Hyodo and Fujiyama proposed a model for explaining this finite value of the depolarization ratio.[9] They considered that a molecule is subjected to both the direct field of a light wave and to an indirect field caused by the dipoles of surrounding molecules induced by the light wave field. Such a field as the latter is a so-called "local field." In this case, it depends only on the relative positions of the molecules surrounding the central molecule, because both the polarizability tensor and its derivative with respect to the ν_1 normal coordinate have spherical symmetry. The local field fluctuates by some magnitudes and directions because of the thermal motion of molecules, therefore causing finite depolarized scattering. Nishikawa and Iijima[10] calculated this depolarization ratio based on the formula of Hyodo and Fujiyama. Their own local-lattice structure model for liquid carbon tetrachloride was found to be quantitatively describable as the observed depolarization ratio. The pressure dependence of this depolarization ratio could be explained by a local field fluctuation up to 10^8 Pa by Ikawa and Whalley.[5] This fluctuation was also found to significantly affect the solvent-mixing fraction dependence of the depolarization ratio for the ν_1 Raman line of the perchlorate anion in mixed-solvent solutions of lithium perchlorate.[11]

On the other hand, Murphy et al. reported the concentration dependence of the depolarization ratio of the ν_1 Raman line of carbon tetrachloride in various binary solutions.[3] Unfortunately, however, the formula of Hyodo and Fujiyama was derived under the assumption that explicit information of the local structure is known. Since the proposed explicit structure models are based on X-ray diffraction data for pure liquid carbon tetrachloride,[12-14] this formula is numerically calculable. The local structure in a solution, on the other hand, seems to be very complicated because of the many possible combinations of multicomponent species. The formula of Hyodo and Fujiyama may be too hard to apply solutions.

One possible idea regarding its formulation has a similar basis as work undertaken by Ladanyi and Keyes[15-18] just before the local lattice model[9] was proposed. Their work concerned the local field effect on the Rayleigh scattering intensity. They explained and averaged from the standpoint of statistical mechanics the effect of induced polarization on each molecule, as well as the treated electric field induced from the dielectric continuum, and obtained a detailed, accurate expression of the local field effect on the light scattering intensities. The local field effect on the Raman scattering intensity seems to be explained in a similar way. However, the local field effect of Ladanyi and Keyes cannot be expected on

Raman lines in usual liquids or solutions, since the term of intermolecular interaction among permanent dipoles has significant effects on the intensity of Raman scattering in such cases. Computer simulation is an indispensable process because it gives terms which cannot be extracted from experiments.[19] In the present article, a formulation similar to that of Ladanyi and Keyes is applied to the expression of the fluctuation of the local field on the Raman scattering intensity. An equation with only experimentally observable quantities can be derived by transforming their expression into an expression that is slightly rougher.

The effect of the local field was first introduced by Kakimoto et al. in order to explain the depolarization ratio of the ν_1 Raman line of a T_d molecule with concentration dependence.[20] However, their idea included no consideration of the fluctuation in a medium. Their work caused some confusion because of its failure to consider fluctuation effects. Although the formulation of the present work is essentially different from theirs, it is much indebted to their preliminary work which established the problem.

In the present article, we have tried to express the fluctuation of the local field in a binary solution without any detailed information concerning the local structure. The local field fluctuation was formulated by including terms involving the fluctuation of the polarizability at each position in the scattering volume. A solution consisting of carbon tetrachloride and carbon disulfide was considered to be an ideal mixing solution. This is the reason why the solution was chosen in the present study.

Experimental

All of the chemicals used in the present study were commercially available products without further purifications. The concentrations of involved solutions were x_{CCl_4}=1.0, 0.8, 0.6, 0.4, and 0.2, where x_{CCl_4} is the mole fraction of carbon tetrachloride in a carbon disulfide solution.

The polarized and depolarized components of the ν_1 Raman line of carbon tetrachloride were measured with an NR-1000 system (Japan Spectroscopic Co., Ltd.). The 488 nm line of an Ar^+ laser (NEC, GLG 3300) was used as the excitation light source at 700 mW power. Polarization measurements were made using a Kenko PL filter mounted in the pathway of the scattered light. The slit widths of the double monochromator were chosen to be 250, 500 (with two slits), and 250 μm for the incident, middle and exit slits, respectively. The slit height was set at 1 mm. The Raman spectra were recorded at 25 °C.

The extinction coefficient of the polarization filter, β, and the transmittance ratio of the spectrometer for the polarized and depolarized components, γ, were simultaneously determined using a W-X lamp (The Eppley Lab., Inc.) at the peak position of a ν_1 Raman line (ca. 460 cm^{-1}) with 488 nm excitation. These instrumental factors were determined by a method which used a relation among the expected intensities from different polarization configurations. This relation with two polarization filters completely identical with each other is presented in Ref. 21 (also see Appendix). The instrumental factors, β and γ, thus obtained, were used for an intensity data correction. The depolarization ratio of a Raman line, ρ, is determined with β and γ, as

$$\rho=\frac{1}{\gamma}\frac{I_\perp-\beta I_{/\!/}}{I_{/\!/}-\beta I_\perp}, \tag{2}$$

where $I_\perp$ and $I_{/\!/}$ are the integrated depolarized and polarized intensities for this Raman line, respectively.

Theoretical

The intensity of Raman scattering is proportional to the mean-square polarization induced on molecules with a respective Raman frequency. Polarization measurements decompose this intensity to the components of a laboratory-fixed Cartesian coordinate system (X, Y, Z). When linear polarized incident light is used, the polarized and depolarized components of the scattering light are parallel and perpendicular, respectively, to the direction of the incident light polarization. For the ν_1 Raman line of a T_d molecule, the symmetry of the molecular vibration shows no intensity for the depolarized components, as can be seen from eq. 1. The possible depolarized intensity of this Raman line is produced by symmetry degradation due to some kind of intermolecular interaction or local field and its fluctuation. In order to estimate the effect of the local field on the depolarized intensity, the mean-square value of the local field is given in this section.

Consider a molecule i at a position $\boldsymbol{R}_i$ in a scattering volume v. This molecule feels a local field originating from induced polarization at each position $\boldsymbol{R}$ in v. The local field fluctuates in both magnitude and direction, depending on the molecular arrangement around $\boldsymbol{R}_i$. If we choose the incident light beam as being Z-polarized, the depolarized components of the Raman intensity are X- and Y-polarized. A component of the coordinate (X, Y, or Z) is denoted here as g. Assuming isotropic polarizability for all positions, the g-component of the local field, $F_g(\boldsymbol{R}_i)$, is expressed as

$$F_g(\boldsymbol{R}_i)=\int_v \alpha(\boldsymbol{R})\, l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\, d\boldsymbol{R}. \tag{3}$$

For this simplified expression, the component of the dipole operator tensor, $l_{gg'}(\boldsymbol{r})$, is defined by

$$l_{gg'}(\boldsymbol{r})=\frac{3\, r_g r_{g'}-\delta_{gg'} r^2}{r^5}, \tag{4}$$

where

$$r\equiv|\boldsymbol{r}|=\sqrt{r_X{}^2+r_Y{}^2+r_Z{}^2}.$$

Here, $\delta_{gg'}$ is the Kronecker delta. Equation 3 is integrated in order to consider the contribution of the polarizabilities on all positions. If we take the molecular viewpoint, this integration must be substi-

tuted by a summation over all positions of the molecules. However, to actually carry out this summation, detailed information is necessary concerning the molecular arrangement. Integration over all positions, including the no-molecule point, is carried out for the expression of the local field in Eq. 3. In the case of isotropic polarizability, the depolarization ratio, ρ, of the Raman line noticed here can be calculated as

$$\rho=\frac{4\langle F_{g'}{}^2\rangle}{1+4\langle F_Z{}^2\rangle}, \tag{5}$$

where g' is X or Y and the brackets $\langle\cdots\rangle$ denote the averaging value over all possible arrangements of the molecules. Factor 4 in Eq. 5 arises from the fact that the two frequency components, Rayleigh and Raman parts, of both $F_{g'}$ and F_Z contribute to the intensity of this Raman line in apparently the same way,[9] as shown in Eq. 5. Here, $\alpha(\boldsymbol{R})$ is decomposed into two parts: an invariable part, $\bar{\alpha}$, and a fluctuating part, $\Delta\alpha(\boldsymbol{R})$. $F_g(\boldsymbol{R}_i)$ can be rewritten as

$$\begin{aligned}F_g(\boldsymbol{R}_i)&=\bar{\alpha}\int_v l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\mathrm{d}\boldsymbol{R}+\int_v \Delta\alpha(\boldsymbol{R})\, l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\mathrm{d}\boldsymbol{R}\\&=\int_v \Delta\alpha(\boldsymbol{R}) l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\mathrm{d}\boldsymbol{R},\end{aligned} \tag{6}$$

where the integral of $l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)$ is zero when the explicit expression of Eq. 4 is considered. If the correlation of the space dependence of $\Delta\alpha(\boldsymbol{R})$ is neglected, the mean-square value of $F_g(\boldsymbol{R}_i)$ is

$$\begin{aligned}\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle&=w\int_v \mathrm{d}\boldsymbol{R}'\int_v \langle\{\Delta\alpha(\boldsymbol{R})\, l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\}^2\rangle\,\mathrm{d}\boldsymbol{R}\\&\quad+w\iint_{\boldsymbol{R}'\neq\boldsymbol{R}}\langle\Delta\alpha(\boldsymbol{R})\,\Delta\alpha(\boldsymbol{R}')\, l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\, l_{gZ}(\boldsymbol{R}'-\boldsymbol{R}_i)\rangle\,\mathrm{d}\boldsymbol{R}\,\mathrm{d}\boldsymbol{R}'\\&=w\int_v \mathrm{d}\boldsymbol{R}'\int_v \langle\{\Delta\alpha(\boldsymbol{R})\}^2\rangle\,\{l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\}^2\,\mathrm{d}\boldsymbol{R},\end{aligned} \tag{7}$$

where w is a statistical weight. Since the dipole operator tensor, of course, does not depend on the molecular arrangement, the averaging procedure affects only $\{\Delta\alpha(\boldsymbol{R})\}^2$ in Eq. 7. The last expression of Eq. 7 is derived from this fact. On the other hand, the homogeneity of the medium allows one to replace $\langle\{\Delta\alpha(\boldsymbol{R})\}^2\rangle$ with $\langle(\Delta\alpha)^2\rangle$, a position-independent mean-square quantity of $\Delta\alpha$. Equation 7 can be expressed by

$$\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle=w\langle(\Delta\alpha)^2\rangle\int_v \mathrm{d}\boldsymbol{R}'\int_v \{l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)\}^2\,\mathrm{d}\boldsymbol{R}. \tag{7'}$$

If the assumption of the space-independence of the $\Delta\alpha(\boldsymbol{R})$ correlation in Eq. 7 is rejected, details concerning the distribution functions are required. The contribution of the pair-distribution function is considered in Ref. 9 and that of the triplet-distribution function is discussed in Ref. 6. Equation 7′ can be calculated numerically using the formula $l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)$. For multi-component systems, however, the integration ranges for each component are different from each other, since the radial part of this integral is restricted by the smallest distance between pairing molecules. The correlation between $\langle\{\Delta\alpha(\boldsymbol{R})\}^2\rangle$ and the integration range, therefore, still holds for multi-component systems. For one-component systems, the problem concerning the integration range is not very complicated. Equation 7′ is rewritten here for one-component systems. In order to consider the discreteness of molecules, the polarizability, α_ϕ, at a no-molecule point is introduced. At that point, α_ϕ is obviously zero. When the probability of finding a molecule at the position is denoted as P, $\bar{\alpha}$, and $\langle(\Delta\alpha)^2\rangle$ are expressed as

$$\bar{\alpha}=P\alpha_M+(1-P)\alpha_\phi=P\alpha_M \tag{8}$$

and

$$\begin{aligned}\langle(\Delta\alpha)^2\rangle&=P\,(\bar{\alpha}-\alpha_M)^2+(1-P)\,(\bar{\alpha}-\alpha_\phi)^2\\&=P\,(\bar{\alpha}-\alpha_M)^2+(1-P)\,(P\alpha_M)^2\\&=P\,(1-P)\,\alpha_M{}^2.\end{aligned} \tag{9}$$

Here, α_M is the polarizability of the molecule in this one-component system. By inserting Eq. 9 into Eq. 7′ and integrating Eq. 7′, the mean-square value of $F_g(\boldsymbol{R}_i)$ for one-component systems can be written as

$$\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle=CP\,(1-P)\alpha_M{}^2N_A{}^2(d/M)^2, \tag{10}$$

where

$$C=\begin{cases}2\,\pi^2/15 & \text{for } g=x \text{ or } y.\\ 8\,\pi^2/45 & \text{for } g=z\end{cases}$$

Further, N_A, d, and M are Avogadro's number, the density of this system, and the molecular weight of the component molecule, respectively. In the derivation of Eq. 10, the following relations were used:

$$\frac{4\pi}{3}a^3N_A=\frac{M}{d}$$

and

$$w=\frac{\langle n\rangle}{v}=N_A\frac{d}{M}=\left(\frac{4\pi}{3}a\right)^{-1},$$

where a and $\langle n\rangle$ are the molecular radius and the mean-number of molecules in volume v. The range of integration, as well as the radial part of the integral in Eq. 7′, was taken from $2a$ to infinity.

The quantities of molecules are included in Eq. 10 as α_M, d, and M. A new variable, Q, is introduced in Eq. 11 in order to calculate Eq. 7′ for multi-component systems, although the problem concerning the range of integration cannot be determined yet.

$$Q\equiv\alpha_M N_A\, d/M. \tag{11}$$

Using this variable, Q, we can assume that Eq. 7 is transformed into

$$\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle=C\,\langle(\Delta Q)^2\rangle. \tag{12}$$

Equation 12 is similar to Eq. 10 derived from Eqs. 8 and 9 in the relation between $\bar{Q}$ and $\langle(\Delta Q)^2\rangle$. The use of Q for each component makes it possible to express the complicated relation of Eq. 7′ without any knowledge of the correlation between $\langle(\Delta\alpha)^2\rangle$ and the range of integration in this equation. Therefore, the

following relations are expected to hold for a binary solution with A and B components:

$$\bar{Q}=P\{x_A Q_A+(1-x_A)Q_B\}+(1-P)\,Q_\phi \qquad (13)$$

and

$$\langle(\Delta Q)^2\rangle=P\{x_A(\bar{Q}-Q_A)^2+(1-x_A)(\bar{Q}-Q_B)^2\}+(1-P)(\bar{Q}-Q_\phi)^2, \qquad (14)$$

where $Q_\phi=0$ because $\alpha_\phi=0$. x_A is the mole fraction of component A. If analytical transformations are made for Eq. 14, the following relation is derived:

$$\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle=C[P^2(Q_A-Q_B)^2\,x_A\,(1-x_A)+P\,(1-P)\,\{(Q_A{}^2-Q_B{}^2)\,x_A+Q_B{}^2\}]. \qquad (15)$$

The equality between Eqs. 15 and 10 is confirmed again when $x_A=1$.

A simpler formulation can be taken if the range of integration is ignored. However, the lower limit of the integration range as well as the radial part of the integral in Eq. 7′ must be given as the mean-value of the nearest-neighbor distances in this case. Since $l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)$ takes a large value at short distances, the contribution of a component molecule of smaller size cannot be satisfactorily considered in this treatment. A schematic view of this problem is given in Fig. 1. As a possible formula based on the above simpler formulation, the following expression can be derived:

$$\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle=C[P^2(\alpha_A-\alpha_B)^2\,x_A\,(1-x_A)+P\,(1-P)\,\{(\alpha_A{}^2-\alpha_B{}^2)\,x_A+\alpha_B{}^2\}]\times N_A\,[\bar{d}/\{M_A\,x_A+M_B\,(1-x_A)\}]^2, \qquad (16)$$

where $\bar{d}$ is the system density. The error originating from adopting the mean nearest-neighbor distance is not thought to be very large when $x_A\approx1$ and 0, since $\bar{d}\approx d_A$ when $x_A\approx1$ and $\bar{d}\approx d_B$ when $x_A\approx0$. On the other hand, Eq. 16 can be underestimated when $0<x_A<1$, since this equation omits part of the contribution of $l_{gZ}(\boldsymbol{R}-\boldsymbol{R}_i)$ at short distances (The shaded

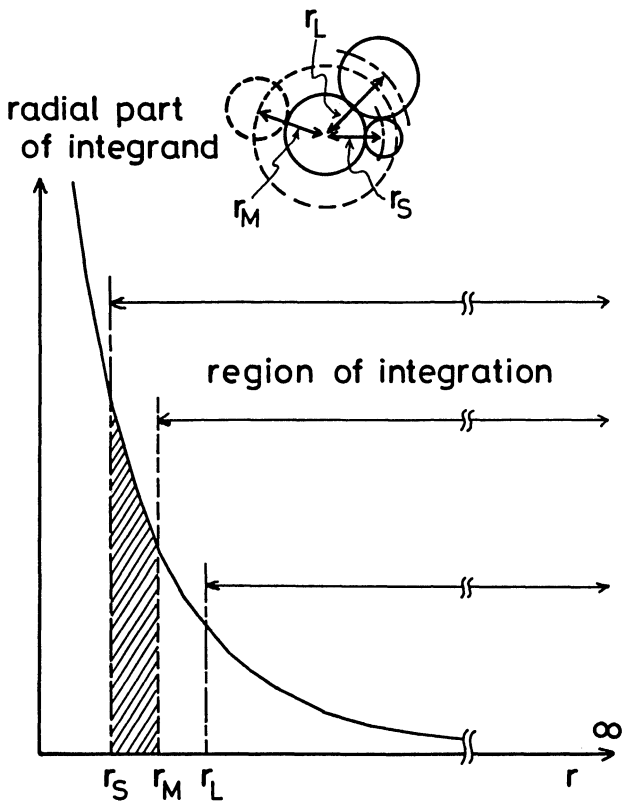

Fig. 1. Schematic view of the problem on the lower limit of the integration range along with the radial part of the integral in Eq. 7. r_M: mean-value of nearest-neighbor distances. r_S:. nearest-neighbor distance between the T_d molecule and a component molecule of smaller size. r_L: nearest-neighbor distance between the T_d molecule and a component molecule of larger size. Shaded regions were parts omitting the contribution of integrand for the formulation with the mean-value of nearest-neighbor distances.

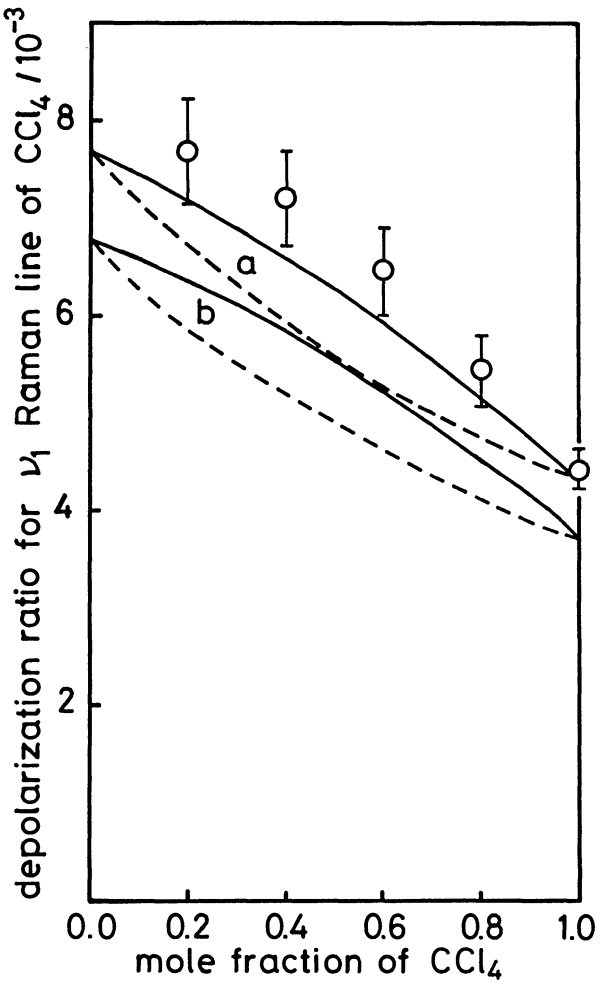

Fig. 2. Observed and calculated depolarization ratios of the ν_1 Raman line of carbon tetrachloride in carbon disulfide solution. Circles with error bars are observed values. Straight and broken lines are curves calculated by Eqs. 15 and 16, respectively. Lines marked "a" are the values for P=0.74, while those marked "b" are the values for P=0.68.

region in Fig. 1). Therefore, we must notice that Eq. 16 possibly gives less quantitative results, except for a system constructed using components of similar size.

The use of distribution functions can result in another explicit formulation of $\langle\{F_g(\boldsymbol{R}_i)\}^2\rangle$ based on some fundamentals from statistical mechanics. Equation 15 is substituted for that derived from this formulation. One example of the use of distribution functions for a pure liquid was given in a previous report.[9] However, numerical calculations using this formulation are impossible if explicit information concerning the distribution functions is not given for an object system. This proves that Eq. 15 is useful.

Results and Discussion

Figure 2 shows the depolarization ratio, ρ, of the ν_1 Raman line of carbon tetrachloride against the mole fraction, x_{CCl_4}, of carbon tetrachloride in carbon disulfide solutions. The instrumental factors of Eq. 2 for deriving the depolarization ratios, β and γ, resulted in 0.0021 and 0.360, respectively, at the wavelength of this Raman line with 488 nm excitation. The observed depolarization ratios are indicated by open circles with a vertical bar through them. These vertical bars indicate the statistic errors, which include the uncertainties of the β and γ values. The observed depolarization ratios increase with the carbon tetrachloride diluted with carbon disulfide along with a curve opening downwards. The extrapolation of this curve to infinite dilution almost duplicates the depolarization ratio of neat carbon tetrachloride. These depolarization ratios agreed fairly well with the previously reported data.[3,22]

The depolarization ratios calculated using Eqs. 15 and 5 are also shown in Fig. 2 as straight lines. The parameters used for these calculations are listed in Table 1. The density data were obtained from Ref. 24. The probability of finding a molecule, P, was defined by simple geometrical calculations for the occupation volume of hard spheres in three types of packing. Calculations regarding two cases of the P value are shown in Fig. 2. The cases for *fcc* and *hcp* are indicated as a, while that for *bcc* is indicated as b. The results obtained by using Eq. 16 are also shown in Fig. 2, as indicated by broken lines in the same manner as those from Eq. 15. The density data were interpolated between each pair of neighboring data points for calculations using Eq. 16.

The observed relation between the depolarization ratio and the mole fraction, ρ-x_{CCl_4}, can be well explained by Eq. 15, because the factor of x_A $(1-x_A)$ must have a positive value. Putting the parameters listed in Table 1 into Eq. 15, the depolarization ratio when $x_{CCl_4}\approx 0$ is found to be almost twice as large as that when $x_{CCl_4}\approx 1$. The calculated curves of Eq. 15 satisfy the experimental ρ-x_{CCl_4} relation for both the P values adopted here. An X-ray diffraction study[10] confirmed that the local structure of pure liquid carbon tetrachloride ($x_A=1$) is *bcc*. A more explicit expression for the depolarization ratio than that given in the present article resulted in 0.0042, supporting the local *bcc* model.[6,10] The calculated value for $P=0.74$ (*fcc* and *hcp* cases) at $x_A=1$ must be considered to accidentally agree with the observed value. It is not known why these two P values are adopted quantitatively. However, Eq. 15 is sufficiently qualitative to express the observed concentration dependence of the depolarization ratio.

The calculated depolarization ratios of Eq. 16 with both two P values show curves opening upwards, although those of Eq. 15 are curves opening downwards. Since the polarizability fluctuation term in Eq. 16 shows a curve opening downwards, the figured tendency that Eq. 16 shows must be dominantly described by the term involving the mean density of these solutions. The use of the mean density of the solution omits the contribution of a component at short distances, as was stated in the previous section. A qualitative disagreement of Eq. 16 with the observed data, therefore, occurs. This fact seems to stress the necessity for considering the nearest-neighbor distances in binary solutions.

It was found that Eq. 15 qualitatively predicts the fluctuation of the local field by comparing the observed and calculated depolarization ratios of the ν_1 Raman line of carbon tetrachloride in carbon disulfide solution. Also, the agreement between those values was observed within about 10% each for the cases of the different P values, although no quantita-

tiveness of the theoretical accuracies was guaranteed. As a result, the sufficiency of Eq. 15 was not very bad regarding quantitativeness. The derivation of Eq. 15 was made for completely random mixing. Fortunately, this equation can easily be expanded to involve solutions containing an ideal associated complex[25] by redefining the concentration of the respective species under consideration in which the associating species are treated as being different ones from the individual component. This fact shows that the concentration dependences of the depolarization ratio are different, depending on the system with different association numbers. The determination of the association number must be made experimentally using Eq. 15. This determination is one of the most difficult problems to be solved, because of the insufficient experimental accuracies of our instrumental set-up.

Concluding Discussion

The fluctuation of the local field was expressed in terms of the fluctuation of the polarizability at each position in the scattering volume. The formulation was made by distinguishing the positions with the polarizabilities of molecules from that of a vacancy, in order to take the discreteness of molecules into account. This expression was found to explain well the concentration dependence of the depolarization ratio of the ν_1 Raman line for carbon tetrachloride in carbon disulfide solutions. This concentration dependence cannot be analyzed using the previously proposed local lattice model,[9] without any explicit information concerning the local structure in each solution. The shape of carbon disulfide was assumed to be spherical, and the probability of finding molecules was considered to have no concentration dependence in this formulation. Therefore, the estimation with this expression seems to be very rough. However, the result of the estimation agreed well with the observed concentration dependence of this depolarization ratio. This result indicated that the finite size of a molecule essentially affects the magnitude of the fluctuation of the local field.

The fluctuation of the local field is affected mainly by the region including the first and second nearest-neighbor molecules around each molecule, because this can be calculated using the mean-square values of the dipolar field created by surrounding molecules. Therefore, the fluctuation of the local field suggests the structure of local molecular arrangements. In the present states, the fluctuation of the local field is found to be reflected only in the depolarization ratio of the ν_1 Raman line for T_d molecules. Consequently, the present study indicates that, regardless of the above-mentioned restriction, studies concerning the local field fluctuation are useful for evaluating model systems for discussions concerning the local structure of solution states.

The author is indebted to Dr. Tomohiko Yamazaki of Toyota Central Research and Development Laboratories, Inc. (TCRDL) for his invaluable assistance with the REDUCE operations, of which results are summarized in the Appendix. The author wishes to thank Professor Tadashi Kato of Tokyo Metropolitan University for directing his attention to the papers on the Rayleigh light scattering intensity. The author also thanks Dr. S. Noda and Dr. A. Isogai of TCRDL for their encouragement of this work, and the director of TCRDL for permission to publish this work.

Appendix

This Appendix presents a determination method of the extinction coefficient of the polarization filter, β, and the transmittance ratio of the spectrometer for polarized and depolarized components, γ.

The transmittance ratio, γ, is defined by

$$\gamma \equiv \tau_\perp / \tau_{/\!/}, \tag{A1}$$

where $\tau_\perp$and $\tau_{/\!/}$ are the transmittances of linear polarized lights which are perpendicular and parallel to the slit of the spectrometer. The observed intensities of these two linear polarized components, $I_\perp^{obsd}$ and $I_{/\!/}^{obsd}$, are expressed as

$$I_\perp^{obsd} = t\,\beta\, I_{/\!/}^{\circ}\,\tau_{/\!/} + t\, I_\perp^{\circ}\,\tau_\perp \tag{A2-a}$$

and

$$I_{/\!/}^{obsd} = t\, I_{/\!/}^{\circ}\,\tau_{/\!/} + t\,\beta\, I_\perp^{\circ}\,\tau_\perp, \tag{A2-b}$$

where t is the transmittance of the polarization filter and superscript $^\circ$ denotes the true intensities. Moreover, the conditions with two polarization filters are considered. The observed intensity is denoted as $I_{\perp/\!/}^{obsd}$ when one filter is set perpendicular and the other parallel to the slit; it is denoted as $I_{\perp\perp}^{obsd}$ when both filters are set perpendicular to the slit. These two intensities are expressed as

$$I_{\perp/\!/}^{obsd} = t_1 t_2(\beta_1\, I_{/\!/}^{\circ}\,\tau_{/\!/} + \beta_2\, I_\perp^{\circ}\,\tau_\perp) \tag{A3-a}$$

and

$$I_{\perp\perp}^{obsd} = t_1 t_2(\beta_1\,\beta_2\, I_{/\!/}^{\circ}\,\tau_{/\!/} + \beta_2\, I_\perp^{\circ}\,\tau_\perp) \tag{A3-b}$$

where subscript 1 and 2 denote the two different polarization filters.

If these two polarization filters are completely identical, the following relations are satisfied:

$$t_1 = t_2 \equiv t \text{ and } \beta_1 = \beta_2 \equiv \beta. \tag{A4}$$

For this condition, the extinction coefficient of the polarization filter, β, can be expressed as

$$\beta = \frac{(1-u+v+uv) \pm \sqrt{(1-u+v+uv)^2-4u^2}}{2u}, \tag{A5}$$

where

$$u \equiv \frac{I_\perp^{obsd}}{I_{/\!/}^{obsd}} = \frac{\beta+\gamma}{1+\beta\gamma} \tag{A6-a}$$

and

$$v \equiv \frac{I_{\perp\perp}^{\text{obsd}}}{I_{\perp/\!/}^{\text{obsd}}} = \frac{\beta^2+\gamma}{\beta+\beta\gamma} \tag{A6-b}$$

Simultaneously, γ and t are

$$\gamma = \frac{u-\beta}{1-u\beta} \tag{A7}$$

and

$$\gamma = \frac{I_{/\!/}^{\text{obsd}} + \tau_{\perp}^{\text{obsd}}}{(1+\beta)I^{\text{obsd}}}, \tag{A8}$$

where I^{obsd} is the observed intensity with no polarization filter. Equations A5-A8 were previously described in Ref. 21.

However, since it is very difficult to obtain two completely identical polarization filters, we analyzed expressions of the observed intensitites without the relations A4. An analysis of the expressions was made using the following definitions:

$$u_i = \frac{\beta_i+\gamma}{1+\beta_i\gamma}, \quad (i=1, 2) \tag{A9}$$

$$v_{12} = \frac{\beta_1\beta_2+\gamma}{\beta_1+\beta_2\gamma}, \tag{A10}$$

$$\beta_1 \equiv \beta, \tag{A11}$$

and

$$\beta_2 \equiv \beta + \beta'. \tag{A12}$$

REDUCE ver. 3.0, a computer language for mathematical analysis, was operated on a computer, IBM 3083. Equations All and A12 are essential for solving the expressions, because of the complexity of the relations. The results of the analysis are

$$\begin{aligned}\beta = [&(u_1^2u_2v_{12} - u_1^2u_2 + 2u_1u_2 + u_2v_{12} + u_2 + u_1^2v_{12} - u_1^2 - 2u_1v_{12} - v_{12} - 1) \\ &\pm (u_1+1)\{(v_{12}+1)(u_1-1) \\ &\times (u_1u_2^2v_{12} - 3u_1u_2^2 - u_2^2v_{12} - u_2^2 + 2u_1u_2v_{12} + 2u_1u_2 \\ &+ 2u_2v_{12} + 2u_2 - 3u_1v_{12} + u_1 - v_{12} - 1)\}^{1/2}] \\ &\div \{2u_1(u_1u_2 + u_2v_{12} - u_1v_{12} - 1)\},\end{aligned} \tag{A13}$$

$$\beta' = \frac{(1+\beta\gamma)u_2 - (\beta+\gamma)}{1-\gamma u_2}, \tag{A14}$$

and

$$\gamma = \frac{u_1-\beta}{1-u_1\beta} = \frac{u_2-(\beta+\beta')}{1-u_2(\beta+\beta')}. \tag{A15}$$

Usually, $u_i \approx \gamma \approx 1$, $\beta \ll 1$, and $v_{12} \gg 1$. Therefore, sufficient care concerning the experimental accuracy must be taken when determinating these equations.

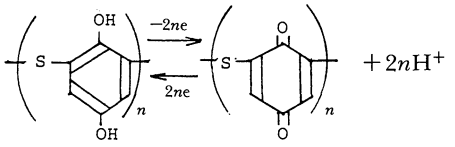
Electrochemical Studies of Poly(mercaptohydroquinone) and Poly(mercapto-*p*-benzoquinone) Films Prepared by Electrochemical Polymerization. V. Spectroelectrochemistry of Ten pH Indicators in the Film

Gorou ARAI,* Kenji IMAI, Ken-ichiro TANAKA, and Iwao YASUMORI
Department of Applied Chemistry, Faculty of Engineering, Kanagawa University, Kanagawa-ku, Yokohama 221
(Received July 26, 1990)

The electroconductive, almost colorless and transparent poly(mercaptohydroquinone/mercapto-*p*-benzoquinone) film, prepared by electropolymerization of mercaptohydroquinone on an SnO_2/glass electrode, was impregnated with a pH indicator. The film exhibited a clear electrochromic behavior arising from proton release/consumption within the film by electrooxidation/reduction, as verified by spectroelectrochemical measurements. For ten different pH indicators examined, such a color change could be well repeated over a long-term continuous experiment by use of potential steps.

There has been considerable interest in examining transition metal oxides,[1] conductive polymer films prepared by electropolymerization,[2] and electrochromic active sites introdueed in polymers as the basis for electrochromic displays.[3] The spectroelectrochemical response observed with these materials comes directly from the coloration of their electrochemically reduced or oxidised form. As described in a series of papers,[4] poly(mercaptohydroquinone) (SQ_{Red}) and poly(mercapto-*p*-benzoquinone) (SQ_{Ox}) are electroconductive and almost transparent films. These redox polymers (SQ, standing for SQ_{Red} and/or SQ_{Ox}) exhibit no change in the shape of the cyclic voltammogram over more than 1000 times repetitive potential scannings from +0.7 V vs. a saturated calomel electrode (SCE) to the H_2 evolution potential. The oxidation-reduction equilibrium between SQ_{Ox} and SQ_{Red} is represented by the following scheme.



Hence, the pH value in an SQ film in contact with an aqueous solution will be decreased by oxidation, while increased by reduction of the film. When a pH indicator is incorporated into the polymer film, the film will exhibit a color change characteristic of the pH indicator by oxidation-reduction of the film. Spectroelectrochemical properties of phenolphthalein, a typical pH indicator, incorporated within the SQ film on a transparent electrode (SnO_2/glass) was briefly reported in a previous paper,[5] where phenolphthalein showed a distinct color change between red by reduction and transparent by oxidation of the film. Here we describe spectroelectrochemical behaviors of ten different pH indicators incorporated within the polymer film and the characteristics of the electrochromic electrodes thus prepared.

Experimental

Chemicals and Preparation of SQ Films. Mercaptohydroquinone was synthesized and purified according to the method described in our previous papers.[6] All of the pH indicators and inorganic reagents used here were of reagent grade and used without further purification. Deionized water was used for preparation of solutions and rinsing the SQ film. The substrate electrode was an SnO_2/glass plate (Taiyo Yuden Co.). The SnO_2/glass plate was washed with acetone and rinsed with water. The SnO_2/glass plate was coated with an SQ film by anodic polymerization of 10 mM (1 M=1 mol dm^{-3}) mercaptohydroquinone at a potential of +0.7 V vs. SCE in a Britton-Robinson buffer solution of pH 7.0 containing 20% volume fraction ethanol in an N_2-atmosphere at room temperature.

Apparatus and Procedure. Potentiostatic electrolysis and cyclic voltammetry were performed with a Toho Technical Research potentiostat/galvanostat Model 2020. The

electrode surface was examined with a JEOL scanning electron microscope (SEM) Model JSM-35C. Spectroelectrochemical study of the pH indicator-impregnated electrodes was done with a three-electrode system consisting of an SCE reference electrode, a Pt wire counter electrode, and an electrochromic working electrode placed in a Shimadzu spectrophotometer Model UV-240. The electrochromic working electrode consisted of a pair of pH indicator-impregnated electrodes held together face to face via two 0.5-mm thick silicone rubber spacers as shown in Fig. 1.

Incorporation of pH Indicators. Incorporation of pH indicators into the SQ films was carried out by three different methods: (1) electropolymerization of mercaptohydroquinone in a Britton-Robinson buffer solution containing 50% volume fraction of ethanol, saturated with the pH indicator, (2) dipping of the SQ film-coated SnO_2/glass electrode in an ethanol solution saturated with the pH indicator for ca. 20 h, and (3) spray of an ethanol solution containing the pH indicator on the SQ film-coated electrode. The electrochromic cells prepared by methods (1) and (2) were inferior to the cell prepared by method (3) with regard to the optical density, which depends the amount of the pH indicator incorporated within the SQ film, for all of the pH indicators examined. Moreover, the electrochromic cell prepared by method (3) exhibited good reproducibility in color change when the SQ film was repetitively oxidized/reduced. In view of this, the electrochromic cell used in this work was prepared by method (3). The SQ_{Ox} film prepared on an SnO_2/glass electrode was rinsed with methanol, washed with water, and then air-dried. A small amount (ca. 0.05 cm^3) of an ethanol solution containing 10% volume fraction of water and 2% mass fraction of a pH indicator was sprayed on a dried SQ film of 1 cm^2 in area. A pH indicator-impregnated SnO_2/glass electrode was then soaked in a 1 M KCl aqueous solution adjusted to a pH value slightly lower than the value where the indicator changes the color, by adding a small amount of an HCl and/or KOH aqueous solution, and used immediately as an electrochromic working electrode. The 1 M KCl solution thus conditioned was also used as the supporting electrolyte solution. The pH value of the 1 M KCl solution adjusted to each of the pH indicators is denoted by "pH in cell" in the last column of Table 1.

Results and Discussion

Properties of SQ Films on SnO_2/Glass. Figure 2 shows the relationship between the time of electrooxidation of mercaptohydroquinone and the amount of the SQ film formed on the SnO_2/glass electrode, calculated from their cyclic voltammograms (CV). The amount of the SQ film increased linearly with the electrolysis time up to 40 min. However, the SQ film became colored in dark yellow by electrolysis for more than ca. 20 min. Therefore, all the SQ films used in this work were prepared by 20-min electrooxidation. A typical CV of the resulting SQ film on an SnO_2/glass electrode is shown in Fig. 3. A pair of broad anodic and cathodic waves arising from reduction-oxidation of the SQ film were observed with peaks at

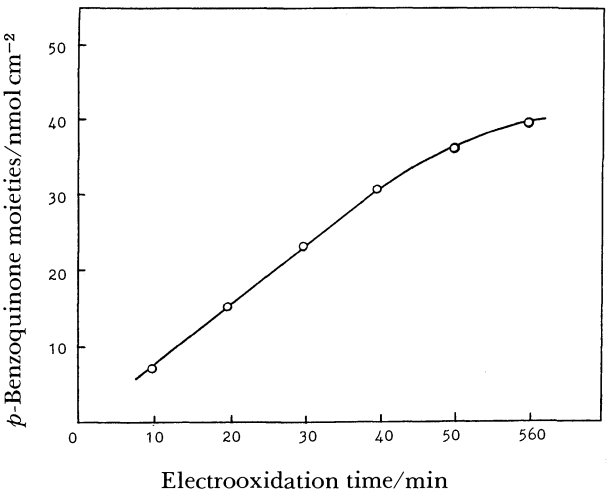

Fig. 2. Increase in the amount of quinone moieties in the SQ film on SnO_2/glass electrode with the lapse of electrooxidation time. The electrooxidation was carried out by anodic oxidation (+0.7 V vs. SCE) of 10 mM mercaptohydroquinone using Britton-Robinson buffer solution (20 vol% EtOH) in N_2 atmosphere.

Table 1. Electrochromic Characteristics of pH Indicator-Impregnated SQ Films Prepared on SnO_2/Glass Electrode[a)]

pH indicator	Color change(pH)	Response time	pH in cell
	Acid color ⟷ Basic color	s	
Bromophenol Blue[b)]	Yellow(3.0) ⟷ Blue(4.6)	5—7	2.9
Bromocresol Green[b)]	Yellow(3.8) ⟷ Green(5.4)	3—4	3.6
p-Nitrophenol	Colorless(5.0) ⟷ Yellow(7.6)	2—3	4.8
Bromothymol Blue	Yellow(6.0) ⟷ Blue(7.6)	2—3	5.8
Indooxine	Red(6.0) ⟷ Blue(8.0)	2—3	5.8
Quinoline Blue	Colorless(6.6) ⟷ Blue(8.6)	<2	6.4
Phenol Red[b)]	Yellow(6.8) ⟷ Red(8.4)	3—4	6.6
o-Cresolphthalein	Colorless(8.2) ⟷ Red(9.8)	<2	8.0
Phenolphthalein	Colorless(8.3) ⟷ Red(10.0)	<2	8.0
Thymolphthalein	Colorless(9.4) ⟷ Blue(10.6)	4—5	9.0

a) All data are average of 10 or more experiments. b) Potential stepping was carried out between −0.5 V and 0.7 V vs. SCE.

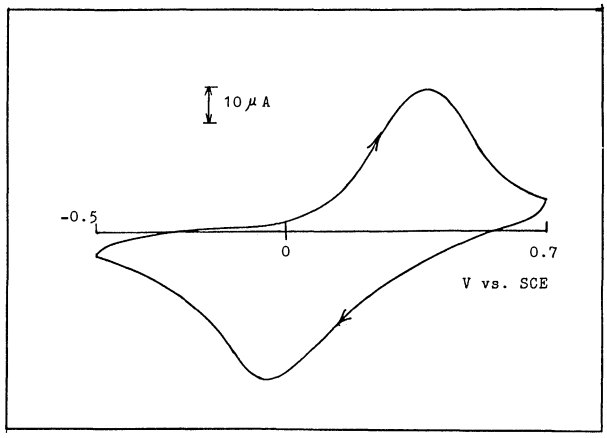

Fig. 3. Cyclic voltammogram of the SQ film prepared on SnO_2/glass electrode (1 cm^2 in area) in Britton-Robinson buffer solution (pH 5.0). The sample electrode was prepared under the same conditions as in Fig. 2.
Electrolysis time: 20 min, Sweep rate: 2 mV s^{-1}.

0.38 V and −0.05 V vs. SCE, respectively. The surface concentration of hydroquinone and/or *p*-benzoquinone moieties was calculated to be ca. 15.6 nmol cm^{-2}. This indicates that in an aqueous solution with a pH value at which one hydroquinone moiety releases two protons via a two-electron reaction, complete oxidation of SQ_{Red} to SQ_{Ox} may increase the amount of proton by 31.2 nmol, while on complete reduction of SQ_{Ox} to SQ_{Red} the same amount of proton may be lost per one sheet of electrode. Hence, in an electrochromic working electrode of 0.5 mm in thickness and 1 cm^3 in area (0.05 cm^3 in volume), the increase and/or decrease in the amount of hydrogen ion is twice this value because two sheets of working electrodes were used. Examination of the SQ film by SEM revealed that the dried film prepared by 20-min electrooxidation of mercaptohydroquinone (Fig. 4(b)) covered the whole surface of the SnO_2/glass electrode, though the film was rougher than that on a glassy carbon electrode.[7] The film thickness was estimated to be 1—2 μm and even after repeated water washings no appreciable morphological change was observed.

Spectroelectrochemical Properties. Figure 5 depicts the absorption spectrum of a colored *o*-Cresolphthalein-impregnated SnO_2/glass electrode when SQ_{Ox} was reduced to SQ_{Red} at −0.7 V, with the dashed curve showing the spectrum of an SnO_2/glass electrode coated with SQ_{Red} alone. In addition, the inset gives a typical absorption spectrum of a colored *o*-Cresolphthalein alkaline solution. The absorption maximum at 565 nm observed for the colored working electrode is in good agreement with that of colored *o*-Cresolphthalein in an alkaline solution. This indicates that the coloration observed on the working electrode is obviously due to that of *o*-Cresolphthalein within the SQ_{Red} film. When the potential of the colored working electrode was stepped to +0.7 V where SQ_{Red} was oxidized to SQ_{Ox}, the absorption spectrum based on the coloration rapidly disappeared. This spectral change was easily observed visually, namely the working electrode became red in a few seconds when reduced and colorless when oxidised. Then the potential was changed by use of square voltage pulses, and both the optical response at 565 nm and the current response were recorded. The result is illustrated in Fig. 6. The time course of absorvance response was almost the same for anodic and cathodic potential steps even after 10 min of the repetitive potential steps. But a small amount of the colored indicator was observed to seep out of the gap between the two sheets of SnO_2/glass electrodes into the solution bulk when the potential step had been continued for more than ca. 10 min.

Similar spectroelectrochemical behaviors were

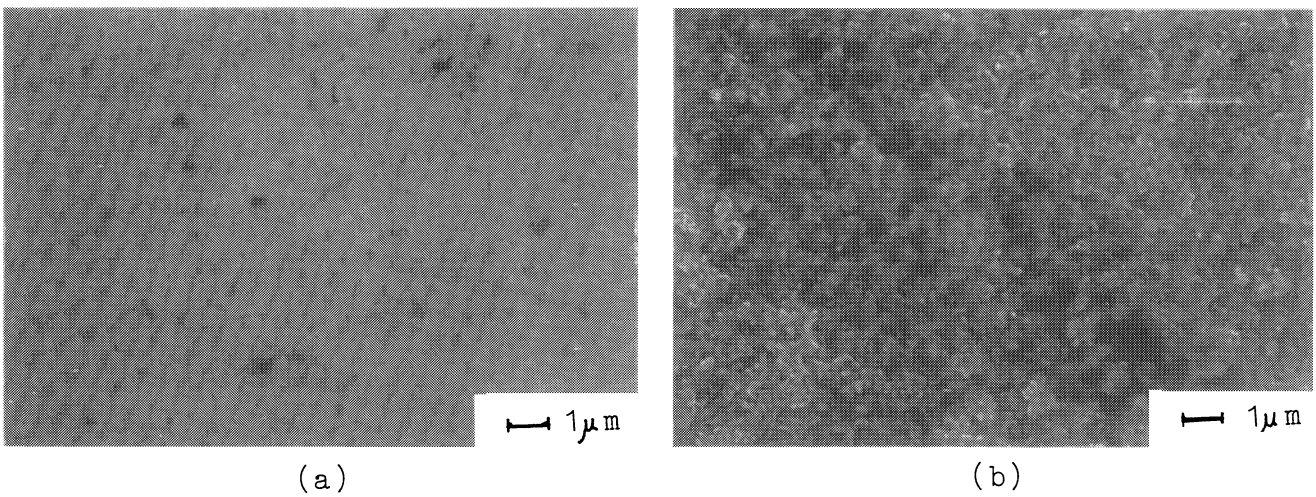

Fig. 4. SEM photograph of the bare surface (a) and the SQ film-coated surface (b) of SnO_2/glass electrode. The SQ film-coated electrode was prepared under the same conditions as in Fig. 3.

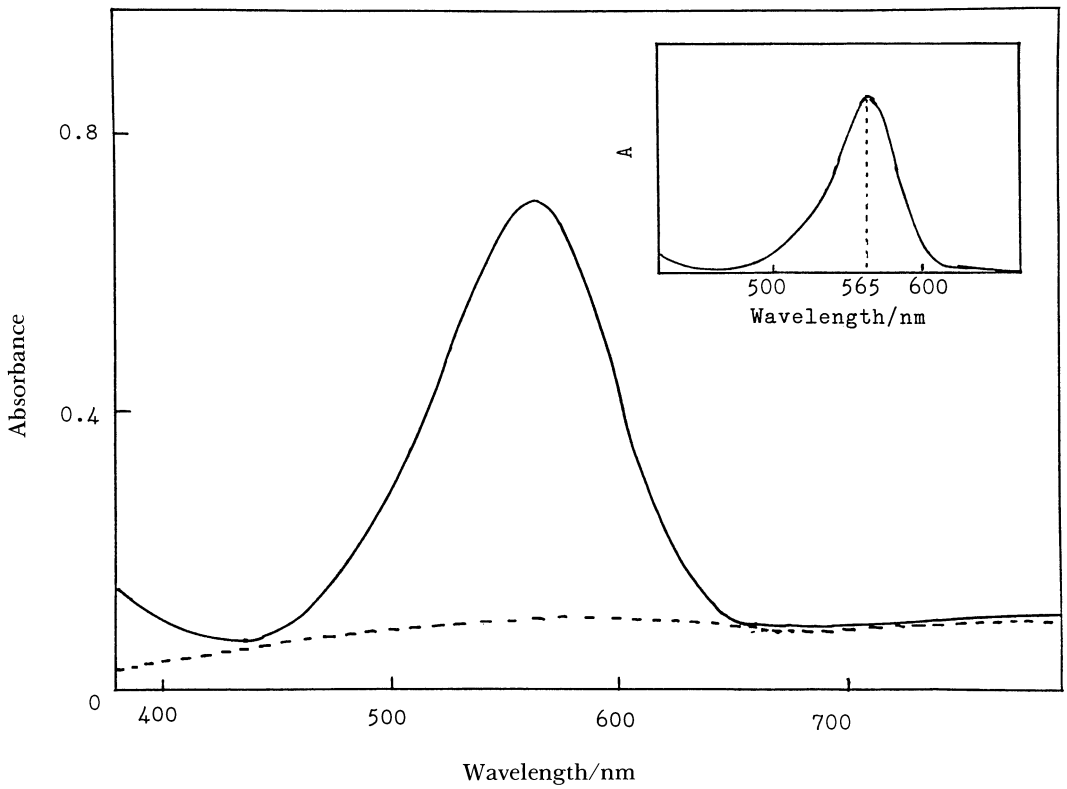

Fig. 5. Absorption spectrum of colored *o*-cresolphthalein incorporated within SQ_{Red} film on SnO_2/glass electrode (solid curve). Dashed curve represents the absorption spectrum of the SQ_{Red} film alone on SnO_2/glass electrode. Inset shows the absorption spectrum of a colored *o*-cresolphthalein alkaline solution.

observed for the other indicators incorporated within the SQ film. Their spectroelectrochemical properties are given in Table 1. Most of the pH indicators examined here exhibited their characteritic color change within ca. 5 s by a potential step of the working electrode. Almost no decrease in optical density of the colored working electrode was observed at least within 10-min run of repetitive potential steps. Moreover, the shaped CV of the SQ film on the SnO_2/glass electrode remained unchanged even after a long-term run of repetitious potential steps. This demonstrates that neither the hydroquinone nor *p*-benzoquinone moiety in the SQ film reacts with the pH indicators examined here. A slight seepage of the colored pH indicator as in the case of *o*-Cresolphthalein was observed in every case.

Bromophenol Blue, Bromocresol Green, and Phemol Red underwent electrochemical reduction in a potential range from −0.7 V to −0.5 V. Therefore, for these indicators the potential of the working electrode was stepped between −0.5 V and +0.7 V. The positive shift in the negative-end potential from −0.7 V to −0.5 V tended to lengthen the response time of the color change at basic pH's. This tendency is reasonable since the response speed of the color change may depend on the rate of reduction-oxidation of the SQ film. Bromophenol Blue which

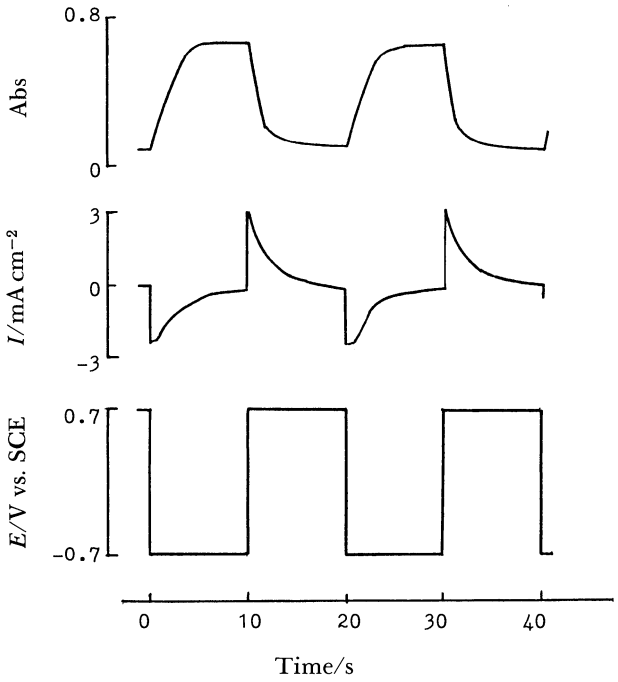

Fig. 6. Response of absorbance and current to a square voltage pulse for the *o*-cresolphthalein-impregnated SQ film (prepared on SnO_2/glass electrode under the same conditions as in Fig. 3) measured in a supporting electrolyte solution of pH 8.0 (see Table 1).

exhibits a color change in the lowest pH range among the pH indicators listed in Table 1, required the longest time for the color change. Thymol Blue, which should change color from red to yellow by a pH range from 1.2 to 2.8, showed no color change even when the potential was stepped between −0.7 V and +0.8 V vs. SCE. Hence Thymol Blue was omitted from Table 1. Judging from the estimate that the decrease in the amount of H^+ ion in the working electrode by reduction of SQ_{Ox} to SQ_{Red} is 62.4 nmol (see above), the phenomena observed for these two pH indicators may be rationalized. In line with this, a slower response in color change was observed also for Thymolphthalein, which should change color in a relatively strong alkaline range, namely between pH 9.4 and 10.6. In a previous work,[8] we found that an SQ_{Red}-coated carbon electrode showed pH response with a slope of ca. −59 mV/pH over a pH range from 1.8 to 8.5, and with a slope of ca. −30 mV/pH above pH 10. This indicates that the pK_1 of the hydroquinone moiety in the SQ film is nearly 8.5. Hence, the slow response of the color change for Thymolphthalein is understandable in this content.

The present results demonstrate that ten different pH indicators incorporated within the SQ film on an SnO_2/glass electrode show well-repetitive characteristic color changes by potential steps. In addition, the pH indicators suitable for use in the electrochromic cell employed here should change color in a pH range from 3 to 10, should not be electrochemically active over a potential range where the SQ film is oxidised or reduced, and should not chemically react with either SQ_{Red} or SQ_{Ox}.

Limiting Partial Molar Volumes of Ions in Water-Methanol and Water-Acetonitrile

Fumio KAWAIZUMI,* Yoshitomo INOUE,† and Hiroyasu NOMURA†
Institute for Molecular Science, Myodaiji, Okazaki 444
†Department of Chemical Engineering, School of Engineering,
Nagoya University, Chikusa-ku, Nagoya 464-01
(Received August 22, 1990)

Measurements of densities of solution of $AgNO_3$ and $Ca(NO_3)_2$ in the mixed solvents water-methanol and water-acetonitrile were carried out at 25 °C and the partial molar volumes V_2^∞ of these electrolytes were determined by taking account of the concentration dependence of the apparent molar volumes predicted by the Debye-Hückel theory. The ionic partial molar volumes of Ag^+, Ca^{2+}, and NO_3^- were evaluated and compared with those of other ions in the two mixed solvent systems. The solvent composition dependence is more remarkable in water-acetonitrile than in water-methanol, and characteristic behavior was observed for Ag^+ and Ca^{2+} ions in water-acetonitrile system.

First light was shed on the selective solvation of ions in mixed solvent wate-acetonitrile(AN) by Schneider and Strehlow[1] more than 30 years ago. These authors argued that the ion Ag^+ is preferentially solvated by acetonitrile, while in the solvation shell of the ion NO_3^- the solvation of water molecules is preferential. In the second paper,[2] they reported the preferential solvation of water to Ca^{2+} and Cl^- ions in water-methanol mixtures. However, this second paper seems to draw less attention than their first paper. Following Schneider and Strehlow[1] a number of workers have investigated the problem of selective solvation of ions in water-acetonitrile mixture. The quantities investigated are, for example, transfers of thermodynamic function,[3-5] $\Delta_t X$ (X=G, H, S), transport numbers,[6,7] and ionic molar conductivities.[8,9]

In our series of work on solute-solvent interaction in mixed solvents,[10-13] special emphasis has been placed on the determination of the partial molar volume and partial molar adiabatic compressibility of ionic solutes and the splitting of these partial molar quantities into cationic and anionic contributions. In this paper, we will report the partial molar volumes of silver nitrate and calcium nitrate in water-methanol and water-acetonitrile systems. The dielectric behavior of these two systems is quantitatively similar up to ca. 70 mol% of water. As for solutes we must add that use of other divalent nitrates as samples was unsuccessful on account of the difficulty in obtaining completely anhydrous sample (case for $Mg(NO_3)_2$) or the limited solubility of the salts for precise measurements of the solution density (case for $Zn(NO_3)_2$, $Ba(NO_3)_2$, and $Pb(NO_3)_2$). Even for $Ca(NO_3)_2$ measurement in pure acetonitrile was impossible on account of its low solubility.

To determine the V_2^∞ values from apparent molar volumes, we adopted the theoretical coefficient S_V, the values of which for water-acetonitrile were calculated as part of this work.

To date, the partial molar volumes of electrolytes in water-acetonitrile system have been treated in the three papers.[14-16] The V_2^∞ values of 1-1 electrolytes up to 25 mol% of acetonitrile was reported recently.[14] In pure acetonitrile the ultrasonic vibration potential measurement[15] was done for the ionic division of V_2^∞ of 1-1 type salt. Using the roughly evaluated V_2^∞ values, Singh et al. reported the $\Delta_t V_2^\infty$ ($H_2O \rightarrow H_2O$/AN) for univalent ions over the whole composition of the solvent system.[16]

Experimental

Samples. Anhydrous calcium nitrate was obtained from $Ca(NO_3)_2 \cdot 4H_2O$ by keeping it in vacuo for more than 48 hours over P_2O_5. The guaranteed grade reagent methanol was dried using the molecular sieves activated at 350 °C for more than three hours. The molecular sieves were set into the solvent methanol two or three days before use and the molecular sieves were eliminated by decantation. The solvent acetonitrile was distilled with phosphorus pentaoxide which was added to the solvent in the ratio of 5 g of P_2O_5 to one dm^3 of solvent. As the anhydrous calcium nitrate is extremely hygroscopic, the sample solution of this product was prepared in a dry-box.

Measurements. As in our recent work,[11-13] densities of solution were measured with a digital vibrating density meter Anton Paar DMA-02C. All measurements were done at 298.15 K.

Results and Discussion

Partial Molar Volumes. The apparent molar volumes V_ϕ were calculated using the conventional equation

$$V_\phi = 1000\,(d_1 - d)/cd_1 + M/d_1, \qquad (1)$$

where c is the concentration of solute in mol dm^{-3} and the subscript 1 refers to solvent. The concentration dependence of V_ϕ in the experimental concentration ranges is expressed in terms of the equation

$$V_\phi - S_V c^{1/2} = V_2^\infty + hc. \qquad (2)$$

In Eq. 2 the parameter S_V is equal to $kw^{3/2}$ and the

quantities w and k are expressed as

$$w = (1/2)\sum \nu_i z_i^2, \quad (3)$$

and

$$k = 2N_o^2 e^3 (2\pi/1000RT)^{1/2} \varepsilon^{-3/2} \{(\mathrm{d}\ln\varepsilon/\mathrm{d}P) - (\kappa_T/3)\}, \quad (4)$$

where κ_T is the isothermal compressibility and other symbols have their usual meaning. The values of κ_T were obtained from the reported data.[17] From the Tait-form equation for dielectric constants found elsewhere,[18] we calculated the pressure derivatives of the dielectric constant at 0.1 MPa. Values of ε, $\mathrm{d}\ln\varepsilon/\mathrm{d}P$ and κ_T at rounded solvent composition are summarized in Table 1.

Figures 1 and 2 show the plot of Eq. 2 for the samples $AgNO_3$ and $Ca(NO_3)_2$, respectively. The parameter h of Eq. 2 is negative except for $AgNO_3$ in water-acetonitrile system. The values of h of the solute $Ca(NO_3)_2$ become negatively larger with increasing content of methanol or acetonitrile. An increase in the negative deviation from Eq. 2 with the content of organic solvent in aqueous mixed solvents has also been observed for $CaCl_2$ in water-methanol

system.[11] Such a negative deviation observed for $Ca(NO_3)_2$ is perhaps due to the ion association, the amount of which increases with decreasing dielectric constant of the solvent. In every case represented in Figs. 1 and 2, extrapolation of V_ϕ to infinite dilution was carried out by the first order least mean-squares fitting to the experimental data.

The partial molar volumes of $AgNO_3$ and $Ca(NO_3)_2$ at infinite dilution obtained are given in Table 2 and are plotted against solvent composition in Fig. 3. In water, our partial molar volumes agree satisfactorily with those found in the literature.[19,20] Among the four systems studied, direct comparison is possible only for $AgNO_3$ in water-acetonitrile. As seen in Fig. 3, our V_2^∞ ($AgNO_3$) falls fairly well on the line connecting the values reported earlier.[16] The difference in the value of V_2^∞ ($AgNO_3$) in pure acetonitrile obtained in this work (−6.4 cm^3 mol^{-1}) and that found in the literature (−3 cm^3 mol^{-1}) is too large to accept in the discussion of the V_2^∞ values in aqueous solutions. In the case of V_2^∞ values in nonaqueous solvents, however, such a degree of difference is not rare. For example, two distinctly different values 4.73[15] and 11[16] cm^3 mol^{-1} have been reported by different authors for the V_2^∞ of sodium iodide in acetonitrile.

Ionic Partial Molar Volumes. At present, experimental techniques for the ionic division of V_2^∞ of a salt are limited to the ultrasonic vibration potential and the sedimentation potential measurements. In a previous paper[12] we measured the sedimentation potential (SP) in solutions of LiCl, NaCl, and KCl dissolved in water-methanol mixtures and split V_2^∞ of these chlorides into cationic and anionic parts. In that paper, the variation of the partial molar volumes of Cl^- as well as Li^+, Na^+, and K^+ in water-methanol system with solvent composition was represented graphically. Combination of the values V_2^∞ (MX) determined in our laboratory[10-12] and those obtained in this work with the numerical values of V_2^∞ (Cl^-) obtained in our previous work[12] permits us to evaluate the partial molar volumes of various ions in water-methanol system. The calculation procedure for the nitrate and silver ions is as follows: first, we calculate

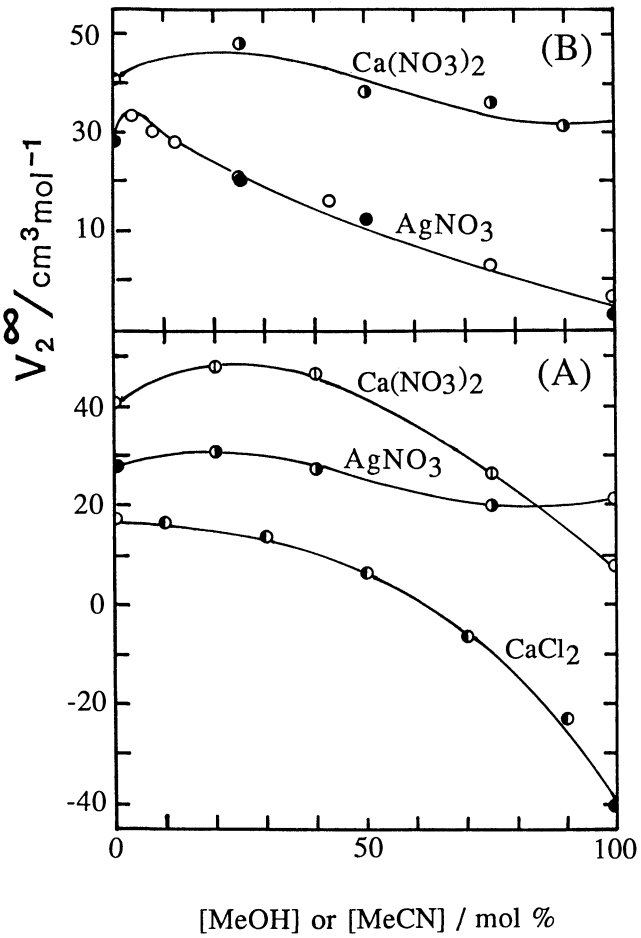

Fig. 3. Variation of the partial molar volumes with solvent composition at 25 °. (A): $Ca(NO_3)_2$, $CaCl_2$, and $AgNO_3$ in water-methanol. (B); $Ca(NO_3)_2$ and $AgNO_3$ (●; this work, ○; reported value) in water-acetonitrile.

V_2^∞ (Ca^{2+}) by subtracting V_2^∞ (Cl^-) from V_2^∞ ($CaCl_2$), then calculate V_2^∞ (NO_3^-) from V_2^∞ ($Ca(NO_3)_2$), and finally obtain V_2^∞ (Ag^+) from V_2^∞ ($AgNO_3$). The ionic partial molar volumes thus evaluated are shown in Table 4 in which the V_2^∞ values in water are included; the values in water are based on the V_2^∞ values of

electrolytes recommended by Millero,[21] while the V_2^∞ values of salt in methanol used are those obtained by adding the most recent values of ionic partial molar volumes listed by French and Criss.[23]

The ultrasonic vibration potential or sedimentation potential method has not been applied to the system water-acetonitrile system. Here, we evaluate the partial molar volumes of ion first by interpolating the V_2^∞ values reported by Singh et al.[16] and then by using the the assumption that

$$\frac{V_2^\infty(Ph_4As^+)}{V_2^\infty(BPh_4^-)} = \frac{V_{vw}(Ph_4As^+)}{V_{vw}(BPh_4^-)} = 1.0337, \quad (6)$$

where V_{vw} means the van der Waals volume. Results of this ionic division are summarized in Table 4 and also represented in Fig. 5.

a) Ref. 15 determined by the ultrasonic vibration potential method.

Making allowance for uncertainties due to various factors (V_2^∞, use of the two different methods for ionic division, etc.) we can mention at least the following several characteristic features of the ion-solvents interactions in water-methanol and water-acetonitrile.

1) The partial molar volumes of metallic ions decrease with the methanol content, except for V_2^∞ (Ag^+) in solvents with 80—100 mol% of methanol. The decrease of V_2^∞ with the methanol content is most remarkable for the divalent cation Ca^{2+} indicating that the decrease of V_2^∞ is mainly electrostatic. The increase of V_2^∞ ($Ca(NO_3)_2$) observed in Fig. 3(A) is totally ascribable to the ion NO_3^-. Roughly speaking, in the mixed solvent water-methanol, the change of partial molar volume accompanying the solvent change, $\Delta_t V_2^\infty$, is similar for all the alkali metal ions (see Fig. 4).

2) In water-acetonitrile system, the solvent composition dependences of ionic partial molar volumes are drastically different from those in water-methanol. As mentioned earlier, for water-methanol and water-acetonitrile the bulk dielectric constants (ε) are similar in magnitude; the only difference is that ε is 35.9 for pure acetonitrile and 32.6 for methanol. The interpretation of the differences in the behavior of various ions represented in Figs. 4 and 5 in terms of the bulk dielectric constant of the solvents is obviously impossible. It must be stressed that the V_2^∞ of ions depends strongly on the degree of steric hindrance of the poles of the solvent molecule dipole and the properties of the solvent layer around the ion.[15,24] The acetonitrile molecule has the dipole moment μ equal to 3.913 Debye (1 Debye=3.336×10^{-30} Cm), while those of methanol and water are 1.69 and 1.94 Debye, respectively. The negative pole of the acetonitrile is located at the nitrogen atom of the -C≡N group, and in both methanol and water, the negative and positive poles are on oxygen and hydrogen atoms, respectively. Hence, the nature of solvation at the microscopic level varies to a lesser extent with the solvent composition in water-methanol than in water-acetonitrile.

3) For large univalent ions [Ph_4As^+] and [BPh_4^-] the differences between V_2^∞ ([Ph_4As^+]) and V_2^∞ ([BPh_4^-]) are independent of the solvent composition.

4) The V_2^∞ (NO_3^-) and V_2^∞ (Cl^-) decrease in a similar way with the acetonitrile content. The increase of V_2^∞ ($AgNO_3$) observed in the water-rich region in the water-acetonitrile system (see Fig. 3) is attributed not to the anion NO_3^- but to the cation Ag^+, in contrast to the case of $Ca(NO_3)_2$ in the water-methanol system mentioned above. For the ions Ag^+ and Na^+, the extremum appears in the relationship between the respective V_2^∞ values and the acetonitrile content in the solvent system. The acetonitrile content giving the maximum V_2^∞ value corresponds to the solvent composition at which the values of isothermal compressibility κ_T pass through a minimum. The fact that the acetone content for the maximum of V_2^∞ (Ag^+) is far lower than that of V_2^∞ (Na^+) demonstrates the different behavior of ion Ag^+ from the alkali metal ion.

5) The result for Ca^{2+} in water-acetonitrile is the most striking one detected by the ionic splitting of V_2^∞ of the electrolytes investigated.

Silica-Supported Boron Phosphate Catalyst Prepared by Chemical Vapor Deposition

Satoshi SATO,* Mitsuharu HASEGAWA, Toshiaki SODESAWA, and Fumio NOZAKI
Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 260
(Received September 6, 1990)

A silica-supported boron phosphate (BPO_4) catalyst was prepared by chemical vapor deposition (CVD) using mixtures of boron triethoxide and phosphoryl trimethoxide. Both the amount and the P/B ratio of deposited BPO_4 were changed with the CVD temperature and time. At the optimum CVD temperature of 300 °C, the amount of deposited BPO_4 was linearly increased with the CVD time. When alkoxide mixtures with the desired P/B ratio were used as CVD sources at 300 °C, the expected P/B ratios were available. At CVD temperatures below 300 °C, neither a sufficient amount nor a desired P/B ratio was given. On the other hand, above 325 °C, the deposition was suppressed by blocking the micropore of silica, especially for long-time CVD operation, owing to the too fast deposition. Although the resulting surface compound was amorphous, it was revealed to have microstructures of BPO_4 by means of a ^{31}P NMR measurement. The amorphous BPO_4 dispersed highly on silica exhibited a high catalytic efficiency for the isomerization of 1-butene and a simultaneous oligomerization of 1-butane in comparison with a catalyst prepared by the conventional impregnation method.

Boron phosphate (BPO_4) is known to be a solid acid which is an effective catalyst for various organic reactions such as hydration,[1] dehydration,[2-5] alkylation,[6-8] and oligomerization.[9,10] The catalytic activities depend on the ratio P/B. In a region including excess phosphorus, BPO_4 catalysts have a large percentage of Brønsted acid sites,[2,11] and exhibit catalytic activities for such reactions as the hydration of ethylene,[1] the dehydration of ethanol to ethylene,[2] and the oligomerization of 1-decene.[10] In contrast, in a region including excess boron, BPO_4 catalysts consist predominately of Lewis acid sites,[2,11] and show catalytic efficiencies for the dehydration of ethanol to diethyl ether,[2] the dehydration of 2-methylbutanal to isoprene,[5] the ethylation of phenol,[8] and the Beckmann rearrangement of cyclohexanone oxime.[2] Unsupported BPO_4, however, has a relatively small surface area and its catalytic activity is often poor. Whereas BPO_4 with surface areas of more than 100 $m^2 g^{-1}$ have been reported,[12,13] carefulness is required for any reproducible preparation. In addition, it is difficult to impregnate a support material with uniform BPO_4 because of its poor solubility.

Several attempts have been made to prepare a supported type of solid acids such as silica-supported boria,[14] alumina-supported boria,[15] and alumina-supported silica[16,17] by means of chemical vapor deposition (CVD) using the respective metal alkoxides. The alkoxides were easily decomposed into the respective metal oxide on the surface of the support in the presence of oxygen. The highly dispersed boria catalysts, having a weak interaction with the support materials, exhibited an excellent catalytic efficiency for a vapor-phase Beckmann rearrangement of cyclohexanone oxime.[14,15] The alumina-supported silica, having a strong interaction between the silica and alumina to form composite-oxides on the surface of alumina support, showed high catalytic activities for several organic reactions such as cracking, isomerization, and dehydration,[16,17] which was comparable to those of commercial silica-alumina catalyst.

In the present work, we prepared a silica-supported boron phosphate catalyst (CVD BPO_4/SiO_2) by the simultaneous deposition of boron and phosphorus components onto a silica surface using a mixed vapor of boron triethoxide and phosphoryl trimethoxide, and investigated both the structural and catalytic properties of the deposited boron phosphate.

Experimental

A CVD BPO_4/SiO_2 catalyst was prepared by bringing a mixture of boron triethoxide ($B(OEt)_3$) and phosphoryl trimethoxide ($PO(OMe)_3$) into contact with a silica (ID type gel supplied by Fuji Davison Chemical Ltd.: surface area, 145 $m^2 g^{-1}$; pore volume, 1.0 $cm^3 g^{-1}$; particle size, 0.1—0.6 mm.) in a CVD reactor described previously.[17] The mixture of alkoxides with the prescribed P/B ratio, containing 5 wt% methanol, was supplied together with air as a carrier gas (400 mmol h^{-1}) at a flow rate of 1.7—2.4 mmol h^{-1}. Both the BPO_4 loading and the P/B ratio in the catalyst sample were determined by the alkalimetric titration of H_3BO_3 and H_3PO_4, which were extracted from the sample with hot water. The extracted H_3PO_4 was titrated with sodium hydroxide, followed by titration of the extracted H_3BO_3, whose acidity was strengthened by addition of mannitol. An impregnation catalyst (IMP BPO_4/SiO_2) was obtained by immersing a silica support in an aqueous solution of H_3BO_3 and H_3PO_4, drying at 110 °C and calcining at 300 °C for 2 h.

Isomerization of 1-butene was carried out in a closed circulation system (reactor volume: 250 ml, catalyst: 0.2 g) with a butene initial pressure of 19 kPa at 50 °C. Prior to the reaction, a catalyst was heated in the reactor at 500 °C for 1 h under reduced pressure (0.1 Pa). The catalytic performance for the isomerization of 1-butene was evaluated by the 1st-order rate constant during the initial reaction period, and for a simultaneous side reaction of 1-butene oligomerization, forming mainly C_8 olefins by a conversion which was calculated from the pressure drop in the circulation system after the reaction had proceeded for 1 h.

An X-ray difractogram (XRD) was recorded using a Rigaku Giger Flex. A ^{31}P magic angle-spinning (MAS) NMR measurement was performed at 161.98 MHz at a spinning rate of 4 kHz with a Bruker AM-400, while H_3PO_4 was used as an external standard. Time intervals of 2 s were allowed between pulse sequences with 4 μs and 500 free induction decays were accumulated for each sample. The samples were used for the measurement without any further pretreatment.

The amount of chemisorbed ammonia was measured using a static volumetric method. Prior to adsorption, 0.5 g of the catalyst was evacuated at 500 °C for 1 h. A first adsorption of ammonia was performed at the prescribed temperature at pressures of about 1.2 kPa, followed by several repetitions of adsorption until obtaining a final pressure of 6.6 kPa. The amounts of physisorbed and chemisorbed smmonia were estimated by extrapolating the given isotherm. The physisorbed ammonia was desorbed by evacuating the sample at the same temperature as in the first adsorption for 1 h; then, only the physisorbed ammonia was measured with the second adsorption. The amount of chemisorbed ammonia was evaluated by the difference between the first and second adsorption of ammonia.

Results and Discussion

Deposition of Boron Phosphate. Figures 1 and 2 show the effects of the CVD temperature upon BPO_4 deposition for a source P/B ratio of 1. For a CVD time of 3 h or above, the BPO_4 loading exhibited a maximum at a CVD temperature of 300 °C, while the BPO_4 loading slightly increased with increasing CVD temperature for CVD times of 1 and 2 h (Fig. 1). This is related to the change in surface area of the catalyst, and is discussed later. At 300 °C, the BPO_4 loading was increased monotonously with a CVD time up to a maximum of 0.96 g g-silica^{-1} for 5 h. Such a large loading could not be realized by the impregnation method. The P/B ratio in the catalyst changed with both the CVD temperature and time (Fig. 2). At CVD temperatures below 300 °C, espe-

cially for a short CVD time, the P/B ratio became smaller than 1. At CVD temperatures of 300 °C and above, however, the P/B ratio nearly equaled 1. Therefore, both the sufficient deposition rate and the expected P/B ratio were attained at 300 °C.

Figure 3 shows a comparison of the individual deposition with a simultaneous deposition of both the boron and phosphorus components. When either $B(OEt)_3$ or $PO(OMe)_3$ was fed individually, the deposition behavior of individual oxides was similar to each other. At a CVD temperature of 325 °C, either B_2O_3 or P_2O_5 was readily deposited on SiO_2, whereas at temperatures lower than 325 °C, the individual oxides were slowly deposited. In contrast to individual deposition, the simultaneous deposition of boron and phosphorus components satisfactorily proceeded, even at 275 °C with a P/B ratio of 1. The simultaneous supply of alkoxides drastically lowered the deposition temperature, and the deposition of BPO_4 proceeded with an excess boron component at 250 °C at which the individual oxides could hardly be deposited. Although oxygen accelerated the deposition rate of individual oxide, such as B_2O_3,[14] BPO_4 was deposited on silica even in the absence of oxygen at 300 °C. Moreover, both B_2O_3/SiO_2 and P_2O_5/SiO_2 prepared by CVD using the corresponding alkoxides at 350 °C were inactive for the isomerization of 1-butene, while the BPO_4/SiO_2 prepared at 300 °C was catalytically active. These results indicate that the deposition of BPO_4 occurred on the surface of silica with an accompanying formation of boron phosphate.

Figures 4 and 5 show the effects of the P/B ratio in the CVD source upon BPO_4 deposition. At an optimum CVD temperature of 300 °C, the BPO_4 loading almost reached the maximum deposition expressed by dashed lines for each CVD time (Fig. 4). Furthermore, the P/B ratio in the catalyst nearly equaled the source P/B ratio, whereas an excess boron component

was deposited for a short CVD time of 1 h (Fig. 5). Consequently, BPO_4 with the desired P/B ratio could be deposited on a silica support at 300 °C by controlling the source P/B ratio in the range between 0.7 and 1.4.

Structure of Deposited Boron Phosphate. Figure 6 shows changes in specific surface area with BPO_4 loading. For CVD BPO_4/SiO_2 catalysts prepared at 300 °C, the surface area based on the unit weight of the silica support did not change, even at a BPO_4 loading of 0.6 g g-silica^{-1}, whereas those of the impregnation catalysts linearly decreased with an increase in BPO_4 loading. Above the loading of 0.6 g g-silica^{-1}, however, it steeply decreased with an increase in BPO_4 loading. On the other hand, for CVD catalysts prepared at 350 °C, the surface area decreased with BPO_4 loading in a similar manner as those of IMP BPO_4/SiO_2 catalysts. As shown in Fig. 1, BPO_4 loading decreased at high CVD temperatures. This fact is speculated to be caused by concentrated deposition onto the entrance of the micropore of the support, followed by a closure of the micropore. These findings in Figs. 1 and 6 suggest that a uniform deposition of BPO_4 was attained at 300 °C, owing to an optimum deposition rate of BPO_4.

Figure 7 illustrates the XRD spectra of BPO_4 catalysts. An unsupported BPO_4 exhibited sharp crystalline diffraction peaks at 2θ=24.5, 40.0, and 49.0 attributed to a cristobalite-type structure[2] (Fig. 7-a). An IMP BPO_4/SiO_2 catalyst also showed the same diffraction patterns as unsupported BPO_4 with low crystallinity, even after drying at 110 °C (Fig. 7-b). None of the CVD BPO_4/SiO_2 catalysts, however, showed any diffraction peaks, indicating that the BPO_4 deposited on silica was amorphous.

The ^{31}P MAS NMR of the catalyst was measured in order to elucidate the amorphous phase of deposited BPO_4. For a P/B ratio of 1, an unsupported crystalline BPO_4 showed a sharp resonance at −29.6 ppm together with two small signals at 0.4 and −21.7 ppm (Fig. 8-a). The chemical shift at −29.6 ppm is a characteristic signal for a crystalline BPO_4, which is considered to be caused by a phosphate anion tetrahedrally coordinated by four boron atoms. An additional shift at 0.4 ppm may be attributed to a free phosphate anion, such as phosphoric acid. The silica-supported P_2O_5 had two characteristic chemical shifts at −43.9 and 0.3 ppm (Fig. 8-b). The chemical shifts of P_2O_5 are quite different from those of BPO_4.

For a P/B ratio of 1.1, the ^{31}P MAS NMR spectra of BPO_4 catalysts are shown in Fig. 9. Both the

unsupported BPO_4 and the IMP BPO_4/SiO had three chemical shifts at −29.5, −21.5, and 0.4 ppm (Fig. 9-a and b) in similar manner as for Fig. 8-a. An increase in the phosphorus content weakened the intensity of the shift at −29.2 ppm, and strengthened that at 0.4 ppm. The CVD BPO_4/SiO_2 had two other signals at −14.3 and −7.4 ppm in addition to the above-mentioned three chemical shifts (Fig. 9-c). Further, the chemical shift at 0.4 ppm was split into two signals at 0 and 1.1 ppm. These five chemical shifts, except for that at 1.1 ppm, each appeared at about 7.2 ppm intervals between 0 and −29.1 ppm. For chemical shifts of ^{29}Si in aluminosilicates, the most characteristic trend is that substitution of the Si ions in silicate tetrahedra by Al ions leads to low-field shifts at each 4 to 6 ppm intervals.[18] The five ^{31}P chemical sifts suggest that not less than 5 different types of phosphate tetrahedra existed on the surface of the CVD BPO_4/SiO_2 catalyst. These results indicate that amorphous composite oxides, having micro-structures of BPO_4, were highly dispersed on silica for the CVD catalyst.

Catalytic Activity of CVD BPO_4/SiO_2. The catalytic activity for the isomerization of 1-butane was affected by the P/B ratio in the CVD BPO_4/SiO_2 catalyst prepared at 300 °C (Fig. 10). In the region of excess phosphorus, the activity was much higher than that in the region of excess boron, and the maximum activity was obtained at a P/B ratio near 1.1. The trans/cis ratio of product 2-butene ranged from 1.0 to 1.3 at a 1-butene conversion level of 50%, irrespective of the P/B ratio. In addition to isomerization, a small amount of butene dimers was produced with

Table 1. Acid Amount Measured by Ammonia Adsorption

BPO_4 catalyst (P/B ratio)		Content	Adsorbed amount/mmol g^{-1}	
		wt%	150 °C[a)]	300 °C[a)]

Impregnation	(1.1)	30	0.22	0.11
Unsupported	(1.1)	100	0.08	0.04

a) Adsorption temperature of ammonia.

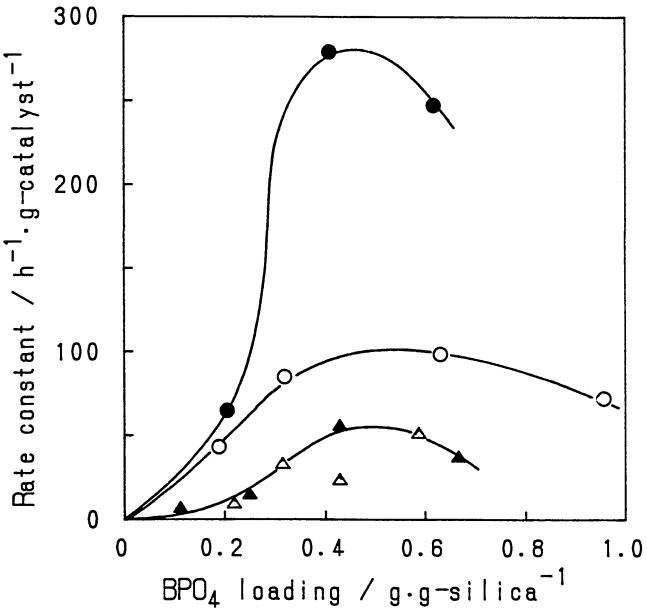

Fig. 12. Isomerization activities of various BPO_4/SiO_2 catalysts at 50 °C.
●, CVD catalyst of P/B=1.1; ○, P/B=1.
▲, Impregnation catalyst of P/B=1.1; △, P/B=1.

passing of the reaction time. The conversions of 1-butene to oligomers were 10—29% after the reaction had proceeded for 1 h. In order to clarify the catalytic behavior for oligomerization, the reaction was performed at lower temperatures. Since the isomerization activity was suppressed, the essential oligomerization activity appeared at 0 °C (Fig. 11). The maximum oligomerization activity was also observed at a P/B ratio near 1.1. This result is consistent with the catalytic behavior of unsupported BPO_4 for the liquid-phase oligomerization of 1-decene.[10)]

Figure 12 shows a comparison of CVD BPO_4/SiO_2 with the IMP BPO_4/SiO_2 catalyst regarding catalytic activity in 1-butene isomerization. For the CVD catalyst with a P/B ratio of 1, the isomerization activity increased with BPO_4 loading, passed through a maximum and then decreased above a loading of 0.6 g g-silica^{-1}. The decrease in the activity was considered to be caused by a closure of the micropore of the support, as has been described in connection with the results of the change in the specific surface area with BPO_4 loading (Fig. 6). The CVD catalysts, especially for the P/B ratio of 1.1, were much more active than both the IMP BPO_4/SiO_2 catalysts and the unsupported BPO_4 (P/B=1.1) whose rate constant for 1-butene isomerization was 89 h^{-1} g-catalys^{-1}. In addition, for the oligomerization activity, the CVD catalysts were also more active than both IMP BPO_4/SiO_2 and unsupported BPO_4 whose conversions were 6—9% at 50 °C (Fig. 10).

In order to evaluate the acid amount of catalyst, the amount of chemisorbed ammonia was measured volumetrically (Table 1). Irrespective of the P/B ratio, the amounts of ammonia chemisorbed on CVD catalysts were almost unchanged. The changes in the catalytic activity with the P/B ratio (Figs. 10 and 11) are not attributable to the acid amount, but probably to acid type (Brønsted or Lewis acid) of catalyst,[2,11)] though further work concerning the acid type and strength of CVD BPO_4/SiO_2 catalysts is in the progress. However, it has been clearly demonstrated that the acid amount of the CVD BPO_4/SiO_2 catalyst is much larger than those of both IMP BPO_4/SiO_2 and unsupported BPO_4. This tentatively explains the superiority of the CVD catalyst for the reactions mentioned above.

In conclusion, amorphous boron phosphate was deposited on a silica support with the desired P/B ratio and with high dispersion by means of a CVD method. The resulting CVD BPO_4/SiO_2 catalyst was superior to the impregnation catalyst for the isomerization of 1-butene and the simultaneous side reaction of oligomerization.

We wish to thank Mr. H. Shoji, Maruzen Petrochemical Co., Ltd., for performing the NMR measurement. The present work was partially supported by the Grant-in-Aid for Development Scientific Research No. 63750807 from the Ministry of Education, Science and Culture.

Reaction of 1,2-Dichloroethane with Pyridine Using the 1*R*,4*S*,8*R*,11*S*-Tetramethyl-1,4,8,11-tetraazacyclotetradecanenickel(II) Cation as a Probe

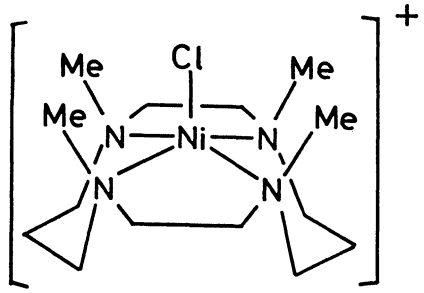
Etsuro IWAMOTO, Takashi YOKOYAMA, Jun NISHIMOTO, Tamao YAMASHITA, and Takahiro KUMAMARU*
Department of Chemistry, Faculty of Sciences, Hiroshima University, Hiroshima 730
(Received September 17, 1990)

A spectral change of the title square planar cation $[Ni(tmc)]^{2+}$ by an axial ligation of the halide ions in nitrobenzene was applied to kinetic studies of pyridine and alkyl halides. The ligation of the chloride ions proceeds with a formation constant of more than 1×10^4 dm^3mol^{-1} and rapidly with a rate of less than millisecond. It was found that 1,2-dichloroethane and dichloromethane react with pyridine through the Menschutkin reaction with a rate constant of 1.2×10^{-8} and 3.7×10^{-9} $dm^3mol^{-1}s^{-1}$ at 35 °C, respectively.

1,2-Dichloroethane (DCE) is a very useful solvent with a favorable boiling point, an intermediate dielectric constant and non-hydrogen-bonding property as an inactive medium for various reactions.

It is well known that the Menschutkin reaction occurs between amines and alkyl halides.[1-9] Nevstad and Songstad[3] examined the reactivity of dichloromethane (DCM) toward amines in DCM at 25 °C and found that the reaction rate of DCM-trimethylamine is considerable: the half-life (τ) is *ca.* 18 h, while pyridine (Py) reacts exceedingly slowly with DCM (τ=ca. 9600 h). On the other hand, no kinetic study has been reported for DCE, and this solvent is widely used without the special precautions at room temperatures. Gutmann[10,11] used DCE as a standard of basicity of solvents in which enthalpy of adduct formation of $SbCl_5$ with donor solvents was measured. However, it was pointed out that DCE rapidly quaternizes triethylamine under the catalytic action of $SbCl_5$.[12,13]

In the course of study of axial coordination of donor solvents to $[Ni(tmc)]^{2+}$ (tmc=1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) in DCE, the time-dependent spectra of the $[Ni(tmc)]^{2+}$ cation were observed when Py is present and it was found that the resultant spectrum is referred to the chloride coordinated $[Ni(tmc)Cl]^+$ cation (Scheme 1), showing the occurrence of the Menschutkin reaction between Py and DCE. Usually, the Menschutkin reaction has been examined by using conductometry and the silver nitrate titration. In this work the reaction between Py and alkyl halides in nitrobenzene (NB) as solvent was studied kinetically by using the square planar $[Ni(tmc)]^{2+}$ cation which shows color change from red to blue by an axial ligation of the halide ion.



[Ni(tmc)Cl]$^+$

Scheme 1.

Experimental

The salt $[Ni(tmc)](ClO_4)_2$ with (1*R*,4*S*,8*R*,11*S*)-nitrogen configuration was prepared by the published method[14,15] and was recrystallized from acetone-diethyl ether mixtures. Purity of the salt was checked by elemental analysis and IR spectra. Tetraphenylphosphonium bromide was prepared by the reported method[16] and the crude product was recrystallized by the method described previously.[17] Tetraphenylphosphonium chloride and tetraethylammonium chloride (Wako Pure Chemical Industries Ltd.) were recrystallized from an acetone-ether mixture. Purification of Py, DCE, and NB has been described previously.[18,19] Bromoethane (BE) of reagent grade (Wako Pure Chemical Industries Ltd.) was purified by fractional distillation through a 1.2-m column without washing.

The instrumentation and the procedure used for measurements of spectra and conductance were the same as described previously.[19]

Results and Discussion

In Fig. 1 are shown the spectra of $[Ni(tmc)](ClO_4)_2$ in a Py-DCE mixed solvent at 25 °C which change with time. The absorption peak at 524 nm is assigned to the low-spin, square planar species and the peaks at 430 nm and 720 nm to the high-spin, square pyramidal species. It is clearly shown that a certain ligand which is generated with the passage of time is coordinated to form a square pyramidal species. In our previous study,[19] it was found that neither DCE nor Py are coordinated because the basicity of DCE is too low and coordination of Py is sterically hindered in spite of its high basicity. If water is contained in their mixture, water molecules hydrogen-bonded to Py can be coordinated because of

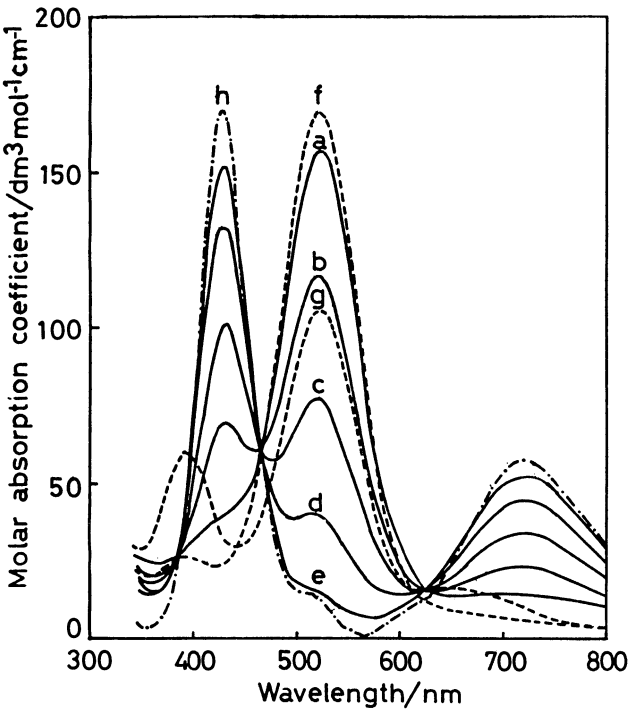


Fig. 1. Visible spectrum variation of a 1×10^{-3} mol dm^{-3} solution of $[Ni(tmc)](ClO_4)_2$ with time and water contents in Py at 25 °C. The DCE molar fraction (0.19): a, 16 min after preparation of the solution; b, 46; c, 76; d, 106; e, 136. Without DCE: f, $[H_2O]=8.6\times10^{-3}$ mol dm^{-3}; g, 5.7×10^{-2}. h, Spectrum of $[Ni(tmc)Cl]ClO_4$ in Py.

the increased basicity of water by polarization through hydrogen-bonding.[20,21] But as shown in Fig. 1, the water-coordinated species has an isosbestic point at 607 nm and absorption peaks at 390 nm and 660 nm, different from the time-dependent spectrum. Therefore, coordination of another ligand should be considered.

Alkyl halides react with amines, that is the Menschutkin reaction, forming quaternary ammonium salts with halide ions, and several works concerning this reaction of Py and alkyl halides at both atmospheric and elevated pressures have been reported.[6-9] As far as we know, however, reactivity of DCE with amines has not been examined in spite of the fact that DCE is very widely used as various reaction media.

The salt $[Ni(tmc)Cl]ClO_4$ was prepared by adding an equivalent sodium chloride to the aqueous $[Ni(tmc)](ClO_4)_2$ solution[14] and its spectrum was recorded ((h) in Fig. 1). The time-dependent spectrum which has absorption peaks at 430 nm and 720 nm coincides with that of the chloride-coordinated species. Therefore, it can be said that DCE reacts with Py to form quaternary ammonium chloride as depicted by Eq. 1. If the resultant chloride ion is

$$ClCH_2CH_2Cl + NC_5H_5 \longrightarrow ClCH_2CH_2N^+C_5H_5\ Cl^- \quad (1)$$

determined, the rate of reaction can be evaluated.

Coordination of the Chloride and Bromide Ions to $[Ni(tmc)]^{2+}$. The first ionic association constant of $[Ni(tmc)]^{2+}$ with the ClO_4^- ion is 1190 dm^3 mol^{-1} [19] in NB which indicates that 49% of $[Ni(tmc)]^{2+}$ are associated with ClO_4^- at 0.001 mol dm^{-3}. The association results from electrostatic attractive forces because of the weak basicity of ClO_4^- and the nickel complex cation remains the four-coordinated species. When a more basic solute is present, its coordination is hardly interrupted by the perchlorate association.[19]

Coordination of the chloride and bromide ions was examined spectrophotometrically by adding tetraphenylphosphonium or tetraethylammonium chloride and tetraphenylphosphonium bromide to the $[Ni(tmc)](ClO_4)_2$ solutions. Table 1 gives variation of the molar absorption coefficient (ε) of the complex cation at 524 nm with the concentration of chloride and bromide ions in DCE-NB mixed solvents. It was found that the ε values decrease linearly with increasing the halide ion concentration. The formation constant K_{NiX} was calculated by equation

$$K_{NiX}=(\varepsilon_o-\varepsilon)/(\varepsilon-\varepsilon_s)[X^-], \quad (2)$$

where ε_o is the molar absorption coefficient of the four-coordinated species at 524 nm and ε_s is the molar absorption coefficient of the five-coordinated species (ε_s=10 dm^3 mol^{-1} cm^{-1} [19]). $[X^-]$ is the concentration of the non-coordinated halide ion. The K_{NiX} values obtained are given in the last column. The activity

Table 1. Coordination of the Chloride and Bromide Ions to $[Ni(tmc)]^{2+}$ at 35 °C

X_{DCE}	Salt	$[X^-]$	$[[Ni(tmc)]^{2+}]$	ε_o	ε	K_{NiX}
		10^{-4} mol dm^{-3}	10^{-3} mol dm^{-3}	dm^3 mol^{-1} cm^{-1}		10^4 dm^3 mol^{-1}
0	Ph_4PBr	0.755	0.983	209	195	1.2
0		2.05	0.970	209	171	1.2

0.40	Ph_4NCl	2.36	1.00	199	155	9.5
0.40		5.35	0.975	199	98	8.2

coefficient is not taken into account because a constant $[Ni(tmc)]^{2+}$ concentration of *ca.* 1×10^{-3} mol dm^{-3} was used throughout the work. It is seen that the formation constant is one order of magnitude larger than the ionic association constant for the perchlorate ion and an increase in DCE molar fraction strengthens the coordination of halide ions. The rate of coordination of Cl^- ions to $[Ni(tmc)]^{2+}$ could not be measured by the stopped-flow method, showing that it is faster than millisecond. The results obtained above show that the $[Ni(tmc)]^{2+}$ cation can be used as a probe for the Menschutkin reaction.

Estimation of the Rate Constant of the Menschutkin Reaction. For the Menschutkin reaction the second-order rate equation Eq. 2 applies,

$$dx/dt = k_2(a-x)(b-x), \quad (3)$$

and then it is rewritten as

$$\ln(b-x)/(a-x) = (b-a)k_2t - \ln a/b \quad (4)$$

where k_2 is the rate constant in dm^3 mol^{-1} s^{-1} and a and b are the initial concentrations of alkyl halide and Py, respectively, and x is the concentration of the product (ammonium salt) formed after an interval of t s. The x values are estimated by using the coordination constant K_{NiX}

$$x = m'[1 + 1/K_{NiX}(m-m')] \quad (5)$$

where m' is the concentration of five-coordinated species, and m is the initial concentration of four-coordinated species. Since the K_{NiX} values are more than 10^4 and so the contribution of the second term in Eq. 5 is very small, the K_{NiX} value in Table 1 in the solvent composition close to the solvent system in question was used for calculation.

Typical examples of plot of Eq. 4 for the DCE-Py system in NB are illustrated in Fig. 2. Good linear relationships were obtained from which the k_2 rate constants were calculated. Similar measurements were made as a reference in the DCE-NB mixture without Py and in the Py-NB mixture without DCE, and it was confirmed that the change in absorbances is negligible compared with that in the DCE-Py system.

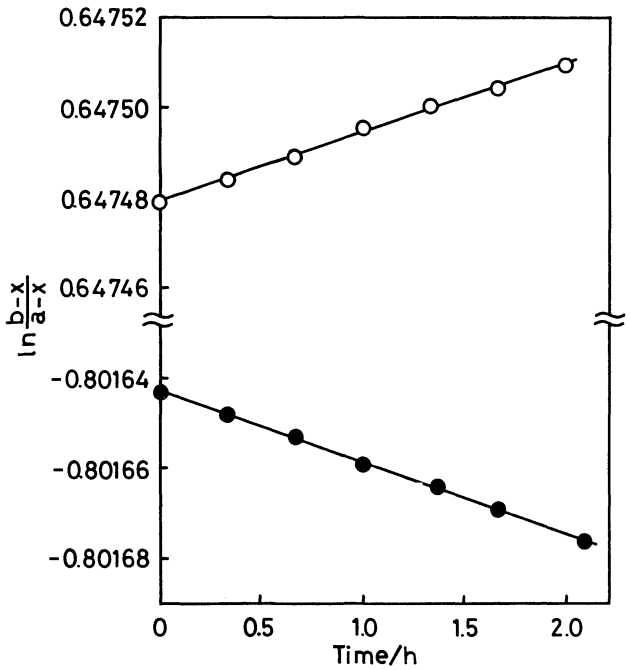

Fig. 2. Plots of $\ln(b-x)/(a-x)$ vs. t in NB at 35 °C. [DCE], [Py] in mol dm^{-3}: a, 0.411, 0.786; b, 0.844, 0.379.

a) Obtained without NB at 25 °C.

The k_2 values obtained in this way are summarized in Table 2.

The conductance measurements were also carried out to evaluate the k_2 value in a different method. Figure 3 typically shows variation of the conductivity with time in a reactant composition of [DCE]=0.826 mol dm^{-3} and [Py]=0.413 mol dm^{-3} in NB at 35 °C. The chloride and bromide concentrations were approximately evaluated by using the molar conductance of tetraphenylphosphonium chloride and bromide, respectively because the corresponding salts are not available.

Figures 4 and 5 show the dependence of k_2 values obtained spectrometrically and conductometrically on the DCE fraction. A slight difference is found for conductometry, this being because the salts using for calibration are not the same as the products. It is seen that for DCE the rate constant slightly increases with decreasing the DCE fraction. This may be due to the secondary Menschutkin reaction of the DCE molecule having two reaction sites leading to the *N,N*-ethylenedipyridinium cation $H_5C_5N^+CH_2CH_2N^+C_5H_5$, in view of the fact that such dependence was not observed for BE having one reaction site. The conductance results show the same trends. In the case of the greater content of more polar NB as the diluent, that is, the lower concentration of reactants, the rate constant is large, reflecting the ionic product in the Menschutkin reaction.

Table 3 gives the rate constants according to spectrophotometry extrapolated to zero concentration of Py at which the 1:2 DCE-Py reaction is negligible. The rate of reaction for DCM is one order of magnitude smaller than that for DCE, DCM being a little more stable than DCE. Maria and Gal[22] pointed out

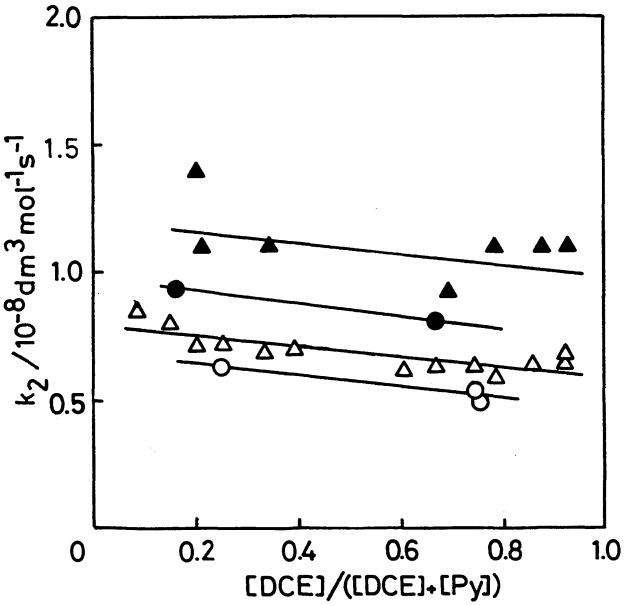

Fig. 4. Variation of the rate constant for the DCE-Py system with the DCE molar fraction in NB at 35 °C. The total concentration of DCE and Py is *ca.* 1.1 mol dm^{-3}: ▲, spectrometry; ●, conductometry. The total concentration is *ca.* 6 mol dm^{-3}: △, spectrometry; ○, conductometry.

Halogeno-solvent(S)	k_2 / $dm^3\,mol^{-1}\,s^{-1}$	Initial concentration ([Py]+[S])/mol dm^{-3}
DCE	1.0×10^{-8}	1.0—1.2
	5.9×10^{-9}	5.9—6.5
DCM	2.2×10^{-9}	1.0—1.1
	5×10^{-10} a)	—
BE	1.1×10^{-5}	0.075—0.26
	8.8×10^{-6} b)	0.12

a) Measured in DCE at 25 °C. From Ref. 3. b) From Refs. 4 and 5.

that a non-negligible amount of charged species is contained in some DCE solutions of $SbCl_5$ and strong basic solute, and instead of DCE they used DCM as the solvent to establish a solvent Lewis basicity scale.

It can be concluded that although the rate of reaction is small, DCE surely reacts with Py through the Menschutkin reaction without the catalytic action of $SbCl_5$: the concentration of the chloride ions in the DCE–Py mixture amounts to 10^{-4} mol dm^{-3} level in 30 min at 25 °C.

The conductometry for the determination of halide ions suffers one disadvantage which is the difficulty in calibrating the conductivity of the salt generated in the Menschutkin reaction. The silver titration method is somewhat troublesome because it contains the procedure of extraction of the halide ions into an aqueous phase.[3] On the other hand, the present system cannot be used when the basic, coordinating solvents such as dimethyl sulfoxide, *N*,*N*-dimethylformamide, acetonitrile and water are present in the reaction system.[19] However, if such basic solvents are not, the Menschutkin reaction can be easily monitored by the spectral change of the square planar $[Ni(tmc)]^{2+}$ cation without relying on conductometry or the silver titration method.

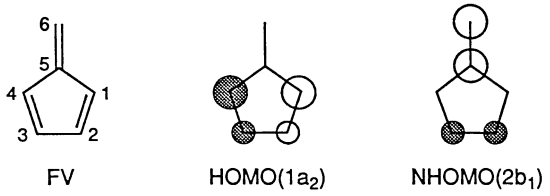
The Electronic Structure of the Fulvene Radical Cation

Ohgi TAKAHASHI and Osamu KIKUCHI*
Department of Chemistry, University of Tsukuba, Tsukuba 305
(Received September 27, 1990)

The molecular and electronic structures of the unsubstituted fulvene radical cation, $FV^{+\cdot}$, were investigated by ab initio SCF calculations. The planar $^2A_2$ state, which corresponds to removing an electron from the butadienic moiety in the five-membered ring, was found to be the ground state of $FV^{+\cdot}$, and is more stable than the planar $^2B_1$ state, which corresponds to an olefin radical cation, by about 26 kcal mol^{-1}. The barrier to rotation around the exocyclic C-C bond in the $^2A_2$ radical cation was calculated to be about 63 kcal mol^{-1}. The importance of electronic relaxation in substituted fulvene radical cations is discussed in connection with the rotational barrier.

Fulvenes have long been a focus of interest because of their unique properties, and their molecular and electronic structures have been widely investigated both experimentally[1] and theoretically.[2] Recently, the radical cations of some fulvenes have been spectroscopically observed[3,4] and several interesting aspects appeared concerning the electronic structures of the radical cations.

Though neutral fulvene (FV) may be regarded as



being an olefin, its HOMO ($1a_2$) is not associated with the exocyclic double bond, but extends within the butadienic moiety in the five-membered ring; the HOMO is essentially the HOMO of butadiene. The

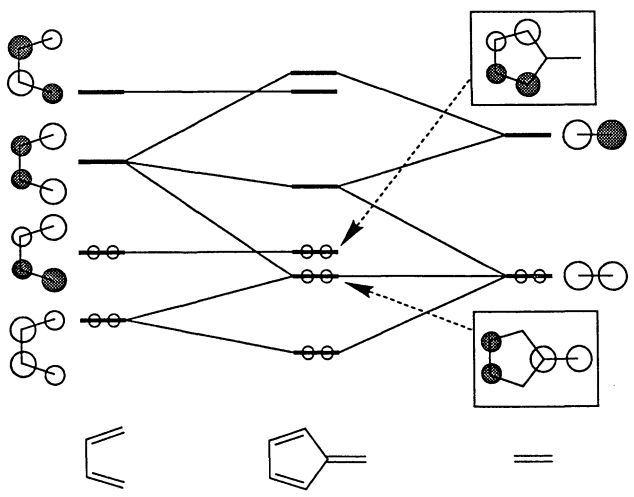


Fig. 1. Construction of π MO's of FV from those of butadiene and ethylene.

electrons associated with the exocyclic double bond are in the next to the HOMO (NHOMO), $2b_1$, which is energetically close to the HOMO. This situation of the MO levels of FV can be understood by constructing π MO's of FV from those of butadiene and ethylene, as shown in Fig. 1. The ground state of the fulvene radical cation ($FV^{+\cdot}$) is then expected to correspond to removing a π electron from the butadienic moiety ($^2A_2$ state).

Indeed, the freon matrix ESR spectrum of the radical cation of 6,6-dimethylfulvene (**1**),[3] and CIDNP observed during UV irraddiation of **1**, 6,6-diphenylfulvene (**2**), 6-phenylfulvene (**3**), (*Z*)- and (*E*)-2,6-di-*t*-butylfulvene (**4**), and (*Z*)- and (*E*)-2-*t*-butyl-6-(dimethylamino)fulvene (**5**) in the presence of electron acceptors[4] have shown that all of the radical cations of these fulvenes have a_2 or a_2-like SOMO.

On the other hand, if the electronic structure of the radical cations merely corresponds to removing an electron from the a_2-like HOMO of the neutral fulvenes, the unpaired electron and positive charge would be constrained to within the butadienic moiety and the double-bond character of the exocyclic double bond would not be reduced. Thus, it is very interesting that (*Z*)-$\mathbf{5}^{+\cdot}$ and (*E*)-$\mathbf{5}^{+\cdot}$ readily interconvert, while (*Z*)-$\mathbf{4}^{+\cdot}$ and (*E*)-$\mathbf{4}^{+\cdot}$ do not show any interconversion.[4] The electronic relaxation in substituted fulvene radical cations may be important in relation to the rotational barrier around the exocyclic double bond. In this respect, it is important to clarify the electronic structure of the unsubstituted fulvene radical cation, $FV^{+\cdot}$, at both the planar and 90°-twisted forms.

$FV^{+\cdot}$ has been carried out in connection with the photoelectron (PE) spectra of a series of alkyl-substituted fulvenes,[5] there are no ab initio level found through theoretical studies on $FV^{+\cdot}$. In this paper the electronic structures of the planar and 90°-twisted forms of $FV^{+\cdot}$ were examined using restricted open-shell Hartree-Fock (ROHF) calculations with the STO-3G[6] and 3-21G[7] basis sets. A C_{2v} symmetry was assumed for both planar and 90°-twisted forms, and the $^2A_2$ and $^2B_1$ states of the planar form and the $^2A_2$, $^2B_2$, and $^2B_1$ states of the 90°-twisted form were examined.

Results and Discussion

Planar $FV^{+\cdot}$. The two lowest energy bands in the PE spectrum of FV have been assigned to formation of the $^2A_2$ (first peak) and $^2B_1$ (second peak) states of $FV^{+\cdot}$.[5] Calculations were carried out for these two states of $FV^{+\cdot}$ using a geometry optimized for FV, so that the calculated relative energies could be compared with the vertical ionization potantials, 8.55 and 9.54 eV for the $^2A_2$ and $^2B_1$ states, respectively, measured for FV.[5] The optimized structures of FV are given in Table 1, and the energies of the two low-lying states of

$FV^{+\cdot}$ calculated using the geometries for FV are given in Table 2 along with the energies of FV and the experimental ionization potentials.[5] The calculated energy differences between the $^2A_2$ and $^2B_1$ states, 0.92 and 0.99 eV at ROHF/STO-3G and ROHF/3-21G levels, respectively, are in good agreement with the experimental value, 0.99 eV, although the ionization potentials are largely underestimated. The vertical ionization potentials estimated by the Koopmans' theorem are 7.07 and 7.96 eV (STO-3G), and 8.53 and 9.46 eV (3-21G) for the $^2A_2$ and $^2B_1$ states, respectively. These values show that the electronic reorganization energies for the $^2A_2$ and $^2B_1$ radical cations are almost the same, although the ionization that produces the $^2A_2$ radical cation is more local.[9]

The structures of the $^2A_2$ and $^2B_1$ states of the planar form of $FV^{+\cdot}$ were then optimized. The optimized structures are shown in Table 3, while the calculated total energies are given in Table 4. The calculated bond lengths well reflect the nodal properties of the MO of FV from which an electron is removed. The $^2A_2$ state is more stable than the $^2B_1$ state by about 26 kcal mol^{-1} (3-21G, 1 cal=4.184 J) when the geometries are optimized for each state, which agrees with spectroscopic observations of the spin distributions of some fulvene radical cations described above. Both the $^2A_2$ and $^2B_1$ states of the planar $FV^{+\cdot}$ correspond to energy minima as confirmed by slight twisting of the radical cations around the exocyclic C-C bond.

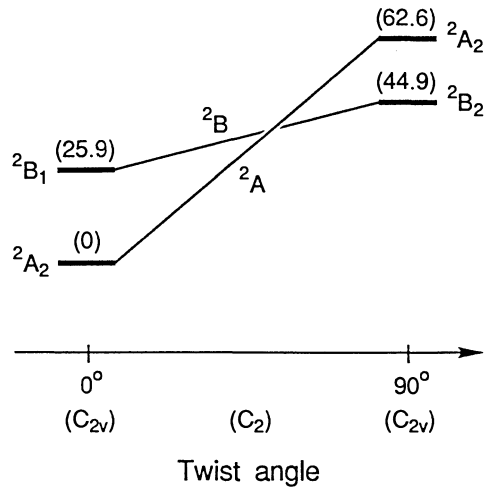

Fig. 2. A state correlation diagram for twisting of $FV^{+\cdot}$. The ROHF/3-21G energies relative to the planar $^2A_2$ state are shown in kcal mol^{-1}.

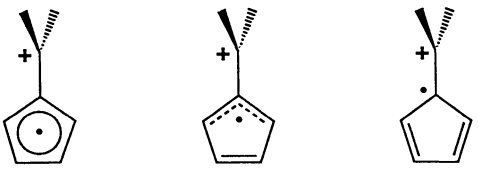
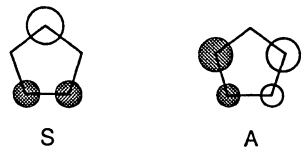
90°-Twisted $FV^{+\cdot}$. Rigid twisting of the radical cations showed that the $^2A_2$ and $^2B_1$ states of the planar $FV^{+\cdot}$ correlate with the $^2A_2$ and $^2B_2$ states of the 90°-twisted $FV^{+\cdot}$, respectively. The structures of the $^2A_2$ and $^2B_2$ states, as well as the $^2B_1$ state, of the 90°-twisted form were then optimized. The optimized structures are shown in Table 3, while the calculated total energies are given in Table 4. Figure 2 is a state correlation diagram for the double-bond twisting. For the 90°-twisted form, the $^2B_2$ state which correlates with the excited $^2B_1$ state of the planar form is the most stable; the $^2A_2$ state of the 90°-twisted form, which correlates with the $^2A_2$ ground state of the planar form, is higher in energy than the $^2B_2$ state by about 18 kcal mol^{-1} (3-21G). Both the $^2A_2$ and $^2B_2$ states of the 90°-twisted form correspond to the maxima of rotation around the exocyclic C-C bond, as confirmed by the slight untwisting of the 90°-twisted radical cations. Although the $^2B_2$ state is more stable than the $^2A_2$ state at the 90°-twisted form, rotation from the planar $^2A_2$ $FV^{+\cdot}$ is expected to proceed via the $^2A_2$ transition state, since the ^2A and ^2B states of the C_2 twisted forms prefer different molecular structures and, hence, a high barrier exists between the ^2A and ^2B valleys; the energy of the 90°-twisted $^2B_2$ state calculated at the geometry optimized for the 90°-twisted $^2A_2$ state is 88.1 kcal mol^{-1} (3-21G) relative to that of the planar $^2A_2$ ground state. Thus, the rotational barriers estimated for the planar $^2A_2$ and $^2B_1$ states are 62.6 and 19.0(=44.9−25.9) kcal mol^{-1}, respectively (3-21G).

It should be emphasized that an expression such as **I**, which was used in Ref. 4, is not appropriate for the 90°-twisted $FV^{+\cdot}$, since it does not distinguish between the $^2A_2$ and $^2B_1$ states, which are well represented by **II** and **III**, respectively. Both of the two states can be regarded as being a cyclopentadienyl radical attached by a positively charged substituent, $-CH_2$; the SOMO's of the two states stem from the doubly-degenerate SOMO of the ideal D_{5h} cyclopentadienyl



I **II**($^2A_2$) **III**($^2B_1$)



radical, the symmetric orbital (S) and the antisymmetric orbital (A).

For the 90°-twisted form, the $^2B_2$ state is calculated to be more stable than the $^2B_1$ state by about 20 kcal mol^{-1} (3-21G), although the $^2B_2$ radical cation has an antiaromatic 4π system. This result, however, is not surprising, since the positive charge in the $^2B_1$ radical cation is constrained at the C_6 atom. Furthermore, in the $^2B_2$ radical cation, two C_6–H bonds interact with the π system of the five-membered ring hyperconjugatively to spread positive charge. However, substitution by electron-donating groups at the C_6 position may reverse the relative stability of the two states, since the positive charge at C_6 in the $^2B_1$ or $^2B_1$-like radical cation is largely stabilized.

Electronic Structure of Planar $^2A_2$ State and Rotational Barrier. As described above, both the planar $^2A_2$ and $^2B_1$ $FV^{+\cdot}$ resist twisting around the exocyclic C–C bond especially in the former. Because substitution of *t*-butyl groups is expected not to greatly affect the π electron distribution of $FV^{+\cdot}$, the present computational results concerning the twisting agree with the experimental observation that (*Z*)-**4**$^{+\cdot}$ and (*E*)-**4**$^{+\cdot}$ do not show interconversion.[4] In contrast to (*Z*)-**4**$^{+\cdot}$ and (*E*)-**4**$^{+\cdot}$, (*Z*)-**5**$^{+\cdot}$ and (*E*)-**5**$^{+\cdot}$ showed ready interconversion, in spite of the spin distribution which corresponds to an $^2A_2$-like state.[4] This is partially due to the large stabilization of the 90°-twisted $^2A_2$-like state caused by an electron-donating group at C_6. On the other hand, this result can also be interpreted based on the electronic properties inherently involved in the planar $^2A_2$ state which can be described as follows.

In Table 5 the π electron and unpaired electron populations of the carbon atoms in planar $^2A_2$ and $^2B_1$ $FV^{+\cdot}$ are shown. The unpaired electron distribution in the $^2A_2$ $FV^{+\cdot}$ simply reflects the shape of the SOMO, $1a_2$; the unpaired electron is located largely on C_1 and C_4 and to a smaller degree on C_2 and C_3. Because the SOMO has a nodal plane perpendicular to the molecular plane and passing through C_5 and C_6, the unpaired electron is not located on C_5 and C_6. This spin distribution seems to correspond to a butadiene radical cation, **IV** or [**V**↔**V′**]. However, as can be seen from Table 5, the π electron density is the most dilute at C_6, which implies a significant contribution of **VI** and **VI′**. Because the SOMO has no coefficient at C_5 or C_6, the electron flow from C_6 can be attributed to π electrons other than the unpaired electron. Namely, the positively charged hole, which is made by removing an electron from the $1a_2$ HOMO of FV, is partially filled by a reorganization of π electrons other than the unpaired electron. If an electron-donating group, such as the dimethylamino group, is introduced at C_6, the contributions of **VI** and **VI′** become large, which may considerably reduce the double-bond character of the exocyclic C_5–C_6 bond and,

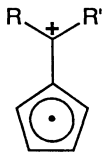
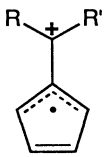
VII



VIII



IX

hence, lower the rotational barrier.[10]

On the other hand, the $^2B_1$ state is essentially an olefin radical cation with a weakened C_5-C_6 bond, as can be seen from Tables 3 and 5. Indeed, the rotational barrier for the $^2B_1$ state is relatively small.

In Ref. 4, **VII** and **VIII** were referred to as "localized" and "relaxed" radical cations, respectively, in order to specify the possible electronic structures of the fulvene radical cations. In a "localized" radical cation, the unpaired electron and positive charge are localized in the endocyclic butadienic moiety; in a "relaxed" radical cation, the unpaired electron is located in the ring and the positive charge is located on C_6. As can be seen from the above discussion, however, both **VII** and **VIII** represent an $^2A_2$-like state with similar SOMO; as the substituent attached to the C_6 atom becomes more electron-donating, the radical cation becomes more "relaxed". Note that fulvene radical cations are more or less "relaxed", and that the boundary between the "localized" and "relaxed"radical cations is not distinct. Furthermore, it should be noted that such a representation as **VIII** used in Ref. 4 does not distinguish between the "relaxed" $^2A_2$ radical cation and the $^2B_1$ radical cation. The former may be explicitly described by **IX**. In the $^2A_2$ radical cation, the unpaired electron is not located on C_5 and C_6, while it is located mainly on C_5 and C_6 in the $^2B_1$ radical cation.

Conclusion

Ab initio SCF calculations using the STO-3G and 3-21G basis sets have shown that the ground state of the unsubstituted fulvene radical cation ($FV^{+\cdot}$) is the planar $^2A_2$ state. Though this state corresponds to removing a π electron from the butadienic moiety in the five-membered ring of FV, the positively charged hole is partially filled by a π-electron flow from the exocyclic region without any significant change in the unpaired electron distribution. The planar $^2B_1$ state, which corresponds to an olefin radical cation with a weakened exocyclic C-C bond, is higher in energy than the $^2A_2$ state by about 26 kcal mol^{-1}. Both the planar $^2A_2$ and $^2B_1$ states correspond to the minima of rotation around the exocyclic C-C bond. Although the 90°-twisted $^2A_2$ state is higher than the planar $^2A_2$ state by about 63 kcal mol^{-1}, the rotational barrier for the $^2A_2$ state was predicted to be considerably lowered by the substitution of electron-donating groups at the C_6 position.

Effect of Batch Factor on a Binary Ion Exchange Equilibrium

Koichi TANIHARA
Government Industrial Research Institute, Kyushu; Shuku-machi, Tosu 841
(Received July 9, 1990)

The relation between the distribution coefficient of Cs^+ on M^{n+} form exchanger and the ratio of the solution volume to the exchanger weight (batch factor) at a constant loading of Cs^+ has been investigated while taking the activity coefficients of ionic species into consideration when the initial concentration of Cs^+ is changed.

The effects of the batch factor on a binary ion exchange equilibrium have often been observed elsewhere[1-6] under specific experimental conditions. Until quite recently, though, very little attention has been devoted to its elucidation.[7]

There are two degrees of freedom in a binary cation exchange system at a constant temperature and pressure[8] where an ion exchanger having a constant exchange capacity is in equilibrium with an aqueous solution of two cations and one common anion. An ion exchange experiment for such a system, therefore, is usually carried out under the one degree of freedom by introducing relevant constant parameters. Taking the effects of the batch factor into consideration, the experimental conditions at a constant temperature and pressure for a binary cation exchange system can be divided into three cases depending on how one specifies the initial concentrations of two cations in the solution.

(1) The sum of the initial equivalent concentrations of two cations is kept constant, while changing the ratio:

In this case, the sum of equivalent concentrations of two cations in equlibrium with the ion exchanger is invariably constant, irrespective of the batch factor. The usual thermodynamic treatments for a binary exchange equilibrium have been conducted under this restriction.[9]

(2) The initial concentration (varied) of the "ingoing" cationic species into an exchanger is much smaller than that (kept constant) of the cationic species displaced from it:

In this case, the ingoing cationic species is a micro component and the equilibrium concentration of the displaced cationic species can be taken as being approximately constant. The distribution coefficient of the ingoing ionic species is virtually invariant with respect to the batch factor, as previously reported.[7]

(3) The initial concentration of either of the two cations is kept constant, changing that of the other:

This is the case when the effects of the batch factor are often observed. By introducing the batch factor as a second parameter, on the other hand, the present author derived a theoretical relationship between the loading of the ingoing ionic species and its equilibrium concentration in the solution, and successfully related it to the distribution coefficient of the ingoing ionic species, as previously reported.[7]

In the present paper, a refined form of theoretical equation previously reported for case (3) is derived in order to elucidate the effect of the batch factor while taking the activity coefficients into consideration.

Theoretical

The present paper is concerned with the case of an exchange involving two cations only, where a single electrolyte solution of cesium chloride is allowed to react with an ion exchanger of M^{n+} form, while changing the initial concentration at a given batch factor. The exchange reaction may be written as

$$n\mathrm{Cs}^+ + \overline{\mathrm{M}^{n+}} \rightleftarrows \overline{n\mathrm{Cs}^+} + \mathrm{M}^{n+}, \quad (1)$$

(overbar: the exchanger phase)

When the initial concentration of M^{n+} in the solution is zero, a "theoretical adsorption isotherm," as previously reported,[7] is given by

$$\frac{Q}{[\mathrm{Cs}^+]_s} = \frac{1}{n}\sqrt[n]{\frac{n\beta(C_{\mathrm{CEC}}-Q)(C_{\mathrm{CEC}}+(n-1)Q)^{n-1}}{Q}K_{\mathrm{M}^{n+}}^{\mathrm{Cs}^+}}, \quad (2)$$

where Q is the Cs^+ loading (mequiv g^{-1}), β the batch factor ($cm^3\,g^{-1}$), C_{CEC} the cation exchange capacity (mequiv g^{-1}), $[Cs^+]_s$ the equilibrium concentration of Cs^+ in the solution, and $K_{\mathrm{M}^{n+}}^{\mathrm{Cs}^+}$ a selectivity coefficient which is defined by the molarities and the mole fractions for cations in the solution and solid phases, respectively. In Eq. 2, $K_{\mathrm{M}^{n+}}^{\mathrm{Cs}^+}$ is written in terms of the thermodynamic equilibrium constant (K_c) and ionic activity coefficients as follows: $K_{\mathrm{M}^{n+}}^{\mathrm{Cs}^+} = K_c\gamma_{\mathrm{Cs}^+}^n\bar{f}_{\mathrm{M}^{n+}}/(\gamma_{\mathrm{M}^{n+}}\bar{f}_{\mathrm{Cs}^+}^n)$. The ionic activity coefficients, γ_{Cs^+} and $\gamma_{\mathrm{M}^{n+}}$, refer to the individual cations in the solution phase. They are defined so as to approach unity as $[Cs^+]_s$ and the equilibrium concentration of M^{n+} in the solution, $[M^{n+}]_s$, approach zero. The ionic activity coefficients, $\bar{f}_{\mathrm{Cs}^+}$ and $\bar{f}_{\mathrm{M}^{n+}}$ refer to the individual cations in the solid phase and are defined so as to be equal to unity for pure homo ionic exchangers in equilibrium with an infinitely dilute solution of the same ion.[10] When the exchange equilibrium is attained in a solution which is sufficiently dilute so that the imbibition of anions by the exchanger can be

neglected, the ratio $\bar{f}_{M^{n+}}/\bar{f}^n_{Cs^+}$ depends only on Q, irrespective of β, since both the ionic activity coefficients, $\bar{f}_{Cs^+}$ and $\bar{f}_{M^{n+}}$ vary with the mole fraction of Cs^+ (Q/C_{CEC}) in the solid solution of two homo-ionic exchangers. It then follows that by substituting $K_d=Q/[Cs^+]_s$ in Eq. 2, the distribution coefficient of Cs^+, K_d, can be expressed in the form

$$K_d = F(Q)\,\xi\sqrt[n]{\beta}, \tag{3}$$

where ξ denotes $\gamma_{Cs^+}/\gamma_{M^{n+}}^{1/n}$, which can be written in terms of the mean activity coefficients, $\gamma_{\pm CsCl}$ and $\gamma_{\pm MCl_n}$, of CsCl and MCl_n, respectively, as

$$\ln\xi = \ln(\gamma_{Cs^+}/\gamma_{M^{n+}}^{1/n}) = 2\ln\gamma_{\pm CsCl} - (n+1)/n\ln\gamma_{\pm MCl_n}. \tag{4}$$

On the basis of Guggenheim's theory,[11] $\gamma_{\pm CsCl}$ and $\gamma_{\pm MCl_n}$ are given by

$$\ln\gamma_{\pm CsCl} = -\frac{a\sqrt{I}}{1+\sqrt{I}} + 2\,\alpha_{Cs,Cl}[Cs^+]_s + (n\,\alpha_{Cs,Cl}+\alpha_{M,Cl})[M^{n+}]_s, \tag{5}$$

and

$$\ln\gamma_{\pm MCl_n} = -\frac{an\sqrt{I}}{1+\sqrt{I}} + \frac{2}{1+n}\left\{2n\,\alpha_{M,Cl}[M^{n+}]_s + (\alpha_{M,Cl}+n\,\alpha_{Cs,Cl})[Cs^+]_s\right\}, \tag{6}$$

where a is a constant in the Debye-Hückel formula (equal to 1.178 at 25 °C), and I the ionic strength, $\alpha_{M,Cl}$ and $\alpha_{Cs,Cl}$ the specific interaction coefficients of M^{n+} and Cs^+, respectively with Cl^-.

Eqs. 4—6 reduce to

$$\xi = \exp\left[\frac{a(n-1)\sqrt{I}}{1+\sqrt{I}} + \frac{2(n\,\alpha_{Cs,Cl}-\alpha_{M,Cl})}{n(n+1)}\left\{2+\theta(n-1)\right\}I\right], \tag{7}$$

where θ is the ionic strength fraction of CsCl.

By substituting $[M^{n+}]_s=Q/n\beta$ and $[Cs^+]_s=Q/K_d$ in the respective definition formulas, I and θ are given as

$$I = 0.5\,n(n+1)[M^{n+}]_s + [Cs^+]_s = 0.5\,Q\{(n+1)/\beta + 2/K_d\}, \tag{8}$$

and

$$\theta = [Cs^+]_s/I = 2\beta/\{2\beta+(n+1)K_d\}. \tag{9}$$

The substitution of Eqs. 7—9 in Eq. 3 indicates that K_d (also $[Cs^+]_s$) can be regarded as a function of Q and β. It is then concluded that plots of K_d/ξ vs. $\sqrt[n]{\beta}$ or $\log(K_d/\xi)$ vs. $\log\beta$ at a given Q should be a straight line passing through the origin or with a slope of $1/n$, respectively.

Experimental

Materials. As a typical organic or inorganic cation exchanger, a sulfonated polystyrene-type resin (Dowex 50W-X8, Dow Chemical Co.) and a synthetic mordenite (Zeolon 100Na, Norton Co.) were used, respectively. The Dowex 50W resin was converted to the homo ionic forms by an exhaustive treatment with the corresponding metal chloride solutions. The synthetic mordenite (Na^+ form) was used without further treatment.

Measurements and Procedures. The experimental procedures were similar to that described previously.[7] The value of $[Cs^+]_s$ for the La^{3+} form resin was determined based on the concentration of displaced La, which was measured using radiofrequency inductively coupled plasma atomic-emission spectrometry. The observed values of K_d and Q for a given β were obtained according to

$$Q = ([Cs^+]_0 - [Cs^+]_s)\beta \quad (\text{mequiv g}^{-1})$$

and

$$K_d = Q/[Cs^+]_s \quad (\text{cm}^3\,\text{g}^{-1})$$

where $[Cs^+]_0$ is the initial concentration (mol dm^{-3}) of Cs^+.

Calculation of ξ. The value of ξ at the observed point (Q, K_d) for a given β was calculated from Eqs. 7—9 where the specific interaction coefficient, that is, $\alpha_{Cs,Cl}$, $\alpha_{Na,Cl}$, $\alpha_{Ca,Cl}$, or $\alpha_{La,Cl}$ was estimated to be 0, 0.16, 1.01, or 3.88, respectively, on the basis of Eq. 5 ($[M^{n+}]_s=0$) or Eq. 6 ($[Cs^+]_s=0$), using the published values of mean activity coefficient for a single chloride solution.

Results and Discussion

Fig. 1 shows the variation of the distribution coeffi-

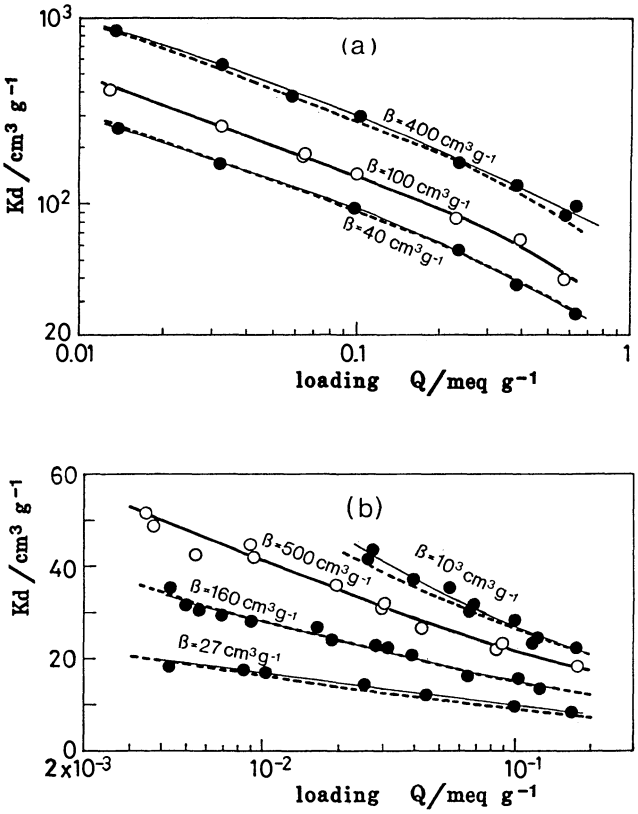

Fig. 1. Variations of K_d with Cs loading, Q, at different batch factors for Dowex 50W resin of Ca^{2+} or La^{3+} form. (a) Ca^{2+}-form, (b) La^{3+}-form. The experimental data point is indicated by a open or closed circle. The dashed curves represent the calculated curves obtained from a reference curve (denoted by a bold solid line among the open circles) at a given batch factor.

cient of cesium, K_d, with its loading, Q, at given values of the batch factor, β, for the Dowex 50W of Ca^{2+} and La^{3+} forms when Ca^{2+} and La^{3+} ions, respectively, are initially absent in the solution. In these experiments

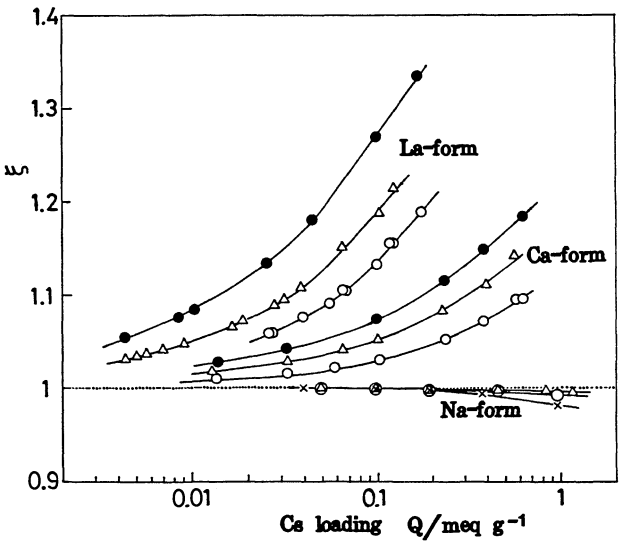

Fig. 2. Variations of ξ with the Cs loading, Q, at different batch factors for Dowex 50W resin of various ionic form: Na^+ form (β($cm^3 g^{-1}$): 20 (×); 50 (○); 100 (△)), Ca^{2+} form (β($cm^3 g^{-1}$): 40 (●); 100 (△); 400 (○)), La^{3+} form (β($cm^3 g^{-1}$): 27 (●); 160 (△); 1000 (○)).

K_d and Q at equilibrium were measured by changing the initial concentrations of Cs^+ at different fixed values of β in the ionic strength range $I<0.1$. Plots of the ξ value at each point of K_d vs. Q data in Fig. 1 and in previous paper[7] for Na^+ form reveal that the effects of Q and β on ξ greatly differ with the n values of the Dowex resin, as can be seen in Fig. 2.

The proportional expression, $K_d/\xi \propto \sqrt[n]{\beta}$, derived from Eq. 3, was verified, as shown in Fig. 3, by good linear relationships with slope of $1/n$ between $\log(K_d/\xi)$ and $\log\beta$, where K_d and β were read for an arbitrarily specified Q ranging from small to relatively large values on the basis of the graphs in Fig. 1 and those drawn in a previous paper[7] for other exchangers. These results indicate that the underlying assumptions in Eq. 3, based on a theory by Gaines and Thomas,[10] are not only valid for an exchanger of non-swelling type, such as Zeolon 100Na, but also for that of the swelling type, such as Dowex 50W, as long as the ionic strengths in the solutions are in a range less

Based on the above results, $K_d(=K_{d_i})$ vs. Q curves at different $\beta(=\beta_i)$ can be drawn from one reference curve of the K_{d_0} curve constructed at a given $\beta(=\beta_0)$, as described below.

The proportionality constant, $F(Q)$, of K_d/ξ to $\sqrt[n]{\beta}$ at an arbitrarily given Q in Eq. 3 can be determined from a point, (Q, K_{d_0}), on the reference curve for β_0 as $K_{d_0}/(\xi_0\sqrt[n]{\beta_0})$, where ξ_0 can be calculated according to

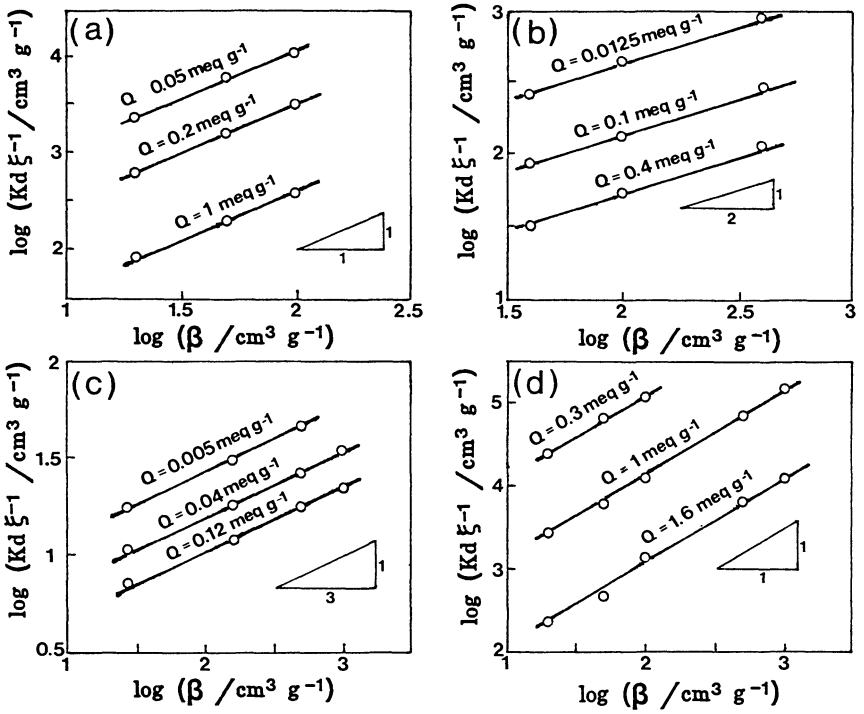

Fig. 3. Linear relationships with slope $1/n$ between $\log(K_d/\xi)$ and $\log\beta$ at different values of Q.
(a) Dowex 50W (Na^+ form), (b) Dowex 50W (Ca^{2+} form), (c) Dowex 50W (La^{3+} form), (d) Zeolon 100Na.

Eqs. 7—9 by substituting $\beta=\beta_0$ and $K_d=K_{d_0}$ into Eqs. 8 and 9. In order to calculate K_{d_i} corresponding to β_i at the given Q using Eq. 3, $\xi(=\xi_i)$ at β_i must be determined. Since the value of $K_{d_i}/\xi_i(=D_i)$ at Q and β_i can be calculated as $K_{d_0}\sqrt[n]{\beta_i}/(\xi_0\sqrt[n]{\beta_0})$ by substituting $F(Q)=K_{d_0}/(\xi_0\sqrt[n]{\beta_0})$ in Eq. 3, a transcendental equation for ξ_i is obtained when $K_d=\xi_i D_i$ and $\beta=\beta_i$ are substituted in Eqs. 8 and 9, followed by the substitutions of I and θ in Eq. 7. This equation can be readily solved by applying a numerical analysis with the aid of a personal computer when Q and β_i are given. Accordingly, K_{d_i} can be calculated as $\xi_i D_i$. As can be seen in Fig. 1, the dashed lines, which represent K_d vs. Q curves predicted from a reference curve (bold solid line) measured for a fixed β, are found to closely agree with the observed values. Similar results were obtained for the Dowex 50W of Na^+ form and Zeolon 100Na. From the K_d vs. Q curves, thus obtained, for different values of β, the corresponding Q vs. $[Cs^+]_s$ curves, that is, "adsorption isotherms" which may be distinguished from the usual "ion exchange isotherm at a constant total solution normality"[9] (independent of the batch factor), can be easily calculated for each β value using the relation $K_d=Q/[Cs^+]_s$.

As demonstrated above, K_d vs. Q curves or "adsorption isotherms" at different β can be calculated without requiring any knowledge concerning the properties of the exchanger, other than one measured K_d vs. Q curve for one value of β.

Application of the SPE Method to Organic Electrochemistry. XI. Influence of the Solvent on the Electrooxidation of Cinnamyl Alcohol on Mn,Pt-Nafion

Zhen CHEN, Toshiyuki MIZOE, Zempachi OGUMI,* and Zen-ichiro TAKEHARA
Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606
(Received July 27, 1990)

The influence of organic solvents on the electrooxidation of cinnamyl alcohol on Mn,Pt-Nafion has been investigated. Though tetrahydrofuran (THF) gave a high current efficiency (90%), carbon tetrachloride gave a low current efficiency (<20%). The importance of a co-solvent for the SPE electrolyzer was proposed and substrate transport to the active site located at the interface platinum/ionic cluster region was enhanced by solvents miscible with water. Though THF behaved as a good co-solvent, carbon tetrachloride did not. A composite electrode deposited with platinum on both surfaces of Nafion was applied to oxidation. The cell voltage was as low as 2 V.

The authors have reported that the application of mediatory systems into SPE (Solid Polymer Electrolyte) electrolyzers is both effective and attractive.[1-3] In a previous paper Mn,Pt-Nafion (a manganese redox system incorporated inside Pt-Nafion prepared by the deposition of a porous platinum electrode on Nafion) was applied to the selective oxidation of cinnamyl alcohol to cinnamaldehyde.[4] Both the current efficiency and selectivity to the aldehyde were remarkably enhanced by the addition of the manganese mediatory system.

The electrode reaction of this mediatory oxidation system is as follows:

$$Mn^{2+} + 2H_2O \longrightarrow MnO_2 + 4H^+ + 2e^-. \quad (1)$$

The MnO_2 formed in this reaction reacts with the alcohol while giving aldehyde and regenerating Mn^{2+}.[5] As shown by the oxidation potential of MnO_2 described in the following equation, the activity of MnO_2 is strongly dependent on such solution properties as the pH and water content:

$$E = E^0 + \frac{RT}{2F} \ln \frac{a_{MnO_2}(a_{H^+})^4}{a_{Mn^{2+}}(a_{H_2O})^2}. \quad (2)$$

In the present work, the effect of the solvent was examined in detail.

