12-Acetoxy-9,10,11,12-tetrahydrocyclohepta[*a*]phenalen-7-(8*H*)-one (22). To a mixture of acetic anhydride (20 mL) and acetic acid (20 mL) were added **21** (3.5 g, 10.7 mmol) and silver acetate (2.7 g, 16.2 mmol), and the resulting mixture was heated at 100—110 °C with stirring for 22 h. After cooling, the solid was filtered off, and the filtrate was evaporated to dryness. The residue was chromatographed on silica gel with CH_2Cl_2–benzene as an eluent to give **22** (2.8 g, 85%): Orange oil; IR(film) 2920w, 1740s, 1630s, 1590s, 780s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=8.58 (dd, J=7.5 & 1.3 Hz, 1H), 8.13 (d, J=7.6 Hz, 1H), 8.05 (dd, J=7.5 & 1.3 Hz, 1H), 7.87 (d, J=7.6 Hz, 1H), 7.63 (t, J=7.5 Hz, 1H), 7.52 (t, J=7.6 Hz, 1H), 6.71 (d, J=6.4 Hz, 1H), 3.48 (dd, J=15.0 & 6.4 Hz, 1H), 2.86 (m, 1H), 2.13 (s, 3H), 2.40—1.40 (m, 6H); MS m/z 306 (M^+, 6.8%), 246 (100%). Found: m/z 306.1242. Calcd for $C_{20}H_{18}O_3$: M, 306.1253.

12-Hydroxy-9,10,11,12-tetrahydrocyclohepta[*a*]phenalen-7-(8*H*)-one (23). To a solution of **22** (2.77 g, 6.8 mmol) in THF (20 mL) was added a solution of sodium hydroxide (5.44 g, 22.7 mmol) in water (25 mL). The mixture was heated with stirring at 50—60 °C for 24 h. After cooling, it was neutralized with dil HCl, concentrated in vacuo to remove THF, and extracted with CH_2Cl_2 (30 mL×3). The organic layer was washed with water and brine twice each, and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation in vacuo, the residue was chromatographed on silica gel to give **23** (1.73 g, 96%) from CH_2Cl_2 elution: Yellow needles; mp 159—160 °C (CH_2Cl_2–hexane); IR(KBr) 3350m, 2920m, 1620s, 1590s, 780s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=8.29 (dd, J=8.1 & 1.3 Hz, 1H), 8.14 (d, J=7.5 Hz, 1H), 7.91 (dd, J=8.1 & 1.3 Hz, 1H), 7.78 (d, J=7.5 Hz, 1H), 7.45 (t, J=8.1 Hz, 1H), 7.44 (t, J=7.5 Hz, 1H), 5.59 (d, J=6.1 Hz, 1H), 3.08 (m, 3H), 2.30—1.30 (m, 6H); MS m/z 264 (M^+, 26%), 181 (100%). Found: m/z 264.1111. Calcd for $C_{18}H_{16}O_3$: M, 264.1148. Found: C, 82.16; H, 6.08%. Calcd for $C_{18}H_{16}O_3$: C, 81.82; H, 6.06%.

8,9,10,11-Tetrahydrocyclohepta[*a*]phenalene-7,12-dione (24). A) To a solution of pyridinium dichromate prepared by the addition of chromium trioxide (CrO_3) (5.5 g, 55 mmol) to pyridine (50 ml) was added **23** (2.97 g, 11.3 mmol) in pyridine (10 mL). The mixture stirred at room temperature for overnight, poured onto ice-water, and extracted with

CH_2Cl_2 (50 mL×3). The organic layer was washed with dil HCl three times, brine twice, and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation, the residue was chromatographed on silica gel to give **24** from CH_2Cl_2 elution. Recrystallization from CH_2Cl_2–hexane gave pure **24** (2.22 g, 75%).

B) To a solution of **23** (2.6 g, 9.83 mmol) in CH_2Cl_2 (100 mL) was added $BaMnO_4$ (27 g) and the mixture was refluxed with stirring for 6 h. The solid was filtered, and the filtrate was evaporated in vacuo. The residue was chromatographed on silica gel to give **24** (2.5 g, 97%) from CH_2Cl_2 elution: Yellow needles, mp 84—85 °C; IR(KBr) 2920m, 1690s, 1630s, 1570s, 780s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.16 (dd, J=7.6 & 1.3 Hz, 1H), 8.15 (dd, J=7.9 & 1.5 Hz, 1H), 7.95 (dd, J=7.6 & 1.3 Hz, 1H), 7.71 (dd, J=7.9 & 1.5 Hz, 1H), 7.71 (t, J=7.6 Hz, 1H), 7.51 (t, J=7.9 Hz, 1H), 2.84 (m, 4H), 1.95 (m, 4H); MS m/z 262 (M^+, 100%), 219 (87%). Found: m/z 262.0950. Calcd for $C_{18}H_{14}O_2$: M, 262.0991. Found: C, 82.31; H, 5.54%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.83%.

11,11-Dibromo-8,9,10,11-tetrahydrocyclohepta[*a*]phenalene-7,12-dione (25). To a solution of **24** (2.18 g, 8.32 mmol) in chloroform (50 mL) was added $CuBr_2$ (11.2 g, 49.9 mmol), and the mixture was refluxed for overnight. After cooling, the solid was filtered off and the filterate was evaporated in vacuo. The residue was chromatographed on silica gel to give **25** (3.2 g, 92%) from CH_2Cl_2 elution: Orange needles, mp 157—158 °C (CH_2Cl_2–hexane); IR(KBr) 1710m, 1630s, 1570s, 780m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.61 (dd, J=7.7 & 1.4 Hz, 1H), 8.18 (dd, J=7.6 & 1.3 Hz, 1H), 8.00 (dd, J=7.7 & 1.4 Hz, 1H), 7.76 (dd, J=7.6 & 1.3 Hz, 1H), 7.72 (t, J=7.7 Hz, 1H), 7.58 (t, J=7.6 Hz, 1H), 3.80—2.30 (m, 2H), 2.02 (m, 2H); MS m/z 422, 420, 418 (M^+, 7%, 12%, 7%). Found: m/z 421.9200, 419.9182, 417.9256. Calcd for $C_{18}H_{12}Br_2O_2$: M, 421.9165, 419.9183, 417.9205. Found: C, 51.50; H, 2.91%. Calcd for $C_{18}H_{12}Br_2O_2$: C, 51.43; H, 2.86%.

Cyclohepta[*a*]phenalene-7,12-dione (4). A mixture of **25** (1.00 g, 2.38 mmol) and lithium chloride (1.00 g, 23.5 mmol) in dry DMF (10 mL) was heated at 100—110 °C with stirring for 3 h. After cooling, the mixture was poured onto ice-water and the solid was filtered. The solid was dissolved in CH_2Cl_2 and dried over anhyd $MgSO_4$. The solvent was evaporated and the residue was chromatographed on silica gel to give **4** (0.70 g, 96%) from CH_2Cl_2 elution: Orange needles, mp 176—177 °C (CH_2Cl_2–hexane); IR(KBr) 3050w, 1640s, 1570s, 760s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.63 (dd, J=7.6 & 1.3 Hz, H-1), 8.43 (dd, J=7.7 & 1.2 Hz, H-6), 8.18 (dd, J=7.6 & 1.3 Hz, H-3), 8.13 (dd, J=10.2 & 1.1 Hz, H-8), 7.98 (dd, J=7.7 & 1.2 Hz, H-4), 7.71 (t, J=7.6 Hz, H-2), 7.53 (t, J=7.7 Hz, H-5), 6.89 (m, H-9, -10, -11), (D_2SO_4–CH_2Cl_2) δ=10.09 (d, J=8.11 Hz, H-1), 9.88 (d, J=10.7 Hz, H-8), 9.68 (d, J=8.1 Hz, H-3), 9.50 (d, J=7.0 Hz, H-6), 9.06 (t, J=8.1 Hz, H-2), 8.94 (d, J=7.0 Hz, H-4), 8.56 (ddd, J=10.7, 9.6, & 2.9 Hz, H-9), 8.54 (m, 10-H), 8.52 (t, J=7.0 Hz, H-5); ^{13}C NMR ($CDCl_3$) δ=190.1 (C-12), 183.3 (C-7), 143.8, 136.1, 133.8, 132.5, 132.4, 131.1, 130.6, 128.0, 127.8, 126.8, 124.4, (D_2SO_4–CH_2Cl_2) δ=181.6 (C-OH, C-12), 178.6 (C-OH, C-7), 156.5 (C-4), 155.6 (C-6), 147.5 (C-5), 146.1 (C-1), 143.6 (C-2), 142.9 (C-3), 140.1 (C-8), 134.2 (C-10), 131.9 (C-11), 130.5 (C-9), 144.6, 134.4, 126.5, 123.7, 120.5 (quart. C); ES (CH_2Cl_2) λ_{max} 432 (log ε=3.72), 382 (3.68), 296sh (3.56), (concd H_2SO_4) λ_{max} 540 (log ε=4.10), 395 (4.12), 307 (4.15), 283 (5.19), 237 nm (5.20), The pK_a value was obtained by the similar manner as **2**; MS m/z 258 (M^+, 100%), 230 (97%). Found: m/z 258.0685. Calcd for $C_{18}H_{10}O_2$: M, 258.0680. Found: C, 83.59; H, 4.09%. Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

9,10-Dihydrocyclohepta[*a*]phenalen-7(8*H*)-one (26). A mixture of **21** (9.04 g, 27.6 mmol) and lithium chloride (1.6 g, 41.1 mmol) in DMF (20 mL) was heated at 100—110 °C with stirring for 1 h. After cooling, the mixture was poured onto ice-water and extracted with CH_2Cl_2 (30 mL×3). The organic layer was washed with water and brine twice each and dried over anhyd $MgSO_4$. The solvent was removed by evaporation and the residue was chromatographed on silica gel to give **26** (5.5 g, 81%) from CH_2Cl_2 elution: Yellow needles, mp 73—74 °C (CH_2Cl_2–hexane); IR(KBr) 2920w, 1630s, 1565s, 785s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.65 (dd, J=7.2 & 1.3 Hz, 1H), 8.13 (dd, J=8.1 & 1.3 Hz, 1H), 7.91 (m, 1H), 7.88 (d, J=1.1 Hz, 1H), 7.75 (s, J=8.1 Hz, 1H), 7.63 (t, J=7.9 Hz, 1H), 6.97 (d, J=11.3 Hz, 1H), 6.61 (dt, J=11.3 & 5.9 Hz, 1H), 4.78 (m, 2H), 2.82 (m, 4H); MS m/z 246 (M^+, 40.3%), 219 (100%). Found: m/z 246.1042. Calcd for $C_{18}H_{14}O$: M, 246.1042. Found: C, 87.48; H, 5.77%. Calcd for $C_{18}H_{14}O$: C, 87.78; H, 5.73%.

8,9-Dihydrocyclohepta[*a*]phenalene-7,10-dione (27). To a solution of pyridinium dichromate in pyridine prepared by addition of CrO_3 (17.1 g, 170 mmol) to pyridine (50 mL) at ca. 5 °C was added **26** (8.53 g, 34.7 mmol) dissolved in pyridine (20 mL). The mixture heated at 50—60 °C with stirring for 7 h, diluted with dil HCl (500 mL), and extracted with CH_2Cl_2 (50 mL). The organic layer was washed with dil HCl twice and brine twice, and dried over anhyd $MgSO_4$. The solvent was evaporated and the residue was chromatographed on silica gel to give **27** (0.59 g, 16%) from CH_2Cl_2 elution along with the recovered starting material **26** (4.85 g, 56.8%). Compound **27**: Yellow needles, mp 177—178 °C (CH_2Cl_2–hexane); IR(KBr) 1660s, 1630s, 1570s, 785s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.65 (dd, J=7.2 & 1.3 Hz, 1H), 8.19 (dd, J=7.9 & 1.3 Hz, 1H), 8.01 (d, J=7.9 Hz, 1H), 7.99 (d, J=6.6 Hz, 1H), 7.76 (dd, J=7.5 & 7.0 Hz, 1H), 7.61 (d, J=12.5 Hz, 1H), 7.59 (dd, J=7.9 & 7.7 Hz, 1H), 6.58 (d, J=12.5 Hz, 1H), 3.17 (m, 2H), 2.77 (m, 2H); MS m/z 260 (M^+, 81.5%), 231 (100%). Found: m/z 260.0778. Calcd for $C_{18}H_{12}O_2$: M, 260.0835. Found: C, 82.78; H, 4.72%. Calcd for $C_{18}H_{12}O_2$: C, 83.06; H, 4.65%.

Cyclohepta[*a*]phenalene-7,10-dione (3). A mixture of **27** (0.64 g, 2.46 mmol) and SeO_2 (0.37 g, 2.95 mmol) in dioxane (30 mL) was refluxed for 3 h. The mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in CH_2Cl_2, washed with saturated aq $NaHCO_3$ twice and brine twice, and dried over anhyd $MgSO_4$. The solvent was evaporated in vacuo and the residue was chromtographed on silica gel to give **3** (0.38 g, 60%) from CH_2Cl_2 elution, along with the recovered starting material **27** (0.15 g, 23%). Compound **3**: Yellow needles, mp 246—247 °C (CH_2Cl_2–hexane); IR(KBr) 3050w, 1640s, 1600s, 1570s, 765s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.67 (dd, J=13.5 & 1.3 Hz, H-6), 8.44 (d, J=12.9 Hz, H-12), 8.38 (bd, J=7.6 Hz, H-3), 8.25 (dd, J=7.6 & 1.3 Hz, H-4), 8.10 (bd, J=7.6 Hz, H-1), 7.80 (t, J=7.6 Hz, H-5), 7.68 (t, J=7.6 Hz, H-2), 7.17 (dd, J=13.5 & 3.1 Hz, H-9), 7.02 (dd, J=12.9 & 3.1 Hz, H-11), (D_2SO_4–CH_2Cl_2) δ=10.15 (d, J=12.3 Hz, H-12), 10.10 (d, J=12.1 Hz, H-8), 9.79 (d, J=9.0 Hz, H-6), 9.69 (d, J=8.8 Hz, H-4), 9.49 (d, J=7.5 Hz, H-3), 9.17 (d, J=7.7 Hz, H-1), 8.61 (d, J=7.7 & 7.5 Hz, H-2), 8.61 (dd, J=9.0 & 8.8 Hz, H-5), 8.40 (d,

J=12.3 Hz, H-11), 8.37 (d, J=12.1 Hz, H-9); ^{13}C NMR ($CDCl_3$) δ=187.0 (C-10), 182.9 (C-7), 143.2, 142.3, 138.3, 136.1, 134.5, 134.1, 133.2, 132.6, 131.6, 128.9, 128.0, 127.8, 127.6, 127.0, (D_2SO_4) δ=184.7 (C-OH, C-10), 178.7 (C-OH, C-7), 155.4 (C-4), 150.3 (C-3), 147.9 (C-1), 147.4 (C-6), 143.3 (C-8), 143.0 (C-12), 137.2 (C-9 or C-11), 131.4 (C-11 or C-9), 131.4 (C-5), 131.2 (C-2), 150.3, 131.9, 131.3, 126.3, 125.5, 120.9 (quart. C); ES (CH_2Cl_2) λ_{max} 432 (log ε=3.48), 390 (3.46), 340 (3.69), 254 (4.22), 228 nm (4.05), (concd H_2SO_4) λ_{max} 520 (log ε=4.05), 489 (4.01), 370 (3.89), 330 (3.94), 282 (4.58), 230 nm (4.30); MS m/z 258 (M^+, 10.2%), 230 (100%). Found: m/z 258.0702. Calcd for $C_{18}H_{10}O_2$: M, 258.0723. Found: C, 83.49; H, 4.15%. Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

We are grateful to the Science and Technical Foundation of Asahi Glass Co. Ltd., for the financial support (1987—1988).

Thermal Behavior and Characterization of Poly[1,3-phenylenebis (methylene)adipamide]

Choichiro SHIMASAKI,* Hisashi SANAGI, Akira UNISHI, Hisakimi NOTOYA, Eiichi TSUKURIMICHI, and Toshiaki YOSHIMURA
Faculty of Engineering, Toyama University, Gofuku, Toyama 930
(Received October 9, 1990)

Thermal degradation of poly[1,3-phenylenebis(methylene) adipamide] (MXD-6) was investigated by DTA-TG, FT-IR, TG-GC/MS, and mass spectroscopy. The DTA-TG/DTG curve showed that the thermal decomposition of MXD-6 occurred in two stages. MXD-6 melted at about 235 °C and decomposed to the oligomer or monomer with a weight loss of about 40% in the temperature region from 330 to 400 °C during the first stage. A TG effluent gas was collected in a cold trap and then directly injected into a GC for separation, the MS for an unequivocal identification. The eleven effluent compounds from the thermal degradation of MXD-6 were identified. The main fragmentation mechanism by electron impact for MXD-6 consisted of two processes: simple cleavage and a rearrangement reaction. The activation energy of the thermal decomposition was estimated to be 230 during the first stage and 150 kJ mol^{-1} during the second stage. From the value of the activation energy in each stage, the kinetic data for MXD-6 was elucidated.

The structual characterization of Poly[1,3-phenylenebis(methylene)adipamide] (MXD-6) has attracted much attention recently, since this material is an important member of a family of polyamides. This family has potential for both thermohardening materials and important commercial polymers. Its, thus, thermal decomposition mechanism is of practical and theoretical relevance. Serveral thermal decomposition products have been identified in a flash pyrolysis GC study of several nylons.[1] Since the advent of modern direct pyrolysis mass spectrometry techniques, the thermal degradation of polyamides has been the subject of several publications.[2] The polymer (**I**) of isophthalic acid and hexamethylenediamine is amorphous and has relatively low melting and heat destortion temperatures.[3] MDX-6 shows the effects caused by a reversal of the position of the carbonyl groups relative to the amide nitrogen, in comparison with **I**.[4] It was of interest to investigate the thermal properties of MXD-6 in question be applying both TG and DTA techniques. Also, since little is known about the thermal behavior, such as the TG-GC/Mass, detailed degradation studies were performed; the results are discussed.

Experimental

Materials. MXD-6 polyamide (**II**) was produced by Mitsubishi Gasukagaku Co., Ltd. The following samples were selected for the present work. Sample (**IIa**): The powdered sample was prepared by cutting the rod of **II** with a saw. Sample (**IIb**): A powdered sample was prepared by refluxing in dimethylformamide solvent, then evaporating to dryness under reduced pressure. Sample (**IIc**): A colloidal solution after refluxing of **IIb** was filtered, washed with chloroform, and dried in air. Sample (**IId**): Powdered sample was prepared by sawing a rod of **II** with an electromobile high-speed saw. The elemental analyses of each sample are summarized, together with the calculated value of the monomer of **II** in Table 1.

All other chemicals were of the highest commercially available purity and were used without further purification, unless otherwise stated.

Thermal Analysis. Thermal analyses were performed using a Rigaku Denki thermogravimetry-differential thermal analysis (TG-DTA) and a differential scanning calorimetry (DSC) apparatus in air at various heating rates. Calcinated alumina was used as the reference material. TG-TRAP-GC/MS was carried out with a Shimadzu combined system in stationary helium gas at a heating rate of 10 °C min^{-1}. Separation and identification of the pyrolysis products were carried out by using a gas chromatograph coupled with a mass selective detector. A Shimadzu gas chromatograph, containing a capillary column of porous polymer beads of poly[oxy(2,6-diphenyl-1,4-phenylene)] (TENAX GC), coupled with a mass selective detector was used. The injector and detector temperatures were maintained at 230 and 250 °C.

Spectroscopic Measurements. A double-focussing JEOL-JMS-D300 mass spectrometer, equipped with the standard EI was used to obtain the mass spectra. The instrument was scanned from m/z 20 to 1000 at a scan rate of 10 s/decade; perfluorokerosene (PFK) was used for the computor calibration. The ion source was maintained at 200 °C. Polymers were pyrolyzed directly in the ion source using direct probes, heated from 20 to 350 °C at a heating rate of 10 °C min^{-1}.

Table 1. Elemental Analysis of **II**

a) MW=Weight-average molecular weight. b) MN=Number average molecular weight. c) MW=Z average molecular weight.

The IR spectrum was recorded using a JASCO FT-IR-3 type for both powder and thin films. The ^{1}H and ^{13}C NMR spectra were measured in trifluoroacetic acid using a JNM-FX-90-FT-NMR instrument. TMS was used as a reference. For the NMR spectrometric detection and identification of **II**, a solution containing trace amounts of insoluble materials was filtered with a molecular sieve. The ^{1}H NMR spectra given in Fig. 1 shows that **II** contains the constituent functional groups. The steps in the integration curve in Fig. 1 provide the ratios for the different kinds of protons in the molecule. These can be compared with the proton count obtained from the off-resonance decoupled ^{13}C spectrum.

GPC Analysis. A Waters 6000A apparatus equipped with a gel permeation chromatography (GPC) HFIP-80M column was used. A differential refractometer was used as the detector. Analyses were performed at 40 °C in 1,1,1,3,3,3,-hexafluoro-2-propanol (HFIP) as the eluent at a flow rate of 0.5 ml min^{-1}. The working curve was obtained by a calibration with poly(methyl methacrylate) of known molecular weight, as shown in Fig. 2(A). Also, Fig. 2(B) shows the relationship between the area and the retention time with the GPC measurements. The experimental data of each molecular weight for **II** are summarized in Table 2.

Results and Discussion

Thermal Analysis. The TG-DTA curves relative to **IIa** and **IId** are shown in Fig. 3. Figure 3 shows that a melting points are present in the DTA curves for **IIa** and **IId** at 234.6 and 235.5 °C, respectively. From the measurement of DSC, the heat of fusion for **II** was estimated to be about 42 J g^{-1}. The TG-DTA curves of **IIa**, **IIb**, and **IIc** are practically coincident, and the maximum volatilization rate was observed at about 370 and 470 °C. It is borne by changes in the IR spectra both before and after the heating of **II**. Figure 4 shows the change of the IR spectra between room temperature and 400 °C. For the IR spectrum of **II**, the absorption band between 1000 and 1200 cm^{-1} is assigned to the C–N stretching vibration. This absorption grew weaker at 400 °C. At about 2400 cm^{-1} the absorption band attributed to the N–H stretching vibration grew strong, showing that the cleavage of C–N proceeded. Upon further heating, the less-stable aliphatic groups were preferentially decomposed through the homolytic cleavages of the C–C, C–H, C–N, and N–H bonds. Since the thermal degradation in the present work was carried out in a static air medium, it can be said that atmospheric oxygen is consumed before combustion is completed, and that the remainder decomposes afterwards in an inert medium. The last exotherm on the DTA curve of **IId** represents a crosslinking and aromatization of the char in an inert medium.

To investigate the thermal decomposition processes which cause the DTA and the TG curves over the range from 200 to 500 °C for **II**, TG-TRAP-GC/MS was carried out in stationary He. In many cases the TG effluent gas was comprised of various components. The identification of less-abundant components became increasing difficult. Another approach is to collect the pyrolysis products and then to analyze this collected material by GC. This method has been applied to the analysis of thermal degradation products.[5] Figure 5 shows a mass chromatogram of the liberated decomposition products of **II** with a tandem thermogravimetric analyzer–gas chromatograph–mass spectrometer system. The thermally degraded products of **II** consist of about eleven components. These components were identified by measuring the mass spectrum of the liberated gas from

the principal portion of the weight loss on the TG curve between 300 and 500 °C. The peaks at *m/z* 28 and 32 due to N_2 (or CO) and O_2 were the most intense. The peak at *m/z* 119 due to $C_8H_9N^+$ was the apparent maximum mass number in the liberated decomposition products of **II**. Other thermally degraded products of **II** consists of a complex mixture of seven components: $(C_7H_7NH_2)^+$ *m/z* 106→$(C_7H_7NH)^+$ *m/z* 105; $(C_7H_7)^+$(Tropylium ion) *m/z* 91; $(C_4H_4CO)^+$ *m/z* 84; $(C_4H_7)^+$ *m/z* 55→$(C_3H_5)^+$ *m/z* 41→$(C_2H_4)^+$ *m/z* 28. These components were identified by measuring the mass chromatograms of the decomposition products of **II** (Fig. 5). This result shows that the thermal degradation of **II** takes place through two alternative pathways. The first one dominates below 300 °C and involves dehydration, rearrangement, evolution of carbon monooxide and carbon dioxide, and the formation of carbonaceous residue. The second one, which starts at about 400 °C and overshadows the first one at higher temperatures, involves cleavages of the *m*-phenylenebis(methyleneimino) units by intramolecular rearrangements and the formation of a tar mixture and some randomly linked low molecular weight aliphatic derivatives, which then evaporate.

Mass Spectrum. The thermal decomposition process may be directly predictable from the corresponding mass spectrum. The main mass spectral data of low- and high-resolution is shown in Table 3. This table tabulates *m/z*, its corresponding elemental composition, and the probable molecular structure of each of the identified components. The ion of largest

intensity in the spectrum was selected in order to obtain the relative intensity of the raw peak height of the fragment ion. The intensity of this ion peak is called the base peak intensity. The base peak appeared at m/z 119 due to $C_8H_9N^+$. The spectrum also indicates that the peak of the maximum mass number is the $(M-H_2O)^+$ of monomer. The observed mass spectrum is an averaged recording of the results of a host of fragmentation events, most of which represent only the results of a relatively few successive fragmentations to a given moiety. A compound of **II** after ionization of the $(M-H_2O)^+$ can produce cleavages to produce fragment of m/z 100, 119, 134, 161, 189, 218, and 246, as shown in Fig. 6. Simple cleavages, such as fragment ion 1, 2, 5, and 6, as indicated by the wave line, of an even-electron ion produce another even-electron ion and a neutral olefin or other neutral particles. In fragment ion 3,4, and 7, however, the cleavage is due to the well-known McLafferty rearrangement process.

Kinetic Analysis of the Thermal Decomposition. The kinetic discussion was carried out in terms of the thermal analysis according to the Ozawa method.[6] The sample was lightly packed with the aid of a special holder into an aluminum pan. Thermal decomposition was studied at heating rates of 1.0, 3.0, 5.0, 7.0, and 10.0 °C min^{-1}. Figure 7 shows the TG curves for **II**, as determined at different heating rates. According to the Ozawa theory, the weight loss (θ) at a constant heating rate can be expressed by

$$\theta = \Delta E/aR \cdot P(\Delta E/RT), \quad (1)$$

where ΔE is the activation energy; a, the heating rate, and R, the gas constant. Also, in the case $60 > \Delta E/RT > 20$,

$$\log P(\Delta E/RT) = -\log a - 0.456\Delta E/RT. \quad (2)$$

Table 5. Kinetic Data for the Thermal Decomposition Process on the TG Curve for **II**

Thermal decomposition process	Reaction order	Frequency factor
First stage	0.974	0.88×10^{10}
Second stage	0.531	0.12×10^{9}

From plots of the logarithms of the heating rate versus the reciprocal of the absolute temperature for the given residual weight, the activation energy was obtained by the slope of the straight lines. In Fig. 8 is shown Ozawa's plot of the logarithmic heating rate versus the reciprocal absolute temperature. Table 4 shows the values of the activation energy, which was calculated from each weight loss on the TG curves. The activation energies of the first and second stage average 230 and 150 kJ mol^{-1}, respectively. The former was due to the main thermal decomposition while the latter resulted in an oxidative reaction. For nylon, the activation energy was evaluated to be 155 kJ mol^{-1} in Inoue and Sumoto's paper,[7] in which the mechanism of the unzipping of the monomer from carboxyl ends was postulated. The difference between the result in the first stage of this paper and in Inoue et al. paper is dependent upon the complexity of the group attached to the carbonyl carbon atom. It is possible to estimate the reaction order and the frequecy factor in each stage of the thermal decomposition process for **II** by employing the values of activation energy and the direct search method. The results are summarized in Table 5. This thermal decomposition process for **II** obeys a first-order rate law during the first stage and 1/2 order during the second stage. In order to examine the kinetic data, the present authors compared the observed value of the reaction rate and the frequecy factor with the calculated value. The results given in Table 6 agree with the expectations.

We wish to thank Miss Misao Shinoda for the Mass spectra and Mr. Yoshiharu Yoneyama for NMR measurements.

Bismuth Trichloride as a New Efficient Catalyst in the Aldol Reaction and the Michael Reaction

Makoto WADA,* Eiji TAKEICHI,† and Takashi MATSUMOTO†
Department of Chemistry, College of General Education, University of Tokushima, 1-1, Minamijosanjima, Tokushima 770

(Received November 7, 1990)

In the presence of a catalytic amount of bismuth(III) trichloride (5 mol%), silyl enol ethers react with aldehydes at room temperature in dichloromethane to give the corresponding aldols in good yields. Silyl enol ethers also have been found to react with α,β-unsaturated ketones at room temperature in dichloromethane to afford the corresponding 1,5-dicarbonyl compounds, the Michael adducts in good yields. The intermediate adducts of the aldol reaction (the silyl ethers) and the Michael reaction (the silyl enol ethers) were also obtained in good yields.

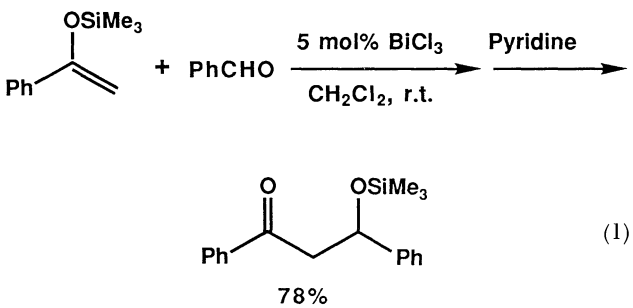
In view of elemental resources for the future, it is important to use various elements for organic synthesis. Among group 15 elements, bismuth metal is cheaper and less toxic than arsenic or antimony and can be expected to play some role in organic synthesis according to its enhanced metallic character. To our knowledge, however, organic synthesis, especially carbon–carbon bond forming reaction by using bismuth and bismuth compounds has been scarcely studied.[1] Recently, the first example of chemoselective metallic bismuch[2] and bismuth (III) chloride ($BiCl_3$)–metallic zinc-,[3] iron-,[3] or aluminium[4]-mediated allylation of aldehydes with allylic halides to homoallylic alcohols was reported by us.[5] We also found that $BiCl_3$ (5 mol%) promotes aldol reaction between silyl enol ethers and aldehydes in CH_2Cl_2 at room temperature.[6] In the course of our continuous investigations, we have found that $BiCl_3$ activates α,β-unsaturated ketones. Herewith, we wish to disclose in full the $BiCl_3$ catalyzed aldol reaction and Michael reaction.

Results and Discussion

Bismuth Trichloride ($BiCl_3$) Promoted Aldol Reaction between Silyl Enol Ethers and Aldehydes. The aldol reactions is one of the standard tools for creating new carbon–carbon bonds, and numerous methods have been developed[7] including the catalytic aldol reaction by the aid of TBAF (tetrabutylammonium fluoride),[8] TASF [Tris(diethylamino)sulfonium (TAS) difluorotrimethylsiliconate],[9] trityl perchlorate,[10] and rhodium complex.[11] Concerning the cross-aldol reaction using silyl enol ethers,[12] the $TiCl_4$-promoted reaction (Mukaiyama method) is the first example, and the reaction has been carried out at −78 °C using an equimolar amount of $TiCl_4$ in most cases to obtain the aldols in good yields.[13] However, it is still desirable to find a new efficient catalyst of cross-aldol reaction between silyl enol ethers and aldehydes under extremely mild conditions (room temperature and weak acid).

In relation to aldol reaction by using bismuth and bismuth compounds, the reaction between 1-trimethylsiloxy-1-cyclohexene and benzaldehyde in the presence of $BiCl_3$ (5 mol%) in $CDCl_3$ at room temperature was monitored by ^1H NMR spectroscopy. The NMR signals at 0.17 ppm (s, O–Si<u>Me</u>$_3$), 4.87 ppm (t, vinyl-<u>H</u>), and 10.00 ppm (s, aldehyde-<u>H</u>) disappeared within 1 h, and new signals appeared at −0.02 ppm (s, O–Si<u>Me</u>$_3$ of the threo product), 0.03 ppm (s, O–Si<u>Me</u>$_3$ of the erythro product), 5.10 ppm (d, O–C<u>H</u> of the threo product, J=7.91 Hz), and 5.37 ppm (d, O–C<u>H</u> of the erythro product, J=3.95 Hz). The above results illustrate that the silyl enol ether reacts with benzaldehyde smoothly under the influence of a catalytic amount (5 mol%) of $BiCl_3$, giving the aldol silyl ether.

Practically, the reaction of 1-phenyl-1-trimethylsiloxyethylene and benzaldehyde followed by the quenching of the reaction mixture using pyridine gave 78% isolated yield of the corresponding silyl ether (Eq. 1). The corresponding aldol was obtained in 94% yield when the reaction mixture was treated with CH_3OH/1M HCl (10/1, 1 M=1 mol dm^{-3}), then H_2O was added.



(1)

The overall reaction is shown in Scheme 1 and typical results are summarized in Table 1. Silyl enol ethers of acetophenone, propiophenone, cyclohexanone, and methyl phenylacetate could be used. Both benzaldehyde and butanal are usable to obtain aldols

9		$PhCOCH_3$	11 h		Low yield[f]
10		PhCHO	1 h		40[e,g] 32[e,g]
11		$CH_3CH(OEt)_2$	6 h		41

a) Isolated yields are given. b) The reaction was carried out at −78 °C and quenched at that temperature. c) 20 mol% $BiCl_3$ was used. d) The ratio of erythro: threo determined by ^1H NMR. e) The ratio of diastereomers was not determined. f) One equivalent of $BiCl_3$ was used. g) The reaction mixture was treated with H_2O instead of MeOH/1 M HCl for the workup.

in good yields, and an aldehyde serves naturally as a better receptor than acetophenone (Entries 4, 5, 7, and 9). The reaction proceeded very sluggishly at −78 °C and an ambient reaction temperature was required (Entry 2). 1-Phenyl-1-trimethylsiloxyethylene/acetaldehyde dimethyl acetal reaction gave the aldol-type product in 41% unoptimized yield (Entry 11).

In the connection of studies concerning the interaction of silyl enol ethers with Lewis acids, Kuwajima and Nakamura found that the transmetallation reaction occurs via either and O- or a C-metalation pathway, in which $SnCl_4$, $TeCl_4$, and $SbCl_5$ took the former pathway and $TiCl_4$ took the latter.[14] Based on the above results, the reaction between 1-trimethylsiloxy-1-cyclohexene and one equivalent of $BiCl_3$ in $CDCl_3$ at room temperature was monitored by ^1H NMR spectroscopy. We found that the transmetalation reaction does not occur, and consequently, it is of note that the active intermediate of the present reaction is not the bismuth enolate. Although the reaction mechanism of the catalytic $BiCl_3$ mediated aldol reaction is not clear, a catalytic cycle can be presumed in which the carbonyl compounds activated by $BiCl_3$, react with silyl enol ethers to give the aldol silyl ethers by Prins or Friedel–Crafts type reaction, regenerating $BiCl_3$.

Bismuth Trichloride ($BiCl_3$) Promoted Michael Reaction. In the course of our continuous investigations to explore useful synthetic reactions using $BiCl_3$, we have found that it also activates α,β-unsaturated aldehydes and ketones.[15] Herewith, we wish to describe the $BiCl_3$ catalyzed Michael reaction, and also the isolation of the intermediate adduct, the synthetically valuable silyl enol ether.

When 1-phenyl-1-trimethylsiloxyethylene was reacted with crotonaldehyde in the presence of $BiCl_3$ (5 mol%) in CH_2Cl_2 at room temperature, 1,2-addition product and 1,4-addition product were obtained in 68% and 31% yields, respectively. Noteworthy is the fact that 1,5-dicarbonyl compound, the Michael adduct, was obtained in good yield, and 1,2-addition product was not detected by the reaction of a silyl enol

ether with an α,β-unsaturated ketone. The overall reaction is shown in Scheme 2 and typical results are summarized in Table 2.

Quenching of the reaction mixture using pyridine gave the satisfactory yield of the intermediate silyl enol ether. Some of the results are summarized in Table 3.

The present reaction is the first example of the cross-aldol reaction and the Michael reaction using $BiCl_3$. It should be stressed that cheap and commercially available $BiCl_3$ is a new efficient catalyst of the present reaction under extremely mild conditions [room temperature and weak acid ($BiCl_3$ is a weak Lewis acid)].

Experimental

General Methods. Infrared spectra were recorded on a Hitachi 215 spectrophotometer. ^{1}H NMR spectra were recorded with JEOL PMX 60Si spectrometer and chemical shifts (δ) were reported in ppm using internal tetramethylsilane. Bismuth (III) chloride was commercial material and used without further purification. Aldehydes and α,β-unsaturated ketones were distilled before use. Trimethylsilyl enol ethers were prepared following the procedure of House.[17]

Isolation of the Aldol Silyl Ether. Bismuth (III) chloride (0.1 mmol) was placed in a 50 ml two-necked flask and dried in vacuo by heating. Anhydrous CH_2Cl_2 (10 ml) was introduced under nitrogen, and then, using a syringe 1-phenyl-1-trimethylsiloxyethylene (2.0 mmol) and benzaldehyde (2.0 mmol) were added at room temperature. The reaction mixture was stirred for 1 h at that temperature and quenched with pyridine (1 ml) followed by the treatment of water (10 ml). The organic materials were extracted with Et_2O (20 ml×3). After drying ether layer over anhydrous $MgSO_4$, the solvent was evaporated to give the oily product in 78% yield. This product was pure by ^{1}H NMR without purification, and it was identified by comparison with an authentic sample prepared from the known procedure.[10]

General Procedure of the Aldol Reaction. In a 50 ml two-necked flask under nitrogen atmosphere, were placed bismuth (III) chloride (0.05 mmol) and dry CH_2Cl_2 (3 ml). Then, an aldehyde (1.1 mmol) and a silyl enol ether (1.0 mmol) were added sequentially at room temperature, and the reaction mixture was stirred at that temperature. The resulting reaction mixture was treated with CH_3OH/1M HCl (10/1, 0.1 ml), then H_2O (10 ml) was added, and the product was extracted with CH_2Cl_2 (10 ml×3). After drying the CH_2Cl_2 layer over anhydrous $MgSO_4$, the solvent was evaporated in vacuo. The crude product was purified on thin-layer chromatography to afford the corresponding aldol in good yield.

3-Hydroxy-1,3-diphenyl-1-propanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=8:1), 94% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[13b]

3-Hydroxy-1-phenyl-1-hexanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 85% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[13b]

3-Hydroxy-1,3-diphenyl-1-butanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 73% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[18]

3-Hydroxy-2-methyl-1,3-diphenyl-1-propanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=7:1), 95% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[13b]

3-Hydroxy-2-methyl-1,3-diphenyl-1-butanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 22% yield. This product was identified by comparison with an authentic sample.[18]

2-(α-Hydroxybenzyl)-1-cyclohexanone: Purified by thin-layer chromatography (SiO_2, hexane:Et_2O=5:1), 84% yield. This product was identified by camparison with an authentic sample.[10a]

Methyl 3-Hydroxy-2,3-diphenylpropionate: Purified by thin-layer chromatography (SiO_2, CH_2Cl_2), 32% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[19]

3-Ethoxy-1-phenyl-1-butanone: Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=15:1), 41% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[20]

Isolation of an Intermediate of the Michael Reaction, an Silyl Enol Ether. Bismuth(III) chloride (0.05 mmol) was placed in a 50 ml two-necked flask and dried in vacuo by heating. Anhydrous CH_2Cl_2 (5 ml) was introduced under nitrogen, and then, using a syring a silyl enol ether (1.0 mmol) and an α,β-unsaturated ketone (1.1 mmol) were added at room temperature. The reaction mixture was stirred for 1 h at that temperature and quenched with pyridine (1 ml) followed by the treatment of water (10 ml).

The organic materials were extracted with Et_2O (20 ml×3). After drying the ether layer over anhydrous $MgSO_4$, the solvent was evaporated to give the oily product in good yield. This product was pure by ^1H NMR without purification. This product was identified by comparison with an authentic sample.

The Silyl Enol Ether (6a): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 70% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[15]

The Silyl Enol Ether (6b): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 75% yield. This product was identified by comparison with an authentic sample.[15]

The Silyl Enol Ether (6c): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 77%. This product was identified by comparison with an authentic sample. [15]

General Procedure of the Michael Reaction. In a 50 ml two-necked flask under nitrogen atmosphere, were placed bismuth(III) chloride (0.05 mmol) and dry CH_2Cl_2 (3 ml). Then, an α,β-unsaturated ketone (1.1 mmol) and a silyl enol ether (1.0 mmol) were added sequentially at room temperature, and the reaction mixture was stirred for 6 h at that temperature. The resulting mixture was treated with CH_3OH/1M HCl (10/1, 0.1 ml), then H_2O (10 ml) was added and the product was extracted with CH_2Cl_2 (10 ml×3). After drying the CH_2Cl_2 layer over anhydrous $MgSO_4$, the solvent was evaporated in vacuo. The crude product was purified on thin-layer chromatography to afford the corresponding 1,5-dicarbonyl compound in good yield.

The 1,5-Dicarbonyl Compound (7a): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=7:1), 80% yield. This product was identified by comparison with an authentic sample.[15]

The 1,5-Dicarbonyl Compound (7b): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 79% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[15]

The 1,5-Dicarbonyl Compound (7c): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 75% yield. This product was identified by comparison with an authentic sample.[15]

The 1,5-Dicarbonyl Compound (7d): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 70% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[15]

The 1,5-Dicarbonyl Compound (7e): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=8:1), 65% yield. This product was identified by comparison with an authentic sample.[15]

The 1,5-Dicarbonyl Compound (7f): Purified by thin-layer chromatography (SiO_2, hexane:AcOEt=9:1), 71% yield. This product was identified by comparison with an authentic sample prepared from the known procedure.[15]

Differential Thermal Analysis of Polyacrylonitrile in the Presence of Chlorine-Containing Polymers

Masao Okamoto,* Ken-ichiro Saito, and Sadayuki Motoishi
Department of Polymer Materials Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992
(Received September 20, 1990)

A differential thermal analysis (DTA) of polymer blends of polyacrylonitrile (PAN) with poly (α-chloroacrylonitrile) (PCAN) and poly (vinyl chloride) (PVC), prepared by coprecipitation from a solution containing both polymers, was carried out under nitrogen. Even if a small amount of PCAN or PVC was added to PAN, the exotherm peak position due to violent polymerization of the cyano groups, which appears at ca. 260 °C in pure PAN, shifts to the higher-temperature side by ca. 40 °C and its intensity becomes lower. Moreover, a new generation of heat is observed above ca. 220 °C and ca. 260 °C in the case of PAN–PCAN and PAN–PVC, respectively. These results were associated with the HCl generated during the heating process, since the chlorine atom formed by the reaction of a thermally degraded PAN polymer radical with HCl can both initiate polymerization of the cyano groups in PAN and terminate progress in polymerization by combination. Namely, DTA behavior could be explained by the effect of initiation (in the case of PAN–PCAN) and termination (in the case of PAN–PVC) upon the polymerization of cyano groups both below and above the temperature, respectively, at which PAN begins to be subjected to a sharp transition.

Hydrogen chloride has the effect of changing the thermal degradation behavior of polyacrylonitrile (PAN).[1] This effect is observed even when differential thermal analysis (DTA) is carried out under nitrogen for copolymers of acrylonitrile with chlorine-containing monomers; the exothermic polymerization of cyano groups is delayed and the differential temperature is reduced, as compared with the DTA curve for pure PAN.[1–3] However, there is a great difference between comonomers concerning the effect.[3] This proved to be caused by a difference in the temperature at which each comonomer unit is dehydrochlorinated; HCl accelerates and retards the polymerization of cyano groups below and above the temperature, respectively, at which pure PAN begins to be subjected to a sharp transition.[1,4]

The purpose of the present paper is to report on the DTA behavior of the two binary polyblends, namely, PAN–poly(α-chloroacrylonitrile) (PCAN) and PAN–poly(vinyl chloride) (PVC), and then to verify the above-mentioned conclusion on the effect of HCl. So far the DTA behavior of a 1:1 by weight of the PVC–PAN mixture has been reported by McNeill et al.[5] Their result shows that when HCl evolution has almost ceased, polymerization of the cyano groups begins to reach a significant rate; this is in accordance with our expectation, since the degradation of the two homopolymers suggests a considerable overlap in their main volatilization reactions.

Experimental

Preparation of Polymer Blends. A polymer blend was prepared by the coprecipitation of two polymers from a solution containing PAN[6] and PCAN[7] or PAN and PVC (Geon 103 EP-8). The powder mixture given in Table 1 was dissolved in 26 cm³ of *N,N*-dimethylformamide (DMF); the solution obtained was then poured into 520 cm³ of methanol at −60 °C. The precipitate was filtered, washed with methanol and dried in a vacuum at 50 °C for eight days to constant weight.

Chlorine Analysis. The method was reported in a previous paper.[7]

Thermogravimetry (TG). A Shimadzu DTG-20 was used. Five milligrams of PAN, PCAN, and PVC were packed in quartz sample holders measuring 5 mm in diameter and 2 mm deep; the measurement was carried out under dynamic nitrogen flow (60 cm³ min⁻¹) at a heating rate of 5 °C min⁻¹.

Differential Thermal Analysis (DTA). A Rigaku CAT. No. 8001 Thermoflex was used. Fifty milligrams of powdered samples were employed and heated to 320 °C at a rate of 5 °C min⁻¹ under nitrogen.

Results and Discussion

Chlorine Content of Polymer Blends. PAN–PVC samples were white, but PAN–PCAN samples became light purple. Figure 1 shows the relationship between

Table 1. Preparation of Polymer Blends

Sample	Composition			Chlorine content
	PAN	PCAN	PVC	
	mg	mg	mg	wt%
PAN	500.2			
PAN–PCAN-1	504.2	15.4		1.06
PAN–PCAN-2	501.9	30.8		1.92
PAN–PCAN-3	502.8	60.7		3.67
PAN–PCAN-4	501.0	120.5		6.71
PAN–PVC-1	500.6		5.1	
PAN–PVC-2	500.4		10.1	
PAN–PVC-3	505.0		18.4	1.77
PAN–PVC-4	509.0		30.1	2.94
PAN–PVC-5	500.8		61.0	6.12
PAN–PVC-6	508.5		120.2	10.98

the actual chlorine content given in Table 1 and the value calculated on the basis of a composition of each sample. Though the two values, Cl_A and Cl_C, in Fig. 1, in the PAN–PVC system agreed with each other, in the case of the PAN–PCAN system the actual value of Cl_A was smaller by ca. 15% than the calculated value of Cl_C. This indicates that PCAN is partially dehydrochlorinated in the course of the preparation of polymer blends. The fact that PCAN is dehydrochlorinated in DMF has been reported before.[7,8] It is clear that coloration in PAN–PCAN samples is caused by such dehydrochlorination.

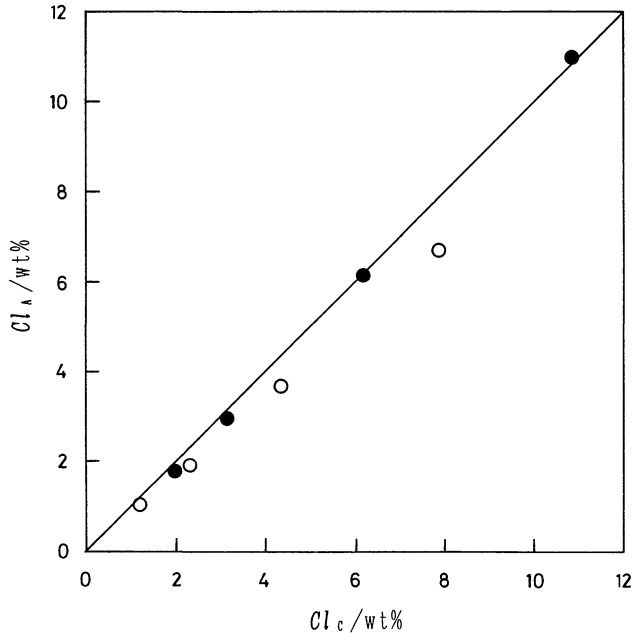

Fig. 1. Actual chlorine content (Cl_A) vs. calculated content (Cl_C). O: PAN-PCAN, ●: PAN-PVC.

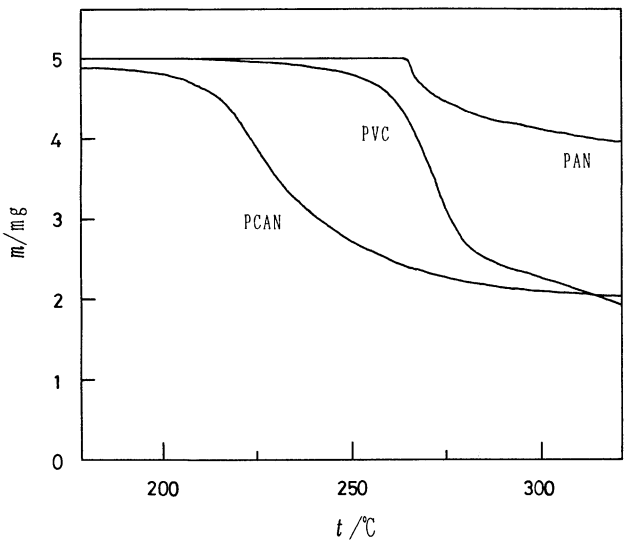

Fig. 2. TG curves for PAN, PVC, and PCAN.

Dehydrochlorination of Chlorine-Containing Polymers during Heating Process. TG curves for PAN, PVC, and PCAN are shown in Fig. 2. The temperature range in which PVC is dehydrochlorinated corresponds to that of the sharp PAN breakdown transition, whereas PCAN shows a weight loss due to dehydrochlorination in a much lower temperature range than PVC. As mentioned in the preceding section, PCAN is partially dehydrochlorinated in the course of preparation of polymer blends. Such PCAN is more easily dehydrochlorinated than the original PCAN.[9] Thus, in the case of the PAN–PCAN system, HCl exists below the temperature at which pure PAN begins to be subjected to a sharp transition, accompanied by an exothermic polymerization of the cyano groups.

Effect of the Composition in PAN-PCAN System on the Exothermic Polymerization of Cyano Groups. DTA curves for PAN–PCAN samples are shown in Fig. 3. As the composition increases in PCAN, the exotherm peak position due to violent polymerization of the cyano groups shifts to the higher-temperature

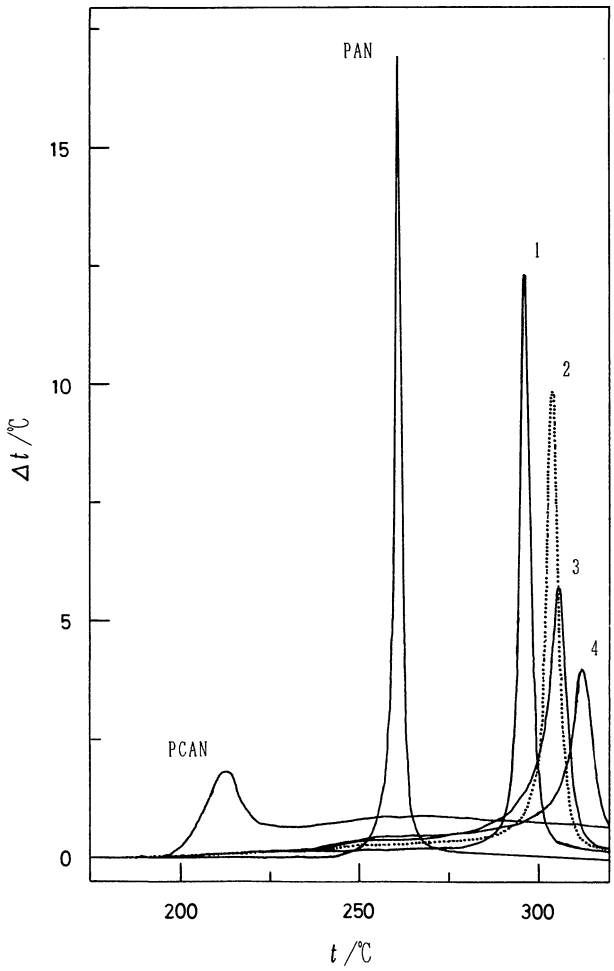

Fig. 3. DTA curves for PAN, PCAN, and PAN–PCAN samples. 1, 2, 3, and 4: PAN–PCAN-1, -2, -3, and -4 shown in Table 1, respectively.

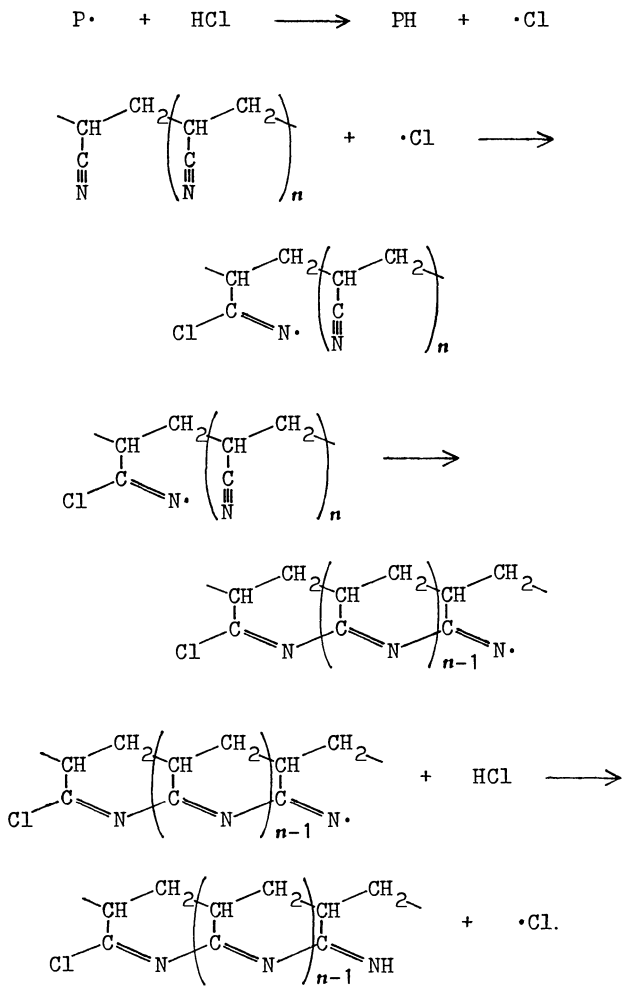
side, and its intensity becomes lower than in the case of PAN. Moreover, in the cases of PAN–PCAN-3 and -4, a broad exotherm appears clearly above ca. 220 °C. This exotherm is due to a polymerization of the cyano groups which is closely associated with HCl generated during the heating process.[1] The mechanism has been explained by the action of a chlorine atom, which was formed by the reaction of thermally degraded polymer radical (P·) with HCl:



Since the chlorine atom is much more mobile at ca. 220 °C than the polymer radical, polymerization of the cyano groups is promoted in the presence of HCl. When the moieties subjected to such polymerization exist in the polymer chain, they should prevent the progress of a rapid polymerization of the cyano groups with which fragmentation[10] in PAN is usually accompanied. This effect is expected to increase in proportion to the PCAN content, since the more HCl that is generated, the more are chlorine atoms formed. Actually, the exotherm peak position due to violent polymerization of the cyano groups shifts to the higher-temperature side with increasing PCAN content (Fig. 3). Such behavior corresponds to that found in DTA curves for the acrylonitrile–α-chloroacrylonitrile copolymers in which the mole fraction of α-chloroacrylonitrile units is below 0.1.[1]

Thermal Degradation Behavior of PAN in PAN–PVC System. DTA curves for PAN–PVC-1— -3 and -4— -6 are shown in Figs. 4 and 5, respectively. Even the DTA behavior of PAN–PVC-1 (the chlorine content being ca. 0.6 wt%) changed remarkably. Namely, the exotherm peak position due to a violent polymerization of the cyano groups shifted to the higher-temperature side than that for pure PAN by ca. 40 °C; its intensity became about 1/3 compared with that for pure PAN. This change is similar to that for PAN–PCAN-3 (the chlorine content being ca. 3.7 wt%), although no broad exotherm was observed below 260 °C. It is evident that there is a great difference between PVC and PCAN concerning the effect on the thermal degradation of PAN. This seems to have been caused by a difference in the temperature range associated with dehydrochlorination. In the case of PAN–PVC-2, -3, or -4, the exotherm peak position is identical with that for PAN–PVC-1 and its intensity

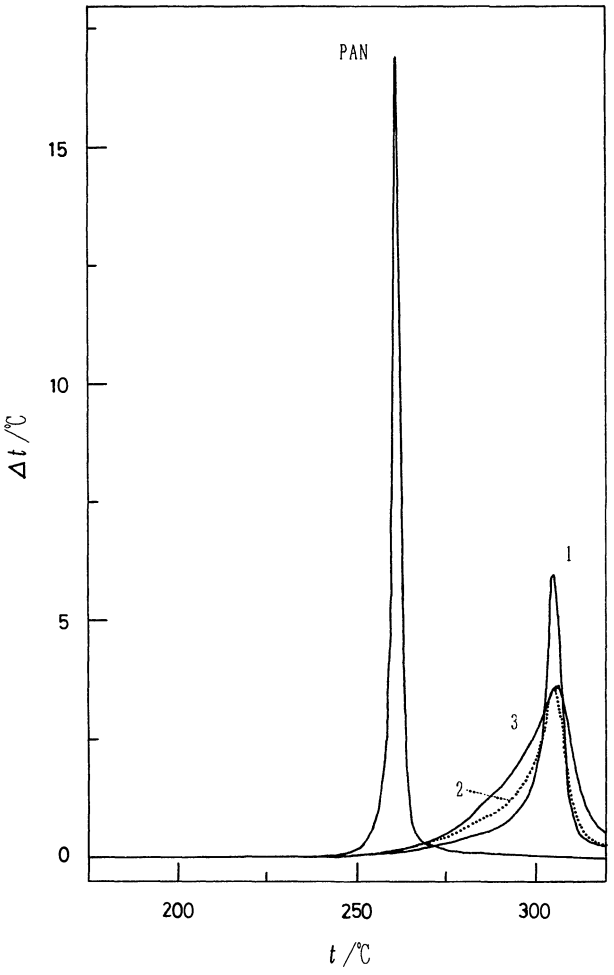


Fig. 4. DTA curves for PAN and PAN–PVC samples. 1, 2, and 3: PAN–PVC-1, -2, and -3 shown in Table 1, respectively.

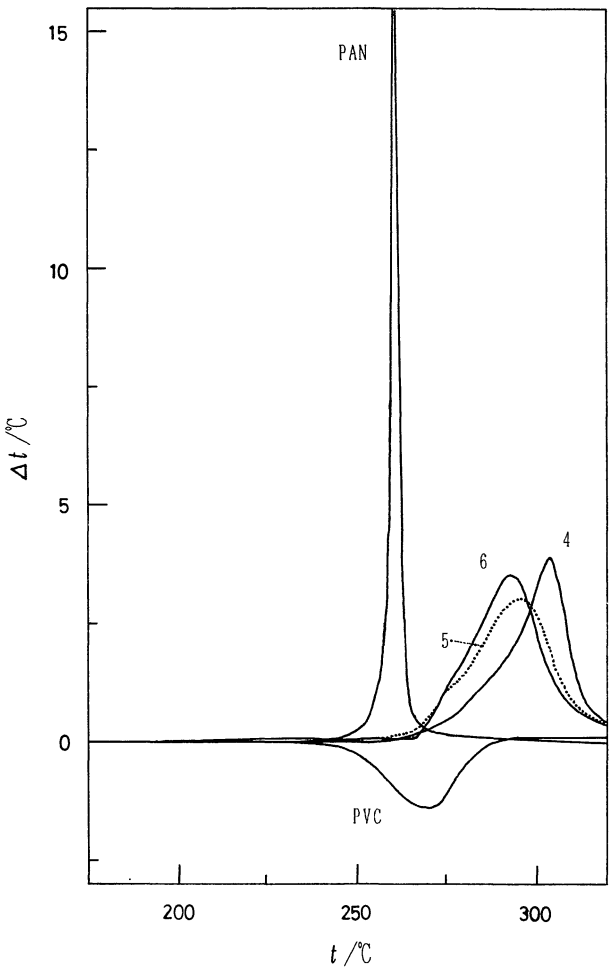

Fig. 5. DTA curves for PAN, PVC, and PAN–PVC samples. 4, 5, and 6: PAN–PVC-4, -5, and -6 shown in Table 1, respectively.

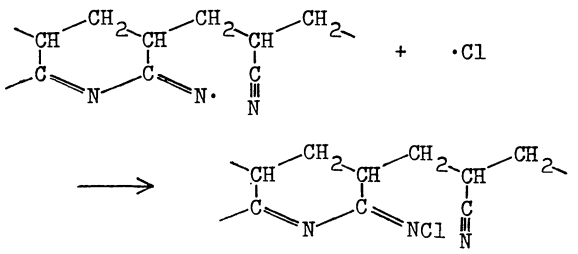
decreases to about 1/5 in comparison with that for pure PAN. This indicates that a very small amount of PVC in the PAN–PVC system is sufficient to change the behavior of the thermal degradation of PAN. It also proved that polymerization of the cyano groups cannot make rapid progress until HCl generated from PVC escapes out of the PAN–PVC system.

The generation of heat was observed in the 260—300 °C range, and increased in proportion to the PVC content (Fig. 4). We cannot conclude that this is due to only polymerization of the cyano groups. In PAN the thermally degraded polymer radicals are much more in number and are much more mobile at 260 °C than at 220 °C. Therefore, in the case of pure PAN, polymerization of the cyano groups progresses rapidly at ca. 260 °C. In the PAN–PVC system, since HCl exists in PAN above 260 °C, chlorine atoms are formed along with the disappearance of an equal number of polymer radicals. At this time although the number of active centers which initiate polymerization of the cyano groups does not change, chlorine atoms can also terminate progress in the polymerization of the cyano groups:



Since this reaction can take place frequently with increasing concentration of chlorine atoms, polymerization of the cyano groups should progress slowly with increasing the PVC content. Therefore, if the generation of heat in the 260—300 °C range is due to only polymerization of the cyano groups, it must decrease in proportion to the PVC content. This is contrary to the facts.

It is clear that the above-mentioned termination reaction is exothermic because of a combination of two active species. The heat of reaction must become larger as the composition increases in PVC. This is not contrary to the results shown in Figs. 4 and 5. In DTA curves for PAN–PVC-5 and -6, the exotherm peak is not observed at ca. 305 °C, but ca. 295 °C (Fig. 5). The magnitude of this broad exotherm is worth noticing. It was not reduced in spite of both a diminished content of PAN and an enlarged influence of the endotherm due to PVC. It can thus be concluded that the termination reaction is considerably exothermic.[11]

The DTA behavior of the PAN–PVC system is similar to that of acrylonitrile–allyl chloride copolymers.[3] This is thought to be attributable to a close resemblance between the two dehydrochlorination behaviors.[4]

Chlorine Content of Polymer Blends Heated to 320 °C. After DTA of polymer blends, a chlorine analysis of the residual products was carried out. The values obtained from PAN–PCAN-4 and PAN–PVC-5 were 0.35 and 2.32 wt%, respectively. These original chlorine contents are 6.71 and 6.12 wt%, respectively, (Table 1) and though they nearly resemble each other, there is a very great difference between the chlorine contents of residual products. In the case of the PAN–PVC system, as mentioned in preceding section, chlorine atoms terminate progress in the polymerization of the cyano groups. Since the termination reaction takes place frequently in the case of PAN–PVC-5 or -6 (Fig. 5), chlorine atoms combined as terminal points are the prime consideration with an increase in residual chlorine. The chlorine content of PAN–PVC-6 heated to 320 °C was 3.07 wt%, and more than that in the case of PAN–PVC-5. This comes up to our expectations, because the generation of heat in the

260—300 °C range is larger than that for PAN–PVC-5 (Fig. 5). Such a change in the residual chlorine is similar to that of the acrylonitrile–allyl chloride copolymers heated to 350 °C.[3] This indicates that these copolymers were also subjected to the above-mentioned termination reaction.

11) McNeill et al.[5] thought, in the case of a 1:1 PVC–PAN mixture, the heat of polymerization of cyano groups is increased by some 50% compared to PAN alone; we believe that the termination reaction is, however, the prime consideration with an increase in the heat of reaction.

The Effect of the Reactor Type on the Selectivity of Thermal Reactions of *p*-Xylene in Temperature Gradient Systems

Shigenobu KAWAKAMI, Shingo IWAKI, Masahiro NAKADA, and Tatsuaki YAMAGUCHI*
Laboratory of Chemistry, Chiba Institute of Technology, Tsudanuma, Narashino-shi, Chiba 275
(Received October 17, 1990)

Thermal reactions of *p*-xylene were investigated in two kinds of reactors, batch type and flow type, with a large temperature gradient. Excellent differences of the resulting products were observed between these two types of reactors. As for a batch type reactor, 4,4′-dimethylbibenzyl was produced in a high yield with [2.2]paracyclophane and toluene as by-products, and as for a flow type reactor, toluene was obtained as a major product with a low selectivity of 4,4′-dimethylbibenzyl, respectively. These results were different from those of the conventional fast flow pyrolysis method in which [2.2]paracyclophane or poly(3,6-dimethylene-1,4-cyclohexadiene) was formed as a major product. These differences can be accounted for by the partial separation of a reaction mixture caused by the thermal diffusion effect, which arises when the mixture is subject to a temperature gradient.

Thermal diffusion arises when a mixture is subjected to a temperature gradient, leading to partial separation of the components. In a reactor, which has a large temperature gradient, partial separation of the components of the reaction mixture due to the thermal diffusion effect prevents such side reactions as reverse reactions and successive reactions. By such a reactor, the reaction products are expected to be different from those in the conventional ones. In 1941 Hirota reported the formation of oily aromatic hydrocarbons and hydrogen from methane using a Clusius–Dickel type thermal diffusion column as a reactor.[1–3] His success in getting the oil in a high yield was attributable to the prevention of the recombination reaction by the instant separation of produced hydrogen from hydrocarbon residues owing to thermal diffusion effect caused by the temperature gradient. His works ought to be regarded as one of the earliest examples of application of a thermal diffusion column as a reactor. However, they had been left unnoticed until very recently. In 1988 Yamaguchi (one of the authors) reexamined Hirota's process, confirming the conversion of methane to C2 compounds.[4] The thermal reactions of simple aromatic hydrocarbons in a temperature gradient system were developed in this laboratory.[5–7] In the preceding paper,[6] we reported the formation of 4,4′-dimethylbibenzyl in a high selectivity by the dehydrogenative coupling of *p*-xylene in a temperature gradient system. The present paper deals with the thermal reactions of *p*-xylene using two kinds of reactors (termed as a batch type reactor and a flow type reactor in this paper), in which the thermal diffusion effect is expected.

Experimental

Batch Type Reactor. The reactions were carried out in a reaction system shown in Fig. 1, where a steep temperature gradient was expected between the surface of the heater and the cold wall of the flask. The spiral heater, made of a nickel chromium steel wire of 0.5 mm in diameter and 25 cm in length was placed horizontally inside of a 1 L three-necked separable flask fitted with a reflux condenser. This reactor is termed as a batch type reactor in this paper, and is characterized by the vertical contact of *p*-xylene vapor with the heater. The flask containing 1 mole of *p*-xylene was heated by a heating mantle under nitrogen. After the boiling of *p*-xylene was started, the power of the heater inside was turned on, and vapored *p*-xylene was contacted with the heater. The surface temperature of the heater was measured

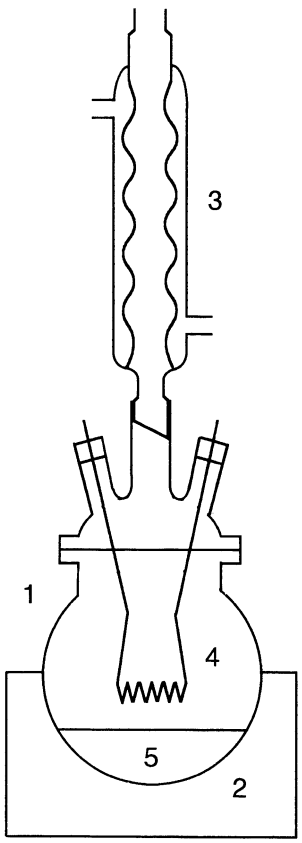

Fig. 1. Batch type reactor. 1: Separable flask, 2: Heating mantle, 3: Reflux condenser, 4: Heater, 5: Reactant.

by a radiation pyrometer (Minolta IR-120) and set at a desired reaction temperature. During the reaction the temperature was monitored by the radiation pyrometer and controlled. The reaction products were identified by GC-MS and GC-IR analysis using authentic samples. After the reaction, the reaction mixture was mixed with chloroform of twice volume of originally employed xylene to dissolve solid products, and analyzed by a gas chromatograph. Gaseous products were also analyzed by a gas chromatograph.

Flow Type Reactor. The flow type reactor used in this experiment is schematically shown in Fig. 2. In brief, the reactor consists of a Pyrex glass-made Liebig condenser (60 cm in length and 5.0 cm in inner diameter) and a heater made of a nickel chromium steel wire (42 cm length and 1.0 mm diameter) mounted at the axis of the condenser. In the flow type reactor, *p*-xylene vapor flowed parallel to the heater. The inlet of *p*-xylene and the outlet of gaseous product were placed at the level 2 cm lower from the top of the heater. The air in the reactor was first replaced by nitrogen and cooling water was supplied. The power of the heater was turned on. The temperature of the heater was measured by a radiation pyrometer and set at a desired temperature. *p*-Xylene was charged downward at a constant rate, and the surface temperature of the heater was further monitored and controlled. The heater was kept at the temperature for two hours by maintaining the voltage and the currency of the electric current. Reaction products were collected every 30 minutes; gaseous products from the upper outlet and liquid products from the lower outlet, and analyzed by gas chromatography.

Results and Discussion

Products of the Batch Type Reactor. The results of the batch type reactor are summarized in Table 1 with experimental details. The reaction started substantially at 1000°C, producing two ring aromatic compounds for the most part. The main product from *p*-xylene was 4,4′-dimethylbibenzyl (**1**). Among other major products were [2.2]paracyclophane (**2**), bis(4-methylphenyl)methane (**3**), *p*-methylstyrene, and toluene. The product, which remained insoluble in the reaction mixture after the addition of chloroform, was identified as poly(3,6-dimethylene-1,4-cyclohexadiene) (**4**) by IR analysis. With the raise of temperature, the selectivity of **1** decreased, while that of **3**, and the sum of **2**+**4** increased. As long as the reaction temperature remained unchanged, the constant selectivity of the products was obtained, even when the conversion of *p*-xylene increased with the prolonged reaction time.

It was shown by GC analysis that the main gaseous products were hydrogen and methane with a small amount of ethane and ethylene. The ratio of hydrogen to methane was approximately 6 to 4, which was consistent with other previous experimental results.[8,9] It should be noted that this ratio slightly decreased with the increase of the conversion of *p*-xylene by the temperature raise.

The formation of hydrogen is best accounted for by the reactions (Eqs. 1 and 2) postulated by Szwarc.[8] Most of the components of the reaction mixture can be traced to a common intermediate, *p*-methylbenzyl radical. This intermediate is formed by thermal scission of the benzylic hydrogen. Most of these radicals recombines to form **1** (Eq. 3), the product of the highest selectivity in the present temperature gradient system. Some of these radicals are converted to 3,6-dimethylene-1,4-cyclohexadiene by dispropor-

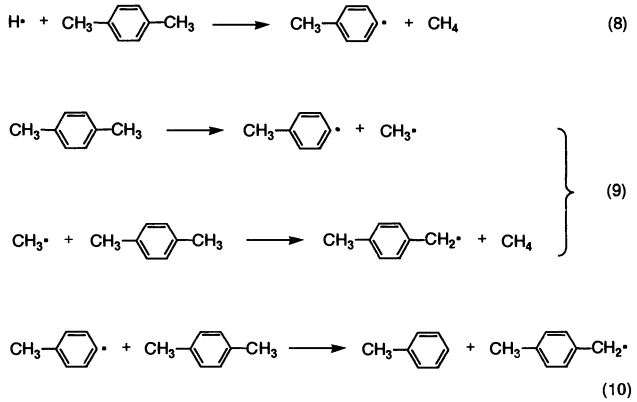
tionation (Eq. 4) or further dehydrogenation of the radicals (Eq. 5).[8,10] 3,6-Dimethylene-1,4-cyclohexadiene is either converted to **2** (Eq. 6) or polymerized to **4** (Eq. 7).

The formation of methane can be accounted for by the reaction (Eq. 8) as suggested by Szwarc[8] or by the reaction (Eq. 9) as suggested by Schaefgen.[9] The *p*-methylphenyl radical thus formed is further converted to toluene (Eq. 10), some of which is further changed to benzene. The radical is also responsible for the formation of **3**.



Comparison with the Results of Fast Flow Pyrolysis. In a conventional reaction method such as fast

flow pyrolysis, where *p*-xylene was pyrolyzed in a vapor phase without temperature gradient, the main products were [2.2]paracyclophane (**2**) and poly(3,6-dimethylene-1,4-cyclohexadiene) (**4**), supposed to be derived from 3,6-dimethylene-1,4-cyclohexadiene.[8–13] 4,4′-Dimethylbibenzyl (**1**) was described as only one of the by-products, the selectivity of which was only 2.9%,[12] although some reference was made to the formation of the compound.[9,11–13]

Contrary to these results, **1** was the main product in the present experiment. The high selectivity of **1** should be attributable to the thermal diffusion effect. In the conventional method, where little temperature gradient is present, *p*-methylbenzyl radical can accept enough energy to undergo dehydrogenation (Eq. 4) or disproportionation (Eq. 5) to be converted to 3,6-dimethylene-1,4-cyclohexadiene, the predecessor of **2** and **4**. Moreover, if **1** is produced from *p*-methylbenzyl radical, it is subject to successive reactions,[9] resulting in the low selectivity of **1**.

On the other hand, in the temperature gradient system as shown in Fig. 1, the thermal diffusion effect, caused by the temperature gradient between the surface of the heater and the cold wall of the vessel, brings about the quenching of the components of the reaction mixture immediately after their production. Thanks to the effect, *p*-methylbenzyl radical leaves the heated surface of the heater for the cold wall to be prevented from further conversion to 3,6-dimethylene-1,4-cyclohexadiene. No process other than the coupling to **1**, which requires almost no reaction energy, should be allowed for the quenched *p*-methylbenzyl radical. 4,4′-Dimethylbibenzyl (**1**), thus produced, is prevented from successive reactions due to the thermal diffusion effect, leading to its high selectivity.

Results of the Flow Type Thermal Diffusion Reactor. Table 2 lists the results of the flow type reactor (a thermal diffusion column), which were quite different from those of the batch type reactor. Toluene was the main product of the reaction under the reaction conditions studied. Only a few quantities of 4,4′-dimethylbibenzyl (**1**), which was the main product of the batch type reactor, was produced. As for gaseous products, a sample (corresponding to the experiment of the fifth column from the left in Table 2) comprised 61.6% of methane, 36.0% of hydrogen, 0.3% of ethane, and 2.1% of butanes. These results contrasted sharply with those of the batch type reactor (shown in Table 1), in which hydrogen occupied about 60% of gaseous products. The results of the flow type thermal diffusion reactor were also inconsistent with those of the conventional fast flow pyrolysis where **2** and **4** were major reaction products.

Thermal Diffusion Effect in the Reactors with the Temperature Gradient. The high selectivity of toluene should also be attributable to the thermal diffusion effect. Thermal diffusion arises when a mixture is subjected to a temperature gradient leading to partial separation of the components. In this process, the component of smaller molecular weight concentrates in the hotter region. In the thermal diffusion reactor of our experiment, molecular hydrogen or atomic hydrogen, evolved in the course of reactions, are separated and concentrated on the surface of the heater

due to thermal diffusion effect. They can retard the formation of *p*-methylbenzyl radicals (Eq. 2) and 3,6-dimethylene-1,4-cyclohexadiene (Eq. 4), and promote the production of *p*-methylphenyl radicals by hydrogenolysis of *p*-xylene (Eq. 8), resulting in the high selectivity of toluene. In other words, in the thermal diffusion column, *p*-xylene appears to have undergone hydrogenative cracking due to the condensation of hydrogen, without supplying hydrogen as a reactant. The analysis of the gaseous products also supports the consumption of hydrogen and the formation of methane. Furthermore, when half amount of hydrogen was added to *p*-xylene at 1150 °C (corresponding to the third column of Table 2), the selectivity of toluene rose to 83.7%, suggesting that hydrogen was responsible for the demethylation.[14]

In the batch type reactor, where the heater was placed horizontally as shown in Fig. 1, gaseous products leave the high temperature region around the heater more immediately than in the flow-type reactor, on account of their low weight and the upward flow of *p*-xylene vapor convection. Hydrogen is less concentrated in the vicinity of the heater and less *p*-methylphenyl radicals are formed in the former reactor than in the latter reactor. This difference of hydrogen concentration is responsible for the difference of products distribution between the two reactors.

Conclusions

Thermal diffusion effect can account for the following difference of product of thermal reactions of *p*-xylene. In a temperature gradient system, *p*-xylene gave as a major product 4,4′-dimethylbibenzyl in the batch type reactor and toluene in the flow type reactor, respectively. However, thermal diffusion effect worked differently, in each reactor in a temperature gradient system. In the former, the effect brought about the quenching of *p*-methylbenzyl radical which was converted to 4,4′-dimethylbibenzyl. In the latter, the effect resulted in the concentration of hydrogen around the heater, and caused *p*-xylene to undergo hydrogenative cracking. Anyway, both results contrast sharply to those of the conventional fast flow pyrolysis of *p*-xylene, where [2.2]paracyclophane and poly(3,6-dimethylene-1,4-cyclohexadiene) were produced mainly, probably because of the little temperature gradient.

The authors wish to express their heartful thanks to Professor Emeritus Kozo Hirota of Osaka University for his useful and informative discussions, and to Mr. Aiming Yu for his helpful assistance.

Temperature-Programmed Desorption of Dimethylpyridine Adsorbed on Silica-Alumina Prepared by Chemical Vapor Deposition

Satoshi SATO,* Masahiro TOKUMITSU, Toshiaki SODESAWA, and Fumio NOZAKI
Department of Applied Chemistry, Faculty of Engineering,
Chiba University, Yayoi-cho, Chiba 260
(Received August 13, 1990)

Synopsis. A temperature-programmed desorption of adsorbed dimethylpyridine clarified the characteristic changes in acid type, acid strength, and acid amount of silica-alumina prepared by depositing silica on an alumina support. Lewis acid sites of the alumina changed into Brønsted acid sites together with a change in the acid strength with increasing silica deposition.

We previously prepared a supported type of silica-alumina by depositing silica on an alumina surface by means of chemical vapor deposition (CVD).[1,2] Silica was effectively deposited on alumina using tetraethoxysilane in the presence of oxygen at 240 °C, and silica loading was readily controlled by the CVD time. The resulting silica-alumina (CVD SiO_2/Al_2O_3) exhibited high catalytic activities for several types of organic reactions such as 2-butanol dehydration, *m*-xylene isomerization, cumene cracking, and heptane cracking. The catalytic activity for 2-butanol dehydration varied with silica loading, and was correlated to the amount of Brønsted acid determined from the extent of the liberated proton in the phase of an aqueous solution.[2]

However, the acid property, especially acid strength, in the absence of water has not been clarified. In this work, a temperature-programmed desorption (TPD) of dimethylpyridine (DMP) adsorbed on a CVD SiO_2/Al_2O_3 catalyst using a conductivity cell immersed in a dilute H_2SO_4 solution was carried out in order to evaluate the entire acid property, including acid type (Brønsted or Lewis), acid strength, and acid amount.

Experimental

Alumina supplied by Dia Catalyst & Chemicals Ltd. (DC-2282: specific surface area, 203 $m^2 g^{-1}$; pore volume, 0.72 ml g^{-1}; granule size, 24—60 mesh.) was used as a support. A CVD SiO_2/Al_2O_3 catalyst was prepared by contacting tetraethoxysilane vapor with the alumina support in a CVD reactor which comprised a glass column rotating in an electrical furnace inclined at 45° at 240 and 300 °C for a prescribed time in a stream of air and nitrogen, respectively;[2] the flow rates of tetraethoxysilane and carrier gas were 2.7 and 400 mmol h^{-1}, respectively. The silica loading was determined by measuring the weight increase of the alumina support after CVD operation followed by calcination at 550 °C for 3 h. K^+ ion-exchange was performed by immersing a sample in 2 mol dm^{-3} potassium chloride solution at room temperature for 2 h.

After a sample (50 mg) placed in a quartz tube (i.d. 4 mm) with quartz wool had been evacuated at 500 °C for 1 h, excess DMP was injected via a microsyringe at 200 °C, and then evacuated at 200 °C for 1 h. A TPD measurement was carried out from 100 to 600 °C at a heating rate of 5 °C min^{-1} in a nitrogen flow of 30 ml min^{-1}. The desorbed DMP was monitored by a conductivity cell immersed in aqueous sulfuric acid (1/2000 mol dm^{-3}). A cumulative amount of desorbed DMP as a function of the desorption temperature was recorded, then differentiated to give the acid strength distribution. Independently, desorbed molecules were collected at −196 °C, then analyzed by GLC.

The isomerization of 1-butene was carried out in a closed circulation system (reactor volume, 200 ml; catalyst, 0.05 g) under the conditions of a 1-butene initial pressure of 19 kPa at 0 °C. Prior to the reaction, the catalyst was preheated at 500 °C under reduced pressure (0.1 Pa). The catalytic activity was evaluated in terms of the first-order rate constant during the initial reaction period.

Results and Discussion

Decomposition of DMP was preliminarily examined. In the TPD process above 500 °C, about 30% of the 3,5-DMP desorbed from the alumina was decomposed into 3-methylpyridine and pyridine. The desorbed amines were detected by the change in the conductivity of a cell solution in which protons are neutralized with them. The conductivity detector was sensitive to such amines as pyridine and DMP, but insensitive to desorbed water as well as to such neutral molecules as benzene and ethanol. In addition, the sensitivity for DMP was almost the same as those for methylpyridine and pyridine. The conductivity detector, therefore, is convenient for the TPD measurement of adsorbed DMP.

Figure 1 shows the cumulative amounts of DMP desorbed from the catalysts. For the alumina support, itself, the cumulative amounts of desorbed DMP were 106 and 14 μmol g^{-1} for 3,5- and 2,6-DMP, respectively. For the CVD SiO_2 (12wt%)/Al_2O_3 prepared at 240 °C

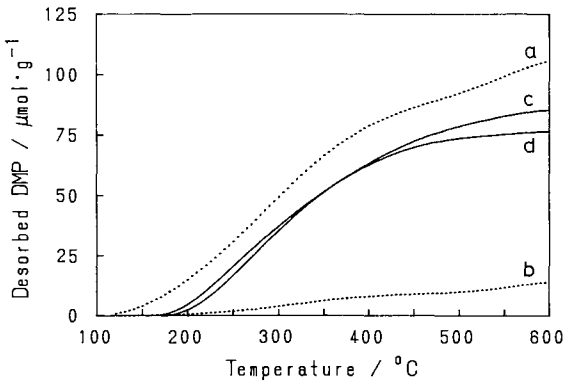

Fig. 1. Cumulative amount of desorbed dimethylpyridine (DMP). Alumina: a, 3,5-DMP; b, 2,6-DMP; CVD SiO_2 (12.4 wt%)/Al_2O_3: c, 3,5-DMP; d, 2,6-DMP.

in air, they were 85 and 77 μmol g^{-1} for 3,5- and 2,6-DMP, respectively. 2,6-DMP is known to selectively adsorb on Brønsted acid sites because of the steric hindrance arising from the two methyl groups, each of which is located adjacent to the nitrogen atom, whereas non-hindered 3,5-DMP is capable of adsorbing on both Lewis and Brønsted acid sites.[3-5] The adsorption of 2,6-DMP on the alumina was seriously restricted, compared to that of 3,5-DMP. The acid amounts measured by 3,5-DMP were also comparable to the amount measured by pyridine.

Figures 2 and 3 show the acid strength distribution of the catalysts. The alumina had a large desorption peak of 3,5-DMP at 300 °C with a shoulder at 570 °C, whereas two small desorption peaks of 2,6-DMP appeared at 300 and 560 °C (Fig. 2). The small peak of 2,6-DMP at 300 °C (Fig. 2b) appears to be caused by desorption from weak Brønsted acid sites. The small peak at 560 °C (Fig. 2b), however, seems to be attributable not to strong Brønsted acid sites, but to strong Lewis acid sites, since alumina has no strong Brønsted acid sites.[2,6] Additionally, IR spectroscopic observations have revealed that 2,6-di-*t*-butylpyridine is strongly adsorbed on alumina,[7] and that 2,6-DMP adsorb on Lewis acid sites together with weak Brønsted acid sites,[8] whereas they have not dealt with the quantitative aspects. Although the TPD of adsorbed 2,6-DMP tends to overestimate the Brønsted acid sites, the large difference between the distribution curves for 3,5- and 2,6-DMP indicates clearly that the acid sites of the alumina are predominantly composed of the Lewis type. On the other hand, the CVD SiO_2 (12wt%)/Al_2O_3 had a wide distribution at a peak top of 250 and 275 °C for 3,5- and 2,6-DMP, respectively (Fig. 3). Since there is no significant difference between two distribution curves for 3,5- and 2,6-DMP, the CVD SiO_2/Al_2O_3 catalyst has a large amount of Brønsted acid sites together with a small amount of strong Lewis acid sites.

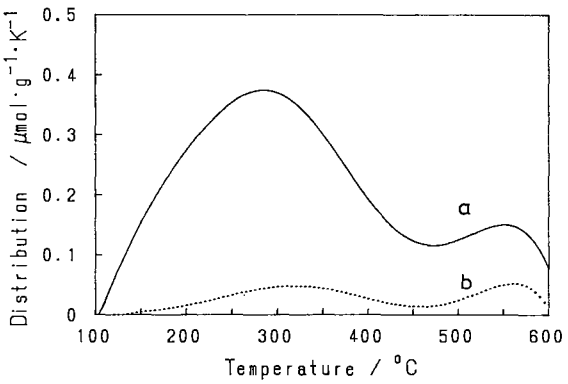

Fig. 2. TPD profiles of alumina. a, 3,5-DMP; b, 2,6-DMP.

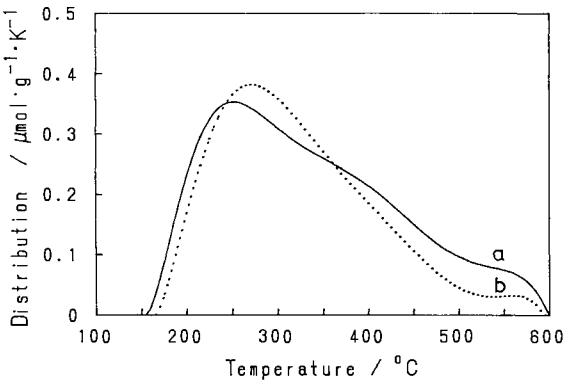

Fig. 3. TPD profiles of CVD SiO_2 (12.4 wt%)/Al_2O_3. a, 3,5-DMP; b, 2,6-DMP.

Figure 4 shows the change in the acid strength distribution measured by the desorption of 2,6-DMP for CVD catalysts prepared at 240 °C in air. When a small amount of silica (5 wt%) was deposited on alumina, the amount of 2,6-DMP desorbed near 250 °C was drastically increased (Fig. 4b). A further increase in silica deposition induced an increase in the strong acid sites represented by desorption around 400 °C; both the highest acid strength and the maximum amount of desorbed 2,6-DMP were attained at a silica loading of 12 wt% (Fig. 4c). Above 12 wt%, the amount was decreased with increasing silica loading, together with a small change in the acid strength (Fig. 4d). On the other hand, the desorption behavior of 3,5-DMP was similar to that of alumina, as is shown in Figs. 2 and 3.

Figure 5 shows changes in the amount of desorbed DMP with silica loading. The amount of desorbed 3,5-DMP was almost unchanged up to about 10 wt% of silica; above this loading it slightly decreased with increasing silica loading. In contrast, the amount of desorbed 2,6-DMP exhibited a maximum at a silica loading of 12 wt%. According to a preliminary ^{31}P magic-angle spinning NMR experiment of chemisorbed trimethylphosphine, the alumina had predominately Lewis acid sites, and Brønsted acid sites were generated on the CVD SiO_2/Al_2O_3, accompanying the disappearance of the Lewis acid sites.[2] The TPD results are consistent with the ^{31}P NMR results, and are allowed to characterize the strength of Brønsted acid sites of the CVD SiO_2/Al_2O_3 catalysts.

For the isomerization of 1-butene, the catalytic

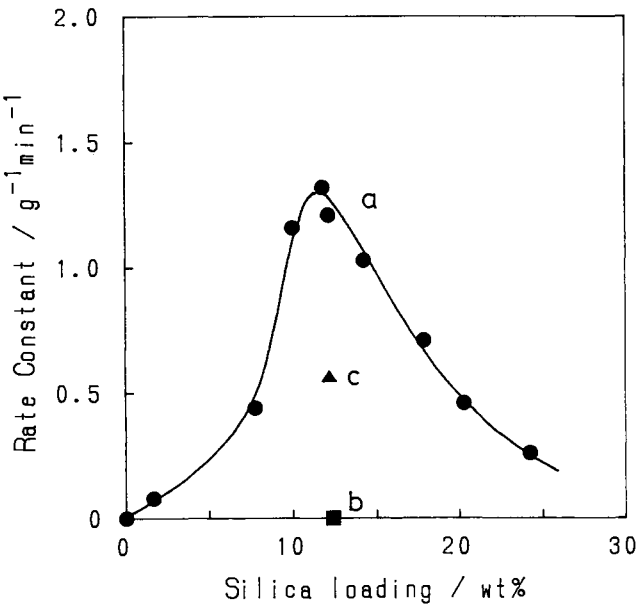

Fig. 6. Change in the initial rate constant for 1-butene isomerization. a, CVD SiO_2/Al_2O_3 prepared at 240°C in air; b, CVD SiO_2 (12.4 wt%)/Al_2O_3 exchanged with 0.11 mmol g^{-1} of K^+ ion; c, CVD SiO_2 (12.2 wt%)/Al_2O_3 prepared at 300°C in nitrogen.

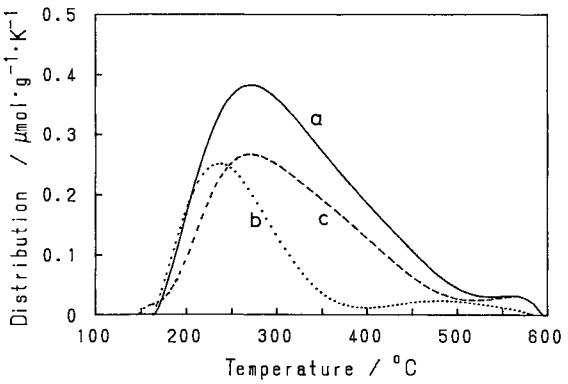

Fig. 7. TPD profiles of 2,6-DMP for various CVD SiO_2 (12 wt%)/Al_2O_3 catalysts. Symbols as those in Fig. 6.

activity was changed with silica loading (Fig. 6), and was maximized at a silica loading of 12 wt%, at which both the acid strength and amount measured by 2,6-DMP desorption showed maxima. Moreover, the CVD SiO_2/Al_2O_3 catalyst has a cation-exchange ability,[2] and an exchange of a proton with the K^+ ion suppressed the catalytic activity for 1-butene isomerization (Fig. 6b). The K^+ ion-exchange decreased both the acid strength and the amount (Fig. 7b), and the amount of desorbed 2,6-DMP drastically decreased at temperatures higher than 400 °C. In addition, a CVD SiO_2/Al_2O_3 catalyst prepared at 300 °C in nitrogen, which had a smaller amount of desorbed 2,6-DMP (Fig. 7c), was less active than that prepared at 240 °C in air (Fig. 6c). The catalytic behavior are well correlated with the Brønsted acidity measured by 2,6-DMP desorption.

ESR Study on Free Radicals Produced from Hexane by Vacuum-Ultraviolet Photolysis, Sensitized Photolysis, and γ-Radiolysis

Hitoshi KOIZUMI,* Takehito YAMAGUCHI,† and Hiroshi YOSHIDA
Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060
(Received August 17, 1990)

Synopsis. The free radicals generated from polycrystalline hexane at 77 K by photolysis with vacuum-ultraviolet light, sensitized photolysis, and γ-radiolysis were compared with each others using the ESR method. The selectivity of radical formation was found to depend on the excitation method.

Although the free radicals produced from saturated hydrocarbons have been extensively studied using ionizing radiation combined with ESR measurements, the mechanism for radical formation has not yet been fully understood.[1,2] Ionizing radiation generates primarily electrons, ions, and excited states, and possibly initiates several reaction channels which produce free radicals; thus, elucidating the reaction mechanism may be both complex and difficult. It seems to be helpful to produce free radicals with different excitation methods in order to obtain a deeper insight into the mechanism of free-radical formation.

In the present investigation free radicals generated from polycrystalline hexane by different methods were compared. The methods of radical generation used were direct photolysis with vacuum-ultraviolet (VUV) light from a Xe resonance lamp, sensitized photolysis with benzene and biphenyl as sensitizers, and radiolysis with ^{60}Co γ-rays. Direct photolysis with a proper wavelength of VUV-light brings hexane molecules to selected excited states either below or above the ionization threshold, from which radical formation proceeds. Although VUV-photolysis combined with ESR spectroscopy is expected to help elucidate the mechanism of radical formation, the reported studies have been scanty[3–6] because of experimental difficulties. Sensitized photolysis results in radical formation from hexane, either through energy transfer from the excited sensitizer or abstraction of an H atom by the excited sensitizer.

Experimental

All chemicals were of spectroscopic grade from Wako Pure Chemical Ind., Ltd. and were used without further purification after deaerating by freezing-thawing-pumping cycles. All irradiations and ESR measurements with an X-band spectrometer (Varian, Model E109) were made at 77 K.

A Xe electrodeless lamp constructed according to a method described in the literature[7] was used as the source of VUV light. Hexane was slowly condensed on the cold finger under vacuum of 10^{-5} Torr for one hour and then irradiated with VUV light. The irradiated sample was protected by covering with further condensation and was quickly transferred into a quartz Dewar vessel for ESR measurements.

For the sensitized photolysis, hexane with dissolved benzene (0.01—1 mol dm^{-3}) or biphenyl (0.1—1 mol dm^{-3}) was deaerated, sealed in a quartz ESR tube, and frozen at 77 K. The samples were irradiated with light from a Xe-Hg lamp through a Toshiba UV-D33S filter (250—400 nm) for one hour.

The γ-radiolysis was made with a ^{60}Co source with a dose of 1—4 kGy for hexane both in the sample tube and on the cold finger.

Results and Discussion

Typical examples of ESR spectra observed for the various radical generation methods are shown in Fig. 1. The spectra are generally a superposition of component spectra due to the hexyl, 1-methylpentyl, and 1-ethylbutyl radicals generated by the loss of an H atom from hexane. The component spectrum due to the hexyl radical is weak, since it is unstable and readily transforms into the 1-methylpentyl radical.[8]

For sensitized photolysis, the observed spectra is partly due to cyclohexadienyl-type and/or phenyl-type radicals originating from sensitizer molecules. However, the component spectra of these radicals are confined to the central, narrow region of the total spectral patterns. The yield of the sensitizer radicals was found to decrease with a decrease in the sensitizer concentration, and to be less for biphenyl than for benzene. Actually, the radicals from sensitizer benzene at 1 mmol dm^{-3} were almost ignored, compared to those from solvent hexane. These results indicate that the formation of radicals from hexane is not due to the hydrogen abstraction by the excited sensitizer but, rather, to the scission of a C–H bond of hexane caused by an energy transfer from the excited sensitizer. The formation of sensitizer radicals (cyclohexadienyl-type and phenyl-type) is due to a reaction between excited and ground-state sensitizer molecules, which can occur due to the heterogeneous dissolution at high sensitizer concentration.

The variation of the spectral shape of the solvent radicals depending on the generation method, as shown in Fig. 1, was found to be essentially due to the varying ratio of the 1-methylpentyl radical to the 1-ethylbutyl radical: the observed spectral shapes could be reproduced by superposing the theoretical shapes simulated for the 1-methylpentyl and 2-ethylbutyl radicals[8,9] and a broad spectrum due to radical pairs.[9] The 1-methylpentyl/2-ethylbutyl yield ratio was determined to be 3/2, 4/1, and 9/1 for VUV photolysis, biphenyl-sensitized photolysis, and γ-radiolysis, respectively.

The spectral shape observed for benzene-sensitized photolysis (Fig. 1d) comprises eight equally-spaced

† Present address: Chemical Products Division, Ricoh Company, Ltd., 16-1 Honda-machi, Numazu-shi, Shizuoka, 410.

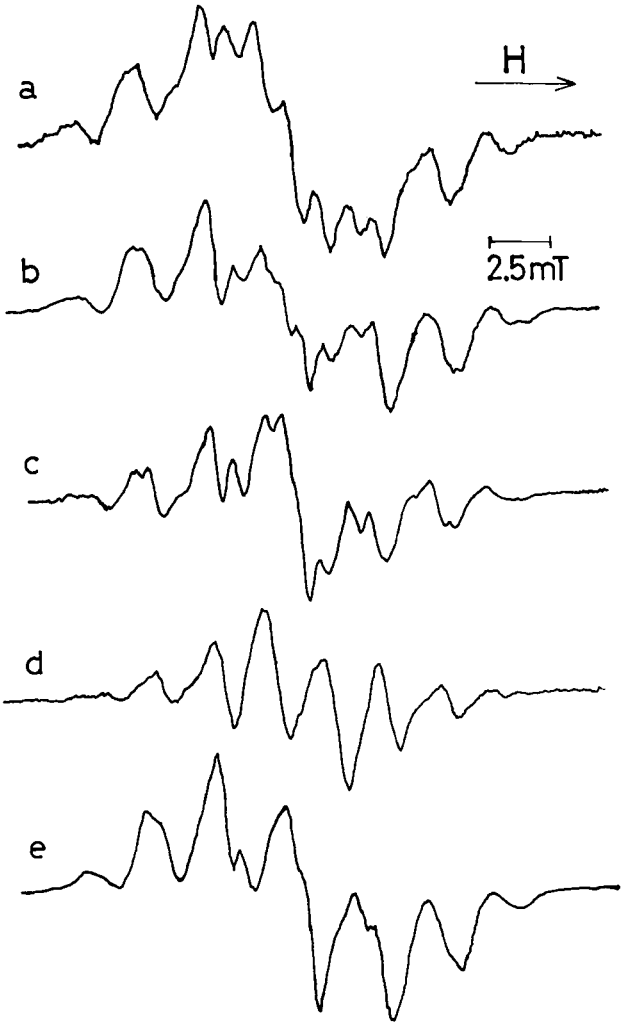

Fig. 1. ESR spectra observed at 77 K for hexane (a) photolyzed with Xe resonance lamp, (b) irradiated with γ-rays on the cold finger, (c) photolyzed by the biphenyl-photosensitization, (d) photolyzed by the benzene-photosensitization, and (e) γ-irradiated in a seal ESR tube.

hyperfine lines. This cannot be reproduced by any ratio of the 1-methylpentyl to 2-ethylbutyl radicals with normal conformation. Based on the McConell's relation, $a_\beta(\theta)=B\cos^2\theta$,[10] the distortion of the conformation by rotating about the C_α–C_β bond by 20° changes the hyperfine coupling constants of the β-CH_2 protons to 4.27 and 1.82 mT. These coupling constants well reproduce the observed spectral shape. Therefore, the free radicals generated by the benzene-sensitized photolysis are attributable to the 1-methylpentyl radicals with a distorted conformation.

A mechanism for radical formation from γ-irradiated n-alkanes has previously been proposed by Iwasaki et al.,[9]

$$RH \longrightarrow (RH^+)^* + e^-, \quad (1)$$

$$(RH^+)^* \longrightarrow R_I^+ + H \xrightarrow{+e^-} R_I + H, \quad (2)$$

$$(RH^+)^* \xrightarrow{+e^-} RH^* \longrightarrow R_I + H, \quad (3)$$

$$(RH^+)^* \xrightarrow{+RH} RH_2^+ + R_I \xrightarrow{+e^-} 2R_I + H_2 \text{ or } RH + H + R_I, \quad (4)$$

and

$$H + RH \longrightarrow R_{II},\ R_{III} + H_2. \quad (5)$$

They claimed that C–H bond scission by ionizing radiations occurs primarily at the chain-end, forming the terminal alkyl radical (R_I, $\dot{C}H_2CH_2$–) and a hydrogen atom, by one of the charge recombinantion processes: (2), (3), or (4). The terminal alkyl radical readily abstracts a hydrogen atom from a neighboring molecule to form a penultimate alkyl radical (R_{II}, $CH_3\dot{C}HCH_2$–) at 77 K in triclinic crystals of linear hydrocarbons with an even number of carbon atoms. The liberated H atom abstracts a hydrogen atom from a nearby molecule to form either R_{II} or an internal radical (R_{III}, –$CH_2\dot{C}HCH_2$–) secondarily (reaction 5).

In contrast, the present VUV-photolysis is a nonionic process, since the photon energy from the Xe resonance lamp (8.43 eV) is lower than the ionization threshold of hexane (10.06 eV in gas phase). The formation of hexyl radicals originates from the excitation:

$$RH + h\nu \longrightarrow RH^* \longrightarrow R + H. \quad (6)$$

Subsequent hydrogen abstraction (reaction 5) is also a possible source of hexyl radicals in VUV-photolysis. Assuming that the excited states in γ-radiolysis and VUV-photolysis (RH* in reaction paths (3) and (6)) are identical, the smaller R_{II}/R_{III} radical yield ratio for VUV-photolysis than for γ-radiolysis seems to results from a comparatively efficient formation of R_{III} through reaction path (3), compared with paths (2) and (4) for radiolysis. Iwasaki et al presumed that all of the reaction paths ((2),(3), and (4)) result in the formation of R_I, which then transforms into R_{II} at 77 K.[9] The present results, however, indicate that the dissociation of excited hexane into R_{III} cannot be ignored.

Kuwata et al.[4] previously reported that the VUV-photolysis of n-alkanes (C_5—C_8) with the Lyman-α line from a hydrogen discharge lamp gives ESR spectra with six hyperfine lines due to R_{III}. Their result is essentially consistent with the present result that the R_{II}/R_{III} yield ratio is comparatively low for VUV-photolysis, compared with γ-radiolysis.

In sensitized photolysis as well, radical formation occurs nonionically through reaction (7), followed by reaction (5),

$$RH + S^* \longrightarrow RH^* + S \longrightarrow R + H + S. \quad (7)$$

It was previously reported that an energy transfer from a benzene or biphenyl molecule occurs from its second or higher triplet state created by T–T absorption.[12] In benzene-sensitized photolysis, the influence of energy-

donating benzene causes a selective formation of R_{II} with a distorted conformation. Takeshita and Tsuji previously observed the selective formation of the 1-methylpentyl radical from hexane by photolysis with benzoic acid used as sensitizer.[13]

In conclusion, the selectivity in radical formation from polycrystalline solid hexane depends on the excitation method used, VUV-photolysis, sensitized photolysis, or γ-radiolysis. This is in contrast with the absence of selectivity reported for 3-methylpentane in the amorphous state.[12,14-17] It is not presently known whether the difference observed between hexane and 3-methylpentane can be attributed to differences in molecular structure or differences in the aggregation state.

It is thankfully acknowledged that this work was partly supported by the Kurata Research Grant to H. K.

Catalytic Isomerization of Trimethylbenzenes over a Graphite-Sulfuric Acid

Susumu TSUCHIYA,* Kenji FUJII, Tadashi MITSUNO, Yoshihisa SAKATA, and Hayao IMAMURA
Department of Industrial Chemistry, Faculty of Engineering,
Yamaguchi University, Tokiwadai, Ube, Yamaguchi 755
(Received September 6, 1990)

Synopsis. The isomerization of 1,2,3- and 1,2,4-trimethylbenzene took place over a graphite–sulfuric acid to form 1,2,4- and 1,2,3-trimethylbenzene, respectively, but that of 1,3,5-trimethylbenzene was not observed.

Since Kondow et al.[1] found that the equilibration of protium–deuterium took place over a caesium–graphite intercalation compound (GIC), much attention has been paid to the characteristic properties of graphite intercalation compounds, and their catalytic properties have been investigated extensively in various reactions.[2,3] Watanabe et al.[4] reported a molecular-sieving-type physisorption of alkali metal graphites at 77 K.Tsuchiya et al.[5,6] have observed structure-selectivity in the hydrogenation and the isomerization of olefins over alkali metal graphites. The results have been explained on the basis of the molecular-sieving-like effect of the compound.

Because the molecular-sieving-like effect has been observed in the case that the intercalant of GIC is basic substances,[5,6] a similar effect would be expected in the case that the intercalant is an acidic substance. Trimethylbenzenes (1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzene) are catalytically isomerized over an acid catalyst.[7] It can therefore be expected that a certain isomer of trimethylbenzene might be selectively formed over a graphite–acid with molecular-sieving effects. In this study interest was centered on a graphite–sulfuric acid.

A closed recirculation system using greaseless stopcocks was employed in order to follow the progress of the reaction; helium was used as the diluent. The reaction mixtures were occasionally analyzed by means of gas chromatography. The graphite–sulfuric acid used as the catalyst was prepared according to Takemoto et al.,[8] and identified by XRD. A bundle of glass-wool impregnated with sulfuric acid was used as "H_2SO_4-cat". Trimethylbenzenes were obtained from Tokyo Kasei Kogyo Co., Ltd., and their purity, more than 99%, was confirmed by gas chromatography.

Four kinds of reactions can be expected over an acid catalyst, as follows:

1) Disproportionation of trimethylbenzenes (1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzene) to form dimethylbenzenes (1,2-, 1,3-, and 1,4-dimethylbenzene) and tetramethylbenzenes (1,2,3,4-, 1,2,3,5-, and 1,2,4,5-tetramethylbenzene).
2) Isomerization of trimethylbenzenes.
3) Isomerization of dimethylbenzenes.
4) Isomerization of tetramethylbenzenes.

Table 1 lists the equilibrium composition, assuming that these four kinds of reactions are in equilibrium. These values were calculated on the basis of reported API thermodynamic data.[9]

Figure 1 shows a typical result, when 1,2,3-trimethylbenzene was introduced over graphite-sulfuric acid at 373 K. 1,3,5-Trimethylbenzene was not observed. Neither dimethylbenzenes nor tetramethylbenzenes were detected. From a thermodynamic analysis the formation of 1,3,5-trimethylbenzene would be expected, if the interconversion of three isomers of

Table 1. Equilibrium Composition

Component	Composition C/mol%		
	300 K	400 K	500 K
1,2,3-Trimethylbenzene	1.38	2.13	2.71
1,2,4-Trimethylbenzene	29.27	29.31	28.74
1,3,5-Trimethylbenzene	19.56	15.59	13.11
1,2-Dimethylbenzene	4.06	5.02	5.86
1,3-Dimethylbenzene	14.89	15.05	15.18
1,4-Dimethylbenzene	5.94	6.42	6.69
1,2,3,4-Tetramethylbenzene	2.00	2.87	3.65
1,2,3,5-Tetramethylbenzene	13.15	13.82	14.28
1,2,4,5-Tetramethylbenzene	9.75	9.80	9.79

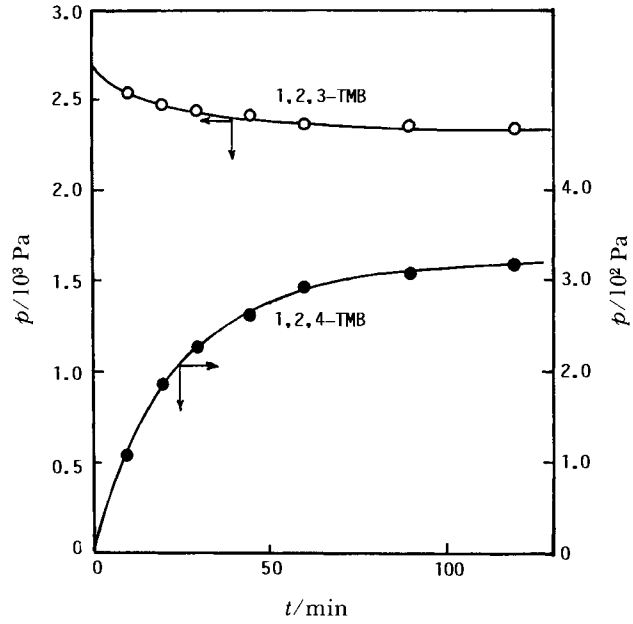

Fig. 1. Isomerization of 1,2,3-trimethylbenzene over a graphite–sulfuric acid at 373 K.

trimethylbenzenes take place. If the disproportionation of 1,2,3-trimethylbenzene takes place, dimethylbenzenes and tetramethylbenzenes might be expected. However, only 1,2,4-trimethylbenzene was selectively formed. This result suggests that only the isomerization of 1,2,3-trimethylbenzene to form 1,2,4-trimethylbenzene took place.

When 1,2,4-trimethylbenzene was the reactant, 1,2,3-trimethylbenzene was only observed as an aromatic compound. The formation of 1,3,5-trimethylbenzene, dimethylbenzenes, and tetramethylbenzenes was not detected. This result suggests that the isomerization of 1,2,4-trimethylbenzene to form 1,2,3-trimethylbenzene took place, and that the disproportionation of 1,2,4-trimethylbenzene did not take place. Another product observed was methane, the amount of which was less than 10% of the 1,2,3-trimethylbenzene formed. Methane might be formed by the decomposition of the reactant.

When 1,3,5-trimethylbenzene was the reactant, any hydrocarbon other than the reactant was observed at 373 K. This result suggests that 1,3,5-trimethylbenzene did not react under the present experimental conditions. Because neither dimethylbenzenes nor tetramethylbenzenes was observed, it is reasonably concluded that the disproportionation of trimethylbenzenes did not take place over the graphite–sulfuric acid under the present experimental conditions. At 413 K, methane was observed, the amount of which was ca. 20% of the reactant at 2 h. The methane might be formed by decomposition, as mentioned above. If the amount of methane is small, the formation of methane is an important problem, since carbon depositing on the catalyst surface might take place. In order to elucidate this point, further investigations are certainly necessary and should be carried out.

The widths of 1,2,3-, 1,2,4-, and 1,3,5-trimethylbenzene are 8.1, 7.6, and 8.6 Å, respectively. Since the interlayer distance of a graphite–sulfuric acid is 11.3 Å, wider molecules probably have more difficulty to penetrate into and move within the space between the graphite layers than do narrow molecules. Accordingly, the present experimental results, that the formation and conversion of 1,3,5-trimethylbenzene were not observed, are reasonably explained on the basis of a size effect of the molecules.

When 1,2,3-trimethylbenzene was introduced over H_2SO_4-cat, on the other hand, both dimethylbenzens and tetramethylbenzenes were observed. This result suggests that the disproportionation reaction took place over H_2SO_4-cat. Accordingly, the catalytic selectivity of H_2SO_4 was varied by forming such intercalation compounds as graphite–sulfuric acid.

In conclusion, graphite–sulfuric acid has shown high catalytic selectivity for the reaction of trimethylbenzenes.

Photofading Reaction of Bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]nickel(0) in the Presence of *N,N'*-Dimethylformamide

Koe ENMANJI* and Kenzou TAKAHASHI
The Materials and Electronic Devices Laboratory, Mitsubishi Electric Co.,
Tsukaguchi-Honmachi, Amagasaki 661
(Received September 11, 1990)

Synopsis. Bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]nickel(0) was found to undergo photofading in the presence of dimethylformamide, by the action of photogenerated superoxide. Addition of a detergent suppressed the formation of superoxide, with an efficiency paralleling the fatty acid chain length.

We previously found that bis[1-(4-dimethylaminophenyl)-2-phenylethanedithione]nickel(0) (BDN), a Q-switch dye for neodimium laser was bleached in the presence of peroxide compounds[1] presumably via oxidation of BDN by peroxide. This bleaching was inhibited by inclusion of BDN into β-cyclodextrin.[1] BDN was also faded under darkness in the presence of *N,N'*-dimethylformamide (DMF).[2] In this case, BDN was reduced to its anion radical and the fading was not inhibited by inclusion into cyclodextrin but rather promoted in its presence.[3]

In addition we found that the reductive fading of BDN was promoted by illumination in the presence of DMF, and the mechanism of this reaction is the subject of the present work. Photo-generation of superoxide was expected to be the main cause as in the photofading of other dyes.[4,5] The authors incidentally found that singlet oxygen generation was inhibited by addition of a detergent in a Methylene Blue aqueous solution.[6] In view of this, the effect of detergents was also examined in the present BDN–DMF system.

Experimental

BDN was purchased from Kodak Co., and DMF, toluene, adrenalin, sodium dodecyl sulfate (SDS), sodium octyl sulfate (SOS), and sodium hexadecyl sulfate (SCS) were obtained from Nakarai Chemical Co.

Electronic spectra were measured with a Shimadzu spectrophotometer MPS-5000. The photochemical reaction system was illuminated with an Ushio high-pressure mercury lamp Model 500 equipped with a Toshiba VY-50 filter.

The photofading rate was estimated by the photodecoloration ratio, r, defined by

$$r = \frac{OD^0 - OD}{OD^0} \quad (1)$$

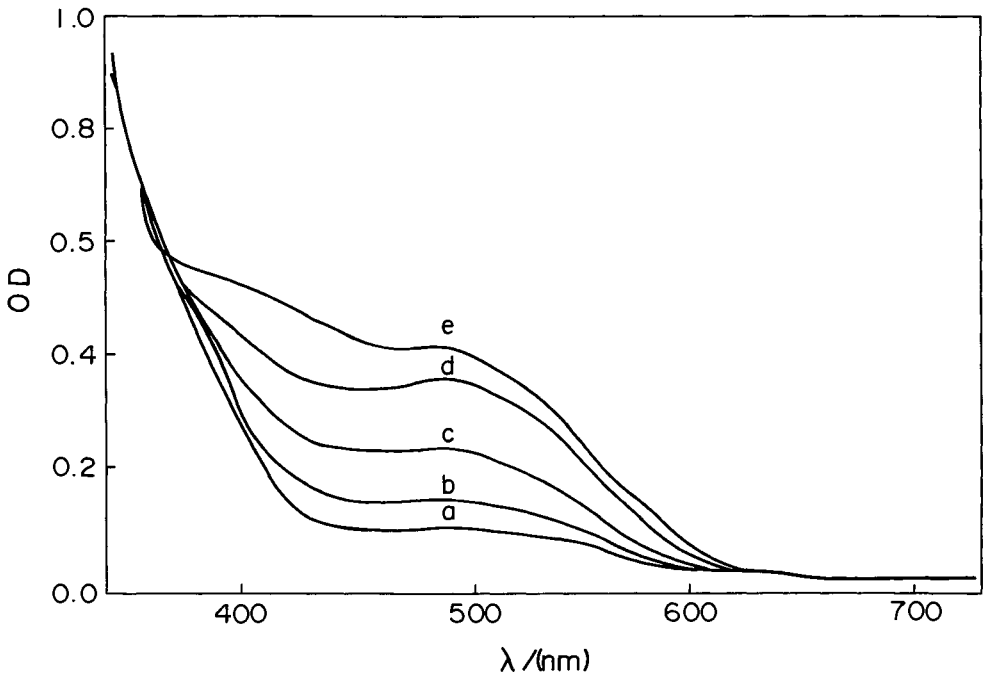

Fig. 1. Photooxidation of adrenalin to adrenochrome. [DMF]=5 mol dm^{-3}, [BDN]=10^{-5} mol dm^{-3}, [Adrenalin]=50 mmol dm^{-3}, I=69.4 mW cm^{-2}. a: 0 min, b: 15 min, c: 30 min, d: 45 min, e: 60 min.

where, OD^0 and OD are the optical density at 1100 nm before illumination and that after t-min illumination, respectively.

Results and Discussion

In darkness BDN fades in DMF via the formation of its anion radical. Illumination in DMF accelerated this reaction yielding the same product, BDNH, as in the fading in darkness. This was ensured by observing a common R_f value (0.79) of the product by alumina thin layer chromatography (TLC), with DMF : toluene : methanol=1 : 0.75 : 1 as developer.

The generation of superoxide in this reaction system was suggested by the oxidative conversion of adrenalin to adrenochrom exihibiting an absorbance maximum at 490 nm (Fig. 1).[7] The following result also indicates the existence of superoxide. The photodecoloration ratio (r) of BDN in a DMF–water system ([DMF]=5 mol dm^{-3}) was 0.065 at 10-min illumination. The value of r was 0.000 in the presence of 75000 units superoxide dismutase, which is a good quencher of superoxide.

It was found that r of BDN was proportional to both the DMF concentration and the light intensity.

The maximum wavelength in the action spectrum of the BDN photofading was estimated to be about 300 nm, through experiments with a series of cutoff filters.

As in other photolysis systems[4,5] the following reaction sequence appears to hold for the present system.

$$\mathrm{BDN} \xrightarrow{h\nu} {}^1\mathrm{BDN} \quad (2)$$

$${}^1\mathrm{BDN} \longrightarrow {}^3\mathrm{BDN} \quad (3)$$

$${}^3\mathrm{BDN} + \text{solvent} \longrightarrow \mathrm{BDN}^{+}\cdot + \mathrm{e(solvent)} \quad (4)$$

$$\mathrm{BDN}^{+}\cdot + \mathrm{e(solvent)} \longrightarrow \mathrm{BDN}\cdot + \text{solvent} \quad (5)$$

$$2\mathrm{BDN}\cdot + \mathrm{H_2O} \longrightarrow \mathrm{BDNH} + \mathrm{BDN}^{+}\cdot + \mathrm{OH}^{-} \quad (6)$$

$$\mathrm{e(solvent)} + \mathrm{O_2} \longrightarrow \mathrm{O_2}^{-}\cdot + \text{solvent} \quad (7)$$

This scheme is supported by the identifying BDNH as a final product by TLC. This compound may be an anion radical of BDN.

To estimate the rate of superoxide penetration through the micellar layer of a detergent, as in the case of singlet oxygen in Methylene Blue–detergent system, the effect of detergents to the BDN system on the oxidation of adrenalin to adrenochrome was investigated in the presence of a small amount of DMF. As seen in Fig. 2, the rate of adrenalin oxidation is in order SOS>SDS>SCS. Probably superoxide is generated in the center of micelles containing BDN molecules, and the triplet ground state oxygen is supplied sufficiently through the micelle membrane. The generated superoxide penetrates through the micelle membrane but it may disappear partly in the course of this penetration. When the micellein membrane is thicker, namely the fatty acid chain of detergent is longer, the disappearing fraction of superoxide is larger and hence the oxidative adrenalin-to-adrenochrome conversion is less efficient. The results in Fig. 2 are in line with this speculation.

Belousov-Zhabotinskii Reaction with 2,3-Diones

Masao TSUKADA* and Naoki INAMOTO
Department of Chemistry, Juntendo University, Inba-gun, Chiba 270-16
(Received September 13, 1990)

Synopsis. 2,3-Butanedione and 2,3-pentanedione have been found to generate chemical oscillations in 2,3-dione/BrO_3^-/Ce^{4+}/H_2SO_4 system. The concentration range within which the oscillatory behavior can be observed for each reactant is reported.

The Belousov-Zhabotinskii(BZ) reaction is probably the best studied chemical oscillation reaction.[1] In BZ reaction, malonic acid is oxidized by bromate ions in sulfuric acid medium in the presence of cerium(IV) ions. After an induction period, the concentration of bromide ions and the redox ratio (=log [Ce^{4+}]/[Ce^{3+}]) oscillate with a frequency and an amplitude which depend on the initial composition of system and temperature. It has been known that cerium(IV) ion, malonic acid, and sulfuric acid in this oscillating system may be replaced by the other appropriate compounds. Most of the organic species capable of replacing malonic acid contain an "active" methylene group. The use of acetone alone as the substrate does not yield any oscillations, but generates oscillations in mixed-substrate BZ systems.[2] We have examined the effects of replacing malonic acid with 2,3-butanedione or 2,3-pentanedione which is of interest in a similarity to acetone.

Experimental

All reagents used were the highest grade commercially available except for 2,3-butanedione which was purified by vacuum distillation. The redox potential was monitored with a platinum electrode. A double junction Hg/Hg_2SO_4/K_2SO_4 electrode was used as a reference. In most experiments, the reaction was performed in a glass container with magnetic stirrer under aerobic conditions.

Results and Discussion

Typical responses of platinum and bromide selective electrodes in the dione/BrO_3^-/Ce^{4+}/H_2SO_4 system are shown in Figs. 1 and 2 along with the oscillations of the malonic acid system for a comparison. In the case of diketone system its oscillatory state consists of a dozen oscillations, while in the malonic acid substrate its oscillation continues for about three hours. On comparing the two systems, each level of bromide ion concentrations overlaps with the other, although the oscillation range of redox potential is considerably different. It has been shown that bromide ion concentration plays a vital role in the BZ system.[1] Thus it could be suggested that dione substrate plays a similar role to malonic acid. There was no gas evolution

Temp/°C	29—33	28—40

a) M=mol dm^{-3}.

during the oscillating reaction. In view of this fact, 2,3-dione behaves in a similar fashion to 2,4-pentanedione.[3)]

Chemical oscillations were observed in a definite range of initial concentrations for the four components, $KBrO_3$, $Ce(SO_4)_2$, H_2SO_4, and dione. We adopted the concentrations used for the reaction shown in Fig. 1 as a standard condition. The range of concentrations is shown in Table 1 where the concentration of one of the four components was varied under the fixed concentrations of the other three components at the standard condition. It is remarkable that the concentration range in which oscillations appear is very narrow for both $KBrO_3$ and H_2SO_4 in the case of 2,3-butanedione.

The induction period (t_{ind}) and the period of oscillation(t_{osc}) varied with temperature. The plots of log ($1/t_{ind}$) and of log ($1/t_{osc}$) were linear with inverse of absolute temperature in the range shown in Table 1. The values of two activation energies, E_{ind} and E_{osc} which correspond to t_{ind} and t_{osc} respectively, were found to be 68±6 and 69±8 kJ mol^{-1} for 2,3-butanedione, 67±9 and 71±7 kJ mol^{-1} for 2,3-pentanedione. E_{osc} can be attributed to the reduction reaction of BrO_3^- with brominated substrate which requires an activation energy between 60 and 70 kJ mol^{-1}.[4)] The value of E_{osc} obtained by us lies in this range.

The induction period depends on the concentrations of dione and of Ce^{4+}, but it is not affected by the concentrations of BrO_3^- and of H^+. This means that the reaction of dione with Ce^{4+} is closely related to the induction period. It has been found that acetone does not yield oscillations when acetone is used alone in the cerium(IV) ion catalyzed BZ system, because acetone can be brominated but is not oxidized.[5)] In the case of dione, it could form a five-membered chelate ring by the coordination of Ce^{4+} with its two carbonyl groups and the complex thus formed would initiate oxidation of dione.

It has been known that mechanical stirring can, in some cases, sensibly affect the oscillation.[6)] For example, in the case of malonic acid substrate system, the oscillations stop suddenly without a change of amplitude when the stirring rate rises more than a threshould and immediately start again when the stirring rate falls below the threshold. In the dione system, more rapid stirring than a threshold resulted in termination of the oscillations, but a switch to slow stirring did not cause the oscillation again. It was also observed that the addition of dione after damping of the oscillations does not regenerate the oscillations, but that under nitrogen atmosphere the addition of dione cause the oscillations again. It would be sure that some mechanical stirring effects are attributed to an increased oxygen transfer into the system. Thus the results suggest that some reaction products formed by oxygen inhibit the oscillation.

Further detailed studies on the mechanism in this system are in progress.

Mixture Dependences of OH($^2\Sigma$) Produced in the Oxidations of C_2H_2 and C_2H_6 in Shock Waves

Tohru KOIKE
Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239
(Received October 17, 1990)

Synopsis. The OH($^2\Sigma$) emissions from shock-heated mixtures of C_2H_2/O_2, $C_2H_2/C_2H_6/O_2$, and C_2H_6/O_2 diluted in Ar were observed and the mixture dependences of the emissions were obtained. OH($^2\Sigma$) production, depending on the test gas mixture, could be in accordance with the view-point that the two oxidations of C_2H_2 and C_2H_6 progress by influencing each other.

The reaction on OH($^2\Sigma$), hereafter abbreviated as OH*, at high temperatures (above 1000 K) has been studied for many reaction systems using shock-tube techniques.[1,2] As for OH* in hydrocarbon oxidation, only single hydrocarbon/O_2 systems, excepting multi-hydrocarbon/O_2 systems, have been investigated.[3]

The temperature reached by hydrocarbon combustion is high due to their large exothermicity. The hydrocarbons used for fuels therefore decay to smaller species, thermally, as well as by oxidation processes. Acetylene is one of the primary products given by such thermal decay. Thus, at high temperatures acetylene could be present from the beginning of combustion; hydrocarbon combustion seems to proceed by self decay, as mentioned above, influenced by acetylene combustion.

We paid attention to the OH* produced in a C_2H_2+C_2H_6 systems, studying it in comparison with those in the C_2H_2 and C_2H_6 systems. The time parameters and intensities of OH* emission were investigated in relation to the test gas compositions used. The production of OH* could be understood by considering that the two oxidations of C_2H_2 and C_2H_6 progress by influencing each other.

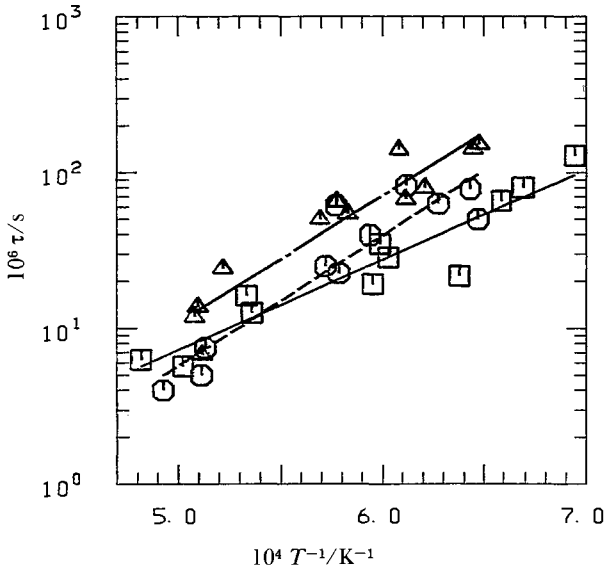

Fig. 1. Induction times, τ, vs. $10^4/T$. Symbols used are; □: $C_2H_2/O_2/Ar$=1/2.5/96.5, ○: $C_2H_2/C_2H_6/O_2/Ar$=1/1/6/92, △: $C_2H_6/O_2/Ar$=1/3.5/95.5. Lines through each data point show least squares fit.

Experimental

The rectangular shock tube used in the present study for incident shock waves was detailed in previous papers.[3,4]

OH* emission at 306.4 nm was observed using a monochromator (Jarrell-Ash, JE-25) and a photomultiplier (Hamamatsu, R-208). The output signal of the photomultiplier was fed into an operational amplifier and then recorded on a digital-oscilloscope (Iwatsu, DS-6121).

The purities of the element gases used for the test gas were; C_2H_2, 99.5% pure; C_2H_6, 99.3% pure; O_2, 99.999% pure; and Ar, 99.999% pure. The compositions of the test gas mixture are shown in the footnote of Fig. 1.

Results and Discussion

The obtained oscillograms show that after shock arrival at the observation window of the shock tube, OH* emission can not be observed for a reaction period (induction time), but increases abruptly to a maximum value and finally decays. Although the time profile and intensity of OH* emission changes depending on the temperature and the test gas mixture examined (as shown below), such profiles of OH* emission are common for the three mixtures, as well as for other hydrocarbons.[1,3]

We evaluated three parameters from these oscillograms: (1) induction time(τ),[3] (2) reaction time at which the emission intensity reaches a miximum (t_m), (3) the maximum emission intensity (I_m).[3] The time parameters, τ and t_m, were evaluated on the laboratory time base. The I_m values are proportional to [OH*].

Figure 1 shows the relation between τ and $10^4/T$. Except for high temperatures (around 2000 K), the dependence of τ on the test gas mixture was found to be $\tau(C_2H_6)>\tau(C_2H_2+C_2H_6)>\tau(C_2H_2)$, where the species in parenthes identifies the hydrocarbons contained in the test gas mixtures used. Such a mixture dependence on τ is in accord with the experimental results reported for both C_2H_2 and CH_4 oxidation:[3,5] that $\tau(CH_4)>\tau(C_2H_2+CH_4)>\tau(C_2H_2)$. Since C_2H_2 and CH_4 oxidation was confirmed to progress by influencing each other in a C_2H_2+CH_4 mixture,[5] in a C_2H_2+C_2H_6 mixture the C_2H_2 and C_2H_6 oxidation are also expected to proceed similarly and to affect the production of OH*.

It should be pointed out here that the values of τ evaluated at high temperatures are not accurate as those evaluated at lower temperatures, since τ at high temperatures becomes small and is hard to estimate from each oscillogram with sufficient precision. In contrast to such a time parameter as τ, both the t_m and

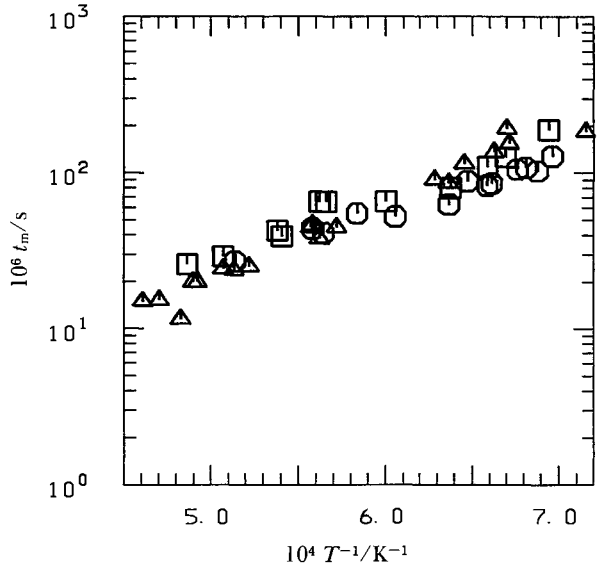

Fig. 2. Reaction times, t_m, vs. $10^4/T$. Symbols used are the same as those in Fig. 1.

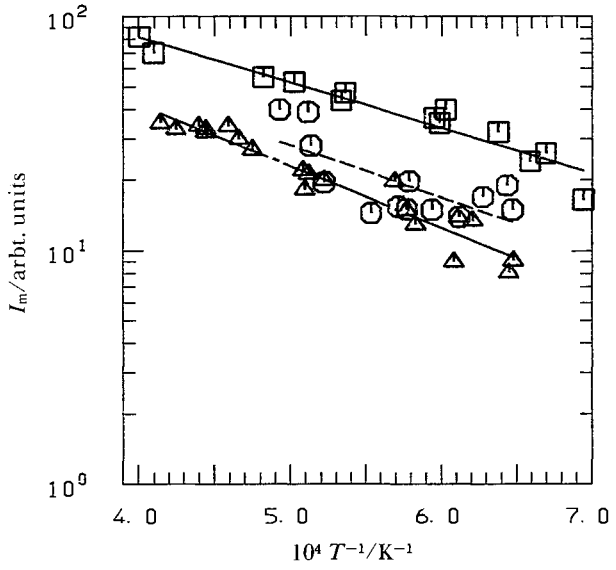

Fig. 3. Maximum emission intensity, I_m, vs. $10^4/T$. Symbols used are the same as those in Fig. 1.

I_m values could be evaluated precisely even at high temperature.

Figure 2 shows the relation between t_m and $10^4/T$. The difference of the t_m values between the three mixtures is not so clear and, thus, the influential relation between C_2H_2 and C_2H_6 oxidation to produce OH* seems to proceed much more.

Figure 3 shows the relation between I_m vs. $10^4/T$. In accordance with the former experimental results regarding I_m for C_2H_2 and CH_4 oxidation,[3] that $I_m(C_2H_2)>I_m(CH_4)$, the mixture dependence $I_m(C_2H_2)>I_m(C_2H_6)$ can be seen. If C_2H_2 and C_2H_6 oxidation could progress independently in a C_2H_2+C_2H_6 mixture, the relation $I_m(C_2H_2+C_2H_6)\approx I_m(C_2H_2)+I_m(C_2H_6)$ would be expected, since t_m is almost same for all three mixtures. The result is that the $I_m(C_2H_2+C_2H_6)$ values lie between those in the other two mixtures.

Taking into account the temperature dependences of the time parameters, τ and t_m, and the I_m values, the production of OH* can be seen to proceed rapidly and violently at high temperature. Such results may support the viewpoint that the difference in the heat of combustion between the two oxidations affects the production of OH* much more than does the difference of the generated radicals between them. As for the reaction temperature in the C_2H_2+C_2H_6 mixture, it must reach the highest value among the three mixtures, and the observed I_m values in the mixture could be largest. The result shown in Fig. 3 does not seem to be in accord with these hypotheses. Therefore, it can be concluded that in OH* production the two oxidations of C_2H_2 and C_2H_6 in the C_2H_2+C_2H_6 mixture proceed with any influence other than the thermal effect.[5] Such influences could arise due to chemical coupling of the generated radicals in each oxidation.

It is also informative regarding the existence of chemical coupling that the time variation of OH* emission is also very smooth in a test gas mixture of C_2H_2+C_2H_6. If C_2H_2 and C_2H_6 oxidation could proceed independently, two peaks of maximum emission, attributed to the two oxidations, should appear.

Although the producing step of OH* in hydrocarbon oxidation is still controversial, the fate of OH* is mentioned here briefly. If OH* is produced by the process CH+O_2=OH*+CO, as proposed by Gaydon,[6] the I_m values should be proportional to the concentration product of [CH][O_2].[1,3] It was, however, found that the I_m does not increase simply with increasing [O_2] in the mixture used. We can thus say that the producing step of OH* depends greatly on the value of [CH].

Shock tube studies concerning the production of OH* in other hydrocarbon mixtures are in progress and the results may appear elsewhere.

The present author wishes to thank Professor Kihei Morinaga, National Defense Academy, for many helpful discussions and also the reviewer for a comment on the OH* production in the present reaction system.

Infrared Spectra of SiO_2 Coating Films Prepared from Various Aged Silica Hydrosols

Masaaki MUROYA
Osaka Electro-Communication University, 18-8 Hatsu-cho, Neyagawa, Osaka 572
(Received October 18, 1990)

Synopsis. Measurements have been made of the vibrational absorption bands of silica films. The results have been used to examine the importance of the polymerization of silica. Seven other absorption bands, which are related to the Si-O group, were clearly found in the region from 1300 to 400 cm^{-1}. A band at a wave number of 1069 cm^{-1} increased with increasing the viscosity of the hydrosol. The band at 974 cm^{-1} was substantially sensitive in intensity to the heat-treatment and the rehydration of silica film, can be assigned to the Si-O stretching vibration of the surface silanol since the intensity of its band is influenced by both the heat-treatment(dehydration) and rehydration.

It has been indicated by several workers[1-4] that silica-coating films can be prepared using several methods. Such silica films have been convenient for investigating the surface properties of silica, and may also be suitable for controlling the transmittance and refractive index in optics materials. It is known that the surface silanols on silicas, such as silica gel, pyrogenic silica and porous glass, play a central role as the active center regarding the adsorption properties, ion-exchange in solutions containing some cations, and surface modification of their materials using surface reactions.[5] Examinations using infrared spectroscopy have proved to be among the most effective means to investigate the bond nature of surfaces and substrate structures in materials.[6] The infrared spectra of such surface-active materials as silicas were normally taken in vacuo since the surface silanol is sensitive to the moisture in air, and the clearness of the spectrum is dependent on the sample preparation for infrared experiments.[7,8] The infrared spectra of the silicas can be clearly measured in the range of about 4000 to 3000 cm^{-1}, the wave number region of which corresponds to the stretching vibration of the O-H in surface silanols and the adsorbed water on such materials.[7] Indistinct spectra were found for the silicas when infrared measurements were carried out over a range of about 2000 to 400 cm^{-1}. This is due to the intense absorption efficiency of silica in this region. However, it could be expected that the problem has been solved by using silica films.

In order to understand the polymerization process of silica in its hydrosol stage, we measured the FT-IR spectra of silica films which were prepared by ageing the silica hydrosol obtained from the hydrolysis of tetraethyl orthosilicate. Moreover, the relationship between the formations of siloxane and the surface silanol and the remarkable feature of absorption bands is discussed in this report.

Experimental

Silica hydrosols were prepared by the hydrolysis of tetraethyl orthosilicate.[7] In this work, solutions of redistilled tetraethyl orthosilicate, ethyl alcohol, and distilled water adjusted to pH 2 by using a hydrochloric acid were mixed in volume ratio, $Si(OC_2H_5)_4$: C_2H_5OH: H_2O=5: 1: 0.5, and then heated at 65 °C for 60 min. After its sol had formed, the hydrolsol was allowed to stand for a long time at room temperature in air; that is, the hydrosol aged with the elapse of time. Metal plate (20×30 mm wide and 0.3 mm thickness), which is stainless steel (SUS 304) pretreated before use, was steeped in such hydrosol for 30 min in air, at a relative humidity of about 50%; its plate was then pulled from the hydrosol at a rate of 1.0 mm s^{-1} and dried at 170 °C for 1 h in air. A filmy specimen with the hues of a rainbow and about 0.9μm thickness, was obtained from the procedures mentioned above. For a pretreatment, the metal plate was immersed into a 2% NaOH solution, washed with distilled water, steeped in acid adjusted with sulfuric acid at 10%, washed with distilled water, and dried at 110 °C for 1 h. A Japan Spectroscopy Co. 5MP FT-1R spectrometer was used for the measuring on the silica films, spectra of which were taken with a polarizing reflection technique.[8]

Results and Discussion

Figure 1 shows the infrared absorption spectra of the silica coating films obtained from various ageing of the hydrosol. A number of absorption bands were found in the range from about 4300 to 400 cm^{-1}. A broad absorption band ranging from 3800 to 3000 cm^{-1}, which was ascribed to the O-H stretching vibration mode,[7,9] was found in a specimen aged for 1536 h. The intensity of this band depended on the time required for ageing. A few absorption bands around 2900 and 1400 cm^{-1}, which were assigned to C-H stretching and deformation vibrations, changed in intensity as a function of the ageing period. It can therefore be understood that the formation of the OH radical and the alkylation occurred at the same time on the surface of particles and that the contents of their chemical species in the films were dependent on the ageing. The very weak band at the water-bending vibration is ascribed to adsorbed water, since the band appeared at its wave number when the specimen was exposed to water vapor. The very strong bands at 1215 and 1069 cm^{-1} can be assigned to the asymmetrical stretching vibration of SiOSi in the layer structure of silica[10,11] and of the ≡Si-O-Si≡ bridge which is formed between particles or small spherical polymer, since the intensity of the band is enhanced with increased ageing with the elapse of time. The assignments of these bands are not in agreement with those found in the literature.[12] These bands were also indicated by Hino et al.,[13] the wave numbers of their bands are not clear due to an overlap of these bands as a result of the high concentration of Si-O species in a disordered structure. The specimens used in the literature[12,13]

were of the silica xerogel, which consist of a rigid three-dimentional network of contiguous particles of colloidal silica; in the filmy silica used in this study it is quenched during the early or middle stage of polymerization. In the later case, when polysilicic acid is formed at low pH (the pH value of the present sol was about 2.8), polymer particles are formed, and the polymerization is sufficiently slow to allow the early stage. When the particles are not charged, they link together into branched chains to form three-dimension network regions in the sol. Such a polymerization process can be followed by taking the spectra of skeletal vibrations of filmy silica prepared from the sol. In a previous study,[8] it was suggested that the 1069 cm^{-1} band is mainly related to polymerization. Actually, the intensity of this band was substantially

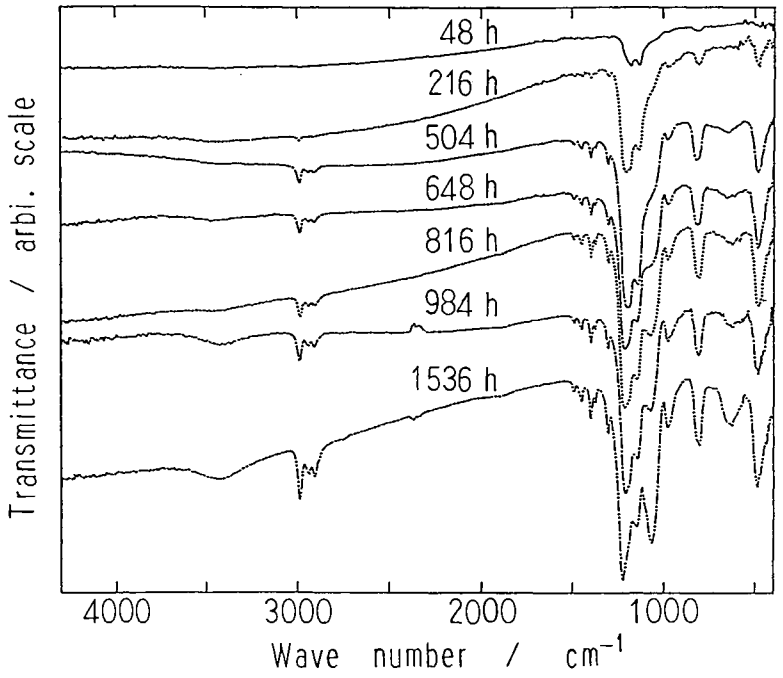

Fig. 1. Spectra of the silica films prepared from the silica hydrosol.

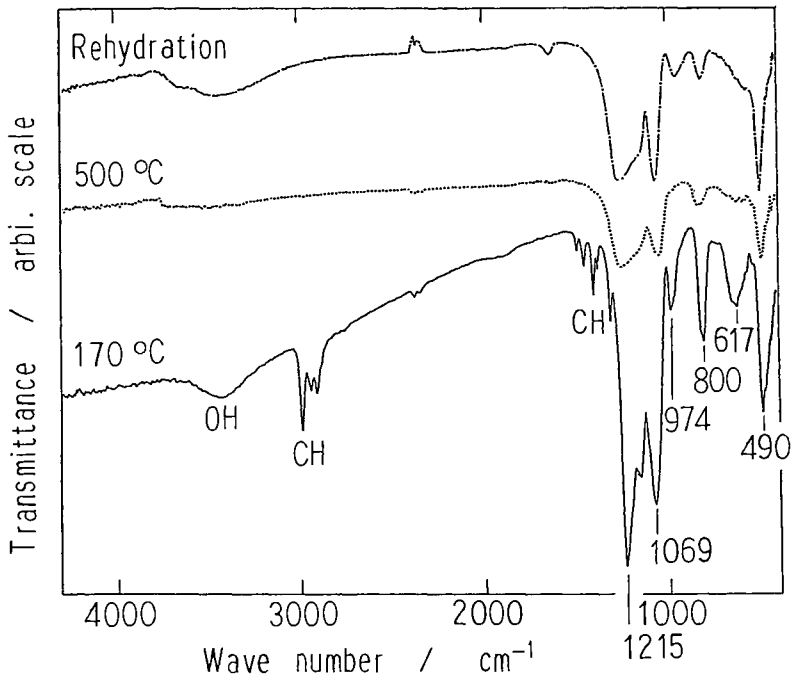

Fig. 2. Spectra of the silica films heat-treated at 500 °C in air and rehydrated with saturated water vapor after its heat-treatment.

sensitive to the elapse of time, as can be seen in Fig. 1. It is therefore thought that a measurement of the intensity change of such a band can be used as an indication of the polymerization rate.

In order to determine the nature of the bands in the lower wave number region of about 1000 to 400 cm^{-1}, a heat-treatment and rehydration experiments were performed on film specimens; their spectra are shown in Fig. 2. When heating a specimen at 500 °C for 1 h in air, both the O–H and the C–H bands disappeared, and the bands at 974 and 617 cm^{-1} also faded out. It is known that the 974 cm^{-1} band weakens as Si–OH groups condense to form Si–O–Si bands.[12,13] When such a specimen is exposed to saturated water vapor, a band at 974 cm^{-1} is recovered and, of course, the O–H stretching broad band at about 3800—3000 cm^{-1} is also observed, though the band at 617 cm^{-1} and the C–H vibration bands are not restored. These results indicate that the bands at 974 and 617 cm^{-1} can be assigned to the Si–O stretching vibration of the silanol and the absorption band related to the C–H vibration, respectively. The assignment of the 974 cm^{-1} band is in good agreement with values found in literature.[12,13] Though the sharp bands at about 800 and 490 cm^{-1} are not clear regarding their origins, they are probably associated with the typical structure of four-coordinate silica.

Stable silica films were formed on a metal plate surface by a dip-coating method from the silica hydrosol obtained from the hydrolysis of tetraethyl orthosilicate. The FT-IR spectra were measured on those films. Two remarkable bands were found at 1069 and 974 cm^{-1}. Among them, the band at 1069 cm^{-1}, which can be assigned to the stretching vibration of the ≡Si–O–Si≡ bridge, is related to the polymerization of silica particles, by which smaller molecular units are linked together into large ones. On the other hand, the band at 974 cm^{-1} is assigned to Si–O stretching vibration of the silanol and in sensitive to a thermal treatment and the rehydration.

Mass Spectral Study of Ionized-Hydroxyacetone Dissociation

Ryuichi ARAKAWA
College of Biomedical Technology, Osaka University,
1-1, Machikaneyamacho, Toyonaka 560
(Received November 13, 1990)

Synopsis. The ionization and appearance energies of hydroxyacetone (CH_3COCH_2OH) were obtained. The metastable dissociation of ionized hydroxyacetone involves the loss of a hydrogen atom and CHO. The results of the metastable-ion intensity and collisional activation indicate that the hydroxyacetone ion does not isomerize to the enol tautomers prior to dissociation.

The unimolecular gas-phase chemistry of ions containing oxygen atoms, such as $C_3H_6O_2^{+\cdot}$ isomers,[1-7] is usually complex in a multistep isomerization/dissociation pattern. Interest has been directed toward determining the configuration of the reacting precusor or the key intermediate. Recently, distonic ions in which the charge and radical sites are separated and/or the ion-dipole complexes have been shown to be the reacting precursor from collisional activation (CA) experiments and theoretical calculations. For instance, in an *ab initio* calculation of ionized methyl acetate,[4] a hydrogen-bridged radical ion/dipole complex, $[CH_3CO\text{–}H\text{–}OCH_2]^{+\cdot}$, is probably a precursor ion which decomposes to the observed $CH_3CO^+ + \cdot CH_2OH$. In the case of ionized propanoic acid, a deuterium-labeling experiment[5] and metastable ion fragmentation[7] indicated that a water-loss reaction involves isomerization to an enol form prior to dissociation. The enol form was found to be ca. 1 eV more stable than the corresponding keto form.

Some of the $C_3H_6O_2^{+\cdot}$ isomers show metastable dissociation, although the activation energy is less than 1 eV. Observation of a metastable ion requires a rate in the $10^5\,s^{-1}$ range. However, the predicted RRKM rate is much greater than $10^7\,s^{-1}$. One explanation for this problem is that the reaction involves isomerization to an energetically stable isomer prior to dissociation. The dissociation of this isomer is a rate-determining step.

The dissociation of ionized hydroxyacetone is within the same category mentioned above. Generally, the ionized enol form is more stable than the keto form, while for the neutral keto and enol form the thermodynamic stability is in reverse order. It is thus possible for the keto ion to isomerize to two kinds of ions (enol-1 or enol-2) by transferring a different hydrogen atom. In this paper interest is focused on the participation of the enol forms shown below as the reacting precursor in the metastable dissociation of ionized hydroxyacetone:

$[CH_3\text{–}CO\text{–}CH_2OH]^{+\cdot}$ keto

$[CH_2{=}C(OH)\text{–}CH_2OH]^{+\cdot}$ enol-1

$[CH_3\text{–}C(OH){=}CHOH]^{+\cdot}$ enol-2

Experimental

The metastable-ion intensities and the CA spectra were measured with a home-made tandem-type mass spectrometer. The CA spectra were measured at a 30% decrease in the main beam intensity by increasing the He gas pressure in the collision cell. The time-dependent appearance energies (*AE*) were measured by an ion-storage technique, which is the same as that described in detail by Herod and Harrison.[8] The enol-1 and enol-2 ions were generated by a McLafferty rearrangement from $(CH_3)_2CH(CH_2)_2COCH_2OH$ (HyMH) and $CH_3(CH_2)_2CH(OH)COCH_3$ (HyH). These precursors were prepared according to the procedure of Stansburg and Proops,[9] and of Baldwin et al.[10]

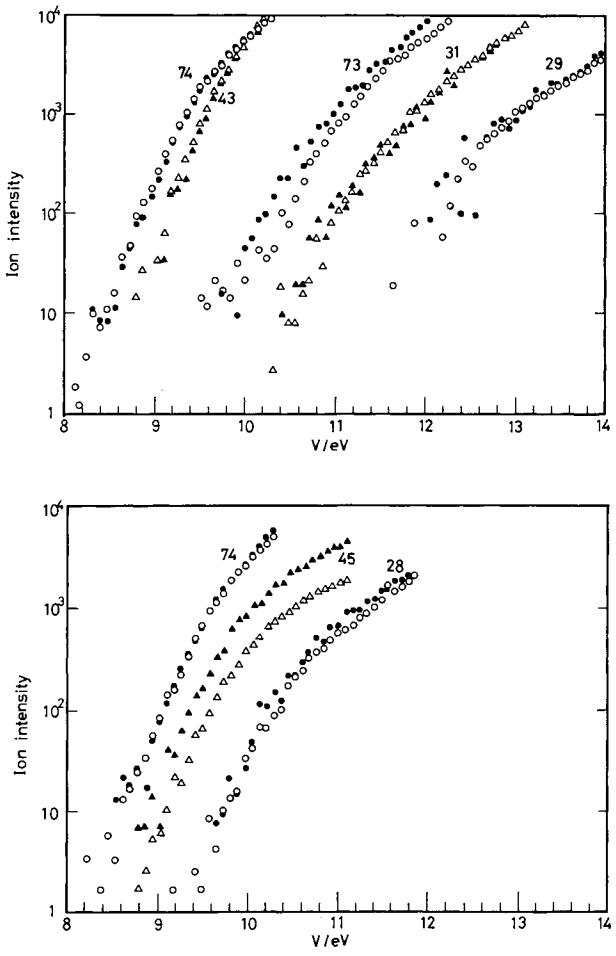

Fig. 1. The semi-log plots of the ion intensity vs. the nominal electron energy, *V* for hydroxyacetone; the storage times of $t=0$ (open mark) and 900 μs (closed mark).

Results and Discussion

Figure 1 shows semi-log plots of the ion intensity vs. the nominal electron energy at ion-storage times of t=0 and 900 μs. These curves were measured with a constant detection sensitivity. The efficiency of ion storage decreases with an increase in the storage time. Thus, the intensity curves for t=900 μs were corrected using the parent ion intensity. The distribution of electron energy was estimated to be ca. 1 eV at the full width of half maximum. The *AE*s were determined by comparing the ion intensity with the reference intensity of a known critical energy at a sensitivity of 10^2. In Fig. 2, the ionization energy (*IE*) of hydroxyacetone was estimated using CH_3OH and CH_3CN as the energy of calibration; their *IE*s are 10.85 and 12.19 eV, respectively.[11] The results of *IE*/*AE* are listed in Table 1.

A shift in the ion-intensity curve with the storage time was observed for m/z 73 and 45 ion. This is a so-called kinetic shift, which increases as the rising slope of the rate vs. energy curve decreases. Ions of m/z 73 and 45 are significant metastable peaks for hydroxyacetone. This is therefore consistent with observations of the kinetic shift. However, a question arises concerning m/z 43: its observed *AE* was almost equal to that of m/z 45. If this is correct, it seems that the dissociations for m/z 43 and 45 are not competitive, since m/z 43 is not metastable. Such nonstatistical behavior is often explained by the formation of two different electronic states during the initial ionization process: one of these states dissociates rapidly, while the other dissociates via an electronic predissociation, though there is no supporting evidence.

Shown in Fig. 3 is an energy diagram constructed from recently published energetic information[11] and the heat of formation, ΔH_f, for the keto and enol ions.

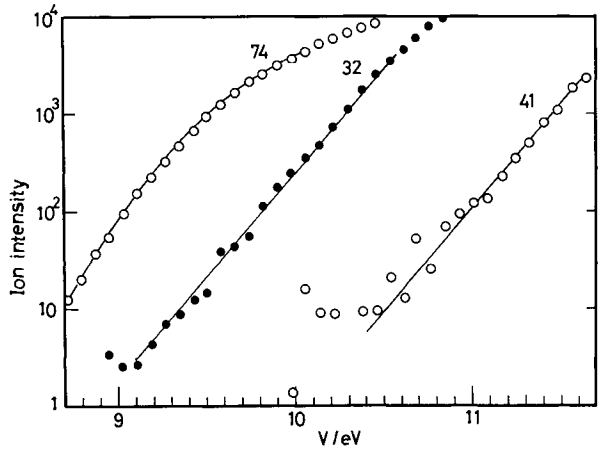

Fig. 2. The semi-log plots of the ion intensity of hydroxyacetone (74), methanol (32), and acetonitrile (41).

Table 1. Ionization and Appearance Energies in the Mass Spectra of Hydroxyacetone

Ions		*AE*/eV	
m/z		t=0 μs	t=900 μs
74	$CH_3COCH_2OH^+$	10.0±0.1	
73	$C_3H_5O_2^+$	11.8	11.6
45	$C_2H_5O^+$	10.5	10.3
43	CH_3CO^+	10.3	10.3
31	CH_3O^+	12.4	12.4
29	$C_2H_5^+$ CHO^+	13.7	13.7
28	$C_2H_4^+$ CO^+	11.3[b]	11.3
74→45*[a]		10.5	

a) The *AE* for the metastable ion was obtained from the procedure of Burgers and Holmes[15] using ethyl acetate as a reference standard. b) For example, *IE*s for N_2 and CO are 15.58 and 14.01 eV, respectively.[11]

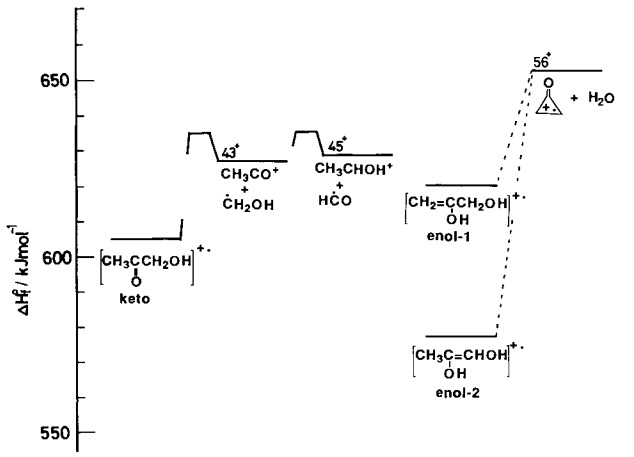

Fig. 3. A potential energy diagram of ionized hydroxyacetone and its enol isomers.

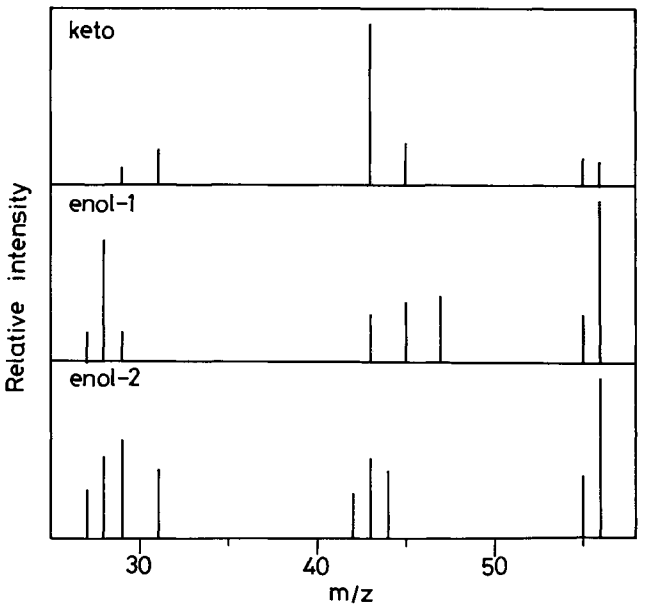

Fig. 4. Collisional activation spectra of ionized hydroxyacetone and its enol isomers.

Table 2. Metastable Ion Intensities and Kinetic Energy Releases for the Keto and Enol Forms

	Intensity ratio			
m/z	73	56	45	28
Keto (Hydroxyacetone)	1 (<10)[a]		9 (<10)	
Enol-1 (HyMH)	1 (<10)	0.5 (30±10)		
Enol-2 (HyH)		1 (<10)		0.09

a) The parentheses are $T_{0.5}$/meV.

These values were obtained from ΔH_f (neutral) estimated by the additivity rule[12] and measured *IE*/*AE*; the estimated values of ΔH_f (neutral) for hydroxyacetone, HyMH and HyH are −360, −459, and −446 kJ mol^{-1}, respectively. The *AE*s of enol-1 and enol-2 were 11.0 and 10.8 eV. The transition-state energies are those derived from the present *AE* measurements. The energy states of products were obtained assuming plausible ion structures, as shown in Fig. 3. Taking the estimation error into account, two enol forms are not so stable relative to the keto form. The activation energies relative to those of the enol isomers are still less than 1 eV. It is therefore difficult to explain the metastable rate based on isomerization prior to dissociation.

As can be seen in Fig. 4, the CA spectrum of the keto form is significantly different from the enol forms. Moreover, the results in Table 2 show that the metastable-ion intensities of hydroxyacetone are different from those of both enols. These results indicate that neither of the enols takes part in the metastable dissociation of ionized hydroxyacetone. The small kinetic energy release for *m/z* 45 is due to the low reverse activation energy (Fig. 3).

Finally, it is concluded that the hydroxyacetone ion does not isomerizes to the enol forms prior to dissociation. In addition, the previous results[1] concerning the metastable and CA spectra indicated that the hydroxyacetone ion was substantially different from the isomer structures produced from various esters, and $CH_3C(=OH^+)$–$CH_2O^\cdot$ from 2-acetoxy-2-methyloxirane. As a result, the keto form seems to be the precursor ion. Therefore, another reason for the slow metastable dissociation should be presented. The tunneling effect through a potential barrier[13] and participation of an anharmonic interaction potential[14] have been studied regarding the origin of slow dissociation. These mechanisms are, however, inadequate for an application to the present system. One possible mechanism for explaining such non-RRKM behavior is a slow predissociation due to an electronic spin-forbidden transition.

The author wishes to thank Dr. M. Hamaguchi for preparation of HyMH and HyH, and Dr. M. Arimura for helpful discussion.

Characteristics of Semiconductor and Ion-Sensitive Layers That Affect Response of Ion-Sensing Devices Based on n-SnO_2/Ion-Exchange Membrane Junction

Keiichi KIMURA,* Yoshiaki KAWASAKI, and Masaaki YOKOYAMA
Chemical Process Engineering, Faculty of Engineering, Osaka University, Yamada-oka, Suita, Osaka 565
(Received October 3, 1990)

Synopsis. The carrier density and thickness of both the semiconductor and ion-sensing membrane were found to significantly affect the sensitivity of ion-sensing devices with a junction of n-type SnO_2 and cation-selective plasticized polymeric membranes. When an anion-selective membrane was employed instead, the resulting device responded in a different way from the corresponding cation-sensing device.

Ion-selective electrodes constitute a group of the most developed ion sensors. They, however, still have some drawbacks, such as high membrane impedance and limited miniaturization. Semiconductors are useful materials for various sensors as well as for ion-sensing devices. Ion-sensitive field-effect transistors are typical ion-sensing devices based on semiconductor/insulator/ion-sensitive membrane/solution junctions,[1-3] which allow the use of high-impedance membranes and the construction of miniaturized multi-ion sensors. Recently, Okawa et al. fabricated ion-sensing devices with semiconductor/ion-sensitive layer junctions, using n-type SnO_2 as the inorganic semiconductor and a polymeric cation-exchanger,[4] valinomycin-containing poly(vinyl chloride) (PVC) film,[5] or crown ether Langmuir-Blodgett film[6] as the cation-sensitive layer. The stimulating research got us interested in the type of ion-sensing device, to which various materials can be applied, while being easy to fabricate.

We have fabricated n-SnO_2-based ion-sensing devices, using the semiconductors with various thicknesses and carrier densities and a typical cation-selective membrane. An anion-selective membrane was also tested as an ion-sensing layer of the device. This paper is concerned with the effects of the semiconductor characteristics and the ion-sensing membranes on the SnO_2-based ion-sensing device.

Experimental

Materials. Dibenzo-30-crown-10 (DB30C10) was prepared according to Pedersen's procedure.[7] Trioctylmethylammonium chloride (TOMACl) was employed as received from Tokyo Kasei. Poly(vinyl chloride) (PVC, polymerization degree of 1100) was purified by reprecipitation from tetrahydrofuran (THF) in methanol. Dioctyl sebacate (2-ethylhexyl sebacate, DOS) was distilled under vacuum. The semiconductors, n-type SnO_2 with thickness of 12—41 nm and carrier density of 1×10^{20} and 4×10^{20} cm^{-3}, which were formed on glass substrates (2×2.5 cm) by chemical mist deposition, were kindly supplied by Taiyoyuden Corporation. The metal salts employed here were of analytical grade. Water was deionized.

Device Fabrication and Measurements. The SnO_2-based ion-sensing devices were constructed with reference to a procedure from the literature.[5] A cutaway view of the device is illustrated in Fig. 1. The SnO_2 layer on the glass was etched to a 1×2.5 cm strip in the center of the glass substrate by treating with dil HCl-Zn powder. The ion-sensing membranes were cast separately. The typical cation- and anion-sensitive membranes of about 0.2 mm thickness were cast by pouring THF solutions (4 ml) of 100 mg PVC/200 mg DOS/10 mg DB30C10 (32.3/64.5/3.2 wt%) and 100 mg PVC/200 mg TOMACl (33/67 wt%) into a flat Petri dish of 43 mm inner diameter, followed by air drying of the THF at room temperature. A square of 1.3×1.3 cm was cut out from the membrane and then placed just at the center of the semiconductor substrate. The thinner cation-sensitive layers were cast or spin-coated directly on the substrate from THF solutions with the same composition as those for the thick membrane. Copper leads were contacted ohmically to each end of the SnO_2 strip by Ag paste and then fixed by an epoxy resin. The resulting device was covered by encapsulation with a silicon rubber (Shin-Etsu, KE44T), except for the ion-sensitive membrane section, the exposed area being about 1×1 cm. The device was soaked in 1×10^{-3} M (1 M=1 mol dm^{-3}) KCl solution in order to condition the ion-sensitive membrane. Electrical conductance measurements were carried out at room temperature according to a reported procedure.[4] The sample solutions did not contain any special pH buffer. The current between the two terminals of the semiconductor part (I_D) was measured with a small applied voltage (V_D), while the electrode potential (V_W) vs. Ag-AgCl was controlled potentiostatically using a double-junction reference electrode (1 M CH_3CO_2Li/3 M KCl/AgCl-Ag). The I_D readings were made in 2 min after changing the applied voltages. Since the relationship between I_D and V_D is ohmic in the V_D range of 0—100 mV, the conductance (G) was calculated from I_D values at V_D of 10 mV. The percent variation of the conductance was

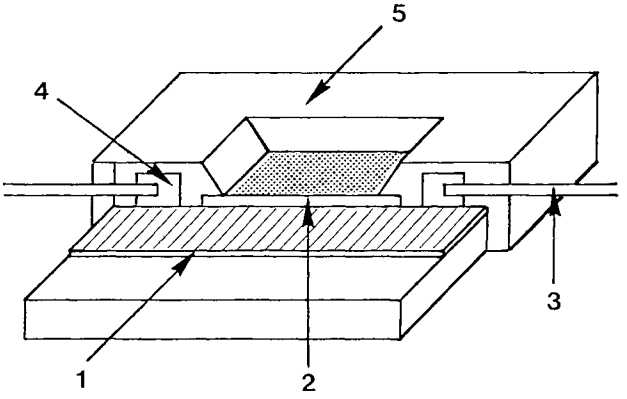

Fig. 1. Cutaway view of schematic diagram for ion-sensing device. 1: semiconductor, 2: ion-sensitive membrane, 3: copper lead, 4: Ag paste, 5: encapsulation.

obtained as 100×[G(at 1×10^{-1} M KCl)−G(at 1×10^{-4} M KCl)]/G(at 1×10^{-4} M KCl). The membrane potentials were measured by using a cell assembly of Ag–AgCl/1×10^{-3} M KCl/membrane/test solution/1 M CH_3CO_2Li/3M KCl/AgCl–Ag and an electrometer. The flatband potentials were measured by using Mott–Schottky plots.[8]

Results and Discussion

A typical response to the K^+ concentration in measured aqueous solutions for the cation-sensing device based on a SnO_2–DB30C10/DOS/PVC membrane junction is shown in Fig. 2. Increasing the cation concentration enhanced the electrical conductance of the device; a greater positive electrode potential resulted in a lower conductance. This was the case in previous SnO_2-based cation-sensing devices.[4,5] It was then proposed that their conductance response to the cation concentration is ascribable to a thickness change in a space-charge layer of the semiconductor, which is in turn caused by a cation-concentration-induced potential change of the ion-sensitive layer. If this response mechanism is reasonable, the sensitivity of ion-sensing devices based on a SnO_2–ion-sensitive membrane junction must appreciably depend upon the characteristics of the semiconductors and ion-sensitive membranes employed. We applied SnO_2 with different thicknesses and carrier densities to our cation-sensing device, using a DB30C10/DOS/PVC membrane with a thickness of 200 μm as the ion-sensitive membrane. The percent variations of conductance for the cation-sensing devices are summarized as a measure of device sensitivity in Table 1. The thinner SnO_2 layers generally afforded a higher percent variation of the conductance in the SnO_2-based cation-sensing device. This suggests that the conductance for thin semiconductors (12—19 nm thickness) are more sensitive to a potential-drop-induced change of the space-charge layer thickness than that for thick types (41 nm thickness). Moreover, low-carrier-density SnO_2 with 12 nm thickness gave better results regarding device sensitivity than did the high-donor-density type with the same thickness. This result may reflect the general observation that the higher carrier density in n-type semiconductors results in a thinner space-charge layer.

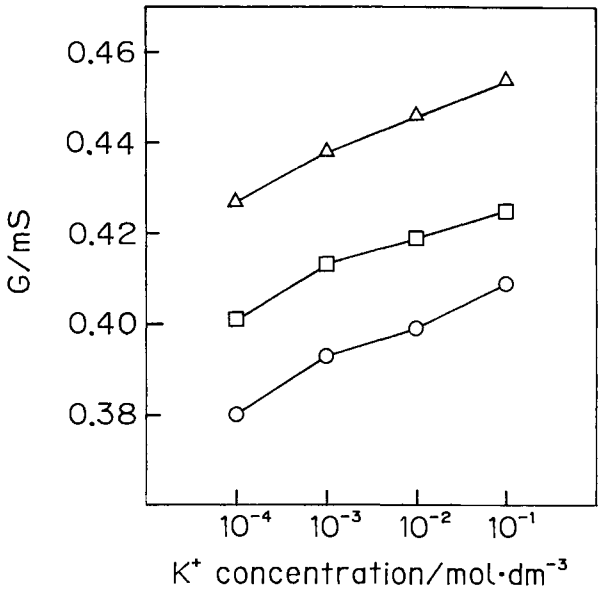

Fig. 2. Conductance response to K^+ concentration for cation-sensing device with SnO_2–DB30C10/DOS/PVC junction. V_w: 0.3 V (○), 0.1 V (□), −0.1 V (△) vs. Ag–AgCl. SnO_2: 19 nm thickness and 4×10^{20} cm^{-3} carrier density. PVC membrane: 200 μm thickness.

Table 1. Dependence of Characteristics of Semiconductor and Ion-Sensitive Layer upon Sensitivity of Ion-Sensing Devices Based on SnO_2–DB30C10/DOS/PVC Junction

Semiconductor		Ion-sensitive layer	Percent variation of conductance[a]
Donor density	Thickness	Thickness	
10^{20} cm^{-3}	nm	μm	%
4	19	200	6.1
4	19	10	1.2
4	19	0.5	1.2
4	19	0.05	1.5
4	12	200	14.4
1	41	200	5.7
1	14	200	20.0
1	12	200	21.2

a) At an electrode potential (V_w) of −0.1 V vs. Ag–AgCl.

The characteristics of the ion-sensitive membrane also affected the response of the SnO_2-based ion-sensing device. Cation-sensitive membranes of DB30C10/DOS/PVC with various thicknesses were tested regarding their conductance response of the resulting device to a K^+ concentration change (Table 1). Only an ion-sensitive membrane of 200 μm thickness allowed good sensitivity (high percent variation of conductance) in the ion-sensing device. Much thinner membranes brought about only poor sensitivity. In separate experiments for measuring the membrane potential, the 200-μm membrane exhibited a near-Nernstian response on the K^+ concentration in test solutions, whereas the thinner ones did not. A substantial thickness of the ion-sensitive layer of the plasticized PVC is, therefore, required to realize a potential drop comparable to the Nernstian response, which in turn causes a significant conductance change accompanied by a space-charge-layer thickness change. The ion selectivity of the ion-sensitive layer should be naturally reflected in the device selectivity, since its potential drop is essentially governed by its ion-exchange selectivity. An ion-sensing device based on SnO_2–DB30C10/DOS/PVC membrane junction is, thus, highly selective to K^+, as shown in Fig. 3.

It is of much interest to see how the SnO_2-based device responds when the cation-sensitive membrane is replaced by an anion-sensitive one. Increasing the Cl^- concentration diminished the electrical conductance in an anion-sensing device based on a SnO_2–TOMACl/PVC junction (Fig. 4). This anion-concentration

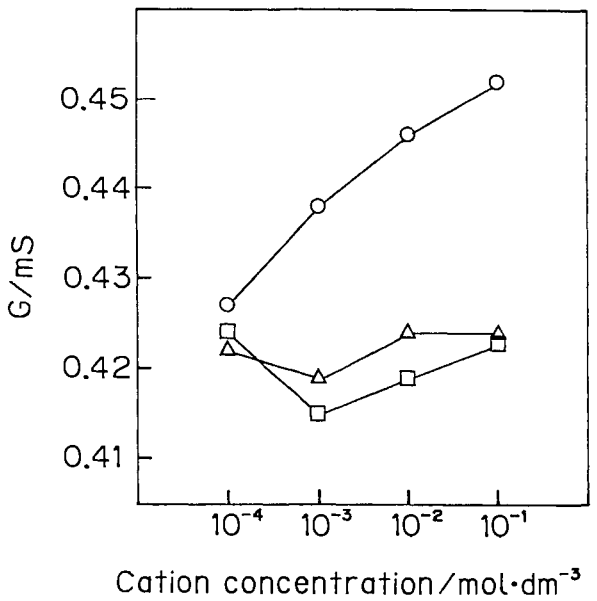

Fig. 3. Ion selectivity of cation-sensing device with SnO_2–DB30C10/DOS/PVC junction. K^+ (○), Na^+ (□), Li^+ (△). V_w: −0.1 V (△) vs. Ag–AgCl. The characteristics for the semiconductor and ion-sensitive layers are the same as for Fig. 2.

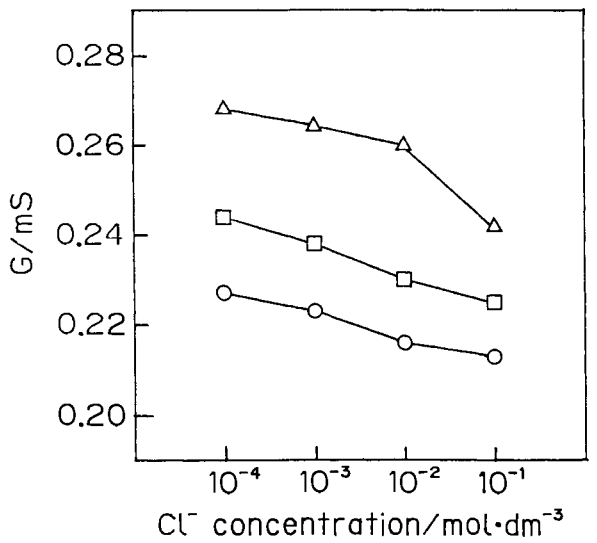

Fig. 4. Conductance response to Cl^- concentration for anion-sensing device with SnO_2–TOMACl/PVC junction. V_w: 0.3 V (○) 0.1 V (□), −0.1 V (△) vs. Ag–AgCl. SnO_2: 19 nm thickness and 4×10^{20} cm^{-3} donor density. PVC membrane: 200 μm thickness.

dependence of the conductance was contrary to the cation-concentration dependence found in the cation-sensing devices, i.e. the conductance decreased with increasing the anion concentration. The anion-sensing device, however, showed the same relationship between the electrode potential (V_W) and the conductance, i.e. the positive shift in the electrode potential diminished the conductance. The near-Nernstian response in the flatband potential of the semiconductor, as depicted in Fig. 5, confirms a response mechanism that the semiconductor conductance change is induced by a potential change in the anion-sensitive layer and, thereby, the space-charge-layer thickness change in the semiconductor.[4]

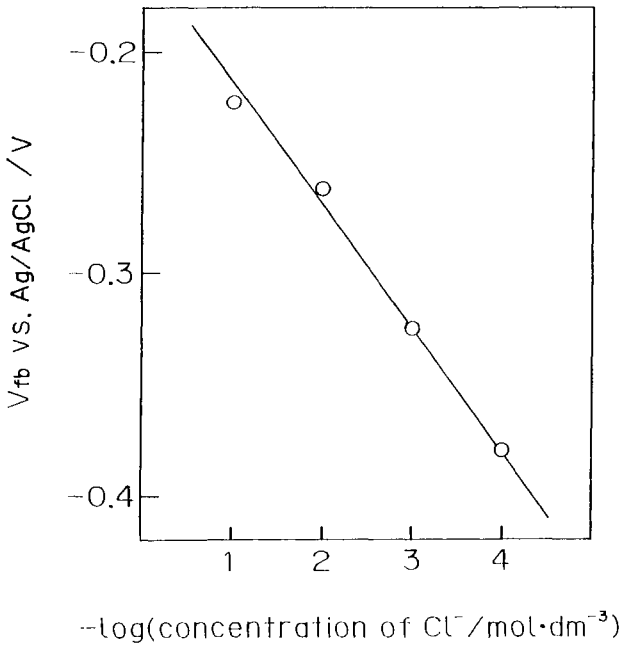

Fig. 5. Dependence of flatband potential of semiconductor upon Cl^- concentration in anion-sensing device with SnO_2–TOMACl/PVC junction. The characteristics for the semiconductor and ion-sensitive layers are the same as for Fig. 4.

In conclusion, the characteristics of the semiconductor and ion-sensitive layer significantly alters the sensitivity of ion-sensing devices based on SnO_2–ion-sensitive PVC membrane junctions; the choice of materials for the semiconductor and ion-sensitive membrane seems to be quite important for designing this type of ion-sensing device.

The authors gratefully acknowledge Dr. Shoichiro Yoshida, Institute of Industrial Science, The University of Tokyo, for his helpful discussion.

Hexaammineruthenium Complex as Two-Electron Catalyst for Oxygen Evolution by Homogeneous and Heterogeneous Water Oxidation

Ramasamy RAMARAJ, Masao KANEKO,*,† and Akira KIRA†
School of Chemistry, Madurai Kamaraj University, Madurai 625 021, India
† The Institute of Physical and Chemical Research (RIKEN), Wako, Saitama 351-01
(Received October 16, 1990)

Synopsis. The $[Ru(NH_3)_6]^{3+}$ complex is shown to be a two-electron catalyst for homogeneous as well as heterogeneous water oxidation to evolve dioxygen. The oxygen evolution is proposed to proceed by two molecules of the complex through a peroxo-bridged intermediate involving higher oxidation state $[Ru^V(NH_3)_6]^{5+}$.

The mechanism of oxygen evolution in plant photosynthesis still remains unsolved. According to the present knowledge, dioxygen evolves as a result of water photooxidation in the active center of photosystem II (PS II) with the participation of Mn ions which are weakly bound to the protein part of PS II.[1,2] Since oxygen evolution by water oxidation is a four-electron process (Eq. 1) only few artificial catalysts have been

$$2H_2O \longrightarrow O_2 + 4H^+ + 4e^- \quad (1)$$

known, because of the difficulty to couple an one-electron reaction with a four-electron process.[3] It is now known that $[Ru(bpy)_3]^{3+}$ is capable of bringing about a four-electron oxidation of water to oxygen if it is coupled with a solid catalyst such as RuO_2, PtO_2, and MnO_2.[4-6] However, these catalysts can not be used as models to elucidate photosynthetic oxygen evolution, since the redox chemistry on their surface is difficult to study.[7] Therefore, the design and synthesis of chemical models of PS II and the study of water oxidation in nonbiological systems by utilizing metal complexes are the best ways to elucidate the mechanism of the photosynthetic oxygen evolution.

The present authors could show that oxygen evolution by water oxidation can be achieved by four-electron oxidation catalysts, in both homogeneous and heterogeneous media.[9-13] Oxygen evolution could be realized, even by two-electron oxidation catalysts, if two molecules of the catalyst can interact with each other under homogeneous as well as heterogeneous conditions to enable four-electron oxidation of two water molecules.[8-13] These catalysts have been successfully applied in a photoelectrochemical system to photolyze water for simultaneous oxygen and hydrogen evolution which mimics PS II.[14] We have already reported[10,12] the catalytic activity of water-coordinated dinuclear ($[(bpy)_2(H_2O)RuORu(H_2O)(bpy)_2]^{4+}$) and mononuclear ($[Ru(NH_3)_5(H_2O)]^{3+}$) ruthenium complexes where the coordinated water molecules are involved in the water oxidation to evolve dioxygen. It is interesting and important to study whether a mononuclear metal complex, whose coordination sites are entirely occupied by ligands other than water, is active as a water oxidation catalyst. From this point of view we studied the catalytic activity of the $[Ru(NH_3)_6]^{3+}$ complex. Although the solution chemistry of ruthenium–ammine complexes has been studied extensively,[15,16] attention has not been focused on redox chemistry involving the higher oxidation states (e.g., Ru(IV) and Ru(V)). In this paper we report on both the homogeneous and heterogeneous catalytic activities of hexaammineruthenium(III) towards water oxidation to evolve dioxygen.

Experimental

Materials. $Ru(NH_3)_6Cl_3$ (Aldrich), ammonium cerium(IV) nitrate (Wako Pure Chemicals Co.) and kaolin clay (Nakarai Chemicals Ltd.) were used as received. The $[Ru(NH_3)_6]^{3+}$ complex was adsorbed into clay by mixing known amounts of clay and the ruthenium complex in deionized water. The mixture was stirred until complete adsorption was indicated by the disappearance of the solution color. The clay was filtered after adsorption, washed with deionized water and dried at 25 °C in air.

Instruments. Uv-visible spectra were recorded using a Hitachi 330 spectrometer. Cyclic voltammograms were run using a function generator (model HB-104) and a potentiostat/galvanostat (model HA-301) from Hokuto Denko Ltd. The electrode used to record the cyclic voltammograms was Nafion-coated basal plane pyrolytic graphite (BPG). Platinum wire was used as a counter electrode and a saturated calomel electrode (SCE) as reference electrode.

Oxygen Evolution. Oxygen evolution by water oxidation catalyzed by $[Ru(NH_3)_6]^{3+}$ was investigated by adding excess Ce(IV) as oxidant to an aqueous solution of $[Ru(NH_3)_6]^{3+}$ in a closed, deaerated vessel. The gas evolved by the reaction was analyzed by a gas chromatograph (Shimadzu GC-4C) as described earlier.[11] Repeated experiments showed that the results are reproducible with a 5% difference in the turnover values.

Results and Discussion

Although the uncoated BPG electrode gave a large catalytic current due to water oxidation, the Nafion-coated BPG electrode gave a better cyclic voltammogram for the $[Ru(NH_3)_6]^{3+}$ complex, probably because of the complex concentration into the coated Nafion film. The $[Ru(NH_3)_6]^{3+/2+}$ couple was observed in the potential region from −0.6 to 0.2 V vs. SCE and in the positive potential region (+0.6 to 1.5 V vs. SCE) two oxidative waves are observed, while their reduction waves were not clear (Fig. 1). These irreversible oxidations in the anodic region must be due to a reduction of the higher oxidation state of ruthenium (Ru(V)) by water rather than by electrochemical reduction. Based on the present results, the various redox processes occurring in $[Ru(NH_3)_6]^{3+}$ would be given by

$$[Ru^{V}(NH_3)_6]^{5} \underset{+e^-}{\overset{+e^-}{\rightleftharpoons}} [Ru^{IV}(NH_3)_6]^{4+} \underset{+e^-}{\overset{+e^-}{\rightleftharpoons}}$$

+1.32 V +1.04 V

$$[Ru^{III}(NH_3)_6]^{3+} \underset{-e^-}{\overset{+e^-}{\rightleftharpoons}} [Ru^{II}(NH_3)_6]^{2+}. \quad (2)$$

−0.22 V

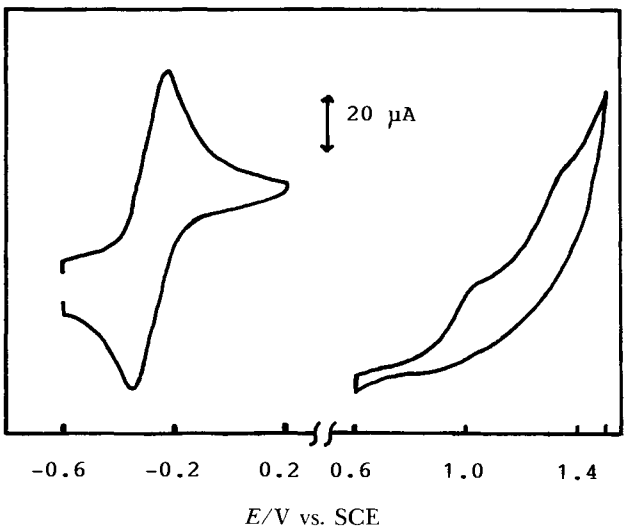

Fig. 1. Cyclic voltammogram of $[Ru(NH_3)_6]^{3+}$ in 0.1 M KNO_3 at Nafion coated BPG at a scan rate of 50 mV s^{-}.

The $[Ru(NH_3)_6]^{3+}$ complex easily forms Ru(V) upon oxidation, and the redox potentials of the complex show that it can be used as a two-electron oxidant for water oxidation. Water oxidation to evolve oxygen was investigated by adding excess ammonium cerium (IV) nitrate as an oxidant to an aqueous solution containing the ruthenium complex. Gas bubbles were readily observed in solution upon the addition of excess (Ce(IV) ion. The experimental results regarding a homogeneous catalysis of water oxidation by the monomeric ruthenium complex was treated with great caution, since decomposition of the complex may produce ruthenium oxide, which is catalytically active for water oxidation.[4,6,7] No ruthenium oxide deposition, however, could be observed after the water oxidation experiment. Though the complex turned over after oxygen evolution, the complex lost catalytic activity after 8—9 turnovers, possibly due to a slow formation of colorless Ru(III) ions from $[Ru(NH_3)_6]^{3+}$ by decomposition during the process.[12]

The amount oxygen evolved with various concentrations of $[Ru(NH_3)_6]^{3+}$ and Ce(IV) in homogeneous and heterogeneous clay-adsorbed states and the turnover numbers of the catalysts towards water oxidation are given in Tables 1 and 2. In both the homogeneous and heterogeneous systems, $[Ru(NH_3)_6]^{3+}$ worked as a catalyst to evolve oxygen by water oxidation. A maximum turnover number of 8.3 was obtained for a homogeneous catalysis and 8.7 for a heterogeneous catalysis.

The higher oxidation state ruthenium-ammine complex ($[Ru^{V}(NH_3)_6]^{5+}$) produced upon the addition of excess Ce(IV) would oxidize water to oxygen (Eqs. 3

Endicott and Taube, who studied[17] the oxidation–reduction reactions of mononuclear ruthenium–ammine complexes, suggested that a spin-paired d^4 ion (Ru(IV)) is well-suited to accommodate seven groups in the coordination sphere of the complex. Ru(III) also forms seven-coordinated species as kinetic intermediates.[18,19] Earley and Fealey have studied[20] the kinetics of the reduction of the trinuclear ruthenium–ammine complex, and showed that Ru(III) and Ru(IV) can accommodate the seventh coordination site in the intermediate step. Such a seven-coordinated intermediate has already been proposed for oxygen evolution by water oxidation using di- and trinuclear ruthenium complexes.[11] Taking these facts into consideration, the involvement of two water molecules in the catalytic water oxidation process to evolve one molecule of oxygen in the absence of any other external catalyst can be explained as follows. The water molecule would form a loose coordination bond with the $[Ru^{V}(NH_3)_6]^{5+}$ complex, and two such intermediates of the water-coordinated monomeric Ru(V) complex would interact to form a Ru–O–O–Ru bonded intermediate upon the removal of 4 protons, which could release one molecule of oxygen. Although such a peroxo-bridged Ru–O–O–Ru intermediate complex is not known, an oxo-bridged stable dinuclear ruthenium complex, $[(NH_3)_5Ru\text{-}O\text{-}Ru(NH_3)_5]^{4+}$, is known.[21] Renger has proposed a model for the water splitting complex that is in better agreement with the reported experimental findings,[22] postulating a dinuclear manganese complex in which water ligands are finally oxidized to oxygen via the stage of a bridging peroxo ligand. The formation of an O–O bond in an intermediate has already been proposed to explain oxygen evolution by water oxidation using other metal complex systems.[8,12]

Our earlier studies[9,12] and the present observations show that one-electron oxidants can mediate oxygen evolution from water only in the heterogeneous state,[9,23] whereas two- and four-electron oxidants can catalyze oxygen evolution from water in the homogeneous state itself.[10–12] This leads to the conclusion that the two molecules of a two-electron oxidant, such as monomeric Ru(V), upon water coordination, can easily interact to form Ru–O–O–Ru with the removal of 4 protons which can spontaneously liberate oxygen. This scheme is supported by the fact that such an interaction was hindered by increasing the ionic strength of the reaction medium.[12,24]

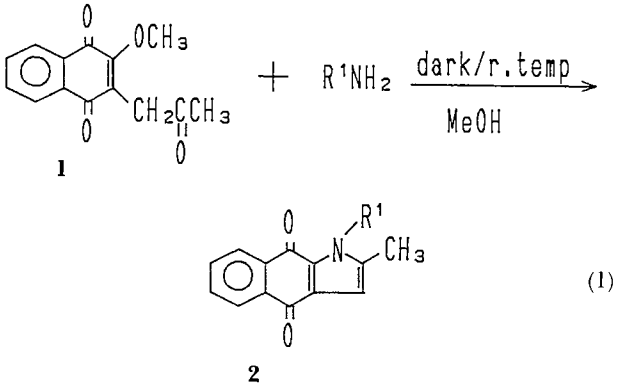
Photoinduced Alkylation Reaction of Benzo[*f*]indole-4,9-dione with Arylalkenes

Katsuhiko NAKAGAWA
Department of Industrial Chemistry, Niihama National College of Technology, Niihama, Ehime 792
(Received August 27, 1990)

Synopsis. Photoreaction of 1-alkyl-2-methyl-1*H*-benz[*f*]-indole-4,9-diones (indolequinones) with arylalkenes in benzene gave 3-alkylated products. Irradiation of 1-allyl substituted indolequinone in benzene gave 1,3-hydrogen shift product in the presence or absence of arylalkenes. The fluorescence of 1,2-dimethyl-1*H*-benz[*f*]indole-4,9-dione exhibits a large bathochromic shift in polar solvents, indicating polar charge-transfer character for its S_1-state.

Photochemistry of quinones has been a subject of many extensive investigations. As a result, a variety of photoreactions of quinones, including photoreduction, photocycloaddtion, photoisomerization, and photosubstitution have appeared in the literature.[1] However, photochemical alkylation reaction of quinones has been much less characterized so far.

Recently, we developed a convenient synthetic method of 1*H*-benz[*f*]indole-4,9-dione (**2**) by the thermal condensation reaction of 2-acetonyl-3-methoxy-1,4-naphthoquinone (**1**) with primary aliphatic



(1)

amines.[2] The compound **2** has an interesting structure containing pyrrole ring fused with naphthoquinone necleus. Since the naphthoquinone structure is electron-deficient and the pyrrole ring is electron-rich, the former ring is expected to be potential electron acceptor for the latter, thus achieving an intramolecular charge-transfer state.

Described herein is a novel photoinduced alkylation of **2** with arylalkenes.

Results and Discussion

Photochemical Alkylation Reactions of 1,2-Dimethyl-1*H*-benz[*f*]indole-4,9-dione (2a) 2-Methyl-1-propyl-1*H*-benz[*f*]indole-4,9-dione (2b) with Arylakenes (3a—c). Irradiation of **2a** (1.2 mmol dm^{-3}) in the presence of 1,1-diphenylethylene (**3a**)(1.5 mmol dm^{-3}) in benzene followed by separation by column chromatography (silica gel) afforded 1,2-dimethyl-3-(2,2-diphenylethyl)-1*H*-benz[*f*]indole-4,9-dione (**4a**) as the sole photoproduct in a 40% isolated yield at 50% conversion of **2a**. The structure of **4a** was determined by its spectroscopic analysis and elemental analysis.

Similary, **2a** was photochemically alkylated at the 3-position with 2-phenyl-1-propene (**3b**) and styrene (**3c**), giving **4b** and **4c** in 38 and 28% yields, respectively. In an analogous fashion, **2b** underwent the photoalkylation at the 3-position upon irradiation

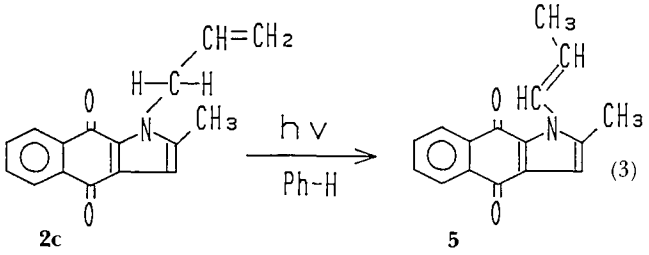
Quinone	Olefins	Irr. time/h	Conv.[a] %	Yields[b] of **4**/%
2a	**3a**	1	50	40
2a	**3b**	1	60	38
2a	**3c**	1	48	28
2b	**3a**	0.3	45	31
2b	**3b**	0.3	57	29
2b	**3c**	0.3	39	16

a) Conversion of **2a** and **2b**. b) Isolated yields were based on the consumed amounts of **2a** and **2b**.

in the presence of **3a—c** in benzene. Results are summarized in Table 1. No photochemical alkylation of **2a** and **2b** did not take place with 2-methyl-1-propene, 2-methoxy-1-propene and methyl acrylate. Interestingly, the alkylation products **4** were formed only in nonpolar solvents such benzene and dichloromethane.

Photochemical Isomerization of 1-Allyl-2-methyl-1*H*-benz[*f*]indole-4,9-dione (2c). Irradiation of the *N*-allyl quinone **2c** in benzene solution led to the formation of 2-methyl-1-(1-propenyl)-1*H*-benz[*f*]indole-4,9-dione (**5**) in 52% yield at 55% conversion of **2c**. The structure of **5** was assigned on the basis of its spectroscopic properties and elemental analysis. The ^{1}H NMR spectrum of **5** showed the presence of *N*-(1-propenyl) substituent at δ=1.95 (N-CH=CH-$\underline{CH}_3$), 5.85 (N-CH=C$\underline{H}$-CH$_3$), and 7.1 (N-C$\underline{H}$=CH-CH$_3$); the mass spectrum showed a peak at 251 (M^+). The



2c **5**

photoisomerization product **5** can be regarded as an intramolecular 1,3-hydrogen shift product. Irradiation of **2c** in the presence of **3a** did not give the photoalkylation product but gave **5** in 10% yield.

Absorption and Fluorescence Spectra of 2a. The shape and wavelength maxima(λ_{max}) of **2a** and **2c** in the absorption spectra of **2a** and **2c** do not exhibit substratial solvent polarity dependence. In contrast, the fluorescence of **2a** was found to undergo a large bathochromic shift upon the increase of solvent polarity (Table 2). The fluorescence of **2a** in benzene exhibited a broad band centered at λ_{max} 500 nm with lifetime of 3.1 ns at room temperature, while the fluorescence maximum in acetonitrile was observed at 526 nm with lifetime of 4.5 ns. These results suggest that the lowest singlet excited state (S_1) of **2a** has a partially charge transfer character.[3] Importantly, the floresence of **2a** was not quenched by **3a—c** in benzene.

Mechanistic Consideration of the Photoinduced Alkylation Reaction of 2 with 3a—c. The fact that the fluorescence of **2a** was not quenched by **3a—c** strongly indicated the triplet origin for the formation of **4**. In accord with this consideration, the photoinduced alkylation reaction was sensitized by benzil (E_T=53 kcal mol^{-1}),[4] but was efficiently quenched by anthracene (E_T=42 kcal mol^{-1}).[4] In ether–isopentane–ethanol (EPA) matrix at 77 K, a broad phosphorescence band of **2a** was observed at λ_{max} 564 nm. Thus, the energy of the lowest triplet excited state(T_1) of **2a** estimated from 0–0 phosphorescence band was ca 51.2 kcal mol^{-1}. In the presence of **3a**, this phosphorescence band was very weakened as compared with that in the absence of **3a**, indicating a decaying path for T_1-state of **2a** through the intereraction of **3a**. Electron transfer from **3a—c** to ^{3}(**2a**)* may be excluded, since the Rehn–Weller estimation[5] of free energy charges (ΔG) associated with the triplet electron transfer gives rather high positive values(+8—+10 kcal mol^{-1}).[6] A plausible mechanism for the formation of **42** is shown in Eq. 2. The reaction of T_1 of **2a** with **3** leads to the formation of 1,4-biradical **11**, which will give the 3-alkylated product **4** by disproportionation. When the photoreaction of **2a** with **3a—c** was conducted in benzene-d_6, no incorporation of deuterium atom in **4** was observed. Therefore, intramolecular 1,3-hydrogen shift may be predominant for the pathway from the intermediate **11** to **4**. In the *N*-allyl compound **2c**, the intramolecular hydrogen adstraction[7] by the quinone carbonyl group from the γ-position and subsequent disproportionation may account for the formation of **5**. Probably, this intramolecular process is much faster as compared to the intermolecular quenching by **3a—c**.

Table 2. Fluorescence Maxima of **2a** in Various Solvents[a,b]

Solvent	Maxima wavelength (λ_{max}/nm)	τ/ns

Acetone	519	4.9
Acetonitrile	526	4.5

a) Excited wavelength, 326 nm. b) In air-saturated solvents at room temperature; [**2a**]=4.4×10^{-5} mol dm^{-3}.

Experimental

Apparatus. Melting points were measured on Yanagimoto micro-melting points apparatus and uncorrected. Infrared spectra were taken on a JASCO-IR-1A spectrometer. Fluorescence spectra and lifetimes were measured by a JASCO FP-550 spectrometer and a Horiba NAES-1100 timeresolved spectrofluorimeter, respectively. Phosphorescence spectra were measured by a Shimazu RF-502A spectrometer. NMR spectra were recorded on a JEOL GX-400 (400 MHz), a JEOL GX-270 (270 MHz), and a JEOL FX-900 (90 MHz) spectrometer with use of tetramethylsilane as an internal standard and the chemical shifts are expressed in δ values. UV spectra were taken by using a JASCO UVIDEC-1 spectrometer. Elemental analyses were performed at the Microanalytical Laboratory of Kyoto University and Advanced Instrumentation Center for Chemical Analysis, Ehime University. Mass spectra were recorded on a Hitachi M-2000 spectrometer.

Materials. 1-Alkyl-3-methyl-1*H*-benz[*f*]indole-4,9-dione **2a—c** were prepared according to a procedure in the literature.[2] Alkenes **3a—c** were commercially available and purified by distillation.

General Procedure for the Photochemical Reaction of 1-Alkyl-3-methyl-1*H*-benz[*f*]indole-4,9-dione 2 with Alkenes 3 and Product Isolation: A degassed solution of **2** (1.50 mmol) and **3** (1.80 mmol) in 300 cm^3 of benzene in a Pyrex vessel, using a 300-W high-pressure mercury lamp. The progress of the reaction was followed by TLC (Merck, Kieselgel 60F_{254}), or NMR. After evaporation of the solvent, the residual oil was separated by column chromatography on silica gel (Wakogel C-200, 74-149 μm) with benzene/dichloromethane as an eluent.

The Effects of Aromatic Compounds on the Hydrogen-Transfer Reaction to Coal Model Compounds

Koji CHIBA,* Hideyuki TAGAYA,* Toru SUZUKI, and Shimio SATO
Department of Materials Science and Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992
(Received September 3, 1990)

Synopsis. A hydrogen-transfer reaction from a hydrogen molecule to benzophenone in 1-methylnaphthalene without a donor was accelerated in the presence of anthracene. Phenanthrene and pyrene were detrimental to the reaction. Dibenzyl ether conversion was also accelerated by the addition of anthracene, pyrene, and fluorene. Conversions of coal model compounds in 1-methylnaphthalene under a hydrogen atmosphere correlated well with conversions in tetralin under a nitrogen atmosphere.

In coal liquefaction the solvent plays a vital role as both a hydrogen donor and a reaction medium to dissolve reactants and products.[1] The selection of the solvent is an important factor for effective coal liquefaction. Hydroaromatic compounds, such as tetralin, are known to be donors.[2] We have already reported that aromatic compounds, such as anthracene and fluorene, are effective hydrogen shuttlers in hydrogen-transfer reactions from a donor, tetralin, to coal model compounds.[3] Such hydrogen-shuttling reactions contribute to an increase in the net amounts of transferred hydrogen from donors to coal.[4] Furthermore, it is well-accepted that the reactive coal fragments not only abstract hydrogen from the donor solvent, but also react with dissolved hydrogen molecules to yield liquefaction products.[5] For example, in the pyrolysis of bibenzyl without a catalyst, significant amounts of benzene and ethylbenzene have been produced, indicating a mechanism involving the direct participation of hydrogen molecules in free-radical reactions.[6] Ouchi and Makabe reported that naphthalene as a model of solvent did not convert under a hydrogen atmosphere without a catalyst.[7] However, recycle solvents include many compounds, and the role of solvent on the reaction of coal with hydrogen molecules has not been clearly understood.

Though it is appropriate to use coal model compounds, in many cases the effectiveness of various hydrogen-donor solvents were investigated. In this study, in order to understand the function and importance of coal liquefaction solvents, the reactions of coal model compounds were performed in the presence of aromatic compounds with hydrogen molecules without a donor and a catalyst.

Experimental

Reagent grade benzophenone and dibenzyl ether were used. All of the reactions were carried out in magnetdriven stainless-steel autoclave according to a method described previously.[3] The liquid products after reactions were washed from the autoclave with acetone and analyzed by gas chromatography (GC).

Results and Discussion

Six aromatic compounds were used in the reaction of benzophenone as a coal model. 1-Methylnaphthalene was used as a diluent since the hydrogen-shuttling ability of 1-methylnaphthalene is very low, as already reported.[3] When no aromatic compound was added, the conversions of benzophenone were 43 to 45% (Table 1). These values were larger than 9.3%, in which initial hydrogen pressure was 2.0 MPa and reaction time was 0.5 h.[9] No benzhydrol was observed in the products. The highest conversion was obtained

Table 1. The Effects of Aromatic Compounds on the Hydrogen Transfer Reaction[a] to Benzophenone (BZP)

Run No.	Aromatic compound	Conv. of BZP	Yield of DPM[b]
		mol%	mol%

9	Dihydroanthracene[c]	31.3	23.6
10	Dihydrophenanthrene	38.8	38.8
11	Dihydrophenanthrene[c]	9.8	9.8

a) Aromatic compound (1.00 g), 1-methylnaphthalene (10.00 g) and benzophenone (1.00 g) were used. Reaction temperature 430 °C; initial hydrogen pressure 3 MPa; reaction time 1 h. b) DPM=Diphenylmethane. c) Under a nitrogen atmosphere.

by adding anthracene (Run 2). It was confirmed that, in the absence of benzophenone, 47% of the anthracene was hydrogenated to dihydroanthracene (DHA; 44%) and tetrahydroanthracene (3%) in 1-methylnaphthalene under a hydrogen atmosphere at 430 °C. DHA was a good donor for benzophenone (Runs 8 and 9). Certainly, no DHA was observed in the reaction of benzophenone with 1-methylnaphthalene and anthracene. This shows that hydrogen transfer from DHA to benzophenone came to completion if DHA was produced. It was considered that a positive effect of anthracene on the hydrogen-transfer reaction was given by its high ability to accept hydrogen. Lower conversions of 20 to 30% than without additive were obtained when phenanthrene or pyrene was used as an aromatic compound(Runs 3 and 4). The facts indicated that pyrene and phenanthrene had negative effects on the conversion of benzophenone. When pyrene alone was reacted under a hydrogen atmosphere, 2% of the pyrene was hydrogenated to give dihydropyrene. In the same reaction, 1% of the phenanthrene was hydrogenated. They have lower abilities to accept hydrogen than does anthracene. However, the presence of 2% dihydrophenanthrene after the reaction of benzophenone in 1-methylnaphthalene and phenanthrene was observed. The presence of dihydrophenanthrene after the reaction and low benzophenone conversion indicated that phenanthrene was hydrogenated in preference to benzophenone and that hydrogen transfer from dihydrophenanthrene to benzophenone was slow. Conversions with additives of fluorene, diphenylmethane and triphenylmethane were the same without additives (Runs 5—7). Their abilities to accept hydrogen may be very low in consideration of their structures.

Dibenzyl ether easily decomposed at 375 °C. About 15% of the dibenzyl ether converted to toluene and benzaldehyde in 1-methylnaphthalene alone (Run 12). No benzyl alcohol was observed in the products. An intramolecular reaction of dibenzyl ether does not give toluene and benzaldehyde through free radicals. On the other hand, two free radicals result from an intermolecular reaction. It is considered that highly reactive radicals would participate in the reaction with hydrogen molecules directly. Simmons and Klein reported that a free-radical chain reaction occurred in preference to an intramolecular type reaction. They evaluated it at 400 °C. However, the exact intermolecular/intramolecular reaction ratio under our reaction conditions has not been estimated. Phenanthrene, diphenylmethane, and triphenylmethane were not effective additives (Runs 14, 17, and 18). These results indicate that the hydrogen-transfering ability of such aromatic compounds is fairly small. On the other hand, the conversion increased to 40% upon the addition of anthracene (Run 17). The high hydrogen-accepting ability of anthracene must contribute to the high conversion. Fluorene and pyrene were also effective additives for the conversion of dibenzyl ether (Runs 15 and 16).

Figure 1 shows the relationship between the conversion of coal model compounds in 1-methylnaphthalene under a hydrogen atmosphere and conversion in tetralin under a nitrogen atmosphere. The hydrogen shuttling ability and the hydrogen-transfer ability from hydrogen molecules are considered to be different. However, the correlation factor between them was as

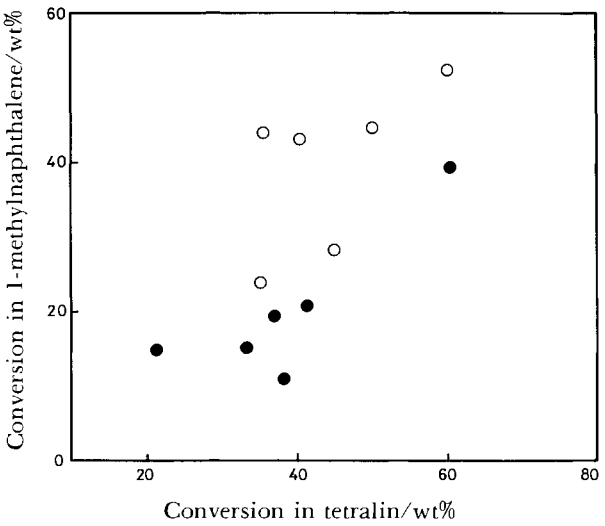

Fig. 1. The relationship between conversion of benzophenone (○), dibenzyl ether (●) in 1-methylnaphthalene under a hydrogen atmosphere and conversion in tetralin under a nitrogen atmosphere.

Table 2. The Effects of Aromatic Compounds on the Hydrogen-Transfer Reaction[a] to Dibenzyl Ether (DBE)

Run No.	Aromatic compound	Conv. of DBE	Yield of TOL[b]	Yield of BZA[b]
		mol%	mol%/2	mol%/2
12	1-Methylnaphthalene	14.6, 15.0	8.9, 9.5	5.7, 5.5
13	Anthracene	39.2	12.7	7.8
14	Phenanthrene	15.2	8.2	4.9
15	Pyrene	19.7	8.9	5.6
16	Fluorene	20.7	11.6	9.1
17	Diphenylmethane	13.8	8.6	3.8
18	Triphenylmethane	12.9	6.9	4.0

a) Aromatic compound (1.00 g), 1-methylnaphthalene (10.00 g) and dibenzyl ether (1.00 g) were used. Reaction temperature 375 °C; initial hydrogen pressure 3 MPa; reaction time 1 h. b) TOL=Toluene. BZA=Benzaldehyde.

high as 0.68. This indicates that the role of aromatic compounds in the hydrogen-transfer reaction with a donor solvent is similar to that with hydrogen molecules.

It is suggested from our results that anthracene has both the highest hydrogen-shuttling ability[3] and the highest ability to transfer hydrogen molecule. Coal liquefaction with an aromatic compound under an argon atmosphere has been reported.[11] In the report coal conversions based on quinoline-insoluble matter with anthracene were 31—34%. The conversions were lower than 48.1% with 1-methylnaphthalene. This indicated that anthracene might play an important role in coal conversion when anthracene is mixed with other compounds as the solvent.

Though the participation of hydrogen molecules in coal liquefaction is fairly complex, we believe that our methods to evaluate the abilities of hydrogen shuttling from a solvent[3] and the transference of hydrogen molecules are appropriate for evaluating solvent abilities.

Technical assistance by Mr T. Suzuki and H. Ando is greatfully acknowledged.

(Received September 17, 1990)

Synopsis. A convenient preparation of 3,5-disubistituted 1,2,4-selenadiazoles was achieved by treatment of various primary selenoamides with *N*-bromosuccinimide.

The syntheses and transformation of selenium atom-containing heterocycles are of current interest in organic chemistry, and various methods for the synthesis of these compounds have been reported within the past several years;[1-6] nonetheless detailed investigation on the reactivities and the synthetic applications of selenazoles and selenadiazoles has been limited owing to the difficulty in preparation of the selenium-containing starting materials. It has been widely known that the most suitable starting material for these selenium-containing heterocycles are primary selenoamides **1**.[7-9] However, the preparation of these primary selenoamides **1** is impeded by the higher lability of **1** toward bases and oxidants, and few methods have so far been reported.[10-16] Cohen reported the synthesis of **1** from nitriles[15] and the subsequent transformation of **1** to the corresponding 3,5-disubstituted 1,2,4-selenadiazoles **2** by using I_2, but the yields of **2** were modest and the reactions were successful only in the cases of aromatic selenoamides **1**.[7]

In our previous paper we also provided a convenient synthesis of primary aromatic or aliphatic selenoamides, selenourea, and selenothiocarbamate by treatment of the corresponding nitriles, cyanamide, or thiocyanate with $(Me_3Si)_2Se$ in the presence of $BF_3{\cdot}OEt_2$.[17] It was naturally regarded that **1** would act as starting materials for the synthesis of 3,5-disubstituted 1,2,4-selenadiazoles **2** possessing various substituents by treatment with oxidizing reagents.[4,7] In this paper we would like to describe a convenient preparation of 3,5-disubstituted 1,2,4-selenadiazoles **2** by treatment of primary selenoamides **1** with *N*-bromosuccinimide (NBS).

Results and Discussion

A general procedure in the preparation of 3,5-disubstituted 1,2,4-selenadiazoles **2** is as follows. To a $CHCl_3$ solution of primary selenoamides **1**, 1.1 equiv

Table 1. Preparation of 3,5-Disubstituted 1,2,4-Selenadiazoles by Treatment of Selenoamides with Oxidizing Reagents[a]

a) The corresponding nitriles were obtained in all runs. b) One equiv of 1-methyl-2-chloropyridinium iodide was added. c) Five equiv of styrene was added. d) Benzyl thiocyanate was obtained in 80% yield.

of NBS in $CHCl_3$ was added dropwise under nitrogen atmosphere at 0 °C and stirred for 1 h. The reaction mixture was then quenched with 10% NaOH solution. After the usual work-up and purification by SiO_2 column chromatography, the resulting 3,5-disubstituted 1,2,4-selenadiazoles **2** were isolated in good to moderate yields as air-stable products. These results are shown in Table 1. By-products of the reaction were the corresponding nitriles in all cases owing to the facile selenium-extrusion of **1**. The physical properties of the obtained products **2** possessing aromatic substituents were identical in all respects with those reported by Cohen.[7] The structures of new products **2** having various aliphatic or heteroatom substituents were confirmed by ^1H NMR, IR, MS, and elemental analyses.

New products possessing heteroatom substituents, 3,5-bis(dimethylamino)-1,2,4-selenadiazole **2h** and 3,5-bis(benzylthio)-1,2,4-selenadiazole **2i**, were also obtained by this method. However, the yield of **2h** from *N,N*-dimethylselenourea **1h** was low, and only a trace amount of **2i** was formed from the corresponding selenothiocarbamate **1i** where benzyl thiocyanate was obtained in 80% yield. No improvement in the yield of **2h** could be achieved by using 30% H_2O_2 or MCPBA in place of NBS. The low yield of **2i** by treatment with NBS might be attributed to the higher affinity of the starting materials to the soft oxidizing reagent. Electron-donating substituents such as the dimethylamino group are expected to accelerate the chemical reactivities of 1,2,4-selenadiazole rings toward electrophilic reagents or Diels–Alder reactions,[18,19] and the introduction of such substituents to the rings would afford possibilities for the further conversions of this ring system to several heterocycles.

Other reagents for the oxidative dimerization of **1** were also investigated for the optimization of the preparation of **2**. However, unlike the synthesis of 3,5-disubstituted 1,2,4-thiadiazoles from primary thioamides,[20] treatment of **1a** with DMSO/1-methyl-2-chloropyridinium iodide system was not fully effective for the synthesis of 3,5-dipheyl-1,2,4-selenadiazole **2a** (Run 2 in Table 1). As was successful in the synthesis of 3,5-disubstituted 1,2,4-thiadiazoles, primary selenoamide Se-oxides were also expected to provide 1,2,4-selenadiazoles **2** by treatment with electrophilic reagents such as H^+. Although attempts for the isolation of *p*-methylselenobenzamide Se-oxide by the reaction of *p*-methylselenobenzamide **1b** with 30% H_2O_2 in MeOH at 0 °C were not successful, 3,5-di-*p*-tolyl-1,2,4-selenadiazole **2b**, *p*-methylbenzonitrile, and elemental selenium were obtained in 66, 27, and 64% yields, respectively.

In these reactions, several points are worth nothing: (1) Among the several reagents, NBS gives good results for the synthesis of 1,2,4-selenadiazoles **2** from primary selenoamides **1** except **1h** and **1i**. (2) The yields of 1,2,4-selenadiazoles **2** possessing aromatic substituents were generally high when NBS was used. On the other hand, aliphatic and heteroatom analogues **2** were obtained in moderate to low yields owing to the facile decomposition of selenoamides **1** to nitriles caused by the reagents.

The oxidative dimerization of selenoamides **1** was assumed to proceed via a similar mechanism that form 3,5-disubstituted 1,2,4-thiadiazoles reported previously by us.[20]

Conclusively, we have established a convenient one-step synthesis of 3,5-disubstituted 1,2,4-selenadiazoles **2** by treatment of primary selenoamides **1** with NBS. These products are expected to promote further chemical conversions by the use of reactivities of carbon–selenium or nitrogen–selenium bonds in the aromatic ring as well as the introduction of various functionalities to the 3- and 5-positions of the nucleus. Chemical conversion of 1,2,4-selenadiazoles **2** toward novel heterocyclic ring systems is now in progress in our laboratory.

Experimental

General. The starting selenoamides **1** were prepared by treatment of the corresponding nitriles with $(Me_3Si)_2Se$ in the presence of $BF_3{\cdot}OEt_2$.[17] The other reagents were commercial reagent grade materials and were purified by recrystallization or by distillation prior to use. IR spectra were recorded with a Hitachi 295 infrared spectrophotometer. ^1H NMR spectra were recorded with a Hitachi R-22 (90 MHz) spectrometer in deuteriochloroform solution containing tetramethylsilane as an internal standard. MS spectra were recorded with a Hitachi RMU-6M and Hitachi M-2000 spectrometer, with a direct inlet system, operating at 20 or 70 eV.

General Procedure for the Reaction of Primary Selenoamides 1 with NBS. A typical procedure is described below for the preparation of 3,5-diphenyl-1,2,4-selenadiazole **2a**. A solution of 196 mg (1.1 mmol) of NBS in 50 ml of $CHCl_3$ was added dropwise to a solution of 184 mg (1 mmol) of selenobenzamide **1a** in 50 ml of $CHCl_3$ at room temperature under nitrogen atmosphere, and was stirred for 1 h. The reaction mixture was then quenched with excess amount of 2M NaOH solution (1M=1 mol dm^{-3}). Precipitated elemental selenium was separated by filtration, and the filtrate was extracted with $CHCl_3$. The organic layer was washed with water and dried over anhydrous sodium sulfate. After removal of $CHCl_3$, the residue was purified by SiO_2 column chromatography using benzene as an eluent to give 3,5-diphenyl-1,2,4-selenadiazole **2a** in 76% yield.

2a: Colorless needles; mp 85 °C (lit, 85 °C);[7] IR (KBr) 1515, 1480, 1440, 1420, 1320, 1278, 1218, 1094, 1068, 1025, 1000, 970, 870, 760, and 680 cm^{-1}; ^1H NMR δ=7.43—7.53 (m, 6H), 7.93—8.05 (m, 2H), and 8.34—8.47 (m, 2H).

2b: Colorless needles; mp 122 °C (lit, 122 °C);[7] IR (KBr) 2925, 2830, 1600, 1482, 1410, 1320, 1300, 1280, 1240, 1160, 1090, 1020, 965, and 822 cm^{-1}; ^1H NMR δ=2.37 (s, 3H), 2.38 (s, 3H), 7.33 (d, J=8 Hz, 2H), 7.34 (d, J=8 Hz, 2H), 7.83 (d, J=8 Hz, 2H), and 8.27 (d, J=8 Hz,2H).

2c: Colorless needles; mp 139 °C (lit, 139 °C);[7] IR (KBr) 2925, 2840, 1600, 1485, 1318, 1245, 1165, 1095, 1022, 965, and 822 cm^{-1}; ^1H NMR δ=3.80 (s, 3H), 3.82 (s, 3H), 6.89 (d, J=8 Hz, 2H), 6.95 (d, J=8 Hz, 2H), 7.83 (d, J=8 Hz, 2H), and 8.30 (d, J=8 Hz, 2H).

2d: Colorless needles; mp 168 °C (lit, 168 °C); IR (KBr) 1590, 1510, 1475, 1400, 1310, 1280, 1230, 1165, 1090, 1015, 970, 875, 830, 735, and 685 cm^{-1}; ^1H NMR δ=7.24 (d, J=8 Hz, 4H), 7.87 (d, J=8 Hz, 2H), and 8.27 (d, J=8 Hz, 2H).

2e: Pale yellow oil; MS (m/z, ^{80}Se) 218 (M^+, 1%); IR (neat) 2950, 2860, 1700, 1515, 1450, 1375, 1268, 1195, 1142, 1080, 1052, 1025, 945, and 850 cm^{-1}; ^1H NMR δ=0.98 (t, J=7 Hz,

3H), 1.06 (t, J=7 Hz, 3H), 1.85 (sextet, J=7 Hz, 4H), 2.92 (t, J=7 Hz, 2H), and 3.06 (t, J=7 Hz, 2H). Found: C, 43.53; H, 6.52; N, 12.44%. Calcd for $C_8H_{14}N_2Se$; C, 44.25; H, 6.50; N, 12.90%.

2f: Pale yellow oil; MS (m/z, ^{80}Se) 274 (M^+, 14%); IR (neat) 2920, 2850, 1510, 1450, 1375, 1260, 1190, 1140, 1055, 940, 720, and 580 cm^{-1}; ^1H NMR δ=0.83—0.98 (m, 6H), 1.27—1.99 (m, 12H), 2.94 (t, J=7 Hz, 2H), and 3.07 (t, J=7 Hz, 2H). Found: C, 52.32; H, 8.27; N, 10.10%. Calcd for $C_{12}H_{22}N_2Se$; C, 52.74; H, 8.11; N, 10.25%.

2g: Pale yellow oil; MS (m/z, ^{80}Se) 330 (M^+, 11%); IR (neat) 2920, 2850, 1510, 1450, 1375, 1265, 1140, 1070, and 720 cm^{-1}; ^1H NMR δ=0.80—0.95 (m, 6H), 1.10—1.19 (m, 20H), 2.93 (t, J=7 Hz, 2H), and 3.07 (t, J=7 Hz, 2H). Found: C, 58.01; H, 9.41; N, 8.33%. Calcd for $C_{16}H_{30}N_2Se$: C, 58.34; H, 9.18; N, 8.50%.

2h: Colorless needles; 49—50 °C, MS (m/z, ^{80}Se) 220 (M^+, 99%); IR (KBr) 2910, 2850, 1590, 1510, 1370, 1330, 1250, 1190, 1110, 1050, 1020, 850, and 720 cm^{-1}; ^1H NMR δ=3.08 (s, 6H) and 3.11 (s, 6H). Found: C, 32.83; H, 5.50; N, 26.39%. Calcd for $C_6H_{12}N_4Se$: C, 32.88; H, 5.52; N, 25.57%.

2i: Colorless oil; MS (m/z, ^{80}Se) 378 (M^+); IR (neat) 3040, 2890, 1490, 1440, 1370, 1160, 990, and 690 cm^{-1}; ^1H NMR δ=4.41 (s, 2H), 4.42 (s, 2H), and 7.20—7.45 (m, 10H). Found: C, 50.57; H, 3.71; N, 7.24%. Calcd for $C_{16}H_{14}N_2S_2Se$: C, 50.92; H, 3.74; N, 7.42%.

Preparation of 3,5-Diphenyl-1,2,4-selenadiazole 2a by DMSO/1-Methyl-2-chloropyridinium Iodide. A solution of 7.36 g (40 mmol) of selenobenzamide **1a**, 25 ml of DMSO, and 10.32 g (40 mmol) of 1-methyl-2-chloropyridinium iodide in 300 ml of CH_2Cl_2 under nitrogen atmosphere was stirred at room temperature for 9 h, and the reaction mixture was then filtered. After removal of CH_2Cl_2 and DMSO, the residue was recrystallized from EtOH to give 3,5-diphenyl-1,2,4-selenadiazole **2a** in 23% yield.

Preparation of 3,5-Disubstituted 1,2,4-selenadiazoles 2 by 30% H_2O_2. A typical procedure is described below for the preparation of 3,5-di-*p*-tolyl-1,2,4-selenadiazole **2b**. To a solution of 198 mg (1 mmol) of *p*-methylselenobenzamide **1b** in 20 ml of MeOH, a solution of 227 mg (2 mmol) of H_2O_2 in 5 ml of MeOH was added at 0 °C. Immediately a reddish solid precipitated. The reaction mixture was then separated by filtration to give 153 mg of solid **A**, and the filtrate was extracted with CH_2Cl_2. The organic layer was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was purified by SiO_2 column chromatography using hexane as an eluent to give *p*-methylbenzonitrile in 27% yield. The solid **A** was treated with CH_2Cl_2 to separate 3,5-di-*p*-tolyl-1,2,4-selenadiazole **2b** and elemental selenium in 66 and 64% yields, respectively.

Preparation of 3,5-Bis(dimethylamino)-1,2,4-selenadiazole 2h by MCPBA. To a solution of 151 mg (1 mmol) of *N,N*-dimethylselenourea **1h** in 5 ml of MeOH, a solution of 258 mg (1.2 mmol) of 80% MCPBA in 5 ml of CH_2Cl_2 was added at 0 °C, and stirred for 30 min. The reaction mixture was then quenched with saturated sodium sulfite solution, and extracted with $CHCl_3$. The organic layer was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was separated by SiO_2 column chromatography using hexane/ether (2/1) as an eluent giving 3,5-bis(dimethylamino)-1,2,4-selenadiazole **2h** and dimethylcyanamide in 32 and 23% yields, respectively.

Synthesis of α-Amino Acids Containing a Cyclopropane Ring via Cobalt-Catalyzed Carbonylation-Amidocarbonylation of Cyclopropanemethanols

Yusuke AMINO and Kunisuke IZAWA*
Central Research Laboratories, Ajinomoto Co., Inc.,
1-1, Suzuki-cho, Kawasaki-ku, Kawasaki 210
(Received September 18, 1990)

Synopsis. *N*-Acetyl-3-cyclopropylalanine and 2-acetamido-3-cyclopropylbutyric acid were prepared under cobalt-catalyzed amidocarbonylation conditions from cyclopropanemethanol and α-methylcyclopropanemethanol, respectively. The reaction has been estimated to comprise the *in situ* formation of aldehyde from alcohol by cobalt-catalyzed hydrocarbonylation followed by subsequent amidocarbonylation.

Some α-amino acids containing a cyclopropane ring are natural products.[1] Their unique structures have been of interest from a physiological viewpoint.

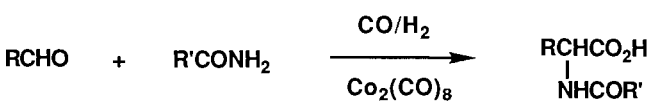
We have prepared various nonproteinogenic α-amino acids utilizing cobalt-catalyzed amidocarbonylation from amide, aldehyde, and carbon monoxide (Scheme 1).

An attempt to prepare an α-amino acid containing a cyclopropane ring from cyclopropanecarbaldehyde via amidocarbonylation was unsuccessful, giving a complex mixture. The reactive cyclopropane ring adjacent to the formyl group did not remain intact under amidocarbonylation conditions. We then turned our attention to alternative routes for the preparation of α-amino acids containing a cyclopropane ring via carbonylation-amidocarbonylation of cyclopropanemethanols.

Results and Discussion

It is well known that the cobalt-catalyzed homologation of alcohol under synthesis gas proceeds through aldehyde formation followed by hydrogenation. Benzyl alcohol having electron-releasing substituents and *t*-butyl alcohol, which easily generate a stable carbonium ion, gave homologated alcohol in good yield.[3]

Since the reaction conditions of the amidocarbonylation is the same as those of the oxo synthesis, except for the coexistence of an amide, alcohol can be carbonylated to give corresponding aldehyde, which subsequently reacts with amide and carbon monoxide to afford *N*-acyl α-amino acid under amidocarbonylation conditions. Yukawa et al. demonstrated the preparation of *N*-acetyl-*O*-methyltyrosine in 50% yield from *p*-methoxybenzyl alcohol under hydroformylation conditions in the presence of acetamide.[4] Cobalt hydridocarbonyl ($HCo(CO)_4$), which behaves as a strong acid in a polar solvent,[5] is generated *in situ* and plays an important role in giving an alkylcobalt tetracarbonyl intermediate (or a carbonium ion) from alcohol in this process. Moreover, the coexistence of an amide is essential to proceed the reactions successfully, since gas absorption could not be observed under the above-mentioned reaction conditions without acetamide, while *p*-methoxyphenylacetaldehyde was obtained in good yield using *N,N*-dimethylformamide in place of acetamide.[4]



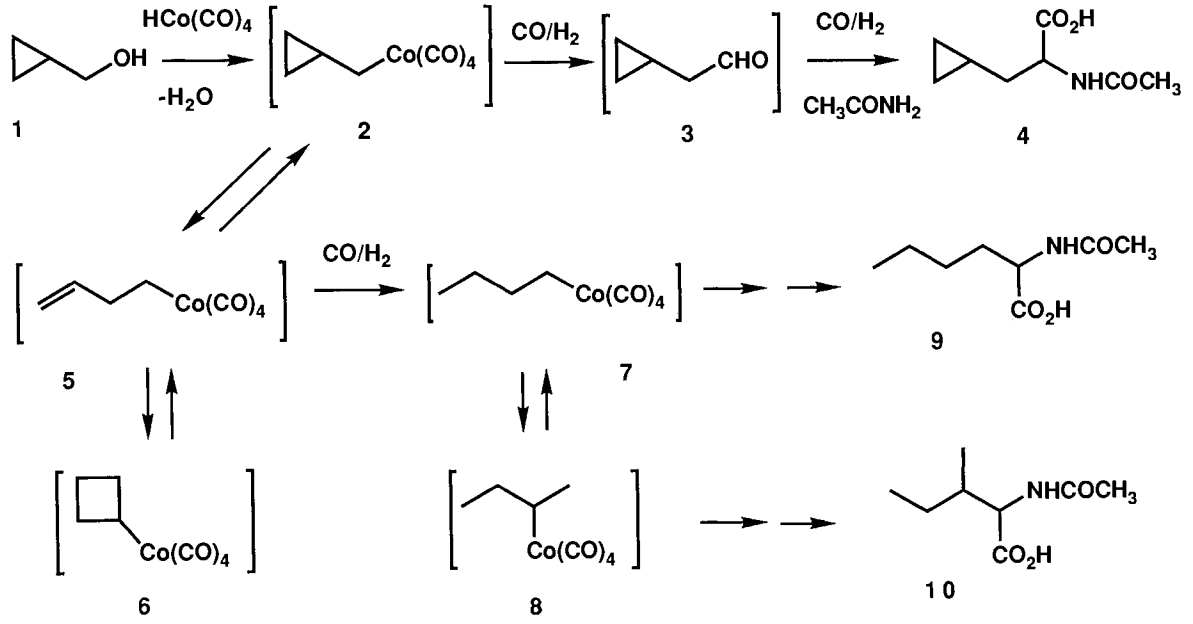
Scheme 1.

The cyclopropylmethyl cation, as well as the benzyl and *t*-butyl cations, are known to be stable carbonium ions. Whereas, the charge of the cyclopropylmethyl cation is delocalized on each of its four carbons. Namely, acidic hydrolysis of cyclopropylmethyl halide proceeds through a so-called "bicyclobutonium ion" to give cyclopropanemethanol, cyclobutanol, and 3-buten-1-ol.[6]

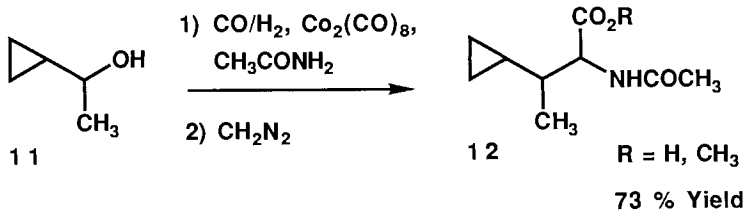
We tried to examine the use of cyclopropanemethanol (**1**) as a source for the carbonylation-amidocarbonylation. Although we had anticipated that the carbonylation-amidocarbonylation of cyclopropanemethanol (**1**) would give a mixture of *N*-acyl α-amino acids, **1** was transformed to *N*-acetyl-3-cyclopropylalanine (**4**) as the sole isolable *N*-acyl α-amino acid under amidocarbonylation conditions (see the experimental section) in ca. 8% yield. A possible mechanism for the formation of **4** is shown in Scheme 2. Changes in the reaction conditions (temperature, reaction time) as well as the addition of I_2 or CoI_2, did not increase the yield. Chloromethylcyclopropane did not give *N*-acyl α-amino acid under the same reaction conditions.

The yield of *N*-acyl α-amino acid was increased to 37% when the reaction was carried out under the following reaction conditions {$CO : H_2 = 3 : 1$ (80 atm at 25 °C), $Co_2(CO)_8$ (0.5 equiv), acetamide (2.0 equiv) at 120 °C for 18 h}. However, the product consisted of *N*-acetyl-3-cyclopropylalanine (**4**), *N*-acetylnorleucine (**9**), and *N*-acetylisoleucine (**10**) in a 1 : 1.5 : 1 ratio.

The formation of the latter two leucine derivatives can be explained as follows. Alkylcobalt tetracarbonyl intermediate (**2**) is considered to be in equilibrium with **5** and **6**. Intermediates (**7**) and (**8**) are generated by the hydrogenation of **5**, being accompanied by isomerization. Carbonylation-amidocarbonylation of **7** and **8** gives leucine derivatives, as shown in Scheme 2. Interestingly, an appreciable amount of 2-acetamido-2-cyclobutylacetic acid was not obtained, though the



Scheme 2.



Scheme 3.

possible involvement of intermediate (**6**) would not be excluded.

Next, the reaction of α-methylcyclopropanemethanol (**11**), which is known to give the 1-cyclopropylethyl cation stabilized by a hyper-conjugation of the cyclopropyl and methyl groups, was successfully revealed, giving *threo*- and erythro-2-acetamido-3-cyclopropylbutyric acid (**12**) in 73% yield. Increasing the stability of the carbonium ion (or the alkylcobalt tetracarbonyl intermediate) resulted in a selective *in situ* generation of the desired aldehyde, which is effectively incorporated into subsequent amidocarbonylation.

The usefulness of amidocarbonylation for the synthesis of nonproteinogenic α-amino acid was demonstrated by a facil preparation of *N*-acetyl derivatives of 3-cyclopropylalanine and 2-amino-3-cyclopropylbutyric acid from cyclopropanemethanols via carbonylation followed by amidocarbonylation.

Isolation of these unique α-amino acids from *Amanita echinocephala* and *A. sp.*, as well as their inhibitory activities against spore germination of *Piricularia oryzae*, were previously reported by Nozoe et al.[7]

Experimental

^{1}H NMR spectra were measured with a Varian XL 300 spectrometer and chemical shifts are given as δ ppm relative to tetramethylsilane (TMS) as an internal standard. Infrared (IR) spectra were recorded on a Hitachi 260-10 spectrophotometer with samples as neat liquid. Mass spectra (MS) were recorded with a JEOL DX-300 instrument using the FAB technique. GC–MS was performed on an HP 5890A–5970B, with a high-performance capilary column (cross linked methyl silicone). The thin-layer chromatographic system employed silica gel Merck Art. 7515. PTLC was performed with a Whatman PLK 5F.

Reaction of Cyclopropanmethanol (1), Carbon Monoxide, and Acetamide Catalyzed by $Co_2(CO)_8$. A mixture of cyclopropanemethanol (**1**) (500 mg, 6.93 mmol), acetamide (409 mg, 6.93 mmol) and $Co_2(CO)_8$ (120 mg) in acetone (20 ml) was heated in a 100 ml stainless-steel autoclave with a 1 : 1 mixture of carbon monoxide and hydrogene (total pressure at 25 °C: 120 atm) at 100 °C for 20 h. The autoclave was then cooled to ambient temperature and depressurized. After the solvent was removed under reduced pressure, the residue was treated with 10% aqueous $NaHCO_3$ (50 ml) and an insoluble material filtered off. The filtrate was washed with AcOEt (50 ml) to remove neutral materials and acidified with concentrated HCl. The solution was extracted with AcOEt (50 ml); the extract was washed with brine, then dried over $MgSO_4$. After concentration of the solution, the residue

was esterified with ethereal diazomethane and purified by PTLC (developed with hexane : AcOEt=1 : 2, v/v) to give *N*-acetyl-3-cyclopropylalanine methyl ester (methyl ester of **4**) (105 mg, 0.57 mmol, 8.2%) as an oil.

***N*-Acetyl-3-cyclopropylalanine Methyl Ester (Methyl Ester of 4):** ^{1}H NMR (300 MHz, $CDCl_3$) δ=0.01—0.13 (2H, m, CH_2), 0.40—0.52 (2H, m, CH_2), 0.60—0.73 (1H, m, CH), 1.62—1.75 (2H, m, CH_2), 2.03 (3H, s, CH_3), 3.75 (3H, s, CH_3), 4.69 (1H, td, J=6.0 and 7.8 Hz, CH), 6.25 (1H, br. d, J=6.0 Hz, NH); IR (neat) 3280, 3060, 3000, 2950, 1740, 1650, 1540, 1435, 1375, 1205, 1160, 1008 cm^{-1}; GC-MS m/z 153 (M^+ −32), 142 (M^+ −43), 126 (M^+ −59). Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
† Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received October 5, 1990)

Synopsis. In the presence of oxygen, amorphous poly(2,5-distyrylpyrazine) film was readily photodegraded, accompanied by cleavage of the pyrazine rings in the main chain. From the photodegraded film, *t*-2,*c*-4-diphenylcyclobutane-*r*-1,*t*-3-dicarbonitrile was isolated in 13% yield.

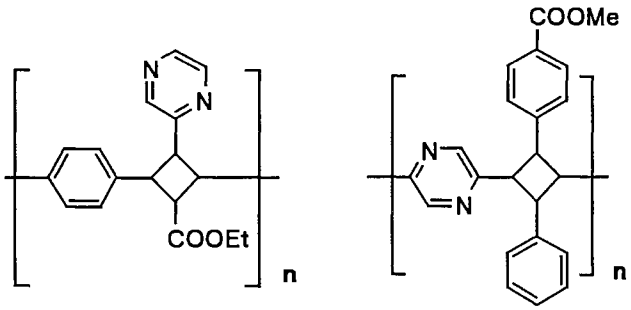
Various kinds of diolefinic compounds have been known to photopolymerize in the crystalline state into crystalline polymers having cyclobutane rings in the main chain. For example, 2,5-distyrylpyrazine (DSP) photopolymerizes in the crystalline state to give a high molecular weight liner polymer, poly(2,5-distyrylpyrazine) (poly-DSP).[1]

Thermal and photochemical behavior of poly-DSP has already been reported.[2–4] The crystalline poly-DSP is thermally depolymerized to the monomer in high yield.[2] In contrast, the photochemical reactivity of poly-DSP is affected by the matrix.[3] While poly-DSP is photodepolymerized in trifluoroacetic acid solution, it is highly stable photochemically in the crystalline state.[3] Furthermore, amorphous poly-DSP film is readily photodegraded with sunlight under air (Scheme 1). Such a high contrast in reactivity among the amorphous, crystalline, and solution states of the same polymer is quite unique in polymeric materials.

In this paper, we describe isolation and determination of one of the major degradation products of the amorphous poly-DSP film.

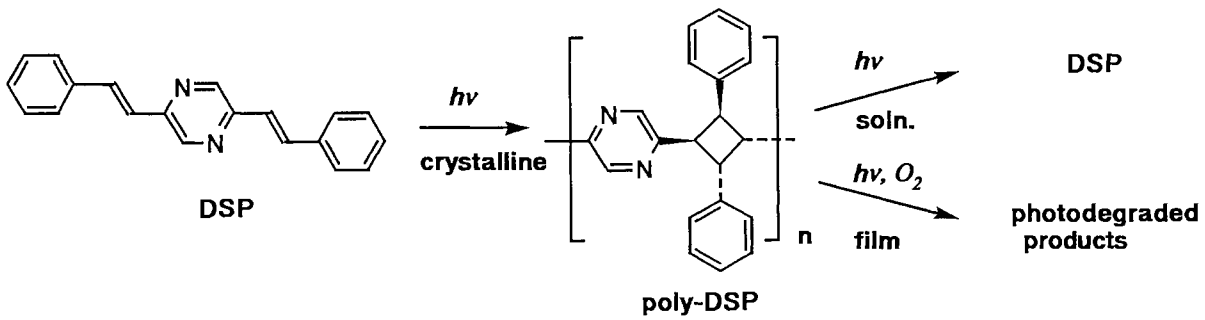
Results and Discussion

When poly-DSP film was stored in air under sunlight, absorption bands ascribable to hydroxyl, carbonyl, and cyano groups appeared in the IR spectrum.[3] Considering the structure of the polymer, the generation of nitrile compounds should be attributed to cleavage of the pyrazine rings in the main chain. On irradiation of amorphous poly[ethyl 4-[2-(2-pyrazinyl)ethenyl]cinnamate] (**1**) film, the nitrile formation was also observed in the IR spectrum.[5] A similar photodegradation was reported in the case of poly[2-(*p*-methoxycarbonylstyryl)-5-styrylpyrazine] (**2**).[6]



1 **2**

In order to confirm the generation of cyano groups and to throw light on the mechanism of photodegradation of the pyrazine ring, the photoreaction of substituted pyrazines such as 2,5-dimethylpyrazine was studied as a model of photodegradation of poly-DSP film.[3,4] In the case of low molecular weight azaaromatics, however, few reports have described on the nitrile formation through photoreaction.[7] Recently, we studied the photoreaction of 2,3,5,6-tetraphenylpyrazine from the viewpoint of a hindered pyrazine ring. On irradiation of the tetraphenylpyrazine in dichloromethane, a trace amount of benzonitrile was formed as detected by thin layer and gas chromatog-



Scheme 1.

raphy. Nevertheless, the tetraphenylpyrazine was not suitable for a model of poly-DSP since the yield of products was not sufficient to attain our aim mentioned above.

Therefore, we tried to isolated directly degradation products of the poly-DSP film. The film was irradiated under oxygen with a super-high-pressure mercury lamp and extracted with chloroform. Evaporation of the solvent and separation with thin layer chromatography afforded a white powder as a product. This compound (**3**) was identified as 2,4-diphenylcyclobutane-1,3-dicarbonitrile by IR, ^{1}H and ^{13}C NMR, and mass spectra as follows. Namely, the IR spectrum of **3** represented the presence of cyano groups (2230 cm^{-1}) and the absence of pyrazine rings. In the ^{1}H NMR spectrum, a multiplet at ca. δ=7.5, and two double doublets at δ=4.3 and 4.0 indicated a diphenylcyclobutane skeleton for **3**. Furthermore, the ^{13}C NMR spectrum was consistent with the above formulation. The peaks at δ=135.19—127.01, 117.80, and 43.59—33.56 indicated the carbons of phenyl rings, of cyano groups, and of cyclobutane rings, respectively. The molecular weight 258 ($C_{18}H_{14}N_2$) for **3** was also confirmed by the mass spectrum. In EI-MS for **3**, a strong peak at *m/z* 129 corresponding to the fragmentation of $[M/2]^+$ (cinnamonitrile) was observed. Furthermore, CI-MS (isobutane) showed significant peaks at *m/z* 315, 259, and 130 corresponding to the fragmentation of $[M+C(CH_3)_3]^+$, $[M+H]^+$, and $[M/2+H]^+$, respectively.

The configuration of **3** was finally confirmed as shown in Fig. 1 by direct comparison of ^{1}H and ^{13}C NMR spectra with those of an authentic sample (**3'**) derived from α-truxillic acid. Consequently, the photodegradation of poly-DSP proceeds with retention of configuration around the cyclobutane rings of the starting polymer.

Although the photo-oxidative degradation mechanism and the origin of simultaneously generated carbonyl and hydroxyl groups have not been clarified yet, the present result is unambiguous proof of generation of cyano groups from pyrazine rings on irradiation under oxygen. Further interest is that a photodegradation product of polymeric material was readily isolated in a significant yield.

Experimental

Infrared spectra were recorded on a JASCO IR-810 spectrometer. ^{1}H and ^{13}C NMR spectra were obtained by using JEOL GX-400 instruments. Melting points were determined by a Laboratory Devices MEL-TEMP and were uncorrected. DSP and poly-DSP were prepared as described in the literature.[2]

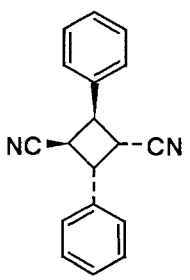


Fig. 1. Configuration of the isolated compound **3**.

Photodegradation of Amorphous Poly-DSP Film. Since crystalline poly-DSP is insoluble in usual organic solvents, trifluoroacetic acid was used as the solvent of poly-DSP. Amorphous poly-DSP film was prepared by casting its trifluoroacetic acid solution on glass plates. After the solvent was removed in vacuo, the film was washed with ethanol. The poly-DSP film (200 mg) in the flask with quartz beads was degassed by means of vacuum line and replaced by oxygen gas. The flask was sealed, and irradiated with stirring by light from a 500 W super-high-pressure mercury lamp through a water filter. After 120 h, the contents were extracted with chloroform (200 ml). The insoluble residue weighed about 40 mg. Separation of the soluble part of the products was carried out by preparative thin layer chromatography (49 : 49 : 2 $CHCl_3$/benzene/Et_2O and then 1 : 1 benzene/hexane), to give a white powder (**3**, 24 mg) as a main product, which was identified as 2,4-diphenylcyclobutane-1,3-dicarbonitrile on the basis of IR, ^{1}H and ^{13}C NMR, and mass spectra: IR (KBr) 3100—2850, 2230, 1495, 1450, 745, 700, and 660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.52—7.39 (10H, m), 4.31 (2H, dd, J=7 and 9 Hz), and 4.03 (2H, dd, J=7 and 9 Hz); ^{13}C NMR ($CDCl_3$) δ=135.19, 129.31, 128.89, 127.01, 117.80, 43.59, and 33.56; MS (EI) *m/z* (rel intensity) 129 (100) and 102 (12); (CI, isobutane) *m/z* (rel intensity) 315 (35), 259 (20), and 130 (100).

Preparation of Authentic Sample of 2,4-Diphenylcyclobutane-1,3-dicarbonitrile. To a stirred suspension of α-truxillic acid (3.0 g, 10 mmol) in benzene (50 ml) was added an excess amount of thionyl chloride in the presence of DMF as a catalyst. The mixture was refluxed for 3 h. The resulting solution was concentrated in vacuo and the residual thionyl chloride was removed as the benzene azeotrope. The corresponding acid dichloride was obtained as a brown solid mass and used directly in the following step without further purification.

To 500 ml of concentrated aqueous ammonia was added dropwise, with vigorous stirring, a solution of the crude dichloride in benzene (60 ml). The reaction mixture was stirred until the precipitation was completed. Filtration followed by crystallization of the precipitate from ethanol–benzene gave the corresponding diamide (1.9 g, 65%).

To a suspension of the diamide (0.15 g, 0.50 mmol) in dichloromethane (100 ml) and DMF (8 ml) was added an excess amount of phosphoryl chloride. The mixture was refluxed for 8 h. The resulting solution was concentrated and the residual oil was poured into water. Filtration and crystallization of the precipitate from dichloromethane–hexane gave colorless plates (**3'**) (66 mg, 51%): Mp (CH_2Cl_2/hexane) 239—240 °C; IR (KBr) 3100—2850, 2230, 1490, 1460, 745, 700, and 660 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.50—7.39 (10H, m), 4.31 (2H, dd, J=7 and 9 Hz), and 4.02 (2H, dd, J=7 and 9 Hz); ^{13}C NMR ($CDCl_3$) δ=135.22, 129.31, 128.89, 127.03, 117.84, 43.56, and 33.56. Found: C, 83.39; H, 5.51: N, 10.95%. Calcd for $C_{18}H_{14}N_2$: C, 83.69; H, 5.46; N, 10.84%.

The authors are pleased to acknowledge Mitsui Toatsu Chemicals, Inc., for the measurement of mass spectrometry.

Oxidation of *s*-Alcohols with "Oxone" in Aprotic Solvents in the Presence of Wet-Aluminium Oxide

Masao HIRANO, Masaki OOSE, and Takashi MORIMOTO*
Department of Applied Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received October 16, 1990)

Synopsis. The oxidation of secondary aliphatic, alicyclic, and benzylic alcohols with Oxone in aprotic solvents in the presence of "wet-aluminum oxide" afforded the corresponding ketones in good yields under mild conditions.

"Oxone" (**1**), a white free-flowing powder, is a stable double salt, consisting of potassium hydrogenperoxomonosulfate ($KHSO_5$), potassium hydrogensulfate, and potassium sulfate in 2 : 1 : 1 molar ratio.[1] Recent development in Oxone chemistry has been exclusively based on the behavior of **1**, intimately analogous to conventional peracids.[2,3] Thus, **1** has been conveniently used for oxygen-transfer-type reactions; viz. epoxidation of olefins,[4,5] allylic alcohols,[6] and unsaturated acid,[7] and oxidation of sulfides to sulfoxides[8] and/or sulfones[9] etc. However, the reactions with **1** so far studied were usually carried out in mixed solvents with water,[2-10] because of the negligible solubility of **1** in organic solvents; to our knowledge, the only exceptional case in a water-free solvent is the oxidation of sulfides mediated by a quarternary ammonium salt.[11] This paper describes the oxidation of various *s*-alcohols with Oxone in aprotic solvents under mild conditions in the presence of aluminium oxide (referred as Alumina). This reaction might be expected to provide a readily available methodology for Oxone oxidations with simple manipulation, and also with facile product isolation.

