C(NHR)= and/or in =C(NHR)-NH-CH_2-NH-CO-: III, the methylene moiety in -CO-NH-CH_2-NH-CO-.

Experimental

Preparation of Bis-CG, Bis-DU, and Resins. Bis(*N'*-cyanoguanidino)methane (Bis-CG) and Bis-DU were prepared by the same procedures already described.[8-10] Various CG-, DU·HCl-, Bis-DU·2HCl-resins were prepared by varying the reaction conditions, such as the feed mole ratios of CG, DU·HCl, Bis-DU·2HCl/formaldehyde, reaction temperature, and reaction periods. The typical preparations for CG- and DU·HCl-resins were as follows.

CG-resin: Forty two grams (0.5 mol) of CG were added to a mixture of 75 ml of 37% formalin (neuralized) (1.0 mol formaldehyde) and 66.3 ml of distilled water. After CG was thoroughly dissolved, 85.2 ml of 6 mol dm^{-3} HCl were added dropwise to the solution, the temperature of which was kept at 70 °C for 4—6 h.

DU·HCl-resin: The preparation procedure for DU·HCl-resin was virtually identical with that for CG-resin except for 69.4 g of DU·HCl and 75.7 ml of distilled water were used instead of 42 g of CG and 66.3 ml of distilled water.

Determination of Amounts of Formaldehyde. (I) Formaldehyde in the Reaction Solution. At 30 min intervals, aliquots of the solution were withdrawn, and the amounts of formaldehyde were determined by the Na_2SO_3 method (A) and iodometry (B). Residual amounts of formaldehyde (HCHO in Fig. 1)=(A); the amounts of formaldehyde in hydroxymethyl groups (-CH_2OH in Fig. 1)=(B)−(A); the amounts of formaldehyde incorporated into the form of methylene moiety (-CH_2- in Fig. 1)=(the initial amount of formaldehyde)−(B) were calculated.

(II) Formaldehyde in the Acid Hydrolysates. In order to obtain a clue to the structure of resins, a few standard samples (Bis-CG, Bis-DU and their hydroxymethyl derivatives) and resins were acid-hydrolyzed with 1.0 mol dm^{-3} HCl at 50 °C or 1.0 mol dm^{-3} H_2SO_4 at 90 °C and the amounts of formaldehyde were determined colorimetrically by the use of acetylacetone.[11] Further details were the same as described in our previous paper.[8] From the results on the standard samples the released formaldehyde molecules were classified into three categories, as follows: The most easily released formaldehyde (type I), from the hydroxymethyl groups; the moderately released ones (type II), from the methylene moiety in =C(NHR)-NH-CH_2-NH-C(NHR)=; and the ones hard to release (type III), from the methylene moiety in -CO-NH-CH_2-NH-CO-.

The Measurement of the Coagulation Efficiency. To carry out the coagulation measurement, 10 ml of a colloidal solution of 0.1% of polystyrene latex of 0.8—1.0 μm radius (or 25 ml of 600 mg dm^{-3} of Kaolin having anionic charges) and the resinous products solution containing 10^{-6}—10^{-2} mol dm^{-3} (the final concentration) were introduced to a stoppered test tube; the total volume was then adjusted to 20 ml (or 50 ml). The depth of the supernatant over the suspended layer was measured at 10-min intervals for 2 h. The coagulation efficiency of the resinous products was evaluated in terms of their minimum concentration in which the most rapid coagulation occurred.

Gel-Permeation Chromatography. A chromatographic separation of an aliquot of the resinous products was carried out on a combination columns comprising TSK gel G2500PW_{XL} and G3000PW_{XL}, eluting by the mixed solution of 0.5 mol dm^{-3} acetic acid and 0.5 mol dm^{-3} sodium acetate (1 : 1) at 40 °C. The molecular weight of the components of the resins were estimated by calibration curves with polyethylene glycol.

^{13}C NMR Spectrometry. The NMR spectra of the products were measured in a D_2O solution with dioxane as the internal standard at 90 MHz on a JOEL FX 90Q instrument.

The authors wish to thank Dr. Takaaki Arai of Nihon University for generous gift of polystyrene latex.

Effect of Anions on the Epoxidation of Styrenes with H_2O_2 in the Presence of Ammonium Heptamolybdate(VI)-Dioctyltin Oxide Catalysts

Masami INOUE,* Eiichi NAKAYAMA, Yuuko NAKAMURA, Seichi RENGAKUJI, and Keiichi NISHIBE
Faculty of Engineering, University of Toyama, Gofuku, Toyama 930
(Received May 18, 1991)

The epoxidation of styrene, α-methylstyrene, β-methylstyrene, *p*-chlorostyrene, and *m*-divinylbenzene with H_2O_2 in the presence of ammonium heptamolybdate(VI)–dioctyltin oxide catalysts in $CHCl_3$–H_2O was studied. The addition of neutral salts, such as $NaNO_3$ or Na_2SO_4, to the catalyst system prevented the successive hydration of styrene oxide once formed. The presence of KCl or NaCl almost suppressed the oxidation, while no substantial effect was observed in $NaClO_4$. The various effects of these anions were related to the results concerning the coordination of anions to Mo(VI)-ions.

The epoxidation catalysts and agents for alkenes provided various kinds of epoxides.[1] Among those, styrene oxide and its derivatives are useful materials for polymer chemistry and organic synthesis. The use of aqueous H_2O_2 as an oxidation agent is easy to handle and clean since H_2O_2 is reduced to give water. In our present reaction conditions, the hydration of styrene oxide to 1-phenyl-1,2-ethanediol was a chief side reaction.

Previously, we proposed ammonium heptamolybdate-(VI)–dioctyltin oxide catalysts for the selective epoxidation of styrene as well as aliphatic alkenes with H_2O_2 in $CHCl_3$–H_2O.[2] In this two-layer solvent system, a longer reaction time (24 h) decreased the yield of styrene oxide after reaching a maximal yield. During the investigation of the effect of anions on the catalytic activity, we found that the addition of a small amount of neutral salts, such as $NaNO_3$ or Na_2SO_4, prevented the hydration of styrene oxide. On the other hand, in the case of KCl and NaCl, the rate of oxidation was decreased remarkably.

In this report, the epoxidation of styrene, α-methylstyrene, β-methylstyrene, *p*-chlorostyrene, and *m*-divinylbenzene was carried out and the effect of anions was studied from the standpoint of the activity of catalysts and the selectivity in epoxide formation.

Experimental

Materials. Styrene (Wako Pure Chemicals Co.), α-methylstyrene, β-methylstyrene, *p*-chlorostyrene, *m*-divinylbenzene (Tokyo Kasei Co.), and dioctyltin oxide (Kyodo Yakuhin Co., Tokyo) were used as received. Aqueous 60% H_2O_2 was kindly supplied from Tokai Denka Kogyo Co., Tokyo. KCl was used after twice recrystallizations. Neutral salts and other materials of GR grade were used for this experiment.

General Procedures. In a 300 ml round-bottom flask equipped with a condenser, the catalyst was prepared in situ by mixing ammonium heptamolybdate(VI) (0.57 mmol), neutral salts (4.8 mmol in H_2O 8.0 ml), and dioctyltin oxide (8.0 mmol). The reaction was carried out by the addition of $CHCl_3$ (8 ml), styrenes (350 mmol), and H_2O_2 (318 mmol) under stirring with TEFLON (poly(tetrafluoroethylene))-covered magnetic stirring bar at 30 °C in a thermostatted water bath. Dioctyltin oxide, dispersed in $CHCl_3$, gradually dissolved and the reaction was started. At intervals, a small portion (0.5 ml) was pipetted out of the $CHCl_3$-layer and diluted with $CHCl_3$ (5 ml). To the solution was added *m*-xylene in acetonitrile solution (0.5 ml) as an internal standard.

Gas-liquid chromatography (GLC) was carried out on a Shimadzu GC-8A instrument using a glass column (2 m) packed with a 2%-Silicone OV-17 (2 m) under programmed oven temperature from 50 to 150 °C (3 °C min^{-1}). In the case of divinylbenzene, the temperature range from 50 to 230 °C (4 °C min^{-1}) was used. In the preparation of authentic epoxides, styrene, α-methylstyrene, β-methystyrene, *p*-chlorostyrene, and *m*-divinylbenzene were oxidized with *m*-chloroperbenzoic acid (mcpba) according to a method described in the literature,[3] and the corresponding epoxides were obtained by column chromatography (Kieselgel 60, Merck Co.) with pentane followed by pentane–diethyl ether (2:1) as eluents. The purities of these epoxides were 85 to 95% according to GLC analysis. The *m*-divinylbenzene monoepoxide separated from the solution was unstable and polymerized upon standing at room temperature for a few days.

Results and Discussion

Effect of Salts in the Epoxidation of Styrene. The oxidation of styrene with H_2O_2 was carried out in a two-phase solvent of $CHCl_3$–H_2O in the presence of ammonium heptamolybdate(VI)–dioctyltin oxide and an equivalent amount of such neutral salts as $NaNO_3$, Na_2SO_4, $NaClO_4$, KCl, or NaCl to Mo(VI) ions. In the absence of salts, the yield of styrene oxide reached a maximum of 60% after 8 h; further reaction (24 h) gradually decreased the yield to as low as a 34%.

Figure 1 shows the time course of the epoxidation of styrene with H_2O_2 in the presence of various salts. The addition of these salts changed the color of the aqueous layer from yellow to orange. When such salts as Na_2SO_4 or $NaNO_3$ were added, the hydration of styrene oxide, once formed, was delayed.

Unexpectedly, although the addition of NaCl and KCl

Salts	Initial rate / mol l^{-1} s^{-1}
None	2.9×10^{-2}
ClO_4^-	2.8×10^{-2}
SO_4^{2-}	1.6×10^{-2}
NO_3^-	1.3×10^{-2}
Cl^-	ca. 0

a) **1** (350 mmol), 60% H_2O_2 (318 mmol), $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (0.57 mmol), dioctyltin oxide (8 mmol), salts (4.8 mmol in H_2O 8 ml), and $CHCl_3$ (40 ml) were used.

strongly suppressed the oxidation, the presence of NaBr and NaI decomposed H_2O_2 vigorously. In the case of $NaClO_4$, no substantial effect upon the yield of epoxide was observed.

Phenylacetaldehyde as a by-product was not found in our reaction products when GLC was carried out on a glass column packed with PEG (2m) with the programmed oven temperature from 50 to 150°C (3°C min^{-1}).

The effect of salts was confirmed quantitatively by taking the initial rates for the oxidation to styrene oxide (Table 1). In all experiments, the selectivities to styrene oxide were >90%, except during the initial stage of a reaction lower than 10% conversion. The rates of epoxidation considerably differed depending on the kinds of anions, as shown by the following order:

$$H_2O,\ ClO_4^- > SO_4^{2-} > NO_3^- > Cl^-.$$

This tendency, except for ClO_4^-, was in accord with that of well-known spectrochemical series observed in the spectral shifts of metal complexes in the presence of various anions.[4] Although the precise structure of Mo(VI) complexes in solution is still unknown, it was supposed that anions such as SO_4^{2-}, NO_3^-, or Cl^- are tightly coordinated on Mo(VI) ions and affected both the oxidation of styrene and the hydration of styrene oxide by decreasing the Lewis acidity of the catalyst. From a practical standpoint, the addition of Na_2SO_4 or $NaNO_3$ is usable as a kind of stabilizer of styrene oxide.

It was interesting that the addition of KCl to Mo(VI) ions in a 1:1 ratio almost suppressed the oxidation. The oxidation rate was decreased in proportion to the amount of KCl to Mo(VI) ions. Figure 2 shows a linear relationship between the initial rate of the oxidation and the amount of KCl to Mo(VI) ions. The extrapolation of the rate of oxidation to zero velocity gave the ratio of KCl:Mo(VI) ion =1:4.

Therefore, from the obtained results, two possible cases were considered. In the first, the amount of active species was only 1/4 of ammonium heptamolybdate(VI) used. The other case was that one active complex molecule was formed from four Mo(VI) ions. In any case, tightly coordinated Cl^- on Mo(VI) ions decreased the activity for the oxidation of styrene. From the obtained results, we supposed that these anions, except ClO_4^-, are also coordinated on Mo(VI) ions as a ligand.

Effect of Salts in the Epoxidation of Styrene Derivatives. The effect of salts on the stabilization of epoxide was also examined for several styrene derivatives. As shown in Table 2, the addition of $NaNO_3$ also stabilized β-methylstyrene oxide and *m*-divinylbenzene monoepoxide. On the other hand, under our reaction conditions,

Table 2. Effect of $NaNO_3$ on the Epoxidation of Styrene Derivatives with H_2O_2[a)]

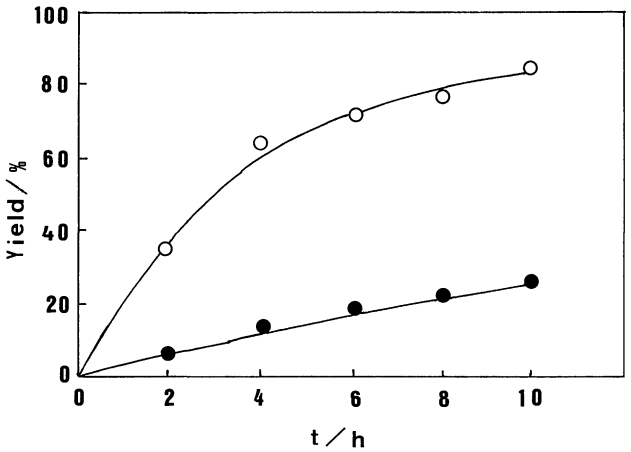

Fig. 3. Effect of stirring on the epoxidation of styrene (**1**) at 30°C,[a)] ○; under stirring, ●; without stirring, a) **1** (394 mmol), 60% H_2O_2 (187 mmol), $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (0.57 mmol), dioctyltin oxide (8 mmol), $NaNO_3$ (4.8 mmol in H_2O 5 ml), and $CHCl_3$ (45 ml) were used. Yields were based on H_2O_2.

α-methylstyrene oxide and *p*-chlorostyrene oxide, once formed, were sufficiently stable, even under a lack of such salts as $NaNO_3$ or Na_2SO_4. In the case of *m*-divinylbenzene, the oxidation was almost stopped when one of two vinyl groups was oxidized.

The effect of the concentration of styrene or H_2O_2 upon the epoxidation rate also gave information concerning the Mo(VI) complexes under oxidation: The rates were approximately first-order with respect to both the styrene and H_2O_2 concentrations. Therefore, the coordination of these substrates to Mo(VI) ions might be very weak. The stirring procedure (150 rpm) increased the oxidation rate by as large as 6 times (Fig. 3). The evaporation of water from the aqueous layer of the reaction solution gave ammonium heptamolybdate(VI) as yellow crystals, while a pale-yellow syrup of organotin compounds was obtained from the $CHCl_3$ layer. However, both of the separated compounds were inactive for epoxidation.

In our catalyst system, the instability of styrene oxide and the denaturalization of Mo(VI) complexes were serious drawbacks. The former could be improved with a slight sacrifice of the catalyst activity by the addition of salts, such as $NaNO_3$ or Na_2SO_4.

The present work was supported in part by The Tamura Foundation for Encouragement of Science and Technology.

Direct Synthesis of Trimethoxysilane from Methanol and Hydrogen-Treated Silicon Using Copper(II) Chloride as a Catalyst

Eiichi SUZUKI, Takatsugu KAMATA, and Yoshio ONO*
Department of Chemical Engineering, Tokyo Institute of Technology,
2-12-1 Ookayama, Meguro-ku, Tokyo 152
(Received April 9, 1991)

Synopsis. When silicon, on which copper(II) chloride was supported, was pretreated under a hydrogen stream at 533 K and brought in contact with methanol at 533 K, trimethoxysilane was formed with an 89% selectivity and a complete silicon conversion in 5.5 h. Pits were formed on the silicon surface, and grew with increasing silicon conversion.

Trimethoxysilane is an important chemical, since various organosilicon compounds can be derived by the reactions of trimethoxysilane and organic compounds. By using a copper compound as a catalyst, trimethoxysilane has been obtained selectively from silicon and methanol. A selectivity of 80—90% for trimethoxysilane has been attained by adding methanol dropwise into a suspension of silicon and copper(I) chloride[1] or copper(II) hydroxide[2] in e.g. dodecylbenzene. By passing methanol vapor through a mixture of silicon–copper(I) chloride–zinc[3] or that of silicon–copper(I) chloride,[4] which was pretreated at 623 K, trimethoxysilane with a selectivity of 84—98% was also yielded.

It is presumed that the reduction of copper(I) chloride powder by silicon (Eq. 1) at the pretreatment stage is involved in the formation of active sites in a silicon–methanol reaction,[3,4] just as in the direct synthesis of methylchlorosilanes from methyl chloride and silicon–copper(I) chloride mixture:[5-8]

$$4\,CuCl + Si \longrightarrow 4\,Cu + SiCl_4. \quad (1)$$

The copper thus formed in the atomic form must be very reactive towards silicon to form the alloy on the silicon surface. Copper compounds other than copper(I) chloride can therefore be used as a catalyst if they can be reduced to the active form.

This work concerns a direct synthesis of trimethoxysilane from silicon and methanol in which a copper-based catalyst is supported on silicon. Copper(II) chloride is chosen as the catalyst since it dissolves in methanol. We wish to report here that if the silicon–copper(II) chloride is pretreated under a hydrogen stream, a complete reaction of silicon with methanol to yield trimethoxysilane with high selectivity can be attained.

Experimental

Silicon (Soekawa Chemical Co., Ltd., 99.5% in purity) was used without any cleaning. The silicon was sieved into grains of 45-63 μm, washed with water, and immersed in a methanol solution of copper(II) chloride (Kanto Chemical Co., Inc., guaranteed reagent grade). Evaporation of methanol at room temperature gave a "silicon–copper(II) chloride contact mass", a 0.5 g portion of which was loaded in a fixed-bed flow reactor. After the pretreatment at 533—723 K for 1 h under a helium or hydrogen stream, methanol was fed at 533—553 K by a motor-driven syringe at a rate of 87 mmol h^{-1}. The effluent gas was analyzed automatically every 2.5 min with a gas chromatograph (2 m-long SE-30 column).

Scanning electron micrographs (SEM) were taken using a Hitachi S-510 instrument with an acceleration voltage of 25 kV.

Results and Discussion

Silicon grains both before and after copper(II) chloride (Cu=2.5 wt.%) was supported were examined by a scanning electron microscopy. The silicon grains exhibited a rather smooth surface (Fig. 1a), while each grain of the contact mass had deposits of copper(II) chloride, as exemplified in Fig. 1b.

The formation of copper from the silicon–copper(II) chloride contact mass may be facilitated by hydrogen during the pretreatment stage, since hydrogen may reduce copper(II) chloride directly to copper or copper(I) chloride, which then undergoes reduction to copper, according to Eq. 1. Such an efficient conversion of copper(II) chloride to copper would lead to an enhanced

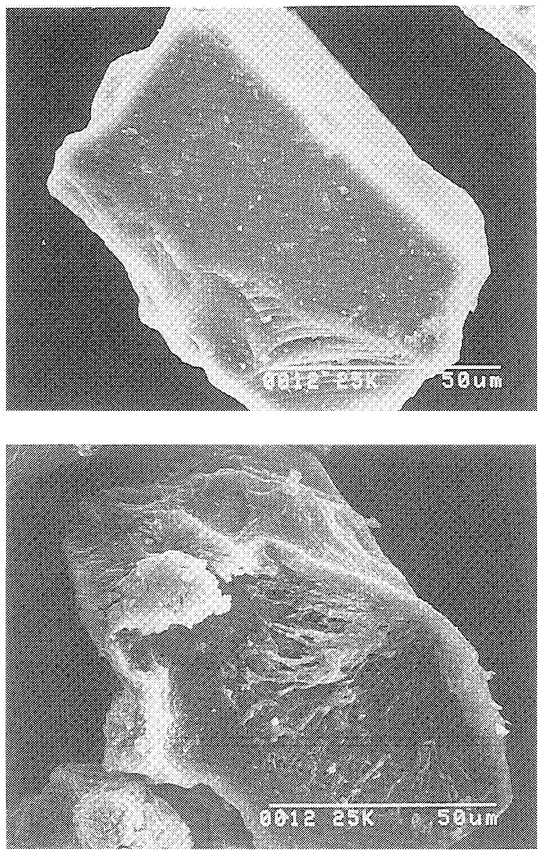

Fig. 1. Scanning electron micrographs of silicon and the silicon–$CuCl_2$ contact mass. Silicon (a), silicon–$CuCl_2$ contact mass (Cu=2.5 wt.%) (b). At 1000 magnifications.

reactivity of silicon. Then, the silicon–copper(II) chloride contact mass (Cu=2.5 wt%) was pretreated under a hydrogen stream at several temperatures (533—723 K) and tested for a reaction with methanol at 533 K. The enhancing effect of the hydrogen-pretretreatment on the reactivity of silicon is striking when the pretreatment is carried out at 533 K. Thus, with the hydrogen-pretreatment, a complete silicon conversion was attained in a reaction time of 5.5 h (Fig. 2a); with the helium-pretreatment, however, only 56% silicon conversion was obtained.

In Fig. 3, the rates of formation of methoxysilanes ($(CH_3O)_3SiH$+$(CH_3O)_4Si$) are plotted against the reaction time. For a pretreatment at 533 K, after an induction period the rate increased and attained a maximum beyond which it decreased, the silicon conversion attaining 100% in 5.5 h. With increasing temperature of the hydrogen-pretreatment, the induction period became shortened and eventually disappeared, and the conversions of silicon to methoxysilanes decreased. The silicon conversion at 5 h was 72, 35, and 4% at 573, 623, and 723 K of the pretreatment temperature, respectively.

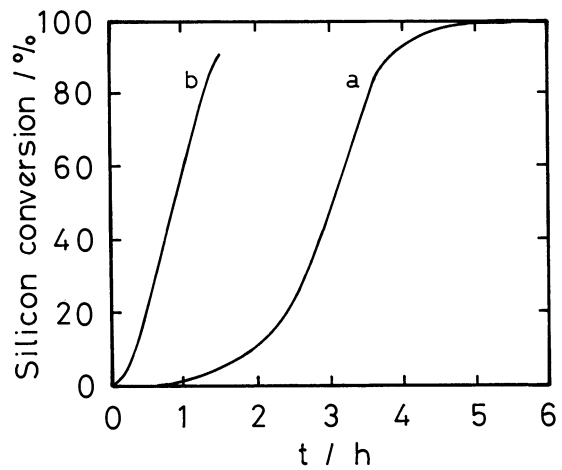

Fig. 2. Change in the cumulative silicon conversion with the reaction time. Pretreatment conditions: Silicon–$CuCl_2$ contact mass (Cu=2.5 wt.%) was pretreated under a hydrogen stream at 533 K (a) and 553 K (b) for 1 h. Reaction conditions: Reaction temperature=533 K (a) and 553 K (b), and CH_3OH= 99 kPa.

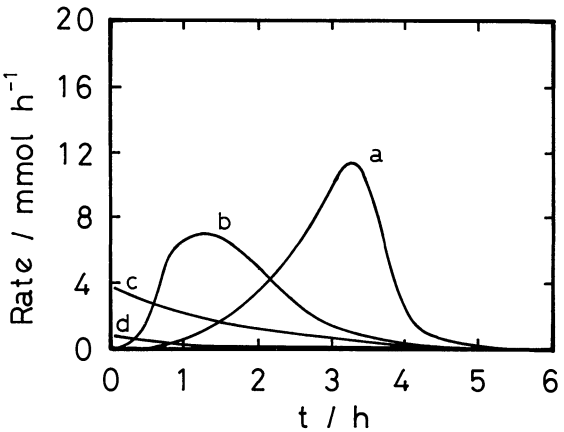

Fig. 3. Effect of hydrogen-pretreatment temperature on the change in the rate of formation of methoxysilanes ($(CH_3O)_3SiH$+$(CH_3O)_4Si$) with reaction time. Pretreatment conditions: Silicon–$CuCl_2$ contact mass (Cu=2.5 wt%) was pretreated under a hydrogen stream at 533 K (a), 573 (b), 623 K (c), and 723 K (d) for 1 h. Reaction conditions: Reaction temperature=533 K and CH_3OH=99 kPa.

We suppose that hydrogen facilitates the formation of copper on the silicon surface and that such a lower pretreatment temperature as 533 K is favorable for avoiding the agglomeration of the atomic copper and thus for the efficient reaction of the copper with silicon to form active sites for silicon–methanol reaction. A change in the morphology of the contact mass by the hydrogen-pretreatment at 533 K, however, was not detected by a SEM examination.

The selectivity for trimethoxysilane averaged over 5 h was 89, 93, 96, and 94% for pretreatments at 533, 573, 623, and 723 K, respectively.

A very efficient conversion of silicon was achieved at a higher reaction temperature of 553 K. Here, the contact mass (Cu=2.5 wt.%) was pretreated under a hydrogen stream at 553 K. Thus, as shown in Fig. 2b, in only a reaction time of 1.5 h, the silicon conversion attained 91%, the selectivity for trimethoxysilane averaged over the reaction time being 90%.

The change in the morphology of the reacting silicon grains with various levels of silicon conversion was examined. The silicon–copper(II) chloride contact mass (Cu=2.5 wt.%) was pretreated under a hydrogen stream at 533 K for 1 h and brought into contact with methanol vapor at 533 K for 0.6, 1, 3, and 4 h, the silicon conversion being 0.1, 1, 48, and 95%, respectively. The SEM images of the samples are shown in Fig. 4. A striking change in the morphology of silicon grains upon exposure to methanol was observed. Thus, the sample with a 0.1% of silicon conversion contained silicon grains with a pit, as exemplified in Fig. 4a.

With an increase in the silicon conversion, the number of silicon grains having detectable pits increased; silicon grains with irregular outlines accounted for the majority part of silicon grains, as shown Figs. 4b—d. The size of the pits develops with increasing silicon conversion. The silicon–methanol reaction does not occur uniformly on the silicon surface, but starts at areas scattered on the surface. The observation of pits on the silicon surface has a similarity to that in a silicon–methanol[9] or –methyl chloride[7,8] reaction using powdered copper(I) chloride as a catalyst, where active-site formation at the defects or pinholes of SiO_2 overlayer is postulated.

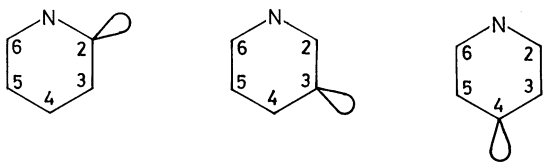
Ab Initio Study of Pyridyl Cations, Anions, and Radicals

Osamu KIKUCHI,* Yuji HONDO, Yukihiro YOKOYAMA, Kenji MORIHASHI, and Mitsunobu NAKAYAMA
Department of Chemistry, University of Tsukuba, Tsukuba 305
(Received April 26, 1991)

Synopsis. Ab initio calculations were carried out for the 2-, 3-, and 4-pyridyl cations, anions, and radicals in order to examine their molecular structures and relative energies among three isomers. The 4-31G//3-21G calculations have predicted that 2-pyridyl cation, 4-pyridyl anion, and 2-pyridyl radical are most stable among the isomers.

Pyridyl is derived formally from pyridine by the CH bond cleavage, and three types of species, cations, anions, and radicals, exist depending on the number of electrons involved in the carbon centered orbital. For the radical, 2-, 3-, and 4-pyridyl radicals have been detected by ESR,[1,2] and the reactivity of 2-pyridyl has been discussed.[3] The pyridyl anions and cations have been considered as the intermediates in chemical reactions.[4-7] Only a few theoretical works have been reported on these species.[8,9] In this note, we report the molecular and electronic structures of pyridyl cations, anions, and radicals determined by ab initio calculations and compare the relative stability among the 2-, 3-, and 4-isomers.

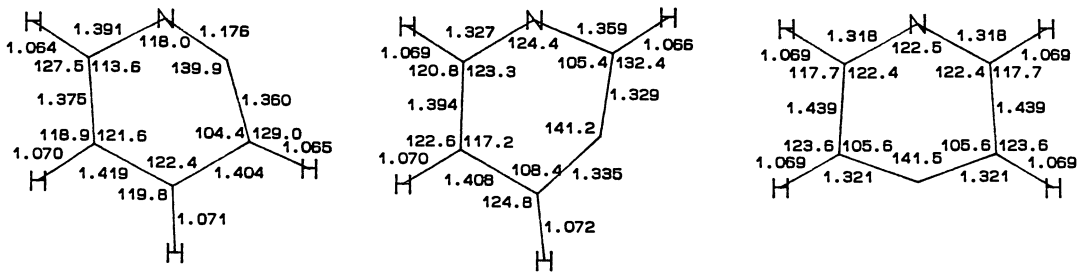


2 3 4

The closed-shell SCF method was used for the cations and anions, while the open-shell RHF method was used for the radicals. The molecular structures were optimized with the 3-21G basis set[10] under the restriction of the planarity for all species. All calculations were carried out using ABINIT program written in our group. The optimized molecular structures are shown in Figs. 1—3 and the relative energies among the isomers are listed in Table 1.

Pyridyl Cations. The calculated bond angles at the cationic carbon center of pyridyl cations are almost constant, 140°—142°, in three isomers. These bond angles are close to that calculated for the phenyl cation by Bernardi et al.[11] as is shown in Fig. 4-b. Since 2-pyridyl cation is isoelectronic with *o*-benzyne, it is interesting to compare the structures between them. Fig. 4-c is the structure of *o*-benzyne reported by Scheiner et al.[12] As may be seen from Fig. 4-c, the distortion of the carbon skeleton from hexagon is not large in *o*-benzyne, while a significant distortion is observed in the 2-pyridyl cation. This is due to the large bond angle at the carbon center in 2-pyridyl cation which is adjacent to the nitrogen atom and has the strong cationic character.

The 2-pyridyl cation is calculated to be more stable than the other isomers. This may simply be understood by the interaction between the cationic center and the nitrogen lone-pair electrons in 2-pyridyl. In spite of this large interaction, the large positive charge remains at the cationic carbon atom in 2-pyridyl; the value of +0.704



2 3 4

a) Values in parentheses are relative energies among three isomers in kcal mol^{-1}.

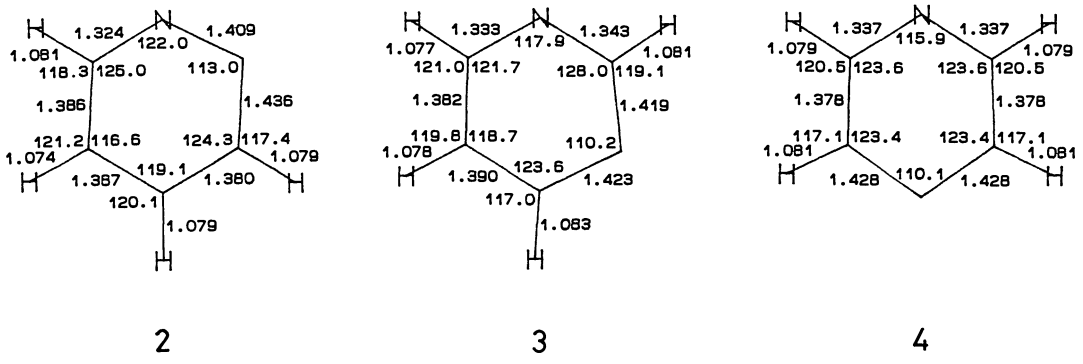

Fig. 2. Molecular structures of pyridyl anions optimized with the 3-21G basis set. Bond lengths are shown in Å and bond angles are in degrees.

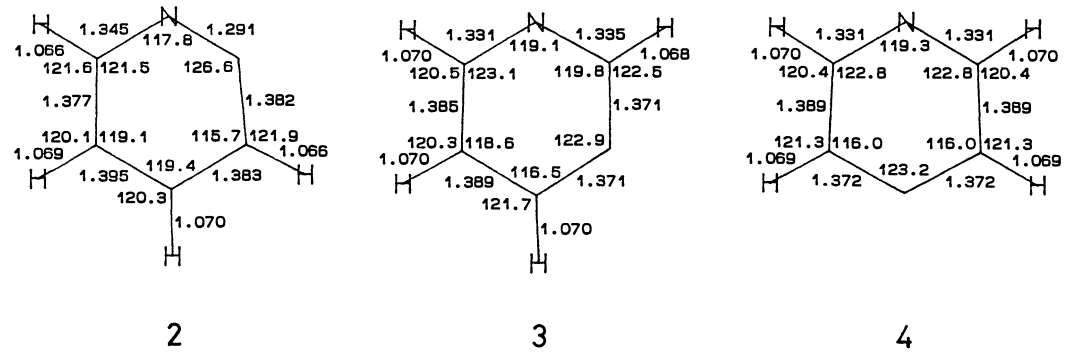

Fig. 3. Molecular structures of pyridyl radicals optimized with the 3-21G basis set. Bond lengths are shown in Å and bond angles are in degrees.

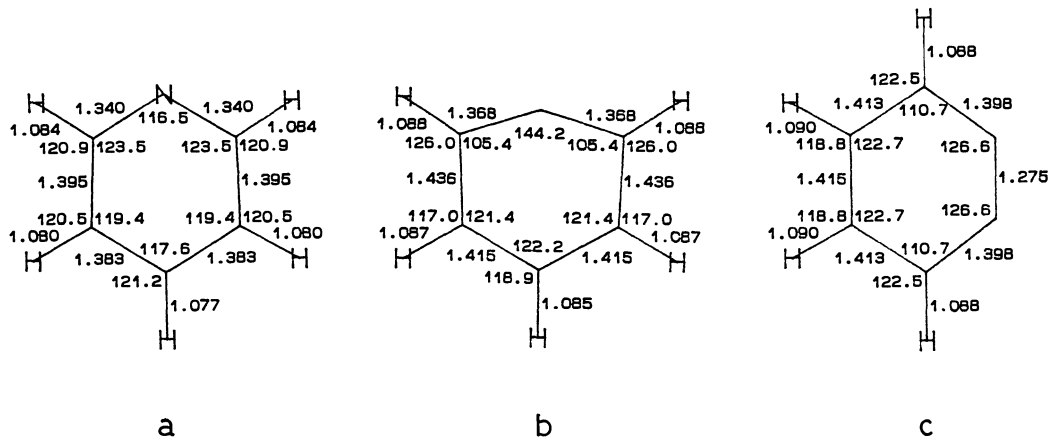

Fig. 4. Molecular structures of a) pyridine from experiment,[13] b) phenyl cation optimized with MCSCF/STO-3G,[11] and c) *o*-benzyne optimized with MP2/DZ+P.[12]

may be compared with those of the cationic centers in other isomers, +0.189 (3-pyridyl) and +0.410(4-pyridyl). This indicates that the stabilization expected in 2-pyridyl is due to the electrostatic interaction.

Pyridyl Anions. The angle at the anionic carbon atom is 110°—113° for three isomers. As may be understood from Fig. 2 and Fig. 4-a, the local structure around the nitrogen atom in 3- and 4-isomers is not largely disturbed by deprotonation of pyridine. In the case of 2-pyridyl anion, a remarkable distortion is observed at the anionic center. This is due to the repulsive interaction between two lone-pair electorns at the adjacent nitrogen and carbon atoms. This interaction makes the 2-pyridyl anion unstable. The 4-pyridyl

anion is calculated to be most stable, although the energy differences among three isomers are not large.

The 6-31G*//AM1 calculations gave the same trend in the relative stabilities among three anions, although AM1 calculations gave incorrect results for the relative energies of these anions.[9]

Pyridyl Radicals. Although the 4-31G//STO-3G calculations of pyridyl radicals have been reported earlier,[8] it may be worth to show the structures and energies obtained by the same level of calculations as for the cations and anions. The molecular structures (Fig. 3) and the relative stabilities of three isomers (Table 1) are parellel to the 4-31G//STO-3G results.

Spin-Lattice Relaxation Time Measurements of Ions and Water Molecules Containing Spin 1 Nuclei in Lyotropic Liquid Crystalline Systems

Masayasu IIDA*,† and Alan S. TRACEY

Burnaby, B. C. V5A 1S6, Canada
(Received May 31, 1991)

Synopsis. The Jeener-Broekaert pulse sequence was applied to the ^{14}N and ^{2}H NMR measurement for studying the dynamic behavior of ions (ammonium and nitrate ions) and water molecules, respectively in lyotropic nematic liquid crystal solutions. The results showed that, in all cases except for the ammonium ion in alkaline solutions, the water molecules and the ions measured gave NMR spectra with properties characteristic of extreme narrowing conditions.

The behavior of ions and water molecules in amphiphilic solutions have been of interest for many years. Nuclear magnetic resonance spectroscopy has provided a powerful tool for the study of specific interactions occuring at the water-amphiphile interface of isotropic micellar and liquid crystalline detergent systems. Relaxation time measurements have been utilized for most investigations on the study of interactions in micellar solutions while the direct observation of quadrupole spittings have been useful in liquid crystalline solutions.[1] When water molecules or ions strongly interact with amphiphiles, two kinds of relaxation times are observed, indicating that a fast anisotropic motion is superposed on a more extensive slow motion.[2] In relaxation studies on liquid crystal systems an application of a phase-shifted, double-quantum pulse sequence on the basis of the Jeener-Broekaert excitation has been known to be useful to determine simultaneously the spectral densities $J_1(\omega_0)$ and $J_2(2\omega_0)$,[3,4] where ω_0 is the nuclear precession frequency. This pulse sequence is applicable to $I=1$ spin systems and most of the studies hitherto performed have been concentrated on deuterium relaxation of water or of amphiphiles.[5-7] In the present work, the Jeener-Broekaert pulse sequence measurements of the ^{2}H relaxation times of water molecules and of the ^{14}N ones of the NH_4^+ and NO_3^- ions have been carried out to reveal their dynamic behavior at water-amphiphile interfaces in aligned lyotropic liquid crystal systems. The present study is the first example of applying the Jeener-Broekaert pulse sequence to the ions containing ^{14}N nucleus to study their interactions with amphiphiles. The extent of the interactions of the water molecules or the ions with the amphiphiles can be seen through the quadrupole splittings and the activation energies of their rotational motions.

Experimental

Materials. The potassium dodecanoate was prepared from the dodecanoic acid by neutralization with aqueous KOH solution followed by a recrystallization several times from 95% ethanol. Sodium and ammonium decyl sulfates and decylammonium chloride were prepared by the standard methods.[8,9] 1-Decanol was obtained commercially and distilled before use. Ammonium nitrate and $^{2}H_2O$ (99.8% ^{2}H) were also obtained commercially and used directly. The solvent used for the $^{2}H_2O$ dynamic study was 5% $^{2}H_2O$ which was prepared by mixing the above $^{2}H_2O$ with a twice distilled H_2O. For the NO_3^- and NH_4^+ dynamic studies, a twice distilled water was used as a solvent.

NMR Measuements. NMR spectra were obtained on a Bruker WM-400 NMR spectrometer using a multinuclear probe operating at 61.48 MHz for deuterium and at 28.94 MHz for ^{14}N. The spin-lattice relaxation times, T_{1Z} (associated with the return of the Zeeman energy to its equilibrium value) and T_{1Q} (the decay of the quadrupolar energy) were measured using the $(\pi/2)_y$-τ-$(\pi/4)_x$-t_1-$(\alpha)_x$ pulse sequence. This is commonly called the Jeener-Broekaert sequence and has been applied according to the method performed by Vold et al.,[3] where $\tau=1/(2\Delta\nu_Q)$ and $\Delta\nu_Q$ is quadrupolar coupling constant. T_{1Z} and T_{1Q} can be determined from the sum and difference of the line intensities measured as a function of evolution time t_1 where α is fixed as 0.31π. In addition to this, the T_1 (I. R.) value for each sample solution was also determined by the conventional inversion-recovery method. The temperature was maintained with an accuracy of ±0.5 °C by a nitrogen gas flow.

Components of Liquid Crystals. The lyotropic mesophases used in this study had the general components of detergents, stock solutions containing salts in H_2O (or 5% $^{2}H_2O$) and 1-decanol (except for the decylammonium chloride system). The liquid crystal systems consisted of: 1) Ammonium decyl sulfate/Sodium decyl sulfate/DeOH/H_2O=362 mg/368 mg/81 mg/1008 mg. 2): Decylammonium chloride/ammonium nitrate/acidic (0.04 mol dm^{-3} pyridine-0.06 mol dm^{-3} HCl) H_2O=600 mg/80 mg/1010 mg. 3) Potassium dodecanoate/ammonium nitrate/DeOH/basic (0.08 mol dm^{-3} ethylenediamine-0.03 mol dm^{-3} HBr) H_2O=298 mg/50 mg/50 mg/1010 mg. The pH values of the 1) solution were 5.3 and 10.3 which are controlled by pyridine-HBr in the acidic region or by ethylenediamine-HBr in the alkaline region, respectively. The pH values were 2.5 for the 2) solution and 10.0 for the 3) solution.

Results and Discussion

The quadrupole splittings, $\Delta\nu_Q$, for the $^{14}NH_4^+$, $^{14}NO_3^-$, and $^{2}H_2O$ were measured in the range where a single phase of the nematic lyotropic liquid crystal is present and were used to decide the τ values as stated above. The $\Delta\nu_Q$, values linearly decreased with increasing temperatures. For each system we calculated $\Delta\nu_Q(0)$ ($\Delta\nu_Q$ extrapolated to $t=0$ °C) and the results are listed in Table 1. For the $^{2}H_2O$ molecule and the counterion in a liquid crystal system, it is generally considered that the magnitude of the $\Delta\nu_Q(0)$ is proportional to the extent of the hydration or the ion-binding if we compare between similar component systems.[1]

Table 1. Quadrupole Splittings Being extrapolated to t=0 °C for ^{14}N of NH_4^+, NO_3^-, and ^2H_2O in Some Liquid Crystalline Systems

a) Potassium dodecanoate system (pH 10.0)			
	i) $^{14}NH_4^+$	ii) $^{14}NO_3^-$	iii) ^2H_2O
$\Delta\nu_Q(0)$/kHz=	4.2±0.3[a]	0.31±0.01	0.15±0.01
b) Decylammonium chloride system (pH 2.5)			
	i) $^{14}NH_4^+$	ii) $^{14}NO_3^-$	iii) ^2H_2O
$\Delta\nu_Q(0)$/kHz=	1.2±0.1	46±2	0.24±0.02
c) Sodium/ammonium decyl sulfate system			
i) $^{14}NH_4^+$	(pH 5.3)	(pH 10.3)	
$\Delta\nu_Q(0)$/kHz=	1.3±0.1	2.2±0.1[a]	
ii) ^2H_2O (pH 5.3)			
$\Delta\nu_Q(0)$/kHz=0.43±0.02 kHz			

a) These values include the values for the ammonia molecule.

For a single I=1 nucleus, application of the Jeener–Broekaert pulse sequence provides two kinds of the spin-lattice relaxation times associated with the return of the Zeeman energy to its equilibrium value T_{1Z} and the decay of the quadrupolar energy T_{1Q}. These two relaxation times can be expressed by the spectral densities ($J_1(\omega_r)$ and $J_2(\omega_r)$) as follows.[3,4]

$$R_{1Z} = 1/T_{1Z} = (e^2qQ/h)^2 3/80(J_1(\omega_r) + 4J_2(2\omega_r)), \quad (1)$$

$$R_{1Q} = 1/T_{1Q} = (e^2qQ/h)^2 3/80(3 \cdot J_1(\omega_r)) \quad (2)$$

where (e^2qQ/h) is the quadrupolar coupling constant.

The usefulness of the application of this method is the ability to simultaneously determine the individual spectral densities of motion, $J_1(\omega_0)$ and $J_2(2\omega_0)$. If water molecules or ions form ion-pairs with amphiphiles so that their motion is restricted, their relaxation times should be frequency dependent and the two spectral densities will have different values. If the interactions do not strongly restrict the motional properties, the relaxation times should be independent of the nuclear precession frequency (extreme narrowing condition), so that J_1 equals J_2. In this case the T_{1Q}/T_{1Z} ratio should be 1.67.

According to the method proposed by Vold and Vold,[3,4] we obtained values of T_{1Q} and T_{1Z} for ^2H_2O and $^{14}NH_4^+$ in various systems with varying temperatures. The results are listed in Tables 2—5 together with T_1 values obtained by the inversion-recovery method. A correspondence between the T_{1Z} and the T_1 (I.R.) value in all cases are satisfactory. We can thus use two kinds of the spin-lattice relaxation times to calculate the T_{1Q}/T_{1Z} ratios and to check whether the extreme narrowing condition is fulfilled or not. The values obtained (listed in the bottom rows of Tables 2—5) show that the ratios coincide with 1.67 within the experimental error in all the cases. It has also been shown for some micellar solutions[10] and for an aqueous sodium dibutyl phosphate lamellar mesophase[11] that the extreme narrowing condition is fulfilled for counterions or water molecules. To compare the extent of the ion binding or the hydration, we calculated activation energies for effective correlation times, τ_{eff}, related with the relaxation rates, R_1. The temperature dependency of R_1 will correspond to that of τ_{eff},[12] which may show an Arrhenius behavior. We obtained the activation energy for τ_{eff} from the Arrhenius plot of $1/T_1$, where we used T_1 values obtained through inversion-recovery method because these values

will be of higher accuracy than the corresponding T_{1Z} values. The Arrhenius plots for all the systems were approximately linear in the temperature range utilized here and the activation energies were obtained as listed in the bottom rows of Tables 2—6. We can generally say, when comparing similar component systems, that larger activation energies are required for the reorientation of the ions or molecules if they interact with the amphiphiles as for instance, NH_4^+/decylammonium mesophase (pH 2.5), E_a=13±2 kJ mol^{-1} vs. NH_4^+/decyl sulfate mesophase (pH 5.3), E_a=33±2 kJ mol^{-1}. Clearly the activation energies increase if the ions or molecules interact more strongly and also the $\Delta\nu_Q$ values of the nuclei of interest also increase with increasing interactions with the amphiphiles.

Only in the case of the ammonium ion in alkaline solutions where formation of the ammonia is appreciable,[13] the ratios obtained were significantly smaller than 1.67 and were around 1.3—1.4. Since the ammonia molecules can be considered to be also under extreme narrowing condition, the T_{1Q}/T_{1Z} ratio for the ammonium ion in alkaline solution is also expected to be close to 1.67. The significantly smaller values of the ratio obtained here may, therefore, arise from the effect of the rapid exchange between the ammonium ion and the ammonia molecule, whose ^{14}N nuclear quadrupolar coupling constants are quite different.[14] Since the coincidence of the T_{1Z} values with the corresponding T_1 (I.R.) values was better than that of the T_{1Q}/T_{1Z} values with 1.67 in these cases, the difference in the latter values can be attributed to a larger effect of the exchange on the T_{1Q} values than the T_{1Z} values. The T_{1Q} value obtained for the ammonium ion in the alkaline solution thus may be different from that defined in Eq. 2. Although the analysis of the result for this system in detail seems to be complicated, the activation energy for the ^{14}N relaxation rate obtained by the inversion-recovery method can be a measure for the extent of the interaction of the ammonium ions with the amphiphiles: As shown in Table 4, the activation energy in the acidic solution is appreciably larger than that in the alkaline solution and this result is consistent with the fact that the interaction of the ammonia molecules with the anionic amphiphiles is slight due to an absence of the electrostatic interactions.

In conclusion, this application of the Jeener-Broekaert pulse sequence to study the dynamic behavior of the nitrate and ammonium ions and the water molecules showed that these systems in most cases undergo the extreme narrowing of their NMR signals. It was not possible to ascertain if they undergo slow motions within the water-amphiphile interface. The activation energies for their reorientational motions, however, described the extent of the binding of the ions and water molecules to the amphiphiles.

The authors are grateful to Professor Hideo Yamatera (Daido Institute of Technology) for helpful discussion. Thanks are gratefully extended to NSERC Canada for its financial support of this work.

Graph-Theoretical Analysis of the Cyclic Bicalicene Conjugated Systems

Jun-ichi AIHARA
Department of Chemistry, Faculty of Science, Shizuoka University,
Oya, Shizuoka 422
(Received June 5, 1991)

Synopsis. The so-called cyclic bicalicene is aromatic although it can be regarded as a perturbed [16]annulene. Graph-theoretical analysis shows that the aromaticity of this molecule arises primarily from three- and five-membered circuits and their combinations. The peripheral sixteen-membered circuit presumably destabilizes the conjugated system to a very slight extent.

In 1981 Yoshida and co-workers synthesized a novel pentacyclic conjugated hydrocarbon **1a**, and chose the appropriate name cyclic bicalicene for it.[1-5] It is stable in air at room temperature for several weeks. Its structural isomer in the form of **2a** has not been prepared yet. Since these two cyclic bicalicenes can be viewed as perturbed [16]annulenes, they are expected to be antiaromatic in nature. However, at least **1a** is aromatic in its chemical behavior.[2-5] Further, it exhibits neither strong first- nor second-order double-bond fixation.[6]

In general, aromaticity is associated straightforwardly with cyclic conjugation of π-electrons. All possible cyclic paths in a mono- or polycyclic conjugated system are responsible for aromaticity.[7-10] Such cyclic paths have been termed ring components or circuits in chemical graph theory.[7-10] Then, what kind of circuits contribute much to the aromaticity of **1a** and **2a**? In this paper, we make a graph-theoretical analysis of total π-electron energy for these cyclic bicalicenes, aiming at clarifying the role of peripheral conjugation. Hückel molecular orbital (HMO) theory is employed.

Results and Discussion

Not only the Dewar resonance energy (DRE) but also the topological resonance energy (TRE) has been used as a good index for determining the degree of aromaticity for cyclic conjugated systems.[7-12] The TREs defined by the simple Hückel model and the ω-technique (ω=1.4) will be denoted by TRE(ω=0) and TRE(ω=1.4), respectively. For alternant hydrocarbons the TRE(ω=0) is equal to the TRE(ω=1.4), whereas for non-alternant hydrocarbons the TRE(ω=1.4) is more or less smaller than the TRE(ω=0). The TRE(ω=1.4) proved more realistic as an aromaticity index for non-alternant hydrocarbons such as cyclic bicalicenes **1a** and **2a**.[10]

The TREs of **1a**, **2a**, and related structures are listed in Table 1. There is no doubt about regarding **1a** as an aromatic species since both the TRE(ω=0) and the TRE(ω=1.4) are large and positive in sign. In contrast, **2a** has a smaller positive TRE(ω=0) and a negative TRE(ω=1.4), which suggest that this molecule is nonaromatic or antiaromatic in its chemical behavior. The DREs of **1a** and **2a** were calculated to be 15.75 and 6.71 kcal mol^{-1}, respectively. Here, the conjugated system of **1a** was assumed to be of D_{2h} symmetry. These DREs are fairly consistent with the corresponding TREs. For comparison, the TRE and the DRE for benzene are $0.273|\beta|$[7,8] and 20.0 kcal mol^{-1},[12] respectively.

If Kekulé structures can be written for a subsystem of any cycle conjugated system, obtained by deleting a given circuit from the system, this very circuit is called a conjugated circuit. In 1976 Randić pointed out that the conjugated circuits are the main source of aromaticity in polycyclic aromatic molecules.[13,14] He successfully estimated the DREs of many polycyclic systems simply by enumerating every type of conjugated circuits.[13,14]

Table 1. Stabilization Energies (SEs) due to Type-II Circuits

Species	Total π-electron energy/β	SE/$\lvert\beta\rvert$	TRE/$\lvert\beta\rvert$
	A. Simple Hückel model (ω=0)		
1a	22.783	−0.020	0.657
1b	22.824	0.020	0.697
2a	22.599	−0.030	0.471
2b	22.659	0.030	0.531
	B. ω-Technique (ω=1.4)		
1a	22.319	−0.017	0.192
1b	22.352	0.017	0.226
2a	21.940	−0.030	−0.188
2b	22.000	0.030	−0.128

The peripheral sixteen-membered circuit is only one conjugated circuit in cyclic bicalicenes **1a** and **2a**. Accordingly, these molecules might be thought to be as antiaromatic as a sixteen-membered conjugated circuit. The DRE value estimated on this basis is −0.06 eV, which is obviously inconsistent with the positive DRE or TREs of **1a**.

Such an inconsistency can be settled by graph-theoretically analyzing the total π-electron energies of each cyclic bicalicene and its Möbius isomer. Here, a Möbius isomer is a hypothetical molecule, obtained by changing the sign of the resonance integral for one of the C–C bonds connecting the three- and five-membered rings in **1a**. A C–C bond with a resonance integral of $-\beta$ is identical with a twisted C–C bond because $-\beta$ usually represents a C–C bond twisted by 180°.[15] Möbius isomers thus defined for **1a** and **2a** are given in **1b** and **2b**, respectively, in which dashed lines indicate twisted C–C bonds. Each has a Möbius-type peripheral conjugated subsystem.

Twenty circuits can be chosen from each cyclic bicalicene conjugated system. Eleven non-identical circuits in **1a** are presented in Fig. 1. Three- and five-membered circuits in **1a** and **2a** will be referred to as type-I circuits with all other ones referred to as type-II circuits. In Fig. 1, A and B are type-I circuits, while all others, including the peripheral conjugated circuit K, are type-II circuits. Type-I circuits in **1a** and **2a** are identical with those in **1b** and **2b**, respectively, whereas type-II circuits in each cyclic bicalicene become singly twisted in the Möbius isomer.

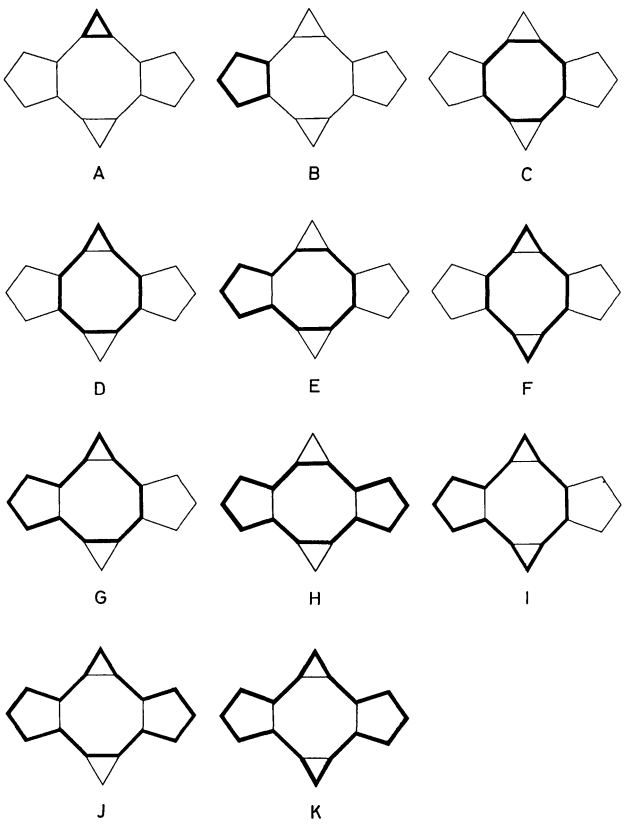

Fig. 1. Non-identical circuits in **1a**.

The total π-electron energy of a molecule can be expressed formally as a function of all circuits.[7–10,16] Some circuits lower the energy of the molecule, while others raise it. The former circuits are classified as aromatic circuits, and the latter ones as antiaromatic circuits. Every type-I circuit in **1a** and **2a** retains essentially the same aromatic character in **1b** and **2b**, respectively. However, aromatic and antiaromatic type-II circuits become antiaromatic and aromatic, respectively, on going from each cyclic bicalicene to its Möbius isomer.[17,18] Therefore, it follows that the energy difference between each cyclic bicalicene and the Möbius isomer represents the change in aromaticity of all type-II circuits.

HMO calculations revealed that each cyclic bicalicene and its Möbius isomer have similar total π-electron energies. For example, **1a** is less stable than **1b** only by $0.041|\beta|$. This fact indicates that type-II circuits, as a whole, destabilize **1a** to a very slight extent, and stabilize **1b** to a similar extent. Therefore, the stabilization energy (SE) of each cyclic bicalicene due to type-II circuits must be about half the energy difference between it and the Möbius isomer. The SE is about $-0.020|\beta|$ for **1a**, the negative sign of which indicates the predominant contribution of antiaromatic $4n$-membered type-II circuits. However, its absolute value is less than 10 percent of the TRE(ω=1.4). The same is essentially true of **2a**. In view of the very small SEs, it seems unlikely that peripheral conjugated subsystems in **1a** and **2a** have large annulenoid character.

It is worthy of note that **1a** has a large positive DRE and TRE although it does not have aromatic $(4n+2)$-membered conjugated circuits. It is type-I circuits such as three- and five-membered ones and their combinations that are important for characterizing electronic properties of **1a** and **2a**. These odd-membered circuits are never conjugated ones in Randić's sense.[13,14] His concept of conjugated circuits must somehow be modified in order to explain aromatic properties of cyclic bicalicenes.

Concluding Remarks

The Hückel $4n+2$ rule was originally proposed for monocyclic conjugated systems.[19] The idea that cyclic bicalicenes (**1a** and **2a**) may be regarded as perturbed [16]annulenes has been based on the unjustified assumption that this rule is applicable to polycyclic conjugated systems. We previously proved that the Hückel $4n+2$ rule in principle holds for monocyclic conjugated systems.[20] However, there is no reason to believe that annulenoid conjugation is important in such polycyclic conjugated systems as **1a** and **2a**. The peripheral conjugated subsystems in these species are so heavily perturbed that it is difficult to treat them naively as perturbed [16]annulenes. The present results are fully consistent with previous graph-theoretical considerations on **1a**.[2–5]

Synopsis. A convenient method was developed for detrmination of methane concentration in old air trapped in Antarctic ice core samples. The air was extracted with a stainless steel bellows pump after quick refreezing of melted ice samples and the methane was measured with a gas chromatograph with an FID. The averaged methane concentration in the Mizuho ice core at a depth of 330 m (ca. 3600 BP, 11 samples) was 750±20 ppbv.

Great concern has been expressed about the increasing concentrations of trace gases in the atmosphere and their effects on the global environment. The atmospheric concentrations in ancient times give us information on their natural background concentrations and the contribution of human activities.

In polar regions, snow is consolidated to firn, which contains permeable pore space for the air. When the firn turns into ice through densification and recrystallization over the course of 100 to 3000 years, the air in the ice pores becomes isolated from the atmosphere and enclosed in the ice as bubbles. A typical ice sample contains about 100 ml air (STP) per kg ice. Analyses of the air trapped in ice bubbles have revealed the historical changes of carbon dioxide[1-4] and methane concentrations.[5-10]

For extraction of the air in ice core samples, the ice block placed in a flask must be either crushed in a vacuum at temperatures below 0 °C (dry extraction method) or thawed (melt extraction method). The melt extraction method has advantages over the dry extraction method because the air in the sample is recovered quantitatively with a very simple apparatus. The dry extraction method requires a sophisticated apparatus with an inevitably large dead volume to extract only the air in bubbles. Moreover, the extracted air was reported to become contaminated by methane when ice was ground by a milling cutter.[7,8]

We, therefore, developed a new melt extraction method in which an ice sample was thawed and quickly refrozen. To transfer the extracted air we used an all-stainless-steel bellows pump instead of a mercury Toepler pump or liquid helium condensation, which may cause contamination and is expensive.

Experimental

Analytical Procedure for Ice Samples. The setup for the extraction and analysis of air is shown in Fig. 1. An ice core sample was cut into several pieces and weighed after removal of the surface layer (1 cm) at −20 °C in the cold room of the National Institute of Polar Research (NIPR). Ice blocks (about 100 g) were placed in a thick-walled, cylindrical glass flask (230 ml) sealed with a Viton O-ring and equipped with a glass-Teflon valve at the top. The flask was first evacuated for one hour at Dry Ice temperature; then the valve was closed and the ice was thawed in a water bath at 80 °C. When about 80% of the ice was thawed, the water bath was removed and the melt water was stirred with a magnetic spinner placed inside to bring the air in gas phase into equilibrium with that in liquid phase. Then it was quickly frozen at liquid nitrogen temperature so as to trap the dissolved gases. It took about 45 min to refreeze 100 g of melt water. The air in the gas phase was extracted, dried by being passed through a cold trap at −100 °C, and transferred into a preevacuated stainless steel sample loop (20 ml) or a small flask by an all-stainless steel bellows pump (specially made by GL Science, Co., using the excellent stainless-steel bellows material AM350) with no polymer parts inside. The gas was eventually analyzed with a gas chromatograph (Shimadzu GC-8A) equipped with a Polapak Q column (3 mm i.d., 4 ml length) and a flame ionization detector (FID).

The methane peak area in the chromatogram was compared with that of the clean air sample in a stainless steel flask calibrated in our laboratory.

Selection of Extraction Conditions. Each component of

the air released from the melted sample is distributed differently between liquid and gas phases depending on its particular solubility in water. Since the water solubility of methane is greater than that of nitrogen or oxygen, the methane mixing ratio is depleted in the gas phase. If we could refreeze the melt water again extremely slowly from the bottom of the flask, most air dissolved in the water might be purged due to its negligible solubility in ice crystals, and the original air composition might be closely reproduced in the head space. However, it would take many hours to free the ice completely of air, or it is almost impossible to do so.

In quick freezing, the air purged from the growing ice crystals condenses at the ice-water interface. When the air at the interface cannot be dissolved in the water, nucleation of air bubbles occurs, and the air bubbles are trapped in the growing ice. Hence, if the growth of ice is faster than the air diffusion in the water, the ice incorporates the initially dissolved air almost completely. In this work, the ice grew at the rate of about 3×10^{-3} cm s^{-1}, which was much larger than the rate of diffusion of air in water (the diffusion coefficient: about 10^{-5} cm^2 s^{-1}), and in practice the ice contained many bubbles. Accordingly, we assume that the dissolved air can be preserved in the quickly refrozen ice and that the air in the gas phase has the same composition with that in equilibrium with the melted water.

It was reported that the air in the bubbles of Camp Century ice from Greenland had almost the same composition as to nitrogen, oxygen and argon as that in the present air.[11] Assuming that the main components are of the same composition as that in the present air and follow Henry's law, we can calculate the methane concentration in the head space air. The methane concentration (C) in the head space of the sample flask is given by

$$C=\frac{(V_a/V_w+\alpha_{air}T/T_0)}{(V_a/V_w+\alpha_{CH_4}T/T_0)}\times C_0$$

where C_0 is the initial methane concentration in ice bubbles; α_{air} and α_{CH_4} are Bunsen solubility coefficients of air and methane, respectively; T is the temperature at which the thawed water was equilibrated; T_0 is 273 K; V_a is the volume of head space of sample flask; and V_w is water volume. Figure 2 shows the ratio of C to C_0 calculated at several equilibrium temperatures as a function of the volume ratio of V_a to V_w. If the volume ratio is <1, methane concentration decreases sharply with the decrease in the volume ratio. If the volume ratio is >1, methane concentration approaches the original concentration in ice bubbles (C_0). In this work, we kept the volume of the sample vessel constant so that V_a/V_w remained at about 1, or the methane concentration was depleted by about 2%.

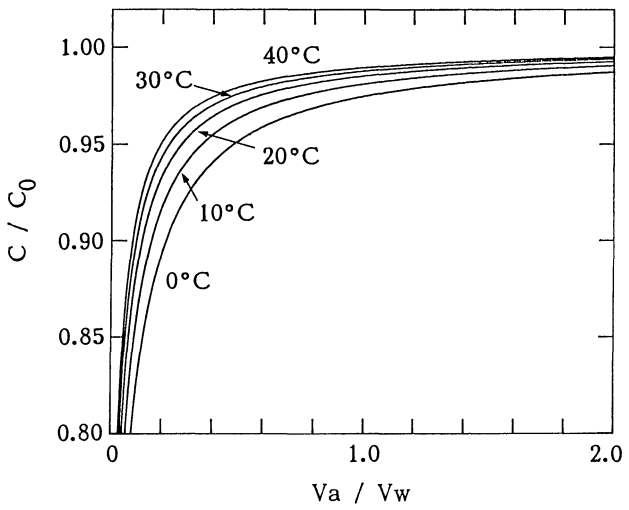

Fig. 2. Relation between the ratio of methane concentration in the air equilibrated with sample water (C) to that in ice bubbles (C_0) and the ratio of volume of headspace (V_a) to that of the water (V_w). The curves correspond to samples equilibrated at indicated temperatures.

Results and Discussion

Contamination and Correction of Methane Concentration. When the air was transferred with a bellows pump, the methane concentration was found to increase with a pumpling motion. In order to estimate the amount of methane emitted from the bellows pump, methane-free nitrogen was introduced into the pump and analyzed after some pumping motions. The amount of methane released from the stainless steel bellows increased linearly with the pumping time. Since this pump had been carefully baked and evacuated before its use, the methane released could not be explained by the desorption of the adsorbed methane from the metal surface. Since the frictional contact between metals is known to produce trace amounts of methane,[7,8] deformation of even the most excellent metal bellows (AM 350) may have produced the methane.

However, in practice, sufficient air can be obtained by one or two strokes of pumping motion to measure methane concentration, and contamination can be kept below 20 ppbv. For correction of the methane contamination during the analysis of ice samples, blank tests were carried out as follows:

(1) Ice prepared under air-free conditions was placed in the sample flask and evacuated. Methane-free nitrogen was then introduced into the sample flask at the same pressure as that for the air released from ice core samples. Following the same thaw-and-freeze procedure, methane concentration was determined.

(2) The same procedure as described above in (1) was used, but in the absence of ice. Blank values obtained were 40±20 ppbv and 20±5 ppbv, respectively. The former was slightly larger than the contamination arising from the bellows pump: even if the ice contained no air bubbles visually, a small amount of methane may have been included in the ice lattice. The latter value was consistent with the contamination from the bellows pump. As has been reported by Rasmussen and Khalil on snow samples from Mt. Hood,[12] we can assume that no methane is contained in falling snow in the Antarctica. Thus it is likely that almost all the contamination was caused by the bellows metal; correction was made for such unavoidable and reproducible contamination. In addition, methane concentration was corrected for change in concentration due to the gas–liquid distribution.

Application to Antarctic Core Samples. Methane concentration in the ice core drilled at Mizuho Station in 1984 was determined by the melt extraction method. The core sample for analysis (30 cm in length) was obtained at 330 m depth and was estimated to be about 3600 years old;[13] a 30 cm span at the depth of 330 m

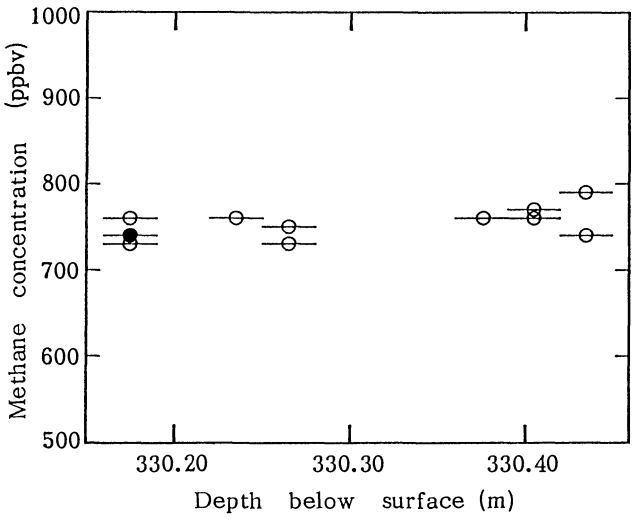

Fig. 3. Observed methane concentrations in the Mizuho core sample drilled in 1984 at 330-m depth below the surface. The solid circle shows the sample from the surface of the core.

corresponds to about 4 years. The core sample (13 cm in diameter) was first sliced horizontally into 3 cm thick disks, which were then divided into two halves after their rims, about 1 cm below the surface, had been removed. We took eleven sections of ice blocks from the core sample; one of them was the surface ice of the sample. The result of the analysis is shown in Fig. 3; the solid circle shows the concentration in the surface ice. The methane concentrations were observed to be uniform over the period studied, and the concentration at the surface was not necessarily higher than the others. The averaged methane concentration of the eleven samples was found to be 750±20 ppbv, a slightly higher value than those previously reported for similar ages.[5,6,10] After the presentation of our results,[14] Nakazawa et al. reported that the methane concentrations of several Mizuho core samples near the depth of 330 m were 690 to 750 ppbv.[15] Since the preesent core sample had many horizontal cracks probably produced during thermal core boring, we cannot exclude the possibility that the air in the ice core sample was contaminated by modern air.

We have developed a technique for extrication of air in polar ice. The precision of the methane analysis with 100 g core samples was about 20 ppbv. Although the bellows pump released negligible amounts of methane during operation, the current analytical system and procedures are simple and convenient; with improvements in the pump, or for analysis of te other components, this method will be quite useful.

The Magnetic Properties of the 2-Pyridone Adducts of Copper(II) Benzoates and Related Copper(II) Compounds

Shuji EMORI,* Hiroyuki SUENAGA, and Naomi GOTO
Department of Chemistry, Faculty of Science and Engineering,
Saga University, Honjo-machi, Saga 840
(Received June 19, 1991)

Synopsis. The 2-pyridone adducts of copper(II) benzoate, copper(II) 2-pyridinolate, and bis(adenine)copper(II) sulfate were prepared, and then characterized by means of magnetic susceptibility and IR spectroscopy. Their magnetic properties were correlated with the basicities and coordinate-bond lengths of the bridging ligands.

Like copper(II) alkanoates, most copper(II) benzoate,[1] copper(II) 2-pyridinolate,[2,3] copper(II) pyrrolo[2,3-*b*]pyridinate,[4] and bis(adenine)copper(II) compounds[5,6] may have dinuclear structures similar to that of copper(II) acetate monohydrate.[7,8] Through the bridging ligands between the copper(II) ions, superexchange couplings operate, and the room-temperature magnetic moments vary with the strength of the spin-exchange couplings (the Bleaney–Bowers equation).[1-6] Naturally, the magnetic moments or the strength of the spin-exchange couplings for these dinuclear compounds have been discussed with reference to the basicity of the bridging ligands (pK_{a1} or pK_{a2}).[9,10] On the other hand, for series of transition metal oxides and fluorides, a correlation between the strength of the spin-exchange couplings and the coordinate-bond lengths has been proposed,[11,12] and rationalized with an exchange perturbation treatment of cation–anion–cation in a three-center, four-electron model.[13] Also, in copper(II) acetate-type dinuclear compounds, the coordinate-bond length must play a role in determining the strength of the superexchange couplings. In order to investigate concurrently the basicity and bond length dependence, we prepared some 2-pyridone adducts of copper(II) benzoates, copper(II) 2-pyridinolates, and bis(adenine)-copper(II) sulfate, and measured their magnetic susceptibilities at room temperature.

The adducts were prepared by heating the hydrates of copper(II) acetate, copper(II) 3- and 5-substituted benzoates, and bis(adenine)copper(II) sulfate with excesses of molten 2-pyridones for 30 min (mp 107, 165, and 185°C for 2-pyridone and 5-chloro- and 5-nitro-2-pyridones, respectively). The excess 2-pyridones were removed by sublimation.[3] The effective magnetic moments were evaluated from the magnetic susceptibilities, which were corrected for the diamagnetic contribution using the Pascal constants[14] and for temperature-independent paramagnetism using the value 60×10^{-6} emu mol^{-1} (1 emu$=4\pi\times10^{-6}$ m^3). The IR spectra of the solid compounds were recorded using nujol mulls in the 4000—600 cm^{-1} range.

The obtained compounds show magnetic moments of 1.25—1.45 BM, similar to those of well-characterized dinuclear copper(II) compounds.[8-10,15] All of the benzoates show COO stretching bands of ca. 1675—1615 and 1435—1405 cm^{-1}, characteristic of bridging carboxylate anions.[16] The magnetic and IR spectral data indicate that the present compounds have copper(II) acetate-type dinuclear structures with 2-pyridones occupying the axial positions (Fig. 1). Although the 2/3 adducts have structures with a partial lack of axial ligands, their magnetic moments are assumed to be practically the same as those of the monoadducts.

For several series of dinuclear copper(II) compounds,[9,10] it has been reported that the room-temperature magnetic moments decrease linearly with the basicities of the bridging ligands. In order to demonstrate the linear correlation for the present compounds, their magnetic moments (in BM), together with literature data regarding related copper(II) com-

pounds,[4,8-10,15] are plotted in Fig. 2 against the basicities of the bridging ligands ($pK_{a1}-0.068\,pK_a'$), where $-0.068\,pK_a'$ is the correction term for the axial ligation. K_{a1} and K_a' are the acid constants of the conjugate cation acids of the bridging and axial ligands, respectively.[17,18] The points for each series of the copper(II) benzoate, copper(II) 2-pyridinolate, and bis(adenine)copper(II) compounds give a straight line with slopes of $K=-0.037$, -0.029, or -0.023, respectively. The slope obtained for the benzoates is in fair agreement with that ($K=-0.052$) for plots of the magnetic moments of dinuclear copper(II) carboxylates[9] against $pK_{a2}-0.068\,pK_a'$, when the linear relationship for carboxylic acids, $pK_{a1}=1.40\,pK_{a2}-13.8$, is taken into account.[19] Three lines intersect at a point, enabling us to summarize them as

$$\mu_{eff} = 1.94[1 + K(pK_{a1} - 0.068pK_a' + 23.0)]. \quad (1)$$

The reasonably good correlation for each series confirms that the strength of spin-exchange couplings is undoutedly affected by the basicity of the bridging ligands; the different slopes for the three series indicate that it is also affected by factors other than basicity.

Although the variation in the slopes seems to be attributable to bondings between pairs of copper(II) ions, this is not consistent concerning the trend in copper(II)-copper(II) separations.[1-6] The coordinate-bond lengths of the present bridging ligands are typically Cu-O(1), 1.967(6)—1.981(6) Å and Cu-O(2), 1.950(10)—1.965(6) Å in dinuclear copper(II) benzoates,[1] Cu-N, 2.000(6)—2.015(10) Å and Cu-O, 1.950(10)—1.959(6) Å in dinuclear copper(II) 2-pyridinolates,[2,3] and Cu-N(1), 2.038(6)—2.043(11) Å and Cu-N(2), 2.008(11)—2.012(6) Å in dinuclear bis(adenine)copper(II) compounds,[5,6] respectively. The longer coordinate bond of each bridging ligand is selected for a comparison, because the strength of the superexchange coupling is determined by the weakest bond in the coupling pathway.[10] Apparently, the above-obtained slopes become steeper as the coordinate-bond lengths decrease; the variation in the K's is in good quantitative agreement with the theoretical prediction regarding the distance dependence of the strength of the spin-exchange coupling.[11] The basicity and bond length dependence was collaborated and evaluated separately. These relations suggest that the spin-exchange couplings in the present compounds operate through the sp^2-orbitals more strongly than through the p_π-orbitals of the bridging ligands.

Synopsis. Trinuclear chromium(III) complexes with optically active amino acids as bridging groups, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}RCH(NH_3)COO)_6(H_2O)_3]X_7$ (R=CH_3, $(CH_3)_2CH$, $(CH_3)_2CHCH_2$, $C_6H_5CH_2$; X=Cl^-, NO_3^-), were prepared, and the X-ray structure of the L-valine complex was determined. Their electronic spectra and magnetic moments are similar to those of analogous carboxylate-bridged trichromium(III) complexes.

Oxo-centered triangular trinuclear metal complexes with bridging carboxylates ($RCOO^-$) between each pair of metal ions are known for various tervalent metal ions such as V, Cr, Mn, Fe, Co, Ru, Rh, and Ir.[2)] They have a general formula, $[M_3(O)(RCOO)_6L_3]^+$ (hereafter abbreviated as M_3, and L stands for a monodentate ligand such as H_2O, pyridine, and so on). Amino acids are also known as bridging ligands (μ-O,O'-$RCH(NH_3)COO$) for the Fe_3 complexes[3-7)] and some mixed Fe_nCr_{3-n} analogs.[8-10)] Complexes with bridging amino acids are important to extend the chemistry of trinuclear complexes. The Fe_3 amino acid complexes are not stable in aqueous solution,[11)] and not suitable for extending their chemistry further particularly in solution. We thought it important to prepare amino acid bridged derivatives of the trinuclear metal complexes with substitution inert metal ions such as Cr(III), Ru(III), and Rh(III). Amino acid complex for these metal ions reported before we started the present study was only $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-glyH})_6(H_2O)_3]^{7+}$ (Hgly=glycine).[9)] The present paper describes the preparation and some properties of new trinuclear chromium(III) complexes with optically active amino acid bridges. Very recently, alanine and α-aminobutane chromium(III) complexes were reported by Fisher et al.[12,13)]

Experimental

Preparation of the Complexes. L-Alanine Complex, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-}CH_3CH(NH_3)COO)_6(H_2O)_3]Cl_7\cdot 5H_2O$ (1). $Cr(NO_3)_3\cdot 9H_2O$ (4.00 g, 0.01 mol) dissolved in absolute ethanol (20 cm^3) was added to the suspension of L-alanine (1.78 g, 0.02 mol) in water (20 cm^3). After pH was adjusted to 2 with diluted nitric acid, the mixture was kept at 70—80 °C for 10 h, during which time L-alanine was dissolved completely. Volume of the solution was then reduced to ca. 20 cm^3 on a rotatory evaporator. The solution was then treated with Sephadex G-10 column chromatography (35 mmϕ×400 mm). The green eluate of 0.1 M HCl (1 M=1 mol dm^{-3}) was concentrated to dryness. The green residue was dissolved in a small amount of ethanol. Green powder was obtained on addition of diethylether, and was collected by filtration and dried under vacuum. Yield, 1.02 g (26%). Anal. Found: C, 19.87; H, 4.68; N, 7.37%. Calcd for $C_{18}H_{58}N_6O_{21}Cl_7Cr_3$: C, 19.67; H, 4.59; N, 7.65%. IR (cm^{-1}): $COO(\nu_a)$, 1655; $COO(\nu_s)$, 1436.

L-Valine Complex, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-}(CH_3)_2CHCH(NH_3)COO)_6(H_2O)_3](NO_3)_7\cdot 5H_2O$ (2). This was prepared similarly as **1** by using L-valine (2.38 g, 0.02 mol) in place of L-alanine. After reducing the volume to ca. 20 cm^3, the solution was set aside for a few days at room temperature instead of treating with the column. Large green crystals were collected by filtration and dried under vacuum. Yield, 1.78 g (36%). Anal. Found: C, 24.53; H, 5.26; N, 13.16%. Calcd for $C_{30}H_{82}N_{13}O_{42}Cr_3$: C, 24.80; H, 5.69; N, 12.53%. IR (cm^{-1}): $COO(\nu_a)$, 1658; $COO(\nu_s)$, 1452.

L-Leusine Complex, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-}(CH_3)_2CHCH_2CH(NH_3)COO)_6(H_2O)_3]Cl_7\cdot H_2O$ (3), and L-Phenylalanine Complex, $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-}C_6H_5CH_2CH(NH_3)COO)_6(H_2O)_3]Cl_7\cdot 6H_2O$ (4). These compounds were synthesized in a similar way to the preparation for **1**. Yield of green powder, 1.08 g (26%) for **3** and 0.33 g (7%) for **4**. Anal. Found for **3**: C, 32.42; H, 7.02; N, 6.53%. Calcd for $C_{36}H_{92}N_6O_{20}Cl_7Cr_3$: C, 32.43; H, 6.95; N, 6.30%. Found for **4**: C, 41.21; H, 5.37; N, 5.32%. Calcd for $C_{54}H_{84}N_6O_{22}Cl_7Cr_3$: C, 41.21; H, 5.34; N, 5.34%. IR (cm^{-1}): $COO(\nu_a)$ 1655, $COO(\nu_s)$ 1445 for **3**; $COO(\nu_a)$ 1660, $COO(\nu_s)$ 1450 for **4**.

Measurements. Electronic and CD spectra were measured with a Hitachi 340 spectrophotometer and a JASCO J-40A spectropolarimeter, respectively. Infrared absorption spectra were recorded on a JASCO IR-810 spectrophotometer by KBr method. Magnetic susceptibilities at room temperature were measured in methanol-d_4 by the Evans method.[14)]

X-Ray Structure Determination for 2. A green crystal of the L-valine complex (**2**) with dimensions 0.3×0.3×0.4 mm was used for the X-ray work. X-Ray data were collected on a Rigaku AFC-5R four circle diffractometer equipped with a rotating Mo anode (40 kV, 200 mA, λ=0.71069 Å). Intensity data were corrected for Lorentz and polarization factors. No absorption correction was applied. Crystallographic data are: monoclinic, $P2_1$, a=13.104(5), b=21.460(7), c=12.218(4) Å, β=110.99(3)°, V=3207(2) Å^3, Z=2, ρ_{obsd}=1.47, ρ_{calcd}=1.50 g cm^{-3}.

The structure was solved by the direct method and refined by use of the block-diagonal least-squares method. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were not included in the calculation. Final R value was 0.099 for 6394 independent reflections ($F_o \geqslant 3\sigma(F_o)$) and 794 parameters.[15)] All the calculations were performed with the Universal Crystallographic Computer Program System UNICS III[16)] on an ACOS-1000 computer at the Computer Center of Tohoku University.

Results and Discussion

Preparation and Stability of the New Complexes. Desired complexes with neutral amino acid (zwitter ion

† Present address: Department of Chemistry, Faculty of Science, Saitama University, Shimo-okubo, Urawa 338.

form) bridges have high electric charge of 7+. In spite of this, preparation and isolation of the complexes were straightforward. Chromium(III) ions and amino acids appear to undergo self-assembly to give desired trinuclear complexes in acidic aqueous ethanol solution. Similar trinuclear complexes would be easily prepared with other amino acids than those used in this study. The complexes are stable in acidic solution. However they decompose slowly in neutral solution and immediately in alkaline solution as evidenced by electronic spectral change. They are soluble in certain organic solvents such as methanol and ethanol. Attempts to prepare complexes with pyridine ligands at the terminal positions were unsuccessful. It is probabbly because the compounds are unstable in basic media.

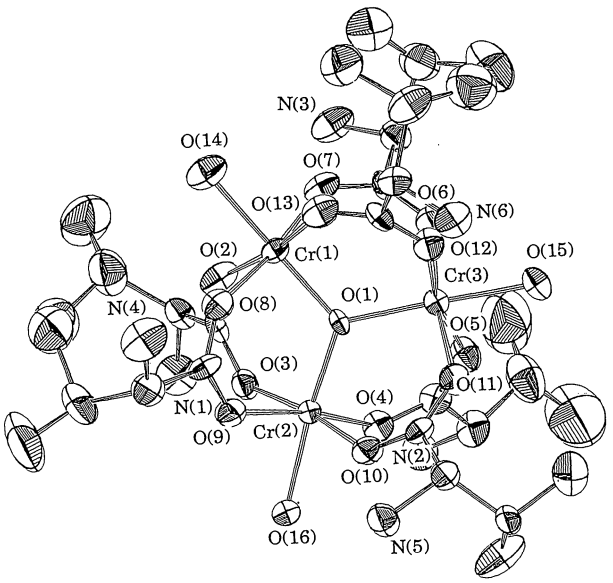

Fig. 1. Structure of $[Cr_3(\mu_3\text{-}O)(\mu\text{-}O,O'\text{-}(CH_3)_2CHCH(NH_3)COO)_6(H_2O)_3]^{7+}$ (**2**) and atomic labelling scheme.

The Structure of the L-Valine Complex. Figure 1 shows the structure of the complex cation. Selected bond distances and angles are summarized in Table 1.[15] The complex contains a triangular Cr_3 unit with an oxide ion in the center of the triangle. Each pair of Cr atoms are doubly bridged by carboxylate groups of two L-valine ligands. Overall skeletal structure is very similar to those of other trinuclear chromium carboxylates.[17-19] Each chromium ion takes slightly distrorted octahedral geometry, shifting towards the central oxide ion from the plane defined by four carboxylate oxygens (0.13—0.20 Å). This is also seen in other trichromium complexes. The Cr···Cr distance is 3.30(2) Å and the Cr–(μ_3-O) distance is 1.90(1) Å. The core structure is similar to amino-acid-bridged trinuclear iron(III) complexes.[20] No regularity is found in the orientation of $(CH_3)_2CHCH$ residue of the bridged L-valine.

Electronic and Circular Dichroism Spectra. Table 2 summarizes electronic absorption and circular dichroism spectral data of the new complexes in aqueous solutions. Spectra of the L-valine and L-phenylalanine complex are shown in Fig. 2. Two absorption peaks in visible region are seen as other trichromium complexes,[21] and are assigned from longer wavelengths to $^4A_{1g}\rightarrow{}^4T_{2g}$ and $^4A_{1g}\rightarrow{}^4T_{1g}$ transitions of octahedral chromium(III) center. Circular dichroism peaks are weak as expected from the fact that the asymmetric centers are apart from the chromophoric center. It is noted that the main CD peaks corresponding to the $^4A_{1g}\rightarrow{}^4T_{2g}$ transition is negative for the L-valine and L-leusine complexes, whereas positive for other two complexes. The reason

for this phenomena is not clear. CD spectra in other region are similar for all the four complexes.

Magnetic Properties. The μ_{eff} values obtained by the Evans method at room temperature were 3.39, 3.31, 3.37, and 3.38 (BM per Cr) for the L-alanine, L-valine, L-leusine, and L-phenylalanine complexes, respectively. These values are close to those reported for the carboxylate-bridged trichromium complexes (3.13–3.48 BM)[22] and glycine complex (3.34 BM).[10] These values are somewhat smaller than the spin-only value (3.87 BM), and may suggest weak antiferromagnetic interactions among the three chromium ions.[22]

Redox Properties. Cyclic voltammograms in methanol of the new complexes were measured in the range from −3.0 to +1.0 V vs. Ag/Ag^+ (0.1 M $AgClO_4$). No redox wave was observed in the range studied.

This work was supported by a Grant-in-Aid for Scientific Research No. 02245106 on Priority Area of "Molecular Approaches to Non-equilibrium Processes in Solutions" and a Grant-in-Aid for Scientific Research No.01430009 from the Ministry of Education, Science and Culture. The authors are indebted to Dr. C. Kabuto of this Department for the X-ray intensity data collection.

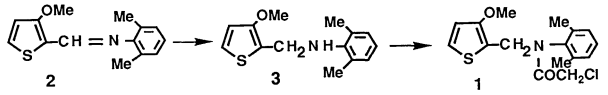
A Facile Reduction of Certain Schiff Bases with Di- and Trichlorosilanes

Hidenori OKAMOTO* and Shozo KATO
Tsukuba Research Lab., Tokuyama Soda Co., Ltd., 40 Wadai, Tsukuba, Ibaraki 300-42
(Received March 29, 1991)

Synopsis. The reduction of *N*-[(3-methoxy-2-thienyl)methylene]-2,6-dimethylaniline (**2**) by use of trichlorosilane proceeded smoothly in the presence of a catalytic amount of BF_3·Et_2O. The trichlorosilane/BF_3·Et_2O combination was applicable to the reduction of various Schiff bases. In the case of dichlorosilane, the reduction of **2** proceeded with a 90% yield without any catalysts.

Recently we have found a highly active chloroacetamide herbicide (**1**) for paddy field rice.[1] Compound **1** has been synthesized in two steps from *N*-[3-methoxy-2-thienyl)methylene]-2,6-dimethylaniline (**2**) which involved a reducing step and a chloroacetylating step as shown in the following scheme.



On a laboratory scale, the above reduction proceeded easily by the use of $LiAlH_4$. However, $LiAlH_4$ is not suitable for industrial use because of the relatively high cost and the difficulty in handing. Common reducing agents such as hydrogen with a catalyst, sodium in methanol, and formic acid, did not afford the amine **3** in satisfactory yield probably due to the steric hindrance around the carbon–nitrogen double bond. In some cases, desulfurization in the thiophene ring was observed.

In this paper, we wish to report an excellent and economical reduction of the Schiff base **2** to the amine **3** by use of di- and trichlorosilanes.

Results and Discussion

According to the literature, reduction of Schiff bases to the corresponding amines has been accomplished by various di- and tri-substituted silanes such as Et_3SiH/CF_3COOH,[2] Et_2SiH_2/Rh,[3] and $HSiCl_3$.[4] At first, we tried to reduce the Schiff base **2** using trichlorosilane in acetonitrile without any catalyst according to Benkeser's method.[4] However, the reaction mixture turned black and the desired amine **3** was not obtained at all after hydrolysis. This result indicated that Benkeser's method could not be applied to certain Schiff bases.

During the course of our investigation, we have found that the reduction of **2** with trichlorosilane proceeds to some extent with the use of benzene as a solvent and more smoothly on the addition of a Lewis acid (e.g. BF_3·Et_2O) as a catalyst. Thus, **2** was reduced with trichlorosilane in the presence of BF_3·Et_2O to afford **3** in a 61% yield.

$$\mathbf{2} \xrightarrow[C_6H_6]{HSiCl_3/BF_3\cdot Et_2O} \xrightarrow{KOH/aq\ EtOH} \mathbf{3}$$

We have extended this reduction with trichlorosilane to other Schiff bases. The results are shown in Table 1. As can be seen in the Table, the reduction of Schiff bases with trichlorosilane was proved to proceed satisfactorily

Table 1. Reduction of Schiff Bases to Amines with Trichlorosilane[a]

Entry	Schiff base	Catalyst	Amine	Yield/%[b]
1		None		17
2		BF_3·Et_2O		40
3		BF_3·Et_2O		37
4		BF_3·Et_2O		89
5		BF_3·Et_2O		82
6		BF_3·Et_2O		81
7		BF_3·Et_2O		61

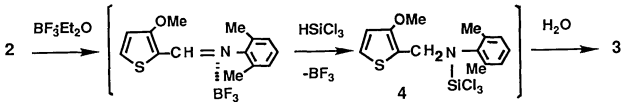
a) The reactions were carried out in benzene for 4 h, followed by hydrolysis using KOH in aqueous EtOH.
b) Yield was determined by GC and ^1H NMR.

in benzene in the presence of $BF_3 \cdot Et_2O$. The Schiff bases derived from alkylamines were converted into the corresponding amines in a better yield than those derived from arylamines (Entries 2, 3, 4, and 5). The reduction of the Schiff base prepared from cyclohexanone proceeded easily, in contrast to the Schiff base prepared from benzaldehyde (Entries 2 and 6). These results might be explained by considering that the lone pair of electrons on the nitrogen atom of the Schiff bases should play a role in complexing with trichlorosilane. A steric effect was noted in the comparison of Entry 6 and 7. The combination of trichlorosilane/$BF_3 \cdot Et_2O$ in benzene was found to be applicable to various Schiff bases.

When the Schiff base **2** was treated with dichlorosilane instead of trichlorosilane, the desired amine **3** was obtained in a 90% yield without a catalyst as described below.

$$2 \xrightarrow[C_6H_6]{H_2SiCl_2} \xrightarrow{KOH/aq\ EtOH} 3$$

The proposed mechanism of the addition of trichlorosilane to a Schiff base in acetonitrile was that the lone pair of electrons of the Schiff base nitrogen reacted with trichlorosilane to form a complex, followed by an intramolecular hydride transfer to give a *N*-trichlorosilyl compound.[4] To clarify this reduction mechanism, we have measured the ^1H NMR spectrum in C_6D_6. When $BF_3 \cdot Et_2O$ was mixed with trichlorosilane, the spectrum was a mere combination of each signal ascribed to both compounds. However, when $BF_3 \cdot Et_2O$ was mixed with **2**, the signal at 8.48 ppm (CH=N) disappeared and a signal appeared at 9.32 ppm. A small amount of solid, which was regarded as a Schiff base-BF_3 complex, was obtained. On the basis of these facts, a rational mechanism can be proposed in the following Scheme.



At first, $BF_3 \cdot Et_2O$ would locate close to the Schiff base to form a certain complex which then reacts with trichlorosilane to form the *N*-silyl compound **4** which affords the amine by hydrolysis. On the other hand, dichlorosilane can form **4** smoothly without a catalyst probably due to the steric factor.

The method described in this report might be useful for the synthesis of a secondary amine from a Schiff base.

Experimental

The ^1H NMR spectra were measured with a Hitachi R1500 spectrometer using tetramethylsilane as an internal standard. The GC Mass spectra were obtained on a Hitachi M80 spectrometer.

Reduction of 2 to 3 with Trichlorosilane. A one-hundred milliliter flask containing **2** (2.48 g, 10 mmol) in benzene (15 ml) was cooled in an ice bath. After trichlorosilane (3.98 g, 29 mmol) and $BF_3 \cdot Et_2O$ (0.1 ml) were added slowly, the resulting mixture was heated to reflux temperature for 7 h. After being cooled to room temperature, the mixture was treated with KOH (3.3 g) in 80% aqueous EtOH (45 ml) in an ice bath and stirred at room temperature for 12 h. The organic layer was extracted with ether and dried over anhydrous sodium sulfate. The solvent was then distilled out and the resulting pale yellow liquid (1.50 g, 61% yield) was composed of **3** which boiled at 122 °C/0.15 mmHg (1 mmHg=133.322 Pa). ^1H NMR ($CDCl_3$) δ=2.25 (6H, s, CH_3), 3.30 (1H, brs, NH), 3.71 (3H, s, OCH_3), 4.14 (2H, s, CH_2), and 6.68—7.03 (5H, aromatic H); IR (KBr) 3380 cm^{-1} (NH); MS *m/z* 247 (M^+). Found: C, 68.08; H, 6.78; N, 5.58%. Calcd for $C_{14}H_{17}NOS$: C, 68.01; H, 6.88; N, 5.67%.

Reduction of Various Schiff Bases with Trichlorosilane. A typical procedure is as follows. A flask containing *N*-benzylidenepropylamine (1.47 g, 10 mmol) in benzene (8 ml) was cooled in an ice bath. After trichlorosilane (1.60 g, 12 mmol) in benzene (2 ml) and $BF_3 \cdot Et_2O$ (0.1 ml) were added slowly, the resulting mixture was heated to reflux temperature for 4 h. After being cooled to room temperature, the mixture was treated with KOH (4.0 g) in 80% aqueous EtOH (35 ml) in an ice bath and stirred at room temperature for 12 h. The organic layer was extracted with ether and dried over anhydrous sodium sulfate. Removal of the solvent in vacuo gave *N*-benzylpropylamine as a pale yellow liquid (1.33 g). The yield was 89% (Table 1, Entry 4).

Other reductions were carried out in a manner similar to that described above and the products were comfirmed by GC, GCMS, and ^1H NMR. In the cases of the reactions resulting in good yields (Entries 4, 5, and 6), the obtained amine was obtained in pure form without any purification. In each case of the reaction resulting in a low yield (Entries 1, 2, 3, and 7), unreacted Schiff base was recovered along with the expected amine.

Reduction of 2 to 3 with Dichlorosilane. A one-hundred milliliter glass autoclave was charged with **2** (2.48 g, 10 mmol) in benzene (15 ml) and cooled in a dry ice–methanol bath. Dichlorosilane (2.81 g, 28 mmol) was introduced and the resulting solution was warmed to room temperature. The reaction mixture was stirred for 8 h in an oil bath (50 °C), treated with KOH (4.0 g) in 80% aqueous MeOH (35 ml) in an ice bath and stirred at room temperature for 12 h. The organic layer was extracted with ether and dried over anhydrous sodium sulfate. The solvent was removed in vacuo and the residue was distilled to give **3** as a pale yellow liquid (2.22 g, 90% yield).

Photochemical Lumiketone-Type Rearrangement of 3-Methoxyphenol Promoted by $AlBr_3$

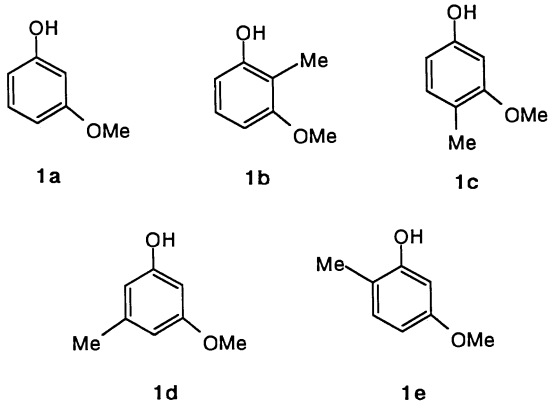
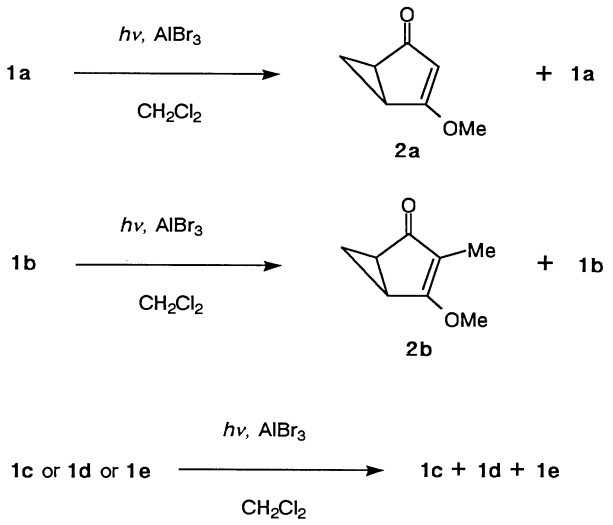
Synopsis. Irradiation of 3-methoxyphenol in the presence of 2 equiv of $AlBr_3$ in CH_2Cl_2 gave 4-methoxybicyclo[3.1.0]hex-3-en-2-one in a 38% yield. 3-Methoxy-2-methylphenol also yielded the lumiketone rearrangement product. On the other hand, 3-methoxy-4-methyl-, 3-methoxy-5-methyl-, and 5-methoxy-2-methylphenol underwent transposition of the methyl group to give equilibrium mixtures of the three methoxycresols.

Protonated alkyl-substituted phenols have been shown to undergo lumiketone-type photorearrangement which was effected by a Brønsted acid (FSO_3H, CF_3SO_3H) or a Lewis acid ($AlBr_3$, aluminosilicates) giving bicyclo[3.1.0]hex-3-en-2-ones.[1] This rearrangement is analogous to the well-known isomerizations of 2,5-cyclohexadienones[2] and provides a useful method for the preparation of bicyclo[3.1.0]hex-3-en-2-ones. Although a variety of methyl-substituted phenols undergo this transformation successfully, there seems to be no reports on those with functional groups other than alkyl moieties on the phenol ring. In the present paper, we describe the isomerization of 3-methoxyphenols **1a** and **1b** to the corresponding 4-methoxybicyclo[3.1.0]hex-3-en-2-ones **2a** and **2b**.[3] Since the products **2a** and **2b** possess a β-methoxy-α,β-enone functionality, they could serve as versatile synthetic intermediates for further manipulation.



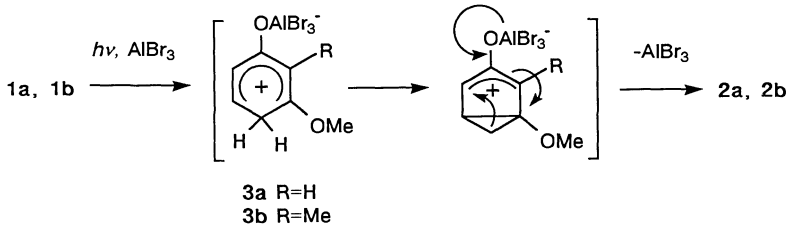
When a solution of **1a** and 2 equiv of $AlBr_3$ in CH_2Cl_2 was irradiated through a Pyrex filter, 4-methoxybicyclo[3.1.0]hex-3-en-2-one (**2a**) was obtained in a 38% isolated yield (74% yield based on **1a** consumed) along with unreacted **1a** (43% conversion).[4] The conversion of **1a** to **2a** reached maximum after about 4.5 h irradiation and by prolonged irradiation the relative ratio of **2a** decreased gradually due to photochemcal cycloreversion to **1a**. Similar cycloreversion of bicyclo[3.1.0]hex-3-en-2-ones has been reported.[5] Indeed, independent irradiation of **2a** showed that **2a** isomerized to **1a** efficiently irrespective of the presence of $AlBr_3$. While irradiation of **2a** in the presence of $AlBr_3$ (2 equiv) gave an equilibrium mixture of **2a** and **1a**, the cycloreversion of **2a** was irreversible in the absence of $AlBr_3$ to afford **1a** in a 83% yield.



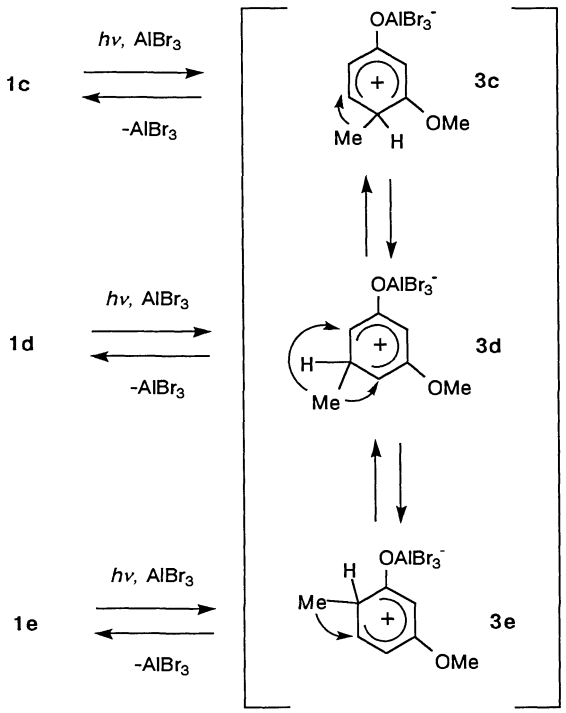
On the other hand, irradiation of the 4-methyl derivative **1c** with $AlBr_3$ (2 equiv) gave an equilibrium mixture composed of **1c**, 3-methoxy-5-methylphenol (**1d**), and 5-methoxy-2-methylphenol (**1e**)(**1c**:**1d**:**1e**= 24:36:39). Similarly, irradiation of **1d** and **1e** with $AlBr_3$ gave mixtures of **1c**, **1d**, and **1e** (7:34:59 from **1d**, 3:26:70 from **1e**). No bicyclohexenones were detected in these cases. It became apparent that the mode of isomerization, i.e., lumiketone-type rearrangement or methyl transposition, of the methyl derivatives **1b**—**1e** is critically dependent on the position of the methyl group.

The above reactivity difference is explained in terms of the reaction pathways shown in Scheme 1 and 2. In view of the previous work done by Childs,[1] it is reasonable to assume that the lumiketone-type rearrangement of **1a** and **1b** proceeds through the para protonated complexes **3a** and **3b**, respectively (Scheme 1). On the other hand, the methyl transposition of **1c**—**1e** is explained by positing the respective complexes **3c**—**3e** which are protonated on the methyl-bearing carbons of the phenol ring. These are interconverted by 1,2-migration of the methyl group, which is located adjacent to the carbocation centers (Scheme 2).

Although the lumiketone-type transformation was successful only for **1a** and **1b**, it should be pointed out



Scheme 1.



Scheme 2.

that products **2a** and **2b** possess a β-methoxy-α,β-enone functionality which is a versatile synthon for further functional group transformation. Moreover, although isolated yields of **2a** and **2b** were only moderate, the products were isolated in an almost pure state by simple extraction and the starting material can be recovered from the alkaline extract. Therefore, despite its limitations, the present transformation provides a useful way to prepare bicyclo[3.1.0]hex-3-en-2-one derivatives from readily available 3-methoxyphenols.

Experimental

IR spectra were recorded on a Hitachi 260-10 spectrometer. ^{1}H NMR (400 MHz) and ^{13}C NMR (100 MHz) spectra were measured with a JEOL JNM-GSX-400 spectrometer. Mass spectra were obtained with a JEOL JMS-DX303 spectrometer. GLC was undertaken with Hitachi G-3000 chromatograph with a capillary column of FFAP (6 m).

3-Methoxyphenol (**1a**) was commercially available and was distilled before use. 3-Methoxy-2-methylphenol (**1b**),[6] 3-methoxy-4-methylphenol (**1c**),[7] 3-methoxy-5-methylphenol (**1d**),[8] and 5-methoxy-2-methylphenol (**1e**)[9] were prepared according to the reported procedures.

Photoisomerization of 3-Methoxyphenol (1a) to 2a. A solution of 500 mg (4.03 mmol) of **1a** and 2.15 g (8.06 mmol) of $AlBr_3$ in 25 ml of CH_2Cl_2 was irradiated with a 500 W high pressure mercury lamp through a Pyrex filter at room temperature. The progress of the reaction was monitored by GLC. After 4.5 h, the mixture was carefully added to ice water and extracted three times with ether. The ether extract was washed with 10% NaOH solution, brine, and dried with $MgSO_4$. Evaporation of the solvent followed by chromatography on silica gel (elution with ether) gave 159 mg (38% yield; 74% based on consumed **1a**) of **2a**. The alkaline washing was acidified with HCl and extracted with ether. The extract was washed with brine, dried, and evaporated. Chromatography on silica gel (elution with 20% ether in petroleum ether) afforded 286 mg (57% recovery) of unreacted **1a**.

2a: IR (neat) 1680, 1580, 1240, and 960 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=4.65 (s, 1H), 3.80 (s, 3H), 2.29 (m, 1H), 2.17 (m, 1H), and 1.4—1.5 (m, 2H); ^{13}C NMR ($CDCl_3$) δ=203.3 (s), 191.2 (s), 95.7 (d), 58.8 (q), 31.4 (t), 24.2 (d), and 20.5 (d); MS *m/z* (rel intensity) 124 (M^+, 100), 96 (45), 81 (36), and 53 (57). Found: C, 67.62; H, 6.44%. Calcd for $C_7H_8O_2$: 67.73; H, 6.50%.

Photoisomerization of 3-Methoxy-2-methylphenol (1b) to 2b. A solution of 100 mg (0.724 mmol) of **1b** and 386 mg (1.45 mmol) of $AlBr_3$ in 5 ml of CH_2Cl_2 was irradiated as above for 30 min. The reaction was worked up as above to give 19 mg (19% yield; 33% based on **1b** consumed) of **2b** and 42 mg (58% conversion) of unreacted **1b**.

2b: IR (neat) 1680, 1620, 1280, 1240, 1000, and 930 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.98 (s, 3H), 2.28 (m, 1H), 2.12 (ddd, *J*=3.9, 6.8, and 8.3 Hz, 1H), 1.47 (ddd, *J*=3.9, 4.9, and 7.8 Hz, 1H), 1.44 (s, 3H), and 1.31 (dd, *J*=3.9 and 7.3 Hz, 1H); ^{13}C NMR ($CDCl_3$) δ=203.4 (s), 185.1 (s), 108.2 (s), 57.0 (q), 33.1 (t), 23.1 (d), 16.1 (d), and 5.6 (q); MS *m/z* (rel intensity) 138 (M^+, 100), 107 (30), 95 (23), 79 (26), and 67 (35). HR MS Found: *m/z* 138.0678. Calcd for $C_8H_{10}O_2$: M, 138.0681.

Photoisomerization of 3-Methoxy-4-methylphenol (1c), 3-Methoxy-5-methylphenol (1d), and 5-Methoxy-2-methylphenol (1e). Irradiation of 100 mg (0.75 mmol) of **1c** or **1d** or **1e** and 398 mg (1.5 mmol) of $AlBr_3$ in 5 ml of CH_2Cl_2 was undertaken as above for 10 h. The mixture was worked up as above and the subsequent flash chromatography on silica gel (ether–hexane=10 : 90 eluent) gave a mixture of **1c**, **1d**, and **1e**. Yields and the ratio of the products (GLC) are as follows: From **1c**: 71 mg (71% yield), **1c** : **1d** : **1e**=24 : 36 : 39. From **1d**: 71 mg (71% yield), **1c** : **1d** : **1e**=7 : 34 : 59. From **1e**: 61 mg (61% yield), **1c** : **1d** : **1e**=3 : 26 : 70. The products were identified by GLC and ^{1}H NMR spectra.

1c: ^{1}H NMR ($CDCl_3$) δ=6.94 (d, *J*=8.3 Hz, 1H), 6.37 (s, 1H), 6.31 (d, *J*=8.3 Hz, 1H), 5.01 (s, 1H), 3.77 (s, 3H), and 2.12 (s, 3H).

1d: ^{1}H NMR ($CDCl_3$) δ=6.31 (br s, 1H), 6.26 (br s, 1H), 6.23 (t, *J*=2.5 Hz, 1H), 5.59 (br s, 1H), 3.74 (s, 3H), and 2.25 (s, 3H).

1e: ^{1}H NMR ($CDCl_3$) δ=6.99 (d, J=8.3 Hz, 1H), 6.41 (dd, J=2.5 and 8.3 Hz, 1H), 6.38 (d, J=2.5 Hz, 1H), 5.28 (br s, 1H), 3.74 (s, 3H), and 2.16 (s, 3H).

Photocycloreversion of 4-Methoxybicyclo[3.1.0]hex-3-en-2-one (2a). A solution of 80 mg (0.65 mmol) of **2a** in 4 ml of CH_2Cl_2 was irradiated for 1 h until the starting material was consumed completely. The solvent was evaporated and the subsequent flash chromatography gave 66 mg (83% yield) of **1a**.

A solution of 80 mg (0.65 mmol) of **2a** and 344 mg (1.3 mmol) of $AlBr_3$ in 4 ml of CH_2Cl_2 was irradiated for 1 h. The mixture was worked up as described for the isomerization of **1a** to **2a**. After chromatography, 40 mg (50% yield) of **1a** and 19 mg (24% yield) of unreacted **2a** were obtained. By prolonged irradiation, while the ratio of **1a** and **2a** did not change appreciably, their yields decreased due to the formation of a small amount of unidentified side products.

We are grateful to the Ministry of Education, Science and Culture for the support of the NMR and Mass Spectral facilities used in this work at the Instrumental Analysis Center of the Faculty of Engineering, Osaka University and for partial support of this work through a Grant-in-Aid.

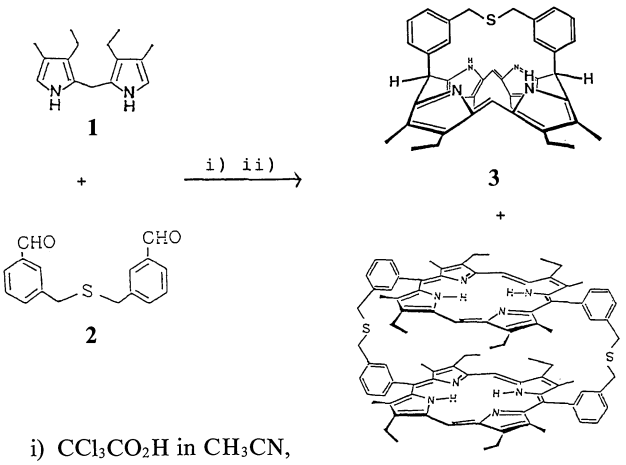
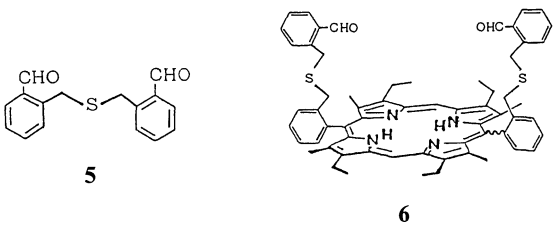
Preparation of Stable 5,15-Dihydroporphyrin

Noboru ONO,* Hiroshi KAZIRO,† and Kazuhiro MARUYAMA†
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790
† Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received May 13, 1991)

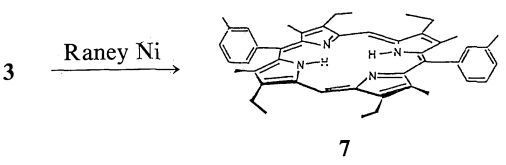
Synopsis. Very stable 5,15-dihydroporphyrin was perpared by the acid catalyzed reaction of dipyrromethane with two benzaldehyde molecules which were linked by an appropriate linkage.

Porphyrin macrocycles constitute an important class of compounds of particular interest owing to their role in biological systems.[1] Recent work has been devoted to the design of new porphyrin ligands with specific properties, or new structural analogues of porphyrins.[2] Dihydroporphyrins, which have two additional hydrogen atoms on the porphyrin nucleus, have also been the subjects of intense study.[3] 5,15-Dihydroporphyrins are intermediates in the formation of porphyrins, but they have not been isolated in the preparation of porphyrins, for they are readily oxidized to porphyrins. The most general synthetic procedure for stable 5,15-dihydroporphyrins is the reductive alkylation of metalloporphyrins. Various 5,15-dihydroporphyrins have been prepared by this method, and they have been used as effective ligands for various metals.[4] In this paper we wish to report a novel method for the preparation of a very stable strapped 5,15-dihydroporphyrin which was not oxidized to the corresponding porphyrins by strong oxidizing agents such as *p*-chloranil. Such strapped 5,15-dihydroporphyrins can not be prepared by the alkylation of an anion of metalloporphyrin with a dihalide.[4]





The acid-catalyzed reaction of dipyrromethane (**1**) with a dialdehyde linked by a thioether group was carried out in order to generate thioether strapped porphyrins or face-to-face dimeric porphyrins bridged by a thioether linkage. The thioether linkage is important, because the sulfur atom may be removed by the procedure established in cyclophane chemistry.[5] Thioether strapped porphyrin can also be regarded as a model of the active electron transporting site of cytochrome c.[6] The two benzaldehyde molecules are linked by CH_2SCH_2 at the *o*- or *m*-position. Such aldehydes were prepared by the reaction of the corresponding bromethylbenzaldehydes with sodium sulfide. The reaction of **1** with dialdehyde (**2**) linked at the *m*-position gave strapped 5,15-dihydroporphyrin (**3**) and face-to-face dimeric porphyrin (**4**) in 65% and 3% yields, respectively. The high yield of **3** was remarkable. On the other hand, the reaction of **1** with dialdehyde (**5**), in which two aldehyde moieties were linked at the *o*-position, gave a complex set of products. It was impossible to isolate any pure products. The mass spectra of the products suggested the formation of porphyrin **6**, but further characterization was very difficult due to the instability and complexity of the products. However, the mass spectra of the corresponding 5,15-dihydroporphyrin and porphirin dimers were not detected. Compound **3** was extremely stable to oxidizing agents, and it was not oxidized to the corresponding porphyrins by chloranil or oxygen. Thus, the formation of stable 5,15-dihydroporphyrins depended on the linkage which connected the two aldehyde moieties. When a longer linkage was used, the strapped porphyrin and face-to-face porphyrin dimers were formed by the similar reaction.[7] The CPK model of **3** showed that the bond angles around the 5 and 15 positions of the tetrapyrrole macrocycle were ideal for the formation of stable 5,15-dihydroporphyrins. The bond angles of the tetrapyrrole which may be obtained from 5 were unfavorable for the formation of 5,15-dihydroporphyrin. 5,15-Dihydroporphyrins were not isolated from the reaction of dialdehydes linked by longer linkages, for they were readily oxidized to the corresponding porphyrins. When the thioether linkage of **3** was cleaved, tetrapyrrole should have been readily oxidized to porphyrins. In fact, treatment of **3** with Raney Ni gave porphyrin **7** in a good yield, which may provide a useful method for the stereoselective synthesis of 5,15-diarylporphyrins.



Compound **3** was an orange solid (λ_{max} 427.5 nm) and has a strong affinity to various metals like porphyrins. Preliminary experiments using an ion selective electrode showed a strong affinity to Ni or Cu. The use of **3** as a ligand is now being studied.

Experimental

Mass spectra were recorded on a JEOL DX-300 spectrometer using the FAB method; the FAB matrix was $CHCl_3$+trifluoroacetic acid/*m*-nitrobenzyl alcohol/glycerol.

Bis(3-formylbenzyl) Sulfide (2). A mixture of *m*-bromomethylbenzadehyde[8] (1.25 g, 6.3 mmol) and $Na_2S \cdot 9H_2O$ (0.87 g, 7.5 mmol) in *N*,*N*-dimethylformamide (80 ml) was stirred for 30 h under Ar at room temperature. The reaction mixture was then poured into water and extracted with CH_2Cl_2. The organic layer was washed with water and dried over anhydrous magnesium sulfate. Evaporation of the solvent gave crude **2**, which was purified by column chromatography (silica gel/hexane–ethyl acetate 3:1) to give pure **2** as a white solid, mp 74—76 °C, 0.64 g (75% yield). ^{1}H NMR (400 MHz, $CDCl_3$) δ=3.68 (s, 4H). 7.48 (t, J=4 Hz, 2H), 7.54 (d, J=4 Hz, 2H), 7.75 (s, 2H), 7.76 (d, J=4 Hz, 2H), and 10.0 (s, 2H). Found: C, 71.05; H, 5.90%. Calcd for $C_{16}H_{14}O_2S$: C, 71.08; H, 5.96%.

Bis(2-formylbenzyl) Sulfide (5). This compound was prepared from *o*-bromomethylbenzaldehyde by the same procedure as the preparation of **2**, mp 60—62 °C, ^{1}H NMR (400 MHz, $CDCl_3$) δ=4.15 (s, 4H), 7.36 (d, J=4 Hz, 2H), 7.45 (t, J=4 Hz, 2H), 7.52 (t, J=4 Hz, 2H), 7.83 (d, J=4 Hz, 2H), and 10.2 (s, 2H). Found: C, 71.12; H, 5.88%. Calcd for $C_{16}H_{14}O_2S$: C, 71.08; H, 5.96%.

Preparation of 5,15-Dihydroporphyrin (3) and Porphyrin (4). A solution of trichloroacetic acid (10 mg) in dry acetonitrile (30 ml) was added to a stirred solution of bis(3-ethyl-4-methyl-2-pyrrolyl)methane[9] (**1**, 0.65 mmol) and dialdehyde (**2**, 0.32 mmol) in dry acetonitrile (30 ml) under N_2 in the dark. After stirring the solution at room temperature for 12 h, *p*-chloranil (0.45 g) in dry tetrahydrofuran (10 ml) was added and the resulting mixture was stirred for 12 h at room temperature. After removing the solvent, the residue was subjected to column chromatography (alumina Woelm N-I/CH_2Cl_2) to give **3** and **4**, respectively. Recrystallization from CH_2Cl_2–CH_3OH gave pure **3** as an orange solid in a 65% yield. Mp 250 °C (decomp), UV-vis (CH_2Cl_2) 427.5 nm. ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.11 (t, J=7 Hz, 12H), 2.11 (s, 12H), 2.53 (q, J=7 Hz, 8H), 3.35 (s, 4H), 5.46 (s, 2H), 6.99 (s, 2H), 7.26—7.36 (m, 8H), and 9.20 (br, 2H, NH). MS (FAB) m/z 691 ($M+H^+$). Found: C, 79.84; H, 7.36; N, 8.02%. Calcd for $C_{46}H_{50}N_4S$: C, 79.96; H, 7.29; N, 8.11%. Porphyrin **4**: 3% yield as a purple solid, UV-vis (CH_2Cl_2) 395, 507, 540, 578, and 627 nm. MS (FAB) m/z 1377 ($M+H^+$). NMR spectra were too complicated to be characterized. The absorption spectra indicated interaction between two chromopheres; the soret band is blue-shifted and the Q bands are red-shifted compared to the monomeric 5,15-diarylporphyrin.

The reaction of **5** with **1** was carried out in the same way as described above. Several unstable products were detected by TLC. All attempts to isolate pure compounds by column chromatography or recrystallization were unsuccessful. MS (FAB) m/z 959, which suggested that porphyrin **6** may have been involved in a complex set of products. However, further charaterization of the products was impossible due to instability of the products.

Preparation of 5,15-Di-*m*-tolyl-2,8,12,18-tetraethyl-3,7-13,17-tetramethylporphyrin (7). A mixture of **3** (30 mg) and Raney Ni W-7 (500 mg) in ethanol (1 ml) and CH_2Cl_2 (15 ml) was heated at reflux temperature for 24 h. The reaction mixture was poured into water and extracted with CH_2Cl_2. The extract was washed with water and dried with anhydrous magnesium sulfate. After the removal of the solvent, the residue was subjected to column chromatography (silica gel/CH_2Cl_2) to give **7** (20 mg, 80% yield). Uv-vis (CH_2Cl_2) λ_{max} 408, 506, 538, 571, and 625 nm. ^{1}H NMR (400 MHz, $CDCl_3$) δ=2.24 (br, 2H, NH), 1.76 (t, J=7 Hz, 12H), 2.20 (s, 6H), 2.43 (s, 12H), 4.00 (m, 8H), 7.8—8.2 (m, 8H), and 10.18 (s, 2H). MS (FAB) m/z 657 ($M+H^+$).

(Received May 23, 1991)

Synopsis. Bakers' yeast reduction of α-substituted or β,β-disubstituted α,β-unsaturated ketones gave saturated chiral ketones with excellent optical purity, while the β,β-disubstituted derivative remained intact.

A number of bakers' yeast reductions of carbon–carbon double bonds, which are functionalized with hydroxymethyl,[1a] formyl,[1b] or nitro group,[1c] have been reported.[1d] However, less attention has been paid on the conjugated enones. For example, the carbonyl group of 4-phenyl-3-buten-2-one is reduced predominantly to give the corresponding (*S*)-allyl alcohol.[2] In contrast, we previously reported the bakers' yeast reduction of the carbon-carbon double bond of functionalized enones such as 3-chloro-3-alken-2-ones[3a] and 3-(1-hydroxyalkyl)-3-buten-2-ones,[3b] both of which afforded the corresponding saturated ketones with high optical purity. The effects of the chloro or the hydroxyl group on the reaction were obscure. We report here the reduction of simple enones such as 3-alkyl-3-buten-2-ones and 3- or 4-phenyl-3-buten-2-one. The α-substituted enones are reduced to the saturated ketones with excellent optical purity. The results are discussed as compared with those of 3-(1-hydroxyalkyl)-3-buten-2-ones.[3b]

Table 1 shows the reduction of 3-alkyl-3-buten-2-ones (**1a—e**) by use of pressed bakers' yeast (PBY). Enones **1b—d** having an alkyl chain of C_6 to C_{11} gave saturated ketones **2b—d** with high enantiomeric excess (ee) (Scheme 1). (2*S**,3*R**)-3-Methyl-2-alkanols **3b**[4] (1% yield) and **3c**[4] (6% yield) were also isolated as a minor component.[5] The absolute configuration for **2b-d** was assigned to be (*R*) by comparison of the rotation with that for authentic (*R*)-**2b**.[6] Interestingly, the enone **1c** was reduced in 30% yield with a rather shorter reaction time (11 h), while the yield could not be increased further even by extension of the time to 22 h. The shorter-chain homolog **1b** and the longer-chain one **1d** required much prolonged reaction times, 64 h and 90 h respectively, to give **2b** and **2d** in rather lowered yields. The shortest homolog **1a** (R=C_5H_{11}) gave neither reduction product nor substrate recovered. The longest one **1e** (R=$C_{12}H_{25}$) remained intact. Thus the yeast reduction of the enones having α-alkyl group **1** was found to be highly dependent on the length of the α-alkyl chain.

The results mentioned above are in contrast to those for the 3-(1-hydroxyalkyl)-3-buten-2-ones:[3b] 1) 3-Pentyl-3-buten-2-one (**1a**) was not reduced nor recovered at all after 87 h incubation, but the 3-(1-hydroxypentyl)-3-buten-2-one was reduced in 56% yield after 69 h. 2) 3-Hexyl-3-buten-2-one (**1b**) was reduced in 24% yield by 64 h incubation without recovery of the starting enone, but 3-(1-hydroxypentyl)-3-buten-2-one was reduced in 72% yield for 114 h. Thus the 1-hydroxy group in the alkyl substituent seems to enhance the yield and prevent the loss of substrate during the incubation.

The substrate was then replaced to the aromatic

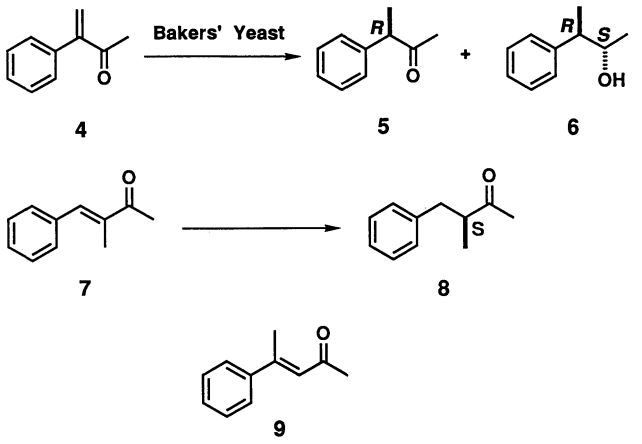
a) Determined by 200 MHz (for **2b**) or 100 MHz (for **2c** and **2d**) ^1H NMR spectra in the presence of (+)-Eu $(hfc)_3$. b) Alcohol **3b** was obtained in 1% yield. c) Reported rotation: $[\alpha]_D$ −12.03°. (neat) for the (*R*) enantiomer (99% ee) (Ref. 6b). d) Alcohol **3c** was produced in 6% yield.



Scheme 2.

analogues. The reduction of 3-phenyl-3-buten-2-one (**4**) was carried out by use of immobilized bakers' yeast (IMBY) to afford (*R*)-(−)-3-phenyl-2-butanone (**5**)[7] (24% yield, 95% ee) and (2*S*,3*R*)-(+)-3-phenyl-2-butanol (**6**)[8] (6% yield) (Scheme 2). The IMBY method required 30 times as much bakers' yeast as the substrate by weight, showing a sharp contrast to the free bakers' yeast method which needed 110 times yeast to give **5** in only 4% yield with 56% ee. The substrate **4** showed a remarkable inhibitory feature to the fermentation.

The reduction of 3-methyl-4-phenyl-3-buten-2-one (**7**) with IMBY gave (*S*)-(+)-3-methyl-4-phenyl-2-butanone (**8**) in 52% yield. However, the optical purity was lowered to 72% ee. The β,β-disubstituted enone such as 4-phenyl-3-penten-2-one (**9**) was recovered unchanged. Thus, the bakers' yeast reduction is found to suffer with the β-substituent(s) of the α,β-unsaturated ketones.

Experimental

Ir spectra were recorded with a Jasco A-102 spectrometer. ^{1}H NMR spectra at 60 and 100 MHz were obtained on JEOL PMX-60SI and JEOL FX-100 spectrometers, respectively, and those at 200 and 500 MHz as well as ^{13}C NMR spectra (50 MHz) were measured on Varian VXR spectrometers. Preparative column chromatography was carried out by using silica gel (Merck Silica Gel 60). Purification by HPLC was performed by use of Hitachi 655 apparatus with Unisil Q column (10.7 mm i.d.×250 mm l). Compounds **7**[9] and **9**[10] were prepared by the reported methods. Elemental analyses were carried out by Eiichiro Amano of this laboratory.

3-Alkyl-3-buten-2-ones (1a—e). These compounds were prepared by the palladium-catalyzed decarboxylation-deacetoxylation of allyl α-acetoxymethyl β-keto carboxylates which were derived from allyl acetoacetate via three steps[11] (method A). Enone **1b** was also synthesized by the formaldehyde-K_2CO_3 promoted deacetylation-methylenation[12] of 3-hexyl-2,4-pentanedione (95% yield), which was prepared by Bu_4NHSO_4 catalyzed alkylation[13] of acetylacetone with 1-iodohexane (70% yield) (method B). The overall yields of **1a—e** (method A) after purification by column chromatography and their spectral and physical data are shown below.

3-Pentyl-3-buten-2-one (1a):[11] 24.9% yield; IR (neat) 1680, 1630 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.75—1.10 (m, 3H), 1.10—2.24 (m, 8H), 2.24 (s, 3H), 5.61 (s, 1H), 5.85 (s, 1H).

3-Hexyl-3-buten-2-one (1b):[14a] 5.6% yield; IR (neat) 1680, 1630 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.65—1.05 (m, 3H), 1.09—1.90 (m, 14H), 2.23 (s, 3H), 5.60 (s, 1H), 5.83 (s, 1H).

3-Octyl-3-buten-2-one (1c):[14b] 22% yield; IR (neat) 1680, 1630 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.70—1.15 (m, 3H), 1.10—1.80 (m, 14H), 2.22 (s, 3H), 5.57 (s, 1H), 5.81 (s, 1H).

3-Undecyl-3-buten-2-one (1d):[14c] 9.7% yield; IR (neat) 1680, 1630 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.70—1.07 (m, 3H), 1.07—1.90 (m, 14H), 2.24 (s, 3H), 5.61 (s, 1H), 5.84 (s, 1H).

3-Dodecyl-3-buten-2-one (1e): 10.5% yield; bp 160 °C (7.5 mmHg, 1 mmHg=133.322 Pa); IR (neat) 1680, 1620 cm^{-1}; ^{1}H NMR (CCl_4) δ=0.70—1.07 (m, 3H), 1.07—1.90 (m, 14H), 2.24 (s, 3H), 5.61 (s, 1H), 5.84 (s, 1H). Found: C, 80.32; H, 12.45%. Calcd for $C_{15}H_{28}O$: C, 80.29; H, 12.58%.

Typical Reduction of 1a—e with Pressed Bakers' Yeast. (*R*)-(−)-3-Methyl-2-undecanone (2c) and (2*S,3*R**)-3-Methyl-2-undecanol (3c):**[4] To a 500 ml round bottomed flask were added boiled water (110 ml), pressed bakers' yeast (7.0 g), and glucose (10.0 g). The suspension was stirred for 20 min at 30 °C and then enone **1c** (275 mg, 1.51 mmol) was added. After stirring for additional 7 h at 30 °C, glucose (10 g) was added and the stirring was continued for 22 h in total. Celite (12 g) was added and the mixture was stirred further for 6 h. After filtration under suction, the filtrate was extracted with ethyl acetate and the residue was washed with ethyl acetate. The combined organic layer was dried over $MgSO_4$ and concentrated under reduced pressure. Fractionation of the crude products with column chromatography on silica gel (30 g, hexane:ethyl acetate=30:1) followed by purification by HPLC (hexane:ethyl acetate 30:1, 1.7 ml min^{-1}) gave ketone **2c** (3.5 min, 80 mg, 29% yield) and alcohol **3c** (7.0 min, 16 mg, 6% yield).

2c: IR (neat) 1720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.70—2.02 (m, 17H), 1.07 (d, 3H, *J*=7 Hz), 2.09 (s, 3H), 2.01—2.60 (m, 1H); ^{13}C NMR ($CDCl_3$) δ=14.1 (q), 16.2 (q), 22.7 (t), 27.3 (t), 28.0 (q), 29.3 (t), 29.5 (t), 29.7 (t), 31.9 (t), 47.3 (d), 212.9 (s). Found: C, 78.44; H, 13.34%. Calcd for $C_{12}H_{24}O$: C, 78.20; H, 13.12%.

3c:[4] IR (neat) 2800—3000 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ= 0.84 (d, 3H, *J*=6.0 Hz), 0.85 (t, 3H, *J*=7.0 Hz), 1.10—1.60 (m, 15H), 1.10 (d, 3H, *J*=6.5 Hz); 3.63 (dq, 1H, *J*=6.0 and 6.0 Hz); ^{13}C NMR ($CDCl_3$) δ=14.1 (q), 14.5 (q), 19.3 (q), 22.7 (t), 27.3 (t), 29.4 (t), 29.7 (t), 30.0 (t), 31.9 (t), 32.6 (t), 40.1 (d), 71.8 (d). Found: C, 77.42; H, 14.01%. Calcd for C: 77.35; H, 14.06%.

(*R*)-(−)-3-Methyl-2-nonanone (2b)[6] **and (2*S**,3*R**)-3-Methyl-2-nonanol (3b).**[15] **2b:** IR (neat) 1715 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.86 (t, 3H, *J*=6.8 Hz), 1.06 (d, 3H, *J*=6.8 Hz), 1.25 (m, 10H), 2.11 (s, 3H); 2.48 (dq, 1H, *J*=6.8 Hz and 6.8 Hz).

3b: 1% yield; ^{1}H NMR ($CDCl_3$) δ=0.87 (d, 3H, *J*=6.6 Hz), 0.89 (bt, 3H), 1.13 (d, 3H, *J*=6.3 Hz), 1.05—1.70 (m, 11H), 3.67 (dq, 1H *J*=6.0 and 6.0 Hz).

(*R*)-(−)-3-Methyl-2-tetradecanone (2d): IR (neat) 1715 cm^{-1}; ^{1}H NMR ($CDCl_4$) δ=0.70—1.90 (m, 23H), 1.03 (d, 3H, *J*=7 Hz), 2.01 (s, 3H), 2.01—2.65 (m, 1H). Found: C, 79.41; H, 13.33%. Calcd for $C_{15}H_3O$: C, 79.58; H, 13.35%.

Determination of ee for (*R*)-2b—d. The ee of **2b** was determined by use of the ^{1}H NMR (200 MHz, $CDCl_3$) spectrum recorded in the presence of 30 mol% of (+)-Eu(hfc)$_3$ at 30 °C. Under the conditions, the singlet due to the terminal methyl group of (±)-**2b**, prepared as described below, resolved to a pair of singlets at δ=3.130 (for *S*) and δ=3.111 (for *R*). Similar ^{1}H NMR (100 MHz) experiments were carried out for **2c** and **2d** by using 50 mol% of (+)-Eu(hfc)$_3$.

Preparation of (±)-2b—d. These compounds were prepared for the references in the ^{1}H NMR shift reagent experiments. A mixture of 3-hexyl-3-buten-2-one (212 mg, 1.37 mmol) and 5% Pd-C (110 mg) was stirred at room temperature under hydrogen atmosphere overnight. Filtra-

tion of the mixture followed by concentration gave a crude product, which was purified by column chromatography (hexane:ethyl acetate=30:1) to give (±)-**2b** in 74% yield. Compounds (±)-**2c** (52% yield) and (±)-**2d** (40% yield) were obtained in a similar way.

3-Phenyl-3-buten-2-one (4).[16] The following method is newly developed here. 1-Phenylvinylmagnesium bromide was prepared by the reaction of α-bromostyrene (2.75 g, 15 mmol) and magnesium turnings (413 mg, 0.017 g-atom) in 10 ml of THF.[17] The dark brown suspension of the Grignard reagent was introduced dropwise to a solution of acetic anhydride (1.53 g, 5 mmol) in 5 ml of THF at −78 °C. After being stirred for 1 h at the temperature, the cooling bath was removed and the mixture was stirred further for 2.5 h. Water was added and the solvent was removed under reduced pressure. The organic layer was extracted with ethyl acetate and washed with aqueous $NaHCO_3$ and brine, dried over $MgSO_4$, concentrated under reduced pressure. The crude product was distilled under vacuum to give 1.40 g (64% yield) of enone **4**: Bp 100—105 °C (5 mmHg); IR (neat) 3070, 1680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.45 (s, 3H), 5.98 (s, 1H), 6.19 (s, 1H), 7.25—7.45 (5H, m); ^{13}C NMR ($CDCl_3$) δ=27.4 (q), 125.7 (t), 128.1 (d), 128.4 (d), 137.0 (s), 149.5 (s), 199.4 (s).

Bakers' Yeast Reduction of Enone (4). (*R*)-(−)-3-Phenyl-2-butanone (5)[7] **and (2*S*,3*R*)-(+)-3-Phenyl-2-butanol (6).**[8] Immobilized bakers' yeast (dry bakers' yeast: sodium alginate= 4:1 in w/w) was prepared by the procedure described previously.[18] To a mixture of the immobilized bakers' yeast (78 ml including 6 g of bakers' yeast), glucose (20 g), and boiled water (150 ml) was stirred at 35 °C for 30 min. Enone **4** (963 mg, 6.59 mmol) was added and the mixture was stirred for 48 h. In the course of the reaction, 110 g of glucose was consumed. The combined ethyl acetate extracts both from the aqueous layer and from the gels were treated in a usual manner[18] and the crude product was purified by column chromatography (hexane:ethyl acetate, 20—10:1) to give ketone **5** (236 mg, 24% yield) and (2*S*,3*R*)-alcohol **6** (55 mg, 6% yield).

5: ($[\alpha]_D$−333° (*c* 0.75, benzene), lit[7] $[\alpha]_D$+368° (benzene) for 3*S*); IR (neat) 3050, 1720, 1500 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.38 (d, 3H, *J*=7.0 Hz), 2.04 (s, 3H), 3.74 (q, 1H, *J*=7.0 Hz), 7.18—7.36 (m, 5H).

6: ($[\alpha]_D$+17.7° (*c* 3.53, EtOH), [lit,[8] $[\alpha]_D$+16.2 (*c* 3.6, EtOH, 81% ee)]; ^1H NMR ($CDCl_3$) δ=1.23 (d, 3H, *J*=6.2 Hz), 1.26 (d, 3H, *J*=7.2 Hz), 1.58 (s, 1H, OH), 2.67 (dq 1H, *J*=7.2 Hz, 7.2 Hz), 3.85 (dq, 1H, *J*=7.2 Hz, 6.2 Hz), 7.2—7.4 (m, 5H).

Optical purity of **5** was determined as 95% ee in a similar manner to that dscribed for aliphatic ketone **2b-d**.

(±)-3-Phenyl-2-butanone (±)-(5). A mixture of enone **4** (200 mg, 1.37 mmol), palladium chloride (23 mg, 0.13 mmol), silica gel (100 mg) in ethanol (3 ml) was stirred under hydrogen at room temperature for 2 d. A usual workup followed by distillation [bp 100—105 °C (5 mmHg)] gave ketone (±)-**5** (152 mg, 75% yield).

(*S*)-(+)-4-Phenyl-3-methyl-2-butanone (8).[19] Incubation was carried out at 35 °C for 82 h by use of enone **7** (160 mg, 1.88 mmol), glucose (90 g in all), water (400 ml), and the immobilized yeast (150 ml, including 18 g of bakers' yeast). Workup in a usual way followed by purification with preparative TLC (20 cm×20 cm, silica-gel plate with 2 mm thickness, hexane:ether 5:1) gave ketone **8** (110 mg, 37% yield): $[\alpha]_D$+33.6° (*c* 2.74, EtOH) (lit, $[\alpha]_D$+45.5° (EtOH) for **8**); IR (neat) 1710 and 1600 cm^{-1}; ^1H NMR (CCl_4) δ=1.02 (d, 3H, *J*=6 Hz), 1.95 (s, 3H), 2.28—3.10 (m, 3H), 7.05 (s, 5H). Optical purity was determined to be 72% ee by a similar ^1H NMR (200MHz) method to that described above.

The authors are grateful to the SC-NMR Laboratory of Okayama University for obtaining ^1H (200 and 500 MHz) and ^{13}C (50 MHz) NMR spectra.

Synopsis. The reaction of 1,2-diphenyl- and 1-methyl-2-phenyl-3,3-dichloro- or dibromocyclopropenes with trialkyl phosphites, dialkyl phenylphosphonites, and alkyl diphenylphosphinites afforded cyclopropenes with 3,3-diorganophosphorous substituents in moderate yields via double Arbuzov type reactions.

In a continuation of our studies on the chemistry of cyclopropenium salts and cyclopropenes possessing heteroatom substituents[1] we have tried to prepare cyclopropenium salts with organophosphorus substituents. The reaction of 1-ethoxy-2,3-diphenylcyclopropenium tetrafluoroborate with diethyl phospite or triethylphosphite provided no good results, yielding the original diphenylcyclopropenone. The reaction with dihalocyclopropene, however, proved to be a new easy route to cyclopropenes substituted with 3,3-diorganophspophorous substituents. The dialkoxyphosphinyl derivatives of the general structure, P–CH_2–P or P–CHR–P, have attracted considerable attention because of their biological activities,[2] chelation to metals,[3] and roles as synthetic tools.[4]

The reactions of cyclopropenones (**1**) with thionyl halides afford 3,3-dihalocyclopropenes (**2**) in good yield.[5] Since **2** are unstable to moisture they were used without isolation.

A mixture of 3,3-dichloro-1,2-diphenylcyclopropene (**2aa**) and trimethyl phosphite (**3a**, mole ratio 1 : 1.1) in dichloromethane at 40 °C for 1 d gave 3,3-bis(dimethoxyphosphinyl)-1,2-diphenylcyclopropene (**4aa**) in 37% yield. The use of a mole ratio of 1 : 2.2 afforded **4aa** in 68% yield. The structure of **4aa** was assigned from IR, ^1H, ^{13}C, ^{31}P NMR, and mass spectroscopic studies and chemical transformation. The cyclopropene **4aa** was stable under acidic conditions in a stirring mixture of $HClO_4$–CH_2Cl_2 at room temperature for 2 h. In contrast, upon heating at 50 °C with sodium hydroxide in methanol for 4 h **4aa** provided **5** in 88% yield, indicating the presence of a cyclopropene ring (Scheme 1). A similar treatment of **2** at 40 °C with 2.2 times excess moles of **3** yielded cyclopropenes with 3,3-diorganophosphorous substituents **4** in moderate yields, as listed in Table 1. No 1 : 1 addition product could be isolated. The yields of **4** decreased in the order OMe>OEt>OPr^{-i} with the substituent of phosphorous esters.

It has been shown that the reaction of 1,1-dibromocyclopropanes with trialkyl phosphite at 90 °C in the

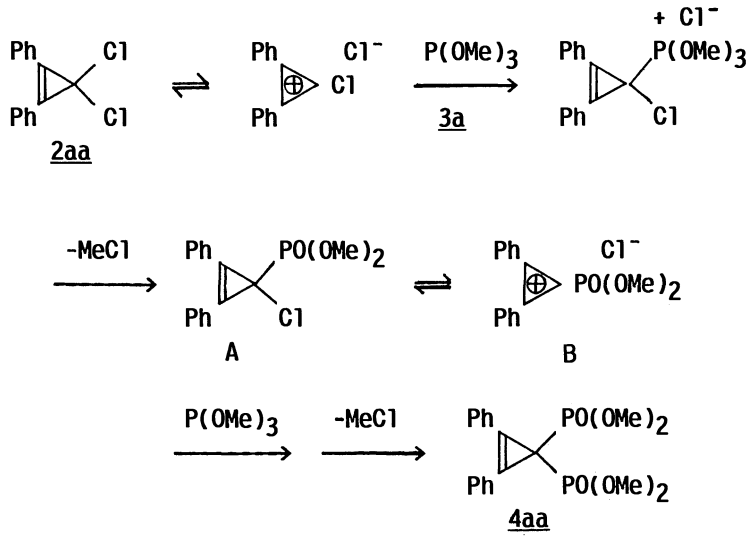

Scheme 2.

presence of triethylamine and water provides cyclopropylphosphonates via reductive phosphonation with dialkyl phosphonates.[6]

Considering the results, we obtained a plausible mechanism for the generation of a representative compound **4aa**, as shown in Scheme 2. Although the isolation of 3-chloro-3-dimethoxylphosphinyl-1,2-diphenylcyclopropene **A**, a mono-Arbuzov reaction product,[7] failed, the intermediacy of mono-adduct **A** was clear from the final product **4**. The reaction of the possible intermediate cyclopropenium salt **B** with **3a** would yield two types of substitution products. One isomer **4** was obtained as stable crystals (Table 1). The formation of another isomer might be prevented by the bulky phenyl group inhibiting substitution onto C-2 with **3** or the subsequent Arbuzov reaction to collapse to the starting reagents. The high activity of the halocyclopropenes was attributed to their aromatic nature.

Experimental

General. The melting points were uncorrected. The ^{1}H NMR spectra were recorded on a Hitachi R-24B (60 MHz) and ^{13}C and ^{31}P NMR spectra on a JEOL JNM FX-90Q (22.40 MHz). NMR spectra were recorded in $CDCl_3$, unless otherwise stated, using TMS (^{1}H and ^{13}C) as an inner or H_3PO_4 (^{31}P) as an external standard. The IR spectra were obtained on a JEOL JIR 100.

The Reaction of 3,3-Dichloro-1,2-diphenylcyclopropene (2aa) with Trimethyl Phosphite (3a). A mixture of 1,2-diphenylcyclopropenone (**1a**) (0.50 g 2.4 mmol) and thionyl chloride (40 mmol) was heated at 40 °C for 2 h; excess of thionyl chloride was removed in vacuo to afford orange crystals of **2aa**. A solution of **2aa** and **3a** (5.3 mmol) in dichloromethane (10 ml) was heated at 40 °C for 24 h. The reaction mixture was condensed in vacuo to dryness, and the obtained crystals washed with petroleum ether; recrystallization from benzene–petroleum ether afforded **4aa** in 68% yield.

4aa: Mp 127—129 °C; IR (KBr) 1860, 1240, and 1030 cm^{-1}; ^{1}H NMR δ=3.72 (dd, J_{POCH}=5.4 and 5.4 Hz, 12H, $4CH_3$) and 7.2—8.1 (m, 10H, 2Ph); ^{13}C NMR δ=23.3 (C-3), 53.0 (CH_3), 104.9, 125.6, 128.8(d), 129.8(d), and 130.1(d); ^{31}P NMR δ=25.26; MS (*m*/*z*) 408 (M^+). Found: C, 55.85; H, 5.36%. Calcd for $C_{19}H_{22}O_6P_2$: C, 55.88; H, 5.43%.

2ab was prepared from **1a** (2.4 mmol) and thionyl bromide (2.9 mmol) in dichloromethane (5 ml) at room temperature for 10 min. Chlorination of **1b** (2.4 mmol) with thionyl chloride (2.4 mmol) was performed at 0 °C for 5 min in dichloromethane (5 ml) to yield **2ba**.

A similar treatment of **2** with **3** yielded **4** in moderate yields, as summarized in Table 1. The physical properties of the products are as follows:

4ab: Mp 99—102 °C; IR (KBr) 1860, 1240, and 1020 cm^{-1}; ^{1}H NMR δ=1.20 (t, *J*=7.2 Hz, 12H, $4CH_3$), 3.8—4.4 (m, 8H, $4CH_2$), and 7.2—8.1 (m, 10H, 2Ph); ^{13}C NMR δ=16.3 (CH_3), 24.3 (C-3), 62.2 (CH_2), 105.4, 126.0, 128.7(d), 129.6(d), and 130.2(d); ^{31}P NMR δ=22.93; MS (*m*/*z*) 464 (M^+). Found: C, 59.43; 6.54%. Calcd for $C_{23}H_{30}O_6P_2$: C, 59.48; H, 6.51%.

4ac: Mp 80—81 °C; IR (KBr) 1840, 1220, and 980 cm^{-1}; ^{1}H NMR δ=1.20 (dd, *J*=6.0 and 6.0 Hz, 24H, $8CH_3$), 4.3—5.0 (m, 4H, 4CH), and 7.2—8.1 (m, 10H, 2Ph); ^{13}C NMR δ=25.9 (CH_3), 26.3 (CH_3), 27.6 (C-3), 72.8(CH), 107.9, 128.4, 130.6(d), 131.4(d), and 132.3(d); ^{31}P NMR δ=21.47; MS (*m*/*z*) 520 (M^+). Found: C, 62.18; H, 7.43%. Calcd for $C_{27}H_{38}O_6P_2$: C, 62.29; H, 7.35%.

4ad: Mp 154—157 °C; IR (KBr) 1820, 1220, and 1020 cm^{-1}; ^{1}H NMR δ=3.5—3.9 (m, 6H, $2CH_3$) and 6.9—7.9 (m, 20H, 4Ph); ^{13}C NMR δ=30.7 (C-3), 51.7 (CH_3), 105.6(d), 125.9(s), 127.6(d), 127.9(d), 128.4(d), 129.5(d), 129.9(d), 131.7(s), and 132.2(d); ^{31}P NMR δ=42.10; MS (*m*/*z*) 500 (M^+). Found: C, 69.65; H, 4.98%. Calcd for $C_{29}H_{26}O_4P_2$: C, 69.59; H, 5.23%.

4ae: Mp 95—97 °C; IR (KBr) 1830, 1230, and 1030 cm^{-1}; ^{1}H NMR δ=1.0—1.5 (m, 6H, $2CH_3$), 3.7—4.5 (m, 4H, $2CH_2$), and 6.9—8.9 (m, 20H. 4Ph); ^{13}C NMR δ=16.4 (CH_3), 18.3 (C-3), 61.2 (CH_2), 106.1 (s), 125.9(d), 127.6(d), 128.3(d), 129.4(d), 130.0(d), 130.2(d), 131.7(s), and 132.5(d); ^{31}P NMR δ=9.88; MS (*m*/*z*) 528 (M^+). Found: C, 70.21; H, 5.82%. Calcd for $C_{31}H_{30}O_4P_2$: C, 70.44; H, 5.72%.

4af: Mp 184—185 °C; IR (KBr) 1190 cm^{-1}; ^{1}H NMR δ=6.8—8.1 (m); ^{13}C NMR δ=36.6(C-3). 108.3(s), 126.5, 127.2, 127.5, 127.8, 128.3, 129.5, 129.8, 131.0, 131.7, 131.9. 132.1, and 133.8; ^{31}P NMR δ=33.68; MS (*m*/*z*) 592 (M^+). Found: C, 79.13; H, 5.01%. Calcd for $C_{39}H_{30}O_2P_2$: C, 79.04; H, 5.10%.

4ba: Mp 83—85 °C; IR (KBr) 1885, 1240, and 1020 cm^{-1}; ^{1}H NMR δ=2.45 (s, 3H, CH_3), 3.6—4.0 (m, 12H, $4CH_3$), and 7.2—7.8 (m, 5H, Ph); ^{13}C NMR δ=11.8 (CH_3), 23.7 (C-3), 54.0 (OCH_3), 103.8(s), 105.1, 126.5, 130.0(d), 130.6(d), and 131.0(d);

MS (m/z) 348 (M^+). Found: C, 48.41; H, 6.13%. Calcd for $C_{14}H_{22}O_6P_2$: C, 48.28; H, 6.36%.

Hydrolysis of 4aa. A solution of **4aa** (0.5 mmol) in ethanol (15 ml) containing 2.5 mmols of sodium hydroxide was heated at 50 °C for 5 h. The reaction mixture was quenched to ice water and acidified with hydrochloric acid. Precipitated crystals were collected and recrystallized from ethanol to yied **5** in 88% yield.

5: Mp 239—242 °C; IR (KBr) 2650, 1210, and 1040 cm^{-1}; ^1H NMR ($CDCl_3$+CF_3CO_2H, 10:1) δ=3.79 (dd, J=5.4 Hz, $2CH_3$) and 7.2—8.0 (m, 10H, 2Ph); ^{13}C NMR ($CDCl_3$+CF_3CO_2H, 10:1) δ=23.2 (C-3), 53.6 (CH_3), 94.1, 124.1(s), 129.2(d), 130.1(d), and 130.9(d); ^{31}P NMR ($CDCl_3$+CF_3CO_2H, 10:1) δ=26.86; MS (m/z) 380 (M^+). Found: C, 53.31; H, 4.51%. Calcd for $C_{17}H_{18}O_6P_2$: C, 53.69; H, 4.77%.

S_H2' Type Reactions of Arenesulfonyl Chlorides with Allylic Compounds Catalyzed by a Ruthenium(II) Complex

Nobumasa KAMIGATA,* Kimiko ISHII, Takeshi OHTSUKA, and Haruo MATSUYAMA
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University,
Minami-Ohsawa, Hachioji, Tokyo 192-03
(Received June 6, 1991)

Synopsis. In the presence of a catalytic amount of dichlorotris(triphenylphosphine)ruthenium(II), the reactions of arenesulfonyl chlorides with allyl phenyl sulfide and allyl phenyl selenide proceeded smoothly to give allyl phenyl sulfone in high yield as well as the corresponding diphenyl disulfide or diphenyl diselenide. An S_H2'-type mechanism involving the arenesulfonyl radical is proposed.

We previously reported that the reactions of alkane- and arenesulfonyl chlorides with olefins in the presence of a catalytic amount of ruthenium(II) phosphine complex gave the corresponding 1:1 adducts in high yields. A radical mechanism in the coordination sphere of the metal complex is proposed since the reactions were suppressed by the addition of radical inhibitors, such as galvinoxyl, *p*-benzoquinone or DPPH.[1] However, there was no further experimental evidence for the radical process; i.e. we failed to detect the radical intermediates by ESR and CIDNP methods. By the way, Kosugi and Migita first reported the S_H2'-type reactions of the allyl sulfides and halides as being characteristic free radical reactions.[2] We have thus studied the ruthenium(II)-catalyzed reactions of arenesulfonyl chlorides with allyl sulfide and selenide, expecting to obtain the S_H2'-type reaction products; the results should provide good evidence to support the radical mechanism previously proposed by us.

When a solution of tosyl chloride (**1**) (2.0 mmol), allyl phenyl sulfide (**2a**) (4.0 mmol), and a catalytic amount of dichlorotris(triphenylphosphine)ruthenium(II) in benzene was degassed and heated at 140 °C for 24 h, the reaction proceeded smoothly, yielding allyl *p*-tolyl sulfone (**3a**) (89%), diphenyl disulfide (**4a**) (5%), 2-chloro-1,3-bis(phenylthio)propane (**5a**) (51%), and 1-chloro-2,3-bis(phenylthio)propane (**5b**) (17%). No such 1:1 adduct as 2-chloro-3-phenylthio-1-tosylpropane was detected in the reaction products. Similarly, the reactions of benzene-, *p*-chlorobenzene-, and methanesulfonyl chlorides with **2a** in the presence of ruthenium(II) catalyst were also carried out. The results are summarized in Table 1.

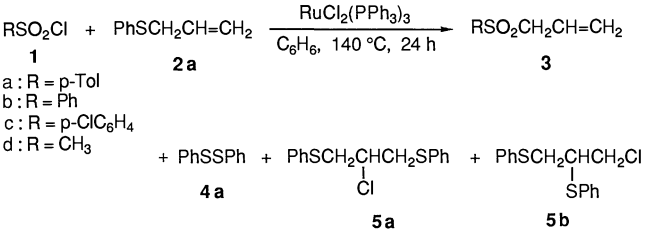
1d CH_3	**3d** 68	2	48	16

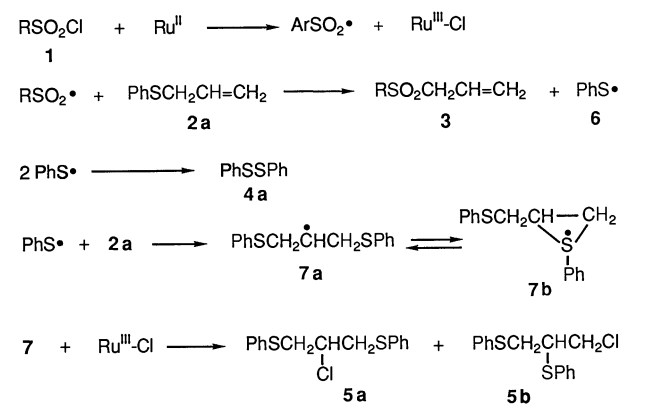
a) Yields were determined by GC based on **1** used.



The formation of these reaction products can be accounted for by the radical mechanism shown in Scheme 1. The S_H2' reaction of the arenesulfonyl radical, formed by the interaction of arenesulfonyl chloride with the ruthenium(II) catalyst, with allyl phenyl sulfide gives allyl aryl sulfone (**3**) and phenylthiyl radical (**6**). Although the dimerization of radical **6** affords diphenyl disulfide (**4a**), this represents a minor reaction course. Alternatively, phenylthiyl radical (**6**) adds to excess allyl phenyl sulfide (**2a**), coexisting in the reaction media, to give carbon radical (**7a**) which is considered to lie in equilibrium with radical (**7b**).[3] The transformation of the chlorine atom from the ruthenium(III)–Cl species to radical intermediate **7** gives products **5a** and **5b**.

The reaction of tosyl chloride (**1a**) with allyl phenyl selenide (**2b**) in the presence of the ruthenium(II) catalyst was also studied under similar conditions. In this case, allyl *p*-tolyl sulfone (**3a**), diphenyl diselenide (**4b**), and allyl chloride (**8**) were obtained in high yields. Similarly, the reactions of benzene- and *p*-chlorobenzenesulfonyl chloride (**1b** and **1c**) with **2b** under the ruthenium(II) catalyst were also studied. The results are summarized in Table 2.

The formation of product **3** is accounted for by a S_H2' reaction of the arenesulfonyl radical with allyl phenyl selenide (**2b**). The dimerization of the phenylseleno

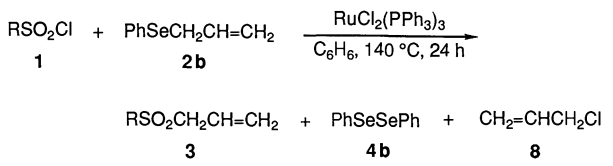


Scheme 1.

Table 2. Reaction of Arenesulfonyl Chlorides with Allyl Aryl Selenide

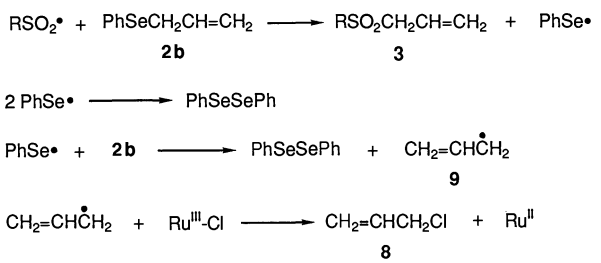
R in RSO_2Cl	Products, yields[a]/%		
	3	**4b**	**8**
1a *p*-$CH_3C_6H_4$	**3a** 78	98	67
1b Ph	**3b** 75	73	60
1c *p*-ClC_6H_4	**3c** 72	83	62

a) Yields were determined by GC based on **1** used.



radical to afford diphenyl diselenide (**4b**) is a minor course. In this case, the phenylseleno radical attacks on the selenium atom of excess allyl phenyl selenide coexisting in the reaction media gives diphenyl diselenide (**4b**) and allyl radical (**9**). The allyl radical abstracts the chlorine atom from the Ru(III)–Cl to afford allyl chloride and regenerate Ru(II) (Sheme 2).

The reason why the phenylseleno radical attacks the selenium atom of allyl selenide (**2b**), whereas the phenylthiyl radical reacts with the carbon–carbon double bond of allyl phenyl sufide (**2a**), is accounted for as follows. Although a soft phenylseleno radical reacts selectively with the soft atom (selenium atom) of **2b**, a hard phenylthiyl radical attacks the hard atom (carbon atom) of **2a**.



Scheme 2.

In order to obtain further evidence for the S_H2' reaction, the reactions of arenesulfonyl chlorides with (*E*)-2-butenyl phenyl sulfide (**10a**) or (*E*)-2-butenyl phenyl selenide (**10b**) catalyzed by the ruthenium(II) complex were studied. As shown in Table 3, aryl 1-methyl-2-propenyl sulfones (**11**) were formed together with aryl (*E*)-2-butenyl sulfones (**12**). The formation of **11** can be accounted for by the S_H2' reaction. Product **12** is considered to be formed by a secondary reaction of the arenesulfonyl radical with aryl 1-methyl-2-propenyl sulfone (**11**), once formed.

In any case, the fact that the S_H2' reaction products were obtained in high yields strongly supports the radical mechanism in the ruthenium(II)-catalyzed reaction of sulfonyl chloride with olefins, as we proposed previously.

Experimental

Measurement. The melting points were determined on a Yamato MP-21 apparatus and are uncorrected. The infrared absorption spectra were determined on a Hitachi Model 260-10 spectrophotometer with samples as either neat liquids or KBr disks. The proton magnetic resonance spectra were taken with JEOL-PMX 60SI (60 MHz) and Varian XL-200 (200 MHz) spectrometers. The mass spectra were determined with a JEOL JMS-DX 300 mass spectrometer with a JEOL JMA 5000 Mass Data System at an ionizing voltage of 20—70 eV. Gas chromatography was performed using a Hitachi 263-30 gas chromatograph with a SE-30 (10%) 1 m stainless-steel column. Gel-permeation chromatography was performed using a JAI LC-08 liquid chromatograph with two JAIGEL-1H columns (20 mm×600 mm) with chloroform as the eluent.

Materials. Allyl phenyl sulfide (**2a**) (bp 73 °C/4 mmHg, 1 mmHg=133.322 Pa) and allyl phenyl selenide (**2b**) (bp 71 °C/3 mmHg) were prepared by the reaction of allyl bromide with sodium benzenethiolate and sodium benzeneselenolate, respectively. (*E*)-2-Butenyl phenyl sulfide (**10a**) (bp 88 °C/4 mmHg) and (*E*)-2-butenyl phenyl selenide (**10b**) (bp 88 °C/3 mmHg) were prepared by the treatment of (*E*)-2-butenyl bromide with sodium benzenethiolate and sodium benzeneselenolate, respectively. Distillation was performed using a precission-distillation apparatus (Kyowa VI-DL Concentric-Tube Fractionator); the regioisomers formed as the by-products, 1-methyl-2-propenyl phenyl sulfide and 1-methyl-2-propenyl phenyl selenide, were completely removed, respectively. Methanesulfonyl chloride and benzenesulfonyl chloride of Tokyo Kasei Chemicals were purified by distillation under nitrogen prior to use. *p*-Toluenesulfonyl chloride (Tokyo Kasei Chemicals) and *p*-chlorobenzenesulfonyl chloride (Wako Chemicals) were recrystallized prior to use. Dichlorotris(triphenylphosphine)ruthenium(II) was prepared by the method described in the literature.[4]

General Procedure for the Reaction of Sulfonyl Chlorides with Allyl Sulfide or Selenide. A solution containing arenesulfonyl chloride (2.0 mmol), allyl phenyl sulfide (4.0 mmol) or allyl phenyl selenide (6.0 mmol), and dichlorotris-(triphenylphosphine)ruthenium(II) (0.1 mmol) in 4.0 cm^3 of benzene was degassed by a freeze-pump-thaw cycle, sealed in an ampoule, and heated at 140 °C for 24 h. The reaction mixture was subjected to short-column chromatography on Florisil with ethyl acetate to remove the metal complex. The products were isolated from the reaction mixture by the use of gel-

permeation chromatography and/or column chromatography over silica gel (Wakogel C-60), and were identified by IR, NMR, and MS. The yields of the products were determined by GC with eicosane as an internal standard. The physical and spectral data of allyl aryl sulfones (**3a**—**3c**) and allyl methyl sulfone (**3d**) were identical to authentic samples. 2-Chloro-1,3-bis(phenylthio)propane (**5a**) IR (neat) 3050, 1480, 1275, 918, and 740 cm^{-1}; ^1H NMR ($CDCl_3$; 200 MHz) δ=3.32 (2H, dd, J=3.75 and 1.92 Hz), 3.47 (2H, dd, J=3.75 and 1.98 Hz), 4.05 (1H, quint, J=1.92 Hz), and 7.13—7.56 (10H, m); MS m/z 294 (M^+), 185, 149, 109, and 77.

1-Chloro-2,3-bis(phenylthio)propane (5b): IR (neat) 3050, 1480, 1275, 920, and 720 cm^{-1}; ^1H NMR ($CDCl_3$; 200 MHz) δ=3.14—3.58 (3H, m), 3.86 (1H, dd, J=3.03 and 1.80 Hz), 4.02 (1H, dd, J=3.03 and 1.17 Hz), and 7.13—7.56 (10H, m); MS m/z 294 (M^+), 185, 149, 135, 123, 116, 109, and 77.

3-Methyl-3-tosylpropene (11a): Mp 63 °C, IR (KBr) 2980, 2260, 1640, 1598, 1315, 1145, and 1085 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.41 (3H, d, J=6.6 Hz), 2.41 (3H, s), 3.42—3.90 (1H, m), 4.84—6.11 (3H, m), and 7.26 and 7.63 (4H, ABq, J=8.4 Hz), MS m/z 210 (M^+), 156, 140, and 91.

3-(*p*-Chlorophenylsulfonyl)-1-butene (11b): IR (neat) 3100, 2090, 1645, 1585, 1315, 1145, and 1090 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42 (3H, d, J=7.2 Hz), 3.45—3.94 (1H, m), 4.85—6.12 (3H, m), and 7.46 and 7.72 (4H, ABq, J=9.0 Hz); MS m/z 230 (M^+), 175, 160, 144, and 112.

1-Tosyl-2-butene (12a): IR (neat) 2920, 1735, 1665, 1585, 1320, 1130, and 1085 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.69 (3H, d, J=4.2 Hz), 2.43 (3H, s), 3.71 (2H, d, J=5.4 Hz), 5.35—5.60 (2H, m) and 7.32 and 7.70 (4H, ABq, J=8.4 Hz); MS m/z 210 (M^+), 156, 135, and 92.

1-(*p*-Chlorophenylsulfonyl)-2-butene (12b): IR (neat) 3080, 2910, 1690, 1665, 1585, 1320, 1145, and 1090 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.68 (3H, d, J=4.2 Hz), 3.70 (2H, d, J=6.0 Hz), 5.25—5.63 (2H, m), and 7.47 and 7.73 (4H, ABq, J=8.4 Hz); MS m/z 230 (M^+), 197, 175, and 112.

Reactivity of Alkaneselenenyl Bromide: Conversion of Alcohols into the Corresponding Alkyl Bromides with Dialkylselenium Dibromide

Sadatoshi AKABORI* and Yoshinori TAKANOHASHI
Department of Chemistry, Faculty of Science, Toho University, Funabashi-shi, Chiba 274
(Received June 7, 1991)

Synopsis. The reaction of alcohols with dialkylselenium dibromide gave the corresponding bromides in moderate to high yields. Alkaneselenyl bromide, produced by the thermal decomposition from dialkylselenium dibromide, acts as a brominating agent. The reaction of alcohols with dialkylselenium dichloride also afforded the corresponding chlorides, although the yields were relatively low compared with those of the bromide.

Although organoselenium compounds have been known for a long time, some compounds being described at the end of the last century, the use of selenium reagents or intermediates has only been recent.[1] Although the structures of the organoselenium functions are similar to those of organic sulfur compounds, the use of selenium reagents often facilitates the reaction to proceed under simpler and milder conditions. It is also well known that alkyl halides can be obtained by the reaction of alcohols with many kinds of halogenating agents.[2] For example, hydrogen halide, phosporous halide, thionyl halide, etc. have been used as halogenating agents. Recently, Furukawa et al.[3] also reported the conversion of alcohols to alkyl bromides using the bromine adduct of dimethyl sulfide (Me_2SBr_2). In a previous paper, we reported a new procedure for the highly selective reduction of tertiary amides to the corresponding amines with $NaBH_4$–diethylselenium dibromide **2a** as the reducing agent in tetrahydrofuran.[4] We also reported a convenient one-pot procedure for the synthesis of symmetric tricalcogena[3]metallocenophanes using **2a** as the selenium insertion reagent.[5] In connection with these results we report here a new procedure for the convenient conversion of alcohols to alkyl halides using dialkylselenium dihalide **2** as the halogenating agent.

Results and Discussion

The reaction was carried out as follows. The reaction of **2a** with a large excess of 1-octanol at 80 °C for 7 h afforded 1-bromooctane in 98% yield together with 1,2-dibromoethane (75%). Similar reactions were carried

$$\underset{\mathbf{1}}{ROH} \xrightarrow{2} \underset{\mathbf{3}}{RX}$$

out using **2b**, **2c**, and **2d** as brominating agents. These results are summarized in Table 1. At room temperature this reaction did not proceed, and the starting materials were recovered quantitatively. Furthermore, among the examined dialkylselenium dibromides used as brominating agents **2a**, **2b**, **2c**, and **2d**, **2a** usually gave the best results; the yields of 1-bromooctane using **2b**, **2c**, and **2d** had nearly similar values. These results suggest that the bromine atom in **2a** may act as an electron-attracting group, and the cleavage of the Se–C bond in **2a** occurred more easily compared with those in **2b**, **2c**, and **2d**. The following bromination of several kinds of alcohols was therefore carried out using **2a** as the bromination reagent. These results are summarized in Table 2. Primary alcohols could be converted to the corresponding bromides in much higher yields compared with those of secondary alcohols. The yields of primary bromides **3a**—**c** were also much higher than that obtained by the methods already reported.[2] In contrast with the above bromination reaction, the reaction of the alcohols with bis(2-chloroethyl)selenium dichloride **4** gave the corresponding alkyl chlorides **5a**—**d**, although the yields were relatively low compared with those for bromination (Table 2). This result may be attributed to the strong Se–Cl bond compared to the Se–Br bond.[6] Furthermore, a similar reaction of alcohols was carried out using diethylselenium diiodide **6** as the iodinating reagent. However, the corresponding alkyl iodides could not be obtained in any cases. The differences in the halogenating abilities between the bromine or

a) The yields were determined by GLC.

chlorine adducts and the iodine adduct are attributable to these structures. Indeed, it was reported that the chlorine and bromine adducts of dialkyl selenide are trigonal bipyramidal structures, while the iodine adduct is a molecular complex.[7,8] The iodine adduct could therefore not react with alcohol, while the reaction of the bromine and chlorine adducts with alcohol gave alkaneselenyl halides and an alkyl halide. In fact, Behagel et al.[9] and Edwards et al.[10] reported that the thermal decomposition of dialkylselenium dibromide easily gave alkaneselenenyl bromide and alkyl bromide. This finding was also confirmed by the following experiments. After a solution of diethylselenium diiodide **6** in methanol-d_4 was refluxed for 7 h, the ^{1}H NMR spectrum of the solution was measured. However, no spectral changes were observed.