Regarding SPE electrolyzers, it is expected that the cell voltage can be decreased by decreasing the gap between the anode and cathode. Composite electrodes deposited with an electrode on both surfaces of SPE materials would limit the electrode gap to the thickness of the SPE material. This type of composite electrode was also examined in the selective oxidation of cinnamyl alcohol.

Experimental

SPE Composite Electrodes. Pt-Nafion was prepared by the deposition of a porous platinum layer onto one surface of Nafion 415 utilizing an electroless plating method that employs hydrazine as a reductant. Details concerning the deposition method have been reported elsewhere.[6,7] Pt-Nafion-Pt, which is a composite electrode deposited with platinum on both surfaces of Nafion 415, was prepared by depositing a porous platinum layer on the second surface in the same manner as depositing one on the first surface. Incorporating a manganese redox system into Pt-Nafion and Pt-Nafion-Pt was achieved as described previously.[3,4]

Electrolysis. The experimental cell was described in a previous paper.[4] Electrolysis was carried out under potentiostatic or galvanostatic conditions.

In all experiments, 0.025 M (M=mol dm^{-3}) aqueous sulfuric acid containing 0.025 M manganese sulfate was used as a catholyte in a counter electrode compartment (CEC). Different kinds of anolytes were prepared and filled in a working electrode compartment (WEC).

Product mixtures were analyzed by an HPLC device (Hitachi 638-30) equipped with a Synchropak SCD column using internal standards.

The amount of manganese dissolved out was measured by atomic absorption spectroscopy after electrolysis under potentiostatic conditions at 1.4 V vs. Ag/AgCl.

Chemicals. All of the chemicals used were of reagent grade, and were used without further purification.

Results

Stability of Solvents. Four solvents (tetrahydrofuran (THF), diethyl ether, benzene, and carbon tetrachloride) were examined. These four solvents were stable on the anode under the experimental conditions. Since no product was isolate by HPLC, except for cinnamaldehyde and cinnamic acid, the main side reaction was considered to involve oxygen evolution.

Current Efficiency in Different Solvents. Using the four solvents, electrolysis was carried out at 1 mA cm^{-2} in 50 vol% cinnamyl alcohol, and 25 °C on Mn,Pt-Nafion. As described in Table 1, carbon tetrachloride gave the lowest current efficiency. Diethyl ether gave a current efficiency that was a little lower than THF. Benzene gave a medium value.

Since carbon tetrachloride showed the most pronounced decrease in the current efficiency, this solvent was examined in detail and compared with THF.

Table 1. Effects of Solubilities of Organic Solvents on the Current Efficiencies of Cinnamaldehyde, at 25 °C

	Solubility in water[a)]	Current efficiencies/%
CCl_4	0.077	13
Benzene	0.178	63
Diethyl ether	6.04	72
THF	Inf.	85

a) g/100 g H_2O.

Steady State Polarization Curves. Figure 1 shows steady state polarization curves for 50 vol% cinnamyl alcohol in carbon tetrachloride and THF. Curve b, obtained in the presence of a manganese mediatory system in carbon tetrachloride, shows a lower potential at a low current density than does curve a, obtained in the absence of a mediatory system in carbon tetrachloride. The difference was much smaller than in the case of using THF as a solvent (curve c). This result suggests that the mediatory system did not work as effectively in carbon tetrachloride as in THF. This ineffectiveness lowered the current efficiency of aldehyde formation. Oxygen evolution was observed in carbon tetrachloride at a high current density.

The Influence of Substrate Concentration. Generally speaking, it is favorable to increase the substrate concentration for a higher performance of electrolyzers. The influence of the substrate concentration was examined using THF and carbon tetrachloride as solvents under potentiostatic electrolysis conditions at 1.5 V. The results are shown in Fig. 2. Using THF, the current efficiency of cinnamaldehyde remained almost unchanged up to an alcohol concentration of 50%, but decreased remarkably beyond 50%. Using carbon tetrachloride as solvent, the current efficiency of aldehyde formation was much lower than the value obtained for THF, and was dependent in a different way on the concentration; the current efficiency showed a maximum at ca. 70%. The production of cinnamic acid remained almost unchanged in both solvents and oxygen evolution was observed as a side reaction.

The influence of the solvent and substrate concentration on the mediatory action and oxidation efficiency was examined in more detail using a mixed solvent of THF and carbon tetrachloride. By fixing the substrate concentration at 50%, the ratio THF/carbon tetrachloride could be changed. As shown in Fig. 3, the current efficiency of the aldehyde increased upon increasing the THF/carbon tetrachloride ratio.

Influence of Current Density. If mass transport plays an important role in the electrochemical system, the current density would provide a major influence on the current efficiency. As shown in Fig. 4, the current efficiency of cinnamaldehyde decreased rapidly from 10 mA cm^{-2} using Mn,Pt-Nafion. On the other hand, the current efficiency of cinnamic acid remained unchanged upon increasing the current density.

The Stability of Mn,Pt-Nafion. The dissolving out of incorporated manganese was also measured using carbon tetrachloride as a solvent. This dissolving out was more remarkable, by 20 to 40%, in carbon tetrachloride than in THF.[4)]

Electrolysis Using Mn,Pt-Nafion-Pt. It is favorable to use an aqueous solution in CEC, since Nafion

(a): anode, (b): cathode.

is known to show ionic conductivity of a few orders of magnitude lower in organic solvents than in aqueous solutions.[8] Nafion shows a fairly high ionic conductivity under a humidified gas atmosphere, as investigated in fuel-cell applications. As described above and in a previous paper, the incorporated redox system tended to dissolve out into an aqueous solution in CEC. If no solution was used in the CEC, no dissolving out could occur. By using Mn,Pt-Nafion-Pt, a 50% cinnamyl alcohol solution in THF was electrolyzed. Argon was filled in CEC. The cell voltage was, however, very high for this electrolyzer and the cell temperature increased. This result suggests that the ionic conductivity of Nafion is very low under the electrolysis conditions. This type of electrolysis was not acceptable from practical viewpoints. An aqueous solution of 0.025 M sulfuric acid containing 0.025 M manganese sulfate was filled in the CEC in order to enhance the ionic conductivity of Mn,Pt-Nafion-Pt. Polarization curves for the anode and cathode are listed in Fig. 5. The electrode potential was measured using a Luggin capillary inserted in the CEC; the ohmic drop was not corrected. The difference in the anodic and cathodic potentials gives the cell voltage at each current density. At low current densities, where mediatory oxidation was predominant, the cell voltage was less than 2 V. The current efficiency for Mn,Pt-Nafion-Pt was compared with the results for Mn,Pt-Nafion. As shown in Fig. 4, Mn,Pt-Nafion-Pt showed a current efficiency change with an increase in the current density similar to that of Mn,Pt-Nafion. The current efficiency decreased abruptly at about 10 mA cm^{-2}. The critical current density corresponded to the value in the polarization curve in Fig. 5, beyond which oxygen evolution became significant.

Discussion

Electrochemical charge transfer reactions take place

at the interface between electronic and ionic conductors. This was also true in the present electrochemical system. The structure of Nafion is accepted to be microscopically separated into two phases: a hydrophilic ionic cluster and a lipophilic polytetrafluoroethylene-like backbone.[9] H. L. Yeager and co-workers have pointed out that a majority of sorbed water is incorporated in an ionic cluster region of Nafion. The ionic cluster region in the membrane is regarded as being surrounded by a lipophilic environment.[10,11] These clusters are connected to each other by a small channel. Ionic conduction of SPE composite electrodes using Nafion is based on ionic migration through the ionic cluster region where most of the ionic groups (fixed ions and counter ions) and water taken up inside the Nafion exist. Since the deposition of a porous platinum electrode on Nafion was carried out in an aqueous solution, platinum likely at least contacted the ionic cluster region. The active site for charge transfer on an SPE composite electrode is located at the platinum/Nafion interface (the interface between the platinum and the hydrophilic ionic cluster region of Nafion), since the hydrophobic region of Nafion solves neither ionic charge carriers nor polar solvents.[12] In the present system, Mn^{2+} is oxidized there to form MnO_2, which must stay in the ionic cluster region (see Fig. 6). The substrate must be transported to the ionic cluster region in order to contact and react with MnO_2, where it is oxidized. As mentioned above, the ionic cluster region is strongly hydrophilic and is considered to be in the condition of an aqueous solution. Since cinnamyl alcohol is hardly soluble in water, it is difficult for the alcohol to enter this region. Some organic solvent is required in the ionic cluster region in order to help the alcohol to penetrate into the active region, the ionic cluster. Nafion swells not only solvents having a high solubility parameter, but also those having a low solubility parameter. It was proposed that solvents with a low solubility parameter interact with the hydrophobic site of Nafion.[13] The four solvents examined here have fairly low solubility parameters. The authors have proposed the existence of a path in the amorphous hydrophobic region of Nafion for the transport of oxygen.[14] This region is responsible for the interaction with hydrophobic solvents. Since cinnamyl alcohol is hardly soluble in water, it is acceptable to consider that the alcohol does not penetrate into the hydrophilic aqueous region but, rather, stays in the hydrophobic region. This hydrophobic region corresponds to the path for oxygen and allows hydrophobic substances to remain.[6,11,14] As mentioned above, cinnamyl alcohol must be transported from a hydrophobic site to the active site of the SPE composite electrode in order to react electrochemically (Fig. 6). The difference in the current efficiency of the four solvents examined can be explained in terms of their miscibility with water. When solvents for cinnamyl alcohol is immiscible with water, transport is very difficult and is not easily oxidized on Mn,Pt-

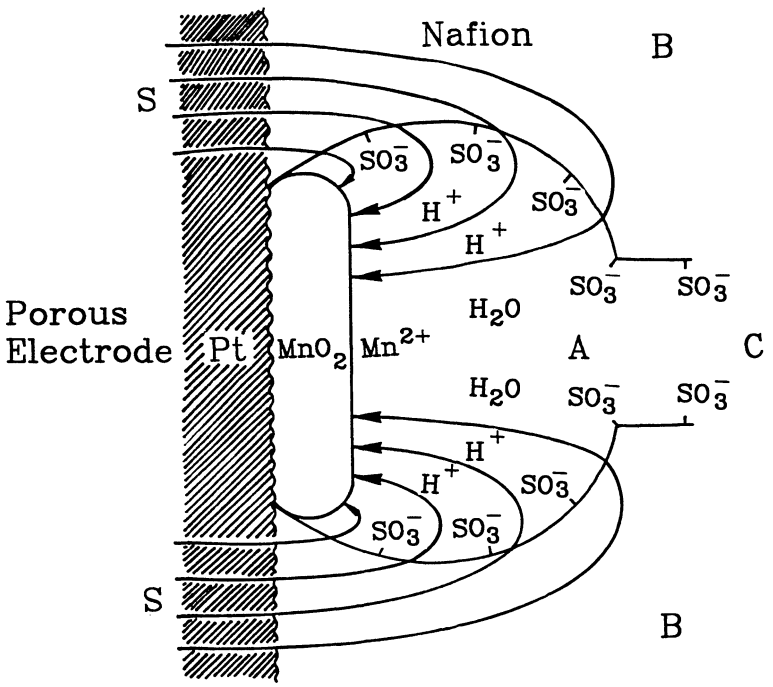

Fig. 6. Simplified schematic model of mass transfer to the active site on Mn,Pt-Nafion.
A: ionic cluster region, B: hydrophobic backbone region, C: channel, S: substrate.

Nafion. The solubilities of four solvents to water are listed in the same table. When THF is used as a solvent of anolyte, the aqueous catholyte and the anolyte mix with each other since Nafion is not a good separator for small neutral species[8] and THF is freely soluble in water; THF behaves as a co-solvent of cinnamyl alcohol and water. This mixing would increase the solubility of the substrate alcohol so that alcohol can be transported into the ionic cluster, reach MnO_2, and be oxidized to aldehyde. The product, cinnamaldehyde, is insoluble in water and mixing also increases its mass transport. Such mixing, however, also enhances the mass transport of both the substrate alcohol and the product aldehyde to the catholyte, while their transport rates are expected to remain small. This transport would make the separation processes difficult, decreasing the merit of SPE electrolyzers.

Since carbon tetrachloride is insoluble in water, on the other hand, it can neither enter into an ionic cluster nor enhance the transport of the substrate alcohol to an ionic cluster, thus differing from the case of a THF solution. The current efficiency of aldehyde formation was therefore very low in the case of carbon tetrachloride.

Benzene, the solubility of which is lower in water than THF and diethyl ether and higher than carbon tetrachloride, gave a medium current efficiency. The results given in Table 1 suggest that a mixture of benzene with water produces a sufficient flux to support mass transport at a current density as low as 1 $mA\,cm^{-1}$. When the current density is increased using benzene as a solvent, the rapid decrease in the current efficiency observed in Fig. 4 using THF appeared at a current density of about half the value for THF; a mass-transfer limitation appeared at a much lower current density for benzene than for THF. Benzene can not support such a large mass-transfer flux to the active site in the same way that THF can. This fact supports the importance of the miscibility of the solvent for mass transport. Diethyl ether has a fairly high solubility in water and gives an efficiency slightly lower than that of THF.

The increase in the substrate concentration seems to enhance its flux to the active site. This was not the case in the present system. An increase in the substrate concentration leads to a decrease in the THF (co-solvent) content. Since the substrate transport is controlled by the concentration of co-solvent around the active site of the deposited platinum electrode, a decrease in the THF content leads to a retardation of the transport of cinnamyl alcohol to the active site, and therefore lowers the current efficiency (Fig. 2). The same consideration is applicable to the result given in Fig. 3, which was obtained by changing the THF/carbon tetrachloride ratio. The decrease in the ratio lowered the THF content in the ionic cluster. This fact made the transport more difficult, decreasing the current efficiency with a decrease in the ratio.

From the above discussion, the path through which the substrate is transported to the active site of SPE composite electrodes seems to have a very large influence on the efficiency. The path includes not only the ionic cluster region, but also the porous electrode layer deposited on the Nafion. The morphology of the deposited platinum, such as its shape, size, porosity, and thickness, as well as the penetration depth of the deposited platinum particles into the Nafion, must have a very large influence on substrate transport. In order to obtain reproducible SPE composite electrodes, platinum must be deposited under controlled conditions regarding pretreatment, reductant composition, chloroplatinic acid concentration, pH, and temperature.[7] For example, the current density at which the reaction shifts from the mediatory oxidation of alcohol to oxygen evolution in a THF solution was dependent on the preparation process of the composite electrodes. On one electrode it was 12—13 $mA\,cm^{-2}$, and on the other it was 2—3 $mA\,cm^{-2}$. On the other hand, the potential at which the shift took place was independent of both the preparation process and the electrode morphology.

Conclusion

The influence of solvents on the electrooxidation of cinnamyl alcohol on Mn,Pt-Nafion was discussed. It is one of the merits of SPE electrolyzers that many different kinds of solvents can be used to dissolve the substrate. However, when an aqueous solution is used as a solution in CEC (that is favorable for electrolysis at a low cell voltage), a limitation in the selection of solvent arises in order to obtain a sufficient flux of substrate transport to the active site of the SPE composite electrode; a co-solvent for substrates and water is required. Solvents which are highly soluble in water, such as THF and diethyl ether, are useful. A composite electrode deposited with platinum on both surfaces of Nafion was applicable for the oxidation of cinnamyl alcohol. The cell voltage was as low as 2 V.

(Received September 13, 1990)

Substantial differences in photocatalytic reactivity were observed on powdered TiO_2 and ZnO, both Pt-loaded and unloaded, in the photocatalytic hydrogenation of $CH_3C{\equiv}CH$ and C_3H_6 in the presence of H_2O. Similar reactivity was observed, however, in the photocatalytic oxidation of i-C_4H_8 and C_3H_6 by O_2 on these same catalysts. Photoluminescence of TiO_2 and ZnO in the presence and the absence of H_2O and/or O_2 indicate that H_2O causes a downward band bending to increase the efficiency of recombination of photogenerated electrons and holes, with a greater effect being observed on ZnO than on TiO_2. These results, together with the direct detection of reaction intermediates by ESR, are rationalized by differences in the yields of the photogenerated intermediates, i. e., $\dot{H}$ (formed from trapped electrons) and $\dot{O}H$ (formed from trapped holes). The steady state concentrations of these intermediates depend on the degree of the positively-charged adducts on the surfaces of these oxides. The addition of O_2 causes an upward band bending of the oxide and suppresses recombination of photo-generated electrons and holes, by formation of negatively-charged surface adducts. With similar degrees of band bending, TiO_2 and ZnO produce almost the same photocatalytic reactivities as are observed for these oxides as dry systems.

Solar utilization via chemical storage can be achieved by photocatalytic and/or photoelectrochemical activation of light-sensitive semiconductor surfaces. Recent studies of photocatalysis have been focused on colloidal semiconductors,[1-4] on extremely small-sized particles in which size quantization effects are expected,[5-11] on highly dispersed well-defined supported catalysts,[12-20] and on various binary metal oxides.[21-28] Detection of the transient processes involving electron and/or energy transfer at the interfaces of the semiconducting materials has been recently contributed to a complete understanding of the true nature of the photocatalysis.[29-41]

Most photocatalytic studies on powdered semiconductors have been concerned only with analysis of reaction products and yields. These studies were mainly carried out as solid-liquid systems, where various electrochemical measurements are relatively easy but direct measurements of the intermediate species by ESR and the excited state of catalysts by photochemical techniques are difficult, compared with those in the solid-gas systems. In fact, besides a small number of mechanistic studies,[39,41-47] few photoelectrochemical measurements at the liquid-solid interface have characterized reaction intermediates or identified the excited state and/or primary processes of photocatalysis. Such mechanistic investigations would be much easier at the gas-solid interface, as has been shown in our earlier works.[4,12]

Most mechanistic studies of metal oxides have investigated on TiO_2,[1-4,12] because of its high activity and stability. A small number have been undertaken on ZnO,[46,1,48-51] although it is very similar electrochemically to TiO_2. Recently, in a preliminary study, a substantial difference in the photoreactivities of powdered TiO_2 and ZnO for the activation of H_2O and/or OH groups on the surface of these oxides has been reported despite similar reactivity for the activation of O_2 and/or lattice oxygen ions on these surfaces.[1] A detailed investigation of this different photoreactivity might clarify photocatalysis on these semiconducting materials.

In the present work we compare photocatalytic reactions on powdered TiO_2 and ZnO in the solid-gas systems in the presence (wet system) and the absence of H_2O (dry system), the effect of Pt loading on the photoreactivities of these oxides, the origin of their different reactivities, and direct measurements of the reaction intermediates by ESR and the excited state of catalysts by photoluminescence spectroscopy.

Experimental

TiO_2 (rutile) (BET surface area; 8.0 $m^2 g^{-1}$, average particle size; 1000—2000 Å) was supplied by Ishihara Sangyo Kaisha, Ltd. Kadox-25 ZnO powder (BET surface area; 8.5 $m^2 g^{-1}$, average particle size; 1000—1500 Å) was used, because it has almost the same surface area and particle size to those of TiO_2 used. Pt-loaded catalysts were prepared by

mixing the desired amount of TiO_2 (or ZnO) and Pt black powder (2.0 wt%) followed by thorough grinding in an agate mortar. $CH_3C{\equiv}CH$, C_3H_6, and i-C_4H_8 were extra pure grade from the Takachiho Kogyo Co., used without further purification. $^{18}O_2$ (90%, E. Merck Co.) was used. Deionized twice-distilled water was degassed by alternate freezing and thawing in vacuo.

The quartz cell used in the present study was about 10 cm long and 5.0 cm in diameter with a total volume of about 300 cm^3. The catalyst could be moved between the window section and the furnace section, so that its temperature could be raised from room temperature to about 1200 K. The cell was connected to a conventional vacuum system. Prior to the reaction, catalysts were degassed at 773 K for 5 h, heated in O_2 at the same temperature for 5 h, and then finally evacuated at 623 K to 10^{-6} Torr (1 Torr=133.322 Pa). After evacuation of the catalyst, water vapor (i. e., wet system) or oxygen (i. e., dry system) was introduced onto the catalyst, followed by the reactant molecules at 298 K. UV irradiation was carried out with a 75-W high-pressure mercury lamp (Toshiba SHL 100UV) through a cut-off and a water filter (λ>280 nm) at 298 K. The reaction products were collected in cold traps.

Analysis of the reaction products was carried out by gas chromatography. Quantum yields were measured at 300 nm by potassium trioxalatoferrate actinometry. Isotopic analysis of O_2 was carried out with a quadrupole mass spectrometer. ESR measurements were carried out at 77 K with a JEOL ME-1 (X-band). UV irradiation for ESR measurments was carried out using a 500-W high-pressure mercury lamp with a color filter (λ>280 nm) in a ESR cavity. Diphenylpicrylhydradyl (DPPH) was used for g values and sweep calibration. Photoluminescence spectra were measured by using a Shimadzu RF-501 spectrofluorophotometer equipped with filters to eliminate scattered light at 298 and 77 K. The amount of desorbed H_2O from the catalysts (TPD spectra) was determined by measuring the pressure of desorbed H_2O as the temperature was increased step by step from 273 to 873 K. A monolayer of H_2O had been adsorbed previously on the catalysts. Analysis of the X-ray diffraction lines of the catalysts showed that the catalysts consist of only pure rutile-type TiO_2 crystallites and pure ZnO, respectively. The particle diameters were determined by X-ray diffraction and/or transmission electron microscopy. Details of the experiments were described in the previous papers.[52-55]

Results and Discussion

1. Photocatalysis on TiO_2 and ZnO Catalysts in Wet Systems. Figure 1 shows the observed differences in the photocatalytic hydrogenation yields for the reactions of $CH_3C{\equiv}CH$ with H_2O (wet system) on Pt-free powdered TiO_2 (TiO_2), Pt-loaded powdered TiO_2 (Pt/TiO_2), Pt-free powdered ZnO (ZnO), and Pt-loaded powdered (Pt/ZnO) catalysts at 298 K. The initial rates and quantum yields of these reactions are described in Table 1. Table 2 includes these values

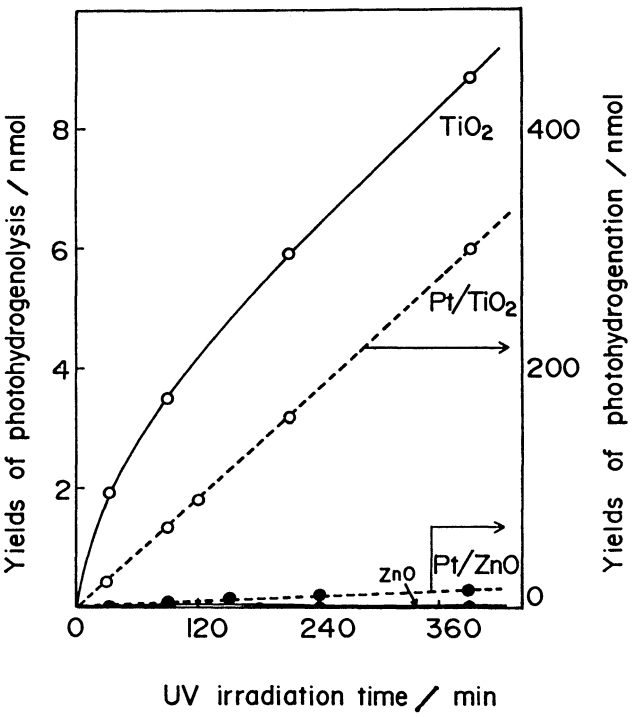

Fig. 1. Photocatalytic hydrogenation of $CH_3C{\equiv}CH$ with H_2O on Pt/TiO_2, TiO_2, Pt/ZnO, and ZnO at 298 K. (UV irradiation: 280 nm, 3 Torr C_3H_4, 8 Torr H_2O,)

Table 1. Comparison of the Rates and Quantum Yields of Photohydrogenation of $CH_3C{\equiv}CH$ with H_2O on TiO_2, Pt/TiO_2, ZnO, and Pt/ZnO Catalysts at 298 K[a]

Catalysts	Major products[b]/10^{-9} mol m^{-2} h^{-1}						
	CH_4	C_2H_4	C_2H_6	C_3H_6	C_3H_8	CO	CO_2
TiO_2	0.10	0.018	0.57	0.013	0.02	1.03	5.75

Pt/TiO_2	0.17	Trace	0.53	5.00	1.07	6.42
Quantum yields	—	—	0.0075	0.071	0.015	0.091

a) The pressures of C_3H_6 and H_2O were 3 and 8 Torr, respectively. b) CH_3CHO, CH_3COCH_3, and $CH_3COC_2H_5$ were detected as minor oxidation products. c) Quantum yields were determined at 350±10 nm on Pt/TiO_2 at 298 K. Quantum yield=(number of photoformed product)/(number of incident photons). Rates of photohydrogenation on ZnO were too low to follow the kinetics.

for the results of the photohydrogenation reaction of C_3H_6 with H_2O on Pt-loaded and unloaded TiO_2. The rates of the photocatalytic hydrogenation of C_3H_6 with H_2O on ZnO and Pt/ZnO catalysts were too low to follow their kinetics. The major products of the photocatalytic hydrogenation of $CH_3C{\equiv}CH$ and C_3H_6 with H_2O on TiO_2 and on ZnO were C_2H_6 as hydrogenation product accompanied by the fission of the carbon-carbon bond of $CH_3C{\equiv}CH$ and C_3H_6, i. e., hydrogenolysis (CH_4 as minor product), and CO_2 as oxidation product. Ketones and aldehydes were also detected as minor photooxidation products.

The product distribution in the photocatalytic hydrogenolysis is in good agreement with that observed on TiO_2 catalysts,[52-55)] which has been attributed to a closely spaced photogenerated electron-hole pair, i. e., Ti^{3+}-$\dot{O}H$ pair species. These electron-hole pairs can interact with $CH_3C{\equiv}CH$ adsorbed on the surface to form the carbenes and/or oxygen-containing compounds via carbon-centered radicals such as $\dot{C}H$ and $CH{\equiv}\dot{C}$ formed in a manner similar to that described previously.[52,54,55)]

On the other hand, as shown in Table 1 and Fig. 1, on Pt/TiO_2 and Pt/ZnO, where the photoelectrochemical mechanism is operating, the major product was C_3H_6: that is, hydrogenation dominated over carbon-carbon bond fission while producing CO_2 as oxidation product. The rates for the photocatalytic hydrogenation are markedly enhanced on both TiO_2 and ZnO by the presence of Pt as a co-catalyst, Table 1. The rates of photocatalytic hydrogenolysis on TiO_2 and hydrogenation on Pt/TiO_2 of $CH_3C{\equiv}CH$ with H_2O are much higher than those on ZnO and Pt/ZnO, respectively, with nearly the same conversion being observed on the Pt-loaded and native systems. With TiO_2 and ZnO, the rates of oxidation are much higher than that of the hydrogenation. However, with Pt/TiO_2 and Pt/ZnO, there is no marked difference between the rates, supporting our previous assertion that photoreactions on Pt-loaded TiO_2 and ZnO are much more catalytic than those on Pt-free TiO_2 and ZnO.[53)]

Figure 2 shows a temperature-programmed desorption (TPD) spectra for desorption of H_2O from TiO_2

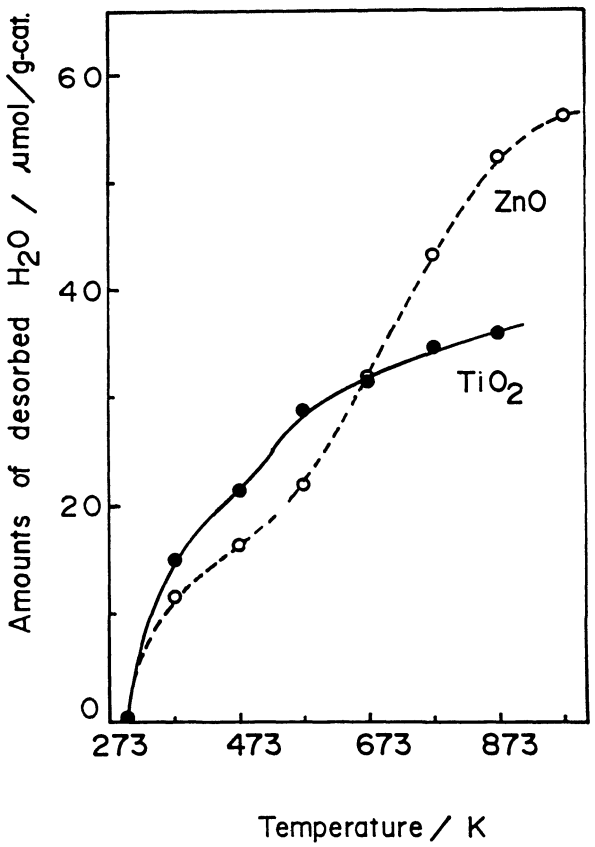

Fig. 2. Amounts of desorbed H_2O from TiO_2 and ZnO. (A monolayer of H_2O had been adsorbed previously on the oxides at 298 K.)

and ZnO after the adsorption of a monolayer of H_2O at 298 K. The amounts of water desorbed from TiO_2 and ZnO in the temperature range from 273 to 673 K are almost the same, whether native or Pt-loaded. Thus, the observed differences in rates of photocatalytic reactions do not correlate with the steady state adsorption of water.

The efficiency of photoreactions on TiO_2 is higher than that on ZnO by a factor of at least 40, irrespective of Pt loading. In these photohydrogenation reactions on TiO_2 (or ZnO) in the presence of adsorbed H_2O, it is likely that both $\dot{H}$ and $\dot{O}H$ radicals are

generated,[12,52-54] Eqs, 1 and 2, respectively, since a water dissociation preequilibrium $H_2O \rightleftarrows H^+ + OH^-$ is established on oxides.[52] Therefore, photogenerated electrons (or Ti^{3+}) are trapped by protons supplied from the acidic groups at the specific surface sites. Photogenerated holes (or O^-) are trapped at basic surface sites, though the nature of the basic OH^- groups associated with the oxidation is still unclear.

$$H^+ + e^- (Ti^{3+}) \longrightarrow \dot{H} + Ti^{4+} \quad (1)$$

$$OH^- + h^+ (O^-) \longrightarrow \dot{O}H + O^{2-} \quad (2)$$

On the Pt-free TiO_2 and ZnO, both $\dot{H}$ and $\dot{O}H$ radicals are formed on these oxides at sites close to each other, their proximity resulting in photocatalytic hydrogenolysis accompanied by the carbon-carbon bond fission, but not hydrogenation.[52-54] On the Pt-loaded TiO_2 and ZnO, however, enhancement of electron trapping by adsorbed protons on Pt results in more efficient charge separation.[53] Thus, the marked increase in the rate of photohydrogenation on Pt/TiO_2 and Pt/ZnO probably arises from addition of H atoms to $CH_3C{\equiv}CH$ and C_3H_6 on Pt particle sites but not on TiO_2 or ZnO. This results in a high efficiency for photocatalytic hydrogenation, and a much better balanced contribution of photogenerated electrons and holes to the surface reactions, i. e., a much more catalytic reactivity. The similarity in the product distribution shown in Fig. 1 and Table 1 clearly suggests that the reaction mechanisms operative on ZnO are the same as those on TiO_2, except for the much lower yields.[1]

2. Photocatalysis on TiO_2 and ZnO Catalysts in Dry Systems. UV irradiation of TiO_2 and ZnO in the presence of the mixtures of hydrocarbons and oxygen leads to the oxidation of these compounds.[1,51,56] Figure 3 shows the observed differences in the yields of the photocatalytic oxidation of i-C_4H_8 by O_2 (i. e., dry system) on Pt-free TiO_2, Pt/TiO_2, Pt-free ZnO, and Pt/ZnO catalysts at 298 K.[1] The rates and quantum yields of photooxidation of i-C_4H_8 and C_3H_6 by O_2 on these Pt-loaded and native catalysts are shown in Table 3. The major products of the photocatalytic oxidation of i-C_4H_8 are CH_3COCH_3 and CO_2 on all four catalysts, but products are formed with different rates and selectivities. In the photocatalytic oxidation of C_3H_6, various oxygen-containing compounds such as CH_3COCH_3, C_2H_5CHO and CH_3OH, in addition to the formation of CO_2, are obtained. The efficiency of TiO_2 for the photocatalytic oxidation of i-C_4H_8 and C_3H_6 is about 1.2—2 times higher than that of ZnO. These values are smaller than those obtained in wet systems by at least an order of magnitude.

UV irradiation of TiO_2 and ZnO in the presence of isotopically-labelled O_2 leads to the photocatalytic oxygen isotopic exchange,[56,57] (Fig. 4). The degassing temperature and the presence of H_2O influence the

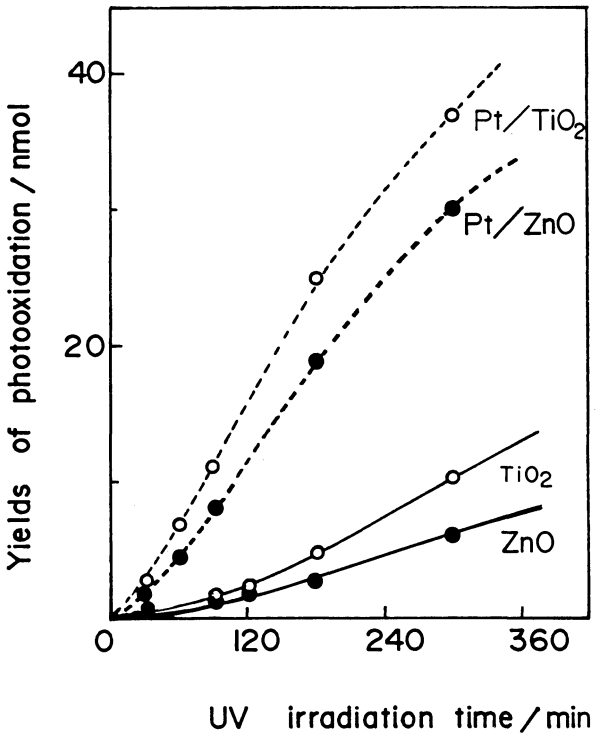

Fig. 3. Photocatalytic oxidation of i-C_4H_8 with O_2 on dry Pt/TiO_2, TiO_2, Pt/ZnO, and ZnO at 298 K. (UV irradiation: 280 nm, 6 Torr O_2, 3 Torr i-C_4H_8.)

Table 3. Comparison of the Rates and Quantum Yields of Photooxidation of i-C_4H_8 and C_3H_6 with O_2 on TiO_2, Pt/TiO_2, ZnO, and Pt/ZnO Catalysts at 298 K

Catalyst	Major products/10^{-9} mol m^{-2} h^{-1}					
	Photooxidation of i-C_4H_8[a]		Photooxidation of C_3H_6[b]			
	CO_2	CH_3COCH_3	CO_2	CH_3COCH_3	C_2H_5CHO	CH_3OH
TiO_2	2.50	0.881	3.1	0.557	0.16	0.52
Pt/TiO_2	45.1	1.863				
ZnO	1.31	0.567	1.92	0.36	0.11	0.28
Pt/ZnO	43.6	1.478				

a) The pressures of i-C_4H_8 and O_2 were 3 and 6.0 Torr, respectively. b) The pressures of C_3H_6 and O_2 were 1 and 3.0 Torr, respectively. c) The experiments of photooxidation of C_3H_6 by O_2 on Pt/TiO_2 and Pt/ZnO catalysts were not carried out yet.

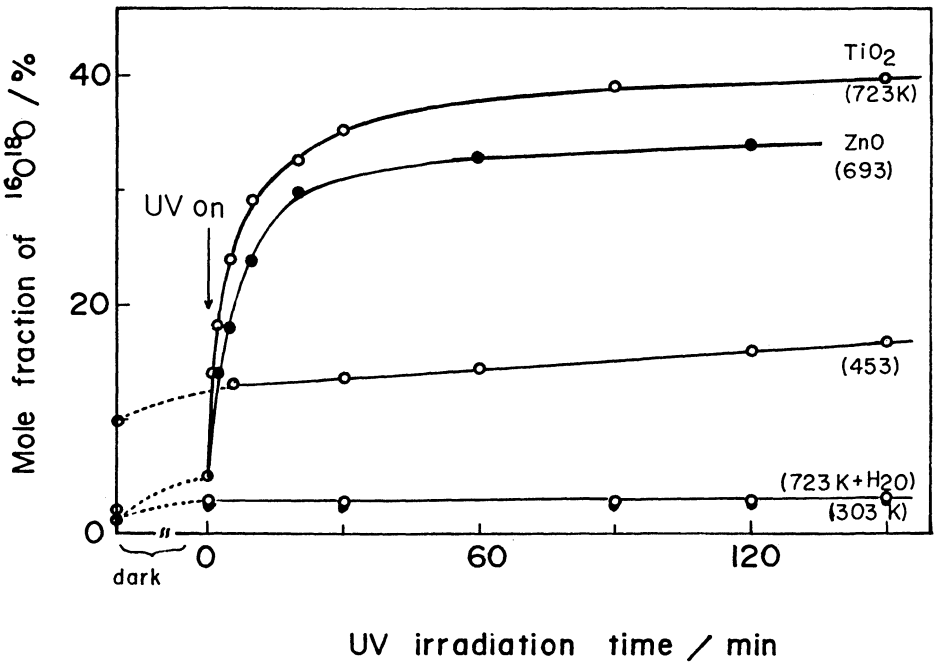

Fig. 4. Photocatalytic oxygen isotopic exchange on TiO_2 and ZnO and the effect of adsorbed H_2O on the exchange reaction on TiO_2 at 298 K. (UV irradiation: 280 nm, value in parenthesis indicates the degassing temperature of the catalyst.)

observed rates of exchange. There is only a small difference in reactivity between TiO_2 and ZnO, the reactivity of TiO_2 being higher than that of ZnO by only 1.5—2 times. Adding H_2O to the TiO_2 catalyst, which had been deggassed at 723 K, the surface OH groups markedly suppresses this reaction.

Both photocatalytic oxygen isotopic exchange and photooxidation of alkenes with O_2 on dry TiO_2 and ZnO probably proceed via O_3^- and O_2^- anion radicals, Eqs. 3 and 4:[41,42,56-58]

$$O_2 + h^+ (O^-) \longrightarrow O_3^- \quad (3)$$

$$O_2 + e^- (Ti^{3+}) \longrightarrow O_2^- \text{-} Ti^{4+} \quad (4)$$

3. Measurements of Reaction Intermediates. UV irradiation of TiO_2 in the presence of O_2 leads to the formation of O_3^- anion radicals with high efficiency, together with the formation of O_2^- anion radicals, (Fig. 5). The ESR signal assigned to O_3^- is obtained as a difference spectrum by subtracting the spectrum before irradiation from that observed after irradiation at 77 K.[54,56] The addition of O_2 to TiO_2 led to the formation of O_2^- species. The photogenerated O_3^- radicals were also observed by ESR at 77 K when ZnO was UV-irradiated in the presence of O_2. O_3^- anion radicals are probably formed via the reaction of O_2 with photogenerated O^-. This species might be formed by hole trapping on the lattice O^{2-} ions as mentioned above (i. e., reaction (3)). In the absence of O_2, the O^- species can be detected by ESR at 77 K under UV irradiation of ZnO, (Fig. 6).[59] O^- is not detected directly on TiO_2 by ESR, probably because of

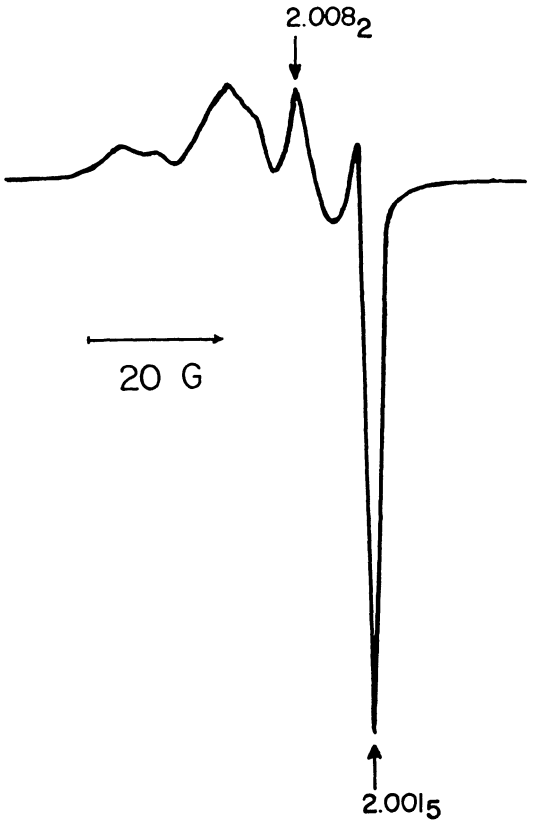

Fig. 5. ESR spectrum of the photogenerated O_3^- anion radical on TiO_2 at 77 K. (UV irradiation and ESR measurments were carried out at 77 K in the presence of O_2.)

its short lifetime even at 77 K and/or incomplete removal of the degeneracy of the p-orbitals in this species. Photogenerated electrons trapped as Ti^{3+} (or Zn^{+}) are directly associated with the photogeneration of O_2^- at Ti^{4+} sites of TiO_2 (or Zn^{2+} ions of ZnO), (Eq. 4).

In the presence of H_2O on TiO_2 and ZnO (wet systems), however, neither O_2^- nor O_3^- anion radicals could be longer detected. On extremely small TiO_2 particles (about 50 Å, and BET surface area 800 $m^2 g^{-1}$) the formation of ȮH radicals was detected by UV irradiation of the TiO_2 in the presence of a monolayer of H_2O.[60] With the present TiO_2 catalyst (2000 Å and BET surface area 8.0 $m^2 g^{-1}$), the detection of the photoformed ȮH radicals was not successful because of its lower photoactivity. Formation of these Ḣ and ȮH radicals may have occurred on these wet systems in lieu of the formation of O_2^- and O_3^-.

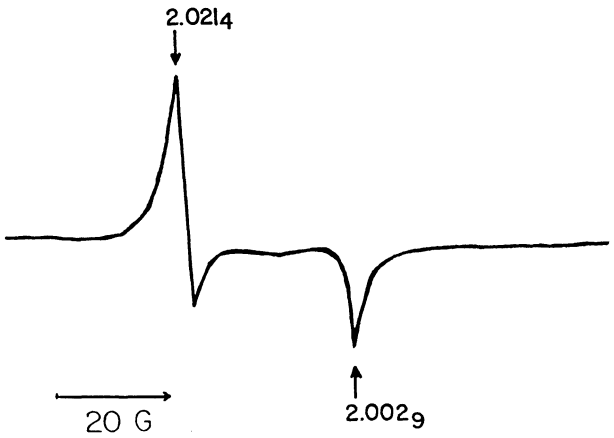

Fig. 6. ESR spectrum of the photo-generated O^- anion radical (hole trapped centers) of ZnO at 77 K. (UV irradiation and ESR measurments were carried out at 77 K in vacuo.)

4. Photoluminescence Behaviors of TiO_2 and ZnO in Dry and Wet Systems. ZnO used in the present work exhibits a high yield photoluminescence when excited with the band-gap light (about 3.2 eV=380 nm).[59] Figure 7 shows the photoluminescence spectrum of ZnO (1) at 298 K and the effect of the addition of H_2O (2—4). The addition of H_2O leads to an increase of the intensity of the photoluminescence, depending on the amounts of adsorbed H_2O. As in a previous study,[61] the addition of $CH_3C{\equiv}CH$ or H_2O onto the TiO_2 led to an enhanced photoluminescence but the magnitude of the enhancement was much smaller than that on ZnO. That is, the addition of excess H_2O led to the 1.5—2.0 times enhancement of the photoluminescence of ZnO, while on TiO_2 it was only 1.1—1.2 times.

The addition of O_2 to ZnO leads to a decrease of the intensity of the photoluminescence, its extent depending on the amounts of added O_2, Fig. 8. As reported previously,[61] the addition of O_2 to TiO_2 also led to

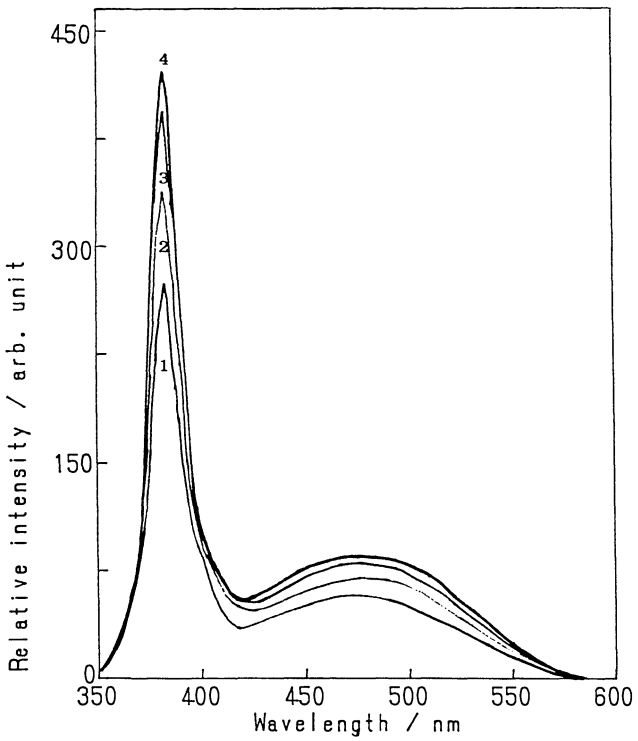

Fig. 7. Effects of H_2O on the photoluminescence of ZnO at 298 K. (Pressure of added H_2O in Torr, 1: 0.0, 2: 0.5, 3: 18, 4: excess amounts.)

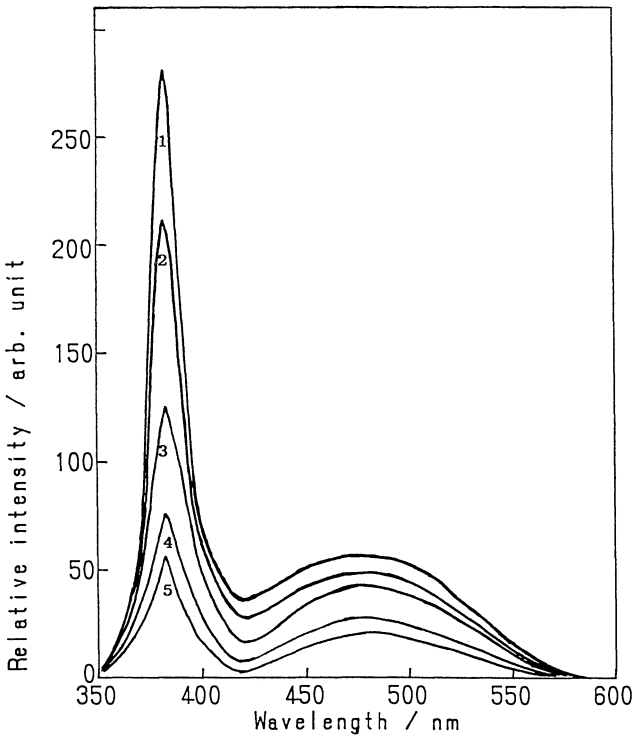

Fig. 8. Effects of O_2 on photoluminescence of ZnO at 298 K. (Pressure of added O_2 in Torr, 1: 0.0, 2: 0.5, 3: 3.5, 4: 12.0, 5: 20 or excess amounts.)

photoluminescence quenching. The addition of 3—10 Torr O_2 (even excess O_2) to TiO_2 and ZnO led to 80—95% quenching of their photoluminescence almost equally on the two oxides, though the initial yield of photoluminescence of TiO_2 is much lower than that of ZnO.

The mechanisms for the enhancement and quenching of the photoluminescence of the powdered semiconductors such as CdS and TiO_2 by added molecules are recently well explained by the models of Ellis et al.[62-64] and Anpo and Fox et al.[61] The formation of negatively-charged adducts (via electron capture) on the surfaces of semiconductors such as TiO_2 and CdS causes photoluminescence quenching, while the formation of positively-charged adducts (via hole trapping) results in an enhancement of the photoluminescence.

Bard et al.[65] have shown that the photoluminescence quenching, photoinduced oxygen adsorption, and photodecomposition observed with ZnS particles are very sensitive to surface effects and concluded that the photoluminescence can be used as a probe of electron-hole surface processes. In fact, recently, Anpo and Fox et al.[61] have found a parallel relationship between the enhancement of photoluminescence of TiO_2 by the addition of unsaturated hydrocarbons and the rates of photocatalytic hydrogenation of those same unsaturated hydrocarbons by H_2O on TiO_2. Thus, these photoinduced surface processes are closely associated with, both depending crucially on the binding of the added molecules to the TiO_2 surface. The results obtained on TiO_2 and CdS clearly suggest that the formation of adsorbed charged species plays a significant role in determining the reactivities of the photogenerated electron-hole pairs on the semiconductors.

Consequently, as shown in Fig. 9, these results suggest that the addition of H_2O and/or $CH_3C{\equiv}CH$ onto the TiO_2 and ZnO causes structural changes in surface band bending to increase the efficiency of recombination of the photogenerated electrons and holes, resulting in an enhancement of the photoluminescence, with larger effects being observed on ZnO than on TiO_2. On the other hand, the addition of O_2 onto these photocatalysts caused a suppression of the efficiency of recombination of the photogenerated electrons and holes (i. e., better charge separation), resulting in a quenching of the photoluminescence to about the same extent on TiO_2 and ZnO (Excess O_2 leads to the almost complete quenching of the photoluminescence.). Although the details are not clear at present, this photoluminescence behaviour is probably associated with the different electronic structures of the TiO_2 and ZnO surfaces, since Ti^{4+} and Zn^{2+} ions can play a significant role in forming surface adducts.

The nature of the photocatalytic action of TiO_2 and ZnO is the same for both Pt-loaded and native systems, respectively, but large differences in reactivities are

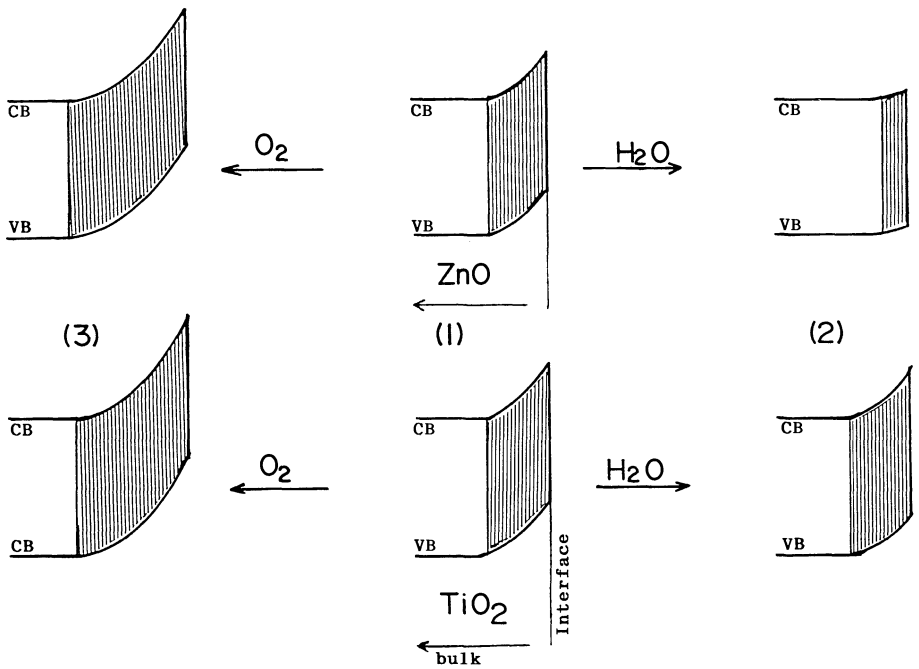

Fig. 9. Schematic description of the surface band bending of ZnO (top) and TiO_2 (bottom). (1): after degassing in vacuo (n-type semiconductors), (2): after adsorption of H_2O (decrease of band bending by formation of positively-charged species on the surfaces), (3) after adsorption of O_2 (increase of band bending by formation of negatively-charged species on the surfaces).

encountered on these catalysts. Much larger differences are observed in the activation of H_2O and/or surface OH groups, while only small differences are observed in reactions associated with the activation of O_2 in dry systems. Thus, the observed large photoreactivity differences between wet TiO_2 and ZnO arise from the much faster recombination of photogenerated electrons and holes on the surface of wet ZnO than that on TiO_2, because the formation of the positively-charged surface adducts from H_2O and/or $CH_3C{\equiv}CH$ results in much smaller upward band bending on ZnO than on TiO_2. On the other hand, in dry systems, the formation of the negatively-charged surface adducts of O_2 leads to much larger upward band bending on both TiO_2 and ZnO, producing higher photocatalytic efficiencies for TiO_2 and ZnO and negligible differences in their reactivities.

Conclusions

The photocatalytic reactivities of powdered TiO_2 and ZnO, both Pt-loaded and native, differed significantly in the photocatalytic hydrogenation of $CH_3C{\equiv}CH$ and C_3H_6 with H_2O but not in the photocatalytic oxidation of i-C_4H_8 and C_3H_6 with O_2. Photoluminescence of TiO_2 and ZnO in the presence and the absence of H_2O or O_2 indicated that addition of H_2O onto the oxides causes downward band bending to increase the efficiency of recombination of photogenerated electrons and holes, to a greater extent on ZnO than on TiO_2. On the other hand, the addition of O_2 led to upward band-bending to suppress recombination of photogenerated electrons and holes almost equally on the two oxides.

Thus, photoluminescence of TiO_2 and ZnO (as radiative recombination of photogenerated electrons and holes), together with the direct ESR detection of reaction intermediates, suggested that the large observed difference in the photoreactivity between wet TiO_2 and ZnO derives from the much faster recombination on ZnO because of the formation of positively-charged surface adducts. In dry systems, the formation of the negatively-charged O_2 proceeds nearly equivalently on these two catalysts, resulting in a net higher photocatalytic efficiencies of both TiO_2 and ZnO but little difference in their reactivities.

The photocatalytic programs in Osaka is supported in part by a Grant-in-Aid for Scientific Research No. 62550595 and 01550632) from the Ministry of Education, Science and Culture. The photocatalytic program in Austin is generously supported by the Office of Basic Energy Sciences, U.S. Department of Energy. Hydrogenation of 1,3-Butadiene over CaO Catalyst Treated with Methanol

Tsuneo MATSUDA,* Masatoshi SUGIMOTO, and Hiroshi YOSHIARA
Department of Applied Chemistry, Faculty of Engineering, Saitama University, Urawa, Saitama 338
(Received October 8, 1990)

When calcium oxide was treated with methanol at low temperature, calcium methoxides i.e., calcium dimethoxide and, calcium hydroxide methoxide, could be easily formed. The catalyst produced by the thermal decomposition of these compounds exhibited remarkably high activity to the hydrogenation of 1,3-butadiene. With the aim to investigate the cause of the high activity, two other calcium oxide catalysts were used for a comparison. The cause was ascribed to the formation of a large amount of electron-donating sites, including both basic ones and those with a high surface area.

Solid base catalysts, such as CaO and MgO, are known to catalyze the isomerization of butenes,[1] the dehydrogenation of alcohols,[2] the hydrogenation of dienes,[3-6] as well as H_2-D_2[7] and CH_4-D_2[8,9] exchange reactions. Tanaka et al.[3] pointed out that CaO prepared by the evacuation of $Ca(OH)_2$ above 1073 K gave a high catalytic activity for the hydrogenation of 1,3-butadiene at 273 K. Miyahara et al.[4] have also shown that the maximum activity for the hydrogenation of 1,3-butadiene is obtained when MgO is prepared around 1073—1273 K under vacum. Thus, treatment at higher temperatures than 1073 K under vacuum are necessary for the appearance of hydrogenation activity. We recently found a remarkably highly active CaO catalyst for the hydrogenation of 1,3-butadiene. The preparation method of the catalyst does not require a higher temperature than 1073 K. By heating under vacum at a rather lower temperature (873 K) after a treatment with methanol, a very high activity could be developed. Why such a high activity appeared through such a simple method as a methanol treatment is a very interestng problem. The aim of this paper is to answer the above question by comparing the three kinds of CaO catalysts.

Experimental

Materials. Three kinds of calcium oxide catalysts were used for a comparion. The calcium oxide purchased from Wako Junyaku Co. was calcined at 1173 K for 15 h in air in order to decompose the calcium carbonate and hydroxide impurities into CaO. This is called CaO(I). The second catalyst, CaO(II), was prepared by the decomposition of $Ca(OH)_2$, which was formed by refluxing a CaO(I) suspension in water for 3 h. In place of water CaO(I) was suspended in methanol, followed by stirring for 24 h at room temperature; methanol was then removed to dryness in an evaporator at ca. 333 K. This catalyst is called CaO-M. All of the catalysts were stored in a desiccator. Just before the reaction all of the catalysts used were slowly heated *in situ* under a vacuum and increasing temperature at a rate of 5 K min^{-1} to 873 K; this temperature was maintained for 1 h. This procesure is abbreviated as a pretreatment hereafter. The surface areas of CaO(I), (II) and CaO-M were measured by the BET method, giving 7.71, 55.2 and 139 $m^2 g^{-1}$, respectively.

1.3-Butadiene (Takacio Co., more than 99% purity) was purified by a repeated freeze-and-thaw technique. Hydrogen with a purity of more than 99.9999% (Takachio Co.)was dried using a trap containig a moleculare sieve (5A) kept at 77 K.

Reaction Procedures. The reaction was carried out in an all-glass static reactor with a volume of ca. 225 ml in a closed recirculation reactor equipped with a sampling manifold. A weighed amount of catalyst specimen (0.05 g as CaO) was placed in a qualtz glass reactor. The weight loss of CaO(II) and CaO-M due to the pretreatment was examined beforehand. A typical hydrogenation mixture of 1,3-butadine : hydrogen=50 : 100 Torr, (1 Torr=133.322 Pa) was used in the reaction. The reaction was carried out at 273 K, and the reaction products analyzed by a gas chromatograph equipped with a 5 m column of VZ-7 at 313 K

IR Measurement, A thin disk of the catalyst sample was treated using the same procedure as in the pretreatment. The IR spectra were recorded with a JASCO Model 810 spectrometer without exposing the sample to air.

ESR Measurement. The ESR spectra were recorded on a Varian E-9 spectrometer (X-band with 100 kHz field modulation) at room temperature. The sample was prepared in an apparatus equipped with both greaseless stop valves and a trap used to cut the vapor from grease. For the *g*-value and spin concentration calibration, DPPH was used as a standard probe in a dual cavity. The relative concentration was estimated as being the ratio of the spin concentration per unit gram of sample vs. the spin concentration of DPPH. An approximate method to measure the spin concentration was adopted comprising the product of the square of the line width and the peak-to-peak height in order to estimate the area under the ESR absorption curve.[10] The electron-donating property of the catalysts was examined with the radical produced by the adsorption of nitrobenzene.

The sample was placed in a qualtz adsorption chamber equipped with a side ESR tube; at room temperature nitrobenzene vapor was adsorbed for 30 min and then evacuated for 15 min at the same temperature. The proper amount of the sample was transfered into the tube and then sealed for an ESR measurement.

XPS Measurement. The X-ray photoelectron spectra were recorded at room temperature on a Ulvac-Phi Model UP ESCA and Auger spectrometer using monochromatic Mg-α exciting radiation with an energy of 1253.6 eV. The spectrometer vacuum was better than 10^{-9} Torr. A thin

disk pressed from powder was treated using the same method as in the pretreatment. The Cls level of a trace of contaminant carbon, 285.0 eV, was taken as a reference.

Basicity Measurement. A CaO-M catalyst after the pretreatment showed a slight dark-gray color. Two other calcium oxide catalysts were white. Consequently, it was impossible to measure the surface basicity of CaO-M by the indicator method. Therefore, the basicity was estimated from the irreversible adsorption amount of CO_2. CO_2 was adsobed at 273 K on the catalyst sample; after attaining equilibrium, it was evacuated at 873 K for 1 h. Again, CO_2 was adsorbed on the sample at 273 K at the same presure as in the case of the initial adsorption. The irreversible adsorption amount of CO_2 was thus estimated from the difference of the adsorbed amount during the initial and secondary adsorption.

Results

Hydrogenation of 1,3-Butadiene. Carbon dioxide and oxygen inhibited the reaction when they were adsorbed on the catalysts. Hydrogenation of 1,3-butadiene over three kinds of CaO catalysts was carried out at 273 K. The conversion vs. the reaction-time plots are shown in Fig. 1. Though no reaction proceeded on CaO(I), the activity appeared on CaO(II) and CaO-M. Especially CaO-M catalyst exhibited a remarkably high activity, while attaining a conversion of 100% in only 2—3 min. Though the activity of CaO(II) was less than that of CaO-M, the conversion reached ca. 100% within 40 min after starting the reaction. The product distribution is shown in Table 1, showing that *trans*-2-butene was preferentially formed on both CaO(II) and CaO-M catalysts. This result agrees with those of Miyahara et al.[4] or of Shima and Yamaguchi.[5] The equilibrium composition of the hydrogenation products at 273 K can be calculated as 1-butene : *trans*-2-butene : *cis*-2-butene=2.3 : 76.1 : 21.6 (%). It can therefore be supposed that the experimental results regarding both CaO(II) and CaO-M catalysts nearly attained the thermodynamic equilibrium state due to the very high reaction rate. The conversion to 2-butene was higher than 96%, indicating that a 1,4-addition of hydrogen on 1,3-butadiene dominated. Strictly, it can also be considered that 1-butene was formed by a 1,2-addition during the initial stage, and then rapidly isomerized to 2-butenes, since the reaction rate was so high. However, from the results concerning the reaction of 1,3-butadiene and deuterium,[6] the 1,4-addition reaction predominantly proceeds on solid-base catalysts, such as MgO and CaO. It is consequently rational to regard that the hydrogenation in this study proceeded by the 1,4-addition mechanism. The reaction temperature of hydrogenation was so low that no further hydrogenation to butane could proceed, although CaO-M was the most active catalyst, as already described. However, if the reaction temperature was increased to as high temperature as 523 K,[11] the formation of butane would be detected. Also, in this study the rate from butenes to butane appears to be remarkably slow compared to the hydrogenation of butadiene. The initial rates of the hydrogenation, which were obtained from a decline of the linear region in 1.5-min intervals from the start of the reaction in the curve of the conversion vs. reaction time plots, are shown in Table 2. The rate on CaO-M was 2-times greater in magnitude than that on CaO(II).

Table 1. Product Distribution in Hydrogenation of 1,3-Butadiene

Catalyst	Reaction time/min	Conversion	Product/%		
		%	1-Butene	*trans*-2-Butene	*cis*-2-Butene
CaO-M	2	98.8	3.65	72.4	24.0
	5	100	3.26	71.8	25.0
	15	100	3.09	72.6	24.3
CaO(II)	2	60.8	3.73	72.4	22.9
	5	76.5	3.43	72.7	24.3
	15	90.9	3.16	72.3	24.6

Table 2. The Relative Spin Concentration and Initial Rate of the Hydrogenation on the Three CaO Catalysts

Catalyst	Initial rate	Relative spin concentration
	mmol g^{-1} min^{-1}	g^{-1}
CaO-M	8.93	3.59×10^{2} a)
CaO(II)	4.20	1.45×10^{2}
CaO(I)	0	4.01×10^{-2}

a) The caliblated value with the relative concentration of graphite carbon.

XRD Measurements. CaO(I) exhibited only CaO peaks as expected. Though before the pretreatment, CaO(II) mainly comprised $Ca(OH)_2$, after heating at 873 K under vacuum it turned to CaO accompanyed by a small amount of $Ca(OH)_2$, although the crystal structure was somewhat distorted. In the case of CaO-M, the XRD pattern exhibited relatively good crystallinity before the pretreatment, in which the peaks corresponded to CaO, $Ca(OH)_2$ and calcium dimethoxide, ($Ca(OCH_3)_2$) or calcium hydroxide methoxide ($Ca(OH)(OCH_3)$) were observed, as shown in Fig.2. However, $Ca(OH)(OCH_3)$ could not be distinguished from $Ca(OCH_3)_2$ by XRD. By the pretreatment the crystal state was remarkably distorted to be amorphous. Whether other alcohols, (for instance, ethanol and propanol) could similarly react with calcium oxide or not was examined. No calcium alcohoxides of ethanol and 2-propanol could be produced. Only the CaO peak was detected by XRD.

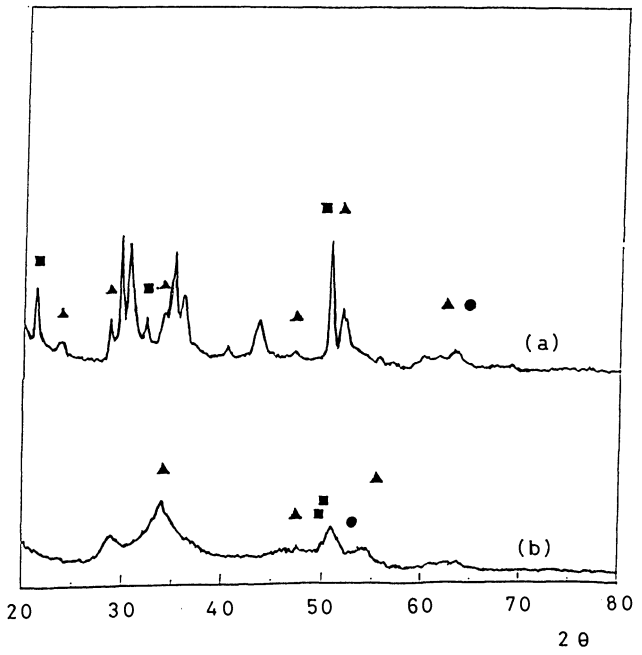

Fig. 2. XRD data of CaO-M (a) before (b) after the pretreatment.
●: CaO, ▲: $Ca(OH)_2$, ■: $Ca(OCH_3)_2$.

IR Measurement. Typical IR spectra of CaO-M measured after the treatment at room temperature and from 373 to 873 K at intervals of 100 K for 30 min under vacuum are shown in Fig. 3. From this data the formation of $Ca(OCH_3)_2$ and $Ca(OH)(OCH_3)$ could be clearly confirmed; i.e. the absorption bands at 1076 and 3640 cm^{-1} were assigned to $Ca(OH)(OCH_3)$[12] and those at 1079, 1159, 1410, 1472, 2072, 2192, 2306, 2592, 2777, 2818, 2864, and 2929 cm^{-1} also assigned to $Ca(OCH_3)_2$[13] (see Fig. 3 (a), (b), and (c)). It can be seen that both $Ca(OCH_3)_2$ and $Ca(OH)(OCH_3)$ were stable until 773 K, then gradually decreasing their strength with increasing temperature; at 873 K they were almost decomposed into CaO, leaving a small amount of $Ca(OH)_2$ (see Fig. 3(d)) which could be derived from the band at 3720 cm^{-1} shifted from 3670 cm^{-1}. The band shifted to 3720 cm^{-1} exhibits an isolated OH on the surface.[14] It is rather surprising that calcium methoxides can be eas-

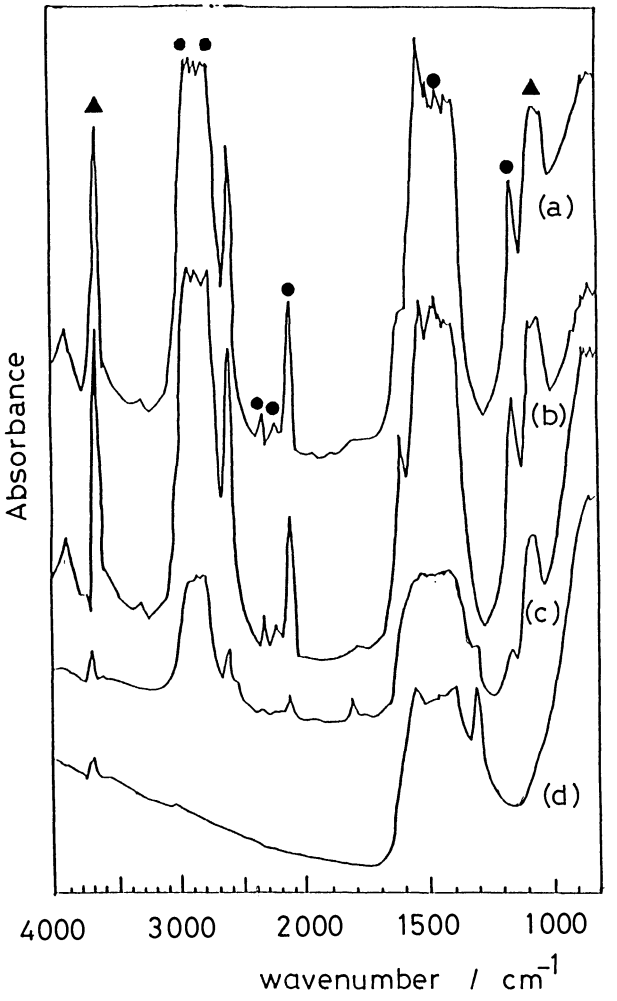

Fig. 3. IR spectra change of CaO-M treated under vacuum, (a): at room temperatures, (b): 573 K, (c): 773 K, (d): 873 K.
●: $Ca(OCH_3)_2$, ▲: $Ca(OH)(OCH_3)$.

ily produced by treatment with methanol at a relatively low temperature and are stable against heat. IR spectra of CaO(I) and (II) are also shown in Fig. 4 for a comparison. The bands between 500 and 1000 cm^{-1} characteristic for CaO, although the assignment was not known. As can be seen in CaO(II), the band at 3670 cm^{-1} can be assigned to basic OH, and that between 1300 and 1600 cm^{-1} probably to the OH of $Ca(OH)_2$.

EPMA (Electron Probe Microanalysis). The surface states of CaO(I),(II) and CaO-M were examined by EPMA. On CaO-M the deposition of free carbon was detected at the wavelength position of ca. 11.5 Å, which would cause the appearance of the dark-gray color on the catalyst after the pretreatment. On CaO(I) and (II) carbon deposition could not be entirely observed. It is therefore clear that the carbon on CaO-M is deposited by the decomposition of calcium methoxides.

ESR. The ESR spectra of CaO(I) and (II) exhibited nothing, except for that due to a Mn impurity.

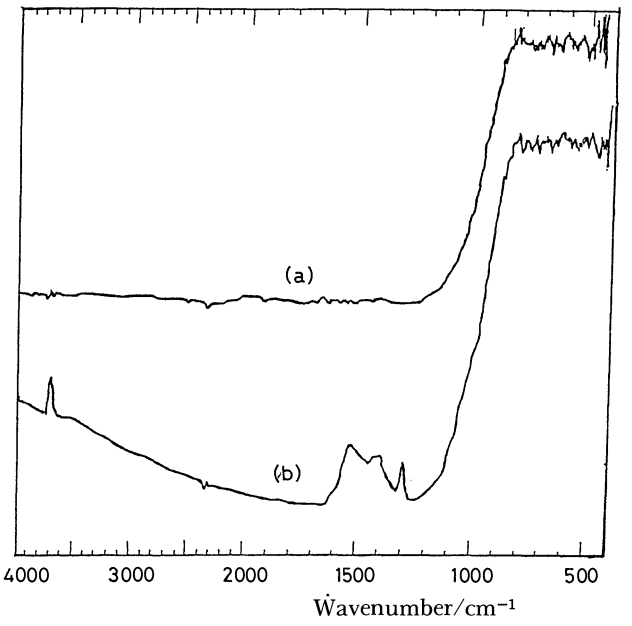

Fig. 4. IR spectra of (a) CaO(I) and (b) CaO(II) after the pretreatment.

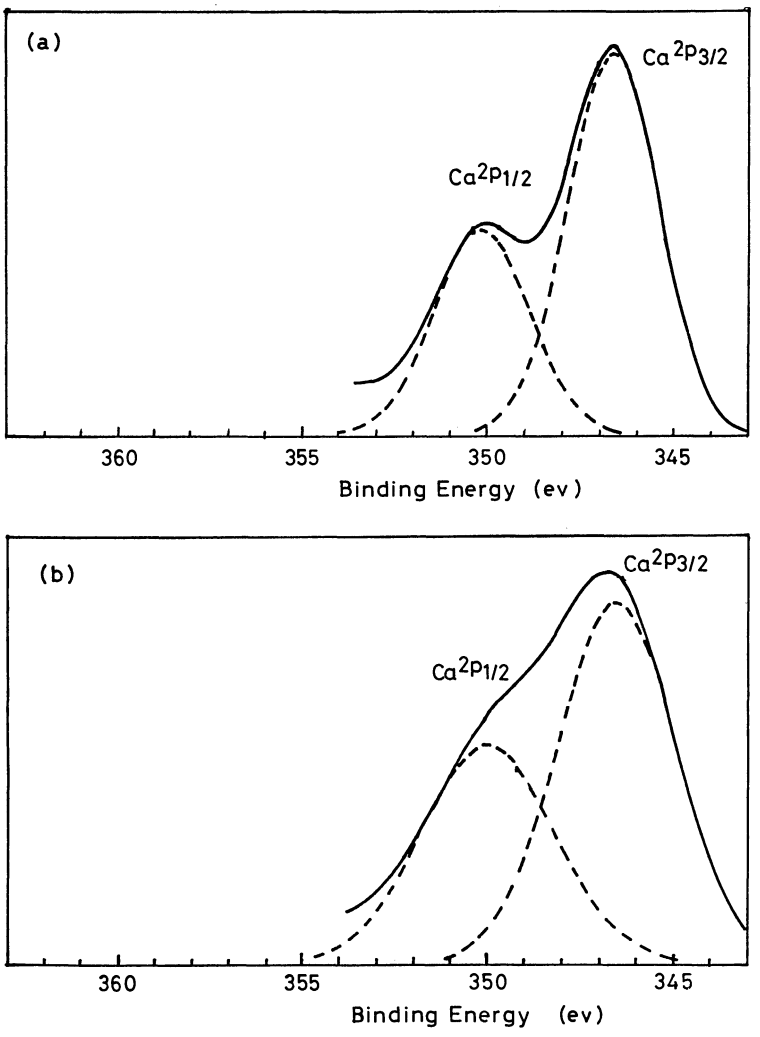

Fig. 5. XPS spectra of Ca $2P_{1/2}$ and Ca $2P_{3/2}$ of (a) CaO-M and of (b) CaO(I).

On the other hand, CaO-M gave a symmetrical Gaussian-shape signal at g=2.0033, which was assigned to graphite.[15,16] The relative spin concentration of the graphite carbon radical was estimated to be 4.31×10^2 per g of CaO-M. When butadiene, H_2 or CO_2 (being catalyst poison) was adsorbed on CaO-M, the carbon-radical signal did not entirely vary. This fact indicats that the carbon radical is not responsible for the hydrogenation. This conclusion was also derived from the fact that the carbon radical did not emerge on the CaO(II) catalyst. Therefore, other active sites should be expected to exist on the catalyst surface.

As described previously such electron-accepting molecules as oxygen inhibit hydrogenation, from which the electron-donating sites on CaO-M and CaO (II) may be active centers. It is further well-known that calcium oxides exhibit surface basicity. The basic sites are considered to be O^{2-} in the low-coordinatation sites.[17,18,19] Other electron-donating sites with the paramagnetic property, (for instance O^-) can be examined by an ESR measurement of the radical formed by the adsorption of an electron-accepting molecule, such as nitrobenzene.[14,20] When nitrobenzene was adsorbed on the three calcium oxide catalysts a relatively symmetrical signal with g=2.0048 could be detected. This also indicates that nitrobenzene adsorbs on graphite carbon on CaO-M to form its radical. By a comparison of the concentration of the nitrobenzene radical with that of DPPH, the relative spin concentrations of the electron-donating sites of these three catalysts were obtained (Table 2). The concentration of CaO-M is a value from which the value for the graphite carbon radical is subtracted. The concentration of CaO(II) and CaO-M were 3600- and 9000-times greater in magnitude than that of CaO(I). Though the existence of electron-donating sites can be detected in CaO(I), there is no hydrogenation activity. This may be due to the small amount of electron-donating sites.

XPS. Though the spectra of $Ca2P_{3/2}$, $Ca2P_{1/2}$, O1s and C1s showed similar binding energies in all samples, the size and shape of the spectra were different to some extent. In Figs. 5 and 6 the spectra derived from CaO(II) were omitted because of the similar behaviors to that of CaO-M and CaO(I). As shown in Fig. 6, the peak of O1s at 532.0 eV can be assigned to O^- derived from OH.[21,22] The peak assigned to O^{2-}, which can be seen at the position of 529.5 eV,[21,22] can not be clearly detected in Fig. 6. This seems to be due to an overlapping by the large O^- peak. The narrowest full width at half maximum (fwhm) of $Ca2P_{3/2}$, as the typical calcium band, O1s and C1s were measured and the ratios of the fwhm value of $Ca2P_{3/2}$ to O1s and to C1s, respectively, were calculated (Table 3). The ratio of $Ca2P_{3/2}$/O1s in CaO-M was the smallest, and increased in the order of CaO(II) and CaO(I). This fact indicates that the surface of CaO-M has somewhat more oxygen excess than does CaO(I) and (II). On the other hand, the ratio of $Ca2P_{3/2}$/C1s of CaO-M is smaller than that of the other two CaO catalysts. This fact indicates that carbon is deposited on the surface of CaO-M, which also agrees with the EPMA results.

Table 3. The Ratio of fwhm Values of $Ca2P_{3/2}$ to O1s and C1s

Catalyst	$Ca2P_{3/2}$/O1s	$Ca2P_{3/2}$/C1s
CaO-M	1.05	1.18
CaO(II)	1.09	1.82
CaO(I)	1.12	1.84

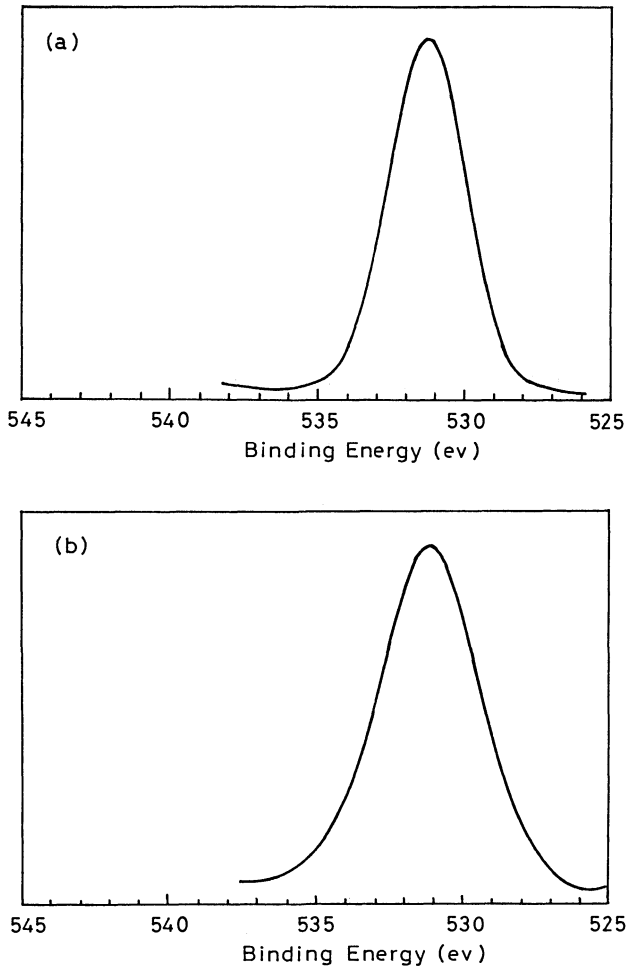

Fig. 6. XPS spectra of O1s of (a) CaO-M and of (b) CaO(I).

Basicity. A measure of the basicity from the amount of irreversible adsorption was obtained for the three CaO catalysts. The basicity of CaO-M, CaO(II) and (I) were 0.767, 0.277, and 0.019 mmol g^{-1}, respectively. As expected, the basicity of CaO-M was the largest. The correlation of the basicity between CaO-M and CaO(II) was 2.47 to 1 and that between the initial rates (Table 2) was 2.18 to 1. A relatively good

correlation could be obtained.

Discussion

Calcium oxide reacts with methanol to form calcium dimethoxide (I) and calcium hydroxide methoxide (II), as confirmed by XRD and IR measurements. These reaction schemes are described as follows, concurrently forming calcium hydroxide:

$$2CaO + 2CH_3OH \longrightarrow Ca(OCH_3)_2 + Ca(OH)_2, \quad (I)$$

and

$$CaO + CH_3OH \longrightarrow Ca(OH)(OCH_3). \quad (II)$$

When CaO treated with methanol was heated at 673 K under vacuum, the calcium methoxides remained. The CaO in this state did not entirely reveal any hydrogenation activity. This fact suggests that these calcium methoxides have no direct connection with activity. However, by a heat-treatment at 773 K under vacuum, in which the decomposition of calcium methoxides seemed to vigorously occur, a slight hydrogenation activity began to appear. At a temperature of 873 K most of the calcium methoxides converted to CaO, and remarkable activity was found. This fact indicates that the active sites are produced by the decomposition of calcium methoxides into CaO. The preparation of CaO by the decomposition of calcium methoxides is similar to the process in the sol-gel method. Generally, this method accompanying the hydrolysis of metal alcohoxides and calcination at a relative low temperature has been used to obtain both ceramics[23] and carriers[24] of high purity and activity; there has, however, been no report concerning a method to prepare highly active catalysts having a high surface area by a direct decomposition of metal alcohoxides.

Calcium hydroxide also showed activity due to a treatment at 873 K under vacuum, although the activity was low, due to an inadequate decomposition of $Ca(OH)_2$ at that temperature. As indicated in the literature,[2] it may be necessary to perform treatments at a temperature higher than 1073 K under vacuum. Martens et al [25] pointed out that the thermal decomposition of $Mg(OH)_2$ under vacuum released water and hydrogen in the temperature range, 570—970 K, leaving O^- and O^{2-} on the surface. Also, in the case of $Ca(OH)_2$, water and hydrogen are released, forming O^- and O^{2-} sites at the same time. In the case of CaO-M CH_3OH, CH_3OCH_3, and other compounds including water, CO, and hydrogen are probably released, although the decomposition process of calcium methoxides has not yet been clarified yet. Regarding the decomposition process of calcium methoxides, the growth of crystalization into CaO is probably suppressed by the release of the decomposed gases, leading to the high surface area of CaO. At the same time, it can be considered that some extent of the point defects accompanying the low coordination sites located at the edges and corners on a surface are formed. This consideration is rational, since CaO-M exhibited a distorted XRD pattern (see Fig. 2) and the surface area increased greatly. By the formation of point defects and low coordination sites, basic sites (i.e., the lattice O^{2-} and electron-donating sites accompanied by a paramagnetic property) are produced on the surface. As previously mentioned, since hydrogenation is ceased by the adsorption of CO_2, the basic sites on the surface are responsible for the hydrogenation; i.e., the O^{2-} sites are active centers. The O^- species are derived from the OH which remains on the surface in the undecomposable state, or which is derived by the adsorption of a proton—an abstracted from, for instance, hydrocarbon—on O^{2-}.[21,22] In this case, the former can be related with the formation of O^- sites. It is known that by XPS O^- and the lattice O^{2-} can be distinguished.[21,22] As shown in Fig. 6, however, the contribution of O1s of O^- at 532.0 eV was so large that the O^{2-} peak could not be found at 529.5 eV. Consequently, though there seems to be no O^{2-} sites on the surface, since CO_2 adsorption could be detected as a measure of the basicity, there must be O^{2-} sites (although the sites could not be clearly found in XPS). Iizuka et al.[14] have suggested that a nitrobenzene radical measurement revealed the property of the reducing sites on the surface and Kijenskii et al.[20] mentioned the property of the one-electron donating sites, although the detailed properties of both sites are not yet well known. If the reducing or one-electron donating sites are O^-, nitrobenezene can be adsorbed on the sites to form the nitrobenzene radical. In our study the relative spin concentration of nitrobenzene and DPPH of the three CaO catalysts were obtained (Table 2). The correlation between the relative spin concentration in the ESR measurement and the initial rate of hydrogenation on both CaO-M and CaO(II) catalysts were sought. The ratios of the relative spin concentration and the initial rate were 1 : 2.48 and 1 : 2.13, respectively. A good correlation between them was obtained. The initial rates, basicity and relative spin concentrations on CaO-M and CaO(II) per unit surface area were obtained as 6.4×10^{-2}, 7.6×10^{-2}, (mmol m^{-2} min^{-1}), 5.0×10^{-3}, 5.5×10^{-3} (mmol m^{-2}), and 2.6, 2.6 (m^{-2}), respectively. Since relatively good correlations between the rates and basicity or spin concentration per unit surface area were also found, it can be considered that the active sites on CaO-M and CaO(II) for hydrogenation consist of the same kind of sites.

It is suspected that the O^- sites are the active center. This conclusion agrees with the fact that Inoue and Yasumori[21] assumed that the active center of the hydrogeantion of ethylene would be O^-. From the results of the basicity measurement the basic sites were correlated with the initial rate, indicating that the

basic sites are also another active center. Especially in the case of CaO-M, a large amount of the active center can be produced. From the results of XPS, it was found that fwhm values of $Ca2P_{3/2}$ and O1s of the three catalysts decrease in the order CaO(I), (II) and CaO-M (see Table 3). This result is responsible for the presence of the excess amount of O^- sites on the CaO-M catalyst, which results in the high activity. It may be concluded that the hydrogenation of 1,3-butadiene proceeds at both basic and paramagnetic sites (i.e., O^{2-} and O^-), which both can be derived from the decomposition of calcium methoxides that have a strong effect on hydrogenation.

The authors gratefully thank Mr. M. Ohsima who is an assistant in the Deparment of Applied Chemistry in Saitama University, for measurements of XPS and basicity and further for drawing of the figures.

The Hypervirial Condition upon Coulson-Longuet-Higgins Polarizabilities in the Hückel Model

Makoto ISIHARA
Department of General Education, Shotoku-Gakuen Women's Junior College, Nakauzura 1-38, Gifu 500
(Received October 15, 1990)

This paper describes a fundamental condition upon Coulson-Longuet-Higgins polarizabilities in the Hückel model. The condition, named the hypervirial condition upon polarizabilities, consists of linear equations to be fulfilled by polarizabilities, being derivable from the hypervirial condition upon site electron densities and bond orders. The hypervirial condition upon polarizabilities can lead us to various simple relationships between polarizabilities, aided by the two auxiliary conditions stemming from the conservation of the number of electrons and from the Hellmann-Feynman theorem. The relationships, being characteristic of a system, will be useful for considering the reactivity of the system within the Hückel model. Several examples for typical systems are given to illustrate how the hypervirial and the auxiliary conditions work practically.

In the previous paper,[1] the author has derived the hypervirial condition upon p-densities[2] in the Hückel model and has set forth the significance of the condition with illustrative applications. The present paper, following the previous one, describes the hypervirial condition upon Coulson-Longuet-Higgins polarizabilities[3-6] (called merely polarizabilities below) in the Hückel model. From now on, the hypervirial conditions upon p-densities and upon polarizabilities are abbreviated to the pHVC and the πHVC, respectively.

The πHVC can lead us to various simple relationships between polarizabilities, aided by the two auxiliary conditions stemming from the conservation of the number of electrons and from the Hellmann-Feynman theorem. The relationships, being characteristic of a system, will be useful for considering the reactivity of the system within the Hückel model. The πHVC must have wide applicability as the pHVC.

We have the four sections below: The first section, deriving the πHVC from the pHVC after preparation of basic definitions, gives some general remarks on the πHVC. The second is a brief account of the symmetry condition and the intrinsic πHVC nontrivial under the symmetry condition. The third concerns the two auxiliary conditions and the last includes several examples illustrating how the πHVC and the auxiliary conditions work practically.

The Hypervirial Condition upon Polarizabilities

Let us consider the Hückel model of an electronic system of m sites. Denote the set $\{1, \cdots, m\}$ of the sites by M and the set of the up- and the down-spin states by Ω. Assume that the Hückel matrix B is real symmetric and that the Hückel model Hamiltonian $H(B)$ depends parametrically on the components $\{b_{rs}\}$ of B under the $m(m-1)/2$ constraints

$$b_{rs}=b_{sr} \qquad (r<s\in M). \tag{1}$$

Using the annihilators $\{a_{r\mu}\}$ and the creators $\{a_{r\mu}^{\dagger}\}$ for the $2m$ one-electron quantum states $\{r\mu\}$, we can write $H(B)$ explicitly as

$$H(B)=\sum_{r,s\in M} b_{rs}\rho_{rs} \tag{2}$$

with

$$\rho_{rs}=\sum_{\mu\in\Omega}(a_{r\mu}^{\dagger}a_{s\mu}+a_{s\mu}^{\dagger}a_{r\mu})/2. \tag{3}$$

For each normalized eigenstate $|B\rangle$ of $H(B)$ we have the matrix $P(B)$ of p-densities

$$p_{rs}(B)=\langle B|\rho_{rs}|B\rangle \qquad (r,s\in M). \tag{4}$$

Polarizabilities $\{\pi_{rs}^{tu}(B)\}$ are defined as[4]

$$\pi_{rs}^{tu}(B)=\frac{\partial}{\partial b_{tu}}p_{rs}(B) \qquad (r,s,t,u\in M), \tag{5}$$

which have the following inherent symmetry for interchange of subscripts.

$$\pi_{rs}^{tu}(B)=\pi_{sr}^{tu}(B)=\pi_{rs}^{ut}(B)=\pi_{sr}^{ut}(B) \tag{6}$$

and

$$\begin{cases}\pi_{rs}^{tu}(B)=\pi_{tu}^{rs}(B) & (r=s,\ t=u \text{ or } r\neq s,\ t\neq u)\\ \pi_{rr}^{tu}(B)=2\pi_{tu}^{rr}(B) & (t\neq u).\end{cases} \tag{7}$$

Let $\Pi^{tu}(B)$ be the matrix having $\pi_{rs}^{tu}(B)$ as r,s-component;

$$\Pi^{tu}(B)=\frac{\partial}{\partial b_{tu}}P(B) \qquad (t,u\in M), \tag{8}$$

which is real symmetric as well as $P(B)$.

Now, the pHVC for the Hamiltonian $H(B)$ can be written in the matrix form as[1]

$$[B, P(B)]=0. \tag{9}$$

Differentiating this with respect to b_{tu}, we obtain the πHVC

$$[B, \Pi^{tu}(B)]=\Phi^{tu}(B) \qquad (t\leqq u\in M), \tag{10}$$

where $\Phi^{tu}(B)$ is the real antisymmetric matrix having the components $\{\phi_{rs}^{tu}(B)\}$ expressible in general form as

$$\phi_{rs}^{tu}(B)=(\delta_{st}p_{ru}(B)-\delta_{rt}p_{su}(B)+\delta_{su}p_{rt}(B)-\delta_{ru}p_{st}(B))/(1+\delta_{tu}). \tag{11}$$

Each of the components is actually quite simple even if nonvanishing. The matrix $\Phi^{tu}(B)$ is invariant for interchange of subscripts tu as well as $\Pi^{tu}(B)$.

What is to be kept in mind is that the πHVC is formally common to all the eigenstates of $H(B)$ without regard to the number of electrons as the pHVC is. Say, supposing the one-electron eigenstate, we can regard polarizabilities and p-densities in the πHVC as being due to one Hückel orbital. We can suppose not only ground but also excited states. Now assume that a system in $|B\rangle$ is perturbed with the change of b_{tu} that alters B to B'. Then, the electron distribution in the system is so rearranged as to fit $|B'\rangle$. What the πHVC means here is that the rearrangement occurs keeping some detailed balance, and that the detailed balance is of the same character for all the eigenstates of $H(B)$.

So far, the Hückel matrix B remains parametric, specified only by its dimension m the number of sites. Actually, we are almost always interested in the effect of small changes of b_{tu} at certain standard "values" $\{\beta_{rs}\}$ of $\{b_{rs}\}$. Let B_0 be the Hückel matrix having the components $\{\beta_{rs}\}$ and let us omit the argument symbol (B) after the substitution of B_0. In what follows, the πHVC at $B=B_0$

$$[B_0, \Pi^{tu}] = \Phi^{tu} \qquad (t \leqq u \in M) \tag{12}$$

is considered exclusively, where B_0 reflects the structural and the symmetry features of the system. The terms "the simple Hückel model" and "the semisimple Hückel model"[7] are operative with regard to B_0. Thus, the simple Hückel model has the πHVC of the form

$$[J, \Pi^{tu}] = \Phi^{tu} \qquad (t \leqq u \in M) \tag{13}$$

Table 1. Dictionary of the Diagrammatic Representation of πHVRs in the Semisimple Hückel Model[a]

Term	Diagram	Term	Diagram
$\alpha_r \pi_{rs}^{tu}$ [b]		ϕ_{rs}^{rs}	$\beta_{rs} \pi_{ss}^{tu}$ [c]		ϕ_{rs}^{rt}, ϕ_{rs}^{tr} $(t \neq s)$	$\beta_{rv} \pi_{vs}^{tu}$ $(v \neq r,s)$		ϕ_{rs}^{st}, ϕ_{rs}^{ts} $(t \neq r)$			ϕ_{rs}^{tu} $\begin{pmatrix} t \neq r,s \\ u \neq r,s \end{pmatrix}$	ψ_{rs}^{tu}		ϕ_{rs}^{rr} [d]			ϕ_{rs}^{ss}			ϕ_{rs}^{tt} $(t \neq r,s)$	
a) The symbols α_r and q_r are used instead of β_{rr} and p_{rr}, respectively. b) This term is ignorable in the simple Hückel model, canceling the corresponding term in ψ_{sr}^{tu}. c) This term appears only for adjacent rs, sharing the factor β_{rs} with the corresponding term in ψ_{sr}^{tu}. d) These three are really special cases of the above.

with the adjacency matrix J.[8] Here, Π^{tu} stands for $\beta\Pi^{tu}$ with β the sole resonance integral between adjacent sites.

The πHVC consists of linear equations to be fulfilled by polarizabilities, which can be written as

$$\psi_{rs}^{tu} - \psi_{sr}^{tu} = \phi_{rs}^{tu} \qquad (r<s,\ t\leqq u\in M) \tag{14}$$

with

$$\psi_{rs}^{tu} = \sum_{v\in M} \beta_v \pi_{vs}^{tu}. \tag{15}$$

The case of $r\geqq s$ is excluded because of the antisymmetry. Each of the equations, specified by upper tu and lower rs subscripts, is called the πHVR (hypervirial relationship between polarizabilities) for $[rs]tu$. In particular, for the simple Hückel model, we can put

$$\psi_{rs}^{tu} = \sum_{v\in C_r} \pi_{vs}^{tu}, \tag{16}$$

using the set C_r of the sites adjacent to r and rewriting $\beta\pi_{rs}^{tu}$ as π_{rs}^{tu}. Exceptional cases aside, no πHVR contains many terms in the simple Hückel model even if m becomes large. The situation is similar in the semisimple Hückel model.

We can represent πHVRs with simple diagrams on structural formulas in the semisimple Hückel model. The diagrammatic representation is especially useful for writing out πHVRs for individual systems. Table 1 is an adequate dictionary of the diagrammatic representation of πHVRs, doubling as a list of the concrete expressions of ϕ_{rs}^{tu}'s. Note that the representation of ψ_{rs}^{tu} is not affected by upper subscripts.

The Symmetry Condition and the Intrinsic πHVC

Let G be the permutation group on M that consists of all the permutations $\{x\}$ keeping B_0 invariant in the sense that[1]

$$\beta_{xrxs} = \beta_{rs} \qquad (r,s\in M). \tag{17}$$

Then, we have the permutational symmetry condition

$$\pi_{xrxs}^{xtxu} = \pi_{rs}^{tu} \qquad (r,s,t,u\in M) \tag{18}$$

for faithful states.[9] Confine ourselves to faithful states whenever the permutational symmetry is taken into account. Incorporating the inherent symmetry into the permutational symmetry condition, we have the symmetry condition.

Let us refer to the πHVR remaining nontrivial under the symmetry condition as the intrinsic πHVR. All the intrinsic πHVRs together constitute the intrinsic πHVC. As to how to draw out intrinsic πHVRs, the situation being similar to that for intrinsic pHVRs[1] (hypervirial relationships between p-densities), details are omitted here. The crucial point peculiar to intrinsic πHVRs is that the value of b_{tu} for the perturbed position tu[10] should be regarded tentatively as being off β_{tu}, and that the tentative perturbed symmetry should be considered for each tu individually.

Let G^{tu} be the subgroup of G that consists of all the permutations $\{x\}$ satisfying $x(tu)=tu$ or $x(tu)=ut$. In many cases, G^{tu} is a tiny group of order one or two, even if the order of G is large. The following guidelines will suffice to draw out intrinsic πHVRs practically. The last one is determinative.

(1) The πHVR for $[x(rs)]tu$ is identical with that for $[rs]x^{-1}(tu)$ for any $x\in G$.

(2) The πHVR for $[r's']tu$ is identical with that for $[rs]tu$ if there exists $x\in G^{tu}$ satisfying $r's'=x(rs)$.

(3) The πHVR for $[rs]tu$ is intrinsic unless there exists $x\in G^{tu}$ satisfying $sr=x(rs)$.

Apart from exceptional cases, all the intrinsic pHVRs of a system are necessarily independent.[1,11] In contrast to this, it is possible for some intrinsic πHVRs to be mutually dependent. When a system has intrinsic pHVRs, it is also possible for some intrinsic πHVRs to contain the intrinsic pHVRs implicitly. Then, reversely, the intrinsic pHVRs make the intrinsic πHVRs mutually dependent.

The symmetry condition classifies polarizabilities into sets of equivalent polarizabilities. Taking one polarizability from each set as a representative, we have the symmetry-independent representatives, which are abbreviated to the SIRs below. When we treat a lot of equations for polarizabilities simultaneously, it is helpful or rather necessary to translate the equation containing arbitrary polarizabilities into that containing only SIRs.

The Auxiliary Conditions

The analysis with the πHVC is facilitated by using the following two auxiliary conditions,[12] particularly when a system does not have many sites. Both conditions are also formally common to all the eigenstates of $H(B)$ without regard to the number of electrons.

The Number Conservation Condition. The number n of electrons can be constant for the change of b_{tu}. Hence, differentiating the number condition

$$\mathrm{Tr}(P(B)) = n \tag{19}$$

with respect to b_{tu} and substituting B_0 for B, we have the number consevation condition

$$\mathrm{Tr}(\Pi^{tu}) = 0 \qquad (t\leqq u\in M), \tag{20}$$

each constituent of which is referred to as the NCR (number conservation relationship) for tu. The NCR for $x(tu)$ is identical with that for tu for any $x\in G$.

The number conservation condition makes πHVRs for $[rs]tt$'s for arbitrary rs and all t's mutually dependent, since we have

$$\sum_{t\in M} [B_0, \Pi^{tt}] = 0 \tag{21}$$

as well as

$$\sum_{t\in M} \Phi^{tt} = 0. \tag{22}$$

The intrinsic πHVC is, therefore, not always inde-

pendent of the number conservation condition.

The Polarizability Sum Condition. It follows from the Hellmann-Feynman theorem[13] immediately that

$$(\frac{\partial}{\partial b_{tu}}\langle B|)H(B)|B\rangle+\langle B|H(B)(\frac{\partial}{\partial b_{tu}}|B\rangle)=0 \quad (t\leqq u\in M). \tag{23}$$

Using the expression

$$\pi_{rs}^{tu}(B)=(\frac{\partial}{\partial b_{tu}}\langle B|)\rho_{rs}|B\rangle+\langle B|\rho_{rs}(\frac{\partial}{\partial b_{tu}}|B\rangle) \tag{24}$$

and substituting B_0 for B, we obtain the polarizability sum condition[14]

$$\mathrm{Tr}(B_0\Pi^{tu})=0 \qquad (t\leqq u\in M), \tag{25}$$

each constituent of which is referred to as the PSR (polarizability sum relationship) for tu. The PSR for $x(tu)$ is identical with that for tu for any $x\in G$. Since

$$\sum_{t\in M}\mathrm{Tr}(B_0\Pi^{tt})=0 \tag{26}$$

holds, PSRs for tt's become mutually dependent under the number conservation condition.

By using the polarizability sum condition it is readily found that

$$\sum_{t\leqq u\in M}\beta_{tu}[B_0, \Pi^{tu}]=0, \tag{27}$$

while we obtain

$$\sum_{t\leqq u\in M}\beta_{tu}\Phi^{tu}=[P, B_0]. \tag{28}$$

That is, πHVRs for $[rs]tu$'s for arbitrary rs and all $t\leqq u$'s[15] together yield the pHVR for rs. This brings on the case that some intrinsic πHVRs become mutually dependent under the polarizability sum condition and the intrinsic pHVC.

To write out PSRs practically, it is preferable to arrange the terms as

$$\sum_{r\in M}\beta_{rr}\pi_{rr}^{tu}+2\sum_{r<s\in M}\beta_{rs}\pi_{rs}^{tu}=0 \qquad (t\leqq u\in M), \tag{29}$$

which is reduced for the simple Hückel model to

$$\sum_{r<s\in M}{}'\,\pi_{rs}^{tu}=0 \qquad (t\leqq u\in M). \tag{30}$$

Here, the prime means that the summation is restricted to adjacent sites.

It remains still possible for other additional dependence to occur in intrinsic πHVRs. However, it seems quite knotty to analyze the situation exhaustively to ascertain a fully systematic way of extracting only independent equations from all the conditions. Fortunately, this annoying point for completeness causes no serious difficulties actually.

Illustrative Examples

To treat typical systems with the πHVC and the auxiliary conditions will be the best way of understanding the nature of the conditions. Throughout this section, π_{rs}^{tu} is used for $\beta\pi_{rs}^{tu}$, being dimensionless and opposite to the original one in sign with β negative. See Fig. 1 for the numbering of sites and the notation for p-densities.

The Symmetric Two-Site System. This system provides the simplest example of the intrinsic πHVC. Let us choose π_{11}^{11}, π_{22}^{11}, π_{12}^{11}, and π_{12}^{12} as the SIRs. Even if b_{12} becomes off β, the two sites remain equivalent; if b_{11} becomes off α, the symmetry vanishes. Hence,

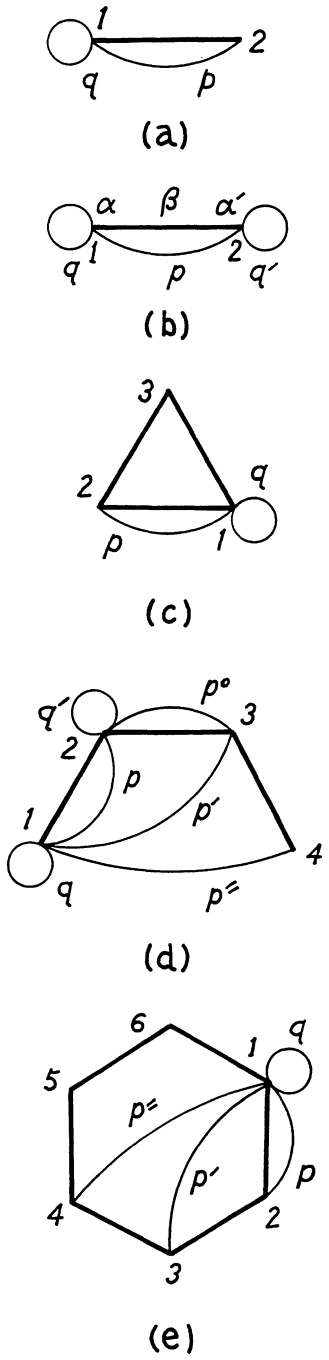

Fig. 1. The notation and the numbering of sites in the examples: (a) The symmetric two-site system, (b) The asymmetric two-site system, (c) The three-site ring, (d) The four-site linear chain, (e) The six-site ring.

only the πHVR for [12]11

$$\pi_{22}^{11}-\pi_{11}^{11}=-p \tag{31}$$

is intrinsic. From this and the NCR for 11

$$\pi_{11}^{11}+\pi_{22}^{11}=0 \tag{32}$$

it follows that

$$\pi_{11}^{11}=-\pi_{22}^{11}=p/2. \tag{33}$$

The PSRs for 11 and 12 are, in themselves,

$$\pi_{12}^{11}=\pi_{12}^{12}=0. \tag{34}$$

We have positive π_{11}^{11}, as expected, for the ground state of less than four electrons. Yet, if p is negative or zero, so is π_{11}^{11}, which is really the case for excited states.

The Asymmetric Two-Site System. This system can exemplifies the relation between the conditions concisely. Choose π_{11}^{11}, π_{22}^{11}, π_{12}^{11}, π_{22}^{22}, π_{12}^{22}, and π_{12}^{12} as the SIRs. Under the NCRs for 11, 22, and 12

$$\pi_{11}^{11}+\pi_{22}^{11}=0, \tag{35}$$

$$\pi_{22}^{11}+\pi_{22}^{22}=0, \tag{36}$$

and

$$\pi_{12}^{11}+\pi_{12}^{22}=0, \tag{37}$$

the PSRs for 11 and 22 become dependent on each other, leading to

$$\lambda\pi_{11}^{11}+\pi_{12}^{11}=0 \tag{38}$$

with

$$\lambda=(\alpha-\alpha')/2\beta. \tag{39}$$

The PSR for 12 is written, by using the NCR for 12, as

$$2\lambda\pi_{12}^{11}+\pi_{12}^{12}=0. \tag{40}$$

These five equations suffice to express all the SIRs in terms of π_{11}^{11}. The π_{11}^{11}-expression

$$\begin{cases} \pi_{22}^{22}=-\pi_{22}^{11}=\pi_{11}^{11} \\ \pi_{12}^{11}=-\pi_{12}^{22}=-\lambda\pi_{11}^{11} \\ \pi_{12}^{12}=2\lambda^2\pi_{11}^{11} \end{cases} \tag{41}$$

is instructive in itself showing the sign and the order of each SIR.

The intrinsic πHVC consists of three πHVRs. The NCRs make the πHVRs for [12]11 and [12]22 dependent on each other. Using the π_{11}^{11}-expression in the πHVR for [12]11

$$2\lambda\pi_{12}^{11}+\pi_{22}^{11}-\pi_{11}^{11}=-p, \tag{42}$$

we find

$$\pi_{11}^{11}=p/2(1+\lambda^2), \tag{43}$$

which enables us to express the other SIRs in terms of p and λ.[16] On the other hand, the πHVR for [12]12

$$2\lambda\pi_{12}^{12}+2\pi_{12}^{22}-2\pi_{12}^{11}=q-q' \tag{44}$$

results in the intrinsic pHVR[1]

$$2\lambda p=q-q'. \tag{45}$$

With this presupposed, the πHVR for [12]12 is no longer independent of the others.

The Three-Site Ring. Next, take the smallest ring in the simple Hückel model, the simplest nonalternant system. This system has the five independent equations connecting the six SIRs π_{11}^{11}, π_{22}^{11}, π_{12}^{11}, π_{23}^{11}, π_{12}^{12}, and π_{23}^{12}. Let us, therefore, find the π_{11}^{11}-expression of the SIRs. From the auxiliary conditions, we have

$$\pi_{22}^{11}=-\pi_{11}^{11}/2, \tag{46}$$

$$\pi_{12}^{11}=-\pi_{23}^{11}/2, \tag{47}$$

and

$$\pi_{23}^{12}=-\pi_{12}^{12}/2, \tag{48}$$

which are substituted into the πHVRs

$$\pi_{22}^{11}+\pi_{23}^{11}-\pi_{11}^{11}-\pi_{12}^{11}=-p \tag{49}$$

and

$$2\pi_{12}^{11}+\pi_{12}^{12}-2\pi_{23}^{11}-\pi_{23}^{12}=p \tag{50}$$

to yield

$$\pi_{23}^{11}=\pi_{11}^{11}-2p/3 \tag{51}$$

and

$$\pi_{12}^{12}=2(\pi_{11}^{11}-p/3). \tag{52}$$

Note that this system has the degeneracy causing nonfaithful states, to which the above relationships are inapplicable. The one- and the two-electron ground states, necessarily faithful, have $\pi_{11}^{11}=4p/9$ and $p=n/3$, which leads to, say,

$$\pi_{23}^{11}-\pi_{12}^{11}=-n/9 \tag{53}$$

and

$$\pi_{12}^{12}-\pi_{23}^{12}=n/9. \tag{54}$$

No explanation will be necessary as to what these mean.

The Four-Site Linear Chain. The number of the SIRs amounts to thirty-one for the four-site linear chain even in the simple Hückel model. The auxiliary conditions give seven independent equations. The number of the intrinsic πHVRs that remain independent of one another and of the auxiliary conditions is twenty-one under the intrinsic pHVC

$$\begin{cases} p'=q'-q \\ p''=p^{\circ}-p. \end{cases} \tag{55}$$

Fortunately, the thirty-one SIRs are seperated into three sets in entering twenty-eight equations because of the alternant symmetry and the number of SIRs of each set is one more than that of equations for the set. All the SIRs of each set are, hence, expressible in terms of one SIR of the set. Because each equations contains, at most, only four SIRs, it is never intractable to work out the equations in spite of the largeness of the number of SIRs.

The twelve SIRs π_{11}^{11}, π_{22}^{11}, π_{33}^{11}, π_{44}^{11}, π_{22}^{22}, π_{33}^{22}, π_{13}^{11}, π_{24}^{11}, π_{13}^{22}, π_{24}^{22}, π_{13}^{13}, and π_{24}^{13} concern the three NCRs for 11, 22, and 13

$$\pi_{11}^{11}+\pi_{22}^{11}+\pi_{33}^{11}+\pi_{44}^{11}=0, \tag{56}$$

$$\pi_{22}^{11}+\pi_{22}^{22}+\pi_{33}^{22}+\pi_{33}^{11}=0, \tag{57}$$

and

$$\pi_{13}^{11}+\pi_{13}^{22}+\pi_{24}^{22}+\pi_{24}^{11}=0, \tag{58}$$

and the eight πHVRs for [12]11, [12]33, [12]13, [23]11, [23]22, [14]11, [14]22, and [14]13

$$\pi_{22}^{11}-\pi_{11}^{11}-\pi_{13}^{11}=-p, \tag{59}$$

$$\pi_{33}^{22}-\pi_{33}^{11}-\pi_{24}^{22}=0, \tag{60}$$

$$2\pi_{13}^{22}-2\pi_{13}^{11}-\pi_{13}^{13}=-p^\circ, \tag{61}$$

$$\pi_{33}^{11}+\pi_{13}^{11}-\pi_{22}^{11}-\pi_{24}^{11}=0, \tag{62}$$

$$\pi_{33}^{22}+\pi_{13}^{22}-\pi_{22}^{22}-\pi_{24}^{22}=-p^\circ, \tag{63}$$

$$\pi_{24}^{11}-\pi_{13}^{11}=-p'', \tag{64}$$

$$\pi_{24}^{22}-\pi_{13}^{22}=0, \tag{65}$$

and

$$\pi_{24}^{13}-\pi_{13}^{13}=-p. \tag{66}$$

The last three may be suggestive by themselves. Expressing the SIRs in terms of π_{11}^{11}, we obtain the result summarized in Table 2. We can reconstruct arbitrary relationships between the SIRs using only π_{11}^{11}, p, and p°, at most. For the four-electron ground state, an easy, direct estimation[5] gives $\pi_{11}^{11}=0.626$, $p=0.894$, and $p^\circ=0.447$, which is enough to estimate the other SIRs.

On the other hand, the seven SIRs π_{12}^{12}, π_{23}^{23}, π_{23}^{12}, π_{34}^{12}, π_{14}^{12}, π_{14}^{23}, and π_{14}^{14} concern the three PSRs for 12, 23, and 14

$$\pi_{12}^{12}+\pi_{23}^{12}+\pi_{34}^{12}=0, \tag{67}$$

$$2\pi_{23}^{12}+\pi_{23}^{23}=0, \tag{68}$$

and

$$2\pi_{24}^{12}+\pi_{14}^{23}=0, \tag{69}$$

and the three πHVRs for [13]12, [13]23, and [13]14

$$\pi_{23}^{12}-\pi_{12}^{12}-\pi_{14}^{12}=-p^\circ, \tag{70}$$

$$\pi_{23}^{23}-\pi_{23}^{12}-\pi_{14}^{23}=p, \tag{71}$$

and

$$\pi_{14}^{23}-\pi_{14}^{12}-\pi_{14}^{14}=-p, \tag{72}$$

which suffice to express the SIRs in terms of π_{12}^{12}. The result is summarized in Table 3. For the four-electron ground state, we can use $\pi_{12}^{12}=0.089$ to estimate the other SIRs. As to the remaining twelve SIRs and eleven equations, the description is omitted for brevity.

It must be relevant to mention here the general features of the πHVC for alternant systems. Define the indicator σ_r of the attribute of site r as

$$\sigma_r=\begin{cases} 1 & (r \text{ starred}) \\ -1 & (r \text{ unstarred}) \end{cases} \tag{73}$$

and classify polarizabilities of an alternant system into three sets as

$$\pi_{rs}^{tu}=\begin{cases} {}^1\pi_{rs}^{tu} & (\sigma_r\sigma_s=\sigma_t\sigma_u=1) \\ {}^2\pi_{rs}^{tu} & (\sigma_r\sigma_s=\sigma_t\sigma_u=-1) \\ {}^3\pi_{rs}^{tu} & (\sigma_r\sigma_s\sigma_t\sigma_u=-1). \end{cases} \tag{74}$$

Then, the πHVRs can be classified also into three sets;

$$\sum_{v\in C_r}\beta_{rv}{}^i\pi_{vs}^{tu}-\sum_{v\in C_s}\beta_{sv}{}^i\pi_{vr}^{tu}={}^i\phi_{rs}^{tu} \qquad (i=1,2,3) \tag{75}$$

with

$$\phi_{rs}^{tu}=\begin{cases} {}^1\phi_{rs}^{tu} & (\sigma_r\sigma_s=-1;\ \sigma_t\sigma_u=1) \\ {}^2\phi_{rs}^{tu} & (\sigma_r\sigma_s=1;\ \sigma_t\sigma_u=-1) \\ {}^3\phi_{rs}^{tu} & (\sigma_r\sigma_s=\sigma_t\sigma_u). \end{cases} \tag{76}$$

The NCRs and the PSRs are classified as

$$\sum_{r\in M}{}^i\pi_{rr}^{tu}=0 \qquad (i=1,3) \tag{77}$$

and

$$\sum_{r<s\in M}{}'\beta_{rs}{}^i\pi_{rs}^{tu}=0 \qquad (i=2,3). \tag{78}$$

In particular, for the m-electron ground state of the m-site alternant system ${}^3\phi_{rs}^{tu}$'s are all vanishing and the equations for $i=3$ give nothing more than

$${}^3\pi_{rs}^{tu}=0 \tag{79}$$

a natural consequence of the fact that no perturbation at the site pair of different attributes violates the alternant symmetry.[17]

The Six-Site Ring. The last example is the simple Hückel model of the six-site ring, which has no intrin-

Table 2. The π_{11}^{11}-Expression of Some SIRs of the Four-Site Linear Chain in the Simple Hückel Model[a]

tu	rs	c_1	c_p	c_{p°
22	22	1	−1/2	1/2

13	13	8	−5	0
13	24	8	−6	0

a) $\pi_{rs}^{tu}=c_1\pi_{11}^{11}+c_pp+c_{p^\circ}p^\circ$.

Table 3. The π_{12}^{12}-Expression of Some SIRs of the Four-Site Linear Chain in the Simple Hückel Model[a]

tu	rs	c_{12}	c_p	c_{p°
23	23	4	2	−4
12	23	−2	−1	2
12	34	1	1	−2
23	14	6	2	−6
12	14	−3	−1	3
14	14	9	4	−9

a) $\pi_{rs}^{tu}=c_{12}\pi_{12}^{12}+c_pp+c_{p^\circ}p^\circ$.

sic pHVR. The intrinsic πHVC gives seventeen independent equations under the auxiliary conditions consisting of seven independent equations. The thirty SIRs enter twenty-four equations, separated into three sets. We have ten, eight, and six equations, respectively, for twelve, ten, and eight SIRs. Hence, all the SIRs of each set are expressible in terms of relevantly chosen two SIRs of the set.

The description here is, however, confined to the derivation of a few relationships between atom-atom polarizabilities. Substituting the πHVR for [14]11

$$\pi_{24}^{11}-\pi_{13}^{11}=-p''/2 \tag{80}$$

into that for [12]33

$$\pi_{22}^{11}+\pi_{24}^{11}-\pi_{33}^{11}-\pi_{13}^{11}=0, \tag{81}$$

we obtain

$$\pi_{22}^{11}-\pi_{33}^{11}=p''/2. \tag{82}$$

From the πHVRs for [12]11, [12]44, and [14]22

$$\pi_{22}^{11}+\pi_{26}^{11}-\pi_{11}^{11}-\pi_{13}^{11}=-p, \tag{83}$$

$$\pi_{33}^{11}+\pi_{35}^{11}-\pi_{44}^{11}-\pi_{24}^{11}=0, \tag{84}$$

and

$$\pi_{13}^{11}+\pi_{35}^{11}-\pi_{26}^{11}-\pi_{24}^{11}=0, \tag{85}$$

it follows that

$$\pi_{11}^{11}-\pi_{22}^{11}+\pi_{33}^{11}-\pi_{44}^{11}=p, \tag{86}$$

which leads to

$$\pi_{11}^{11}-\pi_{44}^{11}=p+p''/2. \tag{87}$$

Further, using the NCR for 11

$$\pi_{11}^{11}+2\pi_{22}^{11}+2\pi_{33}^{11}+\pi_{44}^{11}=0, \tag{88}$$

we attain the π_{11}^{11}-expression

$$\begin{cases} \pi_{22}^{11}=-\pi_{11}^{11}/2+p/4+3p''/8 \\ \pi_{33}^{11}=-\pi_{11}^{11}/2+p/4-p''/8 \\ \pi_{44}^{11}=\pi_{11}^{11}-p-p''/2. \end{cases} \tag{89}$$

Note that these relationships are valid for any faithful states without regard to the number of electrons. For the six-electron ground state, although the values of all the atom-atom polarizabilities are already known,[5] the above relationships remain eloquent of how simply but delicately the polarizabilities are interrelated.

As the above treatment shows, we can often attain the result of significance only by working out some equations in the πHVC and the other conditions. This is an important advantage from an applicational point of view.

1) M. Isihara, *Bull. Chem. Soc. Jpn.*, **62**, 2284 (1989).

2) Site electron densities and bond orders are called generically p-densities, for convenience' sake. Ref. 11 of Ref. 1 includes the reason for the name.

3) The term "polarizability" has been used peculiarly in the Hückel model since Coulson and Longuet-Higgins' papers. The term has another meaning in the theory of dielectrics and it is prevalent to use the term fixedly for that meaning. Some authors prefer "mutability" to "polarizability." Still, we seem to have no decisive alternative at present.

4) C. A. Coulson and H. C. Longuet-Higgins, *Proc. R. Soc. London, Ser. A*, **191**, 39 (1947), the inceptive paper on polarizabilities in the Hückel model.

5) C. A. Coulson and H. C. Longuet-Higgins, *Proc. R. Soc. London, Ser. A*, **192**, 16 (1947); **193**, 447 (1948), which include the first basic applications of polarizabilities.

6) S. Aono and K. Nishikawa, *Bull. Chem. Soc. Jpn.*, **58**, 288 (1985), where polarizabilities are treated in a propagator formalism.

7) For the definition of these terms, see Ref. 1.

8) For the adjacency matrix, see, for example, Refs. 4 and 15 of Ref. 1.

9) The faithful eigenstate was introduced in Ref. 1, associated with the degeneracy, for which P.-O. Löwdin, *J. Chem. Phys.*, **21**, 496 (1953) may be suggestive.

10) Even if β_{tu} is zero, we should not ignore the change of b_{tu}. The perturbed position can be the site pair tu of vanishing β_{tu}.

11) The term "independent" is often used to mean "linearly independent" for short; so is "dependent."

12) Though Coulson and Longuet-Higgins have touched upon both conditions (Ref. 4), they have regarded the conditions only as such as checking tools for numerical calculation.

13) For example, S. T. Epstein, "The Hellmann-Feynman Theorem," in "The Force Concept in Chemistry," ed by B. M. Deb, Van Nostrand Reinhold, New York (1981).

14) This derivation is a little more transparent than Coulson and Longuet-Higgins' one.

15) The simple Hückel model allows us to replace "all $t\leqq u$" with "all adjacent $t<u$" here.

16) This does not mean that the dependence of the polarizabilities on λ is fully resolved, because p itself dependes on λ.

17) Obviously, π_{rr}^{tu} are zero for adjacent tu's, but ${}^1\pi_{rr}^{tu}$ does not vanish, in general.

Ion-Exchange Properties and Thermal Stability of Hydrous Titanium(IV)-Zirconium(IV) Oxide Ion Exchanger

Hiromichi YAMAZAKI, Yasushi INOUE,* Naoki KIKUCHI, and Hiroshi KURIHARA
Department of Nuclear Engineering, Faculty of Engineering, Tohoku University, Aramaki, Aoba-ku, Sendai 980
(Received September 11, 1990)

Ion-exchange properties and thermal stability were studied for hydrous Ti^{IV}-Zr^{IV} oxide ion exchangers with various contents of titanium. The cation-exchange capacity increased with the titanium content in the exchanger, along with a decrease in the anion-exchange capacity. Though the affinity for representative metal ions increases with the acidity of the exchange sites, no such simple relation holds for transition metal ions. Exchangers with 30 to 70 mol% Ti (the mol% of Ti to Ti+Zr) do not suffer from drastic changes in both the water content and crystallinity upon heating to 500 °C; they are much more heat-resistant than component simple hydrous metal oxides. Though the total cation-exchange capacity decreases with increasing temperature during a heat treatment, only a minute amount of the acidic sites dissociating at a pH lower than the isoelectric point of the exchangers with $\leqslant$70 mol% Ti increases upon heating. The effect of a heat treatment on the distribution coefficients of cations has been explained by these observations.

Hydrous metal oxides are sorbents with an ion-exchange selectivity peculiar to the metallic elements forming the materials.[1] However, they are thermodynamically metastable and liable to lose their ion-exchange capacity at high temperature. Tanabe et al. reported that binary metal oxides have a marked higher acidity than do component simple oxides.[2-4] It is conceivable that thermally stable hydrous metal oxides possessing a large ion-exchange capacity can be synthesized by combining more than two kinds of metallic elements. There have been few studies concerning the relation between the ion-exchange properties of binary and simple hydrous metal oxides. For this reason hydrous Si-Ti^{IV} oxides with various titanium contents were synthesized, and both their ion-exchange properties and thermal stability investigated. As a result, a hydrous Ti^{IV} oxide modified with Si, which has a higher ionic potential than does Ti^{IV}, had a larger ion-exchang capacity and was thermally more stable than simple hydrous Ti^{IV} oxide.[5]

In the present study a hydrous Ti^{IV} oxide modified with Zr^{IV}, which has a lower ionic potential than does Ti^{IV}, was investigated in order to clarify the effect of modifiers on the ion-exchange property and thermal stability of the materials.

Experimental

Reagents and Apparatus. Titanium(IV) chloride and zirconium(IV) chloride oxide octahydrate were supplied by Wako Pure Chemical Industries Ltd., and their purity was checked before use. A thermogravimetric analysis (TGA) and a differential thermal analysis (DTA) were undertaken with a Seiko micro thermal analyzer (Model SSC5020-TG/DTA300) at a heating rate of 10 °C min^{-1}. All the other apparatuses were the same as those described previously.[5]

Ion-Exchangers. A 1 M $TiCl_4$ aqueous solution and a 1 M $ZrOCl_2$ aqueous solution (1 M=1 mol dm^{-3}) were prepared by dissolving unhydrated titanium(IV) chloride and zirconium chloride oxide octahydrate in distilled water. They were mixed to make a solution with the desired molar ratio of Ti to Ti+Zr (the mixture). Hydrous Ti^{IV}-Zr^{IV} oxide was then precipitated by pouring the mixture into 1 M NaOH. The pH at precipitation was controlled within 13.0±0.1 by varying the volume ratio of the NaOH solution to the mixture. After being washed with distilled water the precipitate was filtered and dried at 70 °C. The product was immersed in distilled water to break it down into fine particles, which were subsequently dried at room temperature. The particles were then ground in a porcelain mortar and sieved to obtain the required particle size (63 to 210 mm). Hydrous Ti^{IV} and Zr^{IV} oxides were precipitated at pH 13 in the same manner as described above.

The exchanger of a desired particle size was converted to the H^+ form by treating it with 0.05 M HCl by the procedure described previously[5] and stored in a desiccator containing a saturated NH_4Cl solution (relative humidity; 79% at 25 °C).

Total Analysis of the Exchanger. A sample of 0.5 g was ignited at 850 °C; the water content was calculated from the weight loss. A part (0.1 g) of the oxide, thus formed, was decomposed by a mixture of concentrated H_2SO_4 (4 cm^3) and $(NH_4)_2SO_4$ (2.5 g) by heating, followed by dilution to 50 cm^3 with 4 M H_2SO_4. The titanium in this solution was assayed by extraction-spectrophotometry; the absorbance of the titanium-thiocyanate complex extracted from a 9 M H_2SO_4 solution by trioctylphosphine oxide in cyclohexane was measured.[6] The amount of TiO_2, thus determined, was subtracted from the mass of the calcined exchanger to obtain the amount of ZrO_2.

Titration Curves. One tenth gram of each exchanger in the H^+ form was immersed in 25 cm^3 of 0.1 M NaOH for 24 h at 25 °C; the solution pH was then measured. After every addition of a small amount of 1 M NaOH or HCl, the solution pH was measured after standing for 24 h to obtain a titration curve.

Uptake Curves. One tenth gram of each exchanger in the H^+ form was immersed in 15 cm^3 of various solutions prepared by the desired combinations of 0.1 M NaCl, and 0.1

M NaOH or 0.1 M HCl, for 7 d at 25 °C with intermittent shaking. This was followed by pH measurements and a determination of the Na^+ and Cl^-. The chloride concentration was determine by the Fajans' method after the solution had been neutralized. The sodium ions were converted to an equivalent amount of sodium chloride by evaporating the solution with HCl, and indirectly determined by titrating the Cl^-. The amount of ions taken up by the exchanger was evaluated from the difference between the initial and final concentrations of the respective ions in the solutions.

Distribution Coefficients. The distribution coefficients, K_d, were determined in the following way. The exchanger was contacted at 25 °C with a solution containing metal ions to be examined until their concentration in the supernatant solution became constant (8 to 18 d). The ratio of the solution volume (cm^3) to the amount of exchanger (g) was always kept constant at 100. The initial concentration of metal ions was 1×10^{-4} M (except carrier free ^{241}Am) and the ionic strength was adjusted to 0.1 M by using an $NaNO_3$ solution. The pH and metal ion concentration in the supernatant solution were then measured. The K_d, expressed in cm^3g^{-1}, was obtained from a calculation performed in the usual manner. Analyses of Cs, Sr, Ba, Mn, Fe, Co, Zn, Eu, and Am, respectively, were carried out radiometrically using ^{137}Cs, ^{85}Sr, ^{133}Ba, ^{54}Mn, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{152}Eu, and ^{241}Am as tracers. Uranyl(VI) ions were analyzed spectrophotometrically using 2-(5-bromo-2-pyridylazo)-5-(diethylamino)phenol,[7] while the concentration of the other cations was determined by means of atomic absorption spectrophotometry.

Heat Treatment. About 5 g of each exchanger in the H^+ form were heated in air to a constant weight at a constant temperature (150, 300, and 500 °C). After being cooled over P_2O_5, the sample was weighed and then left immersed in water overnight. The sample separated from water was allowed to stand to a constant weight in a desiccator containing a saturated NH_4Cl solution (humidification). The water recovery of the heat-treated sample was calculated according to the difference in the water content between samples cooled over P_2O_5 immediately after the treatment and those subjected to humidification.

Results and Discussion

(I) Synthesis of the Exchangers. The effect of the conditions at precipitation on the yield and the acid-base property of the exchangers was first examined. It was found that exchangers with a variety of acid-base property can be synthesized by controlling the molar ratio of Ti to Ti+Zr in mixed solutions. The cation-exchange capacity of an exchanger of high titanium content increased with pH at precipitation. The total concentration of Ti plus Zr in the solution, the kind of alkali used (NaOH or NH_3), and the mixing method had little effect on the acid-base property of the exchangers. By applying the method described in Experimental, which was established by taking the yield and the convenience of the procedure into consideration, exchangers with various composition were synthesized. As is shown in Table 1, the exchangers, thus prepared, have nearly the same titanium content as that in the mixed solutions. The water content of the exchangers tends to decrease with an increase in the titanium content. Independent triplicate preparation was carried out for each of the exchangers with 50 and 90 mol% Ti (the molar percent of Ti to Ti+Zr is used to distinguish the exchangers with titanium content in the text and the molar ratio R in the figures) in order to examine the reproducibility of the synthesis. The uptake curve (Fig. 1) and the composition of the three samples agree well with each other, except for a small fluctuation in the water content, which is susceptible to environmental conditions (Table 1). The synthetic procedure, therefore, is considered to be reproducible.

The X-ray diffraction patterns of the binary and simple hydrous metal oxides showed that all of the samples were amorphous at room temperature. Being heated at 850 °C, the exchangers showed diffraction peaks: The exchanger with 90 mol% Ti crystal-

lized to anatase TiO_2; the hydrous Ti^{IV} oxide crystallized to the rutile form. Though the diffraction patterns of the orthorhombic (Ti, Zr)O_2 were observed in exchangers with 50 and 70 mol% Ti,[8] no pattern characteristic of the titanium-containing phase was found in exchangers with $\leqslant$30 mol% Ti; an exchanger with 30 mol% Ti crystallized to a mixture of cubic and orthorhombic ZrO_2, and that with 10 mol% Ti and the hydrous Zr^{IV} oxide crystallized to monoclinic ZrO_2.

(II) Ion-Exchange Property. (a) Acid-Base Property of the Exchangers: Figure 2 shows uptake curves of Na^+ and Cl^- on exchangers with various titanium contents, along with those on simple hydrous metal oxides. This figure reveals that all exchangers, except for the hydrous Ti^{IV} oxide, are amphoteric, and that an increase in the zirconium content reduces the cation-exchange while increasing the anion-exchange capacity. The acid-base property of hydrous Ti^{IV}-Zr^{IV} oxides might reflect that of the component simple hydrous metal oxides; the hydrous Ti^{IV} oxide is weakly acidic and the hydrous Zr^{IV} oxide is an amphoteric ion exchanger with an isoelectric point at pH 6.5, having an anion-exchange capacity larger than the cation-exchange capacity.[9,10] In exchangers with $\geqslant$30 mol% Ti, the increase in the titanium content shifted the pH, at which the sorption of Na^+ commenced, to the acidic side and increased the cation-exchange capacity in the region of pH lower than the inflection point of the uptake curves. The acidity was almost constant in exchangers with $\leqslant$30 mol% Ti, which crystallized to the form of Zr^{IV} oxides.

It is apparent from these results that both the acidity and number of OH groups in hydrous Ti^{IV} oxide decrease upon modifying the material with hydrous Zr^{IV} oxide. As has been previously reported, the hydrous Si-Ti^{IV} oxides with 37 to 67 mol% Ti possess a cation-exchange capacity that is much larger than a simple mixture of hydrous Si and Ti^{IV} oxides.[5] These facts would suggest that the cation-exchange capacity of hydrous metal oxides can be improved by modifying them with a metal element having a larger ionic potential.

(b) Selectivity for Cations: In order to examine the relation between the cation-exchange selectivity and the composition of the exchangers, the K_d's for various cations were measured as a function of pH. The pH's at which the K_d's reach 100 are shown in Table 2, as an indicator of the cation-exchange selectivity of the materials.

The pH's for representative metal ions increased with a decrease in the titanium content, while those for transition metal ions did not depend largely on the composition of the exchangers. In exchangers with $\leqslant$70 mol% Ti, the affinity was markedly higher for a transition than for representative metal ions, while in those with $\geqslant$90 mol% Ti such a relation is unclear. The selectivity series for alkali metal or alkaline earth metal ions appears to increase with the ionic potential of hydrated cations. This conforms

to ion-hydration theory, which claims that the strength of the electrostatic interaction between hydrated cations and fixed anionic sites determines the selectivity of a strongly acidic resin.[11] On the other hand, such a simple relation does not hold for transition metal ions. Irrespective of the compositions of the exchangers, the affinity series for bipositive transition metal ions follows the Irving-Williams series: Mn<Fe<Co<Ni<Cu<Zn.[12] This order arise in part from an increase in the acidic strength of metal ions as Lewis acids. In addition, UO_2^{2+} had an affinity higher than that expected value due to the ionic charge. It may therefore be considered that in the ion-exchange reaction of transition metal ions the formation of covalent bonds between anionic sites in the exchanger and metal ions plays an important role in determining the selectivity of the exchanger, along with the remote Coulombic interaction.

These findings are consistent with the decrease in the acidity of the exchange sites with the titanium content in the exchangers (Fig. 2). Due to the higher acidity of the sites, an exchanger with a higher titanium content is preferable for the sorption of representative metal ions, since their ion-exchange reactions are governed by an electrostatic interaction between the ions and dissociated sites in the exchangers. The decrease in the acidity of exchange sites lowers the electrostatic interactions between ions and sites, but increases the ability to form a covalent bond between them. By presuming that the former effect is not completely offset by the latter, we can understand the small positive dependence of K_d on the titanium content in the ion-exchange reaction of transition metal ions. Since the acidity of the exchange sites in the hydrous Ti^{IV}-Zr^{IV} oxides depends on the titanium content, exchangers possessing a variety of selectivity series can be obtained by varying the compositions of the materials.

(III) Effect of Heat Treatment. (a) Water Content: Table 3 shows the relation between the temperature for a heat treatment and the water content of the exchanger immediately after the treatment or being subjected to humidification. Irrespective of the titanium content, the amount of water contained in the exchangers immediately after a heat treatmen at 150 °C was reduced to <20% of the original values; it then decreased to almost zero at 300 °C. On the other hand, the water content of exchangers subjected to humidification varied with the titanium content. For exchangers with 30 to 70 mol% Ti heated at 500 °C, about 1.3 mol of water per 1 mol of the metallic elements were recovered, indicating that 50 to 65% of water lost by heating was recovered by humidification. When exchangers with a composition close to that of the simple hydrous metal oxides were heated at 500 °C, more than 75% of water originally present was released irreversibly.

As shown in Fig. 3, the X-ray diffraction patterns of exchangers with 30 to 70 mol% Ti, display an amorphous structure which did not change, even when heated at 500 °C. Heat-treated exchangers with 10 and 90 mol% Ti, respectively, showed peaks characteristic of monoclinic ZrO_2 and anatase TiO_2. These results indicate that the heat treatment hardly changed the structure of exchangers with 30 to 70 mol% Ti, but easily crystallized exchangers with a composition

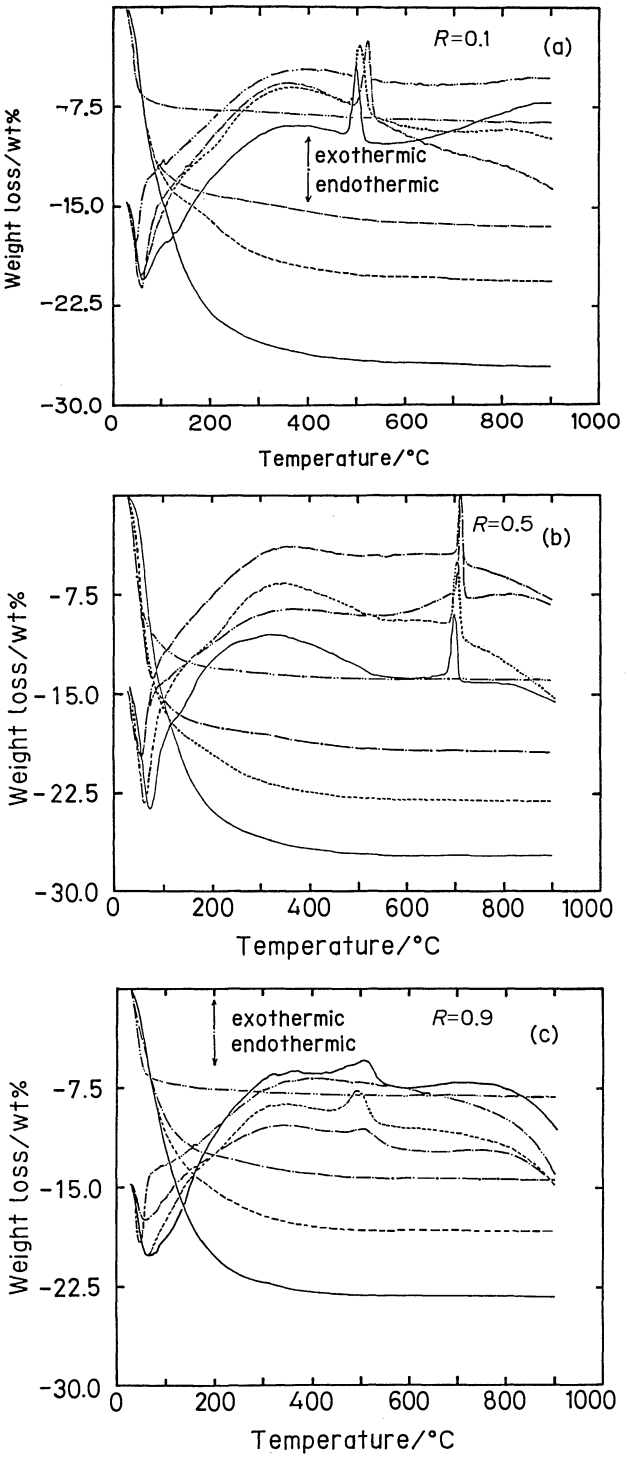

Fig. 4. TGA and DTA curves of the exchangers subjected to humidification.

Temperature for heat treatment, ——: R.T.; ----: 150 °C; — · —: 300 °C; — · · —: 500 °C.

close to that of simple hydrous metal oxides.

The DTA and TGA measurements were made for the heat-treated and a humidified exchangers, along with samples without a heat treatment, as shown in Fig. 4. In the DTA curves, a large endothermic peak with a shoulder appearing in the range below 200 °C is due to a loss of water. A large exothermic peak observed at 450 °C or higher is assigned to the crystallization of exchangers as judged from X-ray data. Exchangers with 30 to 70 mol% Ti crystallized at 660 to 715 °C, while those with a composition close to that of simple hydrous oxides crystallized at a temperature below 520 °C. The large difference in the crystallization temperature reflects the difference in the structures of the exchanger matrices. The shoulder at the high-temperature side of the large endothermic peak indicates that the exchanger has at least two kinds of water having different binding energies. The large endothermic peaks at around 75 °C sharpened and the area under the shoulders decreased as the heat-treatment temperature became higher. When simple hydrous metal oxides and exchangers with 10 and 90 mol% Ti were heated at 500 °C, the water lost in regions with a temperature higher than 100 °C decreased to negligibly small amount, as can be seen from the TGA curves. Exchangers with 30 to 70 mol% Ti, heated at 500 °C, still had a small amount of water of high binding energy.

As discussed previously, the water of lower binding energy is zeolitic or adherent, while the water of higher binding energy is present as either hydroxyl groups or water bound thereto.[13-15] Accordingly, the water recoverable by humidification is considered to correspond mainly to a certain kind of zeolitic water, while the hydroxyl groups and the bound water

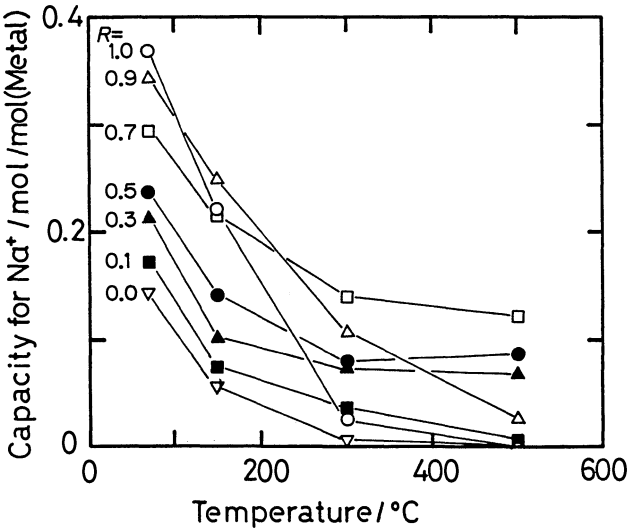

Fig. 5. Effect of heat treatment on the ion-exchange capacities for Na^+.
Exchanger, ■: No. 1; ▲: No. 2; ●: No. 3—5; □: No. 6; △: No. 7—9; ○: No. 10; ▽: No. 11.

are lost irreversibly from a heated exchanger. The irreversible loss of water of high binding energy is smaller in exchangers with 30 to 70 mol% Ti than in those with composition close to the simple hydrous metal oxides.

(b) Acid-Base Property: To examine the dependence of the thermal stability on the titanium content, the ion-exchange capacity of Na^+ was measured at pH 13 on samples with or without a heat treatment (Fig. 5). When simple hydrous metal oxides and an exchanger with 10 mol% Ti were heated at 300 °C, the capacity decreased to about ≤10% of the original values. Exchangers with 30 to 70 mol% Ti retaind larger capacity at the same temperature; an exchanger with 70 mol% Ti had the largest residual capacity. Even when heated at 500 °C, they did not lose their capacity further, which indicates that they were thermally more stable than the component hydrous metal oxides. These findings are compatible with the results of thermal analysis, which indicates that OH groups in exchangers with 30 to 70 mol% Ti once lost by heating, were recovered to a certain degree during humidification. The recovery of the exchange sites may be due to the matrices of these exchangers which are thermally more stable than those of simple hydrous metal oxides (Fig. 3).