Results and Discussion

The oxidation was conducted by mixing **1**, an alcohol, and an aprotic solvent in the presence or absence of Alumina. The heterogeneous mixture was stirred under argon in order to exclude any influence of autoxidation. It should be noted that sufficiently effective stirring throughout a given period is essential to ensure a smooth, reproducible (±5%<) reaction. The progress of the reaction can easily be followed by GLC analysis of the supernatant withdrawn at intervals. The analysis revealed that in the absence of Alumina, the oxidation of 2-methylcyclohexanol (**2**) at 25°C in dichloromethane gave no detectable amount of 2-methylcyclohexanone (**3**), even within 24 h. The reaction with commercial "dry-Alumina" for 24 h led to the result that only 15% of **3** was obtained; 85% of **2** remained unreacted (GLC). On the other hand, a substantial consumption of 2 (92%) was observed for only 2 h in the presence of "wet-Alumina" (see Experimental), resulting in a dramatical increase of **3** (80%; isolated yield). Thus, "wet-Alumina" was proved to play an essential role in the oxidation. In the last case, it was observed that **2** is consumed as soon as the reaction started and that **3** increases with the progress of the reaction. There was no extensive formation of a by-product.

The oxidation was also conducted in acetonitrile and hexane in the presence of "wet-Alumina". In acetonitrile, Oxone showed a higher reactivity than in dichloromethane, and the substrate was almost consumed within 2 h at 25°C. However, a considerable formation of a by-product was observed, giving an inferior yield of **3** (35%) to that in dichloromethane. This compound also increased with a prolonged reaction and/or with the increased concentration of the oxidant at the expense of **3**, clearly indicating that **3** is susceptible to further oxidation in acetonitrile. An extensive formation of unknown by-products was also observed during the oxidations of 3- and 4-methyl, and 4-*t*-butylcyclohexanol in acetonitrile.# The oxidation in hexane was considerably slow under similar conditions, affording only a poor yield of **3**. Thus, dichloromethane might be a solvent of choice for the reactions of Entries 1—4.

The oxidation of the other alcohols (Entries 5—12) was performed in a manner similar to that of **2**, except that acetonitrile was used as a solvent in the place of dichloromethane, since a selective formation of the corresponding ketones, as well as much faster reactions than in dichloromethane, was observed in this solvent.

All of the tabulated alcohols underwent smooth oxidation in the presence of "wet-Alumina" and afforded the corresponding ketones in good yields. The results are presented in Table 1. A steric hindrance of an alkyl substituent on a cyclohexane-ring is small (Entries 1—3 and 6); even **2** or menthol, having a methyl and an isopropyl group adjacent to the hydroxyl groups, gave **3** or menthone, respectively, in high yield.

The present reaction is fairly clean and procedures for the isolation of a product are facile. Insoluble reagents can be readily removed by filtration, and the product can be isolated by evaporation of the solvent. Hence, it is emphasized that this system may be treated in a way quite similar to supported reagents comprising Alumina and various oxidants,[12-14] except that the present procedure can be instantly carried out without any laborious impregnation of the oxidant onto the support. When the purification

Identification of these compounds is now under way independently and will be reported in due course.

Table 1. Oxidation of *s*-Alcohols with Oxone in Aprotic Solvents in the Presence of "Wet-Alumina"[a]

Entry No.	Alcohols	Solvents[b]	Temp °C	Time h	Ketones %[c]
1	2-Methylcyclohexanol	DM	25	2	80
2	3-Methylcyclohexanol	DM	25	2	91

12	Benzoin	AN	30	5	96

a) Under argon, 0.3 g of alcohol and 2.4 g of "wet-Alumina" were used in every run; [Oxone]/[Alcohol]=2.5 (mole ratio). b) 10 cm^3 of dichloromethane (DM) or acetonitrile (AN) was used. c) Isolated yield.

of carbonyl compounds, so obtained, was necessary due to contamination with parent alcohols and/or by-products, the crude products could be chromatographed immediately after evaporation of the solvent. Moreover, the reaction could be performed in an organic solvent, which overcomes the limited solubility of an organic substrate and/or an undesirable loss of water-miscible product attendant on the conventional reaction in a water-mixed solvent. Hence, this procedure serves as a novel and convenient tool for Oxone oxidation and may be a promising approach for the transformation of a variety of functional groups as well.

Experimental

^1H NMR spectra were measured with a JEOL PMX-60 model spectrometer for solutions in carbon tetrachloride or deuterated chloroform. IR spectra were recorded for thin films (neat or Nujol mull) on a JASCO A-100 spectrophotometer. GLC was carried out on a Shimadzu GC-4CM instrument with a 2 m column packed with 5% PEG-20M on Chromosorb GAW-DMCS, with temperature programming.

Materials. Oxone purchased from Aldrich Chemical Co., Inc. was used without purification. All of the alcohols were also commercially available. Solvents were rigorously dried and distilled. "Wet-Alumina" was prepared by vigorous shaking of commercial super-dried aluminium oxide (ICN BIOMEDICALS Alumina A, Super I; 20 g) with distilled water (4 g) untill a free-flowing powder was obtained.

General Oxidation Procedures. The following procedures are representative. To a heterogeneous mixture of "wet-Alumina" (2.4 g) and Oxone (2.5 times moles of an alcohol) in dichloromethane (10 cm^3) in a round-bottomed flask was added 2-methylcyclohexanol (0.3 g) in one portion with magnetic stirring. The flask was flushed with dry argon and then tightly sealed with a silicon-rubber septum, through which the supernatant was withdrawn by a microsyringe in the course of the reaction. The oxidation was conducted at a controlled temperature in a thermostat with efficient stirring. After a given period, the cooled mixture was filtered through a Pyrex Buchner funnel with a fritted disk, and the residue was repeatedly washed with either a solvent or dry ether. Evaporation of the combined filtrate on a rotary evaporator in vacuo gave an oil, which was chromatographed on silica gel eluted with hexane and ethyl acetate, giving pure **3** (0.236 g; 80%).

The purities of the products were checked by GLC: they were identified by a comparison of the GLC retention times, and the NMR and IR spectra with those of authentic samples.

New Curvularin-Type Metabolites from the Hybrid Strain ME 0005 Derived from *Penicillium Citreo-viride* B. IFO 4692 and 6200

Sheng LAI, Yoshikazu SHIZURI, Shosuke YAMAMURA,* Kazuaki KAWAI,† and Hideyuki FURUKAWA†
Department of Chemistry, Faculty of Science and Technology, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223
† Faculty of Pharmacy, Meijo University, Tenpaku-ku, Nagoya 468
(Received October 24, 1990)

Synopsis. Four new curvularin-type metabolites (11-α-methoxycurvularin, 11-β-methoxycurvularin, 11,12-dihydroxycurvularin, and 12-hydroxy-10,11-*trans*-dehydrocurvularin) have been isolated from the mycelium of the hybrid strain ME 0005 derived from *Penicillium citreo-viride* B. IFO 4692 and 6200. And β-hydroxycurvularin, the biologically active principle from *Alternaria tomato*, was identified as 11-β-hydroxycurvularin.

Curvularin-type macrolides are 12-membered ring keto lactones containing a fused 1,3-dihydroxybenzene ring. Because of an interesting macrocyclic skeleton adopting some flexible conformations and novel biological properties as described later, curvularin (**1**) and related macrolides have been receiving much attention of synthetic chemists[1] since the first isolation of curvularin and α,β-dehydrocurvularin (**2**) from *Curvularia* species.[2] These macrolides have also been found later in *Penicillium gilmanii*[3] and in *Alternaria* species.[4,5] Quite recently, six novel curvularin-type metabolites have been isolated by us from a hybrid strain ME 0005 derived from *Penicillium citreo-viride* B. IFO 4692 and 6200.[6]

Last decades, Hyeon et al.[7] isolated β-hydroxycurvularin and α,β-dehydrocurvularin as sporulation-suppressing factors from *Alternaria tomato* and recently Kobayashi et al.[8] also reported the isolation of β-hydroxycurvularin, β-methoxycurvularin[9] as well as curvularin and α,β-dehydrocurvularin as unique spindle poisons from *Penicillium* sp. 511. β-Hydroxycurvularin[7] was idenfied as 11-β-hydroxycurvularin (**3**) by comparison of its spectroscopic data, particularly ^{1}H NMR spectrum, with those of 11-β-hydroxycurvularin and 11-α-hydroxycurvularin (**4**),[10] but no stereochemical evidence of the compound β-methoxycurvularin[8,9] has been revealed. In the continuation of our study on the metabolites of the hybrid strain ME 0005, a mixture of methoxycurvularins was also obtained. It was, therefore, considered desirable to make a detailed investigation, which led to the isolation of 11-β-methoxycurvularin (**5**) and 11-α-methoxycurvularin (**6**) together with 11,12-dihydroxycurvularin (**7**) and 12-hydroxy-10,11-*trans*-dehydrocurvularin (**8**) as follows.

According to essentially the same procedure as described in the previous papers,[6] the EtOAc extract was chromatographed on silica gel (Katayama Chemicals, Type 60) using a gradient solvent of MeOH–$CHCl_3$ (1—10%). Each fraction was further separated by repeated preparative TLC and/or HPLC to give four new compounds (**5**, **6**, **7**, and **8**), in addition to the known metabolites *cis*-dehydrocurvularin, citreofuran, and 12-oxocurvularin (see Experimental).

Compounds **5** and **6** are quite similar to each other in their ^{1}H NMR spectral data. Both have a methoxyl

a) J values were given in Hz. * in CD_3OD; ** in acetone-d_6. b) This J value is an apparent one, because of the close similarity in the chemical shifts.

group [δ=3.33 (3H, s) for **5** and δ=3.25 (3H, s), for **6**] in the spectra which resemble broadly those of 11-hydroxycurvularins (**3** and **4**).[6] They also share the same mass spectrum, showing a molecular ion at m/z 322, and fragment ions at m/z 290, 203, 195, 177, 167, and 150, as that of α,β-dehydrocurvularin.[2] The formation of the prominent ion at m/z 290 (M^+—MeOH) and the ion at m/z 203 requires the presence of the methoxyl group at C-11. Thus, the structures of both **5** and **6** were deduced as 11-methoxycurvularins and were confirmed by chemical transformation of α,β-dehydrocurvularin (**2**) to these two stereoisomers. When treated on SiO_2 with MeOH–EtOAc (1 : 1) at room temperature for 5 d, α,β-dehydrocurvularin was slowly converted into a mixture of **5** and **6** in the ratio of 2 : 3[11] as a colorless oil, which was separated by HPLC to afford two pure 11-methoxycurvularins (**5** and **6**) which were identical with the two natural compounds, respectively. Finally, the stereostructures of the two isomers were determined by comparing their ^{1}H NMR data with those of 11-β-hydroxycurvularin and 11-α-hydroxycurvularin as shown in Table 1, wherein the chemical shifts of the protons at C-10 of the formers are quite different while those of the latters are close or identical to each other.

Compounds **7** and **8** show close similarities in their mass spectra, except for different molecular ions (m/z 324 for **7** and m/z 306 for **8**). Both show a predominent peak at m/z 288 originated from dehydration and the fragment peaks (m/z 203, 195, 177, 167, and 150) characteristic of α,β-dehydrocurvularin[2] and 11-methoxycurvularins (**5** and **6**), strongly suggesting that there should be an olefinic group adjacent to the aromatic carbonyl group or a hydroxyl group at C-11-position. The ^{1}H NMR spectra of **7** and **8** are also similar to each other and similar to curvularin-type compounds[2,6] including 11-methoxycurvularins in spite of somewhat differences as follows. Compound **7** shows two NMR signals at δ=5.25 (1H, m) and 5.46 (1H, m) in addition to δ=4.97 (1H, m), coupled with the molecular ion at m/z 324 in its mass spectrum, indicating the presence of two hydroxyl groups in the molecule. Irradiation of the multiplet at δ=5.25 collapsed the doublet at δ=3.46 (2H, d, J=8.8 Hz) into a singlet and caused partial collapse of the signal at δ=5.46, suggesting that the two hydroxyl groups are adjacent to each other and one should be located at C-11, the other at C-12. Thus, **7** was unambiguously determined as 11,12-dihydroxycurvularin.[12] As for compound **8**, the most significant difference between **7** and **8** is the virtual absence of two adjacent hydroxyl groups in the latter, but instead **8** has one hydroxyl group adjacent to a *trans*-1,2-disubstituted double bond (δ=6.61, 1H, dd, J=15.6, 1.0 Hz; δ=6.68, 1H, dd, J=15.6, 4.4 Hz). Irradiation of the multiplet at δ=4.54 collapsed the olefinc protons to doublets (J=15.6 Hz) and caused changes at δ=2.17 (1H, m) and 1.82 (1H, m). Therefore, compound **8** was unambiguously determined as 12-hydroxy-10,11-*trans*-dehydrocurvularin.[12]

Experimental

Melting points were determined on a Mitamura Riken apparatus and uncorrected. Optical rotations were determined with a JASCO DIP-360 polarimeter. IR spectra were taken on a JASCO A-202 spectrophotometer. ^{1}H NMR spectra were recorded on a JEOL JNM-GX 400 NMR spectrometer in $CDCl_3$ with tetramethylsilane as the internal standard unless otherwise noted. Mass spectra were measured on a Hitachi M-80 GC-MS spectrometer, operating with an ionization energy at 70 eV.

Incubation. Polished rice (600 g) in deionized water (ca. 1600 ml) was cooked using an electric cooker (99 °C, ca. 20 min) and transfered into two Erlenmyer flasks (5 l), which were pasteurized at 120 °C for 20 min at 2 atm. After inoculated with a suspension of the mycelium of the hybrid strain ME 0005 in sterilized water, the rice was incubated stationarily at 25 °C for 23 d and extracted with acetone.

Isolation and Separation. The acetone extract suspended in water (500 ml) was extracted with EtOAc (200 ml×5). The EtOAc extract (dark brown syrup, 4.85 g) was chromatographed on silica gel (300 g, Katayama Chemicals, Type 60) using $CHCl_3$ (2000 ml) and then a gradient solvent of MeOH–$CHCl_3$ (1% MeOH–$CHCl_3$ 2000 ml; 2—10% MeOH–$CHCl_3$ 500 ml for each). Elution with 3—4% MeOH–$CHCl_3$ afforded a dark brown oil, which was separated by repeated preparative TLC (Kieselgel 60 PF_{254}) using hexane–EtOAc (2 : 1), $CHCl_3$–acetone (2 : 1), and $CHCl_3$–MeOH (10 : 1), and then by preparative TLC (Kieselgel 60 F_{254}) using $CHCl_3$–MeOH [(15 : 1)×2], to afford compound **7** (0.02%) in addition to the known compounds *cis*-dehydrocurvularin (0.15%) and citreofuran (0.26%).[6] Elution with 6—7% MeOH–$CHCl_3$ gave a dark brown oil. When subjected to preparative TLC (Kieselgel 60 PF_{254}), developed with $CHCl_3$–acetone (2 : 1),

$CHCl_3$–MeOH (15 : 1), hexane–EtOAc (1 : 1) and then subjected to preparative TLC (Kieselgel 60 F_{254}) using $CHCl_3$–MeOH [(15 : 1)×2], the oil afforded compound **8** (0.15%) and the known 12-oxocurvularin (0.27%),[6] together with a mixture of **5** and **6** in the ratio of 2 : 1[11] as a colorless oil (16.25 mg, 0.34%). The mixture was further separated by HPLC (Unisil Q PH; ϕ 6.0×250 mm) using MeOH–H_2O (3 : 7) (flow rate: 0.5 ml min^{-1}; Detector: UV 250 nm), giving rise to compounds **5** (4.4 mg) and **6** (2.5 g).[13]

Conversion of α,β-Dehydrocurvularin (2) into 11-Methoxycurvularins. α,β-Dehydrocurvularin (**2**) (23.88 mg) in MeOH–EtOAc (1 : 1) (12 ml) was absorbed on SiO_2 (5 g) at room temp for 5 d, and then concentrated to dryness. The residue was subjected to preparative TLC (Kieselgel F_{254}), using $CHCl_3$–MeOH (10 : 1) and then hexane–acetone (2 : 1), to give a mixture of **5** and **6** in the ratio of 2 : 3[11] as a colorless oil (9.56 mg, 36%, c.y. 70%), which afforded compounds 11-β-methoxycurvularin (**5**) and 11-α-methoxycurvularin (**6**) when subjected to HPLC under the same conditions as mentioned above.

Compound 5 (11-β-Methoxycurvularin). Colorless oil; $[\alpha]_D^{23}$ −21.3° (*c* 0.22, EtOH); IR (film) 3300, 2935, 1700, 1656, 1608, 1590, 1460, 1265, 1165, 1132, 1080, 1020, 848, and 760 cm^{-1}; ^1H NMR δ=1.21 (3H, d, *J*=6.35 Hz), 1.4—1.8 (6H, complex), 3.06 (1H, dd, *J*=15.14, 7.81 Hz), 3.27 (1H, dd, *J*=15.14, 4.88 Hz), 3.33 (3H, s), 3.64 (1H, d, *J*=16.30 Hz), 3.81 (1H, m), 3.91 (1H, d, *J*=16.30 Hz), 4.98 (1H, m), 6.17 (1H, d, *J*=2.20 Hz), 6.30 (1H, d, *J*=2.20 Hz), 6.75 (1H, br. s), and 8.50 (1H, br. s); ^1H NMR (CD_3OD) δ=1.12 (3H, d, *J*=6.16 Hz), 1.2—1.7 (6H, complex), 2.60 (1H, dd, *J*=13.25, 10.10 Hz), 3.36 (3H, s), 3.58 (1H, d, *J*=15.40 Hz), 3.64 (1H, m), 3.88 (1H, dd, *J*=13.25, 2.50 Hz), 3.94 (1H, d, *J*=15.40 Hz), 4.81 (1H, m), 6.20 (1H, d, *J*=2.20 Hz), and 6.27 (1H, d, *J*=2.20 Hz); MS (*m/z*) 322 (M^+), 290 (M^+—MeOH, base peak), 203, 195, 177, 167, and 150. Found: *m/z* 290.1156. Calcd for $C_{16}H_{18}O_5$: M^+—MeOH, 290.1153.

Compound 6 (11-α-Methoxycurvularin). Colorless oil; $[\alpha]_D^{26}$ −4.2° (*c* 0.24, EtOH); IR (film) 3300, 2935, 1700, 1656, 1608, 1588, 1460, 1270, 1162, 1080, 986, 845, and 755 cm^{-1}; ^1H NMR δ=1.25 (3H, d, *J*=6.34 Hz), 1.4—1.95 (6H, complex), 3.12 (1H, dd, *J*=13.67, 8.31 Hz), 3.25 (3H, s), 3.34 (1H, dd, *J*=13.67, 4.88 Hz), 3.59 (1H, d, *J*=15.87 Hz), 3.77 (1H, m), 3.95 (1H, d, *J*=15.87 Hz), 5.14 (1H, m), 5.98 (1H, d, *J*=2.20 Hz), 6.36 (1H, d, *J*=2.20 Hz), 6.95 (1H, br. s), and 8.97 (1H, br. s); ^1H NMR (CD_3OD) δ=1.11 (3H, d, *J*=6.35 Hz), 1.44 (4H, m), 1.64 (2H, m), 3.04 (1H, dd, *J*=14.16, 10.26 Hz), 3.32 (3H, s), 3.38 (1H, dd, *J*=14.16, 2.93 Hz), 3.60 (1H, d, *J*=15.14 Hz), 3.66 (1H, m), 3.95 (1H, d, *J*=15.14 Hz), 4.96 (1H, m), 6.22 (1H, d, *J*=2.44 Hz), and 6.28 (1H, d, *J*=2.44 Hz); MS (*m/z*) 322 (M^+), 290 (M^+—MeOH, base peak), 203, 195, 177, 167, and 150. Found: *m/z* 290.1151. Calcd for $C_{16}H_{18}O_5$: M^+—MeOH, 290.1152.

Compound 7 (11,12-Dihydroxycurvularin). Brownish needles; mp 168—170°C (from $CHCl_3$–MeOH). $[\alpha]_D^{25}$ +69.3° (*c* 0.224, EtOH). IR (film) 3350, 1700, 1638, 1610, and 1590 cm^{-1}; ^1H NMR (CD_3OD) δ=1.14 (3H, d, *J*=6.35 Hz), 1.58 (1H, m), 1.63 (1H, m), 2.00 (1H, m), 2.27 (1H, m), 3.46 (2H, d, *J*=8.8 Hz), 3.50 (2H, s), 4.97 (1H, m), 5.25 (1H, m), 5.46 (1H, m), 6.24 (1H, d, *J*=1.95 Hz), 6.26 (1H, d, *J*=1.95 Hz). MS (*m/z*) 324 (M^+), 288 (M^+−2×H_2O, base peak), 203, 195, 177, 167, and 150. Found: *m/z* 288.0945. Calcd for $C_{16}H_{16}O_5$: M^+−2×H_2O, 288.0996.

Compound 8 (12-Hydroxy-10,11-*trans*-dehydrocurvularin). Yellowish powder, $[\alpha]_D^{26}$ −49.5° (*c* 0.86, EtOH). IR (film) 3350, 1705, 1638, 1610, and 1590 cm^{-1}. ^1H NMR (CD_3OD) δ=1.30 (1H, d, *J*=6.35 Hz), 1.70 (1H, m), 1.82 (1H, m), 2.00 (1H, m), 2.17 (1H, m), 3.48 (1H, d, *J*=15.38 Hz), 3.61 (1H, d, *J*=15.38 Hz), 4.54 (1H, m), 4.96 (1H, m), 6.38 (1H, d, *J*=1.95 Hz), 6.43 (1H, d, *J*=1.95 Hz), 6.61 (1H, dd, *J*=15.62, 0.98 Hz), 6.68 (1H, dd, *J*=15.62, 4.40 Hz). MS (*m/z*) 306 (M^+), 288 (M^+—H_2O, base peak), 203, 195, 177, 167, and 150. Found: *m/z* 288.0985. Calcd for $C_{16}H_{16}O_5$: M^+—H_2O, 288.0996.

9) Expected to be identical with one of our 11-methoxycurvularins, but the compound β-methoxycurvularin is quite different from both 11-α-methoxycurvularin and 11-β-methoxycurvularin in both the optical rotation property and ^1H NMR data. As ^1H NMR spectrum of α-methoxycurvularin was recorded in $CDCl_3$ with a JEOL FX 100,[8] we also carefully measured ^1H NMR spectra of 11-α-methoxycurvularin and 11-β-methoxycurvularin in $CDCl_3$ on a JEOL FX 90A NMR spectrometer. These data are in accordance with those reported already in the Experimental, while they are still quite different from that of β-methoxycurvularin cited in the Ref. 8.

10) In order to establish the stereostructure of β-hydroxycurvularin, ^1H NMR spectra of 11-α-hydroxycurvularin and 11-β-hydroxycurvularin were also measured using acetone-d_6. The spectra are quite similar to each other except for the following points. 11-α-hydroxycurvularin: δ=3.25 (1H, dd, *J*=14.2, 3.4 Hz) (H-10β), 3.03 (1H, dd, *J*=14.2, 9.8 Hz) (H-10α), 3.94 (1H, m) (H-11β); 11-β-hydroxycurvularin: δ=3.48 (1H, dd, *J*=13.6, 2.6 Hz) (H-10α), 2.85 (overlapped with the signal of H_2O) (H-10β), and 4.02 (1H, m) (H-α). The spectral data of 11-β-hydroxycurvularin were indistinguishable from those of β-hydroxycurvularin.[7] Thus the latter was identified as 11-β-hydroxycurvularin.[6]

11) Based on the integration heights of their methoxyl groups in ^1H NMR spectra and supported by the calculated results according to the optical rotation of 11-β-methoxycurvularin (**5**, $[\alpha]_D^{23}$=−21.3°) and 11-α-methoxycurvularin (**6**, $[\alpha]_D^{26}$−4.2°): **5** : **6**=1.85 : 1 in the natural mixture ($[\alpha]_D^{25}$−15.3°), while **5** : **6**=0.8 : 1 in the synthetic mixture $[\alpha]_D^{27}$−11.8°).

12) The stereostructures of **7** and **8** have not yet been determined because of the flexible conformations of these new compounds.

13) 11-Methoxycurvularins are very unstable and easily dehydrated to give α,β-dehydrocurvularin during separation on preparative TLC plates or HPLC column.

New Synthesis and Diels-Alder Reactions of 2-Aminomethyl-1,3-butadienes and Related 1,3-Dienes

Akira HOSOMI,* Toshiyuki MASUNARI,† Yoshinori TOMINAGA,† and Makoto HOJO

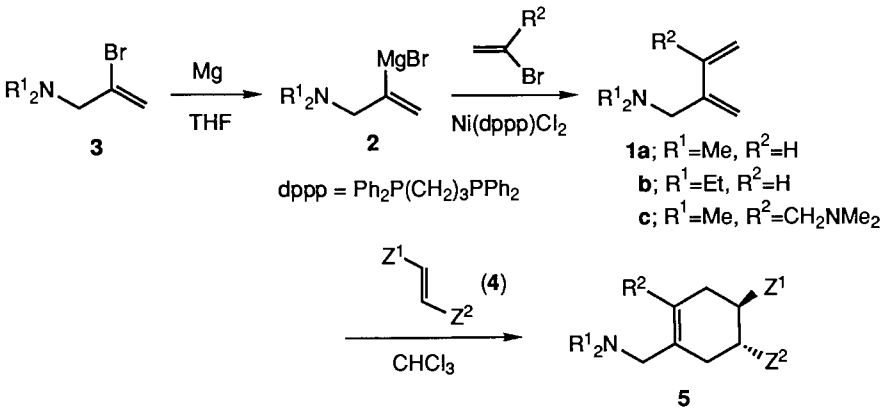
(Received November 2, 1990)

Synopsis. 2-Aminomethyl-1,3-butadienes and 2,3-bis-(aminomethyl)-1,3-butadienes, readily prepared by the Grignard cross-coupling reaction of 2-bromo-2-aminopropene and vinylic bromides, are good Diels-Alder dienes toward various activated dienophiles to afford aminomethyl-substituted cyclohexenes.

The Diels-Alder reaction is important and convenient for the stereo- and regioselective construction of six-membered ring compounds and many efforts have been directed to prepare new 1,3-dienes.[1] We have shown that the organosilyl and organostannyl groups on the methyl group of isoprene dramatically improve both reactivity and regioselectivity, and that these reagents are an excellent building block for the synthesis of isoprene derivatives.[2] Furthermore 2-aminomethyl-3-silylmethyl-1,3-butadiene acts formally as the synthetic equivalent of the 2,2′-bis(allyl) diradical and zwitterion.[3] As a part of a program aimed at exploring a new class of 1,3-dienes, we report here the preparation of new aminomethyl-substituted 1,3-dienes and their cycloaddition.

The starting 1,3-dienes **1** were readily prepared by the cross-coupling of the Grignard reagent **2** with vinylic bromide as shown in Scheme 1.

1,3-Dienes **1**, thus obtained, react smoothly with various dienophiles to give the corresponding cycloadducts **5**. The results are listed in Table 1. In all cases aminomethyl-substituted cyclohexenes were obtained in good yield. The reaction proceeded in a stereospecific mode as it was seen in the reaction with dimethyl fumarate and dimethyl maleate which gave exclusively a *trans* and *cis* adduct, respectively. However the regioselectivity in this reaction with methyl acrylate (3-Me_2NCH_2-:4-Me_2NCH_2-=38:62) decreased presumably due to the electronegative amino



Scheme 1.

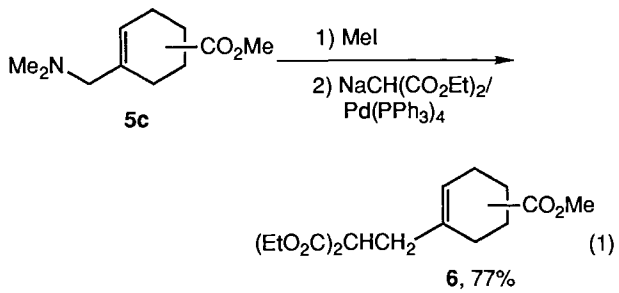
Table 1. The Diels-Alder Reaction of **1**[a]

Entry	Diene **1**	Dienophile **4**	Product **5** (Yield/%)[b]
1	**1a** (R^1=Me, R^2=H)	Dimethyl fumarate (**4a**)	**5a** (*trans*) (92)
2	**1a**	Dimethyl maleate (**4b**)	**5b** (*cis*) (67)
3	**1a**	Methyl acrylate (**4c**)	**5c**[c] (95)
4	**1a**	Ethyl acrylate (**4d**)	**5d** (80)
5	**1a**	3-Buten-2-one (**4e**)	**5e**[d] (98)
6	**1a**	Dimethyl acetylenedicarboxylate (**4f**)	**5f** (73)
7	**1b** (R^1=Et, R^2=H)	**4a**	**5g** (*trans*) (92)
8	**1b**	**4b**	**5h** (*cis*) (50)
9	**1b**	**4f**	**5i** (83)
10	**1c** (R^1=Me, R^2=CH_2NMe_2)	**4a**	**5j** (*trans*) (83)
11	**1c**	**4b**	**5k** (*cis*) (79)
12	**1c**	**4c**	**5l** (85)
13	**1c**	**4f**	**5m** (84)

a) In $CHCl_3$ at reflux for 20 h. b) Isolated by TLC. c) 3-Me_2NCH_2-:4-Me_2NCH_2=38:62. d) A mixture of regioisomers.

group, compared with the results using isoprene (30:70),[4] 2-silylmethyl-1,3-butadiene (16:84) and 2-stannylmethyl-1,3-butadiene (8:92).[2] The ratio was further close to ca. 1:1 when the reaction was carried out in the presence of a Lewis acid (44:56 for $AlCl_3$ and 43:57 for BF_3OEt_2) or hydrochloric acid (47:53). This result can be reasonably explained by the formation of more electronegative ammonium ion or a Lewis acid–amine complex.

The cycloadducts **5** include an allylamine unit which would form an electrophilic part after quaternization with an alkyl halide.[3] Therefore we studied the reaction of **5** with nucleophilic reagent. Thus, diethyl sodiomalonate reacted with the ammonium salt of **5c** in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium to give the substitution product **6** in 77% yield (Eq. 1).



Thus, **1** is an important reagent for construction of aminomethyl-substituted six-membered ring products which are further subjected to electrophilic reactions.

Experimental

The IR spectra were recorded on a Shimadzu IR-460 spectrometer. The NMR spectra were determined on JEOL-JMN-60SI, FX-90Q spectrometers using TMS(tetramethylsilane) as an internal standard. MS spectra were recorded on JEOL-DX303 and Shimadzu QP2000 spectrometers. The microanalyses were performed at the Analytical Center of Nagasaki University and University of Tsukuba. Ether and tetrahydrofuran were distilled from sodium diphenylketyl. All experiments were carried out under an argon atmosphere. Purification of the product was carried out by thin layer chromatography (TLC) on silica gel. Unless otherwise noted, chemicals were purchased from commercial suppliers and used without further purification.

Synthesis of Aminomethyl-Substituted 1,3-Butadienes 1. A Typical Procedure. A Grignard reagent **2**,[3] readily prepared from 2-bromo-3-dimethylaminopropene (**3a**, R^1= Me) (16.4 g, 0.10 mol) and magnesium (4.8 g, 0.20 mol) in THF (10 ml), was added to vinyl bromide (12.8 g, 0.12 mol) in the presence of dichloro[1,3-bis(diphenylphosphino)propane]nickel (200 mg, 0.37 mmol) in THF (10 ml) at 0 °C. After stirring for 17 h at room temperature, hydrolysis of the reaction mixture and successive usual workup were carried out. After evaporation of solvent, the residue was distilled to give a colorless **1a** (9.8 g, 0.088 mol) in 88% yield. Bp 56 °C (1.24×10^4 Pa). Similarly, **1b**, and **1c**, bp 84 °C (5.6×10^3 Pa) and bp 85 °C (5.3×10^3 Pa), were prepared from the corresponding starting materials in 47 and 75% yields, respectively.

2-Dimethylaminomethyl-1,3-butadiene (1a): ^{1}H NMR ($CDCl_3$, 90 MHz) δ=2.22 (s, 6H), 2.99 (s, 2H), 4.97 (1H, d, J=12 Hz), 5.14 (2H, s), 5.38 (1H, d, J=18 Hz), 6.37 (1H, dd, J=12 and 18 Hz); IR (neat) 3030, 2980, 2860, 2830, 2780, 1810, 1457 cm^{-1}. MS m/z 111 (M^+, 100), 96 (13), 67 (16). Found: m/z 111.1053. Calcd for $C_7H_{13}N$: 111.1048. Anal. ($C_7H_{13}N$) C, H, N.

2-Diethylaminomethyl-1,3-butadiene (1b): ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.04. (t, J=7 Hz, 6H), 2.50 (q, J=7 Hz, 4H), 3.14 (bs, 2H), 4.90—5.70 (4H, m), 6.35 (1H, dd, J=10.5 and 16 Hz); MS m/z 139 (M^+, 73), 124 (100). Found: m/z 139.1339. Calcd for $C_9H_{17}N$: 139.1361. Anal. ($C_9H_{17}N$) C, H, N.

2,3-Bis(dimethylaminomethyl)-1,3-butadiene (1c): ^{1}H NMR (CCl_4, 60 MHz) δ=2.20 (s, 12H), 3.05 (s, 4H), 5.05 (bs, 2H), 5.30 (bs, 2H); IR (neat) 2975, 2895, 2860, 2820, 1598, 1457, 1357, 1265, 1177, 1034, 902, 855 cm^{-1}; MS m/z 168 (M^+, 6), 108 (17), 58 (100). Anal. ($C_{10}H_{20}N$) C, H, N.

General Procedure for the Diels–Alder Reaction of 1. In a 20 ml flask a mixture of a 1,3-diene **1** (0.5 mmol) and a dienophile (1.0 mmol) was heated at reflux in chloroform (3 ml) for 20 h. After the solvent was evaporated, the product was purified by TLC on silica gel. The physical properties and analytical data of the adducts obtained are listed below.

Dimethyl 4-Dimethylaminomethyl-4-cyclohexene-*trans*-1,2-dicarboxylate (5a): ^{1}H NMR (CCl_4, 90 MHz) δ=2.15 (s, 6H), 2.3—2.8 (m, 6H), 2.90 (s, 2H), 3.70 (s, 6H), 5.55 (bs, 1H); IR (CCl_4) 2950, 2015, 1738, 1674, 1257, 1234, 1107, 1030 cm^{-1}; MS m/z 255 (M^+, 36), 240 (7), 224 (8), 196 (26), 151 (8), 58 (100). Anal. ($C_{13}H_{21}NO_5$) C, H, N.

Dimethyl 4-Dimethylaminomethyl-4-cyclohexene-*cis*-1,2-dicarboxylate (5b): ^{1}H NMR (CCl_5, 90 MHz) δ=2.05 (s, 6H), 2.2—2.7 (m, 6H), 2.90 (s, 2H), 3.80 (s, 6H), 5.50 (bs, 1H); IR (CCl_4) 2975, 2855, 1741, 1679, 1027 cm^{-1}; MS m/z 255 (M^+, 39), 240 (6), 224 (6), 196 (31), 180 (4), 168 (3), 151 (10), 110 (13), 117 (39), 59 (100). Anal. ($C^{13}H_{21}NO_2$) C, H, N.

Methyl 3- and 4-Dimethylaminomethyl-3-cyclohexene-1-carboxylates (5c, as a Mixture): ^{1}H NMR (CCl_3, 90 MHz) δ=2.15 (s, 6H), 2.0—2.6 (m, 7H), 2.75 (s, 2H), 3.66 (s, 3H×0.38), 3.68 (s, 3H×0.62), 5.30 (bs, 1H); IR (CCl_4) 2975, 2855, 1793, 1673, 1256, 1150, 1021 cm^{-1}. Anal. ($C_{11}H_{19}NO_2$) C, H, N.

Ethyl 3- and 4-Dimethylaminomethyl-3-cyclohexene-1-carboxylates (5d, as a Mixture): ^{1}H NMR ($CDCl_3$, 90 MHz) δ=1.25 (3H, t, J=7 Hz), 1.55—2.64 (7H, m), 2.15 (6H, s), 2.75 (2H, s), 4.31 (2H, q, J=7 Hz), 5.56 (1H, s); MS m/z 211 (M^+, 27), 138 (11), 93 (18), 50 (100). Found: m/z 211.1562. Calcd for $C_{12}H_{21}NO_2$: 211.1573.

4- and 5-Acetyl-1-dimethylaminomethyl-1-cyclohexenes (5e, as a Mixture): ^{1}H NMR (CCl_4, 90 MHz) δ=1.64—2.73 (m, 7H), 2.15 (s, 3H), 2.76 (s, 2H), 5.58 (bs, 1H); IR (CCl_4) 2945, 1713, 1455, 1356, 1180, 1023 cm^{-1}; MS m/z 181 (M^+, 64), 166 (5), 110 (13), 93 (17), 59 (100). Found: m/z 181.1481. Calcd for $C_{11}H_{19}NO$: 181.1466. Anal. ($C_{11}H_{19}NO$) C, H, N.

Dimethyl 4-Dimethylaminomethyl-1,4-cyclohexadiene-1,2-dicarboxylate (5f): ^{1}H NMR (CCl_4, 60 MHz) δ=2.10 (s, 6H), 2.80 (s, 2H), 3.15 (bs, 4H), 4.80 (s, 6H), 5.65 (bs, 1H); IR (CCl_4) 2955, 2820, 1742, 1655, 1214, 1165, 1020 cm^{-1}. Anal. ($C_{13}H_{19}NO_4$) C, H, N.

Dimethyl 4-Diethylaminomethyl-4-cyclohexene-*trans*-1,2-dicarboxylate (5g) ^{1}H NMR (CCl_4, 60 MHz) δ=1.33 (6H, t, J=7 Hz), 2.2—2.8 (6H, m), 2.45 (4H, q, J=7 Hz), 2.85 (2H, bs), 3.70 (6H, s), 5.53 (1H, bs). Anal. ($C_{15}H_{23}NO_4$) C, H, N.

Dimethyl 4-Diethylaminomethyl-4-cyclohexene-*cis*-1,2-dicarboxylate (5h): ^{1}H NMR (CCl_4, 60 MHz) δ=0.96 (6H, t, J=7 Hz), 1.98—2.67 (10H, m), 2.80 (2H, bs), 3.77 (6H, s), 5.75 (1H, bs); MS m/z 283 (M^+, 42), 268 (96), 151 (100). Anal. ($C_{15}H_{23}NO_4$) C, H, N.

Dimethyl 4-Diethylaminomethyl-1,4-cyclohexadiene-1,2-dicarboxylate (5i): ^{1}H NMR ($CDCl_3$, 60 MHz) δ=0.97 (6H, t, J=7 Hz), 1.77—2.83 (8H, m), 2.93 (2H, s), 3.63 (6H, s), 5.83

(1H, bs); MS *m/z* 281 (M^+, 51), 266 (25), 222 (100). Found: *m/z* 281.1623. Calcd for $C_{15}H_{23}NO_2$: 281.1672.

Dimethyl 4,5-Bis(dimethylaminomethyl)-4-cyclohexene-*trans*-1,2-dicarboxylate (5j): ^1H NMR (CCl_4, 60 MHz) δ=2.05 (s, 12H), 2.80 (s, 4H), 2.9—3.2 (m, 6H), 3.6 (s, 6H); IR (CCl_4) 2975, 2355, 1738, 1457, 1197, 1172, 1012 cm^{-1}; MS *m/z* 312 (M^+, 1), 281 (19), 236 (17), 220 (85), 58 (100). Anal. ($C_{16}H_{28}N_2O_4$) C, H, N.

Dimethyl 4,5-Bis(dimethylaminomethyl)-4-cyclohexene-*cis*-1,2-dicarboxylate (5k): ^1H NMR (CCl_4, 60 MHz) δ=2.1 (s, 12H), 2.8 (s, 4H), 2.9—3.3 (m, 6H), 3.7 (s, 6H); IR 2975, 2860, 1738, 1458, 1440, 1260, 1198, 1173, 1023, 785, 761 cm^{-1}; MS *m/z* 312 (M^+, 2), 280 (29), 268 (85), 252 (85), 192 (54), 108 (57), 58 (100). Anal. ($C_{16}H_{28}N_2O_4$) C, H, N.

Methyl 3,4-Bis(dimethylaminomethyl)-3-cyclohexene-1-carboxylate (5l): ^1H NMR (CCl_4, 60 MHz) δ=2.05 (s, 12H), 2.91 (s, 4H), 2.95—3.2 (m, 7H), 3.6 (s, 3H); IR 2975, 2855, 1737, 1457, 1438, 1259, 1108, 1020 cm^{-1}; MS *m/z* 254 (M^+, 2), 166 (6), 195 (100), 134 (90), 117 (100). Anal. ($C_{14}H_{26}O_2N_2$) C, H, N.

Ethyl 3,4-Bis(dimethylaminomethyl)-3-cyclohexene-1-carboxylate (5m): ^1H NMR ($CDCl_3$, 90 MHz) δ=1.28 (3H, t, *J*=7 Hz), 2.22 (12H, s), 2.0—2.8 (7H, m), 2.90 (4H, bs), 4.14 (2H, q, *J*=7 Hz). Anal. ($C_{14}H_{26}N_2O_2$) C, H, N.

Synthesis of Methyl 3- and 4-[2,2-Bis(ethoxycarbonyl)-ethyl]-3-cyclohexene-1-carboxylates (6, as a Mixture). After **5c** (50 mg, 0.25 mmol) was quaternized with excess methyl iodide in THF (5 ml) at room temperature, a THF solution (10 ml) of sodiomalonate, prepared from diethyl malonate (1.6 g, 10 mmol) and sodium hydride (50% in paraffin, 0.48 g, 10 mmol), was added in the presence of tetrakis(triphenylphosphine)palladium (20 mg) and the mixture was stirred for 18 h at room temperature. After usual hydrolysis workup, **6** (60 mg, 0.193 mmol) was isolated by TLC (hexane/ether 1:1, R_f 0.3) in 77% yield. ^1H NMR (CCl_4, 60 MHz) δ=1.2 (t, *J*=7 Hz, 6H), 2.1—3.2 (m, 10H), 3.6 (s, 3H), 4.1 (q, *J*=7 Hz, 4H), 5.4 (bs, 1H); IR (CCl_4) 2920, 2860, 1738, 1450, 1250, 1120, 1012 cm^{-1}; MS *m/z* 312 (M^+, 28), 267 (7), 239 (14), 201 (52), 119 (100). Anal. ($C_{14}H_{20}O_6$) C, H.

(Received September 12, 1990)

Synopsis. The presence of 3- and 4-(ω-phenylalkyl)-catechols in Burmese lac has been confirmed by their synthesis. 3-(ω-Phenylalkyl)veratroles were synthesized by alkylation of ω-phenylalkyl bromide with aryl lithium derived from veratrole. 4-(ω-Phenylalkyl)veratroles were similarly obtained from ω-phenylalkyl bromide and 4-bromoveratrole. Demethylation of 3- and 4-(ω-phenylalkyl)-veratroles with boron tribromide gave the corresponding catechols in good yields.

In Asian countries, the exuded fluid sap from several kinds of lac trees is used as a preservative surface coating material for wood, porcelain, and metallic wares.[1,2] The sap of a Burmese lac tree, *Melanorrhoea usitate*, has been used as a naturally occurring phenolic coating material. In 1922, Majima reported that 4-substituted catechols having an n-C_{17} alkyl side chain were the main constituents of the sap of *Melanorrhoea usitate*,[3] but little is known about the other compounds of the sap of this plant. We executed an intensive compositional investigation of the sap of the Burmese lac tree by use of liquid chromatography, and isolated 3- (**1**) and 4-(ω-phenylalkyl)catechols (**2**), phenolic lipids with novel structure.[4-6] These compounds are included in about 40% in the sap of the Burmese lac tree. Novel structures **1** and **2** and their characteristic properties as phenolic coating materials have promptes us to synthesize **1** and **2**. We describe here the total syntheses of **1** and **2** on the basis of the cross coupling reaction previously developed in our laboratory for the synthesis of terpenoids.[7]

Results and Discussion

ω-Phenyl-1-alkanols (**4**) are useful intermediates in organic synthesis.[8] ω-Phenyl fatty acids are also important compounds in studies of metabolism.[8,9] Generally, **4** were prepared through reduction of ω-phenyl fatty acids[10] starting from the half ester

chloride of aliphatic dicarboxylic acid[11] and benzene, or ω-phenylalkyl bromide and diethyl malonate.[12] In the present case, we needed an efficient and mild procedure for the preparation of **4**. We recently reported a new synthetic method[7] of terpenoids using the copper(I) salt-catalyzed Grignard cross coupling reaction.[13] Based on these, we now report here analogous convenient synthesis of **4** as shown in Scheme 1.

The reaction of ω-bromo-1-(2-tetrahydropyranyloxy)-alkanes (**3**)[14-16] with phenylmagnesium bromide in the presence of copper(I) chloride in THF at reflux temperature gave exclusively cross coupling products, which were then hydrolyzed to the desired **4** in 78—80% isolated yields.

The reaction of 2,3-dimethoxyphenyllithium, prepared from veratrole and butyllithium with 1-bromo-10-phenyldecane (**5a**) gave 3-(10-phenyldecyl)veratrole (**6a**) in 74% yield.[17,18] 3-(12-Phenyldodecyl)veratrole (**6b**) was also prepared in the same manner from veratrole and 1-bromo-12-phenyldodecane (**5b**) in 76% yield (see Scheme 2).

Demethylation of **6a** using boron tribromide[19] yielded 3-(10-phenyldecyl)catechol (**1a**) in 86% yield.

Similarly, 3-(12-phenyldodecyl)catechol (**1b**) was prepared in 87% yield. The IR, ^{1}H NMR, and EI-MS spectra of these products were in good agreement with those of the reported data.[4]

In a next stage, 4-(10-phenyldecyl)- (**7a**) and 4-(12-phenyldodecyl)veratrole (**7b**) were obtained by the coupling reaction of 3,4-dimethoxyphenyllithium[20] with 1-bromo-10-phenyldecane (**5a**) and 1-bromo-12-phenyldecane (**5b**), respectively (see Scheme 3).

Demethylation of **7a** and **7b** using BBr_3 yielded 4-(10-phenyldecyl)- (**2a**) and 4-(12-phenyldodecyl)catechol (**2b**) in 83 and 85% yield, respectively. The IR, NMR, and EI-MS spectra of **2** were in agreement with those of authentic sample. The ^{1}H NMR spectrum of **2** in $CDCl_3$ showed two triplets at δ=2.47 (2H, α-methylene protons of catechol group) and δ=2.57 (2H, α-methylene protons of phenyl group). On the other hand, the ^{1}H NMR spectrum of **1a** and **1b** in $CDCl_3$ each showed a triplet at δ=2.51 (4H, α-methylene protons of catechol and phenyl group).

The presence of **1** and **2** in the Burmese lac was confirmed using GLC by separate co-injection of their synthetic compounds with the natural products.

Experimental

Melting points were determined with a Yanagimoto micromelting point apparatus and were not corrected. IR spectra were measured on a Shimadzu IR-435 spectrometer in a liquid film or in KBr disc. All ^{1}H NMR spectra were taken in deuteriochloroform or carbon tetrachloride with tetramethylsilane as internal standard on a Varian EM 390 spectrometer (90 MHz) or JEOL GSX-270 spectrometer (270 MHz). Low resolution mass spectra were taken on a JEOL DX-300 mass spectrometer at 70 eV or with an emission current of 100 μA. High-performance liquid chromatography (HPLC) was performed on a Gilson liquid chromatograph with a Unisil ODS reverse phase column (4.6 mm×2.5 cm, 5 μm) or Develosil silica gel (4.6 mm×25 cm, 5 μm). Thin-layer chromatography (TLC) was run with precoated silica-gel plates (Merck, Art 5554). Spot detection was carried out with visualization by UV light and/or iodine vapor. Flash column chromatography was performed with glass column packed with Merck silica gel 60 (230—400 mesh). Capillary gas chromatography was performed on a Hewlett-Packard 5890A gas chromatograph using a DB-1 column (25 mm×0.25 mm).

Materials. ω-Bromo-1-(2-tetrahydropyranyloxy)alkane (**3**) were obtained from α,ω- alkanediol in good yields via ω-bromoalkyl alcohols.[14—16]

10-Phenyl-1-decanol (4a). A Grignard reagent was prepared from bromobenzene (7.07 mg, 45 mmol) and magnesium turning (0.96 g, 40 mmol) in dry THF (20 mL) with a small amount of I_2 as starter at 20—25 °C under dry nitrogen. To this Grignard solution, a solution of a mixture of 1-bromo-10-(2-tetrahydropyanyloxy)decane (**3a**) (9.63 g, 30 mmol) and CuCl (20 mg, 0.2 mmol) in dry THF (10 mL) was added at 0 °C for 10 min. The mixture was stirred for 5 h at reflux temperature. Then the ice-cooled reaction mixture was carefully added dropwise to a cold saturated NH_4Cl aq solution. The THF layer was separated and the aqueous layer was extracted with diethyl ether. The combined organic layer was washed with brine, dried (K_2CO_3) and concentrated in vacuo to give 9.8 g of crude cross-coupling product. This was employed in the next step without further purification.

A solution of the cross coupling product 9.8 g and *p*-toluenesulfonic acid (0.5 g, 2.4 mmol) in methanol (50 mL) were stirred for 8 h at room temperature. The mixture was neutralized with potassium carbonate and filtered through Celite. After removal of methanol in vacuo from the filtrate, the residual oil was purified by silica-gel column chromatography. Biphenyl as a by-product was obtained from the eluate with hexane–benzene (1:1) in 18% yield. The pure **4a** was obtained by chromatography over silica gel eluting with benzene–ethyl acetate (9:1) to give a compound (**4a**) (5.62 g) as oil. Yield: 80% from **3a** by 135—138 °C/2 Torr (1 Torr=133.322 Pa), R_f=0.38 (hexane–diethyl ether=1:1); IR (neat) 3300, 1600, 1500, and 700 cm^{-1}; ^{1}H NMR (CCl_4/TMS) δ=0.9—1.8 (br. s, 16H, CH_2), 2.54 (t, J=7 Hz, 2H, CH_2Ar), 2.91 (br. s, 1H, OH, D_2O exchangeable), 3.51 (t, J=6 Hz, 2H, CH_2O), and 6.9—7.3 (m, 5H, ArH). EI-MS *m/z* (rel intensity, %) 234 (M^+, 9), 216 (5), 117 (19) 104 (90), and 91 (100). Found: C, 81.87; H, 11.25%. Calcd for $C_{16}H_{26}O$: C, 81.99; H, 11.18%.

12-Phenyl-1-dodecanol (4b): In the same manner as described for compound (**4a**), 1-bromo-12-(2-tetrahydropyranyloxy)alkane (**3**) was converted to compound (**4b**). Yield: 80%, mp 37—38 °C (Lit,[9] mp 38—40 °C).

ω-Phenylalkyl Bromide (5). Compounds (**5**) were prepared from the ω-phenylalkyl alchols (**4**) and hydrobromic acid in the presence of sulfuric acid by mechanical stirring for 4 h at reflux temperature according to the general procedure reported in the literature.[21]

10-Phenyldecyl Bromide (5a). Yield: 81%, bp 145—146 °C/3 Torr, R_f=0.53 (hexane); IR (neat) 1600, 1500, 700, and 640 cm^{-1}; ^{1}H NMR (CCl_4/TMS) δ=1.15—2.0 (m, 16H, CH_2), 2.58 (t, J=7 Hz, 2H, CH_2Ar), 3.35 (t, J=7 Hz, 2H, CH_2Br), and 7.0—7.3 (m, 5H, ArH). EI-MS *m/z* (rel intensity, %) 298 (M^+, 17), 296 (M^+, 16), 133 (8), 105 (9) 92 (100), and 91 (74). Found: C, 64.54; H, 8.40%. Calcd for $C_{16}H_{25}Br$: C, 64.64; H, 8.48%.

12-Phenyldodecyl Bromide (5b). Yield: 83%, bp 155 °C/3 Torr, R_f=0.54 (hexane); IR (neat) 1600, 1500, 700, and 640 cm^{-1}; ^{1}H NMR (CCl_4/TMS) δ=1.13—2.0 (br. s, 20H, CH_2), 2.58 (t, J=7 Hz, 2H, CH_2Ar), 3.35 (t, J=7 Hz, 2H, CH_2Br), and 7.0—7.3 (m, 5H, ArH). EI-MS *m/z* (rel intensity, %) 326 (M^+, 13), 324 (M^+, 12), 133 (11), 104 (13), 92 (99), and 91 (100). Found: C, 66.48; H, 8.87%. Calcd for $C_{18}H_{29}Br$: C, 66.45; H, 8.99%.

3-(10-Phenyldecyl)veratrole (6a). Ten milliliters of butyllithium (1.6 M in hexane) was added to a stirred solution veratrole (6.62 g, 48 mmol) in dry THF (20 mL) at 0 °C under a nitrogen atmosphere (M=mol dm^{-3}). After stirring for 1 h at room temperature, a solution of 1-bromo-10-phenyldecane (**5a**) (4.75 g, 16 mmol) in dry THF (20 mL) was added and the mixture was refluxed for 4 h. The mixture was then poured into a saturated NH_4Cl aq solution and extracted with ethyl acetate. The ethyl acetate solution was washed with brine, dried (K_2CO_3), and concentrated in vacuo to give crude compound (**6a**). The residual oil was chromatographed over silica gel eluting with hexane to give tetradecylbenzene (15% yield). Compound (**6a**) was obtained from chromatography over silica gel eluting with hexane–benzene (5:95) to give 4.19 g (74% yield) of compound (**6a**) as a colorless liquid. IR (neat) 1600, 1585, 1500, 1080, 740, and 700 cm^{-1}; ^{1}H NMR (CCl_4/TMS) δ=1.1—1.6 (m, 16H, CH_2), 2.50 (t, J=7 Hz, 4H, CH_2Ar, CH_2Ph), 3.70 (s, 3H, CH_3O), 3.75 (s, 3H, CH_3O), 6.6—6.9 (m, 3H, ArH), and 7.1 (br. s, 5H, ArH). EI-MS *m/z* (rel intensity) 354 (M^+, 60), 151 (95), 120 (55), 91 (80), and 73 (100). Found: C, 81.22; H, 9.50%. Calcd for $C_{24}H_{34}O_2$: C, 81.31; H, 9.67%.

3-(12-Phenyldodecyl)veratrole (6b) was obtained by the reaction of compound (**5b**) (3.12 g, 9.6 mmol) with veratrole (3.97 g, 28.8 mmol) and butyllithium (6 ml, 9.6 mmol) in THF (20 mL). Yield 2.79 g (76%), IR (neat) 1600, 1585, 1500,

1080, 740, and 700 cm^{-1}; ^1H NMR (CCl_4/TMS) δ=1.1—1.6 (m, 20H, CH_2), 2.50 (t, J=7 Hz, 4H, CH_2Ar, CH_2Ph), 3.70 (s, 3H, CH_3O), 3.75 (s, 3H, CH_3O), 6.6—6.9 (m, 3H, ArH), and 7.1 (br. s, 5H, ArH). EI-MS m/z (rel intensity, %) 382(M^+, 50), 152 (48), 124 (30), and 91 (100). Found: C, 81.55; H, 9.95%. Calcd for $C_{26}H_{38}O_2$: C, 81.62; H, 10.01%.

4-(10-Phenyldecyl)veratrole (7a). To a solution of butyllithium (2.5 ml, 4 mmol) in dry THF (10 ml) was added 4-bromoveratrole (0.44 g, 2 mmol) in dry THF (10 mL) under nitrogen atmosphere. The mixture is stirred for 1 h at room temperature and then compound (**5a**) (0.60 g, 2 mmol) in dry THF (5 mL) was added under vigorous stirring. The reaction mixture was refluxed for 3 h. Then the mixture was allowed to cool to room temperature, and immediately hydrolyzed by pouring onto an iced NH_4Cl aq solution. The aqueous solution was acidified with hydrochloric acid. The mixture was then extracted with 50 mL of ethyl acetate. The ethyl acetate layer was separated, dried and evaporated. The residue was chromatographed over silica gel eluting with hexane–benzene (5:95) to give 0.43 g (61% yield) of compound (**7a**) as a colorless liquid. R_f=0.61 (hexane–benzene=5:95); IR (neat) 1600, 1520, 1260, 1230, 1140, 1020, 810, and 710 cm^{-1}; ^1H NMR (CCl_4/TMS) δ=1.3—1.8 (m, 16H, CH_2), 2.50 (t, J=7 Hz, 2H, CH_2Ar), 2.53 (t, J=7 Hz, 2H, CH_2Ar), 3.70 (s, 3H, CH_3O), 3.73 (s, 3H, CH_3O), and 6.6—7.3 (m, 8H, ArH). EI-MS m/z (rel intensity, %) 354 (M^+, 80), 151 (100), and 91 (90). Found: C, 81.19; H, 9.58%. Calcd for $C_{24}H_{34}O_2$: C, 81.31; H, 9.67%.

4-(12-Phenyldodecyl)veratrole (**7b**) was obtained by the reaction of compound (**5b**) with 4-bromoveratrole and butyllithium in dry THF. Yield 65%, R_f=0.65 (hexane–benzene=5:95); IR (neat) 1600, 1520, 1260, 1230, 1140, 1020, 810, and 710 cm^{-1}; ^1H NMR (CCl_4/TMS) δ=1.3—1.8 (m, 20H, CH_2), 3.73 (t, J=7 Hz, 2H, CH_2Ar), 2.53 (t, J=7 Hz, 2H, CH_2Ar), 3.70 (s, 3H, CH_3O), 3.73 (s, 3H, CH_3O), and 6.6—7.3 (m, 8H, ArH). EI-MS m/z (rel intensity, %) 382 (M^+, 45), 151 (56), and 91 (100). Found: C, 81.49; H, 10.12%. Calcd for $C_{26}H_{38}O_2$: C, 81.62; H, 10.01%.

3-(10-Phenyldecyl)catechol (1a). To a stirred solution of boron tribromide 0.7 g (2.8 mmol) in dichloromethane 5 mL was added dropwise a solution of compound (**6a**) (0.39 g, 1.1 mmol) in dichloromethane (20 mL) for 1 h at −10 °C. The mixture was allowed to warm up to room temperature slowly over 12 h. The mixture was hydrolyzed with water, diluted with dichloromethane. The dichloromethane layer was separated, washed with brine, dried ($MgSO_4$), and concentrated in vacuo below 30 °C. The residual oil was chromatographed on silica gel eluting with hexane–diethyl ether to give 0.31 g of compound (**1a**). Yield 86%, bp 185 °C/3 Torr, R_f=0.46 (hexane–diethyl ether=1:1); IR (neat) 3400, 1600, 1500, 780, and 730 cm^{-1}; ^1H NMR ($CDCl_3$/TMS) δ=1.1—1.8 (m, 16H, CH_2), 2.51 (t, J=7 Hz, 4H, CH_2Ar, CH_2Ph), 5.05, 5.18 (br. s, 1H, OH, D_2O exchangeable), 6.4—6.7 (m, 3H, ArH), and 6.9—7.3 (m, 5H, ArH). EI-MS m/z (rel intensity, %) 326 (M^+, 48), 124 (100), 123 (96), and 91 (47). Found: C, 80.89; H, 9.20%. Calcd for $C_{22}H_{30}O_2$: C, 80.93; H, 9.26%.

3-(12-Phenyldodecyl)catechol (**1b**) was obtained by the reaction of compound (**6b**) with boron tribromide. Yield 87%, R_f=0.58 (hexane–diethyl ether=1:1), mp 36.5 °C; IR (KBr) 3400, 1600, 1500, 780, and 730 cm^{-1}; IR (neat) 3400, 1600, 1500, 780, and 730 cm^{-1}; ^1H NMR ($CDCl_3$/TMS) δ=1.10—1.82 (m, 20H, CH_2), 2.51 (t, J=7 Hz, 4H, CH_2Ar, CH_2Ph), 5.15, 5.71 (br. s. 1H, OH, D_2O exchangeable), 6.44—6.68 (m, 3H, ArH), and 6.93—7.30 (m, 5H, ArH). EI-MS m/z (rel intensity, %) 354(M^+, 97), 124 (100), 123 (100), and 91 (87). Found: C, 81.25; H, 9.59%. Calcd for $C_{24}H_{34}O_2$: C, 81.31; H, 9.67%.

4-(10-Phenyldecyl)catechol (**2a**) was obtained by the reaction of compound (**7a**) with boron tribromide. Yield 83%, mp 56—57 °C, R_f=0.51 (benzene–ethyl acetate=1:1), IR (KBr) 3300, 1600, 1500, 1100, 800, and 700 cm^{-1}; ^1H NMR ($CDCl_3$/TMS) δ=1.2—1.8 (m, 16H, CH_2), 2.47 (t, J=7 Hz, 2H, CH_2), 2.57 (t, J=7 Hz, 2H, CH_2), 5.52 (br. s, 2H, OH, D_2O exchangeable), 6.5—6.8 (m, 3H, ArH), and 7.1—7.3 (m, 5H, ArH). EI-MS m/z (rel intensity, %) 326 (M^+, 55), 123 (100), and 91 (65). Found: C, 80.98; H, 9.19%. Calcd for $C_{22}H_{30}O_2$: C, 80.93; H, 9.26%.

4-(12-Phenyldodecyl)catechol (**2b**) was obtained by the reaction of compound (**7b**) with boron tribromide. Yield 85%, mp 62 °C, R_f=0.58 (benzene–ethyl acetate=1:1), IR (KBr) 3300, 1600, 1500, 1100, 800, and 700 cm^{-1}; ^1H NMR ($CDCl_3$/TMS) δ=1.2—1.8 (m, 20H, CH_2), 2.47 (t, J=7 Hz, 2H, CH_2Ar), 2.57 (t, J=7 Hz, 2H, CH_2Ar), 5.68 (br. s, 2H, OH, D_2O exchangeable), 6.5—6.8 (m, 3H, ArH), and 7.1—7.3 (m, 5H, ArH). EI-MS m/z (rel intensity, %) 354 (M^+, 55), 123 (100), and 91 (72). Found: C, 81.30; H, 9.75%. Calcd for $C_{24}H_{34}O_2$: C, 81.31; H, 9.67%.

Optical Resolution by Replacing Crystallization of Ammonium Salts of *N*-Acetyl-DL-2-aminobutanoic Acid, *N*-Acetyl-DL-norvaline, and *N*-Acetyl-DL-norleucine

Synopsis. Ammonium salts of *N*-acetyl-DL-2-aminobutanoic acid, *N*-acetyl-DL-norvaline (DL-AcNva·AM salt), and *N*-acetyl-DL-norleucine were optically resolved by replacing crystallization in the presence of the ammonium salt of *N*-acetyl-L-alanine to give their salts with L-configuration. The optical resolution of the DL-AcNva·AM salt, espcially, gave the optically pure L-AcNva·AM salt by purification in 80% yield based on the half amount of the DL-salt used as the starting material.

Ammonium salts of *N*-acetyl-DL-2-aminobutanoic acid (denoted by DL-AcAbu·AM salt), *N*-acetyl-DL-norvaline (DL-AcNva·AM salt), and *N*-acetyl-DL-norleucine (DL-AcNle·AM salt) exist in conglomerates at room temperature and have been optically resolved by preferential crystallization.[1,2] Optical resolution by replacing crystallization is another procedure for obtaining one enantiomer from a conglomerate. Since this optical resolution is based on interactions between each of the enantiomers and an optically active cosolute,[3] it may give a clue to elucidate the chiral interaction in a solution. We, therefore, have been engaged in studying the optical resolution by replacing crystallization.[4] Optical resolutions by replacing crystallization of the DL-AcAbu·AM, DL-AcNva·AM, and DL-AcNle·AM salts were attempted as a part of our study program. This optical resolution seems to give a good result when we employ an optically active cosolute whose structure is similar to that of the racemate. In addition, the cosolute must be more soluble in the solvent than the racemate because crystallization of the cosolute makes it difficult to separate the crystallized mixture into the cosolute and the enantiomer. The ammonium salt of *N*-acetyl-L-alanine (L-AcAla·AM salt) is readily available and seems to be more soluble in ethanol than the DL-AcAbu·AM, DL-AcNva·AM, and DL-AcNle·AM salts. Hence we have been chosen the L-AcAla·AM salt as a cosolute and optically resolved the DL-AcAbu·AM, DL-AcNva·AM, and DL-AcNle·AM salts by replacing crystallization in ethanol.

Experimental

Materials. DL-2-Aminobutanoic acid, DL-norvaline, and DL-norleucine were purchased from Sigma Chemicals, and L-alanine from Wako Pure Chemicals, Ind. DL-AcAbu, DL-AcNva, DL-AcNle, and L-AcAla were obtained, respectively, by acetylating the corresponding compounds in a usual manner.[1,2,5,6] These were then converted to the DL-AcAbu·AM, DL-AcNva·AM, and DL-AcNle·AM, and L-AcAla·AM salts by the procedure described in previous papers.[1,2] L-AcAla·AM salt: Found: C, 40.70; H, 8.24; N, 18.77% (Calcd for $C_5H_{12}N_2O_3$: C, 40.53; H, 8.16; N, 18.91%); mp 161—162 °C; $[\alpha]_D^{20}$ +11.6° (*c* 1.00, ethanol).

Optical Resolution. The DL-AcAbu·AM salt 10.00 mmol (1.622 g), the DL-AcNva·AM salt 10.00 mmol (1.762 g), or the DL-AcNle·AM salt 10.00 mmol (1.902 g) and the L-AcAla·AM salt were dissolved in ethanol at 40 °C; the amounts of the L-AcAla·AM salt and ethanol used were 10.00 mmol (1.482 g) and 100 cm³, 2.00—10.00 mmol (0.296—1.482 g) and 40 cm³, and 8.000 mmol (1.185 g) and 55 cm³, respectively, for the optical resolution of the DL-AcAbu·AM, DL-AcNva·AM, and DL-AcNle·AM salts. The solution was slowly cooled to 5 °C and then stirred for 10—60 min. The precipitated L-salt was collected by filtration, washed with a small amount of cold ethanol, and dried. The optical purities were estimated on the basis of the specific rotations of the L-AcAbu·AM salt ($[\alpha]_D^{20}$ +20.7° (*c* 1.00, ethanol)),[2] L-AcNva·AM salt ($[\alpha]_D^{20}$ +19.7° (*c* 1.00, ethanol)),[2] and L-AcNle·AM salt ($[\alpha]_D^{20}$ +22.8° (*c* 1.00, methanol)),[1] respectively. The degree of resolution was calculated from the equation.

$$\text{Degree of resolution/\%} = [\text{Yield/g} \times \text{Optical purify/\%}]/M,$$

where *M* is the half amount (5.00 mmol) of the DL-salt used as the starting material. The ^{1}H NMR spectra of the L-salt obtained were measured without recrystallization and showed that the L-salts were free from the L-AcAla·AM salt. The L-salts were recrystallized from ethanol;[1,2] the L-AcAbu·AM salt (optical purity 73%) 1.50 g, the L-AcNva·AM salt (optical purity 82%) 3.00 g, and the L-AcNle·AM salt (optical purity 50%) 1.30 g yielded, respectively, 1.05, 2.39, and 0.625 g of the optically pure L-salt.

Measurements. Optical rotation was measured with a Union Giken digital polarimeter PM-101 with a quartz cell of 5.00 cm path length. ^{1}H NMR spectra were recorded on a JEOL NMR spectrometer JNM-PMX 60 in deuterium oxide without internal standard.

Results and Discussion

Optical Resolution of Ammonium Salts of *N*-Acetyl-DL-2-aminobutanoic Acid and *N*-Acetyl-DL-norleucine. The results are summarized in Table 1. Optical resolution of the DL-AcAbu·AM salt gave the L-salt with 70—75% optical purity at 50% or higher degree of resolution in 20—40 min. The L-salt was recrystallized from ethanol to give the optically pure L-AcAbu·AM salt. The yield was estimated to be 50%, based on the half amount (5.00 mmol, 0.811 g) of the DL-salt used as the starting material. In contrast, optical resolution by preferential crystallization of the DL-AcAbu·AM salt gave the D- or L-salt only in 10% yield though its enantiomer can easily be obtained from a mother liquor.[2] Replacing crystallization thus appears to be superior to preferential crystallization for optical resolution of the DL-AcAbu·AM salt.

The result of optical resolution of the DL-AcNle·AM

Table 1. Replacing Crystallization of Ammonium Salts of *N*-Acetyl-DL-amino Acids[a]

Ammonium salt[b]	Resolution time	L-Salt

	50	0.611	40.4	26.0
	60	0.620	37.3	24.4

a) Ammonium salt of *N*-acetyl-DL-amino acid 10.00 mmol; temperature 5 °C. b) AcAbu·AM salt=Ammonium salt of *N*-acetyl-2-aminobutanoic acid; AcNva·AM salt=Ammonium salt of *N*-acetylnorvaline; AcNle·AM salt=Ammonium salt of *N*-acetylnorleucine. c) Ammonium salt of *N*-acetyl-L-alanine (L-AcAla·AM salt) 10.00 mmol; ethanol 100 cm³. d) L-AcAla·AM salt 8.000 mmol; ethanol 40 cm³. e) L-AcAla·AM salt 8.000 mmol; ethanol 55 cm³.

salt was not better than that of the DL-AcAbu·AM salt; purification of the L-AcNle·AM salt with 50% optical purity obtained in 20—40 min gave the optically pure L-salt and the yield was estimated to be 25%.

Optical Resolution of Ammonium Salts of *N*-Acetyl-DL-norvaline. Optical resolution of the DL-AcNva·AM salt gave a better result than those of the DL-AcAbu·AM and DL-AcNle·AM salts. Optimization regarding the mixing ratio was attempted by stirring 10.00 mmol of the DL-AcNva·AM salt with 2.00—10.00 mmol of the L-AcAla·AM salt in 40 cm³ of ethanol for 20 min at 5 °C. The degrees of crystallization of the D- and L-AcNva·AM salts ($DC_{(D)}$ and $DC_{(L)}$/%) were calculated from the equations

$$DC_{(D)}/\% = (1/2)[\text{Yield/g} \times (100 - \text{Optical purity}/\%)]/0.881,$$

$$DC_{(L)}/\% = \text{Yield/g}/0.881 - DC_{(D)},$$

where 0.881 (g) corresponds to the half amount (5.00 mmol) of the DL-AcNva·AM salt used. The dependencies of the $DC_{(L)}$ and $DC_{(D)}$ values on the amount of the L-AcAla·AM salt are shown in Fig. 1.

The D-AcNva·AM salt did not rapidly crystallize under these conditions, because the $DC_{(D)}$ value ranged from 3 to 10%, and the L-AcNva·AM salt obtained was of 76—83% optical purity. When 2.00—7.00 mmol of the L-AcAla·AM salt was used, the $DC_{(L)}$ value increased with an increase in the amoun of the L-AcAla·AM salt. The $DC_{(L)}$ value, however, was approximately constant (75%) in the range of 7.00—10.00 mmol of the L-AcAla·AM salt. Optical resolution at 10—60 min, therefore, was performed with

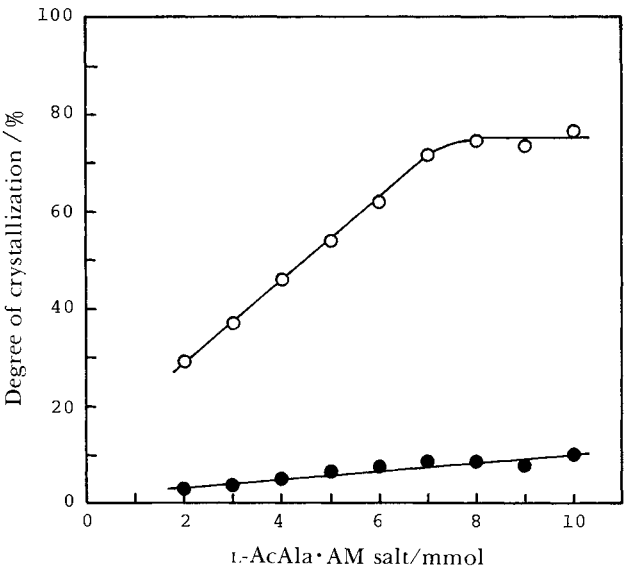

Fig. 1. Influence of the amount of the L-AcAla·AM salt on replacing crystallization of the DL-AcNva·AM salt. Conditions: DL-AcNva·AM salt 10.00 mmol; ethanol 40 cm³; temperature 5 °C; stirring time 20 min. Degree of crystallization: ○ L-AcNva·AM salt; ● D-AcNva·AM salt.

8.00 mmol of the L-AcAla·AM salt for 10.00 mmol of the DL-AcNva·AM salt. The result is listed in Table 1.

The L-AcNva·AM salt rapidly crystallized and the $DC_{(L)}$ value reached 92—94% at 30—60 min, whereas the crystallization of the D-salt was slow at 10—60 min. Optical resolution at 30—60 min gave the L-AcNva·AM salt with 81—84% optical purity at 84% degree of resolution. This L-AcNva·AM salt was recrystallized from ethanol to give the optically pure L-salt. The yield was estimated to be 80%. This result is far better than that by the optical resolution by preferential crystallization[2] and seems to be comparable to that attained by a diastereomeric procedure.

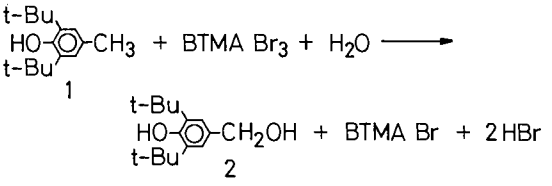
(Received November 5, 1990)

Synopsis. Reactions of hidered phenols, such as 2,6-di-*t*-butyl-4-methylphenol, 3,5-di-*t*-butyl-4-hydroxybenzyl alcohol, and 2,6-di-*t*-butylphenol, with benzyltrimethylammonium tribromide were carried out in dichloromethane in the presence of water, *t*-butyl alcohol, or aqueous sodium hydroxide at room temperature. Sequential reaction processes were provided by the obtained products.

Though the preparation of such hindered phenolic benzaldehyde as 3,5-di-*t*-butyl-4-hydroxybenzaldehyde by the usual methods is appreciably difficult, Coppinger el al. have already obtained this compound from a reaction of 2,6-di-*t*-butyl-4-methylphenol, with bromine in *t*-butyl alcohol.[2] In recent years we have found that benzyltrimethylammonium tribromide (BTMA Br_3) is a useful oxidizing agent.[3] In this paper we wish to report on the oxidation of hindered phenols by the use of BTMA Br_3, instead of bromine.

Results and Discussion

A reaction of 2,6-di-*t*-butyl-4-methylphenol (**1**) with an equimolar amount of BTMA Br_3 in dichloromethane in the presence of water at room temperature for 30 min gave 3,5-di-*t*-butyl-4-hydroxybenzyl alcohol (**2**) in quantitative yield. The reaction scheme can be represented as follows:



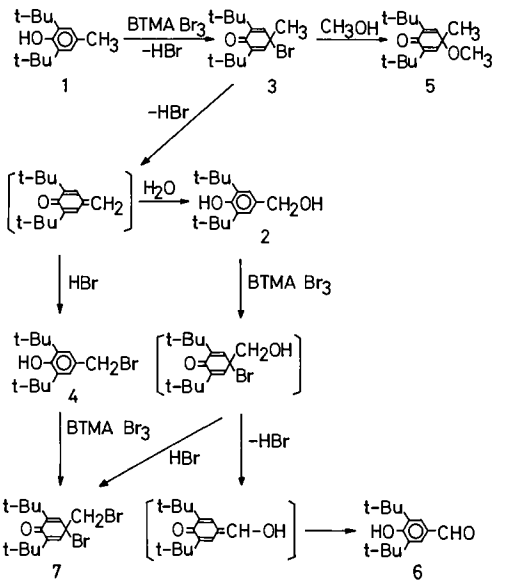
Scheme 1.

In this case, with only a 2-min reaction time, a mixture of **2** and 4-bromo-2,6-di-*t*-butyl-4-methyl-2,5-cyclohexadienone (**3**) was obtained. A mixture of **2** and **3** changed into a mixture of **2** and 4-bromomethyl-2,6-di-*t*-butylphenol (**4**) by a treatment with column chromatography on silica gel. Incidentally, the reaction of **1** with 1.0 equiv of BTMA Br_3 in methanol at 40 °C for 1 h gave 2,6-di-*t*-butyl-4-methoxy-4-methyl-2,5-cyclohexadienone (**5**) in good yield.

The reaction of **1** with 2.0 equiv of BTMA Br_3 and water in dichloromethane at room temperature for 3 h gave a mixture of 3,5-di-*t*-butyl-4-hydroxybenzaldehyde (**6**) and 4-bromo-4-bromomethyl-2,6-di-*t*-butyl-2,5-cyclohexadienone (**7**). In this case, when the reaction was carried out in the presence of *t*-butyl alcohol, compound **6** was obtained in satisfactory yield. Furthermore, when a large excess of BTMA Br_3 was used, compound **7** was obtained in quantitative yield.

The reaction of **2** with 1.0 equiv of BTMA Br_3 and water in dichloromethane at room temperature for 2 min gave a mixture of **6** and **7**. When the reaction of **2** with about 2 equiv of BTMA Br_3 was carried out for 1 h, compound **6** was obtained in good yield. That is, hindered phenolic benzaldehyde **6** was not oxidized into benzoic acid at room temperature, no matter how large was the excess of BTMA Br_3 used.[4]

The results described above are summarized in Table 1; the products might be derived from **1** and **2** through the following sequential reactions:



Scheme 2.

We have previously reported that the reaction of several substituted benzyl alcohols with 1 equiv of BTMA Br_3 in carbon tetrachloride in the presence of water or aqueous sodium hydroxide gave the corresponding benzaldehydes.[3b] In these cases, the obtained benzaldehydes should have been derived by an elimination of the hydrogen bromide from benzyl

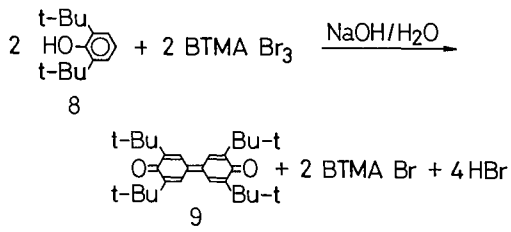
hypobromites (R–C_6H_4–CH_2OBr), which are produced from benzyl alcohols with Br^+. However, in the reaction of **2** with BTMA Br_3, it is reasonable to consider that the reaction proceeded via an intermediate, 4-bromo-4-hydroxymethyl-2,6-di-*t*-butyl-2,5-cyclohexadienone, as shown in Scheme 2, since compound **7** is also obtain together with **6** when the reaction is run for a short time (Run 7). That is, compound **2**, a hindered phenolic benzyl alcohol, should first react with Br^+ at the 1-position, affording the intermediate.

Otherwise, it has already been reported that the reaction of 2,6-di-*t*-butylphenol (**8**) with oxygen in the presence of a base gives 3,5,3′,5′-tetra-*t*-butyl-4,4′-diphenoquinone (**9**).[5] This compound **9** has also been obtained by the oxidation of **6**, **8**, and 3,5-di-*t*-butyl-4-hydroxybenzoic acid with alkaline hexacyanoferrate (III) or lead dioxide in the absence of molecular oxygen.[6] We have now found that the reaction of **8** with 1.0 equiv of BTMA Br_3 in dichloromethane in the presence of aqueous sodium hydroxide at room temperature for 5 h gives **9** in satisfactory yield. This reaction may be included a dimerization of the corresponding phenoxyl radical.[6]

We believe that the main active species for oxidation in the presence of water is probably hypobromous acid, which may be produced from a reaction of



Scheme 3.

$$\text{BTMA Br}_3 + \text{H}_2\text{O} \rightarrow \text{BTMA Br} + \text{HOBr} + \text{HBr}$$

Scheme 4.

BTMA Br_3 with water. The oxidation of 1,4-benzenediols to 2,5-cyclohexadiene-1,4-diones with BTMA Br_3 in aqueous acetic acid was reported in our previous paper.[1] Similarly, it is almost certain that *t*-butyl hypobromite and sodium hypobromite are the main active oxidizing species for the reaction in *t*-butyl alcohol and in aqueous sodium hydroxide, respectively.

Furthermore, the reaction of phenols, which did not have a bulky *t*-butyl group at both *o*-positions for the hydroxyl group, with BTMA Br_3 gave electrophilic bromo-substituted products. For example, the reaction of 4-hydroxy-3-methoxybenzyl alcohol (vanillyl alcohol) with 1.0 equiv of BTMA Br_3 in dichloromethane in the presence of *t*-butyl alcohol gave 3-bromo-4-hydroxy-5-methoxybenzyl alcohol (60% yield).

We emphasize that the stable solid reagent BTMA Br_3 is a useful oxidizing agent for the hindered phenols, since it can be treated safely and quantitatively in comparison with toxic liquid bromine.

Experimental

Oxidation of 2,6-Di-*t*-butyl-4-methylphenol (1) with 1.0 equiv of BTMA Br_3 and Water (Table 1, Run 1): To a solution of BTMA Br_3 (1.17 g, 3.0 mmol) in dichloromethane (10 ml) was added **1** (0.66 g, 3.0 mmol) and water (10 ml). The mixture was stirred at room temperature for 30 min until the initial orange color faded. The water layer was then filtered through wet filter paper. The separated organic layer was washed with water and dried over $MgSO_4$, filtered, and evaporated in vacuo to give 3,5-di-*t*-butyl-4-hydroxybenzyl alcohol (**2**) as a yellow solid; yield 0.69 g (97%); mp 133—135 °C (lit,[2] mp 137.7—138.1 °C).

Oxidation of 1 with 1.0 equiv of BTMA Br_3 in Methanol (Table 1, Run 3): To a solution of **1** (0.66 g, 3.0 mmol) in methanol (30 ml) was added BTMA Br_3 (2.34 g, 6.0 mmol). The mixture was stirred for 1 h at 40 °C. After the reaction mixture was concentrated in vacuo, a yellow solid obtained was extracted with ether (10 ml×3), and the organic layer was evaporated in vacuo to give 2,6-di-*t*-butyl-4-methoxy-4-methyl-2,5-cyclohexadienone (**5**) as colorless needles; yield 0.29 g (87%); mp 95—97 °C (lit,[2] mp 94 °C).

Oxidation of 1 with 2.0 equiv of BTMA Br_3 and *t*-Butyl Alcohol-Water (Table 1, Run 5): To a solution of BTMA Br_3 (2.34 g, 6.0 mmol) in dichloromethane (10 ml) was added **1** (0.66 g, 3.0 mmol), water (10 ml) and *t*-butyl alcohol (10 ml). The mixture was stirred at room temperature for 10 h until the initial orange color faded completely. The mixture was then treated by a similar procedure to that described as Run 1. Thus, 3,5-di-*t*-butyl-4-hydroxybenzaldehyde (**6**) was obtained as colorless crystals; yield 0.49 g (70%); mp 191—193 °C (lit,[2] mp 189 °C).

Oxidation of 1 with Large Excess of BTMA Br_3 and Water (Table 1, Run 6): To a solution of BTMA Br_3 (4.68 g, 12 mmol) in dichloromethane (10 ml) was added **1** (0.66 g, 3.0 mmol), and water (20 ml). The mixture was stirred at room temperature for 3 h. The mixture was then treated by a similar procedure to that described as Run 1. Thus, 4-bromo-4-bromomethyl-2,6-di-*t*-butyl-2,5-cyclohexadienone (**7**) was obtained as yellow crystals; yield 1.11 g (98%); mp 132—134 °C (lit,[5] mp 118 °C). ^{1}H NMR ($CDCl_3$) δ=1.27 (18H, s, $2C_4H_9$), 3.96 (2H, s, CH_2Br), 6.61 (2H, s, Harom). Found: C, 48.74; H, 5.58%. Calcd for $C_{15}H_{22}OBr_2$: C, 47.64; H, 5.86%.

Oxidation of 3,5-Di-*t*-butyl-4-hydroxybenzyl Alcohol (2) with 2.0 equiv of BTMA Br_3 and Water (Table 1, Run 8): To a solution of BTMA Br_3 (2.34 g, 6.0 mmol) in dichloromethane (10 ml) was added **2** (0.71 g, 3.0 mmol) and water (10 ml). The mixture was then stirred at room temperature for 1 h. The mixture was treated as Run 1. Thus, compound **6** was obtained as colorless crystals; yield 0.63 g (90%); mp 191—193 °C.

Reaction of 2,6-Di-*t*-butylphenol (8) with 1.0 equiv of BTMA Br_3 and Aqueous Sodium Hydroxide (Table 1, Run 9): To a solution of BTMA Br_3 (1.17 g, 3.0 mmol) in dichloromethane (20 ml) was added **8** (0.62 g, 3.0 mmol) and aqueous sodium hydroxide (NaOH; 0.25 g, 6.3 mmol, H_2O; 14 ml). The mixture was stirred at room temperature for 5 h. The organic layer was then separated, washed with water, dried over $MgSO_4$, and evaporated in vacuo to give crude 3,5,3′,5′-tetra-*t*-butyl-4,4′-diphenoquinone (**9**) as a brown-red solid. The crude product was purified through a column packed with silica gel using hexane as a developing solvent. Thus, **9** was obtained as purple columnar crystals; yield 0.37 g (61%); mp 255—257 °C (lit,[5] mp 246 °C). IR (KBr) 1598 (C=O); ^{1}H NMR ($CDCl_3$) δ=1.35 (36H, s, 4 C_4H_9), 7.64 (4H, s, Harom). Found: C, 81.98; H, 10.21%. Calcd for $C_{28}H_{40}O_2$: C, 82.28; H, 9.89%.

Oxidation of Cycloalkanes in a Radiofrequency Plasma

Meguru TEZUKA* and Tatsuhiko YAJIMA
Saitama Institute of Technology, Okabe, Saitama 369-02
(Received November 13, 1990)

Synopsis. Cyclopentane, cyclohexane, cycloheptane, and cyclooctane were reacted in a radiofrequency plasma containing oxygen to give mixtures of the corresponding cycloalkanones and cycloalkanols. Tetralin was also oxidized to 1-tetralone and 1-tetralol. Based on the effects of reaction variables on the oxidation rate, the reaction scheme involving the autoxidation of cycloalkyl radicals was proposed.

In the recent decades, much interest of organic chemists has been devoted to nonequilibrium plasma as a novel synthetic tool, since there are molecules activated by energetic electron bombardment to yield a diversity of reactive species which might not be readily generated by conventional chemical methods. Of late, a microwave or radiofrequency (rf) plasma was utilized for the purpose of partial oxidation of hydrocarbons. In this case, the effluents from the plasma containing atomic oxygen were passed over the organic substrates either dissolved in nonvolatile solvents[1,2] or adsorbed on solid supports.[3] Separately, we have also exerted ourselves to exploit a versatile oxidation process using plasma and reported that aromatic hydrocarbons could be effectively hydroxylated when the vaporized substrates flowed together with oxygen gas through an rf plasma.[4]

In this paper, we describe the oxidation of cycloalkanes in the plasma. For the mechanistic study, cycloalkanes were supposed to be suitable as starting materials, because they would yield less complicated products than other saturated hydrocarbons. It seems of not only scientific but also practical significance to establish the fundamental knowledge about the direct partial oxidation of saturated hydrocarbons.

Results and Discussion

The reactions of cyclopentane, cyclohexane, cycloheptane, cyclooctane, and tetralin with oxygen in an rf plasma were investigated. As major organic liquid products, the corresponding cycloalkanone(**1**) and cycloalkanol(**2**) were produced in comparable amounts. Their formation was favored under the conditions giving the conversions below ca. 20%. Typical results are listed in Table 1. The higher conversion was, on the whole, unfavorable, since it tended to induce the formation of tars. However, the ratio of products(**1**/**2**) was mostly unchanged regardless of kind of cycloalkanes and their conversion. The compounds which should be preferably formed in the plasma reactions without oxygen, for example, bicyclohexyl or cyclohexene from cyclohexane were not detected when oxygen was fed sufficiently. As for tetralin, the oxidation took place exclusively on the carbons of 1-position. In addition, the formation of considerable amounts of carbon dioxide and water was observed in each run.

Table 1. Oxidation of Cycloalkanes in an rf Plsma[a]

Substrate	Conversion/%	Product yield[b]/%	
		1	**2**
Cyclopentane	16	12	9
Cyclohexane	19	13	14
Cycloheptane	12	20	15
Cyclooctane	22	26	19
Tetralin	26	9	13

a) Radiofrequency power: 20 W; oxygen flow rate: 5 mmol min^{-1}; substrate flow rate: 0.5—1.5 mmol min^{-1}. b) Based on moles of substrate reacted.

In order to get mechanistic insight into the reaction of cycloalkanes in the plasma containing oxygen, effects of reaction variables, i.e., an rf power, and flow rates of the starting materials and oxygen in the oxidation of cyclohexane were examined in detail. With increasing power, the conversion of cyclohexane rose almost linearly (Fig. 1), while it diminished exponentially as the flow rate of cyclohexane was enhanced (Fig. 2). In practice, such a dependence of the conversion on the power and flow rate is so general in organic plasma chemistry,[5] and has been reasonably interpreted on the basis of a theorem that the

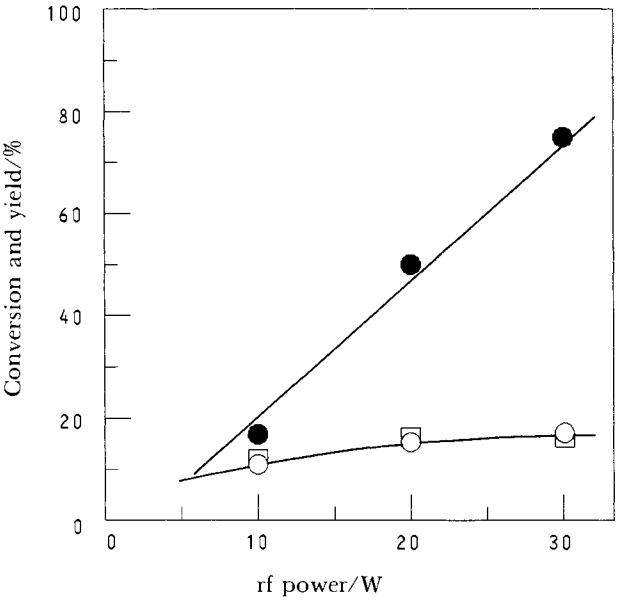

Fig. 1. Oxidation of cyclohexane in an rf plasma. Oxygen flow rate: 5 mmol min^{-1}; cyclohexane flow rate: 0.7 mmol min^{-1}; ●: cyclohexane conversion; ○: cyclohexanone yield; □: cyclohexanol yield.

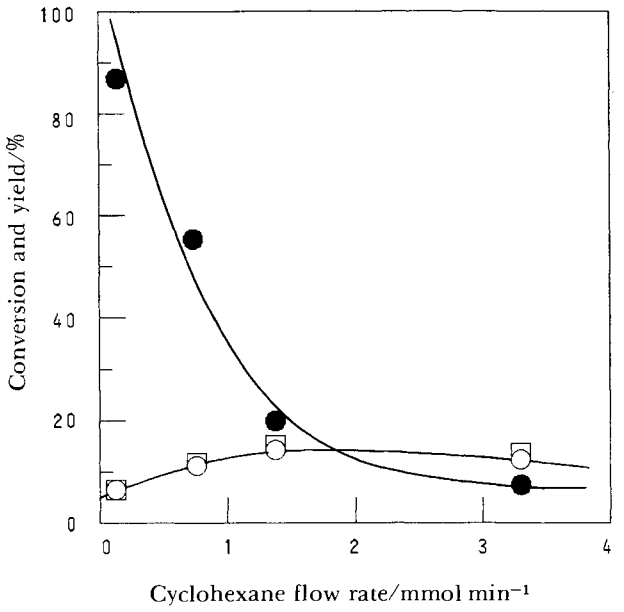

Fig. 2. Oxidation of cyclohexane in an rf plasma. Oxygen flow rate: 5 mmol min^{-1}; rf power: 20 W; ●: cyclohexane conversion; ○: cyclohexanone yield; □: cyclohexanol yield.

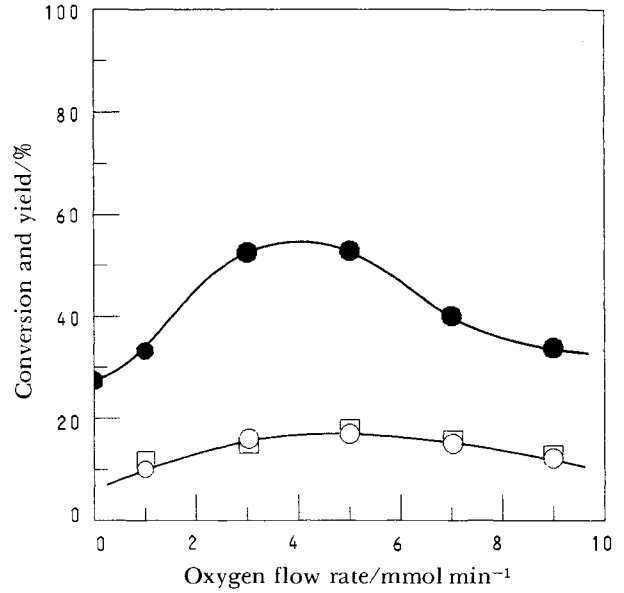

Fig. 3. Oxidation of cyclohexane in an rf plasma. Cyclohexane flow rate: 0.7—1.1 mmol min^{-1}; rf power: 20 W; ●: cyclohexane conversion; ○: cyclohexanone yield; □: cyclohexanol yield.

density and average energy of free electrons which should be most responsible for initiating chemical changes in nonequilibrium plasmas can be primarily controlled by these variables.[6] Thus, one might conclude that the rate-determining step still involves the collision of energetic electron onto molecules even in the presence of oxygen.

An interesting fact is revealed in Fig. 3; cyclohexane underwent the fragmentation or condensation principally in the plasma without oxygen and the conversion was around twenty percents under the conditions therein stated. As oxygen was added, the conversion gradually swelled and culminated around 4 mmol min^{-1} of oxygen flow rate. With a further addition of oxygen, it descended eventually close to the prime value. In contrast, as seen in Figs. 1, 2, and 3, the product yields were not substantially influenced by either of these variables. This can be understood by noting that the yield is based on the product against the starting material reacted. The final products such as **1** or **2** would be yielded through a complex of elementary chemical reactions following the initiation step caused by electron collision, and the relative importance of chemical processes is not supposed to be greatly affected by plasma parameters.

The formation of cyclohexanol and cyclohexanone in almost equimolar amounts strongly suggests that the oxidation involves the autoxidation of cyclohexyl radical as a key step. The cyclohexyl radical might be generated from cyclohexane through either C–H bond cleavage induced by electron bombardment or H abstraction by atomic oxygen. Although it is taken for granted that the latter process is most crucial in the oxidation of organic solids using oxygen plasmas, the former one seems rather superior in the system where organic substrates exist in the gas phase. Nevertheless, Fig. 3 demonstrates that the role of oxygen atom might not be neglected under the appropriate conditions, where the H abstraction should compete with the addition to O_2 giving ozone which is poorly reactive to saturated hydrocarbons. Consequently, the conversion of cyclohexane rose initially with increase in O_2 flow rate and then began to reverse in the presence of large excess O_2.

From the above discussion, the following reaction scheme could be proposed for the oxidation of cyclohexane in an rf plasma;

$$O_2 \xrightarrow{rf} 2O\cdot$$

$$C_6H_{12} \xrightarrow{rf} C_6H_{11}\cdot + H\cdot$$

$$C_6H_{12} + O\cdot \longrightarrow C_6H_{11}\cdot + \cdot OH$$

$$O\cdot + O_2 \longrightarrow O_3$$

$$C_6H_{11}\cdot + O_2 \longrightarrow \longrightarrow \mathbf{1} + \mathbf{2}$$

It seems undoubted that the analogous reaction steps proceed also in the oxidation of other cycloalkanes, since the effects of reaction variables on the products and oxidation rate were essentially identical to those in the cyclohexane oxidation.

Experimental

All of organic substrates and oxygen were of reagent grade from commercial sources and used without further purification.

The assembly and equipment of reaction apparatus are quite similar to those stated in the literature.[7] A starting material and oxygen flowed simultaneously through a plasma zone in a 40 cm×4.5 cm i.d. Pyrex reactor tube at

pressure below a few hundreds Pa. The flow rate of oxygen was controlled with a gas needle valve and monitored with a float-type flowmeter; the flow rate of substrate was controlled with a Teflon needle valve and determined from the quantity of material lost from a reactant reservoir and the elapsed time. Energy was supplied by an inductively coupled 13.56 MHz generator and in every run the impedance matching was conducted so that the reflected power was negligible. The products and recovered starting material were collected in cold traps on liquid nitrogen. The controlled variables were the applied power (10—30 W), the oxygen flow rate (1—8 mmol min^{-1}), and the flow rate of starting material (0.1—3 mmol min^{-1}).

Analysis of organic liquid products was carried out by means of GC(PEG 20 M). Identification of the products was achieved by coinjection of authentic samples with product mixtures and confirmed by GC-MS. For the quantitative analysis, toluene was used as an internal standard. Gaseous products and polymeric deposits on the reactor wall were not analyzed. The product yields were based on the starting material reacted.

Vinyl Polymers Bearing Pyrrole Ring: I. Syntheses of Pyrroles Having 3-Substituent Bearing Vinyl Group

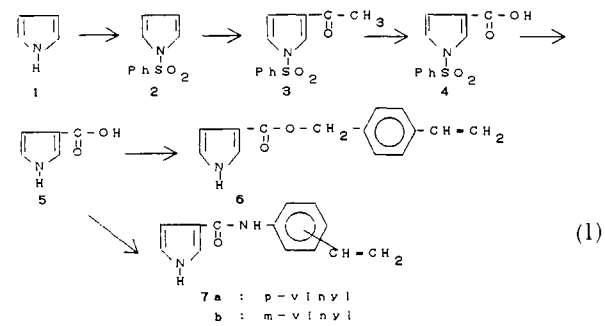
Hiroyoshi KAMOGAWA,* Takuharu NAKATA, Shin OHORI, and Sei KOMATSU
Department of Applied Chemistry, Yamanashi University, Takeda 4, Kofu 400
(Received November 14, 1990)

Synopsis. Pyrroles having 3-substituent bearing the vinyl group with an ester or amide spacer were synthesized starting with 1-(phenylsulfonyl)pyrrole. Homopolymerization of the vinyl monomers thus synthesized provided cross-linked insoluble polymers, but their copolymers with 1-vinyl-2-pyrrolidone were soluble in common solvents.

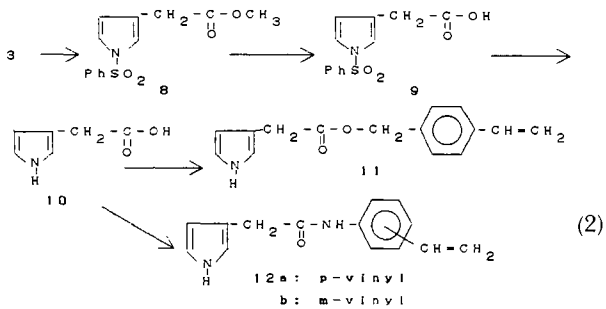
3-Substituted pyrroles have been little synthesized, since, in pyrrole, 2-position is the most reactive for electrophilic attacks such as preparation of 5,10,15,20,-tetraphenylporphyrins and polymerization.[1)]

In the present note, we wish to report the first synthesis of pyrroles having 3-substituent bearing a vinyl group. Accordingly, 3-substituted pyrroles reactive in both vinyl group and the 2-position of the pyrrole ring were obtained and their free-radical polymerization characteristics were investigated.

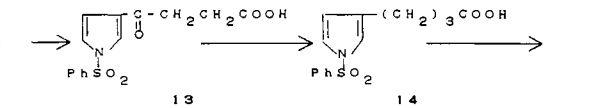
Pyrroles bearing a styrenic double bond **6** and **7a,b**, **11** and **12a,b**, and **16** and **17a,b**, were synthesized taking advantage of a high electrophilic reactivity at the 3 position of the pyrrole ring of **2** according to Eqs. 1, 2, and 3, respectively.

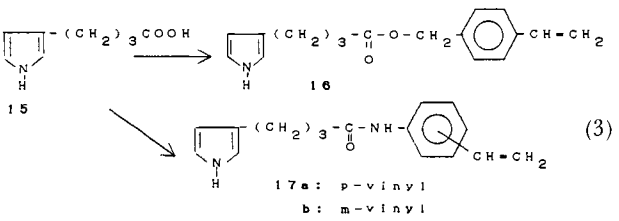


(1)



(2)





(3)

Results and Discussion

Vinyl monomer **6** was prepared by the reaction of **5**, synthesized following the route shown in Eq. 1, with *p*-vinylbenzyl chloride in DMF in the presence of triethylamine (TEA) as HCl-acceptor. Amide monomers **7a** and **7b** were prepared also by treatment of **5** with methyl chloroformate in the presence of TEA to afford a mixed anhydride, followed by addition of *p*- and *m*-vinylanilines.

Vinyl monomers **11** and **12a,b** were synthesized following the route shown in Eq. 2 in the same manners as those for **6** and **7a,b**. The last synthesis of monomers bearing a trimethylene group (**16** and **17a,b**) consisted of the application of the same ester and amide formation procedures as those for **6** and **7a,b** to **15**, synthesized following the route shown in Eq. 3. Ester and amide monomers thus prepared were subjected to free radical polymerization under conventional conditions. The results thus obtained are summarized in Table 1.

It is known from this Table 1 that homopolymerization only afforded cross-linked insoluble polymers for all monomers (Exp. Nos. 1—9), indicating that the reactive 2-position of the pyrrole ring of the monomer and/or the resulting polymer reacted each other during polymerization. Thus, copolymerizations with a large excess of 1-vinyl-2-pyrrolidone (VP) (Exp. Nos. 10—15) were carried out to provide soluble polymers, although their molecular weights, as judged from the values of intrinsic viscosity [η], and conversions were low, as was often the case with copolymerization of VP.[2)]

Conversions for *m*-vinyl polymers (Exp. Nos. 11, 13, and 15) were higher than those for *p*-vinyl ones (10, 13, and 15). In IR spectra, absorptions at 990 and 910 cm^{-1}, attributable to the vinyl group, no longer exist and a large absorption around 1650 cm^{-1}, due to the VP portion in polymer, is discernible, thereby indicating that polymerization took place.

In conclusion, it can be said generally that, by copolymerization of the monomers synthesized as above, vinyl polymers bearing the pyrrole ring as pendant of polymer molecular chain are obtained

leaving the reactive 2-position intact for further electophilic reactions.

Experimental

p- and *m*-Vinylanilines were synthesized according to the methods of Kamogawa[3] and Manecke,[4] respectively. 1-(Phenylsulfonyl)pyrrole (**2**), 3-acetyl-1-(phenylsulfonyl)pyrrole (**3**), methyl 1-(phenylsulfonyl)-3-pyrrolylacetate (**8**), 3-pyrrolylacetic acid (**10**), and 4-[1-(phenylsulfonyl)-3-pyrroly]butyric acid (**14**), were also synthesized following known methods.[5,6]

1-Phenylsulfonyl-3-pyrrolecarboxylic Acid (4). The haloform reaction was applied to **3**. Thus, to an alkaline solution of bromine (4.7 g) in H_2O–dioxane (1:1, 40 ml) cooled with ice was added a solution of **3** (3.0 g, 12 mmol) in dioxane (5 ml), followed by stirring for 5 h. The reaction mixture was diluted with cold water and extracted with ether. The aqueous layer was acidified with 6M H_2SO_4 and extracted with ether(1 M=1 mol dm^{-3}), followed by working-up to afford crystalline powder of mp 146—148 °C in 68% yield. IR (KBr) 3420 cm^{-1}. NMR ($CDCl_3$-DMSO-d_6) δ=9.0 (B, 1H).

***p*-Vinylbenzyl 3-Pyrrolecarboxylate (6).** *p*-Vinylbenzyl chloride (3.1 g, 20 mmol) was added to a solution of **5** (1.1 g, 10 mmol), prepared by alkaline hydrolysis of **4**, and triethylamine (TEA; 1.5 g, 15 mmol) in DMF (10 ml) and the mixture was stirred at 20 °C for 24 h with exclusion of moisture. The reaction mixture was poured into water and extracted with ether (150 ml). The organic layer was washed first with 5% aq Na_2CO_3, then with water, and worked up. Silica-gel (WAKOGEL C-300) column chromatography gave fluid in 45% yield. IR ($CHCl_3$) 3450, 1710, 990, 900 cm^{-1}. NMR ($CDCl_3$) δ=5.3 (s, 2H), 5.6 (q, 2H), 6.9 (q, 1H), 6.3—8.0 (m, 8H).

***N*-(*p*-Vinylphenyl)-3-pyrrolecarboxamide (7a).** Methyl chloroformate (0.9 g, 10 mmol) was gently added to a solution of **5** (1.1 g, 10 mmol) and TEA (1.4 ml, 10 mmol) in anhyd. THF (20 ml) at −15—−5 °C with vigorous shaking. Upon stirring for 10 min, a solution of *p*-vinylaniline (1.2 g, 10 mmol) and TEA (1.4 ml, 10 mmol) in $CHCl_3$ (20 ml) was further added below 0 °C with shaking, followed by stirring at this temperature for one hour and subsequent stirring at 20 °C for 24 h. The reaction mixture was poured into water and extracted with $CHCl_3$. The organic layer was worked up and recrystallization from benzene–hexane provided crystalline powder of mp 64—66 °C in 33% yield. Found: C, 73.26; H, 5.60; N, 13.11%. Calcd for $C_{13}H_{12}N_2O$: C, 73.58; H, 5.66; N, 13.21%. IR (KBr) 3440, 1680, 990, 900 cm^{-1}. NMR (DMSO-d_6–$CDCl_3$) δ=5.4 (q, 2H), 6.7 (q, 1H), 6.5—8.0 (m, 8H), 9.5 (s, 1H). MS *m/z* 212 (M^+).

***N*-(*m*-Vinylphenyl)-3-pyrrolecarboxamide (7b).** The same procedure as that for **7a** provided viscous mass in 19% yield. Found: C, 73.66; H, 5.50; N, 13.09%. MS *m/z* 212 (M^+).

***p*-Vinylbenzyl 3-Pyrrolylacetate (11).** The same procedure as that for **6** was applied to afford fluid in 53% yield. IR ($CHCl_3$) 3480, 1730, 990, 900 cm^{-1}. NMR ($CDCl_3$) δ=3.5 (s, 2H), 5.1 (s, 2H), 5.5 (q, 2H), 6.6 (q, 1H), 6.6—9.0 (m, 8H).

***N*-(*p*-Vinylphenyl)-3-pyrrolylacetamide (12a).** The same procedure as that for **7a** provided crystalline powder of mp 86—87 °C in 66% yield. Found: C, 74.32; H, 6.20; N, 12.17%. Calcd for $C_{14}H_{14}N_2O$: C, 74.34; H, 6.19; N, 12.39%. IR (KBr) 1650, 990, 900 cm^{-1}. NMR ($CDCl_3$—SO-d_6) δ=3.5 (s, 2H), 5.4 (q, 2H), 6.5 (d, 3H), 6.7 (q, 1H), 7.0—7.8 (m), 9.6 (s, 1H), 10.4 (b, 1H). MS *m/z* 226 (M^+).

***N*-(*m*-Vinylphenyl)-3-pyrrolylacetamide (12b).** The same procedure as that for **7b** afforded viscous mass in 21% yield. Found: C, 74.62; H, 6.29; N, 12.01%. MS *m/z* 226 (M^+).

4-(3-Pyrrolyl)butyric Acid (15). Prepared in the same manner as that for **10**. Care was taken so as to keep the pH value of the solution at 2—3 in the isolation of the free acid **15**. Crystalline powder of mp 89—91 °C in 31% yield. Found: C, 62.37; H, 7.52; N, 9.52%. Calcd for $C_8H_{11}NO_2$: C, 62.75; H, 7.19; N, 9.15%. IR (KBr) 3400, 1700 cm^{-1}. NMR (DMSO-d_6–$CDCl_3$) δ=1.0—2.8 (m, 6H), 5.5—6.8 (d, 3H), 9.0—10.6 (b, 2H).MS *m/z* 153(M^+).

***p*-Vinylbenzyl 4-(3-Pyrrolyl)butyrate (16).** The same procedure as that for **6** provided viscous mass in 34% yield. IR ($CHCl_3$) 3480, 1730, 990, 900 cm^{-1}. NMR ($CDCl_3$) δ=1.0—2.8 (m, 6H), 5.1 (s, 2H), 5.5 (q, 2H), 6.7 (q, 1H), 5.8—8.0 (m, 8H).

***N*-(*p*-Vinylphenyl)-4-(3-pyrrolyl)butyramide (17a).** The same procedure as that for **7a** afforded crystalline powder of mp 71—72 °C in 59% yield. Found: C, 75.40; H, 7.02; N,

11.05%. Calcd for $C_{16}H_{18}N_2O$: C, 75.59; H, 7.09; N, 11.02%. IR (KBr) 1650, 990, 900 cm^{-1}. NMR (DMSO-d_6–$CDCl_3$) δ=1.4—3.6 (m, 6H), 5.4 (q, 2H), 6.7 (q, 1H), 5.8—7.7 (m, 7H), 9.8—10.7 c(b, 2H). MS m/z 254 (M^+).

***N*-(*m*-Vinylphenyl)-4-(3-pyrrolyl)butyramide (17b).** The same procedure as that for **7b** provided viscous mass in 16% yield. Found: C, 75.62; H, 7.28; N, 11.11%. MS m/z 254 (M^+). IR and NMR for **7b**, **12b**, and **17b** were essentially the same as those for **7a**, **12a**, and **17a**, respectively.

Polymerization of Pyrrole Monomers. In a typical example, a pyrrole monomer, with or without addition of comonomer, 1-vinyl-2-pyrrolidone (VP), and α,α'-azobisisobutyronitrile (AIBN; 3%/monomer) were dissolved in *N*,*N*-dimethylformamide (DMF; 3 ml) so as to afford 20 wt% monomer concentration. The solution was put into a glass ampule, which was then sealed under N_2 in a conventional manner. The sealed tube was kept at 50 °C for 72 h and the content was poured into ether to precipitate the polymerization product. IR (KBr) 1650 cm^{-1}.

The Photosensitized Oxygenation of Furanoeremophilanes. III.[1,2] The Transformations to the Skeletally Isomeric Lactones from Furanofukinol[3]

Keizo NAYA,* Mitsuaki SHIMIZU, Hideki NISHIO, Motonori TAKEDA, Shogo OKA, and Keiji HIROTA
Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Uegahara, Nishinomiya, Hyogo 662
(Received May 14, 1990)

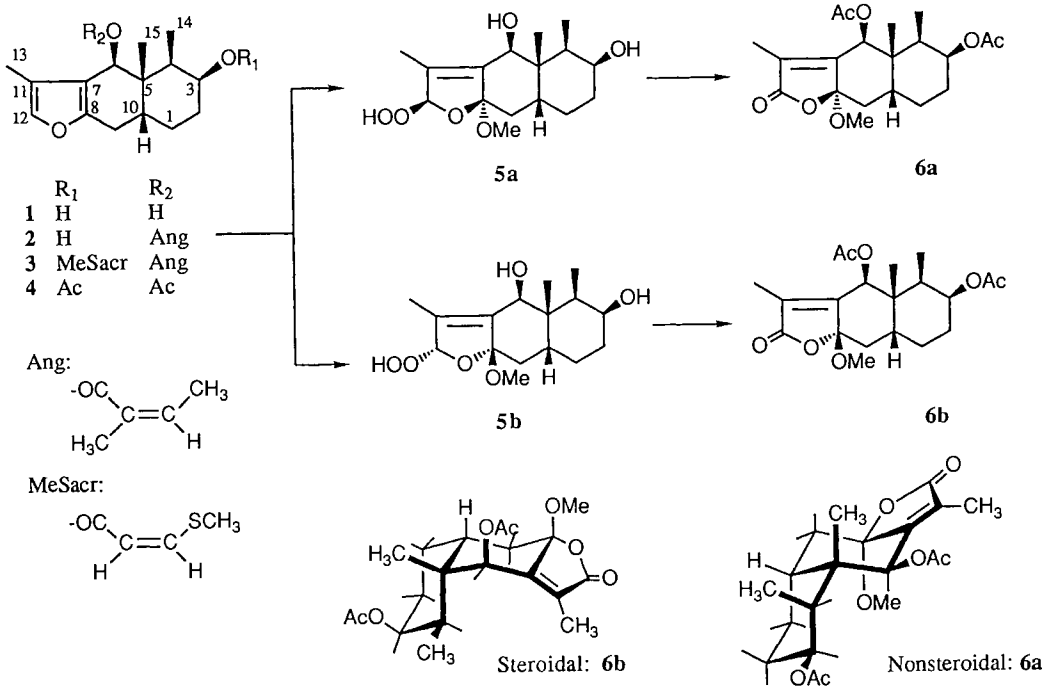
Pairs of the skeletal isomers of eremophilane-type lactones were synthesized from furanofukinol via photosensitized oxygenation, followed by lactone cleavage and reformation. Their stereochemistry has been clarified so as to be consistent with a classification method outlined in our earlier papers.[1,2]

Most of the naturally occurring eremophilane-type lactones possessing *cis*-decalin rings have 8β-substituents,[4,5] except for quite a few recent examples;[6] consequently, the synthesis of 8α-substituted lactone would not, hitherto, be attempted.[7] In previous papers[1,2] we reported on the photosensitized oxygenation of furanoeremophilanes in MeOH, followed by dehydration with Ac_2O-pyridine to yield, quantitatively, an epimeric mixture of 8α- and 8β-methoxylactones, in a ratio of ca. 1 : 1.[8] We have also proposed a procedure to distinguish the stereochemistry of the epimers, that is, 8α-nonsteroidal or 8β-steroidal A/B *cis* chair/chair configurations, according to the substitution mode at C-8.

The present paper deals with syntheses of novel nonsteroidal 8α-substituted eremophilenolides, termed epieremophilenolides, by the photosensitized oxygenation of furanofukinol (**1**) followed by dehydration, as well as by hydrolytic cleavage of lactones, recyclization and further chemical modifications. Recyclization to a nonsteroidal-type 8α-substituted lactone was achieved for the first time by a steric effect due to the 3β-hydroxyl group in furanofukinol (**1**).

Thus, the most simple lactone pair **13a,b** and the four 3-hydroxy skeletal diastereomers, **9a,b** and **16a,b,** were synthesized by recyclization; a further detailed comparison of the spectral data (cf. Tables 1 and 2) between the corresponding pairs was made in order to ascertain the classification procedure[1,2] proposed previously.

Furanofukinol (**1**) was isolated as a minor component from *Petasites japonicus* Maxim. rhizomes,[9] and the major components were its esters, 6-*O*-angeloylfuranofukinol: 6-*O*-[(*Z*)-2-methyl-2-butenoyl] furanofukinol (**2**) and *S*-furanopetasitin: 6-*O*-[(*Z*)-2-methyl-2-butenoyl]-3-*O*-[(*Z*)-3-methylthioacryloyl]furanofukinol (**3**). Hence, the starting material **1** was prepared by the alkaline hydrolysis of **2** and **3**. The stereochemis-



Scheme 1.

try of **1**, possessing a nonsteroidal conformation, has been unambiguously established by a combination of spectroscopic and chemical methods.[10]

A mixture of **1** and methylene blue in MeOH was irradiated with a circular fluorescent lamp (30 W×2) under bubbling air through the solution, affording quantitatively a crystalline product. The product showed two spots on TLC (R_f 0.09 and 0.29, benzene–AcOEt 2 : 1); the mixture was separated on the basis of solubilities in benzene, followed by careful recrystallization which afforded two isomeric hydroperoxides, a less soluble, polar isomer **5a**, mp 165.0—165.5 °C (decomp) and a soluble, less polar isomer **5b**, mp 94.0—96.0 °C (decomp), in a ratio of 2 : 1. Both were positive to peroxide tests, KI–AcOH and $Fe(SCN)_2$.

A mixture of **5a,b** was subsequently treated with Ac_2O–pyridine to give quantitatively an epimeric mixture, which was separated to afford the less polar (R_f 0.60, light petroleum–ether 1 : 1) 3β,6β-diacetoxy-8α-methoxyepieremophilenolide (**6a**), mp 132.5—133.0 °C and the polar (R_f 0.51) 3β,6β-diacetoxy-8β-methoxyeremophilenolide (**6b**), mp 139.0—140 °C, in a ratio of 3 : 1. Meanwhile, **5a** alone was exclusively converted to **6a** in the similar manner as described above (cf. Scheme 1).

The assigned stereoformulas of pairs of **5a,b** and **6a,b** were readily drawn from the coupling pattern of 3α-H in ^1H NMR and, furthermore, from the physical properties along with the generalization reported before.[1,2] Only the nonsteroidal **5a** and **6a** showed homoallylic couplings[2,11] between 13-Me and 6α-H (the mutual dihedral angle=ca. 90°), indicating 8α-configuration (cf. Scheme 1 and Exptl.).

An alkaline hydrolysis of a mixture of **6a,b** gave an 8-oxodienoic acid **7**, mp 163.5—164.0 °C, as a sole product in 85% yield. The Na salt of **7** in MeOH was refluxed with MeI to furnish an ester **8**, mp 114.5—115.5 °C, in 83% yield. Reduction of the ester **8** with $NaBH_4$ in MeOH gave an oily mixture, which was separated by chromatography upon silica gel, followed by recrystallization, to give 3β(*equatorial*)-hydroxyepieremophilenolide (**9a**), mp 167.0—168.0 °C, and 3β(*axial*)-hydroxyeremophilenolide (**9b**), mp 169.5—170.5 °C, in a ratio of 1 : 1; the more bulky 3-*O*-tetrahydropyranyl ether **10** prepared from **8** was subjected to a similar reduction with $NaBH_4$ as mentioned above, giving **9a** and **9b** in a ratio of 5 : 2 (cf. Scheme 2).

Jones' and PDC oxidations of **9a** and **9b** furnished the 3-oxo derivatives, **11a** mp 131.5—132.5 °C and **11b** mp 155.5—156.5 °C in good yields, respectively. However, product **11a** prepared by a Jones oxidation exhibited signals due to 14-Me (δ=1.06 and 1.20, each d, J=6.5 Hz) and 15-Me (δ=0.91 and 1.03, each s). This might be caused by epimerization of 14-Me in an acidic medium.

The dithioacetalization of **11a** and **11b**, and the subsequent desulfurization of dithioacetals **12a** and **12b** with Raney nickel furnished epieremophilenolide (**13a**), mp 86.0—86.5 °C, and eremophilenolide (**13b**), mp 123.5—124.5 °C, respectively.

In additional routes to **13a** and **13b**, the tosylation of **9a** and a subsequent treatment with NaI in acetone resulted in an elimination of the tosyl group, while affording a 3,4-dehydro compound **15a**. The mesylation of **9a** or **9b** also caused dehydration, directly

Scheme 3. (i) 2 M KOH-MeOH, CH_2N_2-ether; (ii) $NaBH_4$; (iii) NaOMe-MeOH, MeI; (iv) 1.5 M KOH-MeOH, 10% H_2SO_4 (1M=1 mol dm^{-3}).

affording 3,4-dehydro compounds, **15a** or **15b**. The hydrogenation of **15a** and **15b** furnished **13a** and **13b** as predominant products, respectively. This result revealed that the addition of hydrogen to the double bond proceeded preferentially from the concave side of the *cis*-decalin ring.

A further approach to the syntheses of all four possible diastereomers of the 3-hydroxy lactones was attempted in order to explore the stereoselectivity upon reduction of the prochiral 3-oxo groups with $NaBH_4$ in MeOH as follows. Thus, **11a** gave a nonsteroidal 3α(*axial*)-OH isomer **16a**, mp 138.5—139.5 °C (56.3%), and the regenerated 3β(*equatorial*)-OH isomer **9a** (36.9%). Similarly, **11b** gave a new steroidal 3α(*equatorial*)-OH isomer **16b**, mp 158.0—159.0 °C (10%) together with the original 3β(*axial*)-OH isomer **9b** (80%). The above-mentioned results can be predicted by an observation of stereoformulas **11a** and **11b**. The 3-oxo groups in **11a** and **11b** were preferentially attacked with $NaBH_4$ from the convex and concave sides of the *cis*-decalin ring, so as to avoid 1,3-diaxial interactions with the 6-CH_2 and 15-Me groups, respectively (cf. stereoformulas **11a** and **11b** in Scheme 3).

For a comparison of the stereoselectivity upon recyclization to lactones, the natural 6β-hydroxyeremophilenolide (**17b**)[1] was subjected to alkaline hydrolysis followed by esterification with CH_2N_2 in diethyl ether, and then by reduction with $NaBH_4$ in a similar manner as in the transformation from 3β-hydroxydienoic ester **8** to **9a** and **9b**. Thus, only eremophilenolide **13b** was obtained via an enoic ester **18**, bp 116—118 °C/0.3 mmHg (40 Pa), in 86% overall yield. In a previous study,[2] 8β-hydroxyeremophilenolide (**20b**) was quantitatively synthesized from a mixture of 8α- and 8β-methoxy lactones **19a,b** by alkaline lactone cleavage, followed by acidic recyclization.

In addition, dienoic acid **21**[1,2] prepared previously from petasalbin (6β-hydroxyfuranoeremophilane) and furanofukinin (6β-methoxyfuranoeremophilane) was transformed into the methyl ester **22**, followed by a treatment with $NaBH_4$ in MeOH in a similar manner as that for ester **8** to furnish only steroidal **13b** (92%).

Therefore, the above-mentioned successful methods for the first preparation of epieremophilenolides by recyclization could be achieved by a steric effect based on the greater stability of the 3β(*equatorial*)-hydroxy group in a nonsteroidal conformation, more than the 3β(*axial*)-hydroxy group in a steroidal conformation, where 3β-substituent has a 1,3-diaxial interaction with 15β-methyl.

Now, the stereochemistry of the above-mentioned products can be clearly assigned by means of a general procedure.[1,2] In Table 1,[12] the 8α-substituted lactones (suffix a-series) showed chemical shifts due to 14-methyls at a lower field than those due to 15-methyls; this relation of the chemical shifts between 14- and 15-methyls is reversed in the 8β-series (suffix b-series). These variations in the chemical shifts could be accounted for in terms of an alteration in the geometric orientations of the 14- and 15-methyls, accompanied by a skeletal change between the steroidal and nonsteroidal conformations.[13] Also, the coupling patterns[14] of the protons at C-3 in the 3-hydroxy lactones, consisting of rigid[15] chair forms, practically serve to define the absolute configuration of 3-hydroxy substituents as well as a determination of the nonsteroidal and steroidal conformations of the

chair-chair *cis*-decalins in 8α- and 8β-isomers, respectively.

The paired lactones exhibited CD spectra with opposite signs (Table 1), which can be rationalyzed by the opposite helicities in the α,β-unsaturated carbonyl moieties caused by lactone ring fusion. Thus, the 8β-isomers possessing a right-handed helix showed positive Cotton effects centered near 240—260 nm corresponding to the π-π^* transition,[16] while the 8α-isomers with a left-handed helix showed negative Cotton effects in the same region, except for the compound **9a** (cf. Table 1).

In the ^{13}C-chemical shifts (Table 2), the comparative chemical shifts between the paired isomers proved, on the whole, to be qualitatively in accord with the empirical calculation presented by Beierbeck et al.,[17] except for the chemical shifts of 9-C and the olefinic carbons, 7-C and 11-C. The chemical shifts of 7-C could not also be rationalized by the diamagnetic γ-effect[18] of the 15(*axial*)-Me group in the 8α-H

isomers. The chemical shifts of the olefinic carbons, 7-C and 11-C, at a higher field in the 8β-H isomers are clearly reflected by shielding of the carbon atoms in the steroidal *cis*-type (*cis-syn-cis*) ring relative to its nonsteroidal *trans*-type (*cis-anti-cis*) ring in 8α-H isomers[19] (cf. stereoformulas **6a,b** and **11a,b**).

Experimental

All of the melting points are uncorrected. The IR, UV, CD, and MS spectra were taken with Hitachi EPI-G3, Cary 118, JASCO Model ORD/CD-5, and JEOL JMS-D300 spectrophotometers, respectively. The ^{1}H and ^{13}C NMR spectra were recorded with a JEOL FX-90Q (90 and 22.5 MHz) spectrometer, and the chemical shifts are reported in δ values (with TMS as the internal reference). The optical rotations were measured with a Perkin-Elmer 141 polarimeter. The TLC were run on a Kieselgel G (Merck).

Isolation of Furanofukinol (1), 6-*O*-Angeloylfuranofukinol (2), and *S*-Furanopetasitin (3). The dried rhizomes of *Petasites japonicus* Maxim. ("Aichiwasebuki" cultivated in Osaka Prefecture) (36 kg) were extracted with benzene (85 l) at room temperature for 12 days. The extract was concentrated in vacuo in order to remove the solvent. The residue was dissolved in ether, washed with saturated $NaHCO_3$ aqueous solution, then with water, dried over anhydrous Na_2SO_4 and evaporated in vacuo, leaving a dark oil (473 g). This oil (100 g) was chromatographed on deactivated alumina (1 kg, grade III). Elution with benzene, and then benzene-ethyl acetate (2:1), afforded a mixture of *S*-furanopetasitin (**3**) and 6-*O*-angeloylfuranofukinol (**2**) (45 g), as well as furanofukinol (**1**) (120 mg). The mixture of **2** and **3** was repeatedly chromatographed on alumina (grade III), and elution with light petroleum-ether (20:1) gave both **3** (11 g, 11% yield based on the crude extract) and **2** (16 g, 16% yield).

Furanofukinol (1): Mp 178.0—180 °C (decomp), colorless needles (from MeOH); $[\alpha]_D^{25}$ −18° (*c* 0.97, dioxane); UV (EtOH) 219 nm (ε 6720); IR (KBr) 3367, 3323 (OH), 1648, 1569 cm^{-1} (furan); ^{1}H NMR ($CDCl_3$) δ=7.06 (q, *J*=1.3 Hz, 12-H), 4.90 (br s, 6α-H), 4.21 (ddd, *J*=5, 5, 10 Hz, 3α-H), 2.07 (d, *J*=1.3 Hz, 13-Me), 0.97 (d, *J*=7.3 Hz, 14-Me), 0.95 (s, 15-Me); ^{13}C NMR (pyridine-d_5) δ=27.0 (t, 1-C), 28.2 (t, 2-C), 68.1 (d, 3-C), 39.3 (d, 4-C), 43.0 (s, 5-C), 66.8 (d, 6-C), 121.4 (s, 7-C), 149.5 (s, 8-C), 30.4 (t, 9-C), 37.0 (d, 10-C), 119.5 (s, 11-C), 138.4 (d, 12-C), 7.7 (q, 13-C), 9.1 (q, 14-C), 20.1 (q, 15-C).

Found: C, 71.82; H, 8.75%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

6-*O*-Angeloylfuranofukinol: 6-*O*-[(*Z*)-2-Methyl-2-butenoyl]furanofukinol (2): A colorless oil (purified by HPLC, μ-Bondapak C_{18}, MeOH-H_2O 8:1); $[\alpha]_D^{25}$ −41.4° (*c* 0.91, $CHCl_3$); UV (EtOH) 215 nm (ε 17150); IR (film) 3440 (OH), 1700, 1640, 1230 cm^{-1} (α,β-unsaturated ester); ^{1}H NMR ($CDCl_3$) δ=7.07 (q, *J*=1.2 Hz, 12-H), 6.50 (s, 6α-H), 6.14 (slightly splitted q, *J*=7.0 Hz, 3-H in butenoyl), 4.40 (ddd, *J*=5.5, 5.5, 10.5 Hz, 3α-H), 2.02 (br d, *J*=7.5 Hz, 4-Me in butenoyl), 1.98 (br s, 2-Me in butenoyl), 1.83 (d, *J*=1.2 Hz, 13-Me), 1.03 (s, 15-Me), 0.95 (d, *J*=6.0 Hz, 14-Me); ^{13}C NMR ($CDCl_3$) δ=27.5 (t, 1-C), 26.9 (t, 2-C), 68.9 (d, 3-C), 39.2 (d, 4-C), 42.0 (s, 5-C), 68.5 (d, 6-C), 115.2 (s, 7-C), 150.4 (s, 8-C), 28.9 (t, 9-C), 36.9 (d, 10-C), 119.6 (s, 11-C), 138.8 (d, 12-C), 7.0 (q, 13-C), 8.5 (q, 14-C), 20.4 (q, 15-C), butenoyl: 168.1 (s, CO), 127.8 (s, 2-C), 138.4 (d, 3-C), 16.0 (q, 2-Me), 20.7 (q, 4-Me).

Preparation of Furanofukinol (1). a) Alkaline Hydrolysis of the Mixture of 2 and 3. Aqueous 20% NaOH (134 ml) was added, drop by drop, to a stirred mixture of **2** and **3** (37 g) in DMSO (240 ml). The mixture was then warmed at 60—65 °C for 9 h under N_2. After dilution with ice-water and acidification with 6 M H_2SO_4 aqueous solution (1 M=1 mol dm^{-3}), the reaction mixture was adjusted to pH 7—8 with a saturated $NaHCO_3$ aqueous solution and kept under cooling to deposit a brownish solid. After working up using the usual method, the crude furanofukinol (**1**) (23 g) was crystallized from MeOH as colorless prisms (11 g), mp 178—180 °C (decomp).

b) To a stirred solution of 1M *t*-BuOK (1 M=1 mol dm^{-3}) in anhydrous DMSO (100 ml) was added a solution of **2** (15 g) in anhydrous DMSO (150 ml) at room temperature over a 0.5 h period under N_2. After stirring for further 12 h, the reaction mixture was diluted with ice-water (300 g) and acidified with 1 M H_2SO_4 to deposit a solid, which was worked up in the usual manner. The crude product **1** was recrystallized from MeOH as colorless prisms (8.7 g); mp 178.0—180.0 °C (decomp). Both of the above-mentioned products were identical in all respects with the natural furanofukinol **1**.

Furanofukinol Diacetate (4). Furanofukinol **1** (100 mg) was treated with pyridine (1 ml) and acetic anhydride (1 ml) at room temperature for 48 h. The usual workup yielded the diacetate **4** (130 mg); mp 144.0—145.0 °C, colorless prisms (MeOH); $[\alpha]_D^{22}$ −53.7° (*c* 0.95, $CHCl_3$); UV (EtOH) 217.5 nm (ε 7720); IR (KBr) 1720, 1253, 1230 (acetate), 1640, 1565 cm^{-1} (furan); ^{1}H NMR ($CDCl_3$) δ=6.98 (q, *J*=1.1 Hz, 12-H), 6.28 (s, 6α-H), 5.28 (ddd, *J*=5.5, 5.5, 10 Hz, 3α-H), 2.11 (s, OAc), 2.00 (s, OAc), 1.82 (d, *J*=1.1 Hz, 13-Me), 0.98 (s, 15-Me), 0.93 (d, *J*=6.0 Hz, 14-Me); ^{13}C NMR ($CDCl_3$) δ=25.6 (t, 1-C), 26.0 (t, 2-C), 72.1 (d, 3-C), 36.0 (d, 4-C), 41.7 (s, 5-C), 68.9 (d, 6-C), 115.8 (s, 7-C), 150.1 (s, 8-C), 26.5 (t, 9-C), 36.4 (d, 10-C), 119.5 (s, 11-C), 138.9 (d, 12-C), 8.5 (q, 13-C), 8.5 (q, 14-C), 19.6 (q, 15-C), 170.3 and 169.1 (each s, Me<u>C</u>OO), 21.2 and 20.8 (each q, <u>C</u>H$_3$COO).

Photosensitized Oxygenation of Furanofukinol (1). A stirred solution of **1** (487 mg) and Methylene Blue (2 mg) in anhydrous MeOH (80 ml) was irradiated with two circular fluorescent lamps (30 W×2) for 55 min under air bubbling. After evaporation of the solvent in vacuo, the crystalline residue (603 mg, quantitative yield) showed two spots on TLC (R_f 0.29 and 0.09, benzene-ethyl acetate 2 : 1), and was positive to peroxide tests: KI-AcOH and $Fe(SCN)_2$ reagents. The above-mentioned crystalline mixture was separated into less and readily soluble hydroperoxides, (**5a**, R_f 0.09) (337 mg, 55%) and (**5b**, R_f 0.29) (157 mg, 27%), according to the solubility in benzene, followed by fractional crystallization.

8α-Methoxy-12β-hydroperoxide (5a): Mp 165.0—165.5 °C (decomp), colorless prisms (MeOH-acetone); $[\alpha]_D^{25}$ −20.0° (*c* 0.92, MeOH); positive to peroxide tests; IR (KBr) 3530, 3410 (OH), 1085, 1030 cm^{-1} (ether); ^1H NMR (acetone-d_6) δ=11.40 (s, OOH); (pyridine-d_5) δ=6.20 (s, 12-H), 5.12 (q, *J*=1.8 Hz, 6α-H), 4.47 (ddd, *J*=5.5, 5.5, 10.5 Hz, 3α-H), 3.29 (s, OMe), 2.33 (d, *J*=1.8 Hz, 13-Me), 1.23 (d, *J*=7.0 Hz, 14-Me), 1.11 (s, 15-Me).

Found: C, 61.12; H, 8.50%. Calcd for $C_{16}H_{26}O_6$: C, 61.13; H, 8.34%.

8β-Methoxy-12α-hydroperoxide (5b): Mp 94.0—96.0 °C (decomp), colorless needles (benzene-pentane); $[\alpha]_D^{22}$ +57° (*c* 0.93, MeOH); positive to peroxide tests; IR (KBr) 3430, 3200sh (OH), 1045 cm^{-1} (ether); ^1H NMR ($CDCl_3$) δ=10.08 (s, OOH), 5.80 (s, 12-H), 4.27 (br m, 6-H and H_2O), 3.79 (ddd, *J*=3, 3, 3 Hz, 3α-H), 3.30 (s, OMe), 1.81 (s, 13-Me), 1.31 (s, 15-Me), 0.95 (d, *J*=6.0 Hz, 14-Me).

Found: C, 60.90; H, 8.35%. Calcd for $C_{16}H_{26}O_6$: C, 61.13; H, 8.34%.

Acetylation of Hydroperoxides, 5a,b. a) A mixture of hydroperoxides, **5a,b** (3.4 g) prepared from **1** (2.7 g), was dissolved in pyridine (35 ml) and acetic anhydride (45 ml). The mixture was left overnight at room temperature. The usual type workup gave quantitatively a crude oily product (4.0 g), which showed two spots on TLC (R_f 0.51 and 0.60, light petroleum-ether 1 : 1). The crude product (1 g) was chromatographed on silica gel (20 g) with light petroleum-ether (10 : 1) to afford a less polar isomer **6a** (772 mg, 60% yield) and a polar isomer **6b** (245 mg, 20% yield), each of which was crystallized from diisopropyl ether.

b) Hydroperoxide **5a** (50 mg) was treated with pyridine (5 ml) and acetic anhydride (5 ml), as mentioned above, to afford an oily product (74 mg, quantitatively). Recrystallization from diisopropyl ether gave **6a**, mp 132.0—133.0 °C (34 mg), which was identical with the above-mentioned sample **6a**, obtained by acetylation of the hydroperoxides mixture (mixed-melting point determination and a comparison of IR spectra).

3β,6β-Diacetoxy-8α-methoxyepieremophilenolide (6a): Mp 132.5—133.0 °C, colorless prisms; $[\alpha]_D^{23}$ −198° (*c* 1.045, $CHCl_3$); UV (MeOH) 220.6 nm (ε 13900); CD (*c* 3.96×10^{-5}, MeOH, 25°) $[\theta]_{244}$ −17000; IR (CCl_4) 1770, 1695 (α,β-unsaturated γ-lactone), 1750, 1730, 1236 cm^{-1} (OAc); ^1H NMR ($CDCl_3$) δ=5.89 (d, *J*=1.8 Hz, 6-H), 4.85 (ddd, *J*=6, 6, 12 Hz, 3α-H), 3.22 (s, OMe), 2.23 and 2.02 (each s, OAc), 1.87 (d, *J*=1.8 Hz, 13-Me), 0.93 (d, *J*=7 Hz, 14-Me), 0.92 (s, 15-Me); ^{13}C NMR (Table 2).

Found: C, 63.08; H, 7.64%. Calcd for $C_{20}H_{28}O_7$: C, 63.14; H, 7.42%.

3β,6β-Diacetoxy-8β-methoxyeremophilenolide (6b): Mp 139.0—140.0 °C, colorless needles; $[\alpha]_D^{26}$ +180° (*c* 1.0, $CHCl_3$); UV (MeOH) 219.9 nm (ε 11540); CD (*c* 1.43×10^{-4}, hexane, 25°) $[\theta]_{263}$ +3500; IR (CCl_4) 1770, 1695 (α,β-unsaturated γ-lactone), 1735, 1233 cm^{-1} (OAc); ^1H NMR ($CDCl_3$) δ=5.65 (s, 6-H), 4.99 (ddd, *J*=3, 3, 3 Hz, 3α-H), 3.08 (s, OMe), 2.12 and 2.08 (each s, OAc), 2.01 (s, 13-Me), 1.24 (s, 15-Me), 0.92 (d, *J*=7 Hz, 14-Me); ^{13}C NMR (Table 2).

Alkaline Hydrolysis of a Mixture of Lactones, 6a,b. A mixture (9.30 g) of 8α- and 8β-methoxy lactones, **6a,b** was dissolved in a 1.685 M KOH-MeOH solution (190 ml) and then left at room temperature for 16 h. After evaporation of the solvent in vacuo and dilution with water, the solution was acidified with aqueous 10% H_2SO_4, and then extracted with ethyl acetate. The usual workup gave an unsaturated acid (5.50 g, 85%) as the sole product, which was crystallized from ethyl acetate to afford a pure acid **7**, mp 163.5—164.0 °C, colorless prisms; $[\alpha]_D^{20}$ −42.5° (*c* 0.89, MeOH); UV (MeOH) 218 (ε 8250), 243 nm (9140); IR (KBr) 3650—2250, 3360, 1703, 1670 (α,β-unsaturated acid), 1618, 945 cm^{-1} (conjugated diene); ^1H NMR (acetone-d_6) δ=6.98 (m, COOH and OH), 6.69 (d, *J*=1.5 Hz, 6-H), 6.11 (d, *J*=1.5 Hz, 13-H), 5.68 (d, *J*=1.5 Hz, 13-H), 3.76 (ddd, *J*=5.5, 6, 6 Hz, 3α-H), 1.28 (s, 15-Me), 0.98 (d, *J*=7.4 Hz, 14-Me); ^{13}C NMR (pyridine-d_5) δ=26.9 (1-C), 28.5 (2-C), 69.9 (3-C), 44.9 (4-C), 40.4 (5-C), 156.7 (6-C), 141.1 (7-C), 197.0 (8-C), 40.7 (9-C), 36.7 (10-C), 136.6 (11-C) , 168.7 (12-C), 125.6 (13-C), 8.2 (14-C), 25.0 (15-C).

Found: C, 68.00; H, 7.84%. Calcd for $C_{15}H_{20}O_4$: C, 68.16; H, 7.63%.

Esterification of the Unsaturated Acid 7. The above-mentioned dienoic acid **7** (1.235 g) in MeOH (1 ml) was neutralized by a dropwise addition of a 1 M NaOMe-MeOH solution using phenolphthalein as the indicator, followed by the addition of MeI (15 g) over a 5 min period. The solution was refluxed for 9 h, and concentrated in vacuo, diluted with water, and extracted with ethyl acetate. The usual workup gave the crude methyl ester **8** (1.081 g, 83%), which was crystallized from ethyl acetate-diisopropyl ether as colorless needles (670 mg, 51.6%), mp 114.5—115.5 °C; $[\alpha]_D^{25}$ −40° (*c* 1.04, $CHCl_3$); UV (MeOH) 242 nm (ε 8870); IR ($CHCl_3$) 3420 (OH), 1715 (ester), 1670 (ketone), 1610, 942 cm^{-1} (conjugated diene); ^1H NMR ($CDCl_3$) δ=6.64 (d, *J*=1.5 Hz, 6-H), 6.20 (d, *J*=1.5 Hz, 13-H), 5.65 (d, *J*=1.5 Hz, 13-H), 3.72 (s, CO_2Me), ca. 3.7 (m, $W_{1/2}$=15 Hz, 3α-H), 1.29 (s, 15-Me), 1.00 (d, *J*=7 Hz, 14-Me); ^{13}C NMR ($CDCl_3$) δ=26.5 (t, 1-C), 27.9 (t, 2-C), 70.6 (d, 3-C), 44.5 (d, 4-C), 40.3 (s, 5-C), 156.9 (d, 6-C), 138.2 (s, 7-C), 197.3 (s, 8-C), 40.2 (t, 9-C), 36.0 (d, 10-C), 135.7 (s. 11-C), 166.8 (s, 12-C), 127.0 (t, 13-C), 7.5 (q, 14-Me), 25.0 (q, 15-C), 52.1 (q, OMe).

Reduction of Dienoic Ester 8 with Sodium Borohydride. A solution of $NaBH_4$ (700 mg) in MeOH (10 ml) was added over a 5 min period at 60 °C into a solution of dienoic ester **8** (1.0 g) in MeOH (20 ml). After stirring for an additional 1.5 h under the same conditions, the reaction mixture was concentrated in vacuo and diluted with water. Extraction with ethyl acetate gave a colorless oil (1.166 g, quantitatively), which showed two spots on TLC (R_f 0.27 and 0.60, benzene-ethyl acetate 2 : 1), and was chromatographed on silica gel (21 g). Elution with benzene-ethyl acetate (15 : 1)

afforded the less polar **9b** (308 mg, 33.8%) and the polar isomer **9a** (305 mg, 33.5%), each of which was recrystallized from the ethyl acetate-diisopropyl ether.

Reduction of 3-*O*-Tetrahydropyran-2-yl Ether 10 with Sodium Borohydride. a) Preparation of 10: A mixture of *p*-toluenesulfonic acid (20 mg) and dienoic ester **8** (357 mg) in CH_2Cl_2 (2 ml) was stirred for 5 min; 2*H*-3,4-dihydropyran (276 mg) was then added into the stirred solution. After stirring for 18 h the reaction mixture was extracted with CH_2Cl_2, and the extract washed with a saturated aqueous $NaHCO_3$ and water. The usual workup gave a colorless oily product **10** (430 mg, 93%): IR (film) 1670, 1610, 1240, 1010, 950 cm^{-1}.

b) Reduction with $NaBH_4$: Into a stirred solution of the above-mentioned ester **10** (240 mg) in MeOH (5 ml) was added $NaBH_4$ (122 mg) over a 5 min period. After stirring for 2 h, the reaction mixture was adjusted to pH 2; stirring was then continued for additional 2 h. The usual workup gave a crude product (163 mg, quantitative yield), which was chromatographed on silica gel (20 g) with benzene-ethyl acetate (15 : 1) to afford the less polar isomer **9b** (46 mg, 28%) and the polar isomer **9a** (109 mg, 66%).

3β(eq)-Hydroxyepieremophilenolide (9a): Mp 167.0—168.0 °C as colorless needles; $[\alpha]_D^{27}$ −157° (*c* 0.99, $CHCl_3$); UV (MeOH) 217.5 nm (ε 5600); CD (*c* 4.010×10^{-3}, MeOH, 22 °C) $[\theta]_{253}$ +350; IR ($CHCl_3$) 3600, 3450 (OH), 1735, 1680, 1095 cm^{-1} (α,β-unsaturated γ-lactone); ^1H NMR ($CDCl_3$) δ=4.80 (br m, $W_{1/2}$=15.8 Hz, 8α-H), 4.10 (ddd, *J*=5.5, 5.5, 11 Hz, 3α-H), 2.78 (d, *J*=14.5 Hz, 6α-H), 1.79 (t, *J*=1.6 Hz, 13-Me), 0.97 (d, *J*=7 Hz, 14-Me), 0.85 (s, 15-Me); ^{13}C NMR (Table 2).

Found: C, 71.82; H, 9.19%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

3β(ax)-Hydroxyereemophilenolide (9b): Mp 169.5—170.5 °C as colorless needles; $[\alpha]_D^{27}$ +196° (*c* 1.04, $CHCl_3$); UV (MeOH) 217.5 nm (ε 15200); CD (*c* 4.140×10^{-3}, MeOH, 22 °C) $[\theta]_{248}$ +10200; IR ($CHCl_3$) 3600, 3470 (OH), 1740, 1690, 1095 cm^{-1} (α,β-unsaturated γ-lactone); ^1H NMR ($CDCl_3$) δ=4.72 (m, *W*1/2=18 Hz, 8β-H), 3.81 (ddd, *J*=4, 4, 5 Hz, 3α-H), 2.89 (d, *J*=14.6 Hz, 6α-H), 1.80 (t, *J*=1.8 Hz, 13-Me), 1.29 (s, 15-Me), 1.01 (d, *J*=6.8 Hz, 14-Me); ^{13}C NMR (Table 2).

Found: C, 72.01; H, 8.89%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Oxidation of 3β(eq)-Hydroxyepieremophilenolide (9a). a) Jones' Oxidation: Jones' reagent (0.8 ml) was added into a stirred solution of **9a** (150 mg) in acetone (3 ml) over a period of 5 min under ice cooling. After stirring for additional 10 min at room temperature, the excess reagent was decomposed with MeOH and the reaction mixture extracted with ethyl acetate. Working up as usual gave a crude crystalline product (114 mg, quantitatively), mp 130.5—132.5 °C, which showed the presence of a pair of epimers concerning the configuration of 14-methyl in its ^1H NMR spectrum (δ=0.91 and 1.03, each s, 15-Me; 1.06 and 1.20, each d, *J*=6.5 Hz, 14-Me). Recrystallization from ethyl acetate gave a pure specimen of 3-oxoepiermophilenolide (**11a**), mp 131.5—132.5 °C (55 mg, 37%).

b) PDC (Pyridinium Dichromate) Oxidation. PDC (1.0 g) was gradually added into a stirred solution of **9a** (118 mg) in CH_2Cl_2 (20 ml). After stirring for additional 2 h, the reaction mixture was shaken with Celite (5 g) and filtered. Evaporation of the filtrate in vacuo gave **11a** (109 mg, 93%).

3-Oxoepieremophilenolide (11a): Mp 131.5—132.5 °C, colorless needles (ethyl acetate-diisopropyl ether); $[\alpha]_D^{26}$ −157° (*c* 1.08, $CHCl_3$); UV (MeOH) 224 nm (ε 9000); CD (c 3.670×10^{-3}, MeOH, 22 °C) $[\theta]_{241}$ −655, $[\theta]_{288}$ −3410; IR ($CHCl_3$) 1740, 1685 (α,β-unsaturated γ-lactone), 1710 cm^{-1} (ketone); ^1H NMR ($CDCl_3$) δ=4.82 (br m, $W_{1/2}$=14 Hz, 8α-H), 1.79 (d, *J*=1.8 Hz, 13-Me), 1.20 (d, *J*=6.5 Hz, 14-Me), 0.89 (s, 15-Me). ^{13}C NMR (Table 2).

Found: C, 72.44; H, 8.13%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Oxidation of 3β(ax)-Hydroxyeremophilenolide 9b. a) Jones' Oxidation. Jones' reagent (1 ml) was added into a stirred solution of **9b** (100 mg) in acetone (2 ml) over a period of 5 min under ice cooling. After stirring for additional 30 min, the reaction mixture was worked up in a similar manner to that mentioned above, giving a crude crystalline product (101 mg, quantitatively), which was recrystallized from ethyl acetate-diisopropyl ether to afford 3-oxoeremophilenolide (**11b**) (126 mg, 95.5%).

b) PDC Oxidation. PDC (1.8 g) was gradually added into a solution of **9b** (153 mg) in CH_2Cl_2 (20 ml) at room temperature. After stirring for additional 2.5 h, the mixture was worked up in a similar manner as to that mentioned above, giving **11b** (148 mg, 97.5%).

3-Oxoeremophilenolide (11b). Mp 155.5—156.5 °C, colorless needles (ethyl acetate-diisopropyl ether); $[\alpha]_D^{26}$ +154° (*c* 0.99, $CHCl_3$); UV (MeOH) 224 nm (ε 11800); CD (*c* 4.301×10^{-3} MeOH, 22 °C) $[\theta]_{245}$ +6790, $[\theta]_{284}$ −10600; IR ($CHCl_3$) 1740, 1695, 1205 (α,β-unsaturated γ-lactone), 1705 cm^{-1} (ketone); ^1H NMR ($CDCl_3$) δ=4.87 (br m, $W_{1/2}$=15.2 Hz, 8β-H), 2.88 (d, *J*=14.0 Hz, 6α-H), 1.83 (t, *J*=1.3 Hz, 13-Me), 1.00 (s, 15-Me) , 0 96 (d, *J*=7 Hz, 14-Me); ^{13}C NMR (Table 2).

Found: C, 72.39; H, 8.14%. Calcd for $C_{15}H_{20}O_3$: C, 72.55; H, 8.12%.

Reduction of 3-Oxoepieremophilenolide (11a) via Ethylene Dithioacetal 12a. Ten drops of BF_3-diethyl ether (1/1) were added into a stirred solution of **11a** (55 mg) in 1,2-ethanedithiol (0.5 ml) under ice-cooling. After stirring for 6 h at room temperature and the addition of MeOH (5 drops), the reaction mixture was concentrated in vacuo, diluted with water, and then extracted with ethyl acetate. The usual workup gave an oily product (75 mg, quantitatively), which was crystallized from ethyl acetate-light petroleum to afford ethylene dithioacetal **12a**, mp 129.5—131.5 °C, as colorless needles; $[\alpha]_D^{26}$ −157° (*c* 1.20, $CHCl_3$); IR ($CHCl_3$) 1742, 1682, 1096, 1036 cm^{-1}; ^1H NMR ($CDCl_3$) δ=4.80 (m, $W_{1/2}$=14 Hz, 8α-H), 3.4—3.1 (m, acetal methylene), 1.79 (t, *J*=1.5 Hz, 13-Me), 1.31 (d, *J*=6.8 Hz, 14-Me), 0.91 (s, 15-Me)

A suspension of dithioacetal **12a** (153 mg) and Raney nickel (500 mg) in ethanol (10 ml) was refluxed for 3 h and then filtered. The filtrate was concentrated in vacuo to leave a colorless oil (110 mg, 90%). Purification by PTLC (benzene-ethyl acetate, 30 : 1) followed by recrystallization from pentane gave epieremophilenolide (**13a**) (32 mg, 26%).

Epieremophilenolide (13a): Mp 86.0—86.5 °C, colorless prisms; $[\alpha]_D^{26}$ −127° (*c* 1.00, $CHCl_3$); CD (*c* 4.22×10^{-3}, MeOH, 22 °C) $[\theta]_{248}$ −1800; IR ($CHCl_3$) 1750, 1675, 1080 cm^{-1} (α,β-unsaturated γ-lactone); ^1H NMR ($CDCl_3$) δ=4.82 (br m, $W_{1/2}$=13.6 Hz, 8α-H), 1.80 (t, *J*=1.5 Hz, 13-Me), 0.92 (d, *J*=6.6 Hz, 14-Me), 0.88 (s, 15-Me); ^{13}C NMR (Table 2).

Found: C, 76.86; H, 9.52%. Calcd for $C_{15}H_{22}O_2$: C,76.88; H, 9.46%.

Reduction of 3-Oxoepieremophilenolide (11b) via Eth-

ylene Dithioacetal 12b. The 3-ketone **11b** (54 mg) was treated with 1,2-ethanedithiol (0.5 ml) and BF_3-diethyl ether (1/1) (7 drops), as described above. A similar type workup gave a crude product (64 mg, 90%), which was crystallized from ethyl acetate as colorless needles to afford the dithioacetal **12b**, mp 195.5—196.5 °C, $[\alpha]_D^{22}$ +133° (*c* 1.0, $CHCl_3$); IR ($CHCl_3$) 1735, 1685, 1090 cm^{-1} (α,β-unsaturated γ-lactone); ^1H NMR ($CDCl_3$) δ=4.65 (br m, $W_{1/2}$=13.3 Hz, 8β-H), 3.5—3.0 (m, acetal methylene), 1.82 (t, *J*=1.4 Hz, 13-Me), 1.20 (s, 15-Me), 1.16 (d, *J*=5.7 Hz, 14-Me).

The dithioacetal **12b** (50 mg) was treated with Raney nickel (250 mg) in ethanol (5 ml) in a similar manner as that stated above to give an oily product (34 mg, 94%), which was crystallized from diisopropyl ether or light petroleum to afford eremophilenolide (**13b**).

Eremophilenolide (13b): Mp 123.5—124.5 °C, colorless needles; $[\alpha]_D^{21}$ +163° (*c* 1.00, $CHCl_3$); UV (MeOH) 224 nm (ε 13500); CD (*c* 8.74×10^{-3}, MeOH, 22 °C) $[\theta]_{248}$ +7950; IR ($CHCl_3$) 1755, 1690 cm^{-1} (α,β-unsaturated lactone); ^1H NMR ($CDCl_3$) δ=4.67 (br m, $W_{1/2}$=16.5 Hz, 8β-H), 2.90 (d, *J*=14.5 Hz, 6α-H), 1.80 (t, *J*=1.4 Hz, 13-Me), 1.04 (s, 15-Me), 0.80 (d, *J*=5.9 Hz, 14-Me); ^{13}C NMR (Table 2). This lactone was found to be identical with the natural specimen by a comparison of the IR and ^1H NMR spectra, and by a mixed-melting point determination.

Tosylation of 3β(eq)-Hydroxyepieremophilenolide (9a). Into a solution of **9a** (55 mg) in pyridine (1.5 ml) was added tosyl chloride (200 mg) at −5 °C; the mixture was left for 24 h at room temperature. The usual workup gave a crystalline product (75 mg, 84.4%), which was recrystallized from ethyl acetate-light petroleum to afford the tosylate **14a** as colorless leaflets, mp 156.5—158.0 °C (decomp); IR ($CHCl_3$) 1740, 1685 (α,β-unsaturated lactone), 1190, 1180, 1040, 885 cm^{-1} (tosylate); ^1H NMR ($CDCl_3$) δ=7.85—7.25 (q, aromatic 4H), 4.83 (ddd, *J*=5.5, 5.5, 11.5 Hz, 3α-H), 2.46 (s, tosyl Me), 1.76 (t, *J*=1.5 Hz, 13-Me), 0.96 (d, *J*=7.2 Hz, 14-Me), 0.80 (s, 15-Me).

Found: C, 65.16; H, 7.19%. Calcd for $C_{22}H_{28}O_5S$: C, 65.32; H, 6.98%.

Treatment of Tosylate 14a with Sodium Iodide. A suspension of **14a** (85 mg) and NaI (300 mg) in dry acetone (3 ml) was stirred for 5 min at room temperature and then left for 1 week. The usual workup gave a crystalline product (40 mg, 82%), which was crystallized from ethyl acetate-light petroleum to afford 3,4-dehydroepieremophilenolide (**15a**).

3,4-Dehydroepieremophilenolide (15a): Mp 134.0—135.5 °C as colorless leaflets; IR ($CHCl_3$) 1750, 1680, 1090 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.34 (br s, 3-H), 4.71 (br m, $W_{1/2}$= 15.2 Hz, 8α-H), 1.73 (t, *J*=1.7 Hz, 13-Me), 1.63 (d, *J*=1.3 Hz, 14-Me), 0.89 (s, 15-Me); ^{13}C NMR ($CDCl_3$) δ=25.7 (t, 1-C), 26.1 (t, 2-C), 122.6 (d, 3-C), 139.6 (s, 4-C), 40.8 (s, 5-C), 36.7 (t, 6-C), 160.8 (s, 7-C), 77.8 (d, 8-C), 40.4 (t, 9-C), 36.7 (d, 10-C), 121.0 (s, 11-C), 174.5 (s, 12-C), 7.9 (q, 13-C), 18.6 (q, 14-C), 22.7 (q, 15-C).

Found: C, 77.29; H, 8.97%. Calcd for $C_{15}H_{20}O_2$: C, 77.55; H, 8.68%.

Mesylation of 9a. Methanesulfonyl chloride (1 ml) was added into a solution of **9a** (134 mg) in pyridine (1 ml) at 0 °C; the mixture was left for 15 h. The usual workup gave **15a** (116 mg, 93%), which was crystallized from ethyl acetate-light petroleum as colorless leaflets, mp 134.0—135.0 °C. This compound was identical in all respects to the above-mentioned sample **15a** derived by tosylation of **9a**, followed by treatment with NaI.

Hydrogenation of 15a. Compound **15a** (67 mg) in ethanol (6 ml) was hydrogenated over 10% Pd-C (35 mg) for 1 h at room temperature. The filtrate was evaporated in vacuo to leave a crystalline product (65 mg, 96%), which was recrystallized from pentane to afford epieremophilenolide (**13a**) as colorless prisms, mp 84.0—85.0 °C. This compound was identical to the above-mentioned sample **13a**, transformed from **11a** via dithioacetal **12a** by a mixed-melting-point determination and a comparison of the IR and ^1H NMR spectra.

Mesylation of 9b. Methanesulfonyl chloride (1 ml) was added into a solution of **9b** (163 mg) in pyridine (1 ml) over a period of 2 min at 0 °C, and then left at room temperature for 14 h. The usual workup gave 3,4-dehydroeremophilenolide (**15b**) (137 mg, 91%), which was crystallized from ethyl acetate-light petroleum.

3,4-Dehydroeremophilenolide (15b): Mp 138.9—139.5 °C as colorless needles; IR ($CHCl_3$) 1755, 1685, 1335, 1090, 755 cm^{-1}; ^1H NMR ($CDCl_3$) δ=5.23 (br s, 3-H), 4.61 (br m, $W_{1/2}$= 16.3 Hz, 8β-H), 3.03 (d, *J*=14 Hz, 6α-H), 1.83 (d, *J*=1.3 Hz, 13-Me), 1.60 (d, *J*=1.1 Hz, 14-Me), 1.24 (s, 15-Me); ^{13}C NMR ($CDCl_3$) δ=23.1 (t, 1-C), 21.5 (t, 2-C), 122.5 (d, 3-C), 135.8 (s, 4-C), 41.3 (s, 5-C), 35.7 (t, 6-C), 160.6 (s, 7-C) , 80.2 (d, 8-C), 34.8 (t, 9-C), 38.6 (d, 10-C), 119.2 (s, 11-C), 174.9 (s, 12-C), 8.7 (q, 13-C), 19.5 (q, 14-C), 25.7 (q, 15-C).

Hydrogenation of 15b. A solution of **15b** (85 mg) in EtOH (7 ml) was hydrogenated with 10% Pd-C (53 mg) for 45 min. The filtrate was evaporated to give a crude eremophilenolide (**13b**) (85 mg, 99%), which was crystallized from light petroleum as colorless needles, mp 123.0—124.0 °C. This compound was identical in all respects with the natural specimen by a mixed-melting point determination, and by a comparison of the IR and ^1H NMR spectra.

Reduction of 3-Oxoepieremophilenolide (11a) with Sodium Borohydride. A solution of **11a** (51 mg) in MeOH (5 ml) was added into a solution of $NaBH_4$ (163 mg) in MeOH (2 ml) over a 3 min period at room temperature. After stirring for additional 35 min and acidification with 0.1 M HCl, the mixture was extracted with ether. The usual workup gave a reduction product (52 mg, quantitatively), which showed 2 spots on TLC (R_f 0.29 and 0.43; benzene-ethyl acetate 2:1). The product was chromatographed on silica gel (5 g) with benzene-ethyl acetate (5:1) to 3α(*ax*)-hydroxyepieremophilenolide (**16a**) (R_f 0.43, 29 mg, 56.3%) and **9a** (R_f 0.29, 19 mg, 36.9%). Both were crystallized from ethyl acetate-light petroleum; the polar product, mp 167.0—168.0 °C, was identified as **9a** (described above) by a mixed-melting point determination and a comparison of the spectral data.

3α(ax)-Hydroxyepieremophilenolide (16a): Mp 138.5—139.5 °C, as colorless prisms; $[\alpha]_D^{24}$ −138° (*c* 0.98, $CHCl_3$); CD (*c* 4.522×10^{-3}, MeOH, 22 °C) $[\theta]_{248}$ −150; IR ($CHCl_3$) 3450 (OH), 1745, 1680 cm^{-1} (α,β-unsaturated lactone); ^1H NMR ($CDCl_3$) δ=4.88 (br t, *J*=9.7 Hz, 8α-H), 3.97 (ddd, *J*=3, 3, 3 Hz, 3β-H), 3.70 (d, *J*=14.5 Hz, 6α-H), 2.16 (d, *J*=14.5 Hz, 6β-H), 1.78 (t, *J*=1.5 Hz, 13-Me), 0.95 (d, *J*=7.3 Hz, 14-Me), 0.80 (s, 15-Me); ^{13}C NMR (Table 2).

Found: C, 71.95; H, 8.71%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Reduction of 3-Oxoepieremophilenolide (11b) with Sodium Borohydride. A solution of the ketone **11b** (152 mg) in MeOH (4 ml) was added into a stirred solution of

$NaBH_4$ (193 mg) in MeOH (5 ml) over a 10 min period at room temperature. After stirring for an additional 30 min, the mixture was acidified with 0.1 M HCl and extracted with ether. The usual workup gave a crude product (135 mg, 90%), which showed 2 spots on TLC (R_f 0.60 and 0.45; benzene-ethyl acetate 2:1). The product was chromatographed on silica gel (12 g) by elution with benzene-ethyl acetate (10:1) to give a less polar compound (R_f 0.60, 120 mg, 80%), which was crystallized from ethyl acetate-diisopropyl ether to afford **9b**, mp 169.5—170.5 °C, as colorless needles. This compound was identified as 3β(ax)-hydroxyeremophilenolide (**9b**), as described above. Further elution with the same solvent gave a polar compound, 3α(eq)-hydroxyeremophilenolide (**16b**) (R_f 0.45, 15 mg, 10%).

3α(eq)-Hydroxyeremophilenolide (16b): Mp 158.0—159.0 °C, colorless needles (ethyl acetate-light petroleum); $[\alpha]_D^{24}$ +214° (*c* 1.12, $CHCl_3$); CD (*c* 4.312×10⁻³, MeOH, 22 °C) $[\theta]_{252}$ +1250; IR ($CHCl_3$) 3440 (OH), 1745, 1690 cm^{-1} (α,β-unsaturated lactone); ^1H NMR ($CDCl_3$) δ=4.70 (br m, 8β-H), 3.61 (ddd, *J*=5, 10.3, 10.3 Hz, 3β-H), 2.90 (d, *J*=14.6 Hz, 6α-H), 1.81 (t, *J*=1.5 Hz, 13-Me), 1.05 (s, 15-Me), 1.01 (d, *J*=8.5 Hz, 14-Me); ^{13}C NMR (Table 2).

Found: C, 71.67; H, 9.04%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%.

Preparation of Eremophilenolide (13b) from the Natural 6β-Hydroxyeremophilenolide (17b). A 2 M KOH-MeOH solution (4 ml) was added into a solution of natural **17b** (300 mg) in MeOH (3 ml); the mixture was left overnight. After removing the solvent in vacuo and dilution with water, the solution was acidified with aqueous 10% H_2SO_4 and extracted with ether. Without isolation of the free acid, the ethereal extract was treated with CH_2N_2 in diethyl ether. The usual workup gave an oil (302 mg, 95%), which was purified by vacuum distillation to furnish an enoic ester **18** as a colorless oil (263 mg), bp 116—118 °C/0.3 mmHg (40 Pa); $[\alpha]_D^{25}$ +15.5° (*c* 0.99, $CHCl_3$); UV (MeOH) 238 nm (ε 14300); IR (film) 1730, 1670, 1635, 1240 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.63 (br s, 6-H), 3.65 (s, OMe), 1.27 (d, *J*=7.2 Hz, 13-Me), 1.12 (s, 15-Me), 0.91 (d, *J*=6.5 Hz, 14-Me); ^{13}C NMR ($CDCl_3$) δ=20.4 (t, 1-C), 27.0 (t, 2-C), 30.2 (t, 3-C), 36.1 (d, 4-C), 38.9 (s, 5-C), 156.4 (d, 6-C), 136.6 (s, 7-C), 198.4 (s, 8-C), 39.4 (t, 9-C), 37.9 (d, 10-C), 38.2 (d, 11-C), 175.0 (s, 12-C), 16.5 (q, 13-C), 15.8 (q, 14-C), 20.8 (q, 15-C), 51.8 (q, OMe).

A solution of $NaBH_4$ (98 mg) in MeOH (6 ml) was added into a solution of the ester **18** (267 mg) in MeOH (3 ml) and left at room temperature for 4 h to deposit a crystalline product. The usual workup gave crude crystals (213 mg, 90%). Recrystallization from light petroleum furnished eremophilenolide (**13b**, 87 mg) as colorless needles, mp 123.5—124.5 °C. This compound was identical in all respects with the natural specimen as well as the above-mentioned synthesized **13b**.

Reduction of Ester 22 with Sodium Borohydride. a) Preparation of Ester 22: Dienoic acid **21**[1,2] (323 mg) was subjected to esterification in a similar method as that used in the preparation of ester **8** to furnish ester **22** as an oily product (273 mg, 80%), which was purified by vacuum distillation, bp 100—120 °C (bath temperature)/10^{-2} mmHg (2.7 Pa); $[\alpha]_D^{23}$ +16.5° (*c* 1.24, $CHCl_3$); IR (film) 1725, 1680, 1620, 1200, 1150, 1050, 945, 930 cm^{-1}; ^1H NMR ($CDCl_3$) δ=6.78 (s, 6-H), 6.21 (d, *J*=1.5 Hz, 13-H), 5.65 (d, *J*=1.3 Hz, 13-H), 3.73 (s, $COOCH_3$), 2.75 (dd, *J*=17, 11 Hz, 9α-H), 1.16 (s, 15-Me), 0.94 (d, *J*=6.6 Hz, 14-Me).

b) Reduction of Ester 22: Into a solution of ester **22** (231 mg) in MeOH (4 ml) was added a solution of $NaBH_4$ (91 mg) in MeOH (3.5 ml) and left at room temperature overnight. Working up as mentioned above furnished quantitatively crude crystals (202 mg). Recrystallization from light petroleum gave eremophilenolide (**13b**), mp 123.5—124.0 °C. This compound was identical with the natural and synthetic samples in all respects.

Syntheses and Properties of *N*-Fluoropyridinium Salts

Teruo UMEMOTO,* Kikuko HARASAWA, Ginjiro TOMIZAWA, Kosuke KAWADA,† and Kyoichi TOMITA†
Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229
(Received July 18, 1990)

Various stable *N*-fluoropyridinium salts with a non- or weakly nucleophilic counter anion such as TfO^-, FSO_3^-, BF_4^-, SbF_6^-, ClO_4^-, $CH_3SO_3^-$ etc., or with an electron-donating or -withdrawing substituent(s) on the pyridine ring were synthesized and their properties investigated. *N*-Fluoropyridinium-2-sulfonates, *N*-fluoroquinolinium triflate, and highly hindered *N*-fluoro-2,6-di-*t*-butylpyridinium salts were also synthesized. They were synthesized by counter anion displacement reactions of unstable pyridine-F_2 compounds, fluorination of salts of pyridines with protonic acids or silyl esters with F_2, and/or fluorination of Lewis acid complexes of pyridines. The scope of each method was examined in detail. Each of the *N*-fluoropyridinium salts was assigned as the first stable 1 : 1 salt structure of the pyridine nucleus and halogen atom on the basis of the spectral and elemental analyses. The stability depended on the nucleophilicity or basicity of the counter anions and electronic nature or position of the ring substituents. These results and NMR analyses clearly showed the unstable pyridine-F_2 compounds to have *N*-fluoropyridinium fluoride salt structure. Some *N*-fluoropyridinium triflates were hydrolyzed and the products were examined, suggesting a unique hydrolysis mechanism.

Although the reactions of pyridine and many substituted pyridines with Cl_2, Br_2, or I_2, producing molecular complexes with linear nitrogen-halogen-halogen atom structure, have been examined extensively, only limited attention has been directed to those of pyridines with molecular fluorine (F_2).[1] F_2 differes greatly from the other halogens[2] and so consequently, the products obtained from its reaction should be of considerable interest.

Simons first found that liquid pyridine smoothly and completely absorbs F_2 and when absorption is conducted at −40 °C, a dark brown solid separates from the liquid, which decomposes on warming to 0 °C.[3] He described that the thermally unstable solid was apparently a molecular complex between pyridine and F_2, $C_5H_5N \cdot F_2$.[3]

Meinert noted a solid, isolated by bubbling F_2 diluted with N_2 into a solution of pyridine in $CFCl_3$ at −80 °C followed by filtering at low temperature, to decompose violently above −2 °C.[4] He considered this solid to be a pyridine-F_2 compound with polar character. However, no spectral or other data on the structure of the pyridine-F_2 compound are presently not available, probably due to its explosive nature.

The authors found unstable pyridine-F_2 compounds to smoothly undergo counter anion displacement reactions with nonnucleophilic anions to give stable *N*-fluoropyridinium salts.[5] It was also found that insertion reactions of F_2 to salts or complexes of pyridines with protonic acids, silyl esters, or Lewis acids gave the *N*-fluoropyridinium salts. In this paper, syntheses of various *N*-fluoropyridinium salts by different methods and their properties are described in detail.

Experimental

General. Melting points were uncorrected. ^1H NMR spectra were measured on a Varian EM 390 or XL-100 NMR spectrometer or a Bruker AM-400 NMR spectrometer. ^{19}F NMR spectra were obtained on a Hitachi R-20B NMR spectrometer and the chemical shifts were given in ppm downfield from $CFCl_3$ as an internal standard. Both ^1H and ^{19}F NMR spectra were taken by using CD_3CN solvent, unless otherwise noted. IR spectra were measured on a JASCO A-202 diffraction grating infrared spectrometer. Mass spectra were recorded on a Hitachi RMU-6MG mass spectrometer at 70 eV or a Hitachi M-80A mass spectrometer by EI (electron impact ionization) method or SIMS (secondary ion mass spectrometry) method. Unless otherwise noted, the data by EI method are given.

Materials. A 20% F_2–80% N_2 cylinder was purchased from Kanto Denka Kagaku Company (Japan). Since the content of HF in the fluorine was very low (0.2—0.3%), it was used without a NaF trap. 3-Chloro-5-trifluoromethylpyridine and 3,5-bis(trifluoromethyl)pyridine were given by Ishihara Sangyo Company (Japan). 2-[(1*R*,3*R*,4*S*)-Menthyloxy]pyridine (bp 112 °C/0.2 mmHg, 1 mmHg=133.322 Pa, $[\alpha]_D^{20}=-110.7$ (c=0.994, $CHCl_3$)) was prepared by treatment of 2-chloropyridine with (−)-menthol by the action of NaH in tetrahydrofuran (THF) under reflux for 19 h. 2-(Fluoromethyl)-4,6-dimethylpyridine was prepared from 2,4,6-trimethylpyridine by oxidation with 35% H_2O_2 in acetic acid, rearrangement reaction with Ac_2O, alkaline hydrolysis, and fluorination with (diethylamino)sulfur trifluoride. 6-Chloropyridine-2-sulfonic acid was prepared by treatment of 2,6-dichloropyridine with sodium sulfite. Dry CH_3CN was made by distillation over CaH_2 and used immediately. Other solvents used were dried by usual methods and stored over molecular sieves.

Synthesis of *N*-Fluoropyridinium Salts 1—46. [CAUTION!]. Since F_2 is a highly oxidizing and toxic gas, the experimenter should familiarize him- or herself with the precautions necessary for the safe handling of F_2.[6] The use of diluted F_2 in an inert gas (N_2 or Ne) is considerably safer than pure F_2.

Apparatus: As shown in Fig 1, the apparatus used for the fluorination consisted of a 20% F_2–80% N_2 cylinder, a N_2 cylinder, two flow meters (Hastings Mass Flowmeters Model CST), a Pyrex®-glass reactor, and valves made of

stainless steel or brass. The cylinders, the flow meters, and the valves were connected with stainless steel or copper tubes. The 20% F_2-N_2 cylinder was equipped with a pressure regulator (Takachiho F_2 Regulator Model 7630H) that was designed for fluorine service. The glass reactor was connected to the outlet of further diluted F_2 (10% F_2-N_2) by using a Viton® tube. The gas outlet of the reactor was connected to a granular alumina trap to consume the F_2 gas. The designed concentration of F_2 in N_2 and the flow rates of a F_2-N_2 mixture gas were adjusted by the flow meters.

Method A (a two-step procedure): **General Procedure;** a 50-mL reaction flask was charged with 3 mmol of a pyridine and 6 mL of dry CH_3CN. The system was purged with N_2 and the reaction mixture was immersed in a cooling bath of −40 °C. A 10% F_2-90% N_2 mixture gas was introduced at a flow rate of 30 mL min^{-1} just above the surface of the rapidly stirred solution. Total amount of F_2 used was 9 mmol. After the flow of F_2 was stopped, N_2 only was flowed through the system at rate of 15 mL min^{-1} for 30 min while keeping the reaction mixture at −40 °C. After that, 3 mmol of TfOH (a reactant shown in Tables 1 and 2) was added into the reaction mixture and it was stirred for 1 h at −40 °C. The post-treatment for *N*-fluoropyridinium triflate (**1a**) was as follows; 50 mL of diethyl ether (Et_2O) was added into the reaction mixture and warmed to room temperature. The resulting solid was collected by filteration to give a solid of 0.306 g, which was sufficiently washed with 1 ml of dry ethyl acetate (AcOEt) to give 0.242 g (33%) of pure **1a**.

Method B (a one-step procedure): **General Procedure;** a solution of 3 mmol of a pyridine, 3 mmol of NaOTf (a reactant shown in Tables 1 and 2), and 6 mL of dry CH_3CN was fluorinated in the same manner as described in Method A. The reaction mixture was then warmed to room temperature, filtered through Celite to remove NaF formed, and evaporated up to dryness at room temperature. The resulting solid was washed with dry AcOEt to give 0.554 g (75%) of **1a**. Analytically pure crystals were obtained by recrystallization from CH_3CN-AcOEt at room temperature. When KOTf was used in place of NaOTf, 12 mL of dry CH_3CN was used as a solvent.

Method C: General Procedure; a solution of a pyridinium hydrogen salt or a *N*-silylpyridinium salt which was in situ prepared by mixing 3 mmol of a pyridine and 3 mmol of a protonic acid or a silyl ester (a reactant shown in Tables 1 and 2) in 6 mL of dry CH_3CN, was treated with 10% F_2-N_2 at −40 °C in the same manner as described in Method A (CAUTION!; a 2% F_2-98% N_2 mixture gas should be used for fluorination of *N*-trimethylsilylpyridinium triflates). The post-treatment for **1a** was as follows; the reaction solution was completely evaporated up to dryness at room temperature and the residue was washed with dry AcOEt to give pure crystals of **1a**.

Method D: General Procedure; a solution of a pyridine-Lewis acid complex, which was in situ prepared by mixing 3 mmol of a pyridine and 3 mmol of a Lewis acid (a reactant shown in Tables 1 and 2) in 6 mL of dry CH_3CN, was treated with 10% F_2-N_2 at −40 °C in the same manner as described in Method A. The reaction mixture was warmed to room temperature and evaporated up to dryness at room temperature. For **29b**, the residue was crystrallized from CH_3CN-Et_2O, giving 79% of **29b**.

Tables 1 and 2 summarize the results. Melting points, spectral data, and elemental analyses of the *N*-fluoropyridinium salts synthesized by the above methods are shown below. Their ^{19}F NMR data will be shown and discussed elsewhere.

***N*-Fluoropyridinium Triflate (1a):** Mp 185—187 °C (recrystallization solvent CH_3CN-Et_2O); ^{19}F NMR δ=48.8 (1F, bs, NF), −77.6 (3F, s, CF_3); ^1H NMR δ=8.32 (2H, dt, $J_{3\text{-H-F}}$=4.8 Hz, $J_{3\text{-H-2-H}}$=$J_{3\text{-H-4-H}}$=7.0 Hz, 3-H), 8.77 (1H, dt, $J_{4\text{-H-F}}$=2.0 Hz, $J_{4\text{-H-3-H}}$=7.0 Hz, 4-H) , 9.33 (2H, dd, $J_{2\text{-H-F}}$= 16.0 Hz, $J_{2\text{-H-3-H}}$=7.0 Hz, 2-H); MS *m/z* 227 (M^+−HF), (SIMS method) 98 (M^+−OTf). Found: C, 29.17; H, 1.99; N, 5.66; F, 30.49; S, 13.21%. Calcd for $C_6H_5F_4NO_3S$: C, 29.16; H, 2.04; N, 5.67; F, 30.75; S, 12.97%.

***N*-Fluoropyridinium Fluorosulfate (1b):** Mp 120—125 °C (CH_3CN-Et_2O); MS *m/z* 177 (M^+−HF). Anal. ($C_5H_5F_2NO_3S$) C, H, N.

***N*-Fluoropyridinium Methanesulfonate (1c):** Mp 140—142 °C; MS *m/z* 173 (M^+−HF). Anal. ($C_6H_8FNO_3S$), C, H, N.

***N*-Fluoropyridinium Trichloromethanesulfonate (1d):** Mp 205.5—207 °C (with decomp) (CH_3CN); MS *m/z* 277, 275 (M^+−HF). Anal. ($C_6H_5Cl_3FNO_3S$) C, H, N.

***N*-Fluoropyridinium Nonafluorobutanesulfonate (1e):** Mp 111—112 °C (AcOEt-Et_2O); MS *m/z* 377 (M^+−HF). Anal. ($C_9H_4F_{10}NO_3S$) C, H, N.

***N*-Fluoropyridinium Tetrafluoroborate (1f):** Mp 196.8—198 °C (CH_3CN-AcOEt, or CH_3CN); MS *m/z* 104. Anal. ($C_5H_5BF_5N$) C, H, N.

***N*-Fluoropyridinium Hexafluorophosphate (1g):** Decomp 202 °C (THF); MS *m/z* 174, 172, 107, 97. Anal. ($C_5H_5F_7NP$) C, H, N.

Synthesis of *N*-Fluoroquinolinium Triflate (49). This salt was prepared in 16% yield according to Method B. Mp (in a sealed tube) 144—154 °C (with decomp) (CH_3CN-AcOEt); ^{1}H NMR δ=9.28 (1H, d, $J_{4-H-3-H}$=8 Hz, 4-H), 9.69 (1H, dd, J_{2-H-F}=18 Hz, $J_{2-H-3-H}$=7 Hz, 2-H); MS *m/z* 277 (M^+−HF), (SIMS method) 148 (M^+−OTf). Anal. ($C_{10}H_7F_4NO_3S$) C, H, N.

Synthesis of *N*-Fluoropyridinium-2-sulfonates 52 and 53. Typical Procedure; a mixture of 0.209 g (1.08 mmol) of 6-chloro-2-pyridinesulfonic acid in 2.1 mL of H_2O-CH_3CN

(1/20 v/v) was fluorinated at −25 °C in a similar manner as Method A. Total amount of F_2 was 3.24 mmol. After the fluorination, 25 mL of THF was added into the reaction mixture at −25 °C under stirring and it was warmed to room temperature. The resulting crystals were collected by filtration and dried to give 0.177 g (77%) of *N*-fluoro-6-chloropyridinium-2-sulfonate (**53**). Analytically pure crystals were obtained by the recrystallization from CH_3CN-Et_2O.

***N*-Fluoropyridinium-2-sulfonate (52):** 81%; Decomp 232—235 °C (CH_3CN); ^1H NMR (400 MHz) δ=9.04 (1H, ddd, J=14.5, 7.0, 1 Hz, 6-H); MS m/z 177 (M^+). Anal. ($C_5H_4FNO_3S$) C, H, N.

***N*-Fluoro-6-chloropyridinium-2-sulfonate (53):** 77%; Mp 171—173 °C (CH_3CN-Et_2O); MS m/z 112 (M^+−F−SO_3). Anal. ($C_5H_3ClFNO_3S$) C, H, N.

Hydrolysis of *N*-Fluoropyridinium Salts 1a, 28, 29a, 30a, and 49. A *N*-fluoropyridinium salt was added into a stirred water at room temperature. The amount of water used was ca. 2 mL to 1 mmol of a *N*-fluoropyridinium salt and 5.2 mmol of **1a**, 1.6 mmol of **28**, 5.3 mmol of **29a**, 4 mmol of **30a**, and 0.34 mmol of **49** were used for the hydrolysis experiments. The reaction mixture was stirred at room temperature for 14 d (**1a**), 6 h (**28**), ca. 10 min (**29a**), 0.5 h (**30a**), and ca. 10 min (**49**) and then neutralized to pH 7 with $NaHCO_3$. The hydrolysis products were isolated by usual post-treatments. The results are described in Result section. The structural assignment of the products was carried out by analyzing their spectral data. 2-Pyridinol and 2-quinolinol were in agreement with authentic samples. The data of other products are shown in the following.

3,5-Dichloro-2-pyridinol (56): ^1H NMR δ=7.42 (1H, d, J=3.0 Hz, 4 or 5-H), 7.61 (1H, d, J=3.0 Hz, 4 or 5-H); IR (KBr) 3100 (NH), 1695 cm^{-1} (CO); MS m/z 167, 165, 163 (M^+).

***N*-Fluoro-6-chloro-2-pyridone (57):** Mp 74 °C; ^{19}F NMR ($CDCl_3$) δ=−44.6 (s, NF); ^1H NMR ($CDCl_3$) δ=6.26 (1H, ddd, J=7.5, 4.5, 2.0 Hz, 3-H), 6.66 (1H, ddd, J=9.5, 8.0, 2.0 Hz, 5-H), 7.26 (1H, dd, J=9.5, 7.5 Hz, 4-H); IR (KBr) 1680 cm^{-1} (CO); MS m/z 149, 147 (M^+). Anal. (C_5H_3ClFNO) C, H, N.

2,6-Dichloro-4-pyridinol (58): ^1H NMR ($CDCl_3$) δ=6.79 (s); IR (KBr) 3100—3000 cm^{-1} (OH); MS m/z 167, 165, 163 (M^+).

***N*-Fluoro-3,4,5,6-tetrachloro-2-pyridone (59):** Mp 102—104 °C (CCl_4); ^{19}F NMR ($CDCl_3$) δ=−33.0 (s, NF); IR (Nujol on NaCl) 1680 cm^{-1} (CO); MS m/z 255, 253, 251, 249 (M^+). Anal. (C_5Cl_4FNO) C, H, N.

Alkaline Hydrolysis of *N*-Fluoropyridinium Triflate (1a). Into a stirred solution of 10 mL of aq KOH (1 mol dm^{-3}) was by portions added 1.29 g (5.21 mmol) of **1a**. After 2 h, the reaction mixture was neutralized to pH 7 with $NaHCO_3$ and extracted with CH_2Cl_2. GC and GC-Mass analyses of the organic layer showed that 2-pyridyl triflate and 2-fluoropyridine were produced in 0.5 and 0.6% yields, respectively. A column (2 m×2 mm) packed with PEG-6000 (15%) on Uniport B was used for the GC analysis. The post-treatment of the organic layer gave 0.246 g (50%) of 2-pyridinol.

Alkaline Hydrolysis of *N*-Fluoro-2,4,6-trimethylpyridinium Triflate (7a). Into a stirred solution of 10 mL of aq KOH (2.9 mol dm^{-3}) was by portions added 1.48 g (5.11 mmol) of **7a**. An exothermic reaction occurred. After it ceased, the usual post-treatment was carried out to give 170 mg (24%) of 2-hydroxymethyl-4,6-dimethylpyridine (**54**) and 166 mg (23%) of 2-fluoromethyl-4,6-dimethylpyridine (**55**). Spectral data of **54** and **55** were in agreement with those of each authentic sample.

Reaction of *N*-Fluoro-2,4,6-trimethylpyridinium Triflate (7a) with Triethylamine or Sodium Hydride. Into a stirred solution of 1 mmol of triethylamine or sodium hydride (50% in oil) in 2 mL of a dry solvent was added 0.289 g (1 mmol) of **7a** at room temperature under argon atmosphere. After 10 min., the reaction mixture was analyzed by ^{19}F NMR. The results are described in Result section. The assignment of product **60** was carried out by the spectral analysis of the isolated product.

3-Fluoro-2,4,6-trimethylpyridine (60): Oil; ^{19}F NMR ($CDCl_3$) δ=−137.1 (bs); ^1H NMR ($CDCl_3$) δ=2.24 (3H, d, J=1.5 Hz, 4-CH_3), 2.45 (3 H, d, J=0.5 Hz, 6-CH_3), 2.46 (3H, d, J=3.2 Hz, 2-CH_3), 6.82 (1H, d, J=5.3 Hz, 4-H); IR (neat) 2940, 1620, 1470, 1230, 1215, 1160, 1025, 928, 860, 755 cm^{-1}. Found: m/z 139.0780 (M^+). Calcd for $C_8H_{10}FN$: M, 139.0796.

Thermal Stability. The sample was heated in a NMR tube under air in an oil bath of which temperature was set and monitored by ^{19}F NMR.

Results

Syntheses of *N*-Fluoropyridinium Salts. Various *N*-fluoropyridinium salts **1**—**46** were synthesized in varying yields as follows; by the fluorination of a pyridine and subsequent acid, metal salt of an acid, silyl ester, or Lewis acid treatment (Method A), fluorina-

a) See Experimental Section. The fluorination was conducted in CH_3CN at −40 °C unless otherwise noted. b) Isolated yields. c) The fluorination was carried out at −20 °C. d) In place of CH_3CN, $CFCl_3$ was used as a solvent in the first fluorination step which was carried out at −78 °C. The solvent of the second step at −40 °C was a 1 : 2 mixture of $CFCl_3$ and CH_3CN. e) The fluorination was carried out at −20 °C by using H_2O-CH_3CN (1/20) solvent. The post-treatment for **1c** was as follows; a large amount of THF was added to the reaction mixture cooled at −20 °C and the resulting precipitates of **1c** was collected by filtration.

tion of a mixture of a pyridine and metal salt of an acid (Method B), fluorination of a pyridinium hydrogen salt or a *N*-silylpyridinium salt (Method C), or fluorination of a pyridine-Lewis acid complex (Method D), as outlined in Scheme 1. The results are summarized in Tables 1 and 2.

According to Method A, the first treatment of pyridine in CH_3CN with 10% F_2-N_2 mixture gas at −40 °C and successive treatment with TfOH (Tf=CF_3SO_2), fluorosulfuric acid, trimethylsilyl triflate, $BF_3 \cdot OEt_2$, or SbF_5 gave the corresponding N-fluoropyridinium salts **1** in 29—45% yields. In case of a more basic pyridine, 2,4,6-trimethylpyridine, the first fluorination step was conducted in the presence of a 4—10 equivalent amount of NaF added as a HF trapping agent (modified Method A) to lessen the formation of 2,4,6-trimethylpyridinium hydrogen triflate (**48**).

Method B, a one-step procedure, afforded good yields of *N*-fluoropyridinium salts. Thus a mixture of pyridine and metal salt of a strong acid such as NaOTf, CCl_3SO_3Na, $NaBF_4$, n-$C_4F_9SO_3Na$, $NaPF_6$, $NaAsF_6$ etc. in CH_3CN was treated with 10% F_2-N_2 mixture gas at −40 °C to produce *N*-fluoropyridinium salt **1** in 63—93% yields, as shown in Table 1. As fluorination proceeded, metal fluoride appeared gradually in the form of precipitates. Table 2 shows that by Method B, the synthesis of a large number of *N*-fluoropyridinium salts possessing an electron-donating or -withdrawing atom(s) or group(s) on the pyridine ring can be effectively carried out using substituted pyridines.

In the Method B fluorination of pyridine, LiOTf, NaOTf, and KOTf were used to obtain 87, 75, and 62% yields of *N*-fluoropyridinium triflate (**1a**), respec-

a) Compound numbers. b) Counter anion part of *N*-fluoropyridinium salts. c) See Experimental Section. Fluorination was conducted in CH_3CN at −40 °C unless otherwise noted. d) Isolated yields. e) Good yields. f) Modified Method using added NaF. g) This reaction was carried out in the similar manner as Run 7 in Table 1. Thus, $CFCl_3$ was used as a solvent in the first fluorination step. h) A crude yield. i) Sodium (+)-10-camphorsulfonate. j) (1*R*,3*R*,4*S*)-Menthyloxy group. k) Products were isolated as 1 : 1 salts with LiOTf. l) This reaction was carried out in dry propionitrile solvent at −60 °C. m) This reaction was carried out in dry propionitrile at −78 °C. n) Fluorination with 20% F_2-N_2 was conducted in CF_3COOH at room temperature (ca. 10 °C).

tively. With 2,4,6-trimethylpyridine, LiOTf gave only a 22% yield of *N*-fluoro-2,4,6-trimethylpyridinium triflate (**7a**). In this reaction, two by-products, **48** (26%) and *N*-fluoro-2-fluoromethyl-4,6-dimethylpyridinium triflate (**19**) (5%) were found. As seen in Table 3, the yield of **7a** depended on the nature of metal triflate used, and KOTf greatly increased **7a** and decreased the by-product **48**. Salt **7a** was obtained in highest yield and **48** suppressed completely by KOTf in H_2O-CH_3CN (1/100) solvent. No significant change was noted in the yields of **19**. Runs 5 and 6 in Table 3 show better yields of **7a** by modified Method B in which the fluorination was conducted in the presence of a 4—10 equivalent amount of NaF added. Salt **7a** could be separated easily from **48** by recrystallization, though its complete separation from **19** was difficult.

Pure *N*-fluoro-2,3,5,6-tetramethylpyridinium triflate (**8**) and -pentamethylpyridinium triflate (**9**) were isolated in very low yields by the modified Method B. Considerable amounts of the corresponding pyridinium hydrogen salts were formed in these reactions.

Table 3. Reaction Conditions for Preparation of *N*-Fluoro-2,4,6-trimethylpyridinium Triflate (**7a**)

Run	Method[a]	MOTf	Solv.	Additive[b]	Yield[c]/%		
					7a	**48**	**19**

6	B[d]	NaOTf	CH_3CN	NaF(10 equiv)	57	15	8

a) See Experimental Section. b) Figures in parentheses mean equivalent amounts of NaF based on 2,4,6-trimethylpyridine. c) Yields of **7a** were isolated yields. The yields of **48** and **19** were determined by ^1H NMR of the crude reaction products, based on the isolated yields of **7a**. d) This method was specified as modified Method B.

Highly hindered pyridines, 2,6-di-*t*-butylpyridine and its derivatives were fluorinated according to the modified Method B to give *N*-fluoro-2,6-di-*t*-butylpyridinium triflate (**11**), *N*-fluoro-2,4,6-tri-*t*-butylpyridinium triflate (**12**), and *N*-fluoro-2,6-di-*t*-butyl-4-methylpyridinium triflate (**13**). The yields, however, were quite low. During the reactions, the corresponding pyridinium hydrogen salts and tars were also formed. The separation of these pure *N*-fluoro salts from the protonated pyridinium salts was successfully carried out by treatment of a CH_2Cl_2 solution of the mixture with aq $NaHCO_3$ followed by recrystallization. Method B using KOTf in the aq CH_3CN solvent improved the yields only to a very slight extent.

The yields of *N*-fluoropyridinium salts possessing an electron-withdrawing ring-substituent(s) by Method B varied depending on the metal salts used, or on the nature, ring-position and number of substituents. Apparently, lithium salts give better yields than sodium or potassium salts. *N*-Fluoro-3,5-dichloropyridinium triflate (**29a**) was obtained in 77% yield using LiOTf, but in 22% yield by NaOTf. Isomeric *N*-fluoro-2,6-dichloropyridinium triflate (**28**) was prepared in only a 38% yield by LiOTf.

As the pyridine nitrogens became weak in basicity, efficiency of the fluorination decreased. When 2,4,6-tris(methoxycarbonyl)pyridine and 2-fluoropyridine were fluorinated by Method B using LiOTf, *N*-fluoro-2,4,6-tris(methoxycarbonyl)pyridinium triflate (**39**) and *N*-fluoro-2-fluoropyridinium triflate (**25**) were isolated in low yields as 1 : 1 crystals with unreacted LiOTf.

Method C fluorination of salts of pyridine, 2,6-dichloropyridine, and pentachloropyridine with triflic acid gave **1a** (66%), **28** (56—62%), and *N*-fluoropentachloropyridinium triflate (**30a**) (32%), respectively, while the corresponding salt **48** of 2,4,6-trimethylpyridine failed to produce **7a** under the same conditions. In the latter case, a large amount of the starting **48** was found to remain. The yield of **1a** was improved by the fluorination at elevated temperature and was high at −20 °C (96%, Run 5 in Table 1). The fluorination of the salt of extremely low basic pentachloropyridine was most efficiently carried out at room temperature using trifluoroacetic acid as a solvent to obtain **30a** in 85% yield.

By Method C, the reaction of *N*-(trimethylsilyl)-pyridinium triflate, easily obtained from pyridine and trimethylsilyl triflate, with F_2 in CH_3CN at −40 °C led to the formation of **1a** in 40% yield. In this reaction, trimethylsilyl fluoride, as another product, was detected by ^{19}F NMR of the reaction mixture. As can be seen from Table 2, Method C is suitable for pyridine itself or pyridines possessing an electron-withdrawing substituent(s). A pyridinium salt with the electron-donating groups, *N*-trimethylsilyl-2,4,6-trimethylpyridinium triflate did not produce **7a** under the same reaction conditions.

Care must be taken when fluorinating *N*-(trimethylsilyl)pyridinium salts. When the very dilute 2% F_2-N_2 was used for the fluorination, there was no *explosion* while at 5% or more, there ensued a violent gas-phase reaction. This may possibly have resulted from a gas-phase reaction of the volatile by-product, trimethylsilyl fluoride, with F_2, since no *violent reaction* occurred with *N*-(dimethylphenylsilyl)pyridinium triflate by which nonvolatile dimethylphenylsilyl fluoride was produced as the by-product (Run 40 in Table 2).

Method D fluorination of a BF_3 complex of 3,5-dichloropyridine formed tetrafluoroborate **29b** in 79% yield while only a trace of **1f** could be formed from pyridine-BF_3 complex under the same conditions. *N*-Fluoropentachloropyridinium tetrafluoroborate (**30b**) was synthesized in 87% yield by Method D fluorination with 20% F_2-N_2 in trifluoroacetic acid at room temperature.

N-Fluoropyridinium trifluoroacetate, regarded as a salt with a weakly nucleophilic counter anion, was produced by Method A using sodium trifluoroacetate or trimethylsilyl trifluoroacetate. The pure salt could not be obtained owing to its failure to be crystallized. The ^1H NMR of the crude product was in good agreement with that of the *N*-fluoropyridinium moiety of **1a** and ^{19}F NMR showed an N-F peak at δ=48.4. *N*-Fluoropyridinium methanesulfonate

(**1c**), a salt with another weakly nucleophilic counter anion, was isolated in good yield according to Method C (Runs 11 and 12 in Table 1). The synthesis of *N*-fluoropyridinium acetate, a salt possessing a considerably strongly nucleophilic counter anion, was attempted by Method B using sodium acetate (NaOAc). Treatment of an equimolar mixture of pyridine and NaOAc in CH_3CN with 10% F_2-N_2 at −40 °C produced new precipitates, probably NaF, but the reaction mixture immediately became dark on rising to room temperature. *N*-Fluoropyridinium acetate may thus possibly be present at low temperature but decomposes with its increase.

A higher homologue of pyridinium salts, *N*-fluoroquinolinium triflate (**49**), was synthesized in 16% yield by Method B using NaOTf. The low yield obtained may possibly have been due to the considerably low stability of **49** toward moisture.

N-Fluoropyridinium-2-sulfonate (**52**) and *N*-fluoro-6-chloropyridinium-2-sulfonate (**53**), counter anion-bound salts, were synthesized as stable crystals in 81 and 77% yields by treating 2-pyridinesulfonic acid (**50**) and 6-chloro-2-pyridinesulfonic acid (**51**) with 10% F_2-N_2 in H_2O-CH_3CN (1/20) solution at −25 °C, respectively.

Hydrolysis Experiment. *N*-Fluoropyridinium salt **1a** was dissolved in water and decomposed very slowly at room temperature. When a solution of **1a** in water stood for 14 days at room temperature, **1a** decomposed completely to give 2-pyridinol in 66% yield. The half decay for its decomposition in heavy water at room temperature was 13 days. Its hydrolysis was accelerated by alkali. Salt **1a** was thus readily hydrolyzed with aq KOH solution at room temperature. GC and GC-Mass analyses of a reaction mixture showed traces of 2-pyridyl triflate (0.5%) and 2-fluoropyridine (0.6%) to form in addition to 2-pyridinol which was isolated in 50% yield.

2,4,6-Trimethyl salt **7a** dissolved in water without decomposing. It remained intact after 30 days at room temperature in heavy water, but decomposed immediately with aq KOH solution to give 2-(hydroxymethyl)-4,6-dimethylpyridine (**54**) and 2-(fluoromethyl)-4,6-dimethylpyridine (**55**) in 24 and 23% yields, respectively. Treatment of **7a** with triethylamine in CH_2Cl_2 and THF afforded a new fluoro product, 3-fluoro-2,4,6-trimethylpyridine (**60**), in addition to **55** in total 62 and 63% yields, respectively. The ratios of **55**/**60** were 2/1 in CH_2Cl_2 and 1/1 in THF. The treatment with NaH in CH_2Cl_2 gave **55**/**60**=8/1 (total yield; 60%).

In water, 3,5-dichloro salt **29a** decomposed immediately and exothermally to give 3,5-dichloro-2-pyridinol (**56**) in 82% yield. 2,6-Dichloro salt **28** decomposed slowly in water, compared to **29a**, to give *N*-fluoro-6-chloro-2-pyridone (**57**) and 2,6-dichloro-4-pyridinol (**58**) in 35 and 7% yields, respectively. Pentachloro salt **30a** decomposed rapidly in water, affording *N*-fluoro-3,4,5,6-tetrachloro-2-pyridone (**59**) in 62% yield. *N*-Fluoroquinolinium salt **49** decomposed immediately in water, so that 2-hydroxyquinoline was obtained in 68% yield.

Thermal Stability. *N*-Fluoropyridinium salts with nonnucleophilic counter anions are generally stable crystals with high melting points. *N*-Fluoropyridinium salt **1a** and 2,4,6-trimethyl salt **7a** remained intact after 5 h at 150 °C, but melted and decomposed within a few minutes at 190 °C. 3,5-Dichloro salt **29a** remained spectroscopically intact after 6 h at 100 °C, though its crystals turned pale brown. Salt **29a**, however, melted and decomposed in less 1 min at 190 °C and in ca. 45 min at 150 °C. These salts may thus be considered to retain their stability for prolonged periods at temperatures less than their melting points, but decompose rapidly or slowly above their melting points.

Solubility. *N*-Fluoropyridinium salts in most cases are freely soluble in polar solvents such as acetonitrile, but insoluble or sparingly soluble in nonpolar organic solvents. The solubilities of *N*-fluoropyridinium triflate **1a**, tetrafluoroborate **1f**, hexafluoroantimonate **1i**, and perchlorate **1j** in CH_2Cl_2 are 0.63, 0.05, 0.09, and 0.035 mg cm^{-3}, respectively. Thus, triflate **1a** has relatively high solubility in this series. Salts having bulky ring-substituents or counter anions such as **10, 11, 12, 14, 15, 16, 18, 23,** or **7c** are soluble in CH_2Cl_2. The solubility of **1a** in THF is 1.71 mg cm^{-3}.

Discussion

Syntheses of *N*-Fluoropyridinium Salts. The pyridine-F_2 compounds produced with pyridine or substituted pyridines and F_2 smoothly underwent the counter anion displacement reactions to give stable *N*-fluoropyridinium salts. They also reacted smoothly with Lewis acids to give *N*-fluoropyridinium salts. The products were determined to have completely ionic structures on the basis of their spectral and elemental analyses. From these results, it appears quite likely that unstable pyridine-F_2 compounds have the *N*-fluoropyridinium fluoride salt structure **47**, which is in agreement with the fact that fluorine atoms have extremely poor two-coordinating ability.[7]

At room temperature, the ^1H NMR spectrum of a homogeneous CH_3CN solution prepared by treating pyridine with 10% F_2-N_2 in CH_3CN at −40 °C, was totally consistent with that of *N*-fluoropyridinium salts. Its ^{19}F NMR showed two peaks at 48.2 and −175 ppm (strong peak), these corresponding to the N-F chemical shifts of the *N*-fluoropyridinium salts and F^- or HF, respectively. An unidentified small peak at 57.4 ppm, however, was also detected. In a concentrated solution, some other small peaks were noted in the range of −63—−100 ppm. Subsequent cooling of the CH_3CN solution to −40 °C followed by treatment with $BF_3 \cdot OEt_2$ gave tetrafluoroborate **1f** in

31% yield, which was the same as that (33%) obtained while keeping the reaction mixture at −40 °C during the treatment.

Since F^- forms a tight hydrogen bond with HF, the pyridine-F_2 compound may quite likely be present as *N*-fluoropyridinium fluoride stabilized by HF, in the form as $[C_5H_5N\text{-}F]^+F^-(HF)_n$. A large part of this compound remained intact in the solution even after standing for 11 days at room temperature.

A comparison of the HF-stabilized salt with the explosive pyridine-F_2 solid, as reported by Meinert,[4] was considered pertinent to the present study. The unstable solid also gave triflate **1a** (32%) and NaF on treatment with NaOTf at low temperature (Run 7 in Table 1). It is thus evident from these data that the unstable solid is *N*-fluoropyridinium fluoride not stabilized by HF, which is most likely formed by immediate precipitation and without the formation of HF as a by-product due to the use of $CFCl_3$ as a solvent inactive toward F_2 under such reaction conditions.

Quantitative ^{19}F NMR analysis indicated the HF-stabilized *N*-fluoropyridinium fluoride to be formed in about a 45% yield, based on the starting pyridine. HF may have been produced by decomposition of the unstable *N*-fluoropyridinium fluoride formed at the first stage and by side-reactions brought about by the extremely reactive F_2. The decomposition reaction would explain well why one-step Method B, in which the unstable *N*-fluoropyridinium fluoride during its formation can immediately react with metal salts of acids, gave good yields of *N*-fluoropyridinium triflates and other salts, while the two-step Method A gave only low yields.

By Method B, in which metal triflates are used, the yield of **1a** increased from 62% to 75% to 87% in the order, KOTf<NaOTf<LiOTf. As noted in the preparation of 3,5-dichloro salt **29a**, the effect of the lithium salt was great in the fluorination of pyridines having electron-withdrawing substituents particularly at β- or γ-positions. It was shown in the related study that *N*-fluoropyridinium salts having an acidic α-proton(s) undergo novel base-initiated decomposition and that even KF causes the decomposition of **1a**, though at a slow rate.[8] The results of the hydrolysis experiments indicated decompostion to occur more easily with *N*-fluoropyridinium salts possessing electron-withdrawing substituents which made the α-proton more acidic. Method B gives metal fluoride as another product as fluorination proceeds. Since their reactivity as a base should decrease in the order of KF>NaF>LiF, the high yields obtained with LiOTf may be attributed to extremely low reactivity of LiF; LiF does not actually decompose any of the formed *N*-fluoropyridinium salts.

To the contrary, in the fluorination of 2,4,6-trimethylpyridine, the yield of product **7a** decreased from 71% to 39% and then to 22% as the metal triflate varied from KOTf to NaOTf and to LiOTf, as shown in Table 3. This may be explained by the decreasing order (KF>NaF>LiF) of the HF-trapping ability of resulting metal fluorides, which can suppress the formation of the by-product **48**. That KOTf in aq CH_3CN completely inhibited **48** is due to the fact that water can act as an additional HF-trapping agent. The effect of NaF as an additive in modified Methods A and B also supports this mechanism. The by-product **19** may be produced by further fluorination of decomposition product **55**, which was shown to form on treatment of **7a** with a base.

N-Fluoropyridinium salts could also be synthesized by insertion reactions of F_2 to proton or silyl salts or Lewis acid-complexes of some pyridines. Thus, pyridinium hydrogen triflate (**63**) and 2,6-dichloro- and pentachloropyridinium hydrogen triflates (**64**) and (**65**) were inserted by F_2 at their N^+-H bonds in CH_3CN at −40 °C to give salts **1a**, **28**, and **30a**, respectively. However, the same treatment of salt **48** of 2,4,6-trimethylpyridine failed to provide **7a**. 3,5-Dichloropyridine-BF_3 complex (**66**) gave a good yield of **29b**, but pyridine-BF_3 complex only a trace of **1f**. It would thus follow that the successful fluorine insertion to N^+-H or N^+-BF_3^- bonds of **63**—**66** is due to their relatively weak bonding. Similarly, the insertion reaction of F_2 into N^+-Si bonds depends on the strength of N^+-Si bonding. The reaction thus proceeded well in the case of the *N*-trimethylsilyl salts of pyridine itself or lower basic pyridine derivatives, while the corresponding silyl salt of more basic 2,4,6-trimethylpyridine did not give **7a** under the same conditions.

In regard to steric hindrance, it should be of considerable interest to fluorinate highly hindered pyridines such as 2,6-di-*t*-butylpyridine and its analogues. Such hindered pyridines react with protonic acid but not with other electrophiles such as BF_3 or methyl iodide by conventional procedure due to steric hindrance between the bulky groups and reactants. They react with methyl iodide or methyl fluorosulfate only under very high pressure of 5000—6000 atm at 90 °C to give stable *N*-methylpyridinium salts.[9] Since van der Waal's radius of fluorine atom (1.47 Å) is close to that of a hydrogen atom (1.20 Å), fluorine should be capable of penetrating into a hindered nitrogen site, as it does in the case of a hydrogen atom.

By the modified Method B, the expected *N*-fluoro-2,6-di-*t*-butyl salts **11**, **12**, and **13** could be obtained along with large amounts of the corresponding pyridinium hydrogen triflates. These *N*-fluoro salts are stable crystals with high melting points, and not sensitive to moisture.

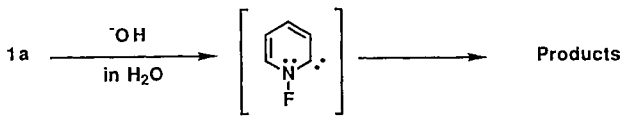
Thus, except for the hydrogen atom, fluorine is the first atom to be inserted into highly crowded nitrogen sites at atmospheric pressure. It is thus clear that, in contrast to the chlorine atom, fluorine atom is capable of substituting all or any hydrogen atom in compounds even though greatly hindered.

Structures and Properties of *N*-Fluoropyridinium Salts. The halogen cations, Cl^+, Br^+, and I^+, have a strong tendency toward two coordination.[10] They thus combine with pyridine or its derivatives to form two kinds of compounds, depending on the nature of the counter anions. One is ionic 2 : 1 salts of pyridine nucleus (Py) and the halogen atom (X) with noncoordinating counter anions such as ClO_4^- or SbF_6^-, as shown by $[Py_2X]^+ClO_4^-$ or SbF_6^-. The other is 1 : 1 covalent molecular complexes with strongly coordinating anions such as carboxylate anions, PyXOCOR.[11] Moderate counter anions such as NO_3^- form both types of compounds, $[Py_2X]^+NO_3^-$ and $PyXONO_2$.

All synthesized *N*-fluoropyridinium compounds possessing non- or weakly coordinating counter anions are concluded to possess completely ionic 1 : 1 structures, $[PyF]^+Y^-$ (Y^-; counter anion). The ease of formation and high stability of 1 : 1 salts contrast sharply with other halogens having the two-coordination form. The reason for this must surely be the low polarizability or lack of d-orbitals of the fluorine atom, or the great difficulty of positive fluorine F^+ formation.[2]

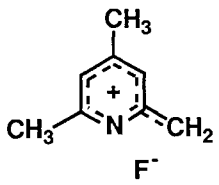
N-Fluoropyridinium fluoride is an unstable solid with an explosive nature, while *N*-fluoropyridinium salts possessing nonnucleophilic counter anions are stable crystals with high melting points. *N*-Fluoropyridinium methanesulfonate (**1c**), a salt having a weakly nucleophilic counter anion, is also stable crystals which melt at 140—142 °C. *N*-Fluoropyridinium trifluoroacetate is also stable at room temperature though its pure salt could not be isolated in the present study. But *N*-fluoropyridinium acetate, a salt having a strongly coordinating or considerably nucleophilic counter anion, was shown by the present data to decompose at room temperature. The stability of *N*-fluoro salts thus clearly depends on the basicity or nucleophilicity of the counter anions. Salts **1** with nonnucleophilic counter anions except for $^-OSO_2F$ are nonhygroscopic crystals.

Electron-withdrawing substituents on the pyridine ring lessen the stability of *N*-fluoropyridinium salts. Particularly 2-fluoro salt **25** and 2,6-dicyano salt **45** were sensitive to moisture. Hydrolysis experiments have afforded some further evidence. The hydrolysis of **1a** in water proceeded quite slowly while that of 3,5-dichloro salt **29a**, rapidly to give 2-pyridinol **56**. Its isomer, 2,6-dichloro salt **28**, was hydrolyzed somewhat slowly, giving other types of hydrolysis products, *N*-fluoro-2-pyridone **57** and 4-pyridinol **58**. Thus, the activating effect of a chlorine atom is outstanding, as is also the blocking effect of an α-chlorine atom. The latter effect suffices to explain why **28** is more stable than **29a** in air in spite of more activation of the N–F moiety of **28**. It should be clear now that, although extremely activated, pentachloro salts **30a** and **30b**, in which all positions are blocked, still possess relatively high stability.



67

Scheme 2.



69

Fig. 2.

The hydrolysis of *N*-fluoropyridinium salts contrasts sharply with that of other pyridinium salts having electron-withdrawing groups at the nitrogen sites. *N*-Cyano, -nitro, -nitroso and -(2,4-dinitrophenyl)pyridinium salts and pyridine–SO_3 complex have all been shown to undergo ring opening reaction by alkaline hydrolysis, giving glutaconaldehyde or its derivatives.[14] The mechanism of this is said to be the addition of a hydroxide anion to the α-position. This marked difference may possibly arise from the very different reaction mechanism of *N*-fluoropyridinium salts. As indicated in the related study, *N*-fluoropyridinium salts react with a base to generate a unique carbene **67** (Scheme 2).[8] The detection of traces of 2-pyridyl triflate and 2-fluoropyridine in the alkaline hydrolysis of **1a** supports this mechanism. In the hydrolysis in water, H_2O may serve as a base.

Treatment of **7a** with aq alkaline solution and with a base in an organic solvent afforded different types of products, **54**, **55**, or **60**. They can be explained by an ion pair intermediate **69** (Fig. 2) resulting from deprotonation of **7a**, similar to those for rearrangement reactions of 2- and 4-methylpyridine *N*-oxides.[15]

Conclusions

N-Fluoropyridinium salts provide a new chemistry of pyridine–halogen compounds. Their syntheses can be conducted by counter anion displacement reactions of unstable *N*-fluoropyridinium fluorides and/or insertion reactions of F_2 with salts or complexes of pyridines with protonic acids, silyl esters, and Lewis acids. Their structures and stability characterization, and hydrolysis experiments indicate unique characters of fluorine. The results of this study demonstrate the presence of a new interesting pyridinium salt system based on the superlative nature of fluorine and thus extend the concept of pyridine and fluorine chemistry.

The authors thank Mr. Shinji Fukami (from Onoda Cement Company) for his technical assistance.

(Received October 29, 1990)

Green crystals were obtained after a reduction of riboflavin (RF) with $Na_2S_2O_4$. These crystals were gradually oxidized to RF when stored in air, even at −10°C. The emission spectra and X-ray powder diffraction analyses of the green crystals clearly showed different patterns from those of RF. The ESR spectra and number of the reduced species determined by the titration with $KMnO_4$ supported the formation of an RF-flavosemiquinone radical (1 : 1) complex. Reduced riboflavin tetrabutyrate prepared according to the same procedure was too unstable for dioxygen to obtain spectroscopic data.

The biochemical activities of riboflavin (RF), vitamin B_2, have long attracted attention, for example, as a precursor of flavin adenine dinucleotide, which has an important role as a coenzyme for the flavoproteins.[1] Although the reduced species of RF were unstable, the presence of flavosemiquinone radicals (RFH) was confirmed with electron spin resonance (ESR) and UV spectroscopy.[2] Further, the in situ reduction of RF with $Na_2S_2O_4$ or $SnCl_2$ in an aqueous solution has resulted in some spectra of mixtures of reduced riboflavins involving RFH, which may be produced according to the equilibrium scheme shown in Chart 1.[2] Unstable RFH, once prepared, was easily oxidized again to RF by exposure to air.[3]

The authors first separated a mixture of RF and RFH as fine green crystals out of a solution of RF reduced with $Na_2S_2O_4$. The stability of the crystals in air was studied quantitatively by reflection spectroscopy. For the separated crystals infrared (IR) and ESR spectra, as well as X-ray powder diffraction patterns, were measured, providing the composition of the green crystals. The same procedures were also applied to riboflavin tetrabutyrate (RTB)[4] to give reduced riboflavin tetrabutyrate (RTBH).

Therefore, the preparation, stability, and composition of RFH and RTBH in the crystals could be described from both chemical and spectroscopic standpoints.

Experimental

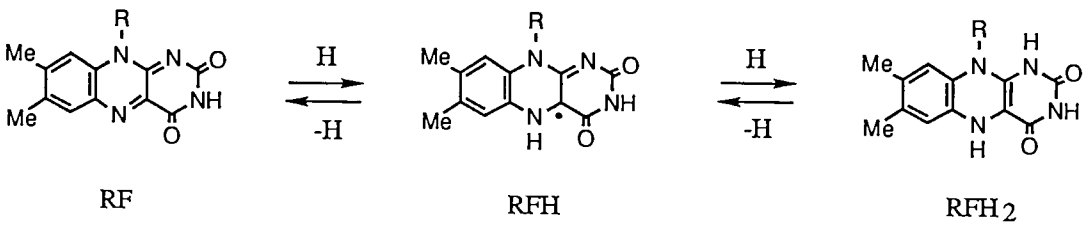
Preparation of RFH. RF (5.0 g) was dissolved in boiling water (3 l). Insoluble powdery materials were removed by filtration. To the solution, cooled at 60 °C, was added $Na_2S_2O_4$ (0.9 g). Within a few minutes a separated dark solid changed to green. The reaction solution was kept in an ice bath for 3 h. Fine crystals which precipitated were separated and washed twice with ice-cold water. Finally, the crystals were washed with ethanol and dried at 60 °C for 24 h under reduced pressure (130 Pa). Dark-green fine needles (ca. 0.1 mm long, yield. 2.89 g) were obtained.

Preparation of RTB. Crude RTB prepared from *n*-butyric acid, pyridine, $POCl_3$, and RF by heating at 70—75 °C for 5 h was recrystallized from 85% MeOH.

Preparation of RTBH. RTB (5.0 g) was dissolved in hot MeOH-H_2O (45 : 55) (2.1 l). To the solution, kept at 60 °C, was added $Na_2S_2O_4$ (0.5 g). After the solution was cooled in an ice bath for 3 h, precipitated green crystals were collected by filtration, washed twice with water, and then dried at 60 °C for 12 h under reduced pressure. Yield 4.3 g. Mp 148.2 °C.

Oxidation of RFH or RTBH with $KMnO_4$. Fine crystals (0.3 g) prepared by the reduction of RF were dispersed in 1% H_2SO_4 (100 ml). The solution was titrated with 2×10^{-3} mol dm^{-3} $KMnO_4$ under magnetic stirring. The end point of titration was determined potentiometrically with an $HgCl_2$-Pt electrode as a standard half cell.

Freshly prepared RTBH (500 mg) was dissolved in acetic acid (50 ml). To the solution was added 10% H_2SO_4 (10 ml) and water (40 ml). Then, RTBH was titrated with 2×10^{-3}



RF RFH RFH_2

R=ribityl

Chart 1.

mol dm^{-3} $KMnO_4$.

Emission Spectra Measurement. Emission spectra were recorded on a Shimadzu RF-502 type spectrophotometer. Powdery samples were packed in a holder and measured under the following conditions: Excitation slit, 15 nm; emission slit 2.2 nm; excitation wavelength, 370 nm.

X-Ray Powder. Diffraction Measurement. An X-ray powder diffraction analysis was carried out using an X-ray diffractometer (Geigerflex D-8C, Rigaku Co.). The conditions were: Target, Cu; filter, Ni; voltage, 30 kV; current, 20 mA; time constant, 1 s; sweep, 2° min^{-1}; divergency slit, 1°; receiving slit, 0.4 mm; detector, Geiger Müller counter.

ESR Measurement. ESR spectra were recorded on a JES-FE3X type spectrometer (X band, 100 kHz modulation). The conditions were: Power, 20 mW; modulation amplitude, 0.63 mT; scan rate, 3.125 mT min^{-1}; time constant, 1 s; gain, 2×1000.

Reflection Spectra Measurement. Reflection spectra were recorded on a Hitachi 228 A type spectrometer equipped with a spherically integrated reflection apparatus (150 mm i.d.). Fine crystals were packed in a dark cell and covered with a glass plate.

IR Spectra Measurement. IR spectra were recorded on a Hitachi 260-50 type spectrometer after preparing KBr tablets by mixing powdery samples (2 mg) with KBr powder (200 mg) and compressing the mixture.

Results and Discussion

The Stability of Reduced RF and Reduced RTB. Fine dark-green needles obtained by the reduction of RF with $Na_2S_2O_4$ were gradually oxidized by exposure to the air.

The color of the crystals changed from green to yellow according to the progress of oxidation. The time courses in the oxidation of the crystals of reduced RF and RTB in air were traced with the reflection spectra.

As shown in Fig. 1, a crystal of reduced RF stored at room temperature was rapidly oxidized into RF during 10 d, followed by slow oxidation. Reduced RF stored at −10 °C also oxidized into RF, although the rate was slower than that at room temperature. The oxidation rate of reduced RTB was twice as fast as that of reduced RF.

Since an RTBH molecule possesses considerably large substituent groups, the average distance between two isoalloxazine rings in a crystal of RTBH may be greater than that in a crystal of RFH. Then, the overlap of the orbitals of the unpaired electron with those of π-electrons on other isoalloxazine rings for RTBH crystal may be smaller than that for the RFH crystal. Therefore, the instability of RTBH crystal against oxidation may be ascribed to delocalization of unpaired electrons over aromatic rings in the crystal.

The nuclear magnetic resonance and high-performance liquid chromatography analysis of a diluted solution of the fine needles failed, since fast oxidation took place to give RF exclusively. Also, an elemental analysis could not be carried out due to an increase in weight during the weighing operation.

IR Spectra. The IR spectra of the fine needles of reduced RF in KBr tablets were obtained and compared with those of RF. A strong, wide spectral band of RFH observed at 3400 cm^{-1} could be assigned to newly formed NH groups. The spectral bands of amide groups of RF at 1736 and 1650 cm^{-1} were spread and duplicated to make one broad band at 1635 cm^{-1}. On the other hand, the IR spectrum of reduced RTB

1: RF, 2: Reduced RF.

crystals was the same as that of RTB, suggesting a fast oxidation of the crystal during the preparation of KBr tablets.

Emission Spectra. The emission spectra of crystals of reduced RF and RTB are shown in Fig. 2. The spectral intensity for reduced RF just after preparation is very weak, whereas that for RF is strong. When the crystals of reduced RF dispersed in water came into contact with oxygen by bubbling through air at room temperature, the spectral intensity gradually approached that of RF. Oxidation with a $KMnO_4$ solution (2×10^{-3} mol cm^{-3}) increased the peak intensity for the reduced RF to that of RF. The same tendency was also observed for reduced RTB, except that the oxidation rate with air was faster than reduced RF.

X-Ray Diffraction of Powders. An X-ray powder analysis was carried out for reduced RF. As shown in Fig. 3, the diffraction pattern clearly differed from that of RF. No peaks from RF were observed. The X-ray diffractogram of reduced RF was rather simple and the number of peaks was smaller than those of RF. Sharp peaks were spread from $2\theta=10°$ to 50°, suggesting the presence of well crystallized solids. The relative intensities of peaks as low as at 7.0° and 8.0° were very strong in reduced RF. These facts suggest that RF and RFH produced new structures. The crystals of reduced RTB were unstable in air. The patterns of the X-ray spectra taken after 3 d were almost the same as those of yellow RTB crystals.

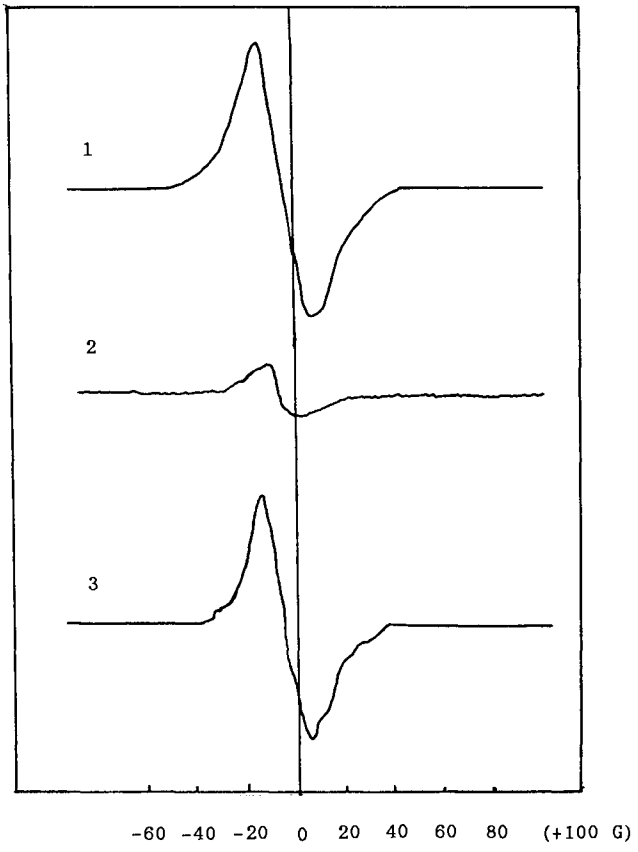

Fig. 4. ESR spectra of the crystals of reduced RF and reduced RTB in the solid state.
1: Reduced RF, 2: RF, 3: Reduced RTB.

ESR Spectra. A solid RF showed weak ESR signals. On the other hand, orange RTB crystals gave no ESR signals.[5] In contrast, the crystals of RFH and RTBH gave strong signals at $g=2.005$ (Fig. 4). The half-width for reduced RF or RTB was 2.278 or 1.964 mT, respectively. Well-resolved hyperfine structures were observed for the latter. The intensities of signals for reduced RF was 5.8-times stronger than that of reduced RTB. These results suggest that the reduced RF crystals contained flavosemiquinone radicals.

Composition of the Crystals of Reduced Riboflavins. The quantitative oxidation of freshly prepared crystals of reduced RF with $KMnO_4$ showed that the molar ratio (RF : RFH) was 47.1 : 52.9. The purity of RF after oxidation was 99.7%. On the other hand, the molar ratio of RTB : RTBH was 86.9 : 13.1. To explain these results, two possible cases were considered. In the first case, a mixture or a complex of RF-RFH (1 : 1) formed a quasi-stable species. The other case involved the formation of a mixture or a complex of RF-RFH_2 (3 : 1). X-Ray powder patterns of RFH contained no peaks from orange RF crystals. The intensity of the emission spectra of the crystals of reduced RF was approximately nil, while those of RF crystals were strong when excited at 370 nm. Furthermore, the ESR spectra showed the presence of radical species in the crystals of reduced RF. When RF was hydrogenated, the color of crystals changed from orange to dark green, and then faded to pale green.

All of these results suggest that unstable RFH_2 formed during the first stage of reduction was quickly oxidized into an RF-RFH (1 : 1) complex followed by successive oxidation to give RF in an oxidative atmosphere.

Manganese(III) or Cobalt(III)-Mediated Oxidative Radical Reactions of Terminal Dienes. One-Pot Synthesis of Bis(dihydrofuran)s

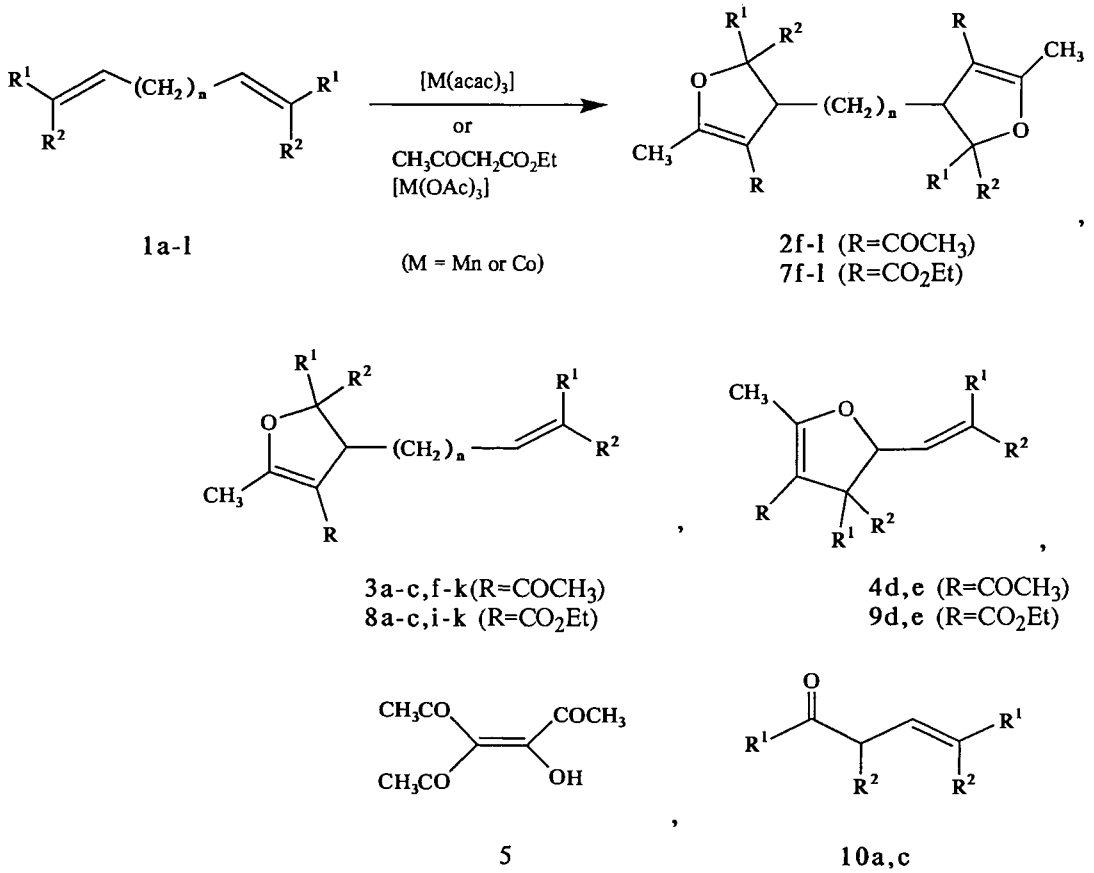
Hiroshi NISHINO,* Tomoaki YOSHIDA, and Kazu KUROSAWA
Department of Chemistry, Faculty of Science, Kumamoto University,
Kurokami 2-39-1, Kumamoto 860
(Received October 31, 1990)

The reactions of terminal dienes such as 1,4-pentadienes and 1,5-hexadienes with tris(2,4-pentanedionato)-manganese(III) ([Mn(acac)$_3$]) gave α,ω-bis(dihydrofuryl)alkanes (abbreviated bis(dihydrofuran)s, hereafter) in good yields. The reactions with tris(2,4-pentanedionato)cobalt(III) ([Co(acac)$_3$]) instead of [Mn(acac)$_3$] yielded the same bis(dihydrofuran)s quantitatively. The dienes also reacted with ethyl 3-oxobutanoate in the presence of manganese(III) acetate ([Mn(OAc)$_3$]) or cobalt(III) acetate ([Co(OAc)$_3$]) to produce the corresponding bis(dihydrofuran)s. The reactions of 1,3-butadienes with the manganese(III) or cobalt(III) complexes afforded only mono(dihydrofuran)s and oxidative rearrangement products, but the corresponding bis(dihydrofuran)s were not formed. The reaction of 1,5-hexadienes with ethyl hydrogen malonate in the presence of [Mn(OAc)$_3$] did not give bis-annulated products, but mono(γ-lactone)s in moderate yields. The synthetic applications and limitations of the bis(dihydrofuran)s formation are discussed.

Recently, one of the most interesting synthetic methods in organic chemistry was reported. That is the technique involving the intermolecular or intramolecular cyclization reaction of alkenes or alkynes using metal compounds, such as palladium, nickel, cobalt, ruthenium, manganese, chromium, and so on.[1] Especially, we are very interested in the intermolecular or intramolecular radical cyclization reaction using manganese(III) or cobalt(III) complexes.[1c] Previously we reported the oxidation of alkenes with malonic acid in the presence of manganese(III) acetate[2] which was simply abbreviated [Mn(OAc)$_3$].[3] This reaction gave 2,7-dioxaspiro[4.4]nonane-1,6-diones in high yields, although we could not control their stereochemistry at the C-3 and C-8 carbons. Similar reactions with malonic acid derivatives, such as methylmalonic acid, bromomalonic acid, chloromalonic acid, and ethyl hydrogen malonate, yielded the corresponding 2-carboxy-4-butanolides and/or 2-buten-4-olides in good yields.[5] Using malonamide or 2-cyanoacetamide instead of malonic acid in these oxidation reactions afforded not only 2-buten-4-olides, but also 1,5-dihydro-2*H*-pyrrol-2-ones in moderate yields.[6,7] Fristad,[8] Snider,[9] Corey,[10] and Citterio[11] also reported the manganese(III)-mediated inter- or intra-molecular radical cyclization reactions. In connection with the oxidative inter- or intramolecular cyclization reaction using [Mn(OAc)$_3$], we noticed that the ligand-exchange reaction of the manganese(III) complex occurred easily in acetic acid and the corresponding ligand radicals were readily formed.[12] Then, we discovered the facile synthesis of dihydrofurans using tris(2,4-pentanedionato)-manganese(III) ([Mn(acac)$_3$]).[12a] It was also shown that tris(2,4-pentanedionato)cobalt(III) ([Co(acac)$_3$]) had a similar role in acetic acid.[12c] Heiba and Dessau reported that the reaction of styrene with ethyl 3-oxobutanoate in the presence of [Mn(OAc)$_3$] also gave the corresponding dihydrofuran in 57% yield.[13] Corey applied these methods to enol ethers and obtained 2-alkoxy-2,3-dihydrofurans which were transformed to fused or spiro 2-cyclopentenones or converted to the corresponding furans in good yields.[14] However, any attempts to get α,ω-bis(dihydrofuryl)alkanes (abbreviated bis(dihydrofuran)s, hereafter), which might have either an antibiotic nature or bioactive character[15] or might be used as a starting material for the synthesis of many kinds of natural products containing furan rings,[16] were not accomplished by taking advantage of the ligand-exchange process of the manganese(III) or cobalt(III) complexes. We describe in this paper the one-pot synthesis of bis(dihydrofuran)s using Mn(III)- or Co(III)-promoted annulation.

Results

Reaction of Dienes with [Mn(acac)$_3$] or [Co(acac)$_3$]. We used 1,3-butadienes (**1a—e**), 1,4-pentadienes (**1f—h**), and 1,5-hexadienes (**1i—l**) as a substrate (Fig. 1). The reaction of **1a** with [Mn(acac)$_3$] was carried out in the molar ratio from 1 : 4 to 1 : 10 in boiling acetic acid until the oxidant was consumed completely, which gave only 4-ethenyl-4,5-dihydrofuran (**3a**) and 3-acetyl-4-hydroxy-3-hexene-2,5-dione (**5**) in the yields shown in Table 1. An expected bis(dihydrofuran), however, was not formed. The reaction of **1b—e** with [Mn(acac)$_3$] also gave only mono(dihydrofuran)s (**3b**,c and **4d**,e) and the dione (**5**). The results for the reaction of **1d** and **1e** were similar to Hanafusa's work.[17] The 1,4-pentadiene (**1f**) reacted with [Mn(acac)$_3$] to afford the expected bis(dihydrofuran) (**2f**) in moderate yield, although mono(dihydrofuran) (**3f**) was also formed together with **2f** in the reaction at a lower oxidant/substrate ratio (Table 1, Entry 11). The same type of products were obtained from the reactions of **1g** and **1h** (Table 1, Entries 14 and 16). Similar reactions of 1,5-hexadienes (**1i—l**) with



a : n=0, R^1=R^2=Ph
b : n=0, R^1=R^2=4-ClC_6H_4
c : n=0, R^1=R^2=4-MeC_6H_4
d : n=0, R^1=Ph, R^2=H
e : n=0, R^1=R^2=Me
f : n=1, R^1=R^2=Ph
g : n=1, R^1=R^2=4-ClC_6H_4
h : n=1, R^1=R^2=4-MeC_6H_4
i : n=2, R^1=R^2=Ph
j : n=2, R^1=R^2=4-ClC_6H_4
k : n=2, R^1=R^2=4-MeC_6H_4
l : n=2, R^1=R^2=4-$MeOC_6H_4$

Fig. 1.

[Mn(acac)3] gave the expected bis(dihydrofuran)s (**2i—k**) in good yields except for **2l** (Table 1).

The reaction using [Co(acac)3] instead of [Mn(acac)3] resulted in an increased yield of the bis(dihydrofuran). Especially, bis(dihydrofuran)s (**2i—l**) were obtained quantitatively. However, the yield of mono(dihydrofuran)s (**3a—c**, **4e**) was not improved in the oxidation of **1a—e**.

Reaction of Dienes with Ethyl 3-Oxobutanoate in the Presence of Manganese(III) Acetate or Cobalt(III) Acetate. The dienes (**1a—l**) were oxidized with [Mn(OAc)3] in the presence of ethyl 3-oxobutanoate under various reaction conditions. The results are shown in Table 2. When **1f—l** were used during this reaction, the corresponding bis(dihydrofuran)s (**7f—l**) were produced in good to moderate yields. However, we could not obtain any bis(dihydrofuran)s in the case of 1,3-butadienes (**1a—e**), but only ethenyl-substituted dihydrofurans (**8a—c**, and **9d,e**) together with oxidative rearrangement products (**10a,c**). On the other hand, the reaction of 1,5-hexadienes (**1i—l**) with cobalt(III) acetate ([Co(OAc)3])[18] gave both bis(dihydrofuran)s (**7i—l**) and mono(dihydrofuran)s (**8i—k**). The product yields of the reactions by [Co(OAc)3], however, were lower than those of the reactions employing [Mn(OAc)3].

Reactions of 1,5-Hexadienes (1i—l) with Ethyl Hydrogen Malonate in the Presence of [Mn(OAc)3]. It was reported that the reaction of 1-heptene with diethyl malonate in the presence of [Mn(OAc)3]/[Cu(OAc)2] afforded heptylmalonate.[20] However, intramolecular cyclization did not occur under the reaction conditions. Fristad examined the reaction of 1,5-hexadienes with malonic acid and obtained 2,7-dioxacyclopenta[*c*]pentalene-1,8-diones in low yields.[8a] So the reaction of **1i—l** with ethyl hydrogen malonate in the presence of [Mn(OAc)3] was examined in order to get bis-annulated lactone and compare this

Table 1. Reaction of Terminal Dienes (**1a**—**l**) with [M(acac)$_3$] (M=Mn, Co) in Boiling Acetic Acid

Discussion

We reported the reaction mechanism for the formation of the dihydrofuran ring involving diacetylmethyl radical, ·CH(COCH$_3$)$_2$, which was produced by the thermolysis of [Mn(acac)$_3$] or [Co(acac)$_3$] in boiling acetic acid.[12a)] Therefore, the formation of bis(dihydrofuran)s (**2f—l**) using [Mn(acac)$_3$] or [Co(acac)$_3$] could be also explained by an akin mechanism previously discussed. The reactions of 1,4-pentadienes (**1f—h**) and 1,5-hexadienes (**1i—l**) with [Mn(acac)$_3$] or [Co(acac)$_3$] gave expected **2f—l** in good yields. However, it was very difficult to get the corresponding bis(dihydrofuran)s by the reaction of 1,3-butadienes (**1a—e**), and considerable amounts of **1a—c** were recovered even for the reactions at a high oxidant/substrate ratio after completion of the reaction. This was considered to be due to the bulky diacetylmethyl radicals not being able to attack the other sterically crowded double bond after forming one dihydrofuran ring in the 1,3-butadiene molecule, because **1a—c** have two pairs of aryl groups at the terminal carbons and the carbon chain (n=0) was very short. Therefore, only mono(dihydrofuran)s (**3a—c** and **4d,e**) were obtained from the reaction of **1a—e**. The generation of isomeric ring systems of **3a—c** and **4d,e** is due to the stability of the intermediate radical (**I** and **II**), that is to say, the benzyl type radical **I** formed from **1a—c** was stabilized by two aryl groups (R^1=R^2=aryl) and the allyl type radical **II** produced from **1d** and **1e** was stabilized by allyl conjugation (Fig. 3). For the reaction of 1,4-pentadienes (**1f—h**) using [Co(acac)$_3$] the yield of **2f—h** was slightly better than that using [Mn(acac)$_3$]. However, the yield of **2g** was low in both cases since the corresponding benzyl radical, e.g., radical **I** was destabilazed by the inductive effect of chloro-substituent on the aryl ring. The reaction of 1,5-hexadienes (**1i—l**) with [Co(acac)$_3$] gave **2i—l** quantitatively and no effect of substituents was

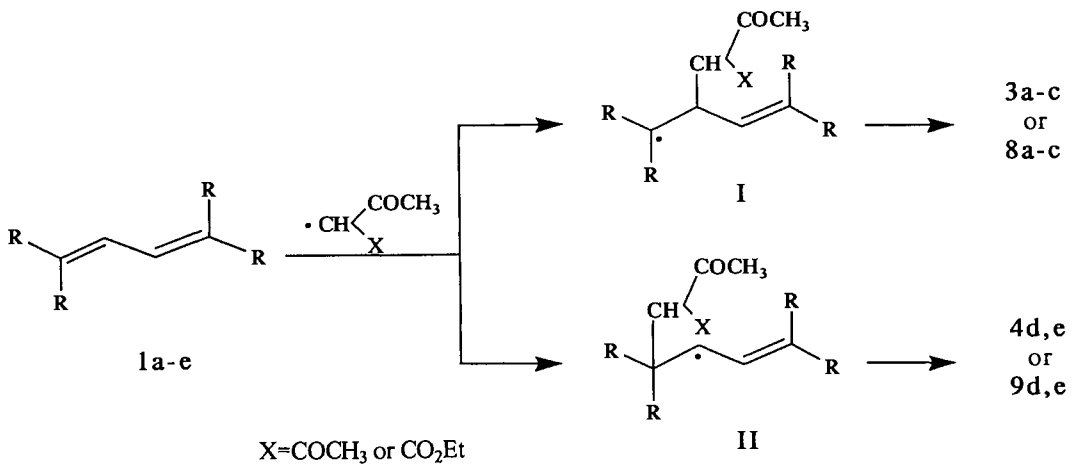

Fig. 3.

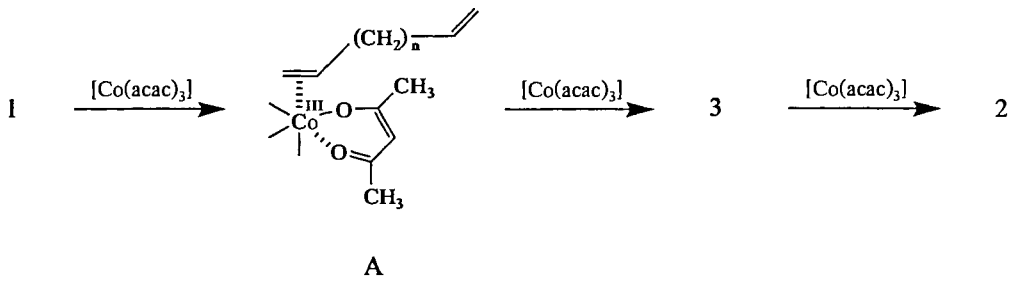
observed. On the other hand, **2l** was obtained in poor yield when [Mn(acac)$_3$] was used. This result clearly showed that the electron-transfer from **1l** to Mn(III), generally observed during the oxidation with metal compounds,[1c,21] occurred predominantly since the electron-donating effect of the methoxyl group on the aromatic ring lowered the ionization potential of **1l**.[6,22-24] Actually 4,4′-dimethoxybenzophenone (**6**), which was a typical product via the electron-transfer reaction process, was obtained as the main product (Table 1, Entry 25).

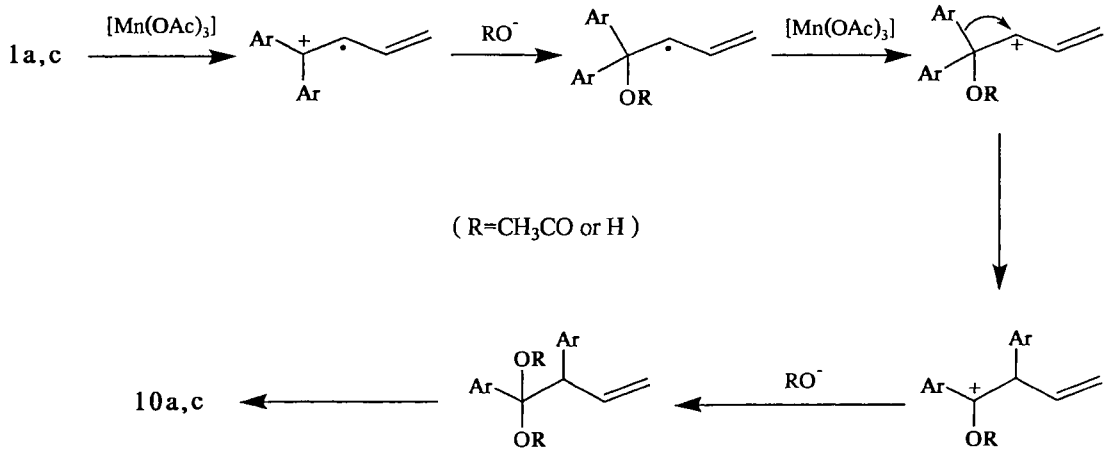
In order to explain the fact that [Co(acac)$_3$] was superior to [Mn(acac)$_3$] for the formation of dihydrofuran ring, we propose the mechanism via the complex formation between [Co(acac)$_3$] and diene. The nature of the complex could be either π- or σ-complex,[25-28] but it is not clear at present moment. Then the oxidation of the complex (**A**) with Co(III) would give rise to mono(dihydrofuran) (**3**). The similar reaction of **3** with [Co(acac)$_3$] was repeated to yield bis(dihydrofuran) (**2**). The reaction mechanism is briefly shown in Scheme 1. On the other hand, it was considered that [Mn(acac)$_3$] could not make a complex (e.g., either π-complex or σ-complex) with the terminal diene or the interaction between [Mn(acac)$_3$] and the diene was very weak. Accordingly, the diacetylmethyl radical has roughly two chances for coupling reactions; one is the coupling between the diene and diacetylmethyl radical and the other is a bimolecular radical coupling of the diacetylmethyl radical itself. In fact, the by-product (**5**), which is usually formed in the [Mn(acac)$_3$]-AcOH oxidation system, was obtained in all of the reactions with [Mn(acac)$_3$] regardless of these substrates.[22] The formation mechanism of **5** via the bimolecular radical coupling of diacetylmethyl radical will be discussed elsewhere.[12c]

Similar results for the synthesis of bis(dihydrofuran)s were obtained by the reaction of dienes (**1a—l**) with ethyl 3-oxobutanoate in the presence of [Mn(OAc)$_3$] or [Co(OAc)$_3$]. In the case of **1i—l**, however, the product yields using [Co(OAc)$_3$] were lower than those using [Mn(OAc)$_3$]. This can be ascribed to the different behavior of [Mn(OAc)$_3$] and [Co(OAc)$_3$] in the reaction system. In other words, if ethyl 3-oxobutanoate radical, ·CH(COCH$_3$)CO$_2$Et, is formed during the ligand-exchange reaction between metal acetate and the oxobutanoate,[8a,29] the ligand-exchange reaction between [Mn(OAc)$_3$] and the oxobutanoate must be much faster than that between [Co(OAc)$_3$] and the oxobutanoate. Therefore, the reaction of **1i—l** in the presence of [Mn(OAc)$_3$] gave the corresponding bis(dihydrofuran)s (**7i—l**) in good yields for much shorter reaction time (4—9 min). On the other hand, it must need much longer reaction time (90—180 min) for the consumption of



A

Scheme 1.