In order to investigate the chemical species in this reaction, the change conversion of 1-octanol **1a** versus the reaction time in the reaction with **2b** and with ethaneselenenyl bromide **7** (which was obtained by the reaction of diethyl diselenide with bromine in quantitative yield) was measured. Very similar results were obtained (yields ca. 30%) in both reactions. Similar results were also obtained in a comparison of the reactions of 1-butanol with **2b** and **7**. The yields of the alkyl bromide using ethaneselenenyl bromide **7** are comparable with those using **2a**, although the reason cannot be detailed at present. However, these finding suggests that bromination occurred as follows: i) after thermal decomposition of **2b** in alcohol gives **7**, the negatively charged bromine atom of **7** attacks the carbon atom attached to the hydroxyl group; ii) perhaps the initial reaction is the formation of alkaneselnenyl bromide and the resulting alkaneselenenyl bromide rapidly reacts with nucleophile to form HBr and RSeOR′. The next step is a nucleophilic replacement of the hydroxyl group of alcohol by the bromine anion. Support for the reaction mechanism (ii) is, however, based on the following. It is well known that the reaction of alkaneselenenyl bromide with methanol gave HBr and a stable selenium compound.[11,12] Furthermore, the reaction of 1-octanol **1a** with bis(2-bromoethyl)selenium dibromide **2a** in the presence of hydrogen chloride gave 1-chlorooctane **5a** together with 1-bromooctane **3a** in 77% yield. Also, as previously described, the relatively higher reactivity of **2a** in comparison with **2b**—**d** has been ascribed to a facile generation of the corresponding alkaneselenenyl bromide from **2a**. This means that the rate-determining step is the generation of the alkaneselenenyl bromide, rather than the brominating step.

This reaction mechanism is completely different from that of the bromination methanism of alcohol using Me_2SBr_2, in which dimethylbromosulphonium bromide plays an important role as the brominating agent.[3]

Experimental

Gas chromatography was performed on a Shimadzu G. C-8APF gas chromatography with a PEG20M (2.0%) 2m glass column.

Materials. Diethylselenium dibromide **2b**,[13] diethylselenium diiodide **6**,[14] bis(2-bromoethyl)selenium dibromide **2a**,[15] bis(2-chloroethyl)selenium dichloride **4**,[16] dihexylselenium dibromide **2d**,[17] diisopropylselenium dibromide **2c**,[17] diethyl diselenide and ethaneselenenyl bromide **7**[18] were prepared according to methods described in the literature. All of the alcohols and alkyl halides purchased from commercial sources were used without further purification; all solvents were purified by distillation in the usual manner.

General Procedure for the Halogenation of Alcohols with Dialkylselenium Dihalide. The following procedure used for the preparation of the alkyl halides is representative. A mixture of bis(2-bromoethyl)selenium dibromide **2a** (2.25 g, 5 mmol) and alcohol **1a** (10 ml) was stirred for 7 h at 80 °C. The reaction mixture was cooled to room temperature and then the supernatant solution was analyzed by GLC. The yield of 1-bromooctane **3a** was 98%.

All products, thus obtained, were known compounds, and were identified by the bp's as well as by comparisons of the NMR and IR spectra and/or the GLC retention times with those of authentic samples prepared independently.

A similar reaction was also carried out at room temperature. However, the brominating products could not be obtained and the starting materials were recovered in quantitative yields.

Preparation of Ethaneselenenyl bromide 7 in 1-Octanol or Tetrachloromethane. Bromine (0.40 g, 2.5 mmol) was rapidly added to a solution of diethyl diselenide (0.78 g, 2.5 mmol) in 1-octanol **1a** (10 ml). After the solution was stirred for 30 min at 0 °C, ethaneselenenyl bromide **7** was obtained in quantitative yield according to a method described in the literature.[18]

The resulting ethaneselenenyl bromide **7** was used without isolation in the following reaction with alcohols, as described below.

General Procedure for the Bromination of Alcohols with Ethaneselenenyl Bromide 7 in Tetrachloromethane. To a tetrachloromethane solution (10 ml) containing diethyl diselenide (1.56 g, 5 mmol) bromine (0.8 g, 5 mmol) was quickly added at 0 °C. After stirring 30 min at 0 °C, 1-octanol **1a** (1.30 g, 10 mmol) was rapidly added to the resulting tetrachloromethane solution of ethaneselenenyl bromide **7**. The reaction mixture was stirred for a further 7 h at 80 °C. After the reaction mixture was cooled to room temperature, the supernatant solution was analyzed by GLC. The yield of 1-bromooctane **3a** was 35%.

General Procedure for the Bromination of Alcohols with Ethaneselenenyl Bromide 7 in Alcohol. A mixture of diethyl diselenide (0.78 g, 2.5 mmol) and bromine (0.40 g, 2.5 mmol) in 1-octanol **1** (10 ml) was stirred for 30 min at 0 °C and then refluxed for a further 7 h at 80 °C. After the reaction mixture was cooled to room temperature, the supernatant solution was analyzed by GLC. The yield of 1-bromooctane **3a** was 35%.

Reaction of 1-Octanol 1a with 2a in the Presence of HCl. A solution of **2a** (2.25 g, 5 mmol) in 10 ml of 1-octanol **1a** containing dry HCl was stirred at 80 °C for 7 h. The reaction mixture was then analyzed. The GLC analyses revealed the presence of **3a** (3.9 mmol, 77%) and 1-chlorooctane **5a** (1.1 mmol).

The authors wish to express their thanks to Professor Naoki Inamoto of the Juntendo University for useful discussion.

Alumina-Catalyzed Addition of Thiols to Methyl Propiolate

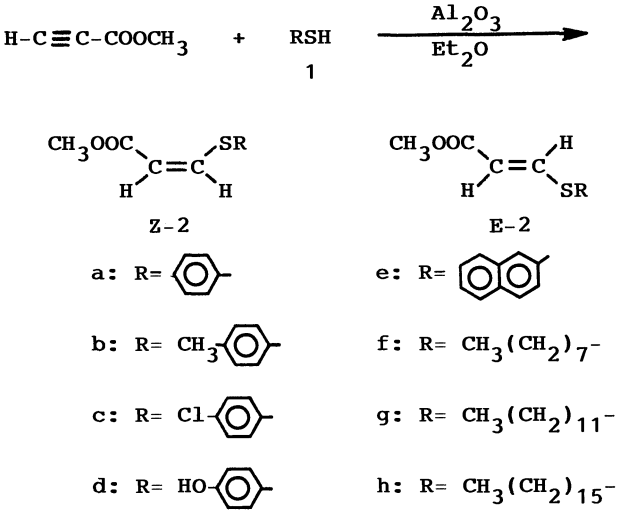
Mitsuo KODOMARI,* Goroh SAITOH, and Suehiko YOSHITOMI
Department of Industrial Chemistry, Faculty of Engineering, Shibaura Institute of Technology, Shibaura, Minato-ku, Tokyo 108
(Received June 10, 1991)

Synopsis. The addition of thiols to methyl propiolate was remarkably accelerated in the presence of alumina to give the *Z*-isomer of the 1:1 adducts stereoselectively, in which alumina acts as a bifunctional catalyst of acid and base.

Recently, a significant improvement of the reagent activity or selectivity has been achieved for a variety of organic reactions by the use of reagents supported on an inorganic solid or by the adsorption of substrates onto the surface of an inorganic solid.[1] The application of an inorganic solid (e.g., silica gel,[2] alumina,[3], zeolite[4]) as a solid base and an acid catalyst for organic reactions in the liquid phase has also attracted the attention of organic chemists. We previously reported that addition of phenols to dimethyl acetylenedicarboxylate adsorbed on alumina in the absence of a base gives *cis*-addition products selectively.[5] Although the addition of phenol to methyl propiolate under similar conditions did not occur, thiols reacted with methyl propiolate in the presence of alumina to give the *Z*-isomer of the 1:1 adducts in high yield. Herein, we report on these results.

Results and Discussion

The reaction of thiols, especially aliphatic thiols, with esters of propiolic acid is very slow in the absence of catalysts, but is remarkably accelerated by a base, giving 1:1 adducts which are a mixture of both the *E*- and *Z*-isomer. The ratio of the *E*- and *Z*-isomer is dependent on the nature of the solvents. The reaction in a protic polar solvent gives predominantly the *Z*-isomer and in an aprotic solvent mainly the *E*-isomer.[6]



Scheme 1.

A reaction of 2-naphthalenethiol (**1e**) with methyl propiolate was carried out in diethyl ether in the absence of a base at 10 °C for 1 h to give a 19% yield of methyl 3-(2-naphthylthio)acrylate (**2e**), which was a mixture of the iosmers (*Z*/*E* 50/50). By adding triethylamine as a catalyst the reaction was accelerated to give a 85% yield of **2e**. The *Z*/*E* ratio of the product isomers, however, was about the same as in the absence of a catalyst. In contrast, the reaction in the presence of neutral alumina under similar conditions gave a 96% yield of **2e**; the *Z*/*E* ratio of the product isomers was 90/10. Neutral alumina was most effective in promoting the reaction. Silica gel and a molecular sieve (5A) were entirely ineffective. The yield of **2e** and the ratio of the product isomers obtained in a variety of solvents are about the same as in diethyl ether (see Table 1). These results suggest that the reaction occurs on the sulface of alumina rather than in the solution. Substituted aromatic thiols also reacted with methyl propiolate in the presence of alumina under similar conditions to give the corresponding *Z*-isomer of **2** in high yields. The reaction with aliphatic thiols, which are less reactive than aromatic thiols, required a long reaction time; the stereoselectivity is slightly lower than in a reaction with aromatic thiols. Neutral alumina showed a higher catalytic activity than that of basic alumina; acidic alumina was ineffective (see Table 2). Although thiol is readily oxidized to disulfide in the presence of alumina under mild conditions,[7] disulfides were not detected under these reaction conditions. It is well-known that *cis*-(2-substituted vinyl) sulfides are isomerized by thiyl radical to an equilibrium mixture consisting mainly of the *E*-isomer.[8] A mixture of *Z*-**2b** and catalytic amounts of *p*-toluenethiol in diethyl ether was stirred at 10 °C for 10 h. However, no isomerization of the *Z*-

a) All reactions were carried out at 10 °C in diethyl ether under nitrogen. b) By GLC. c) By ^{1}H NMR. b, c) Figures in parentheses show the yield and the *Z*/*E* ratio obtained in the reaction without alumina. d) Basic alumina. e) Acidic alumina.

isomer to the *E*-isomer occurred. *Z*-**2b** was isomerized to the *E*-isomer upon heating in the presence of *p*-toluenethiol at 80 °C in benzene. These results show that the *E*-isomer of the product isomers does not arise from the *Z*-isomer by post-isomerization under these reaction conditions. It has been reported that the nucleophilic ring opening of epoxides is catalyzed by zeolite, in which the cooperative function of both the acid and base sites on its surface is thougt to be essential for effective catalysis.[4)] The effective catalysis of neutral alumina in the addition of thiols to methyl propiolate is also likely to be due to the cooperative function of acid and base sites on the alumina surface. Thus, the nucleophilicity of thiol is enhanced by a base site, and methyl propiolate can be activated by an acid site. The interaction between a acid site and a carbonyl group of methyl propiolate facilitates the formation of an enol during an attack by the nucleophile (RS^-) at the triple bond. The stereoselectivity in the reaction with aromatic thiols was higher than that in a reaction with aliphatic thiols, and the *Z*/*E* ratio of the product isomers in the reaction with aliphatic thiols decreased with incresing length of the alkyl group. These observations indicate that the *Z*-isomer is formed preferentially when the thiol molecule is strongly adsorbed on the surface of alumina. The resonance-stabilized anion intermediate, which is formed by the coordination of the thiolate ion at the β-carbon of methyl propiolate, is adsorbed on its surface. The intermediate therefore accepts a proton from thiol on its least hindered side to give the *Z*-isomer (see scheme 2).

Experimental

Methyl (*Z*)-3-(2-Naphthylthio)acrylate (*Z*-2e). General Procedure. Neutral alumina (ICN Biomedicals, N-Super 1, 2.5 g) was added to a solution of methyl propiolate (5 mmol, 0.42 g) in diethyl ether (40 ml), and stirred at 10 °C for 20 min. To the mixture was added a solution of 2-naphthalenethiol (5 mmol, 0.80 g) in diethyl ether (20 ml); stirring continued at 10 °C for 1 h under nitrogen. The product mixture was filtered, and the solid was washed with diethyl ether. The combined filtrate was washed with 5% aqueous sodium hydroxide and water, and dried. Evaporation of the solvent under reduced pressure yielded 1.21 g of **2e** as a white solid. The *Z*/*E* ratio of the product isomers was determined by ^{1}H NMR. The *Z*/*E* ratio was 90/10. Pure *Z*-isomers of **2b**, **2c**, **2d**, **2e**, **2g**, and **2h** were readily obtained by recrystallization of the crude products from appropriate solvents. The melting point and spectrum data for these *Z*-isomers are shown below.

Methyl (*Z*)-3-(*p*-Tolylthio)acrylate (2b). Mp 53—54 °C (lit,[9)] 54—55 °C) (from hexane); ^{1}H NMR ($CDCl_3$) δ=2.31 (3H, s, CH_3), 3.73 (3H, s, OCH_3), 5.86 (1H, d, *J*=9.9 Hz, =CHO–), 7.12 (2H, d, *J*=10 Hz, PhH), 7.34 (1H, d, *J*=9.9 Hz, =CHS–), 7.35 (2H, d, *J*=10 Hz, PhH).

Methyl (*Z*)-3-(*p*-Chlorophenylthio)acrylate (2c). Mp 99—100 °C (from hexane); IR (KBr) 1696, 1222, 1170, 1094, 817 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.76 (3H, s, OCH_3), 5.93 (1H, d, *J*=9.9 Hz, =CHCO–), 7.19 (1H, d, *J*=9.9 Hz, =CHS–), 6.98—7.65 (4H, m, PhH); MS *m*/*z* (%) 228 (M^+; 100), 197 (75), 169 (58), 143 (44), 134 (43), 125 (9), 117 (24), 108 (45). (Received June 28, 1991)

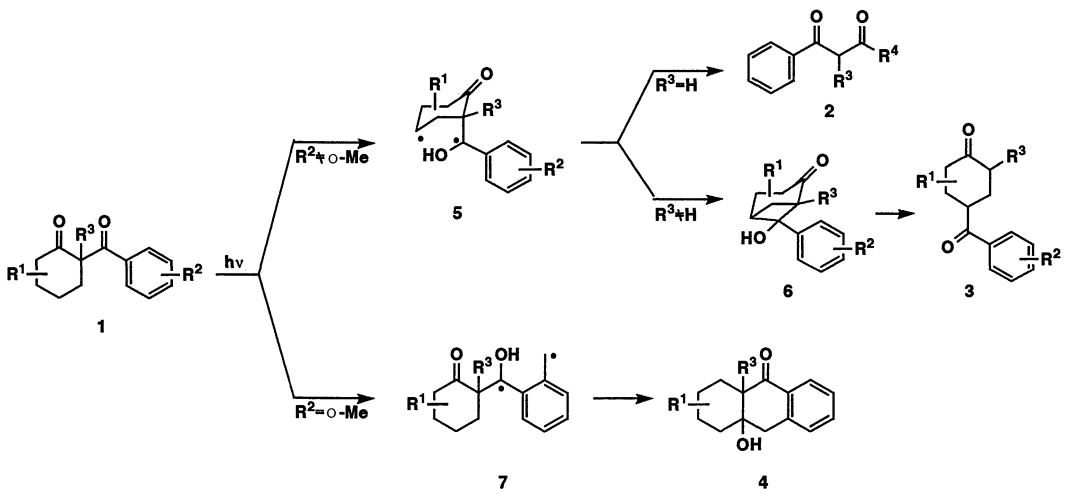
Synopsis. The photoreactivities of substituted 2-benzoylcyclohexanones were distinguished as three different types; 1) the exclusive Norrish Type II cleavage when there were no alkyl groups on the 2- nor on the ortho-position, 2) the benzoyl group shift from the 2- to the 4-position when an alkyl group was present on the 2- and not on the ortho-position, and 3) 1,2,3,4,4a,9a-hexahydro-9(10*H*)-anthracenone derivative formation when an ortho-methyl group was present.

The Norrish Type II photoreactions of alkyl phenyl ketones have been investigated extensively.[1] In the Type II reaction, the cleavage generally competes with the cyclization. We have reported that 2-benzoylcyclohexanone (**1a**) underwent an exclusive Type II cleavage reaction to give **2a** and that the enol from of **2a** acted as an effective internal filter.[2] A 1-phenyl-1,3-alkanedione has been utilized to prevent the coloration of polymers, and ability and efficiency as a preventer are known to be affected by the alkyl chain length of the diketone and alkyl substituents on the chain.[3] Compound **2a** may be utilized as a good preventer with a C=C double bond at the end of the alkyl chain. The Type II cleavage reaction of substituted 2-benzoylcyclohexanones **1** is expected to be a useful method for the preparation of substituted 1-phenyl-6-heptene-1,3-diones **2**. The ratio of the cleavage to the cyclization in the Type II reaction was reported to be affected by α- and β-substituents.[4] We recently found that the introduction of a methyl group to the 2-position of **1a** resulted in a remarkable changeover in the reaction course.[5] We report here a substituent effect on the product distribution in the Type II reaction of substituted 2-benzoylcyclohexanones.

The substituted 2-benzoylcyclohexanones **1c**, **d**, **f**, and **g** have no 2- nor ortho-alkyl substituents. Irradiation of these compounds in benzene under nitrogen with a 450 W high-pressure mercury lamp through a Pyrex filter gave the corresponding Type II cleavage products in high yields as in the case of **1a**.[2] The photoreactions are applicable to the synthesis of **2** because of high product yields.

On the other hand, irradiation of **1i** and **1j**, both of which have 2-methyl groups, gave a pair of isomers of the 1,4-aroyl shift products **3i** and **3j**, respectively. Irradiation of **1k**, which has a 4-methyl group in addition to the 2-methyl group, gave an intractable mixture. Formation of **3** can be explained in terms of the Type II cyclization followed by the cyclobutanol ring opening as reported in the case of **1b**.[5] The enhanced cyclization caused by the 2-methyl group can be explained in terms of the presence of an unfavourable nonbonding interaction in the transition state during the elimination.[6] The 4-methyl group may prevent the recombination of the radical centers in the 1,4-biradical intermediate **5k** because of steric repulsion so as to reduce the yield of the Type II product **3k**. Two isomers of **3**, cis and trans isomers with respect to the C4-aroyl and C2-methyl groups, might be produced in the process of the cyclobutanol ring opening.[5] The major isomer seems to be the more stable trans isomer.

Compound **11** has two γ-hydrogens, one on the ethyl group and one on the cyclohexanone ring. However, only the γ-hydrogen on the ring was abstracted by the excited benzoyl oxygen. Irradiation of **11** gave **31** in a



Scheme 1.

a) Two isomers with respect to C4-aroyl and C2-alkyl groups were isolated. b) An intractable mixture was formed.

91% yield. No products derived from ethyl hydrogen abstraction were detected. The axial hydrogen at the 4-position seemed to be more favored for abstraction by the benzoyl carbonyl group than γ-hydrogen on the ethyl group because of geometical preference.

The excited aroyl oxygen in **1** could abstract a γ-hydrogen on the ortho-methyl group when the group was present.[7,8)] Hornback *et al.* reported that photolysis of **1e** gave **4e** in a 57% yield via intramolecular hydrogen abstraction from the ortho-methyl group.[7)] Compound **1h** had a methyl group on C2 as well as the ortho-position. The presence of the 2-methyl group was expected to affect the direction of hydrogen abstraction. However, irradiation of **1h** gave only the product via the ortho-methyl hydrogen abstraction in a 93% yield. No products arising from abstraction of the C4-hydrogen could be detected. Formation of **4** may be explained in terms of trapping of the benzyl radical center by the cyclohexanone carbonyl.[7)] The 2-methyl group seemed to promote the trapping process.

Experimental

The IR spectra were recorded with a JASCO A-3 spectrometer, ^1H and ^{13}C NMR spectra were measured with a JEOL FX90Q spectrometer using tetramethylsilane as an internal standard. An Ushio 450 W high-pressure mercury lamp was used as an irradiation source. The substituted 2-benzoylcyclohexanones without a 2-methyl group were prepared from the corresponding morpholinocyclohexanone and aroyl chloride[9)] and 2-methylation was performed using a phase-transfer catalyst.[5)]

General Procedure for Irradiation of 1. A solution of the substituted 2-benzoylcyclohexanone **1** (ca. 2 mmol) in 50 cm^3 of benzene was irradiated under nitrogen with a 450 W high-pressure mercury lamp through a Pyrex filter. After removing the solvent the residue was chromatographed on a silica-gel column. Elution with a mixture of benzene and ethyl acetate gave **2**, **3**, or **4**.

4-Benzoyl-2-methylcyclohexanone (3b): Major isomer: 79%[5)] yield. Minor isomer: 11% yield; bp 120—121 °C/3 mmHg (1 mmHg=133.322 Pa); IR (neat) 1680 and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ= 1.09 (3H, d, J=6.7 Hz, CH_3), 1.7—2.9 (7H, m, CH and CH_2), 3.81 (1H, quint, J=5.1 Hz, CHCOPh), 7.4—7.7 (3H, m, aromatic), and 7.9—8.1 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=15.2 (q), 28.4 (t), 36.2 (t), 38.0 (t), 39.7 (d), 41.6 (d), 128.4 (d, 2C), 128.8 (d, 2C), 132.8 (d), 135.9 (s), 202.5 (s), and 212.9 (s). Found: C, 77.65; H, 7.61%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

6-Methyl-1-phenyl-6-heptene-1,3-dione (2c): 68% yield; bp 112—115 °C/2 mmHg; IR (neat) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.79 (3H, s, CH_3), 2.3—2.8 (4H, m, CH_2), 4.11 (0.14H, s, CH_2), 4.78 (2H, s, olefinic), 6.22 (0.93H, s, olefinic), 7.3—7.6 (3H, m, aromatic), 7.8—8.0 (2H, m, aromatic), and 16.23 (0.93H, bs, OH). Found: C, 77.69; H, 7.39%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

4-Methyl-1-phenyl-6-heptene-1,3-dione (2d): 72% yield; bp 110—113 °C/2 mmHg; IR (neat) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.21 (3H, d, J=6.6 Hz, CH_3), 2.1—2.7 (3H, m, CH and CH_2), 4.11 (0.14H, s, CH_2), 5.01 (1H, d, J=1.3 Hz, olefinic), 5.12 (1H, d, J=5.3 Hz, olefinic), 5.6—6.0 (1H, m, olefinic), 6.16 (0.93H, s, olefinic), 7.4—7.6 (3H, m, aromatic), 7.8—8.0 (2H, m, aromatic), and 16.31 (0.93H, bs, OH). Found: C, 77.49; H, 7.69%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

1-(3-Methylphenyl)-6-heptene-1,3-dione (2f): 97% yield; bp 115—120 °C/2 mmHg; IR (neat) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3—2.8 (4H, m, CH_2), 2.36 (3H, s, CH_3), 4.02 (0.18H, s, CH_2), 4.94 (1H, d, J=1.4 Hz, olefinic), 5.10 (1H, d, J=7.5 Hz, olefinic), 5.7—6.1 (1H, m, olefinic), 6.13 (0.91H, s, olefinic), 7.3—7.5 (2H, m, aromatic), 7.6—7.8 (2H, m, aromatic), and 16.33 (0.91, s, OH). Found: C, 77.73; H, 7.59%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

1-(4-Methylphenyl)-6-heptene-1,3-dione (2g): 99% yield; bp 115—120 °C/2 mmHg; IR (neat) 1580 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.3—2.6 (4H, m, CH_2), 2.34 (3H, s, CH_3), 3.99 (0.2H, s, CH_2), 4.93 (1H, bs, olefinic), 5.08 (1H, d, J=8.5 Hz, olefinic), 5.7—6.1 (1H, m, olefinic), 6.10 (0.9H, s, olefinic), 7.17 (2H, d, J=8.4 Hz, aromatic), 7.73 (2H, d, J=8.4 Hz, aromatic), and 16.29 (0.9H, bs, OH). Found: C, 77.76; H, 7.30%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

4a-Hydroxy-9a-methyl-1,2,3,4,4a,9a-hexahydro-9(10*H*)-anthracenone (4h): 93% yield; mp 127.5—135 °C; IR (KBr) 1670, 1685, 3480, and 3520 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (3H, s, CH_3), 1.3—2.1 (8H, m, CH_2), 1.19 (1H, s, OH), 2.93 (2H, ABq, J=17.6 Hz, CH_2), 7.0—7.6 (3H, m, aromatic), and 7.95 (1H, d, J=5.8 Hz, aromatic); ^{13}C NMR ($CDCl_3$) δ=19.8 (t), 20.7 (t), 20.8 (q), 27.6 (t), 34.3 (t), 40.5 (t), 49.3 (s), 75.0 (s), 126.6 (d), 127.5 (d), 129.2 (d), 131.7 (s), 133.0 (d), 138.6 (s), and 202.1 (s). Found: C, 78.32; H, 7.74 %. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

4-(3-Methylbenzoyl)-2-methylcyclohexanone (3i): Major isomer: 78% yield; bp 130—135 °C/2 mmHg; IR (neat) 1680 and 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.07 (3H, d, J=6.2 Hz, CH_3), 1.4—2.8 (7H,m, CH and CH_2), 2.43 (3H, s, CH_3), 3.82 (1H, tt,

J=3.9 and 11.5 Hz, CHCOPh), 7.3—7.5 (2H, m, aromatic), and 7.7—7.9 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=14.4 (q), 21.3 (q), 30.0 (t), 38.1 (t), 40.3 (t), 43.9 (d), 44.5 (d), 125.3 (d), 128.7 (d), 128.8 (d), 133.9 (d), 136.0 (s), 138.5 (s), 201.3 (s), and 210.6 (s). Found: C, 78.16; H, 7.88%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

Minor isomer: 20% yield; bp 120—125°C/2 mmHg; IR (neat) 1680 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.08 (3H, d, J=6.7 Hz, CH_3), 1.6—2.9 (7H, m, CH and CH_2), 2.43 (3H, s, CH_3), 3.77 (1H, quint, J=4.8 Hz, CHCOPh, 7.4—7.5 (2H, m, aromatic), and 7.7—7.9 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=15.3 (q), 21.3 (q), 28.3 (t), 36.1 (t), 37.9 (t), 40.0 (d), 41.6 (d), 125.5 (d), 128.7 (d), 128.9 (d), 133.7 (d), 136.5 (s), 138.6 (s), 202.4 (s), and 211.8 (s). Found; C, 78.24; H, 7.81%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

4-(4-Methylbenzoyl)-2-methylcyclohexanone (3j): Major isomer: 70% yield; mp 74—74.5°C; IR (KBr) 1675 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.08 (3H, d, J=5.9 Hz, CH_3), 1.4—2.7 (7H, m, CH and CH_2), 2.45 (3H, s, CH_3), 3.83 (1H, tt, J=7.2 and 11.7 Hz, CHCOPh), 7.37 (2H, d, J=8.7 Hz, aromatic), and 7.94 (2H, d, J=8.7 Hz, aromatic); ^{13}C NMR ($CDCl_3$) δ=13.9 (q), 21.0 (q), 29.6 (t), 37.8 (t), 39.8 (t), 43.4 (d), 43.8 (d), 127.9 (d, 2C), 129.0 (d, 2C), 133.4 (s), 143.4 (s), 200.2 (s), and 209.7 (s). Found: C, 78.21; H, 7.81%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

Monor isomer: 17% yield; bp 120—123°C/2 mmHg; IR (neat) 1670 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.08 (3H, d, J=6.7 Hz, CH_3), 1.6—3.0 (7H, m, CH and CH_2), 2.45 (3H, s, CH_3), 4.93 (1H, quint, J=5.1 Hz, CHCOPh), 7.29 (2H, d, J=8.7 Hz, aromatic), and 7.90 (2H, d, J=8.7 Hz, aromatic); ^{13}C NMR ($CDCl_3$) δ=15.1 (q), 21.4 (q), 28.3 (t), 36.2 (t), 37.9 (t), 39.7 (d), 41.6 (d), 128.4 (d, 2C), 129.4 (d, 2C), 133.9 (s), 143.7 (s), 201.8 (s), and 211.9 (s). Found: C, 78.25; H, 7.80%. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

4-Benzoyl-2-ethylcyclohexanone (31): Major isomer: 75% yield; bp 125—128°C/2 mmHg; IR (neat) 1680 and 1710 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.2 Hz, CH_3), 1.1—2.6 (9H, m, CH and CH_2), 3.83 (1H, tt, J=7.2 and 11.6 Hz, CHCOPh), 7.4—7.7 (3H, m, aromatic), and 8.0—8.2 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=11.5 (q), 22.2 (t), 30.0 (t), 35.5 (t), 40.6 (t), 44.5 (d), 50.7 (d), 128.2 (d, 2C), 128.8 (d, 2C), 133.0 (d), 136.5 (s), 201.3 (s), and 210.6 (s). Found: C, 77.97; H, 7.83 %. Calcd for $C_{15}H_{18}O_2$: C, 78.23; H, 7.88%.

Minor isomer could not be separated completely from the major isomer. 16% yield (based on the ^{1}H NMR analysis); ^{1}H NMR ($CDCl_3$) δ=0.91 (3H, t, J=7.2 Hz, CH_3), 1.2—2.6 (9H, m, CH and CH_2), 3.83 (1H, quint, J=5.8 Hz, CHCOPh), 7.4—7.7 (3H, m, aromatic), and 7.9—8.1 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=11.5 (q), 23.4 (t), 28.4 (t), 33.7 (t), 38.1 (t), 39.8 (d), 49.1 (d), 128.2 (d, 2C), 128.8 (d, 2C), 133.0 (d), 136.5 (s), 202.5 (s), and 212.8 (s).

Synthesis of Antiprismatic [5.5]Ferrocenophane ([5](1,1′)[5](3,4′)Ferrocenophane)

Masao HISATOME,* Shuichi YOSHIDA, and Koji YAMAKAWA
Faculty of Pharmaceutical Sciences, Science University of Tokyo, 12 Ichigaya-Funagawara, Shinjuku-ku, Tokyo 162
(Received July 8, 1991)

Synopsis. The title compound **2**, which is the first example of a C_2 symmetric dibridged ferrocenophane, has been synthesized via a base-catalyzed condensation of 3,4′-diacyl-[5]ferrocenophane. The spectroscopic properties of **2** are briefly discussed by comparing them with the corresponding prismatic [5,5]ferrocenophane having C_{2v} symmetry.

In intramolecularly 1,3-dibridged ferrocenes with two polymethylene chains, there are, in principle, two geometric isomers bridged at the 1,1′- and 3,3′-positions and at the 1,1′- and 3,4′-positions of the cyclopentadienyl (Cp) rings, which are called "prismatic" and "antiprismatic" ferrocenophanes,[1] respectively. Although a number of 1,3-dibridged ferrocenophanes have been prepared thus far,[1-7] all of them are bridged in a prismatic form. There has been only one report on the preparation of [5](1,1′)[5](3,4′)ferrocenophane derivative (**3**) by Nesmeyanov,[8] though its configuration has not be determined. The reason that no example exists of a structurally confirmed antiprismatic ferrocenophane may arise from the following problems: (i) Bridging of [*n*](1,1′)ferrocenophane-3-propanoic acids ($n>2$) by a heteroannularly cyclization reaction, which is usually employed for the preparation of dibridged ferrocenophanes, selectively gives 3′-bridged compounds, but no 4′-bridged compound. (ii) A spectroscopic distinction between prismatic and antiprismatic structures is not easy. This article describes the preparation of [5](1,1′)[5](3,4′)ferrocenophane (**2**) via a linking between the substituents of the two Cp rings, a determination of its antiprismatic configuration and a spectroscopic characterization of **2**, compared with the corresponding prismatic compound **1**.

An acylation of 3-acetyl[5]ferrocenophane (**4**)[4] with 3-chloropropanoyl chloride and $AlCl_3$ gave three isomeric diacylferrocenophanes, **5a**—**5c**, which were easily convertible to enone **6a**—**6c** by elimination. The α′-substituted structures of **5a** and **5c** were ascertained by means of their ^{1}H NMR spectra, in which the 3′- and 4′-proton signals, respectively, appeared as triplets with ortho coupling constants (J=2.6 and 2.7 Hz). The desired β′-substituted compound **5b** was so unstable in solvents that it could not be characterized by ^{1}H NMR spectrometry. Compound **5b** was readily converted to stable enone **6b**, even by a treatment with neutral alumina in benzene. The ^{1}H NMR spectrum of **6b** showed a triplet signal with a meta coupling constant (J=1.4 Hz); its β′-substituted form was confirmed. At this stage it could not be determined whether **5b** and **6b** were 3,3′- or 3,4′-acylated phanes, although 3,4′-substituted structures were predictable due to a substitution disadvantage just below the position of the acyl group in ferrocenophanes.[9] No other possible β′-acylated compound was isolated in the present reaction.

A second bridge formation was carried out according to a modified procedure in the preparation of [5](1,1′)ferrocenophane-1,5-dione reported by Barr and Watts.[10] A crude mixture, obtained by acylation of **4**, without separating into each component, was treated by aq NaOH; dibridged diketone **7** was isolated (16% from **4**) from the many products by chromatography. An intramolecular Michael condensation of enone **6b** was also attempted, but the yield of **7** could not be improved (9%). The desired antiprismatically bridged structure of **7** was determined by ^{1}H NMR spectrometry in the

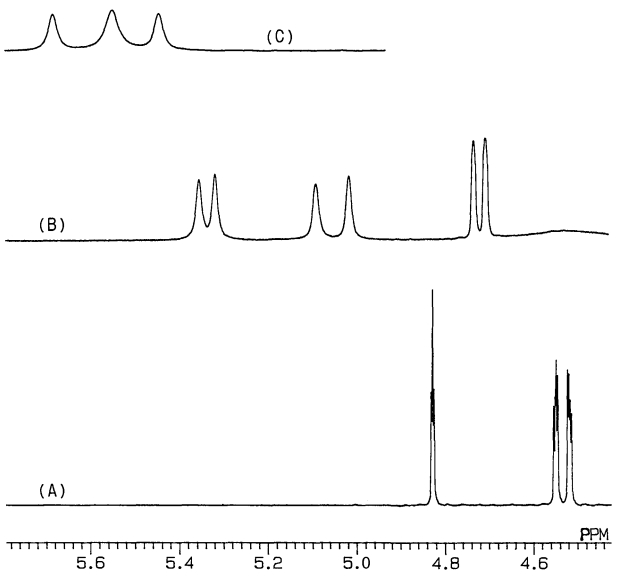

Fig. 1. Cp ring proton region in the ^{1}H NMR spectra of **7** in $CDCl_3$ without any additive (A), with tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]-europium(III) [Eu(tfmc)] (B), and with tris[(heptafluorobutanoyl)pivaloylmethanato]europium(III) [Eu(fod)] (C).

presence of a chiral shift reagent. [5](1,1′)[5](3,4′)Ferrocenophane-1,5-dione (**7**) is a racemic mixture of two chiral molecules, while the corresponding isomeric [5](1,1′)[5](3,3′)ferrocenophane-1,5-dione is a *meso* compound possessing two symmetric planes through the central iron atom. Accordingly, each proton signal of the former in the ^{1}H NMR spectrum should split into two signals due to diastereomeric interactions between a pair of enantiomers and a chiral shift reagent, but that of the latter prismatic diketone does not under the same conditions. The spectra of **7** in $CDCl_3$ without any additive, with chiral a shift reagent, [Eu(tfmc)], and with an achiral shift reagent, [Eu(fod)], are shown in Fig. 1. The desired bridging feature of **7** was proven in terms of the spectral behavior.

The reduction of the two carbonyl groups of **7** gave the antiprismatic [5.5]ferrocenophane **2**. The ^{1}H and ^{13}C NMR spectra of **2** are obviously distinguished from those of ferrocenophane **1**, of which the pprismatic structure was already confirmed.[7] It is interesting that the d–d* band of **2** in the electronic absorption spectrum in tetrahydrofuran (THF) shifted to a longer wavelength (456 nm) than that of **1** (444 nm; ferrocene, 440 nm in THF). The shift value of **2** resembles that of tetra-bridged [5$_4$](1,2,3,4)-ferrocenophane (460 nm).[11] A linear relationship between the hypsochromic shift of the d–d* band and a compression of the Cp–Fe–Cp distance has been found in multibridged ferrocenophanes.[12] An elongation of the Cp–Fe–Cp distance in [5$_4$]ferrocenophane (3.336 Å;[11] ferrocene, 3.32 Å[13]) was observed in an X-ray crystal analysis. It would therefore be suggested that the distance of the two Cp rings of **2** is a little longer than that of **1**, and that the two pentamethylene bridges in antiprismatic manner elongate the distance. A consideration using a Dreiding molecular model supports this assumption, that is, the molecule of **2** is somewhat strained by avoiding steric hindrance among the hydrogens of the polymethylene chains in a zigzag conformation, while that of **1** is in a relaxed conformation.

Experimental

Melting points were uncorrected. IR, mass and electronic spectra were obtained on the same instruments as those used in a previous report,[11] except for NMR spectra, which were measured on a JEOL JNM GSX500 spectrometer relative to tetramethylsilane as an internal standard.

Acylation of 3-Acetyl[5]ferrocenophane (4) with 3-Chloropropanoyl Chloride. A mixture of 3-chloropropanoyl chloride (2.52 g, 20.6 mmol) and $AlCl_3$ (3.10 g, 23.3 mmol) in dichloromethane (50 ml) was prepared under an Ar atmosphere and stirred at room temperature for 2 h. To the resulting suspension was added dropwise 3-acetyl[5]ferrocenophane (**4**)[4] (3.00 g, 10.1 mmol) in dichloromethane (30 ml). The reaction mixture was stirred at room temperature for 22 h, and then quenched with water. The hydrolysate was extracted with dichloromethane; and the extracts were washed with water, dried over $CaCl_2$, and evaporated. The crude was column-chromatographed over silica gel with benzene–ethyl acetate (10:1). The starting material **4** was recovered from first band. The second band yielded 3-acetyl-2′-(3-chloropropanoyl)[5](1,1′)ferrocenophane (**5a**) (0.11 g, 2.8%) as a red solid. IR (KBr) 1650 and 1670 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.64, 1.86, 2.24, 2.33, 2.53, and 3.05 (2H, 4H, 1H, 1H, 1H, and 1H, each m, $-CH_2-$ of bridge), 2.42 (3H, s, $-COCH_3$), 2.94 and 3.23 (each 2H, dt, J=6.2, 18.0 Hz, $-COCH_2-$), 3.90 (2H, t, J=6.2 Hz, $-CH_2Cl$), 4.28, 4.30, 4.57 and 4.67 (1H, 2H, 1H, and 1H, each m, Cp-H), 4.64 (1H, t, J=2.6 Hz, 4′-H of Cp); MS m/z (rel intensity) 386 (25, M$^+$), 350 (100, [M−Cl]$^+$).

The third band yielded 3-acetyl-5′-(3-chloropropanoyl)[5](1,1′)ferrocenophane (**5c**) (0.31 g, 7.9%) as a red solid. IR (KBr) 1640 (C=O) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.67, 1.82, 1.90, 2.30, 2.45, and 2.99 (1H, 1H, 3H, 2H, 2H, and 1H, each m, $-CH_2-$ of bridge), 2.38 (3H, s, $-COCH_3$), 3.04 and 3.28 (each 1H, m, $-COCH_2-$), 3.80 and 4.00 (each 1H, m, $-CH_2Cl$), 4.20 (1H, t, J=2.7 Hz, 3′-H of Cp), 4.27, 4.59, 4.75 and 4.88 (each 1H, dd, J=1.3, 2.7 Hz, 4-, 5-, 2′-, and 4′-H of Cp), 4.54 (1H, t, J=1.3 Hz, 2-H of Cp).

These two compounds, **5a** and **5c**, could not be sufficiently purified due to the easy occurrence of elimination in solvents.

The fourth band yielded 3-acetyl-4′-(3-chloropropanoyl-[5](1,1′)ferrocenophane (**5b**) (1.16 g, 30%) as a red solid. The ^{1}H NMR spectrum of **5b** was contaminated with the many signals of enone **6b** generated by a rapid elimination in $CDCl_3$, and could not be sufficiently analyzed. The structure of **5b** was inferred from a structural determination of **6b** derived by the elimination of **5b**, as mentioned below.

3-Acetyl-4′-propenoyl[5](1,1′)ferrocenophane (6b). A crude mixture obtained by the acylation of **4** (1.00 g, 3.38 mmol) with 3-chloropropanoyl chloride (0.88 g, 7.21 mmol) and $AlCl_3$ (1.03 g, 7.77 mmol) according to the procedure described above was treated with alumina in benzene–ethyl acetate. The mixture was eluted and evaporated. The residue was column-chromatographed over alumina with benzene–ethyl acetate (10:1) to be separated into five bands. The third and fourth bands yielded 2′- and 5′-propenoyl-[5](1,1′)ferrocenophanes (**6a**, 0.06 g, 5% from **4**; **6c**, 0.14 g, 12%), respectively, as red oils.

The fifth band yielded 3-acetyl-4′-propenoyl[5](1,1′)ferrocenophane (**6b**) (0.63 g, 53%), which was recrystallized from hexane–ethyl acetate to give red prisms; mp 113—113.5°C. IR (KBr) 1640 and 1660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.84, 1.99

and 2.38 (4H, 2H and 4H, each m, $-CH_2-$ of bridge), 2.35 (3H, s, $-COCH_3$), 4.38, 4.70, 4.53 and 4.55 (each 1H, dd, J=1.4, 2.6 Hz, 4-, 5-, 2'-, and 3'-H of Cp), 4.59 and 4.61 (each 1H, t, J=1.4 Hz, 2- and 5'-H of Cp), 5.78 (1H, dd, J=1.8, 10.4 Hz, $=CH_2$ of propenoyl), 6.48 (1H, dd, J=1.8, 16.9 Hz, $=CH_2$ of propenoyl), 6.76 (1H, dd, J=10.4, 16.9 Hz, vinyl-H of propenoyl).

Found: C, 68.28; H, 6.27%. Calcd for $C_{20}H_{22}O_2Fe$: C, 68.59; H, 6.33%.

[5](1,1')[5](3,4')Ferrocenophane-1,5-dione (7). (1) The crude mixture obtained by acylation of **4** (3.00 g, 10.1 mmol) with 3-chloropropanoyl chloride (2.52 g, 20.6 mmol) and $AlCl_3$ (3.10 g, 23.3 mmol) was dissolved to ethanol (400 ml), and 10% aq NaOH (400 ml) was added. After the solution was stirred at room temperature for 12 h, a large excess of water was added. The mixture was extracted with dichloromethane, and the extracts was washed with saturated aq NaCl, dried over $CaCl_2$ and evaporated. The residue was column-chromatographed over silica gel to be separated into many bands. The seventh band eluted with benzene–ethyl acetate (20:1) yielded [5.5]ferrocenophane-1,5-dione (**7**) (0.43 g, 16% from **4**), which was recrystallized from hexane–ethyl acetate to give red needles; mp 246—246.5°C. IR (KBr) 1670 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.66, 1.74, 1.94, 2.53 and 2.86 (each 2H, m, $-CH_2-$ of aliphatic bridge), 2.08, 2.11, 2.24, 2.28, 2.35 and 2.38 (each 1H, m, $-CH_2-$ of dioxo-bridge), 4.52 and 4.55 (each 2H, dd, J=1.5, 2.7 Hz, 4-, 5-, 2'-, and 3'-H of Cp), 4.83 (2H, t, J=1.5 Hz, 2- and 5'-H of Cp); ^{13}C NMR ($CDCl_3$) δ=23.83, 25.82, 26.00, 27.17, and 34.41 ($-CH_2-$), 68.67, 73.45 and 95.56 (Cp–C), 205.70 (C=O); MS m/z (rel intensity) 350 (100, M^+).

Found: C, 68.16; H, 6.25%. Calcd for $C_{20}H_{22}O_2Fe$: C, 68.59; H, 6.33%.

(2) To a solution of enone **6b** (80 mg, 0.23 mmol) in ether (5.0 ml) was added dropwise a solution of KOH (0.17 g) in ethanol (1.5 ml) at 0°C. The mixture was stirred for 2 h, and then extracted with dichloromethane. The extracts were washed with saturated aq NaCl, dried over $CaCl_2$ and evaporated. Column chromatography on silica gel with benzene/ethyl acetate afforded two bands. The first band yielded diketone **7** (7 mg, 9%). The second band (24 mg) was an unknown red oil.

Both reactions of **6b** with aq KOH in ethanol (without ether) and with EtONa in ethanol gave no bridged diketone **7**.

[5](1,1')[5](3,4')Ferrocenophane (2). Diketone **7** (200 mg, 0.57 mmol) in ether (50 ml) was added dropwise to a suspension of $LiAlH_4$ (60 mg, 1.6 mmol) and $AlCl_3$ (230 mg, 1.7 mmol) in ether (20 ml) at 20°C. The mixture was decomposed with wet ether, and the hydrolysate was extracted with ether. The extracts were washed with saturated aq NaCl, dried over Na_2SO_4 and evaporated. Column chromatography on silica gel with benzene provided [5](1,1')[5](3,4')ferrocenophane (**2**) (0.171 mg, 93%) as the main band. An analytical sample was obtained by recrystallization from hexane–ethyl acetate as yellow needles; mp 122—123°C. ^1H NMR ($CDCl_3$) δ=1.72, 1.99, 2.23, 2.34 and 2.37 (8H, 4H, 4H, 2H, and 2H, $-CH_2-$ of bridge), 3.75 (2H, t, J=1.5 Hz, 2- and 5'-H of Cp), 3.98 (4H, d, J=1.5 Hz, 4-, 5-, 2'-, and 3'-H of Cp); ^{13}C NMR ($CDCl_3$) δ=23.56, 26.25, and 26.53 ($-CH_2-$), 68.04, 68.71 and 87.92 (Cp–C); MS (m/z rel intensity) 322 (100, M^+); λ_{max} (THF) 456 nm (ε=119).

Found: C, 75.15; H, 8.16%; M^+, 322.1389. Calcd for $C_{20}H_{26}Fe$: C, 74.54, H, 8.13%; M, 322.1383. Calcd for $C_{20}H_{26}Fe \cdot 1/6\ (C_6H_{14})$: C, 74.89; H, 8.49%. (Hexane, C_6H_{14}, may originate in the solvent used in recrystallization.)

[5](1,1')[5](3,3')Ferrocenophane (1). The spectra of **1** previously reported (mp 86—87°C[7]) were also measured on the same instruments in order to compare them with those of **2**. ^1H NMR ($CDCl_3$) δ=1.82, 2.00, 2.13, and 2.36 (8H, 2H, 2H and 8H, each m, $-CH_2-$ of bridge), 3.78 and 3.88 (2H and 4H, t and d, Cp-H); ^{13}C NMR ($CDCl_3$) δ=23.69, 24.60 and 25.94 ($-CH_2-$), 66.87, 68.74 and 87.01 (Cp–C); λ_{max} (THF) 444 nm (ε=124).

(Received July 9, 1991)

Synopsis. Radiation-induced addition reaction of alcohols to hexafluoro-2-butyne provided (*E*)- and (*Z*)-2,3-bis(trifluoromethyl)allyl alcohols, which were dehydrated to afford 1,2-bis(trifluoromethyl)-1,3-butadienes. Thermal cyclization of 3-methyl-1,2-bis(trifluoromethyl)-1,3-butadiene afforded 1-methyl-2,3-bis(trifluoromethyl)cyclobutene.

Although radical addition is one of the most useful reactions to synthesize organic compounds,[1] little is known on the reaction of polyfluoroalkynes. In our continuing series of studies on the radical addition reaction of polyfluoro compounds,[2-8] the reaction of hexafluorobutyne with alcohols to give 1:1 adducts, 2,3-bis(trifluoromethyl)allyl alcohols, and a few reactions of the adducts have been examined in this investigation.

Irradiation of hexafluoro-2-butyne (**1**) with alcohols (**2**) in Freon 113 afforded (*E*)- and (*Z*)-2,3-bis(trifluoromethyl)allyl alcohols **3** (Table 1). The stereoisomers were identified based on the ^{19}F NMR spectroscopy (*E*: J_{CF_3,CF_3}=1 Hz, *Z*: J_{CF_3,CF_3}=12 Hz).[9]

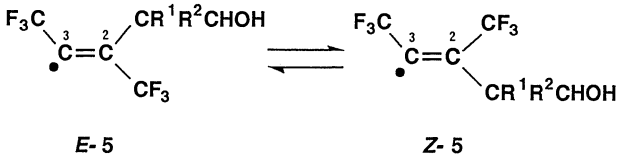
A reasonable reaction path for the formation of **3** is shown in Eqs. 1—3.

$$RR'CHOH\ (\mathbf{2}) \xrightarrow{\gamma\text{-ray}} RR'\dot{C}OH\ (\mathbf{4}) \quad (1)$$

$$RR'\dot{C}OH\ (\mathbf{4}) + CF_3C{\equiv}CCF_3\ (\mathbf{1}) \longrightarrow CF_3\dot{C}{=}C(CF_3)CRR'OH\ (\mathbf{5}) \quad (2)$$

$$CF_3\dot{C}{=}C(CF_3)CRR'OH\ (\mathbf{5}) + RR'CHOH\ (\mathbf{2}) \longrightarrow CF_3CH{=}C(CF_3)CRR'OH\ (\mathbf{3}) + RR'\dot{C}OH\ (\mathbf{4}) \quad (3)$$

More stable 1-hydroxyalkyl radical **4** can give the products **3** in good yields (stability, primary<secondary <tertiary). Radical intermediate **5** is in equilibrium between *E*-**5** and *Z*-**5** (Scheme 1). Steric hindrance between the CF_3 group at the 3-position and an alkyl group at the 2-position can control the product distribution, i.e., the bulky alkyl group at the 2-position may shift the equilibrium to *Z*-**5** to increase the yield of *Z*-**3**.



E-**5** *Z*-**5**

Scheme 1.

Dehydration of a mixture of *E*- and *Z*-**3** gave a mixture of *E*- and *Z*-**6** in 60—95 % yields (Table 2). In the case of **3b** and **3d**, the *E*/*Z* ratio of the products **6** concerning with the double bond with two CF_3 groups was the same as that of starting materials, suggesting that *E*- and *Z*-**3** afforded the corresponding *E*- and *Z*-**6**, respectively. In the case of **3c**, the formation of four isomers was confirmed by gas chromatography.

Thermal cyclization of **6d** gave 1-methyl-2,3-bis(trifluoromethyl)cyclobutene (**7d**) in 25% yield (Scheme 2).

The structure of **7d** was confirmed by its ^{1}H NMR spectrum, i.e., δ values of methylene (5.01—5.23 ppm) and methine (5.95—6.14 ppm) protons of **6d** shifted to 2.57 and 3.90 ppm in **7d**, respectively. The same reaction of **6b** gave an amorphous polymer.

Experimental

Instruments. ^{1}H NMR spectra were measured with a Hitachi R-22 instrument (90 MHz) in carbon tetrachloride and chemical shifts were given as δ ppm relative to tetramethylsilane (TMS) as an internal standard. ^{19}F NMR spectra were obtained with a Hitachi R-20B (56.45 MHz) in carbon tetrachloride and chemical shifts were given as δ ppm relative to trifluoroacetic acid as an external standard. The IR spectra were recorded on a Hitachi EPI-2 grating spectrometer.

General procedure for γ-Ray Irradiation of Hexafluoro-2-butyne with Alcohols. Hexafluoro-2-butyne (**1**, 16.28 g, 0.10 mol), ethanol (**2b**, 5.57 g, 0.12 mol), and Freon 113 (20.15 g, 0.11 mol) were placed in a glass ampoule (100 ml). The ampoule was degassed by a freeze-thaw cycle and was sealed under reduced pressure. The γ-ray irradiation was carried out at 6.2×10^4R h^{-1} by ^{60}Co for 158 h at ambient temperature (total irradiation, 98.2 Mrad). After the reaction, were evaporated the starting material, ethanol, and Freon 113. The residual liquid was distilled to give a mixture (14 g) of (*E*)- and (*Z*)-3,4-bis(trifluoromethyl)-3-buten-2-ol (*E*-**3b** and *Z*-**3b**), which were separated using a preparative gas chromatograph. The physical and spectral data are shown below.

(*E*)-2,3-Bis(trifluoromethyl)-2-propen-1-ol (*E*-3a): Bp 110°C; d_4^{20} 1.501; n_D^{20} 1.3368; IR (neat) 1690 (C=C) cm^{-1}; ^{1}H NMR δ=3.58 (br s, 1H, OH), 4.42 (br s, 2H, CH_2), and 6.35 (qq, *J*=7.8 and 1.8 Hz, 1H, C=CH); ^{19}F NMR δ=11.1 (dq, *J*=2 and 1 Hz, 2-CF_3) and 20.8 (dq, *J*=8 and 1 Hz, 3-CF_3); Found: C, 31.06; H, 2.06 %. Calcd for $C_5H_4F_6O$: C, 30.95; H, 2.08 %.

(*E*)-3,4-Bis(trifluoromethyl)-3-buten-2-ol (*E*-3b): Bp 115°C; d_4^{20} 1.408; n_D^{20} 1.3484; IR (neat) 1682 (C=C) cm^{-1}; ^{1}H NMR δ=1.49 (d, *J*=6.0 Hz, 3H, CH_3), 3.79 (br s, 1H, OH), 5.02 (q, *J*=6.0 Hz, 1H, 1-CH), and 6.22 (qq, *J*=8.4 and 1.2 Hz, 1H, 3-CH); ^{19}F NMR δ=15.6 (dq, *J*=1 and 1 Hz, 2-CF_3) and 21.6 (dq, *J*=8 and 1 Hz, 3-CF_3); Found: C, 34.57; H, 3.04 %. Calcd for $C_6H_6F_6O$: C, 34.63; H, 2.91%.

(*Z*)-3,4-Bis(trifluoromethyl)-3-buten-2-ol (*Z*-3b): Bp 128°C; d_4^{20} 1.427; n_D^{20} 1.3500; IR (neat) 1691 (C=C) cm^{-1}; ^{1}H NMR δ=1.45 (d, *J*=6.0 Hz, 3H, CH_3), 3.23 (br s, 1H, OH), 4.58 (q, *J*=6.0 Hz, 1H, 1-CH), and 6.37 (q, *J*=8.4 Hz, 1H, 3-CH); ^{19}F NMR δ=18.0 (q, *J*=12 Hz, 2-CF_3) and 21.6 (dq, *J*=8 and 12 Hz, 3-CF_3); Found: C, 34.63; H, 2.66%. Calcd for $C_6H_6F_6O$: C, 34.63; H, 2.91%.

(*E*)-1,2-Bis(trifluoromethyl)-1-penten-3-ol (*E*-3c): Bp 126°C; d_4^{20} 1.343; n_D^{20} 1.3579; IR (neat) 1678 (C=C) cm^{-1}; ^{1}H NMR δ=1.02 (t, *J*=6.6 Hz, 3H, CH_3), 1.67 (dq, *J*=6.6 and 6.0 Hz, 2H, CH_2), 3.63 (br s, 1H, OH), 4.74 (d, *J*=6.0 Hz, 1H, 1-CH), and 6.37 (q, *J*=7.8 Hz, 1H, 3-CH); ^{19}F NMR δ=16.8 (q, *J*=1 Hz, 2-CF_3) and 22.8 (dq, *J*=8 and 1 Hz, 3-CF_3); Found: C, 37.56; H, 3.80%. Calcd for $C_7H_8F_6O$: C, 37.70; H, 3.62%.

(*Z*)-1,2-Bis(trifluoromethyl)-1-penten-3-ol (*Z*-3c): Bp 139°C; d_4^{20} 1.360; n_D^{20} 1.3589; IR (neat) 1687 (C=C) cm^{-1}; ^{1}H NMR δ=1.00 (t, *J*=6.6 Hz, 3H, CH_3), 1.62 (br, 2H, CH_2), 2.83 (br s, 1H, OH), 4.37 (br, 1H, 1-CH), and 6.34 (q, *J*=9.0 Hz, 1H, 3-CH); ^{19}F NMR δ=17.6 (q, *J*=12 Hz. 2-CF_3) and 20.4 (dq, *J*=9 and 12 Hz, 3-CF_3); Found: C, 37.85; H, 3.67%. Calcd for $C_7H_8F_6O$: C, 37.70; H, 3.62%.

(*E*)-3,4-Bis(trifluoromethyl)-2-methyl-3-buten-2-ol (*E*-3d): Bp 119°C; d_4^{20} 1.360; n_D^{20} 1.3604; IR (neat) 1673 (C=C) cm^{-1}; ^{1}H NMR δ=1.58 (br s, 6H, CH_3), 2.86 (br s, 1H, OH), and 6.27 (qq, *J*=9.6 and 1.8 Hz, 1H, CH); ^{19}F NMR δ=14.8 (dq, *J*=2 and 2 Hz, 2-CF_3) and 24.8 (dq, *J*=10 and 2 Hz, 3-CF_3); Found: C, 37.73; H, 3.58%. Calcd for $C_7H_8F_6O$: C, 37.70; H, 3.62%.

(*Z*)-3,4-Bis(trifluoromethyl)-2-methyl-3-buten-2-ol (*Z*-3d): Bp 134°C; d_4^{20} 1.356; n_D^{20} 1.3596; IR (neat) 1679 (C=C) cm^{-1}; ^{1}H NMR δ=1.52 (br s, 6H, CH_3), 2.61 (br s, 1H, OH), and 6.56 (q, *J*=8.4 Hz, 1H, CH); Found: C, 37.63; H, 3.62%. Calcd for $C_7H_8F_6O$: C, 37.70; H, 3.62%.

Dehydration of 2,3-Bis(trifluoromethyl)allyl Alcohols (3). In a flask (100 ml) equipped with a distillation apparatus, were placed a mixture of (*E*)- and (*Z*)-3,4-bis(trifluoromethyl)-3-buten-2-ol (**3b**, 12.3 g, 0.06 mol) and phosphorus pentaoxide (24 g, 0.17 mol). The mixture was heated at 100°C. As the reaction proceeded, was distilled out a mixture of (*E*)- and (*Z*)-1,2-bis(trifluoromethyl)-1,3-butadiene (**6b**, 8.9 g), which were separated using a preparative gas chromatograph. The physical and spectral data are shown below.

(*E*)-1,2-Bis(trifluoromethyl)-1,3-butadiene (*E*-6b): Bp 53°C; d_4^{20} 1.302; n_D^{20} 1.3321; IR (neat) 1613 and 1668 (C=C) cm^{-1}; ^{1}H NMR δ=5.4—6.7 (m, 3H, CH=CH_2) and 6.15 (q, *J*=9.0 Hz, 1H, CF_3CH); ^{19}F NMR δ=12.6 (d, *J*=1 Hz, 2-CF_3) and 19.4 (dq, *J*=9 and 1 Hz, 1-CF_3); Found: C, 37.86; H, 2.07%. Calcd for $C_6H_4F_6$: C, 37.91; H, 2.12%.

(*Z*)-Bis(trifluoromethyl)-1,3-butadiene (*Z*-6b): d_4^{20}1.350; n_D^{20} 1.3410; IR (neat) 1691 (C=C) cm^{-1}; ^{1}H NMR δ=5.3—6.7 (m, 3H, CH=CH_2) and 6.00 (q, *J*=7.8 Hz, 1H, CF_3CH); ^{19}F NMR δ=15.2 (q, *J*=11 Hz, 2-CF_3) and 19.7 (dq, *J*=8 and 11 Hz, 1-CF_3); Found: C, 37.49; H, 2.16%. Calcd for $C_6H_4F_6$: C, 37.91; H, 2.12%.

(*E*)-1,2-Bis(trifluoromethyl)-3-methyl-1,3-butadiene (*E*-6d): Bp 67.0°C; d_4^{20} 1.221; n_D^{20} 1.3277; IR (neat) 1641 and 1681 (C=C) cm^{-1}; ^{1}H NMR δ=1.94 (br s, 3H, CH_3), 5.01 (br s, 1H, CH_2), 5.23 (q, *J*=1.2 Hz, 1H, CH_2), and 6.14 (qq, *J*=7.2 and 1.8 Hz, 1H, CH); ^{19}F NMR δ=9.7 (br s, 2-CF_3) and 18.3 (br d, 1-CF_3); Found: C, 40.67; H, 2.87%. Calcd for $C_7H_6F_6$: C, 41.19; H, 2.96%.

(*Z*)-1,2-Bis(trifluoromethyl)-3-methyl-1,3-butadiene (*Z*-6d): Bp 89°C; d_4^{20}1.280; n_D^{20} 1.3441; IR (neat) 1648 and 1669 (C=C) cm^{-1}; ^{1}H NMR δ=1.96 (q, *J*=8.2 Hz, 3H, CH_3), 5.21 (br s, 2H, CH_2), and 5.95 (q, *J*=8.4 Hz, 1H, CH); ^{19}F NMR δ=17.0 (q, *J*=13 Hz, 2-CF_3) and 19.8 (dq, *J*=8 and 13 Hz, 1-CF_3); Found: C, 40.90; H, 2.92%, Calcd for $C_7H_6F_6$: C, 41.19; H, 2.96%.

Cyclization of 1,2-Bis(trifluoromethyl)-1,3-butadiene (6d). In a stainless steel autoclave (100 ml) was placed a mixture of (*E*)- and (*Z*)-1,2-bis(trifluoromethyl)-3-methyl-1,3-butadiene (**6d**, 5.9 g, 28.9 mmol) and *dl*-limonene (1.0 g, a polymerization inhibitor). After heating the reaction mixture at 200°C for 24 h, the product was distilled and purified using a preparative gas chromatograph to afford 1-methyl-2,3-bis(trifluoromethyl)cyclobutene (**7d**, 1.5 g) in 25% yield.

1-Methyl-2,3-bis(trifluoromethyl)cyclobutene (7d): Mp 107°C; d_4^{20} 1.305; n_D^{20} 1.3362; IR (neat) 1694 (C=C) cm^{-1}; ^1H NMR δ=1.90 (br s, 3H, CH_3), 2.57 (br s, 2H, CH_2), and 3.90 (br s, 1H, CH); ^{19}F NMR δ=5.7 (dq, J=8 and 2 Hz, CCF_3) and 13.8 (br, $CHCF_3$); Found: C, 40.90; H, 2.88%, Calcd for $C_7H_6F_6$: C, 41.19; H, 2.96%.

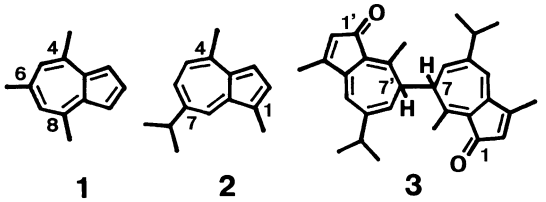
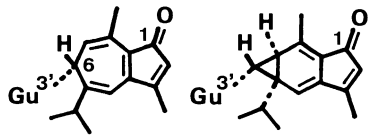
(Received July 12, 1991)

Synopsis. Oxidation of 4,6,8-trimethylazulene (**1**) with hydrogen peroxide in pyridine at 25°C for 18 h gave 4,6,8-trimethyl-1,5- and -1,7-azulenequinones, their 2-(4,6,8-trimethyl-1-azulenyl) derivatives, and 2,3-dihydro-4,6- and -4,7-dimethyl-2-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-ones in much higher yields than those by autoxidation of **1** in DMF at 120°C. The same oxidation of guaiazulene afforded sixteen separable products, among which there were three new dimeric condensates.

We have undertaken a systematic investigation on autoxidation of various azulenes for the past several years and isolated a wide variety of interesting products.[2)] Oxidation of guaiazulene (**2**) with peracetic acid was also conducted recently, and three dimeric compounds **3**, **4**, and **5** were isolated in good yields.[3-5)] These compounds were proved to be important intermediates for the autoxidation products of **2**. We now wish to report on oxidation of two representative trialkyl azulene derivatives, 4,6,8-trimethylazulene (**1**) and guaiazulene (**2**), with hydrogen peroxide in pyridine, which has resulted in isolation of several 1,5- and 1,7-azulenequinone derivatives in much higher yields than those by autoxidation, as well as disclosing several new types of reaction pathways in the oxidation of azulenic hydrocarbons.



1 **2** **3**



4 **5**

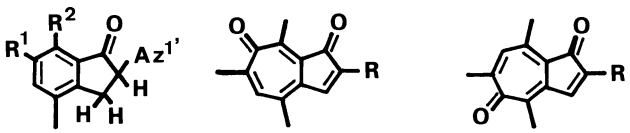
Gu3'= 3-guaiazulenyl

Oxidation of 4,6,8-Trimethylazulene (1). Oxidation of **1** with hydrogen peroxide in pyridine was carried out at 25°C for 18 h, during which the reaction was monitored by the use of the reversed-phase high-pressure liquid chromatography (HPLC) and silica-gel TLC. As in the case of our previous studies no oxidation of azulenes, the reaction products were carefully separated into each component by using chromatography, when about 33% of the starting material **1** was consumed. Thus, we obtained seven products (**6**—**12**); the sequence of the compound numbers corresponds to the decreasing R_f values on silica-gel TLC (15:85 AcOEt–hexane). In Chart 1 are summarized these products, whose structures were established by UV-visible, IR ^{1}H NMR, and EI MS spectroscopy as will be explained below. Yields of the isolated products, which are based on the consumed starting material **1**, totaled to 36%. Besides these, there still remained 63% (w/w) yield of unidentified polar resinous products.

Compound **6** (5% yield) (M^+: m/z 328 by EI MS) contained a carbonyl group (1695 cm^{-1}) and a 4,6,8-trimethyl-1-azulenyl moiety (^{1}H NMR). A careful analysis of the ^{1}H NMR spectra with the aid of decoupling techniques and by comparison of the parameters (δ and J values) with those of related compounds[2)] established the structure of 2,3-dihydro-4,7-dimethyl-2-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-one for **6**. The assignments of the ^{1}H NMR signals are recorded in the Experimental section. Compound **7** (5% yield) turned out to be the 4,6-dimethyl isomer of **6** by the similar analysis of the IR, ^{1}H NMR, and EI MS spectral data.

Compound **8** (1% yield) possesed a dimeric composition ($C_{26}H_{24}O_3$ by HR MS) and contained three carbonyl groups (1705, 1675, and 1570 cm^{-1}). The ^{1}H NMR data indicated the presence of a 2-substituted 4,6,8-trimethyl-1,5-azulenequinone[2b)] moiety and a certain nucleus ($C_{13}H_{13}O$) that exhibited three methyl groups (at δ=2.18, 2.86, and 3.18, all singlet), an olefinic proton (at δ=6.53, singlet), and three aromatic protons [at δ=6.93(2H) and 6.96, both singlet]. However, structure of **8**[6)] is not yet determined.

Compounds **9** and **10** (9% yield), a inseparable mixture, were found to be a mixture of 2-(4,6,8-trimethyl-1-azulenyl)-4,6,8-trimethyl-1,7- and -1,5-azulenequinones in a ratio of ca. 1:1, respectively. The assignment of the coupling positions (C_2–$C_{1'}$) of the two moieties in these compounds were based on an NOE



6: R^1 = H, R^2 = Me **9**: R = $Az^{1'}$ **10**: R = $Az^{1'}$

7: R^1 = Me, R^2 = H **11**: R = H* **12**: R = H*

Chart 1. Oxidation products from **1** with hydrogen peroxide in pyridine at 25°C for 18 h: $Az^{1'}$=4,6,8-trimethyl-1-azulenyl; *previously known compounds.

experiment on the Me-4 and H-3 signals of the 4,6,8-trimethyl-1,7- and -1,5-azulenequinone moieties. Compounds **11** and **12** (8% yield each) were identified by UV, IR, ^{1}H NMR, and EI MS spectroscopy as 4,6,8-trimethyl-1,7- and -1,5-azulenequinones,[2b] respectively. It is noteworthy that azulenequinones (**11** and **12** as well as **9** and **10**) were produced in significantly higher yields under the present conditions than the previous autoxidation of **1** in DMF at 120°C (1% yield each for **11** and **12**).[2b]

No oxidation was found to take place, when **1** was treated with pyridine 1-oxide[7-8] in pyridine at 25°C for 18 h. Therefore, the above results are most likely due to the lower reaction temperature and the neutral conditions that would prevent those products decomposition during the oxidation.

Oxidation of Guaiazulene (2). Compound **2** was treated with hydrogen peroxide in pyridine at 25°C for 8 h in a manner similar to that described for **1**. After separation, sixteen products (**13**—**28**) were obtained as pure compounds besides the recovered starting material **2** (60%). Structures of these products are shown in Chart 2, among which thirteen compounds (**13**, **15**, **17**, and **19**—**28**) were spectroscopically identical with those obtained previously by autoxidation of **2**.[2]

Compound **14** was found to be the 3,5′-isomer by spectroscopy. Compound **16** (M^+: m/z 394 by EI MS) contained a 3-guaiazulenyl moiety attached to a methyl group of the 7-isopropyl substituent of **2** (UV and ^{1}H NMR). Compound **18** (M^+: m/z 354 by EI MS) possessed a 3-guaiazulenyl moiety attached to C-2 of 3,7-dimethyl-1*H*-inden-1-one (UV and ^{1}H NMR).

The total yields of the isolated products from **2** were 72%, but there still remained a 20% (w/w) yield of unidentified polar resinous products. 5-Isopropyl-3,8-dimethyl-1,7-azulenequinone (**28**) was obtained in the highest yield (10%) among the isolated products. The newly isolated compounds **14** and **16** are apparently formed by two new types of bimolecular coupling reactions: Namely, coupling of the most reactive site (C-3) of guaiazulene with a seemingly far less reactive site of the seven-membered nucleus C-7 (to give **14**) and of a side-chain isopropyl group of **2** (to give **16**).

Although the exact reaction mechanism has still remained to be clarified, the present work is believed to provide notable information on potential synthetic application to the preparation of some azulenequinones.

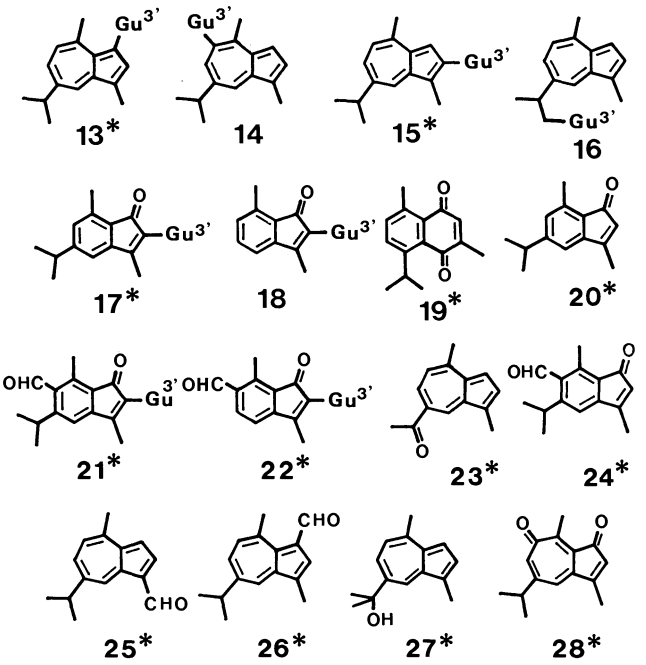


Chart 2. Oxidation products from **2** with hydrogen peroxide in pyridine at 25°C for 8 h: Gu$^{3'}$=3-guaiazulenyl; *previously known compounds.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. Chromatographic saparation and the spectral measurement were carried out according to the procedures described before,[2a] except that ^{1}H NMR spectra were recorded with a JEOL GSX-270 (270 MHz for ^{1}H).

Oxidation of 4,6,8-Trimethylazulene (1). Compound **1**[9] (0.33 g) was added to a stirred solution of hydrogen peroxide (30% aq, 10 ml) in pyridine (20 ml). The mixture was stirred at 25°C for 18 h. The reactant was treated with cold 10% aq HCl (500 ml), carefully neutralized with aq Na_2CO_3, and extracted with hexane (3×100 ml). The extract was washed with water, dried (Na_2SO_4), and evaporated in vacuo. The residue (0.34 g) was purified by silica-gel column chromatography first with hexane (to recover the unreacted **1**), then with hexane-ethyl acetate (to separate several products), and finally with methanol (to eluate the polar substance) as the eluants. Then, each fraction of the products was further purified by preparative HPLC; when necessary, this chromatographic procedure was repeated. Thus, the following seven products were obtained as pure substances (**6**—**12**), besides the recovered starting material **1** [0.22 g (conversion: 33%); R_f=0.94] and polar resinous substances [76 mg, 63% (w/w); R_f=0.0]. The yield of each product is based on the consumed starting material (0.11 g).

2,3-Dihydro-4,7-dimethyl-2-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-one (6): Violet needles; 6 mg (5%); mp 154°C; R_f=0.56; IR ($CHCl_3$) 1695 cm^{-1} (C=O); ^{1}H NMR δ=2.32 (3H, brs, Me-4), 2.59 (3H, s, Me-6′), 2.64 (3H, brs, Me-7), 2.82 (3H, s, Me-4′), 3.14 (3H, brs, Me-8′), 3.17 (1H, dd, J=17.5, 4.0 Hz, H-3), 3.63 (1H, dd, J=17.5, 8.5 Hz, H-3), 4.92 (1H, brdd, J=8.5, 4.0 Hz, H-2), 6.97 (1H, s, H-5′), 6.99 (1H, s, H-7′), 7.08 (1H, brd, J=7.5 Hz, H-6), 7.26 (1H, brd, J=4.0 Hz, H-3′), 7.28 (1H, d, J=4.0 Hz, H-2′), and 7.30 (1H, brd, J=7.5 Hz, H-5); EI MS m/z 328 (M^+; 100%), 313 (39), 285 (50), 270 (54), 253 (24), 239 (20), 170 (62), 152 (15), 128 (13), 115 (21), 91 (9), 77 (4), 65 (4), and 51 (3).

2,3-Dihydro-4,6-dimethyl-2-(4,6,8-trimethyl-1-azulenyl)-1*H*-inden-1-one (7): Violet needles; 6 mg (5%); mp 182°C; R_f=0.49; IR ($CHCl_3$) 1695 cm^{-1} (C=O); ^{1}H NMR δ=2.33 (3H, brs, Me-4), 2.41 (3H, brs, Me-6), 2.59 (3H, s, Me-6′), 2.82 (3H, s, Me-4′), 3.13 (3H, brs, Me-8′), 3.14 (1H, dd, J=17.0, 4.0 Hz, H-3), 3.65 (1H. dd. J=17.0, 8.0 Hz, H-3), 4.94 (1H, brdd, J=8.0, 4.0 Hz, H-2), 6.98 (1H, s, H-5′), 6.99 (1H, s, H-7′), 7.26 (1H, brd, J=4.0 Hz, H-3′), 7.28 (1H, d, J=4.0 Hz, H-2′), 7.30 (1H, s, H-5), and 7.51 (1H, s, H-7); EI MS m/z 328 (M^+; 100%), 313 (60), 285 (38), 270 (56), 253 (26), 239 (21), 170 (45), 152 (17), 128 (14), 115 (20), 91 (11), 77 (9), 65 (4), 51 (4), and 41 (5).

4,6,8-Trimethyl-2-(4,6,8-trimethyl-1-azulenyl)-1,7- and -1,5-azulenequinone (9 and 10): (As a ca. 1:1 mixture, respectively); dark reddish violet needles; 11 mg (9%); mp 185—192°C; R_f=0.38; IR ($CHCl_3$) 1735, 1690, and 1575 cm^{-1} (C=O); ^{1}H NMR for **9** δ=2.27 (3H, brd, $J\approx$1 Hz, Me-6), 2.36 (3H, s, Me-4), 2.615 (3H, s, Me-8), 2.69 (3H, s, Me-6′), 2.72 (3H, s, Me-4′), 2.883 (3H, s, Me-8′), 7.06 (1H, s, H-5′), 7.10 (1H, s, H-7′), 7.11 (1H, brq, $J\approx$1 Hz, H-5), 7.34 (1H, d, J=4.0 Hz, H-3′), 7.62 (1H, d, J=4.0 Hz, H-2′), and 7.69 (1H, s, H-3) and

for **10** δ=2.30 (3H, brd, $J\approx1$ Hz, Me-6), 2.37 (3H, s, Me-4), 2.62 (3H, s, Me-8), 2.70 (3H, s, Me-6′), 2.73 (3H, s, Me-4′), 2.877 (3H, s, Me-8′), 7.085 (1H, s, H-5′), 7.09 (1H, brq, $J\approx1$ Hz, H-7), 7.12 (1H, s, H-7′), 7.40 (1H, d, J=4.0 Hz, H-3′), 7.66 (1H, d, J=4.0 Hz, H-2′), and 7.77 (1H, s, H-3); NOE experiment [obsd NOEs(%) by irradiation of Me-4 for **9**] H-3=29, (for **10**) H-3=38; EI MS m/z 368 (M^+; 74%), 340 (100), 325 (35), 310 (22), 297 (28), 281 (26), 267 (37), 252 (15), 239 (17), 170 (11), 152 (20), 128 (17), 115 (24), 91 (11), 77 (13), and 41 (15).

4,6,8-Trimethyl-1,7-azulenequinone[2b] **(11):** Yellow needles; 10 mg (8%); mp 118°C decomp (lit,[2b] mp 118°C decomp); R_f=0.25; UV, IR, ^{1}H NMR, and EI MS, identical with the spectra of the authentic sample.

4,6,8-Trimethyl-1,5-azulenequinone[2b] **(12):** Yellow needles; 10 mg (8%); mp 120°C decomp (lit.[2b] mp 120°C decomp); R_f=0.23; UV, IR, ^{1}H NMR, and EI MS, identical with the spectra of the authentic sample.

Oxidation of Guaiazulene (2). Oxidation of **2**[9] (0.10 g) with hydrogen peroxide (30% aq, 3 ml) in pyridine (5 ml) was carried out at 25°C for 8 h in a manner similar to that described for **1**, thus affording, after the careful chromatographic separation, sixteen products (**13**—**28**), besides the recovered starting material **2** (60 mg, 40% conversion, R_f=0.95) and polar resinous substances [8 mg, 20% (w/w); R_f=0.0]. The yield of each product is based on the consumed starting material (40 mg).

Previously Known Compounds: Comounds **13** (4 mg, 10%), **15** (3 mg, 8%), **17** (1 mg, 3%), **19** (1 mg, 3%), **20** (2 mg, 5%), **21** (1 mg, 3%), **22** (1 mg, 3%), **23** (1 mg, 3%), **24** (2 mg, 5%), **25** (1 mg, 3%), **26** (1 mg, 3%), **27** (2 mg, 5%), and **28** (4 mg, 10%) were obtained, which had also been produced by autoxidation of **2**.[2]

3,5′-Biguaiazulene (14): (As a ca. 37:63 mixture of **14** and **13**, respectively); dark greenish blue paste; R_f=0.71; ^{1}H NMR δ=1.31, 1.32 (3H each, d, J=7.0 Hz, *i*-Pr-7′), 1.40 (6H, d, J=7.0 Hz, *i*-Pr-7), 2.26 (3H, s, Me-4′), 2.50 (3H, s, Me-4), 2.70 (3H, s, Me-1), 2.71 (3H, s, Me-1′), 3.02 (1H, sept, J=7.0 Hz, Me_2CH-7′), 3.08 (1H, sept, J=7.0 Hz, Me_2CH-7), 6.82 (1H, d, J=10.0 Hz, H-5), 7.29 (1H, d, J=3.5 Hz, H-3′), 7.33 (1H, dd, J=10.0, 2.0 Hz, H-6), 7.46 (1H, s, H-2), 7.62 (1H, d, J=2.0 Hz, H-6′), 7.65 (1H, d, J=3.5 Hz, H-2′), 8.22 (1H, d, J=2.0 Hz, H-8), and 8.23 (1H, d, J=2.0 Hz, H-8′).

7-[2-(3-Guaiazulenyl)-1-methylethyl]-1,4-dimethylazulene (16): Blue prisms; 1 mg (3%); mp 117°C; R_f=0.71; UV λ_{max} (MeOH) 246, 285, 307,[sh] 352, 369, and 613 nm (log ε 4.60, 4.65, 4.52, 3.76, 3.74, and 3.03); ^{1}H NMR δ=1.35 (6H, d, J=7.0 Hz, *i*-Pr-7′), 1.37 (3H, d, J=7.0 Hz, CH_3CH-7), 2.55 (3H, s, Me-1), 2.61 (3H, s, Me-1′), 2.84 (3H, s, Me-4), 2.99 (3H, s, Me-4′), 3.01 (1H, sept, J=7.0 Hz, Me_2CH-7′), 3.24 (1H, dqd, J=8.5, 7.0, 6.0 Hz, CH-7), 3.46 (1H, dd, J=14.5, 8.5 Hz, CH–C-7), 3.66 (1H, dd, J=14.5, 6.0 Hz, CH–C-7), 6.82 (1H, d, J=10.5 Hz, H-5′), 6.99 (1H, d, J=10.5 Hz, H-5), 7.23 (1H, d, J=4.0 Hz, H-3), 7.25 (1H, dd, J=10.5, 2.0 Hz, H-6), 7.36 (1H, s, H-2′), 7.40 (1H, dd, J=10.5, 2.0 Hz, H-6′), 7.62 (1H, d, J=4.0 Hz, H-2), 8.03 (1H, d, J=2.0 Hz, H-8), and 8.16 (1H, d, J=2.0 Hz, H-8′); EI MS m/z 394 (M^+; 6%), 211 (100), 195 (4), 183 (9), 165 (4), 153 (4), and 44 (4).

2-(3-Guaiazulenyl)-3,7-dimethyl-1*H*-inden-1-one (18): Dark red paste; 2 mg (5%); R_f=0.64; UV λ_{max} (MeOH) 248, 283, 307,[sh] 352, 368,[sh] 458, and 490 nm (log ε 4.53, 4.50, 4.45, 3.65, 3.66, 3.39, and 3.38); IR ($CHCl_3$) 1695 cm^{-1} (C=O); ^{1}H NMR δ=1.33 (6H, d, J=7.0 Hz, *i*-Pr-7′), 2.08 (3H, s, Me-3), 2.56 (3H, s, Me-7), 2.64 (3H, s, Me-4′), 2.66 (3H, s, Me-1′), 3.06 (1H, sept, J=7.0 Hz, Me_2CH-7′), 6.93 (1H, d, J=11.0 Hz, H-5′), 6.98 (1H, brd, J=7.5 Hz, H-6), 7.01 (1H, brd, J=7.5 Hz, H-4), 7.27 (1H, t, J=7.5 Hz, H-5), 7.35 (1H, dd, J=11.0, 2.0 Hz, H-6′), 7.40 (1H, s, H-2′), and 8.14 (1H, d, J=2.0 Hz, H-8′); EI MS m/z 354 (M^+; 100%), 339 (19), 321 (4), 309 (6), 296 (5), 279 (5), 265 (5), 253 (6), 239 (4), 177 (3), and 165 (4).

Mass Transfer and Product-Selectivity in Electroreduction of *p*-Methylbenzaldehyde

Po-Chung CHENG and Tsutomu NONAKA*
Department of Electronic Chemistry, Graduate School at Nagatsuta, Tokyo Institute of Technology, 4259 Nagatsuta, Midori-ku, Yokohama 277
(Received July 4, 1991)

Synopsis. Mass transfer coefficients estimated from the formation ratio of the hydrodimeric to hydromonomeric products in electroreduction of *p*-methylbenzaldehyde in parallel plate electrode–flow cell and rotating cylinder electrode–beaker cell systems were shown in good agreement (less than 8% difference) with those obtained by ordinary current–potential and concentration–time methods.

Electroreduction of carbonyl compounds yields the corresponding hydrodimers and hydromonomers. In 1960's, Udupa and co-workers[1] found that the formation ratio of the hydrodimers to hydromonomers at a rotating electrode was larger than that at a stationary electrode. This means that mass transfer plays an important role in controlling product-selectivity in electroorganic synthesis, and it is interesting to describe such behavior by a mathematical model. In previous work,[2] we developed a mathematical reaction model for the electroreductionof *p*-methylbenzaldehyde to the hydrodimer [1,2-bis(*p*-methylphenyl)-1,2-ethanediol] and the hydromonomer (*p*-methylbenzyl alcohol) at a rotating cylinder cathode in an acidic solution, and showed that the product-selectivity (formation ratio of the former to the latter product) is predictable if substrate concentration, current density and mass-transfer coefficient are known. Using the mass transfer coefficients obtained from polarization curves, the values of product-selectivity were estimated and found to be in good agreement with the experimental ones.

Inversely, it is also expected that mass transfer coefficient can be obtained from product-selectivity as described below.

Although a rotating electrode system is conveniently used for a small scale operation and one can control precisely mass transfer to and from electrode surface in this system, a flow cell system is much more practical in view of industrization.[1] In this work, a modification of the above mathematical method devloped for a rotating electrode–beaker cell system was made to be applied to a parallel plate electrode-flow cell one.

Experimental

A parallel plate flow cell (Micro Flow cell, ElectroCell AB, Sweden) was equipped with a Pb plate cathode (3.2×3.2 cm) and a so-called USA anode with a similar dimension. The catholyte of 0.25 mol dm^{-3} H_2SO_4/50% v/v ethanol containing *p*-methylbenzaldehyde (0.08 mol dm^{-3}) was separated from the anolyte by a cationic membrane (Ionac MC-3470, Sybron Chemicals Inc., USA). The electrolytes were circulated with tubing pumps (Masterflex RA-71, Cole-Pamer, USA). Pre-electrolysis without *p*-methylbenzaldehyde was carried out for ca. 15 min before the preparative electrolysis. All the electrolyses were operated at 25±2°C.

An electrolytic cell equipped with a rotating cylinder Pb cathode is described in the previous paper.[2] The products were routinely analyzed with HPLC.

Results and Discussion

A Rotating Cylinder Electrode–Beaker Cell System. The reaction mechanism for electroreduction of *p*-methylbenzaldehyde in an acidic solution is proposed as follows:[2]

$$\mathrm{ArCHO} \underset{}{\overset{\mathrm{H^+}}{\rightleftharpoons}} \mathrm{Ar\overset{+}{C}H(OH)} \qquad \text{(I)}$$

$$\mathrm{Ar\overset{+}{C}H(OH)} \xrightarrow{\mathrm{e}} \mathrm{Ar\dot{C}H(OH)} \qquad \text{(II)}$$

$$\mathrm{Ar\dot{C}H(OH)} \longrightarrow \frac{1}{2}\ \mathrm{Ar\underset{OH}{\underset{|}{C}}H-\underset{OH}{\underset{|}{C}}HAr} \qquad \text{(III)}$$

$$\mathrm{Ar\dot{C}H(OH)} \xrightarrow{\mathrm{e}+\mathrm{H^+}} \mathrm{ArCH_2OH} \qquad \text{(IV)}$$

(Ar = CH_3–C$_6$H$_4$–)

The limiting current density (i_L) for the primary electron-transfer reaction (Eq. II), which yields the radical intermediate, is defined by

$$i_L = k_m FC, \qquad (1)$$

where k_m and C are mass transfer coefficient and bulk concentration of substrate, respectively, and F is the Faraday constant.

Under galvanostatic operation, the product-selectivity for a batch electrolysis at a rotating cylinder electrode is written according to whether current density (i) at the beginning of electrolysis is larger than i_L or not.[2]

$i_L \geqslant i$ at $t=0$: Let t_0 be the time required to decrease i_L to i, then one has

$$C_0 = i/k_m F, \qquad (2)$$

$$t_0 = VF(C_i - C_0)/iA, \qquad (3)$$

where C_i and C_0 are the concentrations of substrate at $t=0$ and $t=t_0$, respectively, A is electrode area, and V is the volume of electrolyte.

The product-selectivity (ζ), defined as the formation ratio of hydrodimer (HD) to hydromonomer (HM), is then written as

$$\zeta = \frac{[\mathrm{HD}]}{[\mathrm{HM}]} = \frac{iA(2t_0-t)/2VF+\{1-\exp[-k_m A(t-t_0)/V]\}C_0}{iA(t-t_0)/VF-\{1-\exp[-k_m A(t-t_0)/V]\}C_0} \qquad (4)$$

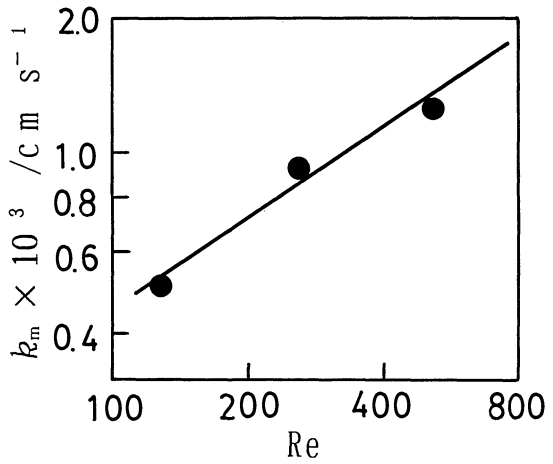

Fig. 1. Mass-Transfer coefficients (k_m) obtained by mathematical analysis of product-selectivity in a rotating cylinder electrode-beaker cell system. $Re=du_r/v$. Straight line: calculated from polarization curves. Plot: Experimentally obtained.

where [HD] and [HM] are the concentrations of HD and HM, respectively.[2]

$i_L < i$ at $t=0$: Substituting t_0 and C_0 with 0 and C_i, respectively, ζ can be calculated by Eq. 4.

If C_i, i and ζ are known, we can obtain k_m from Eq. 4 by Newton's method. Figure 1 shows the k_m values calculated at a rotating cylinder electrode using the data in the previous paper.[2] The sraight line in Fig. 1 is derived from polarization curves (Eq. 1), and it is noticeable that the k_m's obtained by both methods agree with each other. The relationship between k_m and Reynolds number (Re) can be expressed by Eq. 5.

$$k_m = 2.2 \times 10^{-5}\, Re^{0.66}\ (\mathrm{cm\ s^{-1}}), \tag{5}$$

where $Re=du_r/v$, u_r is the peripheral velocity, $v=0.0253$ cm^2 s^{-1} is the kinematic viscosity,[4] and $d=0.50$ cm is the cylinder diameter. The slope in Fig. 1 is 0.66, and the characteristic value for a rotating cylinder electrode is between 0.61 and 0.70 for $100<Re<160000$.[5-7] It must be emphasized here that the mathematical analysis of mass transfer in a rotating cylinder electrode system has not been reported for electroorganic reaction so far as we know.

A Parallel Plate Electrode-Flow Cell System. $i_L \geqq i$ at $t=0$: The concentration in the catholyte reservoir (C, i.e. the concentration at the entrance of the cell) decreases with t in the following way:

$$C = C_i - iAt/VF \qquad \text{when } t \leqslant t_0, \tag{6}$$

$$C = C_0 \exp[-p(t-t_0)] \qquad \text{when } t > t_0, \tag{7}$$

where

$$p = [1-\exp(-k_mA/Q)]Q/V,$$

and Q is the volumetric flow rate. Then Eq. 8 is derived by mathematical analysis similar to that in a rotating electrode system.

$$\zeta = \frac{iA(2t_0-t)/2VF + k_mAC_0\{1-\exp[-p(t-t_0)]\}/pV}{iA(t-t_0)/VF - k_mAC_0\{1-\exp[-p(t-t_0)]\}/pV}. \tag{8}$$

$i_L < i$ at $t=0$: Substituting t_0 and C_0 with 0 and C_i, respectively, ζ is given by Eq. 8.

Table 1 shows the experimental values of product-selectivity (ζ) obtained in the galvanostatic electrolysis of p-methylbenzaldehyde using the flow cell. Here a dimensionless parameter (q) is used instead of t. $q=1$ means that the charge passed for 1 mol of substrate is 96485 coulombs. The relation between q and t is given by

$$t = qVFC_i/iA. \tag{9}$$

As expected from Eq. 8, ζ decreases with an increase in t (i.e.q). On the other hand, ζ increases with an increase in k_m and the effect of Q is attributed to this. However, the correlation between k_m and Q (or Re) for the flow cell used is unknown, hence a numerical method similar to that in a rotating electrode system was used to calculate k_m's and their calculated values were also shown in Table 1. Then the following correlation is established:

Table 1. Product-Selectivity ζ (Hydrodimer/Hydromonomer) for the Reaction of p-Methylbenzaldehyde (Initial Concentration: 0.08 mol dm^{-3}) in a Parallel Plate Electrode-Flow Cell System and k_m Calculated by Newton's Method. $q=iAt/VFC_i$

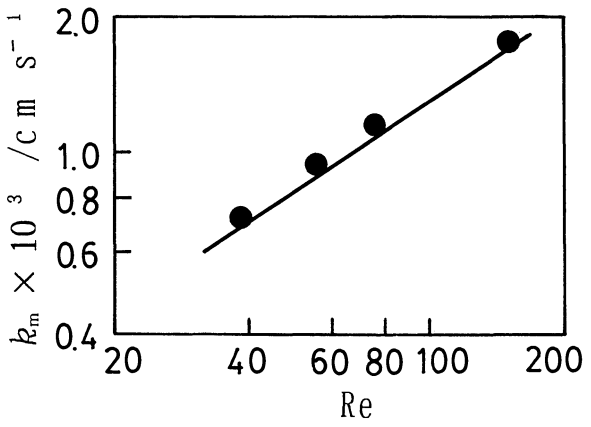

Fig. 2. Mass-Transfer coefficients (k_m) in a parallel plate electrode–flow cell system. $Re=d_e u/v$. Straight line: Eq. 10. Plot: Obtained from Eq. 7.

$$k_m = 5.84 \times 10^{-5}\ Re^{0.67}\ (\mathrm{cm\ s^{-1}}), \qquad (10)$$

where $Re=d_e u/v$, u is the linear velocity, and d_e=0.58 cm is the equivalent diameter of the flow cell.

The validity of Eq. 10 must be examined by comparing with other methods based on different principles. In stead of the information of mass transport from polarization curves (Eq. 1), Eq. 7 was used for this purpose.[8] From the relation of C and t, k_m was derived. The straight line in Fig. 2 comes from Eq. 10. Although k_m's calculated from Eq. 7 are somewhat larger than those of Eq. 10, the difference (4—8%) between them is rather small. Accordingly, the application of this mathematical reaction model to the electroreduction of *p*-methylbenzaldehyde is proven reasonable in the flow cell system.

However, flow in a range of $Re<1000$ is expected to be laminar. The experimental k_m's are larger than those of a correlation for laminar flow,[9] and the power in Eq. 10 indicates that the flow under our operating conditions is in a transition state from laminar flow to turbulent flow. It must be considered that the entrance effect introduces a measure of uncertainty into the prediction of mass-transfer rates in this type of electrolysis system.[10]

From the above discussion we conclude that the product-selectivity is itself an index of mass transport in some electrolytic systems, and mass-transfer coefficients can be estimated theoretically and experimentally in pratical parallel plate flow cell systems as well as in rotating electrode systems used for laboratory study. Furthermore, it is suggested that theoretical prediction of product-selectivity is possible by means of appropriate cell design.

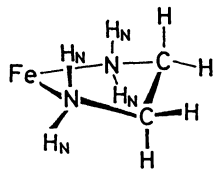
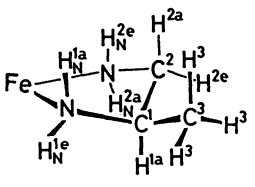
(Received November 26, 1990)

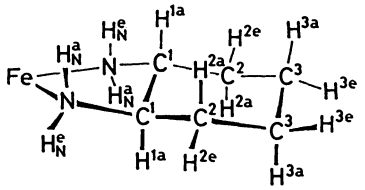
The temperature dependence of the ^1H NMR for low-spin iron(III) complexes, $[Fe^{III}(CN)_4(1,3\text{-diamine})]^-$, with 1,3-propanediamine, (2*R*,4*S*)-2,4-pentanediamine, and (2*R*,4*R*)-2,4-pentanediamine were measured at 323—183 K. The coordinated amine segment, $Fe\text{-}N(H_N)_2\text{-}C(H_\alpha)_2\text{-}C(H_\beta)_2$, resonated in the following magnetic field regions at 323—183 K: H_α^{ax}, 7.2—20.5; H_β^{ax}, 10.8—35.0; H_β^{eq}, 23.9—65.7; H_β^{methyl}, 1.8—9.9 ppm. All of the ^1H signals moved in the downfield direction with a decrease in the temperature, and exhibited a non-Curie behavior. The H_N shifts at 300 K were 110—279 ppm. The temperature and location dependence of the isotropic shift (δ^{iso}) for the ^1H and ^{13}C nuclei were accounted for by the combination of Fermi contact and dipolar contributions. The Fermi constants and spin populations were estimated for the ^1H and ^{13}C nuclei. Not only the spin polarization mechanism, but also a direct mechanism, were suggested for spin propagation from the Fe^{III} to the respective atoms.

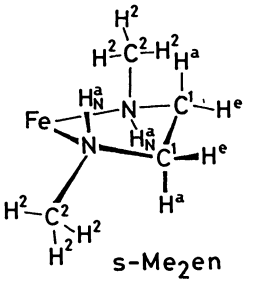
Paramagnetic metal ions affect the NMR shifts of the compounds coordinated to them.[1] Such effects of metal ions have heen extensively investigated for unsaturated compounds.[2,3] On the other hand, studies of saturated compounds have almost been limited to Ni^{II} amine complexes.[4–7] Transition metal ions, such as the low-spin Fe^{III} ion, are expected to have different magnetic effects from those of Ni^{II}, according to their electronic configurations.

The ^1H and ^{13}C NMR spectra of saturated 1,2-diamines coordinated to a low-spin Fe^{III} ion, $[Fe^{III}(CN)_4(1,2\text{-diamine})]^-$, have been studied by using 1,2-ethanediamine (en), (*R*)-1,2-propanediamine (*R*-pn), (1*R*,2*R*)-1,2-cyclohexanediamine (*R*-chxn), *N*,*N*′-dimethyl-1,2-ethanediamine (s-Me$_2$en), etc.[8–10]









These Fe^{III} complexes do not obey the Curie law and show characteristic isotropic shifts (δ^{iso}) which are strongly dependent on the nuclear locations relative to the paramagnetic center, the Fe^{III} ion: downfield and upfield shifts were observed for the axial and equatorial protons bonded to the same carbon atom on the chelate ring, respectively. To clarify these features, δ^{iso} was separated into the Fermi contact shift (δ^{con}) and the dipolar shift (δ^{dip}), based on the electronic states obtained from a *g*-value analysis of the Fe^{III} en complex;[9] these shifts have been related to the nuclear positions.[9,10] This investigation has revealed that (1) nuclei nearer to the average plane of the chelate ring have larger δ^{con} values, and (2) that the non-Curie behavior of δ^{iso} can be accounted for by the temperature dependence of δ^{dip}.

The 1,3-diamine chelates, $[Fe^{III,II}(CN)_4(1,3\text{-diamine})]^{-,2-}$, such as (2*R*,4*S*)-2,4-pentanediamine (*meso*-ptn), 1,3-propanediamine (tn), (2*R*,4*R*)-2,4-pentanediamine (*R*-ptn), and 1,3-butanediamine (1,3-bn) assume a chair or skew-boat conformation, as shown in Fig. 1.[11] These 1,3-diamine chelates have a central methylene part which is absent in the 1,2-diamine chelates, and the nuclei of the former are further apart from the coordination plane than those of the latter with *gauche* conformations.[12–15] These structural differences are expected to make the δ^{dip} and δ^{con} values for the 1,3-diamine chelates different from those for the 1,2-diamine chelates.

The variations of the ^1H NMR shifts of the 1,3-diamine chelates with temperature were previously utilized for estimating the chair⇆chair interconversion rate,[16] though the temperature dependence was treated empirically. We now report on the C^{1}H and N^{1}H shifts of the *meso*-ptn, tn, *R*-ptn, and 1,3-bn chelates measured at 323—183 and 300 K, respectively. The δ^{iso} values for the CH and NH shifts, as well as the previously reported ^{13}C shifts,[11] are separated into δ^{dip} and δ^{con}. The δ^{con} values, thus obtained, are compared with those for the Fe^{III} 1,2-diamine chelates.[9,10]

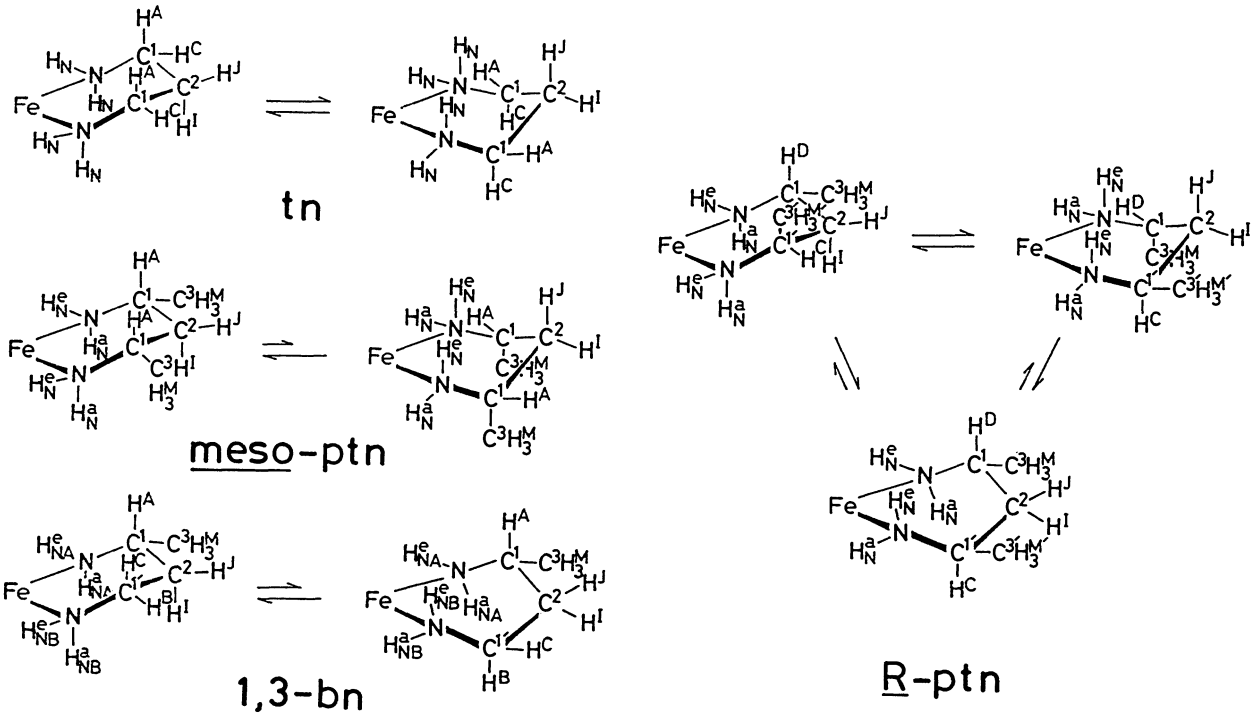


Fig. 1. Schematic structures of the chelates and the numbering of protons and carbons. Fe=Fe(CN)$_4$.

Experimental

Materials. Sodium tetracyano(1,3-diamine)ferrate(III) and ferrate(II) complexes containing 1,3-propanediamine (tn), (2*R*,4*S*)-2,4-pentanediamine (*meso*-ptn), (2*R*,4*R*)-2,4-pentanediamine (*R*-ptn), and 1,3-butanediamine (1,3-bn) as 1,3-diamines were prepared as previously reported.[11]

Measurement. The variable-temperature ^{1}H NMR spectra of the Fe^{III} 1,3-diamine complexes were recorded on a JEOL FX-100 spectrometer with ca. 0.05 M (1 M=1 mol dm^{-3}) solutions in CD_3OD containing 0.25% DCl at 323—183 K. Acidic solutions were necessary to protect the coordinated diamines against dehydrogenation.[17,18] Dilute solutions were required in order to avoid the deposition of complexes below 273 K. FID signals (pulse width: 7 μs; observation time 10 s) were collected 40 times for each sample at each temperature to obtain spectra with S/N ratios over 20/1. The probe temperature was controlled with a JNM-VT-3C temperature-control apparatus, and determined from the chemical shift difference between the methyl and hydroxyl protons of methanol.[19] The N^{1}H shifts of the Fe^{III} 1,3-diamine complexes were recorded on a JEOL FX-100 spectrometer at 300 K using 40—50 mg of the complexes dissolved in pD 2.0 DCl-D_2O (0.3 cm^3). Sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TSP; 0.00 ppm) was used as an internal reference. The positive chemical shifts indicate downfield shifts from the standard.

Results and Discussion

Temperature Dependence of ^{1}H NMR Spectra of $[Fe^{III}(CN)_4(1,3\text{-diamine})]^-$. ^{1}H NMR spectra of $[Fe^{III}(CN)_4(tn)]^-$, $[Fe^{III}(CN)_4(meso\text{-ptn})]^-$, and $[Fe^{III}(CN)_4(R\text{-ptn})]^-$ (tn=1,3-propanediamine, *meso*-ptn=(2*R*,4*S*)-2,4-pentanediamine, *R*-ptn=(2*R*,4*R*)-2,4-pentanediamine) were measured in CD_3OD containing 0.25% DCl. The temperature range was limited to 323—183 K by the boiling and freezing points of the solvent.[16,20] Acidification of the solvent with DCl is necessary to protect the coordinated diamine molecule against dehydrogenation, which yields the corresponding Fe^{II} diimine complex under neutral or basic conditions.[17,18] The observed chemical shifts ($\delta_{Fe^{III}}$) are listed in the fifth column of Table 1.

(a) *meso*-ptn. $[Fe^{III}(CN)_4(meso\text{-ptn})]^-$ showed four CH peaks of H^J, H^I, H^A, and H^M downfield, with an area ratio of 1:1:2:6.[11] These peaks moved in the downfield direction and dispersed with a decrease in temperature. Their line-widths at half-height were broadened from 29, 47, 63, and 17 Hz at 323 K to 210, 350, 530, and 105 Hz at 183 K, respectively.

The large difference in the $\delta_{Fe^{III}}$ values of H^I and H^J, i.e. ca. 13—31 ppm at 323—183 K, indicates that the *meso*-ptn chelate is fixed in a chair conformation with two equatorial methyl groups (See Fig. 1). The H^A shift is less than the H^I and H^J shifts, whereas the corresponding axial protons of the 1,2-diamine chelates show the largest downfield shift among the CH's.[9,10,16,20] The H^A and H^M shifts are less than half the corresponding shifts for the 1,2-diamine chelates. The line-width at half-height is of the order of $H^A > H^I > H^J > H^M$, the reversed order of their distance from the Fe^{III} ion.

(b) tn. $[Fe^{III}(CN)_4(tn)]^-$ exhibited two peaks, one downfield and the other upfield, with an area ratio of 1:2. The former was assigned to H^I and H^J, and the latter to H^A and H^C. The $H^{I,J}$ shift is almost the same as the mean of the H^I and H^J shifts for the *meso*-ptn

Table 1. ^1H and ^{13}C NMR Shifts[a] and Calculated Isotropic, Dipolar, and Fermi Contact Shifts[a] for $[Fe^{III}(CN)_4(1,3\text{-diamine})]^-$

a) Positive values indicate downfield shifts. b) Chemical shifts for $[Fe^{II}(CN)_4(\text{diamine})]^{2-}$ were measured in D_2O at 300 K.[11] c) Isotropic shifts calculated from Eqs. 1—3. d) Dipolar shifts calculated from Eq. 2. e) Fermi contact shifts calculated from Eq. 3. f) The NH signal for $[Fe^{II}(CN)_4(meso\text{-ptn})]^{2-}$ was observed at 2.16 ppm in pD 2.0 DCl-D_2O solution. Since this shift is small enough compared with $\delta_{Fe^{III}}$, we assumed that δ^{con} is equal to $\delta_{Fe^{III}}$. g) From Ref. 11.

chelate in the 323—183 K temperature range.[11] This signal-averaging indicates a rapid interconversion of the tn chelate between the two chair forms (See Fig. 1), the rate constant of which has been already estimated to be 6×10^8 s^{-1} at 298 K.[16]

The magnitude of the $H^{I,J}$ shifts is larger than that of the $H^{A,C}$ shifts, despite the longer distances between the former nuclei and the Fe^{III} ion. This order of $\delta_{Fe^{III}}$ is different from that for the 1,2-diamine chelates, where the nuclei nearer the Fe^{III} ion have shown larger $\delta_{Fe^{III}}$ values.[8-10]

As the temperature decreased, the magnitude of the $H^{A,C}$ and $H^{I,J}$ shifts increased. The $H^{A,C}$ peak was wider than the $H^{I,J}$ peak: The line-widths at half-height were 36 and 27 Hz at 323 K, and 590 and 470 Hz at 183 K, respectively. This broadening with a decrease in the temperature is due to a rapid exchange of the resonance sites, in addition to a reduction of the relaxation time. The expected four peaks corresponding to H^A, H^C, H^I, and H^J, however, could not be observed, even at 183 K.

(c) *R*-ptn. $[Fe^{III}(CN)_4(R\text{-ptn})]^-$ showed three signals of $H^{I,J}$, H^M, and $H^{C,D}$ downfield with an area ratio of 1:3:1. This signal-averaging is attributable to an alteration of the *R*-ptn chelate between the chair and λ-skew-boat forms shown in Fig. 1.[11] The population of the two forms has been estimated to be ca. 50:50, based on the $H^{C,D}$ shift at 300 K.[11]

All of the signals moved in the downfield direction as the temperature decreased. The overlap with the solvent signals prevented any observation of the $H^{C,D}$ signal below 243 K. The widths of the $H^{I,J}$, H^M, and $H^{C,D}$ peaks were 21, 18, and 62 Hz at 323 K, respectively. The decrease in the temperature to 183 K broadened these peaks, but was not sufficient to separate them into the peaks corresponding to the individual protons. The *R*-ptn chelate is, thus, expected to alter between the chair and λ-skew-boat forms as fast as the tn chelate, i.e. $>10^8$ s^{-1} at 298 K.[16]

The ^1H shifts of these Fe^{III} 1,3-diamine complexes are plotted against T^{-1} in Fig. 2. The nonlinearity indi-

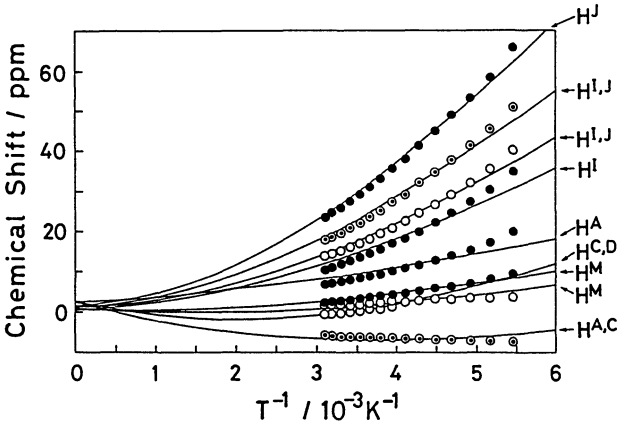

Fig. 2. Temperature dependence of ^1H NMR shifts of $[Fe^{III}(CN)_4(1,3\text{-diamine})]^-$ in CD_3OD containing 0.25% DCl. The circles indicate the observed values: *meso*-ptn (●), tn (⊙), and *R*-ptn (○). The solid curves indicate the estimated values. The chemical shifts at $T^{-1}=0$ are the shifts of the corresponding Fe^{II} complexes.

cates that the 1,3-diamine chelates, as well as the 1,2-diamine chelates,[9,10,20] do not obey the Curie law.

Amino Protons. The ^1H NMR spectra of the amino protons (NH) of $[Fe^{III}(CN)_4(1,3\text{-bn})]^-$ (1,3-bn=1,3-butanediamine), besides the Fe^{III} 1,3-diamine complexes described above, were measured in p*D* 2.0 DCl–D_2O at 300 K. The following chemical shifts and line-widths at half-height were obtained: *meso*-ptn, 110.2 (390) and 278.8 (840); tn, 193.0 (510); *R*-ptn, 134.0 (160) and 231.1 (320); 1,3-bn, 106.9 (580), 118.8 (580), 268.8 (820), and 274.9 ppm (950 Hz). The higher field peaks were assigned to the axial amino protons and the lower field peaks to the equatorial protons, as those for the 1,2-diamine complexes.[10]

The two NH peaks observed for the *meso*-ptn chelate correspond to H_N^a and H_N^e (See Fig. 1). The $\delta_{Fe^{III}}$ difference of the NH peaks amounts to 168.6 ppm, which is ca. 5 times as large as 34 ppm for the *R*-chxn chelate.[10] This large difference indicates that the *meso*-ptn chelate assumes a chair form.

The single NH peak for the tn chelate has almost the same values of chemical shift and line-width as the mean values, 194.5 ppm and 560 Hz, for the H_N^a and H_N^e peaks of the *meso*-ptn chelate. The rapid interconversion of the tn chelate between the two chair forms is, thus, demonstrated by the NH as well as CH line shapes.

The difference between the two NH shifts of the *R*-ptn chleate, 97.1 ppm, is 58% of that for the *meso*-ptn chelate, and the average NH shift of the former differs by ca. 10 ppm from those for the *meso*-ptn and tn chelates. These features are ascribed to a rapid chair⇆ λ-skew-boat alteration of the *R*-ptn chelate.[11] If the λ-skew-boat form is assumed to have the same NH shift difference, 34 ppm, as the 1,2-diamine chelates, the estimated ratio of the chair : λ-skew-boat is ca. 53 : 47. This ratio is almost the same as that reported for $[Ni(H_2O)_4(rac\text{-ptn})]^{2+}$, 54 : 46.[4]

The 1,3-bn chelate exists as an equilibrium mixture of a chair and a skew-boat form with an equatorial methyl group.[11] The population of the chair form has been estimated to be 76—96% from the H^B and H^C shifts,[11] whereas 98% is obtained from the H^A shift (see Table 1). This difference indicates that the conformation at the methyl group-side resembles that of the *meso*-ptn chelate, while the unsubstituted methylene has a different conformation from that of the latter. The four NH peaks were assigned, from downfield to upfield, to H_{NA}^a, H_{NB}^a, H_{NB}^e, and H_{NA}^e, by comparing the NH shifts of the 1,3-bn and *meso*-ptn chelates.

The typical values of $\delta_{Fe^{III}}$ and the line-width for H_N^a

and H_N^e of the 1,2-diamine chelates are 127 (300) and 164 ppm (310 Hz) at 300 K.[10] Almost the same values were observed for H_N^a's of the 1,3-diamine chelates, but H_N^e of the *meso*-ptn chelate exhibited a wide line-width of 840 Hz and resonated at a lower magnetic field by ca. 100 ppm than H_N^e's of the 1,2-diamine chelates.

Geometric Factor. The coordinate system for the analysis of nuclear magnetic resonance is illustrated in Fig. 3, where the z-axis goes through the bonds NC–Fe–CN, and the x-axis bisects the angle N–Fe–N of the six-membered chelate ring. The location of a nucleus relative to the Fe^{III} ion can be represented by the geometric factors (G_A and G_B) defined by the equations $G_A=(3\cos^2\theta-1)/r^3$ and $G_B=\sin\theta\cos 2\phi/r^3$, where the distance r and angles θ and ϕ are defined as shown in Fig. 3.

The geometric factors for the Fe^{III} tn, *meso*-ptn, and *R*-ptn chelates were calculated by assuming that (1) these chelates have the chair, chair, and λ-skew-boat conformations shown in Fig. 1, respectively, and (2) that these conformers have the same geometries as do the complexes, $(-)_{589}$-$[Co(tn)_3Cl_3\cdot H_2O$,[12] $(+)_{510}$-$[Co(meso$-ptn$)_2(ox)]ClO_4\cdot H_2O$,[13] $(-)_{546}$-$[Co(R$-ptn$)_3]Cl_3\cdot 2H_2O$.[14]

The geometric factors for the 1,3-bn chelate were assumed to be equal to those for the *meso*-ptn chelate. The coordinates of the hydrogen atoms were calculated by assuming that these nuclei locate at the vertices of tetrahedrons with bond lengths of C–H=1.09 and N–H =1.02 Å. These bond lengths were obtained from the neutron diffraction of *trans*-$[CoCl_2(en)_2]Cl\cdot(H_5O_2)^+Cl^-$.[15]

The calculated values of G_A and G_B are listed in Table 2. The values for $H^{A,C}$ and $H^{I,J}$ of the tn chelate were taken to be equal to the mean values for the axial and equatorial protons because the alteration of the tn chelate between two chair conformations rapidly exchanges magnetic atmospheres of these protons. The values for the methyl protons of the *meso*- and *R*-ptn chelates were estimated by assuming a free rotation of the methyl groups.

Analysis of Chemical Shift. The effects of an unpaired electron on the ^1H and ^{13}C NMR shifts can be represented by an isotropic shift (δ^{iso}) defined by the difference in chemical shift between the paramagnetic Fe^{III} complex ($\delta_{Fe^{III}}$) and the diamagnetic Fe^{II} complex ($\delta_{Fe^{II}}$) with the same ligands as the Fe^{III} complex:[8–10]

$$\delta^{iso}=\delta_{Fe^{III}}-\delta_{Fe^{II}} \quad (1)$$

The δ^{iso} values for the *meso*-ptn, tn, *R*-ptn, and 1,3-bn complexes, listed in the sixth column of Table 1, were calculated by assuming that the $\delta_{Fe^{II}}$ values[11] are independent of the temperature.

The N$\underline{H}$ peak of $[Fe^{II}(CN)_4$ (*meso*-ptn$)]^{2-}$ appeared at 2.16 ppm in pD 2.0 DCl–D_2O.[11] This $\delta_{Fe^{II}}$ value is, however, negligibly small compared to the corresponding $\delta_{Fe^{III}}$ values, and the $\delta_{Fe^{III}}$ values were regarded as the δ^{iso} values for the N$\underline{H}$'s.

The δ^{iso} values can be separated into a dipolar shift (δ^{dip}) and a Fermi contact shift (δ^{con}) by using Eqs. 2 and 3:[9,20]

$$\delta^{dip}=(10^6/24\pi)[(2\chi_{zz}-\chi_{yy}-\chi_{xx})\cdot G_A+3(\chi_{xx}-\chi_{yy})\cdot G_B], \quad (2)$$

$$\delta^{con}=10^6 a_N\beta[6k_BT\gamma\hbar\sum_{i=1}^{3}\exp(-E_i/k_BT)]^{-1}\cdot\sum_{q=x,y,z}[\sum_{i=1}^{3}\exp(-E_i/k_BT)\cdot\langle\mu_q\rangle_{ii}-2k_BT\sum_{i=1}^{2}\sum_{j=i+1}^{3}Q_{ij}\ \langle\mu_q\rangle_{ij}\langle s_q\rangle_{ij}]. \quad (3)$$

Here, δ^{dip} and δ^{con} are in units of ppm, and their positive values indicate downfield shifts. The other symbols are defined as reported in a previous paper.[9]

The δ^{dip} values in the seventh column of Table 1 were estimated from Eq. 2. Here, we used the eigenvalues and eigenfunctions of the Kramers doublets obtained for $[Fe^{III}(CN)_4(en)]^-$ because the electronic and CD spectra of the 1,3-diamine complexes resemble those of the 1,2-diamine complex.[11] The δ^{con} values in Table 1 were

a) Positive a_N indicates that δ^{con} is downfield shift. The a_N values were obtained for CD_3OD solutions containing 0.25% DCl.

obtained by substracting each δ^{dip} value from the corresponding experimental value of δ^{iso}. The Fermi constants in MHz (a_N) calculated from the δ^{con} values by Eq. 3 are summarized in Table 3.

The $\delta_{Fe^{III}}$ values were also estimated from Eqs. 1—3 by employing a_N as a variable so as to obtain the best agreement with the ^1H shifts observed at 323—183 K, and are indicated by the solid lines in Fig. 2. The insufficient agreement for H^A and H^I of the *meso*-ptn chelate is attributable to the use of a single a_N for each nucleus in order to simplify the calculation, although the a_N values vary with the individual terms in Eq. 3.[1,21]

Fermi Contact Shift and Dipolar Shift. The symbols C_α and C_β are used, for convenience, to refer to the carbon atoms in the sequence Fe–N–C_α–C_β. The axial and equatorial protons bonded to the nitrogen and carbon atoms are designated by the symbols H^a_N, H^e_N, H^a_α, H^e_β etc.

(a) Carbon Atoms. The C_α δ^{iso} values for the 1,3-diamine chelates are in the range 165—180 ppm. These δ^{iso}'s are all positive and are ca. 90% of those for the 1,2-diamine chelates.[8–10] Since the δ^{dip} values for C_α are 21—26 ppm, the δ^{iso} values mostly consist of δ^{con}. The estimated δ^{con} values are in the range 144—157 ppm, which have the same sign and are ca. 5% less than those for the 1,2-diamine chelates.[8–10]

The δ^{iso},δ^{dip}, and δ^{con} values for the methyl carbons ($C_{\beta M}$) are in the ranges −40—−63, 6—7, and −53—−69 ppm, respectively, and are ca. 90% of those for the 1,2-diamine chelates with the same sign.[8–10] The central methylene carbons ($C_{\beta C}$) of the 1,3-diamine chelates have δ^{iso} values of 0.8—8 ppm, which differ in both sign and magnitude from those for $C_{\beta M}$ as well as from those for C_β atoms of the 1,2-diamine chelates. This difference is attributed to the small $C_{\beta C}$ δ^{con} values of −15—−22 ppm, which are ca. one fourth of the δ^{con} values for $C_{\beta M}$ and C_β.

(b) C<u>H</u>. The δ^{iso} value for H^A of the *meso*-ptn chelate is about half those for H^a_α of the 1,2-diamine chelates.[8–10] This decrease in δ^{iso} is due to the small δ^{dip} and δ^{con} values for the former.

The δ^{iso} values for H_β, such as H^I and H^J of the *meso*- and *R*-ptn chelates, are ca. 1—3 times as large as those for H_β of the 1,2-diamine chelates. The δ^{con} values for the former comprise 70—80% of the δ^{iso} values, and are 2—3 times as large as the δ^{con} values for the latter. The equatorial H^J has larger δ^{con} values than does the axial H^I. The H^M protons of the *meso*- and *R*-ptn chelates show δ^{iso} values less than half those for the methyl protons of the 1,2-diamine chelates. This is because the former chelates have more negative δ^{con} values than the latter, whereas both chelates have almost the same δ^{dip} values. The δ^{con} values for H^M are opposite in sign to those for H^I and H^J, although these protons belong to the H_β group. Opposite signs of δ^{con} for H^M and $H^{I,J}$ have been reported for paramagnetic Ni^{II} complexes, $[Ni^{II}(H_2O)_4(1,3\text{-diamine})]^{2+}$, with *meso*-ptn, *rac*-ptn, and 1,3-bn.[4]

The negative δ^{iso} value for $H^{A,C}$ of the tn chelate is less than half those for the en chelate with the same sign. This reduction of δ^{iso} is attributed to the small δ^{dip} values for $H^{A,C}$. The δ^{con} value estimated for H^e_α of the 1,3-bn chelate is −21.36 ppm at 300 K, which is similar to the value, −30.2 ppm, estimated from the δ^{con} values for $H^{A,C}$ of the tn chelate and H^A of the *meso*-ptn chelate. These δ^{con} values are 80—90% of those for H^e_α of the 1,2-diamine chelates.[8–10]

(c) N<u>H</u>. The δ^{iso} for amino protons mostly consist of δ^{con} with large negative values. The differences in δ^{iso} between the 1,3- and 1,2-diamine chelates amount to more than 100 ppm for the lower field H^e_N peaks and ca. 20 ppm for the higher field H^a_N peaks.[10] The replacement of the 1,2-diamine chelates by the 1,3-diamine chelates only slightly affects the distances from H^a_N to the *xy* plane (See Fig. 3), such as 0.89—0.95 Å in the former chelates and 0.94—0.97 Å in the latter, whereas the distances with respect to H^e_N are reduced from 0.62—0.76 Å to 0.19—0.34 Å.[12–15,22,23] This correlation between the δ^{iso} values and distances supports the assignment of the amino protons described above.

Spin Population. The nuclei nearer to the *xy* plane showed larger δ^{con} values, as described above. This tendency is ascribed to the unpaired electron predominantly occupying the $3d_{x^2-y^2}$ orbital of the Fe^{III} ion, as has been reported previously for the 1,2-diamine chelates.[9] Since the 1,3-diamine chelates assume chair and/or skew-boat forms, their C_α and $C_{\beta M}$ nuclei are at a distance 0.5—0.6 Å further apart from the *xy* plane than those for the 1,2-diamine chelates with *gauche* forms. The 1,3-diamine chelates thus have smaller δ^{con} values and, accordingly, smaller spin populations than the latter.

The δ^{con} values for C_α and C_β of the 1,3-diamine chelates are opposite in sign, although these values were estimated by neglecting the contribution of ligand-centered dipolar shift (δ_L^{dip}). This suggests that the unpaired spin propagates through σ bonds by a spin-polarization mechanism,[24–26] just as the 1,2-diamine chelates,[8–10] and that the contribution of δ_L^{dip} is small.

The a_N values are related to the spin population in a 1s orbital of hydrogen (Q_{1s}) and that in a 2s orbital of carbon (Q_{2s}) by the relations $Q_{1s}=a_N/1420$ and $Q_{2s}=a_N/3110$, where 1420 and 3110 MHz are Fermi constants calculated for $^1H\cdot$ and $^{13}C\cdot$ radicals, respectively.[27] The estimated values of Q_{1s} and Q_{2s} are listed in Table 3.

The propagation of the positive spin on the Fe^{III} ion by spin-polarization mechanism is expected to give comparable negative spin-populations to both $C_{\beta C}$ and $C_{\beta M}$. However, the δ^{con} value for the former carbon is ca. one third of that for the latter. Since the $C_{\beta C}$ nucleus locates near the *xy* plane and in the direction of the lobe of the $d_{x^2-y^2}$ orbital,[12–14] $C_{\beta C}$ can directly interact with the positive spin in the d orbital (direct mechanism). This interaction yields a positive spin on $C_{\beta C}$, which compensates the negative spin propagated by spin-polarization mechanism, resulting in a decrease in the

negative spin population on $C_{\beta C}$.

The reversal of the sign of δ^{con} between the carbon atoms and protons at the α and β positions indicates that the spin-polarization mechanism is predominant not only in the C–C bonds but also in the C–H bonds. At both the α and β positions, H^e has larger δ^{con} values than H^a. The spin propagation is, thus, anisotropic and occurs more easily in the equatorial direction. This feature is the same as that observed in the 1,2-diamine chelates.[8–10]

Since H^I and H^J of the 1,3-diamine chelates locate in the direction of the lobe of the Fe $d_{x^2-y^2}$ orbital, a direct mechanism is possible for these protons, in addition to the spin-polarization mechanism. Both mechanisms produce a positive spin on these protons, resulting in an increase in their spin populations. The larger δ^{con} values for the H^I and H^J nuclei relative to the values for H_β of the 1,2-diamine chelates are thus attributable to the direct mechanism. The large δ^{con} values for H_N can also be accounted for by the contribution of the direct mechanism.

Solvent Effect on the ESR Parameters of Di-*t*-butyl Nitroxide and Galvinoxyl. Theoretical Application of the MNDO Effective Charge Model

Hideto TAKASE, Kenji MORIHASHI, and Osamu KIKUCHI*
Department of Chemistry, University of Tsukuba, Tsukuba 305
(Received May 30, 1991)

An effective charge model of the solvent effect was incorporated with the RHF-MNDO-CI method for free radicals, allowing the solvent effect on the hyperfine coupling constants (hfcc) and *g*-values of the di-*t*-butyl nitroxide (DTBN) and galvionxyl radicals to be examined. The calculated solvent dependences of the spin distribution and the n→π* excitation energy of DTBN have well elucidated the observed solvent effect on the hfcc and *g*-value of DTBN. The observed trend for the proton hfcc of galvinoxyl has been correctly reproduced by the present theoretical model.

The hyperfine coupling constants (hfcc) and *g*-value derived from the ESR spectra of a free radical vary with the solvent polarity; the solvent dependences of these ESR parameters have been considered theoretically.[1-4] Among the various theoretical models concerning the solvent effect, the effective charge model is one of the continuum models based on Born's solvation energy.[5] This model was first suggested by Klopman,[6] and a correct description has been given by Tapia[7] as well as by Constanciel and Contreras.[8] In our previous papers, the MNDOS method, in which the effective charge model is incorporated with the MNDO[9] method, was proposed and applied to a conformational analysis of both amine[10] and amino acids in solution,[11] as well as the solvent effect on the potential energy surface of typical S_N2 reactions.[12] In this paper we extend the MNDOS method to an open-shell RHF method for free radicals. The solvent effect was also introduced to the configulation interaction (CI) calculation, and the RHF-MNDOS-CI method was applied in order to examine the solvent effect on the hfcc and *g*-value of typical neutral free radicals, di-*t*-butyl nitroxide (DTBN) and galvinoxyl radicals.

Experimental

DTBN and galvinoxyl were purchased commercially and were used as received. The spectrograde solvents were dried on 3 or 4 Å molecular sieves which were activated before use. The dried solvents were transferred into the sample tube in the vacuum line. Fremy salt was used as the standard sample; the nitrogen hfcc and *g*-value are 13.00 G (1 G=10^{-4} T) and 2.00550, respectively.

Method of Calculation

In a previous paper[13] we reported that the RHF-MNDO-CI method gives better agreement with experiments than does the UHF-MNDO method in calculations concerning hfcc of π-radicals. In this paper the effective charge model is incorpolated with the RHF-MNDO-CI method in order to evaluate the solvent effect on the ESR parameters of π-radicals.

In the effective charge model, the solvation energy is given by a generalized Born formula, which was derived by Hoijtink et al.[14] as well as Chalvet and Jano:[15]

$$E^{\mathrm{solv}}=-\frac{1}{2}(1-\varepsilon^{-1})\sum_{\mathrm{A}}Q_{\mathrm{A}}^2/r_{\mathrm{A}}-\frac{1}{2}(1-\varepsilon^{-1})\sum_{\mathrm{A}}\sum_{\mathrm{B}}Q_{\mathrm{A}}Q_{\mathrm{B}}/R_{\mathrm{AB}}. \quad (1)$$

Here, A and B are atoms in the molecule, Q_{A} and r_{A} are the charge and the radius of the A atom, respectively, and R_{AB} is the distance between A and B. The energy of a free radical in solution (E^{S}) is the sum of the energy in its isolated state (E^0) and the solvation energy (E^{solv}):

$$E^{\mathrm{S}}=E^0+E^{\mathrm{solv}}. \quad (2)$$

E^0 is calculated using the restricted wavefunction for the doublet state:

$$\Psi_g=|\phi_1\bar{\phi}_1\cdots\phi_{m-1}\bar{\phi}_{m-1}\phi_m>. \quad (3)$$

Since the atomic population is derived under the ZDO approximation using semiempirical MO methods, the variational procedure for the solvation energy term (Eq. 1) was carried out under the ZDO approximation. The variational method gives two Fock operators (F^{c} and F^{o}) for a doubly-occupied MO and a singly-occupied MO, respectively:

$$F^{\mathrm{c}}=H_{\mathrm{core}}+\sum_l(2J_l-K_l)+\frac{1}{2}(2J_m-K_m)+G$$

and

$$F^{\mathrm{o}}=\frac{1}{2}[H_{\mathrm{core}}+\sum_k(2J_k-K_k)+G]. \quad (4)$$

The *G* term is an additional operator which reflects the solvent effect:

$$G=-(1-\varepsilon^{-1})(2\sum_l J_l+J_m-L)$$

and

$$L=\left[\sum_{\mathrm{B}}Z_{\mathrm{B}}\int d\tau_2\chi_{\mathrm{B}}^*(2)\frac{1}{r_{12}}\chi_{\mathrm{B}}(2)\right], \quad (5)$$

where Z_{B} is the core charge and χ are the atomic orbitals. The matrix elements of *G* with respect to atomic orbitals are

$$G_{rr}=<\chi_r|G|\chi_r>=(1-\varepsilon^{-1})\sum_{\mathrm{B}}Q_{\mathrm{B}}\Gamma_{\mathrm{AB}}$$

and

$$G_{rs}=\langle\chi_r|G|\chi_s\rangle=0, \tag{6}$$

where Γ_{AB} are the electron repulsion integral and are evaluated by an empirical formula.[12] The off-diagonal elements for G are zero, due to the ZDO approximation. Two Fock operators (F^c and F^o) were unified and solved according to the general SCF procedure by Hirao and Nakatsuji.[16]

In the CI calculation, only one type of singly-excited configulation function ($\Psi_{i\to k}$(II)) which mixes directly with Ψ_g, was included,[13]

$$\Psi_{i\to k}(\mathrm{II})=\frac{1}{\sqrt{6}}\{|\cdots\phi_i\bar{\phi}_k\cdots\phi_{m-1}\bar{\phi}_{m-1}\phi_m\rangle - |\cdots\phi_k\bar{\phi}_i\cdots\phi_{m-1}\bar{\phi}_{m-1}\phi_m\rangle - 2|\cdots\phi_i\phi_k\cdots\phi_{m-1}\bar{\phi}_{m-1}\bar{\phi}_m\rangle\}. \tag{7}$$

The CI matrix elements were calculated for the following operator:

$$H^S=H+\sum_i G(i), \tag{8}$$

where H is the Hamiltonian for an isolated molecule and $G(i)$ is an one-electron operator for the solvent effect. The matrix elements for $G(i)$ with respect to the MO's are related to G_{rr} in Eq. 6 by

$$\langle\phi_i|G|\phi_j\rangle=\sum_r C_{ri}C_{rj}G_{rr}, \tag{9}$$

where C_{ri} and C_{rj} are the LCAO coefficients.

The hfcc were calculated using the following equation:[17]

$$a_A=(8\pi/3)g_e\beta_e\hbar\gamma_A|\chi_S^{(A)}(0)|^2\rho_S^{(A)}, \tag{10}$$

where $\rho_S^{(A)}$ is the spin density of the s-type valence atomic orbital on atom A calculated using the CI wavefunction; the others are constants for the electron and the atom.

The g-value was obtained as an average of three principle values of a g-tensor, which were calculated using Stone's equation:[18]

$$g_{\mu\nu}=g_e\delta_{\mu\nu}+\Delta g_{\mu\nu}, \text{ where}$$

$$\Delta g_{\mu\nu}=\sum_{i=1}^{m-1}2\langle\phi_i|\sum_A L_\mu^{(A)}|\phi_m\rangle\langle\phi_m|\sum_A\xi^{(A)}L_\nu^{(A)}|\phi_i\rangle/\Delta E_{i\to m} - \sum_{k=m+1}^{n}2\langle\phi_m|\sum_A L_\mu^{(A)}|\phi_k\rangle\langle\phi_k|\sum_A\xi^{(A)}L_\nu^{(A)}|\phi_m\rangle/\Delta E_{m\to k}. \tag{11}$$

Here, ϕ_i and ϕ_k are the doubly-occupied and vacant MO obtained by the RHF-MNDOS method, respectively. In this equation, the one-electron excitation energy should be evaluated for a Hamiltonian which includes the solvent effect:

$$\Delta E_{i\to m}=\langle\Psi_{i\to m}|H^S|\Psi_{i\to m}\rangle-\langle\Psi_g|H^S|\Psi_g\rangle$$

and

$$\Delta E_{m\to k}=\langle\Psi_{m\to k}|H^S|\Psi_{m\to k}\rangle-\langle\Psi_g|H^S|\Psi_g\rangle. \tag{12}$$

In this way, an effective charge model has been introduced into both the open-shell RHF-MNDO method and the CI calculation, allowing the solvent effect on the ESR parameters to be evaluated.

Results and Discussion

DTBN. The solvent dependence of the hfcc and g-value of DTBN are listed in Table 1. Since the electronic structure of a free radical is affected by the various properties of the solvent, it may be difficult to rationalize the observed solvent dependence of the ESR parameters by any single property of the solvent. However, Table 1 shows clear trends between the ESR parameters of DTBN as well as the dielectric constant of the solvent; the hfcc of the nitrogen atom increases with an increase in the dielectric constant of the solvent (ε), while the g-value decreases with an increase in ε. These trends are characteristic of nitric oxide radicals.[4]

In the MO calculation, the t-butyl groups in DTBN were replaced by methyl groups and assumed to have C_{2v} symmetry (Fig. 1). The geometry was optimized by the RHF-MNDOS method for several ε values.

The computational results are shown in Table 2. The nitrogen hfcc (a_N) increases with an increase in ε, while the g-value decreases with an increse in ε. These trends were observed in experiments (Table 1). An analysis of the electronic structure of DTBN reveals the essential feature of the solvent dependence of the hfcc and g-value. The calculated net charges of the nitrogen and oxygen (Q_N and Q_O) are shown in Table 2. As can be seen from Table 2, Q_O becomes more negative and Q_N

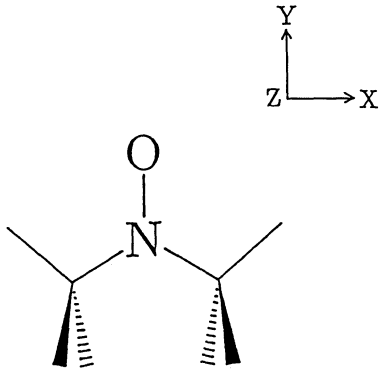

Fig. 1. DTBN model with C_{2v} planar symmetry.

slightly less negative when ε increases. Thus, DTBN is expected to be polarized in a polar solvent. The π spin density on the nitrogen atom increases with an increase in ε (Table 2). This elucidates well the observed solvent dependence of a_N, since it is propotional to the spin density of the 2s-atomic orbital of the nitrogen atom, which is generated by the spin-polarization mechanism.

Little attention has been paid to the solvent dependence of the g-value of a free radical. The present theoretical results reproduce well the solvent effect on the g-value of DTBN. In Table 3, three g-shifts are shown for ε=1 and for ε=40. From this table it is found that the Δg_{yy} is dominant and that $\delta g_{yy}(12,13)$ makes the largest contribution to Δg_{yy}. The 13th MO is the singly-occupied MO (SOMO); the 12th MO corresponds the oxygen lone-pair orbital. Hence, Δg_{yy} can be approximated by

$$\Delta g_{yy} \simeq \rho_\pi^{(O)} / \Delta E_{n\to\pi^*}. \quad (13)$$

When ε increases, $\rho_\pi^{(O)}$ decreases (Table 2), while $\Delta E_{n\to\pi^*}$ increases (Table 3). The tendency calculated for $\Delta E_{n\to\pi^*}$ has been observed in the visible spectra of DTBN in solution by Kawamura et al.[4] in which the $n\to\pi^*$ excitation energy increases with an increase in the solvent polarity. As a result, the observed solvent dependence of the g-value of DTBN is well elucidated by the present calculations.

Galvinoxyl. The solvent dependence of the g-value of galvinoxyl was found to be very small; MNDOS-CI calculations have shown that the g-value of galvinoxyl is almost constant. On the other hand, the hfcc of the methine proton and the ring protons of galvinoxyl decrease as ε increases. Thus, the solvent dependence of hfcc of galvinoxyl was examined in some detail.

In the MO calculations, the t-butyl groups in galvinoxyl were replaced by hydrogen atoms. Four representative structures of galvinoxyl are shown in Fig. 2. The X-ray analysis has shown that the galvinoxyl has a C_2 twisted structure.[19] The UHF-MNDO calculation also supported the C_2 twisted structure as the lowest-energy structure (Table 5). Thus, the C_2 twisted structure was optimized by the RHF-MNDOS method for several ε values, and the hfcc were obtained by RHF-MNDOS-CI calculations. The computational results are shown in Table 6. The hfcc of the methine proton

and two ring protons decrease with an increase in ε. These are the trends observed in experiment. The π spin density of the methine carbon atom decreases with an increase in ε. This is the reason why the hfcc of the methine proton decreases when ε increases.

In this paper, the effective charge model of the solvent effect was introduced into the open-shell RHF formalism and the CI calculations. The RHF-MNDOS-CI method, thus obtained, was used to evaluate the solvent effect on the ESR parameters of DTBN and galvinoxyl. The computational results well elucidated the observed solvent dependences of the hfcc and g-value of these radicals.

Kinetic Study of Casein Micelle Formation Observed by a Stopped-Flow Apparatus

Sadakatsu NISHIKAWA,* Misa TATSUSUE, Tadaomi INOUE,† and Tatsuya YASUNAGA†
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
†Faculty of Engineering, Kinki University, Hiroshingai 5, Kure, Hiroshima 737-01
(Received June 10, 1991)

The time dependent optical density changes were observed when aqueous solutions (Tris buffer) of sodium casein from milk were mixed with those of calcium chloride by a newly constructed stopped-flow apparatus which was controlled by an 8-bit microcomputer. Two approaches for single exponential decay curve analysis were used, i.e. the Guggenheim analysis and an analysis according to a linear relation between the time and the logarithm of the corresponding absorbance change, at a concentration range between 0.02—0.05 wt% of the casein and in that between 10—30 mmol dm^{-3} of calcium chloride at 25 °C. The same time constants and reaction amplitudes were obtained from both analyses of the decay curves. The obtained rate parameters were found to be concentration dependent. The result was interpreted by a stepwise reaction mechanism for the formation of a casein aggregate. The rate-determining step was speculated to be the first step of the larger molecular aggregate of the casein according to the concentration dependence of the apparent rate constant and the reaction amplitude. The rate constant for the casein micellization could be approximately estimated as being of the order of 10^4 mol^{-1} dm^3 s^{-1} at 25 °C. The effects of NaCl, $MgCl_2$, and $CaBr_2$ on casein micelle formation were also examined; it was kinetically confirmed that only calcium cations played an important role in the formation of the casein micelle.

Caseins are proteins comprising several polypeptides; the characteristic properties in aqueous media have been widely studied by various methods.[1-5] It is well known that the casein molecules form the micelle, the aggregation number of which is quite large when it is compared with those of surfactants in aqueous media. The micelle formation mechanism in aqueous solutions of surfactants seems to have been established kinetically by various chemical relaxation methods.[6-8] However, few investigations concerning the dynamic characters for the casein micelles have not been carried out,[9-14] although they are very important regarding the mechanism of protein conformational change. Most of the kinetic studies have been limited to those in the time range of more than few tens of seconds, their time courses seeming to be very complex. One of the attractive procedures used to analyze the aggregation reaction of casein involves an enzymatic model using a von Smoluchowski-type reaction.[12,14,15] However, the reaction mechanisms are still unconfirmed. We have speculated that the primary step in the formation of the casein micelles exists in a shorter time range, and might be observed in dilute solutions. For observing such process, a stopped-flow method involving the observation of the optical density change might be powerful owing to a large change in the optical density which is expected when casein micelles are formed. When stopped-flow equipment is used to follow reaction the process, it is necessary that the observed time courses (the time dependence of the optical density change) are precisely analyzed in order to clarify the reaction mechanism.[16]

Under these circumstances, the present study was undertaken in the hope that an elucidation of a simple time dependence for micelle formation could provide a fundamental understanding of any structural changes in the protein. This information is also important in relation to the dynamic stabilities and solution properties of various proteins, since the protein aggregation is well known to play an important role in both denaturation and renaturation.[17]

Experimental

Apparatus: We used a newly constructed stopped-flow equipment comprising a DC lamp (100 W), a mixer, a monochrometer (Shimadzu monochrometer Grating 1200), a photomultiplier, an offset electronic circuit, an operational DC amplifier, a wave memory (NF MODEL WM-841), a digital voltmeter (Advantest TR6845) and an 8-bit microcomputer (NEC 8800). The mixer was driven by pistons with compressed air; the dead time for the mixing was about 5 ms. The temperature of the mixer and the solution reservoirs was controlled by circulating the water maintained at a constant temperature. For each run, 0.252 cm^3 solutions were mixed; after more than five run drives the data were accumulated and averaged. The absorption spectra were recorded from 370 to 600 nm by Hitachi 323 Recording Spectrophotometer and JEOL Ubest-30 spectrometer.

Chemicals: Highly purified sodium casein was supplied from Technical Research Institute, Snow Brand Milk Products, Co., Ltd. and was used without further purification. The metal contents in the sodium casein samples were analyzed and found to be Na=1200 mg/100 g, Ca=4.3 mg/100 g, P =700 mg/100 g; all other metals were less than 1 mg/100 g. The purest grade calcium chloride, magnesium chloride, calcium bromide and tris(hydroxymethyl)aminomethane [Tris] were purchased from Wako Pure Chemicals. They were used without further purification. The solutions were prepared using a Tris–HCl buffer solvent from doubly distilled water which was degassed by ultrasound under reduced pressure. The desired pH values for the solutions were obtained by changing the ratio of the Tris and HCl concentrations. Most of the experiments were carried out at pH 7.20, unless stated otherwise.

All of the experiments were carried out at least within one day after preparing the casein solutions at 25 °C.

Results

The visible absorption spectra were recorded over the concentration range 0.01 to 0.05 wt% casein. A slight absorbance was observed in solutions of casein. This might mean that the solute molecules do not dissolve in their monomer forms in an aqueous media. When calcium chloride was added, the absorbance was found to increase remarkably at all wavelengths measured. The absorbance decreased monotonously with an increase of the wavelength. No characteristic absorption peak was observed over the range of the measured wavelength. Such a broad change of the absorbance may be due to solution turbidity caused by casein aggregates. Figure 1 shows the concentration dependence of the absorbance at 440 nm. The absorbance increased linearly with concentration, and it increased more steeply when $CaCl_2$ was added. It is important that the absorbance in solutions with $CaCl_2$ is much larger than those without $CaCl_2$.

Most of the stopped-flow experiments were carried out at 440 nm, since the sensitivity of our apparatus was relatively high at this wavelength. When casein solutions were mixed with a solvent buffer, or with the similar solution of casein, no optical density change was observed over a time range of more than 20.48 ms in full scale in the wave memory. Upon mixing with $CaCl_2$ solution, clear changes were observed over the appropriate time range for the apparatus.

The relation between the voltage of the signals from the photomultiplier and the product concentration, [P], is given by $\log\{(V_{100}-V_0)/(V_t-V_0)\}=\varepsilon l\,[P]$, where V_{100} is the signal voltage at the open current, V_0 that at the dark current, V_t the voltage at time t, l the effective observation cell length and ε a constant. We define $\varepsilon l\,[P_\infty]$ as the reaction amplitude where $[P_\infty]$ is the product concentration at infinite time of the reaction. The time dependence of the product is given as follows if it satisfies the first-order rate equation:

$$[P]=[P_\infty]\{1-\exp(-k_{app}t)\}, \quad (1)$$

where k_{app} is the apparent first-order rate constant. Using the relations between the observing voltage change in the signals and the concentration of the product at time t, Eq. 1 is expressed as

$$\log\{(V_t-V_0)/(V_\infty-V_0)\} = \log\{(V_{100}-V_0)/(V_\infty-V_0)\}\exp(-k_{app}t). \quad (2)$$

The voltage at infinite time, V_∞, is determined from the 2% increased values by averaging the last 10 digital signals in the wave memory and digital voltmeter. Plots of the logarithm of the left-hand side of Eq. 2 vs. time, (t), provide an apparent rate constant from the slope and the reaction amplitude from the intercept using a linear least mean-square method. The Guggenheim method can also be used to analyze the time dependence of the output signals, from which the apparent rate constant and reaction amplitude can also be obtained.[18] The appropriateness for these treatments was confirmed by numerical simulations for model calculations. The observed signals were analyzed by the two above-mentioned analytical procedures for the casein solutions in the concentration range from 0.02 to 0.05 wt% with various concentrations of $CaCl_2$. It was found that the time dependence of the optical density change is well fitted to Eq. 2. Figure 2 is one of the traces of the reactions when the casein solutions are mixed with that of $CaCl_2$. The rate constant and the reaction amplitude calculated from the above two procedures were the same. Also, the same apparent first-order rate constant, k_{app}, and the same reaction amplitude were obtained in an appropriate concentration range, even if a different sampling time in the wave memory was used. At concentrations less than 0.02 wt%, the optical density change was too small. On the other hand, upon increasing the casein concentration more than by 0.05 wt%, the reaction traces were not fitted to Eq. 2. This might indicate that more complex reactions proceeded at high concentration.

Figure 3 shows the casein concentration dependence of the apparent first-order rate constant at 10, 15, and 30 mmol dm^{-3} of $CaCl_2$. It can be seen that k_{app} at 10 and 15 mmol dm^{-3} $CaCl_2$ is apparently proportional to the casein concentration. However, at 30 mmol dm^{-3} it seems to be curved, and the rate constants obtained by the two procedures become different at high concentra-

tions of casein. Figure 4 represents the concentration dependence of the reaction amplitude. In order to observe the effect of an anion on the reaction, aqueous solutions of calcium bromide were mixed with casein solution. The results are shown in Figs. 5 and 6 together with those for solutions with $CaCl_2$. As can be seen in these figures, the dependences of the apparent first-order rate constant and the reaction amplitude on the casein concentration are very similar to those of $CaCl_2$. This means that only calcium cations play an

important role in changing the optical density.

The $CaCl_2$ concentration dependences of the apparent rate parameters are illustrated in Figs. 7 and 8. It can be seen that the apparent rate constant is also dependent on the $CaCl_2$ concentration and that the profiles depend considerably upon the casein concentration. In order to see the effects of other salts on this phenomenon, 50 mmol dm^{-3} sodium chloride and 30 mmol dm^{-3} magnesium chloride solutions were also mixed with the casein solutions. However, no optical density changes were observed. These results also indicate that the calcium cations bind specifically to the casein molecules and some conformational or structural changes of casein cause the optical density change for the casein solutions. The apparent rate constant and the reaction amplitude obtained at pH 7.2, 8.2, and 9.1 were almost independent of the solution pH.

Discussion

In kinetic experiments carried out using a stopped-flow apparatus, the method of distinguishing whether the reaction is first order or other is very important in order to consider precisely the reaction mechanisms in solutions. Only one analytical procedure of the reaction trace as a function of time might provide equivocal information. As shown above, in the present study the fact that the two analytical procedures of the time traces give the same rate constant and the same reaction amplitude shows that the observed time-dependent optical density change is due to a first-order rate process in the casein solutions, although the concentration range was restricted.

The effects of the calcium cation on the casein solution have been widely studied by various methods. It is said that the addition of the calcium ions to a casein solution promotes the formation of the casein micelle.[14,19] Not many kinetic studies, on the other hand, have been carried out regarding casein micelle formation. This may be because many complex reactions proceed quite rapidly in the concentrated solutions, even if the experiment is performed in solution with only a single polypeptide. Therefore, the time course of the reaction seems to be very complex.[9-12] It should be noteworthy that a single exponential decay phenomenon was observed in the low concentrations presently studied. It is certain that this phenomenon is associated with the casein aggregates, since the solution turbidity increases upon the addition of calcium cations. It is desired to clarify why such a simple time course is observed as in Fig. 2, and why the apparent rate constant and the reaction amplitude increase with the casein concentration, as can be seen in Figs. 3 and 4.

It has been considered that small aggregates or subunits comprising mainly α_s-, β- and κ-casein held together by hydrophobic interaction, exist in dilute solutions of casein.[4,12] Also, a sufficiently high local protein concentration is also speculated when aggregates of protein are formed.[17] As can be seen in Fig. 1, a small absorbance is observed in the solution of casein without adding $CaCl_2$. This result implies the existence of small aggregates. The absorbance increases dramatically when calcium cations are added. On the basis of the present dynamic and static experimental situations and the previous examinations conducted so far, the aggregation reaction of casein may generally proceed in stepwise processes as follows:

$$A_s + A \overset{k_1}{\rightarrow} A_{s+1} \overset{k_2}{\underset{A}{\rightarrow}} A_{s+2} \overset{k_3}{\underset{A}{\rightarrow}} \cdots\cdots \overset{k_n}{\underset{A}{\rightarrow}} A_n. \quad (3)$$

Here k_i is the rate constant for each process and A_s indicates the small aggregate which might act as a nucleus for larger aggregate formation. When the calcium cations bind specifically to free casein or small aggregate, the repulsive forces between them may be weakened, and then larger aggregates may be formed. The reaction associated with ion binding is so fast that it is far beyond the time stale of the stopped-flow method,[20] since the ion binding sites are expected to be either phosphate or carboxylic groups.[21,22] Also, it may be natural to consider that the aggregates actually consist of various molecules with different aggregation numbers, that is, they exist under a proper distribution.[4] However, we simply analyze the observed phenomenon by a conventional reaction kinetics, which may give us a legible feature of the reaction. It is very hard to decide definitely the rate determining step for such an aggregation reaction. We assume here that the rates of steps beyond the the second are so rapid that the stationary states are established. This assumption is widely used to interpret the aggregation process for relatively small molecules,[23] and may also be reasonably accepted, since such an aggregation process proceeds cooperatively once the reaction starts. Then, the reaction could be simplified as follows:

$$A_s + A \overset{k_f}{\underset{nA}{\rightarrow}} A_{s+1} \rightarrow A_{s+n+1}, \quad (4)$$

where s is the mean aggregation number for small aggregate which may grow to larger aggregate, A_{s+n+1}. For the second step in Eq. 4, we define the equilibrium constant, K, as $K=[A_{s+n+1}]/[A_{s+1}][A]^n$, which arises from the stationary state assumption. The rate equation for formation of A_{s+1} is expressed by

$$d[A_{s+1}]/dt = k_f (A_{s0} - [A_{s+1}])(A_0 - [A_{s+1}]), \quad (5)$$

where A_{s0} and A_0 bare the initial concentrations of the reactants, A_s and A, respectively. The solution of the above equation gives the time course of the reactants as

$$[A] = A_0(A_0 - A_{s0})/\{A_0 - A_{s0}\exp -(A_0 - A_{s0})k_f t\}$$

and

$$[A_{s+1}] = [A_0 A_{s0}\{\exp(A_0 - A_{s0})k_f t - 1\}]/ [A_0 \exp(A_0 - A_{s0})k_f t - A_{s0}]. \quad (6)$$

It is expected that the concentration of small aggregate, A_{s0}, is smaller than that of a free or monomer casein, A_0,

because the analytical concentration is not so high. Therfore, the condition $(A_0/A_{s0})\exp(A_0-A_{s0})k_f t \gg 1$ may be well satisfied. Using the stationary state assumption for the second step in Eq. 4, we obtain the time dependence of larger aggregate, as follows:

$$[A_{s+n+1}] = K(A_0-A_{s0})^n A_{s0}\{1-\exp -(A_0-A_{s0})k_f t\} = [\overline{A_{s+n+1}}]\{1-\exp -(A_0-A_{s0})k_f t\}, \quad (7)$$

where $[\overline{A_{s+n+1}}]$ is the concentration of the larger aggregate at an infinite time of the reaction. This equation indicates that the appearance of larger aggregates may be approximated by a single exponential factor and that the rate of the appearance of larger aggregates depends on the initial concentrations of the monomer and small aggregate casein molecules. It might be possible that the aggregate formation reaction by self-association of the small aggregates, such as $nA_s \rightarrow (A_s)_n$, causes the observed optical density change. However, the concentration dependences of the apparent first-order reaction and the reaction amplitude could not be well explained by such a reaction mechanism. The aggregation reaction associated with only free or monomer casein molecules was also considered to be the cause of the phenomenon, though the observed phenomena was not well interpreted.

The solution turbidity, τ, is related to the molecular weight of the aggregate, M_w, and the concentration, as[14]

$$\tau = QM_w[A_{s+n+1}], \quad (8)$$

where Q is a constant. Using Eqs.7 and 8, and comparing Eq. 2, the apparent rate constant, k_{app} observed by the stopped-flow method is found to be $(A_0-A_{s0})k_f$ and the reachtion amplitude, $\log\{(V_{100}-V_0)/(V_\infty-V_0)\}$, corresponds to $QM_w[A_{s+n+1}]$.

First, following the above relations, we consider the concentration dependence of the apparent rate constant, k_{app}. As can be seen in Fig. 3, plots of k_{app} vs. C_0 seems to indicate a linear increase with almost a zero intercept at 10 and 15 mmol dm^{-3} $CaCl_2$. These may mean that the concentration of small aggregates is much smaller than that of free casein molecules in a relatively dilute solution because $C_0=[A_0]+s[A_{s0}]$. From the slopes of these plots, we obtained rate constants of k_f=2.8 (wt% $s)^{-1}$ for a solution with 10 mmol dm^{-3} and k_f=7.6 (wt% $s)^{-1}$ for that with 15 mmol dm^{-3}. With increasing $CaCl_2$ concentration, the plots gave a slightly curved line and a positive intercept. Therefore, we reluctantly show the experimental results at 30 mmol dm^{-3} $CaCl_2$ without having determined the rate constant. Such an unexpected dependence might mean that an approximated analytical equation (Eq. 7) is not satisfied at higher concentrations of $CaCl_2$. Also, according to previous studies,[11,14] it is said that a von Smolucowski-type reaction proceeds for the formation of larger micelles; this process can be expressed as

$$[M_w] = [M_w(0)](1+k'C_0 t), \quad (9)$$

where $[M_w(0)]$ is the molecular weight at t=0, and k' the rate constant for the coagulation process. Then, the observed time dependence of the optical density change may deviate from single exponential decay at a relatively high concentration of $CaCl_2$. Actually, at concentrations of more than 0.05 wt% casein, the time courses of the stopped-flow could not also be fitted to the single exponential decay function. These results may indicate that more complex reactions start at around these conditions.

Small aggregates or submicelles are expected to be spongy protein particles with molecular weight, 250000.[12] It is said that they consist of 10 or 12 casein molecules. These estimations are quite reasonable if we take into account the constituting molecular structures of casein, namely α-, β- and κ-casein. The mean free casein concentration is roughly estimated from the analytical concentration. If we take the mean molecular weight of monomer casein to be 25000, the obtained rate constants, k_f, are converted to be 7×10^4 mol^{-1} dm^3 s^{-1} at 10 mmol dm^{-3} $CaCl_2$ and 1.9×10^5 mol^{-1} dm^3 s^{-1} at 15 mmol dm^{-3} $CaCl_2$. These rate constants are those for the first step for the aggregation in Eq. 3. The fact that the larger rate constant is obtained at higher concentrations of $CaCl_2$ may be considered as follows. The greater binding of Ca^{2+} ions to the casein molecule makes the repulsive interaction between the proteins decrease, thus facilitating the aggregation. This speculation is also supported by the $CaCl_2$ dependence of the rate parameters, which is considered later. The processes after the second one are considered to be very rapid since the stationary state approximation is well satisfied.

Next, the concentration dependence of the reaction amplitude is considered. As can be seen in Fig. 4, it increases monotonously with the concentration; such a dependence reflects an increase of the larger micelle concentration, $[A_{s+n+1}]$. Unfortunately, however, the quantitative analytical correlation between the absorbance measured by the static method (Fig. 1) and the amplitude of the reaction (Fig. 4) is not given at this stage because the observation cell of the stopped-flow apparatus consists of cylindrical quartz with a 2 mm diameter light pass length. The monotonous increase of the reaction amplitude is easily speculated from Eqs. 7 and 8. Qualitatively, both of the dependences observed by the static and dynamic methods are very similar eah other. This confirms that the observed time dependent phenomenon is associated with the formation of larger casein mielles induced by binding of the calcium cations.

The $CaCl_2$ concentration dependences on the apparent rate constant and the reaction amplitude seem to reflect the specificity of calcium ion binding to the casein. As can be seen in Figs. 7 and 8, they increase for lower concentrations of $CaCl_2$, but tend to reach their plateaus when the casein concentration is low. Such profiles of the rate parameters may indicate that the number of the binding sites in the casein molecule is

limited. With increasing the calcium concentration, the rate increases, which is seen in solutions with 0.03 wt% casein and in the dilute solution of $CaCl_2$ with 0.02 wt% casein. When most of the binding sites are occupied by calcium ions, the aggregation process may tend to reach a constant value.

In conclusion, it was found in the present study that there is a very rapid and simple process regarding the casein micelle formation in aqueous media during the early stage of the reaction process. The time dependence is described by a single exponential time constant, and can be well interpreted in terms of the aggregation reaction mechanism. In a concentrated solution of casein, further, more complex reactions are speculated to take place.

Further dynamical studies concerning the solutions of individual proteins in casein are desired for elucidating more details concerning molecular aggregation mechanism.

The authors gratefully acknowledge Technical Research Institute, Snow Brand Milk Products, Co., Ltd. for supplying the samples of purified sodium casein used in this work.

(Received July 15, 1991)

Analyses of the local structure around La and Ni atoms in amorphous $LaNi_{5.0}$ films have been performed using the extended X-ray absorption fine structure (EXAFS), and the effect of the structure on the difference of hydrogen absorption characteristics between the amorphous and crystalline $LaNi_{5.0}$ has been elucidated. The lengthening of interatomic distances for the Ni–Ni and La–Ni pairs, respectively, was observed for the amorphous samples in comparison with the crystalline ones. A part of the hydrogen sites existed in the crystalline $LaNi_5$ was distorted in the amorphous one. Since the hydrogen atoms appear to be difficult to enter these sites distorted, the hydrogen content in the amorphous $LaNi_5$ is smaller than that in the crystalline one.

Amorphous $LaNi_5$ films have attracted considerable technological and scientific interest, such as hydrogen purification, catalysis, and batteries[1–3] Their physical and chemical properties have been found to be much different from those of the crystalline sample.[4–7] The amorphous $LaNi_5$ film has been known not to pulverize after repeated hydrogenation–dehydrogenation cycling, and absorbs hydrogen less than a half of the amount taken up by the crystalline bulk.[5,7] These differences of properties appear to be closely related to the structure of the films, so that it is necessary to obtain the detailed structural information at an atomic level.

In the present study, the local structure around La and Ni atoms in the amorphous $LaNi_{5.0}$ films is clarified by means of EXAFS, and the results are compared with those in the crystalline sample. The relationship between the structure and the hydrogen absorption characteristics is discussed.

Experimental

The $LaNi_{5.0}$ amorphous films (ca. 1 μm thick which was determined by direct observation of the cross section of the sample using a scanning electron microscope.) were deposited on a polyimide membrane (Kapton, 40 μm thick, Toray-du Pont Co., Ltd.) at room temperature by using sputtering method.[4,6,7] For the sputtering, parameters of 0.395-Pa Argon pressure (99.999%) and a radio-frequency generating power of 400 W were employed for all sputtered samples. The sputtering target consisted of a disk in which 98% of the surface area is $LaNi_{4.8}$ (33.0 wt% La, 66.8 wt% Ni) and 2% is $LaNi_{3.0}$. The La–Ni alloys were supplied by Santoku Metal Industry, Kobe, Japan. X-Ray diffraction measurements were made to verify the amorphous state. Their homogeneity and stoichiometry were checked by means of X-ray fluorescent spectroscopy and X-ray photoelectron spectroscopy. The films precisely having a composition of $LaNi_{5.0}$ were used for the EXAFS measurements. The $LaNi_{5.0}$ crystalline powder and commercially available Ni foil (5 μm thick, 99.98% pure, The Japan Lamp Industries) were used as reference materials. The crystalline $LaNi_{5.0}$ alloy film with a crystallinity of 80% was prepared on a stainless-steel substrate at 530 K by sputtering. The film was peeled from the substrate with an adhesive tape, and the resulting film was applied to the EXAFS measurements. The crystallinity of the film was determined from the heat of crystallization which was estimated by the differential scanning calorimetry (DSC).[7]

The measurement of X-ray absorption spectra (XAS) were performed by means of synchrotron radiation employing the EXAFS facilities of BL-7C of the Photon Factory in the National Laboratory for High-Energy Physics, Tsukuba, Japan. An Si(111) double crystal monochromator was used to monochromatize the X-rays from a 2.5-GeV positron storage ring. The ring current was between 350.5 and 246.9 mA. EXAFS spectra were collected at the Ni K- and La L_{III}-edges. The focusing mirror was used to reduce higher harmonics at the La edge. Energy resolution of 1.4 eV can be achieved at the Ni K-edge (8331.7 eV) when a source-size is not considered. The total thickness of the $LaNi_{5.0}$ films used for the X-ray absorption measurements were about 35 and 20 μm for the La and Ni edges respectively. All the XAS data were obtained at 220 K. Analyses of the EXAFS data were performed with a "KABO" program in the FACOM M382 computer system at the Data Processing Center, Kyoto University, Japan.

The photon energy was calibrated by the characteristic inflection point at the edge of the absorption spectrum of the standard Ni foil (5 μm thick, 8331.7 eV). The EXAFS oscillatory part $\chi(E)$ above the absorption edge was extracted from the XAS data using a simple equation of $A/E^{2.75}$ instead of Victoreen formula and normalized as described elsewhere.[8–10] The photoelectron wave vector k is related to the photon energy E expressed by $k=2\pi[2m(E-E_0)]^{1/2}/h$, where m is mass of an electron, h, Planck's constant, E_0, the threshold energy of the absorption edge. E_0 was determined as $E_{inf}+\Delta E$, where E_{inf} was the inflection point where the differential coefficient of the spectrum near the absorption edge is maximum and ΔE was allowed to be various fixed values. Reconstruction of the crystalline $LaNi_{5.0}$ spectra can only be achieved using +4.5 eV as ΔE at Ni K-edge and +4.0 eV at La L-edge. Subsequently, $E_0(=E_{inf}+\Delta E)$ was determined with these ΔE values for the amorphous and 80% crystallinity films. Fourier transforms are taken over the range of 3.3—14.0 $Å^{-1}$ and 4.0—9.2 $Å^{-1}$ for the Ni and La edges respectively to obtain the

radial structure function (RSF). In order to obtain the bond distance and the coordination number, the main peaks (Ni; 1.6—2.7 Å, La; 2.4—3.4 Å) were Fourier filtered into the k space, where the inverse Fourier transform was analyzed by the single scattering formula of Stern et al.[11—13] The resulting filtered EXAFS was fitted to the formula of Stern et al., with three variables, namely, B ($=N\times S$; N, true coordination number, S, damping factor which was evaluated from the coordination number of the Ni foil.[14]), apparent coordination number, L, interatomic distance, and σ^2, Debye-Waller factor by means of the nonlinear least square curve-fitting method.[15] Theoretical phase shifts and backscattering amplitudes of Teo and Lee are used in the curve fitting analyses.[16,17] As obtained in general EXAFS measurement,[19,20] the errors in the parameters of B and L were determined as the ranges within which the R value changes by a factor of 2 from the minimum value, with the other parameters held fixed, where R is a reliability factor.

Results and Discussion

Figure 1 illustrates XANES spectra on the Ni K-edge

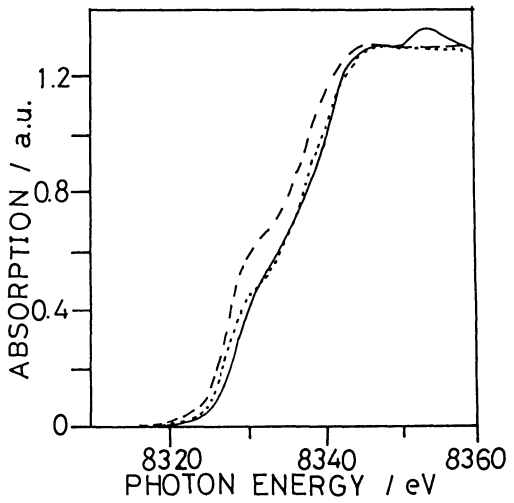

Fig. 1. Ni K-edge XANES spectra for $LaNi_{5.0}$.

.....: $LaNi_{5.0}$ amorphous sputtered film.