In order to examine the effect of a heat treatment on the acid-base properties of exchangers, the pH-titration curves were measured for samples both with or without a heat treatment. Some results are shown in Fig. 6. In hydrous Ti^{IV} oxide[16] and an exchanger with 90 mol% Ti, the pH at which the sorption of Na^+ commenced, greatly shifted to the alkaline side upon heating. This indicates that the acidity of the exchange sites is decreased by a heat treatment. On the other hand, the acidity of the exchange sites in exchangers with ⩽70 mol% Ti was not affected by heating. Regardless of the composition, the exchange capacity at a pH lower than the inflection point decreased with the temperature for a heat treatment, while, in the higher pH region, the curves of samples with a given titanium content were parallel with each other. This observation indicates that a heat treatment destroys mainly the exchange sites with higher acidity.

In hydrous Ti^{IV}-Zr^{IV} oxide, the destruction of the exchange sites by heat treatment occurs mainly at more acidic sites, as in the hydrous Si-Ti^{IV} oxide.[5] The degree of the decrease in the exchange capacity by heat treatment is larger in exchangers with a higher titanium content. Hence, we can give an excellent thermal stability to hydrous Ti^{IV} oxide by modifying it with hydrous Si or Zr^{IV} oxide. The optimum titanium content for the thermal stability depends on the kind of modifiers.

(c) Distribution Coefficients: The distribution coefficients, K_d, of Cs^+, Sr^{2+}, Co^{2+}, Eu^{2+}, and UO_2^{2+} on heat-treated exchangers with various titanium con-

tents were measured at various pH's. Heat treatments did not alter the dependency of the K_d's on the pH, indicating that the stoichiometric relation governing the ion-exchange reaction does not change with a heat treatment.

Figures 7-a to 7-e show plots of the K_d's of Cs^+ and Sr^{2+} at pH 6, of Co^{2+} at pH 5.5, of Eu^{3+} at pH 3.5, and of UO_2^{2+} at pH 2.5 against the temperature for a heat treatment. The K_d's of Cs^+ and Sr^{2+} decreased with increasing temperature for the treatment, with the extent higher on the exchangers with $\geqslant$70 mol% Ti than on those with smaller titanium content (Figs. 7-a to 7-b). On an exchanger with 90 mol% Ti and hydrous Ti^{IV} oxide, the K_d's of Co^{2+} decreased consistently with temperature, while remaining nearly constant on exchangers with 50 and 70 mol% Ti or even increased somewhat on exchangers with 10 and 30 mol% Ti between 150 and 300 °C (Fig. 7-c). On hydrous Ti^{IV} oxide, the K_d's of Eu^{3+} decreased greatly

with increasing temperature for a heat treatment, while on exchangers with 30 to 90 mol% Ti, they changed a little, and even somewhat increased on an exchanger with 10 mol% Ti by a heat treatment. The K_d's of UO_2^{2+} increased with the heat-treatment temperature, irrespective of the composition of the exchangers. The degree of the increase was somewhat larger on exchangers with 50 to 90 mol% Ti than on those with other compositions. These findings suggest that the exchangers after a heat treatment tend to retain their high affinity to cations, which can be sorbed from solution with a pH lower than the isoelectric point of the materials.

In order to understand these observations, the effect

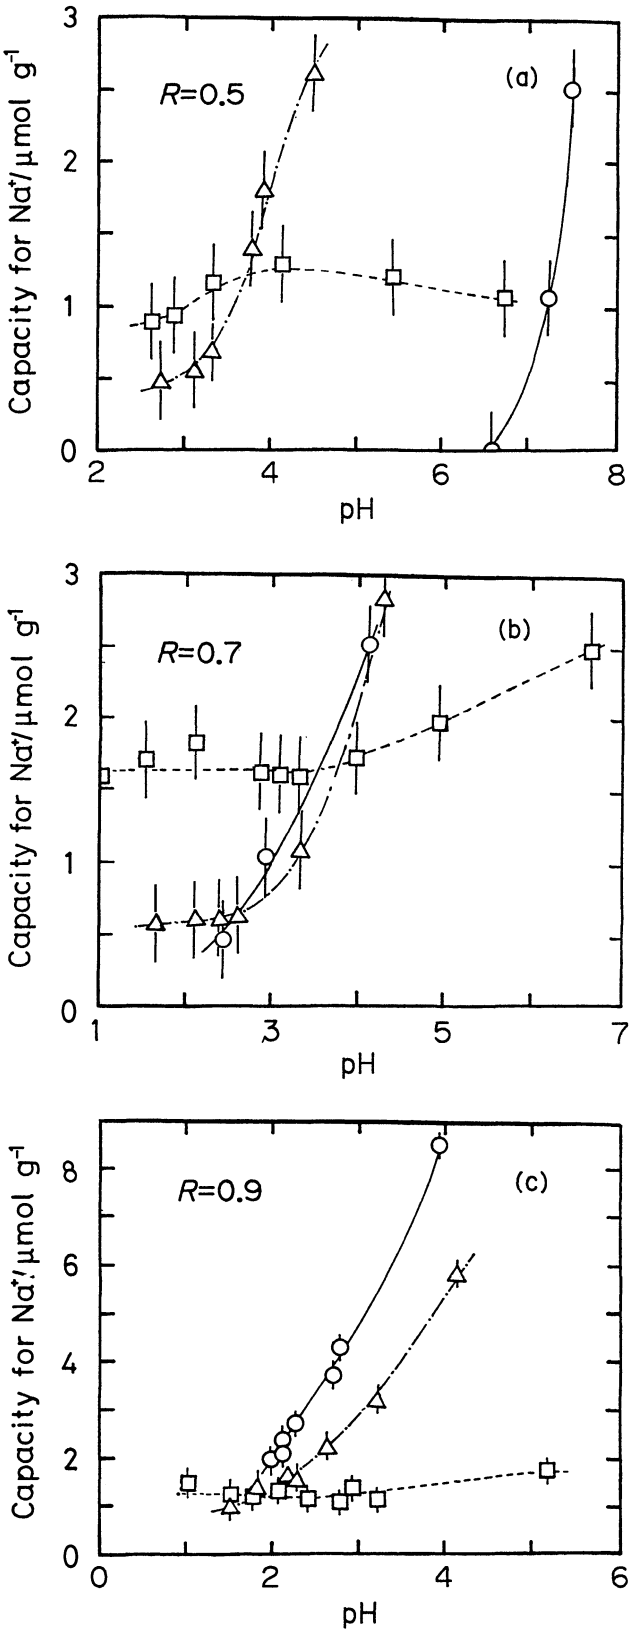

Fig. 8. Effect of heat treatment on a small amount of strongly acidic exchange sites.
Exchangers, (a): No. 3—5; (b): No. 6; (c): No. 7—9.
Temperature for heat treatment, ○: R.T.; △: 150 °C; □: 300 °C.
Solution: 2×10^{-4} M HNO_3-NaOH. Solution volume/Exchanger mass: 20 cm^3/0.2 g.

of a heat treatment on a small amount of the most acidic sites in the exchangers was examined by measuring the Na^+-uptake curve in Na^+-solutions of such low initial concentration as 2×10^{-4} M (Figs. 8-a to 8-c). In a pH range higher than 2, the amount of Na^+ sorbed on an exchanger with 90 mol% Ti and hydrous Ti^{IV} oxide decreased with increasing temperature, while at lower pH, it depended little on the temperature (Fig. 8-c). The curve of an exchanger with 70 mol% Ti was not affected by a heat treatment at 150 °C, but changed appreciably with a heat treatment at 300 °C; the amount of Na^+ sorbed was almost independent of the pH; thus, at a pH lower than 3.5 it was larger than the values for an exchanger without a heat treatment (Fig. 8-b). When exchangers with $\leqslant$50 mol% Ti were heat-treated, the pH at which the sorption of Na^+ commenced largely shifted to the acidic side and the sorption capacity in the region of pH <4 increased with temperature for a heat treatment (Fig. 8-a).

From the above-mentioned observations, the effect of a heat treatment on the distribution coefficients can be understood as follows. Although the total cation-exchange capacity decreases with increasing temperature, a heat treatment brings about a small increase in strongly acidic exchange sites, which can dissociate at a pH lower than the isoelectric point of exchangers with $\leqslant$70 mol% Ti. This is the reason why the distribution coefficients of cations with high affinity increase with a heat treatment. On the other hand, cations with low affinity are sorbed on exchangers by exchanging with hydrogens on abundant ion-exchange sites less acidic than the isoelectric point. The number of these sites determines the total cation-exchange capacity. A heat treatment, therefore, brings about a decrease in the distribution coefficients of cations with low affinity, in keeping with a decrease in the total cation exchange capacity.

Synthesis and Inclusion Properties of Sulfur-Bridged Analogs of Acyclic Phenol-Formaldehyde Oligomers

Yoshihiro Ohba, Kazuhiko Moriya, and Tyo Sone*
Department of Materials Science and Engineering, Faculty of Engineering, Yamagata University, Yonezawa 992
(Received September 10, 1990)

A series of compounds in which a part or all of the methylene bridges of acyclic *p*-methyl- and *p*-*t*-butylphenol-formaldehyde tetramers were replaced by sulfur bridge(s) was synthesized. It was found that though the sulfur-bridged tetramers formed crystalline host-guest complexes with a variety of organic compounds, they were different from the parent tetramers regarding their inclusion behavior. The number and position of the sulfur bridge(s), as well as the *p*-substituent of phenol in the tetramers, had a great influence upon the inclusion property. The thermal stability of complexes of the sulfur-bridged tetramers (**SSS-a,b**) with benzene, as estimated from their thermal dissociation rates, are lower than those of the parent tetramers (**CCC-a,b**).

We recently reported that acyclic *p*-substituted phenol-formaldehyde oligomers with methylene bridges ortho to the phenolic hydroxyl group formed crystalline inclusion compounds with many organic compounds, as did the corresponding cyclic oligomers, calixarenes.[1] The inclusion behavior of the acyclic oligomers was remarkably influenced by the *p*-substituent of phenol and the number of phenol units; tetramers and pentamers consisting of four and five phenol units with the *p*-substituent, such as the methyl, *t*-butyl, or cyclohexyl group, were very effective in complex formation. The oligomers included quite a few molecules which had no group to participate in hydrogen-bonding, suggesting that intermolecular hydrogen-bonding between the oligomers and the guest molecules was not essential for complex formation.

An X-ray crystallographic examination of the *p*-cresol tetramer (**CCC-a**)-benzene complex revealed that hydrogen-bonding between the phenolic hydroxyl groups plays a crucial role in the construction of the host lattice.[2] Namely, two molecules of the tetramer form a cyclic dimer in the crystalline complex through intramolecular hydrogen-bonding between adjacent phenolic hydroxyl groups in the molecule, as well as an intermolecular one between the phenolic hydroxyl groups of the opposite ends of the two molecules. This is in sharp contrast with the non-complexed tetramer, molecules of which are arranged in the crystalline state to chains of indefinite length by intermolecular hydrogen-bonding.[3]

These results suggest that modification in the methylene bridge of the phenol-formaldehyde oligomers affects the inclusion behavior as well. A noteworthy feature of this type of oligomer is that, owing to the bridges between the rigid aromatic skeletons, they can adapt to fit guest molecules through conformational changes in complexation. In the hope of founding a new host family based on phenol-formaldehyde oligomers, we extended our study to their sulfur-bridged analogs. In the present paper we describe the synthesis of sulfur-bridged analogs of acyclic *p*-cresol- and *p*-*t*-butylphenol-formaldehyde tetramers and their ability to form crystalline inclusion compounds with organic guest molecules.

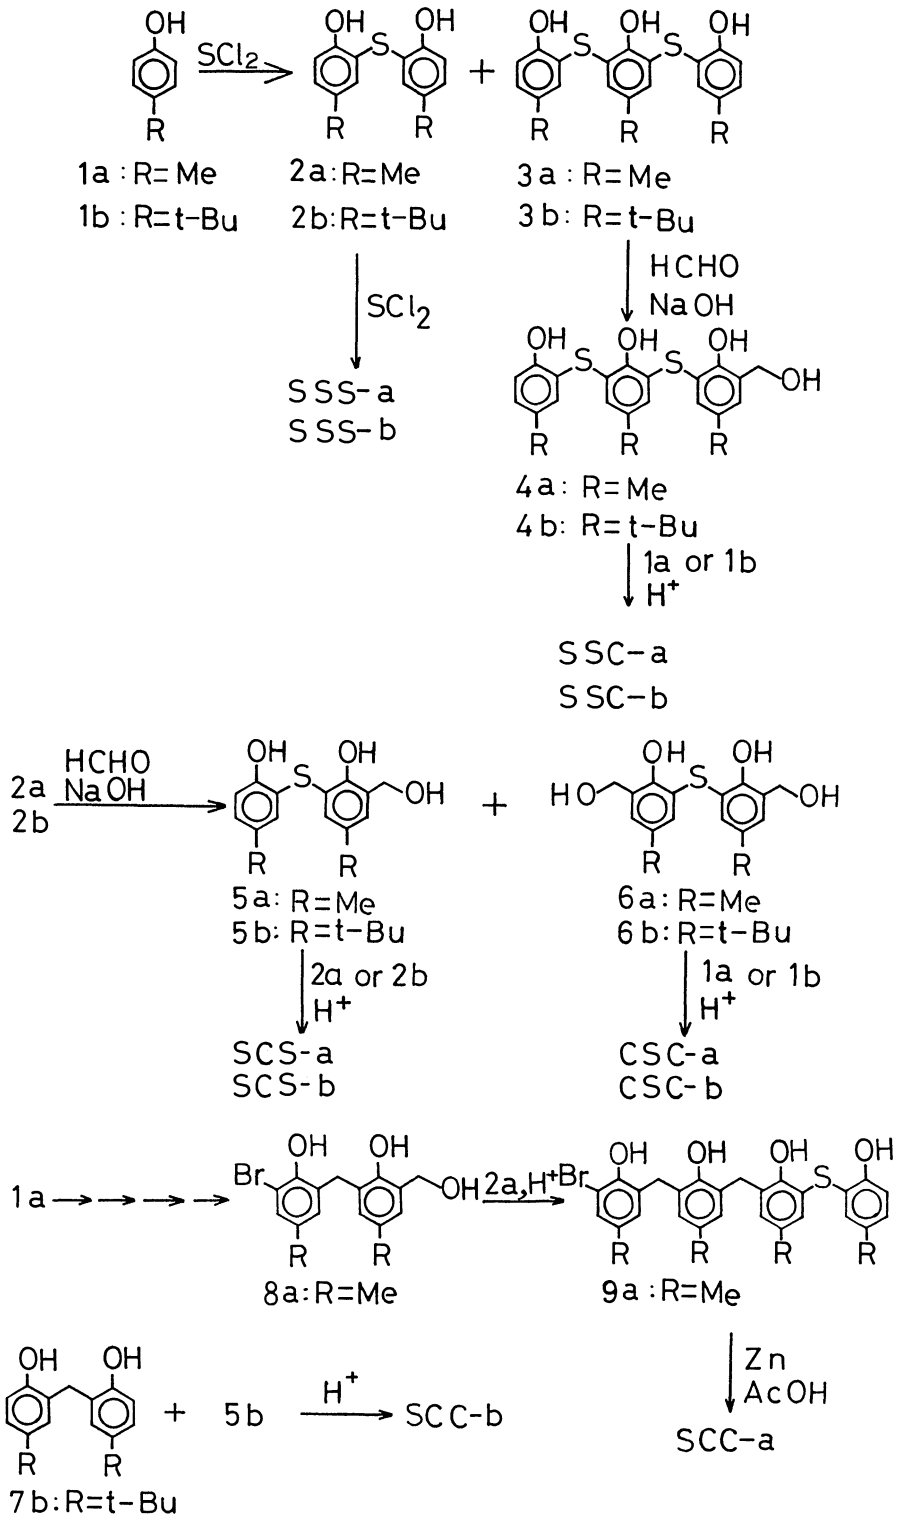
Results and Discussion

Synthesis of Oligomers. The sulfur-bridged analogs of *p*-cresol- and *p*-*t*-butylphenol-formaldehyde tetramers (**SSS-a,b**; **SSC-a,b**; **SCS-a,b**; **CSC-a,b**; **SCC-a,b**)[4] were synthesized as shown in Scheme 1; it involves repeated sulfuration and/or hydroxymethylation of the phenols, followed by condensation of the resulting hydroxymethyl compounds with the phenols.

The reaction of the phenols (**1a,b**) with 0.2 equivalent moles of SCl_2 in CH_2Cl_2 gave phenol-sulfur dimers (**2a,b**) together with a small amount of the corresponding trimers (**3a,b**). Further reaction of **2** (**a,b**) with SCl_2 yielded all sulfur-bridged tetramers, **SSS-a** and **SSS-b**, respectively. The NaOH-catalyzed hydroxymethylation of **3** (**a,b**) with aq formaldehyde, followed by the *p*-toluenesulfonic acid (TsOH)-catalyzed condensation of the resulting hydroxymethyl compounds (**4a,b**) with *p*-cresol (**1a**) or *p*-*t*-



Scheme 1.

butylphenol (**1b**), gave tetramers, **SSC-a** and **SSC-b**, with two neighboring sulfur bridges and one methylene bridge. The symmetrical tetramers, **SCS-a** and **SCS-b**, with one central methylene bridge were synthesized by condensation of the hydroxymethyl derivatives (**5a,b**) of **2** (**a,b**) with an large excess of **2** (**a,b**), while the other symmetrical tetramers, **CSC-a** and **CSC-b**, with one sulfur bridge were obtained analogously from the bis(hydroxymethyl) derivatives (**6a,b**) of **2** (**a,b**) and the corresponding phenols (**1a,b**). On the other hand, treatment of the *p-t*-butylphenol-formaldehyde dimer (**7b**) with **5b** in the presence of TsOH afforded the unsymmetrical *p-t*-butylphenol tetramer, **SCC-b**. The unsymmetrical *p*-cresol tetra-

mer, **SCC-a**, was obtained by the condensation of 3-(3-bromo-5-methylsalicyl)-2-hydroxy-5-methylbenzyl alcohol (**8a**)[5] with **2a**, and a subsequent debromination of the product (**9a**) with zinc powder in AcOH.

Inclusion Properties. The inclusion behavior of the tetramers towards organic molecules was examined by recrystallization of the tetramers from various organic solvents. The results are shown in Tables 1 and 2, together with those obtained for **CCC-a** and **CCC-b**.[1] It was found that the tetramers had an ability to form complexes with many organic compounds as the parent tetramers, and that the sulfur-bridged *p*-cresol and *p*-*t*-butylphenol tetramers were different from each other and from the parent tetramers regarding their inclusion behavior. The stoichiometries of the inclusion range from 3:1 to 1:3 (host:guest); 2:1 or 1:1 exist in most complexes, except for those with amines whose stoichiometric ratios are 1:1 or 1:2.[6]

Concerning the sulfur-bridged *p*-cresol tetramers, replacement of the methylene bridge(s) with sulfur(s) in the molecule of **CCC-a** tends to decrease the inclusion ability; **SCC-a**, **SCS-a**, and **SSS-a** are particularly poor. It seems that the position, rather than the number of the sulfur bridge(s), influences the ability. For example, while **CSC-a** is similar to **CCC-a**, **SCC-a** is decidedly inferior, both of the tetramers having one sulfur bridge. Likewise, **SSC-a** exhibits an inclusion property, whereas **SCS-a** and **SSS-a**, which have two terminal sulfur bridges, are almost ineffective. In spite of the low tendency for complex formation, the introduction of a sulfur bridge(s) in place of a methylene bridge(s) gave some of the tetramers (**SSC-a** and **CSC-a**) a new property to include alcohols.

On the other hand, sulfur-bridged *p*-*t*-butylphenol tetramers are, as a whole, superior to the corresponding *p*-cresol tetramers regarding complexation. Moreover, three (**SSS-b**, **SSC-b**, and **SCS-b**) out of the five tetramers form complexes with many more organic molecules than does the parent, **CCC-b**. For example, they form complexes with thiophene and aliphatic halogen compounds; **SSS-b** forms a 1:1 complex with 1,1,1-trichloroethylene, a water pollutant. The tetramers, **CSC-b** and **SCC-b**, with one sulfur bridge, however, show a low inclusion ability. Contrary to the observation concerning the *p*-cresol series, the number of sulfur bridge(s) seems to affect the inclusion ability in the *p*-*t*-butylphenol series.

It is interesting to note that, regardless of the *p*-substituent of the phenol, though all of the sulfur-bridged tetramers examined exhibit a high preference for aliphatic amines,[6] they lack the ability to include acetone, and neither of the tetramers of the **SCC** type in both series incorporate the aliphatic halogen compounds.

Guest preferences of the sulfur-bridged phenol tetramers, as observed, are dependent upon the *p*-substituent of the phenols, as well as both the number and position of the sulfur bridges. However, it is difficult to find an obvious rule which can explain all of the sulfur effects on the inclusion behavior. The results obtained here suggest that the tetramers build up characteristic host lattices which depend upon the combination of their building blocks. This assumption needs to be confirmed by X-ray structural studies of individual complexes.

The inclusion selectivities of **SSS-b** were examined for several equimolar mixtures of simple benzene derivatives. The results, together with those obtained for **CCC-b**, are shown in Table 3. In some cases, **SSS-b** shows a strong affinity to one guest in the guest mixtures. For example, **SSS-b** includes preferentially *o*-xylene in mixtures with benzene and *p*-xylene, and *m*-xylene in a mixture with benzene. However, **SSS-b** is generally inferior to **CCC-b** regarding inclusion selectivity. Sequences of the selectivity of **SSS-b** towards isomeric xylenes or benzene homologue are indefinite, suggesting that the conformation of the host molecule changes with the guest molecule to be accommodated.

There are only a few data available concerning the thermodynamic properties of crystalline inclusion

Table 3. Selectivity in the Complexation of **SSS-b** and **CCC-b** for an Equimolar Mixture of Guests

Guest(A)/Guest(B)	Host	
	SSS-b	**CCC-b**
	(A)/(B)	(A)/(B)
Benzene/toluene	36/64	47/53
Benzene/*o*-xylene	8/92	0/100

a) See Ref. 1.

complexes of artificial organic hosts with organic molecules.[7] In an attempt to estimate the thermal stability of the host-guest complexes, some kinetic parameters for the dissociation of **SSS-a**-benzene (host : guest=2 : 1) and the **SSS-b**-benzene complex (host : guest=1 : 1) were obtained from their dissociation rates (Table 4). The data indicate that the **SSS-a**-benzene complex is less stable than the corresponding **CCC-a**-benzene (2 : 1) complex. Assuming that the complexation mode of **SSS-a** is similar to that of **CCC-a**, the difference between the two complexes regarding thermal stability is principally attributable to difference in the lengths of the C(aromatic)-S(bridge) and C(aromatic)-C(bridge) bonds in the two host molecules.[8] Replacement of the C-C bonds with longer C-S bonds lengthens the distance between the adjacent hydroxyl groups in the molecule of **CCC-a** and, consequently, weakens the strength of the intramolecular hydrogen bonding between the adjacent hydroxyl groups. Thus, **SSS-a** more easily undergoes a conformational change in the molecule upon heating than does **CCC-a**. Alternatively, a lattice which **SSS-a** built up is too large for the guest molecule to fit. On the other hand, difference between **SSS-a**-benzene and **SSS-b**-benzene complexes in the stability arises from difference in the complexation mode.

Experimental

All melting points are uncorrected. NMR spectra were obtained on a Hitachi R-600 spectrometer at 60 MHz, using TMS as an internal reference. IR and mass (70 eV) spectra were recorded on a Hitachi EPI-S2 and on a Hitachi UMU-6MG spectrometers, respectively. TG/DTA curves were recorded on a Seiko TG/DTA 30 instrument with a heating rate of 10 °C min^{-1} under an air stream. Gas chromatographic-analyses were performed on a Hitachi K 53 chromatograph equipped with a standard golei column, U-90 (0.25 mm×90 m).

Synthesis of 2-[3-[3-(2-Hydroxy-5-methylphenylthio)-2-hydroxy-5-methylphenylthio]-2-hydroxy-5-methylphenylthio]-4-methylphenol (SSS-a). The reaction of *p*-cresol (**1a**) with SCl_2 gave 2,2′-thiobis[4-methylphenol] (**2a**; 61%);[11] 2,6-bis(2-hydroxy-5-methylphenylthio)-4-methylphenol (**3a**) was obtained as a minor product (4%).

3a: Colorless powder (hexane), mp 160—161 °C; IR (KBr) 3250, 880, 870, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (3H, s), 2.23 (6H, s), and 6.85—7.35 (8H, m); MS (70 eV) *m/z* (rel intensity) 384 (M^+, 100). Found: C, 65.53; H, 5.28%. Calcd for $C_{21}H_{20}O_3S_2$: C, 65.59; H, 5.24%.

Sulfur dichloride (0.67 g, 6.5 mmol) was added to a solution of **2a** (8.1 g, 33 mmol) in dry CH_2Cl_2 (100 ml) over a period of 35 min at 0 °C; the mixture was stirred at the same temperature for 1 h. The solvent was evaporated and the residue chromatographed on silica gel (Wako C-200; hexane/AcOEt=4/1) to give **SSS-a** (0.83 g, 24%).

SSS-a: Colorless prisms (hexane), mp 138—140 °C; IR (KBr) 3400, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.12 (3H, s), 2.22 (9H, s), and 6.50—7.35 (10H, m); MS (70 eV) *m/z* 522 (M^+, 100). Found: C, 64.62; H, 5.03%. Calcd for $C_{28}H_{26}O_4S_3$: C, 64.34; H, 5.01%.

Synthesis of 2-[3-[3-(5-*t*-Butyl-2-hydroxyphenylthio)-5-*t*-butyl-2-hydroxyphenylthio]-5-*t*-butyl-2-hydroxyphenylthio]-4-*t*-butylphenol (SSS-b). Sulfur dichloride (5.1 g, 50 mmol) was added to a solution of *p*-*t*-butylphenol (**1b**; 15 g, 0.1 mol) in dry CH_2Cl_2 (100 ml) over a period of 15 min at 0 °C. After stirring for 1 h at the same temperature, the mixture was concentrated and steam-distilled to remove any unreacted **1b**. Crystallization of the residual mass from hexane yielded 2,2′-thiobis[4-*t*-butylphenol] (**2b**; 8.85 g). The mother liquor was concentrated and subjected to medium-pressure liquid column chromatography (Kieselgel 60, 230—300 mesh; hexane/AcOEt=10/1) to afford another crop of **2b** (3.5 g, 75% in total) and 2,6-bis(5-*t*-butyl-2-hydroxyphenylthio)-4-*t*-butylphenol (**3b**; 0.75 g, 6%).

2b: Colorless prism (hexane), mp 101—102 °C; IR (KBr) 3300 and 820 cm^{-1}, ^1H NMR ($CDCl_3$) δ=1.24 (18H, s), 6.28 (2H, s, OH), and 6.80—7.45 (6H, m); MS (70 eV) *m/z* 330 (M^+, 100). Found: C, 72.94; H, 8.13%. Calcd for $C_{20}H_{26}O_2S$: C, 72.69; H, 7.93%.

3b: Colorless needles (hexane), mp 129—130 °C; IR (KBr) 3350, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (9H, s), 1.23 (18H, s), and 6.80—7.30 (8H, m); MS *m/z* 510 (M^+, 24). Found: C, 70.29; H, 7.66%. Calcd for $C_{30}H_{38}O_3S$: C, 70.55; H, 7.50%.

Tetramer **SSS-b** was prepared in 51.5% yield by a similar procedure as described regarding the synthesis of **SSS-a** from **2a**.

SSS-b: Colorless needles (hexane), mp 101.5—103 °C; IR (KBr) 3400, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.13 (18H, s), 1.25 (18H, s), and 6.70—7.65 (14H, m); MS (70 eV) *m/z* 690 (M^+, 100). Found: C, 69.57; H, 7.40%. Calcd for $C_{40}H_{50}O_4S_3$: C, 69.53; H, 7.29%.

Synthesis of 2-[3-[3-(2-Hydroxy-5-methylphenylthio)-2-hydroxy-5-methylphenylthio]-5-methylsalicyl]-4-methylphenol (SSC-a). To a solution of **3a** (2.0 g, 5.2 mmol) in MeOH (1 ml) a 10% NaOH solution (1 ml), and formalin (37%; 0.42 g, 5.2 mmol), were added under ice-cooling; the mixture was then stirred at 50 °C for 80 h in an atmosphere of N_2. The mixture was cooled to room temperature, acidified with 50% AcOH (pH 6), and extracted by $CHCl_3$. After the usual work-up, the product was subjected to medium-pressure column chromatography on silica gel (Kieselgel 60, 230—400 mesh; hexane/AcOEt=4/1) to give 3-[3-(2-hydroxy-5-methylphenylthio)-2-hydroxy-5-methylphenylthio]-2-hydroxy-5-methylbenzyl alcohol (**4a**; 0.65 g, 30%) and unreacted **3a** (0.6 g, 30 %).

4a: Colorless prisms (hexane-AcOEt), mp 163—164 °C; IR (KBr) 3400, 875, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.22 (3H, s), 2.29 (6H, s), 4.72 (2H, br s), 6.15 (1H, s, OH), and 6.60—7.35 (7H, m); MS (70 eV) *m/z* 384 (M^+, 93). Found: C, 63.99; H, 5.54%. Calcd for $C_{22}H_{22}O_4S_2$: C, 63.74; H, 5.35%.

A mixture of **4a** (0.65 g, 1.6 mmol), **1a** (2.0 g, 18.5 mmol), TsOH (50 mg), and benzene (20 ml) was refluxed for 24 h. The benzene was evaporated and excess **1a** removed by steam distillation. The residual mass was chromatographed on silica gel (Wako C-200; hexane/AcOEt=10/1) to give **SSC-a** (0.65 g, 80%).

SSC-a: Colorless needles (benzene), mp 130—131 °C; IR (KBr) 3400, 880, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.05 (3H, s), 2.10 (6H, s), 2.22 (3H, s), 4.40 (2H, s), and 6.60—7.20 (10H, m); MS (70 eV) *m/z* 502 (M^+, 100). Found: C, 68.97; H, 5.22%. Calcd for $C_{29}H_{28}O_4S_2$: C, 69.02; H, 5.59%.

Synthesis of 2-[3-[3-(5-*t*-Butyl-2-hydroxyphenylthio)-5-*t*-butyl-2-hydroxyphenylthio]-5-*t*-butylsalicyl]-4-*t*-butylphenol (SSC-b). Hydroxymethylation of **3b** by an analogy of the procedure described for **3a** yielded 3-[3-(5-*t*-butyl-2-hydroxyphenylthio)-5-*t*-butyl-2-hydroxyphenylthio]-5-*t*-butyl-2-hydroxybenzyl alcohol (**4b**; 40%) and unreacted **3b** (52%).

4b: Colorless powder (hexane), mp 84—87 °C; IR (KBr) 3370, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.10 (9H, s), 1.16 (9H, s), 1.23 (9H, s), 4.80 (2H, br s), and 6.80—7.45 (7H, m); MS (70 eV) *m/z* 540 (M^+, 67). Found: C, 69.33; H, 7.34%. Calcd for $C_{31}H_{40}O_4S_2$: C, 68.85; H, 7.46%.

Tetramer **SSC-b** was prepared from **4b** and **1b** in 73% yield, as described regarding the synthesis of **SSC-a**.

SSC-b: Colorless prisms (*o*-xylene), mp 123—124 °C, IR (KBr) 3400, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.12 (9H, s), 1.21 (9H, s), 1.26 (18H, s), 3.94 (2H, s), and 6.70—7.70 (10H, s); MS (70 eV) *m/z* 672 (M^+, 100). Found: C, 73.46; H, 7.98%. Calcd for $C_{41}H_{52}O_4S_2$: C, 73.17; H, 7.79%.

Synthesis of 2-[3-[3-(2-Hydroxy-5-methylphenylthio)-5-methylsalicyl]-2-hydroxy-5-methylphenylthio]-4-methylphenol (SCS-a). Formalin (37%; 11.3 g, 0.14 mol) was added to a mixture of **2a** (10 g, 0.04 mol), a 10% NaOH solution (30 ml) and MeOH (40 ml) over a period of 5 min at 0 °C in an N_2 atmosphere. After stirring at 50 °C for 26 h, the reaction mixture was cooled to room temperature, acidified to pH 5 with 10% HCl, and then extracted with $CHCl_3$. The organic layer was washed with H_2O and dried over Na_2SO_4. The solvent was removed, and the residue was chromatographed on silica gel (Wako C-200; hexane/AcOEt=2/1) to give 3-(2-hydroxy-5-methylphenylthio)-2-hydroxy-5-methylbenzyl alcohol (**5a**; 4.15 g, 37%) along with 3,3′-thiobis[2-hydroxy-5-methylbenzenemethanol] (**6a**; 6.7 g, 54%).

5a: Colorless prisms (benzene), mp 100—101 °C; IR (KBr) 3370, 850, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.12 (3H, s), 2.20 (3H, s), 4.68 (2H, br s), and 6.65—7.40 (5H, m); MS (70 eV) *m/z* 276 (M^+, 100). Found: C, 65.46; H, 5.82%. Calcd for $C_{15}H_{16}O_3S$: C, 65.19; H, 5.84%.

6a: Colorless needles ($CHCl_3$), mp 133—134 °C; IR (KBr) 3350 and 880 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (6H, s), 4.00—4.70 (2H, m, OH), 4.73 (4H, s), 6.90 (2H, s), and 7.15 (2H, s); MS (70 eV) *m/z* 306 (M^+, 100). Found: C, 62.96; H, 5.94%. Calcd for $C_{16}H_{18}O_4S$: C, 62.72; H, 5.92%.

A solution of **5a** (1.0 g, 3.6 mmol), **2a** (8.0 g, 32.5 mmol), and TsOH (50 mg) in benzene (100 ml) was stirred under reflux for 16 h. The water produced during the reaction was removed by azeotropic distillation using a Dean-Stark condenser. After removing the solvent, the residue was subjected to medium-pressure liquid column chromatography (Kieselgel 60, 230—300 mesh; hexane/AcOEt=4/1) to give **SCS-a** (0.90 g, 50%).

SCS-a: Colorless powder (benzene), mp 160—161.5 °C; IR (KBr) 3350, 860, 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.10 (3H, s), 2.14 (9H, s), 3.70 (2H, s), 6.48—7.35 (10H, m); MS (70 eV) *m/z* 504 (M^+, 100). Found: C, 68.95; H, 5.64%. Calcd for $C_{29}H_{28}O_4S_2$: C, 69.02; H, 5.59%.

Synthesis of 2-[3-[3-(5-*t*-Butyl-2-hydroxyphenylthio)-5-*t*-butylsalicyl]-5-*t*-butyl-2-hydroxyphenylthio]-4-*t*-butylphenol (SCS-b). 2,2′-Thiobis[4-*t*-butylphenol] (**2b**) was treated with formalin and 10% NaOH in MeOH, as described for **2a**, to give 3-(5-*t*-butyl-2-hydroxyphenylthio)-5-*t*-butyl-2-hydroxybenzyl alcohol (**5b**, 47%), and 3,3′-thiobis[5-*t*-butyl-2-hydroxybenzenemethanol] (**6b**, 33%) and unreacted **2b** (15%).

5b: Colorless prisms (hexane), mp 146—146.5 °C; IR (KBr) 3280, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (9H, s), 1.20 (9H, s), 4.80 (2H, br s), and 6.70—7.60 (5H, m); MS (70 eV) *m/z* 360 (M^+, 48). Found: C, 69.89, H, 7.89%. Calcd for $C_{21}H_{28}O_3S$: C, 69.96; H, 7.83%.

6b: Colorless powder (hexane), mp 93—94 °C IR (KBr) 3350 and 880 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.24 (18H, s), 4.78 (4H, s), 7.15 (2H, br s), 7.35 (2H, br s), and 7.95 (2H, br s); MS (70 eV) *m/z* 390 (M^+, 88). Found: C, 67.38; H, 7.80%. Calcd for $C_{22}H_{26}O_4S$: C, 67.66; H, 7.74%.

A solution of **5b** (1.0 g, 2.8 mmol), **2b** (9.2 g, 28 mmol), and TsOH (50 mg) in benzene (70 ml) was stirred under reflux for 21 h. The reaction mixture was worked up as described regarding the synthesis of **SCS-a** to give **SCS-b** (0.8 g, 43%).

SCS-b: Corless plates (hexane), mp 170—174 °C; IR (KBr) 3370, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.20 (18H, s), 1.26 (18H, s), 3.90 (2H, s), and 6.70—7.65 (10H, m); MS (70 eV) *m/z* 672 (M^+, 100). Found: C, 73.24; H, 7.95%. Calcd for $C_{41}H_{52}O_4S_2$: C, 73.17; H, 7.79%.

Synthesis of 2-[3-[3-(5-Methylsalicyl)-2-hydroxy-5-methylphenylthio]-5-methylsalicyl]-4-methylphenol (CSC-a). A solution of **6a** (3.0 g, 9.8 mmol), **1a** (15 g, 0.14 mol), and TsOH (50 mg) in benzene (100 ml) was stirred under reflux for 10 h. After evaporating the solvent excess **1a** was removed by steam-distillation. The crude product was purified by medium-pressure liquid column chromatography (Kieselgel 60, 230—300 mesh; hexane/AcOEt=4/1) to give **CSC-a** (4.1 g, 86%).

CSC-a: Colorless prisms (hexane-AcOEt), mp 157—158 °C; IR (KBr) 3250, 865, and 815 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.20 (6H, s), 2.28 (6H, s), 3.85 (4H, s), and 6.60—7.30 (10H, m); MS *m/z* (70 eV) 486 (M^+, 100). Found: C, 74.23; H, 6.23%. Calcd for $C_{30}H_{30}O_4S$: C, 74.05; H, 6.21%.

Synthesis of 2-[3-[3-(5-*t*-Butylsalicyl)-5-*t*-butyl-2-hydroxyphenylthio]-5-*t*-butylsalicyl]-4-*t*-butylphenol (CSC-b): Treatment of **6b** (3 g, 7.7 mmol) with **1b** (23 g, 0.15 mmol) in a similar manner as that described for the synthesis of **CSC-a** from **6a** gave **CSC-b** (4.3 g, 85%).

CSC-b: Colorless prisms (benzene), mp 172—173.5 °C; IR (KBr) 3370, 875, and 815 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (18H, s), 1.24 (18H, s), 3.91 (4H, s), and 6.60—7.55 (10H, m); MS (70 eV) *m/z* 654 (M^+, 100). Found: C, 77.01; H, 8.39%. Calcd for $C_{42}H_{54}O_4S$: C, 77.02; H, 8.31%.

Synthesis of 2-[3-[3-(2-Hydroxy-5-methylphenylthio)-5-methylsalicyl]-5-methylsalicyl]-4-methylphenol (SCC-a). 3-(3-Bromo-5-methylsalicyl)-2-hydroxybenzyl alcohol[5] (**8a**; 5.7 g, 17 mmol), **2a** (20.8 g, 84 mmol), and TsOH (100 mg) were dissolved in benzene (50 ml); the solution was then stirred under reflux for 9 h. After the usual work-up, column chromatography (Wako Q-200, hexane/AcOEt=3/1) of the reaction mixture yielded 2-[3-[3-(3-bromo-5-methylsalicyl)-5-methylsalicyl]-2-hydroxy-5-methylphenylthio]-4-methylphenol (**9a**; 4.2 g, 43%).

9a: Colorless prism (benzene-hexane), mp 168—170 °C; IR 3340, 860, 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.15 (12H, s), 3.80 (4H, s), 5.30 (4H, br s, OH), and 6.30—7.30 (9H, m); MS (70 eV) *m/z* 564 (M^+, 100). Found: C, 63.88; H, 5.16%. Calcd for $C_{30}H_{29}O_4SBr$: C, 63.72; H, 5.17%.

To a refluxing solution of **9a** (1.3 g, 2.3 mmol) in 80% AcOH, zinc powder (15 g, 0.23 mol) was added over a period of 1 h with stirring. After stirring under reflux for 15 h, the

mixture was cooled to room temperature and filtered. The filtrate was extracted with $CHCl_3$. The residual zinc was extracted with $CHCl_3$ using a Soxhlet extractor. The combined extracts were concentrated and the residual oil subjected to medium-pressure liquid chromatography (Kiesel gel 60, 230—300 mesh; hexane/AcOEt=4/1) to give **SCC-a** (0.9 g, 80 %).

SCC-a: Colorless needles (benzene), mp 180—185 °C; IR 3300, 860, and 810 cm^{-1}; ^1H NMR ($CDCl_3$) δ=2.15 (3H, s), 2.20 (6H, s), 2.25 (3H, s), 3.84 (4H, s), and 6.10—7.40 (14H, m); MS (70 eV) *m/z* 486 (M^+, 57). Found: C, 73.81; H, 6.25%. Calcd for $C_{30}H_{30}O_4S$: C, 74.05; H, 6.21%.

Synthesis of 2-[3-[3-(5-*t*-Butyl-2-hydroxyphenylthio)-5-*t*-butylsalicyl]-5-*t*-butylsalicyl]-4-*t*-butylphenol (SCC-b). A solution of **5b** (2.0 g, 5.6 mmol), 2-(5-*t*-butylsalicyl)-4-*t*-butylphenol (**7b**; 17.2 g, 51 mmol), and TsOH (50 mg) in benzene (100 ml) was stirred under reflux for 40 h; the water produced during the reaction was removed by azeotropic distillation using a Dean-Stark condenser. The reaction mixture was cooled to room temperature and the precipitate filtered off. The solvent was then evaporated and the residual oil (10.6 g) chromatographed (silica gel Wako Q-200, benzene) to give **SCC-b** (2.55 g, 70%) and unreacted **2b** (7.4 g).

SCC-b: Colorless powder (benzene), mp 174.5—177.5 °C IR (KBr) 3260, 880, and 820 cm^{-1}; ^1H NMR ($CDCl_3$) δ=1.18 (9H, s), 1.26 (9H, s), 3.90 (4H, s), and 6.60—7.45 (10H, m); MS (70 eV) *m/z* 654 (M^+, 100); Found: C, 77.09; H, 8.59%. Calcd for $C_{42}H_{54}O_4S$: C, 77.02; H, 8.31%.

Preparation of Inclusion Complexes. The host oligomer was recrystallyzed using a minimum amount of organic solvent (guest). The precipitates were collected by filtration, when necessary, washed with hexane, and dried at ambient temperature overnight. The host-guest ratio was determined by means of ^1H NMR spectroscopy.

Selective guest inclusion was examined as follows: The tetramer **SSS-b** (500 mg) was dissolved in an equimolar mixture of guests by heating. The mixture was treated in a similar manner as the procedure described above. Upon heating the complex under reduced pressure, a liquid mixture was obtained by distillation. The ratio of the components in the distillate was determined by gas chromatography.

Kinetic Study. The weight-decreasing ratio of a complex was measured from the TG-DTA curve using Al_2O_3 as an reference. The programmed temperature was raised at a rate 10 °C min^{-1} up to each temperature. Based on the rate constants, thus obtained, the ΔH^*, $\ln A$ and E_a values were calculated by a least-squares method.

The authors are grateful to Professor Kenzo Matsuki and Mr. Takashi Endo for TG/DTA measurements. They would also like to thank Mr. Kazuaki Sato for elemental analyses and Mr. Hideaki Hino for his assistance in some of the experiments.

(Received September 6, 1990)

[L-Lys$^{2,2'}$]-gramicidin S has been known to possess the same type activity and conformation as that of gramicidin S. The D-isomer of the Lys residue, instead of the Orn residue, was introduced to gramicidin S in order to investigate the contribution of the configurations of the Orn residue in gramicidin S to its activity and conformation. [D-Lys$^{2,2'}$]- and [D-Lys^{2}, L-Lys$^{2'}$]-gramicidin S were synthesized by a liquid-phase method. The CD spectra of these analogs showed a pattern similar to that of gramicidin S, suggesting that the conformation of these analogs at the β-turn parts around the D-Phe-Pro sequence resemble that of gramicidin S. These analogs have either a weak or no activity against the Gram-positive microorganisms tested, indicating the importance of the configuration of the Orn residue in gramicidin S for exhibiting strong activity.

Gramicidin S (GS)[1-2] is an antibiotic cyclodecapeptide isolated from *Bacillus brevis*. In studies of the relationship between the structure and antibiotic activity of GS, various analogs have been synthesized. From these studies it has been recognized that the basic amino groups of the Orn residues in GS are necessary for the activity. For example, the acylation of these amino groups caused a drastic decrease in the activity.[3] On the other hand, changes in the length of the side chain in the Orn residues[4-5] and a conversion of the amino groups into strongly basic guanidino groups[6] did not alter the activity. However, the effects of an alternation of the configuration of the Orn residues on the secondary structure and antibiotic actvity of GS have not been studied.

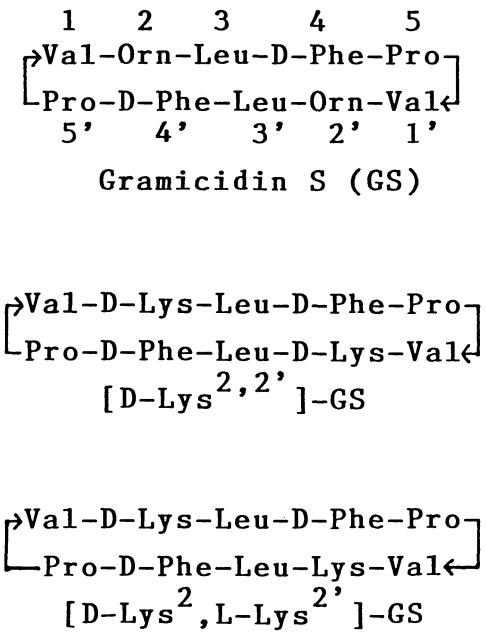

Fig. 1. Primary structure of gramicidin S and its analogs.

Waki et al.[5] synthesized [L-Lys$^{2,2'}$]-GS, in which the Orn residues at the 2- and 2'-positions are replaced with Lys residues, and reported that this analog shows the same ORD curve and antibiotic activity as those of GS.

In the present paper we describe the synthesis, antibiotic activity and CD spectra of [D-Lys$^{2,2'}$]- and [D-Lys^{2}, L-Lys$^{2'}$]-GS (Fig. 1), and discuss the structure-activity relationship of these GS analogs.

The synthetic routes of [D-Lys$^{2,2'}$]- and [D-Lys^{2}, L-Lys$^{2'}$]-GS are shown in Fig.2. In the synthesis of [D-Lys$^{2,2'}$]-GS (**5a**), the Boc-pentapeptide benzyl ester (**1a**) was synthesized from the Pro benzyl ester by a step-by-step elongation using 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (WSCD·HCl) and 1-hydroxybenzotriazole (HOBt), and then saponified to give Boc-pentapeptide (**2a**). A part of **2a** was converted into the corresponding succinimido ester **2a'** with WSCD·HCl and *N*-hydroxysuccinimide (HONSu). Coupling of **2a'** and the pentapeptide derived from **2a** afforded the decapeptide (**3a**), which was converted into the decapeptide succinimido ester (**3a'**). The Boc-group of **3a'** was removed by the action of trifluoroacetic acid (TFA); the succinimido ester was then cyclized under high dilution in pyridine at 45 °C for 5 h. The resulting product was purified by means of high-performance liquid chromatography (HPLC), followed by recrystallization. The cyclodecapeptide (**4a**) was obtained in 26% yield. The removal of all the masking groups of **4a** by hydrogenolysis yielded [D-Lys$^{2,2'}$]-GS (**5a**). [D-Lys^{2}, L-Lys$^{2'}$]-GS (**5b**) was synthesized in a similar manner. The yield of the cyclization of **3b** was 60%. Cyclization of **3a** using a succinimido active ester method gave a very low yield of the desired cyclic peptide, compared with that of **3b**. These phenomena indicate that the substitution of two Orn(*Z*) residues by two D-Lys(*Z*) residues induces a decrease in the chance for collisions between the N- and C-terminals in the linear decapeptide **3a**. The homogeneity of

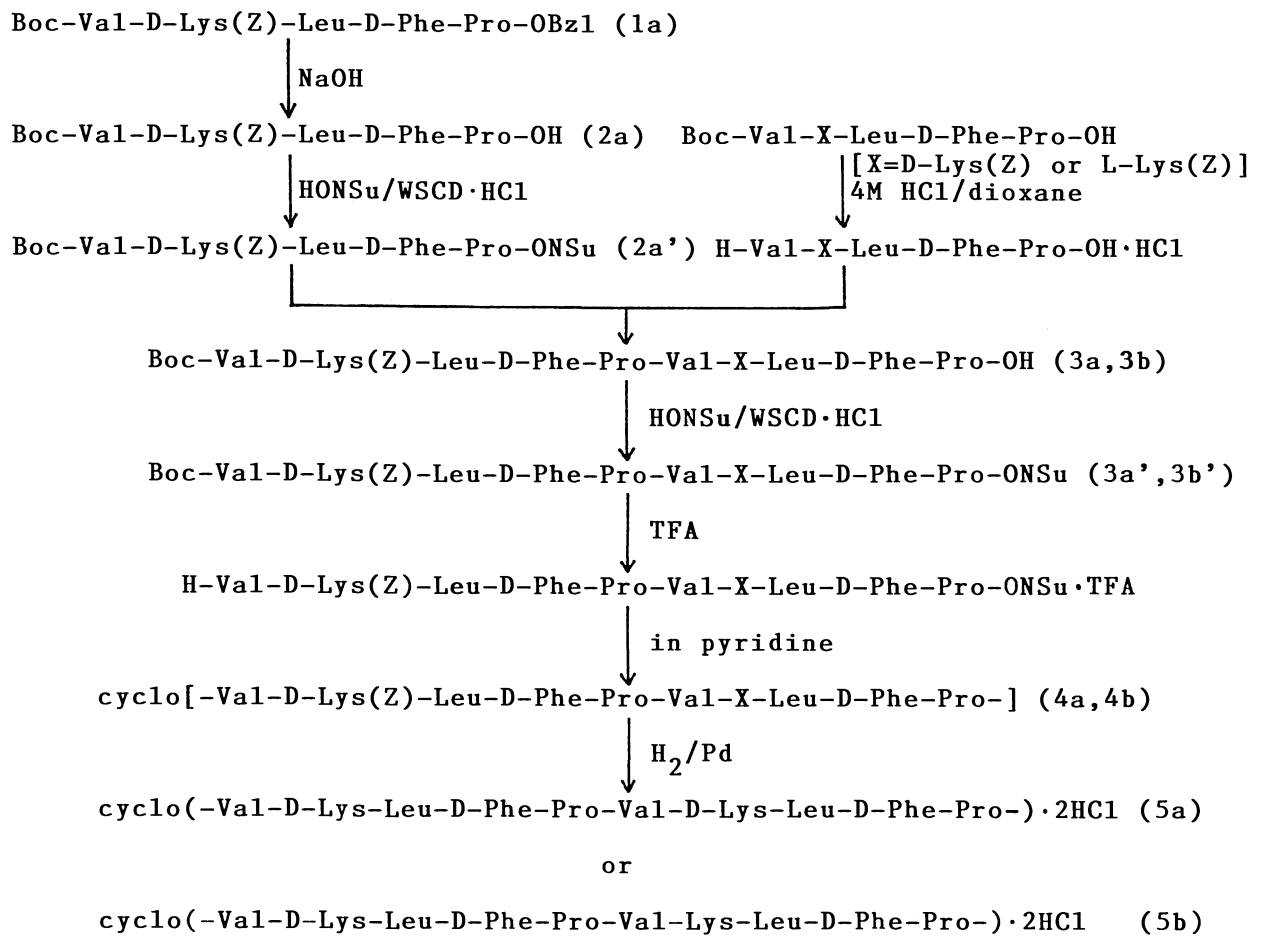

Fig. 2. Synthesis of [D-Lys$^{2,2'}$]-GS and [D-Lys^{2}, L-Lys$^{2'}$]-GS.

[D-Lys$^{2,2'}$]- and [D-Lys^{2}, L-Lys$^{2'}$]-GS was confirmed by means of thin-layer chromatography (TLC), amino acid analysis, HPLC, elemental analysis, and fast atom bombardment (FAB) mass spectrometry.

The CD spectra of GS and the analogs (**5a** and **5b**) were measured in aqueous solutions (Fig. 3). Though the shape of the CD spectrum of **5b** was similar to that of GS, each depth of the two troughs was about 1/2 that of GS. Though two troughs in the CD parttern of **5a** were also observed, their depths were much shallower. In studies regarding an alternation of the configurations of the constituent amino acid residue in GS, it was reported that [D-Val$^{1,1'}$]-,[7] [L-Phe$^{4,4'}$]-,[8] and [D-Pro$^{5,5'}$]-GS,[9] in which L-Val, D-Phe, or L-Pro residues in GS was replaced with D-Val, L-Phe, or D-Pro residues, respectively, possessed a CD spectra different from those of GS in aqueous solutions. These results indicated that the configuration of the amino acid residues at the β-turn parts of GS influences its conformation more than does that of the Orn residue. In CD studies of GS and gratisin, we also reported that their CD spectra mainly reflect the ring features near the Pro residue, but not the entire structure of the molecule.[7-10] The present results suggest that though there exists a similarity among the CD pattern of these synthetic analogs and the GS results from the presence of a D-Phe-Pro sequence of these analogs, the stability of their conformation decreases as the D-Lys residue is introduced.

The antibiotic activity of these synthetic peptides is summarized in Table 1. [D-Lys$^{2,2'}$]-GS possessed about 1/8 of the activity of the natural GS against *C. diphtheriae* P.W.8, and no activity toward the other Gram-positive microorganisms tested. On the other hand, [D-Lys^{2}, L-Lys$^{2'}$]-GS showed activity against all of the Gram-positive microorganisms tested, although it was very weak. Further, it was reported that [D-Val$^{1,1'}$]-,[7] [L-Phe$^{4,4'}$]-,[8] and [D-Pro$^{5,5'}$]-GS[9] shows either a weak or no activity. These results point out the importance of the configuration of the constituent amino acid residue of GS for exhibiting activity. In ESR studies of GS, Ovchinikov et al. reported that the average distance between the NH_3^+ groups of the Orn residues in GS and its analogs with activity is about 8—10 Å, and that the spatial situation is held by a rigid conformation containing two D-Phe-Pro type-II' β-turns.[11] From the present studies, it is deduced that the introduction of one or two D-Lys residues at

positions 2 and 2′ in GS decreases the stability of the type-II′ β-turn around D-Phe-Pro sequences, resulting in a distortion of the spatial arrangement of the NH_3^+ groups required for antibiotic activity.

Experimental

All melting points are uncorrected. The CD spectra were measured by a JASCO spectropolarimeter (model J-500) using a 0.5 mm quarts cell at room temperature. The CD spectroscopy of GS and its analogs was carried out as aqueous solutions of their dihydochlorides at a concentration of 1.5—2.0×10^{-4} M (1 M=1 mol dm^{-3}). The molecular weights of these synthetic peptides were determined by FAB mass spectrometry using a JEOL JMS-D-300 mass spectrometer. Amino acid analyses were carried out using a Hitachi 835 amino acid analyzer, after hydrolysis in 6 M HCl at 110 °C for 24 h. HPLC was performed by an octadecylsilica (ODS) column (φ 4.6×250 mm) using MeOH-5% $NaClO_4$aq (5:1) as an elution solvent. TLC was performed on Merck silica-gel F_{254} plates with the following solvent systems (v/v): R_f^1, $CHCl_3$-MeOH (9:1); R_f^2, $CHCl_3$-MeOH-AcOH (95:5:3); R_f^3, *n*-BuOH-AcOH-H_2O (4:1:1); R_f^4, *n*-BuOH-pyridine-AcOH-H_2O (4:1:1:2). The yields of **1a** and **1b** were calculated on the basis of the amount of Pro-OBzl as a starting material.

Boc-Val-D-Lys(Z)-Leu-D-Phe-Pro-OBzl (1a). Pro-OBzl·HCl (1.20 g, 5 mmol) was dissolved in $CHCl_3$ (20 ml). The solution was then washed with aqueous 5% Na_2CO_3 and water under cooling in an ice bath. To the organic layer were added Boc-D-Phe (1.32 g, 5 mmol), HOBt (0.75 g, 5.5 mmol) and WSCD·HCl (0.96 g, 5 mmol) at 0 °C. This solution was stirred for 1 h at 0 °C and overnight at room temperature. The reaction mixture was washed successively with aqueous 5% citric acid, water, and aqueous 5% Na_2CO_3, and water; the solvent was then evaporated in vacuo. The residue was dissolved in 4 M HCl/dioxane (20 ml) at 0 °C. After stirring for 30 min at room temperature, the solution was concentrated in vacuo. The residue was dissolved in $CHCl_3$ (30 ml); the solution was then washed with aqueous 5% Na_2CO_3 and water under cooling in an ice bath. To this solution was added Boc-Leu (1.25 g, 5 mmol), HOBt (0.75 g, 5.5 mmol) and WSCD·HCl (0.96 g, 5 mmol) at 0 °C. The same procedure as described above was repeated for this reaction mixture. Further, Boc-D-Lys(*Z*) and Boc-Val were successively coupled by the same method. All reactions were followed by TLC on a silica-gel plate. The crude protected pentapeptide obtained from the final reaction mixture was purified by chromatography on a silica-gel column (φ 1.5×60 cm) using a solvent system of $CHCl_3$-MeOH (50:1) and reprecipitation from AcOEt-ether.; overall yield, 3.38 g (73% from Pro-OBzl·HCl); mp, 70—74 °C; $[\alpha]_D^{27}$ −30.8° (*c* 1.1, DMF); R_f^1 0.90, R_f^2 0.54.

Found: C, 65.33; H, 7.65; N, 8.71%. Calcd for $C_{51}H_{70}$-

$N_6O_{10}\cdot 0.5H_2O$: C, 65.43; H, 7.64; N, 8.98%.

Boc-Val-D-Lys(Z)-Leu-D-Phe-Pro-OH (2a). To a solution of **1a** (3.00 g, 3.24 mmol) in MeOH (40 ml), 1 M NaOH (8 ml) was added; the solution was then stirred for 7 h at room temperature. After the addition of water (10 ml), the solution was concentrated in vacuo at low temperature, and aqueous 5% citric acid (100 ml) added to the reaction mixture. The resulting solid was collected by filtration, washed with water and dried. The product was recrystallized from MeOH-ether-hexane; yield, 2.64 g (97%); mp, 82—87 °C; $[\alpha]_D^{27}$ −29.6° (*c* 1.1, DMF); R_f^1 0.38, R_f^2 0.52.

Found: C, 62.47; H, 7.88; N, 9.61%. Calcd for $C_{44}H_{64}N_6O_{10}\cdot 0.5H_2O$: C, 62.47; H, 7.74; N, 9.93%.

Boc-[Val-D-Lys(Z)-Leu-D-Phe-Pro-]$_2$-OH (3a). To a solution of **2a** (800 mg, 0.96 mmol) in DMF (5 ml) were added HONSu (231 mg, 2 mmol) and WSCD·HCl (383 mg, 2 mmol) at 0 °C; the mixture was then stirred for 5 h at room temperature. After the solution was evaporated in vacuo, water was added to the residue. The resulting solid, Boc-Val-D-Lys(Z)-Leu-D-Phe-Pro-ONSu (**2a′**), was collected by filtration, washed with water and then dried. Another crop of **2a** (800 mg, 0.96 mmol) was dissolved in 4 M HCl/dioxane (15 ml) at 0 °C. After stirring at room temperature for 30 min, the solution was concentrated in vacuo. Ether (50 ml) was added to the residue, and the resulting solid was collected by filtration. To a solution of HCl·H-Val-D-Lys(Z)-Leu-D-Phe-Pro-OH (prepared as mentioned above) and triethylamine (0.26 ml, 1.92 mmol) in DMF (20 ml), **2a′** derived from **2a** at 0 °C was added. The mixture was left standing for 2 h at 0 °C and then overnight at room temperature. The solution was evaporated; aqueous 5% citric acid was then added to the residue. The resulting solid was collected by filtration, washed with water and dried. The product was recrystallized from AcOEt-ether; yield, 1.40 g (93%); mp, 120—125 °C; $[\alpha]_D^{27}$ −37.9° (*c* 1.1, DMF); R_f^1 0.40, R_f^2 0.53.

Found: C, 62.28; H, 7.70; N, 10.51%. Calcd for $C_{83}H_{118}N_{12}O_{17}\cdot 2.5H_2O$: C, 62.27; H, 7.74; N, 10.50%.

Cyclo[-Val-D-Lys(Z)-Leu-D-Phe-Pro-]$_2$ (4a). Compound **3a** (750 mg, 0.48 mmol) was converted into the *N*-hydroxysuccinimido ester (**3a′**) by methods described for **2a**. It was then dissolved in TFA (15 ml) at 0 °C. The mixture was stirred for 40 min at room temperatue and then concentrated in vacuo. The residue, the trifluoroacetate of the decapeptide active ester, was triturated with ether and collected by filtration and dissolved in DMF (10 ml). The solution was poured, dropwise, in pyridine (500 ml) at 45 °C. After stirring for 3 h at 45 °C, the solution was concentrated. The addition of water to the reisdue afforded precipitates, which were filtered and washed with water. The purification of this compound was performed by HPLC on ODS column (ϕ 7.6×250 mm) using a solvent system of MeOH-H_2O (6:1), followed by reprecipitation from MeOH-ether; yield, 180 mg (26%); mp, 220—222 °C; $[\alpha]_D^{27}$ −137.7° (*c* 0.65, DMF); R_f^1 0.83, R_f^2 0.56.

Found: C, 63.32; H, 7.64; N, 11.35%. Calcd for $C_{78}H_{108}N_{12}O_{14}\cdot 2H_2O$: C, 63.57; H, 7.66; N, 11.40%.

Cyclo(-Val-D-Lys-Leu-D-Phe-Pro-)$_2$·2HCl (5a). Compound **4a** (120 mg, 0.083 mmol) was dissolved in 90% aq MeOH (40 ml) and then 1 M HCl (0.17 ml) was added to the solution. The compound was hydrogenolyzed in the presence of palladium black for 15 h. After removing the catalyst, the filtrate was concentrated in vacuo. The product was purified by gel filtration on a Sephadex LH-20 column (ϕ 1.2×120 cm) using MeOH as a solvent, and by reprecipitation from MeOH-ether; yield, 90 mg (87%); mp, 246—248 °C; $[\alpha]_D^{27}$ −158.3° (*c* 0.70, EtOH); R_f^3 0.44, R_f^4 0.76.

Amino acid ratios: Val, 0.97; Lys, 0.98; Leu, 1.03; Phe, 1.08; Pro, 0.93. MS (FAB), *m/z* 1169 ($C_{62}H_{96}N_{12}O_{10}$, MH^+).

Found: C, 54.81; H, 8.04; N, 12.40%. Calcd for $C_{62}H_{96}N_{12}O_{10}\cdot 2HCl\cdot 6.5H_2O$: C, 54.78; H, 8.23; N, 12.36%.

Boc-Val-D-Lys(Z)-Leu-D-Phe-Pro-Val-Lys(Z)-Leu-D-Phe-Pro-OH (3b). This compound was prepared from **2a** (600 mg, 0.72 mmol) and Boc-Val-Lys(Z)-Leu-D-Phe-Pro-OH (700 mg, 0.84 mmol) in a manner similar to that described for the preparation of **3a**. Purification of the product was performed by reprecipitation from AcOEt-ether-hexane: yield, 1.03 g (92%); mp, 104—112 °C; $[\alpha]_D^{27}$ −40.9° (*c* 1.2, DMF); R_f^1 0.51, R_f^2 0.57.

Found: C, 62.87; H, 7.77; N, 10.53%. Calcd for $C_{83}H_{118}N_{12}O_{17}\cdot 1.5H_2O$: C, 62.98; H, 7.70; N, 10.62%.

Cyclo[-Val-D-Lys(Z)-Leu-D-Phe-Pro-Val-Lys(Z)-Leu-D-Phe-Pro-] (4b). This compound was prepared from **3b** (750 mg, 0.48 mmol), as described regarding the preparation of **4a**; yield, 417 mg (60%); mp, 133—137 °C; $[\alpha]_D^{27}$ −154.4° (*c* 1.0, DMF); R_f^1 0.76, R_f^2 0.55.

Found: C, 64.32; H, 7.68; N, 11.45%. Calcd for $C_{78}H_{108}N_{12}O_{14}\cdot H_2O$: C, 64.35; H, 7.62; N, 11.54%.

Cyclo(-Val-D-Lys-Leu-D-Phe-Pro-Val-Lys-Leu-D-Phe-Pro-)·2HCl (5b). This compound was prepared from **4b** (200 mg, 0.14 mmol) as described regarding the preparation of **5a**; yield, 150 mg (87%); mp, 228—235 °C; $[\alpha]_D^{27}$ −223.4° (*c* 0.82, EtOH); R_f^3 0.69, R_f^4 0.79.

Amino acid ratios: Val, 0.98; Lys, 0.99; Leu, 1.05; Phe, 1.04; Pro, 0.94.

MS(FAB), *m/z* 1169 ($C_{62}H_{96}N_{12}O_{10}$, MH^+).

Found: C, 56.51; H, 8.08; N, 12.75%. Calcd for $C_{62}H_{96}N_{12}O_{10}\cdot 2HCl\cdot 4H_2O$; C, 56.65; H, 8.13; N, 12.79%.

We are grateful to the staff of the Research Laboratories of the Toyo Jozo Co. for their elemental analysis, microbiological assays, and the measurement of the FAB mass.

Chemical Synthesis of Branched Oligoribonucleotides

Mitsuo SEKINE,* Jarmo HEIKKILÄ, and Tsujiaki HATA
Department of Life Science, Tokyo Institute of Technology, Nagatsuta, Midoriku, Yokohama 227
(Received September 7, 1990)

This paper describes the full detail of the chemical synthesis of branched oligoribonucleotides by use of appropriately protected adenosine 2′,3′-diphosphate derivatives (**13** and **30**), as key intermediates, which were synthesized by a series of reactions involving phosphoryl rearrangement via a new phosphorylation process. Branched triribonucleotides A^{pG}_{pC} (**21**) and A^{pG}_{pU} (**27**) were obtained by using the synthetic unit **13**. Several problems during these syntheses were discussed. The use of **30** as an improved building unit enabled us to prepare synthetic intermediates as neutral, i.e., fully esterified species which allowed facile purification of them by means of silica-gel column thin-layer chromatography throughout the synthesis of a branched hexaribonucleotide derivative $CpUpGpA^{pG}_{pC}$.

Since Wallace and Edmonds[1] discovered branched RNAs, this unique structure has been found as part of the so-called lariat structure in splicing products of messenger RNAs in a variety of eukaryotic cells.[2]

Chemical synthesis of branched RNAs has been reported in several laboratories.[3-15] In this paper,# we report the detailed study of chemical synthesis of branched oligoribonucleotides, involving the regioselective introduction of two different phosphoryl groups into the 2′- and 3′-positions of adenosine at the branched point. Preliminary results of this study have already been reported.[3,13]

Results and Discussion

To introduce a protected phosphate group into the 2′-hydroxyl group of adenosine which is the ribonucleoside found in the target branched RNA, the following method for phosphorylation of the 2′-hydroxyl group of silylated adenosine derivative (**1**) was explored. Caruthers[16] has reported the P-N bond activation of deoxyribonucleoside phosphoramidite derivatives with tetrazole for rapid internucleotidic bond formation. On the other hand, we described previously the synthesis of deoxyribonucleoside phosphonates via phosphorodiamidite intermediates.[17]

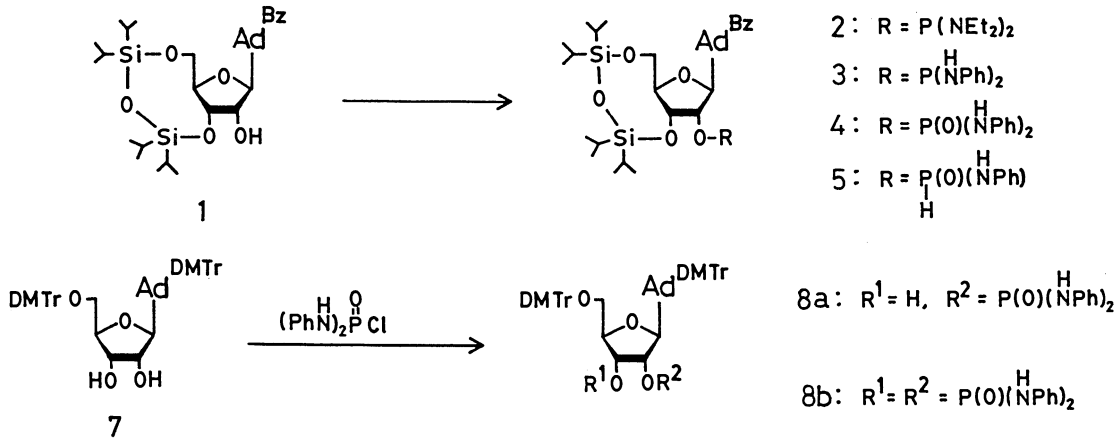
On the basis of these facts, **1** was allowed to react with 1.5 equiv of tris(diethylamino)phosphine (TEAP) in the presence of tetrazole in dichloromethane. The resulting phosphorodiamidite intermediate (**2**) was further treated with 4 equiv of aniline in the presence of 4 equiv of tetrazole for transamidation to give the phosphorodianilidite derivative (**3**). Addition of 1.5 equiv of iodine in pyridine to the mixture resulted in the phosphorylated species (**4**).

Desilylation of **4** with KF-Et_4NBr-H_2O in acetonitrile gave a mixture of the 2′,5′-diol derivative (**6a**) and 3′,5′-diol derivative (**6b**). Fortunately, the latter was easily crystallized from the mixture by evaporation of MeOH from its 1,2-dichloroethane-MeOH solution. However, the former did not crystallize from any solvents tested and decomposed upon silica-gel column chromatography. Therefore, we examined the possibility of isomerization of **6a** to **6b** in a variety of solvents. As a result, it was found that **6a** was gradually isomerized to **6b** in pyridine-water (9 : 1, v/v) at 40 °C for 1 h to attain equilibrium giving rise to a ca. 1 : 1 mixture of **6a** and **6b**. It is interesting that the above isomerization did not occur in anhydrous pyridine. Such effects of water on isomerization have also been reported in the case of the 2′-3′ silyl migration by Ogilvie and his co-workers.[18] Thus, compounds **6b** was ultimately obtained in 55% yield by repeated isomerization of the **6a**-rich filtrate followed by crystallization.

Attempts to obtain monophosphorylated adenosine derivative **8a** or **8b** by reaction of 5′-*O*: 6-*N*-bis(4,4′-dimethoxytrityl)adenosine (**7**) with *N*,*N*′-diphenylphosphorodiamidic chloride[19] failed since chromatographic separation of these compounds caused considerable decomposition.

With the hope that the isomerization could be suppressed by modification of the anilino group with an electron-donating *p*-substituent or by replacement of the P=O by the P=S bond, the corresponding 2′-[*N*,*N*′-bis(*p*-methoxyphenyl)phosphorodiamidate] (**9**) and 2′-(*N*,*N*′-diphenylphosphorodiamidothioate) (**10**) were synthesized in 84 and 75% yields from **1** via

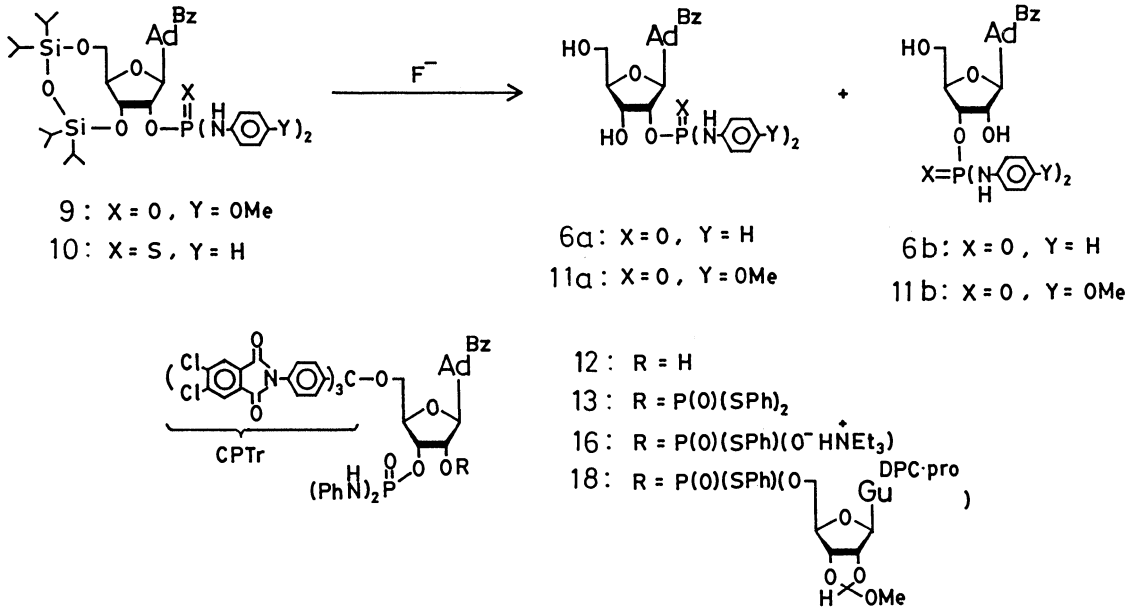
In this paper the following abbreviations are used: Tris(diethylamino)phosphine (TEAP); 4,4′,4″-tris(4,5-dichlorophthalimido)trityl (or tris[4(4,5-dichlorophthalimido)phenyl]methyl) (CPTr); 4,4′,4″-tris(4,5-dichlorophthalimido)trityl bromide (or tris[4-(4,5-dichlorophthalimido)phenyl]methyl bromide) (CPTrBr); bis(anilino)phosphinyl (PNN); cyclohexylammonium *S*,*S*-diphenyl phosphorodithioate (PSS); *N*,*N*′-dicyclohexylcarbodiimide (DCC); mesitylenedisulfonyl dichloride (MDS); isodurenedisulfonyl dichloride (or 1,2,3,5-tetramethylbenzenedisulfonyl dichloride) (DDS); 3-nitro-1*H*-1,2,4-triazole (NT); pyridinium *m*-nitrobenzenesulfonate (PNBS); 4-methoxytrityl (MMTr); 4,4′-dimethoxytrityl (DMTr); 2-cyanoethyl (CE); *N*,*N*-diphenylcarbamoyl (DPC); propionyl (pro); benzoyl (Bz); triethylammonium hydrogencarbonate (or triethylammonium bicarbonate) (TEAB); 2,2-dimethyl-2-silapentane-5-sulfonic acid sodium salt (DSS); snake venom phosphodiesterase (VSP); calf spleen phosphodiesterase (CSP).



similar iodine oxidation and sulfurization, respectively. However, desilylation of **9** resulted in a similar isomerization to give **11a** and **11b** in 18% and 42% yields, respectively. Unexpectedly, desilylation of **10** caused considerable decomposition.

We tried to synthesize a branched triribonucleotide A^{pG}_{pC} by the use of the predominant product **6b** above-mentioned. The 5′-hydroxyl group of **6b** was protected with tris[4-(4,5-dichlorophthalimido)-phenyl]methyl (CPTr) which has recently been proposed as a hydrazine-labile protecting group of primary alcohols.[20] Reaction of **6b** with 2 equiv of tris[4-(4,5-dichlorophthalimido)phenyl]methyl bromide (CPTrBr) in the presence of 2 equiv of silver nitrate in *N*,*N*-dimethylformamide (DMF) gave the 5′-tritylated product (**12**) in 57% yield. Isomerization or decomposition of the 3′-bis(anilino)phosphinyl (PNN) group did not occur during the tritylation.

Phosphorylation of the 2′-hydroxyl group of **12** should be done in a manner where each protecting group of the 2′- and 3′-phosphate groups can be removed without damage of the other protecting group under different conditions in order to elongate the RNA chain in the 2′- or 3′-direction. If possible no chiral center should be introducted on the second phosphorus atom as well as the first as seen in the PNN group to avoid complexity on TLC or for analysis of further reactions. Therefore, we chose the phe-



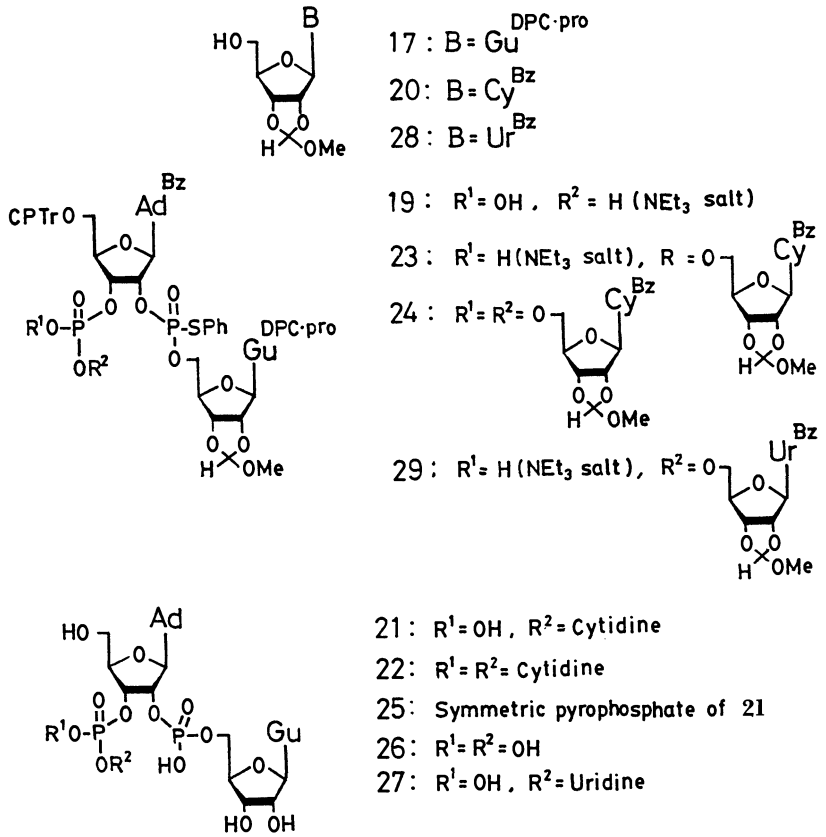
nylthio group for protection of both hydroxyl groups of the second phosphate function, since bis(phenylthio)phosphinyl group was known to be introduced rapidly into hydroxyl groups by reaction with cyclohexylammonium *S,S*-diphenyl phosphorodithioate (PSS)[21] in the presence of tetrazole[20] by use of a bifunctional condensing reagent, mesitylenedisulfonyl dichloride (MDS).[22] Application of this procedure gave a fully protected adenosine 2′,3′-diphosphate derivative (**13**) in 81% yield.

The ^{31}P NMR spectrum of **13** showed indeed two sharp resonance signals at 1.94 and 54.74 ppm. The latter signal was characteristic of *O*-alkyl *S,S*-diphenyl phosphorodithioates. For example, the resonance peak of *S,S*-diphenyl 5′-*O*-(4,4′-dimethoxytrityl)-thymidine 3′-phosphorodithioate[22] appeared at 49.63 ppm in $CDCl_3$. Thus, the homogenity of **13** could be readily ascertained by this spectroscopic analysis.

Next, we attempted to synthesize an appropriately protected adenosine 2′-phosphorothioate derivative (**14**), which seemed to be a fascinating intermediate for chain elongation in the 3′-direction since the same phosphate protecting group could be used commonly for both 2′- and 3′-side chains, from **13** by a two-step reaction. Treatment of **13** with isopentyl nitrite[23] in the presence of acetic anhydride[24] in pyridine–acetic acid for 15 h gave the 2′-unprotected adenylate derivative (**15**) in 50% yield. Under these conditions the phenylthio group was found to be stable as evidenced by ^{31}P NMR of the reaction mixture which showed a characteristic resonance peak at 51.11 ppm due to the 3′-bis(phenylthio)phosphinyl group.

However, conversion of **15** to **14** by treatment with 20 equiv each of tributylphosphine and diphenyl disulfide in acetonitrile[25] resulted in formation of an unexpected product without P–S bond formation.[26] Attempts to introduce the 2-chlorophenyl group into the 3′-phosphate of **15** have also failed. Dicyclohexylcarbodiimide (DCC) promoted reaction gave predominantly a symmetric pyrophosphate derivative of **15**.

Therefore, our attention has been turned to the selective removal of one of the two phenylthio groups from the 2′-PSS group of **13** to change our original project of the first internucleotidic bond formation from the 3′-5′ to 2′-5′ direction. Treatment of **13** with phosphinic acid in pyridine gave the 2′-phosphorothioate derivative (**16**) in 93% yield. Under these conditions the other protecting groups were found to be stable. The ^{31}P NMR spectrum of **16** showed a set of two sharp resonance signals at 15.65 and −0.19 ppm. The former peak was assigned to the 2′-phosphorus of a diester-type of phosphoromonothioate from its chemical shift. Condensation of the resulting 2′-phosphorothioate **16** with 2′,3′-*O*-methoxymethylene-2-*N*-propionyl-6-*O*-diphenylcarbamoylguanosine (**17**) in the presence of 1,2,3,5-tetramethylbenzenedisulfonyl dichloride (DDS)[22] and 3-nitro-1,2,4-triazole (NT)[27] in pyridine for 80 min gave the 2′-5′ linked triester (**18**) in 90% yield. This



dimer should have four diastereomers due to the chirality of the trisubstituted 2′-5′ linked phosphorus and the methoxymethylene group. However, the ^{31}P NNR spectrum of **18** showed two peaks at 26.76 and 26.59 ppm and a broad signal peak at 2.23 ppm, suggesting that the methoxymethylene group did not affect the chemical shift significantly since it was remote from the diasteromeric phosphorus atom.

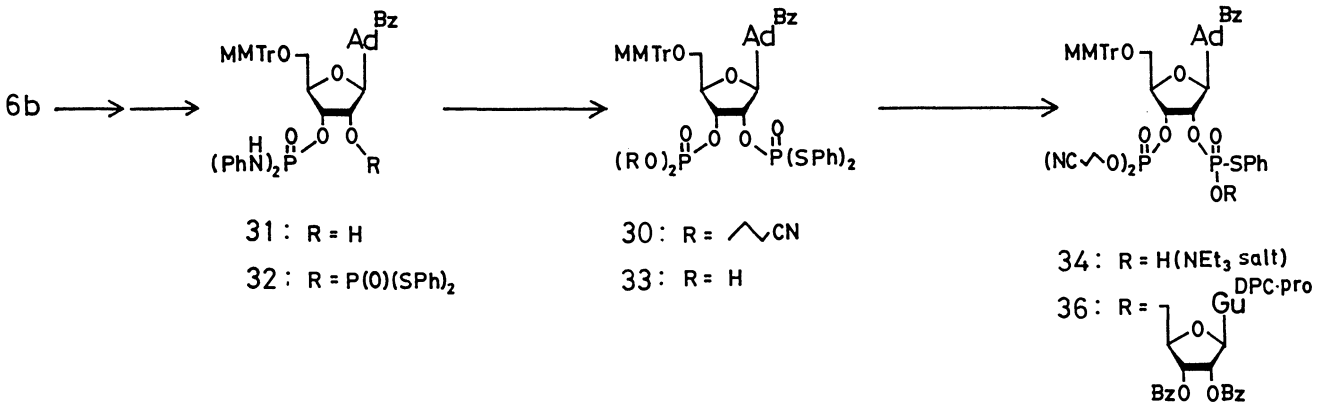
The anilino group was removed from **18** by the isopentyl nitrite treatment as described before to afford the 3′-unesterified phosphate (**19**) in 75% yield. An attempt to introduce the phenylthio group into the phosphate group by means of Bu_3P-PhSSPh has also failed as in the case of **15**. Therefore, direct condensation of **19** with 2′,3′-*O*-methoxymethylene-N^4-benzoylcytidine (**20**) in the phosphodiester method using DDS as the condensing reagent was performed. However, large excess amounts of **20** (8 equiv) and DDS (7 equiv) were required until **19** had disappeared (see Experimental). This reaction ultimately gave a mixture of the desired branched triribonucleotide (**21**) and a doubly esterified tetraribonucleoside diphosphate derivative (**22**) after deprotection.

Since DCC is known as the condensing agent that gives only phosphodiester products without formation of phosphotriesters,[28] the compound **22** should not be obtained when the condensing agent was changed from DDS to DCC. To ascertain this expectation, the condensation was performed in the presence of DCC. Consequently, the reaction became simpler and only two principal products were observed along with recovery of A_p^{pG}. It was indeed confirmed that compound **22** was not formed in the reaction. Since compound **19** was the triethylammonium salt which was difficult for activation with DCC, pyridinium 3-nitrobenzenesulfonate (PNBS)[29] was added as an acid catalyst. Without this salt the reaction was extremely slow to given **21** in only 2% yield after one day. With the improved condensation, the isolated yield of **21** was increased up to 29%. A significant amount of symmetrical pyrophosphate derivative (**25**) was formed as the by product. DCC-mediated condensation usually produced such relatively unreactive species.[28] In this case, it was difficult to activate the pyrophosphate intermediate **25** for condensation with **20**. Prolonged reaction for 4 days did not improve the yield of **21** although A_p^{pG} disappeared.

The structural assignment of **21** was also supported by characterization of the deprotected material of the synthetic intermediate **18**. Incubation of the product with bacterial alkaline phosphatase gave a dephosphorylated material which was digested to A and pG with snake venom phosphodiesterase and resistant to nuclease P_1. Incubation of this material with other enzymes such as Ribonucleases T1, T2, and A, and spleen phosphodiesterase did not result in any change. These properties were in agreement with those of 2′-5′ linked ApG having an internal 3′-phosphate.

In a manner similar to that described in the synthesis of **21**, A_{pU}^{pG} (**27**) was also synthesized via compound **29** which was obtained in 21% yield by DCC-mediated condensation of **19** with 2′,3′-*O*-methoxymethylene-N^3-benzoyluridine (**28**), and characterized by the enzymatic assay. Finally, the structure of A_{pC}^{pG} and A_{pU}^{pG} was confirmed by 500 MHz ^{1}H NMR. As the reference materials, linear triribonucleotide diphosphates, GpApC and GpApU were synthesized according to our method reported previously.[20]

Synthesis of Branched Ribonucleotides via a New Fully Protected Synthetic Unit (30). As described above, the condensation of **23** with **20** or **28** in the phosphodiester approach gave charged products which were bothersome for isolation and further chain elongation. Therefore, we designed a more general approach to branched oligoribonucleotides. Since the CPTr group was rather stable under the conditions of removal of the anilino group which involved pyridine buffered by acetic acid, it was employed for the synthesis of the simplest branched triribonucleotide blocks in the previous method. However, this protecting group required restricted conditions for chain elongation, especially in the 5′-direction, where the pivaloyloxymethyl, 4-methoxytrityl (MMTr), and 4,4′-dimethoxytrityl (DMTr) groups should be used for protection of the



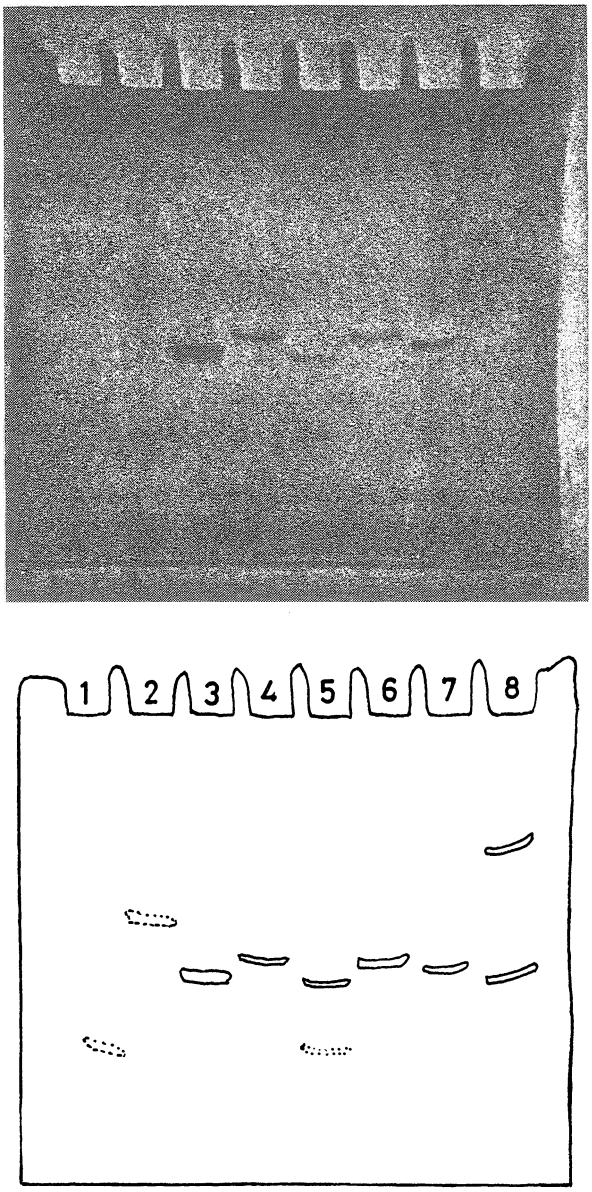


Fig. 1. 20% Polyacrylamide gel electrophoresis of branched and oligoribonucleotides and related compounds. 1: A_p^{pG} **26**; 2: $^{pG}_{(pC)_2}$ **22**; 3: A_{pC}^{pG}; 4: GpApC; 5: a ca. 4:1 mixture of A_{pU}^{pG} and A_p^{pG}; 6: GpApU; 7: $CpUpGpA_{pC}^{pG}$ 8: Bromphenol Blue and Xylene Cyanole FF as markers.

base residues of uridine, adenosine, and cytidine, respectively.[20] Since the DMTr group was somewhat too unstable during the isopentyl nitrite treatment, the MMTr group[30] was chosen as the 5′-hydroxyl protecting group. It was desirable to find more suitable protecting groups for the 3′-phosphate group since removal of the anilino group required a long time and tedious extractive workup. It was again considered that if possible no chiral centers should be produced when a new phosphate protecting group was designed.

On the basis of the above discussion, the anilino group should be changed to the 2-cyanoethyl (CE) group at the stage of the monomer building unit. The new synthetic unit at the branched point was a fully protected adenosine 2′,3′-diphosphate derivative (**30**). Reaction of **6b** with 4-methoxytrityl chloride followed by the successive phosphorylation of the resulting tritylated product (**31**) gave the fully protected adenosine derivative (**32**). Treatment of **32** with isopentyl nitrite in a manner similar to that described in the conversion of **13** to **15** gave the 3′-unesterified derivative (**33**) in 55% yield. Biscyanoethylation of **33** with excess 2-cyanoethanol in the presence of DDS in pyridine gave a fully protected adenosine 2′,3′-diphosphate derivative **30** in 67% yield. The ^{31}P NMR spectrum of **30** exhibited two sharp resonance signals at −3.10 and 51.98 ppm which were due to the 3′- and 2′-phosphoryl groups, respectively. The intermediates **32** and **33** also gave similar ^{31}P NMR spectra as summarized in Table 1.

The protection of each phosphoryl group with the same two protecting groups proved to be indeed useful for the structural assignment of synthetic interme-

diates during the construction of the branched triribonucleotide block. Upon treatment of **30** with the phosphinate reagent gave quantitatively phosphodiester derivative (**34**). The high selectivity of this conversion was confirmed by ^{31}P NMR. Condensation of **34** with 2′,3′-di-*O*-benzoyl-6-*O*-diphenylcarbamoyl-2-*N*-propionylguanosine (**35**) gave the 2′-5′ linked dinucleotide derivative (**36**) in 87% yield. The decyanoethylation of **36** with *N*,*N*-diisopropylethylamine in pyridine at 40 °C for 4 h afforded the 3′-phosphodiester intermediate (**37**) which was purified by preparative TLC and obtained as triethylammonium salt in 82% yield. A similar condensation of **37** with 2′,3′-*O*: N^6-tribenzoylcytidine (**38**) gave the fully protected triribonucleotide unit (**39**) in 63% yield. This unit exhibited the ^{31}P NMR spectrum in which two kinds of resonance signals appeared at ca. −2.3 and 25.5 ppm. The former consisted of three peaks at −2.47, −2.29, and −2.22 ppm in a 2:1:1 ratio. The highest peak seemed to be imposed with

two different peaks. The latter involved two sets of doublets as shown in Table 1.

Since compound **39** was neutral species unlike **23**, it was possible to extend the chain in the 5′-direction after removal of the MMTr group. Acid treatment of **39** with 1% trifluoroacetic acid gave the 5′-hydroxyl compound (**40**), which was further condensed with a triribonucleotide block (**41**) to give the fully protected hexaribonucleotide derivative (**42**) in 56% yield. The trimer **41** was synthesized according to our standard method.[31,32]

Deprotection of **42** was achieved by the following procedure: 1) 0.5 M (M=mol dm^{-3}) bis(tributyltin) oxide in pyridine r.t. 28 h.[33] 2) trimethylsilyl chloride in pyridine, r.t., 15 min. 3) concd aqueous ammonia-pyridine, r.t., 19 h. 4) 0.02 M HCl-dioxane, r.t., 48 h. 5) paper chromatography, *i*-PrOH-concd ammonia-water. Thus, the unprotected hexamer CUGA_{pC}^{pG} (**43**) was isolated in 32% yield. The HPLC profile of the mixture obtained after deprotection is shown in Fig. 2A. The peak at 10.8 min was collected and characterized by enzyme analysis as the desired branched hexaribonucleotide. As shown in Fig. 2C, digestion of this material with nuclease P1 gave four products which were identified with pU,pG, C, and pA_{pC}^{pG}. The latter was further dephosphorylated with alkaline phosphatase to give A_{pC}^{pG} which was also identified with authentic material of **21**.

The branched trimers A_{pC}^{pG} and A_{pC}^{pG} were not phosphorylated with kinase as reported by Caruthers.[5] On the other hand, the branched hexamer could be expectedly labelled with this enzyme in the presence of [γ-^{32}p]ATP to give ^{32}pCpUpGpA_{pC}^{pG} (data not shown).[34]

Finally, the synthetic branched trimers and hexamer were tested for inhibition experiments of splicing reaction using the extract from Hela cell. However, our preliminary results revealed that significant inhibitory effects were not observed under the standard conditions.[34] This is probably because the lariat structure was the ultimate deletion product and did not interact with splicing intermediates.

Conclusion

There have been reported several strategies for construction of branched ribonucleotide fragments. They are mainly classified in two types. One is the use of monomer building blocks having 2′,3′-protected phosphoryl or phosphoramidite groups represented by this research and Ogilvie's original approach.[4] The other involves condensation of 2′- or 3′-phosphorylated species with ribonucleoside 5′-

phosphoramidite units. In the former case, it is possible to add stepwise the oligonucleotide chain in any direction, as shown by the present study. However, multistep reactions for synthesis of such building units are required. Indeed, our approach involves a series of seven reactions to obtain the unit **30** from 6-*N*-benzoyladenosine. Although some improvements should be done to shorten the number of the step, the unit **30** is easy to handle and can be stored for long periods of time without decomposition since this material is a neutral species.

As one of the representative approaches for the latter classification, Kierzek and Caruthers[5] reported the regioselective condensation of 2′-side chains with 3′-5′ linked dimer derivatives in which the internal phosphate and 2′-hydroxyl groups were unprotected. In this case, the number of reactions was less than that of ours but synthetic intermediates and final products were charged molecules. Chattopadhyaya[8] has used a combination of the *p*-toluoyl and 9-phenylxanthene-9-yl groups as the 5′- and 2′-protecting groups, respectively, for his synthesis of branched trimers using a similar amidite approach. Chattopadhyaya[9] also applied the 5′-selective cleavage of Markiewicz's protecting group[35] with dilute HCl to the synthesis of branched tetramers. This method still involved a series of charged intermediates. More recently, his research group reported an improved synthesis of neutral protected branched trimer blocks from a 2′-phosphorylated 6-*N*-benzoyladenosine derivative.[15] The latter intermediate, however, was prepared via 7 step-reactions from 6-*N*-benzoyladenosine. The 3′-5′ phosphate bond formation required large excess amounts (ca. 3.5—9 equiv) of 3′-components bearing the phosphoramidite group. The other approaches reported up to date have encountered similar drawbacks. In our own approach, new methods for regioselective phosphorylation in a more straightfoward manner should be explored. We are now studying improved procedures in this direction.

Experimental

Melting points were determined on a Mitamura MELTPOINTER apparatus and are uncorrected. ^{1}H NMR spectra were recorded at 60 MHz on a Hitachi 24B spectrometer, at 100 MHz on a JEOL UNM PS-100 spectrometer, and at 270 MHz on a JEOL GX270 with Me_4Si as the internal standard and at 500 MHz on a JEOL GX500 with DDS as the internal reference. UV spectra were obtained on a Hitachi 220A spectrophotometer. Paper chromatography was performed by use of a descending technique with Whatman 3MM papers and Toyo Roshi 51A papers using the following solvent systems: Solvent I (2-propanol–concd aq ammonia–water. 7 : 1 : 2, v/v/v); Solvent II (2-propanol–concd aq ammonia–water, 6 : 1 : 3, v/v/v); Solvent III (1-propanol–concd aq ammonia–water, 55 : 10 : 35, v/v/v). Column chromatography was performed with silica gel C-200 purchased from Wako Co., Ltd., and a minipump for a goldfish bowl was conveniently used to attain sufficient pressure for rapid chromatographic separation. TLC was performed on precoated TLC plates of silica gel 60 F-254 (Merck). Reversed-phase HPLC was performed on a Waters Model A25 using a μ Bondapack C-18 column with a linear gradient starting from 0.1 M NH_4OAc, pH 7.0 and applying CH_3CN at a flow rate of 1.5 ml min^{-1} for 30 min (System A). Ribonucleosides were purchased from Yamasa Co., Ltd. Pyridine was distilled two times from *p*-toluenesulfonyl chloride and from calcium hydride and then stored over molecular sieves 3A. The linear trimers of GpApC and GpApU were prepared by condensation of $C^{P}TrG^{DPC\cdot pro}(thp)p(SPh)A^{MMTr}(thp)(O^{-}HN^{+}Et_3)$ with $C^{bz}(bz)_2$ or $U^{bz}(bz)_2$, respectively, followed by the usual deprotection procedure. The detail of these trimers will be reported elsewhere. The yields of branched oligoribonucleotides were estimated by using following ε values at λ_{max}: A_p^{pG} 29.9×10^3 at 257 nm, A_{pC}^{pG} 27.5×10^3 at 258 nm, A_{pU}^{pG} 33.5×10^3 at 256.5 nm, CpUpGpA_{pC}^{pG} 48.3×10^3 at 257 nm. Elemental analyses were performed by the Microanalytical Laboratory, Tokyo Institute of Technology, at Nagatsuta.

5′-*O*: 6-*N*-Bis(4,4′-dimethoxytrityl)adenosine (7). Adenosine (5.34 g, 20 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine (50 mL×3) and finally dissolved in dry pyridine (180 mL). 4,4′-Dimethoxytrityl chloride (15.25 g, 45 mmol) was added to the pyridine solution. After being stirred for 5 h, the mixture was partitioned between CH_2Cl_2 and water. The organic phase was collected and the aqueous layer was extracted two times with CH_2Cl_2. The CH_2Cl_2 extracts were combined, dried over Na_2SO_4, filtered, and evaporated under reduced pressure. The residue was chromatographed on a column of silica gel (300 g) with CH_2Cl_2–MeOH to give the foammy material of **7**, which was reprecipitated from its CH_2Cl_2 solution into hexane to give **7** as the powder (14.5 g, 83%).

7: ^{1}H NMR ($CDCl_3$–D_2O) δ=3.31 (2H, m, 5′-H), 3.74 (6H, s, OCH_3), 3.74 (1H, m, 4-H), 4.33 (1H, m, 3′-H), 4.57 (1H, m, 2′-H), 5.83 (1H, d, J=5.83 Hz, 1′-H), 6.70 (8H, d, J=9 Hz, ArH), 7.16 (18H, m, ArH), 7.95 (1H, s, 2-H), 7.89 (1H, s, 8-H). Anal. Calcd for $C_{52}H_{49}N_5O_8$: C, 71.63, H, 5.66; N, 8.03%. Found: C, 71.40; H, 5.94; N, 7.77%.

3′,5′-*O*-(1,1,3,3-Tetraisopropyldisiloxane-1,3-diyl)-6-*N*-benzoyladenosine 2′-Phosphorodianilidate (4). A mixture of compound **1** (614 mg, 1 mmol) and tetrazole (105 mg, 1.5 mmol) was coevaporated three times with dry toluene (10 mL) and dissolved in dry 1,2-dichloroethane (10 mL). TEAP (411 μL, 1.5 mmol) was added with vigorous stirring to the solution. After the mixture was stirred for 10 min, aniline (365 μL, 4 mmol) and tetrazole (280 mg, 4 mmol) were successively added and stirring was continued for 10 min. Then a solution of iodine (381 mg, 1.5 mmol) in dry pyridine (2 mL) was added to the mixture. After being stirred for 10 min, the mixture was diluted with CH_2Cl_2 and 5% aqueous Na_2SO_3 was added to remove the excess iodine. The organic phase was collected, dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was chromatographed on a column of silica gel (30 g) with CH_2Cl_2–MeOH to give **4** (703 mg, 83%). **4:** ^{1}H NMR ($CDCl_3$) δ=1.03 (24H, m, $(CH_3)_2CH$), 4.10 (3H, m, 4′- and 5′-H), 5.19 (1H, m, 3′-H), 5.63 (1H, dd, $J_{2'\text{-}3'}$=5.3 Hz, $J_{P\text{-}H}$=9.3 Hz, 2′-H), 6.43 (1H, s, 1′-H), 6.80—7.27 (10H, m, ArH), 7.53 (2H, m, ArH), 8.18 (3H, m, ArH), 8.18 (1H, s, 2-H), 8.62 (1H,

s, 8-H), 8.75 (1H, s, NH).

6-*N*-Benzoyladenosine 2′-Phosphorodianilidate (6a) and Its 3′-Regioisomer (6b). Small Scale Synthesis: To a solution of **8** (591 mg, 0.7 mmol) in acetonitrile (8.4 mL) were added KF (236 mg, 4.2 mmol), Et_4NBr (883 mg, 4.2 mmol), and water (0.076 mL, 4.2 mmol). The mixture was stirred at 45 °C for 20 min and diluted with CH_2Cl_2–pyridine (2 : 1, v/v, 30 mL). The resulting solution was washed six times with water (30 mL) to remove quarternary ammonium salts. Each aqueous washing was reextracted with another CH_2Cl_2–pyridine (2 : 1, v/v, 30 mL) solution which was used commonly for six times extraction in another separatory funnel. The two extracts were combined, dried over Na_2SO_4, filtered, concentrated under reduced pressure, and coevaporated four times with toluene. The residue was dissolved in CH_2Cl_2 (15 mL). Upon standing of this solution for a few minutes a powder-like precipitate appeared. Collection of this material by filtration took ca. 1 h to give **6b** (182 mg, 43%). Concentration of the filtrate followed by preparative thin-layer chromatography with CH_2Cl_2–MeOH (8 : 1, v/v) gave **6a** (156 mg, 37%) and **6b** (56 mg, 13%).

6a: ^{1}H NMR ($CDCl_3$–CD_3OD, 5 : 1, v/v) δ=3.72 (2H, m, 5′-H), 4.21 (1H, m, 4′-H), 4.57 (1H, m, 3′-H), 5.43 (1H, m, 2′-H), 6.10 (1H, d, J=7 Hz, 1′-H), 6.37—7.20 (10H, m, ArH), 7.40 (3H, m, ArH), 7.91 (2H, m, ArH), 8.05 (1H, s, 2-H), 8.38 (1H, s, 8-H). Anal. Calcd for $C_{29}H_{28}N_7O_6P \cdot 0.5H_2O$: C, 57.05, H, 4.79; N, 16.06%. Found: C, 56.98; H, 4.76; N, 15.95%.

6b: ^{1}H NMR ($CDCl_3$–CD_3OD, 2 : 1, v/v) δ=3.72 (2H, m, 5′-H), 5.00 (2H, m, 2′- and 3′-H), 6.03 (1H, d, J=6.4 Hz, 1′-H), 6.60—7.30 (10H, m, ArH), 6.43 (3H, m, ArH), 7.91 (2H, m, ArH), 8.32 (1H, s, 2-H), 8.53 (1H, s, 8-H). Anal. Calcd for $C_{29}H_{28}N_7O_6P \cdot 0.5H_2O$: C, 57.05, H, 4.79; N, 16.06%. Found: C, 57.04; H, 4.65; N, 15.98%.

Large Scale Synthesis of 6b: The same procedure described in the small scale synthesis of **6a** and **6b** before crystallization of **6b** was done except that the scale was increased to 16 mmol. The residue containing **6a** and **6b** was dissolved in MeOH (40 mL) and 1,2-dichloroethane (360 mL). Concentration of the solution under reduced pressure to ca 200 mL followed by standing at 0 °C for 15 min resulted in crystallization of **6b**. The crystals were collected by filtration and washed with minimum amounts of 1,2-dichloroethane to give 3.67 g (38.3%) of **6b**. The filtrate, which contained a ca. 5 : 1 mixture of **6a** and **6b**, was concentrated under reduced pressure and the residue was dissolved in pyridine (60 mL) and water (6 mL). The solution was kept at 60 °C for 2 h, at which time the ratio of **6a** to **6b** was changed to ca. 1 : 1. The mixture was then evaporated and coevaporated several times with toluene. The residue was tritulated with petroleum ether (3×20 mL) to remove the remaining silyl derivative derived from the 1,1,3,3-tetraisopropyldisiloxane-1,3-diyl group, dissolved in a mixture of 1,2-dichloroethane (150 mL)–MeOH (30 mL), and the solution was passed through a column of silica gel (100 g). The column was further eluted with a mixture of 1,2-dichloroethane–MeOH (300 mL–60 mL). The eluate was concentrated and the residue was dissolved in a mixture of 1,2-dichloroethane–MeOH (250 mL–25 mL). Concentration to half the volume followed by standing for 15 min and successive collection gave the second crop of **6b** (0.75 g, 7.8%). More two times repetition of the same procedure gave additional crops (0.44 g and 0.31 g) of **6b** from each filtrate. The total yield of **6b** was 5.17 g (55%). Each crop was confirmed to be homogeneous on TLC.

3′,5′-*O*-(1,1,3,3-Tetraisopropyldisiloxane-1,3-diyl)-6-*N*-benzoyladenosine 3′-[*N*,*N*′-Bis(*p*-methoxyphenyl)phosphorodiamidate] (9). Under conditions similar to those described in the case of **4**, 759 mg (84%) of **9** was obtained from 0.4 mmol of **1**.

9: ^{1}H NMR ($CDCl_3$) δ=1.04 (24H, m, $(CH_3)_2CH$), 3.67 (6H, s, CH_3O), 4.05 (3H, m, 4′- and 5′-H), 4.80—6.00 (2H, m, 2′- and 3′-H), 6.11 (1H, s, 1′-H), 6.59 (4H, d, J=8.5 Hz, ArH), 6.90 (4H, d, J=8.5 Hz, ArH), 7.42 (3H, m, ArH), 7.88 (2H, m, ArH), 8.00 (1H, s, 2-H), 8.49 (1H, s, 8-H). Anal. Calcd for $C_{43}H_{58}N_7O_9PSi_2$: C, 57.13; H, 6.47; N, 10.84%. Found: C, 56.93; H, 6.61; N, 10.94%.

3′,5′-*O*-(1,1,3,3-Tetraisopropyldisiloxane-1,3-diyl)-6-*N*-benzoyladenosine 3′-[*N*,*N*′-Diphenylphosphorodiamidothioate] (10). This compound was synthesized by using 0.4 mmol of **1** under the same conditions as described in the case of **4** except that at the final stage the sulfurization (10 min) was undertaken by addition of elemental sulfur (38 mg, 1.2 mmol) in dry pyridine (2.5 mL) to the mixture containing **3** in place of iodine oxidation. The yield was 256 mg (75%).

10: ^{1}H NMR ($CDCl_3$) δ=1.06 (24H, m, $(CH_3)_2CH$), 4.07 (3H, m, 4′- and 5′-H), 5.15 (1H, m, 3′-H), 5.70 (1H, dd, J=5 Hz, J=13 Hz, 2′-H), 6.08 (1H, m, 1′-H), 7.05 (10H, m, ArH), 7.37 (3H, m, ArH), 7.88 (2H, m, ArH), 7.92 (1H, s, 2-H), 8.58 (1H, m, 8-H). Anal. Calcd for $C_{41}H_{54}N_7O_6PSSi_2$: C, 57.25; H, 6.33; N, 11.40; S, 3.73%. Found: C, 57.05; H, 6.42; N, 11.39%.

6-*N*-Benzoyladenosine 2′-[*N*,*N*′-Bis(*p*-methoxyphenyl)-phosphorodiamidate (11a) and Its Regioisomer (11b). These compounds were obtained by the same procedure as described in the small scale synthesis of **6a** and **6b** starting from 0.79 mmol of **10** except that the reaction was carried out at 45 °C for 45 min. The yields of **11a** and **11b** were 86 mg (18%) and 295 mg (42%), respectively.

11a: ^{1}H NNR ($CDCl_3$) δ=3.54 (6H, s, CH_3O), 3.59 (2H, m, 5′-H), 4.26 (1H, m, 4′-H), 4.73 (1H, m, 3′-H), 5.59 (1H, m, 2′-H), 6.00—7.15 (9H, m, 1′-H and ArH), 7.57 (3H, m, ArH), 8.05 (2H, m, ArH), 8.24 (1H, s, 2-H), 8.57 (1H, s, 8-H). Anal. Calcd for $C_{31}H_{32}N_7O_8P \cdot 0.5H_2O$: C, 55.52; H, 4.96; N, 14.62%. Found: C, 55.10; H, 4.92; N, 14.66%.

11b: ^{1}H NMR ($CDCl_3$–CD_3OD, 2 : 1, v/v) δ=3.73 (2H, m, 5′-H), 4.38 (1H, m, 4′-H), 5.03 (2H, m, 2′- and 3′-H), 6.02 (1H, d, J=6.5 Hz, 1′-H), 6.67 (4H, d, J=8.5 Hz, ArH), 6.95 (4H, d, J=8.5 Hz, ArH), 7.44 (3H, m, ArH), 7.95 (2H, m, ArH), 8.30 (1H, s, 2-H), 8.57 (1H, s, 8-H). Anal. Calcd for $C_{31}H_{32}N_7O_8P \cdot 0.5H_2O$: C, 55.52; H, 4.96; N, 14.62%. Found: C, 55.88; H, 5.08; N, 14.36%.

5′-*O*-[Tris[4-(4,5-dichlorophthalimido)phenyl]methyl]-6-*N*-benzoyladenosine 3′-Phosphorodianilidate (12). Compound **6b** (60 mg, 0.1 mmol) was coevaporated two times each with dry toluene and DMF and finally dissolved in dry DMF (1 mL). To the solution were added silver nitrate (34 mg, 0.2 mmol) and tris[4-(4,5-dichlorophthalimido)-phenyl]methyl bromide (193 mg, 0.2 mmol). The mixture was stirred for 45 min and then quenched with 2,6-lutidine (23 μL, 0.2 mmol). The resulting mixture was diluted with dichloromethane, filtered, transferred to a separatory funnel, and washed six times with water. Each washing was reextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, dried over Na_2SO_4, and filtered. Removal of the solvent by evaporation followed by thin-layer chroma-

tography using two plates of Merck 5717 with CH_2Cl_2–MeOH gave **12** (86 mg, 57%).

12: ^1H NMR ($CDCl_3$) δ=3.35 (2H, m, 5′-H), 4.38 (1-H, m, 4′-H), 5.15 (2H, m, 2′,3′-H), 5.99 (1H, m, 1′-H), 6.50—8.00 (27H, m, ArH), 7.83 (6H, s, ArH), 8.01 (qH, s, 2-H), 8.47 (1H, s, 8-H). Anal. Calcd for $C_{72}H_{45}N_{10}O_{12}PCl_6 \cdot H_2O$: C, 57.50; H, 3.15; N, 9.31%. Found: C, 57.52; H, 3.03; N, 9.30%.

2′-*O*-Bis(phenylthio)phosphinyl-5′-*O*-[tris[4-(4,5-dichlorophthalimido)phenyl]methyl]-6-*N*-benzoyladenosine 3′-Phosphorodianilidate (13). To a pyridine solution (3 mL) of **12** (446 mg, 0.3 mmol), cyclohexylammonium *S*,*S*-dipheyl phosphorodithioate (171 mg, 0.45 mmol) and tetrazole (84 mg, 1.2 mmol) dried by repeated coevaporation with dry pyridine was added mesitylenedisulfonyl dichloride (MDS) (190 mg, 0.6 mmol). After being stirred for 15 min, the mixture was partitioned between CH_2Cl_2 and water. The organic layer was collected, washed with 5% $NaHCO_3$, dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was chromatographed on a column of silica gel (20 g) with CH_2Cl_2–MeOH to give **13** (423 mg, 81%).

13: ^1H NMR (270 MHz, $CDCl_3$) δ=3.48 (1H, dd, J=11 Hz, J=3.0 Hz, 5′-Ha), 3.65 (1H, d, J=11.0 Hz, 5′-b), 4.53 (1H, m, 4′-H), 5.38 (1H, m, 3′-H), 6.13 (1H, d, J=5.3 Hz, 1′-H), 6.18 (1H, m, 2′-H), 6.50—7.65 (37H, m, ArH), 7.93 (6H, s, ArH), 8.09 (1H, s, 2-H), 8.63 (1H, s, 8-H), 9.31 (1H, br, NH). Anal. Calcd for $C_{84}H_{54}N_{10}O_{13}P_2S_2Cl_6$: C, 57.65; H, 3.11; N, 8.00%. Found: C, 57.44; H. 3.16; N, 7.96%.

Triethylammonium 2′-*O*-Bis(phenylthio)phosphinyl-5′-*O*-[tris[4-(4,5-dichlorophthalimido)phenyl]methyl]-6-*N*-benzoyladenosine 3′-Phosphate (15). Compoud **13** (175 mg, 0.1 mmol) was dissolved in a mixture of pyridine–acetic acid–acetic anhydride (1 : 1 : 1, v/v/v, 3 mL) and isopentyl nitrite (100 μL) was added. After the mixture being stirred for 11 h, the mixture was diluted with CH_2Cl_2 and water was added. The CH_2Cl_2 layer was collected, washed successively with water and 0.2 M TEAB, and each aqueous layer was backextracted with another CH_2Cl_2. The combined organic phase was dried over Na_2SO_4, filtrated, concentrated under reduced pressure and coevaporated with toluene. The residue was subjected to a preparative TLC developed with CH_2Cl_2–MeOH (9 : 1, v/v) to give **15** (85 mg, 50%).

15: ^1H NMR ($CDCl_3$) δ=1.30 (9H, t, J=7 Hz, $C\underline{H}_3CH_2N$), 3.00 (6H, q, J=7 Hz, $CH_3C\underline{H}_2N$), 3.68 (2H, m, 5′-H), 4.62 (1H, m, 4′-H), 5.58 (1H, m, 3′-H), 6.28 (1H, m, 1′-H), 6.43 (1H, m, 2′-H). 6.90—8.10 (27H, m, ArH), 7.93 (6H, s, ArH), 8.24 (1H, s, 2-H), 8.69 (1H, s, 8-H).

Triethylammonium *S*-Phenyl 3′-*O*-Dianilinophosphinyl-5′-*O*-[tris[4-(4,5-dichlorophthalimido)phenyl]-methyl]-6-*N*-benzoyladenosine 2′-Phosphorothioate (16). Compound **13** (1.75 g, 1 mmol) was treated with a solution of 3 M pyridinium phosphinate (65 mmol) in dry pyridine (21.7 mL) at room temperature for 1 h. The resulting mixture was diluted with CH_2Cl_2, which was washed subsequently with water, 0.2 M TEAB (×2), and water. Each washing was backextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, dried over Na_2SO_4, filtered, and concentrated under reduced pressure. Coevaporation of the residue with toluene followed by precipitation from its CH_2Cl_2 solution into hexane gave **16** as white powder (1.744 g, 99%). This material was used without further purification for the next condensation with **17**.

Synthesis of the Fully Protected 2′–5′ Linked ApG Dimer (18). A mixture of **16** (1.58 g, 0.9 mmol), **17** (778 mg, 1.35 mmol), and 3-nitro-1*H*-1,2,4-triazole (308 mg, 2.7 mmol) was rendered anhydrous by three times coevaporation with dry pyridine and finally dissolved in dry pyridine (10 ml). To the mixture was added DDS (894 mg, 2.7 mmol). After being stirred for 2 h, the extractive workup followed by column chromatography gave **18** (1.83 g, 92%).

Removal of the Anilino Group from 18 by Isopentyl Nitrite Treatment. Compound **18** (130 mg, 58.6 μmol) was treated with isopentyl nitrite (58.6 μL) in pyridine–acetic acid–acetic anhydride (1 : 1 : 1, v/v/v, 586 μL) for 16 h. Then the mixture was diluted with CH_2Cl_2, which was washed subsequently with water (×4), 0.2 M TEAB (×2), and water. Each washing was backextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, dried over Na_2SO_4, filtered, and concentrated under reduced pressure. The residue was coevaporated with toluene and chromatographed on two preparative TLC plates developed with CH_2Cl_2–MeOH (6 : 1, v/v). Elution was performed with CH_2Cl_2–MeOH (4 : 1, v/v). The eluate was evaporated and the residue was partitioned between CH_2Cl_2 and 0.2 M TEAB. The CH_2Cl_2 extract was collected, dried over Na_2SO_4, and concentrated to give **19** free of silica gel as triethylammonium salt (95.3 mg, 75%).

Synthesis of the Partially Protected Branched Triribonucleotide (23). Method A: A mixture of **19** (152 mg, 70 μmol) and **20** (54.5 mg, 0.14 mmol) was rendered anhydrous by repeated coevapoartion with dry pyridine and finally dissolved in dry pyridine (1 mL), and DDS (70 mg, 0.21 mmol) was added. After 9 h, TLC showed that a product which appeared higher than **19** was formed in a considerable amount and ca. 40% of **19** remained unchanged. This faster moving material seemed to be a tetrasubstituted pyrophosphate intermediate. To make the condensation complete, **20** (54.5 mg, 0.14 mmol) and DDS (46 mg, 0.14 mmol) were added. After being stirred for an additional 2 h, DDS (46 mg, 0.14 mmol) was added to convert excess **20** to the corresponding 5′-sulfonated derivative which was hydrolyzed to a more polar sulfonic acid derivative upon addition of water. After the mixture was kept for 3 h, water (0.2 mL) was added, and the resulting mixture was stirred for 15 min and then extracted in the usual manner as described in the synthesis of **16**. Preparative TLC developed with CH_2Cl_2–MeOH (9 : 1, v/v) gave a mixture of **23** and **24** (143 mg).

Method B: A mixture of **19** (28 mg, 13 μmol), **20** (20.1 mg, 52 μmol), and pyridinium 3-nitrobenzenesulfonate (11 mg, 39 μmol) was rendered anhydrous by repeated coevapoartion with dry pyridine and finally dissolved in dry pyridine (0.2 mL). DCC (20 mg, 97 μmol) was added to the mixture. After being stirred for 36 h, the mixture was diluted with CH_2Cl_2 which was washed with 0.2 M TEAB. The organic phase was dried over Na_2SO_4, filtered, concentrated, and chromatographed on a preparative TLC with CH_2Cl_2–MeOH (7 : 1, v/v) to give the crude material of **23** (49.3 mg).

Deprotection of 23 Giving Rise to Branched Triribonucleotide (21). Part (88 mg) of the mixture of **23** and **24** obtained in Method A described in the above experiment was dissolved in pyridine (5 mL) and 0.2 M NaOH (5 mL) was added at 0 °C to the solution. The solution was stirred at 0 °C for 15 min and then neutralized with Dowex 50W X2 (pyridinium form, 5 mL). The supernatant and washing

with pyridine–water (1 : 1, 40 mL) were combined, concentrated, and the residue was dissolved in pyridine (5 mL)–concd ammonia (45 mL). After being stirred at 50 °C for 6 h, the mixture was concentrated and treated with 80% acetic acid (50 mL) for 6h. The solvent was then evaporated and the residue was chromatographed on Whatman 3MM papers developed with Solvent II to give **21** (237 A_{258}, 20%) and **22** (193 $A_{256.5}$, 14%).

21: λ_{max} 258 nm, λ_{min} 227 nm; R_f 0.61 (relative to pU) (Solvent II, R_f 0.74 (relative to pU) (Solvent III); R_m 0.47 (relative to pU) (0.03 M phosphate buffer, pH 7.1); Retension time 11.8 min (HPLC system A); ^{1}H NMR (500 MHz, D_2O/DSS) δ=3.70 (1H, dm, J=11.7 Hz), 3.79 (1H, dd, J=12.8 Hz, J=2.2 Hz, 5′-Ha of A), 3.86 (1H, d, J=12.8 Hz, J=1.3 Hz, 5′-Hb of A), 3.95 (1H, tm, J=11.7 Hz), 4.04 (1H, br. s), 4.20 (1H, m), 4.28 (2H, q, J=5.2 Hz), 4.33 (2H, m), 4.47 (1H, t, J=8.2 Hz), 4.51 (1H, d, J=2.6 Hz), 5.32 (1H, quintet, J=9.6 Hz, J=4.8 Hz, 3′-H of A), 5.64 (1H, d, J=4.9 Hz, 1′-H of G), 5.91 (1H, d, J=4.0 Hz, 1′-H of C), 5.95 (1H, d, J=7.3 Hz, 5-H of C), 6.17 (1H, d, J=5.5 Hz, 1′-H of A), 7.73 (1H, s, 8-H of G), 7.84 (1H, d, J=7.3 Hz, 6-H of C), 7.87 (1H, s, 2-H of A), 8.22 (1H, s, 8-H of A). **22:** λ_{max} 256.5 nm, λ_{min} 225 nm R_f 0.34 (relative to pU) (Solvent II), R_f 0.37 (relative to pU) (Solvent III); R_m 0.12 (relative to pU) (0.03 M phosphate buffer, pH 7.1).

In a similar manner, the partially protected branched trimer **23** (49.3 mg, 13 μmol) obtained in Method B was deprotected except that the ammonia and acid treatments were performed at room temperature for 26 h and for 11 h, respectively. The yield of **21** was 109 A_{258} (29%).

Synthesis of Branched Triribonucleotide A^{pG}_{pU} (27). A mixture of **19** (43.3 mg, 20 μmol), **28** (15.6 mg, 40 μmol), and pyridinium *m*-nitrobenzenesulfonate (16.9 mg, 60 μmol) was coevaporated three times with dry pyridine and then dissolved in dry pyridine (0.5 mL). DCC (29 mg, 0.14 mmol) was added and the solution was stirred for 4 d. The resulting mixture was diluted with pyridine (3 mL) and cooled to 0 °C. To the solution was added 0.2 M NaOH (3 mL), and the mixture was kept at 0 °C for 10 min. Then, cation-exchange DIAION resin (sulfonic acid form, 3 mL) was put to neutralize the solution, and the resin was removed by filtration and washed with pyridine–water (2 : 1, v/v, 36 mL). The eluate was evaporated and the residue was dissolved with pyridine (5 mL). Concentrated aqueous ammonia (50 mL) was added and this solution was kept for 3 d. Then the mixture was concentrated and the residue was treated with 80% acetic acid (50 mL) for 1 d. After the solvent was removed by evaporation, the residue was chromatographed on a Whatman 3MM paper developed with Solvent III to give **27** (122 A_{257}, 20%).

27: λ_{max} 257 nm; λ_{min} 227 nm; R_f 0.82 (relative to pU) (Solvent III) (55 : 10 : 35); R_m 0.71 (relative to pU) (0.03 M phosphate buffer, pH 7.1). ^{1}H NMR (500 MHz, D_2O/DSS) δ=3.60 (1H, dm, J=12.3), 3.80 (1H, d, J=12.3 Hz, 5′-Ha of A), 3.85 (1H, d, J=12.3 Hz, 5′-Hb of A), 3.92 (1H, m), 3.95 (1H, br. s), 4.20 (1H, m), 4.27 (1H, m), 4.35 (1H, quintet, J=5.0 Hz), 4.41 (1H, t, J=5.0 Hz), 4.51 (1H, br. s), 5.32 (1H, m, 2′-H of A), 5.63 (1H, d, J=5.2 Hz, 1′-H of G), 5.84 (1H, d, J=7.6 Hz, 5-H of U), 5.95 (1H, d, J=4.9 Hz, 1′-H of U), 6.20 (1H, d, J=5.8 Hz, 1′-H of A), 7.69 (1H, s, H-8 of G), 7.84 (1H, d, J=7.6 Hz, 6-H of U), 7.85 (1H, s, 2-H of A), 8.23 (1H, s, 8-H of A).

Enzymatic Analysis of 21 and 27. The branched triribonucleotide **21** (10 A_{258} unit) was incubated with snake venom phosphodiesterase (10 μL, 1 mg mL^{-1}) in 50 mM Tris-HCl (pH 7.5, 100 μL). Aliquots of the incubation mixture were analyzed after 1.5 h, 5 h, and 12 h by paper electropheresis using 0.05 M phosphate buffer (pH 8.0, 1250 V, 1 h 15 min). In paper electrophoresis done after 1.5 h and 5 h, two digestion intermediates of A(3′–5′)pC and A(2′–5′)pG were detected at R_m values 0.59 and 0.20, respectively. The ultimate ratio of pG, pC, and A, which was obtained after 12 h, was 1.0 : 1.0 : 1.1.

In a similar manner, **27** was digested under the same conditions to give pG, pU, and A in a ratio of 0.8 : 1.0 : 1.2.

Deprotection of 19 Giving Rise to 3′-*O*-Phosphinyladenylyl(2′–5′)guanylate. To a solution of compound **19** (152 mg, 70 μmol) in pyridine (10 mL) was added with stirring 0.2 M NaOH–pyridine (10 mL) at 0 °C. After being stirred at 0 °C for 15 min, the mixture was neutralized with Dowex 50W X2 (pyridinium form, 5 mL), and the resin was removed by filtration and washed with pyridine–water (1 : 1, v/v, 10 mL and 2 : 1, v/v, 36 mL). The filtrate and washing were combined, concentrated, dissolved in pyridine (10 mL), and mixed with concentrated aqueous ammonia (90 mL). The solution was kept for 24 h and evaporated. The residue was allowed to react with 80% acetic acid (50 mL) for 6 h. The solvent was removed under reduced pressure and the residue was chromatographed on Whatman 3MM papers with Solvent III. A band of R_f 0.66 relative to pU was eluted with water and lyophilized to give **26** (1464 A_{256}): R_m 0.85 (pH 7.1, 0.03 M phosphate buffer, 1 h 40 min, 1200 V).

Enzymatic Assay of 26. Compound **26** (70.4 OD at 256 nm) lyophilized was incubated with bacterial alkaline phosphatase (35.2 U/802 μL) in 50 mM Tris-HCl (pH 7.5, 704 μL) at 55 °C for 3 h. Then the incubation mixture was directly applied to a Whatman 3MM paper developed with Solvent II to give A(2′–5′)pG (62.4 $A_{255.5}$) as the sole product (λ_{max} 255.5 nm, λ_{min} 226.5 nm); R_m 0.32 (pH 7.1, 0.03 M phosphate buffer, relative to pU). The dinucleotide (5 $A_{255.5}$ each) was further incubated with RNase T_1, RNase T_2, RNase A, Nuclease P_1, snake venom phosphodiesterase (SVP), and calf spleen phosphodiesterase (CSP) at 37 °C for at least 13 h under the following conditions: 1) RNase T_1 (30 U, 6 μL), 10 mM Tris-HCl (100 μL) containing 1 mM EDTA, pH 7.5; 2) RNase T_2 (30 U, 150 μL), 20 mM NaOAc (100 μL), pH 5.5; 3) RNase A (150 μg, 15 μL), 10 mM Tis-HCl (30 μL) containing 1 mM EDTA, pH 7.5; 4) Nuclease P_1 (30 μg, 15 μL), 20 mM NaOAc (100 μL), pH 5.5; 5) SVP (30 μg, 30 μL), 50 mM Tris-HCl (100 μL), pH 7.5; 6) CSP (10 μg, 5 μL), 0.01 M pyrophosphate (50 μL) and 0.05 M ammonium acetate (100 μL), pH 6.5.

These enzyme reactions were analyzed after 1.5 h and 13 h by paper electrophoresis (0.03 M phosphate buffer, pH 7.1, 1200 V, 1 h 10 min). Among these enzymes, only SVP degraded the dinucleotide to A and pG in a ratio of 1.03 : 1.00 after 2 h. The digetion products were identified as the authentic samples by comparison of their R_f and R_m values as well as UV spectra.

***S,S*-Diphenyl 3′-*O*-Dianilinophosphinyl-5′-*O*-(4-methoxytrityl)-6-*N*-benzoyladenosine 2′-Phosphorodithioate (32).** Compound **6b** (1.21 g, 2 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (5 mL). 4-Methoxytrityl chloride (1.85 g, 6 mmol) was added and the mixture was stirred for 3

h. To the mixture were added successively cyclohexylammonium *S,S*-diphenyl phosphorodithioate (1.14 g, 3 mmol), tetrazole (560 mg, 8 mmol), and MDS (1.27 g, 4 mmol). The resulting mixture was stirred for 15 min and then diluted with CH_2Cl_2. After the usual workup as described in the synthesis of **13**, chromatography on a column of silica gel (100 g) with CH_2Cl_2–MeOH gave **32** (1.89 g, 83%).

32: ^{1}H NMR (500 MHz, $CDCl_3$) δ=3.43 (2H, br s, 5′-H), 3.61 (3H, s, OCH_3), 4.72 (1H, br s, 4′-H), 5.41 (1H, t, J=6.0, 3′-H), 5.98 (1H, q, J=6.0 Hz, J=6.8 Hz, 2′-H), 6.34 (1H, d, J=6.8 Hz, 1′-H), 6.75 (2H, d, J=8.79 Hz, ArH), 6.83 (2H, q, J=7.33 Hz, J=6.83 Hz, ArH), 6.88 (2H, t, J=7.32 Hz, ArH), 6.98—7.60 (31H, m, ArH), 8.07 (2H, d, J=7.8 Hz, ArH), 8.17 (1H, s, 2-H), 8.46 (1H, s, 8-H), 9.58 (1H, br, NH).

Removal of the Anilino Groups from 32. Compound **32** (1.85 g, 1.6 mmol) was allowed to react with isopentyl nitrite (1.6 mL) in pyridine–acetic acid–acetic anhydride (1 : 1 : 1, v/v/v) for 15 h. Then pyridine (5 mL) was added and the mixture was partitioned between CH_2Cl and water. The organic phase was collected and washed with water, 0.2 M TEAB (×5), water. Each washing was backextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, concentrated, and the residue was chromatographed on a column of silica gel (64 g) with CH_2Cl_2–MeOH in the presence of 0.5% pyridine to give **33** as glassy material. As described in the case of **19**, further extractive workup followed by precipitation of its CH_2Cl_2 solution into hexane gave **33** as white powder (969 mg, 55%).

***S,S*-Diphenyl 3′-*O*-Bis(2-cyanoethoxy)phosphinyl-5′-*O*-(4-methoxytrityl)-6-*N*-benzoyladenosine 2′-Phosphorodithioate (30).** Compound **33** (219 mg, 0.2 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (4 mL). To the solution were added 2-cyanoethanol (272 μL, 4 mmol) and DDS (662 mg, 2 mmol). The resulting mixture was sitirred for 1 h and then diluted with CH_2Cl_2. The CH_2Cl_2 solution was washed with water (×2) and 5% $NaHCO_3$ (×3) and each washing was backextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, dried over Na_2SO_4, filtered, concentrated, and chromatographed on a column of silica gel (20 g) with CH_2Cl_2–MeOH in the presence of pyridine to give **30** as foam (147 mg, 67%).

30: ^{1}H NMR ($CDCl_3$) δ=2.67 (4H, t, J=6 Hz, CH_2CN), 3.55 (2H, m, 5′-H). 3.74 (3H, s, CH_3O), 4.24 (4H, q, J=6 Hz, CH_2O-P), 4.45 (1H, m, 4′-H), 5.36 (1H, m, 3′-H), 6.08 (1H, m, 2′-H), 6.17 (1H, m, 1′-H), 6.73 (2H, d, J=8 Hz, 6.92—7.80 (25H, m, ArH), 7.91 (2H, m, ArH), 8.01 (1H, s, 2-H), 8.58 (1H, s, 8-H). Anal. Calcd for $C_{54}H_{49}N_7O_{10}P_2$: C, 59.94; H, 4.56; N, 9.06; S, 5.93%. Found: C, 60.31; H, 4.81; N, 8.85; S, 5.89%.

The Fully Protected 2′-5′ Linked ApG Derivative (36). A 5 M solution of pyridinium phosphinate in pyridine (1.1 mL) was mixed with triethylamine (0.55 mL) and **30** (100 mg, 91 μmol) was dissolved in this solution. After the mixture was stirred at room temperature for 30 min, the resulting mixture was diluted with CH_2Cl_2, which was washed subsequently with water, 0.2 M triethylammonium hydrogencarbonate (×2), and water. Each washing was backextracted with another CH_2Cl_2. The two CH_2Cl_2 extracts were combined, dried over Na_2SO_4, Filtered, and concentrated under reduced pressure. The residue was mixed with **35** (81 mg, 109 μmol) and 3-nitro-1*H*-1,2-4-triazole (31 mg, 0.27 mmol). The mixture was coevaporated several times with dry pyridine, dissolved in dry pyridine (1 mL), and DDS (90 mg, 0.27 mmol) was added. After the mixture was stirred for 1 h, the usual extractive workup followed by chromatography on a column of silica gel (20 g) with CH_2Cl_2–MeOH gave **36** (137 mg, 87%).

Synthesis of the Fully Protected Branched Trimer (39). The 2′-5′ linked dimer **36** (52 mg, 30 μmol) was treated with *N,N*-diisopropylethylamine (1 mL) in pyridine (2 mL) at 40 °C for 4 h. Evaporation followed by preparative TLC chromatography (CH_2Cl_2–MeOH 9 : 1, v/v) gave **37** as triethylammonium salt (44 mg, 82%).

A mixture of **37** (42 mg, 23 μmol), **38** (19.5 mg, 35 μmol), and 3-nitro-1*H*-1,2,4-triazole (24 mg, 0.21 mmol) was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (0.5 mL). DDS (23 mg, 71 μmol) was added and the resulting mixture was stirred for 1 h. At this time the condensation was almost complete but an additional amount of DDS (23 mg, 71 μmol) was added to convert the excess hydroxy component to a sulfonate derivative. After stirring was continued for 1 h, the mixture was diluted with CH_2Cl_2, which was washed successively with water, 5% $NaHCO_3$, and water. Each washing was backextracted with another CH_2Cl_2. The two extracts were combined, dired over Na_2SO_4, filtered, concentrated and chromatographed on a preparative TLC plate developed with CH_2Cl_2–MeOH (9 : 1, v/v) to give **39** (33 mg, 63%).

Removal of the Methoxytrityl Group from 39. Compound **39** (33 mg, 15 μmol) was treated with trifluoroacetic acid (20 μL) in CH_2Cl_2 (2 mL) for 5 min. Then 5% $NaHCO_3$ was added and the mixture was extracted with CH_2Cl_2 (×3). The extracts were combined, dried over Na_2SO_4, filtered, concentrated, and chromatographed on a preparative TLC plate developed with CH_2Cl_2–MeOH (9 : 1, v/v) to give **40** (17.5 mg, 60%).

Synthesis of Fully Protected UpG Dimer. A mixture of triethylammonium *S*-phenyl 5′-*O*-(4,4′-dimethoxytiryl)-3′-*O*-(tetrahydro-2-pyranyl)-N^3-(*p*-anisoyl)uridine 3′-phosphorothioate (343 mg, 0.33 mmol) and *S,S*-diphenyl 3′-*O*-(tetrahydro-2-pyranyl)-2-*N*-propionyl-6-*O*-(diphenylcarbamoyl)guanosine 3′-phosphorodithioate (170 mg, 0.275 mmol), which were obtained from the corresponding monomer units[31,32] by treatments with phosphinate and trifluoroacetic acid, respectively, was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (5 mL). To the solution were added 3-nitoro-1*H*-1,2,4-triazole (114 mg, 1 mmol) and DDS (331 mg, 1 mmol). After being stirred for 40 min, the mixture was quenched by the addition of water and extracted four times with CH_2Cl_2. Each CH_2Cl_2 extract was washed with 5% $NaHCO_3$. The CH_2Cl_2 extracts were combined, dried over Na_2SO_4, filtered, and evaporated under reduced pressure. The residue was chromatographed on a column of silica gel (15 g) with CH_2Cl_2–MeOH to give the fully protected UpG dimer (329 mg, 78%).

Removal of the DMTr Group of the Fully Protected UpG Dimer. The Fully protected UpG dimer (310 mg, 0.21 mmol) was dissolved in CH_2Cl_2 (20 mL) and the solution was cooled at 0 °C. Trifluoroacetic acid (100 μL) was added and the resulting mixture was kept at the same temperature for 10 min. Then 5% $NaHCO_3$ was added to neutralize the solution. The usual extract with CH_2Cl_2 followed by preparative TLC developed with CH_2Cl_2–MeOH gave the 5′-

hydroxy component of the fully protected UpG dimer (194 mg, 76%).

Synthesis of the Fully Protected CpUpG Trimer. A mixture of *S*-phenyl 5′-*O*-(4,4′-dimethoxytrityl)-3′-*O*-(tetrahydro-2-pyranyl)-N^4-benzoylcytidine 3′-phosphorothioate (174 mg, 0.173 mmol) and the 5′-hydroxy component (186 mg, 0.15 mmol) obtained in the above experiment was rendered anhydrous by repeated coevaporation with dry pyridine and finally dissolved in dry pyridine (3 mL). To the mixture were added 3-nitro-1*H*-1,2,4-triazole (51.4 mg, 0.45 mmol) and DDS (149 mg, 0.45 mmol). After being stirred for 1 h, the mixture was quenched by the addition of water. The usual workup followed by chromatography on a column of silica gel gave the fully protected CpUpG trimer (282 mg, 88%).

Removal of the 3′-Terminal Phenylthio Group from the Fully Protected CpUpG Trimer. The fully protected CpUpG trimer (106 mg, 0.05 mmol) was dissolved in a mixture of 5 M phosphinic acid (pyridine solution) and triethylamine (2:1, v/v, 0.91 mL). The mixture was kept at room temperature for 1 h. Extraction with CH_2Cl_2 as described in the synthesis of **16** was performed. Chromatography on preparative TLC plates (Merck 5717) with CH_2Cl_2–MeOH gave **41** (65 mg, 60%) as triethylammonium salt.

Synthesis of the Fully Protected Branched Hexamer (42). A mixture of **40** (10.0 mg, 5.2 μmol), **41** (14.3 mg, 6.7 μmol), and 3-nitro-1*H*-1,2,4-triazole (3.8 mg, 34 μmol) was rendered an hydrous by repeated coevaporation with dry pyridine, finally dissolved in dry pyridine (0.2 mL), and DDS (11.1 mg, 34 μmol) was added. After being stirred for 1 h, the mixture was diluted with CH_2Cl_2. Extraction followed by preparative TLC gave **42** (8.7 mg, 56%).

Full Deprotection of 42. The fully protected branched hexamer **42** (8.5 mg, 2.1 μmol) was treated with bis-(tributyl)tin oxide (0.15 mL, 0.23 mmol) in pyridine (0.25 mL) for 28 h. Then trimethylsilyl chloride (70 μL, 0.46 mmol) was added and the mixture was kept for 15 min. Pyridine (20 mL) and concentrated aqueous ammonia (20 mL) were added to the solution. After being stirred for 19 h, the mixture was evaporated and coevaporated two times with dioxane to remove the last traces of pyridine. The residue was dissolved in dioxane (20 mL) and 0.02 M HCl (20 mL) was added. The resulting solution was further arranged to pH 2.0 by addition of 0.1 M HCl and stirred for 48 h. Then the solution was neutralized by addition of concentrated aqueous ammonia, evaporated, and the residue was chromatographed on a Toyo Roshi 51A paper developed with Solvent II to give **43** (36 A_{257}, 32%): λ_{max} 257 nm, λ_{min} 226 nm; Retension time 11.0 min (HPLC System A); R_f 0.09 (Solvent II, relative to pT).

Enzyme Analysis of 43. The sample of **43** (0.1 A_{257}) purified by HPLC was incubated with nuclease P_1 (10 μL) in 10 mM sodium acetate (pH 5.5, 200 μL) at 37 °C for 15 min. The result of this enzyme reaction is depicted in Fig. 2C. The peak of pA_{pC}^{pG} was collected, desalted by repeated lyophilization from water, and incubated with bacterial alkaline phosphatase (0.3 μg/μL, 4 μL) in 50 mM Tris-HCl (pH 7.5, 30 μL) for 15 min. The peak of pA_{pC}^{pG} was completely shifted to an authentic sample of A_{pC}^{pG}.

We thank Professor Yasumi Ohshima and Dr. Akira Mayeda, Kyushu University for their helpful discussion throughout this study. This work was supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Science and Culture.

Selective Deoxygenation of Various N-O Bonds Catalyzed by Rhodium Carbonyl Clusters in the Presence of H_2O and CO and Their Heterogenization Using Amino-Substituted Polystyrenes

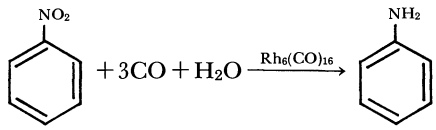
Kiyotomi KANEDA,* Kazuo FUJITA, Tetsuya TAKEMOTO, and Toshinobu IMANAKA
Department of Chemical Engineering, Faculty of Engineering Science, Osaka Univesity, Toyonaka, Osaka 560
(Received September 10, 1990)

Catalytic deoxygenation of various N-O bonds using rhodium carbonyl compounds under a water gas shift reaction was studied. A catalyst system of $Rh_6(CO)_{16}$ and *N,N,N′,N′*-tetramethyl-1,3-propanediamine was found to have high activities for the following deoxygenations: 1) conversion of nitrobenzenes to anilines, 2) aliphatic nitro compounds to nitriles, 3) oximes to nitriles, 4) hydroxylamines to amines, and 5) amine oxides to amines. The above-mentioned rhodium catalyst system was heterogenized by using amino-substituted polystyrenes. Rh_6 and Rh_{14} carbonyl clusters of $[Rh_6(CO)_{15}H]^-$, $[Rh_6(CO)_{15}]^{2-}$, and $[Rh_{14}(CO)_{25}]^{4-}$, were formed on the polymer surface. The characteristic features of the catalysis of the polymer-bound rhodium cluster complexes are described in relation to the corresponding homogeneous ones.