Scheme 2.

[$Co(OAc)_3$] since the ligand-exchange reaction between [$Co(OAc)_3$] and the oxobutanoate is much slower, although Co(III) is a stronger oxidant than Mn(III) according to the comparison with the standard potential ($E°$) of single electrode.[30] Thus, it is considered that the yields of **7i—l** are lower than those using [$Mn(OAc)_3$] since the ligand-exchange reaction between [$Co(OAc)_3$] and the oxobutanoate competes with other side-reactions such as oxidative decarboxylation of solvent.[31] It is noteworthy that the reactions of **1a** and **1c** with [$Mn(OAc)_3$] gave oxidative rearrangement products (**10a** and **10c**) along with mono(dihydrofuran)s (**8a** and **8c**). This rearrangement is presumed to occur via the oxidation through the electron-transfer process regardless of the presence of ethyl 3-oxobutanoate (Scheme 2). Furthermore, it was confirmed that the rearrangement occurred intramolecularly according to the result for the cross-over experiment (see Experimental).

It is not clear why no bis-annulated compound was formed in the reaction with ethyl hydrogen malonate. Even if the molar ratio of **1i**:ethyl hydrogen malonate:[$Mn(OAc)_3$] was increased up to 1:6:7, the corresponding bis-annulated lactone was not isolated and an intractable mixture was obtained (see Experimental). Probably, **11i** was simply oxidized with [$Mn(OAc)_3$] to give a complex mixture before the second attack of $\cdot CH(CO_2Et)CO_2H$ radical to **11i**, or ethyl hydrogen malonate itself was also oxidized to decomposition (the decomposed products were not checked).

In conclusion, [$Co(acac)_3$] has a higher selectivity for the formation of bis(dihydrofuran)s than [$Mn(acac)_3$]. [$Mn(OAc)_3$] is better than [$Co(OAc)_3$] for the production of bis(dihydrofuran)s in the presence of ethyl 3-oxobutanoate under present reaction conditions. In addition, the terminal dienes, which have longer carbon chains than 1,3-butadienes, are advantageous for the synthesis of bis-annulated compounds. We firmly believe that the synthesis of bis(dihydrofuran)s utilizing the present method is important since bis(dihydrofuran)s can be converted to the corresponding bis(furan)s and bis(tetrahydrofuran)s.

Experimental

Instrumentation. ^1H NMR spectra were measured in chloroform-*d* on either a JEOL JNM-PMX60SI or a JEOL FX90Q spectrometer. Chemical shifts are reported in ppm downfield from an intermal TMS standard. Infrared spectra were recorded in chloroform on a JASCO A-102 infrared spectrometer. The IR spectral data are expressed in cm^{-1}. Mass spectra were measured on either a JEOL JMS-01SG-2, JMS-DX303HF, or a Finnigan 6000 GC/MS mass spectrometer at 70 eV of ionization energy. All melting points were determined with a Yanaco MP-J3 micromelting point apparatus (Yanagimoto) and were uncorrected. Elemental analyses were performed by the Elemental Analysis Center, Faculty of Science, Kyushu University.

Materials. Tris(2,4-pentanedionato)manganese(III),[32] manganese(III) acetate,[33] and cobalt(III) acetate[19] were prepared according to methods previously described. Tris(2,4-pentanedionato)cobalt(III) (Wako) was used as received. 1,3-Butadienes (**1a—c**) were prepared by dehydration of the corresponding diols which were synthesized from diethyl succinate (Nacalai) and the corresponding phenylmagnesium bromide. 1,1,4,4-Tetraphenyl-1,3-butadiene (**1a**): Yellow microcrystals (from benzene), mp 195—197 °C (lit,[34] mp 192—193 °C). 1,1,4,4-Tetrakis(4-chlorophenyl)-1,3-butadiene (**1b**): Yellow needles (from benzene), mp 240—242 °C (lit,[35] mp 244 °C). 1,1,4,4-Tetrakis(4-methylphenyl)-1,3-butadiene (**1c**): Pale yellow needles (from acetic acid), mp 251—253 °C (lit,[36] mp 248—250 °C). 1,4-Diphenyl-1,3-butadiene (**1d**) (Aldrich) and 2,5-dimethyl-2,4-hexadiene (**1e**) (Aldrich) were used as received. 1,4-Pentadienes (**1f—h**) were prepared from diethyl glutarate (Tokyokasei) and the corresponding phenylmagnesium bromide according to the similar reaction previously mentioned. 1,1,5,5-Tetraphenyl-1,4-pentadiene (**1f**): Orange liquid; IR 1656 (C=C); ^1H NMR δ=2.80—3.17 (2H, m, $-CH_2-$), 5.90—6.25 (2H, m, 2×=CH-), and 6.90—7.70 (20H, m, 4×Ph). 1,1,5,5-Tetrakis(4-chlorophenyl)-1,4-pentadiene (**1g**): Yellow liquid; IR 1650 (C=C); ^1H NMR δ=2.67—3.13 (2H, m, $-CH_2-$), 5.83—6.23 (2H, m, 2×=CH-), and 6.77—7.78 (16H, m, arom. H). 1,1,5,5-Tetrakis(4-methylphenyl)-1,4-pentadiene (**1h**): Pale yellow microcrystals (from benzene-petroleum ether), mp 94—96 °C; IR 1665 (C=C); ^1H NMR δ=2.30 (6H, s, 2×Me), 2.34 (6H, s, 2×Me), 2.78—3.13 (2H, m, $-CH_2-$), 5.88—6.22 (2H, m, 2×=CH-), and 6.93—7.22 (16H, m, arom.H). 1,1,6,6-Tetraphenyl-1,5-hexadiene (**1i**) was prepared from 1,4-dibromobutane (Wako) and benzophenone (Wako) according to the procedure previously described: Colorless needles (from ethyl acetate-ethanol), mp 101—102 °C (lit,[37] mp 108—109 °C). Other 1,5-hexadienes (**1j—l**) were prepared from diethyl adipate (Nacalai) and the corresponding phenylmagnesium bromide. 1,1,6,6-Tetrakis(4-chlorophenyl)-1,5-hexadiene (**1j**): Colorless microcrystals (from ethyl acetate-ethanol), mp 177—179 °C; IR 1669 (C=C); ^1H NMR δ=2.12—2.33 (4H, m, 2×$-CH_2-$), 5.83—6.20 (2H, m, 2×CH-), and 6.90—7.60 (16H, m, arom.H). 1,1,6,6-Tetrakis(4-methylphenyl)-1,5-hexadiene (**1k**): Colorless microcrystals (from benzene-hexane), mp 134—136 °C; IR 1660 (C=C); ^1H NMR δ=2.11—2.29 (4H, m, 2×$-CH_2-$), 2.31 (6H, s, 2×Me), 2.39 (6H, s, 2×Me), 5.94—6.23 (2H, m, 2×=CH-), and 6.91—7.58 (16H, m, arom.H). 1,1,6,6-Tetrakis(4-methoxyphenyl)-1,5-hexadiene (**1l**): Yellow-green needles (from ether), mp 106—107 °C (lit,[38] mp 108 °C). Ethyl 3-oxobutanoate (Wako) was used as received. Ethyl hydrogen malonate was prepared from diethyl malonate (Wako) according to the literature:[39] Colorless liquid, bp_{19} 145 °C (lit,[39] bp_{21} 147 °C).

Reaction of Terminal Dienes with [Mn(acac)$_3$]. The typical procedure for the reaction of terminal dienes with [$Mn(acac)_3$] was as follows. To a heated solution of a terminal diene (0.5—1.0 mmol) in acetic acid (30 cm^3), [$Mn(acac)_3$] was added. The mixture was heated under reflux until the opaque dark brown color turned a clear yellow. The solvent was removed in vacuo and the residue was triturated with 2M (1M=1 mol dm^{-3}) HCl (30 cm^3), followed by extraction with chloroform. The chloroform extract was concentrated and the residue was separated on TLC (either Wakogel B-10 or Kieselgel 60G) with chloro-

form as the developing solvent. The yields are summarized in Table 1.

Reaction Products. 3-Acetyl-2-methyl-4-(2,2-diphenylethenyl)-5,5-diphenyl-4,5-dihydrofuran (3a): Yellow liquid; IR 1662 (C=O); ^{1}H NMR δ=2.21 (3H, s, COMe), 2.37 (3H, s, Me), 4.81 (1H, d, J=11.0 Hz, >CH-), 5.44 (1H, d, J=11.0 Hz, =CH-), and 6.54—7.79 (20H, m, 4×Ph); MS m/z (rel intensity) 456 (M^+, 44), 414 (60), 289 (58), 231 (65), 215 (81), 165 (100), and 105 (50). Found: m/z 456.2098. Calcd for $C_{33}H_{28}O_2$: M, 456.2089.

3-Acetyl-4-[2,2-bis(4-chlorophenyl)ethenyl]-5,5-bis(4-chlorophenyl)-2-methyl-4,5-dihydrofuran (3b): Yellow liquid; IR 1664 (C=O); ^{1}H NMR δ=2.27 (3H, s, COMe), 2.38 (3H, s, Me), 4.75 (1H, d, J=11.0 Hz, >CH-), 5.37 (1H, d J=11.0 Hz, =CH-), and 6.47—7.57 (16H, m, arom.H); MS m/z (rel intensity) 594 (M^+, 34), 592 (M^+, 26), 552 (75), 550 (60), 534 (56), 532 (44), 357 (26), 315 (18), 299 (33), 277 (37), 264 (26), 251 (36), 235 (26), 199 (41), 165 (13), 139 (56), and 111 (12). Found: m/z 594.0499; 592.0529. Calcd for $C_{33}H_{24}O_2{}^{35}Cl_3{}^{37}Cl$; $C_{33}H_{24}O_2{}^{35}Cl_4$: M, 594.0506; 592.0530.

3-Acetyl-4-[2,2-bis(4-methylphenyl)ethenyl]-5,5-bis(4-methylphenyl)-2-methyl-4,5-dihydrofuran (3c): Yellow liquid; IR 1661 (C=O); ^{1}H NMR δ=2.18 (3H, s, Me), 2.22 (6H, s, 2×Me), 2.25 (3H, s, Me), 2.35 (3H, s, Me), 2.42 (3H, s, Me), 4.76 (1H, d, J=11.0 Hz, >CH-), 5.12 (1H, d, J=11.0 Hz, =CH-), and 6.51—7.40 (16H, m, arom.H); MS m/z (rel intensity) 512 (M^+, 55), 469 (100), 452 (96), 317 (31), 219 (32), and 195 (49). Found: m/z 512.2707. Calcd for $C_{37}H_{36}O_2$: M, 512.2715.

3-Acetyl-2-methyl-5-[(*E*)-2-phenylethenyl]-4-phenyl-4,5-dihydrofuran (4d): Colorless needles (from methanol), mp 101—103 °C; IR 1663 (C=O); ^{1}H NMR δ=1.86 (3H, s, COMe), 2.38 (3H, d, J=1.8 Hz, Me), 4.18 (1H, dq, J=6 and 1.8 Hz, H-4), 4.91 (1H, t, J=6 Hz, H-5), 6.23 (1H, dd, J=6 and 16 Hz, =CH-), 6.55 (1H, d, J=16 Hz, =CH-), and 6.85—7.55 (10H, m, arom.H). Found: C, 82.76; H, 6.57%. Calcd for $C_{21}H_{20}O_2$: C, 82.86; H, 6.57%.

3-Acetyl-5-(2-methyl-1-propenyl)-2,4,4-trimethyl-4,5-dihydrofuran (4e): Yellow liquid; IR 1655 (C=O); ^{1}H NMR δ=1.07 (3H, s, Me), 1.25 (3H, s, Me), 1.68 (3H, d, J=1.2 Hz, Me), 1.76 (3H, d, J=1.2 Hz, Me), 2.19 (3H, s, Me), 2.26 (3H, s, Me), 4.75 (1H, d, J=10 Hz, >CH-), and 5.38 (1H, br.d, J=10 Hz, =CH-); MS m/z (rel intensity) 209 (100), 208 (M^+, 9), 197 (6), 181 (36), 155 (13), 110 (10), and 83 (3). Found: m/z 208.1443. Calcd for $C_{13}H_{20}O_2$: M, 208.1463.

3-Acetyl-4-hydroxy-3-hexene-2,5-dione (5): Colorless prisms (from benzene), mp 113—114 °C (lit,[22] mp 115—116 °C).

Bis(4-acetyl-5-methyl-2,2-diphenyl-2,3-dihydro-3-furyl)methane (2f): Yellow liquid; IR 1679 (C=O); ^{1}H NMR δ=1.65—1.76 (2H, m, -CH_2-), 2.12 (6H, s, 2×COMe), 2.18 (6H, s, 2×Me), 4.1 (2H, br.t, J=6 Hz, 2×>CH-), and 6.70—7.93 (20H, m, arom.H); MS m/z (rel intensity) 568 (M^+, 15), 468 (10), 401 (5), 290 (100), 277 (53), 235 (10), 191 (10), 167 (15), and 91 (8). Found: m/z 568.2626. Calcd for $C_{39}H_{36}O_4$: M, 568.2614.

3-Acetyl-2-methyl-4-(3,3-diphenyl-2-propenyl)-5,5-diphenyl-4,5-dihydrofuran (3f): Yellow liquid; IR 1663 (C=O); ^{1}H NMR δ=2.01 (3H, s, COMe), 2.08—2.17 (2H, m, -CH_2-), 2.25 (3H, s, Me), 4.03 (1H, br.t, J=6.0 Hz, >CH-), 5.70 (1H, t, J=8.0 Hz, =CH-), and 6.72—7.86 (20H, m, arom.H); MS m/z (rel intensity) 471 (100), 470 (M^+, 4), 458 (7), 337 (32), 227 (29), 183 (26), and 105 (7). Found: m/z 470.2236. Calcd for $C_{34}H_{30}O_2$: M, 470.2246.

Bis[4-acetyl-2,2-bis(4-chlorophenyl)-5-methyl-2,3-dihydro-3-furyl]methane (2g): Yellow liquid; IR 1660 (C=O); ^{1}H NMR δ=0.80—1.08 (2H, m, -CH_2-), 2.10 (6H, s, 2×COMe), 2.27 (7H, s, 2×Me), 4.0—4.3 (2H, m, >CH-), and 6.87—7.67 (16H, m, arom.H); MS m/z (rel intensity) 706 (M^+, 3), 704 (M^+, 2), 606 (5), 604 (4), 509 (3), 507 (2), 358 (64), 345 (31), 316 (7), 235 (12), 199 (9), and 139 (8). Found: m/z 704.1011. Calcd for $C_{39}H_{32}O_4{}^{35}Cl_4$: M, 704.1055.

3-Acetyl-4-[3,3-bis(4-chlorophenyl)-2-propenyl]-5,5-bis(4-chlorophenyl)-2-methyl-4,5-dihydrofuran (3g): Yellow liquid; IR 1697 (C=O); ^{1}H NMR δ=1.72—1.97 (2H, m, -CH_2-), 2.10 (3H, s, COMe), 2.22 (3H, s, Me), 3.70—4.18 (1H, m, >CH-), 5.5—5.8 (1H, m, =CH-), and 6.61—7.50 (16H, m, arom.H); MS m/z (rel intensity) 608, (M^+, 4), 606 (M^+, 3), 565 (35), 563 (26), 509 (18), 507 (15), 371 (13), 345 (60), 261 (17), 235 (36), and 139 (18). Found: m/z 608.0678; 606.0660. Calcd for $C_{34}H_{26}O_2{}^{35}Cl_3{}^{37}Cl$; $C_{34}H_{26}O_2{}^{35}Cl_4$: M, 608.0657; 606.0687.

Bis[4-acetyl-2,2-bis(4-methylphenyl)-5-methyl-2,3-dihydro-3-furyl]methane (2h): Yellow liquid; IR 1715 (C=O); ^{1}H NMR δ=0.75—1.40 (2H, m, -CH_2-), 2.17 (6H, s, 2×Me), 2.19 (6H, s, 2×Me), 2.23 (6H, s, 2×Me), 2.31 (6H, s, 2×Me), 3.65 (2H, br.t, J=7.0 Hz, 2×>CH-), and 6.77—7.47 (16H, m, arom.H); MS m/z (rel intensity) 624 (M^+, 65), 523 (5), 480 (3), 428 (4), 368 (3), 317 (65), 263 (17), 219 (28), 195 (40), 179 (25), and 105 (16). Found: m/z 624.3204. Calcd for $C_{43}H_{44}O_4$: M, 624.3240.

3-Acetyl-4-[3,3-bis(4-methylphenyl)-2-propenyl]-5,5-bis(4-methylphenyl)-2-methyl-4,5-dihydrofuran (3h); Yellow liquid; IR 1662 (C=O); ^{1}H NMR δ=1.99 (2H, m, -CH_2-), 2.27 (12H, s, 3×Me), 2.33 (6H, s, 2×Me), 3.93 (1H, br.t, J=6 Hz, >CH-), 5.55 (1H, t, J=7 Hz, =CH-), and 6.67—7.48 (16H, m, arom.H); MS m/z (rel intensity) 526 (M^+, 60), 482 (5), 426 (10), 346 (15), 304 (100), 284 (22), 262 (43), 221 (100), 195 (91), 179 (35), 119 (62), and 91 (32). Found: m/z 526.2902. Calcd for $C_{38}H_{38}O_2$: M, 526.2872.

1,2-Bis(4-acetyl-5-methyl-2,2-diphenyl-2,3-dihydro-3-furyl)ethane (2i): Yellow microcrystals (from benzene-petroleum ether), mp 220—222 °C; IR 1662 (C=O); ^{1}H NMR δ=0.78—1.01 (4H, m, 2×-CH_2-), 1.97 (6H, s, 2×COMe), 2.07 (6H, 2×Me), 3.30.—3.60 (2H, m, 2×>CH-), and 6.78—7.42 (20H, m, 4×Ph). Found: C, 82.31; H, 6.60%. Calcd for $C_{40}H_{38}O_4$: C, 82.44; H, 6.57%.

3-Acetyl-2-methyl-4-(4,4-diphenyl-3-butenyl)-5,5-diphenyl-4,5-dihydrofuran (3i): Colorless microcrystals (from benzene-petroleum ether), mp 109—110 °C; IR 1663 (C=O); ^{1}H NMR δ=1.35—1.78 (4H, m, 2×-CH_2-), 2.15 (3H, s, COMe), 2.19 (3H, s, Me), 3.68—3.95 (1H, m, >CH-), 5.57—5.88 (1H, m, =CH-), and 6.63—7.53 (20H, m, 4×Ph). Found: C, 86.55; H, 6.70%. Calcd for $C_{35}H_{32}O_2$: C, 86.74; H, 6.66%.

1,2-Bis[4-acetyl-2,2-bis(4-chlorophenyl)-5-methyl-2,3-dihydro-3-furyl]ethane (2j): Yellow microcrystals (from benzene-petroleum ether), mp 252—253 °C; IR 1665 (C=O); ^{1}H NMR δ=0.72—1.13 (4H, m, 2×-CH_2-), 2.15 (6H, s, 2×COMe), 2.18 (6H, s, 2×Me), 3.35—3.57 (2H, m, 2×>CH-), and 6.95—7.72 (16H, m, arom.H); MS m/z (rel intensity) 720 (M^+, 13), 718 (M^+, 10), 620 (23), 618 (17), 483 (8), 423 (4), 372 (60), 346 (32), 329 (18), 261 (15), 235 (26), 199 (20), and 125 (10). Found: m/z 720.1184; 718.1193. Calcd for $C_{40}H_{34}O_4{}^{35}Cl_3{}^{37}Cl$; $C_{40}H_{34}O_4{}^{35}Cl_4$: M, 720.1189; 718.1212.

3-Acetyl-4-[4,4-bis(4-chlorophenyl)-3-butenyl]-5,5-bis(4-chlorophenyl)-2-methyl-4,5-dihydrofuran (3j): Yellow microcrystals (from benzene-petroleum ether), mp 174—176 °C; IR 1665 (C=O); ^{1}H NMR δ=1.23—1.80 (4H, m, 2×-CH_2-), 2.23 (6H, s, COMe and Me), 3.67—3.97 (1H, m, >CH-), 5.73—6.07 (1H, m, =CH-), and 6.83—7.60 (16H, m, arom.H). Found: C, 67.58; H, 4.49%. Calcd for $C_{35}H_{28}O_2Cl_4$: C, 67.54; H, 4.53%.

1,2-Bis[4-acetyl-2,2-bis(4-methylphenyl)-5-methyl-2,3-dihydro-3-furyl]ethane (2k): Yellow liquid; IR 1665 (C=O); ^{1}H NMR δ=0.82—1.05 (4H, m, 2×-CH_2-), 1.96 (6H, s, 2×Me), 2.06 (6H, s, 2×Me), 2.22 (6H, s, 2×Me), 2.31 (6H, s, 2×Me), 3.25—3.57 (2H, m, 2×>CH-), and 6.77—7.35 (16H, m, arom.H); MS *m/z* (rel intensity) 638 (M^+, 50), 537 (27), 442 (15), 331 (90), 305 (66), 288 (37), 262 (46), 219 (63), 195 (100), 179 (81), 105 (80), and 91 (30). Found: *m/z* 638.3388. Calcd for $C_{44}H_{46}O_4$: M, 638.3396.

3-Acetyl-4-[4,4-bis(4-methylphenyl)-3-butenyl]-5,5-bis(4-methylphenyl)-2-methyl-4,5-dihydrofuran (3k): Yellow liquid; IR 1660 (C=O); ^{1}H NMR δ=1.12—1.85 (4H, m, 2×-CH_2-), 2.17 (3H, s, Me), 2.22 (3H, s, Me), 2.29 (9H, s, 3×Me), 2.38 (3H, s, Me), 3.68—3.98 (1H, m, >CH-), 5.58—5.88 (1H, m, =CH-), and 6.78—7.48 (16H, m, arom.H); MS *m/z* (rel intensity) 540 (M^+, 18), 306 (100), 263 (22), 234 (81), 219 (31), 195 (17), 105 (15). Found: *m/z* 540.3031. Calcd for $C_{39}H_{40}O_2$: M, 540.3028.

1,2-Bis[4-acetyl-2,2-bis(4-methoxyphenyl)-5-methyl-2,3-dihydro-3-furyl]ethane (2l): Yellow liquid; IR 1665 (C=O); ^{1}H NMR δ=0.71—1.18 (4H, m, 2×-CH_2-), 2.09 (6H,s, 2×Me), 2.13 (6H, s, 2×Me), 3.34—3.64 (2H, m, 2×>CH-), 3.76 (6H, s, 2×OMe), 3.83 (3H, s, OMe), 3.86 (3H, s, OMe), and 6.51—7.96 (16H, m, arom.H); MS *m/z* (rel intensity) 702 (M^+, 25), 602 (6), 475 (10), 364 (72), 338 (100), 227 (52), 211 (15), and 135 (23). Found: *m/z* 702.3201. Calcd for $C_{44}H_{46}O_8$: M, 702.3193.

4,4′-Dimethoxybenzophenone (6): Yellow needles (from ethanol), mp 140—141 °C (lit,[40] mp 144 °C)

Reaction of Terminal Dienes with [Co(acac)$_3$]. In order to determine the optimum reaction conditions for the formation of bis(dihydrofuran), the reactions were examined using diene (**1i**) changing molar ratio, solvent, and reaction temperature. The effect of additive was also tested. When **1i** was allowed to react with [Co(acac)$_3$] at the molar ratio of 1 : 6 in acetic acid at the reflux temperature, the best yield of **2i** was obtained. The reaction predominantly gave **2i** irrespective of the presence of an active methylene compound such as malonic acid, malonamide, and diethyl malonate. The results are shown in Table 4. Accordingly, the reaction with [Co(acac)$_3$] was conducted as follows. To a heated solution of a terminal diene (0.5—1.0 mmol) in acetic acid (30 cm^3), [Co(acac)$_3$] was added. The mixture was heated under reflux until its dark green solution turned pink. The solvent was evaporated in vacuo and the residue was triturated with 2M HCl (30 cm^3), followed by extraction with chloroform. The chloroform was removed in vacuo and the product residue was separated on TLC with chloroform as the developing solvent. The yields are summarized in Table 1.

Reaction of Terminal Dienes with Ethyl 3-Oxobutanoate in the Presence of [Mn(OAc)$_3$]. To a heated solution of a diene (0.5—1.0 mmol) and ethyl 3-oxobutanoate in acetic acid (30 cm^3), [Mn(OAc)$_3$] was added. The mixture was heated under reflux until its dark-brown color turned clear yellow. The solvent was removed and the residue was treated with the same work-up previously mentioned. The results are shown in Table 2.

3-Ethoxycarbonyl-2-methyl-4-(2,2-diphenylethenyl)-5,5-diphenyl-4,5-dihydrofuran (8a): Colorless microcrystals (from ethyl acetate-ehanol), mp 133—134 °C; IR 1686 (C=O); ^{1}H NMR δ=1.24 (3H, t, J=7.0 Hz, Me), 2.39 (3H, s, Me), 4.18 (2H, q, J=7.0 Hz, -CH_2-), 4.92 (1H, br.d, J=11.0 Hz, >CH-), 5.44 (1H, d, J=11.0 Hz, =CH-), and 6.54—7.91 (20H, m, 4×Ph). Found: C, 83.90; H, 6.16%. Calcd for $C_{34}H_{30}O_3$: C, 83.92; H, 6.21%.

1,2,4,4-Tetraphenyl-3-butene-1-one (10a):[41] Yellow liquid; IR 1679 (C=O); ^{1}H NMR δ=5.35 (1H, d, J=10.0 Hz, >CH-), 6.69 (1H, d, J=10.0 Hz, =CH-), and 6.89—7.85 (20H, m, arom.H); MS *m/z* (rel intensity) 374 (M^+, 1), 345 (13), 269 (100), 191 (43), 105 (45), and 91 (13).

4-[2,2-Bis(4-chlorophenyl)ethenyl]-5,5-bis(4-chlorophenyl)-3-ethoxycarbonyl-2-methyl-4,5-dihydrofuran (8b): Colorless prisms (from ethyl acetate-ethanol), mp 181—182 °C; IR 1686 (C=O); ^{1}H NMR δ=1.27 (3H, t, J=7.0 Hz, Me), 2.33 (3H, s, Me), 4.16 (2H, q, J=7.0 Hz, -CH_2-), 4.66 (1H, br.d, J=11.0 Hz, >CH-), 5.26 (1H, d, J=11.0 Hz, =CH-), and 6.36—7.78 (16H, m, arom.H). Found: C, 65.41; H, 4.25%. Calcd for $C_{34}H_{26}O_3Cl_4$: C, 65.40; H, 4.20%.

3-Ethoxycarbonyl-4-[2,2-bis(4-methylphenyl)ethenyl]-

Table 4. Reaction of 1,1,6,6-Tetraphenyl-1,5-hexadiene (**1i**) with [Co(acac)$_3$]

Entry	Solvent	Additive	Molar ratio[a]	Reaction time[b]	Recovered **1i**	Product (yield/%)[c]	
				h	%	**2i**	**3i**

a) **1i**: Additive: [Co(acac)$_3$]. b) The reaction time shows consumption time of the oxidant. c) The yield based on **1i** added. d) The reaction was carried out at 100 °C.

5,5-bis(4-methylphenyl)-2-methyl-4,5-dihydrofuran (8c): Colorless needles (from ethanol), mp 133—135 °C; IR 1687 (C=O); ^{1}H NMR δ=1.23 (3H, t, J=7.0 Hz, Me), 2.19 (6H, s, 2×Me), 2.29 (6H, s, 2×Me), 2.42 (3H, s, Me), 4.11 (2H, q, J=7.0 Hz, -CH_2-), 4.71 (1H, br. d, J=11.0 Hz, >CH-), 5.21 (1H, d, J=11.0 Hz, =CH-), and 6.29—7.52 (16H, m, arom.H). Found: C, 84.05; H, 7.01%. Calcd for $C_{38}H_{38}O_3$: C, 84.10; H, 7.06%.

1,2,4,4-Tetrakis(4-methylphenyl)-3-butene-1-one (10c): Colorless needles (from ethyl acetate-ethanol), mp 130—131 °C; IR 1675 (C=O); ^{1}H NMR δ=2.27 (6H, s, 2×Me), 2.31 (3H, s, Me), 2.39 (3H, s, Me), 5.36 (1H, d, J=10.0 Hz, >CH-), 6.58 (1H, d, J=10.0 Hz, =CH-), and 6.87—7.80 (16H, m, arom.H); MS m/z (rel intensity) 430 (M^+, 1), 311 (100), 219 (33), 203 (3), 119 (6), and 91 (4). Found: C, 89.34; H, 7.03%. Calcd for $C_{32}H_{30}O$: C, 89.26; H, 7.02%.

3-Ethoxycarbonyl-2-methyl-5-[(*E*)-2-phenylethenyl]-4-phenyl-4,5-dihydrofuran (9d): Yellow liquid; IR 1693 (C=O); ^{1}H NMR δ=0.95 (3H, t, J=7.0 Hz, Me), 2.33 (3H, d, J=2.0 Hz, Me), 3.91 (2H, q, J=7.0 Hz, -CH_2-), 4.12 (1H, q, J=2.0 Hz, >CH-), 4.90 (1H, t, J=6.0 Hz, >CH-O-), 6.15 (1H, dd, J=6.0 and 16.0 Hz, =CH-), 6.48 (1H, d, J=16.0 Hz, =CH-), and 6.88—7.45 (10H, m, 2×Ph); MS m/z (rel intensity) 334 (M^+, 84), 305 (3), 292 (66), 279 (17), 260 (14), 245 (100), 231 (28), 217 (78), 202 (28), 180 (30), 167 (18), 149 (30), 115 (25), and 105 (50). Found: m/z 334.1541. Calcd for $C_{22}H_{22}O_3$: M, 334.1569.

3-Ethoxycarbonyl-2,4,4-trimethyl-5-(2-methyl-1-propenyl)-4,5-dihydrofuran (9e): Colorless liquid; IR 1678 (C=O); ^{1}H NMR δ=1.00 (3H, s, Me), 1.19 (3H, s, Me), 1.26 (3H, t, J=7.0 Hz, Me), 1.72 (3H, d, J=1.7 Hz, Me), 1.81 (3H, d, J=1.7 Hz, Me), 2.09 (3H, s, Me), 4.11 (2H, q, J=7.0 Hz, -CH_2-), 4.66 (1H, d, J=10.0 Hz, >CH-), and 5.27 (1H, br.d, J=10.0 Hz, =CH-); MS m/z (rel intensity) 238 (M^+, 59), 223 (100), 195 (67), 149 (73), 121 (88), and 107 (26). Found: m/z 238.1576. Cacld for $C_{14}H_{22}O_3$: M, 238.1569.

Bis(4-ethoxycarbonyl-5-methyl-2,2-diphenyl-2,3-dihydro-3-furyl)methane (7f): Yellow liquid; IR 1685 (C=O); ^{1}H NMR δ=0.71—1.09 (2H, m, -CH_2-), 1.24 (6H, t, J=7.0 Hz, 2×Me), 2.12 (6H, s, 2×Me), 3.38—3.88 (2H, m, 2× >CH-), 4.15 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.68—7.84 (20H, m, 4×Ph); MS m/z (rel intensity) 628 (M^+, 1), 583 (3), 320 (100), 278 (24), 191 (27), and 105 (21). Found: m/z 628.2833. Calcd for $C_{41}H_{40}O_6$: M, 628.2825.

Bis[2,2-bis(4-chlorophenyl)-4-ethoxycarbonyl-5-methyl-2,3-dihydro-3-furyl]methane (7g): Yellow liquid; IR 1681 (C=O); ^{1}H NMR δ=0.69—1.12 (2H, m, -CH_2-), 1.26 (6H, t, J=7.0 Hz, 2×Me), 2.15 (6H, s, 2×Me), 3.19—3.66 (2H, m, 2×>CH-), 4.18 (4H, q, J= 7.0 Hz, 2×-CH_2-), and 6.76—7.69 (16H, m, arom.H); MS m/z (rel intensity) 766 (M^+, 2), 764 (M^+, 1), 634 (3), 632 (2), 388 (100), 346 (16), 302 (12), 259 (10), 199 (12), 167 (22), 149 (50), and 113 (7). Found: m/z 766.1257; 764.1323. Calcd for $C_{41}H_{36}O_6{}^{35}Cl_3{}^{37}Cl$; $C_{41}H_{36}O_6{}^{35}Cl_4$: M, 766.1244; 764.1266.

Bis[4-ethoxycarbonyl-2,2-bis(4-methylphenyl)-5-methyl-2,3-dihydro-3-furyl]methane (7h): Yellow liquid; IR 1687 (C=O); ^{1}H NMR δ=0.73—1.46 (2H, m, -CH_2-), 1.23 (6H, t, J=7.0 Hz, 2×Me), 2.19 (6H, s, 2×Me), 2.29 (6H, s, 2×Me), 2.42 (6H, s, 2×Me), 3.61—3.70 (2H, m, 2×>CH-), 4.11 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.60—7.53 (16H, m, arom.H); MS m/z (rel intensity) 684 (M^+, 1), 639 (3), 348 (100), 306 (27), 261 (10), and 195 (5). Found: m/z 684.3441. Calcd for $C_{45}H_{48}O_6$: M, 684.3451.

1,2-Bis(4-ethoxycarbonyl-5-methyl-2,2-diphenyl-2,3-dihydro-3-furyl)ethane (7i): Colorless microcrystals (from ethyl acetate/ethanol), mp 162—164 °C; IR 1690 (C=O); ^{1}H NMR δ=0.84—1.11 (4H, m, 2×-CH_2-), 1.20 (6H, t, J=7.0 Hz, 2×Me), 2.09 (6H, s, 2×Me), 3.33—3.71 (2H, m, 2× >CH-), 4.09 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.98—7.61 (20H, m, 4×Ph); MS m/z (rel intensity) 642 (M^+, 5), 596 (8), 550 (5), 512 (47), 466 (8), 429 (7), 383 (8), 334 (37), 307 (16), 245 (17), 193 (17), 149 (13), and 105 (30). Found: C, 78.37; H, 6.53%; m/z 642.2990. Calcd for $C_{42}H_{42}O_6$: C, 78.48; H, 6.59%; M, 642.2982.

1,2-Bis[2,2-bis(4-chlorophenyl)-4-ethoxycarbonyl-5-methyl-2,3-dihydro-3-furyl]ethane (7j): Colorless microcrystals (from benzene-petroleum ether), mp 103—105 °C; IR 1686 (C=O); ^{1}H NMR δ=0.82—1.09 (4H, m, 2×-CH_2-), 1.12 (6H, t, J=7.0 Hz, 2×Me), 2.11 (6H, s, 2×Me), 3.19—3.49 (2H, m, 2×>CH-), 4.07 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.89—7.42 (16H, m, arom.H); MS m/z (rel intensity) 780 (M^+, 4), 778 (M^+, 3), 734 (15), 732 (10), 688 (6), 686 (4), 650 (50), 648 (40), 604 (7), 602 (4), 543 (2), 497 (12), 451 (10), 402 (100), 375 (24), 356 (20), 261 (22), 235 (18), 199 (26), 165 (6), and 139 (15). Found: m/z 780.1308; 778.1379. Calcd for $C_{42}H_{38}O_6{}^{35}Cl_3{}^{37}Cl$; $C_{42}H_{38}O_6{}^{35}Cl_4$: M, 780.1401; 778.1423.

1,2-Bis[4-ethoxycarbonyl-2,2-bis(4-methylphenyl)-5-methyl-2,3-dihydro-3-furyl]ethane (7k): Colorless needles (from ethyl acetate-ethanol), mp 161—163 °C; IR 1683 (C=O); ^{1}H NMR δ=0.70—1.06 (4H, m, 2×-CH_2-), 1.23 (6H, t, J=7.0 Hz, 2×Me), 2.07 (6H, s, 2×Me), 2.28 (6H, s, 2×Me), 2.34 (6H, s, 2×Me), 3.19—3.49 (2H, m, 2×>CH-), 4.02 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.81—7.33 (16H, m, arom.H). Found: C, 79.06; H, 7.18%. Calcd for $C_{46}H_{50}O_6$: C, 79.05; H, 7.21%.

1,2-Bis[4-ethoxycarbonyl-2,2-bis(4-methoxyphenyl)-5-methyl-2,3-dihydro-3-furyl]ethane (7l): Colorless microcrystals (from benzene-petroleum ether), mp 97—98 °C; IR 1686 (C=O); ^{1}H NMR δ=0.85—1.08 (4H, m, 2×-CH_2-), 1.23 (6H, t, J=7.0 Hz, 2×Me), 2.08 (6H, s, 2×Me), 3.18—3.48 (2H, m, 2×>CH-), 3.74 (6H, s, 2×OMe), 3.81 (6H, s, 2×OMe), 4.07 (4H, q, J=7.0 Hz, 2×-CH_2-), and 6.58—7.38 (16H, m, arom.H); MS m/z (rel intensity) 762 (M^+, 24), 716 (6), 674 (9), 652 (18), 632 (70), 606 (18), 586 (13), 562 (7), 535 (15), 498 (24), 443 (5), 394 (100), 348 (47), 293 (38), 253 (35), 227 (66), 211 (22), 165 (7), and 135 (24). Found: m/z 762.3378. Calcd for $C_{46}H_{50}O_{10}$: M, 762.3404.

Reaction of Terminal Dienes with Ethyl 3-Oxobutanoate in the Presence of [Co(OAc)$_3$]. A mixture of a diene (0.5 mmol) and ethyl 3-oxobutanoate (3 mmol) was heated under reflux in acetic acid (30 cm^3) and then [Co(OAc)$_3$] (4 mmol) was added. The mixture was continued to be heated under reflux until a dark green color turned pink. On cooling, the solvent was removed in vacuo and the residue was treated by the procedure previously described. The products and their yields are shown in Table 3.

3-Ethoxycarbonyl-2-methyl-4-(4,4-diphenyl-3-butenyl)-5,5-diphenyl-4,5-dihydrofuran (8i): Colorless needles (from ethyl acetate-ethanol), mp 113—114 °C; IR 1683 (C=O); ^{1}H NMR δ=1.20 (3H, t, J=7.0 Hz, Me), 1.39—1.99 (4H, m, 2×-CH_2-), 2.20 (3H, s, Me), 3.77 (1H, br.t, J=5.0 Hz, >CH-), 4.07 (2H, q, J=7.0 Hz, -CH_2-), 5.73 (1H t, J=7.0 Hz, =CH-), and 6.82—7.52 (20H, m, 4×Ph). Found: C, 84.17; H, 6.66%. Calcd for $C_{36}H_{34}O_3$: C, 84.01; H, 6.66%.

4-[4,4-Bis(4-chlorophenyl)-3-butenyl]-5,5-bis(4-chlorophenyl)-3-ethoxycarbonyl-2-methyl-4,5-dihydrofuran (8j):

Yellow liquid; IR 1684 (C=O); ^{1}H NMR δ=1.24 (3H, t, J=7.0 Hz, Me), 1.47—1.91 (4H, m, 2×-CH_2-), 2.20 (3H, s, Me), 3.70 (1H, br.t, J=5.0 Hz, >CH-), 4.14 (2H, q, J=7.0 Hz, -CH_2-), 5.77 (1H, t, J=7.0 Hz, =CH-), and 6.81—7.84 (16H, m, arom.H); MS m/z (rel intensity) 652 (M^+, 8), 650 (M^+, 6), 561 (3), 559 (2), 522 (3), 520 (2), 389 (10), 343 (27), 301 (8), 274 (100), 239 (77), 199 (26), 165 (16), and 125 (22). Found: m/z 652.0901; 650.0922. Calcd for $C_{36}H_{30}O_3{}^{35}Cl_3{}^{37}Cl$; $C_{36}H_{30}O_3{}^{35}Cl_4$: M, 652.0926; 650.0949.

3-Ethoxycarbonyl-4-[4,4-bis(4-methylphenyl)-3-butenyl]-5,5-bis(4-methylphenyl)-2-methyl-4,5-dihydrofuran (8k): Yellow liquid; IR 1685 (C=O); ^{1}H NMR δ=1.22 (3H, t, J=7.0 Hz, Me), 1.44—1.87 (4H, m, 2×-CH_2-), 2.22 (3H, s, Me), 2.26 (3H, s, Me), 2.29 (6H, s, 2×Me), 2.37 (3H, s, Me), 3.77 (1H, br.t, J=6.0 Hz, >CH-), 4.12 (2H, q, J=7.0 Hz, -CH_2-), 5.72 (1H, t, J=7.0 Hz, =CH-), and 6.77—7.47 (16H, m, arom. H); MS m/z (rel intensity) 570 (M^+, 10), 525 (4), 440 (3), 391 (3), 349 (10), 335 (5), 303 (20), 290 (15), 275 (7), 261 (10), 234 (100), 219 (45), 195 (14), 143 (6), 129 (12), and 105 (18). Found: m/z 570.3125. Calcd for $C_{40}H_{42}O_3$: M, 570.3134.

Reactions of Terminal Dienes (1i—l) with Ethyl Hydrogen Malonate in the Presence of [Mn(OAc)$_3$]. A mixture of a diene (0.5—1.0 mmol) and ethyl hydrogen malonate was heated under reflux in acetic acid (30 cm^3) and then [Mn(OAc)$_3$] was added. The mixture was continued to be heated under reflux until a dark-brown color turned clear yellow. After removal of the solvent, the residue was triturated with 2M HCl (30 cm^3). The aqueous solution was extracted with chloroform and separated on TLC. The product and its yield are shown in Table 3.

2-Ethoxycarbonyl-3-(4,4-diphenyl-3-butenyl)-4,4-diphenyl-2-buten-4-olide (11i): Colorless microcrystals (from methanol), mp 181—183 °C; IR 1785 and 1730 (C=O); ^{1}H NMR δ=0.47 (3H, t, J=7.0 Hz, Me), 1.09—1.92 (2H, m, -CH_2-), 2.26—2.96 (2H, m, -CH_2-), 4.28 (2H, q, J=7.0 Hz -CH_2-), and 6.89—7.69 (21H, m, =CH- and 4×Ph); MS m/z (rel intensity) 514 (M^+, 65), 496 (28), 470 (57), 450 (20), 424 (40), 397 (46), 303 (29), 275 (50), 259 (30), 229 (35), 215 (42), 193 (100), 167 (60), 115 (30), and 105 (62). Found: C, 81.48; H, 5.88%. Calcd for $C_{35}H_{30}O_4$: C, 81.69; H, 5.88%.

The reaction of **1i** with ethyl hydrogen malonate in the presence of [Mn(OAc)$_3$] at the molar ratio of 1:6:7 under the similar reaction conditions was completed for 10 min to give a complex mixture, from which **11i** (46%) was obtained as an only isolable product.

3-[4,4-Bis(4-chlorophenyl)-3-butenyl]-4,4-bis(4-chlorophenyl)-2-ethoxycarbonyl-2-buten-4-olide (11j): Colorless needles (from ethyl acetate-ethanol), mp 195—197 °C; IR 1775 and 1730 (C=O); ^{1}H NMR δ=0.57 (3H, t, J=7.0 Hz, Me), 1.09—3.15 (4H, m, 2×-CH_2-), 4.18 (2H, q, J=7.0 Hz, -CH_2-), and 6.88—7.85 (17H, m, =CH- and arom.H); MS m/z (rel intensity) 652 (M^+, 45), 650 (M^+, 33), 634 (37), 632 (27), 606 (59), 604 (31), 588 (19), 586 (14), 535 (26), 533 (22), 490 (8), 437 (9), 389 (35), 372 (20), 343 (75), 261 (100), 235 (37), 202 (15), 165 (20), and 139 (55). Found: m/z 652.0586; 650.0585. Calcd for $C_{35}H_{26}O_4{}^{35}Cl_3{}^{37}Cl$; $C_{35}H_{26}O_4{}^{35}Cl_4$: M, 652.0556; 650.0585.

2-Ethoxycarbonyl-3-[4,4-bis(4-methylphenyl)-3-butenyl]-4,4-bis(4-methylphenyl)-2-buten-4-olide (11k): Colorless needles (from methanol), mp 155—157 °C; IR 1781 and 1729 (C=O); ^{1}H NMR δ=0.50 (3H, t, J=7.0 Hz, Me), 0.72—3.13 (4H, m, 2×-CH_2-), 2.19 (6H, s, 2×Me), 2.26 (6H, s, 2×Me), 4.15 (2H, q, J=7.0 Hz, -CH_2-), and 6.77—7.85 (17H, m, =CH- and arom.H); MS m/z (rel intensity) 570 (M^+, 38), 552 (17), 526 (54), 506 (13), 480 (40), 453 (53), 375 (11), 349 (22), 332 (15), 305 (39), 287 (12), 257 (16), 243 (21), 221 (100), 195 (38), 165 (13), and 119 (33). Found: m/z 570.2776. Calcd for $C_{39}H_{38}O_4$: M, 570.2770.

2-Ethoxycarbonyl-3-[4,4-bis(4-methoxyphenyl)-3-butenyl]-4,4-bis(4-methoxyphenyl)2-buten-4-olide (11l): Colorless needles (from benzene-petroleum ether), mp 143—144 °C; IR 1780 and 1729 (C=O); ^{1}H NMR δ=0.55 (3H t, J=7.0 Hz, Me), 1.40—1.83 (2H, m, -CH_2-), 2.27—2.97 (2H, m, -CH_2-), 3.67 (6H, s, 2×OMe), 3.72 (6H, s, 2×OMe), 4.17 (2H, q, J=7.0 Hz, -CH_2-), and 6.51—7.57 (17H, m, =CH- and arom.H). Found: C, 73.54; H, 6.00%. Calcd for $C_{39}H_{38}O_8$: C, 73.80; H, 6.04%.

Cross-Over Experiment for the Formation of Rearrangement Product. The butadienes **1a** (185.4 mg; 0.5 mmol) and **1c** (203.2 mg; 0.5 mmol) were dissolved in acetic acid (30 cm^3) upon heating and then [Mn(OAc)$_3$] (742.6 mg; 1 mmol=3 equivalents) was added. The mixture was heated under reflux until the dark Mn(III) ion completely disappeared (15 min). The solvent was removed in vacuo and the residue was worked up by the same procedure previously mentioned. After TLC separation, the oxidative rearrangement products **10a** (61.5 mg; 33%) and **10c** (173.4 mg; 81%) were obtained and **1a** (85.7 mg; 46%) was recovered. No cross-over compound was isolated.

We are grateful for the financial support of this work by a Grant-in-Aid for Encouragement of Young Scientists No. 62740301 from the Ministry of Education, Science and Culture. The authors wish to thank Dr. Terry Marriott of the Department of Chemistry, Rice University, Houston, Texas, U.S.A., for his measurement of high-resolution mass spectra. We also acknowledge Mr. Yasunori Sudoh of the Taiho Pharmaceutical Co., Inc., Tokushima, for his arrangement of the measurements of high-resolution mass spectra.

Reactions of α,β-Unsaturated Ketone Acetals with Trimethylsilyl Cyanide and Trimethylsilyl Sulfides

Tsunehiko SOGA, Haruhiro TAKENOSHITA, Masaaki YAMADA, Jeng S. HAN, and Teruaki MUKAIYAMA*
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo,
Kagurazaka, Shinjuku-ku, Tokyo 162
(Received November 8, 1990)

In the presence of a catalytic amount of trityl perchlorate, trimethylsilyl cyanide reacts with the dimethyl acetals of chalcone derivatives, with simultaneous double bond isomerization, to yield γ-methoxy-α,β-unsaturated carbonitriles. Trimethylsilyl sulfides react with dimethyl acetals derived from α,β-unsaturated ketones to yield 1,3-bis(alkylthio)propene derivatives under similar conditions.

In recent years, various reactions between acetals and a silylated nucleophile such as trimethylsilyl cyanide (TMS-CN),[1] silyl enol ethers,[2] ketene silyl acetals,[2] or allyltrimethylsilane[3] have been developed employing several efficient catalysts or promoters. Concerning the reaction of acetals derived from α,β-unsaturated ketones with silyl enol ethers, it was shown that either the Michael product or the β-alkoxy ketone was obtained, and that regioselectivity depends mostly on the reaction conditions.[4] It was also reported that a Lewis acid catalyst such as $SnCl_4$ or $BF_3 \cdot Et_2O$ promotes the reaction of acetals with TMS-CN and, in the case of the reaction of acetals derived from α,β-unsaturated ketones with TMS-CN, α-methoxy carbonitriles are obtained as major products.[1]

Recently, we have reported that, in the presence of a catalytic amount of transition metal salts such as $NiCl_2$, $CoCl_2$, or di-μ-chloro-bis(1,5-cyclooctadiene)-dirhodium ([Rh(COD)Cl]$_2$), TMS-CN reacts readily with various acetals under mild conditions.[5] During subsequent experiments, an interesting observation was made concerning the reaction of dimethyl acetals derived from α,β-unsaturated ketones: in the presence of 2 mol% of [Rh(COD)Cl]$_2$, TMS-CN reacts with (*E*)-chalcone dimethyl acetal to yield (*E*)-2-methoxy-2,4-diphenyl-3-butenenitrile, a normal cyanation product along with its isomerized product. The present study was initiated to examine in detail the reaction conditions required and the mechanism of this reaction in forming predominantly the isomerized product (*Z*)-4-methoxy-2,4-diphenyl-2-butenenitrile, briefly reported in preliminary communications.[6] This report describes in full the results of our investigation of the above reaction, and of a similar reaction employing another silylated nucleophile, trimethylsilyl sulfide, and of the reaction of the isomerized products thus obtained with several silylated nucleophiles.

Results and Discussion

Cyanation of Chalcone Dimethyl Acetal. We have already reported that when (*E*)-chalcone dimethyl acetal (**1**) was allowed to react with TMS-CN in the presence of 2 mol% of $CoCl_2$ in CH_2Cl_2 at room temperature for 18 h, (*E*)-2-methoxy-2,4-diphenyl-3-butenenitrile (**2**) was obtained in 99% yield.[5] On the other hand, **2** and its isomerized compound (**3**) were obtained in 89% yield when the above reaction was carried out in the presence of 2 mol% of [Rh(COD)Cl]$_2$ in CH_2Cl_2 at room temperature for 40 h (**2**:**3**=20:80, Scheme 1).[6] The structure of the above compound **3** was determined, mainly by ^{1}H and ^{13}C NMR measurement, to be (*Z*)-4-methoxy-2,4-diphenyl-2-butenenitrile as shown in Fig. 1. Concerning the geometry of the double bond in **3**, only one isomer was observed by ^{1}H and ^{13}C NMR measurement and we considered that it had the *Z*-configuration on the basis of the value of the coupling constant between the 1-position carbon and the 3-position proton ($^3J_{C1,H3}$=13.9 Hz) as measured by

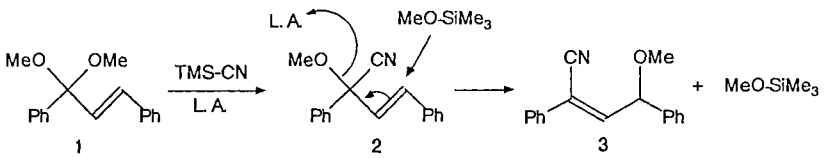
a) Reactions were carried out in CH_3CN at room temperature. b) Determined by ^1H NMR measurement.



Scheme 2.

^{13}C NMR measurement (gated method).[7] In addition, the steric effect of the C2-phenyl group supports the above conclusion.

After experimentation with various reaction conditions, taking acetal **1** as a model substrate, it was found that **3** was obtained in good yield when the reaction was carried out in CH_3CN with the use of $[Rh(COD)Cl]_2$ or trityl perchlorate (Ph_3CClO_4) as catalyst (see Table 1).

Table 1 shows that, in the initial stage of the present reaction (after 5 h in CH_2Cl_2), cyanation gave only **2**, which in turn was isomerized to **3** when the mixture was kept standing for a long time. After a trial of various solvents, it was shown that CH_3CN is the best solvent, and isomerization from **2** to **3** was achieved within 20 h by using $[Rh(COD)Cl]_2$ as a catalyst. Isomerization proceeded slowly when such transition metal salts as $NiCl_2$, $CoCl_2$, $Pd(acac)_2$, or $Pd(OAc)_2$ was used as the catalyst. Very rapid isomerization took place when Ph_3CClO_4 was used, but the process was slower in the presence of generally known strong Lewis acids such as $BF_3 \cdot Et_2O$ and $AlCl_3$.

Concerning the mechanism of the isomerization, it is reasonable to consider that **3** was produced by the following reaction (Scheme 2). Trimethylsilyl methoxide (TMS-OMe), formed by the reaction of **1** with TMS-CN, would attack the 4-position carbon of **2** in the presence of a catalyst to result in the formation of a conjugated nitrile **3**.

Isomerization of isolated **2** to **3** was tried under various conditions (Table 2) and it was found that the isomerization did not occur in the presence of a catalytic amount of Ph_3CClO_4 alone, but was completed within 3 h in the presence of both 5 mol% of Ph_3CClO_4

and 2 equiv of TMS-OMe. This result supported the validity of the above-described mechanism of the isomerization. With the use of $SbCl_5$ catalyst, a stronger Lewis acid, the isomerization took place even in the absence of TMS-OMe.

Similar reactions of various acetals of substituted chalcone derivatives with TMS-CN were tried in the presence of a catalytic amount of Ph_3CClO_4 (Scheme 3, Table 3). It is important to note, in these reactions, that the electronic effect of substituents contained in the aromatic rings of chalcone derivatives influences in the rate of isomerization. On the other hand, compounds having one or both of the phenyl groups in chalcone substituted with non-aromatic groups could be cyanated with TMS-CN to yield α-methoxy carbonitriles, but were not isomerized to γ-methoxy-α,β-unsaturated carbonitriles at all under similar conditions.

Concerning the utility of the isomerized compound **3** in the synthesis, it is thought that substitution by silylated nucleophiles at the allyl ether position[10] is possible in addition to the commonly known reactions of an α,β-unsaturated carbonitrile (Scheme 4). The reactions of **3** with several silylated nucleophiles under promotion by $SbCl_5$ are demonstrated in Table 4.

Reaction of Acetals Derived from α,β-Unsaturated Ketones with Trimethylsilyl Sulfide. In order to extend the scope of the above reaction, trimethylsilyl sulfide was employed as a silylated nucleophile instead of TMS-CN. It is well known that, in the presence of a catalytic amount of ZnI_2, aldehydes or ketones including α,β-unsaturated ketones react with trimethylsilyl sulfide to give the corresponding dithioacetals.[11] However, there have been few reports on the reaction of α,β-unsaturated ketone acetals with trimethylsilyl sulfide; for example, $AlCl_3$ promotes the above reaction to give 3-methoxyallyl sulfides or dithioacetals.[12] Firstly, acetal compound **1** was allowed to react with 2 equiv of phenylthiotrimethylsilane (PhS-TMS) in the presence of a catalytic amount of Ph_3CClO_4 in CH_3CN. It was found that 1,3-diphenyl-1,3-bis(phenylthio)-1-propene (**8**) (a mixture of *E*- and *Z*-isomers, 1 : 4), formed by isomerization of double bond, and 1,3-diphenyl-3-phenylthio-1-propanone (**9**), the Michael adduct, were obtained in 60 and 34% yields, respectively (Scheme 5). The dithioacetal of chalcone was not isolated under the above conditions.

In order to increase the yield of the desired **8**, various reaction conditions (catalyst, solvent, temperature)

were examined (Table 5), and the ratio of **8** to **9** was found to be increased by raising the reaction temperature. Eventually **8** was obtained in good yield without the accompanying by-product **9** when the reaction was carried out using 5 mol% of Ph_3CClO_4 in benzene or toluene at 60 °C (Entries 10 and 11). On the other hand, the Michael adduct **9**, was obtained mainly when the reaction was carried out at −78 °C (Entry 6). In this reaction, PhS-TMS could attack either on the α- or the γ-position of acetal **1** (Scheme 6). In the former possibility, 3-methoxy-3-phenylthio-1-propene would be formed and be attacked by one more PhS-

Fig. 2.

TMS only at the γ-position because of steric hindrance which would result in the formation of isomerized compound **8**. In the latter, the 1-methoxy-3-phenylthio-1-propene formed would not react further, so that the Michael adduct **9**, would be obtained after quenching with water.

Next, similar reactions of various acetals of α,β-unsaturated ketones with PhS-TMS or EtS-TMS were tried in the presence of a catalytic amount of Ph_3CClO_4 in benzene at 60 °C (Scheme 7, Table 6). Isomerized compound **11** was obtained under the above conditions and the ratio between (*E*)-**11** and (*Z*)-**11** was influenced by the structure of **10**. The geometries of the double bond in **11** are considered to be as follows: (1) in Entries 1, 2, and 5—9, the isomer in which an olefinic proton (H^c in Fig. 2) occurs in a lower field on ^{1}H NMR measurement was considered to be a *Z*-isomer; (2) in Entries 3 and 4, only one isomer was obtained and it was thought to be a *Z*-isomer because of the steric hindrance of the ^{t}Bu group; (3) in Entries 9 and 10, the isomer in which a signal of a carbon atom bonded to the double bond (C^a in Fig. 2) occurs in a lower field on ^{13}C NMR measurement suggested the *Z*-configuration.

It is interesting to note that the compounds **10b—d**, and **10f**, which have a *t*-butyl or methoxycarbonyl group instead of a phenyl group in the chalcone (and which could be cyanated with TMS-CN to yield α-methoxy carbonitriles, but were not isomerized to γ-methoxy-α,β-unsaturated carbonitriles at all under conditions similar to those mentioned in the previous section), were also readily converted to the corresponding isomerized products **11**. On the other hand, when these acetals were treated with 1,3-bis(trimethylsilylthio)propane under similar conditions (Scheme 8), it was found that only dithiane **12** was obtained from **10a**, and the mixtures of **12** and 1,5-dithia-2-cyclooctene derivative **13** were obtained from **10b** or **10c** (Table 7).

In relation to the utility of the isomerized compounds **11**, it was considered that allyl sulfides could

Scheme 9.

be activated toward silylated nucleophiles by means of a Lewis acid. It is already known that dithioacetals reacted with silyl enol ethers in the presence of Ph_3CBF_4[13)] and that the allylic methoxyl group of **3** is replaced by silylated nucleophiles in the presence of $SbCl_5$, as mentioned in the previous section. Substitution at the 3-position of **11** with several silylated nucleophiles (Scheme 9) was therefore tried and it was found that $SnCl_4$, promotes the reaction of **11** with the silylated nucleophiles, as shown in Table 8.

In conclusion, it is noted that in the presence of a catalytic amount of Ph_3CClO_4, TMS-CN reacts with dimethyl acetals derived from chalcone derivatives, with simultaneous double bond isomerization, to yield γ-methoxy-α,β-unsaturated carbonitriles; and trimethylsilyl sulfides react with dimethyl acetals derived from α,β-unsaturated ketones to yield 1,3-bis(alkylthio)propene derivatives under similar conditions.

This type of reaction accompanying isomerization of a double bond opens up new possibilities, especially in the synthesis of olefin derivatives.

Experimental

All melting points were uncorrected. The IR spectra were determined on a Hitachi 270-30 or JASCO IRA-2 spectrometer. The NMR spectra were recorded with a Hitachi R-24B, a JEOL FX90Q, a JEOL GSX-400 or a JEOL GSX-500 spectrometer in $CDCl_3$ with tetramethylsilane as an internal standard. The mass spectra were taken on a JEOL JMS-HX110 or a JEOL JMS-D300. Dichloromethane and acetonitrile were distilled from P_2O_5, and then distilled from CaH_2 and stored over Molecular Sieves. Benzene and toluene were dried over $CaCl_2$, then distilled from P_2O_5 and stored over Molecular Sieves. Purification of products was performed by column chromatography on silica gel (Merck, Art. 7734 Kieselgel 60) or preparative TLC on silica gel (Wakogel B-5F).

Dimethyl acetals were prepared by transacetalization of the corresponding ketones with trimethyl orthoformate in the presence of *p*-TsOH·H_2O, and purified by distillation or recrystallization. Trimethylsilyl cyanide, allyltrimethylsilane, and triethylsilane were purified by distillation. Trimethylsilyl sulfides were prepared by silylation of the corresponding lithium salts of mercaptans. Silyl enol ethers were prepared by silylation of the corresponding enolates of ketones, and purified by distillation.

Preparation of γ-Methoxy-α,β-unsaturated Carbonitriles (6) (Table 3). A typical reaction procedure is described for (*E*)-chalcone dimethyl acetal (**1**) with TMS-CN by the use of Ph_3CClO_4, as a catalyst (Entry 1): In an argon atmosphere, Ph_3CClO_4 (3.4 mg, 0.01 mmol) and TMS-CN (34.7 mg, 0.350 mmol) were stirred in acetonitrile (3 ml) at room temperature for 15 min, and to the mixture was added (*E*)-chalcone dimethyl acetal (52.9 mg, 0.208 mmol) in acetonitrile (1 ml). The reaction mixture was stirred for 3 h at room temperature, then quenched with pH 7 phosphate buffer. The organic materials were extracted with ethyl acetate and the combined extract was dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by preparative TLC (silica gel, hexane : AcOEt=5 : 1) to afford (*Z*)-4-methoxy-2,4-diphenyl-2-butenenitrile (**3**) (47.9 mg, 0.192 mmol, 92%). IR (neat) 2220, 1495, 1450, 1085, 755, 690 cm^{-1}; ^{1}H NMR δ=3.43 (3H, s), 5.34 (1H, d, *J*=9.2 Hz), 6.84 (1H, d, *J*=9.2 Hz), 7.3—7.6 (10H, m); ^{13}C NMR δ=56.8 (q), 82.2 (d), 116.2 (s), 116.5 (s), 126.0 (d), 126.6 (d), 128.6 (d), 129.0 (d and d, 2C), 129.7 (d), 132.3 (s), 139.1 (s), 144.9 (d); MS *m/z* 249 (M$^+$), 217, 140, 121, 105. Isomerization from Isolated 2 to 3. The following is a description of a typical procedure for isomerization in the presence of Ph_3CClO_4 and TMS-OMe (Entry 2): In an argon atmosphere, Ph_3CClO_4 (3.2 mg, 0.009 mmol) and TMS-OMe (42.7 mg, 0.410 mmol) were stirred in CH_3CN (2 ml) for 10 min at room temperature, and then (*E*)-2-methoxy-2,4-diphenyl-3-butenenitrile (**2**) (47.8 mg, 0.192 mmol) in CH_3CN (1 ml) was added. The reaction mixture was stirred for 3 h at room temperature and quenched with an aqueous solution of $NaHCO_3$. The organic materials were extracted with ethyl acetate and the combined extract was dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by preparative TLC (silica gel, hexane : AcOEt=7 : 1) to afford (*Z*)-4-methoxy-2,4-diphenyl-2-butenenitrile (**3**) (46.1 mg, 0.185 mmol, 96%).

Reaction of 3 with Silylated Nucleophiles (Table 4). A typical procedure for the reaction of **3** with trimethylsilyl enol ether of *t*-butyl methyl ketone (Entry 1) follows: In an argon atmosphere, (*Z*)-4-methoxy-2,4-diphenyl-2-butenenitrile

(**3**) (49.1 mg, 0.197 mmol) and the trimethylsilyl enol ether of *t*-butyl methyl ketone (57.0 mg, 0.331 mmol) were dissolved in CH_2Cl_2 (2 ml). The solution was cooled to −78 °C, and 0.5 M $SbCl_5$ solution (1 M=1 mol dm^{-3}) in CH_2Cl_2 (0.44 ml, 0.22 mmol) was added. The reaction mixture was stirred for 1 h at −78 °C and quenched with an aqueous solution of $NaHCO_3$. The organic materials were extracted with CH_2Cl_2 and the combined extract was dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by preparative TLC (silica gel, hexane : AcOEt=5 : 1) to afford (*Z*)-7,7-dimethyl-6-oxo-2,4-diphenyl-2-octenenitrile (59.9 mg, 0.189 mmol, 96%); mp 101—103 °C; IR (KBr) 2220, 1700, 1475, 1455, 1070, 760, 695 cm^{-1}; ^{1}H NMR δ=1.03 (9H, s), 2.98 (2H, m), 4.4 (1H, m), 6.82 (1H, d, *J*=10 Hz), 7.2 (10H, m). Found: C, 83.03; H, 7.51; N, 4.37%. Calcd for $C_{22}H_{23}NO$: C, 83.24; H, 7.30; N, 4.41%.

Reaction of α,β-Unsaturated Ketone Acetals with Trimethylsilyl Sulfides (Table 6). A typical procedure for the reaction of (*E*)-chalcone dimethyl acetal **1** with PhS-TMS (Entry 1) was as follows.

In an argon atmosphere, Ph_3CClO_4 (5.4 mg, 0.016 mmol) was suspended in benzene (1 ml), to which was added PhS-TMS (135.0 mg, 0.740 mmol) in benzene (1 ml). The reaction mixture was heated to 60 °C and stirred for 30 min, and (*E*)-chalcone dimethyl acetal (79.7 mg, 0.314 mmol) in benzene (1 ml) was then added over a 5 min period. The reaction mixture was stirred for 3 h at 60 °C and quenched with aqueous $NaHCO_3$ solution. The organic materials were extracted with ethyl acetate and the combined extract was dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by preparative TLC (silica gel, hexane : ether=93 : 7) to afford 1,3-diphenyl-1,3-bis (phenylthio)propene (123.8 mg, 0.302 mmol, 96%) as a mixture of *E*- and *Z*-isomer (*E* : *Z*=12 : 88). Pure *Z*-isomer was obtained by recrystallization from ethanol (90.1 mg).

(Received November 17, 1990)

A catalyst system comprising $[Pd_2(dba)_3]\cdot CHCl_3$ and DPPF was proved to be efficient for the cyanation of aryl iodides and aryl triflates with KCN. The reactivities of aryl substrates decreased in the order ArI>ArOTf>ArBr.

Although a nucleophilic displacement of nonactivated aryl halides with alkali metal cyanides does not take place under conventional conditions, some transition metals like Ni, Pd, and Co induce a reaction through activation of the sp^2 carbon–halogen bonds of the substrates.[2] Regarding the Pd catalyst, $Pd(PPh_3)_4$ and Pd(II) salts, such as $Pd(OAc)_2$, are hitherto known to be active for catalytic cyanation.[3] The former is one of the most extensively used complexes in a variety of transition metal-catalyzed reactions,[4] although its efficiency toward the cyanation is not satisfactory. Several modifications of this method have thus appeared, in which cyanation was accelerated by adding crown ethers as co-catalysts[5] or by using Me_3SiCN[6] or NaCN impregnated on alumina[7] as a cyanide source. Another possible modification, i.e., tuning the reactivity of Pd(0) by controlling the ligating species, has not been explored for this important transformation.[8] In this paper we report that an alternation of the ligand from conventional PPh_3 to 1,1′-bis(diphenylphosphino)ferrocene (DPPF) improves the catalytic efficiency of Pd(0) to a great extent, thereby providing a convenient method for the preparation of aryl cyanides from not only aryl

Table 1. Effect of Solvents and/or Ligands for the Pd(0)-Catalyzed Cyanation of Iodobenzene[a]

a) In the presence of 1 mmol of iodobenzene, 2 mmol of KCN, 0.005 mmol of $[Pd_2(dba)_3]\cdot CHCl_3$, and 0.01—0.04 mmol of ligand in 0.5 cm^3 of the solvent at 60 °C under nitrogen unless otherwise noted. b) Yields were determined by GLC using an internal standard. c) *N*,*N*-Dimethylformamide. d) Tri-*o*-tolylphosphine. e) $Pd(PPh_3)_4$ was used in the place of $[Pd_2(dba)_3]\cdot CHCl_3$ and ligand. f) This run was carried out at 40 °C. g) This run was carried out by a successive procedure. h) Bromobenzene was used in the place of iodobenzene.

iodides, but also aryl triflates:[9]

$$ArX + KCN \xrightarrow[X=I \text{ or } OTf]{\text{"Pd(0)-DPPF"}} ArCN + KX$$

Results and Discussion

Cyanation of Aryl Iodides. At the beginning, the reaction of iodobenzene with KCN was studied using tris(dibenzylideneacetone)dipalladium(0)-chloroform (1/1) ([Pd2(dba)3]·CHCl3; dba=dibenzylideneacetone), a commercially available, air-stable zerovalent palladium possessing substitution-labile ligands,[10] as a catalyst precursor to investigate the effect of ligands and solvents on the progress of the Pd(0)-catalyzed cyanation (Table 1). Even in the absence of supporting ligands, the catalytic reaction took place in 1-methyl-2-pyrrolidinone (NMP), acetone, and tetrahydrofuran (THF), but stopped before it reached completion. Although such additives as PPh_3, PBu_3, 1,3-bis(diphenylphosphino)propane (DPPP), triisopropyl phosphite ($P(OPr^i)_3$), 1,10-phenanthroline (PHEN), and 2,2'-bipyridyl (bpy) lowered the catalytic activity of Pd(0), DPPF raised it reversely.[11] Thus, a clean reaction of iodobenzene with KCN proceeded in NMP or acetone at 60 °C by the catalysis of [Pd2(dba)3]·CHCl3 and DPPF to afford benzonitrile in excellent yield. The present catalyst system is far more reactive than the conventional $Pd(PPh_3)_4$, as exemplified by Runs 9, 15, and 16. The same reaction took place at a lower temperature of 40 °C, as well. In the presence of this catalyst system, a variety of aryl iodides readily underwent cyanation with KCN: substituents like alkyl, alkoxy, acyl, alkoxycarbonyl, and chloro and one attached on the ortho position to iodo-leaving group did not interfere with the progress of cyanation (Table 2). Bromobenzene, however, was ascertained to be far less reactive than aryl iodides for cyanation. It is to be noted that the manner of operation influences the progress of the reaction to a great extent. That is, a simple procedure (see Experimental) required prolonged heating to complete the reaction, compared with a successive procedure: [Pd2(dba)3]·CHCl3, DPPF, and a solvent were mixed at room temperature before the substrate and KCN were added successively; entire mixture was then heated to the cited temperature (Tables 1 and 3).[12] For the sake of convenience, however, the former procedure was adopted for all runs, except otherwise noted.

Cyanation of Aryl Triflates. The catalytic cyanation of phenolic oxygen was examined next. There has hitherto been no convenient way to convert the hydroxyl group into a cyano group, mainly because of a difficult nucleophilic displacement at the sp^2 carbon atoms.[14] In view of the facts that 1) aryl triflates are prepared readily from phenols[15] and 2) their carbon-oxygen bonds are cleaved by transition metals to form the oxidative adducts,[16] the application of our Pd(0)-catalyzed cyanation to aryl triflates looks promising as an approach to this problem. Recently, a reaction of vinyl triflates with LiCN was attempted in the presence of catalytic amounts of $Pd(PPh_3)_4$ and 12-crown-4.[17] As shown in Table 3, with the aid of the catalyst system comprising [Pd2(dba)3]·CHCl3 and DPPF, aryl triflates readily underwent a reaction with KCN to afford the corresponding aryl cyanides in good yields:

Table 2. Cyanation of Aryl Iodides[a]

Run	R-C6H4-I R	Time h	Yield[b] %

a) In the presence of 1 mmol of aryl triflate, 2 mmol of KCN, 0.02 mmol of [Pd2(dba)3]·CHCl3, and 0.08 mmol of DPPF in 0.5 cm^3 of NMP at 60 °C under nitrogen. b) Isolated yield. Yield in parentheses were determined by GLC. c) This run was carried out using 0.005 mmol of [Pd2(dba)3]·CHCl3 and 0.02 mmol of DPPF. d) This run was carried out by a successive procedure. e) The conversion was 50%. f) The conversion was 48%.

alkyl, aryl, chloro, acyl, alkoxycarbonyl, cyano, or nitro substituent but also 2-naphthyl, 2-oxo-2*H*-benzopyran-7-yl, or 8-quinolyl did not interfere with the progress of cyanation. Electron-donating groups, like alkoxyl and acylamino, however, retarded the reaction, so that the catalytic reaction did not reach completion, even after long heating.

The order of reactivity of aryl substrates in the present Pd(0)-catalyzed cyanation is ArI>ArOTf>ArBr>ArCl. For the closely related Pd(0)-catalyzed cross-coupling with organostannanes, however, a different order (ArI>ArBr>ArOTf>ArCl) had been reported.[18]

At present, the reason why the DPPF-ligand works so well is not clear. Recent papers describe the efficiency of chelation with diphosphorus ligands in the Pd(0)-catalyzed carbonylation of aryl halides.[19] In our case, the cyanide anion, although absolutely neccesary as a reagent, has an inhibitory action on the catalyst; it is capable of binding to Pd(0) too strongly to render the catalyst inactive.[2,3,8,13] Therefore, ligands which can appropriately protect the palladium center from an attack of the free cyanide anion might be desirable.

In conclusion, a catalyst system comprising $[Pd_2(dba)_3]\cdot CHCl_3$ and DPPF was found to be effective for the cyanation of various aryl iodides and aryl triflates with KCN. The facile procedure adopted, owing to the stability of the catalyst precursor and the convenience of the batch method, also makes this catalytic reaction attractive as a new synthetic method of aryl cyanides.

Experimental

$[Pd_2(dba)_3]\cdot CHCl_3$ was utilized as obtained from Kanto Chemical Co. KCN was recrystallized from water and dried under reduced pressure (at ca. 300 °C) prior to use. The solvents were distilled and dried over Molecular Sieves. Aryl triflates were prepared according to a procedure described in the literature.[15] The other materials were commercial products and were used without further purification. A Hitachi 160 gas chromatograph was used for the GLC analysis. The ^1H NMR spectra were obtained on a JEOL FX90A spectrometer, using Me_4Si as the internal standard. The IR spectra were recorded on a Hitachi 260-10 spectrometer.

General Procedure for Cyanation. Preparation of *p*-Chlorobenzonitrile: To the dry KCN (139 mg, 2.0 mmol), $[Pd_2(dba)_3]\cdot CHCl_3$ (5.2 mg, 0.005 mmol), DPPF (11.1 mg, 0.02 mmol), *p*-chloroiodobenzene (238 mg, 1.0 mmol), and NMP (0.5 cm^3) were added, evacuated, flushed with nitrogen, and kept at 60 °C with stirring for 2 h. The resulting mixture was chromatographed on a silica-gel column using hexane-ethyl acetate as an eluent, affording 129 mg of *p*-chlorobenzonitrile (93%). Mp 90—91 °C (lit,[20] 90 °C); IR 2220 cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.3—7.5 (m, 4H).

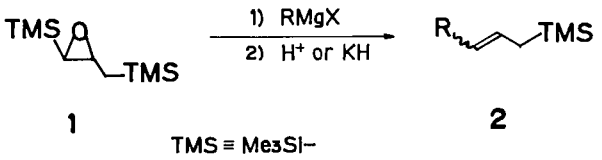
(Received November 20, 1990)

Stereoselective synthesis of various (*E*)- and (*Z*)-2-alkenyltrimethylsilanes ($RCH{=}CHCH_2SiMe_3$; R=Me, Et, *n*-Bu, *i*-Pr, *c*-hexyl, *t*-butyl, and phenyl) has been accomplished by a reaction of 1,2-epoxy-1,3-bis(trimethylsilyl)propane with Grignard reagents (RMgX) followed by subsequent Peterson olefination reactions of resulting 1,2-bis(trimethylsilyl)-3-alkanols [$RCH(OH)CH(SiMe_3)CH_2SiMe_3$]; the acid ($BF_3OEt_2$ or $HClO_4$)-catalyzed olefination yields the (*E*)-isomer, while the base (KH or NaH)-induced olefination yields the (*Z*)-isomer in more than 95% stereochemical purity in most cases.

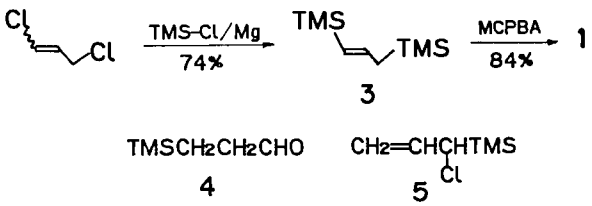
The chemistry of allylsilanes has received continuing synthetic and mechanistic interests.[2,3)] Synthetic methods for acyclic allylsilanes include coupling reactions between allyl-metal species and halosilanes,[4,5)] between silyl-metal species and allyl halides,[6)] or between allyl methyl ethers and halosilanes with the aid of sodium,[7)] Wittig condensation of 2-trimethylsilylethylidenetriphenylphosphorane with carbonyl compounds,[8)] hydrosilylation or reductive silylation of 1,3-dienes,[9)] a Ramberg-Backlund olefination,[10,11)] and transition metal-catalyzed reaction between allylic halides and disilanes.[12)] These methods are generally nonstereospecific and give a mixture of stereoisomers which are usually not readily separable from each other. Furthermore, some of these methods are not regiospecific. During the course of our study on the ene reactions of allylsilanes,[13,14)] we needed a series of (*E*)- and (*Z*)-2-alkenylsilanes in high stereochemical purity. 2-Alkenylsilanes may be prepared stereoselectively from 1-alkynes via hydroboration[15)] and from vinyl triflates via palladium-catalyzed coupling with tris(trimethylsilylmethyl)aluminum.[16)] We describe here a new stereoselective method for (*E*)- and (*Z*)-2-alkenyltrimethylsilanes (**2**) via a Grignard reaction of *trans*-1,2-epoxy-1,3-bis(trimethylsilyl)propane (**1**) followed by the Peterson olefination reaction.[17)]



Results and Discussion

The requisite oxirane **1** was obtained in 84% yield by epoxidation of (*E*)-1,3-bis(trimethylsilyl)propene (**3**) with *m*-chloroperbenzoic acid in dichloromethane at −15 °C. The oxirane was labile and decomposed to 3-trimethylsilylpropanal (**4**) on exposure to acids; however, it could be stored for years in a refrigerator without appreciable decomposition. The precursory olefin **3** can be prepared from allyltrimethylsilane,[18)] but we prepared it more conveniently in 74% yield from 1,3-dichloropropene by in situ coupling with chlorotrimethylsilane with the aid of magnesium in THF under reflux. Although commercial 1,3-dichloropropene was a mixture of (*E*) and (*Z*) isomers in the ratio 45 : 55, the coupling reaction led to almost stereospecific formation of (*E*)-**3**. This arose from the silylation via double rearrangement of the allylic double bonds. The first silylation yields (1-chloroallyl)trimethylsilane (**5**) and the subsequent silylation occurs at the 3-position of allyl group to give (*E*)-**3** from steric reason. Indeed, a controlled reaction afforded **5** in good yield.[19)]

Lithium dibutylcuprate(I) reacted relatively slowly with **1** in ether at −40 °C affording 1,3-bis(trimethylsilyl)-2-heptanol (**6**) together with a small amount of its trimethylsilyl ether **7** in a combined 75% yield, the products of the anticipated α cleavage.[20)] A sodium hydride-induced olefination of the resulting alcohol stereoselectively gave [(*E*)-2-heptenyl]-trimethylsilane [**2c**, (*E*)/(*Z*)=98/2] consistent with syn-elimination[21)] from a configuration shown in **6**. On the other hand, a BF_3OEt_2-catalyzed olefination of **6** proceeded without significant stereoselectivity yielding a 48 : 52 mixture of the (*E*) and (*Z*) isomers in 88% yield. This is presumably due to the steric strain imposed on the anti-oriented transition state. The regiochemistry of this olefination reaction is worth



Scheme 1.

stating. Predominant (>95%) formation of **2c** instead of its regioisomer **8** indicates that the internal $SiMe_3$ is more reactive than the terminal one either in the acid-catalyzed or base-induced reaction. Stability of the producing alkenes appears to play a dominant role in the regiocontrol.

The oxirane **1** smoothly reacted with alkyl and phenyl Grignard reagents (RMgX) in ether at room temperature to give 1,2-bis(trimethylsilyl)-3-alkanols **10a—g** in good yields except for the reaction with *t*-butylmagnesium bromide, as shown in Table 1 which includes the results of the subsequent olefination reactions as well. The reaction obviously involves an initial skeletal rearrangement of **1** to 2,3-bis(trimethylsilyl)propanal (**9**) probably effected by magnesium halides,[22] as shown in Scheme 3. The acid-catalyzed olefination of **10** by use of BF_3OEt_2 or 70% perchloric acid gave the (*E*) isomer of 2-alkenyltrimethylsilanes (**2a—g**), while the sodium hydride- or potassium hydride-induced reaction afforded the (*Z*) isomer with more than 97% stereoselectivity in most cases. These stereochemical results indicate that the alcohol **10** was formed in high diastereomeric purity almost as a single diastereomer of a configuration shown in **10**. The structure of the alcohol is predictable from the Cram's rule[23] if we assume that $SiMe_3$ is larger than CH_2SiMe_3. Relatively low stereoselectivities in the olefination of the alcohol **10a** are presumably attributed to contamination of an alternative diastereoisomer of **10a**. The reaction between **1** and *t*-butylmagnesium bromide

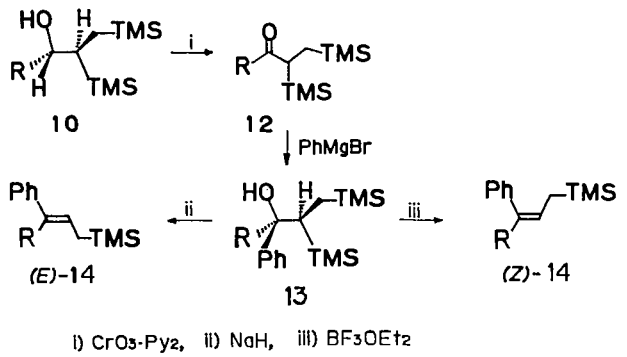
a) Isolated yield unless otherwise noted. b) Reaction conditions are as follows: (A) with ca. 1 equiv BF_3OEt_2 at 0 °C for 30 min in ether; (B) with 3 equiv 70% $HClO_4$ at 0 °C for 30 min in ether; (C) with 2 equiv KH in THF under reflux for 30 min; (D) with 2 equiv NaH in 1,2-dimethoxyethane under reflux for 3—5 h. c) GLC yield. d) At room temperature. e) Reflux for 90 min. f) Stirred for 15 min. g) Stirred for 5 min. h) Reflux for 20 min.

gave the alcohol **10f** in only 10% yield; the major reaction in this case was the formation of (*Z*)-1-trimethylsiloxy-3-trimethylsilyl-1-propene (**11**) which was isolated in 72% yield, indicating that **9** decayed to **11** more rapidly than it reacted with the bulky Grignard reagent.

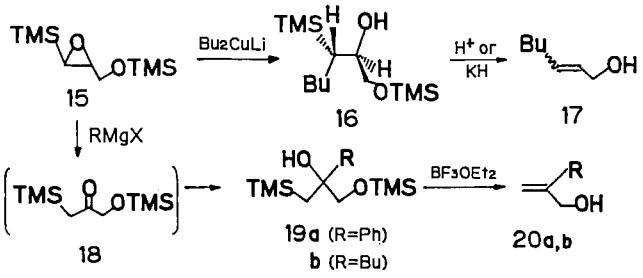
The stereochemistry of **2a—g** was deduced from IR spectra. The (*E*) and (*Z*) stereoisomers of **2a—g** appeared on GLC at different retention times and exhibited the C=C stretching vibration at different wavenumbers; one showed an absorption near 1660 cm^{-1} together with a strong out-of-plane deformation band near 960 cm^{-1}, while the other showed an absorption near 1645 cm^{-1} together with a weak band near 720 cm^{-1} but no significant band near 960 cm^{-1}. These differences in the IR spectra allow us to assign the former to the (*E*) and the latter to the (*Z*) isomers, respectively.[24] Both (*E*) and (*Z*) stereoisomers exhibited very complicated NMR spectra for olefinic protons which were not readily resolvable except for (*Z*)-**2g**.

The oxidation of the alcohols **10** to the corresponding ketones **12** and the subsequent Grignard reaction followed by olefination may provide a stereoselective route to (3,3-disubstituted allyl)trimethylsilanes. This was exemplified by preparation of (*E*) and (*Z*) isomers of (3-phenyl-2-butenyl)trimethylsilanes (**14a**; R=CH_3) from **10a** via a ketone **12a** and an alcohol **13a**, as shown in Scheme 4. The BF_3OEt_2-catalyzed reaction almost stereospecifically gave (*Z*)-**14a** in 92% yield, while the NaH-induced reaction did (*E*)-**14a** in 78% yield. The stereochemical assignment for **14a** was deduced from the NMR analysis and from the fact that **13a** gave (*E*)-2-phenyl-2-butene instead of **14a** on prolonged treatment with NaH. The stereochemical results suggest that PhMgBr added to the ketone **12a** exclusively in an anti-Cram fashion.

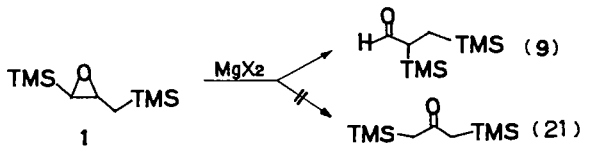
In connection with the stereoselective preparation of allylsilanes from **1**, we briefly examined reactions of a related oxirane **15**. Reaction with (n-Bu)$_2$CuLi gave an expected alcohol **16** which on treatment with perchloric acid and with KH respectively gave (*Z*)- and (*E*)-2-hepten-1-ol (**17**) almost in a stereospecific



Scheme 4.



Scheme 5.



Scheme 6.

manner in each case. On the other hand, phenylmagnesium bromide reacted with **15** yielding 2-phenyl-1-trimethylsiloxy-3-trimethylsilyl-2-propanol (**19**), which on treatment with BF_3OEt_2 afforded 2-phenylallyl alcohol (**20a**) in 91% yield. Similarly, reaction with butylmagnesium bromide and subsequent olefination gave 2-butylallyl alcohol (**20b**). The formation of the alcohol **19** indicates an initial rearrangement of **15** to 1-trimethylsiloxy-3-trimethylsilyl-2-propanone (**18**), as shown in Scheme 5.

Magnesium halide-induced rearrangement of 1-silyl-1,2-epoxyalkanes generally gives 1-silyl-2-alkanones instead of 2-silylalkanals via a regioselective ring-opening through the α-cleavage followed by migration of hydrogen rather than alkyl groups.[25] In addition, a group *cis* to silicon is in general more labile than the corresponding *trans* group.[26] This was indeed true for the oxirane **16**. Accordingly, the magnesium halide-induced rearrangement of **1** might produce 1,3-bis(trimethylsilyl)-2-propanone (**21**) instead of the aldehyde **9**. The absence of **21** suggests either a large migratory aptitude for CH_2SiMe_3 as compared to hydrogen or the selective β ring-opening followed by a 1,2-$SiMe_3$ shift, although we have no compelling evidence for the latter pathway.

Experimental

IR spectra were recorded on a Hitachi 260-10 spectrophotometer. NMR spectra were recorded on a Hiatachi R-600 (60 MHz) spectrometer in carbon tetrachloride using TMS as internal standard except otherwise noted. Mass spectra were recorded on a Hiatchi M-60 mass spectrometer. UV spectra were recorded on a Hitachi 220A spectrophotometer. Analytical and preparative GLC were performed on a Hitachi 163 gas chromatograph equipped with the following columns: (A): 4 mm×25% Apiezon Grease L on Chamelite CK, (B): 4 mm×3 m; 25% Silicone oil SE-30 on Chromosorb W (A.W), and (C): 4 mm×2 m; 25% Silicone DC 550 on

Chromosorb W (A.W), and DMCS.

1,3-Bis(trimethylsilyl)propene (3). To a mixture of chlorotrimethylsilane (49 g) and magnesium (30 g) in THF (100 cm^3) heated to ca. 60 °C was added dropwise a mixture of 1,3-dichloropropene (50 g) and chlorotrimethylsilane (49 g) in THF (200 cm^3) over a period of 8 h at such a rate as to maintain gentle reflux. After completion of the addition, the mixture was stirred for 2 h under reflux and was allowed to cool to room temperature. Hexane (500 cm^3) was then added and inorganic material was filtered off. The filtrate was washed with water, with 10% aq NaOH, and with water, and dried over $MgSO_4$. Fractionation using an efficient column gave 62 g (74%) of 1,3-bis(trimethylsilyl)propene, bp 68—69 °C (20 Torr; 1 Torr=133.3 Pa) [lit,[18a] bp 171 °C].

1,2-Epoxy-1,3-bis(trimethylsilyl)propane (1). To a stirred mixture of *m*-chloroperbenzoic acid (85% purity, 25 g) in dichloromethane (100 cm^3) cooled to −15 °C was added **3** (21 g, 0.113 mol) over a period of 10 min and the mixture was stirred for 3 h at that temperature. Pentane (100 cm^3) was added and a solid was removed by filtration. The solid was washed with pentane and the combined pentane solution was washed three times with every 15 cm^3 of 10% cold aq NaOH, with cold water, and dried over $MgSO_4$. Solvent was removed on a rotary evaporator and the residual oil was distilled to give 19 g (83%) of **1** as a colorless oil: Bp 69—70 °C (9 Torr); IR (neat) 1255, 1185, 870, 840 cm^{-1}; ^1H NMR δ=0.03 (9H, s), 0.05 (9H, s), 0.58 (1H, double d, J=14 and 7.5 Hz), 1.15 (1H, double d, J=14 and 5.5 Hz), 1.71 (1H, d, J=3.2 Hz), 2.62 (1H, m). Found: C, 53.18; H, 10.71%. Calcd for $C_9H_{22}OSi_2$: C, 53.41; H, 10.96%. Acidic workup should be avoided; in a separate experiment, washing a crude pentane solution with 10% aq HCl led to the formation of 3-trimethylsilylpropanal (**4**, 51%) instead: Bp 90—91 °C (118 Torr); IR (neat) 1730, 1250, 860, 840 cm^{-1}; ^1H NMR δ=0.0 (9H, 5), 0.58—0.90 (2H, m), 2.29 (1H, t (J=8.5 Hz) of d (J=1.5 Hz)), 9.60 (1H, t, J=1.5 Hz).

Reaction of 1 with Lithium Dibutylcuprate(1). To a solution of Bu_2CuLi prepared from BuLi (1.73 mol dm^{-3} in hexane, 12 cm^3) and CuI (1.9 g) in ether (20 cm^3) cooled to −78 °C was added the oxirane **1** (1.01 g, 5.0 mmol) and the mixture was stirred for 1 d at ca. −40 °C. Usual workup gave an oil (1.1 g), bp 105—110 °C (7 Torr), which was shown to be a mixture of 1,3-bis(trimethylsilyl)-2-heptanol (**6**) and its trimethylsilyl ether **7** in the ratio 8 : 1.

6: IR 3480 (broad), 1255, 855, 840 cm^{-1}; ^1H NMR δ=0.0 (18H, s), 0.5—1.0 (6H, m), 1.0—1.5 (6H, m), 1.8 (1H, disappeared on addition of D_2O), 3.8 (1H, broad m). Found: C; H, 12.39%. Calcd for $C_{13}H_{32}OSi_2$: C, 59.24; H, 12.24%.

7: IR 1255, 1030, 850, 835 cm^{-1}; ^1H NMR δ=0.0 (18H, s), 0.06 (9H, s), 0.5—1.0 (6H, m), 1.0—1.4 (6H, m), 4.05 (1H, t (J=7 Hz) of d (J=1.5 Hz)).

Preparation of 1,2-Bis(trimethylsilyl)-3-alkanols 10. General Procedure. A small portion (ca. 1 cm^3) of a solution of the oxirane **1** (5.05 g, 25 mmol) in ether (5 cm^3) was added to a solution of a Grignard reagent (30 mmol) in ether (25 cm^3) at room temperature. After an exothermic reaction had commenced, the rest of the epoxide solution was added over a period of 10 min and the resulting mixture was stirred for 1 h at ambient temperature. The mixture was cooled to 0 °C and aq ammonium chloride was added. Organic layer was separated, washed with aq $NaHCO_3$, and dried over $MgSO_4$. A crude product was purified by distillation or by column chromatography over alumina.

3,4-Bis(trimethylsilyl)-2-butanol (10a): Bp 110—111 °C (27 Torr): IR 3420, 1250, 1110, 1080, 850, 840 cm^{-1}; ^1H NMR δ=−0.02 (18H, s), 0.4—1.2 (3H, m), 1.09 (3H, d, J=6.5 Hz), 1.52 (1H, broad s, disappeared on addition of D_2O), 3.86 (1H, q (J=6.5 Hz) of d (J=4.5 Hz)). Found: C, 55.10; H, 12.21%. Calcd for $C_{10}H_{26}OSi_2$: C, 54.98; H, 12.00%.

1,2-Bis(trimethylsilyl)-3-pentanol (10b): Bp 87—88 °C (4 Torr); IR 3475, 1250, 840 cm^{-1}; ^1H NMR δ=0.0 (9H, s), 0.02 (9H, s), 0.51 (2H, d, J=5.4 Hz), 0.81—1.04 (4H, m), 1.43 (3H, m including OH proton), 3.61 (1H, m).

1,2-Bis(trimethylsilyl)-3-heptanol (10c): Bp 89—90 °C (1 Torr); IR 3480, 1250, 1020, 990, 840 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.0 (9H, s), 0.03 (9H, s), 0.44—0.55 (2H, m), 0.81—0.97 (3H, m), 1.38 (8H, m), 3.71 (1H, m). Found: C, 59.21; H, 12.35%. Found: $C_{13}H_{32}OSi_2$: C, 59.24; H, 12.24%.

4-Methyl-1,2-bis(trimethylsilyl)-3-pentanol (10d): Bp 86—87 °C (3 Torr) IR 3500, 1250, 1000, 840 cm^{-1}; ^1H NMR δ=0.0 (18H, s), 0.4—0.6 (2H, m), 0.80 (3H, d, J=7 Hz), 0.87 (3H, d, J=7 Hz), 0.7—1.3 (1H, m), 1.60 (2H, m, including OH proton), 3.19 (1H, m). Found: C, 58.35; H, 12.25%. Calcd for $C_{12}H_{30}OSi_2$: C, 58.47; H, 12.27%.

1-Cyclohexyl-2,3-bis(trimethylsilyl)-1-propanol (10e): After purification by column chromatography: IR 3490, 1250, 995, 840 cm^{-1}; ^1H NMR δ=0.0 (18H, s), 0.53 (2H, m), 0.7—2.05 (13H, m), 3.22 (1H, broad m).

4,4-Dimethyl-1,2-bis(trimethylsilyl)-3-pentanol (10f): IR 3600, 1250, 1055, 1000, 840 cm^{-1}; ^1H NMR δ=0.0 (9H, s), 0.04 (9H, s), 0.86 (9H, s), 0.3—1.3 (3H, m), 3.43 (1H, d, J=10.5 Nz).

1-Trimethylsiloxy-3-trimethylsilyl-1-propene (11): Bp 65—66 °C (22 Torr); IR 1645, 1250, 1155, 1090, 860, 840 cm^{-1}; ^1H NMR δ=0.0 (9H, s), 0.19 (9H, s), 1.37 (2H, double d, J=8.4 and 1.5 Hz), 4.35 (1H, d (J=8.4 Hz) of t (J=5.6 Hz)), 6.02 (1H, broad d, J=5.6 Hz).

1-Phenyl-2,3-bis(trimethylsilyl)-1-propanol (10g): IR 3460, 1255, 1050, 1010, 860, 840, 760, 700 cm^{-1}; ^1H NMR δ=−0.18 (9H, s), −0.15 (9H, s), 0.58 (2H, m), 0.94—1.21 (1H, m), 1.37 (1H, d, J=3.6 Hz, disappeared on addition of D_2O), 4.68 (1H, double d, J=6.6 and 3.6 Hz), 7.22 (5H, almost s). Found: C, 64.48; H, 10.25%. Calcd for $C_{15}H_{28}OSi_2$: C, 64.23; H, 10.16%.

Preparation of 2-Alkenyltrimethylsilanes 2. 1,2-Bis(trimethylsilyl)-3-alkanols (**10**) were olefinated by the following methods under conditions listed in Table 1. Crude product obtained after workup was purified by distillation or by column chromatography.

Procedure A. To a stirred solution of an alcohol **10** (10 mmol) in ether (25 cm^3) cooled to 0 °C was added 0.6 ml of fresh boron trifluoride–diethyl ether. The mixture was stirred for 30 min at 0 °C. Aq 10% NaOH solution was added and organic layer was separated, washed with saturated aq NaCl and dried ($MgSO_4$).

Procedure B. Procedure was the same as the Procedure A except for the use of 70% perchloric acid (0.25 g per 10 mmol of **10**) instead of boron trifluoride–diethyl ether.

Procedure C. Potassium hydride (3.2 g, ca. 25% slurry in oil) was washed three times with pentane, dried under argon, and was weighed. To the residue (ca. 0.8 g) was added THF (10 cm^3) followed by addition of an alcohol **10** (10 mmol) in THF (2 cm^3) at 0 °C. After evolution of gas had ceased, the mixture was heated under reflux for 15 to 30 min.

Procedure D. Sodium hydride (0.87 g, 55% dispersion in

oil, ca. 20 mmol) was washed three times with hexane and dried under argon. To the residue was added a solution of an alcohol **10** (10 mmol) in 1,2-dimethoxyethane (10 cm³) at room temperature and the mixture was stirred under reflux for 3 to 5 h.

2-Butenyl(trimethyl)silane (2a): IR and NMR spectra of (*E*) and (*Z*) isomers [GLC retention time t_R (Column B, 60 °C): 16.4 and 19.6 min, respectively] were identical to those reported.[27]

2-Pentenyl(trimethyl)silane (2b): (*E*)-**2b**: Bp 73 °C (100 Torr) ; IR 1660, 1250, 960, 845, 690 cm⁻¹ ^{1}H NMR δ=−0.04 (9H, s), 0.93 (3H, t, J=7.8 Hz), 1.29—1.39 (2H, m), 1.66—2.20 (2H, m), 5.16—5.35 (2H, m); MS m/z 142 (M^+, 13), 73 (100).

(*Z*)-**2b**: Bp 76—77 °C (98 Torr); IR 1640, 1250, 850, 720 cm⁻¹; ^{1}H NMR δ=−0.01 (9H, s), 0.92 (3H, t, J=7.2 Hz), 1.34—1.46 (2H, m), 1.60—2.22 (2H, m), 5.12—5.35 (2H, m); MS m/z 142 (M^+, 10), 73 (100).

Retention times for (*E*)-**2b** and (*Z*)-**2b** were 16.2 and 19.4 min, respectively (Column A, 100 °C).

2-Heptenyl(trimethyl)silane (2c): (*E*)-**2c**: Bp 102—103 °C (58 Torr); IR 1660, 1250, 960, 850, 690 cm⁻¹; ^{1}H NMR δ=0.0 (9H, s), 0.90 (3H, m), 1.28—1.43 (6H, m), 1.94—2.02 (2H, m), 5.21—5.42 (2H, m); MS m/z 170 (M^+, 8), 73 (100).

(*Z*)-**2c**: Bp 104—105 °C (55 Torr): IR 1640, 1250, 850, 720 cm⁻¹; ^{1}H NMR δ=0.02 (9H, s), 0.91 (3H, m), 1.12—1.6 (6H, m), 1.8—2.15 (2H, m), 4.95—5.6 (2H, m); MS m/z 170 (M^+, 6), 73 (100).

Retention times for (*E*)-**2c** and (*Z*)-**2c** were 23.6 and 25.6 min, respectively (Column B, 100 °C).

Trimethyl(4-methyl-2-pentenyl)silane (2d): (*E*)-**2d**: Bp 76—77 °C (66 Torr); IR 1660, 1250, 1155, 1020, 960, 855, 840 cm⁻¹; ^{1}H NMR δ=−0.04 (9H, s), 0.91 (6H, d, J=8.4 Hz), 1.31 (2H, d, J=6 Hz), 2.15 (1H, m), 4.87—5.32 (2H, m); MS m/z 156 (M^+, 6), 73 (100).

(*Z*)-**2d**: Bp 79—80 °C (65 Torr); IR 1645, 1250, 1150, 855, 840, 730 cm⁻¹; ^{1}H NMR δ=0.0 (9H, s), 0.91 (6H, d, J=6.4 Hz), 1.42 (2H, d, J=7.2 Hz), 2.5 (1H, m), 4.83—5.24 (2H, m); MS m/z 156 (M^+, 5), 73 (100).

Retention times for (*E*)-**2d** and (*Z*)-**2d** were 15.5 and 16.0 min, respectively (Column B, 100 °C).

(3-Cyclohexylallyl)trimethylsilane (2e): (*E*)-**2e**: IR 1660, 1250, 1155, 960, 850 cm⁻¹; ^{1}H NMR δ=−0.03 (9H, s), 0.6—2.3 (13H, m), 4.91—5.51 (2H, m); MS m/z 196 (m/z 4), 73 (100).

(*Z*)-**2e**: IR 1645, 1250, 1150, 850, 725 cm⁻¹; ^{1}H NMR 0.0 (9H, s), 0.6—2.5 (13H, m), 4.85—5.5 (2H, m). MS m/z 196 (M^+, 8), 73 (100).

Retention times for (*E*)-**2e** and (*Z*)-**2e** were 49.6 and 45.4 min, respectively (Column B, 120 °C).

(4,4-Dimethyl-2-pentenyl)trimethylsilane (2f): (*E*)-**2f**: IR 1250, 1155, 970, 850, 840 cm⁻¹; ^{1}H NMR δ=−0.04 (9H, s), 0.95 (9H, s), 1.30 (2H, m), 5.22 (2H, m); MS m/z 170 (M^+, 9), 73 (100).

(*Z*)-**2f**: IR 1645, 1250, 1150, 850, 720 cm⁻¹; ^{1}H NMR δ=0.0 (9H, s), 1.06 (9H, s), 1.56 (2H, m), 4.9—5.2 (2H, m); MS m/z 170 (M^+, 8), 73 (100).

Retention times for (*E*) and (*Z*)-**2f** were 2.6 and 2.0 min respectively (Column C, 150 °C).

(3-Phenylallyl)trimethylsilane (2g): (*E*)-**2g**: Bp 70—71 °C (2 Torr); IR 1640, 1250, 1140, 1020, 960, 855, 730, 680 cm⁻¹; ^{1}H NMR 0.04 (9H, s), 1.62 (2H, m), 6.02—6.30 (2H, m), 7.08—7.32 (5H, m). Found: C, 75.61; H, 9.52%. Calcd for $C_{12}H_{18}Si$: C, 75.72; H, 9.53%.

(*Z*)-**2g**: Bp 62—63 °C (2 Torr); IR 1630, 1250, 1145, 860, 840, 760, 720, 690 cm⁻¹; ^{1}H NMR δ=0.0 (9H, s), 1.76 (2H, double d, J=9.0 and 1.2 Hz), 5.61 (1H, d (J=11.7 Hz) of t (J=8.6 Hz)), 6.26 (1H, d, J=12 Hz), 7.18 (5H, m). Found: C, 75.70; H, 9.42%. Calcd for $C_{12}H_{18}Si$: C; 75.72; H, 9.53.

Retention times for (*E*)-**2g** and (*Z*)-**2g** were 12.8 and 10.8 min, respectively (Column C, 180 °C).

Olefination of 6. Treatment of **6** (260 mg) with BF_3OEt_2 in the Procedure A gave 149 mg (88%) of **2c** (*E*/*Z*=48 : 52). Treatment of **6** (260 mg) with NaH in the Procedure D (reflux, 5 h) gave 127 mg (75%) of (*Z*)-**2c**. A small amount (ca. 5%) of an unidentified compound, which would probably be (1-butylallyl)trimethylsilane (**8**), was also formed in both cases.

Oxidation of 10a. To a solution of $CrO_3 \cdot Py_2$ (3.7 g) in dichloromethane (40 cm³) was added a solution of **10a** (1.03 g) in dichloromethane (5 cm³) at room temperature and stirred for 15 min at ambient temperature. A crude oil obtained after workup was subjected to bulb-to-bulb distillation (ca. 80 °C at 6 Torr) to give 680 mg (70%) of 3,4-bis(trimethylsilyl)-2-butanone (**12a**): IR 1690, 1250, 1085, 840 cm⁻¹; ^{1}H NMR δ=−0.06 (9H, s), 0.06 (9H, s), 0.35 (1H, double d, J=15 and 1.2 Hz), 1.28 (1H, double d, J=15 and 1.2 Hz), 1.99 (3H, s), 2.34 (1H, d, J=12 Hz).

Reaction of 12a with Phenylmagnesium Bromide and Subsequent Olefination. To a solution of phenylmagnesium bromide (5 mmol) in ether (15 cm³) was added **12a** (680 mg) in ether (2 cm²) at room temperature and the mixture was stirred for 1 h at ambient temperature. A crude oil obtained after workup was subjected to column chromatography over alumina eluting with 5% ether in hexane containing 1% methanol gave 497 mg (51%) of 2-phenyl-3,4-bis(trimethylsilyl)-2-butanol (**13a**): IR 3500, 1600, 1250, 840, 760, 695 cm⁻¹; ^{1}H NMR δ=−0.15 (9H, s), −0.09 (9H, s), 1.49 (3H, s), 7.26 (5H, m). Treatment of **13a** (110 mg) with BF_3OEt_2 in the olefination Procedure A (0 °C, 15 min) gave 70 mg (92%) of (*Z*)-(3-phenyl-2-butenyl)trimethylsilane (**14a**) after purification by column chromatography: IR 1600, 1250, 855, 840, 760, 695 cm⁻¹; ^{1}H NMR δ=−0.06 (9H, s), 1.37 (2H, broad d, J=8.0 Hz), 1.99 (3H, s), 5.42 (1H, t, J=8 Hz), 6.9—7.3 (5H, m). Treatment of **13a** (240 mg) with NaH in the Procedure D (reflux, 2 h) gave 94 mg (88%) of (*E*)-2-phenyl-2-butene. ^{1}H NMR 1.77 (3H, d, J=7 Hz), 1.99 (3H, s), 5.77 (1H, broad q, J=7 Hz), 7.18 (5H, m). The same treatment of **13a** (70 mg) under reflux for 15 min gave 38 mg (78%) of (*E*)-**14a** after purification by column chromatography: IR 1640, 1250, 850, 750, 690 cm⁻¹; ^{1}H NMR δ=0.06 (9H, s), 1.62 (2H, d, J=9.0 Hz), 1.95 (3H, s), 5.77 (1H, t, J=9 Hz), 7.0—7.25 (5H, m).

Preparation of 1,2-Epoxyl-3-trimethylsiloxy-1-trimethylsilylpropane (15). To a cold mixture of *m*-chloroperbenzoic acid (7.0 g, 85% purity) in dichloromethane (50 cm³) was added a solution of [(*E*)-3-trimethylsilyl-2-propenoxy]trimethylsilane (6.0 g) in dichloromethane (10 cm³) over a period of 15 min at 0 °C. Usual workup gave 5.3 g (71%) the oxirane *trans*-**15**: Bp 94—95 °C (17 Torr); IR 1255, 1145, 1100, 1020, 860, 840 cm⁻¹; ^{1}H NMR δ=0.05 (9H, s), 0.09 (9H, s), 1.90 (1H, d, J=3.5 Hz), 2.77 (1H, m), 3.50 (1H, double d, J=11.7 and 4.5 Hz), 3.70 (1H, double d, J=11.7 and 3.9 Hz). Found: C, 49.21; H, 10.01%. Calcd for $C_9H_{22}O_2Si_2$: C, 49.49; H, 10.15%.

Reaction of 15 with Lithium Dibutylcuprate(I) and Subsequent Olefination. To a solution of $(n\text{-Bu})_2$CuLi prepared from BuLi (34.5 mmol, 1.7 mol dm⁻³ in hexane) and

CuI (3.23 g) in ether (25 cm³) was added a solution of **15** (1.5 g, 6.9 mmol) in ether (2 cm³) at −40 °C and the mixture was stirred for 1.5 h at −40 °C. Workup followed by bulb-to-bulb distillation (ca. 130 °C at 17 Torr) gave 1.50 g (80%) of 1-trimethylsiloxy-3-trimethylsilyl-2-heptanol (**16**): IR 3480, 1255, 1105, 1085, 870, 845 cm⁻¹; ¹H NMR δ=0.03 (9H, s), 0.12 (9H, s), 0.6—1.6 (10H, m), 2.19 (1H, broad s, disappeared on addition of D_2O), 3.2—3.9 (3H, m). Treatment of **16** (275 mg) with 70% $HClO_4$ in the Procedure B (0 °C, 30 min) gave 135 mg (90%) of a mixture of (*Z*)-2-hepten-1-ol (**17**) [IR 1660, 1250, 990, 875, 840, 740 cm⁻¹; ¹H NMR 0.07 (9H, s), 0.91 (3H, m), 1.15—1.65 (4H, m), 2.0 (2H, m), 3.92—4.19 (2H, m), 5.24—5.56 (2H, m)] and its trimethylsilyl ether [IR 3320, 1660, 1020 cm⁻¹; ¹H NMR δ=0.7—1.7 (7H, m), 1.8—2.3 (2H, m), 4.06 (2H, broad d, *J*=4.5 Hz), 5.3—6.8 (2H, m)] in the ratio 1:1. Treatment of **16** (413 mg) with KH in the olefination Procedure C (reflux, 2 h) gave 229 mg (81%) of (*E*)-2-heptenoxytrimethylsilane: IR 1675, 1250, 1100, 1055, 970, 870, 840 cm⁻¹; ¹H NMR δ=0.07 (9H, s), 0.91 (3H, m), 1.1—1.6 (4H, m), 2.0 (2H, m), 3.95 (2H, m), 5.48 (2H, m). On treatment with methanol, this compound gave (*E*)-**17** quantitatively: IR 3330, 1675, 1085, 1000, 970 cm⁻¹; ¹H NMR δ=0.91 (3H, m), 1.1—1.6 (5H, m), 2.0 (2H, m), 3.95 (2H, m), 5.57 (2H, m).

Reaction of 15 with Phenylmagnesium Bromide and Subsequent Olefination. To a stirred solution of phenylmagnesium bromide (10 mmol) in ether (25 cm³) was added a solution of **15** (1.03 g) in ether (2 cm³) at room temperature and the mixture was stirred for 4 h under reflux. Usual workup gave 857 mg (62%) of 2-phenyl-1-trimethylsiloxy-3-trimethylsilyl-2-propanol (**19a**) after purification by bulb-to-bulb distillation (ca. 120 °C at 6 Torr): IR 3550, 1600, 1250, 1090, 850, 840, 750, 695 cm⁻¹; ¹H NMR δ=−0.20 (9H, s), 0.0 (9H, s), 1.08 (d, *J*=14.5 Hz), 1.24 (1H, d, *J*=14.5 Hz), 2.73 (1H, s, disappeared on addition of D_2O), 3.51 (2H, s), 7.29 (5H, m). Treatment of **19a** (312 mg) with BF_3OEt_2 in the olefination Procedure A (room temperature, 30 min) gave 195 mg (91%) of a mixture of 2-phenylallyl alcohol (**20a**) and its trimethylsilyl ether in the ratio 55:45 after purification by bulb-to-bulb distillation (ca. 120 °C at 35 Torr). Treatment of the mixture with methanol containing a small amount of potassium carbonate cleanly gave **20a**: ¹H NMR δ=2.56 (1H, s, disappeared on addition of D_2O), 4.34 (2H, s), 5.24 (1H, broad s), 5.34 (1H, broad s), 7.26 (5H, m).

Reaction of 15 with Butylmagnesium Bromide and Subsequent Olefination. To a solution of *n*-BuMgBr (6.5 mmol) in ether (25 cm³) was added a solution of **15** (722 mg) in ether (2 cm³) and the mixture was stirred for 5 h under reflux. Workup followed by bulb-to-bulb distillation gave 550 mg (61%) of 1-trimethylsiloxy-2-(trimethylsilylmethyl)-2-hexanol (**19b**): IR 3430, 1250, 1090, 860, 840 cm⁻¹; ¹H NMR δ=0.03 (9H, s), 0.11 (9H, s), 0.65—1.7 (12H, m), 3.28 (2H, s). Treatment of **19b** (270 mg) with BF_3OEt_2 in the Procedure A (room temperature, 15 min) gave 51 mg (45%) of 2-butylallyl alcohol (**20b**) after treatment with methanol: ¹H NMR δ=0.6—1.7 (8H, m), 1.7—2.2 (2H, m), 3.94 (2H, s), 4.77 (1H, s), 4.92 (1H, s).

A Novel Synthesis of Methylenecyclopropane Spiro-Linked with Cycloalkanes via a Cyclization of Allylic Epoxides and Its Application to a Synthesis of Fused 3-Methylfurans[1)]

Tsuyoshi SATOH, Yasushi KAWASE, and Koji YAMAKAWA*
Faculty of Pharmaceutical Sciences, Science University of Tokyo,
Ichigaya-funagawara-machi, Shinjuku-ku, Tokyo 162
(Received November 26, 1990)

Ring closure of allylic epoxides derived from 1-chloroalkyl phenyl sulfoxides and cyclic ketones with lithium diisopropylamide (LDA) in 3-Exo-Tet mode gave spiro-linked methylenecyclopropanes having a hydroxyl group in good yields. Oxidation of these compounds gave ketones, which were then treated with *p*-toluenesulfonic acid in 1,4-dioxane or DMSO at 100 °C to give fused 3-methylfurans in good overall yields. This procedure was applied to a synthesis of menthofuran from 4-methylcyclohexanone.

Intramolecular nucleophilic ring-opening of epoxides with carbanions is one of the most useful reactions for the synthesis of carbocyclic compounds.[2)] We recently reported a new procedure for the synthesis of highly functionalized cyclohexane derivatives from ketones via epoxy sulfone cyclization.[3)] As shown in Scheme 1, treatment of the epoxy sulfone **1a** with LDA, a cyclization in 6-Endo-Tet mode[4)] took place to afford the cyclized product **2** in high yields (path a). In the study we found that treatment of **1b** with LDA did not give the 14-membered cyclized product **2b** but, instead, gave methylenecyclopropane **3** in moderate yield (path b). Clearly, from this case, the 3-Exo-Tet type reaction was shown to be easier than 14-Endo-Tet cyclization.

In this paper we would like to report in detail a novel method for the synthesis of spiro-linked methylenecyclopropanes **8** from cyclic ketones **4** and 1-chloroalkyl phenyl sulfoxides **5** through α,β-epoxy sulfoxides **7** (Scheme 2).[5)] We also report the two-step conversion of the methylenecyclopropanes **8** to cycloalkane-fused 3-methylfurans **10** via ketones **9**.

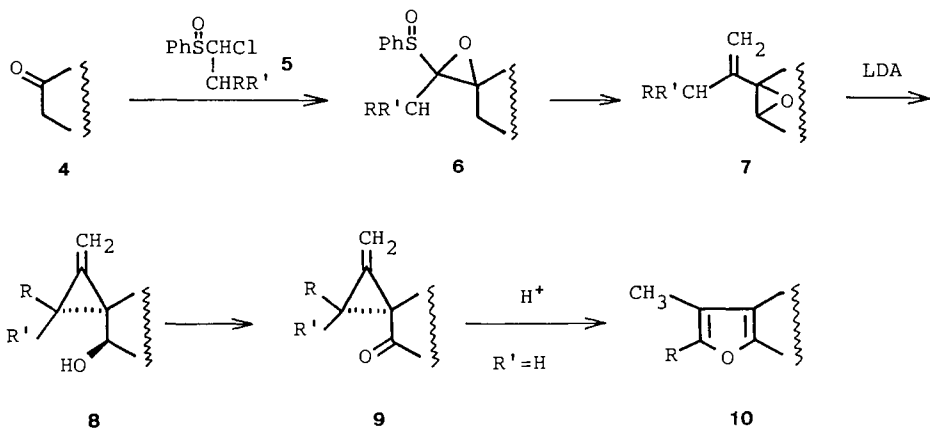
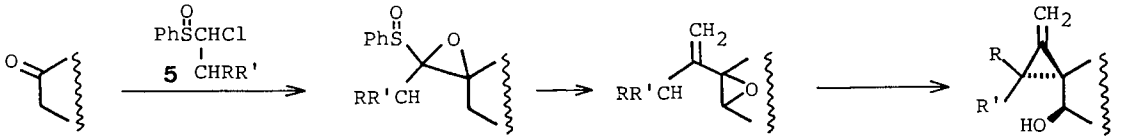


Scheme 2.

Results and Discussion

A Synthesis of Methylenecyclopropane Spiro-Linked with Cycloalkanes. Cyclopropanes are quite interesting compounds in synthetic organic chemistry and their chemistries have extensively been studied.[6] However, methylene-substituted cyclopropanes show somewhat different properties owing to their highly strained nature.[7] Some methods for the synthesis of methylenecyclopropanes and the use of these compounds in organic synthesis have been reported.[8] In perticular, the use of methylenecyclopropanes as a

Table 1. Synthesis of Methylenecyclopropane Spiro-Linked with Cycloalkanes from Cyclic Ketones and 1-Chloroalkyl Phenyl Sulfoxide **5**



Entry	Ketone	R	R′	Allylic epoxide (Yield/%)[a]	Methylenecyclopropane (Yield/%)[b]
1		H	H	**14** (70)	 **15** (88)

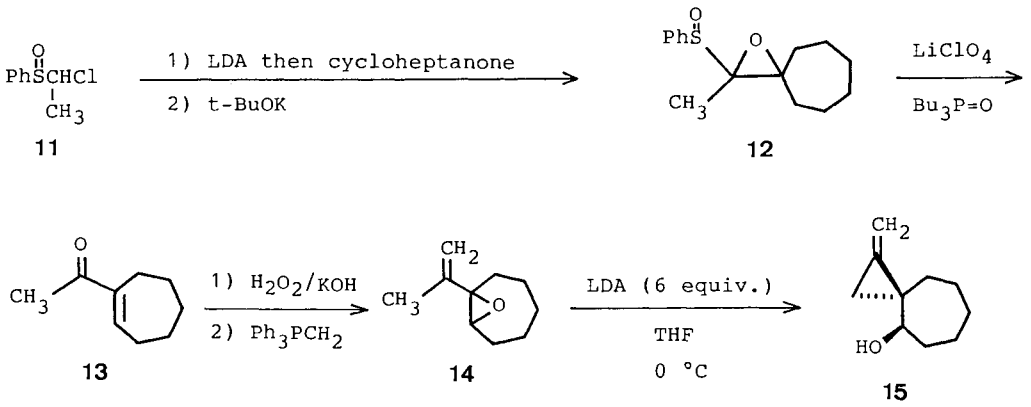


Scheme 3.

precursor for trimethylenemethanes has been known.[7] However, to the best of our knowledge, no report on the synthesis of methylenecyclopropane spiro-linked with cycloalkanes has appeared so far. Here we report a novel synthesis of spiro-linked methylenecyclopropanes; the synthesis of (3*R**,4*S**)-1-methylenespiro[2.6]nonan-4-ol **15** as an example (Scheme 3).

α,β-Epoxy sulfoxide **12** was easily prepared in quantitative yield from 1-chloroethyl phenyl sulfoxide **11** and cycloheptanone through a chloro alcohol. Heating **12** with lithium perchlorate trihydrate in refluxing toluene in the presence of tributylphosphine oxide afforded enone **13** in 85% yield.[9] Epoxidation of **13** was carried out with alkaline hydrogen peroxide in methanol to give the epoxy ketone, which was then treated with methylenetriphenylphosphorane in THF to afford the allylic epoxide **14** in 91% overall yield. Cyclization of **14** to methylenecyclopropane took place cleanly with six equivalents of LDA at 0 °C for 4 h to afford **15** in 84% yield.

The structure of **15** was determined by ^{13}C NMR and IR. In ^{13}C NMR the chemical shift observed (δ=16.3, 102.6, 140.4) was characteristic of methylenecyclopropanes.[10] IR spectrum of **15** showed 3450 cm^{-1} (OH) and the characteristic vibration due to carbon-carbon double bond of methylenecyclopropanes (1760 cm^{-1}).[11] The stereochemistry of **15** was tentatively assigned on the basis of the mechanistic consideration of cyclization of **14**. Representative examples for the synthesis of spiro-linked methylenecyclopropanes from various cyclic ketones and 1-chloroalkyl phenyl sulfoxides are summarized in Table 1.

As shown in Table 1, this procedure can be applied to the synthesis of spiro-linked methylenecyclopropane or its 2-substituted derivatives. Spiro derivatives of 1-methylene-2-alkyl(or phenyl)cyclopropanes were obtained as an inseparable diastereomeric mixture with respect to the asymmetric carbon of the cyclopropane ring. The cyclization of the allylic epoxide **17** having phenyl group took place quite smoothly (the reaction was completed within 1 h) giving **25** in quantitative yield (Entry 3). This result implies that the rate of the cyclization is dependent on the acidity of the allylic hydrogen. α-(Secondary alkyl)-substituted allylic epoxide **19** did not cyclize (Entry 5).

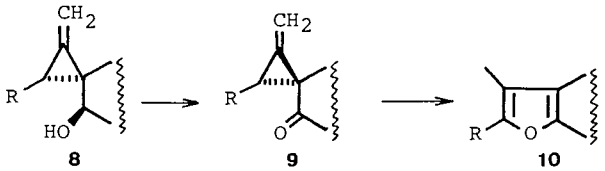
Application of the Method to the Synthesis of Fused 3-Methylfurans. It has been known that cyclopropanes in conjugation with imines undergo acid-catalyzed thermal rearrangement to afford pyrrolines.[12] Analogous with this reaction, it was anticipated that the methylenecyclopropanes in conjugation with the carbonyl group would be rearranged to methylenedihydrofurans or 3-methylfurans. In continuation of our studies with spiro-linked methylenecyclopropanes **8**, we planned to synthesize 3-methylfurans **10**, which are widely found in natural products, especially in sesquiterpenes,[13] through the methylenecyclopropane ketones **9**.[14]

Methylenecyclopropane **28** (see Table 1) was oxidized under the Swern's conditions to give methylenecyclopropane conjugated with ketone **31** in 90% yield. This ketone was quite stable under heating (in refluxing toluene for 2 h, no reaction was observed); however, with 0.3 equivalents of *p*-toluenesulfonic acid it gave the desired 3-methylfuran **34** (see Table 2) in 65% yield. Heating **31** with one equivalent of *p*-toluenesulfonic acid at 100 °C for 2 h was found to be the optimum conditions giving **34** in 84% yield. In this reaction, DMSO was similarly effective as the solvent.

Synthesis of fused 3-methylfurans from methylenecyclopropanes through the ketones is summarized in Table 2. As shown in the table, 1-ethyl-2-methylenecyclopropane **29** gave 2-ethyl-3-methylfuran **35** in a yield similar to that of another example (Entry 2). The rate of the rearrangement was not affected by the size of the ring spiro-linked with cyclopropane (Entry 3).

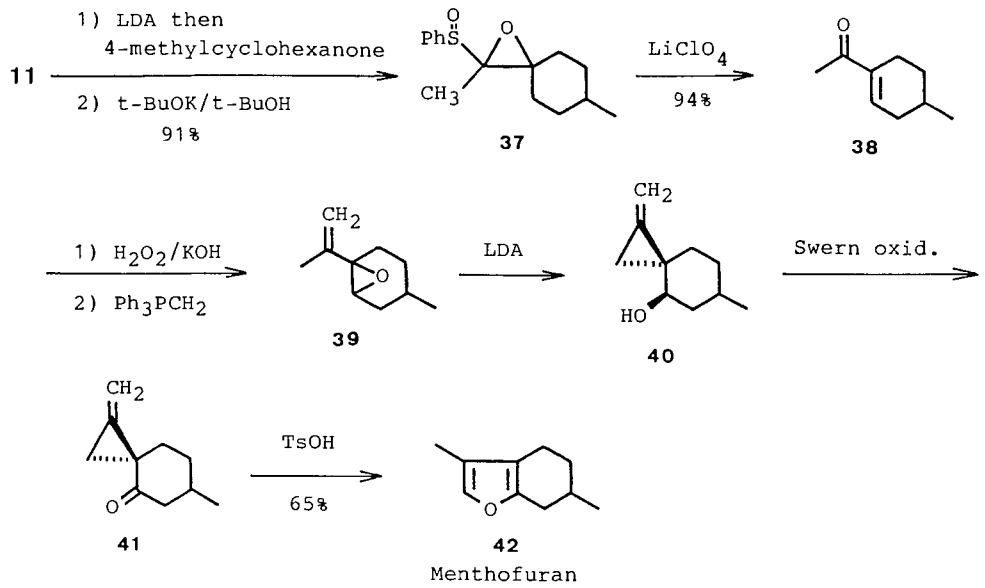
Scheme 4 shows a synthesis of menthofuran **42**[15] from 4-methylcyclohexanone by the method described above. The α,β-epoxy sulfoxide **37** was synthesized from commercially available 4-methylcyclohexanone in 91% overall yield. Treatment of **37** with $LiClO_4$ gave the enone **38**, which was then epoxidized and

Table 2. Synthesis of Fused 3-Methylfurans **10** from Methylenecyclopropanes **8** through Ketones **9**



Entry	Methylene-cyclopropane	Ketone (Yield/%)	Solvent[a] (Time)	3-Methylfuran (Yield/%)
1	**28**	**31** (90)	dioxane (2 h)	 **34** (84)
2	**29**	**32** (83)	dioxane (3 h)	 **35** (58)
3	**30**	**33** (99)	DMSO (3 h)	 **36** (62)

a) All reactions were carried out at 100 °C with one equivalent of *p*-toluenesulfonic acid.



Scheme 4.

methylenated to afford allylic epoxide **39** in good overall yield as a diastereomeric mixture. The cyclization took place smoothly with LDA to give methylenecyclopropane **40** (87%), which was then oxidized to give the ketone **41** in 85% yield. The rearrangement of **41** with one equivalent of *p*-toluenesulfonic acid in DMSO at 100 °C for 2 h gave menthofuran **42** (65% yield), which was identical (IR, NMR, and MS) with the authentic sample.

In conclusion, a novel synthesis of methylenecyclopropane spiro-linked with cycloalkanes and their application to fused 3-methylfurans were achieved. We believe that this study will be of value to explore further the chemistry of methylenecyclopropanes.

Experimental

All melting points are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were measured in a $CDCl_3$ solution with a JEOL FX-100 spectrometer. Electron-impact mass spectra (MS) were obtained at 70 eV by direct insertion. Silica gel BW-127 ZH (Fuji-Devison) containing 2% fluorescence reagent 254 and quartz column were used for column chromatography, and the products having UV absorption were detected by UV irradiation. In experiment requiring dry solvents, THF was distilled from benzophenone ketyl; diisopropylamine, toluene, and DMSO were dried over CaH_2 and distilled. All new compounds, especially oily products, did not give acceptable data for combustion analysis; however, the purity of all the title compounds was judged to be over

95% by ^{1}H NMR spectral determination and chromatographic analyses.

2′-Methyl-2′-(phenylsulfinyl)spiro[cycloheptane-1,1′-oxirane] (12). A solution of **11** (1.02 g; 5.43 mmol) in 3 ml of dry THF was added dropwise to a stirring solution of LDA (6.25 mmol) in dry THF at −60 °C under N_2. The mixture was stirred for 15 min, then cycloheptanone (6.25 mmol) was added. After 5 min the reaction was quenched with saturated aqueous NH_4Cl. The whole was extracted with ether-benzene and after the usual workup the product was purified by silica-gel column chromatography to give 1.61 g (98%) of adduct. *t*-BuOK (6.24 mmol) was added to a solution of the adduct in a mixture of *t*-BuOH-THF (3 : 1, 40 ml) and the solution was stirred at room temperature for 10 min, and then the reaction was quenched with powdered NH_4Cl. The organic solvent was evaporated and the residue was extracted with ether-benzene. The usual workup gave **12** (1.49 g; 92%) as a colorless oil. IR (neat) 1080, 1050 (SO) cm^{-1}; ^{1}H NMR δ=1.32 (3H, s), 1.4—2.0 (10H, m), 2.29 (2H, m), 7.4—7.7 (5H, m); MS *m/z* (%) 139 ([M−PhSO]$^+$ 45), 126 (46), 43 (100).

1-Acetylcycloheptene (13). A mixture of **12** (1.08 g; 4.08 mmol), $LiClO_4 \cdot 3H_2O$ (4.9 mmol), and *n*-Bu_3PO (4.1 mmol) in 40 ml of toluene was refluxed under N_2 for 45 min. The reaction mixture was diluted with benzene and was washed with water. The usual workup followed by silica-gel column chromatography gave 482 mg (85%) of the enone **13** as a colorless oil. IR (neat) 1670 (CO), 1640 cm^{-1}; ^{1}H NMR δ=1.3—1.9 (6H, m) , 2.2—2.56 (4H, m), 2.30 (3H, s), 7.05 (1H, t, *J*=6 Hz); MS *m/z* (%) 138 (M$^+$, 50), 123 (58), 95 (87), 43 (100). Found: *m/z* 138.1037. Calcd for $C_9H_{14}O$: M, 138.1043.

1-Isopropenyl-1,2-epoxycycloheptane (14). To a solution of **13** (470 mg; 3.4 mmol) in 15 ml of MeOH was added 30% H_2O_2 (1.74 ml) and 6 equiv KOH (1.02 mmol). The reaction mixture was stirred at room temperature for 3 h, then the mixture was diluted with water and the whole was extracted with CH_2Cl_2. The usual workup followed by silica-gel column chromatography afforded the epoxide 482 mg (94%) as a colorless oil; IR (neat) 1710 (CO) cm^{-1}; ^{1}H NMR δ=2.03 (3H, s), 3.22 (1H, t, *J*=6 Hz). To a mixture of methyltriphenylphosphonium iodide (1.69 g; 4.19 mmol) and *t*-BuOK (4.19 mmol) in a flame-dried flask was added 8 ml of dry THF and the yellow suspension was stirred at room temperature for 15 min. To this mixture was added a solution of the epoxide (415 mg; 2.7 mmol) and then, the reaction mixture was stirred for 30 min. The reaction was quenched with saturated aqueous NH_4Cl; then the whole was extracted with ether. The usual workup followed by silica-gel column chromatography gave **14** (409 mg; 99%) as a colorless oil. IR (neat) 1655 (C=C) cm^{-1}; ^{1}H NMR δ=1.2—2.3 (10H, m), 1.76 (3H, t, *J*=1 Hz), 2.98 (1H, t, *J*=6 Hz), 4.81 (1H, m), 4.94 (1H, m); MS *m/z* (%) 152 (M$^+$, 32), 123 (63), 109 (48), 81 (100). Found: *m/z* 152.1195. Calcd for $C_{10}H_{16}O$: M, 152.1199.

(3*R,4*S**)-1-Methylenespiro[2.6]nonan-4-ol (15).** A solution of **14** (41 mg; 0.27 mmol) in 1 ml of dry THF was added to a stirring solution of LDA (1.62 mmol) in 3 ml of dry THF at −60 °C under N_2. The mixture was stirred at −60 °C for 10 min and then at 0 °C for 4 h. The reaction was quenched with saturated aqueous NH_4Cl and the whole was extracted with ether. The usual workup followed by silica-gel column chromatography gave **15** (36 mg; 88%) as a colorless oil. IR (neat) 3450 (OH), 1760 (C=C) cm^{-1}; ^{1}H NMR δ=0.8—2.3 (13H, m), 3.38 (3H, t, *J*=6 Hz), 5.37 (1H, m), 5.49 (1H, m); ^{13}C NMR δ=16.33, 22.27, 26.66, 29.34, 30.56, 30.70, 35.82, 76.32, 102.64, 140.41; MS *m/z* (%) 152 (M$^+$, 0.5), 151 (3.5), 123 (34), 109 (91), 81 (100). Found: *m/z* 152.1197. Calcd for $C_{10}H_{16}O$: M, 152.1199.

Allylic Epoxide (16—23). These allylic epoxides were synthesized from cyclic ketones and 1-chloroalkyl phenyl sulfoxides in a similar way as described for **14**.

2-(1,2-Epoxycycloheptyl)-1-pentene (16). Colorless oil; IR (neat) 1660 cm^{-1}; ^{1}H NMR δ=0.92 (3H, t, *J*=7 Hz), 1.0—1.7 (8H, m), 1,7—2.2 (6H, m), 2.90 (1H, t, *J*=5 Hz), 4.76 (1H, m), 4.98 (1H, m); MS *m/z* (%) 180 (M$^+$, 10), 151 (100), 137 (23). Found: *m/z* 180.1520. Calcd for $C_{12}H_{20}O$: M, 180.1514.

2-(1,2-Epoxycyclohexyl)-3-phenylpropene (17). Colorless oil; IR (neat) 1640 cm^{-1}; ^{1}H NMR δ=0.8—2.1 (8H, m), 2.76 (1H, m), 3.42 (2H, bs), 4.80 (1H, m), 5.15 (1H, m), 7.18 (5H, m); MS *m/z* (%) 214 (M$^+$, 33), 185 (21), 129 (78), 91 (100). Found: *m/z* 214.1353. Calcd for $C_{15}H_{18}O$: M, 214.1355.

2-(1,2-Epoxycyclohexyl)-1-pentene (18). Colorless oil; IR (neat) 1650 cm^{-1}; ^{1}H NMR δ=0.91 (3H, t, *J*=7 Hz), 1.1—2.2 (12H, m), 2.93 (1H, m), 4.80 (1H, m), 5.02 (1H, m); MS *m/z* (%) 166 (M$^+$, 22), 137 (100), 123 (82). Found: *m/z* 166.1357. Calcd for $C_{11}H_{18}O$: M, 166.1357.

1-Cyclohexyl-1-(1,2-epoxycyclohexyl)ethylene (19). Colorless oil; IR (neat) 1620 cm^{-1}; ^{1}H NMR δ=0.8—2.2 (19H, m), 2.88 (1H, m), 4.79 (1H, m), 5.04 (1H, m); MS *m/z* (%) 206 (M$^+$, 39), 191 (8), 177 (13), 163 (100). Found: *m/z* 206.1664. Calcd for $C_{14}H_{22}O$: M, 206.1669.

2-(1,2-Epoxycyclopentyl)-1-nonene (20). Colorless oil; IR (neat) 1650 cm^{-1}; ^{1}H NMR δ=0.87 (3H, t, *J*=7 Hz), 1.0—2.1 (21H, m), 3.38 (1H, s), 4.97 (1H, m), 5.15 (1H, m); MS *m/z* (%) 208 (M$^+$, 40), 179 (10), 151 (26), 124 (100). Found: *m/z* 208.1831. Calcd for $C_{14}H_{24}O$: M, 208.1826.

2-(1,2-Epoxy-4-*t*-butylcyclohexyl)propene (21). Colorless oil; IR (neat) 1650 cm^{-1}; ^{1}H NMR δ=0.84 (9H, s), 1.0—2.3 (7H, m), 1.76 (3H, m), 3.10 (1H, bs), 4.79 (1H, m), 4.94 (1H, m); MS *m/z* (%) 194 (M$^+$, 48), 179 (25), 165 (5), 137 (82), 41 (100). Found: *m/z* 194.1669. Calcd for $C_{13}H_{22}O$: M, 194.1669.

2-(1,2-Epoxy-4-*t*-butylcyclohexyl)-1-pentene (22). Colorless oil; IR (neat) 1650 cm^{-1}; ^{1}H NMR δ=0.86 (9H, s), 0.92 (3H, t, *J*=7 Hz), 1.2—2.3 (11H, m), 3.03 (3H, bs), 4.78 (1H, m), 4.99 (1H, m); MS *m/z* (%) 222 (M$^+$, 3), 207 (6), 193 (67), 165 (74), 57 (100). Found: *m/z* 222.1985. Calcd for $C_{15}H_{26}O$: M, 222.1982.

2-(1,2-Epoxycyclododecyl)propen (23). Colorless oil; IR (neat) 1655 cm^{-1}; ^{1}H NMR δ=1.0—1.9 (20H, m), 1.89 (3H, t, *J*=1 Hz), 3.00 (1H, m), 4.85 (1H, m), 4.92 (1H, m); MS *m/z* (%) 222 (M$^+$, 25), 179 (5), 151 (6), 123 (15), 41 (100). Found: *m/z* 222.1980. Calcd for $C_{15}H_{26}O$: M, 222.1982.

Methylenecyclopropane (24—30). These methylenecyclopropanes were synthesized from the corresponding allylic epoxides in a similar way as described for **15**.

(3*R,4*S**)-2-Ethyl-1-methylenespiro[2.6]nonan-4-ol (24).** Colorless oil; IR (neat) 3425 (OH), 1745 (C=C) cm^{-1}; ^{1}H NMR δ=0.8—1.2 (4H, m), 1.2—2.2 (12H, m), 3.40 (1H, m), 5.38 (2H, m); MS *m/z* (%) 180 (M$^+$, 1), 151 (96), 137 (97), 81 (100). Found: *m/z* 180.1514. Calcd for $C_{12}H_{20}O$: M, 180.1513.

(3*R,4*S**)-1-Methylene-2-phenylspiro[2.5]octan-4-ol (25).** Colorless oil; IR (neat) 3420 (OH), 1740 (C=C) cm^{-1};

^{1}H NMR δ=0.8—2.3 (9H, m), 2.90 (1H, m), 3.60 (3/4H, m), 3.84 (1/4H, m), 5.68 (2H, m), 7.0—7.6 (5H, m); MS *m/z* (%) 214 (M^+, 58), 196 (81), 185 (99), 171 (88), 115 (100). Found: *m/z* 214.1359. Calcd for $C_{15}H_{18}O$: M, 214.1356.

(3*R,4*S**)-2-Ethyl-1-methylenespiro[2.5]octan-4-ol (26).** Colorless oil; IR (neat) 3410 (OH), 1750 (C=C) cm^{-1}; ^{1}H NMR δ=0.8—1.1 (4H, m), 1.1—2.3 (11H, m), 3.40 (1H, m), 5.36 (2H, s); MS *m/z* (%) 166 (M^+, 0.6), 151 (14), 137 (100). Found: *m/z* 166.1378. Calcd for $C_{11}H_{18}O$: M, 166.1357.

(3*R,4*S**)-2-Hexyl-1-methylenespiro[2.4]heptan-4-ol (27).** Separable two diastereomeric mixture. Clearly separated more polar isomer is reported. Colorless oil; IR (neat) 3420 (OH), 1755 (C=C) cm^{-1}; ^{1}H NMR δ=0.88 (3H, t, *J*=7 Hz), 1.0—2.1 (18H, m), 3.72 (1H, m), 5.39 (2H, bs).

(3*R,4*S**)-6-*t*-Butyl-1-methylenespiro[2.5]octan-4-ol (28).** Colorless crystals; mp 88—96 °C (AcOEt-hexane); IR (KBr) 3430 (OH), 1740 (C=C); ^{1}H NMR δ=0.88 (9H, s), 0.9—2.2 (9H, m), 3.25 (1H, bs), 5.31 (1H, m), 5.45 (1H, m); MS *m/z* (%) 191 (M^+, 1), 137 (75), 109 (100). Found: *m/z* 194.1663. Calcd for $C_{13}H_{22}O$: M, 194.1668.

(3*R,4*S**)-6-*t*-Butyl-2-ethyl-1-methylenespiro[2.5]octan-4-ol (29).** Colorless oil; IR (neat) 3420 (OH), 1755 (C=C) cm^{-1}; ^{1}H NMR δ=0.88 (9H, s), 0.9—2.1 (13H, m), 3.22 (1H, m), 5.29 (1H, m), 5.33 (1H, m); MS *m/z* (%) 222 (M^+, 33), 207 (16), 193 (60), 165 (70), 123 (66), 41 (100). Found: *m/z* 222.1982. Calcd for $C_{15}H_{26}O$: M, 222.1982.

(3*R,4*S**)-1-Methylenespiro[2.11]tetradecan-4-ol (30).** Colorless crystals; mp 64—65 °C (AcOEt-hexane); IR (KBr) 3370 (OH), 1755 (C=C) cm^{-1}; ^{1}H NMR δ=0.8—1.0 (2H, m), 1.0—2.1 (20H, m), 3.80 (1H, m), 5.37 (2H, m); Anal. Calcd for $C_{15}H_{26}O$: C, 81.08; H, 11.70%. Found: C, 81.17; H, 11.69%.

6-*t*-Butyl-1-methylenespiro[2.5]octan-4-one (31). DMSO (0.4 ml) was added dropwise to a solution of oxalyl dichloride (0.25 ml) in 8 ml of dry CH_2Cl_2 at −60 °C with stirring. The mixture was stirred for 2 min at −60 °C, then a solution of **28** (369 mg; 1.9 mmol) in 2 ml of CH_2Cl_2 was added and the mixture was stirred for 15 min. Et_3N (1.33 ml) was added to the reaction mixture and it was allowed to warm to room temperature. Water (5 ml) was added and the whole was extracted with CH_2Cl_2. The organic layer was washed successively with 5% HCl, saturated aqueous $NaHCO_3$, and saturated brine. The usual workup followed by silica-gel column chromatography gave **31** (332 mg; 90%) as a colorless oil. IR (neat) 1690 (CO) cm^{-1}; ^{1}H NMR δ=0.91 (9H, s), 1.2—2.7 (9H, m), 5.44 (2H, m); MS *m/z* (%) 192 (M^+, 41), 149 (6), 135 (20), 108 (61), 41 (100). Found: *m/z* 192.1513. Calcd for $C_{13}H_{20}O$: M, 192.1513.

6-*t*-Butyl-2-ethyl-1-methylenespiro[2.5]octan-4-one (32). Colorless oil; IR (neat) 1695 (CO) cm^{-1}; ^{1}H NMR δ=0.90 (9H, s), 1.04 (3H, t, *J*=7 Hz), 1.2—2.7 (10H, m), 5.28 (1H, d, *J*=2 Hz), 5.38 (1H, d, *J*=2 Hz); MS *m/z* (%) 220 (M^+, 24), 205 (51), 192 (56), 108 (100). Found: *m/z* 220.1824. Calcd for $C_{15}H_{24}O$: M, 220.1825.

1-Methylenespiro[2.11]tetradecan-4-one (33). Colorless oil; IR (neat) 1700 (CO) cm^{-1}; ^{1}H NMR δ=1.1—2.6 (22H, m), 5.44 (1H, m), 5.51 (1H, m); MS *m/z* (%) 220 (M^+, 14), 205 (30), 177 (63), 163 (67), 79 (100). Found: *m/z* 220.1827. Calcd for $C_{15}H_{24}O$: M, 220.1825.

Cycloalkane-Fused 3-Methylfurans (34—36). A solution of ketone **31** (63 mg; 0.33 mmol) and *p*-TsOH·H_2O (0.33 mmol) in 5 ml of 1,4-dioxane was refluxed under N_2 for 3 h. The reaction mixture was cooled, then saturated aqueous $NaHCO_3$ was added. The whole mixture was extracted with ether, and the usual workup followed by silica-gel column chromatography gave 6-*t*-butyl-3-methyl-4,5,6,7-tetrahydrobenzofuran **34** (53 mg; 84%) as a colorless oil. IR (neat) 1645, 1565 cm^{-1}; ^{1}H NMR δ=0.94 (9H, s), 1.1—2.8 (7H, m), 1.90 (3H, d, *J*=1 Hz), 7.00 (1H, m); MS *m/z* (%) 192 (M^+, 35), 177 (5), 135 (8), 108 (100). Found: *m/z* 192.1513. Calcd for $C_{13}H_{20}O$: M, 192.1513. 3-Methylfuran derivative **35**: Colorless oil; IR (neat) 1665, 1610 cm^{-1}; ^{1}H NMR δ=0.93 (9H, s), 1.16 (3H, t, *J*=7 Hz), 1.83 (3H, s), 2.53 (2H, q, *J*=7 Hz); MS *m/z* (%) 192 (M^+, 34), 135 (8), 108 (100). Found: *m/z* 192.1513: Calcd for $C_{13}H_{20}O$: M, 192.1513. 3-Methylfuran derivative **36**: Colorless oil; IR (neat) 1635, 1570 cm^{-1}; ^{1}H NMR δ=1.0—2.0 (16H, m), 1.93 (3H, d, *J*=1 Hz), 2.35 (2H, t, *J*=7 Hz), 2.54 (2H, t, *J*=7 Hz) 7.02 (1H, m); MS *m/z* (%) 220 (M^+, 92), 205 (35), 109 (100). Found: *m/z* 220.1827. Calcd for $C_{15}H_{24}O$: M, 220.1826.

A Synthesis of (±)-Menthofuran (42). (±)-Menthofuran **42** was synthesized starting from **11** and 4-methylcyclohexanone in a similar way as described above. Spectral data of the intermediates **37—41** are recorded as follows. α,β-Epoxy sulfoxide **37** (91% yield from **11**): Colorless oil; IR (neat) 1090, 1050 (SO) cm^{-1}; ^{1}H NMR δ=0.98 (3H, d, *J*=6 Hz), 1.29 (3H, s), 7.4—7.7 (5H, m); MS *m/z* (%) 264 (M^+, trace), 139 (40), 43 (100). Found: *m/z* 264.1174. Calcd for $C_{15}H_{20}O_2S$: M, 264.1182. Enone **38** (94% yield from **37**): Colorless oil; IR (neat) 1670 (CO), 1645 cm^{-1}; ^{1}H NMR δ=0.98 (3H, d, *J*=6 Hz), 2.27 (3H, s), 6.82 (1H, m); MS *m/z* (%) 138 (M^+, 81), 123 (93), 95 (88), 43 (100). Found: *m/z* 138.1044. Calcd for $C_9H_{14}O$: M, 138.1044. Epoxide **39** (69% from **38**): Colorless oil; IR (neat) 1650 cm^{-1}; ^{1}H NMR δ=0.88 (3H, d, *J*=6 Hz), 1.76 (3H, m), 3.03 (1H, m), 4.82 (1H, m), 4.96 (1H, m); MS *m/z* (%) 152 (M^+, 82), 137 (75), 41 (100). Found: *m/z* 152.1195. Calcd for $C_{10}H_{16}O$: M, 152.1199. Methylenecyclopropane **40** (87% yield from **39**): Colorless oil; IR (neat) 3370 (OH), 1745 (C=C) cm^{-1}; ^{1}H NMR δ=0.92 (3H, d, *J*=7 Hz), 0.9—2.3 (9H, m), 3.23 (1H, bs), 5.31 (1H, m), 5.45 (1H, m); MS *m/z* (%) 152 (M^+, 1), 151 (3), 137 (20), 123 (100). Found: *m/z* 152.1203. Calcd for $C_{10}H_{16}O$: M, 152.1200. Ketone **41** (85% yield from **40**): Colorless oil; IR (neat) 1705 (CO) cm^{-1}; ^{1}H NMR δ=1.05 (3H, d, *J*=6 Hz), 1.2—2.6 (9H, m), 5.40 (2H, m); MS *m/z* (%) 150 (M^+, 22), 121 (4), 108 (52), 79 (92), 39 (100). Found: *m/z* 150.1051. Calcd for $C_{10}H_{14}O$: M, 150.1044.

Conformation in Solution of the Fully Toxic Domain of Heat-Stable Enterotoxin (ST_p) Produced by Enterotoxigenic *Escherichia coli*[1)]

(Received November 27, 1990)

Heat-stable enterotoxin (ST_p) produced by a porcine strain of enterotoxigenic *Escherichia coli* is a peptide of 18 amino acid residues. The full toxicity is generated by a core peptide of 13 amino acids from residue 5 to 17 ($ST_p(5—17)$). Detailed conformational analysis of $ST_p(5—17)$ was performed by NMR spectroscopy and distance geometry calculations. The tertiary structure of $ST_p(5—17)$ was found to have a right-handed spiral fold throughout the whole molecule which was stabilized by the network of disulfide linkages and hydrogen bonds. This folding pattern was demonstrated in both organic and aqueous solutions.

Enterotoxigenic *E. coli* elaborates two kinds of heat-stable enterotoxins (named ST_p and ST_h) with 18 and 19 amino acid residues respectively, which are responsible for acute diarrhea in infants and domestic animals.[2-5)] The ST acts on ST-sensitive cells in the intestine to stimulate guanylate cyclase and to increase the level of cyclic GMP in the cells, resulting in fluid secretion from the intestinal epithelial cells.[6-9)] Recently, a selective and high-affinity binding protein(s) for ST on rat intestinal cell membranes has been identified and membrane bound guanylate cyclase has been suggested to be bound to, or present near this protein(s).[10-12)] The initial step in the biological reaction of ST is the formation of an ST-protein(s) complex. However, details of this step are not yet fully understood. For understanding the molecular basis of the interaction of ST with its receptor protein(s) and the role of amino acid residues of ST in generation of its toxicity, an important problem is to elucidate the molecular conformation of ST and to identify the part(s) of the ST molecule recognized by its receptor protein(s).

Our recent studies demonstrated that the full enterotoxigenic activities of ST_p and ST_h are generated by toxic domains (abbreviated as $ST_p(5—17)$ and $ST_h(6—18)$, respectively) consisting of 13 amino acid residues (boxed by a broken line in Fig. 1).[1)] These findings imply that this domain includes the site(s) for recognition of ST by its receptor protein(s) on the intestinal cell membrane.[13,14)] The conformation of the toxic domain of ST_h in solution was initially studied by us[15)] and by Gariepy et al.[16)] by ^1H NMR spectroscopy and distance geometry calculations. Both studies provided useful information on the conformation of the peptide backbone of the toxic domain of ST_h. However, the structure of the whole molecule could not be refined, because an efficient nuclear Overhauser effect (NOE) could not be observed and the exact disulfide pairings in ST were not known at that time. Thus, the conformation of ST in solution is still uncertain.

In this work, we investigated the conformation in solution of $ST_p(5—17)$, the toxic domain of ST_p, which differs from $ST_h(6—18)$ in only one amino acid residue, by ^1H NMR spectroscopy and distance geometry algorithm analysis.[15,17,18)] $ST_p(5—17)$ rather than $ST_h(6—18)$ was chosen for confomational study of ST, because ST_p is found more often than ST_h. In an organic solvent, $ST_p(5—17)$ was shown to have a spatial structure with a right-handed spiral stabilized by three intramolecular disulfide linkages and hydrogen bondings, and its structure in an aqueous solution

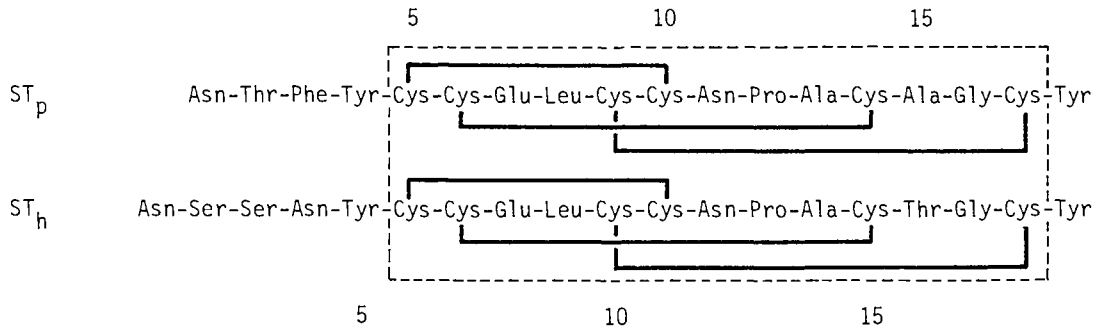

Fig. 1. Amino acid sequences and disulfide linkages of heat-stable enterotoxins (ST_p[5)] and ST_h[4,14)]) of enterotoxigenic *E. coli*.

was suggested to be almost the same. The conformation of $ST_p(5—17)$ elucidated here should be useful for understanding the molecular interaction of ST and its binding protein(s), which proceeds in an aqueous environment, and for examining the conformation-function relationship of the peptide.

Results and Discussion

Resonance Assignment: The ^1H NMR spectrum of

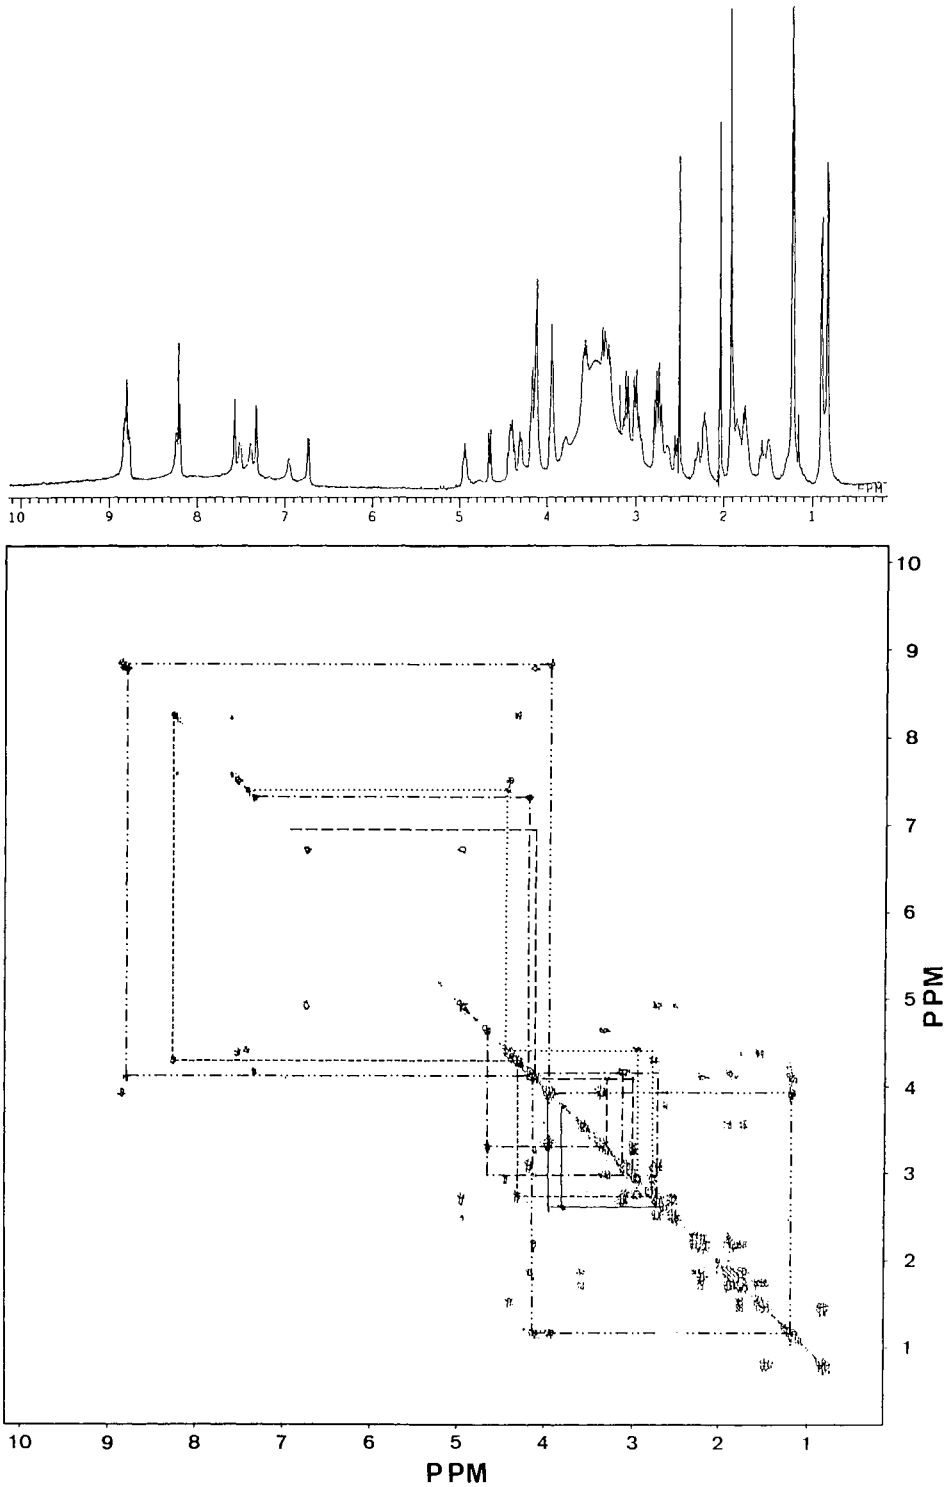

Fig. 2. DQF-COSY spectrum of ST_p (5—17) at 10 °C in DMSO-d_6/CH_3CN-d_3 (v/v, 85/15). Spin systems for six Cys and two Ala residues are indicated: Cys^5 (——), Cys^6 (– · –), Cys^9 (------), Cys^{10} (— —), Cys^{14} (— · —), Cys^{17} (·····), Ala^{13} (— · · —), and Ala^{15} (— ··· —).

ST_p(5—17) was measured in a mixture of DMSO-d_6 and CH_3CN-d_3, as used in ^1H NMR spectroscopy of ST_h(6—19).[15] Peak and sequential assignment were achieved by analyzing spin systems of constituent amino acid residues. These were examined by through-bond connectivities in the DQF-COSY spectrum of ST_p(5—17) and sequential NOE connectivities between the NH proton of an amino acid residue (i+1) and the protons of the $C_\alpha H$, NH and $C_\beta H$ of the neighboring residue (i) according to the procedures described in Refs. 19 and 20, respectively.

Figures 2 and 3 show the DQF-COSY spectrum of the peptide and its NOESY spectrum in the $C_\alpha H$-NH cross peak region, respectively. The chemical shifts of all the constituent amino acid residues of ST_p(5—17) were assigned except for those of Cys^5 and Cys^6. These protons were assigned by comparison of the 1D spectrum of ST_p(5—17) with that of [β,β-d_2-Cys^5]ST_p(5—17), in which two protons on the C_β of Cys^5 were replaced by deuterium, as shown in Fig. 4. However, no sequential connectivity was detected between Cys^5 and Cys^6 or between Cys^6 and Glu^7 in the N-terminal segment Cys^5-Cys^6-Glu^7, because the NH protons were exchanged quickly with protons from a trace of water contaminating the solvent and so the NH protons of Cys^5 and Cys^6 could not be observed in the spectrum and the peak of the NH proton of Glu^7 became broad. The connectivities in the sequence from Asn^{11} to Ala^{13} were confirmed by through space NOEs between the $C_\alpha H$ of Asn^{11} and the $C_\delta H$ of Pro^{12} and between the $C_\delta H$ and $C_\gamma H$ of Pro^{12} and the NH of Ala^{13}, although Asn^{11} could not be connected to Pro^{12} by sequential NOE connectivities. The presence of the former NOE indicated that the peptide bond between Asn^{11} and Pro^{12} had the trans configuration, and this was confirmed by construction of a molecular model. Table 1 summarizes the resonance assignment of ST_p(5—17).

The resonance assignments of the four Cys residues at positions of 5, 6, 9, and 10 in ST_p(5—17) (corresponding to 6, 7, 10, and 11 in ST_h) were essential to provide the distance information in the N-terminal region, as discussed later, because all long-range NOEs observed in the region from Cys^5 to Cys^{10} were derived from the protons of these four Cys residues, as summarized in Table 2. In a previous study of ST_h(6—19),[16] the spin systems of these four Cys were not assigned, because no sequential NOEs in the sequence containing these amino acid residues were detected as the peptide was examined in aqueous

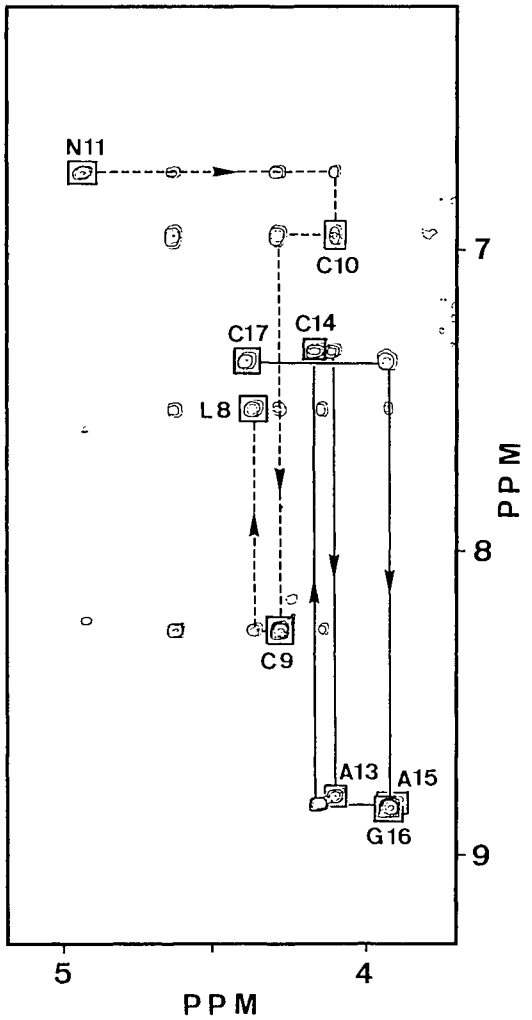

Fig. 3. NOESY spectrum of ST_p (5—17) in the $C_\alpha H$-NH NOE cross peak region. Sequential assignments of segments 8—11 (----) and 13—17 (——) are indicated by arrows according to the direction of the assignment. COSY cross peak positions for each residue are indicated by boxes.

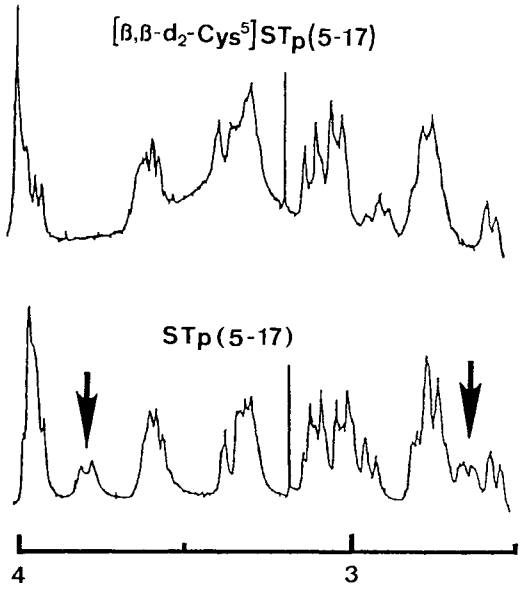

Fig. 4. 1D ^1H NMR spectra of ST_p (5—17) and [β,β-d_2-Cys^5]ST_p (5—17) in DMSO-d_6/CH_3CN-d_3 (v/v, 85/15). The peaks of $C_\beta H$ protons of Cys^5 are indicated by arrows.

1) P and M indicate pseudoatoms of methylene (including β-amido) and methyl protons, respectively. The pseudo position for methyl protons of leucine is Q in Ref. 25. 2) Upper limit of interatomic distances containing pseudoatoms include their corrections of a 1.0, b 0.6, and c 1.7 Å. 3) NOE cross peaks were collected from NOESY spectra in DMS0-d_6/CH_3CN-d_3 (85/15) at 10 °C. 4) NOE cross peaks were collected from NOESY spectra in H_2O/D_2O (80/20) at pH 5.6 and 17 °C. All these NOEs were also observed at 5 °C. Values in parentheses indicate upper constraints for NOEs detected only at 5 °C.

conditions. This was probably the reason for lack of the distance information in the N-terminal region, resulting in uncertainty about the conformation of $ST_h(6—19)$.

The ^1H NMR spectrum of $ST_p(5—17)$ was also measured in aqueous solution to obtain information about the conformation of the peptide in an aqueous environment. Chemical shifts were assigned by two procedures: sequential assignment as described above, and assignment of the NH and $C_\alpha H$ protons derived by titration of the peptide in DMSO-d_6/CH_3CN-d_3 with H_2O. Results on resonance assignment are listed in Table 1.

Folding Pattern of $ST_p(5—17)$: The data on interatomic distance constraints obtained from NOEs are summarized in Table 2. The folding pattern of the peptide backbone of $ST_p(5—17)$ was calculated from these data and disulfide pairings by distance geometry algorithm analysis.[15] Thirty calculations were performed using different random initial structures. The value of the target function (T-value)[15,17] should be zero if a calculated structure satisfies all constraints. Therefore, T-values were used for evaluating the calculated structures. In addition, the compatibility of the interatomic distances in the calculated structures with the input data was examined by checking individual NOE distance constraint violations. For non-bonded contact, 0.1 Å was an acceptable allowance within the range of possible contacts between two atoms. Among the 30 calculated structures, 14 exhibited no individual violations or non-bonded contacts of more than 0.1 Å. All these structures had T-values of less than 0.1. The convergency of these structures was estimated by calculating the RMSDs between these structures, because the average RMSD of calculated structures with the same folding pattern fell within 2.8 Å, as seen in Table 3. The averaged RMSD was 1.80 Å for atoms in the peptide backbone. All these structures showed the same folding pattern, as seen in Fig. 5(R).

For conformational analysis by distance geometry calculation, sufficient distance information is required to define the correct folding pattern of the peptide backbone.[21] In previous conformational studies of ST, its unique conformation could not be determined because of lack of sufficiently useful NOE data, as described above.[15,16] The question arose of how much interatomic distance information was necessary for defining the conformation of the ST molecule. Therefore, we examined the relationship between the amount and kind of distance information and the folding patterns of the calculated structures, as summarized in Table 3. Thirty calculations were carried out for all cases and T-values were used to evaluate the folding patterns of calculated structures. When the distance information was only that for disulfide pairings, the structure ($T<0.1$) were roughly classified into five folding patterns by viewing the folding patterns obtained by computer graphics; (1) a right-handed spiral fold (R), (2) a left-handed spiral fold (L), (3) R in the N-terminal region end L in the C-terminal region (RML), (4) L in the N-terminal and R in the C-terminal (LMR). and (5) a fold in which the N-terminal portion passes through the loop formed in the central region (C). These folding patterns are drawn as ribbon models in Fig. 5. Examination of the folding pattern of the peptide using intra-residual and sequentially connected NOEs and disulfide pairings excluded two folding patterns (LMR and C) and revealed three folding patterns (R, L and RML). By

Table 3. Amount of Distance Constraints Used and Fold Patterns of Calculated Structures

Constraints used	Number of conformers (x/n)	Total RMSD Å	Type of fold pattern[a]	RMSD in fold type Å
S-S	24/30	3.63	R (8)	2.10
			L (5)	2.40
			RML (3)	1.81
			LMR (3)	2.80
			C (5)	1.87
S-S + Short-range NOEs	9/30	3.50	R (3)	2.20
			L (4)	2.02
			RML (2)	1.90
S-S + All NOEs	14/30	1.80	R (14)	1.80
All NOEs	12/30	1.62	R (12)	1.62

a) R, right-handed spiral fold pattern; L, left-handed spiral fold pattern; RML, R in the N-terminal region and L in the C-terminal region; LMR, L in the N-terminal region and R in the C-terminal region; C, the peptide backbone passes through the loop formed by disulfide linkages. Values in parentheses indicate numbers of conformers to the respective folding patterns.

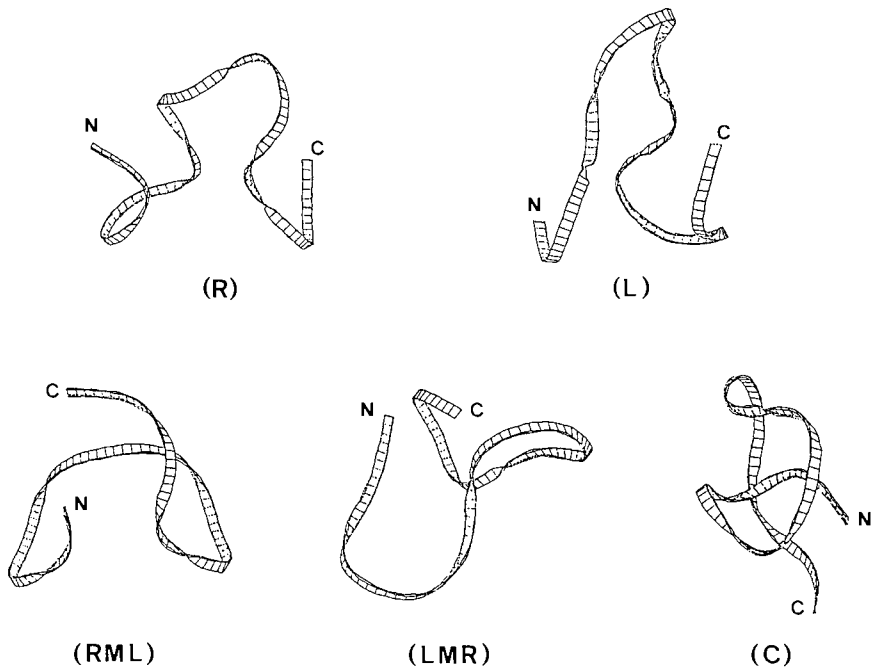

Fig. 5. Typical folding patterns of R, L, RML, LMR and C in Table 3. When the amounts of distance information were not sufficient, the single fold pattern could not be defined. The fold patterns of the peptide backbone are shown as ribbon models.

use of the distance information of all NOEs, all structures ($T<0.1$) gave the R-folding pattern. These results indicated that the distance information of NOEs shown in Table 2, especially the inter-residual NOE set, was indispensable for defining the folding pattern of $ST_p(5—17)$.

During the process of these calculations the possibility was suggested that disulfide pairings can be determined using only the distance information of NOEs, even if the positions of disulfide linkages are not known. Since $ST_p(5—17)$ contains six Cys residues, there are 15 possible combinations of disulfide linkages. Of these combinations, the disulfide pairings that satisfied the constraints of NOEs were searched; that is, the correct disulfide pairings should not affect the violation of NOE constraints and the structure of the peptide with $T<0.1$ should be obtained in the calculation using the distance information of NOE and a given combination of disulfide linkages as well as only the distance information of NOEs. Ten calculations were carried out using random initial structures for each combination of disulfide linkages. In each case, the structure with $T<0.1$ was obtained with only one combination of disulfide linkages, which was the same as that determined chemically.[14] This result demonstrates that with a sufficient amount of distance information, not only the unique folding pattern of $ST_p(5—17)$ but also its disulfide pairings can be determined. These processes may be useful not only for calculation of the folding pattern of ST, but also for determination of disulfide linkages in natural ST and synthetic ST analogs in which the disulfide pairings are unknown, if a NOE set such as that in Table 2, and especially inter-residual NOEs, can be obtained.

The distance constraints from NOEs of $ST_p(5—17)$ in aqueous solution are also summarized in Table 2. Almost all NOEs in an aqueous solvent were the same as those in an organic solvent, although only about 40% of the NOEs of the N-terminal region of the peptide observed in an organic solvent were detected in an aqueous solvent. From twenty calculations using constraints of disulfide linkages and NOEs in an aqueous solvent (Table 2), eight structures ($T<0.1$) were obtained and they all exhibited the R-folding pattern (not shown). Their average RMSD was 1.98 Å for backbone atoms. This result demonstrated that the folding pattern of $ST_p(5—17)$ was the same in an organic solvent as in an aqueous solvent.

Refinement of Tertiary Structure of $ST_p(5—17)$: From an H-D exchange experiment (not shown) five NH protons of Cys^9, Asn^{11}, Ala^{13}, Cys^{14}, and Cys^{17} were found to show slow H-D exchange, although four amide protons of Asn^{12}, Ala^{14}, Cys^{15}, and Cys^{18} of ST_h (corresponding to Asn^{11}, Ala^{13}, Cys^{14}, and Cys^{17}, respectively, in ST_p) were reported to be involved in hydrogen bondings in Ref. 16. The signals of these NH protons were still observed in the spectrum 6.5 h after addition of 500 μl of D_2O to the peptide solution in 500 μl of DMSO-d_6/CH_3CN-d_3 (v/v, 85/15). The NH proton of Cys^{17} was most labile among these protons. Taking account of the size of $ST_p(5—17)$,

these NH protons with slow H-D exchangeability were assumed to be involved in hydrogen bondings. The most plausible CO groups forming hydrogen bonds with these NH groups were searched according to the following criteria: (1) Structures with $T<0.1$ should be obtained for the correct pairing of a given NH and CO, because additional information on a hydrogen bonding does not increase interatomic distance violations. (2) Hydrogen bonding pairs with an angle ∠N-O-C of 100° to 140° are expected to be present in the tertiary structure of the peptide, because in the molecular structure of an analog of ST_p ([Mpr^5]ST_p(5—17)) the angles ∠N-O-C for all intramolecular hydrogen bonds are in this range.[22] (3) The NH protons may be hydrogen-bonded with the CO oxygens in the same loops, as seen in the folding pattern of ST_p(5—17) in Fig. 5(R). Furthermore, upper and lower constraints of 2.5 Å and 2.0 Å, respectively, were input into the calculation as the distance of the hydrogen bonding between an NH proton and a CO oxygen. Ten calculations were carried out from different random initial structures in all cases using the distance constraints of NOEs that were obtained from the measurement of ST_p(5—17) in an organic solvent (Table 2).

First we examined the hydrogen bonding of the NH proton of Cys^9 with either the CO group of Cys^5 or Cys^6 or Glu^7 in the segment from Cys^5 to Cys^{10} in the first loop from the N-terminus, as depicted in Fig. 5(R). Structures with $T<0.1$ were obtained for the CO groups of both Cys^5 and Cys^6 and the values of ∠N-O-C were 73°±6° and 100°±0.5° for Cys^5 and Cys^6, respectively. According to the second criterion described above, the acceptor of the NH proton of Cys^9 was concluded to be the CO group of Cys^6. Similarly, the acceptors of the NH protons of Cys^{14} and Cys^{17} in the segments from Cys^{10} to Cys^{14} and from Cys^{14} to Cys^{17} in the second and third loop, respectively, in Fig. 5(R) were examined and determined to be the CO of Asn^{11} and the CO of Cys^{14}, respectively. The CPK-model constructed from the calculated structures at this stage suggested that the acceptor in the hydrogen bonding with the NH proton of Asn^{11} was the CO group of Cys^5 or Cys^9. The CO of Cys^5 gave structures with $T<0.1$, while the CO of Cys^9 did not. However, the hydrogen bonding of the NH of Asn^{11} to the CO of Cys^5 was excluded by the second criterion. The NH proton of Asn^{11} might be present close to the CO of Cys^5 in the interior of the molecule. Finally, the acceptor for the NH of Ala^{13} was concluded to be the β-CO of Asn^{11}, because only this CO can be present in the space where the NH of Ala^{13} can interact. This type of hydrogen bonding between the side-chain and the main-chain has been reported.[23] These results (in Table 4) indicate that the hydrogen bondings were between the NH of Cys^9 and the CO of the Cys^6, the NH of Cys^{14} and the CO of Asn^{11}, the NH of Cys^{17} and the CO of Cys^{14}, and the NH of Ala^{13} and the β-CO of Asn^{11}.

Table 4. Pairing of Hydrogen Bonds and Bond Angles (∠N-O-C) in Calculated Structures

	Pairing of hydrogen bonds		Number of structures ($T<0.1$)	r^d (∠N-O-C)
	NH	CO		
1	Cys^9	Cys^5	3	73±6
		Cys^6	2	100±0.5
		Glu^7	0	
2[a]	Cys^{14}	Cys^{10}	0	
		Asn^{11}	2	113±0.5
		Pro^{12}	0	
		Gly^{16}	0	
3[b]	Cys^{17}	Ala^{13}	0	
		Cys^{14}	2	102+0.5
		Ala^{15}	2	83±2
4[c]	Asn$_{11}$	Cys^5	3	164±8
		Cys^9	0	
5[c]	Ala^{13}	Asn^{11}(β-CO)	2	117±1

Information on disulfide bonds and all NOEs were used for all calculations. a, b, and c: additional information on hydrogen bonds was used: a, the NH of Cys^9 and the CO of Cys^6; b, a and the NH of Cys^{14} and the CO of Asn^{11}; c, b and the NH of Cys^{17} and the CO of Cys^{14}. d: Averaged angles of ∠N-O-C under consideration are shown in degrees.

Thirty calculations were carried out using constraints from three disulfide bonds, all NOEs and the four hydrogen bonds determined above. Seven structures ($T<0.1$) were obtained and the average RMSD between them was 1.13 Å for all backbone atoms. Thus, the RMSD was further improved by using additional information of hydrogen bondings. Four structures with similar low T-values were superimposed on the structure with the lowest T-value, as shown in Fig. 6.

The tertiary structure of ST_p(5—17) had a right-handed spiral fold throughout the whole molecule with three loops along this spiral. The first loop (Cys^5-Cys^{10}) was fixed by the disulfide bond between Cys^5 and Cys^{10} and the hydrogen bond between the NH of Cys^9 and the CO of Cys^6. The second loop (Cys^{10}-Cys^{14}) was stabilized by the two disulfide bonds between Cys^5 and Cys^{10} and Cys^6 and Cys^{14} and the two hydrogen bonds between the NH of Cys^{14} and the CO of Asn^{11} and the NH of Ala^{13} and the β-CO of Asn^{11}. The third loop (Cys^{14}-Cys^{17}) was stabilized by the two disulfide bonds between Cys^6 and Cys^{14} and Cys^9 and Cys^{17} and the hydrogen bond between the NH of Cys^{17} and the CO of Cys^{14}. The formation and stabilization of the β-turn in each loop were attributed to the hydrogen bonds between the backbone atoms. Thus, the spatial structure of ST_p(5—17) was strongly stabilized by the network of disulfide and hydrogen bonds.

Comparison of the Conformations of ST_p(5—17) in Solution and the Solid State: Recently we determined the molecular structure of an analog of ST_p(5—

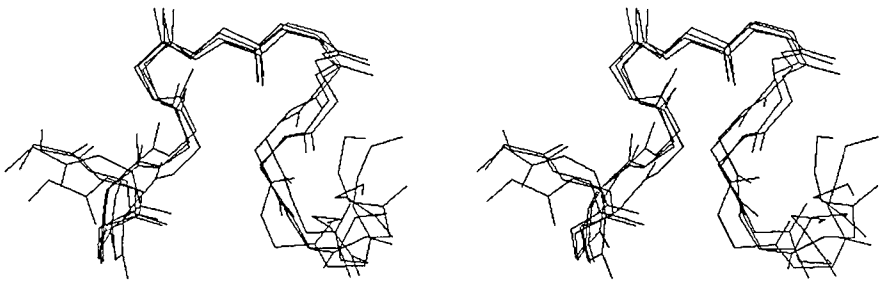

Fig. 6. Stereo view of backbone structures of ST_p (5—17) superimposed to give the minimum averaged RMSD. The all structures exhibited violations of less than 0.1 Å.

17) in which Cys was replaced by Mpr at position 5 ([Mpr^5]ST_p(5—17)).[22] We compared the structure of ST_p(5—17) in solution with that of [Mpr^5]ST_p(5—17) in the solid state, because [Mpr^5]ST_p(5—17) lacks only the N-terminal NH_2-group of ST_p(5—17) and therefore the structure of this Mpr^5-derivative should be very similar to that of ST_p(5—17). The backbone structure of ST_p(5—17) was superimposed on that of [Mpr^5]ST_p(5—17) in the solid state, as shown in Fig. 7. The two structures had the same folding pattern. Four intramolecular hydrogen bonds and three β-turns in the structure of ST_p(5—17) in solution have also been observed in the solid structure of [Mpr^5]ST_p(5—17). The common folding pattern and secondary structure in solution and the solid states might be caused by the tight stabilization by the net work of disulfide and hydrogen bonds. The RMSD values for backbone atoms in the first, second, and third loops were 0.92, 0.45, and 0.76 Å, respectively. The second loop had the smallest RMSD value and fitted extremely well to that in the solid state, implying that this region is scarcely perturbed in solution. The slightly larger deviations of the first and third loops of the structure in solution from those in the solid state might be due to fluctuations in these loops.

In conclusion, the toxic domain of ST_p in solution could be defined by ^{1}H NMR spectroscopy and distance geometry calculations. The conformation of ST_p(5—17) in solution was almost the same as that of [Mpr^5]ST_p(5—17) in the solid state, indicating that the toxic domain of ST_p has a stable conformation with low perturbation in solution. The present finding should be useful for understanding the part(s) of ST_p recognized by its receptor protein(s) and for conformational analyses of analogs of ST_p and its conformation-activity relationship.

Experimental

Boc-amino acids were purchased from the Peptide Institute Inc. (Minoh, Osaka). Deuterated solvents, DMSO-d_6 (99.96%), CH_3CN-d_3 (99.6%), and D_2O (99.95%), were obtained from CEA (Commissariat a L'Energie Atomique, Cedex, France). All other reagents were commercial products and were purified further before use in analytical

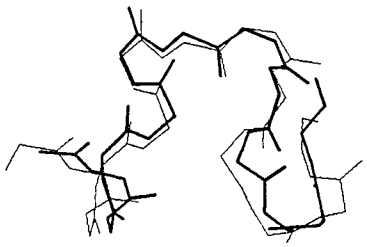

Fig. 7. Comparison of the backbone structure of ST_p (5—17) in solution (——) with that of [Mpr^5]ST_p (5—17) in the solid state (——).

experiments.

Syntheses of ST_p(5—17) and [β,β-d_2-Cys^5]ST_p(5—17): ST_p(5—17) was synthesized by the solid-phase method.[14] [β,β-d_2-Cys^5]ST_p(5—17) was prepared by the same procedure as ST_p(5—17), except for the use of Boc-β,β-d_2-Cys(MeBzl) at position 5 in the sequence of ST_p instead of Boc-Cys-(MeBzl). The synthesis of Boc-β,β-d_2-Cys(MeBzl) was described previously.[24]

NMR Spectroscopy: 2D ^{1}H NMR spectra were measured in DMSO-d_6/CH_3CN-d_3 (v/v, 85/15) (8 mmol dm^{-3}) at 10 °C and in H_2O/D_2O (2.4 mmol dm^{-3}) at 3—20 °C in a JEOL GX-500 spectrometer. DMSO-d_6/CH_3CN-d_3 was chosen as solvent, because ST_p(5—17) was soluble in DMSO but was gradually destroyed under the conditions for ^{1}H NMR measurement, while ST_p(5—17) was stable in CH_3CN but not soluble enough in this solvent. 2D DQF-COSY and NOESY were performed in the phase-sensitive detection mode by the four-quadrant method.[25] Chemical shifts were measured relative to the methyl resonance of tetramethylsilane added as an internal standard. For NOESY in an organic solvent, a mixing time of 150 ms was adopted, because it was short enough to exclude the effects of spin diffusion and coherent magnetization transfer.[15] NOESY spectra in an aqueous solvent were recorded with mixing times of 100, 150, and 300 ms. From evaluation of secondary effects, NOEs for distance geometry calculation were collected from the NOESY spectra recorded with a mixing time of 150 ms. The sizes of the time domain data were 2K or 4K points for the t_2 direction and 256 points for the t_1 direction. The data size was zero-filled once or twice in the t_1 direction.

The H-D exchange experiment was performed by addition of D_2O to a sample solution in DMSO-d_6/CH_3CN-d_3. The time course of change in 1D spectra of this sample was

recorded in a JEOL GX-400 at 22 °C.

Distance Constraints: The intensities of the NOE peaks were translated into the coresponding interatomic distances based on the relation, NOE intensity $\propto 1/r^6$.[18] The aptitude of the interpretation method was discussed in a previous paper.[15,18] The intensity of NOE was evaluated from the number of lines in contour plots of the NOESY spectra of the peptide, and the intensity of the strongest NOE between two C_β protons of Cys was used as a standard intensity for the distance 1.75 Å. The relative intensities with 7—5, 4—3, 2 and 1 contour lines were estimated to be 2.5, 3.0, 3.5, and 4.0 Å, respectively. These values were used as the upper distance constraints. The lower distance constraints were assumed to be the sums of the core radii of the two protons, i.e., 2.0 Å. Information of three disulfide linkages provided an additional distance constraint of 2.04 Å on the S^i-S^j bond (where S^i and S^j are the sulfur atoms of Cys^i and Cys^j residues, which are linked by a disulfide bond) and 3.05 Å on the S^i-$C_\beta{}^j$ and S^j-$C_\beta{}^i$ distances across the disulfide bridge.[26] Since the dihedral angles χ_3 (C_β-S-S-C_β) of disulfide bonds in all proteins observed by high resolution X-ray crystallography are approximately $\pm 90° \pm 10°$,[27] this value of χ_3 was defined by a distance constraint of 3.86 Å on the $C_\beta{}^i$-$C_\beta{}^j$ distance.

Since protons on a methylene or methyl group could not be assigned stereospecifically, these protons were replaced by pseudoatoms as reference points by the method suggested by Wüthrich and his associates.[28]

Distance Geometry Calculations: The distance geometry program DADAS[15,17] was used to construct the tertiary structure of $ST_p(5—17)$. DADAS defines the target function (T) as an error function consisting of the square sum of the differences between atomic distances in calculated structures and the input distance constraints. The initial structure is constructed by generating the random values for dihedral angles. Then T is minimized by the algorism working in the dihedral angle space.[15,17] Calculations were performed with ACOS S2020 and SX-2N computers at the Computer Center of Osaka University. The computed structures were visualized and analyzed using a computer graphics program VENUS at the Research Center for Protein Engineering, Institute for Protein Research, Osaka University.

This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science and Culture. We are indebted to Mrs. Kazuko Kawaguchi for preparation of the manuscript.

Rates and Mechanism for the Solvolyses of 2,2-Dimethyl-2-sila-1-indanyl Bromide and α-Trialkylsilylbenzyl *p*-Toluenesulfonates. α-Silicon Effect on the Stability of Benzylic Cations in Solution

Nobujiro SHIMIZU,* Erika OSAJIMA, and Yuho TSUNO

(Received November 29, 1990)

α-Silicon effect on the benzylic solvolysis has been investigated. The solvolysis of 2,2-dimethyl-2-sila-1-indanyl bromide in aq acetone exhibits a linear response to the solvent ionizing power Y_{Br} with a slope m close to unity (m=0.93) and gives the corresponding alcohol without skeletal rearrangement indicative of a k_c mechanism; it solvolyzes 4.98×10^2 times less rapidly than a carbon reference, 2,2-dimethyl-1-indanyl bromide, in 60% aq acetone at 25 °C suggesting that solvolytic generation of the α-silylated benzylic cation is electronically about 4 kcal mol^{-1} less favorable than that of the corresponding α-alkylated benzylic cation. A more pronounced rate-retardation of 1.65×10^4 by an α-$SiMe_3$ group relative to Me is observed in the solvolysis of an open benzylic system due to the additional steric effect. Mechanism for the solvolysis of α-trialkylsilylbenzyl *p*-toluenesulfonates including $SiMe_3$, $SiEt_3$, and Si(*t*-Bu)Me_2 groups has been also examined on the basis of the solvent effect, salt effect, and ethanol/water selectivity as well as product analysis; a k_c mechanism including a product forming step via preferential front side solvent attack is suggested.

The effect of silicon on the stability of adjacent carbocations has been the subjects of recent theoretical and mechanistic interests.[1] During the course of our study on the mechanism of solvolysis of α-disilanylbenzyl halides, we needed precise estimation for the α-silicon effect relative to carbon on the ionization of benzylic derivatives.[2] While strong electron-releasing property of β-silicon has been verified experimentally[3] as well as theoretically,[4] the effects of α-silicon are rather puzzling. A trimethylsilyl group, the most commonly used silyl group, sometimes acts as a weak electron-accepting group contrary to a low electronegativity of silicon.[5] Theoretical study suggests that a carbocation $SiH_3CH_2^+$ is 17 kcal mol^{-1} more stable than methyl cation but 17 kcal mol^{-1} less stable than ethyl cation.[4b] Experimental results are, however, diverse. For example, $SiMe_3$ relative to methyl accelerates the solvolysis of vinyl triflates,[6] while replacement of one of methyl groups in *t*-butyl bromide with $SiMe_3$ results in a marked rate retardation.[7] On the other hand, $SiMe_3$ exerts essentially the same effect as methyl in the solvolysis of 2-adamantyl derivatives.[8] A deactivating effect of $SiMe_3$ has been also reported in the benzylic solvolysis but the data are not quantitative.[9] These diverse results on the α-silicon effect arise in part from the steric effect which varies with the system and hence is difficult to estimate precisely. The $SiMe_3$ group is undoubtedly a bulky group as compared to methyl, although it is considered to be significantly smaller in its effective size than *t*-butyl.[10,11] Since the solvolysis of α-alkylbenzyl derivatives is susceptible to steric effect of the α-alkyl groups,[12,13] a direct comparison between the solvolysis rates for α-$SiMe_3$- and α-alkylbenzyl derivatives may not provide a reasonable estimation for the α-silicon effect relative to carbon on the stability of adjacent benzylic cations. In order to minimize the steric effect, we selected the solvolysis of 2,2-dimethyl-2-sila-1-indanyl bromide (**1a-Br**) and compared its solvolysis rates with those of a carbon reference, 2,2-dimethyl-1-indanyl bromide (**1b-Br**). Since the two substrates undergo the same structural change during the ionization, rate ratios between the two substrates would be attributable primarily to the difference in stability of the corresponding cations in solution. This paper also deals with the mechanism of the solvolysis of α-trialkylsilylbenzyl derivatives (**2a—c**) on the basis of the Winstein-Grunwald solvent analysis,[14] salt effect, ethanol/water selectivity, and product analysis.

Results

1a-Br was prepared by halogenation of 2,2-dimethyl-2-silaindane with *N*-bromosuccinimide. α-Trimethylsilyl-, α-triethylsilyl-, and α-*t*-butyldimethylsilylbenzyl *p*-toluenesulfonates (**2a-OTs**, **2b-OTs**, and **2c-OTs**) were prepared by treatment of the corresponding benzyl trialkylsilyl ethers with *s*-butyllithium followed by addition of *p*-toluenesulfonyl chloride.

a) At 25 °C. b) Ref. 14. c) Estimated from the rate constant in 80% aq ethanol (Ref. 12) and a k_{EtOH}/k_{80E} rate ratio of 0.021 for **3a-Cl**. d) A. H. Fainberg and S. Winstein, *J. Am. Chem. Soc.*, **79**, 1597 (1957).

Solvolyses were followed spectrophotometrically by measuring decrease in a reactant or increase in a liberated acid as its acridinium salt for $(0.2—2)\times10^{-4}$ M solutions (1 M=1 mol dm^{-3}). In the latter case, the solvolysis was monitored by a 402.5 nm light in the presence of 2—3 equiv acridine and $(5—10)\times10^{-5}$ M of acridinium *p*-toluenesulfonate. The initial addition of the acridinium salt was necessary to assure linear response of absorbance to the concentration of the produced acid. In several cases, the solvolysis were followed conductimetrically. In most cases, the solvolyses followed excellent first-order kinetics over a range of 3 to 4 half-lives (correlation coefficient $R>0.9999$) giving rate constants within ±3% reproducibility. Table 1 shows solvolysis rates for **1**, **2**, and α-methylbenzyl bromide (**3a-Br**) in various solvents including 30/70 to 80/20 (v/v) acetone/water (A-series), 40/60 to 100/0 (v/v) ethanol/water (E-series),

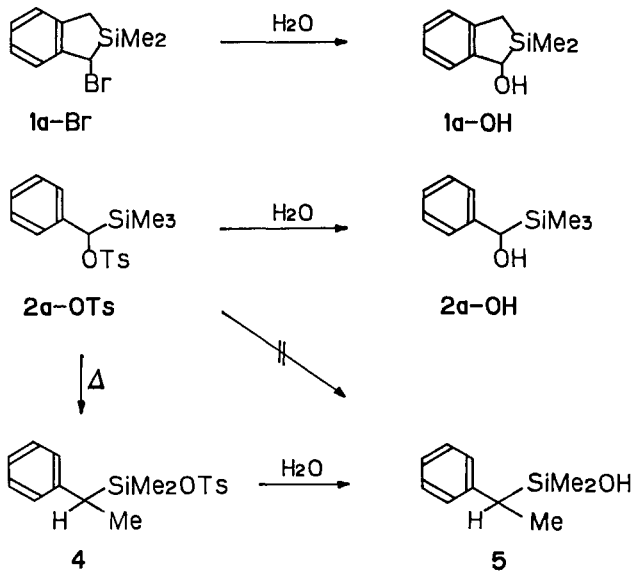
Table 6. Products, Selectivity, and Rate Increment in the Solvolysis of **2a-OTs** in aq Ethanol

Solvent	Products[a]		Selectivity[b]	Rate-increment
	2a-OH	**2a-OEt**	k_W/k_E	k_{obsd}/k_{calcd}[c]
EtOH	0%	100%		6.89
90E	36.9%	63.1%	1.62	2.34
80E	55.9%	45.1%	1.53	1.51
50E	82.1%	17.9%	1.42	0.92
40E	86.1%	13.9%	1.28	1.06

a) Determined by GLC. b) Defined by k_W/k_E=[**2a-OH**][EtOH]/[**2a-OEt**][H_2O]. c) The k_{calcd} is the rate constant expected from the mY correlation line observed for aq acetone: log k_{calcd}=0.915Y_{OTs}−3.648.

and 40/60 to 80/20 (v/v) and 97/3 (w/w) 2,2,2-trifluoroethanol (TFE)/water (T-series) binary solvent mixtures at 25 °C. The α-silicon effects on the solvolysis rates in 1-indanyl and benzyl systems are summarized in Table 2. Marked deactivation effects of α-silicon are apparent in both cases. Table 3 shows a comparison of the solvolysis rates between 1-indanyl and benzylic derivatives. Obviously, the indanyl system solvolyzes much more rapidly than the corresponding benzyl system. Figure 1 illustrates the dependence of solvolysis rates on the solvent ionizing power Y_{Br}[15] for the solvolyses of **1a-Br** and **1b-Br**. Since α-trimethylsilylbenzyl bromide (**2a-Br**) solvolyzed at inconveniently slow rates, we examined the solvent effect on the ionization of α-silylbenzyl derivatives by using α-trialkylsilylbenzyl p-toluenesulfonates **2a-OTs**—**2c-OTs**. Figure 2 represents the solvent dependence of the solvolyses of **2a-OTs** and **2c-OTs** on Y_{OTs}.[16] Table 4 summarizes the results of solvent mY analysis[14] for **1** and **2**. Table 5 shows salt effects on the solvolyses of **2a-OTs** and **2c-OTs**.

Hydrolysis of **1a-Br** in 50% aq acetone cleanly gave the corresponding alcohol **1a-OH**. Similarly, **1b-Br** gave 2,2-dimethyl-1-indanol as a single product on hydrolysis in 80% aq acetone. Solvolytic reactions of **2a-OTs** and **2c-OTs** with TFE, ethanol, and aq acetone cleanly gave the corresponding ethers (**2-OTFE**



and **2-OEt**) or alcohols (**2-OH**) without skeletal rearrangement in contrast to the fact that the solvolysis of 2-trimethylsilyl-2-adamantyl *p*-nitrobenzoate involves an extensive 1,2-methyl shift from the silicon to the carbenium carbon.[17] Thermally, however, **2a-OTs** rearranged to a silyl *p*-toluenesulfonate **4**, which on hydrolysis gave a rearranged alcohol **5**.[18] Product analysis for the solvolysis of **2a-OTs** in ethanol-water binary solvent mixtures was given in Table 6 which includes selectivity, $S=k_W/k_E$, defined by Eq. 1 where k_W and k_E are the rate constants for nucleophilic attack of water and ethanol respectively in the product forming step, [**2-OH**]/[**2-OEt**] is the product ratio determined by GLC analysis, and [EtOH]/[H_2O] is the molar ratio of ethanol to water in binary solvent mixtures.

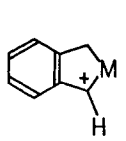
$$S=k_W/k_E=[\textbf{2-OH}][EtOH]/[\textbf{2-OEt}][H_2O] \quad (1)$$

Discussion

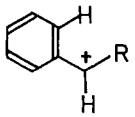
Table 2 shows a marked rate retardation of (1.6—3.0)×10^4 by an α-$SiMe_3$ group relative to methyl in the benzylic solvolysis. A different situation, however, arises when *t*-butyl is selected as an alkyl reference; k(**2a-OTs**)/k(**3b-OTs**) rate ratios suggest the effect of $SiMe_3$ to be comparable to that of *t*-butyl. These results in the benzylic solvolysis contrast to the α-silicon effect in the 2-adamantyl solvolysis where the rates are in the order $k(\alpha\text{-SiMe}_3):k(\alpha\text{-Me}):k(\alpha\text{-}t\text{-Bu})$=ca. $1:1.0:10^5$.[8,19] The discrepancy of the α-silicon effect between the two systems is undoubtedly associated with the steric effect. Whereas a bulky α-alkyl group facilitates the 2-adamantyl solvolysis,[19] it retards the rate of solvolysis of benzyl derivatives.[12,13] The steric rate retardation in the latter system results partly from steric strain imposed on the benzylic cations in which the α-alkyl group is coplanar to the phenyl ring or nearly so and partly from steric hindrance to solvation in the transition state. We have found a rather simple relation between the solvolysis rates of α-alkylbenzyl chlorides (PhCHRCl; R=Me, Et, *i*-Pr, and *t*-Bu) reported by Baddeley and coworkers[12] and a steric parameter *A*-value[11a] (free energy difference between axial and equatorial conformers in mono-substituted cyclohexanes) represented by Eq. 2 where k_R and k_{Me} are the rate constants for α-R and α-methylbenzyl chlorides, and A_R and A_{Me} are *A* values for R and methyl groups respectively. This relationship suggests the α-alkyl effect to be largely steric in the benzylic solvolysis, although this steric rate-retardation effect seems to be complicated by an opposing rate-acceleration effect arising from the release of B-strain for a bulky group larger than *t*-Bu.[12] If an *A* value of 2.5 is used for $SiMe_3$,[10a] a

$$\log k_R/k_{Me}=1.73\,(A_R-A_{Me})^{1/3} \quad (2)$$
(R = Me, Et, *i*-Pr, *t*-Bu; $R=0.999$)

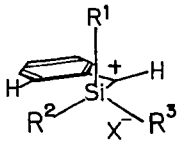
rate retardation by the steric effect of $SiMe_3$ can be estimated to be by a factor of 40 relative to methyl. Obviously, the steric effect alone is insufficient to account for the observed low reactivity of **2a-Br**. Provided the observed k(**3a-Br**)/k(**2a-Br**) rate ratio includes a steric rate retardation of 40 by $SiMe_3$, a rate ratio of (4—8)×10^2 of the total rate difference should be ascribed to the electronic deactivation effect of $SiMe_3$ relative to methyl on the ionization step. In connection with this, α-silicon effect on the solvolysis of the indanyl system is informative. Table 2 shows that the replacement of a C_2 group from CMe_2 to $SiMe_2$ results in a rate retardation by a factor of (3—5)×10^2. A high sensitivity (m) to the solvent ionizing power Y_{Br}, i.e., m=0.93 for aq acetone (Fig. 1 and Table 3), together with the clean formation of the hydrolysis product without skeletal rearrangement is indicative of k_c mechanism for **1a-Br**. Since **1a-Br** and **1b-Br** are structurally close to each other and undergo practically the same structural change during the ionization, the difference in electronic effects between the $SiMe_2$ and the CMe_2 groups must be primarily responsible for the rate difference between the two substrates. The fact that the ethanolysis of **1b-Cl** proceeds ca. 50 times less rapidly than that of **1c-Cl**[20] implies small steric effect to be still operative in the indanyl system probably due to the steric hindrance to solvation in the transition state. Since $SiMe_2$ must have a small effective size as compared to CMe_2,[10a] a slightly more pronounced α-silicon effect than the observed k(**1b-Br**)/k(**1a-Br**) rate ratio would result, if the steric effect is taken into consideration. It is thus concluded that in solution, the α-silicon group destabilizes the adjacent benzylic cation by about 4 kcal mol^{-1} relative to the corresponding carbon group. This is in agreement with the theoretical study.[1,4b] A similar α-silicon effect of $SiMe_3$ relative to *t*-Bu has been reported in the formation of α-



6



7



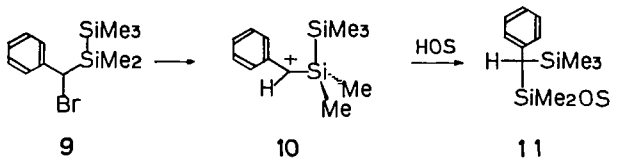
8

methoxycarbenium ions via acid-catalyzed hydrolysis of vinyl ethers.[21] The above conclusion also provides a major reason for the markedly low reactivity of **2a-Br** as compared to **3a-Br** compatible with the discussion mentioned earlier.

Table 3 indicates that indanyl derivatives solvolyze 10^2 to 10^4 times as rapidly as the corresponding benzyl derivatives. Major factors attributable to the rate differences between the two systems include ortho-alkyl effect and difference in conformational requirements of the corresponding cations **6** and **7**. The ortho effect can be estimated from the substituent effect. Provided ρ value is around -5 for the solvolysis of α-alkylbenzyl derivatives[22] and the electronic effect of *o*-alkyls is comparable to *p*-Me ($\sigma^+=-0.31$), *o*-alkylation would lead to a rate acceleration of about 40. Apparently, the *ortho*-effect alone does not explain the observed large rate differences, particularly those between **1a-Br** and **2a-Br**, and between **1b-Cl** and **3b-Cl**, even if we consider anticipated difference in inductive effect between *o*- and *p*-alkyls. Conformational factor must be the chief reason for the rate difference in these cases. 1-Indanyl derivatives ionize probably without significant increase in steric strain yielding the corresponding cations **6** which can receive the maximal resonance stabilization from the aromatic ring, while the formation of planar α-alkylbenzyl cations **7** must involve substantial steric strain because of proximity of *ortho* hydrogens to the α-alkyl group. The k(indanyl)/k(benzyl) rate ratios increase with increasing steric size of the α-groups in the order k(**1b**)/k(**3b**)>k(**1a**)/k(**2a**)>k(**1c**)/k(**3a**); this arises from the fact that the benzylic solvolysis is more sensitive to the steric effect than the indanyl solvolysis.[12,20]

The solvolyses of α-trialkylsilylbenzyl *p*-toluenesufonates **2-OTs** in A, E, and T solvent series do not show a single linear response to the solvolysis of the reference compound, 2-adamantyl *p*-toluenesulfonate, as shown in Fig. 2. Similarly, the solvolysis of **1a-Br** exhibits a diverging response to the solvent ionizing power Y_{Br} for the three solvent series. It should be noted, however, that each substrate shows a straight line with a slope m close to unity (m>0.9) for acetone/water mixtures which are nearly isonucleophilic in a wide range of water contents (Table 4). The high m values together with the absence of skeletal rearrangement during the solvolysis are indicative of the k_c mechanism for these α-silyl substrates. Lithium perchlorate showed normal salt effect on the solvolyses of **2a-OTs** and **2c-OTs**, as shown in Table 5. On the other hand, addition of sodium *p*-toluenesulfonate significantly retarded the solvolysis rate. It is questionable, however, whether this is the common ion effect because external chloride ion also caused a similar rate depression. We do not understand the origin for these rate depression quite well but intervention of the free cation is unlikely because of the following observation on product selectivity. The solvolysis through the free cation is considered to exhibit normal water/ethanol selectivity ($S=k_W/k_E<1$), as has been demonstrated by the solvolysis of diphenylmethyl chloride, e.g., S=0.36 in 80% aq ethanol.[23] **2a-OTs**, however, exhibited small but negative selectivities (S=1.28—1.65) in the solvolysis in 40% to 90% aq ethanol (Table 6). Interestingly, these selectivities are rather close to those observed in the 1- and 2-adamantyl solvolyses (s=1.6—2.2) which include a product formation step exclusively from the solvent-separated ion pair through the front side solvent attack.[24-26] One explanation for the negative selectivity in the present case is to assume a restricted conformation **8** for an intermediate ion pair. It is likely that during the ionization, one of alkyl groups of the α-trialkylsilyl group, probably the largest group of the three alkyls, takes the anti position to the leaving group to minimize the steric interaction between ortho hydrogens and the alkyl groups on the silicon. Such a conformation interferes with solvent attack from the rear side; hence, the product formation would preferentially occur from the front side.

It is worth stating a diverging mY plot pattern for **2-OTs** shown in Fig. 2. Both E- and T-series deviate substantially above the aq acetone line. The deviations for three typical solvents, ethanol, 80E, and 97T, are listed in Table 4 as rate-increments defined by log k_{obsd}/k_{calcd} where k_{obsd} and k_{calcd} are the rate constants observed and calculated from the acetone correlation line, respectively. The rate-increment for ethanol decreases with increasing steric size of the α-silyl group in the order $SiMe_3$, $SiEt_3$, and $SiMe_2$(*t*-Bu), while the rate-increment for 97T increases in this order. Although k_Δ processes often encounter diverging mY plot patterns,[27] the absence of the skeletal rearrangement in the present case eliminates such a possibility. Since α-silicon enhances S_N2 reactivity,[28] the upward deviation for E solvents seems to suggest nucleophilic solvent assistance; however, this is not the case either. Such solvent interaction would lead to downward deviations for T solvents which are much less nucleophilic than aq acetone, clearly against the observation. In fact, the mY correlation for the solvolysis of **2c-OTs** in the A, E, and T solvents was not improved at all by application of the extended Winstein-Grunwald equation[29] which includes a solvent nucleophilicity term. A diverging mY plot is not confined to the present α-silylbenzyl derivatives. α-Alkylbenzyl derivatives, for example, **3a-Cl** and **3b-OTs**, have been shown to exhibit diverging patterns as



9 10 11

well.[22,30] Interestingly, α-(pentamethyldisilanyl)benzyl bromide (**9**), structurally close to **2c-OTs**, exhibits a very similar mY pattern to that for **2c-OTs**.[2] The bromide **9** has been classified as a k_c substrate solvolyzing via α-(pentamethyldisilanyl)benzyl cation **10** despite the fact that it solvolyzes 2×10^5 times more rapidly than the corresponding α-silyl substrate, **2a-Br**, and cleanly gives 1,2-$SiMe_3$ rearranged solvolysis products **11**.[2] Thus, the diverging mY plot does not necessarily mean a mechanistic shift from the k_c solvolysis. Different responses to the solvent ionizing power between adamantyl derivatives and the present α-silylbenzyl substrates are presumably responsible for the apparent diverging solvent effect. Nevertheless, the decreasing deviation for E-solvents with increasing steric hindrance of the α-silyl groups appears to suggest unattested rear side solvent interaction. The fact that the k_W/k_E ratios increase with increasing rate-increment suggest this interaction to be purely kinetic and different from the k_s process; if the rate-increments of E-solvents are related with the k_s interaction, the k_W/k_E ratios should decrease with increasing ethanol content of the E-solvents against the observation.

Experimental

IR spectra were recorded on a Hitachi R-215 spectrophotometer. NMR spectra were recorded on a Hitachi R-20B spectrometer. GLC were performed with a Hitachi 163 gas chromatograph by using glass columns (6 mm×1.5, and 2.0 m) packed with 10% Silicone oil SE-30 on Chamelite CS or 25% Apiezon Grease L on Chromosorb W.

2,2-Dimethyl-2-sila-1-indanyl Bromide (1a—Br). Into a mixture of Mg (6.10 g) and HMPA (20 cm³) in THF (75 cm³) was added slowly a solution of α,α′-dichloro-*o*-xylene (20.0 g 0.114 mol) and dichlorodimethylsilane (16.2 g, 0.126 mol) in THF (50 cm³) during a period of 8 h at ambient temperature. The mixture was stirred overnight at ambient temperature, heated under reflux for 3 h, and worked up. A crude oil was fractionated to give 2,2-dimethyl-2-silaindane (14.5 g), bp 100.5—101 °C (2.9 kPa). The product was heated with *N*-bromosuccinimide (14.3 g) and benzoyl peroxide (160 mg) in carbon tetrachloride (150 cm³) for 1.5 h. Solvent was removed on a rotary evaporator. The residue was washed with pentane and filtered. The filtrate was evaporated and the remaining oil was fractionated using a spinning band column to give **1a-Br** as a colorless oil (11.5 g, 59%); bp 62—63 °C (0.13 kPa); UV (95% EtOH) 235 (log ε=3.76), 275 (3.27); ^{1}H NMR (CCl_4) δ=0.13 (3H, s), 0.48 (3H, s), 1.91 (1H, d J=16.2 Hz), 2.19 (1H, d, J=16.2 Hz), 4.31 (1H, s), 6.9—7.5 (4H, m). Found: C, 49.82; H, 5.44%. Calcd for $C_{10}H_{13}BrSi$: C, 49.80; H, 5.43%.

2,2-Dimethyl-1-indanyl Bromide (1b—Br). To a solution of LDA (0.21 mol) in ether (200 cmm³) was added ethyl isobutyrate (21.8 g) over a period of 15 min at −78 °C and the mixture was stirred for 30 min at −78 °C. Benzyl bromide (30.5 g) was added and the mixture was heated under reflux for 2 d. Usual workup gave 2,2-dimethyl-3-phenylpropionic acid (22 g), which was converted into the acyl chloride by treatment with thionyl chloride. The crude acyl chloride was added to a mixture of $AlCl_3$ (15.7 g) in carbon disulfide (80 cm³) and the resulting mixture was heated under reflux for 30 min. Workup gave 16.2 g of 2,2-dimethyl-1-indanone which on treatment with $LiAlH_4$ (2.0 g) gave 2,2-dimethyl-1-indanol (11.6 g); mp 55—56 °C [lit,[20] mp 56—57 °C]. The alcohol (2.9 g) was dissolved in ether (25 cm³) and dry hydrogen bromide was bubbled into the solution for 30 min at ambient temperature. A crude oil obtained after workup was distilled to give **1b-Br** (3.0 g), bp 69—70 °C (0.27 kPa); NMR (CCl_4) δ=1.17 (3H, s), 1.28 (3H,s), 2.62 (1H, d, J=14.4 Hz), 2.89 (1H, d, J=14.4 Hz), 5.05 (1H, s), 7.04—7.4 (m, 4H). Found: C, 58.83; H, 5.76%. Calcd for $C_{11}H_{13}Br$: C, 58.69; H, 5.82%.

α-Trimethylsilylbenzyl Bromide (2a—Br). Into a cold (−78 °C) stirred mixture of LDA (16 mmol) and chlorotrimethylsilane (2.2 cm³) in THF (20 cm³) was added benzyl bromide (2.4 g) in THF (20 cm³) at −78 °C and the mixture was stirred overnight at −78 °C. Usual workup gave **2a-Br** (3.0 g, 87%), bp 100—101 °C (0.5 kPa) [lit,[9] bp 98 °C (0.5 kPa)].

α-Trimethylsilylbenzyl *p*-Toluenesulfonate (2a-OTs). Into a cold (−78 °C) solution of benzyl trimethylsilyl ether (1.8 g) in THF (25 cm³) was added *s*-BuLi (1.3 M in cyclohexane, 10 cm³) and the mixture was stirred at −78 °C for 4 h. Then, *p*-toluenesulfonyl chloride (1.9 g) in ether (15 cm³) was added and the mixture was allowed to worm to ca. 0 °C. The mixture was stirred for 1 h at 0 °C and worked up. Crude product was recrystallized from hexane to give **2a-OTs** (2.2 g, 66%); mp 103—104 °C; IR (Nujol) 1600, 1355, 1250, 1095, 925, 910, 860, 850, 825, 800 cm⁻¹; ^{1}H NMR ($CDCl_3$) δ=0.01 (9H, s), 2.33 (3H, s), 5.27 (1H, s), 6.8—7.3 (5H, m), 7.21 and 7.59 (4H, A_2B_2, J=7.8 Hz). Found: C, 61.05; H, 6.54%. Calcd for $C_{17}H_{22}O_3SSi$: C, 61.05; H, 6.64%.

α-Triethylsilylbenzyl *p*-Toluenesulfonate (2b-OTs). In the same procedure described for the preparation of **2a-OTs**, benzyl triethylsilyl ether (2.2 g) was converted into **2b-OTs** (2.06 g, 55%); mp 32.8—33.5 °C; ^{1}H NMR (CCl_4) δ=0.3—1.2 (15H, m), 2.30 (3H, s), 5.35 (1H, 6.8—7.15 (5H, m), 6.99 and 7.46 (4H, A_2B_2, J=7.8 Hz). Found: C, 63.70; H, 7.42%. Calcd for $C_{20}H_{28}O_3SSi$: C, 63.79; H, 7.50%.

α-*t*-Butyldimethylsilylbenzyl *p*-Toluenesulfonate (2c-OTs). In the same procedure described for the preparation of **2a-OTs**, benzyl *t*-butyldimethylsilyl ether (2.2 g) was converted into **2c-OTs** (2.1 g, 55 %); mp 93—94 °C; ^{1}H NMR ($CDCl_3$) δ=−0.20 (3H, s), 0.06 (3H, s), 0.93 (9H, s), 2.28 (3H, s), 5.42 (1H, s), 6.8—7.1 (7H, m), 7.41 (2H, d, J=7.8 Hz). Found: C, 63.88; H, 7.50%. Calcd for $C_{20}H_{28}O_3SSi$: C, 63.79; H, 7.50%.

Solvents. Ethanol was distilled twice over sufficient amounts of magnesium ethoxide. Acetone was refluxed with potassium permanganate and the distillate was dried over potassium carbonate and fractionated. 2,2,2-Trifluoroethanol was dried over Molecular Sieve 4A for a week and distilled over sodium carbonate.

Kinetics. Solvolysis rates were measured in most cases spectrophotometrically by use of a Hitachi 220A spectro-

photometer equipped with a programmed data printer. Solvolyses were followed by measuring either decrease in a reactant at an appropriate wavelength [253 (**1a-Br**), 240 (**1b-Br**), 235 (**2a-OTs**), 240 (**2b-OTs** and **2c-OTs**), and 231 nm (**3a-Br**)] or increase in a liberated acid as its acridinium ion at 402.5 nm by using $(0.2—2)\times10^{-4}$ M solutions. In the latter method, each sample solution contained a reactant, 2—3 equiv acridine, and $(0.5—1)\times10^{-4}$ M of acridinium *p*-toluenesulfonate. In the absence of the acridinium salt, the first-order plot exhibited a curve for the initial ca. 25% reaction because of non-linear response of the absorbance to the concentration of the acridium ion below 10^{-5} M. For rapid reactions ($k>10^{-2}s^{-1}$), 1 μl of a stock solution (ca. 0.3 M) of a reactant in acetonitrile was added to a given solvent (3 cm^3) which had been maintained at 25 °C in a UV cell and the reaction was immediately followed after short mixing effected by mechanical stirring or bubbling nitrogen through a syringe needle. In several cases, the rates were determined conductimetrically by using a TOA CM-50AT conductivity meter for $(5—10)\times10^{-4}$ M solutions.

Product Analysis. The following products were isolated and characterized from reactions carried out in TFE, ethanol, and aq acetone in the presence of equivalent amounts of 2,6-dimethylpyridine. The reactions in these solvents gave a single product shown below in each case.

Solvolysis in 2,2,2-Trifluoroethanol: 2a-OTFE (93% yield): IR 1600, 1280, 1250, 1150, 1110, 980, 870, 845, 750, 700 cm^{-1}; ^1H NMR (CCl_4) δ=0.0 (9H, s), 3.69 (2H, m), 4.20 (1H, 5), 6.92—7.42 (5H, m). Found: C, 54.86; H, 6.33%. Calcd for $C_{12}H_{17}F_3OSi$: C, 54.94; H, 6.53%. **2c-OTFE** (100% yield): IR 1600, 1285, 1270, 1160, 1110, 980, 840, 800, 760 cm^{-1}; ^1H NMR (CCl_4) δ=−0.24 (3H, s) , 0.0 (3H, s) , 0.95 (9H, s) , 3.65 (2H, m), 4.37 (1H, s), 6.9—7.3 (5H, m). Found: C, 59.01; H, 7.51%. Calcd for $C_{15}H_{23}F_3OSi$: C, 59.18; H, 7.62%.

Sovolysis in Ethanol: 2a-OEt (91% yield): IR 1600, 1250, 1150, 1085, 1070, 865, 840, 745, 730 cm^{-1}; ^1H NMR (CCl_4) δ=−0.06 (9H, s), 1.15 (3H, t, J=6.8 Hz), 3.37 (2H, m), 3.96 (1H, s), 6.9—7.3 (5H, m). Found: C, 69.08; H, 9.63%. Calcd for $C_{12}H_{20}OSi$: C, 69.18; H, 9.68%.

Solvolysis in 50% aq Acetone. 1a-OH (87% yield): IR 3360, 1250, 1030, 940, 840, 820 cm^{-1}; ^1H NMR (CCl_4) δ=0.19 (3H, s), 0.22 (3H, s), 1.90 (1H, d, J=16.8 Hz), 2.05 (1H, d, J=16.8 Hz), 4.43 (1H, s), 6.9—7.5 (4H, m). Found: C, 67.09; H, 7.68%. Calcd for $C_{10}H_{14}OSi$: C, 67.36; H, 7.91%. **1b-OH** (88% yield; from the reaction of **1b-Br** in 80% aq acetone). **2a-OH** (94% yield): IR 3410, 1600, 1250, 1000, 860, 840, 745, 695 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.03 (9H, s), 4.53 (1H, s), 1.75 (IN, OH), 7.25 (5H, m). **2c-OH** (95% yield): ^1H NMR (CCl_4) δ=−0.23 (3H, s), −0.04 (3H, s), 0.95 (9H, s), 4.59 (1H, s), 7.15 (5H, almost s). Found: C, 70.20; H, 9.81%. Calcd for $C_{13}H_{22}OSi$: C, 70.21; H, 9.97%.

Water/Ethanol Selectivity. After completion of solvolysis of **2a-OTs** in aq ethanol in the presence of 1 equiv of 2,6-dimethylpyridine, the mixture was concentrated, extracted with benzene, and dried. Benzene was evaporated and the residual oil was directly analyzed by GLC (AGL, 170 °C, retention time; 10.4 and 15.2 min for **2a-OEt** and **2a-OH**, respectively).

Thermal Rearrangement of 2a-OTs. 2a-OTs (350 mg) was heated to 150 °C for 30 min in a glass ampoule. ^1H NMR analysis indicated the formation of two products in the ratio 2 : 1. The more abundant product was assigned to (1-phenylethyl)dimethylsilyl *p*-toluenesulfonate (**4**): ^1H NMR (CCl_4) δ=0.35 (6H, s), 1.40 (3H, d, J=7.2 Hz), 2.40 (3H, s), 6.8—7.8 (9H, m). A benzylic proton coalesces in the methyl peak of the tosyl group. The crude product was dissolved in ether, washed with aq sodium carbonate, and dried. Solvent was removed and the residual oil was subjected to column chromatography over silica gel. Elution with 1% methanol in benzene gave (1-phenylethyl)-dimethylsilanol (**5**) (80 mg): IR 3300, 1600, 1250, 840 cm^{-1}; ^1H NMR δ=0.0 (6H, s), 1.33 (3H, d, J=7.2 Hz), 1.61 (1H, disappeared on addition of D_2O), 2.12 (1H, m), 6.8—7.3 (5H, m).

The present work was supported by a Grant-in-Aid for Scientific Research No. 01470025 from the Ministry of Education, Science and Culture.

(Received September 5, 1990)

The structure of cytochrome oxidase from beef heart and its complex with cytochrome *c* were investigated in solution by X-ray small-angle scattering. The contrast variation method was applied to the present analysis. The radii of gyration and maximum dimensions were estimated to be 54 and 165 Å for the cytochrome oxidase and 56 and 165 Å for the complex, respectively. A model of the dimer was constructed so as to interpret the X-ray scattering data well. It was concluded that cytochrome *c* is bound to the hydrophilic surface of the enzyme near the edges of the ellipsoidal molecule, and that detergent molecules exist on the surface of the central parts of the enzyme.

Cytochrome oxidase (ferrocytochrome *c*: oxygen oxidoreductase EC 1.9.3.1) is the terminal component of the electron-transfer chain in the mitochondrial inner membrane of eukaryotes. It catalyzes an electron transfer from ferrocytochrome *c* to molecular oxygen and plays an important role as an energy transducer for ATP synthesis. Many biological and physicochemical studies have been undertaken concerning mitochondrial enzymes.[1] In spite of these extensive studies, no structural evidence concerning its precise subunit composition or the locations of the prosthetic groups has been established. For cytochrome oxidase isolated from beef heart, although the number of subunits and the specific heme *a* and copper contents have been reported in many papers, the results show wide variations.

A small-angle X-ray scattering (SAXS) technique followed by a contrast variation method is useful for investigating the protein structure in solution, even though the structure can not be determined accurately. The enzyme is highly hydrophobic and makes a complex with a large number of detergent molecules, forming a micelle in solution. The relative location of each component is detected by the contrast variation method of small-angle X-ray scattering from a solution in which the electron density is close to those the protein or detergent molecules, utilizing the fact that the mean electron density of the detergent micelle is significantly lower than that of the protein.

In the present work, the molecular structures of the cytochrome oxidase from beef heart and its complex with cytochrome *c* was studied using small-angle X-ray scattering. The binding sites of the detergent molecules and cytochrome *c* in the complex are discussed.

Experimental

Preparation of Samples. Cytochrome oxidase was isolated from beef heart mitochondria according to a method of Fowler et al.,[2] and was refractionated with ammonium sulfate in the presence of 1% cholate by a method of Tzagoloff and MacLennan.[3] The fractionated cytochrome oxidase was further purified by hydrophobic chromatography on phenyl-Sepharose CL-4B[4] and affinity chromatography on cytochrome *c*-Sepharose 4B.[5,6] The purified enzyme was finally applied on Sephacryl S-300 equilibrated with 10 mM Tris-HCl buffer, pH 7.5, containing 0.1% Triton X-100 and 0.1 M NaCl (1 M=1 mol dm^{-3}). An enzyme-cytochrome *c* complex was prepared by adding cytochrome *c* purified by a method of Hagihara et al.[7] to an enzyme solution in heme *c*: a heme *a* ratio of 1 : 2 (1 : 1 mol/mol) and an excess of cytochrome *c* was removed by gel filtration on a Sephadex G-75. The heme *a* concentration was determined from a difference spectrum of oxidase reduced with $Na_2S_2O_4$ using a millimolar extinction coefficient of $\Delta\varepsilon_{605-630}$=16.5 mM^{-1}cm^{-1}.[8] The protein concentration was determined by the biuret method.[9]

The electron densities of the X-ray scatterers were calculated from the number of electrons and the partial specific volumes of the enzyme, bound detergent, and cytochrome *c*. The partial specific volume of the enzyme was calculated to be a weighted mean of those of the enzyme and the bound detergent.[10] The amount of detergent molecules was estimated by gel filtration on Sephacryl S-300.[11] The difference in absorption at 280 nm between an enzyme bound with Triton X-100 and that with cholate resulted in 180 molecules of Triton X-100/heme aa_3. To realize a wide range of electron density of the solvent, sucrose, which exhibits a high electron density, was added to a concentrated protein solution so that the protein concentration could be maintained at 0.5% (w/v). A buffer solution containing the detergent was also prepared under the same conditions as that for the protein solution. Contrast variation measurements were carried out in 0.0, 5.0, 10.0, 18.5, 22.0, 30.7, 36.3, 40.0, 45.0, and 50.0% (w/w) sucrose concentrations, corresponding to averaged electron densities of 0.334, 0.341, 0.348, 0.359, 0.363, 0.377, 0.385, 0.391, 0.400, 0.408 e Å^{-3}.

Small-Angle X-Ray Scattering. The X-ray source was a

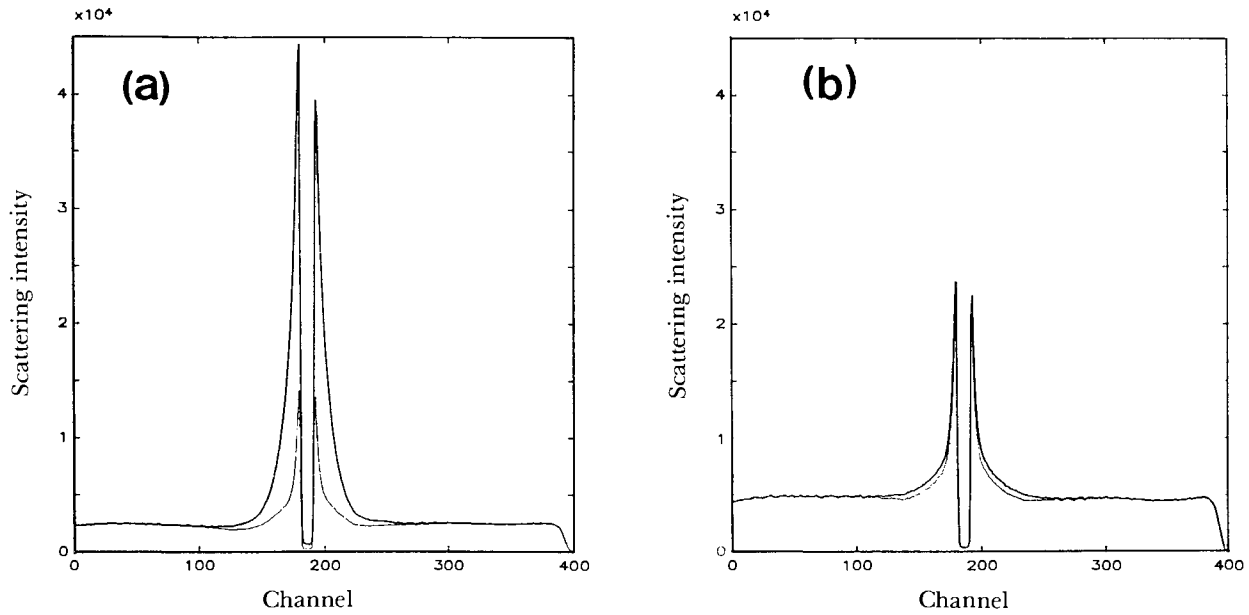

Fig. 1. Typical scattering intensity profiles of cytochrome oxidase solutions containing (a) 0% sucrose and (b) 30.7% sucrose (thick line) and those of the respective cytochrome oxidase free solutions for background intensity subtraction (thin line).

0.4×8 mm spot on the copper anode of a Phillips fine-focus X-ray tube, which was operated at 40 kV-30 mA with a Rigaku Denki D9C X-ray generator. The spot was foreshortened to 0.04×8 mm at a glancing angle of 6°. Ni-filtered X-rays were reflected and focused by a nickel-coated glass mirror (20×60×5 mm), and then introduced to a sample solution through two kinds of limiting slits: the first slit was located behind a mirror holder in order to collimate reflected X-rays; the other one was located in front of a sample holder and was used to reduce parasitic scattering from the edge of the first slit. The scattered X-rays were recorded with a one-dimensional position-sensitive proportional counter (delay-line type) over a scattering range of 4.0×10^{-3} to 7.7×10^{-3} rad. The counter length was 50 mm and was divided into 512 channels on a multichannel analyzer. The sample-to-counter distance was 305 mm. The path between the sample holder and the counter was evacuated in order to eliminate any air scattering. A sample solution was introduced into a 1.0 mϕ thin-walled quartz capillary by an injector incorporated into the sample holder. All X-ray measurements were performed at 5±0.1 °C.

Figure 1 shows typical scattering intensity profiles of cytochrome oxidase and cytochrome oxidase free solutions on a multichannel analyzer. The scattering intensities recorded on both sides of the primary beam were averaged at equivalent points after subtracting background intensities. The center of the primary beam (zero-angle scattering) was adjusted around the center of the quartz capillary, and then refined so as to realize the best coincidence of the scattering intensities at equivalent points. After averaging, an iterative method by O. Glatter[12] was applied in order to deconvolute the slit effects: the beam size, the counter width along the longitudinal axis, and the beam divergent effect. Data smoothing, which was free from random error, was also carried out using the program.

The radius of gyration, R_g, was calculated from both Guinier plots[13] of the scattering intensity data, $I(\boldsymbol{h})$, in a smaller-angle scattering region, and from an integration of the distance distribution function, $P(\boldsymbol{r})$, which (multiplied by 4π) represents for homologous particles (X-ray scatterers) the number of distances within the particle and is obtained from a Fourier transformation of $I(\boldsymbol{h})$ using the following equation:

$$P(\boldsymbol{r}) = 1/2\pi^2 \left(\int_0^\infty I(\boldsymbol{h}) \cdot \boldsymbol{hr} \cdot \sin(\boldsymbol{hr})\, d\boldsymbol{h}\right) \quad (1)$$

$h = 4\pi \sin\theta/\lambda$, 2θ; scattering angle
λ; wavelength

The $P(\boldsymbol{r})$ function was also utilized in order to estimate the maximum dimension of the X-ray scatterer from a distance r, where $P(\boldsymbol{r})$ decreases to zero. The model was constructed by assemblies of spheres to fit the calculated $P(\boldsymbol{r})$ functions to the observed ones.

Results

Table 1 summarizes the R_g and D_{max} obtained in various sucrose concentrations. The R_gs of the enzyme are smaller than that of the complex with cytochrome *c* in all sucrose concentrations, though the D_{max}s are the same as each other in cases (a), (b), and (c). The increase of R_g in the complex indicates that cytochrome *c* is not buried inside but, rather, far from the center of the enzyme. However, cytochrome *c* should not be outside of the enzyme, judging from the equivalent D_{max}. The dimeric enzyme is assumed to bind two molecules of cytochrome *c* symmetrically, and the radius of gyration of the complex is calculated using the radius and molecular weight (R_{g1} and m_1 for oxidase and R_{g2} and m_2 for cytochrome *c*), as well as the distance (X) between the two molecules, as

Table 1. Radius of Gyration(R_g) and Maximum Dimension(D_{max}) of the Cytochrome Oxidase and its Complex with Cytochrome c[a)]

follows:

$$R_g^2(\text{complex}) = (m_1 R_{g1}^2 + 2m_2 R_{g2}^2 + 2m_2 X^2)/(m_1 + 2m_2). \quad (2)$$

By using m_1=260000, m_2=13000, R_{g1}=53.5 Å, R_{g2}=12 Å, R_g(complex)=55.1 Å, X was calculated to be 68 Å, which is less than half of D_{max} by 12 Å. This also indicates that cytochrome c is not deeply buried in the enzyme, but clings to it, since half of the D_{max} of cytochrome c has been estimated to be about 17 Å from a crystal-structure analysis.

The scattering of an X-ray from a particle depends on the difference in the electron density between the particle and the solvent, as follows:[14)]

$$I(\boldsymbol{h}) = \Delta\rho^2 I_v(\boldsymbol{h}) + \Delta\rho I_{vf}(\boldsymbol{h}) + I_f(\boldsymbol{h}), \quad (3)$$

where $\Delta\rho$ is the difference between the averaged electron density between the particle and solvent ($\Delta\rho = \rho_{scatterer} - \rho_{solvent}$), I_v is a shape function of the particle, I_f is from the internal structure of the particle, and I_{vf} is a correlation term between the shape and internal structure of the particle, respectively. The I_v mainly contributes to $I(\boldsymbol{h})$, and the latter two term are quite weak, except for $\Delta\rho$=0. In the present case, a large number of detergent molecules are bound to the hydrophobic surface of the enzyme as a micelle. The averaged electron density of the micelle of Triton X-100 (0.363 e Å^{-3}) was lower than that of the protein, though both were higher than that of 0.1% Triton X-100 solution (pH 7.5, 10 mM Tris-HCl). The square root of the zero-angle scattering intensity, $\sqrt{I(0)}$, was plotted against the electron density of the solvent. In the equation, the I_{vf} and I_f terms are zero at $\boldsymbol{h}$=0, since the average of the internal variation of the structure is zero, and $I(0)$ against the electron density plot may be linear if I_v is not changed; that is, a invariant volume hypothesis[15)] is valid. In Fig. 2, both plots of the enzyme and enzyme-cytochrome c complex revealed excellent linearity to ascertain that the enzyme does not react with sucrose. From this plot, the averaged electron density of the particle was derived to be 0.38 e Å^{-3} at $I(0)$=0, which is in good agreement with the calculated value of the detergent-bound enzyme.

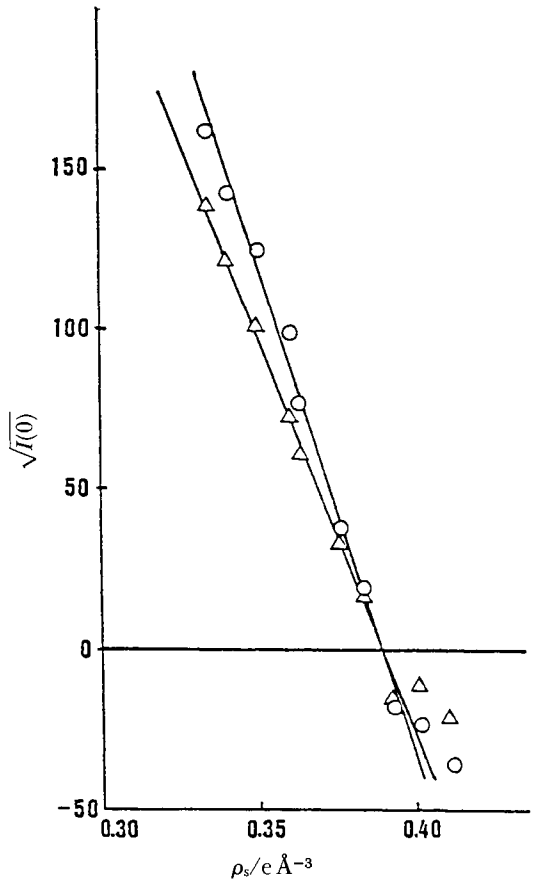

Fig. 2. Relationship between $\sqrt{I(0)}$ and the electron density of a solvent, ρ_s; (△): cytochrome oxidase; (○): cytochrome oxidase -cytochrome c complex.

The distance distribution function, $P(\boldsymbol{r})$, was utilized in the present structural study. As shown in

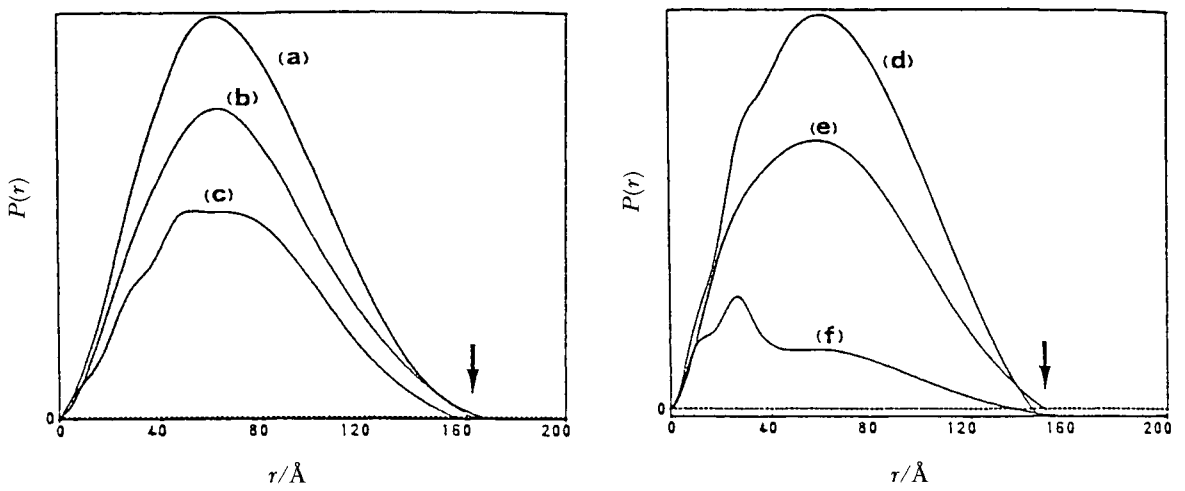

Fig. 3. Distance distribution functions $P(r)$'s for cytochrome oxidase in various sucrose concentrations; ((a) to (f)) correspond to those of Table 1. Arrows indicate the maximum dimension of the enzyme particle.

Fig. 3, the single broad profile of the $P(r)$'s trended to express an undulating character with an increase in the electron density of the solvent. However, the function at the highest sucrose concentration ((f) in Fig. 3) represented a single profile similar to those in the lower sucrose concentration (a)—(c). This behavior suggests that the enzyme comprises different electron-density regions (detergent and protein) separately. When the averaged electron density of the solvent was matched with the detergent, the protein was visible and the detergent invisible ((e) in Fig. 3). The I_f and I_{vf} terms of the protein moiety could be neglected, since the data observed in the present analysis was within a 20 Å resolution, which was too low to show any fine variations of the electron density in one molecule. The electron density of the solvent matched that of the protein erases the part of the protein. The intermediate gives a positive protein and a negative detergent to the $P(r)$ function ((f) in Fig.3).

The SAXS profile was compared with some theoretical intensity curves for various eccentricities. As drawn in Fig. 4, the curve of an ellipsoid with an eccentricity of 2.0 expressed good coincidence with the observed profile in the small-angle region ($2\theta < 14 \times 10^{-3}$ rad). Disagreement of the observed profile at slightly high angles was caused by deviations from a uniform electron density within a prolate ellipsoid model. A molecular model was simulated as assemblies of spheres with a radius of 12 Å, half of the resolution of the observed data, where the electron density of the polypeptide moiety was 0.408 e Å^{-3}, and that of the detergent was 0.363 e Å^{-3}. At first, 56 spheres were gathered in a prolate ellipsoid whose axes were 30, 30, and 50 Å. Spheres as detergent molecules were located around the side surface of the model. The model was refined so as to relate the

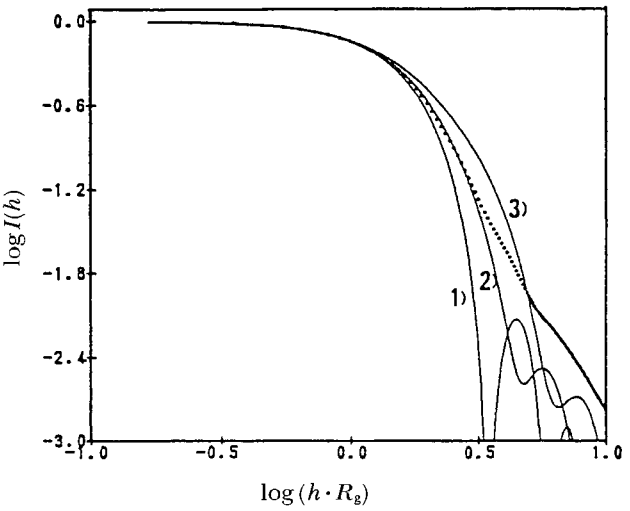

Fig. 4. Log I-log (hR_g) plot of scattering intensities of the cytochrome oxidase in 0% sucrose concentration. calculated scattering data with the observed data, step by step, by the addition of a new sphere and/or the removal of a sphere. The final model comprised 74 spheres, in which 30 were designated as bound-detergent molecules. It should be noted that the relative orientation of individual spheres is not biochemically significant, that is, they do not represent the position of enzyme subunits, but only express a domain having a certain value of electron density. Spheres used as detergent molecules were located around the side surface of the model. Two spheres of cytochrome c were also combined so as to satisfy the distance derived from the complex experiments. The

Fig. 5. The size of spheres for proteins or detergents is not real one, but the spheres are used to depict the positions of their components.

consensus model shown in Fig. 5 shows two monomers in contact with each other by a relation of twofold symmetry and reproduced the structural parameters obtained in the present study, qualitatively. Hydrophobic part of the enzyme was protected by detergents, which seems to be likely in the lipid-bilayer in mitochondrial membrane, while hydrophilic part or cytochrome *c* binding site is far from each other.

Discussion

The maximum dimension of the enzyme under the highest contrast was clarified to be 165 Å, and its volume 650000 Å^3. From an electron microscopic study,[16] the span of the Y-shaped cytochrome oxidase monomer was about 70—80 Å in the mitochondrial membrane. These facts suggest that the enzyme exists as a dimer in a solution containing 0.1% Triton X-100. The enzyme, therefore, as the prolate ellipsoidal form derived from Fig. 4, comprises the connection of two identical monomers so as to contact with each Y-head. The force of this connection is considered to be a hydrophobic interaction of each subunit. This dimeric form is consistent with an ultracentrifugation study in the presence of 0.1% Triton X-100.

The values of maximum dimensions at various electron-density levels reveal an aspect of the binding

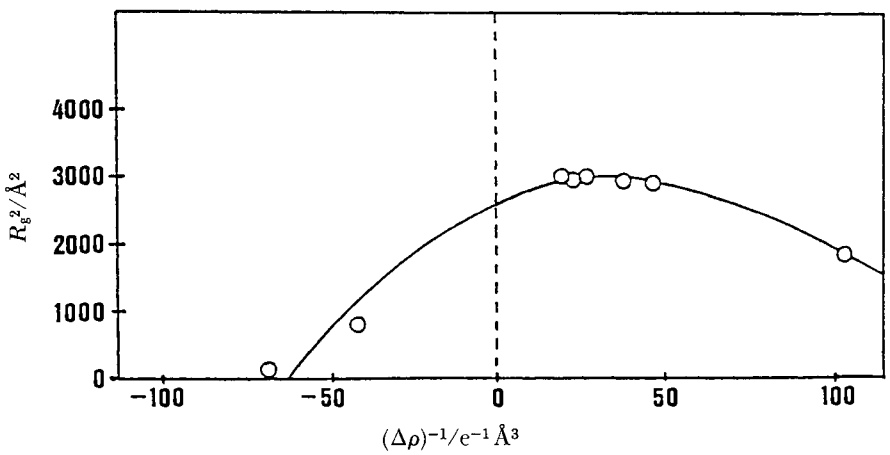

Fig. 6. Relationship between R_g^2 and $1/\Delta\rho$ (Stuhrmann plot) of cytochrome oxidase-cytochrome *c* complex.

site of detergents. A D_{max} of 165 Å under highest contrast exhibits no significant change below sucrose concentrations of 22%, whose electron density is close to that of the bound detergent micelle. This indicates that the enzyme binds the detergent molecules at the sites where its longest span is not varied. Judging from a negative quadratic character of the R_g^2—$1/\Delta\rho$ plot depicted in Fig. 6, the enzyme comprises an electron-dense region in its core and an electron-sparse region at its surface.[14] From these results it may be concluded that the detergent molecules are bound to the side surface of the ellipsoidal dimer, where the Y-heads of two monomers interact with each other by the hydrophobic characters.

A model construction based on the obtained molecular parameters and other structural information[1,16,17] definitely express the characteristics of the enzyme in solution. A preliminary structure analysis shows that the overall structure of the enzyme can be approximated by a prolate ellipsoid with an eccentricity of 2.0. An ellipsoidal model comprising 74 spheres shows that two monomers contact each other through a twofold symmetry. The hydrophobic part of the enzyme is protected by detergents, which seems to be likely in the lipid-bilayer in a mitochondrial membrane, while the hydrophilic part or the cytochrome *c* binding site is far from each other. From these results, the monomer model is consistent with the fact that the molecule passes through the mitochondrial membrane perpendicularly.[16]

The enzyme involves a variety of dense electron regions which are beyond the resolution of the data. Although in the small-angle region the scattering profile calculated according to the rigid body of uniform electron density agreed well with that observed, the consistency between that observed and calculated was worse at the higher-angle region, as is shown in Fig.4. The depicted model, which has two kinds of electron density levels in the ellipsoidal body, decreased the discrepancy, as shown in Fig.7. This feature of the enzyme is also enforced by the effects of contrast on the $P(r)$ function. The calculated $P(r)$s in various contrasts are qualitatively consistent with those of experiments (Fig. 8), from which it may be concluded that the model was constructed correctly. However, the fact that the model is the one which reasonably describes the results from the present study should be noted.

Although there were some errors in X-ray experiments, within the error the present model qualitatively expresses the character of the enzyme in solution, and describes not only the shape of the enzyme

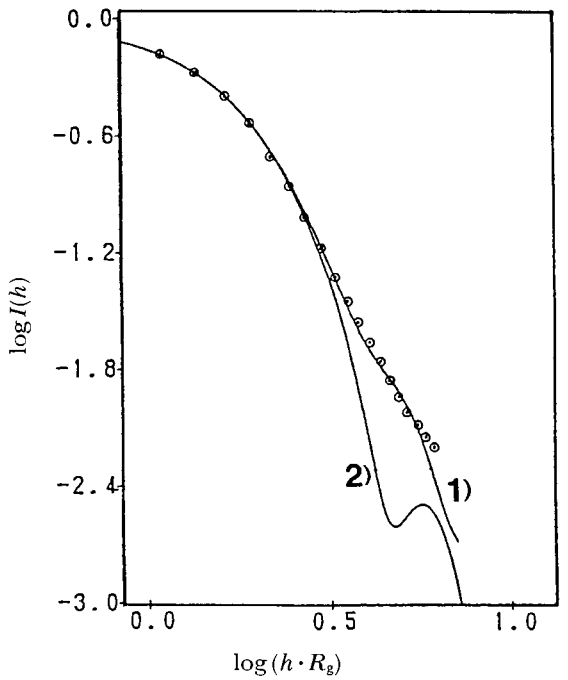

Fig. 7. Log$I$-log (hR_g) plot of the observed scattering intensity. Superimposed are the logarithms of the theoretical scattering intensity functions of a final sphere model: 1) and a preliminary ellipsoidal model with eccentricity of 2.0 : 2).