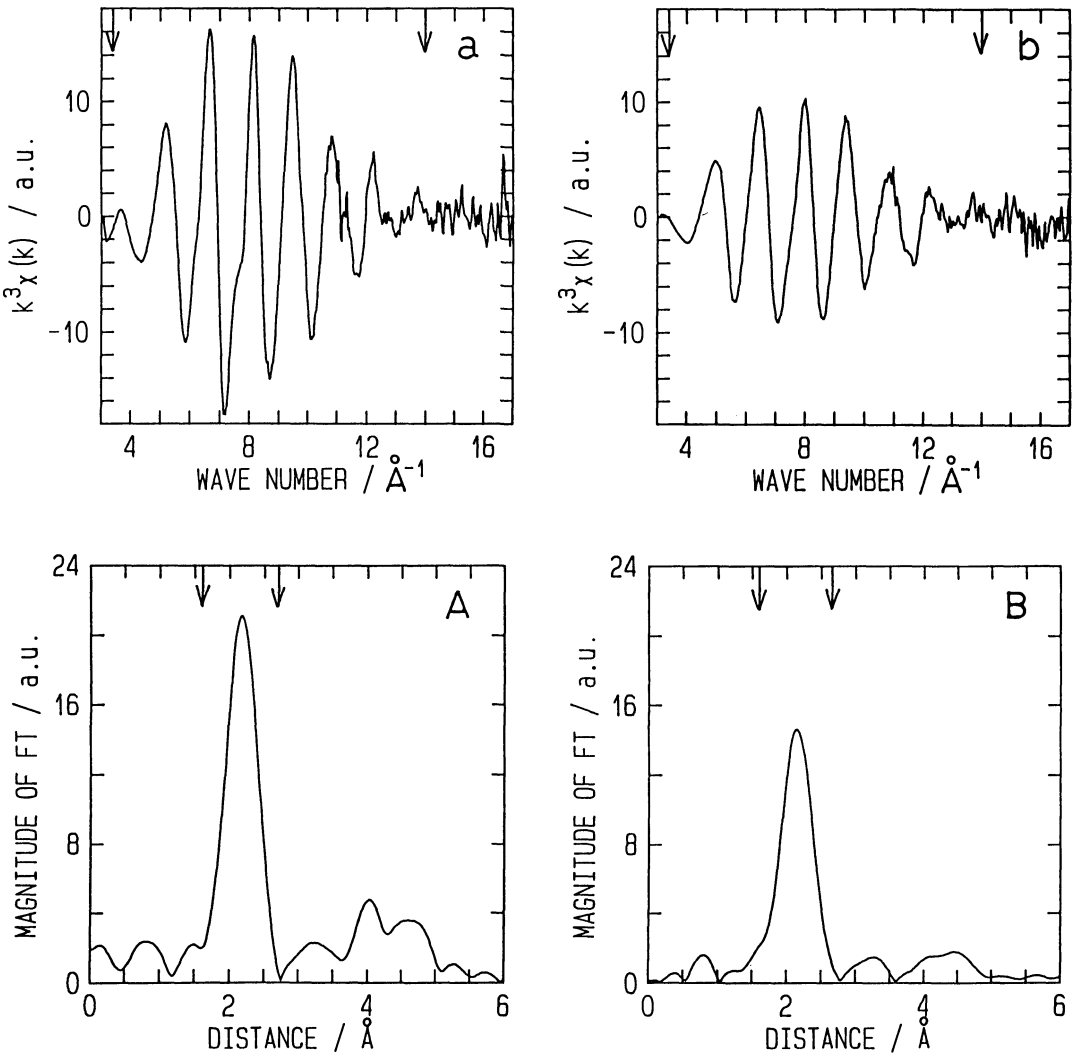

Fig. 2. Ni K-edge k^3-weighted EXAFS spectra (a—b) and magnitudes of their Fourier transforms (A—B), in the 80% crystallinity(a,A) and the amorphous sputtered(b,B) $LaNi_{5.0}$ films. (Arrows (↓) illustrated in the figures indicate the range for Fourier transforms or back Fourier transforms.)

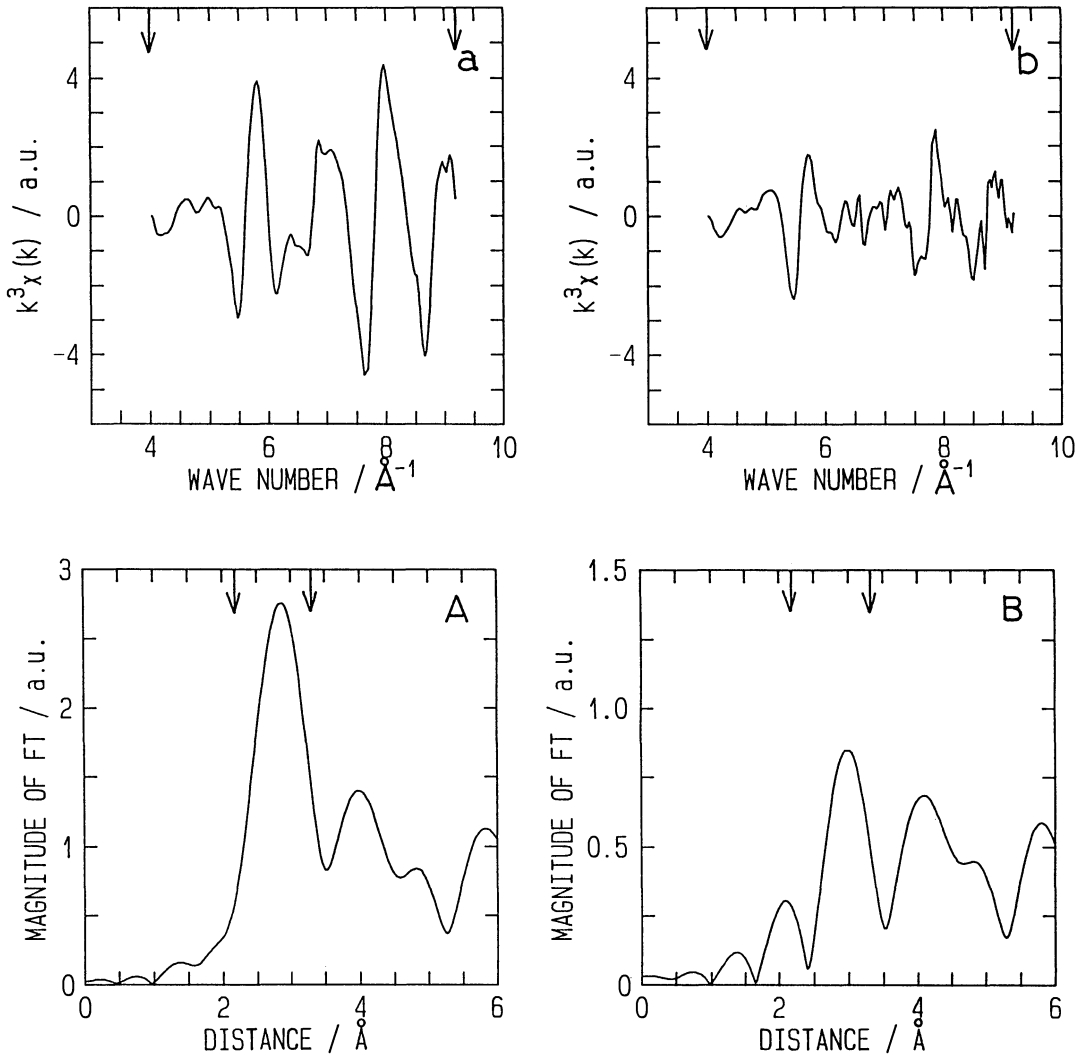

Fig. 3. La L_{III}-edge k^3-weighted EXAFS spectra (a—b) and magnitudes of their Fourier transforms (A—B), in the 80% crystallinity(a,A) and the amorphous sputtered(b,B) $LaNi_{5.0}$ films.

for the Ni foil, the $LaNi_{5.0}$ crystalline bulk and the $LaNi_{5.0}$ amorphous sputtered film. The absorption edge for the $LaNi_5$ crystalline bulk shifted about 1.5 eV to the lower energy side compared with that for the Ni foil due to the narrowing of the Ni 3d-band caused by the charge transfer from the 5d-band of La, which has smaller electronegativity than Ni, to the Ni 3d-band. As for the $LaNi_{5.0}$ amorphous film, the energy position of absorption edge was higher than that for the crystalline bulk. However, no difference of the energy position of absorption edge was observed between the amorphous $LaNi_{5.0}$ film and the Ni foil. This is because the degree of energy transfer from La to Ni for the amorphous film is lower than that for the crystalline bulk.

Figures 2 and 3 show the k^3-weighted EXAFS spectra at the Ni K- and La L_{III}-edges in the sputtered amorphous $LaNi_{5.0}$ films and the 80% crystallinity film. The amplitude of the EXAFS oscillations for the amorphous film was smaller than that for the crystalline film with a crystallinity of 80%. The damping of EXAFS oscillation for the amorphous film seems not to be caused by the decrease in the coordination number, but by the larger static disorder which increases the Debye-Waller factor.

The magnitudes of the Fourier transforms obtained by a Fourier analysis of the EXAFS data in these films are also shown in Figs. 2 and 3. A large peak appeared in these samples on the Ni edge at about 2 Å corresponding to mainly the Ni–Ni and partially Ni–La distance, while on the La edge at about 3 Å corresponding to the La–Ni distance. The profiles of transforms in the sputtered amorphous films show resemblance to that in the 80% crystallinity film, so that it was suggested that the local structures around central Ni and La atoms for the amorphous $LaNi_5$ were similar to those for the crystalline one. The weak intensity of the main peak for the amorphous films was observed on both two edges due to the larger static disorder.

The results of the curve fitting analysis on the Ni edge are presented in Table 1. As for the shortest Ni–

Ni(Ni_I–Ni_{II}) pairs with an interatomic distance of 2.461 Å, the coordination number around Ni_I atoms (CN: 6) is different from that around Ni_{II} atoms (CN: 4), since there are two kinds of Ni atoms (Ni_I and Ni_{II}) having the different symmetry in $LaNi_5$. Therefore, the coordination number for the pairs was estimated with considering the proportion of the number of each Ni atoms in a unit cell. The calculation was performed with the following equation, $(6\times2+4\times3)/5=4.8$.

A fit of the oscillations above the Ni edge was attempted for the crystalline $LaNi_5$ bulk with one shell of Ni atoms. The resulting interatomic distance of the Ni–Ni pair, 2.475 Å, was intermediate between the shortest distance, 2.461 Å, and the second shortest distance, 2.507 Å, which are obtained from XRD analyses,[18] so that it was suggested that the large peak appeared at about 2 Å in the RSF consisted of more than two subshells. When the curve fitting was performed with two subshells of Ni atoms at two different distances from the central atom, the distances of the two Ni–Ni pairs were 2.461 and 2.501 Å respectively. Although these distances were fairly fitted with those estimated from the XRD analyses, the reliability (R) and Debye–Waller (σ^2) factors were still large. Therefore, the interatomic distances were determined by adding one subshell of La atoms at a larger distance (2.89 Å) to the two subshells of Ni atoms. The combination of these three subshells could simulate the spectrum, since both R and σ^2 factors were smaller than the result obtained from the curve fitting with two Ni subshells. For the crystalline bulk, the coordination number obtained with EXAFS is not listed in the table because the XAS was not satisfactory.

The structural parameters of the amorphous film were similar to those of the crystalline bulk though there is the slight difference in the interatomic distance. This indicates that the sites accommodated with hydrogen atoms in the amorphous film were analogous to those in the crystalline bulk. The distances of second Ni–Ni pairs were found to increase about 0.06 Å for the amorphous films in comparison with those for the crystalline bulk. The parameters of interatomic distances for the amorphous sputtered film were slightly different from those for the crystalline film which has a crystallinity of 80%.

The structural parameters for the La edge are summarized in Table 2. The coordination number listed in the table is a tentative value because no adequate result for the $LaNi_{5.0}$ powder as a reference material was obtained from the EXAFS analysis due to inhomogeneities of the particle size in the sample layer.

Lanthanum atoms in the crystalline bulk are known to be coordinated by two kinds of nickel atoms (La–Ni_I; ca. 2.9 Å, La–Ni_{II}; ca. 3.2 Å). For the curve fitting analyses on La L_{III}-edges, the inverse Fourier transform of calculated EXAFS with these two subshells of La–Ni pairs fairly agree with that of experimental EXAFS. The ca. 0.1 Å lengthening of La–Ni_I pairs were found for

the amorphous films in comparison with those for the crystalline bulk. On the Ni K-edge, however, it was not possible to evaluate the differences of Ni_I–La distances between the amorphous film and the crystalline bulk because of large uncertainties in these parameters due to small contribution of the Ni_I–La third subshell to the first nearest neighbor shell consisted of Ni_I–Ni_{II}, Ni_{II}–Ni_{II}, and Ni_I–La subshells.

$LaNi_5$ crystallizes with a hexagonal $CaCu_5$-type structure ($P6/mmm$ space group). The structure consists of two alternating types of plane, the basal plane being consisted of lanthanum and nickel atoms (Ni_I), while the $z=1/2$ plane being consisted of only nickel atoms (Ni_{II}). There are at least three models used to describe the structure of $LaNi_5$ hydride.[21–23] We employed to the model reported by Lartigue et al.,[21], because the refinement of neutron powder diffraction data for their analyses gave better reliability factors. According to the model ($P6_3mc$ space group), as shown in Fig. 4, there are three types of sites (D1, D3, and D5 sites) occupied with hydrogen or deuterium atoms for the crystalline bulk. On the D1 site (2b), hydrogen atoms are found nearly at the center of the Ni_4 tetrahedra ($3Ni_I+1Ni_{II}$). On 6c sites, D3 and D5 atoms are displaced by about 0.4 Å from the center of both the tetrahedra[two lanthanum and two nickel atoms (Ni_{II})], and octahedra[two lanthanum and four nickel atoms ($2Ni_I+2Ni_{II}$)]. On the local structures obtained from the EXAFS analyses, the La and Ni environments do not vary much from the crystalline bulk to the amorphous film, as was suggested by the fact that the Fourier transforms do not change much on the La and Ni edges. Moreover, the Ni–Ni and La–Ni distributions in the amorphous film still have some resemblance to the crystalline bulk, so that the three types of hydrogen sites (D1, D3, and D5) appear to exist in the amorphous film as well as the crystalline bulk. As mentioned above, however, the Ni_{II}–Ni_{II} and La–Ni_I distances were lengthened compared with those for the crystalline bulk, consequently, a part of these three hydrogen sites existed in the crystalline bulk become somewhat distorted. Since the hydrogen atoms appears to be difficult to be stably located in the sites distorted, the amount of hydrogen taken up by the amorphous $LaNi_{5.0}$ is smaller than that by the crystalline one.

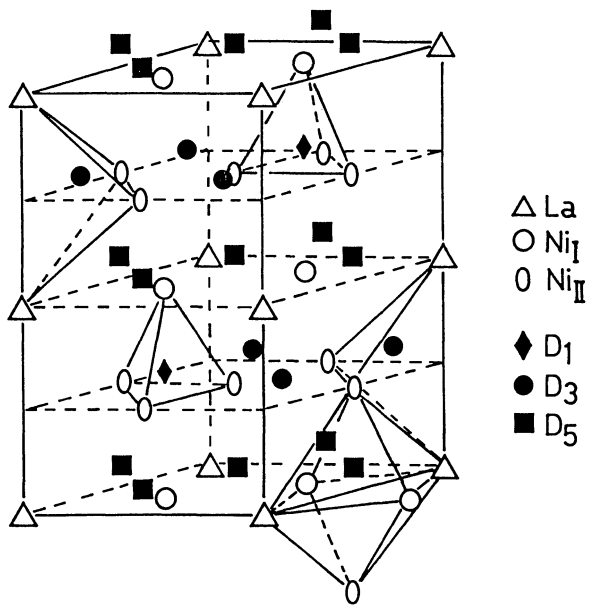

Fig. 4. Structure of the hypothetical fully ordered $LaNi_5D_7$ phase involving three types of sites occupied with hydrogen.

Conclusion

The local structures around La and Ni atoms in amorphous $LaNi_5$ films have been clarified with EXAFS. The distortion of three kinds of sites in which hydrogen atoms are considered to occupy was observed in the amorphous films due to the lengthening of interatomic distances in the Ni–Ni and La–Ni pairs. If the hydrogen atoms become difficult to be stably located in the sites, the hydrogen content in the amorphous $LaNi_{5.0}$ would be smaller than that in the crystalline one.

We thank Dr. M. Nomura and the staff of the Photon Factory at KEK for their helpful advice and technical assistance in the EXAFS measurement. Conformational Stability of V-Amyloses and Their Hydration-Induced Conversion to B-Type Form as Studied by High-Resolution Solid-State ^{13}C NMR Spectroscopy

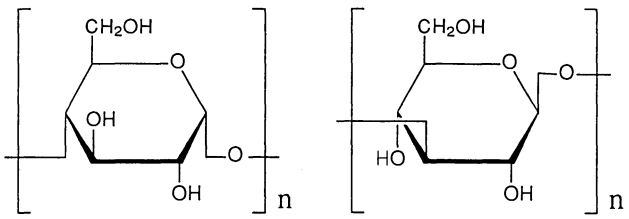
(Received July 19, 1991)

We have recorded ^{13}C NMR spectra of several preparations of amorphous samples, V-amyloses and their hydrates to gain insight into their relative stability and subsequent hydration-induced conformational change. It was found that the ^{13}C NMR line width of the iodine complex prepared as a precipitate in aqueous solution was the narrowest among these preparations, including the iodine complex formed from cast film. It is noteworthy that these V-amyloses are not always stable when they are equilibrated in an atmosphere of 96% R. H. in a desiccator and converted to B-type form, consistent with previous observation by Senti and Witnauer (*J. Am. Chem. Soc.*, **70**, 1438 (1948)). ^{2}H NMR line shape and spin-lattice relaxation times were measured for partially deuterated V and B-type amylose samples containing DMSO-d_6 and deuterium oxide, respectively, to explore the dynamics of the DMSO and water molecules bound to the polymer chains. It is unlikely that any drastic conformational change such as unfolding followed by refolding and plausible change of handedness is caused by such mild physical treatment as humidification. Therefore, it appears that the resulting B-type form should be ascribed to a left-handed single helix as a consequence of a slight modification of V-amylose, in contrast to the previous interpretation based on the data of X-ray diffraction and NMR studies. Gelation mechanism of amylose gel based on this view is also discussed.

It has been shown that amyloses (I) and starches ((1→4)-α-D-glucan) exhibit the following polymorphs, as analyzed mainly by X-ray diffraction study:[1,2] V-, A-, B-, and C- forms. The V-form exists as complexes with small organic molecules, water or iodine, and have in common a left-handed, single six-residue helix.[1,3–6] The A- and B-forms are found for cereal and tuber starches, respectively.[1,2] The detailed structure of the B-form is still the subject of current debate. The B-form was initially considered as a single helical conformation,[7] since the conversion of V- to B-amylose takes place on humidification.[8] Later, the structure was refined as a right-handed double helix packed in an antiparallel fashion,[9,10] following the suggestion by Kainuma and French,[11] although two sixfold helical models were proposed from the data for similar unit cell dimension.[12] The double helical model was later questioned upon taking into account the biosynthesis mechanism[13] and optical rotation.[14] The handedness of the double helix, however, was recently revised as a left-handed one on the basis of refined X-ray diffraction and optical rotation.[15–17] In addition, it was shown that a left-handed, single-stranded helix is formed by crystalline complex between maltoheptaose and glycogen phosphorylase a.[18] An antiparallel, left-handed double-helix[19] was found in the crystal structure of the polyiodide complex, a dimer of *p*-nitrophenyl-α-maltohexaose.

In addition, a number of complementary studies on the conformations of amylose and starch have been performed by ^{13}C NMR method,[17,20–30] since X-ray fiber diffraction study provides only relatively limited information. In general, consistent results between X-ray and NMR studies have been obtained for a number of samples having V-,[20,21,24,26–28] A-, and B-forms,[17,22,23,25–27] although the NMR approach is further able to afford conformational data for less crystalline sample or gels. It seems, however, essential to analyze the process of mutual conversion among the V-, A-, and B-forms to obtain additional information on this subject. In this connection, a comparative study is indispensable to reach any definite conclusion.



I II

(1→3)-β-D-Glucan (II) of high molecular weight is considered to be a pertinent reference compound for the present purpose, because it adopts a single helix similar to that of (1→4)-α-D-glucan[31–33] and because it posseses the ability to form multiple-stranded helices,[34,35] in relation to gel formation. We have previously demonstrated that (1→3)-β-D-glucan as well as (1→3)-β-D-

xylan can assume the three kinds of different conformations: single chain, single helix, and triple helix, depending upon sources and sample history.[36–42] We found that these forms can be mutually converted in a controlled manner by various types of physical treatments such as hydration, dehydration, annealing, etc. The resultant conformational changes are readily monitored by a characteristic displacement of conformation-dependent ^{13}C chemical shifts[43,44] as recorded by high-resolution solid-state ^{13}C NMR spectroscopy.

This sort of ^{13}C NMR study on polysaccharides with systematically manipulated conformations provides a simple and reliable means to distinguish a single chain/helix form from multiple-stranded chains. Such a distinction, however, is not always feasible by X-ray diffraction alone because distinguishing between multi-stranded coaxial helices and nested single helices is often one of the most difficult problems in interpreting fiber-diffraction data.[45,46] Instead, it is emphasized that the present ^{13}C NMR approach, utilizing physically converted samples in a controlled manner, is an excellent means for this purpose, as manifested from our studies on (1→3)-β-D-glucans,[36–41] (1→3)-β-D-xylan,[42] and agarose.[47]

We report here ^{13}C NMR studies on various preparations of V-amyloses and their hydration-induced conversion from V- to B-type forms to gain further insight into the relative stability of these preparations when being exposed to high humidity, handedness of the single or double helical B-type amylose, and distinction between the single- and double-stranded helices for the B-amylose and its consequence to a gelation mechanism of amylose gel.

Experimental

We used several types of amylose samples with different degree of polymerization from different commercial sources: DP 17 (EX-I, Seikagaku Kogyo, Tokyo), DP 100 (EX-III, Seikagaku Kogyo, Tokyo), DP 1000 (Aldrich Chemicals, USA). These samples were used without further purification. As starting materials for conversion study, we prepared either cast film (AF) or lyophilized samples by evaporating solvent from a DMSO solution. For the latter, an amylose film was prepared by casting a DMSO solution (dissolved in DMSO at 40 °C) on $(CH_3)_3SiCl_2$-coated flat dishes, followed by evaporation of DMSO at 50 °C. The preparation of the 1-butanol complex has been previously described.[20] The iodine complex from cast film (AFI) was prepared by placing AF for 3 days in a desiccator (96% R.H.) exposed to iodine vapor. The crystalline iodine complex was isolated as precipitate by addition of excess amount of iodine solution to amylose aqueous solution (ca. 1 g dm^{-3}), and dried over silica gel. The amount of iodine in the complexes was determined by a flask-combustion method. All of the hydrated samples were prepared by placing the samples in an atmosphere of 96% R.H. for 12 h. An annealed amylose sample was prepared by heating an aqueous suspension of V-amylose lyophilized from DMSO solution (DP 1000, Aldrich) at 155 °C in an autoclave for 15 min followed by slow cooling, in a similar manner to that of annealed curdlan.[37] As reference samples of the A- and B- forms, we used corn and potato starches commercially available (Nacalai Chemicals, Kyoto). Partialy deuterated V- or B-amylose samples containing DMSO-d_6 or deuterium oxide, respectively, were prepared by analogous manner, described above.

^{13}C NMR spectra of solid materials were recorded on a Bruker CXP-300 spectrometer (75.46 MHz) utilizing cross polarization-magic angle spinning (CP-MAS). All of samples were contained in a ceramic rotor with a double air bearing and spun as fast as 3 kHz. Pulse width, contact time and repetition time were 3.5 μs, 1 ms, and 4 s, respectively. Spectra were usually accumulated ca. 1000 times. ^{13}C chemical shifts were referred to TMS through ^{13}C chemical shift of carboxyl peak of glycine (176.03 ppm). High power ^2H NMR spectra were recorded on the same spectrometer at 46.08 MHz with a pulse sequence of quadrupole echo.[48]

X-Ray powder diffraction was measured on a Rigaku Denki RINT-1400 utilizing Cu $K\alpha$, 40 kV 200 mA. Samples were placed in a sealed capillary to preserve the relative humidity.

Results

In Fig. 1, we show ^{13}C NMR spectra of two typical examples of V-amyloses, iodine (A) and 1-butanol complexes (B). Five peaks are well resolved and assigned on the basis of previous work.[20] Exactly the same charac-

teristic pattern was seen for both type of V-amyloses, in spite of a difference in guest molecules and molecular weight in host molecules (Aldrich, DP 1000 and EX-III, DP 100 for the former and the latter, respectively).

Figure 2 shows ^{13}C NMR spectra of amylose powder of low molecular weight (EX-I, DP 17) under various conditions. The ^{13}C chemical shifts thus obtained were summarized in Table 1. Clearly, anhydrous powder lyophilized from a DMSO solution (Fig. 2(B)) gave rise to the spectral pattern of V-form, as compared with that of the iodine complex (Fig. 1(A)), although this form might be distorted to some extent compared to that of the crystalline complex. The uppermost signal at 39 ppm is assigned to the methyl signal of DMSO molecules bound to the amylose chain. The anhydrous powder, however, has an amorphous structure distorted from the B-form, as judged from the broad envelope of the ^{13}C NMR signal in the C-1 region and the absence of the C-4 peak at 81 ppm (Fig. 2(A)). It is noteworthy that hydration of the anhydrous powder induced distinct spectral change (Fig. 2(C)). Obviously, the spectral pattern of the resulting hydrate powder (C and D) arises from that of B-amylose (doublet pattern in the C-1 region,[20-24] spectrum not shown). The spectral pattern of Fig. 2(D) is of the B-form despite being the iodine complex. The iodine content for this sample turned out to be less than 0.5%, indicating that the amount of the iodine complex (V-form) is negligible and the rest is the major B-form.

Figure 3 shows the ^{13}C NMR spectra of an amylose of an intermediate degree of polymerization (EX-III, DP 100). The C-1 peak of the lyophilized sample from DMSO solution arises from two components: the downfield singlet signal (the lowermost peak) ascribable to V-form (70%) and the upfield doublet shoulder (the middle and uppermost peak) ascribable to B-form (30%) (Fig. 3A), as estimated from comparison of the respective peak intensities. Again, the peak at 39 ppm is assigned to the methyl signal of DMSO bound to the polymer. Hydration of this sample resulted in partial conformational change from the V- to B-form, as manifested from the buildup of the upfield doublet pattern (up to 50%) in the C-1 with expense of the C-4 intensity (V-amylose) (Fig. 3B).

Table 2. Summary of Conformation Characterized by ^{13}C NMR and X-Ray Diffraction

	Anhydrous (lyophilized from DMSO solution)		Hydrate[a)]	
	NMR	X-Ray	NMR	X-Ray
DP 17 (EX-I)	V	V	B	Amorphous B[b)]
DP 100 (EX-III)	V(70%)+B(30%)	Amorphous	V(50%)+B(50%)	Amorphous
DP 1000 (Aldrich)	V	V	B	Amorphous
Iodine complex	V	V	V	V

a) Anhydrous lyophilized sample from DMSO solution was hydrated under the condition of 96% R.H. for over 12 h. b) Anhydrous powder sample was hydrated.

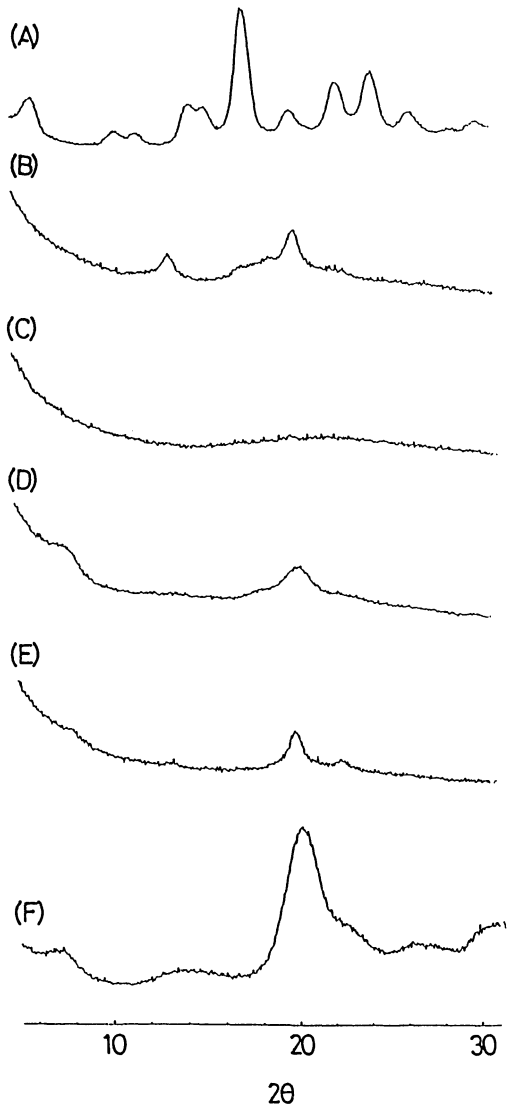

Fig. 6. Comparison of X-ray powder diffraction patterns of various types of amyloses (samples (B)—(E) correspond with the respective samples (A)—(D) of Fig. 4).
(A) hydrated amylose (DP 17) from anhydrous powder, (B) anhydrous amylose (DP 1000) lyophilized from DMSO, (C) hydrated amylose (DP 1000) lyophilized from DMSO, (D) hydrated iodine-complex (DP 1000), (E) anhydrous iodine complex (DP 1000), (F) amylose iodine complex as precipitate (DP 1000).

Similar experiments were repeated for amylose with high degree of polymerization (Aldrich, DP 1000). In contrast to the case of intermediate degree of polymerization, hydration of V-form amylose resulted in complete conversion to B-form (Figs. 4(A) and (B)). Annealing of this sample yielded a very narrow B-type spectrum comparable to that of Figure 2D, although the X-ray diffraction pattern was still a halo (spectra not shown). The iodine content in this complex is ca. 10%, as determined by the change of weight before and after the complexation. It is interesting to note that the iodine complex (Fig. 4(D)) was stable after exposure to an atmosphere of 96% R.H. (Fig. 4(C)). These experiments were also performed for samples prepared from cast film. Interestingly, the hydration-induced conformational change is incomplete but still observable as seen from the increase of the upper field doublet of the C-1 region and the decrease of the peak intensity at the C-4 for the cast film (Figs. 5(A) and (B)), in contrast to the observation for lyophilized powder (Figs. 4(A) and (B)). Again, it is found that the iodine complex prepared from a cast film is stable for the exposure to high humidity.

Typical X-ray powder diffraction patterns of the above-mentioned samples (see Fig. 4) were illustrated in Fig. 6. The resulting conformational features obtained from the X-ray and NMR studies are summarized in Table 2. The conformation revealed by X-ray diffraction is consistent with that obtained by NMR as far as V-amylose is concerned. On the other hand, the hydration-induced B-form converted from V-amylose (as judged from NMR data) turned out to be amor-

Table 3. ^{2}H Spin-Lattice Relaxation Times of DMSO-d_6 and Deuterium Oxide Bound to Amylose and Curdlan (ms)

	Temp/K	DMSO-d_6	D_2O
Amylose, V form	295	42.9	
	303	52.6	
B form	295		14.3
Curdlan, Anhydrous	295	44.2

	314	48.5	
	323	68.3	
Hydrate	295		10.1

phous as shown by X-ray diffraction study (Table 2). The 46.08 MHz ^{2}H NMR signals of DMSO-d_6 (V-amylose) and ^2H_2O (B-amylose) were observed as single peaks with line widths of 1.9 and 2.4 kHz at ambient temperature, respectively (spectra not shown). Almost the same result was obtained for curdlan, a (1→3)-β-D-glucan as a reference compound for amylose. The ^{2}H spin-lattice relaxation times of DMSO-d_6 and D_2O are 44 and 10 ms at 22 °C, respectively, as summarized in Table 3.

Discussion

Relative Stability of V-Amyloses and Molecular Motions of Guest Molecules. The present observations clearly demonstrate that three types of amylose preparations, complexes with 1-butanol, DMSO, and iodine, exhibit similar V-type forms, consistent with the X-ray data (Fig. 6 and Table 2). In fact, previous X-ray diffraction studies showed that all V-amylose structures are almost the same with h (rise per residue) in a very narrow range from 1.32 to 1.36 Å.[1] Complexing agents such as water, small organic molecules, or iodine are found inside the helix channel on the basis of the X-ray diffraction studies.[1] Nevertheless, the relative stability of these complexes varies with the type of complexing agent: Water molecules are readily removed by lyophilization, as in the case of the amorphous form (Fig. 2(A)), and DMSO and 1-butanol (spectra not shown) molecules are readily replaced by water molecules upon exposure to high humidity as a result of a conformational change from the V- to the B-form.

For this reason, it is expected that these complexing agents are not necessarily strongly bound to the amylose chain and can undergo rapid motion in the cavity if the sizes of these molecules are smaller than that of the cavity. Such motion, if any, could be easily detected by examining how ^{2}H quadrupole splittings are averaged out by plausible molecular motions and by the extent of the ^{2}H spin-lattice relaxation times of the deuterated guest molecules.[49,50] It is expected that ^{2}H NMR signals of ^2H_2O or DMSO-d_6 complexed to amylose by forming B- or V-form are split into a doublet pattern whose separation of peaks being about 100—200 and 40 kHz (with C_3 rotation of methyl group), respectively, if they are tightly bound (static). This expectation is based on the fact that the quadrupole coupling constants, e^2qQ/h, of the former and the latter are of the order of 140—300 and 170 kHz, respectively.[49] It turned out that only a singlet signal was visible as a result of rapid isotropic averaging of the quadrupole interaction in the solid state with correlation times of the order of 10^{-6} s.[49] Also, Table 3 shows that the ^{2}H T_1 values of bound ^2H_2O and DMSO-d_6 molecules are 10 and 44 ms, respectively, at ambient temperature and are increased to 68 ms for the latter (in the case of DMSO bound to curdlan). These results indicate that the correlation times of the isotropic tumbling motions of the former and latter are in the vicinity of the T_1 minimum (10 ms),[50] namely about 10^{-8} s, and on the high temperature side of the T_1 minimum.[51]

The existence of such loosely bound guest molecules undergoing rapid isotropic motions is consistent with a view that DMSO molecules inside the cavity are readily replaced by water molecules when these samples were hydrated. Humidification of these samples results in hydration-induced conformational change. Replaced water molecules, however, are not always tightly bound to amylose chains and undergo rapid reorientation motion (correlation time being in the order of 10^{-8} s) as revealed by the present ^{2}H NMR observation, in contrast to the view from X-ray diffraction study.[16]

It is interesting to note that, in contrast, the iodine complex is stable under high humidity. This stability is indicated by the fact that these complexes are formed in the presence of water molecules. The amounts of water bound to the iodine complexes, however, are less than 50% of that of the uncomplexd amyloses.[52] The adsorbed water molecules are consumed in converting the molecular iodine in the cavity to I_3^- or I_5^- ions, which are indispensable for stabilization of the iodine complexes.[53] Consequently, approximately three iodines occupy the helix channel within one fiber repeat, but the iodines form an almost linear polyiodide chain of undetermined length.[1] This is the reason why the iodine complexes are highly stable in the presence of high humidity.

Hydration-Induced Conformational Change. It is now clear that hydration induces a conformational change of amyloses of various molecular weights from either amorphous or V- to B-type forms (Figs. 2—5), although the extent is different between powder and cast film. Here, we use the term "B-type" form instead of B-form when its X-ray diffraction pattern is a halo (Fig. 6) even if its NMR pattern exhibits the spectral feature of B-form. Nevertheless, it is emphasized that the conformation of the "B-type" form is very close to that of the B-form as far as short-range order is concerned, as will be discussed later. This observation is consistent with the previous work of Blackwell et al.[7] who previously described this hydration-induced form as B-form.

It is interesting that conversion is incomplete for amylose preparation of intermediate degree of polymerization (DP 100), as compared with that of high degree (DP 1000) or low degree of polymerization (DP 17). The conformation of amylose of intermediate molecular weight (DP 100) lyophilized from DMSO solution turned out to be a mixture of V- and B-forms. The proportion of the B-type form is increased by humidification but it is not completely converted to pure B-type form. This trend is consistent with the previous study on the effect of chain length on phase behavior and aggregation kinetics utilizing monodisperse amyloses:[54] Amyloses having chain lengths of <110 residues are found to precipitate from aqueous solution, and gela-

tion is found to predominate over precipitation for longer chains (>1100). It is probable that aggregated amylose is rather hydrophobic and can be resistant to conformational change due to hydration. Here, the following two points are noteworthy as to the conformational behavior of amylose in cast film. First, the ^{13}C NMR spectra of cast film (Fig. 5A) are generally broadened compared to those of the lyophilized powder from DMSO solution (Fig. 4A). This is readily explained on the basis that the conformation in cast film can be distorted to some extent when the liquid film was heated up to 50 °C to evaporate the DMSO. This sort of conformational distortion is accelerated when DMSO molecules inside the cavity are also removed, as manifested by the considerably reduced peak intensity of DMSO methyl signal (Fig. 5B). Second, there remains a considerable proportion of unconverted V-form (Fig. 5B) after humidification in spite of the high molecular weight sample used (DP 1000) (see also Fig. 4B). Such a distortion is not necessarily taken into account for the lyophilized sample, because DMSO molecules are removed at frozen state. It is probable that the formation of the aggregated amylose as in the case of intermediate molecular weight sample might prevent complete conformational change due to humidification.

In addition to the present observations from V- to B-change, hydration-induced conversion between amorphous and B-form has been also previously demonstrated.[17,23–27] The "amorphous" structure defined by X-ray diffraction does not necessarily indicate the presence of a completely disordered structure because there are a number of cases where secondary structure is amorphous as viewed from X-ray diffraction but is still quite ordered as viewed from the ^{13}C NMR study.[44] This situation is readily understood in that X-ray diffraction is sensitive to long range order, while NMR is sensitive to short range order. Hence, there appear several types of amorphous structures which are close to either B- or V-forms, or a mixture of both (see Table 3). For instance, the ^{13}C NMR spectrum of an anhydrous powder with a low degree of polymerization (DP 17) (Fig. 2(A)) may be ascribed to a distorted B-form. On the other hand, a number of examples have been presented for dried potato starch[23–27] whose ^{13}C NMR patterns are rather close to those of V-amylose, although dispersion of chemical shifts, especially at the C-1 region, is enormous. Accordingly, the "amorphous"→B-type or B-type→ "amorphous" conversion for samples with intermediate or high degree of polymerization can be considered as a modified V→B-type or B-type→V conversion.

The reverse B→V conversion, however, has not been realized by X-ray diffraction study. This may be one of the reasons why the single helical model of B-amylose by Blackwell et al.[7] has long been neglected. Nevertheless, it is now clear that such reverse conversion can be readily identified by solid-state NMR.[17,23–27] In addition, the B-form amyloses are completely converted to V-form by dissolving those in DMSO solution, followed by lyophilization (spectra not shown). This sort of V→B or B→V conversion is parallel with the conversion between anhydrous and hydrate state as observed for (1→3)-β-D-glucans previously reported, as summarized in Table 4.[37–41] It is emphasized that complete dissolution in aqueous solution is an essential requirement for the conversion of (1→3)-β- D-glucan from the singe helix to the triple helix.[37,39,40] This means that unfolding of the polymer chains followed by refolding in aqueous media is a necessary condition for such conversion. In this connection, it is hardly likely that simple humidification of amylose in a desiccator causes such an unfolding/refolding process leading from the single-stranded helilx (V-form) to double-stranded helix (B-form). It is therefore natural to conclude that the left-hand chirality is preserved upon humidification. The above-mentioned hydration-induced conversion is related to a change among a variety of left-handed single-stranded helices as observed for amylose, its derivative and its oligomers.[19] It is also shown that the helical parameters of an antiparallel double helix of maltohexaose are comparable to those obtained for the left-handed amylose single helix of maltoheptaose complexed with phosphorylase a.[18,19] As mentioned above, annealing of amylose at 155 °C did not induce a spectral change from the B-type form. This means that multiple-stranded helices may not be formed even after annealing followed by slow cooling. It is concluded that the B-type form thus obtained takes a left-handed single helix form, rather than the previously proposed double helix conformation, although the helical parameters should be different from those of the V-form.[18,19] Thus, it is needless to claim that the ^{13}C chemical shifts of the B-type form differ from those of V-form.

Significance of Single Helix and Gelation Mechanism. It is well recognized that biopolymer gels are usually formed by the physical association of parts of the polymer chains at regions of local order or "junction zones" to produce a continuous, three dimensional poly-

Table 4. Summary of Conformational Conversion Achieved for (1→4)-α-D- and (1→3)-β-D-Glucans

Treatment	(1→4)-α-D-Glucans	(1→3)-β-D-Glucans
Lyophilization from DMSO soln	V	Single chain
Hydration (humidification)	B	Single helix
Annealing/slow cooling	B	Triple helix

mer network.[55] So far, two different views have been presented for the gelation mechanism of amylose: Miles et al.[56] have suggested that gels are formed upon cooling molecularly entangled solutions as a result of phase separation of the polymer-rich phase, whereas Wu and Sarko[9] proposed that gelation occurs through cross-linking by double helical junction zones. As an alternative model of the former type of gelation, the presence of short segments of antiparallel double helices between single helical chains also would result in three dimensional network.[19] In principle, it is possible to distinguish which mechanism is more likely for the network structure of the amylose gel on the basis of conformational elucidation of dynamically heterogeneous network by means of variety of ^{13}C NMR technique.[24,40]

In fact, Gidley[24] showed that amylose gel contains two kinds of ^{13}C resonances: The B-type signals from motionally restricted regions as recorded by the CP-MAS technique and the signals identical to those found in aqueous solution. Obviously, the latter signals can be ascribed to the presence of mobile region in the network whose conformation is a random coil.[20] The former peaks, on the other hand, are thus ascribed to aggregated regions of the single helical chains based on our present observation, although they were ascribed to double-helical junction zone by Gidley.[17] At this point, it is worthwhile to point out that only a small amount of cross-linking agent, say 0.1—5%, is sufficient to form elastic gels, as shown by studies of chemically cross-linked gels of synthetic polymers.[57,58] To support this view, we showed that the triple-helical region as cross-links is ca. 10% at most in an elastic curdlan gel.[37,40,57] This means that the amylose gel does not necessarily consist entirely of molecular chains arising from the double-helical structure. Instead, it appears that the "solid-like" region of the amylose gel[17] might be ascribed to the presence of phase-separated aggregates of the B- type single-helical chains as cross-links. This view seems to be in favor of the gelation mechanism of Miles,[56] although alternative cross-links by the antiparallel short segments of the double-helices[19] could also exist. The latter could not be easily distinguished from the aggregated single helices, because the resulting helical parameters are comparable to those of the single-stranded helices.[19]

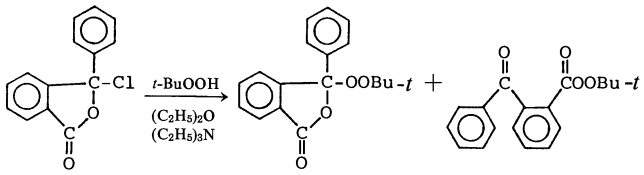
Synthesis and Properties of Peroxy Esters Having a Benzophenone Chromophore

Hiromi KUMURA, Tomoyuki NAKAMURA, Yoshiki HIGUCHI, and Shuji SUYAMA*
Chemicals & Explosives Research Laboratory, Nippon Oil & Fats Co., Ltd.,
Taketoyo-cho, Chita-gun, Aichi 470-23
(Received March 5, 1991)

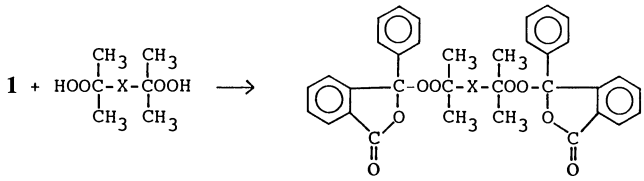
Diperoxy esters having a benzophenone chromophore have been successfully synthesized from the reaction of 3-chloro-3-phenylphthalide (**1**) with 2,5-dihydroperoxy-2,5-dimethyl-3-hexyne (**4a**) or 2,5-dihydroperoxy-2,5-dimethylhexane (**4b**). The corresponding diperoxy esters had a UV absorption above 300 nm. The free radicals produced during the photolysis of these compounds initiated the radical polymerization of methyl methacrylate at room temperature under UV light.

The isomerism of the various derivatives of 3-chloro-3-phenylphthalide (**1**), the pseudo-chloride of *o*-benzoylbenzoic acid, has been reported. Neckers[1] obtained a mixture of the pseudo-type peroxy ester (**2**) and the normal type peroxy ester (**3**) from the reaction of **1** with *t*-butyl hydroperoxide, and isolated **2** and **3** by means of column chromatography.



1 **2** **3** (1)

Rüchardt[2,3] and Chang[4] reported the synthesis of the pseudo-type diperoxy esters from the reaction of **1** with dihydroperoxides in the presence of amines in organic solvent. They obtained a viscous liquid as the reaction mixture of **1** with **4a** or **4b** and isolated the corresponding pseudo-type peroxy esters, 2,5-bis[(1-phenyl-3-oxo-1,3-dihydro-1-isobenzofuranyl)dioxy]-2,5-dimethyl-3-hexyne (**5a**) or 2,5-bis[(1-phenyl-3-oxo-1,3-dihydro-1-isobenzofuranyl)dioxy]-2,5-dimethylhexane (**5b**) by chromatography in poor yields.



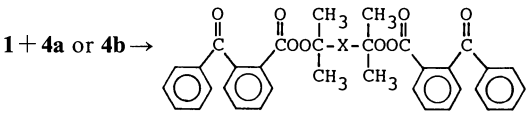
4a (X=–C≡C–)
4b (X=–CH_2CH_2–)

5a (X=–C≡C–)
5b (X=–CH_2CH_2–) (2)

However, no reports concerning the synthesis of the normal type diperoxy esters have been published. If the normal type peroxy esters can be obtained, they will be useful as photoinitiators because they have a UV absorption above 300 nm.[1,5] In the present paper, we report the successful synthesis and the properties of diperoxy esters having a benzophenone chromophore from the reaction of **1** with dihydroperoxides in 40% NaOH aqueous solution.

Results and Discussion

Synthesis in Aq NaOH Solution. When a benzene–dioxane solution of **1** and **4a** was treated with aq 40% NaOH solution at 0—5 °C for 4 h, a white slurry was formed. This was filtrated and washed with water and diethyl ether. After evaporation of the solvent under vacuum, a white powder was obtained. Its structure was ascertained by means of ^{1}H NMR, ^{13}C NMR and other spectral measurements. The ^{1}H NMR spectrum showed this product had twelve methyl and eighteen phenyl protons. The ^{13}C NMR spectrum showed a characteristic absorption at 163.6 (C=O of peroxy ester)[6] and 196.0 (C=O of benzophenone)[7] and the IR spectrum showed absorptions at 1760 (C=O of peroxy ester) and 1680 cm^{-1} (C=O of benzophenone). These data showed that this product was the normal type peroxy ester, 2,5-bis(*o*-benzoylbenzoyldioxy)-2,5-dimethyl-3-hexyne (**6a**) (Eq.3). Compound **6a** contained 5.24% active oxygen measured by iodometric titration and it was shown to be 96.7% pure. The yield of **6a** based on **1** was 62%.



6a (X=–C≡C–)
6b (X=–CH_2CH_2–) (3)

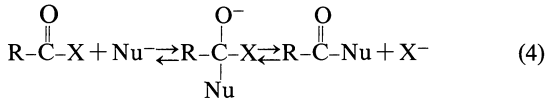
The similar treatment of **1** with **4b** gave a white powder of 2,5-bis(*o*-benzoylbenzoyldioxy)-2,5-dimethylhexane (**6b**) in a 68.4% yield (Eq.3). The structure was also ascertained by means of spectroscopic measurements. The ^{1}H NMR spectrum indicated this prod-

uct had twelve methyl, four methylene and eighteen phenyl protons. The IR and ^{13}C NMR spectra showed the presence of a benzoyl group and a peroxy ester carbonyl group. This product contained 4.34% active oxygen and it was shown to be 80.7% pure. This was the first example of the synthesis of peroxy esters having a benzophenone chromophore in good yields.

Synthesis in Pyridine/Dioxane. In order to confirm the difference between the work of Rüchardt[2,3] and Chang[4] and the present study, we reinvestigated the reaction of **1** with **4a** under the same conditions used by Chang.[4] Thus, **1** was allowed to react with a solution of **4a** and pyridine in dioxane. The reaction mixture was diluted with water and then extracted with diethyl ether. The ether solution was treated as described in the experimental section and white crystals were obtained. The structure of this product was ascertained by means of IR, NMR, and other spectral measurements. The IR spectrum of this compound indicated absorptions at 1780 (C=O of phthalide) and 1100 cm^{-1} (cyclic C–O–C) and the ^{13}C NMR spectrum indicated characteristic absorption at 168.2 (C=O of phthalide). The mass spectrum of this compound showed the molecular weight to be 590. The lack of the absorption of a benzoyl group in the IR and ^{13}C NMR spectra apparently showed that this compound differed from the diperoxy ester **6a**. These data indicated that this compound was the pseudo-type peroxy ester **5a**. It contained 5.30% active oxygen determined by iodometric titration and it was shown to be 97.8% pure. The yield of **5a** was only 3%.

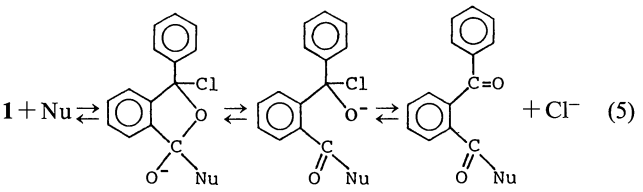
It was found that the peroxy ester **6a** was also formed under these reaction conditions. This was confirmed by HPLC analysis with an authentic sample of **6a**. However, the isolation of **6a** from this reaction mixture was unsuccessful, because only a trace amount of **6a** was formed.

Reaction Mechanism. It is known that **1** is susceptible to attack by nucleophiles at two centers. Displacement at the tetrahedral center leads to the pseudo-type derivatives, whereas an addition-elimination sequence at the phthalide carbonyl group results in opening of the phthalide ring.[8] The formation mechanism of the normal type peroxy ester in aq NaOH solution may be explained as follows. In nucleophilic displacement of esters, it has been shown that the addition-elimination reaction involves a tetrahedral intermediate.[9] The feasibility of the forward reaction depends on whether



(4)

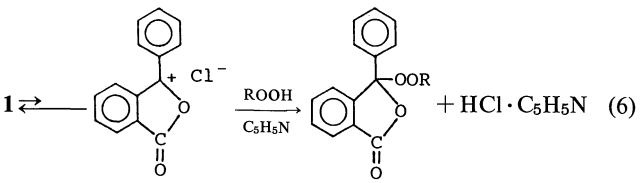
Nu^- is a stronger nucleophile than X^-. A similar situation may exist in the case of the pseudo acid chloride derivatives. Nucleophiles stronger than the PhC(O$^-$)Cl group in **7** may be able to bring about displacement at the phthalide carbonyl group (Eq. 5).



(5)

7

In aq NaOH solution, a certain amount of alkyl hydroperoxide dissociates into alkylperoxide anion (ROO^-). This ROO^- is known to be a very strong nucleophile because of its α-effect[10] and seems to be a stronger one than the PhC(O$^-$)Cl group. On the other hand, the above-mentioned reaction will not occur in pyridine-dioxane solution because of the low concentration of ROO^-. It has been reported[9] that the weaker nucleophiles like organic amines bring about displacement at the tetrahedral center to form the pseudo-type derivatives. Then, in pyridine–dioxane solution, it is expected that the reaction shown in the following scheme would occur by an S_N1 mechanism.



(6)

UV Absorption Spectra. The UV absorption spectra of **5a**, **6a** and benzophenone are shown in Fig. 1. Compound **6a** behaved like benzophenone with respect to the absorption, that is, a maxima in the range 300—380 nm and a typical n–π^* extinction coefficient of 2.29×10^2 $dm^3\,mol^{-1}\,cm^{-1}$. On the other hand, **5a** showed a dif-

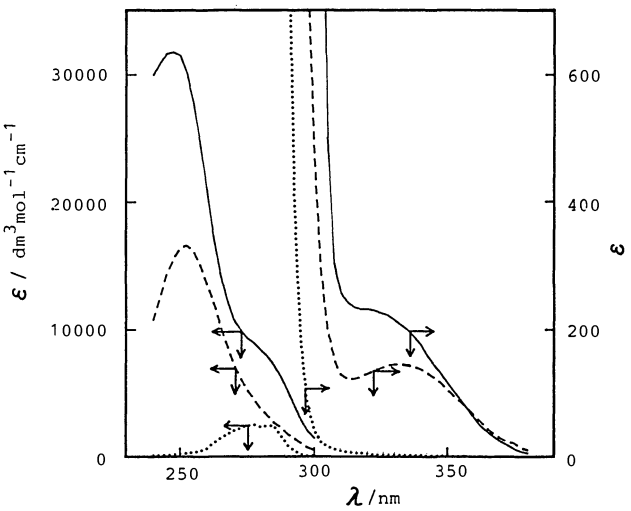


Fig. 1. UV absorption spectra of the peroxy esters and benzophenone in CH_3OH. ·····; **5a**, ——; **6a**, – – –; benzophenone.

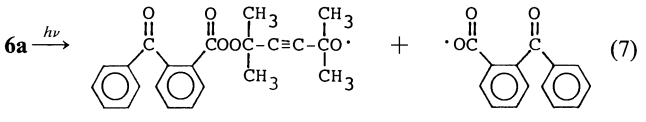
Table 1. Photodecomposition Products of **6a**[a)]

Products	Yield[b)]/%
10	100
o-Benzoylbenzoic acid	61
Benzophenone	20
1,2-Diphenylethane	18

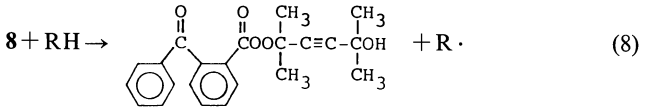
a) Photodecomposition was carried out in toluene at 25 °C. Initial concentration of **6a**: 0.026 mol dm^{-3}. b) Yields of products: [(moles of products)/(moles of **6a** consumed)]×100. The conversion of **6a** was 21.5%.

ferently shaped spectra than that of **6a**. Compound **5a** had a less intense absorption in the range 300—380 nm, which reflected the substituent in the phthalide.

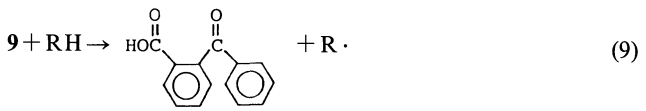
Photodecomposition. Photodecomposition studies of **6a** were carried out in aromatic solvents at 25 °C by irradiating with 366 nm light. The decomposition products in toluene, analyzed by HPLC, were 2-(*o*-benzoylbenzoyldioxy)-5-hydroxy-2,5-dimethyl-3-hexyne (**10**), *o*-benzoylbenzoic acid and benzophenone (Table 1). The total recovery of the benzophenone moiety was 90%. The quantitative formation of **10** indicated that the photolysis of **6a** proceeded stepwise. A likely scheme leading to the products is shown by the following equations.



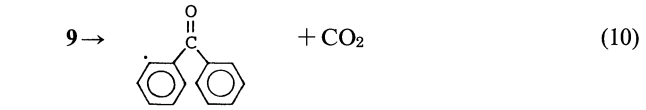
8 **9** (7)



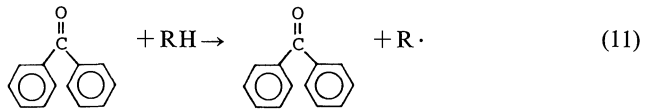
10 (8)



(9)



(10)



(11)

$$2\,R\cdot \rightarrow R\text{-}R \qquad (12)$$

The quantum yield of photolysis of **6a** in benzene was observed to be 0.97. Values of Φ for other peroxides in benzene have been reported by Neckers and Leffler and are 0.94 and 0.97 for *t*-butyl peroxy *p*-benzoylbenzoate (**11**)[1)] and *p*-benzoylbenzoyl peroxide (**12**),[5)] respectively. The value for **6a** was comparable to these data and it was significantly higher than that of the benzophenone-sensitized decomposition of benzoyl peroxide (Φ=0.25 in benzene).[11)] This result clearly indicated the efficacy of the intramolecular energy transfer in **6a** in contrast to the bimolecular process.

Compound **6a** gave linear Stern-Volmer plots when naphthalene was used as a triplet quencher (Fig. 2), which meant the photodecomposition of **6a** proceeded via the excited triplet state.

The resulting value of $k_q\tau$ for **6a** was 4.7 dm^3 mol^{-1}. If the rate constant k_q was assumed to be equal to the diffusion-controlled rate constant (k_q=9×10^9 dm^3 mol^{-1} s^{-1}), the lifetime of the excited triplet, τ, of **6a** was estimated to be 0.5×10^{-9} s. The present τ value for **6a**

a) Light intensity $I_0=7.61\times10^{-4}$ Einstein min^{-1}.

was very close to those for **11** and **12**, that is, τ values of 4×10^{-9} s[1)] and 0.87×10^{-9} s,[12)] respectively. The lifetime of the benzophenone triplet in benzene has been reported to be 8.4×10^{-6} s,[13)] and τ of **6a** was 2×10^4 times shorter than that of benzophenone. Thus, the rates of energy transfer from the excited triplet state of benzophenone having a peroxide group to the O–O bond were about the same in these three peroxides and it was shown that the energy transfer rate was almost independent of the structure of the peroxides.

Thermal Decompositon. The thermal decomposition of the peroxy esters was also investigated to test the effect of the structure of the peroxy esters in the ground state. The thermolysis was carried out in cumene under nitrogen. The rates for the thermolysis were measured by iodometric titration and good first-order plots were obtained in all cases. The results are given in Table 2 together with the calculated activation parameters. The activation parameters for these peroxides indicate a nonconcerted homolytic cleavage of one peroxy bond.

The decomposition of the normal type peroxy ester **6a** occured 4—5 times faster than that of the pseudo-type peroxy ester **5a**. The rate constants and activation parameters of **6a** were comparable to those of *t*-butyl peroxybenzoate (i.e. $\Delta H^{\neq}=156.8$ kJ mol^{-1} and $\Delta S^{\neq}=66.0$ J K^{-1} mol^{-1}).[14)] The activation parameters of **5a** were similar to those of **2**.

In order to clarify the effect of a benzoyl group on the thermal decomposition rate of **6a** and **6b**, the thermolysis of 2,5-bis(benzoyldioxy)-2,5-dimethyl-3-hexyne (**13a**) and 2,5-bis(benzoyldioxy)-2,5-dimethylhexane (**13b**) were carried out. The rate constants of the thermal decomposition of **6a** and **6b** having an *o*-benzoyl group were a little smaller than those of the corresponding **13a** and **13b**, respectively. This could be predicted from the electron-attractive effect of the *o*-carbonyl group.[15)]

Photopolymerization. Some polymerization studies were carried out using the newly developed peroxy ester and methyl methacrylate (MMA) as a monomer. The results are given in Table 3.

Table 3 shows that MMA did not polymerize photochemically in the absence of any initiator under these conditions. Normal type peroxy ester **6a** initiated the photopolymerization of MMA effectively and the pseudo-type peroxy esters **2** and **5a** also initiated it. The rate of photopolymerization with **6a** was two times higher than **5a**. The photopolymerization with equimolar amounts of **13a** and benzophenone was also carried out and the result showed the polymerization rate with the benzophenone-sensitized **13a** was lower than that of **6a**.

In conclusion, the initiation of photopolymerization with **6a** occurred via the intramolecular energy-transfer mechanism from the n–π^* excited state of a benzoyl group to an O–O bond.

These results showed that the peroxy esters having a benzophenone functionality provided an efficient photochemical source of free radicals.

Experimental

^{1}H and ^{13}C NMR spectra were recorded on a JEOL GSX 270 FT-NMR spectrometer using $CDCl_3$ as a solvent and TMS as an internal standard. HPLC analyses were performed with a Shimadzu LC-5A liquid chromatograph by using a 6.0 mm×15 cm Shimpack CLC-ODS column. GPC analyses were performed with a Shimadzu LC-6A liquid chromatograph with a Shimadzu RID-6A refractive index detector, by using two 30 cm Shodex KF-80M columns, a 30 cm Shimadzu HSG-10S, and a 30 cm Shimadzu HSG-15SH column. Infrared spectra were obtained on a JASCO A-3 infrared spectrophotometer; peaks were reported in units of cm^{-1}. UV spectra were measured on a Shimadzu UV-2200 UV-vis spectrophotometer. Melting points were measured with a Yanaco micro melting point apparatus. Mass spectra were obtained on a JEOL JMS-D300 mass spectrometer at 200 eV under chemical ionization conditions and on a JEOL JMS-DX300 mass spectrometer at 70 eV under electron impact conditions.

Materials. Cumene was purified by distillation after washing with concentrated sulfuric acid. Methyl methacrylate was purified by distillation after washing with 5% NaOH aqueous solution. 3-(*t*-Butyldioxy)-3-phenylphthalide (**2**), 2,5-bis(benzoyldioxy)-2,5-dimethyl-3-hexyne (**13a**), and 2,5-bis(benzoyldioxy)-2,5-dimethylhexane (**13b**) were the products of Nippon Oil & Fats Co., Ltd. 3-Chloro-3-phenylphthalide (**1**) was prepared by the reaction of *o*-benzoylbenzoic acid (22.6 g, 1.0 mol) with thionyl chloride (18 g, 1.5 mol in benzene (50 ml)) for 24 h under reflux. After evaporation of the thionyl chloride, the remaining oil proved to be almost pure 3-chloro-3-phenylphthalide (Cl 14.4%, purity 99.4%, no C=O absorption around 1650 cm^{-1}, strong C=O absorption at 1790 cm^{-1}).

Preparation of 2,5-Bis[(1-phenyl-3-oxo-1,3-dihydro-1-isobenzofuranyl)dioxy]-2,5-dimethyl-3-hexyne (5a). Compound **1** (12.2 g, 0.05 mol) was added with stirring to a solution of **4a** (4.4 g, 0.025 mol) and pyridine (4.2 g, 0.052 mol) in 13 ml of dioxane at 20—25 °C. The reaction mixture was stirred at 25—35 °C for 4 h and then allowed to stand at room temperature for about 12 h. It was diluted with 25 ml of water and then extracted five times with 25 ml of diethyl ether. The ether solution was washed five times with 10 ml portions of 5% $NaHCO_3$ aqueous solution and five times with 10 ml portions of water, and dried over anhydrous $MgSO_4$. After filtration, the diethyl ether solution was allowed to stand at −23 °C overnight. A white crystalline substance was separated. Filtration and removal of solvent in a vacuum gave a white powder. Active oxygen 5.30% (calculated 5.42%); Mp 160 °C; IR($CHCl_3$) 2975, 1780, 1610, 1475, 1460, 1290, 1160, 1100, 1060, 1000, 940, 890, and 830 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.37—1.52 (CH_3, 12H, q) and 7.32—7.80 (aromatic, 18H, m); ^{13}C NMR ($CDCl_3$) δ=26.9, 27.2 (each CH_3), 77.9 (acetylenic C), 85.1 (tert C), 110.1 (tert C), 123.9, 125.1, 126.2, 126.5, 126.9, 128.7, 129.8, 130.1 , 130.4, 134.2, 135.3, 146.7 (each Ph) and 168.2 (carbonyl C of phthalide); UV(MeOH) λ_{max} nm (ε) 277(2490) and 284 (2410); MS(CI), Found : m/z 608; Calcd for $C_{36}H_{34}O_8N$:($M+NH_4$), 608.

Preparation of 2,5-Bis(*o*-benzoylbenzoyldioxy)-2,5-dimethyl-3-hexyne (6a). Finely divided **1** (31 g, 0.127 mol) was added with stirring to a mixture of **4a** (10. 3 g, 0.058 mol) and 40% NaOH aqueous solution (12.3 g, 0.124 mol) in benzene-dioxane (20 ml, 40 ml) at 5—10 °C. The reaction mixture was stirred at 0—5 °C for 4 h. A white slurry was obtained and it was filtered and then washed three times with 60 ml of water and twice with 20 ml of diethyl ether. Vacuum drying of the solvent gave a white powder (23 g) in a 62% yield, based on the amount of **1** used; it contained 5.24% active oxygen as determined by iodometric titration. This compound gave one peak on HPLC analysis. Mp 129—130 °C; IR ($CHCl_3$) 2950, 1760, 1680, 1600, 1460, 1320, 1280, 1160, 1120, 1040, 940, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.42 (CH_3, 12H, s) and 7.38—7.93 (aromatic, 18H, m); ^{13}C NMR ($CDCl_3$) δ=26.4 (CH_3), 78.9 (acetylenic C), 84.7 (tert C), 126.7, 128.3, 128.5, 129.7, 129.8, 129.9, 132.7, 133.3, 136.7, 141 .6 (each Ph C), 163.6 (carbonyl C of peroxy ester), and 196.0 (carbonyl C of benzophenone); UV(MeOH) λ_{max} nm (ε) 203 (60800), 247 (31800), 280 (8400), and 320 (sh 230).

Preparation of 2,5-Bis(*o*-benzoylbenzoyldioxy)-2,5-dimethylhexane (6b). Compound **1** (12.2 g, 0.05 mol) was added with stirring to a mixture of **4b** (5.8 g, 0.025 mol) and 40% NaOH aqueous solution (5.0 g, 0.05 mol) in benzene-dioxane (5 ml, 18 ml) at 5—10 °C. The reaction mixture was stirred at 0—5 °C for 4 h and worked up as for **1a**. A white powder (15.8 g) was obtained (yield 68.4%). Active oxygen 4.34% (calculated 5.38%); Mp 154—157 °C; IR ($CHCl_3$) 2950, 1760, 1680, 1600, 1460, 1320, 1280, 1130, 1110, 940, and 880 cm^{-1} ^1H NMR ($CDCl_3$) δ=1.13 (CH_3, 12H, s), 1.57 (CH_2, 4H, s), and 7.36—7.92 (aromatic, 18H, m); ^{13}C NMR ($CDCl_3$) δ=24.2 (CH_3), 32.6 (CH_2), 85.8 (tert C), 127.1, 128.2, 128.6, 129.8, 129.9, 130.0, 132.4, 133.4, 136.6, 141.3 (each Ph C), 164.3 (carbonyl C of peroxy ester), and 196.0 (carbonyl C of benzophenone).

Photodecomposition Products. A 10 ml toluene solution of 0.026 mol dm^{-3} of **6a** was placed in Pyrex tubes (15 mm diameter), degassed by three cycles of freeze-thawing, and sealed under vacuum. The tubes were placed in a merry-go-round around a filtered UV source of 366 nm and the temperature of the tubes was controlled at 25 °C by a water-cooled bath. The light source was a TAIKA 400 W high-pressure mercury lamp combined with a Toshiba UV-D36A filter. The tubes were taken out at different predetermined intervals, and kept frozen in a freezer in the dark until analyses were done. The photolyzed solutions were analyzed by HPLC and compared with the authentic samples. The identification of 2-(*o*-benzoylbenzoyldioxy)-5-hydroxy-2,5-dimethyl-3-hexyne (**10**) was carried out by isolation from the mixture of decomposion products by means of HPLC. The fraction was collected and the removal of solvent in vacuum gave a viscous liquid. The structure was ascertained by means of IR, ^1H NMR and ^{13}C NMR spectroscopy. IR ($CHCl_3$) 2950, 1760, 1670, 1600, 1455, 1320, 1280, 1150, 1130, 1040, 940, 900, and 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.46 (CH_3, 12H, s) and 7.45—7.98 (aromatic, 9H, m); ^{13}C NMR ($CDCl_3$) δ=26.4, 31.0 (CH_3), 79.2, 81.7 (acetylenic C), 64.6, 89.7 (tert C) , 126.9, 128.1 , 128.3, 128.6, 129.9, 130.1, 132.5, 133.7, 136.5, 141.4 (each Ph C), 163.8 (carbonyl C of peroxy ester), and 196.6 (carbonyl C of benzophenone); MS(EI) m/z 366(M^+).

Quantum Yield. A 10 ml benzene solution of **6a** was irradiated at 25 °C. The irradiation conditions were the same as those in the decomposition products study. After irradiation, the remaining amount of peroxide was determined by iodometric titration. A tube containing an actinometric solution (benzophenone (0.1 mol dm^{-3}) and benzhydrol (0.1 mol dm^{-3}) in benzene) was irradiated in parallel with every run and light intensity was determined actinometrically.

Thermal Decomposition. A 10 ml cumene solution of 0. 05 mol dm^{-3} peroxide was placed in a glass ampule. The ampule was purged with nitrogen, sealed, and immersed in a constant-temperature bath regulated ±0.1 °C. At successive time intervals, tubes were removed from the bath and immersed in a Dry Ice–acetone bath. The concentration of peroxide in the solution was then measured by iodometric titration. The reaction was followed up to 75—80% decomposition and exhibited first order kinetics.

Iodometric Titration. 10 ml of a 0.2 mol dm^{-3} KOH–methanol solution was added to the solution of peroxide, then the mixture stood for 5 min in the dark, followed by iodometric titration. The titration procedure involved the use of a mixture (20 : 4 ml) of isopropyl alcohol and acetic acid as the solvent, and saturated potassium iodide aqueous solution as the source of iodine. After boiling for 3 min to liberate the iodide, the iodine was titrated to the end point with 0.01 mol dm^{-3} sodium thiosulfate solution. The values for the observed first-order rate constants and their standard deviations were calculated from the first-order rate equation using the least-squares method. The values for the activation parameters and their standard deviation were calculated from the absolute rate equation of Eying using the least-squares method.

Polymerization Studies. The irradiation of monomer solutions was carried out in degassed sealed Pyrex tubes of 15 mm diameter that were placed in a merry-go-round with a filtered UV source of 366 nm at the center. The light source was the same as that used in the photodecomposition studies. The temperature of the tubes was maintained at 25 °C by a water-cooled bath. The yield of the polymer was measured (below 20% conversion) gravimetrically. The average molecular weight of the purified polymers was determined by GPC.

New ring transformations of 3,5-dinitro-1-(4-nitrophenyl)-4-pyridone and its homologues with hydroxylamine were found to give 4-nitro-5(2*H*)-isoxazolone. These results were rationalized by double ring transformations in sequence. The fact that the 4-position of the 4-pyridone behaved as an electrophlic site was the first example in this series of ring transfomations, and was caused by the alpha-effect of the reagent. Some reactions of the isoxazolone were carried out.

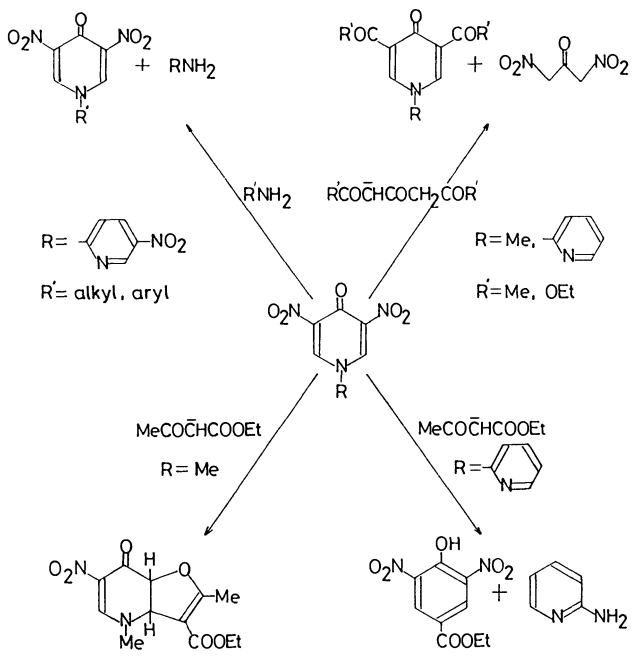
In this series of nucleophilic reactions of elctron-deficient pyridones, we have reported ring transformations of 1-substituted 3,5-dinitro-4-pyridones with either enolate anions or primary amines. Several types of ring transformations were observed depending on the combination of the enolate anion and the 1-substituent of the pyridone used.[2)] Reaction with a primary amine resulted in the exchange of the ring nitrogen moiety of the pyridone with that of the primary amine.[3)] This reaction developed the utility of the 4-pyridone as a protecting group for primary amines. Thus, a variety of amino acids were protected and deprotected by 3,5-dinitro-1-(4-nitrophenyl)-4-pyridone (**1a**) without racemization throughout the sequence.[4)] This replacement of the ring nitrogen moiety was caused by a small difference in the basicity between the primary amine used for the reagent and the liberated one.

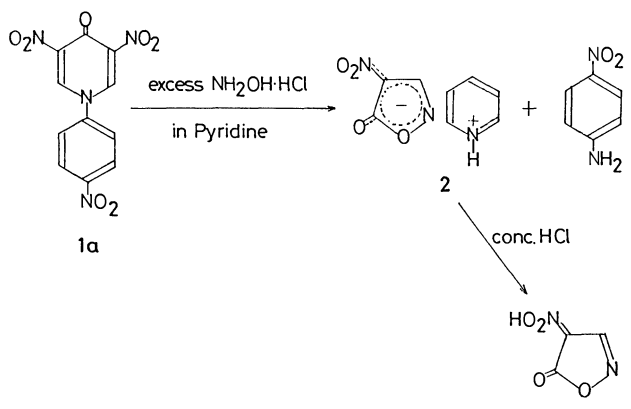
These results prompted us to investigate the behavior of hetero bidentate nucleophilic reagents such as hydroxylamine or hydrazine toward the pyridone. The carbonyl carbon of the pyridone did not act as an electrophilic center in our previous studies of this series, but such ambident reagents were anticipated to attack the carbonyl carbon of the pyridone, because of their strong nucleophilicity caused by the alpha-effect.

In this paper we wish to report a new type of ring transformation of 1-substituted 3,5-dinitro-4-pyridones with hydroxylamine.

Results and Discussion

Reaction of 3,5-dinitro-1-(4-nitrophenyl)-4-pyridone (**1a**) with a twofold excess of hydroxylamine hydrochloride in pyridine occurred smoothly at room temperature. The dark red color of the reaction mixture faded to yellow within an hour, and product (**2**) was obtained as colorless needles together with 4-nitroaniline. Treatment of **2** with concd hydrochloric acid gave a free acid, 4-aci-nitro-5(4*H*)-isoxazolone (**3**), liberating a pyridine molecule. The pyridinium salt of **3** was identical to **2** as confirmed by mixing **3** with pyridine to give **2** quantitatively. The ^{1}H NMR spectrum of **3** showed two singlets at 8.40 and 11.0 ppm; the latter disappeared on addition of D_2O. The broad absorption with its center at about 2300 cm^{-1} (hydrogen bonded O–H) and the strong absorption at 1770 cm^{-1} (C=O) in the IR spectrum





† Present address: Mukogawa Women's University, Ikebiraki-cho, Nishinomiya 663.

suggested that **3** was the aci-nitro form. These spectral characteristics of **3** were very similar to those of 3-methyl-4-aci-nitro-5(4*H*)-isoxazolone as reported by R. Nesi et al.[5]

The structure of **3** was also confirmed by independent synthesis of **3** from the reaction of methyl 2-nitro-3-ethoxypropenoate and hydroxylamine hydrochloride in the presence of pyridine.

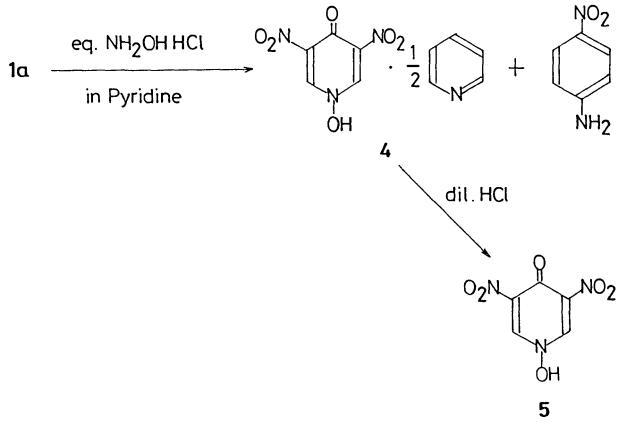
The results apparently showed that the N and O atoms of hydroxylamine attacked at the 2- and 4-positions of the 4-pyridone ring, respectively. Concurrent formation of 4-nitroaniline, however, showed that cleavage of the N(1)–C(2) bond and the N(1)–C(6) bond of the pyridone had occurred. That is, double ring transformations in sequence were suggested to occur, and 2-nitroacetaldehyde oxime must have been produced in addition to **2** and 4-nitroaniline.

The following two reactions were examined from the above viewpoint.

The reaction of **1a** with 1.1 equimolar amounts of the reagent in pyridine yielded the complex of 1-hydroxy-3,5-dinitro-4-pyridone and pyridine in a molar ratio of 2:1 (**4**) as red columns in addition to 4-nitroaniline (Table 1, Entry 2). Product **4** easily gave 1-hydroxy-3,5-dinitro-4-pyridone (**5**) by treating with dil hydrochloric acid, and was regenerated reversibly by treating **5** with pyridine. This fact showed that hydroxylamine acted as a primary amine, and attacked at the 2- and 6-positions of the 4-pyridone to result in exchange of the *N*-substituent moiety of the 4-pyridone as reported in the previous paper.[3]

Treatment of **4** with a slight excess of hydroxylamine hydrochloride in pyridine at room temperature gave **2** in a good yield (Table 1, Entry 3). 2-Nitroacetaldehyde oxime which should supposedly have been derived from the rest of **4** in the ring transformation was not isolated directly under these conditions, but its formation was evidently confirmed by the fact that 2-nitro-2-(phenylhydrazono)acetaldehyde oxime (**6**) was isolated when the filtrate from which **2** had been filtered off was treated with aqueous benzenediazonium chloride. The oxime **6** was independently obtained from authentic 2-nitroacetaldehyde oxime[6] with benzenediazonium chloride.

A provable reaction course matching the above observations may be proposed as follows. Formation of the σ-addut was followed by ring opening to give an intermediate **7**, and the cyclization of **7** with elimination of 4-nitroaniline gave **5**. Pyridone **5** was then easily subject to attack by excess hydroxylamine to give ring-opened intermediate **8**. In the symmetrical intermediate **8**, an intramolecular attack of either oxygen atom of the two hydroxylamino functions at the carbonyl carbon atom lead to 4-aci-nitro-5(4*H*)isoxazolone **3** with liberation of 2-nitroacetaldehyde oxime. Even though either of the more nucleophilic nitrogen atoms of these hydroxylamino groups attacked at the β-position of the nitroolefin part of **8**, the intramolecular reaction resulted in



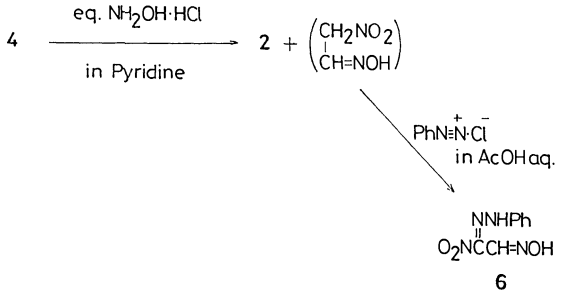


Table 1. Ring Transformations of 1-Substituted 3,5-Dinitro-4-pyridones with Hydroxylamine

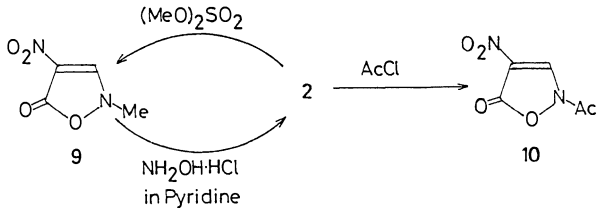
regeneration of **5**.

In order to prove the generality and limitation of the reaction, some 1-substituted 3,5-dinitro-4-pyridones (**1b**, **1c**, and **1d**) were investigated.

The order of reactivity of these pyridones in the ring transformation appeares to be **1a**≈**1b**>**1c**>**1d** from the results of the reactions shown in Table 1. The 1-methyl homologue **1d**, which was the least reactive among the four, however, gave a satisfactory result under modified reaction conditions. These results are reasonably acceptable upon reflection of the electronic effects of the 1-substituent. The electron-releasing effect of the methyl group might have suppressed the reactivity of the pyridone ring. In the case of the reactions of **1a** and **1b**, the color of the reaction mixture turned immediately to dark red when the reactants were mixed, then faded away within an hour. On the other hand, **1c**, and **1d** showed moderate or no evident change in color of the reaction mixture during the reactions. These facts show that the more basic the liberated amine moiety is the smaller the rate of the formation of **5** is. The fact that **2** rather than **4** is obtained as a product with recovery of substrate from the reaction of **1d** with equimolar hydroxylamine (Table 1, Entry 10) contrasts to the result of the reaction of **1a** (Entry 2). The reaction rate of the first step ring transformation of **1a** and **1b** appears to be larger than that of the second step ring transformation, but the rate of **1d** appears to be just the opposite.

Although, 3-methyl[5] and 3-phenyl[7] analogs of **3** have been reported, to our knowledge 3-unsubstituted 4-nitro-5(2*H*)-isoxazolones, **3** and **2**, are unknown compounds. Some reactions of the isoxazolones were carried out to examine their particular chemical properties.

The *N*-methylation of **3** was accomplished by direct treatment of **2** with dimethyl sulfate to give 2-methl-4-nitro-5(2*H*)-isoxazolone (**9**) in a good yield. Acetylation could be performed by heating **2** in excess acetyl chloride at 50 °C to give 2-acetyl-4-nitro-5(2*H*)-isoxazolone (**10**). Reaction of **9** with hydroxylamine hydrochloride in pyridine reproduced **2** quantitatively.



We were able to draw out a new reactivity of the 4-pyridone by the ring transformation with hydroxylamine giving 4-nitro-5(2*H*)-isoxazolone with elimination of the 2-nitroacetaldehyde derivative. The product and its derivatives, especially the *N*-methyl derivative **9**, have a variety of functionalities, such as *β*-nitro enamine, heterodiene and *α*-nitro lactone, in its ring, and are anticipated to demonstrate various types of reactivity including ring transformation. New ring transformations of **9** on the basis of this idea are currently under study.

Experimental

All melting points were measured on a Yanako melting point apparatus and were uncorrected. IR spectra were obtained on a Hitachi 260-10 spectrometer as Nujol mull, and ^{1}H NMR spectra were recorded on a Hitachi R-20B spectrometer with TMS as an internal standard.

Reaction of 3,5-Dinitro-1-(4-nitrophenyl)-4-pyridone (1a) with Excess Hydroxylamine Hydrochloride. Hydroxylamine hydrochloride (0.690 g, 10.0 mmol) was added with stirring by a magnetic stirrer to a solution of **1a** (1.00 g, 3.27 mmol) in pyridine (50 ml). The reaction mixture was allowed to stand at room temperature for 2 h. The pyridine was evaporated under reduced pressure at 35—40 °C, water (50 ml) was added to the residual solid, and the yellow precipitates were collected on a filter to give 4-nitroaniline (0.420 g, 3.04 mmol, 93% yield). The filtrate was concentrated to dryness under reduced pressure. The residual mass was dissolved in ethanol

(20 ml), and the resulting solution was cooled in an ice bath. The crystalline precipitates were collected by filtration to give **2** (0.602 g, 2.88 mmol, 88% yield) as colorless needles (recrystallized from ethanol), mp 136.0—137.0 °C (decomp). IR 2500—1950 (broad) (N–H), 1680 (C=O), 1520, and 1325 cm^{-1} (NO_2). ^1H NMR (DMSO-d_6) δ=8.2 (m, 2H), 8.41 (s, 1H), 9.0 (m, 2H), and 10.4 (broad s, 1H). Found: C, 45.93; H, 3.39; N, 20.20%. Calcd for $C_8H_7N_3O_4$: C, 45.94; H, 3.37; N, 20.09%.

Reaction of 1a with 1.1 Equimolar Amounts of Hydroxylamine Hydrochloride. One gram (3.27 mmol) of **1a** was treated with hydroxylamine hydrochloride (0.250 g, 3.60 mmol) as described above, in this case, the dark red color of the reaction mixture remained during the reaction time. After the solvent was evaporated off, the residual solid was extracted with chloroform. From the extraction, 4-nitroaniline (0.425 g, 3.08 mmol, 94% yield) was obtained. The residual solid was rinsed with a small amount of ethanol to give **4** (0.650 g, 2.70 mmol, 83% yield) as red columns (recrystallized from water), mp 202.0—203.0 °C (decomp). ^1H NMR (DMSO-d_6) δ=7.5 (m, 1H), 7.9 (m, 0.5H), 8.6 (m, 1H), 9.16 (s, 2H), and 9.5 (broad s, 1H). Found: C, 37.16; H, 2.30; N, 20.37%. Calcd for $C_{15}H_{11}N_7O_{12}$: C, 37.43; H, 2.30; N, 20.37%.

Reaction of 4 with Hydroxylamine Hydrochloride. A mixture of **4** (0.500 g, 2.08 mmol) and hydroxylamine hydrochloride (0.175 g, 2.88 mmol) in pyridine (50 ml) was allowed to stand at room temperature for 2 h. The pyridine was evaporated to dryness, ethanol (10 ml) was added to the residue, and the crystalline precipitates were collected on a filter to give **2** (0.350 g, 1.67 mmol, 80% yield). The filtrate was concentrated and the residue was dissolved in water (10 ml), then the resulting aqueous solution was cooled in an ice bath. To the solution was added an aqueous solution of benzenediazonium chloride prepared from aniline (0.250 g, 2.69 mmol) and sodium nitrite (0.220 g, 3.19 mmol) in 1 M (1 M=1 mol dm^{-3}) hydrochloric acid (10 ml) at 0 °C. The precipitates were recrystallized from water to give **5** (0.210 g, 1.01 mmol, 49% yield) as orange needles, mp 186.0—187.0 °C (decomp). ^1H NMR (DMSO-d_6) δ=7.4 (m, 5H), 8.56 (s, 1H), 12.3 (broad s, 1H), and 12.53 (s, 1H). Found: C, 46.72; H, 4.03; N, 27.04%. Calcd for $C_8H_8N_4O_3$: C, 46.15; H, 3.87; N, 25.97%.

Alternate Synthesis of 2. A mixture of methyl 3-ethoxy-2-nitropropenoate[8] (3.50 g, 20.0 mmol), hydroxylamine hydrochloride (1.81 g, 26.0 mmol), and pyridine (5.40 g, 50.6 mmol) in ethanol (75 ml) was heated at 50—60 °C for 2 h. The reaction mixture was cooled in an ice bath, and the crystalline precipitates were collected by filtration giving **2** (3.60 g, 17.2 mmol, 86% yield).

Preparation of 6 from Authentic 2-Nitroacetaldehyde Oxime. A solution of benzenediazonium chloride prepared just as described above was added to a solution of 2-nitroacetaldehyde oxime (0.200 g, 1.92 mmol) in 1 M hydrochloric acid (10 ml) at 0 °C. Yellow precipitates were recrystallized from water to give **6** (0.220 g, 1.06 mmol, 55% yield).

4-Aci-nitro-5(4*H*)-isoxazolone (3). A mixture of **2** (1.00 g, 4.78 mmol) in concd hydrochloric acid (10 ml) was heated at 50—60 °C until **2** dissolved, and then cooled in an ice bath. The precipitates were collected by filtration, rinsed with a small amount of cold water and then with diethyl ether, and were dried in a desiccator over sodium hydroxide to give **3** (0.510 g, 3.92 mmol, 82% yield) as colorless needles, mp 145.0—146.0 °C. IR 2600 (broad) (O–H) and 1700 cm^{-1} (C=O). ^1H NMR (DMSO-d_6) δ=8.40 (s, 1H) and 11.0 (s, 1H). Found: C, 27.86; H, 1.65; N, 21.33%. Calcd for $C_3H_2N_2O_4$: C, 27.70; H, 1.55; N, 21.54%.

Reaction of 1b, 1c, and 1d with Hydroxylamine Hydrochloride. One gram of 4-pyridone was treated with 3 equimolar amounts of hydroxylamine hydrochloride under the conditions shown in Table 1 according to the reaction of **1a**. The solvent was evaporated off, and the residual solid was treated with a small amount of benzene. After removal of the benzene by decantation, the residual mass was extracted with hot chloroform (30 ml×3). The combined extractions were evaporated and the residual solid was rinsed with a small portion of ethanol to give **3**.

2-Methyl-4-nitro-5(2*H*)-isoxazolone (9). A mixture of **2** (1.00 g, 4.78 mmol) and dimethyl sulfate (0.900, 7.14 mmol) was gently heated at 50—60 °C for 100 m. Water (10 ml) was added to the cold reaction mixture, and the precipitates were collected by filtration then rinsed with a small amount of cold ethanol to give **6** (0.585 g, 4.06 mmol, 85% yield) as colorless needles (recrystallized from etrhanol), mp 136.0—137.0 °C (decomp). IR 1775 (C=O), 1615 (C=N), 1510, and 1375 cm^{-1} (NO_2). ^1H NMR (DMSO-d_6) δ=3.79 (s, 3H), and 9.63 (s, 1H). Found: C, 33.44; H, 2.87; N, 19.45%. Calcd for $C_4H_4N_2O_4$: C, 33.44; H, 2.80; N, 19.44%.

2-Acetyl-4-nitro-5(2*H*)-isoxazolone (10). A mixture of **2** (0.500 g, 2.39 mmol) and acetyl chloride (3.0 g, 38.2 mmol) was heated at 50 °C for 30 min. After the acetyl chloride was evaporated, crushed ice (2 9) was added to the residue, and the crystalline precipitates were collected on filter and rinsed with a small amount of cold water to give **10**, (0.281 g, 1.50 mmol, 63% yield), mp 132.0—134.0 °C (decomp). IR 1810 (C=O), 1760 (C=O), 1570, and 1350 cm^{-1} (NO_2). ^1H NMR (DMSO-d_6) δ=1.91 (s, 3H) and 8.43 (s, 1H). Found: C, 35.09; H, 2.41; N, 16.50%. Calcd for $C_5H_4N_2O_5$: C, 34.89; H, 2.34; N, 16.28%.

Reaction of 9 with Hydroxylamine Hydrochloride. A mixture of **9** (0.500 g, 3.47 mmol) and hydroxylamine hydrochloride (0.290 g, 4.17 mmol) in pyridine (20 ml) was heated at 50 °C for 1 h. After the solvent was evaporated in vacuo, ethanol (10 ml) was added to the residue, and the crystalline precipitates were collected by filtration to give **3** (0.690 g, 3.30 mmol, 95% yield).

(Received May 30, 1991)

X-Ray crystal structure data are presented for potassium, rubidium, and cesium salts (**2**, **3**, and **4**) of 2-[[2-[2-[2-[2-[2-[2-[2-(2-hydroxyethoxy)phenoxy]ethoxy]phenoxy]ethoxy]phenoxy]ethoxy]phenoxy]methyl]benzoic acid (**1**). The crystals of the potassium salt (**2**) monohydrate dichloroform solvate ($2 \cdot H_2O \cdot 2CHCl_3$) are triclinic, space group $P\bar{1}$ with two molecules in the unit cell dimensions a=14.517(1), b=16.380(1), c=13.315(1) Å, α=72.313(8)°, β=117.313(8)°, γ=120.853(5)°. R=0.102 for 6351 observed reflections. The crystals of $3 \cdot H_2O \cdot CHCl_3$ are monoclinic, space group $P2_1/a$ with four molecules in the unit cell dimensions a=24.085(6), b=13.068(2), c=13.983(4) Å, β=105.402(32)°. R=0.068 for 5112 observed reflections. The crystals of $4 \cdot H_2O \cdot CHCl_3$ are monoclinic, space group $P2_1/n$ with four molecules in the unit cell dimensions a=24.412(7), b=13.075(2), c=14.077(4) Å, β=106.743(31)°. R=0.071 for 6153 observed reflections. The backbones of **2**, **3**, and **4** form pseudocycles by head-to-tail hydrogen bonding between the terminal carboxylato and hydroxyl groups (O···O distance, 2.672, 2.699, and 2.706 Å, respectively). The conformations about C–C and C–O bonds are gauche and trans respectively, except for two of the C–O bonds which are gauche to make the pseudocyclic backbone bend like the seam of a tennis ball resulting in the formation of cavities fitted for the size of each cation.

Naturally occurring carboxylic ionophores such as monensin and nigericin, which contain a terminal carboxyl group, one or two hydroxyl groups at the other end, and several ether oxygens provided by tetrahydrofuran and tetrahydropyran rings, mediate transport of ions across biological and artificial membranes.[2] They have been studied as antibiotics[3] and have provided an experimental tool for investigating the roles of transmembrane gradients of ions in regulating biological phenomena.[4] Complexation of an ionized ionophore with cations is capable of transporting the cations across membranes and each of the ionophores has a different specificity for various cations.

To understand the complexation properties of the ion carrier, single crystal X-ray structures of various complexes have been analyzed.[5] The conformation of silver salt of monensin in crystal form was first reported in which the monensin anion is held by the head-to-tail hydrogen bondings between the carboxylato group and the two hydroxyl functions of the terminal tetrahydropyran ring to wrap the cation in the cavity.[6] The sodium salts in anhydrous and hydrate crystal forms are nearly identical with one another, and with that of the silver salt complex. However, the structures of the complexes are somewhat different from that of the free acid in terms of the carboxylic acid conformation, the head-to-tail hydrogen bonding, and the conformation of one of the tetrahydrofuran rings.[7,8] Analogous conformations are also found in carboxylic ionophores with the backbones of 21—24 atoms and their complexes.[5,9] The pseudocyclic framework of the ionophores through head-to-tail hydrogen bonding may be called a 'ring' conformation.

However, in the molecular structures of X206 with 28-atoms backbone and its complexes as well as the methyl-substituted analogue (alborixin), the backbone is similar to that of the seam of a tennis ball rather than a ring conformation.[10] Since the backbone of X206 is much longer and more flexible by lack of sterically rigid spiro ring than those of short-chain carboxylic ionophores such as monensin, the pseudocyclic molecule with head-to-tail hydrogen bonding adopts such a 'seam' conformation to form a hydrophobic surface. A ring conformation of monensin and its complexes by head-to-tail hydrogen bonding is rather flat, but enough to form the lipophilic surface of the ionophore molecules. It appears that lipophilicity of the exterior of the complexes with a 'ring or seam' conformation enables these ionophores to transport ions through hydrophobic membranes.

A similar conformation was observed in K^+ complex of a crown ether, dibenzo-30-crown-10.[11] Typical crown ethers with smaller ring sizes have a cavity fitted for coordinated cations in a 'ring' conformation. In this case, however, the cavity size of a 'ring' conformation is too large to be wrapped round potassium ion, but a 'seam' conformation by hinge of the crown ether backbone at two sites form a cavity adjusted for size of

potassium cation resulting in a spherically lipophilic surface of the potassium complex.

We have synthesized a series of linear polyether compounds containing a carboxyl and a hydroxyl groups at one and the other ends as analogues to naturally occurring carboxylic ionophores. Transport of alkali and alkaline earth metal ions mediated by these synthetic ionophores through organic liquid membranes were investigated in terms of effect of the ionophore structures on the ion transport ability and selectivity.[1,12] It was found that the presence of the hydroxyl group, the relative position of the carboxyl group, the number of the ether oxygens, and the hydrophobicity influenced the ion transport ability and selectivity. Among the synthetic carboxylic ionophores, 2-[[2-[2-[2-[2-[2-[2-[2-(2-hydroxyethoxy)phenoxy]ethoxy]phenoxy]ethoxy]-phenoxy]ethoxy]phenoxy]methyl]benzoic acid (**1**) exhibited the highest selectivity for K^+ over Na^+.[13] The backbone of **1** consists of 30 atoms and the length is similar to that of a flexible ionophore (X206) rather than a rigid ionophore (monensin). However, no tetrahydrofuran or tetrahydropyran ring contains in the synthetic ionophore, and instead the molecule is composed of repeating units derived from catechol and ethylene glycol, which largely differs from those of natural ionophores. Therefore, conformations about C–C and C–O bonds are freely rotated except for O–C–C–O of catechol ring. Furthermore, since **1** has neither methyl substituent for aromatic or aliphatic carbon nor hydroxyl group in the backbone, the flexibility is probably higher than that of X206. In fact, the ^{1}H NMR spectra of **1** and the sodium salt show that chemically equivalent protons have the identical chemical shifts one another because of a rapid interconversion between many conformers on the NMR time scale.[13] In contrast, the separation of the chemically equivalent proton resonances was observed in the ^{1}H NMR spectra of the potassium salt (**2**),[13] and the assignments of the signals by two-dimensional NMR methods and the analysis of the proton–proton vicinal coupling constants enabled us to estimate the existing conformations in solution with the highly lipophilic exterior of **2** among many accessible conformations.[14]

Our preliminary X-ray analysis of the potassium salt of **1**, **2**, reveals that the backbone has a conformation similar to those of X206 and the salts, and K^+-alborixin.[15] In this paper we describe the structures of the potassium, rubidium, cesium salts (**2**, **3**, **4**) of the

synthetic carboxylic ionophore (**1**) determined by X-ray crystallography. This study will give us very important information on how a host molecule utilizes local conformational changes to rearrange coordination sites for optimum complexation with a guest cation.

Experimental

Synthesis of carboxylic ionophore (**1**) and the potassium salt (**2**) has been previously described.[13,15] The corresponding rubidium and cesium salts (**3** and **4**) were prepared in a similar manner to that for **2**. Colorless parallelepiped crystals of $2 \cdot H_2O \cdot 2CHCl_3$, $3 \cdot H_2O \cdot CHCl_3$, and $4 \cdot H_2O \cdot CHCl_3$ were obtained from chloroform solutions and sealed in a glass capillary with a drop of chloroform. Crystal data, experimental conditions, refinement details of $2 \cdot H_2O \cdot 2CHCl_3$, $3 \cdot H_2O \cdot CHCl_3$, and $4 \cdot H_2O \cdot CHCl_3$ are shown in Table 1. Intensities of $2 \cdot H_2O \cdot 2CHCl_3$ and $4 \cdot H_2O \cdot CHCl_3$ were collected on a Rigaku AFC-4 four-circle diffractometer; graphite monochromater, Cu $K\alpha$ radiation (45 kV, 25 mA, λ=1.54184 Å) and Mo $K\alpha$ radiation (40 kV, 20 mA, λ=0.71073 Å), respectively. Intensities of $3 \cdot H_2O \cdot CHCl_3$ were collected on a Rigaku off centered four-circle diffractometer; graphite monochorometer, Mo $K\alpha$ radiation (50 kV, 150 mA, λ=0.71073 Å). Cell parameters were obtained by least-squares method. Intensities were measured by using 2θ–ω scan technique. Stationary background counts were accumulated for 5 s before and after each scan. Three standard reflections were monitored every 50 reflections. The intensities of $2 \cdot H_2O \cdot 2CHCl_3$ were not changed significantly, but those of $3 \cdot H_2O \cdot 2CHCl_3$ and $4 \cdot H_2O \cdot CHCl_3$ gradually decreased to 90% compared with their initial values. Corrections were made for Lorentz and polarization, while absorption and extinction were ignored.

The structures were solved by the direct method using the program (MULTAN 78)[16] and subsequent difference Fourier calculation. Refinements were performed by block-matrix least-squares with the program SHELX 76[17] (and block-diagonal least-squares with the program HBLS[18] for $2 \cdot H_2O \cdot 2CHCl_3$). One of the two independent chloroform molecules in $2 \cdot H_2O \cdot 2CHCl_3$ revealed highly disordered structure. Several peaks on the difference map were assigned to the Cl atoms with appropriate occupancy factors. The difference maps of $3 \cdot H_2O \cdot CHCl_3$ and $4 \cdot H_2O \cdot CHCl_3$ showed that the Cl atoms of the chloroform molecule were highly dis-

a) $B_{eq}=\frac{8}{3}\pi^2\sum_i\sum_j U_{ij}a_i^*a_j^*\boldsymbol{a}_i\cdot\boldsymbol{a}_j$.

ordered All the non-hydrogen atoms except those of the disordered chloroform molecule were refined with anisotropic thermal parameter. Some hydrogen atoms found on difference Fourier maps and the others derived geometrically (C–H 1.08 Å) were refined isotropically. The quantity minimized was $\sum w(|F_o|-|F_c|)^2$ with $w=(\sigma(|F_o|)^2+0.004|F_o|)^{-1}$. Atomic scattering factors were taken from International Tables for X-ray Crystallography.[19] Calculations were carried out on HITAC M-680 computer at the Computer Center of the University of Tokyo.

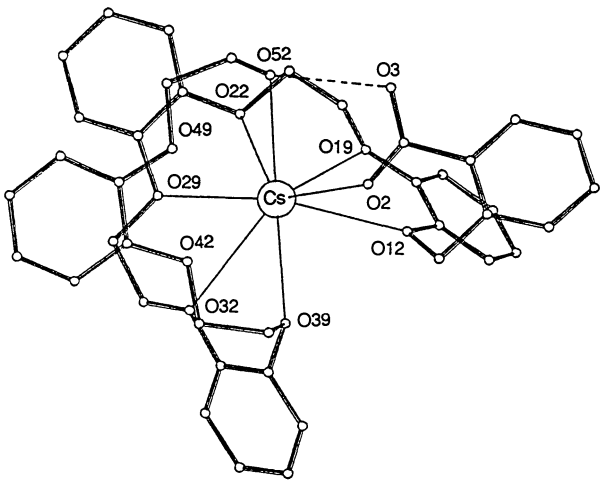

Fig. 3. Molecular structure of **4**. The O(42) has any bond with the Cs ion.

Results and Discussion

Tables 2—4 list the final atomic coordinates and equivalent isotopic thermal parameters of **2**, **3**, and **4**.[20] Molecular structures of **2**, **3**, and **4** are shown in Figs. 1, 2, and 3, respectively. Bond lengths, bond angles, and torsional angles are given in Tables 5, 6, and 7, respectively. They agree well with the usually observed corresponding parameters. In each complex, the intramolecular hydrogen bonding between the carboxylato group and the hydroxyl group at the other end of the molecule produces a pseudocyclic conformation as observed in naturally occurring carboxylic ionophores. The O···O distances are 2.672, 2.699, and 2.706 Å, respectively. As shown in Table 7, the conformations about the aliphatic C–C bonds are gauche with alternate signs through the backbone. Most of the torsion angles about the C–O bonds are close to 180°, whereas both the C(11)–O(12) and O(12)–C(13) bonds and the C(38)–O(39) and O(39)–C(40) bonds have gauche conformations, which play a role of hinges in turning the backbone abruptly. The head-to-tail hydrogen bonding and the torsional angles resulted in the molecular conformation with a thirty-one-membered pseudocycle like the seam of a tennis ball and the ligand wrapped round the potassium ion.

Similar structures with a 29-membered ring through a head-to-tail hydrogen bond are observed in X206, the Na^+ and Ag^+ complexes, and K^+ complex of alborixin.[10] The O···O distances of the hydrogen bonds are 2.91, 2.86, 2.74, and 2.66 Å, respectively. In addition, two other intramolecular hydrogen bonds exist in X206 and the derivatives. These three intramolecular bonds must play a role in the stabilization of the observed structures for the free acid as well as the complexes. In contrast, our synthetic ionophore has a single intramolecular hydrogen bonding. Since a single crystal of **1** has not been obtained so far, the conformation of **1** in the crystal is not known. The free acid may adopt a stable conformation largely different from that of the K^+ complex. X-Ray structure analysis of a crown ether with a thirty-membered ring (dibenzo-30-crown-10) and the complex with KI was reported.[11] Four of the C–C–O–C angles change trans in the free molecule to gauche in the complex. The gauche conformation provides the complex with a structure like the seam of a tennis ball, whereas the free molecule has a rather flat conformation. It appears that the flat conformation of the crown ether is more stable than the 'tennis ball' structure, and coordination of the ether oxygens to the potassium ion in the complex contributes the stabilization of the complex structure.

The overall conformation of **2**, **3**, and **4** is similar to each other as described above, but the cavity size changes by altering the backbone conformation to accommodate the cations with different diameters. Although the difference in bond lengths and angles of **2**, **3**, and **4** is not much as shown in Tables 5 and 6, the torsional angles of the ionophore backbones are significantly different among the three. Compared with the torsional angles about the aliphatic C–C bonds with gauche conformations, the absolute values of **2** are smaller than those of **3** and **4**, except for the case of O(29)–C(30)–C(31)–O(32). Most of dihedral angles about aromatic carbon and oxygen bonds are −6°—+8° except for C(11)–O(12)–C(13)–C(14) and C(37)–C(38)–O(39)–C(40). In the case of C(11)–O(12)–C(13)–C(14), the angle of **2** is larger than those of **3** and **4**. Among aliphatic carbon and oxygen bonds, C(10)–O(11)–C(12)–C(13) and C(38)–C(39)–O(40)–C(41) are gauche. The torsional angle about C(38)–C(39)–O(40)–C(41) of **2** (−98°) is larger than those of **3** and **4**. There is less difference between torsional angles of **3** and **4**. The sum of these conformational changes leads to the different distances between O(12) and O(39), 3.040 Å for **2**, 3.708 Å for **3**, and 4.235 Å for **4**, and to the variety of cavity sizes.

Distances between the ionophore oxygens and the cations are shown in Table 8. With the size of the cations ($K^+ < Rb^+ < Cs^+$), the distance becomes large. The oxygen of terminal hydroxyl group and one of the oxygens of carboxyl group at the other end are close to the cations, but another carboxyl oxygen which has the head-to-tail hydrogen bonding to the terminal hydroxyl group is too distant from the cation to coordinate with them. In addition, two ether oxygens at the hinges have short distances to the cation. Among the two terminal and two internal oxygens of the potassium salt, **2**, the closest oxygen to the potassium is O(39) at the hinge, and then the terminal two oxygens are close and O(12) at the other hinge is furthest. In the case of **3**, the

ether and terminal hydroxyl oxygens of O(39) and O(52) are closer to the rubidium than O(2) and O(12). The distance from the oxygens to the cesium of **4** increases in the order of O(52)<O(39)<O(12)<O(2). Most of the other oxygens far from the cation are also thought to coordinate with the cations.

The crystal radii (CR) which were calculated and tabulated by Shannon based on the many results of X-ray crystal structure analysis, increase with increasing

coordination number.[21] Values of CR plus van der Waals radius of oxygen (1.4 Å) could be considered as a criterion of the largest coordination distance of oxygen to cation (CD). The CD values of potassium, rubidium, and cesium ions for respective coordination number are illustrated in Table 9. M–O distances of the ionophore complexes in Table 8 are compared with the CD values. The compound, **2**, appears to have ten oxygen donor atoms for the potassium, although the distance between O(42) and K (3.156 Å) is slightly larger than the CD (3.13 Å). Only O(3) (K–O distance 3.760 Å) has no interaction with the potassium as described above. In contrast, the coordination number of **3** is nine: The ninth O(49) is nearly on the coordination sphere of Rb^+, but the distance of 3.330 Å between O(42) and rubidium is larger than the CD of 3.20 Å for ten coordination numbers. Nine oxygen atoms of **4** are also donors for the cesium ion in which the distances between the oxygens and cesium are in the range 3.006 to 3.330 Å. Rubidium and cesium cations of **3** and **4** are nonacoordinated to the oxygens except for O(42) and O(3). These results indicate that the potassium ion of **2** is more stabilized than the rubidium and cesium ions of **3** and **4**, which is consistent with the selectivity of ion transport by **1** as described above.

Compared with a centrosymmetric complex of dibenzo-30-crown-10 with KI that has a 'seam' conformation with ten K–O distances in the range 2.850(6)—2.931(6) Å,[11] the complex structure of **2** as well as **3** and **4** may be a relatively loose arrangement. However, the complex structure of **2** seems to be as stable as that of alborixin-K^+ with another 'seam' conformation in which the eight oxygens from one carboxyl and four hydroxyl groups, and three ether linkages coordinate with the potassium with the distances of 2.70—3.06 Å, while there is no interaction of the other six oxygens with the cation.[10c,d]

The crystal packing of the complex, **2**, is shown in Fig. 4. The molecules of **2** are stacked on (010) plane to generate a layer structure. Two chloroform molecules and one water per one of **2** occupy the interlayer space. One of the two nonequivalent chloroform molecules is highly disordered in a column along the *c*-axis. Crystal structures of **3** and **4** are shown in Figs. 5 and 6. Different from **2**, both of **3** and **4** contain one water and one chloroform molecules which are present between

the layer structure formed by the salts. The chloroform molecules are disordered in the interlayer as observed in **2**. These crystal structures with weak interaction between the ionophore molecules of **2**, **3**, and **4** suggest that the alkali metal salts of **1** have stable conformations in chloroform solution similar to those in the crystal.

On the basis of the conformation in the crystal, solution conformations of **2**—**4** by means of NMR spectroscopy are investigated and will be reported in near future.

Reactions of 1,1-Disubstituted Alkenes with Acetoacetamides and Molecular Oxygen in the Presence of Manganese(III) Acetate

Chang-Yi QIAN, Hiroshi NISHINO, and Kazu KUROSAWA*
Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami 2-39-1, Kumamoto 860
(Received June 7, 1991)

The reactions of 1,1-disubstituted ethenes with acetoacetamide or *N*-substituted acetoacetamides, and molecular oxygen in the presence of manganese(III) acetate gave a mixture of *c*-4- and *t*-4-carbamoyl-3-methyl-1,2-dioxan-*r*-3-ols in good yields. Effects of substituents in the alkenes as well as in the carbamoyl group in the acetoacetamides were observed. Stereochemistry and the reactivity of the 4-carbamoyl-3-methyl-1,2-dioxan-3-ols are discussed.

A number of cyclic peroxides having a 1,2-dioxane ring system have been isolated from natural sources and have some biological activities.[1] We recently reported that the manganese(III)-based oxidative free-radical cyclization of alkenes with 1,3-dicarbonyl compounds and molecular oxygen produced 4-acyl-1,2-dioxan-3-ols in moderate to good yields.[2] Since the reaction is extremely facile for the synthesis of 1,2-dioxan-3-ols and the products may have some biological activities, we have investigated the reaction of alkenes with acetoacetamides in the presence of manganese(III) acetate (abbreviated [$Mn(OAc)_3$]) and molecular oxygen (O_2).

Results and Discussion

The reactions were carried out at various molar ratios of alkene : acetoacetamide : [$Mn(OAc)_3$]. When a mixture of 1,1-diphenylethene (**1a**), *N*-(4-methylphenyl)-acetoacetamide (**2a**), and [$Mn(OAc)_3$] was stirred in acetic acid under a current of dried air at 23 °C, the product was found to be 4-(4-methylphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (**3aa**). The structure of **3aa** was elucidated by ^1H and ^{13}C NMR, IR spectra, and elemental analysis (Fig. 1). The maximum yield for **3aa** was attained from the reaction with a molar ratio of 1 : 3 : 1 (Table 1, Entry 3). The yield of **3aa** decreased when the reaction was carried out using a small volume of acetic acid (Entry 5). The reaction under an atmosphere of O_2 gave a slightly decreased yield (Entry 6). The reaction under an atmosphere of argon gave 3-(4-methylphenylcarbamoyl)-2-methyl-5,5-diphenyl-4,5-dihydrofuran (**4aa**) along with a large amount of unchanged alkene (Entry 7). The reactions at a slightly higher or lower temperature resulted in decreased yields of **3aa** (Entries 8, 9). Benzophenone was formed in the reaction at a higher temperature. Addition of water and the use of propanoic acid as a solvent also lowered the yield (Entries 10, 12), but the reactions in the presence of acetic anhydride and potassium acetate gave **3aa** in good yields (Entries 13, 14). Other metal acetates, such as Co(II), Co(III), Mn(II), Cu(II), Ni(II), Tl(III), Pb(IV), and $FeCl_3$ were used and it was found that similar reactions at 23 °C for 12—14 h in the presence of Co(II), Co(III), or Mn(II) did yield 4-

a) The reactions were carried out in acetic acid at a 1:3:1 molar ratio for alkene: acetoacetamide: $[Mn(OAc)_3]$ at 23 °C under a current of air. b) Isolated yield (calculated on the basis of alkene used).

(4-methylphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (**3aa**) (Co(II), 60% yield; Co(III), 66% yield; Mn(II), 92% yield). It was thus shown that Mn(II) was as effective as Mn(III).

The reactions of 1,1-bis(4-methylphenyl)ethene (**1b**), 1,1-bis(4-fluorophenyl)ethene (**1c**), 1,1-bis(4-chloro-

phenyl)ethene (**1d**), 1,1-(4-methoxyphenyl)ethene (**1e**), and 2-ethyl-1-butene (**1f**) using acetoacetamide (**2h**) and various *N*-substituted acetoacetamides: *N*-phenyl- (**2b**), *N*-(4-methoxyphenyl)- (**2c**), *N*-(2-methoxyphenyl)- (**2d**), *N*-(2-methylphenyl)- (**2e**), *N*-(4-chlorophenyl)- (**2f**), *N*-(2-chlorophenyl)- (**2g**), *N*-methyl-(**2i**), *N,N*-dimethyl- (**2j**) and *N,N*-diethylacetoacetamide (**2k**), and *N*-(1,3-dioxobutyl)morpholine (**2l**) were then examined. The reactions were carried out in acetic acid with [$Mn(OAc)_3$] at a molar ratio of 1 : 3 : 1 at 23 °C under an air stream. The results are listed in Table 2. 1,1-Diphenylethenes (**1a**—**e**) always gave 4-carbamoyl-3-methyl-1,2-dioxan-3-ols in excellent yields, whereas 2-ethyl-1-butene (**1f**) yielded the corresponding 4-carbamoyl-3-methyl-1,2-dioxan-3-ols in a slightly lower yield (Entries 39, 40). (*E*)-1,2-Diphenylethene and triphenylethene were not reactive.

Structural Assignments. Contrary to the reactions of the 1,3-diketones which gave a single stereoisomer,[2] the reaction of acetoacetamides yielded a mixture of two stereoisomers. When recrystallized **3ab** was dissolved in DMSO-d_6 for measurement of the ^{1}H NMR spectra, two methyl proton signals appeared at δ=1.27 and 1.53. The intensity of the methyl signal at the lower field gradually increased, while that of the methyl signal at the higher field decreased. The change in the intensities was followed at intervals and it was found that the mixture reached equilibrium after 12 h at room temperature. Thus, each isomer ratio (shown in Table 2) was determined from the intensities of the two methyl signals in the ^{1}H NMR spectrum at 12 h after preparing the solution. The ^{13}C NMR spectrum in DMSO-d_6 exhibited a pair of carbon signals: carbonyl carbons at δ=168.879 and 168.640, carbons attached to two oxygens at δ=101.885 and 98.185, carbons attached to one oxygen at δ=84.894 and 84.416, methine carbons at δ=48.212 and 47.391, methylene carbons at δ=34.234 and 30.624, and methyl carbons at δ=24.239 and 20.063. The assignments were based on their DEPT-135 and -90 spectra. The methyl ^{1}H signals at δ=1.27 and 1.53 were correlated to the methyl carbon signals at δ=24.239 and 20.063, respectively, by measuring a H,C COSY spectrum. The difference of the chemical shifts for the methyl signals in the ^{13}C NMR spectrum would indicate the different conformations of these methyl groups at the C-3 position in a 1,2-dioxane ring, that is, axial and equatorial methyl groups. In order to clarify the matter, methyl and acetyl derivatives of **3ab** were prepared and their ^{13}C NMR spectra were analyzed (Table 3). Treatment of **3ab** with dimethyl sulfate and potassium carbonate in refluxing acetone yielded two isomeric methyl derivatives, **5ab** (49%) and **5ab′** (35%) which were separated on a silica-gel column. It was the methyl carbon at the C-3 position that showed a larger chemical-shift difference than others in the ^{13}C NMR spectrum, and it appeared at δ=18.918 for **5ab** and δ=14.545 for **5ab′** (Table 3). It has been assigned that the methyl carbon with the higher field shift had an axial conformation, and the one with the lower field shift had an equatorial conformation.[3] A $-CH_2-CH<$ unit in **5ab** and **5ab′** was shown as an ABX and an AB_2 spin system, respectively, in the 400 MHz ^{1}H NMR spectra. Since both spin systems had large J values: J_{AB}=13.20, J_{AX}=14.83, J_{BX}=4.57 Hz for **5ab** and J_{AB}=13.9 Hz for **5ab′**, H-4 shoud have had a large J value as an axial hydrogen. It followed that both carbamoyl groups at C-4 in **5ab** and **5ab′** could be assigned as equatorial. Thus, the structures of **5ab** and **5ab′** were shown to be *c*-4-(phenylcarbamoyl)-*r*-3-methoxy-3-methyl-6,6-diphenyl-1,2-dioxane and *t*-4-(phenylcarbamoyl)-*r*-3-methoxy-3-methyl-6,6-diphenyl-1,2-dioxane, respectively (Fig. 1).

A similar situation existed for the acetates of **3ab**, which again consisted of two isomers, **6ab**, (54%) and **6ab′** (21%). The methyl carbon at C-3 appeared at δ=21.332 for **6ab** and δ=17.424 for **6ab′** (Table 3). Therefore, the structures of *c*-4-(phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol acetate and *t*-4-(phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol acetate could be assigned to **6ab** and **6ab′**, respectively.

It was thus shown that 4-(phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ols (**3ab**) exist as an equilibrium mixture of two epimers at the C-3 position. This made quite a contrast with the 4-acetyl-3-methyl-1,2-dioxan-3-ols which were shown to exist as a single stereoisomer having an axial hydroxyl group.[2] It seems possible that hydrogen bonds can be formed

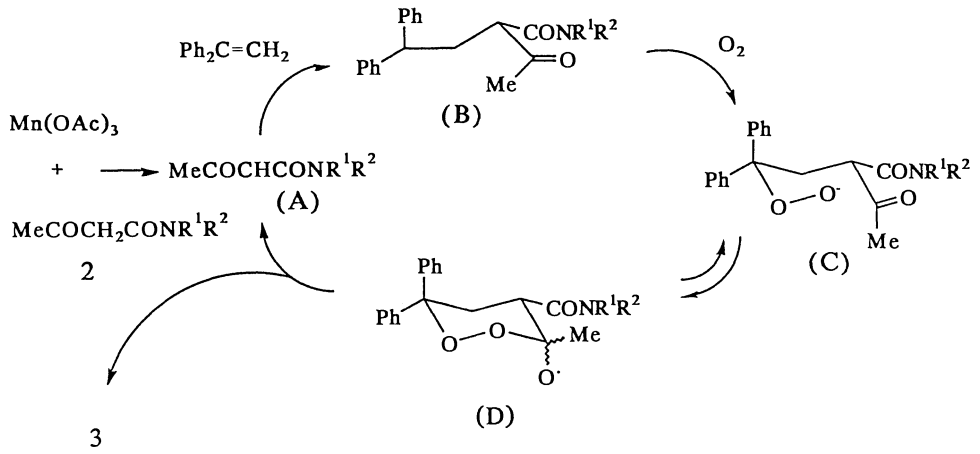


Scheme 1. The reaction mechanisms.

between the hydroxyl and carbamoyl groups in **3ab** irrespective of the conformation of the hydroxyl group, either axial or equatorial, and this could make the stability of the epimers comparable. **3ab** exhibited carbonyl absorption at ν 1657 which was compared with **5ab** (ν 1664), **5ab'** (ν 1692), **6ab** (ν 1665), and **6ab'** (ν 1690) (Table 3). This indicated the presence of hydrogen bonding between the hydroxyl and carbamoyl groups in **3ab**. On the other hand, the hydrogen bonding between the hydroxyl group and the carbonyl function in 4-acetyl-3-methyl-1,2-dioxan-3-ols may be weak, since the carbonyl absorption of this compound appeared at ν 1696 while that of the acetate appeared at ν 1701.[2] Therefore, the conformation of the hydroxyl group in 4-acetyl-3-methyl-1,2-dioxan-3-ol would be controlled mainly by an anomeric effect.[4]

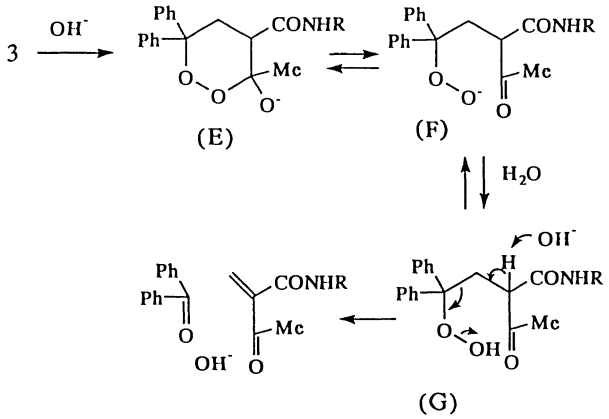
Reactions of 3aa. Compound **3aa** was hydrogenated in the presence of palladium on charcoal as catalyst in ethanol to give 3-(4-methylphenylcarbamoyl)-2-methyl-5,5-diphenyl-tetrahydro-2-furanol (**7aa**), while hydrogenation in acetic acid yielded **4aa**, which was identical with that obtained in the manganese(III) acetate oxidation under an atmosphere of argon. On heating in acetic acid, **7aa** gave **4aa**. Treatment of **3aa** with aqueous potassium hydroxide solution yielded benzophenone in a moderate yield.

Reaction Mechanisms for the Formation of Compounds 3. The reaction could be accounted for in terms of a radical reaction initiated by the acetylcarbamoylmethyl radical (**A**), $\cdot CH(COCH_3)CONR^1R^2$, that was formed either by the interaction of $[Mn(OAc)_3]$ with acetoacetamide (**2**) or by the reaction of **2** with a carboxymethyl radical, $\cdot CH_2CO_2H$, which could be produced by the thermal decomposition[5] of $[Mn(OAc)_3]$. However, it seemed unlikely that the carboxymethyl radical would be formed at room temperature. Although we have not succeeded in obtaining a stable Mn(III)–acetoacetamide complex, the radical **A** could be produced by the interaction of **2** with $[Mn(OAc)_3]$. In fact, the radical **A** was trapped with xanthene to give *N*-phenyl-2-(9-xanthenyl)acetoacetamide (**8**) as in the reaction of malonamide.[6] The radical **A** attacked an alkene forming a stable tertiary carbon radical (**B**) which reacted with molecular oxygen to form a peroxyl radical (**C**), and then the alkoxyl radical (**D**), and finally gave **3** (Scheme 1). The reaction of **B** under an atmosphere of argon or reaction at an elevated temperature yielded the dihydrofuran (**4ab**).

Benzophenone was obtained in a reaction at a slightly higher temperature. The reaction of **1a** with $[Mn(OAc)_3]$ in the absence of acetoacetamide yielded 2,2-diphenyl-2-hydroxyethyl acetate (**9**) (4% yield) and benzophenone (7% yield). Thus, the formation of benzophenone could be envisaged as follows:

$$Ph_2C{=}CH_2 \xrightarrow[AcOH]{Mn(III)} Ph_2C(OH)CH_2OAc \xrightarrow{Mn(III)} Ph_2C{=}O$$
9

Alkaline degradation of **3aa** yielded benzophenone and a polymeric product which exhibited a broad multiplet at δ=3.7 together with other signals at δ=7.3 and 2.2. This could be explained as follows: a hydroxide ion attacked the proton on the $C_{(3)}$–OH to give an alkoxide anion (**E**), in which the 1,2-dioxane ring was



Scheme 2. R=4-methylphenyl.

opened to yield a peroxide anion (**F**). Abstraction of a proton from a solvent molecule and further decomposition of **G** yielded benzophenone and an acrylamide. The latter could not be isolated probably because of polymerization (Scheme 2).

It could thus be concluded that the facile radical reaction of an acetylcarbamoylmethyl radical with an alkene and molecular oxygen yielded a mixture of *c*-4- and *t*-4-carbamoyl-3-methyl-1,2-dioxan-*r*-3-ols (**3**) in excellent yields, although the electro-initiated formation of cyclic peroxide was reported.[7] The latter reaction seemed to be limited to the 1,3-dicarbonyl compounds which could produce only tertiary carbon radicals. Our reaction, on the other hand, has been successful with active methylenes as well as active methine compounds having an acyl and a carbamoyl group. This can be utilized in organic syntheses.

Experimental

Measurements. All the ^1H and ^{13}C NMR spectra were taken either with JNM PMX-60SI (60 MHz), JNM EX-90 FT NMR (90 MHz for ^1H, 22.4 MHz for ^{13}C) or JNM GX-400 FT NMR (400 MHz) spectrometers with tetramethylsilane used as the internal standard. Chemical shifts are shown in δ values (ppm). The IR spectra were measured on a JASCO A-102 IR spectrometer. The IR data are expressed in cm^{-1}. All melting moints were determined with a Yanaco MP-J3 micromelting point apparatus.

Materials. Manganese(III) acetate[8] was prepared according to the method in the literature. 1,1-Diphenylethenes (**1a—e**) were prepared by dehydration of the corresponding alcohols which were synthesized from substituted acetophenones and arylmagnesium bromides.[9] 2-Ethyl-1-butene (**1f**) and the acetoacetamides (**2a—2l**) were purchased from Tokyo-Kasei Co., Ltd. and used as received.

Reaction of Alkenes with Acetoacetamide in the Presence of Maganese(III) Acetate–O_2. The general procedure for the reaction of alkenes with acetoacetamide in the presence of $[Mn(OAc)_3]$–O_2 was as follows. $[Mn(OAc)_3]$ (1 mmol) was added to a stirred solution of an alkene (**1**, 1 mmol) and an acetoacetamide (**2**, 1—3 mmol) in acetic acid (25 cm^3) in a three-necked flask equipped with a dry air inlet tube. The mixture was stirred at 23 °C under an air stream for the period of time shown in Tables 1 and 2. The solvent was removed in vacuo and the residue was triturated with water, followed by extraction with benzene. The products were separated either on TLC (Wakogel B10) while eluting with chloroform, or on a silica-gel column eluting with benzene. The products were further purified by recrystallization from appropriate solvents. The yields are listed in Tables 1 and 2.

Products. 4-(4-Methylphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3aa): Mp 197—199 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1648; ^1H NMR (60 MHz, DMSO-d_6) δ=1.23 and 1.47 (s, s, 3H), 2.22 (s, 3H), 2.71—3.02 (m, 3H), 6.83 and 7.01 (s, s, 1H), 7.05—7.81 (m, 14H), and 9.71 (br. s, 1H). Found: C, 74.38; H, 6.21; N, 3.51%. Calcd for $C_{25}H_{25}NO_4$: C, 74.42; N, 6.25; N, 3.47%.

4-(Phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ab): Mp 168—170 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1657; ^1H NMR (60 MHz, DMSO-d_6) δ=1.27 and 1.53 (s, s, 3H), 2.70—3.01 (m, 3H), 6.72 and 7.03 (s, s, 1H), 7.06—7.77 (m, 15H), and 9.73 (br. s, 1H). Found: C, 74.04; H, 5.85; N, 3.57%. Calcd for $C_{24}H_{23}O_4N$: C, 74.02; H, 5.95; N, 3.60%.

4-(4-Methoxyphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ac): Mp 180—182 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1641; ^1H NMR (60 MHz, DMSO-d_6) δ=1.23 and 1.50 (s, s, 3H), 2.60—3.01 (m, 3H), 3.69 (s, 3H), 6.75 and 6.93 (s, s, 1H), 7.15—7.71 (m, 14H), and 9.62 (br. s, 1H). Found: C, 71.98; H, 6.33; N, 3.13%. Calcd for $C_{25}H_{25}NO_5$: C, 71.58; H, 6,01; N, 3.34%.

4-(2-Methoxyphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ad): Mp 188—190 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1640; ^1H NMR (60 MHz, DMSO-d_6) δ=1.28 and 1.53 (s, s, 3H), 2.60—3.01 (m, 3H), 3.85 (s, 3H), 6.93 and 7.05 (s, s, 1H), 7.13—8.33 (m, 14H), and 9.67 (br. s, 1H). Found: C, 71.48; H, 6.27; N, 3.04%. Calcd for $C_{25}H_{25}NO_5$: C, 71.58; H, 6.01; N, 3.34%.

4-(2-Methylphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ae): Mp 197—199 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1644; ^1H NMR (60 MHz, DMSO-d_6) δ=1.34 and 1.57 (s, s, 3H), 2.23 (s, 3H), 2.70—3.01 (m, 3H), 7.01 and 7.32 (s, s, 1H), 7.68—7.90 (m, 14H), and 9.41 (br. s, 1H). Found: C, 74.62; H, 6.29; N, 3.43%. Calcd for $C_{25}H_{25}NO_4$: C, 74.42; H, 6.25; N, 3.47%.

4-(4-Chlorophenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3af): Mp 192—194 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1662; ^{1}NMR (60 MHz, DMSO-d_6) δ=1.29 and 1.51 (s, s, 3H), 2.70—3.01 (m, 3H), 6.86 and 7.18 (s, s, 1H), 7.30—7.74 (m, 14H), and 9.72 (br. s, 1H). Found: C, 68.07; H, 5.20; N, 3.34%. Calcd for $C_{24}H_{22}ClNO_4$: C, 68.00; H, 5.23; N, 3.30%.

4-(2-Chlorophenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ag): Mp 191—193 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1656; ^1H NMR (60 MHz, DMSO-d_6) δ=1.36 and 1.52 (s, s, 3H), 2.80—3.13 (m, 3H), 7.03 and 7.16 (s, s, 1H), 7.31—7.76 (m, 14H), and 9.88 (br. s, 1H). Found: C, 67.78; H, 5.17; N, 3.30%. Calcd for $C_{24}H_{22}ClNO_4$: C, 68.00; H, 5.23; N, 3.30%.

4-Carbamoyl-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ah): Mp 179—181 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1659; ^1H NMR (60 MHz, DMSO-d_6) δ=1.10 and 1.38 (s, s, 3H), 2.32—3.02 (m, 3H), 6.64 and 6.88 (s, s, 1H), 7.15 (br. s, 2H), and 7.17—7.73 (m, 10H). Found: C, 69.19; H, 6.09; N, 4.45%. Calcd for $C_{18}H_{19}NO_4$: C, 68.99; H, 6.11; N, 4.47%.

4-(Methylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ai): Mp 193—195 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1645; ^1H NMR (60 MHz, DMSO-d_6) δ=1.17 and 1.45 (s, s, 3H), 2.62 and 2.68 (s, s, 3H), 2.27—3.05 (m, 3H), 6.67 and 6.85 (s, s, 1H), 6.95—7.67 (m, 10H), and 7.82 (br. s, 1H). Found: C, 69.67; H, 6.40; N, 4.33%. Calcd for $C_{19}H_{21}NO_4$: C, 69.70; H, 6.47; N, 4.28%.

***c*-4-(Dimethylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol (3aj):** Mp 193—194 °C (from benzene–hexane); IR (KBr) ν 3260 and 1611; ^1H NMR (60 MHz, DMSO-d_6) δ=1.07 (s, 3H), 2.88 (s, 3H), 2.97 (s, 3H), 2.63—3.13 (m, 3H), 6.78 (s, 1H), and 7.16—7.78 (m, 10H); ^{13}C NMR (DMSO-d_6) δ=172.086, 143.653, 141.714, 128.288, 128.154, 127.587, 127.080, 126.304, 125.350, 98.140, 84.103, 42.304, 39.787, 37.068, 31.370, and 24.970. Found: C, 70.41; H, 6.71; N, 4.16%. Calcd for $C_{20}H_{23}NO_4$: C, 70.36; H, 6.79; N,

4.10%.

***t*-4-(Dimethylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol (3aj'):** Mp 190—191 °C (from benzene-hexane); IR (KBr) ν 3236 and 1614; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.38 (s, 3H), 2.91 (s, 3H), 3.01 (s, 3H), 2.65—3.15 (m, 3H), 6.87 (s, 1H), and 7.18—7.81 (m, 10H); ^{13}C NMR (DMSO-d_6) δ=170.202, 145.041, 142.132, 128.286, 128.169, 127.796, 127.080, 126.290, 125.171, 102.705, 84.924, 42.767, 37.334, 35.442, 35.442, and 20.286. Found: C, 70.38; H, 6.78; N, 4.11%. Calcd for $C_{20}H_{23}NO_4$: C, 70.36; H, 6.79; N, 4.10%.

4-(Diethylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ak): Mp 190—191 °C (from benzene-hexane); IR (KBr) ν 3276 and 1613; ^{1}H NMR (60 MHz, DMSO-d_6) δ=0.81—1.23 (m, 6H), 1.06 and 1.23 (s, s, 3H), 2.63—2.96 (m, 3H), 3.05—3.53 (m, 4H), 6.78 and 6.97 (s, s, 1H), and 7.06—7.83 (m, 10H); ^{13}C NMR (DMSO-d_6) δ=171.445, 143.430, 141.610, 128.259, 128.140, 127.617, 127.065, 126.260, 125.410, 97.947, 84.163, 42.767, 41.917, 40.425, 32.026, 24.866, 14.439, and 12.738. Found: C, 71.59; H, 7.36; N, 3.86%. Calcd for $C_{22}H_{27}NO_4$: C, 71.52; H, 7.37; N, 3.79%.

4-(Morpholinocarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3al): Mp 196—197 °C (from benzene-hexane); IR (KBr) ν 3276 and 1612; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.33 (s, 3H), 2.61—3.11 (m, 3H), 3.12—4.01 (m, 8H), 7.03 (s, 1H), and 7.21—7.61 (m, 10H); ^{13}C NMR (DMSO-d_6) δ=168.714, 143.762, 141.982, 128.318, 128.184, 127.140, 127.095, 126.215, 125.171, 102.451, 85.043, 66.142, 46.138, 42.498, 42.051, 35.234, and 20.107. Found: C, 68.63; H, 6.58; N, 3.61%. Calcd for $C_{22}H_{25}NO_5$: C, 68.91; H, 6.57; N, 3.65%.

6,6-Bis(4-methylphenyl)-4-(4-methylphenylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3ba): Mp 165—168 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1650; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.22 and 1.48 (s, s, 3H), 2.20 (s, 3H), 2.25 (s, 3H), 2.27 (s, 3H) , 2.57—2.98 (m, 3H) , 6.77 and 6.90 (s, s, 1H), 6.78—7.60 (m, 12H), and 9.62 (br. s, 1H). Found: C, 75.17; H, 6.77; N, 3.24%. Calcd for $C_{27}H_{29}NO_4$: C, 75.15; H, 6.77; N, 3.25%.

6,6-Bis(4-methylphenyl)-4-(phenylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3bb): Mp 193—195 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1659; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.23 and 1.48 (s, s, 3H), 2.05 (s, 3H), 2.12 (s, 3H), 2.61—3.01 (m, 3H), 6.71 and 6.75 (s, s, 1H), 6.93—7.73 (m, 13H), and 9.83 (br. s, 1H). Found: C, 74.85; H, 6.51; N, 3.37%. Calcd for $C_{26}H_{27}NO_4$: C, 74.80; H, 6.52; N, 3.36%.

6,6-Bis(4-methylphenyl)-4-(2-methylphenylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3be): Mp 164—167 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1624; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.27 and 1.44 (s, s, 3H), 2.17 (s, 3H), 2.21 (s, 3H), 2.29 (s, 3H), 2.61—3.01 (m, 3H) 6.98 and 7.32 (s, 1H), 7.02—7.69 (m, 12H), and 9.28 (br. s, 1H). Found: C, 75.09; H, 6.78; N, 3.24%. Calcd for $C_{27}H_{29}NO_4$: C, 75.15; H, 6.77; N, 3.25%.

4-(4-Chlorophenylcarbamoyl)-6,6-bis(4-methylphenyl)-3-methyl-1,2-dioxan-3-ol (3bf): Mp 120—123 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1658; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.25 and 1.52 (s, s, 3H), 2.18 (s, 3H), 2.29 (s, 3H), 2.63—3.01 (m, 3H), 6.72 and 7.00 (s, s, 1H), 7.03—7.92 (m, 12H), and 9.28 (br. s, 1H). Found: C, 68.83; H, 5.80; N, 3.17%. Calcd for $C_{26}H_{26}ClNO_4$: C, 69.10; H, 5.80; N, 3.10%.

4-(2-Chlorophenylcarbamoyl)-6,6-bis(4-methylphenyl)-3-methyl-1,2-dioxan-3-ol (3bg): Mp 169—171 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1658; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.32 and 1.51 (s, s, 3H), 2.21 (s, 3H), 2.30 (s, 3H), 2.57—3.02 (m, 3H), 7.01—8.20 (m, 13H), and 9.81 (br. s, 1H). Found: C, 68.72; H, 5.80; N, 3.18%. Calcd for $C_{26}N_{26}ClNO_4$: C, 69.10; H, 5.80; N, 3.10%.

6,6-Bis(4-methylphenyl)-4-carbamoyl-3-methyl-1,2-dioxan-3-ol (3bh): Mp 194—197 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1641; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.18 and 1.42 (s, s, 3H), 2.22 (s, 3H), 2.27 (s, 3H), 2.78—3.02 (m, 3H), 6.67 and 6.83 (s, s, 1H), 6.92 (br. s, 2H), and 6.93—7.59 (m, 8H). Found: C, 70.38; H, 6.77; N, 4.11%. Calcd for $C_{20}H_{23}NO_4$: C, 70.38; H, 6.79; N, 4.10%.

6,6-Bis(4-fluorophenyl)-4-(phenylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3cb): Mp 185—188 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1646; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.23 and 1.52 (s, s, 3H), 2.61—3.11 (m, 3H), 6.85 and 7.03 (s, s, 1H), 7.04—7.92 (m, 13H), and 9.81 (br. s, 1H). Found: C, 67.80; H, 4.95; N, 3.31%. Calcd for $C_{24}H_{21}F_2NO_4$: C, 67.75; H, 4.98; N, 3.30%.

6,6-Bis(4-fluorophenyl)-4-(dimethylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3cj): Mp 162—164 °C (from benzene-hexane); IR (KBr) ν 3380 and 1627; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.08 and 1.38 (s, s, 3H), 2.89 (s, 3H), 2.97 (s, 3H), 2.68—3.11 (m, 3H), 6.80 and 6.98 (s, s, 1H), and 6.92—7.86 (m, 8H); Found: C, 63.84; H, 5.65; N, 3.66%. Calcd for $C_{20}H_{21}F_2NO_4$: C, 63.65; H, 5.61; N, 3.71%.

6,6-Bis(4-chlorophenyl)-4-(2-chlorophenylcarbamoyl)-1,2-dioxan-3-ol (3dg): Mp 154—156 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1658; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.35 and 1.51 (s, s, 3H), 2.62—3.01 (m, 3H), 7.13 and 7.25 (s, s, 1H), 7.15—8.12 (m, 12H), and 9.81 (br. s, 1H). Found: C, 57.97; H, 4.17; N, 2.91%. Calcd for $C_{24}H_{20}Cl_3NO_4$: C, 58.49; H, 4.10; N, 2.84%.

6,6-Bis(4-chlorophenyl)-4-(dimethylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3dj): Mp 191—192 °C (from benzene-hexane); IR (KBr) ν 3292 and 1617; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.18 and 1.42 (s, s, 3H), 2.58 (s, 3H), 2.65 (s, 3H), 2.66—3.13 (m, 3H), 6.75 and 6.98 (s, s, 1H), and 7.32—7.61 (m, 8H). Found: C, 58.57; H, 5.20; N, 3.37%. Calcd for $C_{20}H_{21}Cl_2NO_4$: C, 58.54; H, 5.16; N, 3.31%.

4-(2-Chlorophenylcarbamoyl)-6,6-bis(4-methoxyphenyl)-3-methyl-1,2-dioxan-3-ol (3eg): Mp 124—126 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1655; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.30 and 1.52 (s, s, 3H), 2.66—3.04 (m, 3H), 3.71 (s, 3H), 3.77 (s, 3H) , 6.83—8.33 (m, 13H), and 9.81 (br. s, 1H). Found: C, 64.48; N, 5.47; N, 3.08%. Calcd for $C_{26}H_{26}ClNO_6$: C, 64.53; H, 5.42; N, 2.91%.

6,6-Bis(4-methoxyphenyl)-4-(dimethylcarbamoyl)-3-methyl-1,2-dioxan-3-ol (3ej): Mp 200—201 °C (from benzene-hexane); IR (KBr) ν 3192 and 1608; ^{1}H NMR (60 MHz, DMSO-d_6) δ=1.08 and 1.34 (s, s, 3H), 2.88 (s, 3H), 2.96 (s, 3H), 2.64—3.13 (m, 3H), 3.71 (s, 3H), 3.77 (s, 3H), 6.73 and 7.01 (s, s, 1H), and 6.83—7.63 (m, 8H). Found: C, 65.67; H, 6.78; N, 3.48%. Calcd for $C_{22}H_{27}NO_6$: C, 65.82; H, 6.78; N, 3.79%.

4-(Phenylcarbamoyl)-6,6-diethyl-3-methyl-1,2-dioxan-3-ol (3fb): Mp 149—152 °C (from benzene-hexane); IR (KBr) ν 3500—3100 and 1642; ^{1}H NMR (60 MHz, DMSO-d_6) δ=0.72—1.13 (m, 6H), 1.28—2.31 (m, 7H), 2.72—3.08 (m, 3H), 6.50 and 6.83 (s, s, 1H), 7.01—8.02 (m, 5H), and 9.77 (br. s, 1H); ^{13}C NMR (DMSO-d_6) δ=169.789, 169.595, 138.999, 138.701, 128.632, 128.587, 123.411, 123.142, 119.443, 119.147,

101.706, 97.499, 81.970, 80.672, 47.526, 46.064, 32.130, 29.609, 27.953, 27.867, 24.015, 22.777, 24.478, 19.868, 7.502, 7.397, 7.342, and 6.965. Found: C, 65.63; H, 7.62; N, 5.01%. Calcd for $C_{16}H_{23}NO_4$: C, 65.51; H, 7.90; N, 4.78%.

4-(4-Chlorophenylcarbamoyl)-6,6-diethyl-3-methyl-1,2-dioxan-3-ol (3ff): Mp 157—159 °C (from benzene–hexane); IR (KBr) ν 3500—3100 and 1658; ^{1}H NMR (60 MHz, DMSO-d_6) δ=0.63—1.08 (m, 6H), 1.28—2.31 (m, 7H), 2.66—3.12 (m, 3H), 6.50 and 6.83 (s, s, 1H), 7.22—7.78 (m, 4H), and 9.93 (br. s, 1H); ^{13}C NMR (DMSO-d_6) δ=169.799, 169.596, 137.927, 137.673, 128.484, 128.371, 126.962, 126.724, 120.981, 101.618, 97.456, 81.961, 80.659, 47.526, 46.214, 32.037, 29.417, 27.825, 27.821, 24.017, 22.764, 24.465, 19.885, 7.489, 7.384, 7.381, and 6.966. Found: C, 58.49; H, 6.62; N, 4.35%. Calcd for $C_{16}H_{22}ClNO_4$: C, 58.62; H, 6.73; N, 4.27%.

3-(4-Methylphenylcarbamoyl)-2-methyl-5,5-diphenyl-4,5-dihydrofuran (4aa): Mp 251—252 °C (from ethanol); IR (KBr) ν 3264 and 1657; ^{1}H NMR (60 MHz, DMSO-d_6) δ=2.23 (s, 3H), 2.30 (t, J=1.2 Hz, 3H), 3.73 (q, J=1.2 Hz, 2H), 6.98—7.68 (m, 14H), and 9.81 (br. s, 1H). Found: C, 81.34; H, 6.33; N, 3.72%. Calcd for $C_{25}H_{23}NO_2$: C, 81.26; H, 6.28; N, 3.79%.

Methylation of 4-(Phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ab). Anhydrous potassium carbonate (180 mg) and dimethyl sulfate (170 mg) were added to compound **3ab** (389 mg) in anhydrous acetone (5 cm^3). The mixture was heated under reflux for 10 h. Water (5 cm^3) was added to the mixture after cooling and the acetone was removed. The residue was extracted with chloroform (total 60 cm^3) and the extract was dried over anhydrous magnesium sulfate. After the removal of the chloroform, the crude product was chromatographed on a silica-gel column while eluting with benzene to give *c*-4-(phenylcarbamoyl)-*r*-3-methoxy-3-methyl-6,6-diphenyl-1,2-dioxane (**5ab**) (197 mg, 49% yield), and *t*-4-(phenylcarbamoyl)-*r*-3-methoxyl-6,6-diphenyl-1,2-dioxane (**5ab′**) (141 mg, 35% yield).

***c*-4-(Phenylcarbamoyl)-*r*-3-methoxy-3-methyl-6,6-diphenyl-1,2-dioxane (5ab):** Mp 186—187 °C (from benzene–hexane); IR (KBr) ν 3308 and 1664; ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.299 (s, 3H), 2.826—2.856 (m, J=13.20, 14.83, and 4.57 Hz, 2H), 2.970 (dd, J=14.83 and 4.57 Hz, 1H),3.449 (s, 3H), 7.110—7.605 (m, 15H), and 8.807 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=169.316, 143.405, 140.481, 137.840, 128.979, 128.592, 128.323, 127.786, 127.592, 126.995, 125.921, 124.266, 119.820, 100.860, 85.704, 50.439, 49.350, 33.806, and 18.918. Found: C, 74.39; H, 6.33; N, 3.45%. Calcd for $C_{25}H_{25}NO_4$: C, 74.42; H, 6.25; N, 3.47%.

***t*-4-(Phenylcarbamoyl)-*r*-3-methoxy-3-methyl-6,6-diphenyl-1,2-dioxane (5ab′):** Mp 176—177 °C (from benzene–hexane); IR (KBr) ν 3340 and 1692; ^{1}H NMR (400 MHz, $CDCl_3$) δ=1.336 (s, 3H), 2.531 (t, J=13.92 Hz, 1H), 3.032—3.076 (d, J=13.92 Hz, 2H), 3.489 (s, 3H), 7.11—7.49 (m, 15H), and 7.78 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=168.463, 145.684, 141.507, 137.703, 129.066, 128.514, 128.320, 127.738, 126.187, 125.799, 124.292, 119.593, 106.556, 87.208, 50.018, 48.243, 32.863, and 14.545. Found: C, 74.39; H, 6.31; N, 3.49%. Calcd for $C_{25}H_{25}NO_4$: C, 74.42; H, 6.25; N, 3.47%.

Acetylation of 4-(Phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3ab). Compound **3ab** (389 mg) was treated with a mixture of acetic anhydride (102 mg), pyridine (14 mg), and triethylamine (121 mg) at room temperature overnight. The reaction mixture was concentrated to dryness in vacuo and the residue was dissolved in benzene (30 cm^3). The benzene solution was washed with 2 M (1 M=1 mol dm^{-3}) hydrochloric acid (30 cm^3), and with a saturated aqueous sodium hydrogencarbonate solution, then dried over anhydrous magnesium sulfate. After the removal of the benzene, the residue was chromatographed on a silica-gel column while eluting with benzene, giving *c*-4-(phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol acetate (**6ab**) (232 mg, 54% yield), and *t*-4-(phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol acetate (**6ab′**) (91 mg, 21% yield).

***c*-4-(Phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol Acetate (6ab):** Mp 186—187 °C (from benzene–hexane); IR (KBr) ν 3320, 1731, and 1665; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.70 (s, 3H), 2.15 (s, 3H), 2.76—3.36 (m, 3H), 7.06—7.68 (m, 15H), and 7.83 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=167.538, 167.448, 142.760, 140.299, 137.360, 129.170, 128.708, 128.484, 128.230, 127.664, 126.768, 125.724, 124.859, 119.966, 103.259, 85.790, 50.555, 32.833, 22.212, and 21.332. Found: C, 72.50; H, 5.85; N, 3.28%. Calcd for $C_{26}H_{25}NO_5$: C, 72.37; H, 5.84; N, 3.25%.

***t*-4-(Phenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-*r*-3-ol Acetate (6ab′):** Mp 153—154 °C (from benzene–hexane); IR (KBr) ν 3382, 1732, and 1690; ^{1}H NMR (60 MHz, $CDCl_3$), δ=1.73 (s, 3H), 2.21 (s, 3H), 2.78—3.23 (m, 3H), 7.13—7.66 (m, 15H), and 7.83 (s, 1H); ^{13}C NMR ($CDCl_3$) δ=168.836, 167.657, 145.341, 141.051, 137.434, 129.111, 128.588, 128.365, 127.977, 127.335, 126.052, 125.575, 124.680, 119.802, 109.047, 86.939, 48.362, 32.953, 22.257, and 17.424. Found: C, 72.45; H, 5.84; N, 3.24%; Calcd for $C_{26}H_{25}NO_5$: C, 72.37; H, 5.84; N, 3.25%.

Catalytic Hydrogenation of 4-(4-Methylphenylcarbamoyl)-3-methyl-6,6-diphenyl-1,2-dioxan-3-ol (3aa). (a) In acetic acid. A mixture of **3aa** (403 mg) and 5% palladium on charcoal (20 mg) in ethyl acetate (5 cm^3) was stirred under an atmosphere of hydrogen at room temperature for 3 h. The reaction mixture was filtered and the filtrate was concentrated to dryness. The solidified residue was recrystallized from benzene, giving 3-(4-methylphenylcarbamoyl)-2-methyl-5,5-diphenyl-4,5-dihydrofuran (**4aa**) (86% yield): Mp 251—252 °C; (b) In ethanol. Hydrogenation of **3aa** similar to (a) but in ethanol yielded 3-(4-methylphenylcarbamoyl)-2-methyl-5,5-diphenyltetrahydro-2-furanol (**7aa**) (80% yield): Mp 225—227 °C (from ethanol); IR (KBr) ν 3600—3100, and 1642; ^{1}H NMR (60 MHz, DMSO-d_6), δ=1.57 (s, 3H), 2.22 (s, 3H), 2.81—3.12 (m, 3H), 6.11 (s, 1H), 7.03—7.67 (m, 14H), and 9.66 (br. s, 1H). Found: C, 77.51; H, 6.50; N, 3.60%. Calcd for $C_{25}H_{25}NO_3$: C, 77.49; H, 6.50; N, 3.61%.

Dehydration of 7aa. Compound **7aa** (194 mg) was dissolved in acetic acid (0.5 cm^3) and the solution was heated under reflux for 1 h. After the removal of the acetic acid, the residue was recrystallized from benzene, giving **4aa** (87% yield): Mp 251—252 °C, identical with that obtained from the preceding experiment (a).

Decomposition of 3aa with Methanolic Potassium Hydroxide. A mixture of **3aa** (202 mg) and 5% KOH–MeOH (10 cm^3) was heated under reflux for 2 h. After the removal of the methanol, Water (20 cm^3) was added, and the mixture was extracted with benzene (total 60 cm^3). The benzene solution was washed with dilute hydrochloric acid (30 cm^3), a saturated aqueous sodium hydrogencarbonate solution (20 cm^3), and water (20 cm^3), and then dried over anhydrous magnesium sulfate. After the removal of the benzene, the resulting mixture was chromatographed on a silica-gel plate while eluting with benzene, yielding benzophenone (66 mg, 72% yield).

Reaction of Xanthene with *N*-Phenylacetoacetamide (2b) in the Presence of Manganese(III) Acetate. [$Mn(OAc)_3$] (536 mg) was added to a solution of xanthene (180 mg) and **2b** (707 mg) in acetic acid (30 cm^3) at 100 °C. The reaction mixture was heated at the same temperature until the dark-brown color of the solution turned opaque white (approximately 3 min). After the removal of the solvent under reduced pressure, the residue was treated with 2 M hydrochloric acid (30 cm^3) and extracted with chloroform (25 $cm^3 \times 3$). The products were separated on a silica-gel column, while eluting with chloroform, and recrystallized.

***N*-Phenyl-2-(9-xanthenyl)acetoacetamide (8).** (182.1 mg, 51% yield): Mp 203—204 °C (from ethanol); IR (KBr) ν 3328, 1719, and 1659; ^1H NMR (60 MHz, DMSO-d_6) δ=1.99 (s, 3H), 3.90 (d, J=10.0 Hz, 1H), 3.87 (d, J=10.0 Hz, 1H), 6.8—7.6 (m, 13H), and 9.91 (br. s, 1H). Found: C, 77.09; H, 5.31; N, 4.09%. Calcd for $C_{23}H_{19}O_3N$: C, 77.29; H, 5.36; N, 3.92%. Xanthene (34.5 mg, 19% yield) and *N*-phenylacetoacetamide (**2a**, 69.2 mg, 10% yield) were recovered.

Reaction of 1,1-Diphenylethene (1a) with Manganese(III) Acetate. A mixture of **1a** (180 mg) and [$Mn(OAc)_3$] (268 mg) in acetic acid (30 cm^3) was stirred at 23 °C under an air stream for 12 h. The reaction mixture was worked-up in a manner similar to that described above, giving 2,2-diphenyl-2-hydroxyethyl acetate (**9**) (10.2 mg, 4% yield, mp 87—88 °C (lit,[10] mp 91 °C)), benzophenone (12.7 mg, 7% yield), and unreacted **1a** (147.6 mg, 82% yield).

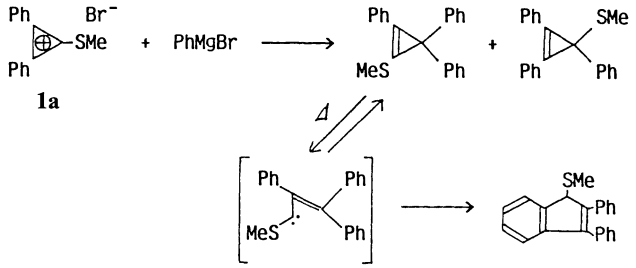
(Received June 26, 1991)

The reaction of 1-methylthio-, 1-(4-methylphenylthio)-, or 1-*t*-butylthio-2,3-diphenylcyclopropenium salts with alcohols, phenols, and thiols in the presence of triethylamine at around 80 °C gave 1*H*-indene-1-thiol derivatives in fair to moderate yields. In contrast, the same reactions at room temperature afforded 1-alkylthio- or arylthio-1-cyclopropene derivatives together with a small amount of the 3-isomer. Some 1-isomers were separated as pure crystals and produced the corresponding indenes in quantitative yields when heated. Kinetic studies of the ring-opening of cyclopropenes suggested a vinylcarbene intermediate based on the small effects of solvent polarities and phenoxyl substituents on the reaction rates. The reaction of diphenylcyclopropenone with thiol in the presence of trifluoroacetic acid yielded 1*H*-indene-1,3-dithiol detivatives via a 1,3-bis(alkylthio)-or (arylthio)-1-cyclopropene intermediate. On acidic hydrolysis of 3-alkoxyindenes and on heating of 3-allyloxy- and 3-(2-propynyloxy)indenes, polyfunctionally-substituted indanones were obtained in good yields.

In recent years, investigations of three membered carbocycles such as cyclopropane, cyclopropene, cyclopropenone, and cyclopropenium ion have been undertaken not only to satisfy physical interests but also to develop a versatile tool for organic syntheses.[1] In the series of our studies of the cyclopropenium salts bearing heteroatom substituents,[2] we have previously reported that the reaction of a mercapto-substituted cyclopropenium salt **1**, e.g. 1-methylthio-2,3-diphenylcyclopropenium bromide (**1a**) with acyclic[3] and cyclic 1,3-diketones[4] afforded pentadienols and 2*H*-pyranes, respectively. Furthermore, the reaction of **1a** with some Grignard reagents yielded a mixture of 1-methylthio- and 3-methylthiocyclopropenes, of which the former isomer lead to the ring opening products, indenes, via vinylcarbene intermediates (Scheme 1).[5]

Encouraged by these results, we undertook further studies of the reaction of **1** with other nucleophiles. We report here the reaction of **1** with alcohols, phenols, and thiols to produce polyfunctional indenes. Current interests in polysubstituted indenes have been focused on synthesis,[6] oxidation with ozone,[7] electrochemical reduction,[8] and application to medical chemistry.[9]

The salt **1a** has been prepared from methylation of diphenylcyclopropenethione,[3] whereas 1-(4-methylphenylthio)- and 1-*t*-butylthio-2,3-diphenylcyclopropenium tetrafluoroborates (**1b**, **c**) were obtained from the reaction of ethoxycyclopropenium tetrafluoroborate with thiols in good yields.



Scheme 1.

Treatment of a mixture of **1a**, methanol, and triethylamine (mole ratio, 1 : 1.1 : 3) in benzene at 80 °C afforded, after column chromatography over silica gel, 3-methoxy-1-methylthio-2-phenyl-1*H*-indene **3aa** in a 68% yield. The structure of the product was unequivocally established by ^{1}H and ^{13}C NMR and mass spectroscopic studies as well as by conversion to indanone **6a** upon standing in a hydrochloric acid–ethanol solution

Scheme 3.

at room temperature for 2 d. Similar treatment of the salts **1a**—**c** with alcohols, phenols, or thiols (**2a**—**g**) afforded indenes **3** in fair to moderate yields (Table 1).

The conversion of indenes with 3-allyloxy- and 3-(2-propynyloxy)-substituents (**3bf** and **3bg**) to indanones **7a** and **7b** was accomplished by means of heating at benzene reflux temperature via a Claisen rearrangement (Scheme 3).

In order to detect the intermediate cyclopropenes, some controlled experiments were performed. Thus, the salt **1a** was treated with methanethiol **2h** in the presence of triethylamine at room temperature for 10 min. The crude product absorbed at around 1780 cm^{-1} in the IR spectrum indicating the presence of cyclopropenes. The ^{1}H NMR spectrum showed a mixture of the cyclopropenes **4ah** and **5ah** together with a small amount of the indene **3ah** (Table 2). The ratio was determined by the integration of methylthio groups of **3ah**, **4ah**, and **5ah**, whose signals appeared at δ=1.20 and 2.12, 1.85 and 2.47, and 2.03 respectively. Attempted isolation of pure **4ah** and **5ah** by cc or tlc was unsuccessful, since **4ah** was thermally unstable and produced the corresponding indene **3ah**, while **5ah** was converted to the cyclopropenone. On cooling to −20 °C, petroleum ether was added to the crude reaction mixture and some cyclopropenes **4** were recovered as crystals (Table 2). The structure of **4** was unambiguously determined from its ^{1}H and ^{13}C NMR, and mass spectra, and transformations to the corresponding indenes **3**. As summarized in Table 2, the crude reaction mixture also contained 3-mercaptocyclopropene **5**. Only **5ak** was isolated as an oil by a short column separation. Although attempts to isolate the other **5**'s failed, ^{1}H NMR and IR spectra as well as isolation of cyclopropenone from the cc elution indicated the presence of **5**.

Cyclopropenes prepared from the reactions of the salts **1b** and **1c** with alcohols were too unstable to isolate in a pure form even by separation on short cc or at lower temperatures.

The distribution of the products **4** and **5** suggested that the employed nucleophiles preferentially attacked the carbon atom unsubstituted by sulfur. This regioselectivity was attributed to the strong electron releasing properties of alkyl- or arylthio groups and steric repulsion between the phenyl substituent of **1** and the entering nucleophiles as have been observed for the reaction between **1** and Grignard reagents.[5]

Keeping a solution of **4** at around 20 to 80 °C resulted in the formation of the corresponding indene **3** in quantitative yields. Kinetic studies were performed in order to clarify the mechanism of the ring opening of **4** (Table 3). The rate was followed at suitable time intervals by analyzing the ^{1}H NMR spectra of the methylthio groups

Table 2. The Reaction of **1a** with **2** under Controlled Conditions

2	Mole ratio **1a**:**2**:amine	Time/min	Temp/°C	Products **4**:**5**[a]	(Isolation/%)[b]

a) E_a=90.1±2.0 kJ mol^{-1}, $\Delta S^{\ddagger}$=−10.1±1.3 eu.
b) E_a=89.1±5.9 kJ mol^{-1}, $\Delta S^{\ddagger}$=−10.1±4.6 eu.
c) E_a=90.1±0.3 kJ mol^{-1}, $\Delta S^{\ddagger}$=−10.1±0.1 eu.

of **4** by using methyl phenyl sulfide or dimethyl sulfone as an internal standard. The disappearance of **4** showed good first-order rate constants (k_1). Small effects of phenoxy substituents (ρ=−0.51) and solvents polarities on the rate indicated the small ionization of the intermediates of ring opening.

Tetraphenylcyclopropene has been reported to rearrange to indene with an activation energy of 167 kJ mol^{-1} (on heating at 240 °C),[10] while the activation energies of the rearrangement to **3** were only about 100 kJ mol^{-1}.

These results show that the ring opening of **4** proceeded via a vinylcarbene, stabilized by the adjacent mercapto group as shown in Scheme 1, followed by intramolecular hydrogen abstraction to produce indene **3**.

The following two reactions (Schemes 4 and 5) also provide support for the vinyl carbene intermediate for the ring opening of cyclopropenes. Treatment of **1** in methanol with triethylamine provided the methyl acetals **8a**, **b**, and **c** in 82, 86, and 85% yields respectively. Hydrolysis of **8** under acidic conditions afforded the vinyl ketones **9** in quantitative yields. Photoisomerization of **9c** in benzene yielded a 1 : 1 mixture of **9c** and **10**. The stereochemistry of **10** was assigned to *Z* on the basis of the ^{1}H NMR spectrum of the *t*-butylthio group at δ=1.39, because that of **9c** appeared at 1.33 (Scheme 4).

The cyclopropene **4ah** also reacted with refluxing methanol to give an unstable mixture of *E*- and *Z*-isomers of 3-methoxy-3-methylthio-1-propene **11** (Scheme 5). The structure was evident from the spectroscopic studies and conversion to the propenals **12** (Scheme 5). Although the two isomers could not be readily separated, high field ^{1}H NMR indicated that the *E*-isomer was the major product (10 : 3).

In our previous paper, we showed the reaction of cyclopropenone with thiol in the presence of potassium hydroxide in ethanol to yield thiolacrylates[11] (Scheme 6). Cyclopropenone is known to form a "salt"[12] with a Brönsted acid, and the salt is considered to be a hydroxy-substituted cyclopropenium.[11] It is reasonable to consider that the mercapto-substituted cyclopropenium ion would be generated in an acidic solution of cyclopropenone and thiol. This consideration was suggested by the following experiments. When a mixture of diphenylcyclopropenone **13**, methanethiol **2h**, and trifluoroacetic acid (mole ratio, 1 : 1 : 1) in benzene was heated at 60 °C, the indene **3ah** was obtained in a 15% yield along with **13** (70% recovery). The use of a mole rario of 1 : 3 : 3 resulted in better yields of **3** (Table 4). The ^{1}H NMR spectroscopic studies indicated that

2j	PhH	80	1	**3jj** (72)
2k	PhH	80	1	**3kk** (86)
	EtOH	80	1	(55)
2l	PhH	80	3	None
	EtOH	80	3	**14** (52)

the reaction mixture with a ratio 1 : 3 : 3 in benzene after 1 h at room temperature contained a mixture of **3ah**, **4ah**, and **5ah** in a mole ratio of 1 : 4 : 1.4. Whereas the bulky thiol **2l** did not yield indene **3**, but the thioacrylate **14** (R′=*t*-Bu), similar treatment of thiols **2i—k** with **13** produced indenes **3** in moderate yields (Table 4). Thus, the indenes **3** were formed from 1,3-bis(alkylthio)- or 1,3-bis(arylthio)-1-cyclopropenes **4** even under acidic conditions.

Experimental

1) General. Melting points were uncorrected. The ^{1}H NMR spectra were recorded on a Hitachi R-24B (60 MHz) and the ^{13}C NMR spectra on a JEOL JNM FX-90Q (22.49 MHz) or EX-90 (22.50 MHz) spectrometer. The IR spectra were obtained on a JEOL JIR 100 spectrometer.

2) Preparation of 1-Mercapto-2,3-diphenylcyclopropenium Salts (1). 1-Methylthio-2,3-diphenylcyclopropenium bromide (**1a**) was prepared as previously described.[3] 1-(4-Methylphenylthio)-2,3-diphenylcyclopropenium tetrafluoroborate (**1b**) was prepared as follows. A solution of triethyloxonium tetrafluoroborate (1.9 g, 10 mmol) and diphenylcyclopropenone (2.06 g, 10 mmol) in dichloromethane (10 cm^3) was stirred at room temperature for 2 h. To the mixture was added 4-thiocresol (1.24 g, 10 mmol) in one portion. 1 h later the precipitates were collected, washed with dry benzene, and dried in vacuo. **1b:** 2.8 g (85%); mp, 204—206 °C; IR (KBr) 1820 cm^{-1}; ^{1}H NMR ($CDCl_3$+CF_3CO_2H, 5 : 1) δ=2.52 (s, 3H, Me) and 7.3—8.2 (m, 14H, arom). The salt **1c** was prepared similarly. The only different point was that benzene was added to the reaction mixture to precipitate the salt. **1c:** 3.12 g (80%); mp 130—133 °C; IR (KBr) 1820 cm^{-1}; ($CDCl_3$+CF_3CO_2H, 5 : 1) δ=1.82 (s, 9H, *t*-Bu) and 7.6—8.4 (m, 10H, 2Ph).

3) The Reaction of 1 with Alcohols, Phenols, and Thiols (2). A mixture of **1** (2.0 mmol), **2** (2.2 mmol), and triethylamine (6.0 mmol) in dry benzene (15 cm^3) was stirred well at an appropriate temperature. The reactions with thiols were carried out in sealed tubes. The resulting solution was washed with aqueous sodium hydroxide (0.5% solution), dried over anhydrous sodium carbonate, and condensed in vacuo. The reactions at 80 °C yielded pure **3** on recrystallization from methanol unless otherwise stated (Table 1). The controlled reactions for shorter times at lower temperatures afforded a mixture of cyclopropenes (**4** and **5**). To the crude product was added petroleum ether and the mixture was cooled to −20 °C to afford crystalline **4**. In only one case was **5ak** provided after a short cc over silica gel (Table 2). The physical properties of **3**, **4**, and **5** were as follows.

3aa: Mp 82—84 °C; IR (KBr) 1600 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.25 (s, 3H, MeS), 3.74 (s, 3H, MeO), 4.58 (s, 1H, CH), and 6.8—8.0 (m, 9H, arom); MS (*m/z*), 268 (M$^+$). Found: C, 75.87; H, 5.99%. Calcd for $C_{17}H_{16}OS$: C, 76.08; H, 5.96%.

5ak: Oil; IR (KBr) 1820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.25 (s, 3H, Me) and 6.3—8.0 (m, 14H, arom); ^{13}C NMR (C_6D_6) δ=1.3 (q, Me), 17.2 (s, C_3), 127.4 (s), 128.3 (d), 128.5 (d), 128.7 (d), 129.8 (d), 131.4 (s), 136.9 (s), 139.3 (s), and 147.3 (d); MS (*m/z*), 333 (M^+−1).

Hydrolysis of **3aa** or **3ba** (0.5 mmol) in a mixture of ethanol (10 cm^3) and 3 mol dm^{-3} aqueous HCl (15 cm^3) for 2 d at room temperature yielded 3-methylthio- or 3-(4-methylphenylthio)-2-phenyl-1-indanone [**6a**(R=Me) or **6b**(R=4-MeC_6H_4)] in 92 or 94% yields.

6a: Mp 76—77 °C (MeOH); IR (KBr) 1690 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.93 (s, 3H, Me), 3.79 (d, *J*=4 Hz, 1H, C_2H), 4.35 (d, *J*=4 Hz, 1H, and C_3H), and 6.9—7.9 (m, 9H, arom); MS (*m/z*), 254 (M^+). Found C, 75.49; H, 5.43%. Calcd for $C_{16}H_{14}OS$: C, 75.55; H, 5.54%.

6b: Mp 102—104 °C (MeOH); IR (KBr) 1710 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.19 (s, 3H, Me), 3.70 (d, *J*=4 Hz, C_2H), 4.60 (d, *J*=4 Hz, C_1H), and 6.5—7.9 (m, 13H, arom); MS (*m/z*), 330 (M^+). Found C, 79.91; H, 5.58%. Calcd for $C_{22}H_{18}OS$: C, 79.96; H, 5.49%.

Heating **3bf** and **3bg** in refluxing benzene for 2 d provided **7a** and **7b** in 95 and 92% yields, respectively, on crystallization from petroleum ether.

7a: Mp 119—122 °C; IR (KBr) 1720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (s, 3H, Me), 2.48—3.45 (m, 2H, CH_2), 4.7—5.2 (m, 2H, CH_2), 4.94 (s, 1H, C_1H), 5.2—6.1 (m, 1H, CH), and 6.4—7.8 (m, 13H, arom); MS (*m/z*), 370 (M^+). Found C, 80.89; H, 5.91%. Calcd for $C_{25}H_{22}OS$: C, 81.04; H, 5.98%.