Metal carbonyl clusters have generated interest as catalysts from the standpoint of faciliting new organic reactions and as a model for metal catalysts.[1] Various organic reactions explored by using metal carbonyl clusters (e.g., hydroformylation, reduction, and deoxygenation) have been carried out under a CO atmosphere since the labile cluster framework consisting of metal-metal bonds must be reinforced by CO molecules.[2] We also studied the application of the water gas shift reaction (WGSR) using CO and H_2O for organic syntheses in the presence of rhodium carbonyl clusters, and found that the rhodium clusters have unique reactivities for the reduction of carbonyl compounds (e.g., aldehydes and α,β-unsaturated carbonyl compounds), carbonylation of olefins, and deoxygenation of various N-O bonds.[3] In the above-mentioned organic reactions, the amines or pyridines are an essential additive to form active species of rhodium catalysts. In order to simplify the work-up procedure, we heterogenized the rhodium catalyst systems using amino-substituted polystyrenes and the rhodium cluster anions $[Rh_6(CO)_{15}H]^-$, $[Rh_6(CO)_{15}]^{2-}$, and $[Rh_{14}(CO)_{25}]^{4-}$ which formed as ammonium salts on the polymer. In this paper, we give a detailed account of the deoxygenation of nitro compounds, oximes, hydroxylamines, and amine oxides using CO and H_2O in the presence of rhodium carbonyl clusters, e.g., $Rh_6(CO)_{16}$ and $Rh_4(CO)_{12}$.[4] Furthermore, the characteristic features of the catalysis of polymer-bound rhodium cluster complexes are mentioned in relation to the corresponding homogeneous ones.

Results and Discussion

Deoxygenation of Aromatic Nitro Compounds. Rhodium carbonyl cluster-diamine catalyst systems showed high activity for WGSR under mild conditions.[5] In relation to WGSR, we have examined the reactivity of various amines and pyridines as additives for the deoxygenation of nitrobenzene to aniline using CO and H_2O at 80 °C. Results using CO of 700 mmHg (1 mmHg=133.322 Pa) and H_2O in the presence of the $Rh_6(CO)_{16}$ cluster are shown in Table 1 together with the activities of the corresponding WGSR. Aniline was the only deoxygenation product. The formation



(1)

of other products (e.g., nitrosobenzene, phenylhydroxylamine, *N,N′*-diphenylurea, and cyclohexylamine) could not be observed under the reaction conditions.[6] The yields of aniline are also strongly dependent on various kinds of bases. It should be noted that there are sharp contrasts between the deoxygenation of nitrobenzene and WGSR regarding the effect of additives. The most effective additive in the deoxygenation reaction is *N,N,N′,N′*-tetramethyl-1,3-propanediamine (TMPDA), which had no activity for generation of H_2 in WGSR. Among the diamine series of $-N(CH_2)_nN-$, increasing the number (n) of methylenes and the introduction of methyl substituents on the nitrogen atoms increase the yield of aniline, respectively, while decreasing H_2 generation from WGSR. For pyridine derivatives, the introduction of electron-releasing substituents on the γ-position of pyridines increases the yields of aniline; 4-(dimethylamino)-pyridine was the most effective additive. On the other hand, methyl substituents on the α-position of pyridines decrease the yield of H_2 while an α-substituent effect could not be observed in the nitrobenzene deoxygenation. The strong basicity of the pyridines with high pK_a value is an essential factor for attaining high yields of aniline in the deoxygenation of nitrobenzene.

The catalytic behavior for nitrobenzene deoxygenation using various metal complexes was examined in the presence of TMPDA as an additive. Typical

a) For deoxygenation; nitrobenzene 1.5 mmol, $Rh_6(CO)_{16}$ 0.05 mmol, base 15 mmol, H_2O 0.72 ml, 2-ethoxyethanol 3 ml, P_{co}=700 mmHg, 80 °C. For WGSR: $Rh_6(CO)_{16}$ 0.05 mmol, base 85 mmol, H_2O 0.72 ml, 2-ethoxyethanol [10-base]ml, P_{co}=700 mmHg, 4 h.[5] b) The pK_a values are cited from Ref. 44. c) Yield of H_2=mol of H_2/mol of $Rh_6(CO)_{16}$ per 6 h. d) Base 17 mmol, 2-ethoxyethanol 10 ml, 12 h, 100 °C.

Table 2. Deoxygenation of Nitrobenzene with Various Metal Carbonyl Compounds in the Presence of H_2O and CO[a]

Catalyst	Aniline	
	Time/h	Yield/%
$Rh_6(CO)_{16}$	2.5	>99
$Rh_4(CO)_{12}$	3.0	>99
$Rh_2(CO)_4Cl_2$	6.0	>99
$RhCl_3 \cdot 3H_2O$	10	20
$RhCl(PPh_3)_3$	10	17
Rh_2O_3	10	4
$Ru_3(CO)_{12}$	10	18
$Fe(CO)_5$	10	54
$W(CO)_6$	10	5

a) Reaction conditions were the same as used in Table 1.

examples are summarized in Table 2. Though Rh carbonyl compounds (e.g., $Rh_6(CO)_{16}$, $Rh_4(CO)_{12}$, and $Rh_2(CO)_4Cl_2$) are good catalysts, other Rh compounds (such as $RhCl(PPh_3)_3$, $RhCl_3 \cdot 3H_2O$, and Rh_2O_3) have low catalytic activities for deoxygenation. Other transition metal carbonyl complexes of $Ru_3(CO)_{12}$, $Fe(CO)_5$, and $W(CO)_6$ are poor catalysts under the reaction conditions. All rhodium carbonyl complexes having high activities were dark brown in solution during deoxygenation. $Rh_2(CO)_4Cl_2$ had a longer induction period for deoxygenation than the Rh_6 and Rh_4 carbonyl clusters did. This phenomenon supports the idea that these rhodium complexes were changed into a common active Rh species during nitrobenzene deoxygenation.

The deoxygenation of various aromatic nitro compounds using the catalyst system of $Rh_6(CO)_{16}$ and TMPDA under 4 atm of CO is shown in Table 3, together with that in the amino-substituted polymer system. Details concerning the heterogeneous deoxygenation of nitro compounds are discussed in a latter section. In a series of *p*-substituted nitrobenzenes, electron-donating substituents decrease their reactivity for deoxygenation, which became more clear by using competitive reactions to unsubstituted nitrobenzene

Table 3. Deoxygenation of Various Nitro Compounds Using $Rh_6(CO)_{16}$ in the Presence of CO and H_2O[a]

a) $Rh_6(CO)_{16}$ 0.05 mmol, substrate 5 mmol, H_2O 2.88 ml, 2-ethoxyethanol 2 ml, P_{CO}=4 atm, 80 °C, *N,N,N'N'*-tetramethyl-1,3-propanadiamine (TMPDA) 5 mmol, 5 h. b) Values of parentheses are for the polymer system. Amino-substituted polymer (**Ia**, 0.8 mg-atom of N), 48 h. c) Relative rates were calculated by initial product ratios of substituted anilines to aniline.

(ρ=2.75). A similar electronic effect of substituents has been reported in the phase-transfer catalyst of $Ru_3(CO)_{12}$[2d] and $Ru(CO)_3(Ph_4C_4CO)$,[7] while in the case of $[Ru(cod)py_4]^{2+}$, electron-donating substituents accelerate the yield of aniline derivatives.[8] Nitronaphthalene also gave naphthylamine in a 61% yield under the above-mentioned conditions.[9]

Aliphatic Nitro Compounds and Oximes. The reaction of 1-nitropropane in place of aromatic nitro compounds was performed by the catalyst system of $Rh_6(CO)_{16}$ and TMPDA at 40 °C under 16 atm of CO. Unexpectedly, propionitrile was obtained as the main product, accompanied by 1-propanol and tripropylamine without propylamine. Typical results of aliphatic nitro compounds are listed in Table 4, together with those of amino-substituted polymer systems. A nitro function on the primary carbon atoms in various nitro compounds was deoxygenated to give the corresponding nitriles as the main product, respectively,

$$C_3H_7\text{-}NO_2 \xrightarrow[Rh_6(CO)_{16}\text{-diamine}]{CO,\ H_2O} C_2H_5CN + C_3H_7OH + (C_3H_7)_3N \quad (2)$$

	 28(21)  OH 12(20)  22(30)

a) Substrate 5 mmol, $Rh_6(CO)_{16}$ 0.05 mmol, 2-ethoxyethanol 2 ml, H_2O 2.88 ml, *N,N,N'N'*-Tetramethyl-1,3-propanamine (TMPDA) 5 mmol, P_{CO}=16 atm, 40 °C, 24 h. For oximes: P_{CO}=8 atm, 5 h. b) Values of parentheses are for the polymer system. Amino-substituted polymer (**Ia**, 0.8 mg-atom of N), 48 h.

while amines, alcohols, and ketones were formed in the case of secondary nitro compounds. The formations of these products are discussed (vide infra). During the initial stage of these deoxygenations, trace amounts of oximes were detected, respectively. The reaction of a prepared propionaldehyde oxime was carried out under the same conditions as in the above 1-nitropropane to give propionitrile as the main product. From the above results, a possible path for the formation of propionitrile via an oxime intermediate can be considered in Scheme 1; the deoxygenation of

$$C_3H_7\text{-}NO_2 + CO \longrightarrow C_3H_7\text{-}NO \rightleftarrows C_2H_5\text{-}CH{=}N\text{-}OH + CO_2$$
$$C_2H_5\text{-}CH{=}N\text{-}OH + CO \longrightarrow C_2H_5\text{-}CN + CO_2 + H_2$$

Scheme. 1. Deoxygenation of 1-nitropropane via an oxime intermediate.

1-nitropropane occurs to give 1-nitrosopropane, which is tautomerized to propionaldehyde oxime, and dehydration of the oxime affords propionitrile with generation of H_2 and CO_2. 1-Propanol originated from hydrolysis of propionaldehyde oxime to give propionaldehyde, followed by a reduction. We have already found that a catalyst system consisting of $Rh_6(CO)_{16}$ and TMPDA has a high catalytic activity for the reduction of formyl groups under WGSR conditions.[3b]

The results of various oximes under 8 atm of CO are also included in Table 4. Aldoximes, except for benzaldehyde oxime, were deoxygenated to selectively give the corresponding nitriles; benzaldehyde oxime afforded benzyl alcohol as the main product, because of its facile hydrolysis to benzaldehyde under the reaction conditions. Deoxygenation with a protected oxime of propionaldehyde *O*-methyloxime did not occur and the starting material was recovered. Interestingly, this nitrile synthesis from oximes is regarded as being a formal dehydration, which occurs with the formation of CO_2 and H_2 (Eqs. 3 and 4).[10]

$$R\text{-}CH{=}N\text{-}OH \longrightarrow R\text{-}CN + H_2O \quad (3)$$

$$R\text{-}CH{=}N\text{-}OH + CO \xrightarrow{Rh_6(CO)_{16}} R\text{-}CN + CO_2 + H_2 \quad (4)$$

Next, the reaction of ketoximes was performed, leading to complicated product distributions of amines, alcohols, and ketones; for example, cyclohexanone oxime gave dicyclohexylamine, cyclohexanone, and cyclohexanol in 28, 22, and 12% yields, respectively. The formation of dicylohexylamine can be explained by the following paths. The hydrogenolysis of cyclohexanone oxime yields cyclohexylamine, followed by the dehydration of cyclohexylamine with cyclohexanone to afford *N*-cyclohexylidenecyclohexylamine, which is further reduced to dicyclohexylamine. In a separate experiment, the Schiff base of *N*-cyclohexylidenecyclohexylamine could be converted into dicyclohexylamine in 83% yield under the same conditions as in the oxime reactions. We planed one-pot *N*-alkylation of amines with ketones via Schiff base intermediates. The reaction of primary amines with ketones was carried out in the presence of $Rh_6(CO)_{16}$ under WGSR conditions. The expected *N*-alkylated products of the amines were obtained in moderate yields, which is shown in Table 5.[11]

Hydroxylamines and Amine Oxides. In previous sections it was revealed that a catalyst system of $Rh_6(CO)_{16}$ and TMPDA was effctive for the deoxygenation of various nitro compounds and oximes. In order to develop the deoxygenation ability of the rhodium catalyst to other nitrogen compounds having N-O bonds, many reactions of hydroxylamines and amine oxides were carried out under conditions similar to those of the above-mentioned oximes. The results are shown in Table 6. Various hydroxylamines and amine oxides were easily deoxygenated to give the corresponding amines in high yields, respectively.[12] The deoxygenation of pyridine *N*-oxide did not occur under the present conditions and the *N*-oxide was recovered quantitatively. Although there are many reagents and catalysts for the deoxygenations of oximes, hydroxylamines, and amine oxides,

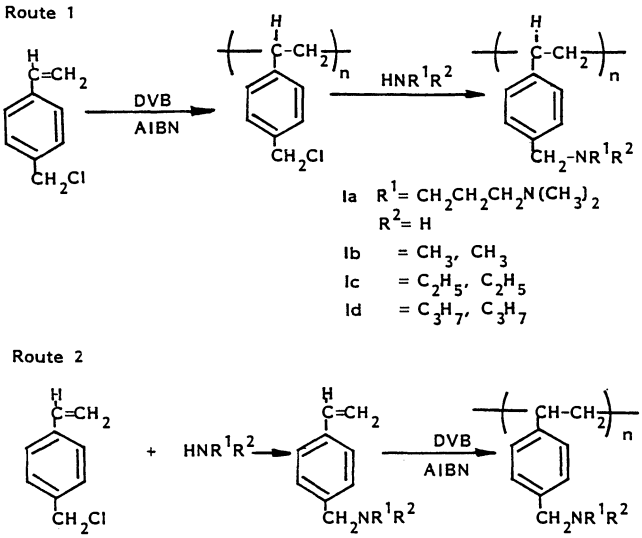
little has been known about such deoxygenations using a reducing agent of CO in organic synthesis.[13] It should be noted that our system of Rh carbonyl clusters and TMPDA can catalyze the deoxygenation of various nitrogen compounds using CO as an inexpensive reducing agent.

$$(C_2H_5)N\text{-}OH + CO \xrightarrow[H_2O,\ 40\,°C,\ 5\ h]{Rh_6(CO)_{16}\text{-diamine}} \underset{93\%}{(C_2H_5)_2NH} + CO_2 \quad (6)$$

$$(C_3H_7)_3N\rightarrow O + CO \xrightarrow[H_2O,\ 40\,°C,\ 5\ h]{Rh_6(CO)_{16}\text{-diamine}} \underset{91\%}{(C_3H_7)_3N} + CO_2 \quad (7)$$

Polymer System in Deoxygenation of N-O Bonds. The most practical advantage of using insoluble polymer-bound metal complexes is to simplify the work-up procedure in organic synthesis.[14] Amines and pyridines are an essential additive in the above-mentioned deoxygenations, and act as a base to induce the formation of active species of Rh carbonyl cluster anions and as an ammonium counter ion to stabilize the Rh cluster anions in an aqueous media (vide infra). We had a plan to heterogenize the $Rh_6(CO)_{16}$ catalyst system by using amino substituted organic polymers in place of TMPDA. The amino-substituted polymers were prepared by the following procedures: 1) polymerization of *p*-(chloromethyl)-styrene, followed by its treatment with amines, and 2) amination of *p*-(chloromethyl)styrene, followed by its polymerization. The above-mentioned synthetic routes are summarized in Scheme 2.

The catalytic behavior of our homogeneous $Rh_6(CO)_{16}$-amine systems is strongly dependent on various kinds of the amines, which was described in a previous section regarding nitrobenzene deoxygenation. It has been of interest whether polymer-heterogenized metal systems keep their instinctive catalytic activities of the corresponding homogeneous systems. Table 7 shows the effect of various amines on the 1-nitropropane reduction in the cases of poly-



Scheme. 2. Synthetic routes of amino-substituted polystyrenes.

a) Reaction conditions were the same as in Table 4. b) Values in parentheses are for the amine monomers of 0.4 mmol used, respectively.

mer and homogeneous systems. Both of the systems gave similar product distributions for a variety of amine additives; the use of a polymer having the diamino moiety (**Ia**) led a high yield of propionitrile, and TMPDA was the most effective additive in homogeneous systems. Various heterogeneous systems of the amino-substituted polymers showed lower reaction rates for the 1-nitropropane deoxygenation than the corresponding homogeneous ones did; the reaction times for heterogeneous reactions had to be prolonged for up to 48 h in order to attain high nitrile yields. However, a relatively small amount of the amino moiety (0.8 mg-atom of N) can cause the selective formation of nitriles, compared with homogeneous systems (10 mg-atom of N). This might be due to the location of amino moieties within a relatively small volume of the polymers;[15] the high concentration of the amines on the polymer surfaces increases the basicity of the reaction media near the polymer surfaces, which facilitates the formation of Rh carbonyl cluster anions as an active species, and also promotes the stability of the Rh cluster anions through ammonium ions.

The effect of the various polymerization degrees of polystyrene supports on the deoxygenation was examined by using polymers prepared from route 1 with *N*,*N*-dimethyl-1,3-propanediamine. In the cases of polystyrenes with M_w=7600, 8600, and 52700, heterogeneous polymer-bound Rh complexes were formed in the above-mentioned deoxygenation, and gave similar yields of the nitrile in 69, 73, and 71%, respectively. The difference of the polymerization degree did not remarkably change the product distribution of 1-nitropropane. Furthermore, the use of amino-substituted polymers having the diamino moiety (**Ia**) prepared from routes 1 and 2 gave similar yields of the nitrile of 70 vs. 75% under the conditions with an equivalent amino amount. We think that the structure of amino moieties on polymers is the crucial factor in the design of a suitable polystyrene support for the selective deoxygenation of 1-nitropropane to propionitrile.

Heterogeneous deoxygenations of nitropropane using Ia were carried out in the presence of various solvents. Since large amounts of water were required for the selective formation of the nitrile, the solvents used here had to be well miscible with organic compounds and water. These results are shown in Table 8. Alcohols having an ether function (e.g., 2-ethoxyethanol and 2-methoxyethanol) were good solvents. Although THF and dioxane have a high swelling ability for polystyrene supports,[16] the use of THF, dioxane, and a mixed solvent of 2-ethoxyethanol-THF did not lead to high yields of propionitrile in a polymer system. It seems that the swelling ability of solvents might not play an important role in the selective formation of the nitrile in the present aqueous systems.

Recycling of the polymer-bound Rh cluster catalyst was examined in the deoxygenation of 1-nitropropane. After deoxygenation, a dark-green polymer was filtered, and was then reused for deoxygenation under the same conditions as in a former reaction. The results are shown in Table 9. Reused Rh com-

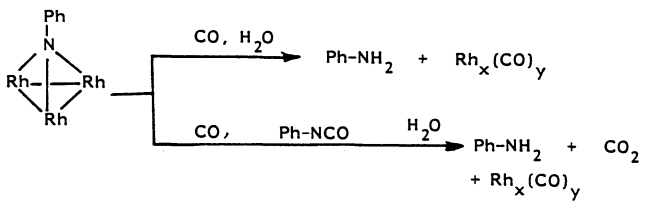
a) Initial conditions were the same as in Table 8. In the recycling study, the polymer-bound Rh catalyst filtered under an atmosphere were used and other conditions were the same as in the fresh reaction.

plexes kept their catalytic activity to give propionitrile as the main product as well as a small amount of new 3-hexanone.[17] In separated experiments, the reaction of 1-nitropropane was interrupted after 5h. A colorless filtrate was separated from the resulting heterogeneous mixture under a CO atmosphere, which did not further show any catalytic activity for deoxygenation under the same conditions as in the above 1-nitropropane reaction. It can be said that deoxygenation proceeds on polymer-bound Rh complexes.

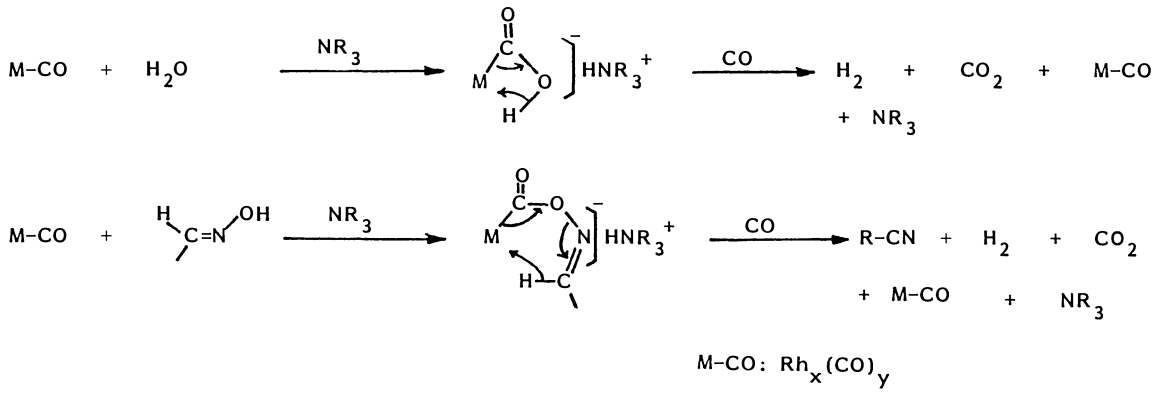
The deoxygenation of organic compounds with various N-O bonds in the presence of the diamino-substituted polymer (**Ia**) was carried out. The results for aromatic nitro compounds, aliphatic nitro compounds, and oximes appear together with the corresponding homogeneous compounds in Tables 3 and 4, respectively. The reactions of hydroxylamines and amine oxides are summarized in Table 6. In the deoxygenations of ortho-substituted nitrobenzenes, polymeric Rh catalyst systems showed extremely low catalytic activities (Table 3) since the approach of the substrates to active metal centers is strongly influenced by the steric hindrance of polymer surfaces. The heterogenization of soluble metal catalysts using organic polymers which leads to a decreasing of their catalytic activities has been reported in many polymer-bound metal catalysts.[18]

Reaction Mechanisms for Deoxygenations. Many of the reactions of aromatic nitro compounds using CO have been studied in the presence of various transition metal carbonyl complexes, e.g., $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$, and $Rh_6(CO)_{16}$.[2] The reaction products from nitrobenzenes were anilines, isocyanides, carbamates, and ureas. All of the above-mentioned metal-catalyzed reactions proceed via nitrene species as a common intermediate derived from the deoxygenation of nitrobenzene with CO. The characterization of various isolated metal nitrene complexes and their reactivities have been actively examined.[19] The μ_3-coordination mode in nitrene complexes is the most common in low-valent organometallics and the phenylnitrene bound to metal clusters reacts with CO and hydrogen to give phenyl isocyanate and aniline, respectively. In our combined catalyst system of $Rh_6(CO)_{16}$ and diamines, aniline would be formed via the nitrene intermediate, as shown in Scheme 3: a phenylnitrene bound to Rh carbonyl clusters reacts with hydrogens generated from the water gas shift reaction to give aniline or reacts with CO to give phenyl isocyanate, followed by hydrolysis to aniline.

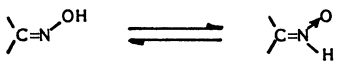


Scheme. 3. Formation of aniline via a nitrene intermeidate.

In the case of our Rh catalysts, primary aliphatic nitro compounds did not give amines but, rather, nitriles as the main product. As mentioned in a previous section, the deoxygenation of aliphatic nitro compounds affords oximes, which further react with CO to give nitriles with formations of H_2 and CO_2. One can image that the deoxygenation of oximes to nitriles is operated by a similar mechanism proposed for WGSR (Scheme 4);[20] a nucleophilic oxygen of oximes or H_2O attacks a carbonyl moiety on Rh clusters to form a metallocarboxyimine or metallocarboxylic acid intermediate, and their decarboxylation gives either nitrile and/or H_2, respectively. Since the reaction of an aldehyde *O*-methyloxime did not occur, oximes would be deprotonated by an amino moiety of additive bases to increase their nucleophilicity in the deoxygenation. The bonding mode of carbonyl moieties on Rh carbonyl clusters can be classified mainly into three types: terminal, edge-bridge, and face-bridge. A nucleophilic attack of oximes or H_2O might favor the terminal CO moiety because of the relatively weak back bonding of Rh metal to the



Scheme. 4. Mechanisms for the water gas shift reaction and deoxygenation of oximes.



(8)

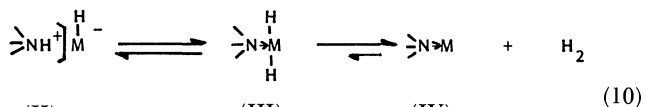
(9)

terminal CO.[21]

Next, the amine oxide forms can be thought as being the corresponding tautomers of oximes and hydroxylamines according to Eqs. 8 and 9, respectively. Recently, Basolo and co-workers have studied the mechanism for a stoichiometric deoxygenation of tertiary alkylamine N-oxides with $M_3(CO)_{12}$ (M= Fe,Ru,Os);[13] a nucleophilic oxygen of amine oxides attacks a carbonyl moiety on the metal clusters to give the corresponding amines and CO_2. Therefore, the amine oxide intermediates might also participate in the present deoxygenation of nitro compounds, oximes, and hydroxylamine using the present Rh cluster catalysts.

In the homogeneous deoxygenation of N-O bonds, e.g., aliphatic nitro compounds, oximes, hydroxylamines, and amine oxides at 40 °C, the reaction solutions had a dark-green color which changed instantly to dark brown upon exposure to air. In polymer systems (Ia), polymer-bound Rh complexes isolated from reaction mixtures were stable as dark-green powders in air for several hours.[22] The IR spectrum of the dark green powder showed the formation of $[Rh_6(CO)_{15}]^{2-}$ and $[Rh_6(CO)_{15}H]^-$ on the polymer.[23] Treatment of the Rh_6 species with aqueous KOH at room temperature gave the $[Rh_7(CO)_{16}]^{3-}$ anion. In Rh cluster chemistry, increasing the reaction temperatures tends to increase the cluster nuclearity.[24] Probably, the Rh_{14} species might be derived from a dimerization of the Rh_7 species during the nitrobenzene reaction.

Under WGSR conditions, hydridorhodium anions can be thought as being one of the important intermediates species which binds to ammonium ions to form an ion-pair complex (II) equilibrated with a dihydrido complex (III) , as shown in Eq. 10.[25] Additive bases having a strong coordinating ability, e.g. ethylenediamine, easily coordinate to Rh clusters to promote H_2 generation,[26] while additives with methyl groups on nitrogen atoms, e.g., TMPDA, can not greatly activate an intermediate species III, because of their weak coordination. Therefore, nitro compounds, oximes,



(II) (III) (IV) (10)

M=$[Rh_x(CO)_y]^{n-}$

hydroxylamimes, and amine oxides can react with the carbonyl moiety on both species of II and/or III to give deoxygenated products. Presumably, a nucleophilic oxygen attack of N-O bonds might favor the species of III over the II because the carbon atom of the CO moieties within the III species are more cationic than that of II. In the course of the deoxygenation of nitrobenzene using TMPDA or 4-(dimethylamino)-pyridine at 80 °C under 700 mmHg of CO, H_2 could not be detected and WGSR did not occur without adding nitrobenzene. Furthermore, using the catalyst system of $Rh_6(CO)_{16}$ and 4-(dimethylamino)-pyridine, only 6% nitrobenzene was reduced at 80 °C during 4 h under 700 mmHg of H_2. It can be said that deoxygenation occurs mainly not with molecular hydrogen, but with $CO+H_2O$ acting as the reducing agent.[27]

Conclusions

The catalyst system of $Rh_6(CO)_{16}$ *N,N,N′,N′*-tetramethy-1,3-propanediamine shows high activity for the deoxygenation of various N-O bonds, e.g., nitro compounds, oximes, hydroxylamines, and amine oxides in the presence of H_2O and CO. Notably, a formal dehydration of oximes to nitriles occurred selectively, even in aqueous media. The unique deoxygenation is due to the strong deoxygenating ability of the CO moiety within the Rh clusters. The Rh catalyst system can be heterogenized by using amino-substituted polystyrenes. The functions of the amines on the polymer are summarized as follows: 1) generation of OH^- in aqueous media to yield Rh-cluster anions, 2) stabilization and heterogenization of the Rh-cluster anions by forming ion-pairs, and 3) control for the reaction course through coordination of amines to Rh clusters. On the basis of the present study, we are now developing a new methodology of organic synthesis in aqueous media.

Experimental

$RhCl_3 \cdot 3H_2O$, $Fe(CO)_5$, $Mo(CO)_5$, $W(CO)_6$ were commercially available. $RhCl(PPh_3)_3$,[28] $Rh_2(CO)_4Cl_2$,[29] $Rh_4(CO)_{12}$,[30], $Rh_6(CO)_{16}$,[31] and $Ru_3(CO)_{12}$[32] were prepared by methods described in the literature. 3-Phenyl-1-nitropropane,[33] tripropylamine *N*-oxide,[34] *N,N*-dimethylaniline *N*-oxide,[35] all oximes,[36] propionaldehyde *O*-methyloxime,[37] and *N*-cyclohexylidenecyclohexylamine[38] were prepared according to published procedures. Other nitro compounds, hydroxylamines, and amine oxides were commercially available. All amines and pyridines used were also commercially available. Chloromethylated polystyrenes with M_w=7600, 8600, and 52700 were available from Toso Chemical Co. Elemental analyses were performed by Yanagimoto CHN-CORDER MT-III. The ^1H NMR spectra were recorded at 100 MHz with a Nihondenshi-JEO-JNM 4H-100 spectrometer. Infrared spectra were obtained with a Hitachi EPI-G spectrometer. Analytical GLPC was performed with a Shimadzu GC-3BT or a Shimadzu GC-8A

with a flame ionization detector,a linear temperature programe, and a Shimadzu CHROMATOPAC CR-3A integrator. The columns used were ASC-H, Apiezon L, and OV-17 for the analysis of liquid products.

Preparation of Amino-Substituted Polystyrenes. Typical examples for the title preparation are shown below. For route 1: bulk polymerization of *p*-(chloromethyl)styrene and divinylbenzenes (98/2, v/v) was carried out at 100 °C using AIBN, followed by amination with *N,N*-dimethyl-1,3-propanediamine in dioxane at room temperature. The MeOH treatment gave an amino-substituted polymer with N 8.7%. Chloromethylated polystyrenes (Toso) were aminated with *N,N*-dimethyl-1,3-propanediamine in dioxane at room temperature, which is a simiar method to that of Lieto:[39] N, 7.1% for M_w=7700; N, 9.0% for M_w=8600; N, 7.0% for M_w=52700. For route 2: reaction of *p*-(chloromethyl)styrene (Seimi Chemical) with *N,N*-dimethyl-1,3-propanediamine gave *N,N*-dimethyl-*N'*-(4-vinylphenylmethyl)-1,3-propanediamine which was identified by elemental analysis, IR, and NMR. ^{1}H NMR ($CDCl_3$) δ=1.5—1.9 (2H, m, CH_2), 2.16 (1H, s, NH), 2.20 (6H, s, $N(CH_3)_2$), 2.34 (2H, t, J=6.5 Hz, NCH_2), 2.68 (2H, t, J=6.5 Hz, NCH_2), 3.77 (2H, s, Ph-CH_2) 5.1—5.9 (2H, m, =CH_2), 6.4—7.0 (1H, m, HC=), and 7.3 (4H, s, phenyl). Bulk copolymerization of the amino-substituted styrene and divinylbenzene (98/2, v/v) was carried out at 100 °C using AIBN. After a MeOH treatment, the obtained polymer showed 11.4% of N. The above-mentioned procedures are described in the literature.[40,41] Polymers having other amino moieties (**Ib—Id**) were prepared only by the method of route 1. **Ib**; N, 7.4%, **Ic**; N, 6.6%, **Id**; N, 5.3%.

General Procedure of the Water Gas Shift Reaction. The reaction vessel was a 25 ml flask with a sidearm sealed with silicone rubber. It was attached to a closed reaction system (510 ml) with a reflux condenser, a gas circulator, and a vent. The Rh compound was placed in the vessel. The reaction system was evacuated and flushed three times with CO and then charged at room temperature to an initial CO pressure of 700 mmHg. Amine, H_2O, and 2-ethoxyethanol were added to the vessel. The solution was heated with stirring to 100 °C. The gas above the dark-brown solution was periodically sampled and analyzed by gas chromatography (3 m column of activated carbon).

General Procedure of Deoxygenation of Nitrobenzene under 700 mmHg of CO. The reaction apparatus was similar to that in the case of previous WGSR.[5] The Rh compound was placed in the vessel; the reaction system was then evacuated and flushed thee times with CO and charged at room temperature to an initial CO pressure of 700 mmHg. Nitrobenzene, 2-ethoxyethanol, amine, and H_2O were successively added to the vessel. The solution was heated with stirring to 80 °C. Both the gas and liquid phases were sampled periodically and analyzed by gas chromatography. The results are shown in Tables 1 and 2.

General Procedure of Homogeneous Deoxygenation of Nitro Compounds, Oximes, Hydorxylamines, and Amine Oxides under CO Pressure. A stainless-steel autoclave containing a Rh complex and an amine additive was evacuated and flushed three times with CO. A substrate, H_2O, and a solvent were added. The reaction was carried out with stirring under apropriate conditions (4—16 atm of CO). After the reaction, the liquid phase was analyzed by GLPC. The results are summarized in Tables 3, 4, 6, and 7.

General Procedure for the Heterogeneous Deoxygenation of Nitro Compounds, Oximes, Hydroxylamines, and Amine Oxides under CO Pressure. A method similar to the above-mentioned homogeneous reactions was used for the title heterogeneous reactions. Amino-substituted polymers (**I**) were used in place of the soluble amines. After the reaction, a polymeric Rh complex was separated by filtration. The filtrate was analyzed by GLPC and then distillated to give pure products. The Results are summarized in Tables 3, 4, 6, 7, 8, and 9. A typical isolation procedure was used for 3-phenyl-1-nitropropane. A mixture of 3-phenyl-1-nitropropane (1.65 g 10 mmol), $Rh_6(CO)_{16}$ (0.107 g, 0.10 mmol), and an amino-substituted polymer (1.6 mg-atm of N, 0.32g) in H_2O (5.76 g) and 2-ethoxyethanol (4 ml) was stirred at 40 °C under 16 atm of CO for 48 h. After the polymer-bound Rh complex was removed by filtration, the filtrate was extracted with diethyl ether. The ether layer was washed with an aqueous NaCl solution and then dried. Kugelrohr distillation afforded 0.97 g of pure nitrile (74%).

IR Measurement of Polymer-Bound Rh Complexes. After deoxygenations, polymer-bound Rh complexes were filtered and washed with 2-ethoxyethanol. The Rh complexes in KBr were measured by IR spectroscopy. All of the above-mentioned procedure were carried out under a CO atmosphere. In the deoxygenation of nitrobenzene at 80 °C under 4 atm of CO, isolated dark-brown powders showed the formation of the $[Rh_{14}(CO)_{25}]^{4-}$ species on the amino-substituted polymer (Ia). IR ν_{co} 1969, 1814 cm^{-1} for $[Rh_{14}(CO)_{25}]^{4-}$.[42] In the deoxygenations of the aliphatic nitro compounds, oximes, hydroxylamines, and amine oxides at 40 °C under 8—16 atm of CO, dark-green polymer showed formations of $[Rh_6(CO)_{15}]^{2-}$ and $[Rh_6(CO)_{15}H]^-$ species. IR ν_{co} 1989, 1960, 1765 cm^{-1} for $[Rh_6(CO)_{15}]^{2-}$;[43] 2063, 2019 cm^{-1} for $[Rh_6(CO)_{15}H]^-$.[42] A treatment of the Rh_6 species with KOH and HCl under a nitrogen atmosphere gave the $[Rh_7(CO)_{16}]^{3-}$ and $Rh_6(CO)_{16}$ species, respectively. IR ν_{co} 1951, 1763 cm^{-1} for $[Rh_7(CO)_{16}]^{3-}$.[43] The above-mentioned values due to the CO stretching frequencies were compatible with the corresponding homogeneous Rh cluster complexes.[42,43]

Reduction of *N*-Cyclohexylidenecyclohexylamine Using $Rh_6(CO)_{16}$ in the Presence of CO and H_2O. A stainless-steel autoclave of 300 ml containing $Rh_6(CO)_{16}$ (0.05 mmol) and *N,N,N',N'*-tetramethyl-1,3-propanediamine (2 ml) was evacuated and flushed three times with CO. The titile Schiff base (5 mmol), H_2O (2.8 g), and 2-ethoxyethanol (2 ml) were then added. The reaction was carried out with stirring under 8 atm of CO at 40 °C. After 5 h, the liquid phase was analyzed to give 83% of dicyclohexylamine by GLPC.

***N*-Alkylation of Amines with Ketones Using $Rh_6(CO)_{16}$ in the Presence of CO and H_2O.** The reaction of cyclohexylamine with cyclohexanone is typical. A stainless-steel autoclave (300 ml) containing a Rh complex (53 mg, 0.05 mmol) was evacuated and flushed three times with CO. Cyclohexylamine (0.496 g, 5 mmol), cyclohexanone (0.491 g, 5 mmol), H_2O (1.40 g), and 2-ethoxyethanol (2 ml) were then added. The reaction was carried out with stirring at 80 °C under 8 atm of CO. After 5 h, the resulting mixture was subjected to chromatography with Silica gel (Wakogel 200). Dicyclohexylamine of 0.72 g (80%) was isolated from hexane-dichloromethane elution. The results are shown in Table 5.

We would like to thank M. Hiraki and M. Doken for their technical assistances. One of the authors, K. Kaneda greatly acknowledges Dr. Martinengo for his helpful information concerning the characterization of Rh carbonyl clusters.

Synthesis of α,ω-Diamino Acids via Amidocarbonylation Reaction: Novel Synthesis of Lysine, Ornithine, and Their Analogs

Yusuke AMINO and Kunisuke IZAWA*
Central Research Laboratories, Ajinomoto Co., Inc., 1-1, Suzuki-cho, Kawasaki-ku, Kawasaki 210
(Received September 18, 1990)

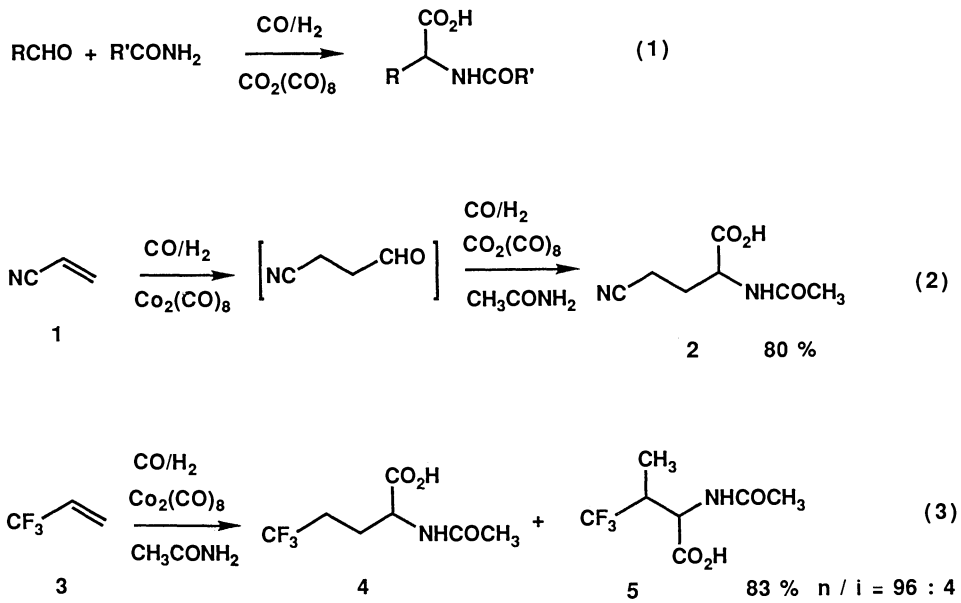
α,ω-Diamino acid derivatives, such as lysine and ornithine, were synthesized via amidocarbonylation (cobalt-catalyzed formation of *N*-acyl α-amino acid from aldehyde, amide and carbon monoxide) of ω-(phthalimido)alkanals in good yield. The phthalimido group was proved to be intact under the conditions of amidocarbonylation. The hydroformylation-amidocarbonylation of *N*-phthaloyl-β,γ- and *N*-phthaloyl-γ,δ-unsaturated amines proceeds very nicely to give α,ω-diamino acid derivatives with good selectivity. Selective deprotection of α-*N*-acyl-ω-*N*-phthaloyl α,ω-diamino acids was achieved using hydrazine for the *N*-phthaloyl group and aminoacylase for the *N*-acetyl group to afford the optically active α,ω-diamino acid, respectively.

The Cobalt-catalyzed amidocarbonylation (Eq. 1) discovered by Wakamatsu et al. in 1971 provides a versatile method for the synthesis of α-amino acids, including a variety of nonproteinogenic α-amino acids, from aldehyde, amide and carbon monoxide.[1] Since the reaction conditions of amidocarbonylation are almost the same as those of hydroformylation, except for the coexistence of an amide, it is possible to combine the two reactions. In fact, 2-acetamido-4-cyanobutyric acid (**2**) was synthesized from acrylonitrile (**1**) in one-pot reactions with high selectivity (Eq. 2).[2] Recently, Ojima et al. also reported that the extremely regioselective hydroformylation of trifluoropropene (**3**) was successfully combined with the amidocarbonylation to give *N*-acetyltrifluoronorvaline (**4**) with 96% selectivity (Eq. 3).[3]

As a continuation of our work directed toward the preparation of nonproteinogenic α-amino acid,[4] we intended to synthesize α,ω-diamino acids, such as lysine, ornithine and their analogs, via the amidocarbonylation of *N*-protected ω-aminoalkanals or the hydroformylation-amidocarbonylation of *N*-protected unsaturated amines.

Results and Discussion

Synthesis of Lysine, Ornithine, and Their Analogs. The choice of the *N*-protecting group was important to successfully achieve the preparation of α,ω-diamino acid derivatives from ω-aminoalkanals or unsaturated amines. We have revealed that the intramolecular amidocarbonylation of ω-(acylamino)alkanals takes place nicely to give *N*-acyl cyclic α-amino acids in good yield.[5] Furthermore, we have found that cobalt-catalyzed carbonylation of *N*-benzoylallylamine (**6**) affords 2-benzamidobutyric acid (**7**) and 3-benzamido-2-methylpropionic acid (**8**) as well as *N*-benzoylproline (**9**) (Eq. 4).[5] The formation of **7** and



Scheme 1.

8 can be explained by the facile migration of the cobalt carbonyl moiety from the β- or γ-position to the α- or β-position of the amido group followed by CO insertion and subsequent hydrolysis.[6] Accordingly, the *N*-acyl group is inadequate as the protecting group of amino group for synthesizing the α,ω-diamino acid.

On the other hand, hydroformylation of *N*-phthaloylallylamine was previously studied by some groups,[7] in which such side reactions as migration or cyclization have not been observed. Moreover, Sato has reported that the hydroformylation of *N*-phthaloylallylamine (**10a**) took place regioselectively to give linear aldehyde, 4-phthalimidobutanal (**11a**) as the sole product.[7a] We therefore examined the synthesis of α,ω-diamino acid from ω-aminoalkanals by choosing the phthaloyl group as the N-protecting group. The results are given in equation 6.

It was thus found that the phthalimido group was intact under the conditions of amidocarbonylation and the derivatives of lysine (**13b**) and ornithine (**13a**) were obtained in moderate yield, regardless of the length of the alkyl chain and the kind of amide used.

Next, we examined the synthesis of α,ω-diamino acid derivatives from *N*-phthaloyl unsaturated amines (**10**) via hydroformylation followed by subsequent amidocarbonylation (Eq. 7). The results are shown in Table 1.

As Table 1 shows, the cobalt-catalyzed carbonylation of *N*-phthaloylallylamine (**10a**) in the presence of benzamide (initial pressure at 25 °C: CO, 65 atm; H_2, 60 atm) at 100 °C for 6 h gave α-*N*-benzoyl-δ-*N*-phthaloylornithine (**13a**) with more than 80% selectivity in 71% yield (Run 1). The reaction of the longer homolog, *N*-phthaloyl-3-butenylamine (**10b**) afforded α-*N*-acyl-ε-*N*-phthaloyllysine (**13b,c**) in similar yield (Runs 3 and 4). As shown in the previous cases, linear isomers were obtained in good selectivity, regardless of the length of the alkyl chaines and the kind of amide. The introduction of a substitution group at the 1- or 2-position of the allyl moiety of **10a** remarkably improved the selectivity (Runs 6 and 7) to give methyl substituted ornithine derivatives. Similarly, the reaction of methyl 2-phthalimido-4-pentenoate (*N*-phthaloylallylglycine methyl ester) gave the 2,6-diaminoheptandioic acid derivative with more than 95% selectivity (Run 5). As shown in the entries, since *N*-phthaloylallylamine derivatives did not give isomerization-carbonylation products, the difference in the phthalimido and acylamino groups in the cobalt-catalyzed carbonylation was revealed.

Sato exclusively obtained a linear aldehyde (**11a**) during the hydroformylation of *N*-phthaloylallylamine,[7a] whereas, in the hydroformylation-amidocarbonylation of the same substrate, we obtained a linear

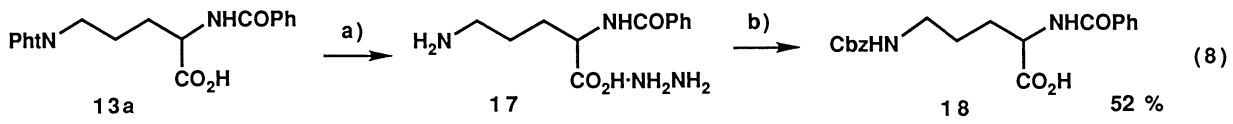
a) Determined by ^{1}H NMR. Obtained by oxydation of alcohols with DMSO-SO_3·Py-Et_3N.
b) Isolated yield after esterification with CH_2N_2. c) *N*-Benzoyl-2-piperidinecarboxylic acid (20%) and α,ε-*N*,*N*′-dibenzoyllysine (3%) were also obtained.

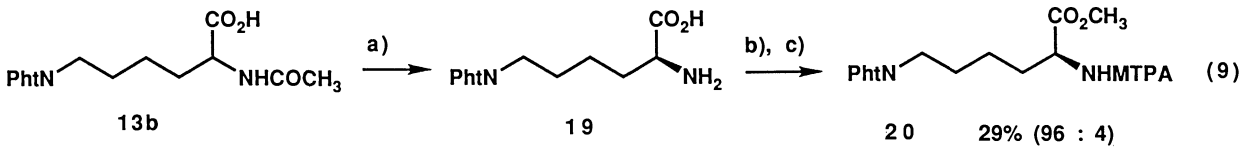
(**13**) and branched (**14**) product (derived from a terminal and internal hydroformylated intermediate, respectively) in the ratio of *ca.* 5 : 1 (Run 1). We thought that the decrease in regioselectivity during the hydroformylation step should be attributed to the coexistence of the amide. To confirm our estimation, after the hydroformylation was almost completed acetamide was added and the reaction resumed (Run 2). The ratio of the linear and branched products was increased to 12 : 1. It is presumed that the property of the cobalt hydridocarbonyl catalyst or the solvent may be affected by the coexistence of the amide, which resulted in the decrease of the regioselectivity of hydroformylation. A similar result was previously observed in the hydroformylation-amidocarbonylation of isobutene.[6]

Since *N*-phthaloyl unsaturated amines (**10**) are easily obtained from the corresponding unsaturated alcohols or unsaturated amines, the hydroformylation-amidocarbonylation of **10** revealed a useful method for the synthesis of nonproteinogenic α-amino acid analogs of lysine and ornithine.

Synthesis of α,β-Diamino Acid Derivatives. We also examined the synthesis of α,β-diamino acid via



Reagents : a) 2eq NH_2NH_2, MeOH, Δ ; b) CbzCl, $NaHCO_3$, H_2O-ether.



Reagents : a) acylase ; b) MTPACl, Na_2CO_3 ; c) CH_2CN_2.

Scheme 4.

amidocarbonylation starting from N-protected α-aminoalkanals (**15**), which are easily obtained from α-amino acids.[8] The preparation of β-functionalyzed α-amino acid via the amidocarbonylation of an α-functionalyzed aldehyde, such as 2-acetoxypropanal, has not yet been successful.[6] The results are shown in Table 2.

The yield of α,β-diamino acid derivatives (**16**) was not very satisfactory when compared with the α,ω-diamino acid derivatives (**13**). This low yield would be ascribed to the liability of the N-protected α-aminoalkanal (**15**) under the reaction conditions. Also, α-(phthalimido)alkanals, *N*-benzoyl- and *N*-benzyloxycarbonyl-2-pyrrolidinecarbaldehyde gave the corresponding α,β-diamino acid derivatives. However, except for the 2-pyrrolidinecarbaldehyde derivatives, the reactions of the *N*-benzoyl or *N*-benzyloxycarbonyl derivatives of acyclic α-aminoalkanal were unsuccessful. The choice of the protective group was also important to successfully achieve the preparation of α,β-diamino acid derivatives. Disappointingly, α,β-diamino acid derivatives were a diastereoisomeric mixture, in spite of the fact that optically active *N*-protected α-aminoalkanals were used; thus, the 1,2-asymmetric induction was not achieved in this process.

Selective Deprotection of α,ω-Diamino Acid Derivatives. The α,ω-diamino acid derivatives, thus obtained, should be very useful compounds, since the two amino groups are protected by different groups which can be selectively removed by conventional methods. Equation 8 shows the selective removal of the ω-phthaloyl group. The treatment of **13a** with hydrazine in methanol gave the α-*N*-benzoyl, ω-free diamino acid derivative (**17**), which was further transformed into α-*N*-benzoyl-ω-*N*-benzyloxycarbonyl-ornithine (**18**).

It is worth noting that an enantioselective hydrolysis of **13b** can be achieved by an enzyme (aminoacylase) to give ω-phthaloyl-L-lysine (**19**) in moderate yield, as shown in Eq. 9. Its optical purity proved to be more than 92% by ^1H NMR and HPLC studies after transformation to **20** by a treatment with Mosher's acid chloride, followed by esterification.

In conclusion, the synthesis of α,ω-diamino acid derivatives was achieved via the amidocarbonylation of the ω-(phthalimido)alkanals and the hydroformylation–amidocarbonylation of *N*-phthaloyl unsaturated amines. A new application of amidocarbonylation to the preparation of nonproteinogenic α-amino acid was represented.

Experimental

^1H NMR spectra were measured with a Varian XL 300 spectrometer and chemical shifts are given as δ ppm relative to tetramethylsilane (TMS) or sodium 3-trimethylsilylpropionate-2,2,3,3-d_4 (TPS) as an internal standard. Infrared (IR) spectra were recorded on a Hitachi 260-10 spcctrophotometer with samples as neat liquid or in KBr disks. Mass spectra (MS) were recorded with a JEOL DX-300 instrument by using the FAB technique. The melting points were determined with a Yanaco micro melting point apparatus and are uncorrected. GC–MS was performed on a HP 5890A-5970B with a high-performance capillary column (cross-linked methyl silicone). The thin-layer chromatographic system employed on silica gel (Merck Art. 7515). PTLC was performed with a Whatman PLK 5F. HPLC was performed on a GILSON 303 with a YMC-A312 (ODS 6×150 mm) column with a mobil phase composed of 70% MeOH-H_2O, at 25 °C. The elution rate was 0.5 ml min^{-1} and detection was carried out at ultraviolet (UV) 254 nm.

Amidocarbonylation of ω-(Phthalimido)alkanals (11). A typical procedure is described for the reaction of 4-phthalimidopentanal (**11b**) catalyzed by $Co_2(CO)_8$.

4-Phthalimidopentanal (**11b**) (1.28 g, 5.56 mmol), acetamide (328 mg, 5.56 mmol), and $Co_2(CO)_8$ (100 mg, 0.29 mmol)

were heated in a 100 ml stainless-steel autoclave with a 1 : 1 mixture of carbon monoxide and hydrogen (total pressure 120 atm, measured at room temperature) at 100 °C for 3.5 h. The autoclave was then cooled to ambient temperature and carbon monoxide and hydrogen purged out. After the solvent was removed under reduced pressure, the residue was dissolved in AcOEt (50 ml) and the insoluble material filtered off. The filtrate was extracted with 10% aqueous $NaHCO_3$ (50 ml) and the extract washed with AcOEt. Then, the aqueous phase was acidified with concentrated HCl and extracted with AcOEt (50 ml). The organic layer was washed with brine and dried over $MgSO_4$. After concentration, the residue was washed with hexane-AcOEt (1 : 1, v/v) to give α-*N*-acetyl-ε-*N*-phthaloyllysine (**13b**) as a solid (1.24 g, 3.90 mmol, 70.1%).

α-*N*-Acetyl-ε-*N*-phthalylolysine (13b): ^{1}H NMR (300 MHz, DMSO-d_6) δ=1.28—1.40 (2H, m, CH_2), 1.50—1.75 (4H, m, CH_2), 1.80 (3H, s, CH_3), 3.55 (2H, t, *J*=7.0 Hz, CH_2), 4.07—4.15 (1H, m, CH), 7.82—7.89 (4H, m, aromatic H), 8.05 (1H, d, *J*=7.6 Hz, NH); IR (KBr) 3300, 3050, 2940, 1770, 1700, 1645, 1540, 1395, 1370, 1295, 1155, 1050, 720 cm^{-1}; mp 170—172 °C (from hexane-AcOEt) ; High mass (FAB) *m/z* Calcd for $C_{16}H_{18}N_2O_5$+H: 319.1294. Found: 319.1301.

α-*N*-Benzoyl-δ-*N*-Phthaloylornithine (13a): ^{1}H NMR (300 MHz, DMSO-d_6) δ=1.60—1.85 (4H, m, CH_2), 3.62 (2H, t, *J*=5.9 Hz, CH_2), 4.35—4.45 (1H, m, CH), 7.43—7.57 (4H, m, aromatic H), 7.80—7.89 (5H, m, aromatic H), 8.57 (1H, d, *J*=7.7 Hz, NH); IR (KBr) 3350, 2940, 1780, 1710, 1645, 1520, 1400, 1050, 720 cm^{-1}; mp 190—193 °C (from hexane-AcOEt); High mass (FAB) *m/z* Calcd for $C_{20}H_{18}N_2O_5$+H: 367.1294. Found; 367.1294.

Hydroformylation-Amidocarbonylation of *N*-Phthaloyl Unsaturated Amines (10). A typical procedure is described for the reaction of *N*-phthalyl-3-butenylamine (**10b**) catalyzed by $Co_2(CO)_8$.

N-Phthalyl-3-butenylamine (**10b**) (1.0 g, 4.97 mmol), benzamide (602 mg, 4.97 mmol), and $Co_2(CO)_8$ (100 mg, 0.29 mmol) in THF (20 ml) were heated in a 100 ml stainless-steel autoclave with a 1 : 1 mixture of carbon monoxide and hydrogen (total pressure 120 atm, measured at room temperature) at 100 °C for 6 h. The autoclave was then cooled to ambient temperature and carbon monoxide and hydrogen purged out. After the solvent was removed under reduced pressure, the residue was dissolved in AcOEt (50 ml) and the insoluble material filtered off. The filtrate was extracted with 10% aqueous $NaHCO_3$ (50 ml) and the extract washed with AcOEt. The aqueous phase was acidified with concentrated HCl and then extracted with AcOEt (50 ml). The organic layer was washed with brine and dried over $MgSO_4$. After concentration, the residue was esterified with etherial CH_2N_2 to give α-*N*-benzoyl-ε-*N*-phthaloyllysine methyl ester (methyl ester of **13c**) (1.33 g, 3.36 mmol, 67.6%) as a solid.

α-*N*-Benzoly-ε-*N*-phthaloyllysine Methyl Ester (Methyl Ester of 13c): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.35—2.10 (6H, m, CH_2), 3.70 (2H, t, *J*=7.2 Hz, CH_2), 3.78 (3H, s, CH_3), 4.75—4.83 (1H, m, CH) , 6.75 (1H, d, *J*=7.2 Hz, NH), 7.40—7.55 (4H, m, aromatic H), 7.65—7.85 (5H, m, aromatic H), minor isomer 1.04 (1.5H, d, *J*=6.6 Hz, CH_3), 1.10 (1.5H, d, *J*=6.6 Hz, CH_3); IR (KBr) 3320, 2950, 1770, 1745, 1710, 1635, 1395, 1335, 1215, 1160, 720 cm^{-1}; GC-MS *m/z* 335 (M^+−59); mp 112—114 °C (from hexane-AcOEt); High mass (FAB) *m/z* Calcd for $C_{22}H_{22}N_2O_5$+H: 395.1607. Found; 395.1611.

α-*N*-Acetyl-ε-*N*-phthaloyllysine Methyl Ester (Methyl Ester of 13b): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.25—1.90 (6H, m, CH_2), 3.68 (2H, t, *J*=7.0 Hz, CH_2), 3.73 (3H, s, CH_3), 4.53—4.61 (1H, m, CH), 6.15 (1H, d, *J*=7.3 Hz, NH), 7.68—7.88 (4H, m, aromatic H), minor isomer 0.95 (1.5 H, d, *J*=6.8 Hz, CH_3), 1.02 (1.5 H, d, *J*=6.8 Hz, CH_3); IR (KBr) 3300, 3080, 2950, 2860, 1765, 1740, 1700, 1645, 1540, 1435, 1400, 1375, 1345, 1295, 1220, 1155, 1055, 720 cm^{-1}; GC-MS *m/z* 300 (M^+−18); 289 (M^+−29), 273 (M^+−45); mp 117—119 °C (from hexane-AcOEt); High mass (FAB) *m/z* Calcd for $C_{17}H_{20}N_2O_5$+H: 333.1451. Found 333.1445.

α-*N*-Benzoyl-δ-*N*-phthaloylornithine Methyl Ester (Methyl Ester of 13a): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.70—2.05 (4H, m, CH_2), 3.72 (2H, br. t, *J*=6.6 Hz, CH_2), 3.76 (3H, s, CH_3), 4.83—4.90 (1H, m, CH), 6.75 (1H, d, *J*=7.8 Hz, NH), 7.40—7.55 (4H, m, aromatic H), 7.65—7.90 (5H, m, aromatic H), minor isomer 0.98 (1.5 H, d, *J*=6.9 Hz, CH_3), 1.13 (1.5H, d, *J*=6.9 Hz, CH_3); IR (neat) 2950, 1770, 1740, 1700, 1650, 1520, 1440, 1395, 1210, 1040 cm^{-1}; GC-MS *m/z* 321 (M^+−59); High mass (FAB) *m/z* Calcd for $C_{21}H_{20}N_2O_5$+H: 381.1451. Found: 381.1434.

Dimethyl 2-Benzamido-6-phthalimidoheptandioate (Methyl Ester of 13d): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.30—2.35 (6H, m, CH_2), 3.72 (6H, s, CH_3), 4.70—4.90 (2H, m, CH), 6.64 (1H, br. t, *J*=7.0 Hz, NH), 7.35—7.55 (4H, m, aromatic H), 7.70—7.85 (5H, m, aromatic H); IR (neat) 2950, 1770, 1740, 1710, 1640, 1520, 1430, 1380, 1240 cm^{-1}; GC-MS *m/z* 393 (M^+−59); High mass (FAB) *m/z* Calcd for $C_{24}H_{24}N_2O_7$+H: 453.1662. Found: 453.1636.

α-*N*-Benzoyl-ε-methyl-ε-*N*-phthaloyllysine Methyl Ester (Methyl Ester of 13g): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.46 (1.5 H, d, *J*=6.8 Hz, CH_3), 147 (1.5 H, d, *J*=6.9 Hz, CH_3), 1.69—2.20 (6H, m, CH_2), 3.70 (1.5H, s, CH_3), 3.71 (1.5H, s, CH_3), 4.38—4.40 (1H, m, CH), 4.70—4.80 (1H, m, CH), 6.65 (1H, br.s, NH), 7.35—7.55 (4H, m, aromatic H), 7.63—7.85 (5H, m, aromatic H); IR (neat) 2950, 2860, 1770, 1740, 1710, 1360, 1325, 1210, 1160, 1040 cm^{-1}; GC-MS *m/z* 408 (M^+), 373 (M^+−32), 349 (M^+−59); High mass (FAB) *m/z* Calcd for $C_{23}H_{24}N_2O_5$+H: 409.1763. Found: 409.1781.

α-*N*-Benzoyl-δ-methyl-δ-*N*-phthaloylornithine Methyl Ester (Methyl Ester of 13f): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.46 (1.5H, d, *J*=6.8 Hz, CH_3), 1.47 (1.5H, d, *J*=6.8 Hz, CH_3), 1.80—1.91 (2H, m, CH_2), 2.14—2.35 (2H, m, CH_2), 3.73 (1.5H, s, CH_3), 3.77 (1.5H, s, CH_3), 4.30—4.42 (1H, m, CH), 4.78—4.88 (1H, m, CH), 6.70 (0.5H, d, *J*=7.7 Hz, NH), 6.76 (0.5H, d, *J*=7.5 Hz, NH), 7.40—7.55 (4H, m, aromatic H), 7.68—7.85 (5H, m, aromatic H); IR (KBr) 3320, 2950, 1770, 1740, 1695, 1630, 1520, 1385, 1360, 1200, 1050, 720 cm^{-1}; GC-MS *m/z*: 394 (M^+), 362 (M^+−32), 335 (M^+−59); mp 120—124 °C (from hexane-AcOEt); High mass (FAB) *m/z* Calcd for $C_{22}H_{22}N_2O_5$+H: 395.1607. Found: 395.1594.

α-*N*-Benzoyl-γ-methyl-δ-*N*-phthaloylornithine Methyl Ester (Methyl Ester of 13e): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.05 (3H, d, *J*=6.8 Hz, CH_3), 1.70—1.90 (2H, m, CH_2), 2.12—2.25 (1H, m, CH) , 3.58—3.67 (2H, m, CH_2), 3.74 (1.5H, s, CH_3), 3.75 (1.5H, s, CH_3), 4.87—4.95 (1H, m, CH), 6.80 (1H, br.s, NH), 7.18 (1H, br.s, NH), 7.35—7.55 (4H, m, aromatic H), 7.65—7.90 (5H, m, aromatic H); IR (neat) 3060, 2950, 1770, 1740, 1710, 1650, 1530, 1440, 1400, 1360, 1210, 1050 cm^{-1}; GC-MS *m/z* 394 (M^+), 362 (M^+−32), 335 (M^+−59); High mass (FAB) *m/z* Calcd for $C_{22}H_{22}N_2O_5$+H: 395.1607. Found 395.1604.

Amidocarbonylation of *N*-Protected α-Aminoalkanal

Derivatives (15). A typical procedure is described for the reaction of *N*-(2,2-diethoxyethyl)phthalimido (**15a**) catalyzed by $Co_2(CO)_8$.

N-(2,2-Diethoxyethyl)phthalimido (**15a**) (1.0 g, 3.8 mmol), benzamide (460 mg, 3.8 mmol), and $Co_2(CO)_8$ (100 mg, 0.29 mmol) in THF (20 ml) were heated in a 100 ml stainless-steel autoclave with a 1:1 mixture of carbon monoxide and hydrogen (total pressure 120 atm, measured at room temperature) at 100 °C for 6 h. The autoclave was then cooled to ambient temperature and carbon monoxide and hydrogen were purged out. After the solvent was removed under reduced pressure, the residue was dissolved in AcOEt (50 ml) and the insoluble material filtered off. The filtrate was washed with 10% aqueous $NaHCO_3$ (50 ml) and brine. The organic phase was dried over $MgSO_4$. The solvent was removed under reduced pressure and the residue purified by PTLC (hexane:AcOEt=3;5, v/v) to give ethyl 2-benzamido-3-phthalimidopropionate (ethyl ester of **16a**) (113 mg, 0.31 mmol, 8.1%) as an oil. The aqueous $NaHCO_3$ extract was acidified with concentrated HCl and extracted with AcOEt (50 ml). The organic layer was washed with brine and dried over $MgSO_4$. After concentration, the residue was esterified with etherial CH_2N_2 and purified by PTLC (hexane:AcOEt=3:5, v/v) to give methyl 2-benzamido-3-phthalimidopropionate (meihyl ester of **16a**) (662 mg, 1.88 mmol, 49.5%) as a solid.

Methyl 2-Benzamido-3-phthalimidopropionate (Methyl Ester of 16a): ^{1}H NMR (300 MHz, $CDCl_3$) δ=3.81 (3H, s, CH_3), 4.20—4.30 (2H, m, CH_2), 5.00—5.10 (1H, m, CH), 7.32 (1H, br.d, J=6.7 Hz, NH), 7.40—7.55 (4H, m, aromatic H), 7.70-7.90 (5H, m, aromatic H); IR (KBr) 3300, 2950, 1770, 1710, 1640, 1525, 1425, 1390, 1320, 1215, 1020, 900, 720 cm^{-1}; GC-MS m/z 293 (M^+−59); mp 123—125 °C (from hexane-AcOEt); High mass (FAB) m/z Calcd for $C_{19}H_{16}N_2O_5$+H: 353.1137. Found: 353.1138.

Ethyl 2-Benzamido-3-phthalimidopropionate (Ethyl Ester of 16a): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.30 (3H, t, J=6.8 Hz, CH_3), 4.15—4.30 (4H, m, CH_2), 5.00—5.08 (1H, m, CH), 7.30 (1H, br.d, J=6.7 Hz, NH), 7.40—7.55 (4H, m, aromatic H), 7.70—7.90 (5H, m, aromatic H); IR (neat) 3320, 2950, 1765, 1710, 1640, 1525, 1390, 1020 cm^{-1}; GC-MS m/z 293 (M^+−73).

Methyl 2-Benzamido-5-methyl-3-phthalimidohexanoate (Methyl Eester of 16b): ^{1}H NMR (300 MHz, $CDCl_3$) δ= 0.89—0.96 (6H, m, CH_3), 1.63—1.70 (2H, m, CH_2), 2.13—2.23 (0.5H, m, CH), 2.63 (0.5H, td, J=11.7 and 1.8 Hz, CH), 3.66 (1.5H, s, CH_3), 3.79 (1.5H, s, CH_3), 4.80—4.92 (0.5H, m, CH), 5.03—5.12 (1H, m, CH), 5.20 (0.5H, dd, J=8.6 and 4.8 Hz, CH), 7.11 (0.5H, d, J=7.5 Hz, NH), 7.41—7.56 (3H, m, aromatic H), 7.72—7.89 (5H, m, aromatic H), 7.97—8.00 (1H, m ,aromatic H), 8.39 (0.5H, d, J=8.6 Hz, NH); IR (neat) 2950, 1770, 1740, 1705, 1660, 1520, 1360, 1210, 1160, 1065 cm^{-1}; GC-MS m/z 377 (M^+−31), 349 (M^+−59); High mass (FAB) m/z Calcd for $C_{23}H_{24}N_2O_5$+H: 409.1763. Found: 409.1739.

Methyl 2-Benzamido-4-phenyl-3-phthalimidobutyrate (Methyl Ester of 16c): ^{1}H NMR (300 MHz, $CDCl_3$) δ=3.21—3.47 (2H, m, CH_2), 3.64 (1.5H, s, CH_3), 3.81 (1.5H, s, CH_3), 5.12 (0.5H, quint, J=5.4 Hz, CH), 5.20—5.29 (1.5H, m, CH), 7.10—7.20 (6H, m, NH and aromatic H), 7.40—7.58 (3H, m, aromatic H), 7.67—7.83 (5H, m, aromatic H), 8.03—8.06 (1H, m, aromatic H), 8.53 (0.5H, d, J=8.3 Hz, NH); IR (neat) 3030, 2950, 1775, 1740, 1710, 1660, 1520, 1485, 1385, 1360, 1210 cm^{-1}; GC-MS m/z 411 (M^+−31), 383 (M^+−59); High mass (FAB) m/z Calcd for $C_{26}H_{22}N_2O_5$+H: 443.1607. Found: 443.1592.

Methyl 2-Benzamido-2-(*N*-benzoylpyrrolidine-2-yl)ethanoate (Methyl Ester of 16e): ^{1}H NMR (300 MHz, $CDCl_3$) δ= 1.40—2.28 (3H, m, CH_2), 2.32—2.45 (1H, m, CH_2), 3.35—3.60 (2H, m, CH_2), 3.78 (1.5H, s, CH_3), 3.83 (1.5H, s, CH_3), 4.25 (0.5H, d, J=5.0 Hz, CH), 4.59—5.05 (1.5H, m, CH), 7.35—7.65 (6H, m, aromatic H), 7.70—7.98 (4H, m, aromatic H), 8.20 (0.5H, d, J=5.6 Hz, NH), 9.16 (0.5 H, d, J=7.9 Hz, NH); IR (neat) 3055, 2950, 1735, 1650, 1575, 1520, 1480, 1415, 1205 cm^{-1}; GC-MS m/z 335 (M^+−31), 307, (M^+−59); High mass (FAB) m/z Calcd for $C_{21}H_{22}N_2O_4$+H: 367.1658. Found: 367.1635.

***α,ε-N,N′*-Dibenzoyllysine Methyl Ester:** ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.38—2.05 (8H, m, CH_2), 3.38—3.52 (2H, m, CH_2), 3.76 (3H, s, CH_3), 4.75—4.85 (1H, m, CH), 6.55 (1H, br.s, NH), 7.00 (1H, d, J=7.3 Hz, NH), 7.30—7.55 (6H, m, aromatic H), 7.70—7.88 (4H, m, aromatic H); IR (neat) 3070, 2950, 1753, 1640, 1535, 1490, 1440, 1310, 1210 cm^{-1}; GC-MS m/z 368 (M^+), 336 (M^+−32), 309 (M^+−59).

Methyl *N*-Benzoyl-2-piperidinecarboxylate: ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.35—1.85 (4H, m, CH_2), 2.20 (0.5H, br.d, CH_2), 2.35 (1H, br.d, CH_2), 2.85 (0.5H, m,CH_2), 3.25 (1H, br.t, CH_2), 3.65 (1H, br.d, CH_2), 3.78 (3H, br.s, CH_3), 4.45—4.70 (0.5H, m, CH), 5.50 (0.5H, br.s, CH), 7.40 (5H, br.s, aromatic H); IR (neat) 2950, 2860, 1740, 1640, 1420, 1280, 1210 cm^{-1}; GC-MS m/z 247 (M^+); High mass (FAB) m/z Calcd for $C_{14}H_{17}N_1O_3$+H: 248.1287. Found 248.1278.

Methyl 2-Benzamido-2-(*N*-benzyloxycarbonylpyrrolidine-2-yl)ethanoate, (Methyl Ester of 16d): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.70—2.10 (3H, m, CH_2), 2.20—2.30 (1H, m, CH_2), 3.25—3.65 (2H, m, CH_2), 3.67 (1.5H, s, CH_3), 3.78 (1.5H, s, CH_3), 4.25—4.55 (1.5H, m, CH), 4.84 (0.5H, dd, J=7.5 and 2.4 Hz, CH), 5.07—5.22 (2H, m, CH_2), 7.20—7.55 (8H, m, aromatic H), 7.80—7.95 (2H, m, aromatic H), 8.24 (0.5H, br.d, J=4.2 Hz, NH), 8.84 (0.5H, d, J=7.2 Hz, NH); IR (neat) 2945, 1753, 1690, 1655, 1520, 1480, 1405, 1350, 1330, 1200, 1100 cm^{-1}; GC-MS m/z 365 (M^+−31), 204 (M^+−192); High mass (FAB) m/z Calcd for $C_{22}H_{24}N_2O_5$+H: 397.1763. Found 397.1766.

Deprotection of ω-*N*-Phthaloyl Group. α-*N*-Benzoyl-δ-*N*-phthaloylornithine (**13a**) (500 mg, 1.42 mmol) and hydrazine monohydrate (2.84 mmol) in MeOH (10 ml) were heated at 80 °C for 1 h. The solvent was removed under reduced pressure. The residue was dissolved in aqueous HCl and an insoluble material was filtered off. The filtrate was concentrated under reduced pressure and washed with AcOEt to give α-*N*-benzoylornithine hydrazine salt (**17**) (319 mg, 1.19 mmol, 83.8%) as a solid.

α-*N*-Benzoylornithine Hydrazine Salt (17): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.75—2.08 (4H, m,CH_2), 3.07 (2H, t, J=7.5 Hz, CH_2), 4.43 (1H, dd, J=8.0 and 5.2 Hz, CH), 7.50—7.70 (3H, m, aromatic H), 7.78—7.84 (2H, m, aromatic H); IR (KBr) 3345, 2950, 1635, 1600, 1530, 1400, 1365, 1300 cm^{-1}; mp 226—228 °C (from H_2O-MeOH); High mass (FAB) m/z Calcd for $C_{12}H_{16}N_2O_3$+H: 237.1239. Found: 237.1257.

α-*N*-Benzoylornithine hydrazine salt (**17**) (319 mg), $NaHCO_3$ (706 mg, 8.4 mmol), and benzyloxycarbonyl chrolide (toluene solution, 4.2 mmol) in H_2O (15 ml) and ether (10 ml) were stirred at room temperature for 15 h. The reaction mixture was washed with ether and acidified with concentrated HCl. The solution was extracted with AcOEt and the extract washed with brine, then dried over $MgSO_4$. After concentration, the residue was washed with hexane-

AcOEt to give α-*N*-benzoyl-δ-*N*-benzyloxycarbonylornithine (**18**) (275 mg, 0.74 mmol, 52.2%) as a solid.

α-*N*-Benzoyl-δ-*N*-benzyloxycarbonylornithine (18): ^{1}H NMR (300 MHz, DMSO-d_6) δ=1.45—1.60 (2H, m, CH_2), 1.70—1.90 (2H, m, CH_2), 2.98—3.07 (2H, m, CH_2), 4.30—4.40 (1H, m, CH), 5.00 (2H, s, CH_2), 7.20—7.58 (8H, m, aromatic H), 7.85—7.92 (2H, m, aromatic H), 8.57 (1H, d, *J*=8.1 Hz, NH); IR (KBr) 3310, 2940, 1700, 1680, 1630, 1530, 1250 cm^{-1}; mp 133—135 °C (from hexane-AcOEt); High mass (FAB) *m/z* Calcd for $C_{20}H_{22}N_2O_5$+H: 371.1607. Found: 371.1625.

Deprotection of α-*N*-Acetyl Group. A solution of α-*N*-acetyl-ε-*N*-phthaloyllysine (**13b**) (300 mg, 0.90 mmol), $CoCl_2$ (3.9 mg, 0.003 mmol), and aminoacylase (19800 u g^{-1}, 60 mg) in H_2O (30 ml) was adjusted to pH 7.0. The solution was shaken at 38 °C for 4 d. The solution was concentrated under reduced pressure. The residue was dissolved in H_2O (5 ml) and acetone (5 ml). To the solution, 1 equiv $NaHCO_3$ (2 ml) and (−)-MTPACl (methoxytrifluoromethylphenylacetyl chloride) (228 mg, 0.90 mmol) were added at 0 °C; the solution was then stirred at room temperature for 1 h. The solution was acidified with concentrated HCl and extracted with AcOEt (20 ml). The extract was washed with brine and dried over $MgSO_4$. After concentration, the residue was esterified with etherial CH_2N_2 and purified by PTLC (hexane : AcOEt=2 : 1, v/v) to give α-*N*-MTPA-ε-*N*-phthaloyl-L-lysine methyl ester (**20a**) (132 mg, 0.26 mmol, 28.9%, 92%de) as an oil.

Authentic samples of α-*N*-(−)- and -(+)-MTPA-ε-*N*-phthaloyl-L-lysine methyl ester (**20a**, **b**) were prepared starting from α-*N*-benzyloxycarbonyl-L-lysine.

ε-*N*-Phthaloyl-L-lysine (19): ^{1}H NMR (300 MHz, D_2O) δ=1.38—1.50 (2H, m, CH_2), 1.65—1.75 (2H, m, CH_2), 1.85—1.95 (2H, m, CH_2), 3.67 (2H, t, *J*=6.9 Hz, CH_2), 3.73 (1H, t, *J*=6.0 Hz, CH), (4H, m, aromatic H), 7.82 (4H, s, aromatic H); IR (KBr) 2940, 1770, 1710, 1700, 1575, 1500, 1400 cm^{-1}; mp 232—233 °C (from H_2O-MeOH); High mass (FAB) *m/z* Calcd for $C_{14}H_{16}N_2O_4$+H: 277.1188. Found: 277.1180.

α-*N*-(−)-Methoxytrifluoromethylphenylacetyl-ε-*N*-phthaloyl-L-lysine Methyl Ester (20a): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.17—1.30 (2H, m, CH_2), 1.58—1.98 (4H, m, CH_2), 3.54—3.56 (3H, m, CH_3), 3.60 (2H, t, *J*=7.3 Hz, CH_2), 3.76 (3H, s, CH_3), 4.65 (1H, td, *J*=8.2 and 5.0 Hz, CH), 7.08 (1H, d, *J*=8.1 Hz, NH), 7.35—7.74 (3H, m, aromatic H), 7.50—7.56 (2H, m, aromatic H), 7.70—7.74 (2H, m, aromatic H), 7.80—7.84 (2H, m, aromatic H); IR (neat) 3350, 2950, 2850, 1770, 1740, 1710, 1610, 1510, 1440, 1395, 1360, 1265 cm^{-1}; High mass (FAB) *m/z* Calcd for $C_{25}H_{25}N_2O_6F_3$+H: 507.1743. Found: 507.1732.

α-*N*-(+)-Methoxytrifluoromethylphenylacetyl-ε-*N*-phthaloyl-L-lysine Methyl Ester (20b): ^{1}H NMR (300 MHz, $CDCl_3$) δ=1.35—1.50 (2H, m, CH_2), 1.62—2.05 (2H, m, CH_2), 3.35—3.38 (3H, m, CH_3), 3.69 (2H, t, *J*=7.1 Hz, CH_2), 3.74 (3H, s, CH_3), 4.61 (1H, td, *J*=8.3 and 5.1 Hz, CH), 7.35—7.43 (4H, m, NH and aromatic H), 7.50—7.58 (2H, m, aromatic H), 7.70—7.74 (2H, m, aromatic H), 7.76—7.83 (2H, m, aromatic H).

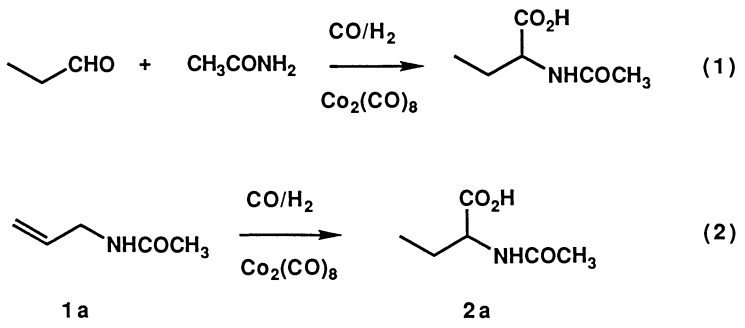
Synthesis of Proline and 2-Piperidinecarboxylic Acid via Cobalt-Catalyzed Isomerization-Carbonylation of *N*-Acyl Unsaturated Cyclic Amines

Yusuke Amino, Seiichi Nishi, and Kunisuke Izawa*
Central Research Laboratories, Ajinomoto Co., Inc., 1-1, Suzuki-cho, Kawasaki-ku, Kawasaki 210
(Received September 18, 1990)

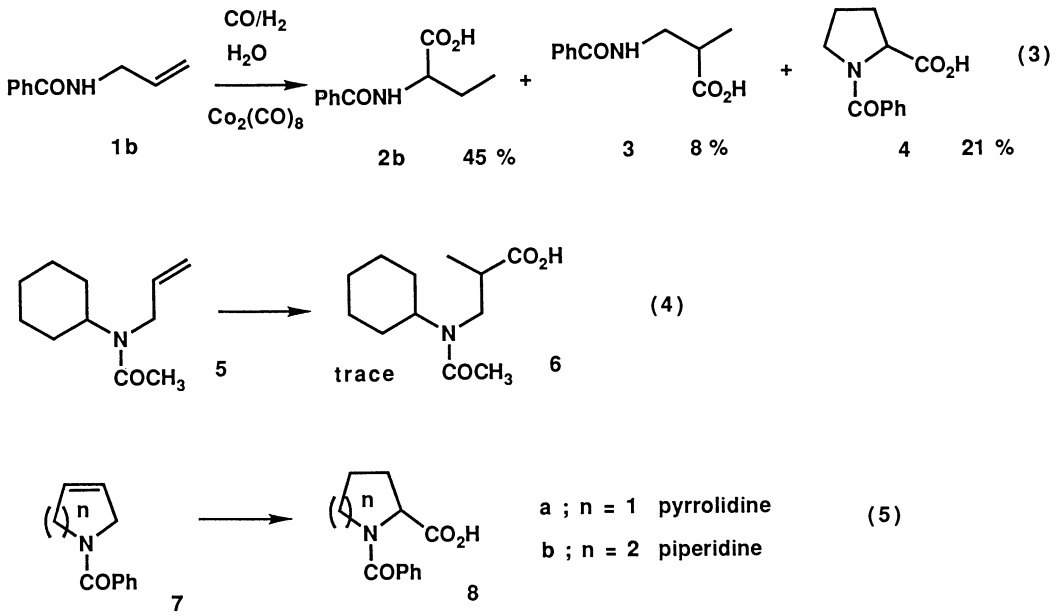
N-Acyl derivatives of proline and 2-piperidinecarboxylic acid (pipecolic acid) were synthesized in moderate yield from *N*-acyl unsaturated cyclic amines through cobalt-catalyzed isomerization-carboxylation under hydroformylation conditions in the presence of H_2O. A possible mechanism for the process is discussed which is related to that of the amidocarbonylation (cobalt-catalyzed formation of *N*-acyl α-amino acid from aldehyde, amide and carbon monoxide).

The cobalt-catalyzed formation of amido carboxylic acid (tentatively designated as amidocarbonylation hereafter) has been developed by Wakamatsu et al. as a useful method for the synthesis of *N*-acyl α-amino acid from aldehyde, amide and carbon monoxide (Eq. 1).[1] The remarkable features of the reaction are its highly regioselective α-carbonylation and hydrolysis, rather than the hydrogenolysis of the acyl complex under hydroformylation conditions.

On the other hand, Sato has reported that *N*-acetylallylamine (**1a**) uniquely reacts with carbon monoxide to give 2-acetamidobutyric acid (**2a**) in 29%



Scheme 1.



Scheme 2.

yield under hydroformylation conditions (Eq. 2).[2]

We have been interested in the fact that the product (**2a**) corresponds to the amidocarbonylation product of propionaldehyde and acetamide. The reaction can be explained by a facile migration of the cobalt carbonyl moiety from the β- or γ-position to the α-position of the acylamino group, followed by CO insertion. The resulting acyltetracarbonylcobalt intermediate [Co(RCO)(CO)$_4$] with the acylamino group on the α-carbon specifically undergoes hydrolytic cleavage to give **2a**.

Previously, the reaction of *N*-benzoylallylamine (**1b**) under hydroformylation conditions by the addition of one mole equivalent of H_2O was reinvestigated. The reaction was complicated, giving 2-benzamidobutyric acid (**2b**) and 3-benzamido-2-methylpropionic acid (**3**) as well as *N*-benzoylproline (**4**) (Eq. 3).[3] The formation of *N*-benzoylproline (**4**) can be explained by hydroformylation followed by subsequent intramolecular amidocarbonylation.

Though Magnus and co-workers examined the reaction of *N*-acetyl-*N*-cyclohexylallylamine (**5**) under hydroformylation conditions, they obtained a β-carboxylation product **6** in low yield, and could not obtain an α-carboxylation product (Eq.4).[4]

We then intended to examine the cobalt-catalyzed isomerization-hydrocarboxylation of *N*-acyl-β,γ-unsaturated cyclic amine (**7**) to obtain *N*-acylproline (**8a**) and *N*-acyl-2-piperidinecarboxylic acid (*N*-acylpipecolic acid) (**8b**) (Eq.5).

Results and Discussion

We found that the cobalt-catalyzed isomerization-hydrocarboxylation of *N*-benzoyl-β,γ-unsaturated cyclic amine (**7**) under hydroformylation conditions with the addition of two equivalents of H_2O (initial pressure at 25 °C: CO, 60 atm; H_2, 60 atm) at 100 °C for 24 h proceeded smoothly to give *N*-benzoyl cyclic α-amino acid (**8**) in moderate yield.

As shown in Table 1, *N*-benzoyl cyclic α-amino acids (**8**), as well as the isomerization-hydroformylation products (**9**) and hydrogenation products (**10**), were obtained as major products. In the case of cyclic

Table 1. Synthesis of Cyclic α-Amino Acids

Run	Substrate	Catalyst	Products, yield[a]/%		
	 7a		 8a	 9a	 10a
1		$Co_2(CO)_8$	54	6	16

7		$Co_2(CO)_8$ + $[RhH(CO)(PPh_3)_3]$ b)	55	21	6

a) Carboxylic acids were isolated as methyl esters. Neutral materials were analyzed by GC–MS. b) 0.25 equiv to $Co_2(CO)_8$. c) 5 equiv to $Co_2(CO)_8$. d) 100 °C, 2 h. e) α-Isomer>90%. f) α-: β- or γ-Isomer=1 : 1.

substrates, the only detectable hydrocarboxylation product was an α-carboxylation isomer, and the corresponding β- or γ-isomer was not obtained. It is postulated that the acylamino group of an (α-amidoalkyl)acylcobalt intermediate participated in the hydrolysis of the acyl-cobalt bond in this intermediate (Scheme 3), while the hydrolysis of sterically restricted (β- or γ-amidoalkyl)acylcobalt intermediates is thought to be difficult to give β- or γ-carboxylation products.

It is interesting that since the hydroformylation also proceeded after isomerization, the α-formyl product (**9a**) was obtained as a major isomer in the reaction of *N*-benzoyl-3-pyrroline (**7a**).

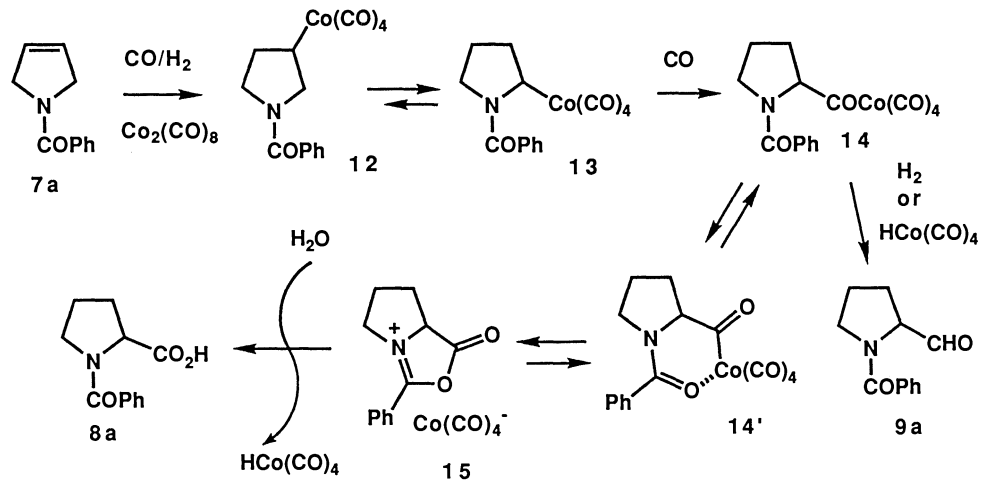
Isomerization of the alkylcobalt intermediate, a key step in this reaction, is thought to be promoted by stabilization to the (α-amidoalkyl)cobalt intermediate (similar to *N*-acyliminium cation). To accelerate isomerization, $PdCl_2(PPh_3)_2$ and $[RhH(CO)(PPh_3)_3]$, which were used by Stille and co-workers as isomerization catalysts of the unsaturated amide and imide,[5a] were added as a co-catalyst. However, the effect of the co-catalyst was not remarkable; only the addition of $PdCl_2(PPh_3)_2$ slightly increased the yield of *N*-benzoyl-2-piperidinecarboxylic acid (Run 6). Evans and co-workers reported a $PdCl_2(PPh_3)_2$ catalyzed hydroesterification [hydro(methoxycarbonyl)ation] of *N*-acetyl-1,2,3,6-tetrahydropyridine.[6] They obtained methyl *N*-acetyl-2-piperidinecarboxylate only in 12% yield, together with regioisomers (major products), *N*-acetyl-2-methoxypiperidine, and *N*-acetyl-1,2,3,4-tetrahydropyridine (minor products). These results indicate that the alkylcobalt intermediate is more liable to isomerize relative to the alkylpalladium intermediate.

The coexistence of an amide sometimes decreases the regioselectivity of the hydroformylation step in the hydroformylation-amidocarbonylation of olefins. This fact may be explained by the exchanged regioselectivity of a cobalt hydridocarbonyl catalyst in the presence of amide.[7] Though the reaction was then tried with the addition of acetamide, the reaction was not affected by the addition of acetamide (Run 3).

The reaction of previously isomerized *N*-benzoyl-2-pyrroline (**11**)[5a] under milder reaction conditions also gave the same products as did *N*-benzoyl-3-pyrroline (**7a**) in different product ratios (Run 4). It is unclear why the hydroformylation product (**9a**) was produced predominantly when **11** was used.

A possible mechanism of this reaction is shown in Scheme 3. (*N*-Benzoyl-3-pyrrolidinyl)tetracarbonylcobalt (**12**) isomerizes to the more stable (*N*-benzoyl-2-pyrrolidinyl)tetracarbonylcobalt (**13**), which then produces the (*N*-benzoyl-2-pyrrolidinoyl)tetracarbonylcobalt (**14**) through the insertion of carbon monoxide. The acyl complex (**14**) then undergoes a hydrolytic cleavage (**14**→**8a**), rather than hydrogenolysis (**14**→**9a**), to give *N*-acyl cyclic α-amino acid in a manner similar to that of amidocarbonylation. We have already proposed that cyclization to the oxazolone-like ion pair (**15**), via an intramolecular nucleophilic attack of the oxygen atom if the acylamino moiety is adjacent to the acylcobalt complex, may promote a solvolytic cleavage of the acyl-cobalt bond in the amidocarbonylation.[8] As shown in the Table 1, though the hydrolytic cleavage is the preferred route to hydrogenolysis in this process, the amount of the hydroformylation product (**9a**) is not negligible. At present, it is not clear why hydrogenolysis proceeds to such a degree.

We have already presented the preparation of *N*-acyl cyclic α-amino acid, such as proline and 2-piperidinecarboxylic acid, via the intramolecular amidocarbonylation of ω-(acylamino)alkanals[9] or cobalt-catalyzed carbonylation of *N*-acyl α-alkoxyalkylamines.[8] Another example regarding the preparation of *N*-acyl cyclic α-amino acid via the cobalt-catalyzed carbonylation was developed here.



Scheme 3.

Stille and co-workers achieved proline derivative synthesis from *N*-*t*-butoxycarbonyl-3-pyrroline, which is a similar starting material to our's, through the subsequent isomerization, hydroformylation and oxidation.[5] We achieved a similar process by one-pot synthesis utilizing cobalt-catalyzed carbonylation.

Experimental

^{1}H NMR spectra were measured with a Varian XL 300 spectrometer and chemical shifts are given as δ ppm relative to tetramethylsilane (TMS) as an internal standard. Infrared (IR) spectra were recorded on a Hitachi 260-10 spectrophotometer with samples as neat liquid. Mass spectra (MS) were recorded with a JEOL DX-300 instrument by using the FAB technique. GC-MS was performed on a HP 5890A-5970B with a high-performance capillary column (cross-linked methyl silicone). The thin-layer chromatographic system employed silica gel (Merck Art. 7515). PTLC was performed with a Whatman PLK 5F.

N-Benzoyl-3-pyrroline (**7a**) and *N*-benzoyl-1,2,3,6-tetrahydropyridine (**7b**) were prepared by the reaction of amines and benzoyl chloride.

***N*-Benzoyl-3-pyrroline (7a):** ^{1}H NMR (300MHz, $CDCl_3$) δ=4.18—4.23 (2H, m, CH_2), 4.44—4.49 (2H, m, CH_2), 5.72—5.78 (1H, m, -CH=), 5.89—5.94 (1H, m, -CH=), 7.38—7.55 (5H, m, aromatic H); IR (neat) 3050, 2850, 1635, 1605, 1570, 1410 cm^{-1}; GC-MS *m*/*z* 173 (M^+).

***N*-Benzoyl-1,2,3,6-tetrahydropyridine (7b):** ^{1}H NMR (300MHz, $CDCl_3$) δ=2.25 (2H, br. s, CH_2), 3.46, 3.86, and 4.20 (4H, br. s, CH_2), 5.50—5.90 (2H, m, -CH=), 7.41 (5H, br. s, aromatic H); IR (neat) 3050, 2940, 2850, 1700, 1630, 1580, 1435, 1290, 1260 cm^{-1}; GC-MS *m*/*z* 187 (M^+).

N-Benzoyl-2-pyrroline (**11**) was prepared by isomerization of *N*-benzoyl-3-pyrroline (**7a**) with $[RhH(CO)(PPh_3)_3]$.[5a] ^{1}H NMR (300MHz, $CDCl_3$) δ=2.67—2.76 (2H, m, CH_2), 4.03 (2H, t, *J*=9.0 Hz, CH_2), 5.15—5.23 (1H, m, -CH=), 6.42—6.67 (1H, m, -CH=), 7.33—7.55 (5H, m, aromatic H); IR (neat) 1610, 1570, 1410 cm^{-1}; GC-MS *m*/*z* 173 (M^+).

Isomerization-Carboxylation of *N*-Acyl Unsaturated Cyclic Amines (7). A typical procedure is described for the reaction of *N*-benzoyl-3-pyrroline (**7a**) and carbon monoxide catalyzed by $Co_2(CO)_8$.

N-Benzoyl-3-pyrroline (**7a**) (606 mg, 3.5 mmol), $Co_2(CO)_8$ (100 mg, 0.29 mmol), and H_2O (0.13 ml, 7.2 mmol) in THF (20 ml) were heated in a 100 ml stainless-steel autoclave with a 1:1 mixture of carbon monoxide and hydrogen (total pressure 120 atom, measured at room temperature) at 110 °C for 24 h. The autoclave was then cooled to ambient temperature and carbon monoxide and hydrogen were purged out. After the solvent was removed under reduced pressure, the residue was dissolved in AcOEt (50 ml) and the insoluble material filtered off. The filtrate was extracted with 10% aqueous $NaHCO_3$ (50 ml) and brine. The organic phase was dried over $MgSO_4$. The solvent was removed under reduced pressure and the residue analyzed by GC-MS; it was then purified by PTLC (hexane : AcOEt=1 : 2, v/v) to give *N*-benzoyl-2-pyrrolidinecarbaldehyde (**9a**) (44 mg, 0.22 mmol, 6.3%) and *N*-benzoylpyrrolidine (**10a**) (98 mg, 0.56 mmol, 16.0%) as major products. The aqueous $NaHCO_3$ extract was acidified with concentrated HCl and extracted with AcOEt (50 ml). The organic layer was washed with brine and dried over $MgSO_4$. After concentration, the residue was esterified with etherial CH_2N_2 and purified by PTLC (hexane : AcOEt=1 : 2, v/v) to give *N*-benzoylproline methyl ester (methyl ester of **8a**) (443 mg, 1.90 mmol, 54.3%) as an oil.

***N*-Benzoylproline Methyl Ester (Methyl Ester of 8a):** ^{1}H NMR (300MHz, $CDCl_3$) δ=1.50—2.30 (4H, m, CH_2), 3.45—3.55 (2H, m, CH_2), 3.75 (3H, s, CH_3), 4.66 (1H, dd, *J*=5.1 and 8.3 Hz, CH), 7.30—7.58 (5H, m, aromatic H); IR (neat) 2950, 2880, 1740, 1630, 1420, 1280, 1200, 1180 cm^{-1}; GC-MS *m*/*z* 233 (M^+), 174 (M^+−59); High mass (FAB) *m*/*z* Calcd for $C_{13}H_{15}N_1O_3$+H: 234.1130. (Received September 27, 1990)

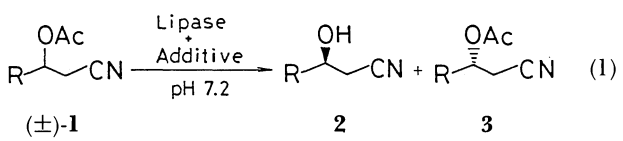
L-Methioninol (L-MetOH) was discovered to be an effective additive for improving the enantioselectivity of lipase-catalyzed hydrolysis. It was found that L-MetOH accelerated the enzyme-catalyzed hydrolysis of (*R*)-3-acetoxybutyronitrile (**1**) and inhibited that of (*S*)-**1**.

The synthetic value of enzymes is being increasingly recognized because enzymatic reactions are highly efficient and proceed under mild conditions.[1] One such enzyme being recommended for use by organic chemists is lipase, which is especially useful,[2] since lipases are uniquely characterized by their ability to catalyze the hydrolysis of many types of ester bonds, they can be used for the kinetic resolution of various racemic alcohols. However, there is only a limited number of commercially available lipases for practical use, and substrates which are applicable to effective kinetic resolution are limited at the present time. Therefore, a new method for improving the ability of the enzymes regarding both enantioselectivity and adaptability toward substrates, has been long awaited.

We have recently developed one such method using the modification of substrates: The introduction of a sulfur functional group to the acyl residue of a substrate increases the enantioselectivity of lipase-catalyzed hydrolysis.[3] We now wish to report here another simple method which extends the synthetic utility of a lipase, an amino alcohol which acts as a very efficient additive to increase the enantioselectivity of a lipase catalyzed hydrolysis of 3-acetoxybutyronitrile.

Results and Discussions

Recently, Sih et al.[4] reported that dextromethrophan (*d*-3-methoxy-*N*-methylmorphinan; DM) improved the enantioselectivity of lipase-catalyzed hydrolysis. Though this finding is very interesting when considering the nature of the enzyme, dextromethrophan, a derivative of morphinan, is not recommended for practical use since it lacks availability and is expensive. During our study of the lipase-catalyzed hydrolysis of 3-acetoxy nitriles, we found that the addition of a catalytic amount of diisopropylamine (33 mol% towards the substrate) considerably increased the rate of hydrolysis, although the enantioselectivity decreased.# This fact prompted us to survey other simple amines which have the ability to enhance the enantioselectivity of a lipase-catalyzed reaction. The effect of additives in lipase PS (*Pseudomonas* sp.)##-catalyzed hydrolysis of (±)-3- acetoxybutyronitrile (**1**) was examined (Eq. 1). The nitrile, **1**, should become a useful chiral building block for the synthesis of many biologically active compounds.[5] Lipase PS (30 mg) and an additive were added to a suspension of (±)-**1** (60 mg, 0.47 mmol) in a 0.1 M phosphate buffer (pH 7.2, 5.0 mL); the resulting suspension was stirred at room temperature. The reaction was monitored by silica-gel TLC and was stopped when spots due to the ester and alcohol became the same size. The optical purity of the hydrolyzed alcohol, **2**, was determined by an ^{1}H NMR analysis of the corresponding (+)-α-methoxy-α-phenyl-α-trifluoromethylacetate (MTPA).[7] The effect of various amines on the enantioselectivity of the lipase-catalyzed hydrolysis of (±)-**1** is shown in Table 1. Of the thirteen amines examined, four of them markedly enhanced the enantioselectivity of the reaction. Among them, DM (Entry 2) and (*S*)-2-amino-4-methylthio-1-butanol (L-MetOH) (Entry 8), which has been derived from L-methionine, showed a remarkable effect on the enantioselectivity. The other four amino alcohols derived from the corresponding amino acid, i.e. L-phenylalanine (Entry 12), L-leucine (Entry 13), glycine (Entry 11), and *dl*-serine (Entry 14), did not enhance the enantioselectivity of this enzyme. Since L-MetOH is easily prepared, we recommended L-MetOH be used as an additive for practical applications.



(1)

In the reaction conditions, the hydrolysis of **1** never occurred without the enzyme. Although the pH value of the reaction mixture was not affected by addition of this amount of *i*-$PrNH_2$ it seemed that this amine acted as an effective base in the enzymatic hydrolysis.

Preliminary experiments involving the hydrolysis of **1** revealed that lipase PS (Amano, *Pseudomonas* sp.) was more promising than any other of the eight enzymes tested. However, it is fair to say that the result was not satisfactory because the ratio of specificity constants for the resolution was only 7. Lipases from *Aspergillus niger* (A and A6), *Candida* sp. (MY and M10), *Rhizopus* sp. (F-AP15 and Newlase F), Porcine Pancreatin (PPL), and Hog pancreatin (F) were not stereospecific.

a) Based on the substrate.

To gain insight into the mechanism of the action of L-MetOH, the hydrolysis was studied under various concentrations of the additive (DM or MetOH) (Table 2). The results can be summarized as follows: (1) L-MetOH is the best additive among isomers of MetOH, i.e. DL-, L- and D-MetOH. (2) The enantioselectivity of the reaction increases accordingly to the amount of L-MetOH until 33 mol% of **1**; the selectivity then decreases. (3) The effects of L-MetOH are similar to those of DM.

To study the mechanism regarding the action of L-MetOH, the enantiomer of **1** ((*R*)-**1**[3a] or (*S*)-**1**[3a]) was used as the substrate. The kinetic inhibition pattern for each enantiomer of the substrates could provide us with useful information relative to the inhibition mechanism.[4] We used an ^{1}H NMR analysis for determining the rate of hydrolysis. The enantiomer of **1** was subjected to hydrolysis and the reaction was stopped after 2.5 h. The relative rate of the reaction was calculated from the conversion rate at that time, since the hydrolysis of (*S*)-**1** is too small to

determine detailed kinetic parameters (Table 3). As can be seen in Table 3, dextromethrophan (DM) inhibited the enzyme-catalyzed hydrolysis of both enantiomers of the acetate (Entries 4 and 8)[4]. It was found that D-MetOH was inferior compared to L-MetOH regarding the inhibitory action of hydrolysis of (*S*)-**1** (Entries 6 and 7). According to the results of hydrolysis under various concentrations of additives (Table 2) the effect of L-MetOH is similar to that of DM. However, the action of L-MetOH to the rate of hydrolysis of (*R*)-**1** was found to be different to that of DM. DM inhibits the hydrolysis of both enantiomers while an enzyme-catalyzed hydrolysis of (*R*)-**1** was not inhibited by L-MetOH. On the contrary, the reaction was accelerated by the addition of L-MetOH (Entry 2). On the other hand, the hydrolysis of (*S*)-**1** was strongly inhibited by L-MetOH and the hydrolyzed product in the presence of L-MetOH was not detected (Entry 6). Evidently, L-MetOH inhibited the hydrolysis of (*S*)-**1** and accelerated that of (*R*)-**1**. It seems therefore that there is a difference in the mechanism for the action to the enzyme between DM and L-MetOH.

According to the experimental results, it seems that L-MetOH and the substrate combine independently with the enzyme at different sites. A conformational change due to the binding of L-MetOH with a certain part of the enzyme may provide a change in the affinity towards the substrates. Therefore, a change of the conformation of the enzyme may provide an increase in the hydrolysis rate of (*R*)-**1** while decreasing the rate of the hydrolysis of (*S*)-**1**. This effect may provide an enhancement of the enantioselectivity of the resolution.

It is not clear at present what geometrical change in the conformation of the enzyme causes a change in the stereoselectivity during hydrolysis. In this study, however, it was established that L-MetOH is an efficient additive that can control the enantioselectivity of a lipase. Considering the broad substrate specificities of lipases, the present method is recommended for use in obtaining optically active alcohols under mild conditions using lipases.

Experimental

Instruments and Materials. NMR spectra were recorded on JEOL MH-100 and Varian VXR-200 spectrometers in $CDCl_3$ with tetramethylsilane (TMS) as an internal reference. Solvents and commercially available starting materials were generally used without additional purification, unless otherwise indicated. TLC analyses were carried out on Merck 60 F_{254} silica-gel plates and Wako gel B-5F. Pyridine and dichloromethane were refluxed over calcium hydride for 5 h, distilled and stored under argon in the presence of 4 Å molecular sieves.

Hydrolysis of 3-Acetoxybutyronitrile (1) by Lipase PS: A suspension of 3-acetoxybutyronitrile (**1**)[8] (60 mg, 0.47 mmol), Lipase PS (30 mg, 50 w%) and L-MetOH (21 mg, 0.16 mmol) in a mixed solvent of 0.1 M phosphate buffer (pH 7.2, 5.0 mL) and acetone(0.5 mL) was stirred by a magnetic stirrer at room temperature. After 14 h, the product was extracted from the reaction mixture with ethyl acetate, the extract was then filtered through a short silica-gel column (5 cm) for removing the L-MetOH, dried over anhydrous magnesium sulfate and evaporated in vacuo to give a crude oily product (160 mg). By ^{1}H NMR analysis of this crude product, the hydrolysis ratio was determine as a 56% conversion. Separation by silica-gel TLC gave **2** (22 mg, 0.26 mmol, 55%) and **3** (20 mg, 0.16 mmol, 33%). The optical purity of the produced alcohol, **2**, was determined by an ^{1}H NMR analysis of the corresponding (+)-MTPA ester. The enantiomeric excess (ee) of the remaining ester, **3**, was also determined by a conversion to the corresponding alcohol with LAH reduction (in THF at −50 °C) and esterification with 100% excess of (*S*)-(+)-MTPA chloride. **2**; 69 %ee; $[\alpha]_D^{23}$ +3.1°(*c* 1.0, EtOH, lit,[3a] +4.1° (*R*), 84 %ee). **3**; 80 %ee; $[\alpha]_D^{23}$ −19.0° (*c* 1.0, EtOH). The (*E*) value, which was calculated by ee of **2** and ee of **3**, agreed well with that calculated from the hydrolysis ratio and ee of **2**.[6]

Preparation of (*R*)- and (*S*)-3-Acetoxybutyronitrile (1): A solution of 3-(methylthioacetoxy)butyronitrile (**4**)[3c] (10 g, 57.7 mmol) in 0.1 M phosphate buffer (pH 7.2, 100 mL) and acetone (6.0 mL) was incubated with lipase P (2.96 g)at RT for 6 h. The mixture was filtered through a celite pad, and then extracted with ethyl acetate. Using silica-gel flash column chromatography, 8.24 g of the recovered ester and 1.25 g (14.7 mmol, 25% yield) of the product, (*R*)-**2**, were obtained. (*R*)-**2** ($[\alpha]_D^{23}$ +6.8°(*c* 1.33, EtOH); The ee of (*R*)-**2** (98%) was determined by 200MHz ^{1}H NMR analysis of the corresponding (+)-MTPA ester. The produced alcohol, (*R*)-**2**, was acetylated by acetyl chloride in the presence of pyridine in a usual manner to give (*R*)-**1**; $[\alpha]_D^{23}$ +19.0° (*c* 1.0, EtOH). To obtain (*S*)-**1** with a sufficient ee for practical use, the recovered acetate (8.24 g) was incubated once more with the lipase to give 2.68 g (36% yield) of (*S*)-(methylthio) acetate; $[\alpha]_D^{23}$ −17.6° (*c* 0.945, EtOH). LAH reduction of the ester in THF at −50 °C provided 98% ee of (*S*)-**2**; $[\alpha]_D^{23}$ −7.1° (*c* 0.98, EtOH), which was acetylated to give (*S*)-**1** ($[\alpha]_D^{23}$ −18.6°, *c* 1.0, EtOH).

Kinetics Experiment: Lipase PS (1.0 g) was dissolved in 20 mL of a 0.1 M phosphate buffer (pH 7.2) and centrifuged (2000 rpm, 2 min.). The resulting supernatant liquid was diluted with the buffer solution until the total volume was doubled and used as an enzyme solution. When the lipase was added as a powder to the reaction mixture, we could not obtain reproducible results concerning the determination of the % conversion. 3-Acetoxybutyronitrile (**1**) (20 mg, 0.157 mmol) and the additive (0.0145 mmol, 33 mol% based on the substrate) were weighed directly into a flask and dissolved into 1.0 mL of acetone. The enzyme solution (4.0 mL) was added and stirred for 2.5 h at 23 °C. The reaction was stopped by the addition of crashed ice; the reaction mixture was then extracted with ethyl acetate, dried, and evaporated. The ^{1}H NMR spectrum was then taken. The hydrolysis ratio was determined by a comparison of the peak intensity of 3-H signals, i. e. alcohols **2**; 3.9—4.1 (m), and the remaining ester **3**; 4.8—5.1(m).

We are grateful to SC-NMR Laboratory of Okayama University for the NMR measurement. We thank Amano Pharmaceutical Co., Ltd. for providing the lipase.

Mechanism of 2-Propanol Dehydrogenation with Suspended Nikel Fine-Particle Catalyst

Masaru YAMASHITA,* Feng-Yuen DAI, Minoru SUZUKI, and Yasukazu SAITO
Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo-ku, Tokyo 113
(Received August 21, 1990)

Selective dehydrogenation of 2-propanol was performed with a suspended nickel fine-particle catalyst at high activity under refluxing conditions. The isotope effects, k_H/k_D, for $(CH_3)_2CDOH$ and $(CD_3)_2CDOD$ were found to be 2.56 and 2.69, respectively, in contrast to 1.68 for $(CH_3)_2CHOD$, suggesting that the C-H bond dissociation at the methine position is rate-determining. With regard to $(CH_3)_2CHOD$ and $(CH_3)_2CDOH$, a distinct difference was observed for the deuterium distributions among the liquid-phase components after the reaction, since deuterium transfer from the hydroxyl to the methyl and other groups proceeded tremendously for $(CH_3)_2CHOD$, whereas the methine group of $(CH_3)_2CDOH$ changed little, even after a 5-h reaction under refluxing conditions. This contrast was well accounted for by the difficult splitting of the methine C-H bond and the facile dissociation of the hydroxyl group, in addition to a gradual H-D exchange due to the keto-enol equilibriation of the adsorbed acetone and the hydrogen transfer from 2-propanol to acetone. Distributions of H_2, HD, and D_2 were interpreted as well, which varied with the reaction periods and the kinds of substrates. Based on the proposed mechanism, strategies for a catalyst improvement suitable for a newly-proposed chemical heat pump system are discussed.

Industrial processes concerning 2-propanol dehydrogenation are carried out on heterogeneous catalysts above 300 °C,[1] since the change in the standard Gibbs free energy becomes negative at high temperature.[2]

2-Propanol dehydrogenation over zinc oxide was investigated by Teichner et al., who concluded that the dissociation of the methine C-H bond is rate-determining.[3] The reaction mechanism was discussed later by Krylov regarding various solid catalysts; the importance of the enol-type adsorption of acetone was pointed out.[4] The dissociation of 2-propanol into isopropoxide and hydrogen surface species on zinc oxide, followed by enforced desorption of acetone with the adsorbed isoproxide species, was revealed by Tamaru et al.[5] The desorption process of 2-propanol from the zinc oxide surface, itself, was studied by Kemball et al. up to a temperature of 300 °C.[6]

Even at a temperature as low as 82.4 °C, however, the reaction can proceed under boiling conditions, since the produced hydrogen is removed from the reaction medium immediately after its formation (Eq. 1).

$$(CH_3)_2CHOH(l) \rightarrow (CH_3)_2CO(l) + H_2(g). \quad (1)$$

Actually, suspended copper chromite and Raney nickel catalysts proved to be active for 2-propanol dehydrogenation under refluxing conditions.[7,8]

Boudart et al. analyzed the reaction using a suspended nickel boride catalyst using the following equation, in which the rate retardation caused by acetone adsorption was taken into account:[9]

$$v = k/(1 + K[\text{acetone}]), \quad (2)$$

where v is the reaction rate, k the rate constant and K the equilibrium constant of acetone adsorption, respectively.

Recently, highly active nickel fine-particle catalysts (116 mmol h^{-1} g^{-1}), prepared by a gas-evaporation method,[10] were reported by Saito et al., where the same rate equation (2) was ascertained to hold for 2-propanol dehydrogenation.[11] Efficient catalysts for reaction (1) are indispensable to a newly-proposed chemical heat pump system,[12] which raises the temperature of low-quality heat from 80 °C to a more valuable temperature of 200 °C.

In the present paper, the mechanism of the nickel fine-particle catalyst is elucidated in order to obtain strategies for catalyst improvement suitable for 2-propanol dehydrogenation in the newly-proposed chemical heat-pump system.

Experimental

A prescribed amount (200 mg) of the nickel fine-particle catalyst (supplied by Vacuum Metallurgical Co. with an average particle diameter of 20 nm and a specific surface area (BET) of 43.7 $m^2 g^{-1}$, Lot. No. 2180) was laid in a Schlenk flask (20 ml). The catalyst was preheated at 160 °C for 1 min under a hydrogen atmosphere, by which a part of the surface oxide was removed from the nickel fine particles. The catalyst was well suspended in 2-propanol by an ultrasonic treatment (Kaijyo Denki Co., Sona 50a) at room temperature for 1 min under an argon atmosphere.

Three kinds of deuterium-substituted 2-propanol, i.e., $(CH_3)_2CHOD$, $(CH_3)_2CDOH$, and $(CD_3)_2CDOD$, in addition to $(CD_3)_2CO$ (all supplied by the Division of Merck, Frost Inc.) were used without further purification. After the catalyst suspension was heated at the boiling temperature with an oil bath kept at 100 °C, the amount of evolved gas was determined time-sequentially with a gas burette (250 ml) through a refluxing condenser. Gaseous products were collected at the exit of the reaction vessel.

Both gaseous and liquid-phase products were analyzed by gas chromatography with MS-5A and PEG 1000 columns,

respectively.

The deuterium distribution of molecular hydrogen was monitored by a quadrupole-type mass spectrometer (NEC Anerva Co., AQA 360), whereas an FT-NMR spectrometer (JEOL Co., GX-270) was used for analyzing the liquid-phase components both before and after the reaction.

Results

Dehydrogenation of Deuterium-Substituted 2-Propanol. The nickel fine-particle catalyst was dispersed in 2-propanol at a concentration ten-times larger than that examined previously.[11] 2-Propanol dehydrogenation proceeded at 82.4 °C under boiling conditions (heat at 100 °C) at high activity and selectivity in a densely suspended solution as well (Fig. 1). The exclusive formation of hydrogen and acetone was confirmed in the gaseous- and liquid-phase components, respectively. The reaction rates and the deuterium distributions were reproducible satisfactorily.

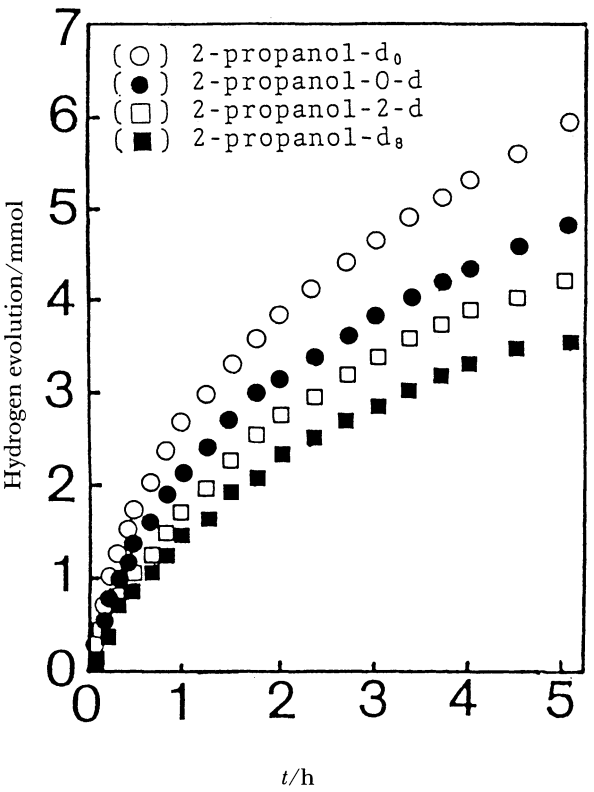

Fig. 1. Dehydrogenation of deuterium-substituted 2-propanol with the suspended nickel fine-particle catalyst (200 mg) at 82.4 °C under refluxing conditions (heat at 100 °C).

A preheat treatment of the nickel fine-particle catalyst under a hydrogen atmosphere was necessary in order to exhibit the dehydrogenation activity.[13] It was revealed that the reaction rates were substantially indifferent to the conditions of a reduction performed with either H_2 or D_2.

The initial rates of hydrogen evolution from 2-propanol-d_0, -O-d, -2-d and -d_8 are summarized in Table 1. Since the gradual decrease of the reaction rates was ascribed to retardation due to the product acetone (Eq. 2),[11] the rate constant k [mmol h^{-1} g^{-1}] was given by the observed initial reaction rate.

As shown in Table 1, the isotope effects, k_H/k_D, related to the methine hydrogen of 2-propanol were obtained as large as 2.56 and 2.69 from 2-propanol-2-d and d_8 respectively, with reference to 2-propanol-d_0 and the catalyst pre-reduced by H_2.

On the contrary, the isotope effect concerning the hydroxyl hydrogen was rather small (k_H/k_D: 1.68 for 2-propanol-O-d).

Table 2. Deuterium Distribution in the Product Hydrogen Evolved from Deuterium-Substituted 2-Propanol at 82.4 °C under Refluxing Conditions (heat at 100 °C) with Nickel Fine-Particle Catalyst

Deuterium-substituted 2-propanol	Preheated atmosphere	Product hydrogen/%		
		H_2	HD	D_2
d_0	H_2	100	0	0
d_0	D_2	100	0	0
O-d	H_2	42.2	41.2	16.6
2-d	H_2	79.0	19.8	1.2
d_8	H_2	0.73	6.37	92.7

Pretreatment of catalyst: Heated at 160 °C for 1 min under hydrogen atmosphere. Catalyst solution: Suspension of 200 mg in 2-propanol (5 ml). Reaction conditions: Refluxing for 5 h under atmospheric pressure.

Table 1. Dehydrogenation of Deuterium-Substituted 2-Propanol at 82.4 °C under Refluxing Conditions (heat at 100 °C) with Nickel Fine-Particle Catalyst and Kinetical Isotope Effect

Deuterium-substituted 2-propanol	Preheat atmosphere	Conversion	Initial rate	Isotope effect
		%	mmol g^{-1} h^{-1}	k_H/k_D
d_0[a]	H_2	9.36	81.3	—
d_0	D_2	9.33	78.1	1.04
O-d	H_2	7.68	48.5	1.68
2-d	H_2	6.71	31.8	2.56
d_8	H_2	6.39	30.2	2.69

a) -d_0 stands for undeuterated. Pretreatment of catalyst: Heated at 160 °C for 1 min under hydrogen atmosphere. Catalyst solution: Suspension of 200 mg in 2-propanol (5 ml). Reaction conditions: Refluxing for 5 h under atmospheric pressure.

Deuterium Distribution in the Product Hydrogen. Even when the catalyst was preheated under a D_2 atmosphere, the gaseous product of 2-propanol-d_0 dehydrogenation was found to be H_2 exclusively. The amount of surface deuterium species left after the pretreatment of D_2 reduction is therefore negligible.

As shown in Table 2, the gaseous products of 2-propanol-O-*d* and 2-*d* were found to be the mixture of H_2, HD, and D_2, as shown in the following equations:

$$(CH_3)_2CHOD(l) \rightarrow (CH_3)_2CO(l) + H_2, HD, D_2(g), \quad (3)$$

and

$$(CH_3)_2CDOH(l) \rightarrow (CH_3)_2CO(l) + H_2, HD, D_2(g). \quad (4)$$

The product hydrogen was more abundant with H_2 from 2-propanol-2-*d* than from 2-propanol-O-*d*.

Figure 2 shows the deuterium distribution of newly-evolved hydrogen from 2-propanol-O-*d* as a function of time. H_2 gradually increased at the expense of both HD and D_2.

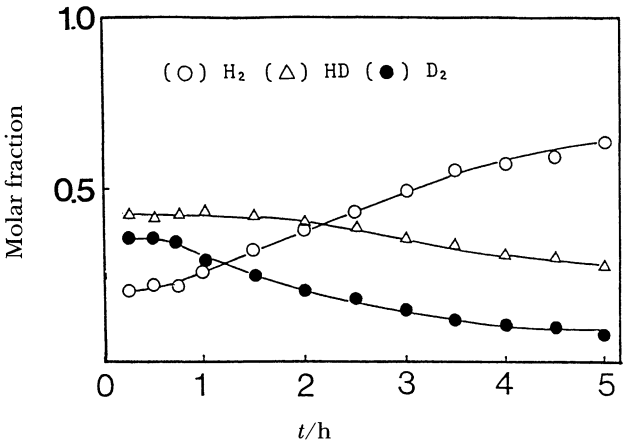

Fig. 2. Variation among the molar fractions of H_2, HD, and D_2 in hydrogen evolved from 2-propanol-O-*d* as a function of time.

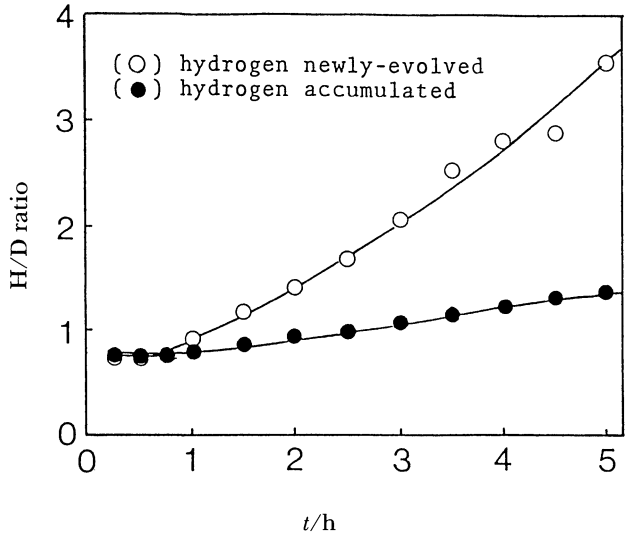

Fig. 3. H/D ratio in newly-evolved hydrogen and the one accumulated till the time concerned.

The time dependence of the deuterium distribution, represented as the H/D ratio in the product hydrogen, was more sensitive to newly-evolved hydrogen than to that accumulated in the gas burette (Fig. 3). The latter was obtained by combining the composition with the amount of hydrogen. Since the reaction rate gradually decreased, the variation of the deuterium distribution in the newly-evolved hydrogen was smoothed out in the accumulated hydrogen during the reaction period from the beginning until the time concerned.

As for 2-propanol-O-*d*, the H/D ratio of the newly-evolved hydrogen gradually increased from 0.82 at the intitial stage to 3.55 after 5 h along with the reaction progress.

Deuterium Distribution Among the Liquid-Phase Components. The ^2H NMR spectra for the solutions of 2-propanol-O-*d*, 2-*d* and d_8 after a dehydrogenation reaction for 5 h are shown in Fig. 4.

The deuterium spectral peaks changed variously. Many deuterium atoms were transferred from the hydroxyl group to the methyl and methine groups of 2-propanol-O-*d*. The strongest peak was not observed at the hydroxyl position but, rather, at the methyl position of 2-propanol (Fig. 4A). On the contrary, most of the deuterium atoms in the methine group of

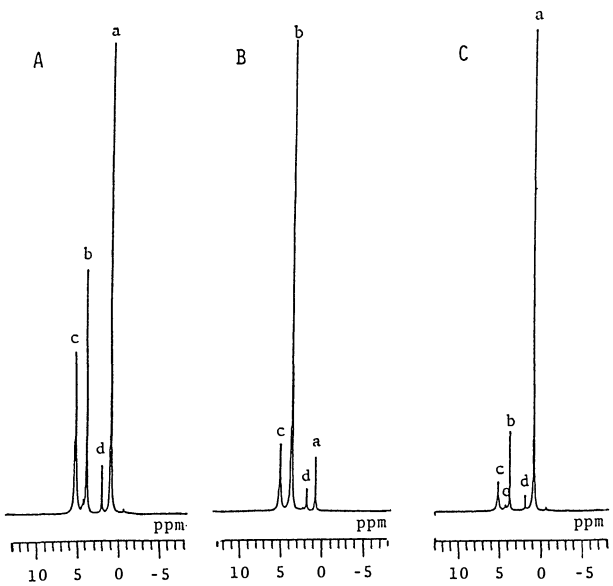

Fig. 4. ^2H NMR spectra of $(CH_3)_2CHOD$ (A), $(CH_3)_2CDOH$ (B), and $(CD_3)_2CDOD$ (C) solutions after 5-h reaction with the suspended nickel fine-particle catalyst (200 mg) at 82.4 °C under refluxing conditions (heat at 100 °C).
Peaks identified as 2-propanol methyl (a), methine (b), and hydroxyl (c) groups, acetone (d) and deuterium oxide (e).
$Si(CD_3)_4$ was used as the standard reference (0.0 ppm).

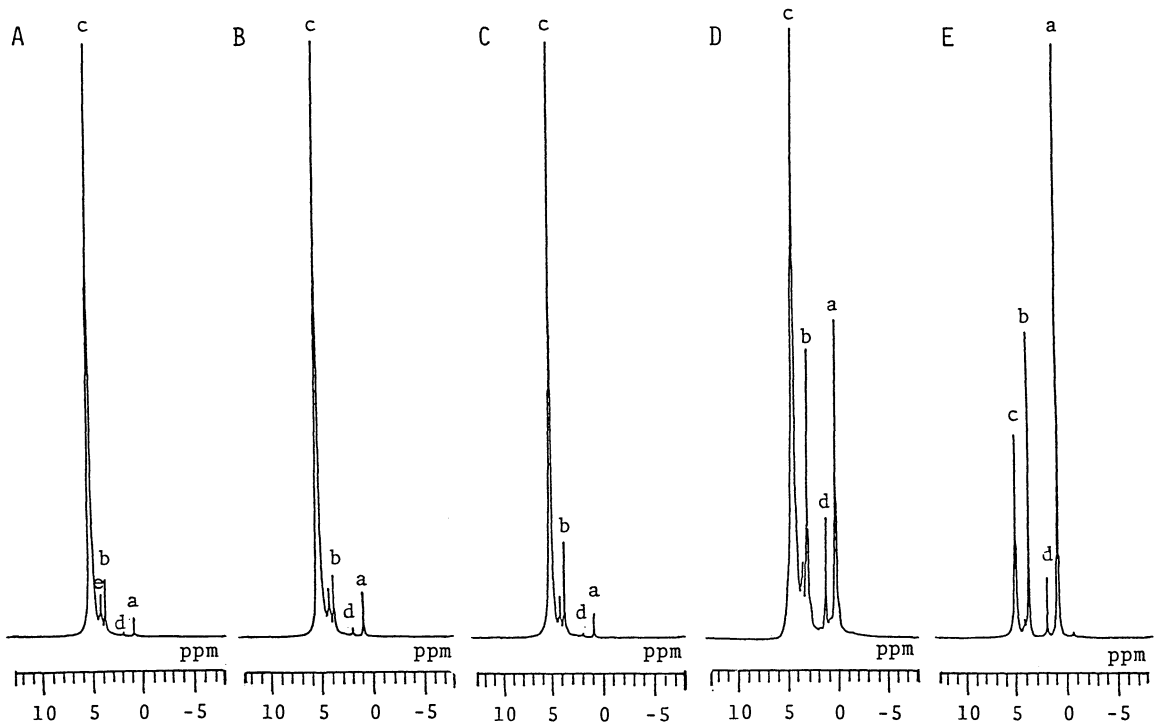

Fig. 5. ^{2}H NMR spectra of 2-propanol-O-*d* after 1/4 h (A), 1 h (B), 2 h (C), and 3 h (D) and 5 h (E) reactions with the suspended nickel fine-particle catalyst (200 mg) at 82.4 °C under refluxing conditions (heat at 100 °C).
Peaks idenified as 2-propanol methyl (a), methine (b), and hydroxyl (c) groups, acetone (d), and deuterium oxide (e) and set as 95% height for the strongest one in each chart.
$Si(CD_3)_4$ was used as the standard reference (0.0 ppm).

2-propanol-2-*d* remained unchanged, though a small amount of deuterium was found at the methyl and hydroxyl groups of 2-propanol (Fig. 4B). The deuterium transfer to acetone was clearly larger from the hydroxyl group than from the methine group of 2-propanol, corresponding to the extents of transfer to the other groups of 2-propanol. As for 2-propanol-d_8, the deuterium peak at the hydroxyl position changed rather extensively, while the other peaks exhibited the smallest variations (Fig. 4C).

A remarkable change which took place in the liquid-phase deuterium distribution of 2-propanol-O-*d* was demonstrated in the ^{2}H NMR spectra after reactions for 1/4, 1, 2, 3, and 5 h time-sequentially (Fig. 5). It should be noted that the deuterium peak at the methine position of 2-propanol increased more rapidly than did the other peaks until 2 h, whereas an extensive change of the hydroxyl peak and a simultaneous increase in the methyl deuterium of 2-propanol became apparent only after 2 h.

Rate Retardation in 2-Propanol Dehydrogenation Due to Acetone. In order to elucidate the retardation effect of acetone on the dehydrogenation rate of 2-propanol, the amounts of hydrogen evolved from solutions of 2-propanol, including acetone-d_6 of 0, 4 and 20 wt%, were pursued as a function of time (Fig. 6). A concentration of 4 wt% corresponded to the

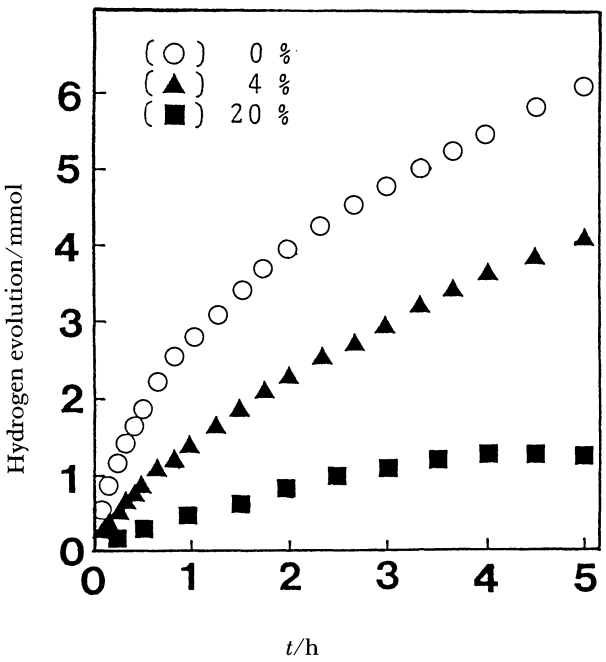

Fig. 6. Dehydrogenation of 2-propanol including acetone-d_6 of 0, 4, and 20 wt% with the suspended nickel fine-particle catalyst (200 mg) at 82.4 °C under refluxing conditions (heat at 100 °C).

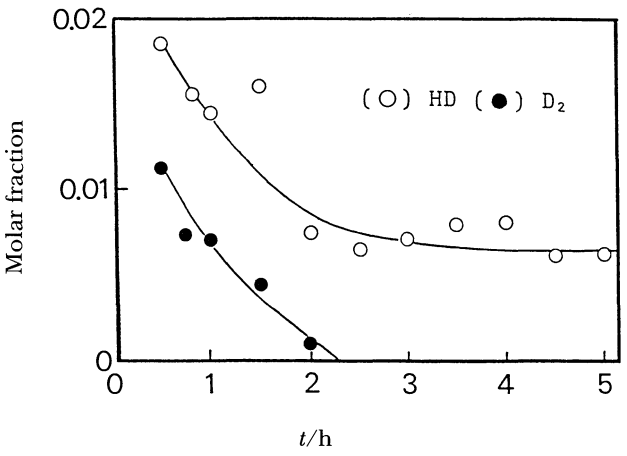

Fig. 7. Variation of HD and D_2 molar fractions in hydrogen evolved from the mixture of 2-propanol-d_0 and acetone-d_6 (4 wt%).

Table 3. Deuterium Distribution among Liquid-Phase Components Yielded from the Mixture of $(CH_3)_2CHOH$ and $(CD_3)_2CO$ (10 vol%) after 1-h or 5-h Reaction with Nickel Fine-Particle Catalyst at 82.4 °C under Refluxing Conditions (heat at 100 °C)

Reaction time/h	Deuterium distribution/% 2-propanol			Acetone
	Methyl	Methine	Hydroxyl	
0	0.00	0.00	0.00	100.00
1	49.5	3.2	19.7	27.7
5	60.1	5.1	17.2	17.7

Catalyst pretreatment: Heated at 160 °C for 1 min under H_2. Catalyst solution: Suspension of 200 mg in the mixed solution (5 ml).

amount of acetone yielded from neat 2-propanol during the 2-h reaction.

The deuterium distribution in hydrogen evolved from a mixed solution of 2-propanol and acetone-d_6 (4 wt%) showed that both HD and D_2 were appreciably formed only during the initial stage (Fig. 7). From the ^2H NMR spectra of a solution mixed with 2-propanol and acetone-d_6 (20 wt%) after the 1- and 5 h reactions, it was found that the deuterium atoms of acetone were transferred mainly to the methyl position of 2-propanol. The variations of the deuterium distribution with the reaction time are summarized in Table 3.

Discussion

Adsorbed Species on the Catalyst Surface. The relatively large molar fractions of HD and D_2 evolved from 2-propanol-O-*d* during the initial stage (Figs. 2 and 3) suggest that 2-propanol adsorbs on the catalyst surface by a facile dissociation of its hydroxyl group. The present view of easy O-D splitting is supported by the fact that an extensive HD exchange was observed among the liquid-phase components after a 5 h reaction for 2-propanol-O-*d*, in contrast to 2-*d* (Fig. 4). The methine C-H bond of adsorbed isopropoxide is rather strong and difficult for dissociation.

$$(CH_3)_2CHOD(l) \rightarrow (CH_3)_2CHO_{ads} + D_{ads}. \quad (5)$$

It is, therefore, deduced that the nickel fine-particle catalyst is covered with the isopropoxide and hydrogen surface species to appreciable extents during the reaction.

The adsorbed acetone is equilibriated rapidly between the keto and enol forms on the catalyst surface,[14] since many deuterium atoms were introduced to acetone during the dehydrogenation of 2-propanol-O-*d* (Figs. 4 and 5).

$$(CH_3)_2CO_{ads} \rightleftarrows CH_2{=}CO{-}CH_{3ads} + H_{ads}. \quad (6)$$

The appearance of deuterium during the earliest stage of the reaction as a gaseous product from acetone-d_6 confirms the view concerning the rapid keto-enol equilibrium of adsorbed acetone (Fig. 7).

Hydrogen Transfer from 2-Propanol to Acetone during 2-Propanol Dehydrogenation. The rapid conversion of acetone-d_6 (20 wt% in 2-propanol-d_0) into the methyl part of 2-propanol (Table 3) strongly suggests that hydrogen transfer from 2-propanol to acetone proceeds on the catalyst surface (Eq. 7)[15] simultaneously with hydrogen evolution.

$$(CD_3)_2CO + (CH_3)_2CHOH \rightarrow (CD_3)_2CHOH + (CH_3)_2CO. \quad (7)$$

The rapid deuterium incorporation from OD into the methine group during the early stage of 2-propanol-O-*d* dehydrogenation (<2 h, Fig. 5) supports the mechanism of hydrogen transfer from 2-propanol to acetone.

The extensive substitution of the methyl hydrogen with deuterium observed during the later stage (>2 h, Fig. 5) is well interpreted in terms of both the keto-enol equilibrium occurring in the product acetone (Eq. 6) and the hydrogen transfer from 2-propanol to acetone (Eq. 7).

These two processes (Eqs. 6 and 7) account for the gradual predominance of H to D species on the surface as well, which was demonstrated by the H/D ratio in the product hydrogen (Fig. 3), especially during the later stage of 2-propanol-O-*d* dehydrogenation.

The sharp contrast in deuterium distribution observed for the product hydrogen from 2-propanol-O-*d* and 2-*d* after the 5-h reaction (Table 2) is ascribed not only to the facile dissociation of the hydroxyl group (Eq. 5) but also to the rapid keto-enol equilibrium (Eq. 6) and the easy hydrogen transfer (Eq. 7).

Rate-Determining Step in 2-Propanol Dehydrogenation. The isotope effects, k_H/k_D, for the dehydrogenation of 2-propanol-2-*d* and d_8 were obtained at 82.4 °C as large as 2.56 and 2.69, respectively, in contrast to 2-propanol-O-*d* of 1.68 (Fig. 1 and Table 1).

The primary isotope effect for eliminating β-hydrogen from the adsorbed propyl species on an aluminium film was reported to be 2.6 at 247 °C.[16] The apparent coincidence in magnitudes suggests that the rate-determining step is the C-H bond dissociation of the methine hydrogen (Eq. 8), which is reconciled with the kinetical conclusion deduced for zinc oxide by Teichner et al.[3]

$$(CH_3)_2CHO_{ads} \rightarrow (CH_3)_2CO_{ads} + H_{ads}. \quad (8)$$

The rate-determining step of the methine C-H dissociation is succeeded by the formation and desorption step of molecular hydrogen:

$$2H_{ads} \rightarrow H_2. \quad (9)$$

Recently, the dehydrogenation rates with a ruthenium catalyst supported on carbon were revealed to be in the order $(CH_3)_2CHOH > (CH_3)_2CDOH > (CH_3)_2CHOD$ under boiling and refluxing conditions, for which the rate-determining step was deduced as the process mentioned above (Eq. 9).[17] On the other hand, the amounts of species adsorbed on the surface can affect the availability of sites for splitting the methine C-H bond of the isopropoxyl moiety. Hence, the predissociation process of the hydroxyl group (Eq. 5) would be relevant to the small, but unnegligible, isotope effects observed for $(CH_3)_2CHOD$ vs. $(CH_3)_2CHOH$ or $(CD_3)_2CDOD$ vs. $(CH_3)_2CDOH$ on the nickel fine-particle catalyst.

Strategies of Catalyst Improvement Suitable for the Newly-Proposed Chemical Heat Pump System. The newly-proposed chemical heat pump[12] requires a catalyst with high selectivity, long life and large space-time yield for 2-propanol dehydrogenation in the presence of acetone.

The strategies for catalyst improvement of the rate constant and the retardation constant consist of: (1) facilitating C-H bond splitting at the methine position and (2) obstructing acetone adsorption in order to avoid any undesirable active-site occupation and hydrogen transfer on the surface.

The reaction rate constant of the nickel fine-particle catalyst (96.9 mmol h^{-1} (metal-g)$^{-1}$) was surpassed by the Ru/carbon catalyst (4630 mmol h^{-1} (metal-g)$^{-1}$),[18] for which the formation and desorption step of molecular hydrogen was elucidated to be rate-determining.[17] Consequently, 2-propanol would be dehydrogenated rapidly as long as the methine C-H bond is easily split.

The adsorption strength of acetone seems to be large with regard to the enol-type surface species. In contrast to the nickel fine-particle catalyst, it was observed that the keto-enol isomerization occurred little on the Ru/carbon catalyst.[17] A larger retardation constant due to acetone adsorption obtained for nickel (0.066 mmol dm^{-3}) than for ruthenium (0.017 mmol dm^{-3})[18] is ascribed to the mode of adsorption (at least partly), since no enol-type species was formed for the latter, according to an ^2H NMR analysis.[17]

Conclusion

(1) The nickel fine-particle catalyst exhibited high selectivity and activity for 2-propanol dehydrogenation at concentrations ten-times larger than those examined previously, with an accompanying rate retardation due to acetone.

(2) The large isotope effects, k_H/k_D, of 2.56 and 2.69 for $(CH_3)_2CDOH$ and $(CD_3)_2CDOD$, respectively, suggested that the C-H dissociation process at the methine position is rate-determining, whereas the unnegligible magnitude of 1.68 for $(CH_3)_2CHOD$ would be related to the predissociation process of the hydroxyl group.

(3) The keto-enol equilibriation of adsorbed acetone proceeded rapidly on the catalyst surface, which would make a certain unfavorable contribution to rate retardation.

(4) The hydrogen transfer from 2-propanol to acetone proceeded simultaneously with the evolution of molecular hydrogen from 2-propanol.

(5) Catalysts more suitable for the chemical heat pump system would be developed by fascilitating methine C-H dissociation and by avoiding enol-type acetone adsorption.

The present work was supported by a Grant-in-Aid on Priority-Area Research from the Ministry of Education, Science and Culture.

A Study of the Reduction of Chelated Palladium on Mercury Electrode

C. K. LAI, Y. Y. WANG,* and C. C. WAN
Department of Chemical Engineering, National Tsing Hua University, Hsinchu, Taiwan, R.O.C.
(Received March 26, 1990)

This paper investigates the reduction kinetics and mechanism of Pd(II)-ethylenediamine with cyclic voltammetry and normal pulse polarography techniques. The results indicate that the reduction is an irreversible process. The major kinetic parameters and diffusion coefficients of Pd(II)-ethylenediamine and other Pd(II)-aliphatic diamine complexes are reported. The influences of concentrations, pH values, and ligand structures on the reduction of Pd(II) complex are also discussed. The electrochemical reaction orders with respect to ethylenediamine and Pd(II)-ethylenediamine are found to be 0 and 1, respectively and these reaction orders demonstrate an undissociated complex reduction mechanism. Finally the iodide effect on normal pulse polarography is studied. The increase in current when iodide is added implies that the reduction is via the outer sphere path way.

A palladium deposit is a good substitute for gold in the electronic industry because of its lower cost and excellent chemical, physical, and electrical properties. Among various Pd plating solutions, Pd-diamine system is an important one.[1-4] Although Pd deposition has become a hot topic in recent years, the electrochemical behavior of Pd^{2+} electrolytes has not received wide attentions yet.