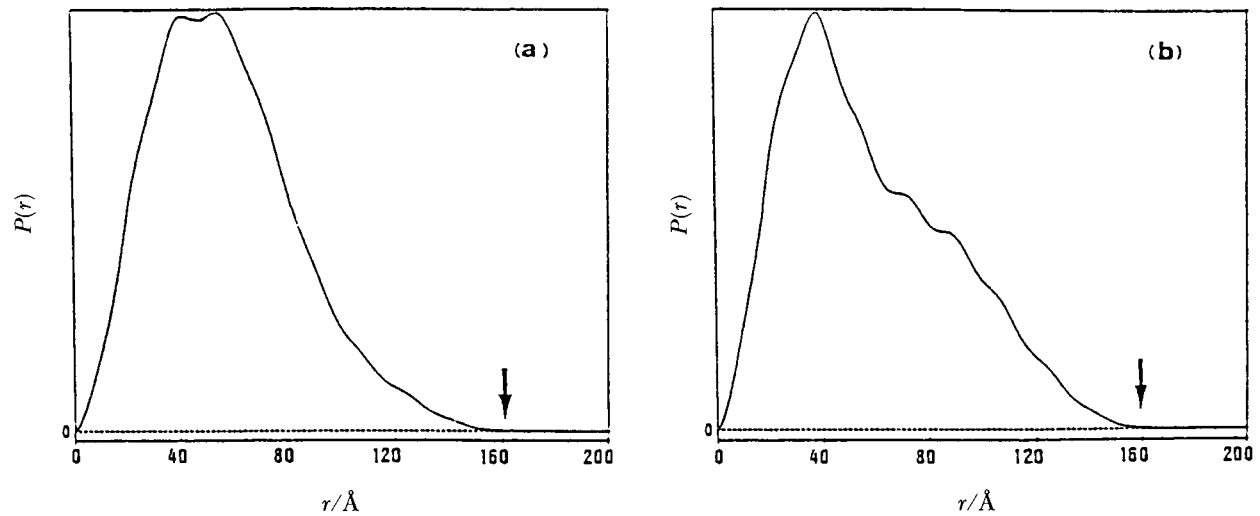

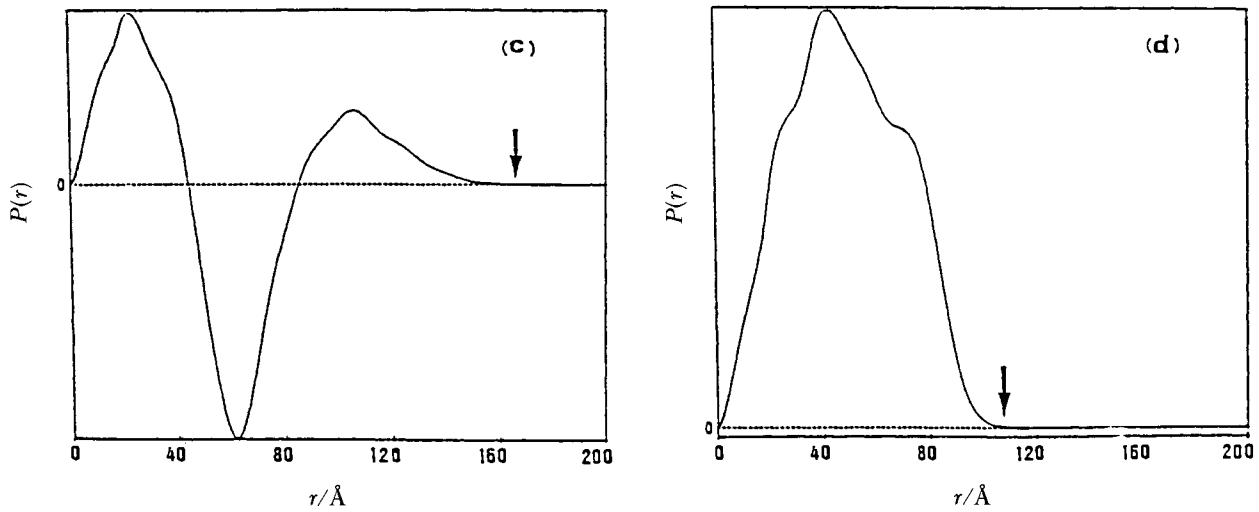

Fig. 8. Distance distribution functions $P(r)$'s for the final sphere model; (a), 0% sucrose; (b), 22% sucrose; (c), 36.3% sucrose; (d), 50% sucrose. Arrows indicate the maximum dimensions.

but also the location of the bound detergent and cytochrome *c*. Judging from only the proposed model, the molecule comprises a hydrophobic central core with detergent molecules and hydrophilic edge regions. Hydrophilic cytochrome *c* is expected to bind to the edge of the oxidase due to the electrostatic character, as discussed and established in our previous paper.[17] The limits of resolution and simulation, however, restrain any detailed modeling of the enzyme. To overcome this problem, high-angle scattering measurements or a crystal structure analysis is indispensable.

One of the authors (Yukio Morimoto) wishes to express his gratitude to Professor Noritake Yasuoka and Dr. Yoshiki Higuchi of Himeji Institute of Technology for their encouragement and to Emeritus Professor Masao Kakudo of Osaka University for variable discussion and encouragement throughout this study.

Oxygen Effect on Photocatalytic Reaction of Ethanol over Some Titanium Dioxide Photocatalysts

Kozo Iseda
Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462
(Received September 25, 1990)

The suspensions of four kinds of TiO_2 photocatalysts in ethanol have been studied under ultraviolet light in an atmosphere of Ar, air, or O_2 at 25 °C. The main products were acetaldehyde, acetaldehyde diethyl acetal (acetal), acetic acid, water, ethylene, methane, carbon dioxide, and hydrogen. Acetaldehyde and acetal were abundantly produced in all of the products. The formation of all of the products under O_2 was more efficient than those under Ar and air. The photochemical activity of each TiO_2 is stronger than that of either Ti_2O_3 or TiO.

Photocatalytic H_2 evolution from ethanol over Pt/TiO_2 catalysts has frequently been reported;[1-6] CH_3CHO,[1,2,4,5] acetal,[2] and acetic acid[1] are major photocatalytic products. However, no instance has yet been reported concerning a quantitative photocatalytic formation on all products from ethanol using various TiO_2 catalysts.

Because the catalytic activity of TiO_2 is presumed to be caused by active oxygen liberated from TiO_2,[7] the activity is decreased by a reduction of the catalyst, itself, due to light illumination;[7] no report, however, has demonstrated the influence of such a decrease in the activity on all products from ethanol, except that regarding the evolution of C_2H_4 and H_2 by the author.[8] To determine the catalytic activity of TiO_2, itself, becomes difficult if Pt is deposited on TiO_2, since the reduction of TiO_2 is depressed by Pt.[9] Therefore, this work was undertaken with only TiO_2, without Pt, and studied in detail regarding effects due to the reactivation of TiO_2 with O_2 on all of the products formed from C_2H_5OH by a comparison of the results from blank tests under Ar, air, or O_2 atmospheres, and that with the TiO_2 under each atmosphere. Furthermore, a comparison was made with that involving TiO_2 as well as Ti_2O_3 or TiO.

Experimental

Photocatalysts. The TiO_2, Ti_2O_3, and TiO used were the same as that described previously.[8] Commercial Ti_2O_3 and TiO used were 99.9%, 300 mesh, Furuuchi Chemical Co., Ltd., respectively.

Ethanol. In the same manner as described in a previous paper,[8] the commercial C_2H_5OH (99.5%, special grade, Katayama Chemical Co., Ltd.) used was purified by distillation after drying over CaO.

Reaction Procedure. The experimental conditions were similar to those published previously.[8] The water tank used was a Riko RH400-10W photochemical reactor. After illumination, the reaction tube was immediately transferred to a beaker containing ice-water and was kept for about 15 min in a refrigerator. This is because the CH_3CHO produced should be kept in the dark while in the liquid-phase as much as possible. A blank test for a mixture of CH_3CHO (0.2 ml) and H_2O (1.8 ml) or that of CH_3CHO (0.2 ml) and C_2H_5OH (1.8 ml) was carried out under an Ar atmosphere without any catalyst in a similar manner as in a previous study.[10]

Analysis. The analytical conditions were also similar to those run in a previous study.[8] A Shimadzu GC-8A gas chromatograph (activated charcoal, 60—80 mesh) was used for the analysis of gaseous products. All liquid products, except for acetic acid, were analyzed using a Shimadzu GC-4B gas chromatograph (PEG-6000 10%, Flusin P, 30—60 mesh). Subsequently, acetic acid was analyzed by a Perkin-Elmer 900 gas chromatograph (PEG-6000 10%, Flusin P, 30—60 mesh, 2 mmϕ×1.8 m glass column, 140 °C, N_2 carrier, FID). In this experiment, the yields of all products with TiO_2, Ti_2O_3, and TiO include that of a blank test under each atmosphere (Figs. 1,2, and 10).

Results and Discussion

Figures 1 and 2 show the formation of liquid products and that of gaseous products from ethanol versus the illumination time observed for a blank test under an Ar or air atmosphere, respectively. Because CH_3CHO and H_2 are produced during the initial illumination, the first reaction of ethanol proceeds as follows:[1]

$$C_2H_5OH \xrightarrow{h\nu} CH_3CHO + H_2 \quad \Delta G^\circ = 41.0 \text{ kJ mol}^{-1}. \quad (1)$$

This result is particularly important in view of the fact that ethanol fails to undergo any reaction; this is because of its absorption maximum at 174 nm[11] under UV light, since Pyrex glass does not pass UV light below about 230 nm. The cause of the reaction described in Eq. 1 is most likely to be due to slight substances having photosensitive action dissolved in ethanol from the natural rubber liner; natural rubber usually contains small amounts of other additive impurities. Once CH_3CHO forms, it serves as a sensitizer, since it has an absorption maximum at 293 nm[12] in its ultraviolet spectrum, and Pyrex glass passes about 40% of the UV light at a wavelength of 290 nm. Accordingly, some of the products shown in Figs. 1 and 2 were slightly produced without TiO_2. Acetal and CH_3COOH were not detected at for illumi-

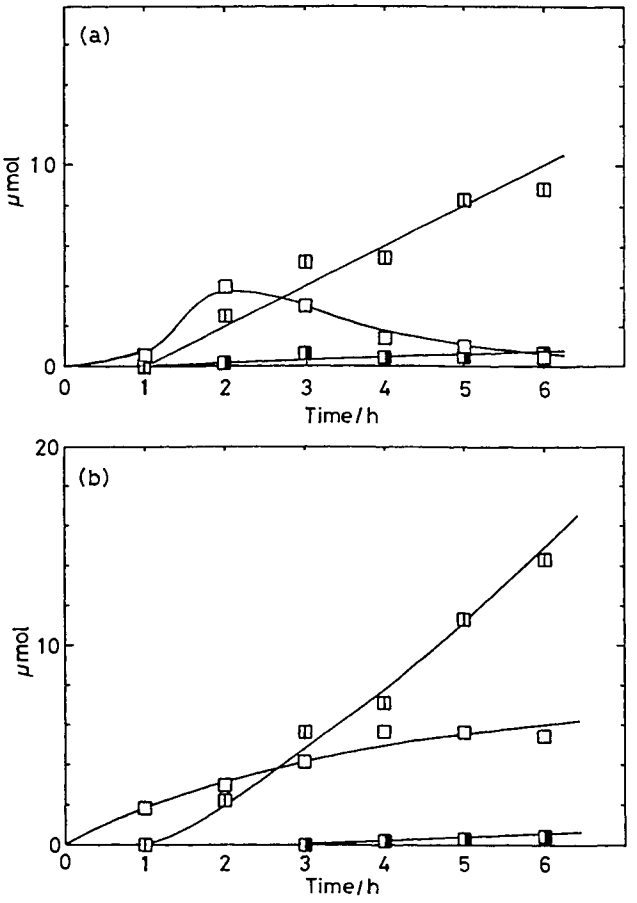

Fig. 1. Formation of liquid products from 2.0 ml ethanol vs. illumination time for a blank test without any TiO_2 under Ar (a) or air (b) atmosphere. □: acetaldehyde, ▥: acetaldehyde diethyl acetal (acetal), ◨: acetic acid.

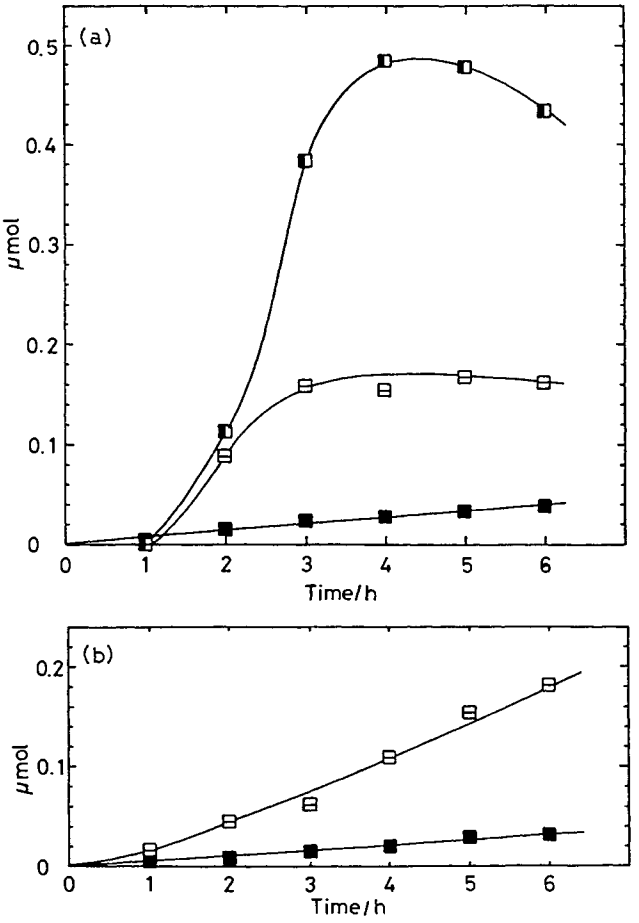

Fig. 2. Evolution of gaseous products from 2.0 ml ethanol vs. illumination time for a blank test without any TiO_2 under Ar (a) or air (b) atmosphere. ◧: CH_4, ⊟: CO_2, ■: H_2.

nation times less than 1 h, and therefore appear to be formed in the following way:

$$CH_3CHO + 2\,C_2H_5OH \xrightarrow{h\nu} CH_3CH(OC_2H_5)_2 + H_2O. \quad (2)$$

Actually, this reaction was confirmed by the formation of acetal and H_2O from a mixture of CH_3CHO (0.2 ml) and C_2H_2OH (1.8 ml) under an Ar atmosphere without TiO_2. Acetic acid is formed as proposed by Sakata and Kawai,[1]

$$CH_3CHO + H_2O \xrightarrow{h\nu} CH_3COOH + H_2 \qquad \Delta G^\circ = -18.9\ \mathrm{kJ\,mol^{-1}}. \quad (3)$$

The formation of CH_3COOH and H_2 was also observed in a mixture of CH_3CHO (0.2 ml) and H_2O (1.8 ml) under Ar. In addition, CH_4 and CO_2 from Eq. 4, shown later, were evolved. The H_2O in Eq. 3 is contained as a small amount of impurity in ethanol and is provided by Eq. 2 as well as by the oxidation of C_2H_5OH by O_2 under an air atmosphere.[8] Actually, H_2O formation under air was more than that under an Ar atmosphere.

No evolution of CH_4 and CO_2 was detected for illumination times less than 1 h under Ar. This is because the decomposition of CH_3COOH gives an evolution of CH_4 and CO_2, as reported by Kraeutler and Bard,[13] and no CH_3COOH was formed during the initial stage.

$$CH_3COOH \xrightarrow{h\nu} CH_4 + CO_2 \quad \Delta G^\circ = -55.8\ \mathrm{kJ\,mol^{-1}}. \quad (4)$$

By the way, in spite of the formation of CH_3COOH and CO_2 under air, no CH_4 was detected. One possible reason for no CH_4 evolution involves the oxidation of CH_4 by O_2 in air.

Figure 3 shows the formation of CH_3CHO from ethanol versus the illumination time observed for four TiO_2 catalysts under an atmosphere of Ar and that of air. Because of the higher yield with each TiO_2, compared to the yield of the blank test, all of the TiO_2 contributes to the formation of CH_3CHO. Acetaldehyde is also formed by the reduction of TiO_2, itself, as shown in Eq. 5 for the following reason. Buss and co-workers proposed the formation of Ti_2O_3 through a color change of the illuminated TiO_2 in normal

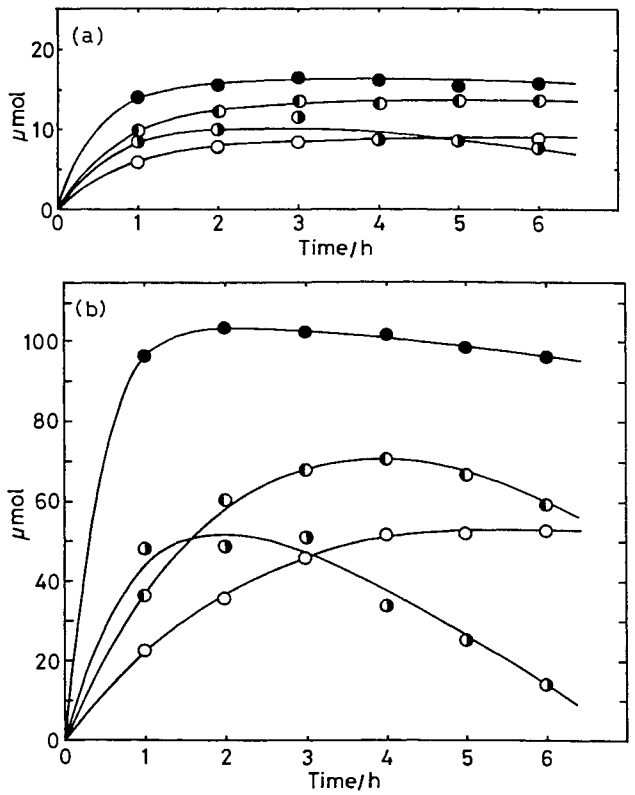

Fig. 3. Formation of acetaldehyde vs. illumination time for suspensions of 30 mg TiO_2 in 2.0 ml ethanol under Ar (a) or air (b) atmosphere. ○: anatase (Aldrich), ◑: rutile (Aldrich), ◐: rutile (Furuuchi), ●: P-25 (Nippon Aerosil).

primary alcohols.[14] Nishimotol et al. demonstrated the cause for the color change by which Ti_2O_3 is formed by a reduction of TiO_2 with 2-propanol.[9] Judging from these two reports, the color change of illuminated TiO_2 in the present work is considered to be caused by a partial formation of Ti_2O_3 due to the reduction of TiO_2 with ethanol,

$$C_2H_5OH + 2\,TiO_2 \xrightarrow{h\nu} CH_3CHO + Ti_2O_3 + H_2O. \quad (5)$$

The molar quantities of TiO_2 required to react with 2.0 ml (343×10^2 μmol) of ethanol are 686×10^2 μmol, as can be seen from Eq. 5. However, 30 mg (375 μmol) of TiO_2 is about 1/200 of the value of μmol required to react with 2.0 ml of ethanol. Therefore, the TiO_2 may be further reduced with a large excess of the ethanol,

$$C_2H_5OH + TiO_2 \xrightarrow{h\nu} CH_3CHO + TiO + H_2O. \quad (6)$$

If only gaseous O_2 in the reaction tube contributed to the formation for CH_3CHO, the ratio of CH_3CHO formation under Ar to that under air in a blank test should be the same as that with TiO_2. However, the formation of CH_3CHO with most TiO_2 catalysts under air is above about 5-times that under Ar, while its formation in a blank test under air is approxi-

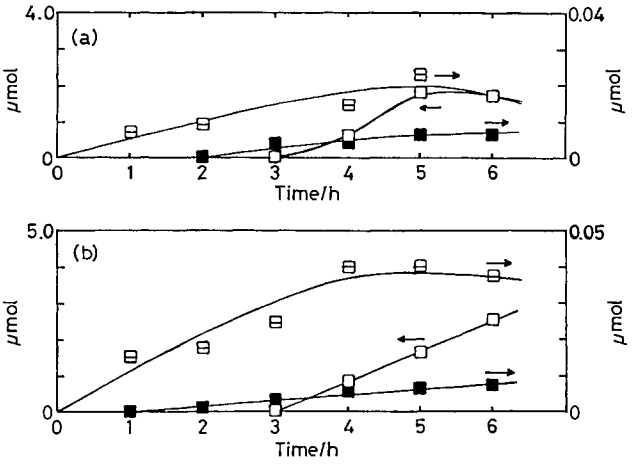

Fig. 4. Formation of products vs. illumination time for suspension of 30 mg Ti_2O_3 in 2.0 ml ethanol under Ar (a) or air (b) atmosphere. □: acetaldehyde, ⊟ CO_2, ■: H_2.

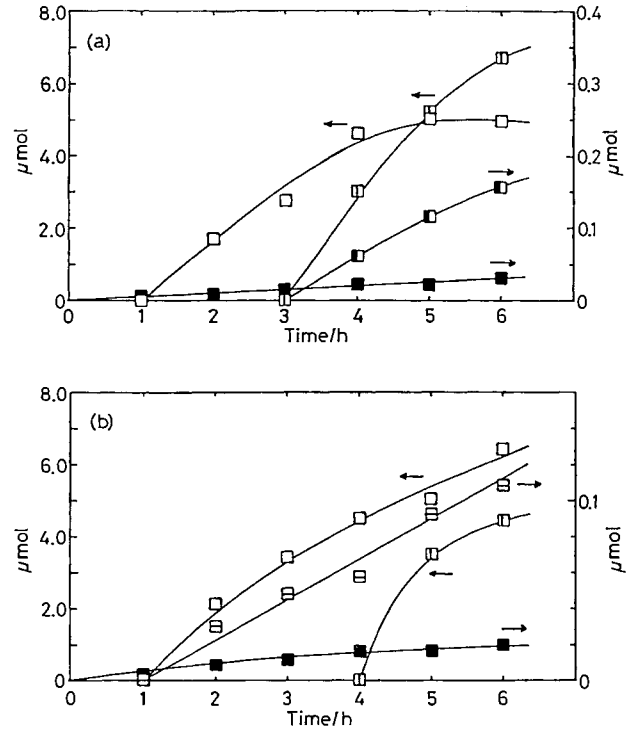

Fig. 5. Formation of products vs. illumination time for suspension of 30 mg TiO in 2.0 ml ethanol under Ar (a) or air (b) atmosphere. □: acetaldehyde, ◫: acetal, ◧: CH_4, ⊟: CO_2, ■: H_2.

mately twice that under Ar. Such a difference between the ratio with the TiO_2 and that in the blank test is remarkably observed for other products, as shown later, since the yields of the other products under Ar in the blank test are roughly the same as those under air, in contrast to the larger difference in the yields with the TiO_2 than the result for CH_3CHO. Consequently, the active O_2 from the reoxidized

TiO_2[7] by O_2 in air seems to be the reason for the higher yield of CH_3CHO under air than that under Ar. If this assumption were correct, the color change[9,14] due to the reduction of TiO_2 observed under air should be much less than that under Ar; further, O_2 in the reaction tube must be decreased, and water must be formed. In fact, these three observations were obtained. To make sure of this estimate, we tried to produce CH_3CHO with Ti_2O_3 or TiO corresponding to the reduction product of TiO_2; these two catalysts gave much fewer products, as shown in Figs. 4 and 5, respectively. Accordingly, the retarding photochemical reduction of TiO_2 under an air atmosphere led to much CH_3CHO formation.

Figure 6 shows the formation of acetal. Under Ar, in spite of the higher yield of CH_3CHO with P-25 and rutile (Furuuchi), compared to the rutile (Aldrich), these two TiO_2 gave no acetal. Although there was no large difference between the yield of CH_3CHO with rutile (Aldrich) and that with anatase, the anatase yielded no acetal. It is therefore evident that these three TiO_2 of P-25, rutile (Furuuchi), and anatase did not catalyze the formation of acetal under Ar.

In the case of an air atmosphere, all of the TiO_2, except for anatase, gave more acetal than that under Ar. That only anatase gave no acetal is interesting, since this TiO_2 produces CH_3CHO.

Figure 7 shows the formation of CH_3COOH. The water in Eq. 3 required to produce CH_3COOH is further supplied from Eqs. 5 and 6, and the evolution of C_2H_4 from C_2H_5OH,[8,10] besides being available from only a small amount of H_2O in ethanol and H_2O from Eq. 2.

In spite of no large difference in the yield of CH_3CHO (Fig. 3, under Ar), no CH_3COOH can be detected on both rutiles (Aldrich and Furuuchi) and P-25 in Ar. However, it seems reasonable to assume that these three TiO_2 may also produce in practice CH_3COOH, due to CH_4 and CO_2 formation in Eq. 4 from the CH_3COOH formed with all of the TiO_2 tested (as is shown later). Each yield of their CH_3COOH, however, seems to be much less than the yield with anatase, and such a minor CH_3COOH is almost consumed during the evolution of CH_4 and CO_2, accordingly to Eq. 4. If a slight amount of CH_3COOH exists in the reaction solution after decomposition to CH_4 and CO_2, it is almost adsorbed on the surface of the analysis path of the gas chromatograph because of the high adsorptive property of the acid. The more rapid decomposition rate of CH_3COOH with both rutiles and P-25 than anatase may have also been a cause for no detection of the acid.

All of the TiO_2 in an air atmosphere catalyzes the formation of CH_3COOH and gives much more CH_3COOH than that under Ar. Anatase did not give as much CH_3CHO as that shown in Fig. 3, but never-

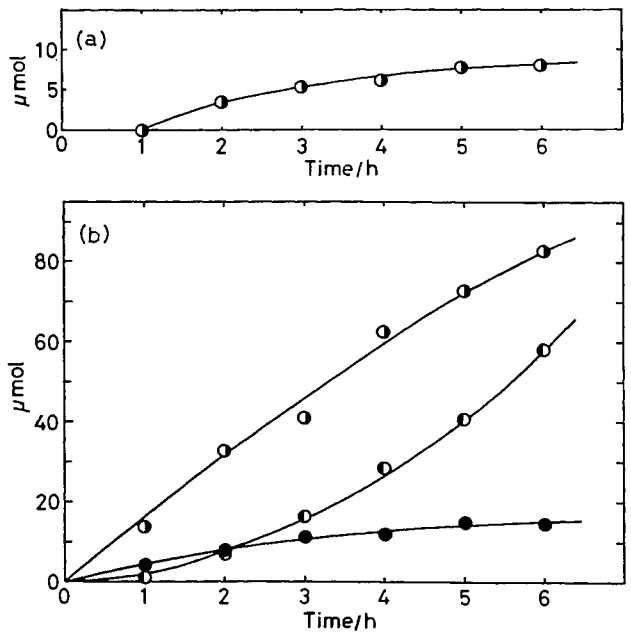

Fig. 6. Formation of acetal vs. illumination time for suspensions of 30 mg TiO_2 in 2.0 ml ethanol under Ar (a) or air (b) atmosphere. ◑: rutile (Aldrich), ◐: rutile (Furuuchi), ●: P-25 (Nippon Aerosil).

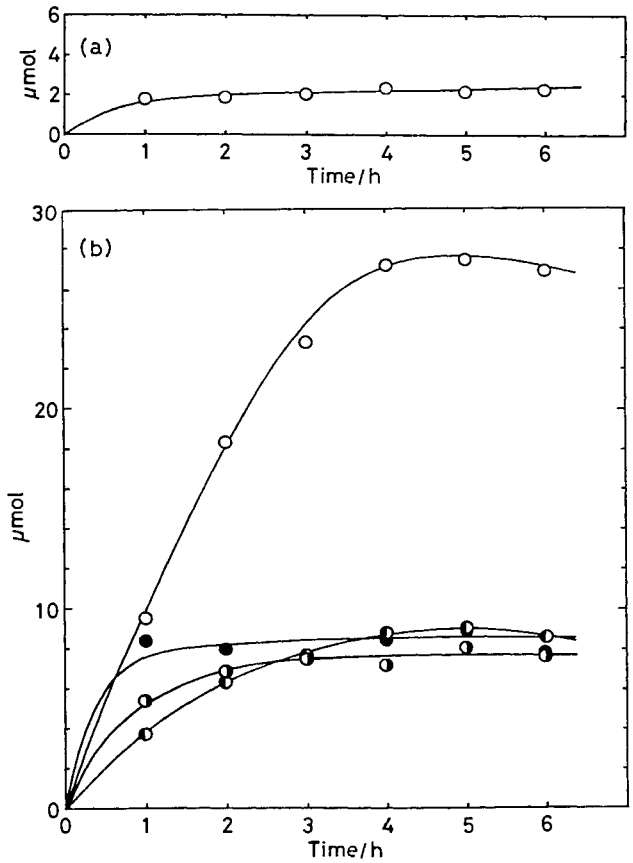

Fig. 7. Formation of acetic acid vs. illumination time for suspensions of 30 mg TiO_2 in 2.0 ml ethanol under Ar (a) or air (b) atmosphere. ○: anatase (Aldrich), ◑: rutile (Aldrich), ◐: rutile (Furuuchi), ●: P-25 (Nippon Aerosil).

theless showed a much higher CH_3COOH yield than did the other TiO_2 catalysts. This is because only anatase did not give acetal (Fig. 6), which is produced from CH_3CHO, as shown in Eq. 2. That is to say, because CH_3CHO with anatase produced CH_3COOH without being used up in the formation of acetal, the anatase could give the greatest CH_3COOH yield.

Figure 8 shows the evolution of CH_4. In the case of an Ar atmosphere, since no evolution of CH_4 took place in the blank test during the initial time, all of the TiO_2 catalyzed evolving CH_4 at that time. However, since the yield of CH_4 was much less than that in the blank test, oxidation of the CH_4 by the O_2 released from TiO_2 seems to be the reason for this result.

All of the TiO_2 under an air atmosphere catalyzed the evolution of CH_4, since no CH_4 evolved in a blank test under air. The result that CH_4 evolution under air is more than that under Ar is consistent with a similar data observed regarding CH_3COOH formation, since CH_4 evolves from CH_3COOH.

Figure 9 shows the evolution of CO_2. All of the TiO_2 gives much more CO_2 under air than that under an Ar atmosphere, because CH_3COOH formation under air is much higher than that under Ar.

Because the evolution of H_2 and C_2H_2 under Ar and air had been previously reported,[8,10] it was omitted.

As described above, air has been found to be effective for the formation of all products; to prove such an effect, further experiments were performed under an O_2 atmosphere.

Figure 10 shows the formation of products from ethanol observed for a blank test under an O_2 atmosphere. Although trace amounts of CH_3COOH and CH_4 were detected, no C_2H_4 evolved. Only the yield of CO_2 was more than that under air (Fig. 2).

Figure 11 shows the formation of liquid products from ethanol versus the illumination time observed for the TiO_2 (rutile, Furuuchi) under an atmosphere of O_2. All of the products were formed in greater quantities than those under air.

Figure 12 shows the formation of gaseous products with TiO_2 (rutile, Furuuchi) under O_2. All of the gaseous products, except for CH_4, were formed in greater quantities than those under an air atmosphere. One possible reason why only CH_4 evolution is less than that under air is as given below. In a blank test, no CH_4 was formed under O_2 and air, although it was evolved under Ar. Judging from

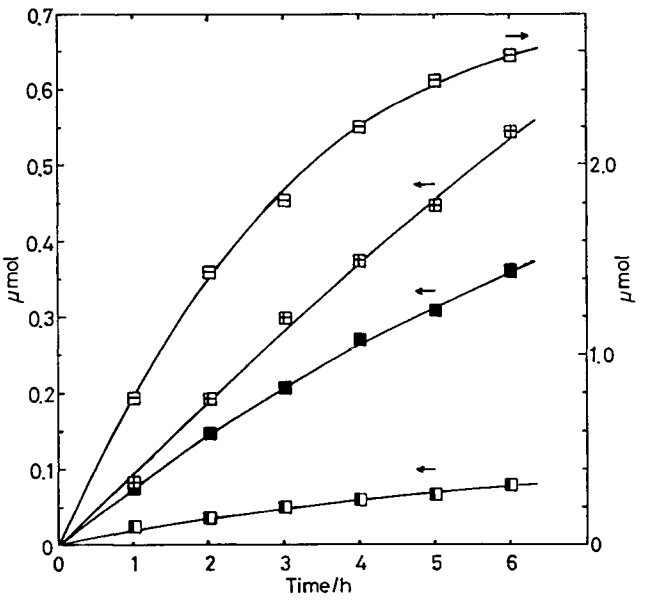

Fig. 12. Evolution of gaseous products vs. illumination time for suspension of 30 mg TiO_2 (rutile, Furuuchi) in 2.0 ml ethanol under O_2. ⊞: C_2H_4, ◧: CH_4, ⊟: CO_2, ■: H_2.

these results, even if CH_4 evolved more than that under air, it was further oxidized by excess O_2 in the reaction tube. The fact that the CO_2 yield was about 5-times that under air supports this assumption.

The yield of C_2H_4 vs. the illumination time is approximately linear, while under air it gave a downward curvature.[8] The reason for such a high activity of TiO_2 is a smaller reduction of part of the TiO_2 than that under air. Actually, no color change[9,14] due to a reduction of TiO_2 was observed, in contrast to the result under air.

The differences among the yields regarding products with TiO_2 under Ar, air, and O_2 was much larger than that in blank tests under these three atmospheres; the yields with TiO_2 increased in the order Ar $<$ air $<$ O_2 atmosphere. Consequently, it has become apparent that active O_2 from reoxidized TiO_2 by O_2 in the reaction tube has a considerably greater effect on the photolysis of ethanol with TiO_2 than does gaseous O_2 present in the reaction tube.

Electrochromism of Octacyanophthalocyanine Thin Film. Investigation by Means of in situ Visible and Raman Spectroscopies

Kimiya TAKESHITA, Yuko AOYAMA, and Michio ASHIDA*
Department of Industrial Chemistry, Faculty of Engineering, Kobe University, Nada, Kobe 657
(Received October 3, 1990)

The electrochromism of an octacyanophthalocyanine ($H_2Pc(CN)_8$) thin film was investigated by in situ visible and Raman spectroscopies in acid and alkaline electrolytes. A new absorption band was observed in the range 700—900 nm of the visible spectra during a reduction of the film. The absorbance reached a constant value at 2 F mol^{-1} of the cathodic electricity in an alkaline electrolyte. The Raman spectra showed a spectral change in the vibration range which is attributed to the macrocycle and the isoindole moiety; hence, the reduction seems to occur in the azaporphyrin ring. From both the visible and Raman spectra, it was revealed that $H_2Pc(CN)_8$ was protonated at the nitrogens in positions 6,13,20,27 by electrochemical reduction. The protonated $H_2Pc(CN)_8$ shows absorption in the near-infrared region in both acid and alkaline electrolytes. The mechanism for the formation of protonated $H_2Pc(CN)_8$ is considered to be analogous to that of hydrogen evolution in alkaline electrolytes. Both the visible and Raman spectra were reversible during reoxidation.

(Phthalocyaninato)metals (MPcs) are composed of a tetraazaporphyrin ring; their structures are analogous to porphyrins, which are important functional compounds found in nature. On account of both chemical and thermal stability, CuPc has been used for a long time as a blue pigment. Recently, MPcs have attracted a good deal of attention as new functional materials, such as catalysts,[1] semiconductors,[2-4] and photoconductors.[5-8] A redox state of MPcs plays an important role in their properties. The electrochromism of MPcs caused by the redox reaction has attracted attention regarding applications in display devices. Since Nicholson and co-workers investigated the electrochromism of lutetium diphthalocyanine films,[9] several other groups have reported results for rare-earth diphthalocyanine.[10-12] Single-ring MPcs (M=Fe, Co, Ni, Cu, Zn, and Mg) films also show electrochromism in the oxidized state.[13,14] In these electrochromic processes, a charge-compensating anion for MPc cation formed by electrolysis usually penetrates into the film from an electrolyte. The charge-compensating anion can be considered to be a dopant to MPcs. According to Marks and co-workers as well as Orr and Dahlberg,[15,16] carefully designed, doped phthalocyanines can show metallic conductivity. Furthermore, modified electrodes with MPcs show catalytic activity induced by the electrochemical redox reaction of MPcs.[17,18] It therefore seems to be useful to investigate the electrochromism of MPc films precisely.

We have recently reported that (Octacyanophthalocyaninato)metal ($MPc(CN)_8$) is synthesized from tetracyanobenzene (TCNB) vapor on metal or alkaline halide substrates.[19] Wöhrle and co-workers have reported that thin films of $MPc(CN)_8$ (M=2H, Cu, Zn) show stable electrochromic redox behavior at the reduced state in an aqueous electrolyte.[20] The eight cyano groups of the molecule play an important role in the redox behavior of $MPc(CN)_8$. According to Louati and co-workers,[21] half-wave potentials of the reduction wave of $MPc(CN)_8$ in *N,N*-dimethylformamide (DMF) shifted to the anodic direction by 0.5—1.0 V, as compared with those of MPcs. This finding indicates that $MPc(CN)_8$ is reduced more easily than MPcs. They mentioned that the property of $MPc(CN)_8$ is very close to an organic electron acceptor, such as tetracyanoquinodimethane (TCNQ).

The redox state of MPcs has generally been investigated using an electrochemical method in company with a spectroscopic type. In most studies, in situ electronic transition spectra have also been reported with electrochemical results. In the case of MPc films, however, the electronic transition spectra may not be used to investigate the electrochromism, since the electronic spectra of MPcs depend on their crystal structures. The change in the spectra is caused not only by electrochemical reactions, but also by a structure change due to the solvent.[22] The possibility of an alternation in the molecular packing or crystalline structure has also been recognized for the electrochromism of MPcs by Kahl and co-workers.[14] This suggests that an investigation of the vibrational spectra should be carried out at the same time. The vibrational spectra during electrochromism of an MgPc film were only reported by Kahl and co-workers.[14] Unfortunately, Wöhrle and co-workers have not reported any in situ electronic and vibrational spectra of $H_2Pc(CN)_8$ film during electrochromism.[20]

In this work, we found a new absorption band in the near-infrared (NIR) region during the electrochromism of $H_2Pc(CN)_8$ films in aqueous electrolytes, and investigated the electrochromism with electronic transition and vibrational spectroscopies.

Experimental

$H_2Pc(CN)_8$ was synthesized following the method of

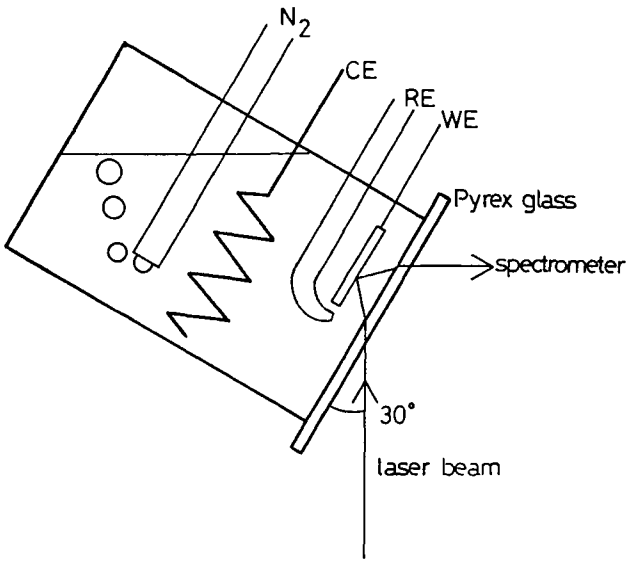

Fig. 1. Experimental setup for in situ Raman spectroscopy of thin film $H_2Pc(CN)_8$ electrodes.

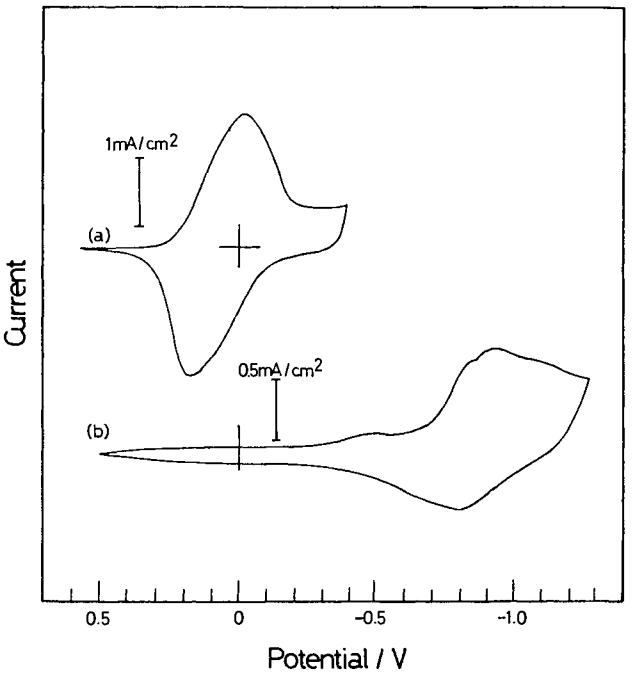

Fig. 2. Stable cyclic voltammograms of $H_2Pc(CN)_8$ films in 1 M HCl (a) and 0.1 M KOH/1 M KCl (b). Thichness of the film are 670 nm (a) and 580 nm (b), respectively. Scan rate 40 mV s^{-1}.

Wöhrle and co-workers,[23] and was purified by column chromatography with silica gel and DMF. $H_2Pc(CN)_8$ was dissolved into DMF and was cast onto an ITO (tin doped indium oxide coated glass) for an optical transparent electrode. The film on ITO was dried in vacuum at 373 K. The amount of $H_2Pc(CN)_8$ on ITO was estimated to be about 10^{-7} mol from the specific gravity of the bulk material (1.49 g cm^{-3}) and the cross section of the film by a direct observation with a scanning electron microscope.

A copper lead wire was attached with silver paste to the ITO, which was used as a working electrode. They were covered with epoxy resin to adjust the electrode area of 1 cm^2. All electrochemical measurements were carried out under an N_2 atmosphere at 298 K with a Hokuto Denko HA-301 potentio/galvanostat and a Hokuto Denko HB-104 potential sweeper. A working electrode, a Ag/AgCl reference electrode and a Pt wire counter electrode were set in an electrochemical cell with quartz windows for optical measurements. Visible spectra of the film in the cell were measured under electrolysis with a Shimadzu UV-240 spectrometer. In the case of potentiostatic electrolysis, visible spectra were recorded when the current reached a stationary state after about 15 min from an application of the potential. The transient time was controlled to be about 30 s in order to avoid any influence of convection and an electric double layer during the galvanostatic electrolysis.

A cell for in situ Raman spectroscopy was shown in Fig. 1. A Raman measurement was made using a Spex Ramalog 5 Raman spectrometer controlled by an NEC PC-9801VM personal computer. An NEC GLS-3300 Ar^+ laser was used as an excitation source. The light power at the sample point was less than 30 mW. The spectral slit width of the spectrometer was set at 4 cm^{-1}.

Results and Discussion

Stable cyclic voltammograms of $H_2Pc(CN)_8$ films on ITO are shown in Fig. 2. In the cathodic scan from the potential of 0.6 V to −0.4 V vs. Ag/AgCl in 1 M HCl (1 M=1 mol dm^{-3}), the film turned from green to blue at ca. 0 V and from blue to purple at ca. −0.2 V. In the reversal scan, the film turned from purple to blue at ca. 0.2 V and from blue to green at about 0.4 V. In a cathodic scan from 0 V to −1.22 V in 0.1 M KOH/1 M KCl, the film turned from green to blue at ca. −0.7 V and from blue to purple at ca. −0.8 V. In the reversal scan, the film turned from purple to blue at ca. −0.7 V and from blue to green at ca. −0.5 V.

The electrochemistry of an $H_2Pc(CN)_8$ film on the Au electrode was intensively investigated by Wöhrle and co-workers.[20] They mentioned that $H_2Pc(CN)_8$ films showed stable electrochromism during reduction in an acid electrolyte, as follows:

$$H_2Pc(CN)_8 + ne^- + nH^+ \longrightarrow H_2Pc(CN)_8^{n-} \cdot nH^+ \ (n=1—3).$$

The cyclic voltammogram of the film showed two reduction peaks; the first and second reduction peaks of the films were 81 and 20 mV vs. Ag/AgCl in 1 M HCl, respectively. On the other hand, the first and second reduction peaks of the films were −756 and −866 mV in 0.1 M KOH/1 M KCl, respectively. They suggested on the basis of those results that the rate-determining step in alkaline electrolytes was the transport of charge-compensating cations in the redox process of $H_2Pc(CN)_8$ film. They did not, however, mention the mechanism of the redox process in an alkaline electrolyte. Although the $H_2Pc(CN)_8$ film on Au electrode showed two distinctive reduction

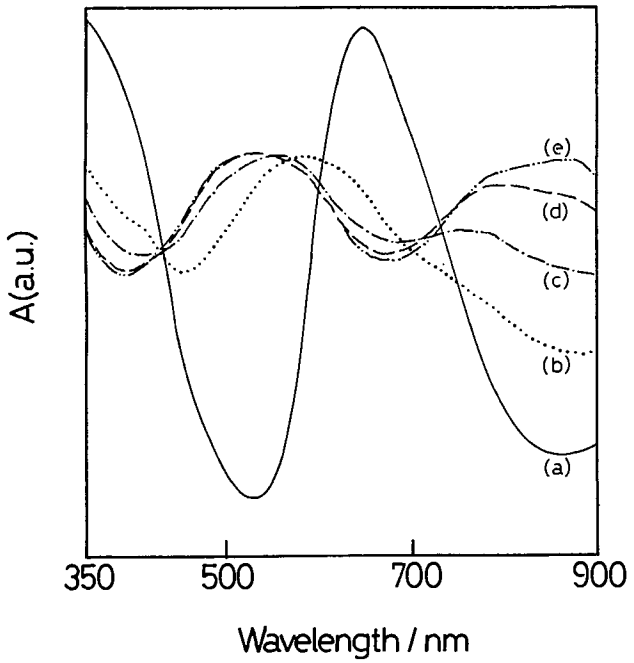

Fig. 3. In situ visible spectra of $H_2Pc(CN)_8$ films in 1 M HCl: original film (a) and films reduced at 0.025 V (b), −0.05 V (c), −0.175 V (d), and −0.4 V (e).

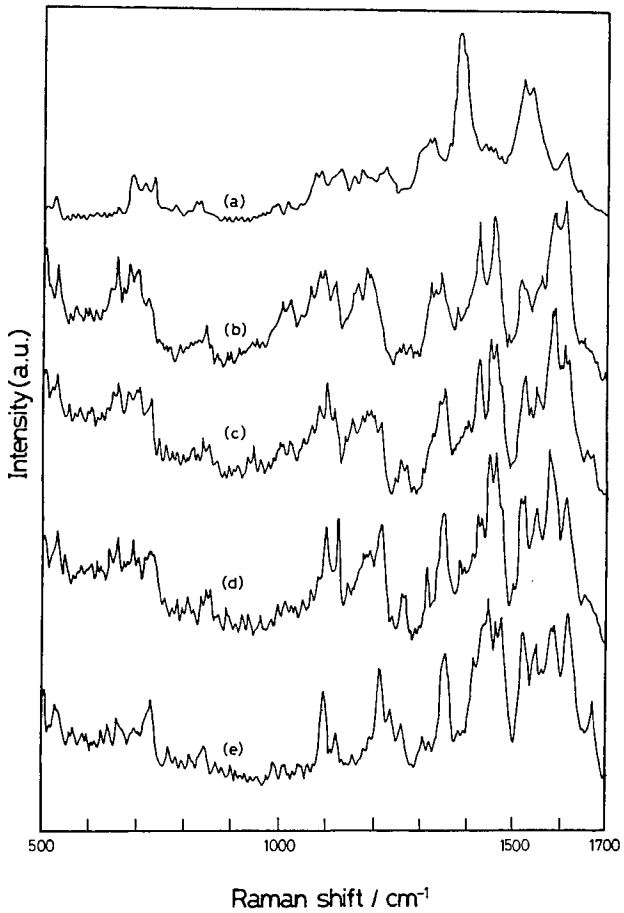

Fig. 4. In situ Raman spectra of $H_2Pc(CN)_8$ films in 1 M HCl: original film (a) and films reduced at 0.025 V (b), −0.05 V (c), −0.175 V (d), and −0.4 V (e). λ_{exc}=514.5 nm.

peaks in the cyclic voltammogram, the $H_2Pc(CN)_8$ film on ITO showed one reduction peak. This may be attributed to a complicated characteristic of a semiconductive ITO electrode.

In Situ Spectra in Acid Electrolyte. In situ visible spectra of $H_2Pc(CN)_8$ films during potentiostatic electrolysis in 1 M HCl are shown in Fig. 3. With the progress of reduction, the absorption peak at 640 nm shifted to a lower wavelength, and a new absorption appeared in the NIR region. When the film was reduced at −0.05 V, the new absorption had a peak at 760 nm; at −0.4 V the absorption had two peaks at 760 nm and 880 nm. During the reduction, the film turned from green to blue at 0.025 V and to violet at −0.4 V. According to Gaspard and co-workers,[24] the Pc protonated at the nitrogen atoms in positions 6,13,20,27 showed absorption in the NIR region; successive protonation of Pc shifted the NIR absorption to a higher wavelength. Therefore, NIR absorption may be attributed to protonated Pcs. The additional absorption appearing at 880 nm suggests further protonation.

In situ Raman spectra of $H_2Pc(CN)_8$ films during potentiostatic electrolysis in 1 M HCl are shown in Fig. 4. Because the film had absorption at the wavelength of the light source (514.5 nm) under electrolysis, the Raman spectra were affected by a resonance Raman effect. The relative intensity of the Raman scattering was compared with that at 531 cm^{-1}, since the intensity at 531 cm^{-1} was changed little by the electrolysis. Fluorescence could be neglected in the Raman spectra as a result of measurements at a different exciting wavelength. The main bands of the Raman spectra were assigned on a basis of those of H_2Pc reported by Aroca and co-workers,[25] since the Raman spectra of $H_2Pc(CN)_8$ have not been reported. The Raman bands are classified into several groups. The Raman band at 1250—1600 cm^{-1} can be mainly attributed to C=C and C=N stretching in the isoindole moieties. In this range, the original film of $H_2Pc(CN)_8$ shown in Fig. 4(a) has peaks at 1391, 1510, 1527, and 1602 cm^{-1}. The second band at 650—800 cm^{-1} is mainly attributed to macrocycle vibration. When the film was reduced at 0.025 V, the peaks at 1391, 1510, and 1527 cm^{-1} disappeared and new peaks appeared at 1423 and 1455 cm^{-1}. The band at 650—800 cm^{-1} changed at the same potential. The result indicated that the isoindole moiety was strongly affected by reduction and that the azaporphyrin ring was distorted by the electrolysis. The same tendency was observed in the oxidation of MgPc film.[14] This finding coincided with the result of Louati and co-workers, in which the redox reaction of $H_2Pc(CN)_8$ took place on the azaporphyrin ring in the DMF solution.[21]

Many strong bands appeared at 1500—1700 cm^{-1} under the electrochemical reduction. According to Sugimoto,[26] phlorin, which is a protonated porphyrins at the *meso* position, has electronic transitions in the NIR region and vibrational modes at 1500—1700 cm^{-1}. By a comparison with the spectra of phlorin, the absorption in the NIR region and the band at 1500—1700 cm^{-1} in the Raman spectra may be attributed to the protonated $H_2Pc(CN)_8$ in the reduced film.

In Situ Spectra in Alkaline Electrolyte. The in situ visible spectra of $H_2Pc(CN)_8$ films during potentiostatic electrolysis in 0.1 M KOH/1 M KCl are shown in Fig. 5. The film turned from green to blue at −0.85 V, and to purple at −0.97 V. As the films were reduced under a more negative potential, the Q-band shifted to a lower wavelength, as in the case in 1 M HCl, and a new absorption peak appeared only at 880 nm. The dependence of the absorption of $H_2Pc(CN)_8$ films on the potential during potentiostatic electrolysis in 0.1 M KOH/1 M KCl is shown in Fig. 6(a). The absorbancies were normalized by absorbance at 640 nm of the original film. The absorbance at 640 nm decreased and that at 530 nm increased at −0.6 V, while that at 880 nm increased at −0.7 V. The change of absorbancies at 640 and 530 nm before the appearance of absorbance at 880 nm indicates that a two-step electrochemical reaction takes place depending on the potential. The dependence of the absorption of $H_2Pc(CN)_8$ films on charge during galvanostatic electrolysis in 0.1 M KOH/1 M KCl is shown in Fig. 6(b). The absorbance at 640 nm gradually decreased and reached a constant value at about 2 F mol^{-1}. The absorbance at 880 nm increased linealy with charge to 1 F mol^{-1} and increased quickly to a plateau which was saturated at about 2 F mol^{-1}. These findings seem to lead to the conclusion that the NIR absorption of the film in 0.1 M KOH/1 M KCl is attributed to $[H_2Pc(CN)_8]^{2-}$. The new absorption in 0.1 M KOH/1 M KCl, however, could not be attributed to $[H_2Pc(CN)_8]^{2-}$, itself, because $[H_2Pc(CN)_8]^{2-}$ does not show any absorption in the NIR region in the DMF solution.[18] To explain the absorption in the NIR region in more detail, the Raman spectra of $H_2Pc(CN)_8$ film is discussed.

The in situ Raman spectra of $H_2Pc(CN)_8$ films during potentiostatic electrolysis in 0.1 M KOH/1 M KCl are shown in Fig. 7. When the film was reduced over −0.62 V, the spectrum coincided with that of the original film. At −0.85 V the band at 650—800 cm^{-1} changed and the peak at 1391 cm^{-1} disappeared as well as in the case of 1 M HCl. The band at 1000—1500 cm^{-1} changed to a different type from that in 1 M HCl. These results indicate that the azaporphyrin ring was affected by electrolysis in alkaline electrolyte, as well as in acid electrolyte and that the charge-compensating cation in the film affected the Raman

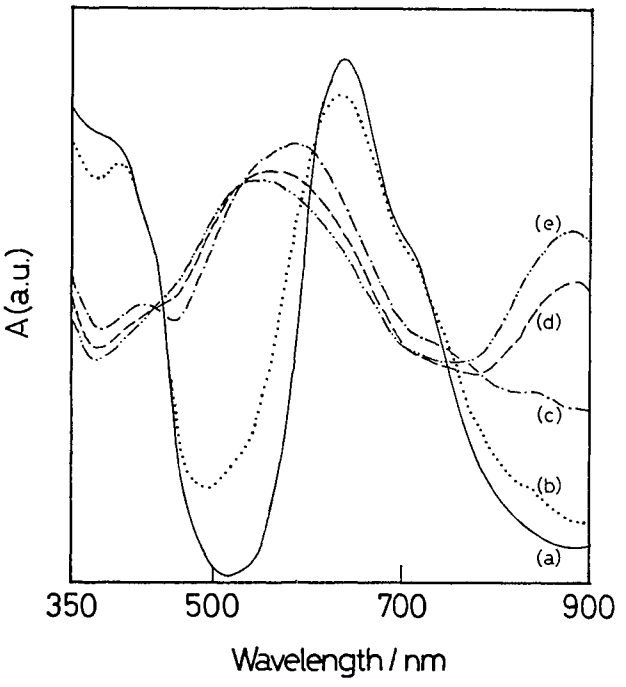

Fig. 5. In situ visible spectra of $H_2Pc(CN)_8$ films in 0.1 M KOH/1 M KCl: original film (a) and films reduced at −0.62 V (b), −0.85 V (c), −0.97 V (d), and −1.22 V (e).

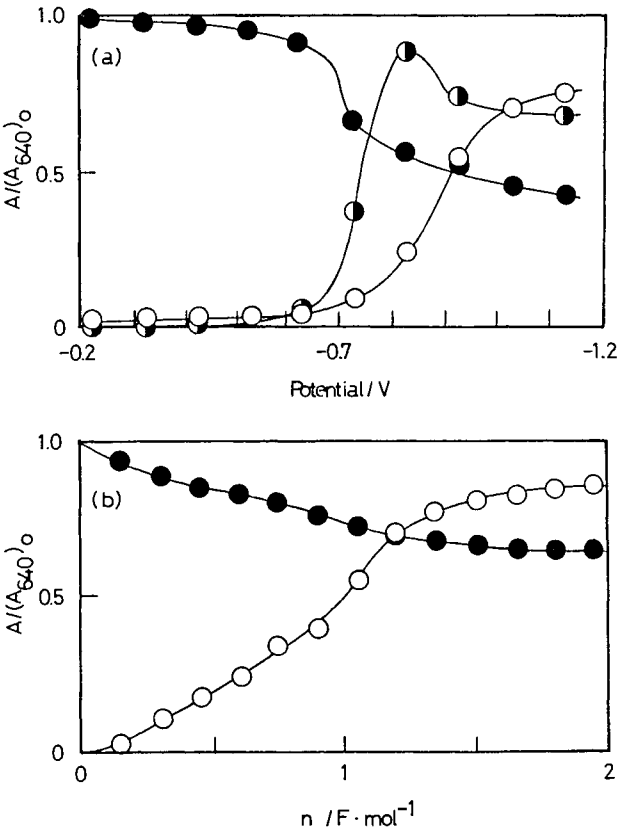

Fig. 6. Dependence of absorbancies of $H_2Pc(CN)_8$ films on potential (a) and charge (b) of the electrolysis in 0.1 M KOH/1 M KCl: ○; at 880 nm, ●; at 640 nm, ◑; at 530 nm.

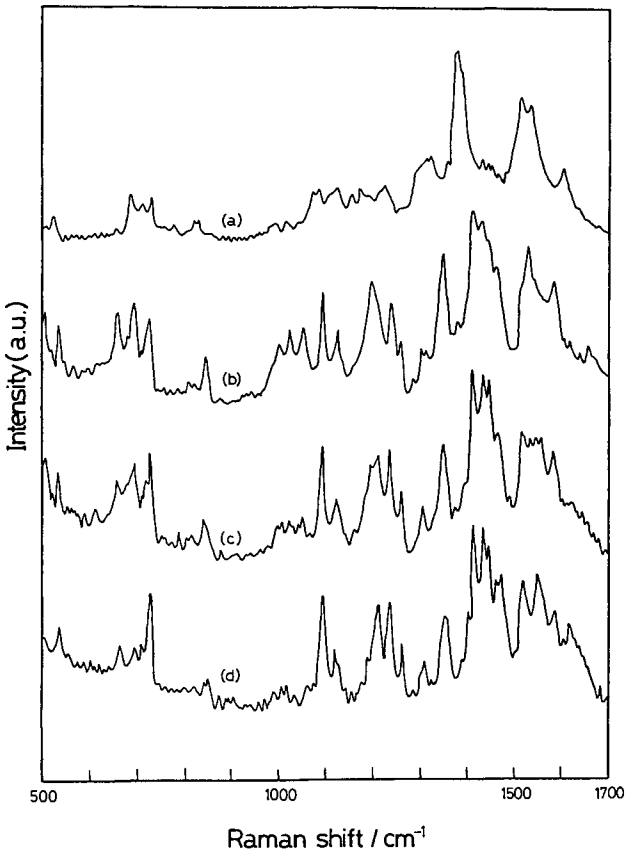

Fig. 7. In situ Raman spectra of $H_2Pc(CN)_8$ films in 0.1 M KOH/1 M KCl: original film and films reduced at −0.62 V (a), −0.85 V (b), 0.97 V (c), and −1.22 V (d). λ_{exc}=514.5 nm.

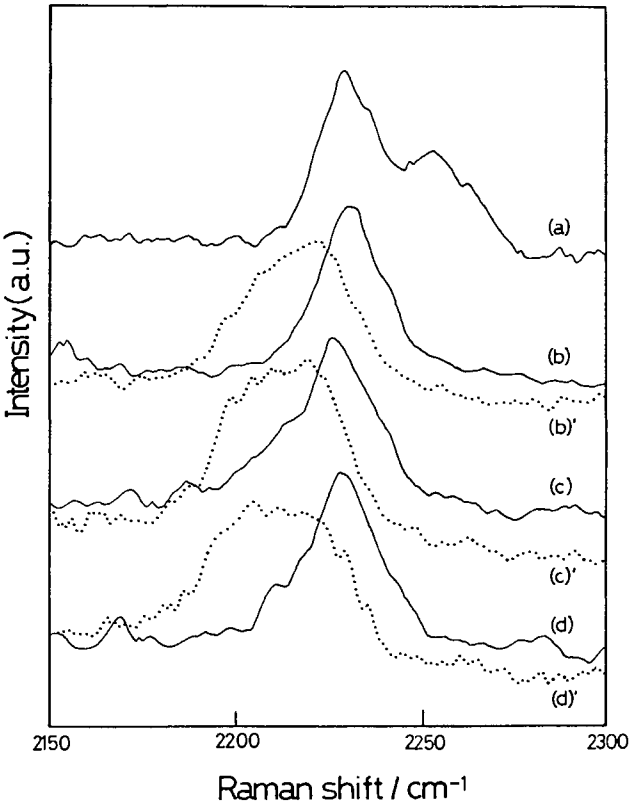

Fig. 8. In situ Raman spectra in C≡N stretching region of $H_2Pc(CN)_8$ films: original film (a), films reduced in 1 M HCl at 0.025 V (b), −0.05 V (c), and −0.4 V (d), and films reduced in 0.1 M KOH/1 M KCl at −0.85 V (b)', −0.97 V (c)', and −1.22 V (d)'. λ_{exc}=514.5 nm.

spectra of the reduced $H_2Pc(CN)_8$. At a potential between −0.97 and −1.22 V, many bands appeared at 1500—1700 cm^{-1}. In consideration of the absorption in the NIR region and for the bands at 1500—1700 cm^{-1}, it seems that $H_2Pc(CN)_8$ is protonated by electrolysis at the potential in 0.1 M KOH/1 M KCl.

From these results, the mechanism of elctrochemical reduction of $H_2Pc(CN)_8$ film in 0.1 M KOH/1 M KCl may be written as follows:

$$H_2Pc(CN)_8 + K^+ + e^- \longrightarrow [H_2Pc(CN)_8]^- \cdot K^+ \quad (1)$$

and

$$[H_2Pc(CN)_8]^- \cdot K^+ + H_2O + e^- \longrightarrow [H_2Pc(CN)_8\text{-}H]^- \cdot K^+ + OH^- \quad (2)$$

Reaction (1) takes place at −0.6 V. At −0.7 V, Reaction (2) produces a protonated $H_2Pc(CN)_8$ anion ($[H_2Pc(CN)_8\text{-}H]^-$) which has absorption in the NIR region. Reaction (1) may be the rate-determining step, since the diffusion of K^+ into the film has been found to be the rate determining step.[20] Reaction (2) is analogous to that of hydrogen evolution in alkaline electrolytes ($2H_2O+2e^- \rightarrow H_2+2OH^-$). The same reaction process occurred in the electrochemical reduction of zinc tetraphenylporphyrin (ZnTPP).[27] In that case, ZnTPP in a DMF solution which contained protic solvent was reduced to $[ZnTPP]^{2-}$, followed by rapid protonation to form a phlorin anion ($[ZnTPP\text{-}H]^-$) which showed absorption in the NIR region. Generally, porphyrin and phthalocyanine have quiet similar electrochemical reactivity and overall redox mechanisms. It therefore seems that such a proposed mechanism of electrochemical reduction is reasonable for the $H_2Pc(CN)_8$ film in an alkaline electrolyte.

C≡N Stretching Vibration. Figure 8 shows the C≡N stretching of $H_2Pc(CN)_8$ films on ITO during potentiostaic electrolysis in 1 M HCl and 0.1 M KOH/1 M KCl. The phthalocyanine films showed two C≡N stretching peaks at 2228 and 2253 cm^{-1}, and a doublet band turned to a singlet in this type of electrolysis. The peak of the singlet band shifted slightly in 1 M HCl during the electrolysis. On the other hand, the band in 0.1 M KOH/1 M KCl shifted to the shorter wavenumber direction by about 50 cm^{-1}, indicating that the charge compensating cation affected the electrochemical reaction of $H_2Pc(CN)_8$ film. In the case of TCNQ films reduced by alkaline metals, C≡N stretchings of TCNQ shifted by about 100 cm^{-1} to a shorter wavenumber.[28] The C≡N stretchings of TCNQ shifted to a shorter wavenumber by electrolysis

to the TCNQ anion in an acetonitrile solution.[29] These findings indicated that the C≡N stretchings of TCNQ were strongly affected by the reduction of TCNQ and the formation of the anion. It is interesting that the C≡N stretchings of the $H_2Pc(CN)_8$ films show a smaller shift than that of TCNQ. For $H_2Pc(CN)_8$, Louati and co-workers mentioned from their electrochemical results that the eight electron-withdrawn cyano groups of $H_2Pc(CN)_8$ interacted indirectly with the conjugated π electron system of the azaporphyrin ring.[21] The reduction of the conjugated π system of $H_2Pc(CN)_8$ probably affects to the cyano group in a weaker way than does that of TCNQ. It therefore seems that the C≡N stretchings of $H_2Pc(CN)_8$ shift less than those of TCNQ by electrochemical reduction.

Spectral Reversibility of $H_2Pc(CN)_8$ Film. The visible and Raman spectra of the film were reversible in the reoxidation process in those electrolytes. When the circuit was opened after the film was completely reduced in the violet state, the film gradually turned to blue during about 10 min, and returned to green after about 30 min. When the film was completely reduced at the violet state and placed into water, it returned to green immediately. The visible and Raman spectra of the film coincided with those of the original film. We have reported that $MPc(CN)_8$ can be synthesized on metal and alkaline halide surfaces, forming a film of an $MPc(CN)_8$-M complex crystal on the substrate. It is expected that $MPc(CN)_8$ in the $MPc(CN)_8$-M film is reduced by an electrochemical reaction and that the electrochromic property of the film is different from that of the $H_2Pc(CN)_8$ film. We are now investigating the electrochromic properties of $MPc(CN)_8$-M films.

(Received October 8, 1990)

In a previous study of graft copolymerization of methyl methacrylate onto polyethylene oxidized with ozone, we clarified that ozone-oxidation reactions produce peroxyl radicals in polyethylene and that the graft copolymerization is assumed to start upon heating, through the decomposition of hydroperoxides which are converted from the peroxyl radicals. A series of reaction processes proposed for the ozone oxidation were examined from the viewpoint of the reaction rate. The time-dependent content of the peroxyl radicals was pursued by observing in situ ESR; the initial evolution rate of the peroxyl radicals and the decay rate after the ozone-stop were discussed on the basis of the proposed ozone-oxidation mechanism, leading to a good agreement between the experiment and theory. The amounts of hydroperoxide and carbonyl species determined from iodometry and the IR spectra, respectively, were also discussed with regard to the oxidation time, showing reasonable linear dependences.

Many investigations regarding polymer degradation have been reported.[1] Free-radical species in polyethylene and polypropylene irradiated by UV light or γ-rays have also been extensively discussed, and a reaction mechanism involving those radical species proposed.[2-10] On the other hand, we recently found that the ozone oxidation of polyethylene is very effective for its graft copolymerization with methyl methacrylate.[11] The influence of the ozone-oxidation and polymerization times on the total conversion, degree of grafting, and graft efficiency were discussed in detail, and the molecular weight of branch polymers estimated. This graft copolymerization can be initiated by active species on polymers introduced by means of ozone oxidation. Making use of ESR spectroscopy, the active species were determined to be peroxyl radicals, as in the case of polypropylene.[12]

The reaction mechanism for the ozone oxidation of polyethylene was presumed in a previous study,[11] based on the detected species in oxidation reactions, such as the peroxyl radical and hydroperoxide. In order to examine the proposed reaction mechanism from the view-point of the reaction rate, we performed in situ ESR measurements and pursued the time-dependent contents of the peroxyl radicals during the initial reaction stage and after stopping the ozone flow (ozone-stop). In addition, the hydroperoxide product was determined from iodometry, and the final inert products were also checked by the IR spectra. The amounts of these products depended on the oxidation time, and were examined on the basis of the proposed reaction mechanism.

Experimental

Polyethylene samples were purchased from Sumitomo Seika Co., Ltd.; 80—100 mesh of low-density type, 0.918 g cm^{-3}, mp 105-111 °C, and molecular weight 4.84×10^4. Polyethylene fibers were obtained from Daiwa Boseki Co., Ltd.; density 0.955—0.961, mp 125—130 °C. Polyethylene films were made by pressing the above-mentioned polyethylene powder at a temperature of 140 °C and a pressure of 10 kg cm^{-2}.

Ozone was produced in a silently discharged oxygen flow (concentration ca. 30 g m^{-3}) and then introduced to a sample tube set in the ESR cavity. For IR measurements polyethylene films were exposed to ozone flow for a prescribed time.

ESR measurements were carried out using a JEOL X-band spectrometer (ME-3X type) with 100-kHz field modulation. Polyethylene fibers of 100—200 mg weight in a quartz glass tube were set inside the ESR cavity and an ozone stream was directly introduced. The decay rate after stopping the ozone was so rapid that the spectral intensity could not be calculated by integration, and was pursued by sitting on the ESR signal; the peak heights were plotted.

The IR spectra were measured for both untreated polyethylene and ozone-exposed polyethylene films using a Shimadzu IR spectrometer (IR-27G type). The absorption intensity was calculated by the usual base-line method.

A determination of hydroperoxide was made according to Chien's method.[13] Details have been described in the literature;[11] data involving the concentration of hydroperoxide vs. the oxidation time were utilized for a rate-process analysis.

Results

The ESR spectrum of polyethylene during ozone oxidation consists of one absorption line with g=2.015 and a line width of ca. 2.4 mT. The radical species was identified as being peroxyl radicals ROO·, as was discussed in a previous paper.[11] The spectral intensities of the ESR spectra during ozone oxidation, as well as after stopping ozone flow, are depicted in Fig. 1, which shows a gradual growth of the radical species for ca. 10 min, then reaching a plateau (a stationary radical concentration). After stopping the ozone flow the intensity decreased rapidly, becoming

very weak after ca. 6 min.

The IR spectra shown in Fig. 2 indicate spectral variations with the ozone oxidation time. The spectra are almost the same as those reported earlier.[7,8] The absorption band at 1710 cm^{-1} can be assigned to a streching vibration of carbonyl groups (C=O) and those at 3400 and 3200 cm^{-1} to that of OH groups. The increased absorption by ozone oxidation can also be seen in the area of 900—1400 cm^{-1}, probably due to other vibration modes of the C=O and OH groups. From these spectral variations, a relationship between the oxidation time and the optical density of the carbonyls (Fig. 3) was obtained, showing a good linear dependence of the C=O content on the oxidation time.

In our spectra the absorption at 3555 cm^{-1}, which was assigned to hydroperoxide by Luongo,[8] was not observed. This discrepancy may be attributed to the treated temperatures, that is, room temperature in our case, as compared to 120 or 145 °C in Luongo's experiment. We determined the content of the hydroperoxide by iodometry, the result of which was reported in a previous paper.[11] Like the C=O content, the hydroperoxide concentration increases linearly with the

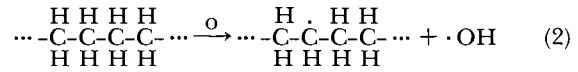
ozone oxidation time.

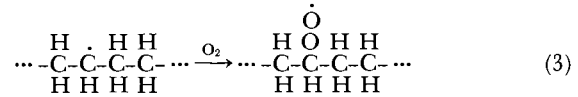
Discussion

Ozone-Oxidation Mechanism. The presumed ozone-oxidation mechanism[11] is first summarized as follows. An atomic oxygen arising from ozone decomposition attacks polymers, producing carbon and hydroxyl radicals. The carbon radical reacts almost immediately with an oxygen molecule, giving a peroxyl radical:

$$O_3 \longrightarrow O_2 + (O) \tag{1}$$

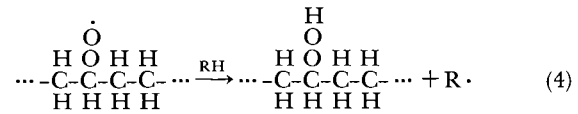


(2)



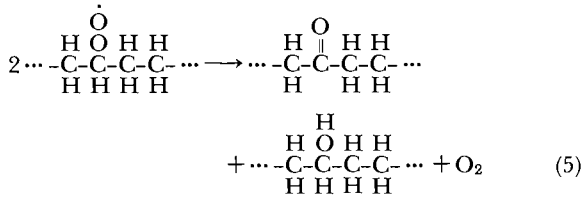
(3)

A part of the peroxyl radicals, thus produced, gives hydroperoxide by pulling out a hydrogen atom from polyethylene:



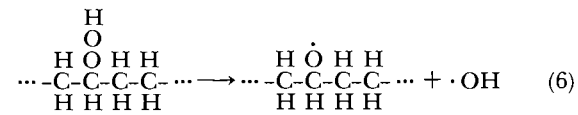
(4)

Another part of the peroxyl radicals gives inert substances, such as ketone and alcohol by recombination:



(5)

The O-O bond of the hydroperoxide given in reaction (4) is broken by heating:



(6)

The alkoxyl and hydroxyl radicals, thus obtained, are presumed to initiate polymerization as active sites and to give graft copolymers and homopolymers, respectively.

Rate-Process Analyses. For simplicity, the following rate processes are taken into consideration. Reactions (2) and (3) can be expected to take place almost concurrently; that is,

$$RH + O_3 \xrightarrow{k_1} ROO\cdot + \cdot OH. \tag{7}$$

The rate constants in reaction (4) and the following chain reaction are set to be k_2 and k_3, respectively:

$$ROO\cdot + RH \xrightarrow{k_2} ROOH + R\cdot \tag{8}$$

and

$$R\cdot + O_2 \xrightarrow{k_3} ROO\cdot. \tag{9}$$

The chain reaction is terminated as in reaction (5):

$$2ROO\cdot \xrightarrow{k_4} \text{inert products.} \tag{10}$$

We assume a steady state of R· in reactions (8) and (9). Then, the production rate of ROO· is obtained as

$$\frac{d[ROO\cdot]}{dt} = k_1[RH][O_3] - k_4[ROO\cdot]^2. \tag{11}$$

Here, we use two parameters, $I = k_1[RH][O_3]$ and $K = (I/k_4)^{1/2}$, and then obtain a solution of the Eq. 11 as[14]

$$\ln \frac{K + [ROO\cdot]}{K - [ROO\cdot]} = \frac{2I}{K} t \tag{12}$$

or

$$[ROO\cdot] = \frac{e^{(2I/K)t} - 1}{e^{(2I/K)t} + 1} \times K. \tag{13}$$

One can see that the saturated concentration of product ROO· is given by the parameter K, where

$$[ROO\cdot]_s = K = (I/k_4)^{1/2}. \tag{14}$$

If we assume a small concentration of intermediate R·, as compared to that of ROO·, the observed ESR intensity becomes proportional to the concentration of ROO·.[15]

Figure 4 shows the time-dependent ESR intensities in the form

$$\ln\{([ROO\cdot]_s + [ROO\cdot])/([ROO\cdot]_s - [ROO\cdot])\},$$

which was calculated from the observed ESR intensity and the saturated value given in Fig. 1. A good linear correlation with the oxidation time given in Fig. 4 is

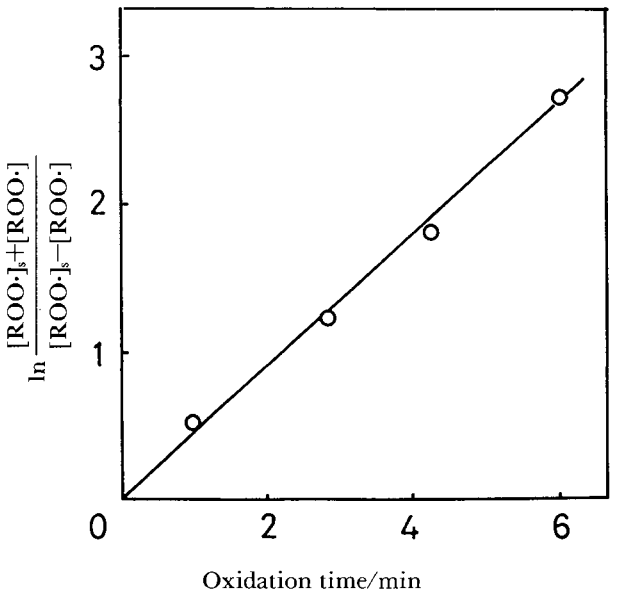


Fig. 4. Plot of $\ln\{([ROO\cdot]_s + [ROO\cdot])/([ROO\cdot]_s - [ROO\cdot])\}$ against ozone-oxidation time.

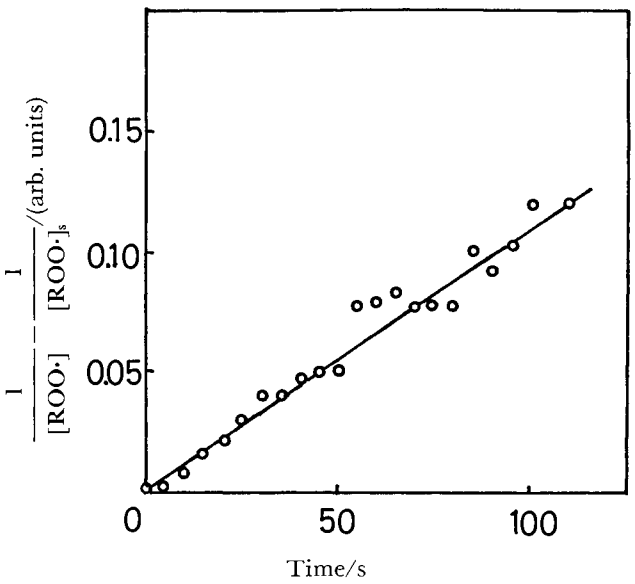

Fig. 5. Plot of $1/[ROO\cdot]-1/[ROO\cdot]_s$ against time after the ozone-stop.

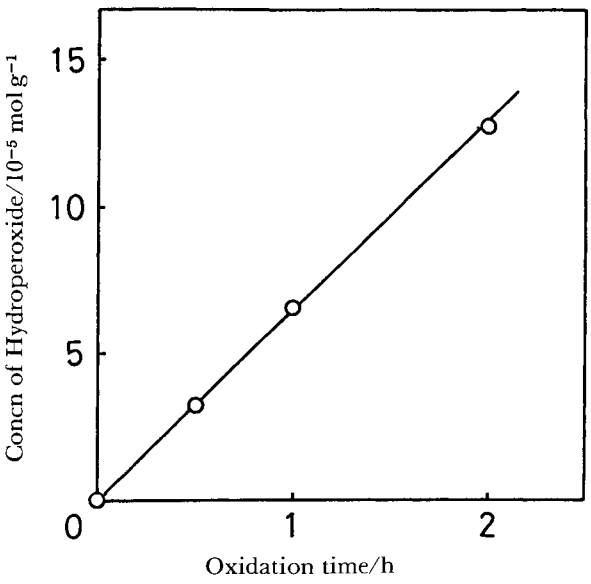

Fig. 6. Relationship between oxidation time and concentration of hydroperoxide in polyethylene oxidized with ozone.

indicative of the validity of Eqs. 12 or 13.

After stopping the ozone flow, the decomposition of ROO· can be expressed by Eq. 10, giving

$$\frac{1}{[ROO\cdot]}-\frac{1}{[ROO\cdot]_s}=k_4t. \tag{15}$$

Using this equation, the decay process is plotted in Fig. 5, which also exhibits a linear time dependence of $1/[ROO\cdot]-1/[ROO\cdot]_s$, supporting Eq. 15.

Products of Hydroperoxide and Ketone. In order to obtain more evidence for the ozone-oxidation mechanism we measured the amounts of products, such as hydroperoxide and ketone, depending on the ozone-oxidation time. From Eq. 8,

$$\frac{d[ROOH]}{dt}=k_2[ROO\cdot][RH]. \tag{16}$$

Here, we use the saturated value, $[ROO\cdot]_s$, for $[ROO\cdot]$ in the case of a longer oxidation time than 10 min. Then, [ROOH] becomes proportional to time:

$$\begin{aligned}[ROOH]&=k_2[ROO\cdot][RH]t\\&=k_2k_1^{1/2}k_4^{-1/2}[RH]^{3/2}[O_3]^{1/2}t.\end{aligned} \tag{17}$$

The iodometry disclosed the content of hydroperoxide, as shown in Fig. 6.[11] It is concluded that hydroperoxide is increasingly yielded with the oxidation time, as is predicted by Eq. 8. This is compatible with reactions (1)—(4).

One of the inert products in reaction (5), the ketone, can be monitored from the IR spectra (Fig. 2). From Eq. 10,

$$\frac{d[C{=}O]}{dt}=k_4[ROO\cdot]^2. \tag{18}$$

Here, we again discuss the process after the saturation of ROO·; Eq. 18 then becomes

$$\frac{d[C{=}O]}{dt}=k_4[ROO\cdot]_s^2. \tag{19}$$

Since $[ROO\cdot]_s$ can be replaced by $(Ik_4)^{1/2}$ from Eq. 14 we obtain

$$[C{=}O]=It. \tag{20}$$

The optical density of the C=O groups in the IR spectra for the various oxidized polyethylenes again shows a linear relation with the oxidation time, as in Fig. 3, indicating the decomposition process of ROO·, like Eqs. 5 or 10.

In this paper concerning the ozone oxidation of polyethylene we pursued the time-dependent radical species ROO· by ESR spectroscopy; the influence of the oxidation time upon such products as hydroperoxide and ketone were clarified by iodometry and IR spectroscopy, respectively. The radical evolution in the initial stage and the radical decay after stopping ozone flow were kinetically analyzed on the basis of several assumptions, affording supporting evidence concerning the reaction mechanism involved in reactions (1)—(5).

The final product, hydroperoxide, which is useful for graft-copolymerization, has a reasonable linear dependence on the oxidation time; the inert product, the ketone, which arises from the decomposition of ROO·, shows the same dependence on the oxidation time. These two findings also support the proposed oxidation mechanism.

14) In the present rate analyses we assumed a constant ozone concentration [O_3] and vast excess of RH.

15) In the case of $k_3 \gg k_2$ this assumption may be plausible. Even if this is not the case, in the steady state approximation about R·, [R·] is related to [ROO·] so that the ESR intensity due to R· and ROO· is eventually proportional to [ROO·].

An Ab Initio Molecular Orbital Study on Twisting in Silyl-Substituted Ethylene Cation Radicals

Ohgi TAKAHASHI, Kenji MORIHASHI, and Osamu KIKUCHI*
Department of Chemistry, University of Tsukuba, Tsukuba 305
(Received October 29, 1990)

Twisting in two silyl-substituted ethylene cation radicals, the cation radicals of vinylsilane (**1**) and vinylidenebissilane (**2**), were investigated by ab initio UHF calculations with the 3-21G and 3-21G(*) basis sets. Both $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ were found to have twisted equilibrium structures, the twist angle being 29° and 42°, respectively. The planarization barriers evaluated for $\mathbf{1}^{+\cdot}$ and $\mathbf{2}^{+\cdot}$ are about 1 and 7 kcal mol^{-1}, respectively. The planar and 90°-twisted forms of $\mathbf{2}^{+\cdot}$ have comparable energies. The hyperconjugation of the C-Si bonds is reflected in the calculated molecular structures.

The possibility of twisting in olefin cation radicals has attracted considerable attention.[1,2] However, it was recently concluded, based on semiempirical UHF/AM1 calculations of hyperfine coupling constants for some alkyl-substituted ethylene cation radicals, that the only olefin cation radicals with a twisted structure are the ethylene cation radical, itself, and a series of trimethylsilyl-substituted ethylene cation radicals.[1] These cation radicals benefit from hyperconjugation of C-H or C-Si bonds, which stabilizes the positive charge, by twisting around the C-C bond. The ethylene cation radical was experimentally found to be twisted by about 25° in the gas phase with a planarization barrier of only 0.7—0.8 kcal mol^{-1} (1 cal=4.184 J);[3] considerable twisting in trimethylsilyl-substituted ethylene cation radicals was suggested based on their ESR spectra by Sakurai et al.[4] and Symons et al.[5] Consequently, the trimethylsilyl-substituted ethylene cation radicals are the only olefin cation radicals which have shown any marked twisted structure so far.

Stabilization of a positive charge center by β-C-Si bonds is now well recognized.[6] This stabilizing effect is orientation-dependent, since the β-C-Si bond interacts with the positive charge center hyperconjugatively.[6,7] Hence, the twist angle in silyl-substituted ethylene cation radicals may be determined by a compromize between the breaking of a one-electron π-bond and hyperconjugative stabilization of the positive charge. Although the hyperfine coupling constants of olefinic protons can be a good measure of the degree of twisting (as discussed in Refs. 4 and 5), a theoretical evaluation of the potential energy surface may be also desirable. This note reports the first ab initio level of calculations concerning the twisting in silyl-substituted ethylene cation radicals. Vinylsilane (**1**) and vinylidenebissilane (**2**) were selected as model compounds for a calculation, and the 3-21G[8] and 3-21G(*)[9] basis sets and UHF formalism were employed. The latter basis set includes d-type polarization functions on silicon atoms.

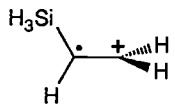
a) Bond lengths are in Å and angles are in degrees. b) One Si-H bond is synperiplanar to the C-C bond. c) The planar carbons were assumed. d) One Si-H bond is antiperiplanar to the C-C bond. e) The twist angle around the C-C bond.

The calculated energies are shown in Table 1, and the structures in Table 2.

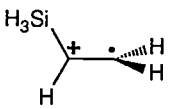
The structure for the planar form was optimized assuming C_s symmetry. Two conformations of the silyl group are possible. In the "*syn*" conformation, one Si-H bond is synperiplanar to the C-C bond, while one Si-H bond is antiperiplanar to the C-C bond in the "*anti*" conformation. The *syn* conformation was calculated to be more stable than the *anti* conformation by 0.5 kcal mol^{-1}, and was found to be the most favorable conformation.

Twisting of the planar cation radical around the C-C bond lowered the energy, and the structure of the twisted form was optimized assuming sp^2 hybridization (planarity) of the carbon atoms (Without this constraint, the energy was lowered by 0.06—0.07 kcal mol^{-1}). The twist angles at the 3-21G and 3-21G(*) optimized structures are 29.3° and 29.5°, respectively. The energy of the twisted form is lower than that of the planar form by 1.2—1.3 kcal mol^{-1}.

The structure of the 90°-twisted form was optimized assuming C_s symmetry. The *anti* conformation of the silyl group was slightly (0.2 kcal mol^{-1}) favored, and was found to be the most favorable. The energy of the 90°-twisted form is higher in energy than that of the twisted equilibrium structure by about 17 kcal mol^{-1}. The ground state of the 90°-twisted form is the



$^2A''$



$^2A'$

$^2A''$ state, which is formally regarded as being a "silylmethyl radical+methyl cation." The energy and structure of the $^2A'$ state, which is regarded as "silylmethyl cation+methyl radical," were also calculated. The $^2A'$ cation radical is higher in energy than the $^2A''$ cation radical by 6—7 kcal mol^{-1}. This result is in contrast to that for the methyl analogue, the propene cation radical.[10] The preference of the $^2A''$ state in $1^{+\cdot}$ is apparently due to a hyperconjugative stabilization of the positive charge by the C-Si bond; in the propene cation radical, the α-methyl group stabilizes the positive charge of the $^2A'$ state.

In summary, $1^{+\cdot}$ is twisted by about 29°, the planarization barrier is about 1 kcal mol^{-1}, and the barrier to rotation through the 90°-twisted form is about 17 kcal mol^{-1}.

Vinylidenebissilane Cation Radical ($2^{+\cdot}$). The structures for the planar, twisted, and 90°-twisted forms of $2^{+\cdot}$ were optimized only with the 3-21G basis set, while the energies were also evaluated with the 3-

21G(*) basis set in some cases, because for $\mathbf{1}^{+\cdot}$, both the 3-21G and 3-21G(*) basis sets gave similar structures, except that the latter gave slightly (0.03—0.05 Å) shorter C-Si bonds, and the 3-21G(*)//3-21G(*), 3-21G(*)//3-21G, and 3-21G//3-21G levels of the calculation all gave very similar results regarding the relative energies (See Tables 1 and 2). The results for $\mathbf{2}^{+\cdot}$ are shown in Tables 3 and 4.

The structure of the planar form was optimized assuming C_{2v} symmetry. The *syn* conformation of the silyl groups was favored by about 1 kcal mol^{-1}. The potential energy surface was found to be very flat against silyl-group rotation in the vicinity of the *syn* conformation.

Twisting of the planar cation radical lowered the energy, and the structure of the twisted form was optimized assuming C_2 symmetry. The twist angle at the optimized structure is 42.4°, which is quite large as an olefin cation radical. The energy of the twisted form is lower than that of the planar form by 7—8 kcal mol^{-1}.

The structure of the 90°-twisted form was optimized first assuming C_{2v} symmetry. The *anti* conformation was slightly more stable (0.3 kcal mol^{-1}) than the *syn* conformation. When a C_2 symmetry was assumed, however, the energy was further lowered by about 0.2 kcal mol^{-1}. The energy of the 90°-twisted form is higher than that of the twisted equilibrium structure by 8—8.5 kcal mol^{-1}. As expected, the ground state of the 90°-twisted form corresponds to "disilyl-

methyl radical+methyl cation" (the $^2B_1$ state in the C_{2v} cases). Another state, the $^2B_2$ state of the C_{2v} 90°-twisted form ("disilylmethyl cation+methyl radical") was also investigated, and was found to be higher in energy than the $^2B_1$ state by 17—18 kcal mol^{-1}. The energy difference between the two states is considerably larger than that between the $^2A''$ and $^2A'$ states of the C_s 90°-twisted form of $1^{+\cdot}$, and is also in contrast to that for the methyl analogue, 2-methylpropene cation radical.[11]

In summary, $2^{+\cdot}$ is twisted by about 42°, the planarization barrier is about 7 kcal mol^{-1}, and the barrier to rotation through the 90°-twisted form is about 8 kcal mol^{-1}. It should be noted that the planar and 90°-twisted forms have comparable energies.

Hyperconjugation of C-Si Bonds. As mentioned in the introduction part, the twisted equilibrium structures of $1^{+\cdot}$ and $2^{+\cdot}$ can be attributed to the hyperconjugative stabilization of the positive charge by the C-Si bond(s). The hyperconjugation effect of the C-Si bond(s) should be maximized at the 90°-twisted form where the overlap between the "vacant" p_π orbital of the carbon atom of $-CH_2$ and the C-Si σ orbital(s) becomes maximum, while the π conjugation between the two carbon atoms is maximized at the planar form. These two competing factors are considered to determine the degree of the twisting. Indeed, $2^{+\cdot}$ which has two silyl groups is more twisted and stabilized by twisting than $1^{+\cdot}$.

The hyperconjugation of the C-Si bond(s) is well reflected in the shape of the LUMO[12] of the 90°-twisted $^2A''$ state of $1^{+\cdot}$ and the 90°-twisted $^2B_1$ state of $2^{+\cdot}$, which are essentially the p_π orbitals of the carbon atom of the $-CH_2$ fragment combined out-of-phase with the C-Si σ orbital(s) (See Fig. 1).[13]

The hyperconjugation is also reflected in the calculated molecular structures. In Table 5, the C-C and C-Si bond lengths and the C-C-Si bond angle at several twist angles are shown (other structural parameters were optimized). As the twist angle is increased, the C-C bond becomes shorter (up to 60°),[14]

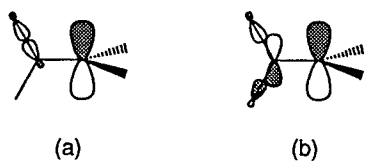

Fig. 1. Schematic representation of the LUMO's of (a) C_s 90°-twisted $^2A''$ state of $1^{+\cdot}$, and (b) C_{2v} 90°-twisted $^2B_1$ state of $2^{+\cdot}$.

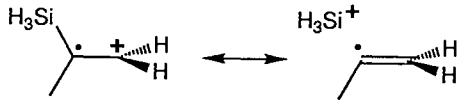
a) In degrees. b) The C-C bond length in Å. c) The C-Si bond length in Å. d) The C-C-Si bond angle in degrees.

while the C-Si bond(s) becomes longer. Considering the following resonance, this trend is attributable to increasing C-Si hyperconjugation.



The change in the C-C-Si bond angle in $1^{+\cdot}$, which decreases as the twist angle is increased, is also attributable to increasing C-Si hyperconjugation. For $2^{+\cdot}$, however, the C-C-Si bond angle unexpectedly increases as the twist angle is increased; the reason for this is not clear.

It should be noted that silyl-substituted ethylene cation radicals are largely twisted by the electronic factor without any steric hindrance, because the trimethylsilyl groups were replaced by the silyl groups in the present calculations.

Orbital Mixing upon Twisting. In the above discussion, the preference of the twisted structures in $1^{+\cdot}$ and $2^{+\cdot}$ was interpreted using the hyperconjugation concept. Here, we see the same thing from a different point of view; we predict twisted equilibrium structures from the MO's of the planar form.

The HOMO ($3b_1$) and NHOMO ($8b_2$) of the neutral

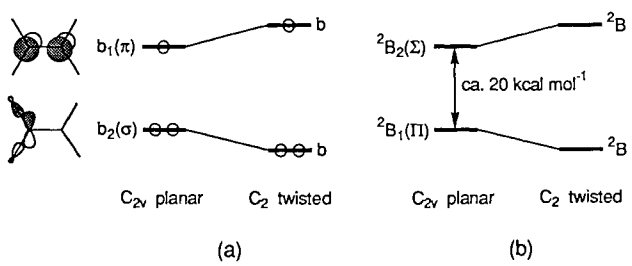


Fig. 2. σ-π Mixing upon twisting of the C_{2v} planar form of $2^{+\cdot}$: (a) Orbital description. (b) State description.

2 (C_{2v} planar) are energetically close to each other;[16] the HOMO is associated with the C-C π bond, while the NHOMO with the two C-Si bonds (Fig. 2). Upon twisting of the molecule around the C-C bond, these two orbitals come to have the same symmetry and mix with each other. This orbital mixing leads to stabilization in the case of the cation radical, as shown in Fig. 2. If we use "state description" instead of "orbital description", the $^2B_1$ (Π) and $^2B_2$ (Σ) states of the C_{2v} planar $\mathbf{2}^{+\cdot}$ interact with each other upon twisting to lower the ground state energy (Fig. 2).[17]

A similar discussion is also valid for $\mathbf{1}^{+\cdot}$. In this case, however, the energy difference between the 3a″ (π) and 13a′ (σ) orbitals (or the $^2A''$ (Π) and $^2A'$ (Σ) states) of the C_s planar form is larger than in **2**,[18] and the interaction of the two orbitals (or states) is weak. This results in smaller stabilization upon twisting.

10) UHF/3-21G calculations have shown that the 90°-twisted $^2A'$ state of the propene cation radical is more stable than the $^2A''$ state by about 16 kcal mol^{-1}.

11) UHF/3-21G calculations have shown that the 90°-twisted $^2B_2$ state of the 2-methylpropene cation radical is more stable than the $^2B_1$ state by about 28 kcal mol^{-1}.

12) The UHF LUMO of the 90°-twisted $^2A''$ state of $\mathbf{1}^{+\cdot}$ and the 90°-twisted $^2B_1$ state of $\mathbf{2}^{+\cdot}$ do not correspond to the SOMO in the RHF case, but to the RHF LUMO. This phenomenon seems to be characteristic of cation radicals in which the positive charge and unpaired electron are separated in different regions. The UHF result is quite natural in view of the most important valence-bond structure.

13) Since the LUMO is not occupied, it has no direct concern with stabilization of the cation radical. Nevertheless, its characteristic shape may be regarded as being a reflection of the hyperconjugation in which the cation center is partially filled by a flow of electrons associated with the C-Si bond(s); the relavent occupied MO, an in-phase combination of the p_π orbital of the carbon atom and the C-Si σ orbital(s), is less apparent due to other mixing. See also Ref. 7.

14) The ethylene cation radical itself also seems to show a similar trend. See Ref. 15.

(Received October 18, 1990)

Crystal structures of the two diastereomeric salts of the title *Δ* complex cation with (*R,R*)-tartrate anion, *Δ-fac*-[Co(*R,S*-chxn)$_3$](ClO$_4$)(d-tart)·*m*H$_2$O (**1**) and *Δ-fac*-[Co(*R,S*-chxn)$_3$]Cl(d-tart)·*n*H$_2$O (**2**) (*R,S*-chxn=(*R,S*)-1,2-cyclohexanediamine and d-tart=dextro-rotatory (*R,R*)-tartrate dianion), have been determined by single crystal X-ray diffraction techniques. The former crystal **1** is orthorhombic with the space group $P22_12_1$, a=12.358(3), b=22.094(5), c=32.770(7) Å, and Z=12, while the latter **2** is trigonal with the space group $P3_121$, a=15.367(7), c=26.208(4) Å, and Z=6. In **1** are found two similar face-to-face contact modes in both of which the d-tart^{2-} ion directs its four almost coplanar O atoms to the complex along the C_3 axis, and three of them, two alcoholic and one carboxylic, are triply hydrogen-bonded to the three N-H protons on one of the triangular faces of the *Δ* complex denoted as the *Δ-cis* RRR face, where R stands for the chirality of the carbon atom adjacent to the N-H group hydrogen-bonded to the d-tart^{2-} ion. The other triangular face of the complex denoted as the *Δ-cis* SSS face is so crowded that only two O atoms of the d-tart^{2-} ion are hydrogen-bonded to the face. In **2** is found one face-to-face contact mode in which the d-tart^{2-} ion approaches the *Δ* complex similarly, but the three O atoms are each placed midway between two of the three N-H protons on the triangular *Δ-cis RRR* face to form three bifurcated hydrogen bonds to them, and the d-tart^{2-} ion tactfully avoids the steric repulsion marginally by inclining its molecular plane a little relative to the triangular face at the least expense of the multiple hydrogen bonds to the face. Based on the assumption that the face-to-face contact mode found in **2** is the most probable interaction mode conceivable in solution, the elution order and separation factor obtained by ion-exchange chromatography for some related [Co(chxn)$_3$]$^{3+}$ complexes are rationally interpreted.

It is well-known that naturally occurring dextro-rotatory (*R,R*)-tartrate anion (abbreviated as d-tart^{2-} hereafter) serves as an effective resolving agent for many chiral metal-amine complex cations, and several studies have been reported on the mechanisms by which the d-tart^{2-} anion discriminates the chirality of these complexes in solution and in the solid state.[1,2] In the preceding paper of this series,[3] a crystal structure analysis has been carried out on a pair of diastereomeric salts of the *lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex (chxn=1,2-cyclohexanediamine) with d-tart^{2-} and Cl$^-$ ions. It has been found there that the d-tart^{2-} anion makes a favorable face-to-face contact with the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex through multiple hydrogen bonds to the three N-H protons on one of the two triangular faces along the C_3 axis. In the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex salt, on the other hand, the d-tart^{2-} ion is forced to rotate its distal carboxylate group when it makes a similar face-to-face contact, because one of the bulky chxn ligands of the *Δ* complex would otherwise impose a severe steric repulsion on the carboxylate group. These observations indicate that the *Δ* complex has two favorable triangular faces which allow a smooth access of the d-tart^{2-} ion along the C_3 axis. These faces are denoted here as the *Δ-trans* SSS face (Fig. 1), where S stands for the chirality of the carbon atom adjacent to the N-H group hydrogen-bonded to the d-tart^{2-} ion. In contrast, the two *Δ-trans* RRR faces (Fig. 1) possessed by the *Δ* complex serve only as a "less-favorable" interaction site, as mentioned above. In this way, highly efficient chiral discrimination attained in these systems has been reasonably interpreted in terms of the steric repulsion expected stereoselectively between the distal carboxylate group and one of the chxn ligands on the *Δ* complex.

Ab initio MO calculations performed on d-tart^{2-} ion[3] have revealed that the rotation of the carboxylate group leads to a substantial destabilization of isolated d-tart^{2-} ion, which is fully compensated in the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex salt, by the multiple hydrogen bonds not only to the triangular face of the

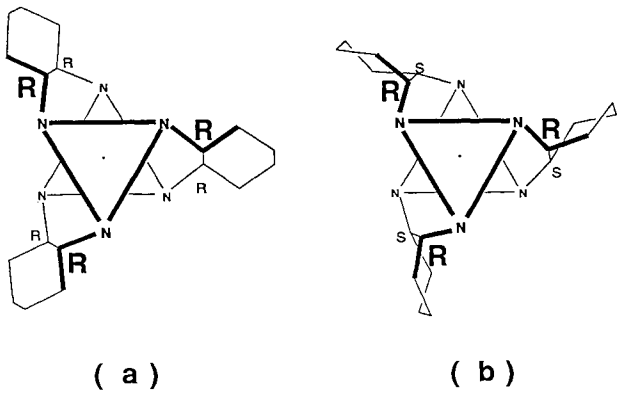

Fig. 1. A schematic presentation of the *Δ-trans* RRR face (a) and the *Δ-cis* RRR face (b). The *Δ-trans* SSS and *Δ-cis* SSS faces are enantiomeric to (a) and (b), respectively, and the *Δ-cis SSS* face is on the opposite side of the *Δ-cis* RRR face in (b) and is enantiomeric to the *Δ-cis* RRR face.

complex but also to another neighboring *Δ* complex. However, d-tart^{2-} ion does not readily assume such an unstable conformation, particularly in solution where another neighboring complex is absent to support the conformational change. Therefore, d-tart^{2-} ion has to adopt a contact mode different from that found in the *Δ* complex salt, when it makes a face-to-face contact in solution with the "less-favorable" *Δ-trans* RRR face of the *Δ* complex. In the present study, X-ray crystal analyses have been made on the two salts with d-tart^{2-} ion of the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ complex which has one triangular *Δ-cis* RRR face (Fig. 1) similar to the "less-favorable" *Δ-trans* RRR face of the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex, in addition to one *Δ-cis* SSS face (Fig. 1), in a hope to search for another interaction mode by which d-tart^{2-} ion makes a face-to-face contact with the "less-favorable" face of these *Δ* complexes having bulky chxn ligands.

Experimental

X-Ray Structure Analysis. *Δ-fac*-[Co(*cis*-chxn)$_3$](ClO$_4$)(d-tart)·mH$_2$O (**1**) formed on mixing *Δ-fac*-[Co(*cis*-chxn)$_3$](ClO$_4$)$_3$[4] with sodium d-tartrate in water, was dissolved in water, and orange crystals were grown by slow evaporation. Orange crystals of *Δ-fac*-[Co(*cis*-chxn)$_3$]Cl(d-tart)·nH$_2$O (**2**) were obtained in a similar manner starting with the corresponding chloride salt.[4] X-Ray data collection was carried out on a Syntex R3 and a Rigaku AFC5 diffractometer for **1** and **2**, respectively with graphite-monochromated Mo$K\alpha$ radiation. The crystal data are summarized in Table 1. The structures were solved by the same procedures as applied previously.[3] The number m and the positions of water molecules present in **1** were not precisely determined because some of them were disordered. The crystal **2** was not big enough to collect ample reflections with $|F_o|>3\sigma(F_o)$, so that the R value was converged only to 9.5%, and since some water molecules were also disordered, they were not unambiguously allocated and counted. However, the molecular structures thus derived were proved to be reasonable both in **1** and **2**, and the accompanying uncertainties had no practical influence on the validity of our discussions described below. With the coordinates of the non-hydrogen atoms thus determined, all hydrogen atoms, except those of water molecules and hydroxyl groups, were assigned idealized positions on the basis of a bond length of 1.09 Å and 1.00 Å for each C–H and N–H bonds, respectively, and a tetrahedral angle around each carbon and nitrogen atoms.

All the computations were done on a HITAC M-680H computer using the programs UNICS-III[5] and ORTEP.[6]

Chromatographic Separation. A racemic mixture of *fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ and its related complexes[4,7] were absorbed on an SP-Sephadex ion-exchange column and were eluted with aqueous 0.2 mol dm^{-3} sodium d-tartrate. Experimental conditions used were the same as described previously.[3] Elution orders and conventional separation factors were determined as before by monitoring the absorption and circular dichroism spectra of the effluents.[4,7]

Results and Discussion

X-Ray Crystallography. All the allocated atomic coordinates in *Δ-fac*-[Co(*cis*-chxn)$_3$](ClO$_4$)(d-tart)·mH$_2$O (**1**) and *Δ-fac*-[Co(*cis*-chxn)$_3$]Cl(d-tart)·nH$_2$O (**2**) except for hydrogen atoms are given in Tables 2 and 3, respectively.[8] The bond distances and angles of the composite ions in both crystals are found to be fairly reasonable and they are deposited as Document No. 9108 at the Office of the Editor of Bull. Chem. Soc. Jpn.[8] The numbering schemes adopted for the respective atoms are those given in several figures that follow.

In the former crystal **1**, the asymmetric unit is composed of three sets each of which is represented as *Δ-fac*-[Co(*cis*-chxn)$_3$](ClO$_4$)(d-tart)·mH$_2$O, each complex cation directs its C$_3$ axis almost parallel to the c-axis of the unit cell, and each d-tart^{2-} ion is sandwiched between the two complex cations. In the

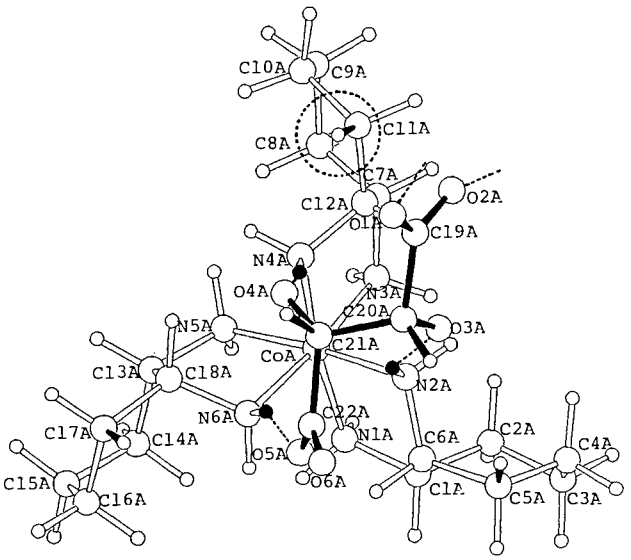

Fig. 2. One face-to-face contact mode of d-tart^{2-} ion with the triangular *Δ-cis* RRR face found in **1** as viewed down the C_3 axis.

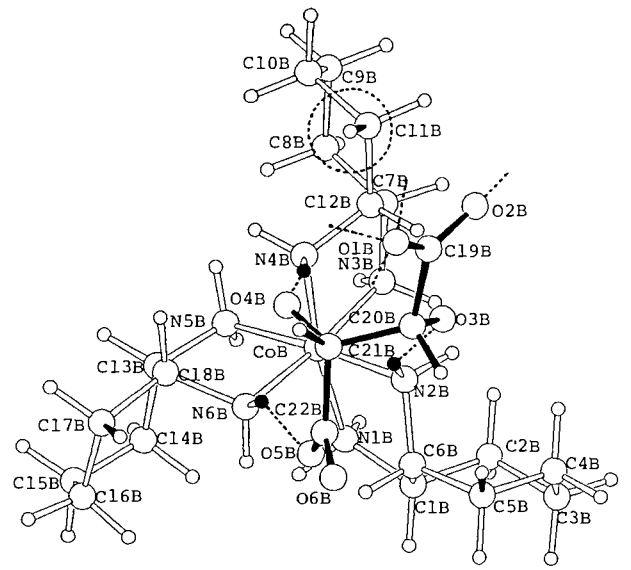

Fig. 3. The other face-to-face contact mode of d-tart^{2-} ion with the triangular *Δ-cis* RRR face found in **1** as viewed down the C_3 axis.

latter crystal **2**, on the other hand, the asymmetric unit is represented simply as *Δ-fac*-[Co(*cis*-chxn)$_3$]Cl(d-tart)·nH$_2$O, in which the complex cation is arranged such that its C_3 axis makes an angle of ca. 52° to the 3_1 screw axis (c-axis), and each d-tart^{2-} ion connects the two complex cations in a different fashion from those found in **1**. That is, the two crystals **1** and **2** are completely different not only in the space group and lattice constants (Table 1) but also in the packing mode. Consequently, it is almost impossible to compare the two crystals even qualitatively with respect to the counter ion effect on the interaction mode of the complex cation with the d-tart^{2-} ion. However, since similar contact modes between the complex and the d-tart^{2-} ions are found in common in **1** and **2**, which we have so far asserted to play a key role in the chiral discrimination, we focus our attention exclusively on these contact modes in the following.

Contact Modes in 1. The two similar face-to-face contact modes found in **1** are shown in Figs. 2 and 3 in both of which the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ complex cation assumes a *lel*$_3$ conformation[4)] and the d-tart^{2-} anion, a normal one usually found.[3)] Consequently, the three N–H protons on each of the two triangular faces[9)] of the complex are disposed almost parallel to the C_3 axis like those of the *lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex.[3)] It appears that conformationally labile metal complexes with three five-membered diamine

chelates assume preferentially a *lel*$_3$ conformation when they form salts with d-tart^{2-} ion or other hydrogen-bonding anions.[10,11]

The two contact modes found in **1** are surprisingly similar to each other; the d-tart^{2-} ion directs its four O atoms (O2, O3, O4, and O5) to the *Δ* complex along the C_3 axis, with three of them (O3, O4, and O5) each hydrogen-bonded to each of the three N-H protons on the "less-favorable" triangular *Δ-cis* RRR face of the complex. However, these contact modes are apparently different from those found in the *Δ-lel*$_3$-[Co(en)$_3$]$^{3+}$ (en=1,2-ethanediamine) and *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ salts.[3,12] In the former salt, the d-tart^{2-} ion comes close to the complex along the C_3 axis and the three O atoms each lie midway between two of the three N-H protons on the triangular face to form three bifurcated hydrogen bonds to them; the d-tart^{2-} ion enjoys up to six hydrogen bonds to the complex without feeling any appreciable steric repulsion from the small en chelates (Table 4). Thus, this contact mode is considered close to an ideal one for the d-tart^{2-} ion coming to the triangular face, and it is adopted with the *Δ-lel*$_3$-[Co(en)$_3$]$^{3+}$ as well.[13] In the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ salt, the three O atoms of the d-tart^{2-} ion are similarly hydrogen-bonded to one of the "less-favorable" *Δ-trans* RRR faces of the complex, but the distal carboxylate group is greatly rotated to avoid the steric repulsion from the C-H proton on one of the bulky chxn ligands; the multiple hydrogen bonds to the complex are almost fully retained at the expense of the conformational energy (Table 4).[3]

In the present crystal, on the other hand, the d-tart^{2-} ion avoids a similar steric repulsion from the "less-favorable" *Δ-cis* RRR face at the expense of the multiple hydrogen bonds to the complex. That is, the d-tart^{2-} ion approaches the complex along the C_3 axis as usual but it rotates itself clockwise as a whole relative to the complex to avoid the repulsion from the C-H proton marked with a broken circle on the chxn ligand (Figs. 2 and 3), and the number of the hydrogen bonds formed is accordingly reduced from six virtually to three. However, the remaining three hydrogen bonds (O3··H-N2, O4··H-N4, and O5··H-N6) are fairly improved with respect to length and angle (Table 4), and the distal carboxylate group is placed such that its two O atoms (O1 and O2) form intimate hydrogen bonds to the N-H group(s) of other neighboring complexes in the *Δ-fac*-[Co(*cis*-chxn)$_3$](ClO$_4$)(d-tart)·*m*H$_2$O (**1**), as shown by dotted lines in Figs. 2 and 3. In this respect, the hydrogen-bonding scheme found in the present crystal is similar to that found in the *Δ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ salt where all of the three N-H groups are oblique to the C_3 axis, so that practically only three but linear hydrogen bonds are formed to them.[11] The hydrogen bonds associated with these face-to-face contact modes are all compared numerically in Table 4.

The other triangular face of the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ denoted as the *Δ-cis* SSS face, is depicted in Fig. 4a. It is seen there that the three C-H protons marked with broken circles on the chxn ligands are

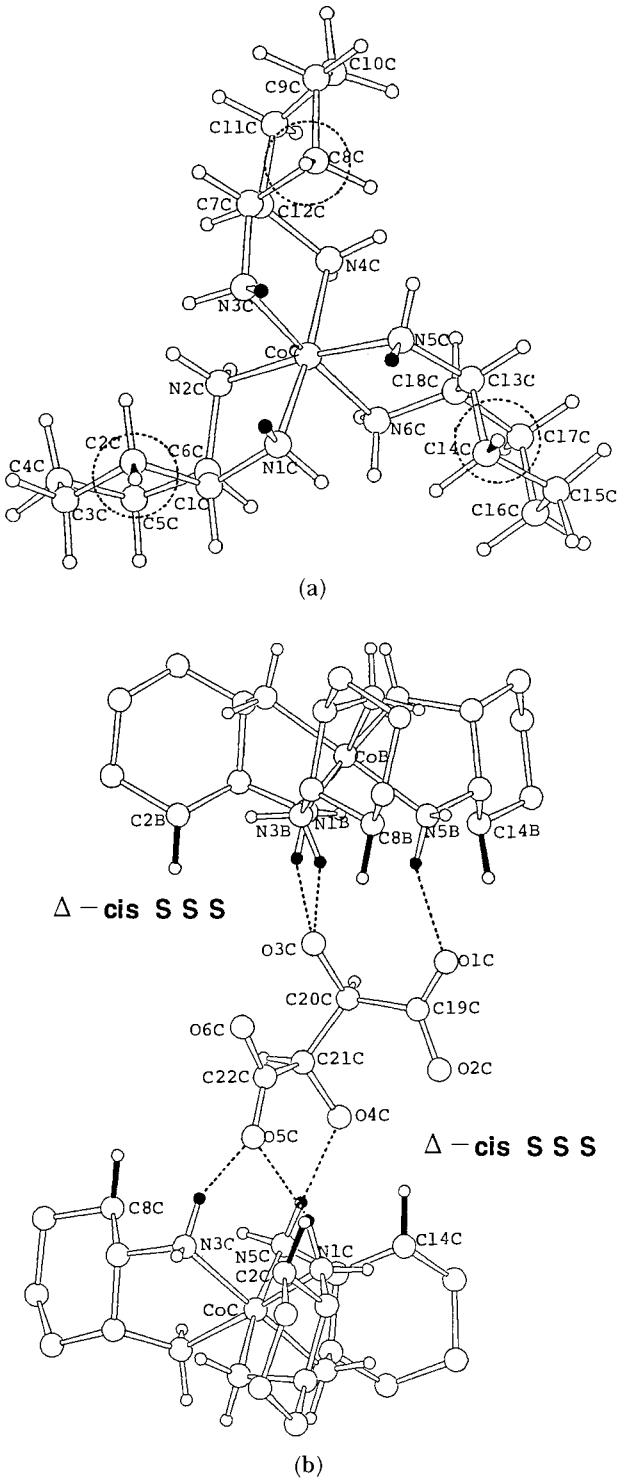

Fig. 4. The structure of the triangular *Δ-cis* SSS face (a) and the contact mode of d-tart^{2-} ion with the face (b). Most of the C-H protons are eliminated for clarity in (b).

disposed so closely to the N-H protons that any of them necessarily serves as an obstacle to the d-tart^{2-} ion when it makes a face-to-face contact with the face. The contact mode of the *Δ-cis* SSS face actually found in **1** is shown in Fig. 4b where the d-tart^{2-} anion is sandwiched between the two *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ complex cations, and only two O atoms, one carboxylic and one alcoholic, of the d-tart^{2-} ion are involved in the hydrogen bonding to the respective *Δ-cis* SSS face. Thus, the *Δ-cis* SSS face does not serve as an interaction site for the face-to-face contact, as supposed in Fig. 4a.

Since the *Λ-cis* RRR face enantiomeric to the *Δ-cis* SSS face depicted in Fig. 4a, is naturally crowded, it follows that the *Λ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ complex has practically only one favorable triangular face available for the face-to-face contact, i.e., the *Λ-cis* SSS face similar in structure to the favorable *Λ-trans* SSS face of the *Λ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complex.

It is additionally noteworthy in Fig. 4b that the d-tart^{2-} ion sandwiched between the two *Δ-cis* SSS faces assumes a conformation appreciably different from a usual one; the torsion angle ϕ of the $^{-}$OOC-C-C-COO^{-} group is 81.5°, whereas it is around 180°, i.e., the two COO^{-} groups are trans to each other, in a usual conformer. To demonstrate how the observed angle of 81.5° is surprisingly unusual, the distribution of the torsion angle ϕ is shown in Fig. 5 for d-tart^{2-} and d-tartH^{-} ions in their simple salts[14] and diastereomeric salts with tris(diamine)-metal complexes.[3,15,16] The conformer found here is probably the first example in which the two COO^{-} groups are in gauche positions.

Contact Modes in 2. In Fig. 6 is shown a face-to-face contact mode found in **2**, where the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ takes a *lel*$_3$ conformation and the d-tart^{2-} ion, a usual one as in **1**, and the triangular face used is naturally the *Δ-cis* RRR face. It is evident that the contact mode bears a close resemblance to the ideal one found in the *Δ-lel*$_3$-[Co(en)$_3$]$^{3+}$ salt;[3,12] the three O atoms of the d-tart^{2-} ion are each placed almost midway between two of the three N-H protons on the triangular face and are involved in the three bifurcated hydrogen bonds to them. The hydrogen bonds pertinent to the present face-to-face contact mode found in **2** are summarized also in Table 4.

A glance of Fig. 6a might lead us to suppose that the distal carboxylate group closely approaches one of the chxn ligands to suffer a severe steric repulsion from the C-H proton marked with a broken circle. However, if the contact mode is viewed normal to the C$_3$ axis (Fig. 6b), it is confirmed that the d-tart^{2-} ion avoids the repulsion by inclining the plane consisting of the three O atoms a little relative to the "less-favorable" *Δ-cis* RRR face of the complex. As a result, the nearest O2 atom of the distal carboxylate group is placed ca. 2.49 Å apart from the C-H proton to avoid the repulsion marginally, and some of the multiple hydrogen bonds are obliged to be somewhat longer[17] than the corresponding hydrogen bonds formed in the *Δ-lel*$_3$-[Co(en)$_3$]$^{3+}$ salt (Table 4). For example, the O3··H-N4 bond distance is 2.61 Å in Fig. 6, while the corresponding distance is 2.26 Å in the *Δ-*

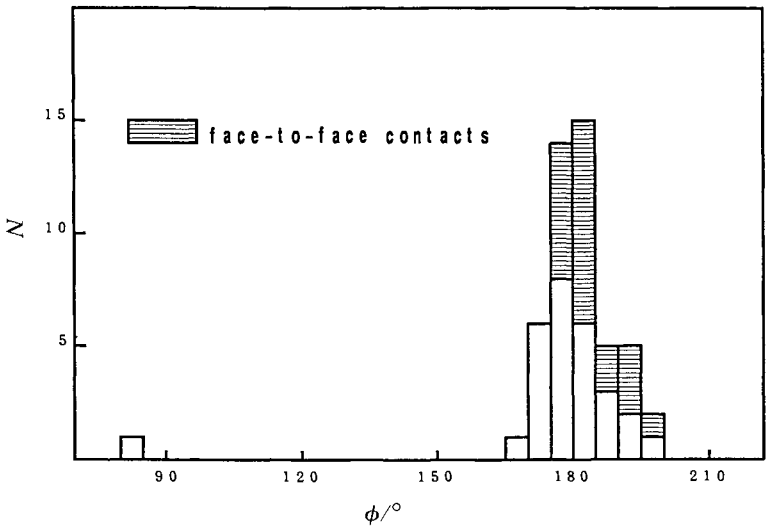

Fig. 5. The distribution of the $^{-}$OOC-C-C-COO^{-} torsion angle (ϕ) in some salts of d-tart^{2-} and d-tartH^{-} ions.

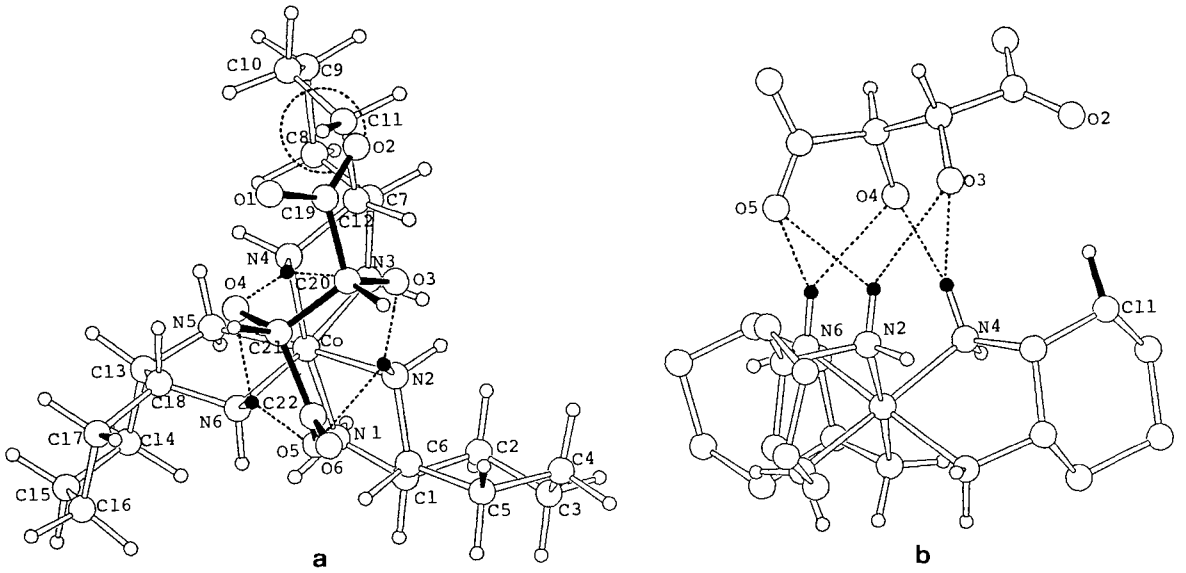

Fig. 6. The face-to-face contact mode of d-tart^{2-} ion with the triangular *Δ-cis* RRR face found in **2** as viewed down (a) and normal to (b) the C_3 axis. Most of the C-H protons are eliminated for clarity in (b).

lel$_3$-[Co(en)$_3$]$^{3+}$ salt.[12] Instead, the distal carboxylate group is in a position to form multiple hydrogen bonds to the triangular *Δ-cis* SSS face of another neighboring complex cation in the *Δ-fac*-[Co(*cis*-chxn)$_3$]Cl(d-tart)·nH$_2$O (**2**) (vide infra).

The other triangular face of the *Δ* complex denoted as the *Δ-cis* SSS face is so crowded as mentioned in Fig. 4a, that it may accommodate only two O atoms of the d-tart^{2-} ion coming to the face in **2**. The contact mode of the *Δ-cis* SSS face actually found in **2** is shown in Fig. 7, where the two O atoms (O1 and O2) of the distal carboxylate group are hydrogen-bonded to the face, as expected, and the remaining three O atoms (O3, O4, and O5) are involved in the face-to-face contact with the "less-favorable" *Δ-cis* RRR face of another neighboring *Δ* complex.[18] Thus, this *Δ-cis* SSS face is again proved to be of no use for the face-to-face contact, probably in solution as well.

We assume here that the face-to-face contact mode found in **2** and shown in Fig. 6 is the one in which the d-tart^{2-} ion avoids the steric repulsion tactfully at the least expense of the multiple hydrogen bonds to the "less-favorable" *Δ-cis* RRR face without any disadvantageous conformational change, and that it is the most probable interaction mode conceivable in solution where another neighboring complex is absent to assist the conformational change. In addition, this contact mode will be adopted in solution by the *Δ-lel*$_3$-

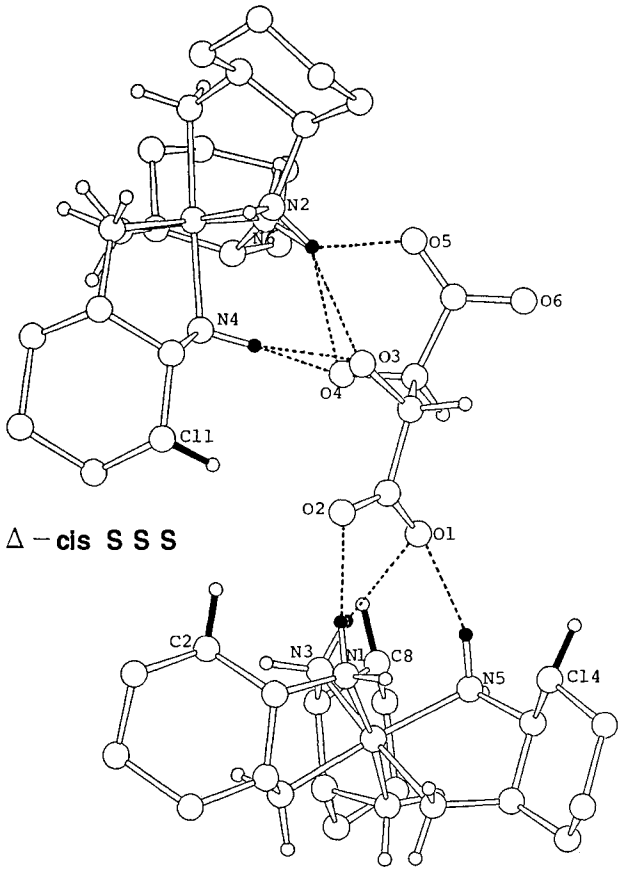

Fig. 7. The contact mode of d-tart^{2-} ion with the triangular *Δ-cis* SSS face found in **2**. Most of the C–H protons are eliminated for clarity.

[Co(*trans*-chxn)$_3$]$^{3+}$ complex as well, since the complex has two "less-favorable" *Δ-trans* RRR faces similar to the *Δ-cis* RRR face. These assumptions are indirectly supported by the results of the chromatographic separation of some related complexes, which will be described in the next section. It goes without saying that the *Δ-cis* SSS and *Λ-cis* RRR faces are neglected in counting the interaction sites available for the face-to-face contact with d-tart^{2-} ion even in solution, because these faces are heavily crowded as seen in Fig. 4a.

Elution Order in Chromatography. The chromatographic separation was carried out for some [Co(chxn)$_3$]$^{3+}$ complexes on an SP-Sephadex ion-exchange column with aqueous sodium d-tartrate (0.2 mol dm^{-3}) as an eluent. The elution order obtained is *Λ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ ≫ *Λ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ ≫ *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ > *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ > *Λ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ ≫ *Δ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$, and the conventional separation factor[3] for an enantiomeric pair is 1.57 for *lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$, 1.37 for *fac*-[Co(*cis*-chxn)$_3$]$^{3+}$, and 1.39 for *ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ (cf. 1.18 for [Co(en)$_3$]$^{3+}$ and 1.33 for *mer*-[Co(*cis*-chxn)$_3$]$^{3+}$). No practical separation of these complexes was attained with aqueous sodium chloride as an eluent, the [Co(*cis*-chxn)$_3$]$^{3+}$ complexes coming out slightly late.

It is notable that the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ is eluted faster than the *Λ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$, though the latter complex has two triangular faces available for the three linear hydrogen bonds with d-tart^{2-} ion.[11] If the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ should adopt in solution the contact mode shown in Fig. 2 or 3 where only three linear hydrogen bonds are formed, the *Λ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ should be eluted faster. Therefore, the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ as well as the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ adopts in solution preferentially the contact mode shown in Fig. 6 where six hydrogen bonds, though some are somewhat long,[17] are formed.

Finally, the elution order and separation factors obtained are interpreted. First of all, the *Λ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ has two equivalent triangular faces (*Λ-trans* SSS) which allow a smooth access of d-tart^{2-} ion along the C_3 axis, and thus it should be eluted the fastest. The *Λ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ has one such favorable face (*Λ-cis* SSS) and is eluted the second. Though no such favorable face is present in either the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ or the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$, the former has two "less-favorable" faces (*Δ-trans* RRR) to which the d-tart^{2-} ion forms six but somewhat long hydrogen bonds and the latter has one such face (*Δ-cis* RRR). Consequently, they should be eluted the next in this order. The fact that the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ is eluted faster than the *Λ-ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ which has two equivalent triangular faces available for the three linear hydrogen bonds with d-tart^{2-} ion, suggests that d-tart^{2-} ion interacts more strongly with these tris(diamine)cobalt(III) complexes when more hydrogen bonds are formed to them rather than when fewer but more linear hydrogen bonds are formed.[11,19,20] In this way, the elution order obtained is readily interpreted in terms of the number of available interaction sites counted above and the number of hydrogen bonds formed there, consistent with the proposals offered by Searle[21] and Sakakibara et al.[22] Consequently, it is concluded that the face-to-face contact mode found in **2** and shown in Fig. 6 but not in Fig. 2 or 3 is the one which is adopted in solution by both *Δ*-[Co(*trans*-chxn)$_3$]$^{3+}$ and *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ complexes; the "less-favorable" *Δ-trans* RRR or *Δ-cis* RRR face is preferentially utilized for the association with the d-tart^{2-} ion.

Since the magnitude of the separation factor has been already discussed for the *lel*$_3$ and *ob*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ complexes,[3] it needs to examine only for the *fac*-[Co(*cis*-chxn)$_3$]$^{3+}$. The conventional separation factor estimated for this complex is 1.37, which is considerably lower than 1.57 estimated for the *lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$. This is apparently because the *Λ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ has one favorable *Λ-cis* SSS face and one useless *Λ-cis* RRR faces but the enantio-

mer has one "less-favorable" *Δ-cis* RRR and one useless *Δ-cis* SSS faces, whereas the *Λ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ has as many as two favorable *Λ-trans* SSS faces but the enantiomer has two "less-favorable" *Δ-trans* RRR faces only. That is, the *Δ-lel*$_3$-[Co(*trans*-chxn)$_3$]$^{3+}$ is more handicapped with respect to the number of the available interaction sites than the *Δ-fac*-[Co(*cis*-chxn)$_3$]$^{3+}$ is, relative to the respective enantiomer.

(Received November 13, 1990)

The redox behavior of the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ couple was examined not only in a CH_2Cl_2 solution of a CH_2Cl_2/H_2O two phase system but also in the absence and presence of Triton X-100 in H_2O to elucidate the solvent effect of water on the redox potential of the cluster. Protonation of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$ takes place in those media, and protonated and unprotonated clusters exist as an equilibrium mixture. Although the redox potential of the cluster is hardly affected by the pK_a value, it is largely influenced by a thickness of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ adsorbed on a surface of an electrode in water. The $E_{1/2}$ value of the cluster in a near monomolecular layer on the electrode exhibits a pronounced anodic shift compared with that in CH_2Cl_2 and falls in the range of that of 4Fe- and 8Fe-ferredoxins. On the other hand, the cluster in the multimolecular layer does not show such an anodic shift of the $E_{1/2}$ value in water.

A variety of Fe_4S_4 clusters have been prepared[1] as a model of the active center of iron-sulfur proteins, which play key roles as electron-transfer catalysts in various biological redox reactions such as photosynthesis,[2] N_2-fixation,[3] NO_3^- reduction.[4] The redox potentials of synthetic Fe_4S_4 clusters in organic solvents obey the Hammet σ_p and Taft σ^* values of terminal thiolate ligands.[5] Water, however, gives a serious effect on the redox potentials of the clusters, since water soluble Fe_4S_4 clusters in the presence of excess of free thiolate ligands (due to an instability of water soluble Fe_4S_4 clusters in water) show a positive potential shift of the redox potentials by 250—400 mV in water compared with those in organic solvents.[6] A positive potential shift of $E_{1/2}$ (60—120 mV) of *Clostridium pasteurianum* ferredoxin in H_2O containing of 0—40 vol% Me_2SO_4, where the protein adopts its normal tertiary structure, compared with a synthetic Fe_4S_4 cluster ligated with cysteine in the same medium, therefore, has been ascribed to the tertiary structure of proteins.[6] We have reported that synthetic Fe_4S_4 clusters are protected from hydrolysis in aqueous lecithin vesicle[7] and micellar solutions,[8] and the redox potentials of the clusters in those media are essentially consistent with those of 4Fe- and 8Fe-ferredoxins. The redox potentials of synthetic Fe_4S_4 clusters as well as ferredoxins, therefore, are considered to be largely influenced by hydrophobic spheres in water. To elucidate the effect of hydrophobic spheres on the redox potential of a Fe_4S_4 cluster in water, the redox behavior of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ was examined not only in a CH_2Cl_2 solution of a CH_2Cl_2/H_2O two phase system but also in the absence and presence of Triton X-100 micellar solution using a glassy carbon and an Hg electrode.

Experimental

General Procedure and Materials. All manipulations were carried out under N_2 atmosphere. Commercially available guaranteed reagent grade of *p*- *t*-butylbenezenethiol was used without further purification. $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ was prepared according to the literature.[9]

Cyclic Voltammetry of the Cluster in a CH_2Cl_2/H_2O Two Phase System. An aqueous H_3PO_4-NaOH buffer (0.1 mol dm^{-3}, 20 cm^3) solution containing Bu_4NBr (1.8 mmol) was poured in a CH_2Cl_2 solution (20 cm^3) containing $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ (20 mg, 12 μmol) and Bu_4NBr (0.6 g, 1.8 mmol), and the mixture was stirred by bubbling N_2 for several minutes. Then, the cell was allowed to stand until the CH_2Cl_2 and H_2O phases were completely separated. The pH of the H_2O phase was adjusted by addition of a small amount of either aqueous NaOH or H_3PO_4 solution (0.1 mol dm^{-3}) to the H_2O phase, followed by stirring the mixture by the same method, and measured with a Toa Electronics pH meter HM-7B. The cyclic voltammograms of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ dissolved in the CH_2Cl_2 phase and adsorbed on a surface of Hg were obtained by using a Yanaco glassy carbon disk electrode GC-2p and Metrohm hanging mercury drop electrode, respectively. When the HMDE was used as a working electrode, voltage scan was started after the surface of a mercury drop (0.0187 cm^2) had been exposed to the aqueous phase. The working electrode, a Pt auxiliary electrode, and a luggin capillary of a reference electrode were immersed into the same phase either a CH_2Cl_2 or H_2O phase.

Solubilization of the Cluster in an Aqueous Triton X-100 Micellar Solution. A DMF (1.0 cm^3) solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ (12 μmol) was added to a stirred aqueous solution (25 cm^3, pH 6—10) containing NaOH-H_3PO_4 (0.1 mol dm^{-3}) and Triton X-100 (0.05 mol dm^{-3}).

Preparation of a Cluster Modified Glassy Carbon and Hg Amalgamated Au Plate Electrode. A given amount of a CH_3CN solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ (1.0 mmol dm^{-3}) was dropped to the surface of a glassy carbon[10] or an Hg amalgamated Au plate (1.0 cm^3) by syringe techniques, and then dried under N_2 atmosphere.

Results and Discussion

Redox Behavior of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ in CH_2Cl_2/H_2O Two Phase System. The cyclic voltammogram (CV) of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ using a glassy carbon disk electrode (GC) shows a cathodic

and an anodic wave of the (2−/3−) redox couple at E_{pc}=−1.03 and E_{pa}=−0.90 V vs. SCE at a sweep rate 10 mV s^{-1} in dry CH_2Cl_2. Those redox waves are also observed at E_{pc}=−0.97 and E_{pa}=−0.89 V in a CH_2Cl_2 solution of a CH_2Cl_2/H_2O (pH=10.06) two phase system (Fig. 1a). Thus, H_2O in the CH_2Cl_2 phase causes a slight potential shift of the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ redox couple. The peak currents of those redox waves in the wet CH_2Cl_2 phase were proportional to one-half order with respect to the sweep rate in the range of 10—300 mV s^{-1}. In addition, the electronic absorption spectrum of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ in wet CH_2Cl_2 did not show an appreciable change for 4 h. These results indicate that $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ stably exists in wet CH_2Cl_2 and undergoes a redox reaction in that medium. The redox potentials of Fe_4S_4 clusters solubilized in aqueous micellar solutions have been shown to be largely controlled by proton concentrations in bulk water.[8] The proton concentration in the CH_2Cl_2 phase of the CH_2Cl_2/H_2O system may also be equilibriated with that in the H_2O phase, as similar to the equilibrium between hydrophobic spheres of micelles and bulk water. Figure 2 shows the $E_{1/2}$ value ($E_{1/2}=(E_{pa}+E_{pc})/2$) of the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ couple in the CH_2Cl_2 solution of the CH_2Cl_2/H_2O system at a sweep rate 10 mV s^{-1} at various pH of the H_2O phase. The $E_{1/2}$ value of the cluster in the CH_2Cl_2 solution is independent on pH of the H_2O phase in the pH range higher than 7.0, while shifted by −60 mV pH^{-1} in the pH lower than 7.0. This result clearly indicates that one proton participates in the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ redox reaction[7,8] in the CH_2Cl_2 solution when pH of the H_2O phase is lower than 7.0, and protonated and unprotonated $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$ exist as an equilibrium mixture. The break point at pH 7.0 in the plot of $E_{1/2}$ vs. pH (○ in Fig. 2), therefore, may be associated with an apparent proton dissociation constant (pK_a') of protonated $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$. Despite a significant difference in the proton concentrations between the CH_2Cl_2 and H_2O phases of the CH_2Cl_2/H_2O system, the present pK_a'=7.0 still falls in the pK_a range of iron-sulfur proteins reported so far (pK_a=6.8—8.9).[11]

An Hg electrode has been used for the measurement of the redox potential of iron-sulfur proteins by taking advantage of a strong affinity of sulfur for Hg.[12] Otherwise, a direct electron transfer between the Fe_4S_4 cores and an electrode is strongly inhibited by an adsorption of polypeptide chains on the electrode. The CV of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ in the CH_2Cl_2 solution of the CH_2Cl_2/H_2O system using a hanging mercury drop electrode (HMDE) exhibited a very strong cathodic current of the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ redox couple maybe due to a strong adsorption of the cluster on the surface of the HMDE, and the anodic and cathodic peak potentials of the redox couple were not determined correctly. To decrease the amount of the cluster adsorbed on the Hg surface, the HMDE was drawn up to the H_2O phase from the CH_2Cl_2 solution of $(Bu_4N)_2[Fe_4S_4$-

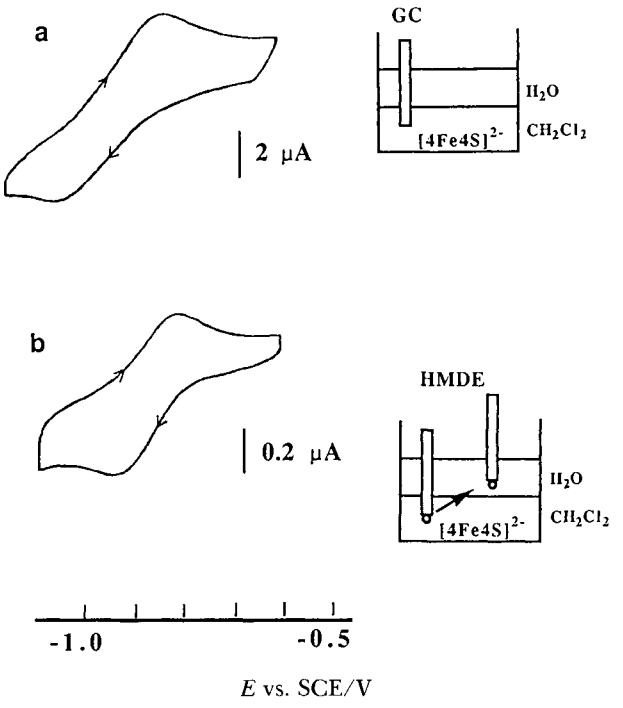

Fig. 1. Cyclic voltammograms of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ using a glassy carbon electrode in a CH_2Cl_2 solution (a) and an HMDE in an H_2O phase (b) of the CH_2Cl_2/H_2O (pH 10.06) system; sweep rate 10 mV s^{-1}.

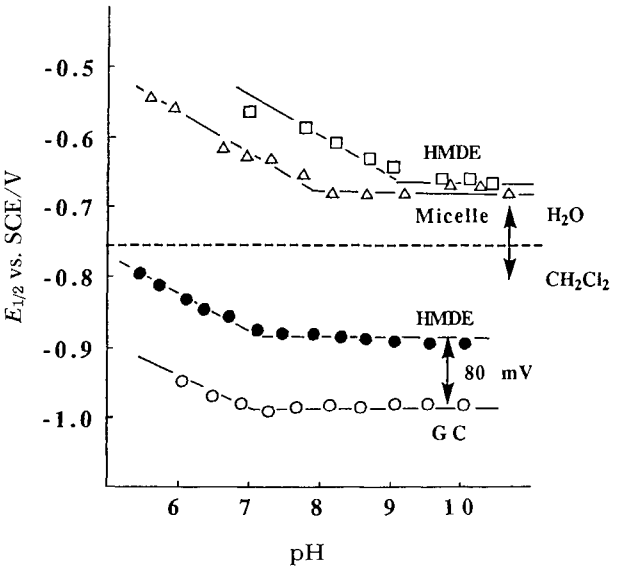

Fig. 2. $E_{1/2}$ values of the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ redox couple in the CH_2Cl_2 solution of the CH_2Cl_2/H_2O system using GC (○) and HMDE (●), and in the absence (□) and presence of Triton X-100 (△) using HMDE.

$(SC_6H_4Bu^t(p\text{-}))_4]$ after dipping the top end of the electrode in the CH_2Cl_2 phase for less than one minute. Even after this procedure, the surface of the HMDE placed in the H_2O phase was covered with a drop of the CH_2Cl_2 solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$. The CV of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ in the CH_2Cl_2 drop in H_2O (pH=10.06) is depicted in Fig. 1b, which shows the (2−/3−) redox couple at E_{pc}=−0.93 and E_{pa}=−0.82 V at a sweep rate 10 mV s^{-1} (Fig. 1b). The $E_{1/2}$ value of the cluster in the CH_2Cl_2 drop on the HMDE against pH are also plotted in Fig. 2 (●). The $E_{1/2}$ value of the cluster in the CH_2Cl_2 drop on the HMDE in the H_2O phase is shifted to a positive potential by 80 mV compared with that determined by a GC electrode in the CH_2Cl_2 phase (○ and ● in Fig. 2). The 80 mV difference in two lines may result from an adsorption of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ on an Hg electrode, since an $E_{1/2}$ value of a synthetic Fe_4S_4 cluster undergoes a positive potential shift by 80 mV due to an adsorption on a surface of an Hg electrode.[7] Taking account of the adsorption energy of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ on Hg, the redox potential of the cluster in the CH_2Cl_2 drop in the H_2O phase may be essentially unchanged that in wet CH_2Cl_2. Furthermore, an agreement of the break points (pK_a') of the plots of pH vs. $E_{1/2}$ in the CH_2Cl_2 drop on the HMDE with that in the CH_2Cl_2 phase (○ and ● in Fig. 2) indicates that the proton concentration in the bulk CH_2Cl_2 phase is maintained in the CH_2Cl_2 drop on the HMDE in the H_2O phase.

Redox Reaction in Aqueous Phases. As described above, one proton participates in the $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-/3-}$ redox reaction in the CH_2Cl_2 solution of the CH_2Cl_2/H_2O system, and protonated and unprotonated $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$ exists as an equilibrium mixture. Comparison of the pK_a value of the protonated $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$ in wet CH_2Cl_2 with that in an aqueous micellar solution may afford an information about the solvent effect of water on the redox potential of the cluster. As an adsorption of the surfactant on a GC electrode[13] inhibited the electron transfer to $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ in an aqueous Triton X-100 micellar solution, the CV of the aqueous micellar solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ was obtained by using HMDE, as depicted in Fig. 3a. Two cathodic waves (E_{pc}=−0.84 and −0.69 V) and one anodic wave (E_{pa}=−0.64 V) were observed at pH 10.20 in the initial scan. The strong cathodic waves compared with the anodic one are indicative of the stronger adsorption of the (2−) state of the cluster on a surface of an Hg electrode than the (3−) one.[7,8] In the following sweep, the −0.84 V cathodic wave almost disappears, while the −0.69 V cathodic wave remains at the same potential with decreasing the peak current. In the micellar solution, the coulombs consumed in the cathodic wave are proportional to the number of the clusters adsorbed on the Hg electrode, since only the

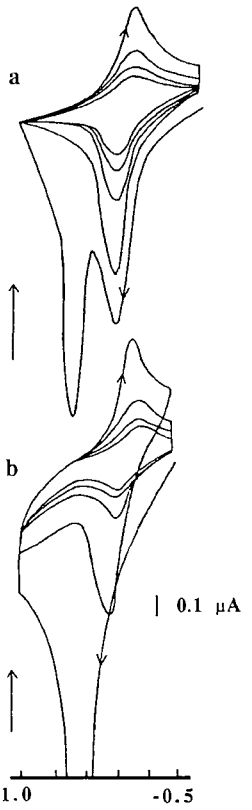

Fig. 3. Multi-sweep cyclic voltammograms of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ in an aqueous Triton X-100 micellar solution at pH 10.20 (a), and of [4Fe4S]/HMDE in H_2O at pH 10.00 (b); sweep rate 10 mV s^{-1}.

cluster adsorbed on the Hg electrode undergoes the one-electron redox reaction. Although the exact area of the −0.83 V cathodic wave in the initial scan could not be determined due to overlap with the −0.69 V cathodic wave, the surface concentration of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ on the HMDE in the second potential sweep could be evaluated from the area of the −0.69 V cathodic wave. On the basis of the surface area of the HMDE (0.0187 cm^2), the surface concentration of the cluster calculated from the wave was 2.9×10^{-10} mol cm^{-2}. This value is somewhat larger than the surface concentration of the monomolecular layer of $[Fe_4S_4(SC_6H_4C_8H_{17}{}^n(p\text{-}))_4]^{2-}$ adsorbed on an Hg electrode (1.6×10^{-10} mol cm^{-2}).[7] The strong −0.83 V cathodic wave observed only in the initial scan, therefore, may be assigned to the redox couple resulting from a multimolecular adsorption of the cluster on the HMDE. The disappearance of the −0.83 V cathodic wave in the second sweep, therefore, may be caused by desorption of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$ due to not only a stronger coulomb repulsion of the neighboring (3−) state of the clusters but also a migration of the counter ion into the multimolecular layer of the cluster formed on a fluid Hg surface to

maintain the charge neutrality (vide infra). The $E_{1/2}$ value of the cluster adsorbed on the HMDE in aqueous Triton X-100 micellar solutions, therefore, was employed after both E_{pc} and E_{pa} values become constant in the multiscanning CV (usually the third or fourth sweep). The plot of $E_{1/2}$ of the cluster vs. pH of the aqueous micellar solution (△ in Fig. 2) also clearly shows the break point at pH 7.8 due to the pK_a of the protonated $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{3-}$. The shift of the p$K_a$ 7.8 in the micellar solution from 7.0 in wet CH_2Cl_2 suggests that protonation of the cluster in the former takes place more easily than in the latter. It is also worthy to note that the $E_{1/2}$ value in the aqueous micellar solution is shifted to positive potentials about by 200 mV compared with that in the CH_2Cl_2 solution, and falls in the range of the redox potentials of 4Fe- and 8Fe-ferredoxins (−0.52 to −0.73 V vs. SCE around pH 7.0).[6]

The redox behavior of the cluster on the HMDE was measured in the absence of Triton X-100 to elucidate the effects of hydrophobic spheres of micelles on the redox potential of the cluster in H_2O. The present cluster is not soluble in H_2O. A cluster modified HMDE ([4Fe4S]/HMDE), therefore, was prepared by dipping the HMDE in a dry CH_2Cl_2 solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ (0.40 mmol dm^{-3}) for less than one minute, followed by drying under N_2 stream. The [4Fe4S]/HMDE displays a very strong cathodic wave at E_{pc}=−0.83 V and an anodic wave at E_{pc}=−0.64 V in the initial scan in H_2O at pH 10.00 (Fig. 3b). As similar to the aqueous micellar solution, the −0.83 V cathodic wave disappears in the second scan, and a new cathodic wave is observed at −0.70 V with the surface concentration of 2.6×10^{-10} mol cm^{-2}. Thus, the very strong −0.83 V cathodic wave in the first scan is assigned to the multimolecular adsorption of the cluster on the Hg electrode. After the second potential sweep, the −0.70 V cathodic wave was slightly shifted to positive potentials with decreasing the peak current, and finally the constant value $E_{1/2}$=−0.65 V (E_{pc}=−0.66 V and E_{pa}=−0.63 V) was obtained. This result also indicates that the peak potential of the (2−/3−) redox couple is dependent on the thickness of the cluster adsorbed on the electrode (or the amount of the cluster adsorbed) and becomes a constant value when the thickness of the adsorbed cluster approaches to a monomolecular layer. The plot of the $E_{1/2}$ obtained after the constant value in H_2O against pH shows the pK_a 8.9, as depicted in Fig. 2 (□). Despite the difference in the pK_a of the cluster in the absence (8.9) and presence of the surfactant (7.8) in H_2O, the $E_{1/2}$ values at higher pH than their pK_a values are essentially consistent with each other (□ and △ in Fig. 2). This result indicates that hydrophobic spheres of micelles hardly affect the redox potential of the Fe_4S_4 cluster on an Hg electrode in H_2O.

Redox Reaction in Multi-Adsorption Layer in H_2O. We have reported that a $(Bu_4N)_3[Mo_2Fe_6S_8(SPh)_9]$ modified glassy carbon plate stably undergoes a redox reaction without desorption from the GG plate in water.[10] In accordance with this, the $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ (1×10^{-8}mol) modified GC plate ([4Fe4S]/GC, 1.0 cm^2) also shows a cathodic and anodic wave at E_{pc}=−1.14 and E_{pa}=−0.87 V in water at pH 10.04 (Fig. 4a). A strong cathodic current at potentials more negative than −1.2 V comes from H_2 evolution catalyzed by the reduced cluster,[10,14] and the pattern was unchanged in the multi-sweep CV for 30 min.[15] Although the peak separation between the cathodic and anodic waves of the [4Fe4S]/GC is fairly large compared with that of the [4Fe4S]/HMDE,[16] the $E_{1/2}$ value (−1.02 V vs. SCE) of the [4Fe4S]/GC at pH 10.04 is close to that in a dry CH_2Cl_2 solution obtained by a GC disk electrode rather than that of [4Fe4S]/HMDE in H_2O. Thus, the redox potential of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ aggregated on the GC plate[17] does not undergo a positive potential shift by water. This is quite contrast to the $E_{1/2}$ value of the monomolecular layer of the [4Fe4S]/HMDE in water at pH 10.0 (□ in Fig. 2). To compare the redox behavior of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ modified GC plate with an Hg electrode in H_2O, a cluster modified Hg amalgamated Au plate electrode ([4Fe4S]/HgAu) was prepared by addition of CH_3CN solution of $(Bu_4N)_2[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]$ on the surface of an Hg amalgamated Au plate (1×10^{-8} mol, 1.0 cm^2),[17] followed by drying under N_2 atmosphere. The [4Fe4S]/HgAu exhibits a cathodic and an anodic waves at

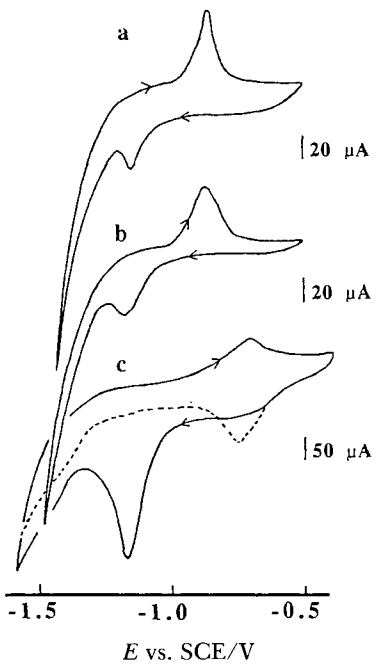

Fig. 4. Cyclic voltammograms of [4Fe4S]/GC at 10 mV s^{-1} (a) in H_2O (pH 10.04), and [4Fe4S]/HgAu at 10 mV s^{-1} (b) and 100 mV s^{-1} (c) in H_2O (pH 10.06); a dotted line is the second potential sweep.

E_{pc}=−1.16 and E_{pa}=−0.87 V at the sweep rate 10 mV s^{-1} in H_2O at pH 10.06 (Fig. 4b). The amounts of the cluster calculated from the areas of the −1.16 V cathodic and the −0.87 anodic waves were 2.9×10^{-9} and 5.6×10^{-9} mol, respectively. The decrease in the coulombs consumed in the cathodic wave compared with that in the anodic one may be due to subsequent H_2 evolution catalyzed by the reduced cluster. Despite the disagreement of the peak currents of those waves, the peak potentials are almost completely consistent with those of the [4Fe4S]/GC at the same pH. On the other hand, the CV of the [4Fe4S]/HgAu affords a quite different pattern, when the sweep rate is increased to 100 mV s^{-1}; a strong cathodic wave and an anodic one are observed at E_{pc}=−1.16 and E_{pa}=−0.70 V in the initial potential sweep (a solid line in Fig. 4c). In the following potential sweep, the −1.16 V cathodic wave completely disappears, and a new cathodic wave appears at −0.76 V (a dotted line in Fig. 4c). It should be noticed that the redox waves at E_{pc}=−0.76 V and the E_{pa}=−0.70 V, which are observed in the second sweep, are close to those of the monomolecular layer of [4Fe4S]/HMDE. The marked difference in the CV of the voltage scanning at 10 and 100 mV s^{-1} may be explained by desorption of the cluster from the multimolecular layer on the surface of HgAu plate; the charge neutrality of the multimolecular layer of the cluster on the HgAu plate is maintained by the transport of the counter ion into and out of the contacting aqueous phase, so that a rapid transport of counter ion into the multimolecular layer of the cluster accelerates the detachment of the cluster from the layer to form a near monomolecular layer on the HgAu electrode. In accordance with this assumption that the amounts of the cluster on the HgAu plate[18] were determined as 5.6×10^{-9} and 5.4×10^{-10} mol from the areas of the −0.87 anodic wave of Fig. 4b (10 mV s^{-1}) and the −0.70 V one of Fig. 4c (100 mV s^{-1}), respectively.

The $E_{1/2}$ value of the near monomolecular layer of [4Fe4S]/HMDE and [4Fe4S]/HgAu is shifted to positive potentials in water, while that of the multimolecular layer of [4Fe4S]/HgAu and [4Fe4S]/GC in water is very close to the value in CH_2Cl_2. Thus, the influence of water on the redox potential of the Fe_4S_4 cluster in the multi- and monomolecular layer is quite different from each other. As similar to the monomolecular layer in H_2O, the redox potential of the cluster contacting with the H_2O phase (near the surface of the multimolecular layer) would undergo a pronounced solvent effect by water. On the other hand, a hydrophobicity of the terminal ligand $SC_6H_4Bu^t(p\text{-})$ of the Fe_4S_4 cluster may depress penetration of bulk water into the multimolecular layer, so that the redox potential of the cluster contacting electrode (at the bottom of the multimolecular layer) may be isolated from bulk water. This assumption suggests that the redox potential of the cluster in the multimolecular layer is largely dependent on the distance from the aqueous phase. The redox reaction of the cluster in the multimolecular layer may be caused by an electron self-exchange between neighboring oxidized and reduced clusters. In addition, the electron transfer between the electrode and the cluster takes place only in the first layer of the adsorption layer (contacted with the electrode), and then the electron is transferred successively to the surface of the multimolecular layer (Fig. 5a). Accordingly, the electrode can detect only the redox potential of the cluster contacted with the electrode. In harmony with this, a multisweep CV of the cluster of the multimolecular adsorption on Hg electrodes displays a positive potential shift of the $E_{1/2}$ value with decreasing the peak current by gradual desorption of the cluster, and reaches a constant value at the near monomolecular layer (Fig. 5b). The fact that the $E_{1/2}$ value of the multimolecular layer of the [4Fe4S]/GC and [4Fe4S]/HgAu in H_2O is close to that in a CH_2Cl_2 solution suggests that the effect of the aggregate of the cluster on the redox potential is essentially same as that of an organic solvent. It is, therefore, concluded that hydrophobic spheres around the Fe_4S_4 core in water do not cause an anodic shift of the redox potential of the cluster.

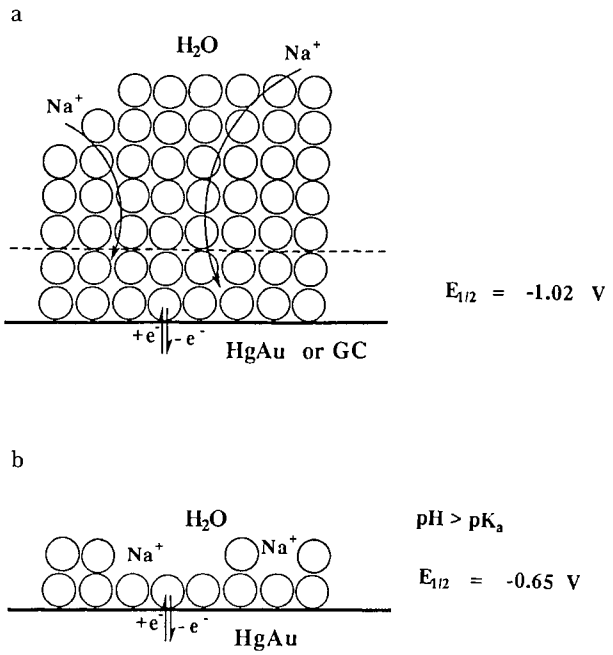

Fig. 5. Redox of Fe_4S_4 cluster in a multimolecular (a) and near monomolecular layer (b) on an HgAu electrode.

15) The fast desorption of $[Fe_4S_4(SC_6H_4Bu^t(p\text{-}))_4]^{2-}$ from the multimolecular layer on the [4Fe4S]/HMDE compared with that from the [4Fe4S]/GC may be due to a fluidity of the surface of an Hg. On the other hand, a strong affinity of sulfur for Hg stabilizes the monomolecular layer on the Hg electrode.

16) Peak separation of an adsorbed species becomes an increase with decreasing the electron transfer of the electrode and the adsorbed species. The configurational change between oxidized and reduced cluster adsorbed on the GC plate may, therefore, be slower than that on an Hg electrode.

17) When the cluster in a CH_3CN solution was solidified on the GC and HgAu plate under N_2, the cluster is not homogeneously distributed over the surface of those electrode.

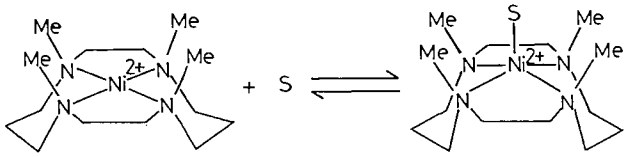
18) The surface of the HgAu plate is not as smooth as that of the HMDE. So, the surface area of the HgAu plate is considered to be fairly larger than 1.0 cm^2.

Solvation and Ionic Association of (1*R*,4*S*,8*R*,11*S*)-1,4,8,11-Tetramethyl-1,4,8,11-tetraazacyclotetradecanenickel(II) Perchlorate in Mixed Solvents of *N,N*-Dimethylformamide and *N,N*-Dimethylacetamide with Nitrobenzene and 1,2-Dichloroethane

Takashi YOKOYAMA, Etsuro IWAMOTO, and Takahiro KUMAMARU*
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730
(Received November 30, 1990)

The conductances of $[NiL]^{2+}$ ($[NiL]^{2+}$=(1*R*,4*S*,8*R*,11*S*)-1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecanenickel(II)) have been measured in *N,N*-dimethylformamide (DMF)-1,2-dichloroethane (DCE), and *N,N*-dimethylacetamide (DMA)-DCE, and iso-relative permittivity mixtures DMF-nitrobenzene (NB), DMA-NB, and DMF-DMA at 25 °C. The first ionic association constant of $[NiL]^{2+}$ with the perchlorate ion in the mixtures with NB decreases with increasing fraction of both DMF and DMA, although DMF is coordinated to $[NiL]^{2+}$ and DMA is not, this showing that DMA as well as DMF in NB selectively solvates the axial coordination site of $[NiL]^{2+}$ to change from contact ion pairs to solvent-separated ion pairs. Bulky and delocalized negative pole of NB of which the dipole moment is larger than that of DMF and DMA results in a weak ion-dipole interaction, leading to a larger degree of ionic association. Ionic association was discussed from the viewpoint of steric hindrance and ion-dipole interactions.

The title metal chelate ($[NiL]^{2+}$=(1*R*,4*S*,8*R*,11*S*)-1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecanenickel(II)) cation exists in solutions as an equilibrium mixture of a red, square species and a green, square-pyramidal species according to the reaction



Reaction (1)

where S is a basic solvent.[1-6] In our previous work,[7] it was found that although *N,N*-dimethylformamide (DMF), *N,N*-diethylformamide, formamide, and *N*-methylformamide were coordinated to $[NiL]^{2+}$, *N,N*-dimethylacetamide (DMA), *N,N*-dimethylpropionamide, and *N,N*-diethylacetamide were not coordinated to the square complex, in spite of these solvents having nearly the same basicity. This was explained by steric hindrance between -CO-Me of the DMA, and four -N-Me and methylene groups of L. This led us to inquire as to whether solvation effects of non-coordinating DMA molecules on ionic association of $[NiL]^{2+}$ is different from that of coordinating DMF. 1,2-Dichloroethane (DCE) of a low relative permittivity (10.36) and nitrobenzene (NB) which has nearly the same relative permittivity (34.82) as the amides were used as diluents.

Experimental

NB, DMF, and DMA were purified as described previously.[7] DCE (reagent grade, Wako Pure Chemical Industries Ltd.) was purified by fractional distillation under reduced pressure through a 1.2-m column and left into molecular sieves 4A for a week.

$[NiL](ClO_4)_2$, $[NiL(N_3)]ClO_4$, where N_3 is the azide ion, butyltriisopentylammonium tetraphenylborate (i-Pent)$_3$BuNBPh$_4$, and butyltriisopentylammonium perchlorate (i-Pent)$_3$BuNClO$_4$ were prepared by the published method.[1,8,9] The purities of all the complexes were confirmed by the elemental analysis.

The instrumentation and the procedure used for measurements of conductances, viscosities, relative permittivities,

and spectra were described previously.[7] The relative permittivities (ε), viscosities (η), and densities (d) of the solvent mixtures used for analyses were given in Tables 1 to 3. The specific conductances (S cm^{-1}) of the solvents are 2.2×10^{-8}—2.9×10^{-7} for NB-DMA mixtures, 2.1×10^{-8}—3.4×10^{-7} for NB-DMF, 1.8×10^{-7}—9.3×10^{-7} for DCE-DMA, 2.0×10^{-7}—9.2×10^{-7} for DCE-DMF, and 1.2×10^{-7}—4.0×10^{-7} for DMF-DMA. All solutions were prepared by weight. Densities were measured by using an Anton Paar model DMA 02D digital density meter at 25±0.002 °C.

Results and Discussion

Conductances for $[NiL](ClO_4)_2$ and $[NiL(N_3)]ClO_4$ were measured at seven to ten concentrations ranging from 1×10^{-4} to 4×10^{-3} mol dm^{-3} in each system. Typical molar conductances measured in the DMA-NB system which of nearly the same relative permittivity are shown in Fig. 1. To analyze conductance data for the 2-1 type of electrolyte the limiting molar conductance for ClO_4^- must be evaluated. In this work, $(i\text{-Pent})_3BuNBPh_4$ was used as a reference electrolyte (i.e. assuming $\lambda_0[(i\text{-Pent})_3BuN^+]=\lambda_0(BPh_4^-)$].[9] The conductances for $(i\text{-Pent})_3BuNBPh_4$ and $(i\text{-Pent})_3BuNClO_4$ in each mixture were measured at 25 °C and analyzed by the Fuoss-Hsia conductance equation for symmetrical electrolytes in the form[10,11]

$$\Lambda=\Lambda_0-S(C\gamma)^{1/2}+EC\gamma\log C\gamma+JC\gamma+J_2(C\gamma)^{3/2}-K_aC\gamma f^2$$

for associated electrolytes, where the coefficients S, E, J, and J_2 have the usual meanings[12] and the relative permittivity and viscosity of solvents were used to calculate these coefficients. The symbol γ is the fraction of solute present as unpaired ions,

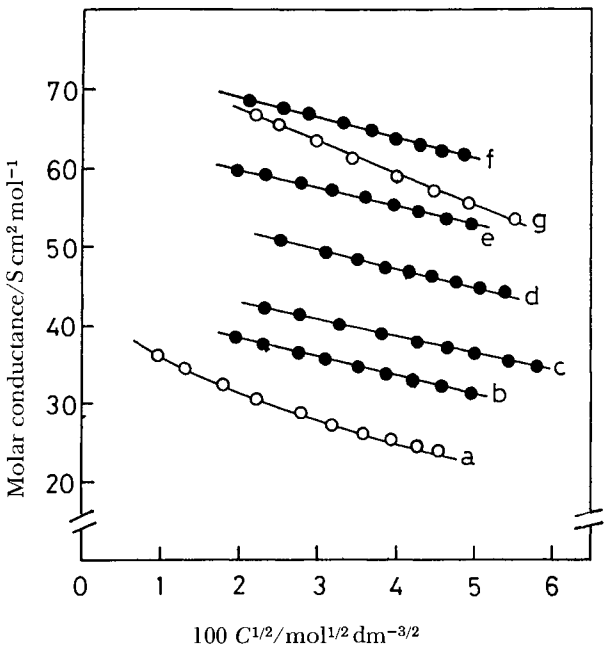

Fig. 1. Plots of molar conductivities of $1/2[NiL](ClO_4)_2$ against the square root of the concentration in DMA-NB mixtures at 25 °C. DMA fraction: a, 0.00; b, 0.14; c, 0.32; d, 0.59; e, 0.81; f, 0.93; g, 1.00.

Λ_0 and Λ are the limiting molar conductance and molar conductance, respectively, and f is the mean ionic activity coefficient on the molarity scale which was evaluated from molality by using the density of solutions. The equation is the form

$$\Lambda=\Lambda_0-SC^{1/2}+EC\log C+JC+J_2C^{3/2}$$

in the cases where association is negligible. For most of the systems the analyses yielded plots of σ against ion distance parameter a with double minimum where is the standard deviation of the individual N points calculated using the expression

$$\sigma=[\Sigma(\Lambda_{obs}-\Lambda_{calc})^2/(N-3)]^{1/2}$$

Tables 4 to 6 give compilation of the values of Λ_0, K_{a1}, and σ corresponding to the minimum at larger a values: Λ_0 and σ are almost the same as those corresponding to the minimum at smaller a values, but K_a is a little larger.

a) Ref. 7. b) Ref. 14.

Conductances for [NiL](ClO$_4$)$_2$ were analyzed using the Fuoss-Edelson technique for unsymmetrical electrolytes.[13] This method consists of evaluating Λ_0 and the first association constant K_{a1} for 2-1 electrolytes with some approximations, such as $\lambda_0(MX^+)=0.5\lambda_0(1/2M^{2+})$ and the second association constant $K_{a2}=0$. Typical Fuoss-Edelson plots of Λ^* against X for DMA-NB solution are shown in Fig. 2, where

$$\Lambda^*=\Lambda F,\ X=C'\Lambda^*(\Lambda^*-\Lambda_0/2),\ C'=2Cf$$

and

$$\Lambda^*=\Lambda_0-(K_{a1}/\Lambda_0)X$$

The function F is given as

$$F=[1/(1+\lambda_0(1/2M^{2+})/2\Lambda_0)][1/\{1-S_{2:1}(2I)^{1/2}/\Lambda_0\}+\lambda_0(1/2M^{2+})/2\Lambda]\Lambda/\Lambda_0$$

where $S_{2:1}$ is the Onsager conductance coefficient for a 2-1 electrolyte and I is the ionic strength. Good linear relations for the plots were obtained. The first association constant K_{a1} is obtained from the negative product of the slope and intercept of the curve. The results obtained for DMA-DCE, DMF-DCE, DMA-NB, DMF-NB, and DMA-DMF binary mixture systems are given in Tables 4 to 6. The extended Jenkins-Monk method[14] was also used to evaluate the second association constants K_{a2} and it was found that

in most cases the K_{a2} values are negligibly small so that neglecting K_{a2} is not serious for evaluating K_{a1}. For example, in NB, where the salts used are most associative, the extended Jenkins-Monk method gave the values of $K_{a1}=1190$ and $K_{a2}=12$[7] and the analysis of conductances on neglecting the K_{a2} value gave the

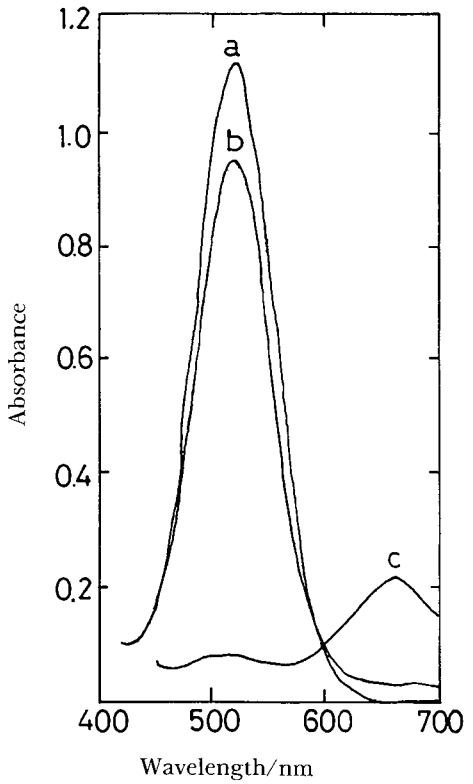

Fig. 3. Visible absorption spectra for [NiL](ClO$_4$)$_2$ (1.0×10^{-3} mol dm^{-3}) in (a) NB, (b) DMA, and (c) DMF at 25 °C.

value of K_{a_1}=1200.

The visible spectra of [NiL]$^{2+}$ in NB, DMF, and DMA are shown in Fig. 3. The absorption peaks at 519 nm in DMA and NB, and 503 nm in DMF are assigned to the square species and those at 660 and 400 nm in DMF are assigned to the square pyramidal species. There is no change in spectra of [NiL]$^{2+}$ in those solvents over 40 h at 25 °C. Therefore, the isomerization of [NiL]$^{2+}$ can be neglected. These spectra clearly show that NB and DMA are not coordinated to the [NiL]$^{2+}$ cation but DMF is done. DCE of a very low basicity is not coordinated.

Thus, there is a clear difference in coordination behavior between DMA and DMF, but the K_{a_1} values obtained for DMA are almost the same as those for DMF in all the mixed solvents. In the relative permittivity-changing media (DMF- and DMA-DCE) the logarithms of K_{a_1} were plotted against the reciprocal of relative permittivity in Fig. 4. Solid and broken lines show the association constants for the 1-1 and 2-1 types of salts, repectively, calculated by the Bjerrum association theory[15] with various ionic size parameters. When the ionic radius of ClO$_4^-$ is 0.236 nm, the Ni-ClO$_4^-$ distance is more than 0.31 nm. The salts of (i-Pent)$_3$BuN$^+$ and [NiL(N$_3$)]$^+$ give the K_a values expected from the electrostatic theory. However, the K_{a_1} values for [NiL]$^{2+}$ are much less than those expected from the Bjerrum calculation with a

Solid and broken lines show the values calculated for 1-1 and 2-1 types of electrolytes, respectively, at 25 °C. Ionic size parameter in nm: a, 0.3; b, 0.5; c, 0.7; d, 0.3; e, 0.5; f, 0.7; g, 1.0.

range of 0.3 to 1.0 nm of a parameter which are reasonable for $[NiL]^{2+}$-ClO_4^- association. On the contrary, NB gives a much greater K_{a1} value which corresponds to an ionic distance parameter of 0.32 nm for the Bjerrum equation. It is interesting that when DMF and DMA are added to NB, the K_{a1} value decreases with increasing fraction of DMF and DMA in spite of nearly the same relative permittivity of the mixed solvents. This means that since DMF is bonded to the nickel on the same side as the four methyl groups, the site of ion pairing is mainly the axial pocket in the second coordination sphere surrounded by the four nitrogen substituents, and the axially associated perchlorate ions are easily displaced by the basic solvent. Furthermore, a similar K_{a1}-decreasing effect of non-coordinating DMA indicates that the perchlorate ion associated is easily displaced by DMA through ion-dipole interactions between $[NiL]^{2+}$ and DMA. The large K_{a1} values in NB suggests that the contact ion pair is possibly formed, considering that the K_{a1} value of the octahedral complex, $[Fe(phen)_3](ClO_4)_2$ (phen=1,10-phenanthroline), of the same 2-1 electrolyte as $[NiL](ClO_4)_2$ is only 39 $dm^3\,mol^{-1}$ in NB,[14] although the dipole moment of NB (μ=4.2 Debye) is larger than that of DMF (μ=3.86) and DMA (μ=3.81). This results from a weaker ion-dipole interaction because of the delocalized negative pole on the oxygen atoms and steric hindrance of nitro group for NB, leading to more degree of ionic association. Although the ion-pair formation constants between $[NiL]^{2+}$ and the perchlorate ion in NB is

larger than in DMA, the absorbance of $[NiL]^{2+}$ at 520 nm in NB is larger than that in DMA. This means the outer-sphere interaction of the perchlorate ion with $[NiL]^{2+}$. The localized negative pole on the oxygen atom of DMA[16,17] can be so close to the central nickel that the contact ion-pair cannot be formed.

The K_{a1} values of $[NiL]^{2+}$ in DMF-DMA mixtures are a little less than the K_a values of $[NiL(N_3)]^+$, showing that the double charge for $[NiL]^{2+}$ interacts more strongly with the DMA dipole than with the perchlorate ion, compared with the case for $[NiL(N_3)]^+$.

Table 7 shows the Stokes radii r_s for ClO_4^-, $[NiL]^{2+}$, and $[NiL(N_3)]^+$ ions in all the media used, where

$$r_s = 0.82|z|/\lambda_0\eta$$

and z is the charge of ions. The r_s values in each medium are almost constant except for the DCE systems of a lower relative permittivity, and the r_s values of $[NiL]^{2+}$ are larger than those of $[NiL(N_3)]^+$ in all the mixed solvents. This is compatible with strong solvation by DMA as well as DMF.

Conclusion

The main site of ion pairing for $[NiL]^{2+}$ is the axial pocket surrounded by the four *N*-methyl groups. DMA preferentially solvates the axial pocket by an ion-dipole interaction without a chemical bond between the central nickel and the oxygen atom of DMA, although DMF solvates by the chemical bond. The solvent-separated ion pair is formed in both DMA and DMF, but the contact ion pair is formed in NB.

ESR and Magnetic Susceptibility Studies on High-Spin Tetrahedral Cobalt(II)-Thiolate Complexes: An Approach to Rubredoxin-Type Active Sites

Kouichi FUKUI, Hiroaki OHYA-NISHIGUCHI,* and Noboru HIROTA
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 3, 1990)

Magnetic susceptibility and ESR studies on high-spin (S=3/2) tetrahedral cobalt(II)-thiolate complexes were performed for $A_2[Co(SPh)_4]$; A=Me_4N (**1a**), Et_4N (**1b**), Ph_4P (**1c**) and $(Et_4N)_2[Co(SR)_4]$; R=C_6H_4-*p*-Me (**2**), C_6H_4-*p*-Cl (**3**), C_6F_5 (**4**). It was found that the magnitude of zero-field splitting and the anisotropy of g-factor are exceptionally large for **1c** as $D\approx-100\,cm^{-1}$, $E\approx0$, $g_x\approx g_y<g_z$. This parameter set shows that $Co(SPh)_4^{2-}$ in **1c** is strongly affected by an axial distortion. On the contrary, a rhombic distortion with moderate magnitude was found for **1a** (D^*=6.5 cm^{-1}, E/D=−0.21) and **1b** (D^*=5.0 cm^{-1}, E/D=0.19). The results for the other compounds are D^*=7.0 cm^{-1}, E/D=0.14 for **2**, D^*=12 cm^{-1}, E/D=0.10 for **3**, and D^*=2.0 cm^{-1}, E/D=0.02 for **4**. Attempts were made to correlate the magnetic properties and the coordination geometry for **1a—c** by use of available X-ray data. As a result, the importance of the orientation of the thiolate ligands was confirmed.

Cobalt is an important element in bioinoganic chemistry because the Co(II) ion is frequently employed as a spectroscopic probe in metal-exchange studies of metalloproteins.[1-6] The advantage of Co(II) is derived from the sensitivity of its d-d absorptions,[7] effective magnetic moment (μ_{eff}),[8] and zero-field splitting (zfs)[9] to coordination environment around the metal ion. It has been also pointed out that the ESR spectra of high-spin Co(II) complexes are susceptible even to slight change and/or distortion of the geometry.[10-15] Many Co(II)-substituted metalloproteins, therefore, have been prepared in order to elucidate their active-site geometries with or without substrate/inhibitor by using UV-visible, MCD,[1,3,4] and ESR spectroscopies.[2-6]

Rubredoxin, which is the simplest iron-sulfur protein, contains a $Fe(SCys)_4$ site relevant to its electron-transfer function.[16] In the $Fe(SCys)_4$ site, four thiolate anions from cysteine residues are ligated to an Fe ion in a distorted tetrahedral arrangement.[17,18] Of paticular interest have been the geometric effects on the electron-transfer properties of this site. Previous molecular orbital (MO) calculations for simple models, $Fe(SR)_4^{-/2-}$ (R=H, CH_3), suggest that the most important geometric factor in the active site is the orientation of the thiolate ligands, rather than the tetragonal compression/elongation of the FeS_4 tetrahedron.[19,20] However, in the studies of synthetic models exemplified by $Fe(SPh)_4^{2-}$, the interest has been rather focused on the tetragonal distortion. In view of the sensitivity of Co(II) to coordination environment, model studies of cobalt thiolates are expected to provide valuable information concerning the relationship(s) between thiolate orientation (or other geometric factors) and electronic structure in metal thiolates. For this reason, we have chosen cobalt thiolates as a target of the present work.

The stereochemistry of metal-benzenethiolate complexes, $M(SPh)_4^{-/2-}$, is now well characterized through extensive X-ray studies of different metal analogs with different counter ions.[21-27] It was pointed out by Coucouvanis et al.[22] and, more explicitly, by Koch et al.,[23] that only two conformations are possible for the overall orientation of the benzenethiolates (Fig.1): One conformation is found in $(Ph_4P)_2[M^{II}(SPh)_4]$ (M=Co, Fe, Zn, etc.).[21,22] Their S'-M-S-C tortion angles are all ca. 0° or 180°, forming a D_{2d} geometry in the idealized case. The other is found in

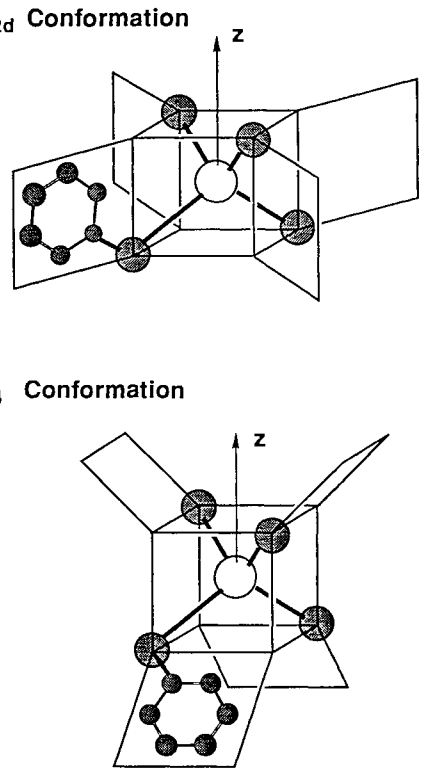

Fig. 1. Schematic drawings of the two idealized conformations for the thiolate-orientation in $M(SPh)_4^{-/2-}$. The phenyl rings lie in the planes standing on edges of the cubes.

$(Et_4N)[Fe^{III}(SPh)_4]$,[23] $(Me_4N)_2[M^{II}(SPh)_4]$ (M=Mn,[24] Zn[25]) and $(Et_4N)_2[M^{II}(SPh)_4]$ (M=Ni,[26] Fe (Fig. 8 in Ref. 22)). In these complexes, two of the four thiolates are rotated by ca. ±120° about the respective M-S bonds from the positions in the D_{2d} conformation. The overall symmetry is S_4 in the idealized case. Such conformational constraint is due to a combined effect of the sulfur p_π-phenyl π interactions and the ortho phenyl hydrogen-sulfur-metal interactions.[22] The active-site geometry of rubredoxin has been classified to the D_{2d} conformation,[17,18] though two of the thiolates are rotated by ca. 30° from the idealized positions.[20]

In the present paper, we report the ESR and magnetic susceptibility results of $A_2[Co(SPh)_4]$; A=Me_4N (**1a**), Et_4N (**1b**), Ph_4P (**1c**) and $(Et_4N)_2[Co(SR)_4]$; R=C_6H_4-*p*-Me (**2**), C_6H_4-*p*-Cl (**3**), C_6F_5 (**4**). Their magnetic properties (*g*-values and zfs parameters) are examined closely. The electronic structures of **1a**—**1c** are discussed based on their zfs and above-described conformational properties.

Experimental

Materials. Acetonitrile was distilled over CaH_2 and stored over molecular sieves 4A. The other reagents were used as purchased. The compounds $A_2[Co(SR)_4]$ were prepared according to a modified Dance's method[27] in vacuo or under dinitrogen atmosphere. They were obtained as emerald-green microcrystals except that **4** as blue-green powder. Their Zn analogs were prepared similarly. Magnetically diluted Zn-doped samples were obtained by recrystallization from an acetonitrile solution containing one of the Co compounds and its Zn analog in a mole ratio of Co/Zn=1% or 10%.

$A_2[Co(SPh)_4]$; A=Me_4N (1a), A=Et_4N (1b), A=Ph_4P (1c). The UV-visible spectra in CH_3CN agree well with those reported previously.[27] ^1H NMR (CD_3CN) δ=16.9 (2,m-H), −23.7 (1,p-H).[28] For **1c**, Found: C, 73.14; H, 5.02; P, 5.19%. Calcd for $CoS_4C_{72}H_{60}P_2$: C, 73.64; H, 5.15; P, 5.27%.

$(Et_4N)_2[Co(SC_6H_4$-*p*-Me$)_4]$ (2). ^1H NMR (CD_3CN) δ= 17.1 (2,m-H), 27.0 (3,p-Me). Found: C, 64.02; H, 8.52; N, 3.28%. Calcd for $CoS_4C_{44}H_{68}N_2$: C, 65.07; H, 8.44; N, 3.45%.

$(Et_4N)_2[Co(SC_6H_4$-*p*-Cl$)_4]$ (3). ^1H NMR (CD_3CN) δ=17.9 (2,m-H). Found: C, 53.05; H, 6.30; N, 3.07; Cl, 15.73%. Calcd for $CoS_4C_{40}H_{56}N_2Cl_4$: C, 53.73; H, 6.31; N, 3.13; Cl, 15.87%.

$(Et_4N)_2[Co(SC_6F_5)_4]$ (4). This compound is unstable to heat, so that the temperature should be kept below 30 °C during the synthesis and stored in a refrigerator.[29] Found: C, 41.10; H, 3.61; N, 2.41; F, 32.93%. Calcd for $CoS_4C_{40}H_{40}N_2F_{20}$: C, 43.05; H, 3.59; N, 2.51; F, 34.08%.

Measurements. ESR spectra were recorded on a JEOL FE-3X spectrometer equipped with an Air Product Model LTR-3-110 Heil-Tran liquid-helium-transferring refrigerator. The microwave frequency (X-band, 9 GHz) was measured with a Takeda Riken TR5211 frequency counter. Cr(III) in MgO was used as a calibrant of the magnetic field. For the ESR measurements, each compound was examined in three forms; magnetically undiluted neat powder, magnetically diluted Zn-doped powder, and frozen MeCN solution. Magnetic susceptibility measurements were performed on a Faraday-type susceptometer over a temperature range of 1.5 K to room temperature at a magnetic field of 700 mT. Neat powder samples were used for the measurements. The temperature was measured with a thermocouple and a Ge resistor, and the magnetic field with a Hall probe. The calibrations of the temperature and the field-gradient were made using $KCr(SO_4)_2\cdot 12H_2O$ and $HgCo(NCS)_4$, respectively. Temperature-independent magnetism and μ_{eff} at room temperature, μ_{eff}(R.T.), were estimated from the least-squares fit of the data in a high-temperature region (typically 100K—room temperature) to the Curie law.

Results and Analyses

Magnetic Susceptibility. In the second column of Table 1 are listed the μ_{eff}(R.T.) values, which are all within the range for high-spin Co(II) complexes (S=3/2).[8] It is notable here that the μ_{eff}(R.T.) value of **1c** (5.0 BM) is significantly larger than the others (4.1—4.4 BM). This result, together with those given later, shows that the magnetic properties of **1c** are exceptional.

The susceptibility data of **3** and **4** are representatively shown in Fig. 2 as a μ_{eff} vs. T plot. The decrease of μ_{eff} at lower temperatures is attributed to thermal depopulation of the upper partner of the zero-field split levels (upper Kramers doublet). Similar temperature dependence was found for **1a**, **1b**, and **2**. The susceptibility data of **1c** is presented in Fig. 3, where a gradual decrease of μ_{eff} occurs over a wide temperature range. Although this magnetic behavior is unusual for a mononuclear complex, the ESR results of **1c** show that no exchange interaction exists between the Co ions (vide infra).

We have analyzed the variable-temperature susceptibility data by using the S=3/2 spin Hamiltonian;

$$H = D(S_z^2 - 5/4) + E(S_x^2 - S_y^2) + \sum \mu g_p S_p H_p \qquad (1)$$

Here D and E denote the conventional zfs parameters and g_p (p=x,y,z) the principal p-component of the g-tensor. Some remarks should be made about the notations: (1) We take $E \geq 0$ throughout this paper, so that the sign of the rhombicity parameter (E/D)

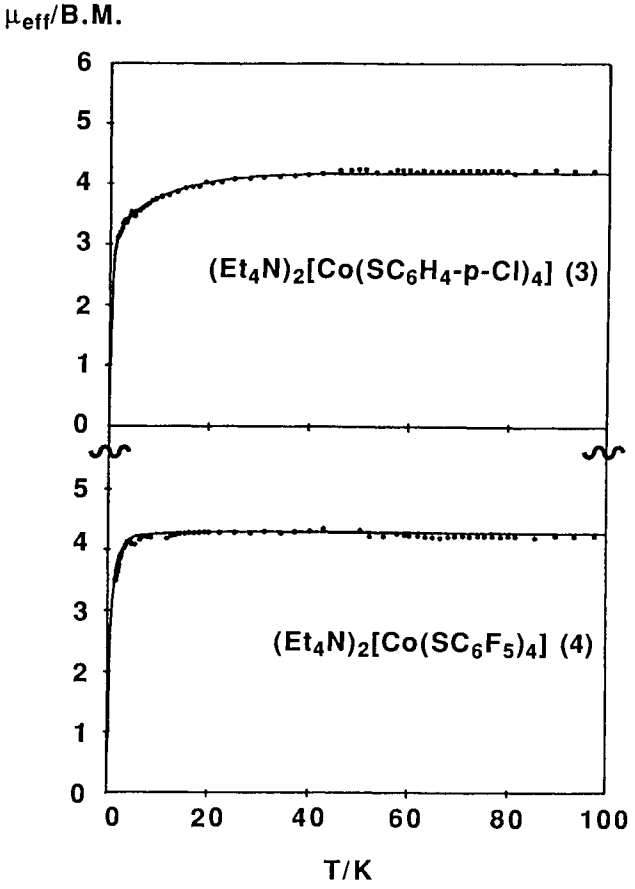

Fig. 2. Temperature dependence of μ_{eff} obtained from the neat powder samples of $(Et_4N)_2[Co(SC_6H_4$-p-$Cl)_4]$ (**3**) and $(Et_4N)_2[Co(SC_6F_5)_4]$ (**4**). The solid curves represent the theoretical fits.

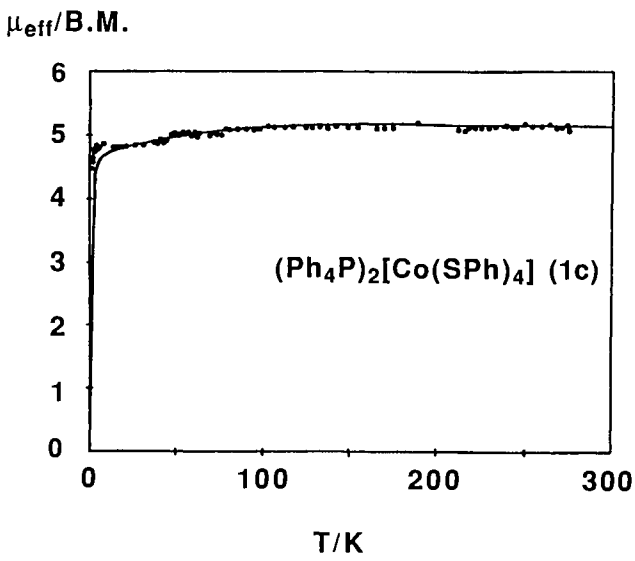

Fig. 3. Temperature dependence of μ_{eff} obtained from the neat powder sample of $(Ph_4P)_2[Co(SPh)_4]$ (**1c**). The solid curve represents the theoretical fit, where $D=-100$ cm^{-1}, $g_x=g_y=2.25$, $g_z=3.13$.

always corresponds to that of D. (2) We distinguish g_p from g'_p ($p=x,y,z$; or $p=1,2,3$). g'_p is used to represent the resonant position of an ESR signal feature. The two parameters, g_p and g'_p, can be connected analytically when the Zeeman term in Eq. 1 is treated as a perturbation.[15]

The anisotropy of g-factor is usually small in tetrahedral high-spin Co(II) complexes.[10-15,30] Thus, in analyzing the susceptibility data, we first assumed that g-factor is isotropic ($g_x=g_y=g_z=g_{av}$). It is important to note that, in this case, variation of E/D has practically no effects on spatially-averaged μ_{eff}. Furthermore, g_{av} is directly connected with μ_{eff}(R.T.) as

$$\mu_{eff}(\text{R.T.})=(15/4)^{1/2}g_{av}. \quad (2)$$

Hence we had only one parameter, $D^*=(D^2+3E^2)^{1/2}$, to be varied in the fitting. For **1a**, **1b**, and **2**—**4**, the best-fit curves obtained in this manner reproduce the experimental data quite satisfactorily, as shown in Fig. 2 for **3** and **4** representatively. The D^* and g_{av} values obtained for these compounds are shown in Table 1. For **1c**, however, we were not able to obtain any reasonable fits when an isotropic g-factor was assumed. The temperature-dependence behavior of μ_{eff} of **1c**, which is presented in Fig. 3, indicates that the D^* value is anomalously large, being on the order of 100 cm^{-1}. Since large zfs implies large g-anisotropy, we should go into the case of anisotropic g-factor. Hence we subsequently assumed the axial case ($E=0$, $g_x=g_y\neq g_z$). This assumption can be justified by the X-ray data showing an approximate D_{2d} structure for $Co(SPh)_4^{2-}$ of **1c**.[21] The ESR results of **1c** also suggest $E\approx 0$, as described in Discussion. The best fit for the axial case was achieved with $D=-100\pm30$ cm^{-1}, $g_x=g_y=2.25$, and $g_z=3.13$ (Fig. 3). This parameter set has a few notable features: (1) D is negative in sign and anomalously large in magnitude. The fits using positive D were always poor, and resulted in unreasonable values (i.e. $g_z=0$) at best. (2) g_z is very large while g_x and g_y are comparable to g_{av} of the other compounds. (3) The relation; g_x, $g_y<g_z$, is consistent with the negative sign of D, and its large anisotropy also with the large magnitude of D. Finally attempted were the analyses including rhombicity ($E\neq0$, $g_x\neq g_y$), where, unfortunately, we were not able to determine the best fit uniquely. Although many sets of parameters gave comparably good fits in this case, the above features still held for the sets. Consequently the above features must exist in the magnetic properties of **1c**.

ESR. It was found that the neat powder samples commonly exhibit broad ESR spectra even at 4.2 K. These results are due to dipolar interactions among neighboring Co ions. The dipolar interactions, as well as intermolecular exchange interactions, can be reduced by doping the compounds in diamagnetic crystals. Sharpened spectra were thus obtained from

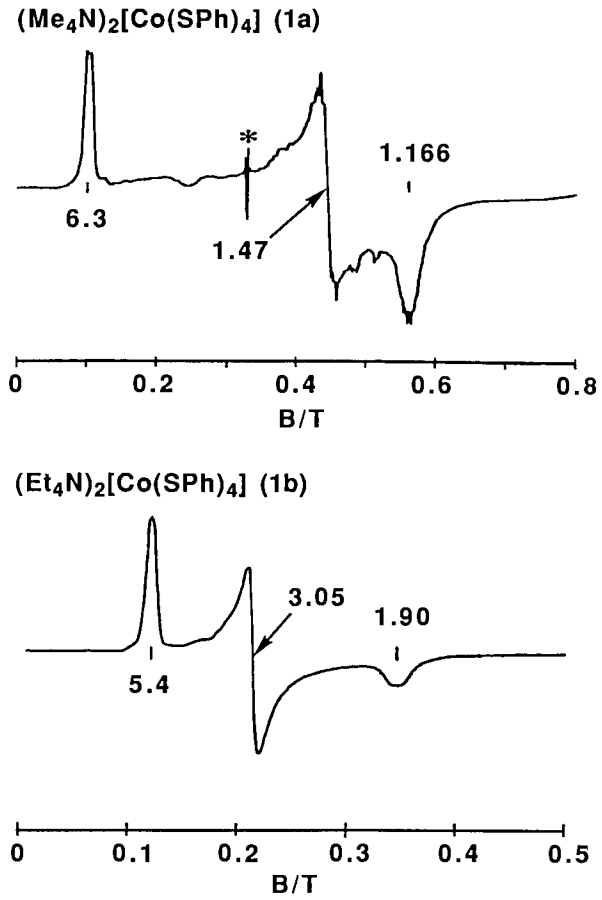

Fig. 4. ESR spectra of the Zn-doped powder samples (Co/Zn=1%) of $(Me_4N)_2[Co(SPh)_4]$ (**1a**) and $(Et_4N)_2[Co(SPh)_4]$ (**1b**) measured at 4.2 K. The signals marked with * are from a radical impurity and Cr(III) in MgO used as a g-value marker.

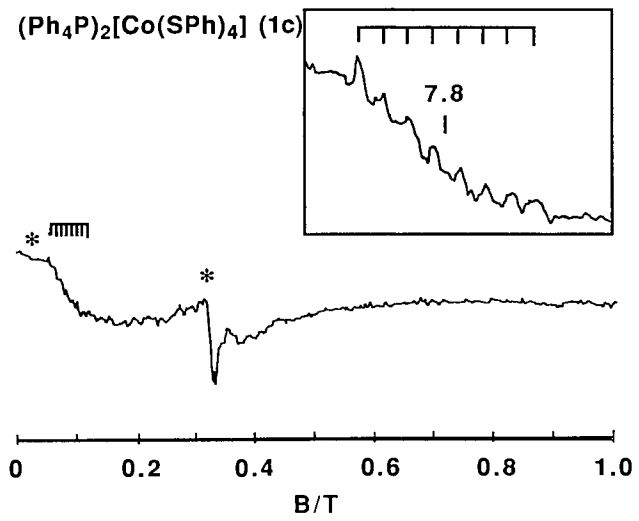

Fig. 5. ESR spectrum of the Zn-doped powder sample (Co/Zn=10%) of $(Ph_4P)_2[Co(SPh)_4]$ (**1c**): Conditions Temperature, 4.2 K; Sample amount, 30 μmol; Power 1 mW; Amplitude, 1.25×1000; Modulation, 10 G at 100 kHz. The signals marked with * are due to impurities. The g'=7.8 signal is enlarged in the inset.

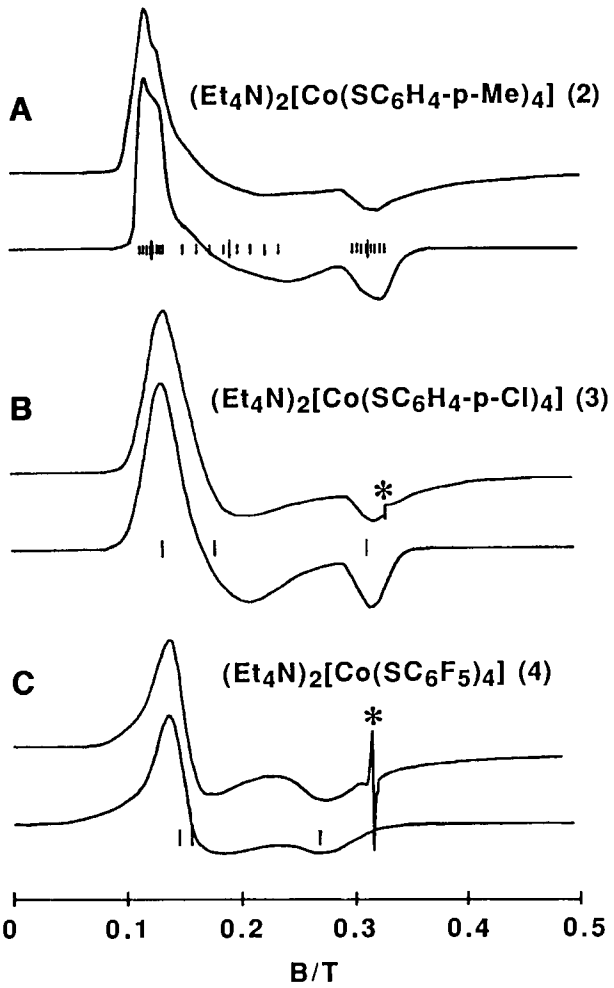

Fig. 6. ESR spectra of the Zn-doped powder samples (Co/Zn=1%) of $(Et_4N)_2[Co(SC_6H_4\text{-}p\text{-}Me)_4]$ (**2**), $(Et_4N)_2[Co(SC_6H_4\text{-}p\text{-}Cl)_4]$ (**3**), and $(Et_4N)_2[Co(SC_6F_5)_4]$ (**4**) obtained at 4.2 K. The lower spectrum for each is the result from the computer simulation. The signals marked with * are from Cr(III) in MgO (B) and from a radical impurity (C).

the Zn-doped samples as shown in Fig. 4 for **1a** and **1b**, in Fig. 5 for **1c**, and in Fig. 6 for **2**—**4**. The sharpening of the spectra was especially drastic for **1a** and **1b**. The principal g'-values obtained from the Zn-doped spectra are summarized in Table 2. For **1b**, **1c**, and **2**—**4**, the Zn-doped powder spectra are practically identical with the corresponding neat powder spectra excepting the difference in line width. This suggests that the geometric distortions are not altered appreciably by the Zn-doping. (Especially **1c** is known to be isomorphous and isostructural to the Zn analog.[21]) For **1a**, however, the two spectra are slightly different, although this difference does not seem to be so important.[31] Thus in the two states the geometric distortions of **1a** are not exactly the same, but still essentially similar.

In the Zn-doped spectrum of **1a**, each signal feature contains a partially resolved hyperfine structure due to

a) The values marked with * are from the simulations. b) The estimated errors are about ±0.02. The negative sign means negative D value. c) Very weak.

^{59}Co (I=7/2). The coupling constants are A/mT=0.8 at g'=6.3, 4.0 at g'=1.47, and 4.4 at g'=1.166. As for **1b**, we did not observe any resolved hyperfine splittings. However, the line shape of the g'=1.90 feature is indicative of unresolved structure of A≈2 mT (Fig. 4).

No apparent ESR signals were obtained from **1c** despite that we measured some forms of samples from different sources each. Both the Zn-doped (Co/Zn=10%) and the neat powder samples of **1c** exhibit only an incomplete and extremely weak signal up to 1.0 T even at 4.2 K. This signal is centered at g'=7.8 with a resolved hyperfine structure of A=9.2 mT, although the signal was too weak to be detected clearly (Fig. 5). Under the same conditions, the low-field components of the other compounds gave 100—1000 times the intensity of the g'=7.8 signal. No signal has been obtained from the Co/Zn=1% sample, which is however consistent with the extraordinary weakness of the g'=7.8 signal. Although uncertainty remains as to whether the g'=7.8 signal is attributable to **1c**, it is at least clear that the ESR signal of this compound is extremely weak or even can not be observed. Weakness (or absence) of ESR signals is often attributed to intermolecular exchange interaction. However, the fact that weak (or no) signal is invariably observed from the three different forms shows that this is not the case. Additionally, the crystallographic data of the X-ray isomorphous Fe analog show that the nearest-neighboring metal ion sites are separated sufficiently by 10 Å. The origin of the weakness is discussed later.

The ESR spectra of Zn-doped **2**, **3**, and **4** are relatively broad, so that we simulated the spectra to estimate the principal g'-values (Fig. 6). The simulations are based on the S'=1/2 effective spin Hamiltonian using the gaussian-type lineshape function.[5] The compound **2** gives a characteristic signal shape from 0.1 to 0.2 T. This shape can only be reproduced when a fairly large but unresolved hyperfine splitting is assigned to the principal g'=3.3 component. On the other hand, the spectra of **3** and **4** show no evidence for hyperfine splittings, so that hyperfine interaction was neglected in the simulations of these spectra.

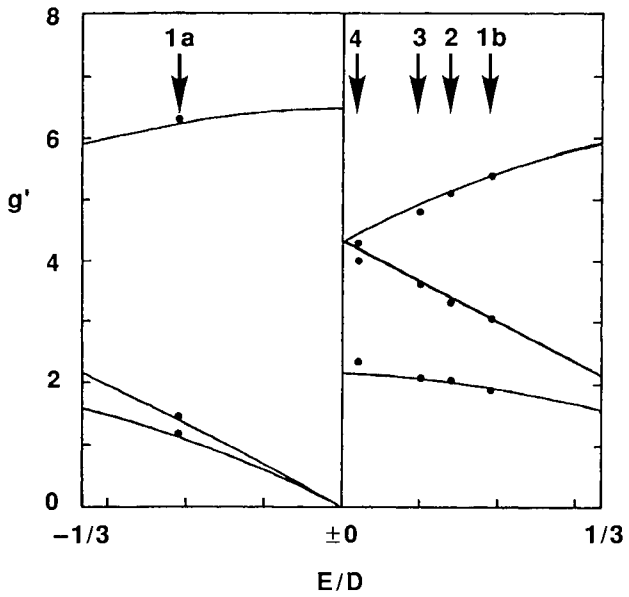

Fig. 7. Theoretical curves of g'-values versus E/D accompanied by the experimental results from the Zn-doped powder samples.

In contrast to the low-temperature behavior of μ_{eff}, g'_p does not depend on D^* but only on g_p and E/D when $D^* \gg h\nu$=0.3 cm^{-1}. The variation of g'_p vs. E/D is graphed in Fig. 7 for the transition within the lower Kramers doublet, together with the experimental values from the Zn-doped powder spectra. Since the intensities of the observed signals all decrease with increasing temperatures above 4.2 K, the signals are assigned to arise from the lower doublets. Based on these assignments and approximation of isotropic g-factor, we have estimated E/D and g_{av} (Table 2). These g_{av} values are in good agreement with those obtained from the susceptibility results.

The ESR spectra obtained from the frozen solution samples are less informative. All the compounds including **1c** exhibit similar spectra, which consist of broad features at g'≈4 and ≈2. However, the observation of such broad spectra is not surprising. In solution, no uniformity is anticipated among the conformations or distortions of the complexes, to which the ESR spectrum is sensitive as typically demon-

strated by the powder spectra of **1a—c**.

Discussion

Magnetic Properties of 1c. We have estimated the zfs parameters, D^* and E/D, from the susceptibility and ESR results, respectively, for **1a**, **1b**, and **2—4**. For **1c**, while it is now clear from the susceptibility data that $D^*\approx 100$ cm^{-1} and $D<0$, E/D still remains ambiguous. The ESR signals from the powder samples of **1c** are always too weak to allow a definite estimate of E/D. However, the extraordinary weakness is indicative of a negligibly small E value. When $E/D=-0$ (here '-0' means $E=0$ and $D<0$ simultaneously), the lower Kramers doublet consists of pure $S_z=\pm 3/2$ states. Then the transition within this doublet is forbidden and no (or very weak) ESR signal is expected. Indeed the transition within the upper doublet is alternatively allowed, but large zfs as in **1c** makes it difficult to detect this transition because of insufficient thermal distribution to this doublet. A literature example for this situation is bis(*N*-*t*-butylpyrrolecarbaldimino)cobalt(II),[13,15] which was reported to be ESR silent and assigned as $E/D=-0$. On the other hand, when E is not negligible, the ground $S_z=\pm 3/2$ states are mixed with the $S_z=\pm 1/2$ ones and, hence the transition gains some intensity. This is the very case for Zn-doped **1a** ($E/D=-0.21$), which exhibits enough intense ESR spectrum. We therefore conclude that $E/D=-0$ is most likely for **1c**. We also point out that the g'_z value predicted for $E/D=-0$ ($g'_z=3g_z=9.4$) can be compared with the observed value of $g'=7.8$.

g-Factor. For high-spin tetrahedral Co(II) complexes, the deviation of g-values from the free-electron value arises mainly from the interaction between the ground $^4A_2$ and the lowest excited $^4T_2$ states through the spin-orbit coupling. Thus g_{av} is expressed as[30]

$$g_{av}\approx 2-8k^2\lambda_0/\Delta_t, \qquad (3)$$

where k represents the orbital-reduction factor, λ_0 the spin-orbit coupling constant for the free ion (-178 cm^{-1}), and Δ_t the energy separation between the e and t_2 orbitals (4030 cm^{-1}).[32] By using the most reliable values of $g_{av}=2.16$—2.19, which are from the ESR results of Zn-doped **1a** and **1b**, we obtain $k=0.67$—0.73. This k value is remarkably small compared with those of other tetrahedral Co(II) complexes; for example, $k=0.8$ for a CoN_4 chromophore,[14] $k=0.9$ for a CoO_4 chromophore,[33] and $k=0.92$ for $CoCl_4^{2-}$.[34] This remarkable reduction of k, together with that of the Racah parameter B,[32] shows a highly covalent character of the Co-S bondings. Such high covalency was also reported for Fe-S bondings.[35]

The remarkable g-anisotropy in **1c**, together with the large zfs, suggests that the electronic structure is deviated extremely from that under T_d symmetry. This deviation must contain a remarkably low excitation energy of the z-component of $^4T_2$, as is evident from the large g_z value. This excitation energy could be estimated by using a modified version of Eq. 3 if the obtained g-values were sufficiently reliable. However, unfortunately, the g-values of **1c** are less reliable because they were obtained only from powder susceptibility data. Further ESR and susceptibility studies on **1c** are now in progress by using single crystals.

ZFS Parameters. Previously Makinen et al.[9] reported that D^* can be a good measure of the coordination number for high-spin Co(II) complexes: The D^* value should be in the range of 0—6.5 cm^{-1} for tetrahedral ones, 10—25 cm^{-1} for pentacoordinate ones, and larger than 25 cm^{-1} for octahedral ones. If we followed this criterion, we could assign **3** as a pentacoordinate complex, and **1c** as an octahedral one. However, these assignments are unreasonable, contradicting the X-ray data which undoubtedly show a tetrahedral geometry for **1c**. As has been pointed out elsewhere,[5] the criterion by Makinen et al. is not so strict. This is because the complexes which they treated are rather simple and possess mild distortions in the coordination geometries.

Interestingly, the D^* values of **1a**, **1b**, and **2**, though they are much smaller than that of **1c**, can be presumed to be *large* (when compared with simple complexes) according to the criterion. It is of great interest to examine whether the *large* D^* values can be interpreted in terms of the tetragonal compression/elongation, which has been supposed to be an important geometric factor in metal-thiolate complexes.[21—27] There have been several theoretical studies concerning the relationship between zfs and the magnitude of the tetragonal distortion. For example, according to the equation given by Fukui et al. (Eq. 25 in Ref. 36), the contribution to D from the tetragonal distortion, D_{tet}, for the CoS_4 cores is expressed as

$$D_{tet}/\text{cm}^{-1}\approx 0.57(\theta/\text{deg}-109.47). \qquad (4)$$

Here we have used $\Delta_t=4030$ cm^{-1}, $\lambda=k\lambda_0\approx -125$ cm^{-1}. θ is the S-Co-S′ angle whose bisector coincides with the tetragonal axis. Equation 4 shows that, as θ varies in a range plausible for the CoS_4 cores (95°—120°),[21] the D_{tet} value varies from -8 to 6 cm^{-1}. Thus, for **1a**, **1b**, and **2**, it seems reasonable to attribute the *large* zfs (in the sense of Makinen's criterion) to large tetragonal distortion of the CoS_4 core. This situation further leads to another important conclusion that the zfs in **1c** is too large to be interpreted in terms of the tetragonal distortion.

Magnetic Properties and Thiolate Orientation. Since **1a**, **1b**, and **1c** have the identical anion complex, the wide variety among their magnetic properties provides a good example for the sensitivity of Co(II) complexes to changes in coordination environment. This wide variety also provides an opportunity to investigate the relationship between the geometric distortion and the electronic structure in metal-thio-

late complexes. The X-ray molecular structure of **1c** was reported previously, showing the D_{2d} conformation for the overall orientation of the SPh^- ligands (Fig. 1).[21] Although no X-ray data are available for the other compounds, the Zn analog of **1a**, $(Me_4N)_2[Zn(SPh)_4]$ (**5**), has been studied by X-ray crystallography.[25] Because the ESR spectrum of Zn-doped **1a** is reasonably sharp, **1a** is expected to have the same geometry as **5** at least in the Zn-doped sample. It is known that **5** has the S_4 conformation for the overall thiolate orientation (Fig. 1). Notably the S-M-S′ angles are very similar between **1c** and **5**. The observation of the remarkably different magnetic properties between **1c** and Zn-doped **1a**, therefore, confirms the importance of the thiolate orientation in metal-thiolate complexes.

In the D_{2d} conformation, the phenyl rings lie in the same direction with respect to the z-axis. Thus the sulfur p_π-orbitals, which are in conjugation with the corresponding phenyl π-orbitals, are all perpendicular to the z-axis. This coordination mode will produce a strong axial ligand field and, hence give large and axial zfs. This expectation is consistent with the observed zfs for **1c**. In the S_4 conformation, on the other hand, the sulfur p_π-orbitals are no more in phase, or interact with a specific metal d-orbital. Little contribution is therefore expected toward zfs from the ligand field due to the sulfur p_π-orbltals. This explains the relatively small D^* value of **1a**.[37] It seems from Eq. 4 that zfs under the S_4 conformation is rather dominated by the tetragonal distortion and some rhombic distortion, where the latter breaks the strict S_4 symmetry and generates the E parameter. Similar explanation can be adopted to the zfs of **1b**, whose Fe(II)[22] and Ni(II)[26] analogs also have the S_4 conformation.

Based on the above consideration, we infer that **2**, **3**, and **4** have the S_4 conformation because their D^* values are rather small.[38] The slightly larger D^* value of **3** is probably due to a minor difference in the thiolate orientation. Here it is worth noting that the ortho-substitutions in **4** may lead to another type of thiolate conformation as found in Fe(2,3,5,6-tetramethylbenzenethiolate)$_4^-$. In this complex, steric hindrance due to the ortho methyl groups prevents the Fe-S-C and phenyl-ring planes from being coplanar. They are rather perpendicular to each other, though the overall geometry retains S_4 symmetry.[39] Recently the electronic structure of this complex was examined closely.[35]

Finally we turn our attention to the active-site geometry of rubredoxin. The ESR spectrum of oxidized rubredoxin is featured by an isotropic $g'=4.3$ feature,[40] which is indicative of an extremely rhombic geometry ($E/D=1/3$) around the Fe ion. Interestingly, nearly extreme rhombicity is found in the zfs of **1a** and **1b** (See Table 2). At the moment it is not clear whether the extreme rhombicity is only an accidental phenomenon or not. Nevertheless, it is notable that the appearance of the extreme rhombicity is not consistent with the D_{2d} conformation proposed so far for the active-site geometry of rubredoxin. This situation implies the importance of the seemingly irrelevant distortion; the rotations of two thiolates by ca. 30° from the idealized positions. The importance of this distortion was previously pointed out by Ueyama et al. from extended Hückel MO calculations.[20] Unfortunately it seems that neither ESR nor magnetic susceptibility study has been performed for Co(II)-substituted rubredoxin, though the Co(II)-substitution has been accomplished.[1] However, the present work arouses the interest in the magnetic properties of Co(II)-substituted rubredoxin, and other Co(II)-substituted metalloproteins possessing rubredoxin-type active sites. Such metal-exchange approaches will provide further insight into the geometric effects on the electronic structure and the electron-transfer properties of the sites.

We thank Dr. Ryuichi Imamura for the measurements of the NMR spectra. This work is partially supported by the Grant-in-Aid for Sientific Research No. 01470050 from the Ministry of Education, Science and Culture.

Synthesis of Strapped, Dimeric, and Trimeric Porphyrins Based on Intramolecular Macrocyclization Reactions

Atsuhiro Osuka, Fumikazu Kobayashi, and Kazuhiro Maruyama*
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received November 2, 1990)

Strapped porphyrins were prepared directly by the acid-catalyzed condensation reaction of 3,3′-diethyl-4,4′-dimethyl-2,2′-dipyrrylmethane and methylenedioxy bridged dialdehydes having a strap linkage longer than 7 atoms. Dimeric and trimeric porphyrins with coplanar and orthogonal (T-shape) geometries were also synthesized in good yields as an application of this method. In the strapped porphyrins, the distortion of porphyrin ring increases systematically on shortening the strap linkage, which is confirmed by their ^{1}H NMR data, red shifted absorption, and fluorescence spectra. In the coplanar dimeric and trimeric porphyrins, the electronic interactions between the porphyrins were distinctly observed, while in the orthogonal "T-shaped" dimers and "H-shaped" trimers, appreciable electronic interactions were not observed.

Important roles of porphyrins and their analogous tetrapyrroles as well as their aggregates in biological proceses such as aspiration, metabolism, and photosynthesis have stimulated the development of a wide range of synthetic porphyrin model compounds in recent years.[1] Among them, 5,15-diaryloctaalkylporphyrin is an useful unit for the model construction because of their easy preparation, high symmetry, and thermal stabillity of atropisomers.[2-4] Synthesis of these porphyrins from 5,5′-unsubstituted dipyrromethane and aromatic aldehydes was first reported by Ogoshi et al.[2] and later modified by Gunter and Mander[3] and Young and Chang.[4] Recently we have found the improved conditions (CCl_3CO_2H/CH_3CN) for the synthesis of these porphyrins[5] and applied them to the synthesis of conformationally restricted oligomeric porphyrins.[6]

Described herein is the direct synthesis of strapped porphyrins from the dialdehydes as well as the synthesis of a novel class of dimeric and trimeric porphyrins based on our improved method.[7,8]

In relation to the importance of porphyrin ring-distortion in biological functions of hemoproteins and photosynthetic pigments, considerable attention has been focused on the synthesis and characterization of permanently distorted porphyrins.[9] One of important issues is the details of how the distortions of the macrocyclic ring influence their electronic and optical properties. Theoretical calculations on the effects of nonplanarity indicate that the highest occupied molecular orbital should be destabilized with respect to the lowest unoccupied molecular orbital, resulting in a red shift of the first visible absorption band.[9] Extremely short-chain-strapped porphyrins are very simple and useful model for this purpose.[10] While the dimeric and trimeric porphyrins synthesized here have rather restricted coplanar and orthogonal geometries and thus are promising models for studies on the geometry dependence of photoinduced excitation energy-transfer and electron-transfer processes.[11]

Results and Discussion

Synthesis of Strapped Porphyrins. Strapped porphyrins synthesized here are 5,15-diphenyl-2,8,12,18-tetraethyl-3,7,13,17-tetramethylporphine derivatives in which ortho positions of the *meso*-phenyl groups are bridged by a methylenedioxy chain with chain length longer than 7 atoms.[12] General procedure is as follows: 3,3′-diethyl-4,4′-dimethyl-2,2′-dipyrrylmethane **1**[13] (100 mg, 0.43 mmol) and the dialdehyde **2** (0.22 mmol) were dissolved or suspended in dry acetonitrile under N_2, and to this mixture a catalytic amount of trichloroacetic acid (10 mg) was added.[5] After standing at room temperature for about 5 h, *p*-chloranil (0.3 g, 1.2 mmol) in dry tetrahydrofuran (THF, 10 ml) was added and the mixture was stirred overnight. Porphyrin product was separated on alumima column (activity III) using CH_2Cl_2 as eluent, and recrystallized from CH_2Cl_2–methanol (Table 1). The cyclization yields were found to be dependent on the concentrations of the reactants (Table 1, Runs 1—4). The highest yield (15%) was obtained at [**1**]= 0.02 M (1 M=1 mol dm^{-3}). At high concentrations [**1**]>0.05 M, the formation of the dark blue insoluble

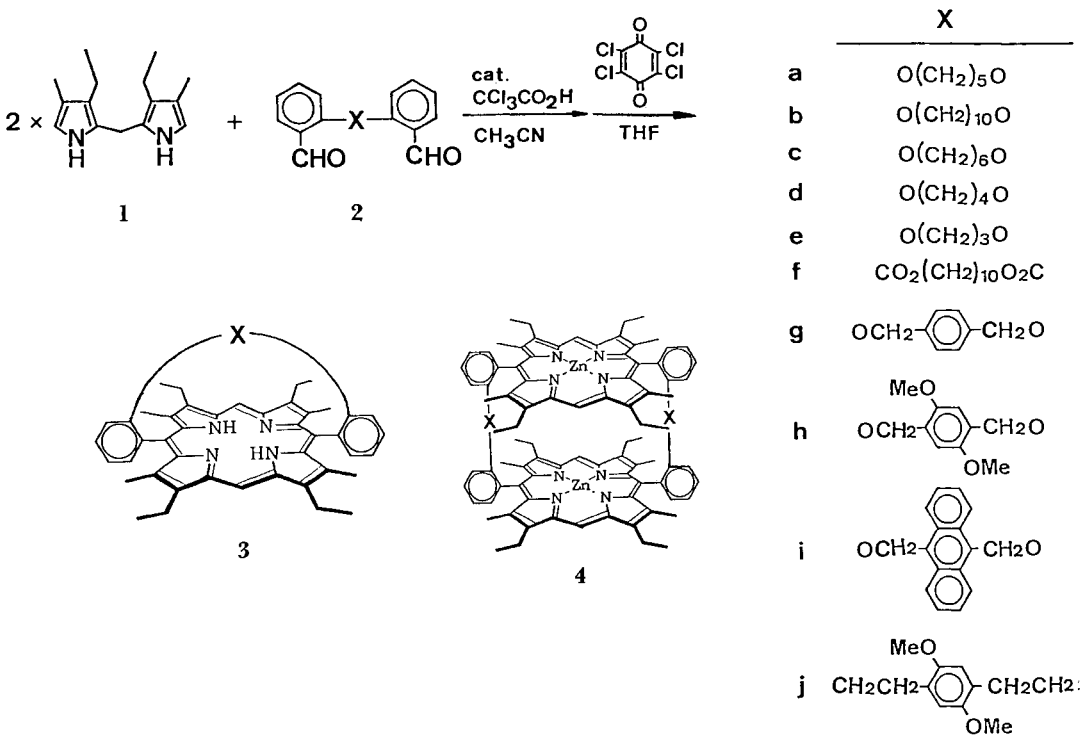
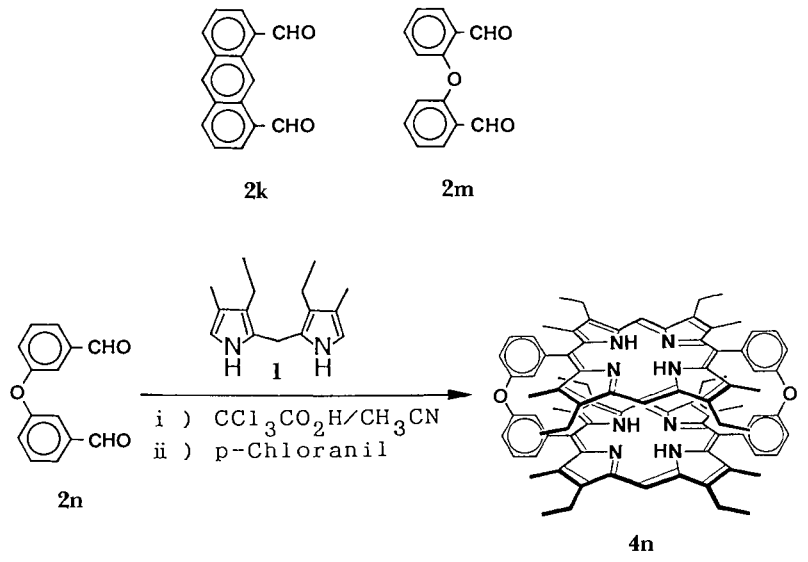


Scheme 1.

solids took place predominantly, while at low concentrations [**1**]<0.01 M, the yield decreased significantly. In the cases of dialdehydes **2d** and **2e**, the corresponding strapped porphyrins were no longer formed but instead face-to-face porphyrin dimers **4d** and **4e** were obtained in 5% and 2%, respectively (Table 1, Runs 7, 8). Although the yields of **4d** and **4e** are not so high, this reaction will be useful for the preparation of porphyrin dimers of this type in view of its simple manipulation, easy separation, and direct synthesis from easily available starting materials. Of dialdehydes (**2k**, **2m**, and **2n**), only **2n** gave dimeric porphyrin **4n** in 2% yield (Scheme 2). This may be ascribed to more conformational flexibility or less steric hindrance of **2n** compared with **2k** and **2m**.

Strapped porphyrins **3g** and **3h**, in which the strap linkage contains an aromatic ring, were also prepared by this procedure in high yields (Table 1, Runs 10, 11). From the CPK (Corey-Pauling-Koltun) models, it is suggested that the porphyrin ring of **3g** and **3h** is



Scheme 2.

forced to be distorted due to the short *p*-xylylene linkages. However, the *p*-xylylene linkages are best-fitted in length for its porphyrinogen precursor. Probably this situation may account for the high yields of **3g** and **3h**. In the dialdehyde **2i**, *syn-anti* isomers exist due to the steric hindrance around 9,10-positions of the anthracene ring, and only the *syn* isomer seemed to adopt the preferred geometry for the porphyrinogen intermediate. Thus the yield of **3i** was lower than **3g**. The dialdehyde **2j**, which has the same number of chain atoms as **2g** and **2h**, gave no strapped porphyrin (Table 1, Run 13), presumably due to the more crowded steric hindrance around the methylene.

Synthesis of Dimeric and Trimeric Porphyrins. For the synthesis of the porphyrin trimer **9**, 5,15-bis(2,6-dimethoxyphenyl)etioporphyrin II (**5**)[5] was used as a precursor. Demethylation with BBr_3 gave the tetrahydroxy porphyrin **6** and then four hydroxyl groups were alkylated with 3-(aryloxy)propyl iodide **12** in refluxing acetone containing K_2CO_3 to give a both-face modified porphyrin **7** (43%). The iodide **12** was prepared in 3 steps from salicylaldehyde in a overall yield of 78% (Scheme 3). The acetal groups were hydrolyzed under acidic conditions[14] to give porphyrin tetraaldehyde **8**(H_2) (92%). We first tried the reaction of free-base porphyrin **8**(H_2) with dipyrrylmethane **1**, which resulted in the formation of the porphyrin trimer **9**(H_6) (*m/z* 2180.5, M^+) in rather poor yields (<10%). In contrast, the yield of the trimer **9**(H_4Zn) was markedly improved (35%) by the use of the zinc complex **8**(**Zn**) as the starting porphyrin (**9**(H_4Zn). Found: *m/z* 2244.120. Calcd for $C_{144}H_{153}N_{12}O_8Zn$: M+H, 2244. 126).

Face-to-face dimeric porphyrin **4e** was alternatively synthesized from the porphyrin dialdehyde (**15**) in a similar manner. Isomerically pure porphyrin dialdehyde **15** was prepared from *p*-xylylene-strapped porphyrin **3g** by the same procedure as **8**. The porphyrin dialdehyde **15**(**Zn**) was treated with dipyrrylmethane **1** in acetonitrile in the presence of trichloroacetic acid followed by oxidation with *p*-chloranil to give the porphyrin dimer **4e**(H_2Zn) in 56% yield as a mono-zinc complex. (Scheme 4).

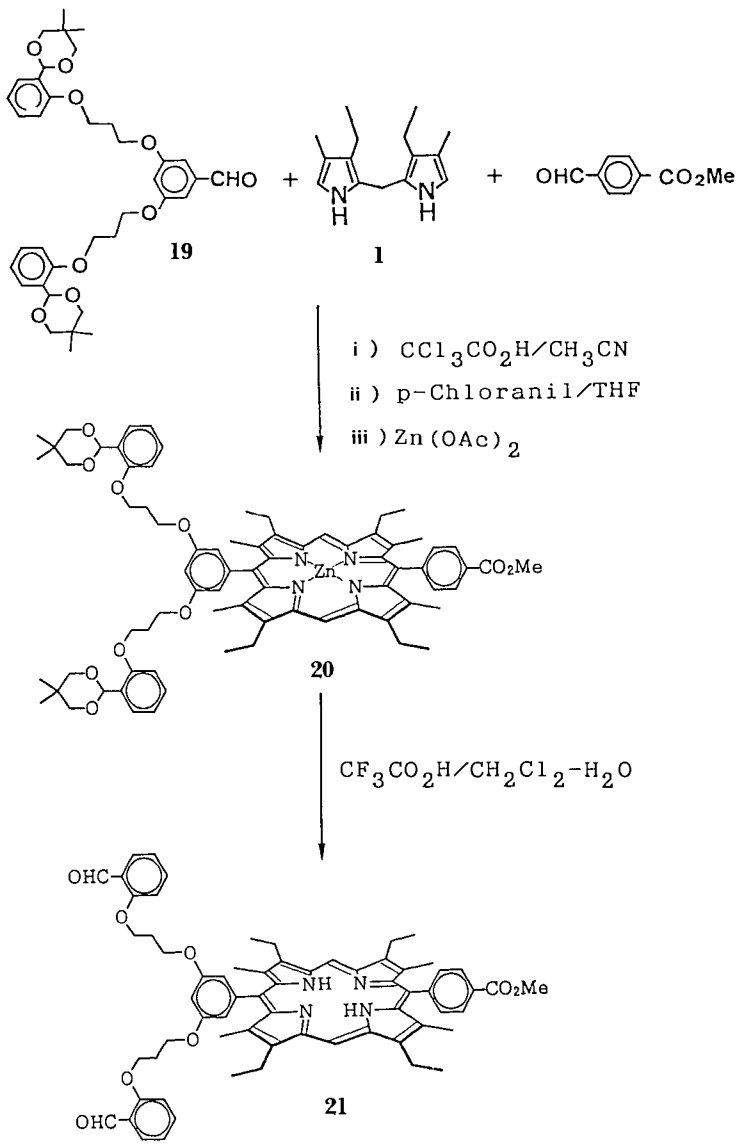


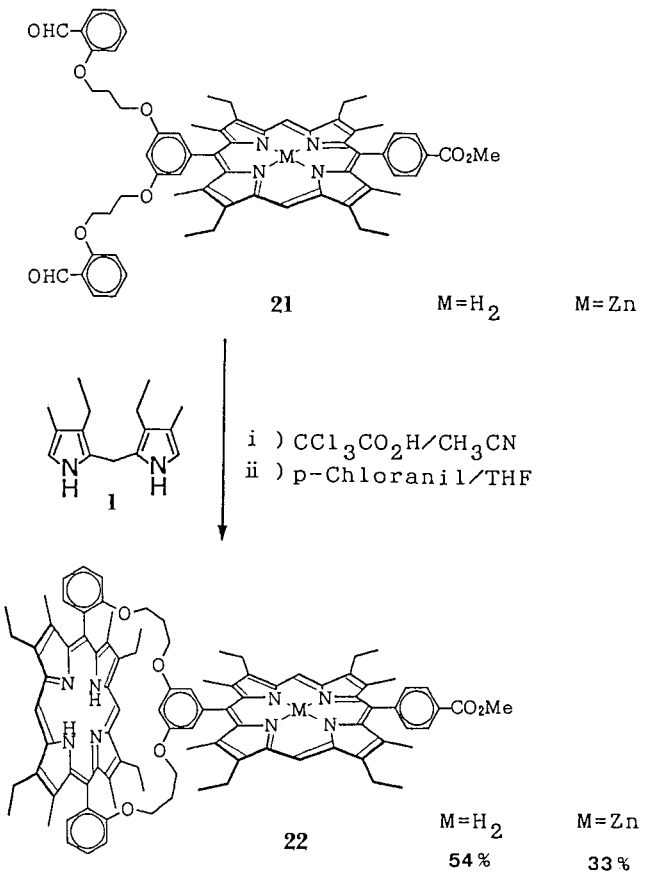
Scheme 6.

The "T-shaped" porphyrin dimers **22**(H_4) and **22**(H_2Zn) were also prepared from porphyrin dialdehydes **21**(H_2) and **21**(**Zn**) in 54% and 33% yield, respectively. (Scheme 5—7).

The "H-shaped" porphyrin trimer **27** was prepared in a different strategy. The strapped porphyrin **24** was first prepared from the corresponding dialdehyde **23** in 41% yield. The ester group on the strap chain was converted into the formyl group by reduction with $LiAlH_4$ followed by oxidation with activated MnO_2 in refluxing chloroform in a overall 82% yield.[15] The strapped porphyrin **26** thus prepared was treated with dipyrrylmethane **1** to give "H-shaped" porphyrin trimer **27**(H_6) in 59% yield (*m/z* 2181.6, $M+H^+$).[6] (Scheme 8).

Ring Distortion of Strapped Porphyrins. ^{1}H NMR and UV-vis Spectra. In their ^{1}H NMR spectra of methylene chain strapped porphyrins (**3a**, **3b**, **3c**, and **3f**), the methylene protons of the strap was significantly upfield shifted in accord with these protons lying above the porphyrin plane (Table 2). On shortening the methylene strap, the ring current effect for the *meso*-H and NH protons decreased systematically presumably due to the ring distortion from planarity. In addition, the ortho protons of the *meso*-phenyl groups were downfield shifted in **3a** and **3c**, suggesting that the phenyl rings are tipped in such a way to place the ortho phenyl protons moving closely into the deshielding field of the porphyrin ring current (Table 2, Fig. 1). Soret and Q-bands of the strapped porphyrins were also red-shifted on shortening the methylene chains, showing the significant perturbations of the π orbitals (Table 3).[9,16]

Similar tendency was observed in the xylene-strapped porpyrins **3g** and **3h**, in which the meso protons were upfield shifted and the ortho phenyl



Scheme 7.

protons were downfield shifted in the ^{1}H NMR spectra (Table 2) and the Soret and Q-bands were 7—17 nm red shifted with respect to the reference porphyrin **28** (Table 3). There exist some conformational differences caused by the methoxyl groups on the xylene moiety between **3g** and **3h**. The aromatic protons of the xylene strap appeared as a singlet at 3.47 ppm for **3g** and 3.50 ppm for **3h**, respectively. But the NH protons of **3g** appeared at −1.36 ppm, while those of **3h** appeared at −2.52 ppm due to the ring current shielding of the xylene cap, indicating that the dimethoxyxylene cap of **3h** was restricted to have a parallel geometry to the porphyrin ring. In accord with this consideration, the benzyl protons of **3h** were observed

Table 3. Absorption Maxima (nm) of the Strapped Porphyrins in CH_2Cl_2

Compound	Free-base		Zinc complex	
	Soret	Q-bands	Soret	Q-bands
3f	411	509 541 580 629	412	540 574

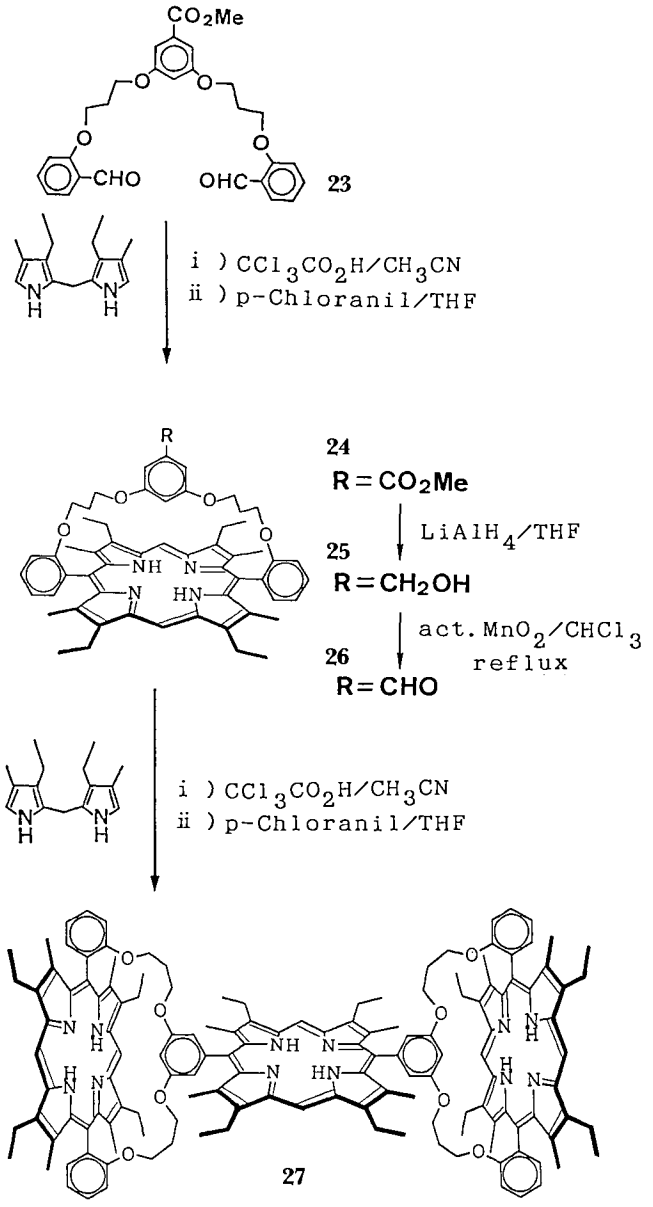

Scheme 8.

as two doublets (3.47 and 2.44 ppm, J=13 Hz). In addition, β-methyl and β-ethyl signals separated to two signals in **3h**, one on the same side with methoxyl groups and the other not. In the case of **3i**, the large anthracene ring was forced to have a parallel geometry to the porphyrin ring, and thus the NH and *meso*-H protons of **3i** appeaed at −2.41 ppm and 9.39 ppm, respectively; both of them were upfield shifted by the ring current shielding of the anthracene cap (Table 2).

Fluorescence Spectra. Fluorescence spectra of the methylene-chain-strapped porphyrins also showed systematic changes. Emission maxima were shifted to the longer wavelength on shortening the strap linkage and the fluorescence quantum yield and fluorescence lifetime were reduced by the ring distortion. The red shift of the emission maxima was in line with those observed in their UV-vis spectra. In addition, a new peak between the two peaks appeared in the free-base porphyrins and this center peak merged with the preceding peak in **3a** and **3c**. (Fig. 2, Table 4). On the other hand, no decrease of the fluorescence intensity and lifetime was observed in the xylylene-strapped porphyrins **3g** and **3h** (Table 4). This difference is presumably due to the difference of the conformational flexibility of the porphyrin ring. The porphyrin ring was distorted in **3g** and **3h** as well as **3a**, but the molecular motion should be restricted in **3g** and **3h** due to the rigid *p*-xylylene linkage.

28(Zn)[a]	409	538 574

a) Zinc 5,15-diphenyletioporphyrin II was used as a reference porphyrin.

UV-vis and ^{1}H NMR Spectra of Dimeric and Trimeric Porphyrins. The stacked type porphyrins **4e** and **9**(Zn_3) showed blue-shifted Soret band similar to the other face-to-face dimeric porphyrins,[1,6] while the UV-vis spectra of **22**(Zn_2) and **27**(Zn_3) were almost unchanged with respect to the monomeric porphyrin **28** indicating that the ground state interactions between the porphyrins were small in the orthogonal geometries. (Table 5).

The unique geometries of "T-shaped" dimer **22** and "H-shaped" trimer **27** were characterized by their

Table 6. Chemical Shifts of H_a

Compd	δ

27(Zn_3)	2.92
21	6.94
21(Zn)	6.95

^{1}H NMR spectra. The inside aromatic protons (H_a, designated in Table 6) appeared at ca. 3 ppm region due to the strong shielding effect of porphyrin ring current. The distance between the H_a and the porphyrin plane was estimated to be 4.1 Å in **22** on the basis of the porphyrin ring current model,[17] then the center-to-center distance between two porphyrin rings was estimated to be 12.8 Å, which was in good agreement with those estimated from Corey-Pauling-Koltun (CPK) molecular models (12.5—13 Å for **22** and **27**).

In summary, the acid-catalyzed intramolecular macrocyclization reaction is particularly useful for the synthesis of strapped porphyrins as well as dimeric and trimeric porphyrins. Use of *o*-alkoxybenzaldehydes as the starting material is also useful for model construction because of their easy preparation, high yield of the porphyrin, sufficient stability of the ether linkage, and the possible separation of the porphyrin atropisomers. Strapped porphyrins synthesized here showed systematic increase of ring distortion on shortening the strap linkage, while "T-shaped" dimeric porphyrins and "H-shaped" trimeric porphyrins had unique geometries. In these dimeric and trimeric porphyrins, there exists no direct π-π conjugation between porphyrin rings, rendering through-bond interactions to be negligibly small. Therefore, these models would be quite useful for studies on through-space electron-transfer process.

Experimental

The ^{1}H NMR spectra were recorded at 400 MHz on a JEOL JNM-GX-400 spectrometer, with tetramethylsilane or $CHCl_3$ as internal reference. All ^{1}H NMR spectra were measured in $CDCl_3$ solution. Mass spectra were recorded on a JEOL JMS-DX-300 instrument (EI, 3 kV). Fast atom bombardment mass spectra were recorded on a JEOL JMS-HX-110 (10 kV) or a JEOL JMS-DX-300 (1.5 kV) with *m*-nitrobenzyl alcohol as the matrix. High-resolution mass spectra of porphyrins were obtained on a JEOL JMS-HX-110 (10 kV) with polyethylene glycol as a standard. UV-vis spectra were recorded in dichloromethane on a Shimadzu UV-200 and a Shimadzu UV-3000 spectrophotometer. Steady-state fluorescence spectra were recorded by using a Shimadzu RF-502a spectrofluorometer. Fluorescence lifetimes were measured on a Horiba NAES 1100. Flash column chromatography was carried out using Wakogel FC-40 or Merck Kieselgel 60HF254 Art. 7739.

Anhydrous acetonitrile was distilled from diphosphorus pentaoxide and stored with Molecular Sieves 3A. Anhydrous acetone was distilled and dried over anhydrous calcium sulfate.

Unless otherwise stated all reactions were performed under an atmosphere of dry nitrogen. All organic extracts were dried over anhydrous sodium sulfate.

Preparation of the Dialdehyde Derivatives. Dialdehydes **2a**, **2b**, **2c**, **2d**, **2e**, **2g**, **2h** and **2i** were prepared according to the published procedure.[10a,18]

C3 Dialdehyde 2e. Colorless needles; mp 94—96 °C; ^{1}H NMR ($CDCl_3$) δ=10.50 (2H, s, CHO), 7.83+7.55+7.03 (2H+2H+4H, dd+m+m, Ar-H), 4.33 (4H, t, OCH_2), 2.43 (2H, m, $OCH_2C\underline{H}_2$). MS(EI) Found: *m/z* 284.1060. Calcd for $C_{17}H_{16}O_4$: M, 284.1049.

XY Dialdehyde 2g. Colorless needles; mp 191 °C. Found: C, 76.01; H, 5.08%. Calcd for $C_{22}H_{18}O_4$: C, 76.28; H, 5.24%. ^{1}H NMR ($CDCl_3$) δ=10.56 (2H, s, CHO), 7.87+7.55+7.49+7.07 (2H+2H+4H+4H, dd+m+s+m, Ar-H), 5.22 (4H, s, OCH_2). MS(EI) *m/z* 346 (M^+), 328 ($M-H_2O$).

XY(OMe)$_2$ Dialdehyde 2h. Dialdehyde **2h** was prepared from 2,5-bis(chloromethyl)-1,4-dimethoxybenzene.[19] Colorless needles; mp 193—5 °C. Found: C, 70.68; H, 5.49%. Caicd for $C_{24}H_{22}O_6$: C, 70.92; H, 5.46%. ^{1}H NMR ($CDCl_3$) δ=10.57 (2H, s, CHO), 7.86+7.56+7.12+7.12+7.06 (each 2H, dd+m+s+d+t, Ar-H), 5.24 (4H, s, OCH_2), 3.84 (6H, s, CH_3). MS(EI) *m/z* 406 (M^+).

AN Dialdehyde 2i. Dialdehyde **2i** was prepared from 9,10-bis(chloromethyl)anthracene.[20] Yellow solid; mp> 190 °C. Found: C, 80.74; H, 5.26%. Calcd for $C_{30}H_{22}O_4$: C, 80.70; H, 4.97%. ^{1}H NMR ($CDCl_3$) δ=10.25 (2H, s, CHO), 8.38+7.60 (4H+4H, m+m, An-H), 7.90+7.70+7.47+7.14 (each 2H, dd+m+d+t, Ar-H), 6.15 (4H, s, OCH_2).

C$_{10}$-Diester Dialdehyde 2f. 1,10-dibromodecane (0.43 g, 1.4 mmol) and 2-formylbenzoic acid (0.50 g, 3.3 mmol) was dissolved in dry acetone (10 ml). Anhydrous potassium carbonate (0.32 g, 2.3 mmol) was added and the mixture was refluxed overnight. After cooling, water (10 ml) was added and acetone was evaporated. The precipitated white solid was filtered, washed with water, and dried. (0.50 g, 1.1 mmol, 80%) mp 73—5 °C. Found: C, 69.52; H, 6.82%. Calcd for $C_{26}H_{30}O_6 \cdot 1/2H_2O$: C, 69.78; H, 6.98%. ^{1}H NMR ($CDCl_3$) δ=10.61 (2H, s, CHO), 7.94+7.63 (4H+4H, m+m, Ar-H), 4.37 (4H, t, OCH_2), 1.76+1.40+1.32 (4H+4H+8H, m+br+br, $OCH_2(C\underline{H}_2)_8CH_2O$). MS(FAB) *m/z* 439 ($M+H^+$).

2,5-Bis[2-(2-formylphenyl)ethyl]-1,4-dimethoxybenzene 2j. 2,5-Bis[2-[2-(methoxycarbonyl)phenyl]ethyl]-1,4-dimethoxybenzene was obtained from 2,5-dimethoxy-1,4-benzenedicarbaldehyde[21] according to the published procedure.[22] (2 steps 46%) The dimethyl ester was converted into the dialdehyde **2j** by lithium aluminium hydride reduction (94%) followed by oxidation with activated MnO_2 (61%) according to the usual procedure. **2j**: Pale yellow needles; mp 142—144 °C. ^{1}H NMR ($CDCl_3$) δ=10.29 (2H, s, CHO), 7.85+7.50+7.35+7.25+6.54 (each 2H, d+t+t+d+s, Ar-H), 3.70 (6H, s, CH_3), 3.26+2.88 (4H+4H, m+m, CH_2CH_2). MS (EI) Found: *m/z* 402.1833. Calcd for $C_{26}H_{26}O_4$: M, 402.1831.

2,2′-Oxybis(benzaldehyde) 2m. To the solution of diphenyl ether (1.0 ml) in dry ether (15 ml), butyllithium (1.6 M solution in hexanes, 12 ml) was added dropwise at 0 °C and the mixture was stirred at room temperature for 2 d.[23] *N,N*-dimethylformamide (3.0 ml) was added dropwise at 0 °C and the solution was stirred for 8 h. The mixture poured into the water, acidified with hydrochloric acid, and extracted with ethyl acetate. The organic layer was washed twice with water, dried, and evaporated. The residue was purified by column chromatography (silica gel, benzene) to give colorless crystals. (0.61 g, 43%) mp 74 °C. Found: C, 74.47; H, 4.53%. Calcd for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%. ^{1}H NMR ($CDCl_3$) δ=10.50 (2H, s, CHO), 7.99+7.58+7.29+6.94 (each 2 H, dd+m+t+d, Ar-H). MS(EI) *m/z* 226 (M^+).