7b: Mp 119—121 °C; IR (KBr) 1950 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.32 (s, 3H, Me), 4.81 (d, *J*=6 Hz, 2H, CH_2), 5.21 (s, 1H, C_1H), 5.70 (t, *J*=6 Hz, CH), and 6.5—8.0 (m, 13H, arom); ^{13}C NMR ($CDCl_3$) δ=21.0 (q, Me), 56.8 (d, C_3), 62.5 (s, C_2) 79.6 (t), 94.1 (d), 124.3 (s), 126.6 (s), 127.6 (d), 127.8 (d), 128.8 (d), 129.0 (d), 129.5 (d), 131.9 (d), 132.2 (d), 134.7 (s), 135.4 (d), 137.3 (s), 139.7 (s), 154.2 (s), 202.7 (s, CO), and 207.0 (s, =C=); MS (*m/z*), 368(M^+). Found C, 81.43; H, 5.55%. Calcd for $C_{25}H_{20}OS$: C, 81.48; H, 5.47%.

4) Kinetic Investigation of the Thermolysis of 4. A solution of **4** and methyl phenyl sulfide (or dimethyl sulfone) in an appropriate solvent was sealed in an NMR tube and was kept standing in a thermostated bath (±0.1 °C); the rate was followed at suitable time intervals by analyzing the ^1H NMR spectra of the methylthio groups of **3**, **4**, and the internal standard. The results are collected in Table 3.

5) Methanolysis of 1. A solution of **1** (2 mmol) and triethylamine (6 mmol) in methanol (15 cm^3) was refluxed for

1 h. The solution was quenched with aqueous NaOH (0.1%) and the organic product was extracted with benzene. The usual workup, followed by recrystallization from chloroform–petroleum ether, yielded the 2-propenalacetals **8**.

8a: 82%; mp 103—105 °C; IR (KBr) 1615 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.29 (s, 3H, MeS), 3.14 (s, 6H, 2MeO), and 6.7—7.8 (m, 11H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=17.4 (q, MeS), 49.1 (s, MeO), 103.0 (s), 126.9 (d), 127.5 (d), 129.3 (d), 131.0 (d), 136.5 (s), 137.5 (s), and 140.2 (s); MS (*m/z*), 300 (M^+). Found C, 71.83; H, 6.71%. Calcd for $C_{18}H_{20}O_2S$: C, 71.96; H, 6.71%.

8b: 86%; mp 90—93 °C: IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.32 (s, 3H, Me), 3.20 (s, 6H, 2MeO), and 6.7—7.5 (m, 14H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=21.0 (q, Me), 49.2 (q, MeO), 102.9 (s), 127.3 (d), 127.4 (d), 127.6 (d), 128.1 (d), 128.9 (d), 129.3 (d), 129.5 (d), 129.8 (d), 130.1 (d), 132.6 (s), 137.1 (s), 138.0 (s), and 139.9 (s); MS (*m/z*), 376 (M^+). Found C, 76.59; H, 6.24%. Calcd for $C_{24}H_{24}O_2S$: C, 76.56; H, 6.42%.

8c: 85%; mp 74—77 °C IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.40 (s, 9H, Bu-*t*), 3.19 (s, 6H, 2MeO), and 7.0—7.6 (m, 11H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=31.1 (q, 3Me), 43.6 (s, $\underline{C}Me_3$), 49.2 (s, MeO), 103.0 (s), 125.5 (d), 126.9 (d), 127.4 (d), 128.2 (d), 129.3 (d), 131.4 (d), 136.7 (s), 137.7 (s), and 140.3 (s); MS (*m/z*), 342 (M^+). Found C, 73.75; H, 7.87%. Calcd for $C_{21}H_{26}O_2S$: C, 73.64; H, 7.65%.

Hydrolysis of **8** (2 mmol) in a mixture of methanol (15 cm^3) and aqueous HCl (3 mol dm^{-3}, 10 cm^3) at room temperature for 1 d afforded phenyl vinyl ketones **9** in a quantitative yield from chloroform–petroleum ether.

9a: Mp 59—61 °C; IR (KBr) 1625 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.29 (s, 3H, Me) and 6.8—7.9 (m, 11H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=18.0 (q, Me), 127.7 (d), 128.0 (d), 128.2 (d), 129.2 (d), 131.4 (d), 135.9 (s), 136.4 (s), 138.6 (s), 148.9 (d), and 193.2 (s, C=O); MS (*m/z*), 254 (M^+). Found C, 75.71; H, 5.42%. Calcd for $C_{16}H_{14}OS$: C, 75.55; H, 5.54%.

9b: Mp 59—60 °C; IR (KBr) 1645 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.25 (s, 3H, Me) and 6.5—7.9 (m, 15H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=21.0 (q, Me), 128.0 (d), 128.1 (d), 128.3 (d), 129.3 (d), 129.5 (d), 130.1 (d), 130.6 (d), 130.8 (d), 131.6 (d), 135.8 (d), 136.8 (s), 138.3 (s), 138.4 (s), 146.5 (d), and 193.4 (s, C=O); MS (*m/z*), 330 (M^+). Found C, 79.88; H, 5.44%. Calcd for $C_{22}H_{18}OS$: C, 79.96; H, 5.49%.

9c: Mp 83—86 °C; IR (KBr) 1640 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.33 (s, 9H, 3Me) and 7.2—7.8 (m, 11H, arom and =CH); ^{13}C NMR ($CDCl_3$) δ=30.9 (q, 3Me), 45.4 (s, $\underline{C}Me_3$), 127.7 (d), 128.0 (d), 128.2 (d), 129.3 (d), 129.4 (d), 131.4 (d), 136.0 (s), 138.9 (s), 144.4 (d), and 193.6 (s, C=O); MS (*m/z*), 296 (M^+). Found C, 77.18; H, 6.64%. Calcd for $C_{19}H_{20}OS$: C, 76.98; H, 6.80%.

The stereochemistry of **9c** was studied under irradiation by a high pressure mercury lamp. The initial signal at δ=3.19 decreased and a new signal at δ=3.44 appeared in equal strength.

6) Methanolysis of 4ah. A crude product mixture of **4ah** and **5ah** (9 : 1, 2 mmol) (obtained from the predescribed workup) was heated at reflux temperature in methanol (10 cm^3) containing 0.5% NaOH for 1 d. The usual workup gave an acid-sensitive oil, whose ^1H NMR spectrum showed major peaks at δ=1.60, 1.79, 1.90, 2.12, 2.18 (MeS's), 3.16, 3.20, and 3.47 (MeO's). An acid hydrolysis with a solution of aqueous HCl (3 mol dm^{-3}, 5 cm^3) in ethanol (5 cm^3) at room temperature for 1 d yielded a mixture of aldehyde **12** in a 53% yield after a short column chromatography over silica gel. The separation of *E*- and *Z*- isomers was unsuccessful.

12: Oil, 1740 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.74 and 1.92 (s, 1 : 0.3, 3H, MeS), 6.8—7.7 (m, 10H, 2Ph), 9.19 and 10.35 (s, 1 : 0.3, 1H, CHO); MS (*m/z*), 254 (M^+). Found C, 75.47; H, 5.61%. Calcd for $C_{16}H_{14}OS$: C, 75.55; H, 5.54%.

7) The Reaction of Diphenylcyclopropenone 13 with Thiol 2 in the Presence of Trifluoroacetic Acid. General Procedure. A mixture of **2**, **13**, and trifluoroacetic acid (3, 1, and 3 mmol, respectively) in benzene or ethanol (5 cm^3) was heated in a sealed tube for an appropriate time. The usual workup in the manner described above yielded indene **3** or thiolacrylate **14** (R′=Bu-*t*) by recrystallization from methanol. The results are collected in Table 4.

3bi: Mp 177—178 °C; ^1H NMR δ=2.22 (s, 3H Me), 2.25 (s, 3H, Me), 5.07 (s, 1H, CH), and 6.5—7.8 (m, 17H, Ar); MS (*m/z*), 436 (M^+). Found: C, 79.62; H, 5.65%. Calcd for $C_{29}H_{24}S_2$: C, 79.76; H, 5.55%.

3jj: Mp 127—128 °C; IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.13 (s, 1H, CH) and 6.5—7.8 (m, 19H, arom); MS (*m/z*), 408 (M^+). Found C, 79.57; H, 4.84%. Calcd for $C_{27}H_{20}S_2$: C, 79.37; H, 4.93%.

3kk: Mp 186—187 °C; IR (KBr) 1600 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.12 (s, 1H, CH) and 6.5—7.9 (m, 17H, arom); MS (*m/z*), 476 (M^+). Found C, 67.79; H, 3.58%. Calcd for $C_{27}H_{18}Cl_2S_2$: C, 67.92; H, 3.79%.

14 (R′=Bu-*t*): Mp 109—111 °C (lit,[11] 109—111 °C).

Studies on the Secondary Structure of Bradykinin in Aqueous Solution. Syntheses, Circular Dichroism Spectra, and Biological Activities of Bradykinin Amide and [D-Ala^4]-Bradykinin[1)]

(Received July 9, 1991)

Bradykinin amide and [D-Ala^4]-bradykinin were synthesized by the 'hold-in-solution' method. The circular dichroism spectra of both peptides were measured and compared with that of bradykinin. These analogs exhibited weak activity (0.01% of bradykinin) in the increment of blood flow in a femoral artery of dog.

The secondary structure of bradykinin (BK), H–Arg–Pro–Pro–Gly–Phe–Ser–Pro–Phe–Arg–OH, has been investigated by several research groups.[2–7)] It is known that the circular dichroism (CD) spectrum of BK shows troughs at about 200 and at 234 nm, and a peak at 221 nm. In our previous papers,[8,9)] on the basis of comparison of the CD spectra of several BK analogs containing a 5-aminovaleric acid residue, the presence of an intramolecular 3→1 hydrogen bond between the carbonyl oxygen of Ser^6 and the amide proton of Phe^8, an intramolecular 4→1 hydrogen bond between the carbonyl oxygen of Pro^2 and the amide proton of Phe^5, and a salt bridge between the guanidino group of Arg^1 and the carboxyl group of Arg^9 was emphasized for the secondary structure of BK in aqueous solution. Further, it was deduced that the intramolecular 3→1 hydrogen bond contributes to the trough at 234 nm and the intramolecular 4→1 hydrogen bond and the salt bridge contribute to the peak at 221 nm. Also, it was suggested that the trough at about 200 nm arises mainly from the sequences Arg^1–Pro^2–Pro^3–Gly^4 and Phe^5–Ser^6–Pro^7. The present study was carried out to investigate further the presence of the salt bridge and the intramolecular 4→1 hydrogen bond in the secondary structure of BK in aqueous solution. The syntheses, the CD spectra, and the biological activities of BK-amide and [D-Ala^4]-BK are described.

Results and Discussion

Synthesis. The side chains of Arg and Ser were protected by Mbs[10)] and Bzl, respectively. Protected BK and [D-Ala^4]-BK were synthesized by a stepwise elongation using H–Arg(Mbs)–ONBzl as a starting material, and Boc-amino acid derivatives as acylating reagents (Z derivative for the final acylation) by the 'hold-in-solution' method.[11–13)] The protected BK and [D-Ala^4]-BK were purified by gel chromatography on a Sephadex LH-20 column and a Sephadex LH-60 column, respectively. The protected BK was converted to the corresponding BK-amide by treatment with NH_3/MeOH. The protected BK-amide and [D-Ala^4]-BK were hydrogenolyzed and then treated with methanesulfonic acid.[14)] Both of the free peptides were converted to the acetate form by a Dowex 1×2 column, and further purified by ion-exchange chromatography on a carboxymethylcellulose column, gel chromatography on a Sephadex G-10 column, and finally, partition chromatography on a Sephadex G-25 column.[15)]

Circular Dichroism Spectra. The CD spectra were measured in the region of 190—270 nm. Free BK-amide and [D-Ala^4]-BK were dissolved in water. The CD data are reported as molar ellipticity, $[\theta]$, which is expressed in degrees square centimeters per decimole.

BK-amide can not form the salt bridge proposed by Ivanov et al.[5)] because of the lack of the C-terminal carboxyl group. Our previous study suggested that the salt bridge brings about the stabilization of the intramolecular 4→1 hydrogen bond and the increment of ellipticity at 221 nm.[8,9)] Therefore, the conversion of the C-terminal carboxyl group into an amide should have resulted in a change for this peak. The CD spectrum of BK-amide in Fig. 1 indicates a trough at 232 nm, a peak at 223 nm, and a deep trough at 202 nm. The peak at 223 nm was considerably lower compared with that of BK. This change can be postulated to be a result of a decrease in the stability of the intramolecular 4→1 hydrogen bond. In regard to the peak at 223 nm, the ellipticity of BK-amide was very similar to that of [5-Ava$^{1-2}$]-BK. [5-Ava$^{1-2}$]-BK also can not form the salt bridge because of the lack of the guanidino group of Arg^1. In spite of the modification of each site remote from others in the primary structure, the similarity of the ellipticities of both the peptides in this region strongly implies the presence of a salt bridge in the BK molecule.

Venkatachalam[16)] indicated that a type-II β-turn is stabilized by the introduction of a D-amino acid residue into the third position (i+2) of the turn. Therefore, the β-turn in the N-terminal part of BK generated by the 4→1 hydrogen bond should be stabilized by replacing the Gly^4 residue with a D-Ala residue. The CD spectrum of [D-Ala^4]-BK in Fig. 2 shows a trough at 202 nm,

† Present address: Department of Chemistry, The Jikei University School of Medicine, 8-3-1, Kokuryo-cho, Chofu-shi, Tokyo 182.

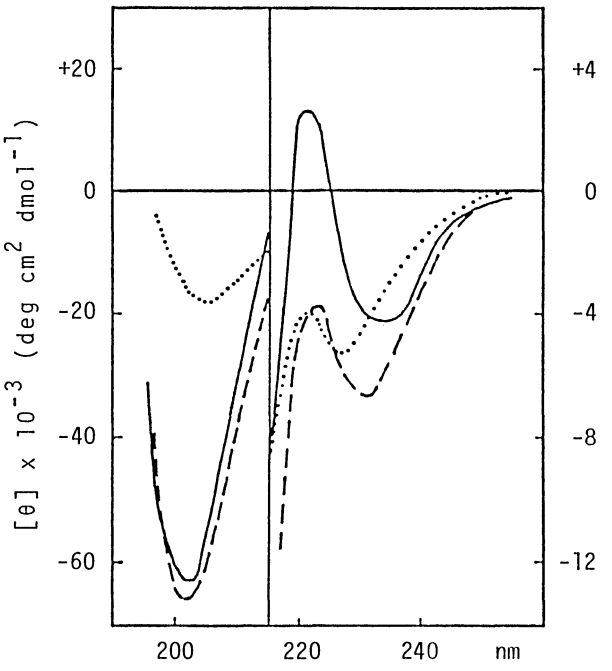

Fig. 1. CD spectra of BK-amide (----), [5-Ava$^{1-2}$]-BK (·····),[8,9] and BK (——) in water.

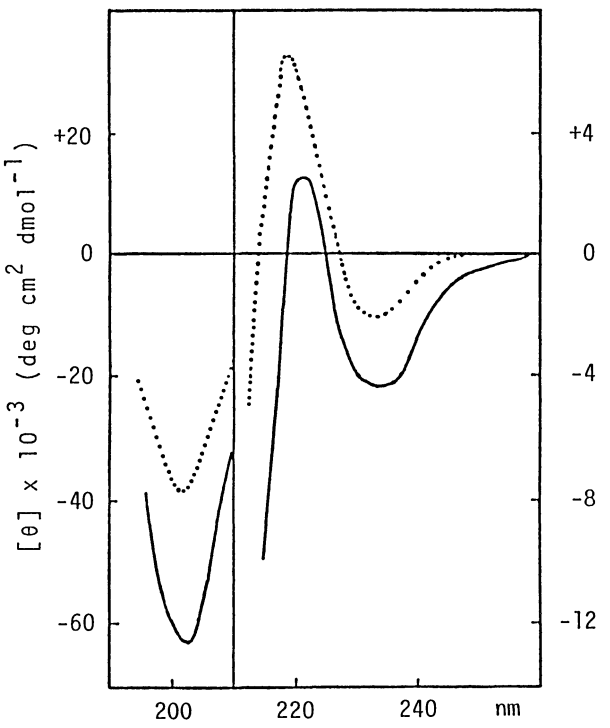

Fig. 2. CD spectra of [D-Ala^4]-BK (·····) and BK (——) in water.

a high peak at 219 nm, and a trough at 234 nm. The increment of the ellipticity at 219 nm compared with BK seems to be based on stabilization of the intramolecular 4→1 hydrogen bond between the carbonyl oxygen of Pro^2 and the amide proton of Phe^5; i.e., the β-turn. This hydrogen bond in BK has Pro and Gly residues at positions (i+1) and (i+2), respectively. It has been reported that the β-turn structure often involves Pro and Gly residues as preferable amino acids at positions (i+1) and (i+2) in the corner of the turn.[16,17] This indication does not conflict with our present conclusion.

As for the CD band near 234 nm, the troughs of BK-amide and [D-Ala^4]-BK imply the presence of the intramolecular 3→1 hydrogen bond proposed by Cann et al.[4,6] in these peptides.

Regarding the trough near 200 nm, the spectrum of BK-amide was similar to that of BK. This result suggested that the C-terminal amide group does not contribute to the trough at about 200 nm. The trough of [D-Ala^4]-BK was shallower than that of BK, that is, it may have been due to a conformational change of the amide bond of Pro^3-Gly^4 caused by replacing the Gly^4 residue with a D-Ala residue. The present results are not in conflict with the previous conclusions that both of the sequences Arg^1-Pro^2-Pro^3-Gly^4 and Phe^5-Ser^6-Pro^7 contribute to this band.[8,9]

Biological Activity. The biological activity of BK-amide and [D-Ala^4]-BK was found to be 0.01% of that of BK in the increment of blood flow in a femoral artery of dog. The low activity of BK-amide was consistent with the fact that the addition of an amino acid residue to the carboxyl terminal of BK generally results in a lowering of biological activity. It showed that the carboxyl group of Arg^9 is important for biological activity.

The analogs of luteinizing hormone-releasing hormone,[18,19] enkephaline,[20] and motiline,[21] containing a D-Ala residue instead of the Gly residue in a sequence -Tyr-Gly- corresponding to positions (i+1) and (i+2) of the β-turn, showed very large activities compared with the corresponding native peptides. However, in the case of [D-Ala^4]-BK, such a structure-activity correlation was not found.

Experimental

Melting points were measured by a capillary method and are given as uncorrected values. Optical rotations were determined with a Shimadzu polarimeter III or a DIP-370 digital polarimeter (JASCO). Amino acid analyses were performed on a JLC-6AS automatic analyzer (JEOL) or an L-8500 amino acid analyzer (Hitachi) after acid hydrolysis with 6 M (1 M=1 mol dm^{-3}) HCl in a sealed tube at 110 °C for 24 h. The theoretical values of amino acid ratios are shown in parentheses after each result.

Thin-layer chromatography was performed on TLC plates of silica gel 60 F_{254} (Merck and Co.) or cellulose (Avicel), using the following solvent systems (volume ratios): R_f^1, chloroform-methanol (95:5); R_f^2, chloroform-methanol (9:1); R_f^3, 1-butanol-acetic acid-water (4:1:1); R_f^4, 1-butanol-acetic acid-water (4:1:2); R_f^5, 1-butanol-pyridine-acetic acid-water (4:1:1:2); R_f^6, 1-butanol-pyridine-acetic acid-water (16:10:3:12); R_f^7, 1-butanol-pyridine-acetic acid-water (15:10:3:12).

The CD spectra were measured on a JASCO J-20 CD, ORD spectropolarimeter using a quartz cell with a path length of 0.50 mm. The measurements were carried out at room

temperature (24 °C) and at concentrations of 3.2×10^{-4} M and 1.5×10^{-3} M.

Biological activity was tested regarding the increment of blood flow in the femoral artery of dog according to a method similar to that in the previous paper.[9] The administration range of the analogs was $1\times(10^{-9}$—$10^{-4})$ g. The threshold dose of BK was 1×10^{-9} g, and its value was estimated as 100%. The activities of the analogs were expressed as relative activity compared with that of BK.

Z-Arg(Mbs)-Pro-Pro-Gly-Phe-Ser(Bzl)-Pro-Phe-Arg(Mbs)-ONBzl. The protected BK was synthesized from H-Arg(Mbs)-ONBzl by the 'hold-in-solution' method, that is, by successive coupling with Boc-Phe-OH, Boc-Pro-OH, Boc-Ser(Bzl)-OH, Boc-Phe-OH, Boc-Gly-OH, Boc-Pro-OH, Boc-Pro-OH, and Z-Arg(Mbs)-OH. Each amino acid residue was introduced by repeating the following five steps. (1) Acylation of the amino component (1.0 mmol) in 1,2-dichloroethane (ca. 10 ml) at room temperature for several hours with a Boc-amino acid (Z-derivative for the final acylation) (2.0 mmol), EDC·HCl[22] (2.0 mmol), and HOBt[23] (2.0 mmol). (2) Washing with 0.1 M HCl, water, 5% Na_2CO_3, and water (removed by pipetting). (3) Cleavage of the Boc group by HCl/dioxane at room temperature for ca. 30 min. (4) Addition of a slight excess of 2 M Na_2CO_3 and removal of the aqueous phase. (5) Washing with water. The crude protected BK was purified by a Sephadex LH-20 column (1.6×116.5 cm) using DMF as eluent. Fractions 19—26 (4.0 g each) were combined and concentrated. The residue was triturated with diethyl ether; overall yield 1.047 g (59%). For analysis, a part of the product was further purified by a silica-gel column and recrystallization from chloroform–diethyl ether; mp 129—132 °C, $[\alpha]_D^{27.5}$ −35.6° (*c* 1.0, $CHCl_3$); R_f^1 0.22, R_f^2 0.54 (silica gel). Amino acid ratios in acid hydrolyzate: Ser 1.00 (1), Pro 3.13 (3), Gly 1.01 (1), Phe 1.92 (2), Arg 1.95 (2). Found: C, 56.99; H, 5.72; N, 12.78%. Calcd for $C_{86}H_{102}O_{21}N_{16}S_2\cdot2.5H_2O$: C, 57.23; H, 5.97; N, 12.42%. FAB mass: *m/z* 1759 (MH^+, $C_{86}H_{103}O_{21}N_{16}S_2$).

H-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg-NH₂. The protected BK (300 mg) was dissolved in a mixture of MeOH (3.0 ml) and DMF (2.0 ml). The solution was saturated with NH_3 gas and then stirred at room temperature overnight. After removal of the solvent, the residue was solidified by the addition of diethyl ether. The product was dissolved in a mixture of DMF (8.0 ml), water (5.0 ml), and acetic acid (1.0 ml), and then hydrogenated over palladium black in a H_2 atmosphere for ca. 3 d. Water was added in several portions during the hydrogenation. After removal of the catalyst, the solvent was evaporated. The residue was treated with methanesulfonic acid (5.5 ml) containing anisole (0.20 ml) for 50 min at room temperature. Diethyl ether was added to this mixture. The solid was dissolved in water (2.5 ml) and the solution was passed through a Dowex 1×2 column (1.28×8.0 cm) (acetate form) with water as eluent. The eluate was concentrated and the residue was dissolved in ammonium acetate buffer (0.04 M, pH 6.0) (2.5 ml). The solution was applied to a carboxymethylcellulose column (1.7×22.5 cm: Whatman CM-52), and then eluted with ammonium acetate buffers (0.04—0.40 M, pH 6.0) by a linear gradient method. Fractions 68—82 (3.0 g each) were combined and concentrated. The residue was dissolved in 4% acetic acid (2.0 ml) and the solution was subjected to a Sephadex G-10 column (1.7×38.0 cm). Fractions 11—15 (2.5 g each) were combined and concentrated to give a first crop. Fractions 16—23 were also combined and concentrated. The residue was rechromatographed on a Sephadex G-10 column (1.7×38.5 cm) to obtain an additional crop. The combined crops were dissolved in 1-butanol–pyridine–acetic acid–water (16 : 10 : 3 : 12) (1.25 ml) and applied to a Sephadex G-25 column (1.7×23.9 cm). After elution by the same solvent, fractions 9—11 (3.0 g each) were collected and concentrated. The residue was lyophilized from water; yield 82.3 mg (36%); $[\alpha]_D^{24}$ −94.7° (*c* 0.10, H_2O); R_f^4 0.53, R_f^6 0.64, R_f^7 0.54 (cellulose). Amino acid ratios in acid hydrolyzate: Ser 1.18 (1), Pro 2.95 (3), Gly 1.01 (1), Phe 1.92 (2), Arg 1.94 (2), NH_3 1.07 (1). Found: C, 49.94; H, 6.57; N, 16.52%. Calcd for $C_{50}H_{74}O_{10}N_{16}\cdot3CH_3COOH\cdot6H_2O$: C, 49.92; H, 7.33; N, 16.63%.

Z-Arg(Mbs)-Pro-Pro-D-Ala-Phe-Ser(Bzl)-Pro-Phe-Arg(Mbs)-ONBzl. The protected [D-Ala⁴]-BK was synthesized from H-Arg(Mbs)-ONBzl (1.5 mmol) by successive coupling with Boc-Phe-OH, Boc-Pro-OH, Boc-Ser(Bzl)-OH, Boc-Phe-OH, Boc-D-Ala-OH, Boc-Pro-OH, Boc-Pro-OH, and Z-Arg(Mbs)-OH (3.0 mmol each) by the same method as described above. The residue was reprecipitated from methanol–diethyl ether (2.565 g). The crude protected [D-Ala⁴]-BK was purified by a Sephadex LH-60 column (1.7×135 cm) with DMF as eluent; overall yield 1.314 g (47%). For analysis, a part of the product was purified by a silica-gel column and recrystallization from methanol–ethyl acetate–diethyl ether; mp 121–123 °C; $[\alpha]_D^{27.5}$ −35.2° (*c* 1.0, $CHCl_3$); R_f^1 0.29, R_f^2 0.63 (silica gel). Amino acid ratios in acid hydrolyzate: Ser 0.98 (1), Pro 3.14 (3), Ala 1.01 (1), Phe 1.91 (2), Arg 1.97 (2). Found: C, 57.45; H, 6.11; N, 12.66%. Calcd for $C_{87}H_{104}O_{21}N_{16}S_2\cdot2.5H_2O$: C, 57.45; H, 6.04; N, 12.32%. FAB mass: *m/z* 1773 (MH^+, $C_{87}H_{105}O_{21}N_{16}S_2$).

H-Arg-Pro-Pro-D-Ala-Phe-Ser-Pro-Phe-Arg-OH. The protected [D-Ala⁴]-BK (350 mg) was dissolved in DMF–water–acetic acid (10, 5, and 1 ml) and then hydrogenated over palladium black for 4 d. After removal of the catalyst, the solvent was evaporated. The residue was treated with methanesulfonic acid (7.0 ml) containing anisole (0.5 ml) for 50 min at room temperature. The precipitates were obtained by the addition of diethyl ether. The solid was dissolved in water (3.0 ml) and the solution was passed through a Dowex 1×2 column (1.28×7.5 cm) (acetate form) with water as eluent. The eluate was combined and concentrated. The residue was dissolved in ammonium acetate buffer (0.04 M, pH 6.0) (3.0 ml) and the solution was chromatographed on a carboxymethylcellulose column (1.7×24.0 cm: Whatman CM-52) using ammonium acetate buffers (0.04—0.40 M, pH 6.0) by a linear gradient method. Fractions 68—76 (3.0 g each) were combined and concentrated. The residue was dissolved in 4% acetic acid (2.0 ml) and the solution was applied to a Sephadex G-10 column (1.7×39.8 cm) with the same solvent as eluent. Fractions of 2.5 g each were collected. Fractions 15—21 were combined and the solvent was removed. The residue was dissolved in 1-butanol–pyridine–acetic acid–water (4 : 1 : 1 : 2) (2.3 ml) and the solution was subjected to a Sephadex G-25 column (1.7×24.5 cm) with the same solvent as eluent. Fractions 28—34 (3.0 g each) were combined and the solvent was evaporated. The residue was further purified by the same chromatographic methods. The product was lyophilized from water; yield 53.24 mg (22%); $[\alpha]_D^{24}$ −63.7° (*c* 0.10, H_2O); R_f^3 0.59, R_f^5 0.65 (cellulose). Amino acid ratios in acid hydrolyzate: Ser 0.94 (1), Pro 2.92 (3), Ala 0.98 (1), Phe 2.03 (2), Arg 2.07 (2). Found: C, 52.23; H, 6.99; N, 15.82%. Calcd for $C_{51}H_{75}O_{11}N_{15}\cdot3CH_3COOH\cdot3H_2O$: C, 52.32; H, 7.16; N,

16.06%.

We are grateful to the Research Laboratory of Toyo Jozo Co., Ltd. for the elemental, amino acid, and FAB mass analyses, and to the Research Laboratory of Nihon Kayaku Co., Ltd. for the measurement of biological activity.

Dehydrooligopeptides. XIII. Selective Enzymatic Hydrolysis of *N*-Protected α-Dehydroglutamic Acid Diesters and Their Analogs Using Papain as Catalyst[1)]

Chung-gi SHIN,* Nobuyuki TAKAHASHI, and Masashi SEKI
Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221
(Received May 2, 1991)

Since the α-ester of α,γ-dimethyl *N*-benzyloxycarbonyl-α-dehydroglutamate (ΔGlu) was found to be hydrolyzed using papain, a variety of *N*-protected α-dehydroglutamates and their analogs, both esters of which were the same or different from each other, were newly synthesized and subjected to a similar hydrolysis. Although the substrates, with bulkier ester group at the γ- as well as α-positions, were found to become difficult to hydrolyze, the kind and size of the *N*-protecting group did not effect the hydrolysis. Moreover, it was found that the length of side chain of the substrate greatly influenced hydrolysis. The present study suggests that papain may become a useful tool for the hydrolysis and coupling of ΔGlu with α-amino acid or peptide.

During about the past two decades, the many successes regarding the synthesis of a number of peptides by utilizing proteolytic enzymes, such as papain and α-chymotrypsin A etc., have contributed great epochal effects to the field of organic synthetic chemistry.[2-5)] Even the complex macromolecules of useful peptide hormones could be synthesized under considerably mild conditions by the widely developed enzymatic synthetic method.[6-8)]

On the contrary, it was hardly believed up to now that the unusual α-amino acid, α-dehydroamino acid (DHA) ester, could be similarly hydrolyzed or coupled with L-α-amino acid (AA) enzymatically. Recently, however, a very selective hydrolysis of the α-ester moiety of α,γ-dimethyl *N*-benzyloxycarbonyl-α-dehydroglutamate [Cbz-ΔGlu(OMe)-OMe; **1b**] and novel peptide formation with L-Leu-NHPh by using papain (EC 3.4.22.2) have for the first time been successful and reported briefly.[9,10)] Since it was thought to be necessary to reexamine and widely develop a similar hydrolysis, we undertook a further detailed study. That is, many kinds of α-dehydroglutamates and their analogs, in which two carboxyl groups and an amino group are protected with various *C*- and *N*-protecting groups, were newly synthesized and the effects of the three protecting groups and the influence of the length of the side chain to enzymatic hydrolysis were thoroughly studied. Regarding the results, the substrate specificity of papain was broadened considerably.

Experimental

General. The melting points were determined with a Yamato Mp-21 micro-melting-point apparatus, and were uncorrected. The IR spectra were recorded with a Hitachi EPI-G2 spectrometer. The ^{1}H NMR spectra were measured with a JEOL LMN-PS-100 spectrometer in a $CDCl_3$ or DMSO-d_6 solution with tetramethylsilane used as the internal standard.

Enzyme. Papain (2.8 units mg^{-1}), purchased from Sigma Chemical Co., U. S. A., was used without further purification.

***N*-Protected α-Dehydroglutamates (1) and Their Analogs.** Cbz-ΔGlu(OMe)-OMe (**1b**), Cbz-ΔGlu(OEt)-OMe (**1c**), and Cbz-ΔGlu(OBzl)-OMe (**1e**) (Bzl=benzyl) were prepared by the γ-esterification of Cbz-ΔGlu-OMe (**1a**)[1)] with an appropriate alcohol, according to a reported method.[1)] Cbz-ΔGlu(OEt)-OEt (**1f**) and Cbz-ΔGlu(OBzl)-OBzl (**1g**) were also obtained similarly by the α,γ-diesterification of Cbz-ΔGlu-OH (**2a**)[11)] with EtOH or BzlOH. Cbz-ΔGlu(OBu^t)-OMe (**1d**) (Bu^t= *t*-butyl) was derived by the treatment of **1a** with isobutene in a sealed tubes.[12)] Similarly, Cbz-ΔGlu(OBu^t)-OBu^t(**1h**) was also obtained from **2a** and isobutene. In addition, *N*-methoxycarbonyl (Moc)-ΔGlu(OMe)-OMe (**1i**), *N*-ethoxycarbonyl (Eoc)-ΔGlu(OMe)-OMe (**1j**), *N*-isopropoxycarbonyl (Ipo)-ΔGlu(OMe)-OMe (**1k**), and *N*-*n*-butoxycarbonyl (Nbc)-ΔGlu(OMe)-OMe (**1l**) were prepared by the condensation of α,γ-dimethyl α-oxoglutarate with an appropriate alkyl carbamate.[1)] As an analog of the ΔGlu derivative, Cbz-ΔAsp(OMe)-OMe (**1m**) was obtained by the elimination of Cbz-β-(hydroxy)aspartic acid dimethyl ester.[13)] Furthermore, 2-(*N*-Cbz-amino)-2-hexenedioic acid dimethyl ester [Cbz-ΔAhx(OMe)-OMe; **1n**] and 2-(*N*-Cbz-amino)-2-heptenedioic acid dimethyl ester [Cbz-ΔAhp(OMe)-OMe; **1o**] were also derived by the condensation of 2-oxohexanedioic acid dimethyl ester and 2-oxoheptanedioic acid dimethyl ester with benzyl carbamate, respectively, by the usual method.[1)] The identification data of **1**, thus obtained, are presented in Tables 1 and 2.

Methyl 2-(*N*-Cbz-Amino)-5-hydroxy-2-pentenoate (1p). To a suspension of Cbz-ΔGlu(OMe)-OH (**2b**) (3 g, 10 mmol) and $NaBH_4$ (2.32 g, 61 mmol) in Bu^{t}OH (15 ml) was added MeOH, with stirring, at 60 °C until it became a transparent solution. After stirring for 3 h, the resulting solution was neutralized with 1 M-HCl (1 M=1 mol dm^{-3}) and concentrated under reduced pressure to give a crude residue, which was dissolved in ethyl acetate (30 ml). The resultant solution was washed with brine and dried over anhydrous Na_2SO_4. Concentration in vacuo gave crystals, which were recrystallized from $CHCl_3$ to give 2-(*N*-Cbz-amino)-5-hydroxy-2-pentenoic acid (**2p**) as colorless needles. Yield 80%, mp 114—115 °C. IR (KBr) 3250 (NH), 1655 (C=C) cm^{-1}. ^{1}H NMR (DMSO-d_6) δ=8.57 (bs, 1H, NH), 6.48 (t, 1H, *J*=7.0 Hz, -CH=). Found: C, 60.34; H, 6.04; N, 5.11%. Calcd for $C_{14}H_{17}NO_5$ C, 60.20; H, 6.14; N, 5.02%. Subsequently, the obtained **2p** (2.1 g, 7.9 mmol) was treated with MeOH (20 ml)

in the presence of $SOCl_2$ (0.64 ml), with stirring, at −10 °C for 30 min. The reaction solution was further stirred at room temperature overnight and concentrated in vacuo. The obtained residue was dissolved in ethyl acetate (30 ml) and the resulting solution was washed with successively saturated $NaHCO_3$ aqueous solution and brine and then dried over anhydrous Na_2SO_4. Concentration in vacuo gave a yellow syrup, which was purified on a silica-gel column using a mixture of $CHCl_3$ and acetone (10 : 1 v/v) as the eluent. The eluate was concentrated in vacuo to give **1p** as a yellow syrup. Yield 82%. IR 3330 (NH), 1660 (C=C) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ=7.00 (bs, 1H, NH), 6.59 (t, 1H, J=7.0 Hz, -CH=). Found: C, 59.03; H, 5.65; N, 5.33%. Calcd for $C_{13}N_{15}NO_5$: C, 58.86; H, 5.70; N, 5.28%.

General Enzymatic Hydrolysis of 1. A suspension (5 ml) of an appropriate **1** [100 mM and papain (30 g dm^{-3}) in the presence of 2-mercaptoethanol (0.1 ml) in McIlvaine buffer was incubated, with shaking, at pH 8.0 and at 35 °C for 24 h. The structures and yields of the hydrolyzates were identified and determined by HPLC on a Hitachi 630-50 model (column 4ϕ×250 mm). The eluent (MeOH : H_2O=60 : 40 v/v) was run with a flow rate of 1 ml min^{-1}. The peaks were determined at 230 nm by comparing the retention times with those of authentic compounds prepared chemically.[1,11] The peak intensities were used to calculate the relative concentrations. Furthermore, to isolate pure **2**, the reaction solution was treated with a saturated $NaHCO_3$ aqueous solution (50 ml) and washed twice with ethyl acetate (60 ml). The aqueous layer was acidified to pH 2.0 with 6 M-HCl and extracted three times with ethyl acetate (100 ml). The combined extracts were washed twice with brine (60 ml) and dried over anhydrous Na_2SO_4. Concentration in vacuo gave crystals or syrup, which were recrystallized from an appropriate organic solvent or purified on a silica-gel column using a mixture of $CHCl_3$ and acetone (10 : 1 v/v) as the eluent to give γ-alkyl esters of *N*-protected α-dehydroglutamic acids (**2a**—**2d** and **2i**—**l**) and their analogs (**2n** and **2o**). The identification data of **2** are summarized in Tables 3 and 4.

Enzymatic Hydrolysis of 1p. Quite similarly, the hydrolysis of **1p** with papain was worked up to give **2p**, which was completely in accord with the compound derived by the reduction of **2b** with $NaBH_4$. Yield 80%.

Results and Discussion

In order to examine and to further develop the new catalytic action of cheaper and readily accessible papain, various DHA esters (**1**) as the substrate were submitted to the enzymatic reaction.

First of all, in particular, to obtain optimal conditions the hydrolysis of **1b** was thoroughly reexamined, since a preliminary run using papain had already been achieved to give **2b**[9] almost quantitatively. In addition to a detailed examination of the effect of the pH,[9] the effects of the reaction time and concentration of both the enzyme and substrate were studied, as shown in Figs. 1—4.

The pH of the reaction solution was changed from 3 to 9, although the optimal pH value of esterase action of papain in a McIlvaine buffer is well-known to be around 7. As a result, the yield of **2b** increased abruptly over the pH range from 6 to 8, and reached more than 90% at pH 8. Consequently, the α-ester hydrolysis of **1b** was found to be extremely dependent upon the pH. That is, Fig. 1 indicates that a rather alkaline pH may be preferred for the such hydrolysis of **1**. Subsequently, the time course of a similar hydrolysis of **1b** at 8.0 was also examined. As Fig. 2 shows, the hydrolysis is comparatively slow and the yield of the hydrolyzate reached ultimately more than 90% over 24 h.

Concerning the amount of papain, the enzyme con-

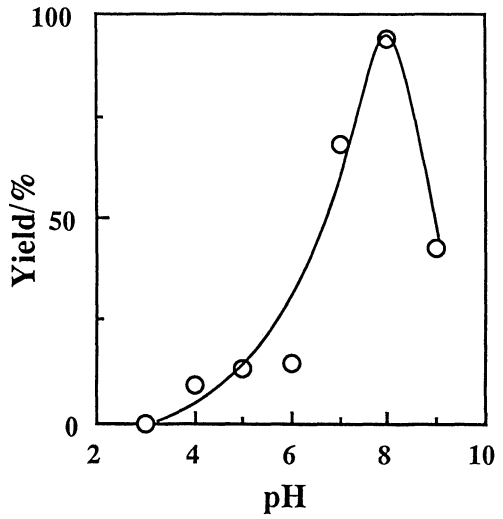

Fig. 1. Effect of pH. The reaction mixture (5 ml), containing 200 mM **1b** and 30 g dm^{-3} papain (2.8 units mg^{-1}) in McIlvaine buffer, was shaken at various pH's at 35 °C for 24 h.

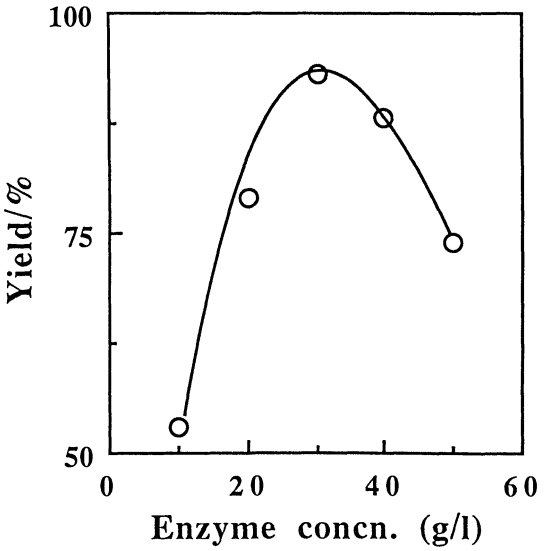

Fig. 3. Effect of enzyme concentration. The reaction mixture (5 ml), containing 200 mM **1b** and various concentrations of papain in McIlvaine buffer, was shaken at pH 8 at 35 °C for 24 h.

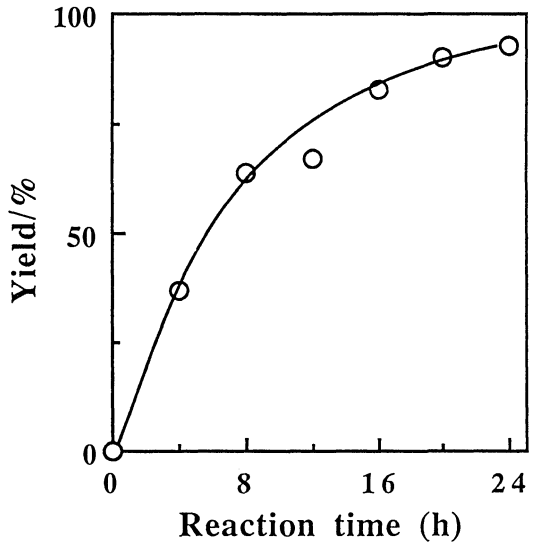

Fig. 2. Effect of reaction time. The reaction mixture (5 ml), containing 200 mM **1b** and 30 g dm^{-3} papain (2.8 units mg^{-1}) in McIlvaine buffer, was shaken at pH 8 at 35 °C for various hours.

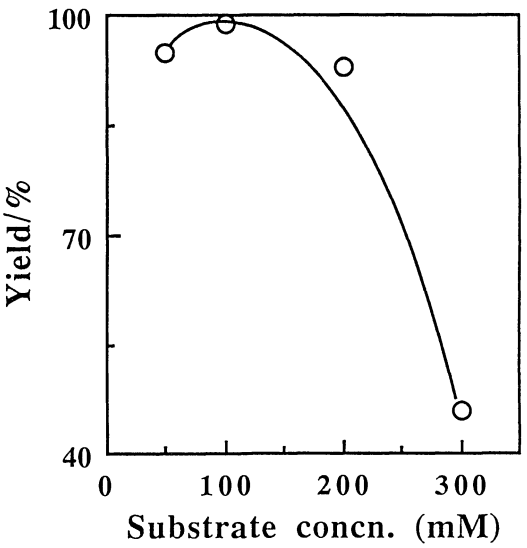

Fig. 4. Effect of substrate concentration. The reaction mixture (5 ml), containing various concentrations of **1b** and 30 g dm^{-3} papain (2.8 units mg^{-1}) in McIlvaine buffer, was shaken at pH 8 at 35 °C for 24 h.

centration at around 30 g dm^{-3} provided the highest yield. Fig. 3 indicates that a considerably large amount of enzyme is required for the hydrolysis. In addition, Fig. 4 indicates that a substrate concentration ranging from 50 to 150 mM affords a very high yield of more than 95%. Consequently, the substrate concentration of 100 mM was found to be the most effective.

As can be seen from Figs. 1—4, the results show that the enzymatic hydrolysis of **1b** requires a considerably prolonged reaction time and higher concentration of enzyme, but closely depends upon a comparatively lower substrate concentration under a slightly alkaline pH.

The optimal conditions of the hydrolysis of **1b** [papain (30 g dm^{-3}), substrate (100 mM) in McIlvaine buffer at pH 8.0 and at 35 °C for 24 h], was applied to a similar hydrolysis of all the substrates (**1**), according to Scheme 1.

From the results and the fact that other DHA esters have also been hydrolyzed,[14] our present study indicates that papain is a potent catalyst for the hydrolysis of various DHA esters. The structural characteristics of

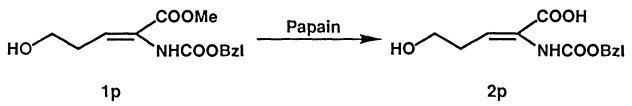
Scheme 1.

the substrates (**1**) to the substrate specificity of papain is discussed below. Particularly, as can be seen from Table 3, in the cases of **1b**, **1c**, and **1f**, when the α,γ-diester groups were comparatively small in size, the α-ester alone was readily hydrolyzed to give the corresponding γ-methyl ester (**2b**) in 94% yield and γ-ethyl ester [Cbz-⊿Glu(OEt)-OH; (**2c**)] in 85% from **1c** and 51% from **1f** yields, respectively. However, a similar hydrolysis of the γ-free ⊿Glu-OMe (**1a**) could not easily give **2a**[1] in only 38% yield.

On the other hand, since the sizes of the γ-ester (**1d** and **1e**) and α,γ-diesters (**1g** and **1h**) gradually become bulky, hydrolysis was found to become more difficult. In the case of **1d**, the hydrolysis proceeded ultimately to give Cbz-⊿Glu(OBu^t)-OH (**2d**) in 23% yield, while in the case of a bulkier γ-benzyl ester (**1e**) hydrolysis didn't take place. Accordingly, as is naturally expected, the bulky α,γ-di-*t*-butyl (**1g**) and α,γ-dibenzyl esters (**1h**) were by no means hydrolyzed. As a result, it can be seen the size and bulkiness of the γ-ester (X), as well as those of the α-ester (Y), are very important factors for the hydrolysis of such substrates [Cbz-⊿Glu(OX)-OY] with papain, except for **1a**.

In addition, besides the above-two *C*-protecting groups, the *N*-protecting groups of **1** are also thought to be another important factor. It is necessary to investigate whether or not the *N*-protecting group influences this type of hydrolysis. Being kept the both sides as methyl esters, the substrates (**1**) protected with five kinds of *N*-protecting groups [that is, from the smallest Moc (**1i**), Eoc (**1j**), Ipc (**1k**), Nbc (**1l**) to the largest Cbz group (**1b**)] were synthesized, and then applied to a similar hydrolysis. As a result, all of the esterase actions took place beautifully to give the corresponding *N*-protected ⊿Glu(OMe)-OH (**2i**—**l**) in ca 91% yields. These results clearly indicate that such enzymatic hydrolysis is not affected by the size of the *N*-protecting groups.



1p 2p

Scheme 2.

However, interestingly, it was found that the length of the side chain of **1** was greatly related to the hydrolysis, as shown in Table 3. Namely, dehydroaspartate (**1m**) was by no means hydrolyzed, whereas dehydroglutamate (**1b**) was hydrolyzed almost quantitatively; then, the longer the side chain from **1b** to **1o** via **1n** became, the yield decreased abruptly.

Furthermore, since a similar hydrolysis of **1b** having a hydroxyl group at the terminus of the side chain was also achieved to give 2-(*N*-Cbz-amino)-5-hydroxy-2-pentenoic acid (**2p**) in 80% yield (Scheme 2), it seems that the existence of the γ-ester group in ⊿Glu derivatives is not necessarily essential; that of the electronegative group near the γ-position, however, may be rather important. On the other hand, it is of particular interest that the results of the hydrolysis are not affected by the kinds and sizes of the *N*-protecting groups at all, but by the length of the side chain.

On the contrary, however, in the case of the treatment of **1b** with α-chymotrypsin A, interestingly, it has been already revealed that the γ-methyl ester is selectively hydrolyzed.[15]

In conclusion, besides being surprised that the enzymatic hydrolysis of the DHA ester occurred, it is very available synthetically that only the α-ester of **1** could be enzymatically hydrolyzed, whereas the selective hydrolysis of **1** was extremely difficult by the chemical method.[9] Furthermore, the results indicate that the reverse reaction, i.e., peptide-bond formation, can also be catalyzed with papain. In fact, the enzymatic synthesis of various dehydroglutamyldipeptides were successful. After all, the present study suggested that papain has become a sufficiently useful tool for organic synthesis.

The Properties of the Multistage Bioreactor Constructed by the LB Technique

Michihiro OHNISHI,* Coe ISHIMOTO, and Jun'etsu SETO
SONY Corporation Research Center, 174, Fujitsuka-cho, Hodogaya-ku, Yokohama 240
(Received June 24, 1991)

A multistage bioreactor consisting of organic ultrathin layers was successfully realized by immobilizing glucose oxidase and glucoamylase by the Langmuir–Blodgett technique (LB technique). Starch as the substrate was quickly converted into gluconic acid and hydrogen peroxide as the products in this bioreactor via the intermediate, glucose. The rate of the sequential reactions was electrochemically measured. This rate increased proportionally with increasing the concentration of starch, and also increased with increasing the amount of glucose oxidase in the LB film. This bioreactor, however, decayed soon. The reason of this decay was considered to be the structural conversion of the LB layers with glucoamylase. The multistage bioreactor constructed by the LB technique will be used not only as a super small-sized, rapid bioreactor or biosensor but also as an investigating means of the reconstitution of membrane enzyme and biomembrane.

The biomembrane is commonly a complex of lipid and protein constituting sequential enzymatic reaction systems. The same reactions may be realized in an artificially reconstructed system. A system using the microcapsule technique[1] as previously been demonstrated. Glucoamylase was adsorbed to the outside of a microcapsule within which glucose oxidase was contained. The construct functioned as an extremely small-sized bioreactor which converted starch into gluconic acid via glucose. Glucose as the intermediate, however, moved slowly into the inside of the microcapsule, and the rate of the overall reaction was not rapid.

If the enzymes are immobilized in ultrathin films the intermediates of sequential reactions will be able to move rapidly from one enzyme to the next. It is easy to immobilize protein in an organic ultrathin film if the Langmuir–Blodgett technique (LB technique) is used.[2]

The LB technique provides the following advantages: i) It is expected that the denaturation of enzymes is minimized as the technique is a wet process at normal temperature and pressure. ii) The devices constructed by this technique are so small and their that rapid diffusion of the substrate molecules of the enzymatic reactions are allowed. iii) The construction of multilayer structures is easy since the LB film is made by consecutively depositing monolayers. Onoue and Moriizumi constructed a glucose sensor by immobilizing glucose oxidase by the LB technique.[3,4] i) and ii) have already been demonstrated by these previous workers. We realized a two-step sequential reaction by constructing an LB film incorporating different enzymes in successive layers, by the introduction of the viewpoint of iii). This multistage bioreactor is a composite system combining the reaction of glucoamylase which hydrolyzes starch to glucose, and that of glucose oxidase which oxidizes glucose to gluconic acid and hydrogen peroxide.

Experimental

Materials. Enzymes: Glucose oxidase (EC 1. 1. 3. 4) from *Aspergillus niger* (Sigma Chemical) and glucoamylase (EC 3. 2. 1. 3) from *Aspergillus oryzae* (Sigma Chemical) were used. Each enzyme was dissolved in ultra pure water at a concentration of 500 mg dm^{-3}. The electric conductivity of ultra pure water produced by using Milli Q Organex-Q type (Millipore) was more than 17.5 MΩ cm.

Amphiphilic Materials: As a result of considering the surface charges of the enzymes, icosanoic acid (Applied Science) was used to adsorb glucose oxidase and a mixture of trimethyloctadecylammonium chloride (Tokyo Kasei Kogyo) and methyl icosanoate (Applied Science), weight ratio 1:4, was used to adsorb glucoamylase.[4,5] The trimethyloctadecylammonium chloride was recrystallized from hot ethanol–ether. The spreading solvents of the amphiphilic materials were prepared in chloroform (Spectrosol series of Dojindo Laboratories), at a concentration of 1 mg cm^{-3}.

Substrates: Glass substrates with two gold-evaporated electrodes were used. The area of each electrode was 10 mm^2. The surface of the substrate was treated with trichlorooctadecylsilane (Shin-etsu Chemical) and made hydrophobic.[6]

Preparations. Fromherz Method:[2] A Fromherz-type trough (Mayer–Feintechnik) was used. The trough has eight trough compartments, and two barriers can move from one trough compartment to another ad libitum. This Fromherz method was used to carry out the following process. The subphase solution is placed in several trough compartments. Then, a monolayer of amphiphilic molecules is organized on the surface of the subphase. Next, a protein solution is placed in the adjoining trough compartments. The monolayer is then moved over onto the surface of the protein solution to allow the protein to adsorb to the monolayer. This composite monolayer with adsorbed protein is returned onto the pure subphase. The composite monolayer is then deposited onto a glass substrate by the LB technique, and in this way the LB film incorporating protein can be constructed.

Conditions for Constructing the Enzyme LB Film: The Fromherz method was carried out. Ultra pure water was used as the subphase (pH approximately 6, 20 °C). The surface pressure of the monolayer of icosanoic acid was 30 dyne cm^{-1} (1 dyne=10^{-5} N) through the adsorption step, and that of the mixed monolayer described above was 20 dyne cm^{-1}. The time allowed for adsorption was 1 h. The surface pressure of the composite monolayer on the subphase was increased to 35 dyne cm^{-1} for deposition. The dipping speed

was 5 mm min^{-1}. A Y-type deposition was obtained for each composite monolayer. The transfer ratio was between 0.9 and 1.0.

The Measurement of the Enzymatic Reaction. Hydrogen peroxide generated by the enzymatic reaction was measured electrochemically.[3] The substrate was placed in a 1 cm×1 cm cell for spectroscopy containing 1 ml of 0.05 M (1 M=1 mol dm^{-3}) acetate buffer (pH 5, 20 °C).[7] The electrodes on the substrate were connected to a potentiostat with the applied potential set at 0.8 volt. The electrode current was recorded by an X-T recorder connected to the potentiostat. Glucose or soluble starch of reagent grade was used as the substrate of the enzymatic reactions. The substrate solution was prepared in acetate buffer, and 200 μl of a concentrated solution was injected into the buffer in the cell to produce the necessary concentrations.

Results and Discussion

The enzymatic reactions is following:

Glucoamylase

$$\text{starch} + (n-1)\cdot H_2O \longrightarrow n\cdot \text{D-glucose}$$

Glucose oxidase

$$\text{D-glucose} + O_2 \longrightarrow \text{D-gluconic acid} + H_2O_2$$

First, the properties of a bioreactor constructed by the deposition of an LB film incorporating glucose oxidase was studied. The response current at 1 min after injecting glucose, two LB layers incorporating glucose oxidase was directly proportional to the concentration of glucose in the range less than 3 g dm^{-3} (Fig. 1). When this bioreactor was kept at 5 °C for several months, the response current changed very little, indicating high stability. These results agreed with the results by Onoue and Moriizumi.[3]

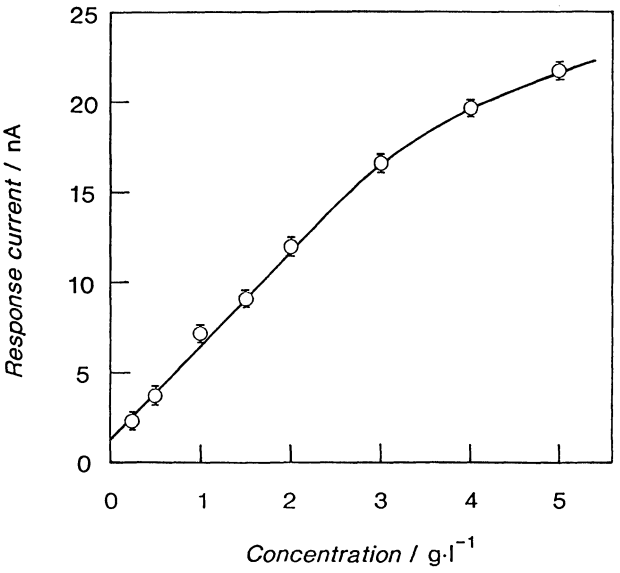

Fig. 1. Response current vs. concentration of glucose. Two LB layers incorporating glucose oxidase was measured. The value (average ±standard error) was observed at 1 min after the addition of glucose solution.

Next, the properties of a multistage bioreactor constructed by depositing two LB layers incorporating glucoamylase onto eight LB layers incorporating glucose oxidase was studied. The time-dependences of the response currents for a series of concentrations of starch are shown in Fig. 2. Rapid response was observed at each concentration of starch solution. These response currents attained steady states in a few seconds. The microcapsule-type bioreactor showed a lag time of sev-

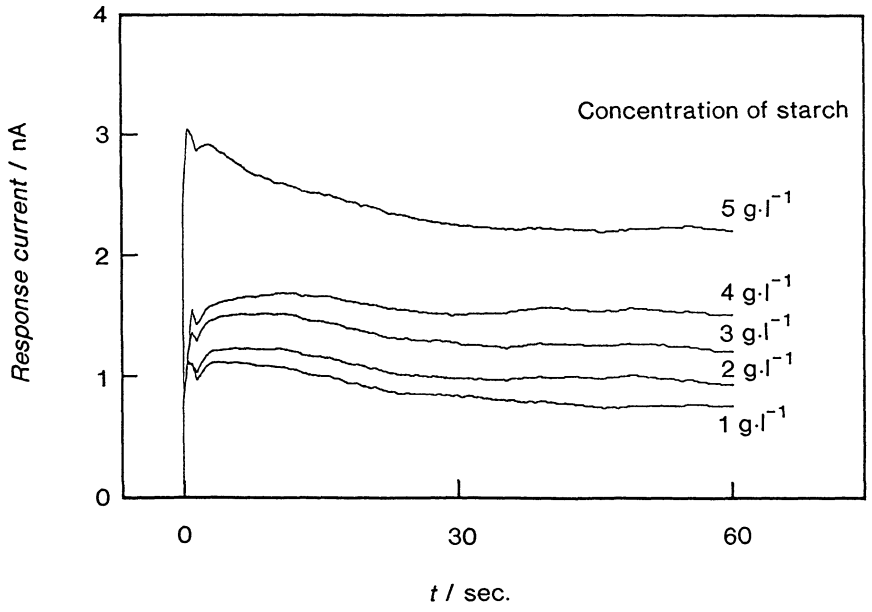

Fig. 2. Response current vs. time after addition of starch solution (t). Two LB layers incorporating glucoamylase on eight LB layers incorporating glucose oxidase were measured.

eral minutes in the reactions.[1] The very short lag time indicates that the diffusion of the intermediate species, glucose, was very rapid in the ultrathin LB film.

Greater concentrations of starch increased the response current. Figure 3 shows the dependence of the response current of the bioreactor, at 1 min after injection, on the concentration of starch. The response current was linearly related to the concentration of starch from 2 to 5 g dm^{-3}, suggesting the possibility of its use as a starch sensor. The reason the fitted line does not go through the origin is probably due to the fact that the solution is not stirred, resulting in some nonuniformity of concentration.

Figure 4 shows the response currents at 1 min after the injection of starch solution plotted against the number of the LB layers incorporating glucose oxidase. In each sample, two LB layers incorporating glucoamylase were deposited on to the LB layers incorporating glucose oxidase. The concentration of starch was 5 g dm^{-3}. The response current was proportional to the number of the glucose oxidase LB layers. As the amount of adsorbed glucose oxidase per one LB layer is constant, this indicated that the activity of the reaction was proportional to the total amount of enzyme incorporated.

The storage stability of the bioreactor constructed was investigated. The bioreactor constructed with two LB layers of glucoamylase deposited on eight LB layers of glucose oxidase was kept at 5 °C. The response current at 1 min after injection of a 5 g dm^{-3} starch solution is plotted in Fig. 5. The response current decreased significantly in five days after construction. The decrease in response current for a bioreactor incorporating only glucose oxidase was found to be very small. Thus, it is suspected that the decay was caused

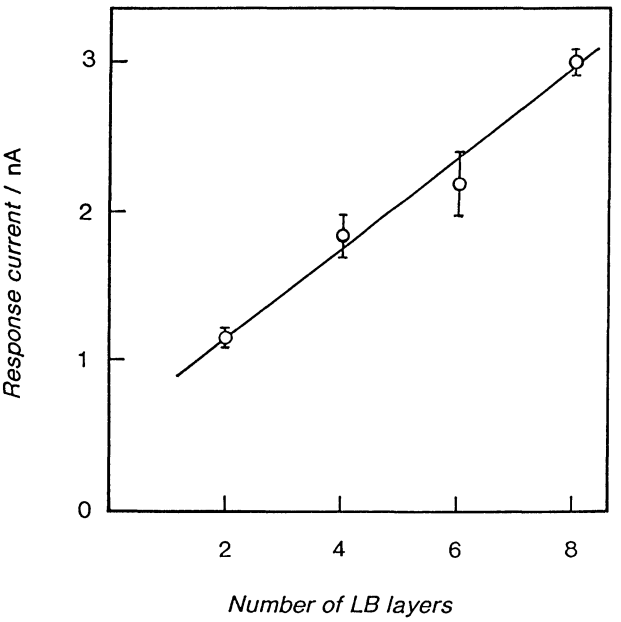

Fig. 4. Response current vs. number of LB layers incorporated with glucose oxidase.

The value (average ±standard error) was observed at 1 min after the addition of starch solution.

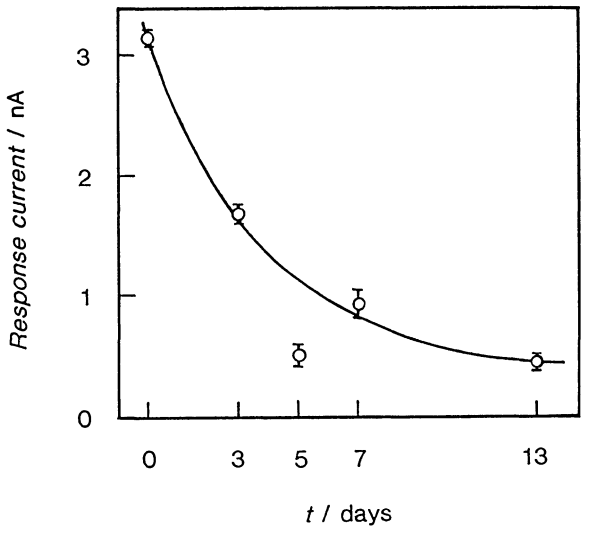

Fig. 5. Storage stability of the bioreactor. Days after preparation (t) vs. response current.
Storage temperature was 5 °C. The bioreactor was constructed with two LB layers incorporated with glucoamylase on eight LB layers incorporated with glucose oxidase. The value (average ±standard error) was observed at 1 min after the addition of starch solution. The concentration of starch was 5 g dm^{-3}.

by the LB layers incorporated with glucoamylase.

The structure of the multistage bioreactor constructed by the LB technique is similar to a biomembrane. Therefore, it will be possible to apply this approach to the study of the property of reconstructed membrane enzyme systems as well as to the construction of ultramicro or ultrarapid bioreactors or biosensors.[8,9] This approach would allow the control of the adsorbed site and the amount of enzyme.[4,10,11]

We thank Dr. Akio Yasuda for his advice about the electrochemical measurement.

Isobutane and isopentane were selectively obtained by polyethylene catalytic decomposition using the NaY-type zeolite catalyst. Back biting reactions are thus essential to gas formation during the catalytic decomposition of polyethylene. Chain-end secondary carbonium ions cause back biting reactions involving intramolecular rearrnagement to form the C_9 fraction. Isobutane and isopentane are then produced by decomposition of the gasification precursor C_9 fraction.

Polymer degradation has mainly been studied for the purposes of attaining greater heat and weather stabilization.[1-4] Many reports describe the mechanisms for this based on radical reactions. However, very little study has been directed to the catalytic degradation of polymers.[5-9] As shown in previous reports,[10,11] unique reactions occur in the catalytic degradation of polyethylene and polystyrene.

For instance, branched ethylene oligomers are produced in the catalytic degradation of polyethylene in the presence of the silica-alumina catalyst.[10] Indan oligomers are produced in the catalytic degradation of polystyrene in the presence of the aluminum chloride catalyst.[11] Gasification was found to occur with the gasification precursor in polyethylene catalytic decomposition. By the zeolite catalyst, the composition of gas resulting from polyethylene catalytic decomposition is unique and differs from that by the silica-alumina catalyst. The gas is composed of isobutane (C_4) and isopentane (C_5), in equimolar amounts at low temperature. The formation mechanisms of these fractions are of interest for the practical utilization of waste polyethylene.

Back biting reactions in gas formation were noted to occur exclusively as elementary reactions. The mechanisms for these reactions are discussed in detail in the following.

Experimental

Sample and Catalyst. The sample was polyethylene (hereafter referred to as PE, $\bar{M}_n$=3.98×10⁴, manufacted by Mitsui Petrochemical Industries Co., Ltd., powder with a mesh of >80).

A NaY-type zeolite catalyst (Na-atoms replacement: Toyo CCI Co., Ltd.) with 24—26 wt% alumina content was used after being heated for 5 h in dry air at 450 °C. It was made into powders of >100 mesh. The physicochemical properties of catalyst are showen in Table 1.

Table 1. Physicochemical Properties of the Catalysts

Catalyst		Zeolite
Al_2O_3	(%)	24—26
SiO_2	(%)	74—76
Na_2O_3	(%)	<0.1
Fe_2O_3	(mmol g^{-1})	0.82
Specific surface area	(m^2 g^{-1})	510—580
Average pore size	(Å)	15—20

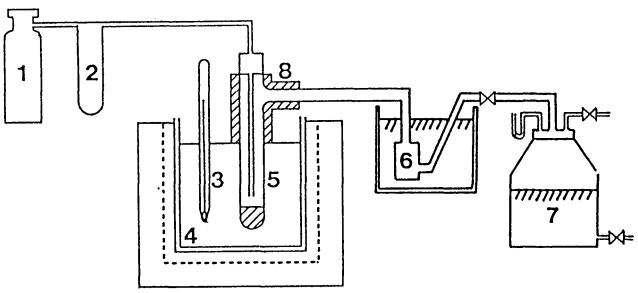

Fig. 1. Batch system reactor for catalytic decomposition. 1) N_2 cylinder, 2) Manometer, 3) Thermometer, 4) Metal bath, 5) Reactor, 6) Trap for liquid, 7) Trap for gaseous products, 8) Asbestos.

Experimental Operation and Procedure. A pyrex glass tube reactor (outer diameter: 25 mm and length: 240 mm) connected to a trap was used to recover gaseous and liquid products as shown in Fig. 1.

The experimental procedure was as follows: 2 g of the sample and 0.06 to 2 g of the catalyst were mixed by stirring. The mixture was placed on the bottom of the reactor and the reaction was conducted from 180 to 300 °C; nitrogen gas was passed through the reactor at a flow rate of 120 ml min^{-1} for 60 min and the ratio of catalyst to sample (C/S) was varied from 0.03 to 1.00.

Analysis Method. To analyze the reaction products recovered, the limiting viscosity method ($[\eta]=5.10\times10^{-4}[\bar{M}_n]^{0.725}$)[12] was used to determine the molecular weight of the degraded polymer. The molecular weight distributions of the oligomer and liquid were determined by field desorption infrared (FD-), field ionization-mass spectrometers (FI-MS)

respectively.[13] The gaseous and liquid products were quantitatively analyzed by a gas–liquid chromatograph (GC-8A of Shimadzu).[14] Chemical structure was determined ^1H and ^{13}C NMR (JEOL, Ltd., JNM-FX100).[10]

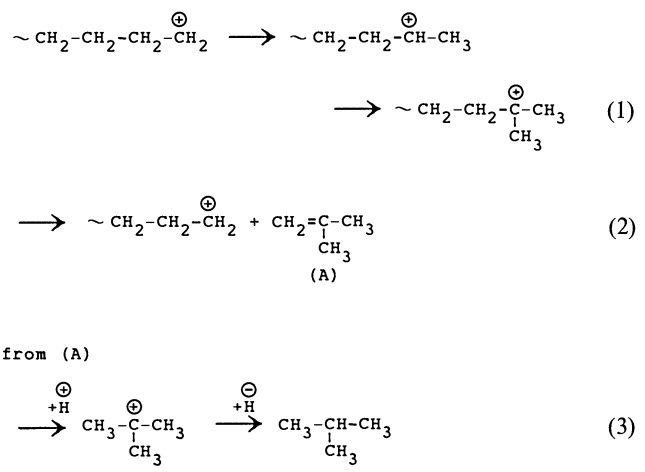
Results and Discussion

Material Balance and Gas Yields by the Zeolite Catalyst. The relationship between reaction temperature and the reaction products of PE decomposition was investigated using the zeolite catalyst. The results are shown in Table 2. The reaction products consisted of 4 fractions, degraded polymer ($\bar{M}_n$=1000<), oligomer ($\bar{M}_w$=300—800), liquid ($\bar{M}_w$=100—250) and gas. The yield of degraded polymer decreased at higher temperature, while that of the liquid fraction containing small amounts of olefins increased rapidly. These results show close agreement with those for PE catalytic decomposition in the presence of the silica–alumina catalyst.[13] As described previously, the gas fraction is produced during liquid fraction (gasification precursor) decomposition and does not derive from chain-end carbonium ions of the oligomer and polymer fractions.[14] If the gas fraction is produced from chain-ends of molecules of the oligomer and polymer fractions, it should be obtainable in a large isobutene yield by isomerization of chain-end carbonium ions without decrease in molecular weight, as shown in Scheme 1.

The formation of 4 fractions indicates that a decrease in molecular weight occurred. From Table 2, the liquid fraction is produced by further decomposition of oligomer and polymer fractions. Gas formation takes place at the chain-ends of the liquid fraction produced by oligomer decomposition, as when using the silica–alumina catalyst.[14]

Table 3 shows the gas composition at each reaction temperature. At a low reaction temperature of 180 °C, the yields of isobutane and isopentane were about 46.5 and 46.9 mol%, respectively.

Gas composition by the silica–alumina catalyst with lower acidity was found to consist of isobutane 54.9 mol%, isopentane 5.9 mol% at 280 °C[13] and thus may possibly depend mainly on the acidity of the catalyst. Isobutane yield was much more than those of the other gaseous products. The formation mechanism of isobutane is possibly direct β-scission of chain-end tertiary carbonium ions produced by redecomposition of the liquid fraction as shown in Scheme 1:



Scheme 1.

In the case of the zeolite catalyst, isopentane yield (36 mol%) was much higher that by the silica–alumina catalyst (6 mol%) at the same temperature 280 °C and isobutane and isopentane would not likely have been formed simultaneously from chain-end primary and secondary carbonium ions. Isopentane was not produced by β-scission from chain-end carbonium ions (primary, secondary and tertiary) in the presence of the zeolite catalyst.

Changes in C_4 and C_5 Fraction Yields as Function of Reaction Conditions. Effects of Reaction Temperature: Figure 2 shows the yields of C_4 and C_5 fractions.

C_4 increased slightly with rise in temperature and was about 50.2 mol% at 180 °C and 51.4 mol% at 300 °C. The C_5 fraction decreased while the C_3 fraction increased at high temperature. The compositions of these fractions were independent of reaction temperature.

Table 3 shows the gas fractions to be produced mainly from the liquid fraction. The decrease in C_5 yield corresponds to the increase in C_3 and C_2 yields at high temperature. The C_5 fraction may possibly decompose into C_3 and C_2 fractions at high temperature.

On using the zeolite catalyst, isobutane and isopentane were produced preferentially. Thus, direct β-scission from chain-end carbonium ions is not important.

The stabilization of chain-end carbonium ions has generally been shown to result from rearrangement of ions (15 kcal mol^{-1}) and direct β-scission (45 kcal mol^{-1}).[15] The intramolecular rearrangement of chain-end carbonium ions thus occurs before direct β-scission. Isobutane and isopentane may possibly be formed from the gasification precursor (liquid fraction) produced by decomposition for the stabilization of internal rearranged ions.

Effects of Contact Time: Figure 3 shows the yield of each fraction at various catalyst concentrations at the same reaction temperature. Decomposition was accelerated of high catalyst concentration even though the temperature was the same. The rapid increase in oligomer yield corresponded to the decrease in degraded polymer yield and the liquid fraction also increased with decrease in oligomer yield. Figure 4 shows the yields of the C_4, C_5 and C_3 fractions at various catalyst concentrations. The composition of gas showed virtually no change with catalyst concentration and yield in each case increased with the catalyst/sample (C/S) ratio. The formation of C_4 and C_5 fractions in equimolar amounts was confirmed. Direct β-scission of secondary or primary chain-end carbonium ions with the formation of C_4 and C_5 was not important and thus, intramolecular rearrangement reactions should be required. In Fig. 4, the rates of C_4 and C_5 formation are nearly equal and these fractions may possibly derive from the same reaction intermediate. If isobutane and isopentane are produced from different reaction intermediates, their yields should also differ.

Gas and liquid yields increased with catalyst concentration at the same temperature (Fig. 3), though gas composition showed no change (Fig. 4). Only reaction temperature affected gas yield (Fig. 2). From Fig. 3, the rapid decrease in oligomer yield can be seen to correspond to increase in liquid yield. The liquid fraction (gasification precursor) is thus shown to be produced by decomposition of oligomers. Thus, changes in the molecular weight of oligomer and liquid fractions were carefully examined.

Molecular Weight and Distribution of the Oligomer Fraction. Figure 5 shows the molecular weight distri-

bution of the oligomer fraction: $\bar{M}_w$=200—1000 (top peak $\bar{M}_w$=350, 180 °C (A)),$\bar{M}_w$=200—700 (top peak $\bar{M}_w$=300, 240 °C (B)), and $\bar{M}_w$=200—500 (top peak $\bar{M}_w$=300, 280 °C (C)) were obtained by FD-MS, respectively. The molecular weight and its distribution shifted to the lower molecular weight side with rise in temperature. Figure 6 shows FI-MS spectrum of the liquid fraction recovered at 280 °C. The molecular weight distribution of M_w=100—250 (top peak M_w=130) was measured for the liquid fraction. That is, the liquid fraction for gas formation are formed during decomposition of the oligomer fraction.

Chemical structure of the Oligomer Fraction. The oligomer structure should thus be carefully analyzed to clarify the mechanism for liquid formation. Figure 7 shows the chemical structure of the oligomer fraction by ^{1}H NMR spectrum (280 °C). The liquid fraction structure was essentially the same as that of the oligomer

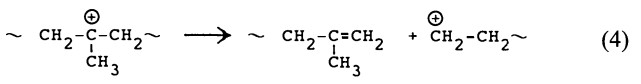
fraction, though the weakest olefinic signals could be detected. The chemical structure of oligomer and degraded polymer mixture are shown in Table 4. The results of analysis of chain-end structures indicated direct β-scission of on-chain tertiary carbonium ions of oligomers. The liquid fraction also possesses these chain-ends. The β-scission is shown in following Scheme 2.



Scheme 2.

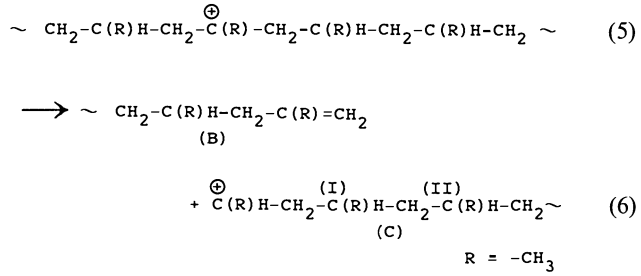
The olefinic liquid fraction flowed into the trap without hydrogenation during a short residence time with high vapor pressure, thus showing it not to possess hydrogenated components.

As shown in Table 5, the oligomer was found to have branched components each possessing short chains of C_1—C_6 6.1 per 20 carbon and $\bar{M}_w$=300 (short chain consist mainly of methyl groups). The extent of branching was essentially the same and showed the back bones of the oligomer structures to be similar to that of copolymer of propylene and 1-butene. The extent of branching has been shown to increase with molecular weight decrease.[13)] The extent of branching of further decomposed liquid from oligomers may possible be the same as that of polypropylene back bones (8 per 20 carbon).

It thus follows that secondary carbonium ions are mainly produced at chain-ends of the liquid fraction produced by β-scission of on-chain carbonium ions of the oligomer. The equimoler formation of C_4 and C_5 by direct β-scission of chain-end secondary carbonium ions from the liquid fraction is difficult and thus internal on-chain carbonium ions should be produced through intramolecular rearrangement of chain-end ions by way of least activation energy which ought to be tertiary carbonium ions. The gasification precursor for the C_4 and C_5 fraction formation may possibly be produced by β-scission of on-chain carbonium ions of the liquid fraction.

Mechanism for the Formation of Isobutane and Isopentane. The β-scission for the catalytic decomposition of the oligomer chains possessing short side chains is shown in Scheme 3.

As shown in Tables 2, 4, and 5, yields of the liquid fraction, chain-end structure of oligomer and the extent of branchings indicate that the oligomer fraction undergo random scission to produce the liquid fraction which has chain-end olefin (B) and chain-end secondary carbonium ions (C). The reactions for this are as follows:



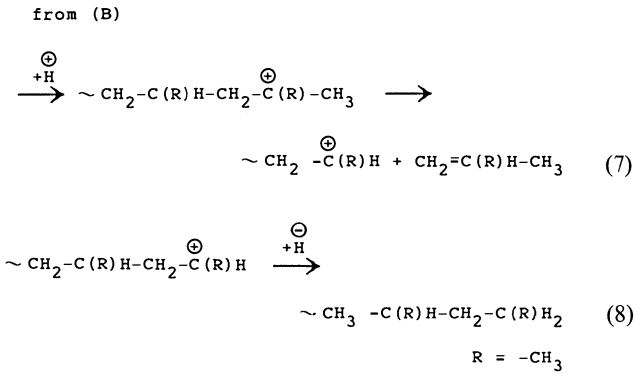
Scheme 3.

Table 5. The Branching Concentration in the Oligomer Fraction

Temp/°C	260	280	300
$CH_3/20CH_2$	2.2	4.3	6.1

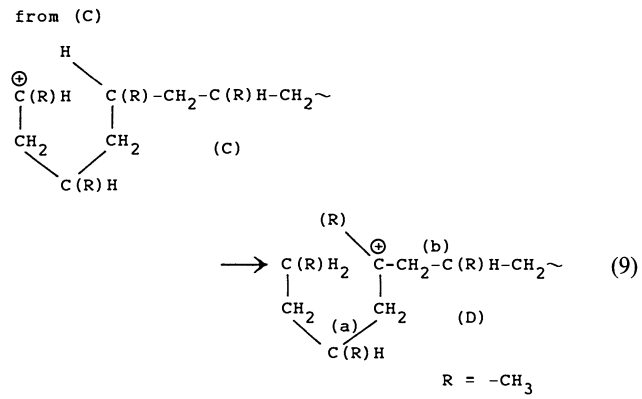
Reaction conditions: zeolite catalyst, time=1 h, C/S =0.25.

Affinity of chain-end olefins for protons released from the catalyst is remarkably high. Consequently, as shown in reaction step (7), olefin (B) immediately undergoes proton addition to form tertiary carbonium ions. These ions are stabilized primarily by β-scission. Hydride ion addition (8) occurs to give the saturated liquid fraction. The reactions for this are as follows:



Only chain-end secondary carbonium ions are produced in the liquid fraction by decomposition of oligomers and are stabilized by an intramolecular rearrangement having the least activation energy. (10—15 kcal mol^{-1}).[15] This occurs most easily through intramolecular rearrangement (15 kcal mol^{-1})[15] rather than by β-scission (45 kcal mol^{-1}).[15] That is, secondary carbonium ions are likely converted preferentially to tertiary carbonium ions.

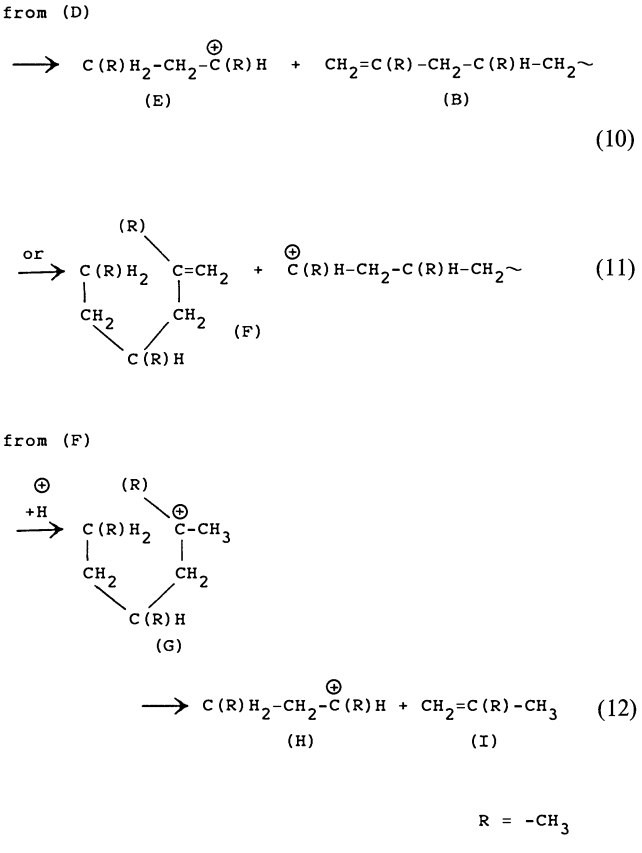
For example, the intramolecular rearrngement of chain-end ions (C) occurs easily on neighboring tertiary carbons by either (I) or (II) (step 6). The formation of ions (I) proceeds via a four membered transition state, while that of ions (II) by a six membered ring. The intramolecular rearrngement of ions (II) occurs exclusively by way of a more stable transition state in step (9).



Chain-end secondary carbonium ions (C) produce internal on-chain tertiary carbonium ions (D) by back biting reactions in step (9). Stabilization of ions (D) occurs by direct β-scission, through either (a) or (b). In the case of the (a) position, 1-methylbutylium ions (E) and chain-end olefins (B) are produced, respectively (step 10). Isopentane is produced by way of hydrogenation and isomerization of (E) ions. The main product produced must thus be only isopentane and the liquid fraction in step (10).

Of course, on the case of this, equimolar yields of C_4 and C_5 could not be recorded. Virtually no gas formation from chain-end olefins occurs continuously. β-scission occurs very little or not at all at the (a) position. Elementary reactions generally lead to the formation of more stable products. The reaction of step (10) is not important.

The stabilization of on-chain carbonium ions (D) occurs through step (11). The C_9 component (F) (branched nonene) is produced by β-scission of (D) ions. From the olefinic branched C_9 fraction (F), reaction intermediate (G) is produced immediately by proton addition in step (12).



The C_4 and C_5 fractions are produced by the redecomposition of intermediate (G). Isobutene is immediately hydrogenated to give isobutane. The 1-methylbutylium ions (H) produced are stabilized by hydride ion addition following isomerization. Isopentane is produced by the hydrogenation of (H) ions.

Table 6. Quantitative Determination of Carbon Number Distribution from the GLC Analysis (Liquid Fraction)

Carbon number	Yield/%
5	0.8
6	2.9
7	6.1
8	7.4
9	17.9
10	17.5
11	20.4
12	11.7
13	13.3

Reaction conditions: zeolite catalyst, temp=260 °C, time=1 h, C/S=O.25.

These steps can be demonstrated by the results of selective formation with equimolar yields of C_4 and C_5 fractions. The continual formation of C_9 is possible only through the reaction intermediate (C) ions in step (9) and not by chain-end olefins (B) in step (10). That is, β-scisssion of (D) ions takes place mainly at the (b) position.

The C_9 fraction (gasification precursor) must first be detected as evidence that these steps actually occur. Table 6 shows the carbon number distribution of the liquid fraction determined by GLC analysis. The liquid fraction consisted of C_9—C_{13} fractions with the C_9 fraction (M_w=128) as the main product. Beltrame, et. al. found the C_9 fraction (saturated and unsaturated isomers) to be the main component in the catalytic decomposition products of PE in the presence of the silica-alumina catalyst.[16]

The C_9 fraction thus corresponds to the reaction intermediate as a gasification precursor. Chain-end secondary carbonium ions of the liquid fraction are formed during the decomposition of the oligomer fraction. These ions are mainly stabilized by back biting involving intramolecular rearrangement. Rearraged on-chain tertiary carbonium ions are also stabilized by β-scission, and consequently, the C_9 fraction is produced. The C_9 fraction cannot be produced by direct β-scission of (a) position, chain-end carbonium ions of the liquid and oligomer fractions but from internal on-chain carbonium ions produced by intramolecular rearrangement via the lowest activation energy than that by β-scission.

The manner in which isobutane and isopentane are formed is shown in Scheme 3. Back biting reactions (step (9)) are quite important to this formation. Isobutane is produced by the hydrogenation of butenes, but no pentenes could be detected in the formation of isopentane and pentane. Pentanes are not produced by hydrogenation of C_5 olefins. That no isopentene could be detected is clear indication of C_9 fraction redecomposition. In this process, only 1-methylbutylium ions are formed. Unstable C_5 ions may possibly be decomposed into the C_3 and C_2 fractions at high temperature. Reaction steps (9) and (11) are repeated. Continuative gasification takes place at step (12) by way of steps (9) and (11).

The oligomer fraction was found to have essentially the same degree of branching as the polypropylene back bone structure. Therefore, the product distribution of polypropylene catalytic decomposition was analyzed. Gas produced by polypropylene decomposition using the silica-alumina catalyst consisted of isobutane 40.4 mol% and isopentane 30.9 mol% at 280 °C.[13] As shown in Table 3, the yield of C_4 and C_5 fractions were 44 and 36 mol% at the same temperature, respectively. The present results confirm the occurrence of these steps PE catalytic decomposition by the NaY-type zeolite catalyst should certainly give rise to isobutane and isopentane as the main products. Back biting reactions are thus shown essential to the formation of the gasification precursor (C_9 fraction) in the catalytic decomposition of PE.

Conclusions

An attempt was made to determine the mechanism for the formation of gas having a peculiar composition in PE decomposition in the presence of the zeolite catalyst. Based on the results obtained, the following conclusions are drawn.

1) The production of isobutane and isopentane in nearly equimolar yields was found at low temperature.

2) The C_9 fraction of the gasification precursor is thus obtained by β-scission of rearrenged on-chain tertiary carbonium ions produced by back biting reactions of chain-end secondary carbonium ions of liquid fraction.

3) Isobutane and isopentane are also produced by redecomposition of the C_9 fraction.

Synthesis, Chemical Properties, and Structure of a Sterically Hindered Ketone, 2,2,5,5-Tetramethyl-4,4-diphenyl-3-thiolanone

Juzo NAKAYAMA,* Atsushi HIRASHIMA, and Yoshinobu YOKOMORI†
Department of Chemistry, Faculty of Science, Saitama University, Urawa, Saitama 338
†Department of Chemistry, The National Defense Academy, Hashirimizu, Yokosuka, Kanagawa 239
(Received July 29, 1991)

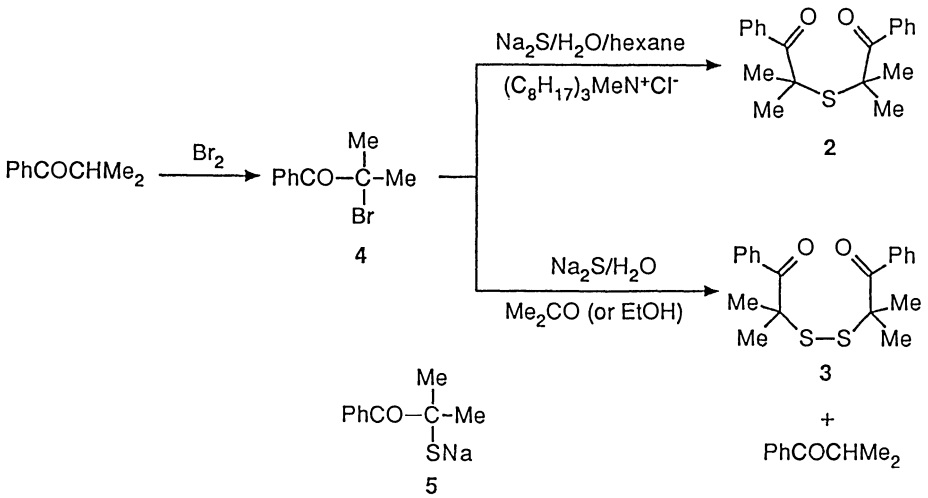
A sterically hindered ketone, 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanone (**1**), was synthesized in two steps starting from 2,2,4,4-tetramethyl-1,5-diphenyl-3-thiapentane-1,5-dione. The carbonyl group of **1** is unreactive toward a series of nucleophiles which are bulkier than hydride or its equivalents. The observed unreactivity is ascribed to the steric hindrance enhanced by the two methyl groups on C-5 ("buttressing" effect). The result of an X-ray single crystal structure analysis of **1** is also described.

We have been investigating the synthesis using 3-thiapentane-1,5-diones and related compounds as starting materials.[1] In this connection we have synthesized a sterically hindered ketone, 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanone (**1**), in two steps starting from 2,2,4,4-tetramethyl-1,5-diphenyl-3-thiapentane-1,5-dione (**2**). We report here the synthesis, chemical properties, and X-ray single crystal structure analysis of **1**.

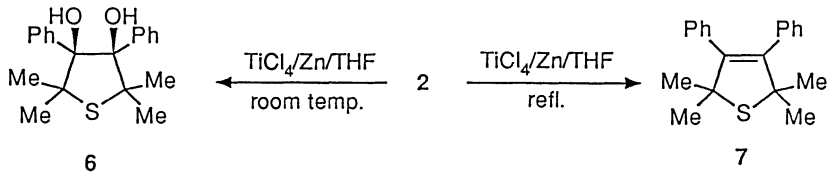
Results and Discussion

Preparation of 1 and Related Compounds. Isobutyrophenone was brominated by molecular bromine in ether and the resulting crude bromide **4** was allowed to react with sodium sulfide in two ways. A two-phase mixture of sodium sulfide and **4** in water–hexane was stirred in the presence of methyltrioctylammonium chloride (a phase transfer catalyst) at room temperature. Usual work-up of the mixture afforded the expected sulfide **2** in 60% yield (based on isobutyrophenone). When an aqueous solution of sodium sulfide was added to a stirred and ice-cooled solution of **4** in acetone or ethanol, however, the disulfide **3** was obtained unexpectedly in 45% yield along with isobutyrophenone. The initial process of this reaction also must involve a nucleophilic substitution leading to **5**. In this case, however, **5** preferentially reacts with sodium sulfide, but not with **4**, to give the enolate of isobutryophenone and sodium disulfide. The reaction of sodium disulfide with **4** should give rise to the final product **3**. Supporting evidence for this mechanism comes from the finding that treatment of α-chlorodeoxybenzoin with one equiv of sodium methanethiolate at 0 °C in ethanol affords α-methylthiodeoxybenzoin, which in turn gives deoxybenzoin and dimethyl disulfide by further treatment with sodium methanethiolate.[2] We have also experienced that α-halodeoxybenzoins and related compounds are reduced to the corresponding dehalogenated products by sodium sulfide even when the reaction was carried out under phase transfer conditions in the presene of methyltrioctylammonium chloride.[1]

We have previously shown that intramolecular reductive coupling of a series of 3-thiapentane-1,5-diones with a low valent titanium reagent, prepared from titanium(IV) chloride and zinc in tetrahydrofuran (THF),[4] around 0 °C affords 3,4-thiolanediols in good yields,[1c,e–g,k] while the reduction in refluxing THF gives 2,5-dihydrothiophenes.[1b,d,f] Thus, treatment of **2** with



Scheme 1.



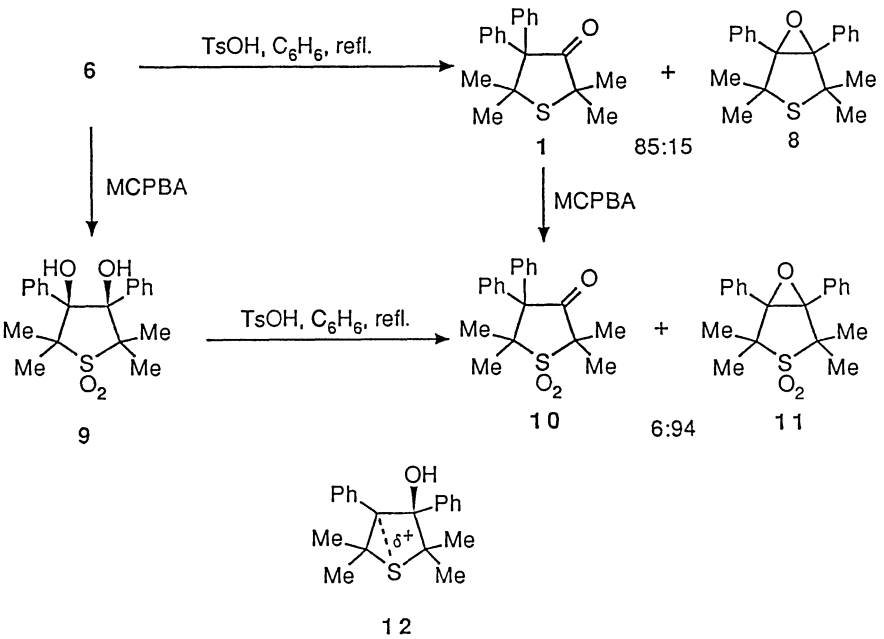
Scheme 2.

the low valent titanium reagent at room temperature affords the diol **6** in 45% yield, while the reduction in refluxing THF gives the dihydrothiophene **7** in 43% yield. Two hydroxyl groups of a number of thiolanediols prepared by the present method have a *cis*-configuration without any exception,[1e,g] and hence two hydroxyl groups of **6** must have a *cis*-configuration.

It is well documented that cyclic *cis*-1,2-diols undergo pinacol rearrangement more smoothly than the corresponding *trans*-1,2-diols do.[5] Thus, heating the diol **6** with a catalytic amount of *p*-toluenesulfonic acid (TsOH) in refluxing benzene for 2 h brings about a smooth pinacol rearrangement to give the expected ketone **1** (84%) in addition to the epoxide **8** (15%). Prolonged heating does not change the ratio of **1** to **8**, revealing that no rearrangement of **8** to **1** occurs under the applied conditions. Oxidation of **6** with 2.3 equiv of *m*-chloroperbenzoic acid (MCPBA) in dichloromethane at room temperature gives the sulfone **9** nearly quantitatively. The pinacol rearrangement of **9** is sluggish; heating **9** with TsOH in refluxing benzene for 5 h affords the ketone **10** only in 3% yield with 50% recovery of **9**, the main product being the epoxide **11** (38%). Oxidation of the ketone **1** with 2.2 equiv of MCPBA at room temperature gives the corresponding sulfoxide (24%) and the sulfone **10** (68%). No clear explanation for the difference of the ratio of ketones to epoxides produced from **6** and **9** is available. More smooth pinacol rearrangement of **6** may be ascribed to the difference of the conformation between **6** and **9** or the stabilization of the carbonium ion intermediate by the neighboring group participation of sulfur such as **12**.

Chemical Properties of 1. Reactivities toward nitrogen nucleophiles were first examined. Many sterically hindered ketones react with hydrazine in refluxing diethylene glycol to give the corresponding hydrazones in good yields.[6] However, **1** does not react with excess hydrazine under the above conditions (refl., 97 h), **1** being recovered nearly quantitatively. Heating **1** with *p*-toluenesulfonohydrazide in the presence of a catalytic amount of hydrochloric acid in refluxing ethanol for 54 h also did not bring about hydrazone formation, but unexpectedly afforded di-*p*-tolyl disulfide (4%) and *S*-*p*-tolyl *p*-toluenethiosulfonate (80%) with quantitative recovery of **1**. A separate experiment showed that heating the hydrazide alone under the above conditions gives the disulfide (32%) and thiosulfonate (48%). Although the mechanism of the reaction is not clear, this type of reaction seems unprecedented.

The ketone **1** is also inert to sulfur nucleophiles.



Scheme 3.

Heating **1** with excess Lawesson's reagent [2,4-bis(4-methoxyphenyl)1,3-dithia-2,4-diphosphetane-2,4-disulfide] in refluxing toluene for 12 h resulted in the quantitative revovery of **1** without formation of the corresponding thioketone. Treatment of **1** with 1,2-ethanedithiol in the presence of $BF_3 \cdot Et_2O$ in refluxing dichloromethane does not bring about dithioacetal formation.

Attempted reduction of **1** with sodium borohydride in refluxing THF resulted in the quantitative recovery of **1**. Lithium aluminum hydride reduced **1** to the corresponding alcohol **13** in 87% yield in THF at room temperature. This is the only example that a soomth reaction occurred at the carbonyl moiety.

Reaction of **1** with excess butyllithium in THF at room temperature for 24 h affords the alcohol **13** in 28% yield with 52% recovery of **1**. The formation of **13** may best be explained by assuming a cyclic transition state mechanism **14**. Such mechanim is often encountered in reactions of sterically hindered nonenolizable ketones with Grignard reagents or organolithium reagents.[7] Thus, methylmagnesium bromide which does not carry a β hydrogen and hence cannot react with **1** by the above mechanism is inactive toward **1** in refluxing THF. The reaction of **1** with excess butylmagnesium bromide in refluxing THF for 27 h affords the dihydrothiophene **7** in 54% yield with 43% recovery of **1**. The most straightforward explanation for the above result involves the initial formation of **13**; dehydration of **13** accompanied by migration of phenyl should lead to **7**. However, neither action of butylmagnesium bromide on **13** nor heating **19** with TsOH in refluxing THF affords **7**. An alternative mechanism producing **7** may, therefore, be operative.

Metallation of α-alkyl substituent of nonenolizable ketones with lithium 2,2,6,6-tetramethylpiperidide (LTMP) was recently reported.[8] Treatment of **1** with excess LTMP afforded a complex mixture containing unreacted **1** (65%), no evidence for metallation of the methyl or phenyl being obtained.

Oxidation of **1** with excess MCPBA at room temperature affords a mixture of the corresponding sulfoxide and sulfone **10** as already described. Oxidation of **1** with a large excess of MCPBA catalyzed by TsOH in refluxing dichloromethane afforded **10** quantitatively; no product due to the Baeyer–Villiger oxidation was formed.

We therefore conclude that the carbonyl of **1** is inactive toward nucleophiles which are bulkier than hydride or its equivalent (butyllithium and probably butylmagnesium bromide). The observed inactivity must be ascribed to steric hindrance. Thus, two methyls on C-2 and two phenyls on C-4 interfere the approach of nucleophiles to the carbonyl carbon. At least, in the present system, phenyl behaves as a bulkier substituent than methyl because the ketone **15** and related ones are able to react with hydrazine,[6b–d] whereas **1** is not.[9] The steric hindrance must be further enhanced by the presence of two methyls on C-5; interaction between two phenyls and these two methyls makes the former substituents conformationally more rigid and inelastic ("buttressing" effect).[10] Incidentally the spacial interaction between carbonyl carbon and sulfur such as **16** is not appreciable and thus is not the cause of the inactivity. In ^{13}C NMR the carbonyl carbon of **1** occurs at δ=215 and that of **10** at δ=205. The observed difference is not the one expected from the presence of spacial interaction. In the IR spectrum the carbonyl stretchin of **1** appears at 1728 cm^{-1}, the normal position as a five-membered ketone.[11]

X-Ray Single Crystal Structure Analysis of 1. Figure 1 shows an ORTEP drawing of the compounds **1**. The

numbering given in Fig. 1 is arbitrary and is not consistent with that of the IUPAC nomenclature. Final atomic coordinates and equivalent thermal parameters are summarized in Table 1. Bond lengths and bond angles are listed in Table 2. These results show that the five-membered ring of **1** is in a half-chair conformation. The longer bond length (1.562 Å) of the C1–C2 bond compared to usual sp^3–sp^3 carbon bonds reveals the presence of large nonbonded repulsion between two methyls on C1 and two phenyls on C2; length of the corresponding bond of the parent thiolane is 1.536 Å.[12] The bond angle C2–C3–O is as large as 125.1°, while the bond angle C4–C3–O is reduced to 120.4°. This indicates that the nonbonded repulsion mentioned above thrusts the phenyls to the carbonyl side, which in turn results in the repulsion between the phenyls and the carbonyl oxygen and thus expands the bond angle C2–C3–O. The repulsion between the carbonyl oxygen and the two methyls on C4 is avoidable by placing these groups in a noneclipsed conformation. This may agree with the fact that the C3–C4 bond (1.543 Å) is slightly shorter than the C2–C3 bond (1.549 Å). Also interesting is the fact that the S–C1 bond (1.840 Å) is longer than the S–C4 bond (1.801 Å). This probably means that the nonbonded repulsion between the phenyls on C2 and methyls on C1 thrusts the latters to the sulfur side, thus in turn making the nonbonded repulsion between the methyls and lone pair electrons on the sulfur large enough to lengthen the S–C1 bond. The C=O bond length (1.201 Å) seems to correspond to those of usual carbonyl compounds.[13] The C1–S–C4 bond angle (96.2°) is larger than the corresponding bond angle (93.4°) of the parent thiolane.[12] The distances between S and C3 and between S and O are 2.675(6) and 3.828(6) Å, respectively. The former value shows that the spacial interaction beween the sulfur and C3 is weak, if present.

Experimental

General. Melting points were measured on a MEL-TEMP capillary tube melting point apparatus and are uncorrected. IR spectra were taken on a Hitachi 270-50 spectrometer. ^{1}H NMR spectra were recorded on a JEOL PMX-60 or a JEOL FX-90Q spectrometer. ^{13}C NMR spectra were determined on a JEOL FX-90Q spectrometer. Chemical shifts are reported as δ values in parts per million relative to tetramethylsilane. Mass spectra (MS) were determined on a Shimadzu QP 1000 spectrometer. Column chromatography was conducted using E. Merck silica gel 60 (70—230 mesh). Tetrahydrofuran (THF) containing no stabilizer from a freshly opened bottle was dried over molecular sieves under nitrogen. Other materials were used as purchased unless otherwise noted. Elemetnal analyses of all new compounds were performed by the chemical analysis center of Saitama University and are consistent with the calculated values within ±0.30%.

2,2,4,4-Tetramethyl-1,5-diphenyl-3-thiapentane-1,5-dione (2). To a stirred and ice-cooled mixture of 25.1 g (0.17 mol)

of isobutyrophenone and a catalytic amount of aluminum chloride (ca. 0.3 g) in 170 ml of ether was added 27.1 g (0.17 mol) of bromine over a period of 1.5 h. After stirring for 0.5 h at room temperature the reaction was quenched by adding 300 ml of ice-water. The organic layer was separated, washed with water, dried over anhydrous magnesium sulfate, and evaporated to give 38.0 g of the crude bromide **4**.

The bromide thus obtained was dissolved in 170 ml of hexane and then mixed with a solution of 93.0 g (0.38 mmol) of sodium sulfide nonahydrate in 170 ml of water. The addition of 2 ml of methyltrioctylammonium chloride under stirring to the above two-phase mixture brought about a mildly exothermic reaction. After stirring for 6 h at room temperature the white crystals deposited were collected by filtration, washed with 20 ml of hexane and then with 20 ml of water, and dried to give 14.6 g of **2**, mp 98.5—99 °C. The filtrate and washings were combined and then the organic layer was separated, washed with water, dried, and evaporated. The residue was recrystallized from methanol to give 2.1 g of **2**, mp 99 °C (combined yield 60%, based on isobutyrophenone). **2**: ^{1}H NMR ($CDDCl_3$) δ=1.55 (12H, s, Me), 7.1—7.7 (6H, m, phenyl), 7.9—8.4 (4H, m, phenyl); MS m/z 326 (M^+). Anal. ($C_{20}H_{22}O_2S$) C, H.

2,2,5,5-Tetramethyl-1,6-diphenyl-3,4-dithiahexane-1,6-dione (3). The crude bromide **4** (22.7g, 0.1 mmol) obtained as above was dissolved in 130 ml of ethanol. To this ice-cooled and stirred solution was added a solution of 12.3 g (51 mmol) of sodium sulfide nonahydrate in 25 ml of water over a period of 0.5 h. The mixture was warmed to room temperature and stirred for 3 h. The resulting crystalline precipitate was collected by filtration, washed with water and then with 10 ml of methanol, and dried to give 7.4 g (41%) of **3**. Analyses of the filtrate by TLC and ^{1}H NMR revealed the formation of isobutyrophenone in a considerable amount. Analytically pure **3** was obtained by recrystallization from methanol: mp 59.5—60 °C; ^{1}H NMR ($CDCl_3$) δ=1.50 (12H, s, Me), 7.1—7.5 (6H, m, phenyl), 7.8—8.1 (4H, m, phenyl); MS m/z 358 (M^+), 179 (base peak). Anal. ($C_{20}H_{22}O_2S_2$)C,H.

2,2,5,5-Tetramethyl-3,4-diphenylthiolanethiolane-3,4-diol (6). To a stirred and ice-cooled suspension of 6.0 g (92 mmol) of zinc powder in 100 ml of THF was added 5 ml (46 mmol) of titanium(IV) chloride during 0.5 h. Alter stirring for 0.5 h at that temperature, a solution of 3.27 g (10 mmol) of the sulfide **2** in 70 ml of THF was added over a period of 0.5 h. The mixture was slowly warmed to room temperature and stirred for 12 h. The reaction was quenched by adding a sufficient amount of ice and a 10% aqueous sodium carbonate solution (100 ml). Dichloromethane (200 ml) was added and the mixture was stirred for 15 min and filtered through a pad of celite. The organic layer was separated, washed with water repeatedly, dried over anhydrous magnesium sulfate, and evaporated. The residue was recrystallized from hexane to afford 0.76 g of **6**, mp 128—129 °C. Purification of the mother liquor of recrystallization by silica-gel column chromatography gave a further amount (0.74 g) of **6**. Total yield, 45% (1.50 g). **6**: IR (KBr) 3556, 3512 cm^{-1} (OH); ^{1}H NMR ($CDCl_3$) δ=1.27 (6H, s, Me), 1.73 (6H, s, Me), 3.41 (2H, s, OH), 6.9—7.6 (10H, m, phenyl). Anal. ($C_{20}H_{24}O_2S$) C, H.

2,2,5,5-Tetramethyl-3,4-dipheyl-2,5-dihydrothiophene (7). A low valent titanium reagent was prepared from 10 ml (92 mmol) of titanium(IV) chloride and 12 g (184 mmol) of zinc powder in 150 ml of THF. A solution of 6.53 g (20 mmol) of **2** in 60 ml of THF was added dropwise to the above reagent which was stirred and cooled by an ice-salt bath. The mixture was slowly warmed to room temperature and then refluxed for 2 h. Treatment of the mixture in a manner silmilar to that described above gave 2.52 g (40%) of **7**: Mp 163—164 °C (from methanol); ^{1}H NMR ($CDCl_3$) δ=1.56 (12H, s, Me), 7.03 (10H, broad s, phenyl). Anal. ($C_{20}H_{22}S$) C, H.

Pinacol Rearrangment of 6. A mixture of 328 mg (1 mmol) of **6** and 30 mg of *p*-toluenesulfonic acid monohydrate in 30 ml of benzene was refluxed for 2 h. The mixture was evaporated and the residue was chromatographed on a column of silica gel. Elution with carbon tetrachloride gave 261 mg (84%) of 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanone (**1**), 47 mg (15%) of 3,4-epoxy-2,2,5,5-tetramethyl-3,4-diphenylthiolane (**8**), and a trace amount of **6** in this order. Prolonged heating (reflux for 6.5 h) also afforded **1** and **8** in 85 and 14.5% yields, respectively, indicating that no rearrangement of **8** to **1** occurs under the applied conditions.

1: Mp 154 °C (from methanol); IR (KBr) 1728 cm^{-1} (C=O); ^{1}H NMR ($CDCl_3$) δ=1.36 (12H, s, Me), 7.13—7.34 (6H, m, phenyl), 7.39—7.59 (4H, m, phenyl); ^{13}C NMR ($CDCl_3$) δ= 29.5, 31.6, 49.5, 54.6, 71.6, 126.8, 127.4, 131.6, 140.9, 214.5 (C=O). Anal. ($C_{20}H_{22}OS$) C, H.

8: Mp 178—179 °C (from ethanol); ^{1}H NMR ($CDCl_3$) δ=1.37 (6H, s, Me), 1.64 (6H, s, Me), 6.96—7.47 (10H, m, phenyl). Anal. ($C_{20}H_{22}OS$)C, H.

Preparation of 9 and Its Acid-Catalyzed Rearrangement. A mixture of 658 mg (2 mmol) of the diol **6** and 781 mg (4.5 mmol) of MCPBA (Tokyo Kasei) in 20 ml of dichloromethane was stirred at room temperature for 4 h. The mixture was diluted with 50 ml of dichloromethane, washed with a 10% aqueous solution of sodium hydrogensulfite, a 10% aqueous solution of sodium carbonate, and water, dried over magnesium sulfate, and evaporated. Purification of the resulting crystalline residue with a short column of silica gel using dichloromethane as the eluent gave 703 mg (98%) of 3,4-dihydroxy-2,2,5,5-tetramethyl-3,4-diphenylthiolane 1,1-dioxide (**9**): Mp 169—171 °C (from cyclohexane); IR (KBr) 3404 (OH), 1268, 1102 cm^{-1} (SO_2); ^{1}H NMR ($CDCl_3$) δ=1.42 (6H, s, Me), 1.64 (6H, s, Me), 3.98 (2H, s, OH), 6.95—7.35 (10H, m, phenyl). Anal. ($C_{20}H_{24}O_4S$) C, H.

A mixture of 360 mg (1 mmol) of **9** and 30 mg of *p*-toluenesulfonic acid monohydrate in 30 ml of benzene was heated under reflux for 5 h. The mixture was evaporated and the residue was chromatographed on a column of silica gel. Elution with dichloromethane gave 8.6 mg (2.5%) of 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanone 1,1-dioxide (**10**), 131 mg (38%) of 3,4-epoxy-2,2,5,5-tetramethyl-4,4-diphenylthiolane 1,1-dioxide (**11**), and 182 mg (50%) of **9** in this order.

10: Mp 191—192 °C (from cyclohexane); IR (KBr) 1738 (C=O), 1296, 1108 cm^{-1} (SO_2); ^{1}H NMR ($CDCl_3$) δ=1.41 (6H, s, Me), 1.48 (6H, s, Me), 7.1—7.7 (10H, m, phenyl); ^{13}C NMR ($CDCl_3$) δ=22.6, 22.9, 23.9, 24.3, 62.0, 66.7, 71.6, 126.1, 129.2, 132.3, 139.4, 207.5 (C=O). Anal. ($C_{20}H_{22}O_3S$) C, H.

11: Mp 259—260 °C (from EtOH); IR (KBr) 1298, 1108 cm^{-1} (SO_2); ^{1}H NMR ($CDCl_3$) δ=1.42 (6H, s, Me), 1.61 (6H, s, Me), 7.0—7.4 (10H, m, phenyl); ^{13}C NMR ($CDCl_3$) δ=18.0, 23.3, 62.9, 74.9, 127.6, 128.4, 128.6, 131.1. Anal. ($C_{20}H_{22}O_3S$) C, H.

Oxiation of 1 with MCPBA. To a stirred solution of 162 mg (0.52 mmol) of **1** in 10 ml of dichloromethene was added 197 mg (1.15 mmol) of MCPBA in small portions. After stirring at room temperature for 21 h, the mixture was washed

with a 10% aqueous sodium hydrogensulfite solution, a 10% aqueous sodium carbonate solution, and water, dried over magnesium sulfate, and evaporated. The residue was chromatographed on a column of silica gel. Elution with dichloromethane gave 122 mg (68%) of the sulfone **10**, which is identical with that obtained by the acid-catalyzed rearrangement of **9** in every respect. Further elution with the same solvent gave 41 mg (24%) of 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanone 1-oxide: Mp 167 °C (from hexane); ^{1}H NMR ($CDCl_3$) δ=1.06 (3H, s, Me), 1.10 (3H, s, Me), 1.40 (3H, s, Me), 1.62 (3H, s, Me), 7.05—7.62 (10H, m, phenyl). Anal. ($C_{20}H_{22}O_2S$) C, H.

A mixture of 156 mg (0.5 mmol) of **1**, 363 mg (2 mmol) of MCPBA, and 10 mg of *p*-toluenesulfonic acid monohydrate in 20 ml of dichloromethane was stirred for several hours at room temperature and then refluxed for 32 h. Workup of the mixture gave the sulfone **10** quantitatively; no product arising from Baeyer–Villiger oxidation was detected.

Attempted Reactions of 1 with Nitrogen Nucleophiles. a) With Hydrazine. A mixture of 621 mg (2 mmol) of **1** and 1.25 ml (25.7 mmol) of hydrazine monohydrate in 10 ml of diethylene glycol was heated under reflux for 97 h. Usual workup of the resulting dark brown mixture afforded **1** in 97% yield.

b) *p*-Toluenesulfonohydrazide. A mixture of 546 mg (1.76 mmol) of **1**, 376 mg (2 mmol) of *p*-toluenesulfonohydrazide, and three drops of concentrated hydrochloric acid in 15 ml of 95% ethanol was refluxed for 54 h. The mixture was cooled and the resulting crystalline precipitate was collected by filtration to give 76% recovery of **1**. The filtrate was evaporated under reduced pressure and the residue was chromatographed on a column of silica gel. Elution with carbon tetrachloride gave 9 mg (3.7%) of di-*p*-tolyl disulfide, mp 44—45 °C, 101 mg (18.5%) of **1**, and 224 mg (80%) of *S*-*p*-tolyl *p*-toluenethiosulfonate, mp 74 °C (lit,[14] mp 76 °C), in this order.

In a separate experiment a mixture of 374 mg (2 mmol) of *p*-toluenesulfonohydrazide and three drops of concentrated hydrochloric acid in 15 ml of 95% ethanol was refluxed for 54 h. Chromatographic workup of the mixture gave the disulfide and thiosulfonate in 32 and 48% yields, respectively.

Attempted Reactions of 1 with Sulfur Nucleophiles. a) With Lawesson's Reagent. A mixture of 155 mg (0.5 mmol) of **1** and 1.03 g (2.5 mmol) of freshly prepared Lawesson's reagent in 10 ml of anhydrous toluene was refluxed for 12 h under nitrogen. Workup of the mixture gave **1** quantitatively.

b) With 1,2-Ethanedithiol. A mixture of 155 mg (0.5 mmol) of **1**, 377 mg (4 mmol) of 1,2-ethanedithiol, and 0.2 ml of boron trifluoride etherate in 5 ml of dichloromethane was refluxed for 12 h. Chromatographic workup of the mixture gave **1** quantitatively.

Hydride Reduction of 1. a) With Sodium Borohydride. To a stirred and ice-cooled solution of 226 mg (0.73 mmol) of **1** in 5 ml of THF was added 100 mg (2.7 mmol) of sodium borohydride. The mixture was warmed to room temperature and then refluxed for 8 h. Usual workup of the mixture gave **1** quantitatively.

b) With Lithium Aluminum Hydride. To a stirred and ice-cooled solution of 155 mg (0.5 mmol) of **1** in 5 ml of anhydrous THF was added 100 mg (2.6 mmol) of lithium aluminum hydride. The mixture was stirred for 0.5 h at that temperature, warmed to room temperature, and stirred for 3.5 h. The reaction was quenched by addition of wet THF and then water. The mixture was extracted with ether. The extract was washed with water, dried over anhydrous magnesium sulfate, and evaporated. The residue was chromatographed on a column of silica gel. Elution with benzene gave 5.4 mg of an unidentified product and then 135 mg (87%) of 2,2,5,5-tetramethyl-4,4-diphenyl-3-thiolanol (**13**):Mp 124 °C (from hexane); IR (KBr) 3560 cm^{-1} (OH); ^{1}H NMR ($CDCl_3$) δ=0.83 (3H, s, Me), 1.09 (3H, s, Me), 1.61 (3H, s, Me), 1.67 (3H, s, Me), 1.45 (1H, d, J=13Hz, OH), 5.14 (1H, d, J=13Hz, methine), 7.06—7.54 (8H, m, phenyl), 7.54—8.01 (2H, m, pheyl); ^{13}C NMR ($CDCl_3$) δ=23.6, 24.1, 35.8, 36.1, 49.6, 51.9, 66.4, 81.9, 126.6, 127.1, 127.8, 128.8, 133.8, 134.0, 139.8, 145.0. Anal. ($C_{20}H_{24}OS$) C, H.

Reactions of 1 with Organometallic Reagents. a) With Butyllithium. To a stirred and ice-cooled solution of 311 mg (1 mmol) of **1** in 5 ml of anhydrous THF was added 1.26 ml (2 mmol) of 1.59 M (1M=1 mol dm^{-3}) solution of butyllithium in hexane under nitrogen. The mixture was slowly warmed to room temperature and stirred for 24 h. The reaction was quenched by addition of wet THF and then water. The mixture was extracted with water, dried over anhydrous magnesium sulfate, and evaporated. Silica-gel column chromatography of the residue with carbon tetrachloride as the eluent gave **1** (52%), 88 mg (28%) of **13**, and three unidentified compounds in small amounts.

b) With Methylmagnesium Bromide. To a solution of 311 mg (1 mmol) of **1** in 5 ml of anhydrous THF was added 0.67 ml (2 mmol) of 3 M solution of methylmagnesium bromide in ether under nitrogen. The mixture was stirred for 2 h at room temperature and then refluxed for 15 h. Usual workup of the mixture gave **1** in 99% yield.

c) With Butylmagnesium Bromide. To a stirred and ice-cooled butylmagnesium bromide solution, prepared from 766 mg (5.6 mmol) of butyl bromide and 122 mg (5 mmol) of magnesium in 3 ml of THF, was added a solution of 303 mg (0.98 mmol) of **1** in 2 ml of THF under nitrogen. The mixture was slowly warmed to room temperature and then refluxed for 27 h. The reaction was quenched by addition of wet THF and then water. The mixture was extracted with ether. The extract was washed with water, dried over anhydrous magnesium sulfate, and evaporated. The residue was chromatographed on a column of silica gel. Elution with carbon tetrachloride afforded 126 mg (44%) of **7**, 109 mg of a mixture of **7** and **1** in the ratio 1 : 2.6, and 50 mg of **1**. The compound **7** obtained above is identical with that prepared by reductive coupling of **2** in every respect.

Neither action of excess butymagnesium bromide on **13** in refluxing THF for 27 h nor heating **13** with *p*-toluenesulfonic aicd monohydrate in refluxing THF for 11 h gave any **7**, **13** being recovered quantitatively.

d) With Lithium 2,2,6,6-Tetramethylpiperidide. The reagent was prepared by addition of 1.6 ml (2.54 mmol) of 1.59 M solution of butyllithium in hexane to a stirred and ice-cooled solution of 2.5 mmol of 2,2,6,6-tetramethylpiperidine in 12 ml of hexane under nitrogen.[15] To this reagent was added 155 mg (0.5 mmol) of **1** all at once. The mixture was slowly warmed to room temperature and heated under reflux for 24 h. Column chromatographic workup of the mixture allowed the isolation of several unidetified products in minute amounts and **1** in 65% yield.

X-Ray Crystal Structure Analysis of 1. A colorless crystal of **1** with dimensions of ca. 0.2×0.2×0.1 mm^3 was mounted on a Rigaku AFC-6 automated diffractometer. Systematic

absences were consistent with the space group $P\,2_1/c$. The intensity data were measured by means of ω-2θ of 60° by using graphite-monochromated Mo $K\alpha$ radiation (λ=0.7107 Å). Usual corrections were made for Lorentz and polarization effects, but no absorption correction was applied. Independent reflections with $|F_o|>4\sigma(F_o)$, 1901 reflections, were used for the structural determination.

Crystal Data: $C_{20}H_{22}OS$, F.W.=310.5, monoclinic, $P2_1/c$, a=9.764(3), b=16.174(9), c=10.755(6) Å, β=100.04(3)°, V=1672 Å^3, Z=4, D_x=1.233 g cm^{-3}, μ(Mo $K\alpha$)=1.84 cm^{-1}. The structure was solved by the direct method (MULTAN 78).[16] Positions of H atoms were fixed at calculated positions (with C–H=1.08 Å) with fixed isotropic temperature factors (B=5.0. Å^2). The structure was refined anisotropically for non-H atoms and isotropically for H atoms by full-matrix least squares method. The final discrepancy factors were R=0.090 and R_w=0.052 [w=$(\sigma^2(F_o)+0.14722|F_o|-0.0015|F_o|^2)^{-1}$], and $(\Delta/\sigma)_{max}$ in the final refinement cycle was 0.01. The scattering factors were taken from Ref 17. The calculations were carried out on a HITAC M-680H computer at the computer room of The National Defense Academy, using UNICS-Nagoya.[18,19]

Selective Mono- and Bis(alkoxycarbonylation)s of Olefins Catalyzed by Palladium in the Presence of Cu(I) or Cu(II) Chloride under Remarkably Mild Conditions. Application to the Synthesis of γ-Butyrolactone Derivatives

Shiho Toda, Masanori Miyamoto, Hideki Kinoshita, and Katsuhiko Inomata*
Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi 1-1, Kanazawa, Ishikawa 920
(Received August 5, 1991)

Palladium-catalyzed mono- and bis(alkoxycarbonylation)s of olefins were controlled by the use of copper(II) and copper(I) chloride, respectively, in alcohol under normal pressure of carbon monoxide and oxygen at room temperature without any other additives. 3-Buten-1-ols gave the corresponding γ-butyrolactones and 2-oxotetrahydrofuran-3-acetic acid esters, respectively, in high yields.

It is well-known that palladium chloride can catalyze the hydroesterification[1] and hydrocarboxylation[2] of olefins in acidic alcohols under mild conditions. In the course of our attempts to improve such hydroesterification reaction using various kinds of palladium catalysts in the absence of hydrochloric acid under mild conditions, we realized that palladium(0) black precipitates prior to the beginning or the completion of the reaction whenever the expected monoesters could be obtained in good yields from terminal olefins. On the basis of this observation, we eventually found that Pd–C is a favorable catalyst for the alkoxycarbonylation of olefins, and have briefly reported in the previous paper[3] that mono- and bis(alkoxycarbonylation)s of olefins can be controlled by the use of copper(II) and copper(I) chloride, respectively, together with the Pd–C catalyst in alcohol under normal pressure of carbon monoxide. However, acceleration of the reaction, which required around 8 d for completion, remained as a problem to be solved for wide synthetic applications.

We wish to report here the remarkably improved method which uses palladium(II) and copper(II) or copper(I) chloride under normal pressure of carbon monoxide and oxygen at room temperature comparing with the previous method[3] (Method A in Tables 1 and 2). The present reaction was applied to the synthesis of γ-butyrolactone derivatives.

The monocarbonylation of 1-undecene (**1b**) using various kinds of palladium catalysts (0.02 equiv) and copper(II) chloride (1.5 equiv) was first investigated under CO and O_2 (ca. 1/1, v/v, 1 atm) atmosphere in methanol at 25 °C without addition of an acid. It was found that (1) $PdCl_2$ and $[PdCl_2(CH_3CN)_2]$ are catalysts of choice, (2) the latter is better in view of selectivity of **2b**/**3b** [form of Pd catalyst, reaction time, total yields of **2b** and **3b**, and ratio of **2b**/**3b** were as follows: $PdCl_2$, 23 h, quant., 49/51; $[PdCl_2(CH_3CN)_2]$, 40 h, 90%, 86/14; $[PdCl_2(PhCN)_2]$ 42 h, 74%, 86/14; $[PdCl_2(PPh_3)_2]$,

i,	$Ts(CH_2)_2$	—	—	—	**i**,	41	91	67/33

a) Pd–C (0.11 equiv), $CuCl_2$ (3 equiv), CO (1 atm), for 8 d at 25 °C. b) $[PdCl_2(CH_3CN)_2]$ (0.02 equiv), $CuCl_2$ (1.5 equiv), CO/O_2 (ca. 1/1, v/v, 1 atm), in MeOH/THF (1/1) at 25 °C. c) Determined by 400 MHz ^1H NMR spectra.

43 h, 14%, 44/56; [$PdCl_2$(dppe)] (dppe=1,2-bis (diphenylphosphino)ethane), 42 h, no reaction; [$PdCl_2$(dppp)] (dppp=1,3-bis(diphenylphosphino)propane), 38 h, no reaction; [$Pd(PPh_3)_4$], 48 h, 37%, 25/75], and (3) phosphine ligands retarded the reaction and gave the linear esters in preference. Regarding solvent systems, it was found that the use of THF, CH_2Cl_2, ether, or benzene as co-solvent with methanol is effective probably because of high solubility of olefin in them, but polar solvents retard the reaction [solvent, reaction time, total yields of **2b** and **3b**, and ratio of **2b**/**3b** were as follows, when [$PdCl_2(CH_3CN)_2$] (0.02 equiv) and $CuCl_2$ (1.5 equiv) were used under similar conditions: MeOH, 40 h, 90%, 86/14; MeOH/THF (1/1, v/v), 24 h, quant., 79/21; MeOH/CH_2Cl_2(1/1, v/v), 30 h, 91%, 82/18; MeOH/Et_2O (1/1, v/v), 75 h, 94%, 85/15; MeOH/benzene (1/1, v/v), 29 h, 95%, 76/24; MeOH/CH_3CN (1/1, v/v), 42 h, 50%, 85/15; MeOH/DMF (1/1, v/v), 51 h, 17%, 87/13; MeOH/DMSO (1/1, v/v), 72 h, trace]. Consequently, various kinds of monoesters (**2a—i** and **3a—i**) were prepared in excellent yields from the corresponding terminal olefins including the functionalized ones (**1g—i**) with [$PdCl_2(CH_3CN)_2$] (0.02 equiv) and $CuCl_2$ (1.5 equiv) in MeOH/THF (1/1, v/v) under CO/O_2 (ca. 1/1, v/v, 1 atm)at 25 °C as summarized in Table 1 (Method B).

The predominant formation of branched monoesters (**2**) by formal Markovnikov addition of methoxycarbonyl group to olefins can be rationalized on the basis of the formation of carbonium ion intermediate,[4] or acidic decomposition of the intermediate (**4**) formed in preference to the regioisomer (**5**) by HCl evolved in the reaction. The reaction mixture using $CuCl_2$ was actually strongly acidic.

6	**6f**, 	2 d	**9f**, 	80[b)]

a) $PdCl_2$ (0.1 equiv), CuCl (1.5 equiv), CO/O_2 (ca. 1/1, v/v, 1 atm), in MeOH at 25 °C. b) Ratios of diastereoisomers were determined by 400 MHz ^1H NMR spectra as follows: **9a** (68/32), **9e** (58/42), **9f** (54/46). c) Determined by GC [OV-17, 2 m×3 mm, N_2, 20 ml min^{-1}, 100—170 °C (20 °C min^{-1})] with internal standard, 1,2,3,4-tetrahydronaphthalene.

On the other hand, when copper(I) chloride was used in place of copper(II) chloride in the above reaction, diesters (succinates, **8a**—**i**) were selectively formed in high yields as well as the case of Pd–C catalyst (Method A) as shown in Table 2 (Method B). The reaction mixture was faintly acidic in contrast to the case of copper(II) chloride. Although the active species formed from copper(I) chloride in the present reaction is not yet clear, the pale green coloration suggests the formation of copper(II) species, at least in part, by oxidation with molecular oxygen. It is likely that the copper(II) species reacts further with carbon monoxide to afford (alkoxycarbonyl)chlorocopper [Cu(Cl)COOR] which is probably involved in the carbonylation of olefins under neutral conditions as described in the literature.[6)] It is noteworthy that the carbonylation reaction was remarkably retarded by the addition of equimolar amount of LiCl, NaCl, or KCl under similar conditions.

Recently Tamaru and his co-workers reported the interesting inter- and intramolecular bis(alkoxycarbonylation) of 3-buten-1-ols catalyzed by palladium(II).[7)] It prompted us to apply the present bis(alkoxycarbonylation) system to 3-buten-1-ols (**6a**—**f**). The results are summarized in Table 3. The reaction proceeded selectively to give the corresponding 2-oxotetrahydrofuran-3-acetic acid esters (**9a**—**f**) in high yields by the use of 0.1 equiv of $PdCl_2$ and 1.5 equiv of CuCl in spite of the absence of additives such as propylene oxide, triethyl orthoacetate, or *N*,*N*,*N*′,*N*′-tetramethylurea employed in the reported procedure.[7)]

Now it has become possible to control the mono- and bis(alkoxycarbonylation)s of olefins catalyzed by palladium(0) or palladium(II) simply employing copper(II) or copper(I) chloride under remarkably mild conditions.

Mechanistic studies and applications of the present carbonylation reactions are now in progress.

Experimental

All the melting points were determined with a micro melting apparatus (Yanagimoto-Seisakusho) and were uncorrected. The ^1H NMR, IR, and MS spectra were recorded on JEOL JNM-GX 400(400 MHz) FT-NMR spectrometer, JASCO IRA-1 diffraction grating infrared spectrometer, and Hitachi M-80 mass spectrometer, respectively. The chemical shifts of NMR are reported in the δ-scale relative to TMS as an internal standard.

Materials. All the solvents were distilled and stored over a drying agent. Thin-layer chromatography (TLC) was performed on Merck's silica gel 60 PF_{254} (Art. 7749). Terminal olefins (**1a**—**e**) were purified by distillation over active

carbon before use. CuCl was freshly prepared from copper sulfate.[8]

Mono(alkoxycarbonylation) of 1b with $CuCl_2$ (Method A). In a flask equipped with a balloon containing carbon monoxide (1 atm), 1-undecene (**1b**, 39 mg, 0.25 mmol) was added to a mixed dispersion of 5% Pd-C (58 mg, 0.11 equiv of Pd) and anhydrous $CuCl_2$ (from Wako Pure Chemical Industries, Ltd., 95% purity, 106 mg, 3.0 equiv) in absolute methanol (4 ml) at 25 °C. After stirring for 8 d at 25 °C, the reaction mixture was added dropwise to aqueous 10% $NaHCO_3$ solution. The filtrate through Celite was diluted by ethyl acetate. The organic layer was separated and successively washed with water and brine, and dried over sodium sulfate. The residue obtained by evaporation of the solvent was subjected to preparative TLC (SiO_2, hexane/ethyl acetate=10/1, v/v) to afford 54 mg of a mixture of regioisomeric monoesters (**2b**/**3b**=81/19, quantitative yield) as a colorless oil. MS *m/z* 214 (M^+, 2.02%), 101 (29.47), 88(100.00), 87 (11.00), 74 (11.53), 57 (10.00), 43 (10.46); IR (neat) 2920, 2850, 1730, 1460, 1425, 1365, 1250, 1185, 1155, 725 cm^{-1};^1H NMR of **2b** (R′=Me) ($CDCl_3$) δ=0.88 (t, *J*=6.87 Hz, 3H), 1.14 (d, *J*=7.02 Hz, 3H), 1.26 (s, 14H), 1.40 (m, 1H), 1.65 (m, 1H), 2.43 (sextuplet, *J*=7.02 Hz, 1H), 3.66 (s, 3H);^1H NMR of **3b** (R′=Me) ($CDCl_3$) δ=0.88 (t, *J*=6.87 Hz, 3H), 1.26 (s, 16H), 1.65 (m, 2H), 2.31 (t, *J*=7.48 Hz, 2H), 3.66 (s, 3H).

In a similar manner, other monoesters (**2c—f**/**3c—f**) were prepared from the corresponding terminal olefins (**1c—f**).

Methyl 2-Methyldodecanoate (2c, R′=Me) and Methyl Tridecanoate (3c, R′=Me): An oil (a mixture of regioisomers); MS *m/z* 229 (M^++1, 0.89%), 228 (M^+, 3.79), 143 (7.44), 115 (5.59), 101 (33.75), 88 (100.00), 87 (15.29), 74 (6.27); IR (neat) 2920, 2840, 1730, 1455, 1420, 1370, 1185, 1150, 710 cm^{-1}; ^1H NMR of **2c** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.14 (d, *J*=7.02, 3H), 1.26 (s, 16H), 1.40 (m, 1H), 1.65 (m, 1H), 2.43 (sextuplet, *J*=7.02 Hz, 1H), 3.67 (s, 3H); ^1H NMR of **3c** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.26 (s, 18H), 1.65 (m, 2H), 2.31 (t, *J*=7.02 Hz, 2H), 3.67 (s, 3H); **2c**/**3c**=78/22.

Ethyl 2-Methyltetradecanoate (2d, R′=Et) and Ethyl Pentadecanoate (3d, R′=Et): An oil (a mixture of regioisomers); MS *m/z* 271 (M^++1, 18.60%), 270 (M^+, 31.28), 227 (11.02), 225 (11.97), 213 (12.90), 157 (14.59), 116 (11.24), 115 (32.30), 102 (100.00), 101 (15.93), 88 (12.68), 74 (11.18), 43 (10.07); IR (neat) 2935, 2860, 1740, 1465, 1380, 1180, 1160 cm^{-1}; ^1H NMR of **2d** ($CDCl_3$) δ=0.92 (t, *J*=7.02 Hz, 3H), 1.17 (d, *J*=7.02 Hz, 3H), 1.29 (m, 23H), 1.43 (m, 1H), 1.65 (m, 1H), 2.44 (sextuplet, *J*=7.02 Hz, 1H), 4.16 (q, *J*=7.02 Hz, 2H); ^1H NMR of **3d** ($CDCl_3$) δ=0.92 (t, *J*=7.02 Hz, 3H), 1.29 (m, 25H), 1.65 (m, 2H), 2.32 (t, *J*=7.32 Hz, 2H), 4.16 (q, *J*=7.02 Hz, 2H); **2d**/**3d**=72/28.

Methyl 2-Methyltetradecanoate (2d, R′=Me) and Methyl Pentadecanoate (3d, R′=Me): An oil (a mixture of regioisomers); MS *m/z* 257 (M^++1, 1.31%), 256 (M^+, 5.60), 101 (16.82), 88 (100.00); IR (neat) 2930, 2860, 1740, 1455, 1370, 1190, 1160 cm^{-1}; ^1H NMR of **2d** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.14 (d, *J*=7.02 Hz, 3H), 1.26 (s, 20H), 1.40 (m, 1H), 1.65 (m, 1H), 2.43 (sextuplet, *J*=7.02 Hz, 1H), 3.66 (s, 3H); ^1H NMR of **3d** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.26 (s, 22H), 1.65 (m, 2H), 2.30 (t, *J*=7.32 Hz, 2H), 3.67 (s, 3H); **2d**/**3d**=85/15 (by Method B).

Ethyl 2-Methyloctadecanoate (2e, R′=Et) and Ethyl Nonadecanoate (3e, R′=Et): An oil (a mixture of regioisomers); MS *m/z* 327 (M^++1, 14.03%), 326 (M^+, 31.35), 269 (12.02), 185 (13.25), 157 (22.19), 129 (19.18), 115 (45.77), 102 (100.00), 101 (22.53), 83 (14.64), 74 (17.62), 57 (21.55); IR (neat) 2920, 2850, 1725, 1460, 1370, 1175 cm^{-1}; ^1H NMR of **2e** ($CDCl_3$) δ=0.88 (t, *J*=6.72 Hz, 3H), 1.13 (d, *J*=7.02 Hz, 3H), 1.25 (m, 31H), 1.40 (m, 1H), 1.64 (m, 1H), 2.40 (sextuplet, *J*=7.02 Hz, 1H), 4.10 (q, *J*=7.02 Hz, 2H); ^1H NMR of **3e** ($CDCl_3$) δ=0.88 (t, *J*=6.72 Hz, 3H), 1.25 (m, 33H), 1.64 (m, 2H), 2.28 (t, *J*=7.32 Hz, 2H), 4.10 (q, *J*=7.02 Hz, 2H); **2e**/**3e**=77/23.

Methyl 2-Methyloctadecanoate (2e, R′=Me) and Methyl Nonadecanoate (3e, R′=Me): An oil (a mixture of regioisomers); MS *m/z* 313 (M^++1, 5.49%), 312 (M^+, 21.71), 101 (36.66), 88 (100.00); IR (neat) 2930, 2860, 1735, 1455, 1190, 1160 cm^{-1}; ^1H NMR of **2e** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.13 (d, *J*=7.02 Hz, 3H), 1.26 (s, 28H), 1.40 (m, 1H), 1.65 (m, 1H), 2.42 (sextuplet, *J*=7.02 Hz, 1H), 3.66 (s, 3H); ^1H NMR of **3e** ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.26 (s, 30H), 1.65 (m, 2H), 2.30 (t, *J*=7.63 Hz, 2H), 3.66 (s, 3H); **2e**/**3e**=83/17 (by Method B).

Methyl 2-Methyl-4-phenylbutanoate (2f, R′=Me) and Methyl 5-Phenylpentanoate (3f, R′=Me): An oil (a mixture of regioisomers); MS *m/z* 192 (M^+, 5.96%), 105 (8.13), 104 (9.52), 91 (33.28), 88 (100.00), 57 (15.07); IR (neat) 3000, 2900, 1720, 1590, 1480, 1440, 1420, 1365, 1230, 1190, 1150, 1040, 735, 690 cm^{-1}; ^1H NMR of **2f** ($CDCl_3$) δ=1.18 (d, *J*=7.02 Hz, 3H), 1.71 (m, 1H), 2.04 (m, 1H), 2.47 (sextuplet, *J*=7.02 Hz, 1H), 2.60 (t, *J*=7.93 Hz, 2H), 3.67 (s, 3H), 7.17 (m, 3H), 7.27 (m, 2H); ^1H NMR of **3f** ($CDCl_3$) δ=1.66 (m, 4H), 2.32 (t,*J*=7.02 Hz, 2H), 2.75 (m, 1H), 2.95 (m, 1H), 2.60 (t, *J*=7.93 Hz, 2H), 3.67 (s, 3H), 7.17 (m, 3H), 7.27 (m, 2H); **2f**/**3f**=96/4.

Mono(alkoxycarbonylation) of 1a with $CuCl_2$ (Method B). In a flask equipped with balloons containing carbon monoxide (1 atm) and oxygen (1 atm), 1-decene (**1a**, 35 mg, 0.25 mmol) was added dropwise to a mixture of $[PdCl_2(CH_3CN)_2]$ (6 mg, 0.02 equiv) and anhydrous $CuCl_2$ (95% purity, 53 mg, 1.5 equiv) in absolute methanol (2 ml) and THF (2 ml) at 25 °C. After stirring for 24 h at 25 °C, the reaction mixture was added dropwise to aqueous 10% $NaHCO_3$ solution. The filtrate through Celite was treated with a small amount of aqueous KCN solution to deactivate palladium catalyst and diluted by ethyl acetate. The organic layer was separated and successively washed with water and brine, and dried over sodium sulfate. The residue obtained by evaporation of the solvent was subjected to preparative TLC (SiO_2, hexane/ethyl acetate=10/1, v/v) to afford 46 mg of a mixture of regioisomeric monoesters (**2a**/**3a**=85/15, 92% yield) as a colorless oil. MS *m/z* 200 (M^+, 5.28%), 101 (29.12), 88 (100.00), 87 (56.67), 74 (79.26); IR (neat) 2940, 2860, 1735, 1455, 1430, 1375, 1190, 1160 cm^{-1}; ^1H NMR of **2a** (R′=Me) ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.13 (d, *J*=7.02 Hz, 3H), 1.26 (s, 12H), 1.40 (m, 1H), 1.64 (m, 1H), 2.43 (sextuplet, *J*=7.02 Hz, 1H), 3.67 (s, 3H) ; ^1H NMR of **3a** (R′=Me) ($CDCl_3$) δ=0.88 (t, *J*=7.02 Hz, 3H), 1.26 (s, 14H), 1.64 (m, 2H), 2.30 (t, *J*=7.62 Hz, 2H), 3.67 (s, 3H).

In a similar manner, other monoesters (**2b—i**/**3b—i**) and lactones (**7a,b**) were prepared from the corresponding terminal olefins (**1b—i**) and 3-buten-1-ols (**6a,b**), respectively. Regioisomers, **2g—i** and **3g—i**, could be separated each other by preparative TLC. Their spectral data except **2b—f**/**3b—f**, those of which have been shown above, are given in the following.

Methyl 2-Methyl-3-phenoxypropanoate (2g, R′=Me): An oil; MS *m/z* 194 (M^+, 40.60%), 149 (99.24), 137 (46.36), 101 (29.07), 94 (30.32), 71 (44.86), 69 (100.00), 59 (40.10); IR (neat) 3030, 2980, 2950, 2880, 1730, 1595, 1580, 1490, 1460, 1430,

1240, 1195, 1165, 1030, 745, 680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.30 (d, J=7.02 Hz, 3H), 2.95 (m, 1H), 3.72 (s, 3H), 3.99 (dd, J=9.16, 6.71 Hz, 1H), 4.19 (dd, J=9.16, 6.14 Hz, 1H), 6.90 (m, 2H), 6.95 (m, 1H), 7.27 (m, 2H).

Methy 2-Methyl-3-phenoxybutanoate (3g, R′=Me): An oil; MS m/z 194 (M^+, 12.63%), 163 (15.04), 101 (100.00), 94 (35.12), 59 (42.09), 28 (33.68); IR (neat) 3020, 2920, 1730, 1590, 1580, 1480, 1460, 1430, 1230, 1160, 1070, 1030, 740, 680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.11 (m, 2H), 2.53 (t, J=7.32 Hz, 1H), 3.69 (s, 3H), 4.01 (t, J=6.11 Hz, 2H), 6.88 (m, 2H), 6.94 (m, 1H), 7.26 (m, 2H).

Methyl 2-Methyl-3-(*p*-tolylsulfonyl)propanoate (2h, R′=Me): Mp 86—87 °C (recrystallized from hexane/ethyl acetate); MS m/z 257 (M^++1, 1.98%), 256 (M^+, 12.28), 155 (28.25), 139 (53.38), 132 (13.80), 101 (100.00), 92 (49.40), 91 (78.49), 73 (22.33), 69 (35.37), 59 (70.00); IR (KBr) 2995, 2970, 1735, 1590, 1450, 1430, 1380, 1300, 1140, 880, 830, 810, 760, 680 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.31 (d, J=7.02 Hz, 3H), 2.45 (s, 3H), 3.01 (m, 1H), 3.07 (dd, J=14.04, 5.19 Hz, 1H), 3.62 (s, 3H), 3.67 (dd, J=14.04, 7.33 Hz, 1H), 7.36 (d, J=8.24 Hz, 2H), 7.78 (d, J=8.24 Hz, 2H). Found: C, 56.18; H, 6.17%. Calcd for $C_{12}H_{16}O_4S$: C, 56.23; H, 6.29%.

Methyl 4-(*p*-Tolylsulfonyl)butanoate (3h, R′=Me): An oil; MS m/z 257 (M^++1, 0.39%), 256 (M^+, 2.22), 225 (14.38), 183 (6.63), 155 (6.30), 139 (9.18), 101 (100.00), 91 (20.55), 59 (39.90); IR (neat) 2965, 2940, 1735, 1590, 1435, 1310, 1300, 1280, 1140, 1080, 810, 720 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=2.02 (m, 2H), 2.45 (s, 3H), 2.46 (t, J=7.17 Hz, 2H), 3.15 (m, 2H), 3.65 (s, 3H), 7.37 (d, J=8.24 Hz, 2H), 7.79 (d, J=8.24 Hz, 2H).

Methyl 2-Methyl-4-(*p*-tolylsulfonyl)butanoate (2i, R′=Me): An oil; MS m/z 271 (M^++1, 0.35%), 270 (M^+, 0.91), 239 (6.92), 183 (6.33), 157 (6.51), 140 (6.10), 139 (6.53), 115 (100.00), 91 (14.13), 59 (39.85); IR (neat) 3040, 2960, 1730, 1595, 1450, 1380, 1300, 1200, 1140, 1085, 1050, 810, 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.16 (d, J=7.01 Hz, 3H), 1.87 (m, 1H), 2.00 (m, 1H), 2.46 (s, 3H), 2.56 (m, 1H), 3.11 (m, 2H), 3.65 (s, 3H), 7.36 (d, J=8.09 Hz, 2H), 7.77 (d, J=8.09 Hz, 2H).

Methyl 5-(*p*-Tolylsulfonyl)pentanoate (3i, R′=Me): An oil; MS m/z 271 (M^++1, 0.28%), 270 (M^+, 1.04), 239 (8.59), 155 (5.98), 115 (100.00), 92 (12.89), 91 (17.87), 83 (26.01), 73 (40.50), 59 (13.91), 55 (41.67); IR (neat) 3040, 2960, 1735, 1600, 1440, 1300, 1285, 1145, 1095, 910, 810, 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.72 (m, 4H), 2.30 (t, J=7.02 Hz, 2H), 2.46 (s, 3H), 3.07 (t, J=7.33 Hz, 2H), 3.65 (s, 3H), 7.36 (d, J=8.24 Hz, 2H), 7.78 (d, J=8.24 Hz, 2H).

2-Methyl-6-phenyl-4-hexanolide (7a): An oil (a mixture of diastereoisomers); MS m/z 204 (M^+, 43.07%), 131 (42.27), 130 (100.00), 117 (50.72), 92 (75.94), 91 (88.26); IR (neat) 3040, 2940, 1770, 1600, 1490, 1450, 1375, 1355, 1180, 1160, 1020, 925, 745, 695 cm^{-1}; ^{1}H NMR of a major diastereoisomer (**M**) ($CDCl_3$, by COSY) δ=1.27 (d, J=7.02 Hz, 3H), 1.53 (m, 1H), 1.81—2.07 (m, 2H), 2.46 (m, 1H), 2.60—2.78 (m, 3H), 4.31 (m, 1H), 7.20 (m, 3H), 7.28 (m, 2H); ^{1}H NMR of a minor diastereoisomer (**m**) ($CDCl_3$, by COSY) δ=1.28 (d, J=7.33 Hz, 3H), 1.90—2.15 (m, 4H), 2.70—2.87 (m, 3H), 4.49 (m, 1H), 7.20 (m, 3H), 7.28 (m, 2H); **M**/**m**=63/37.

3-Methyl-1-oxaspiro[4.5]decan-2-one (7b): Mp 67—68 °C (recrystallized from hexane, lit, 68—70 °C,[9a] 70.5—71 °C[9b,c]); MS m/z 169 (M^++1, 1.47%), 168 (M^+, 10.80), 125 (100), 124 (31.11), 112 (20.87), 82 (39.66), 81 (28.22), 55 (43.90); IR (KBr) 2940, 2860, 1765, 1440, 1210, 1130, 960, 950, 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.27 (d, J=7.33 Hz, 3H), 1.39 (m, 1H), 1.45—1.65 (m, 5H), 1.58 (dd, J=12.81, 11.29 Hz, 1H), 1.65—1.82 (m, 4H), 2.34 (dd, J=12.81, 9.16 Hz, 1H), 2.78 (m, 1H).

Bis(alkoxycarbonylation) of 1b with CuCl (Method A). In a flask equipped with a balloon containing carbon monoxide (1 atm), 1-undecene (**1b**, 39 mg, 0.25 mmol) was added to a mixed dispersion of 5% Pd–C (58 mg, 0.11 equiv of Pd) and CuCl (74 mg, 3.0 equiv) in absolute methanol (4 ml) at 25 °C. After stirring for 9 d at 25 °C, the reaction mixture was added dropwise to aqueous 10% $NaHCO_3$ solution. The filtrate through Celite was diluted by ethyl acetate. The organic layer was successively washed with water and brine, and dried over sodium sulfate. The residue obtained by evaporation of the solvent was subjected to preparative TLC (SiO_2, hexane/ethyl acetate=15/1, v/v) to afford 68 mg of diesters [**8b** (R′=Me), quantitative yield] as a colorless oil. MS m/z 273 (M^++1, 3.75%), 241 (39.63), 199 (43.25), 170 (30.32), 146 (96.68), 138 (23.91), 114 (100.00), 97 (16.45), 87 (20.92), 83 (15.93), 55 (17.30); IR (neat) 2910, 2840, 1730, 1430, 1350, 1250, 1185, 1150, 995, 905, 725 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.71 Hz, 3H), 1.26 (m, 14H), 1.51 (m, 1H), 1.63 (m, 1H), 2.43 (dd, J=16.48, 5.19 Hz, 1H), 2.71 (dd, J=16.48 Hz, 9.15 Hz, 1H), 2.83 (m, 1H), 3.67 (s, 3H), 3.70 (s, 3H).

In a similar manner, other diesters (**8c—f**) were prepared from the corresponding terminal olefins (**1c—f**).

Dimethyl 2-Decylsuccinate (8c, R′=Me): An oil ; MS m/z 287 (M^++1, 2.25%), 286 (M^+, 0.19), 255 (20.54), 213 (31.77), 170 (24.45), 146 (100.00), 138 (16.41), 114 (76.57), 97 (11.86), 87 (12.88), 55 (14.93); IR (neat) 2930, 2860, 1740, 1460, 1435, 1370, 1240, 1200, 1180 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.72 Hz, 3H), 1.25 (s, 16H), 1.50 (m, 1H), 1.62 (m, 1H), 2.43 (dd, J=16.48, 5.19 Hz, 1H), 2.71 (dd, J=16.48, 9.16 Hz, 1H), 2.82 (m, 1H), 3.67 (s, 3H), 3.69 (s, 3H).

Diethyl 2-Dodecylsuccinate (8d, R′=Et): An oil; MS m/z 343 (M^++1, 28.34%), 297 (67.42), 255 (39.36), 184 (37.43), 174 (100.00), 138 (23.41), 128 (84.72), 101 (16.54), 97 (16.71), 55 (17.69), 43 (19.84); IR (neat) 2935, 2860, 1745, 1735, 1465, 1375, 1260, 1175, 1160, 1030 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.83 (t, J=6.72 Hz, 3H), 1.20 (m, 26H), 1.45 (m, 1H), 1.57 (m, 1H), 2.36 (dd, J=16.18, 5.19 Hz, 1H), 2.64 (dd, J=16.18, 9.46 Hz, 1H), 2.76 (m, 1H), 4.09 (m, 4H).

Dimethyl 2-Dodecylsuccinate (8d, R′=Me): Mp 34—35 °C (not recrystallized); MS m/z 315 (M^++1, 0.30%), 283 (10.70), 241 (21.90), 170 (26.96), 156 (10.45), 146 (100.00), 138 (17.03), 114 (60.74), 97 (10.78), 87 (9.44), 83 (9.60), 55 (8.84); IR (neat, melted) 2900, 2830, 1720, 1440, 1420, 1145 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.87 Hz, 3H), 1.25 (s, 20H), 1.50 (m, 1H), 1.63 (m, 1H), 2.43 (dd, J=16.48, 4.89 Hz, 1H), 2.71 (dd, J=16.48, 9.46 Hz, 1H), 2.84 (m, 1H), 3.67 (s, 3H), 3.70 (s, 3H).

Diethyl 2-Hexadecylsuccinate (8e, R′=Et): An oil; MS m/z 399 (M^++1, 0.93%), 398 (M^+, 0.91), 353 (17.41), 311 (16.46), 184 (26.20), 174 (100.00), 138 (15.59), 128 (48.71), 101 (10.99), 97 (12.02), 83 (10.93), 57 (11.50); IR (neat) 2930, 2860, 1735, 1460, 1370, 1250, 1170, 1160, 1025 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.91 (t, J=6.72 Hz, 3H), 1.29 (m, 34H), 1.53 (m, 1H), 1.67 (m, 1H), 2.44 (dd, J=16.33, 5.04 Hz, 1H), 2.72 (dd, J=16.33, 9.32 Hz, 1H), 2.84 (m, 1H), 4.18 (m, 4H).

Dimethyl 2-Hexadecylsuccinate (8e, R′=Me): Mp 35 °C (not recrystallized); MS m/z 371 (M^++1, 1.03%), 370 (M^+, 1.09), 339 (15.56), 297 (23.54), 170 (34.56), 156 (12.37), 146 (100.00), 138 (14.95), 114 (37.74), 97 (10.75); IR (KBr) 2920, 2840, 1730, 1720, 1460, 1430, 1370, 1355, 1205, 1160 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=0.88 (t, J=6.87 Hz, 3H), 1.26 (s, 28H), 1.51 (m, 1H), 1.63 (m, 1H), 2.43 (dd, J=16.33, 4.88 Hz, 1H), 2.71 (dd, J=16.33, 9.46 Hz, 1H), 2.83 (m, 1H), 3.67 (s, 3H),

3.70 (s, 3H).

Dimethyl 2-(2-Phenylethyl)succinate (8f, R′=Me): An oil MS *m/z* 251 (M^++1, 5.36%), 250 (M^+, 8.96), 187 (57.43), 146 (100.00), 144 (11.01), 117 (11.51), 114 (77.49), 104 (31.50), 91 (24.76); IR (neat) 3020, 2950, 2850, 1735, 1600, 1495, 1435, 1365, 1260, 1200, 1160, 730, 700 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.83 (m, 1H), 1.98 (m, 1H), 2.48 (dd, *J*=16.48, 5.19 Hz, 1H), 2.62 (m, 2H), 2.76 (dd, *J*=16.48, 9.16 Hz, 1H), 2.88 (m, 1H), 3.66 (s, 3H), 3.70 (s, 3H), 7.17 (m, 3H), 7.27 (m, 2H).

Bis(alkoxycarbonylation) of 1a with CuCl (Method B). In a flask equipped with balloons containing carbon monoxide (1 atm) and oxygen (1 atm), 1-decene (**1a**, 35 mg, 0.25 mmol) was added to a mixed dispersion of $PdCl_2$ (1 mg, 0.02 equiv) and anhydrous CuCl (37 mg, 1.5 equiv) in absolute methanol (4 ml) at 25 °C. After stirring for 1 d at 25 °C, the reaction mixture was added dropwise to aqueous 10% $NaHCO_3$ solution. The filtrate through Celite was treated with a small amount of aqueous KCN solution to deactivate palladium catalyst and diluted by ethyl acetate. The organic layer was successively washed with water and brine, and dried over sodium sulfate. The residue obtained by evaporation of the solvent was subjected to preparative TLC (SiO_2, hexane/ethyl acetate=10/1, v/v) to afford 45 mg of diester [**8a**(R′=Me), 70%] as a colorless oil accompanied by 10 mg of monoesters (**2a**/**3a**=43/57, 21% yield). **8a**:[10] MS *m/z* 259 (M^++1, 0.59%), 227 (22.03), 185 (44.04), 170 (21.70), 146(100.00), 114 (97.01); IR (neat) 2930, 2860, 1735, 1430, 1160, 1000 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (t, *J*=6.87 Hz, 3H), 1.26 (m, 12H), 1.51 (m, 1H), 1.62 (m, 1H), 2.43 (dd, *J*=16.48, 5.04 Hz, 1H), 2.71 (dd, *J*=16.48, 9.46 Hz, 1H), 2.84 (m, 1H), 3.67 (s, 3H), 3.70 (s, 3H).

In a similar manner, other diesters (**8b**—**i**) and 2-oxotetrahydrofuran-3-acetic acid esters (**9a**—**f**) were prepared from the corresponding terminal olefins (**1b**—**i**) and 3-buten-1-ols (**6a**—**f**), respectively. Their spectral data except **8b**—**f**, those of which have been shown above, are given in the following.

Dimethyl 2-(Phenoxymethyl)succinate (8g, R′=Me): An oil; MS *m/z* 253 (M^++1, 2.86%), 252 (M^+, 18.75), 189 (67.53), 160 (18.92), 159 (100.00), 127 (71.35), 99(29.69), 94 (21.59); IR (neat) 3005, 2960, 1730, 1590, 1580, 1490, 1460, 1435, 1230, 1160, 1070, 1030, 995, 900, 745, 720, 680 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.74 (dd, *J*=17.09, 5.80 Hz, 1H), 2.95 (dd, *J*=17.09, 7.93 Hz, 1H), 3.33 (m, 1H), 3.70 (s, 3H), 3.74 (s, 3H), 4.21 (d, *J*=5.81 Hz, 2H), 6.88 (d, *J*=7.63 Hz, 2H), 6.96 (t, *J*=7.33 Hz, 1H), 7.27 (m, 2H).

Dimethyl 2-(*p*-Tolylsulfonylmethyl)succinate (8h, R′=Me): An oil ; MS *m/z* 315 (M^++1, 0.51%), 314 (M^+, 1.62), 159 (100.00), 139 (25.31), 127 (65.85), 99 (20.52), 91 (26.04); IR (neat) 3020, 2960, 2840, 1730, 1660, 1585, 1430, 1400, 1360, 1310, 1290, 1280, 1200, 1140, 1080, 1030, 820, 800, 720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.46 (s, 3H), 2.91 (d, *J*=6.10 Hz, 2H), 3.29 (m, 1H), 3.38 (dd, *J*=14.35, 7.63 Hz, 1H), 3.67 (dd, *J*=14.35, 5.19 Hz, 1H), 3.67 (s, 3H), 3.68 (s, 3H), 7.37 (d, *J*=8.09 Hz, 2H), 7.79 (d, *J*=8.09 Hz, 2H).

Dimthyl 2-[2-(*p*-Tolylsulfonyl)ethyl]succinate (8i, R′=Me): An oil; MS *m/z* 329 (M^++1, 0.09%), 328 (M^+, 0.16), 297 (13.25), 173 (100.00), 141 (26.60), 139 (13.24), 113 (28.99), 91 (9.46), 71 (18.36); IR (neat) 3000, 2960, 1730, 1590, 1430, 1400, 1310, 1295, 1280, 1200, 1160, 1140, 1080, 1010, 910, 805, 720 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.00 (m, 2H), 2.44 (dd, *J*=16.78, 5.80 Hz, 1H), 2.45 (s, 3H), 2.70 (dd, *J*=16.78, 8.24 Hz, 1H), 2.93 (m, 1H), 3.14 (m, 2H), 3.65 (s, 3H), 3.67 (s, 3H), 7.36 (d, *J*=8.09 Hz, 2H). 7.76 (d, *J*=8.09 Hz, 2H).

2-(Methoxycarbonymethyl)-6-phenyl-4-hexanolide (9a):[7b] An oil (a mixture of diastereoisomers); MS *m/z* 263 (M^++1, 5.73%), 262 (M^+, 29.12), 230 (15.66), 170 (18.43), 132 (27.07), 131 (21.43), 130 (100.00), 92 (44.47), 91 (53.42), 59 (6.81); IR (neat) 3000, 2920, 1760, 1725, 1590, 1480, 1425, 1360, 1250, 1150, 1020, 980, 900, 720, 690 cm^{-1}; ^1H NMR of a major diastereoisomer (**M**) ($CDCl_3$) δ=1.82—2.25 (m, 4H), 2.50—2.93 (m, 4H), 2.93—3.10 (m, 1H), 3.70 (s, 3H), 4.54 (m, 1H), 7.20 (m, 3H), 7.29 (m, 2H); ^1H NMR of a minor diastereoisomer (**m**) ($CDCl_3$) δ=1.82—2.25 (m, 4H), 2.50—2.93 (m, 4H), 2.93—3.10 (m, 1H), 3.70 (s, 3H), 4.38 (m, 1H), 7.20 (m, 3H), 7.29 (m, 2H); **M**/**m**=68/32.

3-(Methoxycarbonylmethyl)-1-oxaspiro[4.5]decan-2-one (9b):[7b] An oil; MS *m/z* 227 (M^++1, 13.04%), 226 (M^+, 79.63), 195 (48.56), 183 (86.10), 166 (100.00), 155 (66.80), 153 (58.32), 151 (35.84), 150 (82.71), 132 (27.67), 123 (22.69), 108 (25.87), 100 (27.57), 67 (25.13); IR (neat) 2960, 2880, 1770, 1740, 1205 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.39—1.84 (m, 10H), 1.69 (t, *J*=12.11 Hz, 1H), 2.44 (dd, *J*=12.11, 9.31 Hz, 1H), 2.53 (dd, *J*=10.04, 9.15 Hz, 1H), 2.90 (dd, *J*=17.04, 4.27 Hz, 1H), 3.13 (m, 1H).

3-(Methoxycarbonylmethyl)-1-oxaspiro[4.4]nonan-2-one (9c): An oil; MS *m/z* 212 (M^+, 1.89%), 183 (41.69), 181 (39.00), 155 (37.14), 152 (100.00), 136 (74.62), 110 (37.98), 94 (56.60), 55 (29.20); IR (neat) 2900, 2840, 1760, 1720, 1420, 1320, 1360, 1260, 1140 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.70—2.09 (m, 9H), 2.45 (dd, *J*=12.51, 8.55 Hz, 1H), 2.50 (dd, *J*=17.09, 9.16 Hz, 1H), 2.92 (dd, *J*=17.09, 3.97 Hz, 1H), 3.13 (m, 1H), 3.71 (s, 3H).

2-(Methoxycarbonylmethyl)-4-butanolide (9d):[7b] An oil; MS *m/z* 159 (M^++1, 1.97%), 127 (37.80), 114 (16.88), 82 (16.91), 72 (22.41), 59 (57.33), 55 (100.00); IR (neat) 2945, 2910, 1760, 1725, 1430, 1360, 1260, 1200, 1145, 1015 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.05 (m, 1H), 2.51—2.59 (m, 2H), 2.89—3.01 (m, 2H), 3.72 (s, 3H), 4.24 (m, 1H), 4.41 (dt, *J*=8.85, 1.83 Hz, 1H).

4-Methy1-2-(methoxycarbonylmethyl)-4-decanolide (9e): An oil (a mixture of diastereoisomers); MS *m/z* 257 (M^++1, 0.38%), 171 (100.00), 143 (25.36), 139 (13.64), 111 (10.33); IR (neat) 2950, 2880, 1770, 1745, 1460, 1440, 1385, 1290, 1240, 1190, 1175, 1140 cm^{-1}; ^1H NMR of a major diastereoisomer (**M**) ($CDCl_3$) δ=0.89 (t, *J*=7.02 Hz, 3H), 1.22—1.40 (m, 8H), 1.44 (s, 3H), 1.55—1.90 (m, 3H), 2.45 (dd, *J*=11.81, 8.85 Hz, 1H), 2.55 (dd, *J*=11.59, 8.85 Hz, 1H), 2.89 (dd, *J*=7.63, 3.96 Hz, 1H), 3.14 (m, 1H), 3.70 (s, 3H); ^1H NMR of a minor diastereoisomer (**m**) ($CDCl_3$) δ=0.89 (t, *J*=7.02 Hz, 3H), 1.22—1.40 (m, 8H), 1.37 (s, 3H), 1.55—1.90 (m, 3H), 2.30 (dd, *J*=12.52, 8.85 Hz, 1H), 2.51 (dd, *J*=11.59, 8.85 Hz, 1H), 2.93 (dd, *J*=7.63, 3.96 Hz, 1H), 3.14 (m, 1H), 3.70 (s, 3H); **M**/**m**=58/42.

4-(Methoxycarbonylmethyl)spiro[furan-2(3*H*),1′-indan]-5(4*H*)-one (9f): An oil (a mixture of diastereoisomers); MS *m/z* 261 (M^++1, 5.08%), 260 (M^+, 27.41), 229 (36.52), 216 (46.17), 184 (67.52), 143 (100.00), 133 (53.64), 128 (80.13), 100 (94.33); IR (neat) 3030, 2960, 1760, 1730, 1600, 1450, 1430, 1360, 1320, 1250, 1210, 1190, 1165, 1140, 980, 900, 750, 720 cm^{-1}; ^1H NMR of a major diastereoisomer (**M**) ($CDCl_3$) δ=2.22—2.43 (m, 2H), 2.56—2.71 (m, 2H), 2.85—3.02 (m, 3H), 3.06—3.15 (m, 1H), 3.48 (m, 1H), 3.73 (s, 3H), 7.24—7.39 (m, 4H); ^1H NMR of a minor diastereoisomer (**m**) ($CDCl_3$) δ=2.22—2.43 (m, 3H), 2.56—2.71 (m, 2H), 2.85—3.02 (m, 2H), 3.06—3.16 (m, 1H), 3.27 (m, 1H), 3.73 (s, 3H), 7.24—7.39

(m, 4H); **M**/**m**=54/46.

Laser-Induced Organic Transformation. Direct and Selective Synthesis of Diols from Methanol, Ethanol, and Their Mixture in the Presence of Hydrogen Peroxide

Yuichi SHIMIZU,* Shun'ichi SUGIMOTO, Shunichi KAWANISHI, and Nobutake SUZUKI
Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, 25-1 Mii-minami, Neyagawa, Osaka 572
(Received August 12, 1991)

The laser-induced transformation of methanol (MeOH), ethanol (EtOH), and MeOH–EtOH mixture have been investigated in the presence of H_2O_2. Ethylene glycol (EG) was highly selectively produced in high quantum yield (ϕ=0.94) by KrF-laser irradiation of the N_2-saturated MeOH and the selectivity was 94% at 3.2 ml h^{-1} of H_2O_2 feeding rate (f). Butanediol (BD) and acetaldehyde (AA) were directly and selectively produced by KrF-laser irradiation of the N_2-saturated EtOH. The quantum yields of BD and AA were 0.42 and 0.29, respectively, and the combined selectivity was 97% at f=3.4 ml h^{-1}. Also, propanediols (PD) were directly produced by KrF-laser irradiation of the N_2-saturated MeOH–EtOH mixture. The quantity of 1,2-PD reached the maximum at about 64 mol% of MeOH content. EG is produced through the dimerization of hydroxymethyl radicals formed by the abstraction of a hydrogen atom from MeOH by hydroxyl radical formed in high density by the laser-photolysis of H_2O_2. Similarly, 2,3-BD is produced by the dimerization of 1-hydroxyethyl radicals formed by the abstraction of α-hydrogen atom from EtOH by hydroxyl radical and 1,2-PD is produced by the recombination between hydroxymethyl radical and 1-hydroxyethyl radical.

The direct transformation of alcohols, which are not petrochemicals, into more valuable compounds is very important from a viewpoint of effective utilization of organic resources. Ethylene glycol (EG), butanediols (BD), and propanediols (PD), present-day manufactured by a multistep process using ethylene, butene, acetaldehyde, and propylene etc. obtained in petrochemical industry,[1] are very important as raw materials for the industrial production of polyester synthetic fiber and polyester resin, and also as antifreezing agent and so on.

In the previous paper,[2,3] we reported that EG was directly and selectively synthesized by steady state UV (low-pressure mercury lamp) irradiation of the N_2-saturated MeOH containing H_2O_2. For the purpose of highly selective synthesis of EG, we have attempted to proceed more efficiently the reaction of MeOH with H_2O_2 using a KrF laser with high intensity. We found that EG was highly selectively synthesized by KrF-laser irradiation of the N_2-saturated MeOH containing H_2O_2.[4] Also, we found that BD and acetaldehyde (AA) were directly and selectively synthesized by KrF-laser irradiation of N_2-saturated EtOH containing H_2O_2.[5]

In this paper, we report in further detail with regard to the laser-induced direct synthesis of EG and BD from MeOH and EtOH, respectively, and discuss the reaction mechanism. Furthermore, we report the laser-induced direct synthesis of PD from MeOH–EtOH mixture containing H_2O_2.

Experimental

Materials. All chemicals were of reagent grade. MeOH and EtOH were purchased from Tokyo Kasei Kogyo Co., Ltd. and were used without further purification. The aqueous 30% hydrogen peroxide was purchased from Santoku Chemical Industries Co., Ltd. N_2 used was of high purity grade of above 99.9%.

Apparatus and Procedures. The laser-induced reactions were carried out in a Pyrex glass cylindrical reaction vessel (volume: 91.5 ml, diameter: 35.5 mm, length: 70 mm) with a Suprasil window for the incidence of laser beam. MeOH, EtOH, and MeOH–EtOH mixture (56—64 ml) were placed in the reaction vessel, respectively, and well-bubbled with nitrogen in order to remove oxygen. The N_2-saturated MeOH, EtOH, and MeOH–EtOH mixture were stirred magnetically (500 rpm), and irradiated with the KrF laser (Lumonics Hyper EX-460, wavelength: 248 nm, pulse energy: 350 mJ per pulse, frequency: 16 Hz, pulse duration: 12—15 ns, beam shape: 9×34 mm) at room temperature. At the same time with irradiation, the aqueous 30% H_2O_2 was added to MeOH, EtOH, and MeOH–EtOH mixture with the feeding rate (f) from 3.2 to 16.0 ml h^{-1} by using a microfeeder (Atto Corp., AC-2120). For the purpose of comparison, some experiments were carried out using a steady state UV (low-pressure mercury lamp, wavelength: mainly 253.7 nm, quantity of light: 3.38×10^{18} photons s^{-1}).