Early in 1945 Willis had studied the polarographic reductions of Pd(II) in various complexing agents such as ammonia, ethylenediamine(en), diethylamine, and ethanolamine. He found that the reductions are incompletely reversible two-electron processes.[5] He also found that the half-wave potentials of the reductions of these complexes are more negative as the ligand becomes more basic. Later, Simpson et al. studied the Pd(II) reductions with polarography and obtained the diffusion coefficients of Pd(II) complexes in solutions containing chloride and acetate.[6] Chakravarty also studied polarographic behavior of Pd(II) complexes and discovered that those Pd(II) complexes with ammonia or ethylenediamine as complexing agents are irreversibly reduced.[7] Hirota et al. studied reductions of Pd(II) complexes and found that the more stable the complex the more difficult the reduction.[8] The polarography studies of Gaur revealed that the reduction of Pd(II) in 0.2 M pyridine, 0.1 M HCl is a quasi-reversible process[9,10] (1 M=1 mol dm^{-3}).

The reduction mechanism of $PdCl_4^{2-}$ on some solid electrodes has been studied by some authors. Confusing results were obtained. Watt and Cunningham reported that $PdCl_4^{2-}$ is the species that was reduced.[11] Later in a series of papers published by Harrison and co-workers, $PdCl_2$ was thought to be the species that was reduced, though the prevailing ion in solution is $PdCl_4^{2-}$.[12-17]

For quantative analysis, both direct current polarography and differential pulse polarography have been used to determine Pd(II) concentration.[18-25]

There have been few studies concerning the electrochemical behavior of chelated Pd(II) though it is an important ingredient of palladium plating solution. In this work both the electrode kinetics and reduction mechanism are investigated. First we study the reduction kinetics of Pd(II) chelated with diamines on a mercury drop electrode with cyclic voltammetry(CV) and normal pulse polarography(NPP) techniques. Both kinetic parameters and diffusion coefficients are reported. The influences of concentrations, pH values, and ligand structures on the reduction of Pd(II) complex are discussed. Then we consider the reduction mechanism of $Pd(en)_2^{2+}$. In order to ascertain the reactive species of $Pd(en)_2^{2+}$ reduction, the electrochemical reaction orders with respect to en and $Pd(en)_2^{2+}$ are used as criteria. Finally the iodide effect on NPP is also investigated for a further understanding of the essence of $Pd(en)_2^{2+}$ reduction.

Experimental

A palladium stock solution was prepared by dissolving reagent grade $PdCl_2$ (Wako Co.) in deionized water with sufficient potassium chloride to enhance its solubility and stability. The Pd content was 0.06 M. NaI, KCl, en, 1,2-propanediamine (1,2-pn, Merck), 1,3-propanediamine (1,3-pn, Janssen), 1,4-butanediamine (bn, Janssen), 1,6-hexanediamine (hn, Merck) were all dissolved in deionized water to 2 M. The concentration of Triton X-100 (Merck) solution was 0.1%. The test solutions were prepared by mixing these stock solutions to desired concentrations. Hydrochloric acid and sodium hydroxide were used to adjust the pH value.

All CV and NPP experiments were performed on an EG&G Model 384B polarographic analyzer. A mercury drop electrode controlled by mechanical motions (EG&G Model 303A) was used as the working electrode (electrode area 0.009 cm^2). Platinum wire and a silver-silver chloride electrode (SSCE) were used as counter and reference electrodes, respectively. In CV experiments the scan rates ranged from 25 mV s^{-1} to 500 mV s^{-1} while the scan rate was 10 mV s^{-1} with a drop time of 1 second for all NPP experiments. Before the measurements, nitrogen purified through the vanadium (II) chloride scrubbing solution was bubbled into test solutions for 10 minutes to exclude the dissolved oxygen.

All chemicals were reagent grade and used without further purification. The complexes were identified by ultraviolet-(UV) absorption experiments (Hitachi, model 320).[26-28]

Results and Discussion

1. Fundamental Kinetic Studies. First we discuss the reversibility of the $Pd(en)_2^{2+}$ reduction process. Fig. 1 shows the cyclic voltammogram of $Pd(en)_2^{2+}$. Obviously the complex reduction is irreversible. For a totally irreversible system, peak current (I_p) is proportional to the square root of scan rate ($v^{1/2}$) which is not the case for a partially irreversible process. Figure 2 confirms this.

The kinetic parameters and diffusion coefficients were derived from NPP experiments. The normal pulse polarogram of $Pd(en)_2^{2+}$ without the addition of

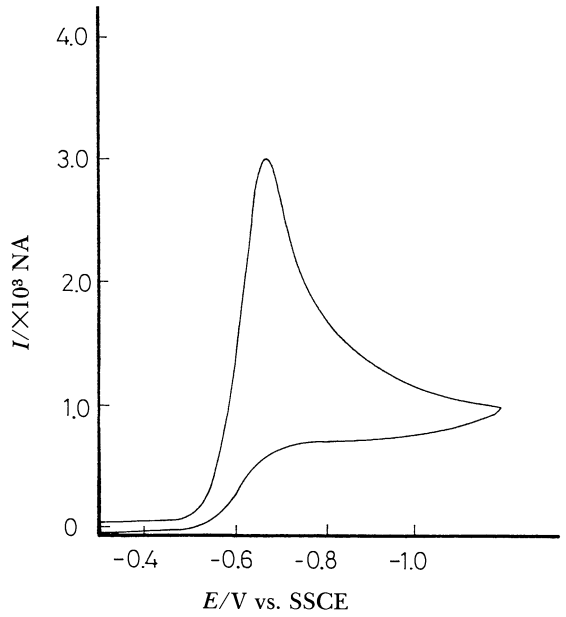

Fig. 1. Cyclic voltammogram of $Pd(en)_2^{2+}$. Solution contains 0.1 M KCl, 0.1 M en, 3×10^{-4} M $Pd(en)_2^{2+}$, scan rate 400 mV s^{-1}.

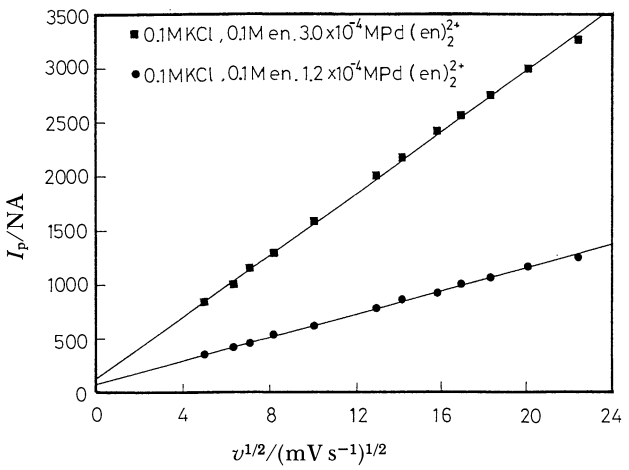

Fig. 2. Plot of I_p vs. $v^{1/2}$.

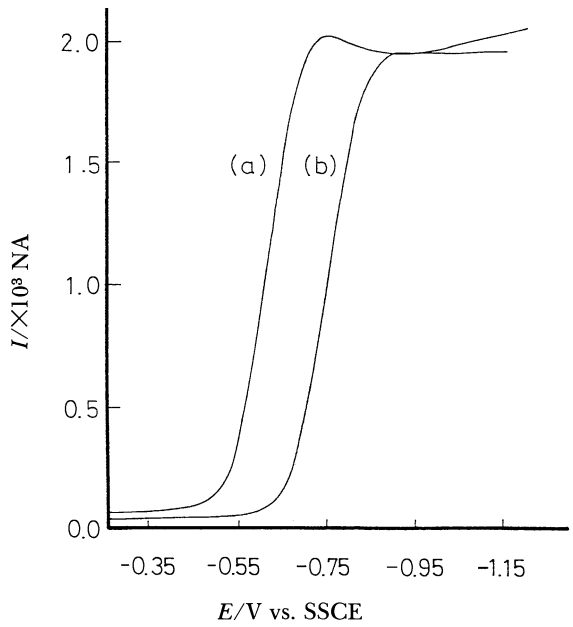

Fig. 3. Normal pulse polarogram of $Pd(en)_2^{2+}$. Solution contains 0.1 M KCl, 0.1 M en, 1.2×10^{-4} M $Pd(en)_2^{2+}$, and (a) no Triton X-100 (b) 0.003% Triton X-100.

Triton X-100 is shown in Fig. 3(a) which contains a maximum. In order to analyze the polarogram successfully, Triton X-100 was added to suppress the maximum. The result is shown in Fig. 3(b). The addition of Triton X-100 shifts the reduction toward negative direction by about 0.15 V.

The relationship between the diffusion-controlled current(I_d) and bulk solution concentration (C_b) is known as:[29]

$$I_d = \frac{nFAD_o^{1/2}C_b}{\pi^{1/2}(t-t')^{1/2}} \quad (1)$$

where n, F, and A are number of electrons transferred, faradic constant, and electrode surface area respectively, D_o is diffusion coefficient, and t-t' is the NPP sampling time (40 milliseconds). With this equation, the diffusion coefficients can be calculated.

The polarograms were analyzed according to the method proposed by Oldham and Parry for irreversible processes.[30] A plot of log $\{x^2(1.75+x^2)/(1-x)\}$ (where $x=i/i_d$) against electrode potential E should yield a straight line whose slope and intercept can be used to calculate the charge transfer coefficient α and rate constant k. All data reported below were obtained in this way and the effects of concentrations, pH values, and ligand structure will be discussed in the following sections.

1.1. The Effects of Concentrations. The effects of concentrations of $Pd(en)_2^{2+}$ and en upon kinetic parameters and diffusion coefficient were studied. It is found that both concentrations have little influences on these figures in the concentration range of 1.5×10^{-5} to 3×10^{-4} M ($Pd(en)_2^{2+}$) and 0.1 to 0.001

M(en). The αn, $E_{1/2}$, and k^r values are 0.51, −0.75 (V vs. SSCE), and 3.7×10^{-4} (cm s^{-1}) respectively. The diffusion coefficient is 1.1×10^{-5} $cm^2 s^{-1}$ which is somewhat larger than those obtained by Simpson et al.[6] ($4—8\times10^{-6}$ $cm^2 s^{-1}$, for Pd(II) in solutions containing chloride and acetate) and by Harrison et al.[13] (7×10^{-6} $cm^2 s^{-1}$, for Pd(II) in chloride solutions).

1.2. The Effects of pH Values. The normal pulse polarograms were also studied in various pH values. Surprisingly different mixing procedures gave different results. Thus it is important to identify the complexes which exist in test solutions. The results in Table 1(a) were obtained from solutions of various pH values which were prepared by adding $PdCl_2^{2-}$, then HCl (or NaOH) to en solution. It is discovered that $Pd(en)_2^{2+}$ was always formed completely since the limiting current observed was the same throughout the pH values studied. The reductions were stable in basic conditions while the half-wave potential shifted negatively with the increase of acidity in acid region. This potential change is attributed to the chloride effect introduced by the addition of HCl since similar results were observed when KCl was used in the experiments instead. It is thus concluded that the accumulation of chloride moves the reduction potential of $Pd(en)_2^{2+}$ toward the hydrogen evolution region and is unfavorable in the electroplating process.

Table 1(b) shows the NPP results obtained from the opposite mixing procedure, i.e., HCl (or NaOH) was added to en solution before the $PdCl_4^{2-}$. Different results were observed in pH 3.55 and 12.56. In acidified solutions the reduction current of $Pd(en)_2^{2+}$ decreased with increasing H^+ concentration and finally the reduction wave disappeared. This phenomenon can be explained by en protonation reported by De Waal and Robb.[31] Since

$$en + H^+ \rightleftarrows Hen^+, \quad (2)$$

$$Hen^+ + H^+ \rightleftarrows H_2en^{2+}, \quad (3)$$

the major species in an acidified en solution is H_2en^{2+}. After complete protonation, H_2en^{2+} loses its ability to form a complex with Pd(II). This en protonation results in a diminution of free en and then $Pd(en)_2^{2+}$ concentration. Finally in highly acidified solutions, the $Pd(en)_2^{2+}$ reduction current can not be found any more.

This explanation is supported by the UV absorption experiments. The pH 3.55 solution in Table 1(b) showed a λ_{max} of 280 nm with high intensity, which is characteristic of $PdCl_4^{2-}$. Obviously there was no free en to subsititute the chloride of the added $PdCl_4^{2-}$ and consequently no $Pd(en)_2^{2+}$ reduction was observed.

The polarogram in highly basic condition (pH 12.56) in Table 1(b) is presented in Fig. 4(a). A two-wave polarogram was observed. Also shown in Fig. 4(b) is the polarogram of the same solution without en (i.e., the complex in solution is $Pd(OH)_4^{2-}$). From Fig. 4(b) it is apparent that $Pd(OH)_4^{2-}$ is not reduced in the potential range studied. Thus the reduction current in Fig. 4(a) should be attributed to $Pd(en)_2^{2+}$ reduction. In fact the half-wave potential of the first wave is almost the same as that of $Pd(en)_2^{2+}$. This result may be explained qualitatively as follows. As $PdCl_4^{2-}$ was added into a highly alkaline en solution,

Table 1(a). Parameters Calculated from NPP Data in Solutions of 0.1 M KCl+0.001 M en+1.2×10^{-4} M $PdCl_4^{2-}$+0.003% Triton X-100+Various Amounts of HCl or NaOH to Desired pH Values

11.56	0.50	0.75	3.9	1.1
12.56	b)	b)	b)	b)

a) No $Pd(en)_2^{2+}$ reduction was observed. b) Two-wave polarogram was observed, see Fig. 4(a).

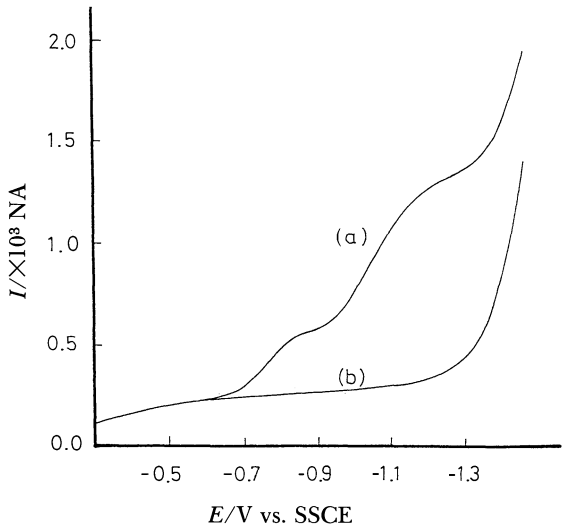

Fig. 4. Normal pulse polarograms of solutions of 0.1 M KCl, NaOH (to pH=12.56), 1.2×10^{-4} M $PdCl_4^{2-}$, 0.003% Triton X-100, and (a) 0.001 M en (b) without en.

chloride was substituted by either en or OH^- group and consequently there exist both $Pd(OH)_4^{2-}$ and $Pd(en)_2^{2+}$ in the solution. The UV absorption of the solution in Fig. 4(a) shows that the absorption maximum occurs at 365 nm, which is the same as that of the solution in Fig. 4(b), but with a smaller intensity. This observation implies that the solution in Fig. 4(a) contains both $Pd(OH)_4^{2-}$ and $Pd(en)_2^{2+}$ and the UV absorption of $Pd(en)_2^{2+}$ may be covered by that of $Pd(OH)_4^{2-}$.

Now the polarogram can be explained. In the first wave, $Pd(en)_2^{2+}$ is reduced and a limiting current which is controlled by the diffusion of $Pd(en)_2^{2+}$ is achieved. But en released due to $Pd(en)_2^{2+}$ reduction accumulates on the electrode surface and reacts with $Pd(OH)_4^{2-}$ to form more $Pd(en)_2^{2+}$. As a result the reduction current increases again and the surface concentration of $Pd(OH)_4^{2-}$ decreases as the potential increases. Finally another limiting current which is subjected to the diffusion of $Pd(OH)_4^{2-}$ appears.

1.3. The Effects of Ligand Structure. In order to investigate the effects of ligand structure on the complex reduction, we also carried out the CV and NPP experiments of Pd(II) in solutions containing aliphatic diamines with different carbon numbers. The experimental results show that they are all reduced irreversibly and the calculated parameters are summarized in Table 2.

The αn values are almost the same although the half-wave potentials do exhibit some difference between the 5 complexes. This is quite reasonable if we consider the essence of these complexes. Willis[5] reported that Pd(II) complexes have increasing negative half-wave potentials as the ligand becomes more basic. Hirota et al.[8] further pointed out that the reduction is directly related to the stability of the complex. Though the diamines studied here have greater basicity when the length of the carbon chain increases, the half-wave potential does not change significantly. This can be explained in terms of the chelate structure of the complexes. As the carbon number increases, the half-wave potential shifts in the negative direction because of the increasing basicity. However, too long a chain makes the chelate ring unstable and results in the shift of half-wave potential in the positive direction. As a result a maximum occurred at the ligand, 1,3-pn. The same effects were also observed in the rate constants.

The variation of ligand also has an influence upon diffusion coefficient as shown in Table 2. Obviously the complex with a larger volume has a smaller diffusion coefficient, which is consistent with the prediction of the Wilke-Chang equation.[32]

2. Reduction Mechanism Studies. For the reduction of $Pd(en)_2^{2+}$ on mercury electrode, we consider three possible mechanisms as follows:

$$\text{(a) } Pd(en)_2^{2+} + 2e^-(Hg) \longrightarrow \text{Pd-amalgam} + 2en, \quad (4)$$

$$\text{(b) } Pd(en)_2^{2+} \rightleftarrows Pd(en)^{2+} + en, \quad (5)$$

$$Pd(en)^{2+} + 2e^-(Hg) \longrightarrow \text{Pd-amalgam} + en, \quad (6)$$

$$\text{(c) } Pd(en)_2^{2+} \rightleftarrows Pd^{2+} + 2en, \quad (7)$$

$$Pd^{2+} + 2e^-(Hg) \longrightarrow \text{Pd-amalgam}. \quad (8)$$

Corresponding to these three mechanisms, the current-concentration relationships are:

$$I = K[Pd(en)_2^{2+}], \text{ for (a)}, \quad (9)$$

$$I = K[Pd(en)_2^{2+}][en]^{-1}, \text{ for (b)}, \quad (10)$$

$$I = K[Pd(en)_2^{2+}][en]^{-2}, \text{ for (c)}, \quad (11)$$

where K is a proportional constant and $[Pd(en)_2^{2+}]$, [en] represent concentrations of $Pd(en)_2^{2+}$ and en respectively. The difference of the electrochemical reaction orders between the three possible mechanisms are listed in Table 3.

First we carried out the NPP experiments without the addition of Triton X-100 to avoid the interference which may be introduced by surface active materials such as gelatin, Triton, etc. Figures 5 and 6 are the $\log I$ vs. $\log C$ plots derived from NPP experiments under various $Pd(en)_2^{2+}$ and en concentrations. These figures show that the electrochemical reaction orders with respect to $Pd(en)_2^{2+}$ and en are 1 and 0 respectively. Hence according to Table 3 we conclude that the reduction mechanism is mechanism (a), i.e., $Pd(en)_2^{2+}$ is reduced to Pd-amalgam directly (Eq. 4).

The influence of Triton X-100 on the reduction mechanism of $Pd(en)_2^{2+}$ was also investigated through NPP analyses. One of the polarograms is shown in Fig. 3(b). It seems that Triton X-100 shifts the reduction toward negative direction and has little effect upon its shape except in the region where diffusion becomes important. The electrochemical reaction orders with respect to $Pd(en)_2^{2+}$ and en in the presence of Triton X-100 were also calculated from $\log I$ vs. $\log C$ plots and were found to be 1 and 0 respectively.

Table 2. Parameters Calculated from NPP Data in Solutions of 0.1 M KCl, 0.003% Triton X-100, and 1.2×10^{-4} M $Pd(L)_2^{2+}$

L	αn	$-E_{1/2}$	$k^r\times10^{-4}$	$D_o\times10^{-5}$
		V vs. SSCE	cm s^{-1}	cm^2 s^{-1}
en	0.51	0.75	3.7	1.1
1,2-pn	0.53	0.73	4.7	1.0
1,3-pn	0.53	0.78	1.7	1.0
bn	0.52	0.74	3.6	0.8
hn	0.51	0.56	83	0.3

Table 3. Electrochemical Reaction Orders for Different Reduction Mechanisms

Electroactive species	Electrochemical reaction order	
	$[Pd(en)_2^{2+}]$	[en]
$Pd(en)_2^{2+}$	1	0
$Pd(en)^{2+}$	1	−1
Pd^{2+}	1	−2

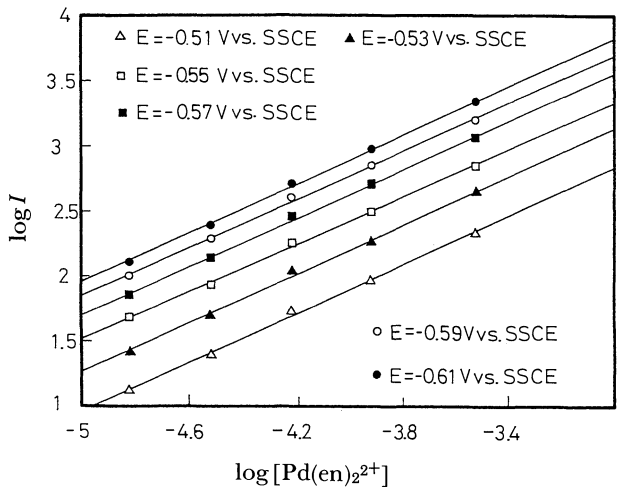

Fig. 5. Plot of $\log I$ vs. $\log[Pd(en)_2^{2+}]$. Solutions contain 0.1 M KCl, 0.1 M en, and various $Pd(en)_2^{2+}$ concentrations.

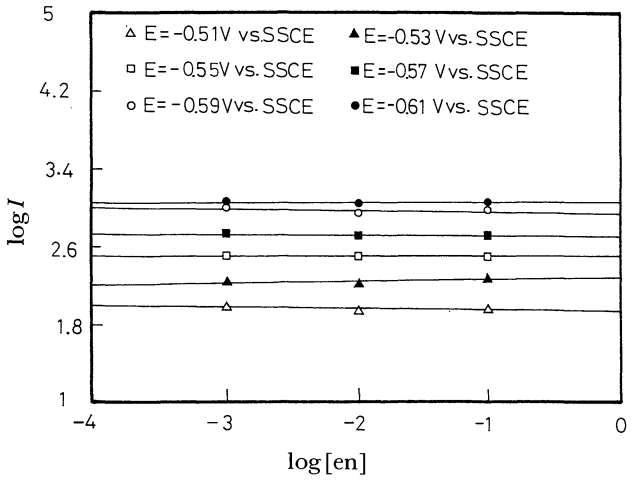

Fig. 6. Plot of $\log I$ vs. $\log[en]$. Solutions contain 0.1 M KCl, 1.2×10^{-4} M $Pd(en)_2^{2+}$, and various en concentrations.

Based on these results we know that Triton X-100 does not alter the reduction mechanism of $Pd(en)_2^{2+}$.

We also studied further the nature of the discharge complex in double layer by adding iodide into electrolyte. Because of its ability to be adsorbed strongly on mercury surface and its electrochemical inactivity,[33-36] iodide is commonly used to distinguish between the inner sphere and outer sphere mechanisms for reductions of positively charged complexes. For an inner sphere mechanism, the transition state will be formed at the inner Helmholtz Plane (IHP). The presence of iodide which is strongly adsorbed on the surface will lead to a competition for adsorption sites which should raise the energy of the transition state and produce a lower reaction rate. But if an outer sphere reaction pathway is involved, the addition of iodide should produce rate changes only if there is an alternation in the potential at the outer

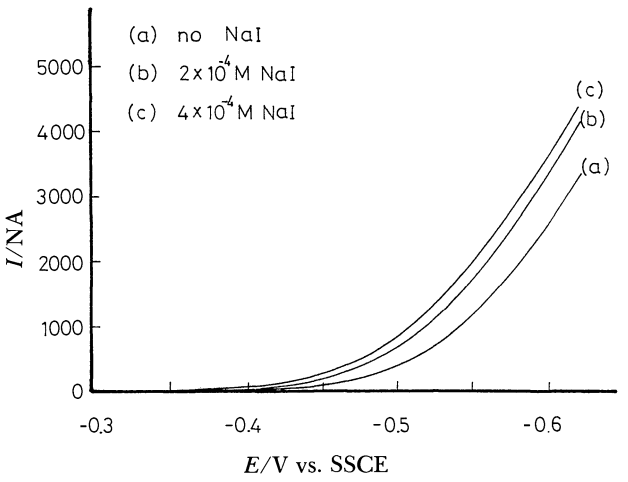

Fig. 7. Iodide effect on NPP experiments. Solutions contain 0.1 M KCl, 0.1 M en, 3×10^{-4} M $Pd(en)_2^{2+}$, and different amounts of NaI.

Helmholtz Plane (OHP). This will result in a surface concentration increase because of the greater electrostatic attraction caused by iodide adsorption. Consequently a current increase is expected.

The iodide effects on normal pulse polarograms of $Pd(en)_2^{2+}$ are shown in Fig. 7. An increase in current was observed which implies that $Pd(en)_2^{2+}$ reduction should proceed via the outer sphere mechanism. That is, the complex does not enter the inner Helmholtz Plane.

Conclusions

Both CV and NPP data show that $Pd(en)_2^{2+}$ reduction is an irreversible process. The reduction is independent of both $Pd(en)_2^{2+}$ and en concentrations. The half-wave potential is -0.75 V (vs. SSCE, in the presence of 0.003% Triton X-100) and diffusion coefficient is 1.1×10^{-5} $cm^2 s^{-1}$.

Different mixing procedures give different complexes which have been identified by UV absorption experiments. If Pd(II) is added to en solution before pH adjustment, $Pd(en)_2^{2+}$ is always formed completely. When Pd(II) is added to an acidified en solution, the $Pd(en)_2^{2+}$ reduction current decreases and finally no $Pd(en)_2^{2+}$ reduction can be observed. On the other hand, adding Pd(II) to an en solution of high OH^- concentration results in a two-wave polarogram. The two waves are controlled by the diffusion of $Pd(en)_2^{2+}$ and $Pd(OH)_4^{2-}$ respectively.

The reduction of different Pd-diamine complexes depends on the coordinated ligands. A compromise of basicity and chelate ring size results in a maximal half-wave potential at $Pd(1,3\text{-pn})_2^{2+}$.

The electrochemical reaction orders with respect to $Pd(en)_2^{2+}$ and en are 1 and 0 respectively and won't be altered by the addition of Triton X-100. The addition of iodide increases the reduction current of $Pd(en)_2^{2+}$. From these two results, we conclude that

the $Pd(en)_2^{2+}$ reduction process can be described as follows:

$$Pd(en)_2^{2+}\ (bulk) \rightleftarrows Pd(en)_2^{2+}\ (OHP),$$

$$Pd(en)_2^{2+}\ (OHP) + 2e^- (Hg) \longrightarrow Pd\text{-amalgam} + 2en.$$

(Received April 9, 1990)

The kinetics of oxidation of *trans*-1,2-cyclohexanediaminetetraacetatocobaltate(II) by peroxodiphosphate (PDP) in acetate buffers was studied in the presence of Ag(I). For the first time, this study gives a clear evidence for the involvement of Ag(I)/Ag(II) cycle in the Ag(I)-catalyzed PDP oxidation reactions in acetate buffers. A plausible mechanism consistent with the observed kinetic features is proposed.

Peroxodiphosphate (PDP) is the structural and electronic analogue of peroxodisulfate (PDS). The Ag(I)-catalyzed reactions of PDP are scanty[1,2] when compared with those of PDS.[3] In acid medium, the PDP reactions are liable to occur via a hydrolytic path and the reactivity was ascribed to the hydrolytic product. In acetate buffered medium, the hydrolysis of PDP is negligible and the reactive species is PDP itself. In this medium, the uncatalyzed reactions were reported to be slow[4] and Ag(I) is recently proposed as an efficient catalyst for these reactions.[4-7] But these studies could not clearly establish whether the reaction occurs through an Ag(I)/Ag(II) cycle or via complexation of PDP with Ag(I). We report in this communication the results of our studies to clarify the role played by Ag(I) in the Ag(I)-catalyzed oxidation of *trans*-1,2-cyclohexanediaminetetraacetatocobaltate(II), $[Co(cydta)]^{2-}$ by PDP in acetate buffers.

Experimental

All the aqueous solutions were prepared afresh with double distilled deionized water. Peroxodiphosphate is a gift sample from FMC Corporation, USA and was used as such. Its aqueous solutions were standardized iodometrically.[8] *trans*-1,2-Cyclohexanediaminetetraacetic acid (H_4cydta) is an Aldrich sample and the aqueous solutions of its disodium salt were standardized against standard zinc sulfate solution in ammonical buffers (pH=10) using Eriochrome Black T as indicator. All other reagents were either AR or GR grade as the case may be. Ionic strength of the medium was maintained by using E. Merck's 'p.a.' grade sodium nitrate. The pH of the medium was maintained by varying [AcOH] and fixing [AcONa]. In all the kinetic runs, the ligand was in 10% excess to that of [Co(II)].

The kinetics of the reaction were monitored spectrophotometrically by measuring the increase in absorbance of the product, $[Co(cydta)]^-$ at 545 nm using a Carl Zeiss 'Spekol' spectrocolorimeter in conjunction with an EK_5 attachment and a Cenco circulation cum immersion thermostat. Toshniwal's CL-46 digital pH meter was used for adjusting the pH of the reaction mixtures. The reaction was initiated by adding the temperature-equilibrated Ag(I) solution to the rest of the reaction mixture kept at 30.0±0.1 °C in a black coated reaction vessel. The reaction mixture was immediately transferred to the optical cell of the spectrocolorimeter and the increase in optical density (OD) at 545 nm against the reagent blank was noted from time to time.

Results

When the spectrum of the reaction mixture in a typical kinetic run was recorded with time on a Shimadzu UV-260 spectrophotometer in the range 360—600 nm, two absorption maxima (380 and 545 nm) were noticed all through the reaction time unlike in earlier reports using other oxidants[9] where the former peak was noticed after a certain period of time since the commencement of the reaction.

The stoichiometry of the reaction was determined under the conditions: $[Co^{II}(cydta)^{2-}] \gg [PDP]$ at 30.0±0.1 °C. The amount of $[Co^{III}(cydta)^-]$ formed

a) I=0.3 mol dm^{-3}: Temp=30.0±0.1 °C.

was estimated by measuring the optical density of the reaction mixture at the end of the reaction (D_∞) as indicated by its constancy with time and the molar absorbance of the [Co^{III}(cydta)$^-$]. It was observed that 2 moles of [Co^{II}(cydta)$^{2-}$] required one mole of PDP for its complete oxidation.

The progress of the reaction was monitored at 545 nm upto 80% completion of the reaction. The plots of (D_∞-D_t) versus time (where D_∞ and D_t are the optical densities of the reaction mixture after completion of the reaction and at time 't' respectively) were linear. From the slopes of these plots, the zero-order rate constants (k_0) were evaluated and are given in Table 1. The zero-order rate constants were found to be independent of [Co(cydta)$^{2-}$], suggesting the independence of the reaction rate on the [Co(cydta)$^{2-}$]. When the substrate was varied in the range (5.0—30.0)$\times10^{-4}$ mol dm^{-3}, keeping all other parameters constant, the D_∞ values were plotted against [Co(cydta)$^{2-}$], a straight line passing through origin was obtained. From the slope of this plot, the molar extinction coefficient (ε) was found to be 310±8 mol^{-1} dm^3 cm^{-1}, which is in good agreement with that reported earlier[10] for [Co(cydta)$^-$] under similar experimental conditions, thus supporting our view that the product is exclusively [Co(cydta)$^-$]. The zero-order rate constants (k_0) were found to increase with increasing [PDP] and a plot of k_0 versus [PDP] was a straight line passing through the origin, suggesting the first-order dependence of the reaction rate on [PDP]. When the kinetic runs were carried out by varying [Ag(I)] in the range (5.0—20.0)$\times10^{-4}$ mol dm^{-3}, keeping all other parameters constant, the zero-order rate constants were found to increase linearly with [Ag(I)] and a plot of k_0 versus [Ag(I)] was a straight line passing through the origin confirming that the reaction is also first-order in [Ag(I)]. Increase in pH of the reaction medium increased the rate. A plot of $k_0\{K_a+[H^+]\}$ versus [H^+], where K_a is the third acid dissociation constant of PDP,[11] was a straight line with a positive slope and positive intercept on the ordinate (Fig. 1). Sodiumacetate and disodiumhydrogenphosphate were found to have no effect on the reaction rate at fixed [H^+] where as increasing [H_2cydta^{2-}] and ionic strength had inhibitory effect on the reaction rate. The reaction mixture initiated polymerization of acrylonitrile monomer suggesting the involvement of free radical intermediates in the reaction. Although at [H^+] used in the kinetic runs, the characteristic test for Ag(II)[12] was not observed, perhaps due to unfavorable conditions for the formation of the orange red colored precipitate of Ag(II)-bipyridyl complex, it was positive when the reaction mixture was acidified.

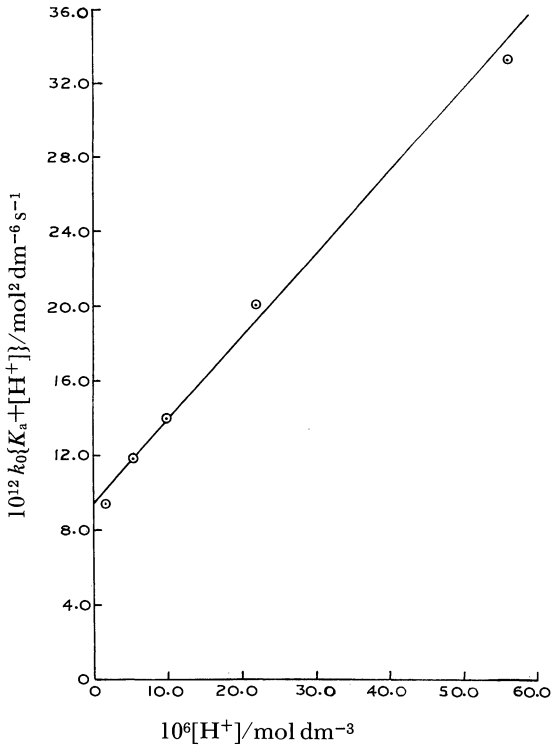

Fig. 1. Plot of $k_0\{K_a+[H^+]\}$ vs. [H^+]. [Co^{II}(cydta)$^{2-}$]= 2.0×10^{-3} M; [PDP]=3.0×10^{-2} M; [Ag(I)]=1.0×10^{-3} M; I=0.3 M; Temp=30.0±0.1 °C.

Discussion

The earlier studies on the oxidation of [Co^{II}(cydta)$^{2-}$] by various oxidants[9,10,13,14] point out to its direct oxidation by the oxidant via the formation of an innersphere complex or in a direct step. In the oxidation of [Co^{II}(cydta)$^{2-}$] by PDS, clear first-order dependence on each [reactant] was reported.[10] With periodate as the oxidant,[13] the order in [Co^{II}(cydta)$^{2-}$] was found to vary between **1** and **2**. In the present study, the direct oxidation of [Co^{II}(cydta)$^{2-}$] by PDP was not observed, thus making the presence of Ag(I) as a catalyst mandatory. This is interesting because the oxidation of metal ions and their complexes by PDP was reported to follow an innersphere path way[15] and Co(II) complexes are known to be labile. Despite this, the reaction doesnot occur in absence of a catalyst like Ag(I).

In the earlier reports[4-7] on the Ag(I) catalyzed oxidation reactions of PDP in acetate buffers, the catalytic role of Ag(I) was ascribed to its complexation with PDP rather than to the formation of higher oxidation states of Ag(I). The earlier investigators could not obtain any experimental evidence for the existence of Ag(II) or Ag(III) in the reaction, but at the same time they could not also rule out the possibility of Ag(II) or Ag(III) being involved in the reaction. In the present case, the zero-order dependence of the reaction rate on [Co(cydta)$^{2-}$] and the positive test for Ag(II) unequivocally suggests that Ag(II), which is formed as an active intermediate, is responsible for the oxidation of the substrate. Further it was observed that in absence of either PDP or Ag(I), the reaction

was negligible, thus ruling out the possibility of oxidation of [Co(cydta)$^{2-}$] by either PDP or Ag(I) alone. In the earlier studies on Ag(I) catalyzed oxidation reactions of PDP in acid media, the formation of Ag(II) as an intermediate was reported.[1,2] In the present study also in absence of the substrate, when PDP is added to Ag(I) in acetate buffers (pH=5.0) a black precipitate which slowly changes to a pale yellow was noticed. It is interesting to recall that Edwards[11] reported that this black precipitate is a peroxodiphosphate complex of silver which rapidly oxidizes water to form Ag(I). When Ag(II) generated electrolytically is added to [Co(cydta)$^{2-}$], an intense pink color characteristic of [Co(cydta)$^{-}$] was immediately noticed. A perusal of the redox potentials of the couples: PDP/PO_4^{3-} (2.01 V); Ag(II)/Ag(I) (1.98 V) and [Co(cydta)$^{-}$]/[Co(cydta)$^{2-}$] (0.62 V)# shows that the oxidation of [Co(cydta)$^{2-}$] is readily feasible. The quantitative nature of the reactions with Ag(II) either as a reactant or a product could not be established unequivocally as it is highly unstable under the experimental conditions. Although in the mechanism now proposed, the $HPO_4^{\cdot-}$ was also shown to be the reactive species responsible for the oxidation, it may be noted that it is formed along with Ag(II) in step(3). Further Michaelis-Menten type kinetic pattern characteristic of the precomplexation equilibrium was not observed. This may be due to the fact that even if the Ag(I)PDP complex is formed, it immediately decomposes to give the reactive intermediates, thus escaping its identification kinetically.

Under the experimental conditions, $H_2P_2O_8^{2-}$ and $HP_2O_8^{3-}$ are the active oxidizing species of PDP. The linearity of the plot of $k_0\{K_a+[H^+]\}$ versus $[H^+]$ suggests that both the species are reactive. Keeping in view these facts, the following mechanism is proposed.

$$H_2P_2O_8^{2-} \overset{K_a}{\rightleftharpoons} HP_2O_8^{3-} + H^+, \quad (1)$$

$$H_2P_2O_8^{2-} + Ag^+ \overset{k_1}{\longrightarrow} Ag^{2+} + HPO_4^{\cdot-} + HPO_4^{2-}, \quad (2)$$

$$HP_2O_8^{3-} + Ag^+ \overset{k_2}{\longrightarrow} Ag^{2+} + HPO_4^{\cdot-} + HPO_4^{3-}, \quad (3)$$

$$[Co^{II}(cydta)]^{2-} + Ag^{2+}/HPO_4^{\cdot-} \overset{fast}{\longrightarrow} products. \quad (4)$$

This mechanism leads to the rate law:

$$k_0 = \frac{[PDP]_t[Ag(I)]_t\{k_1[H^+]+k_2K_a\}}{\{K_a+[H^+]\}},$$

where $[PDP]_t$, $[Ag(I)]_t$ represent the total analytical concentrations of the respective reagents and K_a is the third acid dissociation constant of PDP. This rate law explains all the observed facts. From the slope and intercept values of the $k_0\{K_a+[H^+]\}$ versus $[H^+]$, the k_1 and k_2 were calculated to be: $(14.2\pm0.5)\times10^{-3}$ $mol^{-1}dm^3s^{-1}$ and (43.5 ± 0.8) $mol^{-1}dm^3s^{-1}$ at 30.0 ± 0.1 °C. This shows that $HP_2O_8^{3-}$ is ca. 10^3 times more reactive than $H_2P_2O_8^{2-}$ towards Ag(I). From the Arrhenius plot the activation parameters for the two steps were calculated to be: $E_{act}=(96.9\pm0.6)$ and (58.1 ± 0.5) kJ mol^{-1} and $\Delta S^*=+(68\pm4)$, and $-(29\pm0.2)$ J K^{-1} mol^{-1} respectively at 30.0 ± 0.1 °C.

Experimentally determined by the authors in the present study.

Two of us (PSS and KAK) are thankful to the CSIR and DAE, India for the financial assistance. Our special thanks are due to Frank Caropreso of FMC Corporation, USA for the free gift of a PDP sample.

On the Partitioning of the NMR B'-Coefficient. The Evaluation of Single Ion B'-Coefficients by a New Method and the Correlation with the Viscosity B-Coefficient, Partial Molal Volume and Electrostatic Entropy of Solvation of Ions in Aqueous and Nonaqueous Systems

Moni Mohan BHATTACHARYYA
Physical Chemistry Section, Department of Chemistry, University College of Science, Calcutta 700009, India
(Received July 17, 1990)

A new method of division used for the viscosity B-coefficient has now been extended to the partitioning of the NMR B'-coefficient both in aqueous and various nonaqueous systems. The derived set of B_i'-values, unlike those obtained by other methods in water are found to be quantitatively related to the ionic molal volumes obtained by the UVP method. The usual assumption of equal contributions of K^+ and Cl^- ions has been discarded. Abraham et al.'s electrostatic entropy of solvation of ions has also been found to give excellent linear correlation with the derived NMR B_i'-values in different solvents. The striking feature is that the NMR B_i'-values as derived by Abraham and coworkers by a different method are almost identical to the present values in all the nonaqueous solvents studied. The slight disagreement observed for the aqueous system has been discussed as being due to encroaching of the disordered second layer to the first layer of solvation, thereby making the absolute entropy estimates less certain. Both the cationic and anionic B_i'-values are represented by a single smooth parabolic curve against the crystal ionic radii as predicted by the theory. The hydration number for Cl^- ion as derived from this work agrees excellently with the widely accepted value.

Recently, there are many attempts[1-5] to derive the single ion values of various thermodynamic and transport properties of electrolytes both in aqueous and nonaqueous systems. However, similar activities for the NMR B'-coefficient, first introduced by Hertz and co-workers,[6] are rather limited. From the NMR measurements concerning the molecular motion in solutions, these authors proposed the following equation (1), in analogy with the viscosity B-coefficient,[7] of the relative proton relaxation rate for pure solvent $(1/T_1^\circ)$ and solution $(1/T_1)$ as a function of concentration:

$$\frac{1/T_1}{1/T_1^\circ} = 1 + B'c + C'c^2 + \cdots \quad (1)$$

The NMR B'-coefficient in equation (1) gives information about the reorientational behavior of solvent molecules in the first coordination sphere of the ions.

A survey of the literature shows that there has been no generally accepted method of division for the B'-coefficient in any solvent. In aqueous solution, Hertz et al.[6] partitioned the B'-coefficient assuming $B'_{K^+} = B'_{Cl^-}$ at all temperatures in analogy with the partitioning of the B-coefficient by Kaminsky.[8] Very recently, Sacco and co-workers[9] have utilized the same method as adopted for the B-coefficient in dimethyl sulfoxide (DMSO) by Bicknell et al.[10] for the separation of the B'-coefficient in the same solvent. Abraham and co-workers[11] have also partitioned both the NMR B' and viscosity B-coefficient by means of correspondence plots with the theoretically estimated electrostatic entropy of solvation of ions in various protic and aprotic solvents.

Very recently, a general method of separation of the viscosity B-coefficient applicable to both aqueous and various nonaqueous systems has been developed by the author.[12] Since the NMR B'-coefficient has almost all the attributes of the viscosity B-coefficient and also the fact that the NMR relaxation rate has better theoretical models than the viscosity, it is interesting to see how far the new method is applicable to the division of the B'-coefficient. Moreover, it is also imperative to study the relative merits of the various methods of division of the NMR B'-coefficient as far as the basis of suitable criteria is concerned. With these ends in view, we have compiled the various NMR B'-coefficient of different electrolytes reported by Hertz and co-workers,[6,13] Sacco and co-workers[9] in water, methanol, formamide, N-methylformamide (NMF), DMSO, and ethylene glycol at 25 °C.

Derivation of the Model

Now, that the NMR B'-coefficient is not only additive and a measure of ion-solvent interaction like the B-coefficient, but the hydration number from the two coefficients can also be evaluated from the two analogous expressions as follows:

$$B'^{\pm} = (\tau_c^{\pm}/\tau_c^\circ - 1)\, n_h^{\pm}/55.5 \quad (2)$$

$$B^{\pm} = (\eta_c^{\pm}/\eta_0 - 1)\, n_h^{\pm}/55.5 \quad (3)$$

where $\tau_c^{\pm}$ is the rotational correlation times,[6,13] $\eta_c^{\pm}$ is the coefficient of viscosity for the hydrated ions,[14] $n_h^{\pm}$ is the hydration number of ions, 55.5 and the subscript zero are respectively the number of moles of water per kg of water and the corresponding property for pure solvent.

a) Different estimated values. b) Ref. 11.

Thus, considering the similarity of the two definitions in Eq. 2 and 3, it is now assumed that the ionic NMR B'-values like the viscosity B_i-values should be a monotonic function of crystal radii cubed, independent of the sign of the charge.[12] The above assumption is implicit in the treatment of Couture and Laidler[15] that for large monoatomic monovalent ions, B_i' like $\overline{V}_i^\circ$ is not dependent on the sign of the charge, as the two parameters are also similar in nature. Figure 1 shows two different smooth curves of B_i' versus r_i^3 plots, one for the alkali metal ions and the other for the halide ions on the basis of $B'_{K^+}=B'_{Cl^-}$[6] in aqueous system. According to the assumption, a smooth curve representing all the cations and anions is only obtained, if an estimated correction term of 0.075 is added to the cationic B_i'-values and the same is subtracted from the anionic values. The smooth fusion of the two curves into a single one as also the same derived values obtained for K^+ and F^- ions add support to the above assumption. This is also illustrated in the figure. It is striking to note that the only alkali metal ion off the curve is Cs^+, as was similarly observed for the viscosity B-coefficient in aqueous system.[12]

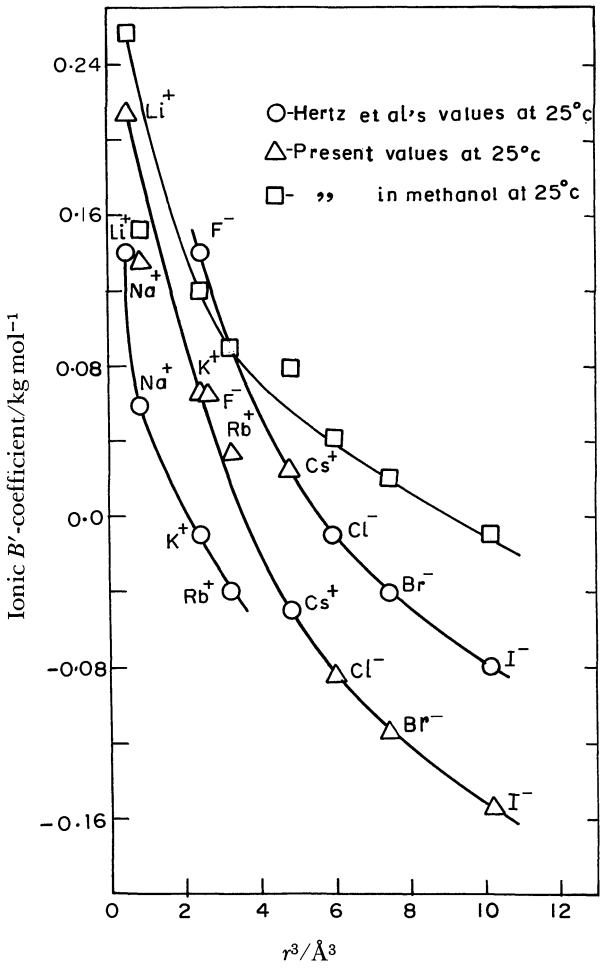

Fig. 1. The NMR B'-coefficient of alkali metal ions and halide ions plotted against r_i^3 in methanol as well as the same for two different values of B_i' based on (i) $B'_{K^+}=B'_{Cl^-}$ scale and (ii) the present scale for aqueous system.

The method of partitioning the B'-values for aqueous system at 25 °C has been extended to other temperatures also, viz. 50 °C, 80 °C with the respective correction terms being 0.080 and 0.070. Thus, in order to get B_i'-values of any ion at any temperature, one requires to add $[Z]$ times the corresponding correction term to the cationic B'-values and subtract the same from the anionic B'-values, as obtained on the assumption that $B'_{K^+}=B'_{Cl^-}$, where Z is the charge on the ion. The correction term which is the direct consequence of the assumption signifies that cations are more and anions are less solvated relative to what are obtained from the assumed equality of B_i'-values for K^+ and Cl^- ions or any other ions. Since the additivity law holds good for the B'-coefficient, the magnitude of the correction term for the oppositely charged ions becomes the same though with opposite sign.

Following the same model, the partitioning of B'-coefficient[6] in methanol, formamide, NMF, DMSO, and ethylene glycol has been carried out at 25 °C. The initial tentative B_i'-values are obtained on the basis of $B'_{Cs^+}=B'_{I^-}$ in formamide, NMF, and DMSO, whereas in methanol and ethylene glycol, $B'_{K^+}=B'_{I^-}$ and $B'_{K^+}=B'_{Cl^-}$ respectively are followed. The different correction terms estimated in various solvents are 0.034, 0.014, 0.022, 0.064, and 0.025 respectively. Also, Fig. 1 illustrates a smooth curve representing the relation between the derived B_i'-values of all the simple ions and r_i^3 in methanol only, thereby confirming the justification of the present method of division in nonaqueous systems. The thus derived B_i'-values together with the corresponding viscosity B_i-values for monovalent ions are recorded in Table 1. Also included in the table are the various ionic entropy of solvation of different ions reported by Abraham et al,[11] as also the corresponding ionic partial molal volumes mostly derived by the ultrasonic vibration potential method.[16,17]

Results and Discussion

The ionic partial molal volume also measures the ion-solvent interaction and is more akin to the B or B'-coefficient than either the more sensitive entropy of solvation[18] or the ion conductance.[19] As there are now reliable estimates of the $\overline{V}_i^\circ$-values from the definitive experimental measurements,[16,17] any quantitative correlation of this parameter with any of the derived B_i'-values by different methods would be the reasonable criterion to evaluate the relative merits of such methods. Moreover, the good linear correlations between the entropy parameter ($\Delta S_{I,II}$) and the derived B' or B-coefficient obtained by Abraham and co-workers,[11] are in fact, the direct consequence of the

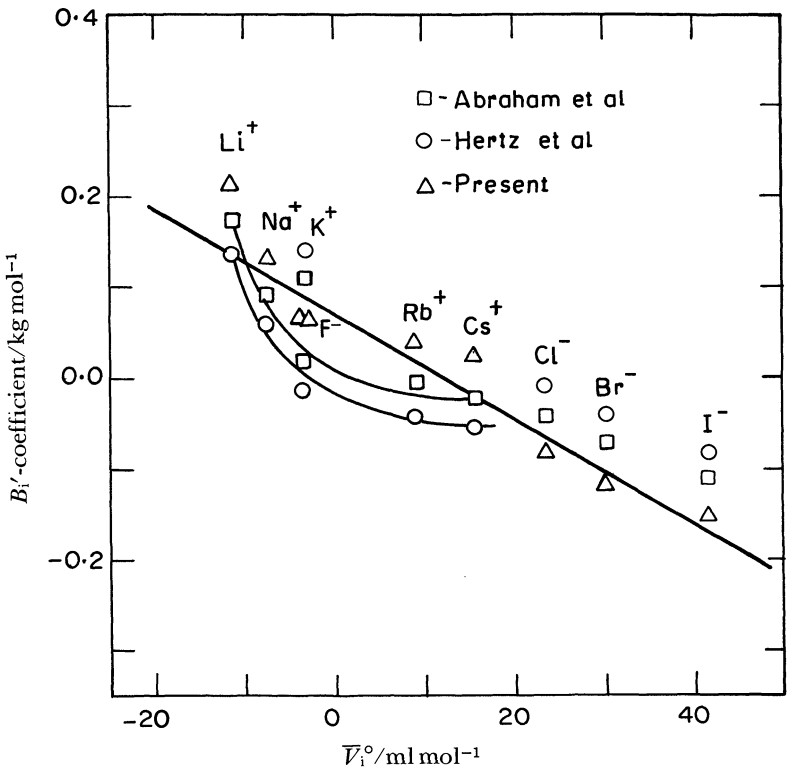

Fig. 2. Comparison of NMR B_i' versus $\overline{V}_i°$ plots for monovalent monoatomic ions between the present work and those obtained by (i) Hertz and co-workers (ii) Abraham and co-workers for aqueous system.

correspondence plots between the two parameters. In the present case, where the ionic B or B'-values are derived by an entirely different approach, any quantitative correlation between the derived B'-values and the entropy parameter ($\Delta S_{I,II}$) should demonstrate the better applicability of the present method of division.

Partial Molal Volume of Ions ($\overline{V}_i°$). Figure 2 illustrates the comparison of the various B_i' versus $\overline{V}_i°$ plots obtained by using the single ion B'-values by different methods, viz., Hertz and co-workers,[6] Abraham and co-workers[11] as well as the present method for aqueous solutions. Apart from the Li^+ ion, the B_i'-$\overline{V}_i°$ plots for all the inorganic ions studied in this work show an excellent linear correlation as anticipated, and the regression data are shown in Table 2. In comparison to this, the B_i'-values by Hertz and co-workers show a U-shaped curve indicating that the assumption $B'_{K^+}=B'_{Cl^-}$ is not satisfactory for aqueous system. Although the nonlinearity is considerably reduced in the case of B_i'-values derived by Abraham and co-workers,[11] it still deviates from the linearity shown by the present work. Exactly the same observation was also obtained in the case of viscosity B_i-$\overline{V}_i°$ plot obtained by the present method[12] in aqueous system, indicating the close similarity of the two coefficients. Moreover, the $\overline{V}_i°$ values of K^+ and F^- ions obtained by the UVP method in water are almost identical, as is similarly obtained for both the B' and B-coefficient for the same ions following the present method (Table 1).

It is striking to note that contrary to what is observed for aqueous system, the B_i'-values obtained in this work and those by Abraham and coworkers[11] are quite close in almost all the nonaqueous solvents studied here.

the B_i'-$\overline{V}_i°$ plots for all the non-aqueous solvent excepting NMF have also been studied taking different derived B_i'-values. The various $\overline{V}_i°$ values required for these plots were compiled from the UVP method for methanol[16] and ethylene glycol,[17] Mukerjee's method[20] for formamide and those reported by Abraham et al.[11] for DMSO. A comparison of B_i'-$\overline{V}_i°$ plots in methanol and formamide obtained by using B_i'-values of this work with those of Abraham et al.[11] clearly shows that the quantitative correlations are quite similar, as is evident from Table 2.

In DMSO, such comparison is made with the two different sets of B_i'-values derived by Sacco and co-workers[9] using two different reference electrolytes,[10,21] as very few data were reported by Abraham et al. in this solvent. While the B_i'-values of Sacco et al. following Lawrence et al.'s method[21] fail to correlate well with the $\overline{V}_i°$, the other set of B_i'-values[10] show comparable linear correlation with those obtained by this work (Table 2). Also, the B_i'-values of only three ions as reported by Abraham et al.[11] in this solvent are quite close to the present values.

a) Sacco et al.[9]

Electrostatic Entropy of Solvation of Ions ($\Delta S_{I,II}$). It is interesting to note that contrary to what is observed for B_i'-$\overline{V}_i^\circ$ plots in aqueous system, the B_i'-values of all the inorganic ions including Li^+ derived by the two methods give good linear correlation with the ionic entropy of solvation as shown in Table 2. A comparison of the regression data for the two linear relations, however, indicates that the Abraham et al.'s correspondence method makes the smaller ions less structure makers and the larger ions less structure breakers in water than the present method. Table 2 also reveals that the B_i'-$\Delta S_{I,II}$ correlations for the various non-aqueous systems studied here obtained by the two methods, are almost similar. However, the corresponding correlations between the viscosity-B_i versus $\Delta S_{I,II}$ also shown in Table 2 are even better than the same for the NMR B_i'-coefficient.

The striking similarity between the B_i'-values by the two methods in the nonaqueous solvents can now be explained as follows. According to Abraham et al.,[11] the entropy calculations either by one layer or two layer model in aprotic solvents result in the same value and these agree well also with the experimental values. However, this is not true in the case of hydrogen-bonded solvents, where a disordered second layer of solvation makes the calculations rather more complicated. For DMSO, NMF, methanol, and formamide, there is either no such disordered region, or the effect due to this is quite insignificant. As a result, the estimated entropy values are of the right order of magnitude. However, water being a predominantly structured solvent is also known to be highly susceptible to structure-breaking in presence of larger inorganic ions.[22] It is perhaps due to encroaching of this disordered region into the first layer that the estimated entropy values as given by Abraham et al. do not reflect satisfactorily the effective picture of ion-solvent interaction in water.

I^-	— —	— (0.3)	— (0.4)	0.2 (0.6)

Crystal Ionic Radii (r). Engel and Hertz[6] deduced the NMR B'-coefficient as a function of ionic radius by the following equation,

$$B'^{\pm} = K(ar^2 - b|Z|e + cZ^2e^2/r^2), \quad (4)$$

where K, a, b, and c are constants, $|Z|e$ is the charge on the ion.

Equation 4 can be conveniently written as

$$B'^{\pm} = A_1r^2 - A_2|Z|e + A_3Z^2e^2/r^2, \quad (5)$$

where A_1, A_2, and A_3 are the products of the various constants.

Equation 5 is a parabolic equation such that the B_i'-coefficient has high values both for smaller and higher ionic radii and a minimum in between. The expression for r_{min} can easily be obtained by equating the first derivative of B' in Eq. 5 to zero

$$r_{min} = (A_3/A_1)^{1/4}(|Z|e)^{1/2} \quad (6)$$

and by substituting r_{min} in Eq. 5 one obtains

$$B'^{\pm}_{min} = |Z|e\,[2(A_1A_3)^{1/2} - A_2]. \quad (7)$$

Thus for a change in $|Z|e$ values, both r_{min} and $B'^{\pm}_{min}$ should change by $\sqrt{|Z|e}$ and $|Z|e$ fold respectively.

Figure 3 illustrates two smooth parabolic curves of B_i' versus r_i plots, one for the monovalent ions and the other for the divalent ions. The different B'-values for various ions for aqueous solution are derived by the present method from those reported by Hertz and co-worker,[6] and are included in Table 3. The noticeable feature is that both the cations and anions of the same valence fall on the same line of the curve. This is contrary to what was demonstrated earlier by Engel and Hertz[6] showing two separate curves for the cations and anions with the B_i'-values derived on the basis of $B'_{K^+} = B'_{Cl^-}$. It is now known that the cation-solvent and anion-solvent interactions are very similar in aqueous as also in many nonaqueous solutions.[16,23] Figure 3 also reveals that while the increase in $B'^{\pm}_{min}$ for $Z=2$ is in accordance with Eq. 7, the same for r_{min} is slightly larger than that predicted by Eq. 6.

Rotational Correlation Times and the Hydration Number. Equation 2 gives the values of $(\tau_c^{\pm}/\tau_c^{\circ})$ for various ions provided the hydration number $(n_h^{\pm})$ is known with certainty. According to Engel and Hertz,[6,13] if $\tau_c^{\pm}/\tau_c^{\circ} > 1$, then the ion is structure forming and for $\tau_c^{\pm}/\tau_c^{\circ} < 1$, the ion is structure breaking. Table 4 compares such values for simple inorganic ions calculated with B_i'-values derived by the two methods, viz., Hertz and co-workers and the present method, assuming arbitrary values of $n_h = 4,6,8$, and 10. The interesting feature of Table 4 is that only the present method rules out the possibility of hydration

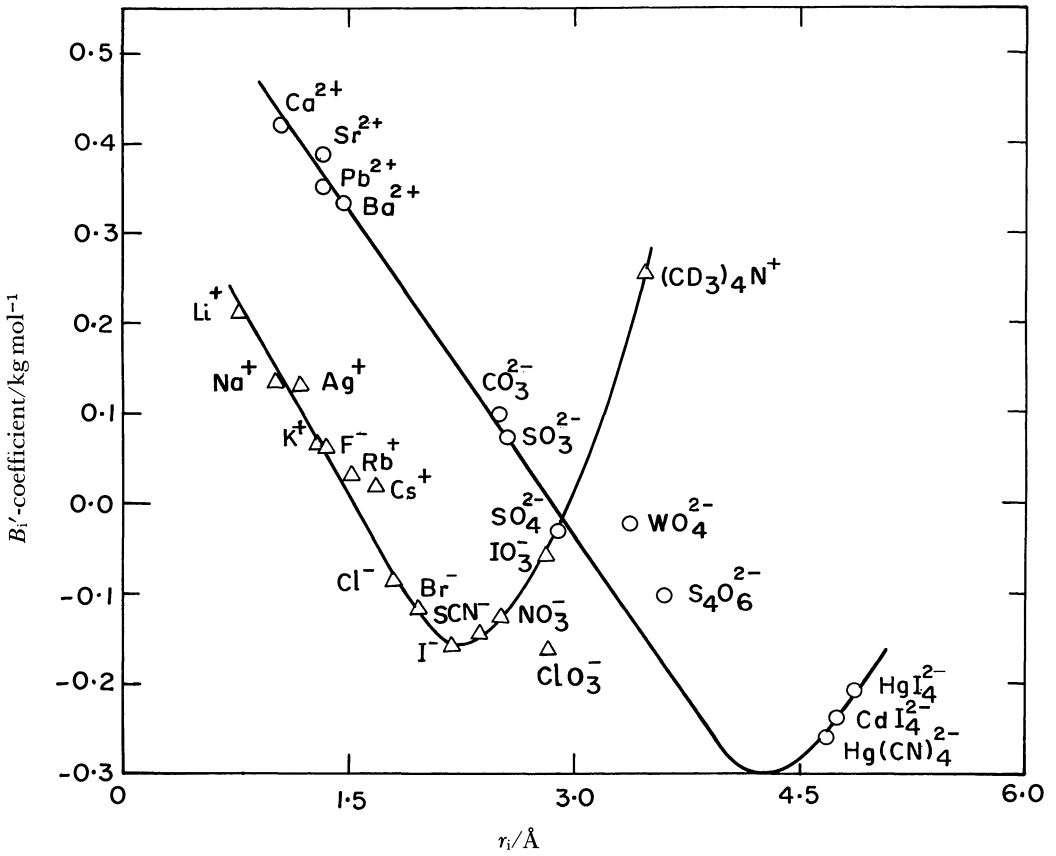

Fig. 3. Variation of ionic NMR B'-values with crystal ionic radii at 25 °C for aqueous system.

number equal to 4 for Cl^- because of the negative value obtained for $(\tau_c^{\pm}/\tau_c^{\circ})$, and agree with a value of 6 instead, which is confirmed by definitive experimental studies.[24]

Moreover, Hertz and co-workers[13] also estimated the correlation time for fluoride ion (τ_c^-) in aqueous solution, considering the unsymmetrical arrangement of water molecule in the hydration sphere (nonrigid) of the ion and the values are $\tau_c^- \approx 1 \times 10^{-11}$ s for $n_h=4$ and $\tau_c^- \approx 0.5 \times 10^{-11}$ s for $n_h=6$. The corresponding values from the proton relaxation data derived by the present method are 0.5×10^{-11} s and 0.4×10^{-11} s respectively. The fair agreement between the values in the case of $n_h=6$ thus strongly favors the latter as the hydration number for F^- ion.

The author is indebted to Professor M. Sengupta, Calcutta University, for initial inspiration in this area of chemistry, and also thankful to the referee for courteous comments.

The redox characteristics of the title compounds are extensively studied using DC-, cyclic voltammetry, coulometry, and controlled potential electrolysis in benzonitrile at platinum electrodes. These compounds are oxidized in one-electron transfer process followed by deprotonation which leads to dimerization. The reduction process differs according to the nature of the compound and the electron-withdrawing power of the substituent in the α-position. They can be reduced in a single two electron or two one electron waves leading in both cases to saturation of the hydrazonic moiety.

The electrochemical behavior of α-arylhydrazononitriles and their *N*-methylated derivatives has been recently reported in literature.[1-8] The increase of interest in the chemistry of this class of compounds arose from their reported biological activity.[9-13] It has been found that these compounds are more effective than cyanides in the uncoupling oxidative phosphorylation in mitoconderial systems.[14,15] In a previous investigation,[16] it has been shown that arylhydrazonomesoxalonitrile (**I**) are electrochemically active in proton-free benzonitrile. These compounds are oxidized in a single irreversible one-electron-transfer process forming the corresponding radical cation which undergoes dimerization reaction. The electrochemical reduction occurs through acceptance of two electrons in two successive irreversible one-electron waves following the well-known ECEC-mechanism. In connection with this work we report here the redox characteristics of different substituted ethyl α-cyano-α-(arylhydrazono)glyoxalates (**II**) and 2-arylhydrazono-3-oxo-3-phenylpropionitriles (**III**).

Experimental

Organic Synthesis. All compounds involved in this investigation are prepared following the procedures described by Bennett[17] and Elnagdi.[18] The obtained products were purified by repeated crystallization from ethanol.

Reagents. Benzonitrile (BN) (Rotitainerm, West Germany) was purified by first distillation under vacuum from orthophosphoric acid, followed by repeated distillations from phosphorus pentaoxide and final fractional distillation from potassium metal. The supporting electrolyte tetrabutylammonium perchlorate (TBAP) (Fluka-Swiss) was crystallized several times from ethanol-water (9:1 v/v) mixture and dried in vacuum before use.

Apparatus and Instruments. The voltammetric measurements were carried out with the following apparatus:

Potential Source : Potential Scan Generator VSG 72.
Potentiostat : Potential Control Amplifier PCA 72C (Bank Electronic, Gottingen, W. Germany).
X-Y Recorder : Servoger XY (Metrawatt, Nurnberg, West Germany).
Digital Multimeter: T 2201 (Hartman & Braun, Frankfurt, West Germany).
Coulometer : (Bank Electronic, Gottingen, W. Germany).

The rotating platinum disc electrode (RDE) is mounted to a rotating motor (750 rpm) (Metrohm, Swiss).

Measurements. The electrochemical measurements were carried out in dry benzonitrile (BN) containing 0.1 M TBAP (1 M=mol dm^{-3}). The voltammetric study involved direct current (DC) voltammetry at RDE and cyclic voltammetry at a stationary platinum disc electrode. The number of electrons participating in each electrode process was obtained by the controlled potential coulometry (CPC) at a platinum sheet electrode. The electrode potentials were measured against saturated Ag/AgCl/Cl^- (BN) electrode, which was from time to time calibrated against the redox potential of cobaltocenium/cobaltocene system.[19] The standard potential of Ag/AgCl/Cl^- (BN) electrode against the normal hydrogen electrode (NHE) is −176 mV.[20,21]

Controlled Potential Electrolysis (CPE). Electrolysis of ethyl α-cyano-α-(*p*-chlorophenylhydrazono)glyoxalate (**IId**). CPE was carried out twice with 300 mg of **IId** in both acetonitrile and benzonitrile. The potential was adjusted at a value on the limiting current plateau (+2.2 V in oxidation and −1.2 V in reduction). The electrolysis was stopped after the passage of a quantity of electricity corresponding to the uptake of 1 mole of electrons per mole of product for oxidation and 2 moles at reduction. In each case, after electrolysis, the resulting solution was evaporated in vacuo and the product was extracted with ethyl acetate solvent which was evaporated in turn. The obtained mixture was chromatographed on thin-layer silica-gel plates using chloroform solvent.

The Reduction Product of CPE. A quantitative yield of the original compound **IId** was obtained. Anal. Calcd: C,

52.49; H, 3.98; Cl, 14.12; N, 16.70%. Found: C, 52.33; H, 3.84; Cl, 13.98; N, 16.80%. IR (KBr) 3220 (NH), 2220 (CN), 1760 (ester CO), 1620 cm^{-1} (C=N). ^1H NMR ($CDCl_3$, TMS) δ=1.4 (t, 3H, $\underline{CH_3}$-CH_2-), 3.6 (q, 2H, CH_3-$\underline{CH_2}$-), 7.2—7.5 (m, 4H, aromatic protons), 10.0 (s, br, 1H, NH).

The Oxidation Product of CPE. Two main products were obtained:

i) The zone with R_f value 0.68 was scraped off the plate and extracted with acetonitrile, filtered and evaporated in vacuo. The resulting solid compound (yield 55 %) was identified as compound **IV**. Anal. Calcd: C, 41.38; H, 3.13; Cl, 22.26; N, 13.17%. Found: C, 41.20; H, 3.01; Cl, 22.40; N, 13.12%. IR (KBr) 3220—3300 (two NH), 2220 (CN), 1760, 1750 (ester CO), 1630 (C=N), 1220 cm^{-1} (ClO_4^-). ^1H NMR ($CDCl_3$, TMS) δ=1.4 (t, 6H, two $\underline{CH_3}$-CH_2-), 3.6 (q, 4H, two CH_3-$\underline{CH_2}$), 7.2—7.5 (m, 8H, aromatic protons), 10.0 (s, br, 2H, two NH).

ii) The zone with R_f value 0.79 was scraped and extracted as above. The obtained product (yield 30%) was identified as compound **V**. Anal. Calcd: C, 52.69; H, 3.59; Cl, 14.17; N, 16.77%. Found: C, 52.52, H, 3.53; Cl, 14.23; N, 16.59%. IR (KBr) 3200—3300 (two NH), 2220 (CN), 1760—1750 (ester CO), 1630 cm^{-1} (C=N). ^1H NMR ($CDCl_3$, TMS) δ=1.4 (t, 6H, two $\underline{CH_3}$-CH_2-), 3.6 (q, 4H, two CH_3-$\underline{CH_2}$-), 7.2—7.4 (m, 6H, aromatic protons), 10.0 (s, br, 2H, two NH).

Results and Discussion

The voltammetric redox data of compounds (**IIa—h** and **IIIa—h**) are summarized in Table 1. Figures 1 and 2 represent typical DC- and cyclic voltammograms of the investigated compounds respectively.

Ethyl (Arylhydrazono)glyoxalate (IIa—h). All the investigated compounds **IIa—h** behave similarly in shape in both oxidation and reduction. They are oxidized in a single irreversible one-electron process which is followed by a coupled chemical reaction (EC-mechanism). This mechanism is clearly indicated by the absence of the corresponding reduction peak in the

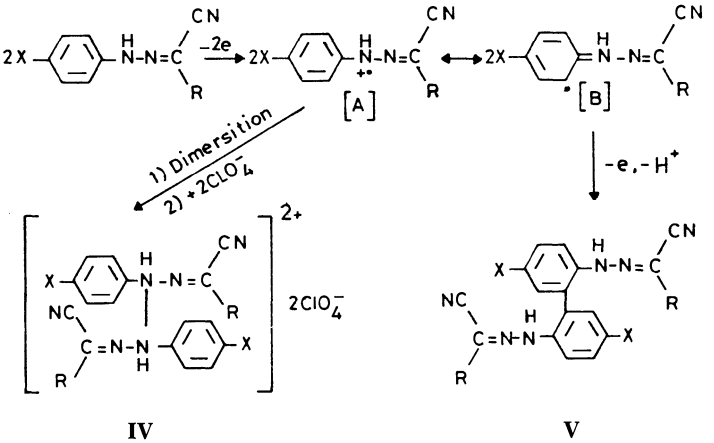
reverse cycle[22] of the cyclic voltammogram (Fig. 2). The reduction process occurs through the acceptance of two electrons in a single irreversible wave following also the EC-mechanism. The irreversibility of the electrode process is obtained also from the slope of the logarithmic analysis curves[23] as shown from Table 1. The amino group in the compound (**IIg**) can be also oxidized in a first oxidation wave and the nitro group in the compound (**IIb**) reduced in the well-known reduction wave of nitro aromatic compounds.

2-Arylhydrazono-3-oxo-3-phenylpropionitrile (IIIa—h). These compounds are oxidized in the same manner as compounds (**IIa—h**) in a single irreversible one-electron transfer process following the EC-mechanism. The reduction process is markedly different: Although the total number of electrons participating in the electrode reaction is two electrons per moelcule as for compounds (**IIa—h**), these two electrons appear not as a single wave but as a two successive irreversible one-electron waves. The *N*-methyl derivative **IIIh** behaves as its similar **IIh**; the reduction occurs in a single two-electron wave.

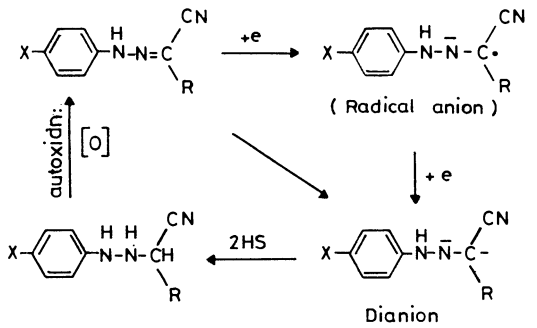
The polarographic behavior of this class of compounds was investigated.[24-29] They are reduced in a 4-electron wave in either acidic or basic media accompanied by N-N bond cleavage to the corresponding amines. Although this reduction process has been well-documented,[30] it cannot be generalized to account for the reduction of other substituted α-arylhydrazono nitriles since these compounds are tautomeric with the corresponding azo forms. The contribution of each form would depend on the nature of substituents in the molecule. Several articles suggested the existence of certain arylhydrazono nitriles in a charge separated azo form.[31,32] Recently the different substituted (*N*-methylarylhydrazono)-mesoxalonitriles were studied in both aqueous and nonaqueous media.[33,34]

In this work, based on the careful analysis of the data obtained and the identification of the resulting product of CPE, Scheme 1 is suggested for the electrochemical oxidation of the investigated compounds.

The electrochemical oxidation (Scheme 1) proceeds through a one-electron transfer forming the radical cation with its canonical forms A and B. Mesomer A undergoes a dimerization process leading to the formation of the dication **IV** which can be stabilized through its combination with two perchlorate ions from the supporting electrolyte forming salt (**IV**). Also mesomer B may be dimerized with proton removal from the ortho-position in the phenyl ring leading



Scheme 1.



VI

Scheme 2.

to the formation of the neutral dimer **V**.

The difference in electron-withdrawing power of the $-COOC_2H_5$ and -CN or $-COC_6H_5$ groups plays a significant role in the mode of the reduction process. The high electron-withdrawing power of the -CN or $-COC_6H_5$ groups compared with that of $-COOC_2H_5$ group stabilized the firstly formed radical anion which appears in a well-defined separate one electron wave.

The reduced center in these compounds is the -N=C double bond which accepts two electrons to form the corresponding dianion. The formed dianion would be strong base enough to abstract protons from the solution (from the solvent-moisture or from the supporting electrolyte or even from the solvent itself)[35,36] forming compound **VI**. It is clear from the structure of **VI** (Scheme 2) that this compound is unstable especially in air, which can be oxidized with air oxygen to give the starting substance. This is in full agreement with the results obtained from CPE. Thus instead of the final product **VI**, a quantitative yield of the starting material was isolated.

Separation of Scandium(III) as Ascorbato Complex by Extraction with Aliquat 336S

M. A. KARVE and S. M. KHOPKAR*
Department of Chemistry, Indian Institute of Technology, Bombay 400076, India
(Received February 8, 1990)

Scandium was quantitatively extracted with 0.1 mol dm^{-3} Aliquat 336S in xylene at pH=6.0 from 0.01 mol dm^{-3} ascorbic acid. It was stripped with 1 mol dm^{-3} hydrochloric acid and determined as its complex with Arsenazo III. It was separated from binary mixtures by exploiting the difference in the extraction behavior from ascorbic acid. Several separations were accomplished by process of selective stripping with concentrated hydrochloric acid. Many interesting separations of scandium from associated elements like yttrium, thorium, uranium, and molybdenum have been carried out.

Solvent extraction separation methods for scandium with liquid anion exchangers from organic acid media are limited. Scandium was separated from solutions of EDTA,[1] malonic,[2] citric,[3] and succinic acids.[4] 4—5% of Amberlite LA-1,[2] Aliquat 336S[3,4] was used with xylene or benzene as the diluent. 0.05—0.1 mol dm^{-3} of organic acid was employed. At pH 2.5—4.5 extraction was carried out while stripping was done from 0.5—8 mol dm^{-3} of mineral acids. However iron(III), zirconium, vanadium (V), thorium, and molybdenum showed strong interference. Similar studies from sulphate[5,6] and nitrate media were also not effective in separating scandium.

In this paper a new method is proposed for extraction of anionic complex of scandium from ascorbic acid at pH 6.0 with 0.1 mol dm^{-3} Aliquat 336S. The chief advantage of the proposed method is the possibility of separation of scandium from large number of less common elements.

Experimental

Apparatus and Reagents. An ECIL spectrophotometer GS866C with matched 10 cm corex glass cuvettes and an ECIL pH meter with combined glass electrodes as well as wrist action flask shaker were used.

A stock solution of scandium was prepared by dissolving 1.50 g of scandium oxide in 100 cm^3 of boiling nitric acid. It was diluted to one liter with distilled water and was standardized complexometrically with EDTA using xylenol orange as an indicator.[8] It contained 1.045 mg cm^{-3} of scandium. The solution containing 40 μg cm^{-3} of scandium was prepared by dilution.

Aliquat 336S (General Mills Ltd., England), Amberlite LA-1 or LA-2 (Rohm and Hass Co., U.S.A.), trioctylamine (Riedel Haen, Germany), and Primene JMT (Rohm and Hass Co., U.S.A.) were used without further purification in the ascorbate form.[9]

General Procedure. To an aliquat of solution containing 40 μg of scandium, 5 cm^3 of 0.01 mol dm^{-3} ascorbic acid was added. The pH of the solution was adjusted to 6.0 with 0.01 mol dm^{-3} ammonia or ascorbic acid. The solution was diluted to 10 cm^3. It was transferred into a separatory funnel. Then 10 cm^3 of 0.1 mol dm^{-3} Aliquat 336S in xylene was added and the solution was shaken on a wrist action flask shaker for 15 minutes. The two phases were allowed to settle and separate. Scandium from the organic phase was stripped with 10 cm^3 of 1 mol dm^{-3} hydrochloric acid. Then 2.5 cm^3 of 8% ascorbic acid, 0.5 cm^3 of 13.6% sodium acetate trihydrate, and 2 cm^3 of 0.1% Arsenazo III were added in total volume of 25 cm^3 to develop blue color. The absorbance was measured spectrophotometrically at 670 nm against a reagent blank. The concentration of scandium was computed from the calibration curve.[10]

Results and Discussion

Extraction of Scandium as a Function of pH. The pH for the quantitative extraction of scandium was ascertained by extracting scandium at pH 1—8 with 4% solutions of various liquid anion exchangers in xylene (Fig. 1). At pH 6.0 the extraction was 15% with Amberlite LA-1 while it was less than 25% with

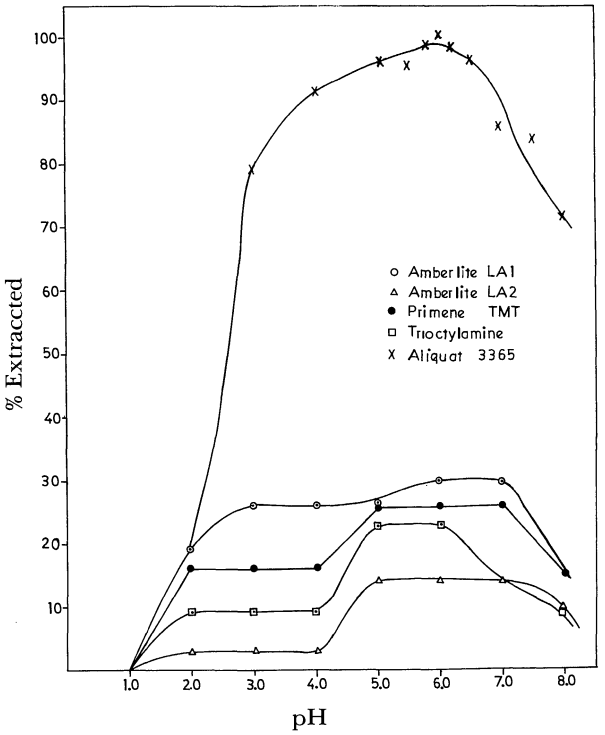

Fig. 1. Extraction of scandium as a function of pH with various liquid anion exchangers.

Primene JMT and Trioctylamine, and with Amberlite LA-1 it was 30%. Since only with Aliquat 336S extraction was quantitative this was used throughout the work.

Effect of Varying Concentration of Aliquat 336S. Scandium was extracted at pH 6.0 with 10 cm^3 of various concentrations and volume of 0.1 mol dm^{-3} Aliquat 336S in xylene. Scandium was quantitatively extracted with 10 cm^3 of 0.1 mol dm^{-3} Aliquat 336S in xylene (Table 1).

Effect of Varying Concentration of Ascorbic Acid. Scandium was extracted at pH 6.0 with 0.1 mol dm^{-3} Aliquat 336S in xylene from varying concentration of ascorbic acid (Table 2). The extraction was quantitative from 0.008 mol dm^{-3} concentration of ascorbic acid. 0.01 mol dm^{-3} ascorbic acid was used in subsequent work.

Effect of Various Diluents. Benzene, toluene, xylene, hexane, cyclohexane, chloroform, and carbon tetrachloride were used as the diluents for Aliquat 336S. The phase volume ratio was maintained as 1 : 1. The aromatic hydrocarbons proved to be efficient while hexane, chloroform, and carbon tetrachloride proved to be poor. Xylene was preferred as the diluent due to nontoxicity and clear phase separation (Table 3).

Period of Shaking. Scandium was extracted for different time of shaking ranging from 2.5, 10, 15, and 20 minutes. The corresponding extraction was 55, 90, 100, and 100% respectively. Hence 15 minutes period of equilibration was employed throughout the work.

Effect of Various Stripping Agents. After extraction, scandium was stripped with various acids and salts (Table 4). 1—8 mol dm^{-3} hydrochloric acid or 0.5—8 mol dm^{-3} sulfuric acid or nitric acid could strip scandium quantitatively. Hydrochloric acid was preferred as it facilitated direct spectrophotometric determination of scandium in the aqueous phase.

Separation from Binary Mixtures. The separation of scandium was attempted from binary mixtures. The alkali, alkaline earths, lead, or iron were not extracted with scandium. This in turn facilitated their separation. Cerium, yttrium, chromium, manganese, cobalt, nickel, copper, zinc, and aluminium formed weak complexes with ascorbic acid, but such complexes could be stripped with water before stripping of scandium with 1 mol dm^{-3} hydrochloric acid. However scandium was coextracted along with titanium, zirconium, hafnium, thorium, vanadium, or molybdenum. Therefore these separations were effected by stripping scandium with 8 mol dm^{-3}

Table 1. Effect of Varying Concentration and Volume of Aliquat 336S

hydrochloric acid followed by, stripping of these elements with 1 mol dm^{-3} hydrochloric acid. During stripping these elements formed anionic chlorocomplexes with hydrochloric acid and were in turn reextracted in Aliquat 336S and were back washed with 1 mol dm^{-3} hydrochloric acid.

Separation of Scandium from Multicomponent Mixtures. When a mixture of manganese, scandium, and vanadium was extracted, manganese was first stripped with water, then scandium with 8 mol dm^{-3} hydrochloric acid and finally vanadium with 0.1 mol dm^{-3} hydrochloric acid.

Iron(II), scandium(III), and hafnium(IV) were separated after extraction by first stripping scandium with 10 mol dm^{-3} hydrochloric acid, then hafnium with 1 mol dm^{-3} hydrochloric acid and finally unextracted iron was determined directly in the aqueous phase.

Cerium(III), scandium(III), and thorium(IV) were separated after extraction by stripping of scandium with 5 mol dm^{-3} nitric acid, thorium with 2 mol dm^{-3} hydrochloric acid and cerium was stripped with water.

After extraction, cerium(III), scandium(III), and uranium(VI) were separated by washing cerium with water, then stripping scandium with 8 mol dm^{-3} hydrochloric acid and finally uranium with 0.5 mol dm^{-3} sodium hydroxide.

Aluminium(III), scandium(III), molybdenum(VI), and uranium were separated after extraction, by stripping aluminium with water, scandium with 4 mol dm^{-3} hydrochloric acid, molybdenum with 4 mol dm^{-3} nitric acid and uranium with 0.5 mol dm^{-3} sodium hydroxide.

Cerium(III), scandium(III), uranium(VI), and thorium(IV) were separated by stripping cerium with water, scandium with 5 mol dm^{-3} nitric acid, uranium with 0.5 mol dm^{-3} sodium hydroxide and thorium with 2 mol dm^{-3} hydrochloric acid (Tables 5 and 6).

The proposed method is simple, rapid, selective, and applicable at tracer concentration. Scandium was separated from uranium, thorium, hafnium, molybdenum, and vanadium which are generally associated with it in fission products.

We are thankful to the Council of Scientific and Industrial Research for sponsoring this project and awarding J.R.F. to M.A.K. (This paper was awarded Professor Pandu Rang Rao memorial award at the 26th Annual Meeting of Indian Chemical Society at Indore in December 1989.)

(Received April 24, 1990)

A series of tetraaryl-substituted cumulenes were synthesized and characterized by elemental analysis, ^{1}H NMR, and MS spectra. Their inclusion capabilities for a variety of organic solvents were examined. It was found that substitution on the phenyl groups connected to both ends of these cumulenes critically influences their inclusion behavior since the substituents dictate the size and shape of lattice space for accommodation of the guest molecules. The crystal structures of an unsolvated butatriene and its 1:2 inclusion compounds with *p*-xylene and *o*-xylene were determined by X-ray crystallography. The structural analysis showed that the guest molecules do not simply fit into the free space of the host lattice, but their presence rearranges the packing mode of the host molecules in the inclusion compounds.

Considerable interest in clathrates[1] and similar systems has arisen over the past few years. This has led to the development of new strategies in clathrate formation[3] and the design of novel host types.[4] Recently we have shown that allene host molecules (e.g. **1** and **2**) provide access to a new family of channel-type clathrates.[5,6] Obviously they depend on the bulk of host substituents present.

In order to ascertain whether inclusion behavior is critically effected by the special geometry and dimensions of the 1,2-diene framework,[7] we became interested in the potential host properties of cumulenes which are the higher analogs of allenes.[8] It is important to note that allenes and cumulenes have either orthogonal or co-planar pairs of substituents at both ends of the molecule depending on the number of double bonds present;[9] i.e. from allenes to the higher cumulenes orthogonal and co-planar orientations alternate. Moreover, the central axle is gradually increased on going from allenes to higher cumulenes. This will allow geometrical and dimensional tuning of possible host molecules. Representative examples illustrating these considerations are the tetraaryl-substituted cumulenes **3**—**7**, which may be contrasted with the allenes **1** and **2**.

In the present work, we describe the preparation of

7

cumulenes **3**—**7**, report on their crystal inclusion properties, and give X-ray crystal structure demonstrations of unsolvated host **6** and of two of its isolated host-guest species, namely **6**·*o*-xylene (1 : 2) and **6**·*p*-xylene (1 : 2).

Results and Discussion

Synthesis. Except for **3**,[10] the cumulenes **4**—**7** have not been reported previously in the literature. Trienes **3**—**6** and the tetraene **7** were prepared on different synthetic routes.[10,11] For trienes **3**—**6**, vinyl bromide was treated with phenyllithium in dry ether to give dilithium acetylide. On reaction with the corresponding ketone, diols **8a**—**c** and **9** were obtained in 39—65% yield. Diols **8a**—**c** and **9** were reduced with tin(II)chloride dihydrate on powder reaction to yield the cumulenes **3**—**6** in 58—80%. For tetraene **7**, diethyl glutarate was treated with four equivalents of 4-*t*-butylphenyllithium to yield 52% of 1,4-diene **10a**. Addition of bromine gave 45% of dibromo intermediate **10b** which was bis-dehydrobrominated with methanolic potassium hydroxide to yield 70% of cumulene **7**.

Inclusion Properties. Because of the co-planar orientation of σ-bonds in the triene-type cumulenes (see above), bulky substituents are required to induce free lattice space for guest inclusion.[3] Consequently **4** and **6** which bear bulky *t*-butyl groups at each aromatic residue are optimal for clathrate formation, as both the parent **3** and lower substituted **5** do not exhibit inclusion behavior. The isolated inclusion compounds of **4** and **6** are listed in Table 1. Due to the nonpolar nature of the hosts, hydrocarbon guests are well to the fore;[12] bromobenzene, cyclopentanone, and 1,4-dioxane are exceptions. Moreover, strict discrimination effects regarding the size and shape of guest molecules are inferrable from Table 1, as will be discussed below. Table 1 makes also reference to solvents not included by **4** and **6**.

Obviously the inclusion capabilities of **4** and **6** differ from each other in more than one respect. To begin with, **4** is more efficient in clathrate formation compared with **6**, which is significantly indicated by the number of isolated complexes formed by both hosts (Table 1). In addition, host **4** forms a broader range of inclusion compounds, i.e. with solvents of different classes (see Table 1) and somewhat varying dimensions (thickness), while **6** is only successful with aromatic substances. Nevertheless, aromatic substances are also the preferred guests for **4**. These findings are in agreement with geometric parameters since bridging in **6** causes flattening of the substituents and thus reduction of the net bulkiness of the host, which is reflected in its low inclusion capability.

However, from the stoichiometric ratio point of view, **6** is superior to **4** in that **6** exclusively forms clathrates of 1 : 2 stoichiometry (high percentage of guest), whereas **4** gives 1 : 1 clathrates (lower percentage of guest) in all cases, except for mesitylene (1 : 2

Table 1. Crystalline Inclusion Compounds of Cumulene Hosts **4** and **6**

Guest component[a]	Host/guest ratio[b] in inclusion compound

a) Equivalent isotropic U_{eq} defined as one third of the trace of the orthogonalized $\boldsymbol{U}$ tensor.

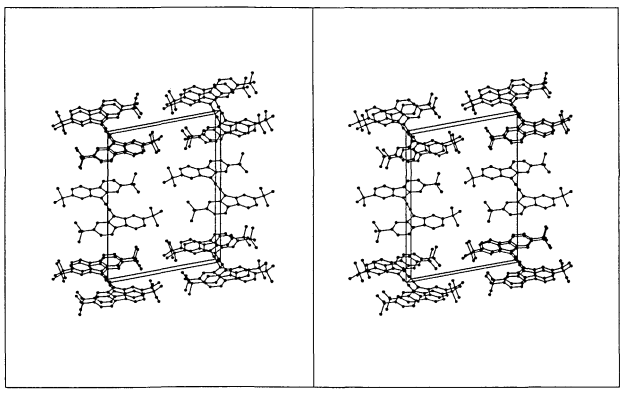

Fig. 2. Stereoview of the crystal structure of **6** parallel to the *b* axis. The origin of the unit cell lies at the upper left corner, with *a* pointing from left to right, *b* towards the reader, and *c* downwards.

stoichiometry). Considering the size of mesitylene, it is not difficult to understand why it occupies a special position. All other guests suitable for inclusion by **4** are molecules of nearly the same breadth (approximately 4.5 Å),[12] as deducible from Table 1, but in length (cf. benzene=6.9 Å with *p*-xylene=8.8 Å) and thickness (cf. benzene=3.8 Å with cyclohexane=5.6 Å) they can vary to some extent. Beyond that, it seems that **6** effects also a selection of guests via molecular thickness, since its inclusion property is limited to flat aromatic substances. This suggests different cavity dimensions and inclusion modes for the clathrates of **4** and **6**, but for the individual host species, similar inclusion structures with similar cavity dimensions

a) Equivalent isotropic U_{eq} [for C(15A)–C(22A) and C(15B)–C(22B)] defined as one third of the trace of the orthogonalized $\boldsymbol{U}$ tensor. The exponent of the isotropic temperature factor takes the form: $-8\pi^2 U \sin^2\theta/\lambda^2$.

are expected.

For the tetraene **7** which is an analog of allene **1c** elongated by two C=C bonds one would possibly anticipate a clathrate lattice suitable for inclusion of larger guest molecules. Surprisingly, however, **7** is inefficient in clathrate formation under the given solvent conditions. This compound is difficultly soluble in the low boiling solvents mentioned in Table 1. In high boiling solvents, such as xylenes or mesitylene, in which **7** is soluble, a partial decompositon of the compound prevents further inclusion studies.

X-Ray Analysis. Structure Description of Unsolvated 6, 6·*o*-Xylene (1 : 2), and 6·*p*-Xylene (1 : 2). In order to elucidate the building principles and host-guest relationships of the cumulene-type clathrates, we have carried out X-ray structural studies of free host **6** and two of its inclusion compounds, namely **6**·*o*-xylene (1 : 2) and **6**·*p*-xylene (1 : 2).

Details of crystal parameters, intensity data collection, and structure refinement are given in Table 2. The coordinates of non-hydrogen atoms for **6**, **6**·*p*-xylene (1 : 2), and **6**·*o*-xylene (1 : 2) are listed in Tables 3, 4, and 5, respectively. Table 6 shows the bond lengths and angles of host triene in the three crystals. Figure 1 is a perspective view of **6** and shows the atom labelling scheme which also applies to the host molecule in the inclusion compounds. Since there are three double bonds in the molecule of host cumulene **6**, four phenyl groups connected to both ends of the triene are almost coplanar. The center of the triene is located at a crystallographic inversion center in all three crystals.

A stereoview of the molecular packing for unsolvated host **6** is shown in Fig. 2. Figure 3 illustrates the mode of molecular packing in crystalline **6**·*p*-xylene (1 : 2). It is seen that *p*-xylene guest molecules related by the *a*-glide are accommodated in zigzag fashion within a column surrounded by *t*-butyl groups of the neighboring host molecules. In the crystal of **6**·*o*-xylene (1 : 2), the host molecules are arranged in a herringbone fashion and centered about planes of the (0 2 0) type, between which the *o*-xylene molecules are accommodated like a corrugated sheet and bounded by the *t*-butyl groups of the neighboring host molecules (Fig. 4).

a) Symmetry transformation: a=(−*x*, 1−*y*, 1−*z*) for **6** and **6**·*p*-xylene (1:2); a=(1−*x*, 1−*y*, 1−*z*) for **6**·*o*-xylene (1:2). Atoms C(16), C(17), and C(18) are to be considered as C(16A), C(17A), and C(18A), respectively, for **6**·*p*-xylene (1:2), and atoms C(1)-C(22) to be considered as C(1A)-C(22A) for **6**·*o*-xylene (1:2).

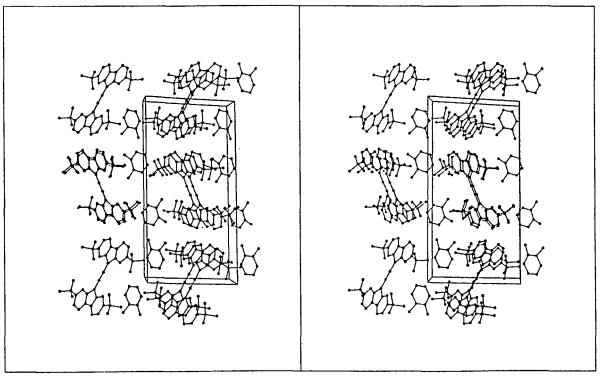

Fig. 4. Stereoview of the crystal structure of **6**·*o*-xylene (1:2) parallel to the *a* axis. The origin of the unit cell lies at the lower left corner, with *a* pointing to the reader, *b* from left to right, and *c* vertically upwards.

Conclusion

A series of cumulenes, **3**—**7**, were prepared. With a rigid backbone and dumbbell molecular shape, they are potentially useful as inclusion hosts. Substitution on the phenyl groups connected to both ends of these cumulenes critically influences their inclusion behavior since the substituents dictate the size and shape of lattice space for accommodation of the guest molecules. It was found that only cumulenes **4** and **6** with bulky *t*-butyl substituents at the phenyl rings can form inclusion compounds with various organic solvent molecules (Table 1), whereas the parent **3** and lower substituted **5** can not. The inclusion capabilities of unbridging substituted **4** differ obviously from those of bridging substituted **6**, and **4** behaves like the

analogous allenes.[5] In contrast to the closely related inclusion compounds of allenes,[5] the crystals of **6**, **6** · *p*-xylene (1 : 2), and **6** · *o*-xylene (1 : 2) not only have very different unit cells but also belong to different space groups (Table 2). The X-ray structural analysis showed that the guest molecules do not simply get into the free crystal space of the host as they do in the clathrates of allenes, but their presence rearranges the packing mode of the host molecules in the inclusion crystals. This is why **6** shows the higher selectivity in the formation of inclusion compounds and forms inclusion compounds with planar aromatic molecules only.

Experimental

General Methods and Materials. Melting points were determined with a Reichert hot-stage apparatus. IR spectra were recorded on an SP-1100 Pye-Unicam spectrometer. ^{1}H NMR spectra were measured with a Bruker WH-90 (90 MHz) spectrometer. Chemical shifts are reported in ppm (δ) down field from tetramethylsilane. Mass spectra were obtained from an A.E.I. MS 50 instrument. Elemental analyses were carried out by the Microanalytical Laboratory of the Institut für Organische Chemie und Biochemie, Universität Bonn. For column chromatography aluminum oxide (grade II—III, Merck) was used. All solvents were of reagent quality or purified by distillation before use. Starting compounds and all other reagents were purchased from Janssen unless otherwise stated.

1,1,4,4-Tetraaryl-2-butyne-1,4-diols 8a—c and 9 (General Procedure). Into a cooled solution of vinyl bromide (5.35 g, 50 mmol) in dry ether (50 ml) a solution of phenyllithium (150 mmol) in dry ether was added dropwise under N_2. The mixture was stirred for 1 h at room temperature. A solution of the corresponding ketone (90 mmol, see below) in dry ether (50 ml) was added dropwise, and the mixture was allowed to stand overnight. Hydrolysis and usual work-up[13] followed by recrystallization yielded the pure product. Specific details for each compound are given below.

1,1,4,4-Tetraphenyl-2-butyne-1,4-diol (8a). Benzophenone was reacted; recrystallization from benzene yielded 65% colorless crystals; mp 197 °C (lit,[14] 196—197 °C); ^{1}H NMR ($CDCl_3$) δ=2.90 (2H, s), 7.00—7.65 (20H, m).

1,1,4,4-Tetrakis(4-*t*-butylphenyl)-2-butyne-1,4-diol (8b). Bis(4-*t*-butylphenyl)methanone was reacted; recrystallization from ethanol/acetone yielded 39% colorless crystals; mp 280—282 °C; IR (KBr) 3650, 3100, 3000, 1120 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.27 (36H, s), 2.70 (2H, s), 7.27, 7.50 (16H, AA′BB′, J=10 Hz). Found: MS m/z (M^+) 614.4108. Calcd for $C_{40}H_{54}O_2$: 614.4124.

1,4-Bis(4-bromophenyl)-1,4-diphenyl-2-butyne-1,4-diol (8c). (4-Bromophenyl)phenylmethanone was reacted; recrystallization from ethanol/acetone yielded 42% colorless crystals; mp 124—125 °C; IR (KBr) 3500, 3100, 1040 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=3.03 (2H, s), 7.10—7.60 (18H, m); MS m/z 546 (M^+). Found: C, 60.92; H, 3.85%. Calcd for $C_{28}H_{20}Br_2O_2$: C, 61.34; H, 3.68%.

1,1 : 4,4-Bis(4,4′-di-*t*-butylbiphenyl-2,2′-diyl)-2-butyne-1,4-diol (9). 2,7-Di-*t*-butylfluoren-9-one was reacted; recrystallization from ethanol/acetone yielded 49% colorless crystals; mp 270 °C (decomp); IR (KBr) 3620, 3100, 3000, 1030 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.28 (36H, s), 2.45 (2H, s), 7.25—7.75 (12H, m). Found: MS m/z (M^+) 610.3014. Calcd for $C_{44}H_{50}O_2$: 610.3011.

1,1,4,4-Tetraarylbutatrienes 3—6 (General Procedure). Following a literature description,[15] 2.0 g of the corresponding diol (**8a—c**, **9**) was mixed with the fivefold amount of tin(II) chloride dihydrate and ground for 30 min using mortar and pistil. The powder obtained was extracted with chloroform. After removal of the solvent in vacuo, the residue was chromatographed on aluminum oxide (petroleum ether, bp 40—60 °C) and recrystallized to yield the pure product. Specific details for each compound are given below.

1,1,4,4-Tetraphenylbutatriene (3). Diol **8a** was reacted; recrystallization from ethanol/acetone yielded 80% yellow needles; mp 237 °C (lit,[15] 235—236 °C). Found: MS m/z (M^+) 356.1568; C, 94.49; H, 5.66%. Calcd for $C_{28}H_{20}$: 356.1565; C, 94.34, H, 5.66%.

1,1,4,4-Tetrakis(4-*t*-butylphenyl)butatriene (4). Diol **8b** was reacted; recrystallization from ethanol/acetone yielded 68% yellow needles; mp 281—282 °C; ^{1}H NMR ($CDCl_3$) δ=1.35 (36H, s), 7.35, 7.52 (16H, AA′BB′, J=9 Hz); MS m/z 580 (M^+). Found: C, 91.17; H, 9.25%. Calcd for $C_{44}H_{52}$: C, 90.97; H, 9.03%.

1,4-Bis(4-bromophenyl)-1,4-diphenylbutatriene (5). Diol **8c** was reacted; sublimation at 230 °C/760 Torr (1 Torr=133.322 Pa) yielded 60% yellow needles; mp 258 °C (lit,[16] 254 °C); ^{1}H NMR ($CDCl_3$) δ=7.00—7.55 (18H, m). Found: MS m/z (M^+) 511.9732; C, 64.96; H, 3.32%. Calcd for $C_{28}H_{18}Br_2$: 511.9779; C, 65.40; H, 3.53%.

1,1 : 4,4-Bis(4,4′-di-*t*-butylbiphenyl-2,2′-diyl)butatriene (6). Diol **9** was reacted; recrystallization from acetone yielded 58% red crystals; mp >320 °C; ^{1}H NMR ($CDCl_3$) δ=1.43 (36H, s), 7.25—7.95 (12H, m). Found: MS m/z (M^+) 576.3751; C, 91.70; H, 8.37%. Calcd for $C_{44}H_{48}$: 576.3756; C, 91.61; H, 8.39%.

1,1,5,5-Tetrakis(4-*t*-butylphenyl)-1,4-pentadiene (10a). Into a solution of 4-*t*-butylphenyllithium, prepared from 4-*t*-butylbromobenzene (60 g, 280 mmol) and granulated lithium (1.94 g, 280 mmol) in dry ether (300 ml), was dropped a solution of diethyl glutarate (5.3 g, 50 mmol) in dry ether (50 ml) under N_2. The mixture was heated for 2 h under reflux and then quenched with water to give a voluminous precipitate of the corresponding diol. The deposit was collected, dried, and dissolved in acetic acid (150 ml). On addition of concd sulfuric acid (0.5 ml), a dark-green solution resulted which was heated for 2 h under reflux. After cooling, the solution was diluted with water to cause a precipitate. It was collected, washed free of acid, and recrystallized from ethanol to yield 52% of colorless crystals; mp 162—164 °C; ^{1}H NMR ($CDCl_3$) δ=1.27 (18H, s), 1.30 (18H, s), 2.90 (2H, t, J=7 Hz), 5.97 (2H, t, J=7 Hz), 7.20—7.90 (16H, m); MS m/z 596 (M^+). Found: C, 90.31; H, 9.23%. Calcd for $C_{45}H_{56}$: C, 90.55; H, 9.45%.

1,1,5,5-Tetrakis(4-*t*-butylphenyl)-2,4-dibromo-1,4-pentadiene (10b). To pentadiene **10a** (20.89 g, 35.0 mmol) was added a solution of bromine (11.2 g, 70.0 mmol) in carbon tetrachloride (50 ml). Gaseous hydrogen bromide formed and a violet-colored solution resulted. After removal of the solvent in vacuo, the residue was recrystallized from ethanol/acetone to yield 45% colorless crystals, mp 225 °C; ^{1}H NMR ($CDCl_3$) δ=1.27 (36H, s), 3.80 (2H, s), 7.00—7.40 (16H, m); MS m/z 752 (M^+). Found: C, 71.35; H, 7.12%;

Calcd for $C_{45}H_{54}Br_2$: C, 71.61; H, 7.21%.

1,1,5,5-Tetrakis-(4-*t*-butylphenyl)pentatetraene (7). To a solution of dibromopentadiene **10a** (2.00 g, 2.65 mmol) in dimethylformamide (50 ml) was slowly added concd methanolic KOH (5 ml), while passing N_2 through the solution. After stirring for 10 min, methanol (20 ml) was added, followed by methanol/water (1/1 v/v, 20 ml). The precipitate formed was collected and recrystallized from benzene to yield 70% yellow needles; mp 130 °C (decomp); ^{1}H NMR ($CDCl_3$) δ=1.30 (36H, s), 7.30—7.55 (16H, m). Found: MS m/z (M^+) 592.4059. Calcd for $C_{45}H_{52}$: 592.4069.

Preparation of the Clathrates (General Procedure). The corresponding host compound (**4** or **6**) was dissolved under heating in a minimum amount of the respective guest solvent. The solution was allowed to cool down slowly. After storage for 12 h at room temperature, the crystals that formed were collected by suction filtration, washed with methanol, and dried (1 h, 15 Torr, room temperature). Host-guest stoichiometry of the isolated crystals was determined by NMR integration. Data for each compound are given in Table 1.

Crystal Structure Determination

Sample Preparation and Data Collection. Crystals suitable for X-ray diffraction were grown from the corresponding solvent. The crystals were sealed inside a Lindemann glass capillary pre-filled with a small amount of solvent at its tip portion. Raw intensities were collected on a Nicolet R3m/V four-circle diffractometer at room temperature (294 K), were processed with the profile-fitting procedure of Diamond,[17] and corrected for absorption using ψ-scan data.[18] Details of data collection and processing are listed in Table 2.

Structure Analysis and Refinement. Unsolvated Host 6. Direct phase determination[19] yielded the positions of all nonhydrogen atoms, which were subjected to anisotropic refinement. The hydrogen atoms were generated geometrically (C-H bonds fixed at 0.96 Å) and allowed to ride on their respective parent C atoms; all hydrogen atoms were assigned appropriate isotropic temperature factors and included in the structure-factor calculations.

6·*p*-Xylene (1:2). Structure solution was accomplished by direct phase determination guided by negative quartets.[19] The host molecule is located at a centrosymmmetric site, and one of the two independent *t*-butyl groups in the asymmetric units exhibits twofold orientational disorder. The six disordered carbon atoms were named C(16A), C(17A), C(18A), C(16B), C(17B), and C(18B), each of half site occupancy. In the final stage of refinement, the phenyl group of the guest molecule was constrained to be a regular hexagon with C-C bonds of 1.395(5) Å in order to overcome the problem of slight positional disorder. All C atoms were subjected to anisotropic refinement. The H atoms except those of the disordered C atoms were generated geometrically, and were included in structure-factor calculations in least-square cycles with assigned isotropic thermal parameters.

6·*o*-Xylene (1:2). The unit cell contains two independent cumulene molecules each occupying a centrosymmetric site, as well as two independent *o*-xylene molecules. Owing to the very unfavorable data-to-parameter ratio, only the C atoms of the ordered *t*-butyl groups [C(15A)-C(22A) and C(15B)-C(22B)] were varied anisotropically, whereas all other C atoms were subjected to isotropic refinement. For the cumulene molecules, the methyl groups were treated as rigid groups, and the aromatic H atoms allowed to ride on their respective parent C atoms; these H atoms were included in structure-factor calculations with assigned isotropic temperature factors. For the guest molecules, the phenyl groups were constrained to be a regular hexagon with C-C bond of 1.395(5) Å, and the distance from the methyl carbon atom to its two nearest carbon neighbors in the phenyl group were constrained to be 1.52(1) and 2.52(2) Å, respectively.

Computations were performed using the SHELTXL-PLUS program package[20] on a DEC MicroVAX-II computer. Analytic expressions of atomic scattering factors were employed, and anomalous dispersion corrections were incorporated.[21] The final atomic parameters of **6**, **6**·*p*-xylene (1 : 2), and **6**·*o*-xylene (1 : 2) are listed in Tables 3—5.[22]

Nitriles in Heterocyclic Synthesis. Synthesis and Reactions of Pyrano[3,2-*h*]quinoline Derivatives

Z. H. KHALIL, A. A. ABDEL-HAFEZ, A. A. GEIES,* and A. M. KAMAL EL-DEAN
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt
(Received May 14, 1990)

8-Quinolinol reacts with cinnamonitrile derivatives in presence of a basic catalyst to afford pyrano[3,2-*h*]quinolines (**3a—f**). The reaction of **3a** with reagents such as acetic anhydride/pyridine, formamide, formic acid/formamide, and carbon disulfide gave the fused heterotetracyclic systems pyrimido[4′,5′:6,5]pyrano[3,2-*h*]quinolines.

A variety of pyrans and condensed pyrans were prepared recently by utilizing nitriles as starting materials.[1-5] The cinnamonitrile derivatives react with different heterocyclic compounds containing hydroxyl group to produce condensed pyran derivatives.[6-8] Within this respect and also for continuation of our work for the synthesis of heterocycles containing the quinoline moiety,[9,10] the present work is aimed to synthesize different pyrano[3,2-*h*]quinolines.

Results and Discussion

8-Quinolinol (**1**) reacts with cinnamonitrile derivatives (**2a—f**) in an ethanolic solution in the presence of piperidine to afford 2-amino-4-aryl-4*H*-pyrano-[3,2-*h*]quinoline-3-carbonitriles (**3a—c**) or ethyl 2-amino-4-aryl-4*H*-pyrano[3,2-*h*]quinoline-3-carboxylates (**3d—f**) in moderate yield.

3e	193—194 (Ethanol)	66 (Yellow)	$C_{22}H_{20}N_2O_4$	3420, 3300 (NH_2), 1690 (C=O).	($CDCl_3$) 1.3 (t, 3H, CH_3), 3.9 (s, 3H, CH_3), 4.1 (q, 2H, CH_2), 5.0 (s, 1H, CH), 6.6 (s, 2H, NH_2), 6.8—8.9 (m, 9H, arom.).
3f	197—198 (Ethanol)	62 (Pala yellow)	$C_{21}H_{17}ClN_2O_3$	3400, 3300 (NH_2), 1680 (C=O).	($CDCl_3$) 1.3 (t, 3H, CH_3), 4.1 (q, 2H, CH_2), 5.0 (s, 1H, CH), 6.7(s, 2H, NH_2), 6.7—8.9 (m, 9H, arom.).
4	257—258 (Acetic acid)	85 (Pale yellow)	$C_{21}H_{15}N_3O_2$	3200 (NH), 2220 (CN), 1700 (C=O).	(DMSO-d_6) 2.3 (s, 3H, CH_3), 4.9 (s, 1H, CH), 7.0—8.9 (m, 10H, arom.), 9.2 (s, 1H, NH).
5	356—357 (Acetic acid)	52 (Brown)	$C_{21}H_{15}N_3O_2$	3100 (NH), 1660 (C=O).	(CF_3COOH) 2.8 (s, 3H, CH_3), 5.1 (s, 1H, CH), 6.9—9.0 (m, 10H, arom.).
6	333—334 (Ethanol)	50 (Brown)	$C_{20}H_{14}N_4O$	3420, 3300 (NH_2).	(DMSO-d_6) 5.1 (s, 1H, CH), 6.8—9.1 (m, 13H, NH_2 and arom.).
7	281—282 (Ethanol)	66 (White)	$C_{20}H_{13}N_3O_2$	3100 (NH), 1650 (C=O).	(DMSO-d_6) 4.9 (s, 1H, CH), 6.2 (s, 1H, NH), 7.1—9.1 (m, 11H, CH and arom.).
8	284—285 (Dioxane)	68 (Yellow)	$C_{20}H_{13}N_3OS_2$	3120, 3100 (2NH), 1230 (C=S).	(CF_3COOH) 5.2 (s, 1H, CH), 6.9—9.1 (m, 10H, arom.).
9	194—195 (Ethanol)	84 (White)	$C_{22}H_{17}N_3OS_2$	2990 (CH, aliph.), 1630 (C=N).	($CDCl_3$) 2.6 (s, 6H, $2CH_3$), 5.0 (s, 1H, CH), 7.2—9.0 (m, 10H, arom.).
10	147—148 (Ethanol)	82 (Pale yellow)	$C_{22}H_{17}N_3O$	2220 (CN).	($CDCl_3$) 1.3 (t, 3H, CH_3),4.3 (q, 2H, CH_2), 4.9 (s, 1H, CH), 7.1—8.9 (m, 11H, CH and arom.).
11a	211—212 (Ethanol)	80 (White)	$C_{20}H_{15}N_5O$	3380, 3300 ($NHNH_2$), 2200 (CN).	(DMSO-d_6) 4.9 (s, 1H, CH), 5.3 (s, 1H, NH), 5.8 (s, 2H, NH_2), 7.1—9.0 (m, 11H, CH and arom.).
11b	177—178 (Ethanol)	74 (White)	$C_{21}H_{16}N_4O$	3320 (NH), 2200 (CN).	($CDCl_3$) 3.3 (s, 3H, CH_3), 4.9 (s, 1H, CH pyran), 5.6 (s, 1H, NH), 7.1—9.2 (m, 11H, CH and arom.).

a) All products gave satisfactory microanalysis (C, ±0.36; H, ±0.22; N, ±0.23; S, ±0.28%).

Compound **3** was subjected for further reactions to produce fused heterotetracyclic systems incorporating pyrimidine nucleus in addition to pyranoquinoline moiety. Thus the reaction of **3a**, with acetic anhydride/pyridine mixture gave pyrimidopyranoquinoline **5**, while reaction of **3a** with acetic anhydride alone gave the acetamido derivative **4**. Interaction of **3a** with formamide afforded aminopyrimidine derivative **6**, while the reaction with formamide/formic acid mixture gave pyrimidinone derivative **7**.

The reaction of **3a** with carbon disulfide in pyridine proceeded through the addition of CS_2 on the amino group followed by cyclization by nucleophilic attack of the sulfur atom on the cyano group which underwent rearrangement to give pyrimidinedithiol derivative **8**.[11,12] Compound **8** reacted smoothly with methyl iodide in ethanol containing anhydrous sodium acetate to give bis(methylthio) derivative **9**.

Also, refluxing of **3a** with ethyl orthoformate in acetic anhydride gave the corresponding ethoxymethyleneamino derivative **10**. The latter compound further reacted with hydrazine hydrate or methylamine to give the corresponding derivatives **11a,b**, respectively. Attempts to cyclize compound **11a** by refluxing in ethanol containing piperidine and/or pyridine were unsuccessful.

Experimental

Melting points are uncorrected. IR spectra were recorded (KBr) on a Pye Unicam spectrophotometer. ^{1}H NMR spectra were obtained on 90 MHz Varian spectrometer in suitable deutrated solvent using TMS as internal standard. Analytical data were obtained by the microanalytical data Unit at Assiut University.

2-Amino-4-aryl-4*H*-pyrano[3,2-*h*]quinoline-3-carbonitriles (3a—c) and Ethyl 2-Amino-4-aryl-4*H*-pyrano[3,2-*h*]-quinoline-3-carboxylates (3d—f). General Procedure. A mixture of cinnamonitrile derivative (**2a—f**) (0.01 mol) and 8-quinolinol (0.01 mol) was refluxed in absolute ethanol (50 ml) containing a catalytic amount of piperidine for 5 h. The reaction mixture was concentrated, cooled and the precipitated product was collected by filtration. The physical and spectral data are summarized in Table 1.

2-Acetamido-4-phenyl-4*H*-pyrano[3,2-*h*]quinoline-3-carbonitrile (4). A mixture of **3a** (0.01 mol) was refluxed in acetic anhydride for 3 h, then cooled and poured onto ice/water mixture. The solid product thus formed was filtered off and washed several times with water.

10-Methyl-7-phenyl-7*H*-pyrimido[4′,5′:6,5]pyrano[3,2-*h*]quinolin-8(9*H*)-one (5). A solution of **3a** (0.01 mol) in Ac_2O/pyridine mixture (30 ml, 2:1 v/v) was heated on a water bath for 8 h, then cooled, and poured into ice/water mixture. The precipitate thus formed was collected by filtration and washed several times with water.

8-Amino-7-phenyl-7*H*-pyrimido[4′,5′:6,5]pyrano[3,2-*h*]-quinoline (6). A mixture of **3a** (0.01 mol) and formamide (20 ml) was refluxed for 1 h. After cooling the precipitated brown crystalline product was filtered off and washed several times with cold ethanol.

7-Phenyl-7*H*-pyrimido[4′,5′:6,5]pyrano[2,3-*h*]quinolin-8(9*H*)-one (7). A mixture of **3a** (0.01 mol) and formic acid (5 ml) in formamide (20 ml) was refluxed for 2 h. After cooling the reaction mixture was poured onto ice/water mixture and the solid product thus formed was filtered off.

7-Phenyl-7*H*-pyrimido[4′,5′:6,5]pyrano[3,2-*h*]quinolin-8,10-dithiol (8). A mixture of **3a** (0.01 mol) and carbon disulfide (5 ml) in pyridine (30 ml) was heated on water bath for 8 h. The solid product thus formed was filtered off while hot and washed several times with ethanol.

8,10-Bis(methylthio)-7-phenyl-7*H*-pyrimido[4′,5′:2,3]-pyrano[3,2-*h*]quinoline (9). A mixture of **8** (0.001 mol) and methyl iodide (2 ml) in ethanol (30 ml) in the presence of anhydrous sodium acetate (2 g) was refluxed for 2 h. The reaction mixture was concentrated, poured into cold water and the solid product was collected by filtration.

2-(Ethoxymethyleneamino)-4-phenyl-4*H*-pyrano[3,2-*h*]quinoline-3-carbonitrile (10). A mixture of **3a** (0.01 mol) and ethyl orthoformate (2 ml) in acetic anhydride (10 ml) was refluxed for 1 h. After cooling the precipitated pale yellow crystalline product was filtered off and washed severl times with cold ethanol.

2-(Hydrazinomethyleneamino)-4-phenyl-4*H*-pyrano[3,2-*h*]quindine-3-carbonitrile (11a) and 2-(Methylaminomethyl-eneamino)-4-phenyl-4*H*-pyrano[3,2-*h*]quinoline-3-carbonitrile (11b). General Procedure: A mixture of **10** (0.01 mol) and hydrazine hydrate or methylamine (0.01 mol) in absolute ethanol (50 ml) was stirred at room temperature for 15 min. The precipitated products (**11a** or **11b**) were collected by filtration.

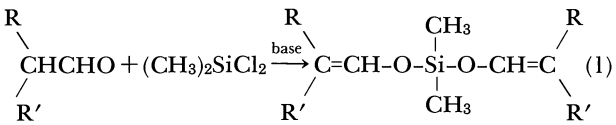
Synthesis of Dimethylsilyl Bis-Enol Ethers Derived from Aldehydes

Z. A. FATAFTAH,* M. R. IBRAHIM, and H. N. ABDEL-RAHMAN
Department of Chemistry, Yarmouk University, Irbid, Jordan
(Received May 28, 1990)

Two procedures for the prepation of dimethylsilyl bis-enol ethers from aldehydes, through enolization, are described. Dimethylsilyl bis-enol ethers, derived from propanal, butanal, 2-methylpropanal, pentanal, hexanal, and heptanal have been synthesized by refluxihg a mixture of triethylamine, dichlorodimethylsilane and the corresponding aldehyde in tetrahydrofuran for 18—38 h. The yields are in the range of 75—90%. Alternatively, a stronger base, lithium 2,2,6,6-tetramethylpiperidide (LiTMP) is used for deprotonation of the above mentioned aldehydes at −23 °C. The enolates are then quenched with dichlorodimethylsilane. The small aldehydes, propanal, butanal, and 2-methylpropanal fail to give the desired products, while the others gave a very good yields (56—85%). Ethanal fails to give the product in either of the two procedures. A competitive rate of polymerization with the rate of proton abstraction or with the rate of mixing of the reactants could explain these failures. The silyl bis-enol ethers have been characterized on the basis of their NMR, IR, and elemental analysis data.

Trimethylsilyl enol ethers were originally introduced as precursors for specific enolates[1,2] and much of their chemistry is like that of enol. Their usefulness surpasses that of all other derivatives,[3] because of their ease of preparation, clean reactions, and the mildness of desilylation processes: They also combine a reasonable reactivity with a high selectivity. Silyl enol ethers' reactions have been widely used as part of synthetic routes to natural products and other complex molecules[4] as well as simple coupling reactions.[5-7] Silyl enol ethers as synthetic reagents have been noted in the regeneration of enolates to react with electrophiles under basic conditions or direct reaction with electrophiles under neutral or acidic (Lewis acid) conditions. Although a great deal of attention has been paid to silyl enol ethers[4,8] derived from ketones and esters (silyl ketene acetals) very limited reports mentioned indirectly the silyl enol ethers derived from aldehydes.[8-10] The reason behind this ignorance of aldehydes is a theoretical problem. These reactions cannot be utilized with the enolates of reactive aldehydes, due to facile base-catalyzed polymerization of the starting material and/or product.[11] For this reason, various indirect methods have been developed for the alkylation of aldehydes, e.g., enamines[12] and imine anions.[13]

In earlier study[14] the preparation and characterization of some dimethylsilyl bis-enol ethers derived from ketones have been reported. The aim of the present work is to synthesize dimethylsilyl bis-enol ethers derived from aldehydes, in which two reactive aldehyde enolates are trapped in the same molecule as shown by Eq. 1. In this paper the preparation methods that we employed and the characterization of various dimethylsilyl bis-enol ethers derived from some aldehydes are described.



Results and Discussion

The first preparative method employed for dimethylsilyl bis-enol ethers derived from aldehydes involves preliminary treatment of a solution of LiTMP in tetrahydrofuran, generated from tetramethylpiperidine and butyllithium at 0 °C under nitrogen, with aldehydes to convert them completely into their enolate anions. Subsequent reaction of the enolate anions with dichlorodimethylsilane has produced the dimethylsilyl bis-enol ethers. Unfortunately the yields are low compared to yields in case of ketones. A better yield was obtained when the reaction temperature is changed to −23 °C instead of 0 °C and the aldehyde to dichlorodimethylsilane ratio is increased to 2 : 1. The results are summarized in Table 1. The small aldehydes fail to give the desired product. Dilution of these small aldehydes with tetrahydrofuran and then addition slowly to the base (LiTMP) do not produce any product either. It seees that in case of small aldehydes a competitive rate of aldol condensation and polymerization with the rate of proton abstraction or with the rate of mixing of the reactants. As the aldehydes get larger, the aldol condensation or polymerization is slowed down to such a degree that dimethylsilyl bis-enol ethers predominate.

In an effort to produce products with the small aldehydes we examined an alternative method in which the quenching reagent, dichloromethylsilane, is added before enolate formation. In this case triethylamine as a base in tetrahydrofuran was the reagent of choice. The silyl bis-enol ethers were prepared by refluxing the mixture of the aldehyde, dichlorodimethylsilane, and three fold excess triethylamine in tetrahydrofuran for 18—38 h. The yields are in the range of 75—90%. In this way the preparation of dimethylsilyl bis-enol ethers (**1—6**) were accomplished regardless the size of the aldehyde. Evidently, in this case, the rate of the reaction of aldehyde enolates with dichlorodimethylsilane is faster than the

a) In procedure A, the enolate, formed by initial reaction of the aldehyde with LiTMP in THF, was quenched with $(CH_3)_2SiCl_2$. In procedure B, the aldehyde was refluxed with a mixture of Et_3N and $(CH_3)_2SiCl_2$. b) GC yields. c) The aldehydic vinyl protons are shown in the experimental section.

rate of polymerization. Ethanal, however, fails to give product in either of the two methods. This result is not unexpected since it is reported[1] that the indirect methods of enolization of aldehydes have never been successfully extended to the alkylation of ethanal, the simplest carbonyl compound having α-hydrogens.

It is interesting to note that the time required for synthesis of dimethylsilyl bis-enol ethers derived from aldehydes (1—2 days) is much shorter than the time required for the synthesis of dimethylsilyl bis-enol ethers derived from ketones (2—20 days).[14] We believe that the reason behind this is the fact that aldehyde enolates are more reactive than ketone enolates.

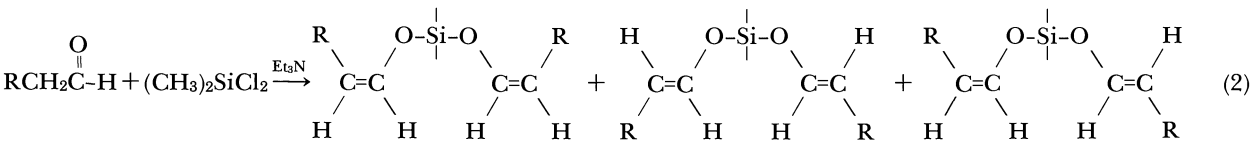
The dimethylsilyl bis-enol ethers derived from propanal, butanal, pentanal, and heptanal show geometrical isomers (Eq. 2). NMR analysis for the vinylic protons shows the predominance of *Z*-protons in these derivatives under thermodynamic conditions (triethylamine method). Under kinetic conditons, the NMR analysis for the vinylic protons of pentanal derivative showed the predominance of the *E*-protons which is in agreement with literature reports[14,15] of ketone enolates under similar conditions.

Experimental

All boiling points are uncorrected. The infrared spectra were determined with a Pye-Unican SP3-100 spectrophotometer. The NMR spectra were determined at Bruker WP 80 EY spectrometer. Vapor phase chromatographic analysis and preparative work were carried out on a Varian Aerograph 1400 thermal conductivity chromatogram. The microanalysis were performed by M-H-W Laboratories, Phoenix AZ.

Commercial samples of aldehyses were purified by redistillation and stored over molecular sieve. Triethylamine and tetrahydrofuran were distilled from $LiAlH_4$ and stored under nitrogen over molecular sieve. Dichlorodimethylsilane was distilled prior to use. Commerical 2,2,6,6-tetramethylpiperidine and a solution of butyllithium were used without further purification.

Illustrative Procedures for the Preparation of the Dimethylsilyl Bis-Enol Ethers. Procedure A. A 250 ml round bottom flask equipped with a magnetic stir bar, septum and a reflux condenser fitted with a calcium chloride tube was flame dried while a stream of nitrogen gas was flowing through the system. 80 ml of tetrahydrofuran was introduced followed by 80 mmol (5.77 ml) of propanal, three fold excess of triethylamine (240 mmol) and 40 mmol (4.8 ml) of dichlorodimethylsilane. The resulting mixture was



(2)

refluxed and followed by GLC analysis (2.5% SE-30, 1/8 in×5ft column). After two hours a peak different from starting materials was noticed. Then the reaction was refluxed for 18 h. The reaction mixture was cooled, diluted with petroleum ether (40—60 °C) and washed with cold saturated solution of sodium hydrogen carbonate. The organic layer was separated and dried over anhydrous sodium carbonate. Then the solvent was removed by simple distillation and residue was vacuum distilled or chromatographed using 40 cm×2 cm column packed with 60/120 mesh silica gel and petroleum ether (40—60 °C). A sample for analysis was prepped from a GLC column (2.5% SE-30, 1/4 in×3 ft, 1 in=2.54 cm, 1 ft=30.48 cm).

Procedure B. A 50 ml flask equipped with a magnetic stir bar, septum, gas inlet valve and mercury bubbler, was flame dried under nitrogen. A 5.0 ml (8 mmol) of butyllithium (1.6 M, 15% in hexane, M=mol dm^{-3}) was added to the flask. The flask was immersed in an ice bath and 1.34 ml (8 mmol) of 2,2,6,6-tetramethylpiperidine was added dropwise over 2 min. Following the addition, the viscous mixture was stirred for an additional 10 min, after which the hexane was removed under reduced pressure at 0 °C. The flask was refilled with nitrogen and the residual white solid was redissolved in sufficient dry THF at 0 °C to give approximately 1 M solution. When dissolution was complete, the ice bath was replaced by CCl_4/liq N_2(−23 °C) bath. The reaction mixture was stirred for 10 min, and then 0.98 ml (8 mmol) of hexanal was added dropwise over 3 min. The mixture was stirred for 20 min, then quenched with 0.24 ml (2 mmol) of dichlorodimethylsilane all added at once at −23 °C. The reaction mixture was removed from the bath and to room temperature with stirring. An internal standard $C_{16}H_{34}$ (2 mmol) was added. The highest yield (85%) was obtained after 24 h of stirring at room temperature.

Dimethylsilyl Bis-Enol Ether Derived from Propanal (1): Bp 23 °C (2 mmHg, 1 mmHg=133.322 Pa); density=0.896 g cm^{-3}; NMR ($CDCl_3$) δ=0.26 (s, 6H), 1.55 (m, 6H), 4.60, 5.07 (two multiplets 70:30, 2H), 6.24 (m, 2H); IR(CCl_4) 3040, 2960, 1660, 1450, 1065, 875, and 815 cm^{-1}. Calcd for $C_8H_{16}O_2Si$: C, 55.76; H, 9.36%. Found: C, 55.87; H, 9.27%.

Dimethylsilyl Bis-Enol Ether Derived from Butanal (2): Bp 30—32 °C (0.7 mmHg), density=0.865 g cm^{-3}, NMR ($CDCl_3$) δ=0.25 (s, 6H), 0.96 (t, 6H), 2.11 (m, 4H), 4.55, 5.16 (two multiplets 80:20, 2H) 6.18 (m, 2H); IR(CCl_4) 3020, 2960, 1655, 1450, 1260, 1070, 850, and 810 cm^{-1}. Calcd for $C_{10}H_{20}O_2Si$: C, 59.95%; H, 10.06%. Found: C, 60.09; H, 9.93%.

Dimethylsilyl Bis-Enol Ether Derived from 2-Methylpropanal (3): Bp 34—36 °C (0.6 mmHg), density=0.865 g cm^{-3}, NMR ($CDCl_3$) δ=0.22 (s, 6H), 1.56 (d, 6H), 1.61 (d, 6H), 6.09 (m, 2H); IR (CCl_4) 2960, 1680, 1450, 1260, 1070, 890, and 800 cm^{-1}. Calcd for $C_{10}H_{20}O_2Si$: C, 59.95; H, 10.06%, Found: C, 60.15; H, 10.09%.

Dimethylsilyl Bis-Enol Ether Derived from Pentanal (4): Bp 48.51 °C (0.6 mmHg), density=0.861 g cm^{-3}, NMR ($CDCl_3$) δ=0.24 (s, 6H), 0.95 (t, 6H), 1.41 (m, 4H), 2.02 (m, 4H), 4.54, 5.06 (two multiplets 76:24, 2H), 6.25 (m, 2H); IR (CCl_4) 2960, 1655, 1450, 1260, 1050, 860, and 810 cm^{-1}. Calcd for $C_{12}H_{24}O_2Si$: C, C, 63.10; H, 10.59% Found: C, 62.91; H, 10.31%.

Dimethylsilyl Bis-Enol Ether Derived from Hexanal (5): Bp 58—60 °C (0.6 mmHg), density=0.893 g cm^{-3}, NMR ($CDCl_3$) δ=0.25 (s, 6H), 0.90 (t, 6H), 1.31 (m, 8H), 2.10 (m, 4H), 4.58 (m, 2H), 6.24 (m, 2H); IR (CCl_4) 2960, 1650, 1455, 1260, 1070, 865, and 810 cm^{-1}. Calcd for $C_{14}H_{28}O_2Si$: C, 65.56; H, 11.00%. Found: C, 65.44; H, 10.86%.

Dimethylsilyl Bis-Enol Ether Derived from Heptanal (6): Bp 68.73 °C (0.6 mmHg), density=1.104 g cm^{-3}, NMR ($CDCl_3$) δ=0.24 (s, 6H), 0.88 (t, 6H), 1.30 (m, 12H), 2.08 (m, 4H), 4.54 (m, 2H), 6.22 (m, 2H); IR (CCl_4) 3025, 2950, 1655, 1260, 1080, 865, and 810 cm^{-1}. Calcd for $C_{16}H_{32}O_2Si$: C, 67.54; H, 11.34%. Found: C, 67.38; H, 11.09%.

Synthesis and Aldol Stereoselectivity of 2-Oxazolidinones Derived from L-Histidine

Francisco BERMEJO GONZALEZ,* Julia PEREZ BAZ, Fabio SANTINELLI, and Fernando MAYOR REAL†
Departamento de Química Orgánica, Facultad de Químicas, Universidad de Salamanca,
Pza de los Caídos 1-5, 37008 Salamanca, Spain
†Departamento de Química Inorgánica, Facultad de Ciencias, Universidad de Valladolid, 47005 Valladolid, Spain
(Received June 21, 1990)

The regiospecific synthesis of the 2-oxazolidinones **5b**, **7**, **12a**, and **12b** starting from L-histidine **1a** is described. The stereoselectivity in the dibutyl(trifluoromethylsulfonyloxy)borane promoted aldol condensation between the chiral imides **13a** and **13b** and benzaldehyde was also studied. The formation of a cationic imidazole-boron complex, **14a**, occurs before the aldol condensation between **13a** and benzaldehyde takes place. However, the condensation between **13b** and benzaldehyde occurs without the formation of any boron complex. The steric hindrance of the substituent at C-4 may account for this difference in behavior.

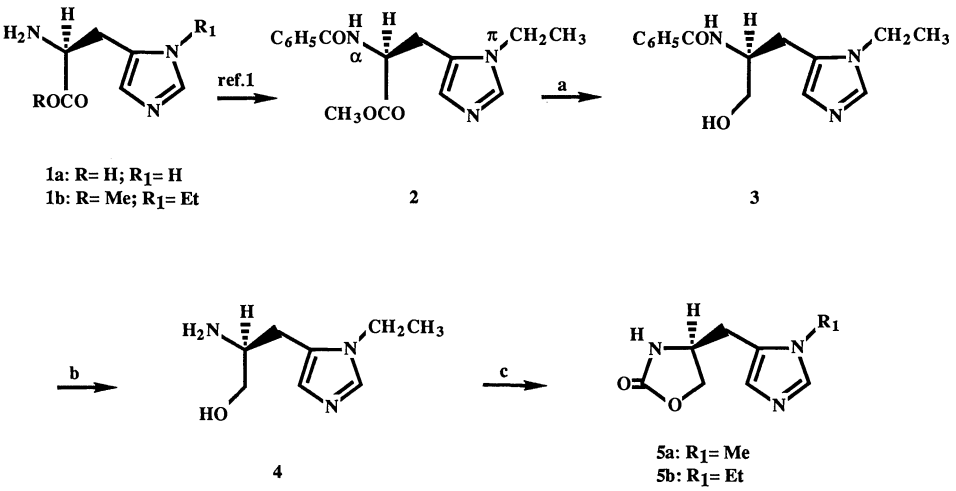
As part of a program aimed at the discovery and development of novel drugs with potential muscarinic activity, our laboratory has examined the preparation of 2-oxazolidinones derived from the naturally occurring amino acid L-histidine **1a**.

As far as we know, the preparation of N^{π}- and N^{τ}-alkyl-substituted 2-oxazolidinones (The N-2 and N-4 positions in the imidazolyl group are tentatively denoted as N^{π} and N^{τ}-, respectively) derived from L-histidine has no precedents in the literature, even though the regiospecific functionalization on the imidazole moiety has been previously resolved.[1-6] We now wish to report our first results on this topic. Our interest in the potential aldol diastereoselectivity exhibited by chiral imides such as **13a** and **13b** lay in the previously announced feature of the amine-boron complexation.[7] These imides display a very different behavior when treated with dibutyl(trifluoromethylsulfonyloxy)borane. While **13a** leads to the formation of a cationic imidazole-boron complex **14a** before the aldol condensation with benzaldehyde takes place, the chiral imide **13b** undergoes aldol condensation without complexing; the steric hindrance at C-4[8] may account for this different behavior. However, since the stereoselectivity obtained in both cases is remarkable, we assume that an important role of the boron complexation on the aldol steroselectivity in the former case seems unlikely.

Results and Discussion

Preparation of the N^{π}-Ethyl 2-Oxazolidinone Derived from L-Histidine 5b. Preparation of the N^{π}-ethyl-substituted 2-oxazolidinone **5b** was achieved using the same synthetic sequence that we have recently reported for the preparation of the N^{π}-methyl-substituted 2-oxazolidinone, **5a**, in the course of the synthesis of some (+)-pilocarpine analogs[9] (Scheme 1).

The reaction of N^{α}-benzoyl-N^{π}-ethyl-L-histidine



a: LAH(4 eq,), THF, 0 °C, 45 min. (90%); b: 1) 6N HCl, 80 °C, 6h.; 2) 1N KOH (EtOH) (95%); c: $(EtO)_2CO$ (1.2 equiv), CH_3OH reflux, $NaCH_3O$ (2 equiv), 1h. (70%)

Scheme 1.

(**2**)[1a] with 4 equiv of LAH in freshly distilled THF at 0 °C (45 min.) yielded a crude material from which the reduction product **3** was isolated by flash chromatography (90%). Hydrolysis of **3** by treatment with 6 M HCl (1 M=mol dm^{-3}) at 80—90 °C afforded the N^{π}-ethyl-L-histidinol dihydrochloride **4·2HCl**. Neutralization of **4·2HCl** with 1 M ethanolic KOH led to the free base **4**, after removal of the KCl and evaporation of the solvent. The structural change was confirmed by the upfield displacement of the signals corresponding to the two aromatic protons from δ H_2^{im}=8.81 and δ H_5^{im}=7.39 in **4·2HCl** to δH_2^{im}=7.51 and δH_5^{im}=6.69 in **4**. Reaction of **4** with 1.2 equiv of diethyl carbonate in refluxing methanol, using CH_3ONa as a base, afforded a crude material from which it was possible to isolate the 2-oxazolidinone **5b** by flash chromatography (70%). The presence of a signal at δ=161.8 in the ^{13}C NMR spectrum confirmed the presence of the cyclic carbamate functionality.

Scheme 2.

Preparation of the 2-Oxazolidinone 7. The starting material to obtain our next target molecule was the oxoimidazo[1,5-*c*]pyrimidine **6**[2] (Scheme 2). Reduction of **6** with an excess of $NaBH_4$[10] afforded the 2-oxazolidinone **7** (80%) (Scheme 2). We assumed that the carbonyl group belonging to the cyclic urea function of **6** undergoes nucleophilic attack by the alkoxide resulting from the reduction of the ester function. The acyl migration is helped by the good leaving character of the imidazole ring. The structural change was confirmed by the displacement of the ^{13}C NMR signals corresponding to the carbonyl groups from δ=149 in the urea **6** to δ=162 in the cyclic carbamate **7**. This result provides a very interesting alternative to the previously reported LAH reduction of **6**.[11]

Preparation of the N^{τ}-Alkyl-Substituted 2-Oxazolidinones Derived from L-Histidine 12a and 12b. The experience gained on the reduction of the oxoimidazo-[1,5-*c*]pyrimidine **6** prompted us to prepare the imidazolium iodides **8a** and **8b**[2] (Scheme 3) and to attempt the cyclization under the conditions described for **6** in an effort to prepare **12a** and **12b**. We expected that the imidazolinium functionality of both molecules would accelerate the process, due to the increased leaving character of the aromatic moiety. However, $NaBH_4$ reduction of **8a** led to a complicated mixture from which the hydroxy-substituted formamide **9** was isolated by flash chromatography (65%). The spectroscopic properties obtained for the new reduction product provided enough evidence for the presence of

11a: R 1= Et
11b: R 1= Me

12a: R 1= Et
12b: R 1= Me

a: $NaCH_3O$ (1.1 equiv), CH_3OH, 24 °C, 2h. (95%); **b**: $NaBH_4$ (5 equiv), CH_3OH, 0 °C, 5h. (70%); **c**: $NaCH_3O$ (2 equiv), CH_3OH, 24 °C, 5h. (87%); **d**: $NaBH_4$

Scheme 3.

the hydroxy (^{13}C NMR: δ=63.95; ^{1}H NMR: δ=3.50 (d, J=7.5 Hz, 2H)) and the formamide moieties (^{13}C NMR: δ=163.8 (CH); ^{1}H NMR: δ=7.95 (s, 1H)). We were able to detect traces of the desired 2-oxazolidinone **12a** by ^{1}H NMR analysis of some of the minor components, but the yield was unacceptable.

This disappointing result led us to attempt the transformation of **8a** into the carbamate **10a**.[6] Treatment of **8a** with 1.1 equiv of CH_3ONa in absolute methanol at room temperature afforded a crude product from which it was possible to isolate the carbamate **10a** by flash chromatography (95%). The presence of two singlets at δ=3.63 and 3.60 in the ^{1}H NMR spectrum together with the appearance of two signals at δ=172 and 156 in the ^{13}C NMR spectrum allowed us to confirm the presence of the two desired functionalities; the methyl ester and the methyl carbamate.

$NaBH_4$ reduction of **10a** led to the isolation of the hydroxy-substituted carbamate **11a** by flash chromatography (70%). The ^{13}C NMR spectrum of **11a** showed only one carbonyl absorption at δ=156 together with a new methylene absorption at δ=64.14 corresponding to the hydroxymethyl group; this allowed us to confirm the chemoselective reduction of the methyl ester functionality.

Base-promoted cyclization of **11a** was successfully achieved with an excellent yield. The treatment of the hydroxy carbamate **11a** with CH_3ONa in methanol at room temperature led to the isolation of the N^{τ}-ethyl-substituted 2-oxazolidinone **12a** (87%). The structural change was confirmed by the displacement of the signals corresponding to the absorption of the carbonyl and hydroxymethyl groups in the ^{13}C NMR spectrum from δ=156 and 64 in **11a** to δ=159 and 68 in **12a**, respectively. Application of the same three-step sequence to the imidazolium iodide **8b** afforded the N^{τ}-methyl-substituted 2-oxazolidinone **12b** with 63% overall yield.

In summary, the effective regioselective synthesis of **12a** and **12b** proceeded in five steps from the methyl ester of L-histidine **1b** with 60% and 58% overall yields, respectively.

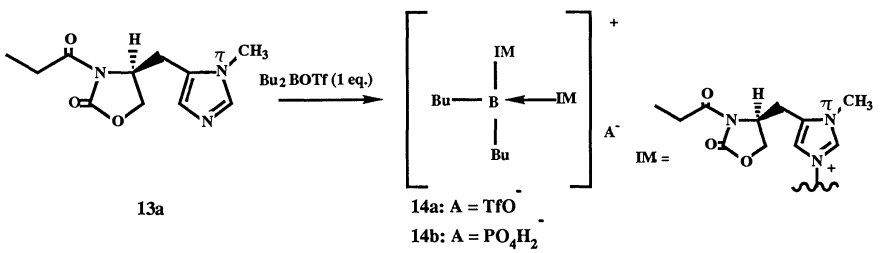
Stereoselection in the Aldol Condensation between the Chiral Imides 13a and 13b with Benzaldehyde. In order to test the induction of the stereoselectivity of these 2-oxazolidinones in the aldol condensation with aldehydes and to see what role the imidazole moiety might play in this type of process, we decided to analyze the reaction of the N-acyl-2-oxazolidinones **13a** and **13b** with benzaldehyde via the boron enolate.