3,3′-Oxybis(benzaldehyde) 2n. 3-Hydroxybenzaldehyde

(5.0 g, 41 mmol), 3-bromobenzaldehyde (5.0 g, 27 mmol), copper (II) oxide (2.9 g) and potassium carbonate (2.8 g) were dissolved in dry pyridine (30 ml) and the solution was refluxed for 20 h.[24] The same work up procedure as described above was carried out to give colorless oil (2.9 g, 47%). Found: C, 74.15; H, 4.32%. Calcd for $C_{14}H_{10}O_3$: C, 74.33; H, 4.46%. ^{1}H NMR ($CDCl_3$) δ=9.98 (2H, s, CHO), 7.67+7.56+7.50+7.32 (each 2H, m+t+m+m, Ar-H). MS (EI) m/z 226 (M^+).

General Procedure for the Synthesis of Strapped Porphyrins. 3,3′-Diethyl-4,4′-dimethyl-2,2′-dipyrrylmethane (**1**)[13] (100 mg, 0.43 mmol) and the dialdehyde **2** (0.22 mmol) were dissolved or suspended in dry acetonitrile (20 ml) under N_2, and to this mixture a catalytic amount of trichloroacetic acid (10 mg) was added. After standing at room temperature for about 5 h, *p*-chloranil (0.3 g, 1.2 mmol) in dry tetrahydrofuran (THF, 10 ml) was added and the mixture was stirred overnight. Porphyrin product was separated on alumina column (activity III) eluting with CH_2Cl_2, and recrystallized from CH_2Cl_2–methanol. Yields are listed in Table 1.

C5 Strapped Porphyrin 3a. ^{1}H NMR ($CDCl_3$) δ=9.79 (2H, s, meso-H), 8.94+7.50+6.73 (2H+4H+2H, dd+m+d, ArH), 3.98+3.82 (4H+4H, m+m, Et), 2.60 (12H, s, Me), 1.70 (12H, t, Et), 0.96+−1.73+−3.49 (4H+4H+2H, t+m+m, $O(C\underline{H}_2)_5O$), −1.27 (2H, br, NH). MS(FAB) Found: m/z 731.4333. Calcd for $C_{49}H_{55}N_4O_2$: M+H, 731.4325.

C10 Strapped Porphyrin 3b. ^{1}H NMR ($CDCl_3$) δ=10.16 (2H, s, *meso*-H), 8.25+7.75+7.46+7.22 (each 2H, dd+m+m+d, ArH), 4.02 (8H, m, Et), 3.68 (4H, t, OCH_2), 2.56 (12H, s, Me), 1.81 (12H, t, Et), 0.55+−0.94+−1.69 (4H+8H+4H, m+m+m, $OCH_2(C\underline{H}_2)_8CH_2O$, −2.33 (2H, br, NH). MS(FAB) m/z 918 ($M+H^+$).

C6 Strapped Porphyrin 3c. ^{1}H NMR ($CDCl_3$) δ=9.93 (2H, s, *meso*-H), 8.87+7.56+6.85 (2H+4H+2H, dd+m+dd, ArH), 4.00+3.89 (4H+4H, m+m, Et), 2.60 (12H, s, Me), 2.29 (4H, t, OCH_2), 1.72 (12H, t, Et), −1.70 (2H, br, NH), −1.85+−2.85 (4H+4H, br+br, $OCH_2(C\underline{H}_2)_4CH_2O$). MS (FAB) Found: m/z 745.4481. Calcd for $C_{50}H_{57}N_4O_2$: M+H, 745.4482.

XY Strapped Porphyrin 3g. ^{1}H NMR ($CDCl_3$) δ=9.74 (2H, s, *meso*-H), 8.95+7.54+6.67 (2H+4H+2H, dd+m+d, ArH), 3.89+3.77 (4H+4H, m+m, Et), 3.42 (4H, s, C_6H_4), 2.92 (4H, s, OCH_2), 2.62 (12H, s, Me), 1.63 (12H, t, Et), −1.36 (2H, br, NH). MS (FAB) Found: m/z 765.4149. Calcd for $C_{52}H_{53}N_4O_2$: M+H, 765.4169.

XY(OMe)$_2$ Strapped Porphyrin 3h. ^{1}H NMR ($CDCl_3$) δ=9.76 (2H, s, *meso*-H), 8.93+7.64+7.07 (2H+4H+2H, dd+m+d, ArH), 3.91 (8H, m, Et), 3.50 (2H, s, $C_6H_2(OMe)_2$), 3.47+2.44 (2H+2H, d+d, J=13 Hz, OCH_2), 2.72+2.57 (6H+6H, s+s, Me), 1.86 (6H, s, OCH_3), 1.82+1.75 (6H+6H, t+t, Et), −2.52 (2H, br, NH). MS (FAB) Found: m/z 825.4351. Calcd for $C_{54}H_{57}N_4O_4$: M+H, 825.4380.

AN Strapped Porphyrin 3i. ^{1}H NMR ($CDCl_3$) δ=9.39 (2H, s, *meso*-H), 8.91+7.67+7.53+6.98 (each 2H, dd+m+t+d, ArH), 6.34+6.11 (4H+4H, m+m, An-H), 4.68 (4H, s, OCH_2), 3.87+3.73 (4H+4H, m+m, Et), 2.66 (12H, s, Me), 1.66 (12H, t, Et), −2.41 (2H, br, NH). MS (FAB) m/z 865 ($M+H^+$).

C10-Diester Strapped Porphyrin 3f. ^{1}H NMR ($CDCl_3$) δ=10.16 (2H, s, *meso*-H), 8.37+7.8 (8H, m, Ar-H), 3.99 (8H, m, Et), 3.31 (4H, t, OCH_2), 2.45 (12H, s, Me), 1.77 (12H, t, Et), −0.28+−0.83+−1.05+−1.18 (each 4H, m+m+br+br, $OCH_2(C\underline{H}_2)_8CH_2O$), −2.19 (2H, br, NH). MS (FAB) Found: m/z 857.5002. Calcd for $C_{56}H_{65}N_4O_4$: M+H, 857.5006.

C4 Dimer 4d. The ^{1}H NMR spectrum of bis-zinc dimer **4d** was broadened and complicated at ambient temperatures. On heating the sample to 100 °C in 1,1,2,2-tetrachloroethane-d_2, the spectrum became sharp and the peak assignment was achieved. **4d**: ^{1}H NMR ($CDCl_2CDCl_2$, at 100 °C) δ=9.67 (s, *meso*-H), 7.64, 7.25—7.14 (each m, Ar-H), 3.73 (m, Et), 3.42 (br, OCH_2), 2.31 (s, Me), 1.56 (t, Et), 0.49 (br, $OCH_2C\underline{H}_2$. MS (FAB) m/z 1558—1563 (M^+). UV-vis (CH_2Cl_2) 408, 538, 575 nm.

C3 Dimer 4e. ^{1}H NMR ($CDCl_3$) δ=9.63 (s, *meso*-H), 7.66+7.41+7.17 (m+m+m, ArH), 3.74(m, Et), 2.25 (s, Me), 1.5 (m, Et). MS (FAB) m/z 1530—1535 (M^+). UV-vis (CH_2Cl_2) 405, 538, 574 nm.

***m*-Oxy Dimer 4n.** ^{1}H NMR ($CDCl_3$) δ=9.46+8.22 (s+s, *meso*-H), 8.12+7.7+7 50 (dd+m+t, ArH), 3.63 (m, Et), 2.17 (s, Me), 1.45 (t, Et). MS (FAB) m/z 1290 ($M+H^+$). UV-vis (CH_2Cl_2) 403, 509, 541, 576, 626 nm.

Preparation of the Iodide 12. 2-(3-Chloropropoxy)-benzaldehyde 10. Salicylaldehyde (4.2 ml, 40 mmol) was added to a solution of potassium hydroxide (85%, 2.6 g, 40 mmol) in ethanol (40 ml) and then 1-bromo-3-chloropropane (4.5 ml, 46 mmol) was added. The mixture was heated under reflux for 10 h and then cooled to 0 °C. The precipitate was filtered off and the filtrate was evaporated. The residue was dissolved in CH_2Cl_2, washed with water, dried and evaporated. Remaining salicylaldehyde and 1-bromo-3-chloropropane were distilled off under reduced pressure to leave colorless oil (7.8 g, 39 mmol, 97%). ^{1}H NMR ($CDCl_3$) δ=10.49 (1H, s, CHO), 7.84+7.55+7.03 (1H+1H+2H, dd+m+m, Ar-H), 4.26+3.38+2.30 (2H+2H+2H, t+t+m, O $(C\underline{H}_2)_3Cl$). MS (FAB) m/z 199 ($M+H^+$).

2-(3-Chloropropoxy)-1-(5,5′-dimethyl-1,3-dioxan-2-yl)-benzene 11. The aldehyde **10** (7.8 g, 39 mmol), 2,2-dimethyl-1,3-propanediol (5.0 g, 48 mmol), and *p*-toluenesulfonic acid monohydrate (0.3 g) were dissolved in benzene (80 ml), and the mixture was heated under reflux. Water was removed using a Dien-Stark apparatus. After 7 h, the mixture was cooled and the organic layer was washed with aqueous sodium hydrogencarbonate, with water, and then evaporated. The residue was purified on silica gel (eluting with benzene–ether) to give colorless oil (9.7 g, 34 mmol, 87%). ^{1}H NMR ($CDCl_3$) δ=7.65+7.29+7.01+6.89 (each 1H, dd+m+t+d, Ar-H), 5.74 (1H, s, ArCH), 4.15 (2H, t, $OC\underline{H}_2CH_2$), 3.76 (4H, m, $OC\underline{H}_2$+$C\underline{H}_2Cl$), 3.66 (2H, d, $OC\underline{H}_2$), 2.26 (2H, m, $C\underline{H}_2CH_2Cl$), 1.32+0.80 (3H+3H, s+s, Me). MS (FAB) m/z 285 ($M+H^+$).

2-(3-Iodopropoxy)-1-(5,5′-dimethyl-1,3-dioxan-2-yl)-benzene 12. The chloride **11** (14.2 g, 50 mmol) and sodium iodide (15 g, 0.1 mol) were dissolved in dry acetone (100 ml) and the mixture was refluxed overnight. After cooling, the precipitate was filtered off and the filtrate was evaporated. The residue was dissolved in CH_2Cl_2, washed with aqueous sodium thiosulfate, with water, dried and evaporated to leave pale yellow oil (17.2 g, 46 mmol, 92%). ^{1}H NMR ($CDCl_3$) δ=7.65+7.29+7.01+6.88 (each 1H, dd+m+t+d, Ar-H), 5.73 (1H, s, ArCH), 4.08 (2H, t, $OC\underline{H}_2CH_2$), 3.76+3.66 (2H+2H, d+d, OCH_2), 3.38+2.30 (2H+2H, t+m, $C\underline{H}_2$-$C\underline{H}_2I$), 1.32+0.80 (3H+3H, s+s, Me). MS (EI) Found: m/z 376.0538. Calcd for $C_{15}H_{21}IO_3$: M, 376.0534.

Synthesis of Trimeric Porphyrin 9. 5,15-Bis(2,6-dihy-

droxyphenyl)etioporphyrin II (6). 5,15-Bis(2,6-dimethoxyphenyl)etioporphyrin II (**5**)[5] (158 mg, 0.21 mmol) in dry CH_2Cl_2 (30 ml) was treated with BBr_3 (0.3 ml) at −78 °C. The mixture was gradually warmed to room temperature and stirred overnight. The mixture was poured into water and extracted with CH_2Cl_2 and then with ethyl acetate. The extract was washed with aqueous sodium hydrogencarbonate, with water, and then evaporated. Recrystallization from CH_2Cl_2–hexane gave purple microcrystals (145 mg, 0.21 mmol, 99%). ^{1}H NMR ($CDCl_3$) δ=10.31 (2H, s, *meso*-H), 7.64+7.00 (2H+4H, t+d, ArH), 4.66(4H, br, OH), 4.05 (8H, q, Et), 2.78 (12H, s, Me), 1.80 (12H, t, Et). MS (FAB) *m/z* 695 ($M+H^+$).

Porphyrin Tetraacetal 7. 5,15-Bis(2,6-dihydroxyphenyl)-etioporphyrin II (**6**, 135 mg, 0.19 mmol), the iodide **12** (2.85 g, 7.6 mmol), and anhydrous potassium carbonate (1.0 g) were dissolved in dry acetone (90 ml) and refluxed for 2 d. After cooling, acetone was evaporated and the residue was dissolved in CH_2Cl_2, washed with water, dried and evaporated. Porphyrin **7** was separated by flash column chromatography (silica gel, CH_2Cl_2) and then recrystallized from CH_2Cl_2–methanol to give purple crystals (140 mg, 0.083 mmol, 44%). ^{1}H NMR ($CDCl_3$) δ=10.06 (2H, s, *meso*-H), 7.72+7.04 (2H+4H, t+d, C_6H_3), 7.43+6.69+6.48 (4H+4H+8H, dd+t+m, C_6H_4), 5.50 (4H, s, ArCH), 4.08+2.82+1.38 (each 8H, t+t+m, $O(C\underline{H}_2)_3O$), 3.82 (8H, q, Et), 3.65+3.51 (8H+8H, d+d, OCH_2), 2.60 (12H, s, β-Me), 1.65 (12H, t, Et), 1.24+0.72 (12H+12H, s+s, acetal-Me), −2.23 (2H, br, NH). MS (FAB) *m/z* 1688 ($M+H^+$).

Porphyrin Tetraaldehyde 8. To a solution of the porphyrin **7** (100 mg, 0.059 mmol) in CH_2Cl_2 (30 ml), trifluoroacetic acid (5 ml) and water (5 ml) were added and the mixture was stirred for 8 h.[14] The mixture was poured into water and extracted with CH_2Cl_2. The extract was washed with aqueous sodium hydrogen carbonate, with water, dried and evaporated. Porphyrin **8** was purified on silica gel (CH_2Cl_2–1% methanol) and recrystallized from CH_2Cl_2–methanol to give purple crystals (**8**(H_2), 74 mg, 0.055 mmol, 92%). ^{1}H NMR ($CDCl_3$) δ=9.98 (4H, s, CHO), 9.96 (2H, s, *meso*-H), 7.78+7.09 (2H+4H, t+d, C_6H_3), 7.29+6.21+5.35+4.18 (each 4H, dd+t+m+d, C_6H_4), 4.12+2.38+1.44 (each 8H, t+t+m, $O(C\underline{H}_2)_3O$), 3.75 (8H, q, Et), 2.60 (12H, s, Me), 1.59 (12H, t, Et), −2.26 (2H, br, NH). MS (FAB) Found: *m/z* 1343.616. Calcd for $C_{84}H_{87}N_4O_{12}$: M+H, 1343.632.

8(Zn): ^{1}H NMR ($CDCl_3$) δ=9.93(2H, s, *meso*-H), 9.39 (4H, s, CHO), 7.79+7.12 (2H+4H, t+d, C_6H_3), 6.89+6.00+5.29+3.95 (each 4H, dd+t+m+d, C_6H_4), 4.12+2.25+1.46 (each 8H, t+t+m, $O(C\underline{H}_2)_3O$), 3.82 (8H, q, Et), 2.61 (12H, s, Me), 1.65 (12H, t, Et). MS (FAB) *m/z* 1404—1409 (M^+).

Trimeric Porphyrin 9. The porphyrin tetraaldehyde **8(Zn)** (14.8 mg, 0.0105 mmol) and dipyrrylmethane **1** (12. 8 mg, 0.056 mmol) were dissolved in dry acetonitrile (10 ml) containing trichloroacetic acid (3.8 mg, 0.023 mmol) and the mixture was stirred for 12 h. *p*-Chloranil (50 mg) in THF (5 ml) was added and stirring was continued overnight. Solvent was evaporated. Trimeric porphyrin **9(H_4Zn)** was separated on alumina (activity III, eluting with CH_2Cl_2) and then on silica gel (CH_2Cl_2–2% methanol). (8.3 mg, 0.0037 mmol, 35%).

9(H_4Zn): ^{1}H NMR ($CDCl_3$) δ=9.58+9.17 (4H+2H, s+s, *meso*-H), 3.63+3.48 (m, Et), 2.19+2.07 (s+s, Me), 1.41+1.30 (t+t, Et). MS (FAB) Found: *m/z* 2244.120. Calcd for the highest peak of $C_{144}H_{153}N_{12}O_8Zn$: M+H, 2244.126 (CsI was used as a standard).

9(Zn_3): ^{1}H NMR ($CDCl_3$) δ=9.56+9.15 (4H+2H, s+s, *meso*-H), 7.62+7.55+7.43+7.15+7.08+6.72 (m, ArH), 3.63+3.45 (m, Et), 2.17+2.06 (s+s, Me), 1.42+1.30 (t+t, Et). MS (FAB) *m/z* 2364—2375 (M^+).

Stepwise Synthesis of Dimeric Porphyrin 4e. α,α-5,15-Bis(2-hydroxyphenyl)etioporphyrin II (13). Strapped porphyrin **3g** (505 mg, 0.66 mmol) was treated with BBr_3 (1 ml) by the same procedure as **6** to give purple microcrystals (400 mg, 0.60 mmol, 91%). ^{1}H NMR ($CDCl_3$) δ=10.26 (2H, s, *meso*-H), 7.75+7.36+7.28 (2H+4H+2H, t+m+m, ArH), 5.6 (2H, br, OH), 4.04 (8H, m, Et), 2.66 (12H, s, Me), 1.81 (12H, t, Et). MS (FAB) *m/z* 663 ($M+H^+$).

Porphyrin Diacetal 14. Porphyrin diacetal **14** was prepared from the porphyrin **13** (200 mg, 0.30 mmol) and the iodide **12** (1.9 g, 5.0 mmol) by the same procedure as **7**. (187 mg, 0.16 mmol, 54%). ^{1}H NMR ($CDCl_3$) δ=10.15 (2H, s, *meso*-H), 7.77+7.46+7.35+6.75+6.56+5.56 (4H+2H+4H+2H+2H+2H, m+dd+m+t+m+d, ArH), 5.53 (2H, s, ArCH), 4.21+2.97+1.56 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 3.96+ 3.85 (4H+4H, m+m, Et), 3.66+3.52 (4H+4H, d+d, OCH_2), 2.53 (12H, s β-Me), 1.72 (12H, t, Et), 1.25+0.72 (6H+6H, s+s, acetal-Me), −2.36 (2H, br, NH). MS (FAB) *m/z* 1160 ($M+H^+$).

Porphyrin Dialdehyde 15. The porphyrin diacetal **14** was hydrolyzed by the same procedure as **8**.

15(H_2): ^{1}H NMR ($CDCl_3$) δ=10.11+10.10 (4H, s+s, CHO+*meso*-H), 7.81+7.39+6.38+5.83+4.71 (4H+6H+2H+2H+2H, m+m+t+m+d, ArH), 4.22+2. 68+1.79 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 3.91+3.84 (4H+4H, m+m, Et), 2.52 (12H, s, Me), 1.69 (12H, t, Et), −2.37 (2H, br, NH). MS (FAB) *m/z* 987 ($M+H^+$).

15(Zn): ^{1}H NMR ($CDCl_3$) δ=10.06 (2H, s, *meso*-H), 9.50 (2H, s, CHO), 7.80+7.39+6.95+6.10+5.72+4.55 (4H+4H+2H+2H+2H+2H, m+m+dd+t+m+d, ArH), 4.23+2.61+1.61 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 4.1—3.8 (8H, m, Et), 2.52 (12H, s, Me), 1.72 (12H, t, Et). MS (FAB) *m/z* 1048—1052 (M^+).

Face-to-Face Dimeric Porphyrin 4e. The porphyrin dialdehyde **15(Zn)** (30.1 mg, 0.029 mmol) was treated with dipyrrylmethane **1** (16 mg, 0.069 mmol) in acetonitrile (6.8 ml) in the presence of trichloroacetic acid (6 mg) followed by oxidation with *p*-chloranil (75 mg) in a similar manner as **9(H_4Zn)** to give the porphyrin dimer **4e(H_2Zn)** (24 mg, 0.016 mmol, 56%). The bis-zinc complex (**4e**) was identical with that prepared in a one-pot procedure.

4e(H_2Zn): MS (FAB) *m/z* 1468—1472 (M^+).

Synthesis of the Aldehyde 19. Methyl 3,5-Bis[3-[2-(5,5-dimethyl-1,3-dioxan-2-yl)phenoxy]propoxy]benzoate 17. Methyl 3,5-dihydroxybenzoate (**16**, 1.50 g, 8.9 mmol), the iodide **12** (7.61 g, 20 mmol), and anhydrous potassium carbonate (1.4 g) were dissolved in dry acetone (60 ml) and refluxed for 2 d. After cooling, acetone was evaporated and the residue was dissolved in CH_2Cl_2, washed with water, dried and evaporated. The methyl ester **17** was purified on silica gel eluting with CH_2Cl_2. Colorless oil (5.0 g, 7.5 mmol, 83%). ^{1}H NMR ($CDCl_3$) δ=7.64+7.27+7.21+7.00+6.88+6.67 (2H+2H+2H+2H+2H+1H,dd+m+d+m+dd+t, ArH), 5.74 (2H, s, ArCH), 4.2+2.28 (8H+4H, m+m, $O(C\underline{H}_2)_3O$), 3.88 (3H, s, OMe), 3.73+3.61 (4H+4H, d+d, OCH_2), 1.29+0.75 (6H+6H, s+s, acetal-Me) MS (FAB) *m/z* 665 ($M+H^+$).

3,5-Bis[3-[2-(5,5-dimethyl-1,3-dioxan-2-yl)phenoxy]-propoxy]benzyl Alcohol 18. The methyl ester **17** (5.0 g, 7.5

mmol) was treated with $LiAlH_4$ (0.56 g) in dry THF (100 ml) at room temperature. The benzyl alcohol **18** was purified on silica gel eluting with CH_2Cl_2. White Solids (3.7 g, 5.8 mmol, 77%). ^1H NMR ($CDCl_3$) δ=7.65+7.28+6.99+6.87+6.51+6.41 (2H+2H+2H+2H+2H+1H, dd+t+t+d+d+t, ArH), 5.74 (2H, s, ArCH), 4.49 (2H, d, $C\underline{H}_2OH$), 4.17+2.26 (8H+4H, t+m, $O(C\underline{H}_2)_3O$), 3.72+3.62 (4H+4H, d+d, OCH_2), 1.88 (1H, t, OH), 1.30+0.76 (6H+6H, s+s, Me). MS (FAB) m/z 637 ($M+H^+$).

3,5-Bis[3-[2-(5,5′-dimethyl-1,3-dioxan-2-yl)phenoxy]-propoxy]benzaldehyde 19. To a suspension of pyridinium chlorochromate (PCC, 0.33 g, 1.5 mmol) and anhydrous sodium acetate (35 mg, 0.42 mmol) in dry CH_2Cl_2, a solution of the benzyl alcohol **18** (0.54 g, 0.85 mmol) in CH_2Cl_2 (25 ml) was added in one portion. After stirring for 2 h, ether (50 ml) was added and the liquid phase was separated by decantation. The residual gummy solids were washed with ether, and the combined liquid phase was passed through a Florisil short column. Evaporation of solvent gave viscous oil (0.47 g, 0.74 mmol, 87%). ^1H NMR ($CDCl_3$) δ=9.87 (1H, s, CHO), 7.65+7.28+7.03+7.00+6.89+6.73 (2H+2H+2H+2H+2H+1H, dd+m+d+m+dd+t, ArH), 5.74 (2H, s, ArCH), 4.20+2.29 (8H+4H, m+m, $O(C\underline{H}_2)_3O$), 3.72+3.61 (4H+4H, d+d, OCH_2), 1.29+0.75 (6H+6H, s+s, Me). MS (FAB) m/z 635 ($M+H^+$).

Synthesis of the "T-Shaped" Dimeric Porphyrin 22. Porphyrin 20. The aldehyde **19** (250 mg, 0.39 mmol), methyl 4-formylbenzoate (128 mg, 0.78 mmol), and dipyrrylmethane **1** (271 mg, 1.18 mmol) were dissolved in dry acetonitrile (22 ml) containing trichloroacetic acid (32 mg, 0.2 mmol) and the mixture was stirred for 15 h. *p*-Chloranil (0.8 g) dissolved in THF (30 ml) was added and stirring was continued overnight. Solvent was evaporated and the residue was purified on alumina (activity III, CH_2Cl_2). The resulting porphyrins were converted to the zinc complexes ($Zn(OAc)_2$ in CH_2Cl_2–methanol) and separated by flash column chromatography (silica gel, CH_2Cl_2).

20: Red crystals (220 mg, 0.17 mmol, 44% based on **19**). ^1H NMR ($CDCl_3$) δ=10.20 (2H, s, *meso*-H), 8.84+8.21 (2H+2H, d+d, $C_6\underline{H}_4CO_2Me$), 7.59+7.30+7.25+6.96+6.91 (2H+2H+2H+3H+2H, dd+d+m+m+d, ArH), 5.71 (2H, s, ArCH), 4.34+4.24+2.35 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 4.13 (3H, s, OMe), 4.01 (8H, m, Et), 3.59+3.51 (4H+4H, d+d, OCH_2), 2.67+2.44 (6H+6H, s+s, β-Me), 1.77 (12H, t, Et), 1.17+0.48 (6H+6H, s+s, acetal-Me). MS (FAB) m/z 1278—1284 (M^+).

Porphyrin Dialdehyde 21. The acetal groups were hydrolyzed under acidic conditions[14] as described for **8** to give porphyrin dialdehyde **21(H)** (99%).

21(H_2): Purple crystals; mp 105—107 °C. ^1H NMR ($CDCl_3$) δ=10.52 (2H, s, CHO), 10.24 (2H, s, *meso*-H), 8.44+8.19 (2H+2H, d+d, $C_6\underline{H}_4CO_2Me$), 7.80+7.51+7.04+6.99 (each 2H, dd+m+d+t, $C_6\underline{H}_4CHO$), 7.28+6.94 (2H+1H, d+t, C_6H_3), 4.36+2.41 (8H+4H, t+t+m, $O(C\underline{H}_2)_3O$), 4.13 (3H, s, OMe), 4.02 (8H, m, Et), 2.60+2.47 (6H+6H, s+s, β-Me), 1.77 (12H, m, Et), −2.44 (2H, br, NH). MS (FAB) m/z 1045 ($M+H^+$).

21(Zn): Red crystals. ^1H NMR ($CDCl_3$) δ=10.34 (2H, s, CHO), 10.20 (2H, s, *meso*-H), 8.44+8.21 (2H+2H, d+d, $C_6\underline{H}_4CO_2Me$), 7.72+7.49+7.01+6.96 (each 2H, dd+m+d+t, $C_6\underline{H}_4CHO$), 7.31+6.95 (2H+1H, d+t, C_6H_3), 4.34+2.40 (8H+4H, t+t+m, $O(C\underline{H}_2)_3O$), 4.13 (3H, s, OMe), 4.01 (8H, m, Et), 2.63+2.44 (6H+6H, s+s, β-Me), 1.77 (12H, m, Et). MS(FAB) m/z 1106—1110 (M^+).

"T-Shaped" Dimeric Porphyrin 22. The porphyrin dialdehyde **21(H_2)** (110 mg, 0.105 mmol) and dipyrrylmethane **1** (58.5 mg, 0.25 mmol) were dissolved in dry acetonitrile (40 ml). Trichloroacetic acid (41 mg, 0.25 mmol) dissolved in dry acetonitrile (1.4 ml) was added and the mixture was stirred for 10 h. *p*-Chloranil (0.18 g) in THF (7 ml) was added and stirring was continued overnight. Solvent was evaporated and the residue was purified on alumina (activity III, CH_2Cl_2), then on silica gel (CH_2Cl_2–2% methanol) and recrystallized from CH_2Cl_2–methanol to give purple microcrystals (82.5 mg, 0.056 mmol, 54%).

22(H_4): Mp >270 °C (decomp). ^1H NMR ($CDCl_3$) δ=10.30+10.10 (2H+2H, s+s, *meso*-H), 8.40+8.13 (2H+2H, d+d, $C_6\underline{H}_4CO_2Me$), 8.32+7.76+7.50+7.2 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 6.36+3.01 (2H+1H, d+t, J=2.4 Hz, C_6H_3), 4.12+3.94+3.87 (8H+4H+4H, m+m+m, Et), 4.11 (3H, s, OMe), 3.77+1.98+1.09 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 2.63+2.41+2.06 (12H+6H+6H, s+s+s, β-Me), 1.87+1.70+1.65 (12H+6H+6H, t+t+t, Et); −2.10+−2.59+ −2.71 (2H+1H+1H, br, NH). MS (FAB) Found: m/z 1463.802. Calcd for $C_{90}H_{103}N_8O_6$: M+H, 1463.800.

The porphyrin dialdehyde **21(Zn)** (14. 4 mg, 0.013 mmol) was treated with dipyrrylmethane **1** (6.7 mg, 0.029 mmol) in the presence of trichloroacetic acid (2 mg, 0.012 mmol) in dry acetonitrile (3.5 ml) as described above to give a monozinc complex **22(H_2Zn)** (6.6 mg, 0.0043 mmol, 33%).

22(H_2Zn): Red crystals. ^1H NMR ($CDCl_3$) δ=10.31+10.06 (2H+2H, s+s, *meso*-H), 8.40+8.14 (2H+2H, d+d, $C_4\underline{H}_6CO_2Me$), 8.32+7.76+7.50+7.2 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 6.37+3.03 (2H+1H, d+t, J=2.4 Hz, C_6H_3), 4.11 (3H, s, OMe), 4.11+3.92+3.85 (8H+4H+4H, m+m+m, Et), 3.77+1.77+1.08 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 2.63+2.38+2.02 (12H+6H+6H, s+s+s, β-Me), 1.87+1.70+1.65 (12H+6H+6H, t+t+t, Et), −2.10 (2H, br, NH.) MS (FAB) m/z 1525—1530 (M^+).

Synthesis of the "H-Shaped" Porphyrin Trimer 27. Dialdehyde 23. The diacetal **17** was hydrolyzed by the same procedure as **8** to give dialdehyde **23**.

White crystals; mp 127 °C. Found: C, 67.81; H, 5.85%. Calcd for $C_{28}H_{26}O_8$: C, 68.28; H, 5.73%. ^1H NMR ($CDCl_3$) δ=10.51 (2H, s, CHO), 7.82+7.53+7.19+7.02+6.66 (2H+2H+2H+4H+1H, dd+m+d+m+t, ArH), 4.29+4.21+2.34 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 3.89 (3H, s, Me). IR (KBr) 1705 and 1680 cm^{-1} (C=O). MS(FAB) m/z 493 ($M+H^+$).

Strapped Porphyrin 24. The strapped porphyrin **24** was prepared from the dialdehyde **23** in 41% yield. ^1H NMR ($CDCl_3$) δ=9.88 (2H, s, *meso*-H), 8.21+7.78+7.48+7.34 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 6.54+2.99 (2H+1H, d+t, J=2 Hz, $C_6\underline{H}_3CO_2Me$), 4.06 (3H, s, OMe), 4.01—3.82 (12H, m, Et+$OC\underline{H}_2$), 2.57 (12H, s, β-Me), 1.75 (12H, t, Et), 1.56+1.22 (4H+4H, t+m, $OC\underline{H}_2C\underline{H}_2$), −2.51 (2H, br, NH). IR (KBr) 1718 cm^{-1} (C=O). MS (FAB) m/z 911 ($M+H^+$).

Strapped Porphyrin 25. The strapped porphyrin **24** (204 mg, 0.22 mmol) was treated with $LiAlH_4$ (120 mg, 3.2 mmol) in dry THF (80 ml) at room temperature for 4 h. The strapped porphyrin **25** was purified by flash column chromatography (silica gel, CH_2Cl_2) and recrystallized from CH_2Cl_2–methanol (196 mg, 0.22 mmol, 99%). ^1H NMR ($CDCl_3$) δ=9.95 (2H, s, *meso*-H), 8.24+7.78+7.48+7.33 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 5.43+2.99 (2H+1H, d+t, J=2 Hz, $C_6\underline{H}_3$), 4.00—3.86 (12H, m, Et+$OC\underline{H}_2$), 3.79 (2H, br, $C\underline{H}_2OH$), 2.56 (12H, s, Me), 1.76 (12H, t, Et), 1.58+1.24

(4H+4H, t+m, $OC\underline{H}_2C\underline{H}_2$), −2.49 (2H, br, NH). MS (FAB) m/z 883 ($M+H^+$).

Strapped Porphyrin 26. To a suspension of activated MnO_2 (1.2 g) in $CHCl_3$ (methanol free, 15 ml), a solution of the strapped porphyrin **25** (196 mg, 0.22 mmol) in $CHCl_3$ (methanol free, 70 ml) was added dropwise and the mixture was refluxed for 2 d.[15] Solid material was filtered off, washed with $CHCl_3$ and the filtrate was evaporated. The residue was recrystallized from CH_2Cl_2–methanol to give purple microcrystals (162 mg, 0.18 mmol, 83%). ^1H NMR ($CDCl_3$) δ=9.88 (2H, s, *meso*-H), 9.61 (1H, s, CHO), 8.17+7.78+7.47+7.35 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 6.02+3.22 (2H+1H,d+t, J=2 Hz, C_6H_3CHO, 4.0—3.8 (12H, m, Et+$OC\underline{H}_2$), 2.56 (12H, s, β-Me), 1.75 (12H, t, Et), 1.71+1.26 (4H+4H, t+m, $OC\underline{H}_2C\underline{H}_2$), −2.57 (2H, br, NH). IR (KBr) 1700 cm^{-1} (C=O). MS (FAB) m/z 881 ($M+H^+$).

"H-Shaped" Trimeric Porphyrin 27. The strapped porphyrin **26** was treated with dipyrrylmethane **1** to give "H-shaped" trimeric porphyrin **27(H$_6$)** in 59% yield.[6] Purple crystals; mp >300 °C. ^1H NMR ($CDCl_3$) δ=10.28+9.95 (4H+2H, s+s, *meso*-H), 8.31+7.75+7.49+7.25 (each 2H, dd+m+t+d, $C_6\underline{H}_4O$), 6.30+2.97 (4H+2H, d+t, J=2. 4 Hz, C_6H_3), 4.09+3.79 (8H+8H, m+m, Et), 3.74+1.95+1.06 (each 4H, t+t+m, $O(C\underline{H}_2)_3O$), 2.61+2.00 (12H+12H, s+s, Me), 1.84+1.57 (12H+12H, t+t, Et), −2.14+−2.91 (4H+2H, br+br, NH). MS (FAB) m/z 2181.6 ($M+H^+$).

This work was partially supported by the Grant-in-Aid for Scientific Research No. 02102005 from the Ministry of Education, Science and Culture and Nissan Science Foundation, and Kurata Research Grant. We thank Professor I. Yamashina of Kyoto Industrial University for measurement of high-resolution mass spectra.

(Received November 9, 1990)

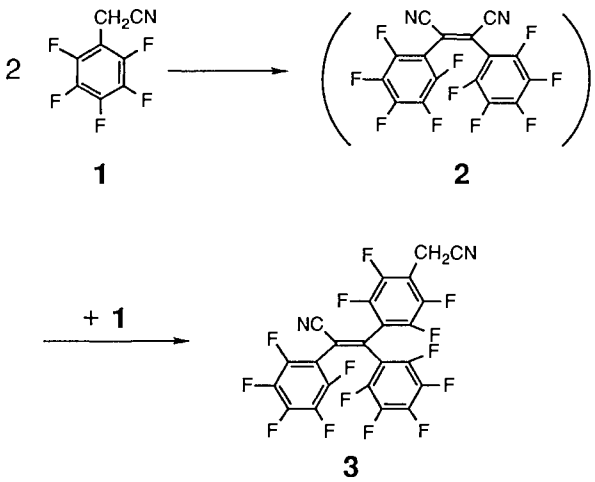
(*E*)-2,3-Bis(2,3,4,5,6-pentafluorophenyl)-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)phenyl]acrylonitrile (**3E**) was synthesized. A benzene solution of **3E** turns into a brilliant red color by the addition of aliphatic amines. The coloration mechanism is studied by optical absorption, conductivity and product analyses. It has become apparent that ion-pair formations between **3E** and the amines by proton transfer reactions are responsible for the coloration. Structural requirements of the amines for the ion-pair formation are discussed.

Molecular complexes of macrocyclic polyethers have been utilized in various directions, such as selective extraction, separation and transport of guest molecules, phase transfer catalyses or models of vital systems.[1-6] In spite of such explosive development of host-guest complexes, much less attention has been paid to ion-pair complexes.[7,8]

The ion-pair formation in less polar solvents via an intermolecular proton transfer is also expected to be useful for recognition of ionizable molecules, such as amines. In the present study, we studied structural requirements for the ion-pair formation by using (*E*)-2,3-bis(2,3,4,5,6-pentafluorophenyl)-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)phenyl]acrylonitrile (**3E**) as a proton donating molecule. The compound **3E** formed ion-pair complexes with various amines in organic solvents along with a brilliant red coloration. The ion-pair formation depends on the structure of the amines and the nature of the solvents. The association constants (K_a) for the formation of ion-pair complexes between **3E** and various amines have been determined to reveal what factors control the complex formation.

Results and Discussion

Synthesis. (*E*)-2,3-Bis(2,3,4,5,6-pentafluorophenyl)-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)phenyl]acrylonitrile **3E** was prepared by a self-coupling reaction of two 2,3,4,5,6-pentafluoro-1-(cyanomethyl)benzenes (**1**) followed by replacement of a cyano group by another molecule of **1**. The reaction process is presumed as follows.[9,10]



Scheme 1.

Isolation of the intermediate **2** was failed. The self coupling product **2** and the active fluorine atom at 4 position of **1** is considered to react easily each other to produce **3**.[11,12] Compound **3** was a chief product and a very small amount of by-product was prepared by further replacement of a cyano group of **3** by another molecule of **1**.[22] Compound **3** was obtained as a mixture of *E*/*Z* isomer whose assignment was performed based on ^{19}F NMR spectra. The mixture was dissolved in benzene and exposed to ultraviolet light (280 nm). The *Z* form was efficiently converted to *E* form by the irradiation. The *E* form was isolated by high-performance liquid chromatography and purified by recrystallization from a benzene-hexane mixture. The structure of the product was determined on the basis of mass spectra, NMR spectra, and material analysis whose data are presented in the experimental section. This material was used for further experiments.

Formation of Ion-Pair Complexes and Absorption Spectral Changes. The absorption spectra of (*E*)-2,3-bis(2,3,4,5-pentafluorophenyl)-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)phenyl]acrylonitrile (**3E**) in 300—650 nm region were measured at 20 °C in benzene solution in the absence and presence of various amines.

Figure 1 shows a typical absorption spectral change of a dilute benzene solution of **3E** ($[\mathbf{3E}]_0=3.4\times10^{-5}$ mol dm^{-3}) by the addition of Et_2NH. The benzene solution turns red in the presence of small amount of Et_2NH. An absorption maxima is observed at about 500 nm. The maximum gradually shifts to 503 nm with increasing the amount of Et_2NH.[13,14] An isosbestic point is observed at 305 nm in the absorption spectrum.

The absorption spectrum maintained a constant

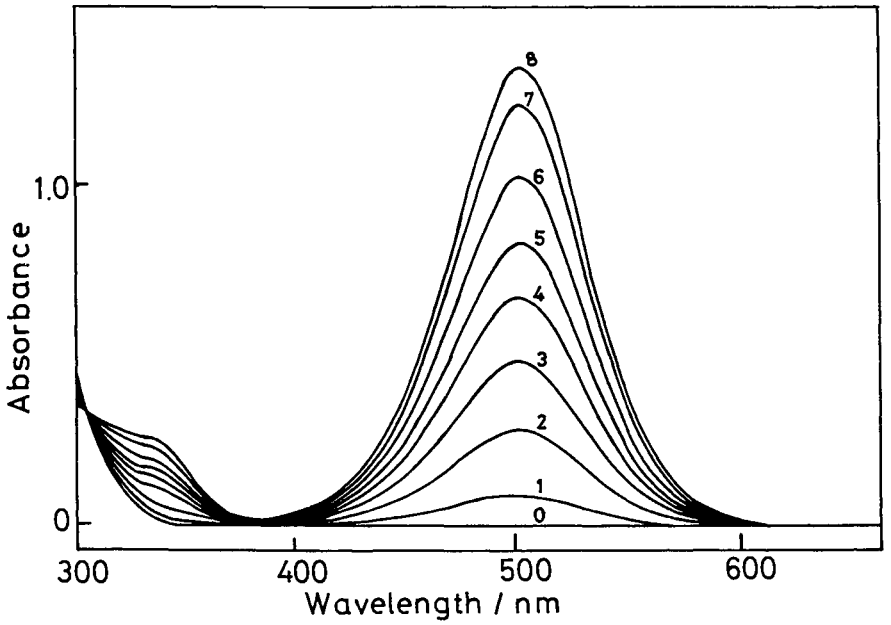


Fig. 1. Absorption spectral change of the benzene solution of **3E** (3.4×10^{-5} mol dm^{-3}) by the addition of Et_2NH.
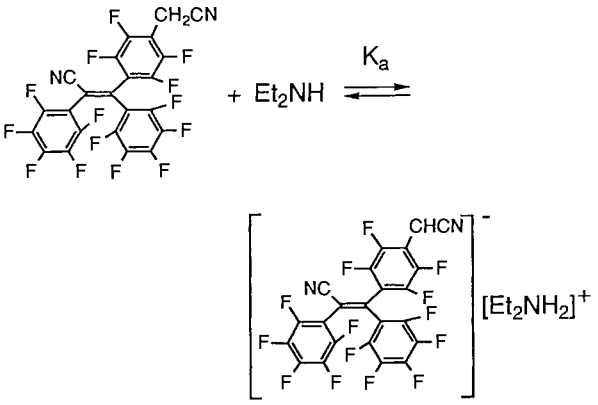
[Et_2NH]: (0) 0, (1) 3.4×10^{-2}, (2) 6.8×10^{-2}, (3) 1.0×10^{-1}, (4) 1.4×10^{-1}, (5) 1.7×10^{-1}, (6) 2.4×10^{-1}, (7) 3.4×10^{-1}, and (8) 5.1×10^{-1} mol dm^{-3}.

intensity, so far the solution being stored in the dark at room temperature. The addition of H^+ (H_2SO_4, HCl) to the reaction mixture decreased the absorption intensity and the initial colorless solution was obtained. The absorption spectrum of 2,3,4,5,6-pentafluoro-1-(cyanomethyl)benzene (**1**) was not affected by the addition of amines. These results suggest that the absorption observed at around 500 nm is ascribable to the ion-pair complex of **3E** with the amine by proton transfer, as shown right.



Bazavluk et al.[8] reported a similar ion-pair formation for heptafluoro-2-naphthol and aliphatic amines system in undecane.

Table 1. Association Constants, Molar Absorption Coefficients and Absorption Maxima of the Complexes of **3E** with Amines in Benzene Solution

Entry	Amine	K_a	$10^4\varepsilon$	λ_{max}
		mol dm^{-3}	$dm^3\,mol^{-1}\,cm^{-1}$	nm

a) In CH_2Cl_2. b) In hexane. c) Not observed.

Association Constants Measurements. The association constants and the molar absorption coefficients of the complexes of **3E** with various amines ($[\mathbf{3E}]_0 = 2.2\times10^{-5}$ mol dm^{-3}) are shown in Table 1. These values were determined by using the UV-vis spectrophotometric method.[15,16]

Table 1 also gives the position of the absorption peaks for the ion-pair complexes of **3E** and various amines.

With some exceptions K_a values increases with increasing λ_{max} and exhibit approximately linear relationships.

Aromatic amines, such as aniline and pyridine do not make ion-pair complexes with **3E**. This is possibly due to the low basicity. The association constant has a tendency to decrease in the order: primary > secondary > tertiary amines. This order agrees with the observation for the charge transfer complex formations.[17,18] Primary amines, n-$PrNH_2$ and n-$BuNH_2$, have large association constants, which are around twice the corresponding secondary amines. Among the secondary amines, Et_2NH has an extraordinary large association value, which is 5 times larger than the values of n-Pr_2NH and n-Bu_2NH. A simple steric hindrance explanation[19,20] that large alkyl groups prohibit the close approach of the amines to **3E** can not be applied to the present system, because the large association constant is observed for cyclohexylamine and the value of Et_3N is close to the values of n-Pr_2NH and n-Bu_2NH. The large value for Et_2NH and cyclohexylamine suggests that **3E** has a site which recognizes the difference in the shape between cyclohexylamine and n-Pr_2NH, and the site favorably accepts Et_2NH. Such a steric requirement to allow close approach is considered to play an important role in the proton transfer process.

The association value is also dependent on the solvent polarity. The value increases with the increases in the solvent polarity. It is worthwhile to note that along with the increases in the association constants the difference in the values between Et_2NH and n-Pr_2NH decreases in polar CH_2Cl_2. In polar solvents, large stabilization in the ion-pair states possibly diminishes the energy barrier difference in the recognition process.

Coloration Mechanism. In order to confirm the ion-pair mechanism for the coloration, we measured conductivity[21] of CH_2Cl_2 solution containing **3E** and Et_2NH.

Figure 2 shows the conductivity change of a dilute CH_2Cl_2 solution of **3E** by the addition of Et_2NH (a) and the change of the optical density at λ_{max} (510 nm) of the same solution (b). Addition of Et_2NH increased the absorption intensity along with the increases in the conductivity. Although slight increase in the conductivity is observed even in the absence of **3E**, the value is much smaller than the value in the presence of **3E**. Both the conductivity value and the intensity of

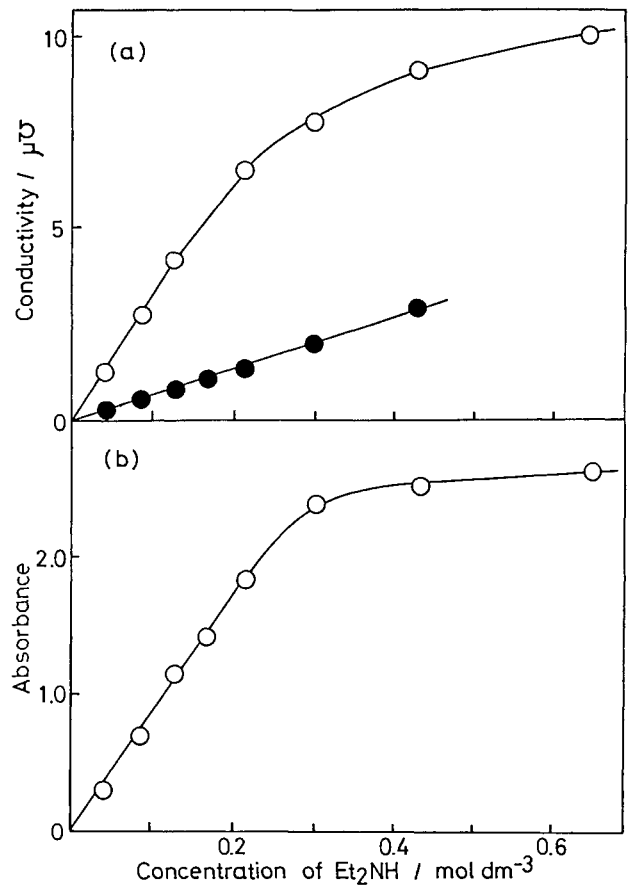

Fig. 2. (a) Conductivity change of **3E**-Et_2NH system in CH_2Cl_2.
(○), with **3E** (4.3×10^{-5} mol dm^{-3}); (●), without **3E**.
(b) Absorption intensity change of **3E**-Et_2NH system in CH_2Cl_2 at 510 nm.

the absorbance showed a saturation behavior above 0.3 mol dm^{-3} of amine. The good correlation between the conductivity and the absorption intensity clearly indicates that the coloration is due to the formation of ion-pair between **3E** and the amine.

Product analysis also supported the ion-pair formation. The colored form was quenched in CH_2Cl_2 by deuterium chloride and then **3E** was analyzed. One of the cyano methyl protons of **3E** was found to be replaced by a deuterium atom.[22] Addition of deuterium chloride to a colorless benzene solution of **3E** does not led to the exchange reaction of a deuterium and proton atom.[22] These are unambiguous evidence that a proton is transferred from CH_2CN group of **3E** to the amine in the formation of ion-pair complex.[23-25]

The compound **3E** also interacts with many compounds with basic nature to produce red colored solutions, such as ethers, THF, or alcohols. When **3E** in solid state was placed in the THF vapor, the solid turned to red. By evacuating THF from the solid, the solid again returned to colorless state. It was possible to repeat the coloration/decoloration cycles many

times.

Experimental

IR spectra were measured with a Shimadzu IR-408 spectrophotometer. ^{1}H NMR spectra (360 MHz) and ^{13}C NMR spectra (91 MHz) were recorded in $CDCl_3$ with a Bruker WN-360 instrument. All chemical shifts are reported in parts per million (δ) downfield from internal tetramethylsilane. ^{19}F NMR were recorded on a Bruker WN-360 instrument at 339 MHz and are reported in ppm from internal trichlorofluoromethane. Mass spectra and elemental analyses were performed in the Material Analysis Center of Osaka University. HPLC analysis was performed on a JASCO 800 system. Absorption spectra were measured with a Shimadzu MPS-200 instrument. Photoisomerization was performed by a mercury lamp (Ushio, 1 kW), associated with a monochrometer (Jobin Yvon H10-UV) and filters (agueous solution of $CuSO_4$ and Toshiba UV-28 glass filter), as a light source. Ion-pair complex formation constants (association constant) (K_a) were determined by using the UV-vis spectrophotometric method.[15,16] K_a and molar absorption coefficients (ε) of the complexes are obtained from the plots of $[\mathbf{3E}]_0[\mathbf{Amine}]_0/OD$ values vs $[\mathbf{Amine}]_0$ values.

$$\frac{l[\mathbf{3E}]_0[\mathbf{Amine}]_0}{OD}=\frac{1}{\varepsilon}[\mathbf{Amine}]_0+\frac{1}{\varepsilon K_a}$$

In the equation, OD is the optical density of the solution and l is the cell width (1 cm). Conductivities were measured at 20 °C using a autobalance universal bridge (WAYNE KERR B642). The solvent was CH_2Cl_2 which was dried with phosphorus pentoxide and distilled from potassium carbonate.

Reversible coloration of **3E** in solid state with THF was performed as follows. Compound **3E** adsorbed on the surface of a silica-gel plate was placed in the THF vapor until the red color was attained. The coloration time was less than few second. Then, upon the adsorbed THF gas was released by heated weakly, the red color disappeared and initial colorless **3E** was restored. It also took less than few second. The coloration/decoloration cycles was repeated.

Materials. All amines were obtained commercially and were purified by distillation.

2,3,4,5,6-Pentafluoro-1-(Cyanomethyl)benzene (1).[26,27] NaCN (9.2 g, 0 19 mol) and tetrabutylammonium chloride (0.108 g, 0.39 mmol) was dissolved in 32.8 mL of water. To this solution was added 2,3,4,5,6-pentafluoro-1-(bromomethyl)benzene (10.0 g, 38 mmol) in 32.8 mL of THF, and stirred for 10 min. The reaction mixture was poured into water and then the product was extracted with ether. Removal of the ether and distillation of the residual under vacuum gave 5.0 g of 2,3,4,5,6-pentafluoro-1-(cyanomethyl)-benzene. 63% yield; bp 101 °C; ^{1}H NMR ($CDCl_3$) δ=3.71 (s); ^{13}C NMR ($CDCl_3$) δ=104.17—104.69, 114.38, 135.70—136.21, 139.50—139.85, 143.03—143.55, 146.83—146.94; ^{19}F NMR ($CDCl_3$) δ=−160.73 (m, 2F), −152.51 (m, 1F), −141.65 (m, 2F); IR (KBr) 2260 cm^{-1} (-CN). MS (EI) m/z (rel intensity) 207 (M^+, 100), 188 (M^+−F, 35), 181 (M^+−CN, 28). Found: C, 46.40; H, 0.97; N, 6.76; F, 45.87%. Calcd for $C_8H_2N_1F_5$: C, 46.64; H, 0.87; N, 6.52; F, 45.75%.

(*E*)-2,3-Bis(2,3,4,5,6-Pentafluorophenyl)-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)phenyl]acrylonitrile (3E).[9,10] To 2.9 mL of 50% NaOH aqueous solution containing tetrabutylammonium bromide (0.195 g, 0.6 mmol) was added, over a period 0.5 h a mixture of 2,3,4,5,6-pentafluoro-1-(cyanomethyl)benzene (**1**) 3 g (14.5 mmol) and CCl_4 2.25 mL (23.3 mmol) at 40 °C. The solution was stirred for 1.5 h at 45 °C. Then, the reaction mixture was poured into water. The aqueous solution was extracted with $CHCl_3$, and the organic phase was dried over $MgSO_4$. After the solvent was removed, the mixture of *E* and *Z* forms of 2,3-Bis[2,3,4,5,6-pentafluorophenyl]-3-[2,3,5,6-tetrafluoro-4-(cyanomethyl)-phenyl]acrylonitrile was obtained in 4.7% yield by column chromatography on silica gel using THF/hexane (1 : 1) and then benzene as the eluting solvent. The *Z*/*E* mixture was dissolved in benzene and exposed to ultraviolet light (280 um). The *Z* form converted to *E* form by the irradiation. The *E* form (**3E**) was separated by HPLC[28] and then purified by recrystallization from a benzene–hexane mixture. The compound **3E** was obtained in 4% yield; mp 135 °C; ^{1}H NMR ($CDCl_3$) δ=5.83 (s); ^{19}F NMR ($CDCl_3$)[29] δ=159.60 (m, 2F), −159.28 (m, 2F), −149.84 (m, 1F), −148.90 (m, 1F), −139.75 (m, 2F), −139.46 (m, 2F), −138.80 (m, 2F), −134.18 (m, 2F). MS (EI) m/z (rel intensity) 572 (M^+, 100), 405 (M^+−C_6F_5, 14); IR (KBr) 2240 cm^{-1} (-CN). Found: C, 48.02; H, 0.52; N, 4.94%, Calcd for $C_{23}H_2N_2F_{14}$: C, 48.27: H, 0.35; N, 4.90; F, 46.48%.

Polymerization Mechanism of Styrene Initiated by 2,2-Bis(*t*-butyldioxy)alkanes

Yasumasa WATANABE, Hideyo ISHIGAKI, Hiroshi OKADA, and Shuji SUYAMA*
Chemicals and Explosives Research Laboratory, Nippon Oil & Fats Co.,
Taketoyo-cho, Chita-gun, Aichi 470-23
(Received November 20, 1990)

The radical polymerization mechanism of styrene initiated by 2,2-bis(*t*-butyldioxy)alkanes (**1**) has been studied in benzene. The decomposition products of **1** are acetone, alkyl methyl ketone, *t*-butyl alcohol, and *t*-butyl peracetate. Styrene monomer converts to polystyrene along with styrene oxide. The peroxides **1** cleave homolytically at one of dioxy bonds to yield intermediate alkoxyl radicals with α-*t*-butyldioxyl group, which undergo β-scission to afford *t*-butyldioxyl or alkyl radicals. The resulting *t*-butyldioxyl radical reacts with styrene to form 2-(*t*-butyldioxy)-1-phenylethyl radical, which decomposes subsequently to styrene oxide and *t*-butoxyl radical via γ-scission. Alternatively, a part of *t*-butyldioxyl radical adds to styrene to afford polystyrene containing dioxy bond.

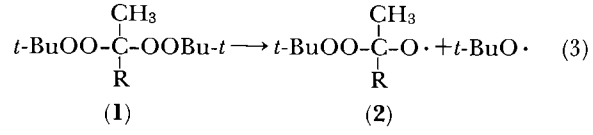
gem-Bis(*t*-alkyldioxy)alkanes can be used as excellent free radical initiators for polymerization of styrene. But only a few studies have been reported on the mechanism of polymerization using them.

Yenal'ev and co-workers[1,2] studied the polymerization of styrene with *gem*-bis(*t*-alkyldioxy)alkanes. Interestingly, they found that parts of polystyrene molecules possessed dioxyl group. It was concluded that the initial decomposition of the peroxides occurred at one of dioxy bonds (Eq. 1) rather than the synchronous two bond scission (Eq. 2), and suggested that the polystyrene molecules containing dioxyl groups were produced by the addition of the alkoxyl radical having dioxyl group to styrene. However, the detailed polymerization mechanism has not been clear.

$$\mathrm{ROOMOOR} \longrightarrow \mathrm{RO}\cdot + \cdot\mathrm{OMOOR} \quad (1)$$

$$\mathrm{ROOMOOR} \longrightarrow 2\mathrm{RO}\cdot + \cdot\mathrm{OMO}\cdot \quad (2)$$

Recently we have reported on the mechanism of thermal decomposition of 2,2-bis(*t*-butyldioxy)alkanes (**1**) in diphenylmethane or cumene.[3,4] The results have shown that the peroxides cleave homolytically at one of dioxy bonds to yield *t*-butoxyl and intermediate alkoxyl radicals (**2**) with α-*t*-butyldioxyl group (Eq. 3), which undergo β-scission to afford *t*-butyldioxyl or alkyl radicals.

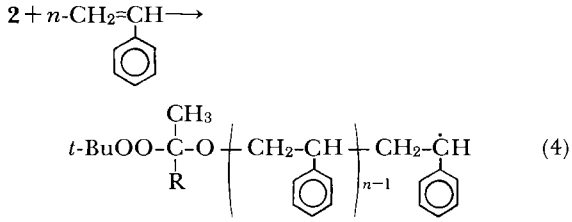


(3)

(**1**) (**2**)

(**1a**): R=CH_3, (**1b**): R=CH_2-CH_3, (**1c**) R=$CH(CH_3)_2$

In the polymerization of styrene using **1**, if the addition reaction of **2** to styrene occurs much faster than the β-scission of **2**, the polymer radical with *t*-butyldioxyl end group would be formed as suggested by Yenal'ev and co-workers (Eq. 4). The terminal dioxyl group of the resulting polymer would further



(4)

cleave at O–O bond and reinitiate the polymerization of styrene, i.e., the peroxides **1** would act as bifunctional initiators. Alternatively, if the β-scission of **2** occurs much faster than the addition of **2** to styrene, radicals generated by β-scission of **2** would initiate the polymerization of styrene.

In the present paper we report the study on the polymerization of styrene using 2,2-bis(*t*-butyldioxy)-alkanes **1** in order to elucidate the initiation mechanism forcusing on the facile β-scission of radicals from **2**.

Experimental

GLC analysis was performed with a Shimadzu GC-9A gas chromatograph with a flame ionization detector by using a 15 m flexible fused silica capillary column (0.53 mm in diameter) coated with silicone OV-1. A Shimadzu Chromatopac C-R6A integrator was used for quantitative analysis. Mass spectra were obtained on a JEOL JMS-DX300 mass spectrometer at 70 eV under electron impact condition. GPC analysis was accomplished on a Shimadzu CTO-6A equipped with a Shimadzu RID-6A using THF as the eluent. Two columns, a Shodex KF-80M (60 cm) and a Shimadzu HSG-10S (60 cm) were connected in series. The calibration curve was made using standard samples of polystyrene.

Materials. 2,2-Bis(*t*-butyldioxy)alkanes were prepared by the methods previously described.[4] The purities of peroxides were over 97.0% by iodometric titration or GLC analysis. Styrene was washed with 2% aqueous sodium hydroxide and water, dried over anhydrous $MgSO_4$, and distilled under reduced pressure. Cumene was purified by distillation after washing with concentrated sulfuric acid.

Polymerization and Thermolysis. Radical polymeriza-

tions of styrene with peroxides were carried out in a sealed-glass ampoule in benzene at 110 °C. After polymerization for a given time, the molecular weight of polystyrene was determined by GPC analysis and reaction products were analyzed by GLC and/or GC-MS in comparison with authentic samples.

Thermolyses of **1** were carried out in cumene under the same conditions as those of polymerization, and reaction products were analyzed by GLC and/or GC-MS.

Determination of Active Oxygen. After polymerization, the content of the ampoule was poured into large amount of methyl alcohol to isolate the polymer. The resulting polymer was purified by two reprecipitations with methyl alcohol and dried in vacuum at room temperature to constant weight. A weighed amount of the purified polystyrene was added to isopropyl alcohol containing acetic acid, sodium carbonate, and potassium iodide. After boiled for 5 min, 36% hydrochloric acid was added to the mixture and boiled further for 3 min. Then the liberated iodine was titrated with aqueous sodium thiosulfate solution.

Results and Discussion

The thermal decomposition of **1** was carried out in cumene under nitrogen. The products obtained by the decomposition were acetone, alkyl methyl ketone, *t*-butyl alcohol, *t*-butyl hydroperoxide, *t*-butyl peracetate (**3**), *t*-butyl 1-methyl-1-phenylethyl peroxide, and 2,3-dimethyl-2,3-diphenylbutane (Table 1A). A likely scheme leading to the products in cumene is shown by following equations. Here, R'H denotes cumene

$$2 \longrightarrow \underset{(\mathbf{3})}{CH_3\text{-}C(=O)OBu\text{-}t} + R\cdot \quad (5)$$

$$2 \longrightarrow CH_3\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_3 + t\text{-}BuOO\cdot \quad (6)$$

$$t\text{-}BuO\cdot + R'H \longrightarrow t\text{-}BuOH + R'\cdot \quad (7)$$

$$t\text{-}BuO\cdot \longrightarrow CH_3\text{-}\overset{O}{\overset{\|}{C}}\text{-}CH_3 + CH_3\cdot \quad (8)$$

$$t\text{-}BuOO\cdot + R'H \longrightarrow t\text{-}BuOOH + R'\cdot \quad (9)$$

$$t\text{-}BuOO\cdot + R'\cdot \longrightarrow t\text{-}BuOOR' \quad (10)$$

$$R'\cdot + R'\cdot \longrightarrow R'\text{-}R' \quad (11)$$

and R'-R' is 2,3-dimethyl-2,3-diphenylbutane. As shown in Eq. 3, the O-O homolysis of **1** produces *t*-butoxyl radical and 1-*t*-butyldioxy-1-methylalkoxyl radical (**2**). The resulting alkoxyl radical **2** undergoes β-scission to afford *t*-butyl peracetate (**3**) and alkyl methyl ketone (Eqs. 5 and 6). *t*-Butyl alcohol and acetone are formed by a hydrogen abstraction of *t*-BuO· from solvent cumene (Eq. 7) and scission of methyl radical from *t*-BuO· (Eq. 8). *t*-BuOO· generated by Eq. 6 undergoes a hydrogen abstraction to afford *t*-BuOOH (Eq. 9) or a coupling reaction with R'· to afford *t*-BuOOR' (Eq. 10). Another coupling reaction of R'· affords R'-R' (Eq. 11).

It is noted that the yield of **3** in cumene changes dramatically with the structure of **1** (i.e., **1a** $\ll$ **1b** $\lesssim$ **1c**). As shown by the previous report,[4] this result can be explained by the difference in elimination rates of alkyl radicals from **2** (i.e., Me < Et < *i*-Pr).

The polymerization of styrene using **1** was carried out in benzene. The liquid products in the reaction were acetone, alkyl methyl ketone, *t*-butyl alcohol, **3**, and styrene oxide (Table 1B). It is worth to note that the yields of **3** obtained in the polymerization of styrene are very close to those obtained in cumene. The result indicates that the addition reaction of **2** to styrene (Eq. 4) is negligibly slow in comparison with the scission reaction of **2**. If Eq. 4 occurs faster than Eq. 5 or 6, the yields of **3** formed in the styrene polymerization shoud be reduced appreciably compared to those of **3** formed in cumene.

The difficulty in addition reaction of **2** to styrene is quite interesting since the analogous alkoxyl radical, *t*-BuO·, is well known to react with styrene easily. For example, Solomon and co-workers[5] showed that the relative rate of β-scission of *t*-BuO· vs. addition reaction to styrene in benzene at 60 °C was 0.11, revealing the facile addition reaction. The difference in reactivity between *t*-BuO· and **2** is explained mainly

Table 1. Products on Decomposition of **1**[a]

Peroxide	Product yield[b]/%							
	Me_2CO	RCOMe	*t*-BuOH	*t*-BuOOH	$MeCO_3Bu$-*t*	*t*-BuOOR'	R'-R'	Epoxide[c]
	A) Decomposition in cumene							
1a	44	[d]	51	19	16	46	44	
1b	30	7	56	<1	61	9	82	
1c	35	3	71	<1	70	2	73

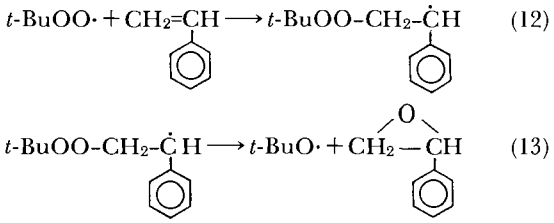
1a	67	[d]	18	<1	17			21
1b	25	8	17	<1	66			2
1c	29	1	28	<1	69			2

a) Decomposition was carried out at 110 °C. Initial concentration: $[\mathbf{1}]_0$=0.1 mol dm^{-3}. Reaction time: **1a**, 4 h; **1b**, 2 h; **1c**, 1 h. b) Yields of products: [(moles of prducts)/(moles of **1** consumed)]×100. The conversion of **1** was 30—40%. R: **1a**=CH_3, **1b**=CH_2-CH_3, **1c**=$CH(CH_3)_2$. Me=CH_3, R'=$C_6H_5C(CH_3)_2$. c) Styrene oxide. d) RCOMe=Me_2CO. e) Styrene/benzene=50 v/v%.

on the basis of the difference in scission rates of radicals from alkoxyl radical. We have recently shown that relative rates of β-scission of radicals from **2** in cumene at 100 °C are isopropyl : ethyl : *t*-butyldioxyl : methyl=133 : 33 : 7 : 1.[4] This result indicates that the β-scission reaction of **2** occurs much faster than that of *t*-BuO· having only methyl groups.

Considerable amounts of acetone and *t*-butyl alcohol were obtained even in styrene/benzene, e.g., for the case of **1b**, the yields were 25% and 17%, respectively. The result indicates that β-scission and hydrogen abstraction reactions of *t*-BuO· occur comparably to the addition reaction of *t*-BuO· to styrene under the present conditions (i.e., at 110 °C). Here, polystyrene produced in the polymerization may be considered as a hydrogen donor. Niki and Kamiya[6] reported the reactivity of polystyrene toward *t*-BuO· and showed that an appreciable amount of *t*-butyl alcohol was obtained by the hydrogen abstraction from polystyrene at relatively high temperature (125 °C). Peroxides **1** are also considered as hydrogen donors. But we have previously showed that the induced decomposition of **1** is negligible in diphenylmethane[3] or cumene.[4] It suggests that the hydrogen abstraction from **1** by *t*-BuO· is a minor reaction, if any, under these conditions.

Interestingly, appreciable amount of styrene oxide (21%) was obtained in the polymerization of styrene with **1a**. The formation mechanism of styrene oxide can be explained by radical epoxidation of styrene by dioxyl radical:[7] *t*-BuO· adds to styrene to produce 2-(*t*-butyldioxy)-1-phenylethyl radical (Eq. 12), which decomposes subsequently to styrene oxide and *t*-BuO· by γ-scission process (Eq. 13). The mechanism is

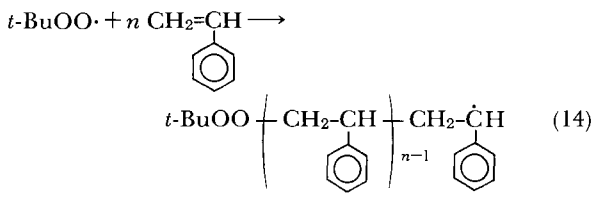


(12)

(13)

suppproted by the dependence of the yield of styrene oxide on the amount of *t*-BuOO· generated from the decomposition of **1**. *t*-BuOO· is a precursor for *t*-BuOOH and *t*-BuOOR'as shown by Eqs. 9 and 10; therefore the total yield of *t*-BuOOH and *t*-BuOOR' on the decomposition in cumene roughly coincides with that of *t*-BuOO· generated from the decomposition of **1** (i.e., 65% for **1a** and <10% for **1b** and **1c**). The significant *t*-BuOO· scission process for **1a** can contribute to the styrene oxide formation.

There is a difference between the total amount of *t*-BuOO· generated from β-scission of **2a** (65%) and the amount of *t*-BuOO· consumed by styrene oxide formation (21%). It can be assumed that the residual *t*-BuOO· (44%) would mainly initiate the polymerization of styrene, resulting in the production of polystyrene containing *t*-butyldioxyl group at the polymer end (Eq. 14).



(14)

Table 2. Characteristics of Polystyrenes[a]

Peroxide	Yield of polystyrene/%	$\overline{M}_n \times 10^4$	Active oxygen[b]/%	Active polymer[c]/%
1a	94	1.4	0.052	46
1b	91	1.2	<0.005	<4
1c	82	1.1	<0.005	<3

a) Polystyrenes were obtained by the same condition as footnote a in Table 1. b) [16×(number of O-O in a polystyrene molecule)/(molecular weight of polystyrene)]×100. See experimental section for the detection. c) Proportion of polystyrene molecules having a dioxy bond: Active oxygen(%)×M_n/16.

The characteristics of polystyrenes obtained by the polymerization with **1** are given in Table 2. The molecular weight ($\overline{M}_n$) of each polystyrene was about 10000. Interestingly, active oxygen (0.052%) was found to be contained in polystyrene obtained with **1a** by iodometric titration; however we could not detect it in polystyrenes obtained with **1b** and **1c** (<0.005%). The detection of active oxygen is an important evidence indicating the existence of dioxy bond. From the values of active oxygen and molecular weight, we can estimate the proportion of polystyrene molecules containing a dioxy bond. For the case of **1a**, it was found that about half of polystyrene molecules had a dioxy bond (Table 2). In analogy with the styrene oxide formation, the amount of active oxygen in polystyrene is consistent with that of *t*-BuOO· generated from **1**. The considerable generation of *t*-BuOO· for **1a** is responsible for the production of the polystyrene containing dioxy bond as shown in Eq. 14.

Yenal'ev and co-workers[1] reported that the polystyrene obtained by the polymerization with gem-bis(*t*-pentyldioxy)alkanes contained dioxyl group. From the results, they suggested that the polystyrene was given by the reaction of alkoxyl radical having α-dioxyl group with styrene. However, our detailed investigation on polymerization mechanism with **1** rules out the possibility of Eq. 4 and leads to the conclusion that *t*-BuOO· eliminated from **2** contributes to the production of active polystyrene. It is attractive that the polymer containing dioxyl group can be obtained easily by the use of **1a** because such active polymer gives the possibility to be applied to the syntheses of block polymers.

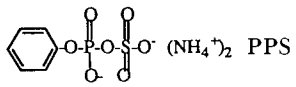
(Received December 13, 1990)

Effects of various metal ions on the methanolysis of phenyl phosphatosulfate having P-O-S linkage were investigated. Metal ions examined were found to be divided into two different groups in the manner of cleavage of P-O-S linkage: Mg^{2+}, Cr^{3+}, Cu^{2+}, Mn^{2+}, and Ca^{2+} with larger ionic radii catalyzed the selective P-O bond cleavage, while Be^{2+}, Al^{3+}, Fe^{2+}, and Zn^{2+} with smaller ionic radii promoted the selective S-O bond cleavage. Such selectivity was discussed in terms of the difference in the mechanisms of P-O and S-O bond cleavage.

In the biological sulfur metabolism, the key intermediates are 3′-phosphoadenosine-5′-phosphosulfate (PAPS) and adenosine-5′-phosphosulfate (APS).[1-9] Both intermediates have a P-O-S linkage as the reactive bond. The enzymes catalyzing the cleavage of this P-O-S bond require a metal ion as the essential cofactor. For example, Mg^{2+} is known to be an essential cofactor for the enzymes catalyzing the sulfuryl group transfer from PAPS to numerous acceptors such as polysaccharides, phenols, steroids, and other nucleophiles.[1-5] For such reactions to occur, the S-O bond must be selectively cleaved. It is also known that an APS reductase contains a non-heme iron with an FAD coenzyme.[4,9] Here again, the S-O bond must be selectively cleaved. On the contrary, it was suggested that the enzyme-catalyzed hydrolysis of PAPS occurs with the selective P-O bond cleavage in the presence of Mn^{2+} or Co^{2+}.[3,6] Yet much remains to be clarified as to the mechanism of metal-ion catalysis, in particular as to the question how a metal ion affects the rate and the selectivity in the cleavage of the S-O vs. P-O bond of P-O-S linkage.

In our previous model studies, Mg^{2+} was found to enhance the rate of acid-catalyzed hydrolysis of phenyl phosphatosulfate (PPS) and suggested to cause the selective S-O bond cleavage.[10-12] On the other hand, the same Mg^{2+} was observed to catalyze the selective P-O bond cleavage with amine nucleophiles at neutral pH.[13,14] More explicitly, it was disclosed that metal ions such as Mg^{2+} and Zn^{2+} catalyze the attack of a nucleophile on the phosphorus of 2-pyridyl phosphonosulfate to result in the selective P-O bond cleavage at neutral pH.[15] Although this mysterious gap between the effects of Mg^{2+} on the model and enzyme reactions has remained unfilled, we reported previously that there are two different groups of metal ions which promote the selective cleavage of either the S-O or the P-O bond of PPS and the selectivity appears to depend on the ionic radii of the metal ions.[17] However, things are not so simple that Zn^{2+} has now been found to promote the selective S-O bond cleavage in the methanolysis, contrary to the expected selective P-O bond cleavage based on the ionic radius. With this additional finding, we describe herein the full account of the previous communication[16,17] on the metal ion-dependent site selective cleavage of P-O-S linkage in the methanolysis of PPS.



Experimental

Materials and Methods. UV and visible spectra were recorded on a Shimadzu UV-200 spectrophotometer and NMR spectra with a Varian A-60 spectrometer. pH was measured with a Hitachi-Horiba F-7DE pH meter. Water used for kinetics was purified by treating deionized water with $KMnO_4$ followed by double distillation. Buffer and other reagents for analysis were obtained from commercial sources as extra pure reagents. Metal salts used were of analytical grade. Organic solvents, *N*-ethylmorpholine and *N*,*N*-diethylaniline were distilled before use according to the standard procedures.

The diammonium salt of PPS was prepared by the reaction of phenyl phosphate with DMF-SO_3 complex in DMF at room temperature according to our method.[18] Bis(triethylammonium) salt of PPS used for the sulfonation of *N*,*N*-diethylaniline was prepared as follows. An excess of triethylamine was added to the methanol solution of diammonium salt of PPS and the exchanged NH_3 was removed by evaporation under reduced pressure to give an oily residue which was recrystallized from a methanol/ether mixed solvent. Anal. Calcd. for $C_{18}H_{37}O_7N_2PS$: C, 47.39; H, 8.11; N, 6.13%. Found: C, 46.94; H, 8.11; N,6.08%.

Alcoholyses. Although the methods of kinetics and product analyses were essentially the same as those reported previously,[13-15,18] the details are now described below.

a) Kinetics. In ampoules, the reaction was carried out in a mixed solvent of DMF-methanol (1 : 1, v/v) containing the diammonium salt of PPS (1.0×10^{-2} mol dm^{-3}), a metal ion (0—0.1 mol dm^{-3}), and *N*-ethylmorpholine (0.55 mol dm^{-3}) at 55 °C. The rate was determined by quenching two samples at appropriate time intervals: one for the monitor of

inorganic sulfate released by colorimetric barium chloranilate or barium chromate method, and the other for the monitor of phenyl phosphate and methyl phenyl phosphate formed by the UV method described below.

b) Product Analysis. Amounts of the liberated inorganic sulfate was determined colorimetrically as mentioned above and the amounts of phosphates formed were determined on the basis of UV absorption intensity. Constants employed for the analyses are listed in Table 1.

(i) UV Method. Two methods were employed. In one method, a reaction mixture (0.5 ml) was mixed with 1 mol dm^{-3} NaOH (0.5 ml) and water (4 ml), and the resulting metal hydroxide precipitate was removed by centrifuge, and the supernatant was subjected to UV analysis (for Be^{2+}, Al^{3+}, Fe^{3+}, Zn^{2+}, Mg^{2+}, Mn^{2+}, and Ca^{2+}). In the other method, a reaction mixture (0.5 ml) was mixed with 0.2 mol dm^{-3} Na_2HPO_4 (4.5 ml), and the precipitated metal ion salt of orthophosphate was removed by centrifuge, and the supernatant was subjected to the UV analysis (for Be^{2+}, Al^{3+}, Fe^{3+}, Zn^{2+}, Cr^{2+}, and Cu^{2+}). The two methods gave the same results.

(ii) NMR Method. (ii-a). For the competitive solvolysis by methanol and 2-propanol (Be^{2+}, Al^{3+}, Fe^{3+}, and Zn^{2+}): A reaction mixture (50 ml) consisting of PPS $(NH_4^+)_2$ (1×10^{-2} mol dm^{-3}), *N*-ethylmorpholine (0.55 mol dm^{-3}), and a metal ion (3×10^{-2} mol dm^{-3}) in a mixed solvent of methanol, 2-propanol, and DMF was kept for ten half-lives at 55 °C. Then the reaction mixture was concentrated to remove the solvent, and the residual oil was dissolved in water (3 ml), and to this was added 0.2 mol dm^{-3} Na_2HPO_4 (10 ml) and 1 mol dm^{-3} NaOH (2 ml). The resulting precipitate of metal ion salt of orthophosphate was separated from the supernatant by centrifuge and washed with water. The combined supernatant and the washings were concentrated to give a solid residue, and the residue was washed with ether to remove remaining *N*-ethylmorpholine. Dried final residue was dissolved in D_2O and subjected to the NMR analysis.

(ii-b). For the cases of Mg^{2+} and Ca^{2+}: A reaction mixture consisting of PPS $(NH_4^+)_2$ (1×10^{-2} mol dm^{-3}), *N*-ethylmorpholine (0.55 mol dm^{-3}), and a metal ion (5×10^{-2} mol dm^{-3}) in a mixed solvent of methanol and DMF (1 : 1, v/v %) was concentrated and the residual oil was dissolved in water (5 ml) and mixed with 0.5 mol dm^{-3} NaOH (5 ml). The metal hydroxide was separated from the supernatant by centrifuge and the precipitate was washed with 0.5 mol dm^{-3} NaOH (5 ml). The combined supernatant and the washings were treated as in the above procedure for the NMR analysis.

(ii-c). For the case of Cu^{2+}: A similar reaction mixture ($Cu^{2+}=2\times10^{-2}$ mol dm^{-3}) was concentrated to give a residual oil, and this was dissolved in 1 mol dm^{-3} HCl (20 ml). To the HCl solution was introduced H_2S gas and the copper sulfide was removed by filtration. The filtrate was treated with active carbon and the colorless filtrate was concentrated after pH adjustment (pH 11). The dried residue was subjected to the NMR analysis as mentioned above.

(iii) HPLC Method (for the reactions of Mg^{2+}, Cu^{2+}, Cr^{3+}, and Mn^{2+}): The column and the elution solvent were YANACO PELAX and 20% H_2O–80% CH_3OH, respectively. A kinetic reaction mixture (0.5 ml) was mixed with 1 mol dm^{-3} NaOH (0.5 ml) and water (4 ml), and the metal hydroxide was removed by centrifuge, and the supernatant was subjected to the NMR analysis.

(iv) Paper Chromatography. Both a raw reaction mixture and the final NMR sample were analyzed. In all the cases, only a single spot corresponding to either methyl phenyl phosphate (MPP), phenyl isopropyl phosphate or phenyl phosphate (PP) was detected.

Sulfonation. Ammonium *p*-(diethylamino)benzenesulfonate used as the authentic sample was prepared by the reaction of *N*,*N*-diethylaniline (3 ml, 19.2 mmoles) with DMF–SO_3 complex (9.6 mmoles) in DMF (6 ml). The reaction mixture was left for 10 h at ambient temperature and quenched with an excess of NH_3 in methanol. The product was precipitated by the addition of ether and recrystallized from methanol–ether. Anal. Calcd. for $C_{10}H_{18}O_3N_2S$: C, 48.79; H, 7.31; N, 11.37%. Found: C, 48.76; H, 7.36; N, 11.37%. Mp. 168—170 °C. UV (see Tables 1).

The $AlCl_3$-promoted sulfonation was conducted by the reaction of bis(triethylammonium) PPS (200 mg, 0.43 mmoles) with *N*,*N*-diethylaniline (4 ml, 25.7 mmoles) in the presence of anhydrous $AlCl_3$ (70.6 mg, 0.53 mmoles) in dry acetonitrile solvent (3 ml) at ambient temperature for 45 h. The product, ammonium *p*-(diethylamino)benzenesulfonate, was obtained in a quantitative yield by treating the reaction mixture according to the above procedure, and identified by comparing UV, ^1H NMR, and IR spectra with those of the authentic sample.

Results

Metal Ion Effects in the Methanolysis. (a) Product Analysis. Methanolysis of diammonium PPS (1×10^{-2} mol dm^{-3}) was carried out in a mixed solvent of methanol and DMF (1 : 1, v/v) under basic conditions containing *N*-ethylmorpholine (0.55 mol dm^{-3}) at

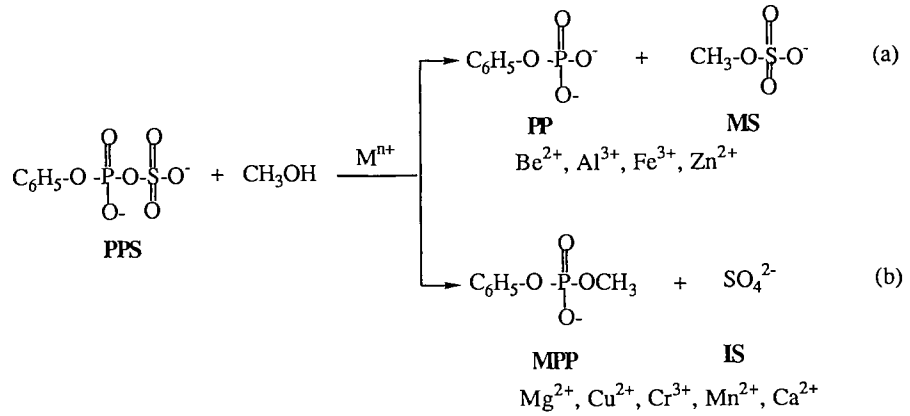

Scheme 1.

55 °C. Previously, *N*-ethylmorpholine was confirmed to be unreactive toward PPS either in the presence or absence of a metal ion examined.[10,13] The reaction was very slow in the absence of a metal ion. All metal ions tested in this study enhanced the rate of reaction. Fortunately, the product analyses described in the experimental section could be performed readily and quantitatively. The reason for the ease of analyses was first due to the simplicity of the products because of the site-selective S-O or P-O bond cleavage of P-O-S linkage. The second was due to the ease of quantitative analyses of the methylated products based on the ^{1}H NMR signals of methyl protons (Table 1) as well as their HPLC analysis. The results are summarized in Scheme 1. Scheme 1 indicates that the metal ions are divided into two different groups in the selectivity of bond cleavage. That is, Be^{2+}, Al^{3+}, Fe^{3+}, and Zn^{2+} promoted an exclusive S-O bond cleavage to form phenyl phosphate (PP) and methyl sulfate (MS) in quantitative yields, whereas Mg^{2+}, Cu^{2+}, Cr^{3+} Mn^{2+}, and Ca^{2+} catalyzed an exclusive P-O bond cleavage to form methyl phenyl phosphate (MPP) and inorganic sulfate (IS) in quantitative yields. The metal ions were used as the chlorides containing hydrated water, but the results obtained with the hydrated metal ions were essentially the same as those obtained with anhydrous metal ions. The counterions of the metal ions such as chloride, nitrate, or perchlorate did not affect the selectivity.

(b) Kinetics. The pseudo-first-order rate constants (k_{obsd}) were obtained by following spectrophotometrically the formation of either one of PP, MPP, or IS.[13,18] In the P-O bond cleavage to form MPP and IS, the metal ions performed as catalysts, i.e. a good peudo-first-order rate constants were obtained regardless of using an excess of substrate or a metal ion over the other. However, in the S-O bond cleavage to form PP and MS, precipitation occurred owing to the formation of a strongly bound PP-metal ion complex in the absence of DMF. This was one of the reasons to use DMF for a component of the mixed solvent. Thus, in the S-O bond cleavage, the rates were of pseudo-first-order in the presence of an excess of a metal ion over the substrate PPS in the mixed solvent, but under reversed conditions of an excess of PPS over a metal ion, burst kinetics were observed, i.e. an initial fast reaction followed by the slow production of PP, as exemplified in Fig. 1 (lower two curves). Most kinetics were carried out with metal ion concentrations below 0.03 mol dm^{-3}. Within this concentration range, the k_{obsd} values were first-order with respect to the metal ion concentration to give second-order rate constants, k_2(S-O) and k_2(P-O) as listed in Table 2. However, at higher metal ion concentrations, saturation kinetics were observed as shown in Fig. 2 for the three representative metal ions, Zn^{2+}, Mg^{2+}, and Ca^{2+}. The saturation curves in Fig. 2 seem to be accounted for by

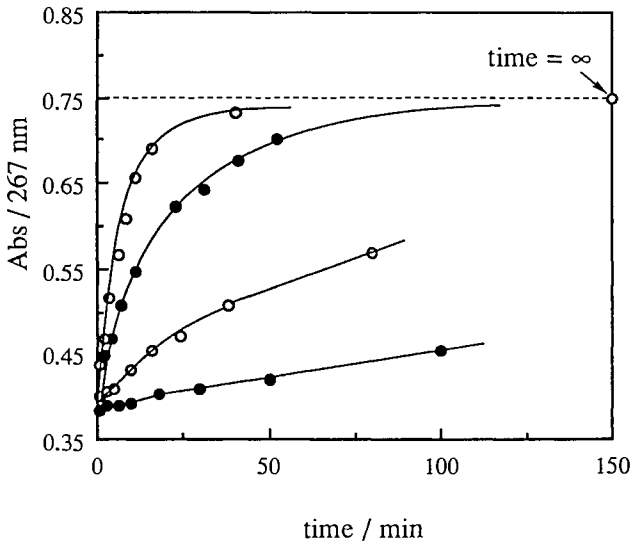

Fig. 1. Absorbance change vs. reaction time in the Zn^{2+} promoted methanolysis of PPS (1×10^{-2} mol dm^{-3}) in MeOH-DMF (1 : 1, v/v) at 55 °C: Zn^{2+} concentration (mol dm^{-3}) from the top, 1×10^{-1}, 3×10^{-2}, 1×10^{-2}, 5×10^{-3}.

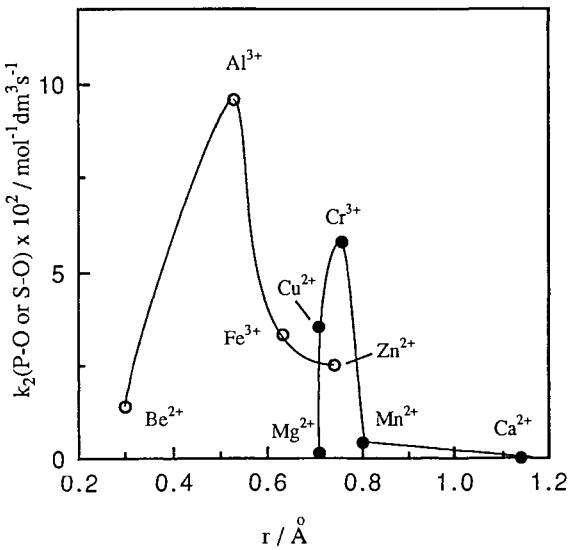

Fig. 3. Plots of the second-order rate constants vs. ionic radii of the metal ions: ○ k_2(S-O); ● k_2(P-O).

$$M+S \underset{}{\overset{K}{\rightleftarrows}} C \xrightarrow{k_m} \text{products} \qquad (1)$$
$$\qquad\qquad \downarrow k_0$$

$$k_{obsd}=k_0+\frac{(k_m-k_0)K[M]_T}{1+K[M]_T+K[S]_T\left(1-\dfrac{k_{obsd}-k_0}{k_m-k_0}\right)} \qquad (2)$$

assuming the preequilibrium formation of a 1 : 1 complex (C) of the substrate (S) and metal ion (M) on the basis of Eq. 1. Eq. 2 is formulated in accordance with Eq. 1,[15,19] where $[M]_T$ and $[S]_T$ are the initial stoichiometric concentration of metal ion and substrate, respectively, k_o and k_m are the rate constants for the methanolyses of the metal-free and metal-coordinated substrate, respectively, and K stands for the formation constant for the 1 : 1 complex (C). In practice, the k_0 value was negligibly small and could be neglected in the rate calculation. The calculated curves in Fig. 2 are obtained by Eq. 2, using the evaluated K and k_m values given in Table 3, where the $k_mK/(1+K[S]_T)$ values in the last column correspond to the above mentioned k_2 values. Table 3 indicates that the k_m value for the Zn^{2+}-promoted S-O bond cleavage is 320- and 824-fold larger than those for the Mg^{2+} and

Ca^{2+} catalyzed P-O bond cleavage, respectively. It is interesting to note that the K value for Mg^{2+} with PPS in the present mixed solvent is much larger than that in water reported previously (K=1.19 $mol^{-1}dm^3$, pH 7.9, 55 °C),[14] suggesting for a strong solvation (hydration) to inhibit Mg^{2+} from complexation with PPS in water.

(c) The k_2 Values vs. Ionic Radii of the Metal Ions. In Fig. 3 are shown the k_2 values in Table 2 as a function of ionic radii of the metal ions.[20] The figure shows that the ionic radii of the metal ions which promote the O-S bond cleavage are shorter than those of the metal ions which catalyze the P-O bond cleavage, although Zn^{2+} appears to be an exception. It is interesting to note that there are two maxima in the vicinity of 0.53 and 0.75 Å corresponding to the S-O and P-O bond cleavage, respectively. These observations suggest that the ionic radius of a metal ion is a key factor for both selectivity and rate enhancement of the bond cleavage.

(d) Effect of Methanol Concentration on the Rates. The results are shown in Fig. 4 for the Al^{3+}-promoted S-O bond cleavage and the Mg^{2+} catalyzed P-O bond cleavage. Fig. 4 shows that the k_2 values of Mg^{2+} increase linearly with increasing methanol concentration, but those of Al^{3+} tend to be saturated with increasing methanol concentration. Since methanol is the nucleophile, it is no wonder that the rate is linear to the concentration of nucleophile if the rate-limiting step is the attacking of nucleophile. However, the rate is presumed to be indifferent to the methanol concentration if the rate-limiting step is the unimolecular cleavage of the terminal S-O bond. This argument may be too simple, because the increasing of methanol concentration should affect the rate through the change of solvent property, perhaps nonlinearly. Nevertheless, the linearlity in the case of Mg^{2+} suggests that the attacking of methanol on phosphorus to cleave the P-O bond is the rate-limiting step. In the case of Al^{3+} the situation seems to be more complex, but the data appear to support unimolecular process, at least at higher methanol concentration.

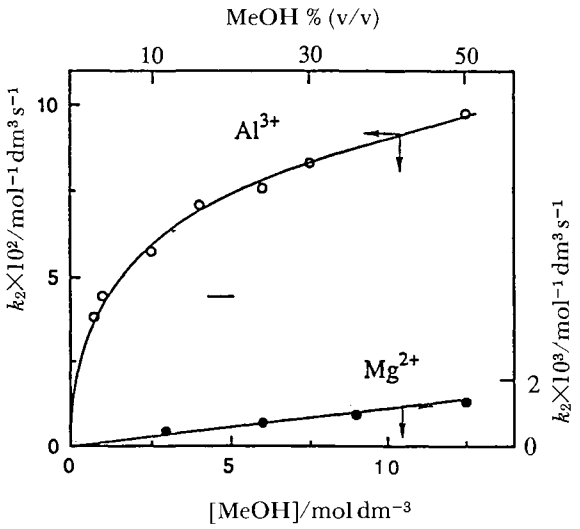

Fig. 4. Dependency of k_2 on methanol concentration in DMF.

(e) Alcoholysis by Methanol vs. 2-Propanol. The metal ions, Be^{2+}, Al^{3+}, Fe^{3+}, and Zn^{2+} were also found to promote the S-O bond cleavage of PPS in the alcoholysis by 2-propanol to give PP and isopropyl sulfate (PS) in quantitative yields. The k_2 value for the Al^{3+}-promoted alcoholysis by 2-propanol in a mixed solvent of 2-propanol and DMF (1 : 1, v/v%) at 55 °C was 1.3 times smaller than that of the corresponding methanolysis. In the case of Mg^{2+}, neither phenyl isopropyl phosphate (P-O bond cleavage) nor isopropyl sulfate (S-O bond cleavage) was obtained, but the detected products were only PP and IS, presumably due to the hydrolysis by a trace of water. In the case of Ca^{2+}, the expected phenyl isopropyl phosphate could be detected after a prolonged reaction as in the methanolysis due to the P-O bond cleavage. Thus, there seemed to be a severe steric hindrance to the attack of 2-propanol on the phosphorus to result in the P-O bond cleavage, whereas such steric hindrance seemed to be less important in the S-O bond cleavage.

In order to obtain more information, the competitive alcoholysis by methanol vs. 2-propanol was examined in the mixed solvents of methanol and 2-propanol in DMF, in the presence of either one of

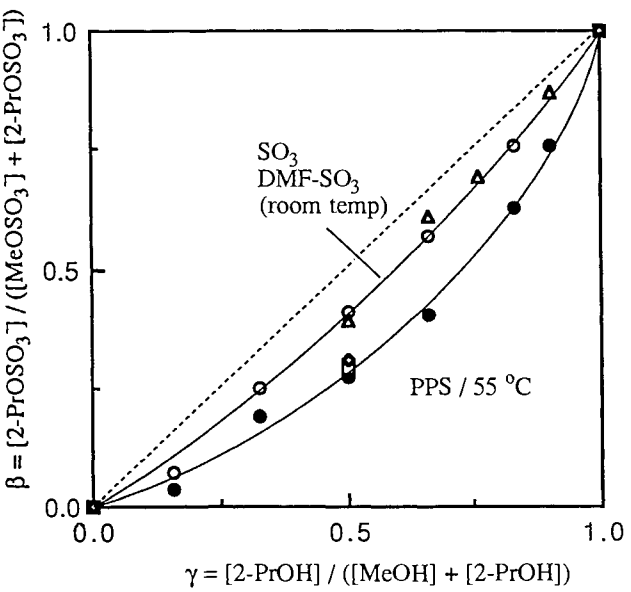

Fig. 5. Competitive solvolyses of PPS, SO_3, and DMF-SO_3 in the mixed solvents of MeOH, i-PrOH, and DMF: concentrations(mol dm^{-3}), [MeOH]+[2PrOH]=6.0, [N-ethylmorpholine]= 0.55, ○ [SO_3]=0.15—1.0×10^{-2}, △ [DMF-SO_3]= 1.6×10^{-2}, [PPS]=1.0×10^{-2} ([Be^{2+}]=3.0×10^{-2} (□), [Al^{3+}]=2.5×10^{-2} (●), [Fe^{3+}]=2.5×10^{-2} (□), [Zn^{2+}]= 2.8×10^{-2} (◇)).

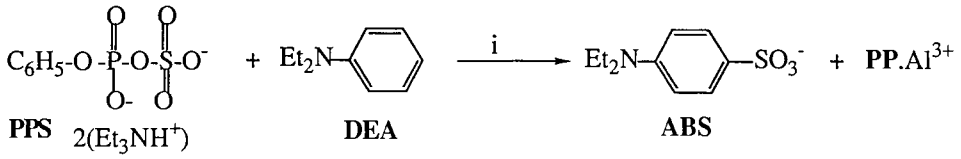


Scheme 2. Reagents: i, $AlCl_3$ in CH_3CN; room temp.

Be^{2+}, Al^{3+}, Fe^{3+}, or Zn^{2+}. The substrates examined were SO_3 and DMF-SO_3 in the absence of a metal ion, and PPS in the presence of a metal ion. The former two may be the same, because their difference was only in that whether SO_3 gas was introduced into a mixed solvent of methanol, 2-propanol and DMF or a mixture of methanol and 2-propanol was mixed with a DMF-SO_3 solution prepared prior to the mixing. The results are shown in Fig. 5. In Fig. 5, the diagonal straight line would be expected if methanol and 2-propanol are equally reactive. The observed line in the absence of a metal ion indicates that methanol is slightly more active than 2-propanol. Namely it shows that the product ratio was PS : MS=1 : 1.5 (β=0.4) when a mixture of equal amount of methanol and 2-propanol (γ=0.5) was used. The solid line was observed for the reaction of PPS in the presence of a metal ion. The four metal ions gave almost the same results in product ratio. When γ=0.5, the observed β value was about 0.3 for each metal ion, corresponding to a ratio of PS : MS=1 : 3. These results indicate that although there is a sizable difference in reactivity between methanol and 2-propanol, it is much less in the S-O bond cleavage than in the above mentioned P-O bond cleavage.

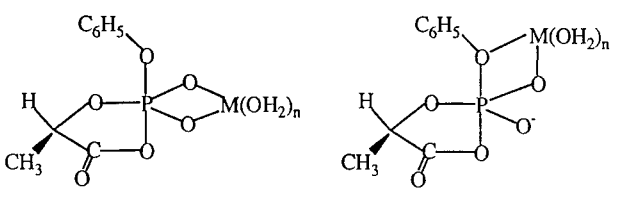
Sulfonation. The different behavior of the two groups of the metal ions was further manifested in the reaction of PPS with *N*,*N*-diethylaniline (DEA) in the presence of Al^{3+} or Mg^{2+} as a representative of each group of the metal ions. In acetonitrile, PPS (bis(triethylammonium) salt) and DEA did not react at room temperature irrespective of the presence or absence of Mg^{2+}. By contrast, Al^{3+} readily promoted the reaction to give *p*-(diethylamino)benzenesulfonate and PP in quantitative yields as shown in Scheme 2.

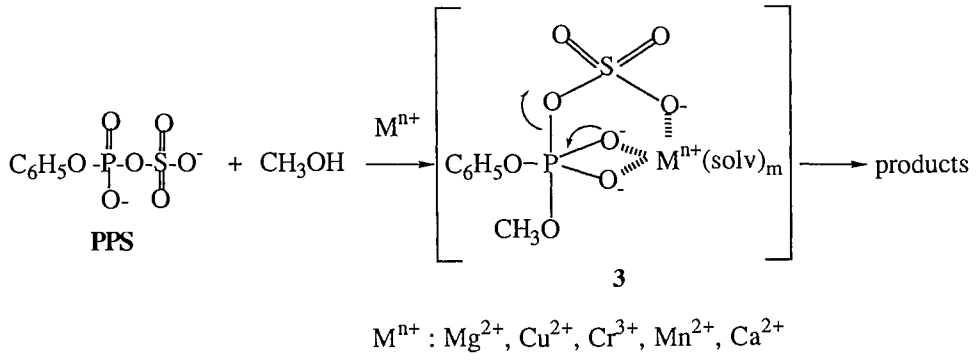
Discussion

The rate of Mg^{2+}-catalyzed methanolysis of PPS (k_2(P-O)) was first-order with respect to the methanol concentration (Fig. 4), suggesting the rate-limiting nucleophilic attack of methanol on phosphorus of PPS. This is in accordance with our previous observation that in aqueous media Mg^{2+} catalyzes the nucleophilic attack of primary and secondary amines on phosphorus of PPS to give the corresponding phosphoramidates and IS, but the reaction does not occur with a sterically crowded amine such as *N*-ethylmorpholine and 2,6-lutidine irrespective of the presence or absence of Mg^{2+}.[10,13]

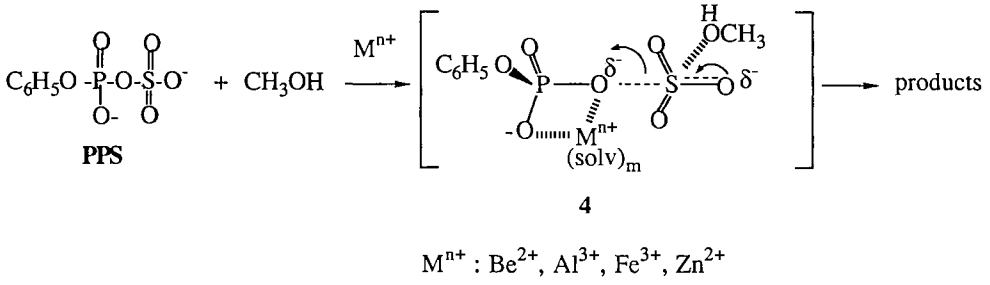
The dependency of rates of Al^{3+}-promoted methanolysis (k_2(S-O)) on the methanol concentration (Fig. 4) was quite different from that mentioned above. The rates tended to become independent of methanol concentration at higher concentration. The two different pathways can be conceivable for the S-O bond cleavage: (1) the unimolecular elimination of sulfur trioxide (SO_3) or its solvated species, and (2) the bimolecular nucleophilic attack of methanol on sulfur as in the case of above mentioned phosphorus attack. However, the latter possibility seems to be unlikely on the following grounds in addition to the above concentration effect. As shown in Fig. 5, the difference between the rates for methanol and 2-propanol is rather small in the S-O bond cleavage as compared to a large difference in the case of P-O bond cleavage, suggesting the formation of a very reactive species, i.e. SO_3 in the former case. Further supporting evidence is the Al^{3+}-promoted sulfonation of DEA with PPS in acetonitrile, where SO_3 is likely generated as the reactive sulfonating agent.

As discussed above, the P-O and S-O bond cleavage appear to occur with different mechanisms. Then, what is the role of a metal ion? The answer seems to be partly obtained by examining the data in Fig. 3 which shows the correlation of k_2 values with the ionic radii of the metal ions. Fig. 3 shows two rate maxima corresponding to the two different groups of metal ions which either catalyze the P-O or promote the S-O bond cleavage of PPS. The ionic radius of the metal ion to give the former rate maximum is in the vicinity of 0.75 Å. Quite interestingly the same ionic radius for the rate maximum was also reported by Benkovic et al. for the divalent metal ion-catalyzed hydrolysis of lactic acid *O*-phenyl phosphate, and it was suggested that the role of metal ion is to facilitate the formation of phosphorus(V)intermediate (**1** or **2**) which then rapidly decomposes to the products.[21]





Scheme 3. A postulated pentacovalent phosphorus intermediate in a metal ion catalyzed methanolysis of PPS to give P-O bond cleavage.



Scheme 4. Proposed transition state involving solvated sulfur trioxide.

The correlation with ionic radius suggests the importance of bidentate coordination with strict geometrical requirements as in **1** or **2**. Similar phosphorus(V) intermediate (**3**) can also be considered for the present metal ion-catalyzed P-O bond cleavage as illustrated in Scheme 3. In the structure **3**, a metal ion occupies a basal position and is chelated with two anionic oxygen ligands to form a four-membered cyclic complex. The metal ion is also assumed to form an ionic bond with sulfate oxygen ion. It is important to notice that the bond angle of the chelating $\angle^{-}O\text{-}P\text{-}O^{-}$ is 120°, the same as that of **1** but different from that of 90° in **2**. As discussed below, the relationship between the metal ion radius and the bond angle of a bidentate ligand seems to be of key importance in determining the selectivity in the P-O and S-O bond cleavage.

In the case of the S-O bond cleavage, Fig. 3 shows that the ionic radius of a metal ion to give the rate maximum is in the vicinity of 0.53 Å, much shorter than 0.75 Å in the case of P-O bond cleavage. A shorter ionic radius suggests a smaller bond angle for the bidentate chelation, and it led us to consider **4** in Scheme 4 as a possible transition state structure. In **4** is assumed a solvent assisted unimolecular S-O bond cleavage which is consistent with the above mentioned results (Figs. 4, 5 and Scheme 2). It is important to notice in **4** that a metal ion assists the S-O bond cleavage by chelating with two anionic oxygen ligands of the leaving phosphoryloxy group, in which the $\angle^{-}O\text{-}P\text{-}O^{\delta-}$ bond angle is near 109.5°, much smaller than the above 120° in the P-O bond cleavage.

The Zn^{2+} which promotes the selective S-O bond cleavage appears to be an exception from the consideration of ionic radius alone, since our previous studies demonstrated that in aqueous media Zn^{2+} always catalyzes the P-O bond cleavage, e.g. in the aminolysis of PPS,[10,13] in the 2-pyridinecarbaldehyde oxime-catalyzed hydrolysis of PPS,[10,22] and in the hydrolysis of 2-pyridyl phosphonosulfate.[15] It is known that Be^{2+} and Al^{3+} with smaller ionic radii, or Zn^{2+} and Fe^{3+} with the electron configuration of $3d^{10}$ and $3d^{5}$, respectively favor tetrahedral coordination.[23] On the other hand, metal ions such as Mg^{2+}, Cu^{2+}, Cr^{3+}, Mn^{2+}, and Ca^{2+} favor octahedral coordination. Thus, it is conceivable that the change in selectivity of Zn^{2+} from the P-O in water to the S-O bond cleavage in methanol is due to the change of solvation in the metal ion-substrate complex which affects the type of coordination, i.e. tetrahedral in methanol but octahedral coordination in water.

Finally, it is considered in general that the effective charge of metal ion is important for an electrophilic catalysis as in the present case. For this point, the above mentioned results are not conclusive, since the difference in k_2 values is rather small between Fe^{3+} and Zn^{2+} or between Cr^{3+} and Cu^{2+}. It is conceibable that the solvation to reduce effective charge is stronger for a trivalent metal ion than for a divalent metal ion, resulting in a smaller difference in their reactivities.

Much remains to be clarified as to the mechanism of

metal ion catalysis in the reactions of P-O-S linkage, as seen in the dual behavior of Zn^{2+}. Moreover, a mysterious gap between the selectivity of Mg^{2+} in the P-O-S bond cleavage in enzyme and model reactions has still remain unsolved. Nevertheless, it is important to notice that there is a certain correlation between the ionic radii of metal ions and the selectivity in the P-O-S bond cleavage.

We are much indebted to Messrs T. Ogihara and A. Kato, and Miss F. Arai who carried out the early part of this study.

(Received December 17, 1990)

The 1 : 1 adduct ion formation between a series of permethylated monosaccharides (M; $\mathbf{I_a}$—$\mathbf{I_h}$) and an organic or a metallic cation (A^+) has been examined in quantitative FAB mass spectrometry. In a careful comparison under the same FABMS conditions, the relative $(M+A)^+$ peak intensities increase in the following order of the monosaccharides, and further increase at nearly the same extents in spite of using three different cations such as octylammonium, (methoxycarbonyl)methylammonium, and potassium ions:

$$\beta\text{-Glc} < \alpha\text{-Glc} < \alpha\text{-Gal} < \beta\text{-Gal} \leq \alpha\text{-Man} < \beta\text{-Man} < \alpha\text{-Tal} < \beta\text{-Tal}.$$

The order and cation-independency clearly indicate the OCH_3 configurational effects of M on $(M+A)^+$ adduct ion formation. The findings can be interpreted in terms of multisite electrostatic interaction of oxygens with the cation. Coupled with the results of gas-phase behavior by FABMS/MS(CAD), solution behavior by ^1H NMR, and model calculations by MNDO, the characteristic structure of the 1 : 1 adduct ion is deduced as host-guest type association between permethylated monosaccharides and cationic species in particular cases, at least β-Tal and α-Tal cases.

Elucidation of stereochemical effects of organic compounds on mass spectra has been a challenging problem for a long time. Much attention has been paid to this problem on the basis of fragmentation patterns in EIMS (electron impact mass spectrometry)[2)] or peak intensities of quasi-molecular ions in CIMS (chemical ionization mass spectrometry),[3,4)] etc.[5)] Recently, Puzo et al. reported epimer-identification of underivatized monosaccharides with metallic cations in FAB/MIKES (Fast Atom Bombardment)/(Mass Analyzed Ion Kinetic Energy Spectroscopy).[6)] However, there are almost no systematic studies concerning stereochemical effects on conventional FABMS.[7-12)] We now focus our attention on the structural factors which promote the 1 : 1 adduct ion formation in quantitative FABMS.

In the present study, permethylated monosaccharides, $\mathbf{I_a}$—$\mathbf{I_h}$ (family **I**), are chosen as the substrates (M), and compared with monomethylated monosaccharides, $\mathbf{II_a}$—$\mathbf{II_h}$ (family **II**), as the references.[13)] The permethylated monosaccharides can avoid the effects of intramolecular hydrogen bonding of M,[14)] and further intermoleculer hydrogen bonding of M with matrix (for example, glycerol; G).[15)] The monomethylated monosaccharides can prevent α, β isomerization during the preparation of sample solutions of M.

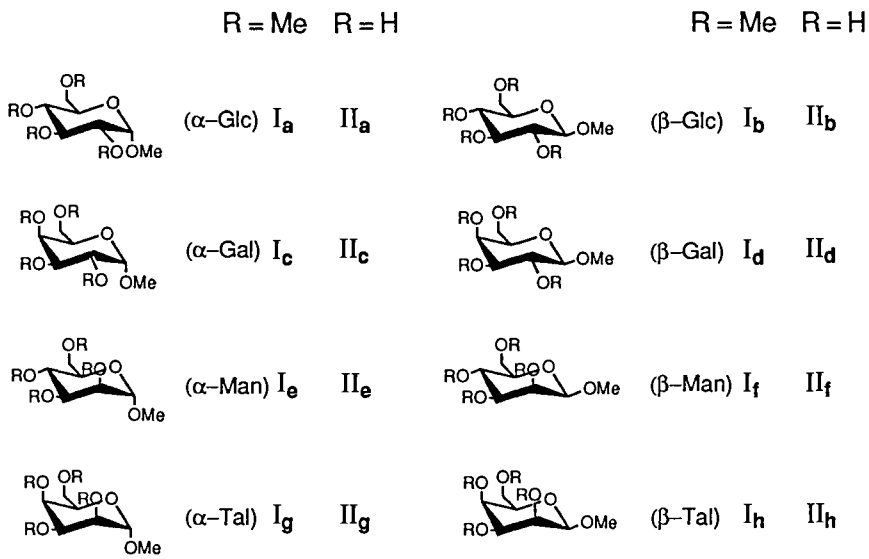

Chart 1.

Complexations of metallic cations with underivatized monosaccharides were extensively studied by Angyal et al. mainly on the basis of ^{1}H NMR and X-ray crystal data, where importance of axial-equatorial-axial arrangement of three sequential OH groups was explored for strong 1 : 1 complexation.[16] This paper describes primarily the stereochemical effects of permethylated monosaccharides (M) on $(M+A)^+$ adduct ion formation with organic cations (A^+) in conventional FABMS, and deduces the structure as host-guest type association in particular cases.[17–19]

Results

Selection of Cations. Table 1 shows the results of qualitative FABMS experiments for searching good cations (A^+), where $\mathbf{I}_f$ (β-Man) is fixed as a common substrate (M). From the relative intensity values, ($I[M+A]^+/I[M+1]^+$), it was found that primary and secondary alkylammonium ions with relatively long alkyl chains, and metallic cations with one positive charge, are suitable for generating abundant $(M+A)^+$ adduct ions. Figure 1 is a typical example of a FAB mass spectrum for the case of adding octylammonium ion salt.

Selectivity of Permethylated Monosaccharides. Based on the data in Table 1, octylammonium (A_1^+), (methoxycarbonyl)methylammonium, $CH_3OCOCH_2NH_3^+$ (A_2^+), and potassium ions (A_3^+) were chosen as better cationic species in the present quantitative

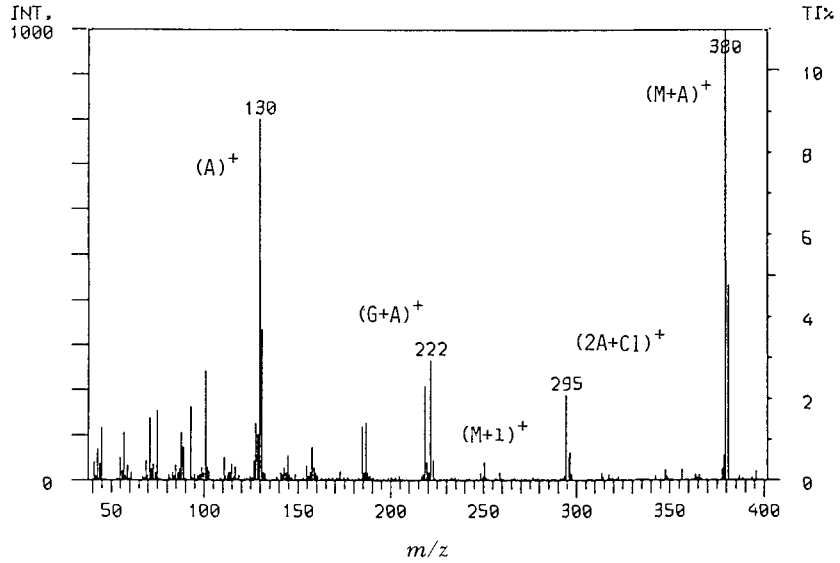

Fig. 1. A FAB mass spectrum of M with A^+X^- (glycerol matrix): M=$\mathbf{I}_f$ (β-Man), A^+X^-=n-$C_8H_{17}NH_3^+Cl^-$ (M: A^+X^-=1 : 1).

study. Affinities of a series of permethylated monosaccharides (family **I**) toward the cation were determined by measuring relative peak intensities of the relevant $(M+A)^+$ adduct ions. Internal standard technique was employed for quantitative measurements so as to get highly reliable peak intensity data in FABMS.[20-22] Deuterated monosaccharide, $\mathbf{I}_e$-d_{12} (methyl tetra-*O*-methyl-d_{12}-α-D-mannoside), was used as an internal standard (R), and competitive conditions[23] where an equimolar amount of M and R was included in a matrix (glycerol) were employed. The relative peak intensity value, $I(M+A)^+/I(R+A)^+$, was taken as a measure of $(M+A)^+$ adduct ion formation. It should be noted here that measuring conditions of a mass spectrometer and concentration conditions of all sample solutions were kept constant throughout the experiments of getting a set of relative peak intensity values.

Different affinities were observed for the set of monosaccharides. By contrast, they were very close to each other for the three sets of cations (A_1^+, A_2^+, and A_3^+; Table 2). The $(M+A)^+$ peak of $\mathbf{I}_h$ (β-Tal) was almost 100 times more intense than that of $\mathbf{I}_b$ (β-Glc). The characteristic ordering of the resulting relative affinities is, β-Tal>α-Tal>β-Man>α-Man≥β-Gal>α-Gal>α-Glc>β-Glc. This indicates that the relative peak intensities of $(M+A)^+$ ions are strongly related with the configuration of the OCH_3 groups in the family **I**.

Table 2. Relative Peak Intensities of $(M+A)^+$ Adduct Ions for Permethylated Monosaccharides in FABMS (Glycerol Matrix)

Monosaccharide M (R)[a]	$I[M+A]^+/I[R+A]^+$ value		
	(A_1^+)[b]	(A_2^+)[c]	(A_3^+)[d]
$\mathbf{I}_a$	0.4	0.5	0.5
$\mathbf{I}_b$	0.3	0.3	0.2
$\mathbf{I}_c$	0.6	0.8	0.7
$\mathbf{I}_d$	1.0	0.9	1.0

$\mathbf{I}_f$	5.8	4.2	3.7
$\mathbf{I}_g$	9.0	6.1	12
$\mathbf{I}_h$	36	22	18

a) R=$\mathbf{I}_e$-d_{12} (α-Man-d_{12}). See text. b) $A_1^+X^-$=CH_3-$(CH_2)_7NH_3^+Cl^-$. c) $A_2^+X^-$=$CH_3OCOCH_2NH_3^+Cl^-$. d) $A_3^+X^-$=K^+Cl^-.

Selectivity of Monomethylated Monosaccharides. Affinities of a series of monomethylated monosaccharides (family **II**) toward the cation were determined by the same method as that mentioned above (Table 3). Here, methyl-d_3 α-D-glucopyranoside ($\mathbf{II}_a$-d_3) was employed as an internal standard (R). As seen in the FABMS columns of Table 3, the differences in affinities toward each cation largely diminished or disappeared. For example, the $(M+A)^+$ peak of $\mathbf{II}_h$ (β-Tal) was at most 2—5 times more intense than that of $\mathbf{II}_a$ (α-Glc), being in marked contrast to a much larger selectivity of the family **I**.

$(M+A)^+$ Adduct Ions Detected by FABMS/MS(CAD). FABMS/MS (mass spectrometry/mass spectrometry) is useful to know purely gas-phase ion phenomena. MS/MS operating principle is (1) a selected ion is directed into a second mass spectrometer, and (2) the ion (precursor ion) is decomposed typically by argon collision, and (3) the resulting fragment ions are analyzed.[24] The MS/MS has been a rapidly growing technique for studying the order of relative binding energies,[25] and for analysing organic ions in the gas-phase.[31] Our precursor ions used were Puzo's three component ions,[6a] $(M+K+DEA)^+$ (m/z 338), which were composed of the family **II**, K^+, and diethanolamine (DEA) (Chart 2).

Relative area intensities of the $(M+K)^+$ adduct ions (m/z 233) to the reference one $(DEA+K)^+$ (m/z 144) were measured under the same experimental conditions,[26] and tabulated in the FABMS/MS column of Table 3. The present FABMS/MS area intensity data

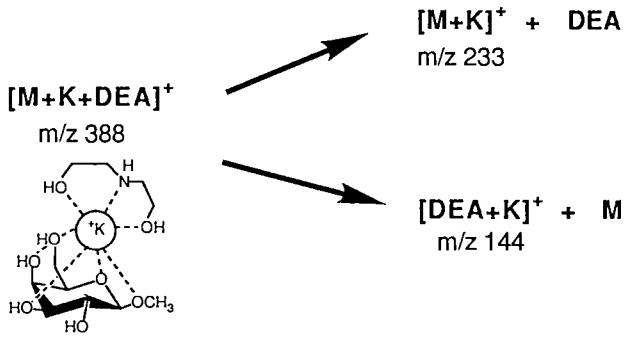

Chart 2.

via CAD (collisionally activated decomposition) process are consistent with earlier FAB/MIKES data via unimolecular decomposition process.[6a] The resulting ordering of the binding energies for $(M+K)^+$ adduct ions is, β-Tal>α-Tal>β-Man>-β-Gal>α-Man>α-Gal>α-Glc=β-Glc, which is in good agreement with the affinity ordering of the family **I** in FABMS.

$(M+A)^+$ Adduct Ions Supported by ^{1}H NMR. ^{1}H NMR experiments were carried out to see if the $(M+A)^+$ adduct ions between the family **I** and organic cations in solution can be detected or if existence of equilibrium (Eq. 1) can be established by means of diamagnetic induced chemical shifts (ICS).[16,27] Because of solubility problems of the alkylammonium ion salts employed, acetonitrile-d_3 was utilized as a solvent.

$$M + A^+ \rightleftarrows (M+A)^+ \quad (1)$$

Typical ^{1}H NMR spectra before and after addition of 2-phenylethylammonium hexafluorophosphate ($A_4^+PF_6^-$) are compared in Fig. 3 ([M]=0.014 M, $[A_4^+PF_6^-]$=0.008 M). Here, M is **I**$_h$ (β-Tal), because it gave the highest $(M+A)^+$ peak in Table 2. Position-dependent ICS was clearly observed after the addition. That is, (1) the broad ammonium proton signal moves to a downfield direction to the greatest extent (ca. 0.15 ppm), (2) the monosaccharide ring proton signals also undergo downfield shifts to different extents, and (3) some of methyl proton signals (around δ=3.4) show downfield shifts. These observations in both sides of A^+ and M suggest that $(M+A)^+$ adduct ion formation is in an fast equilibrium on the NMR time scale, and that apparent ICS

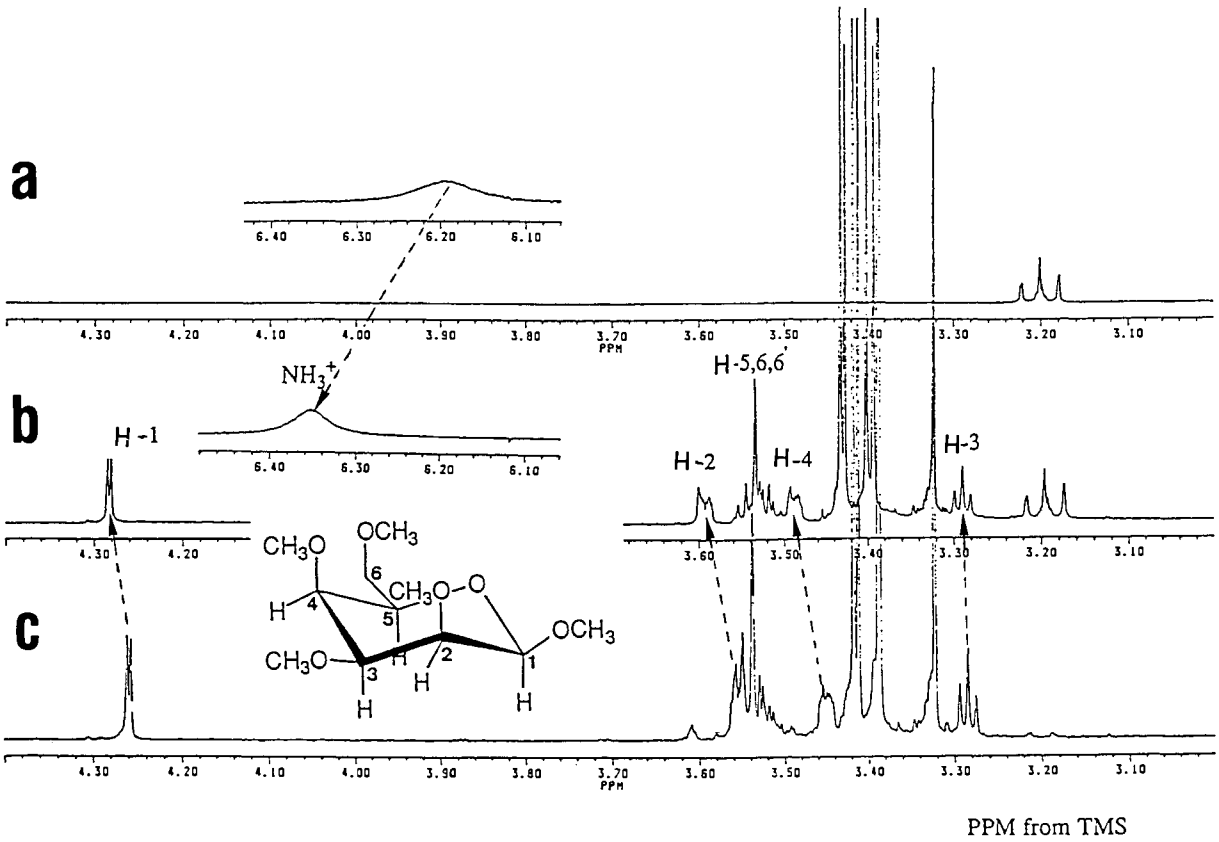

Fig. 3. ^{1}H NMR spectra (360 MHz) of M before and after an addition of A^+X^- in CD_3CN: M=$\mathbf{I_h}$ (β-Tal), A^+X^-=$PhCH_2CH_2NH_3^+PF_6^-$. A solution of (a) A^+X^-, (b) M+A^+X^-, or (c) M.

values reflect weighted averages of the existing M (or A^+) and $(M+A)^+$ species.

(a) Equilibrium Constant in Solution: From the concentration-dependent ICS of the ammonium proton signal, the equilibrium constant (K_s for Eq. 1) could be determined by using a Benesi-Hildebrand equation.[28] The K_s for $(M+A)^+$ adduct ion formation between $\mathbf{I_h}$ and 2-phenylethylammonium ion ($A_4^+PF_6^-$) is estimated to be 9 M^{-1} at 30 °C in CD_3CN ([M]/[$A_4^+PF_6^-$]=10—23, [$A_4^+PF_6^-$]$_{fix}$=0.0045 M, ICS range=113—195 Hz).[29,30]

(b) Position-Dependent Induced Chemical Shifts in Solution: ICS values for different pairs of M and A^+X^- in CD_3CN could be determined by using ^{1}H NMR. Spectral assignment was done by irradiation techniques and in light of the reported assignments.[32] In spite of different cationic species such as 2-phenylethylammonium, ammonium, and potassium ions, similar ICS patterns of M were observed for $\mathbf{I_h}$: that is, (1) the ICS ordering for the ring protons is H_2=H_4>H_1>H_3, (2) three of five methyl proton signals show more downfield shifts than the others (not assigned).

Compared with the results for $\mathbf{I_h}$, those for $\mathbf{I_g}$ are characterized by the decrease of the H_1 ICS value, and the decrease of the number of more downfield methyl proton signsls. On the other hand, $\mathbf{I_f}$ seems to give nearly isotropic shift pattern, and $\mathbf{I_a}$ shows no NMR changes to detectable extents. These position-dependent ICS data are deposited as Document No. 9109 at the office of Bull. Chem. Soc. Jpn.

MNDO Calculations of Model Systems. MNDO optimized structures were obtained by using the simplest model system, where Li^+ was used instead of K^+ (or RNH_3^+) to elucidate the essential complexation sites and relative binding energies of M toward the cation in the gas-phase. As schematically shown in Chart 3, in the cases of $(M+A)^+$ ions for $\mathbf{I_h}$ and $\mathbf{I_g}$, the cationic centers are located at almost equal distance (2.3 Å±0.1) from the three oxygens of the O-2, O-4, and the ring-O.[33] The distance corresponds to a sum of oxygen Van der Waals radius (1.6 Å) and Li^+ radius (0.6 Å).

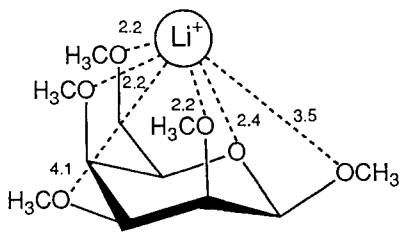

Chart 3.

Discussion

Relative Peak Intensity in FABMS vs. Gas-Phase Stability for $(M+A)^+$ Adduct Ion Formation. An illustration of the importance of gas-phase phenomena for the relative peak intensities in FABMS is shown in Fig. 4. The results are similar to those of Kebarle et al.[34,35] Here, the logarithm of the relative peak intensity, $\log[I(M+K)^+/I(R+K)^+]$, for the family **I** is plotted against that of the corresponding relative area intensity, $\log[A(M+K)^+/A(R+K)^+]$, in FABMS/MS (CAD). The latter quantities are taken as a reference measure of the relative stabilities (relative binding energies) of the relevant $(M+K)^+$ ions in the gas-phase.

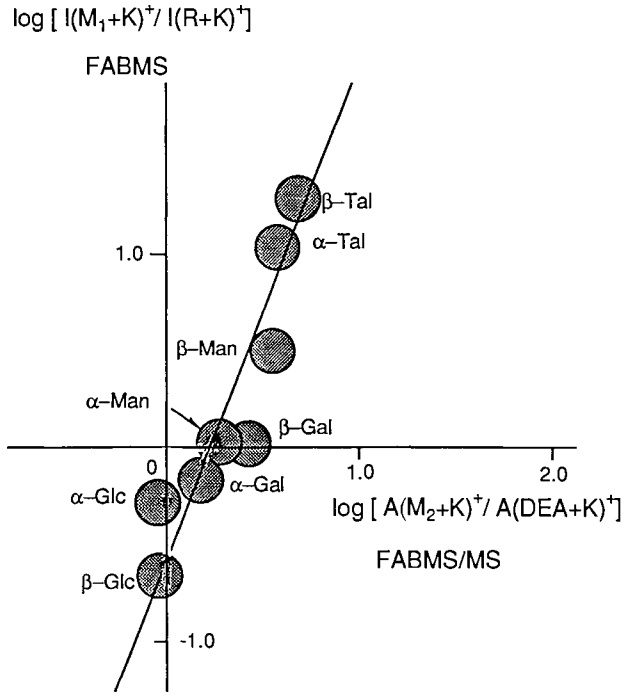

Fig. 4. Relative $(M_1+K)^+$ peak intensity data on FABMS are plotted against relative $(M_2+K)^+$ area intensity data on FABMS/MS(CAD). M_1 is the family **I**, and M_2 is the family **II**.

A good correlation is observed for the family **I**, but not clearly observed for the family **II** because of a narrow range of the relative peak intensities (not shown). This illustrates that the relative peak intensities of the family **I** in FABMS reflect characteristically the relative stabilities of $(M+A)^+$ ions in the gas-phase.[23–25] Recently, there has appeared the other aspect that relative peak intensities in FABMS reflect just solution phenomena on the basis of the results for 18-crown-6 complexations,[20,36] etc.[37] Unfortunately, we can not estimate the K_s values in solution except for $\mathbf{I}_h$. They are too small to be estimated for the entire series of the family **I** by ^{1}H NMR ICS methods.[29] Therefore, there still remains the possibility that the gas-phase stability is essentially parallel to the solution-phase stabilities for $(M+A)^+$ ions of the family **I**. In the family **II**, intramolecular hydrogen bonding toward transannually located oxygens may mask such selective complexations. One of the relevant examples has been seen in the complexation of a modified crown ether.[14]

The demonstration that the family **I**, compared with the family **II**, shows much larger selectivity toward an organic (or metallic) cation is practically important for wider applications of FABMS. Permethylation of saccharides would also provide the increase of electron densities on the oxygen atoms for good complexation. The finding of such a larger selectivity will open a new practical approach that the relative stabilities of saccharide-cation adduct ions can

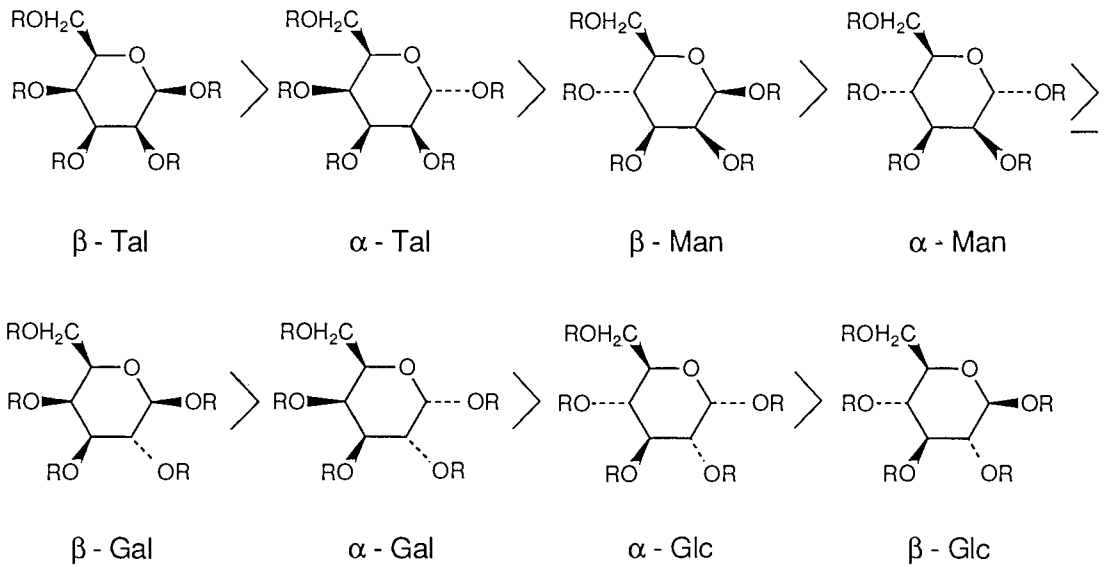

Chart 4.

Table 4. Effects of Alkylammonium Ions on Relative Peak Intensities in FABMS (Glycerol Matrix)

Substrate M	Relative peak intensity			
	$[M+A_1]^{+}$ a)	$[M+A_2]^{+}$ b)	$[M+A_3]^{+}$ c)	$[R+1]^{+}$ d)
I$_f$ (β-Man)	32	23	5	100
I$_h$ (β-Tal)	120	69	8	100
15-crown-5	120	12	—	100
18-crown-6	400	8	—	100

a) $A_1^+X^-$=$PhCH_2CH_2NH_3^+Cl^-$. b) $A_2^+X^-$=$PhCH_2NH_2^+(CH_3)Cl^-$. c) $A_3^+X^-$=$PhCH_2NH^+(CH_3)_2Cl^-$. d) R^+X^-=$(n\text{-}C_4H_9)_4N^+Cl^-$ (internal reference).

be easily judged by the corresponding relative peak intensities in conventional FABMS, (1) if saccharides are permethylated or more generally peralkylated, and (2) if FABMS is applied to a proper stereoisomeric series of saccharides in a careful comparison.

Stereochemical Effects of Permethylated Monosaccharides on $(M+A)^+$ Peak Intenstities. It is obviously found from Table 2 that the relative $(M+A)^+$ peak intensities for the family **I** show a close relationship with the configuration effect of the CH_3O groups included. The ordering is pictured by using Mills formulae (Chart 4). From the comparison among epimers, the more CH_3O groups are located on the same side, the larger the $(M+A)^+$ ion peak is. From the comparison between anomers, the $(M+A)^+$ ion peak for β-anomer is essentially larger than that for α-one.

Let us consider a series of β-anomers for the pyranose set. Here, the O-1, O-3, O-6, and the ring-O are common in the series. In the case of the highest peak-intensity (β-Tal), the monosaccharide has two upward axial oxygens (O-2, O-4). In the case of middle one (β-Man or β-Gal), M has one upword axial oxygen (O-2 or O-4, respectively). In the lowest case (β-Glc), there is no upward axial oxygen. These characteristics are consistent with the fact that the upward axial oxygen is very effective for stabilizing $(M+A)^+$ adduct ions. Further, the β-anomer preference is also consistent with the fact that the upward equatrial oxygen has also a contribution for stabilizing $(M+A)^+$ ions somewhat less than the upward axial one. These findings are in good agreement with some MNDO predictions of the model systems. The intensity difference of β-Man from β-Gal informs that the axial O-2 can act more effectively for stabilization than the axial O-4.

The affinity ordering of different permethylated monosaccharides for the cation by generating $(M+A)^+$ ions can be reasonably interpreted in terms of multisite electrostatic interaction for effective binding.[38,39] The cooperative multisite binding is one of the main interaction mechanisms for the well-known crown ether-cation complexation.[38] A complexation site of the organic (or metallic) cation can be deduced from MNDO model calculations, at least for the cases of **I**$_h$ and **I**$_g$, where the cationic centers are located at nearly equal distance from the O-2, O-4, and the ring-O: that is, the Li^+ cation stands in contact with the three oxygens.[33]

^1H NMR ICS data also support this type of structures with organic (or metallic) cations. The picture is just consistent with the host-guest type association, as seen, for example, in the crystal structure of the complex between benzo-15-crown-5 and Ca^{2+} ion.[40] On the other hand, a different complexation site in the complex between epi-inositol and La^{3+} (D_2O) has been reported.[16] The ^1H NMR limiting shift values[16c,41] of H-3 are completely different each other, supporting the different complexation sites with cations between the two complexes in solutions.

Affinities toward primary, secondary, and tertiary alkylammonium ions are informative (Table 4). In the case of crown ethers (18C6, 15C5), the primary alkylammonium ion provides the highest $(M+A)^+$ peak, and the tertiary one shows no $(M+A)^+$ peak. The affinity ordering (prim.≫sec.≫tert.) is corresponding to the number of ^+N-H hydrogen atoms which can exert hydrogen bondings with host oxygens. Similarly, in the case of the permethylated monosaccharides (β-Tal, β-Man), the ordering is prim.>sec.>tert. Hydrogen bonding between the permethylated monosaccharide and alkylammonium ion may be effective to lesser extents in these complexations.

Experimental

General. ^1H NMR spectra were determined on a Bruker AM360 spectrometer. Chemical shifts are given in units in ppm relative to TMS as an internal standard (δ=0). Liquid column chromatography was carried out on a Yamazen LC apparatus using a column (50×1.5 cm) packed with Merck LiChroprep Si 60 (0.025—0.040 mm) under medium-pressure (1.5—2 kg cm^{-2}, flow rate 1.5 mL min^{-1}); 1:1 hexane/ethyl acetate was used as a typical eluent. For separation of aldopyranose/aldofuranose or its anomer derivative, a fraction collector (Gilson model 203) was employed with continuous TLC checking or RI monitoring (Yamazen, RI-31). The TLC checking was carried out on a piece (size 10×2. 5 cm) of Merck Kieselgel 60 F_{254} sheet. The TLC plates were sprayed with an 10% aqueous H_2SO_4 solution containing 1% $Ce(SO_4)_2$, and then heated on a hot plate until the spots become visible in blown (2—3 min).

Gas chromatography was performed on a Shimadzu GC-

9A instrument using a conventional glass column packed with Silicone OV 17/Chromosorb W or SE 30 (detection by FID mode, data reduction by C-R5A chromatopac). IR spectra were measured with a Hitachi 345 IR or an Analect RFX65 FTIR spectrometer. Mass spectra were recorded with a JEOL DX300 instrument under FAB and/or EI mode. MS/MS spectra were obtained with a JEOL JMS-HX100 instrument having E/B/E-type operation.[26]

Purity of the materials prepared was verified by ^{1}H NMR, EIMS, FABMS, and FTIR spectra. These spectra of the family **I** and the family **II** have been stored in the total computer system designated as 'TASMAC', ISIR, Osaka Univ.[43]

Materials. KF–alumina reagent was prepared according to the published procedure by Ando et al.[44] Alumina (Al_2O_3, Merck Aluminiumoxid 90 aktiv, neutral, 70—230 mesh, 60 g) was poured into an aqueous solution (70 ml) of KF (40 g) and fully shaked and stirred. After then, the water was removed at 50—60 °C with a rotary evaporator in vacuo. The impregnated alumina was further dried in a vacuum oven (15—20 mmHg) for 7 h at 70—80 °C (yield 102 g).

General Preparation of Permethylated Monosaccharides (family I). The respective methyl α- or β-D-aldopyranoside (0.20 g, 1.0 mmol) was mixed with methyl iodide (0.5 mL, ca. 8 mmol), and KF–alumina reagent (2.75 g, ca. 20 mmol) in acetonitrile (20 ml), and magnetically stirred in a teflon sealed tube at room temperature for 2 or 3 d (tetramethylation). The solid material was filtered off and washed several times with acetonitrile. The combined acetonitrile solution was evaporated in vacuo to dryness. The residue was dissolved into chloroform, washed with water, and filtered. Purification by liquid column chromatography usually at atmospheric pressure using Merck Kieselgel 60 (0.040—0.063 mm (230—400 mesh), 15 cm or 50 cm column length, 1 : 1 hexane/ethyl acetate or 5 : 5 : 1 hexane/ethyl acetate/methanol eluent) gave the corresponding methyl tetra-*O*-methyl-D-aldopyranoside (family **I**) in a yield of 70—80% as a ^{1}H NMR pure sample. Examples of starting materials are methyl α-D-glucoside (Wako),[45] methyl β-D-glucoside (Wako),[45] methyl α-D-galactoside (Nakalai), methyl β-D-galactoside (Sigma), methyl α-D-mannopyranoside,[46] methyl α-D-talopyranoside,[47] methyl α-D-ribofuranoside, and methyl β-D-ribofuranoside.[47,48]

In the case of pentamethyl β-D-mannopyranoside ($\mathbf{I}_f$) or pentamethyl β-D-talopyranoside ($\mathbf{I}_h$), the corresponding underivatized D-aldose commercially available was directly methylated (pentamethylation) with KF–alumina reagent by the same method as described before and then, the desired permethylated derivative was separated from a mixture of aldopyranosides and aldofuranosides by using medium-pressure liquid column chromatography (see below).

Preparation of Methyl Tetra-*O*-methyl-β-D-mannopyranoside ($\mathbf{I}_f$). A mixture of D-mannose (Wako. 0.20 g), methyl iodide (0.5 ml), and KF–alumina reagent (2.75 g) in acetonitrile (30 mL) was magnetically stirred at room temperature for a prolonged period (7 d, pentamethylation). After filteration and evaporation, the products were dissolved into chloroform, washed with water. The solution was filtered and evaporated to dryness. TLC analyses showed four major spots suggesting four stereoisomers. By using medium-pressure liquid column chromatography with an eluent of 5 : 5 : 1 hexane/ethyl acetate/methanol (v/v), the fraction showing R_f value of 0.38 (the fourth spot from top) was collected as the major one. The ^{1}H NMR[32] and mass spectral data indicated the product being the desired $\mathbf{I}_f$ (40% yield); ^{1}H NMR ($CDCl_3$) δ=4.29 (d, 1H $J_{1,2}$=0.8 Hz, C_1-H), 3.69 (dd. 1H, $J_{6,6'}$=9.1 Hz, C_6-H), 3.67 (dd, 1H, $J_{2,3}$=3.2 Hz, C_2-H), 3.60 (dd, 1H, $J_{5,6'}$=5.6 Hz, $C_{6'}$-H), 3.35 (t, 1H, $J_{4,5}$=9.5 Hz, C_4-H), 3.29 (octet. 1H, $J_{5,6}$=2.0 Hz, C_5-H), 3.19 (dd, 1H, $J_{3,4}$=8.7 Hz, C_3-H), 3.618, 3.520, 3.518, 3.493, 3.407 (s, 15H, OMe).

Preparation of Methyl Tetra-*O*-methyl-β-D-talopyranoside ($\mathbf{I}_h$). $\mathbf{I}_h$ was prepared by the analogous way mentioned above. Direct pentamethylation of D-talose (Sigma, 0.20 g) gave four TLC spots. Three major materials could be separated. Among them, the fractions showing R_f value of 0.17 (the fourth from top) was collected as the major one (eluent 1 : 1 hexane/ethyl acetate or 5 : 5 : 1 hexane/ethyl acetate/methanol). The product was the desired $\mathbf{I}_h$ on the basis of ^{1}H NMR and mass spectral data (60 mg, 22% yield); ^{1}H NMR ($CDCl_3$) δ=4.33 (d, 1H, $J_{1,2}$=1.6 Hz, C_1-H), 3.75—3.70 (m, 2H), 3.63—3.54 (m, 3H), 3.265 (t, 1H, J=3.17 Hz), 3.593, 3.522, 3.507, 3.485, 3.404. In this pentamethylation process, *N*-methylacetamide was detected as a by-product (^{1}H NMR, IR, and GC analyses).

Quantitative FABMS Measurements. FAB mass spectra were obtained by using argon as the bombarding atom, with a beam energy of 6 keV. A stainless steel probe-tip was employed in each case. Mass conversion was carried out off-line on the basis of perfuruoro kerosene (PFK) calibration. In order to get higher reproducibility on peak intensity data, all the FAB spectra by quantitative measurements were averaged from at least 10 scans (1 scan=4 s) using a JMA-3100 data system.[22]

A typical preparation of sample solution is as the following. (1) The respective permethylated monosaccharide (16 μL) was dissolved into methanol (1 mL) (17.6 mg mL^{-1}; 0.07 M). (2) (Methoxycarbonyl)methylammonium chloride (0.88 g) was dissolved into methanol (10 mL) (8.8 mg mL^{-1}, 0.7 M). (3) Methyl tetra-*O*-methyl-d_{12}-α-D-mannopyranoside ($\mathbf{I}_f$-d_{12}) as an internal standard was dissolved into a mixture of glycerol and methanol (3/1 v/v) (1.0 ml; 0.07 M). The above three solutions were mixed: 10 μL of the solution (1) +10 μL of the solution (2) +20 μL of the solution (3). After mixing well with a vibrater, 1.5 μL of the resulted solution was deposited on a probe-tip as a sample solution for quantitative measurements on positive ion FABMS. This corresponded the molar concentration ratio of each monosaccharide (M) to the internal standard (R) to be 1 : 1.

In the case of octylammonium ion series, octylammonium chloride (0.12 g) was dissolved into methanol (10 mL), (0.07 M), and it was used as the solution (2) in the above series mentioned.

The probe-tip was placed in the ion source and ca. 2 min were allowed for the source vacuum to settle (5×10^{-6} Torr, 1 Torr=133.322 Pa), and the Ar atom gun was turned on. After a further 1 min, FAB spectra were recorded. At an accelerating voltage of 3 kV, the mass range *m/z* 200—400 was scanned in 3 s scan cycle time. Thirty successive spectra of each sample solution were acquired and the 10 scans between 10 and 20 were summed to get the quantitative spectra for the family **I** or the 10 scans between 15 to 25 for the family **II**. The relative abundance at the required *m/z* values was measured and averaged over the 3 runs, and

compared with the data of other monosaccharides after normalization to the constant abundance of the internal standard (R).[20]

MNDO Calculations. Calculations of geometries and energies for the $(M+A)^+$ ion composed of $\mathbf{I}_h$ (or $\mathbf{I}_g$, $\mathbf{I}_f$) and Li^+ were carried out on a FACOM S3500 superminicomputer (ANCHOR in TASMAC system)[43] by using MNDO molecular orbital methods.[49] The geometries and energies were obtained from the standard DFP optimization procedures. For example, for obtaining an initial geometry of $\mathbf{I}_h$, crystal structure data of underivatized α-D-talose were employed.[50]

We are grateful to Mr. Takanori Tanaka and Mrs. Fusako Fukuda for the measurements of FTIR spectra and the elemental microanalyses at Material Analysis Center, ISIR, Osaka University.

Effect of a Hydrogen Pretreatment on the Mechanism of Deuterium Addition and Exchange of Propene over Ni-Cu Alloy Catalysts

Shuichi NAITO* and Mitsutoshi TANIMOTO†

(Received August 30, 1990)

The effects of a hydrogen pretreatment on the activity and reaction intermediate in a C_3H_6–D_2 reaction over a Ni-Cu alloy as well as Ni metal catalysts were investigated in detail by applying an isotope tracer technique. Ni metal and Ni-rich alloy catalysts, cooled down to the reaction temperature under a hydrogen atmosphere (D-surface), exhibited low activity compared to that of a surface evacuated before cooling (E-surface). For Cu-rich alloy catalysts, however, the E-surface exhibited a lower activity and a higher activation energy than did the D-surface. A comparison of the TPD spectra of adsorbed hydrogen with the dependence of the activity upon the evacuation temperature suggests that strongly adsorbed hydrogen retards the reaction over Ni and Ni-rich alloy catalysts at lower temperature. Microwave spectroscopic analysis demonstrated that the reaction intermediates over D- and E-surfaces of Cu-rich alloy catalysts were similar to those over Cu and Ni metals, respectively. This result suggests that a hydrogen pretreatment of Cu-rich alloys forms a specific surface structure which is destroyed by evacuation at elevated temperatures.

Bimetallic alloy systems comprising an active group-VIII metal and an inactive group-IB metal have extensively been investigated, since they allow one to study the role of the "geometric, or ensemble, effect" as well as the "electronic, or ligand, effect" in alloy catalysts.[1-3] Among them, a nickel-copper alloy system has received particular attention from the viewpoint of both the surface structure and the catalytic behavior in hydrogen exchange,[4-6] hydrogenation,[7-12] hydrogenolysis[13] or dehydrogenation[14] of various hydrocarbons. Analyses of its surface composition by various methods, such as selective chemisorption,[15,16] work function change,[17-19] and AES (Auger Electron Spectroscopy) measurements,[20,21] have disclosed a considerable enrichment of copper on the surface, which is inactive for the reactions mentioned above. Accordingly, the dilution effect of active metal ensembles by inactive atoms would be significantly pronounced in these systems (ensemble effect). In fact, it is well known that reactions involving C-C bond fission or formation are suppressed much more efficiently by alloying than reactions involving C-H bonds on this catalyst.[1,4,6,13] The situation is somewhat different in the case of the hydrogenation reaction, which proceeds at a much lower temperature than does hydrogenolysis or dehydrogenation.

Best and Russell[7] examined the hydrogenation of ethene over Ni-Cu alloy catalysts of various composition and observed several orders of magnitude higher activity in the copper-rich range than over a pure Ni catalyst. Hall and Emmett[8] reported a remarkable dependence of the activity for this reaction upon the pretreatment over Ni-Cu alloy catalysts as well as pure Ni catalysts. When the catalysts were evacuated at the temperature at which the reduction had been carried out, and then cooled in vacuo or in flowing helium, the activity decreased as the copper content of the catalyst increased. On the other hand, if the catalysts were cooled in a hydrogen atmosphere the activity showed two maxima at around 30 and 70 atm% of copper in the alloy composition.[9] Hall and Hassell further demonstrated that these results could be explained in terms of a promotion effect of strongly adsorbed hydrogen on the hydrogenation rate over alloy catalysts and a suppression effect over pure Ni metal.[10] To clarify the intrinsic nature of this effect, it is obviously necessary to study changes not only in the reaction rates, but also in the reaction mechanism by these pretreatments.

Deuterium addition and exchange of propene (C_3H_6–D_2 reaction) would be an excellent probe reaction for this purpose, since it enables one to investigate the fine structure of the reaction mechanism by applying microwave spectroscopy.[22] The temporal changes in the isotope distribution in monodeuteriopropene formed during the reaction can be followed. We have examined the effect of a pretreatment on the C_3H_6–D_2 reaction over Ni-Cu alloy catalysts of various compositions and found the same phenomena as in the case of the C_2H_4–H_2 reaction. Moreover, the relative activity of the reaction intermediates, propyl and isopropyl adsorbed species, was demonstrated to change with the manner of pretreatment, as well as the surface composition of Ni and Cu. In the present paper we describe in detail the experimental results and discuss in depth possible features of this effect.

Experimental

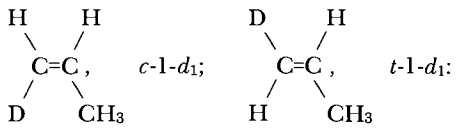
Catalyst Preparation. Powders of Ni-Cu alloy and pure metals (Ni and Cu) were prepared by carefully reducing the corresponding oxide powders according to a method described in the literature.[15] First of all, carbonate powders were coprecipitated by adding aqueous nitrate solutions ($Ni(NO_3)_2 \cdot 6H_2O$ and $Cu(NO_3)_2 \cdot 3H_2O$; Wako Chemicals,

spec. pure) dropwise to aqueous NH_4HCO_3 solutions (Wako Chemicals, spec. pure) with vigorous stirring. The precipitates were filtered, washed thoroughly with distilled water, dried, and calcined in air at 673 K for 2 h. The oxide powders were placed in an U-shaped reactor and reduced with flowing hydrogen by increasing the temperature very slowly from 298 to 773 K (within about 12 h) and then maintaining that temperature for 20 h. The bulk composition of the alloys employed were 0.5, 25, 60, and 90 atom% of copper.

Catalyst Characterizations. The surface areas and surface compositions in alloy catalysts were determined by N_2 physisorption at its normal boiling point and H_2 chemisorption at room temperature. About a one-order-of-magnitude larger amount of the catalysts (10—15 g) than that used for the catalytic reaction were employed in order to obtain precise values for adsorption experiments. Before measurements, the catalysts were reduced with H_2 at 623 K for 2 h and then evacuated at the same temperature for 0.5 h in a volumetric apparatus (base pressure was 1×10^{-3} Pa). The crosssectional areas of the N_2 molecule and the H atom were assumed to be 16.2 and 6.45 Å^2, respectively. Hydrogen was chemisorbed at room temperature in order to obtain total uptake. The catalyst was then evacuated under vacuum for 30 min at room temperature. Readsorption measurements were carried out in order to determine the amount of weakly adsorbed hydrogen. The amount of strongly adsorbed hydrogen was determined from the difference between these two values. The surface area of this strongly adsorbed hydrogen was assumed to correspond to that of surface Ni. Comparing this with the total surface area obtained by the BET method, the surface compositions of Ni and Cu could be estimated. The obtained results were as follows: 0.5 mol% bulk Cu=0.55 surface Cu, 25 mol% bulk Cu=0.77 surface Cu, 60 mol% bulk Cu=0.78 surface Cu, 90 mol% bulk Cu=0.91 surface Cu. These surface compositions were qualitatively confirmed by XPS (X-ray photoelectron spectroscopy) analysis (ESCALAB 5). The formation of a monophase homogeneous alloy was confirmed by observing their characteristic X-ray diffraction pattern. The lattice constants of alloy powders obtained were consistent with Vegard's law: Ni=3.52 Å, Ni-Cu(0.5)=3.52 Å, Ni-Cu(25)=3.54 Å, Ni-Cu(60)=3.58 Å, Ni-Cu(90)=3.60 Å, and Cu=3.61 Å.

Reaction Procedure, Detection Method, and TPD Procedure. H_2 and D_2 gases from commercial cylinders were purified by circulating over a heated palladium black catalyst to remove trace amount of oxygen. C_3H_6 purchased from Takachiho Kagaku K.K. was purified by a freeze-thaw cycle. The C_3H_6-D_2 reaction was carried out in a closed gas circulation system (total volume: 310 cm^3). Before each run the catalyst was freshly reduced by D_2 at 473 K for 2 h. For a reaction over a deuterium pretreated surface (D-surface), the catalyst was cooled to the reaction temperature without evacuating deuterium gas. For a reaction over an evacuated surface (E-surface), the catalyst was evacuated at 473 K for 1 h and then cooled down to the reaction temperature under vacuum. A certain amount of the C_3H_6-D_2 mixture was introduced into the system and the reaction started. The reaction temperature was maintained with suitable slush bathes.

At certain intervals during the reaction, a few percent of the circulating gas was sampled and analyzed. The composition of the gas was determined by gas chromatography (alumina column, He carrier). The deuterium contents in the exchanged propene and formed propane were determined with a mass spectrometer (Hitachi, RMU-6MG) using ionization voltages of 12 and 15 eV, respectively. The location of the deuterium atom in mono- and dideuteriopropene was determined by recording the microwave absorption line (1_{01}—0_{00} rotational transition) characteristic of each isotopic species. The notation for isotopic isomers in monodeuteriopropene is:



CH_2=CD-CH_3, 2-d_1. CH_2=CH-CH_2D, 3-d_1.

TPD (Temperature programmed desorption) experiments were carried out in a separate UHV apparatus (base pressure: 1×10^{-7} Pa), equipped with a mass spectrometer (UTI 100). The heating part was made of a quartz cell, in which about 10 mg of catalyst was placed. The heating rate was set to 15 K min^{-1}.

Results

Kinetics of C_3H_6-D_2 Reaction over D-Surfaces. When a mixture of D_2 (6.7 kPa) and C_3H_6 (2.0 kPa) was introduced over D-surfaces of Ni and Ni-Cu alloy catalysts at 170—220 K, both deuterium addition and exchange reaction took place simultaneously. The D-surface was prepared by D_2 reduction at 473 K or 2 h, followed by cooling down to the reaction temperature without evacuation. Typical time courses of the reaction over Ni metal and Ni-Cu(25) (25 mol% bulk Cu) catalysts are shown in Fig. 1. In the case of Ni metal (Fig. 1(a)), the main product in the exchange process was C_3H_5D (propene-d_1), the formation rate of which was twice as fast as that of propane. During a later stage of the reaction, $C_3H_4D_2$ (propene-d_2) was detected, suggesting a successive reaction in the exchange process. The reaction over Ni-Cu(25) was nearly two orders of magnitude faster than that over Ni metal (Fig. 1(b)). The time course was similar to that over Ni, except that C_3H_5D and propane were formed in comparable amounts. The reaction behavior of other catalysts could be divided into these two categories: Ni-Cu(0.5) alloy was similar to Ni metal; Ni-Cu(60) and (90) alloys were similar to Ni-Cu(25).

The temperature dependence of the turnover frequency (TOF) of propane formation over various catalysts is displayed in Fig. 2. The TOF was estimated assuming that only the surface Ni atoms are active for this reaction. The activity for propane formation decreased in the following order: Ni-Cu(60)≈Ni-Cu(25)>Ni-Cu(90)>Ni-Cu(0.5)<Ni metal. The activation energies of the reaction were also classified into two categories. Ni-Cu(0.5) catalyst exhibited an activation energy (41 kJ mo^{-1}) similar to that of Ni metal (39 kJ mol^{-1}). The activation energy considerably decreased by alloying, and the same value (31 kJ mol^{-1}) was observed for Ni-Cu(25), (60), and (90) alloy catalysts.

The pressure dependence of the turnover frequency for propane formation over Ni and Ni-Cu(25) catalysts is demonstrated in Fig. 3. Over a Ni catalyst the reaction orders for the partial pressures of hydrogen and propene were 0.37 and 0.07, respectively. Upon alloying, they decreased as follows: 0.45 for the partial pressure of hydrogen and −0.15 for propene; this suggests an increase in the adsorption strength of propene by alloying.

Kinetics of C_3H_6-D_2 Reaction over E-Surfaces. Figure 4 demonstrates the temperature dependence of propane formation over the E-surfaces of Ni and Ni-Cu alloy catalysts. The E-surfaces were prepared by D_2 reduction at 473 K, followed by evacuation at the same temperature for 1 h. It was recognized that this evacuation treatment drastically accelerates the propane formation rate over both Ni and Ni-Cu(0.5) catalysts, although their activation energies did not change at all. The situation was completely different over

other alloy catalysts: the rate decreased more than one order of magnitude with an increase in the activation energy to 40 kJ mol^{-1} for Ni-Cu(25), (60), and (90) catalysts.

To investigate the relation between the D- and E-surfaces of Ni and Ni-Cu(0.5) catalysts, the effect of the evacuation temperature upon the rate of propane formation was examined, as summarized in Fig. 5(a). After reduction by D_2 at 623 K for 2 h, the catalyst was evacuated for 1 h at various temperatures from 190 to 623 K and then cooled down to the reaction temperature (190 K for Ni and 210 K for Ni-Cu(5)), before C_3H_6-D_2 reaction was carried out. In the case of the Ni catalyst, the rate gradually increased as the evacuation temperature was increased, and reached a plateau activity at around 450 K. Over a Ni-Cu(0.5) catalyst, this plateau temperature was considerably lowered (360 K). Fig. 5(b) demonstrates the TPD spectra of adsorbed hydrogen over pure Ni, Ni-Cu(0.5) and Ni-Cu(25) alloy catalysts. The adsorption was carried out at 273 K for 1 h (P_{H_2}=6.7 kPa). After evacuation up to 10^{-7} Pa, the catalyst was heated at a rate of 15 K min^{-1}. Two maximum peaks were observed in the case of Ni. The higher temperature peak was considerably diminished and disappeared in the Ni-Cu(25) catalyst.

Microwave Spectroscopic Study of C_3H_6-D_2 Reaction. It has been well established that deuterium addition and exchange processes in the C_3H_6-D_2 reaction over Ni and Cu metal catalysts proceed through common σ-alkyl intermediates: propyl and isopropyl adsorbed species (associative mechanism).[23,24] The situation seemed to be identical over Ni-Cu alloy catalysts in the present study, because the rates of both addition and exchange processes exhibited similar temperature dependences, indicating equal activation energies. Moreover, the rate of the hydrogen exchange in the C_3H_6-C_3D_6 reaction, which should proceed via a dissociative mechanism, was more than two orders of magnitudes slower than that in the C_3H_6-D_2 reaction. Consequently, it is evident that hydrogen exchange in the C_3H_6-D_2 reaction over alloy catalysts takes place via a reverse process of the σ-alkyl intermediate formation, as in Ni and Cu catalysts.

The isotopic distributions of formed propane over

$C_3H_5D_3$	0.09	0.09	0.11	0.12
$C_3H_4D_4$	0.01	0.01	0.02	0.02
$C_3H_3D_5$-C_3D_8	0.00	0.00	0.00	0.00
CD_2=CH-CH_3	0.03	0.04	0.06	0.07
CHD=CD-CH_3	0.85	0.85	0.80	0.79
CHD=CH-CH_2D	0.01	0.00	0.03	0.02
CH_2=CD-CH_2D	0.12	0.12	0.11	0.12
CH_2=CH-CHD_2	0.00	0.00	0.00	0.00

these catalysts are summarized in Table 1. Propane-d_2 was the main product over Cu (24), whereas comparable amounts of propane-d_0, -d_1, and -d_2 were formed over Ni catalyst.[23] The latter phenomenon corresponds well to the first observation by Turkevich et al.[25] that C_2H_6 was mainly formed during the initial stage of the C_2H_4-D_2 reaction over Ni, which was reasonably explained by an associative mechanism.[26]

The relative reactivity of propyl and isopropyl intermediates can be estimated by observing the isotopic distribution of monodeuteriopropene formed in the exchange process of the C_3H_6-D_2 reaction. Microwave spectroscopic results over the D-surface are summarized in Figs. 6 and 7. Over a Ni catalyst (Fig. 6(a)) more than 90% of the exchanged products was propene-2-d_1, which would be formed through a propyl adsorbed intermediate. The remainder of the products were equal amounts of propene *cis*- and *trans*-1-d_1 with a small amount of propene-3-d_1. This result suggests that the isopropyl species is adsorbed in a distorted manner, so that hydrogen exchange takes place mainly on the C_1 carbon of the double bond. On the other hand, over a Cu catalyst (Fig.6(b)), the proportion of propene-2-d_1 decreased from 93 to 73%, with an increase of *cis*- and *trans*-1-d_1. As on the Ni catalyst, the amount of propene-3-d_1 was slight during the reaction, suggesting a sterically distorted adsorption of the isopropyl intermediate. Figure 7 demonstrates the isotopic distribution pattern in the case of Ni-Cu(0.5) and (25) catalysts. This pattern is quite similar to that of Ni metal in the case of a Ni-Cu(0.5) catalyst (Fig. 7(a)), whereas it resembles that of Cu metal in the case of a Ni-Cu(25) catalyst (Fig. 7(b)).

The closed symbols in the figures represent data for

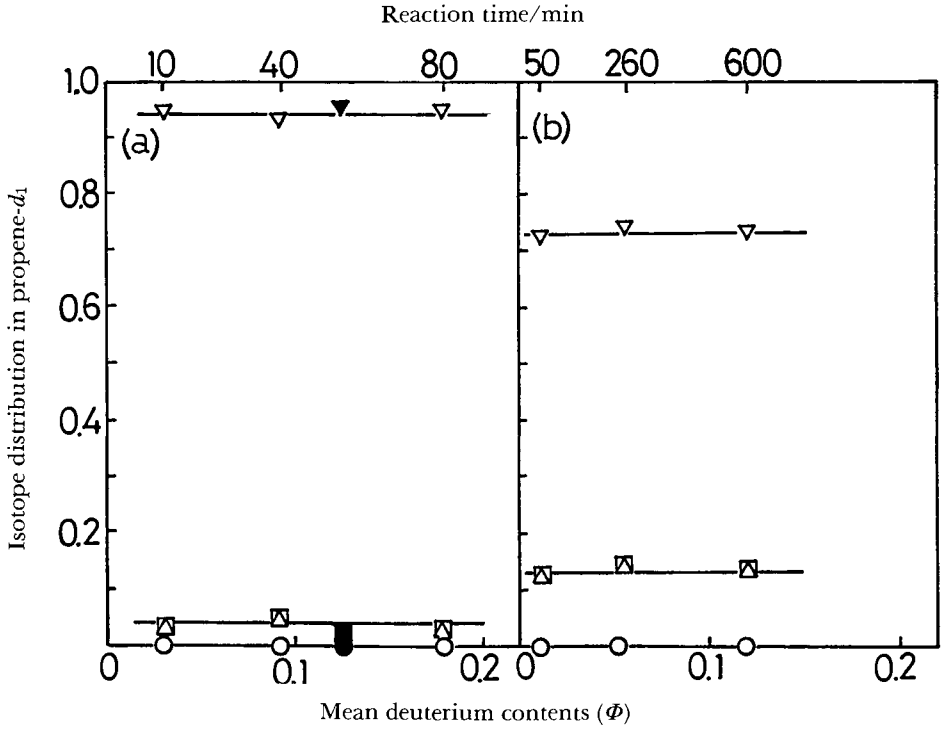

Fig. 6. Time course of the isotopic distribution in monodeuteriopropene during C_3H_6-D_2 reaction over (a) Ni metal at 200 K, and (b) Cu metal at 263 K. p_{D_2}=6.7 kPa, $p_{C_3H_6}$=2.0 kPa, Catalyst=1 g. Open symbols: over D-surfaces, closed symbols: over E-surfaces.

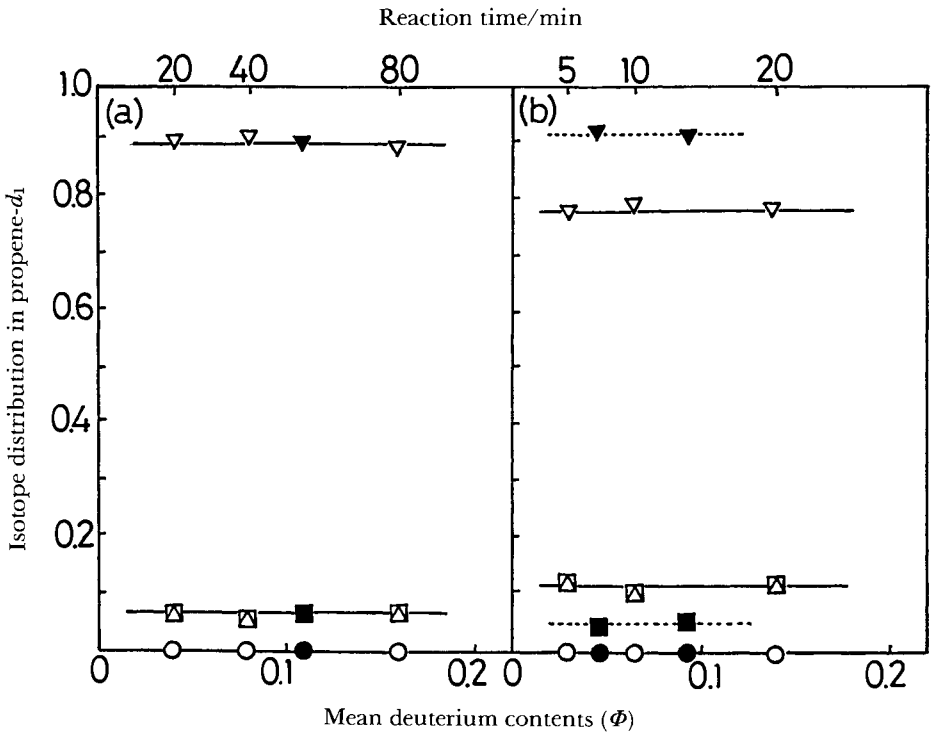

Fig. 7. Time course of the isotopic distribution of monodeuteriopropene during C_3H_6-D_2 reaction over (a) Ni-Cu(0.5) alloy at 190 K, and (b) Ni-Cu(25) alloy at 180 K.
p_{D_2}=6.7 kPa, p_{D_2}=2.0 kPa, Catalyst=1 g. Open symbols: D-surfaces, closed symbols: E-surfaces.
□■: c-1-d_1, △▲: t-1-d_1, ▽▼: 2-d_1, ○●: 3-d_1.

the corresponding E-surfaces. The time-course curves on the E-surface do not differ from those on the D-surfaces in the case of Ni and Ni-Cu(0.5) catalysts, whereas a clear difference can be seen for the Ni-Cu(25) catalyst. Its pattern resembles that on pure Ni metal. Similar results were observed in the cases of Ni-Cu(60) and (90) catalysts.

The results of a microwave spectroscopic analysis of propene-d_2 over D-surfaces of these catalysts are summarized in Table 1. The main d_2-product was propene-1,2-d_2, which can be reasonably explained by a successive reaction in the exchange process; dideuteriopropene may be formed by a repetitive exchange of monodeuteriopropene through σ-alkyl intermediates.

Discussion

It is well known that the surface composition of alloy catalysts is different from the bulk composition.[2,3] In the case of a Ni-Cu alloy, segregation and enrichment of copper on the surface is demonstrated by various methods.[15-21] In the present study, a hydrogen treatment at 773 K realized homogenization of alloys, which was confirmed by their characteristic X-ray diffraction patterns, as described in the experimental section. The surface compositions of alloys were determined by hydrogen chemisorption at room

temperature, under the assumption that strong adsorption of hydrogen occurs only on surface nickel atoms. Since adsorption was measured after evacuation at 623 K, the estimated values should correspond to the surface composition of the E-surfaces. It is impossible to determine the surface composition of the D-surfaces by this method. We therefore assumed that the number of surface Ni atoms does not change upon evacuation of hydrogen gas and the surface composition of E-surfaces was used to estimate the TOF over the D-surfaces.

Figure 8 demonstrates the change in the TOF of propane formation (estimated from Figs. 2 and 4) over D- and E-surfaces against surface copper atomic fractions. The catalytic behavior can be divided into two parts, the boundary being at around 60% of surface copper fraction. Over pure Ni and Ni-Cu(0.5) catalysts (nickel-rich alloy catalyst), the activity of the E-surface is much higher than that of the D-surface. The situation is opposite over Ni-Cu(25), (60), and (90) catalysts (copper-rich alloy catalyst); the D-surface is much more active than is the E- surface. Figure 9 summarizes the change in the initial isotope distribution pattern of monodeuteriopropene formed during a C_3H_6-D_2 reaction, as well as the activation energy of propane formation against surface copper atomic fractions. A similar change in the catalytic behavior was observed at around 60% of the surface copper atomic fraction. Over D-surfaces of nickel rich alloy catalysts, the isotopic distribution pattern as well as the activation energy were similar to those of Ni metal, itself. Over D-surfaces of copper-rich alloy catalysts, the distribution pattern considerably changed and became similar to that of Cu metal. On the other hand, over E-surfaces such changes were not observed even in the copper-rich alloy regions, and isotopic distribution pattern as well as activation energy remained similar to those of Ni metal.

The activity decrease over D-surfaces of Ni and Ni-rich alloy catalyst may be explained by an inhibition effect caused by strongly adsorbed hydrogen at lower temperatures. The existence of such strongly adsorbed hydrogen has been observed in TPD experiments of adsorbed hydrogen over a Ni surface.[16,27,28] Three desorption peaks have been reported in the literature, whose maxima are at temperatures β_1=250 K, β_2=329 K and α=370 K.

We also examined the TPD spectra of H_2 on catalysts employed in this study, displayed in Fig. 5(b). Only two peaks were observed, corresponding to β_2 and α, whose peak maxima shifted by about 50 K to higher temperatures than those reported in the literature. Can be seen from the spectra, the amount of strongly adsorbed hydrogen drastically decreased as the surface copper composition increased in the alloy catalysts. By comparing Figs. 5(a) and (b) it was realized that the hydrogen desorption temperature corresponds well to the temperature of steeply increasing catalytic activity. Accordingly, it is reasonable to suppose that α hydrogen may be responsible for the inhibition of hydrogenation of propene at lower temperatures. Because of the lack of this α hydrogen peak, such inhibition does not occur in Cu-rich alloy catalysts. During a C_3H_6-D_2 reaction over the E-surface at lower temperatures, no drastic decrease in the reaction rate was observed, indicating a slow rate of α hydrogen adsorption at low temperatures. Moreover, the results of a pressure-dependence study indicate that the surface was mostly covered by adsorbed propene during the reaction, which also retards the adsorption rate of α hydrogen. However, once the E-surface was exposed to hydrogen at room temperature, the reaction rate at lower temperatures was considerably reduced, which is consistent with the above-mentioned consideration.

Another interesting point regarding these systems is the high activity of the D-surface in the case of Cu-rich alloy catalysts. Hall suggested that the catalytic activity of the surface alloy phase is increased by enrichment with Ni.[29] The present microwave spectroscopic investigation, however, clearly demonstrated that the structure of the reaction intermediate is sim-

ilar to that on Cu metal. Accordingly, the hydrogen treatment effect is not ascribed to surface-enriched Ni alone, but to some novel sites involving both Cu and Ni atoms. Such an effect was really observed only on the Cu-rich alloy surface, where every surface Ni atom might be surrounded by surface Cu atoms. A marked decrease in the activity over the E-surface suggests that evacuation at higher temperatures causes a reconstruction of the pertinent surface structure.

Application of the SPE Method to Organic Electrochemistry. XII. Lead Dioxide as a Mediator for Electrooxidation of Cinnamyl Alcohol on Pt-Nafion

Zhen CHEN, Zempachi OGUMI,* and Zen-ichiro TAKEHARA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received October 8, 1990)

Lead dioxide was examined as a mediator to oxidize cinnamyl alcohol on Pt-Nafion, and was compared with manganese dioxide. Lead dioxide was deposited into Pt-Nafion. The current efficiency for the formation of cinnamaldehyde reached 65% at room temperature, slightly lower than that in the case of using manganese dioxide. The production of cinnamic acid was more remarkable on Pb,Pt-Nafion than on Mn,Pt-Nafion because of the higher oxidation potential of the former. The mediatory action of both oxides was examined and compared with the activity in chemical oxidation using oxides produced separately. The oxidation of cinnamyl alcohol by lead dioxide was faster than that by manganese dioxide. Their mediatory action reflected their chemical activity for the oxidation.

Due to an inherently high oxidation potential[1,2] of the hydroxyl group, a variety of indirect procedures utilizing appropriate organic and inorganic chemicals as mediators have been devised for oxidizing the group.[3-6] We have reported in previous papers[7,8] that in a system comprising solid polymer electrolyte (SPE) electrolyzers, with Nafion as an SPE material, manganese dioxide deposited into Pt-Nafion behaves as a mediator and enhances the reaction selectivity of alcohol to the corresponding aldehyde.

As known, PbO_2 is widely used in practical rechargeable lead-acid batteries due to its high electrochemical reversibility and high oxidation potential under acidic conditions. These properties are attractive for use as an oxidizing reagent of organic substances. In the present study lead dioxide was focused as a mediator for indirect oxidation of cinnamyl alcohol using an SPE composite electrode prepared by depositing a porous platinum layer on Nafion, Pt-Nafion.[9] It was reported in our previous papers that Mn, Pt-Nafion prepared by incorporating manganese dioxide into Pt-Nafion as a mediator behaved as a good electrode for the selective oxidation of cinnamyl alcohol to cinnamaldehyde, while leaving C=C unchanged.[7] The activity and reaction selectivity of Pb,Pt-Nafion were compared with Mn,Pt-Nafion.

Since the oxidation of cinnamyl alcohol by a metal-oxide mediatory system involves an irreversible catalytic reaction following a reversible charge-transfer reaction producing reactive oxides on the anode, the chemical reactions between oxides (PbO_2 and MnO_2) and cinnamyl alcohol were also investigated in order to improve our understanding of the reaction systems.

Experimental

Electrochemical Oxidation. Pt-Nafion composite electrodes were prepared by an electroless deposition of a porous platinum layer on Nafion 417.[9] After platinum deposition, the Pt-Nafion was immersed in 1 mol dm^{-3} H_2SO_4 for more than 2 h in order to exchange the counter ion for H^+. This H^+-type Pt-Nafion was then immersed in a 0.5 mol dm^{-3} $Pb(NO_3)_2$ aqueous solution for more than 8 h in order to incorporate Pb^{2+} into Pt-Nafion. An electrolytic cell equipped with Pb,Pt-Nafion was described previously.[7] The effective geometric surface area of the anode was found to be 3.14 cm^2. The volumes of the working electrode (anodic) and the counter electrode (cathodic) compartments (WEC and CEC) were 6.5 cm^3 and 16 cm^3, respectively. The electrode potential was set vs. the Ag/AgCl reference electrode via a Luggin capillary inserted in a CEC using a potentio/galvanostat (Hokuto Denko HA-301). In all cases, the set potential was not corrected for both the junction potential at the interface between Nafion and the contacting solution and a fairly large ohmic drop through the Nafion.

Tetrahydrofuran (THF) was selected as a solvent. The concentration of cinnamyl alcohol was fixed at 50 vol% in THF. In order to suppress any dissolving out of Pb^{2+} into a CEC from Pt-Nafion, 0.05 mol dm^{-3} $Pb(NO_3)_2$ was added to a CEC containing 0.05 mol dm^{-3} HNO_3 during electrolysis.

Electrolysis was carried out using a conventional potentio/galvanostatic electrolysis set-up at 25 °C, except for those cases specified. The experimental details were identical to those described in a previous paper.[10]

Chemical Reactions. Electrolytic manganese dioxide (EMD) was donated by Mitsui Mining and Smelting Co., Ltd. Because of the low chemical activity of commercially available lead dioxide, freshly prepared lead dioxide was utilized for chemical reactions.[11] The fresh, active lead dioxide was prepared by decomposition of lead tetraacetate.[12] Then, 50 g of lead tetraacetate was added to 500 cm^3 of water under stirring. It decomposed to brown lead dioxide precipitates. The crude lead dioxide was washed with 100 cm^3 of water 4 times and filtered under suction, followed by washing with 50 cm^3 of acetone 4 times. The yield of a dark-brown powder of lead dioxide was about 20 g. Cinnamyl alcohol (0.2 g) was stirred with a suspension of excess amount of EMD (0.5 g) or PbO_2 (2 g) in acetone (50 cm^3) or in acetone (50 cm^3) containing 0.4 mol dm^{-3} sulfuric acid and 4% water at a fixed temperature.

Analysis. The products were analyzed by an HPLC device (Hitachi 638-30) equipped with a Synchropak SCD 100 column. 4-Nitrotoluene was selected as an internal

standard.

Results and Discussion

Electrochemical Behaviors of Pb,Pt-Nafion. In order to examine the electrochemical behaviors of a lead redox couple in Pt-Nafion, cyclic voltammetry measurements were conducted. The cyclic voltammogram on Pb,Pt-Nafion in 0.05 mol dm^{-3} HNO_3 in a CEC (curve a of Fig. 1) was compared with that on Mn,Pt-Nafion in 0.025 mol dm^{-3} H_2SO_4 in a CEC (curve b of Fig.1). Ar gas was filled in a WEC in both cases. An anodic plateau (E_{ap}=1.42 V) and a cathodic peak (E_{cp}=1.22 V) appear on curve a. The peak separation was fairly large (200 mV) because of an uncorrected ohmic drop caused by the low conductivity of Nafion. This peak and plateau correspond to a reduction and oxidation of the lead redox couple. Oxygen evolution began at a potential close to lead dioxide formation (E>1.50V), according to curve a. Although the deposition of lead dioxide on Pt-Nafion enhanced the oxygen overvoltage, this enhancement was not as large as was expected. On the other hand, Mn,Pt-Nafion gave a better-defined cyclic voltammogram, although the peak separation was still large. Pb,Pt-Nafion gave higher redox peaks, by about 200 mV, than Mn,Pt-Nafion, as was expected from their standard redox potentials reported (1.45 V and 1.23 V vs. NHE, respectively).

Figure 2 shows anodic polarization curves under quasi-steady state conditions for Pb,Pt-Nafion (curve a,c), which were compared with those for Mn,Pt-Nafion (curve b,d). The electrode potentials for Pb,Pt-Nafion were higher than those for Mn,Pt-Nafion in two systems: with (curve a,b) and without (curve c,d) cinnamyl alcohol in a WEC. Even in the presence of alcohol, the potentials of both electrodes were kept low at current densities lower than 2 mA cm^{-2}. This was ascribed to the proceeding of mediatory oxidation processes on both electrodes: the primary electrode reaction involved the oxidation of two metal ions regenerated by reactions of the metal oxides with the alcohol in a low-current density region.

$$Pb^{2+} + 2H_2O = PbO_2 + 4H^+ + 2e^- \quad 1.45 \text{ V vs. NHE} \quad (1)$$

$$Mn^{2+} + 2H_2O = MnO_2 + 4H^+ + 2e^- \quad 1.23 \text{ V vs. NHE} \quad (2)$$

$$C_6H_5CH{=}CHCH_2OH + MO_2 + 2H^+ =$$

$$\text{(acidic)} \quad C_6H_5CH{=}CHCHO + M^2 + 2H_2O \quad (3)$$

$$C_6H_5CH{=}CHCH_2OH + MO_2 =$$

$$\text{(neutral or basic)} \quad C_6H_5CH{=}CHCHO + M(OH)_2 \quad (4)$$

(M=Pb or Mn)

On the other hand, when electrolytic current density exceeded 2 mA cm^{-2}, the anodic potential gradually shifted to the positive direction and reached the value for oxygen evolution on both electrodes. Gas evolution was observed on both electrodes at high current densities. The potential for oxygen evolution was higher on both electrodes in the presence of alcohol (a,b) than in its absence (c,d). This might be caused by a poisoning of the electrodes by by-products from the substrate or solvents which were not detected, though, in HPLC analysis. The by-products might decrease the ionic conductivity of Nafion and enhance the uncorrected ohmic drop. This poisoning was also suggested by a potential change during electrolysis. As shown in Fig. 3, the anode potential of Pb,Pt-Nafion gradually increased, even at a current density

as low as 2 mA cm^{-2}, and reached the potential necessary for oxygen evolution, although its change was very slow at a very low current density of 1 mA cm^{-2}. A similar potential change was also observed for Mn,Pt-Nafion. In addition to the above-mentioned reasons, it was reported that the ionic conductivity of Nafion was remarkably decreased in some organic solvents.[13]

Galvanostatic Oxidation of Cinnamyl Alcohol. As reported in a previous paper,[7] the reaction selectivity for aldehyde formation was remarkably enhanced by the incorporation of a manganese redox couple into Pt-Nafion. The current efficiency of the oxidation of cinnamyl alcohol using Pb,Pt-Nafion was examined under galvanostatic electrolysis conditions. The results are given in Fig. 4 (curves A and a), together with the results using Mn,Pt-Nafion (curves B and b). At low current densities, cinnamaldehyde was produced in high current efficiency (A), which, however, slightly lower than that on Mn,Pt-Nafion (B). On the other hand, the efficiency of cinnamic acid production on Pb,Pt-Nafion (a) was higher at low current densities than that on Mn,Pt-Nafion (b). On both composite electrodes the current efficiency for aldehyde formation decreased upon increasing the current density, although the decrease began at a lower current density on Pb,Pt-Nafion (A) than that on Mn,Pt-Nafion (B). On the former electrode acid production reached 20% at a low current density and then decreased with an increase in the current density; however, it was low, and almost unchanged, on the latter electrode. The rapid decrease in the current efficiencies on the former should be ascribed to easier oxygen evolution since the potential of oxygen evolution was closer to that of lead dioxide formation than on the latter electrode (Fig. 1). The higher efficiency of acid formation on Pb,Pt-Nafion than that on Mn,Pt-Nafion should be ascribed to the more positive potential of lead dioxide (ca. 200 mV) than that of manganese dioxide.

Since no organic by-product was detected on HPLC and gas chromatography analyses, only oxygen evolution was considered to exist as a side reaction.

Oxidation was also affected by the electrolysis temperature. As shown in Fig. 5, the current efficiencies of aldehyde formation increased upon increasing the temperature on both Mn,Pt-Nafion and Pb,Pt-Nafion at 1.5 mA cm^{-2}. At high temperature the reaction between mediator oxides and the alcohol became faster and the mediatory reaction proceeded more smoothly. Thus, the current efficiency of aldehyde formation increased on both electrodes upon increasing the temperature. The current efficiency of cinnamic acid formation increased on Pb,Pt-Nafion with a temperature increase, whereas on Mn,Pt-Nafion it remained almost unchanged with a temperature change, while maintaining a low value. This result suggests that a high potential is necessary for the oxidation of the alcohol to the corresponding acid, and that the potential of MnO_2 was not sufficiently high to oxidize the alcohol to acid. N.L. Weinberg

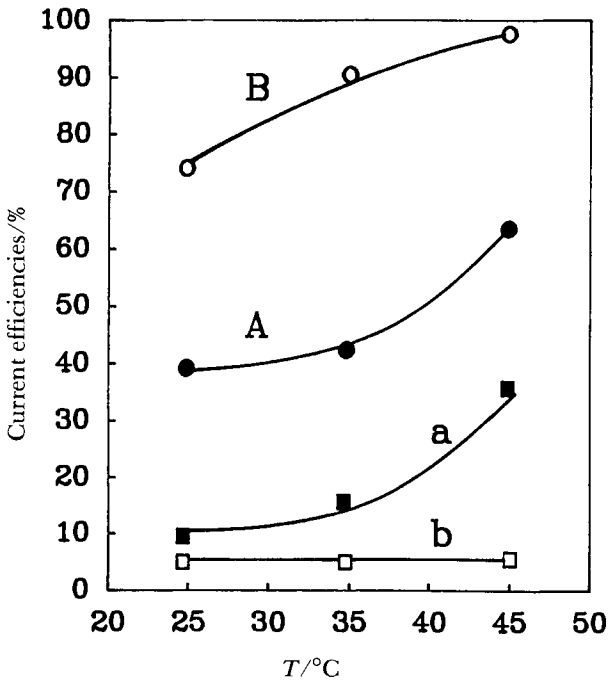

Fig. 5. Dependencies of current efficiencies on electrolysis temperature at 1.5 mA cm^{-2}. Mediator: PbO_2 (A and a), MnO_2 (B and b). Cinnamaldehyde (A and B), cinnamic acid (a and b).

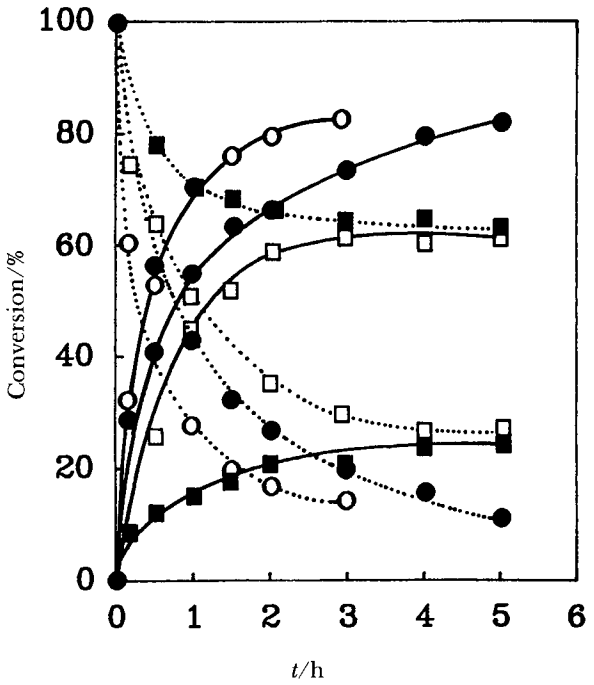

Fig. 6. Oxidation of cinnamyl alcohol by MnO_2 in neat THF (○), acetone (●), benzene (□), and acetic acid (■) at 22 °C. (——): cinnamaldehyde, (------): remaining cinnamyl alcohol.

reported that the half-wave potential for the oxidation of cinnamyl alcohol to cinnamaldehyde was 1.36 V, and that of cinnamaldehyde to cinnamic acid 1.77 V (vs. Ag/0.1 mol dm^{-3} Ag^+) in a CH_3CN-$NaClO_4$ solution system.[1,2] The potential difference between two oxidation steps is about 0.4 V. The above-mentioned potential values can not be directly compared with those in the present system since the electrodes, solvents, and reference electrodes are different. However, judging from the results described above, MnO_2 can oxidize the cinnamyl alcohol to cinnamaldehyde, but can not do so to cinnamic acid. On the other hand, the oxidation potential of PbO_2 is more positive by ca. 0.2 V than that of MnO_2, and it is sufficiently high to oxidize the alcohol to acid.

Chemical Reactions. The electrochemical oxidation of cinnamyl alcohol proceeds via consecutive reactions: electrochemical formation of oxides (Eqs. 1 and 2) is followed by their reaction with alcohol (Eqs. 3 and 4). It is not clear yet which of the reaction steps is rate-determining. We have examined the activation energy of anodic oxidation using Mn,Pt-Nafion. The value was 12.1 kcal mol^{-1}, higher than the value for the anodic formation of MnO_2 from Mn^{2+} on Pt (9.2 kcal mol^{-1}).[14] This result suggests that the reaction step of Eq. 3 or 4 is slower than the electrode reaction and following chemical reactions seem to be important in the mediatory systems. From this point of view, the chemical reactions of the oxides with cinnamyl alcohol were examined.

For electrochemical systems, THF was selected as a solvent, which was stable and did not remarkably swell Nafion. Some solvents were examined for possible use as a solvent for the chemical oxidation of cinnamyl alcohol by MnO_2. As shown in Fig. 6, THF gave the highest oxidation rate among the solvents examined. In all cases using neat solvents, no other product beside cinnamaldehyde was detected during HPLC analysis, while in electrochemical reaction systems acetone gave some unidentified by-products together with cinnamic acid. Since the reaction rate in THF was too high to examine the reaction in detail, acetone was selected as a solvent for the chemical oxidation.

The oxidation of cinnamyl alcohol by PbO_2 was examined in neat acetone. As shown in Fig. 7, the oxidation rate was faster than that by MnO_2. While only a trace amount of cinnamic acid was formed at 25 °C, a significant amount of the acid was formed at 40 °C.

The influence of the water content and acidity is easily inferred from Eqs. 1 to 4.[8] The influence of the water content on the oxidation is exhibited in Fig. 8. The reaction rate decreased with an increase in the water content, since the oxidation potential decreased with increasing water content, as can be expected from Eqs. 1 and 2. In the presence of water cinnamic acid was formed.

$$C_6H_5CH{=}CHCHO + MnO_2 + H_2O = C_6H_5CH{=}CHCOOH + Mn(OH)_2 \quad (5)$$

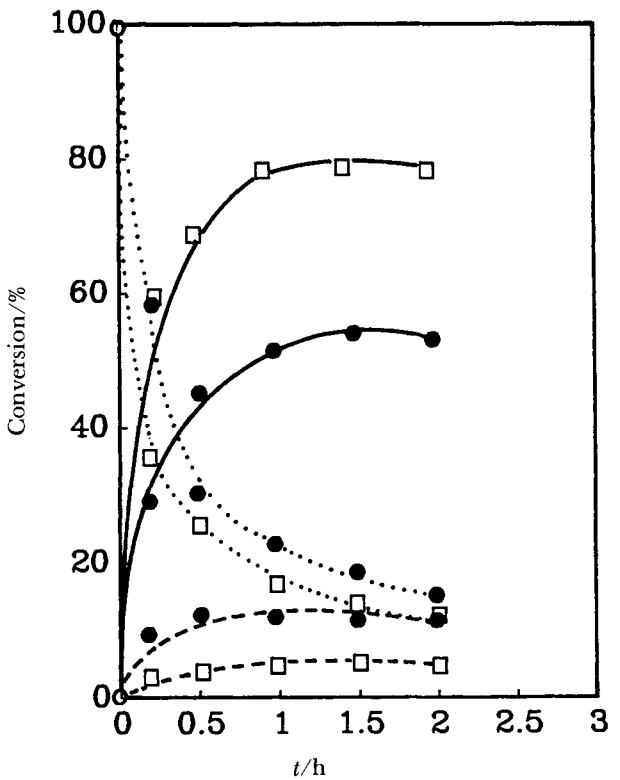

Fig. 10. Reactions of cinnamyl alcohol with PbO_2 at 40 °C in acetone containing 4% water and 0.43 mol dm^{-3} H_2SO_4 (●) and in neat acetone (□). (.....): remaining alcohol, (——): cinnamaldehyde, (----): cinnamic acid.

In the absence of water the aldehyde can not be oxidized by MnO_2. The decrease in acid formation upon increasing the water content can also be ascribed to a decrease in the oxidation potential. These results suggest the existence of an optimum water content.

An increase in the sulfuric acid concentration at a fixed water content of 4% increased the reaction rate as well as acid formation, as shown in Fig. 9. It is easily deduced from Eqs. 1 and 2 that an increase in acidity enhances the oxidation potential of MnO_2, and that this high oxidation potential enhances the reaction rate and acid formation.

Similar influences of the acid concentration were observed in the oxidation of cinnamyl alcohol by PbO_2. As is shown in Fig. 10, its oxidation rate was increased by the addition of sulfuric acid. However, this increase was due to its oxidation to cinnamic acid, and even a slight decrease in the current efficiency of the aldehyde formation was observed. Thereafter, the reaction selectivity to the aldehyde was decreased.

An increase in the acid concentration also accelerates the reaction rate of Eq. 3. The increased oxidation potential of oxides with an increase in a solution acidity, as well as the increased oxidation rate of Eq. 3, additively enhance the oxidation rate, though the contribution from the former seems to be larger at the low acid concentration examined here than that from the latter.

As expected, the increase in the reaction temperature enhanced the reaction rate of both aldehyde and acid formation, as shown in Fig. 11.

Figure 12 shows the difference between MnO_2 and PbO_2 in acetone at 40 °C. PbO_2 gave a greater oxidation rate than did MnO_2. Although cinnamic acid was not formed using MnO_2 (Fig. 6), it was formed using PbO_2. The higher oxidation potential of PbO_2 than MnO_2 explains the results.

It is not easy to determine the conditions surrounding an active site of Pt-Nafion, since Nafion is a strong acid-type cation-exchange membrane and its acidity is considered to correspond to 1—3 mol dm^{-3} H_2SO_4 under aqueous conditions. At the reaction site for the present mediatory electrochemical oxidation, a solvent, THF, is mixed with water, both of which exist in WEC and CEC, respectively. This mixing makes substrate transportation to the reaction site easy.[8] Although the acidity might be decreased by mixing, it may be considered that the reaction site on Pt-Nafion is an aqueous mixture and is fairly acidic. Under these conditions oxidation of the alcohol by two oxides must be rapid enough to supply M^{2+} ions to the electrode by the regeneration reaction (Eq. 3). The critical current density, above which the regeneration rate of Mn^{2+} can not follow up its consumption by a charge-transfer reaction on the anode, was about 2 mA cm^{-2}; this value was dependent on many factors, such as deposition conditions of platinum, the amount of metal oxide incorporated into Pt-

Nafion, solvent composition, and temperature.

The results obtained for the mediatory electrochemical oxidation, that cinnamic acid production is more remarkable on Pb,Pt-Nafion than that on Mn,Pt-Nafion, were coincident with the results obtained through chemical oxidation.

(Received October 18, 1990)

Photo-irradiated TiO_2 particles drive various chemical reactions due to their strong oxidation and reduction ability. This effect is applied in order to kill malignant HeLa cells with TiO_2 particles. During 10-min UV irradiation periods, HeLa cells were completely killed in the presence of TiO_2 (100 $\mu g\,cm^{-3}$). However, without irradiation these particles showed little cytotoxicity up to 360 $\mu g\,cm^{-3}$. It is concluded that the cells were killed by hydroxyl ($OH\cdot$) and perhydroxyl ($HO_2\cdot$) radicals produced from water by the irradiated TiO_2 particles, and also that the cells were directly oxidized by photogenerated holes in TiO_2. The distribution of TiO_2 powders in the cells was observed using a transmission electron microscope. The TiO_2 powder existed not only on the cell membrane, but also in the cytoplasm. Thus, the cells were damaged by photoexcited TiO_2 not only from the cell membrane, but also from the inside of cytoplasm. Finally, the application of this malignant cell photokilling effect to photodynamic therapy is discussed.

When a TiO_2 semiconductor absorbs light with energy greater than its band gap, electrons in the valence band are excited to the conduction band, creating electron-hole pairs and causing various chemical reactions. Photochemical reactions using TiO_2 powders are therefore being studied for solar energy conversion applications,[1-2] and photo-organic synthesis research,[3-5] Few studies, however, have investigated biochemical reactions using the semiconductor photoeffect. Matsunaga et al. reported the photocatalytic sterilization using TiO_2 powder. In their system, microbial (*Escherichia coli*) cells were killed by photocatalytic reaction.[6] The present study proposes applying heterogeneous photocatalysis with TiO_2 dispersion to a biochemical reaction in order to "photo-kill" cancer cells.

It was previously reported that HeLa cells could be photoelectrochemically killed on a TiO_2 electrode.[7] In this system, HeLa cells were cultured on TiO_2 electrode surface, and the electrode was anodically polarized under UV-irradiation. Photoexcited TiO_2 anode has a strong oxidation power, so that the cells on the electrode are damaged from the cell membrane.

Instead of using an electrode, the present study uses small TiO_2 particles which function as a "short-circuit," photoelectrochemical cell. In this "particulate system," both photogenerated electrons and holes reach the surface, thus oxidation and reduction are induced on the surface. Additionally these particulate suspensions yield a large interfacial surface area in small volumes. The ability of a photochemical reaction using particulate TiO_2 becomes higher when the size of particles becomes smaller,[8] allowing the particles to be easily incorporated into the cells. Therefore this method is easier to apply than the electrode method. The effects of small photoexcited TiO_2 particles on cells is an attractive investigation area because it is expected that the small particles are incorporated inside the cell, and the particulate reaction with the cellular components can more effectively proceed as compared to the electrode method.

In the present study, the cytotoxicity of ultrafine TiO_2 powder and the effect of photoexcited TiO_2 particles on malignant cells were investigated. Distribution of TiO_2 particles in the cells was also examined with a transmission electron microscope (TEM), and a cyclic voltammogram technique was applied to get electrochemical information. The possibility to apply this photocatalytic reaction to photodynamic therapy is also discussed.

Materials and Methods

TiO_2 Powder: TiO_2 particles (anatase, p-25; Nippon-Aerosil Co., Tokyo, Japan) with an average size of 300 Å in diameter were used. The particles were ultra-sonically dispersed in water, then sterilized using autoclave. During sterilization the TiO_2 particles aggregated and could not be sonically dispersed, thus they were removed by centrifugation, and the small aggregates were then collected. The average size of TiO_2 aggregates in the suspension, observed by a scannig electron microscope (SEM) [JSM-840, JEOL., Tokyo, Japan], depended on the centrifugal acceleration, with the TiO_2 suspension quantity being measured with combustion analysis. The optimum acceleration was chosen to be 1600×g in the present experiment. This will be discussed later. A minimum essential medium (MEM, Gibco) solution (5×MEM) and 10% fetal bovine serum were added to the ultrafine TiO_2 aqueous suspension to prepare a MEM solution containing TiO_2 (MEM-TiO_2 solution), which was used to investigate both the photokilling ability (with irradiation) and the cytotoxicity (no irradiation) of HeLa cells.

Cell Lines and Antitumor Activity of the TiO_2 Powder: The HeLa cells were cultured in an MEM solution supplemented with 10% fetal calf serum in a humidified incubator with an atmosphere of 5% CO_2 in air at 37 °C.

The antitumor activity of the ultrafine TiO_2 aggregates

was evaluated with a colony forming assay (plating efficiency: 80—85%). The cells were plated in 60 mm petri dishes (Becton-Dickinson Co.), and after incubated for 24 h at 37 °C in 5% CO_2 allow cell attachment, the old MEM solution was replaced with an MEM-TiO_2 solution. The cells were then incubated for 24 h, the solution was removed, and the cells were washed twice with a Hanks' balanced salt solution (Gibco). A TiO_2-free medium was finally added to the cells and the prepared cells were irradiated with a 500-W high pressure Hg lamp (USHIO Co., Tokyo, Japan) at room temperature. For the visible light experiments a sharp cut-off filter (L-44, Kenko Co., Tokyo, Japan) was used to get a light wavelength greater than 440 nm. For the UV light experiments a UV pass filter (UV-D2, TOSHIBA Co., Tokyo, Japan) was used to get a light wavelength between 300—400 nm. After culturing again for 10 days, the colonies were fixed with 70% methanol, stained with a 5% Giemsa solution, and then counted. In cytotoxicity experiment, cultures without drug in dark were used as controls. In irradiation experiment, cultures exposured to the various drugs as described above but not exposured to light were used as controls in irradiation experiments. Each experiment was done using three dishes at the same time and under the same conditions. Then those three data were averaged. Moreover, those experiments were repeated 3 to 4 times. The error bars in the figures represent the maximum and minimum value at each experiment. During the irradiation a water filter was used to remove infrared radiation, and light doses were measured by a photodiode.

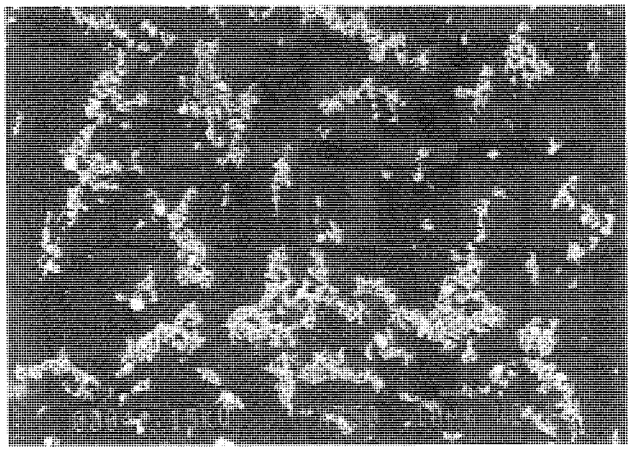
Transmission Electron Microscope Measurement: HeLa cells were incubated in an MEM-TiO_2 (TiO_2=100 $\mu g\,cm^{-3}$) solution for 24 h, and then were collected and immediately fixed using a 2.5% glutaraldehyde solution at 4 °C. In some experiments, TiO_2 aggregates whose size was smaller than 0.22 μm were used. This small aggregates were obtained by filterating the centrifugated TiO_2 solution with a 0.22 μm milipore filter. After 2 h the cells were fixed again with a 2% osmium tetraoxide, then dehydrated by gradually increasing the concentration of alcohol, and embedded in synthetic resin (EPON 812). Semi-thin (2 μm) sections of the cell were stained with methylene blue, which were then made into ultrathin sections (0.05—0.1 μm) by using a Reihert ultramicrotome and a diamond knife, and then double stained with uranyl acetate and lead(II) citrate. Finally, distribution of the ultrafine TiO_2 particles in the cells was observed with a Hitachi H-7000 (75 kV) TEM.

Electrochemical Measurements: Cyclic voltammograms were taken using a slightly modified three-electrode system.[9] A graphite electrode, polished before each run (0.4 cm^2 surface area), a counter electrode (platinum wire), and a reference electrode (saturated calomel electrode: SCE) were fitted into the top of a glass vessel (25 cm^3 capacity). A sufficient number of HeLa cells were first dropped on the membrane filter while applying a slight suction, and were retained on the membrane filter surface. This filter was attached to the surface of the graphite electrode, which was then inserted into phosphate buffered saline [PBS] (pH 7.0, 15 cm^3) to get the cyclic voltammograms, obtained by using a potentiostat (Toho Technical Research Co., Tokyo, Japan; Model UFB-4), function generator (Hokuto Denko Co., Tokyo, Japan; Model HB-III), and X-Y recorder (Riken Denshi Co., Tokyo, Japan; Model F-5c).

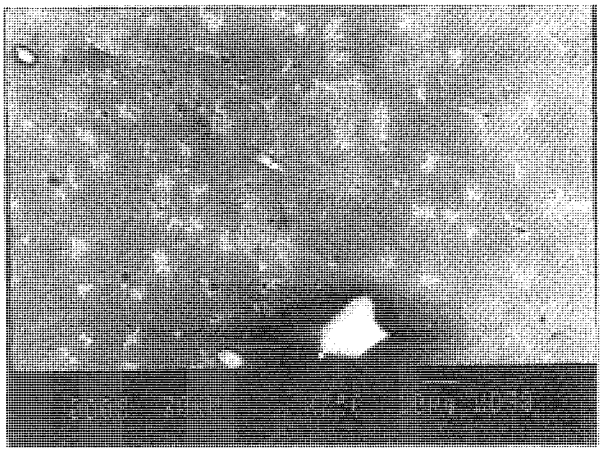
Results and Discussion

Cytotoxicity of TiO_2: Investigation of the cytotoxicity of a drug, without irradiation, is important before it can be used as a photodrug, i.e., antitumor drugs used in PDT are required to be almost nontoxic, and yet have a high photokilling ability under irradiation.

The initial TiO_2 particles had an average size of 300 Å in diameter, and since hydroxyl groups (-OH) exist at the surface of the particles,[10] the hydrogen bond between the hydroxyl groups is formed in the aqueous solution, resulting in aggregation of the particles. Figure la shows an SEM image of the particles in the suspension. The average size of the aggregated TiO_2 was much larger (20 μm) than that of the initial ones. It was found that such large aggregated TiO_2 particles showed a high cytotoxicity to the cells. This is probably because they deposit and covered the



(a)



(b)

Fig. 1. SEM pictures of TiO_2 particles
(a) without centrifugation, (b) after centrifugation at 1600×g.

cells. However, the large aggregated particles can be removed by centrifugation and small aggregates in the suspension can be obtained. The size of TiO_2 aggregates depended on the centrifugal acceleration. Smaller TiO_2 aggregated can be obtained using a higher acceleration. However, if the acceleration was too high, the concentration of TiO_2 in the suspension decreased, therefore the optimum acceleration was chosen to be 1600×g, with the size of the TiO_2 particles being in the range of 0.03—10 μm (Fig 1b), much smaller than the size of HeLa cells (50 μm).

When HeLa cells were incubated in an MEM-TiO_2 for 24 h (without irradiation), the surviving fraction of the cells with respect to the amount of TiO_2 powder is shown in Fig. 2. The surviving fraction was greater than 90% when the concentration of MEM-TiO_2 reached 360 μg cm^{-3}, and it is subsequently concluded that the small TiO_2 particles showed little cytotoxicity without irradiation.

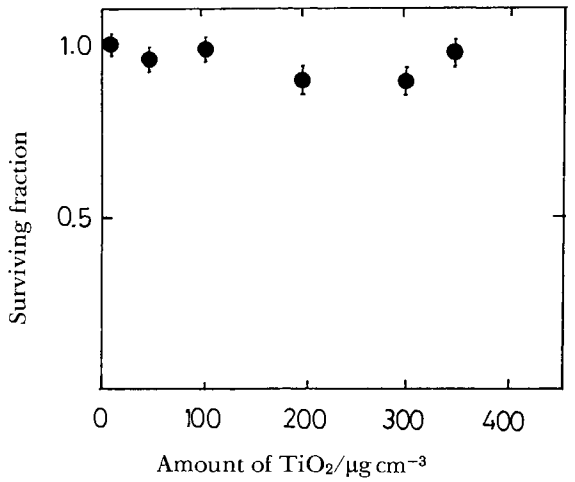


Fig. 2. After HeLa cells were incubated with an MEM-TiO_2 solution for 24 h without irradiation, the surviving fraction of HeLa cells is shown as a function of the amount of ultrafine TiO_2 particles.

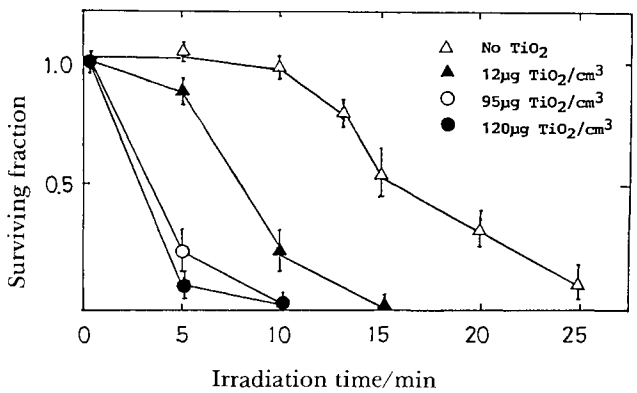

Fig. 3. Surviving fraction of HeLa cells as a function of unfiltered irradiation light in the presence of different concentrations of MEM-TiO_2 solutions.

Photokilling of Cells Using TiO_2 Powders: The irradiation effects when TiO_2 is not used are shown in Fig. 3, with the surviving fraction of HeLa cells given as a function of the unfiltered light irradiation time. The 500-W Hg lamp emitted a relatively strong UV light, thus a significant number of cells were killed after a 25 min exposure, whereas after a 10 min exposure, more than 90% of the cells remained alive.

When TiO_2 was added, the HeLa cells were killed at a much higher rate as shown in Fig. 3. Notice when the amount of TiO_2 was 12 μg cm^{-3}, 20% of the cells were killed after 5 min of irradiation, and also that when the amount of TiO_2 was 95 μg cm^{-3} and 120 μg cm^{-3}, 75% and 90% of the cells were respectively killed. The ultrafine TiO_2 particles showed little cytoxicity at 100 μg cm^{-3}, Therefore, it is concluded that under irradiation the ultrafine TiO_2 particles can actively kill the cells.

When the cultured cells are exposed to the white light from the 500-W Hg lamp, the semiconductor TiO_2 absorbs only the light whose energy is larger than its band gap (the TiO_2 band gap is 3 eV, corresponding to a wavelength of 410 nm). In order to prove whether the cell death was caused by a photo process or a thermal process, the following experiments were done. First the temperature increse of MEM-TiO_2 caused by the light irradiation was measured. The result is shown in Fig.4. In the beginning, it was 27 °C, and was raised up to about 36 °C after 30 min irradiation. However, that temperature was lower than that at culture environment (37 °C). Therefore it is reasonable to expect that such a temperature increase does not affect on the cell. Actually it was reported that the thermal effect is observed at the temperature is higher than 41 °C.[11] Next, a sharp cut-off filter (L-44) was inserted between the Hg lamp and the cells, allowing only light with wavelength larger than 440 nm to irradiate. Figure 5 shows that even after a 25 min irradiation more than 90% of the

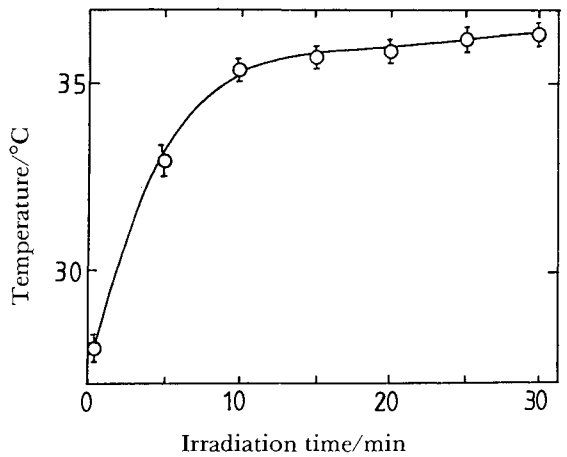

Fig. 4. Temperature increase of MEM as a function of irradiation (white light) time.

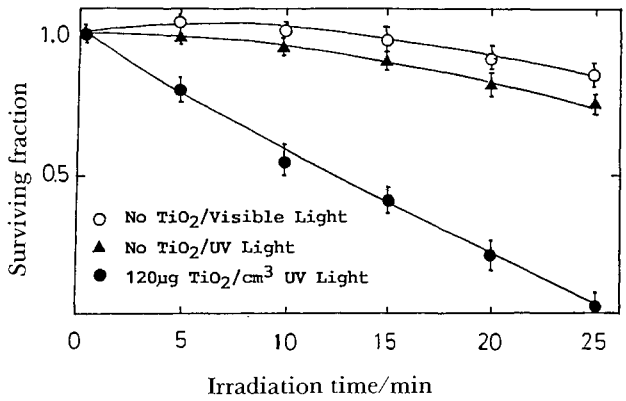

Fig. 5. Surviving fraction of HeLa cells as a function of visible light and UV irradiation with no TiO_2, and UV light irradiation with TiO_2. An MEM-TiO_2 solution (120 $\mu g\,cm^{-3}$) was added to the HeLa cells for 24 h before the UV irradiation.

cells were alive. It indicated that light with wavelength larger than 440 nm do not cause the photokilling effect. Finally, a UV-D2 filter was then used so that only light with wavelength between 300—400 nm irradiated. After a 25 min irradiation (TiO_2=120 $\mu g\,cm^{-3}$) all cells were completely killed, whereas in the absence of TiO_2 more than 85% of the cells remained alive. These results clearly show that the cell death in the presence of TiO_2 is caused by a photoeffect, not a thermal effect.

Distribution of TiO_2 Powder in the Cell: After the cells were incubated with MEM-TiO_2 (TiO_2=100 $\mu g\,cm^{-3}$) for 24 h, the TiO_2 distribution was observed with the TEM as shown in Fig. 6. TiO_2 particles were found on the cell membrane and in the cytoplasm, but not in the nuclei of the cells.

Cells can incorporate small particles by the process of phagocytosis, thus it can be resonably assumed that the same process takes place when the MEM-TiO_2 solution was added to the cells.

Moreover, it was found that the TiO_2 in the cytoplasm was gathered forming larger aggregates. This was concluded by the following experiment. That is, when TiO_2 aggregates whose size was smaller than 0.22 μm were incorporated, much larger aggregates (1.5 μm) were observed in the cytoplasm as shown in Fig. 7.

The observation that TiO_2 exist not only on the cell membrane, but also in the cytoplasm is very important to consider the reason why the present system effectively kill the cells. The organs in the cell were also damaged by the TiO_2. This point is quite different from the mechanism of TiO_2 electrode system. In the latter system, only the cell membrane is damaged by photoexcited TiO_2.

Reaction Mechanism: Two different photochemical processes are proposed which kill the HeLa cells in the present system. The first is the direct reaction between photoexcited TiO_2 and the cells. It is well known that the photoexcited TiO_2 is a strong oxi-

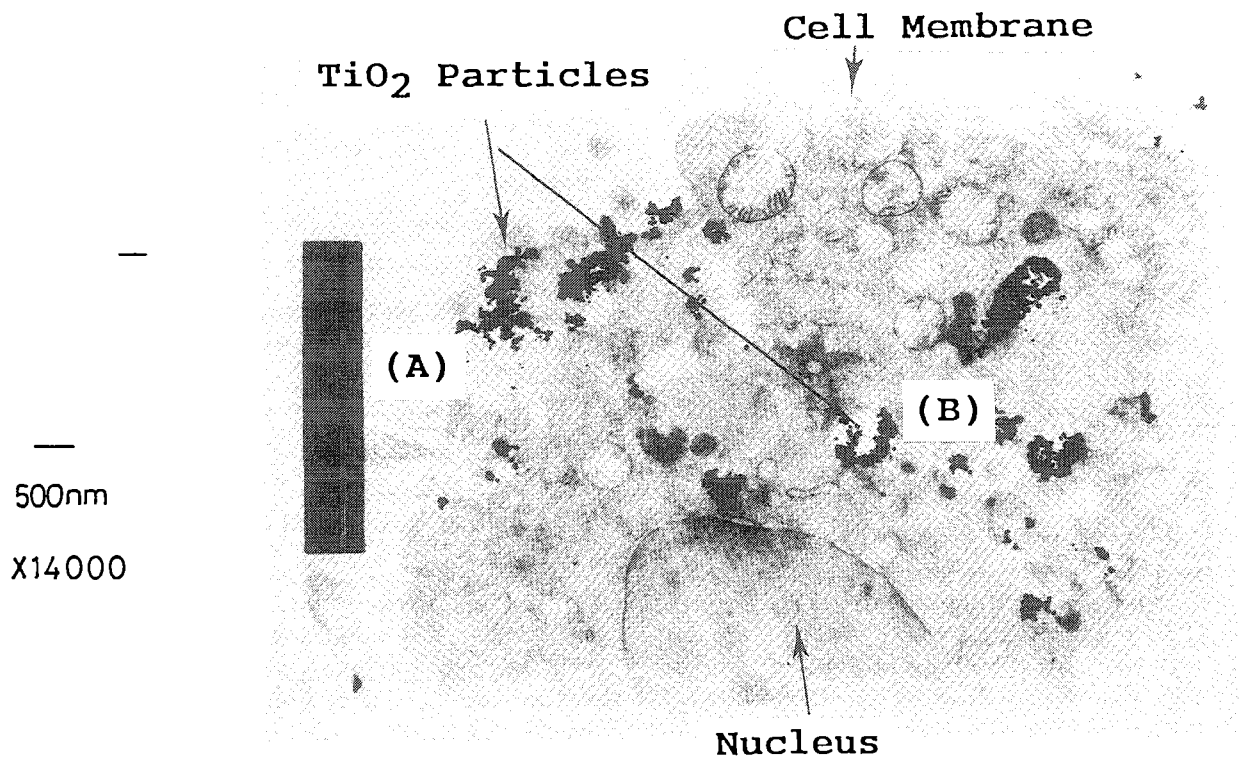

Fig. 6. TEM picture of HeLa cells after the TiO_2-MEM (TiO_2=100 $\mu g\,cm^{-3}$) solution was added to the cells for 24 h. TiO_2 aggregates were found on the cell membrane (A), and in the cytoplasm (B).

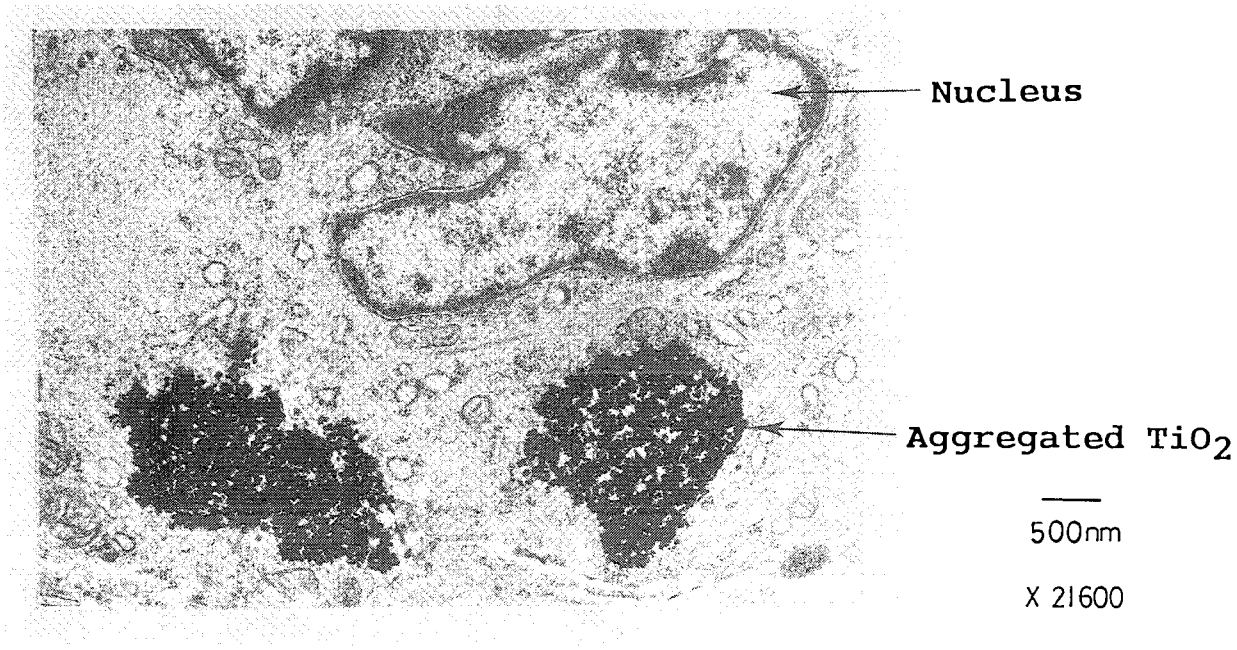

Fig. 7. TEM picture of HeLa cells after the ultrafine TiO_2 (0.03—0.22 μm) was added to the cells for 24 h. The TiO_2 particles was obtained using 0.22 μm milipore filter.

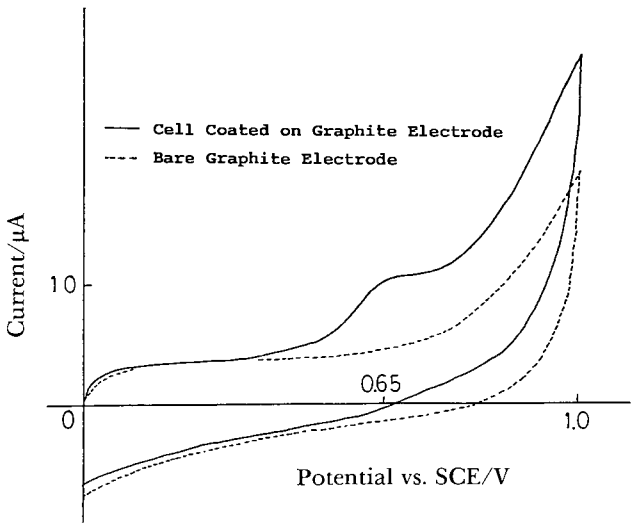

Fig. 8. Cyclic voltammogram of (——) a graphite electrode coated with HeLa cells and (----) a bare graphite electrode, in a 0.1 M phosphate buffer (pH 7.0). 1 M=1 mol dm^{-3}.

dizer.[12] Therefore it is expected that the cells are directly oxidized by the holes formed in the valence band. In order to determine the oxidation potential of the HeLa cells, we measured cyclic voltammograms of the cells adsorbed on a graphite working electrode in the potential range of 0 to 1.0 V vs. SCE in PBS (pH 7.0) solution (See Fig. 8). An anodic peak appeared at 0.65 V vs. SCE in the first positive forward direction scan, with peak intensity increasing as the number of HeLa cells increases on the electrode. However, no corresponding reduction peak was observed during the negative backwards direction scan, indicating that the HeLa cell oxidation process occurred in the potential range of 0.65 V vs. SCE. Since the energy level of valence band edge of TiO_2 is reported to be 2.4 V vs. SCE at pH 7,[12] it is reasonable to assume that the photogenerated holes in TiO_2 can oxidize the cells.

The other proposed process is the indirect reaction between photoexcited TiO_2 and the cells. Hydroxyl radicals ($OH\cdot$) and/or perhydroxy radicals ($HO_2\cdot$) are first created from water. When the photogenerated holes react with water, $OH\cdot$ radicals are produced.[13]

$$(TiO_2) + h\nu(>3\ eV) \rightarrow h^+ + e^- \quad (1)$$

$$H_2O + h^+ \rightarrow OH\cdot + H^+ \quad (2)$$

Additionally, in the presence of oxygen in water, it is reported that both $HO_2\cdot$ and $OH\cdot$ radicals are formed as follows.[13]

$$H^+ + e^- \rightarrow H\cdot \quad (3)$$

$$O_2 + e^- \rightarrow O_2^{-\cdot} \xrightarrow{H\cdot} HO_2^- \quad (4)$$

$$HO_2^- + h^+ \rightarrow HO_2\cdot \quad (5)$$

$$2HO_2\cdot \rightarrow O_2 + H_2O_2 \xrightarrow{O_2^{-\cdot}} OH\cdot + OH^- + O_2 \quad (6)$$

Those radicals may attack the cell membrane and cellular components, and oxidation-reduction substances which are important for producing ATP in a HeLa cell such as reduced glutathione (GSH), reduced nicotinamide adenine dinucleotide(NADH), coenzyme A (CoA), flavin adenine dinucleotide ($FADH_2$), may react with these radicals. The cell will die if these substrates are either depleted or exhausted. Preliminary experiments confirmed that in the presence

of cystein and catalase, respectively scavengers of OH· and H_2O_2, the surviving fraction significantly recovered.

Application of Photocatalytic Reaction of TiO_2 to Photodynamic Therapy: Research on light absorbing anti-cancer drugs is studied in biological systems, with these drugs being exposed to UV or visible light.[14-16] Extensive clinical trials have been performed using HpD as a PDT sensitizer because it is selectively localized in tumors. Further improvement of PDT can be envisaged through the use of more efficient photosensitizers.

In the HpD system two different mechanisms have been found that cause cell damage i.e., the sensitizer molecules excited in the lowest triplet state react directly with biological substrates,[17-18] and the photogenerated triplet state of the sensitizer transfers energy to oxygen to produce singlet molecular oxygen which damages cells by reacting with various biological substrates.[19-20] These two mechanisms are based on photochemical reactions, however, hyperthermal processes are also believed to photokill the tumor cells during irradiation.[21]

In the present system HeLa cells were definitely killed by a photochemical reaction and not by hypothermal effects. This large photokilling ability may be applied to PDT because the TiO_2 particles could be injected into the tumor, irradiated by UV light by laser fiber, thus destroying the tumor.

The UV light is strongly absorbed by patient's body, so the present system may not be useful for PDT of tumor formed in deep part of body. For a tumor formed near skin, such as skin tumor, however, this strong photoeffect may be useful. Compared to the conventional PDT of tumor using HpD, the present system has an advantage that cancer cell can be killed by a rather weak light intensity. We are now applying this method to animal experiment, i.e., bladder tumor of rat.

However, photoexcited TiO_2 has a very strong oxidation power and TiO_2 particles are incorporated not only by cancer cells but also by normal cells. Therefore, if UV light is irradiated uniformly, both the cancer cells and the normal cells are killed. This problem can be solved by focusing the light only on the tumor. Such a site selectivity is one of the superior characteristics of photodynamic therapy.

The other method to kill only the cancer cell is to bind TiO_2 particles to an HpD, causing them to be selectively localized in tumor, and thereby selectively killing the tumor during irradiation. In this case, the tumor formed not only near skin, but also near the surface of the organ, e.g. bladder, stomach, lung, can be killed by using strong photoeffect of TiO_2.

One of the authors (R. Cai) would like to express his gratitude to President H. Komiya of Bionics Co. for his financial support.

Effect of Ether Oxygen on Proton Transfer and Aggregation Reactions of Amines in Water by Ultrasonic Absorption Method

Sadakatsu NISHIKAWA,* Hiroshi HARAGUCHI, and Yasuyo FUKUYAMA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received October 25, 1990)

Ultrasonic absorption coefficients in the frequency range from 6.5 to 220 MHz have been measured in aqueous solutions of 3-ethoxy- and 3-butoxypropylamine as functions of their concentrations along with the sound velocity at 2.5 MHz and the density. In a 3-ethoxypropylamine solution, only one relaxational absorption has been observed up to 3.0 mol dm^{-3}. The cause has been clarified to be due to a proton-transfer reaction of the amine from the concentration dependences of the relaxation frequency and the relaxational amplitude. The rate and thermodynamic parameters have been determined and reasonable values have been obtained as a diffusion-controlled reaction. In the solution of 3-butoxypropylamine, another relaxation process in addition to that due to the proton-transfer reaction has been observed in the concentrations of more than 0.5 mol dm^{-3}. This relaxation process has been attributed to a perturbation associated with an aggregation reaction, $4A \longleftrightarrow A_4$, from the concentration dependences of the relaxation frequency and the relaxational amplitude of the absorption. The rate and thermodynamic constants for the proton-transfer and aggregation reactions have been determined. It has been found from a comparison of the results for the two solutions and others reported previously that the introduction of ether oxygen into amine molecules has little influence on the proton-transfer reaction, but prevents the formation of aggregates due to the hydrophobic interaction. It has also been seen from the results of 3-butoxypropylamine solutions that the butoxyl group has a fairly high ability of hydrophobic interaction and that nonionized molecules form aggregates in the aqueous solution.

The dynamic properties of aqueous solutions of various alkylamines have been clarified so far by measurements of the ultrasonic absorption coefficients in a pulse frequency range from 6.5 to 220 MHz.[1-4] One of the characteristic properties regarding absorption is the observation of a relaxation process due to a proton-transfer reaction. This process has been found in many aqueous and nonaqueous solutions of amines, phenols and benzoic acids in a similar frequency range.[5-9] It is generally expressed for amine solutions as $R\text{-}NH_3^+ + OH^- \leftrightarrow R\text{-}NH_3^+ \cdots OH^- \leftrightarrow R\text{-}NH_2 + H_2O$. In addition, we have proposed from a detailed analysis of the absorption data[3] that the cause of the relaxational absorption observed in the pulse frequency range is only due to the first step though the intermediate of the above mentioned reaction is important. The effect of the second step on absorption is negligibly small. The importance of the proton-transfer reaction mechanisms in biological systems is stressed,[10] and a detailed dynamical interpretation for the process is desired in relation to both the solute structure and kinetics.

When the hydrophobicity of amine molecule increases, such as butyl-[1] and pentylamine,[2,4] another relaxational absorption appears in a slightly lower frequency range, although the position of the relaxation frequency depends on the structure of the solutes. We have predicted that the relaxation process is related to the molecular aggregation of the nonionized amine molecules, and that such aggregates have a relatively small aggregation number. This phenomenon begins remarkably with the solution of butylamines for monoalkylamines, and it is characterized by the so-called Peak Sound Absorption Concentration. This was originally discussed by Barfield and Schneider[11] regarding an aqueous solution of diethylamine in relation to the solute and solvent interaction. However, it is very dependent of the hydrophobicity of solute molecules. If an ether oxygen is introduced to the alkyl group of an amine molecule, it is expected that the hydrophobicity would decrease and that the dynamic characters of the solutions might be changed. It is desired to dynamically elucidate how the ether oxygen affects the balance of the hydrophobicity and hydrophilicity of amine molecules. In order to observe the above speculation, we chose the two solutes, 3-butoxypropylamine and 3-ethoxypropylamine, and the ultrasonic absorption coefficients were measured as functions of both the frequency and concentration. The results are reported in this paper.

Experimental

Chemical: 3-Butoxypropylamine and 3-ethoxypropylamine were purchased from Wako Pure Chemicals. The former was distilled at normal pressure. The latter was used without further purification, since the gas-chromatographic data indicated the purity to be more than 99%. The solvent water was distilled twice and highly pure N_2 gas was passed for about 10 min with boiling. The desired aqueous solutions were made by weight and by dilution for the dilute solutions.

Apparatus: The ultrasonic absorption coefficient was measured by a pulse method in the frequency range from 6.5 to 220 MHz. Detail of the measurement procedure are described elsewhere.[12] The frequency dependence of the absorption coefficient has been analyzed by a Debye-type relaxational equation as

$$\alpha/f^2=\sum_i A_i/[1+(f/f_{ri})^2]+B \quad (1)$$

and

$$\mu=(\alpha/f^2-B)fc=\sum_i A_i fc/[1+(f/f_{ri})^2], \quad (1')$$

where α is the absorption coefficient, f the frequency, A_i the relaxational absorption amplitude for the i-th process, f_{ri} the relaxation frequency, μ the absorption per wave length, c the sound velocity and B includes the residual and classical absorptions. The ultrasonic parameters were determined by a nonlinear least mean-squares computer program, which is also described elsewhere.[12] The sound velocity was measured by an interferometer at 2.5 MHz. These ultrasonic cells were immersed in a water bath maintained at a constant temperature within ±0.002 °C. All the solutions were isolated from the air by circulating dry N_2 gas onto the solutions in the cells in order to maintain a constant hydroxide concentration. The solution density was measured using a conventional Ostwald-type pycnometer, of which the volume was about 5 cm³. The solution pH's were determined by Hitachi-Horiba pH meter and the Towa Denpa HM-60S pH meter. All measurements were carried out at 25 °C.

Results

Figures 1 and 2 show the representative ultrasonic absorption spectra in aqueous solutions of 3-butoxypropylamine and 3-ethoxypropylamine at various concentrations, respectively. The solid curves in the figures indicate the calculated values by Eqs. 1 and 1′ when i=1. The detailed procedure for judging if the spectrum is due to a single relaxational process or not is described elsewhere.[13] The fitnesses between the experimental and theoretical values might look as if a single relaxational process was observed. However, small deviations at a lower frequency range were found at concentrations at around 0.6—1.2 mol dm⁻³ of 3-butoxypropylamine. The concentration

dependences of the relaxation frequency and the relaxational amplitude, thus calculated, are presented in Figs. 3 and 4 for both solutions. The obtained ultrasonic absorption coefficients as a function of the frequency (12 concentrations for 3-ethoxypropylamine solution and 26 concentrations for 3-butoxypropylamine) and the ultrasonic parameters including the probable errors as a function of concentration are available upon request to one of the authors, S. N. As can be seen in Fig. 3, the relaxation frequency for the solutions of 3-ethoxypropylamine increases monotonously with the analytical concentration, C_o, and tends to reach a plateau at more than 1 mol dm^{-3}. The relaxational amplitude also increases and shows a plateau at more than 0.5 mol dm^{-3} (Fig. 4). On the other hand, in the solutions of 3-butoxypropylamine, the relaxation frequency indicates a discontinuous trend regarding the concentration. The relaxational amplitude shows a similar dependence at less than 0.4 mol dm^{-3}, as that for 3-ethoxypropylamine, and increases dramatically at more than 0.4 mol dm^{-3}. It then goes through a maximum at 0.8 mol dm^{-3}. The smooth changes of the relaxation frequency and the relaxation amplitude for 3-ethoxypropylamine seem to suggest that a perturbation of only one equilibrium is the cause of relaxational absorption. On the other hand, the curious dependences of the ultrasonic parameters in 3-butoxypropylamine may indicate that another cause of the absorption also exists in concentrations of more than 0.5 mol dm^{-3}. However, the dependences of the ultrasonic parameters on the analytical concentration at a low concentration range of less than 0.6 mol dm^{-3} for the 3-ethoxypropylamine solution and 0.4 mol dm^{-3} for the 3-butoxypropylamine solution are similar. We therefore first tried to analyze the results at these concentration ranges.

Such dependences of the ultrasonic parameters are characteristic of a perturbation of an equilibrium associated with the proton-transfer reaction of amine. It is generally described by

$$R\text{-}NH_3^+ + OH^- \underset{k_{21}}{\overset{k_{12}}{\longleftrightarrow}} R\text{-}NH_3^+\cdots OH^- \underset{k_{32}}{\overset{k_{23}}{\longleftrightarrow}} R\text{-}NH_2 + H_2O, \quad (2)$$

where k_{ij} is the rate constant for each step. The relation between the relaxation frequency and the concentrations of the reactants is given by the following equation on the assumption that the effect of the second step on the first one is either small or negligible:

$$2\pi f_{r1} = 2k_{12}\gamma^2[OH^-] + k_{21}, \quad (3)$$

where γ is the activity coefficient, which can be estimated by the Davis equations,[14] subscript 1 for the relaxation frequency is indicated in order to distinguish the other process shown next. Figure 5 shows plots of $2\pi f_{r1}$ vs. $\gamma^2[OH^-]$ for the two solutions, the slope and intercept of which provide the forward and backward rate constants. It should be noticed that the intercept is not close to zero. The rate constants, thus obtained, are listed in Table 1.

Table 1. The Kinetic and Thermodynamic Constants for the Proton-Transfer Reaction in Aqueous Solutions of 3-Ethoxypropylamine and 3-Butoxypropylamine at 25 °C

Solute	$10^{-10}\,k_{12}$	$10^{-8}\,k_{21}$	K_{23}	$10^{4}\,K_b$	$10^{6}\,\Delta V_1$
	$mol^{-1}\,dm^3\,s^{-1}$	s^{-1}		$mol\,dm^{-3}$	$m^3\,mol^{-1}$
3-Ethoxypropylamine	1.2±0.2	2.3±0.2	0.0068	1.3±0.4[a] (1.4±0.6)[b]	30
3-Butoxypropylamine	1.8±0.1	0.57±0.08	0.066	2.0±0.5[a] (2.0±0.5)[b]	21

a) Estimated values from the relation, $K_b=\gamma^2[OH^-]^2/(C_o-[OH^-])$. b) The equilibrium constant was determined by the relation between the analytical concentration and the relaxation frequency (Eq. 12 given in Ref. 3). c) All of the rate and thermodynamic constants in this table were determined in the concentration range less than 0.5 mol dm^{-3}.

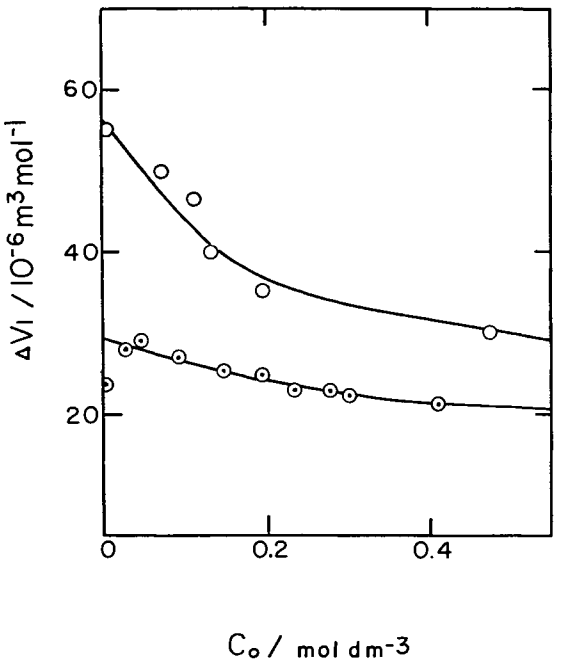

Fig. 6. The concentration dependence of the standard volume change of the proton-transfer reaction for 3-ethoxypropylamine (○) and 3-butoxypropylamine (⊙).

For the proton-transfer reaction it is possible to estimate the concentration dependence of the maximum excess absorption per wave length, μ_{m1}, by

$$\mu_{m1}=0.5\,A_1 f_{r1} c=\pi\rho c^2\Gamma_1\,(\Delta V_1)^2/2RT, \quad (4)$$

where ρ is the solution density, ΔV_1 the standard volume change of the reaction and $\Gamma_1=\{2/[OH^-]+1/[R\text{-}NH_3^+\cdots OH^-]+2\partial \ln \gamma/\partial[OH^-]\}^{-1}$. Using the above relation, the volume change has been determined and the results are shown in Fig. 6. Usually, the standard volume change of the reaction has been considered to be concentration independent. However, as can be seen in this figure, it seems to be dependent on the concentration for both solutions. This trend has also been found by Atkinson et al.[16] for an aqueous solution of *t*-butylamine. A detailed analysis by the present authors[15] also shows that the dependence is quite large in relatively dilute solutions, and that it reaches a constant value with increasing concentration. The values which seem to have become constant are listed in Table 1. In these analyses, the ultrasonic absorption results in relatively concentrated solutions were not used, and those in the concentration range of less than 0.5 mol dm^{-3} were taken. The reason will be considered in the discussion section. The equilibrium constant, K_b, for hydrolysis may provide useful information concerning a clarification of the proton-transfer reaction mechanisms. Unfortunately, it has not been previously reported for these aqueous solutions. It has therefore been estimated by the relation $K_b=\gamma^2[OH^-]^2/(C_o-[OH^-])$, where $C_o=[R\text{-}NH_3^+]+[R\text{-}NH_2]+[R\text{-}NH_3^+\cdots OH^-]$. They are also listed in Table 1. It is seen that the equilibrium constants, K_b, are far apart from the ratio of the forward and backward rate constant, k_{21}/k_{12}.

Secondly, we analyze the absorption mechanism observed in the relatively concentrated solution of 3-butoxypropylamine. A different relaxation process is considered to be observed in the solution from the profile of the ultrasonic parameters, as can be seen in Figs. 3 and 4. The relaxational amplitude goes through a maximum, the so-called Peak Sound Absorption Concentration. Similar dependences of the relaxation frequency and the relaxational amplitude on the concentration were observed in the solutions of various butylamines and pentylamines.[1,2,4] Therefore, we have considered that the same reaction may proceed in solution of 3-butoxypropylamine. However, the proton-transfer reaction is also expected to proceed in the solution; then, the values of α/f^2 due to the proton-transfer reaction should be subtracted from the experimental values. In order to carry out this procedure correctly it is appropriate to express the concentration dependences of the pH, the sound velocity and the solution density by proper functions of the analytical concentration. These experimental values were fitted to appropriate polynomials in order to minimize the standard deviations by a least-mean

squares method. They are as follows:

$$pH = 0.28248C_o^{1/2} + 12.037 \quad (0.596—1.902\ \text{mol dm}^{-3}),$$

$$c = 1495.12 + 139.557C_o - 110.401C_o^2 + 24.8807C_o^3 \quad (0—1.8\ \text{mol dm}^{-3}),$$

and

$$\rho = 0.99727 - 3.6015\times10^{-2}\,C_o + 2.5046\times10^{-2}\,C_o^2 - 8.5832\times10^{-3}\,C_o^3 \quad (0—1.8\ \text{mol dm}^{-3}),$$

where the values indicated in the parentheses are the concentration ranges within which the above equations are applicable. Also, the relaxation frequency and the relaxational amplitude at any concentration can be speculated by Eqs. 3 and 4 for the proton-transfer reaction. It is then possible to calculate $(\alpha/f^2)_{\text{residual}}$ which is the residual absorption subtracted those due to the proton-transfer reaction from the experimental values. The residual absorptions were again analyzed by the single relaxational equation; and it was found that they could be reasonably fit to the theoretical curves. The calculated ultrasonic absorption parameters are shown in Figs. 7 and 8; the numbers which correspond to the data are shown in Figs. 3 and 4. As can be seen, the relaxational amplitude are close to those values given in Fig. 4, but are slightly larger, and the increment at a concentration around 0.6 mol dm^{-3} becomes steeper. The relaxation frequencies shift to a slightly lower frequency and tend to increase monotonously, as can be seen in Fig. 7. These results indicate that the absorption is much larger than that due to the proton-transfer reaction. The cause of the residual relaxational absorption is considered to be due to an aggregation reaction associated with the hydrophobicity of the nonionized amine molecules since the relaxation process disappears when the solution pH decreases, it is not found in 3-ethoxypropylamine aqueous solution, and it is not observed when organic solvents are used. In general, although the aggregation reaction may proceed through a stepwise process,[19] we simply assume that it is given by the following formula for a reaction with a small aggregation number:

$$n\,A \underset{k_{43}}{\overset{k_{34}}{\longleftrightarrow}} A_n. \tag{5}$$

The relation between the relaxation frequency, f_{r2}, and the reactant concentration is derived as[1]

$$2\pi f_{r2} = n^2 k_{34}[A]^{n-1} + k_{43} \tag{6}$$

where subscript 2 for the relaxation frequency is used in order to distinguish that for the proton-transfer reaction and n, the aggregation number. In order to analyze the concentration dependence of the ultrasonic parameters, the concentration of the nonionized monomer molecules is necessary. It may be a good approximation that the equilibrium constant of the hydrolysis, defined as $K_b = \gamma^2[OH^-][R\text{-}NH_3^+]/([R\text{-}$

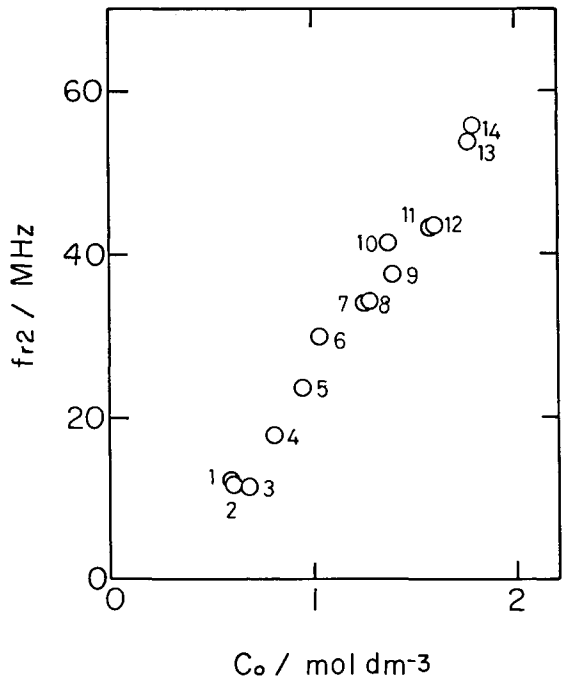

Fig. 7. The concentration dependence of the relaxation frequency, f_{r2}, calculated from the residual absorption for aqueous solution of 3-butoxypropylamine.

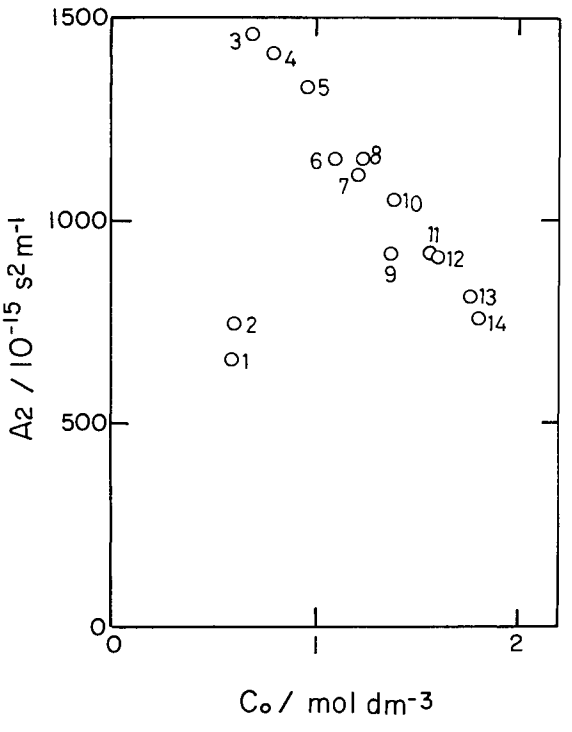

Fig. 8. The concentration dependence of the amplitude of the relaxational absorption, A_2, calculated from the residual absorption for aqueous solution of 3-butoxypropylamine.