Actinometry. The quantity of light from the laser was determined by using a calorimeter (Scientech 38-4UV5). The calorimeter was also placed behind the reaction vessel to determine precisely the quantity of light absorbed by alcohol–H_2O_2 mixture during the laser irradiation. The quantity of light was 4.38×10^{17} photons per pulse.

Analysis. Products were analyzed by gas chromatography (Shimadzu GC-7A: Porapak Q column, GC-4C: Porapak N or Chromosorb 101 column, and GC-3BT: Molecular sieve 5A column) and ion chromatography (Yokogawa IC-100: SAX 1 column).

Results and Discussion

N_2-Saturated Methanol. When the N_2-saturated

MeOH containing H_2O_2 was irradiated with the KrF laser, EG was produced as a major product together with formic acid (FA), methyl formate (MF), formaldehyde, hydrogen, carbon dioxide, carbon monoxide, and methane as minor products. Figure 1 shows the quantities of EG, FA, and MF as a function of number of photon at f=3.2 ml h^{-1}. The quantity of EG increased linearly with number of photon up to about 4.1×10^{20} photons ml^{-1}. The quantities of EG, FA, and MF were 43.3, 0.4, and 0.4×10^{-2} mmol ml^{-1}, respectively, and the sum of the quantities of other products was less than 0.1×10^{-2} mmol ml^{-1} at irradiation of 4.0×10^{20} photons ml^{-1}. The quantum yield of EG formed and the selectivity were 0.94 and 94%, respectively, at irradiation of 4.7×10^{19} photons ml^{-1}. Such high quantum yield and selectivity indicate that the formation of EG proceeds efficiently in this system. Also, when the N_2-saturated MeOH alone was irradiated in the absence of H_2O_2, organic products were hardly produced even after irradiation of about 4.1×10^{20} photons ml^{-1}.

On the other hand, in the case of steady state UV irradiation, the quantum yield of EG formed was 0.73 and the selectivity was 85% at irradiation of 3.7×10^{20} photons ml^{-1}.[3] It was found from these results that the quantum yield of EG formed and the selectivity were much larger in KrF-laser irradiation than in steady state UV one. This indicates that the KrF-laser irradiation is favorable for the effective formation of EG.

Figure 2 shows the effects of H_2O_2 feeding rate on the quantities of EG, FA, and MF. The quantity of EG decreased with increasing H_2O_2 feeding rate in the range of f=3.2—14.4 ml h^{-1}. This indicates that the H_2O_2 feeding rate is an important factor for the efficient formation of EG, and that the efficient formation of EG is favorable in lower H_2O_2 feeding rate. The sum of the quantities of FA and MF was less than 1×10^{-2} mmol ml^{-1} at f=14.4 ml h^{-1}. Table 1 shows the effects of H_2O_2 feeding rate on the quantum yield of EG formed and the selectivity. The quantum yield of EG formed decreased with increasing H_2O_2 feeding rate, that is, from 0.94 at f=3.2 ml h^{-1} to 0.56 at f=14.4 ml h^{-1}. The selectivity of EG formation was 94—97% in the wide range of f=3.2—14.4 ml h^{-1}. It was found from these results that EG was highly selectively synthesized in high quantum yield by KrF-laser irradiation of the N_2-saturated MeOH in lower H_2O_2 feeding rate ranges.

N_2-Saturated Ethanol. When the N_2-saturated EtOH containing H_2O_2 was irradiated with the KrF laser, 2,3-, 1,3-BD, and AA were produced as major products together with 1,4-BD, hydrogen, carbon dioxide, carbon monoxide, and methane as minor products. Figure 3 shows the quantities of 2,3-, 1,3-, 1,4-BD, and AA as a function of number of photon at f=3.4 ml h^{-1}. The

quantities of 2,3-, 1,3-, 1,4-BD, and AA increased linearly with number of photon up to about 4.2×10^{20} photons ml^{-1}. The quantities of 2,3-, 1,3-, 1,4-BD, and AA were 20.2, 5.8, 1.2, and 19.2×10^{-2} mmol ml^{-1}, respectively, and the sum of the quantities of other products was less than 1.6×10^{-2} mmol ml^{-1} at irradiation of 4.0×10^{20} photons ml^{-1}. The quantum yields of 2,3-, 1,3-, 1,4-BD, and AA formed were 0.31, 0.09, 0.02, and 0.29, respectively, and the selectivities were 42, 12, 3, and 40%. Also, when the N_2-saturated EtOH alone was irradiated in the absence of H_2O_2, organic products were hardly produced even after irradiation of about 4.2×10^{20} photons ml^{-1}.

On the other hand, in the case of steady state UV irradiation, the quantities of 2,3-, 1,3-, 1,4-BD, and AA were 11.6, 0.3, 0.7, and 24.7×10^{-2} mmol ml^{-1}, and the selectivities were 29, 1, 2, and 62%, respectively, at irradiation of 4.0×10^{20} photons ml^{-1}. It was found from these results that the quantity and the selectivity of BD were much larger in KrF-laser irradiation than in steady state UV one. This indicates that the KrF-laser irradiation is favorable for the effective formation of BD.

Figure 4 shows the effects of H_2O_2 feeding rate on the quantities of 2,3-, 1,3-, 1,4-BD, and AA. The quantities of BD decreased with increasing H_2O_2 feeding rate, while that of AA increased. The sum of the quantities of 2,3-BD and AA was almost constant (40×10^{-2} mmol ml^{-1}) in the wide ranges of f=3.4—14.7 ml h^{-1}. The quantity of BD was much larger than that of AA in lower f ranges, on the contrary, in higher f ranges the former was smaller than the latter. The quantum yields of BD and AA formed were 0.42 and 0.29, respectively, at f=3.4 ml h^{-1}. The combined quantum yield of BD and AA formed and the combined selectiv-

○: 1,2-Propanediol, ◐: 1,3-Propanediol, □: 2,3-Butanediol, ◧: 1,3-Butanediol, ◨: 1,4-Butanediol, △: Ethylene glycol, ■: Acetaldehyde. Aqueous 30% H_2O_2 feeding rate: 3.6 ml h^{-1}. Methanol content: 66.7 mol%.

ity were 0.70—0.71 and 92—97%, respectively, in the wide f ranges. It was found from these results that BD and AA were directly and selectively synthesized by KrF-laser irradiation of the N_2-saturated EtOH containing H_2O_2. Such high combined quantum yield and selectivity indicate that the formations of BD and AA proceed efficiently in this system.

N_2-Saturated Methanol-Ethanol Mixture. When the N_2-saturated MeOH-EtOH mixture containing H_2O_2 was irradiated with the KrF laser, 1,2-PD, EG, 2,3-BD, and AA were produced as major products together with 1,3-PD, 1,3-BD, 1,4-BD, hydrogen, carbon dioxide, carbon monoxide, and methane as minor products. Figure 5 shows the quantities of main products as a function of number of photon at f=3.6 ml h^{-1}. The quantities of 1,2-PD, EG, 2,3-BD, 1,3-PD, 1,3-BD, 1,4-BD, and AA increased linearly with number of photon up to about 4.4×10^{20} photons ml^{-1}. The quantities of 1,2-PD, EG, 2,3-BD, 1,3-PD, 1,3-BD, 1,4-BD, and AA were 16.8, 12.8, 5.2, 2.2, 0.8, 0.3, and 7.8×10^{-2} mmol ml^{-1}, respectively, and the sum of the quantities of other products was less than 0.3×10^{-2} mmol ml^{-1} at irradiation of 4.0×10^{20} photons ml^{-1}.

On the other hand, in the case of steady state UV irradiation, the quantities of 1,2-PD, EG, 2,3-BD, and AA were 10.2, 9.4, 2.6, and 12.7×10^{-2} mmol ml^{-1}, respectively, at irradiation of 4.0×10^{20} photons ml^{-1}. It was found from these results that the quantities of PD, EG, and BD were much larger in KrF-laser irradiation than in steady state UV one. This indicates that the KrF-laser irradiation is favorable for the effective formation of PD, EG, and BD.

Figure 6 shows the effects of H_2O_2 feeding rate on the quantities of 1,2-PD, EG, 2,3-BD, and AA. The quantities of 1,2-PD, EG, and 2,3-BD decreased linearly with increasing H_2O_2 feeding rate, while that of AA increased. The quantities of 1,2-PD and EG were much larger than that of AA in lower f ranges, on the contrary, in higher f ranges the formers were smaller than the latter. This result indicates that the efficient formation of diols is favorable in lower f ranges.

Figure 7 shows the effects of MeOH content on the quantities of 1,2-PD, EG, 2,3-BD, and AA at f=3.6 ml h^{-1}. The quantity of 1,2-PD increased with MeOH content and reached the maximum at about 64 mol% of MeOH content. The quantity of EG increased linearly with MeOH content, while those of 2,3-BD and AA decreased. In the case of 64 mol% of MeOH content, the quantum yields of PD, EG, BD, and AA were 0.30, 0.17, 0.11, and 0.14, respectively, and the combined quantum yield was 0.72. The selectivities of 1,2-PD, EG, 2,3-BD, and AA were 36, 24, 13, and 19%, respectively, and the combined selectivity of diols and AA formation is 99%. It was found from these results that PD was directly synthesized by KrF-laser irradiation of the N_2-saturated MeOH-EtOH mixture containing H_2O_2. Such high combined quantum yield and selectivity indicate that the formation of diols such as PD, EG, and BD and AA proceeds efficiently in this system.

Reaction Mechanism. As described in the previous paper,[3] in the case of steady state UV irradiation of N_2-saturated MeOH containing H_2O_2, EG was produced

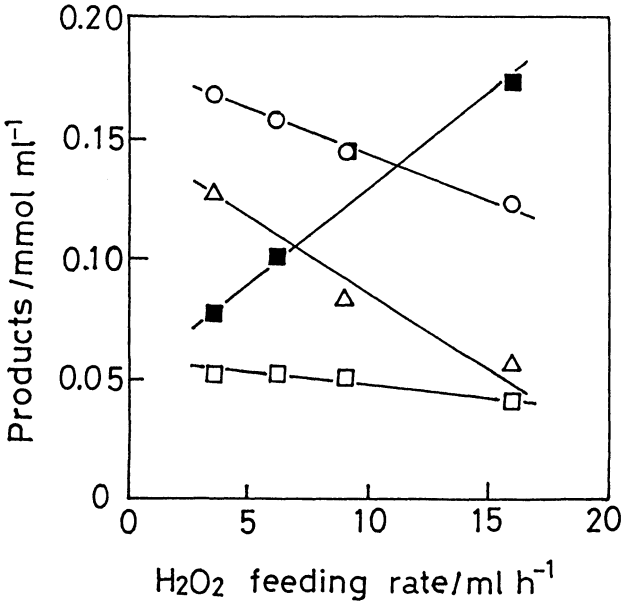

Fig. 6. Effects of H_2O_2 feeding rate on the quantities of main products in the case of KrF-laser irradiation of N_2-saturated methanol-ethanol mixture.
Symbols are the same as in Fig. 5. Number of photon: 4.0×10^{20} photons ml^{-1}. Methanol content: 66.7 mol%.

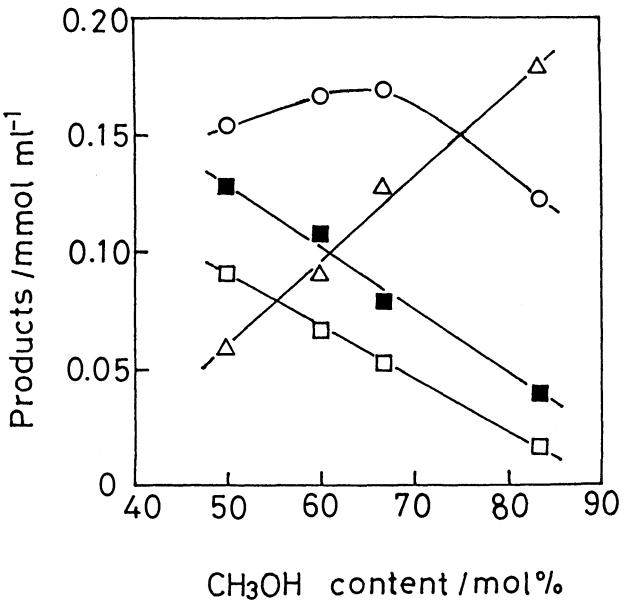

Fig. 7. Effects of methanol content on the quantities of main products in the case of KrF-laser irradiation of N_2-saturated methanol-ethanol mixture.
Symbols are the same as in Fig. 5. Aqueous 30% H_2O_2 feeding rate: 3.6 ml h^{-1}. Number of photon: 4.0×10^{20} photons ml^{-1}.

through the dimerization of hydroxymethyl radicals which were formed by the abstraction of a hydrogen atom from MeOH by hydroxyl radical formed by the photolysis of H_2O_2 as the reactions (1)—(3).

$$H_2O_2 \xrightarrow{h\nu} 2\cdot OH \quad (1)$$

$$CH_3OH + \cdot OH \longrightarrow \cdot CH_2OH + H_2O \quad (2)$$

$$2\cdot CH_2OH \longrightarrow (CH_2OH)_2 \quad (3)$$

The UV absorption spectrum of H_2O_2 gives a strong and very broad absorption band in the wavelength range of UV and vacuum UV regions below 300 nm. The absorbance of H_2O_2 at the wavelength of KrF laser (248 nm) is about 1.3 times that at the wavelength of steady state UV (253.7 nm). In analogy with the case of steady state UV irradiation,[6] H_2O_2 is very efficiently decomposed to form hydroxyl radicals by the laser irradiation. It can therefore be considered that in the case of KrF-laser irradiation of the N_2-saturated MeOH, EG would be produced through the reactions (1)—(3). As described already, quantum yield of EG formed was much larger in the KrF-laser irradiation than in steady state UV irradiation. The light intensity is about 10^7 times larger with the KrF laser than with the low-pressure mercury lamp. It is therefore considered that in KrF-laser irradiation, hydroxyl radical would be formed in high density (Eq. 1), and the abstraction of a hydrogen atom from MeOH occurs more efficiently (Eq. 2), followed by the effective dimerization of hydroxymethyl radicals (Eq. 3).

As shown in Table 1, the high quantum yield of EG formed was obtained in lower f ranges. In the case of f=3.2 ml h^{-1}, assuming the quantum yield of hydroxyl radical formed by the reaction (1) is 2.0,[6] 94% of hydroxyl radical formed is consumed to form EG. This indicates that most of hydroxyl radicals formed are very efficiently consumed by the reaction (2). It is therefore considered that such high quantum yield of EG formed in lower f ranges by KrF-laser irradiation is attributed to the effective dimerization of hydroxymethyl radical formed in high density. Also, in higher f ranges, the quantum yield of EG formed decreased. Since EG hardly has the absorption band at 248 nm, it is considered that the decrease of EG formation in higher f ranges is mainly attributed to the scavenging of hydroxyl radical by H_2O_2 to form hydroperoxyl radical (Eq. 4).[7]

$$H_2O_2 + \cdot OH \longrightarrow \cdot O_2H + H_2O \quad (4)$$

The hydroperoxyl radical formed by the reaction (4) reacts mainly with hydroxyl radical to form H_2O and O_2.[8]

In the case of KrF-laser irradiation of the N_2-saturated EtOH, the hydroxyl radical abstracts competitively α- or β-hydrogen atom from EtOH to form 1- or 2-hydroxyethyl radical (Eqs. 5 and 6).[9] It is therefore considered that 2,3- and 1,4-BD are produced by the dimerization of 1- and 2-hydroxyethyl radicals (Eqs. 7 and 8), respectively, and that 1,3-BD is produced by the recombination between 1- and 2-hydroxyethyl radicals (Eq. 9).

$$CH_3CH_2OH + \cdot OH \longrightarrow CH_3\dot{C}HOH + H_2O \quad (5)$$

$$CH_3CH_2OH + \cdot OH \longrightarrow \cdot CH_2CH_2OH + H_2O \quad (6)$$

$$2CH_3\dot{C}HOH \longrightarrow (CH_3CHOH)_2 \quad (7)$$

$$2\cdot CH_2CH_2OH \longrightarrow (CH_2CH_2OH)_2 \quad (8)$$

$$CH_3\dot{C}HOH + \cdot CH_2CH_2OH \longrightarrow CH_3CHOHCH_2CH_2OH \quad (9)$$

It is also considered that AA is mainly produced by the disproportionation of 1-hydroxyethyl radicals in competition with the dimerization (Eq. 10).[9,10]

$$2CH_3\dot{C}HOH \longrightarrow CH_3CHO + CH_3CH_2OH \quad (10)$$

The quantities of 2,3-, 1,3-BD, and AA formed via 1-hydroxyethyl radical were much larger than that of 1,4-BD formed via 2-hydroxyethyl radical. In the case of irradiation of 4.0×10^{20} photons ml^{-1}, the percentage of the quantity of products formed via 1-hydroxyethyl radical to that formed via 1- and 2-hydroxyethyl radicals was 91% at f=3.4 ml h^{-1}. This value is in excellent agreement with that (90%) obtained by the radiation-induced oxidation of aqueous EtOH solutions.[9] This supports the reaction mechanism for the formations of BD and AA in lower f ranges proposed above.

On the other hand, as shown in Fig. 4, the quantity of AA increased in higher f ranges. Assuming AA is produced by the reaction (10), the percentage of the quantity of products formed via 1-hydroxyethyl radical to that formed via 1- and 2-hydroxyethyl radicals was 94% at f=14.7 ml h^{-1} in the case of irradiation of 4.0×10^{20} photons ml^{-1}. This value is larger than that (91%) at f=3.4 ml h^{-1} described above. It is known that 1-hydroxyethyl radical reacts with H_2O_2 to form AA (Eq. 11).[9]

$$CH_3\dot{C}HOH + H_2O_2 \longrightarrow CH_3CHO + H_2O + \cdot OH \quad (11)$$

Assuming AA is produced by the reaction (11), the percentage of the quantity of products formed via 1-hydroxyethyl radical to that formed via 1- and 2-hydroxyethyl radicals was 91% at f=14.7 ml h^{-1} in the case of irradiation of 4.0×10^{20} photons ml^{-1}, and was in good agreement with the value (90%)[9] in reference. It is therefore considered from these results that AA is preferentially produced by the reaction (11) in higher f ranges.

In the case of KrF-laser irradiation of the N_2-saturated MeOH–EtOH mixture, the hydroxyl radical reacts with MeOH and EtOH to form hydroxymethyl, 1-, and 2-hydroxyethyl radicals. It is therefore considered that 1,2- and 1,3-PD are produced by the recombination between hydroxymethyl radical and 1-and 2-hydroxyethyl radicals (Eqs. 12 and 13), respectively.

$$\cdot CH_2OH + CH_3\dot{C}HOH \longrightarrow CH_3CHOHCH_2OH \quad (12)$$

$$\cdot CH_2OH + \cdot CH_2CH_2OH \longrightarrow HOCH_2CH_2CH_2OH \quad (13)$$

As shown in Fig. 7, the quantity of 1,2-PD reached a maximum at about 64 mol% of MeOH content. The ratio (1.7) of MeOH to EtOH at the maximum of 1,2-PD is in good agreement with the ratio ($k_{EtOH}/k_{MeOH}=1.5$)[11] of the rate constant of the abstraction of hydrogen atoms from MeOH and EtOH by hydroxyl radical. Also, the percentage of the quantity of 1,2-PD to that of total PD was 86% at irradiation of 4.0×10^{20} photons ml^{-1}. This value is close to the relative probability (90%)[9] of the abstraction of a hydrogen atom from α-position to that from β-position of EtOH by hydroxyl radical. These results support the reaction mechanism of the PD formation proposed above. Also, EG and 2,3-BD are produced by the dimerization of hydroxymethyl and 1-hydroxyethyl radicals, respectively, (Eqs. 3 and 7). AA is mainly produced by the disproportionation of 1-hydroxyethyl radicals in lower f ranges (Eq. 10) and the reaction of 1-hydroxyethyl radical with H_2O_2 in higher f ranges (Eq. 11).

(Received June 25, 1991)

Differential thermal analysis (DTA), differential scanning calorimetry (DSC), and the temperature dependences of the ^{1}H spin-lattice relaxation time (T_1) and the second moment (M_2) of ^{1}H NMR absorptions were studied in $(CH_3)_3CNH_3ClO_4$ and its partially deuterated analogs, $(CH_3)_3CND_3ClO_4$ and $(CD_3)_3CNH_3ClO_4$. DTA and DSC studied revealed four solid phases, including a metastable phase, in the temperature range between 80 K and the melting point (414 K). The stable phases (named as I, II, and III) were obtained above 394 K, between 394 and 327 K, and below 327 K, respectively. The metastable phase II′, prepared by rapid cooling the phase II to ca. 100 K, exists below ca. 245 K. The cationic motions in each solid phase were studied by T_1 and M_2 experiments. Three kinds of motions (reorientations of the CH_3 groups about their C–C bond axes, the NH_3^+ group about its C–N bond axis, and the *t*-butyl group about the C–N bond axis) were observed in these phases and their motional parameters were determined

The solid methyl-substituted ammonium perchlorates, $(CH_3)_nNH_{4-n}ClO_4$ (n=1—4), are known to undergo polymorphic phase transitions which are interrelated with changes in the motional states of the cations and anions in crystals.[1-8] In the highest-temperature solid phases of these salts, both ions are in a highly disordered state, obtaining the greatest part of their motional freedom. Especially, in the phases of mono-, di-, and trimethylammonium perchlorates the cations were shown to perform rapid translational self-diffusion as well as isotropic rotation as a whole by NMR techniques.[2-4,6,7]

Since a *t*-butylammonium ion is expected to be easily movable in crystals because of its higher symmetry and more spherical shape than mono- and trimethylammonium ions, *t*-butylammonium perchlorate seems to be an interesting candidate for studying the relation between ionic motions and the polymorphic phase transitions expected to occur. The motions of *t*-butylammonium ions in a solid have been investigated by ^{1}H NMR techniques for *t*-butylamine tropolone adduct,[9] *t*-butylammonium halides,[10-12] and nitrate;[13] in these salts the cations have been found to be tightly fixed in the crystal lattice and to form fairly strong N–H···X type hydrogen bonds between the cation and the anion. Since a perchlorate ion is expected to form a hydrogen bond with a counter cation much weaker than halide ions, it is interesting to elucidate the molecular motions of the *t*-butylammonium ion expected to be more loosely bound in a crystal.

In the present study measurements of the temperature dependences of the ^{1}H spin-lattice relaxation time (T_1) and the second moment (M_2) of the ^{1}H NMR absorptions, differential thermal analysis (DTA), and differential scanning calorimetry (DSC) have been carried out for *t*-butylammonium perchlorate and its partially deuterated analogs to reveal the phase transitions, possible cationic motions, and their time scales in respective solid phases.

† Deceased on 27 February, 1991.

Experimental

^{1}H T_1 was determined at 32 and 8.5 MHz by means of a pulsed NMR spectrometer described elsewhere.[14] A 180°—τ—90° pulse sequence was employed. Continuous-wave ^{1}H NMR spectra were recorded at 40 MHz by using a JEOL JNM-MW-40S spectrometer. A home-made apparatus similar to that reported previously[15] was employed for DTA experiments. Differential scanning calorimetry (DSC) was carried out by use of a Perkin-Elmer 7 Series Thermal Analysis System.

$(CH_3)_3CNH_3ClO_4$ (abbreviated to (*t*-BA)ClO_4) was prepared by neutralizing *t*-butylamine with perchloric acid and recrystallized twice from isopropyl alcohol. $(CH_3)_3CND_3ClO_4$ ((*t*-BAd_3)ClO_4) was prepared from purified (*t*-BA)ClO_4 by repeated crystallization three times from heavy water and was finally purified by recrystallization from CH_3OD. $(CD_3)_3CNH_3ClO_4$ ((*t*-Bd_9A)ClO_4) was obtained from perchloric acid and $(CD_3)_3CNH_2$ purchased from MSD Isotopes and recrystallized from isopropyl alcohol. The obtained crystals were dried under high vacuum at room temperature for 24 h and then at ca. 50 °C for 24 h before elemental analysis and the measurements of NMR, DTA, and DSC. Calcd for $(CH_3)_3CNH_3ClO_4$: C, 27.67; H, 6.91; N, 8.07%. Found: C, 27.64; H, 6.82; N, 8.13%.

Results

DTA curves recorded for (*t*-BA)ClO_4 over the temperature range of 80—420 K are shown in Fig. 1. When the sample was heated from room temperature, three endothermic anomalies appeared at 327, 394, and

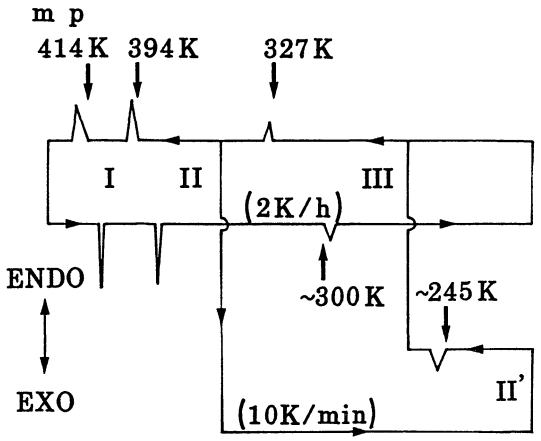

Fig. 1. DTA curves of $(CH_3)_3CNH_3ClO_4$. The cooling and heating rate is ca. 1 K min^{-1} unless otherwise noted. I, II, III, and II′ are the names of obtained solid phases.

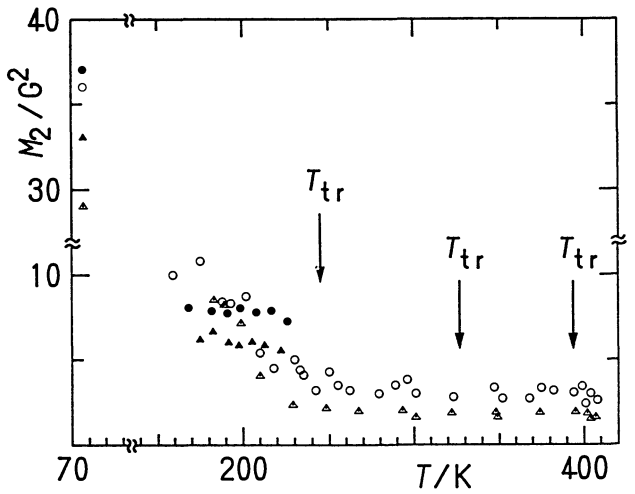

Fig. 2. Temperature dependence of the ^{1}H NMR second moment (M_2) observed for $(CH_3)_3CNH_3ClO_4$ (○ for phases I, II, and III; ● for phase II′) and $(CH_3)_3CND_3ClO_4$ (△ for I, II, and III; ▲ for II′). T_{tr}'s are transition temperatures determined for $(CH_3)_3CNH_3ClO_4$ by DTA.

414±1 K. The first two anomalies were attributed to solid-solid phase transitions and the last one to melting. The corresponding entropy changes determined by DSC were 6.9, 12, and 17 J K^{-1} mol^{-1}, respectively.

The phase obtained between 327 and 394 K could easily be supercooled down to ca. 100 K by cooling at a rate faster than 10 K min^{-1}. With increasing temperature of a rapidly cooled sample, an unusual exothermic anomaly appeared at ca. 245 K. The solid phases revealed by DTA are designated in the order of decreasing temperature as phases I, II, III, and II′, as shown in Fig. 1. The partially deuterated analogs, (*t*-BAd_3)ClO_4 and (*t*-Bd_9A)ClO_4, showed approximately the same DTA curves as in Fig. 1 and their transition temperatures are given in Figs. 4 and 5, respectively.

The temperature variation of M_2 observed for (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4 between 77 and 408 K is shown in Fig. 2. The M_2 values at 77 K determined for (*t*-BA)ClO_4 in phases III and II′ were 36 and 37±2 G^2 (1 G=1×10^{-4} T), respectively, while for (*t*-BAd_3)ClO_4, 33 and 29±2 G^2, they were of the same order. Between 170 and 220 K in phase II′, almost constant values of 7.8 and 5.9±0.3 G^2 were obtained for (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4, respectively. Above 240 K, the M_2 values for both salts were almost constant and no remarkable change was observed at the transition points, T_{tr}(III→II) and T_{tr}(II→I).

The temperature dependences of ^{1}H NMR T_1 determined at 32 and 8.5 MHz are shown in Figs. 3, 4, and 5 for (*t*-BA)ClO_4, (*t*-BAd_3)ClO_4, and (*t*-Bd_9A)ClO_4, respectively. When measured at 32 MHz, (*t*-BA)ClO_4 in phase III yielded three T_1 minima of 25, 42, and 51 ms located at 172, 235, and 323 K, respectively, while (*t*-BAd_3)ClO_4 exhibited two minima of 21 and 59 ms at 169 and 317 K, respectively. Regarding (*t*-Bd_9A)ClO_4, a T_1 minimum of 13 ms was observed at 244 K.

(*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4 in phase II′ gave a broad and asymmetric T_1 minimum, considered to have resulted from superimposed two or more minima. From the T_1 data observed for (*t*-Bd_9A)ClO_4 at 8.5

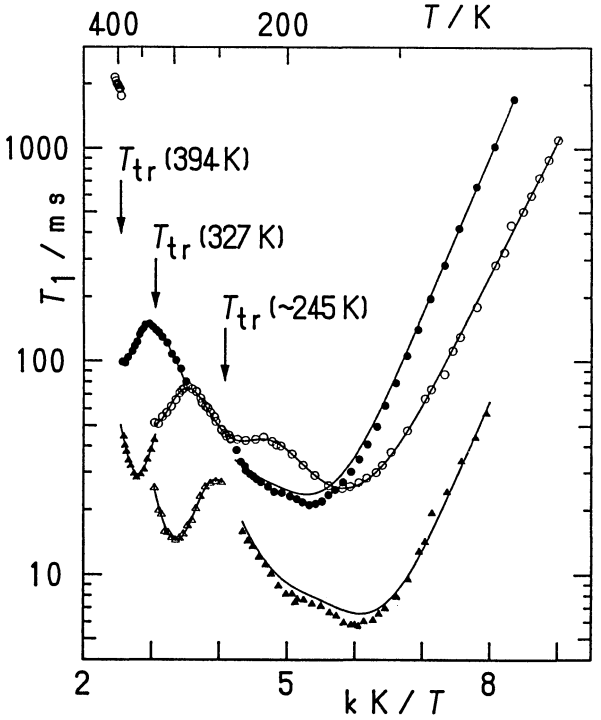

Fig. 3. Temperature dependence of the spin-lattice relaxation time (T_1) observed at 8.5 MHz (△ for phase III; ▲ for phases II and II′) and 32 MHz (○ for I and III; ● for II and II′) in $(CH_3)_3CNH_3ClO_4$. The solid lines in phases II and III indicate the best-fit theoretical values, whereas the lines in phase II′ are the calculated T_1 curves using the motional parameters determined for $(CH_3)_3CND_3ClO_4$ and $(CD_3)_3CNH_3ClO_4$.

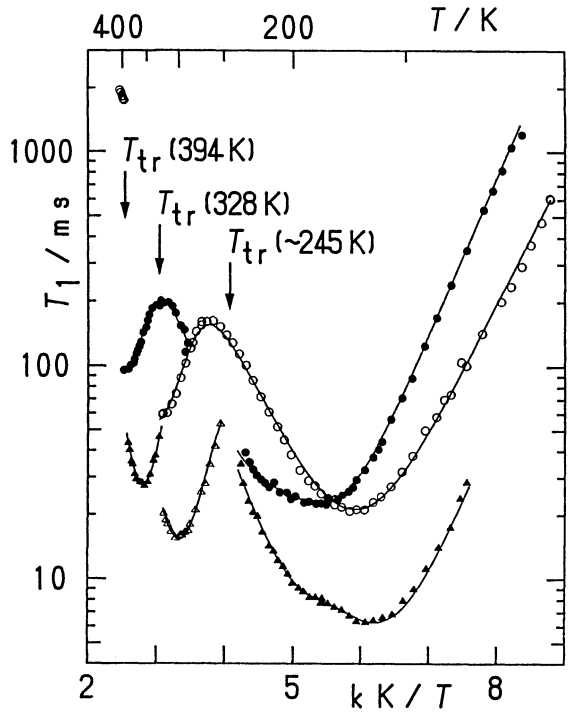

Fig. 4. Temperature dependence of the spin-lattice relaxation time (T_1) observed at 8.5 MHz (△ for phase III; ▲ for phases II and II') and 32 MHz (○ for I and III; ● for II and II') in $(CH_3)_3CND_3ClO_4$. T_{tr}'s are transition temperatures determined for $(CH_3)_3CND_3ClO_4$ by DTA. The solid lines indicate the best-fit theoretical values.

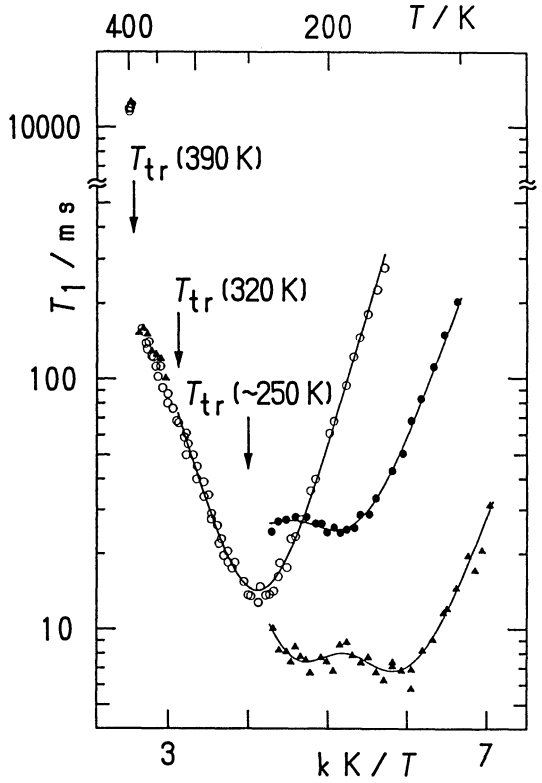

Fig. 5. Temperature dependence of the spin-lattice relaxation time (T_1) observed at 8.5 (▲) and 32 MHz (○ for phases I, II, and III; ● for phase II') in $(CD_3)_3CNH_3ClO_4$. T_{tr}'s are transition temperatures determined for $(CD_3)_3CNH_3ClO_4$ by DTA. Solid lines indicate the best-fit theoretical values.

MHz, two minima could be distinguished at 170 and 210 K.

A sudden increase of T_1 was observed for (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4 at T_{tr}(III→II), above which temperature each salt measured at 8.5 MHz showed a minimum at almost the same temperature (360 K) in phase II. T_1 of (*t*-Bd_9A)ClO_4 showed no remarkable discontinuity at the transition and increased with temperature in phase II; the gradient of T_1 vs. T^{-1} plots in this phase is slightly gentler than in phase III. At T_{tr}(II→I), of all salts increased discontinuously. In phase I, T_1 of (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4 increased with temperature, whereas a decrease of T_1 was observed for (*t*-Bd_9A)ClO_4. T_1 of each salt measured at 32 and 8.5 MHz gave the same values within the experimental error.

Discussion

Second Moments of ^{1}H NMR Absorptions. To interpret the M_2 values obtained for (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4, we calculated the M_2 values for the following motional states of the cation: 1) the rigid lattice, 2) the C_3 reorientations of the three CH_3 groups about the respective C–C bond axes, 3) the C_3 reorientation of the NH_3^+ group about the C–N bond axis in addition to the CH_3 reorientations, and 4) the C_3' reorientation of the *t*-butyl group about the C–N bond axis together with the NH_3^+ and CH_3 reorientations. Since no crystal data are available for this salt, we calculated the M_2 values arising from only intra-cationic magnetic dipole-dipole interactions. In the calculation, the bond distances of C–C, C–N, C–H, and N–H were taken to be 1.54, 1.47, 1.10, and 1.04 Å, respectively;[16,17] all bond angles were assumed to be tetrahedral. The calculated values for the above-mentioned motional modes are given in Table 1 for both *t*-BA^+ and *t*-BAd_3^+ cations.

By comparing the observed M_2 values with the calculated ones, the cations are expected to be rigid at 77 K in phases III and II'. The differences between the

Table 1. Second Moments (M_2/G^2) of ^{1}H NMR Absorptions Calculated for $(CH_3)_3CNH_3^+$ and $(CH_3)_3CND_3^+$ Cations

	$(CH_3)_3CNH_3^+$	$(CH_3)_3CND_3^+$
Rigid	25.7	22.7
CH_3 Reorientation	12.7	6.0
CH_3 and NH_3^+ Reorientation	7.0	6.0
CH_3, NH_3^+, and *t*-Butyl Reorientation	3.8	2.3

observed and calculated values seem to be attributable to intermolecular contributions. The almost constant values of M_2 observed between 170 and 220 K in phase II′ can be explained by a model of the C_3 reorientations of the CH_3 and NH_3^+ groups. Above ca. 240 K, the cations are considered to undergo the C_3 reorientations of the CH_3 and NH_3^+ groups as well as the C_3' reorientation of the *t*-butyl group. The M_2 values of 3.3±0.3 and 2.0±0.2 G^2 obtalned for (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4, respectively, above 240 K are, however, somewhat smaller than the calculated values for this motional model. This implies the existence of additional cationic motions which are activated even below 240 K. The large-amplitude librations of the cation about the C–C and C–N axes can be thought of as one such motional mode. In fact, a large-amplitude torsional motion of the cation about the C–N axis has been reported from an X-ray diffraction study of $(CH_3)_3CNH_3Cl$.[18] Since a ClO_4^- ion forms the hydrogen bond with a cation weaker than a Cl^- ion, it is expected that the cation in perchlorate librates more freely with a much larger amplitude.

The observed entropy changes (ΔS_{tr}) at T_{tr}(III→II) and T_{tr}(II→I) were considerably large, and the sum of the two ΔS_{tr} (ca. 19 $J K^{-1} mol^{-1}$) was comparable with each ΔS_{tr} value at the two transitions reported for $CH_3NH_3ClO_4$.[3] This salt undergoes two solid–solid phase transitions at 321 K (ΔS_{tr}=20.9 $J K^{-1} mol^{-1}$) and 451 K (ΔS_{tr}=16.9 $J K^{-1} mol^{-1}$) and then transforms into a plastic phase in which both cations and anions are freely movable, like in liquid phase. It has been revealed that, at both low- and high-temperature transitions, the anions and the cations, respectively, acquire the greatest part of their motional freedom.[1–5,19] One might expect, accordingly, that the cations and/or the anions in (*t*-BA)ClO_4 also obtain motional freedom to a similar extent through these two transitions. Since the motional state of the *t*-BA^+ cations is thought to be little affected at both transitions, where no marked decrease in M_2 was observed, the increase in motional freedom probably occurs only in the anions and, hence, the isotropic rotation of the anions is expected in phase I.

Room-Temperature Phase (III). Referring to the above discussion on M_2, we can assign the T_1 minimum at 240 K observed for (*t*-Bd_9A)ClO_4 to the C_3 reorientation of the NH_3^+ group. For this motion, ^1H T_1 can be expressed as[20]

$$T_1^{-1} = Cf(\tau), \tag{1}$$

$$C = (9/20)\gamma^4\hbar^2 r^{-6} \tag{2}$$

and

$$f(\tau) = \tau/(1+\omega^2\tau^2) + 4\tau/(1+4\omega^2\tau^2). \tag{3}$$

Here, γ, r, τ, and ω denote the gyromagnetic ratio of a proton, the inter-proton distance in the NH_3^+ group, the correlation time of the motion, and the angular resonance frequency, respectively. Assuming an Arrhenius-type relationship between τ and the activation energy (E_a) for the reorientation process, one obtains

$$\tau = \tau_0 \exp(E_a/RT), \tag{4}$$

where τ_0 is the correlation time at infinite temperature. Eqs. 1—4 were fitted to the T_1 data obtained for (*t*-Bd_9A)ClO_4 using a least-squares method. The optimum values of E_a, τ_0, and C obtained are listed in Table 2.

Table 2. Motional Parameters of *t*-Butylammonium Ions in $(CH_3)_3CNH_3ClO_4$, $(CH_3)_3CND_3ClO_4$, and $(CD_3)_3CNH_3ClO_4$

Phase II′	16.1±0.3	1.3 ±0.3	5.0±0.2	NH_3^+(1)
	19.6±1.0	2.2 ±0.2	4.1±0.2	NH_3^+(2)

The T_1 minimum at 172 K observed for $(t\text{-BA}d_3)ClO_4$ is attributable to the C_3 reorientation of all CH_3 groups in the cation, and the T_1 minima around 310 K observed at 8.5 and 32 MHz to the C_3' reorientation of the *t*-butyl group from the above discussion on M_2. Since the T_1 minima arising from the reorientations of the CH_3 and *t*-butyl groups are well separated, the correlation time (τ_1) for the CH_3 group motion is considered to be much shorter than that (τ_2) for the *t*-butyl group, i.e., $\tau_1 \ll \tau_2$. Thus, assuming that all CH_3 groups in this phase are crystallographically equivalent, we can express ^1H T_1 for these two motions by the sum of the two BBP equations associated with the CH_3 and the *t*-butyl group motions:[10,21,22]

$$T_1^{-1} = C(\text{Me})f(\tau_1) + C(\text{Bu})f(\tau_2), \quad (5)$$

$$C(\text{Me}) = (9/80)\gamma^4\hbar^2 r^{-6}\{(3/2)\sin^4\delta + (1/2)(8-3\sin^4\delta)\}, \quad (6a)$$

and

$$C(\text{Bu}) = \gamma^4\hbar^2\{(9/80)\, r^{-6}(\sin^2 2\delta + \sin^4\delta) + (27/20)R^{-6}\}. \quad (6b)$$

Here, C(Me) and C(Bu), r, R, and δ are the motional constants, the interproton distance in a CH_3 group, the distance between the centers of three protons in each CH_3 group, and the angle between C–C and C–N bonds, respectively. Employing an Arrhenius-type relationship as given by Eq. 4 for these two motions, the activation energies, the correlation times at infinite temperature, and the motional constants could be obtained for $(t\text{-BA}d_3)ClO_4$ by a fitting calculation of Eqs. 5 and 6 to the observed T_1 data. The best-fit motional parameters are listed in Table 2. Good agreement between the observed and calculated T_1 was obtained, as shown in Fig. 4.

From the above discussion on the two deuterated analogs, three well separated T_1 minima of $(t\text{-BA})ClO_4$ located at 172, 235, and 323 K can be assigned to the reorientations of the CH_3, NH_3^+, and *t*-butyl groups, respectively. T_1 for $(t\text{-BA})ClO_4$ can be expressed as

$$T_1^{-1} = (3/4)\{T_1(t\text{-BA}d_3)\}^{-1} + (1/4)\{T_1(t\text{-B}d_9\text{A})\}^{-1}, \quad (7)$$

where $T_1(t\text{-BA}d_3)$ and $T_1(t\text{-B}d_9\text{A})$ are given by Eqs. 5 and 1, respectively. A fitting calculation to the T_1 data of $(t\text{-BA})ClO_4$ was carried out using Eqs. 4 and 7. The results are given in Table 2.

The large activation energy (32.3 kJ mol^{-1}) obtained for the *t*-butyl reorientation implies that the cations were tightly packed in the crystal. Comparable activation energies of 26.9—32.6 kJ mol^{-1} were reported for *t*-BA bromide and iodide.[10,11] This result is reasonable in view of these three kinds of anions with about the same size and shape. E_a=12.1 kJ mol^{-1} for the CH_3 reorientation is also comparable with 9.8—11.7 kJ mol^{-1} for the less hindered CH_3 groups in the *t*-BA cation in halides.[10,11] E_a=21.8 kJ mol^{-1} for the NH_3^+ group, on the other hand, is considerably smaller than 27.3[23]—44.2 kJ mol^{-1} for the same motion in halides.[10,12] This is explainable in terms of a weak hydrogen bond of the N–H···O type formed in perchlorate; E_a in the present perchlorate, however, is much larger than 2—5 and 2—3 kJ mol^{-1} for the NH_3^+ reorientation in $CH_3NH_3ClO_4$[2-4] and for the NH_4^+ reorientation in NH_4ClO_4,[24-26] respectively, the values of which are regarded as being typical examples for perchlorates containing very weak hydrogen bonds. Accordingly, we suppose in the present salt, besides the hydrogen bonding, interionic steric interactions due to tightly packed cations and anions also give a considerable contribution to the barrier for NH_3^+ rotation.

Metastable Phase (II'). The T_1 minima observed for $(t\text{-B}d_9\text{A})ClO_4$ can be attributed to the C_3 reorientation of the NH_3^+ group. Since the two T_1 minima having almost the same values were obtained at 8.5 MHz, it is expected that there exist two crystallographically nonequivalent cations in this phase with an abundance ratio of 1 : 1. ^1H T_1 for the present motion can be expressed by superimposed two BPP equations, as

$$T_1^{-1} = C_1 f(\tau_1) + C_2 f(\tau_2). \quad (8)$$

A fitting calculation was made by use of Eqs. 8 and 4, and the results are shown in Table 2.

The broad and asymmetric T_1 minimum of $(t\text{-BA}d_3)ClO_4$ can be explained in terms of the C_3 reorientation of the nonequivalent CH_3 groups by referring to the M_2 results. When we assume two kinds of CH_3 groups in this phase, an equation similar to Eq. 8 can be used to analyze the T_1 data. A fitting calculation using this equation was successful as is shown in Fig. 4; its results are listed in Table 2. We obtained $C_1 = 5.4\times10^9$ and $C_2 = 2.7\times10^9$ s^{-2} as the optimum values for the motional constants; this implies that the nonequivalent CH_3 groups can be classified into two groups with an abundance ratio of 2 : 1. Since two kinds of cations have been revealed to exist in phase II' from the results of $(t\text{-B}d_9\text{A})ClO_4$, the above results can be interpreted in terms of one of the following two models: 1) each cation includes two kinds of nonequivalent CH_3 groups, and 2) one cation contains three equivalent CH_3 groups, while the other has nonequivalent CH_3 groups (2 : 1), one of which is embedded in almost the same circumstance as the former three CH_3 groups.

From the results of the partially deuterated analogs, the broad T_1 minimum in $(t\text{-BA})ClO_4$ is considered as resulting from at least four T_1 successively overlapped minima, two of which are attributed to CH_3 motions and the other two to NH_3^+ motions. Thus, T_1 of $(t\text{-BA})ClO_4$ can be written using a formula similar to Eq. 7, where both $T_1(t\text{-BA}d_3)$ and $T_1(t\text{-B}d_9\text{A})$ consist of two BBP equations as given by Eq. 8. Since it is difficult to fit this equation to the present data owing to too many adjustable parameters, we only evaluated the activation energy for the CH_3 and NH_3^+ reorientations from the slope of ln T_1 vs. T^{-1} plots below 150 K. In Fig. 3, the calculated T_1 curves using Eq. 7 by substituting

the parameters obtained for (*t*-BAd_3)ClO_4 and (*t*-Bd_9A)ClO_4 are shown. The agreement between the experimental and calculated T_1 is satisfactory.

It is interesting to compare the activation energies for the CH_3 and NH_3^+ groups in phase II′ with those in phase III. Table 2 shows that the activation energies of the CH_3 groups in the metastable phase (phase II′) are higher than that in the stable phase (phase III), whereas those of NH_3^+ are lower in phase II′ than in phase III. The same relation of the activation energies between metastable and stable phases is found in *t*-BA nitrate, where three solid phases (one stable and two metastable) exist below 254 K, between 95 and 350 K, and below 235 K, respectively.[13]

Intermediate Phase(II). The T_1 increase of (*t*-Bd_9A)-ClO_4 with temperature in phase II is attributed to the NH_3^+ reorientation, the activation energy of which evaluated from the slope of T_1 curve is smaller than that in phase III. Since no discontinuous change in T_1 of (*t*-Bd_9A)ClO_4 was observed at T_{tr}(III→II) determined by DTA, the reorientation of the NH_3^+ group is little affected at this transition.

On the other hand, (*t*-BAd_3)ClO_4 showed a sudden increase of T_1 at T_{tr}(III→II), above which temperature this salt yielded a T_1 maximum and a minimum at 32 MHz; measurements at 8.5 MHz gave only a minimum in phase II. From these results, we can expect the presence of the following two kinds of cationic motions which contribute to in T_1 in this phase of (*t*-BAd_3)ClO_4: 1) the motion assignable to the T_1 minima observed at 32 and 8.5 MHz, and 2) the other contributing to T_1 at 32 MHz, mainly in the low-temperature range of the T_1 maximum. Referring to the M_2 results, both of these motions can be regarded as the *t*-butyl reorientation, since the CH_3 group motion is considered to be too frequent to affect T_1 in this phase as predicted from the T_1 results in phase III. This means that there exist two kinds of *t*-butyl groups, or two kinds of cations; the T_1 minimum can be attributed to one of the two kinds of *t*-butyl groups and the T_1 decrease observed in the high-temperature side of the maximum to the motion of the other. This interpretation is supported by the fact that the minimum value of 28 ms observed at 8.5 MHz in this phase is almost twice as large as that of 15 ms in phase III; this minimum was assigned to the motions of all *t*-butyl groups in the crystal.

When the motion of one of the *t*-butyl groups contributing to T_1 at the high temperature range in phase II is sufficiently fast to allow the narrowing limit $\omega\tau_f \ll 1$, where τ_f is the correlation time for this motion, T_1 can be expressed by modifying the Eq. 8 as

$$T_1^{-1} = C_s f(\tau_s) + 5C_f\tau_f. \quad (9)$$

Here, τ_s, C_s, and C_f are the correlation time for the motion yielding the T_1 minimum, the motional constant for this motion, and that for the fast motion, respectively. Assuming an Arrhenius relationship, like that given by Eq. 4, for the two motions, we calculated the motional parameters for (*t*-BAd_3)ClO_4 listed in Table 2 by fitting Eqs. 4 and 9 to the observed T_1 data. It is interesting to note that at T_{tr}(III→II) the cations considered to be equivalent in phase III become nonequivalent and that the C_3' reorientation of half the *t*-butyl groups is slowed down while the other half is accelerated. Further, the cations in phase II seem to be disordered statically rather than dynamically. Even if the cations are dynamically disordered, the jumping rate between the disordered sites of the cations is much slower than the ^1H NMR frequency.

The T_1 minimum of (*t*-BA)ClO_4 can be assigned to the reorientation of one of the two kinds of *t*-butyl groups in accordance with the results regarding its partially deuterated analogs. T_1 in the high-temperature side of the T_1 maximum observed at 32 MHz is attributable to the reorientations of the other *t*-butyl group and the NH_3^+ group. Parameters for these motions were obtained by a fitting calculation using an equation such as that given by Eq. 9.

High-Temperature Phase (I). At T_{tr}(II→I), T_1 of all salts increased discontinuously. Since no marked change in M_2 was observed around this temperature, the discontinuous increase of T_1 is ascribable to sudden decreases in the correlation times of the NH_3^+ and *t*-butyl groups. In phase I of (*t*-BA)ClO_4 and (*t*-BAd_3)ClO_4, the *t*-butyl motion is considered to be a dominant relaxation process. The activation energies for this motion in both salts were estimated as 17.3 kJ mol^{-1} from the slope of the $\ln T_1$ *vs.* T^{-1} curves. This value is quite small as compared with that in *t*-BA halides, indicating that the cation is loosely packed in this phase.

T_1 of (*t*-Bd_9A)ClO_4 in phase I is very long and decreases with increasing temperature. This implies that the motion of the NH_3^+ group is too fast to have any discernible influence on T_1, and that another relaxation process is dominant in this region. Since no marked frequency dependence of T_1 was observed, one of the possible processes is a spin-rotation interaction[24,27-29] due to rapid rotation of the NH_3^+ group.

It is somewhat surprising that the onset of the isotropic rotation of the cation is hindered even in the highest-temperature phase, although the *t*-BA^+ cations packed with globular ClO_4^- anions are expected to be easily rotatable due to their sphere-like shape. In the highest-temperature phase of (*t*-BA)NO_3 crystals involving non-spherical anions, on the contrary, the cations are revealed to perform isotropic rotation and translational self-diffusion.[13]

23) This activation energy for the NH_3^+ reorientation evaluated from the T_1 data of (*t*-BA)I and (*t*-BAd_3)I by Ratcliffe and Dunell[10] is considered to be underestimated because it is difficult to evaluate accurately the activation energy from overlapped T_1 minima due to the *t*-butyl and NH_3^+ reorientations as tried by these authors. A discussion about this was made in our previous paper[12] where the E_a values for the NH_3^+ group in *t*-butylammonium chloride and bromide were determined directly from the T_1 data of (*t*-Bd_9A)Cl and (*t*-Bd_9A)Br.

ENDOR and TRIPLE Studies of Diphenyl Nitroxide (DPNO)

Jun YAMAUCHI,* Hideo FUJITA, and Yasuo DEGUCHI
College of Liberal Arts and Sciences, Kyoto University, Kyoto 606
(Received July 8, 1991)

ENDOR and triple resonance (GTR) of diphenyl nitroxide (DPNO) were observed in solution; it was demonstrated that DPNO is an interesting model radical forming a three-spin system (electron and ^{1}H- and ^{14}N-nuclear spins). The detected ^{14}N-ENDOR belongs to one of the smallest hyperfine cases (A_N=0.9653 mT). Its optimum temperature was 210 K, higher than that of the ^{1}H, which is due to the large anisotropic hyperfine interaction of ^{14}N. In the ^{1}H-ENDOR spectra the effect of cross relaxation was observed, as in the case of the ^{14}N-ENDOR lines; their temperature variations of intensity showed two maximum regions, one due to the optimum energy relaxation in the ^{14}N-spin system and the other due to the energy relaxation inherent in the ^{1}H-spin system. In the triple studies new phenomena were pointed out: An enhancement saturation effect due to the large hyperfine interaction and an intensified enhancement or de-enhancement effect due to the cross relaxation.

In investigations of electron spin resonance (ESR) spectroscopy and its applications to chemistry, diphenyl nitroxide (DPNO) has been used as a model radical for a few decades. The reason may be that DPNO is not only facile in handling, but also it can afford an interesting spin system consisting of an electron spin and two nuclear spins, ^{1}H and ^{14}N. ESR experiments of DPNO were first performed using single crystals, and some variations of exchange narrowed lines were measured by changing the magnitude of magnetic dilution in crystals.[1] Then, well-resolved ^{1}H-hyperfine spectra were observed in order to calculate the linewidth of each hyperfine line.[2] It was also reported that dissolved oxygen in solvents plays a remarkable negative role in diminishing the ^{1}H-hyperfine lines.[3] Some of the present authors et al. have investigated the repulsion scheme between the two ortho-protons of DPNO and the effect of methyl substitution on the ortho-positions of DPNO.[4]

In an electron-nuclear double-resonance (ENDOR) study, on the other hand, DPNO and its methyl derivatives have been investigated in detail from the point of view of steric hindrance.[5] An extension of ENDOR to a general triple resonance (GTR) for DPNO has been attempted in order to assure a negative spin density on the carbon atoms at the meta-positions of DPNO, demonstrating the typical GTR behavior in the spectral intensity change.[6] In these double- and triple-resonance investigations, no ^{14}N signals or a responce have been observed, in spite of the largest hyperfine coupling constant (A_N=0.965 mT) in this system.

Some nitroxide radicals have been investigated extensively with regard to ^{14}N-ENDOR detections.[7] The first observation was accomplished by Leniart et al. for some alicyclic nitroxide radicals.[8] We recently reported on ^{1}H- and ^{14}N-ENDOR studies of *t*-butylphenyl nitroxide (BPNO).[9] In these investigations, the characteristic features in ^{14}N-ENDOR were pointed out, such as cross relaxations in the ^{14}N-ENDOR and the influence of the ^{14}N-spin quantum number on the ^{1}H-ENDOR patterns. In this report we focus attention on ^{14}N-ENDOR observations of DPNO, the temperature dependences of the ^{14}N- and ^{1}H-ENDOR lines, and the ^{1}H-GTR characteristics of the radio-frequency power variations; we discuss especially how the ^{1}H-ENDOR and GTR are influenced by the ^{14}N-spin system. Success involving the ^{14}N-ENDOR detection would again shed light on DPNO as an interesting model sample in both double- and triple-resonance spectroscopies, in which three interacting spins (the electron spin and ^{1}H- and ^{14}N-nuclear spins) play an important role in the energy relaxations.

Experimental

Samples were synthesized as described in a previous paper.[4] For the ENDOR measurements, freshly prepared DPNO gave satisfactory results. Therefore, we used the following procedure. The synthesized DPNO was diluted magnetically in a diamagnetic matrix of benzophenone; this solid solution was kept in a refrigerator. Just before sampling for the measurements, pure DPNO was separated by chromatography.

A broad-band ENDOR spectrometer equipped with a TM_{110} mode cavity was used as described previously.[5] Two signal generators, i.e. HP8601A (Hewlett-Packard) and VP-8179B10 (National), were used for scanning the radio-frequency with FM modulation (6.5 kHz) and pumping the radio-frequency without FM modulation, respectively.[6] The experimental conditions of the multiple resonances are as follows: for the ^{14}N-ENDOR observed at 220 K, a microwave power of 20 mW and a radio-frequency power of 100 W were used; for the ^{1}H-GTR measured at 180 K, a microwave power of 20 mW and a scanning radio-frequency power of 80 W were used. The pumping radio-frequency power was changed between 0—100 W. Ethylbenzene or toluene was used as a solvent and the temperature was controlled by a JEOL ES-DVT2 between 160—230 K.

Results

In the ENDOR measurements, although two pairs of ^{1}H signals centered at the free-proton frequency (14.196 MHz) were usually detected within the observed temperature region, the optimum temperature was found to be

180 K (see Fig. 2 in the literature[6]).

The inner pair at 13.044 and 15.348 MHz was assigned to the meta-protons with a hyperfine coupling constant, A_{Hm}=0.082 mT. The outer one at 11.512 and 16.881 MHz is attributable to the ortho- and para-protons of A_{Ho}=A_{Hp}=0.191 mT. Hereafter, the ENDOR absorption lines are designated as **a'**, **b'**, **b**, and **a** from the low-frequency side, respectively. The temperature dependence of the signal intensities of each line between 170—230 K is plotted in Fig. 1.

For the ^{14}N-ENDOR observation the experimental conditions were carefully chosen with regard to both the microwave and radio-frequency powers, temperature, and sample concentration. The solvents were not varied except for toluene and ethylbenzene. The temperature was found to be optimum at about 210 K, rather higher than in the detection of ^{1}H-ENDOR. The lower sample concentration seemed to be better for accomplishing easy saturation and low-noise detection of the 80 Hz ESR. Figure 2 shows the ^{1}H- and ^{14}N-ENDOR spectra observed at 220 K in a toluene solution. The newly appearing one pair of signals between the ^{1}H-ENDOR lines (**a'**, **b'**, and **b'**, **b**) was assigned to the ^{14}N-ENDOR lines. Spectra (a), (b), and (c) in Fig. 2 indicate ENDOR pattern variations due to the nitrogen nuclear quantum

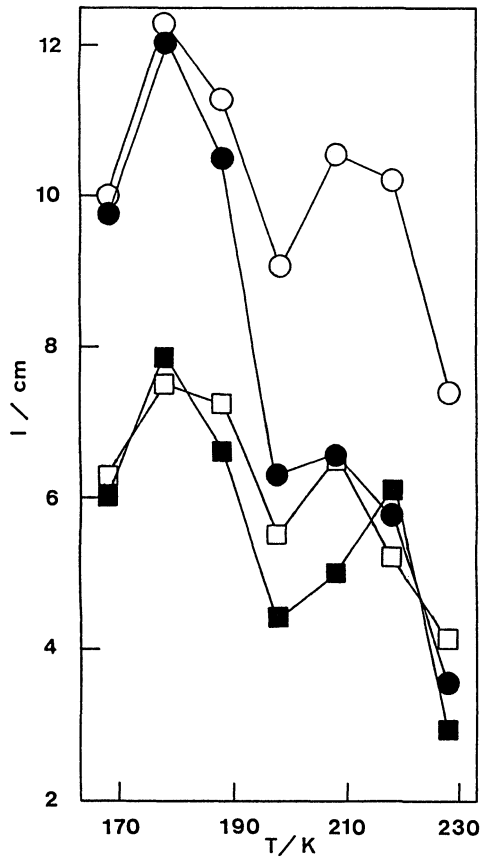

Fig. 1. Intensity variations of the ^{1}H-ENDOR lines taken as a peak-to-peak height. ○ and ● indicate the outer paired lines (**a** and **a'**), and □ and ■ the inner ones (**b** and **b'**).

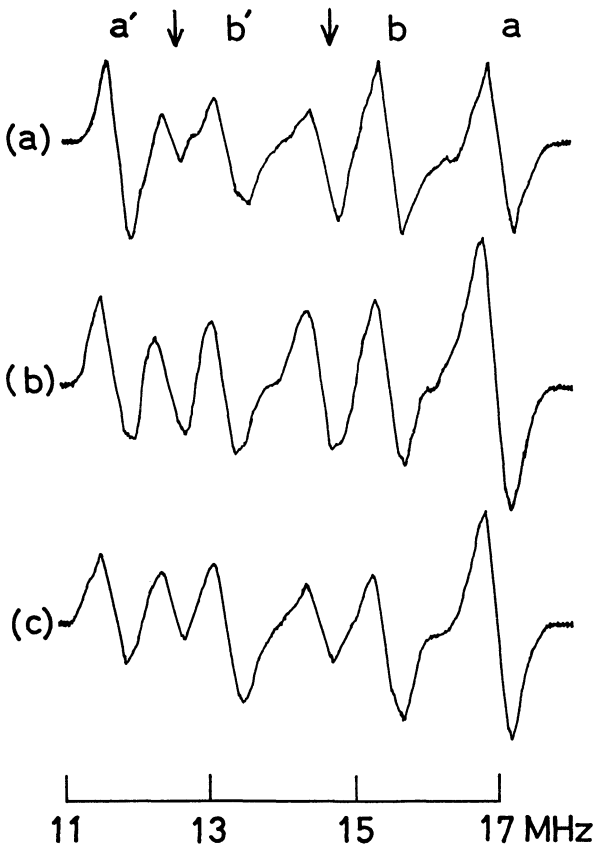

Fig. 2 ^{14}N- and ^{1}H-ENDOR spectra of DPNO observed in toluene at 220 K. The arrows indicate the ^{14}N-ENDOR lines. In these ENDOR observations ESR was monitored at the low-field ESR m_I=1 (**a**), the central ESR m_I=0 (**b**), and the high-field ESR m_I=−1 (**c**).

numbers (m_I=1, 0, and −1) where the ESR was monitored.[10] The spectral intensity change of Fig. 2-(b) vs. temperature was shown in Fig. 3.

In the GTR measurements each of the ^{1}H-ENDOR lines was pumped using the second radio-frequency power; then, the other ^{1}H-ENDOR lines were influenced regarding their absorption intensity (see Fig. 2 in the literature[6]). The intensity variations measured at 180 K are plotted against the pumping radio-frequency power in Figs. 4 and 5. The GTR behaviors were the most

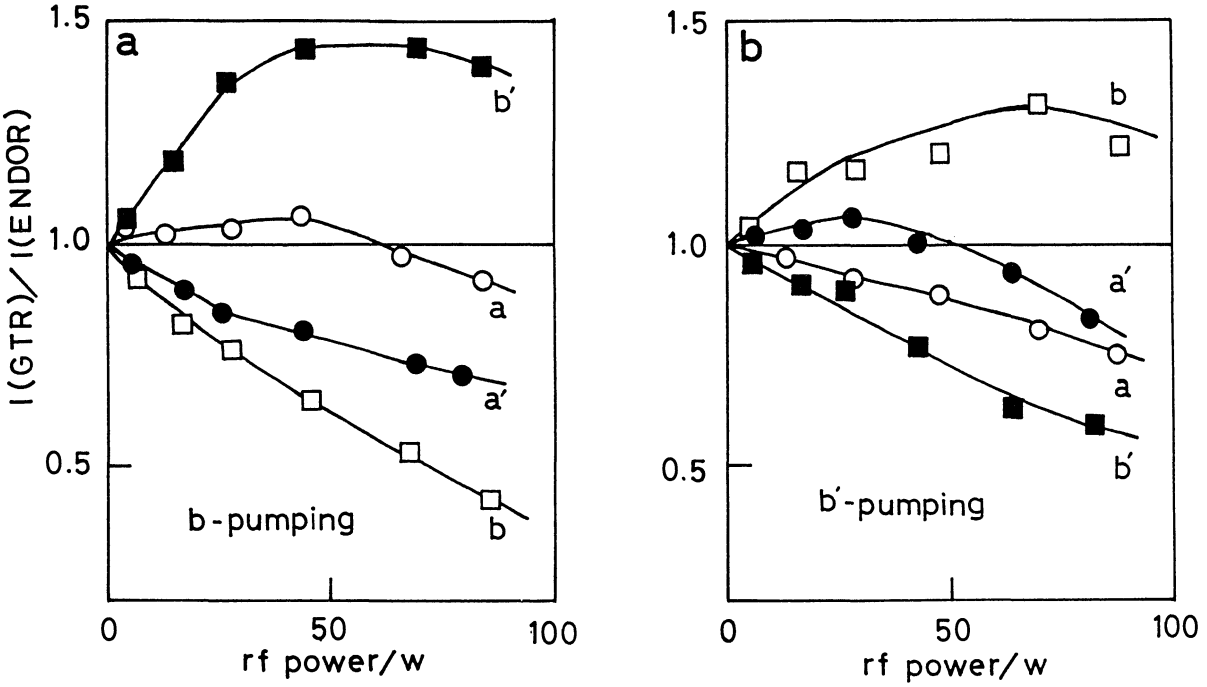

Fig. 4. Enhancement and de-enhancement of the GTR spectra with the inner paired ^{1}H-ENDOR lines (**b** and **b'**) pumped by the radio-frequency powers in the abscissa scale. ESR monitoring was set on the m_I=0 component. (See text concerning the ordinate scale.)

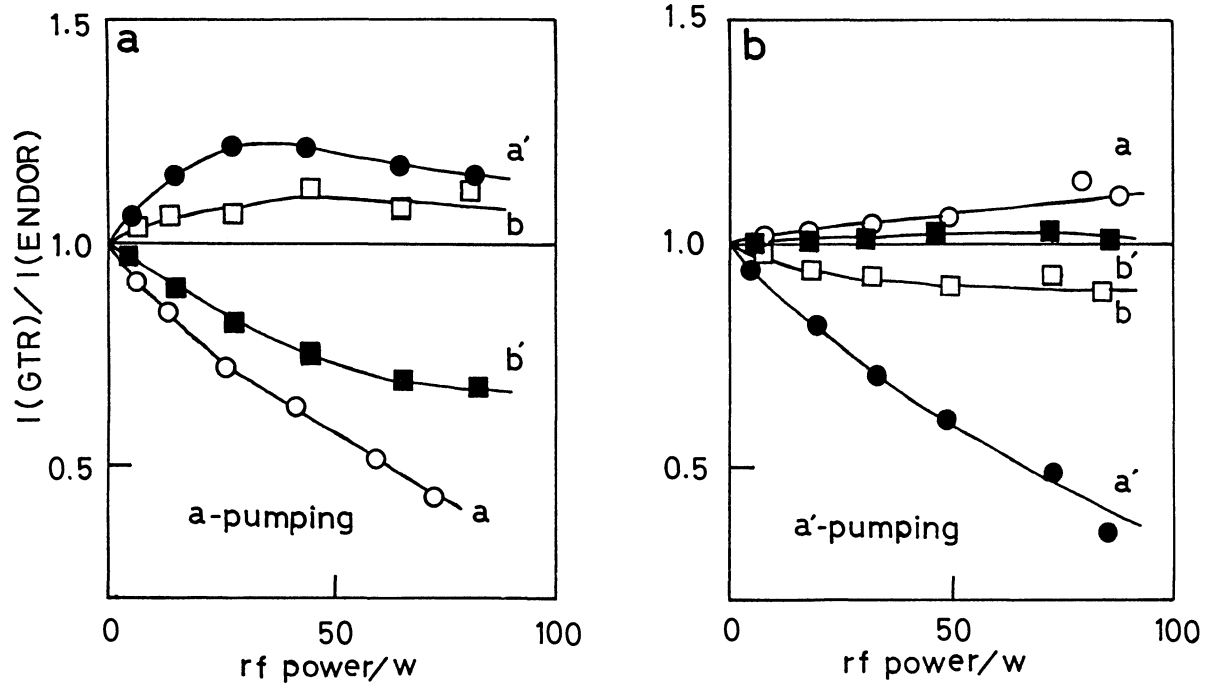

Fig. 5. Enhancement and de-enhancement of the GTR spectra with the outer paired ^{1}H-ENDOR lines (**a** and **a'**) pumped by the radio-frequency powers in the abscissa scale. ESR monitoring was set on the m_I=0 component. (See text concerning the ordinate scale.)

remarkable at the optimum temperature of the ^{1}H-ENDOR (180 K). The spectral enhancement or de-enhancement of the GTR spectra was not emphasized at the optimum temperature of the ^{14}N-ENDOR (210 K), probably due to complicated energy relaxations in the ^{14}N- and ^{1}H-nuclear spin systems, as discussed later. The data in Figs. 4 and 5 were obtained by monitoring the ESR of the m_I=0 component. If we changed the ESR observation to those of m_I=1 or −1, the intensity variations were slightly influenced, as is also discussed later.

Discussion

^{14}N-ENDOR Spectra. The newly appearing lines among the ^{1}H-ENDOR lines can be assigned to the ^{14}N-ENDOR absorptions, because of a separation of the two lines corresponding to $2\nu_N$, where ν_N is the nitrogen nuclear-magnetic-resonance frequency. Therefore, the average frequency of the paired lines is equal to the ^{14}N hyperfine coupling constant, A_N=0.9653 mT, which is in good agreement with the value A_N=0.965 mT determined from the ESR at 188 K in toluene.

The ^{14}N hyperfine coupling constant, A_N=0.9653 mT, is among the smaller values found in ENDOR observations of nitroxide radicals. It is usually true that the lower is the hyperfine coupling constant, the more difficult it is to be detected. Our observation is presently a lower-limit case of the nitroxide radicals. There have been several ^{14}N-ENDOR observations reported for other types of radicals with a smaller ^{14}N hyperfine interaction.[11,12] The difference may be associated with energy relaxation due to an anisotropic hyperfine interaction Tr $\{A'^2\}$, which is described below.

The higher optimum temperature of the ^{14}N-ENDOR (Fig. 3) is attributable to the different anisotropic hyperfine interactions of the ^{14}N and ^{1}H nuclei. In general, the calculated ENDOR signal can be expressed by τ_R and Tr$\{A'^2\}$, based on certain assumptions, where τ_R is the rotational correlation time of the molecule and Tr$\{A'^2\}$ is the trace of the squared anisotropic part of the electron-nuclear dipolar interaction.[11] The anisotropic ^{14}N hyperfine interaction, Tr$\{A'^2\}$, for nitroxide radicals, such as DPNO, is Tr$\{A'^2\}$=2200 MHz^2; whereas that of the ^{1}H, which is attached to the benzene ring, is about 30 MHz^2.[1,13] This difference explains the higher optimum temperature of the ^{14}N-ENDOR.

The ^{14}N-ENDOR lines indicated by the arrows in Fig. 2 show the spectral intensity change depending on ESR monitoring. This phenomenon was first pointed out by Leniart et al.,[8] and could be explained in terms of cross relaxation W_{X1} and W_{X2} depicted in Fig. 6. For instance, when one is sitting on the higher or lower field component of the ESR (m_I=−1 or +1) in the ENDOR observations, the energy relaxation is governed by the W_{X1}, W_{X2}, ω_{n1}, and ω_{n2} transitions associated with the central components of the energy levels. Accordingly, the high- and low-frequency ENDOR absorptions

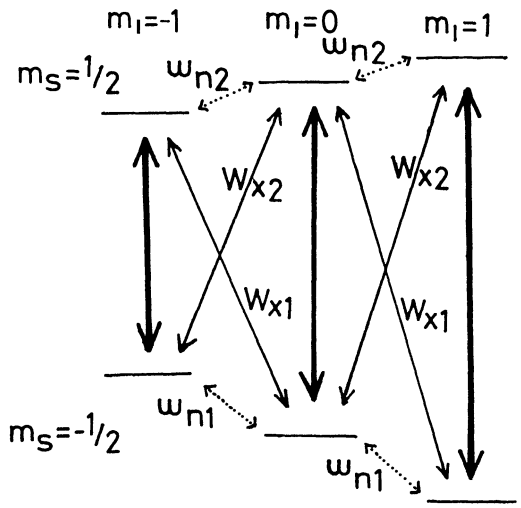

Fig. 6. Energy diagram of the unpaired electron (m_S=1/2, −1/2) and the ^{14}N nucleus (m_I=1, 0, −1). The cross relaxations W_{X1} and W_{X2} relate the transitions $\Delta(m_S+m_I)=0$ and $\Delta(m_S+m_I)=\pm2$, respectively. The high- and low-frequency ENDOR absorptions correspond to ω_{n1} and ω_{n2}, respectively. This diagram is depicted for the case of a positive hyperfine interaction $A_N>0$.

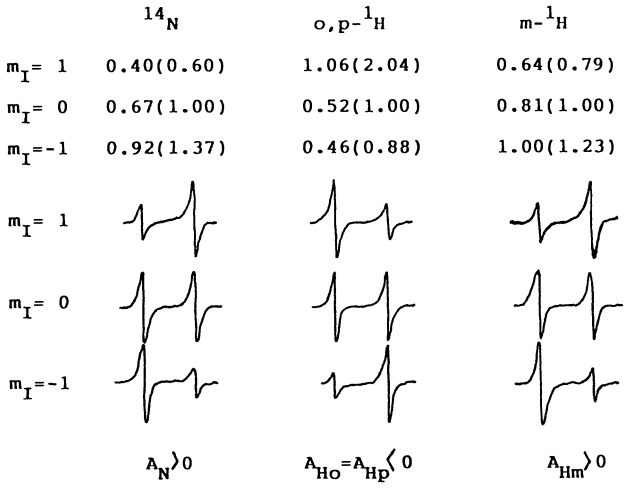

Fig. 7. Intensity ratio and its variations of each paired line for the ESR monitoring on m_I=1, 0, and −1. The schematic paired lines are depicted on the basis of the normalized intensity ratios (values in the parentheses). The meta-protons behave like the ^{14}N, whereas the ortho- and para-protons behave in an opposite way, leading to $A_{Hm}>0$ and $A_{Ho}=A_{Hp}<0$.

(ω_{n1} and ω_{n2}, respectively) show different spectral intensities due to the different W_{X1} and W_{X2} values. On the other hand, the central energy levels, which belong to m_I=0 component, can dissipate their energy to both sides. As a result, the high- and low-frequency ENDOR lines are averaged in intensity. The ^{14}N-ENDOR intensity changes with the m_I values are tabulated in Fig. 7. The values indicate the intensity ratio between the low- and high-frequency components; those

in the parentheses were normalized ones by the intensity ratio of $m_I=0$. The intensity patterns shown schematically in Fig. 7 indicate a positive hyperfine coupling constant of the ^{14}N nucleus, as is supposed in Fig. 6. Interestingly, these ^{14}N-cross relaxations also influence the ^1H-energy relaxation, as is summarized in Fig. 7. This is discussed next.

^1H-ENDOR Spectra. The ^1H-ENDOR lines are rather broad at 220 K, but the intensity changes with the m_I values are clear (Fig. 7). This effect was first pointed out by Janzen et al.[14] and independently by us,[15] and is referred to CRISP (cross relaxation intensity sequence pattern). The spectral intensity changes are opposite for the ortho- or para-protons and the meta-protons. This means the opposite signs of the hyperfine coupling constants (that is, $A_{Ho}=A_{Hp}<0$ and $A_{Hm}>0$) because the energy levels in Fig. 6 are reversed, depending on the signs of the hyperfine coupling constants. We can therefore conclude a negative spin density at the meta-positions of the phenyl rings, which agrees with the conclusion derived from the GTR results. The strong and weak intensity sequence patterns become important regarding the GTR behaviors on the spectral enhancement or de-enhancement.

The influence of the ^{14}N-energy relaxation on the ^1H-nuclear system was also ascertained by the temperature dependences of the ^1H-ENDOR lines. Figure 1 shows the intensities of the ^1H lines of the ENDOR spectra ($m_I=0$) at various temperatures. There are two characteristic features. One is the fact that there are two maximum regions; the other is the good coincidence of the intensity of each paired line at the lowest temperature region. Comparing these results with those of the ^{14}N-ENDOR lines (Fig. 3), one can easily conclude that the first maximum region around 210 K is somewhat related to the optimum temperature of the ^{14}N-ENDOR lines. This means that the effective energy relaxation in the ^{14}N-spin system at this temperature might cause a sufficient energy relaxation in the ^1H-spin system. As a matter of fact, the optimum conditions inherent in the ^1H-spin system are fulfilled at the lower temperatures, exhibiting a second maximum at 180 K. This finding implies the existence of a coupling between the ^{14}N and ^1H nuclei through the electron spin or through a direct interaction.[16] The meaningful effect of the nuclear–nuclear coupling was first pointed out concerning this ENDOR intensity. In addition to the CRISP effect, this is another interesting point regarding a three-spin system comprising one electron and two nuclear spins (^1H and ^{14}N). In the case of a three-spin system with similar nuclei (for instance, two non-equivalent protons), the energy relaxations becomes optimum at almost the same temperature regions, resulting in one maximum. The essential point in our spin system is two different nuclei (^{14}N and ^1H) which have optimum energy relaxation at different temperatures.

The second feature of Fig. 1 can also be explained by the above-mentioned interaction. At lower temperatures the ^{14}N–energy relaxation becomes ineffective and the original characteristics of the pure ^1H-spin system appear. Therefore, approaching the ^1H-optimum temperature region, the intensity of each paired line becomes the same as that shown in Fig. 1. As for this new finding, one comment is noteworthy concerning the previous experiment of BPNO.[9] The temperature dependence of the ENDOR intensities of the ^1H and ^{14}N absorptions were not analyzed in this way. The correct interpretation should be as follows. The first optimum region of the ^1H lines appeared at $-60\,^\circ C$, roughly corresponding to the maximum of the ^{14}N intensity. In BPNO, however, no second maximum, which is originally characteristic of the ^1H nuclei, was found over the observed temperature range (above $-90\,^\circ C$).

Triple Resonance Spectra. Figures 4 and 5 show the intensity variations of the GTR spectra by the pumping radio-frequency power. The spectral enhancement was defined by $I(\mathrm{GTR})/I(\mathrm{ENDOR})$, where $I(\mathrm{GTR})$ and $I(\mathrm{ENDOR})$ are the spectral intensity taken as absorption height with and without the pumping radio-frequency power, respectively. According to the results given in Figs. 4 and 5, one can conclude the opposite signs for the hyperfine coupling constants of the meta- and the ortho- or para-protons, since the inner paired lines (**b′** and **b**) as well as the outer ones (**a′** and **a**) change oppositely in intensity.[17] For instance, in Fig. 4, upon pumping one of the inner pair (**b′**), an enhancement took place on the high-frequency partner (**b**); on the outer paired lines, however, the high-frequency line **a** decreased and the low-frequency one **a′** was enhanced, though its enhancement was quite small. This situation is fully inversed to the case of pumping one of the inner lines, **b**. These observations are also the same for the cases of **a** and **a′** pumping (Fig. 5).

We next consider the enhancement or de-enhancement values. The radio-frequency pumping effect is always clear for the de-enhancement case, whereas the behavior in the enhancement situation is sometimes smeared out and the intensity enhancement is cancelled in the high radio-frequency power region, which may be referred to as enhancement "saturation". Since this tendency seems to be remarkable concerning the outer pair, one of the reasons for this enhancement saturation may be the large hyperfine coupling constant of the ortho- or para-protons, as compared with that of the meta-protons. This effect can be called a radio-frequency enhancement effect at the nucleus through a hyperfine interaction. An intensity enhancement saturation is therefore likely to occur at a relatively small radio-frequency power for nuclei with large hyperfine coupling constants.

How the GTR behavior depends on the ^{14}N-quantum number (m_I) is discussed next. The ENDOR spectral changes by the ^{14}N-quantum number is described above. The spectra were influenced like the patterns summarized in Fig. 7, that is, the intensity height of each line is either increased or decreased, depending on the ^{14}N-

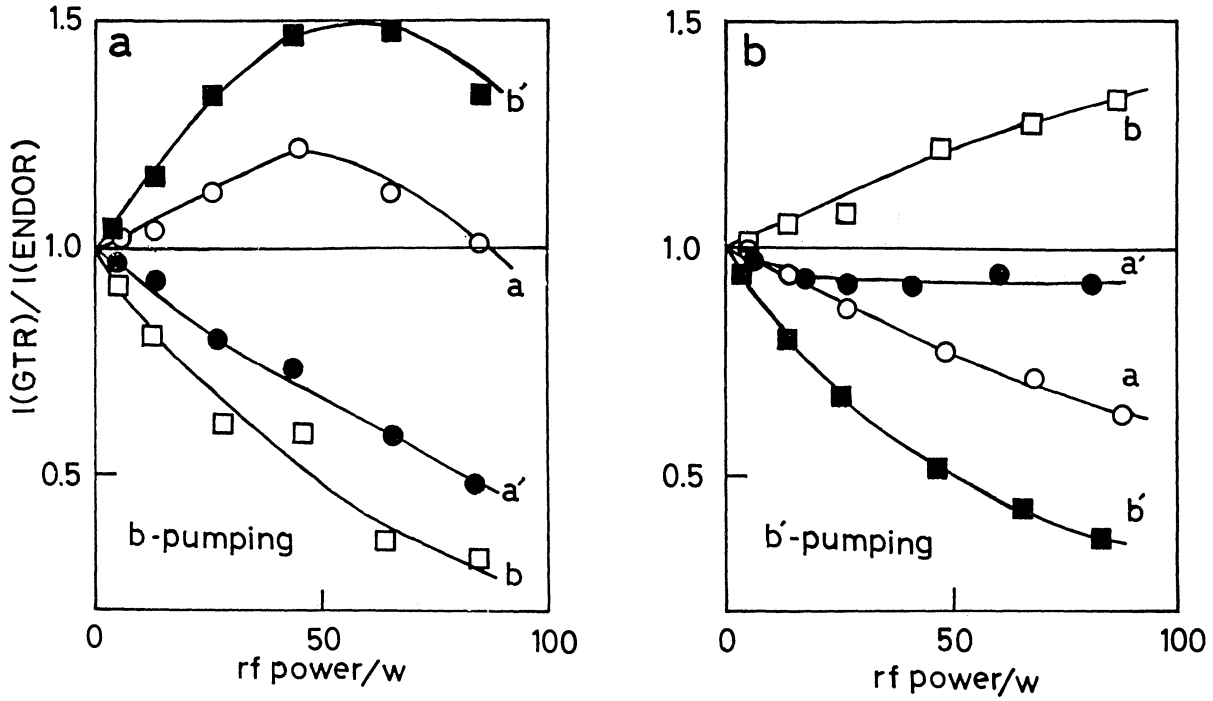

Fig. 8. Enhancement and de-enhancement of the GTR spectra with the inner paired ^{1}H-ENDOR lines (**b** and **b'**) pumped by the radio-frequency powers in the abscissa scale. ESR monitoring was set on the m_I=1 component. Compare with Fig. 4.

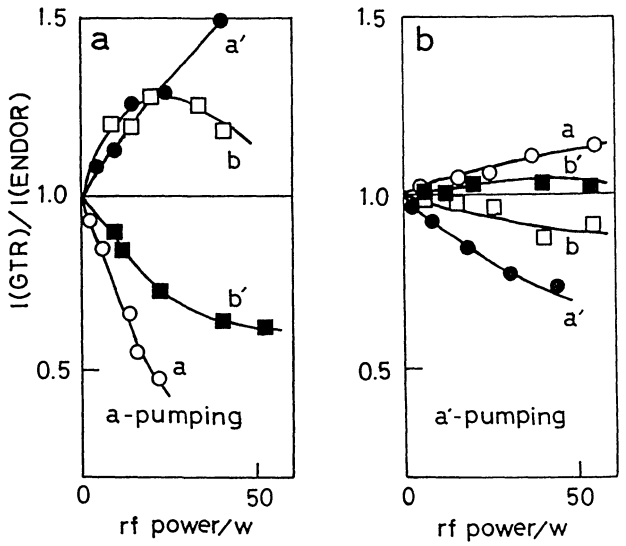

Fig. 9. Enhancement and de-enhancement of the GTR spectra with the outer paired ^{1}H-ENDOR lines (**a** and **a'**) pumped by the radio-frequency powers in the abscissa scale. ESR monitoring was set on the m_I=−1 component. Compare with Fig. 5.

quantum number (m_I) of the monitoring ESR and on the signs of the ^{1}H-hyperfine coupling constant (A_H). Regarding the GTR behavior, these cross relaxation effects should be combined, causing either more-enhanced or less-enhanced variations. This evidence is shown in Figs. 8 and 9. The experimental conditions for Fig. 8 were the same as those for Fig. 4, except for monitoring ESR. In the case of Fig. 8 the low-field ESR component (m_I=1) was monitored; line **b'** thus decreased, and line **b** increased due to the cross-relaxation effect (Fig. 7). Thus, the enhancement of the **b'** line or the de-enhancement of the b line is intensified by **b** pumping. This is the case of Fig. 8-a, which should be compared with Fig. 4-a. On the other hand, the opposite triple pumping (**b'** pumping) may give a dull behavior, like that shown in Fig. 8-b (compare with Fig. 4-b). Completely the same behaviors were also observed for high-field ESR monitoring (m_I=−1). As is hown in Fig. 9-a, enhancement of the **a'** line and the de-enhancement of the **a** line are intensified in the case of the **a** line pumping, because the line **a'** is already decreased and the line **a** increased by the cross relaxation (compare with Fig. 5-a). Fig 9-b should also be compared with Fig. 5-b. These findings belong to another type of three-spin effect in triple resonance spectroscopy.

In conclusion, by observing the ^{14}N- and ^{1}H-ENDOR spectra of DPNO, several interesting types of behavior were disclosed in ENDOR and GTR spectroscopies. The ^{14}N-hyperfine coupling constant detected by this ENDOR experiment is one of the smallest limits for the nitroxide radicals. The paired ^{14}N-ENDOR lines are distorted in intensity by cross relaxation in the ^{14}N nucleus and the unpaired electron. This effect is also present regarding the ^{1}H-ENDOR intensities. The double optimum temperatures for the ^{1}H-ENDOR lines were demonstrated, the higher one being due to the optimum energy relaxation of the ^{14}N nuclei and the

lower one due to that of the ^{1}H-spin system. These phenomena interelating two nuclei are interesting subjects concerning three-spin systems. In GTR experiments the intensity changes due to the radio-frequency-pumping power were analyzed in terms of the opposite signs of the hyperfine coupling constants, the enhancement saturation effect, and the effect of the cross relaxation. The latter two observations are pointed out here as a new interesting point concerning a three-spin system.

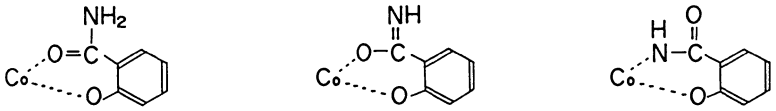
(Received March 7, 1991)

Title complexes of *t*- and *p*-[Co(**A**)(tren)]$Cl_2 \cdot H_2O$, *t*- and *p*-[Co(**C**)(tren)]$Cl \cdot H_2O$, *cis*-β_1 and β_2-[Co(**A**)(trien)]-$Cl_2 \cdot 2H_2O$, *cis*-β_1-[Co(**C**)(trien)]$Cl \cdot H_2O$, *cis*-β_1-[Co(**D**)(trien)]$Cl \cdot H_2O$, [Co(**A**)$(en)_2$]$Cl_2 \cdot H_2O$, [Co(**C**)$(en)_2$]$Cl \cdot H_2O$, and [Co(**D**)$(en)_2$]$Cl \cdot H_2O$ have been obtained from a reaction mixture of [$CoCl_2$L]$Cl \cdot H_2O$ [L: tren, trien, or $(en)_2$], Ag_2O, and salicylamide.



(A) (C) (D)

Separations of the **A**-, **C**-, and **D**-type complexes, and of the geometrical isomers of *t*- and *p*- or *cis*-β_1 and β_2 were attempted by using Dowex 50W-X2 column chromatography. Distinction of the **A**-, **C**-, and **D**-type complexes is described in the IR, ^1H, ^{13}C NMR, and absorption spectra; the solubility in DMSO; and the electric conductivities in aqueous solutions. The formation ratio of the **A**-, **C**-, and **D**-type complexes has been dependent upon the pH of the reaction mixture. The chemical shifts (δ=113—115) of the C-1 carbon signals for the **A**-type complexes are at a higher field than those (δ=117—122) of the **C**- and **D**-type complexes. The ε values (3400—3700) of the charge transfer band at ca. 340 nm in the absorption spectra for the **A**-type complexes are greater than those (2500—3000) of the **C**- and **D**-type complexes. The **C**-type and **D**-type complexes are a linkage isomer. A characteristic property of the linkage isomer has been observed in the absorption and ^{13}C NMR spectra as well as the solubility in DMSO.

We previously described the preparation, properties, and geometrical isomers of mixed-ligand (8-quinolinolato)-,[2-4] (salicylato)-,[5-7] (thiosalicylato)-,[8] or (salicylaldehydato)cobalt(III)[9,10] complexes with ethylenediamine (en), tris(2-aminoethyl)amine (tren), triethylenetetramine (trien), 3,7-diazanonane-1,9-diamine (2,3,2-tet), 4,7-diazadecane-1,10-diamine (3,2,3-tet), and 4,8-diazaundecane-1,11-diamine (3,3,3-tet) ligands. However, the preparation and properties of the mixed-ligand amine(salicylamidato)cobalt(III) complexes have not been of concern.

Salicylamide (*o*-hydroxybenzamide) is a very useful ligand in the field of coordination chemistry, since the $-CONH_2$ group of salicylamide can coordinate to a metal atom through the carbonyl oxygen (**A**-type) or the amide nitrogen (**B**-type), as is shown in Fig. 1. So far, bis- and tris(salicylamidato)metal complexes[11-13] of the **A**-type, $[M(A)_m]^{n+}$ [M: Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), or Hg(II); *m*: 2 or 3], have been reported concerning preparation, magnetic moments, IR spectra, and X-ray diffraction. However, the corresponding **B**-type complexes could not be prepared.

We recently succeeded in preparing the tetraamine(salicylamidato)cobalt(III) complex,[1] [Co(**D**)-$(NH_3)_4$]$Cl \cdot H_2O$, of the **D**-type, which is a bond between a cobalt atom and an imide nitrogen from a reaction mixture of $CoCl_2 \cdot 6H_2O$, aqueous ammonia, H_2O_2, and salicylamide. However, the **A**-, **B**-, and **C**-type complexes could not be obtained. Now, however, complexes of the **A**-, **C**-, and **D**-types have been prepared in this study. Thus, the present paper deals with the preparation and properties of the mixed-ligand amine-(salicylamidato)cobalt(III) complexes of [Co(**A**)L]$Cl_2 \cdot$

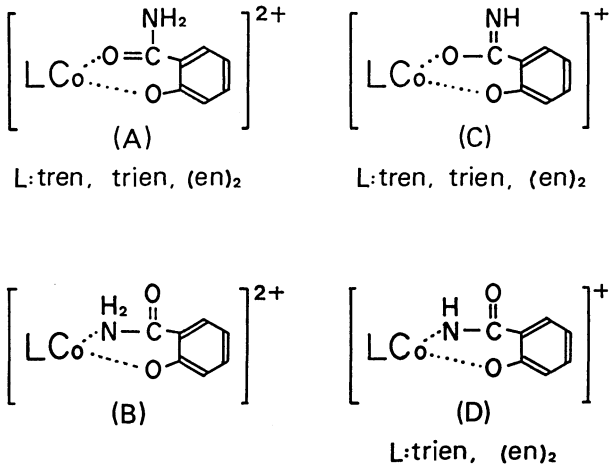


Fig. 1. Configurations of the **A**—**D**-type complexes of amine(salicylamidato)cobalt(III) complexes.

nH$_2$O [L: tren, trien, or (en)$_2$], [Co(**C**)L]Cl·H$_2$O [L: tren, trien, or (en)$_2$], and [Co(**D**)L]Cl·H$_2$O [L: trien or (en)$_2$].

Experimental

Measurements. The electric conductivities were determined by the use of a CM-40S conductivity meter (TOA) in aqueous solutions at room temperature. The IR spectra were recorded in KBr disks with a 270-30 spectrophotometer (Hitachi). The visible absorption spectra were recorded in water with a Shimadzu UV-210 recording spectrophotometer. The ^{1}H and ^{13}C NMR spectra were recorded with a JNM-FX90Q FT NMR spectrometer (JEOL). The melting points were measured on an MP-500D apparatus (Yanako).

Preparation of Complexes. *t*-(Salicylamidato-*O,O*)[tris(2-aminoethyl)amine]cobalt(III) Dichloride Hydrate (1), *p*-(Salicylamidato-*O,O*)[tris(2-aminoethyl)amine]cobalt(III) Dichloride Hydrate (2), *t*-(Salicylamidato-*O,O*)[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (3), and *p*-(Salicylamidato-*O,O*)[tris(2-aminoethyl)amine]cobalt(III) Chloride Hydrate (4): [CoCl$_2$tren]Cl·H$_2$O (10.0 g, 30.3 mmol) was added to moistend fresh Ag$_2$O, which was made from silver nitrate (10.3 g, 60.6 mmol) and potassium hydroxide (3.4 g, 60.6 mmol). The mixture was stirred for several minutes at room temperature; then, 10 cm^3 of water was added to the mixture. The mixture was stirred for about 30 min at 60 °C, and the precipitated silver chloride was filtered off and washed with a small amount of water. A methanol solution (60 cm^3) of salicylamide (4.15 g, 30.3 mmol) was added, drop by drop, to the reddish-violet filtrate (pH 8.6). The solution was stirred for 12 h at 58 °C and was then concentrated on a rotary evaporator, and salicylamide (ca. 0.6 g) precipitated was filtered. The separation of complexes **1**—**4** was achieved by using a column (ϕ 2.5 cm×40 cm) of ion-exchange resin (Dowex 50W-X2, 100—200 mesh). Upon elution with 0.3 mol dm^{-3} NaCl, the effluents of the first reddish-brown band (complex **3**) and second red band (complex **4**) were collected and concentrated, respectively. Then, the third red band (complex **1**) and fourth red band (complex **2**) were eluted with 0.8 mol dm^{-3} NaCl and concentrated, respectively. Complexes **1**—**4** were recrystallized from water–ethanol–ether. Yields: 2.6 g (19.9%) for **1**, 3.8 g (29.2%) for **2**, 0.53 g (4.4%) for **3**, 0.38 g (3.2%) for **4**. Found **1**: C, 36.35; H, 6.11; N, 16.44; Cl, 16.59%. **2**: C, 36.55; H, 6.27; N, 16.31; Cl, 16.70%. Calcd for $CoC_{13}H_{26}N_5O_3Cl_2$ (MW 430.22): C, 36.29; H, 6.09; N, 16.28; Cl, 16.48%. N(1)H_2), 4.5—5.2 (2H, N(4)H_2); 6.22 (2H, N(2)H and N(3)H); 6.7—7.8 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.15—3.28 (12H, CH_2); 3.84 (1H), 5.11 (2H), 5.51 (1H), each NH_2; 6.95, 8.20 (each 1H, NH); 6.4—7.9 (4H, salicylamidato); 8.89, 8.96 (each 1H, -$CONH_2$) in DMSO-d_6. **6**: δ=2.38—2.78 (3H, NH_2- side CH_2), 2.78—3.65 (9H, NH_2- and NH- side CH_2); 4.30 (3H, N(1)H_2 and N(4)H_2), 5.01 (1H, N(4)H_2), 5.95 (N(2)H), 6.30 (N(3)H); 6.6—7.7 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.10—2.60 (3H), 2.60—3.27 (9H), each CH_2; 3.95, 4.69, 5.37, 5.85 (each 1H, NH_2), 7.00, 8.23 (each 1H, NH); 6.4—7.9 (4H, salicylamidato); 8.68, 8.95 (each 1H, -$CONH_2$) in DMSO-d_6. **7**: δ=2.30—3.60 (12H, NH_2- and NH- side CH_2); 4.70 (4H, N(1)H_2 and N(4)H_2), 5.90 (2H, N(2)H and N(3)H); 6.6—7.9 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.10—3.25 (12H, CH_2); 3.7—4.3 (2H), 4.5—5.2 (2H), each NH_2; 5.52, 6.10 (each 1H, NH); 6.2—7.9 (4H, salicylamidato) in DMSO-d_6. **9**: δ=2.32—3.64 (12H, NH_2- and NH- side CH_2); 3.64—4.49 (4H, N(1)H_2, N(4)H_2, and -CONH), 4.65 (1H, N(4)H_2), 5.76 (N(2)H), 6.18 (N(3)H); 6.6—7.9 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ= 1.90—3.25 (13H, CH_2 and NH_2), 4.22 (1H), 4.53 (2H), each NH_2; 4.89 (1H, -CONH); 5.43, 7.61 (each 1H, NH); 6.2—7.9 (4H, salicylamidato) in DMSO-d_6. ^{13}C NMR (D_2O) **5**: δ= 42.7, 47.8 (each NH_2- side CH_2), 48.4, 49.9, 51.9, 53.0 (each NH- side CH_2); δ=115.0 (C-1), 167.3 (C-2), 117.9 (C-3), 136.3 (C-4), 125.0 (C-5), 129.8 (C-6), 173.3 (C-7). **6**: δ=42.3, 47.5 (each NH_2- side CH_2); δ=48.6, 50.0, 52.3, 52.7 (each NH- side CH_2); δ=114.2 (C-1), 167.4 (C-2), 117.6 (C-3), 136.1 (C-4), 125.4 (C-5), 129.6 (C-6), 173.0 (C-7). **7**: δ=41.4, 47.0 (each NH_2- side CH_2), 48.9, 50.0, 52.4, 53.0 (each NH- side CH_2); δ=117.3 (C-1), 165.9 (C-2), 117.6 (C-3), 133.5 (C-4), 123.6 (C-5), 130.7 (C-6), 172.9 (C-7). **9**: δ=41.4, 48.0 (each NH_2- side CH_2), 48.3, 49.3, 52.8, 53.6 (each NH- side CH_2); δ=121.5 (C-1), 166.7 (C-2), 117.0 (C-3), 133.3 (C-4), 123.7 (C-5), 130.5 (C-6), 172.5 (C-7). Mp: 217 for **5**, 225 for **6**, 230 for **7**, 244 °C for **9**.

Bis(ethylenediamine)(salicylamidato-*O,O*)cobalt(III) Dichloride Hydrate (10), Bis(ethylenediamine)(salicylamidato-*O,O*)cobalt(III) Chloride Hydrate (11), and Bis(ethylenediamine)(salicylamidato-*N,O*)cobalt(III) Chloride Hydrate (12): A mixture of complexes **10**—**12** was prepared from the reaction mixture (pH 8.6) of $[CoCl_2(en)_2]Cl$ (10.0 g, 35.0 mmol), fresh Ag_2O (8.11 g, 35.0 mmol), and salicylamide (4.8 g, 35.0 mmol) according to the procedure for complexes **1**—**4**. The separation of complexes **10**—**12** was achieved by a column (φ 2.5 cm×20 cm) of ion-exchange resin (Dowex 50W-X2, 100—200 mesh). Upon elution with 0.2 mol dm^{-3} NaCl, the effluent of the first red band (mixture of **11** and **12**) was collected and concentrated. Then, the second red band (**10**) was eluted with 0.8 mol dm^{-3} NaCl. The effluent of **10** was collected and concentrated. The separation of **11** and **12** was achieved by a column (φ 2.5 cm×40 cm) of ion-exchange resin (Dowex 50W-X2, 200—400 mesh). Upon elution with 0.1 mol dm^{-3} NaCl, the effluents of the lower (**11**) and upper (**12**) layers of the red band were collected and concentrated, respectively. Complexes **10**—**12** were recrystallized from water-ethanol-ether. Yields: 5.31 g (37.5%) for **10**, 0.6 g (4.7%) for **11**, 0.3 g (2.3%) for **12**. Found **10**: C, 32.72; H, 5.88; N, 17.19; Cl, 17.78%. Calcd for $CoC_{11}H_{24}N_5O_3Cl_2$ (MW 404.18): C, 32.69; H, 5.99; N, 17.33; Cl, 17.54%. Found **11**: C, 36.19; H, 6.52; N, 19.18; Cl, 9.78%. **12**: C, 36.04; H, 6.22; N, 18.98; Cl, 9.87%. Calcd for $CoC_{11}H_{23}N_5O_3Cl$ (MW 367.72): C, 35.93; N, 6.30; N, 19.05; Cl, 9.64%. ^{1}H NMR **10**: δ=2.76, 2.84 (each 4H, CH_2); 4.17 (2H), 4.30—4.75 (3H), 4.95 (1H), 5.16 (2H), each NH_2; 6.7—7.7 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.3—2.8 (8H, CH_2); 4.21 (1H), 4.42 (1H), 5.00 (1H), 5.25 (1H), 5.45—6.20 (4H), each NH_2; 6.4—7.9 (4H, salicylamidato); 8.58, 8.80 (each 1H, -$CONH_2$) in DMSO-d_6. **11**: δ=2.85 (8H, CH_2); 4.26 (2H), 4.50 (2H), 4.96 (1H), 5.27 (3H), each NH_2; 6.4—7.9 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.3—2.8 (8H, CH_2); 4.06 (2H), 4.63 (2H), 5.44 (4H), each NH_2; 6.2—7.9 (4H, salicylamidato) in DMSO-d_6. **12**: δ=2.75 (8H, CH_2); 3.93 (1H, -CONH); 4.28 (3H), 4.64 (5H), each NH_2; 6.6—7.9 (4H, salicylamidato) in 1.8 mol dm^{-3} D_2SO_4. δ=2.3—2.8 (8H, CH_2); 3.5—5.0 (7H, NH_2 and -CONH), 5.30 (2H, NH_2); 6.2—7.9 (4H, salicylamidato) in DMSO-d_6. ^{13}C NMR (D_2O) **10**: δ=43.7, 44.1, 45.6, 45.9 (each CH_2); δ=113.9 (C-1), 167.0 (C-2), 117.7 (C-3), 136.1 (C-4), 125.1 (C-5), 129.8 (C-6), 173.1 (C-7). **11**: δ=43.9, 43.9, 45.6, 45.7 (each CH_2); δ=118.1 (C-1), 167.7 (C-2), 117.2 (C-3), 134.5 (C-4), 124.0 (C-5), 132.6 (C-6), 174.2 (C-7). **12**: δ=44.8, 45.1 , 45.2, 45.4 (each CH_2); δ=120.7 (C-1), 166.4 (C-2), 117.0 (C-3), 133.2 (C-4), 123.6 (C-5), 130.6 (C-6), 172.5 (C-7). Mp: 218 for **10**, 245 for **11**, 256 °C for **12**.

Preparation of Complex 3 from 1 and of 4 from 2: Complex **1** (0.3 g, 6.97 mmol) was added to ammonia solution (6 cm^3, pH 10), and the mixture was stirred for 13 h at 62 °C. The solution was concentrated on a rotary evaporator. The purification of **3** was achieved by column chromatography on alumina. Complex **4** was also obtained from the mixture of **2** and ammonia solution. Yields: 0.22 g (80.1%) for **3**, 0.20 g (72.8%) for **4**.

Preparation of Complex 7 from 5 or 6: Complex **5** (1.0 g, 2.23 mmol) was added to an ammonia solution (15 cm^3, pH 10); the mixture was then stirred for 3 h at 62 °C, and concentrated on a rotary evaporator. The precipitated complex **7** was filtered. Yield: 0.64 g (72.9%).

Complex **6** (1.0 g, 2.23 mmol) was added to an ammonia solution (15 cm^3, pH 10); the mixture was then stirred for 12 h at 62 °C, concentrated, and the precipitated complex filtered. This complex was a mixture of complexes **7** and **8**. Complex **8** in the mixture became **7** after 5 h at 62 °C in solution, since **8** isomerizes to **7**. Yield: 0.56 g (63.7%).

Preparation of Complex 11 from 10: Complex **10** (1.0 g, 2.47 mmol) was added to an ammonia solution (15 cm^3, pH 10); the mixture was stirred for 13 h at 62 °C, and then concentrated on a rotary evaporator. The purification of **11** was achieved by column chromatography on alumina. Yield: 0.56 g (61.6%).

Solubility. All complexes were very soluble in water and soluble in methanol. For dimethyl sulfoxide (DMSO), complexes **1**, **2**, **5**, **6**, **9**, **10**, and **12** were soluble, but complexes **3**, **4**, **7**, and **11** were very slightly soluble. All of the complexes were not soluble in common organic solvents, such as acetone and ether.

Results and Discussion

The abbreviations of the octahedral amine(salicylamidato)cobalt(III) complexes in this research are listed in Table 1.

Complexes. Complexes **1**—**12** have been obtained from a reaction mixture of $[CoCl_2(L)]Cl \cdot nH_2O$ (L: tren, trien, $(en)_2$), Ag_2O, and salicylamide. Complexes **1**—**12** were separated by Dowex 50W-X2 column chromatography. The formation ratios of **1**, **2**, **3**, and **4** are ca.

a) Solvent D$_2$O, standard dioxane (δ=67.4). b) Ref. 1.

6 : 9 : 1 : 1, respectively. The formation ratios of **5**, **6**, **7**, and **9** are ca. 5 : 6 : 3 : 1, respectively, and those of **10**, **11**, and **12** are ca. 16 : 2 : 1, respectively. The colors of **1** and **5** are russet. The colors of **2**, **4**, **7**, **10**, and **11** are red, and those of **3**, **6**, **9**, and **12** are brownish-violet, reddish-pink, reddish-violet, and reddish-brown, respectively.

The absorption spectra of all complexes were measured in water (Table 1). The absorption bands at ca. 340 nm of the complexes were assigned to the charge transfer band, while the bands at ca. 520 nm were assigned to the first absorption band[1] (Table 1). The ^{1}H NMR spectra of all complexes were measured in 1.8 mol dm^{-3} D$_2$SO$_4$ and in DMSO-d_6. The signals at δ=6.2—7.9 of the complexes were assigned to the ring protons of the coordinated salicylamidato ligand. The signals at δ=2.4—4.0 and 4.3—5.5 for **1**—**4** in 1.8 mol dm^{-3} D$_2$SO$_4$ were assigned to the methylene and amine protons of the coordinated tren ligand, respectively, by the comparisons with those of *t*- and *p*-salicylaldehydato(tren)cobalt(III) dichloride hydrate,[10] *t*-, *p*-[Co(salad)tren]Cl$_2$·H$_2$O (*t*: **13**, *p*: **14**). The methylene and amine protons of the coordinated trien ligand for **5**—**7** and **9** were assigned on the basis of those of *cis*-β_1 and β_2-salicylaldehydato(trien)cobalt(III) dichloride dihydrate,[9,10] *cis*-β_1, β_2-[Co(salad)trien]Cl$_2$·2H$_2$O (β_1: **15**, β_2: **16**). The signals at δ=2.7—2.9 and 4.1—5.3 for **10**—**12** have been assigned to methylene and amine protons of the coordinated ethylenediamine ligand, respectively. The ^{13}C NMR spectra of all complexes were measured in D$_2$O. Seven signals at δ=113—175 of the complexes were assigned to the carbons of the coordinated salicylamidato ligand by comparisons with those of tetraammine(salicylamidato)cobalt(III) chloride hydrate,[1] [Co(**D**)(NH$_3$)$_4$]Cl·H$_2$O (**17**). The signals at δ=43—45 and 60—62 for **1**—**4** were assigned to the NH$_2$- and N- side methylene carbons[7,10] of the coordinated tren ligand, respectively. The signals at δ=41—48 and 48—54 of **5**—**7** and **9** were assigned to the NH$_2$- and NH- side methylene carbons[6,10] of the coordinated trien ligand, respectively. The signals at δ=43—46 of **10**—**12** were assigned to the methylene carbons of the coordinated ethylenediamine ligand. The data are collected in the Experimental section.

The electric conductivities of **1** and **2** are ca. 240 S cm^2 mol^{-1} in aqueous solutions. The IR spectra of **1** and **2** show the C=O stretching vibration at 1640 cm^{-1}, which is lower than that (1680 cm^{-1}) of free salicylamide[13] in the solid state. This suggests that the carbonyl oxygen of the coordinated salicylamidato ligand of **1** and **2** is bonded to a cobalt atom.[11,13] The ^{1}H NMR spectra in DMSO-d_6 of **1** and **2** showed two singlet signals at δ=8.85 (1H) and 8.92 (1H) for **1** and δ=8.70 (1H) and 8.84 (1H) for **2**. Both signals were assigned to -CONH$_2$ protons of the coordinated salicylamidato ligand by the comparison with those (δ=7.5—8.7) of

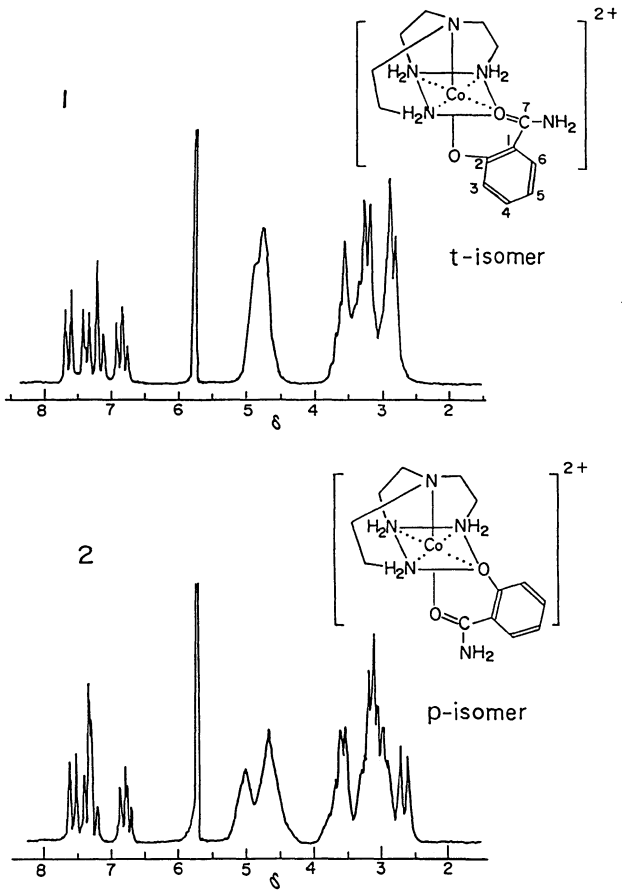

Fig. 2. ^{1}H NMR spectra of complexes **1** and **2** in 1.8 mol dm^{-3} D_2SO_4.
1: *t*-[Co(**A**)tren]$Cl_2 \cdot H_2O$. **2**: *p*-[Co(**A**)tren]$Cl_2 \cdot H_2O$.

free salicylamide.[14] Thus, complexes **1** and **2** have been assigned to **A**-type complexes, $[Co(A)tren]^{2+}$. On the other hand, the electric conductivities of **3** and **4** are ca. 110 S cm^2 mol^{-1}. The IR spectra of **3** and **4** do not show a band due to the C=O stretching vibration. Complexes **3** and **4** have been obtained from a reaction mixture (pH 10) of **1** and **2** with an ammonia solution, respectively (cf. Experimental section). Thus, complexes **3** and **4** have been assigned to **C**-type complexes, $[Co(C)tren]^+$. Complexes **3** and **4** are very slightly soluble in DMSO, though **1** and **2** are soluble. The chemical shifts of the C-1 carbon (position: cf. Fig. 2) signal for **3** and **4** are at a lower field than those of **1** and **2** (Table 1). The ε values of the charge-transfer band at ca. 340 nm in the absorption spectra for **3** and **4** are smaller than those of **1** and **2** (Table 1).

The electric conductivities of **5** and **6** are ca. 250 S cm^2 mol^{-1}. The IR spectra of **5** and **6** showed a band due to C=O stretching vibration at 1630—1644 cm^{-1}. The $-CONH_2$ proton signals of the coordinated salicylamidato ligand of **5** and **6** are observed in the region δ=8.6—9.0 in DMSO-d_6 (Fig. 3). Thus, complexes **5** and **6** are assigned to the **A**-type. The electric conductivity of **7** is 115 S cm^2 mol^{-1}. The IR spectrum of **7** does not show a band due to the C=O stretching vibration. Complex **7** is very slightly soluble in DMSO. Complex **7** was obtained from a reaction mixture (pH 10) of **5** and an ammonia solution. Thus, complex **7** is assigned to the **C**-type. Next, the electric conductivity of **9** is 145 S cm^2 mol^{-1}. The absorption spectrum of **9** shows split first bands at 510 and 535 nm. The

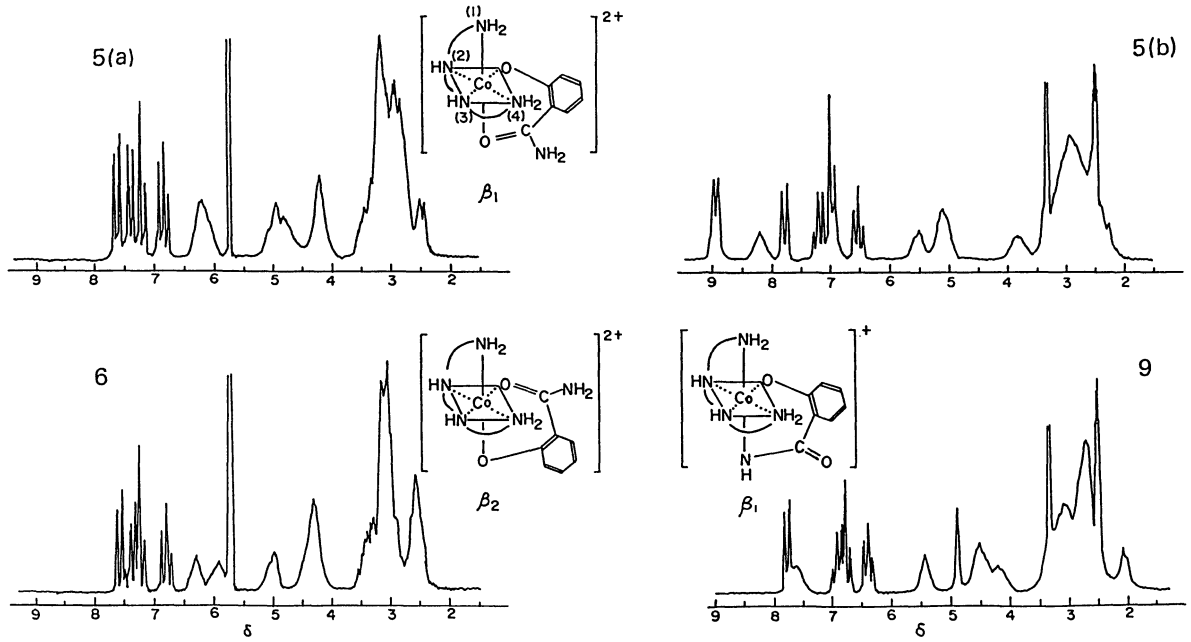

Fig. 3. ^{1}H NMR spectra of complexes **5**, **6**, and **9**.
5(a): *cis*-β_1-[Co(**A**)trien]$Cl_2 \cdot 2H_2O$ in 1.8 mol dm^{-3} D_2SO_4.
5(b): *cis*-β_1-[Co(**A**)trien]$Cl_2 \cdot 2H_2O$ in DMSO-d_6.
6: *cis*-β_2-[Co(**A**)trien]$Cl_2 \cdot 2H_2O$ in 1.8 mol dm^{-3} D_2SO_4.
9: *cis*-β_1-[Co(**D**)trien]$Cl \cdot H_2O$ in DMSO-d_6.

$-CONH^-$ proton signal of the coordinated salicylamidato ligand of **9** is observed at δ=4.89 in DMSO-d_6 (Fig. 3). The C-1 carbon signal of **9** is observed at δ=121.5. These properties of **9** are in agreement with those of **17**, which were reported previously (Table 1). Thus, complex **9** is assigned to the **D**-type, $[Co(\mathbf{D})(trien)]^+$.

The results of the electric conductivities, IR, ^1H, ^{13}C, and absorption spectra of **10**, **11**, and **12** are similar to those of (**1**, **2**, **5**, **6**), (**3**, **4**, **7**), and **9**, respectively, as shown in Table 1 and the Experimental section. Thus, **10**, **11**, and **12** are assigned to the **A**-, **C**-, and **D**-type complexes, respectively.

Isomers of the Complexes. Octahedral salicylamidato(tren)cobalt(III) complexes exist in the *t*- and *p*-isomeric forms[10,15] (Fig. 2). A distinction between **1** and **2** was found in the ^1H NMR spectra in 1.8 mol dm^{-3} D_2SO_4 (Fig. 2). The chemical shift (δ=4.69) of the proton signal of the NH_2 groups of the coordinated tren ligand of **2** is at a higher field than that (δ=4.75) of **1**, i.e., the NH_2 group of **2** is considered to be at a position trans to the phenoxyl oxygen of the coordinated salicylamidato ligand, which is more electronegative than the carbonyl oxygen.[10] Also, the signals of the methylene protons for **2** show two very sharp peaks[10] in the region δ=2.5—2.8; those for **1**, however, do not show the corresponding peaks (Fig. 2). These properties of **1** and **2** are similar to those of the corresponding complexes, **13** and **14**, respectively. Thus, **1** and **2** are assigned to the *t*- and *p*-isomers, respectively, as shown in Fig. 2. Next, the chemical shift (δ=4.85) of the proton signal of the NH_2 groups of the coordinated tren ligand of **4** in the ^1H NMR spectra in 1.8 mol dm^{-3} D_2SO_4 is at a higher field than that (δ=5.00) of **3**. The signals of the methylene protons of **4** show two very sharp peaks in the region δ=2.5—2.8, but those for **2** do not show the corresponding peaks (cf. Experimental section). In addition, complexes **3** and **4** were obtained from a reaction mixture (pH 10) of **1** and **2** with an ammonia solution, respectively. Thus, complexes **3** and **4** are assigned to the *t*- and *p*-isomers, respectively. No isomerization between *t*-isomer (**1**, **3**) and *p*-isomer (**2**, **4**) was observed in water and methanol at room temperature.

Octahedral salicylamidato(trien)cobalt(III) complexes exist in three geometrical isomers of *cis*-α, *cis*-β_1, and *cis*-β_2.[8,10] The IR spectra of **5**—**7** and **9** show four absorption bands in the NH_2 twisting region (990—1100 cm^{-1}) and four absorption bands in the NH stretching region (3000—3300 cm^{-1}) (cf. Experimental section). The ^{13}C NMR spectra of **5**—**7** and **9** show six carbon signals for the coordinated trien ligand. Thus, complexes **5**—**7** and **9** are assigned to the *cis*-β-form.[5,8] A distinction between **5** and **6** was observed in the ^1H NMR spectra in 1.8 mol dm^{-3} D_2SO_4 and the absorption spectra: the methylene proton signals of **6** were divided into two groups at δ=2.3—2.8 (3H) and 2.8—3.7 (9H) (Fig. 3); those of **5** could not be divided. The ε value of the first absorption band of **5** is greater than that of **6**. These properties for **5** and **6** are similar to those of **15** and **16**, respectively. Thus, complexes **5** and **6** were assigned to the *cis*-β_1 and β_2-isomers, respectively, as shown in Fig. 3. No isomerization between **5** and **6** was observed in water at room temperature. The methylene proton signals of **7** in 1.8 mol dm^{-3} D_2SO_4 are very close to those of **5**. Complex **7** was obtained directly from a reaction mixture (pH 10) of **5** and an ammonia solution. Thus, complex **7** was assigned to the *cis*-β_1-isomer. On the other hand, complex **7** and another complex **8** were obtained from a reaction mixture (pH 10) of **6** and an ammonia solution. Complex **8** could be assigned to the *cis*-β_2-isomer, but could not be isolated from the reaction mixture by the chromatographic method, because **8** isomerized to **7**. The methylene proton signals of **9** in 1.8 mol dm^{-3} D_2SO_4 are very close to those of **5** and **7**. Thus, complex **9** can be assigned to the *cis*-β_1-isomer.

In this study, **A**-, **C**-, and **D**-type complexes have been prepared. The formation of the **A**-type complexes is due to the bond between a cobalt atom and carbonyl oxygen of salicylamide ligand. The **C**-type complexes have been formed by the deprotonation of $-CONH_2$ of the coordinated salicylamidato ligand of the **A**-type complexes, since the **C**-type complexes have been obtained from a reaction mixture (pH 10) of the **A**-type complexes and an ammonia solution. The formation of the **D**-type complexes is due to the bond between a cobalt atom and the deprotonated imide nitrogen ($-CONH^-$) from $-CONH_2$ of the salicylamide ligand in an alkaline solution.

The different properties between the **A**-type complexes and the **C**- and **D**-type complexes are as follows: i) Yield (30—50%) of the **A**-type complexes was larger than those (4—9% for **C** and 2—3% for **D**) of the **C**- and **D**-type complexes at pH 8.6, but that (20%) of the **A**-type complexes decreases at pH 10 and those (15% for **C** and 3—5% for **D**) of the **C**- and **D**-type complexes increase. Thus, the preparation of the mixed-ligand cobalt(III) complexes with the salicylamidato ligand has been dependent upon the pH of the reaction mixture. ii) The chemical shifts (δ=113—115) of the C-1 carbon signals for the **A**-type complexes are at a higher field than those (δ=117—122) of the **C**- and **D**-type complexes. iii) The ε values (3400—3700) of the charge-transfer band at ca. 340 nm in the absorption spectra for the **A**-type complexes are greater than those (2500—3000) of the **C**- and **D**-type complexes.

The **C**-type and **D**-type complexes are a linkage isomer. A characteristic property of this linkage isomer has been observed in the absorption and ^{13}C NMR spectra as well as solubility in DMSO: i.e., the first absorption band for the **D**-type complexes shows split first bands at ca. 510 and 535 nm; that for the **C**-type complexes, however, does not show a split first band. The C-1 carbon signals of the **D**-type complexes are observed in the region δ=120—122, but those of the **C**-type complexes are observed at δ=117—118. The **D**-

type complexes are soluble in DMSO, but the **C**-type complexes are very slightly soluble.

Fluorometric Determination of Amino Acids and Proteins Utilizing a Copper(II) Catalyzed Reaction

Hisakazu MORI,* Kazue SAKAI, Kyoko YAMASHINA, Sayuri HIRATA, and Kumiko HORIE
Kyoritsu College of Pharmacy, Shibakoen, Minato-ku, Tokyo 105
(Received May 18, 1991)

Amino acids accelerated the copper(II)-catalyzed oxidation of di-2-pyridyl ketone hydrazone (DPKH) to form a fluorescent compound. With the use of this enhancement effect of catalysis, various amino acids (L-histidine, L-cysteine, L-glutamic acid, glycine, DL-serine, and L-arginine) could be determined by flow injection analysis. The detection limit of L-histidine was less than 2 pmol. On the contrary, proteins decreased the catalysis. Proteins were also determined through the utilization of this effect. In this determination, the addition of citric acid was found to be very effective. The detection limit of bovine serum albumin was less than 20 ng. The effect of protein upon the catalysis of copper(II) was considered to be ascribable to an inhibition of the coordination of DPKH to copper(II).

In trace analyses of amino acids they are usually transformed to derivatives which can be detected colorimetrically or fluorometrically at low level. One mole of the derivative corresponds to one mole of an amino acid in such reactions. Amino acids can also be determined by other methods than those with derivatisation. In these methods, two types of reactions seem to be utilized. One type is such a chemiluminescence reaction as that between luminol and hydrogen peroxide catalyzed by cobalt(II)[1] or copper(II).[2] The addition of an amino acid to this reaction system, forming a complex with a metal ion, reduces the chemiluminescence. Thus, amino acids are determined quantitatively. The other type is a fluorogenic oxidation reaction catalyzed by copper(II) in which amino acids accelerate the reaction rate. With the use of this enhancement effect of catalysis, amino acids were determined[3] by flow injection analysis (FIA). In this catalytic reaction, one mole of an amino acid may correspond to more than one mole of the fluorescent compound. Thus, a more sensitive detection would be achieved by optimizing the reaction conditions. This would also be done by the use of a reaction substrate which is oxidized to a compound having intense fluorescence.

In the present study regarding the determination of amino acids, di-2-pyridyl ketone hydrazone (DPKH) was adopted as a reaction substrate instead of phenyl 2-pyridyl ketone hydrazone (PPKH), which was used in the previous study.[3] It is known[4] that the oxidation product of DPKH shows an intense fluorescence in the acidic media. Thus, the FIA system was applied with a flow line of hydrochloric acid in order to detect the oxidation product in an acidic media. The effects of proteins on the copper(II)-catalyzed oxidation were also investigated, compared with those of amino acids. The necessary conditions for the sensitive detection of proteins were pursued.

Experimental

Chemicals. DPKH was synthesized by the reaction of di-2-pyridyl ketone with hydrazine monohydrate according to a method described in the literature.[4] Amino acids and copper(II) salts were of analytical reagent grade. Bovine serum albumin (BSA) was purchased from Sigma Chemical Co. and human serum albumin (HSA), from Wako Pure Chemical Industries, LTD.

Apparatus and Procedures. Figure 1 shows a schematic diagram of the FIA system used in the present study. It contains four flow lines (Teflon, 0.5 mm i.d.). C_1 is a 5×10^{-5} M(1 M $\equiv$1 mol dm^{-3}) aqueous solution of DPKH. C_2 is 0.1 M NaOH. C_3 is water and C_4 is 0.4 M HCl. An alkaline solution of DPKH could not be used instead of the flow lines, C_1 and C_2, because of the gradual change of the base line on the recorder. All solutions were pumped by two double-plunger-type pumps (Nihonseimitsu NP-D-322U) at a flow rate of 1.2 cm^3 min^{-1}. Samples were injected to the flow system by an injector (Nihonseimitsu NVI-3002) with a 50 mm^3 sample loop. The aerial oxidation of DPKH, catalyzed by the amino acid–copper(II) complex, was carried out in a reaction coil (150 cm) immersed in a water bath thermostated at 25 °C. The fluorescence[4] (λ_{ex} 349 nm, λ_{em} 435 nm) of the reaction

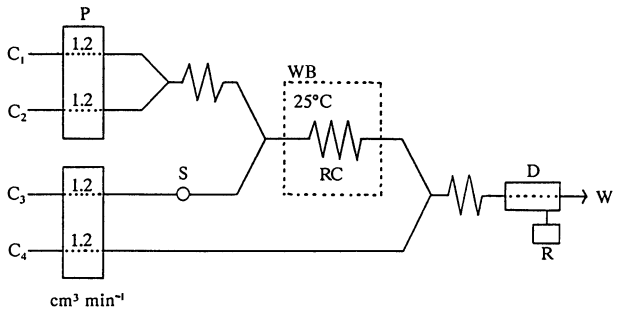

Fig. 1. Schematic diagram of the FIA system.
S: sample injector, C_1: 5×10^{-5} M aqueous solution of DPKH, C_2: 0.1 M NaOH, C_3: water, C_4: 0.4 M HCl, P: pump, RC: reaction coil, WB: water bath, D: detector, R: recorder, W: waste.

product acidified by 0.4 M HCl was monitored by a spectrofluorometer (Hitachi F-1000) with a 12 mm^3 flow cell, and recorded on a recorder (data processor, Shimadzu C-R1A). The peak height of the signal was calculated using this recorder.

The samples of amino acids were prepared in a buffer solution as mixtures of 4×10^{-7} M copper(II) and various amounts of each amino acid. After stirring for 10 min it was subjected to analysis. The samples of proteins were usually prepared in a similar manner as described above. Those in the Atkins–Pantin buffer (boric acid–potassium chloride–sodium carbonate) containing citrate were prepared as follows. A copper(II) solution in a citric acid–disodium hydrogenphosphate buffer (pH 3.0) was diluted with the Atkins–Pantin buffer. This solution was mixed with a Atkins–Pantin buffer solution of protein.

Absorption Spectra Measurements. The absorption spectra of the mixtures of copper(II), L-histidine (or BSA), and DPKH were measured at room temperature as follows. A mixture in a quartz cell of 0.5 cm^3 of 2×10^{-3} M aqueous copper(II) solution, 1 cm^3 of aqueous L-histidine (or BSA) solution, and 0.5 cm^3 of 0.05 M Clark–Lubs buffer (boric acid–potassium chloride–sodium hydroxide, pH 9.0) was bubbled with N_2 gas for 5 min. Then, into this mixture was added 1 cm^3 of a 1×10^{-3} M aqueous solution of DPKH through which N_2 gas had been previously passed. About 5 s after mixing, a measurement of the absorption spectrum was started with a spectrophotometer (Hitachi U-3210).

Results and Discussion

Determination of Amino Acids. As reported in a previous paper,[3] the amino acid–copper(II) complex in the alkaline buffer solution had shown an enhanced catalytic activity in the aerial oxidation of PPKH. In the present work using DPKH, the catalytic activities of the amino acid–copper(II) (1 : 1) complex (4×10^{-7} M) in the buffer solutions of various pH values were compared with those of copper(II). The amino acid used was L-histidine, which had given the maximum activity in a previous study.[3] Phosphate buffer (0.005 M) was employed in the pH range of 5.0 to 7.0, and Clark–Lubs buffer (0.005 M) in the pH range of 8.0 to 10.0. As shown in Fig. 2, copper(II) and the L-histidine–copper(II) complex indicated comparable catalytic activities in weakly acidic media. In more basic media, the catalytic activities of both decreased, though that of the L-histidine–copper(II) complex became superior to that of copper(II), showing that the addition of L-histidine to copper(II) in a basic media enhances the catalytic activity of copper(II), as in the case of the aerial oxidation of PPKH.[3] It was suggested that the determination of this amino acid could be made most sensitively with the use of a buffer of pH 9.0 among those of various pH values. The decrease in the catalytic activity in more basic media would be due to the formation of phosphate(s) or hydroxide(s) of copper(II); this decrease could be partly prevented by the formation of an active L-histidine–copper(II) complex.

Other reaction conditions were examined in order to detect lower amounts of L-histidine. Favorable peaks were obtained at a DPKH concentration of 5×10^{-5} M in the series of 5×10^{-4}, 5×10^{-5} and 5×10^{-6} M. Among three concentrations (0.05, 0.005, and 0.0005 M) of the Clark–Lubs buffer (pH 9.0), that of 0.005 M gave the greatest difference between the signal due to aerial oxidation with and without L-histidine. Several copper(II) salts, i.e., nitrate, chloride, perchlorate, and sulfate were examined, and the use of copper(II) nitrate gave the maximum signal. The temperature of the water bath where the reaction coil was immersed was varied (15, 25, 35, and 45 °C). Since the signal did not increase very

The amount of added L-histidine is represented by the molar ratio to copper(II).

much at temperatures greater than 25 °C, a temperature of 25 °C was adopted for the reaction. The variation of the concentration of hydrochloric acid did not change the peak height, provided that the concentration of hydrochloric acid is higher than that of the sodium hydroxide solution. Thus, concentrations of 0.4 and 0.1 M were respectively employed as those of the hydrochloric acid and sodium hydroxide solutions.

Figure 3 shows the peaks obtained when the samples containing various amounts of L-histidine were subjected to analysis. As the molar ratio of L-histidine to copper(II) was increased, the fluorescence intensity increased linearly in the molar ratio range from 0 to 1. The correlation coefficient (r) was 0.996 (n=7) and the relative standard deviation at a molar ratio of 0.4 was 2.3% (n=5). All of the amino acids investigated increased the catalysis of copper(II). In the cases of L-histidine and L-cysteine, the peak height of the signal increased linearly over a molar ratio range of about 1, but deviated from a linear relationship at a molar ratio greater than 1. The maximum molar ratio below which a linear relationship was observed was 3 for L-glutamic acid, 4 for glycine and DL-serine, and 5 for L-arginine. The calibration curves for all amino acids included the point of molar ratio 0 in the linear range. Table 1 gives the upper limits of the linear range for each amino acid. In Table 1 are also shown the slopes of the calibration curves which were defined as the difference between the peak height at a molar ratio of 1 and that at a molar ratio of 0. The slopes for L-histidine and L-cysteine are larger than those for other amino acids. A similar tendency had been observed in a determination using PPKH,[3] though this tendency was more marked in the present study.

In the determination of L-histidine, the content of this amino acid was 2 pmol in a sample with a molar ratio of 0.1. This value was less than one third of that in the case of PPKH. This difference would come from the character of the oxidation product of DPKH, which shows intense fluorescence in an acidic media.

Table 2 shows the effects of foreign metal ions in the determination of L-histidine. The relative peak height of the signal in the case of the mixture to that in the case of copper(II) was used as an indication of the effect of a foreign metal ion. Zinc(II), manganese(II), silver(I), mercury(II), and cobalt(II) increased the peak height in this order. On the other hand, nickel(II) and iron(III) decreased the peak height. EDTA at the same level as copper(II) interfered with the determination. This would be ascribed to the formation of a copper(II)–EDTA complex with a large formation constant, to which DPKH cannot coordinate.

Determination of Proteins. We further applied this method to the determination of protein which is practically important in biological studies. Preliminary

Table 1. Upper Limits of the Linear Ranges and Slopes of Calibration Curves for Various Amino Acids

Amino acid	Upper limit/10^{-7} M	Slope/10^3 μV
L-Histidine	4	69.0
L-Cysteine	3.2	73.7
L-Glutamic acid	12	15.4
Glycine	16	11.6
DL-Serine	16	6.3
L-Arginine	20	2.1

Table 2. Relative Peak Heights in the Presence of Foreign Metal Ions

Metal ion	Added Amount/[Metal ion][Cu(II)]$^{-1}$				
	0.5	1	10	100	500
None		1			
Co(II)		1.7	4.3		
Hg(II)		1.3	2.8		
Ag(I)		1.1	1.8		
Mn(II)		1.1	1.4		
Zn(II)		1.0	1.1	1.4	1.7

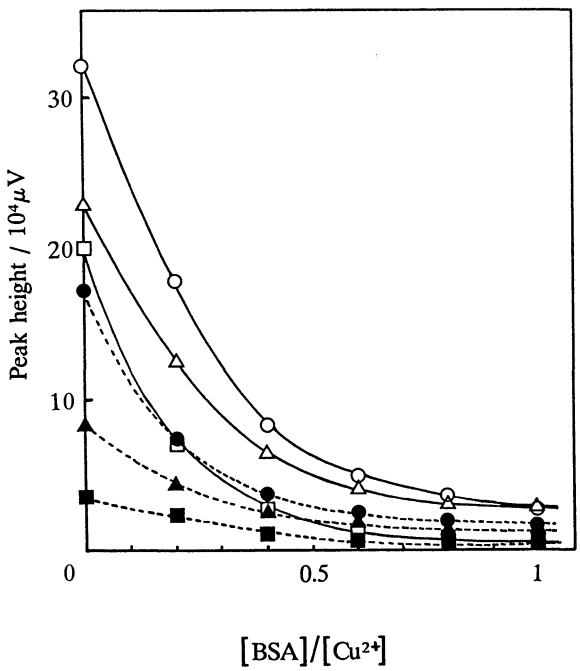

Fig. 4. Calibration curves for BSA samples in phosphate buffers (0.005 M) and citric acid–disodium hydrogenphosphate buffers of various pH values.
phosphate buffer, ●: pH 5.0, ▲: pH 6.0, ■: pH 8.0.
citric acid–disodium hydrogenphosphate buffer, ○: pH 5.0, △: pH 6.0, □: pH 8.0.
BSA samples were prepared on the assumption that the molecular weight of BSA was 69000. Thus, in the case that the molar ratio of BSA to copper(II) is unity, this sample contains 1380 ng of BSA. The samples in a citric acid–disodium hydrogenphosphate buffer contain 0.005 M citric acid.

experiments concerning BSA showed that this protein decreased the catalysis of copper(II), in contrast with amino acids. Figure 4 indicates the effects of the kinds of buffers and their pH values of BSA samples. With respect to the samples in a phosphate buffer, the catalysis of free copper(II) (that is, when no protein was added) was markedly lowered in the alkaline pH region. On the other hand, the samples in citric acid–disodium hydrogenphosphate buffer showed higher catalytic activities than those in phosphate buffer and the catalysis was not so much decreased, even in the alkaline pH region. This effect would be due to the formation of a soluble citric acid–copper(II) complex toward which DPKH can coordinate to be oxidated. Another oxyacid, tartaric acid, also showed a similar effect in the alkaline pH region, which was fairly smaller than that due to citric acid.

By experiments involving spectrum measurements (see below), it was previously confirmed that BSA reacts with greater amounts of copper(II) in more basic solutions. Thus, in order to detect lower amounts of protein, we exclusively examined samples in strongly alkaline buffers containing citrate. The Clark–Lubs buffer (pH 8.0—10.0) and the Atkins–Pantin buffer (pH 9.0—11.0) were employed for sample preparation. In the case of the Clark–Lubs buffer, that of pH 10.0 afforded the most acute decrease in signal over the range of small amounts of added protein. However, plotting of data over this range gave a calibration curve with comparatively large scattering. When the Atkins–Pantin buffer was applied, a more basic buffer reduced more extensively the signal due to free copper(II). Thus, a buffer of pH 9.0 afforded the best calibration curve, containing a linear line (r=−0.997) over the range of less than 200 ng of added protein (Fig. 5). The relative standard deviation upon the addition of 80 ng of BSA was 1.50% (n=5). Figure 5 also shows the calibration curve for HSA; it contains a linear line(r=−1.000) over the range of less than 200 ng. The relative standard deviation upon the addition of 80 ng of HSA was 1.69%, (n=5). The detection limits were less than 20 ng in the respective calibration curves. At present, the sensitivity using the present method for protein determination does not attain to that in the method using the copper(II) catalyzed chemiluminescence reaction between 1,10-phenanthroline and hydrogen peroxide.[5]

We presently have interest in the different effects of proteins from amino acids on the catalysis of copper(II). In order to elucidate this difference, the effect of L-histidine or BSA on the coordination of DPKH to copper(II) was investigated. As the absorption spectrum (a) in Fig. 6 shows, the mixing of a solution of DPKH with a solution of copper(II) in alkaline buffer (Clark–Lubs, pH 9.0) afforded a new absorption maximum at 426 nm, indicating the coordination of DPKH to copper(II). When the solution of DPKH was mixed with a copper(II) solution containing L-histidine, the spectrum was little changed in the region of a molar ratio of L-histidine to copper(II) less than 1. On the contrary, when the DPKH solution was mixed with a copper(II) solution containing BSA, the absorbance was remarkably reduced at a molar ratio less than 1 (spectrum (b)—(e) in Fig. 6). In a more basic buffer, this tendency was much more marked. These facts would

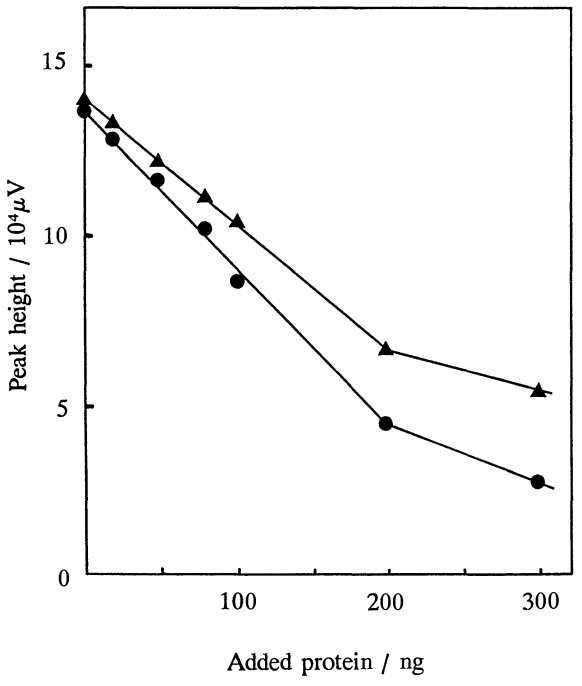

Fig. 5. Calibration curves for BSA and HSA samples in an Atkins–Pantin buffer containing citrate (pH 9.0).
●: BSA, ▲: HSA.
The sample solutions prepared contain 2×10^{-5} M citric acid, 0.05 M boric acid, 0.05 M potassium chloride, and 0.029 M sodium carbonate.

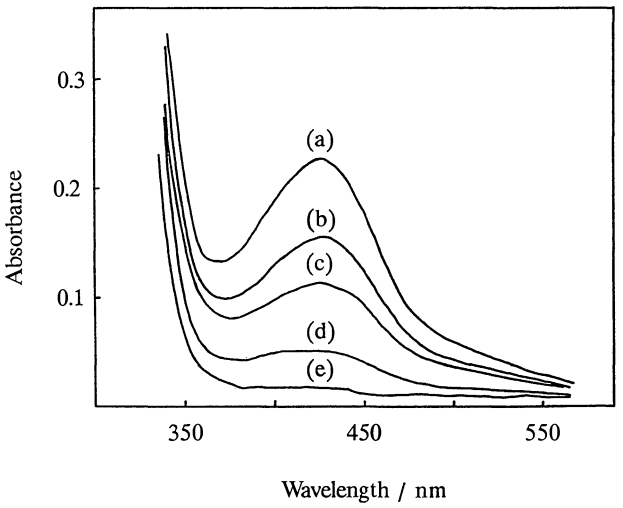

Fig. 6. Absorption spectra of the mixtures of copper(II), BSA, and DPKH with various molar ratios of BSA to copper(II).

indicate that BSA firmly coordinated to copper(II) and inhibited the coordination of DPKH to copper(II), while L-histidine scarcely did so.

The determination of amino acids or proteins by the present method can be performed in 1 min. The sensitive detection of amino acids was achieved by the utilization of DPKH, owing to the intense fluorescence of the reaction product in an acidic media. The use of the compounds whose oxidation product have more intense fluorescence and/or which are oxidized with high velocity would increase the sensitivity in the detection of amino acids or proteins. The study in this direction is in progress.

Ferromagnetic Spin-Coupling between Gadolinium(III) and Copper(II) Ions in Discrete Binuclear Gd(III)-Cu(II) Complexes

Masatomi SAKAMOTO,* Masayuki HASHIMURA, Kimihiro MATSUKI, Naohide MATSUMOTO,*,† Keiji INOUE,† and Hisashi ŌKAWA†

Department of Applied Chemistry, Faculty of Engineering, Ehime University, Matsuyama 790
†Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received May 30, 1991)

Three discrete binuclear gadolinium(III)–copper(II) complexes ($CuGd(fsadien)NO_3 \cdot 5H_2O$ (**1**), $CuGd(hsapn)NO_3 \cdot 3H_2O$ (**2**), and $[Gd(pvm)_3Cu(A)]$ (**3**)) have been synthesized; we use the notation H_4fsadien=*N,N'*-bis(3-carboxysalicylidene)diethylenetriamine, H_4hsapn=*N,N'*-bis(3-hydroxysalicylidene)-1,2-propanediamine, Hpvm= dipivaloylmethane (2,2,6,6-tetramethyl-3,5-heptanedione), and H_2A=4-(6-methyl-8-oxo-2,5-diazanona-1,5,7-trienyl)imidazole. Magnetic susceptibility measurements (4.2—300 K) have revealed that the spin coupling between the Gd(III) and Cu(II) ions is ferromagnetic with coupling constants J=+2.3 cm^{-1} for (**1**), +5.7 cm^{-1} for (**2**), and +0.5 cm^{-1} for (**3**), on the basis of the spin-Hamiltonian $H=-2JS_{Gd} \cdot S_{Cu}$.

Magnetic studies on the d-transition metal polynuclear complexes have shown tremendous progress during the latest decade regarding experimental and theoretical fields.[1,2] Procedures have become fairly well established for predicting the magnetic properties of polynuclear d-transition metal complexes.[1,2] On the other hand, magnetic investigations concerning mixed-metal complexes comprising d- and f-transition metal ions have been overlooked until recently due to the very weak interaction and the large anisotropic effect of lanthanoid ions. Characterization of the magnetic interaction between d- and f-transition metal ions is our next target for elucidation. In particular, the synthesis of ferromagnetic complexes is among the stimulating subjects. Recently, Gatteschi and his co-workers reported on the ferromagnetic interaction operating between Gd(III) and Cu(II) ions in a trinuclear $GdCu_2$ system $\{Cu(saltn)\}_2Gd(H_2O)(NO_3)_3 \cdot 2C_2H_5NO_2$ (H_2saltn=*N,N'*-di(salicylidene)-1,3-propanediamine)[3] and its related complexes[4] as well as a tetranuclear Gd_2Cu_2 system $[Gd(hfac)_3Cu(satn)(OH)]_2$ (hfac= hexafluoroacetylacetonate, Hsatn=*N*-(3-aminopropyl)-salicylideneamine).[5] However, in these complexes the antiferromagnetic interaction operating between the terminal copper ions makes it difficult to evaluate the magnetic interaction between the Cu(II) and Gd(III) ions. In order to establish the magnetic interaction between Cu(II) and Gd(III) ions, it is desirable to synthesize discrete binuclear Gd(III)–Cu(II) complexes and to investigate their magnetic properties. Recently, in a communication, we reported on the synthesis and ferromagnetic property of a discrete Gd(III)–Cu(II) complex, $CuGd(fsaen)NO_3 \cdot 4H_2O$($H_4$fsaen=*N,N'*-bis(3-carboxysalicylidene)ethylenediamine).[6] In order to provide more examples of discrete binuclear Gd(III)–Cu(II) complexes and to investigate the structural variation effects (bridging mode and coordination geometry) upon spin-coupling, we prepared in the present study complexes (**1**), (**2**), and (**3**) and investigated their magnetic properties.

Experimental

Physical Measurements. Elemental analyses for C, H, and N were carried out at the Service Center of Elemental Analysis, Kyushu University. Copper and Gadolinium were determined by titration against EDTA, where NH_4F and thiourea were used as masking reagents for Gd and Cu, respectively. The magnetic susceptibilities were measured with a HOXAN HSM-D SQUID magnetometer over the temperature range 4.2—300 K under the applied magnetic field 500 G. The magnetic susceptibilities were calibrated by the use of $(NH_4)_2Mn(SO_4)_2 \cdot 6H_2O$. Data were corrected for magnetization of the sample holder and for diamagnetism contributions with Pascal's constants. The effective magnetic moments were calculated by the equation $\mu_{eff}=2.828(\chi_M T)^{1/2}$, where χ_M is the magnetic susceptibility per CuGd.

Synthesis. Starting complexes $Cu(H_2fsadien)$,[7] $[Gd(pvm)_3]$,[8] and $[Cu(A)] \cdot 0.5\ CHCl_3$[9] were prepared according to methods described in the literature; where H_4fsadien=*N,N'*-bis(3-carboxysalicylidene)diethylenetriamine, Hpvm=dipivaloylmethane (2,2,6,6-tetramethyl-3,5-heptanedione), and H_2A= 4-(6-methyl-8-oxo-2,5-diazanona-1,5,7-trienyl)imidazole.

$CuGd(fsadien)NO_3 \cdot 5H_2O$ (1). To a suspension of

Cu(H_2fsadien) (1 mmol) in 50 cm^3 of methanol was added a methanol solution (10 cm^3) of $LiOH \cdot H_2O$ (2 mmol) followed by 240 cm^3 of methanol. The mixture was then heated until it became clear. To this solution was added a methanol solution (5 cm^3) of $Gd(NO_3)_3 \cdot 6H_2O$ (1 mmol). After refluxing for 2 h, the solution volume was reduced to 50 cm^3 by a rotary evaporator. Green microcrystals precipitated were collected by suction filtration, washed with methanol and diethyl ether, and dried in air. Yield 60 %. Anal. Calcd for $C_{20}H_{27}N_4O_{14}CuGd$: C, 31.27; H,3.54; N, 7.29; Cu, 8.27; Gd, 21.32%. Found: C, 31.29; H, 3.22; N, 7.38; Cu, 8.28, Gd, 21.30%.

Bis(2-formyl-6-hydroxyphenoxy)copper(II) Monohydrate (2a). To a methanol solution (60 cm^3) of 2,3-dihydroxybenzaldehyde (20 mmol) was added an aqueous solution (50 cm^3) of copper(II) acetate monohydrate (10 mmol) in order to immediately precipitate a yellow-brown powder. After stirring for 1 h at room temperature, the precipitate was collected by suction filtration, washed with water, methanol, and diethyl ether, and dried in air. The yield was 90 %. Anal. Calcd for $C_{14}H_{10}O_6Cu \cdot H_2O$: C, 47.26; H, 3.40%. Found: C, 47.57; H, 3.5%.

[*N,N'*-Bis(3-hydroxysalicylidene)-1,2-propanediaminato-copper(II) Monohydrate Cu(H_2sapn)$\cdot H_2O$ (2b). To a suspension of **2a** (40 mmol) in ethanol (150 cm^3) was added 1,2-propanediamine (20 mmol). The mixture was first warmed on a hot plate for 2 h under stirring, and then cooled to room temperature, resulting in a brown precipitate which was collected by suction filtration, washed with water, ethanol, and diethyl ether, and finally dried in air. Yield 85—90%. Anal. Calcd for $C_{17}H_{16}N_2O_4Cu \cdot H_2O$: C, 51.84; H, 4.61; N, 7.11; Cu, 16.13%. Found: C, 52.33; H, 4.56; N, 7.08; Cu, 15.97%.

CuGd(hsapn)$NO_3 \cdot 3H_2O$ (2). To a suspension of **2b** (2.5 mmol) in 20 cm^3 of methanol was added a methanol solution (25 cm^3) of $LiOH \cdot H_2O$ (5 mmol). To the resulting clear solution was added a methanol solution (10 cm^3) of $Gd(NO_3)_2 \cdot 6H_2O$; the mixture was subsequently refluxed for 2 h. After cooling to room temperature, a brown precipitate was collected by suction filtration, washed with methanol and diethyl ether, and dried in air. Yield 95%. Anal. Calcd for $C_{17}H_{14}N_3O_7CuGd \cdot 3H_2O$:C, 31.55; H, 3.11; N, 6.49; Cu, 9.82; Gd, 24.30%. Found: C, 31.69; H, 3.05; N, 6.86; Cu, 9.48; Gd, 24.10%.

[Gd(pvm)$_3$Cu(A)] (3). To a chloroform solution (20 cm^3) of [Gd(pvm)$_3$] (0.5 mmol) was added a chloroform solution (30 cm^3) of [Cu(A)]$\cdot$0.5$CHCl_3$ (0.5 mmol). The mixture was warmed on a hot plate for 10 min and filtered. To the filtrate was added diethyl ether dropwise until the solution became cloudy. After standing overnight, silky red crystals were collected by suction filtration, washed with ether, and dried in air. Recrystallization was carried out from the mixed solution of chloroform–diethyl ether. The yield was 10 %. Anal. Calcd for $C_{44}H_{71}N_4O_7CuGd$: C, 53.44; H, 7.24; N, 5.67; Cu, 6.43; Gd, 15.89%. Found: C, 53.50; H, 7.23; N, 5.69; Cu, 6.30; Gd, 15.75%.

Results and Discussion

The temperature dependence of the magnetic susceptibility per CuGd unit (χ_M), the reciprocal magnetic susceptibility ($1/\chi_M$), and the effective magnetic moment (μ_{eff}) of CuGd(fsadien)$NO_3 \cdot 5H_2O$ (**1**) are shown in Fig. 1. The numerical magnetic data of (**1**)—(**3**)

CuGd(fsadien)$NO_3 \cdot 5H_2O$ (1).

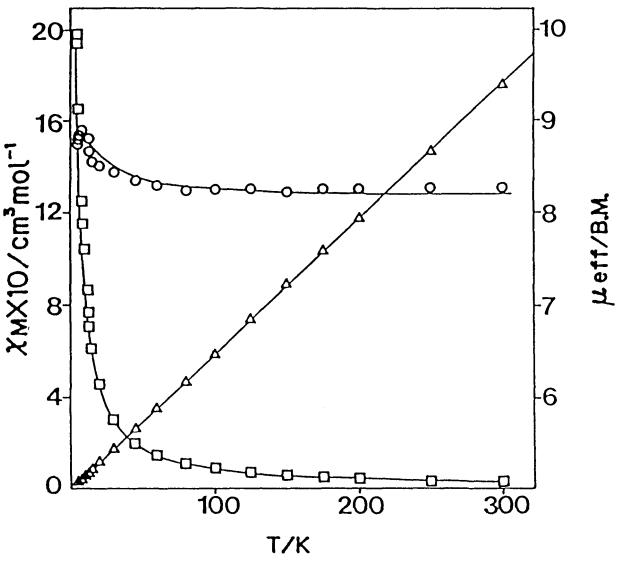

Fig. 1. Plots of χ_M vs. T(△), $1/\chi_M$ vs. T(△), and μ_{eff} vs. T(○) for (**1**), where χ_M is the magnetic susceptibility per GdCu unit, μ_{eff} the effective magnetic moment. The theoretical curve is drawn with the fitting parameters g=2.01, J=+2.3 cm^{-1}, θ=−0.12 K as solid lines.

and the plots of χ_M vs. T, $1/\chi_M$ vs. T, and μ_{eff} vs. T for (**2**) and (**3**) are reported as supplementary materials (Tables SI—SIII, Figs. S1 and S2) as Document No. 8970 at the office of the Editor of Bull. Chem. Soc. Jpn. The $1/\chi_M$ vs. T plot of (**1**) follows the Curie-Weiss law ($\chi_M = C/(T-\theta)$) with a Weiss constant θ=1.1 K, suggesting a weak ferromagnetic interaction. The effective magnetic moment at room temperature is 8.27 μ_B, which is slightly larger than the spin-only value (8.12 μ_B) in the absence of the magnetic interaction of this spin-system (S_{Cu}=1/2, S_{Gd}=7/2). It should be noted here that the ground state of Gd(III) is $^8S_{7/2}$ and that the next excited state is well separated in energy, so that its μ_{eff} value can be approximated by the spin-only equation, $\mu_{eff}=[4s(s+1)]^{1/2}$. As the temperature is lowered, the magnetic moment increasing gradually from 8.27 μ_B at 300 K, reaches a maximum value of 9.10 μ_B at 10.0 K, and then decreases to 8.73 μ_B at 4.8 K. The maximum value (9.10 μ_B) is comparable to the spin-only value (8.94 μ_B) for the spin-state S=4, which should arise from a ferromagnetic spin-coupling of the spin-system Gd(III)–Cu(II) (S_{Gd}=7/2, S_{Cu}=1/2). Thus, the observed magnetic behavior clearly demonstrates the operation of an intramolecular ferromagnetic spin-coupling between Gd(III) and Cu(II) ions. A decrease in the magnetic moment below 10 K may be attributed to an intermolecular antiferromagnetic interaction. The magnetic behaviors of (**2**) and (**3**) are essentially similar to that of (**1**). The magnetic data could be reproduced on the basis of a spin-only expression including a correction

Table 1. Coupling Constants in Gd(III)–Cu(II) Complexes

Compound	System	J_{GdCu}	θ	J_{CuCu}	Ref.
$CuGd(fsaen)NO_3 \cdot 3H_2O$	GdCu	+2.1	—	—	6
$CuGd(fsadien)NO_3 \cdot 5H_2O$ (**1**)	GdCu	+2.3[a]	−0.12	—	This work
$CuGd(hsapn)NO_3 \cdot 3H_2O$ (**2**)	GdCu	+5.7[b]	−1.5	—	This work
$Gd(pvm)_3Cu(A)$ (**3**)	GdCu	+0.5[c]	—	—	This work
$[Cu(hapen)_2Gd(H_2O)_3](ClO_4)_3$	$GdCu_2$	+2.7	—	−2.1	4
$[Cu(salen)_2Gd(H_2O)_3](ClO_4)_3$	$GdCu_2$	+3.7	—	−6.1	4
$[Cu(saltn)_2Gd(H_2O)(NO_3)_2]$	$GdCu_2$	+0.61	—	−1.8	3
$[Gd(hfac)_3Cu(satn)OH]_2$	Gd_2Cu_2	+1.42	—	−1.73	5

The spin-Hamiltonian is taken as the form $H=-2JS_{Gd} \cdot S_{Cu}$ for all the complexes. Cu(hapen) = *N,N'*-ethylenebis[1-(*o*-hydroxyphenyl)ethaniminato]copper(II). Cu(salen)=[*N,N'*-di(salicylidene)ethylenediaminato]copper(II). Cu(saltn)=[*N,N'*-di(salicylidene)-1,3-propanediaminato]-copper(II). H_4fsaen=*N,N'*-bis(3-carboxysalicylidene)ethylenediamine. a), b), c). The agreement factors $R=[\sum(\mu_{obsd}-\mu_{cald})^2/\sum\mu_{obsd}^2]^{1/2}$; a), 0.014; b), 0.015; c), 0.0068.

term of intermolecular interaction (1), where a spin-Hamiltonian is defined as $H=-2JS_{Cu} \cdot S_{Gd}$.

$$\chi_M=\frac{4Ng^2\beta^2}{kT(T-\theta)}\frac{15+7\exp(4J/kT)}{9+7\exp(4J/kT)}, \quad (1)$$

Theoretical curves using the best-fit parameters are represented as solid lines in Fig. 1. The best-fit parameters of (**1**)—(**3**) and the agreement factors $R=[\sum(\mu_{obsd}-\mu_{cald})^2/\sum\mu_{obsd}^2]^{1/2}$, along with the parameters of Gd(III)–Cu(II) oligomers reported so far are given in Table 1. The coupling between Gd(III) and Cu(II) ions are all ferromagnetic, in spite of the differences among the complexes in coordination numbers, coordination geometries, and bridging ligands (phenoxo, hydroxo, imidazolato). The coupling constants (J_{GdCu}) are small and similar to each other. The magnetic behaviors of the present discrete binuclear complexes (**1**)—(**3**) have demonstrated undoubtedly a ferromagnetic spin-coupling between the Gd(III) and Cu(II) ions.

In a superexchange mechanism which is successfully applicable to d-transition metal polynuclear complexes, a weak antiferromagnetic interaction would be expected, since the magnetic orbital of Cu(II) can overlap at least one of the seven f orbitals of Gd(III) ion and the antiferomagnetic contribution is dominat. Accidental orthogonality is also not probable due to the fact that ferromagnetic coupling is always observed in complexes with different coordination numbers, geometries, and bridging groups. One plausible mechanism that can cause a ferromagnetic coupling between Gd(III) and Cu(II) proposed by Benelli et al.[5] is the spin-polarization that occurs when the magnetic orbital of Cu(II) overlaps the empty 6s orbital of Gd(III) through a filled bridging orbital. The fraction of unpaired electron thus polarized from Cu to Gd is parallel to the f electrons due to Hund's rule, affording ferromagnetic coupling between Cu(II) and Gd(III). The fact that the 4 f orbital is shielded by the outer filled 5s and 5p orbitals, and lanthanoid ions generally form complexes using 6s, 6p, and/or 5d orbitals supports the spin-polarization mechanism.

Supplementary Material Available: Tables SI, SII, and SIII (temperatures, magnetic susceptibilities per CuGd unit, and effective magnetic moments per CuGd unit for (**1**), (**2**) and (**3**)), and Figures S1 and S2 (temperature dependence of the magnetic susceptibilities, reciprocal magnetic susceptibilities, and effective magnetic moments for (**2**) and (**3**)).

Studies of the Hydrous Zirconium(IV) Oxide Ion Exchanger. II. The Rate of Isotopic Exchange of Sodium Ions between the Exchanger in the Na^+ Form and Aqueous Solutions

Yasushi INOUE,* Hiromichi YAMAZAKI, and Tomonori NARITA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Aoba-ku, Sendai 980
(Received July 10, 1991)

The rate of the isotopic exchange of Na^+ between hydrous Zr^{IV} oxide in the Na^+ form and aqueous solutions of sodium salts was determined radiochemically. The rate is controlled by particle diffusion, film diffusion, or both, according to the conditions. The exchange rate is controlled by particle diffusion, when the exchanger particles are large (radius, 171 μm), the solutions are more concentrated than 0.1 mol dm^{-3} Na^+ and the flow rate through the exchanger particles is high, whereas under the opposite conditions film diffusion is the rate-controlling step. The activation energies of Na^+ diffusion are 30±3 and 18.9±0.5 kJ mol^{-1} for particle and film diffusion, respectively.

An investigation of ion-exchange kinetics is very important for understanding the ion-exchange mechanism of hydrous metal oxides. A measurement of the isotopic exchange rate of cations between ion exchangers and solutions provides fundamental data which are useful for elucidating ion-exchange kinetics. The authors undertook radiochemical experiments to measure the Na^+ isotopic exchange rates for hydrous Nb^V and Sn^{IV} oxides. The rate controlling step of the reaction was different between two oxides; for the hydrous Nb^V oxide the exchange rate was controlled by the diffusion of Na^+ in the exchanger particles,[1] while for the hydrous Sn^{IV} oxide it was controlled by the diffusion of Na^+ in the primary particles, which were formed during the initial stage of precipitation and aggregated to form an oxide gel.[2] Further investigations, therefore, should be carried out for a variety of other hydrous metal oxides in order to understand the ion-exchange kinetics of these kinds of materials.

This paper deals with the results of radiochemical experiments undertaken to measure the isotopic exchange rate of Na^+ between hydrous Zr^{IV} oxide in the Na^+ form and aqueous solutions of sodium salts.

Experimental

Preparation of the Exchanger in the Na^+ Form Spiked with ^{22}Na. The hydrous Zr^{IV} oxide prepared by a previously recommended method[3] was classified into four particle sizes by using Japan Industrial Standard sieves; it was then converted to the H^+ form by treating it with a 0.05 mol dm^{-3} HCl solution. After being washed with water, the exchanger was air-dried and stored in a desiccator containing a saturated NH_4Cl solution (relative humidity, 79% at 25 °C). Table 1 shows the particle size and some properties of each sample. These properties were determined by the methods described in a preceding paper.[1] The exchanger in the H^+ form was then converted to the Na^+ form by treating it with solutions having the same chemical composition as those used for the rate measurement. The exchanger was then labeled with ^{22}Na by equilibrating it with a ^{22}Na solution having the same chemical composition as the above mentioned solution for longer than 2 d at room temperature. After being separated from the solution by filtration under suction, the exchanger was used for a rate measurement. The Na^+ solutions used for these procedures were prepared by desired combinations of NaCl and NaOH solutions, except for the experiments carried out in 0.01 mol dm^{-3} Na^+ solutions, where 3-(cyclohexylamino)-1-propane sulfonic acid was added as a buffer reagent. The presence of the buffer reagent was confirmed by a preliminary experiment to affect neither the Na^+ exchange capacity nor the rate of the reaction.

Measurement of the Isotopic Exchange Rate. All of the rate measurements were performed in a nitrogen atmosphere by using the same apparatus as described earlier.[4] The rate was measured in a solution with the same composition as that used for converting the exchanger to the Na^+ form; otherwise, the ion-exchange reaction would occur between H^+ and Na^+ ions, since the ion-exchange capacity for Na^+ strongly depends on the pH and on the concentration of the solution. A 0.1 gram portion of the sample was placed in a cage and immersed in 200 cm^3 of a solution of the desired composition while the cage was being rotated. By rotating the cage we can contact the exchanger particles with a rapid stream of the solution

Table 1. Particle Size and Some Properties of the Samples

Average radius	Density	Composition	Specific surface area	Specific pore volume
μm	g cm^{-3}	mol H_2O(mol ZrO_2)$^{-1}$	m^2 g^{-1}	cm^3 g^{-1}
171±5	2.51±0.03	—	—	0.12±0.01
125±4	—	3.66±0.04	288±2	—
88±1	—	—	—	—
56±3	2.48±0.04	—	—	0.10±0.01

with a flow rate determined by the revolution rate, and mix the solution to keep it homogeneous. The frequency of revolution was measured with a Yokogawa, Model 2607, phototachometer. The solution had been adjusted in advance to a constant temperature within ±0.1 °C. Aliquots of the solution (0.2 cm^3) were taken out at appropriate time intervals in order to measure the radioactivity with a well-type NaI(Tl)-scintillation counter (Aroka Model ARC-361). The time of the contact of the exchanger with the solution was taken as the elapsed time between immersing the cage and withdrawing an aliquot of the solution. The fractional attainment of equilibrium $F=Q_t/Q_\infty$, was calculated from these results; here, Q_t is the total radioactivity of the solution at time t and Q_∞ at $t=\infty$. Q_∞ was calculated using $Q_\infty=Q_iM/(M+m)$, where Q_i is the initial total radioactivity of the exchanger, and m and M the total amounts of Na^+ in the exchanger and in the solution, respectively. Although the rate was measured by a batch method, the infinite solution-volume approximation was closely obeyed under the present experimental conditions; the ratio of the total amount of Na^+ in the exchanger to that in solution was less than 0.02, unless as otherwise noted.

Results and Discussion

The fractional pore volume of the hydrous Zr^{IV} oxide was found to be 0.28±0.02 on the basis of the density and the pore volume of the material (Table 1). Figure 1 shows the pore-size distribution; no significant difference was observed between samples with different particle radii. As the diameters of a large majority of the pores are around twice as large as those of hydrated Na^+ ions (reported to be 1.2 to 1.4 nm[5]), the ions (unhydrated or hydrated) can move fast along the pores in the hydrous Zr^{IV} oxide. Since the pores, functioning as the main paths of the ions, occupy a large fraction of the total volume, the particles of hydrous Zr^{IV} oxide can be regarded as being homogeneous from the standpoint of kinetics.

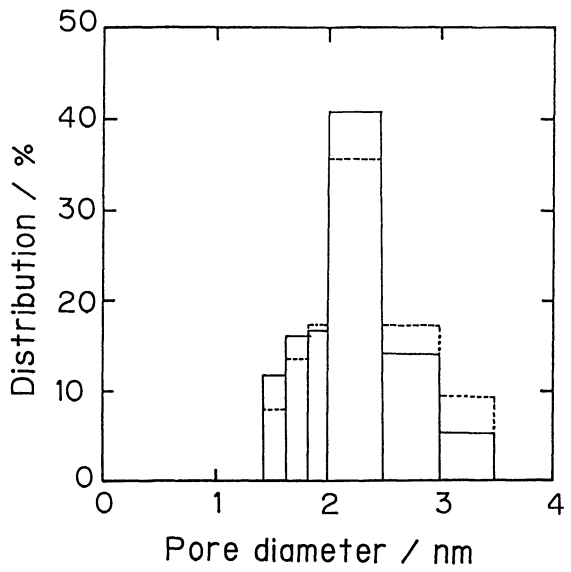

Fig. 1. Pore size distribution.
Particle radius, ----: 171 μm, ——: 125 μm.

When the isotopic exchange rate is controlled by the diffusion of ions in homogeneous spherical exchangers immersed in a well-stirred solution of approximately infinite volume (particle diffusion), the fractional attainment of equilibrium (F) can be obtained by solving the equation,[6]

$$F=1-\frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}\exp(-Bn^2t), \tag{1}$$

where

$$B=\pi^2\,\bar{D}/r^2, \tag{2}$$

$\bar{D}$ is the diffusion coefficient of the ions in the exchanger, and r the radius of the particles. When F is less than about 0.3, Eq. 1 can be approximated by a simpler form,[7]

$$F=\frac{6}{r}\left(\frac{\bar{D}t}{\pi}\right)^{1/2}, \tag{3}$$

which holds to a fairly good approximation. A plot of F against the square root of the contact time, therefore, must give a straight line passing through the point of origin in the region of F less than 0.3.

When F is smaller than 0.85, the Bt values can be calculated to a fairly good approximation from the measured values of F by using an equation derived by Reichenberg,[8]

$$Bt=2-\frac{\pi^2}{3}F-2\pi\left(1-\frac{\pi}{3}F\right)^{1/2}, \tag{4}$$

In this case, a plot of Bt against t gives a straight line passing through the point of origin.