Treatment of **5a**[9] and **12b** with HaH (1.1 equiv) in DMF followed by addition of propionyl chloride (1.1 equiv) led to the imides **13a** (80%) and **13b** (85%), respectively.

Treatment of the chiral imide **13a** with 1 equiv of dibutyl(trifluoromethylsulfonyloxy)borane, followed by addition of benzaldehyde under the conditions described by Evans[7] led to the isolation of a white solid **14b** (Scheme 4), which was soluble in chloroform and could be purified by crystallization in dry THF; flash chromatography of the crude product led also to pure **14b** with partial decomposition. Spectroscopic analysis (IR, ^{1}H NMR, and ^{13}C NMR) clearly showed that the condensation reaction did not take place. The ^{13}C NMR spectrum of the new product exhibited two signals corresponding to two carbonyl groups (δ=174.30 and 153.16) and three upfield signals corresponding to three methyl groups (δ=33.23, 13.93, and 8.14), one of them belonging to a butyl moiety, as the presence of three new methylene signals (δ=26.76, 26.06, and 21.03) seemed to confirm. The ^{1}H NMR spectrum exhibited the presence of the three methyl groups (signals at δ=3.81 (s), 1.11 (t), and 0.80 (t)) and pointed to a structural change in the imidazole ring by the downfield displacement of the aromatic protons from δ H_2^{im}=7.35 and δ H_5^{im}=6.76 in **13a** to δ H_2^{im}=8.02 and δ H_5^{im}=6.85 in **14b**.

According to the assumption of Evans that the ineffectiveness of bases such as pyridine in the enolization process of this type of chiral imides can be attributed to the irreversible amine-boron complexation,[7] we first thought of the formation of an sp^3-hybridized cationic boron complex **14a**;[12] which under the usual workup conditions would undergo metathesis to the phosphate **14b**.[13] The obtained MS (FAB) spectrum for **14b** comfirmed our assumption. The presence of two peaks at m/z: 599 (45%) and 362 (100%) proved the presence of the boron cation in the complex and the loss of an imide fragment, respectively.

Treatment of the imide **13a** with 1 equiv of dibutyl(trifluoromethylsulfonyloxy)borane at 0 °C gave **14b** (80%) after quenching the reaction with phosphate buffer. Apparently, the formation of the boron complex occurred prior to any condensation process.



13a

14a: A = TfO

14b: A = PO_4H_2

Scheme 4.

Since the imidazole base present in **13a** scavenged half of one equiv of the triflate, the use of al least 1.5 equiv of the reagent was necessary to promote the aldol condensation with benzaldehyde. Treatment of **13a** with 2 equiv of dibutyl(trifluoromethylsulfonyloxy)-borane followed by addition of benzaldehyde led to the condensation product **15** (Scheme 5) after the usual work up conditions.

Spectroscopic analysis of the aldol product **15a** excluded the presence of threo isomers and confirmed the formation of the imidazol-boron complex by the downfield shifts obtained for the imidazole protons (δ H_2^{im}=7.98 and δ H_5^{im}=6.84) by comparison with the above-mentioned values exhibited by **13a**.[16]

Transformation of the crude aldol product into the possible mixture of erythro isomers of methyl 3-hydroxy-2-methyl-3-phenylpropionate **16a** by the classical procedure[7] allowed us to obtain an optical value of $[\alpha]_D^{24}$=−18.1° (*c* 1.74, $CHCl_3$), which led us to establish the absolute configuration of the major erythro isomer as (2*S*, 3*S*) **16a** and to determine the optical puriry of the aldol condensation product as >94% in accordance with the data in the literature.[17,18]

Treatment of the chiral imide **13b** (Scheme 6) with 1 equiv of dibutyl(trifluoromethylsulfonyloxy)borane followed by addition of benzaldehyde led to the aldol product **15b** (86%) whose spectroscopic properties excluded the existence of threo isomers in the reaction product. However, in this case the chemical shifts obtained for the imidazole protons at δ H_5^{im}=6.69 and δ H_2^{im}=7.41 excluded the imidazol-boron complexation. We assume that the steric hindrance at C-4 may account for the difficulties of the chiral imide **13b** in undergoing the imidazole-boron complexation.

Transformation of **15b** into **16b** by the reported procedure[7] led us to obtain an optical value of $[\alpha]_D^{21}$=−17.3° and enabled us to determine the optical purity of the aldol product as >90%, in agreement with the data in the literature.[17]

Conclusion

The synthesis of **5b**, **7**, **12a**, and **12b** from L-histidine was successfully achieved. These compounds are useful chiral auxiliaries from which imides such as **13a** and **13b** can be prepared and used in aldol reactions. Since the imidazole base present in the histidine-derived auxiliary **13a** scavenged half of one equiv of the triflate reagent, the use of 1.5 equiv of dibutyl(trifluoromethylsulfonyloxy)borane to promote the aldol condensation between **13a** and benzaldehyde was necessary. However, the chiral imide **13b** led to the aldol product **15b** by treatment with 1 equiv of the boron triflate followed by addition of benzaldehyde. Since the aldol stereoselectivity was remarkable in both cases we assume that the imidazole-boron complexation displayed by **13a** plays no significant role in the high stereoselectivity observed with this chiral imide.

Experimental

Organic extracts were dried with commercially dried Na_2SO_4 and evaporated under reduced pressure below 40 °C. Melting points were determined on a Kofler hot-stage apparatus and are uncorrected. Optical rotations were determined on a digital Perkin-Elmer 241 polarimeter in a 1-dm cell. The ^1H and ^{13}CNMR spectra were recorded on a Bruker WP-200-SY spectrometer operating at 200 MHz and 50.3 MHz respectively. All ^{13}CNMR spectra were obtained using deuteriochloroform as solvent unless otherwise stated; for ^{13}CNMR spectra in D_2O, 1,4-dioxane (δ=67.6) was used as the internal standard. The IR spectra were determined on a Beckman 33-IR spectrophotometer as indicated in each case. Mass spectra were recorded on a Kratos MS-25 instrument operating with either EI (70 eV) or FAB ionization (8 kV, using Xe and $(HOCH_2CH_2S)_2$ as matrix). Elemental analyses were carried out using a Perkin-Elmer 240 B Analyzer. Conductimetric measurements were made on a Crison 522 conductimeter. All compounds discussed in this paper were obtained in a chromatographically homogeneous state.

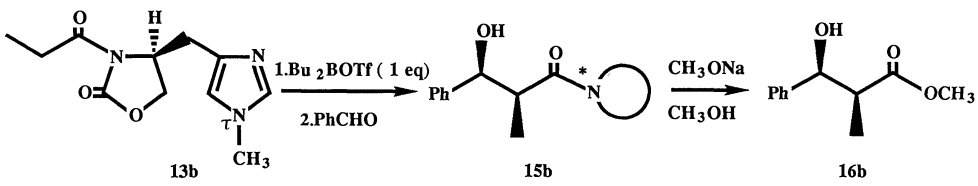

Scheme 6.

N^{α}-Benzoyl-N^{π}-ethyl-L-histidinol: (3). A solution of **2**[1] (5 g, 16.6 mmol) in freshly distilled THF (100 mL) was added dropwise to a stirred suspension of $LiAlH_4$ (1.3 g, 33.2 mmol) in anhydrous THF (100 mL) under a nitrogen atmosphere. After 45 min of stirring the reaction was worked up as usual to obtain a residue (4.2 g) which was fractionated by flash chromatography on silica gel. Elution with chloroform–methanol (80:20) yielded **3** (4.1 g, 90%); $[\alpha]_D^{20}$ −49.3° (*c* 1.02, CH_3OH); IR ν_{max} ($CDCl_3$) 3600—3000, 2950, 1640, 1540, 1230, 1040, 940, and 710 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=1.39 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.94 (2H, m, $\underline{CH_2}Ar$), 3.68 (2H, m, $\underline{CH_2}OH$), 4.06 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 4.14 (1H, m, CH), 6.73 (1H, s, CCHN), 7.36 (3H, m, Ar), 7.44 (1H, s, NCHN), 7.72 (2H, m, Ar); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=16.54 (q, $NCH_2\underline{CH_3}$), 26.30 (t, $\underline{CH_2}Ar$), 40.63 (t, $N\underline{CH_2}CH_3$), 52.53 (d, CH), 64.25 (t, CH_2OH), 127.49 (d, Ar), 128.24 (d, Ar), 129.39 (d, Ar), 130.00 (s, C_4^{im}), 132.51 (d, C_5^{im}), 135.89 (s, Ar), 138.00 (d, C_2^{im}) 170.28 (s, Ar$\underline{CO}$). Anal. Calcd for $C_{15}H_{19}N_3O_2$ (M. W. 273): C, 65.93; H, 6.96; N, 15.38%. Found: C, 65.87; H, 6.90; N, 15.32%.

N^{π}-Ethyl-L-histidinol Dihydrochloride: (4·2HCl) and N^{π}-Ethyl-L-histidinol: (4). A solution of **3** (5 g, 18.3 mmol) in 6 M HCl (350 mL) was heated under reflux for 6 h in a nitrogen atmosphere. The volume of water was reduced (to 50 mL) by evaporation of the solvent. Benzoic acid was removed by extraction of the aqueous solution with ether (3×15 mL). The aqueous solution was evaporated to dryness to afford **4·2HCl** (4 g, 90%); $[\alpha]_D^{21}$ 3.3° (*c* 1.6, CH_3OH); IR ν_{max} (Nujol) 3300, 3030, 2950, 1540, 1470, 1380, 1060, and 860 cm^{-1}; ^1H NMR (200 MHz, CD_3OD) δ=1.35 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 3.0 (2H, m, $\underline{CH_2}Ar$), 3.48 (1H, m, CH), 3.58 (2H, m, $\underline{CH_2}OH$), 4.11 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 7.39 (1H, s, CCHN), 8.81 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, CD_3OD) δ=15.48 (q, $NCH_2\underline{CH_3}$), 24.27(t, $\underline{CH_2}Ar$), 43.63 (t, $N\underline{CH_2}CH_3$), 52.79 (d, CH), 61.18 (t, CH_2OH), 119.98 (d, C_5^{im}), 130.70 (s, C_4^{im}), 136.22 (d, C_2^{im}). Anal. Calcd for $C_8H_{15}N_3O\cdot 2HCl\cdot 2H_2O$ (M. W. 278): C, 34.53; H, 7.55; N, 15.11%. Found: C, 34.49; H, 7.50; N, 15.06%.

Treatment of **4·2HCl** (4 g, 16.5 mmol) with 1 M ethanolic KOH (33 mL) led to the isolation of the free base **4** (2.8 g, 100%); $[\alpha]_D^{20}$ −15.1° (*c* 1.44, CH_3OH), after filtration of the KCl and evaporation of the solvent; IR ν_{max} (film) 3600—3000, 2900, 1490, 1050 cm^{-1}; ^1H NMR (200 MHz, D_2O) δ=1.30 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.62 (2H, m, $\underline{CH_2}Ar$), 2.97 (1H, m, CH), 3.41 (2H, m, $\underline{CH_2}OH$), 3.92 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 6.71 (1H, s, CCHN), 7.53 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, D_2O) δ=16.7 (q, $NCH_2\underline{CH_3}$), 28.57 (t, $\underline{CH_2}Ar$), 40.62 (t, $N\underline{CH_2}CH_3$), 53.27 (d, CH), 66.38 (t, CH_2OH), 127.32 (d, C_5^{im}), 129.98 (s, C_4^{im}), 137.87 (d, C_2^{im}). Anal. Calcd for $C_8H_{15}N_3O$ (M. W. 169): C, 56.80; H, 8.88; N, 24.85%. Found: C, 56.76; H, 8.79; N, 24.81%.

(4*S*)-4-[(3-Ethyl-3*H*-imidazol-4-yl)methyl]-2-oxazolidinone: (5b). Diethyl carbonate (4.3 mL, 35.5 mmol) and 1.78 g (59.2 mmol) of NaH (80%) were added to a solution of **4** (5 g, 29.6 mmol) in absolute methanol (20 mL) under a nitrogen atmosphere. When addition had finished, the reaction mixture was heated to 100 °C for 1 h. Evaporation of the solvent at reduced pressure afforded a residue which was fractionated by flash chromatography on silica gel. Elution with chloroform–methanol (70:30) afforded **5b** (4 g, 70%); mp 111—113 °C (CH_3OH); $[\alpha]_D^{21}$ −12.8° (*c* 1.31, CH_3OH); IR ν_{max} (Nujol) 2950, 1750, 1450, 1360, 1050 cm^{-1}; ^1H NMR (200 MHz, CD_3OD) δ=1.32 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.82 (2H, d, *J*=6.2 Hz, $\underline{CH_2}Ar$), 3.93 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 4.07 (2H, m, CH_2OCO), 4.45 (1H, m, CH), 6.74 (1H, s, CCHN), 7.57 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, CD_3OD) δ=16.56 (q, $NCH_2\underline{CH_3}$), 30.40 (t, $\underline{CH_2}Ar$), 40.74 (t, $N\underline{CH_2}CH_3$), 52.81 (d, CH), 71.01 (t, $\underline{CH_2}OCO$), 127.35 (d, C_5^{im}), 128.21 (s, C_4^{im}), 138.24 (d, C_2^{im}), 161.81 (s, CO); MS *m/z*, (%) 196 (M^++1, 1.5), 195 (4.9), 111 (9), 110 (100), 109 (96.7), 86 (6.3), 82 (43.3), 81 (58.0). Anal. Calcd for $C_9H_{13}N_3O_2$ (M. W. 195): C, 55.38; H, 6.67; N, 21.54%. Found: C, 55.30; H, 6.64; N, 21.50%.

(4*S*)-4-[(4-Imidazolyl)methyl]-2-oxazolidinone: (7). A solution of **6**[2] (5 g, 25.6 mmol) in absolute methanol (100 mL) at 0 °C under a nitrogen atmosphere was added dropwise to a suspension of $NaBH_4$ (4.8 g, 130 mmol) in absolute methanol (100 mL). The reaction mixture was stirred for 30 min at room temperature and was quenched by addition of an aqueous saturated NH_4Cl solution (30 mL). The reaction volume was then reduced (to ca. 50 mL) by evaporation of the solvent at reduced pressure and the aqueous solution was extracted with mixtures of chloroform–methanol (30:10) (5×25 mL). Evaporation of the organic solvent led to the isolation of **7** (3.4 g, 80%); mp 150—152 °C (Hexane); $[\alpha]_D^{23}$ −7.2° (*c* 1.5, CH_3OH); IR ν_{max} (film) 3600—3000, 1750, 1540, 1410, 1240, 1020, 760 cm^{-1}; ^1H NMR (200 MNz, D_2O) δ=2.73 (2H, d, *J*=5.5 Hz, $\underline{CH_2}Ar$), 4.05 (2H, m, CH_2OCO), 4.35 (1H, m, CH), 6.95 (1H, s, CCHN), 7.89 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, D_2O) δ=31.11 (t, $\underline{CH_2}Ar$), 52.45 (d, CH), 70.73 (t, $\underline{CH_2}OCO$), 118.02 (d, C_5^{im}), 131.47 (s, C_4^{im}), 135.80 (d, C_2^{im}), 162.19 (s, CO); MS *m/z* (%) 168 (M^++1, 10), 136 (12), 123 (80), 96 (75), 82 (100). Anal. Calcd for $C_7H_9N_3O_2$ (M. W. 167): c, 50.30; H, 5.39; N, 25.15%. Found: C, 50.26; H, 5.32; N, 25.08%.

N^{τ}-Ethyl-N^{α}-methoxycarbonyl-L-histidine Methyl Ester: (10a). A solution of imidazolium iodide **8a**[2] (5 g, 14.2 mmol) in absolute methanol (35 mL) was added dropwise to a suspension of CH_3ONa (842.4 mg, 15.6 mmol) in absolute methanol at 0 °C under a nitrogen atmosphere. The reaction was stirred for 2h at room temperature and was quenched by addition of an aqueous saturated NH_4Cl solution (50 mL). Evaporation of the methanol at reduced pressure and extraction of the aqueous solution with chloroform led to the isolation of crude **10a** after evaporation of the solvent. Fractionation of the crude was performed by flash chromatography on silica gel. Elution with chloroform–methanol (90:10) yielded **10a** (3.6g, 100%); $[\alpha]_D^{24}$ +1.0° (*c* 1.04, $CHCl_3$); IR ν_{max} (film) 3600—3000, 2950, 1720, 1500, 1450, 1050, and 780 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=1.35 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.98 (2H, m, $\underline{CH_2}Ar$), 3.60 (3H, s, $NHCOO\underline{CH_3}$), 3.63 (3H, s, $COO\underline{CH_3}$), 3.85 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 4.5 (1H, m, CH), 6.62 (1H, s, CCHN), 7.3 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=15.72 (q, $NCH_2\underline{CH_3}$), 29.67 (t, $\underline{CH_2}Ar$), 41.34 (t, $N\underline{CH_2}CH_3$), 51.64 (q, $COO\underline{CH_3}$+q, $NHCOO\underline{CH_3}$), 53.90 (d, CH), 115.76 (d, C_5^{im}), 135.98 (d, C_2^{im}), 137.08 (s, C_4^{im}), 156.35 (s, $\underline{CO}N$), 171.98 (s, $\underline{CO}OCH_3$). Anal. Calcd for $C_{11}H_{17}N_3O_4$ (M. W. 255): C, 51.76; H, 6.67; N, 16.47%. Found: C, 51.70; H, 6.61; N, 16.43%.

N^{α}-Methoxycarbonyl-N^{τ}-methyl-L-histidine Methyl Ester: (10b). Prepared under the same conditions as described for **10a**. Flash chromatography on silica gel. Eluent chloroform–methanol (90:10); **10b** (3.4 g, 96%); $[\alpha]_D^{22}$ +2.3° (*c* 1.03, $CHCl_3$); IR ν_{max} (film) 3600—3000, 1725, 1500, 1450, 1050, and 760 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ=2.96 (2H, m,

$\underline{CH_2}Ar$), 3.54 (3H, s, NCH_3), 3.59 (3H, s, $NHCOO\underline{CH_3}$), 3.63 (3H, s, $COO\underline{CH_3}$), 4.48 (1H, m, CH), 6.57 (1H, s, CCHN), 7.24 (1H, s, NCHN) ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=29.91 (t, $\underline{CH_2}Ar$), 33.02 (q, NCH_3), 51.91 (q, $NHCOO\underline{CH_3}$+q, $COO\underline{CH_3}$), 53.95 (d, CH), 117.59 (d, C_5^{im}), 137.45 (d, C_2^{im}+s, C_4^{im}), 156.59 (s, NCO), 172.11 (s, $\underline{CO}OCH_3$). Anal. Calcd for $C_{10}H_{15}N_3O_4$ (M. W. 241): C, 49.79; H, 6.22; N, 17.43%. Found: C, 49.76; H, 6.18; N, 17.39%.

N^{τ}-Ethyl-N^{α}-methoxycarbonyl-L-histidinol: (11a). A solution of **10a** (5 g, 19.6 mmol) in absolute methanol (50 mL) at 0 °C under a nitrogen atmosphere was added to a suspension of $NaBH_4$ (3.7 g, 98 mmol) in absolute methanol (25 mL). The reaction mixture was stirred for 5 h at room temperature. The reaction was then quenched by addition of an aqueous saturated NH_4Cl solution (30 mL). The organic solvent was evaporated at reduced pressure and the aqueous layer was extracted with $CHCl_3$. The combined organic layers were dried over Na_2SO_4 and evaporated to afford a crude **11a** which was fractionated by flash chromatography on silica gel. Elution with chloroform–methanol (90:10) afforded **11a** (3.1 g, 70%); $[\alpha]_D^{24}$+3.4° (*c* 1.6, $CHCl_3$); IR ν_{max} (film) 3600—3000, 2950, 1700, 1520, 1260, and 1060 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ=1.4 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.8 (2H, m, $\underline{CH_2}Ar$), 3.60 (3H, s, OCH_3), 3.65 (2H, m, $\underline{CH_2}OH$), 3.85 (1H, m, CH), 3.88 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 6.70 (1H, s, CCHN), 7.35 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=16.03 (q, $NCH_2\underline{CH_3}$), 30.23 (t, $\underline{CH_2}Ar$), 41.77 (t, $N\underline{CH_2}CH_3$), 51.84 (q, OCH_3), 52.24 (d, CH), 64.14 (t, CH_2OH), 116.46 (d, C_5^{im}), 135.79 (d, C_2^{im}), 138.17 (s, C_4^{im}), 156.89 (s, CO). Anal. Calcd for $C_{10}H_{17}N_3O_3$ (M. W. 227): C, 52.86; H, 7.49; N, 18.50%. Found: C, 52.82; H, 7.41; N, 18.48%.

N^{α}-Methoxycarbonyl-N^{τ}-methyl-L-histidinol: (11b). Prepared under the same conditions as described for **11a**. Flash chromatography on silica gel. Eluent: chloroform–methanol (90:10); **11b** (3.1 g, 70%); $[\alpha]_D^{22}$+10° (*c* 1.2, $CHCl_3$); IR ν_{max} (film) 3550—3000, 1724, 1480, 1450, 1050, and 760 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ=2.76 (2H, m, $\underline{CH_2}Ar$), 3.54 (3H, s, NCH_3), 3.55 (3H, s, $NHCOO\underline{CH_3}$), 3.83 (2H, m, $\underline{CH_2}OH$), 4.10 (1H, m, CH), 6.63 (1H, s, CCHN), 7.27 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=29.78 (t, $\underline{CH_2}Ar$), 33.02 (q, NCH_3), 51.60 (q, $NHCOO\underline{CH_3}$), 52.29 (d, CH), 63.64 (t, CH_2OH), 117.92 (d, C_5^{im}), 136.94 (d, C_2^{im}), 138.28 (s, C_4^{im}), 156.74 (s, CO). Anal. Calcd for $C_9H_{15}N_3O_3$ (M. W. 213): C, 50.70; H, 7.04; N, 19.72%. Found: C, 50.74; H, 7.07; N, 19.69%.

(4*S*)-4-[(1-Ethyl-1*H*-imidazol-4-yl)methyl]-2-oxazolidinone: (12a). Sodium methoxide (2.4 g, 44 mmol) was added to a solution of **11a** (5 g, 22 mmol) in absolute methanol (40 mL) at room temperature under a nitrogen atmosphere. The reaction mixture was stirred for 5 h at room temperature. The reaction was then quenched by addition of aqueous saturated NH_4Cl solution (15 mL). The aqueous phase was extracted with $CHCl_3$ (3×25 mL). The combined organic layers were dried over Na_2SO_4 and evaporated to afford **12a** (3.7 g, 87%); mp 102 °C (Hexane); $[\alpha]_D^{24}$−44.3° (*c* 1.05, $CHCl_3$); IR ν_{max} (film) 3600—3000, 2950, 1750, 1500, 1400, 1250, 1020 940, and 760 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ=1.38 (3H, t, *J*=7 Hz, $NCH_2\underline{CH_3}$), 2.74 (2H, d, *J*=6 Hz, $\underline{CH_2}Ar$), 3.90 (2H, q, *J*=7 Hz, $N\underline{CH_2}CH_3$), 4.14 (2H, m, CH_2OCO), 4.47 (1H, m, CH), 6.27 (1H, s, NH), 6.69 (1H, s, CCHN), 7.34 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=15.39 (q, $NCH_2\underline{CH_3}$), 32.99 (t, $\underline{CH_2}Ar$), 41.05 (t, $N\underline{CH_2}CH_3$), 51.86 (d, CH), 68.97 (t, $\underline{CH_2}OCO$), 115.65 (d, C_5^{im}), 135.63 (d, C_2^{im}), 136.49 (s, C_4^{im}), 159.13 (s, CO); MS *m/z* (%) 196 (M^++1, 1), 195 (0.4), 111 (7.2), 110 (100), 109 (33.3), 95 (1.6), 82 (5.8), 81 (59.6). Anal. Calcd for $C_9H_{13}N_3O_2$ (M. W. 195): C, 55.38; H, 6.67; N, 21.50%. Found: C, 55.32; H, 6.61; N, 21.50%.

(4*S*)-4-[(1-Methyl-1*H*-imidazol-4-yl)methyl]-2-oxazolidinone: (12b). Prepared under the same conditions as described for **12a**. (92%); mp 132—134 °C (Hexane); $[\alpha]_D^{22}$−9.8° (*c* 1.6, $CHCl_3$); IR ν_{max} (film) 3600—3000, 1750, 1420, 1240, 1010, and 756 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ=2.76 (2H, d, *J*=6 Hz, $\underline{CH_2}Ar$), 3.61 (3H, s, NCH_3), 4.13 (2H, m, CH_2OCO), 4.46 (1H, m, CH), 6.1 (1H, s, NH), 6.68 (1H, s, CCHN), 7.32 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=32.84 (q, NCH_3), 33.14 (t, $\underline{CH_2}Ar$), 52.11 (d, CH), 69.22 (t, $\underline{CH_2}OCO$), 117.61 (d, C_5^{im}), 136.66 (s, C_4^{im}), 137.20 (d, C_2^{im}), 159.33 (s, CO); MS *m/z* (%) 182 (M^++1, 10), 181 (12), 150(10), 137 (25), 121 (20), 109 (30), 96 (100), 81 (30). Anal. Calcd for $C_8H_{11}N_3O_2$ (M. W. 181): C, 53.04; H, 6.08; N, 23.20%. Found: C, 53.09; H, 6.02; N, 23.23%.

(4*S*)-4-[(3-Methyl-3*H*-imidazol-4-yl)methyl]-3-propionyl-2-oxazolidinone: (13a). A solution of **5a** (5 g, 27.6 mmol) in DMF (100 mL) was added to a suspension of NaH (80%) (0.9 g, 30.4 mmol) in anhydrous DMF (6 mL) at room temperature under nitrogen atmosphere.

The reaction mixture was stirred for 30 min at the same temperature; it was then chilled at 0 °C and propionyl chloride (2.6 mL, 30.4 mmol) was added dropwise.

The reaction mixture was stirred at room temperature for 15 h. Then, a sat. NH_4Cl solution (25 mL) was added. The organic layer was separated, dried and evaporated under reduced pressure to give a crude residue which was fractionated by flash chromatography on silica gel. By elution with chloroform–methanol (80:20) a pale yellow solid **13a** (5.2 g, 80%), was obtained; mp 110—111 °C ($CHCl_3$); $[\alpha]_D^{20}$+76.9° (*c*, 1.52, CH_3OH); IR ν_{max} (film) 3100, 2950, 1780, 1770, 1680, 1440, 1360, 1050, 1010, 990, 940, 910, and 740 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ=1.11 (3H, t, *J*=7 Hz, $COCH_2\underline{CH_3}$), 2.72 (1H, dd, J_1=15 Hz, J_2=10 Hz, $\underline{CH_2}Ar$), 2.88 (2H, dq, J_1=3 Hz, J_2=7 Hz, $CO\underline{CH_2}CH_3$), 3.17 (1H, dd, J_1=15 Hz, J_2=3 Hz, $\underline{CH_2}Ar$), 3.60 (3H, s, NCH_3), 4.14 (1H, dd, J_1=3 Hz, J_2=9 Hz, CH_2OCO), 4.23 (1H, t, *J*=7 Hz, CH_2OCO), 4.46 (1H, m, CH), 6.76 (1H, s, CCHN), 7.35 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=7.75 (q, $COCH_2\underline{CH_3}$), 26.45 (t, $CO\underline{CH_2}CH_3$), 28.53 (t, $\underline{CH_2}Ar$), 30.91 (q, NCH_3), 52.51 (d, CH), 66.22 (t, $\underline{CH_2}OCO$), 125.49 (s, C_4^{im}), 127.54 (d, C_5^{im}), 138.41 (d, C_2^{im}), 152.72 (s, $N\underline{CO}O$), 173.66 (s, $\underline{CO}N$); MS *m/z* (%) 238 (M^++1, 10), 181 (80), 96 (100), 77 (40), 64 (80). Anal. Calcd for $C_{11}H_{15}N_3O_3$ (MW. 237): C, 55.69; H, 6.32; N, 17.72%. Found: C, 55.61; H, 6.27; N, 17.69%.

(4*S*)-4-[(1-Methyl-1*H*-imidazol-4-yl)methyl]-3-propionyl-2-oxazolidinone: (13b). Prepared under the same conditions as described for **13a** (85%). $[\alpha]_D^{22}$+72.4° (*c* 1.04, $CHCl_3$); IR ν_{max} (film) 3600—3000, 2900, 1780, 1700, 1380, 1020, and 750 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=1.15 (3H, t, *J*=7 Hz, $NCOCH_2\underline{CH_3}$), 2.95 (3H, m, CHAr+$CO\underline{CH_2}CH_3$), 3.05 (1H, dd, J_1=15 Hz, J_2=3 Hz, CHAr), 3.92 (3H, s ,NCH_3), 4.29 (1H, t, *J*=8 Hz, CHOCO), 4.54 (1H, dd, J_1=7 Hz, J_2=3 Hz, CHOCO), 4.65 (1H, m, CH), 6.68 (1H, s, CCHN), 7.38 (1H, s, NCHN); ^{13}C NMR ($CDCl_3$) δ=8.27 (q, $COCH_2\underline{CH_3}$), 29.01 (t, $CO\underline{CH_2}CH_3$), 30.17 (t, CH_2Ar), 41.72 (q, NCH_3), 54.13 (d, CH), 66.66 (t, CH_2OCO), 116.50 (s, C_5^{im}), 136.34 (d, C_2^{im}+s, C_4^{im}), 153.76 (s, $N\underline{CO}O$), 173.98 (s, $\underline{CO}CH_2CH_3$). Anal.

Calcd for $C_{15}H_{15}N_3O_3$ (M. W. 237): C, 55.69; H, 6,32: N, 17.72%. Found: C, 55.61; H, 6.28; N, 17.65%.

Formation of the Cationic Boron Complex: (14b). A 1 M solution of dibutyl(trifluoromethylsulfonyloxy)borane (4.2 mL, 4.2 mmol) in dichloromethane was added drpwise to a stirred solution of triethylamine (0.6 mL, 4.2 mmol) in dichloromethane (5 mL). Then, a solution of **13a** (1 g, 4.2 mmol) in dichloromethane (5 mL) was added dropwise at 0 °C under an argon atmosphere. The reaction mixture was stirred at 0 °C for 1 h and then quenched by addition to pH=7 phosphate buffer. The mixture was extracted twice with dichloromethane and the combined extracts were washed with brine and concentrated in vacuo. The crude oil was then dissolved in methanol (15 mL) at 0 °C and 30% hydrogen peroxide (4.5 mL) was added. After the mixture had been stirred at room tempetrature for 2h, water (20 mL) was added; the mixture was concentrated and extracted twice with dichloromethane. The combined extracts were washed with brine and concentrated in vacuo. The crude oil was then dissolved in methanol (15 mL) at 0 °C and 30% hydrogen peroxide (4.5 mL) was added. After the mixture had been stirred at room tempetrature for 2h, water (20 mL) was added; the mixture was concentrated and extracted twice with dichloromethane. The combined organic layers were washed with 5% aqueous sodium hydrogencarbonate and brine, dried (Na_2SO_4), and concentrated in vacuo to afford 1.30 g of crude product. By digestion in ethyl acetate, a white solid (mp 131—134 °C) was separated which was recrystallized in THF to give **14b** (1.16 g, 80%); mp 135—136 °C (THF); $[\alpha]_D^{20}$+42.4° (*c*, 1.13, $CHCl_3$); IR ν_{max} ($CHCl_3$) 3600—3200, 3180, 2980, 1790, 1720, 1600, 1550, 1460, 1400, 1280, 1160, 1100, 1020, 770, and 460 cm^{-1}; ^1H NMR (200 NHz, $CDCl_3$) δ=0.81 (3H, t, J=7 Hz, $(CH_2)_3\underline{CH_3}$), 1.11 (3H, t, J=7 Hz, $COCH_2\underline{CH_3}$), 2.86 (3H, m, $CO\underline{CH_2}CH_3$+$\underline{CH}$Ar), 3.17 (1H, dd, J_1=15 Hz, J_2=3 Hz, $\underline{CH}$Ar), 3.81 (3H, s, NCH_3), 4.13 (1H, dd, J_2=2 Hz, J_2=10 Hz, CH_2OCO), 4.37 (1H, t, J=8 Hz, CH_2OCO), 4.66 (1H, m, CH), 6.85 (1H, s, CCHN), 8.02 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=8.14 (q, $COCH_2\underline{CH_3}$), 13.93 (q, $(CH_2)_3\underline{CH_3}$), 21.03 (t, BCH_2), 26.06 and 27.27 (dt, $BCH_2(\underline{CH_2})_2CH_3$), 26.76 (t, $CO\underline{CH_2}CH_3$), 28.92 (t, $\underline{CH_2}$Ar), 33.23 (q, NCH_3), 52.39 (d, CH), 66.89 (t, $\underline{CH_2}OCO$), 121.47 (d, C_5^{im}), 129.00 (s, C_4^{im}), 137.57 (d, C_2^{im}), 153.18 (s, $N\underline{C}OO$), 174.20 (s, $\underline{C}ON$); MS (FAB) *m/z* (%) 599 (45), 362 (100), 250 (90); MS (EI) *m/z* (%) 237 (60), 138 (90), 96 (100). Anal. Calcd for $C_{30}H_{50}O_{10}N_6BP$ (MW: 696): C, 51.73; H, 7.18; N, 12.07%. Found: C, 51.69; H, 7.09; N, 11.96%.

Condensation of 13a with Benzaldehyde via the Formation of the Cationic Boron Complex: (15a). A 1 M solution of dibutyl(trifluoromethylsulfonyloxy)borane (6.3 mL, 6.3 mmol) in dichloromethane was added dropwise to a stirred solution of triethylamine (0.9 mL, 6.3 mmol) in dichloromethane (4 mL) was added dropwise. Then, a solution of **13a** (0.75 g, 3.15 mmol) in dichloromethane (5 mL) was dropwise added at 0 °C under argon atmosphere. The reaction mixture was stirred at 0 °C for 1 h, cooled to −78 °C and a solution of benzaldehyde (0.30 mL, 3.15 mmol) in dichloromethane (5 mL) was added. This mixture was stirred for 30 min at −78 °C and 1 h at 0 °C. The reaction was quenched by addition to pH=7 phosphate buffer. The mixture was extracted twice with dichloromethane and the combined extracts were washed with brine and concentrated in vacuo. The crude was then dissolved in methanol (10 mL) at 0 °C and 30% hydrogen peroxide (4.5 mL) was added. After the mixture had been stirred at room temperature for 2 h, water (20 mL) was added; the mixture was concentrated and extracted twice with dichloromethane. The combined organic layers were washed with 5% aqueous sodium hydrogencarbonate and brine, dried (Na_2SO_4) and concentrated in vacuo to afford **15a** (1.14 g, 80%); mp 95—97 °C (EtOAc); $[\alpha]_D^{20}$+69.1° (*c* 1.38, $CHCl_3$); ^1H NMR (200 MHz, $CDCl_3$) δ=0.81 (3H, t, J=7 Hz, $(CH_2)_3\underline{CH_3}$), 1.06 (3H, d, J=7 Hz, $CH\underline{CH_3}$),2.81 (1H, dd, J_1=15 Hz, J_2=10 Hz, $\underline{CH}$Ar), 3.12 (1H, dd, J_1=15 Hz, J_2=3 Hz, $\underline{CH}$Ar), 3.79 (3H, s, NCH_3), 4.02 (2H, m, $\underline{CH}OCO$+$\underline{CH}CH_3$), 4.22 (1H, dd, J_1=7 Hz, J_2=9 Hz, $\underline{CH}OCO$), 4.59 (1H, m, $\underline{CH}CH_2$Ar), 5.03 (1H, d, J=3.8 Hz, Ar$\underline{CH}$OH), 6.83 (1H, s, CCHN), 7.3 (5H, m, Ar), 7.98 (1H, s, NCHN); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=10.51 (q, $\underline{CH_3}CH$), 13.96 (q, $(CH_2)_3\underline{CH_3}$), 21.07 (t, BCH_2), 26.06 and 26.85 (dt, $BCH_2(\underline{CH_2})_2CH_3$), 27.30 (t, $\underline{CH_2}$Ar), 33.29 (q, NCH_3), 44.88 (d, $CH_3\underline{CH}$), 52.70 (d, $\underline{CH}CH_2$Ar), 66.90 (t, $\underline{CH_2}OCO$), 73.52 (d, Ar$\underline{CH}$OH), 121.52 (d, C_5^{im}), 125.98 (d, Ar), 127.48 (d, Ar), 128.21 (d, Ar), 129.04 (s, C_4^{im}), 137.40 (d, C_2^{im}), 141.58 (s, Ar), 152.87 (s, $N\underline{C}OO$), 176.29 (s, $\underline{C}ON$); MS (EI) *m/z* (%) 889 (M^++1−H_2O, 10), 739 (30), 614 (50), 475 (85), 237 (100), 107 (80). Anal. Calcd for $C_{44}H_{62}O_{12}N_6BP$ (MW. 908): C, 58.14; H, 6.82; N, 9.25%. Found: C, 57.96; H, 6.76; N, 8.97%.

Condensation of 13b with Benzaldehyde: (15b). Prepared under the same conditions as described for **15a** using one equiv of the boron triflate (86%). $[\alpha]_D^{21}$+75° (*c* 1.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ=1.14 (3H, d, J=7 Hz, $CH\underline{CH_3}$), 2.95 (2H, m, CH_2Ar), 3.90 (3H, s, NCH_3), 2.95 (2H, m, CH_2Ar), 3.90 (3H, s, NCH_3), 4.55 (1H, dq, J_1=7 Hz, J_2=3.8 Hz, $CHOH\underline{CH}CH_3$), 4.17 (1H, t, J=8.5 Hz, CH_2OCO), 4.59 (1H, m, $N\underline{CH}(CH_2O)CH_2$), 5.05 (1H, d, J=3.8 Hz, CHOH), 6.69 (1H, s, CCHN), 7.4 (5H, m, Ar), 7.41 (1H, s, NCHN); ^{13}C NMR ($CDCl_3$) δ=15.79 (q, $CH\underline{CH_3}$), 29.74 (t, $\underline{CH_2}$Ar), 42.19 (q, NCH_3), 44.54 (q, $CH\underline{CH_3}$), 54.07 (t, $NCH\underline{CH_2}$), 66.66 (t, $\underline{CH_2}OCO$), 73.62 (d, CHOH), 116.98 (d, C_5^{im}), 136.22 (d, C_2^{im}), 141.64 (s, C_4^{im}), 153.17 (s, $N\underline{C}OO$), 176.57 (s, $\underline{C}ONCOO$). Anal. Calcd for $C_{18}H_{21}O_4N_3$ (M. W. 343) C, 62.97; H, 6.12; N, 12.24%. Found C, 62.92; H, 6.16; N, 12.26%.

Methyl (2*S*,3*S*)-3-Hydroxy-2-methyl-3-phenylpropanoate: (16a). Sodium hydride (180 mg, 80%) was carefully added to methanol (10 mL) under an argon atmosphere. Then, a solution of **15b** (1.4 g, 2 mmol) in methanol (50 mL) was added dropwise at 0 °C. The reaction mixture was stirred 15 min at 0 °C. Addition of an aqueous sat. NH_4Cl solution (25 mL) was followed by extraction with chloroform. The combined organic layers were dried evaporated to afford a crude which was purified by flash chromatography. Elution with hexane-ethyl acetate (80:20) gives **16b** (760.5 mg, 98%); $[\alpha]_D^{20}$−18.1° (*c* 1.7, $CHCl_3$); ^1H NMR (200 MHz, $CDCl_3$), δ=1.10 (3H, d, J=7 Hz, $CH\underline{CH_3}$), 2.78(1H, m, $\underline{CH}CH_3$), 3.65 (3H, s, $COO\underline{CH_3}$), 5.08 (1H, d, J=3.6 Hz, $\underline{CH}$OH), 7.31 (5H, m, Ar); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ=10.81 (q, $CH\underline{CH_3}$), 46.51 (d, $\underline{CH}CH_3$), 51.71 (q, $COO\underline{CH_3}$), 73.76 (d, CHOH), 125.97 (d, Ar), 127.47 (d, Ar), 128.22 (d, Ar), 141.57 (s, Ar), 175.97 (s, CO). Anal. Calcd for $C_{11}H_{14}O_3$ (MW. 194): C, 68.04; H, 7.21%. Found: C, 68.06; H, 7.15%.

Compound **16b** was prepared under the same conditions as described for **16a** staring from **15b** (97%). $[\alpha]_D$−17.3° (*c* 1.89, $CHCl_3$) with identical spectroscopic properties as those described for **16a**.

We thank Dr. Gabriel Tojo Suárez (Univ. Santiago, Spain) for his help on the MS experiments. F. Santinelli wishes to thank The European Foundation for a Grant (Erasmus Program. Contract Nr. ICP-88-092-E). Permanent address: Dipartimento di Chimica; V. Elce di Sotto 8, 06100 Perugia (Italy).

18) The ^{1}H NMR (200 MHz) spectrum of the phenylpropionic derivative **16a** exhibited only one doublet at δ=5.08 (J=4 Hz) which, considering the limits of NMR detection, excluded the presence of the possible threo isomers. The ^{13}C NMR spectra of both products **15a** and **16a** (see Experimental) confirmed the presence of only one diastereomer in the aldol.

Theoretical Study on the Formation of Spherical Micelles

Noriaki FUNASAKI* and Sakae HADA
Kyoto Pharmaceutical University, Yamashina-ku, Kyoto 607
(Received September 4, 1990)

Synopsis. From the Tanford theory for the formation of spherical micelles and a modification of this theory, the aggregation number n_w and monomer concentration x_1 are calculated as a function of total surfactant concentration x. The definition of cmc of $d^3x_1/dx^3=0$ is adequate. Empirical equations for the estimation of n_w and cmc are obtained.

When the concentration of surfactant is raised above the critical micelle concentration (cmc), to a first approximation all added molecules go into micelles. Then the question arises if the micelles grow in size or if only the number of the micelle is increased.[1] Recently, a number of experimental researches have been done, but there is still a matter of controversy whether the micelle of nonionic surfactant grows with increasing concentration or not.[2] Another question arises if the monomer concentration of the surfactant remains constant above the cmc.[3]

By gel-filtration chromatography, we determined the monomer concentration as a function of total surfactant concentration and further calculated the micellar aggregation number from this result.[3-5] These data may be used to test several theories for micellization or to estimate the micelle size distribution and other properties on the basis of these theories. Among these theories, the Tanford theory seems to be of greatest promise.[6] Warr and White modified it for computational simplicity and calculated the concentration dependence of the monomer concentration and aggregation number for spherical micelles.[7]

In this work we compare these theories and obtain useful relations to fit these theories to our experimental data.

Thermodynamic Basis

According to Tanford,[6] the free energy (per RT) of transfer of i surfactant molecules to a spherical micelle of aggregation number i may be expressed as[7,8]

$$\Delta G_i^\circ = -ai + bi^{2/3} + ci^{4/3} - (-a+b+c). \quad (1)$$

This equation holds for all micelles of aggregation number greater than unity. The coefficient a is a bulk free-energy term for transfer of an alkyl chain from water into the micelle core, b is the surface free energy per surfactant at the micelle/solution interface, and c is a term for repulsions etc. between the head groups in the micelle. The mole fraction of micelles of aggregation number i may be given by

$$x_i = x_1{}^i \exp(-\Delta G_i^\circ). \quad (2)$$

Using this equation, one can express the total surfactant mole fraction x and the weight average aggregation number n_w as

$$x = \sum_{i=1}^{\infty} i x_i, \quad (3)$$

and

$$n_w = \sum_{i=2}^{\infty} i^2 x_i / \sum_{i=2}^{\infty} i x_i. \quad (4)$$

From Eqs. 1 and 2, one can obtain a scaled mole fraction of i-mer as a function of a scaled monomer concentration from

$$x_i e^a = (x_1 e^a)^i \exp[-b(i^{2/3}-1) - c(i^{4/3}-1)]. \quad (5)$$

Furthermore Tanford defined the cmc as x at which $x_1/x=0.95$.[6]

For computational simplicity Warr and White modified Eq. 1 as

$$\Delta G_i^\circ = -a(i-1) + b(i-1)^{2/3} + c(i-1)^{4/3}, \quad (6)$$

and gave useful expressions for the cmc and other properies.[7] They defined scaling parameters for ΔG_i° and i:

$$\Gamma = b^2/c, \quad (7)$$

and

$$I = (b/c)^{3/2}. \quad (8)$$

The Γ value varies linearly with ΔG_i° and I gives a rough value of n_w. Furthermore they considered cmc values on the basis of the following equation:

$$d^3x_1/dx^3 = 0. \quad (9)$$

This is a form of the general definition of cmc by Phillips.[9] From Eq. 2 we can obtain

$$d^3x_1/dx^3 = M/x_1{}^2 [\sum_{i=1}^{\infty} i^2 x_1{}^{i-1} \exp(-\Delta G_i^\circ)]^5, \quad (10)$$

where

$$M = 3[\sum_{i=1}^{\infty} i^2 (i-1) x_1{}^{i-1} \exp(-\Delta G_i^\circ)]^2 - [\sum_{i=1}^{\infty} i^2(i-1)(i-2) x_1{}^{i-1} \exp(-\Delta G_i^\circ)] [\sum_{i=1}^{\infty} i^2 x_1{}^{i-1} \exp(-\Delta G_i^\circ)]. \quad (11)$$

From Eq. 9 the cmc is the value of x at which $M=0$.

Results and Discussion

Figure 1 shows plots of n_w against the logarithm of total concentration scaled by exp a in the case of $I=60$. The solid lines were calculated from the Tanford theory, viz., Eq. 1 and the dashed lines were from the Warr and White theory, viz., Eq. 6. The numerals attached to these lines denote the Γ values. Results similar to Fig. 1 were obtained in the cases of $I=20$ and 150. As Fig. 1 shows, at high concentrations the I value is similar to the n_w values calculated from the Warr and White theory, but is slightly larger than

those from the Tanford theory. These results are useful to estimate the values of b and c from observed n_w values and show that n_w is determined by the balance of the b term to the c term in Eqs. 1 and 6.

Figure 2 shows plots of monomer concentration against total concentration calculated from Eq. 1 (solid lines) and Eq. 6 (dashed lines) in the cases of I=60. Similar results were obtained in the cases of I=20 and 150. The monomer concentrations calculated from Eq. 1 are smaller than those from Eq. 6.

Figure 3 shows the logarithm of cmc against the square root of the product bc, calculated from Eq. 1. The filled symbols denote the cmc values calculated from the definition by Tanford, viz., x_1/x=0.95 and the hollow symbols are those from the definition of Eq. 9. Similar results were obtained from Eq. 6. The plots in Fig. 2 show part of these results. Empirically, these cmc values are expressed by the following equation:

$$\ln x_{cmc} = -a + \beta(bc)^{1/2} + \gamma. \quad (12)$$

Table 1 shows the coefficients β and γ in Eq. 12 and the correlation coefficient of linearity determined by a linear least-squares method. In the case of Eq. 6, the cmc values determined by the two definitions are close to each other and also close to the predictions by Eq. 12, as can be seen from the values of the correlation coefficient and the standard deviations of β and γ in Table 1. In the case of Eq. 1 the cmc values determined by the two definitions are far, as shown in Fig. 2 and Table 1. From Fig. 2 we can conclude that the definition of cmc by Eq. 9 is better than that by Tanford. Figure 1 shows the n_w values predicted by Eq. 1 are smaller than those by Eq. 6. As a result, in the case of Eq. 1 the cmc values defined by Tanford

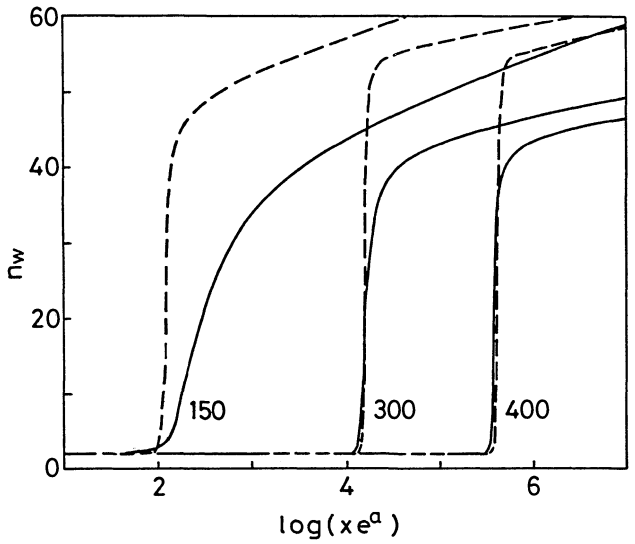

Fig. 1. Weight average aggregation numbers calculated from Eqs. 1 (solid lines) and 6 (dashed lines) as a function of the logarithm of scaled total concentration at different Γ values for I=60.

Table 1. The Coefficients β and γ and the Correlation Coefficient r Fitted to Eq. 12

Eq	Definition	$\beta\pm$sd[a)]	$\gamma\pm$sd[a)]	r
1	x_1/x=0.95	1.96±0.04	−1.23±0.82	0.9978
1	Eq. 9	1.87±0.01	0.25±0.26	0.9998
6	x_1/x=0.95	1.99±0.01	−0.12±0.13	0.9999

a) Standard deviation.

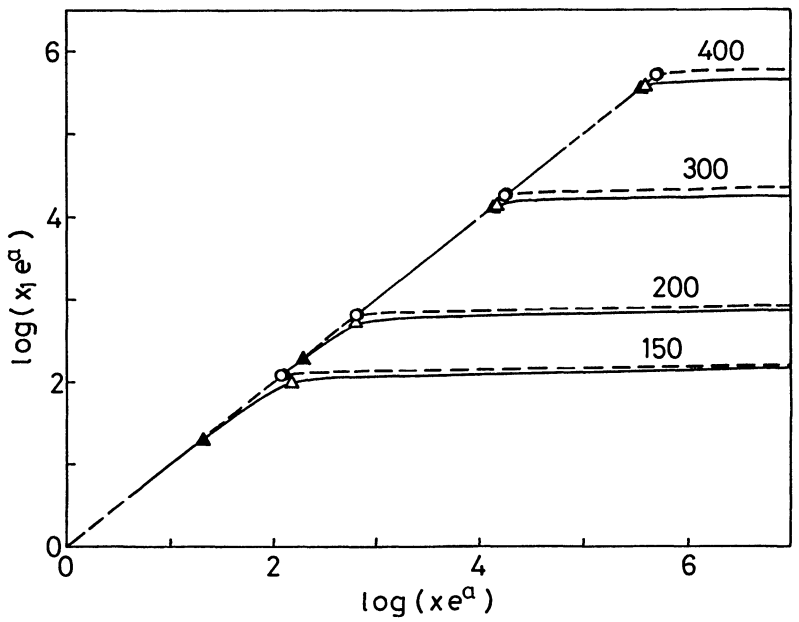

Fig. 2. Plots of scaled monomer concentrations against scaled total concentrations, calculated from Eqs. 1 (solid lines) and 6 (dashed lines) for I=60 at different Γ values. The hollow symbols ○ and △ show the cmc values defined by Eq. 9 and the filled symbols ● and ▲ show those defined by x_1/x=0.95.

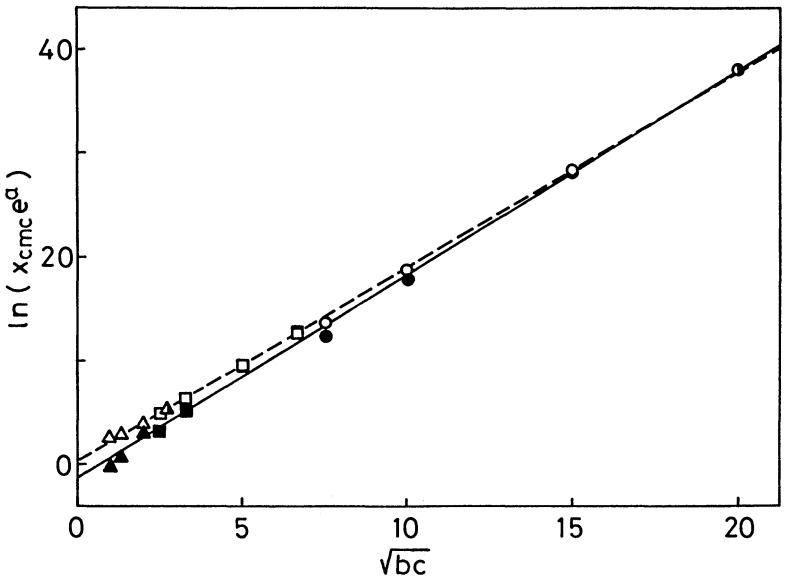

Fig. 3. Plots of scaled cmc values against the square root of the product bc for Eq. 1, calculated from the definitions of Eq. 9 (hollow symbols) and $x_1/x=0.95$ (filled symbols) at different I values: ○ and ●; I=20, □ and ■; I=60, △ and ▲; I=150. The dashed line is fitted to the hollow symbols and the solid line is fitted to the filled symbols.

become too small. From Eq. 12 we can see that the cmc value is controlled mainly by term a viz., interactions between alkyl groups and water, and further by terms b and c, viz., interactions between head groups at the micellar surface. The definition of cmc by Ruckenstein and Nagarajan,[8] viz., $d^2\Delta G_i^\circ/di^2=0$, yielded too small cmc values (data not shown).

In conclusion, the Warr and White theory (Eq. 6) is simple and useful to understand the predictions from the Tanford theory (Eq. 1). In Eq. 1 as well as in Eq. 6, the micelle size parameter I is a good measure of n_w, and the cmc value is empirically given by Eq. 12. These results are useful to fit Eqs. 1 and 6 to experimental data of cmc and n_w.[10] The values of n_w and x_1 predicted by Eq. 1 are significantly different from those predicted by Eq. 6. This result means that the physical meanings of the coefficients a, b, and c in Eq. 1 are different from, though similar to, those in Eq. 6. Therefore Eq. 6 is not a very good approximation of Eq. 1. The definition of cmc by Eq. 9 gives reasonable cmc values for both Eqs. 1 and 6.

Thanks are due to Mr. Shimada and Mr. Yamana for some preliminary calculations.

Chemical Shift Standards in High-Resolution Solid-State NMR (1) ^{13}C, ^{29}Si, and ^{1}H Nuclei

Shigenobu HAYASHI* and Kikuko HAYAMIZU
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received September 17, 1990)

Synopsis. The resonance frequencies of ^{13}C, ^{29}Si, and ^{1}H nuclei in pure tetramethylsilane have been measured accurately by spinning the liquid sample at the magic angle, which are free from the effects of the bulk magnetic susceptibility and the solvent. Using the above resonance positions, the chemical shifts of several second shift-standard materials have been determined with much improved accuracy and precision.

The chemical shift can be expressed as the deviation of the resonance frequency from that of a standard sample. An external reference is usually used in solid-state NMR, where we should be careful of the effect of the bulk magnetic susceptibility.[1,2] In high-resolution solid-state NMR of ^{13}C, ^{29}Si, and ^{1}H, few papers have been presented, in which the chemical shifts have been determined accurately by directly referring to the signal of tetramethylsilane (TMS), except for the Earl and VanderHart's work.[3] In our previous paper,[4] we have reported chemical shift values of several second shift-standard materials in ^{13}C, ^{29}Si, ^{31}P, ^{23}Na, ^{27}Al, and ^{11}B NMR, although the accuracies were not so good as in solution NMR.

In the present work, we can trace the spectra of pure tetramethylsilane with high resolution in the instrumental set-up for solid-state NMR by the magic-angle spinning (MAS) of the liquid sample, to the extent that the error in the first standard is negligible. The resonance position obtained by the above method is free from the solvent effect and the effect of the bulk magnetic susceptibility. Thus, we can determine the "absolute chemical shifts" of the materials to be investigated with markedly improved accuracy.

Experimental

Materials were available commercially. They were used as supplied.

The instrument used for the NMR measurements was a Bruker MSL400 pulsed spectrometer, whose magnetic field strength was 9.4 T. The resonance frequencies were 100.614, 79.496, and 400.136 MHz for ^{13}C, ^{29}Si, and ^{1}H, respectively. The commercial MAS probehead supplied by Bruker was used, in which a double-bearing type rotor made of zirconia was spun at spinning rates between 3 and 4 kHz for solid samples. Sealed inserts which fit the inside of the rotor[5] were used to spin the liquid samples at spinning rates of 0.5 to 1 kHz. A spherical container made of Pyrex was also used to check the effect of the bulk magnetic susceptibility. One did not need to remove the probehead from the magnet bore when the sample was exchanged, which excluded the error in the chemical shift caused by the replacement of the probehead. Temperature was 294 K. Before the NMR measurements, the magnetic field was carefully shimmed to achieve a linewidth less than 0.010 ppm for liquid samples when the magic-angle spinning was applied.

The chemical shifts were determined by use of an external reference. The drift of the magnetic field was less than 0.006 ppm per day, and thus, the drift of the magnetic field was negligible compared to the other experimental errors during a day. Most part of the experimental errors came from the residual linewidth and the line shape both of which caused by the field inhomogeneity and the sample nature.

Results and Discussion

Accurate Determination of Chemical Shifts. TMS can be used as the first standard in ^{13}C, ^{29}Si, and ^{1}H measurements, where pure liquid should be used to avoid the solvent effect. TMS is highly volatile, and a resonance line with a relatively broad linewidth is obtained for a sealed sample in the static state. On the other hand, we can get a very sharp line by spinning the sealed sample at the magic angle. The residual linewidths are 0.008 ppm in the decoupled spectra of ^{13}C and ^{29}Si, and 0.012 ppm in the ^{1}H spectra. Small peaks are observed on both sides of the intense peak in the ^{13}C spectra, which are originated from the coupling with ^{29}Si, where the coupling constant $^{1}J(^{13}C-^{29}Si)$ is 51.4 Hz. The coupling constants with ^{1}H can be determined accurately from the ^{1}H-coupled spectrum, which are $^{1}J(^{13}C-^{1}H)=118.06\pm0.03$ Hz, $^{3}J(^{13}C-^{1}H)=2.16\pm0.03$ Hz, and $^{2}J(^{29}Si-^{1}H)=6.59\pm0.01$ Hz. This high resolution enables the accurate determination of the chemical shifts.

Tables 1 and 2 summarize the results on the second standard materials frequently used in high-resolution

Table 1. ^{13}C Chemical Shifts[a]

Compounds	δ[b] ppm	FWHM[c] ppm
[Pure liquids]		
Tetramethylsilane	0	0.008
Benzene	128.475 (0.005)	0.006

Tetrakis(trimethylsilyl)silane	0.247 (0.011)	0.80[b]
Silicone rubber	[c] 0.123 (0.003)	0.048
	[d] 0.119 (0.003)	0.047

a) All the samples are spinning at the magic angle. b) The linewidth depends on the spinning rate. The listed values were obtained at ν_r=4.04, 3.59, and 4.01 kHz for adamantane, *d*-camphor, and tetrakis(trimethylsilyl)silane, respectively. c) $\nu_r \leqslant 1.0$ kHz. d) $\nu_r \geqslant 2.5$ kHz.

solid-state ^{13}C and ^{29}Si NMR. Among the solid materials, adamantane, tetrakis(trimethylsilyl)silane (Si(Si$(CH_3)_3)_4$; TKS),[6] and silicone rubber have markedly narrow resonance lines, where the dipolar coupling with ^{1}H nuclei is weak due to fast molecular motions. Cross polarization (CP) is not efficient in TKS and silicone rubber. On the other hand, glycine and hexamethylbenzene need cross polarization to get ^{13}C signals with a good signal to noise ratio. To set up the ^{29}Si CP/MAS experiment, sodium 3-(trimethylsilyl)propionate-d_4 ($(CH_3)_3SiCD_2CD_2COONa$; TSPA-d_4), sodium 3-(trimethylsilyl)propionate ($(CH_3)_3SiCH_2CH_2COONa$; TSPA), and sodium 3-(trimethylsilyl)propane-1-sulfonate (sodium 4,4-dimethyl-4-silapentane-1-sulfonate; $(CH_3)_3SiCH_2CH_2CH_2SO_3Na$; DSS) are suitable. However, they have a fine structure in the spectra, as shown in Fig. 1, which is considered to be caused by the crystallographic inequivalence in the solid state. The most intense peaks have chemical shift values of 1.445, 1.459, and 1.534 ppm in TSPA-d_4, TSPA, and DSS, respectively.

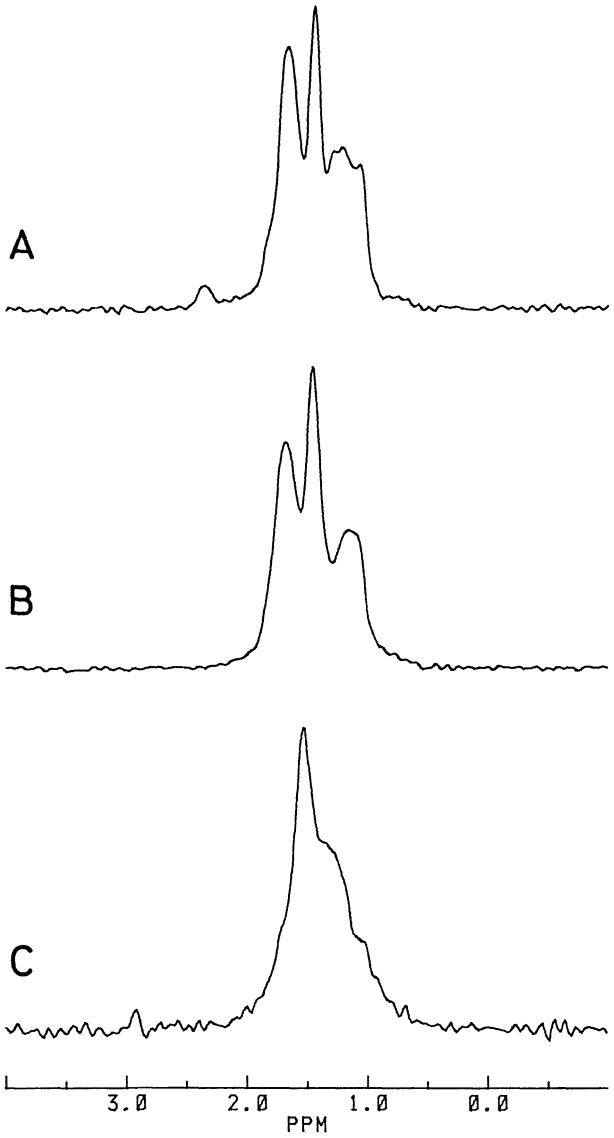

Fig. 1. ^{29}Si CP/MAS NMR spectra of (A) TSPA-d_4, (B) TSPA, and (C) DSS, measured at ν_0=79.496 MHz.

The homonuclear dipole-dipole interaction between ^{1}H spins cannot be usually suppressed by the magic-angle spinning of the normal rate. In this work, the chemical shift values of weakly-coupled ^{1}H are determined only by MAS, which results are summarized in Table 3.

The spectra of silicone rubber have a fine structure in the range of the spinning rate between 1.4 and 2.0 kHz, while only one component is observed outside the range. Thus, the shift values outside the above range are listed in the tables.

Table 4. Summary of the Experiments on the Effect of the Bulk Magnetic Susceptibility[a)]

Nucleus	Shape	Mode	δ	FWHM
			ppm	ppm
^{13}C	Cylinder	MAS	128.475 (0.005)	0.006
	Cylinder	Static	128.51 (0.05)	0.22
	Sphere	Static	128.45 (0.05)	0.19
^{1}H	Cylinder	MAS	6.771 (0.005)	0.011
	Cylinder	Static	6.78 (0.03)	0.22
	Sphere	Static	6.76 (0.02)	0.050

a) The sample is pure benzene.

Effect of Bulk Magnetic Susceptibility on the Shift. Earl and VanderHart[3)] have suggested that the bulk magnetic susceptibility effect is negligible for an infinitely long cylinder spinning about its cylindrical axis which is inclined at the magic angle from the direction of the field. Even if the length of the cylinder is finite, the susceptibility effect is expected to be negligible in the MAS experiment, being derived from VanderHart et al.[7)]

We have checked the above suggestions in practical samples. Three types of experiments have been carried out: First, the resonance frequency of a cylindrical sample is measured under MAS, using the sealed insert with a cylindrical hole. Second, the resonance frequency of a cylindrical sample is measured without the spinning. Third, the spectra of a spherical sample is measured in the static state. In the first and the second experiments, the cylindrical axis is inclined at the magic angle from the direction of the field.

We have measured ^{13}C and ^{1}H signals of pure benzene, the results of which are summarized in Table 4. The resonance positions of the spherical samples are free from the susceptibility effect. As shown in table, the effect is negligible for the cylindrical sample under MAS as well as in the static state. The inclination of the cylindrical axis might be important to cancel the effect. Thus, the MAS experiment can determine "the absolute chemical shift" free from the susceptibility effect and the solvent effect.

Chemical Shift Standards in High-Resolution Solid-State NMR (2) ^{15}N Nuclei

Shigenobu HAYASHI* and Kikuko HAYAMIZU
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305
(Received September 18, 1990)

Synopsis. ^{15}N NMR spectra of the shift standard compound, pure nitromethane, have been measured with high resolution by spinning the liquid sample at the magic angle. Using the precise resonance position of nitromethane, the chemical shifts of the solid second-standard materials such as ammonium salts and glycine have been measured with great precision.

High-resolution solid-state NMR has been widely used recently. Many of them are concerned with ^{13}C and ^{29}Si nuclei, while measurements of ^{15}N nuclei are rather limited.[1] One of the reasons is that the sensitivity of ^{15}N nuclei is very low because of the low natural abundance and the low gyromagnetic ratio. However, the ^{15}N nuclei is important for the studies of biosubstances such as proteins, polypeptides, and amino acids.

The chemical shift can be expressed as the deviation of the resonance frequency from that of a standard material. In solution ^{15}N NMR, pure nitromethane is widely used as the first standard.[1] On the other hand, various materials have been used for the first standard in high-resolution solid-state ^{15}N NMR. NH_4Cl[2] and glycine[3] have been used as the solid shift standards, and various liquid samples used in solution NMR have also been used as the first standard; for example, HNO_3 aqueous solution, NH_4NO_3 saturated aqueous solution, and liquid NH_3.

In our previous paper,[4] we have reported precise chemical shift values of several second standard materials in ^{13}C, ^{29}Si, and ^{1}H NMR determined with respect to pure tetramethylsilane. In the present work, we have extended the previous work to ^{15}N NMR. The key point is how we measure the peak position of the first standard precisely.

Experimental

Materials were available commercially; CH_3NO_2 from Tokyokasei, $HCONH_2$ and $NH_4H_2PO_4$ from Kokusankagaku, $^{15}NH_4Cl$, NH_4Cl (10at.% ^{15}N), $^{15}NH_4NO_3$, and Glycine-^{15}N from Aldrich, NH_4Cl from Mitsubishikasei, NH_4NO_3 and $(NH_4)_2SO_4$ from Nacalai, and glycine from Wako. They were used as supplied.

The instrument used for the NMR measurements was a Bruker MSL400 pulsed spectrometer, whose magnetic field strength was 9.4 T (the resonance frequency, 40.561 MHz). The detail of the hardware has been described previously.[4] The rotor was spun at spinning rates of about 3 kHz and 0.5—1.0 kHz for solid and liquid samples, respectively. Temperature was 294 K, unless otherwise stated.

INEPT pulse sequences with and without ^{1}H decoupling[5] were used for liquid samples as well as the ordinary single pulse sequence. Two kinds of pulse sequences were used for solid samples; single pulse with ^{1}H decoupling only during the data acquisition, and cross polarization (CP) from ^{1}H to ^{15}N with ^{1}H decoupling during acquisition. CP was always used for the unenriched solid samples, in which the contact time was 3 ms, the recycle time was 8—10 s, and the number of scans was 100—200.

Results and Discussion

^{15}N Spectra of Nitromethane and Formamide. Nitromethane is the first standard, and formamide is used as the liquid second standard. Table 1 summarizes the chemical shifts and linewidths obtained in this work. The resonance frequency of pure nitromethane measured without decoupling and with MAS is assumed to be 0 ppm throughout this work, the reason of which is described below.

Figure 1 shows the spectra of pure nitromethane without and with ^{1}H decoupling. Linewidths less than 0.010 ppm have been obtained by the initial careful shimming. Figure 1A shows XH_3 pattern, in which the coupling constant between X and H is 2.33±0.01 Hz. This value agrees excellently with that of Strelenko et al.[6] Figure 1B shows the decoupled spectrum, and only one sharp resonance line can be observed. However, note that the resonance position of the decoupled spectrum does not

Table 1. Results of Pure Nitromethane and Formamide

b) Full width at half maximum. c) Assumed to be 0 ppm.

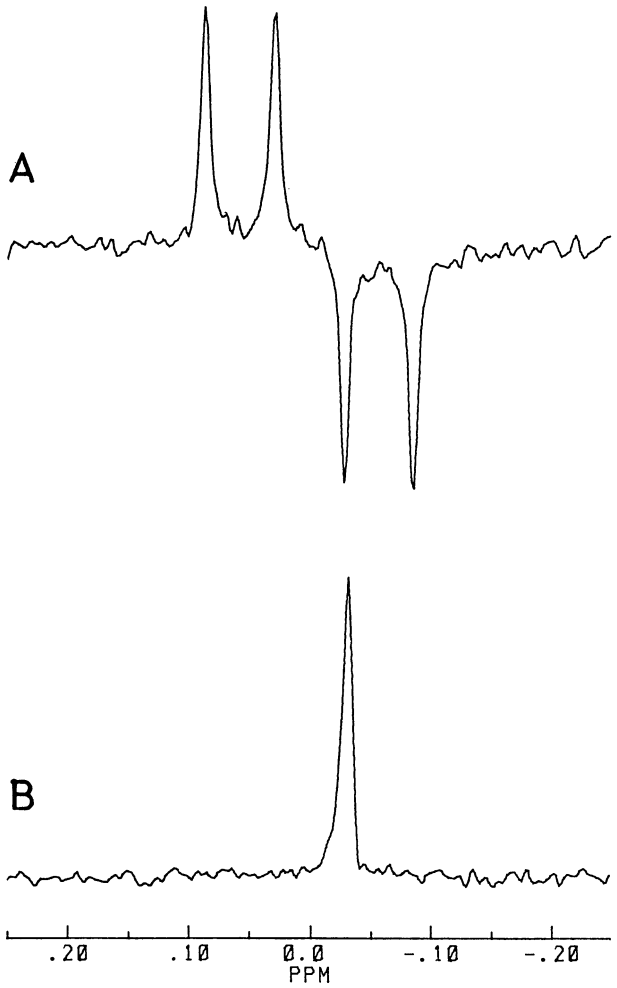

Fig. 1. ^{15}N MAS NMR spectra of neat nitromethane. (A) INEPT without decoupling, and (B) refocused INEPT with ^{1}H decoupling. Experimental parameters are as follows; 100 scans, τ (=1/4J) 109 msec, spectral width 1250 Hz, data size 32 kwords, and line broadening 0.1 Hz.

agree to the center of the coupled spectrum. We have repeated these measurements several times, including the single-pulse-sequence measurements with and without decoupling, and conclude that the deviation is not the experimental error. The deviation ranges from 0.026 to 0.037 ppm, depending on the experiment.

Which spectrum is independent of the measurement, the decoupled or coupled spectrum? The answer comes from the similar measurements on formamide, $HCONH_2$. The coupled spectrum shows XH_2 pattern accompanied by a long-range splitting. The coupling constants are $^{1}J(^{15}N-^{1}H)=89.21\pm0.02$ Hz and $^{2}J(^{15}N-^{1}H)=14.03\pm0.02$ Hz. The decoupling induces a shift of -0.30 ± 0.10 ppm. This deviation is much larger than that observed in nitromethane, and the fluctuation from experiment to experiment is also larger. We have compared the spectra of nitromethane with those of formamide. The difference in the resonance frequency between the coupled spectra of the two compounds are always constant, while the difference between the decoupled specta fluctuates up to 0.20 ppm. Consequently, the coupled spectrum is independent of the experiment. Thus, the coupled spectrum should be taken as the shift standard. In the present work, the center of the coupled spectrum of pure nitromethane (Fig. 1A) is assumed to be 0 ppm.

The origin of the decoupling induced shift is discussed briefly. The most possible mechanism is that the decoupling induces temperature increase in the sample, resulting in the resonance frequency shift. Nitromethane and formamide have large dielectric constants,[7] and thus the decoupling pulse loses its energy, which converts into heat. The heating effect is largely dependent on the experimental conditions, and the shift in the decoupled spectrum fluctuates from experiment to experiment. To check the above hypothesis, we have measured the temperature dependence of the ^{15}N chemical shifts in nitromethane and formamide under the MAS condition. The temperature range studied is between 294 and 304 K. The resonance lines shift towards lower frequency as the temperature increases, which direction is the same as the decoupling induced shift. The magnitudes of the tempearture dependence are -0.0045 and -0.0089 ppm K^{-1} for nitromethane and formamide, respectively. A simple calculation indicates that the decoupling increases the temperature of the sample by 6—8 K and 23—45 K in nitromethane and formamide, respectively. The specific inductive capacities of the two compounds are 35.8 (30 °C) and 111.0 (20 °C).[7] Since the dielectric constant of formamide is markedly large, the decoupler heating is very efficient in this compound. The linewidth in the decoupled spectrum of formamide (0.082 ppm) is much broader than in the coupled spectrum (0.018 ppm). The decoupler heating might produce chemical shift dispersion in the sample.

Anderson and Freeman[8] have proposed a mechanism of the decoupling induced shift, called "Bloch-Siegert shift." However, this mechanism cannot be applied to the present case, since the estimated shift is

Table 2. ^{15}N Chemical Shifts in Solids[a]

Compounds	δ[b] ppm	FWHM[c] ppm
$^{15}NH_4Cl$	−341.168 (0.011)	0.077

much smaller than the experimental shift.

Next the effect of the bulk magnetic susceptibility is checked and discussed for pure nitromethane. The procedure is the same as the previous work,[4] which results are summarized in Table 1. Although the experimental error is large for the static samples, the observed values demonstrate that the effect of the bulk magnetic susceptibility is negligible within the experimental error in MAS NMR. Furthermore, the susceptibility effect is negligible in the static cylinder whose cylindrical axis is inclined at the magic angle.

Second Shift Standards. Practically, solid materials are adequate in order to set up the instrument. We have measured ^{15}N CP/MAS NMR spectra of various ammonium salts and glycine, and have determined their chemical shifts with respect to pure nitromethane. Table 2 summarizes the obtained chemical shifts and linewidths. Cross polarization is not always necessary for the ^{15}N-enriched compounds, while it is indispensable for the compounds with the natural-abundance ^{15}N. Although $^{15}NH_4NO_3$ has two kinds of N atoms, only the chemical shift of $^{15}NH_4$ is listed in the table, since NO_3 was not observed in a few scans. $(NH_4)_2SO_4$ has two peaks originated from crystallographycally inequivalent sites.[9] Since this work delas with the shift standard, detailed discussion on the correlation between the chemical shifts and the structure will be published elsewhere. For routine use, we recommend to use $^{15}NH_4Cl$ and NH_4Cl (10 at.%^{15}N) to set up the instrument and as the second shift standard. The linewidths are smallest among the solid materials measured.

(Received August 6, 1990)

Synopsis. The title complex, $[Eu(NO_3)_2(L)(CH_3OH)]NO_3$, has been synthesized and its molecular structure has been determined by a single crystal X-ray analysis, where L denotes 2,6-diacetylpyridine bis(2-pyridylhydrazone). The complex has a ten-coordinate structure with quinquedentate L, two bidentate NO_3^- ions, and monodentate CH_3OH.

Lanthanoid ions are classified into "hard acids" in the HSAB sence and generally have a low affinity toward nitrogen donor atom. Therefore, lanthanoid complexes derived from nitrogenous ligands (with only nitrogen donor atoms) are still limited to those of phthalocyanine, porphyrines, *o*-phenanthroline, 2,2′-bipyridyl, and aliphatic polyamines.

In 1979, Backer-Dirks et al.[1a] reported the synthesis of lanthanum(III) complex of a Schiff base derived from 2,6-diacetylpyridine and ethylenediamine. Thereafter some synthetic investigations of lanthanoid complexes have been undertaken using related nitrogenous ligands.[1-4] Those previous studies suggest that despite low affinity to nitrogen donor atom lanthanoid ions form significantly stable complexes when a multidentate nitrogenous ligand is appropriately chosen. In this study a quinquedentate nitrogenous ligand, 2,6-diacetylpyridine bis(2-pyridylhydrazone) (abbreviated as L), obtained by the condensation of 2,6-diacetylpyridine and 2-pyridylhydrazine in the 1 : 2 ratio, has been utilized for the synthesis of europium(III) complex. This paper describes the synthesis and single crystal X-ray analysis of $[Eu(NO_3)_2(L)(CH_3OH)]NO_3$.

Experimental

Synthesis of Ligand (L). To a solution of 2,6-diacetylpyridine (10 mmol) and 2-pyridylhydrazine (20 mmol) in ethanol (25 cm^3) was added one drop of concentrated hydrochloric acid, and the mixture was heated at about 60 °C with stirring to give a pale yellow precipitate. After further heating with stirring at this temperature for 1 h, the mixture was allowed to stand overnight at room temperature. The precipitate was collected by filtration, washed with ethanol, and dried in the open air. The yield was 2.3 g (60%).

Found: C, 60.08; H, 5.89; N, 25.72%. Calcd for $C_{19}H_{19}N_7 \cdot 2H_2O$: C, 59.83; H, 6.08; N, 25.70%.

$[Eu(NO_3)_2(L)(CH_3OH)]NO_3$. To a solution of the ligand (L, 1 mmol) in hot methanol (90 cm^3) was added europium(III) nitrate hexahydrate (1 mmol) in methanol (10 cm^3). The solution was refluxed with stirring for 2 h and set aside at room temperature overnight to give orange crystals, which were collected on a glass filter, washed with methanol, and dried in the open air. The yield was 0.54 g (77%).

Found: C, 32.58; H, 3.09; N, 19.72; Eu, 21.49%. Calcd for $C_{19}H_{21}EuN_{10}O_{10}$: C, 32.54; H, 3.02; N, 19.97; Eu, 21.67%.

Recrystallization of the above complex from hot methanol formed single crystals suitable for X-ray analysis.

Measurements. Elemental analyses were carried out at Advanced Instrumentation Center for Chemical Analysis, Ehime University. Molar conductances were measured in methanol (concn 1×10^{-3} mol dm^{-3}) at 25 °C with a Toa CM-S Conductivity Meter. Infrared spectra were recorded on KBr disks with a JASCO IR-G Spectrometer.

X-Ray Crystallography. Reflection data were measured on a Rigaku Denki AFC-5 automated four-circle diffractometer with graphite-monochromatized Mo $K\alpha$ radiation at room temperature. The details of data collection and crys-

tallographic data are as follows:

$[Eu(NO_3)_2(L)(CH_3OH)]NO_3$, formula=$C_{20}H_{23}EuN_{10}O_{10}$, F.W.=715.4, monoclinic, space group $P2_1/n$, a=13.978(4), b=16.487(4), c=11.443(2) Å, β=95.02(2)°, V=2626.9(11) Å^3, D_x =1.808 g cm^{-3}(Z=4), crystal size 0.3×0.3× 0.4 mm, μ(Mo $K\alpha$) =18.16 cm^{-1}, scan mode θ-2θ, scan range 2.5—52°, scan width (1.2+0.35 tan θ)°, octant measured $+h$, $+k$, $\pm l$, number of observed reflections with $|F_o|>3\sigma$ ($|F_o|$) 4284, R=7.22%, R_w=8.81%, highest peak on the final D-Fourier 4.3 e Å^{-3} around Eu atom.

The intensity data were corrected for Lorentz and polarization effects but not for absorption and extinction effects. The structure was solved by the standard heavy-atom method and refined by the block-diagonal least-squares method, in which the function minimized was $\sum w(|F_o|-|F_c|)^2$ and the equal weight w=1 was adopted for all the reflections. The atomic scattering factors were taken from Ref. 5. All computations were performed on a FACOM M 780 computer at the Computer Center of Kyushu University using UNICS III program system.[6] The final atomic coordinates are given in Table 1. Tables of observed and calculated structure factors, listing of atomic positional and anisotropic thermal parameters, and complete lists of bond distances and angles with their estimated standard deviations have been deposited as Document No. 9101 at the office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Some typical IR bands of the free ligand shifted significantly on complexation: ν(C=N), from 1600 cm^{-1} to 1575 cm^{-1}; skeletal bands of pyridine, from 1565 and 1575 cm^{-1} to 1595 and 1612 cm^{-1}, respectively. The shifts of the skeletal bands toward higher frequencies suggest the coordinations of pyridine rings.[2b,d,e] Two nitrate vibrations were observed around 1450 and 1380 cm^{-1}, suggesting the presence of bidentate and non-coordinating groups within a molecule.[1b,2c-e,3b,7] Electrical conductivity in methanol was 101 $S\,cm^2\,mol^{-1}$, indicating that the complex functions as a 1 : 1 electrolyte in this solvent.[8]

The ORTEP drawing of the complex with atom numbering scheme is shown in Fig. 1. The selected bond distances and angles with standard deviations are given in Table 2.

The X-ray structural result demonstrates that the geometry around the europium(III) ion is of ten-coordination with quinquedentate L, two bidentate nitrate ions, and a methanol oxygen. The quinquedentate ligand L forms the basal coordination plane, in which the atoms N_1, N_3, N_4, N_5, and N_7 deviate by −0.27, 0.30, −0.08, −0.16, and 0.23 Å from the best plane of the basal donor atoms, respectively. The third nitrate ion is free from coordination and captured in the crystal lattice. One of the bidentate nitrate ions is situated on one side of the coordination plane formed by the ligand L, with similar Eu-O4 and Eu-O5 bond distances (2.526 and 2.540 Å, respectively). Another bidentate nitrate ion and the methanol molecule are situated on the other side, with the Eu-O1 and Eu-O3 bond distances of 2.599 and 2.503 Å, respectively, and the Eu-OM distance of 2.516 Å. The Eu-O1 bond is significantly elongated probably because of a steric effect from the neighboring methanol molecule. The Eu-N bond distances fall in the range 2.566—2.594 Å, which are short compared with the Sm-N bond distances (2.620—2.655 Å) found for a samarium(III) complex of 3,6,14,17,23,24-hexaazatricyclo[17.3.1.$1^{8,12}$]tetracosa-1(23),2,6,8,10,12(24),13,17,19,21-decaene[3b] but long on the whole compared with the Gd-N bond distances (2.500—2.606 Å) found for a gadolinium(III) complex of *N,N'*-bis(2-pyridylmethylene)ethylenediamine.[9] This trend is in line with that ionic radii of lanthanoid ions decrease with increasing atomic number (lanthanide contraction), i.e., r(Sm)>r(Eu)>r(Gd).

Synthetic Inorganic Ion-Exchange Materials LX. Ion Exchange and Chromatographic Separation of Alkali Metal Ions on Cubic Ammonium Molybdate — A Novel Cation Exchanger

Abdul Jabbar KHAN,* Mitsuo ABE, Masamichi TSUJI, and Yasushi KANZAKI
Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, 2-12-1 Ookayama, Meguro-ku, Tokyo 152
(Received August 29, 1990)

Synopsis. The ion-exchange selectivity of H^+-form of cubic ammonium molybdate (H-CAM) was studied for alkali metal ions in both HNO_3 and NH_4NO_3 media. Ideal ion-exchange reaction was observed in both the media with high selectivity for Rb^+ and Cs^+. The selectivity sequence was found to be $Li^+<Na^+<K^+<Rb^+<Cs^+$ in accordance with the Eisenman sequence-1 in both the media, with separation factors greater than the commercial polystyrene strong acid exchange resin. Efficient separation of alkali metal ions could be achieved on H-CAM column.

The inorganic ion-exchange materials possess significant superiority over the commercial organic ion-exchange resins at high temperatures and ionizing radiations. Some of these materials are very selective showing greater exchange capacity for certain metal ions.[1-4] Abe and Ito[5] studied adsorption properties of various metal oxides and hydrous oxides. An insufficient information about the ion-exchange properties of hexavalent metal hydrous oxides could also be found in the literature.[6] The isopolymolybdates and tungstates have been reviewed by Tytko and Glemser.[7] The heteropoly acid salts of molybdenum have been sufficiently worked on for their ion-exchange properties.[8,9] The acid salts and hydrated compounds of Mo(VI) have drawn a considerable interest for their catalytic properties too. However, less attention has been given to the work concerning the ion-exchange properties of these materials.

The previously reported results[10] indicated that cubic ammonium molybdate (CAM), prepared by the reaction of HNO_3 and hexaammonium heptamolybdate under controlled temperature conditions and reagent specifications, showed a reversible NH_4^+/H^+ exchange reaction. This paper describes the ion-exchange behaviour of H^+-form of CAM (H-CAM) cation exchanger along with some chromatographic separations of alkali metal ions.

Experimental

Synthesis of CAM and H-CAM. CAM was synthesized under optimum conditions and reagent specifications by the reaction of hexaammonium heptamolybdate tetrahydrate and HNO_3 (Wako Pure Chemical Ind., Japan) at 60 °C, following the previously described procedure.[10] The H^+ form (H-CAM) was obtained by conditioning CAM with 0.5 M (M=mol dm^{-3}) HNO_3 by using a column. H-CAM was used throughout the investigations reported here.

Rate of Adsorption and Ion-Exchange Selectivity. The rate of adsorption of alkali metal ions on H-CAM was investigated by equilibrating 0.25 g of the exchanger with 25 cm^3 of 10^{-4} M alkali metal ion solutions containing different concentrations of HNO_3 or $*NH_4NO_3$ (*=NH_4NO_3 solutions in 10^{-2} M HNO_3).

The distribution coefficients (K_d) for alkali metal ions were determined batchwise by equilibrating 0.10 g of H-CAM with 10 cm^3 of 10^{-4} M alkali metal ions in different concentrations of HNO_3 or $*NH_4NO_3$ at 30±0.5 °C with intermittent shaking. The metal ion concentrations in the equilibrated solutions were determined by a Varian Techtron-1100 atomic absorption spectrophotometer using air-acetylene flame. The K_d (cm^3 g^{-1}) values were calculated by the following equation,

$$K_d = \frac{\bar{X}}{X} \times \frac{V}{W},$$

where $\bar{X}$ and X are the amounts of metal ion in exchanger and solution respectively. V is the volume of equilibrated solution and W stands for the weight of H-CAM.

Chromatographic Separations. Separations of mixed alkali metal ions were conducted on H-CAM column (2.5—3.5 cm×0.5 cm i.d.). A mixed solution containing 1.0 μmol of each metal ion was loaded at the top of the column, kept for 12—14 h (to assure complete adsorption of metal ions on H-CAM) and then eluted with HNO_3 or $*NH_4NO_3$ solutions of various concentration. A continuous charging of the eluents was carried out through a high-pressure pump (Nihon Seimitsu Kagaku, model NP-DX-2). The effluent fractions were collected with the help of a fraction collector (Ohtake Works, model UM-160) and analyzed for the metal ion concentrations.

Results and Discussion

Specification of CAM and H-CAM. CAM was a yellowish granular material which could be ground even to <40 mesh size. Characterization of CAM and H-CAM showed the same results as reported previously.[10] Both CAM and H-CAM possessed a body-centered cubic structure with crystal lattice of 12.94±0.005 Å. The chemical formulae of CAM and H-CAM could be represented as $[(NH_4)_{0.78}(NH_4)_2]$-$O_{1.39} \cdot 14.16MoO_3 \cdot 6.08H_2O$ and $[H_{0.68}(NH_4)_2]O_{1.34} \cdot 14.16MoO_3 \cdot 6.92H_2O$, respectively. The H^+ of H-CAM was found to be reversibly exchanged with NH_4^+ with an exchange capacity of 0.31 mequiv g^{-1} for the latter ion.[10]

Exchange Equilibria and Ion Selectivity. The time required for the equilibration of alkali metal ions was determined through the rate of sorption of these ions on H-CAM in HNO_3 and $*NH_4NO_3$ media. The exchanger showed a fair rate of adsorption for all the alkali metal ions. The rate of adsorption in $*NH_4NO_3$ medium was slower for all alkali metal ions by one day as compared to HNO_3 medium. The ion-exchange reaction for all the ions was relatively fast in HNO_3 medium, except Na^+. About 1—2 days were required for ion-exchange equilibria of Li^+, K^+, Rb^+, and Cs^+, whereas for Na^+ it took>2 days.

The ion-exchange reaction where the exchange of micro-amounts of n-valent cations (M^{n+}) follows the stiochiometric ion-exchange mechanism rather than specific adsorption, can be represented as follows,

$$n\overline{H^+} \text{ or } n\,\overline{NH_4^+} + M^{n+} \rightleftarrows \overline{M^{n+}} + n\,H^+ \text{ or } n\,NH_4^+, \quad (1)$$

where bar denotes the exchanger phase then,

$$\log K_d = -n \log\{[H^+] \text{ or } [NH_4^+]\} + \text{const.} \quad (2)$$

The log-log plot of K_d vs. [*NH_4NO_3] (Fig. 1) showed a linear relationship with a slope of -1 for all the alkali metal ions indicating the 1:1 ideal ion-exchange reaction with greater separation factors. The selectivity increased in the order of $Li^+ < Na^+ < K^+ < Rb^+ < Cs^+$ in accordance with the Eisenman sequence-1.[11]

The above mentioned requirements (Eq. 2), however, are not always met with, either due to the nature of the exchanger[12] or the nature of the small number of groups (contained in the exchanger) which interact specifically with the trace ion.[13] The log-log plot of K_d vs. [HNO_3] (Fig. 2-dotted lines) was also linear with a slope of -1 for all the alkali metal ions except K^+. The selectivity sequence was found to be the same as in *NH_4NO_3 medium with very high K_d values for Rb^+ and Cs^+ even in 8.0 M HNO_3 solution. For K^+ the slope was observed to be <-1 due to its greater exchange affinity for the structural NH_4^+ in H-CAM (irrespective of H^+ concentration of equilibrated K^+ solution) owing to the almost same crystal ionic radii,[14,15] The most probable ion-exchange reaction of the K^+ could be described as,

$$\overline{H^+} + K^+ \rightleftarrows \overline{K^+} + H^+, \quad (3)$$

$$\overline{NH_4^+} + K^+ \rightleftarrows \overline{K^+} + NH_4^+, \quad (4)$$

where $\overline{NH_4^+}$ represents the structural NH_4^+ in H-CAM.

A fractional contribution of the process (4) seems to be responsible for the slope of <-1 for K^+ exchange. Almost same behaviour was expected for Rb^+ too, however the selectivity of ions at SA-site seems to be different for K^+ and Rb^+ (or Cs^+) at low metal ion concentration. The ideal exchange of K^+ (slope -1) and greater separation factor for Rb^+ and Cs^+ in *NH_4NO_3 medium may also be due to the same fact mentioned above. The K_d and separation factors for the alkali metal ions in both the media were found to be greater than that of ion-exchange resin (Table 1).

The K_d values for all the alkali metal ions were observed to be inversely dependent on the initial concentrations of metal ions (Fig. 2) indicating the Langmuir-type ion-exchange reaction.[17] The log-log plots of K_d vs. $[H^+]$ were linear indicating an ideal exchange reaction, however the slope of plots decreased than unity with increasing metal ion concentration. This fact can be explained on the basis of following equations. For the ion-exchange reaction,

$$n\overline{H^+} + M^{n+} \rightleftarrows \overline{M^{n+}} + nH^+, \quad (5)$$

where bar represents the exchanger phase and M^{n+} as n-valent cation, at lower $[M^{n+}]$ e.g. 10^{-4} M $[M^{n+}]$, $[H^+]^n \gg [M^{n+}]$ and $\overline{[H^+]^n} \gg \overline{[M^{n+}]}$ then,

$$K_d = \text{constant} \times \frac{1}{[H^+]^n}, \quad (6)$$

and the slope of equation (6)$=-1$ if $n=1$. However, when $[M^{n+}]$ increases e.g. $10^{-3} \rightarrow 10^{-2}$ etc, $\overline{[M^{n+}]} \gg \overline{[H^+]^n}$ and $\overline{[H^+]^n}$ is a variable depending on $\overline{[M^{n+}]}$ then,

$$K_d = \text{constant} \times \frac{\overline{[H^+]^n}}{[H^+]^n}, \quad (7)$$

and slope of equation (7)<-1 depending on the increase in metal ion concentration.

Similar observations have also been reported by Abe et al.[12,18,19] in the ion-exchange isotherms for some inorganic ion exchangers. This fact indicated the rigid structure of H-CAM. Moreover, the strong dependence of K_d on initial metal ion concentration (Fig. 2) which was observed to be stronger for K^+, Rb^+, and Cs^+ shows that, besides the ordinary exchange site {H^+-site or H^+ exchangeable NH_4^+-site (EA-site) in CAM}, H-CAM also contain an additional functional group {structural NH_4^+-site (SA-site)} of high affinity to certain cations e.g. K^+, Rb^+, and Cs^+.

Chromatographic Separations. In view of the K_d values and separation factors for the neighboring ion pairs, separation of alkali ions was carried out with both HNO_3 and *NH_4NO_3 solutions (eluents) of different concentrations at ambient temperature.

Table 1. K_d Values and Separation Factors (α)[a] on H-CAM and BIO-RAD AG 50W-X8[16]

Exchanger	Medium	Parameter	Li		Na		K		Rb		Cs
H-CAM	1 M HNO_3	K_d	1.23×10^{-1} [b]		2.46		6.86×10^2		1.56×10^4		2.0×10^4
		α		2.0×10^2		28		22.8		1.2	
	0.01 M NH_4NO_3 + 0.01 M HNO_3	K_d	*7.2×10^{-3} [b]		6.0		4.9×10		6.4×10^2		4.6×10^3
		α		8.3×10^2		8.2		13.0		7.2	
BIO-RAD AG 50W-X8	1 M HNO_3	K_d	3.9		6.3		11.4		13.4		16.8
		α		1.6		1.8		1.1		1.2	

a) $\alpha = K_{dB}/K_{dA}$. b) Extrapolated values to 1.0 M HNO_3.

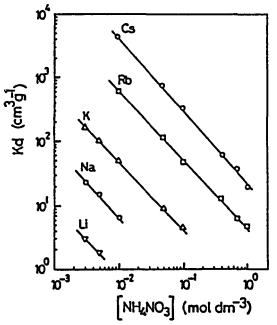

Fig. 1. Distribution coefficients (K_d) for alkali metal ions on H-CAM as a function of [NH_4NO_3] (contained in 0.01 M HNO_3). H-CAM: 0.10 g, Init. [M^+]: 10^{-4} M, Soln vol: 10 cm^3, Temp: 30±0.5 °C.

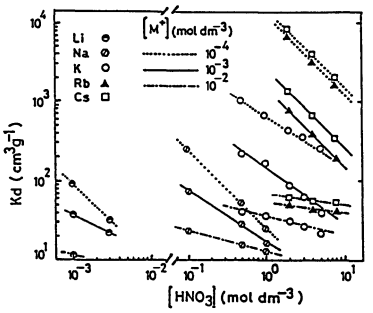

Fig. 2. Distribution coefficients (K_d) for alkali metal ions on H-CAM as a function of HNO_3 concentration and dependence of K_d on the initial concentrations of metal ions. H-CAM: 0.10 g, Soln vol: 10 cm^3, Temp: 30±0.5 °C.

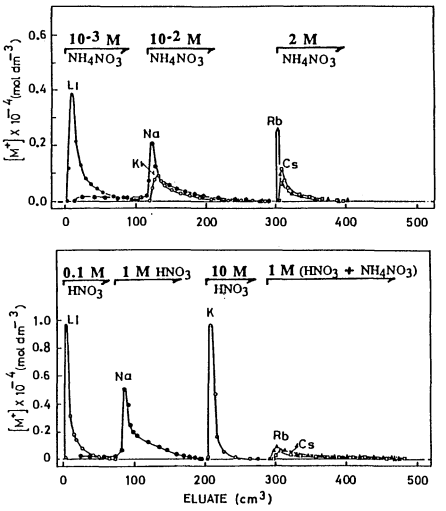

Fig. 3. Chromatographic separations of alkali metal ions on H-CAM. Top—Eluent: NH_4NO_3 soln (in 0.01 M HNO_3), H-CAM: 0.7637 g., Bottom—Eluent: HNO_3, H-CAM: 0.9209 g, Loading: 1 μmol of each M^+, Flow rate: 0.05 $cm^3\,min^{-1}$.

Figure 3(top) indicates the separation chromatogram with *NH_4NO_3 as an eluent. Li^+ was separated with 99% recovery from the Na^+-K^+ and Rb^+-Cs^+ groups with tailing rears. A long leading front was also observed for Na^+.

Successful separation of Li^+, Na^+, and K^+ with a respective recovery of 99.9, 100, and 82% was achieved with HNO_3 of different concentrations (Fig. 3-bottom). A tailing rear was observed for all the ions and long leading front for Na^+ in addition to the tailing rear. The long leading front for Na^+ was observed to be due to some solubility of H-CAM in HNO_3 eluent as well as slow rate of adsorption of the ion on H-CAM.

It has been known that the shape of elution curve depends on the type of ion-exchange isotherm.[20] The retention time may be a function of loading on the exchanger. The peak with a sharp front and a tailing rear (Langmuir type) for the alkali metal ions in the elution curves were evident from the strong dependence of K_d on the initial concentrations of metal ions (Fig. 2).

Complete separation of Rb^+ and Cs^+ was not possible even with concentrated HNO_3 or *NH_4NO_3 solutions. However the recovery of these ions in a mixed eluent {1 M (NH_4NO_3+HNO_3)} was better. The low recovery of Rb^+ (35%) and Cs^+ (25%) with 2.0 M *NH_4NO_3 and 60% and 54% respectively with the mixed eluent may be due to migration of these ions to the less accessible sites, or alternatively that strong bonding forces are involved for low loading.

In conclusion H-CAM (or CAM) can be used as a selective cation exchanger for heavy alkali metal ions even at higher acid concentrations. The very high selectivity of H-CAM towards Cs^+ will enable the latter to be quantitatively removed from the nuclear wastes, rain (fall-out Cs) or even sea water despite a large amount of matrix to Cs^+. It can work as a reliable material for the solid state storage of radioactive cesium at lower cost. H-CAM can be employed to separate K^+ and Rb^+ efficiently which are usualy difficult to do on some of the inorganic ion exchangers.

A Polarographic Study of the Glycine Complexes of Copper(II), Lead(II), Cadmium(II), and Manganese(II)

Hiroshi YAMASHITA,* Toru NOZAKI, Yoshihito FUKUDA, and Toshiyuki KABATA
Department of Resources Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama 790
(Received September 10, 1990)

Synopsis. From the polarographic behavior of copper (II), lead(II), cadmium(II), and manganese(II) in aqueous glycine solutions at an ionic strength of 0.4 mol dm^{-3} adjusted with sodium perchlorate, the species of the metal complexes and their stability constants were determined.

Glycine (abbreviated to HL) is included in industrial waste solutions treated by the hydrolysis of protein. Many studies[1,2] on both the compositions and stability constants of the glycine complexes have been carried out by means of a pH titration method, polarography, calorimetry, etc. However, both the species and the stability constants of the mixed-ligand hydroxo-complexes have remained unknown.

In the present work, both the species and stability constants were determined by means of polarography with respect to the copper(II), lead(II), cadmium(II), and manganese(II) complexes. From the experimental results, it is pointed out that those complexes would be formed within high pH ranges.

Experimental

Apparatus. Current-potential curves were obtained using Yanagimoto (Model PA-102) polarographic analyzer. The used dropping mercury-electrodes (DME) had mercury flow rates (m) of 1.273 to 2.758 mg s^{-1}. The drop time (t) was between 2.70 and 5.82 s in distilled water at −1.0 V vs. SCE. The mercury reservoir was 60 cm in height. The DME potential was referred to at the saturated calomel electrode (SCE). The temperatures of the solutions were maintained by the use of a water thermostat at 25±0.1 °C. High-purity nitrogen gas was bubbled through the solutions in order to remove any oxygen gas dissolved in the solutions. The pH values of the solutions were measured after polarographic measurements with a Toa Electronics Ltd. (Model HM-30S) pH meter.

Reagents. Stock solutions of metal ions were prepared by converting metal nitrates into perchlorates with perchloric acid, which had been redistilled under 50—70 mmHg (1 mmHg=133.322 Pa) at 40 °C. The solutions were diluted to a constant volume with redistilled water and were standardized by chelatometric titration with EDTA. A standard solution of glycine was prepared by dissolving a weighed amount of glycine in redistilled water.

Procedures. Acid dissociation-constants of glycine were measured by means of pH titration[3] at an ionic strength of 0.4 mol dm^{-3} and 25 °C. Both the compositions and stability constants of the glycine complexes were determined by a dc polarographic method under the following conditions: an ionic strength of 0.4 mol dm^{-3}; a metal concentration of 8.0×10^{-5} mol dm^{-3}; glycine concentrations from 8.0×10^{-3} to 2.0×10^{-1} mol dm^{-3}, and a temperature of 25 °C. The ionic strengths of the solutions were adjusted with sodium perchlorate.

Results and Discussion

Reversibility of the Electrode Reactions. The reversibility of the electrode reaction was tested under the following conditions: in the cadmium(II) system, pH values from 2.4 to 12.5; in the manganese(II) system, from 6.3 to 9.1; in the copper(II) system, both from 2.1 to 4.0 and from 8.0 to 12.7; and in the lead(II) system, both from 2.1 to 7.0 and from 11.5 to 12.4.

As mentioned in the procedues section, plots of the potential (E) vs. $\log i/(i_l-i)$ exhibited straight lines under the experimental conditions with respect to polarograms of copper, lead, cadmium, and manganese in the aqueous glycine solutions. The slopes of the lines were from 29.0 to 33.2 mV of the potential so that electrode reactions could be regarded as reversible.

Compositions and Stability Constants of the Complexes. At constant metal and glycine concentrations, the dependence of the half-wave potential, $E_{1/2}$, on the pH is shown in Fig. 1. In the ranges of the dashed lines in Fig. 1, polarograms of the complexes could not to be analyzed due to both poor reversibility in the copper system and the formation of a precipite in the lead system. The half-wave potential, $E_{1/2}$, shifted more negatively with increasing pH, and reached a constant value in the high pH ranges. Beyond about 12.0, the potential, moreover, shifted negatively. In Fig. 2 at pH>12.0, the dependence of the half-wave potential on the pH is shown for various glycine concentrations. From their results, it is

considered that mixed-ligand hydroxo-complexes coordinated both L^- and OH^- to their metals, according to Eq. 1. Therefore, both the compositions and over-all stability constants, β_{ij}, of mixed complexes were determined as described previously.[4] In this method, Eq. 2 was used while also applying the Schaap's equation:[5]

$$M^{2+} + iOH^- + jL^- \rightleftarrows M(OH)_iL_j^{2-(i+j)} \quad (1)$$

$$F_{00}(OH, L) \equiv \sum \beta_{ij}[OH]^i[L]^j = \text{antilog}[0.435(nF/RT)\{(E_{1/2})_s - (E_{1/2})_c\} + \log I_s/I_c], \quad (2)$$

where $(E_{1/2})_s$ is the half-wave potential of simple metal ions, $(E_{1/2})_c$ is the potential of the metal complexes, I_s is the diffusion current-constants of the metal ions, and I_c is a constant of the metal complexes. By considering the coordination number of metal ions, OH^- and L^-, the values of β_{ij} were determined by a previously described method.[4] Both the compositions and stability constants of the complexes, thus obtained in this work, are shown in Table 1 together with the values obtained in the literature. The β_{ij} values of copper(II), lead(II), and cadmium(II) were in fair agreement with the values found in the literature. The complexing ability of glycine with their metals increased in the following order: manganese(II)< cadmium(II)<lead(II)<copper(II). From the results, it is considered that the reactivity of glycine with its metals contributed to the electrostatic effect.

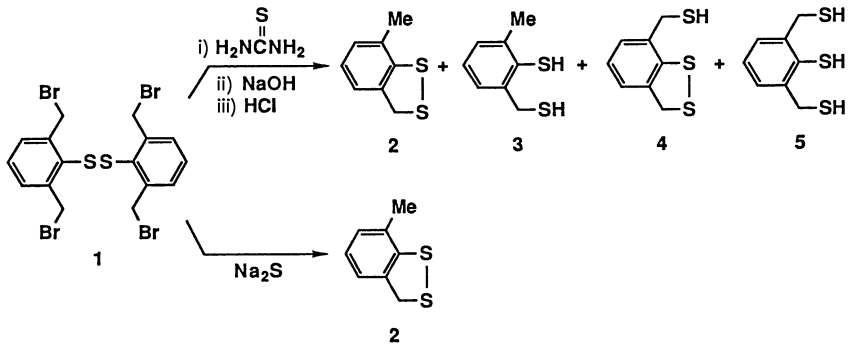
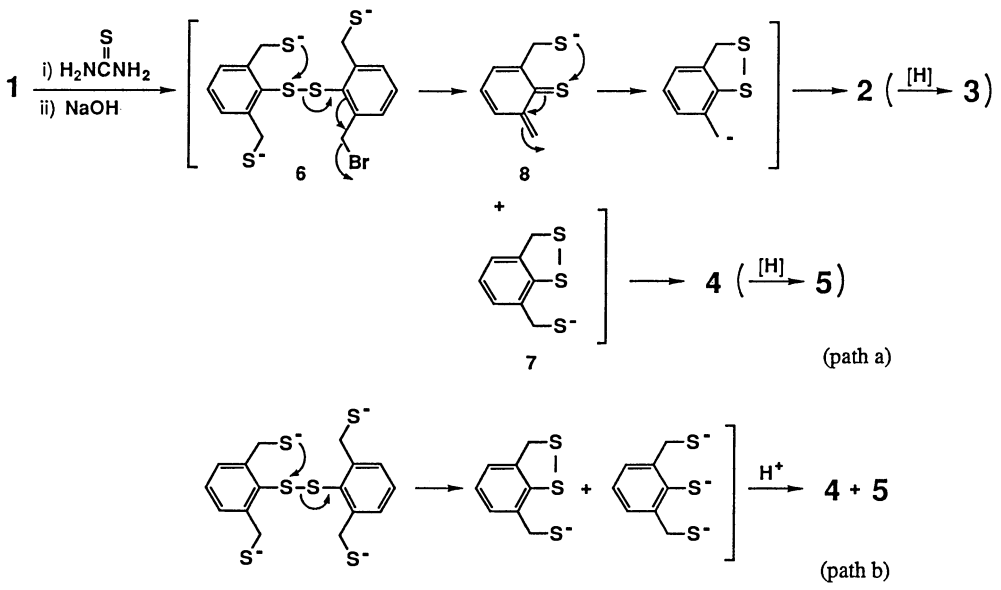
Synopsis. The reaction of bis[2,6-bis(bromomethyl)-phenyl] disulfide with thiourea or sodium sulfide showed an unusual reductive cleavage of disulfide linkage with elimination of bromine by neighboring-group participation of the generated thiolate anion. Its reaction gave the structurally intriguing thiols which indicated the facile anodic oxidation.

Studies of intramolecular interactions and reactions have provided numerous informations on the structures and reactivities of linear and cyclic compounds containing sulfur atoms.[1-3] It has been reported that the oxidative cleavage of disulfides having neighboring nucleophiles (e.g., amide) provides a facile route to the formation of heterocyclic intermediates and products.[4] The intramolecular redox reactions between disulfides and thiols are of considerable important from a biological point of view.[5] Meanwhile, we described an unusual sulfur extrusion in a new quadruply ortho-bridged biphenyl compounds with disulfide linkage, methanodithiomethano-bridged dibenzotrithionin, via the sulfur-sulfur bond formation.[6] Its analogous compounds exhibit interesting physical and chemical properties on account of their unique arrangement of functional groups and heteroatoms in space. This paper presents that the reaction of bis[2,6-bis(bromomethyl)phenyl] disulfide (**1**) with thiourea gave the structurally interesting redox products, thiol-disulfide and trithiol, with the elimination of bromine. The electrochemical and chemical oxidations of their thiols are also described.

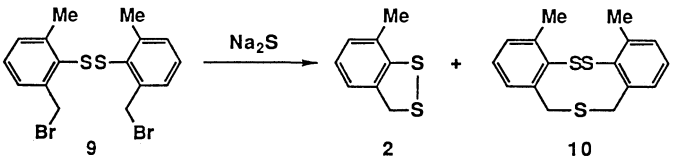
The compound **1** was prepared by photobromination using *N*-bromosuccinimide of bis(2,6-dimethyl-



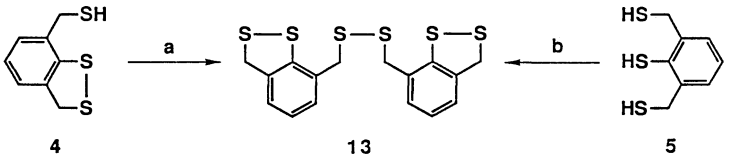
Scheme 1.



Scheme 2.



Scheme 3.



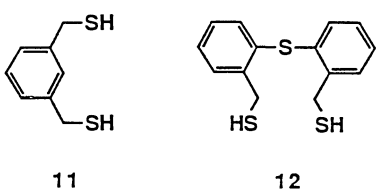
Scheme 4. a) pyridine in $CHCl_3$ under air, b) I_2, Et_3N in $CHCl_3$.

phenyl) disulfide (**14**) which was obtained by oxidation of 2,6-dimethylbenzenethiol with I_2. The reduction of disulfide linkage in **1** was found in the following reactions (Scheme 1). Treatment of **1** with thiourea in ethanol, followed by adding with aqueous sodium hydroxide solution, resulted in formation of four products, disulfide **2** (19%), dithiol **3** (27%), thioldisulfide **4** (18%), and trithiol **5** (25%). The plausible mechanism for formation of the compounds **2**—**5** can be explained as follows (Scheme 2). The reaction of **1** with thiourea produces the thiol **6** via isothiouronium salt whose third stage proceeds intramolecularly and leads to formation of the cyclic disulfide **7** and thione intermediate **8** like quinodimethane with the elimination of bromine. Subsequently, **8** converts to **2** and **3**, and **7** changes finally to **4** and **5**, respectively (Scheme 2, path a). The path b in Scheme 2 is also conceivable mechanism for the formation of **4** and **5**.

On the other hand, when the compound **1** was allowed to react with Na_2S in the presence of tetrabutylammonium bromide as a phase-transfer catalyst in benzene-water at 80 °C for 8 h, disulfide **2** was obtained in 38% yield (Scheme 1). This reaction may proceed likely as shown in Scheme 2.

Meanwhile, bis(2-bromomethyl-6-methylphenyl) disulfide (**9**) was reacted with Na_2S to give the cyclic disulfide **2** (45%) and the nine-membered ring, dibenzotrithionin **10** (14%) (Scheme 3).

The electrochemical oxidations of thiols (**3**, **5**, **11**, and **12**) were studied by cyclic voltammetry. Peak potentials of the first oxidation peak were determined at a glassy carbon working electrode (scan rate; 100 $mV\,s^{-1}$) in CH_3CN-0.1 M $NaClO_4$ vs. Ag/0.01 M $AgNO_3$ as reference electrode (1 M=1 $mol\,dm^{-3}$). The peak potentials (E_p) showed the following values: 0.78 V for **3**, 0.75 V for **5**, 1.35 V for **11**, and 1.52 V for **12**. These anodic oxidations were irreversible at scan rates of 1 $V\,s^{-1}$. There are dramatic shifts in the peak potentials toward more cathodic values for the thiols **3** and **5**. Comparison of the thiols **5** with **11** showed a peak potential ca. 600 mV more cathodic for the former, indicating that **5** is oxidized more readily.



Structural Formula 1.

The oxidation of **4** in the presence of pyridine in chloroform under air at room temperature gave the oxidative dimer **13** in 74% yield (Scheme 4). Trithiol **5** also afforded the oxidation product **13** in 91% yield upon treatment with I_2 in the presence of triethylamine in chloroform at room temperature.

Experimental

^1H and ^{13}C NMR spectra were measured on Hitachi R-600 FT-NMR and Bruker AM 500 spectrometer. The IR spectra were obtained on JASCO A-3 spectrometer. Mass spectra were taken by Hitachi M-80B mass spectrometer. Elemental analyses were carried out by the Chemical Analytical Center at University. For cyclic voltammetry measurements, a Hokuto Denko Co. Model HB-104 electrochemical apparatus was used in conjunction with a Yokokawa Co. Model 3025A X-Y recorder.

Bis(2,6-dimethylphenyl)disulfide (14). To a stirred solution of 2,6-dimethylbenzenethiol[3a] (44.5 g, 0.32 mol) and triethylamine (32.6 g, 0.32 mol) in chloroform (500 ml) was added a solution of iodine (40.6 g, 0.16 mol) in chloroform (150 ml) at 0 °C. The whole mixture was stirred at room temperature for 1 h. The mixture was washed with aqueous sodium thiosulfate solution and the organic layer was dried over anhydrous $MgSO_4$. After evaporation of the solvent, the residue was purified by silica-gel column chromatography (eluent, hexane) to give the disulfide **14** in 89% yield. The compound **14** was recrystallized from hexane: White crystals; mp 103—104 °C; ^1H NMR ($CDCl_3$) δ=2.22 (s, 12H, CH_3) and 7.02 (br s, 6H, ArH). Found: C, 69.99; H, 6.57; S, 23.40%. Calcd for $C_{16}H_{18}S_2$: C, 70.02; H, 6.61; S, 23.36%.

Bis[2,6-bis(bromomethyl)phenyl]disulfide (1) and Bis(2-bromomethyl-6-methylphenyl)disulfide (9). A solution of disulfide **14** (7 g, 25.5 mmol) and *N*-bromosuccinimide (NBS; 18.2 g, 102 mol) in dry carbon tetrachloride (150 ml) was stirred under an Ar atmosphere at 15 °C while being irradiated with a high-pressure mercury lamp for 7 h. The resulting solid was separated by filtration, and the filtrate was concentrated under reduced pressure. The residue was purified by silica-gel column chromatography (eluent, hex-

ane-$CHCl_3$=1 : 1) to afford the tetrabromide **1** in 11% and bisbromide **9** in 52% yields.

1: White crystals; mp 186.5—187 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ=4.42 (s, 8H, CH_2), 7.38 (t, J=8 Hz, 2H, ArH), and 7.45 (d, J=8 Hz, 4H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=31.3, 131.2, 131.6, 134.4, and 143.5. Found: C, 32.60; H, 2.64%. Calcd for $C_{16}H_{14}Br_4S_2$: C, 32.57; H, 2.39%.

9: White crystals; mp 121—121.5 °C; MS m/z 432 (M^+); ^{1}H NMR ($CDCl_3$) δ=2.40 (s, 6H, CH_3), 4.25 (s, 4H, CH_2), and 7.22 (s, 6H, ArH). Found: C, 44.11; H, 3.61%. Calcd for $C_{16}H_{16}Br_2S_2$: C, 44.46; H, 3.73%.

Reaction of Bis[2,6-bis(bromomethyl)phenyl]disulfide (1) with Thiourea. A solution of **1** (750 mg, 1.25 mmol) and thiourea (490 mg, 6.40 mmol) in ethanol (500 ml) was stirred for 12 h under reflux. After concentration of the solution, 6% sodium hydroxide solution (1 l) was added to the residue. The mixture was refluxed for 8 h under an Ar atmosphere and then cooled in an ice-water bath; cooled aqueous hydrochloric acid was then added dropwise. The reaction mixture was extracted with chloroform and the extract was dried over $MgSO_4$. After removal of the solvent, the residue was separated by silica-gel column chromatography (eluent, hexane-$CHCl_3$=1 : 1) and further purified by preparative liquid chromatography to give disulfide **2** in 19%, dithiol **3** in 27%, thiol-disulfide **4** in 18%, and trithiol **5** in 25% yields. Yields of **2—5** are in 1/2 mol%.

2: Yellow oil; MS, m/z 168 (M^+); ^{1}H NMR (500 MHz, $CDCl_3$) δ=2.31 (s, 3H, CH_3), 4.49 (s, 2H, CH_2), 6.96 (d, J=7 Hz, 1H, ArH); 7.00 (t, J=7 Hz, 1H, ArH), and 7.09 (d, J=7 Hz, 1H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=21.2, 44.1, 122.0, 125.5, 128.4, 132.7, 138.8, and 141.7. Found: C, 56.75; H, 4.75%. Calcd for $C_8H_8S_2$: C, 57.10; H, 4.79%.

3: Yellow oil; MS, m/z 170 (M^+); ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.86 (t, J=7 Hz, 1H, SH), 2.40 (s, 3H, CH_3), 3.61 (s, 1H, SH), 3.67 (d, J=7 Hz, 2H, CH_2), 7.06 (t, J=7 Hz, 1H, ArH), 7.10 (d, J=7 Hz, 1H, ArH), and 7.13 (d, J=7 Hz, 1H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=22.2, 29.2, 126.0, 127.0, 129.3, 130.1, 138.3, and 139.9. Found: C, 56.46; H, 5.82%. Calcd for $C_8H_{10}S_2$: C, 56.43; H, 5.92%.

4; Yellow oil; MS, m/z 200 (M^+); ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.67 (t, J=7 Hz, 1H, SH), 3.75 (d, J=7 Hz, 2H, CH_2SH), 4.47 (s, 2H, CH_2), 7.04 (t, J=7 Hz, 1H, ArH), 7.10 (d, J=7 Hz, 1H, ArH), and 7.17 (d, J=7 Hz, 1H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=28.9, 43.7, 123.4, 126.0, 127.2, 136.2, 140.5, and 141.4. Found: C, 47.92; H, 3.89%. Calcd for $C_8H_8S_3$: C, 47.96; H, 4.03%.

5: Yellow oil; MS, m/z 202 (M^+); ^{1}H NMR (500 MHz, $CDCl_3$) δ=1.88 (t J=7 Hz, 2H, SH), 3.92 (d J=7 Hz, 4H, CH_2), 4.10 (s, 1H, SH), 7.14 (t, J=7 Hz, 1H, ArH), and 7.21 (d, J=7 Hz, 2H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=29.1, 126.0, 127.0, 128.4, 129.4, and 141.9. Found: C, 47.58; H, 4.94%. Calcd for $C_8H_8S_3$: C, 47.49; H, 4.98%.

Reaction of Bis[2,6-bis(bromomethyl)phenyl]disulfide (1) with Sodium Sulfide. To a solution of **1** (5 g, 8.5 mmol) and tetrabutylammonium bromide (0.27 g, 0.85 mmol) in benzene (1000 ml) and water (50 ml) was added a solution of sodium sulfide (6.36 g, 25.5 mmol) in water (150 ml). The reaction mixture was stirred at 80 °C for 8 h. The organic layer was separated, washed with water, and dried over $MgSO_4$. After removal of the solvent, the residue was separated by silica-gel column chromatography (eluent, $CHCl_3$) and further purified by preparative liquid chromatography to afford disulfide **2** in 38% yield. Yield of **2** is in 1/2 mol%.

Reaction of Bis(2-bromomethyl-6-methylphenyl)disulfide (9) with Sodium Sulfide. The reaction was performed according to the method described in the reaction of **1** with sodium sulfide. The compound **2** and dibenzotrithionin **10** were obtained in 45% and in 14% yields, respectively. Yield of **2** is in 1/2 mol%, while yield of **10** is in mol%.

10: Off white crystals; mp 140—141 °C; MS m/z 304 (M^+); ^{1}H NMR ($CDCl_3$) δ=2.64 (s, 6H, CH_3), 4.10 (s, 4H, CH_2), and 6.85—7.34 (m, 6H, ArH). Found: C, 63.39; H, 5.32%. Calcd for $C_{16}H_{16}S_3$: C, 63.12; H, 5.30%.

Oxidation of Thiol-Disulfide 4. A solution of **4** (50 mg, 0.25 mmol) and pyridine (39.5 mg, 0.5 mmol) in chloroform (30 ml) was stirred for 12 h under air. After removal of the solvent, the crude product was purified by preparative liquid chromatography to give the compound **13** in 74% yield: Yellow oil; ^{1}H NMR (500 MHz, $CDCl_3$) δ=3.72 (s, 4H, CH_2), 4.46 (s, 4H, CH_2), 7.01 (d, J=7 Hz, 2H, ArH), 7.07 (t, J=7 Hz, 2H, ArH), and 7.20 (d, J=7 Hz, 2H, ArH); ^{13}C NMR (125 MHz, $CDCl_3$) δ=43.2, 43.8, 123.8, 125.6, 129.1, 132.5, 140.5, and 142.4. Found: C, 47.87; H, 3.41%. Calcd for $C_{16}H_{14}S_6$: C, 48.21; H, 3.54%.

Oxidation of Trithiol 5. The oxidation was carried out according to the same method of the preparation of disulfide **14**. The reaction gave the compound **13** in 91% yield.

Electrochemical Study. Cyclic voltammetry (CV) was performed with 10 ml portions of 2 mM solutions of thiol in CH_3CN and 0.1 M $NaClO_4$. The CV cell was equipped with an Ag/0.01 M $AgNO_3$ in CH_3CN reference electrode in a reference well separated from the analyte by a cracked glass bead junction, a Pt wire counter electrode, and a glassy-carbon working electrode polished before use with alumina.

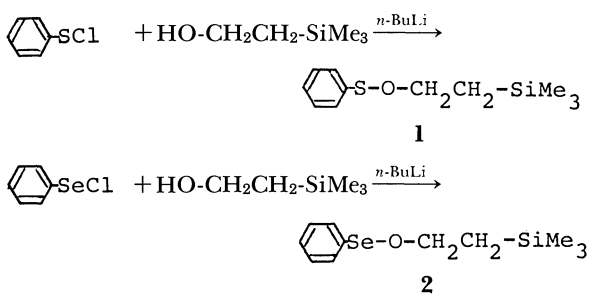
(Received August 13, 1990)

Synopsis. 2-(Trimethylsilyl)ethyl benzenesulfenate was allowed to react with several halides in the presence of tetrabutylammonium fluoride (TBAF) to afford the corresponding phenyl sulfoxides as the main product. In the reaction of 2-(trimethylsilyl)ethyl benzeneselenenate and several halides with TBAF, the corresponding alcohols were obtained as the main product.

When an arenesulfenyl or areneselenenyl halide is allowed to react with an alcohol in order to synthesize the corresponding arenesulfenate or areneselenenate ester, the reaction would rarely be achieved as desired if the halide has no electron-withdrawing group, such as a nitro or keto group on its arene nucleus.[1] Among the arenesulfenate esters[2] isolated previously, only three arenesulfenate esters (methyl benzenesulfenate,[3] methyl and benzyl *p*-toluenesulfenates[4]) were those derived from arenesulfenyl halides having no electron-withdrawing group on their arene nuclei. Also, all of the hitherto isolated areneselenenate esters[5] possess one or two electron-withdrawing groups in their areneselenenic acid moiety. Thus, except methyl alcohol, such alcohol that is capable of converting benzenesulfenyl and/or benzeneselenenyl chlorides, which may be regarded as the parent compounds of arenesulfenyl and/or areneselenenyl halides, to the corresponding benzenesulfenate and/or benzeneselenenate esters has not been found. We propose here 2-(trimethylsilyl)ethyl benzenesulfenate (**1**) and 2-(trimethylsilyl)ethyl benzeneselenenate (**2**) as a new class of arenesulfenate and areneselenenate esters.

The reaction of benzenesulfenyl chloride with 2-(trimethylsilyl)ethanol proceeded by using butyllithium to give **1** in 81% yield after distillation. By the same procedure using benzeneselenenyl chloride instead of benzenesulfenyl chloride, although requiring a relatively lower reaction temperature, **2** was obtained in 56% yield after distillation. The employment of butyllithium in such a condensation reaction has already been reported.[6] It is likely that compound **1** or **2** is structurally a masked benzenesulfenic or benzeneselenenic acid, respectively. Trimethylsilyl 2-nitrobenzenesulfenate[7] is found in the literature as only one example of such a masked sulfenic acid. If the removal of the 2-(trimethylsilyl)ethyl group from **1** or **2** is possible, in analogy with a 2-(trimethylsilyl)ethyl carboxylate,[8] the reaction of the generated benzenesulfenate or benzeneselenenate ion with an appropriate electrophile is expected to occur. Thus, the reactions of **1** or of **2** with some electrophiles in the presence of TBAF were investigated.



1 **2**

When a mixture of **1** and any one of alkyl iodides, alkyl bromides, and allyl bromides was allowed to react with TBAF according to Procedure A, the reaction proceeded at room temperature to provide the compounds listed in Table 1. In these cases, except for Run 2 [only in this case, tris(dimethylamino)sulfonium (trimethylsilyl)difluoride was used instead of TBAF], TBAF was used as the fluoride ion source. As can be seen from Table 1, the reaction of **1**, TBAF and an alkyl iodide provided the corresponding alkyl phenyl sulfoxide as the main product. This was also the same as in the reaction of **1**, TBAF and benzyl bromide or an allyl bromide. The reaction seems to proceed via a process involving an initial attack of the fluoride ion and a subsequent elimination of the trimethylsilyl group and the ethylene molecule, leading to a benzenesulfenate ion which is trapped by the electrophile. The removal of the 2-(trimethylsilyl)-ethyl group by a fluoride ion is well-known, although it concerns only the 2-(trimethylsilyl)ethyl carboxylates.[9,10] Probably, **1** is decomposed in a similar manner to the carboxylates by a fluoride ion generated from TBAF. Also, the experimental fact that the yield of alkyl phenyl sulfoxide obtained in the reaction using an alkyl iodide decreases with increasing its molecular weight is consistent with the proposed mechanism. When a solution of **1** (0.113 g, 0.5 mmol) in tetrahydrofuran (THF) (2.5 ml) was mixed initially with a 1.0 M solution (1.5 ml, 1.5 mmol, M=mol dm^{-3}) of TBAF in anhydrous THF and (after stirring for 30 min) methyl iodide (0.036 g, 2.5 mmol) was added followed by stirring for 2 h, methyl phenyl sulfide, butyl phenyl sulfide, diphenyl disulfide(**3**), and methyl phenyl sulfone(**4**) were obtained in 10, 12, 18, and 31% yields, respectively. It is likely that the reaction of the intermediate benzenesulfenate ion with **1**, itself, providing unstable[11] *S*-phenyl benzenethiosulfinate occurred in competition with the reaction of the sulfenate ion with methyl iodide. The thiosulfinate is probably converted to **3**.[11] However, the process by which **4** has been produced remains equivocal.

When a mixture of **1** and an acetylenic compound having one or two electron-withdrawing groups was

a) The products **5**—**14** were confirmed by their spectral and analytical data. The sulfides among the other products were confirmed by direct comparison with the commercially available samples. And, the sulfoxides among the other products were comfirmed by direct comparison with the authentic samples prepared by the known method.[13] The compound **13** was also confirmed by direct comparison with the authentic sample prepared by the known method.[14] b) Isolated yield by column chromatography on silica gel using ethyl acetate as eluent. c) Only in Run 2, tris(dimethylamino)sulfonium (trimethylsilyl)difluoride was used instead of TBAF. d) Compound **14** showed the presence of two components on GLC analyses. Further, it was estimated to be a mixture of cis- and trans-isomer with the help of its mass and ^1H NMR spectra.

allowed to react with TBAF according to Procedure B, the reaction proceeded at room temperature or −78 °C to provide the compounds listed also in Table 1. If TBAF was omitted from the reaction system, almost all of the starting substrates were recovered, suggesting the participation of TBAF in these reactions. As can be seen from Table 1, the obtained products varied, depending upon the acetylenic compounds used. Also, the reaction using phenylacetylene provided α,β-bis(phenylthio)styrene (**14**), although it is not the main product. In a somewhat analogous reaction[7] of trimethylsilyl 2-nitrobenzenesulfenate with methyl propynoate, the 2-nitrobenzenesulfinyl moiety of the former had been introduced to the latter. Under our conditions, however, the products obtained were such compounds that the benzenethio moiety of **1** was introduced to the acetylenic compounds used.

When a mixture of **2** and one of benzyl bromide, cinnamyl bromide, 1-chloro-, 1-bromo-, and 1-iodododecane was allowed to react with TBAF according to Procedure C, the reaction proceeded at room temperature to provide the compounds listed in Table 2. As can be seen from Table 2, the obtained products were alcohols which correspond to the halides employed as the trapping agent. Also, in Runs 3—5, a small amount of 1-fluorododecane (**16**) was isolated as a by-product. It is likely that the benzeneselenenate ion formed from **2** and TBAF attacks the halide providing benzeneselenenate ester which is hydrolyzed to the corresponding alcohol together with unstable benzeneselenenic acid. It is likely that the intermediate benzeneselenenate ion attacks a halide used with its oxygen atom. If the ion attacks the halide with its selenium atom, the corresponding phenyl selenoxide would be formed as an intermediate. For example, in Run 1, benzyl phenyl selenoxide would be formed and isolated without any further alteration due to its invariability. However, none of benzyl phenyl selenoxide was obtained in Run 1. This suggests that the benzeneselenenate ion has a pair of available electrons only on its oxygen atom as a nucleophile. In a separate experiment, a solution containing benzyl phenyl selenoxide[12] (0.13 g, 0.5 mmol), a 1.0 M solution (1.0 ml, 1.0 mmol) of TBAF in anhydrous THF and tetrabutylammonium bromide (0.16 g, 0.5 mmol) in THF (2.5 ml) was stirred at room temperature for 7 h. The forma-

a) Except **16**, the products in this table were confirmed by direct comparison with the commercially available samples. The compound **16** was confirmed by its spectral and analytical data. b) Yields of alcohols were determined by GLC analysis with 1-tetradecanol as an internal standard. Other yields were obtained by column chromatography on silica gel using hexane or 10% ethyl acetate-hexane as eluent. c) Recovered 1-chlorododecane.

tion of benzyl alcohol, however, could not be recognized after a similar work up as in Procedure C. This experimental fact seems to support the above suggestion.

Experimental

Synthesis of 1. To a stirred, cooled (−78 °C) solution of 2-(trimethylsilyl)ethanol (2.03 g, 17.2 mmol) in ether (110 ml) was added (during 5 min, by syringe under nitrogen) a 1.6 M solution of butyllithium (11.7 ml, 18.7 mmol) in hexane. This mixture was stirred under nitrogen for 30 min at the same temperature and a solution of benzenesulfenyl chloride (2.26 g, 15.6 mmol) in ether (20 ml) was then dropped in. This mixture was allowed to warm to room temperature, stirred for 4 h, filtered, and concentrated in vacuo to give a residue which was distilled, bp, 74—80 °C/2 Torr (1 Torr=133.322 Pa), yield 81%. ^1H NMR ($CDCl_3$) δ=0.01 (s, 9H), 1.1—1.2 (m, 2H), 3.8—3.9 (m, 2H), and 7.1—7.4 (m, 5H).

Synthesis of 2. To a stirred, cooled (−78 °C) solution of 2-(trimethylsilyl)ethanol (1.36 g, 11.5 mmol) in ether (100 ml) was added (during 5 min, by syringe under nitrogen) a 1.6 M solution (7.2 ml, 11.5 mmol) of butyllithium in hexane. The mixture was stirred under nitrogen for 30 min at −78 °C and a solution of benzeneselenenyl chloride (2.20 g, 11.5 mmol) in ether (40 ml) was dropped in. Then, the mixture was stirred for 4 h, during which time it was allowed to slowly warm to −30 °C. The mixture was concentrated in vacuo at −30 °C to give a residue. After adding a large quantity of pentane to the residue, it was filtered and concentrated in vacuo to give the crude product which was distilled, bp 77—83 °C/2 Torr, yield 56%. ^1H NMR ($CDCl_3$) δ=0.01 (s, 9H), 1.0—1.1 (m, 2H), 3.9—4.0 (m, 2H), 7.2—7.5 (m, 3H), and 7.5—7.6 (m, 2H).

Reaction of 1 and a Halide with TBAF (Procedure A). To a stirred solution of **1** (0.113 g, 0.5 mmol) and any one of alkyl iodides (2.5 mmol), alkyl bromides (2.5 mmol), and allyl bromides (1.2 mmol) in THF (2.5 ml) was added, under nitrogen, a 1.0 M solution (1.5 ml, 1.5 mmol) of TBAF in anhydrous THF. The mixture was stirred under nitrogen at room temperature. After adding excess ether to the mixture, it was filtered, and evaporated in vacuo to give a residue which was subjected to column chromatography on silica gel.

Reaction of 1 and an Acetylenic Compound with TBAF (Procedure B). To a cooled (−78 °C), stirred solution of **1** (0.113 g, 0.5 mmol) and an acetylenic compound (1.0 mmol) in THF (2.5 ml) was added, under nitrogen, a 1.0 M solution (1.5 ml, 1.5 mmol) of TBAF in anhydrous THF. The mixture was stirred under nitrogen for 4 h at −78 °C (Run 11) or at room temperature (Runs 10 and 12) after being allowed to warm to that temperature, and worked up in a similar manner as mentioned above.

Reaction of 2 and a Halide with TBAF (Procedure C). To a stirred solution of **2** (0.156 g, 0.55 mmol) in THF (2.5 ml) was added successively, under nitrogen, a halide (0.77 mmol) and a 1.0 M solution (1.65 ml,1.65 mmol) of TBAF in anhydrous THF. The mixture was stirred under nitrogen at room temperature. After adding excess ether to the mixture, it was filtered, washed with water, dried over Na_2SO_4, and evaporated in vacuo to give a residue which was subjected to column chromatography on silica gel.

Yamanashi University, Takeda-4, Kofu 400
(Received August 24, 1990)

Synopsis. The thermochromism of metal complexes of cresolphthalein dye was studied in organic solvents in the presence of pyridine derivatives. Remarkable thermochromic changes were observed for complexes with nickel(II) and magnesium(II) ion; a large temperature dependence was found in a polar aprotic solvent.

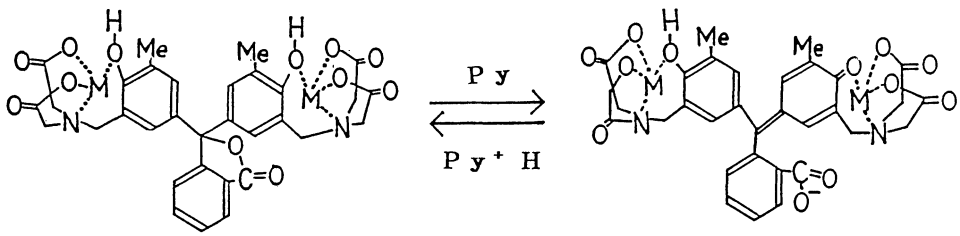
Organic erasable-direct-read-after-write (EDRAW) media have received much attention regarding their application to recording devices with high storage density and responsibility. These include heating-mode recording system employing the abrasive recording of pigments,[1] phase conversion of liquid crystals,[2] and color change of thermochromic compounds.[3] The thermochromism of metal complexes with triphenylmethane dyes observed in aqueous buffer solution[4,5] was also possible in the solid state, and its thermochromic behavior was found to depend distinctly on the kind of polymer matrix employed.[3] This paper describes the thermochromism of cresolphthalein (PC) complexon with various bivalent metal ions and discusses the solvent effect on its temperature-dependence and reversibility.

Results and Discussion

The 2:1-metal complexes of the multidentate ligands of triphenylmethane dyes indicate thermochromism by protolytic equilibrium.[3,4] The reversible color change of a PC-dye was investigated in H_2O, ethylene glycol (EG), and *N*-methylpyrrolidone (NMP) containing pyridine derivatives as organic base, using metal ions having four coordination number such as Cd(II), Co(II), Cu(II), Mg(II), Mn(II), Ni(II), Pb(II), and Zn(II).

Metal ions, Co(II) and Cu(II), formed a complex with an organic solvent to induce an intensive color, and the complex of Fe(III) ion revealed a strong absorption at 517 nm (ε=1600 $dm^3 mol^{-1} cm^{-1}$) in NMP and 532 nm (ε=1400) in EG without the addition of the pyridine derivative. The color development of a PC-metal complex was observed only slightly in the case of PC-Zn(II) possessing a large value of stability constant against PC-dye ($K_{stab.}$).[6] The magnitude of the absorptivity difference between 25 and 80 °C was in the following order: Ni(II), Mg(II)≫Cd(II)> Mn(II), Pb(II)>Zn(II).[7] Proton dissociation of PC-metal complexes to induce thermochromism is not correlated to the value of $K_{stab.}$, but seems to relate to the affinity constant against OH^- ions (K_{OH}) and the metal ionic radius.[8] An intensive reversible color change was obtained with metal ions possessing 2.5—4.0 of pK_{OH} value and approximately 0.7 Å ionic radius.

In Fig. 1, the absorbances of the PC-Mg complex are plotted against the proton dissociation constants of the conjugated acid of pyridine derivatives (K_{py}).[9] The absorbance at 25 °C increased with an increase in the pK_{py} value, and also increased in the order NMP<EG<H_2O. This order is consistent with the values of the proton dissociation constant of relatively low molecular weight phenol derivatives.[10] Since color development takes place by the dissociation of the phenolic proton from a PC-metal complex, its absorbance depends on the stability of a combination of metalloquinonoid anion (PC^--M) and the protonated pyridinium derivatives (Py^+H). Since the salt comprising PC^--M and a pyridinium cation with higher pK_{py} is more stable, its absorbance is large at 25 °C. However, upon heating, a marked increase in the absorbance was observed for the solution of PC-Mg(II) in NMP. Table 1 shows the acid dissociation constant of a PC-metal complex (K_c) and the thermodynamic parameter ΔH and ΔS for the following equation: PC-M⇄PC^--M+H^+ (2). The value of K_c was determined by the following equation $\log K_c = \log K + \log K_{py}$ (3), where K indicates the equilibrium constant for Eq. 1. The values of ΔH and ΔS were determined by plotting the value of $\log K_c$ against



PC-M + Py ⇄ PC^--M + Py^+H (1)

Table 2. Rate Constants for the Reversible Reaction of PC-Ni(II) in Different Solvents[a)]

	H_2O	EG	NMP
k_1/dm^3 mol^{-1} s^{-1}	8.4×10^{-4}	5.1×10^{-4}	1.5×10^{-5}
k_{-1}/dm^3 mol^{-1} s^{-1}	2.2×10^{-1}	1.0×10^{-1}	1.2×10^{-3}
k_{-1}/k_1	3.8×10^{-3}	5.1×10^{-3}	1.3×10^{-2}

a) at 60 °C, PC-dye, 1.5×10^{-3} mol dm^{-3}; Ni(II) ions, 9×10^{-3} mol dm^{-3}; *N*-methylniconinamide, 7.5×10^{-2} mol dm^{-3}.

$1/T$. However, the plot of $\log k_c$-$1/T$ in an organic solvent does not give a straight line, but the gradient increases with a decrease in $1/T$. Although the value of ΔH, or ΔS, was calculated by supposing that the variation of ΔS, or ΔH, with the temperature would be small in the same solvent,[11,12] the errors of both values in EG and NMP amounted to more than 15- and 35 percent, respectively. Accordingly, the values of the Gibbs function are shown in Table 1.

The value of pK_c of PC-dye with Ni(II) and Mg(II) is of the order H_2O<EG<NMP. This order is different from those of the phenol derivatives having a relatively bulky molecular size.[10] Presumably, PC-metal is fully solvated with the H-donor solvent at complexed sites, so that difference in solvation for its conjugated base is small. The values of ΔH of PC-Ni(II) and -Mg(II) in H_2O resemble that of Xylenol orange(XO) with Cu(II) ion.[5] Although the deviation of the estimated values of ΔH and ΔS were large for the equilibrium reaction in EG and NMP, the ΔH-value increased in the order H_2O<EG<NMP. These results correspond to the intensive reversible color change observed for Eq. 1. The ΔS-value is large compared with that of XO-Cu in buffer solution of sodium perchlorate. The difference might be caused by a color development obtained by using the pyridine derivatives as proton acceptor.

The reversibility of the thermochromism of a PC-metal complex is also affected by the kind of solvent. Table 2 shows the reaction rate at 60 °C for Eq. 1.

The amount of the pyridine derivative employed was 50-molar equivalent for the PC-metal complex, so that the rate constants were estimated for the forward reaction(k_1) as the first order and the reverse(k_{-1}) one as the second order.[13] The value of $\Delta\Delta G$ (temperature-dependence) and the ratio of k_1 to k_{-1} (fixing of colored species) were large in a polar aprotic solvent. Since a protic solvent solvates the PC^-–M and Py^+H combination strongly and increases the anion content, strong absorption is induced even at a low temperature.[14] On the other hand, a polar aprotic solvent appears to predominantly solvate the pyridinium cation formed by protonation at an elevated temperature, as compared with an undissociated metallophthalein having a bulky molecular size. This causes a large temperature dependence of thermochromism in an aprotic solvent. The predominant solvation with an aprotic solvent stabilizes the pyridinium cation, so that proton recombination may be retarded in a polar aprotic solvent.[15]

Experimental

Solvents were purified by distillation under reduced pressure. All chemicals were used as supplied. Visible absorption spectra were recorded on a Hitachi 200-10 and a Shimadzu UV-160 spectrophotometer. Absorbance was measured for 1.5×10^{-3} mol dm^{-3} dye solution (2:98 H_2O–solvent) containing 9×10^{-3} mol dm^{-3} metal nitrate and 7.5×10^{-2} mol dm^{-3} pyridine derivative at a given temperature.