$NH_3^+\cdots OH^-]+[R\text{-}NH_2]$), is still held in a slightly concentrated solution. The equilibrium constants for the first and second step in Eq. 2, $K_{12}=k_{21}/k_{12}=\gamma^2[OH^-]^2/[R\text{-}NH_3^+\cdots OH^-]$ and $K_{23}=k_{32}/k_{23}=[R\text{-}NH_3^+\cdots OH^-]/[R\text{-}NH_2]$ may be also defined. Then, Eq. 6 can be arranged as

$$2\pi f_{r2}=n^2(\gamma^2[OH^-]^2)^{n-1}\,k_{34}(1/K_b-1/K_{12})^{n-1}+k_{43}. \quad (7)$$

The aggregation number, n, was changed so as to obtain a least error of plots of $2\pi f_{r2}$ vs. $(\gamma^2[OH^-]^2)^{n-1}$. When $n=3$ the intercept of the plots gave a negative value. By giving more than 4 for the aggregation number, the error is increased. We thus took the aggregation number to be four. Figure 9 shows plots of $2\pi f_{r2}$ vs. $(\gamma^2[OH^-]^2)^3$, which give the backward rate constant, k_{43}, from the intercept to be $(5.7\pm0.8)\times10^7\ s^{-1}$ and the product of the rate and equilibrium constants from the slope. Equation 6 is also arranged using the total concentration of the reactants under consideration, C_o', as

$$2\pi f_{r2}=k_{43}\,nC_o'(\gamma^2[OH^-]^2)^{-1}\,(1/K_b-1/K_{12})^{-1}+(1-n)k_{43}, \quad (8)$$

where

$$C_o'=C_o-[R\text{-}NH_3^+]-[R\text{-}NH_3^+\cdots OH^-]$$
$$=[R\text{-}NH_2]+n[(R\text{-}NH_2)_n].$$

Figure 10 shows plots using Eq. 8 when $n=4$. The obtained backward rate constant, k_{43}, was $(12\pm1)\times10^7\ s^{-1}$ from the intercept, the plots of which gave a better linearity with smaller probable errors. It is therefore shown in Table 2. It seems to be close to that value obtained by Eq. 7. The equilibrium constant, K_b, was thus estimated to be $(3.8\pm0.2)\times10^{-4}$ mol dm^{-3} using the slope and intercept values of linear plots of Eq. 8, since the equilibrium constant, K_{12}, is obtained from the results concerning the proton-transfer reaction. As a result, going back to Eq. 7, it is possible to obtain the forward rate constant, k_{34}, from the slope of the linear plots; it is also shown in Table 2.

The maximum excess absorption per wave length for this process is derived as[1]

$$\mu_{m2}=\pi\,\rho c^2\,k_{34}[A]^n\,\tau\,(\Delta V_2)^2/2RT, \quad (9)$$

where the volume relaxation has been assumed for the above process and $\tau=(2\pi f_{r2})^{-1}$. Once the rate con-

stants, k_{34} and k_{43}, are obtained, the monomer concentration is available. Using the experimental τ values, then, the volume change of the reaction has been estimated, and is given in Table 2.

Discussion

The results of the proton-transfer reaction are first discussed. The forward rate constants, k_{12}, for both solutions are reasonable as a diffusion-controlled reaction.[17] However, the ratio of the forward and backward rate constants, k_{21}/k_{12}, is far apart from the equilibrium constant, K_b, for the hydrolysis, as can be seen in Table 1. Similar results have been obtained in other amine solutions.[3,4,14] The coupling effect of the faster process on the slower one is usually taken into account in order to interpret such phenomena. However, as has been reported in a previous paper,[3] it is rather reasonable that the perturbation of the first step in Eq. 2 is the cause of the observed relaxation and the second step is too fast to affect on the first step. Furthermore, our analytical procedure[3] using the relation between the relaxation frequency and the analytical concentration (Eq. 12 in Ref. 3) has given the reasonable equilibrium constants, K_b, as is shown in Table 1. Another equilibrium constant, K_{23}, was estimated to be less than unity from the relation, $K_b=K_{12}/(1+K_{23}^{-1})$ where the K_b value estimated by the static procedure (listed in Table 1) was used. These results show that the concentration of the intermediate is very small compared with that of R-NH_2. This means that the second step may correspond to a intramolecular proton-transfer and that the intermediate is not very stable. It is expected that this process is too fast to be observed by the time range under study. As can be seen in Table 1, the forward rate constant, k_{12}, is not much affected, even if the structures of amine molecules are different. This means that the most effective term in the reaction includes the diffusion of hyrdoxyl ions in aqueous media. Although only data for relatively dilute solutions of both solutions are used to obtain the proton-transfer reaction rate constants, the same ultrasonic relaxational absorption due to the reaction can be observed in concentrated solutions of 3-ethoxypropylamine (Fig. 3). The relaxation frequencies obtained (more than 0.6 mol dm^{-3}) are lower than those expected from the calculated values (around 100 MHz) using Eq. 2. This might be because a solute-solute interaction, such as the interaction due to hydrogen bonding, interrupts the proton-transfer reaction. However, the aggregates associated with the hydrophobicity of the solute (discussed next) may not exist in solution of 3-ethoxypropylamine. Another possibility may be due to an alternation of the solvent water structure by the addition of an amine at the high-concentration range.

It is not very clear why the volume change of the reaction is dependent on the concentrations of both solutions. One of the reasons might be that the approximation of the volume relaxation for the proton-transfer reaction is not appropriate. If it includes a thermal-relaxation term, the volume change, ΔV_1, should be expressed as $\Delta V_1=\Delta V_{real}-\alpha_p\Delta H/\rho C_p$, were α_p is the thermal expansion coefficient, ΔH the standard enthalpy change of the reaction, and C_p the specific heat at constant pressure. However, without this experimental information concerning α_p and C_p, no definite conclusion can be given at this stage.

Next, the absorption mechanism observed in a relatively concentrated solution of 3-butoxypropylamine is discussed. The difference in the absorption characters from those in solution of 3-ethoxypropylamine can clearly be seen in the profiles given in Figs. 3 and 4; that is, the relaxational amplitude increases steeply and goes through a maximum. Although the original ultrasonic absorption spectra look like those due to single relaxational absorption, as was analyzed in a previous section, the spectra associated with two relaxation processes are considered to be superimposed since the relaxational amplitude due to the proton-transfer reaction is much smaller than that newly observed in the relatively concentrated solution, and the respective relaxation frequencies are not very far apart. Ideally, two relaxation processes should be distinguished by the double relaxational equation (i=2 in Eq. 1) using the observed values of the absorp-

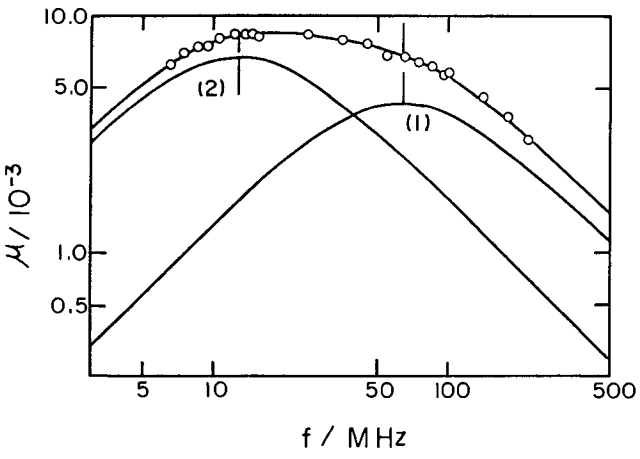

Fig. 11. The spectrum analyzed by the double relaxational equation for 3-butoxypropylamine at 0.605 mol dm^{-3}. The calculated parameters are f_{r1}=(64.4±5.5) MHz, A_1=(88.5±10.5)×10^{-15} s^2m^{-1}, f_{r2}=(12.7±0.6) MHz, A_2=(690.8±16.1)×10^{-15} s^2m^{-1} and B=(27.2±0.8)×10^{-15} s^2m^{-1}. The parameters obtained by the extrapolation by Eqs. 3 and 4 are f_{r1}=79.8 MHz and A_1=90.3×10^{-15} s^2m^{-1} and those calculated by the procedure shown in result section are f_{r2}=11.7 MHz, A_2=745.5×10^{-15} s^2m^{-1} and B=22.3×10^{-15} s^2m^{-1}.
(1): The absorption due to the proton transfer reaction and (2): That due to the aggregation reaction.

tion coefficients. Then, applying the double relaxational equation to the data at more than 0.5 mol dm^{-3}, unrealistic ultrasonic parameters were obtained (e.g. negative ultrasonic parameters and the larger probable errors than the most probable values), except those at 0.596 and 0.605 mol dm^{-3} These data correspond to those indicated by the number, 1 and 2, in Figs. 3 and 4. At these limited concentrations, the relaxation amplitudes are not very much larger and the relaxation frequencies are still quite far apart from that due to the proton transfer. Also, the deviations from the calculated values in the original spectra have been found, as can be seen in Fig. 1. Figure 11 shows one of the spectra calculated by the double relaxational equation at such intermediate concentrations. Thus, the calculated ultrasonic parameters at these two concentrations are very close to those determined in the previous section. These calculations indicate that the superimposed spectra are observed at more than 0.65 mol dm^{-3}. The subtraction procedure used to obtain the ultrasonic parameters given in the previous section seems to be appropriate.

Even if the ether oxygen, which produces hydrophilic activity, is introduced to the molecule, the butyl group seems to play fairly the rule as the hydrophobic interaction. Thus, a small aggregate exists in aqueous media. It should be noticed that the equilibrium constant, K_b, estimated from the aggregation reaction given by Eq. 8, (K_b=3.8×10^{-4} mol dm^{-3}) seems to be close to that obtained in the lower concentration range listed in Table 1. This also supports the idea that the cause of the relaxational absorption is due to reaction associated with aggregates of the nonionized amine molecules. The slightly larger value may be due to a solute-solute interaction, such as a hydrogen-bonding interaction in the relatively concentrated solutions. The aggregation number is close to that in a solution of pentyl or butylamine. This might mean that the activity of the hydrophobicity is close to that of the alkylamines, which have five or four carbon atoms. We speculate that the propyl group has a border activity regarding hydrophobicity to form the aggregate. This is also considered to be true from the fact that the relaxation associated with the aggregation reaction is observed in an aqueous solution of propyl alcohol,[18] although it is not found in a aqueous solution of propylamine. The hydroxyl group may be considered to be less hydrophilic than the amino group. This is also recognized from the solubility difference between the butyl alcohol and butylamine in water. It is interesting to compare the ultrasonic results with those in solutions of pentylamine and butylamine,[1,2] which have previously been reported and are also shown in Table 2. The position of the peak sound absorption concentration in the present solution is lower than that of butylamine. The relaxational amplitude is larger than that of butylamine. These differences seem to indicate that the hydrophobicity of 3-butoxypropylamine is slightly larger than butylamine. This comparison may indicate that the propyl group bonded with the ether oxygen has a slightly the hydrophobic character, which increases the hydrophobicity of the entire molecule. A similar comparison between 3-butoxypropylamine and pentylamine shows that the former is less hydrophobic than the latter. It can then be easily understood why such aggregate is not formed in solution of 3-ethoxypropylamine. Either the ethyl group is too small to form an aggregate through a hydrophobic interaction, or the ether oxygen acts as the hydrophilicity, thus preventing the formation of an aggregate by the hydrophobic interaction.

Finally, it may be meaningful to indicate that the concentration dependence of the relaxation frequency for the aggregation reaction (Eq. 8 used in this study) is very similar to that proposed theoretically by Teubner[19] and widely used.[20,21] That is, the relaxation frequency is proportional to C_0'/[A] in both treatments, even though the former corresponds to a variance of the size distribution of unity and $k_{43}n$ is k^-/m when k^- is the mean of the dissociation rate constant and m is the mean aggregation number.

Although the two relaxation processes due to both proton-transfer and aggregation reactions were observed in the same ultrasonic frequency range in the present study, the coupling effect of the two reactions may be ignored since a very fast intramolecular reaction proceeds between the above-two reactions under consideration.

This work was partly supported by a Grant-in-Aid for Scientific Research No. 02640350 from the Ministry of Education, Science and Culture.

Small-Angle X-Ray Scattering Study on Sol-Gel Transition of Mixtures of Colloidal Silica and Organic Polymer

Hideki MATSUOKA, Sheng-rong CHEN, Hiroshi ISHII, Norio ISE,*
Kazuki NAKANISHI,† and Naohiro SOGA†
Department of Polymer Chemistry, Kyoto University, Kyoto 606
†Department of Industrial Chemistry, Kyoto University, Kyoto 606
(Received November 2, 1990)

Sol-gel transition of mixtures of colloidal silica-water soluble organic polymer (sodium polystyrenesulfonate) has been investigated by the small-angle X-ray scattering technique. With proceeding gelation, an increase of the intensity at small-angle regions was observed and the values of radius of gyration (R_g) were estimated by the Guinier method. The addition of polymer increased the initial increase of R_g with gelation, i.e., sol-gel transition was accelerated by the presence of the polymer. This observation is not in contradiction to the prediction of micro-phase separation into silica-rich phase and polymer-rich phase proposed by Nakanishi and Soga. The fractal analyses predicted that the geometrical structure of the gel finally formed is similar to those of random coil linear polymer and swollen branched polymer.

The sol-gel route to glass or ceramic materials is attracting increasing attention. The main advantage of this method is that the materials can be made at fairly low temperatures compared with conventional methods.[1] For the alkoxy-derived silica system, the sol-gel reaction has been suggested to consist of two steps, i.e., the formation of primary silica particles by hydrolysis of alkyl silicate by water and the gel-network formation by aggregation of primary particles.[2] The structure and properties of the gel-derived materials have been investigated by electron microscopy (EM),[3] BET method,[4] etc. while its mechanism has been studied by Raman scattering,[5] NMR,[6] and so on. Dynamical properties of sol-gel transition of tetramethoxysilane have been well-investigated by a variety of experimental techniques.[7] Very recently, Nakanishi and Soga have found by EM that the glass finally obtained by the sol-gel method from mixtures of alkylsilicate and organic polymer has an interconnected porous structure in the micron-range.[8] The production of glass materials with well-controlled porosity (in size and in its fraction) would have immeasurable value in materials science. The mechanism producing the porous structure has been considered to be microphase separation in the sol-gel system: silica-rich phases and polymer-rich phases are formed in the system whose size determines that of porosity.[8] Porous structures of the glass finally obtained are clearly seen by EM. In addition, the same kind of porous gel can be obtained when colloidal silica is used as a silica source.[8b] However, the mechanism and the structural change in sol-gel process for such systems are not yet clear. In this study, we applied the small-angle X-ray scattering (SAXS) technique to investigate the sol-gel process (from reaction mixture to wet gel with coexistence of an organic, water-soluble polymer). In this study, we used colloidal silica dispersion as a reaction material instead of alkyl silicate, since we can observe only the second step (aggregation of primary silica particles to form gel network). The SAXS technique has been shown recently to be useful[9] to investigate the sol-gel process and the fractal structure[10] of the gel formed.

Experimental

Colloidal silica used was SNOWTEX S kindly supplied by Nissan Chemical Co. (Tokyo, Japan). The diameter was found to be 6.65 nm by the Guinier method.[11] The mother suspension was dialyzed against 10^{-4} NaOH solution to avoid aggregation until the NaOH solution shows a constant conductivity. The conductivity was checked by a Wayne-Kerr Auto Balance Precision Bridge (Model B331, Surry, England) with a glass conductivity cell with platinum electrodes. The organic polymer used was sodium polystyrenesulfonate (NaPSS) purchased from Pressure Chemical Co. (Pittsburgh, PA) whose molecular weight was 88000 by the supplier. NaPSS was also purified by dialysis against high quality Milli-Q water. The end point of dialysis was also determined by the conductivity method. The dialysis tube used both for colloidal silica and NaPSS was made by Union Carbide Corp. (Chicago, IL). The water used for sample preparation and for dialysis was obtained by the Milli-Q system (Millipore, Bedford, MA).

The SAXS apparatus used was made by Rigaku Corporation (Tokyo, Japan) the details of which have been described fully elsewhere.[12] Since our SAXS system has a position sensitive proportional counter (PSPC), no angle-scanning is necessary. This enabled us to perform time-resolved measurements. The power of the X-ray generator was chosen to be 40 kV—100 mA because the strong scattering from the gel formed at high power condition is out of dynamic range of the detector. We used a Mark glass capillary (Diameter: 1.5 mm) as a SAXS cell. The SAXS cell was thermostatted at about 30 °C during measurements by circulating water from a temperature-controlled bath (Model K2R, Neslab, Newington, NH). The data obtained were corrected for slit smearing by Lake's method. The preparation of reaction mixture was as follows: an NaPSS solution at various concentrations was added into a purified colloidal silica suspension (4.0 vol%). An NaCl solution (0.2 M, M=mol dm^{-3})

Table 1. Component of Colloidal Silica-NaPSS Mixtures

[Silica]/vol%	[NaCl]/M	[NaPSS]/g dm^{-3}
4.0	0.2	0.0
4.0	0.2	0.1
4.0	0.2	0.5
4.0	0.2	1.0
4.0	0.2	2.0
4.0	0.2	6.0
4.0	0.2	12.0

Table 2. Component of Colloidal Silica and NapTS Mixtures

[Silica]/vol%	[NaCl]/M	[NapTS]/g dm^{-3}	[NapTS]/M
4.0	0.2	0.095	4.9×10^{-3}
4.0	0.2	0.94	4.8×10^{-2}
4.0	0.2	6.0	3.1×10^{-1}

was then added into the mixture to trigger gelation. Table 1 shows the composition of reaction mixtures at the onset of the reaction.

We used sodium *p*-toluenesulfonate (NapTS, Wako Chemicals Co., Osaka, Japan) as a monomer analog of NaPSS. The purification of NapTS was kindly done by Mr. Naoki Tanaka of our laboratory by recrystallization. Table 2 shows the compositions of NapTS systems. The concentrations of NapTS were determined to be comparable to the monomer concentration of NaPSS systems.

Results

Figure 1 shows the SAXS curves for a colloidal silica-NaPSS mixture at various gelation times. The time when salt solution was added into the system was defined as the gelation time zero. The abscissa q is the scattering vector ($q=4\pi\sin\theta/\lambda$, 2θ: scattering angle, λ: wavelength of X-ray (1.542 Å) and the ordinate is the relative intensity of scattered X-rays. It is clear that, with proceeding gelation, the intensity at very small-angle regions increases remarkably.

Figure 2 shows a comparison of the scattering behavior at three different NaPSS concentrations. The increase of scattered intensity at small-angle regions becomes significant and is rapid for higher NaPSS concentration systems.

Figure 3 shows a similar comparison for the NapTS systems. There was no significant difference at various concentrations.

Discussion

Guinier Analyses of Small-Angle Regions. In the small-angle regions called Guinier region, the scattering behavior follows a well-known Guinier law:[11]

$$I(q)=N\exp[(-1/3)\,R_g^2\,q^2] \qquad (1)$$

where R_g is the apparent radius of gyration of scatterer and N a constant depending on the apparatus and the concentration. In $\ln I(q)$ vs. q^2 plot (Guinier

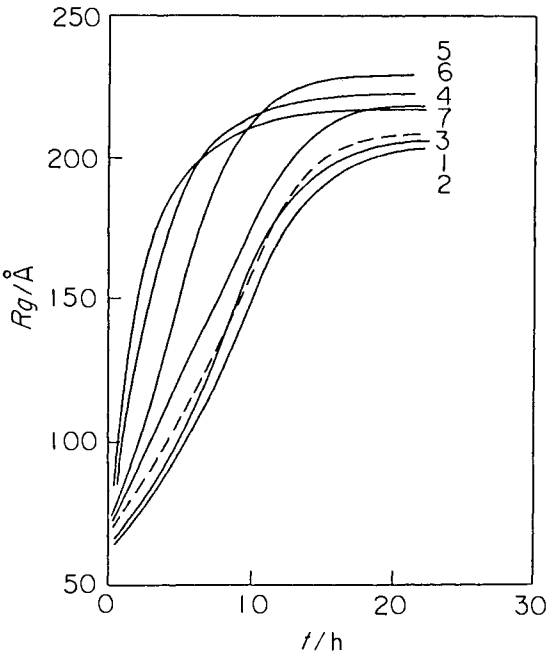

Fig. 5. Changes of the radii of gyration with gelation of colloidal silica dispersion at different NaPSS concentrations. [silica]=4.0 vol%; [NaCl]=0.2 M; [NaPSS]: 1) 0.0, 2) 0.1, 3) 0.5, 4) 1.0, 5) 2.0, 6) 6.0, 7) 12.0 g dm^{-3}.

plot), a linearity should appear in this region and R_g can be calculated from the slope of the straight line. Figure 4 shows typical examples of the Guinier plots, and the R_g values thus obtained are plotted against gelation time in Fig. 5 for different NaPSS concentrations. In general, the R_g value increased rapidly with proceeding gelation and reached constant values. The larger the NaPSS concentration, the steeper and faster the initial increase of R_g value. This tendency can be explained by invoking the concept of phase

separation proposed by Nakanishi and Soga:[8] When a microphase separation occurs, silica-rich phases and polymer-rich phases are formed. The sol-gel process, i.e. aggregation of silica particles occurs in silica-rich phase in which the silica concentration is larger than the average concentration. Due to the higher silica concentration, the aggregation process and hence the sol-gel process is accelerated. A similar phase separation phenomenon has recently been reported by Furusawa et al. for a mixture of polystyrene-based polymer latex and NaPSS systems.[13]

Another possible interpretation of the acceleration phenomena described above may be adsorption of polymer: one linear polymer molecule adsorbed on surfaces of two or more silica particles bringing the particles closer and hence accelerate the aggregation reaction (enhanced collision). This phenomenon is called a bridging effect.[14] However, for our systems, the surface of the silica particles are negatively charged under these conditions (pH=8.9) and NaPSS is, of course, anionic. Adsorption of anionic polymer on negatively charged surface would be implausible due to the electrostatic repulsive interaction between them. In fact, Furusawa et al. reported that no adsorption occurred between NaPSS and polystyrene based, negatively charged polymer latex particle although these two consisted of the same material.[13]

If simple ionic salt is added into the system, the gelation process may be accelerated by the shielding effect of the salt; ionic impurities in the medium reduce the electrostatic repulsive interaction between silica particles, making the contact of the particles easier. Since NaPSS is also ionic, it may act as an ionic impurities and have a shielding effect. However, for our systems, the amount of NaPSS is 0.06 M at maximum, which can be considered to be much smaller than that of simple salt (NaCl, 0.2 M). Moreover, the results for NapTS systems (Fig. 6) clearly rule out this possibility. When compared at the same "monomer" concentration NapTS had nearly no acceleration effect (only at a NapTS concentration of 6.0 g dm^{-3} NapTS, a slight acceleration effect may be seen). Thus it is probable that the acceleration is due to a microphase separation, although the exact mechanism of separation phenomena is not clear at this stage. Further detailed experiments with polymers of various molecular weights are now in progress, and the results will be described in a forthcoming paper.

A few words are necessary on the physical meaning of R_g value. It would be highly possible that, just at the start point of gelation, R_g means the mean size of the colloidal silica particle and that, at the early stage of the reaction, R_g reflects the average size of small (isolated) aggregates of silica particles. However, at a certain point in the middle or late stages of the reaction, a cross-linking reaction should occur to form gel network. Hence, at least, at the final stage of the reaction, R_g should reflect the size of the network (or a correlation length of the network), or the size of "hole" in the network when we take into account the famous Babinet principle in optics.[15] Brinker et al.[16] proposed an interpretation of the meaning of R_g value for both cases of acid and base-catalyzed sol-gel transitions of tetraethoxysilane (TEOS) by a dilution technique. They claimed that the R_g for these two cases should be different; only for the acid case, an increase of R_g by dilution was observable indicating that R_g reflected the network size, while negligibly small changes of R_g for the base case indicated R_g to reflect the mean size of aggregates. However, since the possibility of swelling of the gel by dilution should be taken into account, their proposal of the interpretation might not be universal. For our case, what R_g means is not very clear at this stage. However, we can say that the size of aggregate, the network size, and the phase size in the system if a phase separation occurs, are important factors influencing R_g value.

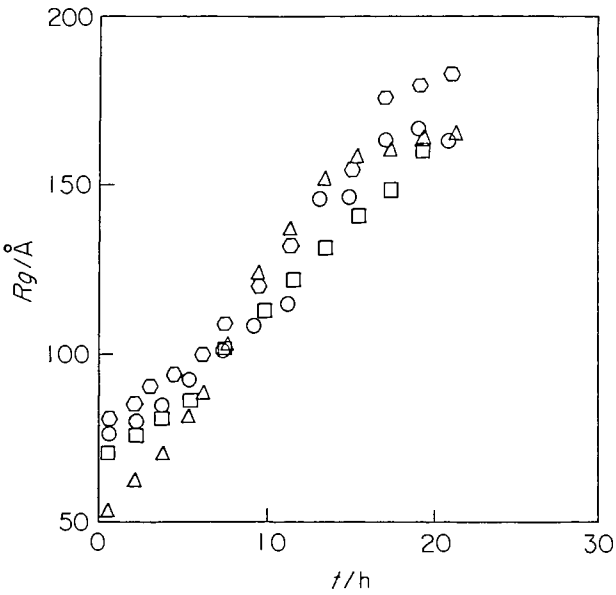

Fig. 6. Changes of radii of gyration with gelation of colloidal silica dispersion at different NapTS concentrations. [silica]=4.0 vol%; [NaCl]=0.2 M; [NapTS]: ○: 0.0, □: 0.095, ○: 0.94, △: 6.0 g dm^{-3}.

Fractal Analyses at the Middle and Large Angle Regions. In relatively higher angle regions, it is well-known that the scattering behavior follows a power law,[17] namely

$$I(q) \propto q^{-\alpha} \tag{2}$$

Hence, the double logarithmic plot of $I(q)$ and q (Porod plot) shows linearity and its slope α is called the Porod slope. When $3 < \alpha \leqslant 4$ holds, α reflects the geometrical structure of the surface of the scatterer and α can be related to the surface fractal dimension D_s by $D_s = 6 - \alpha$.[9] When the surface is perfectly smooth, α

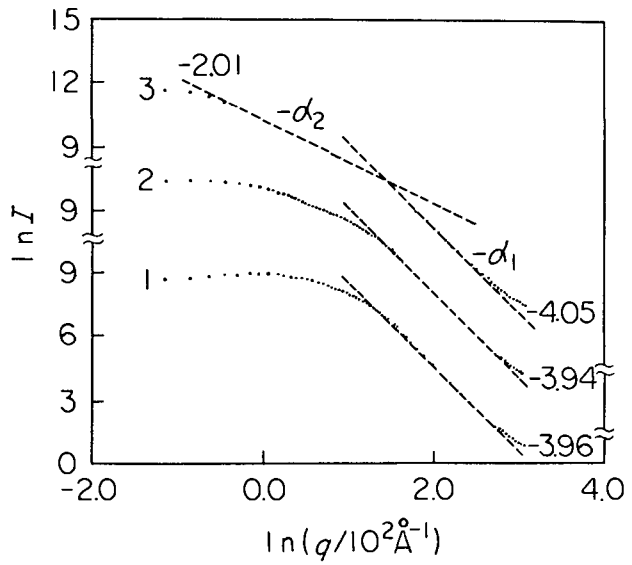

Fig. 7. Porod plots for the gelation of a colloidal silica-NaPSS mixture. [silica]=4.0 vol%; [NaPSS]=1.0 g dm^{-3}; [NaCl]=0.2 M; Gelation time/h: 1) 0.42, 2) 4.6, 3) 23.

should be equal to 4, and this relation had been well-known as a Porod law[18] much before Mandelbrot proposed the concept of fractal.[10] When α is less than or equal to 3, α reflects the geometrical structure of the scatterer itself and α can be related to the volume fractal dimension D_v by $\alpha=D_v$.[9] For both cases, the q range, in which the linearity holds, depends on the dimension of the scatterer which has a fractal character.

Figure 7 shows examples of the Porod plot at three different gelation times. At any gelation time, an excellent linearity is seen at relatively high angle regions. For middle angle region, no linearity is observed at the early stage of the reaction. But as gelation proceeds, linearity appears and at the end of the gelation also excellent linearity holds. The Porod slopes thus obtained for both large (α_1) and middle (α_2) regions are summarized in Table 3. The average radius of the units of the structure, R_u and a correlation length of the gel, R_c obtained from a low q-limit of the linearity for α_1 and α_2, respectively, are also shown in Table 3. The average values of α_1 and α_2 were 4.02 and 1.98, respectively. As mentioned above, it is most reasonable to conclude that α_1 and α_2 reflect the surface and the geometrical structure of the scatterer, respectively. Since the linearity whose slope gives α_1 is already observed at the early stage of the gelation, α_1 reflects the surface structure of colloidal silica particles. The result that R_u values are smaller than the radius of the silica particle corroborates our interpretation. $\alpha_1=4$ means that its surface is smooth (Porod law). The α_2 value, about 2, means the geometrical (fractal) structure of aggregates of primary particles and/or of the gel network formed.

Table 3. Properties of Gels of Colloidal Silica-NaPSS Mixtures

[NaPSS]	Porod slope		Average radius	Correlation
g dm^{-3}	α_1	α_2	R_u/Å	length R_c/Å
0.0	3.99	1.94	24.7	168
0.1	4.02	1.94	25.2	143
0.5	4.00	1.95	25.7	144
1.0	4.05	2.01	23.7	168
2.0	4.06	2.01	22.5	172
6.0	4.01	2.02	23.5	179

[Silica]=4.0 vol%, [NaCl]=0.2 M. $R_u=1/q_u$: q_u is the q value at the crossover point of two straight lines for α_1 and α_2. $R_c=1/q_c$: q_c is the low-q limit of the linearity for α_2.

Since the linearity for α_2 is observed in the angular range between those for the Guinier region and for α_1 linearity, it may be most reasonable to conclude that α_2 reflects the geometrical structure of silica aggregate if R_g reflects the size of the gel network. According to Schaefer,[19] the slope of -2 may be obtained for α at least two geometrical structures, a linear polymer (random coil) and swollen branched polymer. Hence, the structure of the aggregates and/or gel network observed in the present work would be very similar to those of linear polymer or swollen branched polymer, although it is not clear which is correct at the moment. We also observed that the α_2 value increases with increasing polymer concentration, although very slightly. This may reflect the possibility of the control of gel structure by addition of polymer. However, since the change is small, experiments in a much larger polymer concentration range and with other polymers are necessary for further detailed discussion and for study on the relation to the porous structure of final materials, and now are in progress.

Conclusion

Sol-gel transition of a colloidal silica suspension was accelerated by addition of water soluble polymer (NaPSS in this study). This acceleration may have been due to microphase separation between the colloidal silica and polymer, which is not in contradiction with the model proposed by Soga and Nakanishi. The geometrical structure of the gel formed had a fractal nature, and its (volume) fractal dimension was about 2, which is very close to those of linear polymer and swollen linear polymer. The fractal dimension of the gel was slightly affected by the concentration of the coexisting polymer, which makes it feasible to control a gel structure by addition of polymer.

Our sincere gratitude goes to Messrs. K. Tanimoto and S. Ozora, Nissan Chemicals Co., who kindly donated samples. We thank Mr. Naoki Tanaka of our laboratory for the purification of NapTS. This

study was partly supported by Asahi Glass Foundation, to which our sincere gratitudes are due.

Mössbauer Emission Study of Recoil ^{119}Sb and ^{119m}Te Atoms after Nuclear Decays and Reactions in SnS and SnSe

Shizuko Ambe and Fumitoshi Ambe*
The Institute of Physical and Chemical Research (RIKEN), Wako-shi, Saitama 351-01
(Received December 4, 1990)

The chemical fates of ^{119}Sb and ^{119m}Te recoil atoms after p- and α-reactions in SnS and SnSe were studied by Mössbauer emission spectroscopy. The ^{120}SnS and ^{120}SnSe samples irradiated with protons gave a partly resolved asymmetric doublet ascribable to ^{119}Sn at the Sn site of the matrices. The α-irradiated ^{117}SnS and ^{117}SnSe samples gave emission spectra, drastically different from those of p-irradiated ^{120}SnS and ^{120}SnSe as well as that of α-irradiated ^{120}SnTe. The spectra are decomposable into three lines which are hardly assignable to any known chemical species of Sn and S or Se. Two of the lines are assigned to a doublet of divalent ^{119}Sn in the Sn site of SnS or SnSe with a nearby defect on the basis of their behavior on thermal annealing. The other line is ascribed to tetravalent ^{119}Sn in a defect structure.

The defect structures created in metals, semiconductors, and chemical compounds by energetic atoms have been extensively studied by hyperfine techniques.[1-10] However, the physical and chemical factors determining the final states of the atoms are not yet fully understood, especially concerning the last matrices. We previously reported a Mössbauer spectroscopic investigation of the ^{119}Sn atoms produced by nuclear-reaction and decay sequences (^{120}Sn(p,2n)^{119}Sb $\xrightarrow{EC}$ ^{119}Sn and ^{117}Sn(α,2n)^{119m}Te $\xrightarrow{EC}$ ^{119}Sb $\xrightarrow{EC}$ ^{119}Sn) in SnTe.[11,12] In the matrix, the recoil ^{119}Sb atoms were found to be stabilized at both the Sn and Te sites.

In the present work, a similar investigation of the recoil atoms produced by nuclear reactions and decays in SnS and SnSe is described.[13] Although the results concerning SnS and SnSe were similar to each other, they were drastically different from that on SnTe. The ^{119}Sn atoms arising from ^{119}Sb atoms produced by the proton reaction were found exclusively at the Sn sites of SnS and SnSe, while those from ^{119m}Te after the α-reaction were found in defect states not observed in SnTe. The results are discussed in terms of the chemical properties of both the recoil atoms and the matrices.

Experimental

Tin isotopes enriched in ^{120}Sn or in ^{117}Sn and consequently depleted in ^{119}Sn (^{120}Sn 98.39% and ^{119}Sn 0.39% or ^{117}Sn 89.2% and ^{119}Sn 1.12%) were used for the preparation of both SnS and SnSe samples in order to reduce the resonant self-absorption of Mössbauer γ-rays in the samples. Crystalline ^{120}SnS and ^{117}SnS were prepared by the vacuum sublimation of amorphous tin sulfide, obtained by a reaction of H_2S gas on tin(II) ions in an aqueous solution. The samples of ^{120}SnSe and ^{117}SnSe were prepared by fusing a stoichiometric mixture of ^{120}Sn or ^{117}Sn metal with selenium under an Ar stream. The samples were examined by powder X-ray pattern and Mössbauer absorption measurements on the ^{119}Sn contained in them by a minute fraction.

Sample powder (50—100 mg cm^{-2}) pressed onto an aluminum plate was irradiated in a target chamber filled with flowing helium gas with 15-MeV protons or 32-MeV α-particles accelerated by the RIKEN 160 cm cyclotron. In the case of protons, irradiation with a beam of about 2.5 μA cm^{-2} was continued for several hours. For α-particles, the corresponding values were 0.5—0.6 μA cm^{-2} and 10—12 h. The targets were thin enough to let the bombarding particles pass through them, so that the intense energy dissipation of the particles near the end of their tracks did not occur in the samples, but in the aluminum backing. The backside of the aluminum plate was cooled directly with water during irradiation. After irradiation the samples were left standing at ambient temperature for 10—20 h, allowing short-lived nuclides to decay. Although neither the bulk temperature of the samples during irradiation nor the local temperature of the end point of the energetic recoil atoms were measurable, the effects of thermal annealing showed that the bulk temperature were less than 100 °C, and that the effect of local heating along the track of the recoil atoms was not serious, if any. The Mössbauer absorption spectra of the irradiated samples showed no trace of radiation damage. Annealing and fusion of the irradiated samples were carried out under an Ar atmosphere.

The Mössbauer emission spectra of the samples were measured against a $BaSnO_3$ (0.9 mg ^{119}Sn cm^{-2}) absorber, both being kept at liquid-nitrogen temperature. Measurements of the α-irradiated samples were performed after radioactive equilibrium had been attained between ^{119m}Te and ^{119}Sb. The spectra were least-squares fitted with lines of a Lorentzian shape using a FACOM M380 computer in our institute.

Results

The obtained emission Mössbauer spectra are shown in Figs. 1—5. The results of fitting are summarized in Table 1. The isomer shift is given relative to $BaSnO_3$ at room temperature.

The ^{119}Sn atoms produced in ^{120}SnS and ^{120}SnSe irradiated with protons gave a partly resolved asymmetric doublet, as can be seen in Figs. 1(A) and (B).

The emission spectra of ^{119}Sn in α-irradiated ^{117}SnS and ^{117}SnSe were complex (Figs. 2(A) and 3(A)), being completely different from those of p-irradiated ^{120}SnS and ^{120}SnSe sources. They were decomposable into

three Lorentzian lines (designated as Line 1, 2, and 3 from the left to the right). Remarkable changes in the position and in the relative intensities of each line were observed upon thermal annealing of the irradiated samples, as can be seen in Figs. 2(B)—(D) and 3(B)—(D). In both cases of ^{117}SnS and ^{117}SnSe, Line 1 completely vanished upon annealing at 600 °C. Upon elevating the annealing temperature, the relative intensities of Lines 2 and 3 increased in parallel and the two lines shifted closer to each other, their

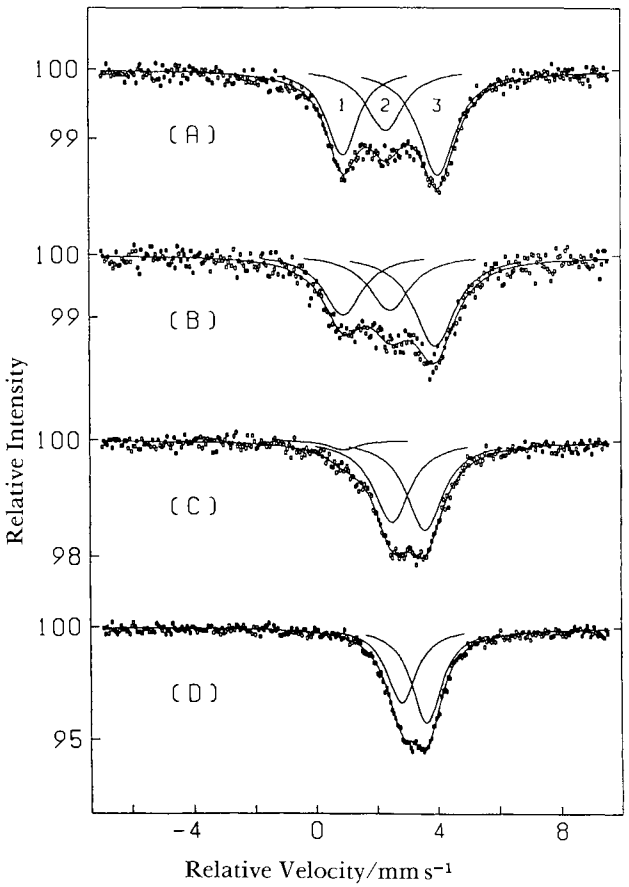

Fig. 3. Mössbauer emission spectra of ^{119m}Te→ ^{119}Sb→^{119}Sn in α-irradiated ^{117}SnSe (measurement at liquid nitrogen temperature). (A) As irradiated, (B) after 1 h annealing at 100 °C, (C) after 1 h annealing at 200 °C, and (D) after 1 h annealing at 600 °C.

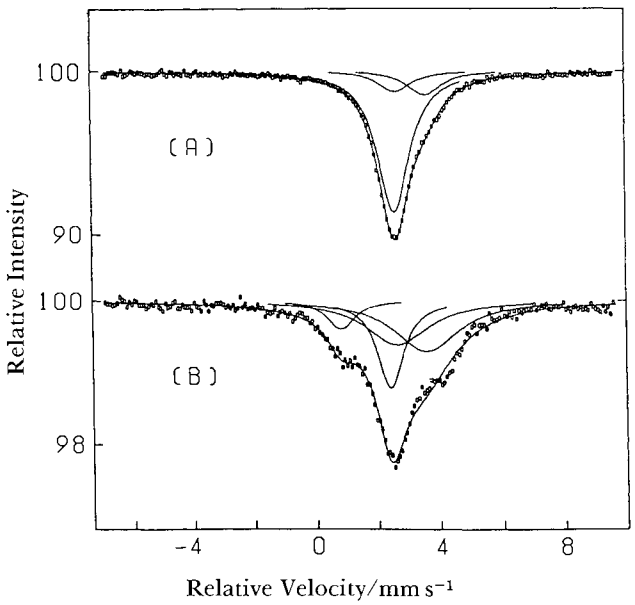

Fig. 4. Mössbauer emission spectra of SnS samples fused and recrystallized with additional 3 at. % ^{120}Sn or ^{117}Sn metal after p- or α-irradiation (measurement at liquid nitrogen temperature). (A) ^{120}Sn$_{1.03}$S(^{119}Sb), (B) ^{117}Sn$_{1.03}$S(^{119m}Te).

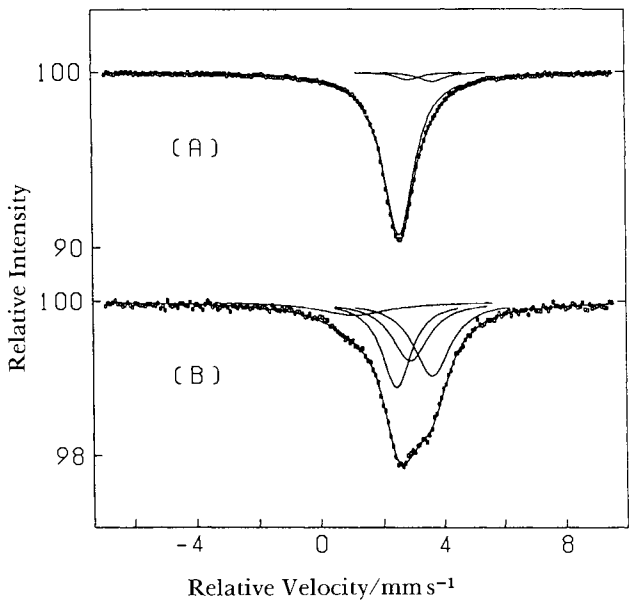

Fig. 5. Mössbauer emission spectra of SnSe samples fused and recrystallized with additional 3 at. % ^{120}Sn or ^{117}Sn metal after p- or α-irradiation (measurement at liquid nitrogen temperature). (A) ^{120}Sn$_{1.03}$Se(^{119}Sb), (B) ^{117}Sn$_{1.03}$Se(^{119m}Te).

centers and widths remaining almost unchanged.

The emission spectra of stoichiometric ^{117}SnS and ^{117}SnSe samples fused and recrystallized after α-irradiation gave spectra similar to those of p-irradiated samples. Figure 4 shows the spectra of ^{120}SnS and ^{117}SnS fused and recrystallized with an additional 3 at. % ^{120}Sn or ^{117}Sn metal after p- or α-irradiation. The samples are designated as ^{120}Sn$_{1.03}$S(^{119}Sb) and ^{117}Sn$_{1.03}$S(^{119m}Te), though their X-ray patterns show that they are not single phase and contain a small amount of β-Sn. The spectra of similarly obtained ^{120}Sn$_{1.03}$Se(^{119}Sb) and ^{117}Sn$_{1.03}$Se-(^{119m}Te) are shown in Fig. 5.

Discussion

Both SnS and SnSe have a rhombically distorted NaCl-type crystal structure (*Pnma*-D_{2h}^{16}). The nuclear reactions and decay sequences studied in this work are:

$$^{120}\text{Sn(p,2n)}^{119}\text{Sb} \xrightarrow{\text{EC}} {}^{119}\text{Sn}^* \longrightarrow {}^{119}\text{Sn}$$

and

$$^{117}\text{Sn}(\alpha,2n)^{119m}\text{Te} \xrightarrow{\text{EC}} {}^{119}\text{Sb} \xrightarrow{\text{EC}} {}^{119}\text{Sn}^* \longrightarrow {}^{119}\text{Sn}.$$

Here, ^{119}Sn* signifies ^{119}Sn in the nuclear first excited state (Mössbauer level).

The p- and α-reactions impart the ^{119}Sb and ^{119m}Te atoms with a recoil energy that is sufficient for their displacement from the sites of the target atoms. In the following EC decay of ^{119m}Te to ^{119}Sb, the neutrino emitted from the nucleus imparts on the atom a recoil energy amounting to 24 eV. The γ-quanta emitted in cascades give recoil energies up to a maximum

value of 20 eV. Assuming that these particles are emitted isotropically, the total recoil energy is estimated to have a distribution with a minimum below the displacement energy, E_d (roughly 25 eV for metals[14]) and somewhat smaller for compounds), and a maximum exceeding it. Therefore, a part of the ^{119}Sb atoms are expected to be displaced from the site of ^{119m}Te as a result of the decay; the others remain in the original site of ^{119m}Te. This was experimentally demonstrated in our previous study on Sn^{119m}Te and $Sb_2{}^{119m}Te_3$ samples.[11] On the other hand, the recoil energy of the EC decay of ^{119}Sb is estimated to be 1.5 eV. Since it is smaller than the displacement energy in a solid, the ^{119}Sn atoms arising from ^{119}Sb remain in the position of the ^{119}Sb atoms after the decay.

We attribute the doublets observed for p-irradiated ^{120}SnS and ^{120}SnSe (Figs. 1(A) and (B)) to ^{119}Sn at normal Sn sites of the matrices on the basis of the similarity of their Mössbauer parameters to those of normal tin atoms in SnS and SnSe observed by conventional Mössbauer absorption measurements on the compounds.[15,16] It is concluded from the observation that the energetic ^{119}Sb atoms produced by the proton reaction are exclusively stabilized at the scarcely perturbed Sn sites of SnS and SnSe, since the recoil energy of the EC decay of ^{119}Sb is smaller than the displacement energy in solid, as described above. Namely, in the last stage of recoil the ^{119}Sb atoms replace an Sn atom in the matrix and the Sn atom is displaced to a position at which the resulting defect structure does not affect the Mössbauer parameters of ^{119}Sn arising from ^{119}Sb. This forms a contrast to the case of ^{120}SnTe, in which ^{119}Sb atoms occupy both the Sn and Te sites after the p-reaction.

The results on α-irradiated samples show that the effect of the α-reaction and the EC decay is entirely different from that of the p-reaction. Lines 1—3 observed for α-irradiated ^{117}SnS and ^{117}SnSe (Figs. 2(A) and 3(A)) can be hardly assigned to known chemical species of Sn having S or Se ligands. On the basis of the isomer shift, Line 1 is assigned to $^{119}Sn^{4+}$ ions accompanied by a nearby defect. The behavior of Lines 2 and 3 upon annealing suggests that they are correlated. After 1 h of annealing at 600 °C, the lines turned out to be a quadrupole doublet assignable to ^{119}Sn at the normal Sn site of SnS or SnSe (Figs. 2(D) and 3(D)). Therefore, Lines 2 and 3 in Figs. 2(A) and 3(A) are ascribed to a quadrupole doublet of ^{119}Sn at Sn site of SnS or SnSe accompanied by a certain defect. Since the isomer shift is virtually the same as that of normal tin atoms in SnS or SnSe, the number of sulfide or selenide ions in the first coordination sphere is not considered to be different from that of normal Sn in SnS or SnSe. The distortion in the first coordination sphere or the defect in the second or further coordination sphere is most probable.

It is to be noted here that the effects of annealing were observed not on ^{119}Sb, but on ^{119m}Te in the experiment described above, since the annealed samples were measured after the ^{119}Sb subjected to annealing had decayed and a radioactive equilibrium between ^{119m}Te and ^{119}Sb had been attained. As described above, the ^{117}SnS and ^{117}SnSe samples fused and recrystallized after irradiation showed no trace of defect structures. Those with chemically doped ^{119m}Te also gave similar results. It is evident from these observations that the defect structures are not the result of the EC decay of ^{119m}Te, but of the α-reaction.

In the thoroughly annealed, fused, and chemically doped samples ^{119m}Te are considered to be at the S or Se site on the basis of a similarity in the chemical properties of the elements. A part of ^{119}Sb atoms arising from ^{119m}Te are displaced from the site due to recoil associated with EC decay. For the rest of ^{119}Sb, although the recoil energy is insufficient for any displacement, the S or Se site is much less favorable for ^{119}Sb than the Sn site with regard to its chemical nature. Namely, the physical and chemical properties of Sb are much closer to that of Sn than to S or Se. Consequently, all of the ^{119}Sb atoms are stabilized at only the Sn site. On the other hand, the properties of Sb lie just in the middle of those of the components of the matrix in the case of SnTe. This enables stabilization of Sb in both sites.

Computer simulations on metal showed that a recoil atom of the same element as the matrix most frequently replaces a lattice atom in the final stage of its energy dissipation and are stabilized at the substitutional site.[17-19] On the other hand, it has been shown that implanted iron atoms tend to occupy interstitial sites in metals having large atomic volumes.[2] In case of ^{119}Sb after the p-reaction, the recoil atom is considered to replace mainly a ^{120}Sn atom, which has a mass close to that of ^{119}Sb and rests at the site. Moreover, the experimental results described above show that the ^{119}Sb atoms stopped at the S or Se site or at an interstitial site move to an Sn site which is chemically much more favorable for them than the S or Se site.

From only a kinematical point of view, the ^{119m}Te recoil atoms are considered to dominantly replace ^{117}Sn in the SnS or SnSe matrix. However, the Sn site is not favorable for ^{119m}Te and a certain metastable defect structure including the surrounding S or Se atoms are formed. This structure is considered to be partly preserved, even after the decay of ^{119m}Te, and to be reflected in the spectra of α-irradiated ^{117}SnS and ^{117}SnSe before annealing (Figs. 2(A) and 3(A)).

Measurements on the SnS and SnSe samples fused and recrystallized with 3 at. % Sn metal were undertaken in order to determine whether stabilization of diluted ^{119}Sb at the S and Se sites is not allowed at all in SnS and SnSe. The SnS or SnSe phase in the samples is considered to be saturated with Sn. This is considered to be a condition promoting ^{119}Sb to the S or Se site based on the result on SnTe.[12] Besides

the doublet of SnS or SnSe, a dominant line with an isomer shift of 2.56±0.03 mm s^{-1} was found in the spectra of $^{120}Sn_{1.03}S(^{119}Sb)$ and $^{120}Sn_{1.03}Se(^{119}Sb)$ samples (Figs. 4(A) and 5(A)). Since the isomer shift is in good agreement with that of β-Sn,[20] this line is assigned to ^{119}Sn arising from ^{119}Sb dissolved in the β-Sn phase of the samples. The large relative intensity of the line shows that ^{119}Sb is much more soluble in β-Sn than in SnS or SnSe. In the $^{117}Sn_{1.03}S(^{119m}Te)$ and $^{117}Sn_{1.03}Se(^{119m}Te)$ samples (Figs. 4(B) and 5(B)), the relative intensity of the peak due to β-Sn is much smaller than in $^{120}Sn_{1.03}S(^{119}Sb)$ and $^{120}Sn_{1.03}Se(^{119}Sb)$. The origin of this large difference is ascribed to the higher solubility of ^{119m}Te, than that of ^{119}Sb, in SnS and SnSe which have a homologous element of Te as a component. The lines with isomer shifts of 0.82 and 1.07 observed for the $^{117}Sn_{1.03}S(^{119m}Te)$ and $^{117}Sn_{1.03}Se(^{119m}Te)$ samples are attributed to the Sn^{4+} species, the origin of which is not understood. They may be the same species as those observed in α-irradiated ^{117}SnS and $^{117}SnSe$. In any case, we conclude that no line ascribable to ^{119}Sn at S or Se site of the matrices has been identified in the specta of samples fused with excess Sn metal,although the possibility is not denied that one is hidden in the large peak due to ^{119}Sb in β-Sn.

The authors are thankful to the staff of the RIKEN 160 cm cyclotron for many irradiation runs and also to Mr. Y. Iimura for X-ray powder pattern measurements.

Dynamical Characterization in Aqueous Solutions of 3-Methoxy- and 3-Ethoxy-1-propanol by Ultrasonic Methods

Sadakatsu NISHIKAWA* and Masayuki UEDA
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840
(Received November 17, 1990)

3-Methoxy-1-propanol and 3-ethoxy-1-propanol were synthesized through potassium propoxide from 1,3-propanediol. Ultrasonic absorptions in their aqueous solutions were measured in the frequency range from 8.5 to 220 MHz as functions of their concentrations along with the sound velocity and density. In a solution of 3-ethoxy-1-propanol, a single relaxational absorption was observed; the cause was attributed to a perturbation of an equilibrium as $AB \leftrightarrow A + B$, where AB represents the solute-solvent complex, A the solute and B the solvent molecules. On the other hand, no relaxational absorption was observed in a 3-methoxy-1-propanol solution up to 4 mol dm^{-3}. The thermodynamic and the kinetic parameters were evaluated for the above-mentioned process from the concentration dependences of the ultrasonic parameters in a 3-ethoxy-1-propanol solution. From evidence concerning the appearance and disappearance of ultrasonic relaxational absorption and comparisons of the rate and thermodynamic constants in aqueous solutions of various alcohols, the alternation of the water structure affected by the addition of the solutes is discussed in connection with the solute structures. The methoxyl group was explicitly found to act as a water structure breaker and the ethoxyl group to do so slightly.

It has been well-known that the addition of a nonelectrolyte into water leads to a water structural change.[1] Recent small-angle X-ray scattering studies[2] in aqueous solutions of nonelectrolytes have provided information about the microscopic properties, and it has been reported that quite large changes of the water structure are caused by the addition of such alcohols, as 2-methyl-2-propanol and 1-propanol and 2-propanol. However, the structural and dynamical properties in the solutions still seem to be beyond our understanding, especially in the concentrated solutions. Ultrasonic absorption methods[3] which provide rather macroscopic or phenomenological properties have been widely used to investigate such concentrated solution properties. From the results of sound absorption in some nonelectrolyte aqueous solutions, the solutes of which have hydroxyl groups,[4,5] we have shown that the cause of ultrasonic absorption is due to a solute-solvent interaction, and have speculated that the methoxyl group acts as a water structure breaker and that the propoxyl group acts as a promoter. Through an investigation of aqueous solutions concerning alcohols with an oxyethylene group,[6] we have predicted that the group has a small breaking effect on the water structure. In 1-propanol aqueous solutions, furthermore, another relaxation process was observed, which was responsible for the hydrophobic interaction of solute molecules. Under these circumstances, it is desired to determine how the ethoxyl group affects the water structure. Another purpose of this study is to observe dynamically whether the methoxyl group causes the hydrophobicity of the molecule to decrease when it is introduced to a molecule with quite high hydrophobicity.

Experimental

The chemicals for 3-methoxy-1-propanol and 3-ethoxy-1-propanol synthesis, 1,3-propanediol, anhydrous potassium carbonate, methyl iodide, and ethyl bromide were purchased from Wako Pure Chemical Co. The desired alcohols were obtained through potassium propoxide. The boiling points were 152 °C for 3-methoxy-1-propanol and 161 °C for 3-ethoxy-1-propanol. Identifications of the synthesized compounds were confirmed by their ^{1}H NMR spectra; the purities were verified by a gas chromatographic method to be more than 96% and the water contents in the synthesized compounds were checked by Karl Fischer method to be less than 2.5%.

The ultrasonic absorption coefficient was measured by a pulse method in the frequency range from 8.5 to 220 MHz. The detail procedure for the absorption measurement is described elsewhere.[7] The sound velocity was measured using an interferometer operated at 2.5 MHz. The cells for the absorption coefficient and the sound velocity measurements were immersed in a water bath controlled within ±0.002 °C. The density was measured by a standard pycnometer, the volume of which was about 5.5 cm^3. All measurements were carried out at 25 °C.

Results and Discussion

There are several procedures to interpret the ultrasonic absorption: analysis of the concentration dependence, frequency dependence, and temperature dependence of the absorption.[8] The experimental absorption coefficients in this study were obtained as functions of the solute concentration and the frequency. In order to obtain the dynamic characteristics in solutions, the analysis of the frequency dependence may provide useful information. A Debye-type equation is well used and is associated with a perturbation of chemical equilibrium, although an analyti-

cal equation for the absorption spectra was still developed.[9] For a single relaxational process, the absorption spectrum is fitted by the following equation:

$$\alpha/f^2 = A/(1+(f/f_r)^2)+B. \quad (1)$$

Here, α is the absorption coefficient, f the frequency, A the amplitude of the relaxational absorption, B the background absorption and f_r the relaxation frequency. The procedures for determining the ultrasonic parameters and for judging whether the spectrum is due to single relaxational absorption or not are described elsewhere.[7,10] Figure 1 shows representative ultrasonic absorption spectra in aqueous solutions of 3-methoxy-1-propanol and 3-ethoxy-1-propanol. A clear frequency dependence of α/f^2 was found for the latter solution, but no dependence was found for the former solution. The frequency-dependent experimental data were analyzed in terms of Eq. 1 by using a nonlinear least-mean-squares method. As can be seen in the figure, the experimental data are well-fitted to the single relaxational curves. The values of $[(\alpha/f^2)_{exp}-(\alpha/f^2)_{cal})]/(\alpha/f^2)_{exp}$ at all frequencies measured were less than ± 0.1, where subscripts *exp* and *cal* indicate those of the experiment and calculation, respectively. The calculated ultrasonic parameters are listed in Table 1 along with the solution density and sound velocity values. Complete sets of the absorption coefficient as functions of the concentration and frequency are available upon request to one of authors (S. N.). Figure 2 shows the concentration dependence of the relaxation frequency for the 3-ethoxy-1-propanol solution. Figure 3 represents the results regarding the amplitude of the relaxational absorption and the background absorption. Because no relaxational absorption was

observed in the 3-methoxy-1-propanol solution within the measured frequency range, the background absorption is only indicated in the same figure.

The sound velocity also goes through a maximum, as can be seen in Table 1. The phenomenon of the peak sound velocity as being a function of the concentration is also a characteristic of aqueous solutions of alcohols, along with the peak sound absorption concentration.

The characteristic phenomena associated with the observed relaxation are that the relaxation frequency goes through a minimum and that the amplitude of the relaxational absorption goes through a maximum. These trends are not interpreted by reaction models only associated with the solutes in the solution. Under these experimental facts, we have proposed the following reaction mechanism for interpreting the relaxational absorption.[4] That is, the solute may interact with solvent water and they form the complex, presumably, due to their hydrogen-bonding ability.

$$AB \underset{k_{21}}{\overset{k_{12}}{\longleftrightarrow}} A+B \qquad (2)$$

where AB is the complex formed by alcohol and water and A the solute molecules. Attention should be paid to the notation, B, which represents non-hydrogen-bonded water molecules, or less-structured water molecules; we assume that such reactants, B, can only participate in the reaction described by Eq 2. Under this assumption, the relation between the analytical concentrations and the relaxation frequency is derived as[5]

$$2\pi f_r = k_{21}\{(C_e-\beta C_w+K_{12})^2+4\beta C_w K_{12}\}^{1/2} \qquad (3)$$

where k_{ij} is the rate constant, C_e and C_w the analytical concentration of alcohol and water, respectively, and β the fraction of non-hydrogen-bonded water; K_{12} is defined as $K_{12}=k_{12}/k_{21}$. The three parameters, k_{21}, β and K_{12}, in Eq. 3 are determined in order to give the best agreement with the experimental data, by means of a nonlinear least-mean-squares. The solid curve in Fig. 2 was calculated from the variation of the concentration. The determined rate and thermodynamic constants are listed in Table 2, along with those for a 1-propanol solution for a comparison.

In order to confirm the cause of relaxational absorption, the concentration dependence of the amplitude of the relaxational absorption should also be analyzed. In ultrasonic studies, the maximum excess absorption per wave length, μ_{max}, is usually considered. For the reaction under consideration, it is given

$$\mu_{max} = 0.5\, A f_r c = (\pi\rho c^2\Gamma/2RT)(\Delta V-\alpha_p\Delta H/\rho C_p)^2, \qquad (4)$$

where ρ is the solution density, ΔV the standard volume change of the reaction, ΔH the standard enthalpy change of the reaction, C_p the specific heat at the constant pressure, α_p the thermal expansion coefficient, and Γ the concentration term given by $\Gamma=\{[AB]^{-1}+[A]^{-1}+[B]^{-1}-([AB]+[A]+[B])^{-1}\}^{-1}$. In order to grasp the precise variation of μ_{max} on the analytical concentration, the values of the specific heat and the thermal expansion coefficient are desired. Without these values, we reluctantly compare the experimental values of μ_{max} with $\rho c^2\Gamma$, which is the most controlling term to μ_{max}. Figure 4 indicates the concentration dependences of μ_{max} and $\rho c^2\Gamma$.

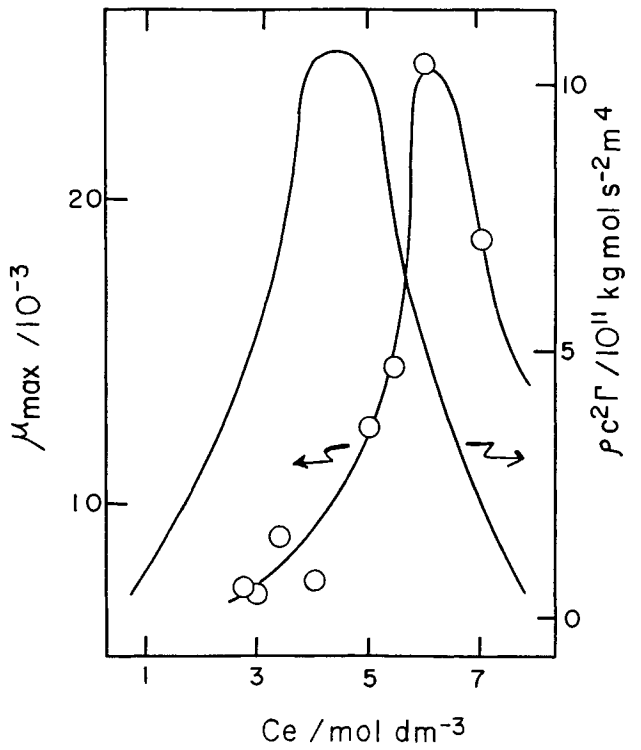

Fig. 4. The comparison of the μ_{max} and $\rho c^2\Gamma$ for 3-ethoxy-1-propanol solution.

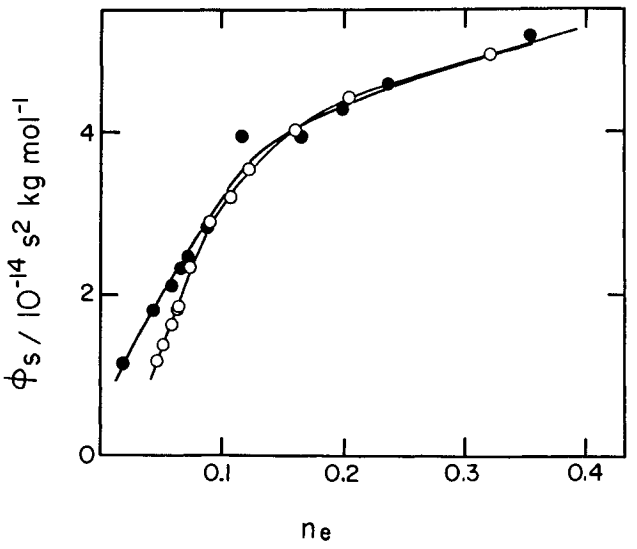

Fig. 5. The apparent molar compressibility for 3-ethoxy-1-propanol (○) and 1-propanol (●) solutions as a function of alcohol mole fraction, n_e at 25 °C.

Though the peak positions are slightly different, the trends seem to be similar, which supports our analysis.

The relaxational absorption in aqueous solutions of alcohols is very sensitive to the hydrophobicity of alcohol molecules. In a solution of methanol, relaxational absorption at room temperature is reported to be observed over a frequency range of more than 500 MHz;[11] in the solution of ethanol it is found at around 300 MHz[12,13] and in that of 1-propanol it exists in a range less than 100 MHz.[5,14,15] Madigosky and et al.[15] have reported the absorption coefficients far below 100 kHz in a solution of 1-propanol, and have preferred to analyze the absorption using fluctuation theories. In this type solution, the absorption coefficient divided by the square of the frequency increases upon decreasing the frequency far below the MHz frequency range. However, in a solution of 2-propanol, the values are almost frequency independent below 10 MHz.[16] As can be seen in Fig. 1, the dependence of α/f^2 in the solution of 3-ethoxy-1-propanol is too small below 10 MHz and the absorption spectrum can be well-analyzed by the Debye-type single relaxational equation. Following our experimental results, we have considered that the absorption is very dependent on the structure of the alcohols, especially on the hydrophobic group. Our analytical results also indicate that the water structure is considered to be altered, depending upon the change in the solute hydrophobicity. As is shown in the present study, no relaxational absorption is observed in the solution of 3-methoxy-1-propanol in the pulse frequency range, and the single relaxational absorption is found in the solution of 3-ethoxy-1-propanol. The cause of the relaxational absorption is reasonably analyzed by a model associated with the interaction between the solute and the solvent; the relaxation process also reflects a change in the ratio of the hydrogen-bonded water and non-hydrogen-bonded water. It is, therefore, interesting to compare the result for the aqueous solution of 3-ethoxy-1-propanol with that of the 1-propanol solution. As can be seen in Table 2, the β value for 1-propanol solution is slightly smaller than that for 3-ethoxy-1-propanol, which means that the introduction of the ethoxyl group makes the hydrophobicity of 1-propanol decrease. The same decreasing trend of the β value has been observed in solutions of alcohols with oxyethylene groups, although the magnitude of the β change is smaller than that for the ethoxyl group.[6] One way to estimate the strength of hydrophobicity is to determine the concentration dependence of the apparent molar compressibility, Φ_s. This method is used by Desnoyers and his co-worker,[17] and is calculated by

$$\Phi_s = \kappa_s\Phi_v + (\kappa_s - \kappa_w)/m\rho_0, \quad (5)$$

where κ_s is the adiabatic compressibility of the solution, κ_w that of solvent, Φ_v the apparent molar volume, ρ_0 the solvent density and m the molality which is converted from the molarity using the solution density. The sharper is the profile of the dependence, the greater is the hydrophobicity. Figure 5 indicates a comparison of the two solutions of 1-propanol and 3-

ethoxy-1-propanol as a function of mole fraction. The latter solution shows a broader dependence than does the former, the result of which is consistent with that obtained from the above-mentioned absorption data. It should be noticed that another relaxation process associated with molecular aggregation through a hydrophobic interaction is observed in the solution of 1-propanol, in addition to absorption due to a solute-solvent interaction. The former absorption disappears when the ethoxyl group is involved. This is because the ether oxygen may prevent the formation of an aggregate in an aqueous solution, and because of a decrease in the hydrophobicity. The small change in the molecular structure of alcohols provides a quite large change in the structure of water. This is clearly seen by comparing the results for the 3-ethoxy-1-propanol solution with that for a 2-propoxyethanol solution,[18] in which the single relaxational absorption due to a solute solvent interaction is found and the β value is 0.10. In general, the ultrasonic relaxational absorption associated with the solute solvent interaction would appear in the MHz frequency region when the sizes of the alcohols are order of propanols or butanols. Upon decreasing the hydrophobicity, the relaxation frequency increases to more than 100 MHz. However, in the solution of 3-methoxy-1-propanol, no relaxational absorption is observed, although the relaxation is found in the solution of 1-methoxy-2-propanol.[3] According to the studies reported so far, 2-propanol has less hydrophobic activity than does 1-propanol. The introduction of a methoxyl group seems to cause the relaxation process to shift to a higher frequency range. It might then be considered that 1-methoxy-2-propanol is less hydrophobic than 3-methoxyl-1-propanol. However, the disappearance of relaxation in the latter solution is speculated since intramolecular hydrogen boning might be plausible in 3-methoxyl-1-propanol, and the total hydrophobic activity of the molecule might decrease. We expect that the hydrophobic and hydrophilic balance of 3-methoxy-1-propanol is close to or less than ethanol, and that the relaxational absorption may appear at more than 200 MHz.

The authors are indebted to organic chemist, Assistant Professor H. Horimoto in the Chemistry Department, for guiding us in the synthesis of the used compounds. This work was partly supported by a Grand-in-aid for Scientific Research on Priority Area of "Molecular Approaches to Non-equilibrium Processes in Solution in 1990" (No. 02640350) from the Ministry of Education, Science and Culture.

Molecular Motion and Phase Changes in Long Chain Solid Normal Alkanes as Studied by ^1H and ^{13}C NMR

Takahiro UEDA, Sadamu TAKEDA, Nobuo NAKAMURA,* and Hideaki CHIHARA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received December 18, 1990)

Proton spin-lattice and dipolar relaxation times and ^{13}C CP/MAS NMR spectra were measured on crystalline samples of n-$C_{50}H_{102}$ and long chain normal alkanes (n-alkanes) with average molecular weight of 595, 1214, and 2305 in order to characterize the static and dynamic molecular structures in the solid state. The ^{13}C CP/MAS spectra indicate that the molecules take all-trans conformation in the orthorhombic unit cell and do not undergo any discernible change on annealing and/or quenching of specimens. On the other hand, the T_{1d} in each material assumes a deep and clear minimum value in the orthorhombic phase; this relaxation process was unambiguously assigned to the molecular uniaxial reorientation about the long chain axis. There is a linear relation between the activation energy and the reciprocal of the chain length. In the case of n-$C_{50}H_{102}$ a solid state phase transition was found at 351 K. The T_{1d} in the high temperature phase led to extremely high activation energy, 150 kJ mol^{-1}, which may be attributable to molecular self-diffusion or other motion accompanying drastic change in the molecular structure.

Normal alkanes, n-C_nH_{2n+2}, crystallize generally in an orthorhombic unit cell in which molecules assume the all-trans conformation and arrange the molecules parallel to each other.[1] Short n-alkanes with carbon atoms less than 50 undergo so-called "rotational phase transition" into the high temperature phase in which molecules rotate about the long axis.[2] The mechanism of this kind of phase transition has been studied extensively in relation to molecular motion as well as the well-known odd-even effect.[3] Long-chain n-alkanes are situated between the short n-alkanes and polyethylene and possess on the one hand some common characteristics to short n-alkanes, and on the other to polyethylene. Indeed, Whiting and others[4] succeeded in the synthesis of pure long-chain n-alkanes with the number of carbons from 102 to 390 and they also found very interesting fact that the partial chain-folding occurs for the n-alkanes with the carbon number of 150 and more but not for that with 102 carbons.

Thus, the studies of structure and dynamics of long-chain n-alkanes are promising and would provide useful clue to studying variety of physical properties as well as structure of polyethylene and other complex polymers from the molecular point of view. However, although numerous thermodynamic studies have been done on high molecular weight n-alkanes,[5] there have been reported very few works on rigorous characterizations, microscopic structure, and molecular dynamical nature for these substances.

In the present work, we attempted to study long-chain n-alkanes from the molecular point of view and conducted experimental works on the phase characterization and molecular structure by differential scanning calorimetry (DSC) and solid state high resolution ^{13}C NMR and on the molecular dynamical structure by proton nuclear magnetic relaxation measurements. This paper presents the results of these experiments and discuss the possibility of very slow molecular motion in "hard" crystalline state.

Experimental

Powdered specimens of linear polyethylene (PE) with M_w of 595, 1214, and 2305 (M_w/M_n=1.11, 1.20, and 1.14, respectively) which were crystallized from o-dichlorobenzene solution were obtained from Scientific Polymer Products, Inc. (U.S.A.), and were used as received. Even numbered n-alkane, pentacontane (n-$C_{50}H_{102}$), was obtained from Tokyo Kasei Co. in the best commercially available quality (Purity >99%) and was also used without further purification. For proton spin-lattice relaxation time T_1 and dipolar relaxation time T_{1d} measurements, these samples were sealed into ampoules with He exchange gas after being pumped overnight at room temperature.

All NMR measurements were carried out with a Bruker Model MSL-200 spectrometer operating at the Larmor frequencies 200.13 MHz and 50.32 MHz for proton and carbon, respectively. The proton line shape was determined by the Fourier transform of the solid echo.[6]

Measurements of the proton spin-lattice relaxation time, T_1, were made using "solid echo" method which consists of $90°_x$—τ—$90°_y$—$90°_x$ three pulse sequence.[6] Typical interval between the second and third pulses was chosen to be 10—15 μs. Measurements of the proton dipolar relaxation time, T_{1d}, were made using the three pulse Jeener-Broekaert $90°_x$—$45°_y$—τ—$45°_x$ sequence.[7] The interval between 90° and phase-shifted 45° pulses was 8—10 μs. The recovery of the magnetization in each specimen was exponential within the experimental error. The experimental errors for the T_1 and T_{1d} were estimated to be within 5% and 10%, respectively.

^{13}C CP/MAS NMR spectra were recorded with the spectrometer described above. The applied cross-polarization time was 1 ms followed by the ^{13}C detection period during which the proton decoupling field was maintained. MAS (magic angle spinning) was carried out at a rate of 1.5—3 kHz with a double bearing type rotor made of zirconia whose volume was about 0.7 cm^3. In the present work, the

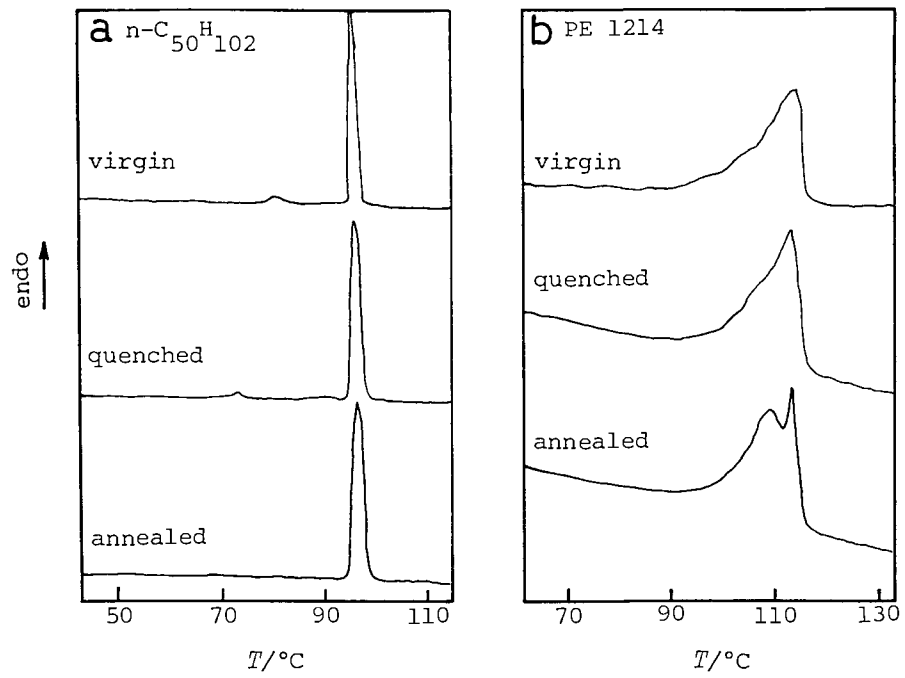

Fig. 1. Differential calorimetric scans for virgin (recrystallized from solution), quenched from the melt, and annealed specimens of n-$C_{50}H_{102}$ (a) and PE 1214 (b).

^{13}C chemical shifts relative to TMS were determined from the CO line (176.46 ppm) of solid glycine.

For all experiments, the temperature control was achieved by Bruker variable temperature unit VT-1000. The melting points and solid state phase transition points of all samples were determined by means of Shimadzu DT-30B differential scanning calorimeter with a heating rate of 5 K min^{-1}. X-Ray diffraction powder patterns were measured by means of RAD-RC type, fully automatic, X-ray diffractometer (Rigaku electronics Inc.).

Results and Discussion

X-ray diffraction powder patterns of all the specimens consisted of sharp reflections which can be indexed to the orthorhombic unit cell corresponding to ordinary polyethylene crystal and weak halo components were discerned, indicating that each specimen can be regarded as good crystals with negligible amount of amorphous components.

Melting points, probable transition points determined by DSC measurements, and crystallinity estimated by proton line shape analysis are listed in Table 1; DSC curves for n-$C_{50}H_{102}$ and PE 1214 are shown in Fig. 1(a) and (b) as typical examples.

The virgin and quenched# samples of n-$C_{50}H_{102}$ undergo solid state phase transition just below the melting point, while the annealed# sample gives no evidence of phase transition. The melting of PE 1214 begins near 363 K as shown in Fig. 1(b) due probably to the melting of the amorphous part, suggesting that even negligible amount of amorphous part causes premelting phenomenon in long chain alkane.[8] The proton spectrum in each substance consists of a narrow and a broad components due obviously to an amorphous part and the rigid crystalline part, respectively, in the specimen. Two components were approximated by a narrow Lorentzian peak and the

Table 1. The Melting Points, the Phase Transition Points Determined by DSC, and Crystallinity for the n-Alkane Specimens with Different Thermal Histories

Sample	Treatment	Melting point/K	Transition point/K	Crystallinity %
n-$C_{50}H_{102}$	Virgin	366	351[a]	
	Annealed	366	—

	Annealed	380	369[b]	95
	Quenched	376	368[b]	
PE 2305	Virgin	391		
	Annealed	392	386[b]	98
	Quenched	393	386[b]	

a) Rotational phase transition for n-alkane. b) Peak or shoulder of the melting curve which was assigned to the permelting of the amorphous part.

Virgin sample was obtained by crystallization from solvent, quenched one by rapid solidification of the melt, and annealed one by slow cooling of the melt.

Pake doublet with an appreciable line broadening (Gaussian) and the whole spectrum was simulated by changing the composition. The result led directly to the crystallinity listed in Table 1. In the case of n-$C_{50}H_{102}$ no narrow component was observed, indicating that the material is pure crystal.

Carbon-13 CP/MAS NMR Spectra. Fig. 2(a) shows the ^{13}C CP/MAS NMR spectrum of n-$C_{50}H_{102}$ at room temperature. The spectrum of n-$C_{50}H_{102}$ consists of four sharp peaks which can be assigned according to Van der Hart[9] to, from the high field side downward, the methyl carbon, the α-methylene carbon bonded to the methyl carbon, inner carbons with trans zig-zag conformation, and the β-methylene carbon bonded to α-carbon, respectively. The signal with star is the spinning side band of the strongest signal due to inner carbons.

The facts that the inner carbon line is very sharp and located at a lower field than α-methylene peak by 8 ppm show obviously that the linear chain molecules have the all-trans conformation in the orthorhombic unit cell,[9] and moreover, the specimen contains only negligible amounts of amorphous part. The spectrum of PE 1214 shown in Fig. 2(b) consists also of four peaks the location of which are almost the same as in n-$C_{50}H_{102}$. The line width of each peak is about twice as large as in n-$C_{50}H_{102}$ due probably to a slight disorder in the molecular arrangement associated with the molecular weight distribution. Then, the spectrum of this material shows that the molecules take the all-trans conformation. The fraction of the gauche form,[10] if any, is estimated to be less than 1% and that of amorphous part is negligibly small as shown in Table 1. We did not see any change in the spectrum due to quenching and/or annealing of specimen.

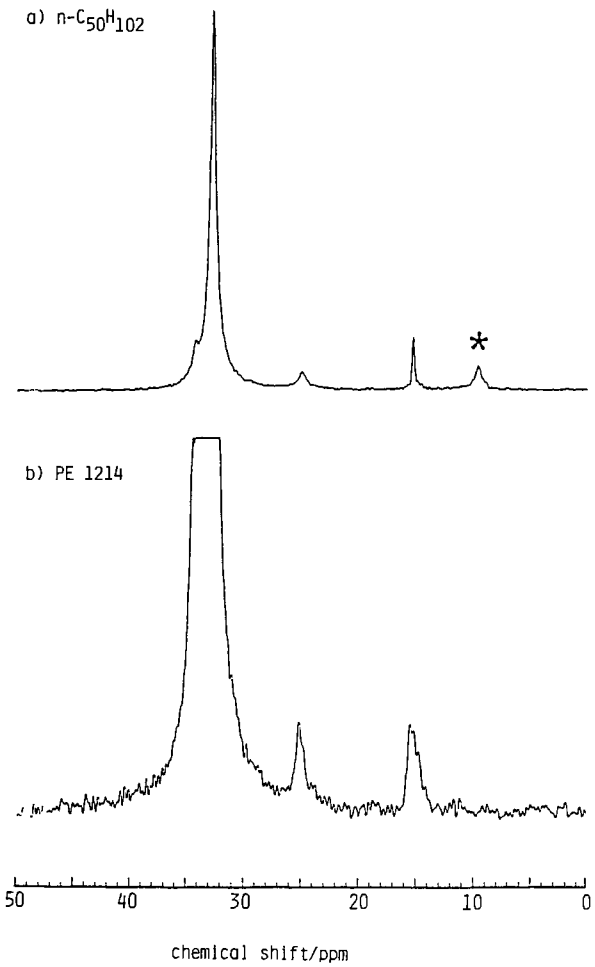

Fig. 2. ^{13}C CP/MAS NMR spectra of n-$C_{50}H_{102}$ (a) and PE 1214 (b) at room temperature. The sign (*) is the spinning side band.

As to the temperature dependence of the spectra only a slight narrowing of the methyl carbon signal on heating were observed for both quenched and annealed specimens due probably to the rapid rotation of the methyl group. The α-methylene and the inner carbon line widths did not show any significant temperature dependence.

Other substances, PE 595 and PE 2305, gave similar spectra to that of PE 1214 although the line width increases slightly with the chain length. It is therefore concluded that all the materials examined here have extremely high crystallinity (see in Table 1) and the molecules assume all-trans conformation; there is no evidence of wrong, gauche conformation nor chain-folding.[10]

Proton Spin Lattice and Dipolar Relaxation Times. n-Alkanes or linear polyethylenes consist of long $-CH_2-$ chain and terminal CH_3 groups. These different groups contribute to the proton relaxation in a different manner from each other. Therefore, the experimental relaxation rates due to these two groups under the condition that the spin temperature is established over the whole spin system, are given by

$$\frac{1}{T_1}=\frac{1}{n}\left(\frac{n(CH_2)}{T_1(CH_2)}+\frac{n(CH_3)}{T_1(CH_3)}\right), \tag{1}$$

and

$$\frac{1}{T_{1d}}=\frac{1}{n}\left(\frac{n(CH_2)}{T_{1d}(CH_2)}+\frac{n(CH_3)}{T_{1d}(CH_3)}\right), \tag{2}$$

where n is the total number of protons in the specimen and $n(CH_2)$ and $n(CH_3)$ are those in the methylene and methyl groups, respectively. In the present specimens the condition that $n(CH_2)\gg n(CH_3)$ holds and moreover, both $T_1(CH_3)$ and $T_{1d}(CH_3)$ are very long because of very rapid internal rotation of CH_3 groups. Hence we can ignore the second terms of Eqs. 1 and 2, and so the relaxation rates can be interpreted in terms of the dipolar relaxation due to the motion of the methylene groups. In such a case the relaxation process is described by a single correlation time τ_c of the motion of CH_2 segments and, under the "weak collision limit",[11] T_1 and T_{1d} are given by

$$\frac{1}{T_1}=K\left[\frac{\tau_c}{1+\omega_0^2\tau_c^2}+\frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right], \quad (3)$$

and

$$\frac{1}{T_{1d}}=\frac{K}{2}\left[\frac{5\tau_c}{1+\omega_0^2\tau_c^2}+\frac{2\tau_c}{1+4\omega_0^2\tau_c^2}+\frac{3\tau_c}{1+4\omega_d^2\tau_c^2}\right], \quad (4)$$

where K represents the strength of the dipolar interaction; in the case of a two-spin system such as CH_2 segment $K\sim(9/40)\ \gamma^4\hbar^2/r^6$ where r is the distance between two protons and γ the proton gyomagnetic ratio, ω_0 is the Larmor frequency and $\omega_d\sim K^{1/2}$ the local field in the frequency unit. When the chain undergoes reorientation about its long axis, the intramolecular interaction between CH_2 segment brings about $\omega_d/2\pi\sim1.3\times10^4$ Hz. If the motion is limited to some local motion such as conformational change or kink diffusion,[12] ω_d should be much smaller.

Figure 3 shows the temperature dependence of T_1 and T_{1d} for PE 1214 between room temperature and the melting point. It shows that each of T_1 and T_{1d} for the virgin sample measured in the heating direction coincides with the result which was observed on cooling from the melt. The fact that T_1 does not vary appreciably with temperature suggests that a trace of some paramagnetic impurity governs the Zeeman spin lattice relaxation. The T_1 in PE 595 and PE 2305 behaves similarly. On the other hand, T_{1d} varies

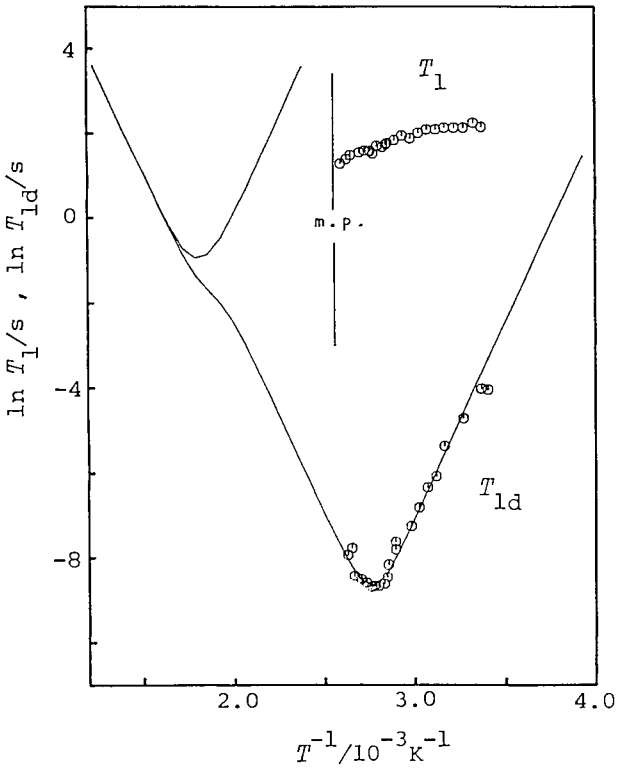

Fig. 3. Temperature dependence of proton spin lattice relaxation time (T_1) and dipolar relaxation time (T_{1d}) in PE 1214 at 200 MHz. The solid lines indicate the calculated T_1 and T_{1d} with Eqs. 4 and 5 and with the parameters listed in Table 2.

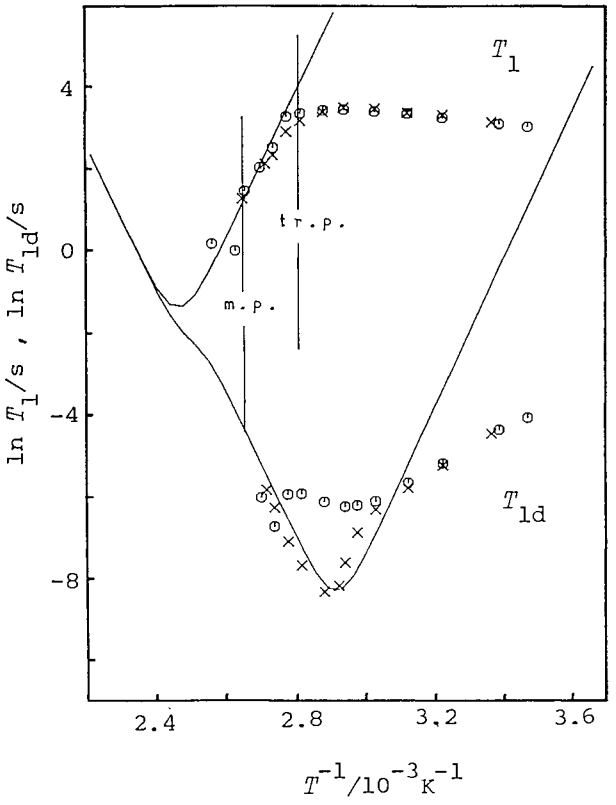

Fig. 4. Temperature dependence of proton spin lattice relaxation time (T_1) and dipolar relaxation time (T_{1d}) in n-$C_{50}H_{102}$ at 200 MHz; heating (O), cooling (X). The solid lines indicate the calculated T_1 and T_{1d} with Eqs. 4 and 5 and with the parameters listed in Table 2.

Table 2. The Temperature of T_{1d} Minimum, the Activation Parameters, and Strength of the Dipolar Field for Each Substance

Sample	T_{min}/K	E_a/kJ mol^{-1}	τ_0/s	K/s^{-2}	$(\omega_d/2\pi)$kHz
n-$C_{50}H_{102}$	340	42.0	2.3×10^{-12}	1.1×10^{8}	13
	344	150	2.3×10^{-29}	3.5×10^{9}	51
PE 595	286	31.0	7×10^{-12}	8.6×10^{8}	29
PE 1214	360	77.0	2.6×10^{-17}	2.3×10^{9}	23
PE 2305	365	85.0	2.4×10^{-18}	1.25×10^{9}	23

with temperature as expected from the usual BPP theory, Eq. 4, and assumes a minimum value at the temperature as listed in Table 2. Hence Eq. 4 was attempted to fit the experimental data in Fig. 3 assuming the Arrhenius activation process,

$$\tau_c = \tau_0 \exp(E_a/RT), \quad (5)$$

for molecular motion, and the resulting values together with those for PE 595 and PE 2305 are recorded in Table 2.

In the case of n-$C_{50}H_{102}$ the T_1 and the T_{1d} show novel temperature dependence as shown in Fig. 4. The T_1 does not change appreciably on heating up to the transition at 351 K but decreases very sharply above the transition point. This behavior of T_1 was reproduced in the cooling direction. On the other hand the T_{1d} decreases on heating and assumes a minimum value, 20 ms, at 340 K, then increases as the transition point is reached, where a sudden decrease of T_{1d} occurs. However, on cooling from the high temperature phase T_{1d} decreases remarkably, assumes a deep minimum value of 270 μs at 344 K, then increases dramatically on further cooling down to 328 K. Below 328 K the value of T_{1d} settles into that determined in the heating direction. The peculiar behavior of T_{1d} on cooling can be accounted for by reference to the results of DSC on this compound: The high temperature phase (HTP) can be easily supercooled. In our NMR experiment it remains down to about 344 K on cooling and so the T_{1d} measured between the melting point and 344 K is attributed to that in the HTP. Between 344 K and about 333 K the phase transition to the low temperature phase (LTP) sets in so that the apparent T_{1d} in this temperature region is the weighted average of the T_{1d} of the HTP and LTP. Since the T_{1d} in the HTP in this temperature range is very short but that in the LTP is significantly longer, the measured T_{1d} goes up dramatically as the phase transformation proceeds from the HTP to the LTP.

For the sake of data analysis, T_{1d} measured on heating was used for the molecular motion in the LTP, and T_{1d} measured between the melting point and 344 K on cooling was used for the HTP. For the LTP the value of ω_d can be accounted for by the model that all CH_2 segments are undergoing the rotation or reorientation about the long chain axis simultaneously. The results of the analysis by the above mentioned procedure are listed in Table 2. The activation energy, 42 kJ mol^{-1}, obtained here for the LTP may be compared with a value of 40 kJ mol^{-1} which was calculated for infinite chain model at 400 K by means of molecular dynamics simulation by Ryckaert and Klein.[13]

On the other hand, very large values of E_a and ω_d in the HTP cannot be fitted to the uniaxial reorientation model. Generally, short n-alkanes with carbon number smaller than 44 undergo "rotational transition" in which the molecular rotation about its long axis is excited in the high temperature rotational phase.[12] In the case of n-$C_{50}H_{102}$ it is suggested that the molecular reorientation or rotation is excited to some extent in the HTP as in other shorter n-alkanes; however, as mentioned above such a local molecular motion cannot account for the extremely large E_a and ω_d. It is therefore considered that some other motion such as molecular translational self-diffusion or drastic and dynamic change of molecular shape occurs

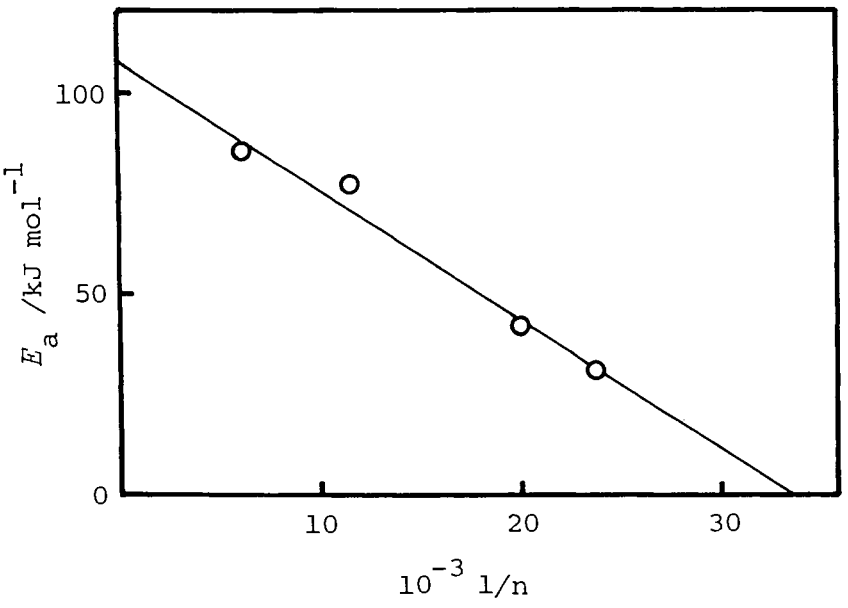

Fig. 5. The plot of E_a against the reciprocal of the number of carbons ($1/n$) in the single molecular chain.

above the transition point.[14]

Figure 5 plots the activation energy E_a for the chain reorientation against the reciprocal of the number of carbons in the single molecular chain. This plot gives a straight line, suggesting that the E_a is not proportional to the number of CH_2 segments but instead approaches a limiting value, 100—110 kJ mol^{-1}, as n increases. This tendency of E_a resembles the chain length dependence of the melting point of long n-alkanes[1-3] that the melting point approaches a limiting value, about 410 K, as n increases. These facts seem to indicate that there exists some close correlation between the activation process of molecular rotation or reorientation about the long axis and the melting phenomenon.

The activation process in the low molecular weight n-alkanes cannot be predicted from Fig. 5 because the assumption of the straight line in this figure leads to the zero activation energy at $n \approx 30$; this means that the orthorhombic structure is not stable for $n < 30$. However odd-numbered n-alkanes with 9 carbons or more crystallize in the orthorhombic unit cell actually.[1] We need the activation energy for short n-alkanes in order to discuss this point in greater detail but only few E_a data have been reported so far[14] for which some ambiguity about the assignment of the relaxation data remains.

(Received December 27, 1990)

A heterogeneous electron-transfer process of the $[Fe(CN)_6]^{4-/3-}$ complex confined electrostatically in cationic perfluoropolymer (CPFP) films on graphite electrodes and a homogeneous charge-transport process within the films were examined by potential-step methods. The relevant kinetic parameters (i.e., standard rate constant; k°/cm s^{-1} and transfer coefficient; α) of the heterogeneous electron-transfer process and the apparent diffusion coefficient (D_{app}/cm^2 s^{-1}) of the homogeneous charge-transport process within the films were evaluated at various concentrations (C°) of the complex within the film. The values of D_{app} and k° slightly decreased with an increase in C°. The value of α was independent of C° (cathodic transfer coefficient, α_c=0.20, anodic transfer coefficient; α_a=0.80). The values of k°, α, and D_{app} were compared with those obtained previously for protonated poly(4-vinylpyridine) ($PVPH^+$)-$[Fe(CN)_6]^{4-/3-}$ system and poly(*N*,*N*-dimethylaniline) (PDMA)-$[Fe(CN)_6]^{4-/3-}$ system. It was found that k°, α_c, and D_{app} decrease, depending on the polymer film in which the complex is confined, in the following order: for D_{app} and k°, $PVPH^+$>PDMA>CPFP and for α_c, $PVPH^+\approx$PDMA>CPFP.

Thus far several polyelectrolytes (e.g., Nafion and protonated poly(4-vinylpyridine), shown in Fig. 1) have been used as an "electrode modifier" in the field of polymer-modified electrodes.[1-5] A number of papers dealing with Nafion film-coated electrodes have been reported since it was found that Nafion, which has the structure consisting of hydrophobic and hydrophilic domains,[6] could be used as an electrode modifier, because of its chemical stability and stable adhesion onto electrode surfaces.[6-21] A perfluoropolycarboxylic acid (PFPC) has also been used as electrode modifier.[5,22]

More recently, a new cationic perfluoropolymer membrane (CPFP, Fig. 1) has been produced by Tosoh Co., Ltd. This is a new cationic anion-exchange membrane with quaternary ammonium groups, in contrast to Nafion and PFPC which are anionic cation-exchange membranes with sulfonyl and carboxyl groups, respectively. In recent papers,[23-25] we have reported the preparation and the

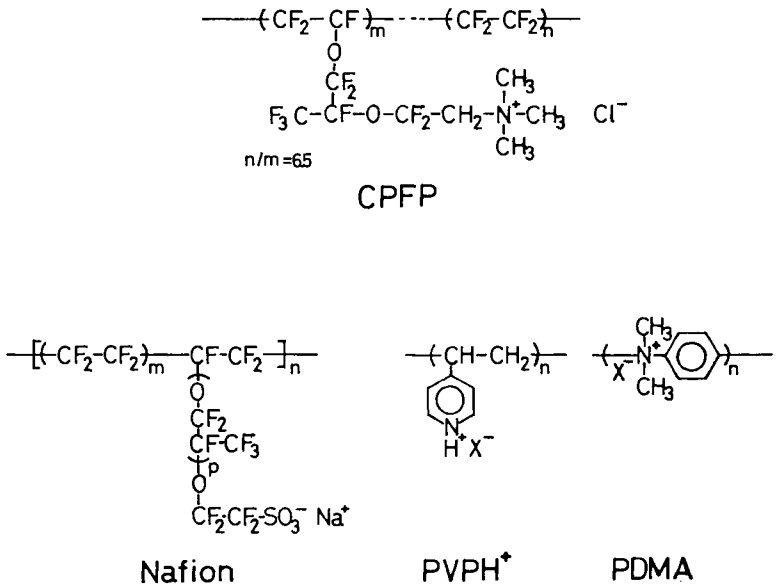

Fig. 1. Structures of cationic perfluolopolymer (CPFP), protonated poly(4-vinylpyridine) ($PVPH^+$), poly(*N*,*N*-dimethylaniline) (PDMA), and Nafion.

basic properties of the CPFP film as an electrode modifier and the charge-transport process within the film in which anionic Alizarine Red S dye is confined electrostatically as electroactive species.

In this work, we aim to examine the kinetics of the heterogeneous electron-transfer process of $[Fe(CN)_6]^{4-/3-}$ complex confined electrostatically in CPFP film on graphite electrode surfaces and the homogeneous charge-transport process within the film. The relevant kinetic parameters (standard rate constant: k°/cm s^{-1}, anodic and cathodic transfer coefficients: α_a and α_c) of the electrode reaction and apparent diffusion coefficient (D_{app}/cm^2 s^{-1}) of the homogeneous charge-transport process within the film are evaluated at various concentrations of the complex within the film. Further, the obtained values of k°,α_c, and D_{app} will be compared with those obtained previously for protonated poly(4-vinylpyridine) ($PVPH^+$)-$[Fe(CN)_6]^{4-/3-}$ system[26] and poly(*N*,*N*-dimethylaniline) (PDMA)-$[Fe(CN)_6]^{4-/3-}$ system.[27]

Experimental

Materials. CPFP membrane specimen was a gift of Tosoh Co., Ltd. Trifluoroacetic acid and sodium trifluoroacetate (Aldrich) used as supporting electrolytes and $K_3[Fe(CN)_6]$ (Merck) were of reagent grade and were used as received.

Basal-plane pyrolytic graphite (BPG) (Union Carbide Co.) was used as a working electrode material. The BPG disk electrodes were prepared and mounted into a glass tube with a heat-shrinkable polyolefin tube. The exposed area of these electrodes was 0.194 cm^2. Before use of electrodes, they were cut with a scalpel and their fresh surfaces were exposed. Aqueous solutions were prepared from doubly distilled water. Other chemicals were of reagent grade.

Preparation of CPFP Film-Coated Electrodes. The stock solution of CPFP, which was prepared as reported previously,[23] was diluted twice with $H_2O/C_2H_5OH/2$-C_3H_7OH(1/1/1(volume ratio)) mixed solvent. Then, the concentration of CPFP in the diluted stock solution was 10.5 mg ml^{-1}. For the preparation of CPFP film-coated electrodes, aliquots (usually 4 μl) of the diluted stock solution were spread by a microsyringe on the freshly cleaved disk surface of BPG electrode, and then were air-dried to remove the solvent at room temperature.

Measurement of the Film Thickness. The film thickness was measured as follows. The glass slide (ca. 1 cm×1 cm) was coated with silicone film (PRX 305-Clear, Toray Silicone Co., Ltd.), keeping a portion of ca. 0.20 cm^2 uncoated. Aliquots of the CPFP stock solution were spread with a microsyringe on the uncoated portion of the glass slide, and they were dried. After that, the silicone film was stripped. With a Surfcom 550A (Surface texture measuring instruments, Tokyo Seimitsu Co., Ltd.), the average difference between the surface profile of the glass slide and that of the CPFP film was measured. As seen from the inset in Fig. 2 this difference was taken as a film thickness under the dry state. After the glass slide which was used to measure the film thickness under the dry state was soaked overnight in a supporting electrolyte aqueous solution (0.2 M $CF_3COONa+CF_3COOH$, pH 1.0, 1 M=1 mol dm^{-3}) and water on the CPFP film was removed, the film thickness was measured again as that under the wet state. The clear difference between the film thicknesses under the dry and wet states was not observed, and thus the film thickness under the wet state was regarded as equal to that under the dry state within experimental errors. Figure 2 shows a linear plot of the film thickness under the dry state (μm in unit) vs. the coverage of the CPFP stock solution (μl in unit). The film thickness on the CPFP film-coated electrode, which was used to examine the kinetics of charge-transfer reaction, was estimated to be ca 1.0×10^{-4} cm from this linear relationship.

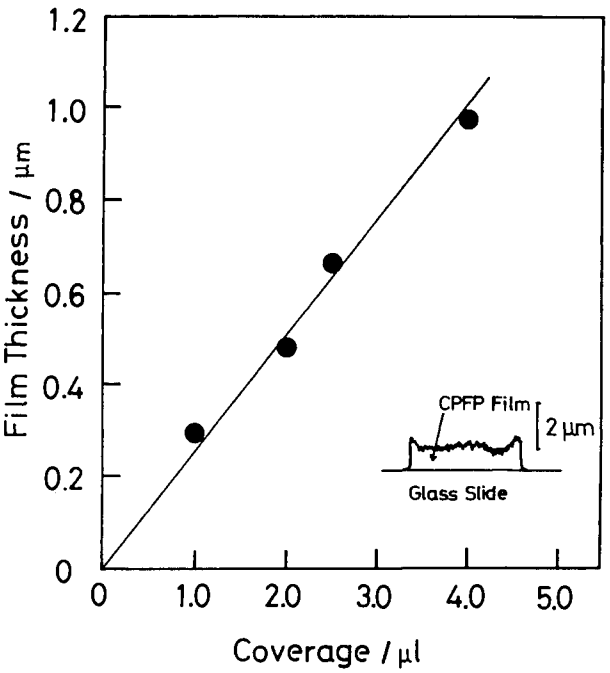

Fig. 2. Correlation between film thickness of CPFP and its coverage.
The coverage means the amount of the CPFP stock solution (see Experimental section) put and solvent-evaporated on the slide glass of a known area. The inset shows a typical vertical sectional profile of the CPFP film prepared on slide glass.

Apparatus and Procedures. The same standard three-electrochemical cell and electrode assembly as described previously were used in this work.[37] Electrode potentials were measured and are quoted with respect to a sodium chloride saturated calomel electrode (SSCE).

For cyclic voltammetry, potential-step chronoamperometry, potential-step chronocoulometry, and normal pulse voltammetry, the same instruments as described previously were used.[26,27] In potential-step chronoamperometric and chronocoulometric experiments, the electrode potentials were stepped from 0.8 to −0.2 V vs. SSCE for the reduction and from −0.2 to 0.8 V vs. SSCE for the oxidation. Then, the time of pulsed electrolysis was 40 ms for each case. In normal pulse voltammetric experiments, the electrode potentials were stepped from 0.8 V vs. SSCE for the reduction and from −0.2 V vs. SSCE for the oxidation, and then the height of pulsed wave was increased with 10 mV after each waiting period (usually 30—60 s). Currents were

sampled in the range from 2 to 24 ms. A positive feedback circuit was used to compensate IR drop of applied voltage resulting from the resistances of the solution and the coating films.

The kinetic measurements were carried out in 0.2 M $CF_3COONa+CF_3COOH$ aqueous solutions (pH 1.0) containing $[Fe(CN)_6]^{3-}$ in the concentration range from 10^{-5} to 10^{-4} M to keep its concentration within the film a given constant value.

The surface concentration (Γ/mol cm^{-2}) of $[Fe(CN)_6]^{4-/3-}$ within the CPFP film was estimated from graphical integration of the cyclic voltammogram, which was obtained at slow potential sweep rates (2—5 mV s^{-1}), with correction of background current for the oxidation and reduction. After substituting dissolved oxygen in a solution with a purified nitrogen gas, all electrochemical measurements were carried out under an atmosphere of nitrogen gas at room temperature.

The temperature dependence of formal potential ($E^{\circ\prime}$) was examined using a "non-isothermal electrochemical cell"[31,32] having a thermally jacketed compartment for the working and counter electrodes and a separate compartment for the reference electrode which was connected to the cell with a 3 M NH_4Cl salt bridge. The reference electrode was maintained at a fixed temperature (25±0.2 °C). The temperature of the cell was varied in the range of 3—37 °C. The values of $E^{\circ\prime}$ were estimated as the average of the anodic and cathodic peak potentials of the cyclic voltammograms.

Results

Cyclic Voltammetry. The cyclic voltammetric experiments were performed with the CPFP-film coated and naked BPG electrodes in a 0.2 M $CF_3COONa+CF_3COOH$ aqueous solution (pH 1.0) containing 0.2 mM $[Fe(CN)_6]^{3-}$. When the CPFP-film coated BPG electrode was immersed into the solution, the anodic and cathodic peak currents (i_p^a and i_p^c) of the cyclic voltammogram gradually increased as the electrode potential was scanned repeatedly between 0.8 and −0.2 V vs. SSCE. After about an hour, as shown in Fig. 3(A), these peak currents indicated constant values, and the steady-state cyclic voltammogram was obtained. In this case, the values of i_p were about 10 times as large as those obtained at the naked BPG electrode in the same solution as used in Fig. 3(A). Then, C° was ca. 0.15 M and was by a factor of about 750 larger than the concentration (0.2 mM) of $[Fe(CN)_6]^{3-}$ in the bulk solution.

Further, the formal redox potential ($E^{\circ\prime}$=0.310 V vs. SSCE) of $[Fe(CN)_6]^{4-/3-}$ couple confined in the CPFP film was different from that (0.367 V vs. SSCE) of the same couple in the bulk solution. This indicates that the environment around the redox couple within the film is different from that in the bulk solution. In this case, it may be presumed that the oxidized half of the redox couple exists within the film more stably than in the bulk solution and/or the reduced one exists in the bulk solution more stably than within the bulk. When the CPFP film-coated electrode used in Fig. 3(A) was transferred into the supporting electrolytic solution containing no $[Fe(CN)_6]^{3-}$, i_p gradually decreased, suggesting the releasing of the complex into the bulk solution. However, when this electrode was re-transferred into the same solution as used in (A), i_p increased and the same cyclic voltammograms as shown in (A) were obtained. From this fact, it is obvious that the CPFP film stably adsorbed on the electrode surfaces. Further, it has previously been demonstrated that two kinds of anionic metal complexes can be simultaneously concentrated into the CPFP film.[23]

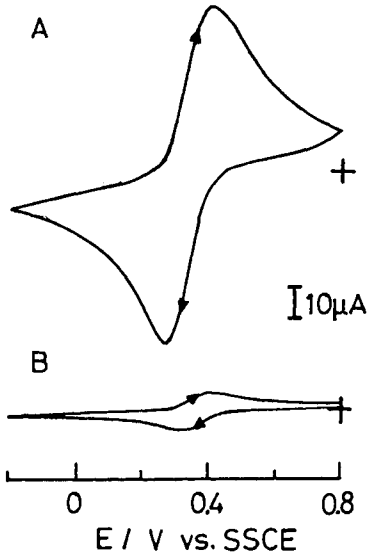

Fig. 3. (A) Steady-state cyclic voltammogram obtained for CPFP film-coated BPG electrode in 0.2 M CF_3COONa aqueous solution (pH 1.0) containing 0.2 mM $[Fe(CN)_6]^{3-}$. Thickness of CPFP film: 3.0×10^{-4} cm. Surface concentration (Γ) of quaternized ammonium site in CPFP film: 5.2×10^{-7} mol cm^{-2} (volume concentration: 1.7 M). (B) Cyclic voltammogram obtained for bare BPG electrode in the same solution as that used in A. In both cases, potential scan rate: 50 mV s^{-1}.

As described above, the overall electrode process at the CPFP film-coated electrode consists of two processes. One is the heterogeneous electron-transfer reaction which is characterized by standard rate constant (k°) and transfer coefficient (α). The other is the homogeneous charge-transport reaction which is characterized by apparent diffusion coefficient (D_{app}). These reactions were quantitatively examined with electrochemical pulse methods, as shown below.

Potential-Step Chronoamperometry (PSCA) and Chronocoulometry (PSCC). The curves A-1 and B-1 shown in Fig. 4 show current-time and coulomb-time responses, respectively, which were obtained with PSCA and PSCC for the reduction of $[Fe(CN)_6]^{3-}$ incorporated into the CPFP film on the electrode. In these figures, the dashed lines show the data of blank experiments obtained at the $[Fe(CN)_6]^{3-}$-free CPFP

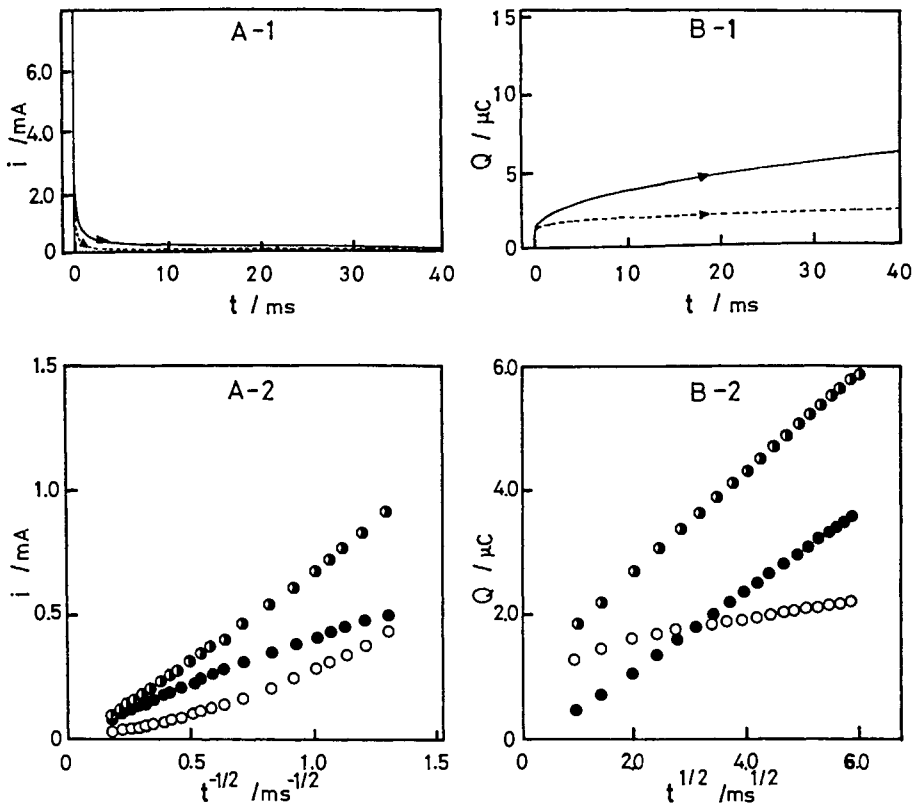

Fig. 4. Typical potential-step (A-1) chronoamperometric and (B-1) chronocoulometric responses for the reduction of $[Fe(CN)_6]^{3-}$ complex confined in the CPFP film on BPG electrode in 0.2 M CF_3COONa solution (pH 1.0). A-2 and B-2 represent chronoamperometric and chronocoulometric Cottrell plots for the data shown in A-1 and B-1, respectively. The dashed lines correspond to the background current responses obtained at the CPFP film (containing no $[Fe(CN)_6]^{3-}$)-coated BPG electrode in 0.2 M CF_3COONa solution (pH 1.0). Open and half-solid circles correspond to the dashed and solid lines in A-1 and B-1, respectively, and solid circles represent the background-current-corrected response.

film-coated electrodes. In these measurements the potential was stepped from 0.8 to −0.2 V vs. SSCE, and the time of pulsed electrolysis was 40 ms. Within this time window, a thickness of diffusion layer, which can be estimated to be ca. $(1—2)\times10^{-5}$ cm based on the D_{app} values obtained (shown below), is much thinner than the film thickness (1.0×10^{-4} cm). Therefore, the homogeneous charge-transport reaction can be regarded as a semi-infinite diffusion. The Cottrell equation and its integrated form were used to analyze the obtained curves.[28]

The plots A-2 and B-2 in Fig. 4 show the Cottrell plots for the data of A-1 and B-1, respectively. The values of D_{app} were estimated from the slopes of the plots which were corrected with the data of blank experiments for A-1 and B-1. The obtained values of

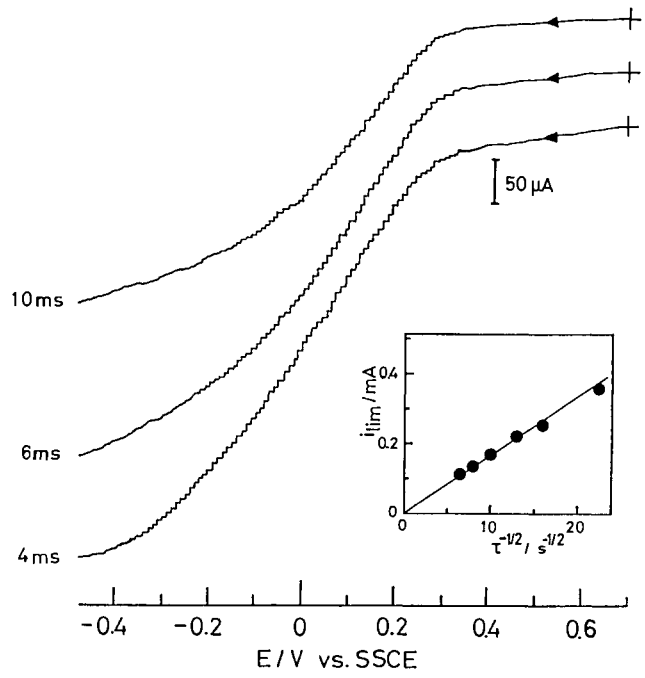

Fig. 5. Typical normal pulse voltammograms for the reduction of $[Fe(CN)_6]^{3-}$ complex confined in the CPFP film on BPG electrode in 0.2 M CF_3COONa solution (pH 1.0) containing 1.0×10^{-5} M $[Fe(CN)_6]^{3-}$. Concentration of $[Fe(CN)_6]^{3-}$ complex confined in the film: 3.2×10^{-2} M. The dashed lines show the background current responses. The inset shows a typical normal pulse voltammetric Cottrell plot of limiting current, i_{lim}, vs. (sampling time)$^{-1/2}$, $\tau^{-1/2}$.

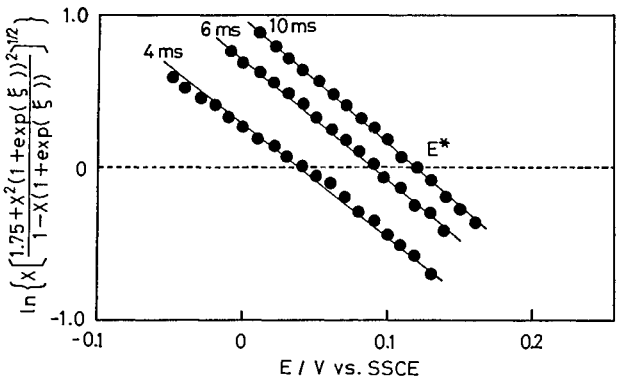

Fig. 6. Modified log-plots for the normal pulse voltammograms shown in Fig. 5. Sampling times are indicated on each straight line.

D_{app} are shown in Fig. 7.

Normal Pulse Voltammetry. Figure 5 shows typical normal pulse voltammograms obtained for the reduction of $[Fe(CN)_6]^{3-}$ confined in the CPFP film at various sampling times (τ/ms). At sufficiently negative applied potentials, the limiting currents (i_{lim}) were obtained. The dependence of the limiting currents (i_{lim}) of these normal pulse voltammograms on τ was examined. As shown in the inset of Fig. 5, i_{lim} was plotted against $\tau^{-1/2}$. This plot gave a straight line and passed through the origin. From this fact, it was found that the homogeneous charge-transport reaction within the film was controlled by diffusion and obeyed Fick's law.[26-28] The values of D_{app}, obtained from the slopes of such linear plots, are shown in Fig. 7 and Table 1. Further, the kinetic parameters (i.e., k° and α) of the heterogeneous electron-transfer reaction were estimated from the conventional analysis of the rising part of each normal pulse voltammogram.[26,27,29] Figure 6 shows the modified log-plots of $\ln(x[\{1.75+x^2(1+\exp(\xi))^2\}/\{1-x(1+\exp(\xi))\}]^{1/2})$ vs. E for each voltammogram shown in Fig. 5, where x is the ratio of the current at potential E to the limiting

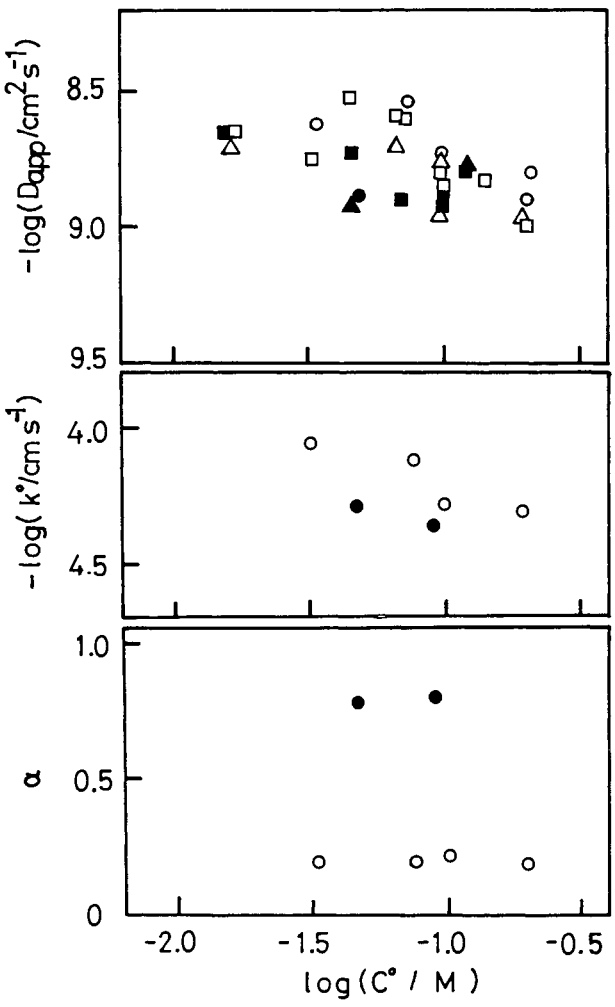

Fig. 7. Dependences of D_{app}, k°, and α on C°. Thickness of CPFP film: 1.0×10^{-4} cm. Supporting electrolyte: 0.2 M CF_3COONa+CF_3COOH (pH 1.0). C° denotes the volume concentration of $[Fe(CN)_6]^{3-}$ (or $[Fe(CN)_6]^{4-}$) complex confined in CPFP film. The data shown by squares, triangles, and circles were obtained by PSCA, PSCC, and NPV, respectively. Solid and open symbols correspond to the anodic and cathodic processes, respectively.

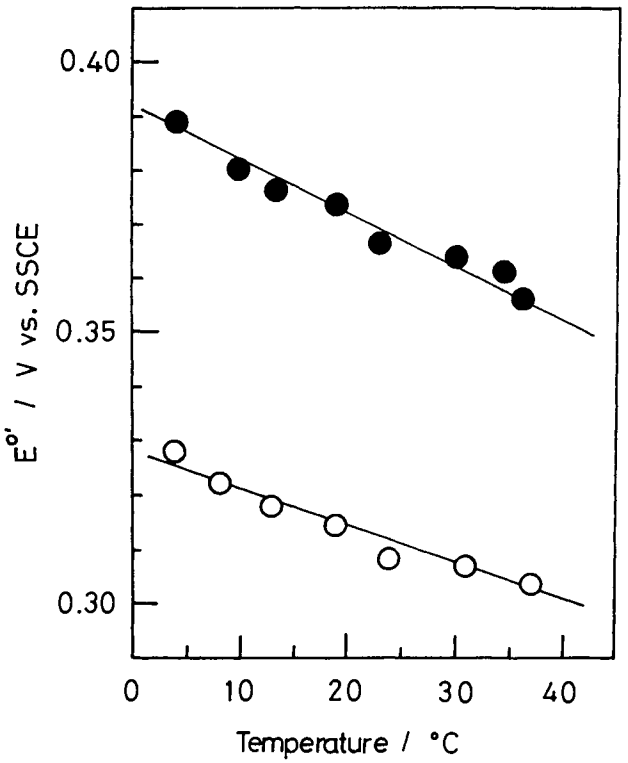

Fig. 8. Temperature dependences of formal potential ($E^{\circ\prime}$) of $[Fe(CN)_6]^{4-/3-}$ redox couple confined in the CPFP film and dissolved in 0.2 M CF_3COONa solution. Solution composition: 0.2 M CF_3COONa+CF_3COOH (pH 1.0) $+1.0\times10^{-5}$ M $[Fe(CN)_6]^{3-}$. Thickness of CPFP film: 1.0×10^{-4} cm, (●) at bare BPG electrode, (○) at CPFP film-coated electrode.

diffusion current expressed by the Cottrell equation[26,27,29] and ξ is the dimensionless parameter expressed as $\{(nF/RT)(E-E^{r}_{1/2})\}$ ($E^{r}_{1/2}$: the reversible half-wave potential, n: the number of electrons involved in the heterogeneous electron-transfer reaction, F: the Faraday constant, R: the gas constant, T: the absolute temperature). The plots gave the straight lines with the almost same slope at different sampling times. The transfer coefficient (α) was determined from the slopes of the plots in Fig. 6, and the standard rate constant (k°) was determined from the difference between the reversible half-wave potential ($E^{r}_{1/2}$) and the intercept potential (E^{*}) on the potential axis.[29] The obtained values of k° and α are shown in Fig. 7 and Table 1.

Figure 8 shows the temperature (T) dependence of the formal potential ($E^{\circ\prime}$) for the $[Fe(CN)_6]^{4-/3-}$ couple confined in the CPFP film and dissolved in solution. The linear relationships between $E^{\circ\prime}$ and T were obtained and thus the reaction entropy differences (ΔS°_{rc}) for the couple were estimated by using the equation:[31,32]

$$\Delta S^{\circ}_{rc} = S^{\circ}_{red} - S^{\circ}_{ox} = F\left(\frac{dE^{\circ\prime}}{dT}\right) \quad (1)$$

where S°_{red} and S°_{ox} are absolute ionic entropies of the reduced and oxidized halves of the redox couple and F is the Faraday constant. The ΔS°_{rc} values were estimated to be -24 ± 2 and -14 ± 2 cal mol^{-1} K^{-1} for the bulk solution (0.2 M CF_3COONa+CF_3COOH, pH 1.0) and the CPFP film, respectively.

Discussion

Figure 7 shows dependence of D_{app} on C°. When C° was increased from 0.01 to 0.2 M, D_{app} slightly decreased from 2.3×10^{-9} cm^2 s^{-1} to 1.2×10^{-9} cm^2 s^{-1}. As shown in Fig. 1, the structure of CPFP consists of the hydrophobic perfluorocarbon chain and ether-bond part and the hydrophilic quaternary ammonium sites, and the former occupies most of the structure. From this fact, it is assumed that the CPFP film as well as Nafion film[6,10,30] may have the domain structure which consists of the hydrophobic and hydrophilic parts in a solvent-swollen state, and that three-dimensional micro channels of the quaternary ammonium ion sites may exist within the CPFP film. Therefore, $[Fe(CN)_6]^{3-}$ (or $[Fe(CN)_6]^{4-}$) may diffuse within such channels with an electrostatic interaction with positively charged sites of the CPFP film and a hydrophobic interaction with the hydrophobic domain.[10,12,30] The fact that D_{app} slightly decreased with an increase in C° may be explained by an electrostatic cross-linking[1-5,7,10,11,14,15,22-27,33-39] of the polyelectrolyte coatings occurring when the multiply charged electroactive species are incorporated into organic polyelectrolyte coatings having the opposite charge, because the electrostatic cross-linking of the film hinders the physical diffusion of electroactive species itself and the motion of counterions associated with the redox reaction, which occurs to keep a charge neutrality.

If an electrostatic cross-linking which is often observed in a well-swollen film (e.g., $PVPH^+$ film) occurs, it could be expected that D_{app} largely decreases with an increase in C°.[26,38,39] However, in the case of the CPFP film, the dependence of D_{app} on C° is small. The CPFP film contains a far more hydrophobic domain compared to the $PVPH^+$ film. The distance between the positively charged sites was calculated to be 3—8 and 19—23 Å for the $PVPH^+$ film and the CPFP film, respectively by assuming a simple cubic lattice model for the statistical distribution of ammonium or pyridinium sites in these films. Therefore, the smaller effect of the electrostatic cross-linking in the CPFP film compared to the $PVPH^+$ film can be ascribed to the lower degree of swelling of this film, as supported by the experimental result that the thickness of a given film under the wet state is almost the same as that under the dry state.

The C° dependence of D_{app} may also be thought to reflect a single-file diffusion effect,[10,11,22,40] because $[Fe(CN)_6]^{4-}$ (or $[Fe(CN)_6]^{3-}$) ions which must move

between more or less fixed sites within the CPFP matrix are considered to have their rate of motion limited by the decreasing availability of sites as C° increases.

In Fig. 7 are also shown the dependences of k° and α on C°. The dependence of k° on C° is similar to that of D_{app} on C°, and k° slightly decreases when C° is increased. In contrast, α is almost independent of C°, and α values of anodic and cathodic processes (α_a and α_c) are ca. 0.80 and ca. 0.20, respectively. In addition, the sum of α_a and α_c is ca. 1.0, indicating that the anodic and cathodic reactions occur by way of the same activated state.[44]

The values of D_{app}, k°, and α_c obtained for the CPFP-$[Fe(CN)_6]^{3-}$ system are compared with those obtained previously for $PVPH^+$-$[Fe(CN)_6]^{3-}$ system[26] and PDMA-$[Fe(CN)_6]^{3-}$ system[27] (Table 1). At almost the same concentration of $[Fe(CN)_6]^{3-}$ in the films, the values of D_{app} and k° decrease in the following order; $PVPH^+$ film system>PDMA film system> CPFP film system. For example, when C° is (1.0—1.2)$\times 10^{-1}$ M, the D_{app} for the CPFP film is about 1/3 and 1/13 of those for the PDMA and $PVPH^+$ films,[26,27] respectively. This may be ascribed to a different extent of the electrostatic cross-linking of these films by $[Fe(CN)_6]^{3-}$ (and $[Fe(CN)_6]^{4-}$) ions which is considered to originate from their different morphologies in the solvent-swollen states. The α_c value for the CPFP film system is ca. 0.2 and is smaller than those (0.30) for the $PVPH^+$ film and PDMA film systems.[26,27] Such different α_c values for different film systems may reflect the different reaction positions of $[Fe(CN)_6]^{4-/3-}$ complex (e.g., with respect to the outer Helmholtz plane) in the transition state of the electron-transfer reaction and/or the existence of the potential-independent chemical reaction preceeding the electron-transfer reaction proper.[14,41-44]

The reaction entropy ΔS°_{rc} is an important parameter in considering the factors influencing the kinetics of electron-transfer process, since it provides a sensitive monitor of the changes in solvent polarization that are necessary in order for electron transfer to occur. The negative value (-24 ± 2 cal mol^{-1} K^{-1}) was obtained for the $[Fe(CN)_6]^{4-/3-}$ couple dissolved in 0.2 M CF_3COONa+CF_3COOH solution (pH 1.0) in qualitative agreement with the expectation from an electrostatic treatment such as the Born model.[31,32] Assuming that the equivalent radii of $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$ are 2 and 2.5 Å, respectively, ΔS°_{rc} is roughly estimated to be -19 cal mol^{-1} K^{-1}.[32] In the case of the $[Fe(CN)_6]^{4-/3-}$ couple confined in the CPFP film, the negative ΔS°_{rc} (-14 ± 2 cal mol^{-1} K^{-1}) was also obtained, but its value is more positive compared to that for the solution-phase $[Fe(CN)_6]^{4-/3-}$ couple. This fact suggests that the degree of the entropy in the oxidized form is smaller in the CPFP film than in the bulk solution and/or the degree of the entropy in the reduced form is larger in the film than in the solution. In other words, $[Fe(CN)_6]^{3-}$ (or $[Fe(CN)_6]^{4-}$) ions seem to interact more strongly (or weakly) with their surroundings within the CPFP film matrix than in the solution.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 01470064 from the Ministry of Education, Science and Culture. The authors express their appreciations to Tosoh Co., Ltd. for providing CPFP membranes.

Electrochemical Formation of 11-Molybdophosphate Anion at the Nitrobenzene/Water Interface and Its Applicability to the Determination of Orthophosphate Ion

Toshiyuki OSAKAI,* Sadayuki HIMENO, and Atsuyoshi SAITO
Department of Chemistry, College of Liberal Arts, Kobe University, Nada-ku, Kobe 657
(Received October 29, 1990)

Transfer of the hexamolybdate ion, $Mo_6O_{19}^{2-}$, at the nitrobenzene(NB)/water(W) interface was studied by ion-transfer voltammetry. The $Mo_6O_{19}^{2-}$ ion decomposed immediately after being transfered from NB to W. In the presence of orthophosphate ions in the weakly acidic W phase (pH 3.1), molybdophosphate anions, i.e. $[H_3PMo_{11}O_{39}]^{4-}$, were formed at the interface. A well-defined voltammetric wave due to the transfer of complex anions from W to NB was observed; the peak current was proportional to the bulk concentration of orthophosphate ions. Thus, the NB/W interface containing $Mo_6O_{19}^{2-}$ in NB can function as an ion-selective electrode surface for a voltammetric determination of orthophosphate ions.

Much attention is presently being paid to a new voltammetric method for the determination of ions with a polarizable oil/water interface.[1-4] Previously, one of the authors (T.O.) and co-workers developed oil/water interfaces which function as voltammetric (or amperometric) ion-selective electrode (ISE)-surfaces for several cations, including: Na^+, K^+, and NH_4^+.[5] Some of these ISE's were further applied to the design of amperometric chemical sensors for ammonia,[6] urea,[7] and volatile amines.[8] Most of the ISE's and sensors, however, are based upon the cation selectivity of crown ethers.

In our recent studies,[9,10] the transfer of heteropolyanions at the NB/W interface was investigated by ion-transfer voltammetry.[1-4] As already described,[9,10] such voltammetric studies shed light on the mechanisms of extraction processes of heteropolyacids. Still, it should be noted that another important objective of the studies is to develop oil/water interfaces which serve as ISE-surfaces for a voltammetric determination of such oxoanions as orthophosphate and silicate ions.

In parallel with the above-mentioned studies concerning the phase transfer of heteropolyanions, we have investigated electrode reactions of heteropoly- and isopolymolybdate anions.[11-13] In a previous study[13] we elucidated that the hexamolybdate ion, $Mo_6O_{19}^{2-}$, is partially electroreduced to decompose rapidly to Mo(V) and Mo(VI) in acidic aqueous-organic media. On the basis of this electrode reaction, the formation of a certain blue (reduced) heteropoly complex(es) can be electrochemically controlled. As an example of the application, we reported on a voltammetric method for the determination of the sulfate ion as the blue molybdosulfate complex.[12]

In this study, it has been found that when $Mo_6O_{19}^{2-}$ transfers across a nitrobenzene(NB)/water(W) interface from NB to W, it decomposes rapidly to some Mo(VI) species. In the presence of orthophosphate ions in W, a yellow (oxidized) heteropoly complex is formed at the interface. The present paper describes the principle of a new method for the voltammetric determination of orthophosphate ions based on such an electrochemical formation of this yellow complex at the NB/W interface.

Experimental

Electrochemical Measurements. Since a large current due to the transfer of $Mo_6O_{19}^{2-}$ flows through the interface, a three-electrode cell (Fig. 1) was used instead of the two-electrode cell previously used.[9] The cell system was supplemented with an Ag/AgCl electrode (F) as the reference

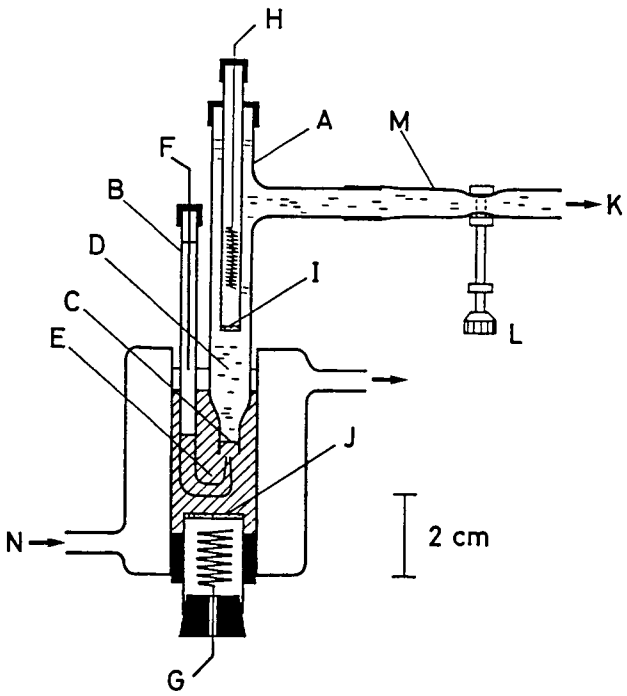

Fig. 1. Diagram of the three-electrode cell. A, glass tube; B, Luggin capillary; C, test interface (0.127 cm^2); D, water phase; E, oil phase; F, G, and H, Ag/AgCl electrodes; I and J, glass sinters; K, to solution reservoir; L, screw cock for the interface adjustment; M, silicone tube; N, thermostated water (25±0.1 °C).

electrode, which was connected to the NB phase close to the test interface (C) through a Luggin capillary (B). The Ag/AgCl electrodes (F and G) were immersed in 0.1 M (1 M=1 mol dm^{-3}) tetrabutylammonium chloride (TBACl) aqueous solutions, while the Ag/AgCl electrode (H) was immersed in a 0.5 M $MgCl_2$ aqueous solution separated from the W phase by means of a glass sinter (I). Accordingly, the electrochemical cell can be expressed as

	I	II		
Ag/AgCl (F or G)	0.1 M TBACl (W)	0.1 M TBATPB a mM $(TBA)_2Mo_6O_{19}$ (NB)		
	III	IV		
	0.5 M $MgCl_2$+buffer ($+b$ mM KH_2PO_4) (W)	0.5 M $MgCl_2$ (W)	AgCl/Ag. (H)	(A)

Here, TBATPB stands for tetrabutylammonium tetraphenylborate. The pH of phase-III was adjusted with a CH_3COOH-$(CH_3COO)_2Mg$ buffer ($[CH_3COO^-]$=0.1 M) or HCl (at pH<3). The potential difference (E) between the metal phases of electrodes F and H was controlled by a programmable function generator (Hokuto Denko Model HB-105) through a laboratory-made potentiostat. The solution resistance between the tip of the Luggin capillary and electrode H was compensated for by positive feedback. The current flowing through the test interface was detected by means of Ag/AgCl electrodes G and H with large surface areas (ca. 15 and ca. 10 cm^2, respectively), and the cyclic voltammograms were recorded with an X-Y pen recorder (Yokogawa Model 3023), unless otherwise noted.

Chemicals. The $(TBA)_2Mo_6O_{19}$ salt was prepared as described previously.[13,14] Other chemicals, except for $(TBA)_4[H_3PMo_{11}O_{39}]$ (see below), were described in the previous paper.[9]

The $(TBA)_4[H_3PMo_{11}O_{39}]$ salt was prepared according to the following procedure: To a stirred aqueous solution containing 120 mM $Na_2MoO_4\cdot 2H_2O$ and 10 mM $Na_2HPO_4\cdot 12H_2O$, concd HCl was added dropwise until the pH became 3.1. The addition of solid TBABr produced yellow precipitates. These precipitates were collected by filtration, washed several times with acetone to remove any TBA^+-salt of the Keggin anion $(TBA)_3[PMo_{12}O_{40}]$ (yellow) formed simultaneously, and then dried at 50 °C. The results of an elemental analysis for the resulting pale-yellow salt are as follows. Found: Mo, 39.12; P, 1.14; C, 28.75; H, 5.50; N, 2.09%. Calcd for $(TBA)_4[H_3PMo_{11}O_{39}]$: Mo, 39.33; P, 1.15; C, 28.65; H, 5.52; N, 2.08%. In the TG-DTA, the evolution of water was not observed up to 120 °C.

Figure 2(a) shows the IR spectrum of $(TBA)_4[H_3PMo_{11}O_{39}]$, which was recorded with a Hitachi Model 270-30 spectrophotometer. The spectrum is characterized by absorption bands at 1081, 1041, 936, 863, 821, and 762 cm^{-1}. For a comparison, Fig. 2(b) shows the IR spectrum of the TBA^+-salt of the Keggin anion, $(TBA)_3[PMo_{12}O_{40}]$, prepared according to a reported method.[15] The strong band at 1062 cm^{-1} for the Keggin anion, which can be assigned to the asymmetric stretch of the PO_4 group, splits into two bands at 1081 and 1041 cm^{-1} for $[H_3PMo_{11}O_{39}]^{4-}$. A similar splitting has been reported for the 11-tungstophosphate anion.[16-18] Rocchiccioli-Deltcheff and Thouvenot[18] reported corresponding bands at 1060 and 1010 cm^{-1} for the NH_4^+-salt of the 11-molybdophosphate anion. However, it should be noted that the crystal $Na_3H_6Mo_9PO_{34}(H_2O)_x$ prepared according to Strandberg's method[19] gave the same two bands at 1061 and 1009 cm^{-1}.

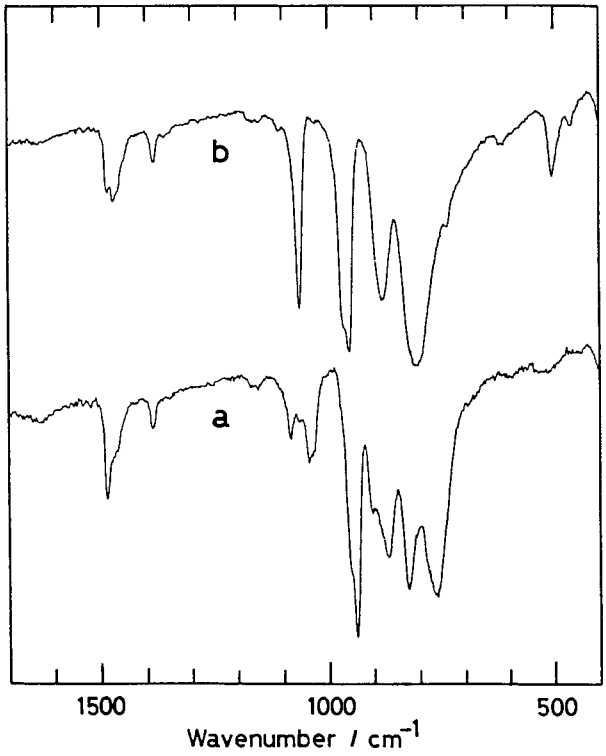

Fig. 2. IR spectra of (a) $(TBA)_4[H_3PMo_{11}O_{39}]$ and (b) $(TBA)_3[PMo_{12}O_{40}]$ in the KBr pellets.

From the above results it may be concluded that the $[H_3PMo_{11}O_{39}]^{4-}$ anion is a so-called "lacunary" derivative of the Keggin structure.[20]

Results and Discussion

Phase Transfer of $Mo_6O_{19}^{2-}$. Figure 3 shows cyclic voltammograms recorded at various scan rates when the NB phase contained 0.2 mM $Mo_6O_{19}^{2-}$ (note that orthophosphate ion was absent in this case).

At high scan rates (1.0—5.0 V s^{-1}), a typical wave with a pair of anodic (positive-current) and cathodic (negative-current) peaks was obtained, as represented by voltammogram (1). The anodic and cathodic peaks correspond, respectively, to the transfer of $Mo_6O_{19}^{2-}$ from NB to W and its transfer back to NB. Both the anodic and cathodic peak potentials, E_{pa} and E_{pc}, were almost independent of the pH of the W phase in the range 1.5 to 5.0. The midpoint potential, E_{mid} ($\equiv(E_{pa}+E_{pc})/2$=0.387±0.002 V), may be taken as a reversible half-wave potential, $E_{1/2}^{r}$, from which the standard potential difference, $\Delta_{NB}^{W}\phi^{\ominus}$, and the standard Gibbs energy, $\Delta G_{tr}^{\ominus,NB\to W}$, for the $Mo_6O_{19}^{2-}$ transfer were determined to be 0.164 V and 32 kJ mol^{-1}, in a similar manner as described previously.[9]

At lower scan rates ($\leq$0.2 V s^{-1}), the cyclic voltammogram showed an irreversible behavior. As can be

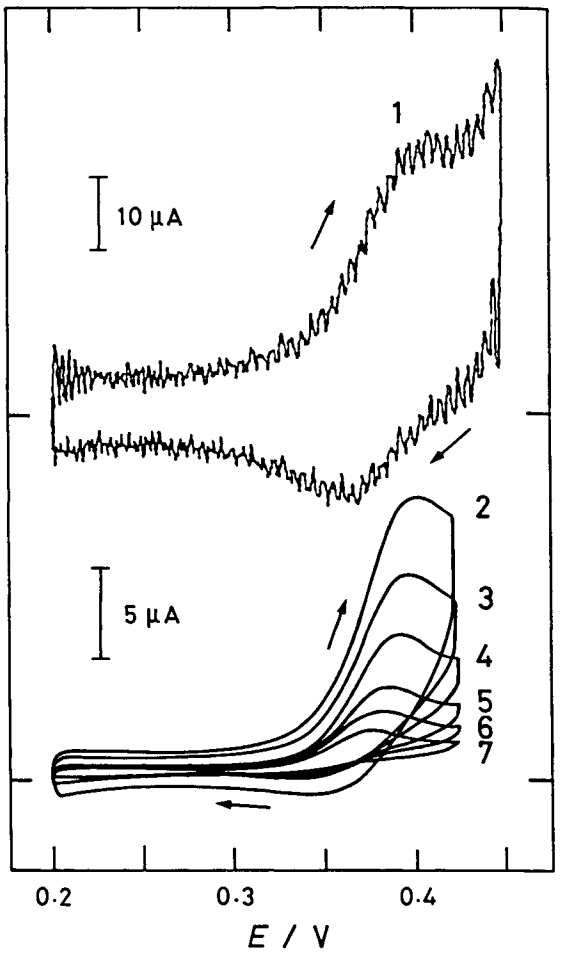

Fig. 3. Cyclic voltammograms of the transfer of $Mo_6O_{19}^{2-}$ at the NB/W (pH 3.1) interface. The NB phase contained 0.2 mM $(TBA)_2Mo_6O_{19}$. Scan rate: (1) 1.0; (2) 0.2; (3) 0.1; (4) 0.05; (5) 0.02; (6) 0.01; (7) 0.005 V s^{-1}. Voltammogram (1) was recorded with a transient recorder (Yokogawa Model 3655) instead of an X-Y pen recorder.

seen in voltammograms (2)—(7) in Fig. 3, no distinct cathodic peak due to the transfer of $Mo_6O_{19}^{2-}$ back to NB was observed, clearly showing that the anion decomposed rapidly in the W phase. This result is in line with the previous observations, that $Mo_6O_{19}^{2-}$ could be hardly detected in aqueous solutions; the anion was stabilized by the addition of certain water-miscible organic solvents.[13,14] Thus, the present ion-transfer process can be represented by

$$Mo_6O_{19}^{2-}(NB) \rightleftarrows Mo_6O_{19}^{2-}(W) \quad (1)$$

and

$$Mo_6O_{19}^{2-}(W) \xrightarrow{k_d} Mo(VI)(W). \quad (2)$$

To this system we can apply the theory of stationary electrode voltammetry[21] for a reversible charge transfer followed by an irreversible chemical reaction. According to the theory, it follows that E_{pa} is given by

$$E_{pa} = E^r_{1/2} - 0.780\,(RT/zF) + (RT/2zF)\ln[k_d(RT/|z|F)/v], \quad (3)$$

where k_d is the first-order rate constant of the decomposition reaction (Eq. 2), v the scan rate, and z the ionic valence (here, $z=-2$). R, T, and F have their usual meanings. In accord with Eq. 3, E_{pa} shifted toward positive potentials by about 18 mV for a ten-fold increase in v. The value of 18 mV is close to the theoretical value of 15 mV ($=-2.303(RT/2zF)$) at 25 °C. Using Eq. 3 and the $E^r_{1/2}$-value of 0.387 V, k_d was estimated to be 12±3 s^{-1} (at pH 3.1).

Electrochemical Formation of a Molybdophosphate Anion. From the above results, we expected that when such an oxoanion as the orthophosphate ion is present in the W phase, the transfer of $Mo_6O_{19}^{2-}$ from NB to W would be followed by the formation of a heteropoly complex at the interface. In Fig. 4, the dashed line indicates the cyclic voltammogram

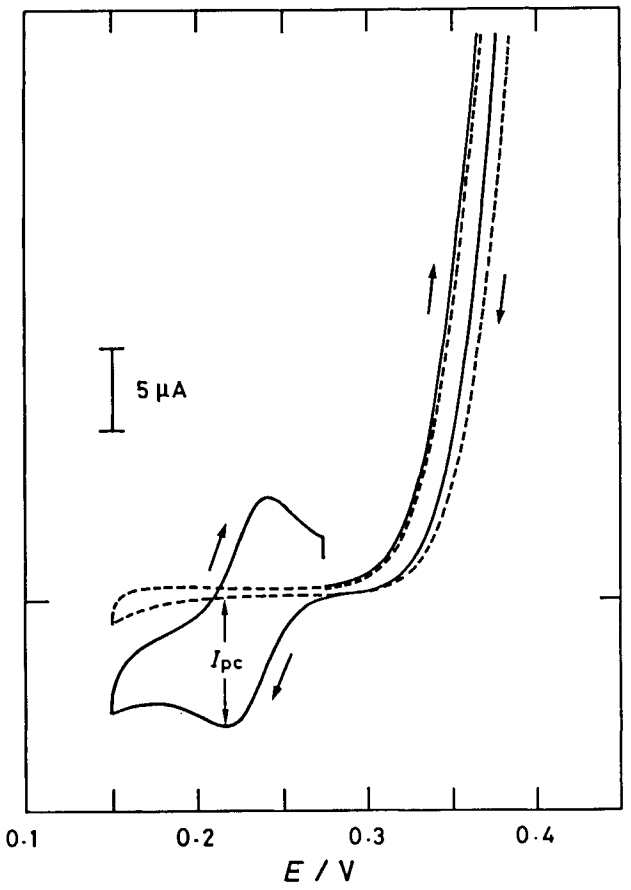

Fig. 4. Cyclic voltammograms of the transfer of $Mo_6O_{19}^{2-}$ at the NB/W interface in the presence (——) and absence (----) of 0.2 mM orthophosphate ion in the W phase (pH 3.1). The NB phase contained 5.0 mM $(TBA)_2Mo_6O_{19}$. The potential sweep was applied from 0.275 to 0.40 V in the anodic direction, followed by the cathodic to 0.15 V, then the anodic back to the initial potential. The potential-holding period at 0.40 V was 0 s in this case. Scan rate: 0.02 V s^{-1}.

obtained when $Mo_6O_{19}^{2-}$ was added in NB in a higher concentration (5.0 mM). On the initial anodic scan from 0.275 to 0.40 V, a large current due to $Mo_6O_{19}^{2-}$ transfer from NB to W was observed. As mentioned above, the anodic current was not followed by a cathodic current because of the rapid decomposition of $Mo_6O_{19}^{2-}$ in W. In the presence of orthophosphate ions in the W phase, however, a well-developed cathodic peak appeared at around 0.22 V on the succeeding cathodic scan, as shown by the solid line in Fig. 4. The cathodic peak was followed by an anodic peak at around 0.24 V. Obviously, these cathodic and anodic peaks were due to a phase transfer of certain molybdophosphate anions formed in the W phase in the vicinity of the interface. As the pH was raised, the wave shifted to negative potentials with a current change. In the following experiments, the pH was set at 3.1 so as to obtain the wave at a preferable potential, as shown in Fig. 4. Under these conditions, the cathodic peak current, i_{pc}, was proportional to the bulk concentration of orthophosphate ions in the range from 0.02 to 0.3 mM (shown in Fig. 5 by open circles). At concentrations higher than 0.3 mM, the cathodic current no longer increased, possibly because of a deficiency of Mo(VI). In this higher concentration range, the reproducibility of the currents was also poor. However, when the initial anodic scan was stopped at a switching potential of 0.40 V for a definite time, the lineality of the concentration dependence of i_{pc}, as well as the reproducibility, was much improved. At a potential-holding period of 60 s, i_{pc} was linear to the orthophosphate-ion concentration up to 0.5 mM (shown in Fig. 5 by full circles). In the lower concentration range (<0.3 mM), i_{pc} was virtually independent of the potential-holding period, indicating that the current was controlled only by the diffusion of orthophosphate ions to the interface.

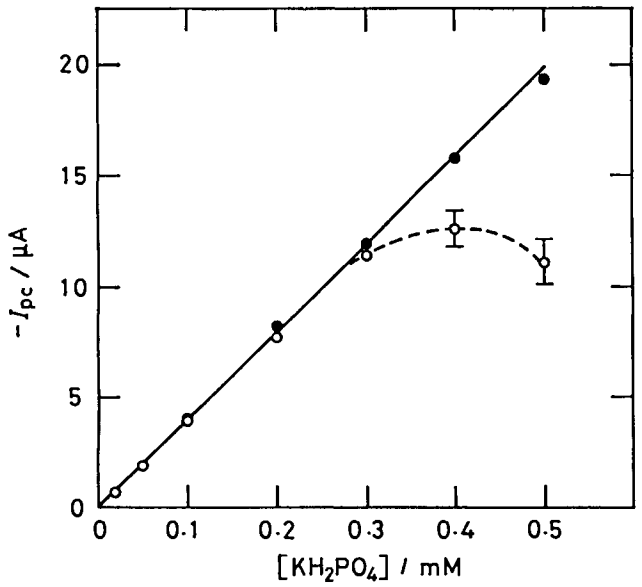

Fig. 5. Dependence of i_{pc} on the bulk concentration of orthophosphate ions added to the W phase. The potential-holding period: (○) 0; (●) 60 s.

These results clearly show that an NB/W interface containing $Mo_6O_{19}^{2-}$ in NB may function as a voltammetric ISE-surface for orthophosphate ions. An investigation is now in progress to develop a voltammetric sensor for practical uses based on such an oil/water interface.

Identification of the Heteropolyanion Formed at the Interface. For this purpose, a molybdophosphate anion formed at pH 3.1 in the aqueous molybdate solution was isolated as a TBA^+-salt, i.e. $(TBA)_4[H_3PMo_{11}O_{39}]$, as mentioned in the experimental section. By adding the salt to the NB phase, where the heteropoly complex was stable, a well-defined voltammogram for the phase transfer of the lacunary anion was observed at the same position as that in Fig. 4 (see Fig. 6). This shows that the heteropoly species formed predominantly as a result of the $Mo_6O_{19}^{2-}$ transfer was the lacunary anion. It should be stressed that the wave in Fig. 4 can never be assigned to the Keggin anion, $[PMo_{12}O_{40}]^{3-}$, whose ion-transfer potential was quite positive ($E_{1/2}^r$=0.475 V).[10]

In the voltammograms shown in Fig. 6, the anodic and cathodic peaks correspond to the transfer of anions from NB to W and their transfer back to NB,

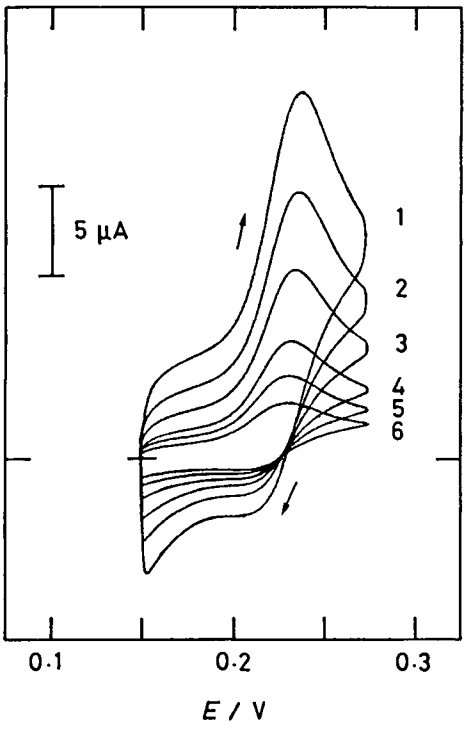

Fig. 6. Cyclic voltammograms of the transfer of $[H_3PMo_{11}O_{39}]^{4-}$ at the NB/W (pH 3.1) interface. The NB phase contained 0.18 mM $(TBA)_4[H_3PMo_{11}O_{39}]$. Scan rate: (1) 0.2; (2) 0.1; (3) 0.05; (4) 0.02; (5) 0.01; (6) 0.005 V s^{-1}.

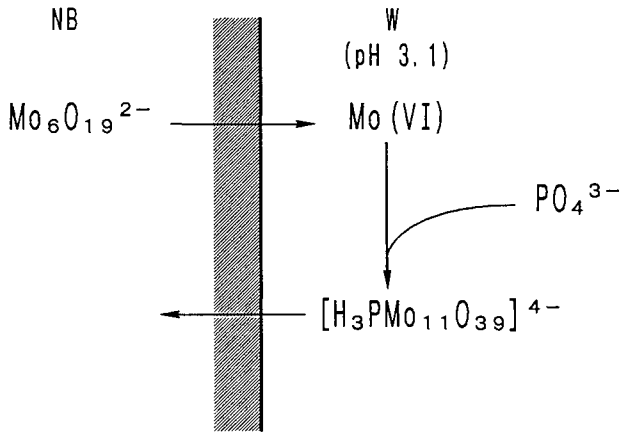

Fig. 7. Illustration of the electrochemical formation of a molybdophosphate anion at the NB/W interface. The succeeding transfer of the resulting $[H_3PMo_{11}O_{39}]^{4-}$ ion from W to NB can be utilized for the voltammetric determination of orthosphosphate ions in W.

respectively. Compared with the anodic peak currents, the cathodic ones were small, particularly at lower scan rates. This shows that the complex anions decomposed partially in the W phase, even at pH 3.1. Accordingly, the same theory[21] as that for $Mo_6O_{19}^{3-}$ transfer may be applied to this ion-transfer process. The slope (8 mV) of the E_{pa} vs. $\log v$ plot at pH 3.1 was close to the theoretical slope (7.4 mV) for $z=-4$. This suggested that the lacunary anion transferred across the interface as the tetravalent anion, i.e. $[H_3PMo_{11}O_{39}]^{4-}$ under these conditions.

Finally, the electrochemical formation of molybdophosphate anions at the NB/W interface may be illustrated graphically in Fig. 7. We would like to add that the present interface system possibly serves as a powerful tool for studying the dynamics of the heteropolyanion formation in aqueous solutions.

We would like to thank Dr. Toshitaka Hori of Kyoto University for his helpful suggestions. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 2740292 from the Ministry of Education, Science and Culture.

Preparation and Characterization of Optically Active Quadridentate Schiff Base-Titanium(IV) Complexes and the Catalytic Properties of These Complexes on Asymmetric Oxidation of Methyl Phenyl Sulfide with Organic Hydroperoxides

Caori SASAKI, Kiyohiko NAKAJIMA,† Masaaki KOJIMA,*,†† and Junnosuke FUJITA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464-01
†Coordination Chemistry Laboratories, Institute for Molecular Science, Myodaiji, Okazaki 444
(Received December 1, 1990)

Titanium(IV) complexes, [TiCl(Schiff base)]$_2$O, with quadridentate Schiff base ligands derived from optically active 1,2-diamines and salicylaldehyde were prepared by treating $TiCl_4$ with an equimolar amount of the Schiff base ligand in wet pyridine. The complexes were characterized by their ^{13}C NMR, absorption, and circular dichroism spectra, and conductivity measurements. The complexes in dichloromethane take a μ-oxo dinuclear structure, and in methanol the complexes break up into a mononuclear species, [Ti(OMe)(MeOH)-(Schiff base)]Cl. The complexes catalyze the asymmetric oxidation of methyl phenyl sulfide into the sulfoxide with organic hydroperoxides; the highest enantiomeric excess (ee) was ca. 60%. The kinetics conform to a rate law which is first order in the concentration of each sulfide, hydroperoxide, and complex catalyst.

Optically active sulfoxides are attracting considerable attention in the asymmetric synthesis of organic compounds.[1] An efficient asymmetric oxidation of prochiral organic sulfides into optically active sulfoxides has been reported, using a modified Sharpless reagent (Ti(OPr^i)$_4$/diethyl (*R*,*R*)-tartrate/Bu^{t}OOH) for asymmetric epoxidation.[2,3] We have succeeded in a similar asymmetric oxidation of sulfides with organic hydroperoxides catalyzed by oxovanadium(IV) complexes containing quadridentate Schiff base ligands derived from optically active 1,2-diamines and salicylaldehyde or its derivatives.[4] Thus, it is interesting to study the catalytic properties of titanium(IV) analogs.

Here, we report the preparation and characterization of optically active quadridentate Schiff base-titanium(IV) complexes, and the asymmetric oxidation of methyl phenyl sulfide with organic hydroperoxides catalyzed by these complexes. A part of this study has been reported briefly.[5]

follows: A methanol solution (20 cm^3) containing [TiCl(sal-(*RR*)-chxn)]$_2$O·2$(CH_3)_2CO$ (7.5×10^{-5} mol) and triphenylmethyl hydroperoxide (1.5×10^{-3} mol) was cooled to 0 °C. Methyl phenyl sulfide (1.5×10^{-3} mol) was added and the mixture was kept at 0 °C for 110 h. The solvent was removed under reduced pressure, and the residue was extracted with diethyl ether, which was evaporated under reduced pressure. From the resulting oil, methyl phenyl sulfoxide was isolated and purified by column chromatography on silica gel (eluent: cyclohexane-ethyl acetate (1 : 1 v/v)). Yield: 87%. The enantiomeric excess (ee) was determined on the basis of the reported optical rotation of the pure enantiomer;[10] $[\alpha]_D$ +79.7° (*c* 1.9, CH_3OH); 53% ee (*R*).

The progress of the reaction could be checked by high-performance liquid chromatography. Portions of the reaction mixture were withdrawn at intervals and then chromatographed (sample volume, 1—4×10^{-3} cm^3) with a column of Develosil ODS-5 (Nomura Chemical Co., Ltd., ϕ 0.46 cm×25 cm; eluent, acetonitrile-water (6 : 4 v/v)) or JASCO Fine Pack C18S (ϕ 0.46 cm×15 cm; eluent, acetonitrile-water (9 : 1 v/v)). Chromatography was carried out with a JASCO Tri Rotar V system and the components were detected with a JASCO UVIDEC 100 IV spectrophotometric detector at 260 nm. The amounts of sulfide, sulfoxide, and sulfone were determined from the absorption spectra of the collected fractions or by paper cut-outs matching the bands in the elution curve, while taking the molar absorption coefficients into consideration. The ee was determined from the circular dichroism (CD) spectrum of the fraction containing the sulfoxide on the basis of $\Delta\varepsilon_{237}$=+13.9 for the pure (*R*)-isomer.[4]

Kinetics Studies. The kinetics of the oxidation reactions was studied by high-performance liquid chromatography as described above. Since triphenylmethyl hydroperoxide is rather unstable, we used stable 1-methyl-1-phenylethyl hydroperoxide as the oxidant. All reactions were carried out under pseudo-first-order reaction conditions.

Spectroscopic Measurements. $^{13}C\{^1H\}$ NMR spectra were recorded on a JEOL GX-400 spectrometer using TMS as an internal reference. Optical rotations were measured with a JASCO DIP 4 polarimeter. Absorption and CD spectra were recorded on a Hitachi U-3400 spectrophotometer and a JASCO J-40CS spectropolarimeter, respectively. Conductivity measurements were carried out with a Toa CM-6A conductivity meter.

Results and Discussion

Preparation, Characterization, and Structure of the Schiff Base-Titanium(IV) Complexes. [TiCl(SB)]$_2$O (SB=Schiff base) was prepared by treating $TiCl_4$ with an equimolar amount of the Schiff base ligand in wet pyridine (water content≧0.4%). Although several titanium(IV) complexes with quadridentate Schiff base ligands have been prepared in the same way, they have been formulated differently.[11,12], Thus, the structure was determined by X-ray analysis on the sal-(*RR*)-chxn complex (Fig. 1); the details have been reported in a separate paper.[13] The structure shows a μ-oxo ligand bridging two TiCl(sal-(*RR*)-chxn) units. It is to be noted that [$TiCl_2$(SB)] is formed instead of [TiCl(SB)]$_2$O when the reaction is carried out in anhydrous solvents. The bridging oxygen atom seems to come from water in wet pyridine (Scheme 1).

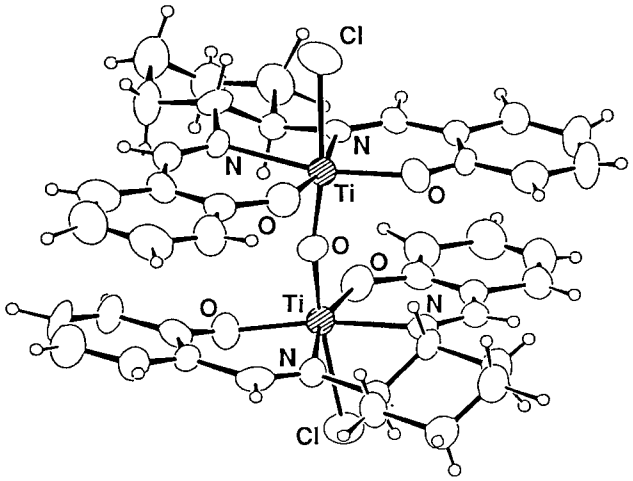

Fig. 1. An ORTEP drawing of [TiCl(sal-(*RR*)-chxn)]$_2$O.

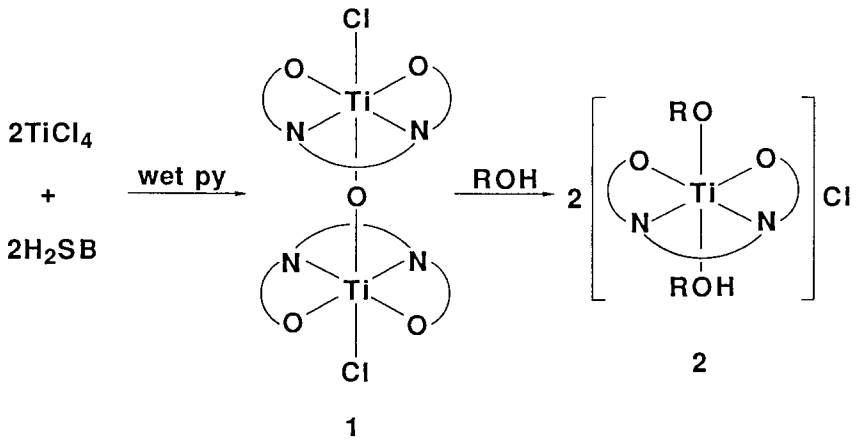

Scheme 1.

Very recently, Mozzanti et al.[14] have reported a μ-oxo dinuclear complex, [TiCl(acen)]$_2$O (acen=*N*,*N*′-ethylenebis(4-imino-2-penten-2-olate), the structure of which is very similar to that of [TiCl(sal-(*RR*)-chxn)]$_2$O.

Conductivity measurement reveals that [TiCl(sal-(*RR*)-chxn)]$_2$O is a non-electrolyte in dichloromethane, and the $^{13}C\{^1H\}$ NMR spectrum of the complex in CD_2Cl_2 shows 20 signals as expected for the crystal structure. On the other hand, the $^{13}C\{^1H\}$ NMR spectrum in CD_3OD shows only 10 signals, suggesting that the complex breaks up into a mononuclear one with a C_2 axis. The molar conductivity of 64 S cm^2 mol^{-1} in methanol calculated on the basis of the mononuclear complex, is in the range expected for a 1:1 electrolyte.[15] The most probable structure in methanol will be **2** in Scheme 1. Since protons migrate quickly on the NMR time scale, a coordinated methanol molecule and a methoxide ion will be indistinguishable by NMR (pseudo C_2). The absorption spectrum of [TiCl(sal-(*RR*)-chxn)]$_2$O in dichloromethane is quite different from those in methanol, ethanol, or 1-propanol, the spectra in alcohols being similar to each other (Fig. 2). Conductivities in ethanol (28 S cm^2 mol^{-1}) and 1-propanol (12 S cm^2 mol^{-1}) also suggest structure **2** in these solvents.

Figure 3 shows the CD spectra of [TiCl(sal-(*RR*)-chxn)]$_2$O in dichloromethane, methanol, ethanol, and 1-propanol. Here, again, the spectral pattern in

0	0.75	1.47×10^{-5}	1.96×10^{-5}

a) In all runs $[S]_0$ was 7.5×10^{-2} M. b) $[Cat]_0$ denotes the initial concentration of the titanium(IV) complex catalyst calculated as the mononuclear species. c) $k_{1(obs)}$ and $k_{1(uncat)}$ were obtained from the slope of the plot of $\log([S]_t/[S]_0)$ vs. time. d) $k_{2(obs)}$ and $k_{2(uncat)}$ were estimated as $k_{1(obs)}/[RO_2H]_0$ and $k_{1(uncat)}/[RO_2H]_0$, respectively. e) $k_{3(cat)}$ was estimated as $(k_{2(obs)}-k_{2(uncat)})/[Cat]_0$.

dichloromethane is quite different from those in alcohols. Figure 4 compares the CD spectra of the titanium(IV) complexes of sal-(*RR*)-chxn, sal-(*RR*)-stien, and sal-(*R*)-pn in methanol. The sal-(*RR*)-stien complex has a CD spectrum similar to that of the sal-(*RR*)-chxn complex. The central chelate ring of sal-(*RR*)-chxn is locked in a λ gauche conformation. The similarity in CD spectra between the two complexes, sal-(*R*)-stien and sal-(*RR*)-chxn, suggests that the sal-(*RR*)-stien complex also takes a λ gauche conformation. Examination of a molecular model indicates that the steric interaction between the phenyl groups and the axial ligands is very severe in the sal-(*RR*)-stien complex when the phenyl groups take axial positions, and the chelate should take the λ form stereoselectively. The CD spectral pattern of the sal-(*R*)-pn complex is almost a mirror image of the others, despite the fact that all parent diamines have the same absolute configuration. The intensity of the sal-(*R*)-pn complex is small compared with the others. Probably the greater part of the sal-(*R*)-pn complex in methanol takes a δ gauche conformation to reduce the steric interaction between the hydrogen on the azomethine carbon and the pn methyl group; the complex will be in an equilibrium mixture of the conformational isomers (δ and λ) with a small preference of the δ form. Similar relationships among the CD spectra have been reported for the corresponding oxovanadium(IV) complexes, VO(sal-(*SS*)-chxn), VO(sal-(*SS*)-stien), and VO(sal-(*S*)-pn).[16]

Oxidation of Methyl Phenyl Sulfide. The $[TiCl(SB)]_2O$ complexes catalyze the oxidation of methyl phenyl sulfide by organic hydroperoxides. Since organic hydroperoxides themselves oxidize sulfides in the absence of any added catalyst, the entire oxidation process must be the result of two independent pathways, catalyzed and uncatalyzed. Uncatalyzed oxidation is known to be first order both in the sulfide concentration ([S]) and in the hydroperoxide concentration ($[RO_2H]$), $R=k_{2(uncat)}[S][RO_2H]$.[17] In the absence of the complex catalyst, the oxidation of methyl phenyl sulfide by 1-methyl-1-phenylethyl hydroperoxide (CHP) was performed in methanol at 40 °C with the hydroperoxide in large excess over the sulfide. Pseudo-first-order behavior was observed, and the second-order rate constant ($k_{2(uncat)}$) for the uncatalyzed oxidation was calculated as $k_{1(uncat)}/[RO_2H]_0$; the result is given in Table 1.

In the presence of a complex catalyst, the rate law can be written as

$$-d[S]/dt = k_{2(uncat)}[S][RO_2H] + k_{3(cat)}[Cat]^p[RO_2H]^q[S]^r. \quad (1)$$

The first term on the right represents the uncatalyzed oxidation, while the second term the catalyzed one. Figure 5(a) shows the reaction profile for the oxidation of methyl phenyl sulfide (7.5×10^{-2} M, 1 M=1 mol dm^{-3}) with large excess CHP (7.5×10^{-1} M) in methanol in the presence of $[TiCl(sal\text{-}(RR)\text{-}chxn)]_2O$ (3.75×10^{-3} M) at 40 °C. The formation of the sulfone and the decomposition of the catalyst were negligibly small during the reaction. A plot of $\log([S]_t/[S]_0)$ vs. time gave a straight line for at least three half-lives (Fig. 5(b)); the pseudo-first-order rate constant ($k_{1(obs)}$) is given in Table 1. Table 1 also shows that at reasonable catalyst concentrations the complex-catalyzed reaction proceeds much faster than does uncatalyzed oxidation. In order to determine the order in CHP, we studied the oxidation with different $[RO_2H]_0$. The data in Table 1 suggest that $q=1$. Thus, Eq. 1 reduces to Eq. 2 under the conditions given in Table 1.

$$\begin{aligned} -d[S]/dt &= (k_{2(uncat)} + k_{3(cat)}[Cat]^p)[RO_2H][S] \\ &= k_{2(obs)}[RO_2H][S] \\ &= k_{1(obs)}[S] \end{aligned} \quad (2)$$

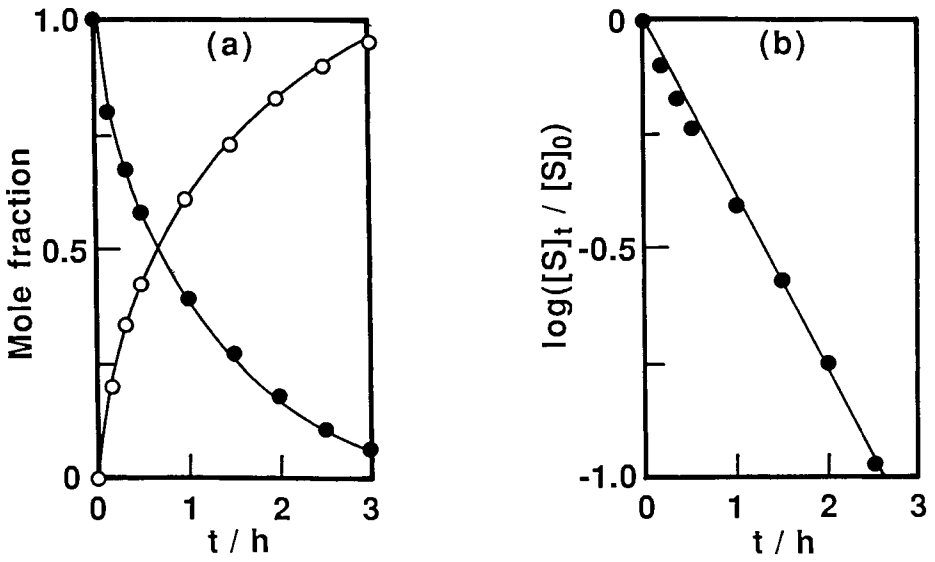

Fig. 5. Oxidation of methyl phenyl sulfide (7.5×10^{-2} M) by 1-methyl-1-phenylethyl hydroperoxide (7.5×10^{-1} M) with the [TiCl(sal-(*RR*)-chxn)]$_2$O (3.75×10^{-3} M) catalyst in methanol at 40 °C. (a) Reaction profile: ●, sulfide; ○, sulfoxide, and (b) the plot of $\log([S]_t/[S]_0)$ vs. reaction time. [S]=sulfide concentration.

At constant CHP and MeSPh initial concentrations, the rates increase upon increasing the catalyst concentration (Table 1). A $\log(k_{2(obs)}-k_{2(uncat)})$-$\log[Cat]_0$ plot gives a slope of 0.95, indicating that the order in the catalyst is unity ($p=1$). Hence, the catalytic third-order rate constant, $k_{3(cat)}=(k_{2(obs)}-k_{2(uncat)})/[Cat]$, could be estimated to be 3.9×10^{-2} $M^{-2}s^{-1}$. The first-order dependence on sulfide, hydroperoxide, and titanium catalyst implies that one molecule of each reactant is involved in the transition state of the rate-determining step. Since the probability of a trimolecular collision would be extremely small, two of the components must have interacted at a prior stage. Neither the addition of CHP nor methyl phenyl sulfide in moderate excess had any effect on the absorption and CD spectra of [TiCl(sal-(*RR*)-chxn)]$_2$O. However, an appreciable CD change was observed upon the addition of a large excess of dibutyl sulfide, which is considered to be a stronger ligand than methyl phenyl sulfide. Coordination of sulfides to Ti(IV) is not an unlikely process, and various titanium complexes with sulfide ligands have been identified.[18,19] We therefore suggest that the mechanism of oxidation involves an external attack by CHP on the coordinated sulfide, as proposed by Colombo et al.[20]

Several optically active Schiff base-titanium(IV) complex catalysts, solvents, and peroxides were used for the asymmetric oxidation of methyl phenyl sulfide; the results are given in Table 2.

Among the four organic hydroperoxides that we used, triphenylmethyl hydroperoxide (THP) gave higher ee's than did the others; the results may be associated with a steric effect of the phenyl groups in THP. In asymmetric catalytic reactions the importance of the orientation of the phenyl groups has been pointed out.[21,22] Recently, it has been reported that a similar oxidation of MeSPh with H_2O_2 catalyzed by titanium(IV) complexes containing optically active Schiff base ligands, such as sal-(*SS*)-chxn, led to low ee's (<20%) of the sulfoxide, the structures of the complexes being not described clearly.[20] The low ee's may result from the use of H_2O_2 in EtOH-H_2O.

Lowering of the temperature results in an enhancement in the enantioselectivity. However, as the temperature is lowered the reactivity decreases, and it takes an extremely long reaction time to oxidize the sulfide below 0 °C. We thus studied most of the oxidation at 0 °C by THP.

The ee shows a remarkable solvent dependence (Table 2); enantioselectivity decreases in the order MeOH>CH_2Cl_2>EtOH>PrOH in the oxidation of MeSPh by THP with the [TiCl(sal-(*RR*)-chxn)]$_2$O catalyst. The results may be partly attributed to a difference in the structure of the complex catalyst in solution. The complex has a dinuclear structure in CH_2Cl_2, while in alcohols it breaks up into a mononuclear species (vide supra). The difference in ee among the alcohols seems to be related to the different reactivities of the catalyst. For example, the oxidation of the sulfide in MeOH for 19 h and in EtOH for 110 h gave the sulfoxide in 73% (58% ee, Entry 6) and 61% (18% ee, Entry 18), respectively, while the same reaction in PrOH took as long as 240 h to yield the sulfoxide in 74% (ca. 0% ee, Entry 19). The oxidation of the sulfide is the result of the catalyzed and uncatalyzed pathways, and chiral discrimination occurs only

Table 2. Asymmetric Oxidation of Methyl Phenyl Sulfide to the Sulfoxide Catalyzed by the Titanium(IV) Complexes

a) Peroxide: THP, triphenylmethyl hydroperoxide; TBHP, *t*-butyl hydroperoxide; TMBHP, 1,1,3,3-tetramethylbutyl hydroperoxide; CHP, 1-methyl-1-phenylethyl hydroperoxide. b) [Ti]:[O]:[S] denotes molar ratio of $[TiCl(SB)]_2O$ (calculated as the mononuclear species):organic hydroperoxide:methyl phenyl sulfide (8.0×10^{-2} M). c) Analyzed by high-performance liquid chromatography unless otherwise stated. d) Based on the CD spectral data or the optical rotation of the pure enantiomer (see Experimental). e) In addition there is 12% sulfone. f) In addition there is 36% sulfone. g) In addition there is 5% sulfone. h) Isolated yield, based on the sulfide.

in the former. Hence, the ee becomes lower as the reactivity of the catalyst decreases. The greater part of the oxidation in PrOH may result from the uncatalyzed process. The solvent plays an important role in the present catalyzed reaction. Entries 25—28 show that the uncatalyzed oxidation of the sulfide with THP proceeds rather fast, even in MeOH; we therefore carried out the oxidation with different catalyst concentrations in order to estimate the contribution of the uncatalyzed pathway to the entire oxidation. At reasonably high catalyst concentrations, [Ti]/[S]>0.05, the ee stayed almost constant (ca. 60% ee), suggesting that the catalyzed process dominates the uncatalyzed one under these conditions. The ee did not change appreciably during the oxidation.

The complex catalysts containing an (*RR*)-chxn moiety or an (*RR*)-stien moiety gave the (*R*)-sulfoxide, while that containing an (*R*)-pn moiety gave the (*S*)-sulfoxide (Entry 24). These results can be understood if we assume that the catalytically active species has a conformational chirality similar to that of the added complex. As described before, the central chelate rings of the sal-(*RR*)-chxn and sal-(*RR*)-stien complexes take a λ gauche conformation. On the other hand, $[TiCl(sal\text{-}(R)\text{-}pn)]_2O$ in solution is suggested to be an equilibrium mixture of the conformational isomers (δ and λ) with a small preference of the δ form. Such a difference in conformational chirality among the complexes should be responsible for the enantioselectivity. It should be noted that oxovanadium(IV) complex catalysts give the antipode in a similar oxidation; for example, VO(sal-(*RR*)-chxn) gives the (*S*)-sulfoxide. Although the reason is not clear it may be related to a difference in mechanism between the two systems. As described above, we suggested coordination of sulfur to titanium prior to oxidation. Prochiral sulfides become chiral upon coordination, and chiral induction occurs at this stage. On the other hand, in a similar reaction with the VO(SB) complex catalyst, the catalytically active species was suggested to be a vanadium peroxide complex and the activated peroxide will oxidize sulfides.[4]

On the Reaction of (Vinylimino)phosphoranes. Part 17.[1] Preparation of *N*-Vinylcarbodiimides and Their [4+2] Cycloaddition with Several Dienophiles to Give Pyridine Ring System[2]

Makoto NITTA,* Hironobu SOEDA, Shinya KOYAMA, and Yukio IINO
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 169
(Received November 14, 1990)

The aza-Wittig reaction of (vinylimino)triphenylphosphorane and its several derivatives was examined to give *N*-phenyl-*N'*-vinylcarbodiimide and its derivatives, all of which underwent a [4+2] cycloaddition reaction with electron-rich dienophiles (enamines) and/or electron-deficient dienophiles (activated acetylenes), resulting in the formation of a pyridine ring system. The regioselectivity of the cycloaddition reaction could be rationalized on the basis of a frontier orbital consideration.

The [4+2] cycloaddition reaction of azadiene has proved to be one of the most powerful methods for the synthesis of six-membered nitrogen heterocycles.[3] Thus, the development of a new azadiene should provide a convenient way to produce heterocycles containing a pyridine ring. During the last decade, the synthesis and reaction of acyclic 2-aza-1,3-butadiene **1** have been studied extensively. For example, the [4+2] cycloaddition reaction of a 2-aza-1,3-butadiene (**1A**) having an electron-donating substituent, such as an amino[4-6] or silyloxy[7] group, with electron deficient dienophiles has been successfully examined; the reactivity and regioselectivity of the reaction have been rationalized on the basis of the frontier orbital treatment.[6] A compound of type (**1B**), which has an alkyl or aryl substituent, has been demonstrated to undergo [4+2] cycloaddition with both hetero-dienophiles[8,9] and electron-deficient dienophiles.[9,10] Furthermore, a 2-aza-1,3-butadiene (**1C**) having an electron-withdrawing substituent[11] has also been clarified to undergo a [4+2] cycloaddition reaction with enamines.[12] A few examples of C=C-conjugated carbodiimide, which also has a 2-aza-1,3-butadiene unit, has been known[13-15] and intermolecular cycloaddition with tetracyanoethylene[13] and intramolecular cyclization[14] has been reported.

We have recently demonstrated a simple preparation method of various (vinylimino)phosphoranes, which were found to react with α-bromo ketones, α,β-unsaturated ketones, and tropone derivatives in an enamine alkylation process followed by aza-Wittig reaction to provide convenient routes to pyrroles,[16,17] pyridines,[18] [*n*](2,4)pyridinophanes (*n*=6—9),[19] and 1-azaazulenes.[20] As part of a series of studies on (vinylimino)phosphoranes and related compounds, we examined the aza-Wittig reaction of (vinylimino)-phosphoranes with phenyl isocyanate to give C=C-conjugated carbodiimide derivatives, which undergo a [4+2] cycloaddition reaction with several dienophiles to give a pyridine ring system.

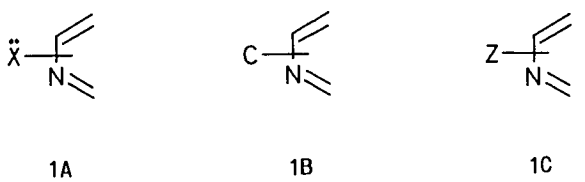

Fig. 1.

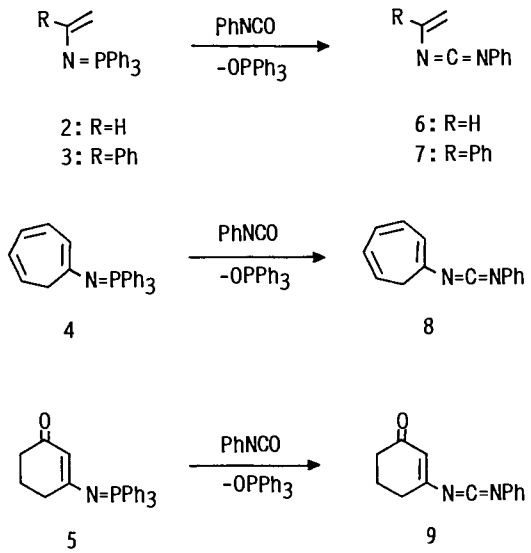
Results and Discussion

Preparation and [4+2] Cycloaddition Reaction of *N*-Phenyl-*N'*-vinylcarbodiimide and Its Derivatives. *N*-Vinyl-, *N*-(1-phenylvinyl)-, *N*-(1,3,5-cycloheptatrienyl)-, and *N*-(3-oxo-1-cyclohexenyl)-substituted carbodiimides (**6**), (**7**), (**8**), and (**9**), were prepared by the aza-Wittig reaction of phenyl isocyanate with the corresponding (vinylimino)triphenylphosphorane (**2**) and its derivatives **3**—**5** (Scheme 1). Compounds **6**—**8** could be purified by column chromatography on silica gel, and the structural assignment was based on high-resolution mass, IR, and ^{1}H NMR spectral data.



Scheme 1.

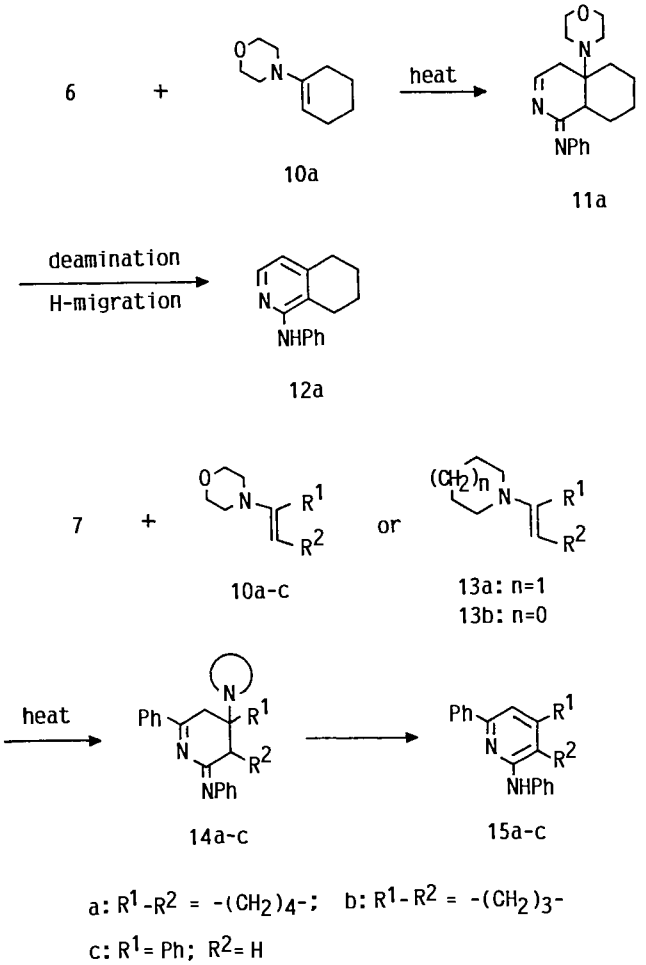
Entry	Compound	Enamine	Solvent	Product	Yield/%
1	**6**	**10a**	PhMe	**12a**	9
2	**7**	**10a**	PhBr	**15a**	41
3	**7**	**10a**	DMF[b]	**15a**	33
4	**7**	**10b**	PhBr	**15b**	34
5	**7**	**10c**	PhBr	**15c**	30
6	**7**	**13a**	PhBr	**15a**	38
7	**7**	**13b**	PhBr	**15b**	39

a) Reactions were carried out under refluxing for 0.5 h. b) Denote *N*,*N*-dimethylformamide.



Scheme 2.

Compound **9** was unstable and decomposed through chromatography on silica gel, and the structural proof for **9** was not obtained from the ^{1}H NMR spectrum of crude **9**. Thus, the reaction was conveniently carried out using a one-pot procedure without isolating **9**.

A thermal reaction of **6** with enamine **10a** was carried out in toluene to give an isoquinoline derivative **12a** in low yield (Scheme 2, Table 1, Enty 1). Similarly, reactions of **7** with enamines **10a—c** and **13a,b** were carried out in bromobenzene under refluxing to give isoquinoline derivatives **15a,b** and pyridine derivative **15c** in modest yields (Scheme 2). The results are also summarized in Table 1 (Entries 2—7). Neither the yields of the products nor the reaction time was dependent on the amine moiety of the enamines (Entries 7 and 8). Furthermore, no drastic change in the reaction time and yield of the product was observed, even in a polar solvent (DMF) (Entry 3). Thus, the reaction seemed to proceed via a concerted [4+2] cycloaddition rather than an ionic process. Furthermore, enamines from cycloalkanones, **10a,b**, resulted in higher yields of the products, as compared to that of **10c**.

Each of the ^{1}H NMR spectra of the new compounds **12a** and **15a,b** showed, besides signals for the aromatic ring, characteristic signals for the alicyclic methylene chain. The assignment of the signals are summarized in the Experimental section. Furthermore, the structure of **15c** was deduced on the basis of the spectral data, the ^{1}H NMR spectrum of which showed a pair of doublets at δ=7.02 and δ=7.42 (J=1.1 Hz, meta-coupled), thus, **15c** could be differentiated from the other regioisomer, 2-phenylamino-3,6-diphenylpyridine (**23**), which exhibited a signal at δ=7.34 (J=7.7 Hz, ortho-coupled) (vide infra). Thus, in the formation of compounds **12a**, **15a—c** is postulated to proceed through intermediates **11a** and **14a—c**, all of which undergo hydrogen migration and subsequent deamination. The regioselectivity of the enamine addition process giving **11a** or **14a—c** is suggested by the formation of **15c**, as well as with frontier molecular orbital consideration (vide infra).

The reaction of the carbodiimide **8** with enamines **10a—c** were examined in bromobenzene under refluxing to give a mixture of 9*H*-cyclohepta[*b*]pyridine (**17a—c**) and 7*H*-cyclohepta[*b*]pyridine (**18a—c**) derivatives (Scheme 3). Compounds **18a—c** are possibly derived from base catalyzed isomerization of **17a—c**,

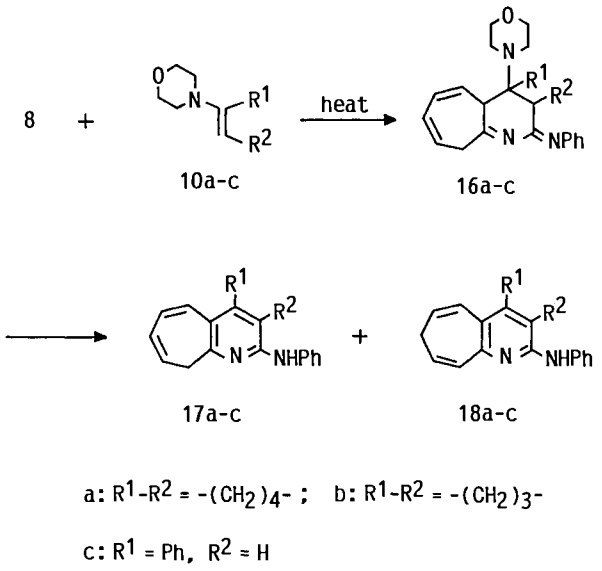
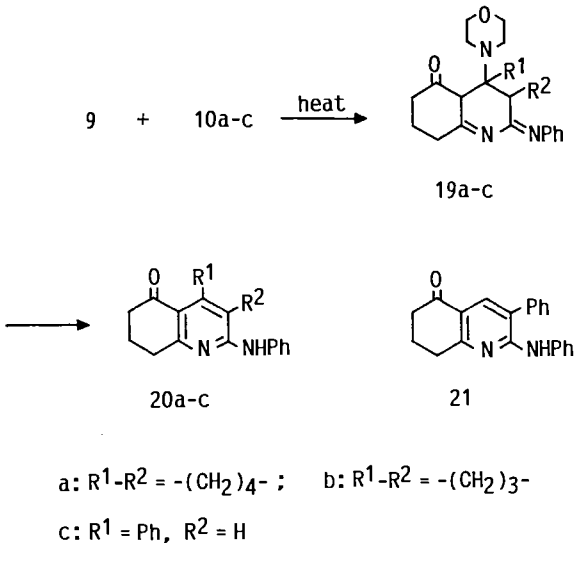


Scheme 3.



Scheme 4.

respectively. The results are summarized in Table 2. The spectral data of the new compounds were consistent with the proposed structures (Experimental). Each of the ^{1}H NMR spectra of the mixtures showed, in addition to signals for the substituted pyridine ring and phenyl group, characteristic signals for the cycloheptatriene ring and annulated methylene chain.[18]

The methylene signal of the cycloheptatriene moiety of **17a—c** appears around δ=2.4 as a triplet, and that of **18a—c** appears around δ=3.2, which is typical for 9*H*-cyclohepta[*b*]pyridines.[18] Thus, the ratio (**17**/**18**) was estimated by using these signals (Experimental). The regiochemistry of the enamine addition process giving intermediate **16a—c** was postulated as depicted in Scheme 3 by assuming a similarity to the reaction of **7**. Although the position of a phenyl group on the pyridine ring of **17c** and **18c** is unclear from the ^{1}H NMR spectrum, the structures of **17c** and **18c** have been tentatively assigned by assuming a mechanistic similarity (vide infra) to the reaction of **7** with enamine **10c**.

The reaction of the carbodiimide **9**, which could not be isolated in its pure form, with enamines **10a—c** were also examined in a one-pot procedure to give ring-annulated pyridine derivatives (Scheme 4). After a solution of iminotriphenylphosphorane **5** was reacted with phenyl isocyanate in bromobenzene at room temperature, the enamines **10a—c** were added to the solution. The mixtures were then heated under reflux to give **20a—c**. The results are summarized in Table 3. The structures of the new compounds **20a,b** were easily assigned on the basis of the spectral data. However, compound **20c** could not be differentiated from the other regioisomer **21** by spectral data. Therefore, **20c** was tentatively assigned by assuming a mechanistic similarity (vide infra) to the reaction of **7** with enamine **10c**.

On the other hand, the cycloaddition reaction of **7** with phenylacetylene in bromobenzene under refluxing for 3 h resulted in the formation of a pair of regioisomers, **23** and **15c**, in 5 and 2% yields, respectively (Scheme 5). This reaction was not regioselec-

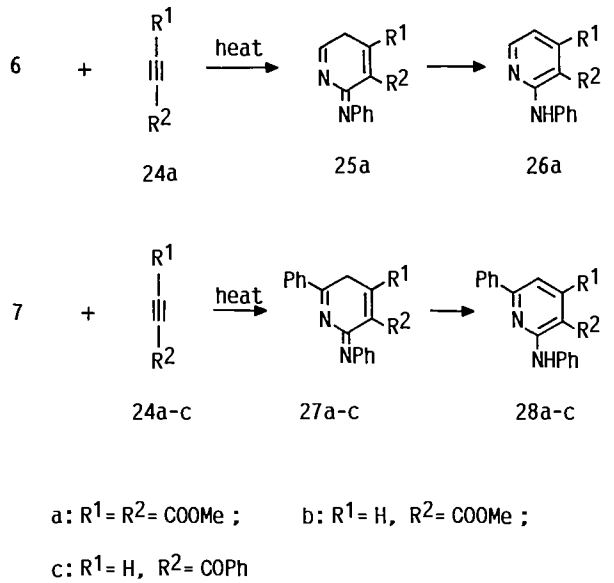

Scheme 6.

tive, and the new compound **23** was easily assigned on the basis of a comparison of the spectral data with those of **15c**.

The cycloaddition reaction of **6** or **7** with activated acetylenes, **24a** or **24a—c**, respectively, in bromobenzene under refluxing also resulted in the formation of a pyridine derivative **26a** or **28a—c** in modest yield (Scheme 6). The results are summarized in Table 4. The spectral data of the new compounds, **26a** and **28a—c**, were consistent with the proposed structures. In the reaction of **7** with **24b,c**, regioselectivity was observed and only one regioisomer was obtained in each case. The regioselectivity was rationalized with the frontier molecular orbital consideration (vide infra).

Molecular Orbital Consideration. A frontier molecular orbital treatment has been successfully applied in order to rationalize both the reactivity and regioselectivity of cycloaddition reactions.[21] We found that this treatment predicts the high regioselectivity for cycloaddition reactions of the vinylcarbodiimide **7**. The frontier orbital energies and coefficients of butadiene (**29**), 2-aza-1,3-butadiene (**30**), vinylcarbodiimide (**31**) (model for **6**, **7**, **8**, and **9**), aminoethylene (**32**) (model for enamines **10a—c**), acetylene (**33**) (model for phenylacetylene), and propynal (**34**) (model for activated acetylenes **24a—c**) were estimated using the MNDO method (Fig. 2). In the [4+2] cycloaddition reaction, both the HOMO(diene)-LUMO(dienophile) and LUMO(diene)-HOMO(dienophile) interactions are important.[21] Since the HOMO of propynal (**34**) is located in a plane including the molecular framework (H-C≡CCH=O), the NHOMO is considered to be the frontier orbital. As shown in Fig. 2, the energy levels of HOMO and LUMO of vinylcarbodiimide **31** are lower than those of butadiene (**29**) and 2-aza-1,3-butadiene (**30**). The lower energy of LUMO (**31**) would increase the interaction with HOMO of dienophiles, such as aminoethylene (**32**). The magnitudes of coefficients of the LUMO (**31**)-HOMO (**32**) interactions were in accord with the observed regioselectivity in the reaction of **7** with unsymmetrical enamine **10c**. Carbodiimide **6**, **7**, **8**, and **9**, all of which have a phenyl group on the nitrogen atom, and **7**, **8**, and **9** are further conjugated with phenyl, C=C and C=O double bond, respectively. Consequently, the energy level of the

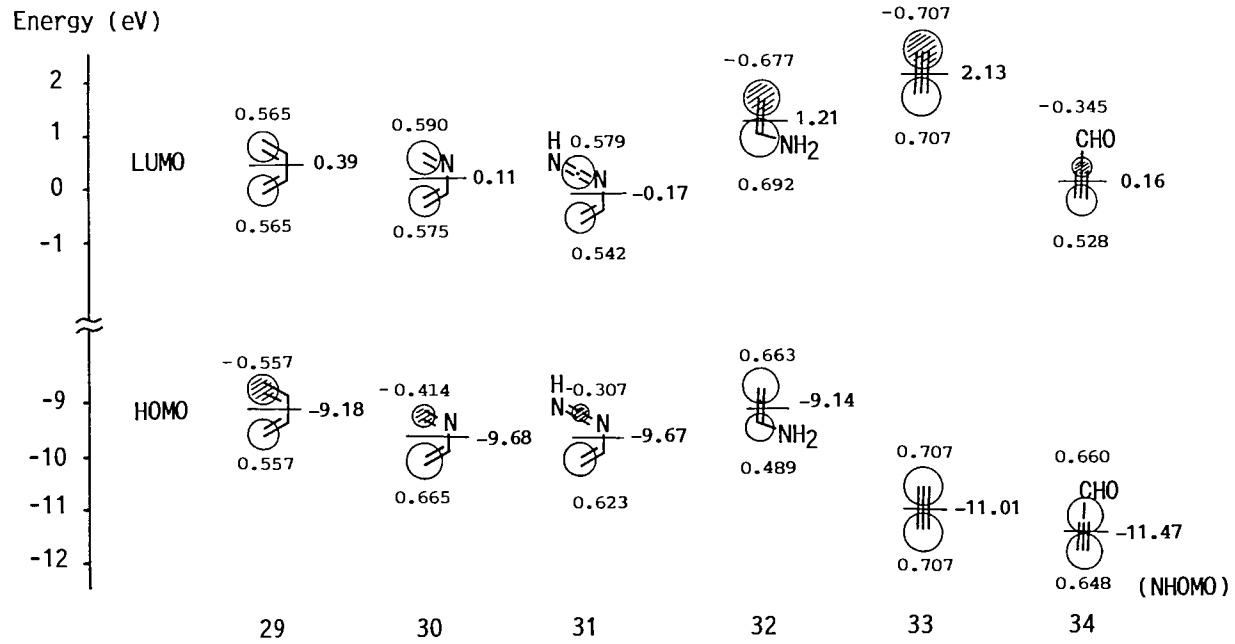

Fig. 2. Energies and coefficients of HOMO and LUMO estimated with MNDO method.

HOMO's of these compounds are expected to be raised and those of the LUMO's are lowered, and the LUMO(**6**—**9**)-HOMO(**10a**—**c**) interaction seems to be operative in the reaction of *N*-vinylcarbodiimides with enamines. Thus, the assignments of the structures of **17c**, **18c**, and **20c** also seems to be reasonable.

On the contrary, the lower energy of the LUMO (**34**) would increase the interaction with HOMO (**31**). The magnitude of the coefficient of the HOMO of **31** was also in accord with the observed regioselectivity in the reaction of **7** with unsymmetrical activated acetylenes, **24b,c**. In the reaction of **7** with phenylacetylene (**22**), the regioselectivity was not observed, and a pair of regioisomers was obtained.

In conclusion, the *N*-phenyl-*N'*-vinylcarbodiimides, which are easily prepared by the reaction of (vinylimino)triphenylphosphoranes with phenyl isocyanate, underwent a regioselective [4+2] cycloaddition reaction with electron-rich enamines as well as activated acetylenes. This type of cycloaddition reaction could also serve as a convenient route for the preparation of pyridines and an annulated pyridine ring system.

Experimental

The IR spectra were recorded on a Shimadzu IR-400 spectrometer. The ^{1}H NMR spectra were recorded on a Hitachi R-24, R-90H, JEOL JNM-PMX60SI, and JNM-GSX400 spectrometers, and the chemical shifts are given in ppm (δ) relative to the internal $SiMe_4$ standard. Mass spectral and high-resolution mass spectral studies were run on a Shimadzu GCMS-QP1000 or a JEOL DX-300 spectrometer. All of the melting points are uncorrected.

Preparation of *N*-Phenyl-*N'*-vinylcarbodiimide (6). A solution of (vinylimino)triphenylphosphorane (**2**)[18] (303 mg, 1 mmol) and phenyl isocyanate (143 mg, 1.2 mmol) in anhydrous benzene (5 ml) was refluxed for 4 h under a nitrogen atmosphere. After the reaction mixture was concentrated in vacuo, the residue was dissolved in hexane and the mixture was filtered to remove insoluble materials. The filtrate was concentrated and chromatographed on silica gel using hexane as an eluent to give **6** (74 mg, 51%): ^{1}H NMR (60 MHz, CCl_4) δ=4.73 (1H, d, J=7.6 Hz, H-*trans*), 5.06 (1H, d, J=15.0 Hz, H-*gem*), 6.43 (1H, dd, J=15.0, 7.6 Hz, H-*cis*), 7.01—7.36 (5H, m, Ph); IR (film) 3056, 2914, 2139, 1623, 1594, 1449, 1487, 1202, 1161, 1070, 755 cm^{-1}. Found: m/z 144.0651. Calcd for $C_9H_8N_2$: 144.0688.

Preparation of *N*-Phenyl-*N'*-(1-phenylvinyl)carbodiimide (7). A solution of [(1-phenylvinyl)imino]triphenylphosphorane (**3**) (3.78 g, 10 mmol) and phenyl isocyanate (1.19 g, 10 mmol) in anhydrous benzene (20 ml) was stirred for 30 min at room temperature under a nitrogen atmosphere. After the reaction mixture was concentrated in vacuo, hexane was added to the residue. The mixture was filtered to remove any insoluble materials, and the filtrate was concentrated. The resulting residue was chromatographed on silica gel using ether-hexane (1/49) as an eluent to give **7** (1.65 g, 75%): ^{1}H NMR (60 MHz, CCl_4) δ=5.08 (1H, s, H-*cis*), 5.25 (1H, s, H-*trans*), 7.00—7.69 (10H, m, Ph); IR (film) 3040, 2258, 2132, 1586, 1480, 1253, 1195, 749 cm^{-1}. Found: m/z 220.0995. Calcd for $C_{15}H_{12}N_2$: M, 220.1002.

Preparation of *N*-(1,3,5-Cycloheptatrienyl)-*N'*-phenylcarbodiimide (8). A solution of [(1,3,5-cycloheptatrienyl)imino]triphenylphosphorane (**4**) (3.67 g, 10 mmol) and phenyl isocyanate (1.19 g, 10 mmol) in anhydrous benzene was stirred for 20 min at room temperature under a nitrogen atmosphere. The reaction mixture was concentrated in vacuo and hexane was added to the residue. After the mixture was filtered to remove any insoluble materials, the filtrate was concentrated and the residue was chromatographed on silica gel using ether-hexane (1/19) as an eluent to give **8** (1.70 g, 82%): ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.61 (2H, d, J=6.9 Hz, H-7), 5.45 (1H, td, J=7.1, 9.0 Hz, H-6), 6.00—6.10 (1H, m, H-2), 6.22 (1H, dm, J=9.0 Hz, H-5), 6.40—6.50 (2H, m, H-3,4), 7.00—7.40 (5H, m, Ph); IR (film) 3016, 2881, 2123, 1611, 1593, 1501, 1239, 1161, 1072, 756, 708, 690 cm^{-1} Found: m/z 208.1001. Calcd for $C_{14}H_{12}N_2$: M, 208.1002.

Reaction of 6 with Enamine 10a. A solution of **6** (74 mg, 0.5 mmol) and enamine **10a** (167 mg, 1 mmol) in anhydrous toluene (3 ml) was refluxed for 15 min under a nitrogen atmosphere. The reaction mixture was separated by TLC on silica gel using AcOEt-hexane (1/2) as a developer to give 5,6,7,8-tetrahydro-1-(phenylamino)isoquinoline **12** (10 mg, 6%): Mp 181—182.5 °C (picrate); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.65—2.00 (4H, m, H-6, 7), 2.33—2.71 (4H, m, H-5, 8), 6.15 (1H, broad s, NH), 6.40 (1H, d, J=5.0 Hz, H-4), 6.90—7.00 (1H, m, Ph), 7.14—7.51 (4H, m, Ph), 7.85 (1H, d, J=5.0 Hz, H-3); IR ($CHCl_3$) 3422, 2925, 1606, 1578, 1518, 1502, 1443, 1388, 1358 cm^{-1}. Found: m/z 224.1303. Calcd for $C_{15}H_{16}N_2$: M, 224.1315.

General Procedure for the Reaction of 7 with Enamines 10a—c and 13a,b. A solution of **7** (110 mg, 0.5 mmol) and enamines **10a**—**c** and **13a,b** (3 molar equiv) in anhydrous bromobenzene (3 ml) was refluxed for 30 min under a nitrogen atmosphere. The reaction mixture was chromatographed on silica gel using AcOEt-hexane (1/19) as an eluent to give pyridine derivatives **15a**—**c**. The results are summarized in Table 1. The structural proof for the pyridine derivatives **15a**—**c** were based on the following physical data.

5,6,7,8-Tetrahydro-1-phenylamino-3-phenylisoquinoline (**15a**): Mp 159—160 °C (from ethanol); ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.60—2.00 (4H, m, H-6, 7), 2.30—2.90 (4H, m, H-5, 8), 6.19 (1H, broad s, NH), 6.90—7.50 (7H, m, H-4 and Ph), 7.68 (2H, dm, J=7.8 Hz, Ph), 7.90—8.10 (2H, m, Ph); IR ($CHCl_3$) 3456, 3014, 2936, 1603, 1571, 1517, 1495, 1425, 1409, 1389 cm^{-1}. Found: m/z 300.1639. Calcd for $C_{21}H_{20}N_2$: M, 300.1628.

6,7-Dihydro-1-phenylamino-3-phenyl-5*H*-cyclopenta[*c*]pyridine (**15b**): Mp 128.5—129.5 °C (from ethanol); ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.85—2.35 (2H, m, H-6), 2.66 (2H, t, J=7.0 Hz, H-7), 2.85 (2H, t, J=6.2 Hz, H-5), 6.00 (1H, broad s, NH), 6.90—7.50 (7H, m, H-4 and Ph), 7.60 (2H, dm, J=8.0 Hz, Ph), 7.90—8.10 (2H, m, Ph); IR ($CHCl_3$) 3441, 3011, 2961, 1605, 1573, 1521, 1497, 1447, 1413, 1401 cm^{-1}. Found: m/z 286.1480. Calcd for $C_{20}H_{18}N_2$: M, 286.1471.

2-Phenylamino-4,6-diphenylpyridine (**15c**): Mp 220.5—222.0 °C (picrate): ^{1}H NMR (400 MHz, $CDCl_3$) δ=6.79 (1H, broad s, NH), 7.02 (1H, d, J=1.1 Hz, H-3), 7.07 (1H, tt, J=7.3, 1.1 Hz, Ph), 7.36 (2H, t, J=8.1 Hz, Ph), 7.42 (1H, d, J=1.1 Hz, H-5), 7.42—7.50 (8H, m, Ph), 7.62—7.65 (2H, m, Ph), 8.04—8.06 (2H, m, Ph); IR ($CHCl_3$) 3416, 3002, 1594,

1550, 1498, 1450, 1419, 1077, 1010 cm^{-1}. Found: *m/z* 322.1469. Calcd for $C_{23}H_{18}N_2$: M, 322.1471.

General Procedure for the Reaction of 8 with 10a—c. A solution of **8** (104 mg, 0.5 mmol) and enamines **10a—c** (3 molar equiv) in anhydrous bromobenzene (2 ml) was refluxed for 30 min under nitrogen atmosphere. The reaction mixture was chromatographed on silica gel using AcOEt-hexane (1/19) as an eluent to give a mixture of pyridine derivatives **17a—c** and **18a—c**. The results are summarized in Table 2.

2,3,4,7-Tetrahydro-5-phenylamino-1*H*-cyclohepta[*c*]-isoquinoline (**17a**) and 2,3,4,9-tetrahydro-5-phenylamino-1*H*-cyclohepta[*c*]isoquinoline (**18a**): ^1H NMR (90 MHz, $CDCl_3$) δ=1.70—2.00 (4H, m, H-2, 3), 2.30—2.90 (4H, m, H-1, 4), 2.39 (0.7 H, t, *J*=6.3 Hz, **18a**-H-9), 3.13 (1.3 H, d, *J*=6.3 Hz, **17a**-H-7), 5.60—7.70 (10H, m, olefin, Ph, and NH); IR ($CHCl_3$) 3456, 3011, 2941, 2876, 1598, 1581, 1555, 1499, 1441, 1381 cm^{-1}. Found: *m/z* 288.1619. Calcd for $C_{20}H_{20}N_2$: M, 288.1628.

1,2,3,6-Tetrahydro-4-(phenylamino)cyclohepta[*b*]cyclopenta[*d*]pyridine (**17b**) and 1,2,3,8-tetrahydro-4-(phenylamino)cyclohepta[*b*]cyclopenta[*d*]pyridine (**18b**): ^1H NMR (90 MHz, $CDCl_3$) δ=1.95—2.25 (2H, m, H-2), 2.44 (1.5H, t, *J*=6.7 Hz, **18b**-H-8), 2.50—3.00 (4H, m, H-1, 3), 3.18 (0.5H, d, *J*=6.8 Hz, **17b**-H-6), 5.50—7.70 (10H, m, olefin, Ph, and NH); IR ($CHCl_3$) 3440, 2965, 2855, 1587, 1567, 1499, 1437, 1395, 1369, 1303, 910 cm^{-1}. Found: *m/z* 274.1481. Calcd for $C_{19}H_{18}N_2$: M, 274.1471.

4-Phenyl-2-phenylamino-9*H*-cyclohepta[*b*]pyridine (**17c**) and 4-phenyl-2-phenylamino-7*H*-cyclohepta[*b*]pyridine (**18c**): ^1H NMR (60 MHz, CCl_4) δ=2.45 (0.8H, t, *J*=6.6 Hz, **18c**-H-7), 3.09 (1.2H, d, *J*=6.0 Hz, **17c**-H-9), 5.50—7.32 (16H, m, olefin, H-4, Ph, and NH); IR ($CHCl_3$) 3416, 3011, 1593, 1561, 1497, 1417, 1401 cm^{-1}. Found: *m/z* 310.1482. Calcd for $C_{22}H_{18}N_2$: M, 310.1471.

General Procedure for the Reaction of *N*-(3-Oxo-1-cyclohexenyl)-*N'*-phenylcarbodiimide (9) with Enamines 10a—c. A solution of [(3-oxo-1-cyclohexenyl)imino]-triphenylphosphorane (**10**) (186 mg, 0.5 mmol) and phenyl isocyanate (71 mg, 0.6 mmol) in anhydrous bromobenzene (3 ml) was stirred for 1 h under a nitrogen atmosphere. To the solution was added enamines **10a—c** (3 molar equiv) and the mixture was refluxed another 3 h. The reaction mixture was concentrated and the residue was chromatographed on silica gel using AcOEt-hexane (1/4) as an eluent to give quinoline derivatives **20a—c**. The results are summarized in Table 3.

6-Phenylamino-3,4,7,8,9,10-hexahydro-1(2*H*)-phenanthridinone (**20a**): Mp 164—165 °C (from ethanol); ^1H NMR (60 MHz, $CDCl_3$) δ=1.60—2.20 (6H, m, H-3, 8, 9), 2.20—2.75 (4H, m, H-2, 7), 2.85—3.30 (4H, m, H-4, 10), 6.49 (1H, broad s, NH), 6.80—7.40 (3H, m, Ph), 7.62 (2H, dm, *J*=8.0 Hz, Ph); IR ($CHCl_3$) 3451, 3006, 2946, 2876, 1657, 1598, 1563, 1497, 1438, 1375, 1271, 1179 cm^{-1}. Found: *m/z* 292.1573. Calcd for $C_{19}H_{20}N_2O$: M, 292.1577.

4-Phenylamino-1,2,3,6,7,8-hexahydro-9*H*-cyclopenta-[*c*]quinolin-9-one (**20b**): Mp 182.5—183.5 °C (from ethanol); ^1H NMR (60 MHz, $CDCl_3$) δ=1.90—2.40 (4H, m, H-2, 7), 2.40—2.70 (4H, m, H-3, 8), 3.02 (2H, t, *J*=6.0 Hz, H-6), 3.34 (2H, t, *J*=8.0 Hz, H-1), 6.30 (1H, broad s, NH), 6.90—7.40 (3H, m, Ph), 7.62 (2H, dm, *J*=8.0 Hz, Ph); IR ($CHCl_3$) 3436, 2956, 1661, 1605, 1573, 1497, 1443, 1369, 1271 cm^{-1}. Found: *m/z* 278.1405. Calcd for $C_{18}H_{18}N_2O$: M, 278.1420.

4-Phenyl-2-phenylamino-7,8-dihydro-5(6*H*)-quinolinone (**20c**): Mp 182.5—183.5 °C (from ethanol); ^1H NMR (60 MHz, $CDCl_3$) δ=1.90—2.35 (2H, m, H-7), 2.54 (2H, t, *J*=6.0 Hz, H-6), 2.99 (2H, t, *J*=5.9 Hz, H-8), 6.40 (1H, s, NH), 6.90—8.00 (11H, m, H-3 and Ph); IR ($CHCl_3$) 3406, 3011, 2956, 1663, 1581, 1543, 1493, 1411, 1289 cm^{-1}. Found: *m/z* 314.1427. Calcd for $C_{21}H_{18}N_2O$: M, 314.1420.

Reaction of 7 with Phenylacetylene (22). A solution of **7** (1.01 g, 4.59 mmol) and phenylacetylene (1.40 g, 13.7 mmol) in anhydrous bromobenzene (3 ml) was refluxed for 3 h. The reaction mixture was separated by column chromatography on silica gel. The fractions eluted with ether-hexane (1/49) contained 2-phenylamino-3,6-diphenylpyridine (**23**) (81 mg, 5%): Mp 115.5—116 °C (from ethanol); ^1H NMR (400 MHz, $CDCl_3$) δ=6.66 (1H, broad s, NH), 6.99 (1H, tt, *J*=7.3, 1.1 Hz, Ph), 7.30 (2H, tm, *J*=7.3 Hz, Ph), 7.34 (1H, d, *J*=7.7 Hz, H-5), 7.41 (1H, tt, *J*=7.3, 1.1 Hz, Ph), 7.43—7.53 (8H, m, H-4 and Ph), 7.67 (2H, broad d, *J*=7.7 Hz, Ph), 8.08—8.10 (2H, m, Ph); IR (KBr) 3406, 3051, 1603, 1587, 1563, 1519, 1493, 1429, 1409, 1331, 1184, 750, 694 cm^{-1}. Found: *m/z* 322.1447. Calcd for $C_{23}H_{18}N_2$: M, 322.1471.

The fractions eluted with AcOEt-hexane (5/95) contained **15c** (26 mg, 2%).

Reaction of 6 with Dimethyl Acetylenedicarboxylate (24a). A solution of **6** (30 mg, 0.21 mmol) and **24a** (118 mg, 0.84 mmol) in anhydrous toluene (2 ml) was refluxed for 72 h under nitrogen atmosphere. The reaction mixture was concentrated and separated by TLC on silica gel using AcOEt-hexane (5/1) as a developer to give 2-phenylamino-3,4-bis(methoxycarbonyl)pyridine (**26a**) (12 mg, 20%): Mp 145.5—147 °C (picrate); ^1H NMR (90 MHz, $CDCl_3$) δ=3.91 (6H, s, Me), 6.74 (1H, d, *J*=3.2 Hz, H-5), 7.07 (1H, t, *J*=8.1 Hz, Ph), 7.33 (2H, t, *J*=8.1 Hz, Ph), 7.58 (2H, d, *J*=8.1 Hz, Ph), 8.39 (1H, d, *J*=3.2 Hz, H-6), 9.64 (1H, broad s, NH); IR ($CHCl_3$) 3337, 3008, 2960, 1731, 1697, 1600, 1580, 1562, 1525, 1434, 1286, 1158, 1122, 1014 cm^{-1}. Found: *m/z* 286.0941. Calcd for $C_{15}H_{14}N_2O_4$: M, 286.0954.

General Procedure for the Reaction of 7 with 24a—c. A solution of **7** (110 mg, 0.5 mmol) and **24a—c** in anhydrous bromobenzene (3 ml) was refluxed for the period indicated in Table 4 under a nitrogen atmosphere. The reaction mixture was concentrated and the residue was chromatographed on silica gel using CH_2Cl_2. The fractions eluted with CH_2Cl_2 were concentrated and further separated by TLC on silica gel using AcOEt-hexane (3/1) as a developer to give pyridine derivatives **28a—c**. The results are summarized in Table 4.

2-Phenylamino-6-phenyl-3,4-bis(methoxycarbonyl)pyridine (**28a**): Mp 107.0—107.5 °C (from ethanol); ^1H NMR (90 MHz, $CDCl_3$) δ=3.82 (3H, s, Me), 3.87 (3H, s, Me), 7.00—7.50 (7H, m, H-5 and Ph), 7.70 (2H, dm, *J*=8.0 Hz, Ph), 7.90—8.10 (2H, m, Ph), 9.85 (1H, broad s, NH); IR ($CHCl_3$) 3325, 3000, 2945, 1733, 1688, 1599, 1578, 1549, 1241, 1160, 1126 cm^{-1}. Found: *m/z* 362.1247. Calcd for $C_{21}H_{18}N_2O_4$: M, 362.1267.

2-Phenylamino-6-phenyl-3-(methoxycarbonyl)pyridine (**28b**): Mp 66.5—67.0 °C (from ethanol); ^1H NMR (90 MHz, $CDCl_3$) δ=3.88 (3H, s, Me), 6.90—7.50 (6H, m, Ph), 7.14 (1H, d, *J*=8.1 Hz, H-5), 7.73—8.00 (4H, m, Ph), 8.22 (1H, d, *J*=8.1 Hz, H-4), 10.23 (1H, broad s, NH); IR ($CHCl_3$) 3325, 3004, 2857, 1586, 1603, 1590, 1571, 1293, 1251, 1146 cm^{-1}. Found: *m/z* 304.1231. Calcd for $C_{19}H_{16}N_2O_2$: M, 304.1213.

3-Benzoyl-2-phenylamino-6-phenylpyridine (**28c**): Mp 118.0—118.5 °C (from ethanol); ^{1}H NMR (90 MHz, $CDCl_3$) δ=6.90—7.60 (11H, m, Ar), 7.12 (1H, d, J=8.4 Hz, H-3), 7.75—8.10 (4H, m, Ph), 7.88 (1H, d, J=8.4 Hz, H-4), 11.10 (1H, broad s, NH); IR ($CHCl_3$) 3280, 3008, 1601, 1590, 1563, 1519, 1500, 1298, 1245, 909 cm^{-1}. Found: m/z 350.1409. Calcd for $C_{24}H_{18}N_2O$: M, 350.1420.

Cross-Dehydrocycloaddition of 1,3-Butadiene with Isoprene over MgO and ZrO_2

Hiroyasu SUZUKA and Hideshi HATTORI*
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received October 3, 1990)

A mixture comprising of equal amounts of 1,3-butadiene (BD) and isoprene (IPN) was allowed to react over MgO and ZrO_2 at 473 K in order to examine the relation between the product distribution and the reaction mechanisms. Over ZrO_2 the most abundant product was 4-ethyltoluene, which was produced by a base-catalyzed Diels-Alder reaction between BD and IPN, followed by double-bond migration and dehydrogenation. In the Diels-Alder reaction, IPN acts as a diene and BD acts as a dienophile. Over MgO, *o*-xylene was primarily produced by anionic mechanisms. Among the products formed from BD and IPN, 4-ethyltoluene was produced most, though the production of 3-ethyltoluene was considerable. The active sites on ZrO_2 were strongly poisoned by both CO_2 and NH_3. The active sites on MgO were completely poisoned by CO_2, and were modified by NH_3 in such a way that the reaction mechanisms changed from the anionic mechanisms to those involving the Diels-Alder reaction.

The dehydrocyclodimerization of dienes to aromatics has been reported to proceed over metal-acid bifunctional catalysts and solid acid catalysts at reaction temperatures above 673 K.[1-6] We recently found that the dehydrocyclodimerization of conjugated dienes to form aromatics proceeds over solid base catalysts even below 473 K. Among solid base catalysts, MgO and ZrO_2 exhibit high activity.[7] The product distribution over MgO is different from that over ZrO_2. In the dehydrocyclodimerization of 1,3-butadiene (BD), *o*- and *p*-xylenes were mainly produced over MgO, whereas ethylbenzene was the main product over ZrO_2. We proposed that different mechanisms operate in the reaction for MgO and ZrO_2.[8] Anionic intermediates are involved in the reaction over MgO, while the base-catalyzed Diels-Alder reaction precedes double-bond isomerization, followed by dehydrogenation over ZrO_2.

In the reaction of a mixture containing equal amounts of two different dienes, three different combinations of dienes result. In the case of a mixture containing equal amounts of BD and isoprene (IPN), products arising from combinations of BD-BD, BD-IPN, and IPN-IPN are possible. It is expected that the mechanistic differences are reflected in the product distribution caused by different combinations of the dienes. In the present study, a mixture of BD and IPN was allowed to react over MgO and ZrO_2 in order to examine how the differences in the mechanism reflect the product distribution in the cross-dehydrocycloaddition of BD with IPN.

Experimental

MgO was purchased from Merck. ZrO_2 was prepared from a 10% aqueous solution of $ZrOCl_2$ by hydrolysis with 28% aqueous ammonia to precipitate $Zr(OH)_4$ followed by washing with deionized water, drying at 373 K and calcining at 773 K.

The reactions were carried out in an all-glass H-shaped batch-type reactor. Two branches were separated by a breakable seal. A catalyst sample (200 mg) was placed in one branch, pretreated at 1073 K for MgO or 773 K for ZrO_2, and sealed. Since the product distributions were not significantly changed with the pretreatment temperature for both catalysts in the reaction of BD,[8] the pretreatment temperature was fixed at one temperature for each catalyst in the present study. The reactant, a mixture of 0.19 mmol BD and 0.19 mmol IPN, was stored in the other branch until it was introduced into the branch containing the catalyst thermostated at liquid-nitrogen temperature. The reaction was started by rapid melting of the reactant at the reaction temperature. Most of the reactions were run at 473 K for 17 h. The products were collected in a liquid-nitrogen trap and dissolved into 1 cm^3 of benzene, and then analyzed by gas chromatography. Styrene was used as an internal standard.

Poisoning experiments using carbon dioxide and ammonia as poisons were performed. Following a pretreatment of the catalyst, the poison was adsorbed at room temperature for 10 min, followed by evacuation at the same temperature for 10 min. The amounts of poisons adsorbed on the catalyst were measured as follows. The poisoned catalyst was heated to 1073 K, while the evolved poison was trapped in liquid nitrogen. The trapped poison was evaporated and measured volumetrically.

Results and Discussion

The product distributions in the reaction of a mixture containing equal amounts of BD and IPN, both with and without catalyst, are given in Table 1. Without catalyst, practically no reaction occurred at 393 K. At 473 K, though products resulting from the Diels-Alder reaction were formed, no aromatics were formed. The percentages of the products containing carbon numbers 8, 9, and 10 were 22, 52, and 26%, respectively. The ease to combine two diene molecules for a non-catalytic reaction is in the following order:

$$\text{BD}+\text{IPN} \gg \text{IPN}+\text{IPN} > \text{BD}+\text{BD}$$

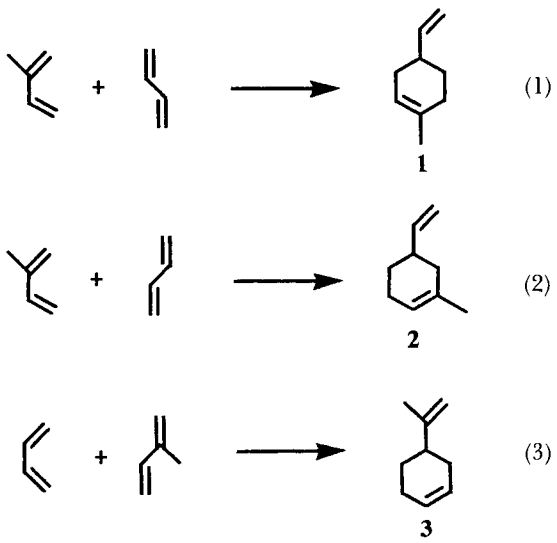
a) Mol of each product to 200 mol of a reactant mixture. C_8: dimer of 1,3-butadiene, EB: ethylbenzene, *o*-X: *o*-xylene, *p*-X: *p*-xylene, CM: isopropylbenzene (cumene), 4ET: 4-ethyltoluene, 3ET: 3-ethyltoluene, C_9: adduct of 1,3-butadiene to isoprene, C_{10}: dimer of isoprene, *p*-C: *p*-cymene, *m*-C: *m*-cymene. Gaseous compounds were produced, but not counted into calculation of composition. Catalyst weight 200 mg, Reactant: 1,3-butadiene 0.19 mmol, isoprene 0.19 mmol, Reaction time 17 h.

In the Diels-Alder reaction, both BD and IPN may act as a dienophile and diene. For the combination of BD with IPN, the possible reactions and the products are as follows:



In Eqs. 1 and 2, IPN acts as a diene and BD as a dienophile. In Eqs. 3 and 4, BD acts as a diene and IPN as a dienophile.

The product distributions among compounds containing carbon number 9, excluding aromatics, are given in Table 2. The relative amounts of 1-methyl-4-vinyl-1-cyclohexene (**1**): 1-methyl-5-vinyl-1-cyclohexene (**2**): 4-isopropenyl-1-cyclohexene (**3**): 4-methyl-4-vinyl-1-cyclohexene (**4**) were 8.5 (57.8%): 1.3 (8.8%): 3.6 (24.6%): 1.3 (8.8%), which correspond to the reaction probability of equation (1): (2): (3): (4). A reaction in which BD acts as a dienophile and IPN as a diene is predominant. This is expected because the Diels-Alder reaction is favored due to the presence of electron-releasing groups in the diene.

With a catalyst, the reaction proceeded to some extent, even at 393 K. In particular, the formation of

a) 1-Methyl-4-vinyl-1-cyclohexene. b) 1-Methyl-5-vinyl-1-cyclohexene. c) 4-Isopropenyl-1-cyclohexene. d) 4-Methyl-4-vinyl-1-cyclohexene.

aromatics was observed over ZrO_2 at this temperature. At 473 K, the product yields greatly exceeded those observed without a catalyst; the products consisted mostly of aromatics over both MgO and ZrO_2.

The product distributions were different for MgO and ZrO_2. Over ZrO_2, the percentages of the products containing carbon numbers 8, 9, and 10 were 26, 61, and 13, respectively. These percentages are close to those observed in non-catalytic product distribution, 22 : 52 : 26. The ease to combine two diene molecules for a ZrO_2-catalyzed reaction is in the following order:

$$BD + IPN \gg BD + BD > IPN + IPN$$

The combination of BD with IPN is the most favorable. A small difference in the combination between a ZrO_2-catalyzed reaction and a non-catalytic reaction is that the combination of two BD molecules is more favorable than that of two IPN molecules over ZrO_2. In a non-catalytic reaction, the combination of two IPN molecules is slightly favorable.

The relative amounts of C-9 aromatics produced over ZrO_2 were 4-ethyltoluene (6.9%), 3-ethyltoluene (1.8%), isopropylbenzene (2.6%). 4-Ethyltoluene, 3-ethyltoluene, and isopropylbenzene are formed from 1-methyl-4-vinyl-1-cyclohexene (**1**), 1-methyl-5-vinyl-1-cyclohexene (**2**) and 4-isopropenyl-1-cyclohexene (**3**), respectively, by successive double-bond migration and dehydrogenation. 4-Methyl-4-vinyl-1-cyclohexene (**4**) is not able to undergo double-bond migration and dehydrogenation and is difficult to convert to aromatics unless the C-C bond cleaves. The relative amounts of non-catalytic Diels-Alder reaction products are close to the relative amounts of the corresponding C-9 aromatics formed over ZrO_2, though the formation of 3-ethyltoluene over ZrO_2 was twice as great as that of 1-methyl-5-vinyl-1-cyclohexene by a non-catalytic Diels-Alder reaction.

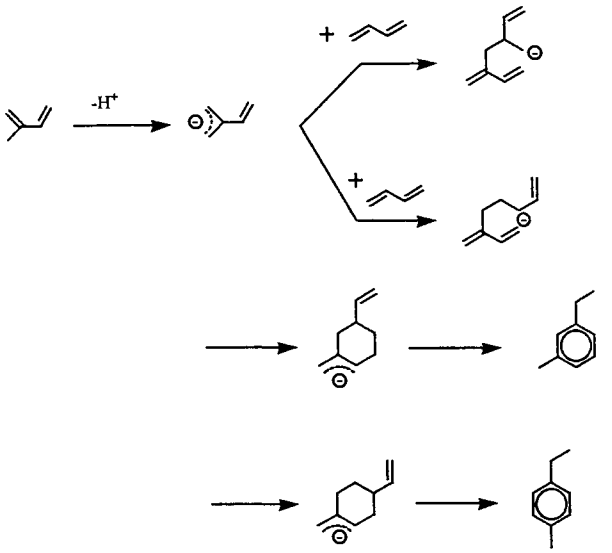
Almost the same percentages of the two main products over ZrO_2 (4-ethyltoluene and isopropylbenzene) to those produced without a catalyst (1-methyl-4-vinyl-1-cyclohexene and 4-isopropenyl-1-cyclohexene) suggest that dehydrocycloaddition results from a ZrO_2 catalyzed Diels-Alder reaction, followed by double-bond migration and dehydrogenation.

The percentages of the products for MgO were 73, 19, and 8% for products containing carbon numbers 8, 9, and 10, respectively, which are different from those for a non-catalytic reaction and a reaction over ZrO_2. The ease to combine two diene molecules over MgO is in the following order:

$$BD + BD \gg BD + IPN > IPN + IPN$$

A reaction involving two BD molecules is the most favorable combination over MgO. By this combination, *o*- and *p*-xylenes were mainly formed. As reported in a previous paper,[8] the formation of *o*- and *p*-xylenes results from anionic intermediates.

In the combination of BD with IPN, if an anionic mechanism is operating, 3-ethyltoluene would predominantly be formed as compared to 4-ethyltoluene, since the formation of 3-ethyltoluene involves a primary anion, while a less stable secondary anion is involved in the formation of 4-ethyltoluene, as illustrated below.



The ratio of 3-ethyltoluene to 4-ethyltoluene formed over MgO was 0.9/1.2, which is much larger than the ratio 1.8/6.8 over ZrO_2. This also supports the idea that the contribution of the anionic mechanism takes place to a considerable extent in a reaction over MgO, though the occurrence of a Diels-Alder reaction can not be neglected.

In the IPN molecule, the allylic hydrogen on the methyl group can be released much more easily as a proton. However, for the formation of isopropylbenzene by the anionic intermediate, an H atom on the carbon atom 4 of IPN should be abstracted, which is not plausible. Therefore, isopropylbenzene is difficult to form by an anionic mechanism. No isopropylbenzene was formed over MgO, in contrast to its formation over ZrO_2, which also suggests that the anionic mechanism is favored, compared with the Diels-Alder reaction over MgO.

As reported in the previous paper,[8] the active sites on ZrO_2 for dehydrocyclodimerization were completely poisoned by both carbon dioxide and ammonia. The poisoning effects on the active sites of MgO are different for carbon dioxide than for ammonia. Although carbon dioxide completely poisoned the active sites, ammonia modified them. The results of poisoning experiments for a mixture containing BD and IPN over MgO and ZrO_2 are given in Table 3. The amounts of the poisons retained on the surfaces were small compared with that of the reactant.

Although no aromatics were produced over the ZrO_2 poisoned by ammonia and carbon dioxide, the Diels-

a) Mol of each product to 200 mol of a reactant mixture. EB: ethylbenzene, *o*-X: *o*-xylene. C_8: dimer of 1,3-butadiene, *p*-X: *p*-xylene, CM: isopropylbenzene (cumene), 4ET: 4-ethyltoluene, 3ET: 3-ethyltoluene, C_9: adduct of 1,3-butadiene to isoprene, C_{10}: dimer of isoprene, *p*-C: *p*-cymene, *m*-C: *m*-cymene. Gaseous compounds were produced, but not counted into calculation of composition. Catalyst weight 200 mg, Reactant: 1,3-butadiene 0.19 mmol, isoprene 0.19 mmol, Reaction time 17 h, Reaction temperature: 473 K.

Alder reaction proceeded to some extent at the same level as those without a catalyst. The poisoning effect with ammonia on the activity of ZrO_2 was more severe than that with carbon dioxide. The product distribution was essentially the same as that for the non-catalytic type. The ZrO_2 poisoned by NH_3 was inert to the Diels-Alder reaction.

With a MgO catalyst, carbon dioxide completely poisoned all of the active sites. The product distribution was the same as that of the non-catalytic type.

Ammonia preadsorption decreased the activity of MgO to a small extent. However, marked effects by ammonia preadsorption appeared in the product distribution. Upon the adsorption of ammonia, the formations of *o*- and *p*-xylenes and 3-ethyltoluene greatly decreased, and isopropylbenzene, which was not formed on unpoisoned MgO, appeared. By an anionic mechanism, *o*- and *p*-xylenes as well as 3-ethyltoluene were favored; isopropylbenzene was unfavored. The decrease in the *o*- and *p*-xylenes and 3-ethyltoluene, and the formation of isopropylbenzene suggest that ammonia retards the formation of anionic intermediates, but not the Diels-Alder reaction and the following isomerization and dehydrogenation. This is consistent with the result of BD, as reported in a previous paper.[8] The relative ease to combine two diene molecules also changed upon ammonia preadsorption on MgO. The combination of BD with IPN became most favorable. The catalytic behavior of the MgO preadsorbing ammonia was similar to that of ZrO_2. Therefore, ammonia preadsorption modified the active sites on MgO so that the mechanisms for dehydrocycloaddition changed from one involving anionic intermediates to those involving a Diels-Alder reaction followed by isomerization and dehydrogenation.

Synthesis and Properties of High Molecular Weight Polypeptides Containing of Tryptophan[1)]

Yasuko IIZUKA, Toshiya ENDO,† and Masanao OYA*
Department of Biochemistry and Engineering, Faculty of Engineering,
Gunma University, Kiryu-shi, Gunma 376
(Received October 11, 1990)

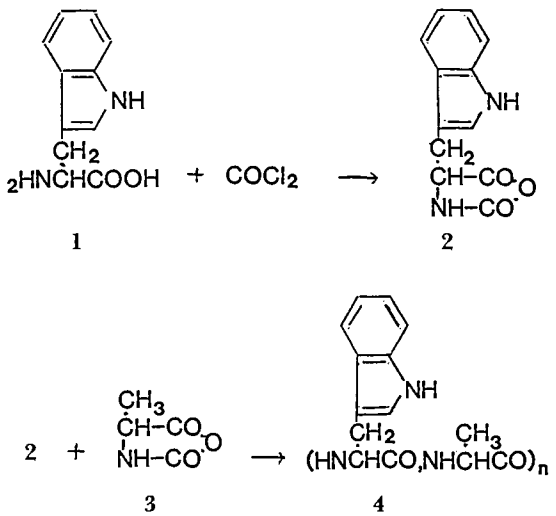
High purity *N*-carboxy-DL-tryptophan anhydride (DL-4-indoylmethyl-2,5-oxazolidinedione, DL-Trp NCA) was synthesized in good yield. Copolypeptides with a random sequence of DL-Trp with L-alanine (Ala) and DL-alanine (DL-Ala) were synthesized by copolymerization of the corresponding *N*-carboxy-α-amino acid anhydrides (NCA) in solution. Copolypeptides of DL-Trp with L-Ala and DL-Ala were partially soluble in water. The water-soluble copolypeptides of DL-Trp and L-Ala mostly gave disordered conformations, while the water-insoluble copolypeptides were found in a mixture of α- and disordered conformations. The solubility of the copolypeptides was not influence by the tryptophan content in the polypeptides but, rather, by the conformation of the polypeptides.

Tryptophan (Trp, **1**) is widely found in native proteins or several peptide hormones such as snake venom neutrotoxin, ACTH, glucagon, and tyrocidin as a minor component of one to two percent. A very small amount of tryptophan residue influences the emergence of their toxicity or higher-order conformations.[2,3)] Tryptophan has a side chain comprising the indole nucleus, which is characteristic of both a hydrophilic aromatic group and a hydrophobic indol nitrogen capable of hydrogen bonding as a donor. Tryptophan has an interesting structual arrangement in water-soluble proteins, such as cobrotoxin.[2,3)]

High molecular weight synthetic copolypeptides containing the tryptophan residue are therefore both interesting and important in the conformational and biological approach to proteins.

E. Kachalski, et al. first reported the synthesis of poly(DL- or L-tryptophan), which are obtained by the polymerization of *N*-carboxy-DL or L-tryptophan anhydride (Trp NCA) at 150 °C in a high vacuum.[4)] Cosani, et al. have reported on a block copolymer (ethyl DL-glutamate)$_m$(L-Trp)$_n$. High-molecular-weight and synthetic random copolypeptides of tryptophan, however, are very little known.[5)]

In this paper we report on the copolymerization of DL-Trp NCA (**2**) with L-Ala NCA (**3**) to produce high molecular-weight copolypeptides (**4**). In addition, the solubility and conformation of the copolypeptide in solvents and in the solid state were studied.



† Present adress: Department of Chemistry, Faculty of Science, Nagoya University, Furou-cho, Tikusa-ku, Nagoya 460-01.

Experimental

Synthesis of NCA (2,3). All NCA were prepared in high purity and good yield by a previously reported method.[6)] DL-Trp NCA was reprecipitated volumetrically by adding hexane to the ethyl acetate solution of NCA, producing high-purity DL-Trp NCA in 46% yield; mp 135—138 °C. Found: C, 61.16; H, 4.56; N, 11.46%. Calcd for $C_{12}H_{10}O_3N_2$: C, 62.60; H, 4.34; N, 12.17%.

Polymerization of NCAs. NCA were copolymerized in 1,2-dichloroethane or ethyl acetate at the concentrations given in Table 1.

Copolypeptides Soluble in Water. The copolypeptide (1g) was placed into water (100 ml) at 20—30 °C, and kept in a refrigerator for 24 h at about 8 °C. An insoluble polymer was separated on a sintered-glass filter and then washed with water and a small amount of ethanol. The residue was dried in vacuo at room temperature. The filtrate was lyophilized under reduced pressure. A water-soluble copolypeptide was obtained.

Viscosity Measurement. The viscosities of the copolypeptides were measured in a solution of 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP) using ubbelohde viscometer at 25 °C.

Gel Filtration. High-performance liquid chromatography was performed on a Shimadzu LC-6A. A column (1.3×30 cm, void volume 1×10^5) TSK Gel G3000SW was calibrated in Tris HCl (Buffer pH 7.5) using carbonic anhydrase (MW 29000), albumine, bovine serum (MW 66000), and Cytochrome C (MW 12400) as standards of the molecular weight.

Spectroscopic Measurements. Tryptophan components in the copolymers were estimated from the UV absorbance at

268 nm for solutions of the copolymers in HFIP. Circular dichroism (CD) spectra were recorded on a JASCO J-20A at wavelengths of 300 to 190 nm at 21—23 °C, using a 0.1 mm path length cell, at a concentration of about 0.03 mol/1000 cm³ (residue basis) in HFIP.

The reduced mean residue ellipticity, $[\theta]'$, was defined as

$$[\theta]' = 3 \cdot \theta / C \cdot L \cdot 10 \cdot (n^2+2),$$

where θ is the observed ellipticity in deg, L the optical path length in cm, C the polymer concentration in mol/1000 cm³ (residue basis) and n the refractive index (n_D^{20} 1.275) of the solvent.[7] The infrared spectra were recorded on a Nippon Densi JIR FX 6160 by KBr disks or nujol mull.

Results

DL-Trp NCA was copolymerized with L-Ala NCA and DL-Ala NCA in solution to produce copolypeptides. The polypeptides were obtained by filtration of the polymerization mixture and then dried in vacuo. The polymerization conditions and properties of copolypeptides are shown in Table 1.

Yields of copolypeptides were remarkably decreased by increasing the fed Trp NCA. The composition of the Trp residue in the copolymer formed was normally less than that of the initial monomer ratio. Katchalski reported the polymerization of Trp NCA in the fusion state because of difficulty in the polymerization of Trp NCA in solution.[4] High-purity DL-Trp NCA polymerized at a slower rate than that of Ala NCA in a solution of 1,2-dichloroethane with butylamine as an initiator. In a previous paper we reported that when the polymerization of DL- or L-Ala NCA is initiated with butylamine, the initiation reaction is completed within 60 min, for a monomer conversion of about 10%. The polymerization reaction after this time takes place for 23 h at a conversion of about 70%; it must be proceeded only through the propagation reaction. This suggests that the initiation rate is faster than that of propagation reaction.[8] Most polymerizations of NCAs in acetonitrile were considered regarding this mechanism. The polymerizaton of NCA in 1,2-dichloroethane may proceed by almost the same mechanism as in acetonitrile. The copolymerization of L-Ala NCA with DL-Trp NCA suggests that the propagation reaction of the Trp residue with DL-Trp NCA is slower than the other propagation i.e., a reaction of the Ala residue with Ala NCA and Trp NCA, and a reaction of the Trp residue with Ala NCA.

The water-soluble parts of the obtained copolypeptides could be increased by increasing the amount of Trp NCA fed. In the copolypeptides of DL-Ala and DL-Trp, the water-soluble parts were not proportional to the contained DL-Trp residue. Although all of the copolypeptides formed were soluble in dichloroacetic acid and trifluoroacetic acid, very soon a blue precipitate separated out. Cosani determined the degree of polymerization of the copolymer by the ratio of the initiator to the amount of NCAs fed.[5] The degree of polymerization, however, did not always depend on the ratio of the monomer with the initiator when the polymerization was propagated by activated NCA.[9] The viscosity of the copolypeptides was thus measured in a solution of HFIP. The results are given in Table 1. No relationship has been studied between the viscosity of the HFIP solution and the molecular weight of the polypeptides. The molecular weights of poly(γ-benzyl L-glutamate) (poly(OBzlGlu)) and poly(DL-Ala) are given by the equations (1)[10] and (2),[8] respectively, and $[\eta]$ is given by the equation (3):

$$[\eta] = 2.78 \times 10^{-5} M^{0.87} \quad (1)$$

$$[\eta] = 5.1 \times 10^{-4} M^{0.74} \quad (2)$$

and

$$[\eta] = (\ln \eta_{rel})/c, \quad \eta_{sp} = \eta_{rel} - 1. \quad (3)$$

Here, $[\eta]$ is the intrinsic viscosity, M the molecular

a) Polymerization was initiated with butylamine (BA). at an NCA-to-BA molar ratio of 200 at 30 °C for 15 d in 1,2-dichloroethane. b) Polymerization was initiated with BA at an NCA-to-BA molar ratio 100, at 30 °C for 14 d in ethyl acetate. c) c=0.25 g/100 cm³ in HFIP. d) c=0.1 g/100 cm³. e) c=0.25 g/100 cm³ in mixed solvent HFIP/DCE: 4/1. Insoluble part of 7—10b have low solubility to measure the viscosity of solutions. f) Yield after cutting off a low molecular weight by dialysis tube of 3000 dalton.

weight of the polymer, c the concentration of the polymer (g/100 cm^3), η_{rel} the relative viscosity, and η_{sp}/c the specific viscosity of the dichloroacetic acid solution. The specific viscosity of the poly(OBzl-Glu), with a molecular weight of 20000, is 0.04 in a solution of HFIP at a concentration of 0.5 g/100 cm^3 at 30 °C. The specific viscosity of poly(DL-Ala) with a molecular weight of 6000 (determined by the specific viscosity 0.45 in dichloroacetic acid) was 0.4 in HFIP at 25 °C at a concentration of 0.25 g/100 cm^3. T. Ozaki, et al.[11] reported that in the oligomeric peptides derived from OBzlGlu the formation of α-helix begins in the range from the hexapeptides to the octapeptides derived from γ-benzyl L-glutamate. Most oligomeric peptides are capable of forming a secondary structure, such as an α-helix or β-sheet conformation, in a range which is almost the same as the chain length of poly(OBzlGlu). Gel permitation chromatography was carried out in order to evaluate the relation between the specific viscosity and molecular weight of copoly(Trp, Ala). The result (Fig. 1) shows that the specific viscosity of a copolymer (No. 3,(A)) with a molecular weight of 15000—18000, (plotted as a calibration curve for the elution parameter) is 0.16 in HFIP. This suggests that these copoly(Trp, Ala) have a chain length which is capable of constructing a secondary conformation, such as an α-helix or β-structure. Poly(L-Ala) is insoluble in water, and poly(DL-Trp) partly soluble. Entry 1 in Table 1 is for a copolypeptide formed containing 2.2% of a water-soluble copolypeptide which contains 2.4 mol% of the Trp residue. The indol nucleus of the Trp residue exerts a hydrophilic group in the copolypeptides. The insoluble part of the copolypeptides mentioned in the same entry, however, contained 2.7 mol% of the Trp residues. The tryptophan content in the water-soluble copolypeptide was less than that in the water-insoluble copolypeptide in each entry. The viscosity of the water-soluble parts was lower than that of the water-insoluble parts in each entry. This suggests that the solubility of the copolypeptides in water is essentially independent of the rate of the tryptophan residue in the copolypeptides.