When the rate is controlled by the diffusion of the ions in the liquid film on the surface of the particles (film diffusion), F is given by

$$F=1-\exp\left(-\frac{3DCt}{r\delta\bar{C}}\right) \tag{5}$$

under infinite solution-volume conditions. D is the Na^+ diffusion coefficient in the solution, C and $\bar{C}$ the concentration of Na^+ in the solution and that in the exchanger, respectively, and δ the film thickness.[6]

Span et al. and Tsai analyzed the ion-exchange rates in the case where the diffusion of ions was about equally fast in the exchanger particles and in the film.[9,10] They suggested that any decrease in the product of $(\bar{C}/C)\times(\bar{D}/D)\times(\delta/r)$ favored particle diffusion over film diffusion control; the contribution of these processes to the overall rate can be judged according to the manner of deviation from linearity between F and $\sqrt{t}$ or between $-\log(1-F)$ and t.

Figure 2 shows the effect of the frequency of revolution of the cage on the rate of the isotopic exchange between the samples with an average radius 171 μm and 0.1 mol dm^{-3} Na^+ solutions at pH 12. The rate increased with the revolution frequency up to 1310 min^{-1}, wherefrom the linearity between F and $\sqrt{t}$ held during the initial stage of the reaction. This fact indi-

cates that the exchange rate is controlled by Na^+ diffusion in the exchanger particles (Eq. 3). When the revolution rate was slower than 1160 min^{-1}, the plot of F against $\sqrt{t}$ became sigmoid. Hence, the rate cannot be controlled solely by particle diffusion. When the same data were plotted with t as the abscissa against

−log (1−F) as the ordinate (Fig. 3), a linear relation was obtained in the region of larger F at a revolution rate slower than 1160 min^{-1}. The linear part broadened, and its slope decreased with decreasing revolution rate of the cage. This observation suggests that an increased contribution of film diffusion to the overall exchange rate is due to an increase in δ. The rate of Na^+ diffusion in the film, however, does not entirely control the exchange rate, even at such a slow revolution rate as 660 min^{-1}, since the shoulder is observed during the early stage of the exchange reaction.

Figure 4 shows the effect of particle size on the rate in a 0.1 mol dm^{-3} Na^+ solution at a revolution frequency of 1310 min^{-1}. The overall rate increased with decreasing particle size. The relation between F and $\sqrt{t}$, initially linear at 171 μm, deviated from linearity and became sigmoid when smaller particles were used. This shows the increasing contribution of film diffusion to the overall rate with decreasing particle size, since higher δ/r favors film diffusion control. In order to realize pure particle diffusion control, particles as large as those with a radius of 171 μm should be used, even when the revolution rate of the cage is very high.

Figure 5 shows the influence of the Na^+ concentration on the exchange rate at a high revolution frequency of 1310 min^{-1}. The rate was independent of the concentration of the solutions. This fact also suggests particle diffusion control, since Eq. 1 does not involve term C.

The effect of temperature on the isotopic exchange rate was then studied under the conditions which were required to realize pure particle diffusion control. The results are shown in Fig. 6, which indicate that the rate increases with temperature. The $\bar{D}$ values were then

evaluated by means of Eq. 2 from the slopes of these lines and the average radius of the particles (Table 2). When $\ln \overline{D}$ was plotted against $1/T$, good linearity was obtained. From the Arrhenius equation, $\overline{D}=\overline{D}_o \exp(-E_a/RT)$, the activation energy, E_a, and the constant, $\overline{D}_o$, were determined. The activation energy (30±3 kJ mol^{-1}) is similar to that reported for Na^+ diffusion in other hydrous metal oxides (35±2 and 27±4 kJ mol^{-1}, respectively, in the hydrous Sn^{IV} oxide and in the hydrous Nb^V oxide) and in a sulfonated polystyrene type resin (35 kJ mol^{-1}).[1,2,11] The larger $\overline{D}$ in hydrous Zr^{IV} oxide, as compared with that in other kinds of exchangers, therefore, is due to a larger $\overline{D}_o$. According to Eyring, this means either a large distance between the equilibrium positions in the process of diffusion or activation accompanied by an increase in entropy, or both.[12]

Table 2. Effect of Temperature on the Na^+ Particle Diffusion Coefficients

Na^+ concentration in solutions/mol dm^{-3}, ○: 0.10; □: 1.0.

Figure 7 shows the influence of the Na^+ concentration on the exchange rate at a slow revolution rate of the cage (660 min^{-1}). Dissimilarly to the case of a higher revolution rate, the exchange rate increased with Na^+ concentration in solution. In the region where $-\log(1-F)$ is linear with t and the film diffusion controls the rate, the rate increases with the ratio $C/\overline{C}$, as can be

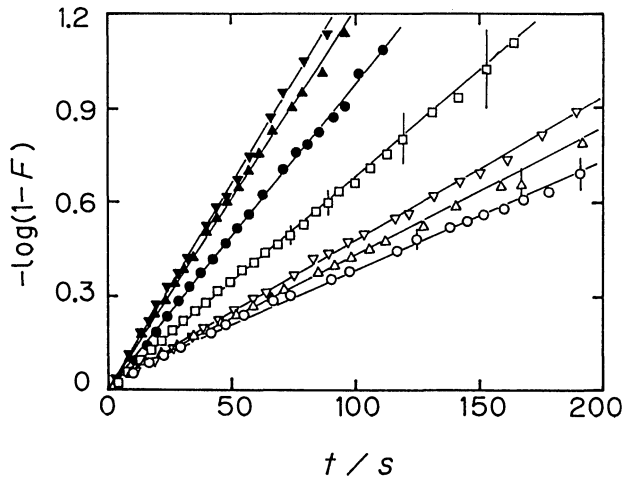

Fig. 8. Effect of temperature on the isotopic exchange rates (film diffusion).

expected from Eq. 5. The Na^+ exchange capacity of hydrous Zr^{IV} oxide at pH 12 increased from 0.67 mmol g^{-1} in a 0.1 mol dm^{-3} Na^+ solution to 0.99 mmol g^{-1} in a 1 mol dm^{-3} Na^+ solution. The concentration dependence of the exchange rate suggests that film diffusion mainly controls the rate at a low flow rate of the solution through the exchanger particles.

In order to realize pure film-diffusion control, the experimental conditions should be such as those to minimize the value of $C/\overline{C}$ and the flow rate of the solution through the exchanger particles. The $C/\overline{C}$ ratio determined experimentally at pH 10 to 12 decreased with decreasing Na^+ concentration, reaching a minimum at 2×10^{-3} mol dm^{-3}, wherefrom it increased due to an abrupt decrease in $\overline{C}$. At this concentration, however, the infinite solution volume approximation is not obeyed in the present experimental conditions. The authors, therefore, adopted a 0.01 mol dm^{-3} Na^+ solution with pH 11.0 as a concentration to obtain a $C/\overline{C}$ as small as possible under the infinite solution volume condition. The revolution rate of the cage was set to 104±4 min^{-1}, and supplementary agitation was made by using a magnetic stirrer to keep the surrounding solution homogeneous.

The isotopic exchange rate at varying temperatures was measured as is shown in Fig. 8. The plots of $-\log(1-F)$ vs. t, except for smaller particles at 9.9 °C, were straight lines passing through the point of origin, indicating pure film diffusion control. Furthermore, the exchange rate increased with temperature and with decreasing particle size. The activation energy of Na^+ diffusion in the film (E_a') can be determined from the Arrhenius plot, since all parameters, except D, in the exponential term in Eq. 5 can be assumed to be constant over the limited temperature range studied; E_a'=18.9±0.6 and 18.8±0.5 kJ mol^{-1}, respectively, for the exchangers with r=171 and 125 μm. They agreed well with the activation energy reported for the Na^+ diffusion coefficient in a NaCl solution (18.4 kJ mol^{-1}).[13] These results indicate that the rate of Na^+ diffusion in the film governs the rate of Na^+ isotopic exchange between hydrous Zr^{IV} oxide and 0.01 mol dm^{-3} Na^+ solutions. The film thickness (δ) was estimated from the slopes of the lines in Fig. 8 by using D values which were calculated from Robinson's data.[13] In this evaluation, the exchange capacity expressed volumetrically (mmol Na^+ cm^{-3}) was used. The film thickness was 2.3×10^{-3} cm at r=171 μm and 1.6×10^{-3} cm at r=125 μm, which were compatible with the values estimated from a hydrodynamic measurement (10^{-3} to 10^{-2} cm).[6] The increase in δ with particle radius is consistent with both the theoretical and empirical relations between the film thickness and the dimensionless hydrodynamic numbers.[6]

(Received August 7, 1991)

The thermochemical changes in coordination structure of diaquabis(*N,N*- or *N,N'*-dialkylethylenediamine)nickel(II) complexes ($[Ni(H_2O)_2(diamine)_2]X_2 \cdot nH_2O$) were reinvestigated by means of TG-DTA and electronic spectroscopy at room and elevated temperatures, where diamine is *N,N*- (or *N,N'*)-dimethylethylenediamine (*NN*- or *NN'*-dmen) or *N,N*-(or *N,N'*)-diethylethylenediamine (*NN*- or *NN'*-deen); X is Cl^-, Br^-, I^-, or NO_3^-; *n* is 0, 1, 2, or 3. The diaqua complexes prepared were all trans except for *cis*-$[Ni(H_2O)_2(NN\text{-dmen})_2]I_2$. The trans complexes with the symmetric (*N,N'*-dialkylsubstituted) diamines brought about a deaquation-anation upon heating, retaining the original trans configuration, while those with the asymmetric (*N,N*-dialkylsubstituted) diamines transformed into the cis complexes. In the case of the *NN*-dmen complexes, *cis*-halogenoaqua species were isolated as a stable intermediate during the thermal reactions. The complex nitrates changed to *trans*-dinitrato or *cis*-mononitrato species depending upon the diamines. The effects of the *N*-substituents in the diamines and of the anions on the patterns of thermal reactions were also discussed.

Nickel(II) complexes provide various informative examples of thermochromism in solid phase, which are mainly associated with a change in coordination geometry.[1] However, systematic knowledge is still lacking for the factors which govern the preference of particular coordination geometries at different temperatures.

We have studied the coordination structures of many bis(*N*- or *C*-substituted ethylenediamine)nickel(II) complexes and the products of their solid-phase thermal reactions, and the effects of *N*- or *C*-substituent group(s) upon their structural changes during the thermal treatment.[2–6] Our previous reports[2,3] clarified that the thermal reactions of the complexes containing *N,N*- or *N,N'*-dimethylethylenediamine (*NN*- or *NN'*-dmen) and *N,N*- or *N,N'*-diethylethylenediamine (*NN*- or *NN'*-deen) can be classified into either deaquation-anation(1) or deaquation(2) as shown below:

$$[Ni(H_2O)_2(diamine)_2]X_2\ (Oh) \xrightarrow{-2H_2O} [NiX_2(diamine)_2]\ (Oh') \quad (1)$$

$$[Ni(H_2O)_2(diamine)_2]X_2\ (Oh) \xrightarrow{-2H_2O} [Ni(diamine)_2]X_2\ (Sp) \quad (2)$$

where Oh (or Oh') and Sp represent octahedral and square planar species, respectively. Unfortunately, we were not able to decide whether the Oh and Oh' complexes are cis or trans in spite that the decision is fundamental for understanding the details of their thermal reactions.

The present study was therefore undertaken to reinvestigate the thermal reactions of the nickel(II) complexes containing the above four diamines especially for clarifying the details of cis-trans isomerism and the effects of *N*-substituents on the structural changes during the thermal reactions.

Experimental

Materials. Four diamines (*NN*-dmen, *NN'*-dmen, *NN*-deen, and *NN'*-deen) of commercial reagent grade were used without further purification. The complexes, $[Ni(H_2O)_2(diamine)_2]X_2 \cdot nH_2O$ (X=Cl^-, Br^-, I^-, or NO_3^-; *n*=0, 1, 2, or 3), were prepared by the known methods.[7,8] The *NN*-deen complexes, $[Ni(NN\text{-deen})_2]X_2$ (X=I^- and NO_3^-), were exclusively isolated as anhydrous square planar complexes.

Measurements. Electronic spectra in solid phase were measured by the diffuse reflectance method with a Hitachi U-3400 spectrophotometer. The spectra at elevated temperatures were monitored by use of a hand-made heating cell, which was set up on the apparatus and was controlled by a REX-C72 temperature controller equipped with a copper–constantan thermocouple. IR spectra were recorded on a JASCO A-3 spectrophotometer in Nujol mulls. The standardized cell for the apparatus was used for the IR spectral measurements at elevated temperatures. The measurements of TG-DTA and DSC were carried out with a Seiko TA station SSC 5000 apparatus under a constant flow of nitrogen (0.2 $dm^3\ min^{-1}$ for TG-DTA; 0.03 $dm^3\ min^{-1}$ for DSC). Samples (10—20 mg) were triturated into fine powders beforehand, and were heated at the rate of 2.0 °C min^{-1}.

Results

Structures of $[Ni(H_2O)_2(diamine)_2]X_2 \cdot nH_2O$. Diagnosis of cis and trans isomers of the bis(diamine)nickel(II) complexes has already been established by means of electronic spectroscopy.[9–11] The energy levels derived from F and P terms of a d^8 system (Ni^{2+}) in ligand fields of different symmetries (Oh, D_{4h}, and C_{2v}) are shown in Fig. 1, along with the rough sketches of the typical electronic spectra of *trans*- and *cis*-$[NiX_2(diamine)_2]$. In a D_{4h} system, three or sometimes four bands are practically observed in visible-near IR region. The band due to $^3B_{1g} \rightarrow {}^3E_g$ (from $^3T_{1g}(F)$) transition is

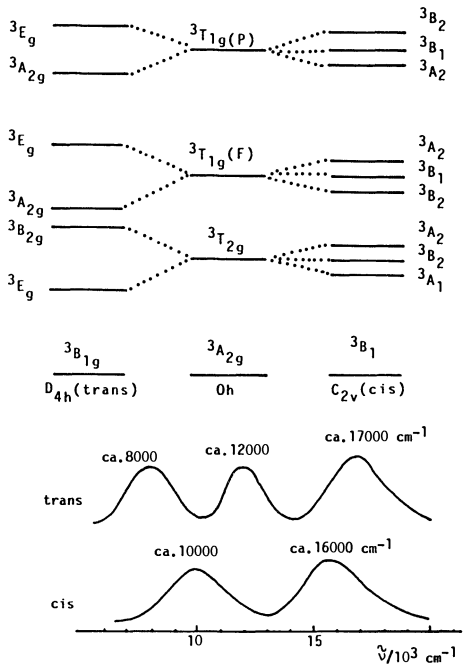

Fig. 1. Top: Energy level diagrams of a d^8 system in ligand fields of different symmetries. Bottom: Rough skeches of the electronic spectra of *trans*- and *cis*- [NiX_2(diamine)$_2$].

normally observed at ca. 17000 cm^{-1}. The band of $^3B_{1g}\rightarrow{}^3A_{2g}$ (from $^3T_{1g}$(F)) transition seems to lie very close to that of $^3B_{1g}\rightarrow{}^3B_{2g}$ transition, giving one or two peaks around ca. 12000 cm^{-1}. The band at ca. 8000 cm^{-1} is assigned to $^3B_{1g}\rightarrow{}^3E_g$ transition. On the other hand, in a C_{2v} system, the splittings of the respective terms are close so that two rather broad bands are observed at ca. 16000 cm^{-1} and ca. 10000 cm^{-1}.

Table 1 summarizes the spectral data of the diaqua complexes and the configurational assignments along with those of their thermal reaction products. At room temperature, only [$Ni(H_2O)_2$(*NN*-dmen)$_2$]I_2 gives apparently a single band in near IR region, indicating that the complex belongs to cis configuration. All the other complexes show spectral patterns characteristic of trans geometry which gives three or four bands due to d–d transitions.

Chaudhuri et al. have pointed out[12] that the complex chloride and bromide with *NN*-dmen prepared by the same methods as ours are not the diaqua species, but *trans*-halogenoaqua ones, *trans*-[$NiX(H_2O)$(*NN*-dmen)$_2$]$X\cdot nH_2O$ (X=Cl or Br), because the complexes behave as an 1 : 1 electrolyte in methanol (Λ_m=70 and 80 Ω^{-1} cm^2 dm^{-3} for the chloride and bromide, respec-

tively). Indeed, our complex chloride with the same composition gave nearly the same molar conductivity (92 $\Omega^{-1}\,cm^2\,dm^{-3}$). However, the X-ray single-crystal analyses for the complex chloride[13] have revealed that the two water molecules undoubtedly occupy trans position in the octahedral environment. The low value in molar conductivity may be due to the contribution of chloroaqua species which are formed by deaquation-anation in methanol, because the violet powder slightly changed towards blue on dissolution, giving the spectrum whose peak maxima shift towards the red compared with that of the diaqua complex in solid state.

Thermal Reactions of Complex Halides Containing Symmetric Diamines. Table 2 summarizes the results of TG-DTA and the color changes upon dehydration of all the complexes. The TG-DTA curve of *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2]Cl_2 \cdot 3H_2O$ is shown in Fig. 2. The complex loses the five moles of waters (three lattice waters plus two coordinated waters) in one step at 25—75 °C, changing to the anhydrous complex. As shown in Fig. 3, the spectral pattern of the anhydrous product remains nearly unchanged in comparison with that of the original complex except that the red shifts of the

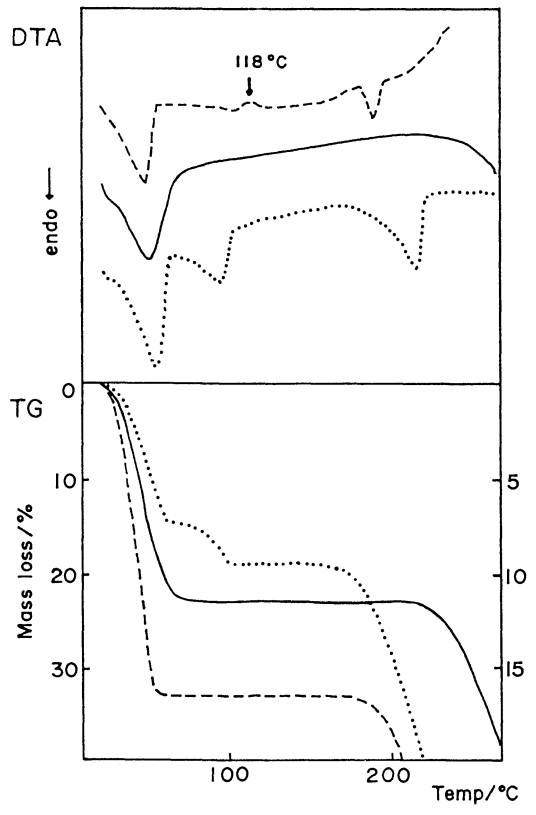

Fig. 2. TG-DTA curves for *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2]Cl_2 \cdot 3H_2O$ (——), *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ (·····), and *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2](NO_3)_2 \cdot 2H_2O$ (----). The TG data of the last complex is illustrated against the right-hand axis.

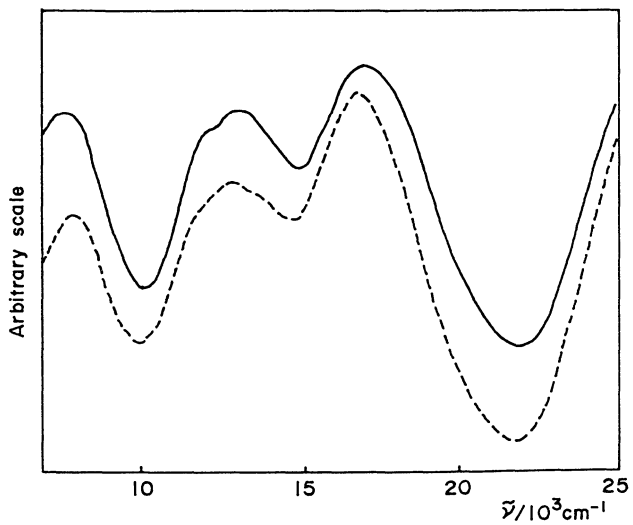

Fig. 3. Electronic spectra of *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2]Cl_2 \cdot 3H_2O$ (——) and the product obtained by heating the *trans*-complex at 110 °C (----).

peak maxima take place because of the replacement of axial ligands ($H_2O \rightarrow Cl$). The remaining five complex halides with *NN'*-dmen and *NN'*-deen also liberate their waters below 100 °C, giving the stable anhydrous products with color changes, as summarized in Table 2. These products show three or four bands in their electronic spectra, indicating that the *trans*-octahedral configurations are still retained upon dehydration. It can thus be concluded that a simple deaquation-anation (*trans*-diaqua→*trans*-dianiono) occurs in all the complex halides with the symmetric diamines, retaining the original geometries.

Thermal Reactions of Complex Halides Containing Asymmetric Diamines. The *NN*-dmen or *NN*-deen complexes showed various patterns of thermal reactions depending on the anions. The TG-DTA curve of *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ (Fig. 2) indicates that the complex dehydrates in two-steps. The violet diaqua complex loses three moles of water (two lattice waters plus one coordinated water) to become blue at 25—60 °C and then blue-green at 60—100 °C with evolution of the remaining one mole of coordinated water.

Figure 4 shows the electronic spectra of *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$, and the products obtained by heating the trans complex at 60 °C and 95 °C. As seen from the figure, both products display a spectral pattern characteristic of cis configuration. The corresponding bromide gives almost the same results in TG-DTA and spectral changes (Table 1). Accordingly, thermal reactions of the two complexes may proceed as follows: *trans*-diaqua→*cis*-halogenoaqua→*cis*-dihalogeno species.[14]

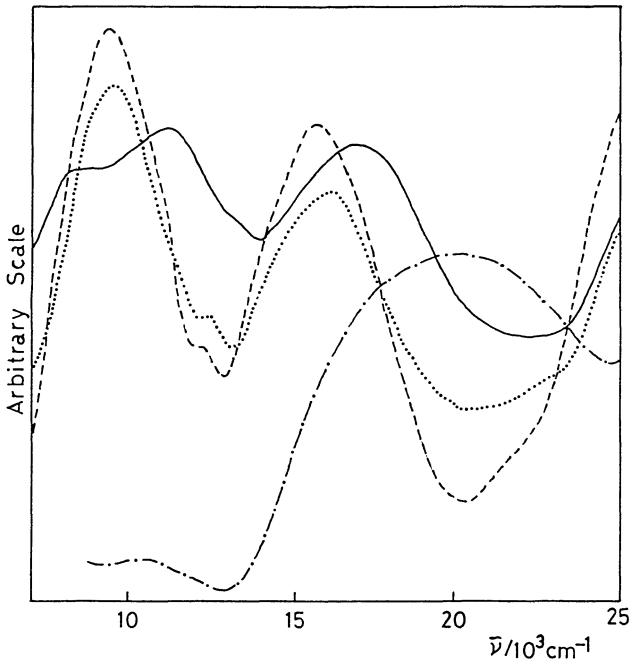

Fig. 4. Electronic spectra of *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ (——), the products obtained by heating the *trans*-complex at 60 °C (·····) and 95 °C (----), and the anhydrous product obtained by heating *cis*-$[Ni(H_2O)_2(NN\text{-dmen})_2]I_2$ at 90 °C (— - —).

The blue iodide isolated as a *cis*-diaqua complex changes to orange species after thermal deaquation. The orange product obtained at 90 °C is diamagnetic and gives a broad band at ca. 20000 cm^{-1} in its spectrum (Fig. 4) assignable to $^1A_{1g} \rightarrow {}^1A_{2g}$ transition of a square planar structure.[15]

In the *NN*-deen complexes, the chloride changed to *cis*-dichloro complex at 100 °C (Table 1) with no formation of chloroaqua species. The bromide became diamagnetic square planar upon dehydration, and the iodide was anhydrous square planar even at room temperature.

Thermal Reactions of Complex Nitrates. The complex nitrate with *NN'*-deen undergoes dehydration in one-step. As seen from Table 1, the anhydrous product exhibits two bands at 10100 cm^{-1} and 17000 cm^{-1}, indicating that trans-to-cis configurational change takes place simultaneously with deaquation-anation. The coordination mode of nitrate ion was also determined IR spectrophotometrically. It is well-known that, in general, a NO_3^- ion in a metal complex gives rise to a weak combination band in the range of 1700—1800 cm^{-1}.[10,15]. In the present case, the diaqua complex shows a single peak at 1748 cm^{-1} assignable to the free NO_3^- ions. This peak splits into three peaks at 1718, 1750, and 1767 cm^{-1} in the spectrum at 100 °C. The peak at 1750 cm^{-1} indicates that a part of the NO_3^- ions remains uncoordinated, while the large separation (49 cm^{-1}) between the other two peaks indicates that the coordinated NO_3^- ion functions as a bidentate ligand. This reaction can thus be understood as shown below:

$$trans\text{-}[Ni(H_2O)_2(NN\text{-deen})_2](NO_3)_2 \longrightarrow cis\text{-}[Ni(NO_3)(NN\text{-deen})_2](NO_3)$$

The TG-DTA curve for *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2](NO_3)_2 \cdot 2H_2O$ (Fig. 2) shows that the complex gives a small but clear exothermic peak at 118 °C with no mass loss after dehydration. The complex changed in color from blue-violet to violet before and after the peak. The enthalpy change of the reaction was estimated to be −6.4 kJ mol^{-1} by means of DSC measurement.[17] The spectral differences between the blue-violet and violet products (Table 1) indicate that this exothermic peak is associated with the cis-to-trans isomerization. The IR band at 1757 cm^{-1} assignable to the free NO_3^- ions of the diaqua complex splits into three peaks at 1718, 1747, and 1767 cm^{-1} in the spectrum at 60 °C (just after dehydration): the peak at 1747 cm^{-1} is due to the free NO_3^- ions, while the other two peaks with a separation of 49 cm^{-1} show the presence of bidentate NO_3^- ions. On the other hand, the spectrum at 130 °C (after the exothermic DTA peak) is split into two peaks with a small separation (16 cm^{-1}), showing that the two NO_3^- ions are coordinated as monodentate ligands. These results are consistent with the configu-

rational assignments from the electronic spectra. This reaction can thus be described as follows: *trans*-$[Ni(H_2O)_2(NN'\text{-dmen})_2](NO_3)_2 \cdot 2H_2O$ first undergoes dehydration-anation accompanied by a trans-to-cis configurational change, yielding *cis*-$[Ni(NO_3)(NN'\text{-dmen})_2](NO_3)$, which then isomerizes to *trans*-$[Ni(NO_3)_2(NN'\text{-dmen})_2]$ at 118 °C. On the other hand, the *NN*-dmen complex shows a simple deaquation-anation, retaining the original trans configuration (Table 1).[12]

The corresponding ethylenediamine (en) complex, *trans*-$[Ni(H_2O)_2(en)_2](NO_3)_2$, was also studied, the results of which are contained in Tables 1 and 2. This complex first transformed into the violet *trans*-dinitrato complex upon deaquation-anation. Then the *trans*-dinitrato complex isomerized to blue-violet *cis*-mononitrato species at 170 °C, which is in contrast to the above case of the *NN'*-dmen complex. This isomerization was endothermic and reversible.

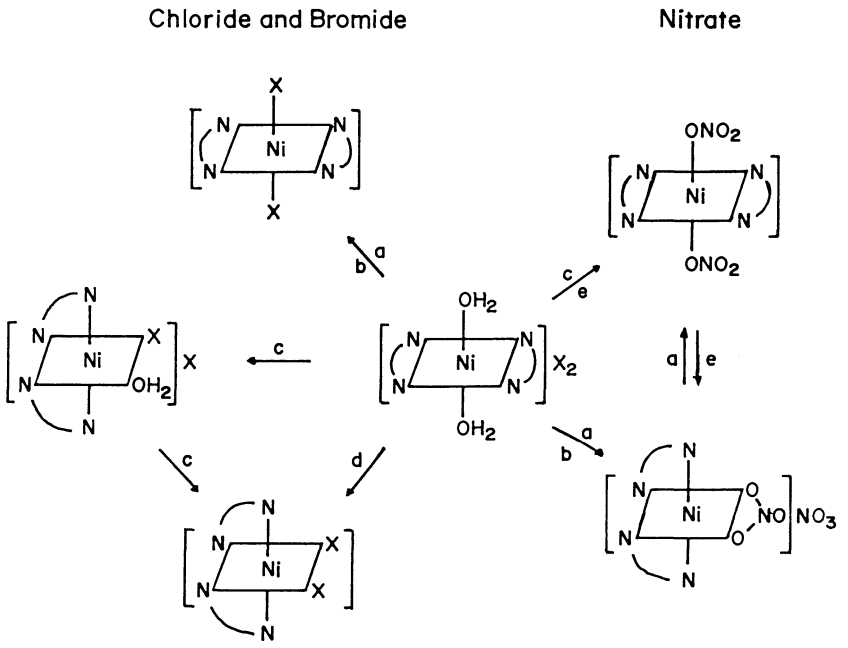
Discussion

Scheme 1 summarizes the thermal reaction pathways of the complex chlorides, bromides, and nitrates clarified in this work. The thermal behaviors of the complex nitrates are quite different from those of the halides, and the reactions of the complexes with the symmetric diamines are different from those of the asymmetric ones. It is thus clear that the preferred geometry of a complex depends on the combination of diamine and anion, and either trans or cis configuration is strongly stabilized for a particular combination of ligands.[18]

In the case of halides, the *NN'*-dmen and *NN'*-deen complexes undergo dehydration-anation, during which their trans configurations are retained; the anation takes place at the axial positions which are occupied by the water molecules before heating. On the other hand, the stable halogenoaqua species can be isolated for the complex halides of *NN*-dmen, since two moles of coordinated waters are liberated one by one in two separate steps. Another significant feature of the complexes with asymmetric diamines is that cis configuration is favored in both halogenoaqua and dihalogeno complexes.

Such peculiar reactions of the asymmetric diamine complexes must be associated with the structures of starting diaqua complexes. According to the X-ray structural study[13] on *trans*-$[Ni(H_2O)_2(NN\text{-dmen})_2]Cl_2 \cdot 2H_2O$ and *trans*-$[Ni(H_2O)_2(NN\text{-deen})_2]Cl_2$, both complexes take tetragonally distorted octahedrons with four in-plane neighbors ($N(H_2)N(H_2)OO$) and two remote axial ones ($N(R_2)N(R_2)$):[19] i.e., the two alkylated nitrogen atoms occupy axial sites apart from each other to minimize their mutual steric hindrance and the distances of $Ni\text{–}N(R)_2$ bonds are remarkably longer than the other. These structural results are obviously different from those of the symmetric diamine complexes with the stronger Ni–NH(R) bonds.[20,21] Thus, it appears reasonable to assume that, in the case of the complexes with asymmetric diamines, a process of the $Ni\text{–}NR_2$ bond rupture is involved in the mechanism of thermal deaquation-anation.

In the case of the nitrates, interesting thermal



Scheme 1.

cis→trans and trans→cis isomerization were observed in the anhydrous complexes with *NN'*-dmen and en, respectively. On the other hand, only the *NN*-dmen complex kept the original geometry upon dehydration and showed no isomerization after dehydration.

Ligand-Mediated Pseudohypersensitivity of Some 4f–4f Transitions in Neodymium(III) Interaction with Fluorinated Nucleic Acid Components

Sudhindra N. Misra* and Surendra B. Mehta
Chemistry Department, Bhavnagar University, Bhavnagar 364002, India
(Received November 19, 1990)

Absorption difference and comparative absorption spectrophotometry of the systems containing Nd(III) and fluorinated nucleic bases (fluoroadenine, fluorocytosine, fluorothymine, and fluorouracil) and fluorinated nucleosides (fluoroadenosine, fluorocytidine, fluorothymidine, and fluorouridine) in ethyl acetate–water (90 : 10), have shown that certain 4f–4f transitions ($^4I_{9/2}\rightarrow{}^4G_{7/2}$, $^4F_{7/2}$, $^4F_{5/2}$, and $^4F_{3/2}$), which are generally considered to be insensitive, have been found to exhibit substantial sensitivity towards even minor changes in the coordination environment around neodymium(III). The observation has been referred to as "Ligand-Mediated Pseudohypersensitivity." The magnitude of various spectral parameters (energy interaction, Slater–Condon interelectronic repulsion F_k, spin–orbit interaction ξ_{4f}, nephelauxetic $\bar{\beta}$, b, δ, and Judd–Ofelt T_λ intensity and oscillator strength (P)), computed using regression analysis, has been used in exploring the degree of inner and outer sphere coordination, incidence of covalency and extent of involvement of metal 4f orbitals in bonding. The isolation of solid complexes and their characterization by elemental analysis, infrared spectral, and Karl Fischer titration suggested octa and nona coordinated environment around neodymium and some probable structures for these complexes have been proposed.

Complexation of lanthanoids brings about drastic changes in the intensity of certain transitions[1] which are characterized by the large values of $U^{(2)}$ matrix element and exhibit substantial increase and variation of Judd[2]–Ofelt[3] T_2 parameter while the intensities of other 4f–4f transitions are almost unaffected.[4–7] Such transitions called hypersensitive transitions and the shape, energy, and oscillator strength of these transitions have successfully been used to extract information about the degree of outer and inner sphere coordination and extent of involvement of metal 4f orbital,[9] in identifying binding sites of the biomolecules and in following the biochemical reactions involving calcium.[10,11]

During the course of our work on neodymium(III) with β-diketones, diols, and 1,10-phenanthroline, we have found unusual sensitivity of some nonhypersensitive transitions like $^4I_{9/2}\rightarrow{}^4G_{7/2}$, $^4F_{7/2}$, $^4F_{5/2}$, and $^4F_{3/2}$. These transitions were earlier considered to be almost insensitive[1–9] towards coordination changes but in this present investigation these transitions have been found to show substantial sensitivity towards even minor changes in the immediate coordination environment around neodymium(III). The name "Ligand-Mediated Pseudohypersensitivity" has been given for this observation because the coordinating ability, denticity, normalized bite, size of chelate ring of the different ligands affect the sensitivity of these nonhypersensitive transitions to different extent.[12]

The present communication describes the absorption difference, comparative absorption spectrophotometry along with the variation of various spectral parameters in exhibition of Ligand-Mediated Pseudohypersensitivity of $^4I_{9/2}\rightarrow{}^4G_{7/2}$, $^4F_{7/2}$, $^4F_{5/2}$, and $^4F_{3/2}$ using the interaction of Nd(III) with fluorinated nucleic bases like fluoroadenine, fluorocytosine, fluorouracil, and fluorothymine and fluorinated nucleosides, fluoroadenosine, fluorocytidine, fluorouridine, and fluorothymidine.

To support the absorption spectral studies, the neodymium(III) complexes with these fluorinated biomolecules have been isolated and characterized by analysis and IR. Peliminary ultrasonic studies have shown the ligating behavior of these biomolecules in aqueous as well as semi-nonaqueous (50 : 50 DMF–water) media. Probable structures have been proposed on the findings of the present study.

Experimental

Neodymium(III) oxide of 99.99% purity from Indian Rare Earths Ltd., India, was converted into nitrate and then was used for synthesis and spectral studies. Fluorocytosine, fluorouridine, and fluorocytidine were prepared by the methods described.[13] Fluoroadenosine and fluorothymidine were prepared by selective fluorination of adenosine and thymidine by xenon difluoride in genetron.

Absorption spectra in the visible region was recorded on Shimadzu FS 260 and Beckman DU-7 spectrophotometer. The hypersensitive $^4I_{9/2}\rightarrow{}^4G_{5/2}$ and pseudohypersensitive $^4I_{9/2}\rightarrow{}^4G_{7/2}$, $^4F_{7/2}$, $^4F_{5/2}$, $^4F_{3/2}$ were resolved and recorded on expanded scale and were used as Marker bands.

Preparation Complexes of Fluorouracil Fluorocytosine, and Fluorothymine with Neodymium(III). The reactions of neodymium(III) nitrate (0.001 M, 1M=1 mol dm^{-3}) and fluorinated nucleic base (0.005 M) in ethyl acetate and acetone (50 : 50) mixture with constant stirring in inert atmosphere for several hours, resulted in the separation of pinkish microcrystalline solids corresponding to the formula; $[Nd(base)_4\cdot(H_2O)_4]^{3+}$ established after elemental analysis, and analysis of water by Karl Fischer titration.

Preparation of Complexes of Fluorouridine, Fluorocytidine, Fluorothymidine, and Fluoroadenosine. The solution of neodymium(III) nitrate (0.002 M) was added to the ethyl acetate–acetone mixture containing 0.005 M nucleoside and was stirred for 6 h at 20 °C. The reaction mixture was then

placed in a vacuum desiccator and after four days, the crystalline complex slowly separated out from the liquor. These crystals were washed with ethyl acetate and dried in desiccator. The analysis of the product suggested the stoichiometry: $[Nd(nucleoside)_2 \cdot (H_2O)_3]^{3+}$. The amount of coordinated water was estimated in the complex by Karl Fischer titration. The reaction involving fluoroadenosine yielded a mixture of 1:2 and 1:3 products. These could not be separated effectively in pure state. The analytical data showed that observed and calculated percentage of Nd, C, N, H_2O of the neodymium(III) complexes with the fluorinated nucleic bases and fluorinated nucleosides tally within ±2%. The analytical data can be provided by the author on request.

Results and Discussion

The $^4I_{9/2} \rightarrow {}^4G_{5/2}$ transition of Nd(III) is universally accepted as hypersensitive transition as it obeys selection rules for quadrupole transitions and undergoes very high intensification on complexation.[1,8,9,12,14,15] Small changes in the immediate coordination environment around Nd(III) bring about wide variation of oscillator strength. Contrary to this the intensities of nonhypersensitive transitions are reported either vary slightly or not changed at all or sometimes decrease.[4-6] Iftikar[15] has reported a marginal increase (ca. 15%) in the oscillator strength of the nonhypersensitive transition, contrary to the several fold increase shown by hypersensitive $^4I_{9/2} \rightarrow {}^4G_{5/2}$ transition.

Table 2 clearly shows that the percentage variation of the oscillator strength of $^4I_{9/2} \rightarrow {}^4G_{7/2}, {}^4F_{7/2}, {}^4F_{5/2}, {}^4F_{3/2}$ which does not obey selection rule, yet these show significant sensitivity evidenced by large percentage variation of oscillator strength which is almost same as shown by the hypersensitive $^4I_{9/2} \rightarrow {}^4G_{5/2}$ transition. We are reporting the high sensitivity of these nonhypersensitive transitions for the first time. The name "Ligand-Mediated Pseudohypersensitivity" has been suggested for such observation. It appears that the nature of the ligand (denticity, number and coordinating power of ligating sites, degree of chelation, normalized bite of the ligand) and the nature, lability, and geometry of complex species, induce the unusual sensitivity to these nonhypersensitive transitions, Other factors may also be attributed to the enhancement and sensitivity of these transitions.

i) The second-order interactions which are two order magnitude less than the Coulombic interaction (generally ignored) may become prominent by the ligating characteristics of the coordinating molecule. This may lower the excited state of these pseudohypersensitive transitions and in consequence their transition possibility enhances.

ii) The nephelauxetic effect may induce some broadening of the bands and hence may contribute to the intensification of the bands.

iii) These transitions may be borrowing intensities from the neighboring transitions.

Really we are not in a position to give some concrete explanation for this unusual sensitivity of these nonhypersensitive f–f transitions.

Judd[2]–Ofelt[3] theory predicts that the intensity of 4f–4f transition arises principally from forced electric dipole mechanism. Thus the electric dipole oscillator strength (P) is expressed as the product of T_λ parameters and appropriate transition matrix element $U^{(\lambda)}$ at frequency of transition ν, of the transition J→J′

$$P_{e.d} = \sum_{\lambda=2,4,6} T_\lambda \nu (f^n \psi_J \| U^{(\lambda)} \| f^n \psi'_{J'})^2$$

The Judd–Ofelt intensity parameters are empirical, yet these show high sensitivity towards even minor changes in the coordination environment (T_2) and symmetry of the molecule (T_4, T_6).[16] These parameters have been widely used in the structure elucidation of lanthanoid coordination compounds both in the solid as well as in solution. The T_λ and P have also been computed by regression analysis and are summarized in Table 2.

The energy of a 4f–4f transition comprises of two major components: the Coulombic (represented by inter-electronic repulsion F_k Slater Condon parameter) and spin orbit (Lande-ξ_{4f}) components (Table 1). The complexation of lanthanoids brings about lowering of these components resulting in the phenomenon of nephelauxetic effect represented by nephelauxetic ratio ($\bar{\beta}$):

$$\beta_1 = \frac{F_k{}^c}{F_k{}^f};\ \beta_2 = \frac{\xi_{4f}{}^c}{\xi_{4f}{}^f};\ \bar{\beta} = \frac{\beta_1 + \beta_2}{2}$$

$$b^{1/2} = \left[\frac{1-\bar{\beta}}{2}\right]^{1/2};\ \delta = \left[\frac{1-\bar{\beta}}{\bar{\beta}}\right] \times 100$$

Bonding (b) and percentage covalency parameter (δ) which are related to nephelauxtic ratio ($\bar{\beta}$) are also used to describe the structural features of a lanthanoid complex. The significance and evaluation of these (F_k, $\bar{\beta}$, δ, ξ_{4f}, and b) parameters have been discussed in earlier publications.[12,14]

Peacock[4] has shown that the inclusion of covalency can affect the angular part of the 4f wave function and thus can affect preferentially T_2 parameter. Writing ligand wave function, as the sum of the renormalized radial wave function, multiplied with spherical harmonics with the origin at central metal ion,

$$\Phi_{Ligand} = \sum_k \bar{\alpha}_{km} \sum_m Y_{km} \text{ with } k, \text{ odd},$$

while metal wave function can be written as the sum of the original 4f wave function and ligand wave function weighted by mixing coefficient (b) also known as bonding parameter and related to nephelauxetic effect.

$$\Phi_{Metal} = (1-b)^{1/2} |4f\rangle - b^{1/2} |\Phi_{Ligand}\rangle$$

Hence the relevant term which can affect T_λ parameter is b. Generally covalency increase is accompanied by increase in T_λ parameter. Nephelauxetic effect which is caused by the lowering of the excited state, of the metal ion by surrounding ligand field, is influenced by the asymmetric part of the crystal field. The significant

changes in the T_λ parameters in absence of significant nephelauxetic effect (as observed in our system) show that the unsymmetrical part of the field has major influence on these (T_λ) parameters. The chromophore present in these complexes is identical, while changes are due to the attachment of functional groups which are not directly involved in the metal ligand bonding. These appear to be most probably responsible for the distortion of the oxygen around neodymium lowering the site symmetry and thus increasing the probability of 4f–4f transition. Using Judd–Ofelt theory, above assumption can be explained where the expression for T_λ parameters is

$$T_\lambda = \chi\left[\frac{8\pi^2 m}{3h}\right](2\lambda+1)\sum_{t,p}A_{t,p}|^2\xi^2(t,\lambda)>$$

In the above equation $A_{t,p}$ (t, odd) are odd parity term in crystal field expansion depending upon the site symmetry of the complex. The quantity $\xi^2(t, \lambda)$ contains integral involving radial part of the wave function and excited parity electronic wave function measuring the symmetric part of the ligand field (amount of covalency) and does not vary appreciably in Nd(III) complexes with these fluorinated biomolecules. However, T_λ prameters vary substantially with the change and stoichiometry of the ligands. Hence the quantity $\xi^2(t, \lambda)$ which is not dependent on the nature and stoichiometry of the ligand is not the factor causing change in T_λ. Thus the remaining part of the equation ($A_{t,p}$) the asymmetric part of the ligand field expansion appears to be responsible for the variation of T_λ parameter. These remaining quantities arise therefore from the distortion of the geometry around neodymium.

Binding of Fluorinated Nucleic Bases with Neodymium(III). These fluorinated nucleic bases possess both nitrogen and oxygen as potential donor sites except fluoroadenine, which has only nitrogen as coordinating sites. The complexes isolated with fluorocytosine, fluorouracil, and fluorothymine corresponded to the composition $[Nd(Base)_4\cdot(H_2O)_4]^{3+}$. The pure compound with fluoroadenine could not be isolated, however, some ill defined complexes appear to be formed with fluoroadenine. A look at the Table 2 shows that the oscillator strength (P) of neodymium(III) fluoroadenine system was almost similar to that neodymium(III) fluorouracil system suggesting that fluoroadenine inter-

acts in some way with neodymium(III), most probably involving pyrimidine or imidazole nitrogen in semi-nonaqueous 80:20 DMF:water.

The infrared spectra of the ligands in the carbonyl region show considerable changes on complexation. For fluorouracil and fluorocytosine complexes, the carbonyl absorption in the infrared region appears as a broad band, with its center of gravity shifted to lower energy as compared to corresponding ligand. Susi and Ard[17] considered the band in the 1540—1800 cm^{-1} region to $\nu(^2C{=}O)$ in phase $\nu(^4C{=}O)+\nu(C{=}O)$ and out phase $\nu(C{=}O)+\nu(C{=}O)$. In case of fluorothymine complex the bands at 1735 cm^{-1} (m), 1677 cm^{-1} (s) of fluorothymine shifted to the lower energy side indicating the participation of carbonyl oxygen in complexation with neodymium(III). Susi and Ard[17] suggested, that highest band in the region 1540—1800 cm^{-1} can be ascribed to $\nu(^2C{=}O)$, on the basis of the bond length reported for thymine hydrate by Gerdil.[18] Though the complexation can also be expected through ($^4C{=}O$), the donor capability of ($^2C{=}O$) will be more than that of ($^4C{=}O$). In fluorothymine the presence of electron-releasing CH_3 group on the fifth carbon atom will make ($^4C{=}O$) a less attractive donor. This points out clearly that the pyrimidinone oxygen atom can effectively act as donor. The weakness of the field is in accordance with the high π-electron density calculated for both oxygen in fluorouracil and fluorothymine. These atoms would be expected to act as moderate donor with ligand field at this low end of the oxygen donor range. The metal-ligand bond may well be fairly strong with very low crystal field stabilization energy. This situation in neodymium(III) complexes will make them very labile. The lability of neodymium(III) complexes with fluorinated nucleic bases will impart only weak intensities to the intra 4f-4f bands as is observed in the present study.

Preliminary ultrasonic studies of fluorouracil, fluorocytosine, fluorothymine in aqueous medium in presence of neodymium(III), have clearly shown that these fluorinated nucleic bases weaken water structures, while the same metabolite strengthen water structure in presence of aprotic solvent.[19]

(i) In water, fluorouracil, fluorocytosine, fluoroadenine, and fluorothymine gave positive values for partial metal compressibility (Φ_k°). This appears to be due to the displacement of net water molecules into the interstices, with the result these fluorinated bases in aqueous medium become highly hydrated and hence are not

readily available for coordination with neodymium.

(ii) The high dielectric constant of water induces significant ionization of metal-ligand bond hence the energies of various 4f–4f transition vary very little while the shape of the intra 4f–4f bands, specially $^4I_{9/2} \rightarrow {}^4G_{5/2}$ and $^4I_{9/2} \rightarrow {}^4F_{5/2}$ hypersensitive and pseudohypersensitive bands respectively change significantly.

(iii) The addition of aprotic solvent (DMF/DMSO) lowers the dielectric constant of the solvent mixture and decreasing the ionization of metal ligand bond. Secondly in the DMSO–water mixture these nucleic bases strengthen water structure (shown by negative values of partial molal compressibility Φ_k°),[19] hence these metabolites behave as better ligands. Thirdly the addition of DMSO also removes partly the water molecules from the coordination shell around Nd(III) and hence create different immediate coordination environment around neodymium(III).

(iv) Preliminary stability constant measurements of neodymium(III) fluorinated base systems have indicated significant stacking,[19] which also contributes towards weak intensities of intra 4f–4f bands.

Thus one can infer from infrared, absorption spectral and solution studies that these fluorinated nucleic bases act as better ligands in DMSO–water than in H_2O and their binding to neodymium is through carbonyl oxygen preferably through $\nu(^2C{=}O)$ carbonyl oxygen as unidentate manner as the bands due ν(N–H) do not appear to show any appreciable change. The presence of four water molecules of coordination and four base molecule coordinated in neutral unidentate manner through carbonyl oxygen and thus providing an octacoordinated environment around Nd(III) in these complexes.

Binding of Fluorocytidine, Fluorothymidine, Fluorouridine, and Fluoroadenosine with Neodymium(III). Significant shifts have been observed in ν(C=O) vibration which occurs around 1660—1680 cm^{-1} in fluorocytidine, fluorouridine, and fluorothymidine shifts to ca. 1700 cm^{-1} as asymmetric shaped broad band, whose center of gravity is around ca. 1700 cm^{-1} probably indicative of the participation of oxygen of the carbonyl group in bonding to neodymium(III). The presence of three water molecules have been indicated by Karl Fischer titration. The ν(OH) bands of the ligand change into broad band, suggesting the participation of ribose hydroxyl group in complexation to neodymium. These informations suggest the probable structure for $[Nd(nucleoside)_2(H_2O)_3]^{3+}$ complexes, involving nona coordinated Nd(III). Similar structure has been proposed by Brittain[20] and Richardson[21] earlier for $[Nd(uridine)_2(H_2O)_2]$ complexes. The terdentate attachment of the nucleoside to metal involves two cis hydroxyl oxygen of ribose and participation of carbonyl oxygen.

The proposed structures for Nd–adenosine complexes are given on our observations in Nd–fluorouridine/fluorothymidine/fluorocytidine systems. Since the pure 1 : 2 and 1 : 3 complexes could not be separated and hence the structure proposed are only on analytical data (C, H, N, H_2O, and Nd) and the conclusion derived from other Nd(nucleoside) complexes.

Absorption spectra of the solution containing neodymium(III) and fluoroadenosine, fluorouridine, fluorocytidine, fluorothymidine, and fluoroadenine, fluorouracil, fluorocytosine, and fluorothymine in 1 : 1, 1 : 2, and 1 : 3 stoichiometry have shown that the intensities increase with the ligand stoichiometry. However, the spectra recorded in 1 : 4 stoichiometry did not show change from that observed in 1 : 3 stoichiometry hence the data has not been included. There has been significant variation in intensity parameters while the variation in the energy interaction parameters has been insignificant. No doubt the energy interaction parameters are quite different from that of neodymium(III) aquo and more so from neodymium(III) free ion. Comparing the magnitude of spectral parameters like P and T_λ for fluorinated nucleic bases and their nucleosides, the parameters have higher values for fluorinated nucleosides as compared to these observed for corresponding to non-fluorinated nucleic base which is understandable in view of the better complexing power shown by the former biomolecule.

Conclusion

The interaction of fluorouracil, fluorocytosine, and 1fluorothymine and their nucleosides with neodymium involves participation of oxygen donor sites of the ligand. The attachment of the ligand is as neutral species. The presence of water molecules complete the nona- or octa-coordination around neodymium in presence of fluoronucleosides and fluoronucleic bases respectively. The magnitude and variation of spectral parameter shows significant changes in the intensities and intensity parameters but less prominent changes in the coulombic and spin orbit interaction parameters. These point to the fact that the changes in the symmetry of the complex play dominant role. The unusual intensification and wide variation of oscillator strength of some nonhypersensitive 4f–4f transitions was observed which was given the name 'LIGAND-MEDIATED PSEUDOHYPERSENSITIVITY'.

Study of Various Factors Affecting the Stability of Ternary Cu(II) and Ni(II) Complexes

Mohammd Rafiqe ULLAH and Pabithrak K. BHATTACHARYA*
Department of Chemistry, Faculty of Science, M. S. University of Baroda, Baroda 390002, India
(Received September 10, 1990)

The stability constants of the ternary M(II) complexes [MAL], where M(II) refers to Cu(II) and Ni(II), A refers to 2,6-pyridinedicarboxylic acid (dpa) and iminodiacetic acid (imda) and L refers to glycine, α-alanine, phenylalanine, tyrosine, tryptophan, ethylenediamine, 1,3-propanediamine, oxalic acid, catechol, catechuic acid, tiron, pyrogallol, *o*-aminophenol, and *o*-phenylenediamine, have been determined potentiometrically by using SCOGS computer programme. Probable reasons for less negative $\Delta\log K$ values of the ternary complexes have been discussed.

The nature of the two ligands involved in the formation of the ternary complex greatly affects its stability constant.[1,2]

These effects vary with the nature of the metal ion involved. The interesting comparisons have been made of Cu(II) and Ni(II) ternary complexes.[3,4] Five main nonstatistical factors have been observed to be of significance in determining the stability of a ternary complex.

i) The charges on the two ligands leading to electrostatic repulsion.[5,6]

ii) π Acid character of one of the ligands.[7,8]

iii) Tridentate character of one of the ligands.[9,10]

iv) Large groups in the vicinity of the coordinating atoms leading to steric hindrance between the ligands.[11,12]

v) Intramolecular interligand interactions.[13,14]

It was thought of interest to study the ternary complexes involving 2,6-pyridinedicarboxylic acid (dpa=AH_2), as one of the ligands, which is subject to the effect of four of the above factors. Complexes of the type MAL have been studied where, M=Cu(II) and Ni(II) and L=glycine, α-alanine, phenylalanine, tyrosine, tryptophan, ethylenediamine, 1,3-propanediamine, oxalic acid, catechol, catechuic acid, tiron, pyrogallol, *o*-aminophenol, *o*-phenylenediamine and AH_2=dpa or iminodiacetic acid (imda). Formation constants of some of the M-imda complexes have been reported eariler,[15] but they have been redetermined to get the values under similar experimental conditions.

Experimental

All the reagents used were of A.R. grade and the titrations were carried out in aqueous medium using a G.P. Electronics pH meter (No. 8021, accuracy±0.01 pH unit). The proton-ligand formation constant of the ligands and the formation constants of the binary complexes CuL, CuL_2, NiL, NiL_2, and NiL_3 were determined in aqueous medium at 25 °C and I=0.2 M ($NaClO_4$) (1 M=1 mol dm^{-3}) using the SCOGS[16] computer programme (charges on the species have been omitted for simplicity). In the case of proton-ligand formation constants L, LH, and LH_2 and for formation constants of the binary complexes L, LH, LH_2, M, ML, ML_2 species were considered. ML_3 species was also considered in case of Ni(II) complexes. These refined values are in close agreement with the values reported earlier in literature.[17–19] These values were used as fixed parameters for the refinement of the formation constants of the ternary complexes [MAL]. For the determination of the formation constant of the ternary complexes MAL, the following sets of solutions (50 cm^3) having M : A : L in the ratio 1 : 1 : 1 and 1 : 2 : 2 were prepared and titrated against standard alkali:

i) 0.02 M $HClO_4$, 0.002 M metal perchlorate, 0.002 M ligand (A), 0.002 M ligand (L) and 0.174 M $NaClO_4$.

ii) 0.02 M $HClO_4$, 0.002 M metal perchlorate, 0.004 M ligand (A), 0.004 M ligand (L) and 0.170 M $NaClO_4$.

Titrations of each set were carried out twice to check the reproducibility of the data. In case of catechol and its derivatives titrations were carried out under nitrogen atmosphere. The pH range selected for the computer programme was 3—7 for [CuAL] and 5—9 for [NiAL] complexes. The experimental values of pH and volume of alkali used in this range were fed to the computer. Calculations were carried out using the computer programme SCOGS. The species considered for the calculation of formation constants of the ternary complexes were A, AH, AH_2, L, LH, LH_2, M, MA, MA_2, ML, ML_2, and MAL. ML_3 species were also considered in case of Ni(II) complexes. The formation constants $\log K^{M}_{MAL}$, $\Delta\log K$ and $\Delta(\Delta\log K)$ have been presented in Tables 1 and 2. The deviations in the $\log K^{M}_{MAL}$ values have been shown in brackets. These indicate random errors in the titration, dependent on the precision of the instruments.

Discussion

The stability of the ternary complexes can be quantitatively evaluated in terms of $\Delta\log K$.

$$\Delta\log K = \log K^{MA}_{MAL} - \log K^{M}_{ML}$$
$$= \log K^{ML}_{MAL} - \log K^{M}_{MA}.$$

Alternatively it can be shown as

$$\Delta\log K = \log \beta^{M}_{MAL} - (\log K^{M}_{MA} + \log K^{M}_{ML}).$$

It is observed, that in general, $\Delta\log K$ for the MAL complexes studied is negative, as expected from the statistical considerations. $\Delta\log K$ becomes more negative with increasing charge on the ligand L, e.g. oxalate$\gtrsim$glycinate~ethylenediamine. This is because imda and dpa have two negative charges. The second negatively charged ligand faces electrostatic repulsion in

forming the ternary complex. Hence, the tendency of L^{n-} to get bound to neutral MA will be less than to get bound with charged M^{2+} ion in the formation of binary complex ML, leading to negative $\Delta\log K$ value. The electrostatic replusion is more with increasing charge on L^{n-}, resulting in more negative $\Delta\log K$ values.

However, it is observed that $\Delta\log K$ in [M–dpa–L] complexes is less negative than [M–imda–L]. This is attributable to the fact that dpa coordinates from two carboxylates and one tertiary amine nitrogen. There is π acidic character in the ligand, due to the possibility of $M\rightarrow N\pi$ bond formation. On the other hand imda coordinates from two carboxylates and one σ bonding secondary amine nitrogen. Due to the π acidic character of dpa $\Delta\log K$ is less negative as observed in [M–dipyridyl–L] complexes.[7,8]

It is interesting to observe that $\Delta\log K$ is more negative in case of Cu(II) complexes compared to Ni(II) complexes. This is due to the tridentate character of dpa and imda.

In the binary complex the tridentate ligand dpa or imda occupy the three equatorial positions around the metal ion. Hence in the formation of the termary complex, the bidentate ligand(L) has to occupy one equatorial and one axial position,[20] or the tridentate ligand has to change to two equatorial and one axial position, and there may be equilibrium between the two forms. Due to Jahn Teller effect, in case of CuAL complexes either ligand is strained in occupying the axial position and hence its tendency to coordinate with the MA is much less than in the binary complex, hence $\log K^{MA}_{MAL}$ is much less than $\log K^{M}_{ML}$ and $\Delta\log K$ is more negative. In the absence of Jahn Teller distortion in Ni(II) complexes, the bidentate or the tridentate ligand does not feel any strain in occupying one equatorial and one axial position, and hence $\Delta\log K$ is less negative.

It is interesting to observe that $\Delta(\Delta\log K)(=\Delta\log K_{NiAL}-\Delta\log K_{CuAL})$ is less in MdpaL complexes than MimdaL complexes. This can be explained by considering the fact that the stabilizing effect of π acidic character of ligand (A) is more pronounced in CuAL complexes than in NiAL complexes. Hence the destabilization of the Cu–dpa–L complexes due to J. T. effect, is compensated by the increase in stability due to greater π acidic character of dpa. Hence $\Delta(\Delta\log K)$ $(=\Delta\log K_{NiAL}-\Delta\log K_{CuAL})$ is less in case of MdpaL complexes, compared to M–imda–L complexes.

It is observed that for the complexes Cu–dpa–L and Ni–dpa–L, where L=phenylalanine, tyrosine and tryptophan, $\Delta\log K$ value is less negative than the complexes where L=glycine or α-alanine. This is because of intramolecular interligand interaction as observed by Sigel[21] in complexes of the type $M(phen)(pheCA)^{+}$ where $M=Cu^{2+}$, Zn^{2+}, phen=1,10-phenanthroline and pheCA =phenylalkane carboxylates as also by Yamauchi[22] in complexes of the type Cu(DA)(AA), where AA=amino acids with side chains and DA= diamines. In the present complexes, the amino acids are bidentate, hence occupy one equatorial and one axial position or both equatorial positions as in case of glycinate and α-alaninate. Model building shows that in case where the amino acid occupied both equatorial positions, the non-coordinated side group, phenyl, hydroxyphenyl, and indole ring of phenylalanine, tyrosine, and tryptophan respectively, come over the pyridyl ring of dpa and hence non-covalent hydrophobic interaction stabilizes the ternary complex, leading to less negative $\Delta\log K$ values. Thus in cases of M–dpa–L complexes, the bidentate amino acid L should prefer two equatorial positions.

We are thankful to the referee for helpful suggestions.

(Received September 20, 1990)

The dropping mercury electrode polarographic behavior of sulfur and selenium solutions in hydrazine hydrate has been studied in highly alkaline aqueous solution containing supporting electrolyte of 0.1 M ammonium tartrate (1 M=1 mol dm^{-3}). Both the sulfur and selenium revealed a composite anodic-cathodic waves. The values of $E_{1/2}$ for sulfur and selenium solutions, taken from the cathodic wave of the polarograms corresponded to $E_{1/2}$=−0.78 and −1.03 V vs. SCE respectively. The effect of mercury pressure and concentration of depolarizer on the relative magnitude of the wave heights has also been studied on the basis of typical reactions involved at DME in this solvent medium. No maxima supressor was used in the present study for both cases.

Polarographic study of sulfur solution in pyridine and ethanol, using sodium acetate–acetic acid buffer, exhibits elemental behavior[1–4] while in strongly alkaline medium, sulfur dissolves as sulfide and polysulfide ions.[5–7] Elemental sulfur and selenium dissolve in alkaline solution of sulfides of alkali metals with the formation of selenosulfide (Se_2S^-),[11] and in concentrated alkaline solutions to give polysulfides and polyselenides.[12] This transformation of elemental sulfur and selenium into selenosulfide is a convenient method for determining these elements. Konapik and Werner[7–9] carried out the polarographic studies of polysulfide ions in 2 M (M=mol dm^{-3}) NaOH and suggested the following reaction mechanism. They proposed that the anodic wave of the polarogram is due to the oxidation of mercury by sulfide ions, and the reduction of polysulfide and elemental sulfur is responsible for the cathodic wave as:

$$Hg + S^{2-} \longrightarrow HgS + 2e$$
$$S_2^- + 2e \longrightarrow 2S^{2-}$$
$$S + 2e \longrightarrow S^{2-}$$

Lingane and Niedrach[10] reported the polarography of selenide ions in different media with pH ranging from 1 to 14. Toropova et al.[11,12] have shown that selenium dissolves in highly alkaline media, as polyselenide ions. They proposed similar reaction mechanism at DME as suggested by Konapik and Werner.[7–9] In highly alkaline solutions like hydrazine hydrate the elemental selenium and sulfur are transformed to selenosulfide and polysulfide for determination. In the case of hydrazine hydrate, it is reported that sulfur and selenium in any oxidation state is readily reduced to elemental sulfur/selenium and dissolved in hydrazine forming solvation complex. The polarographic behavior of sulfur and selenium in hydrazine hydrate solutions at DME is less studied. In the present study, hydrazine hydrate in 50–50% mole ratio with water was employed as solvent for the polarographic determination of S and Se in elemental form and in various oxidation states. In our preliminary studies it was observed that 50% hydrazine hydrate+50% water was the suitable solvent composition for analysis. The effect of mercury pressure and depolarizers on wave heights of the polarograms have also been studied and results have been discussed.

Experimental

The commercially available (BDH) analytical grade hydrazine hydrate ($N_2H_4 \cdot H_2O$) was further purified by standard distillation procedure before use. Various volume ratios of distilled hydrazine hydrate was mixed with deionized water. Since, 50 volume % $N_2H_4 \cdot H_2O$+50% H_2O was found to have high solubility for sulfur and selenium, the same ratio of the solvent was used as the solvent in the present investigation. The standard solutions of AR-grade sulfur and selenium were prepared by dissolving accurately weighed quantity of the elements in 25 ml of the solvent. Ammonium tartarate (0.1 M) was used as the supporting electrolyte. The total volume of the supporting electrolyte and the analyte was made upto 25 ml and transferred to the polarographic cell. The flow rate 'm' and time 't' of the dropping mercury electrode (DME) assembly at a mercury height of 35 cm were 1.5 mg s^{-1} and 5.0 s, respectively. All the currents and potentials reported in this work were corrected for the residual current as well as the IR drop involved. The solutions were deaerated by bubbling nitrogen and the polarograms were recorded with the Leeds and Northup Electrochemograph type E at 25±1 °C.

Results and Discussion

As evident from Figs. 1 and 2, both the sulfur and selenium solutions in hydrazine hydrate, produce a composite anodic-cathodic waves.

Hydrazine hydrate dissociates according to the equilibrium in aqueous solution.

$$N_2H_4 \cdot H_2O \rightleftarrows N_2H_5^+ + OH^-$$

Hydrazinium ions reduce sulfur to sulfide (S^{2-}) and polysulfide (S_n^{2-}) ions with the evolution of nitrogen according to the following reactions.

$$4N_2H_5^+ + S_8 + 20OH^- \longrightarrow 4N_2 + 8S^{2-} + 20H_2O$$
$$S^{2-} + nS \rightleftarrows S_n^{2-}$$

Similarly, elemental selenium produces selenide (Se^{2-})

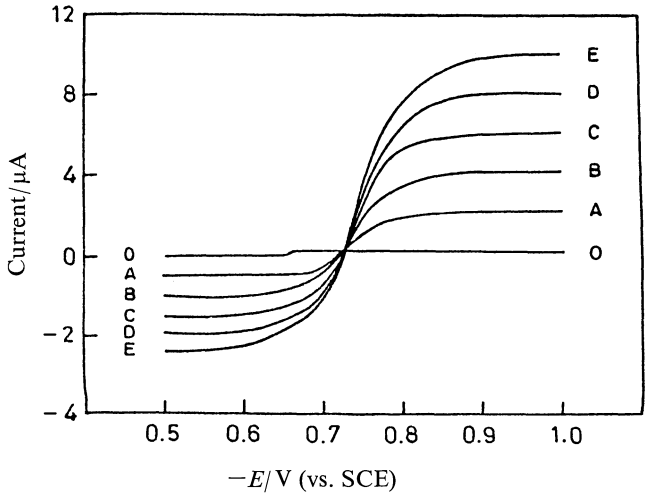

Fig. 1. Polarographic curves of sulfur solutions in hydrazine hydrate at various concentrations: A, 0.5079 mM; B, 1.0080 mM; C, 1.5000 mM; D, 1.9850 mM; E, 2.4610 mM (Line '0' is residual current, H_{Hg}=35 cm, pH=ca. 12).

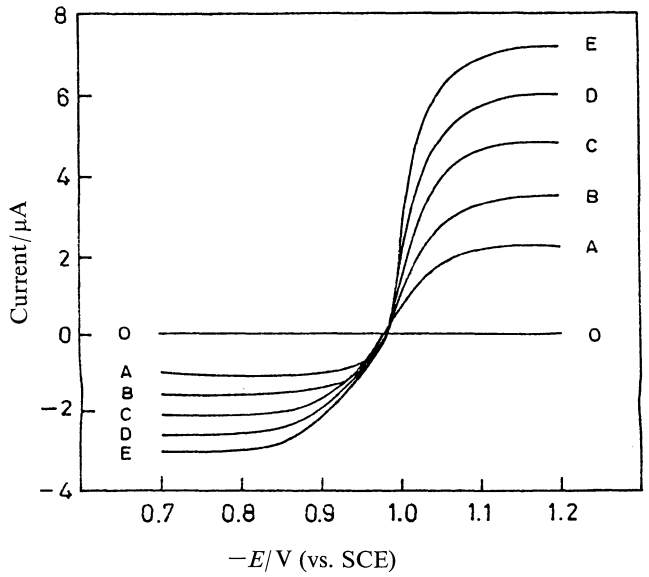

Fig. 2. Polarographic curves of selenium solutions in hydrazine hydrate at various concentrations: A, 0.6640 mM; B, 0.9911 mM; C, 1.3151 mM; D, 1.6358 mM; E, 1.9535 mM (Line '0' is residual current, H_{Hg}=35 cm, pH=ca. 12).

and polyselenide (Se_n^{2-}) ions, when dissolved in hydrazine hydrate.

The typical reaction mechanism proposed by Konopik and Werner,[7-9] and Totopova et al.[11,12] can be utilized in explaining the existence of composite anodic-cathodic waves in both cases. The sulfide (S^{2-}) and polysulphide (S_n^{2-}) ions produced in the solution react with mercury drop according to the following reactions.

$$S^{2-} + Hg \longrightarrow HgS + 2e \quad (1)$$

$$S_2^{2-} + Hg \longrightarrow HgS + S^{2-}$$
$$HgS + 2e \longrightarrow Hg + S^{2-}$$
$$S_2^{2-} + 2e \longrightarrow 2S^{2-} \quad (2)$$

and

$$Hg + S \longrightarrow HgS$$
$$HgS + 2e \longrightarrow Hg + S^{2-}$$
$$S + 2e \longrightarrow S^{2-} \quad (3)$$

The anodic wave can be attributed to the oxidation of mercury by sulfide (S^{2-}) ions, whereas the reduction of polysulfide (S_n^{2-}) ions and elemental sulfur is responsible for the cathodic step. Selenium also revealed a composite anodic-cathodic wave based on the similar mode of reaction mechanism. The values of $E_{1/2}$ for sulfur and selenium solutions taken from the cathodic wave of the polarogram correspond to $E_{1/2}$=−0.78 and −1.03 V vs. SCE, respectively. Similarly, the values reported in Tables 1 and 2 corresponded to the cathodic wave of the respective polarograms. Although there is no other direct evidence to prove this assumption, there appears to have no other options. One of the important advantages of this procedure is that the sulfur and selenium in any oxidation state can be reduced to elemental state and slowly dissolved in the hydrazine hydrate+water solvent. Therefore, this may be utilized as a new and convenient method for the determination of sulfur and selenium present in various analytes.

A plot of concentration vs. diffusion current gave a straight line, and the values calculated for diffusion current constant (I) were fairly constant (Tables 1 and 2) indicating the utility of the data for analytical purposes.

Table 1. Relationship of Diffusion Current with Sulfur Concentration and Values of Diffusion Current Constant

Curve	Sulfur concentration C/mM	Diffusion current i_d/μA	Diffusion current constant, I	Half wave potential $E_{1/2}$/V (vs. SCE)
A	0.5079	1.95	2.2	
B	1.0080	3.90	2.2	
C	1.5000	5.85	2.2	
D	1.9850	7.80	2.3	
E	2.4610	9.75	2.3	−0.78

Table 2. Relationship of Diffusion Current with Selenium Concentration and Values of Diffusion Current Constant

Curve	Selenium concentration C/mM	Diffusion current i_d/μA	Diffusion current constant, I	Half wave potential $E_{1/2}$/V (vs. SCE)
A	0.0640	2.25	2.0	
B	0.9911	3.45	2.0	
C	1.3151	4.80	2.1	
D	1.6358	6.00	2.1	
E	1.9535	7.20	2.1	−1.03

Table 3. Relationship of Diffusion Current with Mercury Height for Sulfur Solution

Mercury height H_{Hg}/cm	Diffusion current i_d/μA	$i_d/\mu A/\sqrt{H_{Hg}}$/cm
30	4.05	0.73
40	4.50	0.71
50	5.10	0.72
60	5.40	0.69

Table 4. Relationship of Diffusion Current with Mercury Height for Selenium Solution

Mercury height H_{Hg}/cm	Diffusion current i_d/μA	$i_d/\mu A/\sqrt{H_{Hg}}$/cm
35	6.00	1.01
45	6.75	1.00
55	7.50	1.01
65	8.25	1.02

The plot of $\log i_d$ vs. $\log H_{Hg}$ was a straight line with the slope closer to 0.5 and the values calculated for $i_d/\sqrt{H_{Hg}}$ at different heights of mercury column were fairly constant (Tables 3 and 4) showing that the waves were diffusion controlled in both systems.

Sincere thanks of the authors are due to Head of the Chemistry Department, Banaras Hindu University for providing necessary facilities. One of the authors (KSCB) acknowledges CSIR, Government of India for awarding Senior Research Fellowship.

Reaction of Tetraiodomercurate Anion with HSO_3Cl: Synthesis of and Physico-Chemical Studies on $M_2[Hg(SO_3Cl)_4]$ (M=Cu(I), K), $(Et_4N)_2[Hg(SO_3Cl)_2I_2]$, and $K_2[Hg(SO_3Cl)_nI_{4-n}]$ (n=1, 2, and 3)

Mohammad YAMIN SIDDIQI,* Zafar Ahmad SIDDIQI, and Mohammad SHAKIR
Inorganic Chemistry Division, Department of Chemistry, Aligarh Muslim University, Aligarh 202002, India
(Received February 25, 1991)

Reactions of $[M_2HgI_4]$ with excess of HSO_3Cl afford $M_2[Hg(SO_3Cl)_4]$ (M=Cu(I), K). However, the reactions of K_2HgI_4 with stoichiometric amounts of HSO_3Cl, i.e., in 1 : 3, 1 : 2, and 1 : 1 molar ratios, yield $K_2[Hg(SO_3Cl)_nI_{4-n}]$ (n=3,2,1). In these reactions HSO_3Cl acts as both chlorosulfating agent as well as medium of the reaction. Et_4NI reacts with $Cu^I_2[Hg(SO_3Cl)_4]$ suspended in CH_2Cl_2 affording $(Et_4N)_2[Hg(SO_3Cl)_2I_2]$ and $[CuSO_3Cl]_x$. All these compounds have been characterized by elemental analysis, electrical conductivity measurements, IR and electronic spectral studies.

Tetrahalometallate complex anions of the type $[MX_4]^{-2}$ ($M=Mn^{II}$, Fe^{II}, Ni^{II}, Cu^{II}, Zn^{II}, Hg^{II}; $X=Cl^-$, Br^-, and I^-) and also of $[FeX_4]^-$ are quite well known.[1-7] The halogen complex anions of Mn^{II}, Fe^{II}, Fe^{III}, and Hg^{II} have been thoroughly investigated using IR,[8,9] electronic,[10] Raman,[11] Chlorine nuclear quadrupole resonances[8] and Mössbauer spectroscopic studies for analysing molecular structure and mode of bonding in these complex anions. Tetrakis (chlorosulfato)metallate anions, $[M(SO_3Cl)_4]^-$, [$M=B^{III}$, Al^{III}, and Ga^{III} are obtained,[14-18] by utilizing either the addition reactions of sulfuric acid anhydrides or the solvolytic reactions of chlorosulfuric acid with corresponding tetrachlorometallates. The preparation and characterization of complex (chlorosulfato) metallates of heavier transition metals, i.e., $Na_2[Pd(SO_3Cl)_4]$ and $Na_2[Ir(SO_3Cl)_6]$, have been reported[19] from this laboratory. Here we are communicatingg for the first time the synthesis and characterization of $M_2[Hg(SO_3Cl)_4]$, [M=K and Cu(I)], $(Et_4N)_2[Hg(SO_3Cl)_2I_2]$ and $K_2[Hg(SO_3Cl)_nI_{4-n}]$ (n=1, 2, and 3).

Experimental

Materials. Pure chlorosulfuric acid (Riedel) was used as such; HgI_2, Et_4NI, $CuSO_4 \cdot 5H_2O$, and KI all were commercially pure samples which were used after recrystallization. However, Cu_2HgI_4 and K_2HgI_4 were synthesized according to the reported methods.[20] The solvents diethyl ether, DMSO, CH_2Cl_2, hexane, and acetonitrile were used after drying.[21]

Preparation of $Cu_2[Hg(SO_3Cl)_4]$ (1). Solid [Cu_2HgI_4] (0.9340 g or 1.11 mmol) was placed in a reaction flask and chlorosulfuric acid was added in excess (ca. 15 ml) at room temperature with magnetic stirring. A vigorous exothermic reaction took place with evolution of violet fumes. The reaction mixture was stirred for about three hours. The light brown colored solid material was filtered off through a sintered glass frit under N_2, washed with HSO_3Cl, and finally with thionyl chloride and then dried in vacuo at 60 °C to a constant weight (mp 300 °C, yield 0.75 g (ca. 80%) based on Cu_2HgI_4).

Preparation of $(Et_4N)_2[Hg(SO_3Cl)_2I_2]$ (2). Tetraethylammonium iodide (1.285 g or 5.42 mmol) was reacted with 1.9688 g (2.4 mmol) of **1** suspended in 25 ml dichloromethane and stirred for about 4 h. The wine red colored solution was filtered off leaving behind some colorless residue. The solution was then mixed with hexane and kept at ca. 10 °C for a week. Dark brown, hexagonal crystals appeared along with some dirty white powdery mass which settled at the bottom. The crystals were collected and again recrystallized in the same manner. The recrystallized material melts at 135 °C (Yield 1.38 g (ca. 70%) based on **1**). The white amorphous solid was washed several times with CH_2Cl_2 and vacuum dried. The result of the elemental analysis proved it $[CuSO_3Cl]_x$. Found: Cu, 35.12; S, 17.8; Cl, 19.90%. Calcd for $[CuSO_3Cl]_x$: Cu, 35.48; S, 18.87; Cl 19.82%, respectively.

Preparation of $K_2[Hg(SO_3Cl)_nI_{4-n}]$ [n=1, 2, 3, and 4; (6, 5, 4 and 3)]. For $K_2[Hg(SO_3Cl)_4]$ (3) solid K_2HgI_4 (0.7860 g or 0.001 mol) was mixed with excess of frozen HSO_3Cl. The temperature of the reaction mixture was slowly brought to room temperature with continuous magnetic stirring. The resulting dark red solution was poured dropwise in chilled dry diethyl ether in a closed vessel which resulted in the separation of colorless solid material. The solution was decanted off and the solid was repeatedly washed with ether till the washing did not show any color. The solid was vacuum dried, mp 197 °C, yield 0.55 g (ca. 70%) based on K_2HgI_4.

Compounds **4**, **5**, and **6** were prepared by mixing K_2HgI_4 with frozen HSO_3Cl in 1 : 3, 1 : 2, and 1 : 1 molar ratios, respectively, and the reaction mixture was allowed to warm up to room temperature with continuous stirring giving brownish-yellow colored solutions. These solutions separately resulted in the solid material when poured dropwise to chilled diethyl ether and the solid compounds were isolated in the manner as described above for **3**, melting points: **4** decomp 298—300 °C; **5** decomp 253—255 °C, **6** decomp 232—235 °C; yields: 2.7 g, 0.55 g, 3.79 g (70%, 70%, 80%, respectively based on K_2HgI_4).

Analysis. The results of C, H, N analyses were obtained from the microanalytical laboratory of I.I.T. Kanpur, whereas Cu, Hg, S, Cl, and I were determined by established methods.[22,23] The IR spectra (4000—250 cm^{-1}) were recorded as Nujol mulls using a Perkin Elmer Model 621 Spectrophotometer. Electrical conductivity was measured in 10^{-3} mol dm^{-3} solutions in DMSO or CH_3CN using a sys-

* Present address: Department of Medical Elementology/ Toxicology, Faculty of Science, Hamdard University, New Delhi 110062, India.

tronic bridge model 302 thermostated at 25±0.1 °C. The electronic spectra were recorded in DMSO or CH_3CN using a PYE Unicam 8800 spectrophotometer.

Results and Discussion

For the synthesis of **1** and **3** the solvolytic reaction of $[M_2HgI_4]$ with HSO_3Cl has been utilized where HSO_3Cl also serves as the reaction medium and the formation may be typified by the following reactions.

$$M_2HgI_4 + 4HSO_3Cl \rightarrow M_2[Hg(SO_3Cl)_4] + 4HI \quad (1)$$

$$2HI + 2HSO_3Cl \rightarrow H_2SO_4 + 2HCl + I_2 + SO_2 \quad (2)$$

(M=K, Cu(I)).

Reaction of **1** with Et_4NI in CH_2Cl_2, where both the reactants are separately insoluble, seems to be an interesting one. It was anticipated to get the replacement of copper(I) ion by the bulky cation, Et_4N^+ together with the release of Cu(I)iodide. It is noteworthy that in this reaction the final products obtained (Experimental Section) have been characterized as **2** and $[CuSO_3Cl]_x$, but only **2** is soluble in CH_2Cl_2 giving a dark brown solution. This implies that during the course of the reaction, in addition to the exchange of the cation, an anion replacement also takes place which may reasonably be due to the soft nature of iodide ion.[24-26] The reaction may be represented by the following equation.

$$Cu_2[Hg(SO_3Cl)_4] + 2Et_4NI \rightarrow (Et_4N)_2[Hg(SO_3Cl)_2I_2] + 2CuSO_3Cl \quad (3)$$

Stoichiometric amounts of $[K_2HgI_4]$ and HSO_3Cl, i.e., 1 : 1, 1 : 2, and 1 : 3 molar ratios, have been used for the preparation of **6**, **5**, and **4** where chlorosulfuric acid is an efficient chlorosulfating agent[27] effectively displacing an iodine atom as shown below.

$$K_2HgI_4 + nHSO_3Cl \rightarrow K_2[Hg(SO_3Cl)_nI_{4-n}] + nHI \quad (4)$$

(n=1, 2, and 3).

The magnitudes of the molar conductivity measured in DMSO for **3**, **4**, **5**, **6** and in CH_3CN for **1** and **2** (Table 1) suggest these to be strong electrolytes.[28]

Table 1. Elemental Analysis and Molar Conductance of the Compounds[a]

Copounds		Melting points	Found (Calcd)/%					μM^{b}	Yield

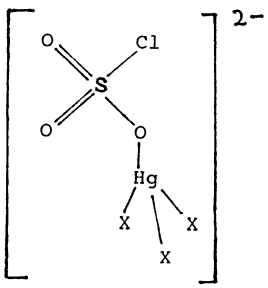
a) w=weak, m=medium, s=strong, b=broad, sh=shoulder, ν_1(A) sym·SO_3 stretch, ν_4(E) asym·SO_3 stretch, ν_5(E) asym·SO_3 def., ν_3(A) sym·SO_3 def., ν_2(A) S–Cl stretch, ν_6(E) S–Cl wag.

The IR spectra of the compounds (Table 2) show bands which may reasonably be assigned to the characteristic SO_3Cl^- group vibrations. The chlorosulfate group is known[19,30] to coordinate to a metal ion in a uni- or bidentate manner exhibiting considerable cation–anion interaction. The free SO_3Cl^- ion has C_{3v} symmetry[27] which would comprise of six IR active fundamentals, namely ν_1(A), ν_2(A), ν_3(A), ν_3(E), ν_5(E), and ν_6(E) with three of these being degenerate. It has been observed[29–31] that ν_1(A) frequency in transition metal and rare earth metal chlorosulfates lies to a higher energy by about 35 cm^{-1} from that indicated[27] in ionic $CsSO_3Cl$, owing to an increased cation–anion interaction leading to a reduced C_s symmety. The lowering of the symmetry from C_{3v} to C_s causes the splitting of the degenerate modes exhibiting in all nine IR active fundamentals.[27] The present IR data are consistent with a covalent bonding of the SO_3Cl^- group to the Hg^{2+} ion. The nature and the positions of the bands in the IR spectra of all these compounds are identical, suggesting the formation of similar species with most likely tetrahedral geometry.

Goodgame et al.[32,33] have reported that in $K_3[Hg(NO_2)_4](NO_3)$ and $K_2[Hg(NO_2)_4]$ there are four chelating NO_2 groups surrounding the Hg^{2+} ion in an approximately tetrahedral array. The characteristic stretching frequency for (Hg–I) bond expected[34] at ca. 120 cm^{-1} could not be recorded as it occurs beyond the range of our instrument. The probable tetrahedral geometry of the anion $[Hg(SO_3Cl)_2I_{4-n}]^{2-}$ (n=1, 2, 3, and 4) may reasonably be represented as shown below, where X is I or SO_3Cl.



It has been reported that the two bands observed in the UV-region (250—300 nm) for transition metal chlorosulfate,[35] are due to charge transfer as well as the $n \rightarrow \sigma^*$ transition of the SO_3Cl^- group, irrespective of the IR geometry. Wolfsberg and Helmholtz[36] have proposed the LCAO-MO scheme to account the electronic spectra of the molecules like MnO_4^-, CrO_4^{2-}, $CoCl_4^{2-}$, and ClO_4^- etc. (Td symmetry). The observed lowest energy band of the $[Hg(SO_3Cl)_4]^{2-}$ anion (Table 2) in qualitative terms reasonably corresponds to the transition, HOMO [filled nonbonding π-orbital]→LUMO [unfilled antibonding π*-orbital]. The possibility of a Jahn–Teller distortion[37] in the molecule could not be ruled out as the spectrum contains closely spaced bands in the UV-region. The electronic spectra[38] of $[HgI_4]^{2-}$ and of $[HgI_3]^-$ anion[26,34] are similar showing maxima at 270 and 320 nm, characteristic of a tetrahedral geometry of the complex anion.[39] Although the exact nature of the transitions responsible for these bands has not authoritatively pronounced, they were considered to be due to promotion of a nonbonding electron to the available two unfilled orbitals. It has been indicated[40] that the substitution of halogen for oxygen atoms in CrO_4^{2-} (CrO_3F^-, CrO_3Cl^-, CrO_2Cl_2) shifts the absorption band to longer wavelengths suggesting that the $[Hg(SO_3Cl)_4]^{2-}$ anion also would exhibit a similar red-shift on substituting iodine atoms in place of a SO_3Cl^- group. However, no such information is revealed in the electronic spectra of **2**, **4**, and **5** rather the band occurring in the visible region of **1** and **3** does not appear in the former cases.

Electrochemical Reactions at Sacrificial Electrodes. VII. Synthesis of Some Unique Mercury(II) Alkoxides and Glycolates and Their Coordination Compounds

Jagtar Singh BANAIT,* Rani DEVI, and Baljit SINGH
Department of Chemistry, Punjabi University, Patiala 147002, India
(Received March 22, 1991)

The electrochemical oxidation of malononitrile, diethyl malonate, ethyl cyanoacetate, cyanoacetamide, ethyl acetoacetate, and acetylacetone has been carried out in acetonitrile at sacrificial mercury anode using tetrabutylammonium chloride as supporting electrolyte. The products of these reactions have been identified by elemental analysis and IR spectral studies and are found to be mercury(II) alkoxides/glycolates. Electrochemical oxidation of these compounds in the presence of ligands like 1,10-phenanthroline and 2,2′-bipyridyl yields coordination compounds of these alkoxides/glycolates. All these reactions have been found to proceed with a very high current efficiency.

Recently in our laboratories, eleotrochemical reactions of carboxylic acids, polyhedric alcohols, and monohydric alcohols have been conducted at sacrificial copper,[1-3] mercury,[4] and cadmium[5] anodes. It has been observed that the acidic proton in these compounds has been replaced by the anode metal through these electrochemical reactions. The present paper reports the electrochemical reactions of malononitrile, diethyl malonate, ethyl cyanoacetate, cyanoacetamide, ethyl acetoacetate, and acetylacetone (H_2R) at sacrificial mercury anode. These compounds have no acidic proton but can loose protons to yield carbanions under suitable experimental conditions. Adducts of these products of the above reactions with ligands such as 1,10-phenanthroline and 2,2′-bipyridyl have also been prepared by the electrochemical technique.

Experimental

Material and Equipment. Acetonitrile was dried over phosphorus pentaoxide and distilled. Freshly distilled acetonitrile was used as solvent in all these electrochemical reactions.

Tetrabutylammonium chloride was crystallized from conductivity water and dried under reduced pressure at 100 °C and used as supporting electrolyte.

Mercury was distilled in before use. Other organic compounds (Reidel Pure) were used as supplied.

Electrolysis was carried out in an H-type cell[1-3] made of Pyrex glass. The cathode and anode compartments were separated from each other by a sintered disc of G-3 porosity. Volume of the anode compartment (ca. 200 cm^3) was almost three times as large as that of cathode compartment (ca. 65 cm^3).

Platinum foil (1×1 cm^2) was used as a cathode and mercury pool (surface area 25 cm^2) as anode.

Direct current was obtained with the help of a Toshniwal electrophoresis power supply.

Procedure. A solution of tetrabutylammonium chloride (0.5×10^{-2} mol dm^{-3}) in acetonitrile (250 cm^3) was taken in the electrolysis cell. Two grams of the organic compound (H_2R) was also added to this solution. Necessary connections were then made with the power supply and potential accross the electrodes was adjusted so that a current of about 20 mA passed through the cell. The other experimental details were essentially the same as reported earlier.[1] White/grey colored solids separated in the anode compartment after a prolonged electrolysis of about ten hours. The products were collected by filtration, washed several times with dry acetonitrile in an all glass filtration unit and dried in vacuum.

Coordination compounds of the products of the above electrolytic processes were prepared through the electrolysis of the solution of tetrabutylammonium chloride (0.5×10^{-2} mol dm^{-3}) in acetonitrile containing 2.0 g of the organic compound (H_2R) and 1.0 g of the ligand at the sacrificial mercury anode. The details of the experimental procedure are the same as above.

Current efficiencies were determined from the ratio of actual and theoretical amounts of mercury dissolved when a current of 20.0 mA was passed for 2 h through the cell in the given system.

Infrared spectra of the products in Nujol were recorded with Beckman IR-20 spectrophotometer using sodium chloride plates in the region of 4000 to 600 cm^{-1} and polyethylene plates in the region of 600 to 200 cm^{-1}.

Mercury contents in the electrochemical products were estimated potentiometrically.[6]

Results and Discussion

Products of the electrochemical reactions of malononitrile, diethyl malonate, ethyl cyanoacetate, cyanoacetamide, ethyl acetoacetate, and acetylacetone are not affected much by moisture and air and are quite stable. All these compounds are insoluble in the common organic solvents. The product of acetylacetone, however, is soluble in most of the polar solvents.

The products of these electrochemical reactions do not melt upto a temperature of 250 °C. However, in some of the cases there has been a color change of the product in the temperature range of 230 to 250 °C.

Elemental analysis (Hg, C, H, and N) of these compounds have been carried out and the data are listed in Table 1 alongwith the electrolysis characteristics. Perusal of Table 1 reveals that the elemental analysis of the products corresponds to a general formula of $Hg(HR)_2$

Table 1. Electrolysis Characteristics, Analytical and Other Relevant Data of the Electrolysis Processes of H_2R at Mercury Anode

H_2R	Potential applied	Electricity passed	Product	Color	Elemental analysis[a]/%				Current efficiencies
	V	Coulombs			Mercury	Carbon	Hydrogen	Nitrogen	%
Malononitrile	30	650	$C_6H_2N_4Hg$	White	59.6 (60.7)	23.9 (21.8)	0.5 (0.6)	15.8 (16.9)	88

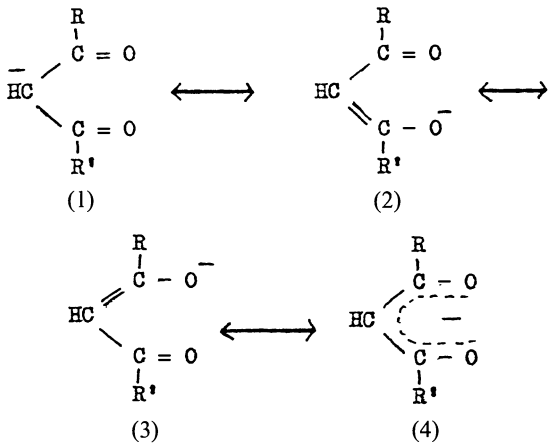
a) Results in parenthesis are the theoretical values.

which shows that a proton from the organic molecules (H_2R) has been replaced by the mercury anode.

Infrared spectral data of the electrochemical products recorded in the region of 4000 to 200 cm^{-1} reveal that the characteristic bands of all the products except that of malononitrile appear in the regions of 1020 to 1060 and 450 to 460 cm^{-1}. Survey of literature[7,8] reveals that the ν(C–Hg) stretching band appears in the region of 515 to 554 cm^{-1} and no such band has been observed in the infrared spectra of the present products.

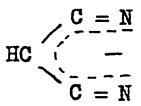
The carbanions formed by the abstraction of proton from the present organic molecules have been reported to exist in different resonance forms:



(1) (2) (3) (4)

Absence of ν(C–Hg) absorption band in the infrared spectra of the electrochemical products indicate that these products may have formed through the resonance form (4). Survey of literature[9,14] reveals that the ν(C–O)M and ν(M–O) absorption bands in various metal alkoxides appear in the regions of 1000 to 1150 cm^{-1} and 400 to 500 cm^{-1} respectively. Infrared spectra of some mercury(II) alkoxides have been reported recently from our laboratories.[4] The absorption bands in the regions 1000 to 1060 cm^{-1} and 450 to 460 cm^{-1} have been assigned to ν(C–O)Hg and ν(Hg–O) respectively. Thus the infrared studies support the formation of these products through the resonance form (4).

In case of malonitrile, a strong absorption band appears at 2180 cm^{-1}. Generally, ν(C≡N) bands appear in the region of 2240 to 2260 cm^{-1} in alkanenitriles.[15] Appearance of ν(C≡N) stretching modes in the lower region also supports the formation of the product of the electrochemical reaction of malononitrile through the resonance form (5):



(5)

Absorption bands at 2200 and 2150 cm^{-1} have also been observed in the product of ethyl cyanoacetate and cyanoacetamide respectively in addition to the absorption bands in the regions 1010 to 1020 and 450 to 460 cm^{-1}. This also supports the formation of these products through the resonance forms of the type (4) and (5). Thus all these organic compounds except malononitrile yield mercury(II) alkoxides/glycolates through the present electrochemical reactions.

Survey of literature[9–11,16–18] reveals that the metal alkoxides, generally exist as polymers by forming bridged structure through alkoxide groups. Appearance of ν(C–O)Hg absorption bands in the lower region and comparatively broad peaks indicate the polymer structure of these compounds through alkoxyl groups. Insoluble behavior of these compounds in almost all organic solvents also supports this fact. Molecular weight of these compounds, however, could not be determined because of their insolubility in various solvents having convenient melting point.

Current efficiencies of all these reactions have been

determined and are listed in Table 1. Reactions of alcohols at sacrificial anodes[2-4] reveal that the metal alkoxide is the only product containing metal atom. The present electrochemical reactions are similar to those of alcohols as in both the cases a proton from the organic molecule is replaced by the sacrificial metal anode. Current efficiencies have, therefore, been evaluated on the basis of equivalents of metal dissolved per Faraday of electricity passed. Perusal of Table 1 reveals that crrrent efficiencies of all these reactions are quite close to 100% showing thereby that the reactions leading to the formation of mercury(II) alkoxides/glycolates are the predominant reactions of these systems. The reaction scheme may be written as:

At the cathode:

$$2\,H_2R + 2e^- \longrightarrow 2\,HR^- + H_2$$

At the anode:

$$2\,HR^- + Hg_{(+)} \longrightarrow (HR)_2Hg + 2\,e^-$$

Coordination Compounds. The electrochemical products of ethyl cyanoacetate and diethyl malonate have been refluxed with 1,10-phenanthroline and 2,2′-bipyridyl in solvents like methanol, ethanol, acetonitrile, and benzene for more than 48 h. However, the elemental analysis showed that the donor molecules could not rupture the alkoxide bridges to form their coordination compounds. It is, therefore, considered worthwhile to add the ligand molecules to these compounds before these are polymerized. Electrolysis of the organic compounds has therefore, been carried out in the presence of sufficient amount of 1,10-phenanthroline or 2,2′-bipyridyl.

The products of these electrochemical reactions are also insoluble in the common organic solvents. This indicates that these may also be polymer in nature like the parent alkoxides/glycolates. Melting points of these products are above 250 °C. Some of these compounds, however, show slight color change in the temperature range of 200 to 250 °C. These compounds are not affected by moisture or air and are quite stable.

Elemental analysis (Hg, C, H, and N) has been carried out and the data are recorded in Table 2. The analytical data of these compounds agree with the molecular formula, $Hg(HR)_2 \cdot L$.

Infrared spectral data of these compounds show the characteristic ν(C–O)Hg stretching vibrations[9-14] between 1030 and 1120 cm^{-1}. The absorption bands are slightly broad, appear in a slightly higher region as compared to the parent mercury(II) alkoxides/glycolates and distinct two or three absorption bands are observed in this region. Increase in the number of bands in this region indicates the presence of both the terminal and bridged alkoxide groups in these compounds. The presence of terminal alkoxyl groups may be attributed to the coordination of the ligand molecules and the presence of bridged alkoxyl groups shows that the present coordination compounds of mercury(II) alkoxides/glycolates have still polymeric structure. Insoluble behavior of these compounds also supports the polymeric structure of these compounds. Many such metal alkoxides in which in addition to the ligand

a) Results in parenthesis are the theoretical values.

molecules, alkoxyl bridging are also present have been reported in literature.[19–21]

Current efficiencies of all these systems are recorded in Table 2. It has been observed that the current efficiencies of most of the systems are quite close to 100% showing thereby that the reactions leading to the formation of coordination compounds of mercury(II) alkoxides/glycolates are the predominant reactions of these systems.

The present methods for the synthesis of mercury(II) alkoxides/glycolates and their coordination compounds are quite simple as compared to the usual multistep methods[10] for the synthesis of such compounds. These methods are associated with quite high values of current efficiencies also. Thus the electrochemical technique presents a new route for the synthesis of metal alkoxides/glycolates and their coordination compounds.

Acid-Base and Complex-Formation Properties of *N*-Hydroxy-3-pyridinecarboxamide and *N*,2-Dihydroxybenzamide in Aqueous Solution

Enrico Leporati
Istituto di Chimica Generale ed Inorganica dell'Università degli Studi di Parma, Viale delle Scienze 78, 43100-Parma, Italy
(Received April 22, 1991)

The protonation and complexation equilibria of the iron(III) and copper(II) complexes of *N*-hydroxy-3-pyridinecarboxamide (hpca) and *N*,2-dihydroxybenzamide (dhbc) have been investigated by potentiometric and spectrophotometric techniques in 0.5 mol dm^{-3} (KCl) at 25±0.1 °C. It was shown that the properties of iron(III) and copper(II) chelates under study are similar to those of corresponding chelates of simple aromatic hydroxamic acids (without any additional donor groupings in the molecule). The hydroxamate and carbonyl oxygens may also take part in coordination in the copper(II) and iron(III) systems.

Because of their pronounced chelating properties the organic derivatives of hydroxylamine are used in analytical chemistry for a long time. Beside of oximes and *N*-alkyl or *N*-aryl derivatives of hydroxylamine there are hydroxamic acids that are known to be useful in analytical praxis.[1] The occurrence of hydroxamic acid derivatives in living organisms (where they play an important role in biochemical processes as the iron binders and transfers, growth regulators, pigments and precursors of other compounds)[2,3] and especially the discovery of antibiotic properties of aspergillic acid have initiated extensive investigation of hydroxamic acids as potential antimicrobial substances. New hydroxy- and amino-substituted benzohydroxamic acids[4] were prepared and tested along with other previously reported benzohydroxamic acids (see Table 2 of Ref. 4) for enzyme inhibition and antitumor activity. Among numerous hydroxamic acids synthesized and studied up to now, the group of hydroxamic acids derived from pyridine occupies an important place. It has been shown that various ring-substituted 4-pyridinecarbohydroxamic acids exhibit an antiviral effect.[5] Derivatives of 3-pyridinecarbohydroxamic acid (acting as the inhibitor of urease) was even patented as the domestic animal and poultry feed additive which should improve the nitrogen uptake during the meat production.[6] As a loose continuation of our previous work dealing with the properties of amino-substituted aliphatic hydroxamic acids[7—10] (which are related to 3-pyridinecarbohydroxamic acid with respect to the presence of the nitrogen atom in the vicinity of the *N*-hydroxycarbamoyl group) we decided to fill the gap in the knowledge of fundamental physicochemical properties of hpca and their iron(III) chelates by the paper presented. Moreover, we extended the study to analogous aromatic hydroxamic acid (dhbc) that has not yet been described in the literature.

Experimental

Potentiometric Measurements. Potentiometric titrations were carried out using a Metrohm E 636 Titroprocessor and a combined electrode 8102SC Ross (ORION Research). The range of concentration of ligand in the potentiometric titrations was 0.0107—0.0141 mol dm^{-3} for hpca-H$^+$ (pH range 2.55—11.91; number of titrations 4); 0.00673—0.01009 mol dm^{-3} for dhbc-H$^+$ (pH range 2.51—11.50; number of titrations 6); 0.0142—0.0283 mol dm^{-3} for hpca-Fe^{3+} (pH range 1.86—6.09; number of titrations 5); 0.0105—0.0283 mol dm^{-3} for dhbc-Cu^{2+} (pH range 2.37—6.09; number of titrations 4). The metal concentration varied between 0.002124—0.007258 mol dm^{-3} for hpca-Fe^{3+} and 0.003413—0.005784 mol dm^{-3} for dhbc-Cu^{2+} systems, and potassium chloride (I=0.5 mol dm^{-3}) was used as supporting electrolyte.

Spectrophotometric Measurements. Absorption spectra in the ranges 300—700±0.3 nm for Fe^{3+}-hpca were measured with a KONTRON UVIKON 860 spectrophotometer to the fourth decimal place with a stepping of 2 nm. Solutions containing the ligand and the iron prepared and maintained under purified nitrogen at the ionic strength 0.5 mol dm^{-3} (KCl), were measured at pH from 1.83 to 8.01 at 25.0±0.1 °C using 10 mm cells.

Results and Discussion

Protonation Equilibria. Starting from several sets of potentiometric data, at first the macroscopic protonation constants of the ligands (hpca and dhbc) and the initial amounts of reagents (T_L, T_H/mmol) were refined at the same time by using the SUPERQUAD[11] computer program without introducing the liquid-junction potentials (A_j and B_j) into the calculations, as shown in previous publications.[7—10] After the refinement procedure, the variances (σ^2) as regards the initial amounts of the reagents (T_L, T_H) were 4.061×10^{-7} and 5.919×10^{-7} mmol^2 for hpca and 2.753×10^{-8} and 1.074×10^{-7} mmol^2 for dhbc, respectively. The calculated cumulative and stepwise protonation and complex-formation constants (β_{pqr}) of hpca and dhbc are reported in Table 1. The potentiometric titration curves of the protonated ligand (hpca), H_2L^+ (Scheme 1), show two distinct deprotonation centers: the pyridine nitrogen (>NH$^+$) [pH 2.5—4.5; (H^2, Scheme 1), log K_2=3.189(5)], and the hydroxyl group of the -NHOH moiety [pH 7.0—9.0; (H^1, Scheme 1), log K_1=7.986(3)]; while the dhbc ligand (dhbc=H_2L,

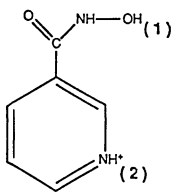
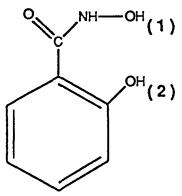


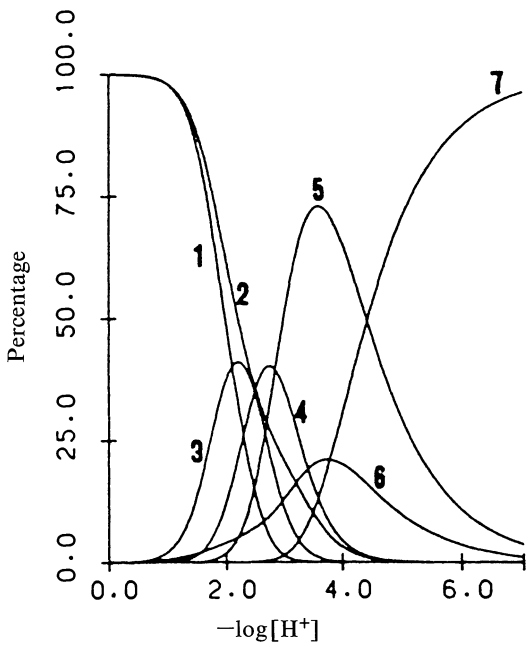
Scheme 1. (H_2L^+)=Hhpca



Scheme 2. (H_2L)=dhbc

Scheme 2) can only liberate two protons, one from the -OH group of the hydroxamic moiety [pH 6.1—8.2; (H^1, Scheme 2), $\log K_2$=7.369(4)] and one from the phenolic hydroxyl group [pH 8.4—10.6; (H^2, Scheme 2), $\log K_1$=9.722(3)]. The introduction of the CONHOH group into the pyridine ring (Scheme 1) resulted in a significant decrease of the basicity of the pyridine nitrogen from pK_a=5.3[12] to $\log K_2$=3.189(5) for hpca. This fact can be explained by a negative induction effect of the -CONHOH group on the nitrogen heteroatom. On the other hand, the substitution of an -NHOH group for the carboxyl OH^- group in the hydroxybenzohydroxamic acid examined (dhbc, Scheme 2) significantly lowers the protonation constant of the -OH group [$\log K_1$=9.722(3)] as compared to the analogous protonation constant of the corresponding -OH group in salicylic acid [$\log K_1$=13.4[13]] according to the electron-withdrawing character of the -NHOH moiety. The value for the protonation equilibrium of the hydroxamate moiety (-NHO^-) for the hpca is the same as obtained previously by conventional spectrophotometric method.[14] Rowland et al.[14] reported value of $\log \beta_{011}$=8.09 at I=0.1 mol dm^{-3} ($NaClO_4$) at 25 °C.

Metal-Complex Equilibria. Initial estimates of formation constants and the stoichiometries of possible complexes were obtained, in the case of the binary systems, from the features of formation curves. Following our usual approach, SUPERQUAD was employed to refine the formation constants and, on the basis of the usual numerical criteria, to select the initial sets of complexes. The final choices from the equilibrium models attempted are demonstrated by the excellent matching of the experimental and calculated potentiometric data and are reported in Table 1. The refinement included fixed contributions from the known metal hydrolysis constants of the species $[Fe(OH)]^{2+}$, $[Fe(OH)_2]^+$, $[Fe_2(OH)_2]^{4+}$, and $[Fe_3(OH)_4]^{5+}$. The relative importance of the various species in each pH range is shown by the typical distribution diagram, reported in Fig. 1. The species distribution curves show that complexation begins at low pH values: ca. 1.5 for $[FeH_2L_2]^{3+}$ (13.6%). The titration curves obtained on varying the iron and ligand concentrations were also processed by the FICS method (subprogram of STBLTY[15]) to give $(\partial C_H/\partial C_M)_{CL,pH}$ or $(\partial C_H/\partial C_L)_{CM,pH}$



Distribution diagram for system

Fig. 1. Typical distribution diagram for Fe^{3+}-hpca system. The percentage of each species has been calculated from the data of a hypothetical solution of iron ions (0.004 mol dm^{-3}) and hpca (0.012 mol dm^{-3}) by the Haltafall program (N. Ingri, W. Kakalowicz, L. G. Sillén, and B. Warnqvist, **14**, 1261 (1967)), and using a PLOTTER Calcomp 936. The percentages of the species not containing iron were calculated as percentages of the total ligand, those containing iron as percentages of the total metal. (1) Fe^{3+}, (2) H_2L^+, (3) $FeH_2L_2^{3+}$, (4) $FeHL_2^{2+}$, (5) FeL_2^+, (6) HL, (7) FeL_3.

respectively, as a function of pH. The displacement of two protons at pH 2.2 presumably gives an $[FeH_2L_2]^{3+}$ (41.0%) species and at pH 2.7 the predominant species is $[FeHL_2]^{2+}$ (40.1%) corresponding to the displacement of two protons with neutralization of one proton residing on the pyridinic nitrogen. At pH 3.6, the proton displacement value corresponding to the iron coordination rises to about 2.0 and can be attributed to the formation of the $[FeL_2]^{+}$ (72.8%) species when the hydroxamate moiety is about 79.1% ionized. On raising the pH further, $[FeL_3]$ (max. 96.35 at pH 7.0) species is formed. At pH=7.0, approximately three protons per mol of Fe^{3+} are liberated and the hydroxamic acid group is about completely ionized.

The spectrophotometric study was carried out on solutions containing hpca and iron ion, with concentrations and pH values selected from those employed in the potentiometric titrations. Some typical absorption spectra obtained for Fe^{III}–hpca system at different pH values are reported in Fig. 2. When the pH is increased from 1.830 to 5.346 (Fig. 2), small hypsochromic and high hyperchromic shifts (from 478 to 436 nm) are observed (intense reddish brown) [maximum, 0.683 A at 478 nm(1); 0.722 A at 476 nm(2); 0.803 A at 472 nm(3); 0.884 A at 464 nm(4); 0.963 A at 454 nm(5); 1.069 A at 442 nm(6); 1.141 A at 436 nm(7); Fig. 2], revealing changes previously described qualitatively by Neilands.[16] A maximum at 436 nm (curve 7, Fig. 2) is reached at pH 5.3, which corresponds to the maximum in the concentration (75.4%) of the species, $[FeL_3]$ (Fig. 1, curve 7). As the pH is raised from 1.83 to 8.01 the λ_{max} is observed to shift from 478 to 422 nm (Fig. 2). This charge-transfer band is typical of iron(III) hydroxamates but the pH dependence of the λ_{max} is not like that of the other naturally occurring siderophores as ferrichromes and ferrioxamines. A sharp color change is observed from red-brown to orange at about pH 5.5. No further changes are seen until approximately pH 8.0 when the color lightens to yellow-orange. Above pH 10.5 the iron is observed to precipitate as the hydroxide. Elaboration of the visible spectral data (300—700 nm) by a refinement procedure with the SQUAD[17] program indicates that at least four colored species are present between pH 1.83—8.01 ($[FeH_2L_2]^{3+}$, $[FeHL_2]^{2+}$, $[FeL_2]^{+}$, and $[FeL_3]$). Our best model is in partial agreement only with those given by El-Ezaby and Hassan,[18] Brown et al.,[19] and E. Farkas et al.,[20] for the iron(III)–aha (aha=2-amino-*N*-hydroxyacetamide) and iron(III)–ahpr (ahpr=2-amino-*N*-hydroxypropanamide) systems, respectively. Since iron(III) is a typical hard ion, we assume coordination through the *O,O* atoms of the hydroxamate moiety of hpca. Accordingly, the protonated $[FeH_2L_2]^{3+}$ (Scheme 3), and $[FeHL_2]^{2+}$ (Scheme 4) complexes contain the pyridinic nitrogen in its protonated form. This assumption is supported by the spectrophotometric results, and those recorded for iron(III) hydroxamate systems.[8,21–23] The pH dependence of iron(III)–hpca system differs from that of the iron(III) trihydroxamate siderophores, which have a broad visible maximum from 420 to 440 nm and do not

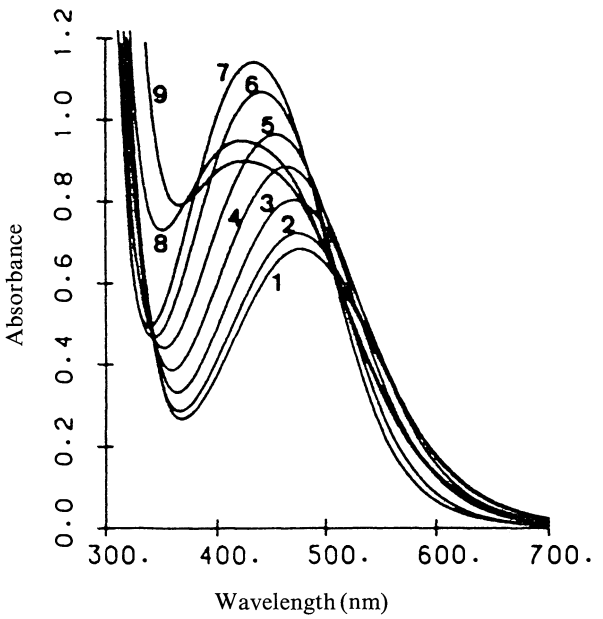


Fig. 2. Plots of experimental absorbance data versus wavelength for solutions [C_L range 2.536×10^{-2}—2.830×10^{-2} mol dm^{-3}, C_M range 3.058×10^{-3}—3.413×10^{-3} mol dm^{-3}; (1) pH=1.830, (2) pH=1.970, (3) pH=2.279, (4) pH=2.734, (5) pH=3.234, (6) pH=3.841, (7) pH=5.346, (8) pH=7.038, (9) pH=8.013] of Fe^{3+}–hpca system at 25 °C using the program VISION with the plotter Calcomp 936.

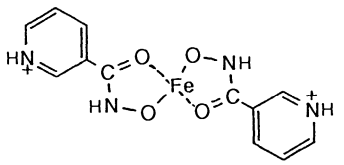
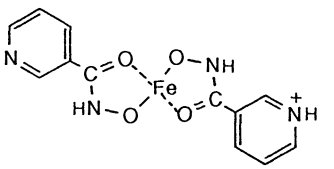
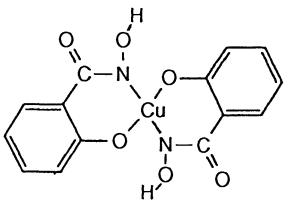


Scheme 3. $[FeH_2L_2]^{3+}$



Scheme 4. $[FeHL_2]^{2+}$



Scheme 5. $[CuL_2]^{2-}$

exhibits the marked pH-dependent spectral shifts seen for example with aerobactin.[24] Only one absorption band was observed in the pH range 1.83 to 5.35 with λ_{max} changing from 478 (pH=1.83) to 436 (pH=5.35) nm. The increase in absorption and shift to smaller wavelengths with increase in pH indicates greater complexation, and, above pH 7.3, both λ_{max} and ε_{max} remain constant, consistent with formation of the [FeL_3] species which predominates in this range. Our results concerning the main species in neutral solution of Fe^{3+}–hpca system are in good agreement with those reported earlier for iron(III) hydroxamate systems (Table 1). Nevertheless the large difference in log β_{pqr} over 5—6 log units reflects a very instable ligand structure of *N*-hydroxy-3-pyridinecarboxamide (hpca) probably due to the large variation in basicity of the only *N*-hydroxyamide grouping involved in coordination as simple aromatic hydroxamic acids. The Fe^{3+}–hpca system therefore probably satisfies different criteria for biological activities and analytical roles, strongly indicating Fe^{3+}–hpca complexes as suitable sources of iron as trace element essential in animal nutrition. However our results show clearly that, at least at physiological pH, the assumption of an uncoordinated α-amino group (heteroatom), which may be particularly active because of a possible surface-active role, is incorrect since the major species in this pH range is FeL_3.

In Cu^{II} complexes with dhbc it is certain that the copper hit on the ligand takes place following the *N,O* coordination (six membered chelate rings, Scheme 5). In comparison with the amino hydroxamic acids till now investigated, where the coordination to copper ion was *N,N* type, here the mononuclear complexes are much more stable (log K_1 and log K_2 much greater), perhaps it is due both to the kinds of atoms (*N,O* rather than *N,N*, Scheme 5) and to greater basicity of the groups involved in the coordination. The trend of potentiometric titration curves for Cu^{2+}–dhbc system has only a buffer zone (spectrophotometric titrations reveal only a intense green color), while in the systems studied till now and involving Cu^{2+} and amino hydroxamic acids were perfectly visible two buffer zones shared by inflection point, where you could observe the formation of polynuclear hydrolized species, that does not present in the Cu^{2+}–dhbc system because probably of the high stability of simple complexes.

Grateful acknowledgement is made to the Ministero dell'Università e della Ricerca Scientifica e Tecnologica (M.U.R.S.T.) and National Research Council of Italy (C.N.R.) for generous grants. I am greatly indebted to Professors P. Gans, A. Vacca, and A. Sabatini for their generous support of the program SUPERQUAD.

(Received May 16, 1991)

Liposomes formed with synthetic double-chain ammonium amphiphiles were used for DNA transfection into eukaryotic cells. We studied the correlation between the efficiency of various cationic amphiphiles in DNA transfection and their physicochemical properties. The efficiency of amphiphiles in the transfection was examined by the transient expression of β-galactosidase from its cDNA in COS cells. Amphiphiles with a phase-transition temperature (T_c) lower than 37 °C, as measured by differential scanning calorimetry, could introduce DNA into the cells. Electron microscopic observation indicated that amphiphiles possessing DNA transfection ability form vesicular structures in aqueous solution. Thus, fluid and vesicular bilayer structures were much higher than rigid and helical bilayer structures regarding the effectiveness of amphiphiles in DNA transfection. The efficiency of didodecyl *N*-[*p*-(2-trimethylammonioethoxy)benzoyl]-L-glutamate bromide was the highest of all the synthetic amphiphiles examined.

In 1977 it was found that stable bilayer membranes were formed from dialkyldimethylammonium bromides[1] and a large number of cationic amphiphiles with long dialkyl chains were shown to form bilayer membranes.[2] As these synthetic bilayer membranes have physicochemical characteristics, such as an aggregate morphology,[3] phase transition,[4] fusio,[5] and phase separation,[5] similar to those of the biolipid bilayer membranes, possibly they can be used for various biological systems, without harmful effects. Use of synthetic amphiphiles in biological systems has the advantage in that the physicochemical characteristics of amphiphiles can be controlled by designing specific molecular structures.

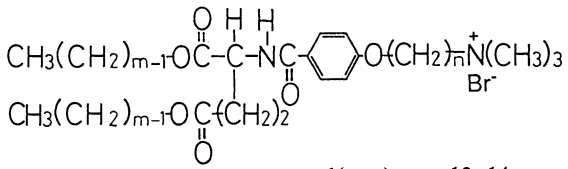
Cationic liposome-mediated transfection is one of effective methods of introducing DNA into eukaryotic cells. The liposomes spontaneously interact with DNA, fuse with cultured cells and facilitate the delivery of functional DNA into the cells. A cationic liposome formed from [2,3-bis(oleoyloxy)propyl]-trimethylammonium chloride (DOTMA) was first reported to be effective in DNA transformation.[6,7] In the foregoing paper we showed that one of dialkyl ammonium amphiphiles, didodecyl *N*-[*p*-(2-trimethylammonioethoxy)-benzoyl]-L-glutamate bromide, which can form a stable bilayer membrane, had a higher DNA transfection potential than did DOTMA.[8,9]

We have examined the correlation between the efficiency of synthetic amphiphiles in DNA transfection and their physicochemical characteristics, such as membrane fluidity and aggregate morphologies. We show that amphiphiles forming fluid and vesicular bilayer are highly effective in DNA transfection.

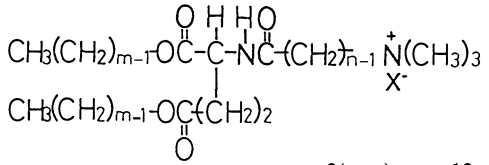
Results and Discussion

Two series of chiral dialkylammonium amphiphiles, **1** and **2** (Fig. 1), were synthesized and the correlation between physicochemical properties and DNA transfection ability was examined. A first series of amphiphiles, **1**(*m,n*), consists of two tails (length of "tail", *m*), trifunctional glutamate and phenylene groups as a connector, methylene spacer (the length of "spacer", *n*) and ammonio group as a cationic head. A second series of amphiphiles, **2**(*m,n*), has the same basic structure as **1**, but there is no phenylene group in the connector.

Transfection Efficiency of Amphiphiles. To examine the relative efficiency of amphiphiles in the delivery of DNA into cells, we used the transient expression of plasmid pCH110 with a β-galactosidase gene in COS cells. The extent of the expression was determined



1(*m,n*) $m=12, 14$ $n=2, 4, 6, 8$



2(*m,n*) $m=12, 14$ $n=2, 4, 6$

X=Cl (n=2, 4)
=Br (n=6)

Fig. 1. Structures of the synthetic cationic amphiphiles examined.

by measuring the percentage of cells expressing β-galactosidase and by assaying enzyme activity in the cell extracts. Figure 2 shows the efficiency of various amphiphiles in the expression of β-galactosidase. COS cells were transformed with 1 to μg of pCH110 DNA using 10 μg (13 nmol) of liposomes prepared from the amphiphiles, as described under Experimental. Since less than 5% of the total cells were detached from the dish during the culture periods, in all the experiments, the amphiphiles were not cytotoxic, under the condition used. As can be seen in the figure, two measurements of the expression of β-galactosidase, the number of cells expressing the enzyme and the total enzyme activity in the cell extract, correlated fairly well, hence all the cells incorporating plasmid DNA seem to express the gene and produce the enzyme protein, to almost the same extent. In a series of **1**, the transfection efficiency varied greatly according to differences in lengths of a tail and spacer of the amphiphiles. An increase in spacer length of a series of **1**(12,*n*) caused a remarkable decrease in the transfection efficiency. A more dramatic difference was observed between series of **1**(12,*n*) and **1**(14,*n*). Change of dialkyl chains from dodecyl to tetradecyl groups resulted in an almost complete loss of transfection ability. In the second series, **2**(12,*n*) and **2**(14,*n*), all compounds listed in Fig. 1 had the ability to transfer a gene, though their efficiencies were less than a half of **1**(12,2). There seems to be no correlation between the efficiency of the amphiphiles of series **2** in gene transfection and their structural characteristics, lengths of a tail and spacer (Fig. 2). In the series of **1**(12,*n*) and **2**(12,*n*), 1-2 μg of DNA was optimum for the transfection, and 5 μg of DNA led to a marked decrease in the efficiency. Since a preliminary experiment showed that about 2 μg of DNA could bind to 10 μg of the amphiphiles, free DNA might interfere with the liposome-mediated transfection of DNA into the cells when 5 μg of DNA was used. Among the amphiphiles examined, **1**(12,2) showed the highest efficiency in DNA transfection.

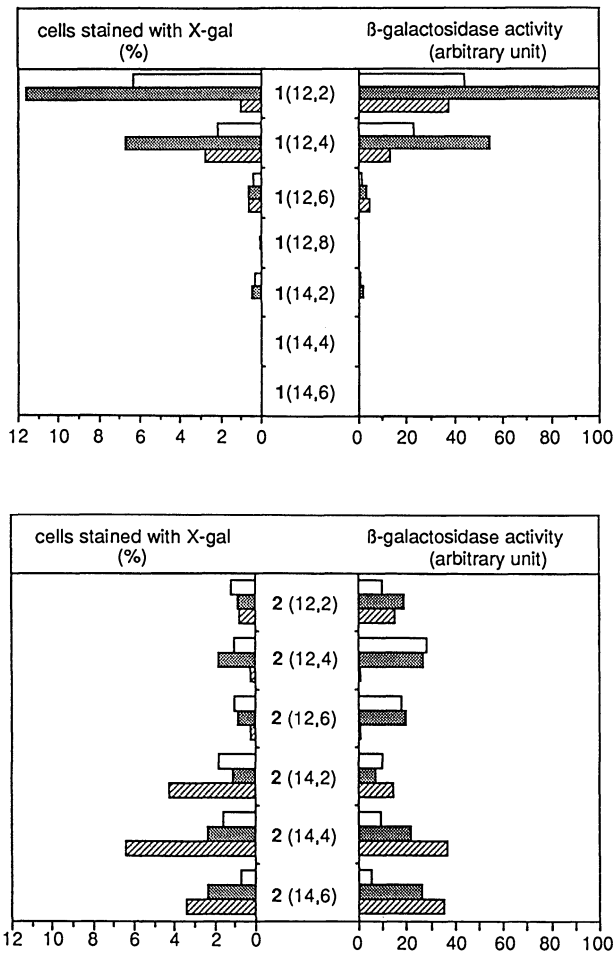


Fig. 2. Transfection efficiency of various amphiphiles. Cells were transfected with amphiphiles/DNA complexes containing 13 nmol of amphiphiles and μg (open bar), 2 μg (dotted bar), 5 μg (oblique line bar) of plasmid DNA, pCH110, per 22 mm dish. After incubation of the cells for 48 h, the cells were harvested and subjected to assay of transfection, as described under Experimental. The relative activity of β-galactosidase was expressed by setting the enzyme activity in the extract of the cell transformed with **1**(12,2) at 100.

Table 1. Phase Transition Temperature T_c and Aggregation Morphology of Amphiphiles **1** and **2**

Amphiphile (*m*, *n*)	T_c[a] (DSC peak)/°C	Aggregate morphology[b]
1 (12, 2)	24.8	Vesicle
1 (12, 4)	29.4	Vesicle
1 (12, 6)	39.4	Lamella
1 (12, 8)	39.9	Filament
1 (14, 2)	41.1	Vesicle
1 (14, 4)	45.0	Vesicle & lamella
1 (14, 6)	51.2	Filament
2 (12, 2)	N. D.[c]	Vesicle & lamella
2 (12, 4)	N. D.	Vesicle & lamella
2 (12, 6)	9.0	Vesicle & lamella
2 (14, 2)	22.0	Vesicle
2 (14, 4)	21.8	Vesicle
2 (14, 6)	25.4	Vesicle

a) Sample, 20 mM in water. Temperature was elevated from 5 °C at a rate of 1 °C min^{-1}.
b) Sample, 10 mM in water. c) N. D.: not detected.

Physicochemical Characteristics of Amphiphiles. To determine which physicochemical properties of amphiphiles are responsible for transfection efficiency, we measured thermal and morphological behavior, of amphiphiles in aqueous solution and searched for a possible correlation between transfection efficiencies and physicochemical characteristics.

Phase Transition. The transition between the crystal and liquid-crystal phases is one of the most fundamental characteristics of a bilayer membrane. The phase transition can be detected directly by differential scanning calorimetry (DSC).[4] The phase-transition temperature T_c (peak top temperature in the DSC scan) is summarized in Table 1. As pointed out d by Kunitake and Ando,[4] T_c increased with an increase in tail and spacer lengths of the amphiphiles. A series of **2** without a phenylene unit in the connector region had much lower T_c values than did a series of **1**. In a series of **1**, enhanced aromatic stacking may suppress molecular disordering in the liquid crystalline state. T_c values of **2**(12,2) and **2**(12,4) were too low to be determined by DSC measurements. These results indicate that all the amphiphiles possessing measurable DNA transfection ability, **1**(12,2), **1**(12,4), and a series of **2**, had T_c values lower than 37 °C. Since the transfection experiment was carried out at 37 °C, these amphiphiles were in the fluid liquid crystalline state in the culture medium. Thus, the primary requirement for the transfection of DNA appears to be fluidity of the liposomes.

Aggregate Morphology. Electron microscopy is a useful tool for the direct observation of bilayer formation and aggregate morphology of the amphiphiles. Some representative electron micrographs are shown in Fig. 3. All the amphiphiles had bilayer structures. However, the aggregate morphology varies with the molecular structure of the component amphiphile. Amphiphile **1**(12,2) formed well-developed vesicles with a diameter of 300—600 Å, as shown in Fig. 3a. Similar morphologies were observed for **1**(12,4), **1**(14,2), **1**(14,4), **2**(14,2), **2**(14,4), and **2**(14,6), but with different diameters of 500—3000, 400—1000, 300—600, 800—1500, 1000—2500 and 500—3000 Å, respectively. Figure 3b shows multiwalled vesicles and/or lamellae aggregates formed from **2**(12,2), with a diameter of 400—2000 Å. Amphiphiles **2**(12,4) and **2**(12,6) had similar morphologies. Amphiphile **1**(12,6) gave fragmentary lamellae (Fig. 3c), and **1**(12,8) and **1**(14,6) gave helical filaments with a length of 1—3 μm (Fig. 3d). Aggregate morphology of amphiphiles **1** and **2** are summarized in Table 1. These morphological observations indicate that amphiphiles forming vesicular structure had DNA transfection ability and that the smaller vesicles appeared to be more

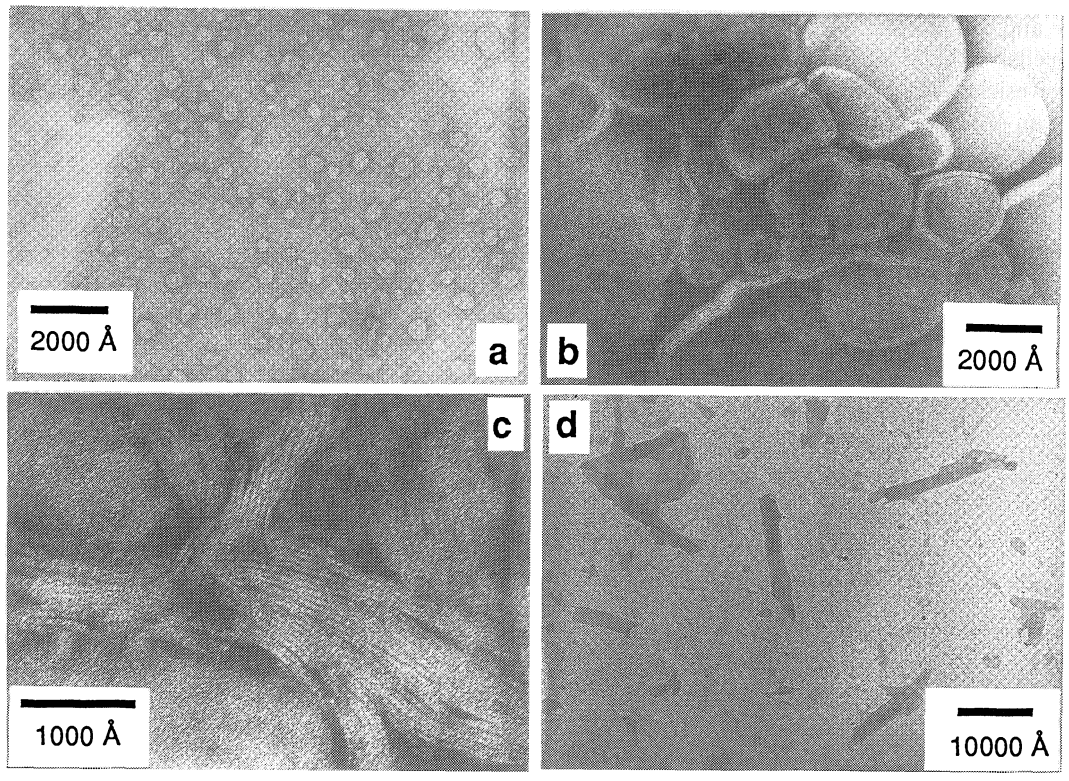

Fig. 3. Electron micrographs of aggregates formed from **1** and **2**. Amphiphiles **1** and **2** were suspended in water (10 mM), sonicated, and stained with uranyl acetate.
a. **1**(12,2), original magnification×50000
b. **2**(12,2), original magnification×50000
c. **1**(12,6), original magnification×150000
d. **1**(14,6), original magnification×10000

effective than larger ones.

Aggregate Size. Stability of the aggregates was studied by measuring change in size while standing. Aqueous dispersions of the amphiphiles were kept at room temperature (about 25 °C) for 0.5 and 24 h and size of the aggregates was measured using a dynamic light scattering apparatus (Table 2). Average size of the aggregates of the amphiphiles **1** and **2** was much the same as those determined by electron microscopy. After leaving for 24 h at room temperature, aggregate sizes of **1**(12,2), **1**(12,4), **1**(14,2), and **1**(14,4) increased by less than 20% of the original size, hence that the vesicular structures formed by these amphiphiles were stable and little fusion occurred between the vesicles. On the other hand, aggregates of **1**(12,6), **1**(12,8), and of a series of **2** increased in size by 4—20 times. In these aggregates, fusion and/or morphological change from vesicular structure to lamella, tubular, or filamentous structure, of the bilayer membranes seemed to readily occur. These results suggest that amphiphiles forming stable aggregates had a higher DNA-transfection ability.

In conclusion, we found a good correlation between the efficiency of the synthetic amphiphiles in gene transfection and their physicochemical characteristics, such as membrane fluidity and aggregate morphologies. The primary requirement of an amphiphile for DNA transfection is that the T_c value be lower than 37 °C so that it is in the fluid liquid crystalline state at the culture temperature and can interact with plasma membranes of the culture cells. The second requirement is to form a small stable vesicle. The vesicular structure might be required for an effective interaction between aggregates and DNA and/or the cells. Thus, amphiphiles that form small stable vesicles in the fluid state are suitable for DNA-transfection, and **1**(12,2) is highest in efficiency of all the amphiphiles we tested.

Table 2. Aggregate Size of Amphiphiles **1** and **2**

Amphiphile (m, n)	Aggregate size[a]/10^3 Å	
	0.5 h	24 h
1 (12, 2)	1.2	1.5
1 (12, 4)	1.6	1.9
1 (12, 6)	1.6	6.9
1 (12, 8)	4.7	25.9
1 (14, 2)	1.2	1.3
1 (14, 4)	1.3	1.4
1 (14, 6)	1.5	—[b]
2 (12, 2)	0.8	16.3
2 (12, 4)	1.3	18.7
2 (12, 6)	1.1	4.0
2 (14, 2)	0.7	11.0
2 (14, 4)	0.9	8.8
2 (14, 6)	0.8	9.4

a) Aqueous dispersion of amphiphiles (0.043 mM) were left at room temperature (about 25 °C) for 0.5 and 24 h. The measurements were carried out using dynamic light scattering spectrophotometer at 25 °C. b) Not determined.

Experimental

Chemicals. Double-chain amphiphiles **1** and **2**, listed in Fig. 1, were synthesized according to the method of Kunitake et al.[10]

Cells and Plasmids. Cos-1, a simian kidney cell line transformed with simian virus 40 (SV40), was maintained in a Dulbecco's modified Eagle Medium (DMEM) supplemented with 10% inactivated fetal calf serum in an atmosphere of 10% CO_2 at 37 °C. Plasmid DNA (pCH110) has a β-galactosidase gene (lac Z) and SV40 early promoter.

Amphiphiles-Mediated Transfection. Transfection experiments were carried out as described by Felgner et al.[6,7] with some modifications.[8,9] COS-1 cells were grown to just before confluency in 22 mm dishes and washed twice with 1 ml of Hepes-buffered saline (HBS; 20 mM Hepes-KOH buffer containing 150 mM NaCl (1 M=1 mol dm^{-3}), pH 7.4). Plasmid DNA (in 10 mM Tris-HCl, 1 mM EDTA, pH 8.0) and amphiphiles suspension (13 nmol, prepared by sonication) were diluted separately with 0.15 ml of HBS. Both solutions were combined and 0.4 ml of amphiphiles–DNA mixture was poured gently onto the cells. After incubation for 3—5 h at 37 °C, 2 ml of DMEM supplemented with 10% fetal calf serum was added and the detached cells became suspended. The medium was replaced with 2 ml of a fresh medium after 12—20 h, and the cells were incubated for 48 h from the first addition of DMEM.

Transfection Efficiency. Monolayer cells were harvested after a 48 h culture. The efficiency of amphiphiles in the expression of β-galactosidase was measured by counting the number of the cells visualized by histochemical staining of the enzyme activity and by assaying of the total enzyme activity in the extract of the cultured cells using 5-bromo-4-chloro-3-indolyl β-D-galactopyranoside (X-gal)[11] and *o*-nitrophenyl β-D-galactopyranoside[12] as the substrate, respectively.

Phase-Transition Temperature. An aqueous solution of amphiphile (20 mM) was sealed in a silver sample pan. Measurements were carried out using a Seikosha differential scanning calorimeter Model DSC-210 heating rate, 1 °C min^{-1}.[4]

Electron Microscopy. Amphiphiles suspended in distilled water (10 mM) were sonicated using a Tomy Sonifier for several minutes to give a clear solution and this solution was applied to carbon-coated grids and dried in vacuo. The sample was stained with a 2% aqueous uranyl acetate solution and subjected to electron microscopic examination[13] using a Hitachi electron microscope, Model H-7000.

Dynamic Light Scattering. Amphiphiles suspended in water (0.043 mM) were sonicated for several minutes to give a clear solution. After standing at room temperature (about 25 °C) for 0.5 and 24 h, the suspension was subjected to dynamic light scattering experiment[13] using an Otsuka Electronics Co., Model DLS-700 with a laser light source.

The Claisen Rearrangement of 2-Phenylsulfinyl-2-propenyl Phenyl Ethers —A New Route to Functionalized Phenols and 2-Methylbenzofurans

Muhammad Akram KHAN†
Department of Chemistry, University of Kuwait, P.O. Box 5969, Safat 13060, Kuwait
(Received December 1, 1990)

The hitherto unknown Claisen rearrangement of 2-phenylsulfinyl-2-propenyl phenyl ethers to the corresponding 2-(2-phenylsulfinyl-2-propenyl)phenols is reported. The latter compounds underwent Michael reactions with a variety of nucleophiles to provide functionalized phenolic adducts. *O*-Alkylation of the initial rearrangement products with 3-bromo-2-phenylsulfinyl-1-propene and 2,3-dibromo-1-propene followed by [3,3] sigmatropic rearrangement provided a promising route to 7-substituted 2-methylbenzofurans.

Although the [3,3] sigmatropic rearrangement of enol or phenol ethers to the corresponding *C*-alkylated products also known as the Claisen rearrangement[1] has enjoyed widespread application in organic synthesis for over seven decades, it continues to be a rewarding reaction for the construction of carbon–carbon bonds. We report here in this context a hitherto unknown Claisen rearrangement of (phenoxy-substituted alkenyl) phenyl sulfoxides (**2a—d**). Alkenyl sulfoxides are versatile molecules in organic synthesis. They act as dienophiles, Michael acceptors, and as precursors to alkenyl sulfides, chloroalkyl sulfides, ketones, allenes, enamines, and enamides.[2] The alkenyl sulfoxides (**2a—g**) were prepared efficiently by the regiospecific addition of benzenesulfenic acid to the terminal alkynes (**1a—g**). The benzenesulfenic acid was generated in situ by the thermolysis of 1-cyano-2-(phenylsulfinyl) ethane.[3]

The sulfoxides (**2a—d**) as solutions in mesitylene were very cleanly transformed upon reflux into the corresponding phenols (**3a—d**) (yields ca. 50%). The reaction progress was monitored by TLC which showed the phenolic products (**3a—d**) to have relatively lower R_f values compared with the starting ethers (**2a—d**). Using 1,2-dichlorobenzene (DCB) as the reaction solvent the yields of the products (**3a—d**) were significantly improved (80%). ^{1}H NMR and IR spectroscopies tentatively established the product structures. The appearance of OH absorptions (ca. 3200 cm^{-1}) in the IR spectra of products (**3a—d**) and the change in the chemical shift of the diastereotopic allylic methylene protons from low field (δ=4.1—4.5 in starting materials **2a—d**) to high field (δ=3.1—3.5 in products **3a—d**) were the most noticeable spectroscopic features that witnessed the rearrangement process.

Under similar reaction conditions to above the thioether (**2e**) rearranged to yield 2-methylbenzothiophen (**4**) along with *O*-phenyl and *S*-phenyl benzenethiosulfinates (PhSSOPh), a product known to arise from the intermolecular condensation of benzenesulfenic acid. 2-Methylbenzo[*b*]thiophens and 2-methylbenzofurans have previously been obtained from the Claisen rearrangement of 2-chloro-2-propenyl

phenyl ethers and thioethers.[4]

The corresponding amino-substituted sulfoxides (**2f**, **2g**) resisted rearrangement under similar reactions. Although it is known that the amino Claisen rearrangement is greatly accelerated by acids and Lewis acid catalysis,[5] the use of these reagents in our case was negated by the fact that sulfoxides are decomposed by such reagents.

The (phenoxy-substituted alkenyl) sulfoxides (**3a**—**d**) underwent Michael reactions in alcoholic solutions with diethyl sodiomalonate, thiolate anions, β-alanine ethyl ester and sodium ethoxide to furnish the adducts (**5a**—**d**) in good yields. Since suitably substituted phenolic compounds are pharmacologically rewarding compounds,[6] the Michael reactions of the phenols (**3a**—**d**) provides a method for synthesizing a great variety of new hetero derivatives such as (**5a**—**d**) that otherwise are difficult to produce.

O-Alkylation of **3** with synthons 2,3-dibromo-1-propene and 2-bromo-2-phenylsulfinyl-1-propene[2] gave the ethers (**6a**) and (**6b**) respectively which underwent [3,3] sigmatropic rearrangement upon reflux in mesitylene to afford the acyclic adducts (**7a**) and (**7b**) as the only reaction products. However, rearrangement of the ethers (**6a**) and (**6b**) under catalysis by SiO_2 (Fluka 60H) resulted in the formation of 2-methylbenzofurans (**8a**) and (**8b**) respectively. Repeating the SiO_2-catalyzed reactions in DCB as the solvent resulted in decomposition and polymerization. Dark oily compounds in the case of **7b** were obtained that crystallized upon the addition of diethyl ether. Although soluble in chloroform the identification of the solid proved difficult, however. Benzofurans are biologically important molecules.[7] The Michael reactions of the 7-(phenylsulfinyl-substituted alkenyl) benzofuran (**8b**) with various nucleophiles should provide a route to a wide variety of hetero derivatives that might have interesting physiological properties.

Experimental

NMR spectra were recorded on either JEOL EX90 FT or Perkin-Elmer R34 (220 MHz) NMR spectrometers for solutions in $CDCl_3$ with $SiMe_4$ as an internal standard. IR spectra were recorded on a Perkin-Elmer 520B spectrophotometer. Mass spectra were obtained on either Finnigan MAT 311A or Nermag R10-10 connected to a Varian Vista 6000 GC. Analytical TLC was performed on Eastman Kodak Silica Chromatogram sheets using diethyl ether (ether) as the eluent. Column chromatography was performed on Fluka SiO_2 60H under pressure using the short path technique.

Preparation of Acetylenic Precursors (1a—g). The preparations of compounds **1a**,[8] **1e**,[8] **1f**,[8] and **1g**,[2] are described elsewhere.

3-(4-Chlorophenoxy)-1-propyne (1b). This was prepared (11.7 g, 70%) from NaOEt (0.1 mol) in dry EtOH (45 ml), 4-chlorophenol (12.86 g, 0.1 mol) and 3-bromo-1-propyne (12.9 g, 0.108 mol); bp 60 °C/0.2 mm Hg (1 mmHg=133.322 Pa); IR (neat) 3295 (HC≡C–), 2115 (–C≡C–) cm^{-1}; ^1H NMR δ=2.50

(1H, t, J=2 Hz acetylenic proton), 4.60 (2H, d, J=2 Hz, $-OCH_2-$), 6.80 (2H, d, J=9 Hz, ArH *ortho* to oxygen), 7.22 (2H, d, J=9 Hz, ArH *ortho* to Cl). Found: C, 64.7; H, 4.1%. Calcd. for C_9H_7OCl: C, 64.86; H, 4.20%.

3-(*p*-Tolyloxy)-1-propyne (1c). It was prepared in a similar way to above from *p*-cresol (10.8 g, 0.1 mol), 3-bromo-1-propyne (12.9 g, 0.108 M) (1 M=1 mol dm^{-3}) and NaOEt (0.1 mol); bp 50 °C/0.2 mm Hg; IR (neat) 3290 (HC≡C–), 2110 (–C≡C–) cm^{-1}; ^{1}H NMR δ=2.23 (3H, s, $-CH_3$), (1H, t, J=2 Hz, acetylenic proton), 4.57 (2H, d, J=2 Hz, $-OCH_2-$), 6.76 (2H, d, J=9 Hz, ArH *ortho* to oxygen), 7.03 (2H, d, J=9 Hz, ArH *ortho* to CH_3). Found: C, 82.0; H, 6.7%. Calcd for $C_{10}H_{10}O$: C, 82.19; H, 6.85%.

3-(4-Methoxyphenoxy)-1-propyne (1d). This was prepared (65 g, 86%) from *p*-anisole (58 g, 0.47 mol), 3-bromo-1-propyne (57 g, 0.48 mol), and NaOEt (0.47 M); bp 112—114 °C/7 mmHg; IR (neat) 3295 (HC≡C–), 2125 (–C≡C–) cm^{-1}; ^{1}H NMR δ=2.45 (1H, t, J=2 Hz, acetylenic proton), 3.63 (3H, s, $-OCH_3$), 4.50 (2H, d, J=2 Hz, $-OCH_2-$), 6.73 (4H, m, ArH). Found: C, 74.0; H, 6.1%. Calcd for $C_{10}H_{10}O_2$: C, 74.07; H, 6.17%.

Preparation of Alkenyl Sulfoxides (2a—g). The alkenyl sulfoxides **2a**,[8] **2e**,[8] **2f**,[8] and **2g**,[2] have been prepared by us and described elsewhere.

3-(4-Chlorophenoxy)-2-phenylsulfinyl-1-propene (2b). Thermolysis of 1-cyano-2-(phenylsulfinyl)ethane (4.0 g, 22.3 mmol) in the acetylene **1b** (15 g, 90 mmol) for 3 h under N_2 at 110 °C in a toluene vapor jacket gave an oily residue, after distillation to remove excess **1b**, which was purified by column chromatography [(a) (1 : 1) ether–petroleum ether (40 : 60) (b) ether] to give **2** (5.8 g, 89%) as an oil which solidified on keeping. Recrystallization [acetone–petroleum ether (40 : 60)] yielded pure **2b** as a white powder, mp 92—95 °C; IR (KBr) 1040 (>S=O) cm^{-1}; ^{1}H NMR δ=4.33 (1H, d, J=13.5 Hz, diastereotopic allylic proton), 4.70 (1H, d, J=13.5 Hz, diastereotopic allylic proton), 5.93 (1H, s, olefinic proton *trans* to –SOPh), 6.25 (1H, s, olefinic proton *cis* to –SOPh), 6.65 (2H, d, J=8 Hz, ArH *ortho* to oxygen), 7.16 (2H, d, J=8 Hz, ArH *ortho* to Cl), 7.36—7.93 (5H, m, –SOPh); MS m/z 293 (M$^+$), 277, 167, 126. Found: C, 61.3; H, 4.3%. Calcd for $C_{15}H_{13}O_2SCl$: C, 61.54; H, 4.44%.

3-(*p*-Tolyloxy)-2-phenylsulfinyl-1-propene (2c). Thermolysis of 1-cyano-2-(phenylsulfinyl)ethane (2.0 g, 11.1 mmol) in **1c** (11 g, 75.3 mmol) in the above manner gave pure **2c** (2.8 g, 93%) as an oil which solidified on keeping. Recrystallization [acetone–petroleum ether (40 : 60)] yielded a white powder, mp 48—50 °C; IR (KBr) 1040 (>S=O) cm^{-1}; ^{1}H NMR δ=2.25 (3H, s, $-CH_3$), 4.30 (1H, d, J=13.5 Hz, diastereotopic allylic proton), 4.68 (1H, d, J=13.5 Hz, diastereiotopic allyl proton), 5.93 (1H, s, olefinic proton *trans* to –SOPh), 6.20 (1H, s, olefinic proton *cis* to –SOPh), 6.63 (2H, d, J=8 Hz, ArH *ortho* to oxygen), 7.0 (2H, d, J=8 Hz, ArH *ortho* CH_3), 7.36—7.75 (5H, m, –SOPhH); MS m/z 272. Found: C, 70.4; H, 5.8%. Calcd for $C_{16}H_{16}O_2S$: C, 70.59; H, 5.88%.

3-(4-Methoxyphenoxy)-2-phenylsulfinyl-1-propene (2d). Thermolysis of 1-cyano-2-(phenylsulfinyl)ethane (7.0 g, 39.1 mmol) in **1d** (33 g, 6.204 mol) in the above manner yielded pure **2d** (9.6 g, 85%) as a thick brown oil which solidified after prolonged keeping. Recrystallization (as above) yielded a white powder, mp 90—94 °C; IR (KBr) 1050 (>S=O) cm^{-1}; ^{1}H NMR δ=3.70 (3H, s, $-OCH_3$), 4.33 (1H, d, J=14.5 Hz, –OCH–), 4.65 (1H, d, J=14.5 Hz, –OCH–), 5.95 (1H, s, olefinic H *trans* to –SOPh), 6.23 (1H, s, olefinic H *cis* to –SOPh), 6.66 (2H, d, J=7.5 Hz, ArH *ortho* to oxygen), 6.75 (2H, d, J=7.5 Hz, ArH *ortho* to OCH_3), 7.43—7.53 (5H, m, SOPh); MS m/z 288 (M$^+$), 195, 162, 141, 77 (100%). Found: C, 66.5; H, 5.4%. Calcd for $C_{16}H_{16}O_3S$: C, 66.67; H, 5.55%.

Claisen Rearrangement of the Sulfoxides (2a—e). The following procedure illustrated for **2a** was typical. A solution of the sulfoxide **2a** (1.9 g, 7.36 mmol) in dry mesitylene (19 ml) was heated under N_2 in an oil bath maintained at 180 °C for 20—24 h. After removal of the solvent under reduced pressure an oily residue was obtained which was chromatographed [(a) (1 : 1) ether–petroleum ether (40 : 60) (b) ether] to yield mesitylene followed by unchanged **2a** (480 mg, 25%), and finally 2-(2-phenylsulfinyl-2-propenyl)phenol **3a** (1.33 g, 70%) as a pale yellow oil which solidified on keeping. Recrystallization [(CH_2Cl_2–petroleum ether (40 : 60)] afforded pure **3a** as a white powder, mp 94—95 °C; IR (KBr) 3200 (OH, broad), 1020 (>S=O) cm^{-1}; ^{1}H NMR δ=3.10 (d, J=16 Hz, 1H, diastereotopic allylic –OCH–), 3.50 (d, J=16 Hz, 1H, diastereotopic allylic –OCH–), 5.65 (s, 1H, olefinic H *trans* to –SOPh), 6.00 (s, 1H, olefinic H *cis* to SOPh), 6.6—7.20 (m, 4H, ArH), 7.25—7.90 (m, 3H, –SOPh); MS m/z 258 (M$^+$), 218, 131 (100%). Found: C, 69.6; H, 5.3; S, 12.3%. Calcd for $C_{15}H_{14}O_2S$: C, 69.77; H, 5.43; S, 12.40%. Rearrangement of **2a** in 1,2-dichlorobenzene (DCB) gave in **3a** in a higher yield (86%).

4-Chloro-2-(2-phenylsulfinyl-2-propenyl)phenol (3b). Similar to above the sulfoxide **2b** (550 mg, 1.88 mmol) in mesitylene (6 ml) yielded upon heating **3b** (281 mg, 51%) together with unchanged **2b** (260 mg, 47%). The pale yellow oily phenol **3b** solidified upon keeping. Recrystallization (as above) afforded **3b** as a white powder, mp 130—131 °C; IR (KBr) 3195 (OH, broad), 1025, 1030 (>S=O) cm^{-1}; ^{1}H NMR δ=3.05 (d, J=15 Hz, 1H, –OCH–), 3.45 (d, J=15 Hz, 1H, –OCH–), 5.63 (s, 1H, olfefinic H *trans* to SOPh), 6.00 (s, 1H, olefinic H *cis* to SOPh), 6.5—7.15 (m, 3H, ArH), 7.3—7.7 (m, 5H, –SOPh); MS m/z 292 (M$^+$), 277, 165 (100%), 126. Found: C, 61.4; H, 4.3; S, 11.0%. Calcd for $C_{15}H_{13}O_2SCl$: C, 61.54; H, 4.44; S, 10.94%. Rearrangement of **2b** in DCB gave **3b** in 80% yield.

4-Methyl-2-(2-phenylsulfinyl-2-propenyl)phenol (3c). Thermal rearrangement of **2c** (550 mg, 2.02 mmol) in mesitylene (6 ml) in the above manner afforded **3c** (440 mg, 80%) as an oil which solidified on keeping. Recrystallization (as above) yielded **3c** as a white powder, mp 128—130 °C; IR (KBr) 3195 (OH, broad), 1030, 1040 (>S=O) cm^{-1}; ^{1}H NMR δ=2.15 (d, J<2 Hz, 3H, CH_3), 3.12 (d, J=15 Hz, 1H, –OCH–), 3.53 (d, J=15 Hz, 1H, –OCH–), 5.70 (s, 1H, olefinic H *trans* to SOPh), 6.05 (s, 1H, olefinic H *cis* to –SOPh), 6.65—7.05 (m, 3H, ArH), 7.4—7.7 (m, 5H, –SOPh); MS m/z 272 (M$^+$). Found: C, 70.5; H, 5.7; S, 11.6%. Calcd for $C_{16}H_{16}O_2S$: C, 70.59; S, 11.76%. Rearrangement of **2c** in DCB yielded **3c** in higher yield (95%).

4-Methoxy-2-(2-phenylsulfinyl-2-propenyl)phenol (3d). The thermal rearrangement of **2d** (3.0 g, 16.4 mmol) in mesitylene (30 ml) in the above manner produced **3d** (2.55 g, 85%) as a thick dark brown oil; IR (neat) 3190 (OH, broad), 1035 (>S=O) cm^{-1}; ^{1}H NMR δ=3.13 (d, J=16 Hz, 1H, –OCH–), 3.45 (d, J=16 Hz, 1H, –OCH–), 3.67 (s, 3H, $-OCH_3$), 5.67 (s, 1H, olefinic H *trans* to –SOPh), 6.07 (s, 1H, olfefinic H *cis* to –SOPh), 6.50 (d, J=2 Hz, 1H, H-3), 6.65 (dd, J=2 Hz and 8 Hz, 1H, H-5), 6.77 (d, J=8 Hz, 1H, H-6), 7.4—7.55 (m, 3H, –SOPh), 7.55—7.70 (m, 2H, –SOPh); MS m/z 288 (M$^+$), 162 (100%). Found: C, 66.6; H, 6.5; S, 11.0%. Calcd for

$C_{16}H_{16}O_3S$: C, 66.67; H, 5.55; S, 11.11%. Rearrangement of **2d** in DCB afforded **3d** in higher yield (95%).

2-Methylbenzothiophene (4). Thermal rearrangement of **2e** (210 mg, 7.66 mmol) in mesitylene (3 ml) gave **4** (135 mg, 64%), as a pale brown solid; mp 50—52 °C (lit,[4] mp 51—52 °C). The compound had identical ^{1}H NMR with that reported in the literature. The other product obtained from column chromatography of reaction mixture was *S*-phenyl benzenethiosulfinates (PhSSOPh).

The Michael Reactions of the Alkenyl Sulfoxides (3a—d). 2-[4,4-Bis(ethoxycarbonyl)-2-(phenylsulfinyl)butyl]phenol (5a). A solution of **3a** (1.0 g, 3.87 mmol) in absolute EtOH (1 ml) was added to a solution of diethyl sodiomalonate (1.24 g, 7.75 mmol) in absolute EtOH (2.5 ml) and the mixture heated under N_2 in EtOH vapor jacket (ca. 80 °C) for 14 h. The EtOH was evaporated and the residue, after acidification with H_2SO_4 (2 M), was extracted with CH_2Cl_2 (60 ml) and washed with H_2O once. After drying ($MgSO_4$) the organic layer, the solvent was evaporated to yield an oily residue which crystallized upon addition of ether. Recrystallization [CH_2Cl_2–petroleum ether (40 : 60)] yielded pure **5a** (955 mg, 59%) as a cream colored powder that was racemic modification; mp 127—130 °C; IR (KBr) 3240 (OH, broad), 1735 (>S=O, broad, W. 1/2 1.5 cm), 1030 (>S=O) cm^{-1}; ^{1}H NMR δ=0.9—1.40 (m, 6H, 2×CH_3), 2.0—2.30 (m, 2H, H_2C–$C(CO_2Et)_2$), 2.7—3.2 (m, 3H, $-CH_2CHSOPh$), 3.3—3.7 (m, 1H, $-CH(CO_2Et)_2$), 3.9—4.4 (m, 4H, 2×$-OCH_2-$), 6.4—7.30 (m, 4H, ArH), 7.35—7.80 (m, 6H, –SOPh and OH); MS *m/z* 292 (M−PhSOH). Found: C, 63.1; H, 6.1; S, 7.5%. Calcd for $C_{22}H_{26}O_6S$: C, 63.16; H, 6.22; S, 7.65%.

2-[3-[2-(Ethoxycarbonyl)ethylamino]-2-(phenylsulfinyl)propyl]phenol (5b). A solution of **3a** (1.13 g, 4.38 mmol) in absolute EtOH (2 ml) was added to a solution of 2-(ethoxycarbonyl)ethylammonium chloride (700 mg, 4.56 mmol) in absolute EtOH (13 mmol) containing triethylamine (0.7 ml, 1 equiv). The reaction was conducted in an analogous manner to above to yield crude oily product which was purified by column chromatography [(a) ether (b) ether–EtOH (2 : 1)] to give **5b** (1.07 g, 65%) as a pale brown oil; IR (neat) 3440 (NH), 3300 (OH) , 1730 (>S=O) cm^{-1}; ^{1}H NMR δ=1.23 (t, *J*=7 Hz, 3H, CH_3), 2.3—2.8 (m, 5H, $-CH_2CHSOPh-$ and $-CH_2CO_2Et$), 2.8—3.2 (m, 4H, $-CH_2-N-CH_2-$), 4.10 (q, *J*=7 Hz, 2H, $-OCH_2-$), 6.7—7.3 (m, 5H, ArH and OH), 7.33—7.76 (m, 5H, –SOPh). Found: C, 63.8; H, 6.6; N, 3.6; S, 8.5%. Calcd for $C_{20}H_{25}NO_4S$: C, 64.00; H, 6.67; N, 3.78; S, 8.53%.

2-[3-[Ethoxycarbonyl)methylthio]-2-(phenylsulfinyl)-propyl]phenol (5c). In a similar manner to above the alkenyl sulfoxide **3a** (620 mg, 2.40 mmol), sodium ethoxide (2.4 mmol) and ethyl mercaptoacetate (0.6 ml, an excess) in EtOH (1.5 ml) yielded an oily mixture which was chromatographed [(a) (1 : 1) ether–petroleum ether (40 : 60) (b) ether] to yield **5c** (745 mg, 82%) as a light brown oil; IR (neat) 3400 (OH, broad), 1740 (>C=O), 1025 (>S=O) cm^{-1}; ^{1}H NMR δ=1.26 (t, *J*=7 Hz, 3H, CH_3), 2.2—2.5 (m, 2H, $-CH_2S-$), 2.66—3.30 (m, 3H, $ArCH_2CHSO$), 3.45 (s, 2H, $-SCH_2CO_2Et$), 4.13 (q, *J*=7 Hz, 2H, $-OCH_2-$), 6.6—7.3 (m, 4H, ArH), 7.3—7.6 (m, 5H, –SOPh), 7.9 (s, 1H, OH). Found: C, 60.2 H, 5.6; S, 16.8%. Calcd for $C_{19}H_{22}O_4S_2$: C, 60.32; H, 5.82; S, 16.93%.

2-[3-Ethoxy-2-(phenylsulfinyl)propyl]-4-methoxyphenol (5d). This was obtained in a similar manner from **3d** (630 mg, 20.19 mmol) and sodium ethoxide (2.2 mmol) in EtOH (16 ml) as an oil (548 mg, 75%) after column chromatography [ether]; IR (neat) 3320 (OH), 1030 (>S=O) cm^{-1}; ^{1}H NMR δ=1.27 (m, 3H, CH_3), 2.3—2.8 (m, 3H, $-OCH_2CHSO$), 3.76, (s, 3H, $-OCH_3$), 6.4—7.0 (m, 3H, PhH), 7.3—7.6 (m, 6H, –SOPh and OH); MS *m/z* 334 (M$^+$). Found: C, 64.6; H, 6.4; S, 9.4%. Calcd for $C_{18}H_{22}O_4S$: C, 64.67; H, 6.59; S, 9.59%.

2-Bromo-2-propenyl-4-methoxy-2-(2-phenylsulfinyl-2-propenyl)phenyl Ether (6a). This was made by the Williamson synthesis from **3c** (1.35 g, 4.69 mmol), 2,3-dibromo-1-propene (1.1 g, 5.5 mmol) and sodium ethoxide (4.69 mmol) in EtOH (25 ml) to give, after chromatography [ether], **6a** (1.24 g, 68%) as a dark gum; IR (neat) 1040 cm^{-1}; ^{1}H NMR δ=3.25 (d, *J*=17 Hz, 1H, diastereotopic –OCH–), 3.45 (d, *J*=17 Hz, 1H, diastereotopic –OCH–), 3.70 (s, 3H, $-OCH_3$), 4.45 (s, 2H, $-OCH_2-$), 5.36 (s, 1H, –C=CH *trans* to Br), 5.60 (s, 1H, C=CH *cis* to Br), 5.80 (s, 1H, –C=CH *trans* to –SOPh), 6.10, (s, 1H, –C=CH *cis* to SOPh), 6.56 (s, 1H, ArH-3), 6.70 (s, 2H ArH-5,6), 7.50 (m, 3H, –SOPh), 7.66 (m, 2H, *ortho* SOPh); MS *m/z* 408 (M+1, 4%), 280 (58), 161 (1). Found: C, 55.8; H, 4.5; S, 7.6%. Calcd for $C_{19}H_{19}O_3SBr$: C, 56.02; H, 4.67; S, 7.86%.

4-Methoxy-2-(2-phenylsulfinyl-2-propenyl)phenyl 2-Phenylsulfinyl-2-propyl Ether (6b). 3-Bromo-2-phenylsulfinyl-1-propene (650 mg, 2.6 mmol) was reacted in a similar manner to above with a solution of **3c** (730 mg, 2.53 mmol) and sodium ethoxide (2.53 mmol) in EtOH (15 ml) to give, after chromatographic purification [(a) ether (b) ether : : MeOH (2 : 1 : 1)], **6b** (1.03 g, 90%) as a thick dark oil; IR (neat) 1030 (>S=O) cm^{-1}; ^{1}H NMR δ=3.08 (d, *J*=15 Hz, 1H, diastereotopic –CH–), 3.40, (d, *J*=15 Hz, 1H, diastereotopic –CH–), 3.66 (s, 3H, $-OCH_3$), 4.15 (d, *J*=16 Hz, 1H, diastereotopic –OCH–), 4.56 (d, *J*=16 Hz, 1H, diastereotopic –OCH–), 5.27 (fine t, *J*=2 Hz, 1H, –C=CH *trans* to SOPh in allylic group), 5.77 (fine t, *J*=2 Hz, 1H, –C=CH *trans* to SOPh in allyloxy group), 6.05 (s, 1H, –C=CH *cis* to SOPh in allyloxy group), 6.13 (s, 1H, –C=CH, *cis* to SOPh in allyloxy group), 6.4—6.75 (m, 3H, ArH-3,5,6), 7.35—7.75 (m, 10H, –SOPh); MS *m/z* 452 (M$^+$, 12%), 327 (42), 200 (100). Found: C, 66.1; H, 5.1; S, 13.9%. Calcd for $C_{25}H_{24}O_4S_2$: C, 66.38; H, 5.31; S, 14.16%.

The Claisen Rearragement Reactions of 6a and 6b. 2-(2-Bromo-2-propenyl)-4-methoxy-6-(2-phenylsulfinyl-2-propenyl)phenol (7a). A solution of **6a** (1.0 g, 2.46 mmol) in mesitylene (15 ml) was rearranged in the previously mentioned manner to yield, after chromatography [ether], **7a** (650 mg, 65%) as dark brown oil; IR (neat) 3240 (OH, broad), 1040 (>S=O) cm^{-1}; ^{1}H NMR δ=3.12 (d, *J*=17 Hz, 1H, –CH–CSOPh), 3.45 (d, *J*=17 Hz, 1H, –CH–CSOPh), 3.6—3.8 (m, 5H, $-CH_2-CBr=C$ and OCH_3), 5.45 (s, 1H, *trans* –CBr=CH), 5.52 (s, 1H, *cis* –CBr=CH), 5.74 (s, 1H, *trans* –OSPhC=CH), 6.02 (s, 1H, *cis* –OSPhC=CH), 6.47 (m, 1H, ArH-3), 6.65 (m, 1H, ArH-5), 7.25 (s, 1H, OH), 7.44 (m, 3H, –SOPh), 7.55 (m, 2H, *ortho* –SOPh). Found: C, 55.7; H, 4.5; S, 7.6%. Calcd for $C_{19}H_{19}O_3SBr$: C, 56.02; H, 4.67; S, 7.86%.

7-(2-Bromo-2-propenyl)-5-methoxy-2-methylbenzofuran (8a). Repeating the above reaction for **6a** (1.0 g) in the presence of SiO_2 (Fluka 60H) (ca. 1 g) in the reaction mixture gave **8a** (476 mg, 69%); IR (neat) 1620 (s), 1595 (m), 1490 (s), 1440 (s), 1225, 1215 (s) cm^{-1}; ^{1}H NMR δ=2.25 (s, 3H, CH_3), 3.70 (s, 3H, $-OCH_3$), 3.83—4.15 (m, 2H, $-CH_2-CBr=C$), 5.47 (s, 1H, *trans* –CBr=CH), 5.54 (s, 1H, *cis* –CBr=CH), 6.37 (s, 1H, ArH-3), 6.60—6.93 (m, 2H, ArH-4,6). MS *m/z* 281 (M$^+$, 100%), 200 (8), 185 (13). Found: C, 55.3; H, 4.3%. Calcd for $C_{13}H_{13}O_2Br$: C, 55.5; H, 4.63%.

4-Methoxy-2,6-bis(2-phenylsulfinyl-2-propenyl)phenol (7b). A solution of **6b** (100 mg, 0.22 mmol) in mesitylene (2 ml) was

rearranged as above to give, after chromatography [(a) ether, (b) ether–MeOH (3 : 1)], **7b** (72 mg, 72%) as a thick dark oil; ^{1}H NMR δ=2.30 (s, 1H, -OH), 3.15 (d, J=16 Hz, 2H, -CH-CSOPh), 3.45 (d, J=16 Hz, 2H, -CH-CSOPh), 3.70 (s, 3H, OCH_3), 5.63 (s, 2H, *trans* -SOPhC=CH), 6.08 (s, 2H, *cis* -SOPhC=CH), 6.45 (s, 2H, ArH-3,5), 7.4—7.9 (m, 10H, -SOPh); MS m/z 452 (M^+, 6%), 327 (M—SOPh, 44), 202 (13), 201 (55), 200 (100), 185 (30). Found m/z (M^+) 452.5852. Calcd for $C_{25}H_{24}O_4S_2$: M, 452.5822. Rearrangement of **6b** in DCB yielded an oily residue which upon addition of ether partially crystallized to yield an unidentifiable dark brown solid as flakes, mp 170—172 °C (decomp); IR (KBr) 3450, 2925, 1650 (s), 1510 (s), 1490 (s), 1260 (s), 1110 (s), 830 (m), 770 (m) cm^{-1}. The solid was soluble in $CHCl_3$; ^{1}H NMR δ=1.55 (s), 3.2—4.0 (broad peak), 7.2—7.5 (broad peak); ^{13}C NMR δ=8.58, 15.24, 28.14, 45.96, 55.63, 55.86, 114.82, 120.8, 124.74, 129.20, 131.08. MS proved difficult to measure.

5-Methoxy-2-methyl-7-(2-phenylsulfinyl-2-propenyl)-benzofuran (8b). Rearrangement of **6b** (100 mg) in mesitylene (2 ml) in the presence of SiO_2 (Fluka 60H) (ca. 50 mg) yielded **8b** (37 mg, 51%) after chromatography [(a) petroleum ether (40 : 60), (b) ether], as a brown oil; ^{1}H NMR δ=2.50 (d, J=2 Hz, 3H, CH_3-2), 3.10 (d, J=16 Hz, 1H, CH-7), 3.45 (d, J=16 Hz, 1H, -CH'-7), 3.65 (s, 3H, -OCH_3), 5.65 (s, 1H, *trans* -SOPhC=CH), 6.10 (s, 1H, *cis* -SOPhC=CH), 6.40 (q, J=2 Hz, 1H, H-3), 6.75—7.0 (m, 2H, H-4,6), 7.4—7.8 (m, 5H, -SOPh); MS m/z 326 (M^+; 12) , 200 (100). Found: m/z 326.4118. Cacld for $C_{19}H_{18}O_3S$: M, 326.4094.

Enhanced Production of Formic Acid by *Halobacterium halobium* MMT_{22} by Reduction of Hydrogencarbonate in Aqueous Solution

Mirza Mohammad Taqui KHAN* and Jayshree BHATT
Central Salt and Marine Chemicals Research Institute, Bhavnagar 364002, India
(Received April 9, 1991)

Enhanced production of formic acid was observed by reduction of hydrogencarbonate in aqueous solution by *Halobacterium halobium* MMT_{22}. A one and half fold increase in the production of formic acid was observed in the presence of ascorbic acid as electron donor and $[Ru(Bipy)_3]^{2+}$ as photosensitizer.

Since 1970's there has been a considerable research effort directed toward harnessing photochemical reactions for solar energy conversion and storage.

Fixation of carbon dioxide has bee extensively studied[1] because of its importance in photosynthesis as a source of C_1 chemicals.[2] Moreover the catalytic, reduction of CO_2 to organic molecules may be fundamentally important to cope with the rapid increase of the concentration of carbon dioxide in the atmosphere as a pollutant resulting from the combustion of fossil fuels.[3-6]

In a previous paper[7] we have reported photobiological as well as photoelectrochemical conversion of CO_2 to formic acid by *Halobacterium halobium* MMT_{22}. As the hydrogencarbonate ion in solution can act as a source of CO_2 in solution where concentrations can be studied over a wide range we report in this paper its reduction to formic acid by *H. halobium* MMT_{22}. The yield of formic acid obtained was 0.42 M (mg cells)$^{-1}$ h^{-1} which increasrs to 0.532 M (mg cells)$^{-1}$ h^{-1} in presence of ascorbic acid and to 0.646 M (mg cells)$^{-1}$ h^{-1} in the presence of ascorbic acid and $[Ru(Bipy)_3]^{2+}$ (1 M=1 mol dm^{-3}).