The Reaction of Diphenyl(trimethylsilylmethyl)phosphine with Carbonyl Compounds in the Presence of Fluorides

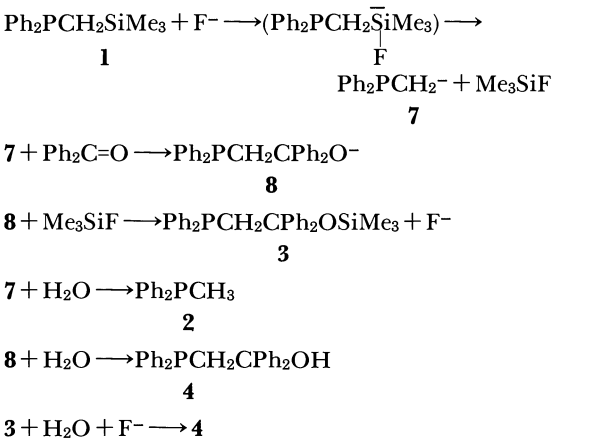
Takayuki KAWASHIMA,* Noriaki MITSUDA, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received August 28, 1990)

Synopsis. Diphenyl(trimethylsilylmethyl)phosphine (**1**) was allowed to react with benzophenone in the presence of CsF in *N,N*-dimethylformamide to give a mixture of methyldiphenylphosphine (**2**), (2,2-diphenyl-2-trimethylsiloxyethyl)diphenylphosphine (**3**) and (2-hydroxy-2,2-diphenylethyl)diphenylphosphine (**4**) in good yield. The use of about 10 mol% of CsF gave **3** with fairly good selectivity. The reaction with benzaldehyde gave a similar result, but only protodesilylation occurred in the reaction with enolizable carbonyl compounds.

The direct deprotonation of methyldiphenylphosphine was achieved successfully by using organolithium compounds with a help of *N,N,N′,N′*-tetramethylethylenediamine. However, it was accompanied by the substitution reaction at the phosphorus atom because of their nucleophilicity enhanced by the disaggregation.[1] In the course of our studies on the Horner-Emmons reaction, we uncovered the fluoride induced Horner-Emmons reaction.[2] We decided to examine the generation of diphenylphosphinomethyl anion by the fluoride-induced desilylation and the olefination via quaternalization from its carbonyl adduct. In this paper we wish to report on the results.

Results and Discussion

The Reaction of Diphenyl(trimethylsilylmethyl)phosphine (1) with Carbonyl Compounds in the Presence of CsF. Diphenyl(trimethylsilylmethyl)phosphine (**1**) was allowed to react with benzophenone in the presence of CsF in *N,N*-dimethylformamide (DMF) to afford a mixture of methyldiphenylphosphine (**2**), a protodesilylation product of **1**, (2,2-diphenyl-2-trimethylsiloxyethyl)diphenylphosphine (**3**), and (2-hydroxy-2,2-diphenylethyl)diphenylphosphine (**4**). The results are shown in Table 1. Sulfurization of the reaction mixture followed by usual workup gave a mixture of methyldiphenylphosphine sulfide (**5**) and (2-hydroxy-2,2-diphenylethyl)diphenylphosphine sulfide (**6**).[3] The signal due to **3** decreased with an increase in that of **4** with the elapse of the reaction time, indicating the hydrolysis of **3** occurred under the conditions. About 10 mol% of CsF is enough to complete the reaction, indicating that the present reaction proceeds as shown in the following scheme. An alternative mechanism where the resulting **8** reacts with **1** to afford **3** and **7** cannot be ruled out. It is interesting to point out that the carbanion **7** can be generated in the present system in spite of the lack of carbanion-stabilizing ability compared with cases of phosphonio[4,5] or phosphoryl derivatives[2] and that the yield of **7** is very high, though a part of **7** reacts with water existing in the system to give **2**.



The use of LiF or NaF as a fluoride ion source gave no adduct (**3** or **4**) besides a small amount of **2**, presumably because of its poorer solubility. The use of HMPA as a solvent gave almost the same results, but the reaction using an ethereal solvent such as tetrahydrofuran or diethylene glycol dimethyl ether was unsuccessful. An addition of molecular sieves 4A to remove water caused a decrease in the yields of the products as well as a reduction in the rate of the reaction.

In the case of the reaction of **1** with 1,5-diphenyl-3-pentanone in the presence of CsF the resulting carban-

Table 1. The Reaction of **1** with Benzophenone in the Presence of CsF in DMF

Entry	**1**/mmol	CsF[a]/mmol	Temp/°C	Time/h	**2**:**3**:**4**[b]
1	1.5	2.6	40	24	60:10:30
2	0.75	0.79	90	3	29:40:31
3	0.75	0.38	60	2	24:72:4
4	0.75	0.10	60	4	14:82:4
5	0.75	0.10	50	6	19:75:7[c]

a) Dried by heating with a heat gun under vacuum. b) The ratio of peak heights of signals at δ_P=−27.7, −26.3, and −24.8 due to **2**, **3**, and **4**, respectively. c) About 9% of **1** (δ_P=−22.7) remained.

ion acts as a base to afford only protodesilylation product **2**. Considering the fact that the reaction of dimethyl lithiomethylphosphonate gives the corresponding adduct in 95% yield,[6] it is concluded that unexpectedly low nucleophilicity for the present reactive species is probably attributed to the following reason: It may not be a free carbanion but solvated one, or it exists in equilibrium with "silicon ate complex".

$$\underset{\mathbf{1}}{Ph_2PCH_2SiMe_3} + Me_2NCHO \xrightarrow{F^-}$$

$$Ph_2PCH_2CH(NMe_2)OSiMe_3 \xrightarrow{-Me_3SiOH}$$

$$\underset{\mathbf{9}}{Ph_2PCH{=}CHNMe_2} \xrightarrow{S_8} \underset{\mathbf{10}}{Ph_2P(S)CH{=}CHNMe_2}$$

In the reaction with sterically hindered carbonyl compounds such as (−)-fenchone the desired adduct was not obtained, but a new peak appeared at δ_P=−14.0 besides −27.7 in the ^{31}P NMR spectrum, which is assignable to 1-dimethylamino-2-diphenylphosphinoethylene (**9**), a reaction product with DMF, from the following facts: 1) The chemical shift (δ_P=−14.0) is similar to that of diphenylvinylphosphine (δ_P=−11.7).[7] 2) Sulfurization of the reaction mixture gave **5** and trans-1-dimethylamino-2-(diphenylphosphinothioyl)ethylene (**10**).[8]

Olefination via P-Methylation. The reaction mixture which was obtained by the reaction of **1** with benzophenone in the presence of CsF was treated with iodomethane (1.1 equiv) and subsequent CsF-H_2O (1 equiv) to give 1,1-diphenylethylene (**11**). The isolated yield of **11** and the reaction conditions are summarized in Table 2.

$$Ph_2PCH_2\overset{OSiMe_3}{\overset{|}{C}}Ph_2 \xrightarrow[2)\ H_2O/F^-]{1)\ MeI} Ph_2P^+CH_2\overset{OH}{\overset{|}{C}}Ph_2\ I^- \xrightarrow{F^-} \underset{\mathbf{11}}{CH_2{=}CPh_2} + Ph_2\overset{O}{\overset{\|}{P}}Me$$

Besides the desired olefination side reactions such as the C-C bond cleavage (Entry 2) and the dehydration (Entry 3) occurred depending on the reaction conditions. Interestingly, an addition of more than 1.5 equivalents of water gave good results. A similar effect of water was reported in the case of the conversion of β-hydroxyalkylphosphonates into the corresponding olefins.[6,9] The ^{31}P NMR shows siloxyphosphonium salt is converted into the hydroxyphosphonium salt before the olefination.

Experimental

All melting points and boiling points are not corrected. ^{1}H NMR and ^{31}P NMR spectra were measured with a JEOL FX-90Q using tetramethylsilane as an internal standard and 85% H_3PO_4 as an external standard, respectively.

Preparation of Diphenyl(trimethylsilylmethyl)phosphine (1). To a solution of chlorodiphenylphosphine (5.1 g, 23 mmol) in dry ether (50 ml) was added dropwise an ethereal solution[10] of trimethylsilylmethylmagnesium chloride (1 M, 1 M=1 mol dm^{-3}, 23 mmol) at −78 °C under Ar. The reaction mixture was allowed to warm to room temperature and the resulting precipitates were filtered under Ar. The filtrate was evaporated under reduced pressure and the residue was distilled under vacuum with Kugelrohr to give **1** in 76% yield. Bp 105—110 °C/0.03 Torr (1 Torr=133.322 Pa) (lit,[11] bp 139—143 °C/0.6 Torr). ^{31}P NMR ($CDCl_3$) δ_P=−21.6. ^{1}H NMR ($CDCl_3$) δ=−0.05 (9H, s, Si(CH_3)$_3$), 1.3 (2H, d, J=1 Hz, P-CH_2-Si), and 7.0—7.5 (m, 10H, 2×Ph).

Reaction of 1 with Carbonyl Compounds in the Presence of CsF. Benzophenone: In a two-necked flask CsF (0.03 g, 0.1 mmol) was placed and heated by a heat gun under vacuum. A mixed solution of **1** (0.20 g, 0.75 mmol) and benzophenone (0.24 g, 1.3 mmol) in dry DMF (10 ml) was added to the flask and the mixture was heated at 60 °C for 4 h. The ^{31}P NMR spectrum of the reaction mixture showed three signals at δ_P=−27.7, −26.3, and −24.8 due to methyldiphenylphosphine (**2**), (2,2-diphenyl-2-trimethylsiloxyethyl)-diphenylphosphine (**3**), and (2-hydroxy-2,2-diphenylethyl)-diphenylphosphine (**4**) in a ratio of peak heights of 14 : 82 : 4, respectively.[12] Sulfurization of the reaction mixture by treatment with excess of sulfur, followed by usual workup afforded a mixture of methyldiphenylphosphine sulfide (**5**) and (2-hydroxy-2,2-diphenylethyl)diphenylphosphine sulfide (**6**), which could be separated by preparative high-pressure liquid chromatography (LC) (Japan Analytical Industries: JAIGEL 1H, 2H).

5 (10%):[13] ^{1}H NMR ($CDCl_3$) δ=2.27 (3H, d, $^2J_{H,P}$=13.4 Hz, PCH_3), 7.39—7.54 (6H, m, para and meta), and 7.65—7.97 (4H, m, ortho). ^{31}P NMR ($CDCl_3$) δ_P=35.81.

6 (80%): mp 151—152.5 °C (hexane) (lit,[1] mp 142—145 °C). ^{1}H NMR ($CDCl_3$) δ=3.64 (2H, d, $^2J_{H,P}$=10.3 Hz, PCH_2), 6.63 (1H, s, OH), 6.98—7.18 (5H, m, Ph), 7.18—7.50 (11H, m, Ph′ and para and meta of PPh), and 7.50—7.80 (4H, m, ortho of PPh). ^{31}P NMR ($CDCl_3$) δ_P=34.66. The results of the reactions carried out under various conditions are shown in Table 1.

Benzaldehyde: A mixture of **1** (0.10 g, 0.38 mmol), benzaldehyde (0.04 g, 0.38 mmol), and CsF (0.03 g, 0.19 mmol) was heated in DMF (8 ml) at 0 °C for 2 h. The ^{31}P NMR spectrum of the reaction mixture showed three signals at δ_P=−27.7, −22.3, and −21.6 due to **2**, (2-phenyl-2-trimethyl-

(−)-Fenchone: The reaction using **1** (0.20 g, 0.75 mmol), (−)-fenchone (0.14 g, 0.93 mmol), and CsF (0.05 g, 0.33 mmol) in DMF (10 ml) gave a mixture of **2** and trans-2-dimethylamino-1-diphenylphosphinoethylene (**9**), which was sulfurized and subjected to LC to afford trans-dimethylamino-1-diphenylphosphinothioylethylene (**10**) in 36% yield.

9: ^{31}P NMR (DMF) δ_P=−14.0.

10: Mp 99—101 °C (hexane). ^{1}H NMR ($CDCl_3$) δ=2.92 (6H, s, NMe_2), 4.48 (1H, dd, $^2J_{H,P}$=13.5 Hz, $^3J_{H,H}$=17.2 Hz, PC$\underline{H}$=CH), 7.24 (1H, dd, $^3J_{H,P}$=14.0 Hz, $^3J_{H,H}$=17.2 Hz, =C$\underline{H}$NMe_2), 7.31—7.56 (6H, m, meta and para), and 7.62—7.96 (4H, m, ortho). ^{31}P NMR ($CDCl_3$) δ_P=37.49. HRMS (70 eV): *m/z* Found: 287.0907. Calcd for $C_{16}H_{18}NPS$: 287.0897.

Olefination via P-Methylation. To the reaction mixture which was obtained by the reaction of **1** (0.20 g, 0.75 mmol) with benzophenone (0.20 g, 1.1 mmol) in the presence of CsF (0.06 g, 0.38 mmol) were added iodomethane (1.1 equiv), CsF (0.20 g, 0.75 mmol), and H_2O (1.19 mmol). After stirring for 2 h at room temperature the reaction was quenched with water, and then the reaction mixture was extracted with dichloromethane. After removal of the solvent the residue was subjected to dry column chromatography (SiO_2) to give 1,1-diphenylethylene (**11**) in 60% yield. The isolated yield of **11** and the reaction conditions are summarized in Table 2.

The authors wish to express their thanks to Shinetsu Kagaku Co. for a gift of chlorotrimethylsilane. The present work was partially supported by a Grant-in-Aid for Scientific Research No. 61540365 from the Ministry of Education, Science and Culture.

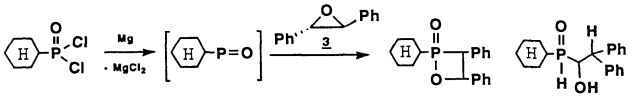
(Received September 10, 1990)

Synopsis. The correct structure of the title compound was elucidated to be cyclohexyl(2,2-diphenyl-1-hydroxyethyl)phosphine oxide, which seems to be formed via migration of a phenyl group, from the NMR spectral data and synthesis of the dimethyl derivative.

In the course of our study on the reactions of phosphinylidenes and phosphinothioylidenes,[1] we have reported that 1,2-oxaphosphetane derivative (**1**) was formed in the reaction of cyclohexylphosphonic dichloride (**2**) with magnesium in the presence of *trans*-stilbene oxide (**3**) as shown in the following scheme.[2]



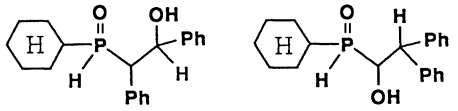
2 **1** **4**

Further investigation on this compound allows us to reach the conclusion that the product is not 1,2-oxaphosphetane 2-oxide (**1**), but an acyclic secondary phosphine oxide (**4**), which seems to be formed via migration of a phenyl group. In this paper we wish to revise the structure.

Results and Discussion

In order to confirm whether the sample, which was obtained previously,[2] remains unchanged as it was or not, we took a ^{1}H NMR spectrum (90 MHz). Its spectrum showed the same signals as taken previously except a double doublet with a large coupling constant, indicating the existence of a direct P-H bond. We overlooked a double doublet in the 60 MHz-^{1}H NMR spectrum, because a lower field signal had appeared about δ=9.7 and upper one, which was expected to appear at δ=2.2, was unfortunately superimposed with the signals of the cyclohexyl group. In the IR spectrum the stretching frequencies for O-H and P-H bonds had been observed at 3150 and 2330 cm^{-1}, respectively. However, the former band had been assigned to that of water of crystallization, as expected from the results of elemental analysis, and the latter band had been completely neglected because the presence of P-H bond was beyond the consideration. Judging from the existence of P-H bond we at first presumed Structure A, which is considered to be formed by the reduction and the subsequent ring opening by hydrolysis of the oxaphosphetane.

The ^{13}C NMR spectrum showed the signals due to three methine groups at δ_C=34.54 (J=65.4 Hz), 53.31 (J=3.4 Hz), and 69.74 (J=74.5 Hz). The chemical shifts are reasonable for the carbons bonding to a phosphorus, phosphorus, and oxygen atom, respectively, but the magnitudes of coupling constant with



Structure A Struucture B (**4**)

Fig. 1. Possible Structures of the Product.

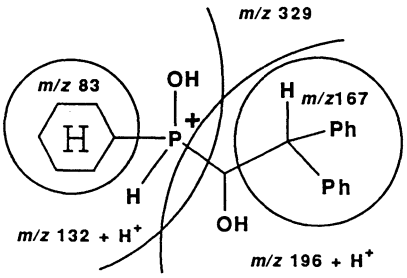


Fig. 2. Fragmentation of **4**.

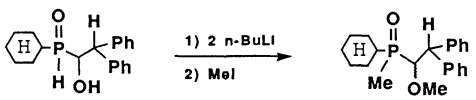
phosphorus nucleus cannot be explained for Structure A at all. From the data a phosphorus atom must directly be attached to the carbon bonded with an oxygen atom. Structure B (**4**) is consistent with these facts (see Fig. 1).

The ^{31}P NMR spectrum showed a very small peak at δ_P=44.96 (<1/18) due to a minor diastereomer besides a major peak at δ_P=39.11. A negligibly small doublet was observed at δ=6.14 in the ^{1}H NMR spectrum, suggesting the formation of diastereomer also. Interesting features in the NMR spectrum are nonequivalences in cyclohexane ring carbons and in two phenyl groups, because of neighboring chiral center.

On the other hand the mass spectrum measured by electron impact ionization gave no parent peak, as mentioned previously,[2] but in the chemical ionization mass spectrum using methane gas the protonated molecular peak was observed at m/z 329 (7%). The base peak was m/z 105, which is assigned to a rearranged fragment ($PhCO^+$). Peaks at m/z 197 (14%), 167 (44%), 133 (46%), and 83 (51%) were also observed, supporting the structure **4** (see Fig. 2).

Methylation of 4. Compound **4** was allowed to react with 2 equivalents of *n*-BuLi at −78 °C in tetrahydrofuran (THF) and with excess iodomethane to afford a mixture of cyclohexyl(methyl)(2,2-diphenyl-1-methoxyethyl)phosphine oxides (**5a** and **5b** in 3 : 1



4 **5a** and **5b**

diastereomer ratio. The structure of **5** was determined by the observations of a pair of doublets at δ=0.84 and 0.98 due to PMe groups and a pair of singlets at δ=3.22 and 3.30 due to OMe groups instead of the signals due to PH and OH groups in the ^{1}H NMR spectrum. In the ^{13}C NMR spectrum of **5** the signals of the minor diastereomer could not be observed clearly, because of an insufficient amount of the sample, but those of the major one support the structure **5**. The high resolution mass spectrum gave the exact mass number of the parent peak. The change in the diastereomer ratio can be explained reasonably if one considers the difference in sterical bulkiness between hydrogen atom and methyl group.

It is very surprising that such a secondary alkylphosphine oxide remains without any change even after being exposed to air for 14 years. Unexpected stability of this compound having a readily oxidizable moiety seems to come from the following factors: intramolecular hydrogen bonding stabilizes a pentavalent tautomer and a reaction center is hindered by two bulky substituents.

Experimental

^{1}H NMR spectra were measured with a Bruker AM-500 (500.13 MHz) spectrometer using tetramethylsilane (TMS) as an internal standard. ^{13}C NMR spectra were taken with a Bruker AM-500 (125.77 MHz) spectrometer using TMS as an internal standard. ^{31}P NMR spectra were obtained with a JEOL FX-90Q spectrometer using 85% H_3PO_4 as an external standard. IR spectra were taken with a Hitachi 260-30 spectrophotometer. Mass spectra were recorded with a JEOL 300-D mass spectrometer.

The sample stored in a vial, which was reported to be 2-cyclohexyl-3,4-diphenyl-1,2-oxaphosphetane 2-oxide (**1**),[2] was used after confirming it remains unchanged as it was.

Spectral Data of the Compound 4. ^{1}H NMR ($CDCl_3$)[3] (500.13 MHz) δ=1.10—1.14 (4H, m, C(2)H$_2$, ax. H-C(3′), and eq. H-C(4) of c-Hex), 1.65—1.70 (2H, m, C(3)H$_2$ of c-Hex), 1.70—1.80 (3H, m, C(2′)H$_2$ and eq. H-C(4) of c-Hex), 1.80—1.95 (1H, m, C(1)H of c-Hex), 1.95—2.05 (1H, m, eq. H-C(3′) of c-Hex), 4.25 (1H, s, OH), 4.50—4.60 (2H, m, CHCHOH), 6.02 (1H, dd, $^3J_{H,H}$=4.8 Hz, $^1J_{H,P}$=451.1 Hz, PH), 7.20—7.25 (2H, m, para-H of Ph and Ph′), 7.28—7.31 (2H, m, meta-H of Ph), 7.32—7.36 (4H, m, meta and ortho-H of Ph′), and 7.43—7.45 (2H, m, ortho-H of Ph). A small doublet appeared at δ=6.14 ($^1J_{H,P}$=458.6 Hz). ^{13}C NMR ($CDCl_3$)[3] δ_C=25.16 (s,[4] C-4 of c-Hex), 25.22 (d, $^3J_{C,P}$=2.9 Hz, C-3′of c-Hex), 25.73 (s, C-2 of c-Hex), 25.80 (d, $^3J_{C,P}$=14.8 Hz, C-3 of c-Hex), 25.91 (d, $^2J_{C,P}$=12.8 Hz, C-2′ of c-Hex), 34.54 (d, $^1J_{C,P}$=65.4 Hz, C-1 of c-Hex), 53.31 (d, $^2J_{C,P}$=3.4 Hz, PCHCHPh$_2$), 69.74 (d, $^1J_{C,P}$=74.5 Hz, PCHOH), 126.92 (s, para-C of Ph), 127.48 (s, para-C of Ph′), 128.49 (s, ortho-C of Ph′), 128.69 (s, ortho-C and meta-C of Ph), 129.06 (meta-C of Ph′), 139.91 (s), and 140.35 (d, $^3J_{C,P}$=10.5 Hz) (ipso-C of Ph and Ph′). ^{31}P NMR ($CDCl_3$) δ_P=39.11 and 44.96 (>18:1). Mass spectrum (chemical ionization: Methane gas): m/z 329 (M^++1, 7%), 197 (HCOCHPh$_2$+H$^+$, 14), 167 (CH$^+$Ph$_2$, 44), 133 (c-C$_6$H$_{11}$P(O)H$_2$+H$^+$, 46), 105 (PhCO$^+$, 100), and 83 (c-C$_6$H$_{11}^+$, 51). IR (KBr disc) ν_{OH}=3150 cm^{-1} and ν_{PH}=2330 cm^{-1}.

Methylation of 4. To a solution of **4** (7.2 mg, 0.022 mmol) in THF (2 ml) was added dropwise *n*-BuLi (0.96 M hexane solution, 0.05 ml, 0.048 mmol) at −78 °C with stirring, then excess of iodomethane (0.1 ml, 1.6 mmol) was added to the solution. The reaction mixture was allowed to warm to room temperature, treated with aq NH_4Cl. Organic layer was extracted with dichloromethane and dried over anhydrous $MgSO_4$. After removal of the solvent the residue was subjected to high-pressure liquid chromatography (column: Japan Analytical Industries (JAIGEL 1H, 2H)) to give a diastereomer mixture of cyclohexyl(methyl)(2,2-diphenyl-1-methoxyethyl)phosphine oxides (**5a** and **5b**) (2.0 mg, 26%) as viscous oil in a ratio of 3:1. **5:** ^{1}H NMR ($CDCl_3$) δ=0.84 (d, $^2J_{H,P}$=12.4 Hz, PCH$_3$ of **5b**), 0.98 (d, $^2J_{H,P}$=11.9 Hz, PCH$_3$ of **5a**), 0.80—1.35 (m) and 1.55—1.92 (m) (c-C$_6$H$_{11}$ of **5a** and **5b**), 3.22 (s, OCH$_3$ of **5b**), 3.30 (s, OCH$_3$ of **5a**), 4.26 (dd, $^3J_{H,H}$=7.1 Hz, $^2J_{H,P}$=4.9 Hz, PCHOMe of **5a**), 4.29 (t, $^3J_{H,H}$=$^3J_{H,P}$=5.1 Hz, PCHOMe of **5b**), 4.56 (t, $^3J_{H,H}$=$^3J_{H,P}$=7.1 Hz, CHPh$_2$ of **5a**), 4.66 (t, $^3J_{H,H}$=$^3J_{H,P}$=5.1 Hz, CHPh$_2$ of **5b**), 7.20—7.24 (m, all para-H), 7.24—7.35 (m, all meta-H), 7.42—7.46 (m, ortho-H of Ph of **5a** and **5b**), 7.52—7.55 (m, ortho-H of Ph′ of **5a**), and 7.57—7.62 (m, ortho-H of Ph′ of **5b**). ^{13}C NMR ($CDCl_3$) δ_C=10.13 (d, $^1J_{C,P}$=59.9 Hz, PCH$_3$), 24.76 (d $^4J_{C,P}$=3.6 Hz, C-4 of c-Hex), 25.98 (d, $^3J_{C,P}$=2.5 Hz, C-3′ of c-Hex), 26.23 (d, $^3J_{C,P}$=8.4 Hz, C-3 of c-Hex), 26.31 (s, C-2 of c-Hex), 26.35 (d, $^2J_{C,P}$=4.9 Hz, C-2′ of c-Hex), 36.71 (d, $^1J_{C,P}$=64.0 Hz, C-1 of c-Hex), 51.11 (d, $^2J_{C,P}$=5.8 Hz, CHPh$_2$), 60.68 (s, OCH$_3$), 83.36 (d, $^1J_{C,P}$=76.3 Hz, PCHOMe), 127.00 (s, para-C of Ph), 127.07 (s, para-C of Ph′), 128.44 (s, ortho-C of Ph), 128.73 (s, meta and ortho-C of Ph′), 129.53 (s, meta-C of Ph), 140.29 (s), and 141.3 (d, $^3J_{C,P}$=5.7 Hz) (ipso-C of Ph and Ph′). ^{31}P NMR ($CDCl_3$) δ_P=51.28 and 51.64 (ca. 3:1). High resolution mass spectrum (70 eV): m/z Found: 356.1895. Calcd for $C_{22}H_{29}O_2P$: 356.1905.

The authors wish to express their thanks to Tosoh Akzo Co. for a gift of *n*-BuLi and also to Dr. Hiroshi Hirota, The University of Tokyo, for his measuring chemical ionization mass spectrum. This work was partially supported by the Grant-in-Aid for Scientific Research on Priority Area of Organic Unusual Valency No. 02247205 from the Ministry of Education, Science and Culture.

The Correct Structure of Cyclic Adducts of (Diphenylmethylene)-oxophenylphosphorane with Aromatic Aldehydes

Takayuki KAWASHIMA* and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 10, 1990)

Synopsis. The title cyclic adducts have been reported to be 4-aryl-2,3,3-triphenyl-1,2-oxaphosphetane 2-oxides. However, these compounds are concluded not to be the 1,2-oxaphosphetanes, but 1-aryl-3,4-diphenyl-3,4-dihydro-1*H*-2,3-benzoxaphosphorin 3-oxides from our detailed NMR studies and the investigation of the chemical behavior of the adduct of benzaldehyde.

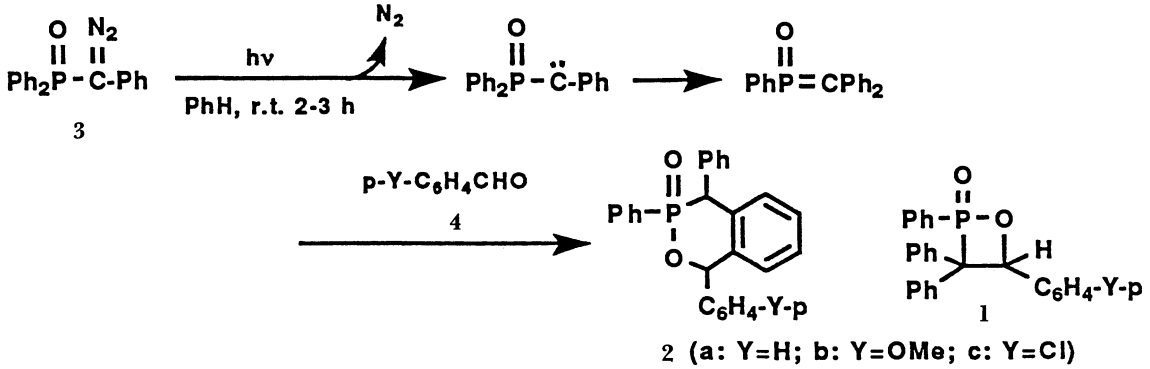
Recently, pentacoordinate 1,2-oxaphosphetanes have attracted much attention as the reactive intermediates of the Wittig reaction, which can be observed by the low temperature NMR spectroscopies.[1] 1,2-Oxaphosphetane 2-oxides, their tetracoordinate analogs, were known to be much more stable in the earlier time. Since the compound, which we reported previously as an example,[2] was not 1,2-oxaphosphetane 2-oxides, as mentioned in the preceding paper,[3] we decided to prepare 4-aryl-2,3,3-triphenyl-1,2-oxaphosphetane 2-oxides (**1**), which were reported as other examples of stable oxaphosphetane oxide,[4] in order to investigate their chemical behavior toward various nucleophiles. However, we have found that the compound prepared by the method reported in the literature are not 1,2-oxaphosphetane 2-oxides (**1**), but 3,4-dihydro-1*H*-2,3-benzoxaphosphorin 3-oxides (**2**). Here, we wish to report on the results.

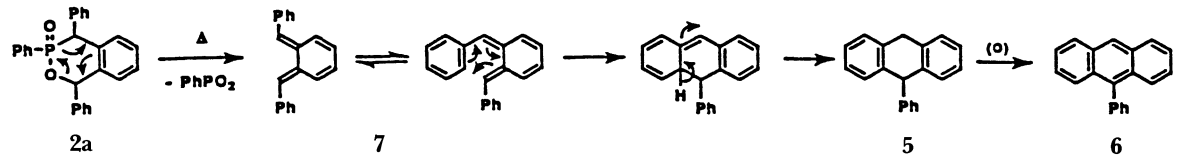
Results and Discussion

(Diphenylphosphinyl)phenyldiazomethane (**3**) was irradiated in benzene at room temperature in the presence of aromatic aldehydes (**4**) according to the literature,[4] to give a complex mixture, which was treated with MeOH to afford 1-aryl-3,4-diphenyl-3,4-dihydro-1*H*-2,3-benzoxaphosphorin 3-oxides (**2**) instead of 4-aryl-2,3,3-triphenyl-1,2-oxaphosphetane 2-oxides (**1**) as reported previously.[4]

In order to confirm the structure ^{13}C NMR spectrum was taken in various measuring modes. In the proton-noise decoupled ^{13}C NMR signals due to PC and CO were observed at the expected positions for the structure of **1**, but these signals also appeared in its DEPT (distortionless enhancement by polarization transfer) spectrum, indicating that both of them are not signals due to quaternary carbon. In the detailed study of the ^{1}H NMR spectrum of **1a**, the existence of a doublet was elucidated in the region of aromatic protons. This coupling was confirmed to be that with a phosphorus nucleus by the ^{1}H-{^{31}P} NMR spectroscopy. Thus, it was clarified from both ^{1}H and ^{13}C NMR spectral data that this compound has two methine groups except aromatic protons in the molecule. In order to assign the signals, two-dimensional NMR spectra were taken. Figure 1 shows the C,H-COSY (correlation spectroscopy) spectrum of **2a**, indicating that two doublets at δ=4.7 and 6.7 correlate with two doublets at δ_C=49 and 78, respectively. From the magnitudes of coupling constants the following conclusion were drawn: one methine group is bonded directly with a phosphorus atom and the other is attached to an oxygen atom. These methines must not be bonded with each other. These facts cannot be explained from Structure **1**, but they are consistent with Structure **2**. Four continuous proton system of benzo moiety was elucidated by the H,H-COSY spectrum of **2a** as shown in Fig. 2.

Although the fragmentation pattern of mass spectrum was used as evidence for Structure **1**,[4] observation of the fragment (M^+-$PhPO_2$) can also be explained nicely as Structure **2**, by considering that the fragmentation takes place via the retro-Diels-Alder reaction. In order to undergo thermally this retro-Diels-Alder reaction **2a** was heated at 250 °C in toluene-d_8 in a sealed NMR tube. High-pressure liquid chromatography gave 9-phenyl-9,10-dihydroanthracene (**5**) and 9-phenylanthracene (**6**), oxidation product of **5**, in 26 and 13% yields, respectively. Dihydro compound **5** seems to be formed by the cyclization of the first product **7** of the retro-Diels-Alder reaction of **2a**. A similar result has been reported by Cava and his co-workers in the thermolysis of 1,3-





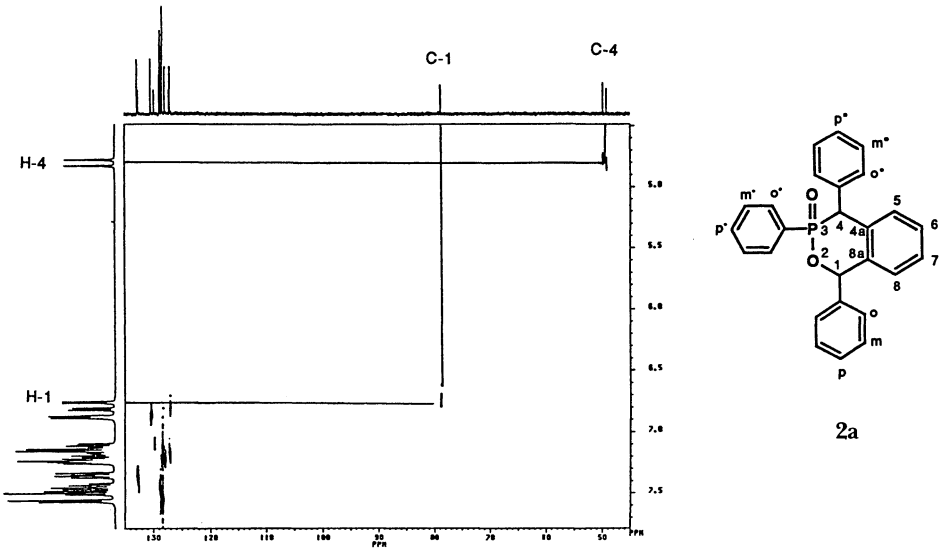


Fig. 1. The C,H-COSY Spectrum of **2a**.

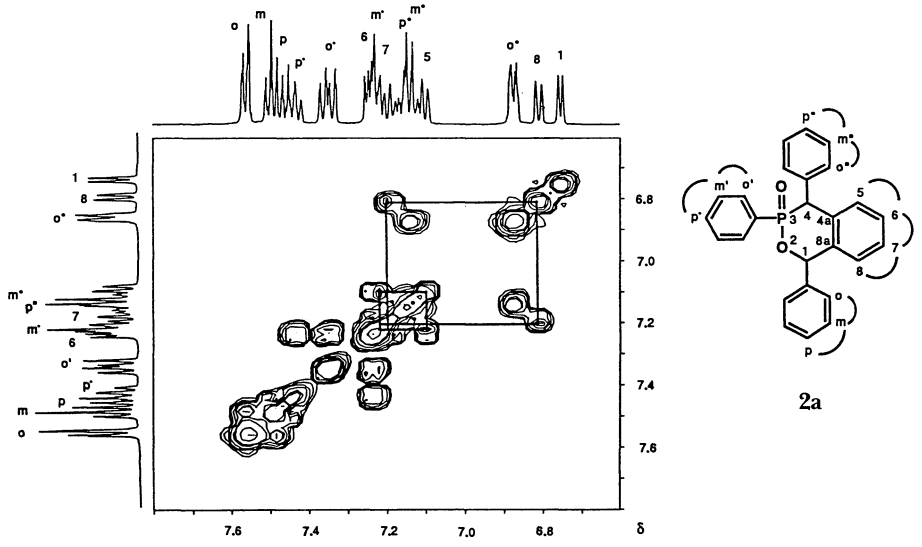

Fig. 2. The Partially H,H-COSY Spectrum of **2a**.

diphenyl-1,3-dihydrobenzo[*c*]thiophene 2,2-dioxide (**8**).[5] The structure with a fused benzene ring for **2a** is strongly supported by the fact that 9-phenyl-9,10-dihydroanthracene was obtained in its thermolysis. Judging from these spectral data and chemical behavior it is reasonably concluded that the compound is not 1,2-oxaphosphetane 2-oxide, but 2,3-benzoxaphosphorin 3-oxide. For 2,3-benzoxaphosphorin ring system only one example has been reported until now.[6]

The stereochemistry of **2a** was also studied. The NOESY (nuclear Overhauser effect spectroscopy) spectrum of **2a** (Fig. 3) shows the cross peaks between H-1 and H-4 and between ortho-protons of three phenyl groups, indicating that all phenyl groups are cis.

Experimental

All melting points are uncorrected. ^{1}H NMR spectra were measured with a Bruker AM-500 (500.13 MHz) spectrometer using tetramethylsilane (TMS) as an internal standard. ^{13}C NMR and ^{31}P NMR spectra were taken with a Bruker AM-500 (125.77 MHz) using TMS as an internal standard and with a JEOL FX-90Q spectrometer using 85% H_3PO_4 as an external standard, respectively. Mass spectra were recorded with a JEOL 300-D mass spectrometer.

Photolysis of (Diphenylphosphinyl)phenyldiazomethane (3) in the Presence of Aromatic Aldehydes (4). A benzene (20 ml) solution of **3** (0.207 g, 0.649 mmol), which was prepared by the method described in the literature using *n*-BuLi instead of PhLi,[7] and benzaldehyde (**4a**) (0.198 ml,

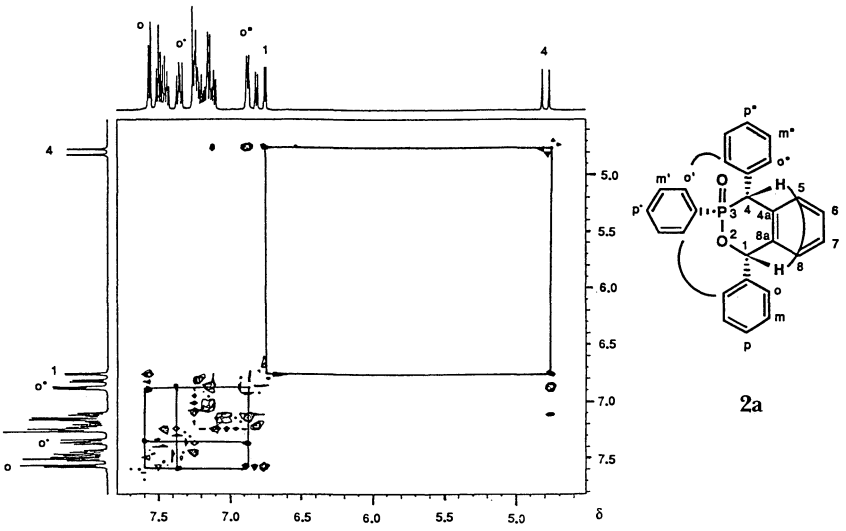

Fig. 3. The NOESY Spectrum of **2a**.

1.95 mmol) was irradiated with a 100-W medium-pressure mercury arc lamp for 2.5 h at room temperature under nitrogen atmosphere. After removal of the solvent the residue was treated with methanol to give crude 1,3,4-triphenyl-3,4-dihydro-1*H*-2,3-benzoxaphosphorin 3-oxide (**2a**), whose physical and spectral data agreed with those reported as 2,3,3,4-tetraphenyl-1,2-oxaphosphetane 2-oxide. Recrystallization from methanol afforded pure **2a** in 14% yield.

2a: mp 254—257 °C (decomp). ^{1}H NMR ($CDCl_3$)[8] δ= 4.80 (1H, d, $^2J_{H,P}$=24.4 Hz, PCHPh), 6.75 (1H, d, $^3J_{H,P}$=5.8 Hz, POCHPh), 6.81 (1H, d, $^3J_{H,H}$=7.6 Hz, H-8), 6.86—6.89 (2H, m, ortho-H of C(4)-Ph), 7.10 (1H, d, $^3J_{H,H}$=7.5 Hz, H-5), 7.11—7.27 (7H, m, H-6, H-7, meta and para-H of C(4)-Ph, and meta-H of P-Ph), 7.33—7.38 (2H, m, ortho-H of P-Ph), 7.41—7.52 (4H, m, para-H of P-Ph, meta and para-H of C(1)-Ph), and 7.54—7.58 (2H, m, ortho-H of C(1)-Ph). ^{13}C NMR ($CDCl_3$)[8] δ_C=49.47 (d,[9] $^1J_{C,P}$=81.1 Hz, PCHPh), 78.73 (d, $^2J_{C,P}$=8.0 Hz, POCHPh), 127.04 (s, C-7 and C-8), 127.19 (d, $^5J_{C,P}$=3.3 Hz, para-C of C(4)-Ph), 127.94 (d, $^3J_{C,P}$=13.3 Hz, meta-C of P-Ph), 128.33 (s, ortho-C of C(1)-Ph), 128.35 (d, $^4J_{C,P}$=3.8 Hz, meta-C of C(4)-Ph), 128.43 (d, $^1J_{C,P}$=140.2 Hz, ipso-C of P-Ph), 128.50 (s, C-6), 128.90 (s, para-C of C(1)-Ph), 129.75 (d, $^3J_{C,P}$=9.0 Hz, C-5), 130.35 (d, $^3J_{C,P}$=5.2 Hz, ortho-C of C(4)-Ph), 132.51 (d, $^4J_{C,P}$=2.7 Hz, para-C of P-Ph), 132.71 (d, $^2J_{C,P}$=9.4 Hz, ortho-C of P-Ph), 134.17 (d, J=4.8 Hz), 134.82 (d, J=4.7 Hz), 137.29 (d, J=5.7 Hz) (C-4a, C-8a, ipso-C of C(1)-Ph), and 138.55 ($^3J_{C,P}$=9.5 Hz, ipso-C of C(1)-Ph). ^{31}P NMR ($CDCl_3$) δ_P=35.47. Compounds **2b** and **2c** were obtained in 12 and 14% yields, respectively, as described above.[10]

Thermolysis of 2a. A solution of **2a** (10 mg, 0.025 mmol) in d_8-toluene (1 ml) was heated at 250 °C for 7 h in a degased sealed NMR tube until starting material disappeared completely. ^{1}H NMR showed a new AB quartet at δ=3.92. The solvent was distilled with a Kugelrohr to give tarry material, which was subjected to high-pressure liquid chromatography (column: Japan Analytical Industries: JAIGEL 1H, 2H) to afford 9-phenyl-9,10-dihydroanthracene (**5**)[11] and 9-phenylanthracene (**6**) in 26 and 13% yields, respectively. Besides these hydrocarbons some of unidentified products containing a phosphorus atom were obtained. Dihydro compound **5** was oxidized readily on silica gel to afford **6**.

5: ^{1}H NMR ($CDCl_3$) δ=3.91 (1H, d, $^2J_{H,H}$=18.1 Hz, CHH'), 4.02 (1H, d, $^2J_{H,H}$=18.1 Hz, CHH'), 5.26 (1H, s, CHPh), 7.06—7.09 (2H, m, ortho-H of Ph), 7.12—7.16 (1H, m, para-H of Ph), 7.19—7.23 (6H, m, meta-H of Ph, H-1, H-2, H-7, H-8), 7.29—7.33 (4H, m, H-3, H-4, H-5, H-6). ^{13}C NMR ($CDCl_3$) δ_C=35.65 (t,[12] C-10), 51.42 (d, C-9), 126.19 (d), 126.35 (d), 126.40 (d), 127.75 (d), 128.04 (d), 128.41 (d), 128.43 (d), 136.42 (s), 139.48 (s), 143.57 (s). High-resolution mass spectrum (70 eV): m/z Found: 256.1244. Calcd for $C_{20}H_{16}$: 256.1250. Compound **6** agreed with authentic sample.

The authors wish to express their thanks to Tosoh Akzo Co. for a gift of *n*-BuLi. This work was partially supported by the Grant-in-Aid for Scientific Research on Priority Area of Organic Unusual Valency No. 02247205 from the Ministry of Education, Science and Culture.

On the Mechanism of the Cleavage Reaction of (Methylthio)methyl Ether with Triphenylmethyl Cation

Haruki NIWA* and Yasuyoshi MIYACHI
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received September 21, 1990)

Synopsis. The cleavage reaction of a (methylthio)methyl (MTM) ether with triphenylmethyl cation was not initiated by the previously proposed hydride abstraction with triphenylmethyl cation but promoted by the coordination of triphenylmethyl cation as a Lewis acid to the sulfur atom in the MTM group.

In the synthesis of polyfunctional molecules, (methylthio)methyl (MTM) ethers have been recognized as excellent protecting groups for hydroxyl functions, especially for tertiary alcohols owing to their facile formation and unique stability characteristics.[1] Although there have been reported various methods for removing the MTM protecting groups,[2] the reaction with triphenylmethyl tetrafluoroborate (Ph_3CBF_4)[2g] seems to be the most efficient and promising procedure owing to the mild reaction conditions, the simple procedure, and the wide applicability to polyfunctional molecules.[3] The mechanism of cleavage reaction of the MTM group has been thought *a priori* to be the same as proposed by Barton[4] for the oxidative cleavage of methylenedioxy ($O-CH_2-O$) groupings with Ph_3CBF_4: The initial step is abstraction of a hydride anion from MTM ether **A** with triphenylmethyl (trityl) cation to form intermediate **B**, which upon hydrolysis (workup) gave parent alcohol **C** (Scheme 1).[2g] However, we have found that this cleavage reaction is not initiated by hydride abstraction with trityl cation but promoted by the coordination of trityl cation to the sulfur in the MTM group.

As the substrate for the present investigation, we have chosen 1-adamantanol (tricyclo[3.3.1.1^{3,7}]decan-1-ol) MTM ether (**1**) prepared from 1-adamantanol (**2**) by Yamada's procedure (Ac_2O-DMSO).[2b] The reaction of **1** with 1.05 equiv of Ph_3CBF_4 in CH_2Cl_2 at room temperature for 10 min followed by quenching with aqueous $NaHCO_3$ (workup) provided 1-adamantanol (**2**) (88%) together with Ph_3COH (**6**) (77%) and Ph_3CSCH_3 (**8**) (16%) (Scheme 2). However, Ph_3CH was detected in only trace amounts (<1%). When the cleavage reaction of **1** with Ph_3CBF_4 was quenched with a large excess of methanol prior to aqueous workup, **2** was again obtained in 87% yield together with 1-adamantanol MOM ether (**3**) (11%), Ph_3COCH_3 (**7**) (84%), and Ph_3CSCH_3 (**8**) (8%). Only trace amounts (<1%) of Ph_3CH was again detected.

The above results clearly indicate that the cleavage of the MTM ether **1** with Ph_3CBF_4 is not initiated by hydride abstraction with trityl cation as proposed previously.[2g] Although trityl cation is well-documented[5] as a hydride ion acceptor, it has been also known to behave as a Lewis acid.[6] Therefore, the initial step in the cleavage reaction of the MTM ether **1** with Ph_3CBF_4 is supposed to be the complexation of trityl cation to the sulfur atom in the MTM group, forming the sulfonium salt **9** (Scheme 3).[6] Then, the sulfonium salt **9** comes to equilibrium with the collapsed oxonium salt **10** and Ph_3CSCH_3(**8**). During workup the sulfonium salt **9** and oxonium salt **10** may be decomposed via two competing reaction pathways [**a** and **b**]. When the reaction is quenched with H_2O (aqueous workup) (R=H) route **a** gives rise to the parent alcohol **2** and Ph_3COH (**6**) via **11**, whereas route **b** affords also **2** along with Ph_3CSCH_3 **8** through the intermediate **12** generated from **10**. On the other hand, quenching the reaction with methanol ($R=CH_3$) prior to aqueous workup provides the MOM ether **3** arising from the intermediate **10**, and again Ph_3CSCH_3 **8** in a ratio of ca. 1:1 through route **b**, whereas route **a** provides the parent alcohol **2** and

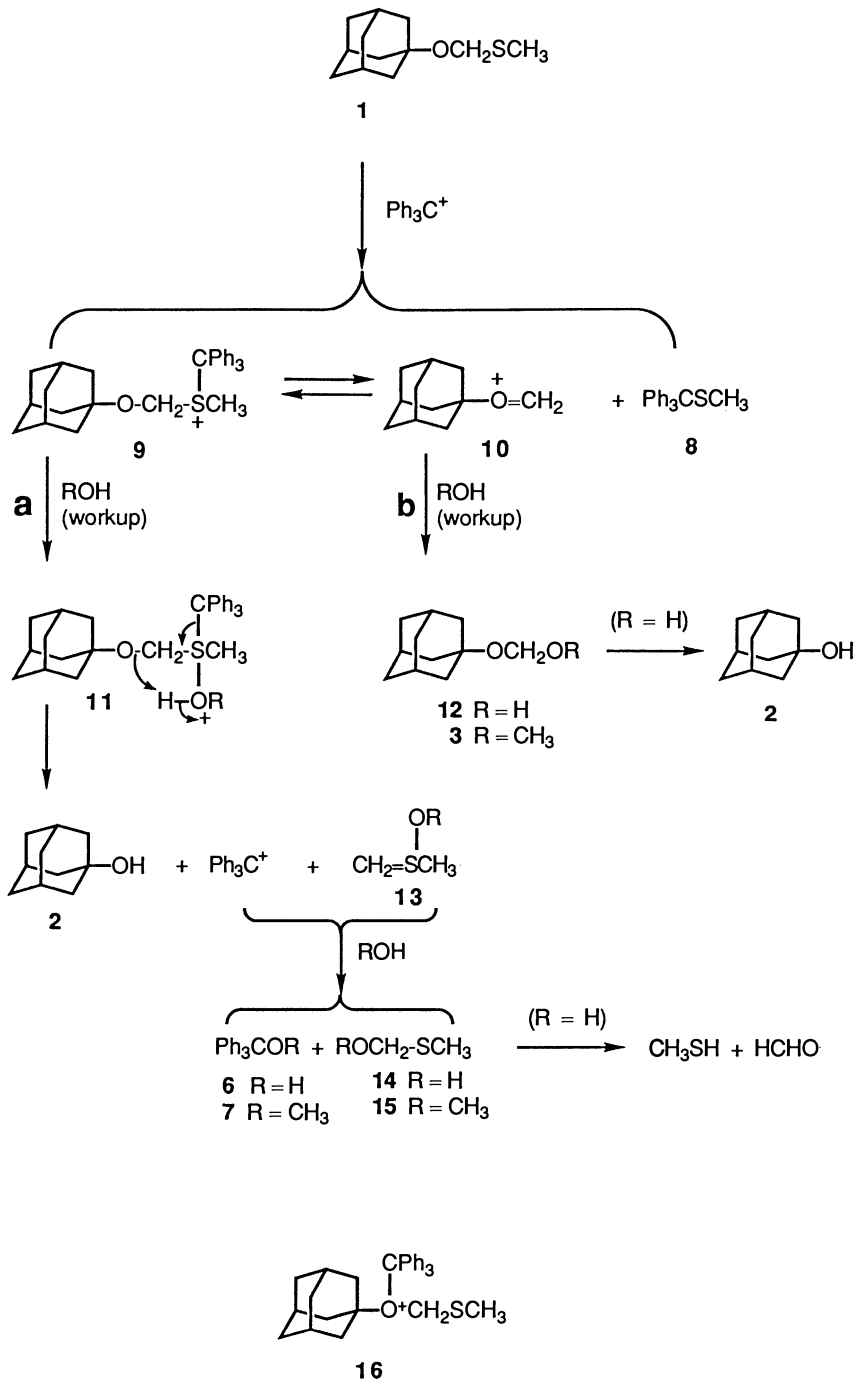
Scheme 2.



Scheme 3.

Ph_3COCH_3 (**7**) in a ratio of ca. 1:1. These experimental results suggest that the cleavage of the MTM ether **1** with Ph_3BF_4 predominantly proceeds through route **a**. The clean generation of the parent alcohol **2** without forming the corresponding trityl ether **4** precludes the intervention of the oxonium intermediate **16** during the course of the cleavage reaction. Intervention of 1-adamantyl cation is also ruled out because none of 1-adamantyl methyl ether (**5**) was formed on treatment of the reaction mixture with MeOH prior to aqueous workup. The reported results[2g,3] also indicate that the MTM groups can be removed with the complete retention concerning the configuration of the corresponding hydroxyl groups, precluding intervention of carbocation intermediates during the cleavage reactions.

Based on our understanding of the mechanism of this cleavage reaction, one would expect that Ph_3CClO_4 is also effective reagent to cleave the MTM ether **1**. Our experimental results on the reaction of **1** with Ph_3CClO_4 agree with this prediction, giving the similar result as the cleavage of **1** with Ph_3CBF_4 (see Experimental section).

In summary, the cleavage reaction of the MTM

ether **1** with Ph_3CBF_4 or Ph_3CClO_4 is found to be promoted by the coordination of trityl cation to the sulfur in the MTM group and not initiated by hydride abstraction with trityl cation.

Experimental

Infrared (IR) spectra were recorded on a JASCO Model IR-810 spectrophotometer in $CHCl_3$. Proton nuclear magnetic resonance (^1H NMR) spectra were determined on a JEOL FX-90QE (90 MHz) spectrometer in $CDCl_3$. Chemical shifts are expressed in ppm downfield from internal tetramethylsilane using the δ scale. The low (EIMS) and high resolution (HREIMS) mass spectra were measured on a JEOL-LG2000 instrument. Fuji-Davison silica gel BW-820-MH was used for column chromatography. Merck precoated silica gel 60 F_{254} plates, 0.25 mm thickness, were used for analytical thin-layer chromatography. Unless otherwise stated, materials were obtained from commercial suppliers and used without further purification. Trityl tetrafluoroborate (Ph_3CBF_4)[6] and trityl perchlorate (Ph_3CClO_4)[7] were purified by the reported procedures, respectively. Dichloromethane was freshly distilled from CaH_2. Methanol was distilled from magnesium methoxide. The organic solutions obtained by extractive workup were washed with saturated brine, dried over anhydrous sodium sulfate, and concentrated with a rotary evaporator under reduced pressure.

1-[(Methylthio)methoxy]tricyclo[3.3.1.1^{3,7}]decane (1). A mixture of tricyclo[3.3.1.1^{3,7}]decan-1-ol (**2**) (200 mg, 1.32 mmol), dimethyl sulfoxide (2.5 mL), and acetic anhydride (2.5 mL) was stirred at room temperature for 19 h and then 40 °C for 4 h.[2b] After cooling, the mixture was concentrated in vacuo and the resulting oily residue was purified by column chromatography on silica gel (1 : 1 benzene–ethyl acetate) to give **1** (141 mg, 51%) as a colorless oil: IR 1450, 1355, 1300, 1070, 1035 cm^{-1}; ^1H NMR δ=4.60 (s, 2H), 2.0—2.3 (m, 3H), 2.19 (s, 3H), 1.86 (m, 6H), 1.64 (m, 6H); EIMS *m/z* (rel intensity) 212 (M^+; 7), 182 (9), 165 (5), 152 (10), 136 (15), 135 (100), 95 (28), 79 (16). HREIMS. Found: *m/z* 212.1252. Calcd for $C_{12}H_{20}OS$: M, 212.1235.

Cleavage Reaction of 1 with Ph_3CBF_4. A. Quenching with Saturated $NaHCO_3$ Solution. To a stirred solution of **1** (93 mg, 0.44 mmol) in dichloromethane (4 mL) under nitrogen was added Ph_3CBF_4 (152 mg, 0.46 mmol) at room temperature. After being stirred for 15 min at room temperature, the reaction mixture was diluted with saturated $NaHCO_3$ solution (3 mL) and the mixture was stirred for 10 min and extracted with chloroform (3×10 mL). The combined organic layers were washed with saturated $NaHCO_3$ solution and saturated brine, dried and concentrated. The crude product was purified by column chromatography on silica gel (2 : 1 hexane–chloroform→chloroform) to provide 1-adamantanol (**2**) (59 mg, 88%), trityl alcohol (**6**) (92 mg, 77%), and methyl trityl sulfide (**8**) (22 mg, 16%). The spectral (IR , ^1H NMR, MS) properties of these compounds were identical with those of the authentic samples, respectively.

B. Quenching with MeOH Prior to Aqueous Work Up. After reaction of **1** (82 mg, 0.39 mmol) with Ph_3CBF_4 (134 mg, 0.41 mmol) in dichloromethane (4 mL) for 10 min at room temperature, the reaction mixture was diluted with MeOH (1 mL). After being stirred for 10 min at room temperature, the mixture was diluted with H_2O (5 ml) and extracted with chloroform (4×7 mL). The combined organic solutions were washed with saturated $NaHCO_3$ solution and saturated brine, dried, and concentrated. Purification of the resulting crude product by column chromatography on silica gel (2 : 1 hexane–chloroform→chloroform) afforded **2** (51 mg , 87%), 1-(methoxymethoxy)tricyclo-[3.3.1.1^{3,7}]decane (**3**) (8 mg, 11%), methyl trityl ether (**7**) (93 mg, 84%), and **8** (9 mg, 8%). **3**: A colorless oil; IR 1455, 1355, 1145, 1035, 910 cm^{-1} ^1H NMR δ=4.77 (s, 2H), 3.37 (s, 3H), 2.0—2.3 (m, 3H), 1.82 (m, 6H), 1.63 (m, 6H); EIMS *m/z* (rel intensity) 196 (M^+; 76), 166 (37), 139 (47), 135 (100), 109 (78), 107 (63), 95 (44), 79 (33). HREIMS. Found: *m/z* 196.1491. Calcd for $C_{12}H_2O_2$: M, 196.1463.

Cleavage Reaction of 1 with Ph_3CClO_4. To a stirred solution of **1** (44 mg, 0.21 mmol) in dichloromethane (2 mL) under nitrogen was added Ph_3CClO_4 (78 mg, 0.23 mmol) at room temperature. After being stirred for 30 min, the reaction mixture was diluted with saturated $NaHCO_3$ solution (3 mL). The mixture was vigorously stirred for 10 min and extracted with chloroform (4×10 mL). The combined organic solutions were washed, dried and concentrated. Purification of the crude residue by column chromatography on silica gel (2 : 1 hexane–chloroform→chloroform) provided **2** (27 mg, 85%), **6** (44 mg, 75%), and **8** (17 mg, 25%).

We are deeply indebted to Professor Kiyoyuki Yamada for the valuable discussions and the encouragement for the present research.

Preparation of Pyrazoles Using Hydrazyl Radicals Initiated by DPPH

Nobutoshi YOSHIHARA,* Tadashi HASEGAWA, and Sadao HASEGAWA
Department of Chemistry, Tokyo Gakugei University, Nukuikitamachi, Koganei, Tokyo 184
(Received September 28, 1990)

Synopsis. Hydrazyl radicals, initiated by DPPH, reacted with α,β-unsaturated ketones without any good leaving group on their β-positions to yield pyrazoles regioselectively.

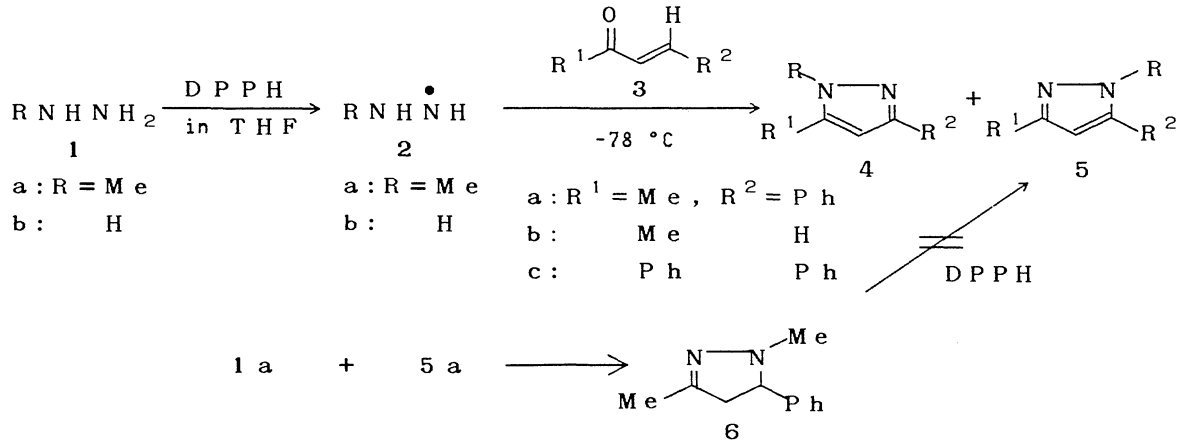
Recently, though free radicals have been actively used as intermediates in organic synthesis.[1] only a little is known about the application of such a reaction to the synthesis of heteroaromatics. The physical properties of these hydrazyl radicals have been well studied;[2,3] nevertheless, these radicals have not been used in any successful organic synthesis. The hydrazyl radicals can be expected to be useful as synthetic intermediates for introducing a nitrogen-nitrogen chromophore in the synthesis of such heteroaromatics as pyrazoles, which are important and useful compounds in organic and drug synthesis.[4] The widely accepted methods for the synthesis of pyrazoles involve the reaction of hydrazines with bifunctional compounds, such as 1,3-diketones[5] or α,β-unsaturated ketones with good leaving groups on their β-positions.[5] Unsaturated ketones without any good leaving group on their β-positions have been scarecely used in the synthesis of pyrazoles. We report here on a novel, convenient method for the synthesis of pyrazoles using hydrazyl radicals, initiated by 2,2-diphenyl-1-picrylhydrazyl (DPPH), and simple α,β-unsaturated ketones without any good leaving groups on the β-positions.

The reaction of methylhydrazine (**1a**) with 4-phenyl-3-buten-2-one (**3a**) in the presence of DPPH at −78 °C proceeded resioselectively to give 1,5-dimethyl-3-phenyl-1*H*-pyrazole (**4a**) in 12% yield. Only a trace amount of an isomeric pyrazole, 1,3-dimethyl-5-phenyl-1*H*-pyrazole (**5a**), was detected. Similarly, the reaction of **1a** with 3-buten-2-one (**3b**) under the same conditions gave dimethylpyrazoles **4b** and **5b** in 50 and 7% yields, respectively. The reaction of **1a** with 1,3-diphenyl-2-propen-1-one (**3c**) under the same conditions also gave 1-methyl-3,5-diphenyl-1*H*-pyrazole (**4c**) in 30% yield. The structures of the pyrazoles, **4a—c** and **5a—b**, were determined by a comparison with authentic samples.[6-8]

In these pyrazole formations, the role of DPPH is quite important. No pyrazoles were produced when DPPH was absent. Methylhydrazine did not react with **5a** at −78 °C. When a mixture of **1a** and **3a** was refluxed in benzene, 1,3-dimethyl-5-phenyl-2-pyrazoline (**6**) was obtained in 92% yield. The structure of the pyrazoline **6** was determined by a comparison with an authentic sample.[9] The pyrazoline **6** may be considered to be a precursor of the pyrazoles. However, this idea can be excluded for the following reasons: 1) The resioselectivity of pyrazoline formation is completely reversed to that in the pyrazole formation. The dehydrogenation of the pyrazoline **6** should give a minor isomer of the pyrazoles **5a**. 2) When **6** was stirred with DPPH, no pyrazoles were formed. Pyrazoline formation can be explained in terms of the 1,2-addition of the hydrazine **1a** to the α,β-unsaturated ketones **3** followed by cyclization and dehydration.

Table 1. Yields of the Reaction of **1** with **3** in the Presence of DPPH

	R	R^1	R^2	Yield/%	
				4	**5**
a	Me	Me	Ph	12	Trace
b	Me	Me	H	50	7
c	Me	Ph	Ph	30	
d	H	Me	Ph	27	
e	H	Me	H	24	
f	H	Ph	Ph	23	



Scheme 1.

The behavior of **1a** in the pyrazole formation should be quite different from that in pyrazoline formation. When **1a** was added to a THF solution of DPPH, a purple color characteristic of the DPPH radical in THF changed to the brown characteristic of $DPPH_2$. This implies that DPPH abstracts hydrogen from **1a** to form $DPPH_2$ and the 2-methylhydrazyl radical. Both of the hydrogens on and N_1 and N_2 in 1-methylhydrazine (**1a**) may be abstractable by DPPH. However, sterically less hindered hydrogen on N_2 seems to be predominantly abstracted by the sterically hindered DPPH radical. The 2-methylhydrazyl radical (**2a**) is probably an intermediate in pyrazole formation. The quite different regioselectivlty in pyrazole formation from that in a normal Michael addition[10] can be reasonably explained in terms of the addition of radical **2a** to the β-position of enones.

Hydrazine itself (**1b**) could also be used as a radical precursor. The hydrazyl radical (**2b**) was easily prepared by the addition of DPPH to a THF solution of **1b** at −78 °C. The reactions of **2b** with the enones **3a**, **3b**, and **3c** gave the corresponding pyrazoles **4d**, **4e**, and **4f** in 27, 24, and 23% yields, respectively. The structures of **4d—f** were determined by a comparison with authentic samples.[1]

The hydrazyl radicals, initiated easily and rapidly by DPPH, reacted with simple α,β-unsaturated ketones without any good leaving group on their β-positions. The hydrazyl radicals can be used as reagents for introducing a nitrogen-nitrogen chromopher in the synthesis of heteroaromatics.

Experimental

General Procedure for Preparation of Pyrazoles. To the solution of a hydrazine (0.75—1.5 mmol) dissolved in 30 cm^3 of THF and cooled to −78 °C, was added DPPH (0.75—1.5 mmol) with stirring. The mixture was cooled to −78 °C and added dropwise to a solution of enones (0.5—1 mmol) in 50 cm^3 of THF at −78 °C. The mixture was stirred for 2 h at the same temperature. After concentration in vacuo, the residue was chromatographed on a silica-gel column (Merck Kieselgel 60). Elution with benzene or a mixture of benzene–ethyl acetate gave **4** and/or **5**. The structures of **4a-f** and **5a-b** were determined by a comparison with direct comparisons with authentic samples.[6,7,8,11]

Preparation of 1,3-Dimethyl-5-phenyl-2-pyrazoline (6). A solution of benzalacetone (0.50 g, 3.4 mmol) and methylhydrazine (0.51 g, 4.7 mmol) in 50 cm^3 of benzene was refluxed overnight. The mixture was poured into water and extracted three times with 30 cm^3 of dichloromethane. The dichloromethane solution was washed with water and then dried over magnesium sulfate. After filtration and removal of the solvent, the residue was chromatographed on a silica-gel column (Merck Kieselgel 60). Elution with benzene gave **6** (0.54 g, 3.1 mmol, 92%): 131 °C/25 mmHg (lit,[9] 123—4 °C/20 mmHg) (1 mmHg=133.322 Pa). The structure of **6** was determined by a comparison with an authentic sample.[9]

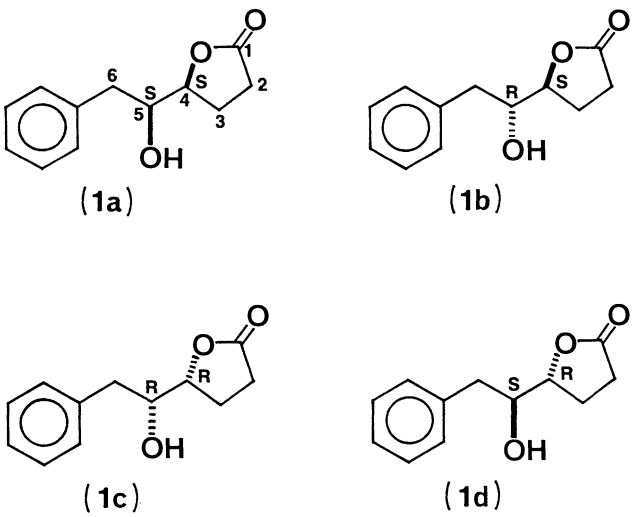
(Received October 1, 1990)

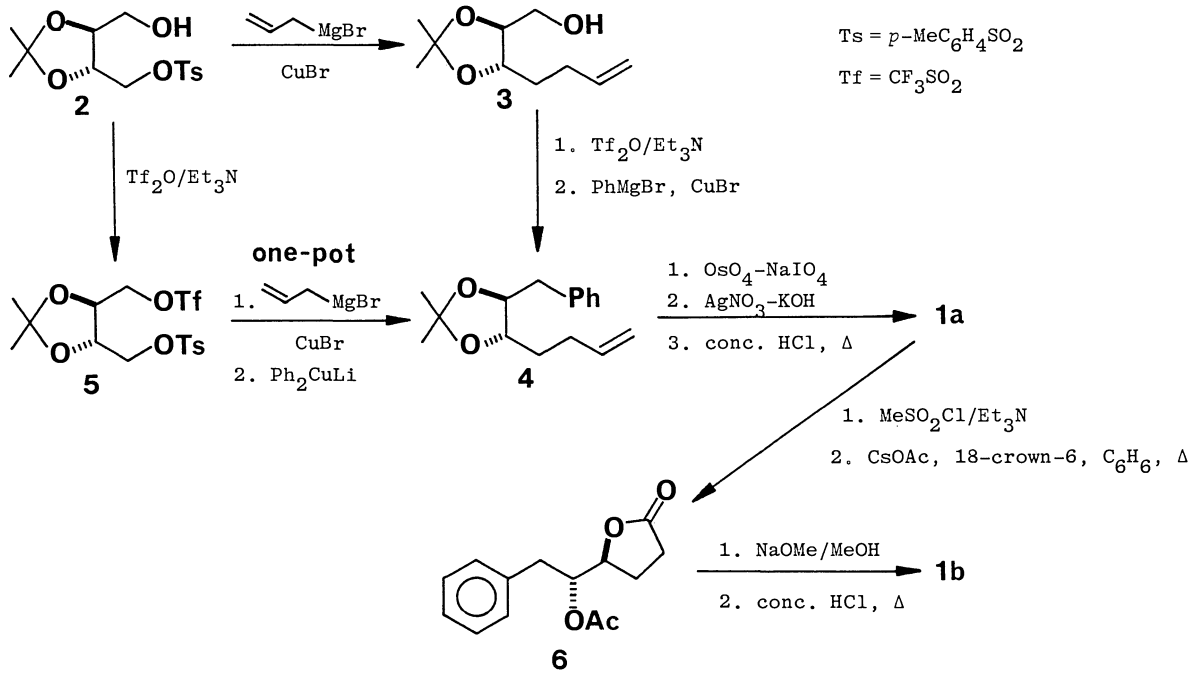
Synopsis. Lateral root-inducing compounds, isolated from the bacterium *Erwinia quercina*, have been synthesized by using a coupling reaction of chiral triflates derived from L- or D- tartrates and their biological activities examined.

Recent studies in our laboratories have revealed that the copper(I)-catalyzed coupling reaction of chiral trifluoromethanesulfonates (triflates) with Grignard reagents is a powerful technique to synthesize optically active natural products.[1] As an extension of these studies, we herein wish to describe a new versatile strategy towards lateral root-inducing compounds isolated from the bacterium *Erwinia quercina*.[2] Sims et al. reported that these compounds are a mixture of two diastereomers of 4,5-dihydroxy-6-phenylhexanoic acid; synthetically, they confirmed that all four possible chiral isomers possess biological activity.[2] However, their synthesis involves a non-stereoselective reduction step and, hence, requires an unavoidable separation stage from the diastereomeric mixture. Compared with this example, our route is of great advantage for deriving these compounds in complete enantioselectivity while providing a rapid means for bioassay.[3]

A concise route to (4*S*,5*S*)- and (4*S*,5*R*)-isomers (**1a** and **1b**)[4] is shown in Scheme 1. Utilizing the strategy already developed in these laboratories,[1d] mono-*p*-toluenesulfonate (tosylate) **2** was converted into the key intermediate **4** either stepwise or by a one-pot double alkylation method.

Thus, the reaction of **2** with allylmagnesium bromide (7 equiv) in the presence of a catalytic amount of CuBr produced **3** in 83% yield. Triflation followed by treatment with PhMgBr (3 equiv)-CuBr gave the





Scheme 1.

required intermediate **4** in 71% yield. Alternatively, after conversion of **2** into the corresponding tosyltriflate derivative **5**, one-pot double alkylation first with allylmagnesium bromide (1.1 equiv)-CuBr (at 0 °C for 1 h) and secondly with Ph_2CuLi (3.0 equiv) (at −15 °C for 4 h) afforded **4** in 33% yield from **2**. In contrast to the stepwise method, unfortunately, this one-pot double alkylation procedure could not improve so much the overall yield. This, however, does not loose its synthetic superiority from the viewpoint of the experimental simplicity as well as the economical usage of two kinds of alkylating agents.

The double bond in **4** was smoothly oxidized to the corresponding carboxylic acid (OsO_4-$NaIO_4$ then $AgNO_3$-KOH), which underwent lactonization under acidic conditions to give the (4*S*,5*S*)-isomer (**1a**) {$[\alpha]_D^{21}$ +59.8° (*c* 1.04, $CHCl_3$); lit,[2] $[\alpha]_D$ +49.06° (*c* 1.28, $CHCl_3$)} in 91% yield from **4**. Applying the Ikegami's inversion technique,[5] **1a** was efficiently converted into acetate **6**, which was further treated with NaOMe in MeOH to afford the (4*S*,5*R*)-isomer (**1b**) {$[\alpha]_D^{20}$ +34.0° (*c* 0.96, $CHCl_3$); lit,[2] $[\alpha]_D$ +29.22° (*c* 0.84, $CHCl_3$)} in 69% yield from **1a**.

The application of the same synthetic procedure on the enantiomer of **2**, available from D-tartrates, furnished the (4*R*,5*R*)-isomer (**1c**) {$[\alpha]_D^{21}$ −60.0° (*c* 0.5, $CHCl_3$); lit,[2] $[\alpha]_D$ −50.77° (*c* 0.2, $CHCl_3$) and also the (4*R*,5*S*)-isomer (**1d**) {$[\alpha]_D^{20}$ −34.2° (*c* 1.20, $CHCl_3$); lit,[2] $[\alpha]_D$ −29.23° (*c* 0.2, $CHCl_3$) in good overall yields.

A comparison of the specific rotation of our samples with literature data showed a higher optical purity for all of our chiral isomers. These results prompted us to reexamine the structure-activity relationship of these molecules.[6] However, we found that all of our compounds were active at 10^{-5} M (1 M=1 mol dm^{-3}), with only a slight difference between isomers.[7] These results are compatible with previous evidence.[2] Apparently, the stereochemistry of the compounds is not critical to the activity. One possibility is that the chirality is changed or destroyed by metabolism in the carrot discs; a bioassay required 10 days to complete. Further experiments are required to clarify this observation and to identify the actual active compound.

Experimental

All melting points are uncorrected. The NMR spectra were recorded on a Hitachi R-90H spectrometer (90 MHz for ^{1}H NMR analysis and 22.6 MHz for ^{13}C NMR analysis). All NMR spectra were taken in a $CDCl_3$ solution and tetramethylsilane was used as an internal standard. The IR spectra were measured with a JASCO Model FT/IR-5000 Fourier Transform Infrared spectrometer. High-resolution mass spectra were obtained with a JEOL HX-100 spectrometer. Optical rotations were measured on a Union PM-101 polarimeter. Thin-layer chromatography was conducted by using Merck precoated Kieselgel 60F-254 plates (0.25 mm). Column chromatography was carried out on a Wakogel C-300, and for flash chromatography, Merck Kieselgel (230—400 mesh) was employed.

All solvents were dried immediately before use. Et_2O, C_6H_6 and tetrahydrofuran (THF) were distilled from sodium diphenylketyl; dichloromethane and triethylamine were distilled from CaH_2. All Grignard and organolithium reagents were titrated before use according to methods described in the literature.[8] All reactions were carried out in a nitrogen or argon atmosphere.

Preparation of 3 from 2. To an ice-cooled suspension of CuBr (65 mg, 0.45 mmol) in 1.5 ml of dry Et_2O was added 0.39 M of an allylmagnesium bromide/Et_2O solution (5.4 ml, 2.1 mmol), followed by the introduction of an Et_2O solution (1.5 ml) of monotosylate **2** (95 mg, 0.3 mmol); the mixture was then stirred for 1 h. During the reaction a black insoluble substance was gradually formed. The reaction was quenched by the addition of aqueous NH_4Cl-aqueous NH_3 (9:1); the mixture was then filtered through Celite. The filtrate was extracted with Et_2O, and the combined extracts were washed with aqueous saturated $NaHCO_3$ and brine, and dried over Na_2SO_4. Evaporation of the solvent gave a crude product which was purified by column chromatography (C-300; from hexane/Et_2O=2:1 to 1:1) to give 46 mg (83%) of **3** as a colorless oil.

3: R_f 0.49 (Et_2O); $[\alpha]_D^{23}$ −27.1° (*c* 1.1, $CHCl_3$); IR (neat) 3500, 1644, 1054, 913, and 855 cm^{-1}; ^{1}H NMR δ=1.41 (6H, s), 1.5—1.8 (2H, m), 1.88 (1H, s), 2.05—2.4 (2H, m), 3.5—4.0 (4H, m), 4.98 (1H, brd, *J*=10.0 Hz), 5.02 (1H, brd, *J*=17.2 Hz), 5.84 (1H, ddt, *J*=17.2, 10.0, 6.5 Hz); ^{13}C NMR δ=27.03, 27.33, 29.98, 32.30, 62.06, 76.39, 81.42, 108.56, 114.87, 137.64. Found: *m/z* 186.1248. Calcd for $C_{10}H_{18}O_3$: M, 186.1256.

Enantiomer of **3**: $[\alpha]_D^{19}$ +27.3° (*c* 1.1, $CHCl_3$).

Preparation of 4 from 3. To a mixture of alcohol **3** (520 mg, 2.8 mmol) and Et_3N (1.2 ml, 8.6 mmol) in 9 ml of dry CH_2Cl_2 was added dropwise a CH_2Cl_2 solution (3 ml) of $(CF_3SO_2)_2O$ (710 μl, 4.2 mmol) at −15 °C; the mixture was then stirred for 20 min. After dilution with CH_2Cl_2, the mixture was treated conventionally. The crude product was dried azeotropically with toluene and used in the following step.

To an ice-cooled suspension of CuBr (80 mg, 0.56 mmol) in 6 ml of dry THF was added 1.6 M of PhMgBr/Et_2O solution (5.3 ml, 8.5 mmol) followed by the introduction of a THF solution (12 ml) of the triflate (obtained as mentioned above); the mixture was then stirred at 0 °C for 8 h. The reaction was quenched by the addition of aqueous NH_4Cl-aqueous NH_3 (9:1), the mixture filtered through Celite. After removing the solvent, the residue was extracted with Et_2O. After the usual workup, the crude product was purified by column chromatography (flash silica gel; hexane/Et_2O=50:1) to give 495 mg (72%) of **4** as a colorless oil.

4: R_f 0.60 (hexane/Et_2O=2:1); $[\alpha]_D^{23}$ −28.0° (*c* 2.0, $CHCl_3$); IR (neat) 2988, 2936, 1642, 1497, 1456, 1375, 1058, and 913 cm^{-1}; ^{1}H NMR δ=1.36 (6H, s), 1.2—1.6 (2H, m), 1.9—2.3 (2H, m), 2.81 (1H, dd, *J*=14.0, 5.3 Hz), 2.94 (1H, dd, *J*=14.0, 5.7 Hz), 3.55—4.0 (2H, m), 4.8—5.1 (1H, m), 5.75 (1H, ddt, *J*=17.1, 9.6, 6.1 Hz), 7.24 (5H, s); ^{13}C NMR δ=27.27, 27.39, 30.05, 32.12, 39.38, 79.87, 80.99, 108.04, 114.72, 126.33, 128.19(×2), 129.23(×2), 137.49, 137.86. Found: *m/z* 246.1601. Calcd for $C_{16}H_{22}O_2$: M, 246.1620.

Enantiomer of **4**: $[\alpha]_D^{22}$ +28.4° (*c* 2.0, $CHCl_3$).

Preparation of 5 from 2. To a mixture of monotosylate **2** (116 mg, 0.37 mmol) and Et_3N (155 μl, 1.1 mmol) in 2 ml of dry CH_2Cl_2 was added dropwise a CH_2Cl_2 solution (1 ml) of $(CF_3SO_2)_2O$ (95 μl, 0.56 mmol) at −15 °C; the mixture was then stirred for 20 min. After dilution with CH_2Cl_2, the mixture was treated conventionally and the crude tosyltriflate **5** was used in the following step, as described above.

Preparation of 4 from 5. To an ice-cooled suspension of CuBr (10 mg, 0.07 mmol) in 1.5 ml of dry Et_2O was added a 0.39 M allylmagnesium bromide/Et_2O solution (1 ml, 0.39 mmol), followed by the introduction of an Et_2O solution (0.5 ml) of tosyl-triflate **5** (obtained as mentioned above); the mixture was then stirred at 0 °C for 1 h. During the reaction, a black insoluble substance was gradually formed.

Then, Ph_2CuLi (prepared from CuI (211 mg, 1.11 mmol) and 1.19 M of PhLi/Et_2O solution (1.9 ml, 2.26 mmol) in dry Et_2O (3 ml)) was introduced at −15 °C; the mixture was then stirred at this temperature for 4 h. The reaction was quenched by the addition of aqueous NH_4Cl-aqueous NH_3 (9:1) and the mixture filtered through Celite. After the usual workup, the crude product was purified by column chromatography (flash silica gel; hexane/Et_2O=50:1) to give 30 mg (33%) of **4** as a colorless oil.

Preparation of 1a from 4. The starting material **4** (74 mg, 0.3 mmol) was dissolved in 9 ml of THF/H_2O (5:4) and an Et_2O solution of OsO_4 (5 mg in 0.5 ml) was added at room temperature. After stirring for 10 min, $NaIO_4$ (330 mg, 1.5 mmol) was added and the mixture stirred for 0.5 h. The mixture was then quenched by the addition of brine, and the conventional treatment gave a crude aldehyde which was subjected to the next reaction.

To a stirred solution of the aldehyde obtained above in 2.5 ml of MeOH were successively added $AgNO_3$ (102 mg, 0.6 mmol) in 1.5 ml of H_2O and KOH (67 mg, 1.2 mmol) in 1 ml of H_2O. After stirring for 0.5 h at 0 °C, the mixture was acidified with concentrated HCl and heated at 50 °C for 0.5 h. After removing the insoluble substance by filtration through Celite, the filtrate was concentrated in vacuo. The usual treatment of the residue gave a crude product which was purified by column chromatography (flash silica gel; from hexane/Et_2O=1:2 to Et_2O only) to give 56 mg (91%) of **1a** as a colorless oil.

1a: R_f 0.26 (Et_2O); $[\alpha]_D^{21}$ +59.8° (*c* 1.04, $CHCl_3$); IR (neat) 3500, 1769, and 1191 cm^{-1}; ^1H NMR δ=2.0—2.4 (2H, m), 2.4—2.7 (2H, m), 2.58 (1H, s), 2.91 (2H, d, *J*=7.0 Hz), 3.80 (1H, dt, *J*=6.8, 3.1 Hz), 4.42 (1H, dt, *J*=7.1, 3.3 Hz), 7.27 (5H, s); ^{13}C NMR δ=23.92, 28.55, 39.89, 74.26, 81.21, 126.61, 128.53(×2), 129.26(×2), 137.19, 177.43. Found: *m/z* 206.0932. Calcd for $C_{12}H_{14}O_3$: M, 206.0943.

1c, enantiomer of **1a**: $[\alpha]_D^{21}$ −60.0° (*c* 0.5, $CHCl_3$).

Preparation of 1b from 1a. To an ice-cooled mixture of alcohol **1a** (65 mg, 0.32 mmol), Et_3N (88 µl, 0.63 mmol) and a catalytic amount of 4-(dimethylamino)pyridine in 3.0 ml of dry CH_2Cl_2 was added methanesulfonyl chloride (30 µl, 0.39 mmol); the mixture was then stirred at room temperature for 1 h. The usual workup gave a crude methanesulfonate which was used without further purification in the following step.

A mixture of the methanesulfonate (obtained as mentioned above), CsOAc (200 mg, 1.0 mmol) and 18-crown-6 (100 mg, 0.38 mmol) was refluxed in dry C_6H_6 (9 ml) for 12 h. After dilution with Et_2O, the organic layer was treated conventionally and the crude product was purified by column chromatography (flash silica gel; hexane/Et_2O=1:2) to give 56 mg (71%) of acetate **6** as colorless needles (recrystallized from Et_2O-hexane).

6: Mp 75.0—76.0 °C; R_f 0.40 (Et_2O); $[\alpha]_D^{19}$ +43.1° (*c* 0.52, $CHCl_3$); IR ($CHCl_3$) 1779, 1744, 1236, and 1044 cm^{-1}; ^1H NMR δ=2.00 (3H, s), 2.1—2.4 (2H, m), 2.4—2.7 (2H, m), 2.91 (1H, dd, *J*=14.3, 6.6 Hz), 2.98 (1H, dd, *J*=14.3, 6.6 Hz), 4.47 (1H, dt, *J*=6.6, 5.1 Hz), 5.28 (1H, dt, *J*=6.6, 4.8 Hz), 7.24 (5H, m). Found: C, 67.77; H, 6.51%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50.

Enantiomer of **6**: Mp 74.5—75.0 °C; $[\alpha]_D^{19}$ −41.8° (*c* 1.3, $CHCl_3$).

Preparation of 1b from 6. To a solution of acetate **6** (80 mg, 0.32 mmol) in 5 ml of absolute MeOH was added 0.4 M NaOMe/MeOH (1 ml, 0.4 mmol) at 0 °C and the mixture was stirred at the same temperature for 1 h. At the end of the reaction the mixture was acidified with concentrated HCl and heated at 50 °C for 0.5 h. After removing most of the organic solvent, the residue was extracted with AcOEt. The usual workup gave a crude product which was purified by column chromatography (flash silica gel, hexane/Et_2O=1:4) to afford 64 mg (97%) of **1b** as colorless needles (recrystallized from Et_2O-hexane).

1b: Mp 60.0—61.0 °C (lit,[2] 59—60 °C); R_f 0.30 (Et_2O); $[\alpha]_D^{20}$ +34.0° (*c* 0.96, $CHCl_3$); IR ($CHCl_3$) 3434, 1775, and 1187 cm^{-1}; ^1H NMR δ=1.8—2.7 (6H, m), 4.10 (1H, ddd, *J*=7.7, 5.7, 4.4 Hz), 4.41 (1H, dt, *J*=7.0, 4.0 Hz), 7.27 (5H, m); ^{13}C NMR δ=21.60, 28.49, 39.01, 72.52, 81.85, 126.64, 128.53(×2), 129.14(×2), 136.94, 177.37. Found: C, 69.89; H, 6.86. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84.

1d, enantiomer of **1b**: Mp 58.0—60.5 °C; $[\alpha]_D^{20}$ −34.2° (*c* 1.20, $CHCl_3$).

The authors are grateful to Dr. Ayumi Ohsaki of Kinki University for the measurements of high-resolution mass spectra. We also thank Central Glass Co., Ltd., for partial support of this work.

Photoinduced Intramolecular Cyclization Reaction of 2-(2-Alkenoyl)-3-isopropylthio-1,4-benzoquinones to Heterocyclic Compounds

Hidetoshi IWAMOTO* and Akio TAKUWA
Department of Chemistry, Faculty of Science, Shimane University, Matsue 690
(Received October 8, 1990)

Synopsis. Irradiation of 2-acryloyl- and 2-(1-cycloalkenylcarbonyl)-3-isopropylthio-1,4-benzoquinones in benzene gave tricyclic and tetracyclic compounds in good yields, respectively.

We recently reported that photochemical reactions of 3-alkoxy- (**1**, X=O)[1] and 3-alkylthio-2-cinnamoyl-1,4-benzoquinones (**1**, X=S)[2] give tricyclic compounds (**5**, X=O or S) in good yields together with other minor secondary products.[2,3] In these reactions, the biradical intermediate **2** generated by an intramolecular hydrogen abstraction of **1** easily cyclizes with the carbonyl oxygen of the cinnamoyl group to give another cyclic intermediate **3**; it finally yields the tricyclic product **5** (Eq. 1).[1,2] For an extension of this cyclization reaction, we examined the photochemical reaction of 2-acryloyl- (**6**) and 2-(1-cycloalkenylcarbonyl)-3-isopropylthio-1,4-benzoquinones (**11**).

X=O or S; R^1=R^2=H, R^1=Me, R^2=H, R^1=R^2=Me

Results and Discussion

Irradiation of a benzene solution of **6** (0.01 mol dm^{-3}) with light of wavelength longer than 410 nm under a nitrogen atmosphere for 1 h afforded a mixture of **7**, **8**, **9**, and/or **10** (Eq. 2, Table 1), which were separated by column chromatography on silica gel. The tricyclic product **7** was a major product. A structural identification of these products was elucidated by spectral analyses and a chemical transformation. For example, the IR spectrum of **7** showed the presence of a hydroxyl group at ca. 3500 cm^{-1} and the absence of a carbonyl group. The ^{1}H NMR spectrum of **7** showed the presence of two methyl groups arising from the isopropylthio group at δ ca. 1.69 (6H, s), and also suggested a change in the alkenoyl group to the corresponding enol type, as shown in the Experimental section. The ^{1}H NMR spectra of **8** and **9** also agreed with the proposed structures (Experimental section).

c: R^1=R^2=R^2=Me; **d**: R^1=R^3=H, R^2=Me;
e: R^1=H, R^2=R^3=Me

On the basis of the following results and a comparison with the reaction of **1**,[2,3] products **8** would be oxidation products of **7**, and **9** would be an isomerization product of **7**. As shown in Table 1, the formation of **8** was always accompanied by hydroquinone **10** (Runs 1, 2, and 4). These results indicate that the quinone **6** oxidized product **7** to give **8**, together with

Table 1. Photochemical Reaction of **6**

Run	Quinone	Substituents			Yields of prodicts/%[a]			
		R^1	R^2	R^3	**7**	**8**	**9**	**10**
1	**6a**	Me	H	H	80	11	0	6
2	**6b**	Me	Me	H	82	10	0	5
3	**6c**[b]	Me	Me	Me	79	0	0	0
4	**6d**[b]	H	Me	H	49	17	11	14
5	**6e**[b]	H	Me	Me	77	0	8	0

a) Isolated yields based on the quinone used. b) The starting quinones **6c**, **6d**, and **6e** were recovered in 9%, 4%, and 12% yields, respectively.

10. The amount of **8** is always greater than that of hydroquinone **10** (Runs 1, 2, and 4), suggesting that product **7** can also be oxidized with air.

Since hydrogen at the R^3-position of **7a**, **b**, or **d** is situated in both the allylic and α-alkoxyl positions, it should easily be abstracted by the quinone.[4] This idea is supported by the fact that **7c** and **e**, which have no hydrogen at R^3-position, afforded neither **8** nor **10** (Runs 3 and 5).

Product **9** was observed only in the reactions of **6d** and **e** (Runs 4 and 5). Therefore, products **7d** and **e**, which have a hydrogen at the R^1-position, may be less stable than **7a**, **b**, and **c**, which have a methyl group (Runs 1, 2, and 3).[5]

Irradiation of **11** under the same conditions gave the corresponding tetracyclic product **12** in good yield together with **13** and **15** (Eq. 3, Table 2). Since the structures of **11a—c** agreed with the type of **6b**, the isomerization product **14** was not obtained.[5] The amounts of the oxidation products, **13b** and **c**, were larger than that of **13a**. This result indicates that products **12b** and **c**, which have a six- or seven-membered ring, are more reactive than **12a**, which has a five-membered ring.[6]

Table 2. Photochemical Reaction of **11**

Run	Quinone	$(CH_2)_n$ n	Yields of products/%[a]			
			12	**13**	**14**	**15**
6	**11a**	1	90	5	0	4
7	**11b**	2	63	21	0	14
8	**11c**	3	69	20	0	10

a) Isolated yields based on the quinone used.

In any event, these cyclization paths can be consistently explained by a modification of Eq. 1, and the irradiation of 2-(2-alkenoyl)-3-isopropylthio-1,4-benzoquinones which have an α,β-unsaturated carbonyl group as an alkenoyl side chain, should generally give the corresponding cyclization product in good yield.

Experimental

All of the melting points are uncorrected. The ^{1}H NMR spectra were measured using a JEOL JNM-GX 270 spectrometer in $CDCl_3$ using TMS. The IR (CCl_4) spectra were recorded on a Hitachi 260-50 spectrometer. Elemental analyses (C and H) were agreed within ±0.3%.

Quinones **6** and **11** were prepared by modified methods of Farina and Valderrama[7] and Jacob et al.,[8] as described in a previous paper.[2] The characteristic physical properties of **6** and **11** are described.

3-Isopropylthio-3-methacryloyl-5-methyl-1,4-benzoquinone (6a): Red oil; IR (CCl_4) 1660 cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$) δ=1.24 (6H, d, J=6.8 Hz, SCHMe$_2$), 2.01 (3H, dd, J=1.5 and 0.7 Hz, COCMe=CH$_2$), 2.12 (3H, d, J=1.7 Hz, CH=CMe), 3.96 (1H, m, J=6.8 Hz, SCHMe$_2$), 5.74 (1H, m, J=0.7 Hz, COCMe=CHH), 6.02 (1H, m, J=1.5 Hz, COCMe=CHH), 6.61 (1H, q, J=1.7 Hz, CH=CMe). Anal. ($C_{14}H_{16}O_3S$) C, H.

6b: Red oil; IR 1675 cm^{-1}; ^{1}H NMR δ=1.89 (3H, d, J=7.3 Hz), 1.90 (3H, d, J=1.7 Hz), 6.47 (1H, mq, J=7.3 and 1.7 Hz). Anal. ($C_{15}H_{18}O_3S$) C, H.

6c: Red oil; IR 1665 cm^{-1}; ^{1}H NMR δ=1.85 (3H, d-like, J=1.2 Hz), 1.91 (3H, s), 2.11 (3H, d-like, J=1.2 Hz). Anal. ($C_{16}H_{20}O_3S$) C, H.

6d: Orange prisms, mp 70—72 °C; IR 1670 cm^{-1}; ^{1}H NMR δ=1.96 (3H, dd, J=6.8 and 1.5 Hz), 6.28 (1H, dq, J=15.9 and 1.5 Hz), 6.71 (1H, dq, J=15.9 and 6.8 Hz). Anal. ($C_{14}H_{16}O_3S$) C, H.

6e: Orange prisms, mp 55—56 °C; IR 1650 cm^{-1}; ^{1}H NMR δ=1.95 (3H, d, J=1.2 Hz), 2.25 (3H, d, J=1.0 Hz), 6.11 (1H, m). Anal. ($C_{15}H_{18}O_3S$) C, H.

2-(1-Cyclopentenylcarbonyl)-3-isopropylthio-5-methyl-1,4-benzoquinone (11a): Orange needles, mp 87—89 °C; IR 1660 cm^{-1}; ^{1}H NMR δ=1.95—2.10 (2H, m, J=7.6 Hz), 2.50—2.75 (4H, m), 6.54 (1H, ms). Anal. ($C_{16}H_{18}O_3S$) C, H.

11b: Orange prisms, mp 78—80 °C; IR 1670 cm^{-1}; ^{1}H NMR δ=1.6—1.75 (4H, m), 2.23 (2H, bs), 2.36 (2H, bs), 6.63 (1H, ms). Anal. ($C_{17}H_{20}O_3S$) C, H.

11c: Orange prisms, mp 67—69 °C ; IR 1660 cm^{-1}; ^{1}H NMR δ=1.52—1.62 (4H, m), 1.75—1.85 (2H, m), 2.30—2.40 (2H, m), 2.60—2.65 (2H, m), 6.79 (1H, t J=6.6 Hz). Anal. ($C_{18}H_{22}O_3S$) C, H.

Photochemical Reaction of 6. A solution of **6** (0.3 mmol) in 30 cm^3 of benzene was degassed under reduced pressure and replaced with N_2, and then irradiated with a 300-W halogen lamp through a yellow glass filter (<410 nm cut off) at room temperature for 1 h. After irradiation, the solvent was removed in vacuo and the resulting oil chromatographed on a silica-gel column with benzene as the eluent. The first yellow component was **7** and/or **9**, the second was **8**, and the third was **10**. The yields of products **7**, **8**, **9**, and **10** are summarized in Table 1.

2,2,4,8-Tetramethyl-5*H*-pyrano[4,3,2-*de*][3,1]benzoxathiin-9-ol (7a): Oil; IR 3500, 1670 (w), 1180 cm^{-1}; ^{1}H NMR δ=1.69 (6H, s, 2-Me$_2$), 1.70 (3H, d, J=1.2 Hz, 4-Me), 2.18 (3H, s, 8-Me), 4.65 (1H, bs, 9-OH), 4.70 (2H, bs, 5-H$_2$), 6.41 (1H, s, 7-H).

2,2,4,8-Tetramethyl-9*H*-oxathiolo[4,5-*f*][1]benzopyran-9-one (8a): Pale yellow prisms, mp 131—132 °C; IR 1650, 1430 cm^{-1}; ^{1}H NMR δ=1.85 (6H, s, 2-Me$_2$), 1.99 (3H, d, J=1.0 Hz, 8-Me), 2.29 (3H, s, 4-Me), 6.86 (1H, s, 5-H), 7.67 (1H, q, J=1.0 Hz, 7-H). Anal. ($C_{14}H_{14}O_3S$) C, H.

7b: Oil; IR 3510, 1665 (w), 1180 cm^{-1}; ^{1}H NMR δ=1.34 (3H, d, J=6.6 Hz), 1.62 (3H, s), 4.65 (1H, s), 4.82 (1H, q, J=6.6 Hz).

8b: Pale yellow needles, mp 182-183 °C; IR 1635, 1430 cm^{-1}; ^{1}H NMR δ=2.01 (3H, s), 2.35 (3H, s). Anal. ($C_{15}H_{16}O_3S$) C, H.

7c: Oil; IR 3510, 1650 (w), 1185 cm^{-1}; ^{1}H NMR δ=1.40 (6H, s), 1.74 (3H, s), 4.47 (1H, s).

9c: Pale yellow oil; IR 1680, 1610, 1420 cm^{-1}; ^{1}H NMR δ=1.19 (3H, d, J=7.1 Hz), 1.27 (3H, s), 1.46 (3H, s), 2.67 (1H, q, J=7.1 Hz). Anal. ($C_{16}H_{20}O_3S$) C, H.

7d: Oil; IR 3500, 1670 (w), 1185 cm^{-1}; ^1H NMR δ=1.42 (3H, d, J=6.3 Hz), 4.73 (1H, bs), 5.00 (1H, d, J=3.2 Hz), 5.00—5.10 (1H, m, 5-H).

8d: Pale yellow needles, mp 140—141 °C; IR 1650, 1420 cm^{-1}; ^1H NMR δ=2.31 (3H, s), 6.05 (1H, s). Anal. ($C_{14}H_{14}O_3S$) C, H.

2,2,4,7-Tetramethyl-7*H*-oxathiolo[4,5-*f*][1]benzopyran-9(8*H*)-one (9d): Pale yellow prisms, mp 94—95 °C; IR 1685, 1615, 1415 cm^{-1}; ^1H NMR δ=1.47 (3H, d, J=6.3 Hz, 7-Me), 1.81 (6H, s, 2-Me_2), 2.19 (3H, d, J=0.7 Hz, 4-Me), 2.55—2.70 (2H, m, 8-H_2), 4.40—4.55 (1H, m, 7-H), 6.43 (1H, q, J=0.7 Hz, 5-H).

7e: Oil, IR 3500, 1645 (w), 1185 cm^{-1}; ^1H NMR δ=1.42 and 1.43 (6H, each s), 4.55 (1H, s), 4.99 (1H, s).

9e: Pale yellow prisms, mp 118—119 °C; IR 1680, 1615, 1415 cm^{-1}; ^1H NMR δ=1.41 (6H, s), 2.55 (2H, s). Anal. ($C_{15}H_{18}O_3S$) C, H.

A photochemical reaction of **11** was similarly carried out for **6** described above. On the column, the first yellow component was **12**, the second was **13**, and the third was **15**. The yields of products **12**, **13**, and **15** are summarized in Table 2.

2,2,5-Trimethyl-7a,8,9,10-tetrahydrocyclopenta[5,6]-pyrano[4,3,2-*de*][3,1]benzoxathiin-4-ol (12a): Oil; IR 3500, 1680 (w), 1180 cm^{-1}; ^1H NMR δ=1.55—2.0 (4H, m), 2.25—2.60 (2H, m), 4.75 (1H, bs), 5.07 (1H, t-like).

2,2,4-Trimethyl-7,8,9,10-tetrahydrocyclopenta[*b*][3,1]-oxathiolo[4.5-*f*][1]benzopyran-10-one (13a): Yellow needles, mp 236—238 °C; IR 1630, 1440 cm^{-1}; ^1H NMR δ=2.09 (2H, m, 7.5 Hz), 2.81 (2H, t-like, J=7.5 Hz), 2.92 (2H, t-like, J=7.5 Hz). Anal. ($C_{16}H_{16}O_3S$) C, H.

12b: Oil; IR 3500, 1665 (w), 1185 cm^{-1}; ^1H NMR δ=1.15—1.45 (2H, m), 1.55—1.90 (4H, m), 2.15—2.25 (1H, m), 2.95 (1H, bd, J=14.0 Hz), 4.55 (1H, s), 4.92 (1H, dd, J=11.0 and 5.4 Hz).

13b: Pale yellow needles, mp 149—151 °C; IR 1630, 1430 cm^{-1}; ^1H NMR δ=1.65—1.9 (4H, m), 2.51 (2H, t-like, J=6.3 Hz), 2.59 (2H, t-like, J=6.3 Hz). Anal. ($C_{17}H_{18}O_3S$) C, H.

12c: Oil; IR 3500, 1645 (w), 1190 cm^{-1}; ^1H NMR δ=1.5—2.1 (7H, m), 2.65—2.75 (1H, m), 4.70 (1H, s), 4.92 (1H, dd, J=6.5 and 3.5 Hz).

13c: Pale yellow prisms, mp 173—174 °C; IR 1615, 1420, 1205 cm^{-1}; ^1H NMR δ=1.55—1.9 (6H, m), 2.70—2.80 (4H, m). Anal. ($C_{18}H_{20}O_3S$) C, H.

Indium-Induced Reaction of Phenacyl Iodide. Deiodinative Dimerization to β,γ-Epoxy Ketone and Aldol Condensation with Aldehydes

Shuki ARAKI* and Yasuo BUTSUGAN
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466
(Received October 15, 1990)

Synopsis. The reaction of phenacyl iodide with indium metal gave 3,4-epoxy-1,3-diphenyl-1-butanone which, on treatment with silica gel, gave 2,4-diphenylfuran and 2,4-diphenyl-4-oxobutanal. Metallic indium as well as indium(I) iodide were found to mediate the aldol condensation between α-halo ketone and aldehyde.

We have recently reported that activated halides such as allylic halides[1] and α-iodoacetate[2] react with metallic indium to form organoindium compounds and these reagents have been proved to be useful in organic synthesis. In order to extend the synthetic utility of organoindium reagents, we have studied the generation and reaction of indium enolates of ketones. We describe here the reaction of phenacyl iodide with indium metal which leads to a β,γ-epoxy ketone. The same reaction in the presence of an aldehyde gave aldol condensation products. The aldol reaction using indium(I) iodide is also described.

An exothermic reaction of phenacyl iodide and indium powder took place in DMF at room temperature. Aqueous workup and distillation gave 3,4-epoxy-1,3-diphenyl-1-butanone (**1**) (57% yield) together with small amounts (<3%) of acetophenone and 1,2-dibenzoylethane. The epoxy ketone **1** is acid-labile; by adsorption on silica gel, **1** was completely converted to 2,4-diphenylfuran (**2**) and 2,4-diphenyl-4-oxobutanal (**3**), in 40 and 48% yields, respectively. The above transformations are illustrated in Scheme 1, in which the indium enolate **4** is postulated as an intermediate.

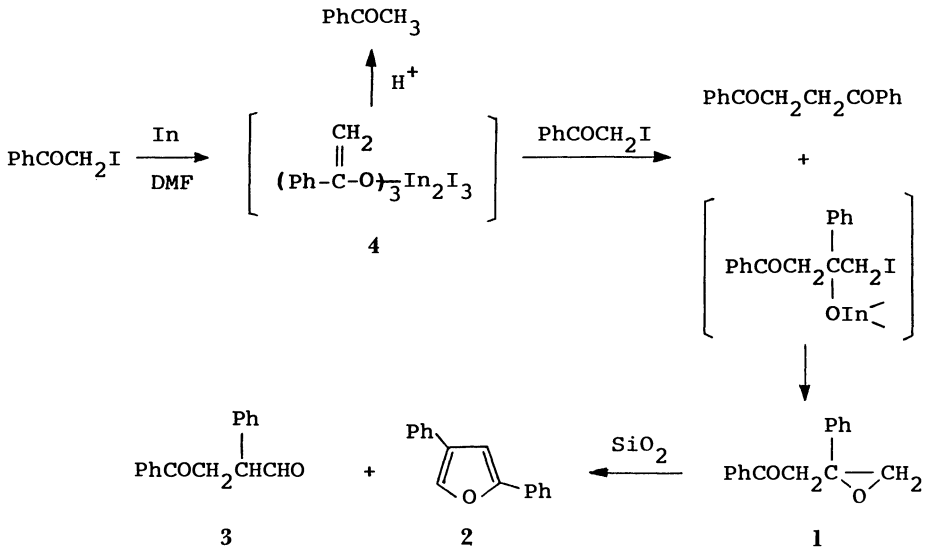
The syntheses of 2,4-disubstituted furans from the reaction of α-halo ketones have been performed by using magnesium,[3] zinc,[4] tetracarbonylnickel(0),[5] or copper(I) chloride.[6] Yoshisato and Tsutsumi have reported the synthesis of β,γ-epoxy ketone from aliphatic α-bromo ketone and realized its thermal transformation to 2,4-dialkylfuran.[5b] However, the compound **1** has never been obtained so far by the reactions of the metal enolates derived from phenacyl bromide,[5a,6,7] probably owing to its instability.

When the above reaction of phenacyl iodide with indium was conducted in the presence of an aldehyde, the aldol condensation proceeded; i.e., with benzaldehyde were formed β-hydroxy ketone **5** and chalcone (**6**) in 53 and 17% yields, respectively. Octanal gave similar results (Eq. 1).

$$\mathrm{PhCOCH_2I + RCHO} \xrightarrow[\mathrm{DMF}]{\mathrm{In}} \mathrm{PhCOCH_2CH(OH)R + PhCOCH{=}CHR} \quad (1)$$

5 (R=Ph) 53% **6** (R=Ph) 17%
7 (R=heptyl) 43% **8** (R=heptyl) 17%

It has previously been shown that indium(I) iodide can be used for oxidative addition to allylic halides and α-iodoacetate in place of metallic indium.[8] Indium(I) iodide has now been found to be effective also for the formation of the indium enolate from phenacyl iodide. Thus, refluxing of a mixture of phenacyl iodide and indium(I) iodide in THF for 12 h and aqueous workup of the reaction mixture gave



Scheme 1.

Table 1. Indium(I) Iodide-Induced Condensation of α-Bromo Ketones with Aldehydes

9

acetophenone in 75% yield together with a trace amount of 1,2-dibenzoylethane. This supports the in situ formation of the indium enolate **9** (Eq. 2). Phenacyl bromide was equally reactive to the iodide. When the reaction of α-bromo ketones and indium(I) iodide was carried out with aldehydes, α,β-unsaturated ketones were obtained. Table 1 summarizes the results. Both aromatic and aliphatic α-bromo ketones gave moderate yields of α,β-unsaturated ketones. The corresponding β-hydroxy ketones were not found in the reaction mixtures owing to a facile dehydration under the reaction conditions employed.

Experimental

General. Melting points were determined with a Mitamura Riken micro melting point apparatus and are uncorrected. IR spectra were taken with a JASCO A-102 spectrophotometer. Mass spectra (MS) were recorded with a Hitachi M-2000 instrument at 70 eV. ^1H NMR spectra were obtained with a Hitachi R-90 (90 HMz) spectrometer. ^{13}C NMR spectra were obtained with a Varian XL-200 (50.3 MHz) spectrometer. Elemental analyses were performed at Elemental Analysis Center of Kyoto University. Indium powder (99.99%, stabilized by 0.5% MgO) was obtained from Nacalai Tesque Co., Ltd. THF (tetrahydrofuran) and DMF (*N,N*-dimethylformamide) were distilled from lithium aluminum hydride and calcium hydride, respectively. All reactions were conducted under argon.

Reaction of Phenacyl Iodide with Indium. To a suspension of indium powder (114 mg, 1 mmol) in DMF (1 cm^3) was added phenacyl iodide (492 mg, 2 mmol) at room temperature. An exothermic reaction started immediately. The mixture was stirred at room temperature for 100 min. Water was added and the products were extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent left an oil which was distilled (Kugelrohr) to give acetophenone [bp 100 °C/1 Torr (1 Torr=133.322 Pa), bath temperature] (8 mg, 3%) and **1** (bp 190 °C/1 Torr, bath temperatures) (136 mg, 57%). The latter contained a trace amount of 1,2-dibenzoylethane which was crystallized and filtered (mp 142 °C, lit,[5a] mp 145 °C).

3,4-Epoxy-1,3-diphenyl-1-butanote (1). Colorless oil; IR (neat) 1680 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=2.97 (1H, d, *J*=5 Hz, OCH_2), 3.10 (1H, d, *J*=5 Hz, OCH_2), 3.58 (1H, d, *J*=17 Hz, $PhCOC\underline{H}_2$), 3.77 (1H, d, *J*=17 Hz, $PhCOC\underline{H}_2$), 7.36 (8H, m, aromatic), and 7.95 (2H, m, aromatic); ^{13}C NMR ($CDCl_3$) δ=45.3 (t), 55.3 (t), 57.1 (s), 125.8 (d), 127.8 (d), 128.3 (d), 128.4 (d), 128.6 (d), 133.4 (d), 136.8 (s), 139.6 (s), and 196.8 (s); MS *m/z* 238 (M^+); Found: C, 80.56; H, 5.98%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

Treatment of 1 with Silica Gel. A solution of **1** (114 mg, 0.48 mmol) in dichloromethane was adsorbed on a silica-gel column. After 1.5 h at room temperature, the column was eluted with acetone. The eluate showed two spots on a thin-layer chromatogram, which were separated by column chromatography on silica gel (hexane-dichloromethane gradient) to give **2** (42 mg, 40%) and **3** (55 mg, 48%).

2,4-Diphenylfuran (2). Colorless crystals; mp 111 °C (lit,[5a] mp 111 °C); ^1H NMR ($CDCl_3$) δ=6.95 (1H, d, *J*=1 Hz, H^3), 7.38 (8H, m, aromatic), 7.70 (2H, m, aromatic), and 7.75 (1H, d, *J*=1 Hz, H^5).

2,4-Diphenyl-4-oxobutanal (3). Colorless oil; IR (neat) 1722 (aldehyde C=O) and 1680 cm^{-1} (ketone C=O); ^1H NMR ($CDCl_3$) δ=3.30 (1H, dd, *J*=18, 5 Hz, CH_2), 3.93 (1H, dd, *J*=18, 8 Hz, CH_2), 4.41 (1H, dd, *J*=8, 5 Hz, $C\underline{H}CHO$), 7.31 (8H, m, aromatic), 7.98 (2H, m, aromatic), and 9.81 (1H, bs, CHO); ^{13}C NMR ($CDCl_3$) δ=39.3 (t), 53.5 (d), 127.8 (d), 128.0 (d), 128.5 (d), 129.0 (d), 129.2 (d), 133.2 (d), 135.3 (s), 136.3 (s), 197.2 (s), and 198.9 (d); MS *m/z* 238 (M^+); Found: C, 80.39; H, 5.72%. Calcd for $C_{16}H_{14}O_2$: C, 80.65; H, 5.92%.

Indium-Induced Reaction of Phenacyl Iodide with Aldehydes. To a mixture of indium powder (114 mg, 1 mmol) and benzaldehyde (159 mg, 1.5 mmol) in DMF (1 cm^3) was added phenacyl iodide (246 mg, 1 mmol) at room temperature. After a reaction started (exothermic), the mixture was cooled to 0 °C and stirred for 70 min. Water was added and the products were extracted with ether. Extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on silica gel (eluent: CH_2Cl_2) to give **5** (120 mg, 53%) and **6** (35 mg, 17%). The reaction with octanal was similarly carried out.

3-Hydroxy-1,3-diphenyl-1-propanone (5). Colorless oil; (lit,[9] mp 50—50.5 °C); ^1H NMR ($CDCl_3$) δ=3.35 (2H, d, *J*=6 Hz, CH_2), 3.40 (1H, bs, OH), 5.32 (1H, t, *J*=6 Hz, CH), 7.38 (8H, m, aromatic), and 7.90 (2H, m, aromatic).

Chalcone (6). Yellow crystals; mp 55 °C (lit,[10] mp 56—58 °C); ^1H NMR ($CDCl_3$) δ=7.50 (10H, m, =CH- and aromatic) and 7.97 (2H, m, aromatic).

3-Hydroxy-1-phenyl-1-decanone (7). Colorless crystals; mp 48 °C; IR (KBr) 3420 (OH) and 1672 cm^{-1} (C=O); ^1H NMR ($CDCl_3$) δ=0.90 (3H, bt, *J*=6 Hz, Me), 1.30 (12H, m, CH_2), 2.90 (1H, bs, OH), 3.08 (1H, dd, *J*=18, 7 Hz, $COCH_2$), 3.13 (1H, dd, *J*=18, 4 Hz, $COCH_2$), 4.20 (1H, m, $C\underline{H}(OH)$), 7.53 (3H, m, aromatic), and 7.97 (2H, m, aromatic); MS *m/z* 230 ($M-H_2O$); Found: C, 77.02; H, 9.95%. Calcd for $C_{16}H_{24}O_2$: C, 77.38; H, 9.74%.

1-Phenyl-2-decen-1-one (8). Colorless oil; IR (neat) 1668 and 1620 cm^{-1} (CH=CH-C=O); ^1H NMR ($CDCl_3$) δ=0.88 (3H, bt, *J*=6 Hz, Me), 1.30 (10H, m, CH_2), 2.32 (2H, bq, *J*=6 Hz, CH_2), 6.87 (1H, d, *J*=15 Hz, =CH-), 7.00 (1H, dt, *J*=15, 6 Hz, =CH-), 7.50 (3H, m, aromatic), and 7,93 (2H, m, aromatic); MS *m/z* 230 (M^+); Found: C, 82.70; H, 9.69%. Calcd

for $C_{16}H_{22}O$: C, 83.43; H, 9.63%.

Reaction of Phenacyl Iodide with Indium(I) Iodide. A mixture of phenacyl iodide (123 mg, 0.5 mmol) and indium(I) iodide[11] (130 mg, 0.54 mmol) in THF (5 cm^3) was heated at reflux for 12 h. Hydrochloric acid (3%) was added and the products were extracted with dichloromethane. The extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on silica gel (eluent: CH_2Cl_2) to give acetophenone (45 mg, 75%) and a trace amount of 1,2-dibenzoylethane (ca. 3 mg).

Indium(I) Iodide-Induced Reaction of α-Bromo Ketones with Aldehydes. General Procedure: A mixture of α-bromo ketone (0.8 mmol), aldehyde (0.5 mmol), and indium(I) iodide (0.8 mmol) was refluxed in THF (5 cm^3) for 12—17 h. Diluted hydrochloric acid (3%) was added and the product was extracted with dichloromethane. The extracts were dried (Na_2SO_4) and evaporated. The residue was chromatographed on silica gel (eluent: CH_2Cl_2) to give α,β-unsaturated ketone.

3-(4-Chlorophenyl)-1-phenyl-2-propen-1-one (10). Yellow crystals; mp 112 °C (lit,[10] mp 114—115 °C); ^1H NMR ($CDCl_3$) δ=7.55 (9H, m, =CH- and aromatic) and 7.99 (2H, m, aromatic).

1,5-Diphenyl-2,4-pentadien-1-one (11). Yellow crystals; mp 100 °C (lit,[12] mp 102—103 °C); ^1H NMR ($CDCl_3$) δ=6.9—7.7 (12H, m, =CH- and aromatic) and 7.95 (2H, m, aromatic).

1-(4-Bromophenyl)-3-(4-chlorophenyl)-2-propen-1-one (12). Yellow crystals; mp 161 °C (lit,[13] mp 167—168 °C); ^1H NMR ($CDCl_3$) δ=7.3—7.9 (m, 10H, =CH- and aromatic).

4-Phenyl-3-buten-2-one (13). Yellow crystals; mp 40 °C (lit,[14] mp 41.5—42 °C); ^1H NMR ($CDCl_3$) δ=2.37 (3H, s, Me), 6.73 (1H, d, J=16 Hz, =CH-), and 7.45 (6H, m, =CH- and Ph).

3-Undecen-2-one (14).[15] Colorless oil; ^1H NMR ($CDCl_3$) δ=0.90 (3H, bt, J=6 Hz, Me), 1.30 (10H, m, CH_2), 2.23 (5H, m, CH_2 and COMe), 6.07 (1H, d, J=16 Hz, =CH-), and 6.80 (1H, dt, J=16, 7 Hz, =CH-).

Reversible Color Changes of Polydiacetylene Induced by Monomer Solid Phase Transition

Kotaro ARAYA
Advanced Research Laboratory, Hitachi Ltd., Hatoyama, Saitama 350-03
(Received August 23, 1990)

Synopsis. Color change associated with solid phase transition is observed in the diacetylene derivatives, partially polymerized 4,6-decadiyne-1,10-bis(propylurethane). Moreover, the temperature of this color change can be altered by mixing with other derivatives.

Polydiacetylene,-(-RC=C=C=CR-)$_n$-, belongs to a unique class of polymers obtained by topochemical polymerization of a diacetylene(1,4-disubstituted 1,3-butadiyne) monomer in the solid state upon either thermal annealing or exposure to high energy radiation.[1] The polymers are colored either red, purple, or blue because π-electrons are delocalized along the conjugated backbone. The polymers also exhibit several types of color change; namely, thermochromism,[2,3] solvatochromism,[4-6] and photochromism.[7,8]

This paper reports a color change triggered by a solid phase transition of a diacetylene monomer. Color changes of polydiacetylene are understood to be due to changes in the length of the conjugated chain and/or in the planality of the polymer backbone. Therefore, the change would be caused by differences in the packing condition of the conjugated backbone. In the partially polymerized diacetylene, the polymer chain is dissolved in a monomer matrix and it forms a solid solution with a monomer. If a diacetylene monomer has a solid phase transition, changes in the packing condition of the polymer chains would be induced, leading to a color change. This type of color change has been reported only for the partially polymerized 1,6-di(1-carbazolyl)-2,4-hexadiyne.[9] The transition temperature, however, is very low (142 K) and, of course, unchangeable. This low temperature constrains other measurements and applications.

With this in mind, diacetylenes have been extensively synthesized in search of a diacetylene with a solid phase transition at a proper temperature, which would make this transition temperature changeable. Suitable diacetylenes are reported here. These compounds are 4,6-decadiyne-1,10-bis(propylurethane), R=-$(CH_2)_3$-$CONHC_3H_7$ and 4,6-decadiyne-1,10-bis(butylurethane), R=-$(CH_2)_3$-$CONHC_4H_9$. Hereafter, these compounds are designated as 3PU and 3BU, respectively. These compounds were prepared according to a procedure reported by Patel.[10] The calorimetric data were recorded with a Perkin-Elmer DSC-7 differential scanning calorimeter (DSC). The respective melting points of 3PU and 3BU were 117.6 °C and 110.0 °C. The solid phase transition of 3PU was observed at 76.6 °C and it was reversible.

A crystalline 3PU monomer is a white powder and turns blue upon exposure to daylight. The polymer content of this partially polymerized sample is about 1 wt%. The polymer conversion was determined by extracting a monomer with acetone using a Soxhlet extractor and weighing the residual polymer. Solid state absorption spectra were measured using a Hitachi U-3400 spectrophotometer with reflectmetric

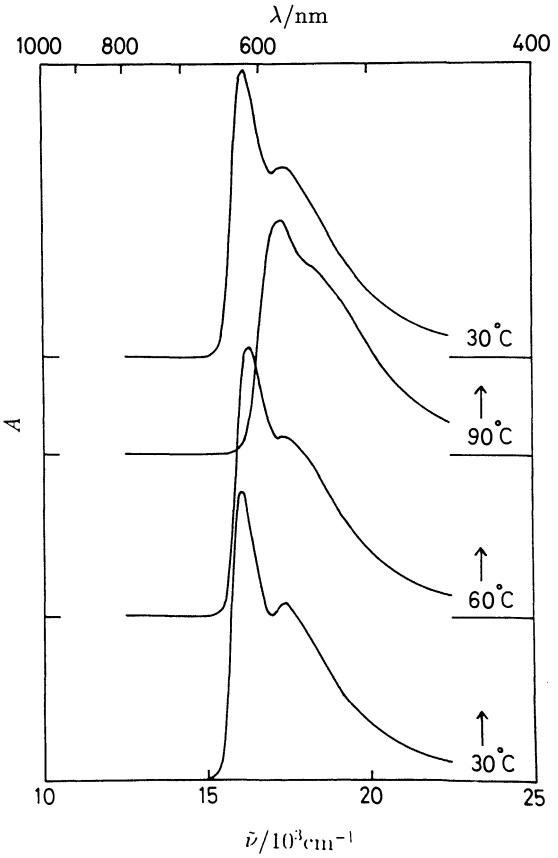

Fig. 1. Absorption spectra of partially polymerized 3PU.

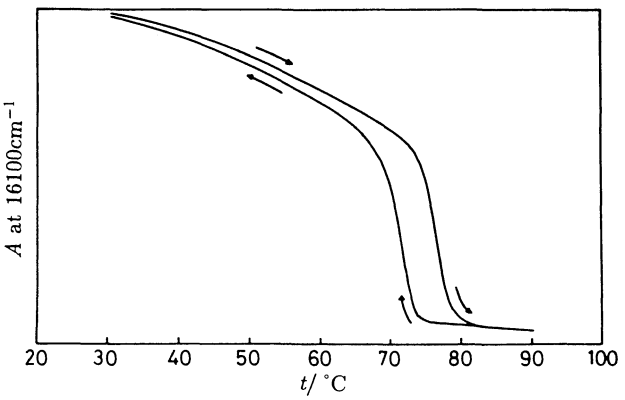

Fig. 2. Temperature dependence of absorbance at 16100 cm^{-1} of partially polymerized 3PU.

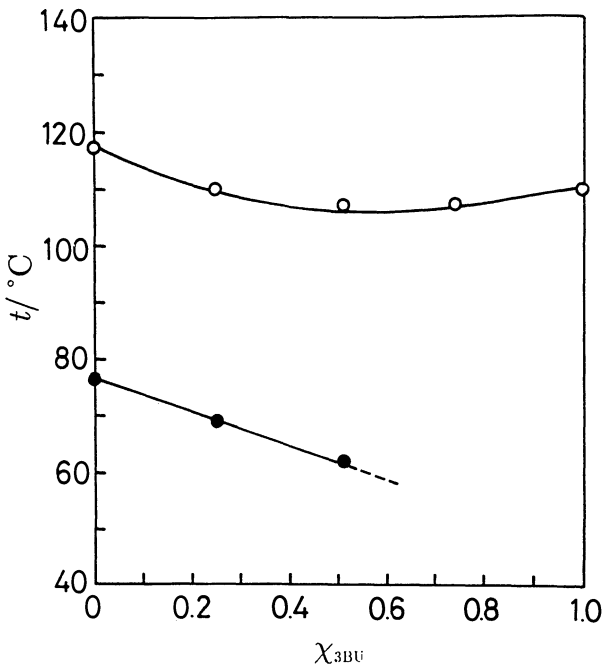

Fig. 3. Phase diagram of the 3PU-3BU system. Open circles: melting points. Closed circles: solid phase transition temperatures.

equipment, and were derived from diffuse reflection spectra of the solid dispersed in powdered sodium chloride. The temperature dependences of the absorption spectra are shown in Fig. 1. The maximum at 30 °C is located at 16100 cm^{-1} (620 nm). The spectrum at 60 °C is almost the same as at 30 °C. A large blue shift, however, is observed at 90 °C, when the color changed to purple. The maximum is shifted to 17200 cm^{-1} (580 nm). The spectral shift amounts to about 1100 cm^{-1}. When the solid is cooled to 30 °C again, the maximum turns back to 16100 cm^{-1}. For a detailed study of the temperature dependences of these spectra, the absorbance at 16100 cm^{-1} was monitored as a function of temperature. The results are shown in Fig. 2. During heating, absorbance drastically decreases at 76 °C and falls to almost zero at 80 °C. During cooling, absorbance sharply increases at 75 °C. This spectral change is reversible, and the temperature coincides with the solid phase transition temperature of 3PU, 76.6 °C. It is therefore concluded that the spectral change is induced by the monomer phase transition.

The most interesting feature of this diacetylene derivative is that the temperature of this color change can be changed. The 3PU and 3BU compounds form a solid solution over the entire composition. The phase diagram of the 3PU-3BU system determined by DSC is shown in Fig. 3. The phase transition of 3PU observed at 76.6 °C is also clearly observed up to 50 mol% of 3BU. The transition temperature is reduced to 62.0 °C at 50 mol% of 3BU. Accordingly, the temperature of the color change can be varied from 76.6 °C to 62.0 °C. If many diacetylenes having a phase transition were found, the color change of this type would be attained at a desired temperature and could be more effectively applied, for example, as a thermoindicator.

Although many types of color change have already been reported, a detailed understanding of this phenomenon has not been attained. The system reported here may help in understanding the relationship between the electronic state and the structure of polydiacetylenes.

Preparation and Property of Zirconia-Pillared Montmorillonite Having Different Pillar Populations

Kenzi SUZUKI, Masakazu HORIO, Hiroyuki MASUDA, and Toshiaki MORI*
Government Industrial Research Institute, Nagoya, Hirate-cho, Kita-ku, Nagoya 462
(Received August 29, 1990)

Synopsis. Zirconia-pillared clay was prepared by ion-exchanging montmorillonites having different cation exchange capacities (CEC's) in an aqueous solution of $ZrOCl_2$. The amount of zirconia incorporated as pillars varied depending on the CEC of the starting clay. The interlayer distance was almost the same: ca., 0.8 nm. These findings suggest that the distance between pillars or the lateral distance should be different from one zirconia-pillared clay to another. As a result of pillaring the surface area was 200—260 $m^2 g^{-1}$. The thermal stability was examined in terms of a decrease in the surface area after heating at elevated temperatures.

By pillaring with alumina,[1] zirconia,[2] chromia,[3] titania,[4] or other kinds of oxide clusters,[5] a swellable layered clay mineral has been converted to a zeolite-like high surface area material. The resultant pillared clay has pores with sizes comparable to the dimension of many simple molecules. It is, therefore, expected that pillared clay can be used as a shape-selective catalyst or a molecular sieving separation material.[6,7]

The pore structure of pillared clay is characterized by both the distances between the silicate layers and between pillars, which are called, respectively, the interlayer distance and the lateral distance. It is not easy to prepare pillared clay with the desired interlayer distances. On the other hand, the lateral distance may be readily altered by altering the number of pillars: i.e., the lateral distance should be smaller in pillared clay with a larger number of pillars, as long as the interlayer distance is the same. By pillaring a montmorillonite having different CEC's with alumina we prepared a pillared clay with different lateral distances and studied its catalytic property.[7,8]

In the present study we similarly altered the pillar population in zirconia-pillared montmorillonite in order to change the lateral distance. Thermal stability was also investigated by measuring the surface area after heating at elevated temperatures.

Experimental

Na-montmorillonite [Kunipia-F, CEC; 1.28 mequiv g^{-1}] was obtained from Kunimine Industries, Co. The CEC was similarly altered by partially exchanging Na-montmorillonite with Ni^{2+}, followed by heating.[9] Zirconia-pillared clay was prepared by suspending the (Na, Ni)-montmorillonite with the CEC previously altered from 1.28 to 0.51 mequiv g^{-1} in an aqueous solution of $ZrOCl_2$, followed by washing chlorine free, drying at 333 K overnight and then calcined at elevated temperatures for 2 h. The amount of zirconia incorporated as pillars was determined by inductively coupled plasma (ICP) emission spectrometry (Shimadzu, ICPQ-1000). X-Ray powder diffraction was taken using a diffractometer with Ni-filtered monochromatic Cu $K\alpha$ radiation (Philips, APD-1700). The surface area was measured using an automatically controlled nitrogen-adsorption apparatus (Carlo Erba, Sorptomatic 1800).

Results and Discussion

Incorporation of Zirconia. The amount of zirconia introduced in the clay is plotted in Fig. 1 as a function of the CEC of the starting montmorillonite. Above 0.5 mequiv g^{-1}, the amount of zirconia increased linearly with increasing CEC, which is natural, since zirconia pillars are introduced in clay via ion-exchange. The tetrameric cation, $[Zr_4(OH)_{14}(H_2O)_{10}]^{2+}$ has been proposed as a plausible precursor for the zirconia pillar.[2a,d] Therefore, the number of zirconia pillars observed can be compared with the number expected from the divalent tetrameric cation. For a CEC of 1.28 mequiv g^{-1}, the observed number was 338 mg-ZrO_2 g^{-1}, while that expected was 315 mg-ZrO_2 g^{-1}, showing good agreement. However, it is obvious from a precise examination of Fig. 1 that when CEC decreased, the amount of observed zirconia was smaller than that expected, the possible reason for

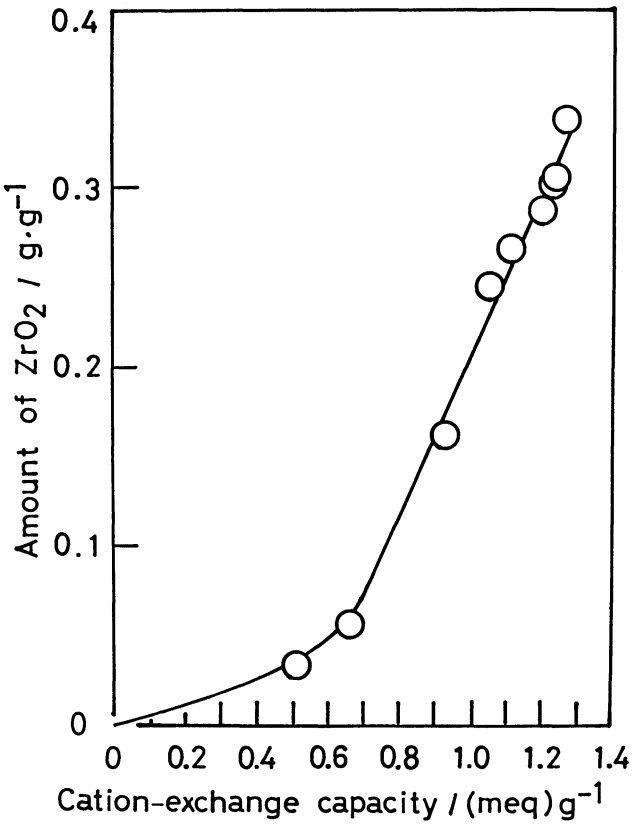

Fig. 1. The amount of ZrO_2 incorporated in montmorillonite with various CEC.

which is discussed below.

X-Ray Powder Diffraction. Since, as described below, the present zirconia-pillared montmorillonite was less thermally stable, X-ray powder diffraction was taken mainly for samples before calcination. Figure 2 summarizes the results. A diffraction peak, attributable to the 0 0 1 reflection, was observed at 4.5—5° for the CEC of the starting montmorillonite from 1.28 to 0.93 mequiv g^{-1}. The intensity of the 0 0 1 reflection increased with decreasing CEC to 1.06 mequiv g^{-1} and then decreased again for a CEC of 0.93 mequiv g^{-1}. Alumina-pillared montmorillonite also showed a similar variation in the intensity of the 0 0 1 reflections.[8] The intensity of the 0 0 1 reflection indicates the extent of the long-range ordering of the stacking of the silicate layers. Therefore, a favorable range of CEC seems to be present for preparing pillared clay well ordered in the longrange. From 0.93 to 1.28 mequiv g^{-1} of CEC, an additional peak also appeared at 8—9°, probably attributable to the 0 0 2 reflection. The variation in the intensity of the 0 0 2 reflection was found to be similar to that in the intensity of the 0 0 1 reflection, which may support the validity of the attribution.

For a CEC of 0.66 or 0.51 mequiv g^{-1}, a new main peak appeared at 9°, accompanying a very broad peak at 4.5—5°. The latter peak is again attributed to the 0 0 1 reflection. The diffraction for Ni-montmorillonite indicates that the former main peak is attributed to the 0 0 1 reflection of the non-pillared montmorillonite. The non-pillared portion present explains why the number of zirconia pillars was smaller than that expected. The reduced charge montmorillonite was reported to show a heterogeneous property with respect to a layer charge reduction.[9] This heterogeneity may be responsible for the presence of the non-pillared portion.

Interlayer Distance and Lateral Distance. The 0 0 1 basal spacing, d(0 0 1), was about 1.8 and 1.0 nm for the peak at 4.5—5 and at 9°, respectively. Since the thickness of the silicate layer was 0.96 nm, the respective interlayer distance was ca. 0.8 and 0.05 nm. The former interlayer distance assures pillaring, while the latter assures non-pillaring.

Figures 1 and 2 show that the number of zirconia pillars varied with the CEC of the starting montmorillonite from 1.28 to 0.93 mequiv g^{-1}, while the interlayer distance was virtually the same: ca., 0.8 nm. This suggests that the lateral distance is different from one zirconia-pillared montmorillonite to another: i.e., the greater number of zirconia pillars, the smaller is the lateral distance.

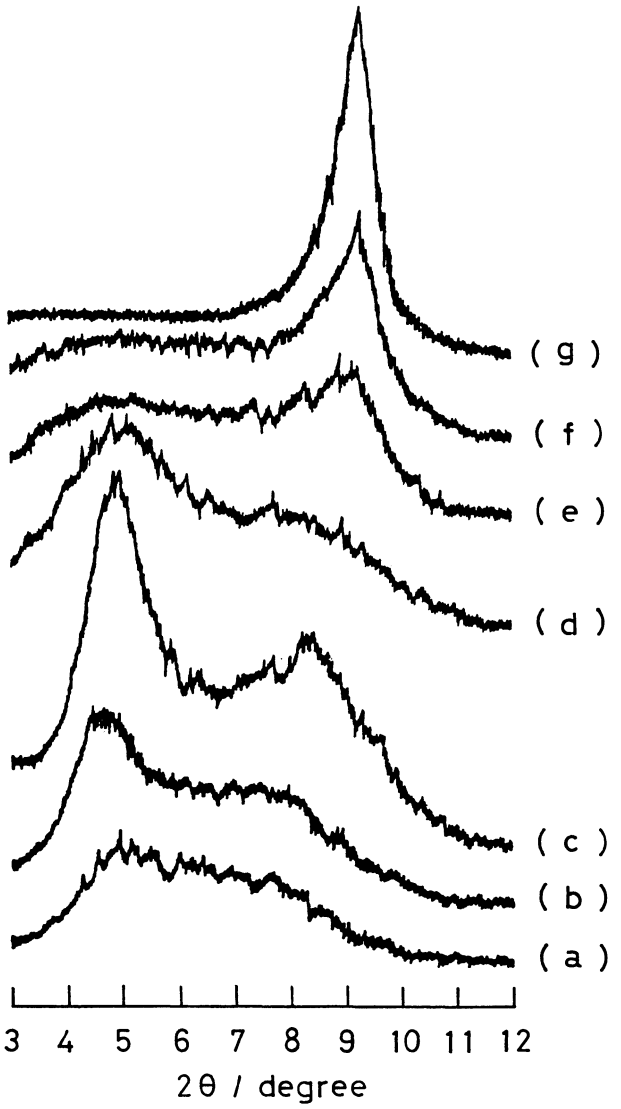

Fig. 2. X-Ray powder diffractions for the montmorillonite involving zirconium tetrameric cations in it. The CEC of the starting montmorillonite is 1.28 (a), 1.21 (b), 1.06 (c), 0.929 (d), 0.660 (e), and 0.506 mequiv g^{-1} (f). X-ray powder diffraction was taken for Ni-montmorillonite in a different scale (g).

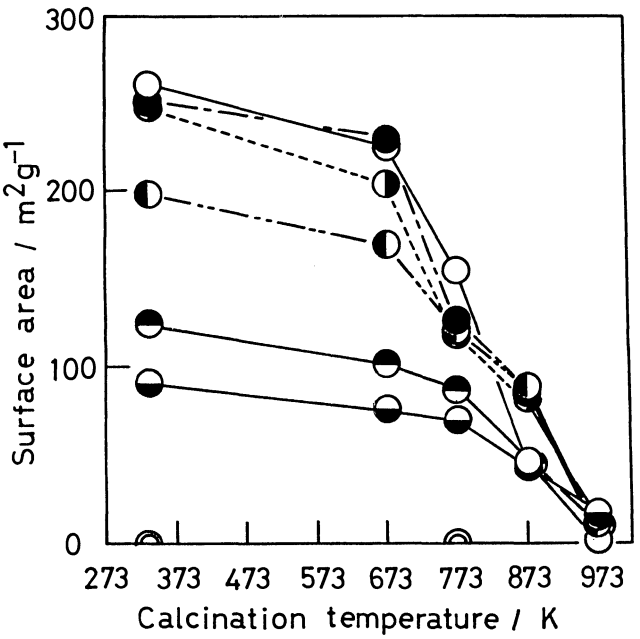

Fig. 3. Surface areas varied with calcination temperatures for typical zirconia-pillared montmorillonites. The CEC of the starting montmorillonite is 1.28 (◐), 1.21 (●), 1.06 (○), 0.929 (◑), 0.660 (◒), and 0.506 mequiv g^{-1} (◒). ◎; Ni-montmorillonite.

Surface Area Varied with Calcination at Elevated Temperatures. As a result of pillaring, the surface area was 200—260 $m^2 g^{-1}$. The surface area of montmorillonite partially pillared was also much larger than that of Ni-montmorillonite: 120 or 90 $m^2 g^{-1}$ vs. >1 $m^2 g^{-1}$. The surface area is plotted in Fig. 3 as a function of the calcination temperature. For all pillared montmorillonites, the surface area slightly decreased up to 673 K accompanying a drastic decrease for a further elevation of the calcination temperature.

Our previous study showed that the decrease in the surface area caused by high-temperature calcination was much less pronounced for an alumina-pillared montmorillonite: the surface area was 285, 260, and 180 $m^2 g^{-1}$ after calcination at 773, 873, and 973 K, respectively.[10] Compared with this pillared montmorillonite, the thermal stability of the present zirconia-pillared montmorillonite does not seem to be high. Here, the thermal stability was evaluated on the basis of a decrease in the surface area caused by high-temperature calcination. It is known that for zirconia-pillared clay the preparation method strongly affects the thermal stability.[2d] Samples synthesized from refluxed $ZrOCl_2$ solutions were reported to have higher surface areas than those prepared using fresh, unrefluxed solutions. The highest thermal stability was obtained by refluxing a $ZrOCl_2$ solution prior to mixing with dispersed clay, combined with a subsequent refluxing of the mixture, while the lowest stability was produced by using a fresh solution followed by mixing at room temperature. Lower thermal stability of the present zirconia-pillared montmorillonite may be due to the preparation method: the fresh solution was used followed by mixing at room temperature.

Catalytic Activity of Bismuth(III) Chloride for Dehydrochlorination of Poly(vinyl chloride)

Yoshio UEMICHI,* Kazuhiko TAKUMA,† Masatoshi SUGIOKA, and Takaji KANAZUKA
Department of Applied Chemistry, Muroran Institute of Technology, Mizumoto, Muroran 050
(Received August 30, 1990)

Synopsis. Bismuth(III) chloride was found to be highly active as a catalyst for the dehydrochlorination of poly(vinyl chloride). The degree of dehydrochlorination was 97% at the highest. The catalyst showed high activity even in water vapor.

It is well-known that many metal chlorides with surface acidity catalyze various reactions such as alkylation, acylation, isomerization, polymerization, halogenation, etc.[1,2] In particular, chlorides of Fe, Al, Sb, Sn, and Ti are effective catalysts. However, there have been few reports to date on the catalytic activity of bismuth(III) chloride. In this paper, we report that $BiCl_3$ is an active catalyst for the dehydrochlorination of poly(vinyl chloride) (PVC). The reaction has recently attracted considerable attention in connection with the disposal of PVC waste[3] or the transformation of PVC into a polyene material which is one of the electrically conductive polymers.[4]

Experimental

Guaranteed-grade $BiCl_3$ purchased from Kishida Chemical Co. was used as catalyst after grinding it into a fine powder of 160 mesh or under. The chloride was so hygroscopic that it was handled in a dry nitrogen atmosphere. A commercial PVC (Aldrich Chemical Co.) was used without further purification. Its particle size and average molecular weight were 100—160 mesh and 48,000, respectively.

The dehydrochlorination of PVC was carried out at 100—175 °C in a stream of He (30 $ml \cdot min^{-1}$). A powdered mixture of PVC (5.6 mmol in monomer units) and $BiCl_3$ (0.3—2.2 mmol) was loaded into a U-shaped glass tube reactor. The reaction was started by immersing the reactor in an oil bath with a prescribed temperature. The evolved HCl gas was absorbed by water and the aqueous solution was periodically titrated with a sodium hydroxide solution. The total HCl consisted of HCl evolved from PVC and that from $BiCl_3$. The amount of HCl from the reaction of $BiCl_3$ with trace amounts of H_2O adsorbed on the chloride was evaluated from the decrease in the Cl content of catalyst. The content was determined by the Mohr's method; $BiCl_3$ was dissolved in water and the free Cl^- ions were titrated with silver nitrate after filtration of the precipitated BiClO. In some cases, the Cl content in dehydrochlorinated PVC was measured by combustion of the sample, followed by titration with silver nitrate. The total fraction of the eliminated plus residual Cl was 95% or more.

Results and Discussion

The experimental data showing the HCl evolution from PVC and $BiCl_3$ are given in Table 1. The dehydrochlorination of PVC in the absence of catalyst scarcely occurred at 175 °C, while in the presence of $BiCl_3$ it readily proceeded even at lower temperatures. However, HCl was also formed from the catalyst according to the reaction:

$$BiCl_3 + H_2O \longrightarrow BiClO + 2HCl \quad (1)$$

since the $BiCl_3$ originally contained trace amounts of water. The occurrence of Eq. 1 has been verified experimentally; i.e., the amount of HCl evolved from $BiCl_3$ agreed with the decrease in the Cl content of catalyst on heating $BiCl_3$ alone. Therefore, the net HCl from PVC was calculated by subtracting this decrease from the total HCl evolved.