The circular dichroism spectra observed for water-insoluble copolypeptides (Table 1) are shown in Figs. 2-1 and -2. The CD spectra of the polypeptides in the helical, β-sheet, and random forms have been studied extensively.[12-17] The ellipticity bands between 185 and 225 nm are associated with the α-helix, β-sheet, and random-coil peptide. The negative dichroisms near 206 and 220 nm have been used for assigning the helix, and the strong negative band near 190 nm for the random-coil of the polypeptides. The insoluble polymer (No. 1—4 in Fig. 2) exhibited a maximum peak at about 190 nm, a minimum at 204 nm, and a shoulder peak at about 220 nm. For all four poly-

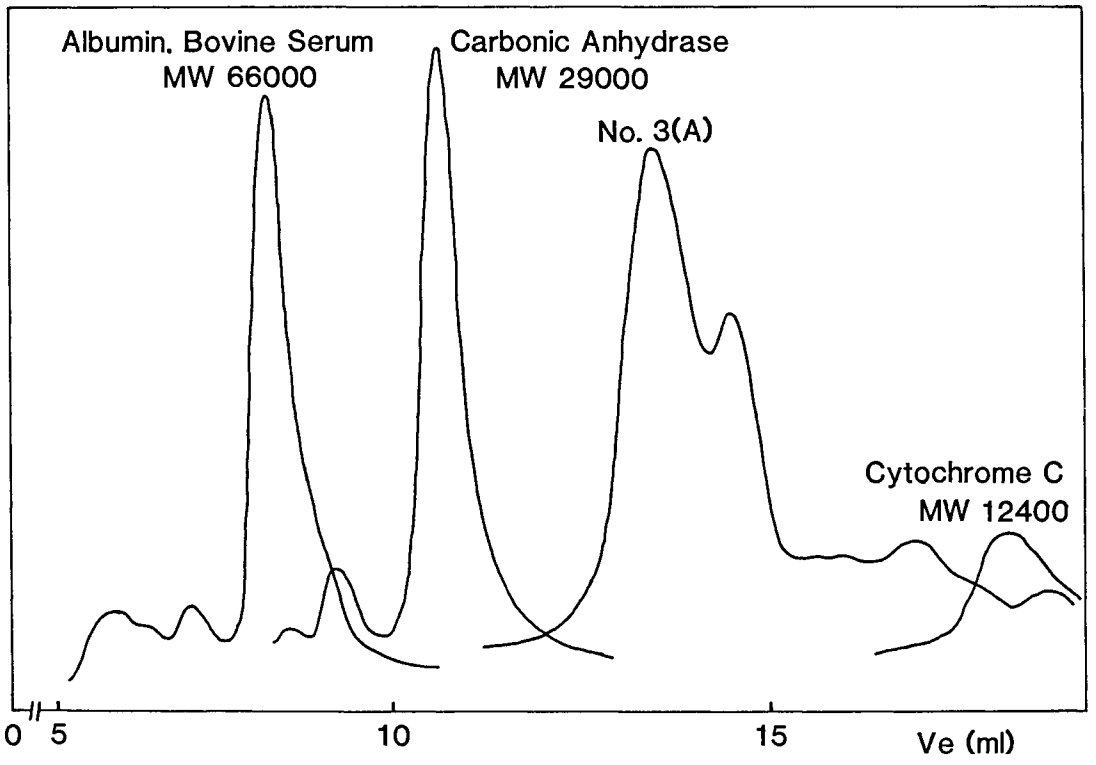

Fig. 1. GPC elution curve of water-soluble copolymer No. 3(A) after dialysis and cutting off MW below 3000) and standard proteins. Column; TSK Gel G3000SW, Developer: 100 mM Tris (pH 7.0), Flow: 0.3 ml min^{-1}, Wave: 280 nm.

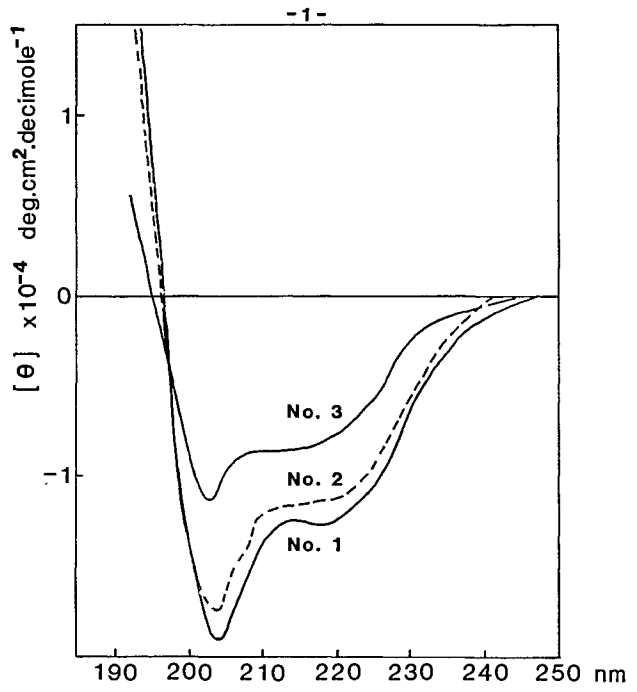

Fig. 2-1. Circular dichroism spectra of water-insoluble copolypeptides(B) shown in Table 1.

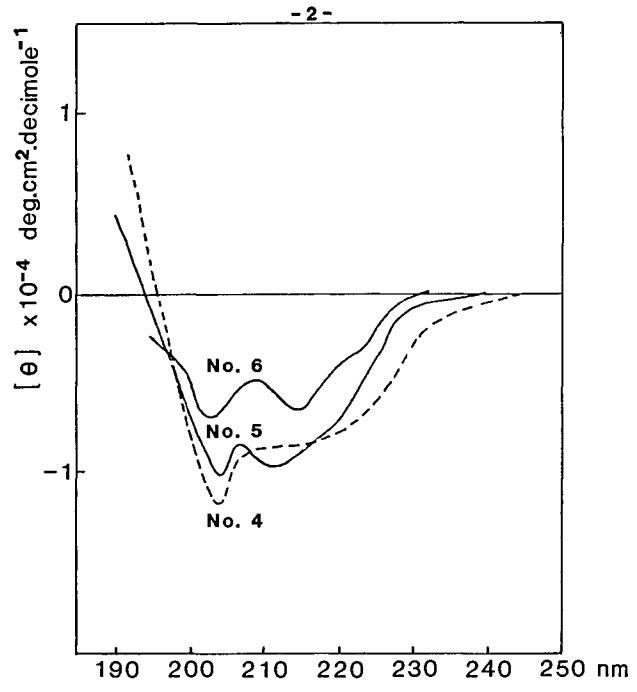

Fig. 2-2. Circular dichroism spectra of water insoluble copolyptides(B) shown in Table 1.

mers given in Fig. 2, the spectra indicate that a right-handed α-helix conformation can be assumed. The intensity of negative peak, which is proportional to the helix content, was decreased by an increase in the tryptophan residue. Polymers No. 5 and 6 given in Fig. 2 have two negative peaks at 212 and 216 nm, respectively, in addition to those of Entries 1—4. These differences in the spectrum patterns could result in an overlapping pattern of the α-helix with β I. The CD spectra of many water-soluble copolypeptides shown in Table 1 (Fig. 3) gave a minimum peak at 197 nm. Furthermore, a minimum peak was observed at

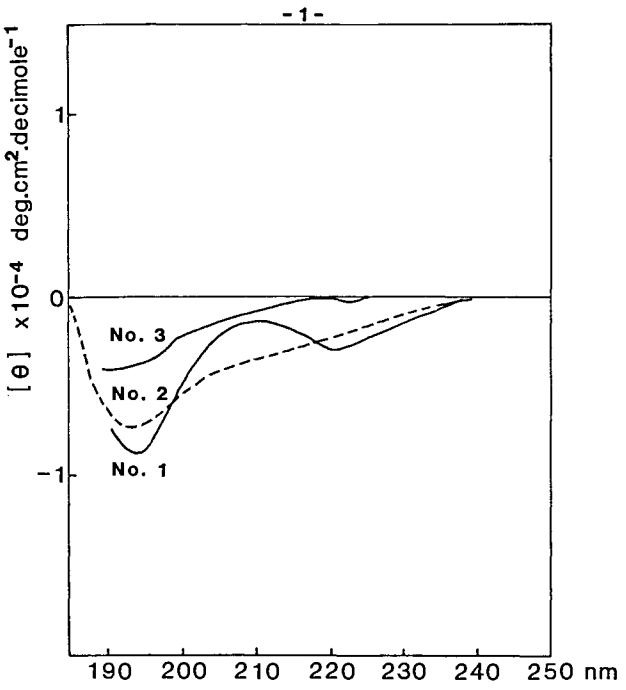

Fig. 3-1. Circular dichroism spectra of water-soluble copolypeptides(A) shown in Table 1.

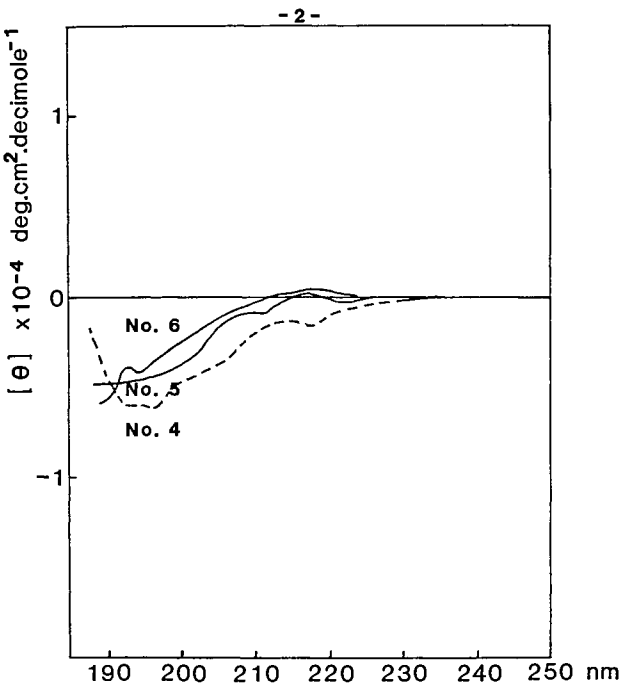

Fig. 3-2. Circular dichroism spectra of water-soluble copolypeptides(A) shown in Table 1.

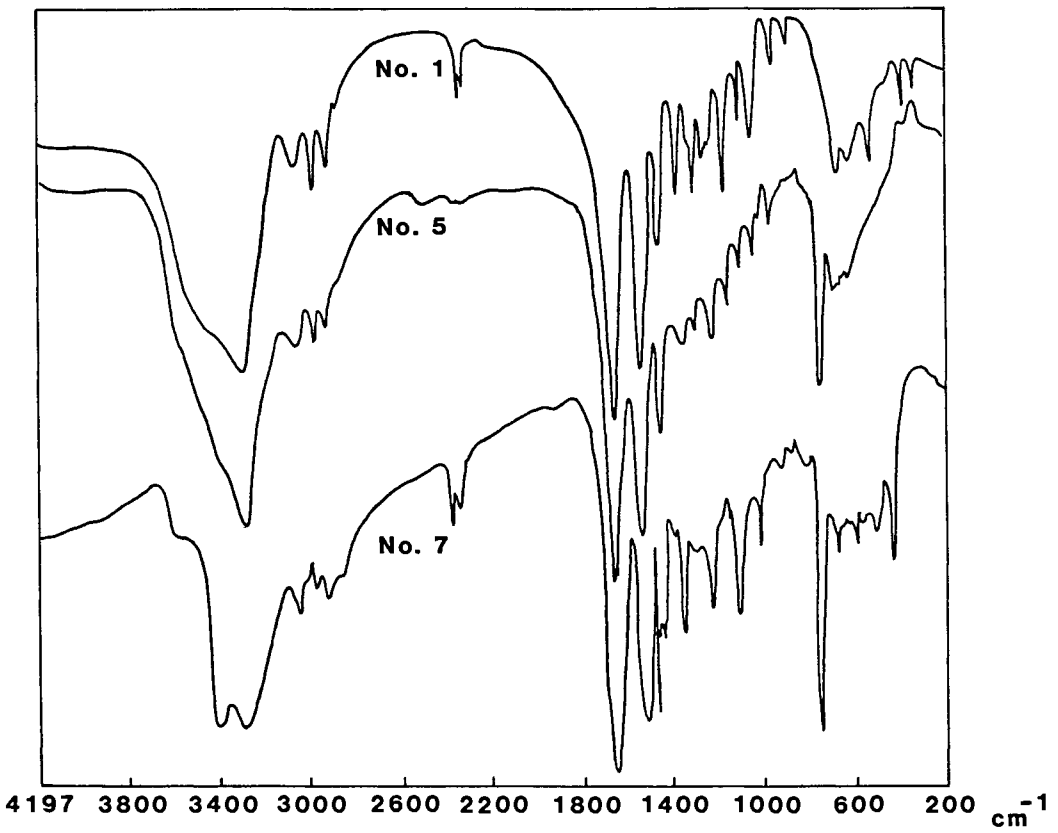

Fig. 4. Infrared spectra of water-insoluble copolypetides(B) shown in Table 1 in KBr disk.

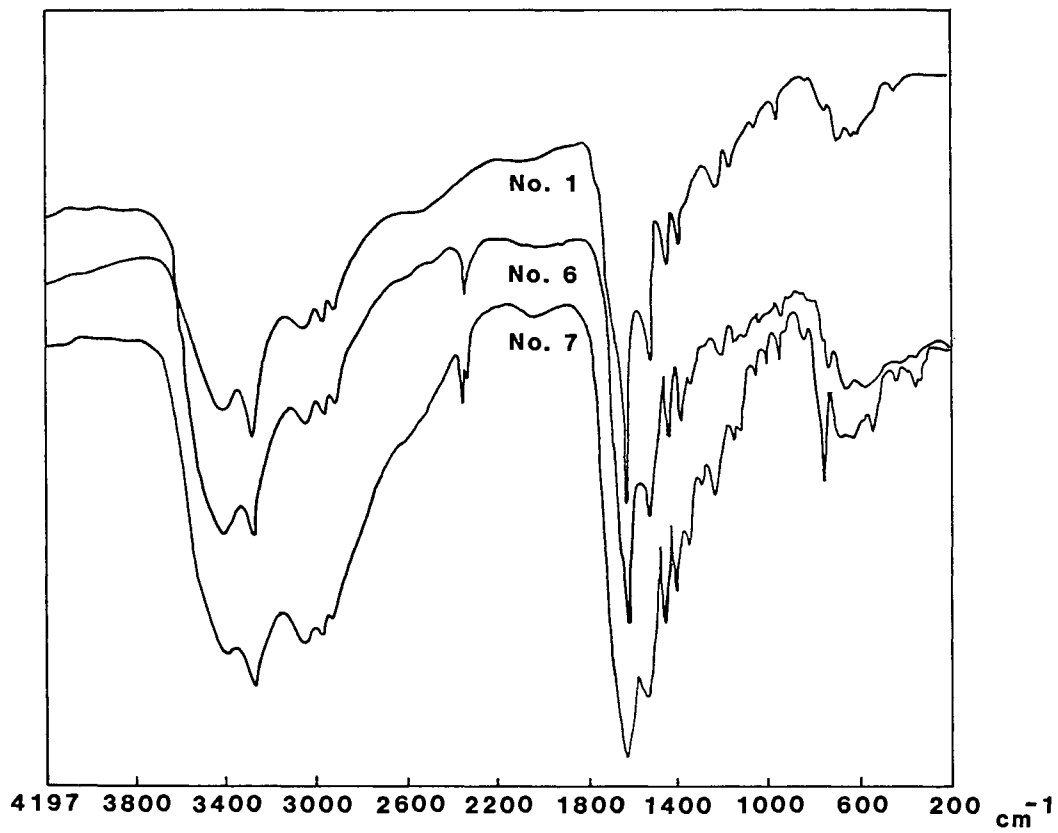

Fig. 5. Infrared spectra of water-soluble copolypeptides(A) shown in Table 1 in KBr disk.

225 nm for Entry 1 and a maximum peak at 222 nm for Entries 5 and 6. Fasman reported a strong negative peak of CD at 197 nm and a weak maximum peak at 217 nm for a poly(L-Lys) aqueous solution to be characteristic of a disordered conformation. Although the shapes were similar, the positive peak of polymer Entries 5 and 6 were higher than that of poly(L-Lys).

The infrared spectra of the copolypeptides listed in Table 1 are shown in Figs. 4 and 5. The insoluble fraction of poly(DL-Trp) gave amide I and II bands at 1654 and 1520 cm^{-1}, respectively. The insoluble fraction of polymer No. 1 gave amide I and II bands at 1656 and 1542 cm^{-1}, respectively, in addition to a band at 1306 cm^{-1}. The frequency value of these bands correspond to those for α-helical poly(L-alanine),[18-20] and the band at 1306 cm^{-1} is considered to be the characteristic of crystalline α-poly(L-Ala).[21] As is evident from the spectra in Entries 2—6 in Table 1, an insoluble polymer with a Trp residue content of 5.6—29.4 mol% gives the amide I band at 1654 and 1634 cm^{-1}, the II band at 1538 and 1305 cm^{-1}, as shown in Entry 5 of Fig. 4. The relative intensity of the 1654 cm^{-1} band was stronger than that of 1634, but almost identity upon increasing the Trp residue. Although the band at 1634 cm^{-1} corresponds to β-polypeptide,[20] the other bands for the β-conformation disappear. This may indicate that only the strongest peak of amide I for the β-conformation was observed, due to the small content of the β-conformational polypeptide. Thus, the infrared spectra coincided with the result of the CD spectra. This would also mean that the conformation of the insoluble polymers in the solid state produces little change in the solution of HFIP. The water-soluble fraction of poly(DL-Trp) No. 7 shows peaks at 1623 and 1540 cm^{-1} due to the β-conformation. The soluble fraction of Entries 1B—6B gave peaks at 1695 and 1628 cm^{-1} (amide I), due to an antiparallel and extended β-conformation, and no peak at about 610 cm^{-1} due to the α-helix conformation. Polymer 1B gave an additional peak at 445 cm^{-1}, which is characteristic of β-polyalanine. As described above, the CD spectra of the soluble polymer indicate a coiled conformation. This may indicate that the conformation of the soluble polymers in the solid state changed from β to a disordered form upon dissolution in HFIP. The infrared spectra of water-soluble copolypeptides No. 8—10 gave an amide I band at 1715—25, 1655 and amide II at 1540 cm^{-1}, characteristic of an α-helix-like conformation of (Ala-Ala-Ala-D-Ala)$_n$.[22] These bands were different from that of the water-soluble parts of Entries 1—6. For water-insoluble parts No. 8—10, bands at 1652 and 1530 cm^{-1} were observed, which are characteristic of a parallel β-conformation. These conformations were different from that of the water-insoluble parts of Entries 1—6.

The authors wish to express their thanks to Professor emeritus Dr. Y. Iwakura of the University of Tokyo, Dr. T. Hayashi of Kyoto University, and Mr. M. Iwatsuki of Ajinomoto Company for useful advice. The present work was partly supported by a Grant-in-Aid for Scientific Research No. 61490008 from the Ministry of Education, Science and Culture.

Formation of Acrylaldehyde by Vapor-Phase Aldol Condensation I. Basic Oxide Catalysts

Mamoru Ai
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
4259 Nagatsuta, Midori-ku, Yokohama 227
(Received October 30, 1990)

Vapor-phase aldol condensation of formaldehyde with acetaldehyde to form acrylaldehyde was studied with various oxides supported on silica gel using 35% formalin as the source of formaldehyde. The silica gel unsupported catalyst prepared from colloidal silica showed a relatively high activity and selectivity to form acrylaldehyde. The catalytic activity was markedly enhanced by the incorporation of a basic or amphoteric oxide into the silica gel, while it fell with the incorporation of an acidic oxide such as P_2O_5 or B_2O_3. The highest yields of acrylaldehyde were obtained with the Si-Mg, Si-Li, Si-Na, and Si-Zn oxide systems. Effects of reaction variables were also studied using a catalyst with an Si : Mg atomic ratio of 100 : 10.

Acrylaldehyde is currently produced by a partial oxidation of propene, which process has already been well studied. On the other hand, acrylaldehyde is obtained also by an aldol condensation of formaldehyde (HCHO) with acetaldehyde (AcH) in the presence of basic catalyst. This reaction is called "Tollence Reaction":[1,2]

$$CH_3CHO + HCHO \longrightarrow CH_2(OH)CH_2CHO$$
$$\longrightarrow CH_2{=}CHCHO + H_2O.$$

Schulz and Wanger[3] reported a process involving a contact catalytic conversion of an equimolecular amount of AcH and 30% HCHO aqueous solution on silica gel impregnated with 10% sodium silicate [$Na_2Si_2O_5$] at 305 to 310 °C.[4] The yield of acrylaldehyde was 41 mol% with an AcH conversion of 48%; the selectivity was about 85 mol%. The yield (mol%) is defined as 100×(moles of product)/(moles of AcH fed). The selectivity is defined as 100×(moles of product)/(moles of AcH consumed). Malinowski et al.[5] reported 46—62 mol% yields of acrylaldehyde over alkali and alkaline earth hydroxides.

This reaction is attractive in view of the utilization of C_1 chemical resources. However, aside from the above-cited works,[3,5] very little has been reported on this reaction in the literature. In this study, various kinds of metal oxides were examined as catalysts for this reaction, and then, characteristics of this reaction were studied using a silica gel containing MgO in about 10 mol%.

Experimental

Catalysts. The catalysts used in this study were oxides supported on silica gel. For example, the Si-Mg catalyst with an atomic ratio of 100 : 10 was prepared as follows. Magnesium nitrate [$Mg(NO_3)_2 \cdot 6H_2O$] (25.6 g) was dissolved in 100 ml of water and the solution was added to 300 g of colloidal silica "Snowtex O" (Nissan Chem. Ind.) containing SiO_2in 20%. Excess water was evaporated with stirring by means of a hot air current to yield a cake. This cake was dried in an oven for 6 h by gradual heating from 50 to 200 °C. The resulting solid was ground and sieved to get the 8—20 mesh portion. It was finally calcined at 500 °C for 6 h in a stream of air.

Reaction Procedures. The reaction was carried out with a continuous-flow system at atmospheric pressure. The reactor was made of a stainless steel tube, 50 cm long and 1.8 cm in i.d., mounted vertically and immersed in a lead bath. Nitrogen was fed in from the top of the reactor at a fixed rate of 140 $cm^3\,min^{-1}$ as the carrier or diluent, and a mixture of AcH and 35% formalin (containing methanol in about 8%) was introduced into a preheating section of the reactor by means of a syringe pump. Unless otherwise indicated, the feed rates of AcH, HCHO, methanol, water, and nitrogen were 13, 26, 5.6, 71, and 350 $mmol\,h^{-1}$, respectively. The effluent gas from the reactor was led into four chilled scrubbers to recover the water-soluble compounds. After 1 h time-on-stream, the contents of the scrubbers were collected (100 cm^3). The products were analyzed by gas chromatogarphy using a 6 m column of propylene carbonate for CO_2 and a 2 m column of PEG (polyethylene glycol) 20 M at 110 °C for aldehydes and alcohols.

The contact time, defined as (volume of catalyst)/(flow rate of gaseous feed), was changed by changing the amount of catalyst used with the feed rate fixed.

Results and Discussion

Performance of Metal Oxides Supported on Silica Gel. Various kinds of oxides supported on silica gel were tested as catalysts. The main products were acrylaldehyde, CO_2 and methanol. A very small amount of methyl formate was found in the product, but crotonaldehyde was not detected. In some cases, a large deviation was observed between the acrylaldehyde yield and the AcH conversion. It thus seems likely that the deviation is to be ascribed to formation of unidentified polymers. The conversions and yields obtained for each catalyst tested at a fixed temperature of 320 °C are listed in Tables 1 and 2.

The silica gel catalyst, prepared from the colloidal silica "Snowtex O," possesses a certain activity; the yield of acrylaldehyde reached 78 mol% with the selectivity of 98 mol% when the amount of catalyst used was 20 g (the contact time was about 10 s). The

incorporation of a basic oxide, such as alkali or alkaline earth oxide, induces a large increase in the activity. However, it seems hard to get a clear correlation between the electronegativity of metal ions and the activity. The acrylaldehyde yield exceeds 85 mol% with the Si-Li, Si-Na, and Si-Mg systems. However, the yield does not exceed 75 mol% with the Si-Cs, Si-Ba, and Si-Ca systems.

The incorporation of an acidic oxide, such as P_2O_5 or B_2O_3, decreases the activity (Table 2). The effect of the amounts of both P_2O_5 and MgO on the activity is shown in Fig. 1. The activity increases sharply with the incorporation of a small amount of MgO, while it decreases sharply with that of P_2O_5. The results strongly suggest that the reaction is promoted by basic sites, as generally believed. However, it should be noted that the silica-supported MgO catalysts are much more active than the unsupported MgO catalyst. Possibly, the combination of silica-gel with metal oxides induces a large increase in surface area and, moreover, a generation of new acidic sites which may also serve to promote the reaction.

The incorporation of V_2O_5 or Al_2O_3 increases strongly the activity. However, the yield of acrylaldehyde does not exceed 50 mol%, though the formation of CO_2 and methanol is relatively slow. Possibly, the acrylaldehyde formed initially is converted to unidentified polymers under the action of strongly acidic sites present on the Si-V and Si-Al oxides:

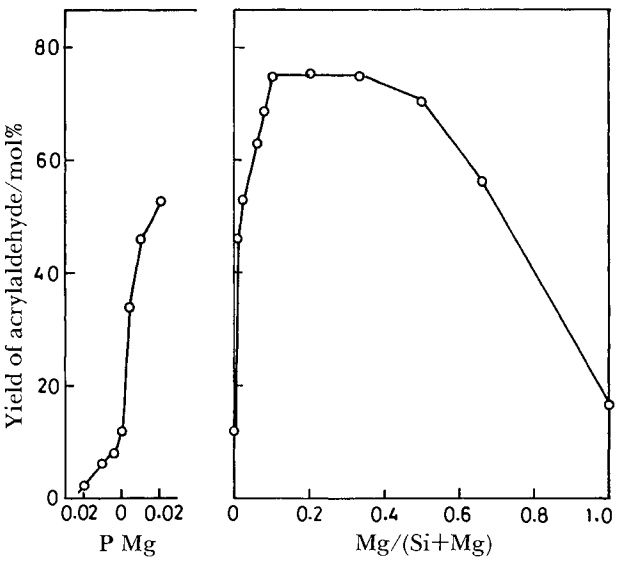

Fig. 1. Effect on activity of the amount of MgO or P_2O_5 incorporated in silica gel. Temperature=320 °C; the amount of catalyst used=20 g.

$$CH_3CHO + HCHO \longrightarrow CH_2{=}CHCHO \longrightarrow \text{polymers.}$$

A relatively good performance in both activity and selectivity was obtained with the Si-Zn oxide catalyst. The yield of acrylaldehyde reached 90 mol% with a

selectivity of almost 100 mol%, though the formation of by-products such as CO_2 and methanol is relatively fast.

The incorporation of an oxide of heavy metal, such as Fe_2O_3, PbO_2, or CuO, promotes strongly the formation of by-products. The amount of obtained methanol is almost in parallel with that of CO_2, which suggests that these two by-products are formed from HCHO via the process,

$$2HCHO \longrightarrow HCOOCH_3 \longrightarrow CH_3OH + HCOOH$$
$$\longrightarrow CH_3OH + CO_2 + H_2.$$

It has been reported that the formation of methyl formate by dimerization of HCHO is promoted by an acid-base dual function,[6] and that the decomposition of formic acid to CO_2 and H_2 is promoted very strongly by basic sites.[7] Possibly, the balance of acidic and basic properties of these catalysts may fit for the dimerization of HCHO.

It should also be noted that the incorporation of V_2O_5, an amphoteric oxide, or an oxide of heavy metal can enhance the catalytic activity to the level of catalysts comprising an alkali or alkaline earth metal oxide. This finding leads us to assume that active sites with a strong base, araising from alkali or alkaline earth metal oxide, are poisoned selectively by acidic reactants such as CO_2 and, further, that the reactions, especially the proton-abstraction from AcH

$$CH_3CHO + OH^- \longrightarrow {}^-CH_2CHO + H_2O,$$

are promoted enough by active sites with a very weak base, araising from V_2O_5 and amphoteric oxides.

Effects of Reaction Variables. The study in the preceding section has revealed that the Si-Li, Si-Na, Si-Mg, and Si-Zn catalysts exhibit a good performance for the acrylaldehyde formation. Thus, the characteristics of this reaction were studied using the catalyst with an Si : Mg atomic ratio of 100 : 10.

Product Distribution. The yields of acrylaldehyde, CO_2, and methanol obtained at 280 °C are shown in Fig. 2 as a function of contact time. The yield of acrylaldehyde on the AcH basis reaches 96 mol%, whereas those of CO_2 and methanol reach 12 and 43 mol%, respectively. The sum of the yields of the three products exceeds far 100 mol%. This also indicates that CO_2 and methanol are not formed from AcH but from HCHO.

Effect of Temperature. The yields of acrylaldehyde btained at four temperatures are shown in Fig. 3 as a function of contact time. From the initial rates at 240 and 280 °C, the apparent activation energy was calculated to be about 15 kcal mol^{-1}. The yield of acrylaldehyde reaches 96 mol% at a temperature between 280 and 340 °C.

Effect of AcH Concentration on Rate. The effect of AcH concentration was studied by changing the initial concentration in the feed gas from 0.78 to 5.6 mol%, while fixing the concentrations of HCHO, methanol, and water at about 6, 1.2, and 16 mol%, respectively. The rate increases steadily with the AcH concentration.

Effect of the HCHO/AcH Molar Ratio on the Yield of Acrylaldehyde. The effect of the HCHO/AcH molar ratio on the yield of acrylaldehyde was studied

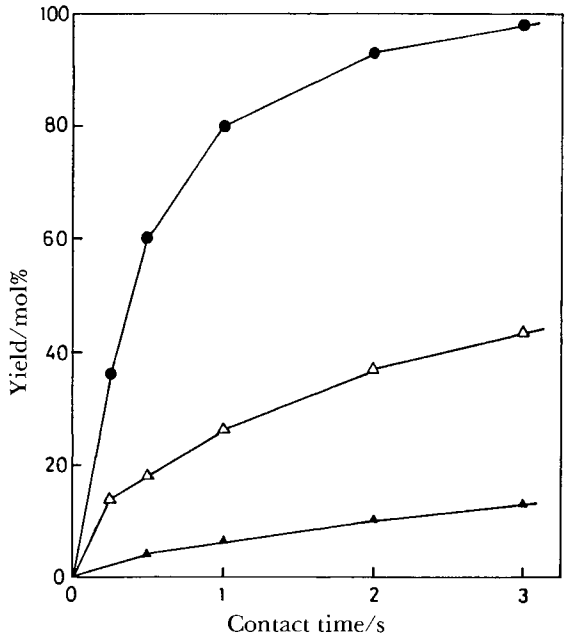

Fig. 2. Reaction of HCHO with AcH with the Si : Mg=100 : 10 catalyst. ● Acrylaldehyde; ▲ CO_2; △ methanol.

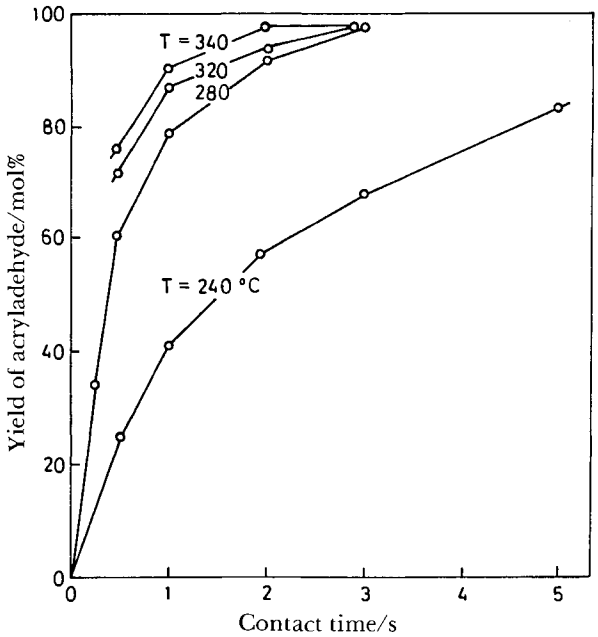

Fig. 3. Effect of temperature on the yield of acrylaldehyde.

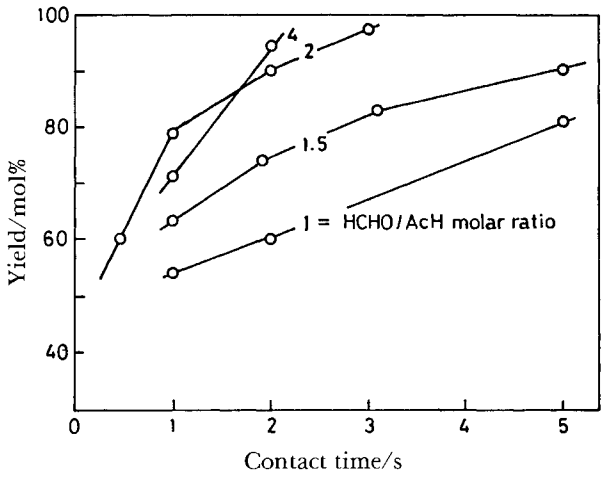

Fig. 4. Effect of the HCHO/AcH molar ratio on the yield of acrylaldehyde. Temperature=280 °C.

at a fixed AcH feed rate of about 13 mmol h^{-1} by changing the feed rate of formalin. Figure 4 shows the yields obtained at 280 °C with four different HCHO/AcH ratios. Longer contact time is required to achieve a certain level of acrylaldehyde yield as the HCHO/AcH ratio decreases, which indicates that the rate increases with the HCHO concentration, too.

Effect of Feed Rate. The reaction was conducted by changing the feed rates of AcH and HCHO, while fixing the HCHO/AcH molar ratio at 2. The initial rate of acrylaldehyde formation at 240 °C increased steadily with the increase in the feed rate, as reasonably expected from the above-mentioned results.

Conclusion. The silica gel prepared from the colloidal silica exhibits a relatively good catalytic performance in both activity and selectivity to form acrylaldehyde by aldol condensation of HCHO with AcH. The incorporation of a small amount of alkali or alkaline earth oxide, V_2O_5, an amphoteric oxide, or an oxide of heavy metal enhances markedly the activity. However, the formation of acrylaldehyde is accompanied by two side-reactions the polymerization of produced acrylaldehyde to unidentified polymers and the dimerization of HCHO to methyl formate which is decomposed readily to methanol and CO_2. The highest acrylaldehyde yields are obtained with the Si-Na, Si-Li, Si-Mg, and Si-Zn oxides.

Formation of Acrylaldehyde by Vapor-Phase Aldol Condensation II. Phosphate Catalysts

Mamoru Ai
Research Laboratory of Resources Utilization, Tokyo Institute of Technology,
4259 Nagatsuta, Midori-ku, Yokohama 227
(Received October 30, 1990)

Vapor-phase aldol condensation of formaldehyde with acetaldehyde to form acrylaldehyde was studied with various oxide and phosphate catalysts using 35% formalin as the source of formaldehyde. Almost all of the tested oxides exhibited a certain activity as the catalysts. Acidic oxides, such as MoO_3 and WO_3 showed a relatively high selectivity to acrylaldehyde, though the activities were low. V_2O_5 and amphoteric oxides exhibited a much higher activity, but they promoted also the formation of CO_2 and methanol. The catalytic performance was improved, to a certain extent, by combination of an acidic oxide with an amphoteric oxide. Further, the combination of phosphorus with V_2O_5 or an amphoteric oxide induced a large increase in the selectivity to acrylaldehyde. A good performance was obtained with the Ni-P, Mn-P, Fe-P, and V-P systems. The yield of acrylaldehyde reached 86 mol% on the AcH basis with a very slow formation of CO_2 and methanol.

The preceding paper[1] was concerned with performances of silica-supported basic oxides used as catalysts in the vapor-phase aldol condensation of formaldehyde (HCHO) with acetaldehyde (AcH) to form acrylaldehyde:

$$CH_3CHO + HCHO \longrightarrow CH_2{=}CHCHO + H_2O.$$

It was recently found that the aldol condensation of HCHO with a carboxylic acid, such as acetic acid or propionic acid

$$RCH_2COOH + HCHO \longrightarrow CH_2{=}CRCOOH + H_2O \quad (R{=}H, CH_3),$$

is promoted selectively with phosphate catalysts, for example, V-P,[2,3] V-Ti-P,[4] and V-Si-P[5] oxides. On the other hand, basic oxides were found to be unsuitable as catalysts, because they promote the side-reaction

$$2RCH_2COOH \longrightarrow RCH_2COCH_2R + CO_2 + H_2O \quad (R{=}H, CH_3).$$

This led us to infer that certain phosphates would exhibit performance comparable to that of basic oxides as catalysts for the condensation of HCHO with aldehydes, much as for the reaction with carboxylic acids. In this study, we focused our attention on finding out some phosphate catalysts effective for the formation of acrylaldehyde.

Experimental

Catalysts. The catalysts used in this study were various kinds of single, binary, and ternary oxides. Some of them were the same as those used in our previous studies.[2-4] For example, the Ni-P oxide with an atomic ratio of 1 : 0.9 was prepared as follows. Nickel nitrate [$Ni(NO_3)_2 \cdot 6H_2O$] (291 g) was dissolved in 200 ml of water and 104 g of 85% H_3PO_4 was added to the solution. Excess water was evaporated with stirring in a hot air current to yield a viscous paste. This paste was then dried in an oven at 200 °C for 6 h. The obtained solid was ground and sieved to get the 8—20 mesh portion. It was finally calcined at 500 °C for 6 h in a stream of air.

Reaction Procedures. The reaction procedures were almost the same as those described in the preceding paper.[1] As the source of HCHO, 35% formalin, containing methanol in about 8%, was used. Unless otherwise indicated, the feed rates of AcH, HCHO, methanol, water, and nitrogen were 13, 26, 5.6, 71, and 350 mmol h^{-1}, respectively.

Results and Discussion

Performance of Metal Oxide Catalysts. Since little information has been reported on this reaction, it seems necessary to make a character sketch of catalytic function. Therefore, various kinds of oxides were tested as catalysts. Table 1 shows the conversions of AcH and the yields of acrylaldehyde, CO_2, and methanol obtained at 320 °C with 20 g portions of single and binary oxide catalysts.

The results may be summarized as follows.

(1) The acidic oxides, such as MoO_3 and WO_3, show a relatively high selectivity to form acrylaldehyde, though the activity is low.

(2) V_2O_5 shows a high activity, but it promotes also the formation of CO_2 and the selectivity to acrylaldehyde is low.

(3) Amphoteric oxides, such as TiO_2, SnO_2, and Fe_2O_3, show a high activity, but they also promote the formation of CO_2 and methanol and the selectivity to acrylaldehyde is low.

(4) MgO shows a low activity. The Mg-K=9-1 oxide shows a relatively high activity, but the selectivity to acrylaldehyde is low.

(5) The catalytic performance is improved by combination of V_2O_5 or an amphoteric oxide with an acidic oxide, such as MoO_3 or WO_3.

(6) The best performances are obtained with the W-Sn and W-Fe oxide systems. The yield of acrylaldehyde reached 67 mol%.

Table 2 shows the results obtained with various phosphate catalysts. The results may be summarized as follows.

$Fe_4(P_2O_7)_3$		45	43	1	0						

a) Conditions: temperature=320 °C; amount of catalyst used=20 g; contact time=10 to 15 s; AcH/HCHO/MeOH/water/nitrogen feed rates=13/26/5.6/71/350 mmol h^{-1}. b) AcH=acetaldehyde; Acryl=acrylaldehyde; MeOH=methanol.

(1) The combination of phosphorus with an acidic oxide, such as MoO_3 or WO_3, decreases the activity markedly.

(2) The V-P oxide consisting of divanadium(IV) dioxide pyrophosphate [$V_2O_2(P_2O_7)$] exhibits a relatively good performance in both activity and selectivity.

(3) The combination of phosphorus with a certain

amphoteric oxide, such as TiO_2, SnO_2, Fe_2O_3, NiO, Co_3O_4, MnO_2, Cr_2O_3, or CuO, induces a large increase in the selectivity to acrylaldehyde, though the activity decreases gradually as the content of phosphorus increases. Therefore, there exists an optimum value in the amount of phosphorus.

(4) The combination of phosphorus with an oxide without oxidizing function, such as B_2O_3, Al_2O_3, ZrO_2, ZnO, Bi_2O_3, or MgO, is less effective.

(5) The best performances are obtained with the Ni-P, Co-P, Mn-P, Fe-P, and V-P oxide systems.

To get more detailed information about the catalytic functions, the effect of contact time on the AcH conversion and yields was examined for several phosphate catalysts which had showed a good performance. The results are listed in Table 3. The results may be summarized as follows.

(1) The best performance in the yield of acrylaldehyde is obtained with the Ni-P oxide with a P/Ni atomic ratio of 0.9/1.

(2) The next best catalyst is the Fe-P oxide with a P/Fe atomic ratio of 0.75/1.

(3) The combination of TiO_2 with the V-P oxide, which improves the performance for the reaction of HCHO with acetic acid,[4] increases the activity markedly, but the maximum yield of acrylaldehyde decreases from 79 to 63 mol%.

a) Conditions: temperature=320 °C; AcH/HCHO/methanol/water/nitrogen feed rates=13/26/5.6/71/350 mmol h^{-1}. b) Acryl=acrylaldehyde.

The Mo-P and W-P oxides consisting of heteropoly compounds, such as $H_3PMo_{12}O_{40}$ and $H_3PW_{12}O_{40}$, which possess strongly acidic sites, are not active as catalysts for this reaction, which suggests that the reaction is not promoted solely by acidic sites. V_2O_5, amphoteric oxides, and oxides of heavy metals, which are considered to be more basic than MoO_3 and WO_3 because of the lower electronegativity of metal ions, show a higher catalytic activity. Further, the activity of these oxides falls with the incorporation of phosphorus. These findings suggest that the reaction is catalyzed by basic sites. However, the sites required to promote the acrylaldehyde formation seem to consist of very weakly basic sites, present in metal tungstates, molybdates, and phosphates, but not of strongly basic sites, which is in conformity with the results obtained in the preceding study.[1]

The formation of acrylaldehyde is accompanied by the following side-reactions, as has been pointed out in the preceding work:[1] (i) formation of CO_2 and methanol from HCHO via methyl formate, which is promoted mainly by basic sites, and (ii) polymerization of acrylaldehyde to unidentified polymers, which is promoted by strongly acidic sites.

The activity and selectivity may, therefore, be governed by the balance of acidic and basic properties. When the basic property is too strong, the formation of CO_2 and methanol is promoted. On the other hand, when the basic property is suppressed too much by the incorporation of an acidic oxide, the catalyst loses the activity.

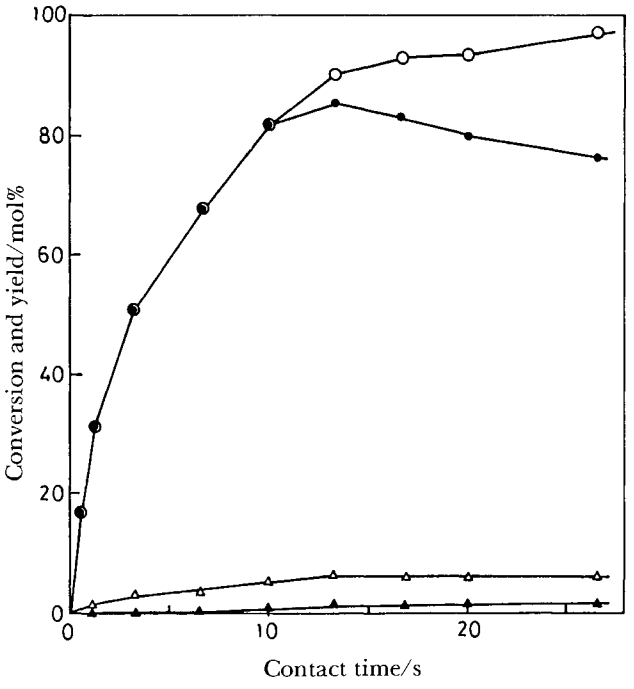

Fig. 1. Performance of the catalyst with an Ni:P atomic ratio=1:0.9. ○ AcH conversion; ● acrylaldehyde; ▲ CO_2; △ methanol.

The control of the acid-base property of catalysts is performed by the combination of an acidic oxide with a more basic oxide. It is, therefore, considered that the acid-base properties of the Ni-P, Mn-P, Co-P, Fe-P, and V-P oxide systems are best fit for promoting solely the formation of acrylaldehyde.

Performance of the Ni-P=1-0.9 Catalyst. The study in the preceding section has revealed that the best results for the formation of acrylaldehyde are obtained with the nickel phosphate with a P/Ni atomic ratio of 0.9/1. Thus, the characteristics of this catalyst were studied.

Product Distribution. The conversion of AcH and the yields of acrylaldehyde, CO_2, and methanol obtained at 280 °C are plotted in Fig. 1 as a function of contact time. The selectivity to acrylaldehyde is almost 100 mol% up to the AcH conversion of 80%, but it falls gradually with a further increase in the conversion. The results indicate that the acrylaldehyde formed initially is converted to polymers. The maximum yield of acrylaldehyde is about 85 mol%. This value is lower than those obtained with silica-supported basic oxides (96 mol%).[1] However, the formation of CO_2 and methanol is clearly slower than that obtained with the silica-supported basic oxides.[1] Possibly, the Ni-P oxide catalyst possesses strongly acidic sites, while the silica-supported basic oxides possess strongly basic sites.

Effect of Temperature. The yield of acrylaldehyde obtained with 2 g portions of catalyst (contact time 1.3 s) are plotted in Fig. 2 as a function of temperature. It was found that the effect of temperature on the rate is very small. The apparent activation energy was calculated to be about 3.5 kcal mol^{-1}. This value is clearly lower than that observed with the Si-Mg catalyst (15 kcal mol^{-1}),[1] which suggests that the active sites of the Ni-P catalyst are different from those of the Si-Mg catalyst. Possibly, the rate determining step is different; for example, it is the protonation of HCHO by acidic sites, $HCHO+H^+ \longrightarrow H_2C^+OH+H_2O$, over the Si-Mg catalyst, whereas over the Ni-P catalyst it is the proton abstraction from AcH by basic sites, $CH_3CHO+OH^- \longrightarrow {}^-CH_2CHO+H_2O$.

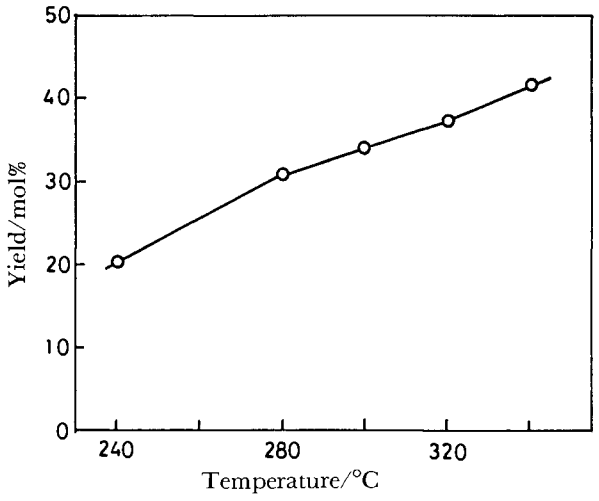

Fig. 2. Effect of temperature on the yield of acrylaldehyde. Contact time=1.3 s.

The effect of temperature on the selectivity to acrylaldehyde was studied. The results obtained at the AcH conversion of around 90% are shown in Table 4. It was found that the selectivity is scarcely affected by temperature up to 320 °C. It is, therefore, concluded that the optimum temperature is 320 °C.

Effect of Feed Rate. The effects of the AcH concentration and AcH-HCHO feed rate on reaction rate were studied at 280 °C. The results were similar to those obtained with the Si-Mg catalyst in the preceding study;[1] the rate increases steadily with the increase in either the AcH concentration or AcH-HCHO feed rate (the HCHO/AcH molar ratio was fixed at 2).

Table 5 shows the effect of the HCHO/AcH molar

ratio on the selectivity to acrylaldehyde. It was found that the selectivity is scarcely affected by the change in the HCHO/AcH molar ratio, though the rate decreases as the HCHO/AcH ratio decreases. This is understood from the finding that the Ni-P catalyst is inactive for the formation of CO_2 and methanol, which proceeds in parallel with the formation of acrylaldehyde.

The effect of the AcH-HCHO feed rate on the selectivity to acrylaldehyde was studied with the HCHO/AcH molar ratio fixed at 2. As is seen in Table 6, the effect of the feed rate on the selectivity is small. This is also understood from the finding that the catalyst is inactive for the side-reaction.

Mixed-Ligand Palladium(II) and Platinum(II) Complexes—Photosensitizers of $^1O_2$ Production and Chemical Quenchers of $^1O_2$

Shobha S. KAMATH, Santwana SHUKLA, and Tapeshwari S. SRIVASTAVA*
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400076, India
(Received July 9, 1990)

[M(nn)(dhn)] (where M is Pd(II) or Pt(II), nn is 2,2′-bipyridine, 1,10-phenanthroline, 2,2′-biquinoline, or 4,7-diphenyl-1,10-phenanthroline, and dhn is dianion of 2,3-naphthalenediol) photooxidizes the 2,2,6,6-tetramethyl-4-piperidinol in *N,N*-dimethylformamide via $^1O_2$ when irradiated with light of wave-lengths of 420 to 800 nm in presence of molecular oxygen. The presence of $^1O_2$ as an intermediate is confirmed by quenching studies using bis(dibutyldithiocarbamato)nickel(II) and 20% water in DMF. The relative efficiency of $^1O_2$ production sensitized by the above complexes depends on nature of metal, ligand, and geometry of the complexes. However, [Pd(bpy)(dmt)] and [Pd(phen)(dmt)] undergo photooxidation via $^1O_2$ when sensitized by hematoporphyrin IX and its metal derivatives on photolysis under similar conditions. The relative efficiency of $^1O_2$ production depends on the nature of metal in porphyrin.

Photolysis of chloroform solution of [Pt(bpy)(dmt)] (where bpy is 2,2′-bipyridine and dmt is dianion of 3,4-toluenedithiol) at 577 nm in ligand-to-ligand charge-transfer (LLCT) transition region results in an electron transfer from the complex to chloroform. A ligand-centered radical (probably the easily oxidized dmt) $[Pt(bpy)(dmt)]^+$ decomposes into unidentified products.[1] Photolysis of [Ni(phen)(dmde)] (where phen is 1,10-phenanthroline and dmde is dianion of cis-1,2-diphenylethylene-1,2-dithiol) in $CHCl_3$ in LLCT transition region has also promoted analogous photooxidation.[2] Similar mixed-ligand complexes of palladium(II) and platinum(II) complexes of formula [M(nn)(xx)] (where M is Pd(II) or Pt(II), nn is 2,2′-bipyridine or 1,10-phenanthroline, and xx is dianion of catechol, 4-*t*-butylcatechol, 3,4-dimercaptotoluene or thiosalicylic acid (tsa)) in *N,N*-dimethylformamide (DMF) have been used to photosensitize the singlet molecular oxygen ($^1O_2$) production when irradiated in their LLCT transition region between 400 and 700 nm in presence of molecular oxygen.[3,4] However, [Pt(nn)(dmt)] and [Pt(nn)(tsa)] undergo self-sensitized photooxidation via $^1O_2$,[4-6] and [Ni(nn)(dmt)] as physical quenchers of $^1O_2$.[7] In this paper we report the photo-sensitizing ability of [M(nn)(dhn)] (where nn is 2,2′-bipyridine, 1,10-phenanthroline, 2,2′-biquinoline (biq), or 4,7-diphenyl-1,10-phenanthroline (dpp) and dhn is dianion of 2,3-naphthalenediol) in DMF to produce $^1O_2$, and the chemical quenching of $^1O_2$ by [Pd(bpy)(dmt)] and [Pd(phen)(dmt)] using hematoporphyrin IX and its metal derivatives as photosensitizers.

Experimental

Materials: [Pd(nn)(dmt)] and [M(nn)(dhn)] were prepared and characterized as described elsewhere.[4,8] Bis(dibutyldithiocarbamato)nickel(II), [Ni(dbdc)$_2$], was prepared by the reported procedure.[9] Nickel(II), palladium(II), and platinum(II) complexes of hematoporphyrin IX were prepared and purified by the literature methods.[10,11] Chemicals used were of reagent grade and purified before use. The reagent grade solvents were purified before use by the standard procedures.[12]

Physical Measurements: Phosphorescence measurements were made with a SPEX 1934C phosphorimeter with RCA C13034 photomultiplier attachment having facility to give corrected emission spectra. Metal complexes dissolved in ethanol (1×10^{-6} M, 1M=1 mol dm^{-3}) were frozen in liquid nitrogen (77 K) in a 10 mm quartz cuvette and the spectra of the frozen solutions were recorded using different wavelengths of excitation. Other physical methods used were described elsewhere.[3,8]

General Irradiation Procedures: The irradiation of molecular oxygen saturated DMF solutions of metal complexes were carried out in a triple jacket merry-go-round apparatus as described earlier,[3] except 250 W tungsten halogen lamp was used in place of 150 W.

The photochemical measurements were also carried out by following modified method of Diamond and coworkers[13] as described elsewhere.[6]

Results and Discussion

Phosphorescence Spectra of [M(bpy)(dhn)]. The phosphorescence spectra of [M(bpy](dhn)] (where M is Pd(II) or Pt(II)) in ethanol glass at 77 K on excitations at their different absorption maxima show a broad band at about 600 nm. [Pd(bpy)(dhn)] on excitation at 457, 337, and 297 nm gives a phosphorescence band at 607 nm. [Pt(bpy)(dhn)] exhibits a band at 601 nm on excitation at 478, 338, and 296 nm as shown in Fig. 1. The phosphorescence band at about 600 nm in the above complexes is due to the longest wavelength LLCT transition as reported earlier for [Pt(bpy)(dmt)].[1] These data suggest that the triplet state of LLCT transition is expected to be involved in the following photooxidation reactions.

Photooxidation of 2,2,6,6-Tetramethyl-4-piperidinol (XH) and Its Quenching Studies: Molecular oxygen saturated DMF solution of [M(nn)(dhn)] (200 μM) in presence of XH (10 mM) was irradiated with light of wavelengths from 420 to 800 nm for different irradi-

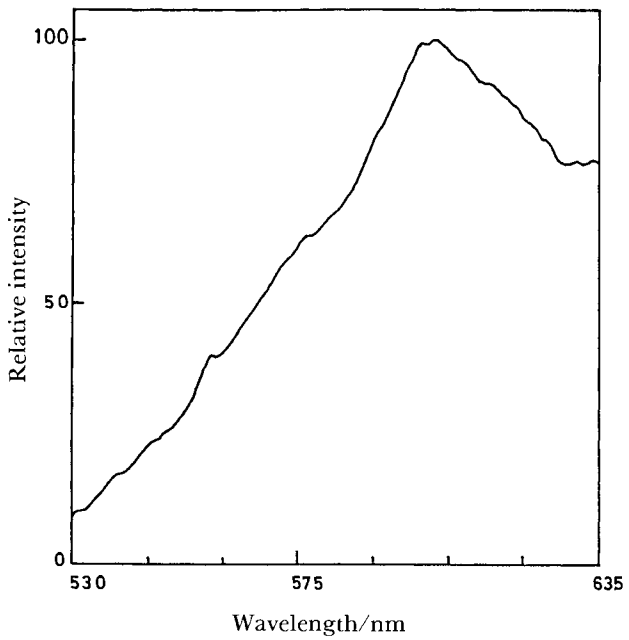

Fig. 1. A phosphorescence spectrum of [Pt(bpy)-(dhn)] in ethanol glass at 77 K.

ation times in a merry-go-round apparatus. The $^1O_2$ molecules formed combine with XH molecules to produce 4-hydroxy-2,2,6,6-tetramethylpiperidinyloxy free radicals (XO) which is measured by EPR method.[3] There is a linear relationship between the amount of XO free radicals formed and the irradiation times for different [M(nn)(dhn)] as shown in Fig. 2. It is supposed that [Pd(dpp)(dhn)] yields the maximum amount of $^1O_2$ as it has the highest slope, whereas [Pd(biq)(dhn)] yields the lowest amount of $^1O_2$ as it exhibits the smallest slope. The relative yields of $^1O_2$ production referred to [Pd(dpp)(dhn)] are given in Table 1. The values of relative efficiency calculated after correcting for the amounts of light absorbed using relative integrated areas under the absorption curves. After correcting the wavelength distribution of the lamp, they are given in Table 1. The relative efficiencies follow the order: [Pd(dpp](dhn)]>[Pt(dpp)(dhn)]>[Pt(bpy)(dhn)]>[Pt(phen)(dhn)]>[Pt(biq)(dhn)]>[Pd(biq)(dhn)]≈[Pd(bpy)(dhn)]≈[Pd(phen)(dhn)].

The formation of nitroxide free radicals was not observed when the solution of [M(nn)(dhn)] or 2,2,6,6-tetramethyl-4-piperidinol was kept in dark or irradiation in presence of molecular nitrogen. There was also no change in the position and intensity of absorption bands between 420 and 800 nm of [M(nn)(dhn)] in molecular oxygen saturated DMF after irradiations for two hours. The photooxidation of XH sensitized by [M(nn)(dhn)] was studied in 20% water-DMF. In these experiments the molecular oxygen saturated solutions of [Pd(dpp)(dhn)] (200 μM) in presence of XH (10 mM) in 20% water-DMF and in 100% DMF respectively were irradiated with light of wavelengths from 420 to 800 nm for different irradiation times. The plots of amount of XO free radicals against irradiation time are given in Fig. 3. The slope decreases in 20% water-DMF. The shortening of lifetime (τ) of $^1O_2$ can be affected by using mixed solvents such as 20% water in DMF (τ of $^1O_2$ in pure water is 2 μs and τ of $^1O_2$ in pure DMF is 7.1 μs).[14] There is an appreciable decrease in slope in 20% water in DMF than in pure DMF as shown in Fig. 3.

The quenching of photooxidation of 2,2,6,6-tetramethyl-4-piperidinol sensitized by [M(nn)(dhn)] was studied using bis(dibutyldithiocarbamato)nickel-(II) as physical quenchers of $^1O_2$. In these quenching experiments the molecular oxygen saturated solutions containing [Pt(phen)(dhn)] (5×10^{-5} M), bis(dibutyldithiocarbamato)nickel(II) (10^{-5} M or 10^{-6} M) and five different concentrations of XH (varying from 1×10^{-2} to 2×10^{-3} M) were irradiated using light of wavelengths from 420 to 800 nm for 1 h. The amount of XO free radicals produced was measured by EPR method.[3] The 1/[XO] was plotted against 1/[XH] for two concentrations of the nickel(II) complex. Two linear plots with their intercepts meeting at a

Table 1. Relative Yields and Efficiencies of [M(nn)(dhn)] for Sensitizing the Generation of $^1O_2$[a]

Complex	Relative yield of $^1O_2$ production referred to [Pd(dpp)(dhn)]	Relative efficiency of $^1O_2$ production referred to [Pd(dpp)(dhn)]
[Pd(dpp)(dhn)]	1.00	1.00
[Pt(dpp)(dhn)]	0.27	0.63
[Pt(bpy)(dhn)]	0.22	0.15
[Pt(phen)(dhn)]	0.30	0.13
[Pt(biq)(dhn)]	0.12	0.07
[Pd(biq)(dhn)]	0.04	0.05
[Pd(bpy)(dhn)]	0.05	0.04
[Pd(phen)(dhn)]	0.08	0.02

a) Relative integrated areas under absorption curves between 420 and 800 nm of [Pd(dpp)(dhn)], [Pt(dpp)(dhn)], [Pt(bpy)(dhn)], [Pt(phen)(dhn)], [Pt(biq)(dhn)], [Pd(biq)(dhn)], [Pd(bpy)(dhn)], and [Pd(phen)(dhn)] for 5×10^{-5} M are in the ratio 1.00 : 0.43 : 1.49 : 2.39 : 1.71 : 0.89 : 1.11 : 3.50, respectively.

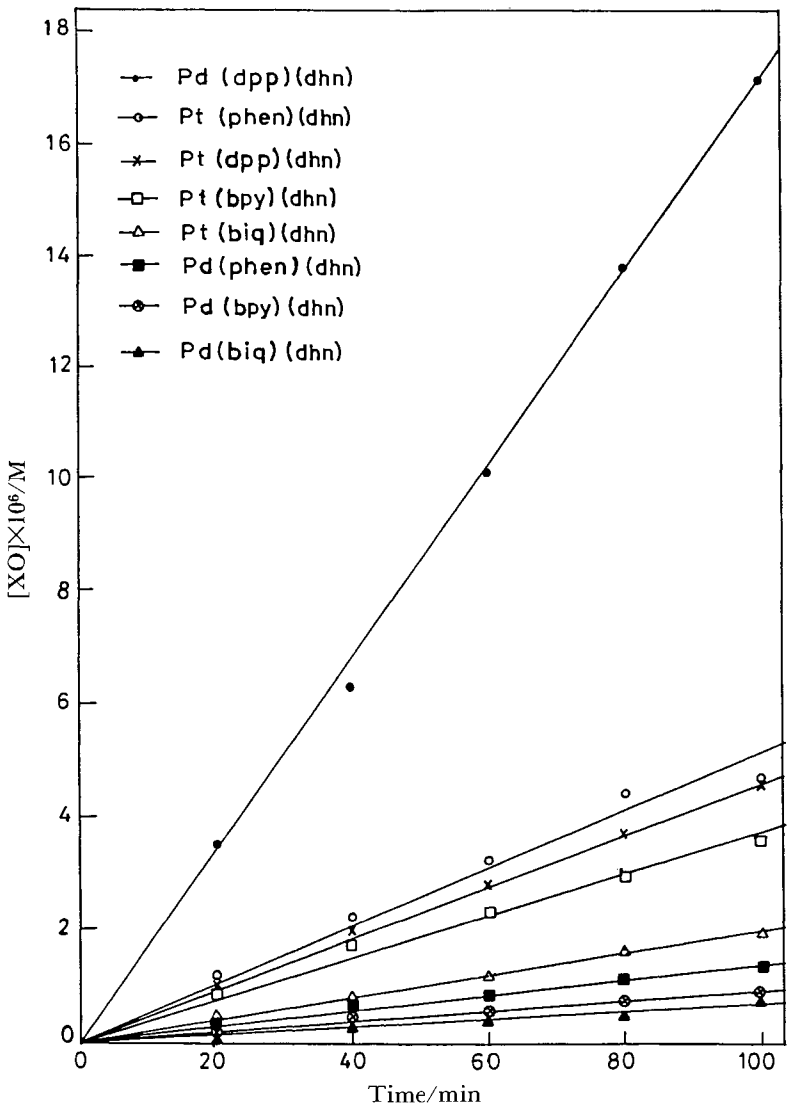

Fig. 2. Plots of XO free radical concentration versus irradiation time of solutions of [M(nn)(dhn)] (2×10^{-4} M) in presence of 2,2,6,6-tetramethyl-4-piperidinol (1×10^{-2} M) in DMF.

same point on the y-axis were obtained and they are given in Fig. 4. The relative amount of light absorbed by the nickel(II) complex in the wavelength range of 420 to 800 nm, at 10^{-5} or 10^{-6} M, is less than 0.1% as compared to [Pt(phen)(dhn)] and, therefore, there is no competition for light absorption between the sensitizer and the quencher.

The above results suggest that the photooxidation of 2,2,6,6-tetramethyl-4-piperidinol sensitized by [M(nn)(dhn)] involves the $^1O_2$ as an intermediate and the triplet state of LLCT transition in [M(nn)(dhn)] is responsible for the production of the $^1O_2$ by energy transfer.[3] The following Scheme 1 suggests the mechanism for the above reaction.[3] (S is one of the [M(nn)(dhn)] as photosensitizer, ^1S and ^3S are its first excited singlet and triplet states respectively, $h\nu$ is the energy of a photon, ISC is the inter system crossing, ET is the energy transfer, k_d is the rate constant of

$$S \xrightarrow{h\nu} {}^1S \quad \text{(i)}$$

$$^1S \xrightarrow{ISC} {}^3S \quad \text{(ii)}$$

$$^3S + {}^3O_2 \xrightarrow{ET} {}^1S + {}^1O_2 \quad \text{(iii)}$$

$$^1O_2 \xrightarrow{k_d} {}^3O_2 \quad \text{(iv)}$$

$$^1O_2 + XH \xrightarrow{k_r} XO \quad \text{(v)}$$

$$^1O_2 + Q \xrightarrow{k_q} {}^3O_2 + Q \quad \text{(vi)}$$

Scheme 1.

quenching of $^1O_2$ by DMF molecules, k_r is the rate constant of chemical quenching of $^1O_2$ by XH to produce XO, and k_q is the physical quenching of $^1O_2$ by the bis(dibutyldithiocarbamate)nickel(II) (Q).

On the assumption of above mechanism (see Scheme

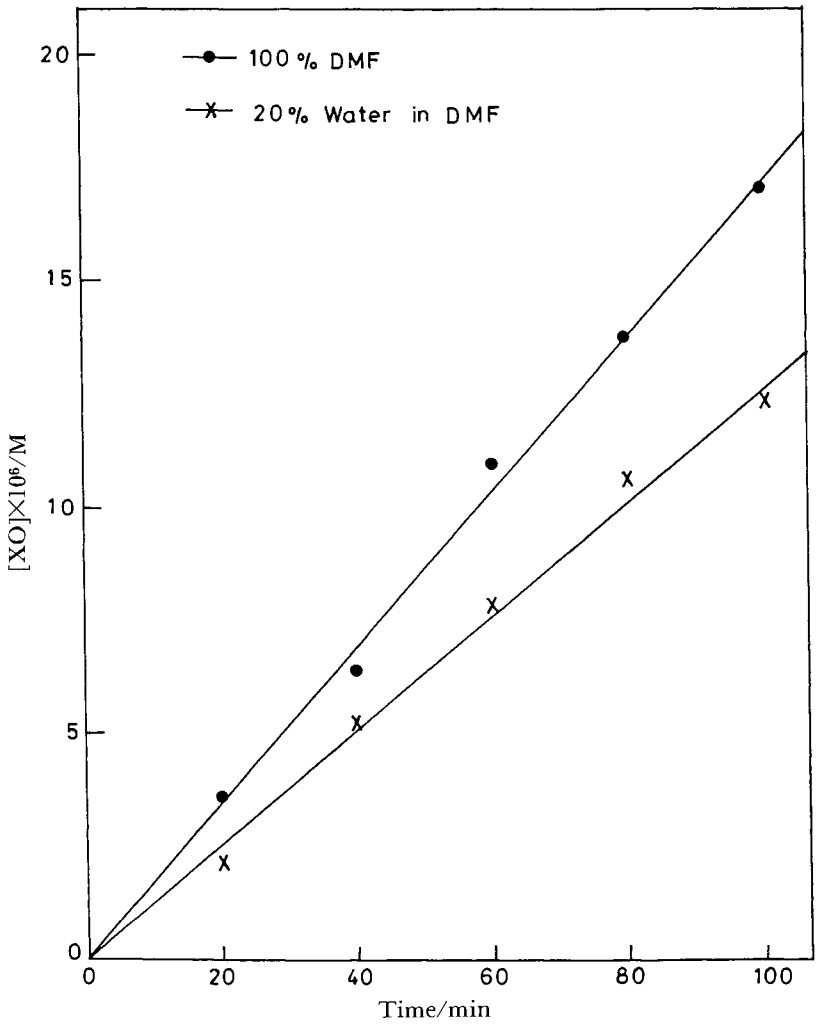

Fig. 3. Plots of XO free radical concentration versus irradiation time of [Pd(dpp)(dhn)] (2×10^{-4} M) and 2,2,6,6-tetramethyl-4-piperidinol (1×10^{-2} M) in DMF and 20% H_2O in DMF.

1) the rate of formation of XO free radicals by oxidation of XH with $^1O_2$ using steady state approximation, can be given by Eq. 1.[3] (I_{abs} is the intensity of

$$\frac{d[XO]}{dt} = I_{abs}\,\phi_{^1O_2}\frac{k_r[XH]}{k_r[XH]+k_d}, \qquad (1)$$

irradiation and $\phi_{^1O_2}$ is the quantum yield of $^1O_2$ production). If I_{abs} is not constant for [M(nn)(dhn)] and k_d, k_r, and [XH] are kept constant, the slope of the plot of the amount of nitroxide radicals produced versus irradiation time is related to $I_{abs}\phi_{^1O_2}$ (called yield of $^1O_2$ production). The slopes of linear plots of amount of nitroxide radicals produced versus irradiation time for [M(nn)(dhn)] are shown in Fig. 2. The relative yields of $^1O_2$ production for [M(nn)(dhn)] referred to [Pd(dpp)(dhn)] were obtained from the slopes of Fig. 2 and they are given in Table 1.

On correcting for the relative amounts of light absorbed by [M(nn)(dhn)] using Eq. 2, the relative

$$\frac{(\phi_{^1O_2})_2}{(\phi_{^1O_2})_1} = \frac{(\text{slope})_2}{(\text{slope})_1}\times\frac{(I_{abs})_1}{(I_{abs})_2}, \qquad (2)$$

efficiencies of $^1O_2$ production for [M(nn)(dhn)] referred to [Pd(dpp)(dhn)] were obtained. These values are also given in the last column of Table 1 and the order follows as given above. The efficiency order seems to depend on nature of metal ion, nature of α-diimine ligand, and the energy of ligand-field A_2 state with respect to the lowest triplet state (π,π^*).[3,15]

If the last step in parentheses of the above mechanism is included, Eq. 3 is obtained as

$$\frac{1}{[XO]} = \frac{1}{[^1O_2]} + \frac{k_q[Q]+k_d}{k_r}\times\frac{1}{[^1O_2]}\times\frac{1}{[XO]}. \qquad (3)$$

On plotting 1/[XO] against 1/[XH] (see Fig. 4) a linear plot is obtained with the slope=$1/[^1O_2]\times(k_q[Q]+k_d)/k_r$ and the intercept=$1/[^1O_2]$. Knowing k_d (1.4×10^5 s^{-1} in DMF),[14] k_r (2.45×10^7 $M^{-1}s^{-1}$)[3,16] and concentrations of Q (1×10^{-5} M or 1×10^{-6} M), slope and inter-

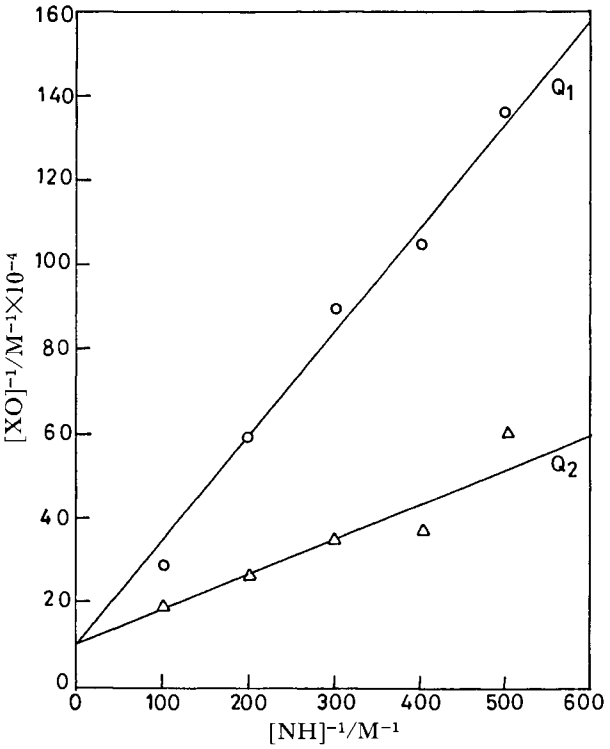

Fig. 4. Plots of reciprocal of XO free radical concentration versus reciprocal of 2,2,6,6-tetramethyl-4-piperidinol in presence of bis(dibutyldithiocarbamato)nickel(II) (10^{-5} M (Q_1) and 10^{-6} M (Q_2)) using [Pt(phen)(dhn)] (5×10^{-5} M) as a photosensitizer.

cept (from above mentioned plot), the k_q can be obtained. The k_q values obtained for bis(dibutyldithiocarbamato)nickel(II) ([Ni(dbdc)$_2$]) at concentrations of 1.0×10^{-5} and 1×10^{-6} M are 4.6×10^{10} and 6.3×10^{10} $M^{-1}s^{-1}$, respectively. Thus, the average value of k_q is 5.5×10^5 $M^{-1}s^{-1}$, which is higher than the reported value.[14] For the two plots as given in Fig. 4, the intercepts meet at a point on the y-axis for 1×10^{-5} M and 1×10^{-6} M [Ni(dbdc)$_2$]. However, the slope increases with increase in concentrations of [Ni(dbdc)$_2$]. This suggests that the physical quenching of $^1O_2$ by the [Ni(dbdc)$_2$] is involved and it rules out any quenching of excited sensitizer [Pt(phen)(dhn)].[14]

Photooxidation of [Pd(nn)(dmt)] Sensitized by Hematoporphyrin IX and Its Metal Derivatives: A solution of [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] (5×10^{-4} M) and porphyrin (5×10^{-5} M) in DMF was bubbled with DMF saturated molecular oxygen for 15 min. This solution was taken in a stoppered quartz cuvette of 1 cm path length and was then irradiated for different intervals of time by the light source directed first through the filter and then through an acrylic cylinder.[13] The course of the photolysis of [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] (5×10^{-4} M) sensitized by a free porphyrin or a metal porphyrin (5×10^{-5} M), after irradiating with light of wavelengths between 455 and 800 at different irradiation time (0 to 10 min), was followed by the difference absorption spectroscopy using same concentration of free porphyrin or metal porphyrin (5×10^{-5} M) in a reference cuvette in the visible region using a Shimadzu UV-260 spectrophotometer. The absorbance (A) of the [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] at different time of photolysis was calculated by substracting the reduction of absorbance at 498 or 500 nm obtained by difference absorption spectroscopy from the initial absorbance of the [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] (5×10^{-4} M). The reduction of absorbance of the palladium(II) complex (5×10^{-4} M) due to photolysis for 10 min irradiation was less than 1% of total absorbance of a free porphyrin or a metal porphyrin (5×10^{-5} M).

The plots of logarithm A of [Pd(bpy)(dmt)] at 498 nm versus different irradiation time of 0 to 10 min for free hematoporphyrin IX and its metal derivatives are shown in Fig. 5. These linear plots have different slopes and the ratio of these slopes is related to relative yields of $^1O_2$ production for different metal hematoporphyrin IX as compared to free hematoporphyrin IX (with its normalized value taken as 1) and these ratios are given in Table 2.

The relative efficiencies of $^1O_2$ production by the

a) Relative integrated areas under absorption curves between 420 and 800 nm of hematoporphyrin IX (H_2HP), PdHP, PtHP, NiHP for 1×10^{-5} M after correcting for amounts of light absorbed are in ratio of 1.0 : 1.2 : 1.2 : 1.1, respectively.

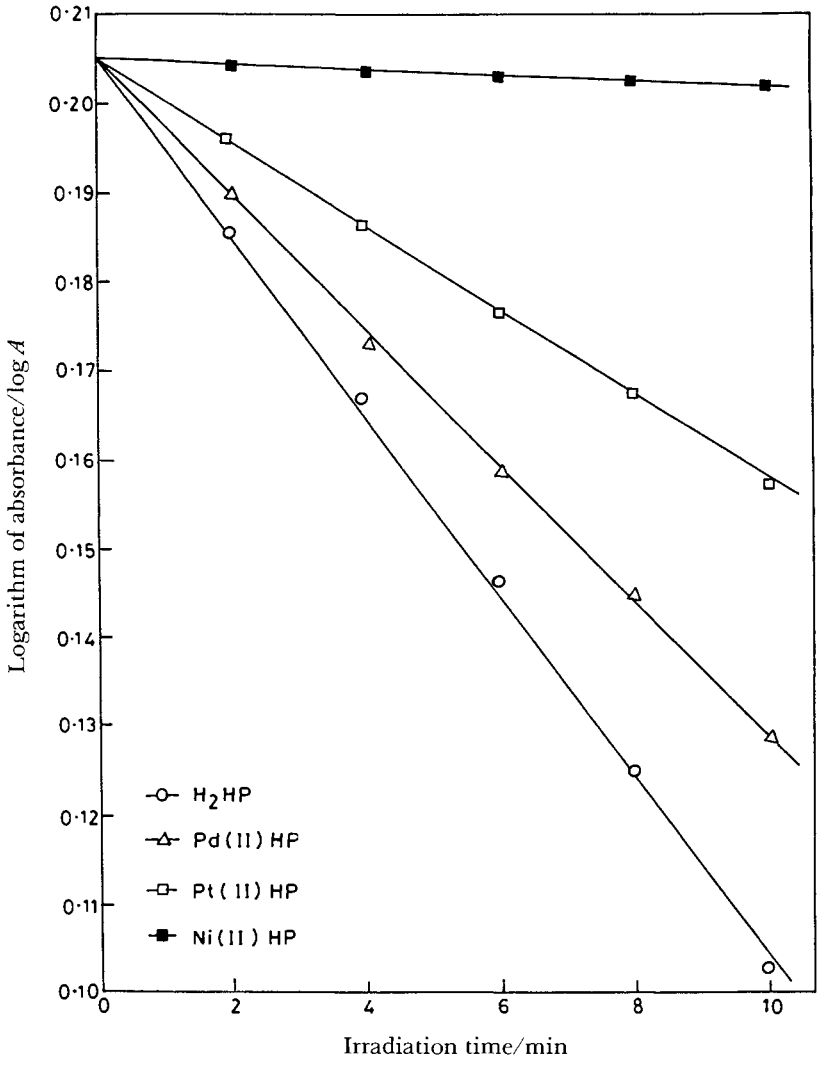

Fig. 5. Plots of log A versus irradiation time (A is absorbance at 498 nm of [Pd(bpy)(dmt)] (5×10^{-4} M) in DMF containing porphyrins (5×10^{-4} M)).

different metal hematoporphyrin IX referred to free hematoporphyrin IX after making corrections for the relative amounts of light absorbed by them have been compared and the values are also given in Table 2. The relative yields or the relative efficiencies of $^1O_2$ production by above porphyrins using [Pd(bpy)(dmt)] as a chemical quencher (see Table 2) follow the order: $H_2HP>PdHP>PtHP\gg NiHP$. Similar plots were obtained using [Pd(phen)(dmt)] as a chemical quencher. In this case the relative yields or relative efficiencies of $^1O_2$ production by porphyrins (see Table 2) follow the same order: $H_2HP>PdHP>PtHP\gg NiHP$.

Hematoporphyrin IX and its metal derivatives are good photosensitizers of $^1O_2$ production[17] and this $^1O_2$ oxidizes the chemical quenchers [Pd(bpy)(dmt)] and [Pd(phen)(dmt)].[18] The mechanism suggested earlier to explain the photooxidation of [Pd(bpy)(dmt)] and [Pd(phen)(dmt)] sensitized by hematoporphyrin IX is also acceptable when Ni(II), Pd(II), and Pt(II) hematoporphyrin IX complexes were used as photosensitizers in place of hematoporphyrin IX in the above photooxidation reactions. The steps involved in these photooxidation reactions are same as given for Scheme 1 (see above) except that S is one of the porphyrins acting as sensitizer, and XH and Q are replaced by Q′ (where Q′ is [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] because the Q′ behaves both as chemical and physical quencher (see steps V and VI in Scheme 1). In the light of this mechanism the log[Q′] can be given by the following relationship.[18,19]

$$\log[Q'] = -kt + c \quad (\text{if } k_d \gg (k_q + k_r)[Q'], \tag{4}$$

and

$$k = I_{abs}\phi_{^1O_2}\frac{k_r}{k_d}, \tag{5}$$

where I_{abs} is the intensity of absorbed light, $\phi_{^1O_2}$ is the quantum yield of $^1O_2$ production, k_d is the rate constant of quenching of $^1O_2$ by DMF, k_q is the rate constant of physical quenching of $^1O_2$ by Q′, k_r is the rate constant of chemical quenching of $^1O_2$ by Q′, Q′ is quencher [Pd(bpy)(dmt)] or [Pd(phen)(dmt)], and t is irradiation time.

If the decay of Q′ is followed by visible spectroscopy, a plot of log[Q′] (or log$A$) against different irradiation time gives a straight line with the slope of k (see Eq. 4) as given in Fig. 5. If I_{abs} is not constant for different porphyrins and the k_d, k_r and the initial concentration of Q′ are kept constant in Eq. 5, the slope of log[Q′] versus irradiation time is related $I_{abs}\phi_{^1O_2}$ (yield of $^1O_2$ production). The relative yields of $^1O_2$ production for different metal hematoporphyrin IX relative to free hematoporphyrin IX were obtained from the slopes (see Fig. 5) and are given in Table 2. If the correction for the relative amounts of light absorbed by different porphyrins is made using Eq. 6, the relative efficiencies of $^1O_2$ production for

$$\frac{(\phi_{^1O_2})_2}{(\phi_{^1O_2})_1}=\frac{k_2\times(I_{abs})_1}{k_1\times(I_{abs})_2}, \quad (6)$$

different metal porphyrins referred to free porphyrin were obtained. The relative efficiencies of $^1O_2$ production follow the order: $H_2HP>PdHP>PtHP \gg NiHP$.

The irradiation of DMF solution of only [Pd(bpy)(dmt)] or [Pd(phen)(dmt)] (5×10^{-4} M) in presence of molecular oxygen or molecular nitrogen for more than 10 min shows no change in absorbance of [Pd(bpy)(dmt)] at 498 nm or [Pd(phen)(dmt)] at 500 nm. Similar irradiation of DMF solution of free hematoporphyrin IX (5×10^{-5} M) in presence of molecular oxygen or molecular nitrogen for more than 10 min shows also no change of absorbance of 498 or 500 nm.

The relative efficiencies of $^1O_2$ generation by the free base hematoporphyrin IX and its metal derivatives were further obtained by the EPR method using 2,2,6,6-tetramethyl-4-piperidinol as a chemical acceptor of $^1O_2$.[16] This method has advantage that 2,2,6,6-tetramethyl-4-piperidinol is a specific quencher of $^1O_2$, which does not react with superoxide ions, hydrogen peroxide and hydroxyl radicals.[16,20] In this method a solution of a free base porphyrin or a metal porphyrin (5×10^{-5} M) and 2,2,6,6-tetramethyl-4-piperidinol (2.5×10^{-3} M) was irradiated on the merry-go-round apparatus[3] for different irradiation time. The photoproduction of $^1O_2$ was measured by recording the EPR spectra of the nitroxide free radicals

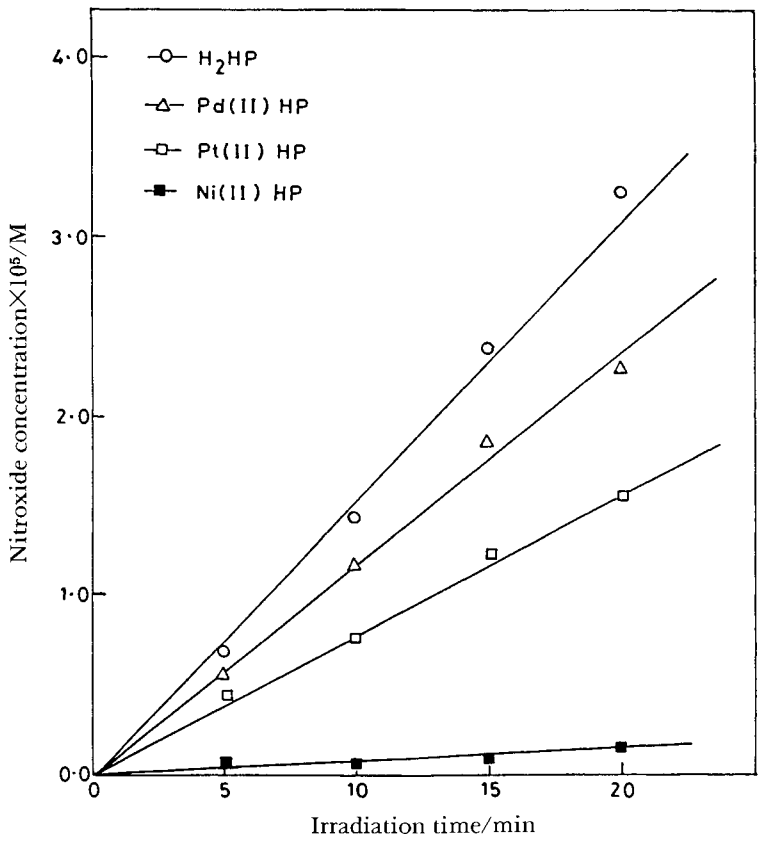

Fig. 6. Plots of XO free radical concentration versus irradiation time of DMF solution of 2,2,6,6-tetramethyl-4-piperidinol (2.5×10^{-3} M) and porphyrins (5×10^{-5} M).

generated by the reaction of 2,2,6,6-tetramethyl-1,4-piperidinol with $^1O_2$.[3,21] The linear plots of amount of nitroxide radicals produced for a free base hematoporphyrin IX and its metal derivatives versus irradiation time are given in Fig. 6. Hematoporphyrin IX gives the largest slope and the NiHP gives the smallest slope. The relative yields and relative efficiencies of $^1O_2$ production for different metal hematoporphyrin IX, as compared to free hematoporphyrin IX are given in Table 2.

The relative yields or relative efficiencies of $^1O_2$ production by the porphyrins follow the order: $H_2HP>PdHP>PtHP\gg NiHP$. This order is same as obtained above using [Pd(bpy)(dmt)] and [Pd(phen)(dmt)] as chemical quenchers.

The above results suggest that PdHP and PtHP are expected to have the energy of their $^3B_{1g}$ state arising from the d-d transition of d^8 configuration of metal ion in a square planar crystal field well above the first triplet state of porphyrin arising from π-π^* transition.[15] On the other hand NiHP shows virtually no photosensitizing ability to produce $^1O_2$ because its ligand-field $^3B_{1g}$ state has energy just lower than that of phosphorescent triplet state of porphyrin. The ligand-field $^3B_{1g}$ state provides the pathway of radiationless decay and thus reduces very considerably the transfer of energy from $^3O_2$ to produce $^1O_2$. The higher efficiency of PdHP as compared to PtHP may be due to longer lifetime of triplet state of former than later.[22]

Conclusion

The above study shows that the Pd(II) and Pt(II) complexes of α-diimine ligands with 3,4-naphthalenediol dianion can sensitize the photooxidation of 2,2,6,6-tetramethyl-4-piperidinol involving $^1O_2$ as intermediate. This intermediate is produced by energy transfer from triplet state of LLCT transition of the complexes to molecular oxygen. In addition [Pd(nn)(dmt)] as chemical quenchers of $^1O_2$ can be used in determining the relative efficiency of $^1O_2$ production sensitized by porphyrins.

We are grateful to DST and DAE (Govt. of India) for financial support and Dr. K. H. Puthraya for his help in earlier research.

Crystal Structure of 2′-*O*-Succinyladenosine 3′,5′-(Cyclic)phosphate Monohydrate: A Model Compound to Study Protein-Nucleic Acid Interactions

Natarajan PADMAJA, Suryanarayana Rao RAMAKUMAR,* and Mysore A. VISWAMITRA
Department of Physics and Jawaharlal Nehru Centre for Advanced Scientific Research, India Institute of Science, Bangalore 560012, India
(Received June 13, 1990)

The crystal and molecular structure of 2′-*O*-succinyladenosine 3′,5′-(cyclic)phosphate monohydrate has been determined by X-ray diffraction techniques. The compound crystallizes in the orthorhombic space group $P2_12_12_1$; Z=4 with a=5.633(1), b=15.853(2), c=20.607(3) Å. The final R value is 0.029. The adenine base is protonated at N(1). The base is in syn conformation (χ=−95.8°) with respect to the sugar, which has a C(3′)-*endo*-C(4′)-*exo* pucker ($_4T^3$). A six-membered ring formed by phosphate group and ribose shows chair conformation. The succinic acid moiety, which resembles side chains of certain amino acids, is found to have a bent skeleton. The cyclic AMP, which is known to play diverse roles in many metabolic processes, forms the nucleotide portion of the title compound. The succinic acid moiety that is covalently linked to this nucleotide in the present compound, shows direct and water mediated interactions with phosphate and base nitrogens of the nucleotide respectively. Such compounds can therefore serve as models to study the protein-nucleic acid interactions, which play a central role in many of the biological processes.

Adenosine cyclic 3′,5′-phosphate (cAMP) is known to play a central role in various hormonal metabolic control mechanisms.[1,2] It is also known to influence the activity of certain enzymes.[3,4] In light of these observed biological properties a few crystal structure studies of cyclic nucleotides and their analogues have been carried out in the past,[5] to understand the conformational flexibility and interactions of the cyclic nucleotide in the presence of different chemical groups. We report in this context, the crystal structure of 2′-*O*-succinyladenosine 3′,5′-(cyclic)phosphate monohydrate. It has the cyclic nucleotide covalently linked to a succinic acid moiety that resembles the side chains of amino acids like glutamic acid, aspartic acid etc. It is of interest to study the interactions between the nucleotide and the succinic acid moiety in the title compound, as a model for amino acid side chain-nucleic acid interactions, which are important in determining the structures and functions of protein-nucleic acid assemblies. Structural studies on similar model compounds have been reported in literature.[6-10]

Experimental Studies and Structure Determination

Needle-shaped crystals were grown from an aqueous solution of the title compound which was purchased from Sigma Chemicals. Intensity data were collected on a CAD-4 diffractometer with Ni-filtered Cu $K\alpha$(λ=1.5418 Å) radiation using a crystal of dimensions 0.04×0.06×0.64 mm. Cell parameters refined from 18 accurately measured reflections. The crystal data are given in Table 1.

Intensities were measured using ω-2θ scans. Three strong reflections monitored periodically showed that the crystal was stable to X-rays. Absorption correction[11] applied: transmission factors varied from 91.9 to 98.1%. Lorentz and polarization corrections were also applied. 1784 reflections were measured in the range $0<\theta<65°$, of which 1656 reflections were considered to be observed with $|F_o| \geqslant 3\sigma(F)$.

Table 1. Crystal Data

Formula	$C_{14}H_{16}N_5O_9P_1 \cdot H_2O$

b/Å	15.853(2)
c/Å	20.607(3)
V/Å^3	1840.2
Z	4
D_x/g cm^{-3}	1.55

The structure was solved by the direct methods using MULTAN11/82[12] and the calculations were performed with the Enraf-Nonius Structure Determination Package[13] on a PDP11-44 computer. An E-map computed with the best set of phases (CFOM=2.979) revealed the atoms of the six-membered ring formed by phosphate group and ribose sugar. A weighted Fourier synthesis at this stage gave rest of the structure. Of the 18 hydrogens, 17 were located from difference Fourier maps computed at various stages of full-matrix least-squares refinement on F's using SHELX 400[14] with the non-H atoms refined anisotropically and the H atoms refined isotropically. One of the water hydrogens which was not located from the difference maps, was fixed in the direction of the hydrogen bond initially, but was varied in the final stages of refinement. Final R=0.029, R_w=0.032; no. of parameters refined were 343. Individual weights $w \propto 1.0/[\sigma^2(F)+0.002\ F^2]$ were used. Maximum shift/error is 0.11; residual density in the final difference electron density map is within ±0.20 e Å^{-3}. The atomic scattering factors are as supplied in SHELX 76.

Results and Discussion

The conformation of the molecule along with atomic numbering scheme is shown in Fig. 1. The

final positional parameters with equivalent isotropic temperature factors for the non-H atoms are given in Table 2.[15] Bond lengths and bond angles are listed in Table 3.

Base: The molecule is found to be in zwitter ionic form with the adenine base protonated at N(1) and a single negative charge on the phosphate group. The bond lengths and bond angles in the base are in good agreement with the average values reported[16] for structures with protonated adenine base. The base shows syn conformation[17] with χ (C(8)-N(9)-C(1')-O(4'))=−95.8°.

Ribose: The ribose in the present structure is covalently linked to succinic acid moiety at 2'-position and is cyclized between 3' and 5' ends by the phosphate group. The ribose ring shows C(3')-

endo-C(4′)-*exo* pucker, a conformation generally found in cyclic 3′,5′-phosphate nucleotide structures.[5,18,19] The pseudorotation parameters[20] of the furanose ring are P=49.9° and τ_m=47.8°.

Phosphate: The six-membered ring formed by phosphate group and ribose is in the chair form with the best mirror bisecting C(4′) and P(1) atoms and with asymmetry parameter[21] ΔC_s[C(4′)-P(1)]=3.3°. The torsion angles ω' (O(5′)-P-O(3′)-C(3′)) and ω (C(5′)-O(5′)-P-O(3′)) fall in the region for 3′,5′-cyclic monophosphate nucleotides on ω' vs. ω map.[22]

Succinic Acid: The succinic acid moiety in the present structure is neutral. It shows a bent skeleton conformation (C(9)-C(10)-C(11)-C(12)=59.5°), which is not uncommon to this moiety.[23,24] In an analysis carried out on the energetically favored side-chain conformations of amino acids,[25] the glutamine and glutamic acid side chains which have a similar carbon backbone structure as that of succinic acid, show this bent conformation in about 50% of these residues in the total sample of oligopeptides considered. Also, this folded or gauche conformation is observed in many of the crystal structures of the compounds containing glutamic acid.[26]

A Comparison with the Biologically Important cAMP: The conformation of the nucleotide part in the present structure (χ=−95.7°, P=49.9°, and τ_m=47.8°) is close to that of one of the molecules in the asymmetric unit (χ=−90°, P=50°, and τ_m=48°) in the crystal structure of cAMP free acid.[5]

The ribose in the cyclic 3′,5′-phosphate nucleotides generally shows a small range of conformations ${}_4T^3 \leftrightarrow {}^3T_4$ and the six-membered ring containing the phosphate group is observed to have chair conformation with a slight flattening at the phosphate end. The flexibility of the cyclic nucleotide seems to lie mostly about the glycosidic bond, C(1′)-N(9), as can be seen from the fact that the cAMP and its analogues have been observed to be in anti or syn conformation and not generally restricted to the anti conformer as in the crystal structures of cyclic monophosphates of pyrimidines.

Hydrogen Bonding Pattern: The crystal structure is stabilized by a number of hydrogen bonds, the details of which are shown in Fig. 2 and Table 4. No base stacking has been observed.

In the present structure, a water molecule forms hydrogen-bonded bridge between the N(6) and N(7) of the same adenine base. This pattern has also been observed in crystal structure of a modified cAMP.[18] In a recent review,[27] on hydration of oligonucleotides in crystals, it is cited that such intra-residue bridges

have been observed for purines in crystals of all the three (A, B, and Z) forms of DNA. In general, bridging water molecules in several nucleic acid structures[28,29] are believed to play a significant role.

The hydroxyl oxygen atom, O(10), of the succinic acid moiety forms a direct hydrogen bond with the phosphate oxygen, O(7), and the carbonyl oxygen atom, O(9), hydrogen bonds to the water molecule (Fig. 2, Table 4) which bridges the N(6) and N(7) atoms of the adenine base. It is interesting to note that a similar mode of interaction, although not involving a water molecule, is observed in the crystal structures of cAMP-Catabolite activator protein (CAP) complex[30] and cAMP and adenosine-CAP mutant complex,[4] where the hydroxyl group of Ser side chain is at hydrogen-bonding distance from the same two nitrogens, N(6) and N(7) of adenine base. This mode of interaction could be a recurring feature, considering the fact that these nitrogens are free to take part in additional hydrogen-bonding interactions even for an adenine base involved in Watson-Crick base pairing. Water mediated interaction between the nucleotide part and the amino acid-like succinic acid moiety observed in the present structure seems to be a biologically important mode of interaction. A similar interaction has been observed in the crystal structure of 1:1 cytosine-*N*-(benzyloxycarbonyl)-glutamic acid dihydrate,[31] where in a water molecule oxygen is at hydrogen-bonding distance from both carboxyl oxygen of glutamic acid and O(2) atom of the cytosine base. In fact, such indirect interactions have also been observed between amino acid side chains and the nucleotides in the crystal stuctures of certain repressor-operator complexes.[32] In the crystal structure of 434 phage repressor-DNA operator complex,[33] four of the six water molecules present are involved in bridging the residues Arg 43, Gln 33, and Ser 30 to base pairs and phosphates of the DNA operator. Also, in the crystal structure of Trp repressor-DNA operator complex,[34] water mediated polar contacts to the bases appear to contribute part of the specificity. The structure shows three water mediated hydrogen bonds, two of which bridging peptide nitrogens of Ile 79 and Ala 80 to adenine and guanine bases, and the third water molecule interacts with hydroxyl of Thr 83 and both the nitrogens N(6) and N(7) of adenine 7 of the DNA operator.

(Received July 23, 1990)

The stability of small unilamellar vesicles (SUV) formed by egg phosphatidylcholine has been examined in the presence of four DNA-intercalating drugs—carboxamides of acridine, anthracene, phenylquinoline, and phenylbenzimidazole. The physicochemical stability of the vesicle-membrane changed as the total drug concentration increased and, of the four drugs investigated, the phenylquinolinecarboxamide was the most destructive. The presence of cholesterol in the liposomal bilayer increased resistance to physicochemically induced damage by the drugs except the anthracenecarboxamide. In all cases, coating the liposomes with a polysaccharide made the liposomal surface more hydrophobic and led to the vesicle rupture by the cytotoxic agents. The cytotoxic 9-anilinoacridine derivatives, amsacrine and 9-[2-methoxy-4-(methylsulfonylamino)-anilino]-5-methylacridine-4-*N*-methylcarboxamide (CI-921), were too insoluble to be encapsulated within the aqueous core of liposomes, but the neutral form of CI-921 was intercalated into the liposomal membrane of pullulan-derivative-coated liposomes. In this formulation, CI-921 was more effective against BM 314 carcinoma-cells than the free drug, but an anticarcinoembrionic antigen (anti-CEA) antibody binding liposome provided no additional advantage.

N-[4-(9-Acridinylamino)-3-methoxyphenyl]methanesulfonamide, amsacrine (**1**) was the first synthetic DNA-intercalating agent successfully to enter clinical use,[1] and has been shown to be beneficial in the treatment of leukemia but not for the more common solid tumors.[2] Multi-parameter structure-activity relationships for amsacrine analogues suggested that alterations in the DNA-binding acridine moiety would be beneficial.[3] While high activity was associated with strong binding to DNA, it was also important to develop analogues with better distributive properties which could reach remote tumor sites. The requirement was, therefore, for weakly basic compounds which would have a higher proportion of the diffusable free base, and focussed attention on electron-withdrawing substituents with hydrogen bonding donor/acceptor properties.[4]

In 1982 the analogue 9-[2-methoxy-4-(methylsulfonylamino)anilino]-5-methylacridine-4-*N*-methylcarboxamide (CI-921) (**2**) was selected for clinical evaluation on the basis of its experimental solid tumor activity and its different physicochemical prop-

erties compared with amsacrine (stronger DNA-binding, higher water-solubility, and lower pK_a).[5]

Later studies showed that, although high DNA-binding affinity correlates with high in vitro and in vivo drug potency for several series of DNA-intercalating agents, it also limits the distributive properties of the compounds. Emphasis was therefore placed on the development of weakly-binding cationic DNA-intercalating agents.[1,6] One of the first of these was the acridinecarboxamide (**3**), which showed extraordinary activity against the remotely-sited Lewis lung carcinoma in mice.[6] A considerable number of tricyclic carboxamides has now been prepared and evaluated, and these are represented in this study by the linear tricyclic anthracene (**4**)[7] and two '2-1' tricyclic systems, the phenylquinoline (**5**)[8] and the pheylbenzimidazole (**6**).[9] This last cornpound, which possesses the chromophore of lowest aromaticity, displays the lowest DNA-binding constant of all the tricyclic carboxamides which have been investigated.[9]

Liposomes have been of particular interest in cancer chemotherapy, where treatment is required to be systemic to deal with metastatic disease, and is nearly always limited by the toxic side-effects of the drugs. Drug encapsulation within tumour-cell specific liposomes has been chosen to permit smaller quantities to be administered, reducing general side effects. Active targeting of the liposomes to specific tissues such as the lung, or to specific cell types such as alveolar macrophages, may be enhanced by coating them with naturally occurring polysaccharide-derivatives such as mannan and amylopectin[10] anchored by a cholesterol moiety. However, the most deliberate approach to the specific targeting of liposomes has been to attach them to monoclonal antibody fragments capable of recognizing tumor associated antigens. Recent work has shown that such "immunoliposomes" bind selectively to target tumor cells in vitro[11] and in vivo,[12] and that doxorubicin encapsulated into such liposomes is more effective against human lung tumor xenografts in mice than either free drug or drug encapsulated in conventional liposomes.[13]

In this paper we examine first the extent of damage of a variety of egg phosphatidylcholine liposomes caused by the antitumor agents (**3—6**) and how this varies with drug hydrophobicity. Through this experiment, we are able to obtain two different sorts of information. The first is information about the membrane toxicity of these drugs since liposomes are considered to be a simple model of intact cells. The more destructive drug for liposomes should, in general, be more membrane toxic to any kind of cells. The second is information of more technical concern; namely, if one wishes to encapsulate an anti tumor drug into the liposomal drug carrier, the carrier liposome should not be destructed by drugs during the encapsulation procedure. We, therefore, report on the effectiveness of **2**, encapsulated in a carcinoembrionic antigen (CEA)-specific immunoliposome, against a CEA-producing cell line, BM 314, and a CEA-nonproducing cell line, RPMI#4788.

The drugs investigated herein belong to the DNA-intercalating class of antitumor agents. They possess planar aromatic ring systems capable of intercalating reversibly between the basepairs of the double helix and distorting the DNA geometry.

Materials and Methods

Materials. Egg yolk phosphatidylcholine was isolated and purified from egg yolk as described in the literature[14,15] and found to be pure by thin layer chromatography (using a precoated silica gel plate and development with chloroform/methanol/water (65 : 25 : 4, v/v/v). Carboxyfluorescein (CF), the marker entrapped in the liposomes, was from Eastman Kodak. The polysaccharide [CHP-50-1.9 (AECM 2.1)] (i.e. pullulan of average molecular weight 50000, and the primary alcohol moieties are substituted by 2.1 free *N*-(2-aminoethyl)carbamoylmethyl (AECM) residues per 100 glucose units, of which 1.9 residues are bound to cholesterol), was similar to that used in previous work.[11]

Cell Lines. Human colon carcinoma cells (BM 314 and RPMI#4788) were maintained in RPMI 1640 medium (Nissui Pharmaceutical Co. Ltd., Tokyo) supplemented with 10% heat inactivated Fetal Calf Serum (FCS, Protein Institute, Osaka University).

Cytotoxic Assay. 3×10^4 BM 314- or RPMI#4788-cells in 0.5 ml of RPMI 1640 (10% FCS) were added into each of a 24 well culture plate (Corning). Subsequently, an aliquot of CI-921-encapsulated liposome or immunoliposome was added to the cell suspension. The mixture was maintained at 37 °C under 5% CO_2-95% air condition for 3 days. After the cells were stripped from the culture wells by treatment with 0.05% trypsin-0.02% ethylenediaminetetraacetic acid (EDTA), the cell number was counted by trypan blue dye

exclusion.

Preparation of Liposomes. Small unilamellar vesicles, SUV, encapsulating 6-carboxyfluorescein in the interior water phase, were prepared by the method described elsewhere.[16] Polysaccharide-coated liposomes were prepared as follows. After sonication of a suspension of lecithin (30 mg) in a 4 ml solution of carboxyfluorescein (200 mM, 1 M=1 mol dm^{-3}) in tris(hydroxymethyl)methanamine (Tris) buffer (20 mM, pH 8.6) containing 200 mM NaCl, the polysaccharide, CHP-50-1.9 (AECM 2.1) (3 mg), in 0.5 ml of Tris buffer containing 200 mM NaCl, was added. The 1 : 10 (by wt) mixture of polysaccharide: liposome was stirred gently for 30 min and then separated from the multilamellar vesicles (MLV) by gel chromatography. Cholesterol containing liposomes (1 : 10 mol percent) were prepared by adding cholesterol (1.5 mg) to the solution of lecithin (30 mg) in an appropriate amount of chloroform at the beginning of the preparation. For all preparations, the concentration of phosphatidylcholine in the liposomal suspension was determined as inorganic phosphate according to the procedure of Eibl and Lands.[17]

Large unilamellar vesicles (LUV) were prepared by the method of reversed-phase evaporation. Lecithin (60 mg) was dissolved in diethyl ether (8 ml) and an aqueous solution (4 ml) of the material to be encapsulated was added. The mixture was sonicated in an ultrasonicator bath until formation of a homogeneous emulsion was obtained. This step is important, as difficulties in achieving high encapsulation or a primarily unilamellar population of vesicles may arise from failure to obtain a good emulsion. The organic solvent was then removed by rotary evaporation for 60 min at 350 mmHg[a] followed by a further 30 min at 650 mmHg.[a] The jelly-like residue was dissolved in Tris-HCl buffer, 20 mM, in 200 mM NaCl and centrifuged for 30 min at 35,000 G. After each centrifugation the supernatant was decanted and replaced by fresh Tris buffer and the process was repeated three times. The addition of excess buffer to the gel state has been found to decrease the time required to go from the gel state to the final liposomal dispersion, without reducing significantly the percent encapsulation of the initial aqueous material.[18] Sodium chloride is required in the buffer solution to balance the osmolarity between the interior and exterior of the liposome.

Preparation of Immunoliposomes. Dry pyridine (5 ml) was added to 3 ml dry dimethyl sulfoxide containing the CHP-50-1.9 (AECM 2.1) (300 mg) and *N*-[4-maleimidobutyryloxy]succinimide (50 mg) (Dojindo Laboratories, Kumamoto) at room temperature. Substitution of the 4-maleimidobutyryl (GNB) group into the free AECM group in the polysaccharide[11] was completed in 48 h, as confirmed by the fluorescamine test.[19] The reaction mixture was poured into 300 ml ethanol, stored overnight, and then the water soluble portion of the precipitate was lyophilized to yield the polysaccharide derivative coded as GMB-CHP.

Egg phosphatidylcholine liposomes containing CI-921 were prepared in Tris-buffer (200 mM NaCl), pH 8.6. Immediately after sonication, the liposome suspension was mixed with 1 ml Tris buffer (pH 8.6) containing 200 mM NaCl, and containing 3 mg of CMG-CHP. After stirring for 1 h at room temperature, 2 ml of the mixture were adjusted to pH 6.2 with 0.1 M HCl. Phosphate buffer (1.5 ml, pH 6.2) containing 72.5 μg of the anti-carcinoembrionic antigen (CEA) antibody fragment Fab′ (personal donation from S. Nishi, the First Department of Biochemistry, School of Medicine, Hokkaido University) was added and the reaction mixture was incubated with gentle stirring for 20 h at 4 °C. After gel filtration of the immunoliposomal suspension (using phosphate buffer (pH 6.2) as eluant), the MLV fraction (3.6 ml) contained 30.5 μg CI-921 and 4.6 Fab′ as determined by the fluorescamine test[20] (22% of the antibody employed) per ml. The corresponding GMB-CHP-coated multilamellar liposomes, kept at pH 8.6, contained 42.4 μg CI-921 per ml after gel filtration. Thus the loss of CI-921 during the change of pH from 8.6 to 6.2 and the conjugation of the antibody fragment was ca. 30%.

Monitoring the Release of 6-Carboxyfluorescein. A 3 ml sample of 0.1 mM 6-carboxyfluorescein-loaded SUV suspen-

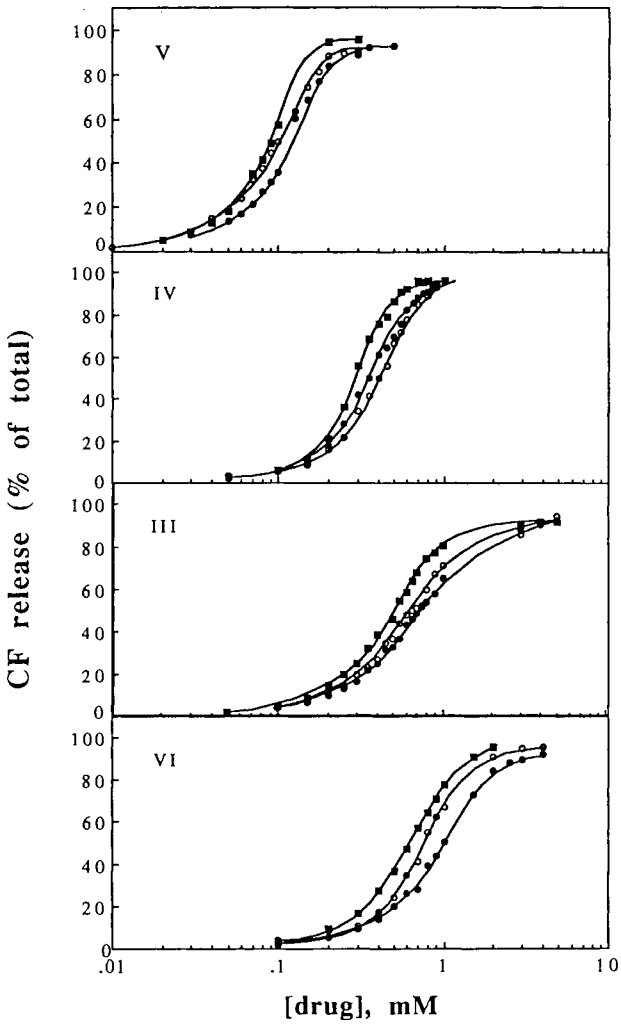

Fig. 1. Cytotoxic agent-induced leakage of 6-carboxyfluorescein (CF) from a 0.1 mM egg phosphatidylcholine small unilamellar vesicle suspension in 200 mM NaCl at 36.5 °C: ○, uncoated liposomes; ●, liposomes containing 10 mol % cholesterol: ■, liposomes coated with pullulan anchored by a cholesterol moiety. The drugs used were the carboxamide derivative of acridine (**3**), anthracene (**4**), the phenylquinoline (**5**), and phenylbenzimidazole (**6**).

[a] 1 mmHg=133.322 Pa.

sion in 20 mM Tris-HCl buffer (pH 8.6) containing 200 mM NaCl was placed in a thermoregulated cuvette cell and preincubated for 10 min at 36.5 °C. During the preincubation, we found no spontaneous release of the marker. The carboxyfluorescein-release (induced by adding 200 μl of an aqueous solution of the drug under investigation) was followed by monitoring an increase in the fluorescence intensity, I, at 520 nm, by excitation at 470 nm on a Shimadzu RF540 fluorescence spectrometer. The intensity of the total amount of the liposome-encapsulated marker, I_∞, was determined after complete destruction of the liposomes with 100 μl of Triton X-100 (10% v/v). The measured percentage of 6-carboxyfluorescein released was obtained by the following equation: % 6-carboxyfluorescein released$=((I_t-I_0)/(I_\infty-I_0))\times 100$, where t and 0 refer to times of sampling and to the instant when the solution of the drug was applied to the liposomal suspension. A standard time of 5 min was used to determine the relative ability of the drugs to effect lysis. Duplicate experiments were performed and the data shown in Fig. 1 represent the mean of two measurements. The experimental error was within ±2%.

Due to interference between the fluorescent properties of the probe and the compounds under investigation (e.g. the acridinecarboxamide, **3**, and the anthracene carboxamide, **4**, possessed fluorescence maxima at excitation wavelengths of 380 and 402 nm, and emission wavelengths of 450 and 472 nm, respectively), it was necessary to apply a correction factor equal to (I_∞(in the absence of drug))/(I_∞(in the presence of drug)) to the measured percent probe released.

Results

Stability of Liposome-Encapsulated Drug Formulations. The amount of amsacrine in the liposomal fraction was below the spectroscopic (λ_{max} 435 nm, ε=12300) detection limit (<80 ng ml^{-1}), but the concentration of neutral CI-921 (λ_{max} 445 nm, ε=10300) dissolved in the lipid membrane increased to 3—8 μg ml^{-1} for the cationic form. Coating the liposomes with cholesterol-substituted pullulan increased the concentration of neutral drug embedded in liposomal bilayer to 70—80 μg ml^{-1} CI-921 and 1.2 μg ml^{-1} amsacrine. The neutral form of CI-921 precipitates rapidly from the uncoated liposomes after sonication and gel filtration, but the polysaccharide-coated liposomes are stabilized and release the drug slowly: at 0, 8, and 11 days the relative concentrations were 90, 66, and 55 μg ml^{-1}, respectively. At the same time the lipid concentration decreased from 2.5 to 2.3 mM.

However, the tricyclic carboxamides (**3**—**6**) were not able to be encapsulated, and in fact degraded liposomal membranes. The rate of this destruction was measured by carboxyfluorescein release. Figure 1 shows comparative data for the percent release of liposome-encapsulated carboxyfluorescein by increasing concentrations of the acridine-(**3**), anthracene-(**4**),

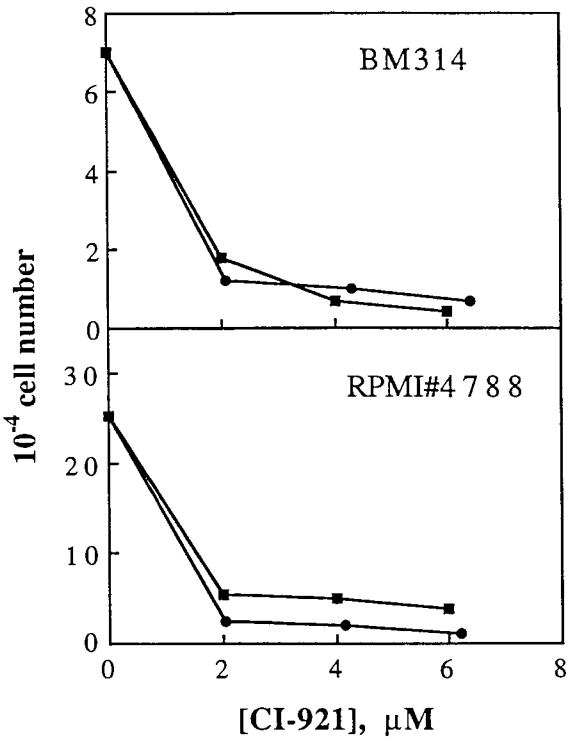

Fig. 2. Antitumor activity of CI-921. The protonated free drug, ●, and the deprotonated form of the drug encapsulated in 60 μM egg phosphatidylcholine MLV, ■, were incubated with CEA-producing BM-314 cells (upper plot) and RPMI#4788 (lower plot) for 3 days at 37 °C. The initial cell number was 3×10^4.

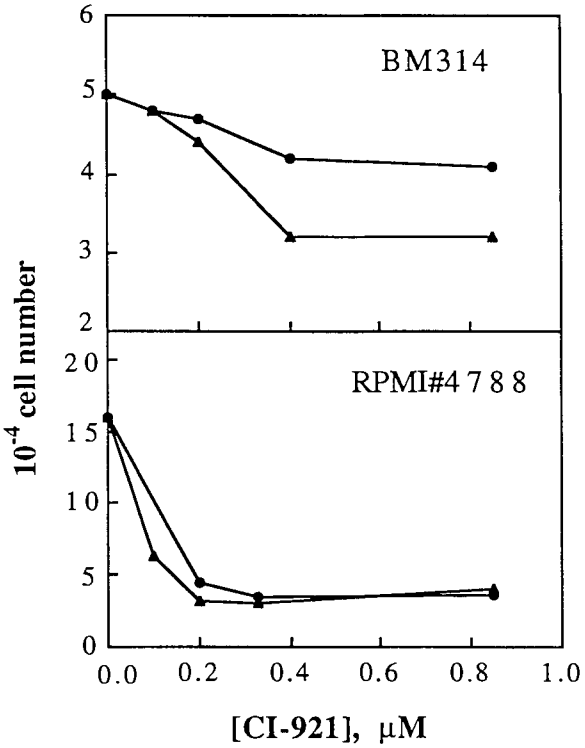

Fig. 3. Antitumor activity of CI-921. The deprotonated drug encapsulated in GMB-CHP coated liposomes, ●, and in immunoliposomes, ▲, were incubated with BM-314 cells (upper plot) and RPMI#4788 cells (lower plot) for 3 days at 37 °C. The initial cell number was 3×10^4.

phenylquinoline-(**5**), and phenylbenzimidazolecarboxamides (**6**) from a variety of liposomes (uncoated, with 10% cholesterol, and coated with pullulan anchored by a cholesterol moiety in the lipid bilayer).

Comparative Antitumor Effect of Liposome Encapsulation of CI-921. The cytotoxicity of CI-921, which was presented to BM-314 and RPMI#4788 tumor cell lines in vitro as either the free drug in its protonated form or the deprotonated drug encapsulated into MLV, is compared in Fig. 2. There was a minor difference in effectiveness in the latter case but no difference in the former.

The deprotonated drug was also encapsulated into GMB-CHP-coated liposomes and into immunoliposomes, and the results for the two cell lines are compared in Fig. 3. In the case of BM-314 cells, the immunoliposome-encapsulated drug was less effective, while for RPMI#4788 there was no significant difference.

Discussion

Our initial interest was to determine whether egg phosphatidylcholine liposomes could be used as a carriers for the cytotoxic drugs amsacrine (**1**), CI-921 (**2**), and acridinecarboxamide (**3**). We had thought that acridinecarboxamide would be the most promising compound for encapsulation because of its high solubility in water (>17 mg ml^{-1}) compared with amsacrine (0.12 mg ml^{-1} in water, 2—3 μg ml^{-1} in saline) and CI-921 (0.72 mg ml^{-1} in water, 23 μg ml^{-1} in saline). Surprisingly, LUV containing the acridinecarboxamide, prepared by the reversed-phase evaporation method, were found to encapsulate only 0.2 to 0.4 percent of the compound. This unexpected result arose from drug induced damage of the liposomal membrane and therefore this compound proved to be unsuitable for encapsulation within egg phosphatidylcholine liposomes. By analogy, therefore, these membrane destructive drugs would be expected to cause some membrane toxic effects even on normal cells in vivo.

Because of their low solubility in water, both amsacrine and CI-921 were unsuitable for encapsulation into the aqueous phase. Furthermore, attempts to encapsulate them into the liposome showed that amsacrine was not detectable in the liposomal fraction and the concentration of CI-921 was less than 0.4 μg ml^{-1}. However, when the pH was raised and the drugs were presented to the liposome in their neutral form, there was a significant increase in the concentration of CI-921 incorporated within the lipid bilayers of MLV. Coating the liposomes with cholesterol substituted pullulan (CHP-50-1.9) increased the drug content of CI-921 more than ten fold.

Of the three compounds investigated, only CI-921 was suitable for encapsulation into liposomes, and then only when applied in its neutral form and when the surface of the liposomes was coated with polysaccharide. When the deprotonated drug was encapsulated in pullulan coated liposomes (results not shown) it appeared to be more effective than the free drug against BM-314 cells, but less effective for RPMI#4788-cells. Anti-CEA bearing immunoliposomes (which encapsulated deprotonated CI-921) were also less effective than the free drug, tested against RPMI#4788 and BM-314 cells, even though Sunamoto et al.[13] have shown that these immunoliposomes are very effectively endocytosed by target (BM-314) cells which are CEA-producing. The cytotoxicity of empty egg-PC liposomes and of anti-CEA monoclonal antibodies, at the concentrations employed herein, was negligible (data not shown).

Since the ability of antitumor agents to lyse a cell membrane may be an important parameter in the design of more effective chemotherapeutic agents, we investigated in more detail the ability of four tricyclic carboxamide DNA-intercalating agents, differing in the aromaticity of their tricyclic chromophore, to interact with egg phosphatidylcholine membranes. In order that these lipid-bilayer structures could act as more effective mimics of a cell membrane they were modified by adding cholesterol therein and by coating them with polysaccharide anchored by a cholesterol moiety.

The results shown in Fig. 1 suggest that cholesterol containing liposomes acquired increased resistance against physicochemically induced damage. High concentrations of both the parent phenylquinoline and phenylbenzimidazole were needed to lyse the cholesterol containing liposomal membrane compared with the concentrations required for the conventional and polysaccharide-coated vesicles.

Unexpectedly, the polysaccharide-uncoated liposomes showed greater resistance to lysis compared with the cholesterol containing vesicles if the lysing drug were the parent anthracene (**4**). However, only ten mol percent cholesterol to phospholipid had been added into the membrane and it is possible that at higher concentrations of cholesterol the liposomal membrane may have shown improved stability. Unfortunately, by increasing the ratio of cholesterol to phospholipid above that of ten percent, one runs the risk of altering the structure of the liposomal membrane to such an extent that the bilayer is damaged. Similar results to these present ones were found by O'Connor et al.[20] who reported that incorporation of cholesterol into the liposomes did not affect the ability of some bile salts to lyse the membrane. In fact, in the case of chenodeoxycholic acid, even the addition of fifty mol percent cholesterol to phospholipid did not significantly alter the magnitude of carboxyfluorescein-release from the liposomal membrane.

Previously, Sunamoto et al. had assembled a cell wall-like coat on the outer surface of liposomes using the modified polysaccharides, *O*-palmitoylpullulan

and *O*-palmitoylamylopectin and showed that such liposomes were more tolerant against permeability of water soluble drugs[21] and changes in ionic strength, pH, osmotic pressure as well as enzymatic lysis by lipases or lipoxygenases.[10] However, unlike these previous experiments the present study dealt with the cytotoxic agents which were injected into the external media rather than being encapsulated within the aqueous interior. Under these conditions, the liposomes coated with pullulan-derivative showed the greater susceptibility to lysis. Interestingly, the present results reported on the cytotoxic agents are similar to those obtained by O'Connor et al.[20] for lysis of polysaccharide-coated liposomes by bile salts. They found that coating the surface of SUV with *O*-palmitoylpullulan led to faster release of carboxyfluorescein for all the bile salts investigated. Coating the liposomes with polysaccharides made the vesicles more hydrophobic and resulted in enhanced lysis by the bile salts.[20]

It seems probable, therefore, that the cytotoxic agents interact more favorably with the polysaccharide-coated vesicles than with the unmodified or cholesterol containing liposomes because of the increased hydrophobicity of the interface. Furthermore, it seems that the increased hydrophobicity of the neutral drugs themselves plays a major role in determining lysis. The relative hydrophobicity values[22] of the carboxamides of the parent phenylbenzimidazole, acridine, anthracene, and phenylquinoline are −0.26, −0.20, −0.02, and 0.01, respectively (determined by liquid-liquid chromatography[22,23] compared with the values of log(1/10% lysis) (i.e. the log of the inverse of the concentration (molar) of drug needed to achieve 10 percent release of carboxyfluorescein from SUV after 5 min at 36.5 °C) equal to 3.54, 3.73, 3.80, and 4.49, respectively.

An investigation of the lysing ability of an extended series of phenylquinolines and phenylbenzimidazoles has been reported separately.[23]

We are indebted to T. Koji and N. Ishii (Health Administration Center, Nagasaki University) for the generous donation of the cell lines and N. Nishi (Hokkaido University) for the gift of the monoclonal antibody. H. Tank acknowledges the award of a New Zealand Universities' Grants Committee postdoctoral fellowship. C. J. O'Connor, W. A. Denny, and J. Sunamoto acknowledge financial support from the Research Committees of the New Zealand Universitie' Grants Committee and the University of Auckland, the Auckland Division of the Cancer Society of New Zealand, and the Ministry of Education, Science and Culture, Japan, respectively.

Formation of Small Cobalt Clusters from CoNaY by Reduction with H_2 and Consecutive H_2-O_2 Treatments

Jae C. Kim† and Seong I. Woo*
Department of Chemical Engineering, Korea Advanced Institute of Science and Technology, P.O. Box 131, Cheongryang, Seoul 130-650, Korea
(Received May 11, 1990)

In order to raise the degree of reduction and promote the formation of zerovalent cobalt clusters, repetitive treatments of CoNaY with hydrogen and oxygen were carried out. The intensity of FMR (ferromagnetic resonance) band of CoNaY reduced for 36 h at 773 K with intermittent oxygen treatments was twice as much as that of CoNaY reduced only with hydrogen. This fact meant that reduction of CoNaY with H_2-O_2 treatments favored to produce zerovalent cluster due to the increase in the mobility of Co^{2+} ions in CoNaY. The size of clusters is so small that such conventional methods as hydrogen chemisorption, X-ray diffraction, and TEM can not detect the quantity of zerovalent cobalt clusters. FMR spectroscopy, H_2-consumption measurement, and catalytic probe reaction method were used to measure the degree of reduction and were correlated well with one another.

During the last decade, the properties of small metal cluster have become of increasing interest to physics and physical chemistry of catalysts.[1-3] The prospect of catalytic applications has motivated a large body of research about the preparation of well-defined metal clusters and their characterization to find out the electronic and structural properties in the range of size less than 1 nm. However, the physicochemical properties of supported small metal clusters of size less than 1 nm have not been studied extensively. The major obstacles are the preparation of supported small metal clusters showing stability toward agglomerization and reactant accessibility to the supported metal clusters of very small size. Ag, Cu, Ni, Pt, Pd, and Ru ions exchanged with NaY were easily reduced with hydrogen below 773 K.[4-6] However, these metals were found to migrate to the exterior surface of the zeolite to form clusters of size larger than 1 nm in diameter during reduction. In the case of cobalt, although it was very difficult to reduce cobalt ions exchanged in zeolite even at 773 K, reduced cobalt clusters remained inside zeolite pores.[1,9] This material is adequate to study the catalytic properties of small clusters of size less than 1 nm. Hence, our aim is to find out the method to increase the degree of reduction of cobalt ions in CoNaY to produce more cobalt metal clusters in CoNaY.

Many investigators reported that oxidation-reduction treatments of metal surface can change their catalytic properties in various catalytic reactions.[10-19] This phenomenon was explained based on the surface cleaning by O_2 treatment,[10] the possible promoting influence of oxygen remaining in chemisorbed state on the sub-surface region of metals,[11,12] or the increase in the surface area due to the repeated oxidation and reduction.[13] Amariglio et al.[14-16] recently reported that catalytic activities of cobalt ribbon in CO_2 methanation reaction was largely dependent on various oxidation-reduction treatments due to the significant rearrangement of the surface indicated by AES(Auger electron spectroscopy) and electron microscopy. This rearrangement was ascribed to the increase in the mobility of cobalt atom during oxidation cycles. These studies on the effects of H_2-O_2 suggested that repeated oxidation and reduction of CoNaY might increase the degree of reduction of Co^{2+} in CoNaY. The degree of reduction was measured with FMR which can detect the small amounts of zerovalent cobalt clusters of size less than 1 nm as well as paramagnetic cobalt ions in CoNaY. This FMR result was compared with the results of static H_2-consumption measurement and CO hydrogenation probe reaction.

Experimental

Preparation of Cobalt-Exchanged NaY (CoNaY). NaY zeolite (Strem Chem. Inc.) was used for cobalt ion-exchange. It was pretreated with 0.1 M of NaCl aqueous solution (1 M= 1 mol dm^{-3}) to remove sodium deficiency in NaY. Chloride ions were completely removed by washing with deionized water until AgCl was not precipitated when $AgNO_3$ was added to the spent deionized water. The detailed procedures are described elsewhere.[20] The cobalt loadings of CoNaY were found to be 5.4 wt%. This sample will be abbreviated as Co-IE-5.4 in the following text.

Measurement of H_2-Consumption during the Reduction of CoNaY. The amount of hydrogen consumed at 773 K was measured using chemisorption apparatus to estimate the degree of reduction of Co-IE-5.4 with reduction time. One gram of Co-IE-5.4 was dehydrated under 1.2×10^{-5} Torr (1 Torr=133.322 Pa) at 773 K for 2 h to remove physisorbed water and part of hydroxyl groups on the surface of the zeolite. After dehydration, known volume of H_2 purified with oxytrap and molecular sieve column was introduced to the chemisorption cell. The pressure changes inside the cell during the reduction of CoNaY at 773 K were recorded

† Present address: Chemical Engineering Division, Research Institute of Industrial Science and Technology, Pohang 790-600, Korea.

with MKS Baratron Pressure Guage (Model 170 series). After 20 h of reduction of CoNaY at 773 K, the pressure change with time was insignificant. Total amount of hydrogen either consumed in the reduction of CoNaY, adsorbed on zeolite, or adsorbed on the cobalt clusters reduced at 773 K was calculated from the pressure changes in the cell. In order to find out the exact amount of H_2 only consumed for the reduction of CoNaY, the reduced CoNaY was evacuated to 10^{-5} Torr at 773 K to remove H_2 either physisorbed on zeolite or chemisorbed on the reduced cobalt clusters. And then known volume of H_2 was introduced again into the cell. Because the reduction of CoNaY was completed in the first treatment of hydrogen, the pressure changes in this second treatment are due to the hydrogen adsorbed on zeolite and cobalt clusters. The difference between the amount of first hydrogen consumption and that of second hydrogen consumption indicated the amount of hydrogen consumed for the reduction of CoNaY at 773 K.

FMR Study. FMR spectra were recorded with Varian E-4 ESR (electron spin resonance) spectrometer equipped with a temperature controller to record the FMR spectra in the range of temperature from 153 K to 573 K. The spectrometer was operated in the X-band microwave frequency (9.115 GHz) with a modulation frequency of 100 kHz. An in situ FMR cell to pretreat CoNaY without contact of air reported elsewhere was used.[20] 0.3 g of Co-IE-5.4 was dehydrated under 1.2×10^{-5} Torr at 773 K for 1 h to avoid the complication of water vapor during the pretreatment at 773 K. This dehydrated sample was reduced in 60 ml min^{-1} flow of hydrogen then oxidized in 40 ml min^{-1} flow of oxygen at 773 K. This procedure was repeated. After this pretreatment, sample was evacuated to 10^{-5} Torr for 1 h at 773 K to remove chemisorbed H_2 or O_2 and lowered to 298 K under vacuum. Then the sample was transferred to quartz ESR tube attached to the in situ FMR cell. This ESR tube (o.d.: 4 mm) was placed in the cavity of the ESR spectrometer to record FMR spectra.

CO Hydrogenation Reaction. CO hydrogenation reaction was carried out at 1 atm in a differential flow tubular reactor. Carbon monoxide (Research grade, 99.95%, Takachiho, Japan) and hydrogen (99.995% purity) prepared with electrolysis (Teledyne Electro Cell hydrogen gas generator, Model MG 251) were further purified with oxytrap and molecular sieve trap. Oxygen (UHP, 99.99%, Matheson, USA) was used for oxidation of catalyst. Small amount of iron carbonyl was removed by decomposing it above 623 K in the preheating zone. The flow rates of CO and H_2 were controlled with fine metering valve and mass flow meter (Brooks Inc., Model 5841). Reaction temperature was controlled with digital programmable controller with microprocessor (PID type controller, RKC Instrument Inc. Model Rex-100). Reaction products were analyzed with a gas chromatograph (Hewlett-Packard, Model 5840A) equipped with porapak Q column (0.32 cm diameter, 1.83 m long). 0.2 g CoNaY was introduced to the reactor and pretreated with 60 ml min^{-1} of hydrogen flow at 523 K for 30 min. Temperature was raised slowly to the desired reduction or oxidation temperature (10 °C min^{-1}). After reduction-oxidation pretreatments, temperature was set at the reaction temperature under 20 ml min^{-1} of hydrogen flow. CO hydrogenation reaction was initiated by introducing 10 ml min^{-1} of carbon monoxide.

Results

Measurement of the Degree of Reduction. The amount of H_2-consumption during the reduction of Co-IE-5.4 was measured to estimate the degree of reduction of Co-IE-5.4. The amount of cobalt clusters was calculated from the amount of H_2 consumed in reducing Co^{2+} ions to Co metal clusters ($Co^{2+}+H_2\rightarrow Co+2H^+$). Figure 1(A) showed total amount of

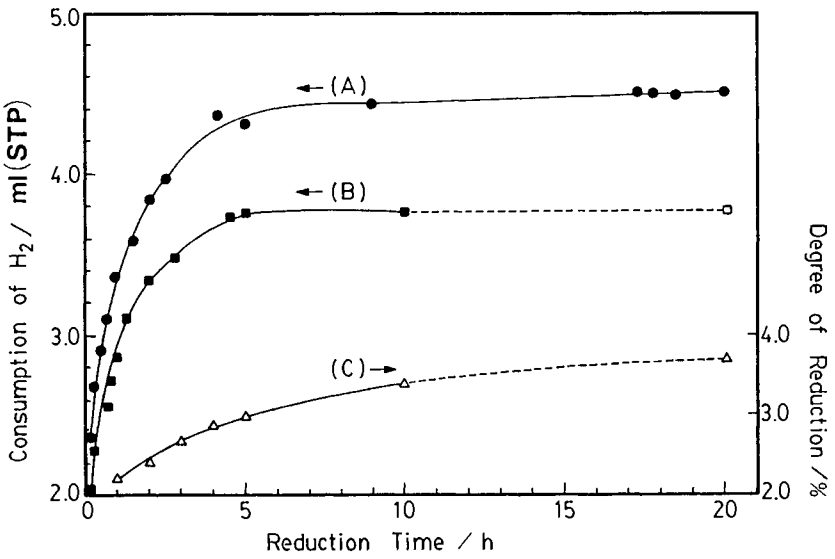

Fig. 1. H_2-consumption and % degree of reduction measured at 773 K as a function of reduction time. (A): total amount of H_2-consumption, (B): amount of H_2 adsorbed either on zeolite or reduced cobalt cluster at 773 K, (C): amount of H_2 consumed only for the reduction.

hydrogen consumed as a function of reduction time at 773 K. Total consumption of H_2 increased rapidly up to 1 h followed with a slow increase. The amount of H_2-consumption was very small after 3 h and negligible after 25 h. This sample was evacuated at 10^{-5} Torr and 773 K for 30 min, then the experiment was repeated to measure the amount of reversible adsorption (Fig. 1(B)). By subtracting the amount of H_2 reversibly adsorbed from total amount of H_2 consumed, the amount of H_2-consumption to reduce Co^{2+} ions to Co metal clusters was calculated. Percent degree of reduction was calculated from this value as shown in Fig. 1(C). The degree of reduction is 3.8% after 20 h of reduction at 773 K. Lee and Ihm[21] measured the degree of reduction with the method developed by Jacobs et al.[22] Their value is almost twice as much as ours, because the amount of H_2 consumption by Jacobs' method included H_2 physisorbed on zeolite or chemisorbed on cobalt clusters formed during reduction.

The general static method of H_2-chemisorption at room temperature with this reduced Co-IE-5.4 did not give any reproducible results either because the amount of zerovalent cobalt clusters (0.2 wt%) is too small or because H_2 chemisorption is suppressed on the cobalt clusters of size less than 1.3 nm in NaY.

FMR Study on the Formation of Cobalt Clusters on CoNaY. FMR spectra of Co-IE-5.4 reduced only with hydrogen at 773 K are shown in Fig. 2. An FMR band of weak intensity appeared overlapped with a weak EPR (electron paramagnetic resonance) band of Co^{2+} (g=2.007) after 1 h of reduction (Fig. 2(A)). A broad and asymmetric band appeared after reduction of Co-IE-5.4 with H_2 for 6 h (see Fig. 2(B)). The temperature dependence of this FMR spectrum is shown in Fig. 3. The FMR band of Fig. 2(B) was deconvoluted based on the assumption that the band is composed of two bands, i.e., broad band (I) of Gaussian type and narrow band (II) of Lorenzian type. Computer simulation with adequate g-values, band widths, and band heights of bands (I) and (II) gives the amount of contribution of bands (I) and (II) to total bands as shown in Table 1. A symmetric and broad band (band (I)) appeared (g=2.278, ΔH_{pp}, peak-to-peak band width=900 G) at the FMR recording temperature of 303 K (Fig. 3). A sharp band (band (II)) started to appear (g=2.132, ΔH_{pp}=330 G) at the FMR recording temperature of 423 K, which was superimposed with band (I). Because of appearance of band (II) the whole FMR band became asymmetric, which was more pronounced at 523 K. FMR spectra of Co-IE-5.4 became symmetric and ΔH_{pp} decreased as the reduction time increased as shown in Figs. 2(C) and 2(D).

It was expected that as the reduction time increased, the size of cobalt clusters must increase, which should be reflected in the increase in ΔH_{pp}. However, the opposite phenomenon was observed. At the initial stage of reduction for 1 h, a broad FMR of weak intensity appeared (Fig. 2(A)). The intensity of this broad band increased rapidly during the reduction for 6 h. Cobalt ions located in the sodalite and the

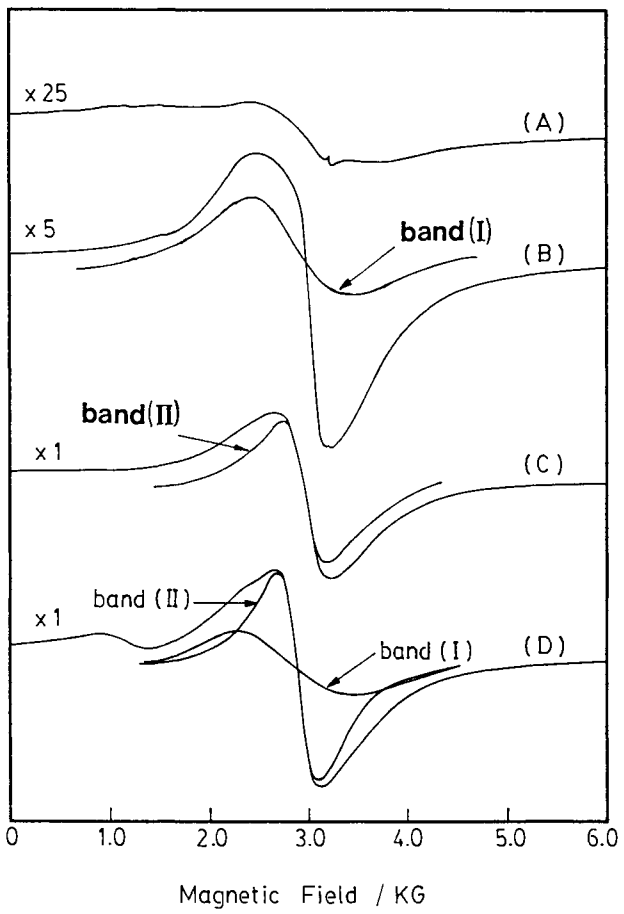

Fig. 2. FMR spectra of Co-IE-5.4 recorded at 523 K reduced with H_2 at 773 K. (A): reduced for 1 h, (B): reduced for 6 h, (C): reduced for 20 h, (D): reduced for 40 h.

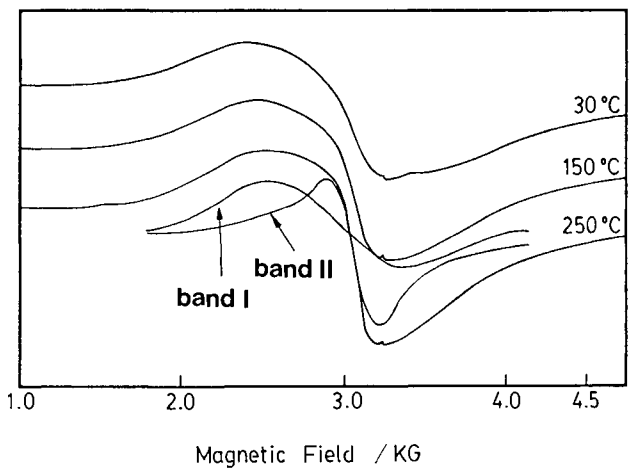

Fig. 3. FMR spectra of Co-IE-5.4 reduced at 773 K for 6 h as a function of recording temperature.

Table 1. Relative Portions of Band(II) in Total FMR Band of CoNaY Reduced with Hydrogen and H_2-O_2 Cycles

Seq. No.	Pret. cond.	Amplitude of total band[a)]	ΔH_{pp} / G	Amplitude of band(II)	Ratio of amplitude of band(II) to that of total band
	R-6	12.4	760	10.6	0.85
	R-20	35.0	600	31.8	0.88
	R-40	45.0	490	43.2	0.96
1	R-3	1.7	825	1.2	0.71
2	O-1-R-5	12.8	840	8.4	0.65
3	O-1-R-12	43.0	900	17.0	0.40
4	O-1-R-15	55.0	880	14.0	0.25

a) Amplitude indicates the height of FMR band (a.u.).

supercage are found to be reduced very slowly.[20] Hence, the band of Fig. 2(A) and the broad band of Fig. 2(B) must be ascribed to unexchanged cobalt hydroxide remained on the exterior surface or the cobalt ions located on the exterior surface of the zeolite because of their fast reduction rate. However, the amount of this cobalt species was smaller than cobalt ions located inside zeolite pores. Further redution of Co-IE-5.4 produced more cobalt clusters inside zeolite pores, resulting in the increase of the intensity of narrow FMR band (Fig. 2(C)) overlapped with broad band (I) whose intensity is much less than that of narrow band (II) (see Table 1). After reduction for 40 h, ΔH_{pp} was 490 G at 523 K while g-value did not vary much (g=2.20). The intensity of band (II) increased more rapidly than that of band (I) as reduction time increased.

The FMR spectra of Co-IE-5.4 reduced with H_2-O_2 cycles are shown in Fig. 4. The FMR spectrum of Co-IE-5.4 after reduction for 3 h showed two peaks similar to the FMR band of Co-IE-5.4 reduced for 6 h (see Fig. 4(A) and Fig. 2(B)). After oxidation for 1 h and further reduction for 5 h, the intensity of band (I) increased, while the contribution of band (II) superimposed with band (I) decreased as compared with that of Co-IE-5.4 reduced with only H_2 for 6 h (see Fig. 2(B) and Table 1). However, band (II) is clearly present in Fig. 4(B) (g=2.122, ΔH_{pp}=300 G). After repeated pretreatments of H_2-O_2 the shape of FMR band became symmetric without much change in ΔH_{pp} and g-value ($800<\Delta H_{pp}<900$ G and g=2.3). However, the intensity of the band increased.

The intensity of FMR band obtained from the double integration of FMR spectrum is proportional to the amount of Co metal clusters reduced from Co-IE-5.4 if the magnetic susceptibility per cobalt atom is constant regardless of size and shape of cobalt clusters. The intensity of FMR band of cobalt clusters reduced from Co-IE-5.4 with H_2 is shown in Fig. 5(A). When Co-IE-5.4 was pretreated with H_2-O_2 repeatedly, the intensity of FMR band increased more rapidly as shown in Fig. 5(B). The intensity of FMR band of Co-IE-5.4 reduced for 36 h at 773 K with intermittent oxygen treatments is twice as much as that of Co-IE-5.4 reduced with H_2 only.

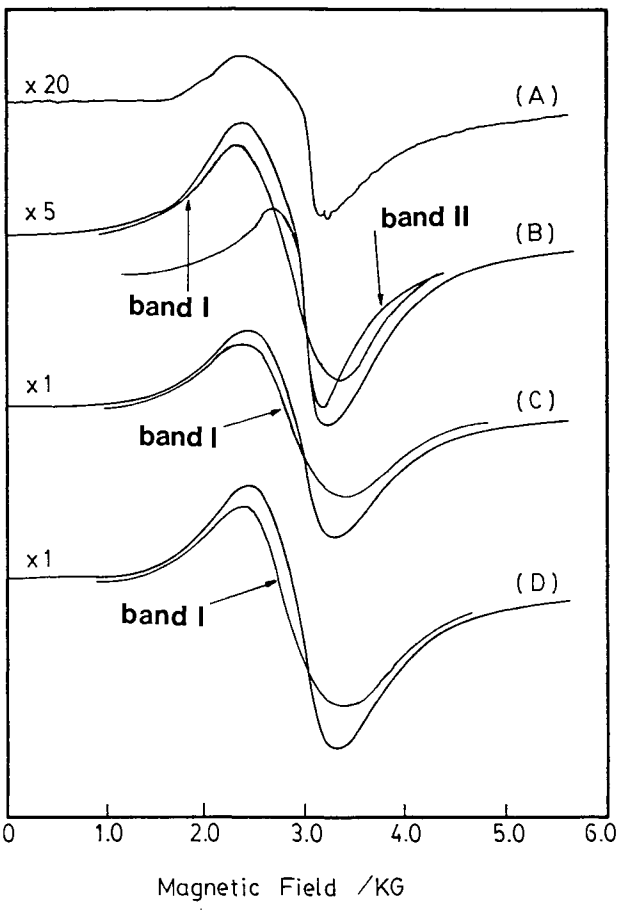

Fig. 4. FMR spectra of Co-IE-5.4 after repetitive pretreatments of H_2-O_2 recorded at 523 K. (A): reduced only for 3 h, (B): oxidized for 1 h and then reduced for 5 h after pretreatment of (A), (C): oxidized for 1 h and then reduced for 12 h after pretreatment of (B), (D): oxidized for 1 h and then reduced for 15 h after pretreatment of (C).

CO Hydrogenation Reaction. Catalytic activities per gram of cobalt of Co-IE-5.4 reduced by either H_2 or cyclic pretreatments of H_2 and O_2 are shown in Figs. 6(A) and (B), respectively. Co-IE-5.4 was pretreated by O_2 at 773 K for 1 h at each point in Fig. 6(B) and purged by helium for 30 min before reduction with

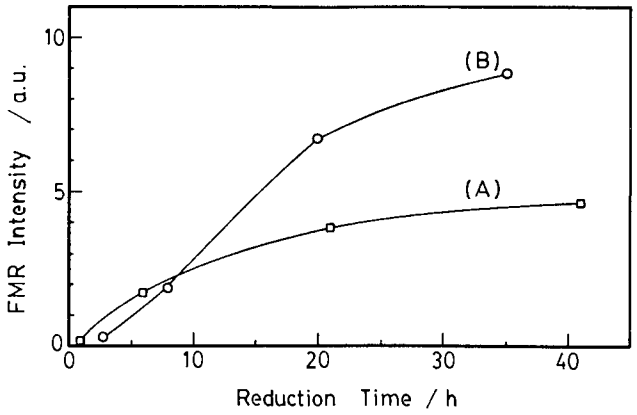

Fig. 5. The intensity of FMR band obtained from double integration of FMR band. (A): as a function of reduction time, (B): as a function of total reduction time. One hour of oxidation was carried out at each point prior to reduction.

H_2. The activities of Co-IE-5.4 reduced by H_2-O_2 treatments were higher by 1.6 times than that of Co-IE-5.4 reduced by only H_2 after 36 h of reduction. In the case of reduction with H_2 only, the pattern of increase in the catalytic activity with reduction time was different from that of increase in the amount of zerovalent cobalt cluster as shown in Figs. 1 and 5. The activity did not increase much up to 25 h of reduction but increased rapidly after 25 h of reduction. In contrast, the catalytic activity of Co-IE-5.4 reduced with H_2-O_2 cycles increased more rapidly than that of Co-IE-5.4 reduced with H_2 only up to 20 h of reduction. After 20 h of reduction, the activity of Co-IE-5.4 reduced with H_2-O_2 cycles increased in the rate similar to that of Co-IE-5.4 reduced with H_2 only.

Selectivities, activities, and TON are shown in Tables 2 and 3. The methane selectivity of Co-IE-5.4 pretreated with only H_2 was lower than that of Co-IE-

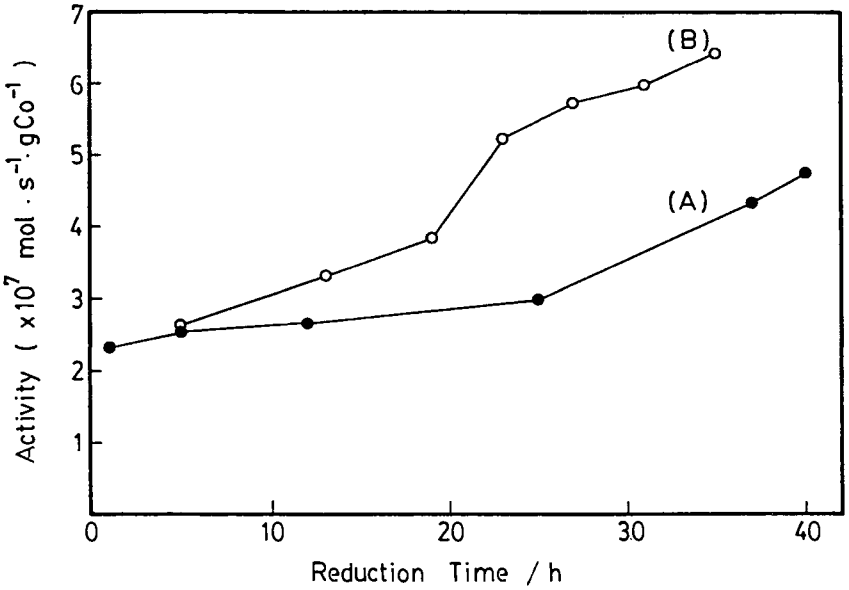

Fig. 6. The catalytic activities of Co-IE-5.4 in CO hydrogenation reaction. (A): as a function of reduction time, (B): as a function of total reduction time. Oxidation was carried out for 1 h at each point prior to reduction.

Table 2. Catalytic Activities and Selectivities of Co-IE-5.4 in CO Hydrogenation Reaction at 723 K as a Function of Reduction Time

Pret. cond.	Activity[b]	Selectivity/mol%			TON[c]
	$\times 10^7$ mol s^{-1} (g-Co)$^{-1}$	C_1	C_2	C_3	$\times 10^3$ s^{-1}
R-1[a]	2.33	71.0	23.9	5.1	0.01
R-5	2.55	74.4	21.1	4.5	0.50
R-12	2.67	75.2	20.5	4.3	0.46
R-25	2.99	75.2	20.5	4.3	0.48
R-37	4.43	77.6	19.1	3.3	—
R-40	4.78	77.2	19.1	3.7	—

a) R-1 means reduction in H_2 flow (60 ml min^{-1}) for 1 h at 773 K. b) Based on the amount of hydrocarbons produced after 30 min of reaction. c) TON based on the amount of zerovalent cobalt cluster of 100% dispersion measured with H_2 consumption method.

Table 3. Catalytic Activities and Selectivities of Co-IE-5.4 in CO Hydrogenation Reaction at 723 K after Cyclic Pretreatments of H_2-O_2

Sequence No.	Pret. cond.	Activity[b]	Selectivity/mol%		
		$\times 10^7$ mol s^{-1} (g-Co)$^{-1}$	C_1	C_2	C_3
1	R-5	2.55	74.4	21.1	4.5
2	O-1-R-8[a]	3.32	78.4	18.0	3.6
3	O-1-R-6	3.84	78.8	17.8	3.4
4	O-1-R-4	5.25	81.8	15.3	2.9
5	O-1-R-4	5.71	84.1	13.2	2.7
6	O-1-R-4	5.99	84.5	12.9	2.6
7	O-1-R-4	6.41	85.5	12.1	2.4

a) O-1-R-8 means that after experiment of seq. no. 1, Co-IE-5.4 was oxidized at 773 K for 1 h, then reduced at 773 K for 8 h. b) Based on the amount of hydrocarbons produced after 30 min of reaction.

5.4 pretreated H_2-O_2 cycles. In both cases, the activities and selectivities of methane increases with increasing reduction time. Ethane and propane were not produced. Only ethylene and propylene were produced. In contrast, the cobalt clusters of size larger than 2 nm at 723 K in CO hydrogenation reaction produced only methane.

Discussion

Reducibility of Co^{2+} Ions in Co-IE-5.4. As shown in Fig. 1(C), 90% of reduction proceeded within 10 h and thereafter reduction proceeded very slowly (H_2-consumption rate=0.06 ml h^{-1}). Co^{2+} ions in CoNaY were reduced rapidly at the initial stage of reduction (H_2-consumption rate=0.46ml h^{-1}). This result suggests that the location of cobalt ions in CoNaY to be reduced determines the rate of reduction. Co^{2+} ions located on the exterior surface of CoNaY or on supercage (site II and site III) are reduced more rapidly than Co^{2+} ions located in sodalite cage (site I′ and site II′), resulting in higher H_2-consumption rate at the initial stage of reduction. Co^{2+} ions located in hexagonal prism (site I) may not be reduced at all. Our sample used in H_2-consumption measurement was dehydrated at 773 K to avoid adverse effect of water vapor on the reduction of Co^{2+} with H_2. During dehydration, Co^{2+} ions were migrated from supercage into either sodalite cage or hexagonal prism.[23-25] Gallezot and Imelik[25] reported through their X-ray diffraction study that 83 and 17% of Co^{2+} ions were located in hexagonal prism and sodalite cage, respectively, when 55% cobalt-changed CoNaY was completely dehydrated. When CoNaY was partially dehydrated, 41, 37, and 22% of Co^{2+} ions were located in hexagonal prism, sodalite cage, and supercage, respectively. The degree of ion-exchange in Co-IE-5.4 is 58%, which is similar to that of the work of Gallezot and Imelik. Our sample has a small amount of Co^{2+} ions located in the supercage which can be reduced rapidly at the initial stage of reduction. Most of Co^{2+} ions located inside sodalite cage and hexagonal prism can not be reduced, resulting in the small degree of reduction (3.8%).

FMR results are also in agreement with H_2-consumption measurement. After 1 h of reduction, band (I) appeared without the appearance of band (II) (Fig. 2(A)). Band (II) was ascribed to the cobalt clusters located in supercage indicated by the narrow ΔH_{pp} and its Lorenzian line shape according to the results of Che et. al.[26] Jacobs et. al.[27] also reported that Lorenzian line shape or Gaussian line shape of FMR band was obtained if the spherical metal particles had a certain particle size distribution and that FMR band of Gaussian line shape was assigned to the population of large particles. The FMR bands of Co-IE-5.4 reduced with H_2 were composed of band (I) of Gaussian line shape and band (II) of Lorenzian line shape estimated by Poole's method.[28] The intensity of band (II) increased with reduction time, suggesting that Co^{2+} ions inside zeolite cage were slowly reduced. The relative portion of band (II) superimposed with band (I) increased with reduction time (see Table I). ΔH_{pp} and g-values of band (II) did not change much with recording temperature (see Fig. 3), which is characteristic of superparamagnetic cobalt particles. Prolonged reduction did not cause ΔH_{pp} of band (II) to be increased indicating that there was no sintering of cobalt clusters. Cobalt clusters are stabilized inside zeolite pores (see Table 1, Figs. 2(B) and 2(D)). Band (I) appeared right after the reduction started. And its contribution to the total FMR band of Co-IE-5.4 reduced for 40 h at 773 K is only 4% (see Table 1). These results indicated that cobalt ions present as a hydroxide form on the exterior surface or in the half sphere of supercage on the exterior surface are reduced to show band (I).

Iton et. al.[3] reported the FMR spectra of cobalt clusters prepared from the reduction of $Co(NH_3)_6^{3+}$-exchanged Y zeolite. High temperature FMR data suggested that a small amount of Co metal particles was produced. ΔH_{pp} of their FMR spectrum of cobalt clusters at FMR recording temperature of 523 K was 600 G, which is larger than that of Co-IE-5.4 reduced

with hydrogen for 40 h at 773 K (ΔH_{pp}=490 G). This indicated that the size of cobalt clusters in Co-IE-5.4 is less than that of cobalt clusters reported by Iton et al.[3] Zerger et al.[29] also reported the FMR spectra of cobalt clusters supported on NaX obtained from the decomposition of $Co_2(CO)_8$ with microwave discharge. The ΔH_{pp} of prepared cobalt clusters (30 Å in diameter) was 1050 G at 523 K, which is larger than that of our sample. From these previous results, it can be concluded that the size of cobalt clusters obtained from the reduction of Co-IE-5.4 with H_2 is the smallest and that the size of cobalt clusters is dependent on the preparation method of cobalt clusters, although we failed to measure the size of cobalt clusters in CoNaY with TEM and hydrogen chemisorption method.

Reduction of Co-IE-5.4 Facilitated with H_2-O_2 Treatments. The FMR spectra of Co-IE-5.4 reduced with H_2 with intermittent oxygen treatments are presented in Fig. 4. The relative portion of Lorenzian band (II) in the FMR band decreased as the number of oxygen treatment increased (see Table 1). In addition to the change in line shape of FMR band, the degree of reduction with H_2-O_2 treatment is twice as much as that of reduction with only hydrogen (see Fig. 5).

It is clear that H_2-O_2 treatment facilitated the reduction of cobalt ions in Co-IE-5.4. It produced cobalt clusters larger than those produced by H_2-reduction. This result can be explained by the fact that O_2 pretreatment increases the mobility of Co^{2+} ions in CoNaY, resulting in the migration of nonreducible Co^{2+} ions located either in hexagonal prism or in sodalite cage to supercage. Co^{2+} ions in supercage were reduced more easily than Co^{2+} ions in hexagonal prism and sodalite cage. The probability that Co^{2+} ions can migrate to the supercage and the exterior surface of zeolite and collide with the cobalt clusters to form a large cobalt cluster was enhanced during the oxygen treatment at 773 K. The contribution of band (I) to the total FMR band increased with the number of oxygen treatment at 773 K indicating that the cobalt clusters inside supercage migrated out to the exterior surface of zeolite to form larger cobalt clusters. However, the size of cobalt clusters on the exterior surface of zeolite is still in the range of superparamagnetic particles evidenced by the fact that the g-value, intensity, ΔH_{pp} and symmetric shape of FMR band of cobalt clusters produced did not change much with the FMR recording temperature.

Catalytic Properties of Small Cobalt Clusters in CoNaY. Many authors showed that TON's in CO hydrogenation reaction increased with decreasing dispersion in the case of Co,[30,31] Ni,[32,33] Ru,[34,35] and Fe.[36] Jung et al.[36] reported that the TON increased more than 20 fold as iron crystallite size increased from about 1 to 10 nm, whereas the activities of gram iron or gram catalyst basis were similar because the low TON's on high dispersion catalysts were compensated by the higher iron surface area. We reported that TON of cobalt clusters (100 nm in diameter) prepared by impregnating aqueous $Co(NO_3)_2 \cdot 6H_2O$ solution to NaY (10 wt% cobalt loading) is 34 s^{-1} and that TON of cobalt clusters prepared by the reduction of Co-IE-5.4 (0.8 nm in diameter by CO chemisorption method) is 0.46×10^{-3} s^{-1} in the CO hydrogenation reaction at 723 K.[20] The TON's of cobalt clusters obtained by the H_2 reduction of Co-IE-5.4 are in the range of order of 10^{-4} s^{-1} in the CO hydrogenation reaction at 723 K (see Tables 2 and 3). We suspected that this small catalytic activity may come from the impurity of metals in NaY produced by H_2 reduction. Hence, we reduced NaY with H_2 in the same manner as the reduction of CoNaY and found out that NaY reduced with H_2 has no catalytic activity in the CO hydrogenation reaction at 723 K. This allows us to conclude that the small catalytic activity of Co-IE-5.4 reduced with H_2 is ascribed to the small cobalt clusters produced. This low catalytic activity must be due to the suppression of hydrogen chemisorption on the small cobalt clusters less than 1.3 nm, which is the approximate size of the supercage in NaY. The appreciable amount of H_2 could not be chemisorbed on cobalt clusters in Co-IE-5.4 at room temperature. However, very small amount of H_2 can be dissociatively chemisorbed at 723 K, because the H_2 chemisorption on cobalt clusters is known to be an activated chemisorption.[37] The appreciable catalytic activity in CO disproportionation reaction at 393 K with small cobalt clusters of Co-IE-5.4[38] indicated that CO is easily dissociatively chemisorbed on the cobalt clusters of sizes less than 1.3 nm at 393 K. These results lead us to conclude that the small catalytic activity of small cobalt clusters in the CO hydrogenation reaction is due to the suppression of H_2 chemisorption. The capability to produce C_2- and C_3-hydrocarbon at the reaction temperature of 723 K also suggests a unique catalytic properties of small cobalt clusters. The suppression of H_2 chemisorption is also evidenced by the formation of C_2- and C_3-olefinic hydrocarbons.

The catalytic activity in CO hydrogenation reaction increased with reduction time as shown in Fig. 6(A). The activity of Co-IE-5.4 increased more rapidly with intermittent O_2 treatments between each reduction steps than with reduction by only H_2. The similar increasing trend of activity with that of FMR intensity means that the increase in the catalytic activity is related to the increase in the amount of cobalt metal clusters reduced from CoNaY whether it is prepared by H_2 only or repetitive H_2-O_2 treatment. This result indicated that the reduction is facilitated by the intermittent O_2 treatment due to the increase in the mobility of Co^{2+}, which is consistent with FMR results.

In summary, small cobalt clusters obtained by the reduction of CoNaY are adequate materials to study the catalytic properties of supported small cobalt clusters of diameters less than 1.3 nm. The reduction was facilitated by the consecutive H_2-O_2 treatment evi-

denced by FMR and CO hydrogenation probe reaction results. The chemisorption of H_2 on the very small size of cobalt clusters in Co-IE-5.4 was suppressed, while the CO chemisorption was not suppressed. The extraordinarily low catalytic TON's and 100% selectivity toward to olefinic hydrocarbons are supporting the suppression of H_2 chemisorption on the small cobalt clusters of Co-IE-5.4.

The Conformational Changes of Poly(L-ornithine) with Organic Counter Ions in Aqueous Sodium 1-Decanesulfonate Solution

Makoto AOYAGI, Tamaki MAEDA, Katumitu HAYAKAWA, and Iwao SATAKE*
Department of Chemistry, Faculty of Science, Kagoshima University, Korimoto, Kagoshima 890
(Received October 3, 1990)

Synopsis. The circular dichroism study was made of the coil-helix transitions of poly(L-ornithine) with 1-alkanesulfonate counter ions of the chain length from 3 to 6 in sodium 1-decanesulfonate solution. The conformational change is insensitive to the counter ion chain length and becomes appreciable even at surfactant concentrations as low as $(1—2)\times10^{-4}$ mol dm^{-3}.

It is well known that additions of the ionic surfactants to the oppositely charged polypeptides in neutral solutions induce conformational transitions from coil to ordered structures.[1-9] For instance, poly(L-ornithine) (PO) undergoes a coil to helix transition in solutions of anionic surfactants such as sodium alkyl sulfate[10-12] and alkanesulfonate[8,9] even at remarkably lower concentrations than critical micelle concentrations. It has been inferred from the binding isotherm measurements that the surfactant ion binds cooperatively onto PO chain to give rise to a micelle like cluster.[8,9,12] The presence of such clusters has been pointed out to be essential for the surfactant-induced coil to helix transition of PO.[8]

So far as we know, however, all of the studies reported so far are concerned only with the ionic polypeptides with inorganic counter ions. It is thus interesting to study the surfactant induced conformational change of polypeptide with organic counter ion of varying hydrophobicity, since the presence of such counter ions is anticipated to affect the binding characteristics of surfactant ion. In this paper we report on the conformational changes of poly(L-ornithine) with 1-alkanesulfonate counter ions of carbon atoms n=3, 4, 5, and 6 (PO·C$_n$) in sodium 1-decanesulfonate (SDeS) solution.

Experimental

SDeS was synthesized from vacuum distilled 1-bromodecane by the sulfonation with sodium sulfite. Sodium 1-alkanesulfonates (Guaranteed grade, Tokyo Kasei Kogyo Co., Ltd.) were used without further purifications. Hydrochloride of PO (PO·Cl) and PO·C$_n$ were prepared by dialyzing hydrobromide of PO (Sigma, MW=41000 for n=5 and 6, and 25000 for the rest) against 0.1 mol dm^{-3} HCl and the corresponding sodium 1-alkanesulfonate respectively, and then against distilled water. The polypeptide concentration (C_p) in molarity of ionic groups was determined by colloid titration with poly(potassium vinyl sulfate) (Wako Pure Chemical Industries Ltd.).

Circular dichroism (CD) spectra of PO·Cl and PO·C$_n$ were measured as a function of SDeS concentration under the condition of constant C_p of 2.5×10^{-4} mol dm^{-3}. The spectra were recorded on JASCO spectropolarimeter J-20A. The potentiometric measurement on PO·C$_5$ - SDeS system was made with a cell based on nitrobenzene membrane electrode. The construction of the cell was described elsewhere.[13] All measurements were conducted in the absence of added salt at 25 °C.

Results and Discussion

Figure 1 shows the typical CD spectra of PO·C$_5$ recorded shortly after mixing with SDeS solutions of varying concentrations (C). Similar results are also obtained for PO·Cl and PO·C$_n$ with n=3, 4, and 6. In all cases, the CD spectrum varies successively from a characteristic spectrum of random coil at C=0 to that of helical conformation with a double minimum located around 207 and 222 nm. The presence of the isoelliptic point at 205 nm suggests the occurrence of a simple conformational transition from coil to helix under our experimental conditions.

According to the theory of polyelectrolyte solutions, the fraction of condensed counter ions is given by

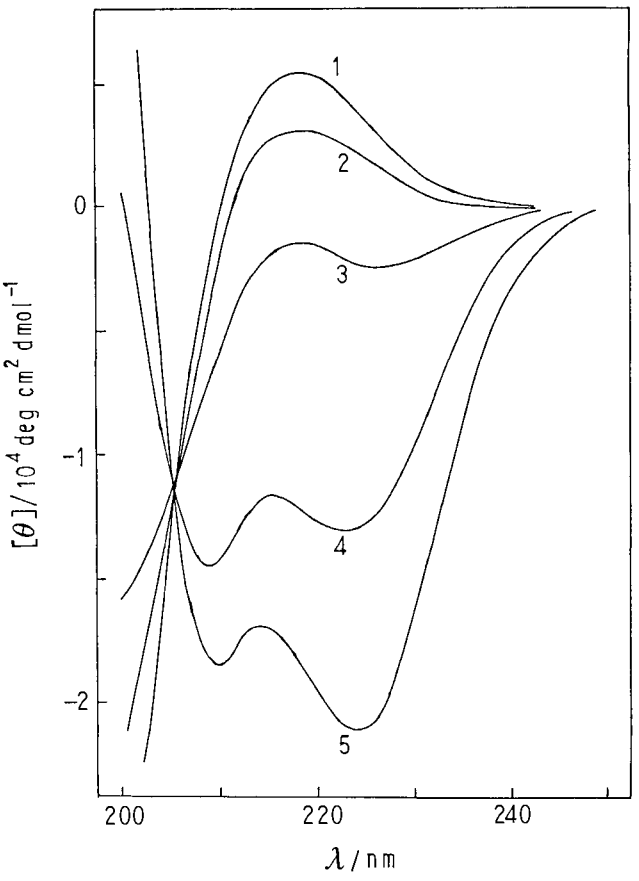

Fig. 1. The change in CD spectrum of PO·C$_5$ with SDeS concentration (C). C_p=2.5×10^{-4} mol dm^{-3}; C/mmol dm^{-3}=0 (1), 0.25 (2), 0.5 (3), 1.25 (4), 3.0 (5).

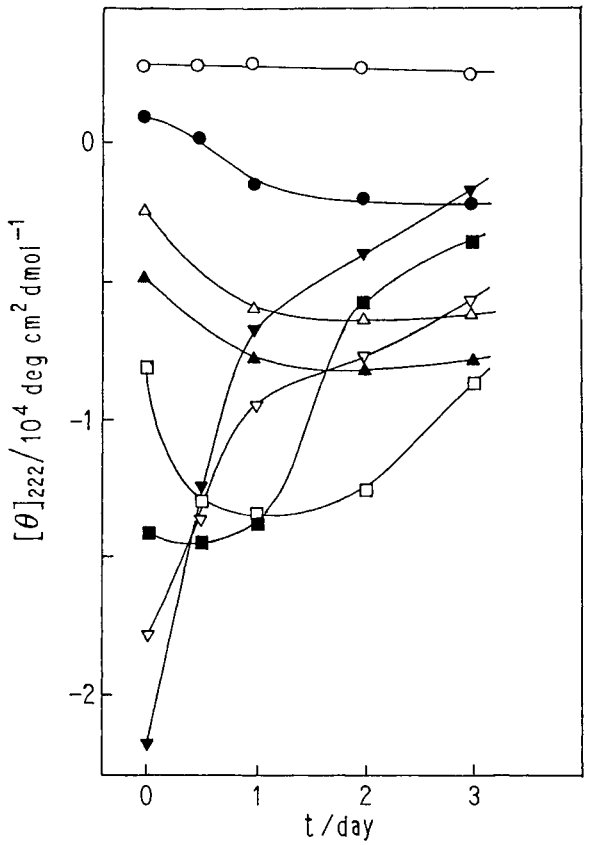

Fig. 2. The time-course of $[\theta]_{222}$ for PO·C_5 in SDeS solutions. C_P=2.5×10^{-4} mol dm^{-3}; C/mmol dm^{-3}=0 (○), 0.50 (●), 0.75 (△), 1.00 (▲), 1.25 (□), 1.50 (■), 2.00 (▽), 3.00 (▼).

$1-1/\xi$, where ξ represents a dimensionless structural parameter defined in terms of the average axial charge spacing (d) in nm as $\xi=0.714/d$ in water at 25 °C.[14,15] For the present systems, the structural consideration suggests that roughly 50% of counter ions are condensed onto PO chain. Therefore, it is highly probable that the average hydrophobicity around PO chain increases monotonically with increasing chain length of the counter ion even in the absence of surfactant ion. Nevertheless, CD spectrum of PO shows the characteristics of a random coil regardless of n. This fact implies that the presence of condensed hydrophobic counter ions with n up to 6 is insufficient to induce a conformational change of PO·C_n alone.

The CD spectrum of PO·C_n in SDeS solution varies gradually over a period of days on standing. A typical example for PO·C_5 is shown in Fig. 2. At lower surfactant concentrations, the mean residue ellipticity at 222 nm, $[\theta]_{222}$, the magnitude of which is proportional to the helical content, decreases monotonically with time and tends eventually to a constant. At higher surfactant concentrations, however, $[\theta]_{222}$ goes through a minimum or increases rapidly with time, because of the progress of aggregation process. Taking these into consideration, we adopted the minimum value of $[\theta]_{222}$ as a measure of helical content at a given surfactant concentration.

In Fig. 3 are plotted the values of $[\theta]_{222}$ thus determined as a function of surfactant concentration. In all cases, the helical content of PO increases monotonically with increasing surfactant concentration and becomes eventually constant at higher concentrations where the visible precipitate of PO—surfactant complex appears.

An interesting feature of Fig. 3 is an unexpected resemblance among $[\theta]_{222}$ vs. C curves for PO with counter ions of varying hydrophobicity. As a result of counter ion condensation phenomenon as noted above, the average hydrophobicity around binding

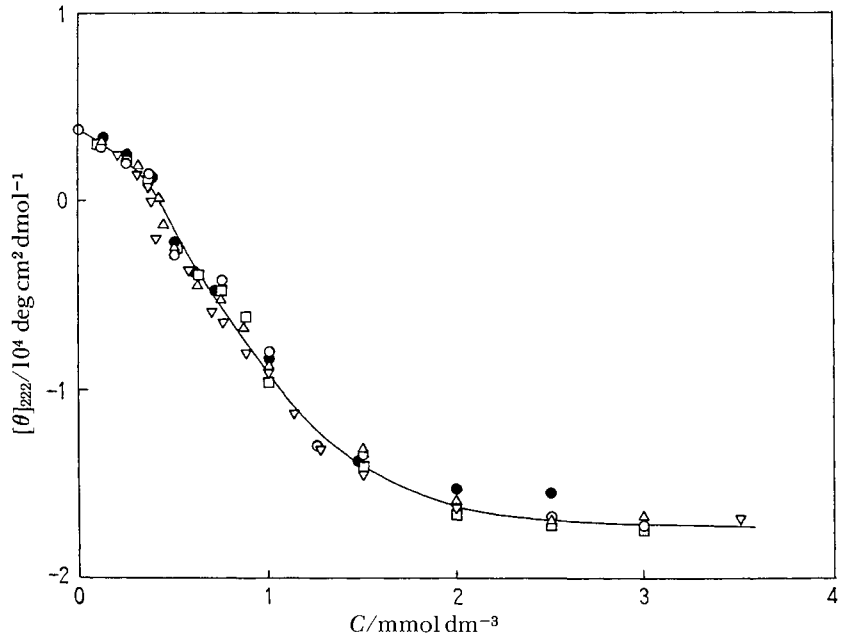

Fig. 3. The change in $[\theta]_{222}$ for PO·Cl and PO·C_n with SDeS concentration. C_P=2.5×10^{-4} mol dm^{-3}: ○, PO·Cl; △, n=3; □, n=4; ▽, n=5; ●, n=6.

site is supposed to increase regularly with increasing chain length of the counter ion. This effect will bring about a change in the intrinsic binding constant of the surfactant ion to PO. In addition, the bound surfactant ions are anticipated to form a mixed cluster with condensed counter ions, especially of a longer chain length. In solutions of PO·C_n, therefore, the binding mechanism on which the conformational change rests is considered to differ somewhat from that in solutions of PO with inorganic counter ions. In the latter case, the average cluster size of the bound surfactant ions is pointed out to be a primary determinant of the surfactant induced coil to helix transition.[8] Although the detailed explanation for the observed resemblance among $[\theta]_{222}$ vs. C curves can not be offered at the present stage, it is probable that the overall hydrophobicity of PO·C_n-surfactant complex at a given surfactant concentration is nearly identical with one another regardless of the counter ion chain length.

Another feature of Fig. 3 is the onset of conformational change at remarkably low concentration range as low as $(1—2)\times10^{-4}$ mol dm^{-3}. This behavior is in marked contrast with that of PO·Cl in SDeS solutions in the presence of added NaCl.[8,9] Under the conditions of $C_p=2.15\times10^{-4}$ mol dm^{-3} and [NaCl]$=2.1\times10^{-2}$ mol dm^{-3}, $[\theta]_{222}$ of PO·Cl was found to decrease abruptly around $C=7\times10^{-4}$ mol dm^{-3}, where the steep rise in binding isotherm occurs.[8,9] Moreover, an addition of the salt has been noted to affect the binding characteristics of the surfactant ion to polyelectrolyte in such a way that the logarithm of the equilibrium surfactant concentration at half binding decreases linearly with the logarithm of the added salt concentration.[16–18] Thus the present result can reasonably be attributed to an onset of surfactant ion binding in the concentration range much lower than that in salt solutions. In order to make this point clear, the potentiometric study was made for PO·C_5 system. Figure 4 shows the plots of electromotive force (E) of the cell vs. log C for SDeS solutions with and without PO·C_5. In the absence of PO·C_5, the electrode responds to the 1-decanesulfonate ion down to 5×10^{-5} mol dm^{-3} with a slope of 58.2 mV. In the presence of PO·C_5, E vs. log C curve is seen to deviate remarkably from that of SDeS solution alone. Under our experimental conditions, the interference of 1-pentanesulfonate ion can safely be neglected since the selectivity coefficient of 1-pentanesulfonate ion with respect to 1-decanesulfonate ion is of the order of 3×10^{-3}.[19] Unfortunately, we can not construct the binding isotherm from Fig. 4 because of the lack of a detailed knowledge of the counter ion activity coefficient in such a complex system as surfactant-polyelectrolyte solution without added salt. With these reservations in mind, an equilibrium surfactant concentration is considered to be small enough even at the lowest concentration studied ($C=2\times10^{-4}$ mol dm^{-3}). This in turn supports the foregoing presumption that the surfactant ion binding starts at remarkably low concentration range around $(1—2)\times10^{-4}$ mol dm^{-3}.

Electrochemical Halogenation of Trisubstituted Germanes and Silanes

Mitsutoshi OKANO* and Kunio MOCHIDA
Department of Chemistry, Faculty of Science, Gakushuin University, 1-5-1 Mejiro, Toshima-ku, Tokyo 171
(Received November 14, 1990)

Synopsis. Electrochemical halogenation of trisubstituted germanes and silanes in acetonitrile occurred in the cathode compartment in contrast to the well-known electrochemical halogenations which always occur in the anode compartment.

Organogermanium compounds and organosilicon compounds are interesting as the objects of electrochemical studies, because (1) they easily undergo electrochemical reactions as a result of their higher HOMO levels and lower LUMO levels compared with the carbon analogues,[1] and (2) electrochemically generated germanium and silicon species, such as anions, radicals, and cations, may have chemical properties, which are different from those of the corresponding carbon species.[2]

It is well-known that electrochemical halogenations occur in the anode compartment and dehalogenations in the cathode compartment.[3] Such electrochemical dehalogenations have also been reported for halogermanes and halosilanes.[4] The authors wish to report here an unusual cathodic halogenations, in which trisubstituted germanes and silanes afford halogenated germanes and silanes.

Experimental

All trisubstituted germanes and silanes were synthesized by the reduction of chloro-germanes and -silanes with $LiAlH_4$. They were identified by comparing their physical properties with those of reported values.[5]

Constant current electrolyses were carried out in a two-compartment cell using platinum plates (electrode surface= 6 cm^2) as the anode and the cathode. Aboout 2.5×10^{-4} mol of trisubstituted germanes or silanes was dissolved in 20 cm^3 of acetonitrile solution containing 0.1 mol dm^{-3} of tetrabutylammonium perchlorate (TBAP) or tetrabutylammonium tetrafluoroborate (TBATFB). Current density passed was about 0.17 mA cm^{-2}.

After the electrolyses, alliquots were sampled from each compartment and analysed directly with GC-MS for qualitative analyses and with HPLC for qualitative and quantitative analyses.

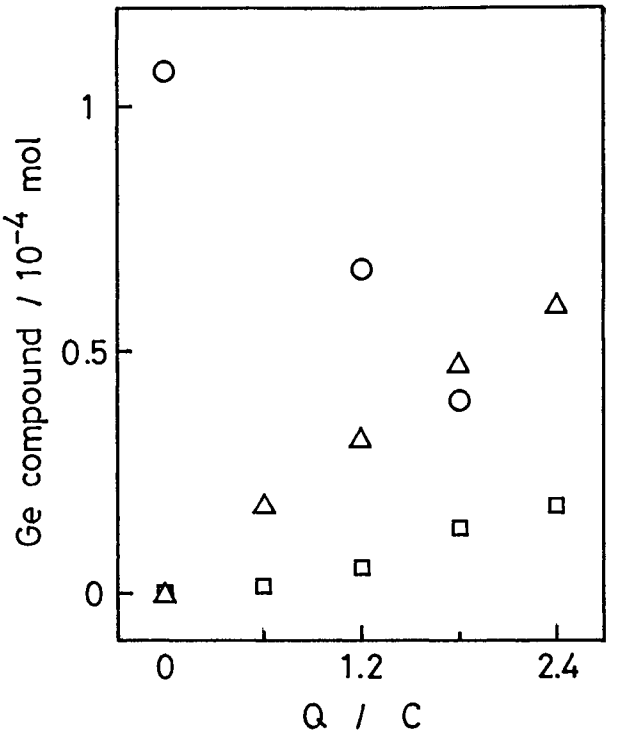

Fig. 1. Generation of Ph_3GeCl (△) and $(Ph_3Ge)_2O$ (□) in the cathode compartment during the electroreduction of Ph_3GeH (○).

Results and Discussion

The results in Fig. 1 were obtained by the constant current (1 mA) electrolysis of Ph_3GeH in the presence of TBAP. In the cathode compartment, Ph_3GeCl and $(Ph_3Ge)_2O$ were generated at constant rates while Ph_3GeH decreased at a constant rate. No such products were found in the anode compartment. After the passage of 0.21 F mol^{-1} of electricity, 63% yield of Ph_3GeCl and 37% yield of $(Ph_3Ge)_2O$ were obtained. A novel reaction pathway must be given for the formation of $(Ph_3Ge)_2O$ in the catholyte because the hydro-

Table 1. Products in the Catholyte Solution Detected by GC-MS. Typical Yields Determined by HPLC are Shown in Parentheses

Ph_3GeH	Ph_3GeCl, (60)	$(Ph_3Ge)_2O$ (40)	Ph_3GeF, (a)	$(Ph_3Ge)_2O$ (70)
Ph_3SiH	—,	$(Ph_3Si)_2O$ (80)	Ph_3SiF, (a)	$(Ph_3Si)_2O$ (90)
Ph_2MeGeH[b]	$Ph_2MeGeCl$,	$(Ph_2MeGe)_2O$	Ph_2MeGeF,	$(Ph_2MeGe)_2O$
Ph_2MeSiH[b]	—,	$(Ph_2MeSi)_2O$	—,	$(Ph_2MeSi)_2O$

a) The yield could not be determined by HPLC. b) Yields are not shown because halogenated compounds were readily hydrolyzed.

lysis of Ph_3GeCl did not occur under the experimental conditions. Supposing a one electron reaction for the conversion of Ph_3GeH, the current efficiency is as high as 300—400%. Assuming again a one electron reaction for the following electrochemical generation of Ph_3GeCl, the current efficiency is calculated as 240% (see below Eqs. 1 and 2). The chlorine source for the Ph_3GeCl must be the electrolyte TBAP because there is no other chlorine source. Oxygen may come from TBAP, O_2, and/or residual H_2O in the electrolyte solution.

Table 1 summarises the experimental data. Typical product yields are shown though they varied experiment to experiment. When TBATFB was used as the supporting electrolyte, Ph_3GeF was obtained. The fluorine source must be TBATFB. The generation of $(Ph_3Ge)_2O$ here reveals that the oxygen source was O_2 and/or residual H_2O in the system. In the electrolysis of Ph_3SiH in the presence of TBAP, Ph_3SiCl was not obtained although the experiments were repeated carefully. Using TBATFB as the electrolyte, a trace amount of Ph_3SiF was detected by GC-MS, but it was not detectable by HPLC. These product distributions may be undersood by means of the lower dissociation energy of Si-Cl bond compared with that of Si-O.[6]

Electrolyses were also carried out with other compounds, such as Ph_2MeEH, $PhMe_2EH$, and Et_3EH (E= Ge and Si). However, the expected products, such as Ph_2MeEX, $PhMe_2EX$, and Et_3EX (X=Cl and F) were readily hydrolyzed under the experimental conditions. Among the expected products, only $Ph_2MeGeCl$ and Ph_2MeGeF were detected by GC-MS analyses besides germoxanes and siloxanes.

Germyl (silyl) anions and germyl (silyl) radicals are candidates for the reaction intermediates (see Eqs. 1 and 2).

$$R_3EH + e \longrightarrow R_3E^- + H\cdot \quad (1)$$

$$R_3EH + e \longrightarrow R_3E\cdot + H^- \quad (2)$$

Accordingly, the reactivity of anions was examined as follows. Firstly, Ph_3Ge^- was prepared in tetrahydrofuran (THF) from Ph_3GeBr and Li. An alliquot was added to a THF solution containing 0.1 mol dm^{-3} of TBAP. Another alliouot was added to an acetonitrile solution containing 0.1 mol dm^{-3} of TBAP. However, no halogenated products were obtained in either case. Therefore, it was concluded that anions do not react with TBAP directly. In addition, it was found that the anions are not stable in acetonitrile, because only trace amount of Ph_3GeH was observed after hydrolysis.

Nextly, the reactivity of radicals was examined. Ph_3GeH was heated up to 80 ° in acetonitrile to generate $Ph_3Ge\cdot$. Trace amount of Ph_3GeCl was observed in the presence of TBAP after 6 h. Another experiment without Ar blanket gave $(Ph_3Ge)_2O$ as an additional product.

These results suggest that radical species are more probable as the reaction intermediates. However, it should be noted that by the electrochemical method Ph_3GeCl was obtained with a good yield. It seems that the reaction mechanism is more complicated than the simple reaction scheme: the generation of radicals by electrochemical reduction followed by their attack toward TBAP (or TBATFB).[7]

The authors would like to express their thanks to Miss Tomoko Ueda for her hard work in the very beginning stage of this work.

7) Lately, it has been suggested by the authors that germyl and silyl radicals have a strong tendency to lose one electron to give the corresponding cations; M. Okano and K. Mochida, 37th Symposium on Organometallic Chemistry, Japan, 1990, Osaka. These cations are also candidates for the reaction intermediate. However, existence of such cations is not yet generally accepted in chemistry of organogermanium and organosilicon compounds and reactivity of them is still unknown.

Reaction between Nitrogen Monoxide and Carbon Monoxide over Superconducting Bi-Sr-Ca-Cu and Related Mixed Oxides

Synopsis. Bi-Sr-Ca-Cu-O mixed oxides having a $Bi_2Sr_2CaCu_2O_y$ structure were very active for reactions between nitrogen monoxide and carbon monoxide among the prepared catalysts having perovskite and related structures.

Nitrogen oxides (NO_x) from vehicle engines and industrial boilers cause air pollution and acid rain, and their removal or suppression is an urgent social necessity.[1] The reductions of nitrogen monoxide (NO) by carbon monoxide (CO) and hydrocarbon are the major reaction pathways for the removal of NO_x from automobile exhaust.[2]

It has been reported that superconducting $YBa_2Cu_3O_y$ shows interesting catalytic properties for the ammoxidation of toluene, oxidation of methane, and the dehydrogenation of methanol.[3] Bi-Sr-Ca-Cu mixed oxides are new superconducting materials, and extensive studies of their electronic properties and structures have been reported. However, little is known of their catalytic properties.

Here, we wish to report on the high catalytic activity of a Bi-Sr-Ca-Cu mixed oxide having a $Bi_2Sr_2CaCu_2O_y$ structure for the reaction between nitrogen monoxide and carbon monoxide.

Experimental

All of the perovskite- and K_2NiF_4-type mixed oxides were prepared by calcining the precipitate from the appropriate mixture of aqueous solutions of the metal acetates or nitrates of each components at 1123—1273 K in air in the same manner as has been described previously.[4,5] Although the actual compositions may be nonstoichiometric with respect to oxygen, i.e., $La_{1-x}Sr_xBO_{3\pm\delta}$($x$=0—0.4, B=Co, Mn, Cr, δ; nonstoichiometry) and $La_{2-x}A'_xCuO_{4\pm\delta}$($x$=0—0.5, A'=Ce, Sr), in this paper they are designated as $La_{1-x}Sr_xBO_3$ and $La_{2-x}A'_xCuO_4$, respectively. Y-Ba-Cu-O and Bi-Sr-Ca-Cu-O mixed oxides were prepared by the calcination of appropriate mixtures of metal oxides and/or metal carbonates with nominal compositions of Y : Ba : Cu=1 : 2 : 3 and Bi : Sr : Ca : Cu=4 : 3 : 3 : 4 or 1 : 1 : 1 : 2, respectively, in O_2 at 1123—1193 K according to the methods described in the literature.[6,7] Bi-Sr-Ca-Cu-O mixed oxide was further annealed at 1123 K for 24 h. Bi-Sr-Ca-Cu-O mixed oxides with nominal compositions of Bi : Sr : Ca : Cu=4 : 3 : 3 : 4 and 1 : 1 : 1 : 2 are designated as Bi-Sr-Ca-Cu-O (4 : 3 : 3 : 4) and Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2), respectively. These structures were confirmed by their X-ray diffraction patterns. A reaction between NO and CO was carried out in a closed circulation system (ca. 190 cm^3), as described previously.[5,6b] The catalysts (25—200 mg) were mixed with inert SiC (250 mg) to prevent any undesirable temperature rise. The standard procedures were as follows: After the catalysts were treated in O_2 at 573 K for 1 h, the system was evacuated for 15 min. Then, the catalysts were exposed to the reaction gas mixture at ca. 8 kPa (NO : CO=1 : 1). Small portions of the reaction gas were intermittently taken from the system using a glass sampler and then analyzed with a gas chromatograph that was directly connected to the reaction system. The N and C balances were confirmed to be good.

Results and Discussion

The crystal structures and surface areas are summarized in Table 1. The X-ray diffraction pattern of Bi-Ca-Sr-Cu-O (4 : 3 : 3 : 4) showed only a $Bi_2Sr_2CaCu_2O_y$' structure, while two extra peaks at 35.5 and 38.7° corresponding to CuO were observed for Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2), as was reported in Ref. 7. Although the nonstoichiometry of those catalysts was not determined, it is known that Bi-Sr-Ca-Cu-O, thus prepared, exhibits superconductivity. The X-ray diffraction patterns of the other catalysts showed only a perovskite-type, K_2NiF_4-type, or orthorhombic $YBa_2Cu_3O_y$ structure. It has been reported that y in $YBa_2Cu_3O_y$, thus prepared, ranges from 6.5 to 6.9[8] and that y' in $Bi_2Sr_2CaCu_2O_{y'}$ was ca. 8.13.[7]

NO reacted with CO at 573 K over Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2, Fig. 1) to form N_2 and CO_2 in an approximately stoichiometric ratio in accordance with the reaction $NO+CO \rightarrow 1/2N_2+CO_2$; the amount of NO uptake was comparable with that of CO uptake and the amount of N_2O formed was small. The reaction proceeded over Bi-Sr-Ca-Cu-O (4 : 3 : 3 : 4) at 573 K in a similar way to that of Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2). A similar time course was observed upon performig a repeated reaction. Absorption of NO was not observed for either Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2) or Bi-Sr-Ca-Cu-O (4 : 3 : 3 : 4) mixed oxides. No change in the XRD pattern of Bi-Sr-Ca-Cu (1 : 1 : 1 : 2) was observed between fresh and used catalysts.

The selectivities and rates changed little when the reaction was repeated over perovskite-type mixed oxides, while the rates of K_2NiF_4-type mixed oxides and $YBa_2Cu_3O_y$ varied in various ways, depending on the catalysts, as reported previously.[5,6b]

The rate and selectivity of Bi-Sr-Ca-Cu-O (4 : 3 : 3 : 4) were close to those of Bi-Sr-Ca-Cu-O (1 : 1 : 1 : 2), while the former has a CuO phase in addition to the $Bi_2Sr_2CaCu_2O_{y'}$ phase. We previously reported that the catalytic activity of $La_{1.8}Ce_{0.2}CuO_4$ for the reaction of NO and CO was little affected by the small amount of coexisting CuO.[5] These facts indicate that the coexisting Cu or CuO had little influence on the rate and selectivity.

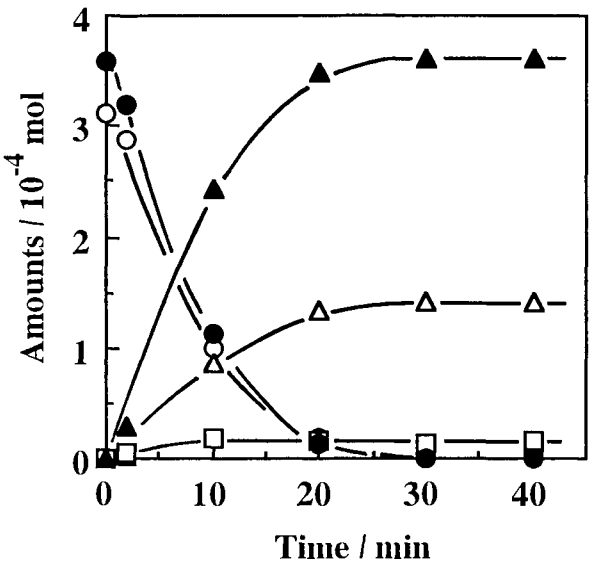

Fig. 1. Reaction between NO and CO at 573 K over Bi-Sr-Ca-Cu-O (1:1:1:2) catalyst.
○, NO; △, N_2; □, N_2O; ●, CO; and ▲, CO_2. Catalyst weight, 0.2 g.

The number of surface copper ions for Bi-Sr-Ca-Cu-O (4:3:3:4), calculated from the crystallographic data of the $Bi_2Sr_2CaCu_2O_y$ structure (assuming that the most frequently exposed plane is CuO_2 plane where the concentration of copper ions is the highest in this structure), is 6.8×10^{18} ions·m^{-2}. The total turnover number of Bi-Sr-Ca-Cu-O (i.e., the number of CO reacted per number of surface copper ions) for Runs 1—4 was greater than five hundred, showing that the reaction is catalytic. It is noteworthy that the catalytic activity of Bi-Sr-Ca-Cu-O mixed oxides for the reaction of NO and CO, as well as the selectivity to N_2, were of the highest level among the catalysts listed in Table 1, which summarizes the stationary rates and selectivities.[9] The formal charge of copper for $Bi_2Sr_2CaCu_2O_{8.13}$ is 2.13. It is remarkable that this value is close to that of $La_{1.8}Sr_{0.2}CuO_4$ (2.10), which was the most active for the reaction of NO and CO among $La_{2-x}A'_xCu_{1-y}B'_yO_4$(A'=Sr, Ce; B'=Al, Zr; x or y=0—0.5) catalysts.[5]

Even using the highest number of surface copper ions (6.8×10^{18} ions·m^{-2}), the calculated turnover frequency was still 1.7×10^{-1} mol s^{-1}(Cu-atom)$^{-1}$, which was 10^2 times higher than the turnover frequency of Rh/Al_2O_3 catalyst (1.7×10^{-3} mol s^{-1}(Rh-atom)$^{-1}$ at 573 K, extrapolated value in Ref. 1b).

As for the other catalysts, the following trends were noted. The rate decreased with Sr^{2+}-substitution for $LaCoO_3$, and $LaMnO_3$ (perovskite-type structure), while the rate increased in the case of La_2CuO_4.[5] Copper-containing catalysts showed the high selectivity to N_2.

The activity of $YBa_2Cu_3O_{y'}$ which changed among the different lots, was comparative to, or a little lower than, that of Bi-Sr-Ca-Cu-O. The difference in the rates between the lots of $YBa_2Cu_3O_y$ may be due to the water which was either absorbed or adsorbed.[10] In fact, the activity of $YBa_2Cu_3O_y$ changed considerably after its exposure to water vapor. The more NO that was absorbed, the higher the activity of Y-Ba-Cu-O for the reaction between NO and CO was. It has been reported for Ba-Cu-O that NO is absorbed into the bulk as in the case of $YBa_2Cu_3O_y$[5b] and that the absorptivity of NO is accelerated by the coexistence of Cu^{3+}.[11] Therefore, the valence of copper may be another influential factor regarding the activity for the reaction between NO and CO.

In contrast, the activity of Bi-Sr-Ca-Cu-O was reproducible. It is noteworthy in the above respect that Bi-Sr-Ca-Cu-O is stable in water vapor and carbon dioxide.[12]

This study was supported by a Grant-in-Aid for Scientific Research No. 02227202 from the Ministry of Education, Science and Culture.

Spinning Effect on Magic-Angle-Spinning NMR Spectra of Silicone Rubber

Shigenobu HAYASHI* and Kikuko HAYAMIZU
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received December 11, 1990)

Synopsis. High-resolution solid-state ^{13}C, ^{29}Si, and ^{1}H NMR spectra of silicone rubber have been measured using the magic-angle spinning of the sample. The spectra of the three nuclei split into two or three components in the range of the spinning rate between 1.4 and 2.0 kHz. Below 1.4 kHz and above 2.0 kHz, the spectra consist of only one component. Stress caused by the fast spinning is considered to cause conformational changes in the polydimethylsiloxane chains.

Silicone rubber is a very popular material which is widely used in a daily life as well as in chemical laboratories. It is very flexible, and is usually composed of polydimethylsiloxane. Molecular motions are very rapid in silicone rubber as if they were in liquid state from the standpoint of NMR. The dipolar interactions between the nuclei are weak, and they can be easily averaged out by the magic-angle spinning (MAS) of the sample. Thus, one can get high-resolution spectra of ^{13}C, ^{29}Si, and ^{1}H nuclei in silicone rubber only by MAS. Due to this favorable property, silicone rubber has been used as the shift reference frequently.[1] Cross polarization (CP) is not at all effective in this material.

Recently we have measured the NMR spectra of silicone rubber with very high resolution to determine the chemical shift precisely. In the course of the measurement we have found that the line shape changes in a certain range of the spinning rate.[2] In other words, the spinning induces a change in the NMR spectra. We have recently reported spinning-rate dependent phenomena; one is Cu and halogen NMR signals in copper (I) halides,[3] and the other is ^{31}P MAS NMR spectra of inorganic pyrophosphates.[4] In the former case, the Lorentz force working on the charged particles excites the ion motion, resulting in the frequency shift. In the latter, the homonuclear dipole-dipole interaction is not averaged out by MAS.[5] Bjorholm and Jakobsen[6] have reported a crystalline-to-plastic phase transition induced by MAS in ^{31}P NMR in P_4S_3, although the true origin is the temperature rise induced by the spinning. In the present case, the stress caused by the spinning is considered to influence the conformation of silicone rubber. In this note, we present the spinning-induced changes in the ^{13}C, ^{29}Si, and ^{1}H MAS NMR spectra of silicone rubber. To our knowledge, this is the first observation of the conformational change induced by the stress in MAS NMR.

Experimental

The instrument used for the NMR measurements was a Bruker MSL400 pulsed spectrometer, whose magnetic field strength was 9.4 T. The resonance frequencies were 100.614, 79.496, and 400.136 MHz for ^{13}C, ^{29}Si, and ^{1}H, respectively. The details of the high-resolution measurements were described previously.[2] Chemical shifts were referenced directly to pure tetramethylsilane under MAS, being expressed the higher frequency side as positive. The experimental errors in the shift values was about ±0.004 ppm, and the relative shifts in the same sample had the better accuracies with errors less than ±0.002 ppm. Temperature was 294 K. Two kinds of pulse sequences were used; single pulse, and single pulse with ^{1}H decoupling only during the data aquisition. Simulation of the spectra was carried out using the CLINFIT program supplied by Bruker.

Materials were available commercially. Although there were many kinds of silicone rubber, we have characterized the sample by NMR, as described below.

Results and Discussion

^{1}H and ^{13}C MAS NMR spectra have only one signal,

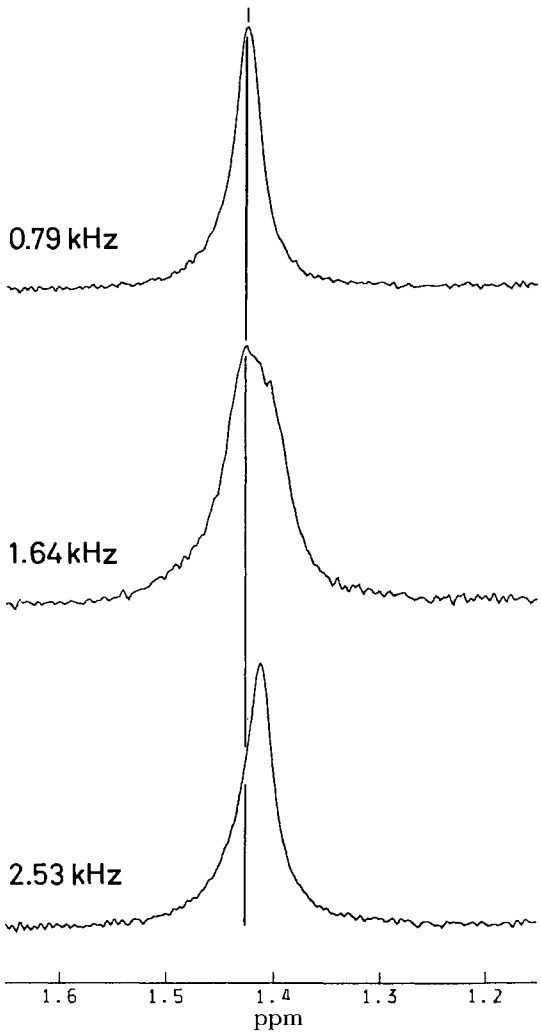

Fig. 1. ^{13}C MAS NMR spectra of silicone rubber with ^{1}H decoupling (ν_0=100.614 MHz). Numbers in the figure are the spinning rates.

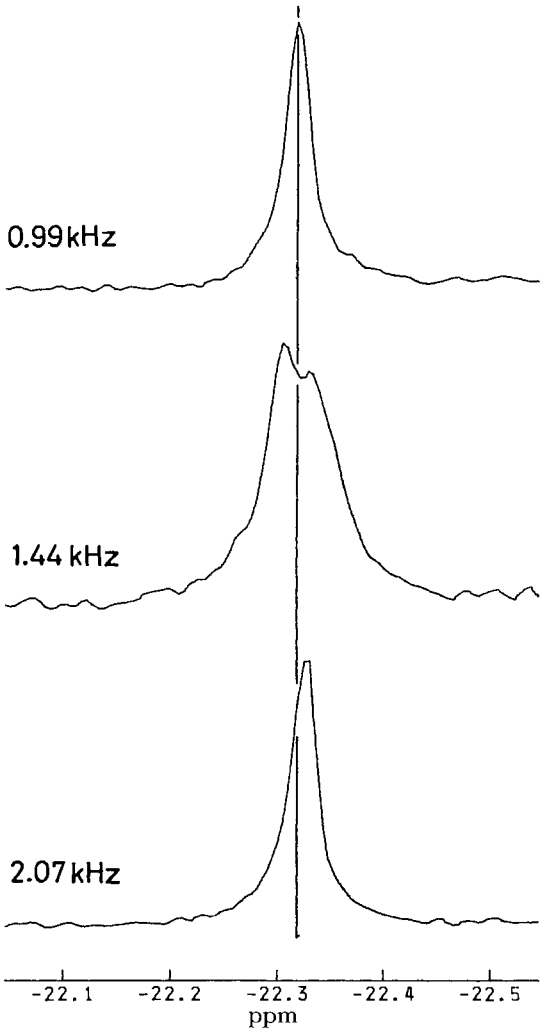

Fig. 2. ^{29}Si MAS NMR spectra of silicone rubber with ^{1}H decoupling (ν_0=79.496 MHz).

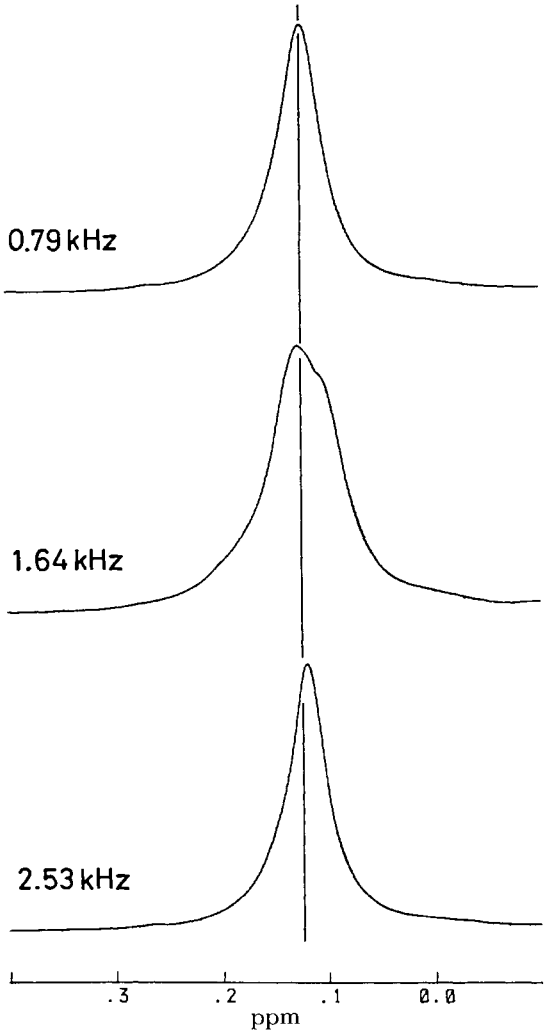

Fig. 3. ^{1}H MAS NMR spectra of silicone rubber (ν_0=400.136 MHz).

which is attributed to methyl groups attached to Si. ^{29}Si MAS NMR spectra have two signals; one is O-Si$(CH_3)_2$-O, and the other is amorphous SiO_2. The amorphous SiO_2 has a broad signal centered at −108 ppm with a full width at half maximum (FWHM) of about 13 ppm, and its mole fraction is 21% of the total Si. The upper limits of the presence of the other species are 2.2, 0.14, and 0.01% for C, Si, and H atoms, respectively, being estimated from the noise levels in the spectra. From these results, it can be concluded that the material is composed of linear polydimethylsiloxane chains and amorphous silica. The density of the sample is 1.17 g cm^{-3}.

Figure 1 shows ^{13}C MAS NMR spectra with ^{1}H decoupling. Note that the spectrum at the spinning rate 1.64 kHz shows line broadening and that the other two spectra have similar narrow linewidths. In the ^{1}H-coupled spectra, the scalar coupling can be observed, whose constant $^{1}J(^{13}C\text{-}^{1}H)$ is 118 Hz. The scalar coupling constant does not change with the spinning rate. Similar spectral changes are observed also in ^{29}Si and ^{1}H MAS NMR spectra, as shown in Figs. 2 and 3. The scalar coupling with ^{1}H is observed also in ^{29}Si spectra without decoupling ($^{2}J(^{29}Si\text{-}^{1}H)$=7.3 Hz). The spectral changes are reversible, and we can observe them repeatedly.

The spectral changes take place in the range of 1.4 to 2.0 kHz, called a "transition region." Below 1.4 (a slow spinning region) and above 2.0 kHz (a fast spinning region) the spectra consist of only one component, whose line shape is Lorentzian. The spectra between 1.4 and 2.0 kHz have fine structures, which can be deconvoluted into two or three Lorentzian lines. We present only the ^{1}H NMR results in Table 1. The ^{13}C and ^{29}Si results show similar behavior to ^{1}H, although there are no correlations among the three nuclei. From the table and the figures, several trends common to the three nuclei can be extracted:

(1) The chemical shifts in the fast spinning region deviate slightly towards lower frequency from those in the low spinning region.

(2) In the transition region, one component has a higher frequency than the signal in the slow spinning region, and the other has a lower frequency than that in the fast spinning region. Consequently, the spectra in the transition region are not the superposition of those in the slow and fast spinning regions. Apparently, the signal splitting takes place, keeping

Table 1. ^{1}H MAS NMR Results

the weight point almost constant.

As described above, we have recently reported several spinning-induced phenomena. However, in the present case, the stress caused by the spinning is considered to influence the conformation of silicone rubber. Temperature rise induced by the spinning is negligible in the range of the spinning rate used in this work.

Silicone rubber can be regarded as liquid from the standpoint of the NMR measurement. The high flexibility is considered to make the silicone rubber easily influenced by the spinning. The magnitude of the stress, S, can be estimated using the formula presented previously,[5]

$$S=(1/3)\,\rho\, r^2\omega_r^2, \qquad (1)$$

where ρ is the density, r is the distance from the spinning axis, and ω_r is the spinning rate expressed in angular frequency unit. In the present case, ρ=1.17 g cm^{-3} and $0 \leqq r \leqq 0.28$ cm. The maximum stresses just inside the wall of the rotor are 2.4×10^5 and 5.0×10^5 Pa for ν_r=1.4 and 2.0 kHz, respectively.

The characteristics of the present phenomena is that the conformation changes as if there were a phase transition. No monotonic change is observed with the spinning rate. Conformations in the slow and fast spinning regions are homogeneous. In the slow spinning region the conformation is relaxed, while it is deformed in the fast spinning region. The conformation in the transition region is not a mixture of the relaxed and deformed forms, but a kind of "transition form." Several conformations are considered to coexist inhomogeneously in the transition form.

Recently, spinning rates above 20 kHz are possible.[7] In those cases, more rigid solids than silicone rubber might undergo the similar transition. The maximum stress at ν_r=20 kHz amounts to 5.0×10^7 Pa.

Aside from the range between 1.4 and 2.0 kHz, silicone rubber is a good shift standard. Even in the range between 1.4 and 2.0 kHz, it can be used as a shift standard, since the spectral change of the order of 0.04 ppm is usually negligible if compared with the larger linewidth in normal solids.

In summary, we have found that the conformation in silicone rubber is influenced by the fast spinning in MAS NMR. This effect might become more general as the spinning rate as high as 20 kHz is applied.

Photolysis of Thietane and Thietane-d_6 in Argon Matrix: Infrared Spectra of Matrix-Isolated Thioformaldehyde and Thioformaldehyde-d_2

Osamu WATANABE, Eiichi SUZUKI, and Fumio WATARI*
Department of Resource Chemistry, Faculty of Engineering, Iwate University, Morioka 020
(Received December 17, 1990)

Synopsis. Argon-matrix isolated thietane at 10 K decomposed by irradiation (λ>290 nm) to form ethylene and thioformaldehyde. The photolysis of thietane under these conditions has been shown to be a clean source of thioformaldehyde. The CH_2S and CD_2S molecules generated this way are indefinitely stable and their infrared spectra could be recorded.

Thioformaldehyde easily polymerizes to a cyclic trimer (trithiane) under normal conditions. It has been generated by pyrolysis or photolysis of various precursors for spectroscopic investigations.[1] Recently infrared spectrum of thioformaldehyde generated by photolysis of matrix isolated methylene trithiocarbonate has been fully analyzed.[2]

Pyrolysis or photolysis in general results in formation of by-products that obscure frequently parts of spectrum of an aimed species in infrared studies. Haines et al.[3] reported that thietane decomposed by the action of light to form only ethylene as a gaseous product and a white solid which was probably a trimer of thioformaldehyde. We expected that photolysis of thietane in the argon matrix would produce thioformaldehyde in a monomeric form and ethylene,

$$H_2C\begin{matrix}H_2\\ C\\ S\end{matrix}CH_2 \xrightarrow{h\nu} H_2CS + CH_2{=}CH_2$$

and the infrared spectrum of thioformaldehyde would be obtained by subtraction of absorptions of ethylene from the spectrum of the photolysis products.

Experimental

Thietane (Tokyo Kasei Kogyo Co.) was distilled under vacuum before use. Thietane-d_6 was prepared from 1,3-dibromopropane-d_6 (MSD ISOTOPES, Montreal) by the method similar to the procedure of Bordwell and Pitt[4] for preparation of thietane, and purified by trap-to-trap distillation. Ethylene-d_4 was prepared by dehydration of ethanol-d_6 (MSD ISOTOPES, Montreal) with sulfuric acid-d_2.

A mixture of thietane or thietane-d_6 with argon gas (Ar : thietane=200 : 1 in a mole ratio) was prepared using standard manometric procedure. The mixture was deposited within 2 h on a CsI plate cooled at 20 K by a CTI Cryogenics Cryodyne Cryocooler Model 21 closed-cycle helium refrigerator. The argon-matrix isolated precursor cooled down to 10 K was exposed to radiation from a high-pressure mercury lamp (Ushio Denki) through a water filter (10 cm) fitted with quartz windows. Since this irradiation experiment resulted in complicated fragmentation, a cut-off filter was used. The irradiation through a UV-29 filter (Toshiba Glass) gave favorably clean infrared spectra, though it took a long exposure time to decompose the precursor completely.

Infrared spectra (4000—250 cm^{-1}) were recorded on a Hitachi Model 260-50 grating spectrometer, which was calibrated with standard gases.[5]

Results and Discussion

Irradiation (λ>290 nm) of argon-matrix isolated thietane and thietane-d_6 for 8 h resulted in the disappearance of the initial infrared spectra, Figs. 1(a) and 2(a), and the appearance of new absorptions, Figs. 1(b) and 2(b). The absorptions due to ethylene and ethylene-d_4 in Figs. 1(b) and 2(b) could be identified by comparing them with the spectra of argon-matrix isolated ethylene and ethylene-d_4 (Figs. 3(a) and 3(b)). By the agreement with the absorptions observed previously,[2] the remaining spectra could be evidently identified as those of CH_2S and CD_2S. The observed frequencies were collected in Table 1 together with the results of Torres et al.[2]

Three absorptions remained at 3019(vw), 2956(m), and 2863(w) cm^{-1} after elimination of the CH_2 stretchings of ethylene in the CH stretching region, in agreement with previous observations, and in the CD stretching region two absorptions were observed at 2277(vw) and 2149(m) cm^{-1} aside from the CD_2 stretch-

a) Photolysis of matrix isolated methylene trithiocarbonate, Ref. 2. b) Overlaps with the symmetric CH_2 deformation of ethylene.

ings of ethylene-d_4 also in agreement with the previous observations. The 2863 cm^{-1} band has been assigned to $2\nu_2$,[2] whereas $2\nu_2$ of CD_2 must overlap with the 2327 cm^{-1} band of ethylene-d_4, if would appear.

Torres et al. assigned the symmetric CH_2 deformation to the absorption at 1447 cm^{-1} and it was observed to be slightly stronger than the C=S stretch (1052 cm^{-1}).[2] In Fig. 1(b), there is a very weak absorption at 1449 cm^{-1}, but it is too weak as compared with the C=S stretch (1052 cm^{-1}). On the other hand, the symmetric CD_2 deformation of CD_2S is distinguishable from the symmetric CD_2 deformation (1071 cm^{-1}) of ethylene-d_4 (Fig. 2(b)). Thus the symmetric CH_2 deformation of CH_2S must accidentally overlap with the symmetric CH_2 deformation of ethylene.

For the out-of-plane and in-plane CH_2 deformations, there is only a prominent absorption at 994 cm^{-1}, which is accompanied with a shoulder at 990 cm^{-1}. There is often observed a vibrational mode as splitting into various bands in a matrix spectrum. However, on the basis of no splittings for the other bands, these should be interpreted to be due to different modes and we tentatively assinged the strong band at 994 cm^{-1} to the out-of-plane CH_2 deformation and the shoulder at 990 cm^{-1} to the in-plane in accordance with the interpretation of Torres et al.[2] Two bands of CD_2S at 783(s) and 779 (shoulder) cm^{-1} were assigned similarly.

The exclusive photolysis product of ethylene and the good agreement of the remaining spectrum with the CH_2S absorptions previously reported shows that thietane is a clean source compound for the photochemical generation of thioformaldehyde.

^{1}H NMR Conformational Study of Viologen-Linked Porphyrins (*p*-PC*n*V)

Yasuhiko YAMAMOTO, Sumio NODA,† Norishige NANAI, Ichiro OKURA,† and Yoshio INOUE*
Department of Biomolecular Engineering, Tokyo Institute of Technology,
O-okayama, Meguro-ku, Tokyo 152

O-okayama, Meguro-ku, Tokyo 152
(Received January 5, 1991)

Synopsis. Conformation of viologen-linked porphyrins (*p*-PC*n*V, *n*=4—7), which are capable of intramolecular electron transfer, was studied by ^{1}H NMR in order to gain insight into the relative geometry of the donor and acceptor during the electron transfer process. The orientation of the viologen with respect to the porphyrin was interpreted in terms of the rate of the intramolecular electron transfer between the two π-systems.

The viologen-linked porphyrins (Fig. 1) exhibit the intramolecular electron transfer process from the porphyrin to the viologen.[1-5] The rate of this process depends crucially on the length of the methylene chain intervening between the two π-systems. The electron transfer rate of *m*-PC*n*V in dimethylsulphoxide (DMSO) decreases monotonously with the methylene chain length and, in the case of *p*-PC*n*V in DMSO, only *p*-PC4V exhibits the intramolecular electron transfer with the rate comparable to that of *m*-PC3V.[5] We have studied the conformation of *p*-PC*n*V in DMSO by ^{1}H NMR. The orientation of the viologen with respect to the porphyrin ring in *p*-PC*n*V was compared with that of *m*-PC*n*V[6] and the difference of the efficiency in the electron transfer process for these compounds was interpreted in terms of the distance between the porphyrin and the bipyridine, based on a proposed relationship, i. e., an exponential dependence of the electron transfer rate on the distance of the donor-acceptor separation.[7]

Experimental

Materials. The viologen-linked porphyrins (*p*-PC*n*V) were synthesized as described previously.[5] Dimethyl-d_6 sulfoxide (DMSO-d_6) was purchased from MSD Isotopes.

NMR Measurements. Solutions of 10 mM *p*-PC*n*V in DMSO-d_6 (1M=1 mol dm^{-3}) were used for ^{1}H NMR measurements. 500 MNz ^{1}H NMR spectra were recorded on a JEOL GSX-500 FT-NMR spectrometer at 27 °C. Typical spectra were recorded with 64 transients, 32 k data points,

a) Chemical shifts are given in ppm from TMS. The numbers in the parentheses are the porphyrin ring-current induced shift changes and positive value indicates the downfield shift.

7000 Hz spectral width, and 5.9 μs 90° pulse. Chemical shifts were referenced to the solvent peak (2.5 ppm relative to the signal of tetramethylsilane) and are given in parts per million, ppm.

Results and Discussion

^{1}H NMR spectra of *p*-PC*n*V have been unambiguously assigned from the combined analyses of the connectivities in ^{1}H-^{1}H chemical shift correlated and nuclear Overhauser effect correlated spectroscopies. Chemical shifts for the viologen proton resonances of *p*-PC*n*V are given in Table 1. Pyridyl 2′, 6′ and 3′, 5′ protons resonate at 9.09 and 9.52 ppm, respectively, and the shifts of the other proton resonances are essentially identical with those of the corresponding resonances of *m*-PC*n*V previously reported. These shifts are essentially independent of the sample concentration (1—50 mM), indicating the absence of significant intermolecular interaction. The porphyrin ring current induced shifts for the viologen proton resonances of *p*-PC*n*V were calculated using the data obtained for appropriate model compounds as previously described.[6] The ring current shifts (δ_{RC}) of the viologen proton resonances are summarized in Fig. 2 and their plots are individually compared with those of *m*-PC*n*V in Fig. 3. The δ_{RC} value of the 1-CH_2 proton resonance for *p*-PC*n*V is +0.34 ppm and decreases to ca. 0 almost monotonously for protons further away, along chemical bonds, from the porphyrin ring. Similarity in their δ_{RC} plots (Fig. 2) indicates that the orientation of the viologen with respect to the porphyrin is not significantly different among the *p*-PC*n*V. These results suggest that the methylene chain of *p*-PC*n*V is in energetically stable all-*trans* extended conformation as found for *m*-PC*n*V. Anomalously large negative δ_{RC} detected for the δ and N-Me protons of *p*-PC5V may not be explained in terms of its conformational features.

Assuming the extended all-*trans* conformation for the methylene chain, the closest edge-to-edge distances between the two π-systems ($R_{\pi\pi}$) in *p*-PC*n*V with *n*=4, 5, and 6 are 1.03, 1.13, and 1.27 nm, respectively, and are compared with $R_{\pi\pi}$ of 0.85, 0.92, and 1.09 nm for *m*-PC*n*V with the corresponding *n* value, respectively. Therefore, the fact that *p*-PC*n*V (*n*>4) does not exhibit the intramolecular electron transfer leads to conclusions that the electron transfer in DMSO occurs

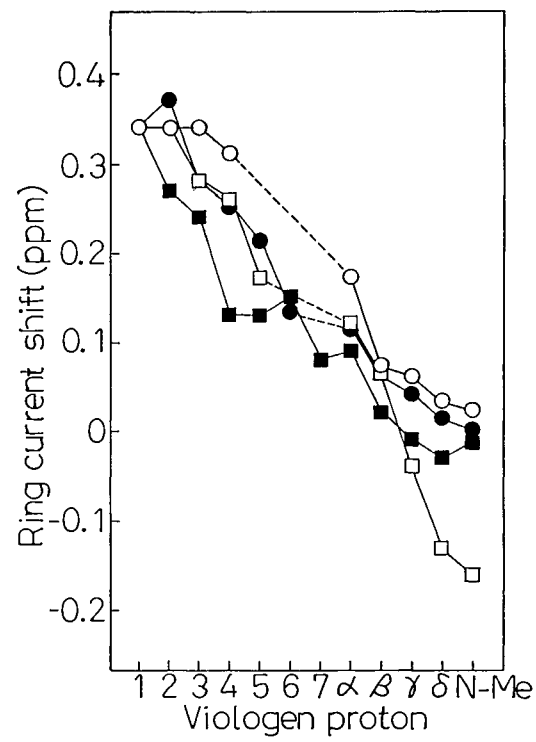

Fig. 2. Plots of the ring current induced chemical shift against viologen protons of *p*-PC*n*V in DMSO-d_6. *p*-PC4V(○), *p*-PC5V (□), *p*-PC6V (●), *p*-PC7V (■).

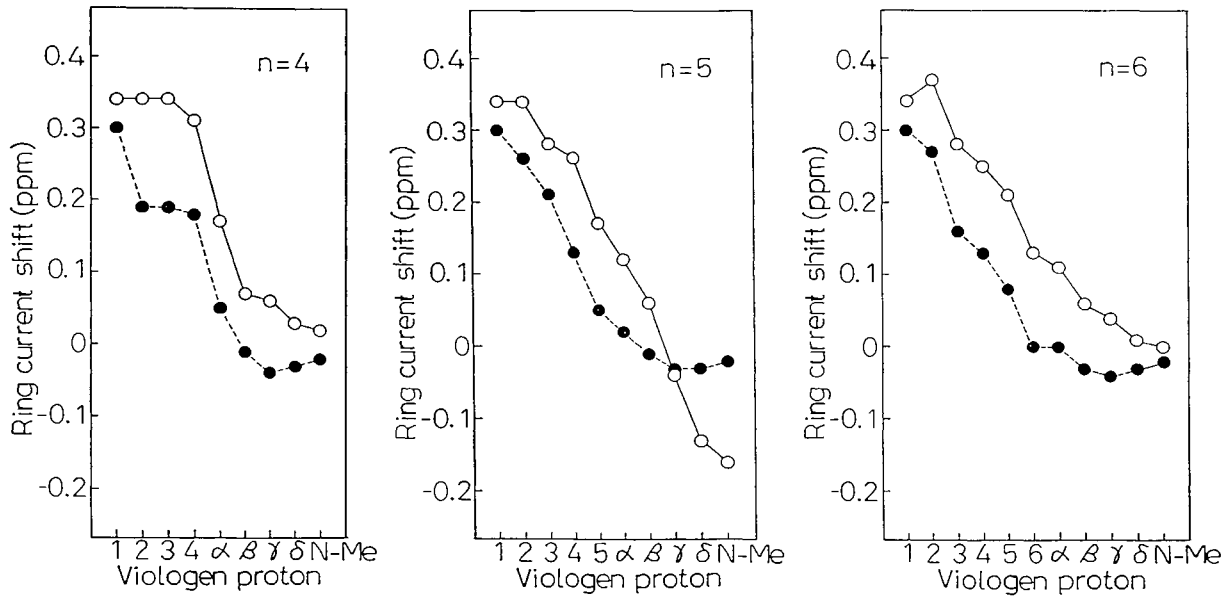

Fig. 3. Plot of the ring current induced chemical shift against viologen proton resonance of *p*-PC*n*V (○) in DMSO-d_6. Similar data for *m*-PC*n*V (●)[6] are also shown for comparison.

when $R_{\pi\pi}<$ ca. 1.1 nm and that the electron is not transfered through the methylene chain. $R_{\pi\pi}$ of 1.1 nm is greater than the theoretical estimate, 0.8 nm, for electron transfer by a short-range tunneling mechanism.[8] Furthermore, $R_{\pi\pi}$ should be considered as a semiquantitative parameter for interpreting the intramolecular electron transfer rate in terms of the molecular structure of these viologen-linked porphyrins, because it does not account for the fact that *m*-PC3V and *p*-PC4V exhibit similar rates.[5] Considering both the conformational flexibility of the methylene chain in solution and the time scale, ns, of the process, $R_{\pi\pi}$ calculated for a molecular structure infered from NMR data may not simply correlate to the electron transfer rate. A conformational change around one of the C-C bonds in themethylene chain, for example, *trans*→*gauche*, alters $R_{\pi\pi}$ as much as ca. 10 and ca. 15% for *p*- and *m*-PC*n*V, respectively.

Synthesis of Ti-Containing Pillared Montmorillonite Using a Trinuclear Acetatochlorohydroxo Titanium(III) Complex

Tsuyoshi KIJIMA,*,† Hiromoto NAKAZAWA, and Satoshi TAKENOUCHI
National Institute for Research in Inorganic Materials, Namiki 1-1, Tsukuba, Ibaraki 305
(Received August 22, 1990)

Synopsis. Trinuclear acetato-chloro-hydroxo titanium(III) chloride, $[Ti^{III}_3(OCOCH_3)_{6.4}Cl_{1.2}(OH)_{0.4}]Cl \cdot 11H_2O$, was prepared; its aqueous solution was reacted with Ca- and Cu-montmorillonites in air. Titanium(III) complex ions were mostly hydrolyzed, oxidized and condensed into their polynuclear forms, replacing the interlayer metal ions of montmorillonite. The calcined forms of both reaction products maintain large interlayer spacings of 22.2 and 21.3 Å, and have specific surface areas of 105 and 128 m^2g^{-1}, respectively.

Much attention has been paid to the pillaring of layered compounds by bulky inorganic or organic species,[1] including other host molecules, such as cyclodextrins.[2] Similar to zeolites, smectite clays may have micropores, thus affording another family of shape selective catalysts if they are pillared by polynuclear hydroxy metal cations. Titanium oxide is a typical photocatalyst which in combination with, for instance, platinum, is responsible for a variety of organic reactions, such as a one-step preparation of phenol from benzene.[3] These considerations have led to an expectation that smectite clays pillared with titanium oxide may act as a new type of photocatalyst possessing shape-selectivity.

In order to incorporate titanium oxide clusters into the interlayer space of montmorillonite, an attempt was made similar to a method applied to the synthesis of an iron oxide pillared montmorillonite.[4] Ca- and Cu-montmorillonites were reacted with aqueous solutions of a trinuclear acetato-chloro-hydroxotitanium(III) complex, resulting in the formation of titanium-containing pillared montmorillonites. After the present work was underway, Yamanaka, Nishihara, Hattori, and Suzuki[5] reported the synthesis of a titanium oxide pillared clay using montmorillonite and titanium hydoxide soll prepared by the hydrolysis of titanium alkoxide. This was followed by the report of Yoneyama, Haga, and Yamanaka[6] on the photocatalytic activities of the pillared materials.

Experimental

The Na-, Ca-, and Cu-montmorillonite samples used were the same as those used in previous studies.[7] An acetato complex of titanium(III) was prepared by a manner similar to that[8] reported for acetato complexes of iron(III), chrominum(III), and aluminum with a general composition of $[M_3(OCOCH_3)_7(OH)\ (H_2O)_n]NO_3$(M=Fe(III), Cr(III), Al; n=0—4). Fifty cm^3 of anhydrous acetic anhydride were slowly added to a mixed solution of 6.17 g of titanium trichloride, 10 cm^3 of ethyl alcohol, and 5.8 cm^3 of water.

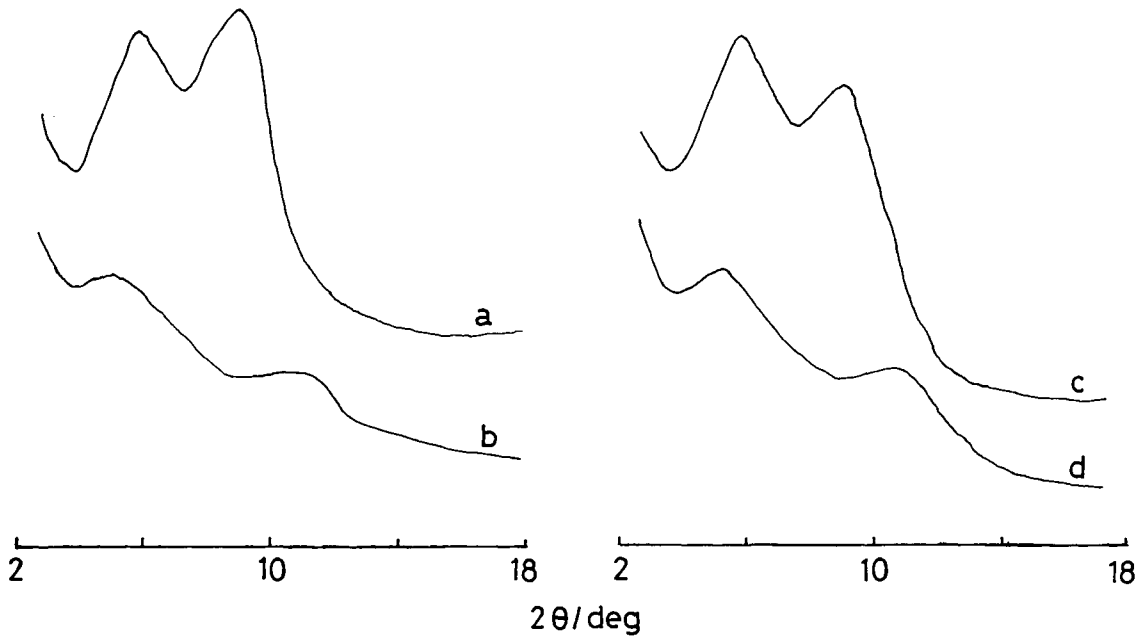

Fig. 1. X-Ray diffraction patterns of the reaction products of (left) Ca- and (right) Cu-montmorillonites heated at 40 °C (a, c) and 400 °C (b, d).

† Present adress: Department of Industrial Chemistry, Faculty of Engineering, Miyasaki University, Miyazaki city, Miyazaki 889-21.

After stirring for 12 h, the resulting solid, black in color and ca. 2.9 g in weight, was separated by filtration. A part of the solid was washed with acetic anhydride and diethylether, allowed to stand in a stream of nitrogen for 2 h, and used for a microanalysis. The other part of the solid was used without washing for a reaction with montmorillonite.

The montmorillonite sample (1 g) was weighed in a flask containing 100 cm^3 of an aqueous solution of the acetato titanium(III) complex (10 g), and kept at 25 °C for 24 h with stirring while the flask was unstoppered in air. The final products were centrifuged, fully washed with water, and dried in air at 40 °C, followed by calcination at 400 °C. When the Ca- and Cu-montmorlllonites were reacted with the acetato titanium complex solution in a stoppered flask, no significant indication of interlayer expansion was observed in the X-ray diffraction patterns of the resulting solids.

X-Ray diffraction measurements were carried out using Fe-$K\alpha$ radiation. The contents of C, H, and metal cations in the resulting materials were determined by a combined use of ICP or atomic absorption, C, H, N elemental and thermogravimetric analyses. A part of the purified acetatotitanium(III) sample was dissolved in water, hydrolyzed with sodium hydroxide, and centrifuged; the chlorine concentration of the supernatant was measured by a Dionex 2000i ion chromatograph. The surface area was measured by a conventional BET method using nitrogen at −196 °C.

Results and Discussion

The composition analysis of the acetatotitanium complex yielded: Ti, 17.7; C, 18.9; H, 3.7; Cl, 9.7 in wt%. This corresponded to a composition of $[Ti^{III}_3(OCOCH_3)_{6.4}(OH)_{0.4}Cl_{1.2}]Cl \cdot 11H_2O$, indicating that the acetatotitanium(III) complex prepared in this work is a trinuclear complex of titanium(III) isotypic with known trivalent metal acetato complexs, but partly including chlorine atoms as a ligand. It was also observed that the complex is gradually oxidized in air accompanying a weight loss and a change in color from black to white.

Table 1. Chemical Analyses of the Ca- and Cu-Montmorillonites Reacted with An Aqueous Solution of Trinuclear Acetato-Chloro-Hydroxo Titanium(III) Complex in Air

	Ca-Product	Cu-Product

a) Total weight loss observed by heating up to 1000 °C in air. b) Tentative values for the OH and H_2O contents were determined by assuming $y=0$ in $Ti_xO_y(OH)_z(Acetoxy)_w$ for the incorporated titanium complex ions.

The X-ray diffraction patterns of the reaction products are shown in Fig. 1. The dried forms of the Ca- and Cu-exchanged products show a strange XRD pattern, in that the d values of the first reflections are 18.2 and 18.8 Å and the second ones are 12.2 and 12.1 Å, respectively. Both apparently show no rational relation. One interpretation is that the first and the second reflection peaks are so broad that they partly overlap each other and, thus, their separation is apparently reduced. In the present case, however, it seems to be difficult to find two such elementary peaks. It is, therefore, much more likely that the dried forms comprise two phases or, more likely, two types of domains with interlayer spacings of 18.2 or 18.8 and 12.2 or 12.1 Å. On the other hand, the calcined forms show two orders of reflections corresponding to interlayer spacings of 22.2 and 21.3 Å, respectively. These observations suggest that during calcination two types of interlayer titanium complexes in the dried form are rearranged to form a single phase of titanium-containing intercalate with larger spacings.

When the acetatotitanium(III) complex had been partly oxidized before dissolving in water, the reaction products showed a distinct peak at $2\theta=31.95°$ ($d=3.52$ Å) attributable to the 101 reflection of titanium dioxide (anatase). However, the above dried and the calcined samples showed no trace of the titanium oxide peak.

Analytical data for products dried at 40 °C are summarized in Table 1. Preliminary analyses of the reaction products indicated that the intralayer composition of the initial montmorillonites remained unexchanged in a reaction with the acetato-hydroxo titanium(III) complex. The chemical formulae of the dried products were, therefore, determined on the basis of the intralayer anion composition, $O_{10}(OH)_2$, as well as the observed content of magnesium ions in the intralayer octahedral sheets.

From the color (white) of the reaction products, the titanium ions incorporated between the silicate layers were assumed to be tetravalent. The amounts of the acetoxy groups were calculated from the carbon content. The total weight loss observed upon heating to 1000 °C in air was attributed to a loss of interlayer water and acetoxy groups, as well as the water produced by condensation of the intra- and inter-layer hydroxide groups. Although the incorporated titanium complex ions would have a composition of $Ti_xO_y(OH)_z(acetoxy)_w$, it is difficult to precisely determine the hydrogen content and the total weight loss for an evaluation of y and z. Tentative values for z and the water content were calculated by assuming $y=0$; the results are listed in Table 1.

Both of the initial Ca- and Cu-momtmorillonites contain 0.203 moles of interlayer Ca^{2+} and Cu^{2+} ions per formula weight.[7] According to the composition data listed in Table 1, the interlayer cations are almost completely replaced by titanium complex ions. This exchange reaction is accompanied by a large decrease in the molar ratio of acetoxy to titanium for the exchanged ions, relative to an expected value of 7/3 for the initial acetatochlorohydroxo titanium(III) complex. The molar exchange ratios of titanium to the initial interlayer Ca^{2+} and Cu^{2+} ions are 4.8 and 7.4, respectively.

When the dried Ca- and Cu-samples were heated at 400 °C, the resulting solids were fully decarbonized, and decreased in weight by 13.5 and 18.7 wt%, respectively, due to a loss of interlayer water and acetoxy groups as well as the water produced by the interlayer condensation. This observations suggest that the interlayer species in calcined samples are formed from titanium(IV) complex ions, during which the molar ratio of intralayer cations to titanium remains unexchanged.

The thicknesses of the titanium complex ion layer for the calcined samples can be estimated by subtracting 9.5 Å for the silicate layer from the observed interlayer spacings of 22.2 and 21.3 Å, yielding 12.7 and 11.8 Å, respectively. The latter two values are in good agreement with a value of 12.1 Å for the van der Waals length of a HO-Ti-O-Ti-OH sequence. These facts suggest that the titanium complex ions taken up by Ca- and Cu-montmorillonites are polynuclear hydroxooxotitanium(IV) ions comprising mainly HO-Ti-O-Ti-OH units directed to the silicate layers. Such polynuclear ions would be formed by an incomplete hydrolysis of the initial acetato titanium complex ions and subsequent condensation. Specific surface areas of 105 and 128 $m^2 g^{-1}$ were obtained for the calcined forms of the Ca- and Cu-montmorillonite based products. These values are much smaller than 300 $m^2 g^{-1}$ for a titanium oxide pillared montmorillonite, obtained by the hydrolysis of titanium alkoxide.[5] This is probably due to the polynuclear forms of titanium resulting from trinuclear acetatochlorohydroxo titanium(III) ions, which are smaller in size than those from titanium alkoxide.

The reaction product obtained from Na-montmorillonite showed a much smaller tendency to intercalate polynuclear titanium complex ions, presumably due to the higher population of interlayer Na^+ ions than that of Ca^{2+} or Cu^{2+} ions.

Synopsis. Tetraammine(7-chloro-5-nitro- or 5,7-dinitro-8-quinolinolato)cobalt(IV) complexes and the corresponding cobalt(III) complexes have been isolated, and characterized by analytical, spectroscopic, magnetic, and XPS methods. The effective magnetic moments of cobalt(IV) complexes were ca. 1.6 BM, suggesting an unpaired spin. An unpaired spin on the complex is located over the π-orbitals of the 7-chloro-5-nitro- or 5,7-dinitro-8-quinolinolato ligand (abbreviation: chelated ligand) and on the cobalt atom from the results of the C 1s and Co 2p spectra by XPS. The Cl 2p binding energy of the chloride ion suggests that the valence electrons of the chloride ions may have some interaction with the π-orbitals of the chelated ligand.

In this series, the preparation, properties, and electronic states of cobalt(IV) complexes, $[Co(5\text{-}NO_2sal)L]Cl(NO_3)\cdot nH_2O$ (L: $(NH_3)_4$, $(bpy)_2$, quadridentate amine),[2] radical cobalt(III) complexes, $[Co(5\text{-}NO_2salam)(NH_3)_4]Cl_2(NO_3)$[3] and $[Co(5\text{-}NO_2salam)_2(NH_3)_2]Cl(NO_3)\cdot 2H_2O$,[1] and biradical cobalt(II) complex, $[Co(5\text{-}NO_2salam)_2(NH_3)_2]Cl(NO_3)\cdot 2H_2O$,[1] have been reported. The electronic states of the above mentioned complexes have been solved by physicochemical and XPS methods. Through the above studies, there was an implication that free chloride ions in the complexes may contribute to their stability. So far, the electronic state of the chloride ions has remain unsolved, since no measurement of the chloride ions by XPS was carried out. The present paper deals with the preparation and properties of the title cobalt(IV) complexes, and with the role of the chloride ions in the complexes.

Experimental

Measurements. The XPS measurements were carried out with a VG ESCALAB Mk-II electron spectrometer by irradiating Mg $K\alpha$ X-rays (60—150 W). Sample was placed either on a nickel holder with a copper mesh adhesive or on a indium foil with a gold mesh, and then introduced into the spectrometer. After evacuation to a vacuum of better than 3×10^{-6} Pa, the sample was cooled to ca. 200 K. Sample cooling was initiated within 10 min of the introduction to the spectrometer. Spectra were analysed using a VGS-5000 data system: Peak separation was carried out by a nonlinear least squares method using a mixed Gaussian-Lorentzian curve shape; background level was determined by a method proposed by Shirley,[4] and the contribution from X-ray satellites was subtracted. The electron-binding energies, E_B, were calibrated by assigning either 285.0 eV to the C 1s peak of 8-quinolinol or 407.0 eV to the N 1s peak of the nitrate free anion. The latter value was an average of the values from previous studies;[1,2b,5] the 90% confidence limits of the average are ±0.15 eV. The ^{1}H NMR spectra were recorded with an FX-90Q apparatus (JEOL). The visible absorption spectra were recorded with a Shimadzu UV-210 recording spectrophotometer. The magnetic susceptibilities were measured by the Faraday method using a magnetic balance (Shimadzu) from liquid N_2 to room temperature. The electric conductivities of aqueous solutions were determined by the use of a conductometer, CM-30 (Shimadzu), at room temperature.

Preparation of Complexes. Tetraammine(5,7-dinitro-8-quinolinolato)cobalt(III) Dinitrate (2a) and Tetraammine(5,7-dinitro-8-quinolinolato)cobalt(IV) Trinitrate (3a): Eight cm^3 of 60% HNO_3 were added, drop by drop, to 2.0 g (5.06 mmol) of $[Co(oxin)(NH_3)_4](NO_3)_2$ (**1a**).[6] Soon, a crystalline precipitate (complex **2a**) separates out, and was collected by filtration, and recrystallized from water. The green filtrate was added to acetone (150 cm^3) and stirred at 5 °C. The green cobalt(IV) complex (**3a**), thus precipitated, was filtered, washed with acetone and ether at 5 °C, and dried. Yields: 0.68 g (27.7%) for **2a**, 0.91 g (32.8%) for **3a**. Found **2a**: C, 22.06; H, 3.54; N, 25.77%. Calcd for $CoC_9H_{16}N_9O_{11}$: (MW 485.22) C, 22.28; H, 3.32; N, 25.98%. Found **3a**: C, 19.47; H, 3.09; N, 25.32%. Calcd for $CoC_9H_{16}N_{10}O_{14}$: (MW 547.25) C, 19.75; H, 2.95; N, 25.60%. Absorption spectra **2a** (H_2O): 383 (ε 13800), 398 nm^{sh} (12500); **3a** (60% HNO_3): 384 (5000), 398^{sh} (4600), 670 (1100). Λ=240 S cm^2 mol^{-1} for **2** in water. ^{1}H NMR (DMSO-d_6) **2a**: δ=3.60 (3H, NH_3), 3.75 (6H, NH_3), 4.18 (3H, NH_3); δ=8.25 (q, H_3), 8.74 (d, H_2), 9.15 (s, H_6), 9.40 (d, H_4).

Tetraammine(7-chloro-5-nitro-8-quinolinolato)cobalt(III) Dinitrate (2b), Tetraammine(7-chloro-5-nitro-8-quinolinolato)cobalt(IV) Dichloride Nitrate (3b), and Tetraammine(5,7-dinitro-8-quinolinolato)cobalt(IV) Chloride Dinitrate (3c): Eight cm^3 of 60% HNO_3 were added, drop by drop, to 2.0 g (5.55 mmol) of $[Co(oxin)(NH_3)_4]Cl_2\cdot H_2O$ (**1b**).[7] The precipitated yellowish-brown crystalline complex **2** (mixture of **2a** and **2b**) was collected by filtration and recrystallized from water. The green filtrate was added to acetone (200 cm^3) and stirred. Thus, the precipitated green cobalt(IV) complex **3** (mixture of **3b** and **3c**) was filtered, washed with acetone and ether, and dried. Complex **2b** was isolated from an orange-colored acetone filtrate of **3**. The ratio of **2b** and **2a** in **2** was 7 to 3, according to the results of elemental analyses and ^{1}H NMR spectra, and the ratio of **3b** and **3c** in **3** was 7 to 3 from the results of elemental analyses. Yields **2b**: 0.32 g (12.15%); **2**: 0.91 g (34.3%); **3**: 0.56 g (20.4%). Found **2b**: C, 22.56; H, 3.61; N, 23.52; Cl, 7.19%. Calcd for $CoC_9H_{16}N_8O_9Cl$: (MW 474.66) C, 22.77; H, 3.40; N, 23.61; Cl, 7.47%. Found **2**: C, 22.24; H, 3.62; N, 24.12, Cl, 5.61%. Calcd for $CoC_9H_{16}N_{8.3}O_{9.6}Cl_{0.7}$: (MW 477.85) (**2b**:**2a**=7:3) C, 22.62; H, 3.38; N, 24.33, Cl, 5.19%. Found **3**: C, 22.15; H, 3.55; N, 21.81; Cl, 16.88%. Calcd for $CoC_9H_{16}N_{7.6}O_{7.5}Cl_{2.4}$: (MW 494.70) (**3b**:**3c**=7:3) C, 21.85; H, 3.26; N, 21.52, Cl, 17.20%. Absorption spectra **2b** (H_2O): 412 nm (ε 11800); **2** (H_2O): 407 (12800); **3** (60% HNO_3): 405 (3340), 720 (1500). Λ=240 for **2b** and 410 S cm^2 mol^{-1} for **3**

in water. ^{1}H NMR (DMSO-d_6) **2b**: δ=3.54 (3H, NH_3), 3.65 (6H, NH_3), 4.11 (3H, NH_3); δ=8.10 (q, H_3), 8.64 (d, H_2), 8.69 (s, H_6), 9.40 (d, H_4).

Results and Discussion

Complexes **2a** and **3a** have been obtained from a reaction mixture of **1a** and 60% HNO_3. Complexes **2b**, **2**, and **3** have been obtained from a reaction mixture of **1b** and 60% HNO_3 (Scheme 1). The colors of **2a**, **2b**, and **2** are yellowish-brown, yellowish-orange, and yellowish-orange, respectively and those of **3a** and **3** are green. Complexes **2a**, **2b**, and **2** were soluble in DMSO, and slightly soluble in water and methanol. Complexes **3a** and **3** were soluble in 60% HNO_3 and DMSO.