Experimental

$[Ru(Bipy)_3]^{2+}$ was prepared by literature procedure.[8] All the other chemicals used were of analytical grade.

The extreme halophile, *H. halobium* MMT_{22} was isolated from the brine obtained from the salt farm of CSMCRI in a nutrient medium at pH 7.0. Incubation was carried out at 40 °C under illumination.

Photocatalytic experiments were carried out in a double walled Pyrex glass cylindrical reaction vessel (40 ml) with a flattened surface positioned perpendicular to the incident light (exposed area 10 cm^2, 250 W Xe lamp from Applied Photo Physics).

For the optimization of reaction conditions, different sets of experiments were carried out. In a typical photocatalytic experiment an aqueous system containing 25 ml 25% NaCl; *H. halobium* MMT_{22} as biocatalyst (1—5 mg wet weight); $NaHCO_3$ as a source of CO_2 (0.2—2.0 M) was irradiated with a monochromatic excitation spectral line (420—480 nm). Water at (10—50 °C) was continuously circulated through a water jacketed cell containing the reaction mixture to maintain the desired temperature within ±0.2 °C.

In other sets of experiments investigations were carried out to study the effect of electron donor and photosensitizer on formic acid production.

In a similar experimental system containing 25.0 ml 25% NaCl, 1 mg *H. halobium* MMT_{22}, 1.0 M $NaHCO_3$; with $[Ru(Bipy)_3]^{2+}$ as photosensitizer (10^{-4} M) and ascorbic acid as electron donor (10^{-1}, 10^{-2}, 10^{-3} M) was irradiated with a monochromatic excitation spectral line (460 nm). Water at 40 °C was continuously circulated through a water jacketed cell containing the reaction mixture.

Samples were taken out at various time intervals and made free of bacterial cells. The product analysis was done by HPLC.

Results and Discussion

Under strictly anaerobic conditions on illumination, each bacteriorhodopsin cycling in the purple membrane of *H. halobium*, release 2—3 protons which are released on the exterior of the cells. Simultaneously carbon uptake is greatly increased as CO_2 is fixed through the reductive pathways and NADH is produced during illumination by reversal of electron transport. Thus NADH functions as electron donor in the system.[9-11]

In our previous paper we have reported photobiological as well as photoelectrochemical conversion of CO_2 to formic acid by *H. halobium* MMT_{22}. The yield of formic acid increased considerably by regenerating NADH by cathodic reduction at −0.60 V or in the

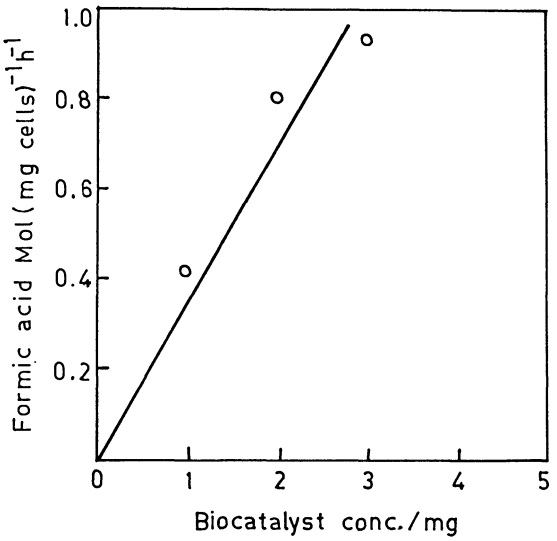

Fig. 3. Formic acid production at different biocatalyst concentrations.

presence of the two electron donor ascorbic acid. Under photoelectrochemical reduction, a maximum yield of 0.2 mol of HCOOH (mg cells)$^{-1}$ h^{-1} was obtained.[7]

In our present studies $NaHCO_3$ was used as a substrate for formic acid production. Optimization of the reaction conditions revealed the following results. 1 M $NaHCO_3$ concentration (Fig. 1), monochromatic excitation spectral line at 460 nm at 40 °C (Fig. 2) were found to be optimum conditions for formic acid production. An increase in the biocatalyst concentration causes a linear increase in formic acid production (Fig. 3).

Tris(bipyridyl)ruthenium complexes $[Ru(Bipy)_3]^{2+}$ have been intensively tested as sensitizers for photochemical water splitting using visible light.[12] There are many reports which describe application of such com-

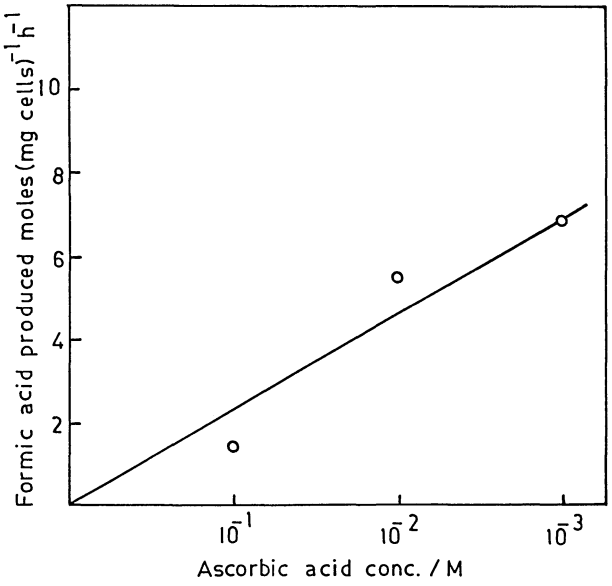

Fig. 4. Effect of ascorbic acid on formic acid production.

plexes to CO_2 fixation.[12] Using $[Ru(Bipy)_3]^{2+}$ as a photosensitizer in visible light and ascorbic acid as a sacrificial electron donor and *H. halobium* as the biocatalyst, formic acid was found to be the sole organic product in our present investigations.

In the earlier report[7] *H. halobium* MMT_{22} showed continuous production of HCOOH at the rate of 0.2 M (mg cells)$^{-1}$ h^{-1}. In the present studies using hydro-

gencarbonate in solution an enhanced production of formic acid was observed in aqueous solution. The rate of formation of formic acid is 0.45 M h^{-1}. Figure 4 shows the effect of ascorbic acid concentration on formic acid production. In presence of ascorbic acid the rate increases to 0.55 M h^{-1}. Here ascorbic acid serves as two electron donor which enhances the rate of CO_2 reduction by maintaining the NADH/NAD^+ cycle. In presence of $[Ru(Bipy)_3]^{2+}$ formic acid production was found to be maximum with a rate of 0.66 M h^{-1}. Figure 5 and Table 1 compares the rates of formic acid production when ascorbic acid and $[Ru(Bipy)_3]^{2+}$ were used for the investigations. A 1.5 times increase in formic acid production was observed when $[Ru(Bipy)_3]^{2+}$ was used as a photosensitizer. The mechanism of the reaction is shown in Scheme 1.

(Received March 20, 1991)

The crystal structure of the low-melting point phase (L-phase) of a single component organic semiconductor, $TSeC_1$-TTF, is determined and compared with that of the high-melting point phase (H-phase). The intracolumnar overlap mode and the calculated intermolecular overlap integrals are slightly larger in the L-phase, to which is ascribed the low resistivity of the L-phase. The L-phase, however, does not have two-dimensional networks of intercolumnar Se···Se contacts, which exist in the H-phase. This may be associated with the difference of the melting points.

Tetrakis(alkylthio)tetrathiafulvalenes(TTC_n-TTFs) are very unique semiconductors with fairly low resistivity as single component organic compounds. This character is derived from the short intermolecular distance between the adjacent central π systems, because a bundal of long alkyl chains assemble TTC_n-TTF molecules in a fashion that the central π-systems can pile up one after the other very tightly (Fastener Effect).[1,2] $TTeC_n$-TTFs and $TSeC_n$-TTFs, in which the outer sulfur atoms of TTC_n-TTF are replaced by Te and Se atoms respectively, were designed in order to increase the intermolecular interactions. We have found that $TTeC_1$-TTF reveals noticeably low resistivity of 8.1×10^4 (Ω cm) although alkyl chains are too short to attain the Fastener Effect.

The $TTeC_1$-TTF crystal has very unique packing and intercolumnar zigzag Te···Te interactions along the stacking axis.[3] The title compound, $TSeC_1$-TTF, (Fig. 1) crystallizes in two phases, of which electrical conductivities are different by two orders.[4,5] We have reported the structure of the H-phase crystal, $TSeC_1$-TTF(H), in the previous paper.[6] In order to discuss the differences of electrical and thermal properties between these two phases, here, we report the structure of the L-phase crystal, $TSeC_1$-TTF(L) and compare the intermolecular overlap integrals with those of $TSeC_1$-TTF(H).

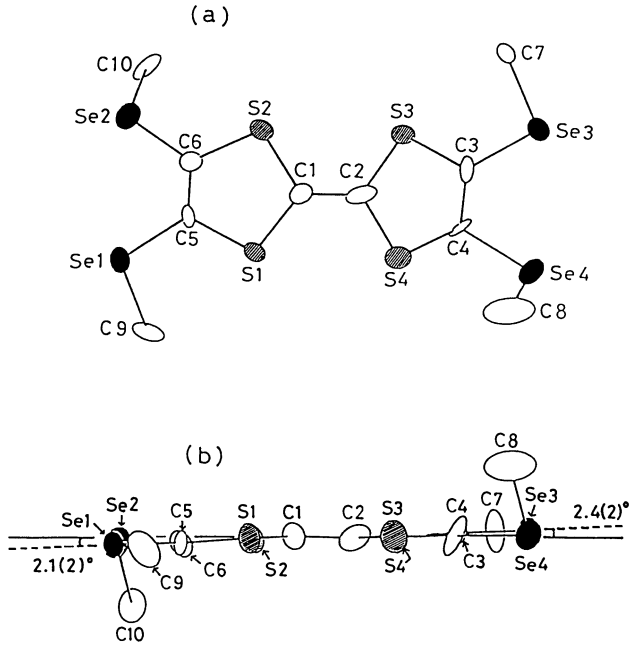

Fig. 1. The molecular structure of $TSeC_1$-TTF(L).

Experimental

The synthesis of the $TSeC_1$-TTF compound was reported in the preceding paper.[4] Two kinds of single crystals were prepared by recrystallization from different solvents. Red needle crystals ($TSeC_1$-TTF(L)) were obtained from the mixture of hexane and benzene. On the other hand, dark red plate crystals ($TSeC_1$-TTF(H)) were obtained from pure hexane solution, sometimes together with red needle crystals.

Intensity data of X-ray diffraction were measured on a Rigaku automated four-circle X-ray diffractometer AFC-5R by the θ-2θ scan technique with graphite monochromatized Mo $K\alpha$ radiation ($2\theta<60°$). Crystal data ($TSeC_1$-TTF(L)): $C_{10}H_{12}S_4Se_4$, F.W.=576.28, orthorhombic, space group $Pca2_1$, =18.534(5), b=5.284(1), c=17.533(4) Å, V=1717.0(7) Å^3, Z=4, D_x=2.23 g cm^{-3} and μ(Mo $K\alpha$)=89.12 cm^{-3}, crystal size: 0.02×0.6×0.04 mm^3. The intensity variation of the three standard reflections during the measurement was less than 5%. 2925 unique reflections were measured. The intensity data were corrected for absorption effects using a Gaussian integration procedure. The crystal structure was solved by the Patterson method and refined by the block-diagonal least squares procedure by using 1145 independent reflections ($|F_o|>3\sigma(|F_o|)$). The final R=0.072, R_w=0.068 $\{w=[\sigma^2+(0.015\,F_o)^2]^{-1}\}$ and $(\Delta/\sigma)_{max}$=0.89. Thermal parameters were anisotropic for all the non-hydrogen atoms and isotropic for hydrogen atoms. In the final difference Fourier map, the residual electron density corresponds to |1.7| e Å^{-3} near Se1 atom. Although we assumed the space group was *Pcam* first, in this case we found difficulty in analyzing the structure.

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7] All the calculations were carried out on a HITAC M-680H computer with the UNICS III program system.[8]

Results and Discussion

Final atomic coordinates of TSeC1–TTF(L) are shown in Table 1.[9] The molecule is noncentrosymmetric, while the TSeC1–TTF(H) molecule is centrosymmetric,[6] and the terminal parts are slightly twisted because of the large atomic radius of Se atom as compared with those of the S and C atoms (Fig. 1). The dihedral angles between the central C_2S_4 part and terminal $C_2S_2Se_2$ are 2.4(2)° and 2.1(2)°, respectively (TSeC1–TTF(H): 2.72(5)°).

TSeC1–TTF(L) molecules are stacked along the *b*-axis (corresponds to the needle axis) and the overlapping mode is shown in Fig. 2. Although the shortest intracolumnar S ··· S distance is a little longer than that of TSeC1–TTF(H), the overlap along the stacking axis is a little larger. The shortest intracolumnar S ··· S distance is 3.73(1) Å and Se ··· S distances are 3.856(8) Å and 3.885(8) Å. There is no short Se ··· Se contact within a column in both two phases. The distance between the two least squares planes of the central

(b) TSeC1–TTF(H). Intracolumnar distances (<4 Å): d_1(S1*···S1***)=3.663(3), d_2(Se1*···S2**)=3.890(2), d_3(Se1*···S1**)=3.969(2) Å.
Symmetry operations: *(*x*, *y*, *z*), **(*x*, *y*, 1+*z*), ***(−*x*, −*y*, 2−*z*).

$C_6S_4Se_4$ skeletons is 3.568(4) Å and is nearly the same as that of $TSeC_1$–TTF(H) (3.570(1) Å). The densities of these two crystals are also nearly the same (Table 2).

Crystal structure of $TSeC_1$–TTF(L) is shown in Fig. 3. There exist intercolumnar short Se1 ··· Se3 contacts (3.620(5) and 3.639(5) Å), which are much shorter than the sum of the van der Waals radii (4.00 Å). These Se atoms form zigzag chains between neighboring columns along the stacking axis (Fig. 3(b)). These Se ··· Se chains are important to extend the molecular overlapping along the *b*-axis. However, these zigzag chains are formed by Se1 and Se3 atoms, and the other Se2 and Se4 atoms do not have strong intercolumnar interaction (only with the terminal methyl groups with the van der Waals contacts along the stacking axis). There are no short Se ··· Se contact along the *c*-axis. On the other hand, in the case of $TSeC_1$–TTF(H), short intercolumnar Se ··· Se contacts exist in nearly $a+b$ and $a-b$ directions (Fig. 4(b)). The H-phase has two-dimensional array of the short Se ··· Se contacts, whereas the L-phase has short Se ··· Se contacts only along one direction. It could be one of the reasons that melting point of $TSeC_1$–TTF(L) (92.5 °C) is lower than that of $TSeC_1$–TTF(H) (106.3 °C).

We tried to estimate the intermolecular overlap integrals to understand the cause of the difference of the electrical conductivities between these two phases. The overlap integrals calculated by the extended Hückel molecular orbitals between HOMOs for these two crystals are shown in Table 3. The overlap of $TSeC_1$–TTF(L) along the stacking axis (direction *s*) is a little larger than that of $TSeC_1$–TTF(H) (direction *s*). Moreover, in the $TSeC_1$–TTF(L) crystal, one molecule can have intermo-

q3	−0.0114		

lecular interactions with many neighboring molecules (Fig. 3(a) and (b)) and has larger overlap integrals in many directions than the case of $TSeC_1$-TTF(H). These facts are compatible with the result that the electrical resistivity and activation energy for conduction of $TSeC_1$-TTF(L) are lower than those of $TSeC_1$-TTF(H) (Table 2).

In summary, the $TSeC_1$-TTF(L) crystal has better overlap mode along the stacking axis and has larger intermolecular overlap integrals. This may be related to the low resistivity of the L-phase. On the contrary, these Se ··· Se contacts are only along the *b*-axis and do not form network like in $TSeC_1$-TTF(H). This two-dimensional Se ··· Se network may be associated with the higher melting point of the H-phase.

We thank Dr. T. Inabe (Institute for Molecular Science) and Professor T. Enoki (Tokyo Institute of Technology) for their valuable discussion.

Deuterium Isotope Effects on Aromatic Carbon-13 Chemical Shifts. III. One-, Two-, and Three-Bond Isotope Effects on the ^{13}C Chemical Shifts of 3-Substituted Pyridines

Yasuki NAKASHIMA,† Sadanori BAN, Satoru ITOH, and Kensuke TAKAHASHI*
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
†Research and Development Department, Menicon Co., Ltd., Biwajima, Nishi-ku, Nagoya 451
(Received May 14, 1991)

The one-, two-, and three-bond deuterium isotope effects ($^1\Delta$, $^2\Delta$, and $^3\Delta$) on the ^{13}C chemical shifts of 3-substituted pyridines are reported. $^1\Delta$, $^2\Delta$, and $^3\Delta$ are correlated with the ^{13}C chemical shifts of the observed carbons. $^1\Delta$ show a linear correlation with the ^{13}C chemical shifts with a positive slope. On the other hand, $^2\Delta$ and $^3\Delta$ show linear correlations with the negative slopes. They can thus be interpreted in terms of the π-electron density change by the substituent and the electron release effects by carbons one and two bonds apart from deuterium, respectively.

Even though the deuterium isotope effects on the NMR chemical shifts ($^n\Delta$, where n is the number of intervening bonds) have been known for a long time,[1] the true cause for $^n\Delta$ is still unclear. Since experimental data for $^n\Delta$ in π-systems are scarce, it is difficult to discuss them systematically.[2] Especially, only a few studies concerning the $^n\Delta$ of heteroaromatics have been reported.[2,3] Further studies are desired. We have shown that $^1\Delta$ and $^2\Delta$ for substituted benzenes are correlated with the π- and σ-electron densities, respectively.[4] In this study, we chose 3-substituted pyridines and here discuss their $^1\Delta$, $^2\Delta$, and $^3\Delta$. One of the reasons for our selection was that pyridine is an analogue of benzene. Additionally, the interaction between the nitrogen atom and the substituent seems to be small in a 3-substituted pyridine system.[5] It is therefore possible to estimate simply the substituent effect on the isotope shifts. In the present system,$^1\Delta$ were observed at the C_2, C_4, and C_6 positions, and $^2\Delta$ were observed at the C_3 and C_5 positions. The former values enable us to consider the mesomeric effects of the substituent. The latter values enable us to consider the inductive effects. Both $^1\Delta$ and $^2\Delta$ are correlated linearly with the ^{13}C chemical shifts of the observed carbons. The slope of a correlation line for $^1\Delta$ has a positive value. On the other hand, that for $^2\Delta$ is negative. This fact can be explained in terms of the π-electron density changes by the substituents and the electron-release effects due to the α-carbons (D-labelled carbons), respectively. In addition, $^3\Delta$ can be observed on alkyl side-chain carbons; they also show a linear correlation with δ_c. This can be explained in terms of electron release effects due to the β-carbons (*C–C–D).

Experimental

The samples were selected for ten 3-substituted pyridines and the unsubstituted pyridine. The substituents were 3-Me, 3-Et, 3-Bu^n, 3-Cl, 3-NH_2, 3-CH_2NH_2, 3-OH, 3-CH_2OH, 3,5-Me_2, and 3,5-Cl_2. Deuterium-labelled compounds were prepared with base-catalyzed proton–deuteron exchange reactions of the selected pyridines in either D_2O or 5—10 wt% NaOH–D_2O solutions. The starting materials used were commercially available and were used without further purification. The reaction vessels were Pyrex ampoules. A suitable amount of the starting material and a catalyst solution were sealed into an ampoule, and kept at 200—230 °C in an autoclave. H/D exchange reactions occurred at the 2-, 4-, and 6-positions of the pyridines. Therefore, $^1\Delta$ were observed at the C_2, C_4, and C_6 atoms, while $^2\Delta$ were observed at the C_3 and C_5 atoms. Although $^3\Delta$ could be observed on the carbons in the alkyl side chains, the long-range isotope shifts via more than three bonds were not observed on the ring carbons. Pyridine-4-*d* was prepared by a previously reported method.[6] The hydroxyl and amino hydrogens of the substituents exchanged with those in water, and could not be separately observed on the NMR time scale. Then, labelled substituents such as OD, NHD, or ND_2 showed no isotope effect on the ^{13}C chemical shifts. The NMR spectra were measured with a Varian XL-200 FT-NMR spectrometer at 50.3 MHz and a temperature of about 22 °C. The NMR samples were neat for liquid samples. For solid samples, they were dissolved in solvents having high solubility (see Tables 1 and 2). Peak assignments were carried out on the basis of their intensity changes occurring along with H/D exchange reactions, or on

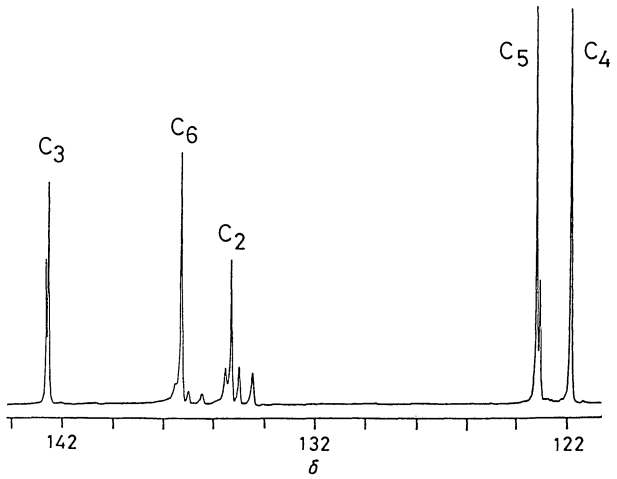

Fig. 1. ^{13}C NMR spectrum of 3-aminopyridine (a mixture of 2-D, 6-D, 2,6-D_2, and nondeuterated compounds).

the basis of splittings and/or broadenings by C–D couplings. An example of the ^{13}C spectra is shown in Fig. 1. In this figure two additional triplets at the C_2 and C_6 carbons are assigned to the signals coming from the deuterated species. The extent of deuteration proceeded fast at C_2, and slow at C_6. No triplet could be observed at C_4.

The isotope effects were evaluated from comparisons of the expanded spectra of these mixed species in the same sample tube, as described previously.[7] MNDO MO calculations were carried out using an NEC PC-9801 RA 32-bit personal computer with a "PASOCON MOPAC/386" program, which is based on the MOPAC (V3.1 QCPE No. 516) by Toray Systems Center.

Results and Discussion

All of the observed $^1\Delta$, $^2\Delta$, and $^3\Delta$ are listed in Tables 1, 2, and 3, respectively. The $^1\Delta$ are in a range from 252 to 363 ppb, while $^2\Delta$ are from 45 to 137 ppb. Their magnitudes are similar to those of the substituted benzenes.[4,7] All of the observed $^1\Delta$, $^2\Delta$, and $^3\Delta$ were toward the high field. The signs, however, are neglected in the tables. The substituents introduced to the pyridine ring usually decreased both $^1\Delta$ and $^2\Delta$. Particularly, large changes were observed at the ipso-positions of the substituents. $^3\Delta$ on alkyl side chains varied from 27 to 52 ppb. Correlations between isotope shifts and the chemical shifts have been reported in several articles.[7,8] We thus investigated them in the present system.

$^1\Delta$ vs. δ_c. A linear correlation is found between the $^1\Delta$ and ^{13}C chemical shifts of the observed carbons, as shown in Fig. 2. $^1\Delta$ in ppb can be expressed as

$$^1\Delta\,(\text{ppb}) = 3.70\,\delta_c(\text{ppm}) - 211 \qquad (1)$$

The slope of the least-square line is positive and similar to that of para-substituted benzenes (D–C_6H_4–X), which was previously reported by Berger and Diehl.[8] For further discussions, the π-electron charges (Δq_π) of pyridine ring carbons were evaluated by an MNDO MO

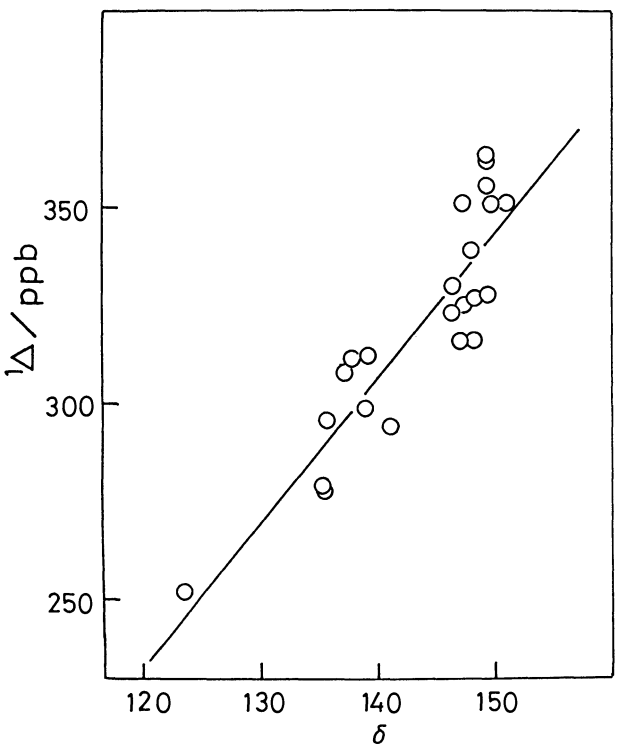

Fig. 2. Correlation between $^1\Delta$ (ordinate in ppb) and δ_c (abscissa in ppm) for 3-substituted pyridines with r=0.895 and a standard deviation of 13 ppb.

calculation. They are listed in Table 4. Plots between Δq_π and $^1\Delta$ are shown in Fig. 3. As can be seen, a linear correlation exists. The slope of the line is 642 ppb/electron unit, close to that of substituted benzenes (517 ppb/electron unit).[4] Recent theoretical findings have established the isotope shifts' origin as discussed below.[2c] The difference in the anharmonicities between the C–H and C–D bonds produce averaged bond-length changes in the NMR time-scale. Therefore, the time-averaged position of the C–D bonding electron should be different from that of the C–H bonding electron. The former will be nearer to the carbon atom than the latter. The D-labelled carbon would therefore be more shielded than the unlabelled carbon. Thus, upfield shifts $^1\Delta$ are observed. If we assume that the contribution of anharmonicity in shorter, stronger C–H bonds is small, the anharmonicity change on going from C–H to C–D is small. Therefore, in such a case, shielding changes of the carbon nuclei will be small. Thus, $^1\Delta$ will be diminished. We recently obtained several experimental results which strongly support this isotope shifts model. One is a correlation between $^1\Delta$ and ν_{CH} in the IR region for monosubstituted methane derivatives.[11] The other is a correlation between $^1\Delta$ and the C–H bond lengths optimized by MNDO MO calculations for several aromatic compounds.[12] From this information, a correlation between Δq_π and $^1\Delta$ is found to exist in the present system, and can be interpreted as discussed below. Electron release effects by substituents increase the π-electron densities at the ortho- and para carbons. For a sp^2 carbon, if it has a high π-electron density, its s-character increases. Its C–H bond length thus becomes shorter, and a smaller $^1\Delta$ is observed. Comparing $^1\Delta$ with the C–H bond lengths optimized by MNDO MO calculations (Table 5), increasing the C–H bond length roughly tends to increased $^1\Delta$.

$^2\Delta$ vs. δ_C. Correlations between the $^2\Delta$ and ^{13}C chemical shifts were also investigated. Different $^2\Delta$ values were obtained for the same carbons in the isotopomers; one was from the 2-D or 6-D isotopomer, and the other was from the 4-D isotopomer, as shown in Scheme 1. Typical expanded ^{13}C NMR spectra of C_3 and C_5 of the products obtained from an H/D exchange reaction of the 3-pyridinol are shown in Fig. 4. Since the reaction occurred at the 2-, 4-, and 6-positions, $^2\Delta$ are observed at C_3 and C_5. In the C_3 signals, the peaks can be assigned from left to right as follows: (a) 2-H, 4-H, (b) 2-H, 4-D, (c) 2-D, 4-H, (d) 2-D, 4-D isotopomers. From signal b, $^2\Delta$ was determined to be 45 ppb, and from signal c, 70 ppb. The value from signal d is consistent with the sum of 45 and 70 ppb. In each isotopomer, two kinds of $^2\Delta$ were differentiated as follows: $^2\Delta$ from 2-D or 6-D is always larger than that from 4-D for the isotopomers.

Since the difference between the two values is nearly constant, two good linear correlations between the $^2\Delta$ and ^{13}C chemical shifts of the observed carbons are obtained (Fig. 5). The two correlation lines have almost a parallel relationship with each other, and their slopes are very close to that of the substituted phenols.[7] These facts suggest that $^2\Delta$ can be explained in terms of electron release effects from the α-carbons (deuterium-labelled carbons).

It is well known that there are linear correlations between the electron densities and the NMR chemical shifts. We therefore evaluated the electron densities on $^2\Delta$-observed carbons by MNDO MO calculations. The calculated net atomic charges are given in Table 6. As shown in Fig. 6, plots between $^2\Delta$ and the net atomic charges (Δq_t) gave two parallel linear correlations. In our previous report, which is concerned with substituted benzenes, we proposed that there is a linear correlation between the $^2\Delta$ and σ-electron charges (Δq_σ).[4] In the present system, however, there are two better correlations between $^2\Delta$ and the total electron charges ($\Delta q_t = \Delta q_\sigma + \Delta q_\pi$) than $^2\Delta$ and Δq_σ, as shown in Fig. 6. The mean proportional coefficient of the two correlated lines is -372 ppb per unit charge. That for substituted benzenes is -355 ppb, which is calculated only for the ipso- and meta-carbons from previously reported data.[4] The present system is therefore similar to the substituted benzenes regarding the behavior of $^2\Delta$ and the charge densities.

In our previous report, we proposed a mechanism to explain $^2\Delta$.[4] The shielding of a D-labelled carbon, which directly reflects $^1\Delta$, is inductively transmitted to its adjacent carbon, whose $^2\Delta$ is dependent upon its net atomic charge (Δq_t) as shown in Fig. 6. However, $^2\Delta$ are not apparently correlated with $^1\Delta$.

As shown in Fig. 6, the almost constant difference between the two parallel correlated lines can be considered to be a part of $^2\Delta$ which is independent of the substituent. Therefore, $^2\Delta$ will be separated into two. One component is dependent on the substitutent and the other is independent of the substituent. The difference

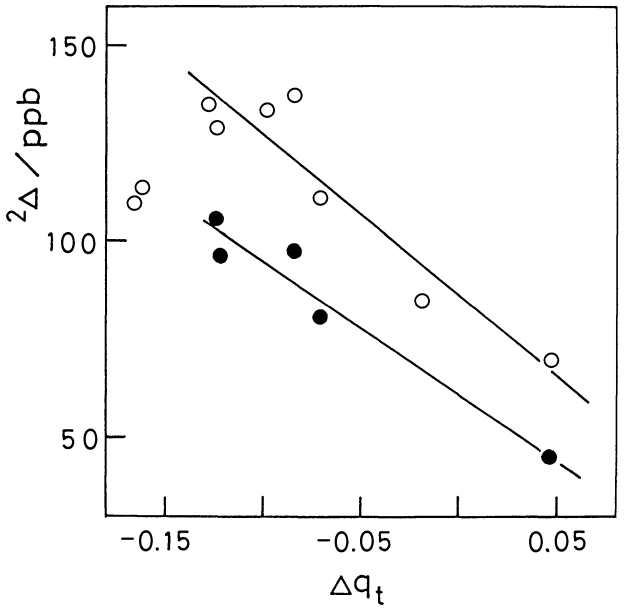

Fig. 6. Correlations between $^2\Delta$ and Δq_t. The white circles are for the 2-D or 6-D isotopomers. The black filled circles are for the 4-D isotopomers. The two correlated straight lines are expressed as $^2\Delta$=−405 Δq_t+87 and $^2\Delta$=−339 Δq_t+61, respectively, except for two points for 2-methyl- (and 3,5-dimethylpyridines.

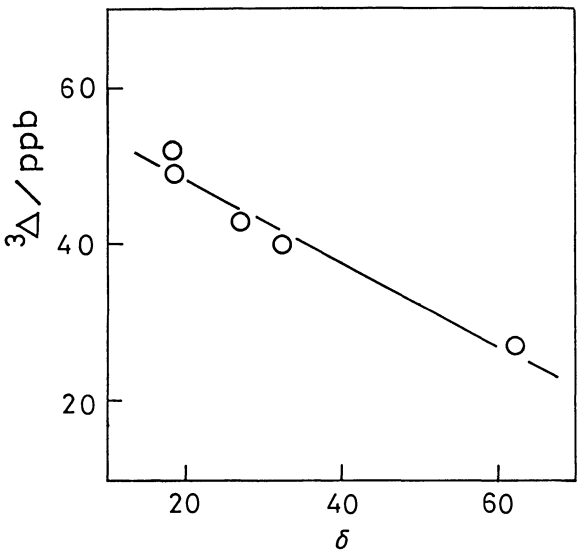

Fig. 7. Correlation between $^3\Delta$ (ordinate in ppb) on the alkyl side-chain carbons and δ_c (abscissa in ppm) for 3-substituted pyridines with r=0.980 and the standard deviation of 2.2 ppb.

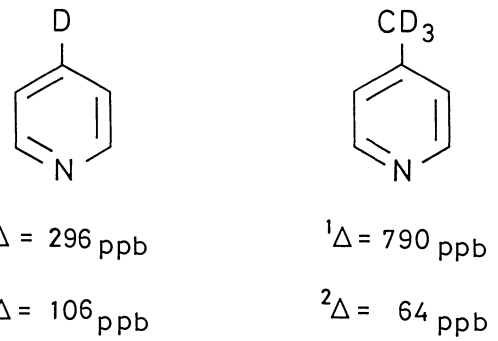
mentioned before reflects the latter component. Therefore, $^2\Delta$ from 2-D or 6-D is always larger than that from 4-D for carbons in the isotopomers. In a sense, $^1\Delta$ of the D-labelled carbon will be transmitted to the adjacent $^2\Delta$-observed carbon. Then, $^2\Delta$ would be expected to reflect $^1\Delta$. This shows that $^1\Delta$ induced by 2-D or 6-D are always larger than $^1\Delta$ induced by 4-D for carbons in the isotopomers. These appear exactly in Table 1. However, $^2\Delta$ are strongly dependent upon the electron densities in the observed carbons.

It is considered that the magnitude of electron release effect from D-labelled carbon is controlled by the electron densities on the $^2\Delta$-observed carbon. A comparison of the data between the pyridine-4-*d* and the 4-(methyl-d_3)pyridine[10] (Scheme 2) is also of interest in that two compounds with very large $^1\Delta$ and small $^1\Delta$ give almost similar $^2\Delta$. The transmitting route of the former case is C(sp^2)–C(sp^2); the latter one is C(sp^3)–C(sp^2). Thus, for $^2\Delta$, the transmitting route of the shielding change of the D-labelled carbon may play an important role. For $^2\Delta$ in the present system, however, all routes are similar in C(sp^2)–C(sp^2). Therefore, $^2\Delta$ will be mainly dominated by the electron densities in the $^2\Delta$-observed carbon.



Scheme 2.

$^3\Delta$ vs. δ_c. $^3\Delta$ on the ring carbons could not be observed. They can therefore be considered to be negligibly small. In contrast, $^3\Delta$ on the alkyl side-chain carbons could be observed, as shown in Table 3. Plots of $^3\Delta$ on the alkyl side-chain carbons and δ_c of the observed carbons give a linear correlation, such as in the cases of $^2\Delta$, as shown in Fig. 7. Since the least-square line has a negative slope, we can propose that $^3\Delta$ originates from the transmitted shielding change of the β-carbon ($^2\Delta$-observed carbon). That is to say, $^3\Delta$ is generated by an electron-release effect from the β-carbon. This mechanism is similar to that of $^2\Delta$.

Conclusion

$^1\Delta$ observed on the pyridine ring carbons are dependent upon the π-electron density changes originating from the substituents on the observed carbons. $^2\Delta$ arise as a result of transmitted shielding changes of the α-carbons. The transmitted shielding changes are controlled by the electron density changes in the observed carbons. $^3\Delta$ is generated by a mechanism similar to that for $^2\Delta$.

On the Splittings of J-Aggregate Band in Pseudoisocyanine

Hirotoshi Ito,* Masaru Agatsuma, and Y. J. I'Haya
Department of Applied Physics and Chemistry, The University of Electro-Communications, 1-5-1, Chofugaoka, Chofu, Tokyo 182
(Received June 3, 1991)

The observation of J-band splittings in the Fano–DeVoe type calculations of pseudoisocyanine aggregates is reported. Based upon the monoclinic structure of pseudoisocyanine iodide crystal, we build four models which respectively assume the lattice constants of the crystal structure. The one-dimensional (1D-) single polymer model is selected along a particular direction from the crystal structure. As we diminish the lattice constants uniformly, the 1D-single-polymer model comes to reproduce single J-bands, while two kinds of 2D-two-inter-polymer interaction models resolve the single J-bands into doublet through multiplet structures for the corresponding parameters. The 3D-four-inter-polymer interaction model brings about doubly split J-bands, but the shortening of the parameters resolves the doublet J-bands into quartet through multiplet structures. However, a single J-band is obtained by the assumption of an orthorhombic 3D-four-inter-polymer model which has the same parameters as those of the monoclinic iodide crystal except for the angle. The shapes calculated are found to be extremely sensitive to the geometrical values as well as the monomer spectroscopic parameters. The cause of the J-band splittings is ascribable to the excitonic interactions between at least two column polymers.

Aqueous solutions of pseudoisocyanine dyes (1,1′-diethyl-2,2′-cyanine, PIC dyes) at high concentrations show extraordinarily narrow, intense *single* bands.[1,2] Similar kinds of bands observed in various cyanine dye aggregates are called J-bands after the discover Jelley,[1] and such aggregates are called J-aggregates or sometimes Scheibe-aggregates. Cooper[3,4] first observed that in a transparent ethylene glycol–water (EGW) matrix at 77 K, such a single J-band of PIC bromide is split into two extremely sharp bands of almost equal intensity separated by 151 cm^{-1}. Also in EGW solution at 77 K, a weak doublet structure of the J-band of PIC iodide was found by Tanaka et al.[5] as a shoulder at shorter wavelength side of the main peak. Perhaps due to the excess amount of iodide ions,[5] Marchetti et al.[6] did not observe the split J-band of PIC iodide in the same EGW solution with 0.1 M KI at 77 K (1 M=1 mol dm^{-3}). Furthermore, Yu et al.[8] observed that the intensities of split J-spectra of PIC bromide in EGW solution become stronger gradually as temperature is reduced below 210 K down to 80 K. It has recently been reported that the relative intensity of split J-bands of PIC bromide changes with the cooling procedure of the glassy solution.[9,10] However also in Ref. 10, Murata has found that the peak appeared at shorter wavelength side of the single J-band of PIC iodide is always weaker than the peak appeared at longer wavelength side, as was reported before.[5] These phenomena lends qualitative supports for the present assumption that J-aggregate models in solutions are similar to the structures of microcrystals of PIC halides.

Any theoretical work has not been done to elucidate the cause of J-band splittings. Cooper[3,4] suggested that the split J-transitions are assigned to two energy levels respectively for the mixed J_1 and J_2 aggregates consisting two different configurations of PIC dye to the axis of PIC polymer chosen in a particular direction. However, he also referred to the excitonic nature of the split J-band, and from Refs. 3 and 4, we cannot deny in a broad meaning such a scheme that the coupling between at least two linear (1D-) J-aggregates of different geometrical orientations gives rise to Davydov splitting.

Our calculations to elucidate this are based upon the Fano–DeVoe theory and its versions,[11–16] which have provided an excellent tool for predicting bandshapes of various polymer systems. First, Briggs and Herzenberg[13,14] beautifully predicted the *single* J-bandshape for the most simplified PIC aggregate model in terms of their coherent exciton scattering theory equivalent to the Fano–DeVoe one. Also, Sumi[15] carried out a coherent potential approximation (CPA) calculation, which gives a single J-like band. Later on, to a rather real model than before, Knapp et al.[16] have applied a simplified version of the CPA theory.[15] They have been able to reproduce a single J-band for the cyclic 1D-aggregate model consisting of 11 PIC molecules by making use of model parameters determined for the PIC monomer and dimer spectra.[17] This treatment is based upon the assumption that the structure of dimer is almost similar to those of dimer units in the longer as well as wider spread J-aggregates. Scherer and Fischer[18] have also followed this treatment for the linear J-aggregates. Thus in their calculations, equi-magnitudes of inter-(sub)molecular interactions have been taken into account as geometrical factors. However, the interaction potentials of J-aggregates are supposed to be not only of short-range forces, but also of long-range forces. Tanaka et al.[5] suggested that such interactions have highly direction dependences for specific neighboring PIC molecules, that is, such interactions are highly anisotropic. Therefore first of all, for a better understanding of J-bands, it is important and necessary to take into account the *explicit geometries* of models which are derived from the crystal structure of the PIC molecule,[29] so that we can involve all the possible

inter(sub)molecular interactions.

Polymer Polarizability Tensor

The *extended* Fano–DeVoe model Hamiltonian of the polymer (N-mer) is assumed to be[19]

$$H=\sum_{f}^{\text{levels}}\sum_{m}^{N}\sum_{g}^{\text{levels}}\sum_{n}^{N}|\psi_m^f\prod_{k\neq m}^{N}\psi_k^0\rangle\langle\psi_m^f\prod_{k\neq m}^{N}\psi_k^0|\,\mathcal{H}|\psi_n^g\prod_{k\neq n}^{N}\psi_k^0\rangle\langle\psi_n^g\prod_{k\neq n}^{N}\psi_k^0|$$

$$-\langle\prod_{k=1}^{N}\psi_k^0|\,\mathcal{H}|\prod_{k=1}^{N}\psi_k^0\rangle\equiv\sum_{f,g}^{\text{levels}}\sum_{m,n}^{\text{sites}}|fm\rangle\langle fm|\,\mathcal{H}|gn\rangle\langle gn|$$

$$-\langle 0|\,\mathcal{H}|\,0\rangle$$

$$=\sum_{f\neq 0}^{\text{level}}\sum_{m}^{\text{sites}}E_{fm,0}|fm\rangle\langle fm|+\sum_{f,g\neq 0}^{\text{levels}}\sum_{m,n}^{\text{sites}}|fm\rangle\langle fm|\mathcal{V}_{mn}|gn\rangle\langle gn|$$

$$\equiv H_0+V, \tag{1}$$

with

$$\mathcal{H}=\sum_{m=0}^{\text{sites}}\mathcal{H}_{\text{m}}^{0}+\sum_{m>n}^{\text{sites}}\sum^{\text{sites}}\mathcal{V}_{mn},\qquad(\mathcal{V}_{mn}\approx\boldsymbol{\mu}_m\cdot\boldsymbol{U}_{mn}\cdot\boldsymbol{\mu}_n) \tag{2}$$

and with the unit dipole–dipole interaction tensor

$$\boldsymbol{U}_{mn}=\frac{1}{|\boldsymbol{R}_{mn}|^5}\{|\boldsymbol{R}_{mn}|^2\mathbb{1}-3\,\boldsymbol{R}_{mn}\boldsymbol{R}_{mn}\},\qquad\boldsymbol{R}_{mn}=\boldsymbol{R}_n-\boldsymbol{R}_m. \tag{3}$$

In the present calculations however, the lowest excited level only is taken in account for simplicity, so that we put actually $f=g$ in the second term of Eq. 1. Note that for the *original* Fano–DeVoe approximation, we must drop the electrostatic term $\langle fm|V|gm\rangle$ involved in Eq. 1. In Eqs. 1 and 2, $\mathcal{H}_m^0$ is the electronic Hamiltonian for the mth submolecule, $\mathcal{V}_{mn}$ the inter(sub)molecular interaction operator, and $\boldsymbol{\mu}_m$ the mth electric dipole moment operator. The eigen-functions ψ_m^0 *and* ψ_m^f for the monomer Hamiltonian $\mathcal{H}_m^0$, respectively, denote the *ground* and the fth *locally excited* states associated with the eigen-values E_0^m and E_f^m, their difference being put to be $E_{fm,0}$. For simplicity, we do not consider the electrostatic shift of $E_{fm,0}$ due to neighboring PIC cations and their counter anions, although we can theoretically make an allowance for such effects, for instance on the basis of Refs. 17—19 and Ref. 24. In Eq. 3, we assume the validity of the dipole–dipole approximation, since it was shown by Tanaka et al.[5] that the distances of neighboring molecules in PIC crystals are larger than the overlapping size of pi-electron clouds from the calculations of overlap integrals.

For the *crude* and *true* Green's operators G_o(E) and $G(E)$ defined by Eq. 1, we have the sum of the mth monomer polarizability tensor $\boldsymbol{\alpha}_{mm}(E)$

$$-\langle 0|\boldsymbol{\mu}G_o(E)\boldsymbol{\mu}|0\rangle=-\langle|\boldsymbol{\mu}(E-H_o+i\eta)^{-1}\boldsymbol{\mu}|0\rangle$$

$$=-\sum_{m}^{N}\sum_{f\neq 0}^{\text{levels}}\frac{\boldsymbol{\mu}_{0f}^{(m)}\boldsymbol{\mu}_{f0}^{(m)}}{E-E_{fm,0}+i\eta_{fm}}\equiv\sum_{m}^{N}\boldsymbol{\alpha}_{mm}(E), \tag{4}$$

where the matrix element of the total electric dipole operator is given by

$$\boldsymbol{\mu}_{0f}^{(m)}=\langle 0|\boldsymbol{\mu}|fm\rangle\equiv\langle 0|\sum_{m}^{N}\boldsymbol{\mu}_m|fm\rangle$$

$$=\langle 0|\sum_{m}^{N}\{\sum_{i\in m}^{\text{elec}}e\boldsymbol{r}_{mi}-\sum_{J\in m}^{\text{nuc}}eZ_J\boldsymbol{r}_{mJ}\}|fm\rangle,\qquad(\boldsymbol{r}_{mi}=\boldsymbol{r}_i-\boldsymbol{r}_m) \tag{5}$$

The m,n-element of the polymer polarizability tensor ${}^p\boldsymbol{\alpha}_{mn}(E)$ is then reduced to

$$-\langle 0|\boldsymbol{\mu}G(E)\boldsymbol{\mu}|0\rangle=-\langle 0|\boldsymbol{\mu}(E-H+i\eta)^{-1}\boldsymbol{\mu}|0\rangle$$

$$=-\langle 0|\boldsymbol{\mu}\{G_o(E)+G_o(E)VG_o(E)+\cdots\}\boldsymbol{\mu}|0\rangle$$

$$\equiv\sum_{m=1}^{N}\sum_{n=1}^{N}{}^p\boldsymbol{\alpha}_{mn}(E) \tag{6}$$

Inserting the resolution of identities ($\sum\sum|fm\rangle\langle fm|=1$) with use of the relationships such as $\langle fm|\mathcal{V}_{mn}|gn\rangle\approx\boldsymbol{\mu}_{f0}^{(m)}\cdot\boldsymbol{U}_{mn}\cdot\boldsymbol{\mu}_{0g}^{(n)}$, we can derive

$${}^p\boldsymbol{\alpha}_{mn}(E)=\{\mathbb{1}+\mathfrak{A}(E)\cdot\mathbb{U}\}_{mn}^{-1}\cdot\boldsymbol{\alpha}_{nn}(E),\qquad m,n=1,2....,N \tag{7}$$

where the suffices m,n of $\mathbb{1}$, $\mathfrak{A}(E)$, and $\mathbb{U}$ denote the elements of the corresponding $3N\times3N$ matrices.

Vibronic Description of Monomer Polarizability Tensor

The purely electronic scheme in the previous section can be extended to the vibronic problem. In the adiabatic approximation, the ground and fth excited states of the mth monomer appearing in Eq. 1 are replaced by the products:

$$\psi_m^f\rightarrow\psi_m^f(\boldsymbol{r},\boldsymbol{Q})\chi_m^{f,v}(\boldsymbol{Q})=\psi_m^f(\boldsymbol{r},\boldsymbol{Q})\prod_{k}^{3N-6}X_m^{f,v_k}(\boldsymbol{Q}_k),\qquad(f=0,f) \tag{8}$$

where the $\boldsymbol{r},\boldsymbol{Q}$ represent collective coordinates for electrons and nuclei. $\chi_m^{f,v}$ represents the total vibrational eigenstate associated with the eigenvalue $E_{f,v}^{m,\text{vib}}$, where v denotes a set of vibrational quantum numbers, i.e., $v\equiv(v_1,v_2,v_3,\cdots v_k\cdots v_{3N-6})$ for the $3N-6$ harmonic-oscillator wavefunctions. In the adiabatic approximation, the mth monomer Hamiltonian for the fixed nuclei is expressed by

$$H_m^0=\sum_{f=f,0}^{\text{levels}}E_f^m(\boldsymbol{Q})|\psi_m^f(\boldsymbol{r},\boldsymbol{Q})\rangle\langle\psi_m^f(\boldsymbol{r},\boldsymbol{Q})|.\qquad(\text{in }H^0=\sum_{m}^{\text{sites}}H_m^0) \tag{9}$$

Now, $E_f^m(\boldsymbol{Q})$ becomes the effective adiabatic potential for the nuclear motion. The nonadiabatic (NA) Hamiltonian of the mth monomer is then represented by

$$H_m^0\rightarrow H_m^0=\sum_{f=f,0}\sum_{v}(E_f^m+E_{f,v}^{m,\text{vib}})|\psi_m^f\rangle|\chi_m^{f,v}\rangle\langle\chi_m^{f,v}|\langle\psi_m^f|$$

$$+\sum_{f\neq g}\sum\sum_{v}\sum_{v'}\sum_{k}^{\text{vib. mode}}|\psi_m^f\rangle|\chi_m^{f,v}\rangle\mathcal{V}_{m,\text{NA}}^{(\text{f,k,g})}\langle\chi_m^{g,v'}|\langle\psi_m^g|, \tag{10}$$

where the off-diagonal term is the *intra*(sub)molecular vibronic coupling (NA) operator.[22] However, to simplify the problem, we do not take such a coupling operator into account. After all, modification of Eq. 1 in terms of Eq. 8 needs the replacement of $E_{fm,0}$ with $E_{\text{fm},0}^{(v)}$ that denotes the vth vibrational state on the fth electronic excited state of an mth monomer. Namely, a vibronically excited level relative to the zero-temperature ground state, leaving the other vibrational

states in the ground state, is written down

$$E_{fm,0} \rightarrow E^{(v)}_{fm,0} = E_{fm,0} + [E_{fm,v} - E_{0m,0}] \equiv E_{fm,0} + E_{fm,0;v0}$$
$$= E_{fm,0} + vE_{fm,0;10} = hc\tilde{\nu}^{(v)}_{fm,0} = h\nu(\tilde{\nu}_{fm,0} + v\,\tilde{\nu}_{fm,0;10}), \quad (11)$$

where $E_{fm,0;10}$ becomes a fundamental vibrational energy on the fth electronic level. The purely electronic transition moment $\boldsymbol{\mu}^{(m)}_{0f}$ is also replaced with the vibronic moment multiplied by the Franck–Condon overlap integral, so that the inter(sub)molecular interaction becomes

$$\langle fm|\boldsymbol{\mathcal{V}}_{mn}|gn\rangle \approx \boldsymbol{\mu}^{(m)}_{f0} \cdot \boldsymbol{U}_{mn} \cdot \boldsymbol{\mu}^{(n)}_{0g}$$
$$\rightarrow \boldsymbol{\mu}^{(m)}_{0f} \langle \chi^{0,0}_m | \chi^{f,v}_m \rangle \cdot \boldsymbol{U}_{mn} \cdot \boldsymbol{\mu}^{(n)}_{0g} \langle \chi^{0,0}_n | \chi^{g,v}_n \rangle. \quad (12)$$

The imaginary part of the usual type of monomer polarizability tensor(in units of cm^3) is given by

$$\mathrm{Im}\ \boldsymbol{\alpha}_{nn}(\tilde{\nu}) = \sum_{g\neq 0} \sum_{v} \frac{+e^2}{hc} \{\boldsymbol{\mu}^{(n)}_{0g}/e\}\{\boldsymbol{\mu}^{(n)}_{g0}/e\} \times$$
$$|\langle \chi^{0,0}_n | \chi^{g,v}_n \rangle|^2 \pi\delta[\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0}], \quad (e^2/hc = 1.16138 \times 10^{-3}), \quad (13)$$

which corresponds to the treatment made by Hemenger.[23] Actually, the lowest excited sate alone is taken into account for the gth states in Eq. 13, so that we put $f=g$ in Eq. 12.

The δ function in Fq. 13 are usually approximated by both the *Gaussian* and *Lorentzian* type functions. By many investigators,[13,14,16,20] it has been revealed that use of Gaussian type monomer functions can predict J-bands, whichever monomer function we may choose of vibronic and purely electronic polarizabilities. However, Lorentzian type functions were found to require the *vibronic* type monomer polarizability in order to reproduce J-bands.[20,21] We also replace Eq. 13 by the Gaussian function as follows:

$$\mathrm{Im}\ \boldsymbol{\alpha}_{nn}(\tilde{\nu}) = \sum_{g\neq 0} \sum_{v} \frac{+e^2}{hc} \{\boldsymbol{\mu}^{(n)}_{0g}/e\}\{\boldsymbol{\mu}^{(n)}_{g0}/e\} |\langle \chi^{0,0}_n | \chi^{g,v}_n \rangle|^2 \times$$
$$\left(\frac{\sqrt{\pi}}{\tilde{\Delta}^{(v)}_{gn}}\right) \exp\left\{-\left(\frac{\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0}}{\tilde{\Delta}^{(v)}_{gn}}\right)^2\right\} \equiv \sum_{g\neq 0} \sum_{v} \mathrm{F}[(\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0})/\tilde{\Delta}^{(v)}_{gn}], \quad (14)$$

where the bandwidth (FWHM in cm^{-1}) has a relationship such as $\tilde{\Gamma}^{(v)}_{gn} = 2\sqrt{\ln 2}\,\tilde{\Delta}^{(v)}_{gn}$ for the normalized Gaussian, and $\tilde{\Delta}^{(v)}_{gn}$ is the half-width at $1/e$ of the peak. Then, we determine the magnitude of $\tilde{\Gamma}^{(v)}_{gn}$ related with $\tilde{\Delta}^{(v)}_{gn}$ so as to adjust $\tilde{\Gamma}^{(v)}_{gn}$ to the observed monomer bandshape, i.e., so as to satisfy the following relationship,[24]

$$f_{gn} = 4.59663 \times 10^{-9} \sum_{v}^{\mathrm{M}} \varepsilon(\tilde{\nu}^{(v)}_{gn,0})\,\tilde{\Gamma}^{(v)}_{gn}, \quad (15)$$

where we assume the *same* bandwidth for each vibrational peak. Thus using the observed oscillator strength[6] and the corresponding molar extinction coefficient[30] in Eq. 15, the FWHM for the vth vibrational level on the gth (=lowest) electronic level is calculated to be $\tilde{\Gamma}^{(v)}_{gn} = 1119.7$ cm^{-1}. In Eq. 11, the values $\tilde{\nu}_{gn,0} = 1915$ cm^{-1} and $\tilde{\nu}^{(v)}_{gn,0;10} = 1368$ cm^{-1} are chosen for the *three* vibrational levels (v=0,1,2) on the gth electronic level from Ref. 17. For the Franck–Condon factor, we assume Poisson's distribution,[14,17]

$$|\langle \chi^{0,0}_n | \chi^{g,v}_n \rangle|^2 = \exp(-a^2/2)\frac{(a^2/2)^v}{v!}, \quad (a=1.2) \quad (16)$$

where an adjustable parameter a=1.2 well reproduces the monomer bandshape.

The Kronig–Kramers transform of Eq. 14 gives rise to its real part:[26]

$$\mathrm{Re}\ \boldsymbol{\alpha}_{nn}(\tilde{\nu}) \sum_{g\neq 0} \sum_{v} \frac{P}{\pi} \int_{-\infty}^{\infty} \mathrm{d}X \frac{F(X)}{X - (\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0})/\tilde{\Delta}^{(v)}_{gn}}$$
$$= \sum_{g\neq 0} \sum_{v} \frac{P}{\pi} \int_{-\infty}^{\infty} \mathrm{d}X \frac{\mathrm{Im}\ \boldsymbol{\alpha}_{nn}(\tilde{\nu})}{X - (\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0})/\tilde{\Delta}^{(v)}_{gn}}$$
$$= \sum_{g\neq 0} \sum_{v} \frac{+e^2}{hc} \{\boldsymbol{\mu}^{(n)}_{0g}/e\}\{\boldsymbol{\mu}^{(n)}_{g0}/e\} |\langle \chi^{0,0}_n | \chi^{g,v}_n \rangle|^2$$
$$\times \left(\frac{2}{\sqrt{\pi}}\right)\left(\frac{\sqrt{\pi}}{\tilde{\Delta}^{(v)}_{gn}}\right) \exp\{-[(\tilde{\nu} - \tilde{\nu}^{(v)}_{gn,0})/\tilde{\Delta}^{(v)}_{gn}]^2\}$$
$$\times \int_0^{(\tilde{\nu}^{(v)}_{gn,0} - \tilde{\nu})/\tilde{\Delta}^{(v)}_{gn}} \exp(X^2)\mathrm{d}X, \quad (17)$$

which we have numerically calculated. We must report that instead of Eq. 17, use of the simple formula of asymptotic function[24,26] derived from Eq. 17 has not reproduced the J-band.

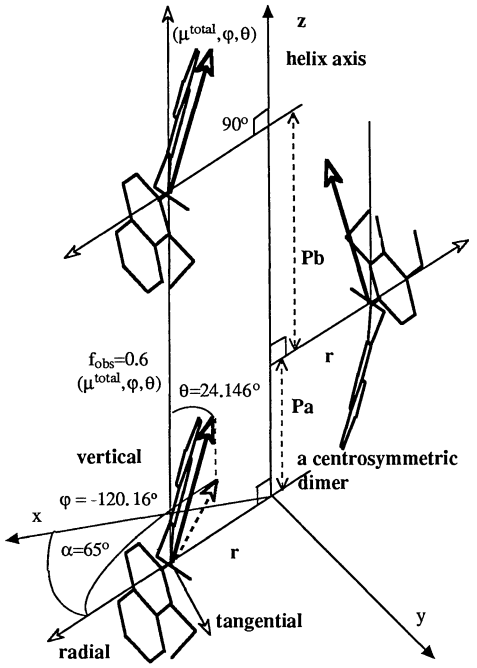

Fig. 1. Schematic illustrations of a quasi 1D-J-aggregate model of PIC which consists of centrosymmetric dimer pairs of PIC's, whose structure is the same as the columns shown on the bottom of Fig. 2. The definitions of the parameter *Pa*, *Pb*, α, r, μ, φ, and θ are given. The direction of the transition moment μ is defined by the angle φ and θ which have been calculated by the CNDO/S method in the Cartesian coordinates used here. We use α=−65.24°, θ=−120.16°, φ=24.16°.

Polymer Bandshape Function J-Aggregate Models

The molar extinction coefficient of the electronic absorption of a polymer system per monomer unit is calculated by

$$^{p}\varepsilon(\tilde{\nu}) = (8\pi^2 N_A/2301.6)\tilde{\nu}\frac{1}{N}\sum_{m}^{N}\sum_{n}^{N}\mathrm{Im}\left[\frac{1}{3}\mathrm{Tr}\,{}^{p}\boldsymbol{\alpha}_{mn}(\tilde{\nu})\right], \quad (1\ \mathrm{mol}^{-1}\,\mathrm{cm}^{-1}). \quad (18)$$

In Fig. 1, we give schematic illustrations of 1D-J-aggregate model with defintion of parameters. The model consists of a helical array of the transition moments $\boldsymbol{\mu}_{g0}^{(n)}$ of propeller-like molecule PIC. As mentioned before, the magnitudes of $|\boldsymbol{\mu}_{g0}^{(n)}|$, $\tilde{T}_{gn}^{(\nu)}$ and $\tilde{A}_{gn}^{(\nu)}$ are estimated from the observed oscillator strength f_{gn}=0.6[6] and its molar extinction coefficient.[30] However, we have no knowledge about the direction of the transition moment. So on the bottom in Fig. 1, we have shown the results of CI calculation of the direction (φ=24.146° and θ=−120.16°) of the total transition moment $\boldsymbol{\mu}_{g0}^{(n)}$ of the lowest electronic excited level for the Cartesian coordinate system given here. Clearly, the transition has the $\pi\pi^*$-character. The 40×40 singly excited CI calculation, whose configurations are chosen from the 8 higher occupied MO's involving HOMO and the 5 low-lying vacant MO's involving LUMO, has been carried out by the CNDO/S method[31] using the geometry of PIC chloride.[27] Also, other X-ray data of PIC halides gave almost similar results. The values of $\tilde{\nu}_{gn,0}$ and f_{gn} for the lowest level are respectively calculated to be 19544 cm^{-1} and 1.07, which are compared with the observed values 19150 cm^{-1} and 0.6. Similarities of J-aggregate models in solutions to the microcrystals of PIC halides were discussed by several authors.[6,29,30] In Fig. 2, we depict a rather simplified 3D-column model picked out along the[101]-direction from the crystal structure of PIC iodide reported by Nakatsu et al.[29] They indicated that the crystal structure is similar to the stair case orientation of dyes of the slipped-deck-of-card type[33] and also to the A1 of the brickstone model.[30] In Fig. 2, each column consists of quasi-1D-sequences of centrosymmetric dimer pairs, so that each column (A,B,A′,B′) constitutes the 1D-polymer model (*1D-J-aggregate*) for which we here assume 10-mer. *Two*-column interactions between A and A′ and/or between B and B′ define the 2D-polymer model (*2D-J1-aggregate*), while *two*-column interactions between A and B and/or between A′ and B constitute the 2D-polymer model (*2D-J2-aggregate*) which is slightly different from the 2D-J1-aggregate model. Here, we do not consider 2D-polymer models such as (A,B′) as well as (A′,B) models. The 3D-polymer model (*3D-J-aggregate*) is defined from *four*-column interactions among A,B,A′, and B′.

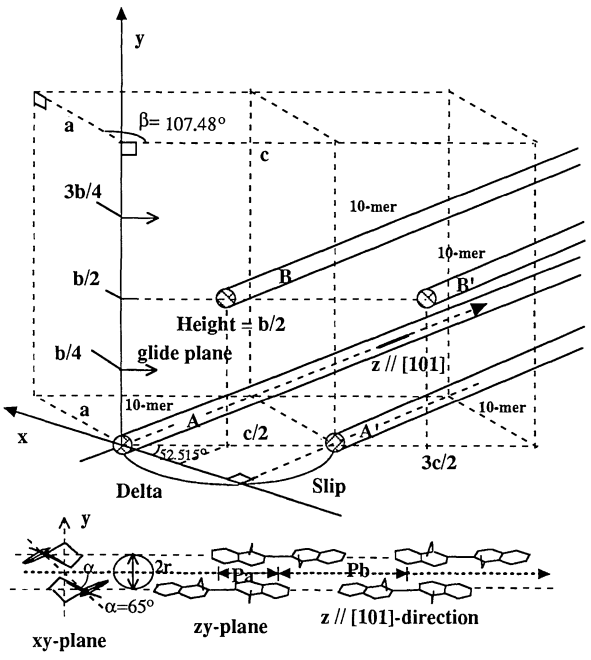

Fig. 2. The 3D-continuation of columns consisting of quasi-1D sequence of centrosymmetric dimer pairs,[29] which are produced by the operations of the *c* glide planes and specified with three parameters such as Delta, Slip, and Height. Each column contains the polymer of PIC's as shown on the bottom. As mentioned in the text, we can defined *four* J-aggregate models such as 1D-J-aggregate, 2D-J1-aggregate, 2D-J2-aggregate, and 3D-J-aggregate.

Results and Discussion

In the calculations, we plot the absorptions of PIC aggregates in the ordinate against the wavelengths with the increment 0.5 nm in the abscissa. In Eq. 18, the summation over large number N is expected to give sufficiently good convergence of bandshapes for any model, but for the 1D-J-aggregate model, all the inter-(sub)molecular interactions between 10-mer give a good convergence. It becomes another reasonable criterion for justifying the 10-mer unit model the fact that the aggregate size of our 10-mer falls into the range within such a molecular size (the values 120 Å $\leqslant$length $\leqslant$500 Å) estimated by Kuhn's energy transfer model of a 1D J-aggregate,[34] so that the range of interactions to be considered may be sufficient. Consequently, the results obtained by considering sufficient chain length effect may be not so different from the present results. In Eqs. 14 and 17, we only take the lowest level over the index g. We have not introduced an isotropic dielectric constant for Eq. 3, although it has often been introduced. This is simply because the introduction of this parameter leads to totally different features of bandshapes for the PIC aggregates. For instance, when we introduce the isotropic dielectric constant 2.0 which is often used in DNA's systems,[12,24] we need to diminish the mutual distances of PIC molecules inappropriately in more compact forms than in the present J-aggregate models in order for reproducing J-bandshapes.

In order to show the dependence of the aggregate

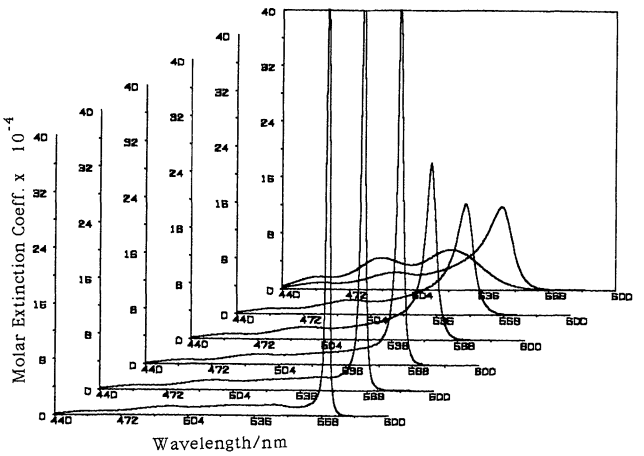

Fig. 3. The absorption spectra for 1D-J-aggregates (*1D-10-mer*). In the L-shaped frames from the left-side to the right-side, each bandshape plotted is calculated by uniformly shortening the parameter (Pa, Pb, Delta, and Slip) of the 1D-J-aggregate crystal model, respectively by the factor 0.6, 0.65, 0.7, 0.8, 0.9, 1.0, but with making the radius r=2.136 Å be constant. In the unscaled model made from Nakatsu's crystal data, we put a=10.787, b=11.626, c=16.484 Å, *Pa*=8.386 Å, *Pb*=1.093 *Pa*, Delta=10.028 Å, Slip=13.080 Å, Height=b/2 in Fig. 2. In the most backward frame, the approximate monomer band is plotted.

models upon their geometries, the bandshapes are plotted in Fig. 3 for the small changes of the 1D-J-aggregate crystal model (*1D-10-mer*). Namely, each band shown is calculated by uniformly shortening the lattice constants a, b, c as well as related parameters (Pa, Pb, Slip, and Delta) of the PIC iodide crystal,[29] respectively by the factor 0.6, 0.65, 0.7, 0.8, 0.9, 1.0, but with making the radius r=2.136 Å be constant. These scalings of geometrical parameters are based merely upon the assumption that the structures of J-aggregates in liquids are given by small modifications of PIC crystal structures. The observed peak position 571 nm of the J-band is reproduced by the scaling factor 0.65, while the unsealed 1D-J-aggregate model does show a sharp J-band.

In the *first four* frames of Fig. 4 from the forward one, each bandshape given is calculated respectively by uniformly scaling down the 2D-J2-aggregate crystal model (*2D-20-mer*) by the factor 0.6, 0.7, 0.8, 0.9, and further in the *last four* frames of Fig. 4, each bandshape is respectively plotted by scaling down the 2D-J1 aggregate crystal model (*2D-20-mer*) by the factor 0.6, 0.7, 0.8, 0.9.

In the first four frames of Fig. 5, we plot bandshapes for the 3D-J-aggregate crystal model (*3D-40-mer*), each of which is calculated respectively by uniformly shorten-

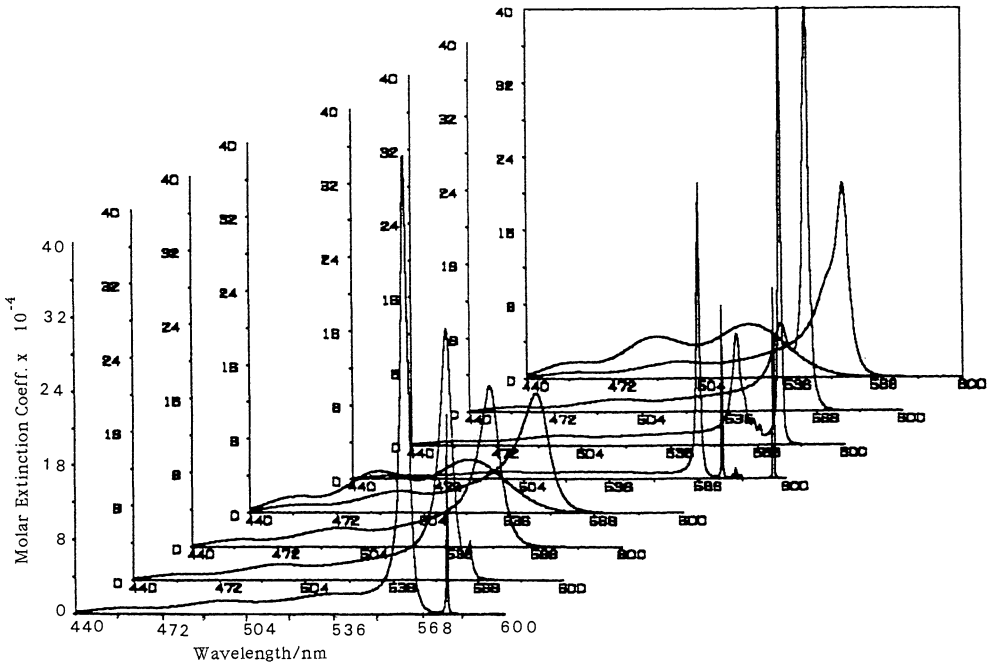

Fig. 4. The absorption spectra for the 2D-J1- and 2D-J2-aggregates. In the L-shaped frames from the left-side to the right-side, each bandshape plotted is calculated by uniformly scaling down the lattice constant (*a, b, c*) as well as the related parameters (*Pa, Pb,* Delta, and Slip) of the 2D-J2-aggregate crystal mode (*2P-20-mer*) respectively by the factor 0.6, 0.7, 0.8, 0.9, and also by uniformly scaling down the 2D-J1-aggregate crystal model (*2D-20-mer*) respectively by the factor 0.6, 0.7, 0.8, 0.9, but with making the radius r=2.136 Å be constant for the both cases. All the parameters used for the unscaled model are the same as those used in Fig. 3.

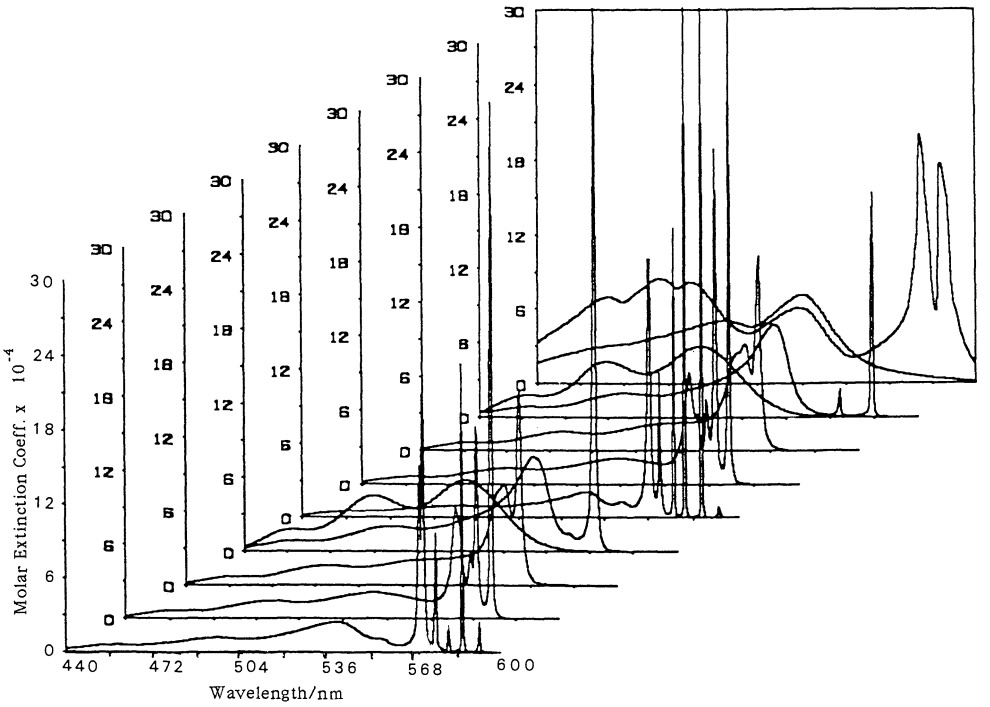

Fig. 5. The absorption spectra for the 3D-J-aggregates. In the *first four* frames, each bandshape shown is calculated by uniformly shortening, respectively by the factor 0.6, 0.7, 0.8, 1.0, the 3D-J-aggregate orthorhombic model (*3D-40-mer*), i.e., β=90° and Delta=Slip=11.656 Å with other parameters being same as those of monoclinic model. In the *last four* frames, each bandshape is calculated respectively by uniformly scaling down, by the factor 0.6, 0.7, 0.8, 1.0, the 3D-J-aggregate monoclinic model [(*3D-40-mer*) with Delta=10.028 Å, Slip=13.080 Å. In the *first* and *eighth* frames, the same monomer bands of PIC molecule are plotted. In the backward frame, the monomer band and the J-split band of the PIC bromide are plotted from Ref. 8.

ing, by the factor 0.6, 0.7, 0.8, 1.0, the crystal model which is modified to be orthorhombic, i.e., β=90° and Delta=Slip=11.656 Å with other parameters being same. However, in the last four frames of Fig. 5, we plot the absorption bandshapes calculated respectively by scaling down the 3D-J-aggregate monoclinic crystal model (*3D-40-mer*) with Delta=10.028 Å, Slip=13.080 Å,[29] that is, by uniformly shortening the crystal structure by the factor 0.6, 0.7, 0.8, 1.0.

As seen in the three Figures, the *split* J-bands are not observed for the 1D-J-aggregate model. In Fig. 4, the 2D-J1- and 2D-J2-models with the shorter lattice constants, respectively, give rise to the *doubly* and/or *multiply* split J-bands. When we look at the most backward frame of Fig. 4, the 2D-J1-model scaled by the factor 0.9 appears to give the bandshape similar to the weak doublet J-band of PIC iodide observed,[5] while in the most forward frame, the 2D-J2-model scaled by the factor 0.6 seems to give the feature of the J-split band observed in the PIC bromide aggregate.[3,4,8] However, the peak positions (563 and 572 nm) of J-split band by the factor 0.6 are insufficient to give a good agreement with the experimental values (571 and 577 nm). These doublet and/or multiplet structures obtained may be assigned to the Davydov splitting of J-band due to the interaction among 1D-J-aggregates, as suggested tacitly by Cooper.[3,4]

On the other hand, the unscaled orthorhombic 3D-J-model gives the single J-band as shown in the fourth frame of Fig. 5, but the orthorhombic model scaled by the factor 0.6 as shown in the most forward frame appears to give the split J-band with main two peaks (570 and 586 nm) separated by 430 cm^{-1}, which is compared with the split J-band of PIC bromide plotted in the most backward frame. However, we must note that the present orthorhombic model scaled by the factor 0.6 is not equal to the orthorhombic crystal model of PIC bromide.[27] It is noticed that as shown in the *eigth* frame of Fig. 5, the *unscaled monoclinic* crystal model PIC iodide is calculated to give the split J-band, i.e., the weak peak at 571 nm and the strong peak at 583 nm with a separation 360 cm^{-1}, which has a feature of J-split aggregate of PIC iodide.[5] It is to be noted that contrary to the unscaled orthorhombic 3D-J-model, the unscaled 1D-J-aggregate model which has the same geometrical parameters those of the crystal does not show a sharp J-band, as mentioned above.

From the monomer and the dimer spectra of PIC

molecule, Kopainsky el al.[17] estimated the essential parameters required also in the present calculations, for an example, the nearest neighbor electronic interaction which Knapp et al.[16] have applied to the bandshape calculations of linear J-aggregates ignoring non-nearest neighbor interactions. Different from Refs. 16 and 17 however, the calculations obtained indicate that the J-aggregate models assumed from the crystal structure do not necessarily have the same structure of essential dimer unit as Knapp et al. have assumed, in each process of aggregation in solution such as monomer→dimer→H-aggregate→J-aggregate.[10,29,30,32] The present calculations have revealed that the bandshapes are extremely sensitive to the geometrical values as well as the monomer spectroscopic parameters used. In case when the polymerization energy shift[16-18] appeared as Stokes shift is tentatively considered by changing $E_{fm,0}$ in Eqs. 1 and 4, the banshapes obtained are found to fall into the range of the present results. So before going a step further to consider the more exact formalism in order for cultivating a better understanding of unusual features of PIC aggregates, it is rather necessary to accumulate the numerical experiences about the geometries of PIC aggregate models, of course by making use of appropriate monomer spectroscopic data of PIC halides, in the belief that the real aggregate model in either solution or glassy solution is quite similar to the crystal structure. We need further studies to get a goal for predicting the whole feature of J-split bands, although the monoclinic 3D-J-four-inter-polymer model of PIC iodide leads to the qualitative feature of the doublet J-band as shown in the the *eighth* frame. For instance, the prediction for the two bands appeared at the shorter wavelength side of the split J-band in the *eighth* frame is failed. However, tentative calculations in the present formulation have been found to give some qualitative features in this region by increasingly piling up the PIC dimers and the columns of PIC's along the *y*-direction (*b*-axis) as shown in Fig. 2. Studies on such models are now in progress.

The Energy Aspect of Oil/Water Partition and Its Application to the Analysis of Quantitative Structure-Activity Relationships. Aliphatic Alcohols in the Liposome/Water Partition System

Hideaki FUJIWARA,* Yong-Zhong DA, Katsuhiko ITO, Tatsuya TAKAGI, and Yukako NISHIOKA
Faculty of Pharmaceutical Sciences, Osaka University, 1-6 Yamada-Oka, Suita, Osaka 565
(Received July 5, 1991)

The energy aspect of oil/water partition has been examined for several solutes in different partition systems by determining the thermodynamic parameters of the partition. The thermodynamic parameters changed systematically, depending on the polarity of the nonaqueous phase of the partition. To further investigate the partition system dependency of the QSAR (quantitative structure-activity relationships) treatments the thermodynamic properties have been determined for various aliphatic alcohols in a liposome/water system; the results are discussed with regard to the previous ones obtained in a 1-octanol/water system, while paying special attention to applicability in the QSAR analysis. The following trends were observed in common with the two partition systems of liposome/water and 1-octanol/water: 1. The enthalpy term (ΔH_p°) can well reproduce the toxicity data for halogenated and nonhalogenated alcohols collectively, whereas the conventional log P (partition coefficient) term can be applied only for the two types of alcohols separately; 2. The entropy term (ΔS_p°) adds a discernible contribution to the refinement of the regression analysis. A distinctive characteristic is also discussed from a statistical method of analysis for the thermodynamic properties obtained in the two partition systems.

Hitherto, oil/water partition coefficients have been studied extensively in relation to the quantitative structure-activity relationships (QSAR) for compounds with biological activity.[1,2] The coefficients reflect the Gibbs free energy change of solutes upon going from a water to an oil medium when the logarithm is taken. Hence, an energy consideration of the partition phenomena will be of great importance in discussing partition phenomena. Most frequently, the partition coefficients have been measured regarding a 1-octanol/water system.[2] It has, however, yet to be debated whether this system can well simulate the partition phenomena which occur in the biophase. Even though studies with a few different partition systems have proved that a linear relation is observed when a partition system is changed from one to another, there exist instances in which such a relation is not followed exactly, or even deviates extremely, for some of the solutes tested. As for the latter cases, dissimilar solute-solvent interactions, such as hydrogen bonding, can be pointed out as a cause. These facts indicate that different partition systems need to be tested before deducing a definite conclusion concerning characteristic aspects of partition for any solute. In a previous paper,[4] the authors attempted to separate the logarithm of the partition coefficient, which corresponds to the Gibbs free energy term, into its components of enthalpy and entropy. The results have disclosed the potential importance of the enthalpy term in the QSAR analysis for alcohol toxicities.

In the present study, different kinds of partition systems are first tested regarding the thermodynamic properties of partition using some typical solutes. The characteristic aspects of partition and its importance in QSAR analyses are then examined for aliphatic alcohols using a liposome/water partition system.

Experimental

Commercially available egg lecithin (Merck) and sodium dodecyl sulfate (Tokyo Kasei Co.) were used without further purification. The lecithin was ascertained to give only a single spot on a silica gel 60 plate in thin-layer chromatography. All other chemicals were distilled in a glass vessel.

Titration calorimetry was performed, following a previous study.[4] Liposome was prepared according to a reversed-phase evaporation method.[5] The concentration of lecithin in the suspension was determined by phosphorus colorimetry.[6] The concentration was typically around 10 mg ml^{-1}.

Determination of Partition Coefficients as Well as Enthalpies and Entropies of Partition. Measurement of partition coefficients was achieved as follows. Each alcohol was first dissolved in water; this aqueous phase was then mixed with a lecithin solution (5 ml) and shaken for 12—18 h in a constant-temperature bath. The bath temperature was regulated within an error of ±0.2 °C. The mixed solution was then separated by ultracentrifuge equipment (Beckman L8-80M). The supernatant aqueous solution was analyzed by gas chromatography using an internal reference, and the alcohol concentration was determined. The initial aqueous phase was also analyzed using the same method. The partition coefficient (K_p) was calculated according to

$$K_p=\left(\frac{A_0-A}{w/d}\right)\Big/\left(\frac{A}{V_s-w/d}\right), \quad (1)$$

where A_0 and A are the relative peak intensities in the gas chromatogram for the brank (initial aqueous phase diluted with 5 ml water) and separated solutions, respectively; w and d are the weight and density of lecithin in the liposome solution, and V_s is the total volume of the solution. The density was cited from a reference.[7] These experiments were repeated several times and the obtained K_p values were averaged so as to give the means and standard deviations. The partition equilibrium was also achieved several times at temperatures near 25 or 40 °C; the resulting K_p values were used to derive

the enthalpy (ΔH_p°) and entropy (ΔS_p°) of the partition:[8]

$$\ln K_p = -\frac{\Delta H_p^\circ}{R}\cdot\frac{1}{T}+\frac{\Delta S_p^\circ}{R}. \quad (2)$$

Since the partition coefficient was defined as the ratio in mol dm^{-3}, the standard state of the derived thermodynamic properties corresponds to unit mol dm^{-3} at 25 °C in solution. Although the symbol K_p is used for the partition coefficient in Eq. 2, in the QSAR analysis below P is also used for this parameter, appearing as log P.

Results and Discussion

Partition System Dependency of the Partition Properties of Some Typical Solutes. The thermodynamic parameters of the partition change depending on the partition system adopted. Such a dependency has hitherto been studied in some different partition systems for the partition coefficient, the logarithm of which corresponds to the Gibbs free energy term, as evidenced by the equation $\Delta G_p^\circ = -RT\cdot\ln K_p$. However, a detailed discussion of the full dependency of the thermodynamic parameters, including the enthalpy and entropy terms, has been prevented because of the necessary extra work in experiments and the limited number of available experimental data. Such data are obtained from titration calorimetry for a few solutes in some partition systems, such as SDS micelle, 1-octanol, tetralin, and 2,2,4-trimethylpentane/water. The resulting data are compiled in Table 1 together with data from different sources. The free energy term (ΔG_p°) is seen to change monotonously, depending on the partition system: it decreases in the order of the nonaqueous phase of 2,2,4-trimethylpentane(saturated hydrocarbon), tetralin(aromatic hydrocarbon), 1-octanol(hydroxy compounds), and micelle(organic salt) or liposome (phospholipid). This order is consistent with the decreasing order in ΔH_p° and with the increasing order in the polarity of a nonaqueous medium. This fact supports the idea that solute–nonaqueous solvent interactions including electrostatic and hydrogen bonding parts stabilize the solutes in the nonaqueous phase, while decreasing the enthalpy (ΔH_p°) and increasing the partition coefficient. Since the entropy (ΔS_p°) changes parallel to the enthalpy (ΔH_p°), it contributes inversely to the free energy (ΔG_p°) as judged from a relation $\Delta G_p^\circ = \Delta H_p^\circ - T\cdot\Delta S_p^\circ$. It is, therefore, concluded that the enthalpy-entropy compensation relation holds and that the ΔH_p° term is the factor governing the partition system dependency regarding the thermodynamic properties. Since the enthalpy and entropy terms cancell each other, at least partly to yield the free energy, the partition system dependency becomes much larger when the free energy is separated into the two components of enthalpy and entropy. This is a merit of studying partition phenomena from a thermodynamic standpoint.

Model membrane (liposome) or micelle systems afford a lower ΔG_p° and a higher partition coefficient than does the widely used 1-octanol system. Since the former systems can better simulate the organized structure of a biophase medium, liposome or micelle systems may be recommended for the purpose of QSAR treat-

ment. In following sections of this paper, the partition properties of aliphatic alcohols (which the authors studied in the 1-octanol/water system[4)]) are examined in the liposome/water system and compared with previous results.

Partition Properties of Aliphatic Alcohols in the Liposome/Water System. The data regarding K_p (at 25 °C), ΔH_p°, and ΔS_p° obtained in the present study are summarized in Table 2. The thermodynamic parameters (ΔG_p°, ΔH_p°, and ΔS_p°) change linearly with the molar volume (V_m) of alcohols (Figs. 1 to 3) when halogenated and nonhalogenated alcohols are veiwed separately. The molar volume dependency of ΔH_p° is parallel for the halogenated and nonhalogenated alcohols (Fig. 2); that of ΔS_p°, however, differs in

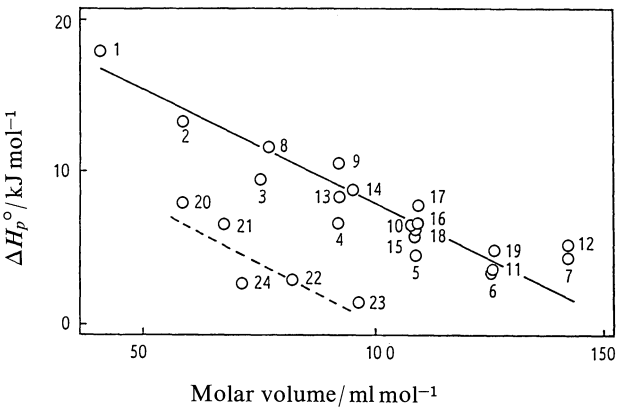

Fig. 2. Plots of ΔH_p° against the molar volume of solutes.

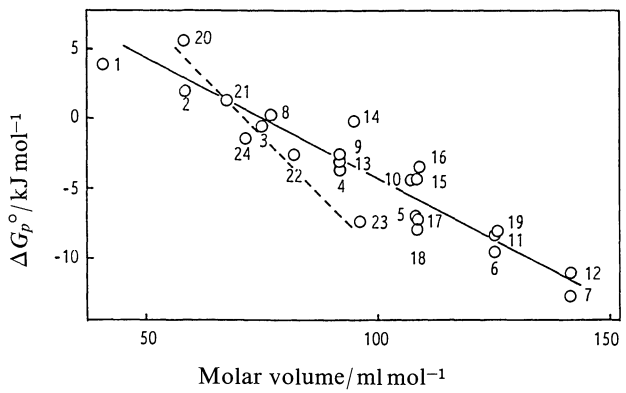

Fig. 1. Plots of ΔG_p° against the molar volume of solutes.

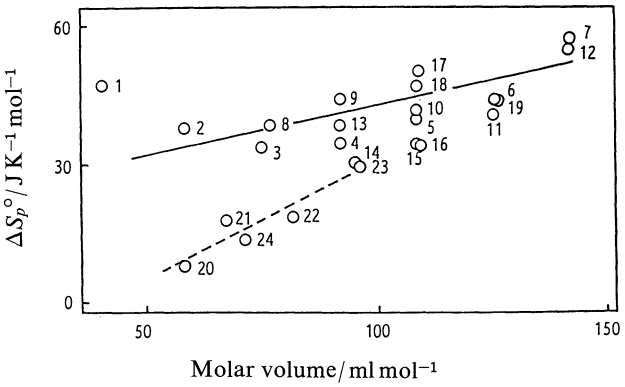

Fig. 3. Plots of ΔS_p° against the molar volume of solutes.

its slope between the two types of alcohols (Fig. 3). The latter difference is responsible for the difference in the slope shown in Fig. 1 for the halogenated and nonhalogenated alcohols. This result offers a rather clear contrast with that reached in the 1-octanol/water partition system:[4] in the latter system, the enthalpy (ΔH_p°; not the entropy) is responsible for the different slope of the molar volume dependency in ΔG_p°. When ΔG_p° and $\log K_p$ at 25 °C, as well as ΔH_p° and ΔS_p°, are interrelated between the partition systems of 1-octanol/water and liposome/water, linear relations are successfully obtained in regression analyses (Table 3). It is seen from the regression coefficients (smaller than 1.0 in Table 3) that the variations in the values of $\log K_p$, ΔG_p°, ΔH_p°, and ΔS_p° are smaller in the liposome/water system than those in the 1-octanol/water system when the solute alcohols are changed. The results listed in Tables 1 and 3 show a trend in that ΔH_p° and ΔS_p° are larger when observed using a more polar (ionic) nonaqueous phase. This trend, however, is inversed with respect to the free energy term. That is, ΔG_p° is increased, being decreased in absolute value, for the aliphatic alcohols in the liposome/water system, compared to that in the 1-octanol/water system (see 1-pentanol in Table 1 and also Table 3). This means that, for the aliphatic alcohols, ΔH_p° does not decrease very much in the liposome system compared to the data observed in other systems; this situation is reversed for ΔS_p°. This is equivalent to saying that the ratio of the enthalpy/entropy changes and the contribution of the enthalpy term is increased in the liposome/water system.

QSAR Analyses of the Biological Activities of Alcohols. Among the alcohols treated in the present study the biological activities are reported for twelve nonhalogenated alcohols,[15] as well as eight nonhalogenated and five halogenated alcohols.[16] The data concerning nonhalogenated alchohols,[15] which include LD_{50} (the concentration causing death in 50% of female white mice from i.v. injection), H (the concentration causing instantaneous hemolysis of erythrocytes), WI (the concentration causing inhibition of all the Tubifex worm movement within 2 min after immersion in a solution of alcohols), and FI (the dose that all fish assumed a side position or inverted position after 9—10 min of exposure to alcohols), were analyzed by means of the molecular connectivity index ($^1\chi$). The data, however, were also found to be quite successfully correlated with $\log P$ (Table 4).[17] Here, the $\log P$ data may be taken from either the liposome/water or the 1-octanol/water system, since the data from these two systems exhibit a high mutual colinearity, especially within the nonhalogenated alcohols (Table 2).

The toxicity data of alcohols, including halogenated ones,[16] are analyzed in Table 5. These data include the product of intrinsic toxicity, T_i (the slope of the dose-response curve in tissue culture), the tissue culture toxicity, ID_{50} (the concentration required to produce 50% inhibition of growth), the hemolytic activity, H_{50} (the concentration required to produce 50% hemolysis in saline at 37 °C), and the acute in vivo toxicity, LD_{50} (the single intraperitoneal dose required to kill 50% of the mice in 7 d). For the sake of a comparison the previous analyses using the partition properties in the 1-octanol/

water system are also included in Table 5. The in vivo datum (LD_{50}) is excluded for 2-fluoroethanol in Table 5, since this alcohol is metabolized to a more active intermediate in vivo.[18] All other available data are included in Table 5.

Trends in the analysis of the toxicity data are summarized as follows:

1. All of the data can be correlated well with ΔH_p°.
2. The data exhibit no high correlation with ΔS_p°, but the regression analyses are improved when ΔS_p° is incorporated besides the ΔH_p° term.
3. The data can be correlated with log P only when the halogenated and the nonhalogenated alcohols are treated separately.
4. A slightly higher correlation is observed against ΔS_p° when in vivo toxicity data (LD_{50}) are concerned.

These trends are all in common with the two partition systems of liposome/water and 1-octanol/water. In order to examine more closely the difference of using the data of the two partition systems, a bootstrap method[19] is applied for statistical tests of the regression co-

r[a]	0.892— 0.984	0.763—0.989

a) Multiple regression coefficient.

efficients (Table 6). The results indicate that within the 95% confidence intervals the coefficients of ΔH_p° and ΔS_p° are not reduced to zero in the liposome/water system, whereas they are reduced in the 1-octanol/water system. This supports the superiority of data obtained in the liposome/water system for the QSAR analysis.

We would like to express our sincere gratitude to Professor (Emeritus) Yoshio Sasaki, Osaka University, for his continuous interest and invaluable suggestions.

Kinetic Studies on the Chemical and Electrochemical Reduction of Some 4-Arylidene-5-pyrazolone Compounds

Mahmoud A. ABDEL-RAHMAN, Refat ABDEL-HAMID,* Mostafa K. RABIA, and Mohamed M. EL-DESSOUKI
Department of Chemistry, Faculty of Science, Sohag, Egypt
(Received March 11, 1991)

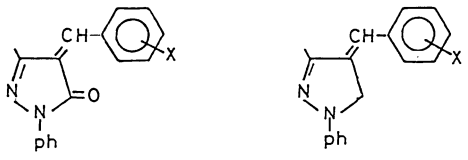
Kinetics of chemical and electrochemical reduction of some 4-arylidene-5-pyrazolones were studied. The chemical reduction was performed using aluminum hydride. The electrochemical reduction in 0.1 mol dm^{-3} TEAP/DMF was studied by cyclic and convolution potential sweep voltammetry at HDME. The title compounds exhibit two diffusion-controlled irreversible mono electronic cv waves. Both waves follow EC kinetics and they are attributed to the reduction of the pyrazolin carbonyl group. The kinetics of the chemical and electrochemical reduction were proposed and discussed in terms of the molecular structure of the subject arylidenes.

Though many investigations have been reported concerning the synthesis of arylidenes,[1] dyes[2,3] and electronic absorption spectra of arylidenepyrazolones,[4] scarcely attention has been paid to chemical and electrochemical reduction of such compounds.[5] It was found that the polarographic half-wave potentials of some 4-(4-substituted arylidene)-5-pyrazolones correlate with the Hammett's constant. Kinetics of the chemical and electrochemical reduction of the title compounds were not yet studied.

In continuation of our work[6] an investigation of the chemical and electrochemical reduction mechanism of a series of 4-(4-substituted arylidene)-5-pyrazolones is carried out. Herein, chemical and cyclic and convolution potential sweep voltammetric results are reported and discussed in terms of the molecular structure of the subject arylidenepyrazolones.

Experimental

a) Synthesis of 4-Arylidene-5-pyrazolones. 1-Phenyl-3-methyl-4-arylidene-5-pyrazolones were synthesized and purified as described before.[7] The subject compounds are:



$\mathbf{a}_{1-3}$ $\mathbf{b}_{1-3}$
1, X=H, **2**, X=OCH_3, **3**, X=Br

Stock solution (1.0×10^{-2} mol dm^{-3}) of arylidenepyrazolone was prepared in the supporting electrolyte (0.1 mol dm^{-3} TEAP/DMF).

b) Synthesis of Aluminum Hydride (alane). To a cooled stirring solution of lithium aluminum hydride, $LiAlH_4$, 0.12g (3.0 mmol) in 20.0 ml dry ether was added, 0.12 g (1.0 mmol) of anhydrous aluminum chloride, $AlCl_3$, in portions to give stoichiometrically required amount of AlH_3. The mixture was stirred at room temperature until $AlCl_3$ dissolved and LiCl was completely precipitated.

$$3\ LiAlH_4 + AlCl_3 \rightarrow 3\ LiCl + 4\ AlH_3 \quad (1)$$

c) Selective Reduction of Arylidenepyrazolones with alane. (General Procedure). 20.0 ml etheral solution of AlH_3[8] was added to a stirring solution of the pyrazolone derivative (2.0 mmol) in dry ether. The reaction mixture was refluxed under dry conditions (6—7 h). The excess hydride was decomposed by addition of dilute HCl then the reductive product was extracted with ether and dried over anhydrous $MgSO_4$. Evaporation of the solvent under reduced pressure gave a viscous residue which after grunding with petroleum ether solidifies as colored solid. The products were crystallized from acetone. The arylidenepyrazolones subjected for the selective chemical reduction are: **2a**, **3a**, and 1-phenyl-3,4,4-trimethyl-5-pyrazolone (**4a**). Experimental data of all the isolated products were summarized in Table 1.

Tetraethylammonium perchlorate, TEAP, (Fluka), and *N,N*-dimethylformamide (A.R. grade DMF) were purified as described earlier.[6,9]

d) Controlled Potential Coulometric Measurements. Controlled potential coulometric electrolyses were performed at the peak current potential of the two cv waves. Coulometric measurements were conducted in 1.0×10^{-3} mol dm^{-3} solu-

Table 1. Experimental Data for the Reductive Arylidenepyrazolone Products

					76.50	8.70	14.75

tions. The cell was continuously flushed with nitrogen and the analysis was continued until the current had decayed to the background level. Completion of the electrolysis was confirmed by cv measurements.

e) Instrumentations. An EG&G PAR model SMDE 303 mercury drop system of small hanging-drop mode was used as HDME working electrode at 298 K. The electrode area was 1.83×10^{-3} cm^2. The counter electrode was platinum wire. Silver/silver ion (0.01 mol dm^{-3} $AgNO_3$ in 0.1 mol dm^{-3} TEAP/DMF) electrode was used as a reference electrode throughout. All solutions were purged with pure nitrogen.

An EG&G PAR model 173 Potentiostat/Galvanostat with positive feedback IR compensation and EG&G PAR model 175 Universal programmer function generator were used for the cyclic voltammetric measurements. The cyclic voltammograms were recorded on PAR model RE 0091 X-Y recorder.

Controlled potential coulometry was carried out with EG&G PAR model 179 Digital Coulometer and PAR model 337A Coulometric cell system.

Electrochemical data were performed using an AMSTRAD personal computer PC 1512.

Spectrophotometric measurements (IR and ^{1}H NMR spectra) were performed on a Perkin-Elmer 137 IR Spectrophotometer in KBr and Varian A-60 ^{1}H NMR Spectrophotometer at 60 MHz.

Results and Discussion

i) Cyclic Voltammetry. Two cyclic voltammetric reduction waves are observed for all the 1-phenyl-3-methyl-4-arylidene-2-pyrazolin-5-ones (4.98×10^{-4} mol dm^{-3}) in 0.1 mol dm^{-3} tetraethylammonium perchlorate/dimethylformamide (TEAP/DMF) at hanging dropping mercury electrode. The cyclic voltammetric data obtained are given in Table 2. The cv waves appear to be irreversible, their anodic counterparts are lacking at all scan rates explored.

The potential width measured by ($E_p-E_{p/2}$) for the two cv waves are larger than the values expected for a mono-electronic charge-transfer reversible processes (56.5/n mV at 298 K) (c.f. Table 2).[10,11] The peak potential of the two cv waves does shift to more negative potentials on increasing the scan rate, to the extent of 30.0±0.3 and 35±0.2 mV for the tenfold increase in scan rate for the first and second cv waves, respectively. This reveals that, the cv waves are due to a reversible one electron-transfer process coupled with an irreversible first-order follow-up chemical reaction. The chemical reaction is suggested to be protonation.

The peak current, i_p of both cv waves correlates significantly with $\nu^{1/2}$, (r=0.998) and concentration of the depolarizer as well (r=0.999). This evidences that the two cv waves are diffusion-controlled[10] with no adsorption complications.

On comparing i_p–$\nu^{1/2}$ relations with the diagnostic criteria for EC mechanism presented earlier,[10] the diffusion coefficient, D, for the subject arylidenepyrazolones are computed. The data obtained are collected in Table 2.

According to Nicholson and Shain,[10] an excellent agreement between the experimental and calculated peak width ($E_p-E_{p/2}$) is seen. This provides completing evidence that the cv waves follow solely the $E_{rev}C_{irr}$ mechanism. Furthermore, the first-order rate constants of the follow-up irreversible protonation reaction, k_c, are estimated. Moreover, the polarographic half-wave and the formal electrode potentials, if one considers that $D_R=D_O$ (the diffusion coefficients of the reduced and oxidized forms, respectively) are determined using Eqs. 2 and 3.[10]

$$E_p = E_{1/2} - 0.780\,(RT/nF) + RT/2nF \ln\lambda, \quad (2)$$

where $\lambda=k_c(RT/nF)\nu$.

$$E_{1/2} = E^\circ + (RT/nF) \ln\sqrt{(D_R/D_O)}. \quad (3)$$

The computed values of E° and k_c are depicted in Table 2.

a) ±2.1%. b) in $\mu A(V^{-1}s)^{-1/2}$. c) ±3.2%. d) ±2.5%. e) ±3.5%.

On the other hand, a further verification that the substrate reduces electrochemically via an $E_{rev}C_{irr}$ mechanism is revealed from the slightly decrease in the current function with increasing the scan rate (c.f. Table 2).

The number of electrons involved along the two cv waves is determined on controlling the potential at their peak current potentials. It is found that 1.1 and 0.9 moles of electrons per mole of the arylidenepyrazolone are consumed for electrochemical reduction of the first and second cv waves, respectively. Thus, the number of electrons transferred is one for both cv waves. Similar behavior is seen with the other arylidenepyrazolones under investigation.

ii) Convolution Sweep Voltammetry. Analysis of cyclic voltammetric data has a disadvantage that the potential dependent rate law must be selected before the treatment of data. However, convolution technique allows this disadvantage to be overcome. This is made by convolution of the current with the function $(\pi t)^{1/2}$ and data are processed in terms of both current and convoluted current. It is no longer necessary, under this conditions, to (a priori) state the charge transfer rate law which is instead obtained as a result of the treatment of data[12–16].

Examination of the cyclic voltammetric convoluted data for the 4-arylidenepyrazolones in the scan rate range of 20—500 mV s^{-1} reveals that they electrochemically reduce irreversibly. This is established from the feature of the cyclic convoluted current voltammogram, since the convoluted current, I, neither returns to its initial (zero) value nor superimposes during the reverse half of the sweep with I on the forward sweep regardless of the scan rate. Figure 1 illustrates the cyclic original and convoluted voltammograms for the first cv wave for **1a** at scan rate of 200 mV s^{-1} as a representative example.

The logarithmic analysis of the convoluted data is used to established the mechanism of the electrochemical reduction process. The analysis is tested for the various reaction mechanisms (E_{rev}, E_{irr}, *CE*, *ECE*, ...etc).

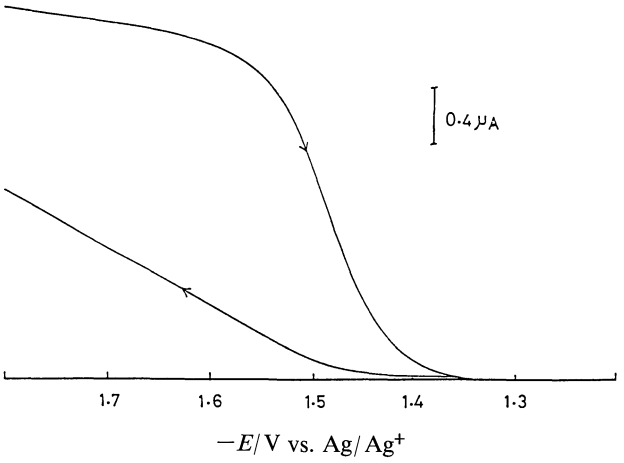

Fig. 1. Convolution voltammogram for the first cv wave of the reduction of 4-arylidenepyrazolone, **1a**, at scan rate of 200 mV s^{-1}.

In the entire range of scan rate, the data fit satisfactorily the following equation for all the subject pyrazolones:

$$E = E^\circ + (RT/2nF)\ln k_c + (RT/nF)\ln[(I_l - I)/i], \quad (4)$$

where I is the convoluted current, i is the original current, $I_l = nFAC_0D^{1/2}$ is the limit of I as E approaches infinity and the remaining symbols have their usual significances. They give rise straight lines with slope values close to the theoretical value ($59.1/n$ mV at 298 K for decimal logarithm) for an $E_{rev}C_{irr}$ mechanism. The regression line obtained for the first cv wave of **1a** as a representative example can be represented by Eq. 5. The linearity and the location of the obtained straight line on the potential axis do not depend on the sweep rate. This behavior verifies the above conclusion that the electrochemical reduction of the subject pyrazolones take place via an $E_{rev}C_{irr}$ kinetics.

$$E = -(1.445 \pm 0.005) + (61.1 \pm 1.1) \times 10^{-3} \log[(I_l - I)/i] \quad r = 0.998 \quad (5)$$

From Eqs. 4 and 5 the formal electrode potential, E°, for the subject arylidenepyrazolones are computed. The results obtained depicted in Table 1. It is clear that these values are in good agreement, within the experimental error limits, with those obtained from the above cyclic voltammetric data.

iii) Chemical Reduction: Special attention is paid to the selective reduction suitable for the reduction of the carbonyl group without reduction of the arylidene group of the subject arylidenepyrazolones.

The most common reducing agents are the metal hydrides and hydrogenation catalysts. The reagents used in the reduction by hydride transfer (metal hydrides)[17] are two types. They are nucleophilic substances such as lithium aluminum hydride (LAH) and sodium borohydride, as well as the electrophilic species diborane, aluminum hydride (alane) and derivative thereof.[18,19]

Lithium aluminum hydride often reduces the α,β-unsaturated ketones.[20,21] The double bond reduction is avoided by the use of aluminum hydride, which selectively reduces the carbonyl group only.

The selective reduction of **2a**—**4a** is carried out using aluminum hydride. The reduction process was followed by ^{1}H NMR spectra, which show a shift in the vinylic proton resonance to a higher magnetic field.

Table 3. IR Spectroscopic Data (KBr, cm^{-1})

Compd	νC=O	νC=N	νC=C Exocyclic
2a	1670	1630	1610
2b	—	1625	1610
3a	1670	1630	1610
3b	—	1630	1590
4a	1685	1620	—
4b	—	1625	—

Table 4. ^{1}H NMR Spectra δ (DMSO)/ppm

Compd	=CH	Arom. proton	OCH_3	$-CH_2$	$-CH_3$
2a	8.8 (s, 1H)	7.1—8.2 (m, 9H)	3.9 (s, 3H)	—	2.4 (s, 3H)
2b	8.3 (br, 1H)	6.8—8.2 (m, 9H)	3.8 (s, 3H)	3.6 (s, 2H)	2.3 (s, 3H)
3a	8.3 (s, 1H)	7.1—8.0 (m, 9H)	—	—	2.2 (s, 3H)
3b	8.1 (br, 1H)	6.7—7.9 (m, 9H)	—	3.9 (s, 2H)	2.2 (s, 3H)
4a	—	7.8—7.2 (m, 9H)	—	—	2.6 (s, 3H); 2.45 (s, 6H)
4b	—	7.8—7.4 (m, 9H)	—	4.2 (br, 2H)	2.2 (s, 3H); 1.2 (d, 3H); 1.2 (s, 3H)

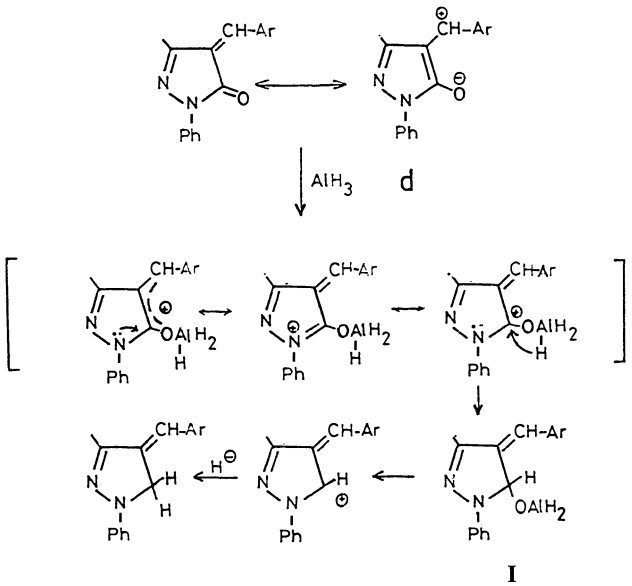
This is attributed to the disappearance of deshielding effect of the carbonyl group. Moreover, new singlet signals are developed due to the appearance of methylene group. The structure of the isolated products are assigned on the basis of elemental and spectral analyses.

A comparison between IR spectra of the reduced products, **2b**—**4b**, and those of the starting materials, **2a**—**4a**, (c.f. Table 3) gives conclusive evidence of the nature of the reaction, since the products show a lack of the C=O bond. ^{1}H NMR spectra (Table 4) are in agreement with the suggested structures.

The mechanism of the reduction by alane differs somewhat from that of complex hydride (LAH). The main difference is in the entirely different chemical nature of the two types (alane and complex hydride). Whereas complex hydride anion is a strong nucleophile which attacks centers of lowest electron density, alane is electrophile and combines with that part of the organic molecule which has a free electron pair.[22]

Thus, the following reaction mechanism of the chemical reduction of **2a**—**4a** with alane (Scheme 1) is suggested.

Coordination is first assumed to occur between the carbonyl oxygen atom and alane. Intramolecular hydride transfer is possible in the complex and intermediate (**I**) still contains hydrogen atom directly attached to the aluminum atom. The intermediate heterolyses by loosing an aluminate ion, a good leaving group, to give carbonium ions which are reduced to methylene group leading to the final product.



Scheme 1.

From the foregoing results it can be deduced that:

1) $AlCl_3$ is added to reduce the reduction tendency power of $LiAlH_4$ and consequently produces a reagent more specific for the particular reaction as described by elsewhere.[18]

2) The arylidene substituents play a role in the stabilization of the dipolar form **d** (Scheme 1). Introduction of an electron-withdrawing group in the *p*-position of the arylidene moiety increases the facility of the reduction.

Kinetics of the Electrochemical Reduction. Electrochemical reduction kinetics of 1-phenyl-3-methyl-4-arylidene-2-pyrazolin-5-ones in 0.1 TEAP/DMF at 298 K, the electrode reaction mechanism are discussed on the basis of the above results. They are electrochemically reduced via two irreversible diffusion-controlled single-electronic cv waves. These cv waves follow an $E_{rev}C_{irr}$ kinetics.

The subject arylidenepyrazolones have three possible reduction sites, the azomethine, -CH=N, of the pyrazolone nucleus, the cyclic carbonyl, C=O, and the exocyclic arylidene =CH-Ar, groups. The endocyclic -CH=N- group requires high energy for reduction. Therefore, the two other sites are susceptible for reduction.

To establish the site of reduction in the subject substrates, they are subjected to selective chemical reduction for the carbonyl group and then are tested voltammetrically. The reduced products show no cv waves. This is ascribed to the lacking of their 5-carbonyl group. Thus, the electrochemical reduction site is most likely the 5-carbonyl group, while the arylidene group is electroinactive at such circumstances.

The kinetics of the electrochemical reduction of the 4-arylidene-5-pyrazolones is proposed and discussed as follows:

The first irreversible mono-electronic reduction wave is due to reversible addition of an electron to the pyrazo-

lone molecule and can be represented by reaction (6). Simple charge-transfer reaction (6) does not, however, justify the irreversibility of the first wave and other step must be invoked to rationalize the data obtained. Taking into account that the first cv wave proceeds via an $E_{rev}C_{irr}$ mechanism and the reduction of carbonyl group consumes at least two electrons and two protons, an irreversible first-order protonation reaction (7) is assumed to be taken place. At more negative potentials, further electron is reversibly added to the radical ArpyH$^{\cdot}$, according to reaction (8). Another irreversible first-order proton addition, reaction (9), to the ArpyH^{-} anion takes place to the final product. Occurrence of reactions (7) and (9) can justify the irreversibility of the two cv waves.

$$\mathrm{Arpy} + \mathrm{e} \rightleftneq \mathrm{Arpy}^{\cdot-} \quad (6)$$

$$\mathrm{Arpy}^{\cdot-} + \mathrm{H}^{+} \xrightarrow{k_c} \mathrm{ArpH}^{\cdot} \quad (7)$$

$$\mathrm{Arpy}^{\cdot} + \mathrm{e} \rightleftneq \mathrm{ArpyH}^{-} \quad (8)$$

$$\mathrm{ArpyH}^{\cdot-} + \mathrm{H}^{+} \xrightarrow{k_c} \mathrm{ArpH_2} \quad (9)$$

Structural Effects. From the examination of the data obtained (cf. Table 2), it is evident that the influence of the para substituents in the 4-arylidene moiety on the electrochemical reduction (expressed in the values of the peak current potential, E_p) is as expected. The *p*-methoxy substituted derivative exhibits the most negative shift of E_p, whereas the *p*-bromo one shows a positive shift compared to the parent unsubstituted arylidenepyrazolone **1a**. This is explained as follows. On introduction of electron-donating group (methoxyl group) in the arylidene phenyl moiety, an increase in the electron density of the carbonyl group is expected. Consequently, the electrochemical reduction of the carbonyl group becomes more difficult. This appears as a shift in E_p to more negative potentials. On the other hand, introduction of electron-withdrawing group (bromo) reduces the electron density on the carbonyl center. This in turn makes the electrochemical reduction easier and appears as a positive shift in E_p.

The substituent effect is expressed quantitatively by the relation between the peak current potential of the arylidenepyrazolones and the Hammett's substituent constants, σ_p^-. It is evident that, the peak potentials for the first cv wave correlate with the σ_p^- Hammett constants. The best linear least-square line obtained is represented as follows:

$$E_p = (0.218 \pm 0.002)\,\sigma_p^- - (1.463 \pm 0.013) \quad r = 0.983(10) \quad (10)$$

This confirms that the electrochemical reduction of the subject arylidenepyrazolones follow the same mechanism for all the compounds under investigation. On the other hand, the reaction constant ρ obtained is 218 mV comparable to those of substituted benzaldehyde (310 mV), benzophenone oximes (300 mV) and azomethine (300 mV) etc.[23] These are interpreted on the basis as the arylidene moiety becomes a structure completely coplanar with the rest of the molecular plane. Also, this verifies strongly that the electrochemical reduction center is the α,β-unsaturated 5-carbonyl group.

Conductivity of *N*-Methylpyridinium Iodide and Its Methyl Substituted Derivatives in Water-Ethanol Mixture

Ranjan Kumar Swain and B. Behera*
Department of Chemistry, Sambalpur University,
Jyotivihar, Sambalpur 768019, India
(Received April 4, 1991)

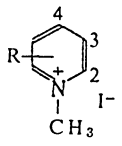
The conductivity of *N*-methylpyridinium iodide (NMPI) and its methyl substituted derivatives at 2-, 3-, and 4-positions in water–ethanol solvent mixtures is reported at 25 °C. The conductivity data are analyzed by the Shedlovsky method to get both Λ_0 and K_A, the association constant, simultaneously. The Λ_0 values decrease or increase with increase or decrease of the viscosity of the solvent mixtures. The values of Λ_0 and K are in the order of H>3->4->2-. The Walden product $\Lambda_0\eta$ for these iodide salts behaves in a manner as is expected for highly hydrogen bonded water–alcohol mixtures. A mole fraction of 0.15 to 0.2 in ethanol indicates maximum interaction between water and ethanol. The values of Λ_0 and K_A indicate greater solvation and hence less ion–ion interaction in case of NMPI and 3-CH_3 salts than 2- and 4-CH_3 salts.

N-Methylpyridinium iodide (NMPI) and its methyl substituted derivatives are formed from reaction of pyridine and picolines with methyl iodide in the form of ionic compounds. Kosower,[1] Roy,[2] Hemmes,[3] Jong-Gi Lee,[4] Bagchi[5] and co-workers have reported spectral, kinetic, and thermodynamic studies on NMPI in 90% and 100% ethanol and acetone solvent mixtures. All these studies point out to formation of solvent shared ion-pairs which is represented as:

$$\underset{\text{Contact ion pair}}{CH_3Py^+I^-} \rightleftarrows \underset{\text{Solvent shared ion pairs}}{CH_3Py^+, I^-} \rightleftarrows \underset{\text{Solvent separated ion pair}}{CH_3Py^+ + I^-} \quad (1)$$

Recently we have carried out the viscosity, apparent molar volume[6] in water at various temperatures and conductance[7] studies in water–methanol mixtures in the entire solvent composition range at 25 °C. All these studies indicate existence of solvent shared ion-pair. A mole fraction of 0.27 in methanol has indicated greater interaction between water and methanol. These studies also indicate difference in the solvation of ions and ion–ion interaction in this solvent system.

Conductance[3] studies of NMPI is only reported in 100% and 90% ethanol–water mixture at 25 °C. The entire solvent composition range has not been studied. In this paper we report conductance measurements of iodide salts of *N*-methylpyridinium ($NMPR^+I^-$) and its methyl substituted derivatives (**I**) in the entire water–ethanol composition range at 25 °C.



I

$NMPR^+I^-$: R=H, CH_3 at 2-, 3-, 4-positions.
When R=H the salt is NMPI.
Short abbreviations for the salts are H, 2-, 3- and 4-.

Experimental

The iodide salts (**I**) were prepared as already described.[6,7] The purity of the salts was checked by gravimetric estimation of iodide as silver iodide.[8] Ethanol was purified by refluxing over calcium oxide. Conductivity water having specific conductivity of 1.2×10^{-6} $\Omega^{-1}cm^{-1}$ was used. All the solvent mixtures of various composition were prepared by weight at 25 °C. Conductivity measurewments, in triplicate, were carried out as described earlier.[9] The conductivity measurements in the concentration range of 10^{-2} to 10^{-4} M(1 M=1 mol dm^{-3}) of the iodide salts were carried out at 25 °C.

Results and Discussion

NMPI ionizes in solution as

$$CH_3Py^+I^- \rightleftarrows CH_3Py^+ + I^- \quad (2)$$

and the ionization constant K is given by

$$K=\frac{\alpha^2 c}{1-\alpha}f_\pm^2. \quad (3)$$

The symbols have got their usual meaning. By analyzing the conductivity data by the Shedlovsky method[10] we employed

$$\alpha=\frac{\Lambda S(Z)}{\Lambda_0}$$

$$S(Z)=\left[\frac{Z}{2}+\left\{1+\left(\frac{Z}{2}\right)^2\right\}^{1/2}\right]^2 \quad (4)$$

$$Z=S\Lambda_0^{-1.5}(c\Lambda)^{1/2}$$

and

$$S=B_1\Lambda_0+B_2.$$

Both K and Λ_0 were obtained by least-square analysis of Eqs. 5 and 6.

$$\frac{1}{\Lambda S(Z)}=\frac{1}{K\Lambda_0^2}\Lambda C f_\pm^2 S(Z)+\frac{1}{\Lambda_0}, \quad (5)$$

$$\mathrm{Log}f_\pm=-\frac{A\sqrt{I}}{1+\sqrt{I}}, \quad (6)$$

where $I=\alpha C$ and A, B_1, and B_2 are Debye–Hückel and Onsager constants. The values of the physical constants of water–ethanol system[11] are set out in Table 1. In all the calculations the correlation coefficient was found to lie between 0.99 and 1 and the error of estimate

100	98.49 (107)[a]	122.14	105.65	112.74

Error of estimate is 0.02% and r lies between 0.99 and 1.
a) Data from Ref. 3.

was 0.02%. The initial value of Λ_0 needed for calculation was obtained from the plot of Λ against $\sqrt{C}$. The results of such calculations are set out in Tables 2 and 3.

The variation of Λ_0 of these compounds and the η of the solvent mixtures with the mole fraction of ethanol are shown in Fig. 1. The viscosity of water-ethanol

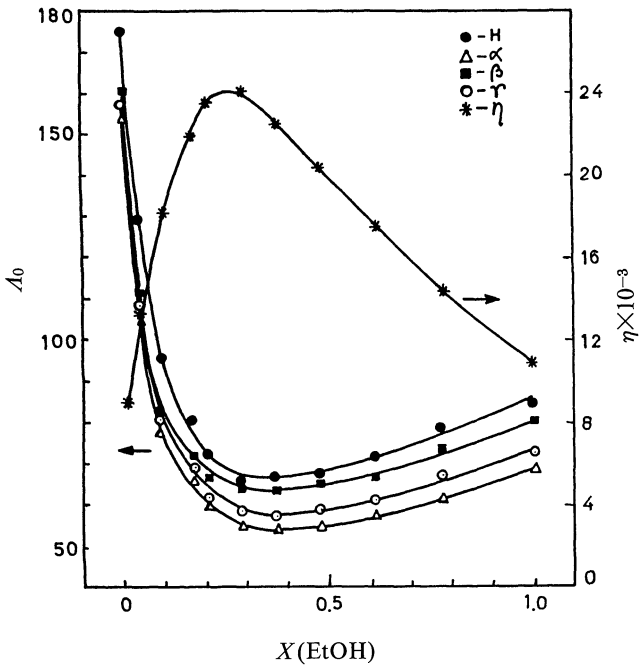

Fig. 1. Variation of Λ_0 and η against mole fraction of ethanol.

mixtures increases up to a mole fraction of 0.31 and then gradually decreases. The Λ_0 values of these iodide salts decrease up to this mole fraction and then increase in ethanol-rich region, showing opposite behavior to the viscosity of the medium. The association constant, K_A, of these salts gradually increases with increase in ethanol composition (Fig. 2). The association constants are in the order H<3-<4-<2-. The Λ_0 values are in the order H>3->4->2-. These results indicate that the viscosity of the medium plays an important role on the mobility of ions in solution.

Fuoss[12] has pointed out that the plot of $\log K_A$ vs. $1/\varepsilon$ should be linear in the vicinity of the dielectric constant, lying below 40. This prediction by Fuoss is obeyed by NMPI and its methyl substituted derivatives in alcohol-rich region where the dielectric constant lies

90	1.118	0.874	1.051	0.965
100	0.925	0.746	0.883	0.796

below 40 (Fig. 3).

The Walden product $\Lambda_0\eta$ for the entire solvent range for these salts is given in Table 4 and shown in Fig. 4 as a function of mole fraction of ethanol. The Walden product passes through a maximum which lies between 0.15 and 0.2 in ethanol mole fraction and then decreases at higher ethanol content. It has been pointed out[13] that the Walden product of water–alcohol mixtures passes through a maximum and the values are quite high as expected for highly hydrogen-bonded solvents. Both cation $NMPR^+$ and anion I^- can move through the solutions overcoming the viscous forces in the solvent system. The structure of water determines the Walden product in water–ethanol mixtures. The trend in the Walden product of these salts in water–ethanol solvent mixtures clearly indicates strong interaction between water and ethanol.

The Λ_0 and K values indicate that NMPI and 3-CH_3 salts are more close to each other than 2- and 4-salts. The ion–ion interaction takes place between $NMPR^+$ and I^- to form ion-pairs through preferential solvation of these ions in both water-rich and ethanol-rich regions. The electron donating capacity of methyl group at 2- and 4-positions partially neutralizes the positive charge in the pyridinium ion. Such partial neutralization is not possible in NMPI and 3-CH_3 salts. Therefore the 2- and 4-salts are less solvated than NMPI and 3-CH_3 salts. This results in greater ion–ion interaction between $NMPR^+$ and I^- ions of 2- and 4-salts is

reflected in the low values of Λ_0 and high values of K_A than the corresponding values of NMPI and 3-CH_3 salts. All these data favor the existence of solvent shared ion-pairs of these salts in water–ethanol solvent mixtures.

Financial assistance by Council of Scientific and Industrial Research, New Delhi for this piece of work is highly acknowledged.

Thermospray Ionization Mass Spectrometry of Polydimethylsiloxane Antifoams

Toshihide NISHIMURA,* Yukimi AOKI, Yukio HIYAMA, and Akio SONODA
Control Research and Development, Upjohn Pharmaceuticals Ltd., 23 Wadai, Tsukuba, Ibaraki 300-42
(Received June 28, 1991)

Mass Spectrometric characterization of several polydimethylsiloxane (PDSI) antifoams has been studied using a thermospray (TSP) ionization technique. The PDSI antifoams dissolved into an eluent were flow-injected to a TSP interface without column separation. A selective formation of PDSI ammonium adduct ions directly reflecting their molecular weight distributions was observed in the mass region up to 3500 daltons. Both cyclic PDSIs and fatty acid esters were detected for a water-dilutable antifoam and their relative abundances and species were characteristic to a particular formulation of antifoam emulsion. Thus TSP mass spectrometric technique seems suitable and useful for analysis of an aqueous antifoam sample to identify both its molecular weight distribution of PDSIs and a type of antifoam formulations used in various fields such as food and pharmaceutical industries.

Since silicone oils are offen used to eliminate foam that has already formed (defoam) and to prevent the formation of foam (antifoam). There are mainly two types of silicone antifoams: One is the antifoam emulsion which is a water-dilutable formulation containing fatty acid esters as emulsifiers, and another is so called the antifoam oil which is a formulation without a water-dilutable emulsifier.

Very few mass spectrometric studies of PDSI polymers have been reported so far. Appeared in the literature were the electron ionization (EI)[1] and fast atom bombardment (FAB)[2] techniques which provided mass spectra covering only the range less than 500 daltons, and their interpretations were limited to fragment ions because of such a hard ionization. Mass spectra reported, therefore, suffer from lack of PDSI molecular weight distribution which is highly important to characterize and/or to identify a formulation of antifoam in a sample to be analyzed.

Field desorption and laser desorption mass spectrometries may be applicable to measure molecular weight distributions of PDSI polymers. There has been a recent publication of mass spectra of quasi-molecular ions obtained by a laser microprobe.[3] However, thermospray (TSP) ionization mass spectrometry[4] is another soft ionization technique to produce mainly quasi-molecular ions, and is directly applicable to an aqueous sample. Here reported is a study on measurement of PDSI molecular weight distributions over a high mass range up to 3500 daltons using TSP ionization mass spectrometry.

Experimental

Instruments. TSP mass spectra were obtained on a Finnigan MAT-90 double-focusing magnetic sector mass spectrometer equipped with a TSP interface and a DEC PDP 11/73 data primary processor system. Voltages applied to an ion source and extraction lens were adjusted to optimize both the intensity and peak shape of m/z 141 ions which are the acetonitrile cluster ions, $(CH_3CN)_3NH_4^+$. All experiments were carried out under mass resolution of ca. 5500 (at 10% valley) at this mass and with the vaporizer and ion source temperatures of about 160 and 230 °C, respectively. The eluents for antifoam emulsions and antifoam oils were a mixture of 30% acetonitrile and 70% reagent water containing 0.1 M (M=mol dm^{-3}) ammonium acetate and that of 30% acetone and 70% 0.1 M ammonium acetate, respectively. The former eluent was chosen since emulsion antifoams are soluble to an aqueous solution but oil antifoams are not. The latter eluent was used for oil antifoams since those such as the KF-96 series partially dissolve into acetone and also acetone itself has a good solubility to water. The eluents were degassed by a continuous purge with helium at about 30 ml min^{-1} to maintain very low levels of dissolved air. The eluents were introduced into a thermospray vaporizer at a flow rate of 1.2 ml min^{-1} using a Waters MS-600 HPLC pump and were effectively pumped out from the ion source by a Bulzers UNO-016B rotary pump with volume flow rate of 16 m^3 h^{-1}. PDSI samples were prepared to be in a concentration of 100—1000 ppm level by an eluent, and were flow-injected directly to a TSP interface by a 100 μl Rheodyne 7125 loop injector without column separation.

Materials. Anti-foaming silicone oils were obtained commercially: Two typical oil antifoams, KF-96-10CS (lot 908646) and KF-96-100CS (lot 906524), and two typical water-dilutable emulsions, KM-72A (lot 909609) and KM-82F (lot 904228). These were all obtained from the Shin Etsu Silicone Corp. Acetonitrile and acetone were of the super special grade (Wako Pure Chemical Industries, LTD.), and reagent water was obtained from a Milli-Q (Millipore Corp.) water purification system. Ammonium acetate was of the JIS super grade (Wako Pure Chemical Industries, LTD.).

Results and Discussion

Molecular Weight Distribution of Polydimethylsiloxanes. TSP ionization of a molecule (A) using ammonium acetate solution results mainly in formation of both molecular protonated ions (AH^+) (Reaction 1) and ammonium adduct ions (ANH_4^+) (Reaction 2), although generally other ions (Reaction 3—5) could be produced. A schematic picture of ion formation could be given briefly as follows:

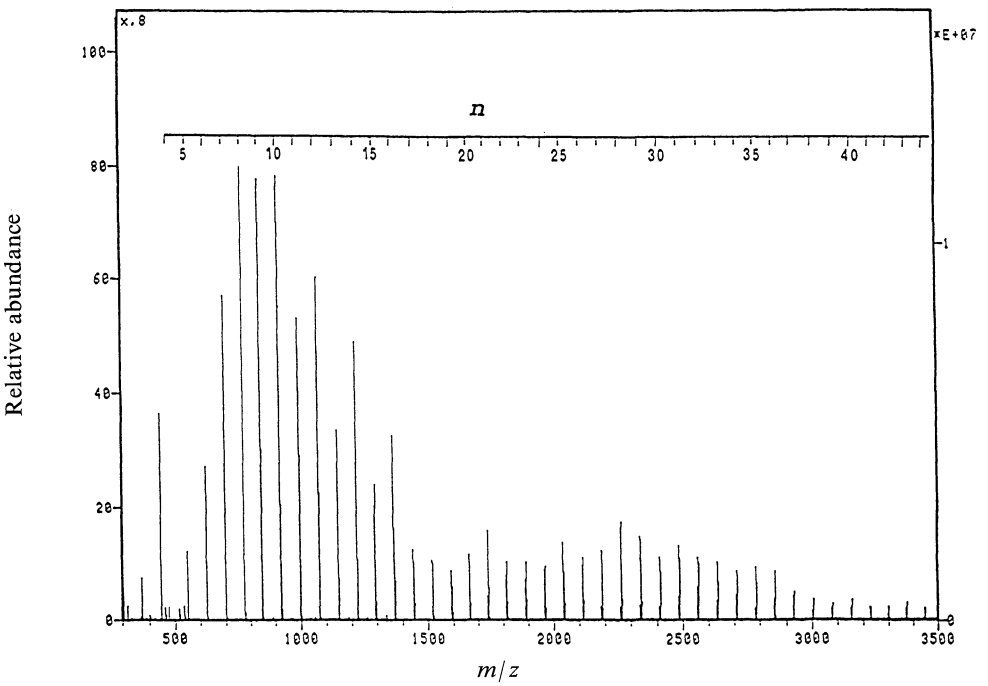

Fig. 1. A TSP mass spectrum of a medium size silicone oil antifoam (Shin Etsu KF-96-10CS).

$$A + (CH_3CN)_3NH_4^+ \longrightarrow AH^+ + 3\ CH_3CN + NH_3 \quad (1)$$

$$\longrightarrow ANH_4^+ + 3\ CH_3CN \quad (2)$$

$$\longrightarrow A(CH_3CN)NH_4^+ + 2\ CH_3CN \quad (3)$$

$$\longrightarrow A(CH_3CN)_2NH_4^+ + CH_3CN \quad (4)$$

$$\longrightarrow A(CH_3CN)_3NH_4^+ \quad (5)$$

when $(CH_3CN)_3NH_4^+$ is a reactant ion, which is one of reagent ions observed commonly in TSP mass spectra obtained using the eluent of ammonium acetate-acetonitrile, while their exact mechanisms of formation have not been known. Abundances of product ions may depend entirely on chemical nature such as proton affinities etc. of both a sample molecule A and a conjugate base of reactant ion. The formation of PDSIs ammonium adduct ions (Reaction 2) took place selectively. The chemical formula of both linear and cyclic PDSIs are respectively:

$$[(CH_3)_3Si\text{-}O\text{-}\{(CH_3)_2Si\text{-}O\text{-}\}_n\ Si(CH_3)_3 + NH_4^+] \quad (6)$$

$$[\{\text{-}(CH_3)_2Si\text{-}O\text{-}\}_{l+2} + NH_4^+] \quad (7)$$

Herein n and l correspond to the size of linear and cyclic PDSIs. Figire 1 shows a typical TSP mass spectrum obtained for the linear silicones (KF-96-10CS) in which individual peaks correspond to quasi-molecular ions formed via ammonium addition to PDSIs of their different sizes. This silicone oil has two maxima in its molecular weight distribution: One is located around n=9 and another is around n=27.

A high natural abundances of Si isotopes results in broad isotope distributions which vary drastically with increasing the size of PDSI, n (Fig. 2). The isotope ratio of $[P_{M+1}]/[P_M]$ for the linear silicones can be

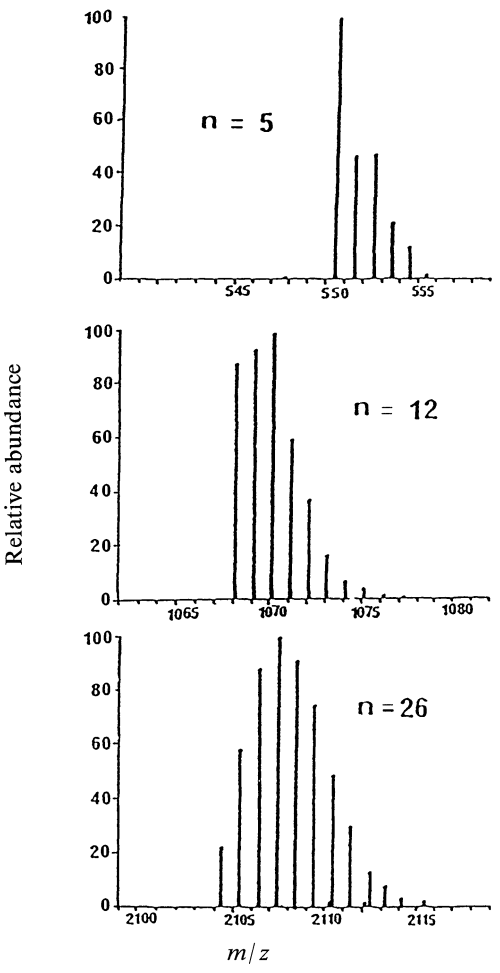

Fig. 2. Typical isotope distributions of several large linear PDSIs (Shin Etsu KF-96-10CS).

approximately expressed by[5]

$$[P_{M+1}]/[P_M]=0.07438n+0.17593 \quad (8)$$

using both the chemical formula of M= $C_{2n+6}H_{6n+22}O_{n+1}Si_{n+2}N_1$, which is the ammonium adduct quasi-molecular ions of linear PDSIs, and the natural isotope abundances for the individual component atoms known in the literature.[6]

Experimental ratios of $[P_{M+1}]/[P_M]$ observed were compared to those calculated by Eq. 8 in Fig. 3, and showed a reasonably good agreement with the calculation. Scattered points for $n>20$ in the figure may be due to low signal-to-noise ratio of the [M] and [M+1] signals observed for a large size silicone. This result may support validity of our estimation of molecular sizes. Detection of very large PDSIs and their quantification will encounter difficulties because of their low solubility to the eluents currently used.

Figure 4 shows a TSP mass spectrum of quasi-molecular ions of PDSI contained in the KF-96-100CS

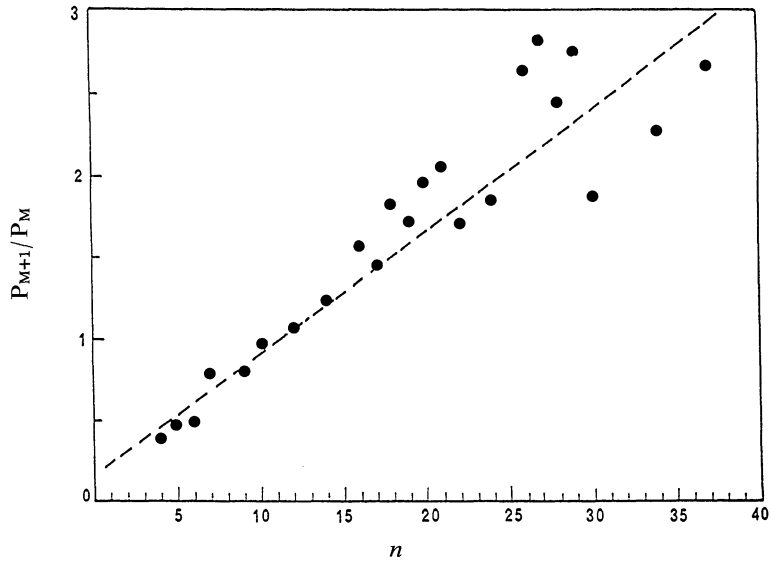

Fig. 3. Experimental isotope ratios $[P_{M+1}/P_M]$ (closed circles) together with theoretical calculations (dashed line).

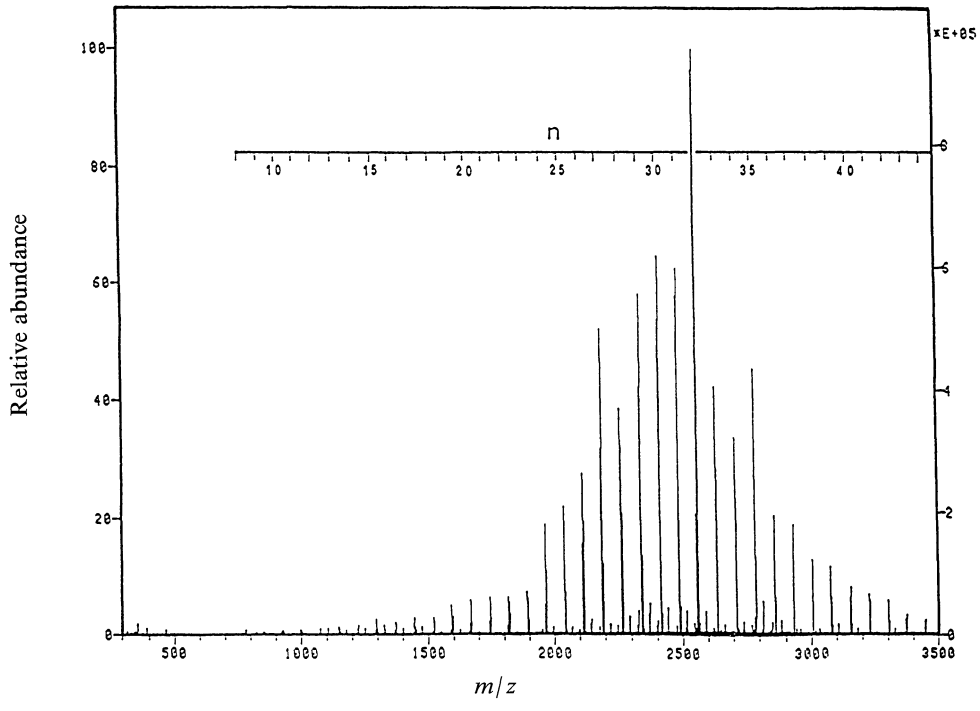

Fig. 4. A TSP mass spectrum of a large size silicone oil antifoam (Shin Etsu KF-96-100CS).

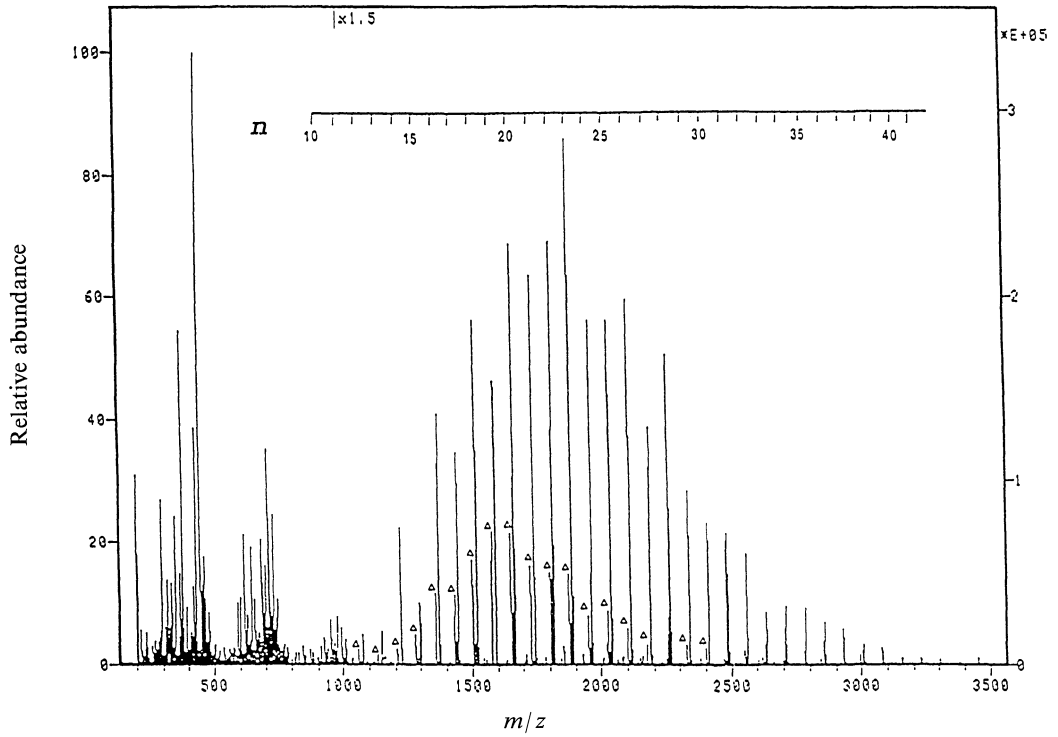

Fig. 5. A TSP mass spectrum of the antifoam emulsion formulation (Shin Estu KM-72A).

silicone oil. Its distribution maximum lay around n=30, and the mass spectrum showed the size of PDSI much larger than those in the KF-96-10CS formulation.

Figure 5 is a typical TSP mass spectrum of the KM-72A water-dilutable antifoam. Its distribution of PDSI quasi-molecular ions spreads from n=12 to n=44, and has a distribution center around n=22 to n=25. Additionally, a considerable amount of cyclic PDSIs

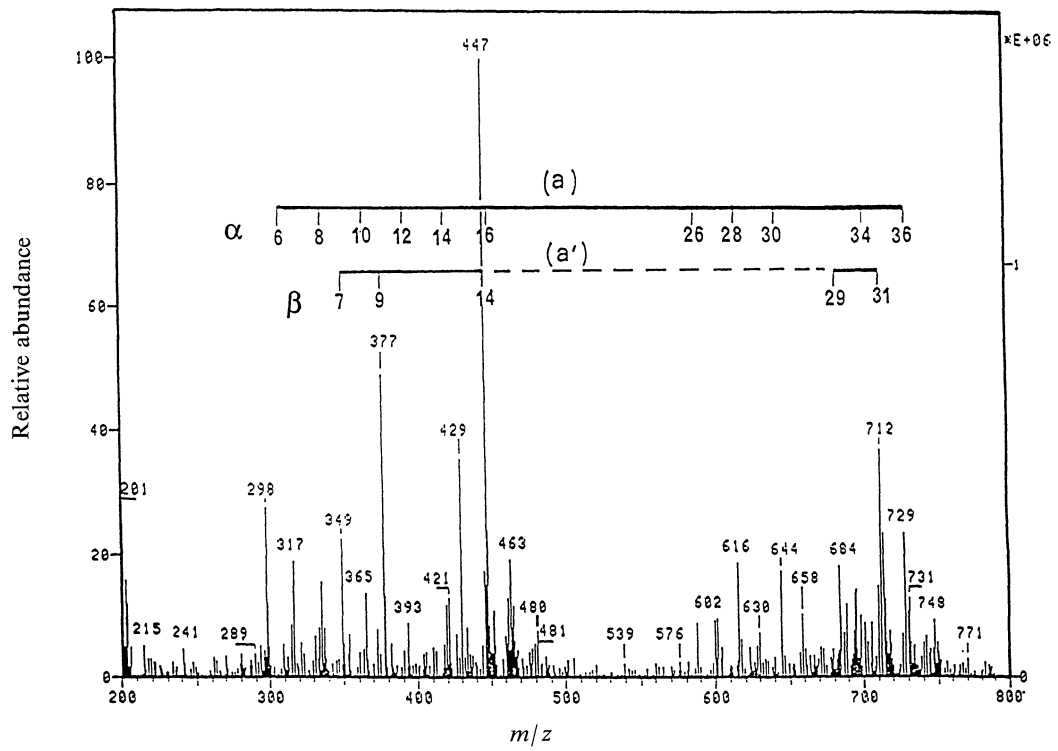

Fig. 6. A mass spectrum of fatty acid esters contained in the antifoam emulsion (Shin Etsu KM-72A): (a) and (a′) denote saturated and unsaturated fatty acid esters with sorbitol, respectively.

(indicated by open triangles) were also observed together with those of linear PDSIs in its mass spectrum.

For the KM-82F, which is another example of antifoam emulsions, its distribution of PDSIs lies from n=7 to n=38, indicating the size of PDSIs slightly smaller than those in the KM-72 formulation. Its distribution center of PDSIs is located around n=20, and the amount of cyclic PDSIs contained is considerably lower than that in the KM-72A formulation.

Fatty Acid Esters in Antifoam Emulsions. Commercial antifoam emulsions (oil-in-water emulsion) contain fatty acid esters as emulsifiers. Species and amounts of these emulsifiers are specific to a type of antifoam emulsion. Their quasi-molecular ions were observed in the mass regime less than 1000 daltons. The TSP mass spectra obtained were characterized by series of molecular protonated ions with the separation of m/z 28 or 14 due to size difference of fatty acid chains.

Typical emulsifiers are esters of fatty acids

Saturated fatty acids

$$CH_3(CH_2)_\alpha COOH \tag{9}$$

Unsaturated fatty acids

$$CH_3(CH_2)_a CH=CH(CH_2)_b COOH$$
$$\beta = a + b \tag{10}$$

with sorbitan, glycerol and sucrose. TSP mass spectra obtained for commercial antifoam emulsions containing sorbitan fatty acid esters often showed quasi-molecular ions of sorbitol fatty acid esters. These sorbitol fatty acid esters seems to be formed via elimination of a water molecule from a sorbitan ester under TSP ionization conditions.

TSP mass spectra of the KM-72A formulation (Fig. 6) showed an inclusion of both sorbitol saturated fatty acid esters (α=6, 8, 10, 12, 14, 16, 26, 28, 30, 34, and 36) and sorbitol unsaturated fatty acids (β=9, 11, 16, 31, and 33) in the region less than 800 daltons. The base ion peak was ascribed to the sorbitol ester with an unsaturated fatty acid, that is sorbitol oleate (MH^+= m/z 477).

In contrast with the KM-72A formulation, both glycerol saturated fatty acids (α=14, 16, and 21) and sucrose saturated fatty acid esters (α=12, 14, and 16), were observed in a TSP mass spectrum of the KM-82F antifoam formulation. The base peak corresponds to the glycerol stearate (m/z 360).

Conclusion

The TSP ionization technique provided mass spectra reflecting molecular weight distribution of polydimethylsiloxane polymers and fatty acid esters contained in emulsion formulations. Both cyclic PDSIs and fatty acid esters observed were found to be characteristic to individual water-dilutable formulations. TSP mass spectrometric analysis of PDSI antifoams thus seems useful to identify a particular type of antifoams contained in aqueous samples.

Reaction of α-Oxo Ketene Dithioacetals with Glycine

Naoaki FUKADA* and Masato YUZAWA
Department of Chemistry, Faculty of Science, Chiba University, Yayoicho, Chiba 260
(Received April 8, 1991)

Synopsis. 3-Carboxymethylamino-3-methylthio-1-phenyl-2-propen-1-ones were synthesized by the reaction of 3,3-bis(methylthio)-1-phenyl-2-propen-1-ones with glycine in the presence of sodium hydroxide.

We were interested in studying the polarized α-oxo ketene *N,S*- and *N,N*-acetals, a new class of vinylogous amides, which are versatile synthons used for the synthesis of various heterocyclic compounds.[1] Many displacement reactions of α-oxo ketene dithioacetals[2,3] with nucleophiles have been reported, but there have been few reactions with amino acids mentioned in the literature. Gante et al. described the synthesis of glycine ester derivatives (**1**; R^1=CN, R^2=CN or $COOC_2H_5$) from the bis(methylthio)methylene compounds and glycine ethyl ester.[4] Also, Junjappa et al. reported that the reaction of methyl 2-benzoyldithioacetate with glycine ethyl ester gave *N*-ethoxycarbonylmethyl-2-benzoylthioacetamide, which was converted by methylation into 3-ethoxycarbonylmethylamino-3-methylthio-1-phenyl-2-propen-1-one(**1**; R^1=C_6H_5CO, R^2=H).[5]

In this note we report on a new synthesis of 3-carboxymethylamino-3-methylthio-1-phenyl-2-propen-1-ones (**3**) by a reaction of 3, 3-bis (methylthio)-1-phenyl-2-propen-1-ones (**2**)[6–8] with glycine. The starting materials **2**, including new compounds **2b** and **2e**, were prepared from acetophenones, carbon disulfide, and methyl iodide in the presence of sodium hydride.

The reaction of **2** with glycine was conducted in ethanol–water (10 : 1) in the presence of sodium hydroxide under reflux for 20 h. Double molar quantities of glycine and sodium hydroxide were used; yellow or orange products **3** were obtained in moderate to good

a) The yield in parenthesis refers to that of the recovered starting material **2**. b) Decomposition.

yields. A larger excess of the base resulted in a lower yield and often gave the corresponding acetophenone in a decomposed form. In the absence of sodium hydroxide the yield was only about 3%, and in the case of using triethylamine or sodium acetate used as a base, the reaction hardly proceeded. A reflux time of 20 h was set in order to make comparisons with the substituent effect of the phenyl groups. Nitro derivatives **2e** and **2f** afforded the desired products, **3e** and **3f**, in good yields; from methyl and methoxy compounds **2b—d**, however, the glycine derivatives **3b—d** were obtained in lower yields and about 30% of the corresponding unreacted starting materials were recovered (Table 1).

The IR spectra of **3** showed a carbonyl absorption of the free carboxyl group at 1725—1735 cm^{-1} as those of other *N*-substituted glycines, *N*-phenylglycine (1720 cm^{-1}) and hippuric acid (1750 cm^{-1}). From the ^1H NMR spectrum of **3a** a single structure of *Z*-isomer was derived, which had the same geometry as its ethyl ester **1** ($R^1=C_6H_5CO$, $R^2=H$).[5] The spectrum showed a single methyl absorption at $\delta=2.55$ and a triplet assigned to NH at a higher field ($\delta=1.70$). This was due to a non-hydrogen-bonding NH proton to the carbonyl oxygen. The reactions of α-oxo ketene dithioacetals with nucleophiles, just as with organocopper reagents, appear to proceed in a stereoselective fashion, and also to involve an addition-elimination sequence.[2,9] In general, the α-oxo ketene *S,S*-acetals arising from alkyl and aryl ketones react with amines to afford *E*- and *Z*-isomers of the α-oxo ketene *N,S*-acetals, respectively.[2] Thus, our reaction probably led to more stable *Z*-isomers.

Attempts to prepare doubly displaced derivatives using a large excess of glycine were unsuccessful.

Experimental

α-Oxo Ketene Dithioacetals (2) were prepared by the reaction of the corresponding acetophenone (0.057 mol) with carbon disulfide (4.5 g, 0.059 mol) and methyl iodide(18 g, 0.13 mol) in the presence of sodium hydride (5 g; 60% dispersion in oil; 0.13 mol) in tetrahydrofuran (80 ml) with 3 h cooling in ice.

3,3-Bis(methylthio)-1-(*m*-tolyl)-2-propen-1-one(2b): Yellow crystals; yield 83%; mp 82—84 °C (CCl_4–hexane); IR(KBr) 1608s cm^{-1} (C=O); UV(EtOH) λ_{max} 225sh (log ε 3.77), 270sh (3.94), 277sh (3.94), and 345 nm (4.28). Found: C, 60.53;H, 5.94%. Calcd for $C_{12}H_{14}OS_2$: C, 60.47; H, 5.92%.

3,3-Bis(methylthio)-1-(*m*-nitrophenyl)-2-propen-1-one(2e): Yellow crystals; yield 84%; mp 130—131 °C (acetone); IR(KBr) 1615vs cm^{-1} (C=O); UV(EtOH) λ_{max} 240 (log ε 4.21), 287 (3.91), and 353 nm (4.26). Found: C, 49.08; H, 4.10; N, 5.17%. Calcd for $C_{11}H_{11}NO_3S_2$: C, 49.05; H, 4.12; N, 5.20%.

3-Carboxymethylamino-3-methylthio-1-phenyl-2-propen-1-ones (3). General Procedure. A solution of glycine (0.3 g, 0.004 mol) and sodium hydroxide (0.16 g, 0.004 mol) in ethanol (20 ml) and water (2 ml) was refluxed for 1 h. The α-oxo ketene dithioacetal **2** (0.002 mol) was added and the mixture was refluxed for 20 h. After the solvents were evaporated, 10 ml of water was added to the residue, and the mixture was stirred for 30 min. An insoluble solid, **2**, was collected, washed with water, and dried. To the filtrate was added a large excess of dilute hydrochloric acid; the mixture was kept overnight. The yellow or orange precipitate, **3** was collected, washed with water, dried, and recrystallized. In the case of **3e** or **3f**, 20 ml of water was added to the residue described above, and the mixture was stirred with warming. The collected **2e** was washed with hot water. Compound **2f** was not recovered.

^1H NMR (DMSO-d_6) of **3a** $\delta=1.70$ (t, 1H, NH), 2.55 (s, 3H, CH_3), 4.17 (d, 2H, CH_2), 5.79 (s, 1H, HC=), 7.32—7.49 (m, 3H, 3′, 4′, 5′-H), and 7.87—7.91 (m, 2H, 2′, 6′-H); ^{13}C NMR (DMSO-d_6) of **3a** $\delta=13.79$ (CH_3), 44.86 (CH_2), 86.50 (CH=), 126.75 (4′-C), 128.20 (3′, 5′-C), 130.58 (2′, 6′-C), 139.94 (1′-C), 168.62 (=CS(N)), 169.94 (COOH), and 183.88 (C=O).

Asymmetric Transformation of (*RS*)-1,2,3,4-Tetrahydro-3-isoquinolinecarboxylic Acid via Salt Formation with (1*S*)-10-Camphorsulfonic Acid

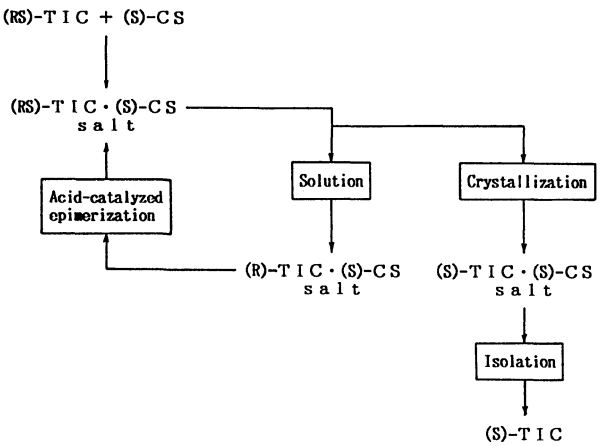
Tadashi SHIRAIWA,* Tsuyoshi FURUKAWA, Tamotsu TSUCHIDA, Shinji SAKATA, Michio SUNAMI, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received June 4, 1991)

Synopsis. Asymmetric transformation of (*RS*)-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid [(*RS*)-TIC] by use of (1*S*)-10-camphorsulfonic acid [(*S*)-CS] as a resolving agent gave a salt of (*S*)-TIC with (*S*)-CS with 90% optical purity in hexanoic acid. The TIC obtained from the salt was purified to give optically pure (*S*)-TIC in 80% yield based on the starting (*RS*)-TIC.

(*S*)-1,2,3,4-Tetrahydro-3-isoquinolinecarboxylic acid [abbreviated as (*S*)-TIC] is a useful intermadiate for synthesizing antihypertensive agents such as (*S*)-2-(3-mercapt-1-oxopropyl)-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid derivatives.[1—3] Although (*S*)-TIC has been obtained by condensation of L-phenylalanine [L-Phe] with formaldehyde in concentrated hydrochloric acid,[4,5] this reaction gives partially racemized (*S*)-TIC. Acquisition of optically pure (*S*)-TIC, therefore, seems to require a tedious procedure.[4,5]

We found that optically active TIC was apt to racemize only on heating in carboxylic acids and that optical resolution of (*RS*)-TIC by use of (1*S*)-10-camphorsulfonic acid [(*S*)-CS] as a resolving agent gave a salt of (*S*)-TIC with (*S*)-CS as the less soluble diastereomeric salt. In view of this, an asymmetric transformation of (*RS*)-TIC was attempted here via salt formation with (*S*)-CS on heating in a carboxylic acid to convert (*RS*)-TIC efficiently into (*S*)-TIC, as illustrated in Scheme 1.

In what follows, (*S*)·(*S*) salt denotes the salt of (*S*)-TIC with (*S*)-CS, (*R*)·(*S*) salt that of (*R*)-TIC with (*S*)-CS, and (*S*)·(*R*) salt that of (*S*)-TIC with (*R*)-CS.



Scheme. 1. Illustration of asymmetric transformation of (*RS*)-1,2,3,4-tetrahydro-3-isoquinolinecarboxylic acid.
TIC: 1,2,3,4-Tetrahydro-3-isoquinolinecarboxylic acid.
(S)-CS: (1*S*)-10-Camphorsulfonic acid.

Experimental

Materials. L-Phe was purchased from Kokusan Chemical Works, Ltd., DL-Phe from Sigma Chemicals Co., and (*S*)- and (*RS*)-CS and (*R*)-CS monohydrate from Wako Pure Chemicals Ind.

(*RS*)- and (*S*)-TIC were prepared by a reaction of the corresponding Phe with formaldehyde in concentrated hydrohchloric acid.[4,5] (*RS*)-TIC was obtained in 69% yield and (*S*)-TIC ($[\alpha]_D^{20}$ −143° (*c* 1.00, 1 mol dm^{-3} aqueous sodium hydroxide)) in 78% yield. (*S*)-TIC was purified via formation of a salt with (*S*)-CS as described below.

Preparation of Standard Salts. (*S*)-TIC (4.43 g, 25.0 mmol) was added to a 10 cm^3 methanol solution containing 25.0 mmol of (*S*)-CS (5.81 g) or (*R*)-CS monohydrate (6.26 g). After stirring for 30 min in an ice bath, the mixture was allowed to stand overnight at 5 °C. The precipitated salt was collected by filtration, washed with diethyl ether, and dried. (*S*)·(*S*) salt: Mp 268—269 °C; $[\alpha]_D^{20}$ −41.3° (*c* 1.00, methanol). Found: C, 58.54; H, 6.58; N, 3.45%. Calcd for $C_{20}H_{27}NO_6S$: C, 58.66; H, 6.65; N, 3.42%). (*S*)·(*R*) salt: Mp 249—250 °C; $[\alpha]_D^{20}$ −85.1° (*c* 1.00, methanol). Found: C, 58.61; H, 6.62; N, 3.33%.

Asymmetric Transformation. A mixture of 1.77 g (10.0 mmol) of (*RS*)-TIC and 2.09 g (9.00 mmol) of (*S*)-CS in 15 cm^3 of butanoic acid or hexanoic acid was stirred for 2—25 h at 120 °C. After further addition of 0.23 g (1.0 mmol) of (*S*)-CS, the mixture was stirred for 5 min and then for 0.5 h in an ice bath. The (*S*)·(*S*) salt formed was collected by filtration, thoroughly washed with diethyl ether, and dried; the optical purity of the salt obtained was determined on the basis of the specific rotations of the standard salts.

After adding an equivalent of triethylamine to a solution of the salt obtained in methanol (25 cm^3 g^{-1}), the mixture was stirred for 1 h in an ice bath. The precipitated (*S*)-TIC was collected by filtration, washed with methanol, and dried. The optical purity was determined on the basis of the specific rotation of (*S*)-TIC; lit,[5] $[\alpha]_D^{19}$ −177.4° (*c* 1.00, 1 mol dm^{-3} aqueous sodium hydroxide).

The (*S*)-TIC (2.00 g) obtained by reaction for 12 h in butanoic acid and those for 20 and 25 h in hexanoic acid were added to a solution containing an equivalent of (*S*)-CS in 17 cm^3 of methanol. After stirring the mixture for 20 min at 20 °C, the (*S*)·(*S*) salt formed was collected by filtration, washed with diethyl ether, and dried. The (*S*)·(*S*) salt was treated with triethylamine in methanol to give optically pure (*S*)-TIC.

Optical Resolution. (*RS*)-TIC (1.77 g, 10.0 mmol) was added to a solution of 2.32 g (10.0 mmol) of (*S*)-CS in 10 cm^3 of methanol. After stirring the mixture for 0.5 h at 20 °C, the formed (*S*)·(*S*) salt of 74.7% optical purity was collected by filtration, washed with diethyl ether, and dried; yield, 40.6% (1.66 g) based on 4.09 g of the salt; $[\alpha]_D^{20}$ −25.3° (*c* 1.00, methanol). The filtrate was dried under reduced pressure to give the (*R*)·(*S*) salt of 57.3% optical purity in 51.1% (2.10 g) yield; $[\alpha]_D^{20}$ +58.1° (*c* 1.00, methanol). The (*S*)·(*S*) and

(*R*)·(*S*) salts obtained were treated with triethylamine in methanol to give (*S*)- and (*R*)-TIC; (*R*)-TIC of 56.1% optical purity was obtained in 49.0% (0.867 g) yield; $[\alpha]_D^{20}$ +99.6° (*c* 1.00, 1 mol dm^{-3} aqueous sodium hydroxide). The (*S*)-TIC obtained was purified via salt formation with (*S*)-CS to obtain (*S*)-TIC of 99.2% optical purity in 33.3% (0.590 g) yield; $[\alpha]_D^{20}$ −176° (*c* 1.00, 1 mol dm^{-3} aqueous sodium hydroxide).

Rate Constant for Racemization. (*S*)-TIC (1.00 mmol) and 0.900, 0.950, or 1.00 mmol of (*RS*)-CS were immediately dissolved in 50 cm^3 of acetic acid, propanoic acid, or butanoic acid at 120 °C, respectively. Portions of the solution were pipetted out at appropriate time intervals and the optical rotation at 589 nm was measured with a Union Giken PM-101 digital polarimeter equipped with a quartz cell of 0.500 dm path length. The rate constant for racemization (k_R/s^{-1}) was calculated by least-squares fitting to the equation

$$\ln \alpha_0/\alpha_t = k_R \cdot t, \quad (1)$$

where α_t is the optical rotation at time t and α_0 that extrapolated to zero time.

Results and Discussion

Racemization of (*S*)-1,2,3,4-Tetrahydro-3-isoquinolinecarboxylic Acid. The racemization of (*S*)-TIC could be regarded as a pseudo first-order reaction because a linear relationship was found between $\ln \alpha_0/\alpha_t$ and time t. The rate constant (k_R/s^{-1}) and half-life period ($t_{1/2}$/s) are listed in Table 1.

The racemization of (*S*)-TIC seems to start with the protonation to the carbonyl oxygen atom by the carboxylic acid used as solvent, followed by the formation of an enol and the concomitant α-proton abstraction by the resulting carboxylate anion, and hence should be influenced by the acidity of the carboxylic acid.[6,7] The acidity constant (pK_a) of acetic acid, propanoic acid, and butanoic acid at 120 °C were estimated from the data at 0—60 °C[8] to be 5.07, 5.21, and 5.27, respectively. Since the k_R value paralells the pK_a value, the rate-determining step seems to be the enol formation.[7] In addition, the k_R value increased with a decrease in the amount of (*RS*)-CS, as seen in Table 1.

Asymmetric Transformation of (*RS*)-1,2,3,4,-Tetrahydro-3-isoquinolinecarboxylic Acid. In the optical resolution by use of (*S*)-CS, the (*S*)·(*S*) salt was obtained as the less soluble diastereomeric salt, as mentioned in the Experimental section. The asymmetric transformation, based on the results of the optical resolution and racemization, gave the (*S*)·(*S*) salt of 75—79% optical purity in 87—90% yield by reaction for 10—14 h in butanoic acid at 120 °C, as shown in Table 2. The (*S*)-TIC obtained from the (*S*)·(*S*) salt of 79% optical purity was purified to give (*S*)-TIC of 98% optical purity in 74% yield, based on the starting (*RS*)-TIC.

The epimerized salt seems to have a relatively high solubility in butanoic acid at 120 °C, and hence cooling of the reaction mixture would lower the optical purity of the resulting (*S*)·(*S*) salt. The (*S*)·(*S*) and (*R*)·(*S*) salts seem to be less soluble in higher carboxylic acids. Although the rates of racemization in the higher carboxylic acids could not be measured because of a poor solubility of (*S*)-TIC, the estimated pK_a value (5.26)[9] of hexanoic acid at 120 °C would suggest that the rate in hexanoic acid is approximately equal to that in butanoic acid. The asymmetric transformation, therefore, was carried out in hexanoic acid and gave the (*S*)·(*S*) salt of 90% optical purity in 86% yield by reaction for 20 and 25 h. Optically pure (*S*)-TIC was obtained in 80% yield by purification of the (*S*)-TIC obtained from these salts.

To summarize, the present results demonstrate that

(Received June 5, 1991)

Synopsis. *N*-(Substituted formyl)dialkylamino(thioxo)-methanesulfenamides ($R_2NCSSNHCOR'$, **2**), anti-foggants for silver halide photographic materials as well as potential precursors for 1,4,2-dithiazolium salts, were prepared in good yields in two "one-pot" procedures. Various amide-type compounds ($R'CONH_2$, **1**) were treated successively with NaH and I_2 and then condensed with dialkyldithiocarbamates (Method A); or **1** were reacted with tetraalkylthiuram disulfides after treatment with NaH (Method B). These methods allowed a wide variation of substituents R′ in **2**: R′=H, dialkylamino, alkoxy, aryl, alkyl, and heterocyclic substituent.

The syntheses of 1,4,2-dithiazolium salts (**3**) were recently established by three research groups independently. 3-Aryl-5-methylthio,[1a] 3-aryl-5-dialkylamino,[1b,c,e] 3,5-diaryl,[1d,g] and 3,5-bis(dialkylamino)[1e] derivatives and parent ring systems[1f] have been prepared so far. Systematic studies on the reactivity of **3** have also been performed.[2]

Our approach for preparation of 1,4,2-dithiazolium salts have been the cyclization of *S*-dialkylthiocarbamoyl and *S*-thioaroyl-*N*-acylsulfenamides with dehydration in strong acidic media.[1b] As an extension of this strategy, we used amide-type compounds (**1**) ($R'CONH_2$: R′=H, dialkylamino, alkoxy, aryl, alkyl, heterocyclic substiluent) as starting materials to prepare various *N*-(substituted formyl)dialkyl(thioxo)methanesulfenamides (**2**), the potential precursors for **3**.

Recently we found that both the sulfenamides (**2**) and the 1,4,2-dithiazolium salts were new types of lead compounds with high fog restraining ability for silver halide photographic materials, e.g., commercial color films.[3] In particular, several derivatives among **2** have been found to show far superior efficacy to the conventional ones only with a little amount of addition.

We now report two alternative methods for successful preparation of **2**, by means of direct formation of S–N bond in the sulfenamide moiety, the methods of which allow a wide variation of substituents R′ in **2**.

Results and Discussion

Our initial approach for preparation of *N*-acyl or *N*-

Scheme.

aroyldialkylamino(thioxo)methanesulfenamides (**2**) was the acylation or aroylation of the corresponding *N*-unsubstituted sulfenamides by treating with the corresponding acyl or aroyl chlorides, respectively.[1b] As far as this method was employed, however, variation of substituents R′ in **2** was limited to alkyl (including hydrogen) and aryl groups because of limited availability or poor reactivity of R′COCl (or $(R'CO)_2O$ as substitute) bearing other substituents R′.