In the ^{1}H NMR spectra in DMSO-d_6, the signals at δ=3.5—4.2 (12H) and at δ=8.1—9.4 (4H) of **2a**, **2b**, and **2** were assigned to the ammine protons and the coordinated 8-quinolinolato ligand, respectively. The signals at δ=8.25, 8.74, 9.15, and 9.40 of **2a** were very close to those of 5,7-dinitro-8-quinolinol,[8] while those at δ=8.10, 8.64, 8.69, and 9.40 of **2b** were very close to those of 7-chloro-5-nitro-8-quinolinol.[8] This indicates that **2a** and **2b** contain the coordinated 5,7-dinitro-8-quinolinolato and 7-chloro-5-nitro-8-quinolinolato ligands, respectively. A proportion between **2b** and **2a** in **2** was estimated to be 7 to 3 from the intensity ratio of the H_6 proton signals of **2** (Fig. 1). The electric conductivities of **2a**, **2b**, and **2** in the aqueous solutions are ca. 240 S cm^2 mol^{-1}. Complexes **2a**, **2b**, and **2** were diamagnetic by the magnetic susceptibility. Absorption bands at 383—412 nm in water of **2a**, **2b**, and **2** were assigned to the charge-transfer band.[6] In XPS, the Cl $2p_{3/2}$ spectra of **2b** and **2** were observed at 200.4—200.5 eV (Fig. 2). The peak at 200.4—200.5 eV was assigned to the chlorine atom of the coordinated 7-chloro-5-nitro-8-quinolinolato ligand, since the E_B of the peak was close to that (201.0 ev) of chlorobenzene,[9] but was different from that (197.6 ev) of **1b**. The N 1s spectra of **2a**, **2b**, and **2** were observed at ca. 400 and ca. 406 eV. The lower E_B peak was separated to two peaks which were assigned to -NH= and NH_3 nitrogens. The higher E_B peak was also separated into three peaks which were assigned to 5-NO_2, 7-NO_2, and NO_3 nitrogens (Table 1).[1,2b,3]

The magnetic susceptibilities of **3** and **3a** obeyed the Curie-Weiss law, with an effective magnetic moment of 1.58 BM for **3** and 1.50 BM for **3a**, suggesting the presence of an unpaired spin. The absorption spectra in 60% HNO_3 of **3** and **3a** showed two peaks at 405 and 720 nm for **3** and three peaks at 384, 398(sh), and 670 nm for **3a**. The peaks at 720 and 670 nm are due

to the unpaired spin.[3] The ^{1}H NMR spectra of **3** and **3a** did not show the expected signals, because of paramagnetism. The electric conductivity in an aqueous solution of **3** was 410 S cm^2 mol^{-1}. In the XPS of **3**, the N 1s spectrum was observed at ca. 400 and ca. 406 eV. Each peak was separated into two (-N= and NH_3) or three peaks (5-NO_2, 7-NO_2, and NO_3) (Table 1). The C 1s peak was separated into two peaks at 285.6 and 288.2 eV. The peak that appeared in the higher E_B region was assigned to the electron-

a): In higher E_B region. b): An average E_B [N 1s] for NO_3^- calculated from the previous data,[1,3,7] 407.00±0.15 eV, was used to the energy calibration. c): An average E_B [C 1s] for carbons in 8-quinolinol was taken to be 285.0 eV. Uncertainties in parentheses are 90% confidence limits.

poor carbons[1,3] relative to the normal ring carbons at 285.5 eV. The proportion of electron-poor carbons in the higher binding energy region was about 2-times larger than that of **2**. The Co $2p_{3/2}$ peak at 782.2 eV showed satellites. These results are in agreement with those of tetraammine(5-nitrosalicylato)cobalt-(IV) complexes,[2b] $[Co(5\text{-}NO_2sal)(NH_3)_4]Cl(NO_3)\cdot H_2O$ (**4**), previously reported. Thus, an unpaired spin is located over the π-orbitals of the chelated ligand and on the cobalt atom. The Cl $2p_{3/2}$ spectrum of **3** was observed at 198.0 and 200.8 eV (Table 1 and Fig. 2). The peak at 198.0 eV was assigned to a free chloride ion (Cl^-), and the peak at 200.8 eV was assigned to the chlorine atom of the coordinated 7-chloro-5-nitro-8-quinolinolato ligand. The intensity ratio between the lower E_B and higher E_B peaks was about 2 to 1. The E_B (198.0 eV) of the chloride ion is higher than those (196.7—197.6 eV) of **1b**, hexadecyltrimethylammonium chloride, $[(C_{16}H_{33})(CH_3)_3N]Cl$ (**5**), and tetramethylammonium chloride,[10] $[(CH_3)_4N]Cl$ (**6**) (Table 1). The higher E_B suggests that the valence electrons of the chloride ions in **3** may have some interaction with the π-orbitals of the chelated ligand and a part of electrons of the chloride ion may flow over the π-orbitals of the chelated ligand, since such a shift to higher E_B is not observed for compounds without a localized spin on the π-orbitals, which is the case in **2**. Further, **3a**, which has an unpaired spin but no chloride ions as a free anion, is unstable under X-ray irradiation and in an aqueous solution. These experimental results indicate that the interaction between the chloride ions and the π-orbitals of the chelated ligand contributes to the stability of **3**.

Difference in Kinetic Behavior on the Photosensitized Decomposition of the Tris(oxalato)cobaltate(III) Ion by Tris(2,2′-bipyridine)ruthenium(II) and Bis(3,3′-biisoquinoline) (2,2′-bipyridine)ruthenium(II)

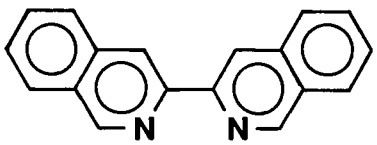
Synopsis. The photo-sensitized decomposition of $[Co(ox)_3]^{3-}$ (ox=oxalate) was performed using $[Ru(bpy)_3]^{2+}$ (bpy=2,2′-bipyridine) and $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ (*i*-biq=3,3′-biisoquinoline). The dramatic difference in the decomposition behavior appeared between them. In appearance, the decomposition rate obeys first-order with respect to the $[Co(ox)_3]^{3-}$ concentration for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ system, whereas zero-order for the $[Ru(bpy)_3]^{2+}$ system. The cause was discussed on the basis of the kinetic analysis.

It is widely known that the tris(2,2′-bipyridine)-ruthenium(11) complex, $[Ru(bpy)_3]^{2+}$, acts as a useful homogeneous photocatalyst for many photochemical systems. The photosensitized reductive decomposition of the tris(oxalato)cobaltate(III) ion, $[Co(ox)_3]^{3-}$, is one of the typical examples.[1] In our previous work, it was found that the rate of the decomposition is of zero-order with respect to the concentration of $[Co(ox)_3]^{3-}$ and is proportional to the incident light-intensity only.[2] For the purpose of comparing the catalytic behavior, we have been used several analogous ruthenium(II) complexes in place of $[Ru(bpy)_3]^{2+}$ as photosensitizers of the reaction. $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ (*i*-biq=3,3′-biisoquinoline) contains only one bpy ligand on which an excited electron can be populated in the lowest MLCT excited state. As *i*-biq ligands in the complex hardly affect the lowest excited state, the photophysical properties such as emission energy and emission lifetime of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ are very similar to those of $[Ru(bpy)_3]^{2+}$.[3,4] Nevertheless, the dramatic difference between $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ and $[Ru(bpy)_3]^{2+}$ was observed in the decomposition behavior of $[Co(ox)_3]^{3-}$ in appearance. Thus we have carried out the kinetic approach in order to explain the difference between them.



i-biq

Experimental

$[Ru(bpy)_3]Cl_2 \cdot 6H_2O$[5] and $K_3[Co(ox)_3] \cdot 3H_2O$[6] were prepared according to the literatures and recrystallized twice. 3,3′-Biisoquinoline and the $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ complex were available from previous investigation.[3] To obtain higher solubility in water, chloride of the complex was prepared by the anion exchange (Dowex 1-X8). The other chemicals used are of guaranteed reagent grade.

The sample solution for the photo-sensitized decomposition was prepared as follows: 2×10^{-5} mol dm^{-3} of the ruthenium(II) complex, 3×10^{-3} mol dm^{-3} of $[Co(ox)_3]^{3-}$, 0.095 mol dm^{-3} of HCl, and 0.2 mol dm^{-3} of NaCl. For the solution that sodium oxalate was added, the concentration of NaCl was lowered to keep the ionic strength constant. The solution was irradiated continuously with visible light (>400 nm) at 25 °C using the same apparatus as reported previously.[2] The reaction solution was purged of oxygen by bubbling pure nitrogen gas through it. Aliquot samples were withdrawn at appropriate times to measure the absorbance of $[Co(ox)_3]^{3-}$ at 602 nm (ε=148 mol^{-1} dm^3 cm^{-1}). While, the concentration of the ruthenium(II) complexes was checked by the absorption spectra after removal of the $[Co(ox)_3]^{3-}$ ion by the anion-exchange resin (Dowex 1-X8).

Results and Discussion

Figure 1 shows plots of the absorbance of $[Co(ox)_3]^{3-}$ vs. time under three different conditions. In the presence of $[Ru(bpy)_3]^{2+}$, $[Co(ox)_3]^{3-}$ decomposed efficiently in proportion to the time (Fig. 1A). When $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ was used instead of $[Ru(bpy)_3]^{2+}$ as a photosensitizer under the same acid conditions, the decomposition of $[Co(ox)_3]^{3-}$ was as slow as the self-decomposition by the intramolecular electron transfer, showing the very small photosensitizing effect (Fig. 1C). In the system, absorbance at 395 nm of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ decreased with time and a new

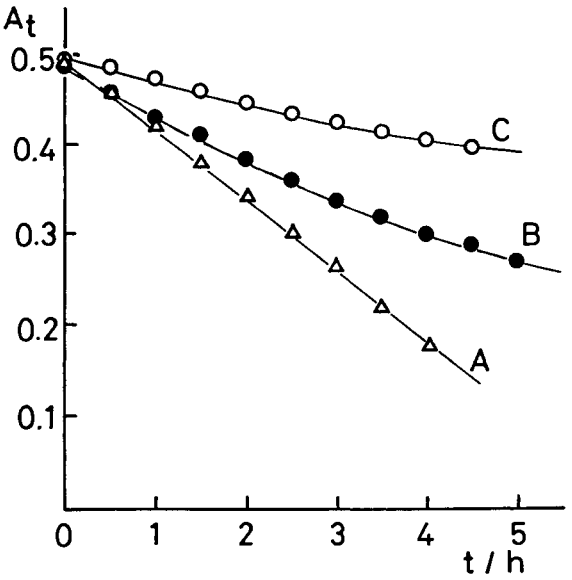


Fig. 1. Plots of the absorbance of $[Co(ox)_3]^{3-}$ vs. time in the presence of: (A) 2×10^{-5} mol dm^{-3} of $[Ru(bpy)_3]^{2+}$, (B) 2×10^{-5} mol dm^{-3} of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ and 0.05 mol dm^{-3} of $Na_2C_2O_4$, (C) 2×10^{-5} mol dm^{-3} of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$.

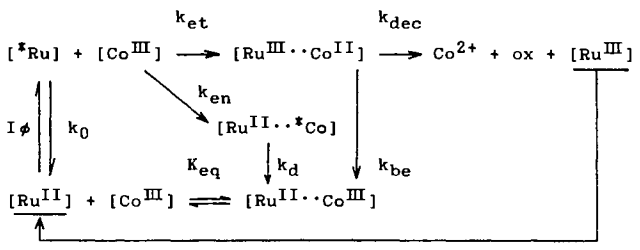
absorption band at 370 nm appeared instead. The peak corresponds to the spectrum of a tervalent complex, $[Ru(i\text{-}biq)_2(bpy)]^{3+}$ obtained by the oxidation of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ using PbO_2 in a 1 mol dm^{-3} sulfuric acid. This indicates that $[Ru(i\text{-}biq)_2(bpy)]^{3+}$, generated due to the oxidative quenching by $[Co(ox)_3]^{3-}$, accumulated during the reaction time. This phenomenon for the mixed ligand complex results from a little higher stability of the tervalent state of the ruthenium ion than that for the tris(bipyridine) complex. The standard redox potentials are 1.26 V and 1.17 V vs. NHE for $[Ru(bpy)_3]^{2+}$ and $[Ru(i\text{-}biq)_2(bpy)]^{2+}$, respectively.[7] In the case of the tris(bipyridine) complex, $[Ru(bpy)_3]^{3+}$ can be reduced rapidly to the bivalent state by the oxalate ion released by the reductive decomposition of $[Co(ox)_3]^{3-}$. Thus when sodium oxalate as a reductant of ruthenium(III) species was beforehand added to the sample solution with $[Ru(i\text{-}biq)_2(bpy)]^{2+}$, the decomposition of $[Co(ox)_3]^{3-}$ proceeded smoothly keeping the constant concentration of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ (Fig. 1B). However, the apparent kinetic behavior was quite different from that for the $[Ru(bpy)_3]^{2+}$ catalysis. In the case of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ catalysis, the decomposition rate of $[Co(ox)_3]^{3-}$ seems to be of first-order rather than of zero-order with respect to the $[Co(ox)_3]^{3-}$ concentration.

To explain the difference, we carried out the kinetic approach. The photo-sensitized decomposition takes place as shown in Scheme 1. According to the scheme, the kinetic expression can be described as Eq. 1

$$-d[Co']/dt = (k_{et}+k_{en})[{}^*Ru][Co^{III}] - k_{be}[Ru^{III}\cdots Co^{II}] - k_d[Ru^{II}\cdots {}^*Co] \quad (1)$$

where [Co'] represents the total concentration of $[Co(ox)_3]^{3-}$ involving an encounter complex in the ground state denoted by $[Ru^{II}\cdots Co^{III}]$: [*Ru], $[Co^{III}]$, $[Ru^{III}\cdots Co^{II}]$, and $[Ru^{II}\cdots {}^*Co]$ indicate the concentrations of the excited species of the ruthenium complexes, $[Co(ox)_3]^{3-}$, and encounter complexes generated by electron- and energy-transfer, respectively: The rate constant on each step is defined as shown in Scheme 1. The association constant for $[Ru(bpy)_3]^{2+}$ with $[Co(ox)_3]^{3-}$ on the ground state was reported to be 1900 mol^{-1} dm^3 at zero ionic strength.[7] Using the



$[Ru^{II}]$ = Ruthenium(II) Complexes

$[Co^{III}] = [Co(ox)_3]^{3-}$

$ox = (COO)_2^{2-}$

Scheme 1.

value and 2×10^{-5} mol dm^{-3} for the $[Ru(bpy)_3]^{2+}$ concentration, it is estimated that only a few percents of $[Co(ox)_3]^{3-}$ are paired with $[Ru(bpy)_3]^{2+}$. Under the experimental conditions of much higher ionic strength, the ion pairing of the ground state species would be negligible. The assumption of the steady state concentration for [*Ru], $[Ru^{III}\cdots Co^{II}]$ and $[Ru^{II}\cdots {}^*Co]$ leads to Eq. 2:

$$[Co'] + k_0/k_q \ln [Co'] = -Bt + C. \quad (2)$$

In this equation, k_q is the bimolecular quenching rate constant:

$$k_q = k_{et} + k_{en}, \quad (3)$$

and B is a constant related to the quantum yield of the reaction:

$$B = I\phi k_{et}k_{dec}/(k_{et}+k_{en})(k_{dec}+k_{be}). \quad (4)$$

Equation 2 indicates that the reaction obeys the zero order rate law under the conditions of $[Co'] \gg |k_0/k_q \ln[Co']|$, while the first-order rate law under the conditions of $[Co'] \ll |k_0/k_q \ln[Co']|$. Thus the data for both $[Ru(bpy)_3]^{2+}$ and $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ were analyzed on the basis of Eq. 2. The decomposition data were corrected for the self-decomposition of $[Co(ox)_3]^{3-}$. The decay rate constant (k_0) of $[Ru(bpy)_3]^{2+}$ was fixed to the value of 1.7×10^6 s^{-1}.[8] On the other hand, a similar value of k_0 is also expected for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ from the data in acetonitrile (1.0×10^6 s^{-1}).[8] As shown in Fig. 2, both data were well fitted by Eq. 2 with reasonable values of k_0 and k_q. The result indicates that the quenching rate constant of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ in the system is smaller than that for $[Ru(bpy)_3]^{2+}$. It would be related to the existence of the bulky ligands which do not participate in the lowest excited states for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$. Such a situation particularly makes the intermolecular elec-

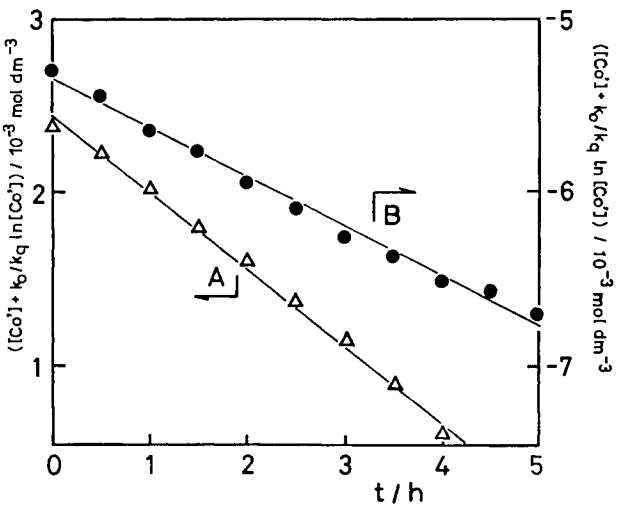


Fig. 2. Plots of $([Co']+k_0/k_q \ln[Co'])$ vs. time in the systems of (A) $[Ru(bpy)_3]^{2+}$ and (B) $[Ru(i\text{-}biq)_2(bpy)]^{2+}$. The straight lines are the least-square-fitting lines on the basis of Eq. 2: (A) $k_0=1.7\times10^6$ s^{-1}, $k_q=1\times10^{10}$ mol^{-1} dm^3 s^{-1}, $B=7.4\times10^{-6}$ mol dm^{-3} s^{-1}, (B) $k_0=1.5\times10^6$ s^{-1}, $k_q=1\times10^9$ mol^{-1} dm^3 s^{-1}, $B=4.7\times10^{-6}$ mol dm^{-3} s^{-1}.

tron transfer (i.e. k_{et}-path) much more difficult.

$[Ru(i\text{-}biq)_2(bpy)]^{2+}$ has several advantages as a photosensitizer compared with $[Ru(bpy)_3]^{2+}$. For example, the lowest excited state of $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ could act as a stronger reductant than that for $[Ru(bpy)_3]^{2+}$, since the oxidation potential of the excited species is estimated to be -0.95 V and -0.79 V vs. NHE for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ and $[Ru(bpy)_3]^{2+}$, respectively, from the potential of the ground state and the zero-zero excitation energy. The wider and stronger absorption bands in the visible region due to charge transfer to both *i*-biq and bpy ligands for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ is another merit as a photosensitizer. Nevertheless, $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ is not so effective as $[Ru(bpy)_3]^{2+}$ as indicated by the *B* values (7.4×10^{-6} mol dm^{-3} s^{-1} for $[Ru(bpy)_3]^{2+}$ and 4.7×10^{-6} mol dm^{-3} s^{-1} for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$). The smaller value for the $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ system would come from the yield in the electron transfer step, the part of $k_{et}/(k_{et}+k_{en})$ in the *B* value (Eq. 4). For the $[Ru(bpy)_3]^{2+}$ system, the limiting quantum yield of the photosensitized decomposition of $[Co(ox)_3]^{3-}$ was reported to be 0.85 in 0.05 mol dm^{-3} H_2SO_4.[1] Such a high yield suggests that $k_{et}/(k_{et}+k_{en})$ in Eq. 2 must be a fairly high value near one. This results in a relation of $k_{et}>k_{en}$ for the $[Ru(bpy)_3]^{2+}$ system. On the other hand, k_q (i.e. $k_{et}+k_{en}$) for the $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ system has been estimated to be smaller than that for the $[Ru(bpy)_3]^{2+}$ system by one order as discussed above. Assuming that k_{en} is similar between both systems, there is a possibility that k_{et} is comparable to k_{en} in the $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ system. A sensitive change in $k_{et}/(k_{et}+k_{en})$ and thus the *B* value can occur in the situation. As for the part of $k_{dec}/(k_{dec}+k_{be})$ in Eq. 4, the higher value is expected for the $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ system rather than the $[Ru(bpy)_3]^{2+}$ system because the bulkiness for $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ makes the stability of the encounter complex, $[Ru^{III}\cdots Co^{II}]$, weaker.

In conclusion, the different behavior on the photosensitized decomposition of $[Co(ox)_3]^{3-}$ by $[Ru(bpy)_3]^{2+}$ and $[Ru(i\text{-}biq)_2(bpy)]^{2+}$ can be explained in terms of the difference in the electron transfer step (k_{et}) from the ruthenium complexes to $[Co(ox)_3]^{3-}$.

Synopsis. 2,4-Dioxo-3,3-Pentanediselenolato(Se_2-ac) platinum(II) complex [Pt(Se_2-ac)(PMe_2Ph)$_2$] and its dithiolato analog [Pt(S_2-ac)(PMe_2Ph)$_2$] have been prepared by treating *cis*-[$PtCl_2$(PMe_2Ph)$_2$] with 2,3-diseleno-1,1,4,4,-tetraacetylbutane and 2,3-dithio-1,1,4,4-tetraacetylbutane in a KOH/acetone-methanol mixed solution. The IR, ^{1}H, ^{13}C, and ^{31}P NMR and mass spectra of these complexes are discussed.

In our previous paper, a 2,4-dioxo-2-pentene-3-thiolato Pt(II) complex was prepared via the S–S bond cleavage of 2,3-dithio-1,1,4,4-tetraacetylbutane under basic conditions.[1] We have newly synthesized a 2,4-dioxo-3,3-pentanediselenolato Pt(II) complex and its dithiolato analog by treating *cis*-[$PtCl_2$(PMe_2Ph)$_2$] with 2,3-diseleno-1,1,4,4-tetraacetylbutane and 2,3-dithio-1,1,4,4-tetraacetylbutane in a KOH/acetone-methanol mixed solution. These novel Pt(II) complexes, which were produced via S–C and Se–C bond cleavages, were rather unstable in solution. Their IR, ^{1}H, ^{13}C, and ^{31}P NMR and mass spectra are discussed in this paper.

Experimental

Bis-(dimethylphenylphosphine)(2,4-dioxo-3,3-pentane diselenolato)platinum(II), [Pt(Se_2-ac)(PMe_2Ph)$_2$]: To *cis*-[$PtCl_2$(PMe_2Ph)$_2$] (0.51 g) in acetone charged with N_2 was added 0.33 g of 2,3-diseleno-1,1,4,4-tetraacetylbutane,[2] followed by KOH (ca. 0.11 g) in methanol. The solution, after stirring overnight, was evaporated to produce a brownish-orange solid. The product was developed with TLC(SiO_2) in acetone–CH_2Cl_2. An eluate of the brownish-orange band was developed again with TLC. The eluate was evaporated to produce a brownish-orange residue, which was crystallized from CH_2Cl_2–hexane to give brownish-orange needles (0.25 g: 37%). Anal. Found: C, 34.68; H, 3.90%. Calcd for $C_{21}H_{28}O_2P_2Se_2Pt$: C, 34.67; H, 3.88%. Electron impact mass spectrum (In-beam direct method at 70 eV). *m/z* 727 M^+, 684 $[M-CH_3CO]^+$, 648 $[M-Se]^+$. [Pt(Se_2-ac)(PMe_2Ph)$_2$] is soluble in $CHCl_3$, CH_2Cl_2, and acetone, but is insoluble in diethylether and hexane. The complex in CH_2Cl_2 or $CHCl_3$, by allowing the solution to stand fo several hours, undergoes a decompositon.

Bis-(dimethylphenylphosphine)(2,4-dioxo-3,3-pentane dithiolato)platinum(II), [Pt(S_2-ac)(PMe_2Ph)$_2$]: To *cis*-[$PtCl_2$(PMe_2Ph)$_2$] (0.6 g) in acetone charged with N_2 was added 0.29 g of 2,3-dithio-1,1,4,4-tetraacetylbutane,[3,4] followed by KOH (ca. 0.13 g) in methanol. After stirring the solution for 2 d, a white precipitate was filtered, and the filtrate was evaporated. A brownish-orange product was developed with TLC(SiO_2) in acetone–CH_2Cl_2. A brownish-orange band was eluted by acetone-methanol. The eluate, after the addition of diethylether and hexane, was allowed to stand in a refrigerator for 3 d to give a brownish-orange solid (0.41 g: 52% yield). Anal. Found: C, 39.82; H, 4.47%. Calcd for $C_{21}H_{28}O_2P_2S_2Pt$: C, 39.81; H, 4.45%. The complex is soluble in CH_2Cl_2, $CHCl_3$, and acetone, but is insoluble in hexane. The complex gradually decomposes in CH_2Cl_2 or $CHCl_3$ and changes into an insoluble white solid whose empirical formula is [Pt(SCO-ac)(PMe_2Ph)$_2$], with its molecular ion at *m/z* 628 (100) by SIMS. This white product has not been characterized. SIMS of [Pt(S_2-ac)(PMe_2Ph)$_2$](3-nitrobenzyl alcohol). *m/z* 633 (5) M^+, 602 (13) $[Pt(S\text{-}ac)(PMe_2Ph)_2]^+$, 471 (12) $[Pt(PMe_2Ph)_2]^+$, 336 (56) $[Pt(PMe_2Ph)]^+$. The other intense peaks at 455 (100) and 488 (56) were assigned to $[Pt(C_6H_4NO_2)(PMe_2Ph)]^+$ and $[PtS(C_6H_4NO_2)(PMe_2Ph)]^+$ which may be formed by a decomposition in the matrix. In addition, a peak was observed at *m/z* 628 (38).

Elemental analyses were performed at the micro Analytical Center, Kyoto University. ^{1}H NMR spectra at 90.04 MHz and ^{13}C NMR spectra at 22.66 MHz were recorded on a Hitachi R-90-H FT NMR spectrometer operating Fourier transform modes in sealed tubes saturated with N_2. The IR spectra were recorded on a Hitachi 260-10 infrared spectrometer. An electron impact mass spectrum was, recorded on a Hitachi M-80 mass spectrometer and secondary ion mass spectra were produced using 3-nitrobenzyl alcohol as a matrix and Xe gas as the first ion source.

Results and Discussion

2,3-Diseleno-1,1,4,4-tetraacetylbutane[2] has been obtained from 2,2,4,4-tetraacetyl-1,3-diselenetane[2,3] by reducing it with aq HI. 2,3-Diseleno-1,1,4,4-tetraacetylbutane has a dienolic from both in solid and solution, which is analogous with 2,3-diseleno-1,1,4,4-tetraacetylbutane.[3,4] These bis(β-dicarbonyls) ligands linked by selenium or sulfur atoms between the two β-diketones under basic conditions readily undergo a cleavage of the M–M or M–C (M=S or Se) bond. We have thus prepared a 2,4-dioxo-2-pentene-3-thiolato Pt(II) complex[1] via an S–S bond cleavage of 2,3-dithio-1,1,4,4-tetraacetylbutane. A treatment of *cis*-[$PtCl_2$(PMe_2Ph)$_2$] with 2,3-diseleno-1,1,4,4-tetraacetylbutane and 2,3-dithio-1,1,4,4-tetraacetylbutane in a KOH/acetone-methanol mixed solution gave 2,4-dioxo-3,3-pentanediselenolato (Se_2-ac) and -dithiolato (S_2-ac) Pt(II) complexes, [Pt(Se_2-ac)-(PMe_2Ph)$_2$] and [Pt(S_2-ac)(PMe_2Ph)$_2$] via a Se–C′ and an S–C′ bond cleavage of the corresponding bis(β-dicarbonyls) respectively.

J(P-H) and J(Pt-H) are in parentheses and brackets respectively. c) Measured in $CDCl_3$; Chemical shifts are relative to $SiMe_4$. J(P-C) and J(Pt-C) are in parentheses and brackets respectively. d) Measured in $CDCl_3$; Chemical shift is relative to 85% H_3PO_4. $J(^{195}Pt\text{-}P)$ is in bracket. e) 2,3-Diseleno-1,1,4,4-tetraacetylbutane is abbreviated as DSTAB. f) 2,2,4,4-Tetraacetyl-1,3-diselenetane is abbreviated as TADSN.

The ^{1}H, ^{13}C, and ^{31}P NMR and IR spectral data of $[Pt(M_2\text{-ac})(PMe_2Ph)_2]$ (M=Se, S) are given in Table 1. Carbonyl stretching absorption bands observed for $[Pt(Se_2\text{-ac})(PMe_2Ph)_2]$ are at 1699 and 1656 cm^{-1}, and exhibit two carbonyls of the 2,4-pentanedione group in the keto form. The other absorption pattern very closely resembles those of 2,2,4,4-tetraacetyl-1,3-diselenetane. ^{1}H NMR resonance arising from methyl protons of the 2,4-pentanedione in the complex at 2.64 is appreciably close to 2.63 of 2,2,4,4-tetraacetyl-1,3-diselenetane. These spectral data indicate that two acetyl group of the 2,4-pentanedione is symmetrically arranged in the complex. A ^{13}C NMR resonance arising from its C^3 at 59.0 is in a region which is sufficiently higher field as observed for the central carbon bonded complexes of 2,4-pentanedione[5] and 1,1,2,2-tetraacetylethane.[6] $J(^{195}Pt\text{-}C)$ 53.89 found in $[Pt(Se_2\text{-ac})(PMe_2Ph)_2]$ apparently exhibits no Pt-C bond included, but Se-C^3 bonds maintained.[7] Resonance arising from methyl carbons of the 2,4-pentanedione group in the complex, as is consistent with its ^{1}H NMR, shows a singlet at 24.39, which is also noticeably close to 24.67 of 2,2,4,4-tetraacetyl-1,3-diselenetane. On the other hand, the ^{13}C NMR resonance arising from the methyl carbons of PMe_2Ph unexpectedly exhibits an ABC spin system (Fig. 1), but no AB spin system as predicted for the phosphines arranged at a cis-position mutually. The spectrum is in good agreement with the simulated lines of [ABC(3.5)+ABCM(1)] with $J_{AB}=J_{AC}=19.69$ Hz and $J_{AM}=39.38$ Hz. This ABC spin system which arises from $^{31}P\text{-}^{31}P$ coupling could not be discerned in its ^{1}H NMR spectra as observed in *trans*-$[PtI_2(PMe_2Ph)_2]$ and $[Pd(PMe_2Ph)_3(2,9\text{-}R_2\text{-phen})][BF_4]_2$.[9] The ^{13}C NMR at the present case suggests that two phosphines in the complex are symmetrically arranged with the P-Pt-P bond angle fairly unusually expanded from 90° to give a $^{31}P\text{-}^{31}P$ coupling magnetically. Its ^{31}P NMR with J(Pt-P)=2947 Hz is consistent with the ^{13}C NMR, and the J(Pt-P) is intermediate between 2379 Hz for *trans*-$[PtCl_2(PMe_3)_2]$[10] and 3480 Hz for *cis*-$[PtCl_2(PMe_2Ph)_2]$,[11] in addition to 2311 and 3407 Hz for $[PtCl(PMe_2Ph)_3][PF_6]$.[1] $[Pt(Se_2\text{-ac})(PMe_2Ph)_2]$ is relatively unstable in solution. Its EIMS by In-beam direct method, however, explicitly shows a molecular ion peak at m/z 727. The structure of $[Pt(Se_2\text{-ac})(PMe_2Ph)_2]$ is supposed to have a high symmetry with a diselenetane framework in which the 2,4-dioxo-3,3-pentanediselenolate ligand bonds to Pt(II) as a (η^2-Se_2)-linkage, as is found in a diselenocarbonate Rh(III) complex.[12] Any other conceivable structure

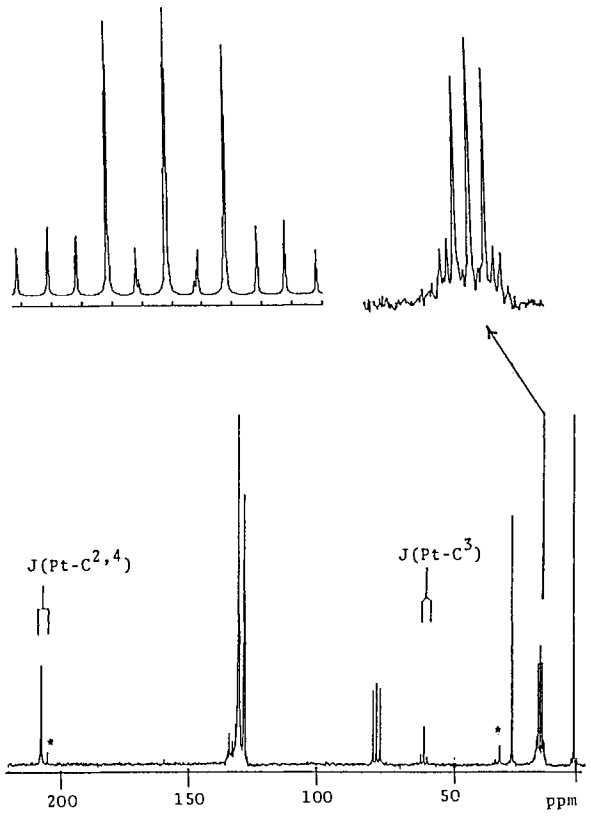

Fig. 1. $^{13}C\{^{1}H\}$ NMR spectrum of $[Pt(\eta^2\text{-}Se_2\text{-ac})(PMe_2Ph)_2]$ in $CDCl_3$ and a simulated line as ABC spin system (expanded) of Me-carbons of PMe_2Ph. *An acetone impurity included.

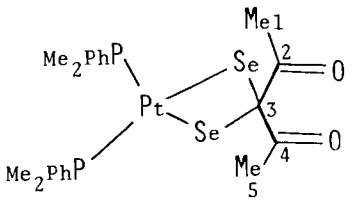

Fig. 2. A supposed structure of [Pt(Se$_2$-ac)-(PMe$_2$Ph)$_2$].

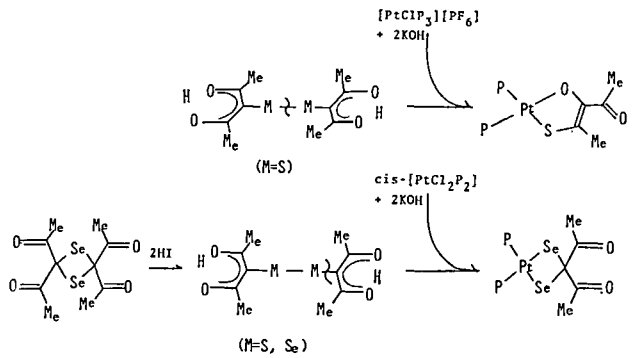
for [Pt(Se$_2$-ac)(PMe$_2$Ph)$_2$], in which a 3-acetyl-4-oxo-1,2-pentanediselenolate ligand may bond to Pt(II) as a (C^3, Se)-chelate, can be excluded since no corresponding J(Pt-C^3) could be obtained and the ^{31}P NMR datum explicitly shows an equivalency of the phosphines. It is also unlikely that the 2,4-dioxo-3,3-pentanediselenolate ligand with a diselenetane framework having a Se-Se bond can coordinate Pt(O) through its oxygen atoms, since J(Pt-$C^{2,4}$)=18.66 Hz observed in [Pt(Se$_2$-ac)(PMe$_2$Ph)$_2$] is quite different from such a presumed configuration.[13]

[Pt(S$_2$-ac)(PMe$_2$Ph)$_2$] is less stable than the corresponding diselenolato Pt(II) complex, and gradually decomposes in $CHCl_3$ producing an insoluble white precipitate(uncharacterized). The ^{1}H and ^{13}C NMR data of [Pt(S$_2$-ac)(PMe$_2$Ph)$_2$] listed in Table 1 involve resonances due to this white species(10—15% included under the condition). The predominant resonances due to [Pt(S$_2$-ac)(PMe$_2$Ph)$_2$] are however sufficiently comparable with those of [Pt(Se$_2$-ac)(PMe$_2$Ph)$_2$]. SIMS datum of [Pt(S$_2$-ac)(PMe$_2$Ph)$_2$] exhibited a molecular ion peak at m/z 633 with a relatively weak intensity(5), although the spectrum was accompanied by an intense peak at m/z 628 due to the white product already formed by a decomposition in the matrix (experimental section).

[Pt(η^2-M$_2$-ac)(PMe$_2$Ph)$_2$] (M=S, Se) produced via a Se′-C′ or S′-C′ bond cleavage of 2,3-diseleno-1,1,4,4-tetraacetylbutane and 2,3-dithio-1,1,4,4-tetraacetylbutane may be given by supposing subsequent reaction steps: a Se′-C′ or S′-C′ bond cleavage of the 3,3′-diseleno or -dithiobis (β-dicarbonyls) and a synchronous Se′-C or S′-C bond formation causes a Se-Se′ or S-S′ bond cleavage resulting in the formation of M$_2$-ac^{2-}, and a following metathesis of the complex. A 2,4-dioxo-2-pentene-3-thiolato Pt(II) complex[1] was previously isolated via an S-S′ bond cleavage of 2,3-dithio-1,1,4,4-tetraacetylbutane under basic conditions. In the present case, no analogous 2,4-dioxo-2-pentene-3-selenolato Pt(II) complex was obtained, which may be formed via a Se-Se′ bond cleavage of 2,3-diseleno-1,1,4,4-tetraacetylbutane. It should also be noticed that 2,2,4,4-tetraacetyl-1,3-diselenetane undergoes a cleavage of the Se-C′ bonds by reducing with aq HI to afford 2,3-diseleno-1,1,4,4-tetraacetylbutane with a Se-Se′ bond. Accordingly, a supposed rearrangement forming (η^2-M$_2$)-bonding to the metal interestingly seems to be a reversed pattern from the reaction cited above (Scheme 1). Yet, J(Pt-P) obtained in [Pt(Se$_2$-ac)(PMe$_2$Ph)$_2$] may be valid only in the configuration of a d-8 electron species.



Scheme 1. (Reaction scheme of S-S, S-C, and Se-C bond cleavages of 2,3-dithio-1,1,4,4-tetraacetylbutane and 2,3-diseleno-1,1,4,4-tetraacetylbutane).

An author (Shinsaku Yamazaki) appreciates Dr. Tomoharu Ama (Department of Chemistry, Faculty of Sciences, Kochi University) for obtaining NMR spectra.

Synopsis. Fluorogenic substrates of pepsin; Dns-Ala-Phe-Trp-Val-Leu-OCH_2Py and Dns-Phe-Trp-Val-Leu-OCH_2Py were synthesized by a solution method. Incubation of pepsin with Dns-Ala-Phe-Trp-Val-Leu-OCH_2Py resulted in specific cleavage at the Phe-Trp bond and the time-dependent increase in fluorescence intensity at 345 nm paralleling the extent of substrate hydrolysis. The optimum pH of the substrate was 3.0 and the K_m and k_{cat} values were 8.0×10^{-5} M and 0.10 s^{-1}, respectively. The linearity of the plot of fluorescence intensity vs. enzyme concentration was satisfactory in the range of 50 nM to 500 nM of pepsin at a substrate concentration of 50 μM. Because of its simplicity and rapidity, this method is useful for the measurement of pepsin action. In contrast, Dns-Phe-Trp-Val-Leu-OCH_2Py was not cleaved by pepsin.

Pepsin [EC. 3.4.4.1.] is a gastric proteinase active in acidic solutions (pH 1—5). To determine the pepsin activity, hemoglobin is generally used as a protein substrate.[2] In addition, many synthetic substrates have been used for the measurement of pepsin activity.[3,4] The widely used analytical procedures to estimate the hydrolysis rate are based on the determination of amine products by observing their reaction with ninhydrin. These procedures usually require much intension and are time-consuming. The task of enzymic activity assay is simplified by use of chromogenic substrates. However, a good chromogenic substrate for pepsin has not been obtained. For example, pepsin does not cleave *p*-nitroanilide substrates.

Inouye et al. synthesized chromogenic substrates containing *p*-nitrophenylalanine at the P_1 site such as Z-His-Phe (NO_2)-Phe-OMe and determined the rate of hydrolysis in terms of the increase in absorbance at 310 nm.[5] However, the sensitivity of these substrates for the pepsin action was low.

Fluorometric methods are employed for the detection of peptidase activity as convenient and very sensitive methods. Most of the fluorogenic substrates for peptidases are acyl derivatives of highly fluorescent amines.[6,7] These substrates would not be cleaved by pepsin in analogy with *p*-nitroanilide substrates.[8,9] Latt et al. reported the synthesis of intramolecularly quenching substrates for carboxypeptidase, where the resonance energy transfer phenomenon was utilized with dansylated tryptophan-peptides.[10] Recently, Sato et al. reported applications of 3,4,6,7-tetramethyl-9,10-dioxa-*syn*-bimane to prepare intramolecularly quenching substrates for assay of some peptidases.[11,12]

Since pepsin cleaves the peptide bond between two aromatic amino acids, the peptides containing a dansyl group at the NH_2-terminal, phenylalanine at the P_1 site and tryptophan at the P_1' site must be cleaved between two aromatic amino acid residues by pepsin, with a concomitant increase in the tryptophan fluorescence. However, N-protected peptides are not soluble in acidic buffers. Then, 4-pyridylmethyl ester of N-protected substrates for pepsin was employed, since it confers moderate solubility in acidic buffers.[13] Z-Ala-Ala-Phe(NO_2)-Phe-$O(CH_2)_3Py$ and Phe-Gly-His-Phe(NO_2)-Phe-Val-Leu-OMe are reported by good substrates for pepsin.[9] In view of this, Dns-Phe-Trp-Val-Leu-OCH_2Py (**1**) and Dns-Ala-Phe-Trp-Val-Leu-OCH_2Py (**2**) have been synthesized in the present work as fluorogenic substrates for pepsin.

Results and Discussion

The substrates and the peptides which will arise from cleavage of the substrates were synthesized by a solution method. Each protected amino acid was coupled with amino acid 4-pyridylmethyl ester or peptide 4-pyridylmethyl esters from C-terminus. The obtained Boc-peptide-OCH_2Pys were treated with HCl/AcOH and the resulting deblocked peptide 4-pyridylmethyl esters were dansylated by the usual manner. The dansyl peptides obtained gave one spot by thin layer chromatography and a single peak by HPLC. Compounds **1** and **2** were sufficiently soluble in an acidic buffer containing 10% DMF for use in kinetic studies. The chromatographic patterns for the mixtures of substrates (**2** and **1**) and products (Dns-Ala-Phe, Dns-Phe, and Trp-Val-Leu-OCH_2Py) are shown in Fig. 1-A and 1-C. The elution times of synthetic peptides were as follows: **2**, 27.2 min; **1**, 27.2 min; Dns-Ala-Phe, 20.0 min; Dns-Phe, 18.9 min; Trp-Val-Leu-OCH_2Py, 18.9 min.

The substrates **2** and **1** were incubated, respectively, with pepsin for 3 h and the reaction mixtures were applied on HPLC. Fig. 1-B indicates disappearance of the substrate (**2**) and concomitant appearance of two products (Dns-Ala-Phe and Trp-Val-Leu-OCH_2Py). This result suggests that the substrate was cleaved quantitatively at a single bond between phenylalanine and tryptophan. On the other hand, compound **1** was not cleaved by pepsin (Fig. 1-D).

As seen in Fig. 2, hydrolysis of the substrate (**2**) decreased dansyl emission (500 nm) and increased tryptophan fluorescence (345 nm). When pepsin was added to the substrate solution, the fluorescence at 345 nm increased momentarily, then decreased gradually up to about 2 min. Subsequently, the fluorescence at 345 nm increased linearly in proportion to the concentration of added pepsin. Consequently, measurement of the increase in the fluorescence was started at the incubation time of 2 min. Similarly, addition of pepsin to the substrate produced an increase in the fluorescence intensity at 500 nm. This indicates that the dansyl group of the substrate was bound at a hydrophobic region of the enzyme.[14] Then, the fluo-

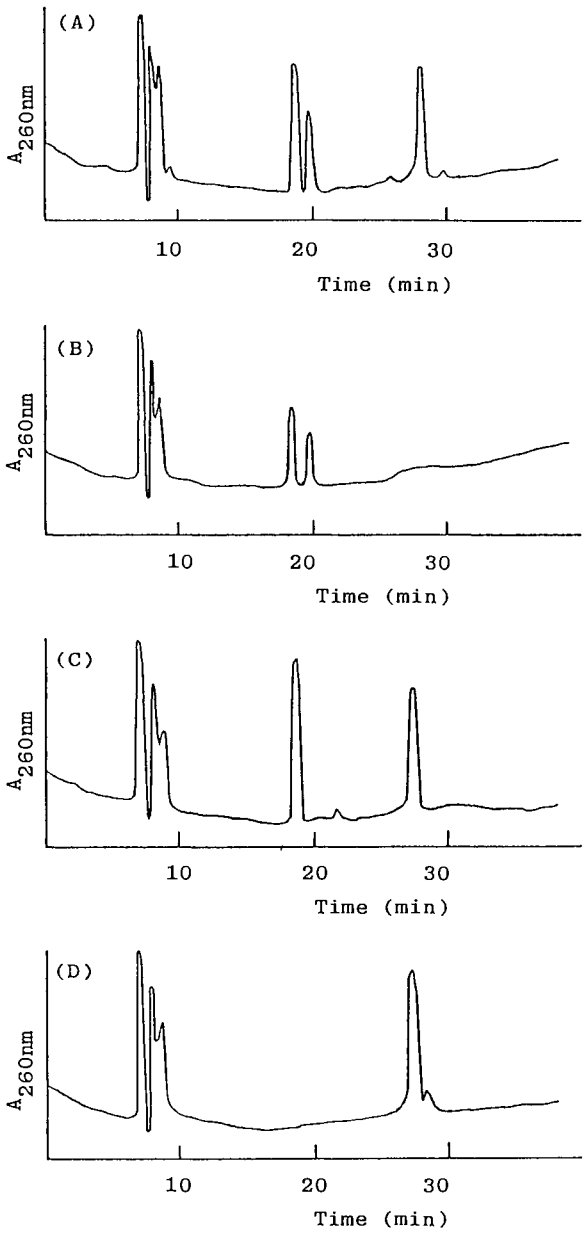

Fig. 1. HPLC traces of fluorogenic substrates and reaction products. (A) Mixture of **2**, Dns-Ala-Phe, and Trp-Val-Leu-OCH_2Py; (B) Reaction mixture of **2** and pepsin; (C) Mixture of **1**, Dns-Phe, and Trp-Val-Leu-OCH_2Py; (D) Reaction mixture of **1** and pepsin.

rescence at 500 nm decreased with the hydrolysis of the substrates. The increase in the fluorescence at 345 nm subsequent to complete hydrolysis of the substrate by pepsin was not influenced by the amount of added pepsin. The molar fluorescence intensity of the complete hydrolysis of compound **2** was 50000.

Comparative measurements of the effect of pH on the pepsin action were made with compound **2**. The optimum pH was 3.0. A pH 3.0 buffer was thus used as solvent for the substrate in the following experiments. K_m and k_{cat} values of 8.0×10^{-5} M and 0.10 s^{-1} were obtained from the Lineweaver-Burk plot of compound **2**. The linearity of the plot of fluorescence

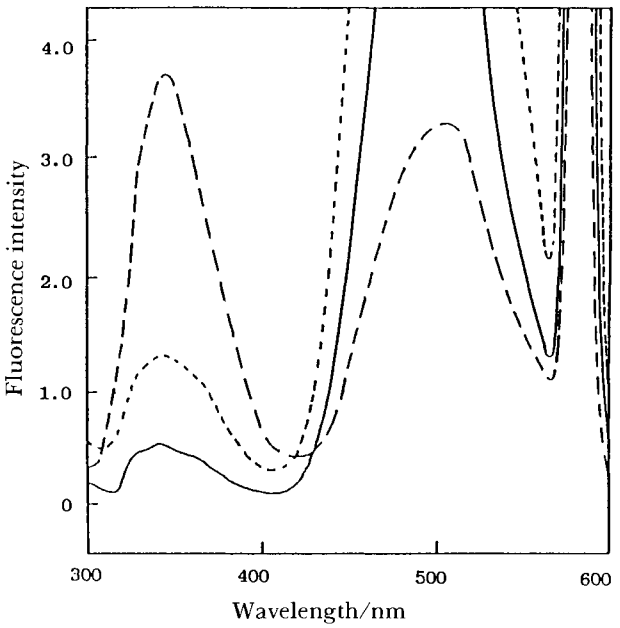

Fig. 2. Fluorescence emission spectra of **2** and the hydrolysate of **2**. (——) **2**; (------) **2** was incubated with pepsin for 10 s; (— —) **2** was incubated with pepsin for 3 h.

intensity vs. enzyme concentration was satisfactory in the range of 50 nM to 500 nM of pepsin.

Compound **2** is the first fluorogenic substrate of pepsin. The resultant assay for pepsin was sensitive and convenient. The product formed can be detected directly as hydrolysis occurs. This contrasts with the case of the nynhydrin methods, where at least several minutes elapse between the formation and detection of the products. The fluorogenic substrate described here may be useful for the assay of pepsin activity.

Experimental

All melting points are uncorrected. Optical rotations were determined with a JASCO spectropolarimeter J-20A. Fluorescence measurements were performed with a Shimadzu spectrofluorophotometer RF-5000.

Synthesis of Substrates. Boc-Leu-OCH_2Py (3). To a solution of Boc-Leu (2.31 g, 10 mmol) and 4-pyridylmethanol (1.09 g, 10 mmol) in CH_2Cl_2 (20 ml) was added DCC (2.06 g, 10 mmol) at 0 °C. The mixture was stirred for 2 h at 0 °C and overnight at room temperature, then evaporated in vacuo, and ethyl acetate was added to the residue. After dicyclohexylurea was filtered off, the filtrate was washed successively with 4% sodium bicarbonate, 10% citric acid and water. The organic layer was dried over anhydrous sodium sulfate and was evaporated in vacuo to yield Boc-Leu-OCH_2Py as an oil (3.07 g). ^1H NMR ($CDCl_3$) δ=0.94 (6H, d, J=5 Hz), 1.40 (9H, s) 1.40—1.92 (3H, m), 4.48 (1H, q, J=6 Hz), 4.90 (1H, d, J= 6 Hz), 5.15 (2H, s), 7.22 (2H, dd, J=1 and 5 Hz), 8.58 (2H, dd, J=1 and 5 Hz).

Boc-Val-Leu-OCH_2Py (4). Compound **3** (3.07 g) was treated with 1M (1 M=1 mol dm^{-3}) HCl/AcOH for 1 h at room temperature and the resulting HCl · Leu-OCH_2Py was converted into free base as described previously.[13] The obtained oily Leu-OCH_2Py was coupled with Boc-Val (2.17 g, 10 mmol) in the same manner using DCC (1.65 g, 8 mmol) in CH_2Cl_2 (30 ml) to yield Boc-Val-Leu-OCH_2Py as an oil (3.16 g). ^1H NMR ($CDCl_3$) δ=0.95 (12H, d, J=6 Hz), 1.40

(9H, s), 1.37—1.87 (2H, m), 2.03 (2H, t, J=6 Hz), 3.88 (1H, dd, J=6 and 8 Hz), 4.73 (1H, q, J=7 Hz), 5.06 (1H, brd, J=7 Hz), 5.13 (2H, s), 6.47 (1H, brd, J=8 Hz), 7.23 (2H, brd, J=4 Hz), 8.62 (2H, dd, J=2 and 4 Hz).

Boc-Trp-Val-Leu-OCH_2Py (5). Boc-Trp (3.0 g, 10 mmol) and Val-Leu-OCH_2Py (derived from 3.16 g of **4** in the manner descrived for Leu-OCH_2Py) were coupled in the same manner using DCC (1.56 g, 7.6 mmol) in CH_2Cl_2 (30 ml). The product was recrystallized from ethyl acetate-petroleum ether; yield, 3.75 g, (81%); mp 89—91 °C; $[\alpha]_D^{25}$ −22.5° (c 1, DMF).

Found: C, 64.59; H, 7.72; N, 11.04%. Calcd for $C_{33}H_{45}O_6N_5 \cdot 1/2H_2O$: C, 64.26; H, 7.35; N, 11.36%.

Boc-Phe-Trp-Val-Leu-OCH_2Py (6). Compound **5** (3.1 g, 5.1 mmol) was treated with 1 M HCl/AcOH for 1 h at room temperature and the solvent evaporated in vacuo. The resulting crystals were collected with the aid of ether; yield, 3.5 g. The product (3.5 g) was dissolved in water (8 ml) and cooled in an ice bath. To this solution was added 50% saturated aqueous K_2CO_3 (13 ml) and the resulting precipitate was collected by filtration, washed with water and dried. The resulting Trp-Val-Leu-OCH_2Py and Boc-Phe (1.33 g, 5 mmol) were coupled in the same manner using DCC (0.9 g, 4.5 mmol) in DMF (10 ml) and CH_2Cl_2 (20 ml). The product was recrystallized from ethyl acetate-petroleum ether; yield, 1.94 g, (57%); mp 121—123 °C; $[\alpha]_D^{25}$ −18.0° (c 1, DMF).

Found: C, 66.15; H, 7.05; N, 11.00%. Calcd for $C_{42}H_{54}O_7N_6 \cdot 1/2H_2O$: C, 66.03; H, 7.26; N, 11.00%.

Boc-Ala-Phe-Trp-Val-Leu-OCH_2Py (7). Boc-Ala (80 mg, 0.42 mmol) and Phe-Trp-Val-Leu-OCH_2Py (derived from 0.3 mmol of **6** in the manner described for Leu-OCH_2Py) were coupled in the same manner using DCC (65 mg, 0.32 mmol) in DMF (1 ml) and CH_2Cl_2 (4 ml). The product was recrystallized from ethyl acetate-petroleum ether; yield, 200 mg, (81%); mp 161—163 °C; $[\alpha]_D^{25}$ −19.5° (c 1, DMF).

Found: C, 64.85; H, 7.23; N, 11.75%. Calcd for $C_{45}H_{59}O_8N_7 \cdot 1/2H_2O$: C, 64.73; H, 7.24; N, 11.74%.

Dns-Phe-Trp-Val-Leu-OCH_2Py (1). Compound **6** (90 mg, 0.12 mmol) was treated with 1 M HCl/AcOH for 1 h at room temperature, and the resulting deblocked peptide ester was dansylated according to the procedure described by Gray.[15] The product was recrystallized from ethyl acetate-petroleum ether; yield, 65 mg, (61%); mp 125—127 °C; $[\alpha]_D^{25}$ −41.0° (c 1, DMF).

Found: C, 65.48; H, 6.34; N, 10.87%. Calcd for $C_{49}H_{57}O_7N_7S_1 \cdot 1/2H_2O$: C, 65.60; H, 6.52; N, 10.93%.

Dns-Ala-Phe-Trp-Val-Leu-OCH_2Py (2). This compound was obtained from **7** (120 mg, 0.15 mmol) by the same procedure as described above, and recrystallized from DMF-ether; yield, 72 mg, (50%); mp 232—234 °C; $[\alpha]_D^{25}$ −31.5° (c 1, DMF).

Found: C, 64.29; H, 6.52; N, 11.68%. Calcd for $C_{52}H_{62}O_8N_8S_1 \cdot 1/2H_2O$: C, 64.51; H, 6.56; N, 11.57%.

Dns-Ala-Phe (8). This compound was obtained from Ala-Phe (200 mg, 0.17 mmol) by the same procedure as described above. The product was recrystallized from ethyl acetate-petroleum ether; yield, 160 mg, (48%); mp 114—116 °C; $[\alpha]_D^{25}$ +7.5° (c 1, DMF).

Enzyme and Methods. Pepsin (salt free crystalline sample from Worthington Biochemical Co. U.S.A.) was dissolved in 0.1 M citrate buffer pH 3.0. The substrates were dissolved in 0.1 M citrate buffer (pH 3.0) containing 10% DMF.

Analysis of Reaction Products. Fifty microliters of the pepsin solution (0.1 mM) was added to 5 ml of the substrate solutions (50 μM) at 37 °C. After incubation for 3 h, the reaction mixtures were subjected HPLC assays. The reaction mixtures (100 μl) were applied to a C_{18} reversed-phase column (DYNAMAX-60A, 4.6×250 mm, Rainin Instrument) and eluted with a linear gradient of 10—70% 2-propanol/acetonitrile (7/3. v/v) in 0.1% trifluoroacetic acid for 30 min at a flow rate of 0.5 ml min^{-1}.

Measurement of Fluorescence Emission Spectrum. The substrate (**2**) was dissolved in a 0.1 M citrate buffer (50 μM). Fifty microliters of the pepsin solution (0.1 mM) was added to the substrate solution (5 ml) at 37 °C. After incubation for 10 s and 3 h, the fluorescence emission spectrum was measured (excitation at 290 nm).

pH-Activity Curve. The substrate (**2**) was dissolved in 0.1 M citrate buffers in the pH range 2.0—4.5 (50 μM). Fifty microliters of the pepsin solution (0.1 mM) was added to the substrate solutions (5 ml) at 37 °C. After incubation for 2 min, the increase in emission at 345 nm was recorded during the following 6 min of the incubation time at 37 °C (excitation at 290 nm).

Linear Relation of the Fluorescence Intensity vs. Enzyme Concentration. Various amounts (5—100 μl) of the pepsin solution (0.1 mM) was added to 5 ml of the substrate solutions (50 μM, pH 3.0) at 37 °C and the increase in emission was measured in the manner described above.

Kinetic Parameter Measurement. Twenty five microliters of the pepsin solution (0.1 mM) was added to various concentrations (5—50 μM) of the substrate solution (5 ml) at 37 °C, and the increase in emission was measured in the manner described above.

Halogenative Allylation and Reduction of Aromatic Acetals by Double Substitution of Alkoxyl Groups in Acetal

Takeshi ORIYAMA,* Katsuyuki IWANAMI, Kazuhisa TSUKAMOTO, Yuichi ICHIMURA, and Gen KOGA
Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo, Mito 310
(Received September 27, 1990)

Synopsis. In the presence of excessive amount of acetyl halide along with a catalytic amount of tin(II) halide, aromatic acetals react with allyltrimethylsilane or triethylsilane to give α-allylbenzyl halides or benzyl halides, respectively, in good to excellent yields.

In continuation of our studies of the new carbon-carbon bond formation between acetals and silyl nucleophiles effected by the combined use of a catalytic amount of tin(II) halide (SnX_2) and an excessive amount of reactive organic halide such as acetyl chloride (AcCl) and methoxymethyl chloride (MOMCl), we have already demonstrated a convenient synthesis of conjugated enones from acetals and silyl enol ethers.[1]

Now we wish to report novel reaction of aromatic acetals with allyltrimethylsilane[2] or triethylsilane[3] as a silyl nucleophile to give α-allylbenzyl halides or benzyl halides respectively.

In the first place, we have examined the allylation according to the procedure similar to that for the aldol-type reaction reported in the previous paper.[1] Reaction of benzaldehyde dimethyl acetal (**1**) with allylsilane using a combined activator, $SnCl_2$ and AcCl both in a catalytic amount, afforded the known product, 4-methoxy-4-phenyl-1-butene (**3**), in 72% yield (Run 1 in Table 1). In a striking contrast, when 2.5 molar amount of AcCl to the acetal was employed, an allylation with concomitant substitution of methoxyl for chloride[4] occurred to give 4-chloro-4-phenyl-1-butene (**2**, X=Cl) in 83% yield (Run 2 in Table 1). AcCl did not function as an electrophile to acylate allylsilane. Screening of various combined activator system using benzaldehyde dimethyl acetal as a reference substrate revealed that SnX_2/AcX (molar ratio of acetal : SnX_2 : AcX=1.0 : 0.05 : 2.0—2.5) gave the best result as shown in Table 1. When a combination of $SnBr_2$/AcBr was used as an activator, corresponding 4-bromo-1-butene was obtained as a sole product (Run 8 in Table 1). The results of the reaction with various acetals are summarized in Table 2.

The reaction is similarly effective to ketone acetal,

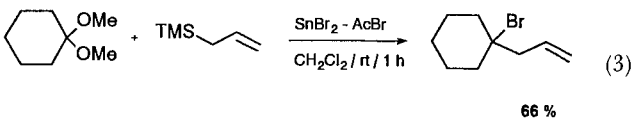
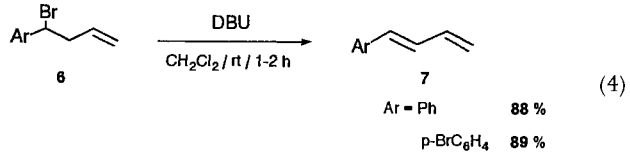
e.g. cyclohexanone dimethyl acetal, to result in 1-allyl-1-bromocyclohexane (Eq. 3).



(3)

4-Aryl-4-bromo-1-butenes (**6**), above obtained, were easily converted to 1-aryl-1,3-butadienes (**7**) by a convenient procedure as illustrated in Eq. 4.



(4)

The above shown double substitution of alkoxyl groups in acetal by a nucleophile from reactive silanes and a halogen from reactive organic halides has led us to examine the hydride reduction of acetals with simultaneous halogen substitution to obtain benzyl halides. Thus, the reduction of aromatic dimethyl acetals by triethylsilane in the presence of a combined AcX/SnX_2 reagent was tried and was proven to be successful as well. The results are summarized in Table 3.

Reaction of alkyl halides with *n*-Bu_3SnH under radical conditions[5] gave the corresponding alkane in good yield as shown in Eqs. 6 and 7. This overall three step reduction from carbonyl to methylene provides a mild and effective alternative to conventional Wolff-Kishner[6] and Clemmensen reductions,[7] both of which necessitate drastic reaction conditions.

(5.1 mg, 0.02 mmol) and benzaldehyde dimethyl acetal (54.8 mg, 0.36 mmol) in dichloromethane (2.5 ml) were added triethylsilane (65.0 mg, 0.56 mmol) in dichloromethane (1.5 ml) and acetyl bromide (96.8 mg, 0.79 mmol) in dichloromethane (1 ml), successively at room temperature under argon atmosphere. The mixture was stirred for 3 h at this temperature, and quenched with a phosphate buffer (pH 7). The organic materials were extracted with dichloromethane and dried over Na_2SO_4. Benzyl bromide (54.7 mg, 89%) was isolated by thin layer chromatography on silica gel.

It should be noted that the present halogenative allylation and reduction of aromatic acetals are extremely mild and exceptionally simple in operation.

The present work was partially supported by a Grant-in-Aid for Scientific Research No. 02854053 from the Ministry of Education, Science and Culture.

Cyclotriveratrylene Crown Ethers: Metal Ion Extraction and Transport Abilities through Organic Membrane

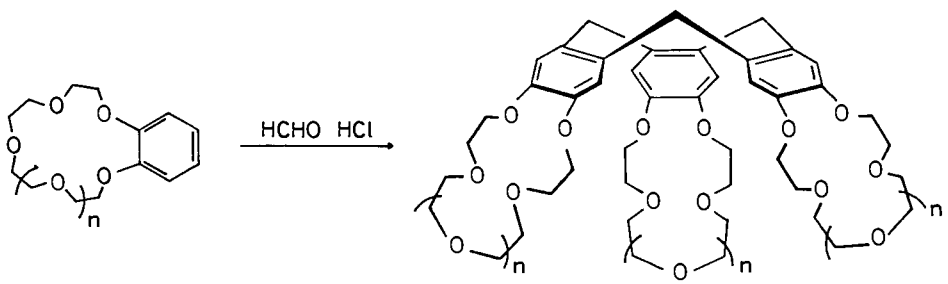
Sadatoshi AKABORI,* Masakazu TAKEDA, and Hiroshi KAWAKAMI
Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274
(Received November 19, 1990)

Synopsis. Extraction abilities of cyclotriveratrylene crown ethers (**2**) toward alkali, alkaline earth, and other metal ions were examined. Transport of metal ions by **2** through a liquid membrane was also examined.

Many research groups are recently modifying crown ethers in order to develop a new kind of functionality in the host-guest chemistry.[1] Cyclotriveratrylene attracts considerable attention for the following reasons: i) it exists in a "crown (or cone)" conformation with a high energy barrier for interconversion;[2,3] ii) it forms stoichiometric inclusion compounds with small neutral molecules.[4] Although syntheses of the cyclotriveratrylene crown ethers such as **2b** and **2c** and the isolation of their 1 : 3 complexes with sodium and potassium thiocyanates have already been reported by Frensch and Vögtle,[5] the complexing ability of **2** for metal ions has not been studied in detail. In this paper we report the extraction and transport of metal ions by **2**.

Cyclotriveratrylene crown ethers **2a**, **2b**, and **2c** were prepared by the method of Frensch and Vögtle with minor modification.[5] Thus, compound **2a** was obtained in a 4.8% yield by the reaction of benzo-12-crown-4 (**1a**) with formaldehyde in the presence of hydrochloric acid.

The extraction abilities of the crown ethers **1a—c** and **2a—c** toward alkali, alkaline earth, and other metal ions were determined by the method described in our previous paper.[6] However, the measurement of extraction and transport abilities was carried out using a three-fold concentration of **1a—c** compared with that of **2a—c** in order to clarify the selectivities of **2a—c** and the corresponding monomers **1a—c**. The results are summarized in Table 1. The extraction ability of cyclotriveratrylene crown ether **2a** toward alkali, alkaline earth metals, and other bivalent metal ions is low or zero. Similar results were obtained with the corresponding monomer **1a**. In addition, it was found that **2c** showed a relatively high extraction ability toward alkali metal (excluding lithium) ion, alkaline earth metal ions, silver(I) ion, and thallium(I) ion, while it showed little or no extraction ability toward Li^+, Mg^{2+}, Ca^{2+}, Co^{2+}, Ni^{2+}, and Cu^{2+}. Furthermore, **2c** showed only slightly higher extraction abilities toward Na^+, Rb^+, Cs^+, Sr^{2+}, Ba^{2+}, and Ag^+ than those of the corresponding monomer **1c**. Similar results were obtained in the case of **2b** (except for Sr^{2+} and Ba^{2+}), although the extraction ability of **2b** is relatively low compared with that of **2c**. Consequently, the extraction abilities of cyclotriveratrylene crown ethers **2a**, **2b**, and **2c** are very similar to those of the corresponding monomers **1a**, **1b**, and **1c**, although the complexing manner of the cyclotriveratrylene



1a : n=0

a) Solvent: Water and dichloromethane (equal volumes). Picric acid=7.0×10^{-5} M. Metal nitrate=0.1 M. Crown ether=7.0×10^{-4} M. b) Crown ether=2.1×10^{-3} M.

crown ether **2** with metal ions cannot be determined from the present results.

Alkali metal cation transport mediated by **1** and **2** through an organic liquid membrane was investigated using a double cylindrical glass cell in which the inner and outer aqueous phases were bridged by a dichloromethane solution containing crown ether **1** or **2**. Practically no ion transport occurred in the absence of the crown ether. The results and the selectivity of Rb^+ over other alkali metal cations are summarized in Tables 2 and 3, respectively. The rate of ion transport is dependent on the ring size of the cyclotriveratrylene crown ethers and the kind of metal ions. Crown ethers **2a** and **2c** showed a similar tendency of ion transport abilities toward alkali metal cations with the corresponding monomers **1a** and **1c**, although **1a** and **1c** generally showed slightly higher ion transport abilities compared with **2a** and **2c**, respectively. However, **2b** showed much higher ion transport abilities toward alkali metal cations compared with those of the corresponding monomer **1b**. Interestingly, **2b** transported Rb^+ more efficiently than **1b**, while the transport abilities of **2b** and **1b** toward Li^+, Na^+, K^+, and Cs^+ were nearly the same. These observations suggest that the Rb^+ ion is incorporated into the cavity surrounded by the three benzo-crown ether moieties of **2b**, thereby forming a 1 : 1 complex. Furthermore, **2b** showed higher transport abilities toward K^+ and Cs^+ ions compared with the corresponding monomer **1b**, although complexing manner cannot be detailed at present. As shown in Table 3, the difference in the selectivity of Rb^+ over other alkali metal cations between **1** and **2** may be insignificant and the preference of Rb^+ over Na^+ in the transport was in the range from 0.3 to 6.9 except for **2c**. However, it is noticeable that the selectivity (Rb^+/Na^+) of **2c** in the transport was 43.8. This value is very large compared with that (5.5) of the corresponding monomer **1c**, or those of the other crown ethers **1a**, **1b**, **2a**, and **2b**. It is well known that in ion-transport from an IN aq phase to an OUT aq phase across a liquid membrane, there exist two possible rate-determing steps: ion-extraction from the IN aq phase to the membrane phase and ion-releasing from the membrane phase to the OUT aq phase. Therefore, the high selectivity of **2c** for Rb^+/Na^+ may be mainly due to the slow ion-releasing step of Na^+, because the extraction abilities (48 and 53%) of **2b** and **2c** for Na^+ are nearly the same, while the transport abilities (2.18 and 0.66) of **2b** and **2c** for Na^+ are very different.

Experimental

All melting points are uncorrected. ^1H NMR spectra were measured on a Hitachi R-1100 spectrometer (60 MHz) with TMS as the internal standard. Mass spectra were taken on a Hitachi M-80 spectrometer.

Materials. Benzo-12-crown-4 (**1a**), benzo-15-crown-5 (**1b**), and benzo-18-crown-6 (**1c**) were prepared according to a method reported in the literature.[7] Other reagents employed were either commercially available or synthesized by the usual methods. The solvents were purified by distillation.

6,9,12,15,23,26,29,32,40,43,46,49-Dodecaoxaheptacyclo-[$O^{3,18}$.$O^{5,16}$.$O^{20,35}$.$O^{22,33}$.$O^{37,1}$.$O^{39,50}$]heptaconta-3,5(16),17,20,22(33),34,37,39(50),51-nonaene (2a). To a mixture of concentrated hydrochloric acid (135 ml) and 37% formalin (10 ml, 0.13 mol), benzo-12-crown-4 (**1a**) (4.03 g, 18 mmol) was added under stirring at 0 °C. After being stirred for 7 h at 30 °C, the viscous solution was poured onto water. The mixture was then extracted with chloroform and the extracts were washed with water until they became neutral. The combined extract was dried over $MgSO_4$ and concentrated under reduced pressure. Chromatography on silica gel using ethyl acetate as the eluent gave a colorless solid. Recrystallization of the solid from chloroform-hexane gave **2a** (0.2g, 4.8%) as a colorless powder, mp 253-256 °C. ^1H NMR ($CDCl_3$) δ=6.99(s, 6H), 4.75 (d, J=14.0 Hz, 3H), 4.40—3.72 (m, 36H), 3.54 (d, J=14.0 Hz, 3H). MS m/z 708 (M^+). Found: C, 62.09, H, 6.52%. Calcd for $C_{39}H_{48}O_{12}$. 1/2$CHCl_3$: C, 61.74, H, 6.36%.

Compounds **2b** and **2c** were also obtained by a method similar to that previously described.[5]

2b: Yield 3.6%, mp 204.5—206.0 °C (lit,[5] 203.5—205.5 °C).

2c: Yield 12%, mp 166.0—167.0 °C (lit,[5] 169—172 °C).

Solvent Extraction. Equal volumes (5 ml) of dichloromethane containing 7×10^{-4} M of **2** and/or 2.1×10^{-3} M of **1** and an aqueous solution containing 0.1 M of metal nitrate and 7.0×10^{-5} M of picric acid were mixed and agitated (1 M=1 mol dm^{-3}). The solution was then separated by centrifugation. The upper solution was withdrawn and its absorbance was measured at 380 nm. A similar extraction and measurement were performed with pure dichloromethane and an aqueous solution containing 0.1 M metal nitrate and 7.0×10^{-5} M picric acid. Extraction abilities were calculated by the following equation: extraction ability=$(A_0-A)/A_0\times100$. A_0 is the absorbance in the absence of a crown ether and A is the absorbance in its presence.

Cation Transport through Liquid Membranes. Cation transport experiments were conducted using a double cylindrical glass cell (cylinder diameter: inner, 7 mm; outer, 16 mm) in which the inner cylinder had small channels connecting the inner and outer areas at its bottom. A dichloromethane solution (5 ml) containing 0.33 mM of crown ether **2** or 1 mM of crown ether **1** was placed at the bottom. Atop the dichloromethane solution inside the inner cylinder

was placed 1.5 ml of water. Simultaneously, atop the outer ring of the dichloromethane solution was placed an aqueous solution (3 ml) containg metal thiocyanate (1 M). The organic phase was gently stirred at ca. 130 rpm and 24 °C using a stirrer. At specified time intervals, the concentrations of metal ion in the receiving phase were determined by atomic absorption spectroscopy.

A Convenient Synthesis of 4-(Phenylsulfonylthio)-2-azetidinones[1)]

Hideo TANAKA, Masatoshi TANIGUCHI, Seiryu UTO,† Takashi SHIROI,† Michio SASAOKA,† and Sigeru TORII*
Department of Applied Chemistry, Faculty of Engineering, Okayama University, Okayama 700
†Tokushima Research Laboratories, Otsuka Chemical Co., Ltd., Tokushima 771-01
(Received September 12, 1990)

Synopsis. 4-(Phenylsulfonylthio)-2-azetidinones have been prepared conveniently by the reaction of 4-(2-benzothiazolyldithio)-2-azetidinones with 2-benzothiazolyl benzenethiosulfonates. A combination of this reaction with the electrolytic cross-coupling of bis(benzothiazolyl) disulfide and ammonium benzenesulfinate can establish a recycling system, in which *S*-(2-benzothiazolyl) benzenethiosulfonate is regenerated to play a critical role in penicillin-cephalosporin conversions.

4-(Phenylsulfonylthio)-2-azetidinones **2** are versatile intermediates for the synthesis of useful β-lactam antibiotics.[2)] For example the ene-type chlorination and/or C=C bond fission of **2** followed by intramolecular cyclization can provide C(3)-substituted cephems, such as 3-chloromethyl-[3)] and 3-hydroxycephems **3** (Y=CH_2Cl or OH),[4)] wherein the phenylsulfonyl group works not only as a protecting group of the 4-thiol moiety but also as a leaving group in the cephem-ring forming process. (Scheme 1). In spite of a strong interest of **2** in cephem synthesis, only a few reports for the preparation of **2** have appeared so far.[4,5)] Woodward and Gosteli prepared **2** by the replacement of the 2-benzothiazolylthio moiety of Kamiya's disulfides **1** derived from penicillins[6)] with arylsulfonyl groups.[4)] However, the method has disadvantages that it inevitably requires a stoichiometric or excessive amount of heavy metal salts or silver salt of arenesulfinates. Thermolysis of penicillin sulfoxides in the presence of arenesulfinic acids was also attempted by Allan et al.,[5)] but they failed in obtaining **2** owing to a terminal/internal olefin migration of the *N*-alkenyl substituent of **2** (R^2=CH_2CCl_3) under the conditions. Thus, the lack of an acceptable method for the large scale production of **2** enabled us to develop an alternative access to **2**.

Incidentally, the reaction of **1** with arenesulfinates **4** produced **2** together with 2-benzothiazolethiolate **5** but the reaction reached rapidly a state of equilibrium and only 30—45% yields of **1** were obtained. Hence, one can expect that removal of **5** from the equilibrium mixture may shift the equilibrium to the right so as to complete the reaction leading to **2**. Herein, we disclose a new device for this purpose, in which 2-benzothiazolyl benzenethiosulfonate **6** works as an efficient trapping agents of **5** and at the same time liberates benzenesulfinate **4** to complete the transformation of **1** to **2** as illustrated in Scheme 1.

A representative procedure is as follows (Entry 1 in Table 1): A mixture of 4-(2-benzothiazolyldithio)-2-azetidinone **1a** (R^1=$PhOCH_2$; R^2=CH_2Ph) and *S*-(2-benzothiazolyl) benzenethiosulfonate **6** (1 : 1.1) in aqueous acetone containing a catalytic amount of sodium benzenesulfinate **4** was stirred at an ambient temperature for 3.5 h. During the course of the reaction, pale yellow precipitates were formed. The solids were collected by filtration and air-dried to afford disulfide **7** (96%) and the filtrates afforded the 4-(phenylsulfonylthio)-2-azetidinone **2** in 91% yield. The presence of a catalytic amount of **4** is influential to effect the reaction smoothly. Indeed, the reaction hardly started without **4** and did not complete even after the prolonged reaction time (Entry 2).[7)] In place of **4**, sodium 2-benzothiazolethiolate **5** can be used without any disadvantages (Entry 3) presumably because **5** reacts with **6** liberating **4** together with disulfide **7**.

The elimination of the disulfide **7** as precipitates from the equilibrium mixture (vide supra) is also essential to shift the equilibrium to the desired direction. The disulfide **7** is virtually insoluble in various

solvents and, thus, chloroform, acetonitrile, benzene, nitromethane, and isopropyl alcohol were successfully used in place of aqueous acetone without any appreciable change of the products.

The reaction of azetidinones **1b**, **1c**, and **1d** with **6** was performed in a similar manner, affording the corresponding 4-(phenylsulfonylthio)-2-azetidinones **2** in good yields (Entries 4—7 in Table 1).

It has already been described that azetidinones **2** were able to be converted to 3-substituted cephems **3**[3,4] and ammonium benzenesulfinate **4** was liberated in the course of the thiazolidine ring formation. On the other hand, we have recently reported a facile electrolytic cross-coupling of benzenesulfinates **4** and disulfide **7** affording **6** in good yields.[8] These two interesting results provided a clue that **6** could be supplied from **4** given in the course of **2**→**3** transformation for the **1**→**2** conversion as indicated by dotted arrows in Scheme 1.

Experimental

Melting points were determined on a Yamato melting point apparatus Model MP-21 and were uncorrected. IR spectra were obtained on a JASCO IRA-1 grating spectrometer or a JEOL RFX-3002 FTIR spectrophotometer. ^1H NMR spectra were mesured at 60 MHz with a Hitachi R-24 spectrometer or at 300 MHz with a Varian VXR-300S spectrometer. Chemical shifts are expressed in parts per million downfield from Me_4Si as an internal reference. Mass spectra were obtained on a Hitachi M-80 spectrometer. Elemental analyses were performed in our laboratory on a Yanaco CHN corder MT-3. 4-(2-Benzothiazolyldithio)-2-azetidinones **1**[6] and *S*-(2-benzothiazolyl) benzenethiosulfonates **6**[8,9] were prepared by the reported procedures.

4-Phenylsulfonylthio-3-phenoxyacetamido-1-(1-benzyloxycarbonyl-2-methyl-2-propenyl)-2-azetidinone (2a): Procedure A (Table 1, Entry 1). 4-(2-benzothiazolyldithio)-2-azetidinone **1a** (R^1=$PhOCH_2$, R^2=$PhCH_2$, R^3=H, 1.68 g, 2.8 mmol), 2-benzothiazolyl benzenethiosulfonate **6** (0.89 g, 2.9 mmol), and sodium benzenesulfinate hydrate (26 mg, 0.13 mmol) in acetone (35 mL) and water (5 mL) was stirred at room temperature for 3.5 h. The mixture was filtered and the solids were washed with acetone (5 mL) and air-dried to give bis(benzothiazolyl) disulfide (0.88 g, 96%). The filtrate and washings were combined and concentrated in vacuo. The residue was taken up with benzene (30 mL), washed with water (20 mL), and dried (Na_2SO_4). After evaporation of the solvents, the residue was chromatographed (SiO_2, benzene/EtOAc: 5/1) to afford **2a**[10] (1.46 g, 91%) as colorless solids: IR(KBr) 1794, 1756, 1692, 1615, 1537 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ=1.79 (s, 3H), 4.38 (d, J=15 Hz, 1H), 4.15 (s, 1H), 4.51 (d, J=15 Hz, 1H), 4.83 (s, 1H), 4.85 (s, 1H), 5.14 (d, 12 Hz, 1H), 5.21 (d, J=12 Hz, 1H), 5.30 (dd, J=5 and 8 Hz, 1H), 5.92 (d, 5 Hz, 1H), 6.90—7.90 (m, 16H); MS (FD) *m/z* 780 (M^+).

Anal. Calcd for $C_{29}H_{28}N_2O_7S_2$: C, 59.98; H, 4.86; N, 4.82%. Found: C, 59.80; H, 4.84; N, 4.76%.

Procedure B (Table 1, Entry 3). A mixture of 4-(2-benzothiazolyldithio)-2-azetidinone **1a** (R^1=$PhOCH_2$, R^2=$PhCH_2$, R^2=H, 200 mg, 0.33 mmol), S-(2-benzothiazolyl) benzenethiosulfonate **6** (112 mg, 0.36 mmol), and sodium 2-benzothiazolethiolate (1 mg, 0.005 mmol) in acetone (5 mL) and water (1.5 mL) was stirred at room temperature for 3.5 h. Workup in the same manner as described above afforded **2a** (171 mg, 89%).

The reactions of 4-(2-benzothiazolyldithio)-2-azetidinone **1b** (R^1=$PhCH_2$, R^2=*p*-$CH_3OC_6H_4CH_2$, R^3=H), **1c** (R^1=$PhOCH_2$, R^2=$PhCH_2$, R^3=5-CH_3O), and **1d** (R^1=$PhOCH_2$, R^2=$PhCH_2$, R^3=4-CH_3O) with *S*-(2-benzothiazolyl) benzenethiosulfonates **6** were carried out according to Procedure A and/or B. Reaction conditions and results are summarized in Table 1.

4-Phenylsulfonylthio-3-phenylacetamido-1-[1-(*p*-methoxybenzyloxycarbonyl)-2-methyl-2-propenyl]-2-azetidinone (2b): Mp 115—116 °C from $CHCl_3/C_2H_5OH$ (1/10); IR (KBr) 1794, 1749, 1653, 1627, 1557, 1531 cm^{-1}; ^1H NMR ($CDCl_3$, 300 MHz) δ=1.73 (s, 3H), 3.56 (d, J=16 Hz, 1H), 3.62 (d, J=16 Hz, 1H), 3.82 (s, 3H), 4.43 (s, 1H), 4.75 (s, 1H), 4.76 (s, 1H), 5.04 (d, J=12 Hz, 1H), 5.10 (d, J=12 Hz, 1H), 5.11 (dd, J=5 and 8 Hz, 1H), 5.78 (d, J=5 Hz, 1H), 5.87 (d, J=8 Hz, 1H), 6.90—7.90 (m, 14H); MS (FD) *m/z* 594 (M^+).

Anal. Calcd for $C_{30}H_{30}N_2O_7S_2$: C, 60.59; H, 5.09; N, 4.71%. Found: C, 60.45; H, 5.07; N, 4.58%.

Reactions of 1,1-Diphenyl-2-methylpropene Cation Radicals with Methanol. Ketone Formation Involving Carbocation Rearrangement

Ryoichi AKABA,*,† Shin AIHARA, Hirochika SAKURAGI, and Katsumi TOKUMARU*
Department of Chemistry, University of Tsukuba, Tsukuba, Ibaraki 305
(Received November 26, 1990)

Synopsis. Anodic oxidation of 1,1-diphenyl-2-methylpropene (**1**) in an acetonitrile-methanol mixture under argon gave 3,3-diphenyl-2-butanone (**2**) in high yield together with small amounts of 1,2-diphenyl-2-methyl-1-propanone (**3**) and benzophenone (**4**). Similar anodic oxidation of **1** in the presence of oxygen was also carried out, and the mechanisms for the novel ketone forming reactions are discussed.

Photoinduced electron transfer generating cation radicals has gathered sustained interest during the last decade.[1] Among the cation radicals which have so far been studied, olefin cation radicals have attracted continuing interest. Reactions of the olefin cation radicals with nucleophiles such as methanol have been studied by electrochemical generation of the cation radicals as well as by photoinduced electron transfer. For example, it is well-known that the photochemically generated cation radicals of aromatic olefins react with methanol to give anti-Markovnikoff adducts.[2] In contrast, electrochemical oxidation of olefins in methanol usually gives dimethoxylated monomeric or dimeric products.[3-6]

During the course of our investigation of photosensitized oxygenation of 1,1-diphenyl-2-methylpropene (**1**) in acetonitrile,[7] we have found that electrochemical oxidation of **1** in the presence of methanol gives almost exclusively a skeletally rearranged product, 3,3-diphenyl-2-butanone (**2**). This is a novel example demonstrating that the electrochemically generated aromatic olefin cation radical reacts with methanol to give the skeletally rearranged carbonyl compounds instead of the usually observed dimethoxylation products, although similar skeletal rearrangement was observed in photosensitized electron transfer reaction of styrylcyclopropane in methanol.[8] We have also carried out electrochemical oxidation of **1** in the presence of oxygen in acetonitrile/methanol mixed solvents in order to compare the reactivities of the olefin cation radical toward oxygen and methanol.

Results and Discussion

Controlled-potential electrolysis of **1** (45.4 mg, 0.22 mmol) in acetonitrile/methanol (4:1) under argon at 1.6 V/SCE for 3.2 h gave **2** in 79% yield together with small amounts of 1,2-diphenyl-2-methyl-1-propanone (**3**, 4%) and benzophenone (**4**, 4%). The yields of the products were monitored as a function of the electricity passed, and are shown in Fig. 1. The results show that the reaction involves two one-electron oxidation processes as shown in Scheme 2. Thus, electrochemical oxidation of **1** generates the cation radical of **1**, $\mathbf{1}^{+\cdot}$, which is captured by methanol to afford a β-alkoxy radical, **5**. Radical **5** is further oxidized electrochemically to produce a carbocation **6**. Rapid 1,2-migration of a methyl group followed by addition of methanol gives an acetal, **7**, which will be hydrolyzed

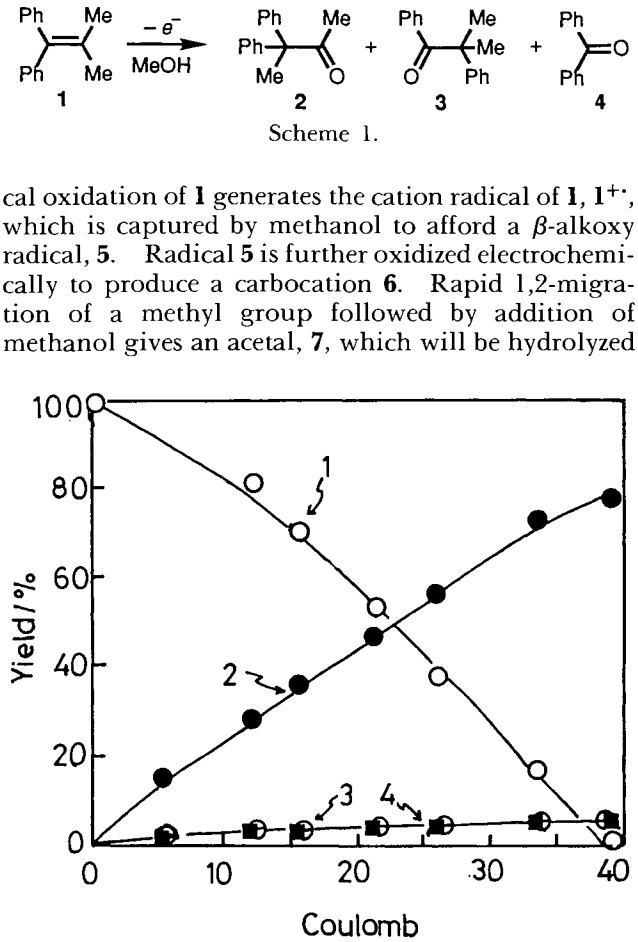

Fig. 1. Correlations of product yields with the electricity passed on electrochemical oxidation of **1** in CH_3CN/CH_3OH under argon.

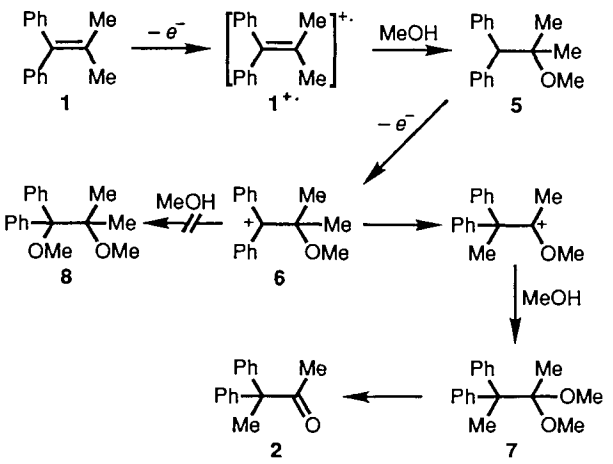

Scheme 2.

† Present address: Gunma College of Technology, Toriba-machi, Maebashi, Gunma 371.

during work-up to afford **2**. Attempts to isolate the acetal were unsuccessful, although similar conversion of an acetal was observed in 9,10-dicyanoanthracene-sensitized electron-transfer reactions of styrylcyclopropane in methanol.[8]

The mechanism shown in Scheme 2 is supported by coulometric studies, which indicated that the electricity of 2 F mol^{-1} was required for 99% consumption of **1**. The formation of **3** can be similarly explained by 1,2-migration of a phenyl group in the carbocation formed by addition of methanol to $\mathbf{1}^{+\cdot}$ at the phenylated carbon. Benzophenone **4** may be afforded by the reaction of $\mathbf{1}^{+\cdot}$ with residual oxygen (vide infra).[9]

In order to get further insight into the reactivity of $\mathbf{1}^{+\cdot}$, we have also carried out electrochemical oxidation of **1** in the presence of oxygen in acetonitrile/methanol. Thus, as in the case under argon, **1** (45.1 mg, 0.22 mmol) was oxidized at 1.6 V/SCE for 3.7 h in acetonitrile/methanol under an oxygen stream to give **2**, **3**, and **4** in 67, 6, and 22% yields, respectively. A plot of the yields of the products as a function of the electricity passed (Fig. 2) indicates that the presence of oxygen significantly decreases the yield of **2** but enhances that of **4**, suggesting that $\mathbf{1}^{+\cdot}$ reacts competitively with methanol and oxygen. The mechanism for formation of **4** was previously explained in terms of the decomposition of a dioxetane afforded by a reaction of $\mathbf{1}^{+\cdot}$ with molecular oxygen followed by the reduction by the electrode and/or **1** (ECbE mechanism).[9] The decrease of the total current (10%) passed in the presence of oxygen is not inconsistent with the ECbE mechanism for the formation of **4**.

The above result that the skeletal rearrangement product **2** is formed in a good yield is in contrast with electrochemical oxidation of olefins usually giving dimethoxylation products.[3-6] The formation of **2** in high yield and the complete absence of dimethoxylated products in **1** indicate that $\mathbf{1}^{+\cdot}$ is reluctant to undergoing self-dimerization or addition to **1**, and

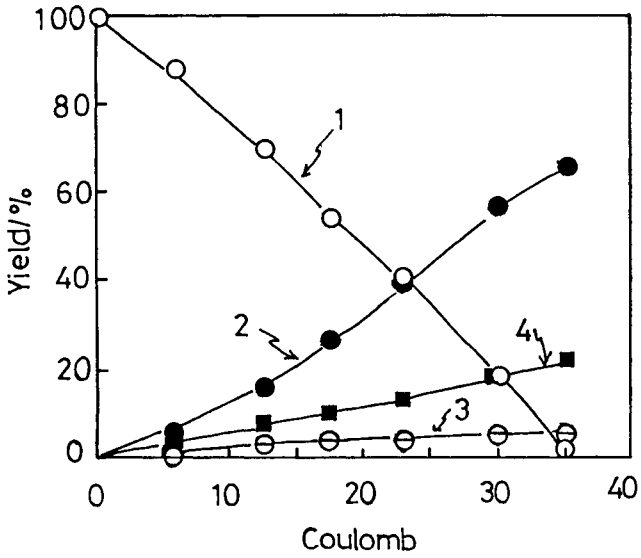

Fig. 2. Correlations of product yields with the electricity passed on electrochemical oxidation of **1** in CH_3CN/CH_3OH in the presence of oxygen.

that the resulting **5** does not dimerize but is rapidly oxidized at the electrode to give carbocation **6**. Rapid rearrangement of **6** followed by the addition of methanol prevents 1,2-addition of methanol.

The dominant formation of **2** over **3** shows that the addition of methanol to $\mathbf{1}^{+\cdot}$ takes place preferentially at the ethenyl carbon with the methyl groups. It is of particular interest to point out that the observed orientation is seemingly contradicting to that expected from the distribution of the spin density and positive charge in $\mathbf{1}^{+\cdot}$; recent ESR[10] and CIDNP[11] studies indicate that the spin density is higher at the methylated carbon than at the phenylated one, and that the latter is more positively charged than the former. Therefore, assuming that steric effects by phenyl and methyl groups are similar at each olefinic carbon, the present findings suggest that the regiochemistry of addition of nucleophiles such as methanol to olefin cation radicals is not governed by the distribution of positive charge on the ethenyl carbons but by the stability of the resulting free radicals; **5** is more stable than the other species $\cdot CMe_2CPh_2OMe$. This trend is parallel to the orientation often observed in the addition of atoms or free radicals and electrophiles to olefins giving free radicals and carbocations, respectively.

Once **6** is produced from **5**, only a methyl group can migrate to give the final product. This situation is consistent with the result of pinacol rearrangement of a glycol of **1**, $Ph_2C(OH)CMe_2OH$,[12] where the dehydration takes place exclusively from the phenylated carbon to give a more stabilized cation, $^{+}CPh_2CMe_2OH$. This carbocation results in the migration of a methyl group affording **2** finally as a sole product though the absolute migratory aptitude is much higher for a phenyl group than for a methyl group in pinacol rearrangement.[13]

In conclusion, we have shown that the electrochemically generated $\mathbf{1}^{+\cdot}$ reacts with methanol to give the skeletally rearranged ketone **2**. This is unusual since the electrochemical oxidations of aromatic olefins in methanol usually give dimethoxylated monomeric or dimeric products. It should be also emphasized that the present study revealed that $\mathbf{1}^{+\cdot}$ reacts competitively with molecular oxygen as a radical and methanol as a cation in solution.

Experimental

General. Nuclear magnetic resonance spectra were taken on a JEOL MH-100 or a JEOL FX-100 FT NMR spectrometer at room temperature in $CDCl_3$. IR spectra were measured with a Hitachi 215 infrared spectrophotometer. Gas chromatographic analyses were performed with a Shimadzu GC-4CM-PF gas chromatograph with an FID. Acetonitrile was distilled over phosphorus pentaoxide and then over potassium carbonate. Commercially available methanol was distilled once and stored over molecular sieve (Waco synthetic zeolite A-3).

Materials. 1,1-Diphenyl-2-methylpropene (**1**),[14] 3,3-diphenyl-2-butanone (**2**)[15] and 1,2-diphenyl-2-methyl-1-propanone (**3**)[16] were prepared by the published procedures, and their IR, ^1H, and ^{13}C NMR spectra were consistent with their structures.

Preparative Electrolysis. Preparative electrolyses were done in a three-compartment cell separated with glass frits (G-3.5). The working and counter electrodes were platinum wire, and the reference electrode was an SCE. Preelectrolysis of the solvent containing a supporting electrolyte under argon was carried out to remove possible electroactive impurities before the substrate was injected into the solvent. A Hokuto HA-201 potentiostat, a Hokuto HB-104 function generator, and a Rika Denki RE-11 X-Y recorder were employed.

Typically, 45.4 mg (0.22 mmol, 4×10^{-3} M, 1 M=1 mol dm^{-3}) of **1** was dissolved in the preelectrolyzed acetonitrile/methanol mixed solvent with tetrabutylammonium perchlorate (TBAP, 0.1 M) as a supporting electrolyte, and the solution was electrolyzed at 1.6 V/SCE for 3.2 h until **1** ,was almost consumed (99%). The progress of the reaction was monitored by taking aliquots periodically from the reaction mixture and examining them by GLC. The GLC analyses of the reaction mixture indicated the formation of 3,3,-diphenyl-2-butanone **2**, 1,2-diphenyl-2-methyl-1-propanone **3**, and benzophenone **4** in 79, 5, and 5% yields, respectively. For isolation of the products, the reaction mixture was poured into water and then extracted with benzene to remove TBAP. The resulting benzene solution was then subjected to TLC separation. The products were identified by comparing their NMR and IR spectra with those of authentic samples.

Reinvestigation of the Phosphazo Method and Synthesis of *N*-(*t*-Butoxycarbonyl)-L-arginine *p*-Nitroanilide and a Chromogenic Enzyme Substrate for the Factor Xa

Hidekazu OYAMADA, Takashi SAITO, Shinsaku INABA, and Masaaki UEKI*
Department of Applied Chemistry, Faculty of Science, Science University of Tokyo, 1-3 Kagurazaka, Tokyo 162
(Received November 27, 1990)

Synopsis. Reaction conditions for the phosphazo method were reinvestigated in order to apply this method to the synthesis of *p*-nitroanilide(*p*NA)s of *t*-butoxycarbonyl(Boc)- and benzyloxycarbonyl(*Z*)-amino acids.

p-Nitroanilides of amino acids and peptides are among the most popular chromogenic enzyme substrates and their synthesis has been studied intensively. However, since *p*-nitroaniline is a very poor nucleophile, the usual peptide bond forming reactions including the dicyclohexylcarbodiimide-*N*-hydroxybenzotriazole method[1] and the mixed anhydride method[2] could not give sufficient results. As an alternative, the reaction of N^{α}-protected amino acids with *p*-nitrophenyl isocyanate, isolated[3] or obtained in situ by the modified Curtius reaction using diphenyl phosphorazidate,[4] has up until now been the method of choice. The phosphazo method,[5] which had fallen into disuse as a general method for peptide synthesis, was recently utilized for the synthesis of *p*-nitroanilides.[1] However, its applicability to Boc-amino acids had not been examined. In this study we reinvestigated and optimized the conditions for the formation and reaction of the phosphazo compound from *p*-nitroaniline in order to establish a synthetic method for Boc-amino acid *p*-nitroanilides including Boc-arginine *p*-nitroanilide.

Results and Discussion

Optimization of the conditions of the phosphazo method was achieved by focusing on the following points; 1) the reaction time necessary for the complete formation of the phosphazo derivative of *p*-nitroaniline, 2) the lowest necessary temperature for the reaction of the phosphazo compound with acyl components, and 3) molar ratios.

p-Nitroaniline (**1**) was mixed with phosphorus trichloride (**2**) in pyridine at room temperature for 1 h to afford the corresponding phosphazo compound, *N*,*N*′-bis(4-nitrophenyl)phospheneimidous amide (**3**). To this *Z*-L-Phe-OH (**4**) was added (molar ratio of **2**:**4**=1:1) and the mixture stirred for 30 min. Then the temperature was elevated stepwisely to 30, 40, 50, and finally to 60 °C maintaining each temperature for 30 min. At the end of each period the amount of *Z*-L-Phe-*p*NA (**5**) formed was quantitated by HPLC. The yield dramatically increased (24→84%) when the temperature was elevated from 30 °C to 40 °C. Therefore, it was concluded that the lowest necessary temperature for the reaction of **3** with the acyl component was 40 °C. This temperature is much lower than the boiling point of pyridine which had been previously used.[5]

In the above reaction the first step (the reaction of **1** with **2**) was carried out for 1 h. When this step was interrupted after 15 min, as described in the literature,[5] by the addition of **4** and warming the mixture to 40 °C, the reaction was not complete after 4 h. On the other hand, when the first step was continued for 1 h, subsequent reaction with **4** was complete after 1 h. Although this reaction time was not the minimal time required, it was used in the subsequent reactions.

The molar ratio of **2** to **4** appears to be another important factor. In the phosphazo method carboxyl components are usually used in excess, however yields of *p*-nitroanilides under these conditions are low. Better results were obtained when the phosphazo derivative of *p*-nitroaniline was used in excess. When 1.2 and 2.0 equivalents of the phosphazo compound (molar ratios of **2**:**4**=0.6:1 and 1:1, assuming the complete formation of the phosphazo compound) were used yields of the *p*-nitroanilide **5** after 1 h were 81% and quantitative, respectively. Since the former yield could not be significantly improved by increasing the reaction time, it was concluded that an equimolar amount of the phosphazo compound, which corresponds to 2 equivalents of the acyl component, should be used.

In summarizing the above results the optimal conditions for the synthesis of protected amino acid *p*-nitroanilides were decided as follows: 2 mol of *p*-nitroaniline are mixed with 1 mol of PCl_3 in pyridine for 1 h at room temperature. After the addition of 1 mol of a protected amino acid to the mixture the reaction is performed at 40 °C for 1 h or more depending on the structure of the amino acid used.

Under these conditions syntheses of various kinds of N^{α}-protected amino acid *p*-nitroanilides were performed and the results are summarized in Table 1. As the result of the lowering of the reaction temperature, preparation of Boc- and *p*-methoxybenzyloxycarbonyl-amino acid *p*-nitroanilides was possible (Entries 6, 7, 8, 9, and 10). It should also be noted that dicyclohexylamine (DCHA) salts of protected amino acids could be used quite as same as the free acids. Using this technique *p*-nitroanilide of Boc-L-glutamine was obtained, albeit in modest yield because of nitrile formation.[10]

N^{α}-Acylated arginine *p*-nitroanilides are well-known as substrate for trypsin,[11] papain,[12] tissue plasminogen activator, and plasmin.[13] In the synthesis of these compounds the guanidino function of arginine was protected by nitro[11,13] or arenesulfonyl groups.[12] However strong acid treatment in the total deprotection step often gives a complex mixture of

Table 1. Preparation of Protected Amino Acid *p*-Nitroanilides

products. The most important feature of the modified phosphazo method is the facile availability of Boc-L-Arg-*p*NA, which was obtained as a crystalline hydrochloride (**6**) in 75% yield starting from Boc-L-Arg-OH·HCl·H_2O. To the best of our knowledge, synthesis of Boc-L-Arg-*p*NA by direct coupling of Boc-arginine and *p*-nitroaniline with phosphorus trichloride in pyridine has been recorded only in a patent.[9]

Compound **6** thus obtained was then utilized for the preparation of a peptide *p*-nitroanilide, Bz-L-Ile-L-Glu(OMe)-Gly-L-Arg-*p*NA (**7**), which is known as a substrate for the factor Xa.[14] Protected *N*-terminal tripeptide ester, Boc-L-Ile-L-Glu(OMe)-Gly-OPac, was obtained by stepwise elongation by the mixed anhydride method using dimethylphosphinothioyl chloride.[15] After the Boc group was changed to benzoyl group, the C-terminal phenacyl ester was removed to give protected tripeptide acid, Bz-L-Ile-L-Glu(OMe)-Gly-OH (**8**). Segment condensation of **8** with arginine *p*-nitroanilide dihydrochloride (**9**), which was obtained by deprotection of **6** with HCl in acetic acid, was performed using dimethylphosphinothioyl azide[16] in *N,N*-dimethylformamide. Since the final deprotection step was not necessary in this synthesis, the pure product was readily obtained.

Experimental

Thin-layer chromatography was carried out on silica-gel plates (Merck, Kieselgel 60 F_{254}) in the following solvent systems; A: $CHCl_3$, B: $CHCl_3$:CH_3OH=9:1, C: $CHCl_3$:CH_3OH=4:1, D: $CHCl_3$:CH_3OH:CH_3CO_2H=20:5:1. For amino acid analysis peptides were hydrolyzed with constant boiling hydrochloric acid in evacuated and sealed ampoules for 24 h at 110 °C. The analyses were performed on an Atto Model 203 Amino Acid Analyzer. Optical rotations were determined using a JASCO DIP-360 digital polarimeter. ^1H NMR spectra were observed with a Hitachi R-1100 and JEOL JNM-PMX-60 spectrometers (60 MHz). Analytical reversed-phase HPLC was performed using a Unisil Q C_{18} column (4.6×300 mm) with an isocratic solvent system (0.01 M HCl:CH_3OH=35:65, flow rate 1.0 ml min^{-1}) at 60 °C using Shimadzu LC 6A liquid chromatograph system monitored at 254 nm (1 M= 1 mol dm^{-3}).

General Procedure for the Preparation of Protected Amino Acid *p*-Nitroanilides: To a solution of phosphorus trichloride (0.872 ml, 10 mmol) in pyridine (10 ml) was added *p*-nitroaniline (1.38 g, 20 mmol) at 25 °C, and the mixture stirred for 1 h. To this solution was added a protected amino acid (Method A) or a protected amino acid DCHA salt (Method B) (10 mmol) in pyridine (20 ml) and the mixture stirred at 40 °C for the period given in Table 1. After removal of the solvent under reduced pressure the residue was triturated with ethyl acetate and water and filtered. The organic layer was separated and washed successively with a 5% citric acid solution (3 times), water, a 5% sodium hydrogencarbonate solution (3 times), water and saline, and dried over sodium sulfate. After removal of the solvent, the crystalline residue was rinsed with cold benzene or chloroform and then with ether before recrystallization. When necessary silica-gel column chromatography using dichloromethane for elution was performed prior to recrystallization.

***N*-(*t*-Butoxycarbonyl)-L-arginine *p*-Nitroanilide Hydrochloride (6):** To a solution of the phosphazo compound prepared from PCl_3 (0.436 ml, 5 mmol) and *p*-nitroaniline (1.381 g, 10

mmol) was added Boc-L-Arg-OH·HCl·H_2O (1.644 g, 5 mmol) in pyridine (5 ml). The mixture was stirred at 40 °C for 4 h and the solvent removed under reduced pressure. The residue was dissolved in water (50 ml) and ether (20 ml) and kept at 0 °C overnight. Precipitates were collected by filtration, washed successively with ether, dichloromethane and a small quantity of ethanol and recrystallized from ethanol-ether to give **6** as a colorless granular solid; 1.616 g (75%); ^{1}H NMR ($CDCl_3$+DMSO-d_6) δ=1.4 (s, 9H), 1.5—1.9 (m, 6H), 3.1—3.4 (m, 2H), 4.25 (br, 1H), 6.7—7.3 (m, 4H), 7.6—8.2 (m, 5H), 10.9 (s, 1H).

***N*-(*t*-Butoxycarbonyl)-L-glutamine *p*-Nitroanilide and *N*-(*t*-Butoxycarbonyl)-(2-cyanoethyl)glycine *p*-Nitroanilide:** Boc-L-Gln-OH·DCHA (4.276 g, 10 mmol) was treated with the phosphazo compound as described above. After the usual washing procedures, the products were separated by silica-gel column chromatography using dichloromethane-methanol (50 : 1 v/v) as eluent to give 1.578 g (43%) of Boc-L-Gln-*p*NA as colorless crystals; ^{1}H NMR ($CDCl_3$+DMSO-d_6) δ=1.4 (s, 9H), 1.8—2.6 (m, 4H), 4.1—4.4 (br, 1H), 6.0—6.4 (br, 2H), 6.8—7.0 (br, 2H), 7.7 (d, 2H), 8.1 (d, 2H), 10.5 (br, 1H). Further elution gave 0.802 g (23%) of Boc-(2-cyanoethyl)glycine-*p*-nitroanilide as a fluffy solid; mp 148—149 °C; $[\alpha]_D^{27}$ −21.1° (*c* 1.1, CH_3OH); IR (KBr) 2260 cm^{-1} (C≡N); ^{1}H NMR ($CDCl_3$) δ=1.4 (s, 9H), 1.9—2.7 (m, 4H), 4.3—4.7 (br, 1H), 5.5—6.9 (br, 1H), 7.6 (d, 2H), 8.0 (d, 2H), 9.2—9.5 (br, 1H).

L-Arginine *p*-Nitroanilide Dihydrochloride (9): To a solution of **6** (1.077 g, 2.5 mmol) in acetic acid (2 ml) was added 2.17 M HCl in acetic acid (23 ml) at RT. The mixture was kept standing for 2 h and diluted with ether. Precipitates were collected by filtration, washed with ether and dried to give **9** as a pale yellow powder: 883 mg (96%); mp 262—264 °C (decomp); $[\alpha]_D^{26}$ +73.2° (*c* 1, 0.1 M HCl). Lit,[8] mp 245 °C; $[\alpha]_D^{20}$ +80.6° (*c* 1, water). Found: C, 39.44; H, 5.55; N, 22.65%. Calcd for $C_{12}H_{18}N_6O_3$·2HCl: C, 39.25; H, 5.49; N, 22.88%.

***N*-Benzoyl-L-isoleucyl-L-α-glutamylglycyl-*N*-(4-nitrophenyl)-L-argininamide Methyl Ester [Bz-L-Ile-L-Glu(OMe)-Gly-L-Arg-*p*NA] (7):** To an ice-cooled solution of Bz-L-Ile-L-Glu(OMe)-Gly-OH (0.218 g, 0.5 mmol), **9** (0.184 g, 0.5 mmol) and triethylamine (70 μl, 0.5 mmol) in *N*,*N*-dimethylformamide (1 ml) was added dimethylphosphinothioyl azide (0.081 g, 0.6 mmol) in *N*,*N*-dimethylformamide (0.5 ml) and triethylamine (70 μl, 0.5 mmol). The mixture was stirred for 24 h at 0 °C and concentrated. The residue was solidified by trituration with ether and cold 1 M hydrochloric acid and purified by preparative thin-layer chromatography ($CHCl_3$: CH_3OH : CH_3CO_2H=20 : 5 : 1) and gel chromatography on Sephadex LH-20 (CH_3OH) to give 224 mg (58%) of **7** as an amorphous solid: $[\alpha]_D^{26}$ −31.3° (*c* 0.5, CH_3OH); R_{f_4}=0.51. Amino Acid Ratios: Ile, 0.96; Glu, 1.01; Gly, 1.00; Arg, 1.04. Found: C, 51.76; H, 6.26; 16.65%. Calcd for $C_{33}H_{45}O_9N_9$·HCl·H_2O: C, 51.73; H, 6.31; N, 16.45%.

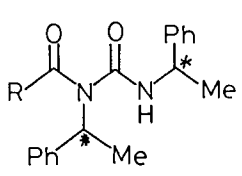
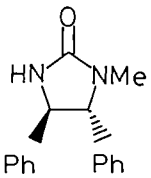
(Received November 29, 1990)

Synopsis. The aldol reaction of the boron enolate bearing the titled chiral auxiliary proceeded with high face selectivity.

In the last few years, we have investigated the utility of acyclic urea (**1**) in enantioselective Diels-Alder[1] and aldol reactions.[2] Though the stereoselectivity observed in these reactions was moderate, the urea auxiliary possessed excellent separability[1-3] so that we could obtain both of enantiomerically pure forms of the products. In order to gain absolute asymmetric induction in a modified system, we have designed the new recyclable chiral auxiliary, 4,5-diphenyl-1-methyl-2-imidazolidinone (**2**).[4] Owing to the rigidity and the planarity of five-membered ring of **2**, complete *syn* selectivity ($\geqslant$99% de) was resulted in this aldol addition reaction.



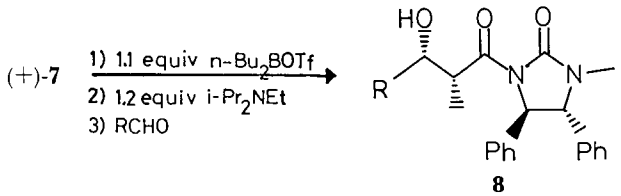
1



(+)-**2**

N-propionyl derivative (+)-(**7**) was prepared from (+)-(1*R*,2*R*)-1,2-diphenyl-1,2-ethanediamine (**3**) in three steps. Initially, **3** and urea (**4**) were heated with few drops of H_2O at 200 °C for 2 h to give 2-imidazolidinone (**5**) in 87% yield.[5] Monoacylated product (**6**) was obtained by treatment of **5** with 2 equiv of *n*-BuLi (−10 °C, THF) followed by stirring with 1 equiv of propionyl chloride at ambient temperature (84%).[4] The last step was carried out by deprotonation of **6** (*n*-BuLi, 1 equiv, −10 °C, THF) and methylation with excess of methyl iodide (r.t., 79%).

Our first attempt to investigate the utility and the limitations of this chiral auxiliary was made on an aldol reaction. Enolization of **7** with *n*-Bu_2BOTf (1.1 equiv)[6] and *N*,*N*-diisopropylethylamine (*i*-Pr_2NEt, 1.2 equiv) at 0 °C for 30 min, and subsequent addition of aldehydes (1—3 equiv, −73 °C then slowly warmed to room temperature) afforded only optically active syn aldol adduct (**8**). The results are summarized in Table 1. Good yields were obtained with benzaldehyde and 2-naphthaldehyde (Entries 1 and 3). In the case of benzaldehyde, triethylamine also worked well



Scheme 2.

Table 1. Aldol Reaction of **7** with Aldehydes

Entry	RCHO	Yield[a]/%	de of **8**[b]/%
1	PhCHO (**8a**)	66	$\geqslant$99
2	PhCHO[c] (**8a**)	72	$\geqslant$99
3	2-NaphCHO (**8b**)	69	$\geqslant$99
4	MeCHO (**8c**)	48	$\geqslant$99
5	EtCHO (**8d**)	38	$\geqslant$99
6	CH_2=CHCHO (**8e**)	23	$\geqslant$99

a) Isolated yield after chromatography. b) Determined by 500 MHz ^{1}H NMR spectroscopy. c) The amine used was Et_3N.

Scheme 3.

as a base (Entries 1 and 2). The lower yields with acetaldehyde and propionaldehyde (Entries 4 and 5) may be due to the presence of their active α hydrogens. Because of the long reaction time, acrylaldehyde might polimerize before to react with boron enolate, which resulted in only 23% yield of the aldol adduct (Entry 6). This chiral 2-imidazolidinone boron enolate did not react with hindered 2,2-dimethylpropionaldehyde.

An aldol reaction of **6** was also examined under similar conditions (2.2 equiv n-Bu_2BOTf, 2.3 equiv i-Pr_2NEt) but merely the recovery of the starting material was observed.

The absolute stereochemical assignment of aldol (**8a**) was firmly established by comparison of the optical rotation of methyl ester (**9a**) with the literature value (Scheme 2)[7,8] after methanolysis of it with sodium methoxide (2 equiv, 0 °C then r.t., 17 h, MeOH). In a similar manner all aldol adducts were attested to have syn stereochemistry.

From the results above we propose that the boron enolate formed should have Z-geometry as in the oxazolidinone system and the observed stereoselectivity can be rationalized by the transition state model proposed by Evans.[8]

These results demonstrate that chiral 2-imidazolidinone has the comparable efficacy in asymmetric induction as a 2-oxazolidinone,[8] oxazolidine,[9] 2-oxazolidinethione,[10] or prolinol.[9]

Experimental

Melting points were determined on a Yanaco MP-S3 apparatus and are uncorrected. Infrared spectrum were run on a JASCO A-202 infrared spectrophotometer. ^{1}H NMR spectra were recorded on a Hitachi R-600, JOEL JNM-GX270, JNM-FX270, GSX-400, and GSX-500 spectrometers. ^{13}C NMR spectra were recorded on a JEOL JNM-GX270 and JNM-FX270 spectrometers. Chemical shifts are reported in ppm downfield from trimethylsilane and splitting patterns are designated as s, singlet; d, doublet; t, triplet; q, quartet; m, multiplet; br, broad. Mass spectra were taken with a Hitachi RMU-7M mass spectrometer at 70 eV. Optical rotations were recorded at 21 °C on a JASCO DIP-140 Digital Polarimeter. Tetrahydrofuran (THF) was distilled from lithium aluminium hydride and stored over molecular sieves 5A 1/16. Dichloromethane was distilled from calcium hydride and stored over molecular sieves 5A 1/16. Diisopropylethylamine and triethylamine were used after simple distillation. The purity of all the aldol adducts were shown to be diastereomerically pure by HPLC and ^{1}H NMR spectroscopy.

Preparation of (4*R*,5*R*)-4,5-Diphenyl-2-imidazolidinone (5). (1*R*,2*R*)-1,2-Diphenyl-1,2-ethanediamine **3** (0.606 g, 2.86 mmol), urea **4** (0.172 g, 2.86 mmol), and H_2O (5 drops) were reflux at 200 °C for 2 h. Flash chromatography (ethyl acetate) of the residue gave 0.590 g (87%) of **5**; mp 196.0—197.5 °C; $[\alpha]_D^{21}$ +58.6° (*c* 1.06, $CHCl_3$); IR ($CHCl_3$) 3460, 3250 (broad), 3010, 1710, and 700 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=4.55 (s, 2H), 5.85 (br s, 2H) 7.33 (s, 10H); ^{13}C NMR (67.8 MHz, $CDCl_3$) δ=66.0, 126.5, 128.3, 128.8, 140.2, 163.0; HRMS Found: *m/z* 238.1098. Calcd for $C_{15}H_{14}N_2O$: 238.1107. Found: C, 75.33; H, 5.93; N, 11.75%. Calcd for $C_{15}H_{14}N_2O$: C, 75.60; H, 5.92; N, 11.76%.

Preparation of (4*R*,5*R*)-4,5-Diphenyl-1-propionyl-2-imidazolidinone (6). To a solution of **5** (0.856 g, 3.60 mmol) in 20 ml of THF, butyllithium (1.55 M in hexane (1 M=1 mol dm^{-3}), 4.60 ml, 7.13 mmol) was added drpowise at −10 °C and stirred for 30 min before propionyl chloride (0.330 g, 3.57 mmol) was added. The reaction temperature was gradually raised to room temperature and stirring was continued overnight. After quenching the reaction mixture with saturated aqueous ammonium chloride, the solution was diluted with dichloromethane and the organic layer was separated. The aqueous layer was extracted with dichloromethane (20 ml×2) and the combined organic layer was dried ($MgSO_4$) and evaporated. Flash chromatography (ethyl acetate-hexane) gave white solid **6** (0.885 g, 84%); mp 120.0—121.0 °C; $[\alpha]_D^{22}$ +98.6° (*c* 0.29, $CHCl_3$); IR ($CHCl_3$) 3475, 3280, 3230, 1740, 1695, 1455, 1374, 1340, 1280, and 700 cm^{-1}; ^{1}H NMR (60 MHz, $CDCl_3$) δ=1.02 (t, *J*=7.6 Hz, 3H), 2.91 (q, *J*=7.6 Hz, 2H), 4.48 (d, *J*=3.4 Hz, 1H), 5.10 (d, *J*=3.4 Hz, 1H), 6.65 (br s, 1H), 7.31 (s, 10H); ^{13}C NMR ($CDCl_3$) δ=8.4, 29.4, 61.0, 66.1, 125.5, 125.6, 128.2, 128.7, 129.1, 129.3, 140.8, 140.9, 156.4, 174.0; HRMS Found: *m/z* 294.1371. Calcd for $C_{18}H_{18}N_2O_3$: 294.1369. Found C, 73.32; H, 6.17; N, 9.55%. Calcd for $C_{18}H_{18}N_2O_3$: C, 73.45; H, 6.16; N, 9.52%.

Preparation of (4*R*,5*R*)-4,5-Diphenyl-1-methyl-3-propionyl-2-imidazolidinone (7). Butyllithium (1.58 M in hexane, 0.75 ml, 1.18 mmol) was added to a solution of **6** (0.317 g, 1.08 mmol) in THF (10 ml) at −10 °C. The mixture was stirred for 30 min and methyl iodide (0.296 g, 2.09 mmol) was added. The temperature was raised to ambient temperature and stirred overnight. Work up with saturated aqueous ammonium chloride and extraction with dichloromethane (10 ml×2) before flash chromatography (ethyl acetate-hexane) afforded **7** (0.262 g, 79%); mp 67.5—69.5 °C; $[\alpha]_D^{21}$ +119.6° (*c* 0.76, $CHCl_3$); IR ($CHCl_3$) 3040, 1733, 1670, 1430, 1390, 1195, 1150, and 700 cm^{-1}; ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.13 (t, *J*=7.3 Hz, 3H), 2.79 (s, 3H), 3.06 (q, *J*=7.3 Hz, 2H), 4.26 (d, *J*=3.6 Hz, 1H), 5.05 (d, *J*=3.6 Hz, 1H), 7.16—7.43 (m, 10H); ^{13}C NMR (67.8 MHz, $CDCl_3$) δ=8.6, 29.1, 29.4, 63.5, 67.4, 125.4, 126.2, 128.1, 129.0, 129.1, 129.4, 138.6, 141.0, 155.0, 174.0; MS *m/z* (rel intensity, %) 308 (M^+, 83), 251 (79), 175 (23), 132 (100), 120 (49), 118 (38), 91 (20), 77 (20), 57 (20), 29 (20). Found; C, 73.86; H, 6.56; N, 9.05%. Calcd for $C_{19}H_{20}N_2O_3$: C, 74.00; H, 6.54; N, 9.09%.

General Procedure for the Aldol Addition of 7. To a solution of **7** (0.2 mmol) in dichloromethane (0.2—0.5 M) at 0 °C were added dibutylboron triflate (1 M in dichloromethane, 1.1 equiv) and diisopropylethylamine (1.2 equiv).

The mixture was stirred at 0 °C for 30 min and cooled to −73 °C, and the solution of the corresponding aldehyde in dichloromethane (1—2 equiv) was added. After stirring at −73 °C for 2 h, the mixture was slowly warmed to ambient temperature and stirred overnight. The mixture was quenched with phosphate buffer (pH 7) and diluted with ether. The layers were separated, the aqueous layer was extracted with ether (4 ml×2), and the solvent was removed on a rotary evaporator. The residue was dissolved in 3 ml of methanol and cooled to 0 °C, and 1 ml of 30% H_2O_2 was added dropwise. After 60 min at 0 °C, 3 ml of water was added and the methanol was removed in vacuo. The aqueous layer was extracted with ether (3 ml×3) and the combined organic layer was washed with saturated aqueous sodium hydrogencarbonate (3 ml), and brine (3 ml), and dried ($MgSO_4$). After evaporation of the solvent, the crude product was purified by flash chromatography (ethyl acetate-hexane) to give the corresponding aldol adducts.

(4*R*,5*R*)-3-[(2*R*,3*R*)-3-Hydroxy-2-methyl-1-oxo-3-phenylpropyl]-4,5-diphenyl-1-methyl-2-imidazolidinone (8a). Yield 66%. Colorless glass; $[\alpha]_D^{22}$ +45.4° (*c* 0.32, $CHCl_3$); IR ($CHCl_3$) 3510, 3070, 3010, 2945, 1720, 1665, 1450, 1430, 1380, 1360, and 700 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) δ=1.15 (d, *J*=7.2 Hz, 3H), 2.77 (s, 3H), 3.42 (d, *J*=2.2 Hz, 1H, OH), 4.23 (d, *J*=3.8 Hz, 1H), 4.42 (dq, *J*=3.6, 7.2 Hz, 1H), 5.0 (d, *J*=3.6 Hz, 1H), 5.1 (m, 1H), 7.08—7.44 (m, 15H); ^{13}C NMR (125 MHz, $CDCl_3$) δ=11.0, 29.1, 44.4, 63.4, 67.2, 73.3, 124.9, 126.2, 127.1, 128.1, 128.3, 129.0, 138.2, 140.4, 141.6, 154.3, 177.2. Synopsis. *endo*-Dicyclopentadiene has been selectively metallated with the base complex BuLi·*t*-BuOK in hexane at the olefinic positions in the norbornene moiety and a number of derivatives prepared by reaction of the metallated intermediate with electrophilic reagents. In particular, bromodicyclopentadiene thus obtained is a useful stock precursor for lithiodicyclopentadiene.

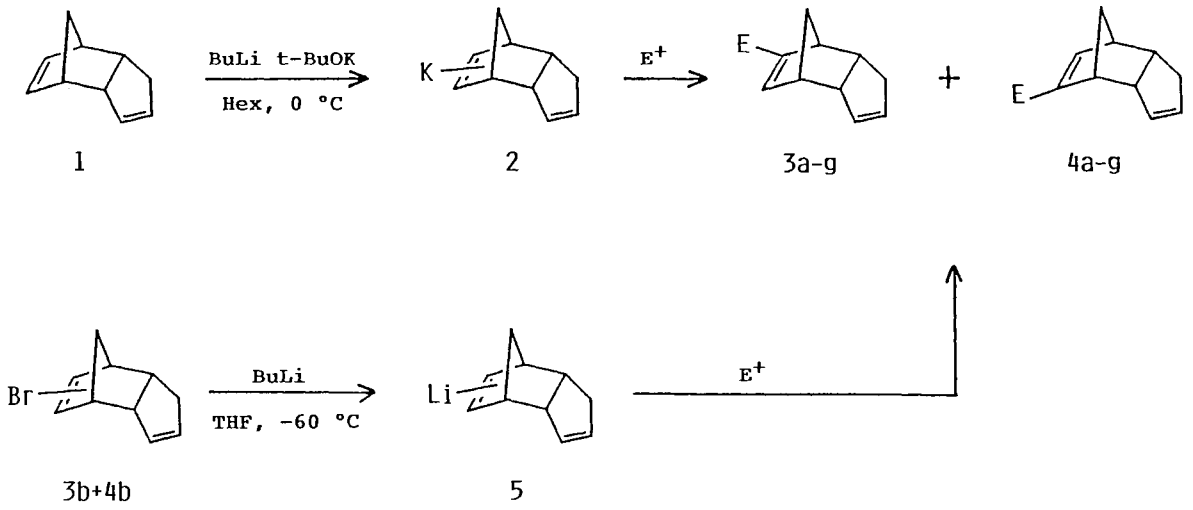
endo-Dicyclopentadiene (*endo*-tricyclo [5.2.1.$0^{2,6}$] deca-3,8-diene) (**1**) is an important compound as a direct precursor of synthetically useful cyclopentadiene. In view of ready thermal cycloreversion of dicyclopentadiene to cyclopentadiene, dicyclopentadienes can be regarded as stabilized as well as protected forms of usually labile cyclopentadienes. However, only a small number of substituted dicyclopentadienes have been obtained mostly by thermal dimerization of the corresponding monomers, and no practical way for derivatization of **1** itself has been described.[1] Here we report a metallation and functionalization of **1**.

Norbornene and norbornadiene have been metallated at the olefinic position with the base complex BuLi·*t*-BuOK.[2] There are essentially three possible sites for metallation with a strong base in the molecule of dicyclopentadiene (**1**) from the viewpoint of acidity of C-H bond; namely, the olefinic position of the norbornene part, the olefinc and allylic positions of the cyclopentene part. In fact, **1** was found to be metallated with the base complex selectively at the olefinic positions of the norbornene part (C-8 or -9). The metallated intermediate was assigned to be the potassium compound **2** in analogy with the metallation of norbornene.[2,3] Reactions of **2** with electrophilic reagents gave about 1 : 2.5 mixture of 8- and 9-substituted dicyclopentadienes, **3** and **4**, in moderate yields (Table 1, Method A). Hexane as solvent gave



Scheme 1.

Table 1. Yields and Some NMR Data of Derivatives of Dicyclopentadiene

Entry	Electrophile	Product[a] (3+4)	Yield/%		^{1}H NMR[b]	
			Method A	Method B	δ(HC=)	δ(HC=CH)
a	$HCON(CH_3)_2$	E=CHO	42	57	6.9	5.4
b	$BrCH_2CH_2Br$	Br	61		5.95	5.6
c	C_6H_5CHO	$CH(OH)C_6H_5$	46	91	5.7	5.5
d	$(C_6H_5)_2CO$	$C(OH)(C_6H_5)_2$	63	91	5.2—5.7	
e	$(CH_3)_2CO$	$C(OH)(CH_3)_2$	13	45	5.7	5.45

g	$(C_6H_5)_2S$	SC_6H_5	55	89	5.7	5.5

a) High-resolution mass spectroscopy gave the expected mol. weights. b) Data of mixture at 90 MHz. c) The anion solution was inversely added to an ethereal solution of excess reagent.

the best results for the metallation. Use of tetrahydrofuran (THF) resulted in very poor yields of products even at low temperatures. In hexane, the metallation was most conveniently and reproducibly conducted by stirring a 2:1 mixture of **1** and the base complex at 0 °C (ice bath) for 4—6 h.

Bromodicyclopentadiene (**3b**+**4b**), which can be prepared in fairly large quantity by Method A, is also a useful precursor for a metallated dicyclopentadiene; thus, treatment of the bromide mixture with BuLi in THF at −60 °C smoothly generated lithiodicyclopentadiene (**5**) which generally afforded quenching products in higher yields (Table 1, Method B).[4)]

The product ratios were little affected by reaction conditions and the mixtures were usually difficult to separate, although **3a** and **4a**, and **3d** and **4d** were partially separated by chromatography on silica gel. The structures of products were mainly elucidated by ^{1}H NMR spectroscopy. The 400 MHz ^{1}H NMR spectrum of the bromide mixture (**3b**+**4b**) in $CDCl_3$ shows a set of two signals particularly for the three olefin protons (H-3,4, and H-8 or 9) and the bridgehead proton at C-1 (H-1) with 1:2.4 ratio. Appearance of two doublets (J=3.3 Hz) at δ=6.00 (0.7H) and 5.94 (0.3H), which are assignable to H-8 or -9, indicates introduction of the bromine atom at the norbornene double bond (C-8 or -9). H-1 is observed at δ=3.38 and 3.29 with the former predominant. Since H-1 of **4b** is expected to resonate at lower field than H-1 of **3b** owing to anisotropic effect of nearby bromine atom, the observation suggests the predominance of **4b** over **3b**. This is also supported from ^{1}H NMR analysis of other quenching products.

Although the present metallation and functionalization of **1** affords mixtures of two regioisomers, they can be used in mixtures for organic syntheses, because both isomers should lead to the same products through thermolytic cycloreversion.

Experimental

^{1}H NMR spectra were recorded on a JEOL FX-90Q or JEOL GSX-400 spectrometer in $CDCl_3$ using tetramethylsilane as an internal standard. IR spectra were obtained from Hitachi EPI-G3 spectrometer, and mass spectra measured on a JEOL JMS-OlSG-2 or JEOL JMS-SX102 spectrometer. The microanalysis was performed at the Elemental Analysis Center, Faculty of Science, Osaka University.

Hexane was distilled from sodium metal and stored on sodium wire. Tetrahydrofuran (THF) was freshly distilled from sodium metal using diphenylketyl as indicator. BuLi and *t*-BuOK were purchased and used as such. Dicyclopentadiene was distilled in vacuo and middle fraction was used. For large scale preparation of bromodicyclopentadiene, commercial dicyclopentadiene was successfully used without further purification.

Metallation and Formylation of Dicyclopentadiene—A Standard Procedure for Method A. To a suspension of *t*-BuOK (1.12 g, 0.01 mol) in hexane (8 ml) was added dropwise hexane solution of BuLi (1.6 M, 6.6 ml) over a few min using a syringe with stirring in an ice bath under nitrogen atmosphere (1 M=1 mol dm^{-3}). After 15 min, dicyclopentadiene (**1**) (2.64 g, 0.02 mol) was added and the mixture stirred for 5 h. A solution of dimethylformamide (1.10 g, 0.015 mol) in dry ether (3 ml) was added in a few minutes. After 20 min, the reaction mixture was poured into ice-dil aq HCl, and extracted with ether (2×25 ml). The ether extract was washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was chromatographed on a short silica-gel column (hexane: AcOEt=9:1) to afford a mixture of **3a** and **4a** (0.67 g, 42% yield based on *t*-BuOK used) as a colorless oil. Found: m/z 160.0882. Calcd for $C_{11}H_{12}O$ 160.0888. ^{1}H NMR spectrum of this mixture showed two singlets of formyl proton at δ=9.52 (assigned for **4a**) and 9.63 (**3a**) in 2.5:1 integral ratio. The mixture was partially separated to **3a** and **4a** by careful chromatography.

3a: IR (CCl_4) 1675, 1590 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.3—1.9 (m, 3H), 2.25 (m, 1H), 2.7—3.6 (m, 4H), 5.46 (s-like, 2H), 6.89 (d, J=3.0 Hz, 1H), 9.63 (s, 1H).

4a: IR (CCl_4) 1675, 1590 cm^{-1}; ^{1}H NMR (90 MHz) δ=1.3—1.9 (m, 3H), 2.25 (m, 1H), 2.7—3.6 (m, 4H), 5.52 (s-like, 2H), 6.96 (d, J=3.0 Hz, 1H), 9.52 (s, 1H).

Large Scale Preparation of Bromodicyclopentadiene (3b+4b): In a 1 L three necked flask equipped with a thermometer and two dropping funnels was placed dry hexane (350 ml) and then *t*-BuOK (44.88 g, 0.4 mol) under nitrogen atmosphere. The mixture was cooled below −50 °C in an ethanol-Dry Ice bath and added dropwise with BuLi in hexane (1.5 M, 280 ml, 0.42 mol) over 35 min under efficient magnetic stirring. After 15 min, **1** (100 ml, 98.6 g, 0.75 mol) was added over 10 min. The cold bath was replaced with an ice-bath and stirring continued for 6 h. The mixture was cooled again below −40 °C and 1,2-dibromoethane (42 ml, 91.6 g, 0.49 mol) in THF (60 ml) added at such rate that the inner temperature did not exceed −35 °C (ca. 40 min). The reaction mixture was allowed to warm up to about 0 °C over 1 h, and then added dropwise with water (100 ml). The organic layer was separated, washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was fractionally distilled in vacuo using a distilling column (1.5×25 cm) packed with glass helix: fraction 1, bp 40—49 °C/6 Torr (1 Torr=133.322 Pa), unreacted **1**, 54.8 g (0.415 mol); fraction 2, bp 52—83 °C/5 Torr, mixture of **1** and (**3b**+**4b**), 7.5 g; fraction 3, bp 85—87 °C/5 Torr (bp 76 °C/3 Torr), (**3b**+**4b**), 52.1 g (0.247 mol, 61.7%). ^{1}H NMR (400 MHz) δ=1.33 (d, J=8.0 Hz, 1H), 1.74—1.85 (m, 1.7H), 2.22—2.32 (m, 1.3H), 2.75 (m, 0.7H), 2.85—2.95 (m, 2.3H), 3.29 (m, 0.3H), 3.38 (m, 0.7H), 5.47 (m, 0.3H), 5.57 (m, 1H), 5.66 (m, 0.7H), 5.94 (d, J=3.3 Hz, 0.3H), 6.00 (d, J=3.3 Hz, 0.7H). Found: C, 57.15; H, 5.32; Br, 37.33%. Calcd for $C_{10}H_{11}Br$: C, 56.90; H, 5.25; Br, 37.85%.

Lithiation and Formylation of Bromodicyclopentadiene (3b+4b)—A Standard Procedure for Method B. To a solution of (**3b**+**4b**) (3.13 g, 0.015 mol) in THF (8 ml) was added dropwise BuLi (1.6 M in hexane, 8.3 ml, 0.013 mol) over a few minutes at −60 °C. The solution became cloudy in 20 min due to separation of LiBr. Dimethylformamide (1.16 g, 0.016 mol) was added dropwise, and the mixture allowed to warm up to room temperature over 30 min. The reaction mixture was worked up as described for Method A to afford (**3a**+**4a**) (1.21 g, 57%).

(Received December 20, 1990)

Synopsis. A new, general synthesis of *N*-benzoyl-2-arylethenesulfonamides by the reaction of aryl halides including heteroaryl halides with [2-(benzoylsulfamoyl)ethyl]-pyridinium chloride in the presence of palladium acetate is described.

Although palladium-catalyzed vinylation of aryl halides with olefinic derivatives, known as the Heck reaction,[1] has been widely investigated for its usefulness in organic synthesis, there has been no report concerning a vinylation reaction of aryl halides with saturated ethane derivatives as a versatile vinyl synthon. We have been studying the chemistry of 2-arylethenesulfonamides regarding their biological activity and important precursors of 2-arylethynyl-sulfonamides.[2] Only their benzene derivatives have been known,[3] because heteroaryl derivatives are difficult to prepare by the known method.[4] Then, for the synthesis of these compounds, palladium-catalyzed ethenesulfonamidation of aryl halides by applying the Heck reaction was examined. We found that aryl halides react with [2-(benzoyl-sulfamoyl)ethyl]pyridinium chloride (**1**) as a versatile vinyl synthon in the presence of a catalytic amount of palladium acetate ($Pd(OAc)_2$) and triethylamine (NEt_3) in dry *N*,*N*-dimethylformamide (DMF) to give *N*-benzoyl-2-arylethenesulfonamides. It is the first example, to our knowledge, of such a coupling reaction. Here, we wish to report on general syntheses of the *N*-benzoyl-2-arylethenesulfonamides by two procedures.

A two-step synthesis of *N*-benzoyl-2-arylethene-sulfonamides was successfully achieved as follows. Ethenesulfonamide (**2**)[5] reacted with various aryl halides in the presence of palladium acetate[6] to give the *E*-form of 2-aryl ethenesulfonamides **7**—**14**. The *E*-configuration of these compounds was confirmed by their ^{1}HNMR spectral data, such as the ^{1}H-^{1}H coupling constants (J=14—15.5 Hz) of the protons on the vinyl moiety. In this reaction, a great improvement in the yields of 2-arylethenesulfonamide **7**, **8**, and 4-phenyl-1,3-butadiene-1-sulfonamide **9**[7] was obtained, compared to those of the former method (Table 1). Furthermore, 2-(heteroaryl)ethenesulfonamides **10**—**14** could be prepared only by this method. 2-(2,4-Dimethoxy-5-pyrimidinyl)ethenesulfonamide (**13**) and its 6-methyl derivatives **14** were transformed to the uracil derivative of ethenesulfonamides **15** and its 6-methyl derivative **16**, respectively. They are of interest regarding their antitumor activity because of their structural similarity to the sparsomicine[8] and potential precursor for 5-uracilethynesulfonamides, which is known to have an antitumor activity.[9] Since the generality and superiority of this method were verified, compounds **7**, **10**, and **11**, chosen as typical examples for comparing the yields of the following one-step synthesis, were benzoylated with benzoyl chloride to give **22**—**24** (Table 1). Similarly,3-aryl-2-propene-1-sulfonamides **17**—**21**, homoderivatives of 2-arylethenesulfonamides, were prepared without isomerization of the double bond by the reaction of aryl halides with 2-propene-1-sulfonamide (**4**)[10] in the place of **3**.

Since it was considered that the use of *N*-benzoyl-ethenesulfonamide (**3**) would shorten the preparation steps of *N*-benzoyl-2-arylethenesulfonamides **22**—**24**, benzoylation of ethenesulfonamide **2** in the presence of pyridine used as a base was attempted. However, this benzoylation reaction gave only unexpected pyridinium salt **1** in 56% yield.

It was incidentally found that the reaction of this salt **1** with aryl halides in the presence of a catalytic

Table 1. Synthesis of 2-Arylethenesulfonamides **7**—**14** and 3-Aryl-2-propene-1-sulfonamides **17**—**21**

Aryl Halide	2-Arylethene-sulfonamide	Yield/%	3-Aryl-2-propene-sulfonamide	Yield/%
Iodobenzene	**7**	55 (21)[a]		
Bromobenzene	**7**	61	**17**	42
1-Bromonaphthalene	**8**	72 (19)[b]	**18**	38
2-Bromostyrene	**9**	56 (13)[a]		
2-Bromothiophene	**10**	56	**19**	39
3-Bromopyridine	**11**	54	**20**	30
4-Bromopyridine	**12**	30		
5-Bromo-2,4-dimethoxy-pyrimidine	**13**	10	**21**	10
5-Bromo-2,4-dimethoxy-6-methylpyrimidine	**14**	16		

a) Yield from Ref. 6. b) Our own result obtained by using Culbertson's method.

amount of $Pd(OAc)_2$ and triethylamine in dry DMF gave *N*-benzoyl-2-arylethenesulfonamides **22—24** in better yields than those of the former two-step synthesis (Table 1), and that 20—30% of the unreacted aryl halides were recovered in all cases. The use of **1** is better than that of **2**, not only regarding yields but also in view of the easiness of preparation of **1**, though it was derived from **2**.

A detailed examination of this reaction in order to obtain more information about its mechanism revealed that the salt **1** does not change in the absence of triphenylphosphine and triethylamine at 140 °C. However, the treatment of **1** with triethylamine as a base in DMF at 140 °C gave *N*-benzoylethenesulfonamide (**3**) in 65.8% yield. In consideration of this result, benzoylation of **2** in the presence of NEt_3 (but not pyridine) successfully gave **3** in 13.4% yield. The reaction of **3** with a typical aryl halide of bromobenzene under similar conditions as above gave an expected *N*-benzoyl-2-phenylethenesulfonamide (**22**), but in low yield (16%), which is rather lower yield than that of the case used pyridinium salt **1**. Thus, the above results suggest that the salt **1** was generated *N*-benzoylethenesulfonamide (**3**) in situ under the conditions and that it reacted with aryl halides to give *N*-Benzoyl-2-arylethenesulfonamides **22—24**.

Experimental

All melting points are uncorrected. The IR spectra were taken on a IR-810 spectrometer. The ^1H NMR spectra were taken on Hitachi R-24 (60 MHz) and JEOL-FX 90 (90 MHz) spectrometers in chloroform-*d* (TMS as internal standard), and dimethyl-d_6 sulfoxide (TMS). The ^{13}C NMR spectra were taken on a JEOL-FX 90 (23 MHz) spectrometer in chloroform-*d* (TMS) and dimethyl-d_6 sulfoxide (TMS). The Mass spectra were taken on a JEOL-OISG-2 mass spectrometer.

General Procedures for the Preparation of 2-Arylethenesulfonamides 7—14 and 3-Aryl-2-propene-1-sulfonamides 17—21. A solution of triphenylphosphine (61 mg, 0.23 mmol) and palladium acetate (26 mg, 0.116 mmol) in DMF (16 mL) was stirred at room temperature for a few min under a nitrogen atmosphere. To this solution, a mixture of aryl bromide (5.88 mmol), **2** (or **4** for **17—21**) (7.01 mmol), and triethylamine (1.480 g, 14.7 mmol) was added. The mixture was heated at 140 °C for 24 h under a nitrogen atmosphere with stirring and, after cooling, filtered. The filtrate was concentrated under reduced pressure. The residue was dissolved in 50 mL of 1 M-sodium hydroxide (1M=1 mol dm^{-3}). The resulting solution was heated with 5 g of active carbon and filtered. The filtrate was brought to pH 3 with dil hydrochloric acid and the precipitate was collected by filtration.

7: Colorless needles; mp 140-142 °C (water), (lit,[3] 143 °C).

2-(1-Naphthyl)ethenesulfonamide (8): Colorless needles, mp 162—165 °C (ethanol); IR (KBr) 3345s, 3230s, 3050w, 1625m, 1495m, 1445m, 1319vs, 1308vs, 1172s, 989m, 908s, 748s cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.23 (m, 1H), 8.00—7.20 (m, 10H); MS *m/z* 217 (M^+, 57%). Anal. ($C_{12}H_{11}NO_2S$) C, H.

4-Phenyl-1,3-butadienesulfonamide (9): Colorless needles, mp 193—194 °C, (lit,[7] 198—199 °C).

2-(2-Thienyl)ethenesulfonamide (10): Colorless needles, mp 144—145 °C (by adding ethyl acetate dropwise to a solution of **10** in water); IR (KBr) 3360s, 3260s, 3080w, 1600m, 1520w, 1400w, 1300s, 1270s, 1140s, 960w, 900w, 820m, 780w, 720m cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.69 (d, *J*=5.0 Hz, 1H, H-3), 7.53 (d, *J*=15.5 Hz, 1H, H-b, CH_b=CH_aSO_2), 7.52 (d, *J*=3.2 Hz, 1H, H-5), 7.15 (dd, *J*=5.0 & 3.2 Hz, 1H, H-4), 7.14 (s, 2H, NH_2), 6.90 (d, *J*=15.5 Hz, 1H, H-a); ^{13}C NMR δ=136.9 (s), 131.2 (d), 129.7 (d), 129.2 (d), 128.4 (d), 128.3 (d); MS *m/z* 189 (M^+, 41%), 108 (100%). Anal. ($C_6H_7NO_2S_2$) C, H.

2-(3-Pyridyl)ethenesulfonamide (11): Pale yellow needles, mp 167—169 °C (water); IR (KBr) 3300s, 3050w, 2900m, 2650w, 1615m, 1590m, 1475m, 1421m, 1331vs, 1202m, 1139vs, 1122m, 969s, 900m, 870s, 815s, 778s cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.83 (bs, 1H, H-2), 8.60(bd, *J*=6.5 Hz, 1H, H-6), 8.15 (dt, *J*=1.0 & 7.5 Hz, 1H, H-4), 7.43 (m, 3H, H-5, H-a, b, CH_a=CH_bSO_2), 7.28 (bs, 2H, NH_2); ^{13}C NMR (DMSO-d_6) δ=150.7 (d), 149.4 (d), 134.9 (d), 133.4 (d), 132.2 (d), 128.9 (s), 122.9 (d); MS *m/z* 184 (M^+, 53%), 104 (100%); Anal. ($C_7H_8N_2O_2S$) C, H.

2-(4-Pyridyl)ethenesulfonamide (12): Colorless needles, mp 180 °C (decomp) (water); IR (KBr) 3320s, 3060w, 2980w, 2420w, 1596s, 1410m, 1322vs, 1135vs, 990m, 972vs, 932m, 810m, 795s cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.59 (dd, *J*=1.2 & 6.2 Hz, 2H, H-2, 6), 7.59(dd, *J*=1.2 & 6.2 Hz, 2H, H-5, 3), 7.51(dd, *J*=1.0 & 15.7 Hz, 1H, H-b, CH_b=CH_aSO_2), 7.24 (bs, 2H, NH_2), 7.22 (d, *J*=15.7 Hz, 1H, H-a); MS *m/z* 184 (M^+, 74%), 104 (92%). Anal. ($C_7H_8N_2O_2S$) C, H.

2-(2,4-Dimethoxy-5-pyrimidinyl)ethenesulfonamide (13): Colorless crystals, mp 172—173 °C (ethyl acetate); IR (KBr) 3300m, 3220m, 1590s, 1540s, 1470s, 1400m, 1380m, 1320s, 1300s, 1230m, 1130s, 1060m, 1000m, 850m, 809m, 759m cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.61 (s, 1H, H-6), 7.23 (s, 2H, H-a,b, CH_a=CH_bSO_2), 7.08 (s, 2H, NH_2), 4.01 (s, 3H, OMe), 3.92 (s, 3H, OMe); ^{13}C NMR (DMSO-d_6) δ=168.2 (s), 165.0 (s), 160.1 (d), 130.9 (d), 128.2 (d), 108.4 (s), 54.9 (q), 54.4 (q); MS *m/z* 245 (M^+, 100%), 164 (72%). Anal. ($C_8H_{11}N_3O_4S$) C, H.

2-(2,4-Dimethoxy-6-methyl-5-pyrimidinyl)ethenesulfonamide (14): Colorless needles, mp 195—197 °C (ethyl acetate); IR (KBr) 3300m, 3140w, 3020w, 1610m, 1560s, 1470s, 1450m, 1370s, 1130s, 1060m, 910m, 800m, 785m cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.33 (d, *J*=15.6 Hz, 1H, H-b, CH_b=CH_aSO_2), 7.09 (d, *J*=15.6 Hz, 1H, H-a), 7.06 (s, 2H, NH_2), 4.00 (s, 3H, OMe), 3.90 (s, 3H, OMe), 2.46 (s, 3H, Me); ^{13}C NMR (DMSO-d_6) δ=168.9 (s), 168.7 (s), 163.3 (s), 132.5 (d), 126.9 (d), 105.8 (s), 54.6 (q), 54.4 (q), 22.3 (q); MS *m/z* 259 (M^+, 100%), 178 (93%). Anal. ($C_9H_{13}N_3O_4S$) C, H.

3-Phenyl-2-propene-1-sulfonamide (17): Colorless crystals, mp 110—111 °C (benzene) (lit,[10] 126—127 °C).

3-(1-Naphthyl)-2-propene-1-sulfonamide (18): Pale yellow needles, mp 176—178 °C (EtOH); IR (KBr) 3350s, 3260s, 3050w, 1596w, 1416m, 1310vs, 1145vs, 975s, 890m, 820m, 800s, 772s cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.18 (m, 1H), 7.90—7.50 (m, 7H), 6.69 (s, 2H, NH_2), 6.25 (dt, *J*=15.0 & 6.0 Hz, 1H, H-b, CH_c=$CH_bCH_{a2}SO_2$), 3.50 (d, *J*=6.0 Hz, 2H, CH_2); MS *m/z* 247 (M^+, 8%), 116 (100%). Anal. ($C_{13}H_{13}NO_2S$) C, H.

3-(2-Thienyl)-2-propene-1-sulfonamide (19): Pale yellow crystals, mp 141—142 °C (benzene); IR (KBr) 3390vs, 3280s, 3040w, 1642m, 1550m, 1400m, 1328vs, 1138vs, 1125vs, 965s, 930m, 842m, 810m, 739m, 700s cm^{-1}; ^1H NMR (DMSO-d_6) δ=7.42 (d, *J*=5.0 Hz, 1H, H-5), 7.00 (m, 2H, H-2, 4), 6.92 (bs, 2H, NH_2), 6.82 (d, *J*=14.5 Hz, 1H, H-b, CH_c=$CH_bCH_{a2}SO_2$), 5.98 (dt, *J*=14.5 & 7.2 Hz, 1H, H-c), 3.85 (d, *J*=7.2 Hz, 1H, H-a); MS *m/z* 203 (M^+, 3%), 122 (100%). Anal. ($C_7H_9NO_2S_2$) C, H.

3-(3-Pyridyl)-2-propene-1-sulfonamide (20): Colorless needles, mp 120—121 °C (H_2O); IR (KBr) 3260vs, 3050w, 2900s, 2620s, 1640w, 1580m, 1558m, 1460m, 1318vs, 1285vs, 1232s, 1150s, 1128vs, 962s, 800m, 780s, 718 cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.62 (bs,1H, H-2), 8.43 (bd, *J*=7.0 Hz, 1H, H-6), 7.89 (dt, *J*=9.5 & 1.1 Hz, 1H, H-4), 7.35 (dd, *J*=9.5 & 7.0 Hz, 1H, H-5), 6.93 (bs, 2H, NH_2), 6.72 (d, *J*=14.5 Hz, 1H, H-c, CH_c=CH_b-CH_{a2}), 6.40 (dt, *J*=14.5 & 8.0 Hz, 1H, H-b), 3.92

(d, J=8.0 Hz, 2H, H-a); MS m/z 200 (M^+, 7%), 118 (100%). Anal. ($C_8H_{10}N_2O_2S$) C, H.

3-(2,4-Dimethoxy-5-pyrimidinyl)-2-propene-1-sulfonamide (21): Colorless crystals, mp 273 °C (decomp AcOEt); IR (KBr) 3280m, 3160w, 1590s, 1480s, 1400s, 1380s, 1330s, 1160m, 1000s, 960m, 780m cm^{-1}; ^1H NMR (DMSO-d_6) δ=8.44 (s, 1H, H-6), 6.88 (s, 2H, NH_2), 6.60 (d, J=15.8 Hz, 1H, H-c, CH_c=CH_b-CH_{a2}), 6.30 (dt, J=15.8 & 7.9 Hz, 1H, H-b), 3.98 (s, 3H, OMe), 3.89 (s, 2H, H-a), 3.80 (s, 3H, OMe); MS m/z 259 (M^+, 43%), 179 (-SO_2NH_2, 100%). Anal. ($C_9H_{13}N_3O_4S$) C, H.

2-(1,2,3,4-Tetrahydro-2,4-dioxo-5-pyrimidinyl)ethenesulfonamide (15). A solution of **13** (1.00 g, 4.00 mmol) and sodium iodide (1,84 g, 12 mmol) in acetic acid (9 mL) was heated at 100 °C with stirring for 4 h. After cooling, the solvent was evaporated in vacuo and the residue was dissolved in water (9 mL). To this solution was added dil sodium thiosulfate untill the color of the solution disappeared. The precipitate was collected by filteration to give **15** (83%): colorless crystals, mp 266—268 °C decomp (water); IR (KBr) 3320s, 3220m, 3020w, 1710s, 1690vs, 1670vs, 1620m, 1500w, 1420m, 1320s, 1230s, 1150s, 810m, 769m cm^{-1}; ^1H NMR (DMSO-d_6) δ=11.45 (m, 2H, NH), 8.02 (d, J=7.0 Hz, 1H, H-6), 7.49 (d, J=15.1 Hz, 1H, H-b, CH_b=CH_a-SO_2), 7.01 (d, J=15.1 Hz, 1H, H-a), 6.88 (s, 2H, NH_2); ^{13}C NMR (DMSO-d_6) δ=162.7 (s), 150.2 (s), 145.7 (d), 130.1 (d), 128.3 (d), 105.9 (s); MS m/z 217 (M^+, 3%), 137 (100%). Anal. ($C_6H_7N_3O_4S$) C, H.

2-(1,2,3,4-Tetrahydro-2,4-dioxo-6-methyl-5-pyrimidinyl)-ethenesulfonamide (16). Similarly 6-methyl derivative **16** was obtained from **14** by the above method: Colorless crystals, mp 269—272 °C decomp (water); IR (KBr) 3300s, 3220s, 3080m, 1700vs, 1660vs, 1580m, 1540m, 1412s, 1310s, 1140s, 900m, 760m cm^{-1}; ^1H NMR (DMSO-d_6) δ=11.21 (bs, 2H, NH), 7.56 (d, J=15.1 Hz, 1H, H-b, CH_b=CH_aSO_2), 7.02 (d, J=15.1 Hz, 1H, H-a), 6.89 (s, 2H, NH_2), 2.26 (s, 3H, Me); ^{13}C NMR (DMSO-d_6) δ=162.7 (s), 155.6 (s), 149.9 (s), 129.0 (d), 127.9 (d), 102.3 (s), 16.6 (q); MS m/z 231 (M^+, 7%), 151 (100%). Anal. ($C_7H_9N_3O_4S$) C, H.

[2-(Benzoylsulfamoyl)ethyl]pyridinium Chloride (1). To a solution of **2** (9.29 g, 86.8 mmol) and dry pyridine (14.73 g, 186 mmol) in dry acetone (30 mL) was added benzoyl chloride (25.95 g, 184 mmol) dissolved in dry benzene (10 mL). The mixture was refluxed for 30 min and, after cooling, the precipitate was collected by filteration to give salt **1** (15.38 g, 53%): Pale yellow prisms; mp 186—187 °C (DMF); IR (KBr) 3128m, 1690s, 1343s, 1150s cm^{-1}; ^1H NMR (DMSO-d_6) δ=9.42 (d, J=5.8 Hz, 2H, H-2, 6), 8.63 (t, J=7.7 Hz, 1H, H-4), 8.54—7.45 (m, 4H, H-3,5, and NH_2), 5.26 (t, J=6.4 Hz, 2H, CH_2-C-SO_2), 4.42 (t, J=6.4 Hz, 2H, CH_2SO_2); ^{13}C NMR (DMSO-d_6) δ=166.6, 146.1, 145.8, 133.2, 131.4, 128.9, 128.3, 127.6, 54.7, 52.4. Anal. ($C_{14}H_{15}N_2O_3S$) C, H.

***N*-Benzoylethenesulfonamide (3).** To a solution of **2** (10.8 g, 0.10 mol) and triethylamine (12.7 g, 0.12 mol) in acetone (55 mL) was added benzoyl chloride (17.8 g, 0.13 mol) dropwise with stirring at room temperature. After the addition, the reaction mixture was stirred at room temperature for 30 min. The salt was removed by filteration and the filterate was evaporated in vacuo. The residue was chromatographed on silica gel with dichloromethane as eluent to give **3** (2.7 g, 13%): Colorless needles, mp 87—92 °C (ether); IR (KBr) 3274m, 1710s, 1336s, 1151s, 1060m, 899m, 848m, 733m, 842m cm^{-1}; ^1H NMR ($CDCl_3$) δ=9.50 (bs, 1H, NH), 7.92 (m, 2H, ortho protons on Ph), 7.28 (m, 3H, *m*- & *p*-protons on Ph), 6.99 (dd, J=16.6 & 9.7 Hz, 1H, H-a), 6.49 (d, J=16.6 Hz, 1H, H-b), 6.14 (d, J=9.7 Hz, 1H, H-c); ^{13}C NMR δ=165.5, 135.3, 133.6, 131.0, 130.4, 128.9, 128.1; MS m/z 211 (M^+, 5%), 105 (−$PhCO^+$, 100%). Anal. ($C_9H_9NO_3S$) C, H.

***N*-Benzoyl-2-arylethenesulfonamide (22—24). Method A:** The procedure for the preparation of **22**, **23**, and **24** is similar to that described in general procedure for the arylethenesulfonamines, except for using **1** in place of ethenesulfonamide **2**.

Method B: 2-Arylethenesulfonamides **7**, **10**, and **11** were treated with benzoyl chloride in a manner similar to the case of **3**, giving **22**.

22: (**A**: 23%; **B**: 19%) Colorless needles, mp 232—232.5 °C; IR (KBr) 3290s, 1692s, 1418s, 1335s, 1159s, 1061s, 870m, 839m, 752m, 703m cm^{-1}; ^1H NMR (DMSO-d_6) δ=12.1—12.5 (bm, 1H), 8.01—7.34 (m, 12H); ^{13}C NMR (DMSO-d_6) δ=165.6, 143.2, 133.0, 132.1, 131.6, 131.1, 128.9, 128.8, 128.5, 125.8; MS m/z 223 (M^+ −SO_2, 0.7%). Oxidation by Cobalt(III) Acetate. Part 13.[1] Oxidation of Substituted Phenols with Cobalt(III) Acetate in Acetic Acid

Masao HIRANO, Tadamichi ISHII, and Takashi MORIMOTO*
Department of Applied Chemistry, Faculty of Technology, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184
(Received December 20, 1990)

Synopsis. The oxidation of 2,6-di- and 2,4,6-tri-substituted phenols with cobalt(III) acetate has been investigated in acetic acid under an inert atmosphere; the former gave the corresponding diphenoquinones in excellent yields, and the latter yielded side-chain or nuclear acetoxylated products in moderate to good yields.

In connection with natural organic products and antioxidants, phenols enjoy important and specific positions in organic chemistry. The oxidation of phenols has also been of considerable significance in the synthesis of a variety of organic chemicals, especially for the biogenetic syntheses of natural products. Thus, fairly extensive methodologies have been demonstrated for the phenol oxidations using ample chemical and biological processes; viz. oxidation with metal oxidants (particularly with iron(III) salts), organic and inorganic peroxides (or peroxy acids), halides, quinones, and Fremy's salt, and electrolytic, enzymatic, auto-, and photo-oxidations and so on.[2]

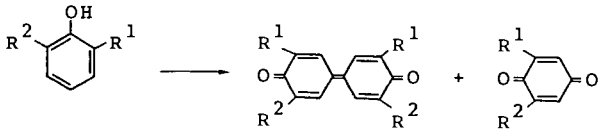
Although cobalt(III) acetate (**1**) is a potent and versatile one-electron oxidant and has been successfully used for the transformation of various functional groups, especially for the selective oxidation of alkylbenzenes[3] and olefins[1,4] via an electron-transfer mechanism, little attention has been paid to the oxidation of the hydroxyl compounds. We have thus recently examined product and/or kinetic studies concerning the catalytic[5] and stoichiometric oxidations of alcohols[6] and glycols[7] with **1** in acetic acid. Nevertheless, since there have been no data on the oxidation of phenols, the validity of **1** for the hydroxyl compounds has not been fully established. In this article we wish to describe some observations concerning the phenol oxidation with **1**. This is the first case in which **1** has been utilized for this objective.

Results and Discussion

The oxidation of phenols with **1** in acetic acid was carried out under nitrogen in order to exclude any influence of autoxidation. The reaction was stopped at a time in which the dark-green color of the reaction solution disappeared, a clear indication of the complete reduction of the cobalt(III) species into cobalt(II). After the conventional work-up procedures (see the Experimental section), the oxidation products formed were isolated and/or analyzed by GLC.

2,6-Dimethylphenol (**2a**) was readily oxidized at 70 °C, giving 3,3′,5,5′-tetramethyl-4,4′-diphenoquinone (**3a**) as the main product, along with a minor amount of 2,6-dimethyl-*p*-benzoquinone (**4a**). The other 2,6-disubstituted phenols (**2b—e**) exclusively afforded the corresponding diphenoquinones **3b—e** in fairly good yields, while the benzoquinones **4b—e** were absent (Table 1). Thus, *para-para* coupling predominates in the oxidation of the 2,6-disubstituted phenols. On the other hand, the oxidation of 2,4-di-*t*-butylphenol (**5**) at ambient temperature for 15 h ([**1**]/[**5**]=1.2; mole ratio) yielded solely the 2,2′-biphenyldiol (**6**) in 87 mol% GLC yield at 94% conversion, as a result of exclusive *ortho-ortho* coupling.[8]

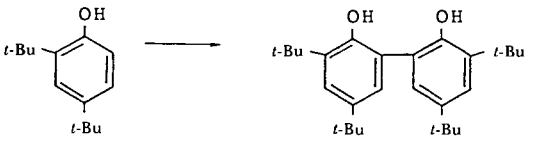
Table 1. Oxidation of 2,6-Disubstituted Phenols[a]



2 **3** **4**

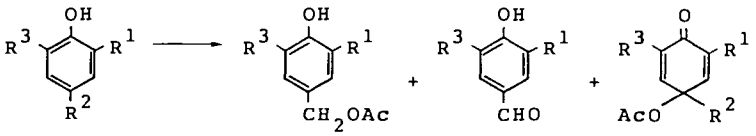
Phenols **2**		Temp	Time	[**1**]/[**2**]	Isolated yields/%	
R^1	R^2	°C	h	Mole ratio	**3**	**4**
(a) Me	Me	70	5.5	2.5	75	23
(b) Me	*t*-Bu	70	15	2.5	97	
(c) *i*-Pr	*i*-Pr	50	15	5.0	91	
(d) *t*-Bu	*t*-Bu	70	72	2.5	95	
(e) MeO	MeO	Ambient	24	2.5	95	

a) Under nitrogen, [$Co(OAc)_3$]=0.420 mol dm^{-3}; 8.4 mmol of phenols were used in every run.



5 **6**

These results are of considerable interest in considering the steric and electronic effects of the substituents on the reactivity of the phenols, as well as product selectivity. As compared with "less" hindered phenols, **2a—c**, a steric hindrance of the *t*-Bu groups of **2d** is prominent; they may severely limit the initial attack of **1** on the "more" hindered hydroxyl group. For example, when oxidations of **2a—d** were conducted at 50 °C ([**1**]/[**2**]=2.5), the reaction times required for complete reduction of **1** were 16, 20, 24, and 72 h, respectively. These results are well consistent with the previous observation that oxidation with **1** is highly sensitive to steric factors.[3c-e,4a-c] The selectivity of the products can also be explained in terms of a steric hindrance of the substituents; thus, carbon-

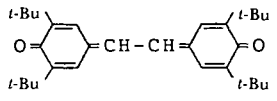


7 8 9 11

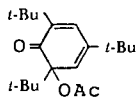
Scheme 1. (a); R^1=Me, R^2=Me, R^3=Me: (b); R^1=*t*-Bu, R^2=Me, R^3=*t*-Bu: (c); R^1=*t*-Bu, R^2=*t*-Bu, R^3=*t*-Bu.

carbon couplings occurred at the unhindered *para*- of **2a—e** and *ortho*-position of **5**. Smooth oxidation of **2e**, even at room temperature, evidently indicates that the electron-donating group contributes to promote the reaction. A similar electronic effect has been observed in the oxidations of alkylbenzenes[3a,b] and olefins.[4d,e]

The oxidation of 2,4,6-trisubstituted phenols (**7a—c**) was conducted in a manner analogous to that of **2** in acetic acid (Scheme 1). The oxidation of **7a, b** ([**1**]/[**7**]=2.5) at 50 °C for 1 and 15 h, respectively, afforded 49 and 73 mol% of the benzyl acetates (**8**), and 27 and 7 mol% of the benzaldehydes (**9**) (GLC yields), respectively. In the latter case, a small amount of 3,3′,5,5′-tetra-*t*-butyl-4,4′-stilbenequinone (**10**) was formed (3 mol% by GLC).[9] Control experiments showed that



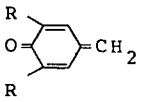
10



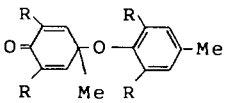
12

upon treatment of **8a, b** with **1** ([**1**]/[**8**]=2.5) at 50 °C for 1 and 15 h, respectively, **9a, b** were formed as the sole products in 67 and 47 mol% yields, respectively, implying that **9** was derived from a consecutive oxidation of **8**, as expected. The difference in the reactivity of **7a** and **7b** can also be explained by the difference in the steric effect of the Me and the *t*-Bu groups, as noted above. The oxidation of **7c**, having no labile hydrogen on the side-chains, with 2.5 equiv of **1** at 50 °C for 15 h, gave 4-acetoxy-2,4,6-tri-*t*-butyl-2,5-cyclohexadien-1-one (**11**) in 83% yield, along with only a trace amount of the 2-acetoxylated derivative (**12**). It has been comparatively rare that such a *p*-acetoxylated product as **11** is selectively formed in high yield. In fact, it has been reported that a mixture of **11** and **12** is obtained from **7c**, where **12** is formed (≈60%) in preference to **11** (<30%) as typically observed in Pb oxidations.[10]

In order to obtain some information on the possible route leading to **8**, close GLC as well as GC-MS analyses of the product mixtures obtained from **7a, b** were carried out, where components (<10%; GLC selectivities) assignable to the 4-methylene-2,5-cyclohexadien-1-ones (**13**) were detected. Although



13



14 [(a); R=Me, (b); R=*t*-Bu]

the isolation of **13a, b** from the product mixtures of **7a, b** failed because of their extreme instability, these facts may be suggestive of a reaction pathway via the 4-aryloxy-2,5-cyclohexadien-1-ones (**14**) as key intermediates, as proposed in the oxidations with Pb, Mn, and DDQ.[11]

The oxidation of phenol and *p*-cresol only afforded amorphous solids, which were infusible upon heating over 350 °C; possibly, polymeric materials were formed.

Experimental

^{1}H NMR spectra were measured with a JEOL JNM-C-HL model spectrometer for solutions in carbon tetrachloride or deuteriochloroform. The IR spectra were recorded for KBr disks or nujol mull on a JASCO DS-403G spectrophotometer. GLC was carried out on a Shimadzu GC-4CM instrument, with a 2 m column packed with 1.5% Silicone OV-17 on Shimalite WAW-DMCS, with temperature programming. The mass spectra were determined on a Shimadzu GC-MS 7000 spectrometer which was coupled via a heated 2 m column packed with 1.5% Silicone OV-17 on Shimalite WAW-DMCS to a GLC apparatus. Melting points were measured on a Yamato capillary mp apparatus and were uncorrected.

Starting Materials. All phenols were commercially available and were purified by recrystallization just before use. Cobalt(III) acetate in acetic acid was prepared by the oxidation of cobalt(II) acetate tetrahydrate with ozone in acetic acid containing acetic anhydride.[12]

Oxidation Procedures. The typical oxidation procedures are as follows: 2,6-Dimethylphenol (**2a**, 1.02 g, 8.4 mmol) was mixed with a solution of cobalt(III) acetate (2.5 mole equiv) in acetic acid in a reaction vessel. The vessel was then flushed with dry nitrogen gas, sealed with a glass stopper, and maintained at a controlled temperature in a thermostat without agitation. After a given period, the reaction mixture was poured into water to precipitate a dark-red solid. Separation of the solid by filtration, followed by recrystallization from acetic acid, afforded dark-purple needles **3a**: 1.51 g, 75%; mp 203—204 °C (lit,[13] 206 °C).

The aqueous filtrate was extracted three times with ether; the combined ether was successively washed with water, 10% aqueous sodium carbonate, and water and then dried (Na_2SO_4). Removing the ether on a rotary evaporator left a red solid, which was chromatographed on silica gel with chloroform as an eluent to give crude **4a**. Upon recrystallization from petroleum ether, the solid yielded yellow needles of pure **4a**: 0.263 g, 23%; mp 71—72 °C(lit,[14] 70—72 °C).

All products thus obtained were known compounds, and were identified by the mps as well as comparisons of the NMR and IR spectra and/or GLC retention times with those of authentic samples prepared independently. For the measurement of the GLC yields of the products, biphenyl or benzophenone was added to the reaction mixture as an internal standard; they were found to be intact

under the reaction conditions employed.

The Reaction between Hydrogen Spiro-Borates and Carbinol Form of Crystal Violet in Toluene with Applications to Reagent Selection in Extraction-Spectrophotometry of Boron

Susanta K. SENGUPTA* and O. BALASUBRAMANIAN
Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi 221005, India
(Received July 21, 1990)

Synopsis. A study on equilibrium and kinetics of the reactions of boron complexes of a judiciously chosen series of hydroxy and dicarboxy acids (benzilic acid, mandelic acid, 3-chloro- and 4-hydroxy mandelic acid, salicylic acid, and phenylmalonic acid) as well as of the free acids with carbinol form of crystal violet in toluene demonstrated the distinct superiority of mandelic acid over the others, as a reagent for extraction-photometry of boron.

A popular method for the determination of boron is extraction-spectrophotometry of $(dye)^+(spiroborate)^-$ ion pair in a low dielectric constant aprotic solvent. Boron as boric acid is well-known to complex with a diol, hydroxy acid or gem-dicarboxy acid (H_2R) to form hydrogen spiro-borate, HBR_2. A spiroborate anion (BR_2^-), if sufficiently hydrophobic, can be extracted even into a toluene-like solvent in pairing with a triphenylmethae dye cation. Spectrophotometry of the ion pair $(dye^+BR_2^-)_{org}$ is used to determine boron. In fact, combinations of various H_2Rs such as α-hydroxy acids, *o*-hydroxy benzoic acids, catechols or naphthols, dye cations, and solvents were tried to get the best possible reagent system.[1-5] These extraction processes are considered to follow the mechanism.[2]

$$H_2R \rightleftarrows (H_2R)_{org} \quad (1a)$$

$$dye^+ + (H_2R)_{org} \rightleftarrows (dye^+)(HR^-)_{org} + H^+ \quad (1b)$$

$$H_3BO_3 + 2(H_2R)_{org} + dye^+ \rightleftarrows (dye^+)(BR_2^-)_{org} + 3H_2O + H^+ \quad (1c)$$

$$(dye^+HR^-)_{org} + H_2O \longrightarrow (dye\text{-}OH)_{org} + (H_2R)_{org} \quad (1d)$$

$$(dye^+\ BR_2^-)_{org} + H_2O \longrightarrow (dye\text{-}OH)_{org} + (HBR_2)_{org} \quad (1e)$$

In such extraction systems, color fading based on hydrolysis of a cationic dye to the colorless carbinol, dye-OH has been skillfully used to diminish the absorbance of a reagent blank. To develop a sensitive method, the overall rate of Eq. 1d must be sufficiently larger than that of Eq. 1e. Further, the equilibrium of Eq. 1b can be considered as equivalent to the sequences,

$$dye^+ + H_2O \rightleftarrows (dye\text{-}OH)_{org} + H^+ \quad (1b')$$

$$(H_2R)_{org} + (dye\text{-}OH)_{org} \rightleftarrows (dye^+\ HR^-)_{org} + H_2O \quad (1b'')$$

and that of Eq. 1c can be to 1b′ and

$$H_3BO_3 + 2(H_2R)_{org} \rightleftarrows (HBR_2)_{org} + 3H_2O \quad (1c')$$

$$(HBR_2)_{org} + (dye\text{-}OH)_{org} \rightleftarrows (dye^+\ BR_2^-)_{org} + H_2O \quad (1c'')$$

So, determinations of rate constants of Eqs. 1d and 1e and of equilibrium constants of Eqs. 1b″, 1c″ and of 1b′, 1c′ would allow complete evaluation and prediction of such extraction systems. It can be shown that given a dye, solvent and pH for the suitability of a H_2R in boron determination, both the equilibrium constant and the rate constant of the reverse step of Eq. 1b″ must be sufficiently larger than those of Eq. 1c″. The case has been critically examined for a selected set of H_2Rs (salicylic acid, mandelic acid, 3-chloro- and 4-hydroxy mandelic acid, benzilic acid, and phenylmalonic acid) in reference to Crystal Violet dye for toluene as extractant. Herein, are reported the results.

Experimental

Reagents: Reagents used were either of analytical reagent grade or highly purified by standard procedures. Carbinol form of Crystal Violet was prepared by basification of the aqueous dye solution (10^{-5} M) by 2 M NaOH (M=mol dm^{-3}) and subsequent extraction into toluene.[7] HBR_2 was prepared by reacting a definite quantity of a H_2R with aqueous boric acid, followed by extraction into toluene cxcept for 3-chloro- and 4-hydroxy mandelic acid. Its toluene solution was obtained by careful evaporation of chloroform extract and dissolution in toluene.

Choice of Reagents: The medium chosen was toluene due to its relatively low toxicity.[2] The choice of the dye fell on Crystal Violet because its carbinol form is enough basic to undergo slow reaction with acids of widely different strengths in benzene and the like media.[7-9] Any hydroxy carboxy or dicarboxy acid (H_2R) reagent chosen should form a boric acid complex (HBR_2) having sufficient solubility and stability in toluene. Accordingly, the choice fell on H_2Rs having aromatic moiety: phenylmalonic acid, salicylic acid, benzilic acid, mandelic acid, and 3-chloro- and 4-hydroxy mandelic acid.

Procedure: Kinetics as well as equilibrium of the reaction of the carbinol form of Crystal Violet (1.12×10^{-5} M) with both a HBR_2 and the corresponding H_2R (10^{-4} to 10^{-3} M) in toluene were followed by measurements of absorbance at 610 nm in a Shimadzu 160A spectrophotometer as well as in a Systronics 103 spectrocolorimeter at 25±0.5 °C.

Results and Discussion

The carbinol form of Crystal Violet (tris-4-(dimethylamino) phenyl methanol) is an example of an aquo-base.[6] Its reaction with an acid is written in a general form as

$$D + HA \rightleftarrows DH^+A^- \quad (2)$$

Where, D stands for the colorless carbinol form and DH^+A^- is the colored ion pair. The equilibrium constant is defined as:

$$K = \frac{[DH^+A^-]}{[D][HA]^n}. \quad (3)$$

Where, the acid exponent, n, is greater than unity but nonintegral and significantly dependent on the spe-

cific acid (HA), solvent and temperature as well.[7,10,11] The equilibrium 2 should thus be writlen as

$$D + fHA \rightleftarrows DH^+A^- + rHA \quad (4)$$

where, f and r stand for acid exponents of the forward and the reverse steps, respectively. Symbolizing the rate constant for forward and reverse reaction as k_1 and k_{-1} respectively, the following relations follow:

$$n \text{ (overall acid exponent)} = f - r, \quad (5)$$

$$K = k_1/k_{-1}. \quad (6)$$

When [HA]≫[D] the kinetic data[7-9] fitted the formula

$$k = \frac{2.303}{t} \log \frac{x_e}{x_e - x}, \quad (7)$$

where, x_e and x stand for $[DH^+A^-]$ at equilibrium and at the time interval t, respectively, in terms of absorbance. The rate constant, k, can be expressed as

$$k = k_1[HA]^f + k_{-1}[HA]^r. \quad (8)$$

Combining the relations 5, 6, and 8, the following equation can be derived

$$\log\left(\frac{k}{K+[HA]^{-n}}\right) = \log k_{-1} + f \log[HA]. \quad (9)$$

A plot of the left hand side of the Eq. 9 vs. log[HA] was linear for many acids.[7-9] Using the above relations one can obtain K (Eq. 3), k (Eq. 7), k_1 (Eq. 6), k_{-1} (Eq. 9), n (Eq. 3), f (Eq. 9), and r (Eq. 5).

Under the present conditions, where [HA]/[D] is in general 10—500, it was observed that for the reaction of the carbinol form of Crystal Violet with the HBR_2 as well as the H_2R chosen in wet toluene the equilibrium and the kinetic data fitted well the relations 3, 7, and 9. The results and the parameters (obtained by least square analysis) were given in Tables 1, 2, 3, and 4.

Implications of the Results in Boron Determination: On the basis of the mechanism (Eqs. 1a—1e) the extraction-photometry of boron would be more sensitive, larger the overall rate of hydrolysis of a (dye^+HR^-) compared to that of the corresponding ($dye^+BR_2^-$). The relative rate of hydrolysis, for a given dye, extractant and pH, depends on the differences in the intrinsic quantities k_{-1} and K (Eqs. 1b″ and 1c″) as also on the difference between $[H_2R]_{org}$ and $[HBR_2]_{org}$. Use of $[H_2R] \gg [HBR_2]$, a general condition in the boron determination, is thus of advantage to the method's sensitivity. Results on k_{-1} and K (Tables 3 and 4) lead clearly to the prediction that except salicylic acid, all the other acids should be potential reagents and that among these, mandelic acid or phenylmalonic acid should be preferred over benzilic acid and 3-chloro- and 4-hydroxy mandelic acid. However, the last one would be a poor choice owing to very low extractability of its BR_2^- into toluene. Further, between mandelic acid and phenylmalonic acid, the magnitudes of k_{-1} and K cause the rate of hydrolysis of dye^+HR^- very high for both the acids but that of $dye^+BR_2^-$ distinctly less for the former acid.

Thus, evaluation of the physicochemical results distinguishes mandelic acid as the most potential one

Studies on Some Dithiocarbamato-Bridged Heterobimetallic Complexes: Part II

N. K. SINGH,* Chetna KAW, and Nanhai SINGH
Department of Chemistry, Banaras Hindu University, Varanasi 221005, India
(Received July 30, 1990)

Synopsis. Some dithiocarbamato-bridged heterobimetallic complexes of the type $M^{I}[Zn(dtc)_3]$ and $M^{II}[Zn(dtc)_3]_2$, (M=Co(II), Ni(II), Cu(II), Pd(II), Pb(II), Cd(II), Tl(I), Ag(I), dtc=diethyldithiocarbamate), have been synthesized and characterized by elemental analysis, molar conductance, magnetic susceptibility, (^{1}H, ^{13}C) NMR, UV-visible, and infrared spectral studies. The complexes are nonelectrolytes. The infrared spectral bands and NMR signals indicate the presence of only one type of dithiocarbamate group. The electronic spectra of the complexes recorded in chloroform, pyridine, and dimethyl sulfoxide are similar to their nujol mull spectra indicating no change in the geometry of the central metal. Magnetic moment, electronic spectra, and ESR studies are commensurate with a square-planar geometry around Co(II), Ni(II), Pd(II), and Cu(II).

In the previous paper,[1] the synthesis and spectroscopic studies of some novel xanthato-bridged heterobimetallic complexes of the type M[M'(Etxant)$_3$]$_2$ and M[M'(Etxant)$_3$] have been reported. The ligand dithiocarbamate is closely related to xanthate, nevertheless due to replacement of oxygen with nitrogen some interesting changes in bonding behavior and reactivity of the complexes may be expected. With this viewpoint, we wish to report here the synthesis and structural studies of some analogous dithiocarbamato-bridged heterobimetallic complexes involving some transition and non-transition metal ions.

Experimental

All the chemicals used in the preparative work were BDH (AR) or equivalent grades. The solvents were freshly distilled. Sodium diethyldithiocarbamate trihydrate (Nadtc·3H$_2$O) was prepared according to literature procedure.[2] The experimental details pertaining to analysis of metals, sulfur, carbon, hydrogen, nitrogen, room-temperature magnetic susceptibility measurements, and recording of infrared and NMR spectra are same as described earlier.[1] ESR spectrum of Cu[Zn(dtc)$_3$]$_2$ was recorded in $CHCl_3$ on a Varian E-117 X-band spectrophotometer using DPPH (g=2.00277) as a g marker at room temperature.

Preparation of the Complexes: Na[Zn(dtc)$_3$] required for the synthesis of M[Zn(dtc)$_3$] and M[Zn(dtc)$_3$]$_2$ was prepared[3] in situ by adding 25 cm^3 acetone solution of zinc acetate (1 mmol, 0.220 g) to 40 cm^3 acetone-water mixture 90:10 (v/v) solution of Nadtc·3H$_2$O (3 mmol, 0.675 g). To the above Na[Zn(dtc)$_3$] solution, 25 cm^3 solution (1 mmol or 0.5 mmol) of $AgNO_3$ (0.17 g), Tl_2SO_4 (0.12 g), $CoCl_2·6H_2O$ (0.12 g), $NiCl_2·6H_2O$ (0.12 g), $CuSO_4·5H_2O$ (0.12 g), $Pb(NO_3)_2$ (0.16 g), $CdSO_4$ (0.15 g), or K_2PdCl_4 (0.16 g) dissolved in acetone-water 80:20 (v/v) was added gradually with constant stirring. All the heterobimetallic complexes which precipitated as fine crystalline material were filtered, washed with acetone-water 50:50 (v/v) mixture and dried in vacuum.

Results and Discussion

The analytical results (Table 1) indicate the formation of heterobimetallic complexes of the types M[Zn(dtc)$_3$] and M[Zn(dtc)$_3$]$_2$ by the metathetic reaction of Na[Zn(dtc)$_3$] and the corresponding metal salts in an appropriate molar ratio. The heterobimetallic complexes do not melt but decompose in the temperature range 165—225 °C. They are insoluble in water but soluble in most of the common organic solvents such as methanol, benzene, chloroform, *N*,*N*-dimethylformamide, dimethyl sulfoxide, and pyri-

a) In methanol. b) (d) Decomposition temp.

dine. The very low molar conductance values (1.01—6.89 $S cm^2 mol^{-1}$) in methanol are indicative of their nonelectrolytic nature.[4]

The magentic moment value of 2.03 BM and electronic spectral bands at 7000, 11400, 15600, and 20000 cm^{-1} for $Co[Zn(dtc)_3]_2$ suggest square-planar geometry around Co(II). The first and third bands are assigned to $^2A_{1g} \rightarrow {}^2E_{1g}$ and $^2A_{1g} \rightarrow {}^2E_{2g}$ transitions, respectively.[1] The most characteristic band at 11400 cm^{-1} for square-planar Co(II) complex gives the value of B=760 cm^{-1}.

The magnetic moment value of 2.23 BM for $Cu[Zn(dtc)_3]_2$ corresponds to one unpaired electron. Three bands at ca. 13600, ca. 14900, and ca. 21700 cm^{-1} in the visible region spectrum of this complex are assigned to $^2B_{1g} \rightarrow {}^2A_{1g}$, $^2B_{1g} \rightarrow {}^2B_{2g}$ and $^2B_{1g} \rightarrow {}^2E_g$ transitions in a square planar geometry[5,6] around Cu(II). The room-temperature ESR spectrum of $Cu[Zn(dtc)_3]_2$ in chloroform which gives the parameters $g_{\parallel}$=2.02, $g_{\perp}$=2.02, and g_{av}=2.02, together with the electronic spectral bands, indicate a four coordinate square-planar Cu(II) species.

The diamagnetic nature of $Ni[Zn(dtc)_3]_2$ and occurrence of bands at ca. 15900 and ca. 20400 cm^{-1} suggest square planar geometry around Ni(II). The latter absorption bands may be assigned to $^1A_{1g} \rightarrow {}^1B_{1g}$ and $^1A_{1g} \rightarrow {}^1A_{2g}$ transitions,[1] respectively. The value of the ligand field paremeter, Δ_1=18700 cm^{-1}, places the dithiocarbamate after xanthate in the spectrochemical series in a planar NiS_4 environment.

As expected $Pd[Zn(dtc)_3]_2$ complex is diamagnetic and exhibits a band at 22900 cm^{-1} which may be assigned to metal-ligand charge transfer. As compared to Ni(II) complexes, the first spin-allowed d-d transition in the Pd(II) complex is expected to occur at higher energy but it is generally not observed probably because it is masked by the tail of the following charge-transfer band.

In order to study the Lewis acid behavior, the heterobimetallic complexes containing Co(II), Ni(II), Pd(II), or Cu(II) as one of the metal ions have been dissolved in some coordinating as well as non-coordinating solvents like dimethyl sulfoxide, pyridine, chloroform and their UV-visible spectra were studied. The electronic spectral pattern of the complexes is almost similar to their nujol mull spectra, indicating no change in the geometry of the central metal and ruling out the possibility of ligand coordination to cobalt, nickel, palladium, or copper. $M[Zn(dtc)_3]_2$ [M=Ni(II), Co(II), or Cu(II)] complexes are quite insensitive to axial perturbation and their electronic spectra in donor solvents such as pyridine remain unchanged. In general NiS_4 complexes vary substantially in their ability to interact with Lewis bases. This tendency is closely related to the change in the electronic properties of the ligand as a whole rather than to the donor atoms alone. Thus xanthate,[7] dithiophosphate[8] complexes interact strongly, while dithiocarbamate complexes are generally unperturbed similar to the 1,2-dithiolene complexes[9] by dissolution in strong donor solvents such as pyridine. The reluctance of dithiocarbamate complexes to undergo axial interaction has been rationalized[2,10] by considering that sulfur atoms can donate electrons of π-symmetry into a nonbonding MO containing $4p_z$ function of the nickel ion. Any strong π-interaction of this kind should decrease the availability of the $4p_z$ orbital for interaction with bases. Thus the behavior of NiS_4 in this context suggests substantial S→Ni π-bonding and that the π-bonding increases in the order dithiophosphates≈xanthates<dithiocarbamates< dithiolene. This is also because, resonance form (b) is more dominating in dithiocarbamate complexes similar to dithiolene while resonance form (a) is dominating in case of binary metal xanthates. Electronic spectra of these complexes as nujol mull are almost similar to those of the analogous xanthato-bridged heterobimetallic complexes but the solution spectra show the absence of ligand-metal interaction.

The infrared spectra of all the heterobimetallic complexes studied over the region 4000—200 cm^{-1} (Table 2) are very similar and have been assigned on the basis of earlier studies.[2] The thioureide bands occurring at 1445—1460 cm^{-1} are attributed to the CN stretching vibration of the S_2C-NC_2H_5 bond. This band is in the midway of ν(C-N) (1250—1350 cm^{-1}) and ν(C=N) (1640—1690 cm^{-1}) and shows an increase in the double bond character of the C-N bond thereby justifying the major contribution of resonance form (b) for

2. $M'[Zn(dtc)_3]$

Fig. 1.

dithiocarbamate complexes. The two bands occurring in the region 990—1070 and 970—1095 cm^{-1} are associated with $\nu(C\cdots S)$ vibrations, indicating unsymmetrical bidentate/bridging behavior of the dithiocarbamate moiety linked to two different metal centers. The bands observed below 400 cm^{-1} are due to metal-sulfur stretching vibrations.

^1H NMR spectra of the complexes (Table 2) exhibit signals due to $-CH_3$ and $-CH_2$ protons[10] around δ=1.24—1.34 and 3.62—3.84 in the intensity ratio of 3 : 2 which are in between monodentate and bidentate dithiocarbamate. This may be probably due to the bridging/unsymmetrical bidentate behavior of dithiocarbamate linked to two different metal centers. The downfield shift observed in $-CH_3$ protons and the upfield shift in $-NCH_2$ protons as compared to sodium dithiocarbamate indicate the deshielding of $-CH_3$ protons and shielding of $-NCH_2$ protons in these complexes. For $Co[Zn(dtc)_3]_2$ the increased number of peaks for $-CH_3$ and $-NCH_2$ protons is due to the presence of paramagnetic Co(II) and diamagnetic Zn(II) centers. However, in the case of $Cu[Zn(dtc)_3]_2$, the $-CH_3$ and $-NCH_2$ protons show broad signals because of the presence of paramagnetic Cu(II) center.

^{13}C NMR spectra of the diamagnetic complexes show two signals at δ=12.13—12.4 and 43.77—49.89 corresponding to $-\underline{C}H_3$ and $-N\underline{C}H_2$ carbons respectively and suggest the intermediate behavior (unidentate and bidentate) of dithiocarbamate attached to two metal centers. Each of these signals shows splitting for $Co[Zn(dtc)_3]_2$ indicating the presence of two types of $-N\underline{C}H_2-\underline{C}H_3$ carbons due to the presence of unpaired electron of Co(II).

On the basis of these studies the complexes are expected to have structures similar to the xanthato-bridged heterobimetallic complexes[1] (Fig. 1).

Synthesis of Tribromoacetic Anhydride and Its Reaction with Dimethyltin(IV) Oxide

Ram PARKASH,* Meena MEENA, and Sukhjinder SINGH
Department of Chemistry, Panjab University, Chandigarh 160014, India
(Received July 12, 1990)

Synopsis. The synthesis of previously unknown tribromoacetic anhydride and its reaction with dimethyltin(IV) oxide is reported. The compounds were characterized by analytical methods, IR, ^{1}H, ^{13}C, ^{119}Sn NMR, and MS (EI) spectral studies.

Conventional method of preparing carboxylic anhydrides by heating the respective carboxylic acid with P_4O_{10} and subsequent distillation of the anhydride formed, even under reduced pressure, lead to partial decomposition of the product in certain cases.[1] Consequently, a few halo carboxylic anhydrides were yet to be synthesized.[2-4] In continuation of the synthesis of dibromoacetic anhydride in these laboratories,[1] preparation of previously unknown tribromoacetic anhydride is reported by a similar method. Its reaction with dimethyltin(IV) oxide and the structural diagnosis of $(CH_3)_2Sn(O_2CCBr_3)_2$ using various techniques especially the multinuclear NMR spectral studies, was also carried out keeping in view the wide application of diorganotin(IV) carboxylates as catalysts and stabilizers.[5]

Experimental

Tribromoacetic acid (Fluka) was used as such. Dimethyltin(IV) oxide was prepared by literature methods.[6,7] The solvents were dried and distilled before use.

The IR spectra were recorded as Nujol/hexachlorobutadiene/CCl_4 smears between AgCl plates on a Perkin-Elmer 1430 IR spectrophotometer. ^{1}H, ^{13}C (proton decoupled), and ^{119}Sn NMR spectra were taken on a JEOL-FX-90Q spectrometer using TMS (Me_4Si), TMS(Me_4Si), and TMT (Me_4Sn), respectively, as external references. Mass spectra (EI) were obtained on a Vg Micromass 7070 F at 70 eV. Melting points are uncorrected. All manipulations were carried out in a dry box filled with nitrogen.

Synthesis of Tribromoacetic Anhydride. Tribromoacetic acid (9.45 g, 31.8 mmol) and phosphorus(V) oxide (14.5 g) were loaded into a 100 cm^3 Pyrex reactor in a dry box, and 60 cm^3 of CCl_4 was added to it. The reactor was then fitted with a reflux condenser and a drying tube. The contents were refluxed at 77 °C for 20 h. The reaction mixture was filtered under positive pressure of dry nitrogen, and the residual portion was repeatedly washed with CCl_4 (5×10 cm^3). Tribromoacetic anhydride (7.35 g, 12.8 mmol) was obtained as a white solid, mp 62—64 °C, yield: 80% after removing the solvent from the filtrate in vacuo. The product was checked for the absence of phosphorus and then recrystallized from CCl_4 as a shining white solid, mp 63—64 °C, yield: 72%. Found: C, 8.31; Br, 82.94%. Calcd for $C_4Br_6O_3$: C, 8.33; Br, 83.33%. IR#: 1855 sh, 1830 vs, 1778 m, 1265 vw, 1125 m, 1085 ms, 935 m, 780 m, 745 sh, 685 vw, 615 ms, 580 sh cm^{-1}.

Preparation of Dimethyltin(IV) Tribromoacetate. Tribromoacetic anhydride (1.18 g, 2 mmol) dissolved in 30 cm^3 of CCl_4 was added to 0.33 g (2 mmol) of dimethyltin(IV) oxide in a 100 cm^3 Pyrex reactor in a dry box. The contents were heated to reflux (80 °C) till a clear solution was obtained. The white solid separated out on cooling the solution to room temperature, was filtered under positive pressure of dry nitrogen and washed twice with CCl_4 (1 cm^3) and finally dried in vacuo. $(CH_3)_2Sn(O_2CCBr_3)_2$ (1.36 g, 1.8 mmol) was obtained as a white solid, mp 145—147 °C, yield: 90%. Found: C, 9.6; H, 0.83; Br, 64.1; Sn, 15.6%. Calcd for $C_6H_6Br_6O_4Sn$: C, 9.72; H, 0.81; Br, 64.8; Sn, 16.02%. IR: 1605 s, 1460 vw, 1360 ms, 1277 vw, 955 mw, 925 w, 805 mw, 760 ms, 720 sh, 515 vw, 460 m cm^{-1}. NMR (CD_2Cl_2) ^{1}H, δ=1.19 ($^{2}J(^{119}Sn, ^{1}H)$ 83.5 Hz); ^{119}Sn, δ=−190.6; ^{13}C (C_6D_6) δ=4.6 ($^{1}J(^{119}Sn, ^{13}C)$ 680 Hz).

Results and Discussion

Reaction between tribromoacetic acid and phosphorus(V) oxide in CCl_4 at 77 °C results in the formation of tribromoacetic anhydride in good yield.

$$2CBr_3COOH \xrightarrow[20\ h,\ 77\ ^{\circ}C]{P_4O_{10},\ CCl_4} (CBr_3CO)_2O$$

The progress of the reaction was monitored by ^{1}H NMR and IR spectroscopy. The reaction was considered to be complete when the test solution did not show any peak relating to OH of the CBr_3COOH in its IR and ^{1}H NMR spectra (tribromoacetic acid has sufficient solubility in warm CCl_4 to check its IR and NMR). Attempts to purify tribromoacetic anhydride by distillation, even under reduced pressure (0.1 Torr, 1 Torr=133.322 Pa), resulted in its significant decomposition. Purification was rather achieved by recrystallizing the product from CCl_4.

Tribromoacetic anhydride is a shining white powder stable at room temperature for more than 20 days in a dry atmosphere. Nearly 5% decomposition of the product was observed in 40 days. The decomposition of $(CBr_3CO)_2O$ was taken into account by the formation of free Br_2 in the storage vessel. Tribromoacetic anhydride is soluble in common organic solvents giving colorless solutions. It is extremely moisture sensitive and reacts readily with water to give tribromoacetic acid. The IR spectrum of $(CBr_3CO)_2O$ free from CBr_3COOH absorptions was obtained as a Nujol smear between AgCl optics. The anhydride is reactive towards KBr plates. Attempts to obtain IR spectra of neat anhydride led to the formation of some CBr_3COOH due to its hydrolysis by atmospheric moisture. A parent or molecular peak was not observed in the EI mass spectra of $(CBr_3CO)_2O$. However, peaks relating to CBr_3COO^+, CBr_3CO^+, CBr_3^+, CBr_2COOH^+, CBr_2CO^+, Br_2CH^+, Br_2C^+, Br_2^+, $BrCO^+$, $BrCH^+$, BrC^+, BrH^+, Br^+ fragment ions were observed. The

s, strong; m, medium; w, weak; v, very; sh, shoulder.

above protonated fragment ions observed in the mass spectra are due to hydrolysis of $(CBr_3CO)_2O$ by traces of moisture either in the probe or during manipulations.

The reaction between dimethyltin(IV) oxide and tribromoacetic anhydride in CCl_4 at 80 °C produces dimethyltin(IV) tribromoacetate in good yield:

$$(CH_3)_2SnO + (CBr_3CO)_2O \xrightarrow[80\,^\circ C]{CCl_4,\ 6\ h} (CH_3)_2Sn(O_2CCBr_3)_2$$

The reaction was complete in nearly 6 h, when a clear solution was obtained (dimethyltin(IV) oxide is completely insoluble in CCl_4 by itself). That the product is soluble in hot CCl_4 but separates out on cooling the solution to room temperature, serves the purpose of recrystallization. So this reaction provides a facile synthesis of $(CH_3)_2Sn(O_2CCBr_3)_2$ in one pot. The yield was not quantitative as some of the product remained in solution even at room temperature.

The preparation of $(CH_3)_2Sn(O_2CCBr_3)_2$ by the above route is not unprecedented. Dialkyltin(IV) acetates have been prepared by reacting dialkyltin(IV) oxide with acetic anhydride.[8]

Dimethyltin(IV) tribromoacetate, a white solid is extremely moisture sensitive and soluble in common organic solvents. It has, however, very low solubility in CCl_4 at ambient temperature.

A comparison of IR frequencies of $(CH_3)_2Sn(O_2CCBr_3)_2$ (see experimental section) with that of sodium tribromoacetate[9] revealed the covalently bonded tribromoacetato ligands in the former. The magnitude of $\Delta\nu$ ($\nu_{as}CO_2-\nu_sCO_2$) in $(CH_3)_2Sn(O_2CCBr_3)_2$ of the order of 245 cm^{-1} ($\nu_{as}CO_2-\nu_sCO_2$=1605−1360=245 cm^{-1}) is less than that in NaO_2CCBr_3 (1664−1355=309 cm^{-1}) and is thus indicative of bidentate tribromoacetato ligand. The magnitude of $\Delta\nu$ has been used in deciding the bonding modes of a carboxylato group. Generally, the magnitude of $\Delta\nu$ in a given carboxylate complex greater or lesser than that of sodium carboxylate reveals the unidentate or bidentate carboxylato ligand.[10,11] The splitting of ν_sCO_2 mode i.e. an additional weak band at 1460 cm^{-1}, may be attributed to the unsymmetrical bidentate tribromoacetato ligand.

The excellent agreement[12] of the NMR prediction and X-ray structure determination for $(CH_3)_2Sn(O_2CCH_3)_2$ has reinforced the power of the NMR structure correlations developed previously[13-15] for the structural analysis of methyltin(IV) compounds in solution and in solid state. It has been shown that the magnitude of tin-hydrogen J coupling, $|^2J(^{119}Sn, ^1H)|$ ($|^2J|$), is related to the H_3C-Sn-CH_3 angle according to the quadratic expression:[14]

$$\theta = (0.0161)\,(|^2J|)^2 - 1.32(|^2J|) + 133.4$$

and the magnitude of tin-carbon J coupling, $^1J(^{119}Sn, ^{13}C)$ ($|^1J|$), is linearly related to the H_3C-Sn-CH_3 angle by the following equation:[14]

$$|^1J| = 11.4(\theta) - 875$$

Where θ is the H_3C-Sn-CH_3 angle in deg and $|^1J|$ and $|^2J|$ are in Hz.

These relationships provide a simple method for estimating H_3C-Sn-CH_3 angles of methyltin(IV) solids from coupling constant values.

The ^1J and ^2J values for $(CH_3)_2Sn(O_2CCBr_3)_2$ are found to be 680 and 83.5 Hz, respectively. H_3C-Sn-CH_3 angle calculated for $(CH_3)_2Sn(O_2CCBr_3)_2$ from ^1J and ^2J values by using the above expressions, comes out to be 136.4° and 135.4°, respectively. These findings are in excellent agreement with that calculated (135°) for $(CH_3)_2Sn(O_2CCH_3)_2$ from $^1J(^{119}Sn, ^{13}C)$ both in solution and solid state and from $^2J(^{119}Sn, ^1H)$ values.[12,14] H_3C-Sn-CH_3 angle in $(CH_3)_2Sn(O_2CCH_3)_2$ has been found to be 135.9° by X-ray structural studies.[12] So distorted octahedral geometry may be anticipated around tin in $(CH_3)_2Sn(O_2CCBr_3)_2$ similar to that in $(CH_3)_2Sn(O_2CCH_3)_2$ on the basis of H_3C-Sn-CH_3 angle. The ^{119}Sn chemical shift of the order of −190.6 ppm relative to TMT also supports the six coordination[12,15-17] around tin in $(CH_3)_2Sn(O_2CCBr_3)_2$.

We wish to thank Ashwani Vij for recording ^1H and ^{119}Sn NMR spectra.

Comments on the "Synthesis and Characterization of Some New Organophosphonates and Their Adducts with Some Metals" by Saad and Ramadan[1]

Eli BREUER* and Amiram GOLDBLUM
Department of Pharmaceutical Chemistry, The Hebrew University School of Pharmacy, Jerusalem, 91120 Israel
(Received December 12, 1990)

Synopsis. This NOTE criticized experimental work, calculations and the conclusions based on them, in a paper recently publishied.[1]

In the above paper the authors claim to have synthesized ethyl hydrogen benzoylphosphonate and ethyl hydrogen butyrylphosphonate by hydrolyzing the corresponding diethyl esters by sodium hydroxide. They claim to have obtained the compounds, although they describe neither their appearance and criteria for their purity nor analytical results, except for ionization constants and selected infrared data.

The authors of the paper cited above are apparently unaware of the long known fact that dialkyl acylphosphonates are sensitive to alkaline conditions,[2-5] and hydrolyze rapidly to the corresponding carboxylic acids and to dialkyl phosphonate. Thus diethyl benzoylphosphonate and diethyl butyrylphosphonate certainly have undergone hydrolysis to benzoic or butyric acid and to diethyl (and/or ethyl hydrogen) phosphonate under the forcing conditions used by Saad and Ramadan (heating at 80 °C with a 6-fold molar excess of sodium hydroxide for 5 h in a sealed flask). This assumption is supported by the fact that the related dimethyl acetylphosphonate has been shown to hydrolyze with a half life of seconds at pH 7 at room temperature.[6] More detailed studies of the kinetics of the hydrolysis have also been reported.[7,8] Acylphosphonates are generally sensitive towards bases. For instance primary amines readily cleave the C-P bond in acylphosphonates and yield carboxamides and dialkyl phosphonates.[9]

Because of this sensitivity to hydrolytic conditions, the preparation of salts of unesterified acylphosphonic acids requires the use of silyl halide dealkylation.[10] Similarly, the preparation of salts of alkyl hydrogen acylphosphonate requires the use of a non-hydrolytic method, namely nucleophilic dealkylation by halides.[11]

We were the first to isolate and to characterize acylphosphonic acids and the corresponding monoesters.[12] Comparison of the infrared carbonyl frequencies reported by Saad and Ramadan for ethyl hydrogen benzoylphosphonate (1718 cm^{-1}) and ethyl hydrogen butyrylphosphonate (1740 cm^{-1}) with those reported by us for methyl hydrogen benzoylphosphonate (1650 cm^{-1}) and alkanoylphosphonates (1690 cm^{-1}) suggests that Saad and Ramadan had indeed benzoic acid and butyric acid, and not the compounds they claim, in their hand.

It is unfortunate that Saad and Ramadan did not make an effort to purify their hydrolysis products and seek proof of purity such as elemental analysis or homogeneity by chromatographic techniques. There is no doubt that the correct structures of the products would have become apparent if such efforts would have been made or if the products would have been examined by ^{31}P nuclear magnetic resonance spectroscopy.

The authors used the HMO method to correlate

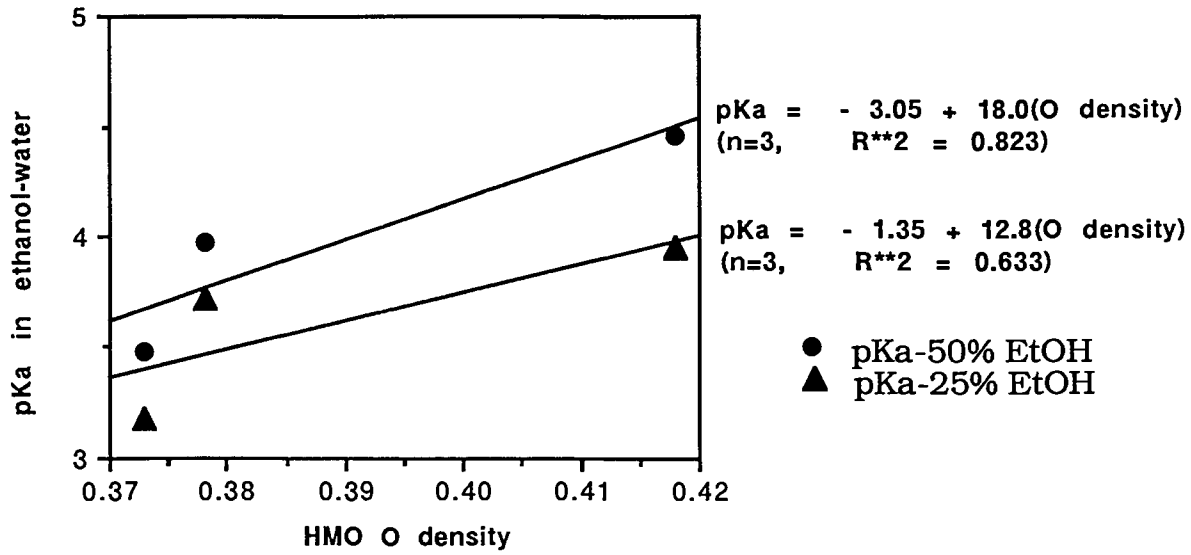

Fig. 1. pK_a dependence on oxygen densities, as reported by Saad and Ramadan.[1] The equations and correlations are marked on the right hand side for each of the two lines, for 50% and 25% ethanol-water.

between measured pK_a values and electron density on the hydroxylic oxygen in these compounds. We would like to comment on the use of Hückel calculations by the authors as well as on their claim of existing correlation.

The reference for HMO cited by the authors[13] does not list any parameters for phosphorus, and the paper does not indicate which parameters were employed for α and for β of this element. In addition, it is clear, and also established by X-ray data (e.g. for sodium hydrogen acetylphosphonate[14]), that the phosphonate group is not planar. In such cases nonplanarity should be taken into account by variation of the value of β for the relevant atoms according to their angular deviation from planarity.[13] This is not mentioned as the procedure which was followed.

pK_a values represent a difference in stability between the neutral and deprotonated molecules in the current environment. Such an environment effect is reflected also in the experimental differences found by the authors between 50% and 25% ethanol-water mixtures. It is possible, in the framework of HMO,[13] to study such differences between neutral molecules and their anions. Unfortunately, the authors do not appear to have tested this option.

The authors further claim that the decrease in electron densities of the hydroxylic oxygen in the three compounds "··· is consistent with the order of increasing acidity and accounts for the closest pK_a values of the butanoyl and benzoyl derivatives, 3.98 and 3.48, respectively". However, the correlation coefficient for the three compounds is very poor with R^2=0.823, for these pK_a values in 50% ethanol-water. The correlation for the 25% ethanol-water is even poorer, with R^2=0.633. Figure 1 clarifies this point.

A final point concerns the values of electron densities obtained by the authors. The overall density on the phenyl ring of the benzyl derivative is 5.272 (out of the original 6 electrons). In the benzoyl derivative, it is 5.610. This indicates that with their calculations, the authors find that a carbonyl adjacent to a phenyl ring is donating electrons to the ring, compared to a methylene at the same position, all other things being equal. This result should have made clear to the authors that something is wrong with the results, with the method or with their scheme of parametrization.

Spin-Trapping Studies on the Reaction of Iron Complexes with Peroxides and the Effects of Water-Soluble Antioxidants

Masahiro KOHNO,* Masako YAMADA, Keiichi MITSUTA, Yokio MIZUTA, and Toshikazu YOSHIKAWA†
ESR Application Laboratory, Analytical Instruments Division, JEOL Ltd.,
1-2 Musashino 3-Chome, Akishima, Tokyo 196
† First Department of Medicine, Kyoto Prefectural University of Medicine, Kamigyo-ku, Kyoto 602
(Received October 29, 1990)

Using ESR spin-trapping techniques we measured the levels of free radical species generated from six different systems (hypoxanthine–xanthine oxidase, iron(II)–hydrogen peroxide, iron(III)–hydrogen peroxide, iron(II)–*t*-butyl hydroperoxide, iron(III)–*t*-butyl hydroperoxide, and catalase (CAT)–*t*-butyl hydroperoxide). Six types of radicals ($O_2^{-\cdot}$, ·OH, ·H, ·CH_3, $(CH_3)_3CO$·, and $(CH_3)_3COO$·) were detected as spin adducts of spin traps 5,5-dimethylpyrroline 1-oxide (DMPO) or 3,5-dibromo-4-nitrosobenzene sulfonate (DBNBS). Quantitative analysis of the levels of generated radicals by means of an ESR instrument also presents important information regarding the reduction of peroxides [hydrogen peroxide (H_2O_2) or *t*-butyl hydroperoxide (ROOH)] by iron(II) or iron(III) as well as catalase. In addition, the scavenging potencies of different water-soluble antioxidants such as L-ascorbic, D-isoascorbic, gallic, sorbic, and protocatechuic acids were evaluated in terms of their ability to reduce the peaks of spin adducts.

Active oxygens such as superoxide anion radical ($O_2^{-\cdot}$, ·OOH), hydroxyl radical (·OH), hydrogen peroxide (H_2O_2), and singlet oxygen ($^1O_2$) have been implicated as being major damaging species in pathology and have been widely investigated.[1] These compounds react with the lipids of membranes and through a series of reactions generate carbon-centered (R·), alkoxyl (RO·), and then peroxyl (ROO·) radicals, all of which are used as markers of lipid peroxidation and the disruption of cellular homeostasis.[2,3] Also widely explored are studies scavenging phenomena of these active oxygens and free radicals by such antioxidants as vitamins C and E, and glutathione, and by scavengers such as superoxide dismutase (SOD) as well as catalase (CAT).[4-7]

The ESR spin-trapping technique is very useful for stabilizing short-lived free radicals. This technique has therefore been a powerful tool for studying generation mechanisms of free radicals and active oxygens[8-10] as of free radicals.[11-23]

The present study was carried out in order to establish a detection method for such free radicals as $O_2^{-\cdot}$, ·OH, ·H, ·CH_3 (R·), $(CH_3)_3CO$· (RO·), and $(CH_3)_3COO$· (ROO·). The six radical-generating systems were: hypoxanthine–xanthine oxidase which generates $O_2^{-\cdot}$ and ·OOH; iron(II)– hydrogen peroxide which gives ·OH; iron(III)–hydrogen peroxide, ·OH; iron(II)–*t*-butyl hydroperoxide and iron(III)-*t*-butyl hydroperoxide, R·, RO·, ROO·, and CAT–*t*-butyl hydroperoxide, RO·. The mechanism in Fenton's or catalase reactions between iron(II), iron(III), or CAT and ROOH or H_2O_2, are also described based on the results obtained from experiments performed under several conditions. Finally, the potencies of water-soluble antioxidants (L-ascorbic acid, D-isoascorbic acid, gallic acid, sorbic acid, and protocatechuic acid) in scavenging $O_2^{-\cdot}$, ·OH, ROO·, and/or RO· are described.

Experimental

Materials. Spin trapping reagents 5,5-dimethylpyrroline I-oxide (DMPO) and 3,5-dibromo-4-nitrosobenzene sulfonate (DBNBS), were supplied by Mitsui Toatu Chemicals and by Sigma Chemical Co., Ltd., respectively. Diethylenetriamine-*N*,*N*,*N*′,*N*″,*N*″-pentaacetic acid (DETAPAC), used to chelate trace metal impurities, was obtained from Wako Pure Chemical. The following were the sources of different radicals and their corresponding suppliers: sources of superoxide radical [hypoxanthine (HPX) from Sigma Chemical, and xanthine oxidase (XOD) from Boehringer Mannheim, cow milk]; source of hydroxyl radical [iron(II) sulfate heptahydrate (ferrous iron) and iron(III) sulfate *n*-hydrate (ferric iron) from Wako Pure Chemical Ins., Ltd., and hydrogen peroxide (H_2O_2)]; source of methyl, *t*-butoxyl, *t*-butylperoxyl radicals [iron(II) or iron(III) and *t*-butyl hydroperoxide (ROOH) from Nakarai Kagaku Co.]. Antioxidant reagents L-ascorbic acid, D-isoascorbic acid (erythorbic acid), and gallic acid were purchased from Daiichi Pure Chemical, while sorbic acid and protocatechuic acids were obtained from Wako Pure Chemical Ins.

Instruments. ESR spectra were recorded on a JEOL JES-RE1X spectrometer using aqueous quartz flat cell (Inner size 60 mm×10 mm×0.31 mm) with an effective sample volume 160 μl.

Preparation of Samples. All measurements were carried out both in 0.1 M (M=mol dm^{-3}) of PBS (sodium phosphate buffer solution) (pH=7.8) and in pure water at room temperature. Both peroxides, H_2O_2 and ROOH, were used as aqueous solutions. The concentration of the antioxidants used in this experiment was 1.0 mM (1 mM=1.0×10^{-3} mol dm^{-3}). Superoxide radicals were generated from a hypoxanthine xanthine oxidase reaction system under the conditions reported previously.[15,17]

Results and Discussion

Detection and Identification of Radicals [$O_2^{-\cdot}$, ·OH, ·H, R·, RO·, and ROO·]. The ESR spectra of the spin

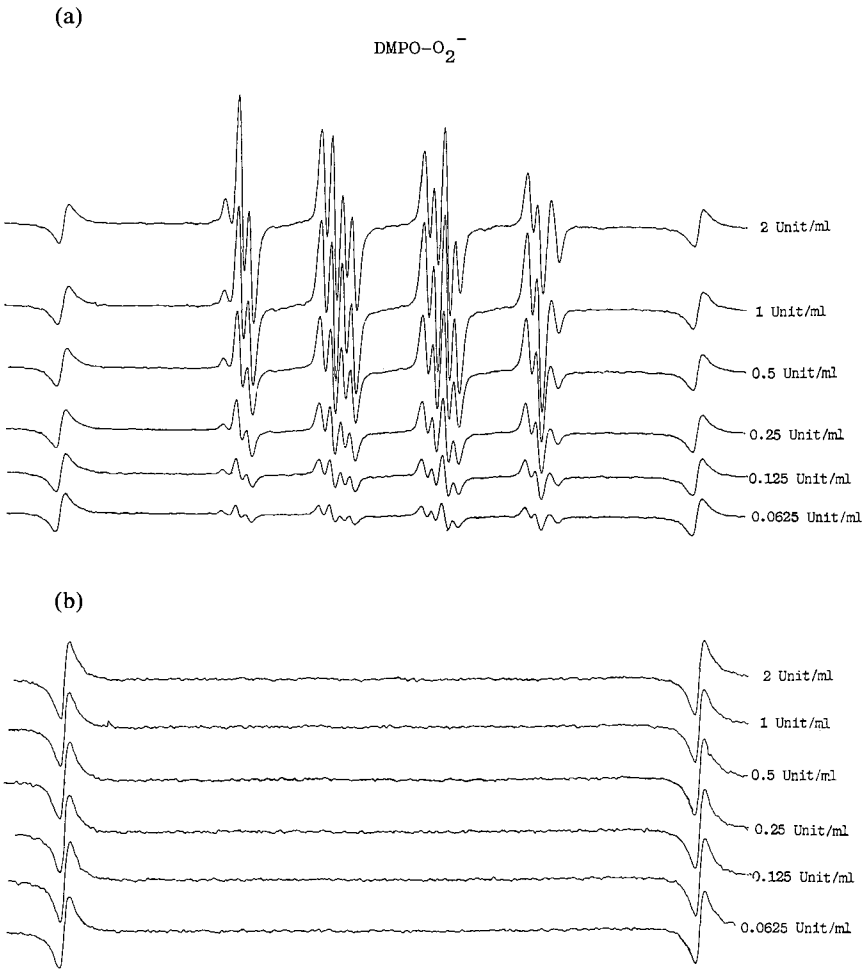

Fig. 1. ESR spectra of spin adducts of $O_2^{-\cdot}$, observed by the use of spin traps DMPO (a) and DBNBS (b). Spectrum (a) recording started 30 s after mixing 50 μl 2 mM HPX, 35 μl 5.5 mM DETAPAC, 15 μl 9.2 M DMPO (a), 50 μl 0.1—0.5 U ml^{-1} XOD, and 50 μl PBS. Spectrum (b) was observed under same conditions but without 15 μl 60 mM DBNBS.

adducts obtained in the hypoxanthine–xanthine oxidase reaction by using two kinds of spin traps, DMPO and DBNBS, are shown in Figs. 1a and 1b. In these figures, the peaks at either ends are of Mn^{2+} in MgO, which is used as an internal standard. The g values of both peaks are 2.0334 and 1.9810 at the resonance frequency of 9450.0 MHz, respectively. The method of measurement and the reaction conditions used in the experiments have been described previously.[10,17] As shown in Fig. 1a, a spin trapped by DMPO increases with the XOD concentration, and the hyperfine coupling constants (hfcc) obtained from the spectra coincide with the values of DMPO–O_2^- reported previously.[8] Using the spin trap DBNBS instead of DMPO, no signals were observed under the same conditions (Fig. 1b). However, the addition of DBNBS (60 mM) reduced the signal intensity of DMPO–O_2^-. From the experimental results for changing the concentration of DBNBS, the value of 50% inhibition(ID_{50}) of DMPO–O_2^- was measured to be 0.3 mM. The reaction rate constant (k_2) of DBNBS with $O_2^{-\cdot}$ in a hypoxanthine–xanthine odixase reaction were determined to be 3.9×10^4 M^{-1} s^{-1} at pH=7.8 from ID_{50} by treating for competitive reaction.[14] This value is 5.9-times larger than the previous reported value, 6.6×10^3 M^{-1} s^{-1} at pH=7.0, obtained by a pulse radiolysis method.[26] The difference may be due to differences in the pH and generation system of $O_2^{-\cdot}$. The results clearly indicate that both DMPO and DBNBS react with $O_2^{-\cdot}$. However, only DMPO gives a spectrum of the $O_2^{-\cdot}$ spin adduct. No $O_2^{-\cdot}$ spin adduct signals can be detected in the case of DBNBS. It is speculated that nitrones are better than nitroso compounds in detecting $O_2^{-\cdot}$ as a spin adduct.

Figures 2a and 2b show the spectra of the spin adducts obtained using DMPO or DBNBS, respectively, in reactions between 0.1 mM iron(II) chelated by DETAPAC (0.1 mM) and H_2O_2 (1 mM) in pure water.

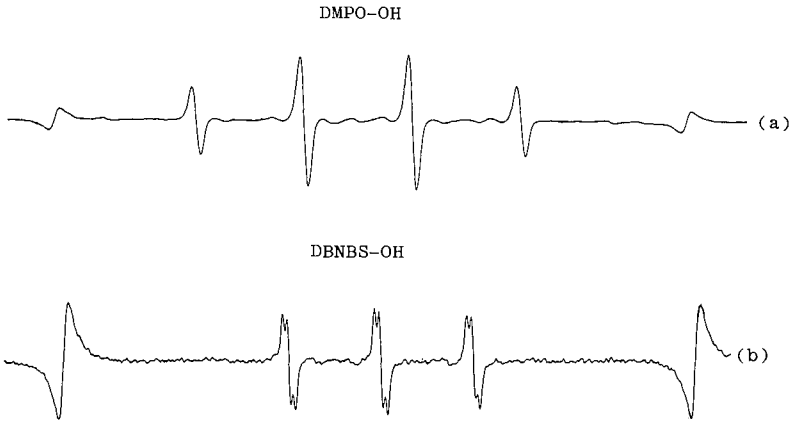

Fig. 2. ESR spectra of spin adducts of ·OH observed by the use of spin traps DMPO (a) and DBNBS (b). Spectra recording started 30 s after mixing 75 μl 0.1 mM iron(II) chelated by 0.1 mM DETAPAC before use [iron(II)-DETAPAC], 75 μl 1 mM H_2O_2, 50 μl 60 mM DMPO and 60 mM DBNBS, in 50 μl pure water.

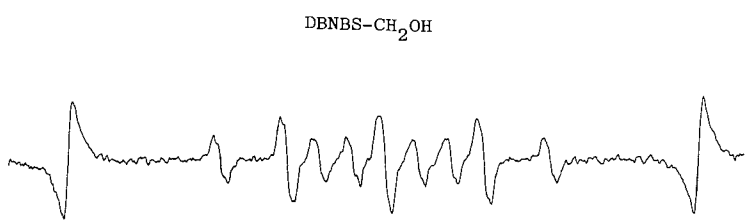

Fig. 3. ESR spectra of spin adducts of ·CH_2OH after mixing 75 μl 0.1 mM iron(II)-DETAPAC, 75 μl 1 mM H_2O_2, 15 μl 60 mM DBNBS and 50 μl 1.6 mM methanol.

In the case of DMPO (Fig. 2a), a typical hfcc was obtained as a_N=1.48 and $a_{H\beta}$=1.48 mT, which is the same as the typical value of DMPO-OH.[12] Using iron(III) (0.1 mM) instead of iron(II), less DMPO-OH is generated (Fig. 2b).

The results of the above-mentioned experiments demonstrate that iron(II) is more active than iron(III) in the reduction reaction of H_2O_2. With DBNBS, the hfcc of the signal is analyzed as a_N=1.24 mT and a_H=0.063 mT (Fig. 2b), which coincide with those reported previously.[26,27] However, the previous studies have many uncertainties,[27] since this adduct was assigned to DBNBS-O_2^-. In order to confirm that this radical species was DBNBS-OH, the methanol, which is a specific scavenger of ·OH, was added to the reaction system. Then, the signal decayed with increasing methanol concentration. When 1.6 mM methanol was added, another spin adduct, which is assigned as methanol radical (DBNBS-CH_2OH; a_N= 1.36 mT, a_H=0.91 mT and a_H=0.06 mT),[20,27] is detected as is shown in Fig. 3. In addition, a concomitant increase in the intensity of the DBNBS-OH signal is observed with increasing amount of added H_2O_2 (Fig. 4). Thus,·OH can be trapped not only by DMPO, but also by DBNBS. The rate constant (k_2) for the reaction of DBNBS with ·OH is determined to be 2.2×10^{10} M^{-1} s^{-1}, as measured from its competitive reaction with DMPO in trapping ·OH radicals. In this treatment, $k_2=3.4\times10^9$ M^{-1} s^{-1} [19] was used as the rate constant for the reaction of DMPO to trap ·OH. From these values, DBNBS is more sensitive than DMPO for detecting ·OH.

In the reaction between iron(II) of 0.1 mM chelated by DETAPAC of 0.1 mM, and H_2O_2 (0.01 mM), two kinds of spin adducts, DMPO-OH and DMPO-H, are observed (Fig. 5). Thus, from these spectra, it is confirmed that at least two types of radicals (·H and ·OH) are generated in the reaction. The concentration of the generated DMPO-OH agrees with that of DMPO-H under this reaction.

Using DMPO, both the reactions between iron(II) or iron(III) and ROOH give three kinds of spin adducts of methyl (R·), *t*-butoxyl (RO·), and *t*-butylperoxyl (ROO·) radicals (Fig. 6). However, when DBNBS was used, only the spin adduct of methyl radical (DBNBS-CH_3: a_N=1.37 mT and a_{CH_3}=1.35 mT and a_H=0.07 mT) was observed (Fig. 7). The reaction between the iron(III) and ROOH give a relatively weak signal of methyl

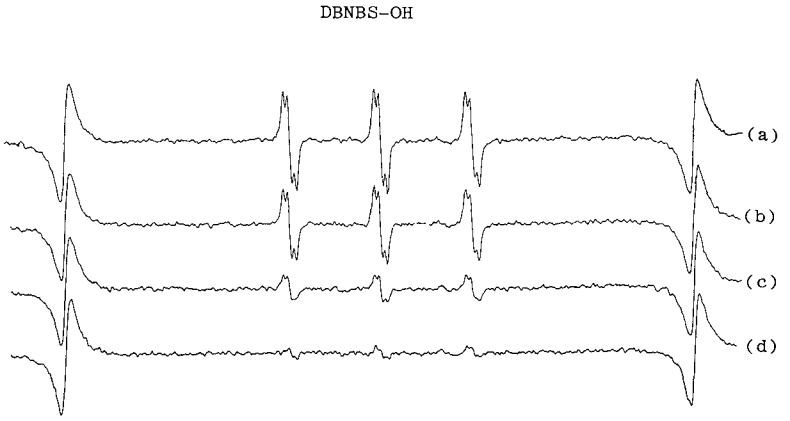

Fig. 4. ESR spectra of spin adducts of ·OH observed by the use of spin trap DBNBS. 75 μl 0.1 mM iron(II)–DETAPAC, 75 μl of (a) 1 mM, (b) 0.5 mM, (c) 0.25 mM and (d) 0.125 mM H_2O_2 concentration, 15 μl 60 mM DBNBS, in 50 μl pure water.

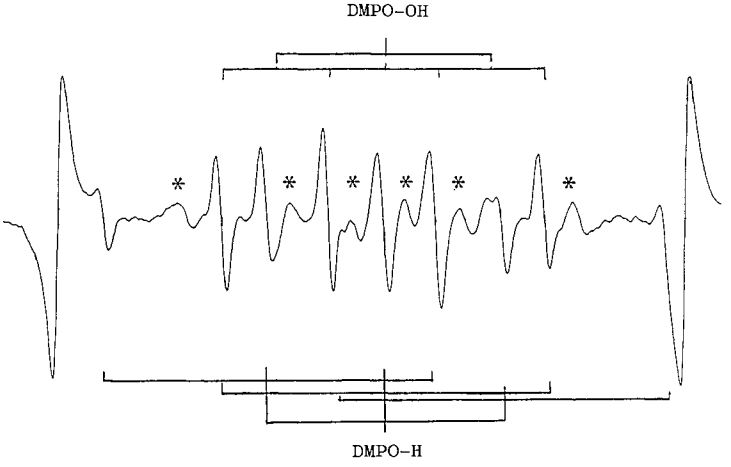

Fig. 5. ESR spectra of spin adducts of ·OH and ·H after mixing 75 μl 0.1 mM iron(II)–DETAPAC, 75 μl 0.01 mM H_2O_2, 15 μl, 0.92 M DMPO, in 50 μl pure water. The signal with "*" is the adduct of carbon center radical.

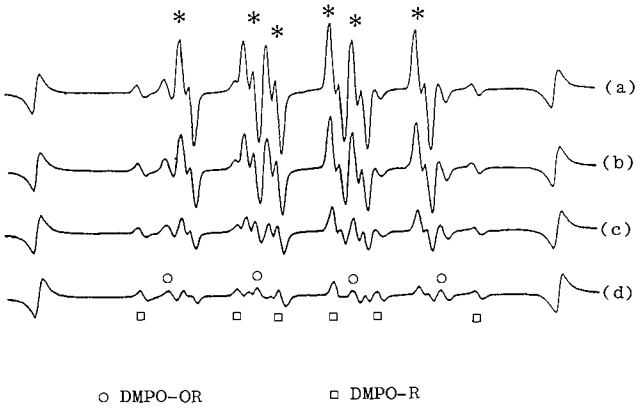

Fig. 6. ESR spectra observed in the reaction between 0.1 mM iron(II)–DETAPAC and ROOH of (a) 10 mM, (b) 5 mM, (c) 2.5 mM, (d) 1.25 mM ROOH concentration. The signal with "*" is the adduct of ROO·.

Table 1. Hyperfine Coupling Constants of Spin Adduct of Radicals, O_2^{-}, ·OH, ·H, R·, RO·, and ROO·[a)]

Spin adduct.	a_N	a_H^β	a_H^γ
DMPO-O_2^-	1.41	1.14	0.13
DMPO-OH	1.48	1.48	
DMPO-H	1.64	2.25	
DMPO-OOR	1.45 (1.45)	1.05 (1.05)	0.14 (0.15)
DMPO-OR	1.49 (1.48)	1.57 (1.60)	
DMPO-R	1.64	2.24	

a) ( ) is reported values.

adducts (Fig. 7). In the case of the reaction with CAT, only RO· is observed (Fig. 8). The spin adducts of R·, RO·, and ROO· were identified using the hfcc values listed in Table 1.[29,30)] As shown in Figs. 7 and 8, the spin adducts of ROO· and RO· changed, depending on each concentration of iron(II), CAT and ROOH.

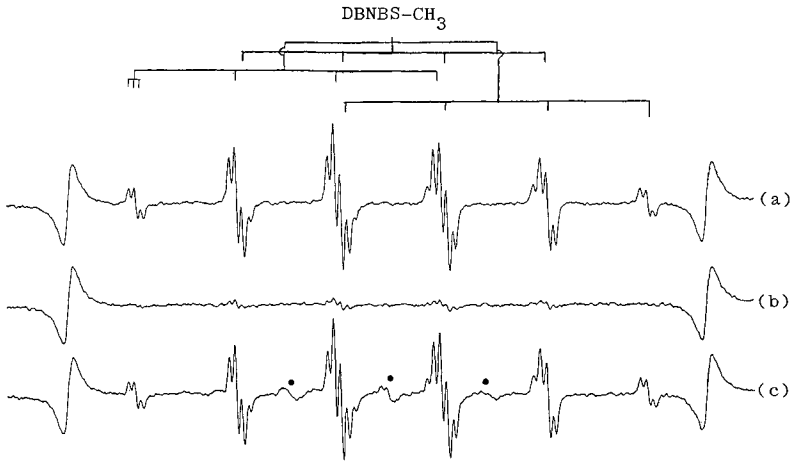

Fig. 7. ESR spectrum of $\cdot CH_3$ was observed by the use of DBNBS in the reaction between 1.0 mM iron(II) (a), iron(III) (b), iron(II)–DETAPAC (c) and 10 mM ROOH. The signal with "*" is the adduct of carbon center radical.

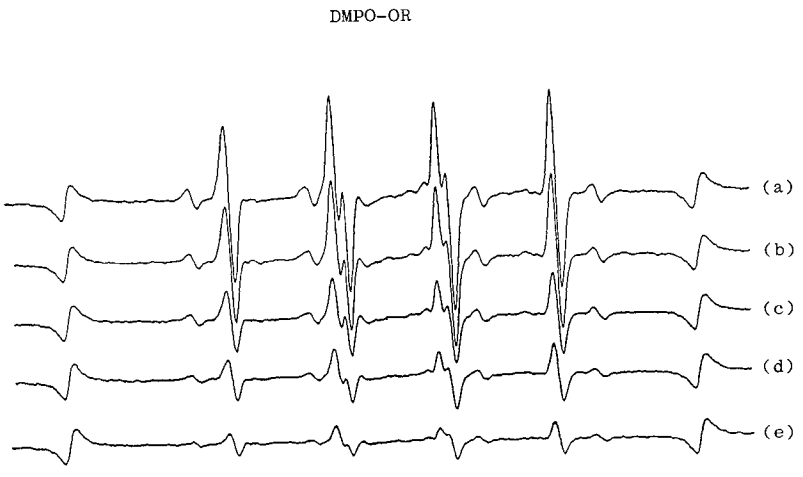

Fig. 8. ESR spectra observed in the reaction between ROOH and catalase of (a) 0.086 mM, (b) 0.043 mM, (c) 0.022 mM, (d) 0.011, (e) 0.006 mM catalase concentration.

In spin-trapping experiments, it can be confirmed that the results are very much affected by the concentration of DMPO used. For instance, if the DMPO concentration changed from 23 mM to 690 mM, the main observed spin adduct changed from RO· to ROO·, as well as the experiments for detecting ·OH and ·H. Thus, varying the DMPO concentration allows one to analyze specific radicals.

Reactivity of Water Soluble Antioxidants with $O_2^{-\cdot}$, ·OH, ROO·, and RO·. When DMPO was added to a solution of a radical-generating system, several spin adducts such as DMPO-O_2^-, DMPO-OH, DMPO-OOR, and DMPO-OR were detected. Various antioxidants such as L-ascorbic acid, D-isoascorbic acid, gallic acid, sorbic acid, and protocatechuic acid were diluted to 1 mM in pure water and added to a solution of the radical-generating system. Then, the amount of each spin adduct was found to decrease. These changes in the intensity of the ESR spectra were evaluated for the scavenging potencies of various antioxidants on $O_2^{-\cdot}$, ·OH, ROO·, and RO·. Table 2 shows the percent intensities of the spin adducts after the addition of antioxidants under the measurement conditions, as shown in the table, all of which were of equal concentration (1 mM). Based on Table 2, the scavenging action on $O_2^{-\cdot}$ of various antioxidants investigated decrease in the order D-isoascorbic acid > gallic acid > L-ascorbic acid > protocatechuic acid ≫ sorbic acid. As for ·OH, the potencies of antioxidants decrease in the order D-isoascorbic acid > L-ascorbic acid ≫ gallic acid = protocatechuic acid = sorbic acid=0%. For RO·, that order is gallic acid > protocatechuic acid ≫ sorbic

Table 2. Scavenging Activities(%) of Water Soluble Antioxidants L-Ascorbic Acid, D-Isoascorbic Acid, Sorbic Acid Protocatechuic Acid, and Gallic Acid against $O_2^{-\cdot}$, ·OH, ROO·, and RO·

Compound	$O_2^{-\cdot}$ [a]	·OH [b]	ROO· [c]	RO· [d]
L-Ascorbic acid	93.3	70.3	0	0
D-Isoascorbic acid	100.0	100.0	0	0
Sorbic acid	0	0	0	5.8
Protocatechuic acid	63.6	0	10.3	3.0
Gallic acid	96.5	0	0	28.5

Measurement conditions for generating $O_2^{-\cdot}$, ·OH, RO·, ROO· are shown as follows. a) $O_2^{-\cdot}$, 2 mM HPX+5.5 mM DETAPAC+0.4 U ml^{-1}+0.7 M DMPO. b) ·OH, 0.1 mM iron(II)-DETAPAC+1 mM H_2O_2+0.92 M DMPO. c) ROO·, 1.0 mM iron(II)-DETAPAC+5 mM ROOH+0.07 M DMPO. d) RO·, 1.0 mM iron(II)-DETAPAC+5 mM ROOH+0.07 M DMPO.

acid $\gg$ L-ascorbic acid = D-isoascorbic acid= 0%. In the case of ROO·, only protocatechuic acid show the function.

Reaction Mechanisms

The Fenton's Reaction. It has been reported that the formation of ·OH in a Fenton's reaction was directly confirmed using the spin trapping technique.[31,32] However, the reaction mechanism between iron(II) and H_2O_2 was assumed[33] to be

$$H_2O_2 + Fe^{2+} + H^+ \longrightarrow \cdot OH + Fe^{3+} + H_2O. \quad (1)$$

In our experiment two radical species (·OH and ·H) were observed in a Fenton's reaction used the H_2O_2 of low concentration for the concentration of iron(II). We thus propose the following reaction scheme, whereby both ·OH and ·H are generated:

$$H_2O_2 + Fe^{2+} \longrightarrow Fe^{3+}\text{-}OOH^- + \cdot H \quad (2)$$
$$Fe^{3+}\text{-}OOH^- \longrightarrow Fe^{4+}{=}O^{2-} + \cdot OH \quad (3)$$
$$H_2O_2 + Fe^{2+} \longrightarrow \cdot H + \cdot OH + Fe^{4+}{=}O^{2-} \quad (4)$$

In addition, it can be speculated that the existence of ·OOH generates a reaction between O_2 and ·H. In the case of a high H_2O_2 concentration,[13] ·OH is mainly observed. We therefore propose the follow reaction:

$$H_2O_2 + Fe^{2+} \longrightarrow \cdot OH + Fe^{3+}\text{-}OH. \quad (5)$$

Catalase Reaction. As in the case of a Fenton's reaction, this catalase reaction mechanism with regard to the radical reaction has not been proven experimentally. The proposed catalase reaction mechanism is according to

$$\text{Catalase} + 2H_2O_2 \longrightarrow 2H_2O + O_2. \quad (6)$$

To clarify the mechanism for the oxidation of H_2O_2, the reaction of iron(II), iron(III), or ROOH with CAT and H_2O_2 were assayed under different conditions. Mixtures of just catalase and H_2O_2 gave no signals. However, the ESR spectrum of alkoxyl radical[$(CH_3)_3CO\cdot$] was detected in a reaction between the catalase and ROOH. We therefore propose the existence of the following reaction mechanism:

$$\text{Catalase} + (CH_3)_3COOH \longrightarrow (CH_3)_3CO\cdot + \text{catalase-OH} \quad (7)$$

$$2\ \text{Catalase} + H_2O_2 \longrightarrow 2\ \text{catalase-OH (Compound-II)}^{7} \quad (8)$$

However, the generation of molecular O_2 in the reaction (Eq. 6) has been confirmed. Unknown factors in the mechanisms in the catalase reaction are as follows:

$$H_2O_2 \longrightarrow 2\cdot OH \quad (9)$$
$$H_2O_2 \longrightarrow \cdot H + \cdot OOH \quad (10)$$
$$\cdot OOH \longrightarrow \cdot H + O_2 \quad (11)$$
$$2\cdot H + 2\cdot OH \longrightarrow 2H_2O \quad (12)$$
$$2H_2O_2 \longrightarrow 2H_2O + O_2 \quad (13)$$

The net equation (Eq. 13) is the same as that of Eq. 6.

Peroxides Reaction.[34] The reaction between iron(II) and ROOH generates three kinds of radicals (RO·, R·, and ROO·). Catalase reacts with ROOH, and generates RO·. Both results show that radical generation is modulated by the redox state and the conformation of the iron sites. The reaction of catalase is expressed as a function of the peroxidase.

These studies confirmed the previous results obtained from indirect assays, which indicated that $O_2^{-\cdot}$, ·OH, ·H, R·, RO·, and ROO· are generated by bio-relative reaction systems. Whether these compounds are the natural microbiological products of the oxidation process or simply intermediates in a complex series of reactions has yet to be determined. The methods employed here allow us to measure the antioxidant potencies of L-ascorbic, D-isoascorbic, sorbic, protocatechuic, and gallic acids on radical species such as $O_2^{-\cdot}$, ·OH, ROO·, and RO·.

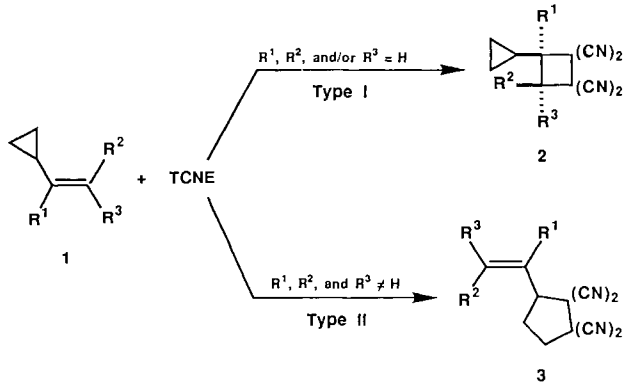
Preferential Incorporation of a Cyclopropyl σ Bond Over an Ethylenic π Bond in the TCNE Cycloaddition of 1,2-Dicyclopropylethylene. Occurrence of the Type-II Reaction in Some Disubstituted Substrates

Shinya NISHIDA,* Masakazu MASUI, Masashi MURAKAMI, Toshiro IMAI, and Takashi TSUJI†
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido 060
(Received November 29, 1990)

Among the two types of cycloadditions known to take place in the reactions of cyclopropyl-substituted ethylenes (**1**) with tetracyanoethylene (TCNE) (type-I gives a cyclobutane derivative (**2**) and type-II yields a vinylcyclopentane derivative (**3**)), the type-II reaction has been practically limited to occur in reactions of tetrasubstituted substrates. However, some disubstituted substrates, namely *cis*- and *trans*-1,2-dicyclopropylethylene (**4** and **5**), were found to produce a mixture of **2** (R^1=R^2 or R^3=H, R^2 or R^3=*cyclo*-Pr) and **3** (R^1=R^2 or R^3=H, R^2 or R^3=*cyclo*-Pr). In acetonitrile at 80 °C, **2** predominated in the reactions of both **4** and **5**, but **3** became the major adduct in 1,2-dichloroethane or benzene. The other 1,2-disubstituted ethylenes, such as 1-cyclopropylpropene, 1-cyclopropyl-3-methyl-1-butene and 1-cyclopropyl-3,3-dimethyl-1-butene, produced a small amount of **3** in solvents of low polarity; the type-II, however, has never become a major process. Parent vinylcyclopropane failed to give the type-II adduct in all of the solvents examined. Participation of the cyclopropyl σ bond in the reaction with TCNE is thus shown to have a scope wider than that presumed previously; hence, both the type-I and the type-II processes may be the two principal modes of the reaction of **1** with TCNE.

It may be natural to expect that an ethylenic π bond is more reactive than a cyclopropyl σ bond towards an electrophilic reagent.[1] Thus, it was not surprising when we observed that mono- and disubstituted cyclopropylethylenes **1** (R^1, R^2, and/or R^3=H) reacted with electrophilic tetracyanoethylene (TCNE) at their π bond to give a cyclobutane derivative **2** (type I reaction).[2] However, we found successively that TCNE preferentially reacted with the cyclopropyl σ bond of certain trisubstituted **1** (R^1, R^2, and R^3≠H) to give a vinylcyclopentane derivative **3** (type II reaction).[3] Although it has recently been demonstrated that the spiro-activation of a cyclopropane ring brought about a change of the reaction course from type-I to type-II in the reaction of 1,1,2-tricyclopropylethylene,[4] the type-II reaction has actually been limited to occur only in the reaction of tetrasubstituted olefins.[3]



1 2 3

In a previous paper[2] we reported that *cis*- and *trans*-1,2-dicyclopropylethylenes (**4** and **5**) were not exceptions for the disubstituted substrates. Namely, they gave crystalline **2**, albeit in relatively low yields, in a reaction with TCNE at elevated temperature in a polar solvent.[5] Recently, however, we noticed a second oily product, which was assignable to **3**. This finding occurred to us when we examined the mutual isomerization of **4** and **5** in the presence of some acceptor molecules. The observation suggests that the type-II reaction could have a scope wider than what we had presumed.[3,4] Accordingly, we carried out minute investigations on the reactions of some rather simple cyclopropylethylenes. In the present paper we report that the type-II reaction, indeed, gains significance to a certain extent in the reaction of some 1,2-disubstituted substrates.

4 5

Results and Discussion

Substrates. The ethylenes examined in the present study include, in addition to **4** and **5**,[6,7] *cis*- and *trans*-1-cyclopropylpropene (**6** and **7**),[8] vinylcyclopropane (**8**),[9] *cis*-1-cyclopropyl-3-methyl-1-butene (**9**), and *cis*-1-cyclo-

propyl-3,3-dimethyl-1-butene (**10**). The relative reactivities of these substrates toward TCNE were **5**>**4**>**6**=**7**=**8**>**9**>**10**.

Reactions of 4 and 5 with TCNE. In the previous study we examined the reactions of **4** and **5** as a part of an investigation aimed to show the generality of the type-I reaction.[2] Thus, the reaction of **4** was previously observed to occur at 100 °C in nitromethane[5] and crystalline *cis*-3,4-dicyclopropylcyclobutane-1,1,2,2-tetracarbonitrile (**2**: R^1=R^3=H, R^2=cyclo-Pr) was obtained in 25% isolated yield; **5** yielded *trans*-**2** (R^1=R^2=H, R^3=*cyclo*-Pr) in 11% yield. Since **2** was usually obtained in crystalline forms and was known to undergo fragmentation readily upon heating,[10] no effort, such as GC analysis, was made for the remaining oily portion of the reaction mixture.

In the present study we reexamined the same reaction in various solvents and found that 3-(2-cyclopropylvinyl)-cyclopentane-1,1,2,2-tetracarbonitrile (**3**: R^2 or R^3=*cyclo*-Pr) is produced as an oily product in addition to crystalline **2** (R^2 or R^3=*cyclo*-Pr). We realized that **3** is stable under GC conditions; it was therefore purified by preparative GC. As expected, **2** (R^2 or R^3=*cyclo*-Pr) underwent fragmentation under GC conditions to give two molecules of cyclopropylmethylenemalononitrile (**11**). Although the GC peak of **2** (R^2 or R^3=*cyclo*-Pr) was not symmetric (a steep maximum with a relatively long tailing), the shape was reproducibly recorded during each analysis. It was therefore possible to analyze the reactions of **4** and **5** with GC.[11]

As summarized in Table 1, heating **4** and TCNE in acetonitrile for 30 h resulted in a 76% consumption of **4**; **2** and **3** were produced in 74 and 18% GC yields, respectively.[12] The recovered olefin was found to be a mixture of **4** and **5** in a 53:47 ratio. In a separate experiment, **2** was isolated in 62% yield as an 84:16 mixture of geometrical isomers,[13,14] whereas **3** was collected by preparative GC in 11% yield; it was found to be a 52:48 mix-

a) A=acetonitrile, D=1,2-dichloroethane, B=benzene, and C=carbon tetrachloride. Reaction time is given in h. b) In the reactions of **4** and **5**, yields of **2** and **3** were determined by GC analysis, whereas yields in the reactions of **6**—**10** were based on the amount of the adduct isolated. c) An abbreviation "s" refers to stereochemically practically single (>99 : <1) on either HPLC or GC analysis. d) More than 99% isomerically pure. e) Based on the HPLC analysis. f) In the text, the ratio of isomers (500 MHz ^{1}H NMR) observed in isolation experiments is given.[13] g) Analyzed by GC. h) Undetectable either by HPLC or by GC. i) By 100 MHz ^{1}H NMR. j) On the GC analysis with an $AgNO_3$-glycerol column, the peak of the olefin overlapped badly with the solvent peak so that no reliable figure could be obtained. k) See the text. l) No characterizable material corresponding to **2** was isolated although the yield of **3** was relatively low. m) A mixture of stereoisomers in a 6 : 4 ratio. n) See the experimental section.

ture of isomeric **3** possessing a *cis*- and a *trans*-2-cyclopropylvinyl side chain.