In order to extend the variation of the substituents in **2**, we chose the amide-type compounds **1** as starting materials because of a wide variation of substituents R′ in **1**. Consequently, our alternative strategy for preparation of **2** was the introduction of dialkylthiocarbamoylthio group on N-atom in **1** to form a sulfenamide S–N bond directly.[4]

When dialkyldithiocarbamates are used as a substrate, the reaction requires involvement of umpolung of amino reactivity. From this standpoint, we carried out the following "one-pot" procedure including an oxidative process, denoted "Method A" for convenience. After treatment with NaH, **1** were iodinated by I_2-oxidation leading to *N*-iodoamide-type intermediates, which subsequently reacted with dialkyldithiocarbamates to afford **2**. As shown in Table 1, good yields were obtained only when alkyl carbamates were employed (Entries 10—14). The lower yields obtained in many cases are attributable to the formation of considerable amounts of tetraalkylthiuram disulfides as a side reaction. It is most likely that $(R_2NCSS)_2$ is formed by condensation of unreacted $R_2NCSS^-M^+$ with R_2NCSSI which temporarily arises from $R_2NCSS^-M^+$ by oxida-

a) In $CDCl_3$, ppm from TMS. No *J* values were often given because the resonances were unresolved. b) Using KBr disks. c) No distinct N–H band was observed. d) Low solubility in ordinary deuterated solvents.

tion with the *N*-iodoamide as a competing pathway.

It is well-known that thiuram disulfides are liable to suffer from cleavage of the S–S bond homolytically[5a] and heterolytically.[5b] Therefore an umpolung synthon R_2NCSS^+ is expected to be produced from $(R_2NCSS)_2$ by the attack of a nucleophile. On the other hand, a convenient method for synthesis of sulfenamides from disulfides and lithium amides has been reported.[6] From this viewpoint, we examined another method, "Method B", using tetraalkylthiuram disulfides as substrates instead of dialkyldithiocarbamates. When **1** were treated with NaH followed by the reaction with $(R_2NCSS)_2$, successful formation of **2** was observed. As seen in Table 1, for R′=alkyl (Entries 1—5), dialkylamino (Entries 6—9), and aryl groups (Entries 15—18), Method B gave far better results than Method A. Furthermore, for R′=heterocyclic substitutent, hydrogen, and PhCH=CH, **2** were also prepared by Method B in moderate to good yields.

Davis et al. have developed a one-step synthesis of sulfenamides from disulfides and amines in the presence of silver salts.[7] The mechanism is believed to involve the complexation of Ag^+ with one of the disulfide sulfurs, followed by nucleophilic attack on the other sulfur by the amine. We attempted some application of this method to our system; but no satisfactory results were obtained. It may be attributable to the lower nucleophilicity of **1** and the instability of products **2** in the presence of Ag^+.

Some attempts to convert **2** into **3** were also carried out according to the same procedure as described in our previous report.[1b] When 40% tetrafluoroboric acid was added dropwise to an acetic anhydride solution of **2b**, **e**, and **r**, respectively, a pale yellow precipitate was immediately deposited in each case. It was found that the three precipitated products were not the corresponding 1,4,2-dithiazolium salts but identical with one another, by means of IR, ^1H NMR, and elemental analysis. The common product was identified with 3,5-bis(dimethyliminio)-1,2,4-trithiolane bis(tetrafluoroborate) by direct comparison with the authentic one which was prepared by the treatment of tetramethylthiuram monosulfide with mCPBA in HBF_4/Ac_2O.[8] Further attempts to prepare **3**, for instance by use of other strong acids or Lewis acids, are currently under way.

Experimental

All melting points were uncorrected. ^1H and ^{13}C NMR spectra were recorded on a Hitachi R-40 and a JEOL FX-90A spectrometer. Mass spectra were taken on a Hewlett Packard 5995A spectrometer by electron impact ionizing technique at 70 eV. IR spectra were measured on a JASCO A-302 spectrometer. The substrates, i.e., dialkyldithiocarbamates,[9] tetraalkylthiuram disulfides,[10] and the amide-type compounds, are readily obtainable according to literatures or commercially.

Preparation of Sulfenamides 2: Method A: General Procedure. Sodium hydride (ca. 60% in oil) (60 mg; 1.5 mmol) was added to a dry THF solution (10 ml) of the amide-type compounds **1** (2 mmol). The reaction mixture was stirred for ca. 15 min at room temperature or, if necessary, by short heating at 60 °C. After the evolution of hydrogen ceased, iodine (254 mg; 1 mmol) was added to the cooled suspension, which was stirred for ca. 15 min at room temperature. Finally, sodium or silver dialkyldithiocarbamates (often hydrated) (1 mmol) were added to the dark red suspension. After the initial dark red color faded, the resulting pale yellow solution was stirred for 1 h. The crude product was extracted with dichloromethane after addition of an aqueous sodium hydrogencarbonate. After the solvent was removed in vacuo, the residue was purified by column chromatography on silica gel and/or recrystallized from appropriate solvents.

Method B: General Procedure. After the amide-type compounds **1** were treated with NaH in the same manner as Method A, tetraalkylthiuram disulfides were added to the reaction suspension, which was stirred for 1 h at room temperature. It should be noted that prolonged standing on the reaction mixture is apt to decrease the yields of **2**. Subsequent work-up and purification were accomplished by a procedure similar to Method A.

The yields of sulfenamides **2** are presented in Table 1, and their melting points and spectral data are listed in Table 2. Characterization of **2l**, **m**, **n**,[1b] and **2r**[1f] have been reported in the literatures. The results of elemental analyses of several representative sulfenamides, i.e., **2b** (R′=alkyl), **2g** (R′=dialkylamino), **2h** (R′=alkoxy), **2p**, **q** (R′=heterocyclic), and **2t** (R′=PhCH=CH), are shown below.

Novel Transformation of Formyl Groups into Hydroxyl Groups Utilizing Deformylative Autoxidation of Aldehydes

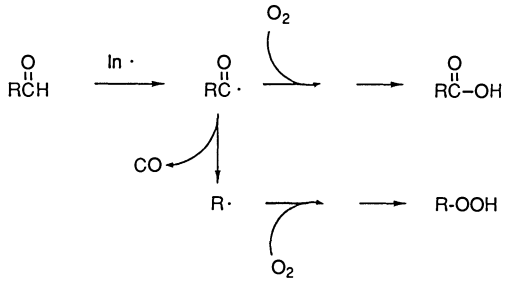
Hideo KIGOSHI, Yoshifumi IMAMURA, Akihiko SAWADA, Haruki NIWA, and Kiyoyuki YAMADA*
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received June 24, 1991)

Synopsis. Structural requirements that cause deformylative autoxidation of aliphatic aldehydes are investigated. Decarbonylation of acyl radicals proceeds smoothly when the alkyl radicals that are formed can be stabilized by allylic conjugation. Further conjugation of the double bond in the allyl radical with a carbonyl or a cyclopropyl group allows position-selective peroxidation of the alkyl radical.

In the course of the synthetic study on ptaquilosin (**2**), the aglycone of ptaquiloside (**1**) which is a bracken carcinogen, we encountered a necessity to convert an angular formyl group into the hydroxyl group efficiently. After unsuccessful trials, we found that autoxidation of **3** smoothly proceeded with deformylation to give hydroperoxide **4a**, reduction of which gave the desired alcohol **4b** in very high yield (Eq. 1). This novel transformation was applied to aldehydes **5** and **7**, culminating in the total synthesis of racemic ptaquilosin (**2**)[1] and (+)-ptaquilosin (**8b**) (the enantiomer of **2**)[2] via **6a** and **8a**, respectively (Eq. 2, 3). Herein we disclose the experimental details of deformylative hydroxylation of the aldehydes as well as the study on structural requirements causing deformylative autoxidation of aldehydes.

We have chosen aldehydes **9**, **10**, and **11** as the substrates suitable for the study on deformylative autoxidation (Table 1). Autoxidation of **3**, **5**, **7**, **9**, **10**, and **11** was performed in a concentrated ethyl acetate solution under oxygen (1 atm) at 40—65 °C. The resulting peroxides were reduced with Ph_3P and the crude products were purified chromatographically. The results are summarized in Table 1.

In general, autoxidation of aldehydes provides carboxylic acids through peroxidation of acyl radical intermediates. However, acyl radicals are also known to fragment with loss of carbon monoxide to generate alkyl radicals (Scheme 1).[3] If the rate of decarbonylation of



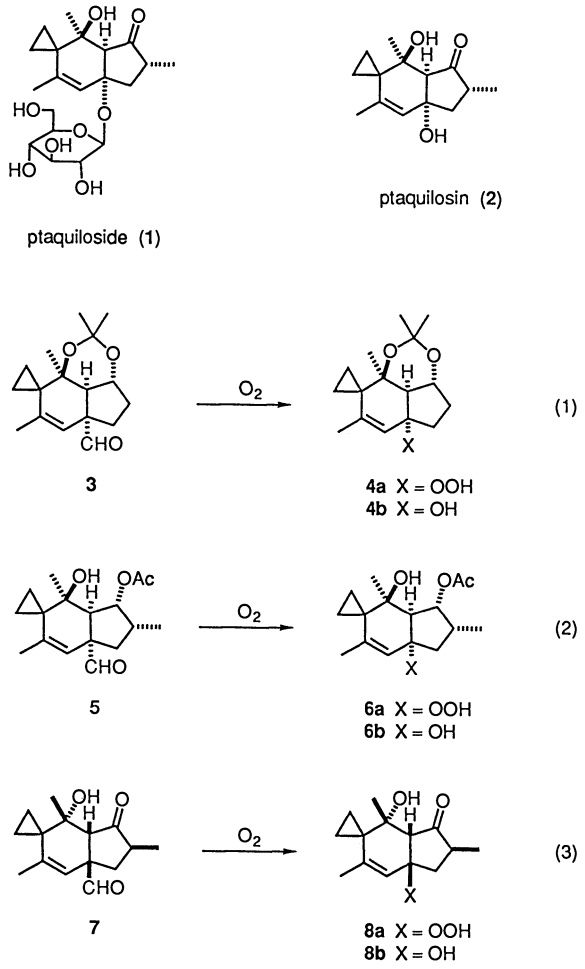
Scheme 1. Autoxidation of aldehydes.

Table 1. Deformylative Hydroxylation of Aldehydes

Entry	Substrate	Conditions temp (°C)/time (h)	Product (%)[a]
1	**3**	40/5	**4b** (92)
2	**5**	45/3.5	**6b** (89)
3	**7**[b]	50/18	**8b** (37)
4	 **9**[b]	65/23	 **12**[c] (17)  **13**[c] (20)
5	 **10**[b]	65/23	 **14**[d] (25)
6	**11**[b]	65/23	 **15**[e] (5)  **16** (5)  **17**[e] (4)  **18**[c] (4)

a) Isolated yields after treatment with Ph_3P. b) This substrate afforded a complex mixture in this reaction, and ill-defined polar compounds were obtained as the major products. c) Stereochemistry of this compound was not determined. d) The carboxylic acid was isolated as methyl ester **14**. e) A mixture of diastereomers.

acyl radicals is faster than that of peroxidation of those, deformylative peroxidation becomes a predominant process in autoxidation of aldehydes. The ease of decarbonylation of acyl radicals may depend on stability of the alkyl radicals that are formed. In autoxidation of **3**, **5**, **7**, **9**, and **11** the facile decarbonylation occurs, being attributable to stabilization of the fragmented alkyl radical by allylic conjugation with the adjacent double bond (Entries 1—4 and 6). Autoxidation of **10**, which lacks structural features stabilizing the fragmented alkyl radical, proceeds without fragmentation to give the corresponding carboxylic acid (Entry 5). Peroxidation of the alkyl radicals generated from **3**, **5**, **7**, and **9**, proceeded in the position-selective manners, while peroxidation of the alkyl radical derived from **11** is nonselective.



Experimental

Melting points are uncorrected. Optical rotations were measured on a JASCO DIP-181 polarimeter. Infrared (IR) spectra were obtained on a JASCO Model IR-810 spectrophotometer. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a JEOL JNM-C675 (270 MHz) spectrometer in $CDCl_3$ or C_6D_6 using tetramethylsilane (TMS) as an internal standard. Chemical shifts are expressed in parts per million (ppm) downfield from TMS (δ=0.0) and coupling constants in Hz. The low-resolution (EIMS) and high-resolution (HREIMS) mass spectra were recorded on a JEOL JMS-LG2000 instrument. Fuji-Davison silica gel BW-820MH was used for column chromatography. Merck precoated silica gel 60 F_{254} plates, 0.25 mm thickness, were used for analytical and preparative thin-layer chromatography (TLC).

Preparation of (3′*R,3′a*R**,4′*S**,7′a*R**)-1′,2′,3′,3′a,4′,7′a-Hexahydro-3′,4′-dihydroxy-4′,6′-dimethyl-spiro[cyclopropane-1,5′-[5*H*]indene]-7′a-carbaldehyde Acetonide (3).** Compound **3** was prepared from compound **A**[1] by a three-step sequence [(1) CH_2=C(OCH_3)CH_3, H^+, benzene; (2) Bu_4NF, THF; (3) $CrO_3 \cdot 2Py$, CH_2Cl_2].

3: Colorless solids; IR (CCl_4) 2810, 2710, and 1725 cm^{-1}; ^{1}H NMR (C_6D_6, 270 MHz) δ=0.30—0.37 (1H, m), 0.62—0.77 (2H, m), 1.02—1.15 (1H, m), 1.20 (3H, d, *J*=1.7 Hz), 1.30 (3H, s), 1.31—1.38 (1H, m), 1.40 (3H, s), 1.53 (3H, d, *J*=0.7 Hz) 1.55—1.63 (1H, m), 1.79—1.91 (2H, m), 2.84 (1H, d, *J*=11.2 Hz), 4.12 (1H, ddd, *J*=11.2, 11.2, 5.6 Hz), 5.10 (1H, br s), and 9.23 (1H, s); EIMS *m/z* (rel intensity) 276 (M^+, 3), 218 (20), and 189 (100). HREIMS. Found: *m/z* 276.1752. Calcd for $C_{17}H_{24}O_3$: M, 276.1725.

Autoxidation of 3. A solution of **3** (3.9 mg, 0.014 mmol) in EtOAc (0.05 ml) was stirred under oxygen (1 atm) at 40 °C for 5 h. After the reaction mixture was diluted with ether (0.2 ml), Ph_3P (18 mg, 0.069 mmol) was added. The mixture was stirred at room temperature for 1 h and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel [1 g, hexane–ether (5 : 1→1 : 1)] to give **4b** (3.4 mg, 92%) as colorless crystals: Mp 166.0—167.5 °C (hexane); IR (KBr) 3400, 3200, and 1660 cm^{-1}; ^{1}H NMR (C_6D_6, 270 MHz) δ=0.29—0.40 (2H, m), 0.66—0.80 (2H, m), 1.21 (3H, d, *J*=1.5 Hz), 1.41 (6H, s), 1.49 (3H, d, *J*=0.7 Hz), 1.51—1.63 (2H, m), 1.77—1.93 (3H, m), 2.54 (1H, d, *J*=11.6 Hz), 3.97 (1H, ddd, *J*=11.6, 10.1, 5.6 Hz), and 5.32 (1H, br s); EIMS *m/z* (rel intensity) 264 (M^+, 0.1), 246 (8), 231 (14), 206 (96), 191 (47), and 177 (100). HREIMS. Found: *m/z* 264.1745. Calcd for $C_{16}H_{24}O_3$: M, 264.1726.

Autoxidation of (2′*R,3′*R**,3′a*R**,4′*S**,7′a*R**)-3′-(Acetoxy)-1′,2′,3′,3′a,4′,7′a-hexahydro-4′-hydroxy-2′,4′,6′-trimethyl-spiro[cyclopropane-1,5′-[5*H*]indene]-7′a-carbaldehyde (5).** Autoxidation of **5**[1] (4.0 mg, 0.014 mmol) at 45 °C for 3.5 h and subsequent treatment with Ph_3P were performed as described above. The crude product was purified by column chromatography on silica gel [1 g, hexane–EtOAc (2 : 1)] to give racemic **6b** (3.5 mg, 89%) as a colorless oil. HREIMS. Found: *m/z* 280.1681. Calcd for $C_{16}H_{24}O_4$: M, 280.1675. Spectral properties of racemic **6b** were identical with those of authentic **6b**[4] derived from natural ptaquiloside (**1**), in all respects.

Autoxidation of (2′*S*,3′a*R*,4′*R*,7′a*S*)-1′,2′,3′,3′a,4′,7′a-Hexahydro-4′-hydroxy-2′,4′,6′-trimethyl-3′-oxo-spiro[cyclopropane-1,5′-[5*H*]indene]-7′a-carbaldehyde (7). Autoxidation of **7**[2] (8.3 mg, 0.033 mmol) at 50 °C for 18 h and subsequent treatment with Ph_3P were performed as described above. The crude product was purified by column chromatography on silica gel [1.5 g, hexane–ether (2 : 1→1 : 1)] to give (+)-ptaquilosin (**8b**) [2.9 mg, 37%, $[\alpha]_D^{20}$ +232° (*c* 0.17, $CHCl_3$) as a colorless oil. HREIMS. Found: *m/z* 236.1418. Calcd for $C_{14}H_{28}O_3$: M, 236.1412. Spectral properties of (+)-**8b** were identical with those of authentic (−)-ptaquilosin (**2**)[4] [$[\alpha]_D^{20}$ −246° (*c* 0.824, $CHCl_3$)] derived from natural ptaquiloside (**1**), in all respects.

Preparation of (3*R*,3a*R*)-1,2,3,4,5,6-Hexahydro-3-methyl-6-oxo-3a*H*-indene-3a-carbaldehyde (9), (3*R*,3a*R*,7a*S*)-Octahydro-3-methyl-6-oxo-3a*H*-indene-3a-carbaldehyde (10), and (3*R*,3a*R*)-1,2,3,4,5,6-Hexahydro-3-methyl-3a*H*-indene-3a-carbaldehyde (11). Compounds **9**, **10**, and **11** were prepared from compound **B**[5] as follows: (i) a two-step sequence for **9** [(1) $LiAlH_4$, THF; (2) PCC, CH_2Cl_2]: (ii) a three-step sequence for **10** [(1) H_2/Pd–C, EtOH; (2) $LiAlH_4$, THF; (3) Swern oxidation]: (iii) a four-step sequence for **11** [(1) $HSCH_2CH_2$-

SH, $BF_3 \cdot OEt_2$; (2) Raney-Ni (W-2), EtOH; (3) $LiAlH_4$; (4) Swern oxidation].

9: A colorless oil; IR ($CHCl_3$) 2830, 2740, 1715, and 1660 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.15 (3H, d, J=7.9 Hz), 1.59—1.79 (2H, m), 1.89—2.18 (2H, m), 2.30 (1H, ddd, J=17.8, 13.5, 5.0 Hz), 2.41 (1H, ddd, J=17.8, 5.6, 2.3 Hz), 2.59—2.68 (1H, m), 2.70—2.78 (1H, m), 2.89 (1H, dddd, J=20.1, 10.6, 2.3, 2.3 Hz), 6.01 (1H, dd, J=2.3, 1.3 Hz), and 9.73 (1H, s); EIMS m/z (rel intensity) 178 (M^+, 77) and 149 (100). HREIMS. Found: m/z 178.0990. Calcd for $C_{11}H_{14}O_2$: M, 178.0994.

10: A colorless oil; IR ($CHCl_3$) 2820, 2720, and 1715 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.06 (3H, d, J=7.4 Hz), 1.26—1.48 (2H, m), 1.72—1.83 (1H, m), 1.88—2.41 (7H, m), 2.48 (1H, dd, J=15.5, 5.9 Hz), 2.78—2.89 (1H, m), and 9.68 (1H, s); EIMS m/z (rel intensity) 180 (M^+, 100), 165 (7), 151 (35), and 133 (72). HREIMS. Found: m/z 180.1130. Calcd for $C_{11}H_{16}O_2$: M, 180.1150.

11: A colorless oil; IR ($CHCl_3$) 2830, 2720, and 1710 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.92—1.11 (1H, m), 1.06 (3H, d, J=7.3 Hz), 1.26—1.58 (2H, m), 1.68—1.83 (2H, m), 1.89—2.07 (3H, m), 2.25—2.48 (1H, m), 2.48 (1H, ddd, J=12.9, 3.4, 3.4 Hz), 2.56—2.71 (1H, m), 5.61—5.66 (1H, m), and 9.63 (1H, s); EIMS m/z (rel intensity) 164 (M^+, 14), 149 (1), and 135 (100). HREIMS. Found: m/z 164.1207. Calcd for $C_{11}H_{16}O$: M, 164.1201.

Autoxidation of 9. Autoxidation of **9** (51.1 mg, 0.287 mmol) at 65 °C for 23 h and subsequent treatment with Ph_3P were performed as described above. The crude product was purified by column chromatography on silica gel [16 g, hexane–EtOAc (2 : 1→1 : 1→1 : 2)] to give a mixture of **12** and **13**. Further separation of this mixture by preparative TLC [hexane–EtOAc (1 : 3)] provided pure **12** (7.9 mg, 17%) and **13** (9.5 mg, 20%) as a colorless oil, respectively.

12 (the less polar compound): IR ($CHCl_3$) 3600, 3430, 1660, and 930 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.08 (3H, d, J=6.3 Hz), 1.61—1.78 (2H, m), 1.76 (1H, br s, -OH), 1.82—1.96 (2H, m), 2.22 (1H, ddd, J=13.9, 5.3, 2.0 Hz), 2.34—2.54 (2H, m), 2.67—2.82 (2H, m), and 5.85 (1H, dd, J=2.0, 1.0 Hz); EIMS m/z (rel intensity) 166 (M^+, 100), 148 (2), 138 (79), 124 (81), and 96 (87). HREIMS. Found: m/z 166.0996. Calcd for $C_{10}H_{14}O_2$: M, 166.0994.

13 (the more polar compound): IR ($CHCl_3$) 3600, 3420, 1660, and 935 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.87 (3H, d, J=7.3 Hz), 1.49 (1H, dddd, J=12.5, 8.2, 3.0, 1.3 Hz), 1.95 (1H, br s, -OH), 1.97—2.15 (2H, m), 2.17—2.45 (3H, m), 2.55 (1H, dddd, J=19.5, 8.2, 8.2, 2.0 Hz), 2.71 (1H, dddd, J=19.5, 9.5, 3.0, 1.0 Hz), 2.78 (1H, ddd, J=17.5, 12.2, 6.3 Hz), and 5.91 (1H, dd, J=2.0, 1.0 Hz); EIMS m/z (rel intensity) 166 (M^+, 48), 148 (3), 138 (100), 124 (98), and 96 (98). HREIMS. Found: m/z 166.1004. Calcd for $C_{10}H_{14}O_2$: M, 166.0994.

Autoxidation of 10. Autoxidation of **10** (58.5 mg, 0.325 mmol) at 65 °C for 23 h and subsequent treatment with Ph_3P were performed as described above. Treatment of the crude product with excess CH_2N_2 and subsequent separation by column chromatography on silica gel [18 g, hexane–EtOAc (5 : 1→5 : 2→1 : 1)] gave **14** (17.4 mg, 25%) as a colorless oil, along with the recovered **10** (7.2 mg, 12%).

14: IR ($CHCl_3$) 1715, 1225, and 1195 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.91 (3H, d, J=6.9 Hz), 1.22—1.50 (2H, m), 1.76—2.08 (4H, m), 2.13—2.63 (5H, m), 2.92—3.05 (1H, m), and 3.74 (3H, s); EIMS m/z (rel intensity) 210 (M^+, 42), 178 (100), and 150 (96). HREIMS. Found: m/z 210.1228. Calcd for $C_{12}H_{18}O_3$: M, 210.1256.

Autoxidation of 11. Autoxidation of **11** (88.4 mg, 0.539 mmol) at 65 °C for 23 h and subsequent treatment with Ph_3P were performed as described above. The crude product was subjected to separation by column chromatography on silica gel [30 g, hexane–ether (2 : 1→1 : 1→0 : 1)] to give a mixture of **15** and **16**, crude **17**, and crude **18**. Further purification by preparative TLC [$CHCl_3$–acetone (20 : 1) for the mixture of **15** and **16**; benzene–acetone (5 : 1) for **17**; benzene–acetone (7 : 1) for **18**] provided **15** (4.3 mg, 5%; a 1 : 1 mixture of diastereomers), **16** (4.1 mg, 5%), **17** (3.9 mg, 4%; a 1 : 1 : 2 : 2 mixture of diastereomers), and **18** (4.0 mg, 4%; a 1 : 1 mixture of diastereomers) as a colorless oil, respectively.

15: IR ($CHCl_3$) 3600, and 3450 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.98 (1.5H, d, J=6.9 Hz), 1.00 (1.5H, d, J=6.6 Hz), 1.20—1.43 (2H, m), 1.57—2.32 (8H, m), 2.35—2.62 (2H, m), and 4.12—4.21 (1H, m); EIMS m/z (rel intensity) 152 (M^+, 100), 137 (18), and 134 (16). HREIMS. Found: m/z 152.1229. Calcd for $C_{10}H_{16}O$: M, 152.1201.

16: IR ($CHCl_3$) 1655 and 1630 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=1.11 (3H, d, J=7.3 Hz), 1.37—1.51 (1H, m), 1.98—2.62 (9H, m), and 2.76—2.92 (1H, m); EIMS m/z (rel intensity) 150 (M^+, 81), 135 (19), and 122 (100). HREIMS. Found: m/z 150.1047. Calcd for $C_{10}H_{14}O$: M, 150.1044.

17: IR ($CHCl_3$) 3600, and 3450 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.91—2.57 (15H, m), and 3.93—4.28 (1H, m); EIMS m/z (rel intensity) 168 (M^+, 13), 153 (16), 150 (11), and 111 (100). HREIMS. Found: m/z 168.1154. Calcd for $C_{10}H_{16}O_2$: M, 168.1150.

18: IR ($CHCl_3$) 3600, 3460, and 1715 cm^{-1}; ^1H NMR ($CDCl_3$, 270 MHz) δ=0.91—1.36 (2H, m), 1.18 (3H, d, J=7.3 Hz), 1.51—2.52 (10H, m), and 2.66—2.75 (1H, m); EIMS m/z (rel intensity) 168 (M^+, 43), 153 (5), 150 (13), 126 (100), and 84 (91). HREIMS. Found: m/z 168.1125. Calcd for $C_{10}H_{16}O_2$: M, 168.1150.

Synopsis. Carbon dioxide was directly fixed into fluorene in the presence of diphenylcarbodiimide (DPC) as a model of a biotin enzyme active site and potassium hydrogencarbonate. It was considered that not only carbon dioxide but also the hydrogencarbonate ion were the carbon source in the presence of DPC. Weak bases such as potassium acetate, potassium propionate, and potassium formate were also effective for carboxylation.

The chemical fixation of carbon dioxide has been widely studied,[1-5] since carbon dioxide is an abundant natural source of carbon. Photosynthesis is known to be the most efficient system for carbon dioxide fixation. However, enzymatic carboxylation without the aid of photoenergy was also known in which biotin enzyme plays an important role.[6,7] It is well known that the active site of biotin is a urea derivative.

We have already reported that active methylene compounds were effectively carboxylated by employing a reagent system, carbon dioxide, diphenylurea or diphenylcarbodiimide (DPC) as a model of biotin active site and potassium carbonate.[8]

In the case of DPC, the reaction occurred even in the presence of water, surprisingly.[8a] The carbonate ion reacts with water to give the hydrogencarbonate ion. Since the hydrogencarbonate ion is a weak base, it is ineffective for a conventional carboxylation reaction. Actually, no carboxylation reaction occurred when potassium hydrogencarbonate was added with diphenylurea. We have found that active methylene compounds can be carboxylated using such weak bases as alkalin metal hydrogencarbonate and DPC. Furthermore, instead of potassium hydrogencarbonate, weak bases such as potassium acetate, potassium propionate, and potassium formate were also effective.

Results and Discussion

It is well known that a strong base, like 1,8-diazabicyclo[5.4.0]undec-7-ene, abstracts a proton from an active methylene compound, producing its carboxylated compound in the presence of carbon dioxide.[9] Since potassium hydrogencarbonate is a weak base, no carboxylation occurred when only potassium hydrogencarbonate was reacted with fluorene under a carbon dioxide atmosphere in DMSO (Table 1). In carboxylation using diphenylurea, a strong base is required since it is believed that the first step is an imine proton abstraction by a strong base. Actually, no carboxylation reaction occurred when a weak base, potassium hydrogencarbonate, was added to diphenylurea. However, when potassium hydrogencarbonate was used with DPC, fluorene was carboxylated and the yield of 9-FLC was as high as 44—47% (Table 1). Sodium hydrogencarbonate was also an effective base.

Table 1. Carboxylation of Fluorene Using a Model of the Biotin Enzyme Active Site[a] and Base under a Carbon Dioxide Atmosphere

Model of the biotin enzyme active site	Base	Water added /mmol	Yield of 9-FLC/%[b]
None	$KHCO_3$	0	0.0
Diphenylurea	$KHCO_3$	0	0.0
Diphenylcarbodiimide	None	0	0.0
Diphenylcarbodiimide	$KHCO_3$	0	43.9, 46.9
Diphenylcarbodiimide[c]	$KHCO_3$	0	49.1
Diphenylcarbodiimide[d]	$KHCO_3$	0	48.5
Diphenylcarbodiimide	$KHCO_3$	10	18.0
Diphenylcarbodiimide	$NaHCO_3$	0	3.7
Diphenylcarbodiimide	$NaHCO_3$	10	11.2

a) Fluorene, 5 mmol; imine, 16.8 mmol; base, 60 mmol; DMSO, 25 ml; reaction temp., 20 °C; reaction time, 2 h. b) The yields were calculated on the basis of fluorene used. c) Under a nitrogen atmosphere. d) Under an air atmosphere.

Table 2. The Solubility of Base

Base	Solubility A[a] H_2O	Solubility B[b] H_2O	The amounts of CO_2 absorption[c] H_2O
	0 (10 mmol)	0 (10 mmol)	0 (10 mmol)
None			16.0 (17.3)
K_2CO_3	0.1 (0.2)	3.7 (8.8)	15.1 (20.0)
$KHCO_3$	0.2 (0.2)	41.0 (19.2)	3.6 (13.0)
$NaHCO_3$	0.2 (0.2)	2.3 (3.3)	17.6 (16.4)
HCOOK	3.6	14.0	31.0

C_2H_5COOK	2.1	4.5	52.6

a) Solubility of base in DMSO 100 ml. b) Solubility of base in DPC (67.2 mmol) and DMSO 100 ml. c) The amount of CO_2 absorption (mmol) in the solution of base (240 mmol or 120 mmol), DPC (67.2 mmol), and DMSO 100 ml.

Although the solubilities of carbonate and hydrogencarbonates in DMSO were small, they increased upon the addition of DPC, as shown in Table 2. Especially, the solubility of potassium hydrogencarbonate in DMSO with DPC was as large as 41 mmol/100 ml DMSO, suggesting a reaction of DPC with the base to produce an active intermediate. Upon the addition of water, although the solubilities of potassium carbonate

and sodium hydrogencarbonate increased, the solubility of potassium hydrogencarbonate decreased. The effects of the water addition on the solubility had the same tendency as did the effects of water on carboxylation (Table 1).

In the case of DPC and potassium carbonate, fluorene was carboxylated even in the absence of carbon dioxide, indicating that the carbonate ion was the carbon source. However, the yield of 9-FLC was as low as 6.6%.[8a] In the case of DPC and potassium hydrogencarbonate, the yield of 9-FLC under a nitrogen atmosphere was 49%; the yield under an air atmosphere was also 49%. These values were nearly equal to those under a carbon dioxide atmosphere, clearly indicating that the hydrogencarbonate ion was a carbon source. It was considered that a hydrogencarbonate ion attacked an imine carbon to give anionic intermediates which could transfer carbon dioxide to fluorene.

In biological carboxylation catalyzed by a biotin enzyme, the hydrogencarbonate ion is a carbon source and carboxylation occurs through the activation of a hydrogencarbonate ion. We believe that our result is the first example of a model reaction of biotin enzymatic carboxylation using the hydrogencarbonate ion.

Active methylene compounds other than fluorene were also carboxylated by using a reagent system, DPC, potassium hydrogencarbonate and carbon dioxide. They include indene, indanone, acetophenone, cyclohexanone, 1-tetralone, phenylacetonitrile, and *p*-methoxyacetophenone (Table 3). Higher yields than those using potassium carbonate were obtained in the cases of fluorene, phenylacetonitrile, 1-tetralone, and *p*-methoxyacetophenone. There was no correlation between the pK_a of an active methylene compound and the yield.

Similarly to potassium hydrogencarbonate, potassium acetate, being a weak base, was not an effective base for carboxylation if DPC was not used. However, high yields of more than 50% were obtained by employing a reagent system, carbon dioxide, DPC, and potassium acetate (Table 4). Potassium formate and potassium propionate were also effective, even though the yields were about one half those using potassium acetate. Lithium acetate was not effective.

No carboxylation occurred under a nitrogen atmosphere in the case of potassium acetate, indicating that the acetate ion was not a carbon source, and that only atmospheric carbon dioxide was a carbon source. The amounts of carbon dioxide absorption in the case of potassium acetate are also shown in Table 2. The value (48.3) was fairly larger than 15.1 in the case of potassium carbonate. It is considered that the acetate ion attacks an imine carbon, and that the resulting intermediate easily reacts with carbon dioxide to give carbon dioxide donors.

We have already reported that *o*-substitutions in the phenyl moieties of DPC and diphenylurea were harmful for carboxylation using potassium carbonate. The same result was obtained in the case of potassium hydrogencarbonate, as shown in Table 4. The amounts of carbon dioxide adsorption were not affected by the *o*-substitutions, suggesting that the reaction of carbon dioxide with imine was not blocked by the *o*-substitutions. We considered that *o*-substitutions inhibited the reaction of fluorene with an intermediate including carbon dioxide. However, potassium acetate and potassium propionate were effective bases, even in the case of the *o*-substitution of DPC. We could not clarify any mechanism, however, but speculate two reaction routes. At first, acetate and propionate moieties having a larger space than does the hydrogencarbonate

Table 3. Carboxylation of Active Methylene Compounds Using Potassium Hydrogencarbonate in Carbon Dioxide Atmosphere[a]

Substrate	Yield of carboxylic acid/%[b] (using potassium carbonate)
Indene	21.1 (53.8)
Indanone	44.3 (45.5)
Fluorene	43.9 (35.2)
Acetophenone	4.2 (28.7)
Cyclohexanone	3.6 (14.0)
1-Tetralone	35.9 (21.5)
Phenylacetonitrile	51.5 (29.2)
p-Methoxyacetophenone	20.7 (14.4)

a) Substrate, 5 mmol; diphenylcarbodiimide, 16.8 mmol; $KHCO_3$ 60 mmol or K_2CO_3, 30 mmol; DMSO, 25 ml; reaction temp, 20 °C; reaction time, 2 h. b) The yields of carboxylic acid were calculated on the basis of substrate used. The products were monocarboxylic acids. They were identified by comparision of IR spectra with those of the authentic samples, after esterification with diazomethane, if necessary.

ion may remove the blocking of *o*-substitutions. The second is that the acetate and propionate moieties may activate carbon dioxide.

In any case, we first indicated that weak bases, such as potassium acetate and potassium propionate, are also effective in the case that diphenylcarbodiimide is used as a biotin enzyme active site.

Experimental

DPC and substituted DPC were synthesized according to a method of Campbell et al.[10] Fluorene and DPC were dissolved in DMSO (25 ml); to this solution was added powdered alkali carbonate or alkali hydrogencarbonate. Dry carbon dioxide was then passed into the mixture. The reaction mixture was worked up in the same manner as described previously.[8] The yield of 9-FLC was measured gravimetrically. A reaction under pressure was carried out using a 100 ml magnet-driven autoclave and was treated in the same manner as mentioned above. The solubilities of alkali hydrogencarbonates were determined by titration using aquous HCl (0.01 or 0.001 mol dm^{-3}) after filtration.

The amounts of carbon dioxide absorption in a DMSO solution containing DPC were determined by measuring the weights both before and after carbon dioxide bubbling.

Facile Production of D-Histidine by Asymmetric Transformation of L-Histidine

Tadashi SHIRAIWA,* Kazuyuki SHINJO, Yoko MASUI, Atsushi OHTA, Hisashi NATSUYAMA, Hideya MIYAZAKI, and Hidemoto KUROKAWA
Faculty of Engineering, Kansai University, Yamate-cho, Suita, Osaka 564
(Received July 3, 1991)

Synopsis. An asymmetric transformation from L-histidine [L-His] to D-His was achieved by using salicylaldehyde as a catalyst for epimerization, and (2*R*, 3*R*)-tartaric acid as a resolving agent, in acetic acid. Treatment of the obtained salt with triethylamine in methanol gave D-His with 100% optical purity in 95% yield based on the starting L-His.

Both D- and L-amino acids are useful as chiral reagents in asymmetric syntheses. L-Amino acids are obtained as natural products, whereas D-amino acids are difficult to obtain in large quantities. Although an optical resolution of synthetic DL-amino acid gives both D- and L-amino acids, DL-histidine [abbreviated as DL-His] has not been synthesized on an industrial scale because there is no efficient procedure for preparation of its imidazole ring. L-His, therefore, is inexpensive but D-His is significantly costly. The optical resolution of DL-His by using (2*R*, 3*R*)-tartaric acid [(*R*)-TA], as a resolving agent, gives a salt of D-His with (*R*)-TA as a less soluble diastereomeric salt.[1] In addition, an optically active amino acid is racemized easily by using aldehydes as a catalyst in a carboxylic acid.[2,3] We therefore attempted an efficient production of D-His by the asymmetric transformation of L-His.

Experimental

Materials. L-His ($[\alpha]_D^{20}$+12.2° (*c* 3.00, 6 mol dm^{-3} HCl)) and (*R*)-TA ($[\alpha]_D^{20}$+13.2° (*c* 2.00, water)) were purchased from Kokusan Chemical Works, Ltd. and Wako Pure Chemicals Ind., respectively.

Asymmetric Transformation. A mixture of 3.10 g (20.0 mmol) of L-His, 3.00 g (20.0 mmol) of fine powdery (*R*)-TA, and 2.00 or 10.0 mmol of salicylaldehyde or butanal in 20 cm^3 of acetic acid was stirred for 0.5—7 h at 80 or 90 °C, and subsequently for 0. 5 h in an ice bath. The salt formed (5.7—6.1 g) was collected by filtration, washed thoroughly with diethyl ether, and dried.[4] The D-His·(*R*)-TA salt thus obtained was of 100% optical purity: $[\alpha]_D^{20}$+13.3° (*c* 2.00, water). Found: C, 39.32; H, 4.98; N, 13.52%. Calcd for $C_{10}H_{15}N_3O_8$: C, 39.35; H, 4.95; N, 13.77%. After suspending the obtained salt in 70 cm^3 of methanol, followed by adding 2 molar equivalents of triethylamine for the salt, the mixture was stirred for 1 h in an ice bath. Insoluble D-His was collected by filtration, washed with methanol, and dried. The optical purity of the obtained D-His was estimated on the basis of the specific rotation ($[\alpha]_D$+12.43° (6 mol dm^{-3} HCl))[5] of L-His. The D-His obtained was of 100% optical purity. Found: C, 46.11; H, 5.84; N, 27.13%. Calcd for $C_6H_9N_3O_2$: C, 46.45; H, 5.85; N, 27.08%; $[\alpha]_D^{20}$−12.5° (*c* 3.00, 6 mol dm^{-3} HCl). The degrees of crystallization of D- and L-His ($DC_{(D)}$ and $DC_{(L)}$/%) were calculated from the formulae

$$DC_{(L)}/\% = (1/2)\,[\text{Yield}/\% \times (100 - \text{Optical purity}/\%)]/100, \quad (1)$$

$$DC_{(D)}/\% = \text{Yield}/\% - DC_{(L)}/\%, \quad (2)$$

where the yield was calculated on the basis of 20.0 mmol (3.10 g) of His and, when L-His was obtained, the subscripts D and L in Eqs. 1 and 2 were exchanged with each other.

Rate Constant for Racemization. L-His (40.0 mmol) was dissolved in 50 cm^3 of formic acid, acetic acid, or propanoic acid at 40, 70, or 90 °C. After adding 4.00 mmol of salicylaldehyde or butanal, the solution was stirred at each temperature. A 5-cm^3 aliquot of the solution was pipetted out at appropriate time intervals, cooled rapidly, and diluted to 10 cm^3 with water. The optical rotation of the solution was measured at 589 nm with a Union Giken PM-101 digital polarimeter equipped with a quartz cell of 5.00 cm path length. The rate constant for racemization (k_R/s^{-1}) was calculated by the least-squares method from

$$\ln \alpha_0/\alpha_t = k_R \cdot t, \quad (3)$$

where α_t is the optical rotation at time t and α_0 that extrapolated to zero time. The half-life period ($t_{1/2}$/s) was calculated by using the k_R value from Eq. 3.

Results and Discussion

Racemization of L-Histidine. Racemization of L-His was regarded as a first-order reaction because a linear relationship was found between ln α_0/α_t and time t. The rate constant (k_R/s^{-1}) and half-life period ($t_{1/2}$/s) are summarized in Table 1.

The racemization of L-His was accelerated by using salicylaldehyde as a catalyst rather than butanal. We reported that, in racemization of L-proline [L-Pro] and (*R*)-2-piperidinecarboxylic acid [(*R*)-Pia], the rate of racemization by use of butanal increased with a decrease in acidities of the carboxylic acids used as solvents.[6] An alternative result has been reported that the rates of racemization of optically active amino acids may be largest in acetic acid.[2] As seen in Table 1, the rate of racemization of L-His is largest in acetic acid and the tendency differs from those of L-Pro and (*R*)-Pia.[6] In the racemization of L-His, after forming the Schiff base by reaction of L-His with an aldehyde, the racemization seems to proceed by protonation on its nitrogen atom by the carboxylic acid, followed by α-proton abstraction

Table 1. Kinetic Data for Racemization of L-Histidine[a]

Aldehyde	Carboxylic acid	Temperature / °C	k_R[b] / 10^{-4} s^{-1}	$t_{1/2}$[c] / 10^3 s
SA[d]	AcA[e]	40	3.42	2.03
Butanal	FrA[f]	90	0.114	60.8
	AcA[e]	70	3.06	2.27
		90	34.2	0.203
	PrA[g]	90	10.4	0.666

a) Conditions: L-His 40.0 mmol; aldehyde 4.00 mmol; carboxylic acid 50 cm^3. b) k_R: Rate constant for racemizaion. c) $t_{1/2}$: Half-life period. d) Salicylaldehyde. e) Acetic acid. f) Formic acid. g) Propanoic acid.

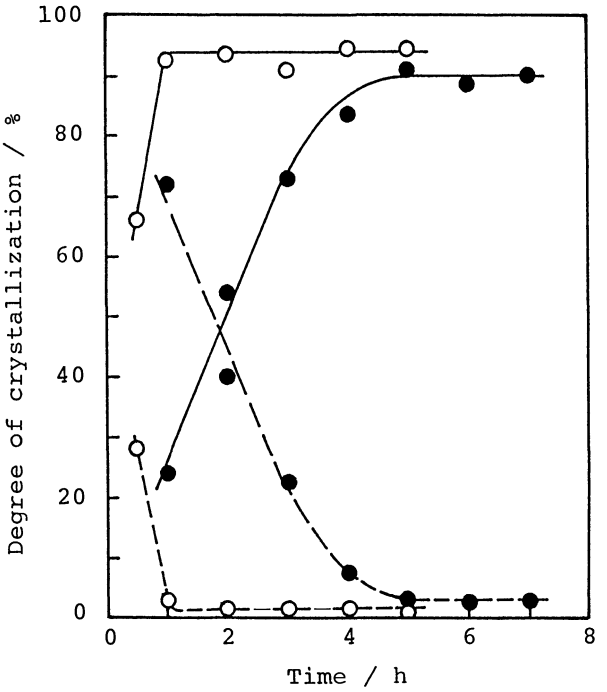

Fig. 1. Comparison of asymmetric transformation by use of salicylaldehyde and butanal as catalyst for epimerization.

by its carboxylate anion.[2,3] On the other hand, the racemization of L-Pro or (*R*)-Pia proceeds by formation of the Schiff base with concomitant protonation by the carboxylic acid, followed by α-proton abstraction by the resulted carboxylate anion.[2] Since the formation of the Schiff bases seems to be extremely rapid, the rates of racemization of L-Pro and (*R*)-Pia are determined by the process of α-proton abstraction, as described in our previous paper,[6] and that of L-His by both processes of protonation and α-proton abstraction. An order of protonation at 90 °C is estimated from the acidity constant[7] at 90 °C to be formic acid > acetic acid > propanoic acid and that of proton abstraction to be formate anion < acetate anion < propanoate anion. The rate of racemization of L-His, therefore, is estimated to be most rapid in acetic acid, as summarized in Table 1.

Asymmetric Transformation from L-Histidine to D-Histidine. The asymmetric transformation from L-His to D-His was tried by using half molar equivalent of salicylaldehyde or butanal for L-His in acetic acid (Fig. 1); D-His with 15% optical purity was obtained by using 0.1 molar equivalent of butanal at 5 h. Figure 1 suggests that the rate of epimerization of the L-His·(*R*)-TA salt by use of salicylaldehyde as the catalyst is larger than that by butanal, as predicted from the racemization of L-His. The asymmetric transformation was also successfully achieved by using 0.1 molar equivalent of salicylaldehyde for L-His in acetic acid (Table 2). The asymmetric transformation gave efficiently D-His with 100% optical purity in 95% yield, based on the starting L-His, by reacting for 6—7 h at 80 °C and for 3—4 h at 90 °C, respectively.

Asymmetric Hydrocyanation of Benzaldehydes Catalyzed by (5*R*)-5-(4-Imidazolylmethyl)-2,4-imidazolidinedione

Hidenori DANDA
Takarazuka Research Center, Sumitomo Chemical Co., Ltd.,
2-1, 4-Chome, Takatsukasa, Takarazuka, Hyogo 665
(Received July 5, 1991)

Synopsis. The catalytic activity of (5*R*)-5-(4-imidazolylmethyl)-2,4-imidazolidinedione (**3**) was examined in the asymmetric hydrocyanation of 3-phenoxybenzaldehyde (**1a**) to (*S*)-2-hydroxy-2-(3-phenoxyphenyl)acetonitrile ((*S*)-**2a**), an important alcohol moiety of optically active pyrethroid insecticides. Among the catalysts, 3-benzyl derivative (**3d**) exhibited moderate enantioselectivities for **1a** and other benzaldehydes.

(*S*)-2-Hydroxy-2-(3-phenoxyphenyl)acetonimle ((*S*)-**2a**) is an important alcohol moiety of optically active pyrethroid insecticides.[1] With regard to the asymmetric synthesis of optically active cyanohydrins, there have been many reports concerning the enantioselective hydrocyanation or silylcyanation in the presence of a chiral catalyst.[2] Recently, Inoue et al. have reported that the chiral cyclic dipeptides containing an (*S*)-histidine residue, such as *cyclo*[(*S*)-phenylalanyl-(*S*)-histidyl], exhibit high enantioselectivities in the asymmetric hydrocyanation of aldehydes.[3] In conjunction with this finding, our interest has been focussed on the design and screening of catalysts containing the (*R*)-histidine residue to prepare (*S*)-**2a** in high optical yield. We thus prepared various kinds of (5*R*)-5-(4-imidazolylmethyl)-2,4-imidazolidinedione (**3**), which have a structural similar to that of *cyclo*[(*S*)-phenylalanyl-(*S*)-histidyl], and investigated their catalytic activities in the enantioselective addition of hydrogen cyanide to 3-phenoxybenzaldehyde (**1a**) as well as other benzaldehydes (**1b**—**d**) (Scheme 1). Herein, we report on the results concerning asymmetric hydrocyanation catalyzed by **3**.

Results and Discussion

The preparation of the catalyst (**3**) was carried out as illustrated in Scheme 2. The urea (**6**) was prepared by coupling of (*R*)-histidine monohydrochloride hydrate

with the isocyanate (**5**) which was obtained by a reaction of the corresponding amine (**4**) with phosgene. The urea (**6**) was dehydrated under acidic conditions to give **3** in reasonable yields. The asymmetric hydrocyanation was carried out by using 2.2—5 mol% of the catalyst (**3**) (based on the aldehyde (**1**)). The optical yield (ee) of (*S*)-**2** was determined by HPLC analysis (Sumipax OA-4100).[4]

The asymmetric hydrocyanation of the aldehyde (**1a**) catalyzed by **3** was examined; the results are summarized in Table 1. In all of the catalysts, except for **3f**, (*S*)-cyanohydrin ((*S*)-**2a**) was preferentially obtained, while **3f** gave the opposite enantiomer ((*R*)-**2a**) as a major product (Entry 8). Among the catalysts (**3**), **3d** and **3e** gave (*S*)-**2a** in moderate optical yields (37% ee and 18% ee, Entries 4 and 6). Extending the reaction time decreased the optical yield, which may be due to a racemization of the products (Entry 5). The use of DMF as a solvent decreased the optical yield, even

a) The reactions were casrried out by using 99 mmol of hydrogen cyanide and 50 mmol of **1a**. 40 mL of solvent was used in Entries 1—5. b) Determined by HPLC (LiChrosorb SI-60). Any by-product was not observed on HPLC. c) Determined by (Sumipax OA-4100). d) **3d** is insoluble.

Table 3. Asymmetric Hydrocyanation of Aldehydes Catalyzed by **3d**[a)]

Entry	Aldehyde	Solvent	Time/h	Conv. of **1**/%[b)]	Optical yield of (*S*)-**2**/%ee[c)]
1	**1b**	Neat	1	90	33
2	**1c**	DMF	3	67	20
3	**1d**	DMF	1	93	16

a) The reactions were carried out at 0 °C by using 1.1 mmol of **3d**, 99 mmol of hydrogen cyanide and 50 mmol of aldehyde. 40 mL of DMF was used in Entries 2 and 3. b) Determined by HPLC (LiChrosorb SI-60). Any by-product was not observed on HPLC. c) Determined by HPLC (Sumipax OA-4100).

though the conversion of **1a** increased (compare Entry 7 with Entry 6). And even though the 3-substituent of **3d** was replaced by chiral benzyl groups, using **3g**—**j**, the optical yield was not improved (Entries 9—12).

Next, the optimal conditions were investigated in the asymmetric hydrocyanation of **1a** catalyzed by **3d**. The results are summarized in Table 2. No reaction was observed when toluene, cyclohexane or CH_2Cl_2 was used as a solvent, because of the poor solubility of **3d** in these solvents. The use of CH_3CN or DMF as a solvent decreased the optical yields. When the reaction temperature was lowered to 0 °C, the optical yield of (*S*)-**2a** was improved (40% ee, Entry 6), whereas it was not improved so much by increasing **3d** (41% ee, Entry 7).

The asymmetric hydrocyanation of benzaldehydes (**1b**—**d**) catalyzed by **3d** was examined. The results are exemplified in Table 3. In all cases, (*S*)-cyanohydrin ((*S*)-**2**) was obtained preferentially, ranging from 16% ee to 33% ee.[4)] However, racemic cyanohydrin was obtained when isobutyraldehyde was employed for the reaction under the same reaction condition as Entry 1 (90% conv. at 1 h).

Thus, **3d** exhibited moderate enantioselectivities in the asymmetric hydrocyanation of benzaldehydes (**1**), particularly atfording (*S*)-**2a** with a maximum optical yield of 41% ee.

We can discuss the mechanism of the enantioselective hydrocyanation catalyzed by **3d**, based on the mechanism which Inoue et al. postulated for the enantioselective hydrocyanation catalyzed by *cyclo*[(*S*)-phenylalanyl-(*S*)-histidyl].[3b)] The carbonyl oxygen of the aldehyde (**1**) is considered to coordinate to the catalyst (**3d**) by a hydrogen bond with the NH group of the histidine residue, and hydrogen cyanide interacts with the imidazolyl moiety of the histidine residue to form a cyanide ion which attacks the *re*-face of the activated carbonyl group, while the *si*-face is blocked by the aromatic ring of benzyl isocyanate residue. However, the blocking by the aromatic ring would be too loose to afford a satisfying enantioselectivity.

A further study dedicated to improving the enantioselectivity is in progress.

Experimental

General. The melting points are uncorrected. Optical rotations were taken on a JASCO DIP-140 digital polarimeter. ^1H NMR spectra were obtained at 200 MHz on a Varian XL-200, except for those of **3**, which were obtained at 90 MHz on a Hitachi R-40; ^{13}C NMR spectra were obtained at 50.3 MHz on a Varian XL-200. IR spectra were obtained on a Hitachi 260-10. HPLC were recorded on a Shimadzu LC-6A, LiChrosorb SI-60 and Sumipax OA-4100 being used as columns for determination of the conversion of **1** and the optical yield of the resulting cyanohydrins ((*S*)-**2**: (*R*)-**2**), respectively. Toluene and xylene were distilled from sodium benzophenone ketyl. DMF and CH_3CN were distilled immediately prior to use. Hydrogen cyanide was provided by Ehime Factory. All other solvents and chemicals were used without further purification.

Preparation of (5*R*)-5-(4-Imidazolylmethyl)-2,4-imidazolidinedione (3). (5*R*)-3-Benzyl-5-(4-imidazolylmethyl)-2,4-imidazolidinedione (3d). To a solution of 7.49 g (70 mmol) of benzylamine in 50 mL of xylene was added at 120 °C over 100 min 27.7 g (280 mmol) of phosgene. After removing the solvent and excess phosgene in vacuo, the crude isocyanate was subjected to the following procedure.

To a solution of 15.7 g (75 mmol) of (*R*)-histidine monohydrochloride hydrate in 180 mL of water was added 2 equiv NaOH until the solution showed pH 9. After the addition of the crude isocyanate obtained above, the reaction mixture was kept at 40 °C for 1 h, adjusted to pH 1 with 35% aqueous HCl, and kept under reflux for 1 h. After being cooled to 5 °C and neutralized to pH 5 with 2 equiv NaOH, the reaction mixture was allowed to stand at 5 °C overnight. The precipitate was filtered, washed with cold water and recrystallized from aqueous ethanol to give 15.2 g (85%) of **3d** as white crystals: Mp 219 °C; $[\alpha]_D^{25}$ 10.6° (*c* 0.87, DMSO); IR (KBr) 3300, 1760, 1710, 1455, 1430 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.95 (d, *J*=5.2 Hz, 2H), 4.36 (*t*, *J*=5.2 Hz, 1H), 4.47 (s, 2H), 6.80 (s, 1H), 6.9—7.4 (m, 5H), 7.52 (s, 1H), 8.17 (br.s, 1H). Found: C, 65.41; H,

5.49; N, 16.23%. Calcd for $C_{14}H_{14}N_3O_2$: C, 65.61; H, 5.51; N, 16.40%.

(5*R*)-5-(4-Imidazolylmethyl)-3-phenyl-2,4-imidazolidione (3a). The procedure given for **3d** was carried out on the same scale using aniline to give 14.0 g (83%) of **3a** as white crystals: Mp 192—194 °C; $[\alpha]_D^{25}$ 151.1° (*c* 1.02, methanol); IR (KBr) 3200, 1760, 1700, 1430, 1190 cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.08 (d, *J*=6.0 Hz, 2H), 4.44 (t, *J*=6.0 Hz, 1H), 6.90 (s, 1H), 7.2—7.5 (m, 5H), 7.60 (s, 1H), 8.20 (br.s, 1H). Found: C, 64.39; H, 4.87; N, 17.22%. Calcd for $C_{13}H_{12}N_3O_2$: C, 64.45; H, 4.99; N, 17.35%.

(5*R*)-3-(4-Chlorophenyl)-5-(4-imidazolylmethyl)-2,4-imidazolidinedione (3b). The procedure given for **3d** was carried out on the same scale using 4-chloroaniline to give 14.3 g (74%) of **3b** as white crystals: Mp 220—221 °C; $[\alpha]_D^{25}$ 14.5 °C (*c* 0.86, DMSO); IR (KBr) 3300,1710, 1660, 1570, 1400, 1190 cm^{-1}; ^1H NMR (DMSO-d_6) δ=3.01 (d, *J*=5.8 Hz, 2H), 4.45 (t, *J*=5.8 Hz, 1H), 6.89 (s, 1H), 7.1—7.7 (m, 4H), 7.73 (s, 1H), 9.00 (br.s, 1H). Found: C, 56.27; H, 3.89; N, 14.93%. Calcd for $C_{13}H_{11}N_3O_2Cl$: C, 56.43; H, 4.01; N, 15.19%.

(5*R*)-5-(4-Imidazolylmethyl)-3-(4-methylphenyl)-2,4-imidazolidinedione (3c). The procedure given for **3d** was carried out on the same scale using *p*-toluidine to give 13.8 g (77%) of **3c** as white crystals: Mp 243 °C; $[\alpha]_D^{25}$ 113.7° (*c* 0.872, DMSO); IR (KBr) 3200, 3000, 1760, 1705, 1600, 1520, 1430, 1190 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.30 (s, 3H), 3.02 (d, *J*=5.8 Hz, 2H), 4.42 (t, *J*=5.8 Hz, 1H), 6.86 (s, 1H), 7.0—7.4 (m, 4H), 7.56 (s, 1H), 8.27 (br.s, 1H). Found: C, 65.59; H, 5.35; N, 16.17%. Calcd for $C_{14}H_{14}N_3O_2$: C, 65.61; H, 5.51; N, 16.40%.

(5*R*)-3-Cyclohexyl-5-(4-imidazolylmethyl)-2,4-imidazolidinedione (3e). The procedure given **3d** was carried out on the same scale using cyclohexylamine to give 13.9 g (80%) of **3e** as white crystals: Mp 172—174 °C; $[\alpha]_D^{25}$ 15.6° (*c* 0.87, H_2O); IR (KBr) 3300, 2950, 1620, 1580, 1400 cm^{-1}; ^1H NMR (DMSO-d_6) δ=0.8—0.9 (m, 11H), 2.90 (d, *J*=6.0 Hz, 2H), 4.33 (t, *J*=6.0 Hz, 1H), 6.93 (s, 1H), 7.90 (s, 1H). Found: C, 62.71; H, 7.19; N, 16.84%. Calcd for $C_{13}H_{18}N_3O_2$: C, 62.88; H, 7.31; N, 16.92%.

(5*R*)-5-(4-Imidazolylmethyl)-3-(1-naphtyl)-2,4-imidazolidinedione (3f). The procedure given for **3d** was carried out on the same scale using 1-aminonaphthalene to give 16.6 (81%) of **3f** as white crystals: Mp 205—206 °C; $[\alpha]_D^{25}$ −39.4° (*c* 0.76, DMSO); ^1H NMR (DMSO-d_6) δ=3.07 (d, *J*=6.2 Hz, 2H), 4.53 (t, *J*=6.2 Hz, 1H), 6.97 (s, 1H), 7.3—7.7 (m, 4H), 7.8—8.3 (m, 4H), 8.80 (br.s, 1H). Found: C, 69.76; H, 4.64; N, 14.25%. Calcd for $C_{17}H_{14}N_3O_2$: C, 69.85; H, 4.83; N, 14.38%.

(5*R*)-5-(4-Imidazolylmethyl)-3-[(*R*)-1-phenylethyl]-2,4-imidazolidinedione (3g). The procedure given for **3d** was carried out on the same scale using (*R*)-α-methylbenzylamine to give 12.3 g (65%) of **3g** as white crystals: $[\alpha]_D^{25}$ −20.1° (*c* 1.00, DMSO); IR (KBr) 3300, 1755, 1630, 1550 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.33 (d, *J*=6.5 Hz, 3H), 2.88 (d, *J*=6.0 Hz, 2H), 4.36 (t, *J*=6.0 Hz, 1H), 4.73 (q, *J*=6.5 Hz, 1H), 6.82 (s, 1H), 7.15—7.4 (m, 5H), 7.65 (s, 1H). Found: C, 66.41; H, 5.80; N, 15.39%. Calcd for $C_{15}H_{16}N_3O_2$: C, 66.65; H, 5.97; N, 15.55%.

(5*R*)-5-(4-Imidazolylmethyl)-3-[(*S*)-1-phenylethyl]-2,4-imidazolidinedione (3h). The procedure given for **3d** was carried out on the same scale using (*S*)-α-methylhenzylamine to give 11.5 g (61%) of **3h** as white crystals: $[\alpha]_D^{25}$ −36.8° (*c* 0.40, DMSO); IR (KBr) 3300, 1760, 1630, 1560 cm^{-1}; ^1H NMR (DMSO-d_6) δ=1.30 (d, *J*=6.5 Hz, 3H), 2.88 (d, *J*=6.0 Hz, 2H), 4.30 (t, *J*=6.0 Hz, 1H), 4.71 (q, *J*=6.5 Hz. 1H), 6.83 (s, 1H), 7.13—7.43 (m, 5H), 7.65 (s, 1H). Found: C, 66.60; H, 5.92; N, 15.47%. Calcd for $C_{15}H_{16}N_3O_2$: C, 66.65; H, 5.97; N, 15.55%.

(5*R*)-5-(4-Imidazolylmethyl)-3-[(*R*)-1,2-diphenylethyl]-2,4-imidazolidinedione (3i). The procedure given for **3d** was carried out on the same scale using (*R*)-1,2-diphenylethylamine to give 13.2 g (55%) of **3i** as white crystals: $[\alpha]_D^{25}$ −15.1° (*c* 1.01, DMSO); IR (KBr) 3340, 1630, 1550, 1510, 1260 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.85 (d, *J*=6.5 Hz, 2H), 2.88 (d, *J*=6.5 Hz, 2H), 4.27 (t, *J*=6.0 Hz, 1H), 4.80 (t, *J*=6.5 Hz. 1H), 6.80 (s, 1H), 6.9—7.5 (m, 10H), 7.68 (s, 1H). Found: C, 72.68; H, 5.70; N, 11.99%. Calcd for $C_{21}H_{20}N_3O_2$: C, 72.81; H, 5.82; N, 12.13%.

(5*R*)-5-(4-Imidazolylmethyl)-3-[(*S*)-1,2-diphenylethyl]-2,4-imidazolidinedione (3j). The procedure given for **3d** was carried out on the same scale using (*S*)-1,2-diphenylethylamine to give 12.9 g (53%) of **3j** as white crystals: $[\alpha]_D^{25}$ −37.0° (*c* 1.01, DMSO); IR (KBr) 3350, 1630, 1560, 1520, 1260 cm^{-1}; ^1H NMR (DMSO-d_6) δ=2.83 (d, *J*=6.5 Hz, 2H), 2.90 (d, *J*=6.0 Hz, 2H), 4.25 (t, *J*=6.0 Hz, 1H), 4.82 (t, *J*=6.5 Hz, 1H), 6.80 (s, 1H), 7.0—7.6 (m, 10H), 7.68 (s, 1H). Found: C, 72.77; H, 5.71; N, 11.95%. Calcd for $C_{21}H_{20}N_3O_2$: C, 72.81; H, 5.82; N, 12.13%.

General Procedure for Asymmetric Addition of Hydrogen Cyanide to Benzaldehyde (1) Catalyzed by 3. To a mixture of 1.1 mmol of the catalyst (**3**) and 50 mmol of the aldehyde (**1**) (if necessary, 40 mL of an appropriate solvent was used) at 5 °C was added dropwise 3.8 mL (2.67 g, 99 mmol) of hydrogen cyanide under nitrogen; stirring was continued at 0 °C (or 10 °C) for an appropriate period. The reaction mixture was quenched with 0.5% aqueous HCl, and the crude cyanohydrin was extracted twice with toluene. The combined organic layers were dried over Na_2SO_4 and concentrated in vacuo, producing a brown oil which was chromatographed on silica gel to give the pure cyanohydrin. The ^1H NMR and IR spectra were found to be identical with those of an authentic sample. The optical yield of the resulting cyanohydrin ((*S*)-**2**: (*R*)-**2**) was determined by HPLC analysis (column, Sumipax OA-4100; eluent, hexane/1,2-dichloroethane/ethanol/ethyl acetate=800/200/10/1; flow rate, 1.0 mL min^{-1}: detection, 254 nm light). The conversion of **1** was also determined by HPLC analysis (column, LiChrosorb SI-60; eluent, hexane/ethyl acetate/acetic acid=500/60/3; flow rate, 1.0 mL min^{-1}; detection, 254 nm light).

3-Aryl-3-butenoic Acids and Their Esters: Practical Synthesis from Diketene by the Palladium-Catalyzed Grignard Coupling Reaction and Application as Monomers for the Radical Copolymerization with Styrene

Kenji ITOH,* Tatsumi HARADA, and Hideo NAGASHIMA

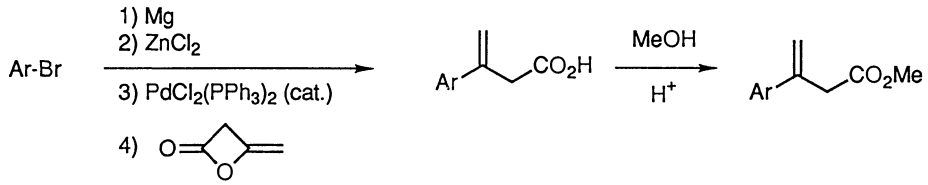
Synopsis. Treatment of arylmagnesium bromide with an equimolar amount of zinc chloride followed by the reaction with diketene in the presence of a catalytic amount of $PdCl_2(PPh_3)_2$ provided an improved synthetic method for 3-aryl-3-butenoic acids in a large scale. Application as a monomer for the substituted polystyrenes is exemplified by the copolymerization of methyl 3-phenyl-3-butenoate with styrene.

It is well-known that the reactions of diketene with nucleophiles proceed via the cleavage of its carbonyl–oxygen bond, providing general synthetic methods for acetoacetic acid derivatives.[1] Nonetheless, little has been explored on the nucleophilic reactions via the cleavage of its vinyl–oxygen bond. In 1977, we have reported the first nucleophilic substitution of the carboxylate moiety on the vinyl group in diketene by trimethylsilylmethyl moiety of Me_3SiCH_2MgCl with the aid of simple nickel catalysts, which provides a novel synthetic method for 3-(trimethylsilylmethyl)-3-butenoic acid.[2] Although attempted reactions of diketene with other Grignard reagents under similar conditions only resulted in the formation of intractable materials, improved procedures by Fujisawa[3] and Kato[4] provided preparative routes to 3-(alkyl,[3] aryl,[4] benzyl,[4] ethynyl,[4] and vinyl)-3-butenoic acids[4] by judicious choice of either the transition metal catalysts or organometallic nucleophiles.

We are interested in potential utility of 3-aryl-3-butenoic acids and their derivatives as a novel monomer for the polymerization. Since at least several to several ten grams of the monomer are required for the polymerization studies, the preparative process from diketene by Kato,[4] in which diketene is coupled with arylzinc reagents in situ prepared by aryllithium and zinc chloride, is attractive as a potential large scale synthesis for the monomer. However, there are several problems on the manipulation which should be improved in Kato's process; for example, use of rather expensive organolithium reagents and complicated catalyst system consisting of $PdCl_2(PPh_3)_2$ and diisobutylaluminium hydride (DIBAH). In this paper, we describe a modified process for the synthesis of 3-aryl-3-butenoic acids using rather inexpensive and easily available Grignard reagents as the precursor, acid-catalyzed esterification of the resulting 3-aryl-3-butenoic acids, and application of one of the esters to copolymerization with styrene (Scheme 1). After we started this project, Yamamoto and coworkers briefly reported modification of Kato's process to produce 3-phenyl-3-butenoic acid in their studies of asymmetric hydrogenation of 3-aryl-3-butenoic acids.[5] They used rather complicated procedure than the present method, in which the reaction was undertaken in THF with air-sensitive $Pd(PPh_3)_4$ as the catalyst.[5]

Modification of Kato's procedure was made by successive treatment of an ethereal solution of arylmagnesium bromide with $PdCl_2(PPh_3)_2$ (0.5—1 mol%), $ZnCl_2$, and diketene, providing the desired 3-aryl-3-butenoic acids in 50—80% isolated yields. As shown in Table 1, this procedure can be applied to the synthesis of various 3-aryl-3-butenoic acids. Advantages of this improved process are focussed on the use of less expensive Grignard reagents than aryl lithium compounds and of a catalytic amount of $PdCl_2(PPh_3)_2$ without the aluminium co-catalyst. Furthermore, the following two points are useful for the large scale synthesis. First, a sequence of reactions including synthesis of the Grignard reagents from aryl bromides and magnesium,



Ar = Phenyl, 1-Naphthyl, o-Tolyl, p-Tolyl, p-Methoxyphenyl, 2-Thienyl

transmetallation of the resulting Grignard reagents to aryl zinc reagents by the reaction with $ZnCl_2$, and the palladium-catalyzed coupling reactions with diketene can be carried out in one reaction vessel. Second, 3-aryl-3-butenoic acids are generally solids sparingly soluble in hexane, and hence, pure products were obtained only by extraction of the crude acids by hot hexane. In a typical example, 19 g of 3-phenyl-3-butenoic acid was easily obtained from 7.3 g of bromobenzene and 16 ml of diketene.

Addition of Zn(II) salts (one molar equivalent to the Grignard reagents) is crucially important, and an intractable mixtures of the products were formed in their absence. Use of THF instead of ether also caused serious decrease of the yields. Screening of the reaction conditions revealed that other transition metal salts or complexes such as CoI_2, and $NiCl_2(PPh_3)_2$ also gave the acid but in very low yields. Stoichiometric amounts of Ph_2CuLi in ether reacted with diketene to give 3-phenyl-3-butenoic acid in 40—60% isolated yields. However, attempted reactions of PhMgBr in the presence of catalytic amounts of copper salts only resulted in the formation of intractable products.

Esterification of the 3-aryl-3-butenoic acids involves potential formation of 3-aryl-2-butenoates as the by-product because of facile olefin migration. To avoid the olefin isomerization, Yamamoto and coworkers used diazomethane as the reagent for the esterification.[5] However, we found that the acid-catalyzed esterification of 3-phenyl-3-butenoic acid, 3-(*p*-tolyl)-3-butenoic acid, and 3-(1-naphthyl)-3-butenoic acid was made in MeOH in the presence of H_2SO_4 in 60—80% yields. In the case of 3-(*p*-methoxyphenyl)-3-butenoic acid, 3-(2-thienyl)-3-butenoic acid under the same conditions gave a mixture of isomers due to the isomerization of the olefinic bond from the β,γ- to α,β-position.

Radical polymerization studies were made by methyl 3-phenyl-3-butenoate using α,α'-azobis(isobutyronitrile) (AIBN) as the initiator at 60 °C. Since α-substituted

styrenes are in general less reactive toward the radical polymerization than styrene, it is reasonable that attempted polymerization of methyl 3-phenyl-3-butenoate itself was in failure. However, copolymerization with styrene successfully produced new polystyrenes including methoxycarbonylmethyl group as the side chain. As shown in Table 2, average molecular weights of the formed polymers were from 13000 to 75000. With higher molar ratios of styrene monomer to methyl 3-phenyl-3-butenoate, copolymers including lower ratios of the ester component with relatively higher molecular weights were formed in high yields. In contrast, with lower molar ratios of styrene monomer to methyl 3-phenyl-3-butenoate were formed copolymers including relatively higher ratios of the ester component but in low yields. Reactivity of styrene (M_1) to methyl 3-phenyl-3-butenoate (M_2) at 60 °C in the copolymerization was estimated by the curve-fitting method as $r_1=6.3$ and $r_2=0.02$.

In conclusion, a simple and versatile synthetic preparative procedure for 3-aryl-3-butenoic acids and their esters suitable to large scale synthesis was established. Furthermore, utility of these compounds as monomer was exemplified by copolymerization of styrene with methyl 3-phenyl-3-butenoate to produce new polystyrenes including polar methoxycarbonylmethyl appendages in their side chain.

Experimental

All manipulations were carried out under nitrogen atmosphere with dry solvents. Reagents were distilled before use. NMR spectra were measured in $CDCl_3$ by a JEOL GX-270 spectrometer (^1H; 270 MHz, ^{13}C; 67.8 MHz) and their δ-values (ppm from TMS) are listed below. IR spectra were measured by a Jasco IR A-3 spectrometer and recorded with the wavenumber. Elemental analysis was made by a Yanaco CHN meter. Mass spectra were measured by a Hitachi M-80B spectrometer. The Grignard reagents described below were prepared from the corresponding aryl bromide and magnesium, which can be stored in a refrigerator as a stock solution. Use of either the freshly prepared Grignard reagents or the stock solution provided similar yields of the desired acids.

General Procedure for the Preparation of 3-Aryl-3-butenoic Acid from Diketene and Arylmagnesium Bromide: The Grignard reagent prepared from Mg turnings (7.3 g, 0.3 mol),

aryl bromide (0.285 mol), and ether (200 ml) was diluted with additional ether (100 ml). Anhydrous $ZnCl_2$ (35 g, 0.257 mmol) was gradually added to the solution and stirred for 45 min to give suspension of white solids in brown solution. Then, $PdCl_2(PPh_3)_2$ (0.726 g, 0.001 mol, 0.5 mol%) and a solution of diketene (16 ml, 0.207 mol) in ether (400 ml) were added dropwise and the mixture was stirred for 30 min. The reaction mixture was poured into a cold 2 equiv HCl aq, and the mixture was extracted with ether. The acid was extracted from the organic layer by 3 equiv NaOH aq. The aqueous layer was acidified by 6 equiv HCl and extracted with ether. The extracts were combined and dried over $MgSO_4$. Removal of the solvents afforded crude 3-aryl-3-butenoic acid (60—80%). This crude acid contained no organic impurities detectable by ^1H NMR spectrum, and can be used for the esterification without further purification. Most of the acids can be purified by recrystalization from hot hexane.

3-Phenyl-3-butenoic Acid: White crystals. Mp 46—47 °C [lit, 46—47 °C].[4,5] ^1H NMR δ=3.54 (2H, s, CH_2CO), 5.26, 5.58 (s, 1H, each, olefin), 7.28—7.45 (m, 5H, Ph). ^{13}C NMR δ=40.8, 116.8, 125.8, 128.0, 128.5, 139.4, 140.2, 177.2. IR (KBr) 1700. Found: C, 74.06; H, 6.21%. Calcd for $C_{10}H_{10}O_2$: C, 74.01; H, 6.25%.

3-(1-Naphthyl)-3-butenoic Acid: White solids. Mp 74.5 °C. ^1H NMR δ=3.56 (s, 2H, CH_2CO), 5.35, 5.62 (s, 1H each, olefin), 7.34—8.03 (m, 7H, aromatic). ^{13}C NMR δ=43.3, 120.3, 125.2, 125.3, 125.4, 125.8, 126.1, 127.8, 128.4, 130.9, 133.7, 139.5, 140.3, 177.1. IR (KBr) 1710. Found: C,79.30; H, 5.76%. Calcd for $C_{14}H_{12}O_2$: C, 79.23; H, 5.70%.

3-(*o*-Tolyl)-3-butenoic Acid: Extraction of the crude acid by hot hexane (100 ml×3) followed by the concentration of the combined extracts gave the pure acid as a yellow oil; ^1H NMR δ=2.32 (s, 3H, Me), 3.39 (s, 2H, CH_2CO), 5.13, 5.41 (s, 1H each, olefin), 7.14—7.18 (m, 4H, aromatic). ^{13}C NMR δ=19.4, 42.5, 118.7, 125.2, 127.0, 128.0, 129.9, 134.5, 140.8, 141.0, 176.6. IR (neat) 1715. Found: C, 74.86; H, 6.95%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%.

3-(*p*-Tolyl)-3-butenoic Acid: White solids. Mp 106—107 °C [lit, 113—114 °C].[4] ^1H NMR δ=2.34 (s, 3H, Me), 3.52 (s, 2H, CH_2CO), 5.20, 5.54 (s, 1H each, olefin), 7.13, 7.32 (d, J=8.3 Hz, 2H each, aromatic). ^{13}C NMR δ=20.6, 40.5, 115.4, 125.1, 128.6, 136.0, 137.2, 139.4, 176.8. IR (KBr) 1700. Found: C, 74.93; H, 6.84%. Calcd for $C_{11}H_{12}O_2$: C, 74.98; H, 6.86%.

3-(*p*-Methoxyphenyl)-3-butenoic Acid: Yellow solids. ^1H NMR δ=3.52 (s, 2H, CH_2CO), 3.81 (s, 3H, OMe), 5.16, 5.50 (s, 1H each, olefin), 6.86, 7.38 (d, J=8.8 Hz, 2H each, aromatic). ^{13}C NMR δ=40.6, 54.9, 113.3, 114.6, 126.4, 131.4, 139.0, 158.9, 176.0. IR (KBr) 1700. Found: C, 68.76; H, 6.28%. Calcd for $C_{11}H_{12}O_3$: C, 68.74; H, 6.29%.

3-(2-Thienyl)-3-butenoic Acid: Pale yellow solids; yield: 2.52 g (53%); mp 65—66 °C. ^1H NMR δ=3.51 (s, 2H, CH_2CO), 5.14 and 5.61 (s, 1H each, olefin), 6.96 (dd, J=3.4, 5.4 Hz, 1H, 4-H on the thiophene ring), 7.04 (d, J=3.4 Hz, 1H, 5-H on the thiophene ring), 7.18 (d, J=5.4 Hz, 3-H on the thiophene ring). ^{13}C NMR δ=40.8, 114.9, 123.9, 124.6, 127.1, 133.5, 143.2, 176.0. IR (KBr) 1680. Found: C, 57.13; H, 4.86. Calcd for $C_8H_8O_2S$: C, 57.12; H, 4.79%.

Preparation of Methyl Esters: General Procedure: A mixture of the acid (0.13 mol), H_2SO_4 (3 ml, 56 mmol), and methanol (100 ml) was heated under reflux for 30 min. After cooling, H_2SO_4 was neutralized with aqueous $NaHCO_3$ (9.5 g in 100 ml water). Methanol was removed under a reduced pressure and the residue was extracted with CH_2Cl_2. The combined extracts were dried over $MgSO_4$, concentrated, and purified by distillation.

Methyl 3-Phenyl-3-butenoate: Colorless oil; yield 76%; bp 98—106 °C/4 mmHg. ^1H NMR δ=3.51 (s, 2H, CH_2CO), 3.62 (s, 3H, OMe), 5.22, 5.54 (s, 1H each, olefin), 7.25—7.44 (m, 5H, aromatic). ^{13}C NMR δ=40.5, 51.4, 115.7, 125.2, 127.3, 127.9, 139.1, 140.2, 171.1. IR (neat) 1740. HAMS; Found: m/z 176.0836. Calcd for $C_{11}H_{12}O_2$: M, 176.0837.

Methyl 3-(*p*-Tolyl)-3-butenoate: Colorless oil; yield 77%; bp 110—120 °C/4 mmHg. ^1H NMR δ=2.33 (s, 3H, Me), 3.50 (s, 2H, CH_2CO), 3.65 (s, 3H, OMe), 5.18, 5.51 (s, 1H each, olefin), 7.13, 1.32 (d, J=8.3 Hz, 2H each, aromatic). ^{13}C NMR δ=20.7, 40.7, 51.6, 115.0., 125.3, 128.7, 136.4, 137.2, 140.2, 171.4. IR (neat) 1740. HAMS; Found: m/z 190.0994. Calcd for $C_{12}H_{14}O_2$: M, 190.0992.

Methyl 3-(1-Naphthyl)-3-butenoate: Pale yellow oil; yield: 65%; bp 153—156 °C/5 mmHg. ^1H NMR δ=3.54 (s, 2H, CH_2CO), 3.59 (s, 3H, OMe), 5.31, 5.59 (s, 1H each, olefin), 7.33—8.06 (m, 7H, aromatic). ^{13}C NMR δ=43.6, 51.7, 119.7, 125.2, 125.3, 125.4, 125.7, 126.0, 127.7, 128.3, 131.0, 133.7, 139.7, 140.9, 171.3. IR (neat) 1740. Found: C, 79.62; H, 6.28%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%.

General Procedure of Copolymerization of Methyl 3-Phenyl-3-butenoate with Styrene: A representative experiment was given below. A mixture of methyl 3-phenyl-3-butenoate (2.3 g, 13 mmol), styrene (1.5 ml, 13 mmol), and AIBN (17 mg, 0.1 mmol) was freezed and degassed in a pyrex tube. The tube was sealed under vacuum, and then the mixture was heated at 60 °C for 12 h. The resulting solution was poured into methanol. The formed precipitates were separated by filtration, washed with methanol, and dried under vacuum. The crude polymer was dissolved in benzene and poured into methanol. The precipitates were filtered, washed with methanol, and dried under vacuum to give the copolymer as white solids (92 mg). ^1H NMR δ=0.9—2.7 (br, methylene, methine), 2.8—3.05 (br, CH_2CO), 3.1—3.4 (br, CH_2CO), 6.0—7.3 (br, aromatic ring).

The authors are grateful to Dr. Tsutomu Takeichi and Mr. Seigou Kawaguchi of Toyohashi University of Technology for their helpful discussion on the copolymerization of methyl 3-phenyl-3-butenoate with styrene. One of the authors (K. I.) is grateful to the Ministry of Education, Science and Culture for Grant-in-Aid for The Scientific Research No. 63470073.

Reaction of Dichlorotriphenylphosphorane with Bis(trimethylsilyl) Peroxide. A New Method for the Formation of Electrophilic Chlorine Source

Kazusato SHIBATA, Yukinori ITOH, Norihiro TOKITOH, Renji OKAZAKI,* and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received August 23, 1991)

Synopsis. Reactions of dichlorotriphenylphosphorane with bis(trimethylsilyl) peroxide in the presence of some organic compounds have been found to give chlorinated products. Aromatic hydrocarbons bearing electron-donating substituents give the corresponding monochloroarenes, while an enol silyl ether is converted into α-chloro ketone. The mechanism is briefly discussed.

In the course of our study on silicon-Polonovski reactions,[1] we became interested in a reagent which was capable of transferring "Me_3SiO^+" species. We thought that the reaction of dichlorotriphenylphosphorane (DCTP) with bis(trimethylsilyl) peroxide (BSPO) would afford a peroxide **1** which might act as a "Me_3SiO^+" source (Scheme 1).

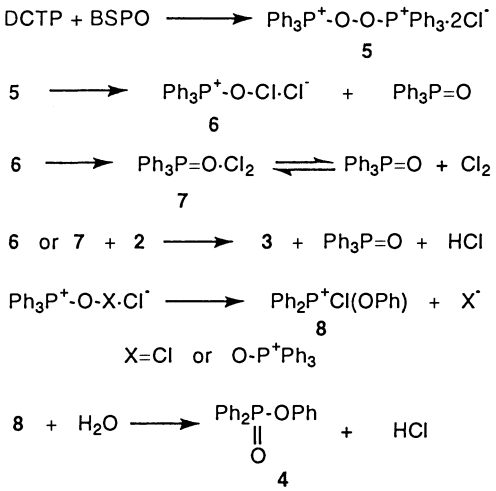
We have found that the reaction of DCTP with BSPO does not produce **1** but it provides a new source for electrophilic chlorine. Reported and discussed are the results observed for chlorination of some organic substrates using this DCTP-BSPO system.

When the reaction of DCTP (2 equiv) (generated in situ from triphenylphosphine and hexachloroethane[2]) with BSPO (1 equiv) in acetonitrile at room temperature was monitored by ^{31}P NMR, a new, single signal (δ_P=30.4) appeared while the signal of DCTP (δ_P=49.0) disappeared completely. When a similar reaction was carried out using 4 equiv of DCTP and 1 equiv of BSPO, two signals were observed roughly in a 1 : 1 ratio; one was the same as the above-mentioned signal while the other is a signal due to remaining DCTP. These facts clearly indicate that DCTP and BSPO react in a 2 : 1 ratio. Furthermore, ^1H, ^{13}C, and ^{29}Si NMR of the solution resulting from the reaction of 2 equiv of DCTP with 1 equiv of BSPO showed the presence of chlorotrimethylsilane (δ_H=0.00, δ_C=2.3, δ_{Si}=31.65) as a sole compound having a trimethylsilyl group; under identical conditions in acetonitrile an authentic sample of chlorotrimethylsilane showed δ_H=0.00, δ_C=1.92, and δ_{Si}=31.61 while that of BSPO exhibited δ_H=−0.29, δ_C=−2.65, and δ_{Si}=26.57. This observation is also in keeping with the above conclusion that DCTP and BSPO react in a 2 : 1 ratio.

When the reaction of DCTP (2 equiv) with BSPO (1 equiv) was conducted at room temperature in the presence of 1,3,5-tri-*t*-butylbenzene (**2**) (1 equiv), 1,3,5-tri-*t*-butyl-2-chlorobenzene (**3**) was obtained in 86% along with triphenylphosphine oxide (95%) and phenyl diphenylphosphinate (**4**, 5%). A similar reaction using DCTP, BSPO, and **2** in a molar ratio of 4 : 2 : 1 gave **3** in 95% in addition to triphenylphosphine oxide (73%) and the phosphinate **4** (13%).

The formation of **3** is suggestive of the generation of electrophilic chlorine in the reaction of DCTP with BSPO. A plausible mechanism for the reaction is shown in Scheme 2.

A combination of a chloride anion with some organic peroxides such as benzoyl peroxide[3] and nitrobenzenesulfonyl peroxides[4] has been known to act as a chlorinating reagent in electrophilic aromatic substitutions and the corresponding acyl or sulfonyl hypochlorites have been proposed as a species responsible for the chlorination. Although a hypohalite like **6** has not been known in the literature, it can be a chlorinating agent. It is not clear at present, however, whether the real reactive species is **6**, phosphine oxide–chlorine complex **7** or molecular chlorine. It has been reported that phosphine oxides including triphenylphosphine oxide form a complex with halogen.[5] Since the only one ^{31}P NMR signal (δ=30.4) was observed in the reaction mixture from DCTP (2 equiv) and BSPO (1 equiv) as



Scheme 2.

Table 1. Chlorination with Dichlorotriphenylphosphorane (DCTP)–Bis(trimethylsilyl) Peroxide (BSPO) System[a]

Substrate	Reaction time	Product	Yield/%[b]
ArH[c]	6 h	ArCl[c]	86 (95)[d]
Mesitylene	6 h	MesCl[e]	44
Anisole	1 h	*p*-chloroanisole	61 (71)[d]
		o-chloroanisole	7 (9)[d]
	4.5 h		44
10		11	
Ph_2S	2.5 d	Ph_2S=O	12[f]
$(PhCH_2)_3N$	6 d	$(PhCH_2)_2NH \cdot HCl$	20[g]

a) Reactions were carried out in acetonitrile at room temperature using 1 equiv of the substrate, 2 equiv of DCTP and 1 equiv of BSPO. b) Isolated yield except for chloroanisoles where the yields were determined by gas chromatography. c) Ar denotes 2,4,6-tri-*t*-butylphenyl. d) Values in parentheses are yields for the reactions where DCTP(4 equiv) and BSPO(2 equiv) were used. e) Mes denotes mesityl (2,4,6-trimethylphenyl). f) Ph_2S was recovered in 88% yield. g) $(PhCH_2)_3N$ was recovered in 77% yield.

mentioned above, the exchange reaction between **6** and triphenylphosphine oxide as well as the equilibrium between **7** and triphenylphosphine oxide/molecular chlorine is considered to be fast on NMR time scale at room temperature.

Although a mechanism involving an oxygenation followed by a displacement with a chloride anion as shown in Scheme 3 is also conceivable, this possibility can be ruled out by the fact that **9** prepared in a separate experiment from 2,4,6-tri-*t*-butylphenol and DCTP was intact under the reaction conditions even in the presence of chlorotrimethylsilane which might act as Lewis acid by coordination toward the phenolic oxygen to promote an nucleophilic attack by a chloride anion. The formation of the phosphinate **4** can be explained by the shift of a phenyl group in **5** and/or **6** onto the adjacent oxygen atom followed by hydrolysis as shown in Scheme 2. Similar rearrangement of a phenyl group from phosphorus to oxygen has been reported for bis(diphenylphosphinyl) peroxide, $[Ph_2P(=O)O]_2$,[6] suggesting the validity of the involvement of **5** and **6** in the present reaction.

In order to study the scope and limitation of the present chlorinating system (DCTP–BSPO system), some other substrates were submitted to chlorination, the results being summarized in Table 1. Activated arenes such as mesitylene and anisole were also chlorinated, but less reactive substrates like toluene, benzene, and chlorobenzene did not react under similar conditions even when the prolonged reaction time (2 d) was used. This result suggests that the DCTP–BSPO system is less reactive than arenesulfonyl peroxide-chloride system[4] where benzene and toluene are reportedly chlorinated at room temperature. Enol silyl ether **10** was also chlorinated to give α-chloro ketone **11** in a moderate yield, thus providing a new approach to α-chloro ketones. Oxidation of a sulfide to a sulfoxide[6] and dealkylation of a tertiary amine[7] by positive halogen reagents are known processes.

Experimental

Melting points are uncorrected. ^1H (89.60 MHz), ^{13}C (22.53 MHz), ^{29}Si (17.80 MHz), and ^{31}P NMR (36.27 MHz) spectra were measured with JEOL FX-90Q and Brucker AM-500 spectrometers using tetramethylsilane as an internal or external standard for ^1H, ^{13}C, and ^{29}Si NMR, and 85% phosphoric acid as an external standard for ^{31}P NMR. Mass spectra were obtained with a JEOL D-300 mass spectrometer. Gas chromatographic analyses were performed with Shimadzu GC-7A. All reactions were carried out under an argon atmosphere.

Material. Bis(trimethylsilyl) peroxide (BSPO),[9] 1,3,5-tri-*t*-butylbenzene (**2**),[10] and 4,6,6-trimethyl-2-trimethylsilyloxy-1,3-cyclohexadiene (**10**)[11] were prepared by the reported method. Dichlorotriphenylphosphorane (DCTP) was prepared in situ in acetonitrile at room temperature by the method of Appel[2] and used for reactions with BSPO without isolation.

Reaction of 1,3,5-Tri-*t*-butylbenzene (2) with DCTP–BSPO System. An acetonitrile solution of the phosphorane DCTP was prepared[2] by stirring triphenylphosphine (253 mg, 0.966 mmol) and hexachloroethane (229 mg, 0.966 mmol) in acetonitrile (0.4 ml) for 30 min at room temperature. To this solution was added the peroxide BSPO (103 µl, 0.483 mmol) by a syringe (exothermic reaction). After stirring for 30 min an acetonitrile solution (1.4 ml) of **2** was added and the mixture was stirred at room temperature for 6 h during which time white precipitates were formed gradually. The solvent was evaporated to give 520 mg of crude products, which were separated by dry column chromatography (DCC) (silica gel, hexane) to give a mixture of **2** and 1,3,5-tri-*t*-butyl-2-chlorobenzene (**3**) (129 mg), phenyl diphenylphosphinate (**4**) (30 mg, 5%), and triphenylphosphine oxide (257 mg, 95%). The yields of **2** (10%) and **3**[12] (86%) were determined by gas chromatography (column, OV-1; column temperature, 150 °C) by comparing the authentic samples. **3**: ^1H NMR ($CDCl_3$) δ=1.31 (s, 9H), 1.53 (s, 18H), and 7.38 (s, 2H); ^{13}C NMR ($CDCl_3$) δ=30.63, 31.49, 34.96, 37.29, 123.16, 131.36, 147.13, and 147.83.

The phosphinate **4**[13] was identified by NMR and mass spectra; ^1H NMR ($CDCl_3$) δ=6.65—7.54 (m, 5H), and 7.54—8.06 (m, 10H); ^{13}C NMR ($CDCl_3$) δ=120.56, 120.77, 124.62, 127.57, 128.28, 128.87, 129.58, 131.47, 131.96, 132.42, 132.53, and 133.72; ^{31}P NMR δ=28.8 (CH_3CN); δ=30.4 ($CDCl_3$); MS *m/z* (rel intensity) 294 (M^+, 52), 293 (53), 20 (100), 77 (71), 65 (25), and 51 (44).

Reactions of Other Substrates with DCTP–BSPO System. Reactions with other substrates were carried out in a similar way to that described for **2**.

(a) Reaction with mesitylene (112 mg, 0.935 mmol), after separation by preparative TLC, gave 2-chloro-1,3,5-trimethylbenzene[14] (63 mg, 44%), phosphinate **4** (55 mg, 9%), and triphenylphosphine oxide (483 mg, 87%) along with recovered mesitylene (11%). 2-Chloro-1,3,5-trimethylbenzene: ^1H NMR ($CDCl_3$) δ=2.19 (s, 3H), 2.28 (s, 6H), and 6.78 (s, 2H); ^{13}C NMR ($CDCl_3$) δ=20.48, 20.61, 129.18, 131.59, 135.49, and 135.81.

(b) In the reaction with anisole (100 µl, 0.92 mmol), the products, chloroanisoles, were analyzed by gas chromatog-

raphy (column, Carbowax 20M; column temperature, 130 °C). The yields thus obtained are listed in Table 1. The yields of **4** and triphenylphosphine oxide were not determined.

(c) Reaction products with enol silyl ether **10** (0.23 ml, 0.973 mmol) were purified by DCC (silca gel, hexane : ether=2 : 1—1 : 2) to give 6-chloro-3,5,5-trimethyl-2-cyclohexen-1-one (**11**) (74 mg, 44%),[15] phosphinate **4** (18 mg, 3%), triphenylphosphine oxide (544 mg, 97%), and 3,5,5-trimethyl-2-cyclohexen-1-one (isophorone) (23 mg, 17%) which was identified by comparison with an authentic sample. **11**: ^{1}H NMR ($CDCl_3$) δ=0.84—1.35 (m, 6H), 1.80—2.15 (m, 3H), 2.15—2.50 (m, 2H), 3.99 (s, 1H), and 5.85 (br s 1H); ^{13}C NMR ($CDCl_3$) δ=23.78, 24.27, 26.30, 27.95, 38.17, 43.12, 69.26, 123.08, 160.22, and 191.85; MS *m/z* (rel intensity) 172 (M^+, 16), 118 (11), 116 (29), 82 (100), 77 (11), 54 (11), 53 (12), and 52 (16).

(d) Reaction of tribenzylamine (159 mg, 0.553 mmol) gave white precipitates (tribenzylamine hydrochloride, 115 mg, 64 %) after 2.5 d. DCC (alumina, ether) of the filtrate afforded tribenzylamine (20 mg, 13%), dibenzylamine hydrochloride (26 mg, 20%), **4** (56 mg, 34%), and triphenylphosphine oxide (71 mg, 47%).

(e) Reaction of diphenyl sulfide (0.14 ml, 0.84 mmol) afforded, after DCC (silica gel, hexane–ether), diphenyl sulfoxide (21 mg, 12%) and triphenylphosphine oxide (468 mg, 96%) along with recovered diphenyl sulfide (88%). Diphenyl sulfoxide was identified by comparison with an authentic sample prepared by oxidation of diphenyl sulfide with *m*-chloroperbenzoic acid.

The authors thank Shin-etsu Chemical Co., Ltd. and Tosoh Akzo for the generous gift of chlorosilanes and alkyllithiums, respectively.

A Convenient Synthesis of Sulfones by the Oxone Oxidation of Sulfides in an Aprotic Solvent in the Presence of Clay Minerals

Masao HIRANO, Jun-ichirou TOMARU, and Takashi MORIMOTO*
Department of Applied Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received June 28, 1991)

Synopsis. The title oxidation in dichloromethane in the presence of "wet"-montmorillonite and -kaolin afforded the corresponding sulfones in excellent to almost quantitative yield under neutral and mild conditions.

Sulfones are an important intermediate in organic synthesis and, thus, a large number of types of reactions have been developed.[1] Among these, oxidative procedures have been readily accessible and there have been ample methods for this objective.[2] However, there is still a need for effective, inexpensive, and manipulatively secure and simple methods that are performable under mild conditions.

Recently, Oxone[3] has attracted considerable interest because of its versatility as an oxygen-donor for Baeyer–Villiger-type lactonization,[4] the epoxidation of olefins,[5] and the oxidation of sulfides to sulfoxides[6] and sulfones.[4,7] However, Oxone chemistry in a water-free solvent has been hardly explored compared with routine oxidation under aqueous conditions.[4–7] In the course of studies on Oxone oxidation in non-aqueous media,[8] we have disclosed that a montmorillonite clay serves as a highly reactive site for Oxone in the oxidation of sulfides to the sulfones,[8c] which prompted us to search for an initiative and extensive application of various clay minerals for organic synthesis. This paper describes the oxidation of sulfides with Oxone in an aprotic solvent in the presence of such clay minerals as montmorillonite and kaolin, since the reaction offers a facile synthesis of sulfones, the results of which are comparable to chemoselective oxidation under aqueous conditions.[7]

Results and Discussion

The oxidation of sulfides with Oxone in an aprotic solvent was carried out in an inert atmosphere in order to avoid autoxidation. A product study by GLC showed that in addition to a sulfoxide as an incipient product, the sulfone was concomitantly formed, even during the early stage of the reaction. It has been generally accepted that the priority of the formation of a sulfoxide or a sulfone depends on the concentration of the oxidant, as is typically observed in peroxy acid oxidations.[2] In view of an analogous property of Oxone to peroxy acids,[4] the effect of the concentration of Oxone on the selectivity of the products, **2** and **3**, in the oxidation of methyl phenyl sulfide (**1**) was examined. Upon treatment of **1** with one equiv of Oxone in dichloromethane (DM) at room temperature for 24 h, a mixture of **2** (40%) and **3** (18%) was formed, even

$$\underset{\mathbf{1}}{\mathrm{PhSMe}} \xrightarrow{\text{Step 1}} \underset{\mathbf{2}}{\mathrm{PhSOMe}} \xrightarrow{\text{Step 2}} \underset{\mathbf{3}}{\mathrm{PhSO_2Me}}$$

though a considerable amount of **1** (42%; by GLC) still remained. The failure of the selective formation of **2** can be explained in terms of a relatively high susceptibility of **2** to a further oxidation to **3**; this phenomenon is distinctly in contrast with peroxy acid and periodate oxidations,[2] where step 2 is much slower than step 1. Consequently, our interest has been focused on a selective and facile synthesis of the sulfones. To determine favorable conditions for the formation of a sulfone, the effects of the reaction variables on the reactivity of a sulfide, as well as on the selectivity and the yield of the sulfone, were initially investigated.

In the absence or presence of a commercial "dry"-clay mineral, the oxidation of a sulfide was considerably slow, giving a mixture of the sulfoxide and the sulfone. Indeed, the oxidation of **1** ([Oxone]/[**1**]=2.5; mole ratio) in DM at room temperature for 24 h in the absence or presence of a commercial montmorillonite gave 50 or 44% of **2** and 27 or 56% of **3**, respectively (by GLC); 23% of **1** remained in the former case. Whilst in the presence of "wet"-montmorillonite (see Experimental) **1** was completely consumed, even within 2 h under comparable conditions, solely giving **3**. These results indicate that "wet"-montmorillonite plays an important role in facilitating the oxidation. The use of a greater or less amount of "wet"-montmorillonite and of a reagent with a greater or smaller water content than that indicated in the Experimental section resulted in an inferior yield of the sulfone.

The effect of solvents was then examined in the presence of "wet"-montmorillonite. The reactivity of a sulfide was not so affected by the solvents, but the product distribution was strongly dependent on the solvents. For example, upon the oxidation of **1** in benzene, DM, and tetrahydrofuran at room temperature for 2 h ([Oxone]/[**1**]=2.5), **3** was selectively formed; **3** could be isolated in 92, 98, and 95% yields, respectively. Mixtures of **2** and **3**, however, were formed in other solvents in varying ratios: viz., in hexane, $CHCl_3$, CCl_4, ether, AcOEt, MeCN, and acetone, 88, 61, 90, 87, 89, 75, and 94% of **3**, along with 12, 39, 10, 13, 11, 25, and 6% of **2** were formed (by GLC), respectively.

The electronic effect of a ring substituent on the reactivity of a sulfide was also examined in the oxidation of the methyl phenyl sulfides. The time dependence of the product distribution in the oxidation of **1**, and the consumption curves of **1** and the *p*-MeO (**4**) and *p*-NO_2 derivatives, are illustrated in Fig. 1. The apparent reactivity order of the sulfides could be related to the electron-donating property of *para*-substituents, viz. MeO>H>NO_2, as observed in peroxy acid oxidations.[2b] The conversion of sulfoxide (**5**) to the sulfone (**6**) was also faster than that of **7** to **8**; the reaction of

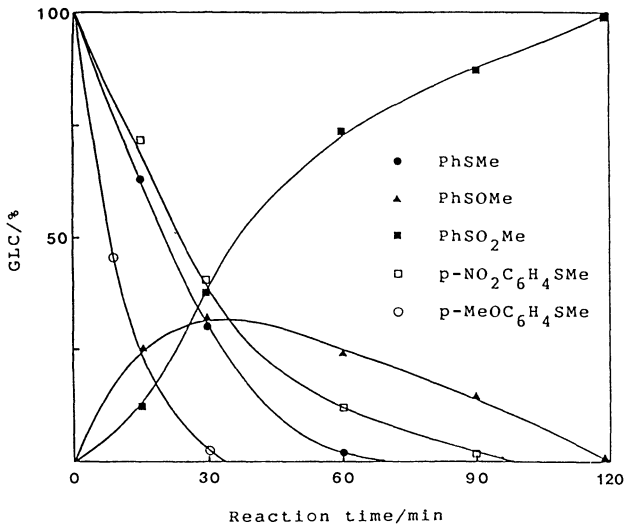

Fig. 1. Conversions and products distribution vs. reaction time in the oxidation of the methyl phenyl sulfides; reaction conditions are identical to those indicated in the oxidation procedure (see the Experimental section).

Table 1. Oxidation of Sulfides with an Oxone–"Wet"-Kaolin System[a]

a) Under argon and under reflux; 1 mmol of sulfide, 1.2 g of "wet"-kaolin, 7 cm^3 of CH_2Cl_2, and ca. 100 cm^3 of an eluent were used in every run; [Oxone]/[Sulfide]=2.5 (mole ratio). b) Isolated yields. c) [Oxone]/[Sulfide] =3.0 (mole ratio). d) In benzene (6 cm^3) at 333 K.

p-$MeOC_6H_4SOMe$ (**5**) *p*-$MeOC_6H_4SO_2Me$ (**6**)

p-$NO_2C_6H_4SOMe$ (**7**) *p*-$NO_2C_6H_4SO_2Me$ (**8**)

4 was thus completed in a shorter period.

Based on the data described above, a synthetic reaction of sulfones was performed at room to reflux temperature in DM in the presence of "wet"-montmorillonite. Using 2.5 moles of Oxone per mole of a sulfide is recommended, since the reaction with two equiv or with a slightly greater amount of Oxone is rather slow. It should be noted that efficient stirring is essential to ensure a smooth oxidation and also to obtain a reproducible result. Under these conditions, the reactions were completed in one to several hours and there was no detectable amount of by-products, giving pure sulfones in usually better than 90% yields.[8c] In order to obtain a high yield of the sulfones, an appropriate choice of an eluent is necessary (see also the forth column in Table 1), since the yield of a sulfone strongly depends on the eluent used. Indeed, **8** was isolated in 70, 60, 67, 96, and 91% yields when DM, ether, $CHCl_3$, AcOEt, and acetone were used as eluents, respectively.

The oxidation of sulfides was also carried out in the presence of "wet"-kaolin in DM in a manner similar to that with an Oxone–"wet"-montmorillonite system, except that the reaction was conducted at an elevated temperature (reflux) and for a longer period, since the efficiency of kaolin is slightly inferior to that using montmorillonite. The results are presented in Table 1. The aromatic-ring (Entries 1—8) and the heterocyclic-ring (Entry 18), as well as the allylic double bond (Entry 9) were found to be intact, leading to a selective formation of the sulfones in excellent yields. The electronic effect of the substituents on the benzene-ring regarding the yield of the sulfones was small (Entries 1—5); they afforded almost quantitative yields of the sulfones. In all instances, some differences in the concentration of Oxone and the reaction times could be mainly ascribed to a difference in the reactivity of the sulfides. Although diphenyl sulfide showed an exceptionally low reactivity in DM (Entry 6), which gave only 75% of the sulfone (**9**), along with 22% of the sulfoxide, the reaction in benzene at 333 K for 3 h exclusively yielded **9** in 90% yield (Entry 7).

The present system is closely related to a conventional clay-supported reagent[9] in the sense that the reaction should be considered to occur on an external surface and/or in an interlayer of a clay mineral, because of the negligible solubility of Oxone in organic solvents, although a relative significance of the phases is obscure. Since the present purpose was synthetic, clear information concerning the observed effects of water and solvents on the reactivity of the sulfides and of the eluents on the yield of sulfones has not yet been obtained. It is well known[9,10] that in addition to water, inorganic as well as organic molecules are adsorbed on a clay surface, and the resultant swelling of the clay, complexation of the clay with these species etc. exert a modified activity of the clay and/or a specific product selectivity. The present reaction may be affected by diverse combinations of possible interactions of a clay with Oxone, a sulfide and/or a sulfone, as well as a solvent (or an eluent), the elucidation of which would provide a satisfactory explanation for the results.

In summary, the oxidation of sulfides with Oxone–"wet"-clay mineral systems in dichloromethane efficiently afforded sulfones in excellent yields. All of the reagents used are inexpensive and safe to handle, and the reaction is fairly clean. The system can be treated just like a clay-supported reagent and, thus, the procedures for isolating the sulfones are facile; it can be emphasized, however, that the reaction is performable instantly without any preparation of a supported re-

agent. The present system thus constitutes an improved version not only of a clay-supported reagent, but of the previous method under aqueous conditions,[7] owing to there being no need to buffer the reaction medium or to carry out tedious work-up procedures. An estimation of the scope and limitations of the systems for organic synthesis is now being undertaken.

Experimental

^{1}H NMR spectra were measured with a JEOL PMX-60 spectrometer for solutions in carbon tetrachloride or deuteriochloroform. IR spectra were recorded for thin films (neat) or KBr disks on a JASCO A-100 spectrophotometer. GLC was carried out on a Shimadzu GC-4CM instrument with a 2 m column packed with Silicone OV-17 on Shimalite WAW-DMCS, with temperature programming.

Starting Materials. All sulfides are commercially available and were used without purification. Oxone and clay minerals are also commercially available. The solvents were rigorously dried and distilled. The "wet"-clay mineral was prepared by adding distilled water (2 g) in eight portions to a commercial clay mineral (10 g) and by vigorous shaking of the mixture upon every addition for a few minutes until a free-flowing powder was obtained.

Oxidation Procedure. The typical procedure is as follows. To a cloudy slurry of "wet"-montmorillonite (1.2 g) and Oxone (2.5 moles of a sulfide) in dichloromethane (6 cm^3; 7 cm^3 of the solvent was used in the case of "wet"-kaolin) in a round-bottommed flask was added methyl phenyl sulfide (1 mmol) in a portion. The flask was flushed with dry argon and then capped with either a glass stopper or a silicon-rubber septum, through which the supernatant was withdrawn by a microsyringe at intervals in order to follow the progress of the reaction. After magnetic stirring for 2 h at room temperature, the whole mixture was transferred onto a Pyrex Buchner funnel with a fritted glass disk; the product was thoroughly eluted with dichloromethane (required ca. 100 cm^3). Rotary evaporation of the combined clear solvent in vacuo left pure (100% by GLC) methyl phenyl sulfone.

The sulfones, thus prepared, had satisfactory purities (over 98%) and were identified by their NMR and IR spectra, as well as the GLC retention times with those of authentic samples.

The partial financial support from Nippon Silica Industrial Co., Ltd. and Daicel Chemical Industries, Ltd. is gratefully acknowledged.

Selective Hydroxymethylation of Emodin

Tarasankar PAL* and Anjali PAL
Department of Chemistry,
Indian Institute of Technology, Kharagpur 721302, India
(Received March 30, 1991)

Synopsis. Electrochemical oxidation of 1,3,8-trihydroxy-6-methylanthraquinone, emodin, in dry alkaline methanol under a constant current of 0.05 A for 10 h under an applied potential difference of 15 V at room temperature resulted, for the first time, in an efficient and selective hydroxymethylation at C-2. The structure of the product was established from the detailed spectral analyses of its trimethyl ether and tetraacetylated derivative.

The field of electrochemistry, so far added many incredible routes to various electroorganic syntheses. Oxidative phenol coupling reaction has also enjoyed its applicabilities when tried with a number of simple substituted phenols,[1-4] though in some cases they ended with usual oxidation products,[5,6] The electrooxidative coupling of phenols has also been extended towards the synthesis of the alkaloidal skeletons.[7-9] Compared with other oxidation routes, electrooxidation appears to be more sensitive to steric factors and the tendency towards the specific formation of the single isomer on electrooxidation is rationalized as arising from a surface reaction, presumably on or near the electrode surface. In spite of the synthetic utility of such an oxidation procedure phenolic polyaromatic quinones, however, remained totally unexplored, though many of them can be used as dyes,[10] and bear clinically important antitumor activities, [11] and indicator properties.[12]

Our primary target was therefore to dimerize 1,3,8-trihydroxy-6-methylanthraquinone, emodin (**1**) an uniquely functionalized phenolic anthraquinone by electrochemical means simulating its chemical transformation.[13,14]

In this report, we wish to present our findings on the electrochemical reaction on emodin (**1**) in dry alkaline methanolic solution, which resulted in the isolation of the hydroxymethylated emodin (**2**) as the sole product (ca. 38%). Anodic oxidation of phenols in methanol has been reported to be a viable route to methoxylation

in many cases.[15–18] However, here a hydroxymethylated product was isolated from this type of reaction. The most interesting feature of the product isolated from the reaction in methanol involved the incorporation of the solvent and that too through the formation of a C–C bond, instead of a C–O bond. So this type of hydroxymethylation reaction may have a potential to be used for the synthesis of several important naturally occurring anthraquinonoid compounds like ferruginol,[19] lucidin,[20] tritisporin,[21] asperthecin[22] etc.

The reaction apparently seems to proceed through the formation of a radical cation (**1a**—**c**) followed by the solvent incorporated addition via hydrogen abstraction (Scheme 1). Such type of hydroxymethylation is well known in photochemistry.[23] However, generation of carboxymethyl[24] or nitromethyl[25] radicals by electrolysis of acetic acid and nitromethane in presence of some inorganic or organic mediators are possible, which speaks in favor of the formation of hydroxymethyl radical from methanol. Thus the introduction of hydroxymethyl group in the product isolated seems to be rather unusual though not improbable. The formation of the sole product is the outcome of the balance of the steric and stereoelectronic factors of the radical cation. The other way, the reaction can be rationalized as a hydroxymethylation caused by formaldehyde in-cell generated from the oxidation of methanol in presence of alkali. Such an electrooxidation of methanol to formaldehyde is well documented during the industrial preparation of glycol.[26] In that case also the selective orientation of hydroxymethyl group, as reflected in the product **2**, occurs most efficiently. In this context it is worthwhile to mention that when emodin was allowed to react with formaldehyde in presence of alkali at room temperature, it gave three products, the minor one isolated being authenticated as **2**.

Conversion of emodin (**1**) into **2** was accomplished by carrying out the electrolysis of a dry alkaline methanolic solution of emodin with Pt electrodes for 10 h. The product was established unambiguously to be 2-(hydroxymethyl)emodin (**2**) by a detailed comparative study of the ^{1}H NMR spectral data of the trimethyl ether (**3**) and the tetraacetylated derivative (**4**) of the product with those of the emodin trimethyl ether (**5**)[13] and emodintriacetate (**6**)[27] respectively.

Thus the absence in the ^{1}H NMR spectrum ($CDCl_3$) of **3** of a one proton signal at δ=6.72 corresponding the readily identifiable most upfield aromatic proton signal for H-2 in **5** and the appearance of the proton signal at δ=7.50 as a very sharp singlet, which can be attributed to H-4 of **3** in analogy with H-4 (δ=7.30) of emodin trimethyl ether (**5**), clearly indicates the hydroxymethylation has taken place at C-2. The remaining two aromatic protons appear as two separate doublets at δ=7.10 and 7.67 and can be recognized as H-7 and H-5 respectively when compared with H-7 (δ=7.02) and H-5 (δ=7.57) of trimethyl ether (**5**) of emodin. The coupling (2.0 Hz), however, while lower than is typical for *meta*-standing protons, is not outside the range of some examples, e.g., phthalic acid (0.5 Hz), isophthalic acid (1.6 Hz) and catechol (1.3 Hz). The three aromatic methoxyls in **3** resonated at expected positions (δ=4.0, 3H, s and 4.07, 6H, s). The aromatic methyl appeared at δ=2.50 (3H, s). The presence of two benzylic protons adjacent to a hydroxyl group in **3** is revealed by the appearance of a two proton singlet at δ=4.8.

Table 1. Carbon-13 NMR Spectral Data of Emodin Trimethyl Ether (**5**) and the Trimethylated Derivative of the Product (**3**)

Carbon atoms	Chemical shifts (δ values)	
	5	**3**

a) In the absence of adequate data of appropriate model compounds definite assignments were not made. b)—d) Values are interchangeable.

A very interesting feature of the ^{1}H NMR spectrum of the tetraacetyl derivative of **2** is the extraordinary upfield shift of one of the acetoxymethyl groups (δ=2.03) and the other three appeared at δ=2.40, 2.46, and 2.53, which clearly indicates the presence of one aliphatic and three aromatic acetoxyl groups. The benzylic protons appeared at δ=5.30 (2H, s). The aromatic protons resonated at δ=7.35 (1H, d, J=2 Hz; H-7) and δ=8.15 (2H, d, J=2 Hz; H-5) [the signal of H-4 was embedded in the signal of H-5] could also be rationalized when compared with the ^{1}H NMR spectrum[27] of emodintriacetate (**6**).

The most convincing evidence in support of the structure **2** for the product was provided by a comparison of the ^{13}C NMR spectral data of its trimethyl ether (**3**) with those of trimethyl ether (**5**) of emodin[13] (Table 1). The noise-decoupled spectrum of **3** displays 19 carbon signals. The degree of protonation of each carbon atom of the compound was determined by Attached Proton Test (APT) method[28] and the assignments of the carbon chemical shifts were made on the basis of the reported δ_c values of the appropriate anthraquinone monomers.[29]

Experimental

Mps reported are uncorrected. Silica gel (60—100 mesh) was used for column chromatography. TLC analyses were on silica gel plates with 0.2 mm thickness (E. Merck). In all cases of NMR measurements $CDCl_3$ was used as the solvent and TMS as the internal standard. IR spectra were run on a Beckman 20 spectrophotometer, ^{1}H and ^{13}C NMR spectra on a Varian EM-390 instrument operating at 90 MHz and Varian

LX300 (75 MHz) instrument respectively. MS was recorded in an instrument equipped with a direct inlet system and operating at 70 eV. All analytical samples were routinely dried over P_2O_5 for 24 h in vacuo. Na_2SO_4 was used for drying and petrol used had bp 60—80 °C.

Electrolysis and Product Analysis. Electrolysis of the dry methanolic solution (70 ml) of emodin (**1**, 0.14 g) in alkaline medium (pH 9.0 with respect to NaOH) was carried out at a constant current (0.05 A) for 10 h under an applied potential difference of 15 V at room temperature, using platinum plates with an area of 1 cm^2 as the electrodes. After the electrolysis, the electrolytic solution was acidified with 1 M (M=mol dm^{-3}) HCl and then extracted thrice with 30 ml portions of ether. The combined ether layers were dried over anhydrous Na_2SO_4, the solvent was evaporated and the residue was chromatographed.

Unconverted emodin (**1**, 0.06 g) was obtained from the earlier petrol–EtOAc (5:1) eluate and subsequent elution of the column with petrol–EtOAc (3:1) gave 2-(hydroxymethyl)emodin (**2**, 0.054 g) as an orange-red solid, mp>300 °C (petrol–EtOAc); TLC R_f 0.53 (silica gel, 1:1 petrol–EtOAc); IR (KBr) 3550 (OH) cm^{-1}; MS m/z 300 (M^+). Found: C, 64.30; H, 4.11%. Calcd for $C_{16}H_{12}O_6$: C, 64.00; H, 4.00%.

General Procedure for the Formation of the Trimethyl Ether of 2-(Hydroxymethyl)emodin. A solution of 2-(hydroxymethyl)emodin (**2**, 0.025 g) in dry acetone (100 ml) was heated under reflux with Me_2SO_4 (3 ml) over anhydrous K_2CO_3 (100 g) for 10 h. Usual work up and careful column chromatography of the reaction product yielded, along with the tetramethyl ether as a minor product,[12] the trimethyl ether **3** (0.018 g), mp 215 °C (petrol–EtOAc); TLC R_f 0.16 (silica gel, 1:1 petrol–EtOAc); ^1H NMR δ=2.50 (s, 3H, CH_3), 4.0 (s, 3H, OCH_3), 4.07 (s, 6H, OCH_3), 4.80 (s, 2H, CH_2O), 7.10 (d, 1H, J=2.0 Hz, 7-H), 7.67 (d, 1H, J=2.0 Hz, 5-H), 7.50 (s, 1H, 4-H); IR (KBr) 3500 (aliphatic OH) cm^{-1}; MS m/z 342 (M^+). Found: C, 66.80; H, 5.28%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.26%. As the major product in its petrol–EtOAc (5:1) eluate.

General Procedure of the Formation of the Tetraacetylated 2-(Hydroxymethyl)emodin (4). Usual acetylation of **2** (0.02 g) (Ac_2O/Py) yielded a tetraacetate **4** (0.016 g), mp 190 °C (petrol–EtOAc); TLC R_f 0.66 (silica gel, 1:1 petrol–EtOAc); ^1H NMR 2.03 (s, 1H, aliphatic $OCOCH_3$), 2.40 (s, 3H, $ArOCOCH_3$), 2.46 (s, 3H, $ArOCOCH_3$), 2.50 (s, 3H, Ar-Me), 2.53 (s, 3H, $ArOCOCH_3$), 5.30 (s, 2H, CH_2O), 7.35 (d, 1H, J=2 Hz, 7-H), 8.15 (d, 2H, J=2 Hz, 5-H) [the signal of 4-H was embedded in the signal of 5-H]; IR (KBr) 1740 (aliphatic $OCOCH_3$) and 1780 (aromatic $OCOCH_3$) cm^{-1}; MS m/z 468 (M^+). Found: C, 61.70; H, 4.29%. Calcd for $C_{24}H_{20}O_{10}$: C, 61.53; H, 4.27%.

We are grateful to our group leader Dr. Tuan Vo-Dinh of the Oak Ridge National Laboratory, Oak Ridge, Tennessee for his invaluable suggestions and all possible help to complete the work.

Absorption and Fluorescence Spectra of 1-Methyl-2(1*H*)-pyridinimines and 2-Methylaminopyridine-Acetic Acid Complex

Akira FUJIMOTO and Kozo INUZUKA*
Department of Applied Science, Faculty of Engineering, Tokyo Denki University, Kanda, Chiyoda-ku, Tokyo 101
(Received July 10, 1991)

Synopsis. Upon the addition of acetic acid to 2-methylaminopyridine in isooctane, weak absorption and fluorescence bands appeared near 350 and 465 nm at the tail of the main bands, respectively. These new bands were attributed, on the basis of the spectral results of 1-methyl-, 1,3-dimethyl-, 1,4-dimethyl-, 1,5-dimethyl-, and 1,6-dimethyl-2(1*H*)-pyridinimines, and 1-methyl-2-methylimino-1,2-dihydropyridine, to have originated from 2(1*H*)-pyridinimine moiety (imino-form tautomer) in the 2-methylaminopyridine-acetic acid complex. In addition, the fluorescence quantum yields of the 1-methyl-2(1*H*)-pyridinimines in isooctane were shown to be very small.

Only a limited number of papers have been written on the amino–imino tautomerizations concerning 2-aminopyridine and its related compounds in the ground state.[1–3] In a previous investigation,[1] the UV absorption spectrum of 2-aminopyridine was measured in an acetic acid and isooctane (2,2,4-trimethylpentane) mixed solvent, and its spectrum showed a shoulder band near 335 nm as the concentration of acetic acid increased. A similar shoulder band had been observed at around 345 nm in the case of the 2,6-diaminopyridine–ethanol system; it was assigned to the π, π^* transition of 6-amino-2(1*H*)-pyridinimine.[2] On the other hand, the fluorescence spectra of the 2-aminopyridine-acetic acid system showed a new emission band at 420 nm, and another peak at 360 nm with an increase in the acetic acid concentration.[3] The latter peak was assigned to the monocation species, that is, the aminopyridinium from the fluorescence spectra of 2-aminopyridine in acidic aqueous solution and from the theoretical consideration by the molecular orbital method.[3] However, the shoulder absorption band near 335 nm and the fluorescence band at 420 nm were not clarified experimentally, though these bands had been theoretically assigned to the π–π^* transition of the 2(1*H*)-pyridinimine moiety in the 2-aminopyridine–acetic acid complex.[1,3]

It was found in the present study that the absorption band at 350 nm and the fluorescence bands at 390 and 465 nm for the 2-methylaminopyridine–acetic acid system correspond to the absorption band at 335 nm, and the corresponding bands at 360 and 420 nm for the same system of 2-aminopyridine,[3] respectively. In order to make these bands of 2-methylaminopyridine experimentally more clear the absorption and fluorescence spectra of 1-methyl-2(1*H*)-pyridinimine and its methyl derivatives were investigated by spectroscopic methods.

Results and Discussion

The UV absorption and fluorescence spectra of 2-methylaminopyridine with acetic acid in isooctane solution are shown in Figs. 1 and 2, respectively. The addition of a small amount of acetic acid to 2-methylaminopyridine in isooctane perturbs the absorption spectrum. The large band-shift to the longer wavelength and the appearance of clear isosbestic points at 257 and 305 nm are attributed to the formation of a hydrogen bonded 1 : 1 complex between 2-methylaminopyridine and acetic acid, as shown in Eq. 1.

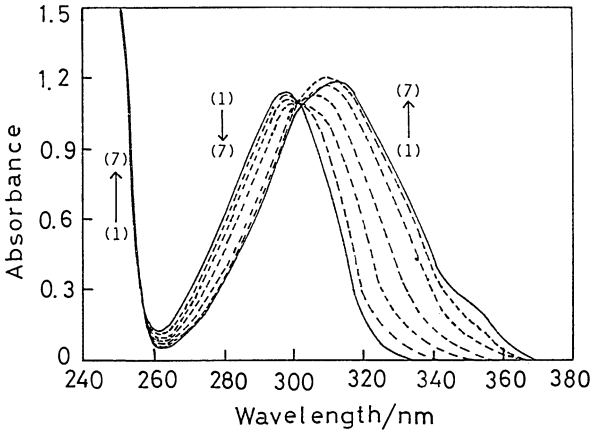

Fig. 1. Absorption spectra of the 2-methylaminopyridine–acetic acid system in isooctane at 20 °C. Concentration of 2-methylaminopyridine: 2×10^{-4} mol dm^{-3}, concentration of acetic acid (mol dm^{-3}): (1) 0, (2) 1×10^{-4}, (3) 5×10^{-3}, (4) 1×10^{-2}, (5) 5×10^{-2}, (6) 1×10^{-1}, (7) 3×10^{-1}.

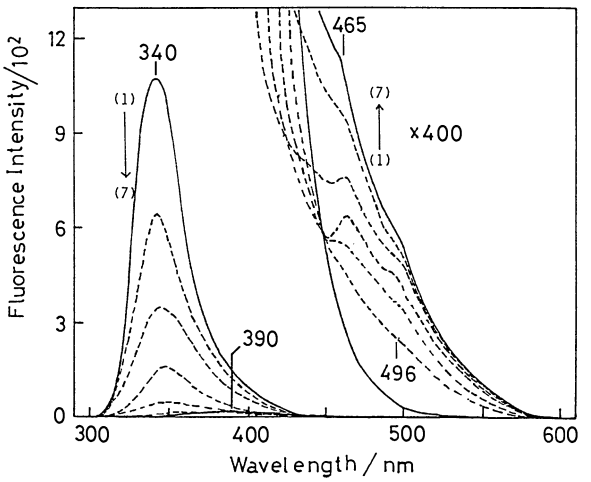

Fig. 2. Fluorescence spectra of the 2-methylaminopyridine–acetic acid system obtained by excitation at 300 nm in isooctane at room temperature. These spectra were measured at the same concentrations as those in Fig. 1.

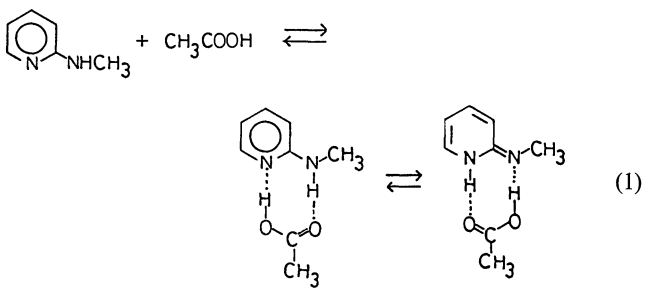

(1)

In a previous paper,[1] similar results had been reported for 2-aminopyridine and its methyl derivatives. In Fig. 1, the absorption band at 315 nm is due primarily to the complex and can be used to determine the equilibrium constant (K) by the method of Benesi and Hildebrand.[4] The enthalpy changes ($-\Delta H$) accompanying hydrogen bond formation can be obtained from knowledge concerning of the variation of K with temperature. In the present experiment the values of K were determined for the methylaminopyridine–acetic acid system at four temperatures within the range from 15 to 40 °C. The values of K, $-\Delta H$, and $-\Delta S$ for 2-methylaminopyridine with acetic acid are 1.8×10^{3} dm^3 mol^{-1} (20 °C), 25.5 kJ mol^{-1}, and 2.5×10^{-2} J K^{-1} mol^{-1}, respectively. The $-\Delta H$ value is smaller than that of 2-aminopyridine with acetic acid (47.3 kJ mol^{-1}).[3] 2-Methylaminopyridine has two conformations with respect to the methylamino group. One of them has a steric hindrance for hydrogen bond formation with acetic acid. The other makes a hydrogen bond without this situation, as shown in Eq. 1. The smaller hydrogen bond energy may be attributed to the above-mentioned two conformations.

Furthermore, upon the addition of acetic acid to 2-methylaminopyridine in isooctane a new, weak shoulder band appeared near 350 nm at the tail of the main band of the hydrogen-bonded complex between 2-methylaminopyridine and acetic acid (Fig 1.). As is shown in Fig. 3, the absorption bands of 1-methyl-2(1H)-pyridinimine[5] and 1-methyl-2-methylimino-1,2-dihydropyridine (as the model of the 2(1H)-pyridinimine moiety (imino-form tautomer) for the 2-methylaminopyridine–acetic acid system) were observed at 345 and 372 nm. These values of 345 and 372 nm are close to the above-mentioned observed value of 350 nm. Therefore, as shown in Eq. 1, it seems reasonable that the shoulder band is due to the 2-methylimino-1,2-dihydropyridine–acetic acid complex formed from the 2-methylaminopyridine–acetic acid complex. The corresponding shoulder bands of the 2-aminopyridine–acetic acid system and the same system of its methyl derivatives had been reported in a previous paper.[1] In Fig. 4, the wavelengthes of the shoulder band of methyl-substituted 2-aminopyridine-acetic acid system and those ones of the absorption band maxima of methyl-substituted 1-methyl-2(1H)-pyridinimine are plotted against the position of the methyl group. Figure 4 shows the existence of a close relationship between the two systems.

On the other hand, the fluorescence spectra of 2-methylaminopyridine in isooctane changes drastically upon the addition of acetic acid (Fig. 2). On the disappearance of the emission at 340 nm with an increase in the acetic acid concentration, a new, very weak emission band appeared at 465 nm; then, with the disappearance of the new, weak emission band, another intense emis-

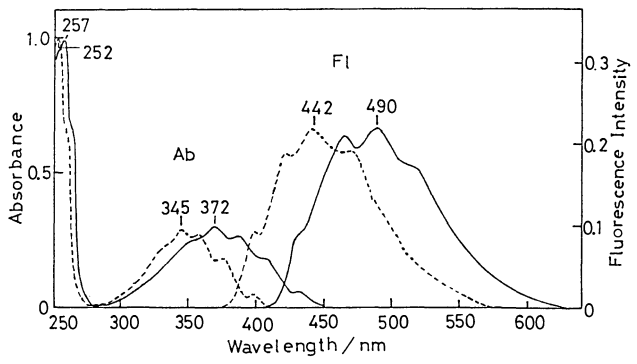

Fig. 3. Absorption (Ab) and fluorescence spectra (Fl) of 1-methyl-2(1H)-pyridinimine (----) and 1-methyl-2-methylimino-1,2-dihydropyridine (——) in isooctane at room temperature. The concentrations of these compounds are 2×10^{-4} mol dm^{-3}.

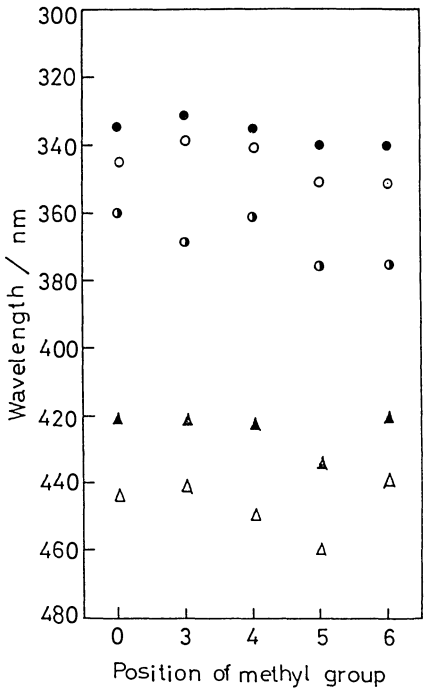

Fig. 4. Plots of the wavelengths of the absorption shoulder bands of the methyl-substituted 2-aminopyridine–acetic acid systems (●), those of the absorption band maxima of methyl-substituted 1-methyl-2(1H)-pyridinimines (○), those of the fluorescence band maxima near 390 nm of the methyl-substituted 2-aminopyridine–acetic acid systems (◑), those of the fluorescence band maxima near 465 nm of the methyl-substituted 2-aminopyridine–acetic acid systems (▲), and those of fluorescence band maxima of methyl-substituted 1-methyl-2(1H)-pyridinimines (△) vs. the position of methyl group. The zero position corresponds to the 2-aminopyridine–acetic acid system or 1-methyl-2(1H)-pyridinimine. The plot ◑ at the zero position is due to the fluorescence band maximum of the pyridinium form of the 2-aminopyridine–acetic acid system.

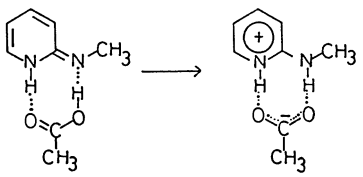
Table 1. Fluorescence Quantum Yields (ϕ_f) of 2-Methylaminopyridine, 2-Aminopyridine, and Unsubstituted and Monomethyl-Substituted 1-Methyl-2(1*H*)-pyridinimines in Isooctane at Room Temperature

Compound	ϕ_f
2-Methylaminopyridine	$(4.0\pm0.4)\times10^{-2}$
2-Aminopyridine	$(4.3\pm0.4)\times10^{-2}$
1-Methyl-2(1*H*)-pyridinimine	$(3.7\pm0.9)\times10^{-5}$
1-Methyl-2-methylimino-1,2-dihydropyridine	$(3.6\pm0.9)\times10^{-5}$
1,3-Dimethyl-2(1*H*)-pyridinimine	$(1.2\pm0.3)\times10^{-5}$
1,4-Dimethyl-2(1*H*)-pyridinimine	$(7.2\pm1.8)\times10^{-6}$
1,5-Dimethyl-2(1*H*)-pyridinimine	$(9.1\pm2.3)\times10^{-6}$
1,6-Dimethyl-2(1*H*)-pyridinimine	$(9.6\pm2.4)\times10^{-6}$

sion peak was observed at 390 nm, as the acetic acid concentration increased. In Fig. 2, a clear isoemissive point is observed at 448 nm in the fluorescence spectra. The emission near 465 nm has a band progression of ca. 1400 cm^{-1}, while that near 390 nm is a broad band. In order to ascertain an experimental interpretation of the emission bands at 465 and 390 nm, the fluorescence spectra of 1-methy-2(1*H*)-pyridinimine and 1-methyl-2-methylimino-1,2-dihydropyridine as the imino-form model of the 2-methylaminopyridine-acetic acid system were measured. As is shown in Fig. 3, emission peaks having a band progression of ca. 1400 cm^{-1} were observed at 442 and 490 nm, respectively. From the similarity of the band progression and position, the new emission band of the 2-methylaminopyridine-acetic acid system at 465 nm may be considered to correspond to the fluorescence band of the 2-methylimino-1,2-dihydropyridine-acetic acid complex (tautomer) formed through the hydrogen-bond formation of 2-methylaminopyridine with an acetic acid. The fluorescence band of the tautomer at 465 nm can be clearly observed by excitation in the region of the absorption shoulder band near 350 nm.

On the other hand, the fluorescence of 2-methylaminopyridine in 0.1 mol dm^{-3} hydrochloric acid was observed at 388 nm. The observed band of 388 nm of 2-methylaminopyridine in the acidic solution is in fair correspondence with that of 390 nm of the 2-methylaminopyridine–acetic acid system. Accordingly, the fluorescence band at 390 nm may be assigned to the 2-methylaminopyridinium produced from the tautomer in the excited states, as is shown in Eq. 2.



(2)

Both of the emission bands near 465 and 390 nm were observed for the 2-aminopyridine-acetic acid[3] and its methyl derivative–acetic acid systems. The wavelengths of the emission band maxima near 465 nm of the methyl-substituted 2-aminopyridine-acetic acid systems are compared with those ones of the fluorescence band maxima of methyl-substituted 1-methyl-2(1*H*)-pyridinimines, as given in Fig. 4. The former is closely related to the latter. Therefore, the fluorescence band near 465 nm of the methyl derivative–acetic acid systems are due to the imino-forms. On the other hand, the fluorescence bands corresponding to 390 nm for the methyl-substituted derivative–acetic acid systems would be due to the aminopyridinium already described above.

The fluorescence quantum yields (ϕ_f) of 1-methyl-2(1*H*)-pyridinimines in isooctane at room temperature are given in Table 1, with those of 2-methylaminopyridine and 2-aminopyridine. It is noted that the ϕ_f's of the pyridinimines are smaller than those of 2-methylaminopyridine and 2-aminopyridine. This result suggests that the fluorescence quantum yields of imino-form of 2-aminopyridines may be appreciably smaller than those of the amino-forms.

Experimental

Commercial 2-methylaminopyridine (Aldrich) was purified by repeated silica-gel column chromatography using ether as an eluent. 1-Methyl-2(1*H*)-pyridinimine and its methyl substituted derivatives were prepared according to a procedure of Taylar et al.[6] These compounds were purified by alumina column chromatography using isooctane as an eluent. The purification of 2-aminopyridine and its methyl derivatives, isooctane, and acetic acid has been described in the literature.[1,3] The UV absorption and fluorescence spectra were measured with Hitachi model 3410 and F-4010 spectrophotometers, respectively. The fluorescence quantum yields were normalized to a value of 0.006[7] for 1-methyl-2-pyridone in alcohol (ethanol containing 10% methanol) mixture.

This work was supported by grants from Tokyo Denki University Research Institute for Technology.

Synopsis. ^{13}C and ^{15}N NMR data are reported for 1,8-bis(dimethylamino)naphthalene (DMAN) and two of its salts in both the solid state and solutions in CD_3CN. Only the ^{15}N results are sufficiently sensitive to show the presence of the fully protonated form of DMAN in the solid state and of a partially protonated structure in solution.

We have previously reported some ^{13}C and ^{15}N NMR results taken on the solid, and in solution, for 1,8-bis(dimethylamino)naphthalene (DMAN) and its monoprotonated salt with tetrazole.[1] It was found that the ^{13}C chemical shifts were relatively insensitive to salt formation whereas the ^{15}N chemical shifts were very informative regarding differences in structures between the solution and solid states. The present report concerns a similar investigation of a further two salts of DMAN.

Results and Discussion

The results of some ^{13}C and ^{15}N NMR measurements on DMAN and two of its salts at room temperature are presented in Table 1 for both the solid state and for solutions in CD_3CN. The reported assignments of the observed NMR signals are straightforward and in the case of the salts with 1-methyl-1,4-dihydro-5*H*-tetrazole-5-thione (MDTT) the procedures given elsewhere[2] were employed. In general, the ^{13}C chemical shifts for a given compound in Table 1 are very similar for both the solid state and solution cases. Thus not all of the observed ^{13}C chemical shifts are reported in Table 1. In contrast the ^{15}N chemical shifts show some significant differences between the solid state and solution. An exception being the ^{15}N signals for the bis(dimethyl-

a) ^{13}C chemical shifts are given with respect to TMS and ^{15}N chemical shifts with respect to neat nitromethane. b) Two methyl ^{13}C signals are observed in the solid state spectrum. These probably are due to packing effects. c) Very broad ^{13}C signal indicating that averaging of the four ring carbon atom environments may not be complete in the solid state.

amino) groups of DMAN. This relative insensitivity of the ^{15}N resonance position to protonation of two dimethylamino groups has been discussed previously.[3]

As noted in the case of the DMAN salt with tetrazole,[1] the N_4 signal of the salt with MDTT shows a large difference between the solid and solution cases. As observed before[1] the solid state ^{15}N signal for N_4 is shielded with respect to that for the solution. In the present case this shielding amounts to about 80 ppm. Comparison of the present ^{15}N chemical shifts for the DMAN salt may be made with those for the free MDTT published previously.[2] For N_4, the position of the signal for the solution of the salt in CD_3CN solution of the salt in CD_3CN solution lies between that of the salt in the solid state and that of the free MDTT in DMSO solution. This suggests that in CD_3CN solution the salt exists in an equilibrium involving the half protonated form of the base as discussed previously.[1]

For the DMAN salt with squaric acid(3,4-dihydroxy-3-cyclobutene-1,2-dione) there are no nitrogen atoms in positions which are sensitive to differences between the solution and solid state cases. However, the averaged position of the ^{13}C signal from the four carbons of the squarate ring shows a small difference between the solution and solid state. Thus ^{13}C NMR is unable to provide information of the type noted above from ^{15}N measurements concerning a possible equilibrium for the salt in solution.

In addition we have some ^{1}H NMR results, for the compounds studied, taken on CD_3CN solutions. We observe that the $N-CH_3$ protons of DMAN are deshielded upon protonation from a chemical shift of 2.7 ppm for DMAN to 3.2 ppm for $DMANH^+Cl^-$, the other salts reported here lie between these values. In the case of $DMANH^+Cl^-$ we have observed $^3J(H-H)$, for the $N-CH_3$ protons and the proton transferred upon salt formation, this is found to be 2.6 Hz in CD_3CN solution. The chemical shift of the transferred proton is observed to be 18.5 ppm, and this proton has a value of 5.1 Hz for $^2J(C-H)$ for its coupling to the carbon atom of the $N-CH_3$ group of DMAN which has a chemical shift of 48.2 ppm in the hydrochloride salt.

The chemical shift of the nitrogen atom in the hydrochloride is -352 ppm which is the most highly shielded of the $N-CH_3$ nitrogens observed in solutions in the present work. Further supporting the conclusion of partial protonation for the other salts studied in solution.

We conclude that nitrogen NMR measurement have again been demonstrated to be the most satisfactory means of investigating the structures studied both in solution and the solid state. Rather less information becomes available for those compounds which do not contain nitrogen atoms in the deprotonated ring.

Experimental

The compounds studied were prepared by published procedures.[4] The solution NMR spectra were taken on a Bruker AM 500 spectrometer operating at 125 and 50.5 MHz for ^{13}C and ^{15}N nuclei, respectively. Solid state NMR measurements were performed on a JEOL GSX 270 instrument operating at 67.5 and 27.3 MHz for the ^{13}C and ^{15}N nuclei respectively. ^{15}N INEPT and inverse gated decoupling measurments were taken on the solutions of the samples.

Studies on Stigmasterol Liquid Membranes

M. L. SRIVASTAVA* and Nikhil K. SHUKLA
Department of Chemistry, University of Gorakhpur, Gorakhpur 273009, U.P. India
(Received December 28, 1990)

Synopsis. Cellulose acetate supported stigmasterol liquid surfactant membrane has been characterized by measuring membrane potentials, using NaCl solutions of different concentrations. Fixed charge density, $\phi\overline{X}$, permselectivity, P_s, have been estimated from ionic transport numbers. Variation of membrane potential with pH and concentration of NaCl solution has also been examined.

Experimental

Cellulose acetate film was prepared as reported elsewhere.[1] The thickness of the film used was 7×10^{-5} m and its cross-sectional area was 1.73×10^{-4} m^2. Water content determined as usual[2,3] was found to be 11.5%.

Results and Discussion

Liquid membranes are formed at every interface encountered by a surfactant solution. Such membranes are of immense importance owing to many of their biological and technological applications.[4-8] The formation of liquid membrane was ascertained by measuring membrane resistance using stigmasterol suspensions of different concentrations. The resistivity changed due to accumulation of stigmasterol in the interfacial region, approaching a constant value after 3—4 h (Fig. 1). Membrane potential was measured using the experimental cell of the type:

Reference Calomel Electrode	Solution	Membrane	Solution	Reference Calomel Electrode

The formation of liquid membrane results in the lowering of membrane potential as it is clear from membrane potential values given in Table 1.

For cellulose acetate which is practically uncharged, the selectivity is considerably low. Permselectivity was estimated using the equation[9]

$$P_s=\frac{\bar{t}_+-t_+}{t_+-(2t_+-1)\,\bar{t}_+}. \quad (1)$$

The transport number on the basis of TMS theory may be given as [10]

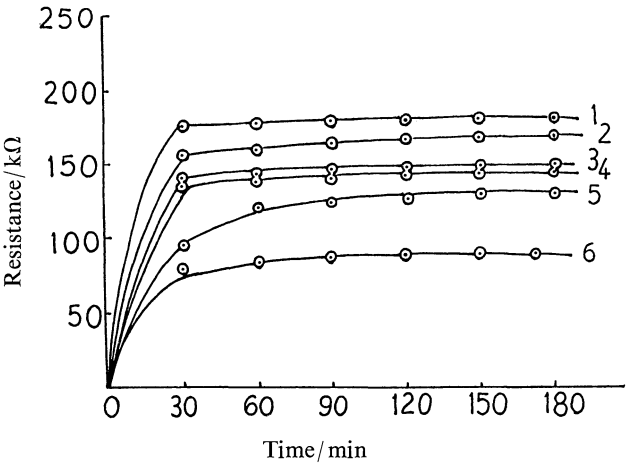

Fig. 1. Variation of resistance with time during liquid membrane formation 1, 30 nM; 2, 25 nM; 3, 20 nM; 4, 15 nM; 5, 10 nM; 6, 5 nM.

Table 1. Membrane Potential Data

Mean concn	C_1	C_2	E/mV

0.075	0.10	0.05	6.8	7.3
0.15	0.20	0.10	6.2	6.8
0.30	0.40	0.20	5.7	5.9
0.60	0.80	0.40	4.9	5.1
0.75	1.00	0.50	4.0	4.5

Table 2. Transport Numbers Derived Using Eq. 2

Mean concn	f_1	f_2	E_{max}/mV	Cellulose acetate $\bar{t}_+$		t_+
mol dm^{-3}				Without Stigmasterol	With Stigmasterol	
0.075	0.7730	0.8336	16.13	0.7107	0.7232	0.402
0.15	0.6949	0.7730	15.31	0.7024	0.7219	0.392
0.30	0.5976	0.6949	14.15	0.7013	0.7083	0.388
0.60	0.4828	0.5976	12.52	0.6955	0.7035	0.379
0.75	0.4430	0.5623	11.87	0.6684	0.6895	0.376

$$\bar{t}_+ = \frac{E}{2E_{max}} + 0.5, \quad (2)$$

where the symbols have their usual meaning. A simplification of TMS theory gives:

$$E = \frac{RT}{F}(2\bar{t}_+ - 1)\ln\frac{a'}{a''} \quad (3)$$

and if the membrane is ideally selective,

$$E_{max} = \frac{RT}{F}\ln\frac{a'}{a''}. \quad (4)$$

Permselectivity is related to fixed charge density as[11]

$$\phi\bar{X} = \frac{2\bar{C}P_s}{\sqrt{1-P_s^2}}, \quad (5)$$

where $\bar{C}$ is the mean concentration. Transport numbers derived using Eq. 2 alongwth the values of E_{max} and activity coefficient (f_1 and f_2) using Eq. 4 are given in Table 2. The values of t_+ (solution) have been obtained from Ref. 12. Permselectivity and and fixed charge density values derived using Eqs. 1 and 5 are given in Table 3. It is clear that the fixed charge density increases with increasing mean concentration.

Cellulose acetate is reported[13] to contain a low concentration of weakly ionizable carboxyl group. In Fig. 2 the membrane potential against pH has been plotted, which shows that due to reduction in selectivity of the cellulose acetate, membrane potential increases with decreasing pH values. A steady increase in the values of membrane potential has been observed when cellulose acetate film supports stigmasterol liquid membrane. Table 4 includes the values of permselectivity and fixed charge density at different pH values.

The values for various parameters in the case of stigmasterol liquid membrane supported on cellulose acetate film are larger than those obtained by Singh and Tiwari,[1] showing that it is more effective surfactant than cholesterol. This may be attributed to basic structural difference between stigmasterol and cholesterol. Stigmasterol inspite of having the same skeleton as cholesterol, possesses a double bond in the side chain. The presence of two sp^2 carbons, which essentially have higher electronegativity than sp^3, would be responsible for enhanced surface activity of stigmasterol leading to

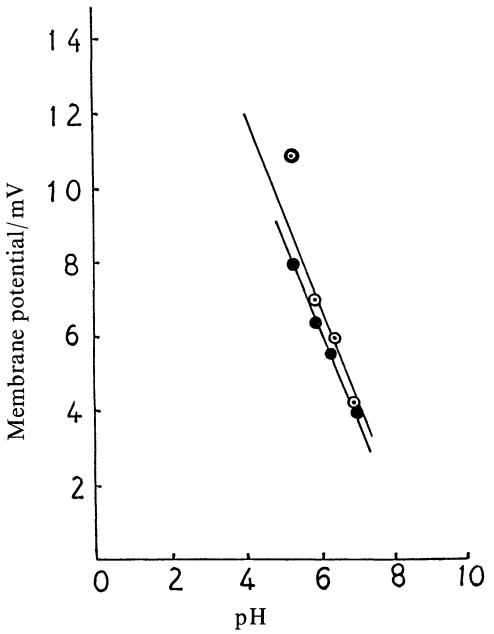

Fig. 2. Variation of membrane potential with pH: ⊙ without stigmasterol, ● with stigmasterol. Mean concentrations of sodium chloride solution used is 0.30 M; C_1=0.40 M; C_2=0.20 M.

Partial Oxidation of [Octakis(dodecyloxy)phthalocyaninato]zinc(II) with 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone

Kuninobu KASUGA,* Tadahiro NAKAO, Takuya MIHARA, and Kunihisa SOGABE†

†Department of Chemistry, Faculty of Education, Shimane University, Matsue 690
(Received July 19, 1991)

Synopsis. While an organic oxidant such as 2,3-dichloro-5,6-dicyano-*p*-benzoquinone oxidized [Zn{Pc($OC_{12}H_{25}$)$_8$}] in a chloroform solution, it did not oxidize H_2Pc($OC_{12}H_{25}$)$_8$ and [Cu{Pc($OC_{12}H_{25}$)$_8$}]. Oxidation was confirmed by the electronic and ESR spectra, as well as cyclic voltammograms. The electrical conductivity of the zinc(II) complex increased 10^5 times in partial oxidation.

The partial oxidation of metallophthalocyanines with iodine, bromine or nitrosyl tetrafluoroborate($NOBF_4$) significantly increased their electrical conductivity.[1] The electrochemical oxidation of the complexes was carried out in solution, resulting in single crystals which exhibit metallic conductivity.[2] The conductivity also increased in a partial reduction of the complexes with metallic potassium or sodium dithionite.[3,4] Furtheremore, phthalocyaninatosilicon(IV) polymers bridged by a halogen or an oxygen atom were prepared, and showed good conductivity under partial oxidation.[5]

It was recently reported that metallophthalocyanine complexes with long-chain alkyl or alkoxy substituents were transformed to discotic mesophase.[6,7] It is of interest to prepare the oxidized metallophthalocyanine derivatives which show conductivity in the mesophase.[8] We previously reported the chemical oxidation of tetra-*t*-butylphthalocyanine, H_2Pc(*t*-Bu)$_4$, and its metal(II) complexes with 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) to confirm their oxidation behavior by chemical oxidants.[9] This paper describes the chemical oxidation of [octakis(dodecyloxy)phthalocyaninato]-zinc(II), [Zn{Pc($OC_{12}H_{25}$)$_8$}], with DDQ, and its conductivity both in the solid state and in the mesophase.

Experimental

Materials. H_2Pc($OC_{12}H_{25}$)$_8$, [Cu{Pc($OC_{12}H_{25}$)$_8$}], and [Zn{Pc($OC_{12}H_{25}$)$_8$}] were prepared in a similar method described in the literature.[7] Bu_4NBF_4 was prepared and purified using the method shown in a text book.[10] DDQ was recrystallized from benzene under an argon atmosphere.

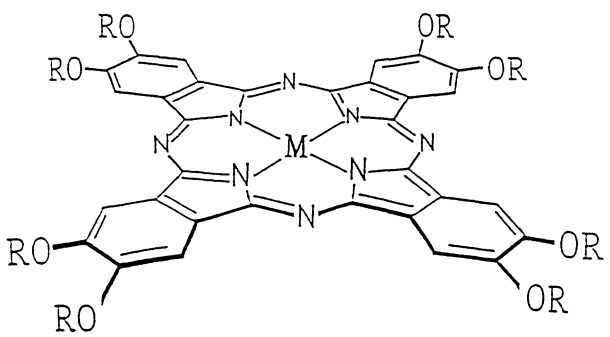

Fig. 1. Schematic representation of the [M{Pc(OR)$_8$}] complex:
OR=$OC_{12}H_{25}$.

Partial Oxidation. The zinc(II) complex was dissolved into a solvent mixture of chloroform and hexane (7 : 3, v/v), to which the chloroform solution of DDQ was added dropwise under a nitrogen atmosphere. The mixture was subsequently stirred at room temperature for several min, and then the dark-black precipitates were obtained upon the concentration of the solution under reduced pressure. The oxidized complex was dried at room temperature under reduced pressure.

Measurements. The electronic spectra in solution were measured on a Hitachi 200-20 spectrophotometer. The ESR spectra were measured with a JEOL-IX spectrometer. Cyclic voltammetric measurements were performed in a chloroform solution containing Bu_4NBF_4 (0.1 mol dm^{-3}) on a Hokuto Denko HA-501 potentiostat with a Hokuto Denko HF-201 function generator.[9] Differential scanning calorimetry experiments were carried out on a Shimadzu DSC-50. Conductivity measurements of pressed pellets were carried out with a two-probe method.

Results and Discussion

By the addition of adequate amounts of DDQ, the green solution of [Zn{Pc($OC_{12}H_{25}$)$_8$}] changed to reddish purple; in the absorption spectrum, the intensity of the Q band at 680 nm decreased, while new bands appeared at 545 and 721 nm. On the other hand, the spectra of the green solution of H_2Pc($OC_{12}H_{25}$)$_8$ or its copper(II) complex did not change upon the addition of DDQ.

When the zinc(II) complex was oxidized with DDQ in a chloroform solution, two ESR signals arising from cationic phthalocyanine ring and anionic DDQ radicals were observed at g=2.002 (line width=7 G) and 2.005 (3 G) at room temperature, respectively. These results show that although the phthalocyanine ring of the zinc(II) complex was oxidized by DDQ, those of H_2Pc($OC_{12}H_{25}$)$_8$ and its copper(II) complex were not oxidized, which is consistent with the oxidation results for H_2Pc(*t*-Bu)$_4$ and its metal(II) complexes.[9]

Cyclic voltammograms of the phthalocyanine derivatives exhibited four redox couples. The half-wave potentials of the first step on the oxidation side are listed in Table 1 to confirm the chemical oxidation. By considering the potential of the first reduction step of DDQ (0.59 V vs. SCE), the zinc(II) complex was only oxidized by DDQ, which is consistent with the results of the absorption and ESR spectra.

H_2Pc($OC_{12}H_{25}$)$_8$ and its copper(II) and zinc(II) complexes showed endothermic peaks at 93, 100, and 107 °C, respectively, indicating their transition to the mesophase.[6,7] The zinc(II) complex doped by DDQ (20 mol %) showed endothermic peaks at 100 °C, and its

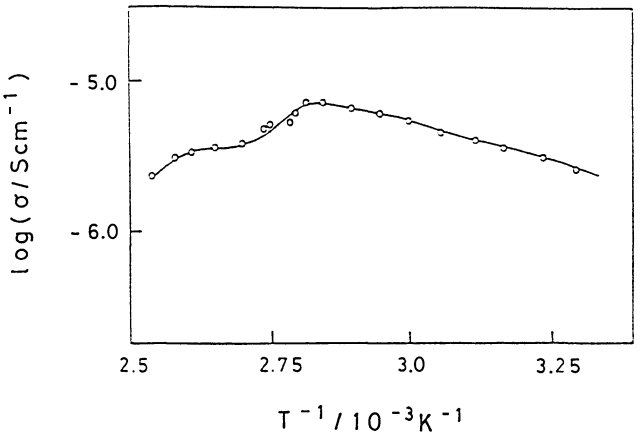

Fig. 2. Specific conductivity (σ/S cm^{-1}) vs. reverse temperature. The concentration of the added DDQ was 20 mol %.

peak reappeared with rising temperature, although the peak shifted to 95 °C with some broadening. Upon the addition of DDQ (more than 20 mol %), the sample did not show the peak.

Although the $[Zn\{Pc(OC_{12}H_{25})_8\}]$ complex was an insulator ($\sigma<10^{-11}$ S cm^{-1} at room temperature) the complex increased its conductivity (2.5×10^{-6} S cm^{-1} at room temperature) in partial oxidation by DDQ (20 mol %) (Fig. 2). In partial oxidation of the complex with $NOBF_4$ (15 mol %), the conductivity was about 10^{-3} times that of the complex doped by DDQ (20 mol %).[11] This may result from the unsuitable position of the tetrafluoroborate anion in the oxidized sample. It was also reported that the conductivity of [bis{octakis(octadecyloxymethyl)phthalocyaninato}lutetium(III)] partially oxidized by phenoxathin hexachloroantimonate (80 mol %) was 1.6×10^{-7} S cm^{-1} at 60 °C.[8] The long paraffinic chains of these phthalocyanine complexes promote the formation of a hexagonal columnar,[12] which might increase the intracolumnar conduction.

The conductivity of the $[Zn\{Pc(OC_{12}H_{25})_8\}]$ complex doped by DDQ increased with rising temperature, but decreased above 80 °C (Fig. 2). The ESR signal arising from the anionic DDQ radical diminished above 80 °C, while that from the cationic phthalocyanine radical remained. The DDQ radical might form an ESR silent dimer upon heating, as shown in the case of cosublimation of [fluoro(phthalocyaninato)aluminium(III)] and DDQ.[13] Although the conductivity seems to decrease with an increase of the temperature in the mesophase, details are presently unknown, because some deformation of the specimen might occur and cause a decrease in the conductivity.

Synthesis and Application of 5-Arylazothiophene Derivatives

Ram Wasudeo SABNIS,* Ghadir KAZEMI, and Dinesh Wamanrao RANGNEKAR
Dyes Research Laboratory, Department of Chemical Technology,
University of Bombay, Matunga, Bombay 400019, India
(Received February 21, 1991)

Synopsis. Synthesis of 5-(hetoarylazo or arylazo)thiophene derivatives (**6a—g**) was achieved by diazotization of ethyl 5-amino-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (**3**) using nitrosyl hydrogensulfate, coupling with suitable heterocyclic hydroxy and *N,N*-dialkyl-substituted arylamines which resulted in thiophene azo dyes. The key intermediate **3**, used as the diazonium component, was synthesized in one pot and in excellent yield from diethyl 3-oxopentanedioate, sulfur and ethyl cyanoacetate following the Gewald Synthesis. The dyes when applied as disperse dyes on polyester fibres gave excellent results.

Several patents[1—6] describe the synthesis and technical importance of azo thiophene disperse dyes. We have recently reported the synthesis of novel heterocyclic dyes and fluorescent brighteners such as benzo[*b*]-thiophenes,[7] thiophenes,[8] 1,2,3-triazoles,[9] pyrimidines,[10] quinoxalines,[11] thiazoles,[12] and their application on synthetic fibres, which gave encouraging results. Thiophene moiety has been extensively studied in the field of medicine[13] and fungicides.[14]

In the present study, we report the synthesis of model compounds of azo dyes derived from novel diazonium component, 5-aminothiophene derivative synthesized by the Gewald Synthesis[15] and their use as disperse dyes for polyester fibres. Azo disperse dyes derived from thiophene have many advantages, such as color deepening effect as an intrinsic property of thiophene ring, small molecular structure leading to better dyeability and heterocyclic structure of thiophene ring resulting in good sublimation fastness of dyed fibres.

Ethyl 5-amino-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (**3**) is a versatile intermediate in the synthesis of heterocyclic systems. The principle advantages of the key intermediate used here are that the yields are high, time of the reaction is short, the procedure involves only one facile step, the work-up is convenient and thus the starting material can be easily prepared. The presence of diazotizable amino group adjacent to electron-withdrawing groups results in deepening of the dye hues on the polyester fibres.

Results and Discussion

The thiophene intermediate, ethyl 5-amino-2,4-bis-(ethoxycarbonyl)-3-thiopheneacetate (**3**), was synthesized from diethyl 3-oxopentanedioate (**1**), sulfur, and ethyl cyanoacetate (**2**) with diethylamine as a catalyst, using the Gewald Synthesis. Compound **3** was diazotized using nitrosyl hydrogensulfate in the cold and coupled with a variety of heterocyclic hydroxy couplers such as 3-methyl-1-phenyl-1*H*-pyrazol-5-ol (**5a**), 3-cyano-4-methylpyridine-2,6-diol (**5b**), 4-hydroxy-1-methylquinolin-2(1*H*)-one (**5c**), 2,4,6-pyrimidinetriol (barbituric acid) (**5d**), and *N,N*-dialkyl-substituted arylamines such as *N,N*-dimethylaniline (**5e**), *N,N*-bis(2-cyanoethyl)aniline (**5f**), 3-chloro-*N,N*-bis(2-hydroxyethyl)aniline (**5g**) to yield ethyl 5-(hetoarylazo or arylazo)-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (**6a—g**).

The absorption maxima of these dyes recorded in their DMF solution are shown in Table 1. Their absorption maxima were in the range of 472—588 nm. The absorption maxima of the dyes **6a—d** derived from heterocyclic hydroxy-coupling components, were in the range of 472—502 nm, whereas dyes **6e—g**, derived from *N,N*-dialkylsubstituted arylamines, showed absorption maxima in the range of 576—588 nm.

Dyes **6a—g** were applied on polyester fibres as 1% shade. The hues of the polyester dyed fibres were golden yellow, orange, red, pink, violet, and blue and are shown in Table 1. The pickup values of the dyed polyester fibres varied from two to three, with most of them having a pickup value of three. The light fastness of these dyes varied from three to six, thus the dye **6d** had poor light fastness (three), dyes **6e**, **6g** had fair

Table 1. Absorption Spectra and Dyeing Properties of 5-Arylazothiophene Derivatives

Dye	Color on dyed polyester fibres	Absorption maxima (nm)	log ε	Pick-up	Light fastness	Sublimation fastness
6a	Brilliant golden yellow	472	4.34	3	6	5
6b	Brilliant orange	484	4.39	3	5	4
6c	Brilliant red	498	4.28	3	5	4
6d	Pink	502	4.19	2	3	3
6e	Blue	588	4.64	2	4	4
6f	Blue	582	4.61	3	5	5
6g	Violet	576	4.57	3	4	4

light fastness (four), dyes **6b**, **6c**, **6f** had good light fastness (five) and dye **6a** had very good light fastness (six). The sublimation fastness of these dyes was in the range of three to five, thus the dye **6d** showed good sublimation fastness (three), dyes **6b**, **6c**, **6e**, **6g** showed very good sublimation fastness (four), dyes **6a**, **6f** showed excellent sublimation fastness (five). Dyes **6a**—**c**, **6f**, and **6g** among these dyes thus showed good fastness properties on polyester fibres.

Experimental

All melting points are uncorrected. The IR spectra were recorded on a Perkin-Elmer Model 397 spectrophotometer in Nujol mull. The ^{1}HNMR spectra were recorded on a Varian-60 MHz instrument EM-360L using TMS as internal standard and the chemical shifts are given in ppm. Mass spectra were recorded on a Varian Mat-311 instrument (70 eV). Absorption spectra in DMF solution were recorded on a Beckman Model-25 spectrophotometer.

Ethyl 5-Amino-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (3). In a 100 ml round bottomed flask, were placed a mixture of diethyl 3-oxopentanedioate (**1**) (20.2 ml, 0.1 mol), sulfur (3.2 g, 0.1 mol), ethyl cyanoacetate (**2**) (11.3 ml, 0.1 mol), ethanol (20 ml), and diethylamine (10 ml). The reaction mixture was stirred on a waterbath for 2 h at 40—50 °C. At the end of the reaction, a reddish brown solid was separated. After cooling to room temperature, the reaction mixture was filtered, washed with cold ethanol and dried. The product was recrystallized from ethanol as shiny white needles. Yield: 87%, mp 179 °C. Anal. Calcd for $C_{14}H_{19}NO_6S$: C, 51.06; H, 5.77; N, 4.25; S, 9.72%. Found: C, 51.11; H, 5.57; N, 4.27; S, 9.74%. IR (Nujol mull) 3330, 3430 (NH_2), 1675 (COOEt), 1720 (CH_2COOEt) cm^{-1}. ^{1}HNMR (DMSO-d_6) δ=1.34 (t, 9H, $3CH_3$), 3.5—4.8 (m, 8H, 4-CH_2)), 5.5—6.1 (s, 2H, NH_2).

Ethyl 5-[(5-Hydroxy-3-methyl-1-phenyl-1*H*-pyrazol-4-yl)-azo]-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6a). Ethyl 5-amino-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (**3**) (1.64 g, 0.005 mol) was added in portions during 1 h to a cooled mixture of nitrosyl hydrogensulfate prepared from sodium nitrite (0.38 g, 0.0055 mol) and concentrated sulfuric acid (10 ml) at 0 °C. The mixture was stirred for an additional 1 h at 0 °C, then added to an ice-water mixture under stirring, excess of nitrous acid was destroyed by the addition of urea (1 g) and the solution was filtered to obtain a clear diazonium salt solution **4**. 3-Methyl-1-phenyl-1*H*-pyrazol-5-ol (**5a**) (0.87 g, 0.005 mol) was dissolved in dilute sodium hydroxide. The solution was cooled by external cooling so that the temperature was at 0—5 °C. To this cooled solution, the prepared diazonium salt **4** was added slowly so that the temperature did not rise above 5 °C. The pH of the reaction mixture was maintained alkaline throughout the coupling period (1 h) by the addition of solid sodium carbonate in portions. After the addition of the diazonium salt was completed, the reaction mixture was stirred for 4 h at 0 °C, when the dye which partially separated was neutralized with dilute hydrochloric acid (5%), filtered, thoroughly washed with water and dried. The product was recrystallized from methanol. Yield: 89%, mp 246 °C. Anal. Calcd for $C_{24}H_{26}N_4O_7S$: C, 56.03; H, 5.05; N, 10.89; S, 6.22%. Found: C, 56.08; H, 5.11; N, 10.82; S, 6.19%. IR (Nujol mull) 3200—3400 (OH), 1680—1700 (COOEt) cm^{-1}.

Ethyl 5-[(2,6-Dihydroxy-5-cyano-4-methyl-3-pyridyl)azo]-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6b). the dye was synthesized in the same manner as given for dye **6a**, except that instead of **5a**, 3-cyano-4-methylpyridine-2,6-diol (**5b**) (0.75 g, 0.005 mol) was used. The product was recrystallized from methanol. Yield: 92%, mp 230 °C. Anal. Calcd for $C_{21}H_{22}N_4O_8S$: C, 51.42; H, 4.48; N, 11.42; S, 6.53%. Found: C, 51.39; H, 4.51; N, 11.46; S, 6.58%. IR (Nujol mull) 3380—3440 (OH), 1660—1700 (COOEt), 2210 (CN) cm^{-1}.

Ethyl 5-[(4-Hydroxy-1-methyl-2-oxo-1,2-dihydro-3-quinolyl)azo-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6c). The dye was synthesized in the same manner as given for dye **6a** except instead of **5a**, 4-hydroxyl-1-methylquinolin-2(1*H*)-one (**5c**) (0.87 g, 0.005 mol) was used. The product was recrystallized from chloroform. Yield: 81%, mp 144 °C. Calcd for $C_{24}H_{25}N_3O_8S$: C, 55.92; H, 4.85; N, 8.15; S, 6.21%. Found: C, 55.93; H, 4.87; N, 8.18; S, 6.23%. IR (Nujol mull) 3310—3400 (OH), 1675—1720 (COOEt), 1680 (CO) cm^{-1}.

Ethyl 5-[(2,4,6-Trihydroxy-5-pyrimidinyl)azo]-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6d). The dye was synthesized in the same manner as given for dye **6a**, except instead of **5a**, 2,4,6-pyrimidinetriol (barbituric acid) (**5d**) (0.64 g, 0.005 mol) was used. The product was recrystallized from ethanol. Yield: 74%, mp 152 °C. Anal. Calcd for $C_{18}H_{20}N_4O_9S$: C, 46.15; H, 4.27; N, 11.96; S, 6.83%. Found: C, 46.08; H, 4.22; N, 11.93; S, 6.81%. IR (Nujol mull) 3200—3400 (OH), 1680—1700 (COOEt) cm^{-1}.

Ethyl 5-[4-(Dimethylamino)phenylazo]-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6e). Ethyl 5-amino-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (**3**) (1.64 g, 0.005 mol) was added in portions during 1 h to a cooled mixture of nitrosyl hydrogensulfate prepared from sodium nitrite (0.38 g, 0.0055 mol) and concentrated sulfuric acid (10 ml) at 0 °C. The mixture was stirred for an additional 1 h at 0 °C, then added to an ice-water mixture under stirring, excess of nitrous acid was destroyed by the addition of urea (1 g) and the solution was filtered to obtain a clear diazonium salt solution **4**. *N,N*-Dimethylaniline (**5e**) (0.60 g, 0.005 mol) was dissolved in acetic acid. The solution was cooled by external cooling so that the temperature was 0—5 °C. To this cooled solution, the prepared diazonium salt **4** was added slowly so that the temperature did not rise above 5 °C. The pH of the reaction mixture was maintained acidic throughout the coupling period (1 h). After the addition of the diazonium salt was completed, the reaction mixture was stirred for 4 h, when the dye which partially separated was neutrallized with sodium carbonate, filtered, thoroughly washed with water and dried. The product was recrystallized from ethyl acetate. Yield: 76%, mp 296 °C. Anal. Calcd for $C_{22}H_{27}N_3O_6S$: C, 57.26; H, 5.85; N, 9.11; S, 6.94%. Found: C, 57.29; H, 5.88; N, 9.16; S, 6.92%. IR (Nujol mull) 1680—1710 (COOEt) cm^{-1}.

Ethyl 5-[4-[Bis(2-cyanoethyl)amino]phenylazo]-2,4-bis-(ethoxycarbonyl)-3-thiopheneacetate (6f). The dye was synthesized in the same manner as given for the dye **6e** except that instead of **5e**, *N,N*-bis(2-cyanoethyl)aniline (**5f**) (0.99 g, 0.005 mol) was used. The product was recrystallized from DMF. Yield: 68%, mp 324 °C. Anal. Calcd for $C_{26}H_{29}N_5O_6S$: C, 57.88; H, 5.38; N, 12.98; S, 5.93%. Found: C, 57.81; H, 5.34; H, 12.92; S, 5.96%. IR (Nujol mull): 1660—1680 (COOEt), 2220 (CN) cm^{-1}.

Ethyl 5-[2-Chloro-4-[bis(2-hydroxyethyl)amino]phenylazo]-2,4-bis(ethoxycarbonyl)-3-thiopheneacetate (6g). The dye was synthesized in the same manner as given for the dye **6e**, except that instead of **5e**, 3-chloro-*N,N*-bis(2-hydroxyethyl)aniline (**5g**) (1.07 g, 0.005 mol) was used. The product was recrystallized from DMF. Yield: 62%, mp >360 °C. Anal. $C_{24}H_{30}ClN_3O_8S$: C, 51.89; H, 5.40; Cl, 6.30; N, 7.56; S, 5.76%. Found: C, 51.81; H, 5.42; Cl, 6.27; N, 7.59; S, 5.72%. IR (Nujol mull) 3320—3400 (OH), 1680—1700 (COOEt) cm^{-1}.