Table 1 indicates that a considerable amount of HCl was evolved when only $BiCl_3$ was heated, but with the mixture of PVC and $BiCl_3$ the HCl evolution from the catalyst decreased remarkably. This result could be

Table 1. HCl Evolution from PVC and $BiCl_3$ at 125 °C

Sample	Bi/PVC	Reaction time	Total HCl	Cl decrease in $BiCl_3$/mmol	HCl from PVC[a]

rationalized as follows. Eq. 1 is a reversible reaction, so that the equilibrium between $BiCl_3$ and BiClO favors the former in the presence of HCl eliminated from PVC. This explanation was supported by the result shown in Fig. 1, in which the evolution of HCl from $BiCl_3$ at 150 °C started after about 3 h where the dehydrochlorination of PVC, and hence the HCl evolution from PVC, became very slow. This also suggests that a significant amount of water remained on the catalyst surface even after 3 h. Therefore, water is probably not desorbed from the surface as separate molecules. Hydrolysis of $BiCl_3$ resulted in the formation of BiClO and HCl. The catalytic activity of bismuth chloride oxide will be commented on later.

The degree of dehydrochlorination of PVC was heavily dependent on the reaction conditions. Table 1 shows that the degree of dehydrochlorination increases by raising the molar ratio of $BiCl_3$ to the vinyl chloride unit of PVC (Bi/PVC), but the increase is almost saturated at the molar ratio of 0.2. Figure 1 illustrates the time course of PVC dehydrochlorination at various temperatures. A significant dehydrochlorination activity of the $BiCl_3$ catalyst was observed at temperatures higher than 125 °C, while a sublimation of catalyst took place at 175 °C. The degree of dehydrochlorination increased almost linearly up to about 60% with the reaction time. This result suggests that no essential deactivation of the catalyst occurred. Nevertheless, complete dehydrochlorination was not attained under the conditions employed in this study. The degree of dehydrochlorination was 97% at the highest at 150 °C and Bi/PVC=0.4. The existence of the limit of the dehydrochlorination level may be attributed to the formation of Cl atoms isolated from reactive neighbors, such as -CH=CH-CH(Cl)-CH=CH-, by random elimination of HCl.[5] In the course of the reaction, the PVC sample rapidly turned from white to black. This color development seems to be a result of the formation of polyene sequences. In thermal dehydrochlorination of PVC without any additive, PVC particles strongly adhered each other and to the reactor wall. The adhesion made it difficult to handle the dehydrochlorinated residue. In the presence of $BiCl_3$, in contrast, the PVC residue remained fine powdery throughout.

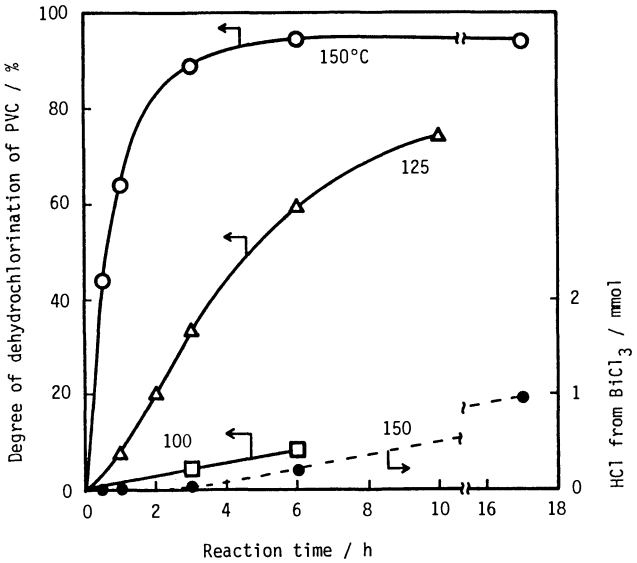

Fig. 1. Time course of PVC dehydrochlorination at various reaction temperatures. Bi/PVC=0.2.

Thus, $BiCl_3$ is active as a catalyst for dehydrochlorination of PVC. There have been many studies on the stabilization of PVC. In this regard, oxides or chlorides of Al, Cd, Fe, Mo, and Zn[6-10] were found to catalyze dehydrochlorination of PVC although their catalytic activities were not always assayed quantitatively. Silica-supported $FeCl_3$ was claimed to be an active catalyst for dehydrochlorination of PVC; the degree of dehydrochlorination was about 90% at 200 °C in 3 h under air, while it was 50% in a N_2 stream.[8] In this study, the catalytic activity of $BiCl_3$ was compared with that of $FeCl_3$ (Merck Co.). The latter was slightly more active than the former in the initial stage of the reaction. However, a rapid reduction in the reaction rate with time was observed and consequently the final dehydrochlorination level was much lower with $FeCl_3$ as catalyst (Table 1). Hence the overall catalytic activity is higher for $BiCl_3$ than for $FeCl_3$.

To obtain further information about the catalysis by $BiCl_3$, the effects of adsorbed pyridine and water on its activity were examined. The results are summarized in Table 2. $BiCl_3$ was treated with 4 Torr (1 Torr=133.322 Pa) of pyridine at room temperature for 10 min in a vacuum system, followed by outgassing at the same temperature for 30 min. After pyridine adsorption the activity of catalyst was reduced by roughly an order-of-magnitude. This strongly suggests that the acidic property of $BiCl_3$ is responsible for the dehydrochlorination activity. In general, the catalytic activity of solid acids is remarkably influenced by addition of water. Since $BiCl_3$ used in this study contained water, removal of water was attempted by outgassing the catalyst at room temperature for 4 h. However, this pretreatment exerted little effect on the catalytic activity, due probably to strong adsorption of the water molecules. The strong adsorption is also substantiated by the observation that no decrease in the amount of HCl evolved from

Table 2. Dehydrochlorination Activity of $BiCl_3$ after Various Treatments

Treatment	Activity/%[a]
None	59.3
After pyridine adsorption at room temperature	6.5
After outgassing at room temperature	58.5
After treatment with water vapor (3 mol% in He) at 125 °C	0.5
In the presence of water vapor (3 mol% in He)	55.5

a) At 125 °C for 6 h.

$BiCl_3$ took place by the outgassing (Table 1). On the other hand, when $BiCl_3$ was treated with water vapor (3 mol% in He) at 125 °C for 10 h prior to use, the catalytic activity disappeared almost completely. During the pretreatment $BiCl_3$ was transformed mostly into BiClO according to Eq. 1, and the resulting chloride oxide showed no catalytic activity for dehydrochlorination of PVC. This was the reason for the complete loss of the catalytic activity. Then, water vapor was introduced into the reaction system simultaneously with the start of PVC dehydrochlorination and was continuously supplied throughout the reaction. Here the formation of BiClO occurred only to a small extent, most probably because the HCl eliminated from PVC interfered with the formation of the chloride oxide. Owing to this behavior, which is advantageous on a practical viewpoint, the $BiCl_3$ catalyst remains sufficiently active even in the presence of water.

Sorption of Anionic Surfactants with Wood Charcoal

Itsusei FUJITA,* Jyo TOMOOKA, and Tsugiharu SUGIMURA
Kumamoto Prefectural Institute of Public Health, 4-33 Minamisendanbata-machi, Kumamoto 860
(Received August 20, 1990)

Synopsis. The possibility of wood charcoal as an adsorbent, not as an energy source as in the past, was confirmed by the use of an anionic surfactant as the model adsorbate, and a trial sorption of polluting substances in an actual river by a wood charcoal column was conducted.

The rapidly progressing population centralization and the change of life style in urban areas are today having an extremely adverse effects on river environments. Although this has been caused by a delayed construction of basic social facilities (such as sewage disposal facilities) to cope with the increasing population, hasty perfection of social facilities would be difficult in view of the present status of Japan. In order to improve the water environment, it is therefore necessary to reduce the pollution loading amount at each disposal point. As one possible measure, there have been movements to recommend a reduction of polluting materials discarded by each home. In some parts of the country there have also been trial installations of simplified water-purification facilities at disposal points of homes or at nearby small rivers. Simplified water purification facilities include those utilizing catalytic oxidation and those using hydrophytes.

The catalytic oxidation method is a method for cleaning water by the utilization of a self-purifying action of water ways packed with contracting materials covered with a biomembrane. As contracting materials gravel[1] and wood charcoal have commonly been tried.

Wood charcoal, with a history going back to the Heian Era in Japan, was one of national necessaries of life until about 30 years ago. Its annual production sharply decreased from 2 million tons around 1955 to 40 thousand tons at present. The development of new applications of wood charcoal, therefore, not only activates its business circle, but is also expected to stimulate the average person's concern for wood as well as for the concept of "green", leading to a heightened movement fowards "green" cultivation. Wood charcoal has had two major uses: one as an energy source, and the other as a carbon material. The characteristics of wood charcoal as a carbon material are: a large inner surface area with both high reactivity and adsorptivity, high content of valuable minerals, and only a small content of hazardous components. The incorporation of wood charcoal, to which microorgraisms readily adhere, into soil improves the filtration ability and water retention of soil; efficient farming producers, therefore, have applied wood charcoal into soil. From long ago wood charcoal has been used for the filtration of well water; there has also been an idea[2] to use wood charcoal as a water-purifying agent. However, systematic studies concerning the water-purifying function of wood charcoal, which have rarely been carried out, are strongly desired. In the present study, in terms of the abovementioned background, the possibility of wood charcoal as an adsorbent was investigated using anionic surfactants found in river water as a model substance.

Experimental

Materials and Reagents. The wood charcoal used for the adsorption experiment, a product made from lumber produced by thinning, was presented by the Federation of Kumamoto Forestry Association. The sodium alkylbenzenesulfonate, an anionic surfactant that was used for a batch process experiment, has an alkyl chain of C_{11} to C_{14} and is made by Nacalai Tesque, Inc. The other reagents used were of special reagent grade obtained from commercial sources.

Determination of Surfactants. The determination of surfactants was made by highperformance liquid chromatography.[3] Along with the method using 225 nm ultraviolet absorption, fluorescence spectroscopy using on excitation wavelength of 225 nm and fluorescence light at 285 nm was employed.

Determinations of Other Items. The determination of COD, pH, total nitrogen(T-N), ammonium nitrogen (NH_4-N), nitrite nitrogen (NO_2-N), nitrate nitrogen (NO_3-N), phosphate phosphorus (PO_4-P), and total phosphorus (T-P) was conducted according to Japan Industrial Standad (JIS) K0102. The determination of the chloride ion was made by Mohrs's method.

Sorption Study by Batch Process. One gram of crashed wood charcoal was put into a 300 cm^3 conical flask, and then 100 ml of sodium alkylbenzenesulfonate solution was added. The flask was shaken at 25 °C for 24 h, and the wood charcoal separated by centrifugation. The concentration of sodium alklbenzenesulfonate in the supernatant was measured.

Experimental Conditions of the Wood Charcoal Column for the Adsorption of River Water. A glass column packed with wood charcoal was 15 mm in inner diameter and 500 mm in length. The wood charcoal packed was of crashed irregular shapes with an average diameter of 5 mm. The packed height was 200 mm, and the temperature 25 °C. A 250 cm^3 sample of river water was filtered by suction through a GF/B glass filter, which was washed in 1 ml of methanol and 50 cm^3 of distilled water. The filtrate was passed through a wood charcoal column at a rate of 5 $cm^3 min^{-1}$ to adsorb chemical components in river water; the column effluent was collected at 200 cm^3. Similarly, the filtrate was passed through the activated-carbon column. This column-sorption experiment was triplicated, respectively. The mean concentrations of the chemical components in the eluate are tabulated in the table.

Results and Discussion

Table 1 shows data concerning the wood charcoal used: the specific surface area, ion exchange capacity,[4] chloride ion adsorption, and nitrogen content by ele-

◇: $CH_3(CH_2)_{13}C_6H_4SO_3Na$.

mental analysis. The specific surface area[5-8] was smaller compared to that of the powdery activated carbon generally used as an adsorbent. Basic groups, the presence of which in low-temperature (300 °C)-treated activated carbon has been reported,[5,6] are supposed to also exist in wood charcoal as a possible precursor of activated carbon.

A surfactant (more specifically, sodium alkylbenzenesulfonate in this experiment), commonly used in adsorption experiments, was used as a model organic substance to be adsorbed by wood charcoal. The experiment was conducted in a batch process. Figure 1 shows the adsorption isotherm, a general means for a comprehensive expression of the adsorption capacity or adsorbed amount of an adsorbent. The adsorbed amount did not show such an increase corresponding to the increase in the length of the alkyl chain of the surfactant.

Figure 2 and Table 2 show the results of an investigation involving the application of Freundlich's adsorption equation, which has been applied to activated carbon. In an adsorbed amount, though wood charcoal showed lower values than did activated carbon, the $1/n$ value which expresses the readiness for adsorption, showed values paralleling those of a previous evaluations.[7]

Wood charcoal, found to have the function described above, was then subjected to an investigation concerning its adsorption capacity in a column of actual river water. Generally, though the particle diameter of an adsorbent to be packed in a column is

Table 2. Freundlich's Absorption Constant

	k	$1/n$

desinably very small, considering practical applications (to avoid column choking by suspended matter and the removal of river water pollution by the whole experiment system) wood charcoal was powdered to an average diameter of 5.0 mm. Evaluations of the overall pollution loading amount from organic materials in river water has generally been made in terms of the biochemical oxygen demand (BOD); in this experiment, however, it was made in terms of the chemical oxygen demand (COD) owing to its operation simplicity. Evaluations were also made for linear alkylbenzenesulfonate sodium salt (LAS), the principal component of detergents deemed as a model substance of pollution loading by waste water from living, and for nutrient salts (N, P), the loading of which in lakes and ponds is becoming a problem. Water samples taken at Kengun river in a new residential quarter where there were no public water-treatment facilities, were subjected to an investigation concerning their sorption by the wood charcoal column developed in this study.

As can be seen in Table 3, wood charcoal is considered to be efficient as a factor only for the overall removal by sorption. Regarding ionic adsorption of the surfactant, NO_3^-, NO_2^-, and PO_4^{2-}, however, the values remain at the level of about 1/5 of the ion exchange capacity (Table 1). The contact time in the column is very deeply related to this.

The main purpose of using natural materials in conventional water purification processes has been as the carrier of a biomembrane for biological catalytic oxidation. In recent years there have been examples of using wood charcoal for such catalytic oxidation. There have been a number of reports stating that wood charcoal has a greater specific surface area than do conventional materials for catalytic oxidation and is excellent concerning the living conditions of soil bacteria.[2] Wood charcoal might therefore possibly become more useful through additional detailed

Effects of Pretreatment of Yubari Coal by Solvent-Extraction on the Reductive Alkylation with Molten Potassium and Iodoethane

Mikio MIYAKE,* Kazushi TAMADA, Hiroo MINAMI, and Masakatsu NOMURA*
Department of Applied Chemistry, Faculty of Engineering, Osaka University, 2-1, Yamada-oka, Suita, Osaka 565
(Received September 29, 1990)

Synopsis. Effects of pretreatments of Yubari coal by solvent-extraction on the reductive alkylation with molten potassium and iodoethane have been investigated by comparing the reactions with and without ultrasonic irradiation. Important roles of electron-transfer agents and secondary bonds between coal macromolecules on the anionization were elucidated.

The Sternberg's method of reductive alkylation[1] has been accepted as one of the most effective procedures for the coal solubilization in conventional organic solvents under mild reaction conditions.[2] We have demonstrated previously that highly efficient coal anionization with molten potassium in refluxing tetrahydrofuran (THF)[3] can be further enhanced by ultrasonic irradiation.[4,5] For example, ethylated Yubari coal, prepared by anionization for only 10 min under ultrasonic irradiation, followed by alkylation with iodoethane, yielded 70 wt% of benzene-soluble materials, compared with 41 wt% obtained without ultrasonic irradiation under otherwise the same conditions.[5] Prolonged anionization time both with and without ultrasonic irradiation showed an increase in solubility of alkylated products. Nearly quantitative solubilization in benzene was achieved within 1 h by ultrasonic irradiation but more than 6 h were necessary without the irradiation.[3,5]

In this study, two reactions mentioned above were carried out for the residues of Yubari coal after extraction with different solvents. Such an approach will enable us to assess the role of solvent-extractable constituents in coal on the reactions and to elucidate the reason why ultrasonic irradiation leads to highly efficient reductive alkylation.

Experimental

Pulverized Yubari and Kairan coal samples (−200 mesh) were dried at 110 °C under vacuum overnight. Elemental analyses (dry ash-free basis) are as follows: C, 87.3; H, 6.1; N, 2.0; O (difference), 4.6 wt% for Yubari coal and C, 87.6; H, 4.8; N, 1.5; O (difference), 6.1 wt% for Kairan coal. Extraction solvents (hexane, heptane, chloroform, and benzene) and potassium metal were used as received. Naphthalene used as an electron-transfer agent was purified by recrystallization from ethanol. Purification procedures of THF and iodoethane were described elsewhere.[3-5]

Yubari coal was thoroughly extracted with heptane, chloroform, or benzene using a Soxhlet apparatus for one week. The extract and the residue were dried overnight at 90 °C under vacuum.

A typical reductive alkylation procedure is as follows: a three-necked flask containing THF (50 cm^3) and potassium metal (4 g) was heated in an oil bath until potassium melted and dispersed completely in the refluxing THF. Then, the coal or residue sample (3 g) was added into the flask and agitated by a magnetic stirrer for 6 h under a stream of dry argon. After the anionization of the coal or residue sample with molten potassium, the flask was cooled to 0 °C and then a large excess of iodoethane was added dropwise to the reaction mixture. The resulting mixture was stirred overnight at room temperature.[3] This procedure using molten potassium is called the M-K method. The same procedure was carried out under ultrasonic irradiation by immersing the flask in a heated water bath of an ultrasonic laboratory cleaner (Bransonic B-220, 100 W, 45 kHz, 0.5 W cm^{-2}).[4,5] This procedure under ultrasonic irradiation is called the M-K/US method. Kairan coal sample (3 g) in the presence or absence of naphthalene (0.3 g) was made to react with molten potassium metal (2.4 g) for 2 h under otherwise the same conditions as the M-K and M-K/US methods. It should be mentioned that molten potassium is explosive when exposed to atmosphere. Ethylated products, after repeated washing with deionized water, were subjected to Soxhlet extraction with hexane and benzene for 48 h, and the soluble materials were named Hexane solubles (HS) and Benzene solubles (BS), respectively. Procedures were described in detail elsewhere.[3-5]

The Curie-point pyrolysis of the coal extract (3 mg) was done at 670 °C for 3 s by a pyrolyzer (Japan Analytical Industry Co., model JHP-3). Volatile pyrolysates were analyzed by GLC (Hewlett-Packered, model 5970) and mass spectrometer (JEOL, model DX-303) which were connected to the pyrolyzer, as described in detail elsewhere.[6] The number of ethyl groups per 100 carbon atoms was determined from an increase in weight of the ethylated products.[3]

Results and Discussion

The yield of the extract from Yubari coal increased in the order, heptane (1 wt%) < chloroform (5 wt%) < benzene (12 wt%). The heptane extract showed a high H/C value (1.222) and a low N/C value (0.005), whereas the chloroform extract showed a high N/C value (0.014). In order to characterize the extracts obtained by nonpolar solvents (heptane and benzene), the Curie-point pyrolysis-GC/MS analysis was carried out, indicating that the heptane extract is predominantly composed of long-chain alkanes and that the benzene-extract contains alkylbenzenes in addition to long-chain alkanes. Thus, each extraction solvent (heptane, chloroform, and benzene) may remove aliphatic compounds especially long-chain alkanes, polar compounds containing heteroatoms, and aromatic compounds in addition to heptane solubles, respectively.

Table 1 summarizes properties of Yubari coal, the solvent-extracted residues, and their ethylation products. The properties given are H/C ratio, number of ethyl groups per 100 carbon atoms, and solubility in hexane and benzene (HS and BS, respectively). By the M-K method with molten potassium and iodoethane in THF, ethylated products from the original

a) Kairan coal (3 g) was anionized in the presence or absence of naphthalene (0.3 g) with molten potassium (2.4 g) using magnetic stirrer (M-K method) or under ultrasonic irradiation (M-K/US method) for 2 h, followed by alkylation with iodoethane. b) See Table 1.

coal and the heptane-extracted residue showed a similar solubility in hexane (HS yields were 36 and 35 wt%, respectively) and in benzene (BS yields were 78 and 79 wt%, respectively). The results indicate that long-chain alkanes, which were removed by heptane-extraction, affect little on the reaction. On the other hand, the chloroform-extracted residue gave the product with the highest HS and BS yields (49 and 83 wt%, respectively), whereas the product from the benzene-extracted residue showed the lowest HS and BS yields (11 and 63 wt%, respectively). In contrast, the product from the benzene-extracted residue obtained by the M-K/US method (under ultrasonic irradiation, otherwise the same conditions as the M-K method) sustained rather high HS and BS yields (33 and 83 wt%, respectively), although these values were lower than those of the original coal (60 and 85 wt%, respectively).

The restricted reaction of the benzene-extracted residue by the M-K method (Table 1) may be related to the removal of aromatic compounds from coal by benzene-extraction. In the M-K method, these extracted aromatic compounds may play an important role as electron-transfer agents from molten potassium to bulk constituents in coal. An enhancement of coal anionization with molten potassium in THF in the presence of 18-crown-6, which is known to accelerate the formation of solvated electrons,[7)] suggests the importance of an electron carrier, even for the system with molten potassium. In the case of the M-K/US method, however, the benzene-extractable materials as electron-transfer agents may play a less important role in the anionization reaction (Table 1).

In order to examine the effects of an electron-transfer agent on the coal anionization by both the M-K and M-K/US methods, Kairan coal was subjected to reductive ethylation in the presence and absence of naphthalene as an electron-transfer agent. The results are summarized in Table 2. By the M-K method in the absence of naphthalene, number of ethyl groups added per 100 carbon atoms was 4, and the yields of the HS and BS were 6 and 20 wt%, respectively. By the M-K/US method, number of ethyl groups added (15) and the yields of HS and BS (34 and 75 wt%, respectively) were much higher than those by the M-K method in the absence of naphthalene (Table 2). In the case of the M-K method, however, the presence of naphthalene significantly enhanced the extent of the reaction; The number of ethyl groups added per 100 carbon atoms increased 3 times and the yields of HS and BS increased more than 3.5 times. In contrast, only a small degree of enhancement of the reaction was observed by the M-K/US method. Thus, the results in Table 2 demonstrate that by using the M-K method electron-transfer agents enhance coal anionization with molten potas-

sium compared to the reaction solely with solvated electrons produced in THF. Such acceleration effect of electron-transfer agents has been commonly observed in the reduction of various organic compounds with alkali metal in THF.[8-10] Under ultrasonic irradiation, however, reductive alkylation of Yubari coal in Na/HMPA system has been reported to proceed more efficiently than that in Na/THF/naphthalene system,[11] suggesting that anionization via solvated electrons is more important than that via electron-transfer agents by the M-K/US method.

Since extraction with chloroform was carried out extensively for one week, significant amount of polar compounds, which form secondary bonds (e.g., hydrogen bond) between macromolecules in coal, will be removed for the chloroform-extracted residue. Although THF as the reaction solvent may also remove polar compounds similarly to chloroform, such an effect of THF may be ignored because of much shorter reaction time (6 h) than the Soxhlet extraction with chloroform (one week). The absence of secondary bonds prevents the formation of associated macromolecules to increase mobile constituents in the chloroform-extracted residue[12] compared to the case of the original coal and the heptane-extracted residue, resulting in efficient diffusion of electron-transfer agents to bulk constituents in the residue. This seems to be a reason why the ethylation product from the chloroform-extracted residue shows the highest HS yield among those prepared by the M-K method (Table 1).

The ultrasonic energy adopted in the present study (0.5 $W\,cm^{-2}$) is reported to be too weak to cleave covalent bonds in coal constituents, but strong enough to destruct secondary bonds between coal constituents.[13] Destruction of such secondary bonds by ultrasonic irradiation may make essentially the same effect as the removal of polar compounds mentioned above. In addition, cavitation induced by ultrasonic irradiation leads to highly efficient diffusion of solvent molecules[14] and presumably of solvated electrons into bulk constituents in coal. This will be the major reason why the M-K/US method leads to the efficient reaction of the benzene-extracted residue as well as the original coal containing polar compounds (Table 1).

Gold(III) Complexes of 2-Amino-4,6-dimethylpyrimidine

Dimitra KOVALA-DEMERTZI
Laboratory of Inorganic Chemistry, Department of Chemistry, University of Ioannina, Ioannina 45110, Greece
(Received March 26, 1990)

Synopsis. The reactions of Au(III) with 2-amino-4,6-dimethyl pyrimidine (ADMPY) are reported. Complexes of Au(III) with ADMPY have been isolated from reactions in aqueous and in methanolic solutions, and characterized by elemental analysis, IR spectra ^{1}H NMR spectra, electronic absorption spectra, conductivity in DMF solutions, and thermal gravimetric analysis.

The pyrimidine ring system present in nucleic acids, several vitamins, coenzymes, and antibiotics etc., provides potential binding sites for metal ions and any information on their coordinating properties is important as a means of understanding the role of metal ions in biological systems. The interaction of metal ions with nucleic acids constituents has been the subject of extensive investigations in recent years.[1,2]

The gold complexes are interesting in biological chemistry.[3] Many gold compounds were recently found to be strong antitumor agents,[4] more promising were found the binuclear gold complexes.[4] Gold complexes with nitrogen donor ligands[3,5] have been considered suitable for modern chrysotherapy associated with the treatment of rheumatoid arthritis. The gold antiarhritic compounds include important examples of inorganic-based pharmaceuticals.[6,7]

Experimental

Preparation of the Complexes. Au(ADMPY)Cl$_3$. (1) and Au(ADMPY)Br$_3$, (2). The complexes were prepared by mixing aqueous solutions of the ligand and $HAuCl_4$. aq or $AuBr_3$ [1 : 1 ligand to metal molar ratio]. The reaction mixture was stirred for 2h at room temperature. The precipitate was filtered off, washed with small amounts of ice-cold water and dried in vacuum over silica gel. Compound **1**; yellow powder, Found: C, 16.48; H, 2.04; N, 9.80; Au, 45.80; Cl, 24.80%. Calcd for C, 16.89; H, 2.12; N, 9.85; Au, 46.18; Cl, 24.93%. Compound **2**. red-brown powder, Found: C, 12.30; H, 1.15; N, 7.20; Au, 35.32; Br, 42.02%. Calcd for C, 12.87; H, 1.62; N, 7.50; Au, 35.17; Br, 42.82%.

[Au(ADMPY)$_2$Br]$_2$Br$_4$ (3). The complex was prepared by mixing methanolic solutions of the ligand and $AuBr_3$ [3 : 1 or 2 : 1 ligand to metal molar ratio]. After stirring for 24h at room temperature no precipitate was separated. The yellow solution was evaporated to dryness under reduced pressure. When the residual was dissolved in a small volume of CH_2Cl_2 and an excess of C_6H_6 was added, a red powder was precipitated. After filtration the powder was again dissolved in CH_2Cl_2 and precipitated by C_6H_6. The complex was washed with petroleum ether and dried as before. Compound **3**. Found: C, 21.20; H, 2.77; N, 12.64; Au, 28.64; Br, 34.65%. Calcd for C, 21.10; H, 2.63; N, 12.30; Au, 28.84; Br, 35.09%.

[Au(ADMPY)$_2$Cl$_2$](ADMPY)Cl · 2H$_2$O (4). The complex was prepared by mixing methanolic solutions of the ligand and $HAuCl_4$. aq [3 : 1 or 2 : 1 ligand to metal molar ratio]. When the reaction mixture was stirred for 24 h at room temperature, no precipitate was separated. The clear solution was evaporated to a small volume (2—3 ml CH_3OH) under reduced pressure. With addition of an excess of ether, a yellow powder was precipitated. After filtration the powder was redissolved in methanol and precipitated with ether. Compound **4**. Found: C, 30,08; H, 4.02; N, 17.67; Au, 27.50; Cl, 14.80%. Calcd for C, 30.54; H, 4.37; N, 17.81; Au, 27.82; Cl, 15.02%.

Physical Measurements. Infrared spectra were recorded on a Perkin-Elmer 580 spectrophotometer on KBr pellets in the 4000—400 cm^{-1} region and on Nujol mulls supported by polyethylene windows in the 500—200 cm^{-1} region. The electronic absorption spectra of the solution in dimethylformamide were recorded on Hitachi 100-70 and Cary 17D spectrophotometers. Solid state electronic reflectance spectra were run on Varian 634 and Cary 14 spectrophotometers. Analyses and other experimental techniques were as described previously.[8,9]

Results and Discussion

The complexes **1** and **2** were non conductors in dimethylformamide solutions in agreement with their four coordination and square planar geometry. The complex **3** was 1 : 2 electrolyte while the complex **4** was 1 : 1 electrolyte in DMF solution.[10] Λ_m **1**=9; Λ_m **2**=21; Λ_m **3**=108; Λ_m **4**=46 S cm^2 mol^{-1}.

The significant bands observed in the IR spectra of the ligand and their complexes are presented in Table 1. All the complexes showed reductions in the observed values of $\nu_{as}(NH_2)$, $\nu_s(NH_2)$ by 25—60 cm^{-1}, but they were not as large as expected if coordination of the -NH_2 nitrogen atom occurs,[9] indicating the presence of intermolecular hydrogen bonding of the -NH_2 protons.[11] No appreciable changes were observed in the 700—1000 cm^{-1} region, in which coordinated water bands appeared.[12] On the other hand, various IR absorptions of free ADMPY, corresponding to ring vibrations modes underwent more sizeable shifts and occasional splittings in the spectra of the new complexes, this is consistent with coordination of the ADMPY through ring nitrogen in the complexes.[8] The complexes **1** and **2** showed one strong band at 367 and 251 cm^{-1} respectively, which were assigned to the asymmetric stretching vibration of the X-Au-X group possibly coinciding with the ν(Au-X) of the same motion.[13] The ν(Au-Cl) stretching vibration was assigned to the very strong band at 360 cm^{-1} for the complex **4**. The appearence of one band may indicate a trans rather a cis square planar structure. The complexes exhibited an intense infrared band in the 400—430 cm^{-1} region, but no bands are observed in the spectra of the ligand in this region, this band thus must have a large ν(Au-N) character.[8]

The ^{1}H NMR spectrum of the ligand in DMSO-d_6 showed a peak at 2.15 ppm downfield from TMS, which assigned to the equivalent C_4-CH_3 and C_6-CH_3 group protons, a sharp singlet at 6.48 ppm was

assigned to the $-NH_2$ protons and another sharp singlet at 6.38 ppm was assigned to the C_5-H proton. The ^1H NMR spectra of the complexes **1** and **2** showed a downfield shift of the signal of the C_4-CH_3 and C_6-CH_3 protons and splitting of the signal was observed it can be noted that the symmetry of the pyrimidine molecule is disturbed. The protons of the amino groups exhibit characteristic downfield shifts by ca. 1.0—2.0 ppm in all the complexes indicating the occurrence protonation and/or coordination.[9] The spectra of the complex **4** showed two broad peaks centered at 7.4 and 6.1 ppm, assigned to the protons of the amino groups coordinate and free respectively.

The electronic absorption spectral data of square planar Au(III) complexes and the assignments of the observed bands are given in Table 2. The band at ca. 25.000—26.000 cm^{-1} is assigned to the $^1A_{1g}\rightarrow{}^1E_g$ transition. Brown, McKinlay, and Smith reported[14] that the positions and intensities of the lowest energy band $^1A_{1g}\rightarrow{}^1E_g$ appear to depend on the nature of the com-

plexing species. For the complexes of Au(III) with pyrimidine derivatives it was shown that, the intensity of the lowest energy band $^1A_{1g} \rightarrow {}^1E_g$ depended on the nature of the complexing species. The intensity range was much greater for the chlorides than the bromides (Table 2).

The thermal decomposition of the complex **4** was also studied by TG/DTG technique the TG and DTG curves showed that the dehydration process took place in two steps at 100 and 110 °C, and the dehydrated compound decomposed in the temperature range of 125—500 °C. The anhydrous compound $[Au(ADMPY)_2Cl_2]Cl$ (ADMPY) dissociated in three steps, two fast decomposition between 125—225 °C and 355—500 °C and another slow one between 225—340 °C. The complex **4** underwent and the endothermic reaction at 100—110 °C with mass loss corresponding to two molecules of water and also two endothermic and one exothermic reactions at 175 and 300 and at 440 °C respectively, with mass loss corresponding to the pyrimidine ring and halogen. The residue obtained at the end of the pyrolysis at 500 °C was 27.90% of the original weight, corresponding to Au(theoretical value 27.82%).

In accordance with the trans effect, the cis Pt(II), Pd(II), and Au(III) complexes can be synthesized directly from the $[MCl_4]^{2-}$ ions by reaction with N-donor ligand in methanolic or aqueous media, indicating that Cl^- has a greater trans effect compared to the N-donor ligand (L). While the replacement of chloride ions from $[MCl_4]^{2-}$ by (L) molecules give the cis isomer for the Pt(II) complexes, when $[AuCl_4]^-$,[15] $[PdCl_4]^{2-}$ [16] ions react with N-donor ligands (L) cis-trans isomerisation took place because of the higher stability of the trans-isomer. The *trans*-$Pd(L)_2Cl_2$[16] and *trans*-$[Au(L)_2Cl_2]Cl$ [15] isomers were thermodynamically more stable, so the *trans*-$[Au(ADMPY)_2Cl_2]Cl : ADMPY : 2H_2O$ isomer was precipitated instead of cis-isomer. The uncoordinated molecule of pyrimidine probably gives more stability to the compound. The failure to isolate $[Au(ADMPY)_4]Cl_3$ complexes is attributed to steric hindrance effects.

In the solid state, the ADMPY acts as unidentate through the endocyclic nitrogen N_1 or N_3 than through the nitrogen of the amino group. ^1H NMR data obtained for the diamagnetic complexes in DMSO-d_6 solution suggests a different coordination mode in which ADMPY coordinates via amino group nitrogen atom.[17] The most plausible structures for the isolated new complexes, based on the above results, are monomeric for **1**, **2**, and **4**. The latter complex exists rather in the trans form in view of the single band observed in the far ir spectra.[15] Considering the high value of molar conductivity in DMF solution and that there are no bands in the far IR spectra assignable to ν(Au-Br), the new complex $Au(ADMPY)_2Br_3$ seems to have a dimeric square planar structure $[Au(ADMPY)_2Br]_4$.

Finally it is worth noting that the four new compounds are possible candidate for antiarthritic activity[3,6,7] while the compounds **3** and **4** are possible candidate for antitumor activity.[4,18]

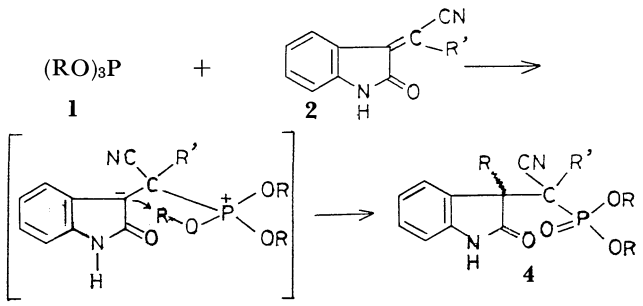
Organophosphorus Chemistry. XV.[1] The Reaction of 10-Dicyanomethylene-9(10*H*)-phenanthrenone with Alkyl Phosphites

Wafaa M. Abdou,* Neven A. F. Ganoub, and Mohamed R. Mahran
Department of Pesticide Chemistry, National Research Centre, Cairo, Egypt
(Received November 30, 1989)

Synopsis. The titled compound **5a** reacts with trialkyl phosphites and dialkyl phosphonates to give, in each case, two conformers (**A**+**B**) of the corresponding phosphonate **8** and **9**. The yields of the two isomers were estimated on the basis of ^{31}P NMR data. Besides, structures **8** and **9** were supported by analytical and spectroscopic measurements of the major isomer **8A** and **9A**. The rotational isomers were assigned in terms of the Newman projection and NMR data. Relative ratios were studied in the light of dynamic NMR spectroscopy.

Recently,[2] we have reported on the reaction of trialkyl phosphites with 3-cyanomethylene-1,3-dihydro-2*H*-indol-2-ones (**2**) which offered a new pattern of attack by these reagents on α, β-unsaturated carbonyl systems. The initially observed *C*-alkylation at the phosphonium intermediate **3**, accounted for the formation of the 1 : 1 phosphonate adducts **4** (Scheme 1).



Scheme 1.

This, together with the growing interest[3] in this area of research, has prompted us to study the behavior of 10-dicyanomethylene-9(10*H*)-phenanthrenone (**5a**) with trialkyl phosphites (**1a—c**) and with dialkyl phosphonates (**6a—c**).

Results and Discussion

Treatment of **5a** with trimethyl phosphite yielded a reaction mixture with two resonances at δ=29.47 and 26.31 in its ^{31}P NMR.[4] These absorptions were assigned to two phosphonate 1 : 1 conformers (**8Aa**+**8Ba**). The relative percentages were 70% and 30% respectively. The ^{1}H NMR spectrum of this material had signals at δ=3.49 (s, -COCH$_3$) and 3.89 [d, -P(OCH$_3$)$_2$][5] assigned to the major isomer **8Aa**, as well as, at δ=3.85 and 4.1 assigned to -COCH$_3$ and -P(OCH$_3$)$_2$, respectivley for the minor conformer **8Ba**.

The possible interconversion for the rotational isomers **8Aa**$\rightleftarrows$**8Ba** was studied by variable temperature ^{31}P NMR spectral measurements. At −20 °C, a marked increase was shown in the signal around δ=26 with recording a proportion of **8Aa** : **8Ba**=15 : 85. On the

other hand, at 100 °C, the relative ratio of the same isomers became 90 : 10. At this stand point, it could be concluded that the first product, less stable, is the kinetic product and that the isomerization occurs, for steric reasons, to the thermodynamically stable product.[6] The activation energy, computed for the ^{31}P NMR spectra for the process of retention of configuration is $\Delta G=8$ kcal mol^{-1}. The incomplete permutational isomerization is verified by the variable temperature ^{1}H NMR studies which gave the same results.

On the basis of these observations, and by an inspection of a model, drawn by Newman projection,[7] there is no plausible alternative structure for **8** other than the staggered conformers, which could exist as **A** [vicinal trans, (anti), major] or **B** [gauche, minor].

However, only the major rotational isomers (**8Aa—c**) could be obtained in pure form (CH_2Cl_2), which gave compatible analytical and spectroscopic measurement for the assigned structure (see Tables 2 and 3). On the other hand, all attempts to isolate **8B** in a pure analytical form were not successful, even by chromatographic technique.

Formation of the vinyl ether phosphonate 1 : 1 adducts **8** is believed to involve 1,4-carbophilic addition by the tervalent phosphite ester on the α,β-unsaturated carbonyl system in **5a** by Arbuzov-like rearrangement[8] of the resulting dipolar intermediate **7**.

Next, we have studied the behavior of **5a** toward dialkyl phosphonates (**6a—c**). When **5a** was heated with dimethyl phosphonate a non-crystalline material

a) See experimental for details of NMR experiments. b) The solvent is $CDCl_3$, qt.=quintet, sept.=septet.

^{1}H NMR and ^{31}P NMR spectra of **9a** showed that it was possible, as in case of **8a**, to change only the proportion of **9A** and **9B** in the mixture of **9a**, but with incomplete interconversion. Thus, the ligand rearrangement should be intramolecular in nature due to fluxioning of the molecule and does not involve any ionization process. The well-established structures for the two isomers are **9A** and **9B**.

Structural assignments for **9Aa—c** were supported by the mass spectra, IR, ^{1}H, ^{13}C, and ^{31}P NMR spectral data, and analyses which obtained for the new products **9Aa—c** (see, Tables 2 and 3).

Conclusion

It is evident that the initial step in the reaction of trialkyl phosphites with both **2** and **5a** is a carbophilic attack by the P(III) reagent on the most electrophilic carbon atom of the exo-conjugated system to yield phosphonium betaines **3** and **7**, respectively. However, while **3** is stabilized by *C*-alkylation (1,2-pattern) to give adducts **4**,[2] betaine **7** is stabilized by *O*-alkylation (1,4-pattern) to afford adducts **8**. In this respect, the behavior of **5a** toward trialkyl phosphites is also in great disparity to 9,10-phenanthrenequinone-monoimine (**5b**) and 9,10-phenanthrenequinone-monoxime (**5c**) which produce cyclic phosphorane structures with the same phosphite esters.[9,10]

Experimental

All melting points are uncorrected. The IR spectra were run on a Perkin-Elmer Infracord Spectrometer 157 (Grating) in KBr. Variable temperature, ^{1}H NMR and ^{31}P NMR spectra, were taken on a Varian Model FT-80 Spectrometer equipped with a 5 or 10 mm variable temperature, broad band probe. The mass spectra were performed at 70 eV on MS-50 Kratos (A.E.I.) Spectrometer. All reactions were carried out under N_2 atmosphere.

1. Reaction of 10-Dicyanomethylene-9(10*H*)-phenanthrenone (5a) with Trialkyl Phosphites (1a—c). General Procedure: To a stirred solution of **5a**[11] (0.01 mol) in 20 ml of CH_2Cl_2 (ether, acetonitrile, or toluene) at 0—5 °C were added a solution of TAP [TMP, TEP, and/or $(i\text{-PrO})_3$P (**1a—c**), respectively] (0.02 mol) in the same solvent (5 ml). After being warmed to room temperature, the reaction mixture was stirred for 10 h. The volatile materials were removed at 30 °C (first at 20 mm, then at 0.5 mm Hg, 1 mmHg=133.322 Pa) and the mixture of diastereomers **8** was collected. ^{31}P and ^{1}H NMR spectra of compounds **8** are collected in Table 1. Proportions of **8A**:**8B** are listed in Scheme 2. The mixture of isomers was redissolved in CH_2Cl_2 and kept at −10 °C for 3 days. The solvent was decanted and the procedure was repeated with fresh CH_2Cl_2. Crystals that separated out were collected and proved to be the major isomer (**8A**). Percentage yields (based on the isolated mixtures), physical and analytical data for compounds **8Aa—c** are presented in Tables 2 and 3.

The CH_2Cl_2 mother liquor was evaporated to give a colorless substance which still has two isomers **8A** and **B** in equal proportion (^{31}P NMR).

2. Reaction of 10-Dicyanomethylene-9(10*H*)-phenanthrenone (5a) with Dialkyl Phosphonates (6). General Procedure: A mixture of **5a** (0.01 mol) and dialkyl phosphonates [dimethyl, diethyl, and/or diisopropyl phosphonate] (4 ml) was heated at 100 °C in absence of solvent for 8—10 h (TLC). Excess DAP was distilled off to give a mixture of rotational isomers (**9A** and **B**) as a colorless substance. Compounds **9a—c** neither dissolve in NaOH (10%) solution nor respond to the $FeCl_3$ 1% color reaction. ^{31}P and ^{1}H NMR data for mixtures **9a—c** are given in Table 1. For **9A**:**9B** ratio in the diastereomeric mixture, see Scheme 3.

Working up the reaction mixture **9** in the same way as described in the case of **8**, resulted in isolation of **9Aa—c** in a pure form, see Tables 2 and 3.

Thermal Decomposition of the Adduct 9a. Compound **9a** (0.5 g) was heated in a cold finger sublimator at 220 °C (bath temperature) for about 30 minutes under reduced pressure (0.5 mm Hg). The substance that sublimed was boiled in light petroleum, filtered and recrystallized from cyclohexane to give (0.3 g, 85%) of **5a**, identified by mp, mixed mp and comparative IR spectra.[11] **6a** was detected in the receiver by the development of a violet color on addition of 3,5-dinitrobenzoic acid in the presence of alkali.[12]

Action of Diazomethane on 9Aa. **9Aa** (0.5 g) in ether (10 ml) was treated at 5 °C with an ethereal diazomethane solution (from 3 g, *N*-nitroso-*N*-methyl urea). The mixture was then kept at room temperature for 3 h. After removal of CH_2Cl_2, the residual substance was recrystallized from ether to give **8Aa** (0.46 g, 88.6%) (mp, mixed mp 167 °C, and comparative IR spectra).

Studies on 4-Thiazolidinones. IX.[1] The Conversion of 5-Substituted 2-Thioxo-4-thiazolidinones into Corresponding 2,4-Thiazolidinediones

Mohamed T. Omar,* Abd-Elrehiem Fouli, and Mahmoud Z. El-Garhi
Chemistry Department, Faculty of Science, Ain Shams University, Abbassia, Cairo, Egypt
(Received June 4, 1990)

Synopsis. The thioxo to oxo conversion in a variety of 2-thioxo-4-thiazolidinones **1** and **2** has been achieved simply by treating with bromine. A postulate for the route of interconversion is given and structures of all products are evidenced by analytical and spectral data.

Several methods have been used to effect the thioxo to oxo conversion in 2-thioxo-4-thiazolidinones. Thus, chloroacetic acid in aqueous solution[2] and hydrogen peroxide[3] were used successfully with 2-thioxo-4-thiazolidinone and its 5-alkylidene derivatives. However, the insolubility of many aryl-substituted 2-thioxo-4-thiazolidinones in aqueous chloroacetic acid prevents its use to effect the required transformation.[4] Furthermore, hydrogen peroxide may further oxidize the formed 2,4-dione into sulfoxides, sulfones, and even to sulfate ion.[3,5] The thioxo to oxo conversion has been achieved in 5-arylmethylene-2-thioxo-4-thiazolidinones via two step processes involving first conversion into 2-alkylthio-,[6] 2-(disubstituted amino)[7] 2-thiazolin-4-ones or 2-arylimino-4-thiazolidinones,[6] then treating the product with a hydrolyzing agent.[6,8] The use of the two-step method is somewhat limited as the first step affords mixture of products.

Now, we report an easy method for the conversion of aryl-substituted 2-thioxo-4-thiazolidinones into corresponding 2,4-thiazolidinediones. The reaction is carried out by treating the thioxo compound with bromine in 90% acetic acid solutions. The versatility of this method is illustrated by the successful results obtained upon application on a variety of 2-thioxo derivatives comprising 5-aroylmethyl-3-benzyl-, (*E,Z*)-5-aroylmethylene-3-benzyl-, 5-aroylmethyl- and (*E,Z*)-5-arylmethylene-2-thioxo-4-thiazolidinones (compounds **1a—e** and **2a,b,f,g**). Thus, refluxing the acetic acid solutions of **1a** and **2a** and of **1b** and **2b** with bromine for 2h gives 5-benzoylmethylene- and 5-(4-methylbenzoylmethylene)-3-benzyl-2,4-thiazolidinediones (**3a** and **3b**), respectively. The reaction of the 3-unsubstituted derivatives **1c—g** with bromine is faster than with the 3-benzyl counterparts and the reaction is completed after warming for 5 min in the case of **1c,d,e** and 15 min in the case of **2f,g**, affording the 2,4-diones **3c,d,e** and **3f,g**, respectively. However, treatment of **1c,d** with bromine at room temperature yielded 5-benzoylmethylene- and 5-(4-methylbenzoylmethylene)-2-thioxo-4-oxo-1,3-thaizolidinones, respectively. This latter method represents a new route to synthesize the hitherto unknown 5-aroylmethylene-2-thioxo-4-thiazolidinones **2c,d**.

Conversion of **1** into **3** has occurred, most probably, via the dehydrogenated product **2** since it has been reported that **2a** is formed upon treating **1a** with bromine for 5 min.[9] This is supported chemically by the independent transformation of **2a** and **2b** into **3a** and **3b**, respectively.

The structures of **3f,g** are based exclusively on comparsion (mp and IR) with authentic samples[10,11] and that of **3c** is rigidly confirmed by identity (mp and IR) with the (*E*)-isomer isolated from the (*E,Z*)-mixture obtained upon treating 2,4-thiazolidinedione with phenylglyoxal. The structures of **3a,b,c,d,e,g** and **2c,d** are deduced from analytical data and infrared spectra. All the spectra of **3** show the complex carbonyl pattern extending to 1745 cm^{-1} consistent with the stretching vibrations of coupled carbonyl groups and those of **2** show one carbonyl group stretching vibration at ca. 1680 cm^{-1}. Moreover, compounds **2** give the color reaction reported previously by Turkevich et al.[12] to characterize the 2-thioxo-4-thiazolidinones.

The problem of configurational assignment to **2c** and **3c,f,g** has been solved by ^1H NMR spectroscopy. The (*E*)-configuration has conferred to **2c** and **3c** as they are identical with the (*E*)-isomers isolated from

the (*E,Z*)-mixtures obtained upon condensing 2-thioxo-4-thiazolidinone and 2,4-thiazolidinedione with phenylglyoxal. However, **3f,g** are (*E,Z*)-mixtures and integrated proton ratios show that the (*Z*)-isomers constitute 10% and 30%, respectively. The (*E*)- and (*Z*)-configurations are deduced by comparing the observed chemical shift values of the exocyclic olefinic protons with the incremented values.[13] The olefinic proton is relatively deshielded in the (*Z*)-rather than the (*E*)-isomers.

The thioxo to oxo conversion may be visualized to occur via the route represented in Scheme 1. The possibility of formation of **3** via the action of water on 5-aroylmethylene-2-bromothio-2-thiazolin-4-one (**6**) which is believed to be formed via elimination of hydrogen bromide directly from **4**, in compounds having no substituents at the 3-position, cannot be ruled out, especially that easy displacement of the 2-alkylthio group by nucleophiles in similar systems has been reported.[6] A chemical support for the formation of **4** is gained from the isolation of semisolids containing bromine upon treating **1a** and **2g** with bromine in chloroform. Formation of sulfonium salts is well-known upon treating sulfides with N-halo amides, but to our knowledge, formation of it upon treating with bromine is not reported.

The 5-aroylmethyl- and 5-aroylmethyl-3-benzyl-2-thioxo-4-thiazolidinones **1b—e** are synthesized by treating the respective 3-aroylacrylic acids[15] with ammonium dithiocarbamate and benzyl dithiocarbamate.

The structures of **1b—e** are based on microanalysis, infrared and ^{1}H NMR spectroscopy. The structures of **2a,b** are based on analytical and infrared spectral data which show the stretching absorptions consistent with ketonic and amidic C=O groups.

Experimental

All melting points are uncorrected. IR spectra were measured on a Unicam SP 1200 spectrometer as KBr discs. ^{1}H NMR were recorded in DMSO-d_6 on a Varian EM 390, 90 MHz instrument except those of **2c** which were recorded on a JEOL FX-900, 90 MHz apparatus, using TMS as an internal standard with chemical shifts (δ) expressed in ppm downfield from it. ^{13}C NMR was recorded on a JEOL FX-900, 22.5 MHz instrument. Mass spectrum was measured on a Varian MAT SM 1 spectrometer. The term acetic acid used herein refered to a 90% (v/v) solution.

Starting Materials. The following compounds were prepared as described previously: 5-Benzoylmethyl-3-benzyl-2-thioxo-4-thiazolidinone (**1a**).[9] 5-Benzoylmethylene-3-benzyl-2-thioxo-4-thiazolidinone (**2a**).[9] 5-Benzylidene-2-thioxo-4-thiazolidinone (**2f**).[16] 5-(4-Methoxybenzylidene)-2-thioxo-4-thiazolidinone (**2g**).[17]

5-(4-Methylbenzoylmethyl)-3-benzyl-2-thioxo-4-thiazolidinone (1b) and 5-Aroylmethyl-2-thioxo-4-thiazolidinones (1c—e). A solution of ammonium benzyldithiocarbamate or ammonium dithiocarbamate (10 mmol) in ethanol (10 ml) was added to a stirred solution of 3-benzoyl-, 3-(4-methylbenzoyl)- or 3-(4-bromobenzoyl) acrylic acid (10 mmol) in ethanol (10 ml) at room temperature. Stirring was continued for 30 min, then concentrated hydrochloric acid (3.0 ml) was added in three portions during 30 min and the pale yellow solid prepicipitated after stirring for 2 h was filtered off, washed successively with water, dried and recrystallized from the proper solvent to give the title compounds.

Conversion of 1c,d into 2c,d. Bromine (20 mmol) was added to a solution of each of **1c,d** (10 mmol) in acetic acid (20 ml) and the mixture left to stand at room temperature for 1 h during which hydrogen bromide gas evolved. The reaction mixture was poured into cold water and the precipitated solid was filtered off, washed several times with cold water, dried and recrystallized from the proper solvent to give the respective **2c,d**

Conversion of 1b into 2b. A solution of **1b** (10 mmol) in glacial acetic acid (20 ml) was heated with bromine (10 or 20 mmol) for 5 min. The reaction mixture was treated with charcoal, concentrated and the faint yellow crude product was recrystallized from toluene to give 5-(4-methylbenzoylmethylene)-3-benzyl-2-thioxo-4-thiazolidinone (**2b**).

5-Aroylmethylene-3-benzyl- (3a,b), 5-Aroylmethylene- (3c,d,e), and 5-Arylmethylene-2,4-dioxo-1,3-thiazolidinediones (3f,g). A solution of **1** (10 mmol) or **2** (10 or 20 mmol) in acetic acid (20 ml) was heated with bromine (20 mmol) for the time required. The reaction mixture was treated with charcoal, concentrated and the pale yellow crude product was filtered off, washed several times with small portions of ice-cold diethyl ether and dried.

Compounds **1a** and **2a** and **1b** and **2a** were refluxed for 2 h and afforded **3a** and **3b**, respectively.

Compounds **1c,d,e** were refluxed for 5 min and gave **3c,d,e** respectively.

Compounds **2f,g** were refluxed for 15 min and gave **3f,g** respectively.

Synthesis of Authentic Samples. A mixture of 2,4-thiazolidinedione or 2-thioxo-4-thiazolidinone (10 mmol), phenylglyoxal (10 mmol), anhydrous sodium acetate (30 mmol), and glacial acetic acid (50 ml) was refluxed for 40 min. The reaction mixture was poured into ice-cold water and the precipitated solid was filtered off, washed successively with water and dried. The faint brown crude product (80%) melted at 200—205 °C obtained from 2,4-thiazolidinedione is found to be a mixture of the (*Z*)- and the (*E*)-isomers in the ratio of 1 : 9, respectively, by ^{1}H NMR spectroscopy. Separation of the isomers was attained by dissolving the crude product in glacial acetic acid and allowing to stand overnight. The faint brown crystals which separated are filtered off and recrystallized from glacial acetic acid to give (*E*)-5-benzoylmethylene-2,4-thiazolidinedione (**3c**), 90%.

Dilution of the original mother liquor with water precipitated a faint brown solid which was recrystallized from benzene to give the (*Z*)-isomer 10%.

The crude yellowish brown product (80%), mp 214—220 °C obtained from 2-thioxo-4-thiazolidinone was found to be a mixture of (*Z*)- and (*E*)-5-benzoylmethylene-2-thioxo-4-thiazolidinones (**2c**) in the ratio of 3 : 7, respectively, as evidenced by ^{1}H NMR spectroscopy. The fraction which precipitated upon allowing the 1-butanol extract to cool was filtered off and recrystallized from 1-butanol to give (*Z*)-**2c** 30%.

The insoluble fraction was recrystallized from dioxane to give (*E*)-**2c** 70%.

Reactions of 1a and 2g with Bromine in Chloroform. A mixture of **1a** or **2g** (5 mmol), bromine (10 mmol) and chloroform (20 ml) was refluxed for 3 h. Evaporation of the solvent using rotary evaporator left a viscous oil. Trituration with light petroleum (bp 40—60 °C) followed by recrystallization from toluene failed to give a pure praduct. The faint yellow crystals obtained upon dissolution in 90% acetic acid solution was filtered off, dried and recystallized from glacial acetic acid.

Compound **1a** gave a product (70%) identical (mp and IR) with **3a**.

Compound **2g** afforded **3g** (70%), identical (mp and IR) with an authentic sample.[11]

Authors are grateful to Dr. H. Fröhlich, Institute of Organic Chemistry, University of Vienna for Microanalysis, ^{1}H NMR and ^{13}C NMR measurements of compound **2c**.

(Received September 12, 1990)

Depth profiling for thin film sample using laser induced fluorescence spectroscopy under normal incidence conditions, based on the principle of reciprocity, was studied. A laminated Langmuir–Blodgett model film sample (187 nm in thickness) with a concentration depth profile which varies as a stair-like function with 20.8 nm steps was prepared. Using this model film sample, observation angle dependence of fluorescence intensity was compared with theoretical results based on the principle of reciprocity, and it was shown that the principle held for the thin film sample having a continuous concentration depth profile. Secondly, these data were used to reconstruct the concentration depth profile by the least square method. The quantitative concentration depth profiling results obtained for the model film sample were satisfactory. This method can be used for film samples thinner than the wavelength of the excitation light and its spatial resolution in the depth direction is estimated to be in the order of a nanometer.

The importance of measurements of local concentration depth profiles and three-dimensional profiles with resolution in submicrometer or nanometer regions has been emphasized in many technological fields such as electronic devices,[1] solid surface physics,[2] and cell biology.[3] Optical spectroscopical concentration depth profiling methods should be non-destructive, non-contact methods without using a high vacuum system. Attenuated total reflection infrared (ATR IR) adsorption spectroscopy[4] and total internal reflection fluorescence spectroscopy[3] are well known non-destructive depth profiling methods. Although it is estimated theoretically that the ATR IR method has a depth resolution about one-tenth that of the wavelength,[5] practical analysis for thin film samples thinner than the wavelength used is difficult. Total internal reflection fluorescence spectroscopy has been used to determine concentration depth profiling of proteins adsorbed at a solid/liquid interface,[6] depth distribution of fluorescent species in silk fabrics,[7] and the concentration ratio of a fluorophore between a two layer film sample.[8] However, until now only qualitative results or results for a simple concentration depth profile model, such as a uniform concentration distribution, have been reported.

Recently, Suci and Reichert[9] have studied the reciprocity in an angular pattern of fluorescence, and they have investigated the possibility of depth profiling, using Langmuir–Blodgett (LB) films, for the sample having a uniform concentration depth profile.[10] For such film samples in which fluorophores were uniformly distributed over a range of 52.8 nm, i.e., a rectangular profile, the central position of the rectangular profile could be accurately determined, which demonstrated the possibility of determining the width of the rectangular distribution profile. This depth profiling method using variable angle fluorescence date is attractive, since it can be used for the concentration depth profile of a film sample thinner than the wavelength of the excitation light, with highest sensitivity applying laser as the beam source. However, as actual samples usually have a complicated concentration distribution, it is important to study the validity of this method for the thin film sample which has a concentration depth profile varying continuously with distance from the surface.

In the present study, a 187 nm thick LB film sample, having a concentration depth profile which varies as a stair-like function with 20.8 nm steps, was prepared as the model sample. By using variable observation angle fluorescence data obtained under normal incidence conditions, it is shown that the reciprocal principle holds for the sample having a nonuniform concentration depth profile. Then the profile is determined by applying this method.

Method Outline

According to the reciprocal principle for fluorometry proposed by Suci and Reichert,[9] as shown in Fig. 1, fluorescence intensity $F(\theta)$ measured at the observation angle θ under normal incidence conditions is expressed as,

$$F(\theta) = k\int_0^t C(z)T(\theta, z)\mathrm{d}z, \quad (1)$$

where $C(z)$ is the concentration distribution in the depth direction z, t is the thickness of the sample, and k is a constant related to spectroscopical parameters such as absorption coefficient and fluorescence quantum yield. The function $T(\theta, z)$ is defined as a transmission function, and its functional form has been given by a

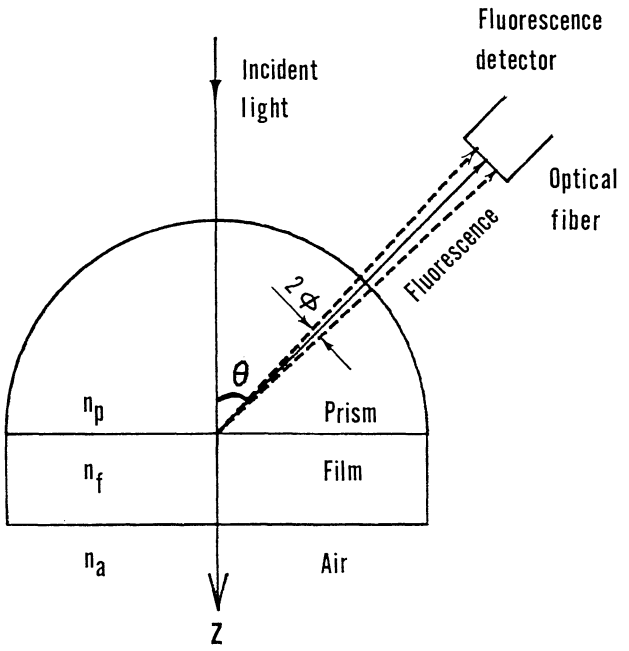

Fig. 1. Schematic of laser induced fluorescence spectroscopy under normal incidence conditions based on the reciprocal principle.

theoretical analysis of the multiple reflection of the electromagnetic waves between the prism/film and film/air interfaces.[9]

Suci and Reichert verified the propriety of the reciprocity described by Eq. 1 using the sample in which a fluorophore is localized at a certain distance z_0 from the surface. As the fluorophore localizes at z_0, the concentration distribution $C(z)$ becomes $C_0\delta(z-z_0)$, and Eq. 1 becomes

$$F(\theta, z_0) = kC_0T(\theta, z_0). \quad (2)$$

They measured the observation angle dependence of the fluorescence intensity $F(\theta, z_0)$ and compared it with the calculated value of $T(\theta, z_0)$ to show the propriety of the transmission function $T(\theta, z)$. In addition, they applied it to a uniform concentration distribution with which $F(\theta)$ is the integrated form of $T(\theta, z)$.[10]

In the present study, we tried to obtain the concentration distribution $C(z)$ from the measured data $F(\theta)$ and the relationships described in Eq. 1. The function $C(z)$ can be obtained by solving the inverse integral of Eq. 1, because $T(\theta, z)$ is known theoretically and $F(\theta)$ is given experimentally. However, the inverse problem of the convolutions, as it well known, does not always have an analytical solution, and the numerical method is frequently confronted with the problem of divergence and precision. Then, a numerical fitting method was applied to obtain $C(z)$. If the physical and chemical processes leading to the concentration distribution can be guessed, a general functional form of $C(z)$ is roughly estimated. For example, $C(z)$ is an error function type for a diffusion limiting process, and an exponential one for a chemical kinetics system. Hence, an exact function $C(z)$ is obtained by the following numerical fitting, which utilizes the least square method. The functions $F_{cal}(\theta)$ and $F_{mea}(\theta)$ are defined as the calculated function $F(\theta)$ for a guessed or trial function $C(z)$ and an experimentally obtained one, respectively. The exact form of $C(z)$ is determined by minimizing the following value of s,

$$s = \sum_i [F_{mea}(\theta_i) - F_{cal}(\theta_i)]^2/g_{\theta_i}, \quad (3)$$

where i means the i-th measurement data, and g_{θ_i} is a weight factor. In the present report, this fitting method was used to obtain $C(z)$.

Experimental

A block diagram of the experimental set up is shown in Fig. 2-A. An argon-ion laser provided the excitation light (λ_i=488 nm). The laser output power was adjusted to about 10 mW. A quarter-wave plate and a polarizer were used to adjust the polarization of incident light. The laser beam was modulated with a chopper. The chopped beam was focused on the focal plane of hemicylindrical prism (n_p=1.88 at 587.6 nm). The prism was 1 cm in diameter and 2 cm in length. The hemicylidrical prism was mounted on the rotating stages as shown in Fig. 2-B. Both the rotating stages and hemicylindrical prism were coaxially adjusted. An optical lightguide (50 cm length; 0.11 cm bundle diameter; step index type glass fiber; 0.57 numerical aperture) was used to collect the fluorescence transmitted through the prism. One end of the optical lightguide was fixed at the focal plane of the prism and the other end was coupled with a monochromator. A film polarizer was placed in front of the optical lightguide. The film polarizer restricted the collected fluorescence to the perpendicularly polarized component. A photomultiplier (Hamamatsu R928) was used as a detector. The signal from the photomultiplier was fed into and amplified with a lock-in amplifier.

The incident angle and the observation angle can be varied by adjusting the relative position of the two rotating stages. In the experiment, the incident angle was kept at 0°, while the observation angle θ was changed from 15° to 80° with 1° steps. The absolute value of the observation angle was determined as follows; rotating the upper stage from the location at which the laser beam is in normal incidence condition to that at which the reflected beam irradiated on the center of the fiber. The value of the observation angle is double the upper rotating stage angle. As shown in Fig. 1, the uncertainty ϕ at the observation angle θ is determined by the fiber bundle size and the distance between the fiber and the irradiation point. For this system, ϕ is estimated to be ±0.7°.

Sample. The method of Langmuir-Blodgett deposition used was the same as described elsewhere.[11] The two species used to fabricate the model film sample were icosanoic acid (eicosanoic acid) (analytical grade, Kanto Kagaku) and *N,N'*-dioctadecylrhodamine B (DORB) (Nippon Kankoh-Shikiso Kenkyusho).[12] Aqueous cadmium sulfate solutions (5×10^{-5} mol dm^{-3}) was used as a subphase. A benzene solution of

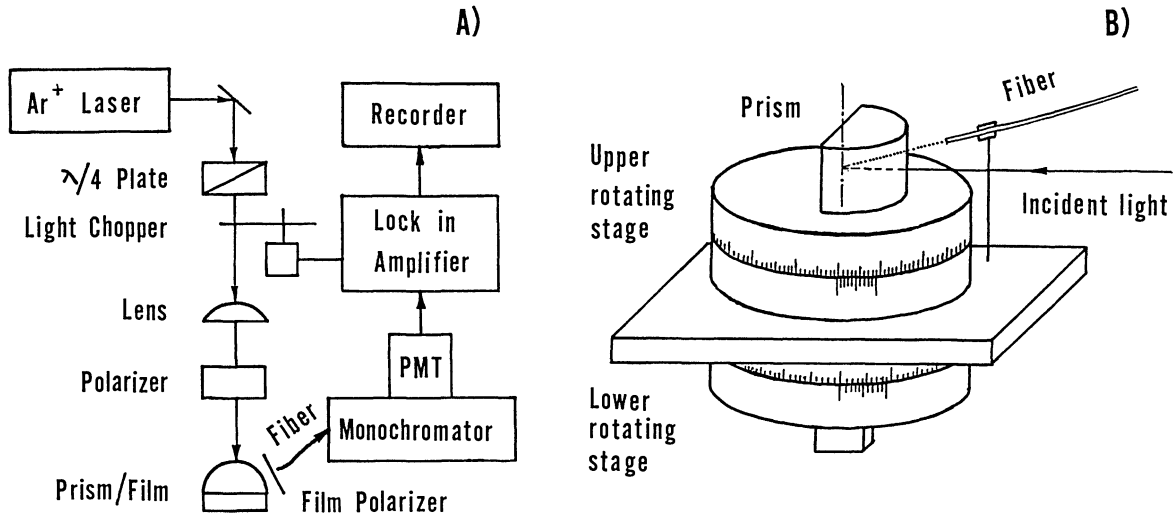

Fig. 2. Schematic diagram of the experimental setup including a detailed optical arrangement of the detection unit.

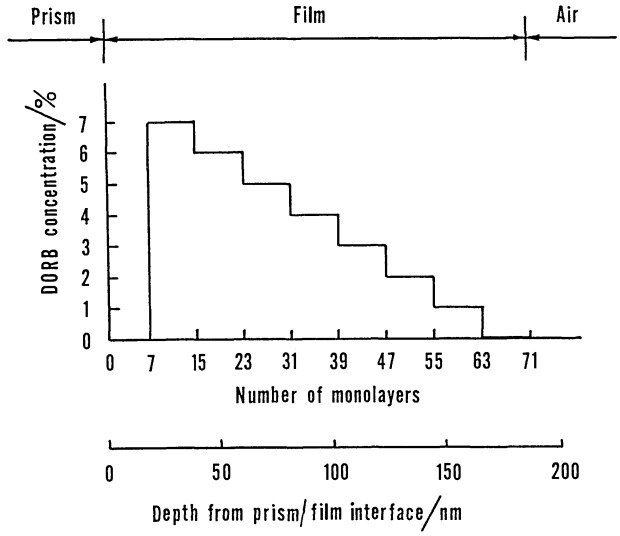

Fig. 3. Concentration depth profile of the model LB film sample.

icosanoic acid and mixtures of icosanoic acid and DORB with a certain molar ratio were spread on the subphase in a Langmuir trough (Kyouwakagaku). The LB layers were deposited onto the prism at a film pressure of 25—30×10^{-3} N m^{-1}. The prism surface was first precoated with seven layers of cadmium icosanoate to ensure the surface was uniform and hydrophobic. Secondly, eight layers of 7% DORB (the unit of DORB concentration is the molar percent) and cadmium icosanoate mixture were deposited. Then another eight layers of 6% DORB and cadmium icosanoate mixture were deposited. This procedure was repeated eight times to laminate layers of DORB in which the concentration was being changed from 7% to 0% as shown in Fig. 3. The total number of monolayers was 71.

When the molar ratio of dye to icosanoic acid is less than 10%, the mixed monolayers and multilayers have a similar structure to cadmium icosanoate LB films.[11,13] The reported thickness of a monolayer of cadmium icosanoate and the refractive index of the multilayers are 2.64 nm and 1.53, respectively.[11] Thus the total film thickness can be estimated from the number of monolayers, and it was calculated to be 187 nm. The multilayers deposited onto the curved part of the prism were removed with an acetone-soaked wadding[14] to prevent interference with the fluorescence measurement.

The fluorescence peak of the model sample appeared at 580 nm, and this peak was used in the following experiments.

Results and Discussion

To verify the propriety of the reciprocity for a nonuniform $C(z)$, fluorescence dependence on the observation angle was measured for the model sample under normal incident conditions, and the results were compared with the theoretical values calculated using Eq. 1. The experimental results are plotted in Fig. 4. As the concentration distribution $C(z)$ for the model sample shown in Fig. 3 is written as follows,

$$C(z) = \begin{cases} 0\% & 0 \leqslant z \leqslant 7d \\ (8-j) & 8jd \leqslant z \leqslant 8(j+1)d,\ j = 1, 2, 3, \cdots, 8 \end{cases} \quad (4)$$

where d is the thickness of the monolayer, 2.64 nm, then the theoretical value $F_{cal}(\theta)$ can be calculated by substituting Eq. 4 into Eq. 1 (the values of the parameters and material constants are described in the experimental section). The calculated results are shown by a solid line in Fig. 4. The theoretical values agree well with the experimental results, where the most appropriate value of k in Eq. 1 is 2.3×10^{-3} (%$^{-1}$ nm^{-1}). Therefore, the propriety of the reciprocity is confirmed for the nonuniform concentration distribu-

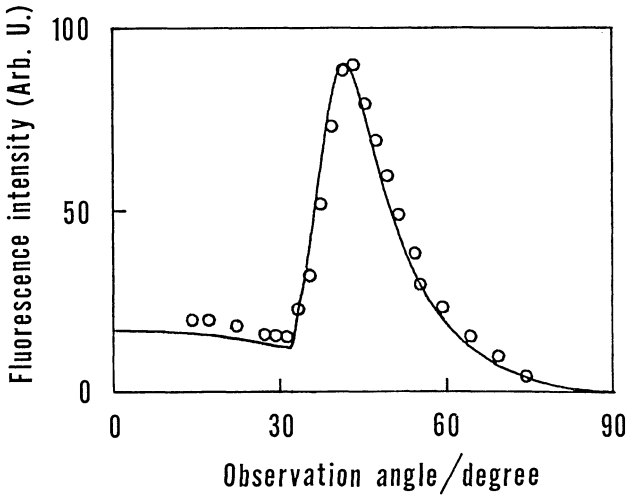

Fig. 4. Theoretical and experimental results of the angular dependency of the fluorescence intensity measured for the model sample. The theoretical values are described by the solid line, and the experimental results are plotted as circles.

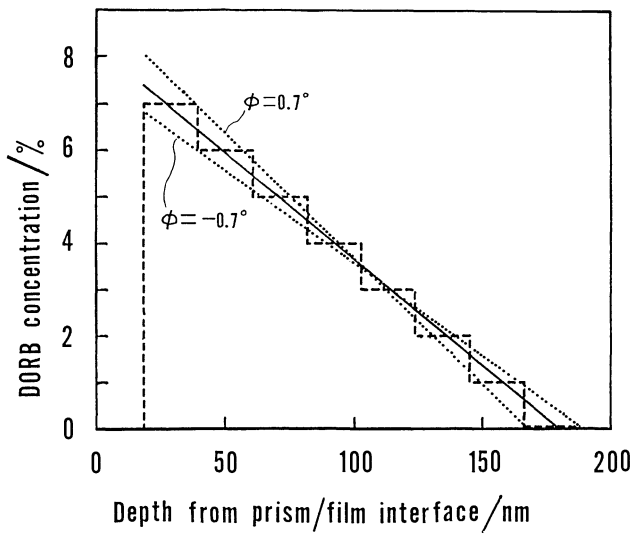

Fig. 5. Reconstructed concentration depth profile for the model film sample. The solid and dashed lines represent reconstructed and actual $C(z)$ values, respectively. The dotted lines represent the error region of the reconstructed results given by the experimental uncertainty of the observation angles.

tion, and it is proved that the reciprocity described in Eq. 1, which has been partially verified for localized and uniform concentration distribution, is applicable to a general functional form of $C(z)$. These results suggest that the arbitrary concentration depth profile $C(z)$ can be obtained from Eq. 1.

Next, concentration depth profiling which was proposed in the method outline section, based on the reciprocal theory, was examined. As mentioned in the method outline section, $C(z)$ can be obtained from the least square method of Eq. 3, when the functional form of $C(z)$ is roughly estimated. In the present case, the linear function,

$$C(z) = Az + B, \tag{5}$$

is assumed to be a trial function, and the constants A (% nm^{-1}) and B (%) which give the nearest form to the actual distribution shown in Fig. 3 are tentatively obtained from Eq. 3. Using the data presented in Fig. 4 and the most appropriate value of k obtained above, the constants A and B are obtained as $-0.04\%\ \mathrm{nm}^{-1}$ and 8.0%, respectively, and the reconstructed line is shown in Fig. 5 with the actual distribution indicated by a dashed line. The obtained result $C(z)$ reconstructs well the absolute value of the concentration, and shows the decreasing profile. Hence the calculated concentration depth profile of DORB in the model sample is considered to be reasonable, and the propriety of the present depth profiling method is verified.

The main experimental error factor of this system is the uncertainty of the observation angle. As stated in the experimental section, the uncertainty ϕ at observation angle was estimated to be $\pm 0.7°$. The reconstructed results in which uncertainty was taken into consideration are shown in Fig. 5 with dotted lines. These reconstructed results become better when a fiber with smaller bundle size is used to reduce the uncertainty of the observation angle. In this experiment, the concentration changes of 20 nm steps in a 187 nm thick sample shown in Fig. 3 can be recognized. Considering the experiment errors in Fig. 5, although the exact value of the spatial resolution in the depth direction is not given, a resolution of less than 20 nm can be expected for the present method. It is no exaggeration to say that the present experiment is the first which obtains a quantitative depth profile for a thin film thinner than the excitation wavelength using a nondestructive spectroscopic technique. For thin film samples with thickness on the order of a wavelength or thinner, this method is particularly meaningful, since other optical depth profiling methods such as photoacoustic spectroscopy[15] cannot easily yield information on depth profiling for such thin film samples.

As stated above, the reconstructed concentration depth profiling results would become better when a fiber with a smaller bundle size is used. A smaller bundle size also leads to a decreased signal to noise ratio. A detailed discussion on the application limits of the present method, which are considered to be restricted by the experimental conditions such as the uncertainty and accuracy of the observation angle and signal to noise ratio, will be reported elsewhere.

Althouth the absolute value of A (% nm^{-1}) and B (%) were obtained for the present model film sample, it is generally difficult to known k for the actual samples.

Hence only a relative concentration depth profile can be obtained using the least square method.

The present method is similar to the conventional ATR method, where variable incident angle data are used to reconstruct $C(z)$.[4,5,7] For a bulk sample, the ATR method has been proved to be effective. However, in the conventional ATR method, only total internal reflection occurring at the prism/film interface shown in Fig. 1 is considered, thus only the data obtained beyond the critical angle can be used to reconstruct $C(z)$. For the film sample with a thickness on the order of the incident light wavelength or the thinner, such as our model film sample, the conventional ATR method in which only consider evanescent wave decays from prism/film interface exponentially cannot be applied. It is also necessary to consider the reflection effect which occurs at the film/air interface for the evanescent wave. On the other hand, in the present method, $T(\theta, z)$ is derived by considering multiple reflection occurring at the interfaces of the prism/film and film/air shown in Fig. 1,[10] so data at any observation angle can be applied to samples which are thinner than the excitation wavelength or the evanescent wave.

In summary, concentration depth profiling using fluorescence spectroscopy under normal incidence conditions based on the reciprocal principle was demonstrated for a 187 nm thick film sample. The present depth profiling method had a high spatial resolution and could be used for ultra thin film samples. Using normal incidence conditions, it was possible to obtain a local three-dimensional profile by scanning the excitation beam. In addition, dynamics and kinetics of the fluorophore can be measured if array detectors are applied to obtain various angular data simultaneously. Therefore, this method is expected to be a useful one for analytical and spectroscopical studies of thin films and surfaces.

The authors wish to express their thanks to Professor Y. Gohshi of the University of Tokyo, for his useful advices in preparation of model LB film sample.

X-Ray Crystal Structures of Ti(IV)-4,4′-Methylenebis(antipyrine) Complexes, $[Ti(dam)_3](ClO_4)_4$. Formation of Eight-Membered Chelate Rings and Aromatic Ring Stacking Responsible for Characteristic Coloration

Akio YUCHI,* Motoo SHIRO,† Hiroko WADA, and Genkichi NAKAGAWA
Department of Applied Chemistry, Nagoya Institute of Technology, Gokiso, Showa, Nagoya 466
† Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima, Osaka 553
(Received September 28, 1990)

X-Ray crystallographic studies have been made for two Ti(IV) complexes with 4,4′-methylenebis(antipyrine) (so-called diantipyrylmethane, abbreviated to dam) used for spectrophotometry of Ti(IV). The crystal data and final R values are: $[Ti(dam)_3](ClO_4)_4$ (**1**), triclinic, $P\bar{1}$, a=15.099(2), b=22.308(2), c=14.015(2) Å, α=100.00(1), β=116.68(1), γ=87.16(1)°, V=4151(1) Å^3, Z=2, R=0.124 for 8060 reflections; $[Ti(dam)_3](ClO_4)_4 \cdot H_2O$ (**2**), monoclinic, $P2_1/c$, a=14.075(3), b=29.127(7), c=21.386(6) Å, β=122.42(1)°, V=7401(3) Å^3, Z=4, R=0.105 for 6685 reflections. The reagent dam acts as a bidentate ligand to form eight-membered chelate rings. Between a pyrazolone moiety of one ligand and a phenyl ring of another prevails aromatic ring stacking, which gives extra stability to these complexes and is responsible for the characteristic charge transfer band around 385 nm.

4,4′-Methylenebis(antipyrine) (so-called as diantipyrylmethane abbreviated to dam; Fig. 1) reacts with titanium(IV) in a strongly acidic medium to form a yellow complex having an absorption maximum at around 385 nm. This reaction has widely been used for selective photometric determination of titanium(IV).[1–10]

Although the metal-to-ligand ratio of the species was determined to be 1:3, the exact composition including the hydrolysis degree of Ti(IV) center has been unknown. Provided dam forms a chelate ring (Fig. 1), it will be a large one containing not less than eight members, which is known to be hardly formed.[11,12] Furthermore, the mechanism for strong coloration upon coordination to titanium(IV) is not clear.

Preparative works in a strongly acidic medium used for spectrophotometry afforded two kinds of crystalline compounds having the composition of $[Ti(dam)_3](ClO_4)_4$. To elucidate the points mentioned above, we have made X-ray crystal structure analysis for these compounds and found unusual eight-membered chelate rings and remarkable aromatic ring stacking responsible for the coloration.

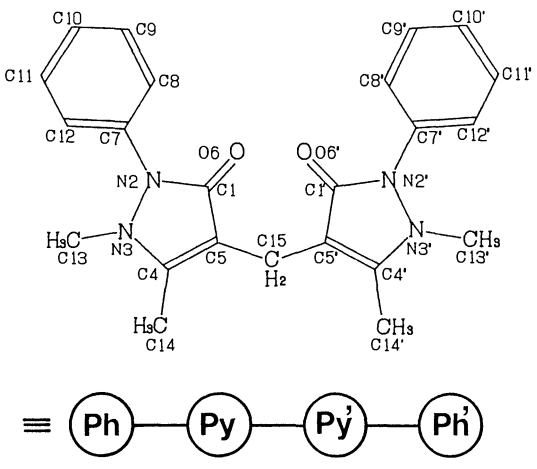

Fig. 1 Atom-numbering system of diantipyrylmethane.

Experimental

Preparation of the Complexes. Titanium(IV) tetrachloride was reacted with 4,4′-Methylenebis(antipyrine) in perchloric acid solution. Slow evaporation gave only small amounts of orange crystals(**1**) together with yellow powder. We could not perform chemical analysis for the complex **1**.

After these were filtered off, the filtrate was further stood to give larger amounts of violet crystals(**2**). Found: C, 50.53; H, 4.57; N, 10.41%. Calcd for $[Ti(dam)_3](ClO_4)_4 \cdot H_2O$: C, 50.86; H, 4.59; N, 10.32%. The water content determined by Karl Fischer's method (1.1%) was in good agreement with the calculated value (1.11%). The compound **2**, when ground, changes in color to orange similar to crystalline **1**.

X-Ray Analysis. Crystallographic details for **1** and **2** are given in Table 1. The space group of **1** was possible to be either $P1$ or $P\bar{1}$, but was determined to be the latter, after the structure refinement, on the basis of the significance test of the R values for the respective space groups. Intensity data were collected on a Rigaku AFC-5R diffractometer with graphite-monochromatized Cu $K\alpha$ radiation (λ=1.54178 Å). The ω–2θ scan technique was employed with an ω-scan width of $(1.2+0.2 \tan\theta)$ deg at a scan rate of 6 deg min^{-1} with 5 s background counts. No significant variations in intensities of 3 standard reflections monitored every 100 measurements were observed during data collection.

The structures were solved by the conventional heavy-atom method. In difference Fourier maps for **1** and **2** synthesized without the contributions of the perchlorate O atoms, five or more peaks were found around respective Cl atoms. We assumed the O atoms to be disordered, but could not clearly interpret the arrangement of peaks on the basis of any superpositions of the disordered anions. For each anion, four rather high peaks exhibiting an approximate configuration of the anion were adopted and kept fixed during refinement. The geometries thus obtained are of less accuracy: mean Cl–O=1.43 Å (ranging in 1.29—1.66 Å),

Table 1. Crystallographic Details for **1** and **2**

	1	**2**
Formula	$C_{69}H_{72}N_{12}O_{22}Cl_4Ti$	$C_{69}H_{74}N_{12}O_{23}Cl_4Ti$

Crystal size/mm	0.3×0.2×0.1	0.3×0.1×0.1
$2\theta_{max}$/deg	110	120
No. of unique reflections	10417	10993
No. of observed reflections with $F_o>3\sigma(F_o)$	8363	6874
R	0.124	0.105
R_w	0.180	0.148
S (goodness of fit)	1.145	1.253
No. of reflections used at the last stage of refinement	8060	6685

1.37 Å (1.18—1.46 Å); mean O-Cl-O=108° (83—137°), 109° (99—122°) for **1** and **2**, respectively. Though the results of Karl Fischer's method suggested the crystal of **2** to be monohydrated, we could not locate any water molecule in a difference Fourier map.

The structures were refined by the block-diagonal least-squares technique using the positional and anisotropic thermal parameters for the non-H atoms excluding disordered perchlorate O atoms for which only isotropic temperature factors were refined. No H atoms were located. Absorption corrections were applied after isotropic least-squares refinement by an empirical method based on the differences between the observed and calculated structure factors.[13] Atomic scattering factors were evaluated by analytical procedures, $f=\sum[a_i \exp(-b_i\lambda^{-2}\sin^2\theta)]+c$ (i=1, ··, 4).[14] Weights were taken as $w=[\sigma^2(F_o)+c^2|F_o|^2]^{-1}$ for the reflections with $w^{1/2}|\Delta F|<4$, and w=0 otherwise. The values of c^2 were 0.02297 and 0.00966 for **1** and **2**, respectively. No peaks larger than 0.5 e Å^{-3} were found in the last difference electron density maps of **1** and **2**. Comparatively large R values for **1** and **2** may be due to the poor quality of intensity data measured by using very small and inferior crystals and to the disordered structures of ClO_4 anions. Computations using the programs of PLUTO and XPACK86 SHIONOGI were performed on a FACOM M-730 computer at Shionogi Research Laboratories.[15]

Results and Discussion

Atomic coordinates and equivalent isotropic temperature factors for **1** and **2** are listed in Table 2. Stereoscopic views of the cations are represented in Fig. 2. The atoms of one ligand referred to as (A) in the respective complex ions are numbered as shown in Fig. 1, and those of the other two ligands (B and C) are represented by the corresponding numbers of 100 and 200 levels. The ClO_4 anions are given by the numbers

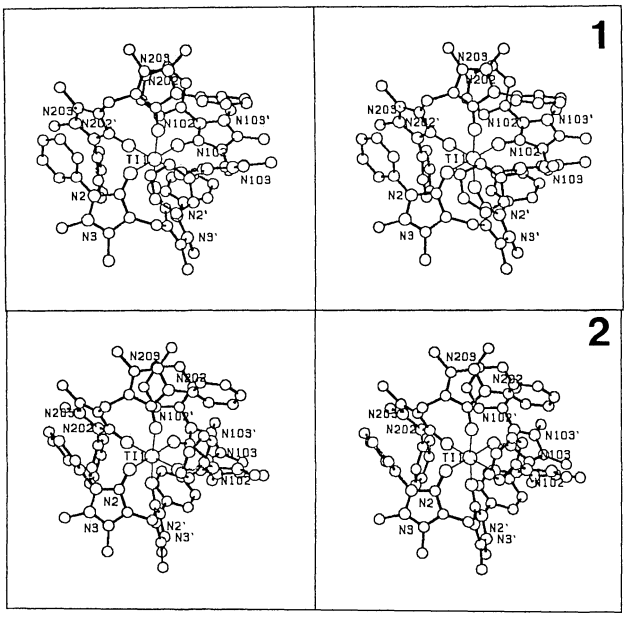

Fig. 2 Stereoscopic views of **1** and **2**.

of 300 level. The four anions of **1** are statistically distributed at five locations: two of them labeled as Cl(300) and Cl(310) are fully occupied and the other three labeled as Cl(320), Cl(330), and Cl(340) with partial occupancy of 2/3.

Coordination Geometry around Ti(IV). The metal-ligand distances and angles for **1** and **2** are summarized in Table 3. The Ti–O distances (av 1.93 Å for **1** and 1.94 for **2**) are shorter than those of other Ti(IV) complexes hexa-coordinated only by oxygen atoms, such as $Ti_2O_2(acac)_4$ (2.01 Å; acac=acetylacetonate),[16] $Ti(OR)_2(acac)_2$ (1.96 Å; OR=2,6-diisopropyl-

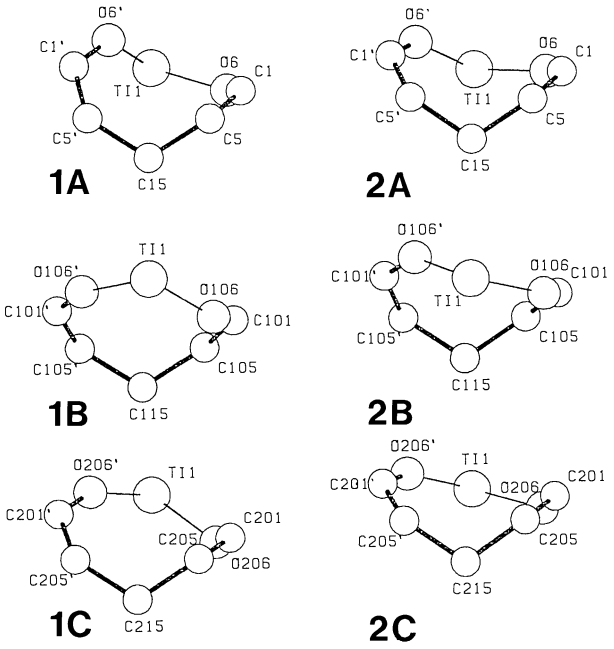

Fig. 3 Projection of the eight-membered chelate rings on the C(5)–C(15)–C(5′) planes.

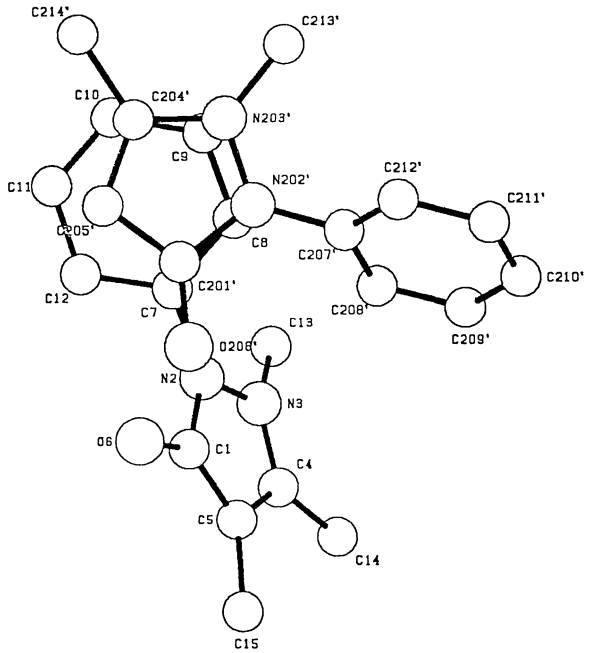

Fig. 4 Projection of the phenyl ring (Ph of A) on the least squares plane of the pyrazolone moiety (Py of C) for **1**.

because of ring strain and entropy factor in the ring closure process.[11,12] In **1** and **2**, however, dam acts as a bidentate ligand to construct an eight-membered ring. It is partly because of the rigidity of this ligand; free rotation is possible only for C(5)–C(15) and C(5′)–C(15). Six eight-membered rings adopt varying conformation as shown in Fig. 3. Within a ligand, one pyrazolone moiety is almost perpendicular to the plane through C(5), C(15), and C(5′), whereas the other not. Dihedral angles between two pyrazolone moieties within a ligand are between 61.4—70.1° (av 65°) except ligand B of **1**, which has an exceptionally small value of 47.0°.

Another striking feature of these complexes is aromatic ring stacking between a pyrazolone moiety of one ligand and a phenyl ring of another. An example for **1** is shown in Fig. 4, and relationship between twelve rings is schematically presented in Fig. 5, together with the closest interatomic distances and dihedral angles between rings. To bring about this stacking, phenyl groups are not coplanar with pyrazolone moieties within a ligand as shown by dihedral angles(47.5—77.3°, av 60°) in Fig. 5.

It is evident that the stacking is more pronounced for the complex **1** than for **2**; for example, that between phenyl group of B and pyrazolone ring of C (Fig. 2). Such stacking not only facilitates the formation of eight-membered rings, but also contributes to the whole stability of these complexes.

Implication for the Coloration. When both crystals were suspended in 1 mol dm^{-3} hydrochloric acid solution, **1** was rapidly and **2** was slowly dissolved to give a solution having an absorption maximum at 385 nm, which agrees well with that of the species used for photometric determination of Ti(IV).

In the ternary systems of Cu–an aromatic amine–a nucleotide, a phenylalkanecarboxylate or an aromatic amino acid, a single well-defined absorption peak appears around 360 nm, which is ascribed to a CT

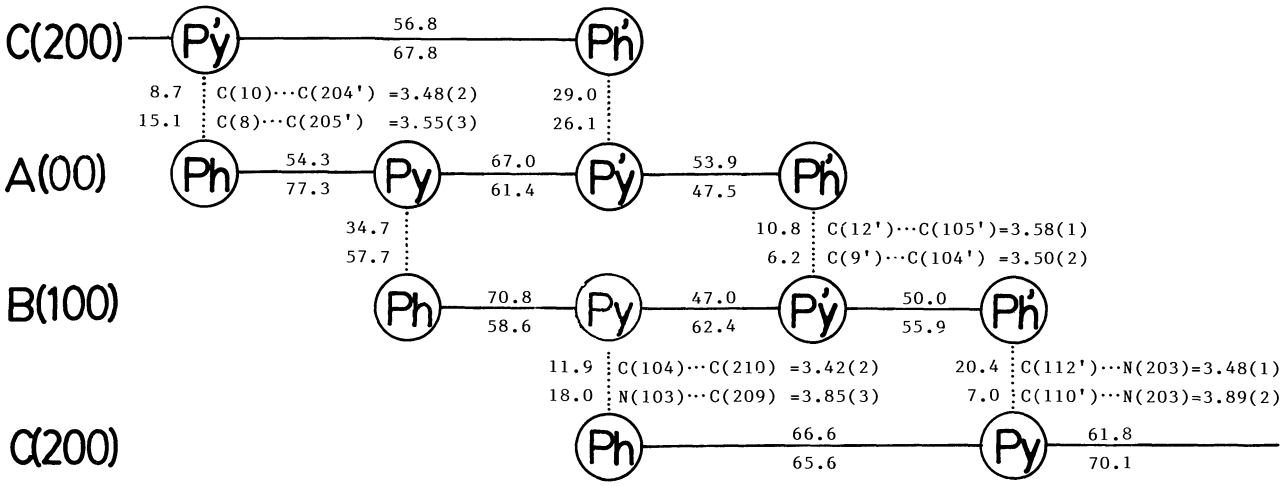

Fig. 5 Relationship between twelve aromatic rings. Ⓟh, Ⓟh′: phenyl group; Ⓟy, Ⓟy′: pyrazolone moiety. Solid line: covalent bond; dotted line: aromatic ring stacking. The closest interatomic distances are given for appreciable ring-overlapping. Other numbers are dihedral angles between two rings. Upper: **1**; lower: **2**.

band.[19–23] X-ray crystal structures just demonstrate the intramolecular aromatic ring stacking in Cu–phenanthroline–tryptophan.[24,25]

Since Ti-dam has several stacking of appreciable ring overlapping, the absorption band at around 385 nm is likewise assigned to a CT band. The electron flows from phenyl groups to pyrazolone moieties made electron-deficient by the coordination to Ti(IV) center.

A Facile Synthesis of 2-Aza-1,3-butadienes

Hidenori OKAMOTO and Shozo KATO
Tsukuba Research Lab., Tokuyama Soda Co., Ltd., 40 Wadai, Tsukuba, Ibaraki 300-42
(Received August 29, 1990)

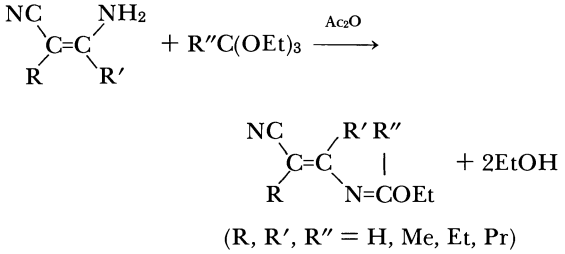
2-Aza-1,3-butadienes bearing alkoxyl substituent were obtained easily by the reaction of ketimines with orthoesters. The reaction proceeded smoothly by the addition of small amount of *p*-toluenesulfonic acid. When acetals were used in place of orthoesters, the corresponding 2-aza-1,3-butadienes were similarly prepared.

Due to the usefulness in various organic syntheses, several reports have been published on 2-aza-1,3-butadienes.[1] However, there have been few reports about 2-aza-1,3-butadienes bearing an alkoxyl group at the end position. For example, Saegusa and co-workers[2] reported that the reaction of vinyl isocyanide with alcohols in the presence of Cu(I) catalyst gives the corresponding 1-alkoxy-2-aza-1,3-butadienes.

$$CH_2{=}CHNC + ROH \xrightarrow{Cu_2O} CH_2{=}CHN{=}CHOR \quad (R = Me, Et, C_6H_{11} \text{ etc.})$$

Aue and co-worker[3] described that thermolysis of 2-methyl-1-azetine affords 1-alkoxy-2-aza-1,3-butadienes via electrocyclic ring opening followed by a 1,5-hydride shift.

Brown and co-worker[4] reported that the reaction of the orthoester with an enamino nitrile gives rise to the corresponding ethoxy derivative. This method, however, is only applicable to the enamines having electron-withdrawing groups.



(R, R′, R″ = H, Me, Et, Pr)

Although a number of reactions of orthoesters with amine compounds have been reported,[5] little has been known of the reaction with ketimines. During the course of our study on ketimine compounds, we found that ketimines easily react with orthoesters and acetals to give 2-aza-1,3-butadienes.

In this paper, we wish to report a facile, extensive synthesis of 2-aza-1,3-butadienes having alkoxyl substituent or dialkylamino substituent.

Results and Discussion

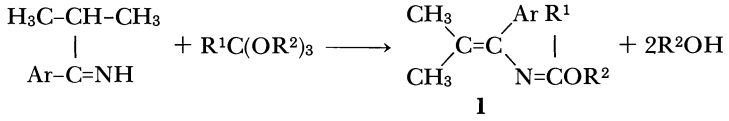
1-Alkoxy-2-aza-1,3-butadienes (**1**) were prepared from 1-aryl-2-methyl-1-propanimines and orthoesters as shown in Scheme 1.

General procedure is as follows. To a flask equipped with distillation head were added 1-aryl-2-methyl-1-propanimines, orthoester and a small amount of *p*-toluenesulfonic acid (PTS). The mixture was heated in an oil bath (120—160 °C) for about 10—20 min until the corresponding alcohol, which was formed during the reaction, was distilled out. The resulting mixture afforded a colorless, pale yellow or yellow liquid after distillation under a reduced pressure.

These results are summarized in Table 1. As can be seen in the Table, 2-aza-1,3-butadienes, having branched alkoxyl group, especially isopropoxyl group, were obtained in good yields (Entry No. **1e—j**). Furthermore, 2-aza-1,3-butadienes derived from triethyl orthoacetate and triethyl orthopropionate were formed in considerable yields (Entry No. **1m** and **1n**). These results seemed to be attributed to the steric protection around the carbon–nitrogen double bond. Good results were obtained by use of excess amount of orthoesters in the cases of trimethyl orthoformate and triethyl orthoformate because of their low boiling points. When the reaction was carried out for a long time, polymeric substance was obtained.

Although this condensation reaction proceeded without catalyst, the presence of a small amount of PTS was favorable to afford good yields. For instance, the reaction of 2-methyl-1-phenyl-1-propanimine (**2**) with triethyl orthoacetate or triethyl orthopropionate in the presence of a small amount of PTS at 120 °C for 15 min gave the products **1m** and **1n** in 70 and 63% yields, respectively, while in the absence of PTS at 120 °C for 3h **1m** and **1n** were obtained in yields of 30 and 20%, respectively.

The 2-aza-1,3-butadiene (**3**), which is the dimer of **2**, was produced as a by-product in the reaction of **2** with orthoesters. Dimerization of ketimines has been



1

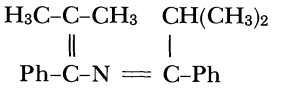
a) Method A: PTS catalyst at 150—160°C for 10—15 min; Method B: PTS catalyst at 120—130°C for 5—15 min; Method C: No catalyst at 110—120°C for 2—8 h.

previously accomplished by refluxing a THF solution of ketimines in the presence of trifluoroacetic acid.[6] When **2** was heated at 150 °C in the presence or absence of PTS, **3** was obtained along with the evolution of ammonia.



(**3**)

To synthesize 1-phenoxy-2-aza-1,3-butadiene (R^2= Ph), diethyl phenyl orthoformate (**4**) was allowed to react with **2**. However, this reaction was failed to give 2-ethoxy-2-aza-1,3-butadiene as shown in the following scheme because of higher ability of elimination of phenol.

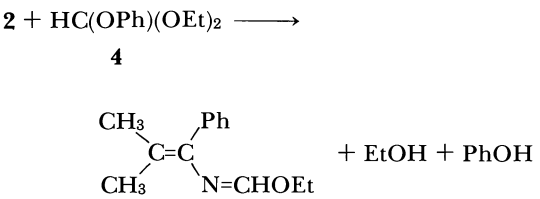


Table 2. 2-Aza-1,3-butadienes (**5**)[a]

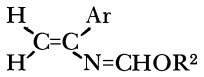

(**5**)

No.	Ar	R^2	Yield/%	Bp/°C/mmHg
a	C_6H_5	Et	11	65—66/0.15
b	2-Me-C_6H_4	Et	20	86—90/1.0

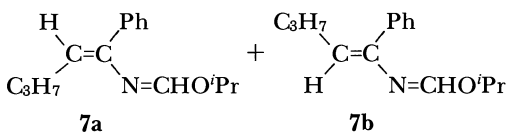
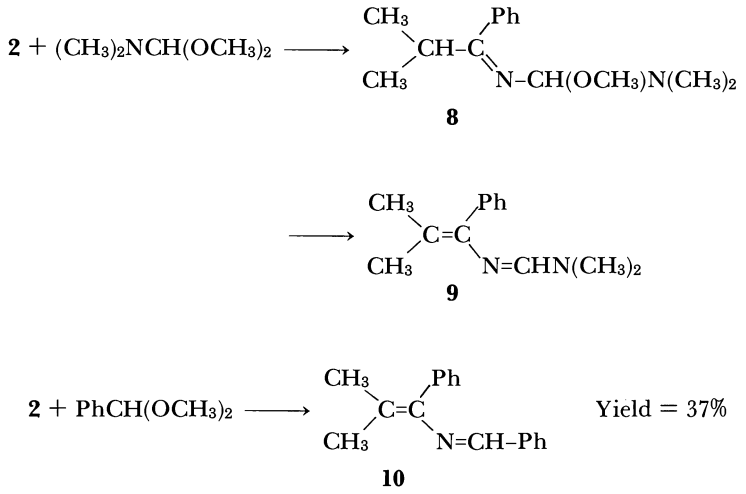
a) Reaction was carried out in the presence of small amount of PTS at 140—160°C for 5 min.

We carried out the reaction between 1-aryl-1-ethanimines and orthoesters. 1-Alkoxyl-2-aza-1,3-butadienes (**5a—d**) were obtained similarly as described in Table 2. The yield seemed to become higher with the increase of the steric protection around the carbon–nitrogen double bond to suggest the importance of the steric factor in these reactions. When 1-phenyl-1-pentanimine (**6**) was treated with triisopropyl orthoformate, a mixture of two isomers (**7a**:**7b**=2:1) were formed. The isomer ratio was determined by ^{1}H NMR.



In the course of extention of 2-aza-1,3-butadiene synthesis using ketimines, we have investigated the reaction of ketimines with acetals instead of orthoesters. When *N*,*N*-dimethylformamide dimethylacetal was allowed to react with **2**,1-amino-2-aza-1,3-butadiene (**9**) was obtained as shown in Scheme 2. In this reaction, the formation of intermediate (**8**) proceeded smoothly. Subsequent reaction which involves removal of the methanol from **8** was slow. It was



Scheme 2.

difficult to separate these two compounds (**8** and **9**) by vacuum distillation. To make the reaction complete, longer reaction time at high temperature was required. It was also effective to carry out the reaction under a reduced pressure. R. Gompper and co-worker[7] have reported the synthesis of 4-amino-2-aza-1,3-butadienes by the reaction of *N,N*-dimethylformamide diethylacetal with azomethines. Moreover, the treatment of benzaldehyde dimethylacetal with **2** in a similar manner gave 1-phenyl-2-aza-1,3-butadiene (**10**). Since the condensation was rather slow in comparison with that of orthoesters, the competitive formation of **3** and **10** was observed. They could not be separated with each other by distillation under a reduced pressure. These results indicate that acetals, as well as orthoesters, react with ketimine to give 2-aza-1,3-butadienes. Although **10** was similarly prepared by the reaction of **2** with benzaldehyde, the yield was only 5% at 160 °C for 30 min.

In conclusion, the present reaction affords a facile and useful preparative method for 2-aza-1,3-butadienes bearing an alkoxyl or an amino group at the end position. At present, we are trying to prepare biologically active compounds by use of thus obtained 2-aza-1,3-butadienes.

Experimental

The IR spectra were measured with a Hitachi I-2000 spectrometer. The ^{1}H NMR spectra were measured in a $CDCl_3$ solution with a Hitachi R-1500 spectrometer using tetramethylsilane as an internal standard. The mass spectra were obtained on a Hitachi M-80 spectrometer. Elemental analysis data (C, H, and N) agreed within ±0.3% for the calculated values.

Materials. Most of the orthoesters and acetals were commercially available. Triisopropyl orthoformate and tri-*s*-butyl orthoformate were prepared by the transesterification of trimethyl orthoformate and triethyl orthoformate with 2-propanol and 2-butanol, respectively.

Synthesis of Ketimines.[8] Some compounds were prepared by the reaction of benzonitrile with methyllithium or *n*-butyllithium, followed by the addition of ice at low temperature. Some compounds were synthesized by the reaction of aryllithium with isobutyronitrile. The other compounds were prepared by the reaction of aryl Grignard reagent with isobutyronitrile or isopropyl Grignard reagent with arylnitrile.

Synthesis of 2-Aza-1,3-butadienes (1). Method A: A typical procedure is as follows. To a 100 ml flask equipped with distillation head were added 1-(3-methoxy-2-thienyl)-2-methyl-1-propanimine (6.11 g, 33 mmol), triisopropyl orthoformate (6.98 g, 36 mmol) and a small amount of PTS. The mixture was heated in an oil bath (160 °C) for about 20 min until 2-propanol, which was formed during the reaction, was distilled out. The resulting mixture afforded a yellow liquid (5.82 g, 69%) of 1-isopropoxy-3-(3-methoxy-2-thienyl)-4,4-dimethyl-2-aza-1,3-butadiene which boiled at 94 °C/0.1 mmHg (1 mmHg=133.322 Pa) (Table 1, **1j**). ^{1}H NMR ($CDCl_3$) δ=1.28 (6H, d, J=6 Hz, CH_3×2), 1.68 (3H, s, CH_3), 2.00 (3H, s, CH_3), 3.74 (3H, s, OCH_3), 5.10 (1H, quint., J=6 Hz, OCH), 6.76 (1H, d, J=5 Hz, thienyl H), 7.12 (1H, d, J=5 Hz, thienyl H), 7.27 (1H, s, N=CHO); IR(KBr) 1630 cm^{-1} (N=CHO); MS m/z 253 (M^+), 210 ([$M-C_3H_7$]$^+$). Found: C, 61.73; H, 7.53; N, 5.49%. Calcd for $C_{13}H_{19}NO_2S$: C, 61.63; H, 7.56; N, 5.53%.

Method B: A typical procedure is as follows. To a 100 ml flask equipped with distillation head were added 1-phenyl-2-methyl-1-propanimine (10.44 g, 71 mmol), triethyl orthoacetate (15.90 g, 98 mmol) and a small amount of PTS. The mixture was heated in an oil bath (120 °C) for about 15 min until ethanol, which was formed during the reaction, was distilled out. The resulting mixture afforded a pale yellow liquid (10.84 g, 70%) of 1-ethoxy-1,4,4-trimethyl-3-phenyl-2-aza-1,3-butadiene which boiled at 80—82 °C/0.4 mmHg (Table 1, **1m**). ^{1}H NMR ($CDCl_3$) δ=1.25 (3H t, J=7 Hz, CH_3), 1.63 (3H, s, CH_3), 1.73 (6H, s, CH_3×2), 4.13 (2H, q, J=7 Hz, OCH_2), 7.12 (5H, s, aromatic H); IR(KBr) 1670 cm^{-1} (N=CMeO); MS m/z 217 (M^+), 188 ([$M-C_2H_5$]$^+$). Found: C, 77.59; H, 8.66; N, 6.34%. Calcd for $C_{14}H_{19}NO$: C, 77.37; H,

8.81; N, 6.45%.

Method C: A typical procedure is as follows. To a 100 ml flask equipped with distillation head were added 1-(3-methylphenyl)-2-methyl-1-propanimine (10.10 g, 63 mmol) and triethyl orthoformate (10.34 g, 70 mmol). The mixture was heated in an oil bath (110 °C) for about 3 h until ethanol, which was formed during the reaction, was distilled out. The resulting mixture afforded a pale yellow liquid (7.10 g, 52%) of 1-ethoxy-4,4-dimethyl-3-(3-methylphenyl)-2-aza-1,3-butadiene which boiled at 92—94 °C/0.6 mmHg (Table 1, **1c**). ^{1}H NMR ($CDCl_3$) δ=1.28 (3H, t, J=7 Hz, CH_3), 1.59 (3H, s, CH_3), 1.96 (3H, s, CH_3), 2.30 (3H, s, CH_3), 4.20 (2H, q, J=7 Hz, OCH_2), 6.80—7.33 (5H, m, N=CHO and aromatic H); IR(KBr) 1625 cm^{-1} (N=CHO); MS m/z 217 (M^+), 188 ([M−C_2H_5). Found: C, 77.25; H, 8.78; N, 6.50%. Calcd for $C_{14}H_{19}NO$: C, 77.37; H, 8.81; N, 6.45%.

Synthesis of 3. To a 100 ml flask were added **2** (5.06 g, 34 mmol) and a small amount of PTS. The mixture was heated in an oil bath (150 °C) for about 20 min. The resulting mixture afforded a yellow viscous liquid (1.65 g, 35%) of 1-isopropyl-4,4-dimethyl-1,3-diphenyl-2-aza-1,3-butadiene which boiled at 123 °C/0.3 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.18 (6H, d, J=6 Hz, CH_3×2), 1.59 (3H, s, CH_3), 1.65 (3H, s, CH_3), 2.85 (1H, quint., J=6 Hz, OCH), 6.80—7.80 (10H, m, aromatic H); IR(KBr) 1632 cm^{-1} (N=C); MS m/z 277 (M^+).

Synthesis of 5d. To a 100 ml flask equipped with distillation head were added 1-(2-methylphenyl)-1-ethanimine (4.55 g, 39 mmol), triisopropyl orthoformate (8.25 g, 43 mmol) and a small amount of PTS. The mixture was heated in an oil bath (140—150 °C) for about 5 min until 2-propanol was distilled out. The resulting mixture afforded a pale yellow liquid (4.33 g, 55%) of 1-isopropoxy-3-(2-methylphenyl)-2-aza-1,3-butadiene which boiled at 74—75 °C/0.1 mmHg (Table 2, **5d**). ^{1}H NMR ($CDCl_3$) δ=1.27 (6H, d, J=6 Hz, CH_3×2), 2.32 (3H, s, CH_3), 4.56 (1H, s, =CH), 4.92 (1H, s, =CH), 5.10 (1H, quint., J=6 Hz, OCH), 7.19 (4H, m, aromatic H), 7.43 (1H, s, N=CHO); IR(KBr) 1622 cm^{-1} (N=CHO); MS m/z 203 (M^+). Found: C, 76.55; H, 8.32; N, 7.04%. Calcd for $C_{13}H_{17}NO$: C, 76.81; H, 8.43; N, 6.89%.

Synthesis of 7. To a 100 ml flask equipped with distillation head were added **6** (4.93 g, 31 mmol), triisopropyl orthoformate (7.89 g, 41 mmol) and a small amount of PTS. The mixture was heated in an oil bath (160 °C) for about 5 min until 2-propanol was distilled out. The resulting mixture afforded a yellow liquid (3.03 g, 42%) of 1-isopropoxy-4-propyl-3-phenyl-2-aza-1,3-butadiene which boiled at 92 °C/0.15 mmHg. ^{1}H NMR ($CDCl_3$) δ=0.94 (t, J=7 Hz, CH_3), 1.25 (d, J=6 Hz, CH_3×2), 1.35 (d, J=6 Hz, CH_3×2), 1.40—1.70 (m, CH_2), 1.90—2.30 (m, CH_2), 5.11 (quint., J=6 Hz, OCH), 5.24 (t, J=7 Hz, C=CH), 5.45 (t, J=7 Hz, C=CH), 7.10—7.50 (m, N=CHO and aromatic H); IR(KBr) 1648 cm^{-1} (N=CHO); MS m/z 231 (M^+). From the NMR spectrum and GC of the mixture, it was assigned as being a 2:1 mixture of **7a** and **7b**.

Synthesis of 9. To a 100 ml flask were added **2** (4.05 g, 28 mmol), *N*,*N*-dimethylformamide dimethylacetal (3.77 g, 32 mmol) and a small amount of PTS. The mixture was heated in an oil bath (130—150 °C) for about 1h until methanol was distilled out. The resulting mixture afforded a yellow liquid (3.10 g, 56%) of 4,4-dimethyl-1-dimethylamino-3-phenyl-2-aza-1,3-butadiene which boiled at 88 °C/0.15 mmHg. ^{1}H NMR ($CDCl_3$) δ=1.53 (3H, s, CH_3), 2.02

Synthesis of 10. To a 100 ml flask were added **2** (4.27 g, 29 mmol), benzaldehyde dimethylacetal (4.68 g, 31 mmol) and a small amount of PTS. The mixture was heated in an oil bath (160 °C) for about 30 min until methanol was distilled out. The resulting mixture afforded a yellow viscous liquid (3.60 g) of 4,4-dimethyl-1,3-diphenyl-2-aza-1,3-butadiene which boiled at 120—125 °C/0.15 mmHg. The obtained liquid contained 70% of **10** and 30% of **3**, which was confirmed by GC. The other 2-aza-1,3-butadienes were prepared by the methods described above. Their ^1H NMR data are summarized in Table 3.

Formation and Molecular Structure of the 2:1-Adducts of 1-Alkoxy-2-benzopyrylium-4-olates with Carbon Disulfide

Hirofumi NAKANO, Hatsue TAMURA, and Toshikazu IBATA*
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560
(Received September 14, 1990)

The $Rh_2(OAc)_4$-catalyzed decomposition of alkyl *o*-(diazoacetyl)benzoates in the presence of carbon disulfide gave two 2:1-adducts of the intermediate 1-alkoxy-2-benzopyrylium-4-olates with carbon disulfide together with a small amount of 5-(*o*-alkoxycarbonylphenyl)-1,3-oxathiole-2-thiones. The intramolecular carbene-carbonyl reaction of the carbenoid generated by the decomposition of the diazo ketones was clarified to be much faster than the intermolecular attack on carbon disulfide. The molecular structure of the major 2:1-adduct of 1-methoxy-2-benzopyrylium-4-olate with carbon disulfide was determined by means of X-ray crystallography. The crystals of the adduct are triclinic with space group $P\bar{1}$, and with the unit-cell dimensions of a=12.213(1), b=11.846(1), c=7.0403(2) Å, α=93.395(6), β=102.147(5), γ=109.536(7)°, and Z=2. The final R value is 0.044 for 2597 observed reflections. The structure was confirmed to be (S-*endo*, S′-*endo*).

Recently, formation of carbonyl ylides by carbene–carbonyl reaction,[1] and their 1,3-dipolar cycloaddition with various types of dipolarophiles have been studied extensively from the synthetic interests.[2] The authors reported previously the 1,3-dipolar cycloaddition of 1-methoxy-2-benzopyrylium-4-olate (**3a**), which was formed by the intramolecular carbene–carbonyl reaction of the carbenoid **2a**, with ethylenic,[1b,3] acetylenic,[1b,4] and carbonyl compounds.[5] In the continuation of these studies we report here the reaction of **3** with carbon disulfide as an example of dipolarophiles having a C–S double bond.

Results and Discussion

The Catalytic Decomposition of Alkyl *o*-(Diazoacetyl)benzoates (1) in the Presence of Carbon Disulfide. The medium pressure column chromatography of the $Rh_2(OAc)_4$-catalyzed reaction mixture of methyl *o*-(diazoacetyl)benzoate (**1a**) with carbon disulfide at 46 °C gave two 2:1-adducts **5a** of the corresponding carbonyl ylide intermediate **3a** with carbon disulfide along with 5-(*o*-methoxycarbonylphenyl)-1,3-oxathiole-2-thione (**6a**). The formation of **6a** was described in the previous papers.[6,7]

Elemental analysis of the 2:1-adducts **5a** indicates that they contain two molecules of **3a** and a molecule of carbon disulfide. The NMR spectra of the major 2:1-adduct (**5a-A**; 64.5% yield) showed that two moieties of **3a** are equivalent each other in **5a-A**. For example, the ^1H NMR spectrum of **5a-A** has only one signal of methine protons at δ=5.01 and that of methoxyl-protons at δ=3.95. Similarly, the ^{13}C NMR spectrum of **5a-A** also exhibited only one signal for each pairs of methoxyl-carbons (δ=53.41), methine-

carbons (δ=89.86), carbonyl-carbons (δ=188.89), and other carbons of two benzopyrylium-olate moieties as are shown in Table 1. On the other hand, in the minor 2:1-adduct (**5a-B**; 10.8% yield) two **3a** moieties involved are not equivalent each other, and the corresponding protons and carbons of two **3a** moieties show their signals at different positions in its ^{1}H and ^{13}C NMR spectra (Table 1).

Quite similar results were also obtained in the $Rh_2(OAc)_4$-catalyzed decomposition of isopropyl *o*-(diazoacetyl)benzoate (**1b**) in the presence of carbon disulfide.

In these reactions of **1a** and **1b**, no 1:1-adduct **4** between **3** and carbon disulfide was observed in spite of the detailed inspection of the reaction mixture by column chromatography. This indicates that the second cycloaddition of **3** with the 1:1-adducts **4** is much faster than the first attack of **3** on carbon disulfide.

There are two sites of the second attack of **3** in a molecule of the 1:1-adduct **4**. One is thiocarbonyl group to give **5**, and the other is carbonyl group to give **7**. From our previous studies,[5c,8] **7** should show a signal of an aromatic proton H_a at high field in its ^{1}H NMR spectrum due to the ring current of the neighboring aromatic ring system. The fact that our major and minor 2:1-adducts show no such a high field signal indicates that the second attack of **3** to give these 2:1-adducts did not occur on the carbonyl group but occurred on the thiocarbonyl group of **4**. Absence of a signal of thiocarbonyl carbon in the ^{13}C NMR spectra of these adducts in the region of δ=202—203[7] also supports the reaction site described above. The regiochemistry of the first and the second cycloadditions of **3** is consistent with the presence of singlet signals of nonaromatic quaternary carbons having orthothioformate structure at near δ=117 in the ^{13}C NMR spectra of **5**.[5]

These 1,3-dipolar cycloadditions of carbonyl ylides have been found to proceed through the interaction

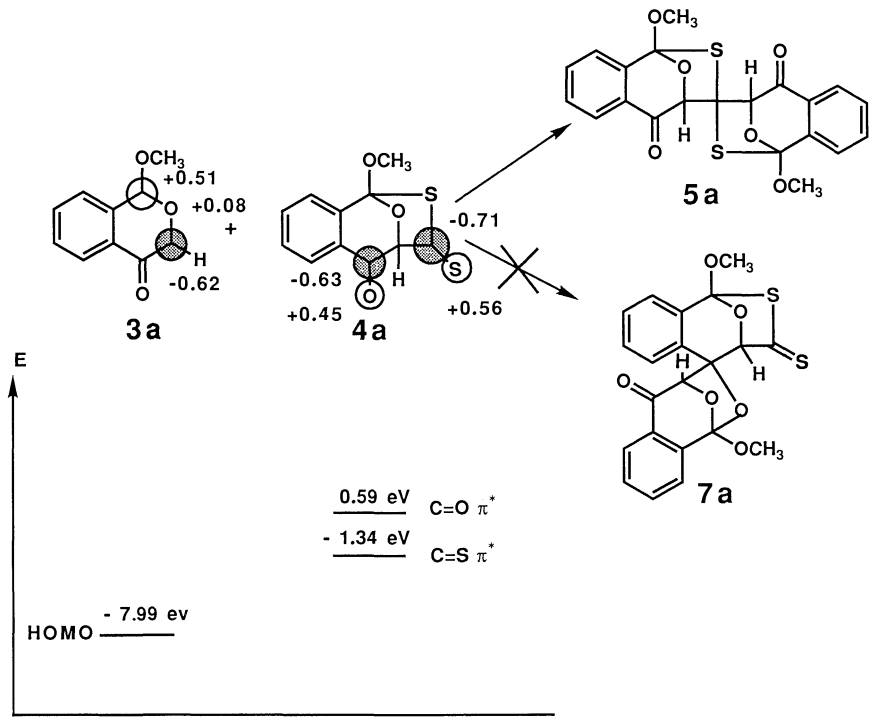

Fig. 1. The energy levels and atomic orbital coefficients of frontier orbitals of **3a** and **4a**.

controlled by carbonyl ylide-HOMO and dipolarophile-LUMO.[5b,9] In order to presume the reaction site of the second attack of **3a** toward 1:1-adduct **4a**, energy levels of the C=O π^* and C=S π^* of **4a** were calculated together with HOMO level of **3a**. Results of MNDOC calculation[10] shown in Fig. 1 revealed that the energy level of C=S π^* (−1.34 eV) is lower than that of C=O π^* (0.59 eV). This indicates that the reaction site is not the C=O group but the C=S group affording the 2:1-adducts **5** as is described above. The atomic orbital coefficients of the related frontier orbitals of **3a** and **4a** also explain the regiochemistry of the cycloaddition.[5b]

There are four possibilities in the second attack of **3** on C–S double bond of the 1:1-adduct **4** in a regiochemistry similar to that of the first cycloaddition to afford four stereoisomers, **5-A** (*S-endo, S′-endo*),[11] **5-B** (*S-endo, S′-exo*), **5-C** (*S-exo, S′-endo*), and **5-D** (*S-exo, S′-exo*) as shown in Fig. 2. In these four isomers, **5-B** and **5-C** are enantiomers each other, and the two benzopyrylium-4-olate moieties of **5-B** (=**5-C**) are not equivalent. Therefore, the minor 2:1-adduct can be assigned to the structure **5-B**. On the other hand, both **5-A** and **5-D** have a symmetric structure having a C_2-axis through spiro-carbon bisecting both S–C–S and CO–C–CO planes. Because the two benzopyrylium-4-olate moieties are equivalent in **5-A** and **5-D**, the structural assignment for the major 2:1-adducts to **5-A** or **5-D** was not successful on the basis of the NMR data. Single crystal X-ray analysis of the major 2:1-adduct **5a-A** was therefore studied.

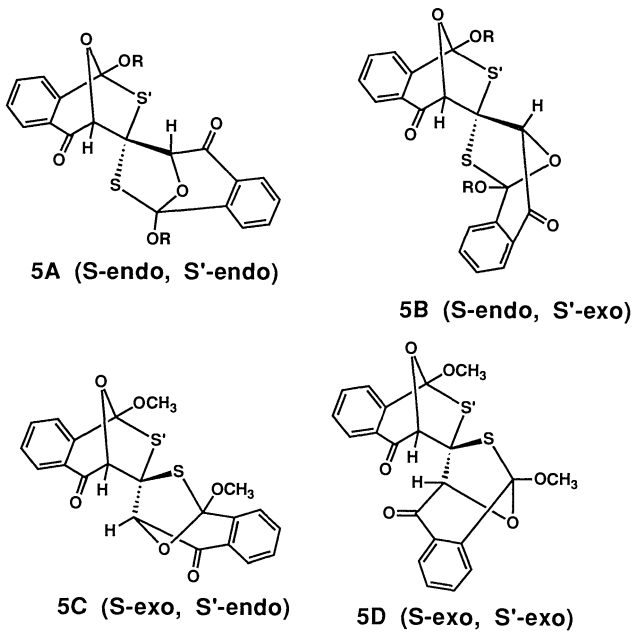

Fig. 2. Possible four structures of the 2:1-adduct **5**.

X-Ray Crystallography of the 2:1-Adduct 5a-A. The crystal data of **5a-A** are listed in Table 2 along with the experimental details. The ORTEP[12] drawing (see Fig. 3) shows that the major 2:1-adduct **5a-A** has the symmetric structure **5-A** (*S-endo, S′-endo*).

Inspection of the CPK model of **5-A** and **5-D** indicates that carbonyl groups of two benzopyrylium-

olate moieties of **5-D** come in the region of van der Waals radii of these groups, and that the approach to give **5-D** is hindered by the steric repulsion. On the other hand, isomers **5-A** and **5-B** (=**5-C**) are free from this sort of steric repulsion. The model of **5-B** is a little crowded than that of **5-A**. These facts will explain the product ratio of the reactions described above.

Experimental

Melting points were measured with a Yanagimoto Melting Point Apparatus and are not corrected. IR spectra were recorded on a Perkin-Elmer Model 983. ^{1}H NMR and ^{13}C NMR spectra were measured on a Varian EM 390 and a Brucker AM 360 spectrometers in a $CDCl_3$ solution using TMS as an internal standard.

Materials. Methyl *o*-(diazoacetyl)benzoate (**1a**) and isopropyl *o*-(diazoacetyl)benzoate (**1b**) were prepared by the procedure described in the previous paper.[5b] Benzene and carbon disulfide were purified by distillation over CaH_2 and P_2O_5, respectively.

General Procedure of the $Rh_2(OAc)_4$-Catalyzed Decomposition of 1 in the Presence of CS_2. A benzene solution (10 ml) of **1** (3.00 mmol) was added dropwise into a solution of $Rh_2(OAc)_4$ (1.6 mg, 3.62×10^{-3} mmol) in carbon disulfide (20 ml) at 46 °C under stirring in a N_2 atmosphere. After being refluxed for about 1 h, the reaction mixture was concentrated under reduced pressure, and the residue was separated by medium pressure column chromatography over silica gel using hexane–benzene as an eluent. Two types of 2:1-adducts **5-A** and **5-B** were obtained together with 1,3-oxathiole-2-thione derivative **6**.

Major 2:1-Adduct 5a-A: Yield 64.5% from **1a**; colorless crystals; mp 236.1—237.0 °C (from benzene–hexane); IR (KBr) 1697 (C=O), 1597, 1456, 1308, 1292, 1272, 1237, 1206, 1149, 1097, 1075, 1054, 1042, 1022, 968, 846, 756, 740, and

656 cm^{-1}; MS (EI) 328 (1.4%, M^+), 396 (8.4), 176 (100), 133 (8), and 77 (10). Found: C, 58.93; H, 3.77%. Calcd for $C_{21}H_{16}O_6S_2$: C, 58.87; H, 3.76%.

Minor 2:1-Adduct 5a-B: Yield 10.3% from **1a**; colorless crystals; mp 200—202 °C (from benzene–hexane); IR (KBr) 2985, 2942, 1700 (C=O), 1598, 1455, 1435, 1318, 1291, 1267, 1242, 1202, 1146, 1085, 1058, 1021, 1009, 980, 962, 904, 849, 794, 765, 852, 711, and 655 cm^{-1}; MS (EI) 423 (3.4%, M^+), 396 (8.4), 176 (3), 163 (100), 133 (8), and 77 (8).

5-(*o*-Methoxycarbonylphenyl)-1,3-oxathiole-2-thione (6a):

Yield 6.3% from **1a**; pale yellow crystals; mp 120.1—121.0 °C (from benzene–hexane).[7]

Major 2:1-Adduct 5b-A: Yield 65.7% from **1b**; colorless crystals; mp 211.0—211.8 °C (from acetone); IR (KBr) 3070, 2977, 1700 (C=O), 1598, 1456, 1384, 1371, 1294, 1270, 1236, 1190, 1171, 1140, 1095, 1074, 1053, 998, 968, 914, 894, 885, 834, 807, 775, 758, 747, 688, and 653 cm^{-1}. MS (EI) 484 (3%, M^+), 452 (7), 424 (6), 382 (14), 367 (7), 349 (6), 323 (7), 294 (9), 252 (7), 234 (19), 191 (17), 149 (100), 133 (7), 111 (6), and 104 (8). Found: C, 61.87; H, 5.23%. Calcd for $C_{25}H_{24}O_6S_2$: C, 61.96; H, 4.99%.

Minor 2:1-Adduct 5b-B: Yield 8.8% from **1b**; colorless crystals; mp 210.8—211.2 °C (from benzene–hexane); IR (KBr) 3191, 3073, 2975, 1697 (C=O), 1598, 1457, 1383, 1371, 1292, 1269, 1243, 1191, 1171, 1141, 1111, 1099, 1079, 1056, 993, 926, 903, 854, 836, 792, 753, 720, 701, 669, and 653 cm^{-1}; MS (EI) 484 (8%, M^+), 452 (5), 424 (10), 382 (7), 377 (7), 349 (5), 294 (10), 251 (8), 234 (19), 191 (13), 162 (6), 149 (100), 133 (5), 111 (4), and 104 (11). Found: C, 62.16; H, 5.04%. Calcd for $C_{25}H_{24}O_6S_2$: C, 61.96; H, 4.99%.

5-(*o*-Isopropoxycarbonylphenyl)-1,3-oxathiole-2-thione (6b): Yield 8.8% from **1b**; yellow oil.[7]

X-Ray Crystallography of the 2:1-Adduct 5a-A. Single crystals of **5a-A** recrystallized from a mixed solvent of benzene–hexane were used for X-ray analysis. Intensity data were measured on a Rigaku four-circle diffractometer with Ni-filtered Cu $K\alpha(\lambda=1.5418$ Å) radiation. The reflections of 2752 with $|F_o|\geq 2\sigma(F_o)$ were used in the structure determination. The space group $P\bar{1}$ was confirmed by the statistical distribution of E values and a successful refinement of the structure.

$B_{eq}=(4/3)\{a^2B_{11}+b^2B_{22}+c^2B_{33}+ab\cos\gamma\,(B_{12}/2)+ac\cos\beta(B_{13}/2)+bc\cos\alpha\,(B_{23}/2)\}$.

The crystal structure was determined by direct methods with the program of MULTAN 80.[12] The E-map computed with the phase set of the highest combined figure of merit (2.864) revealed the positions of all the non-hydrogen atoms. The hydrogen atoms were located on a difference map and their positional parameters were refined together with isotropic thermal parameters, while the other atoms were refined anisotropically by block-diagonal least-squares. The final R value was 0.044. The function minimized was $\sum w(|F_o|-k|F_c|)^2$ with the following weighting scheme: $w=1/(\sigma^2(F_o)+0.0476|F_o|+0.0041|F_o|^2)$.

All the atomic scattering factors were taken from the "International Tables for X-Ray Crystallography".[14] The computations were carried out with "The Universal Crystallographic Computing System-Osaka"[15] on an ACOS-S930 computer at the Research Center for Protein Engineering, Institute for Protein Research, Osaka University. Table 3 lists the final atomic and thermal parameters with their estimated standard deviations. The bond distances and angles are given in Fig. 4.[16]

The authors are grateful to Mr. Yoshio Takai, Institute of Scientific and Industrial Research, Osaka University for the measurement of ^{13}C NMR spectra, and to Mr. Hiroshi Moriguchi, Faculty of Engineering, Osaka University for obtaining mass spectra.

Strong van der Waals Interactions in Water. Molecular Complexes of Porphyrins and Quinones in Organic and Aqueous Media

Koji KANO,* Tadashi HAYAKAWA, and Shizunobu HASHIMOTO
Department of Applied Chemistry, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto 602
(Received October 6, 1990)

The stability of the molecular complexes between 5,10,15,20-tetraarylporphyrins and quinones in organic solvents has been compared with that in water. 5,10,15,20-Tetrakis(mono-substituted phenyl)porphines (RTPPs) hardly form molecular complexes with *p*-benzoquinone (BQ), 2,3,5,6-tetramethyl-*p*-benzoquinone (DQ), and 2,3,5,6-tetrachloro-*p*-benzoquinone (CQ) in dichloromethane ($K<10$ mol^{-1} dm^3). In contrast, the stability constants ($K>60$ mol^{-1} dm^3) for the molecular complexes of cationic porphyrins (TMPyP and TAPP) with BQ in water are much larger than those in methanol. The thermodynamic parameters clearly indicate that complexation in water is an enthalpically favorable process, suggesting that the van der Waals interactions are the main binding forces and that hydrophobic interaction does not play an important role in complex formation in water. The larger stability of the molecular complexes in water can be interpreted in terms of the nature of water, as demonstrated by Smithrud and Diederich (D. B. Smithrud and F. Diederich, *J. Am. Chem. Soc.*, **112**, 339 (1990)). The microscopically hydrophobic porphyrin ring many hardly be hydrated and interact with BQ through the van der Waals interactions without an extensive dehydration process. The water molecules bound to BQ should be released upon complexation, and the released water molecules may be incorporated tightly into the hydrogen-bonding networks of water. Such complexation in water seems to be an enthalpically favorable process.

We have demonstrated that anionic and cationic porphyrins in water tend to form molecular complexes with guest aromatics throught van der Waals interactions.[1-5] Enthalpic (ΔH) and entropic changes (ΔS) in the complexation of water-soluble porphyrins are summarized in Table 1. In all of the cases shown in Table 1, the complexation of water-soluble porphyrins with guest aromatics is an enthalpically favorable process. This suggests that the main binding forces for molecular association in water are the van der Waals interactions. During these studies, we came to recognize that the association between anionic and/or cationic porphyrins and various aromatics, as well as the porphyrin dimerization,[5-7] is strictly suppressed in organic solvents (the results have not been published except for dimerization of a cationic porphyrin[6]). Why are the van der Waals interactions so strong in water? Answering this question is the aim of the present study.

Table 1. Enthalpic (ΔH) and Entropic Changes (ΔS) for Molecular Complex Formation of 5-Phenyl-10,15,20-tris(4-sulfophenyl)porphine Trisodium Salt ($TPPS_3$) and TMPyP in Water

Porphyrin	Guest[a]	$-\Delta H$/kJ mol^{-1}	$-\Delta S$/J mol^{-1} K^{-1}	Ref
$TPPS_3$	AQαS	10.5	−19.1	2

TMPyP	PNP	46.1	99.9	4

a) AQαS; sodium 9,10-anthraquinone-1-sulfonate, AQβS; sodium 9,10-anthraquinone-2-sulfonate, AQDS; disodium 9,10-anthraquinone-2,6-disulfonate, PyS; sodium 1-pyrenesulfonate, AnS; sodium 2-anthracenesulfonate, MV; 1,1′-dimethyl-4,4′-dipyridinium dichloride, PFl; 2,6-diaminoacridinium hydrogensulfate, PNP; *p*-nitrophenol.

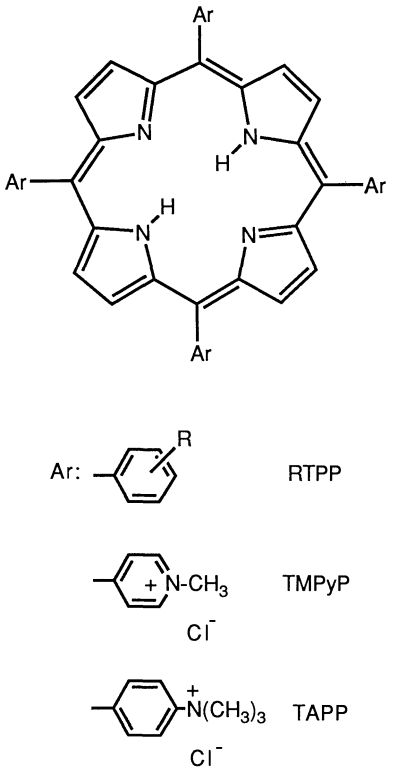
At first, in order to known the extent of the van der Waals interactions in an organic solvent, we investigated the complex formation of 5,10,15,20-tetrakis(mono-substituted phenyl)porphines (RTPPs) with quinones, such as *p*-benzoquinone (BQ), 2,3,5,6-tetramethyl-*p*-benzoquinone (DQ), and 2,3,5,6-tetrachloro-*p*-benzoquinone (CQ), in dichloromethane (CH_2Cl_2). The quinones were chosen as guests because ground-state complexes can be detected easily by measuring the static fluorescence quenching of prophyrins by quinones. The substituents (R) attached to the phenyl groups at the meso positions seem to alter the electron density of the porphyrin ring. It is expected, therefore, that the substituent effects on the formation of molecular complexes with quinones through the van der Waals interactions can be studied. We also presumed that a charge-transfer interaction may act as an cooperative force for forming stable molecular complexes, since porphyrin and quinone can behave as an electron donor and acceptor, respectively. Moreover, some tetrakis(*o*-substituted phenyl)porphines have a possibility to bind with quinones through hydrogen bonding.

Second, the stability of the molecular complexes of cationic porphyrins, such as 5,10,15,20-tetrakis(1-methyl-4-pyridinio)porphine tetrachloride (TMPyP) and 5,10,15,20-tetrakis[4-(trimethylammonio)phenyl]-porphine tetrachloride (TAPP), and BQ in methanol was compared with that in water. Although the experiments were limited due to the solubilities of

porphyrins and quinones in organic and/or aqueous media, we expected to obtain information about the specialty of water as a solvent for molecular complex formation through van der Waals interactions.

Experimental

RTPPs (R=*o*-, *m*-, *p*-OH, *o*-, *m*-, *p*-CH_3, *o*-, *m*-, *p*-OCH_3, *o*-NH_2, *o*-$NHCOCH_3$, *o*-, *m*-, *p*-Cl, *o*-Br, *o*-, *p*-NO_2, *p*-$COOCH_3$, *p*-CN) were prepared according to the procedures described in the literatures.[8] The TMPyP[7] and TAPP[5] employed were previously described. BQ, DQ, CQ,



and 1,4-naphthoquinone (NQ) were purchased from Nacalai Tesque (Kyoto) and purified by sublimation in vacuo.

The absorption and fluorescence spectra were measured on a Shimadzu UV-2100 spectrophotometer and a Hitachi 650-60 spectrofluorometer (uncorrected, band width=5 nm), respectively, whose cell holders were thermostated. The 400 MHz ^{1}H NMR spectra in $CDCl_3$ were recorded with a JEOL GX-400 spectrometer at 23±0.5 °C using TMS as an internal standard. The fluorescence lifetimes of RTPPs were determined by an Ortec-PRA single-photon counting apparatus, as described previously.[7] The cyclic voltammograms (CV) of RTPPs were taken in CH_2Cl_2 containing tetrapropylammonium perchlorate as a supporting electrolyte at 10 °C with a CV-1B voltammograph manufactured by Bioanalytical Systems. Platinum and silver-silver chloride electrodes were used as the working and reference electrodes, respectively. All samples containing both porphyrin and quinone were prohibited from exposure to room light.

Results and Discussion

Substituent Effects on ^{1}H NMR and CV of RTPPs. The complexation of porphyrin with quinone through van der Waals and/or charge-transfer interactions should be affected by the electron density of the porphyrin ring. Worthington et al.[9] have determined the reduction potentials ($E_{1/2}^r$) of various RTPPs in DMSO and found that the electron density on the porphyrin ring is slightly affected by the substituent attached to the phenyl group at the meso position.

We measured ^{1}H NMR in $CDCl_3$ and the oxidation potentials ($E_{1/2}^o$) in CH_2Cl_2 in order to determine the effects of the substituents (R) on the electron density of the porphyrin ring. The chemical shifts of the β-protons of pyrrole, as well as of the N–H protons of RTPPs, are expected to be the measures of the π-electron density on the porphyrin ring. The chemical shifts of the β-protons (δ_{CH}) and the N–H protons (δ_{NH}) and the first ($E_{1/2}^o(1)$) and second oxidation potentials ($E_{1/2}^o(2)$) of RTPPs are listed in Table 2.

Although δ_{CH} tends to shift to a lower magnetic field upon increasing the electron-donating ability of R, no clear relationship has been found between δ_{CH} as well as δ_{NH} and Hammett's σ-values. Figure 1 shows a plot of $E_{1/2}^o(1)$ vs. Hammett's σ-values. A linear relationship was found ($E_{1/2}^o(1)=0.38\sigma+1.05$, $R=0.980$), suggesting that the substituent at the phenyl group of RTPP regularly alters the electron density on the porphyrin ring.

Molecular Complexes of RTPPs with Quinones in Organic Solvents. It has been well-known that the fluorescent states of the porphyrins and their metal complexes are quenched by quinones and that an electron transfer from photoexcited porphyrin to quinone can be accounted for by a quenching mechanism.[10] For dynamic fluorescence quenching, a

Stern–Volmer linear relationship can be applied:

$$I_0/I = \tau_0/\tau = 1 + K_{SV}[Q] = 1 + k_q\tau_0[Q], \quad (1)$$

where I_0 and I are the fluorescence intensities in the absence and the presence of a quencher (Q), respectively; K_{SV} is the Stern–Volmer constant, k_q is the rate constant for fluorescence quenching, and τ_0 and τ are the fluorescence lifetimes in the absence and the presence of Q, respectively. If static quenching due to the formation of nonfluorescent ground-state complex competes with a dynamic type, the Stern–Volmer equation is modified as[11]

$$I_0/I = (1 + K(\varepsilon_2/\varepsilon_1)[Q])(1 + K_{SV}^{\tau}[Q]), \quad (2)$$

where K is the binding constant of the ground-state complex, K_{SV}^{τ} is the Stern–Volmer constant for dynamic quenching, and ε_1 and ε_2 are the extinction coefficients of fluorophore and complex at the excitation wavelength, respectively. In the case where Eq. 2 can be applied, the absorption spectral change should be observed. When the fluorophore is excited at an isosbestic point, Eq. 2 can be simplified as

$$I_0/I = (1 + K[Q])(1 + K_{SV}^{\tau}[Q]). \quad (3)$$

The fluorescence quenching technique is very convenient for determining molecular complex formation as well as the binding constant, K, when a Benesi–Hildebrand plot[12] for an absorption spectral change cannot be applied for reasons such as a small change in the optical density upon complexation.

Table 3. Fluorescence Quenching of RTPPs by DQ, BQ, and CQ in Dichloromethane at 10 °C

R	τ_0/ns	$10^{-9}\,k_q$/mol^{-1} dm^3 s^{-1}		
		DQ	BQ	CQ

We initially sought RTPP–quinone pairs which form molecular complexes in an organic solvent by using the 17 RTPPs listed in Table 3 as well as BQ, DQ, and CQ. Dichloromethane (CH_2Cl_2) was used as an organic solvent. The $E_{1/2}^{r}$(1) of DQ, BQ, and CQ determined using a cyclic voltammograph are −1.08, −0.72, and −0.10 V, respectively, at 10 °C. Contrary to expectations, linear Stern–Volmer plots were obtained for all cases when the fluorescence emissions from RTPPs (4×10^{-5} mol dm^{-3}) were quenched by the quinones at concentrations below 1×10^{-2} mol dm^{-3}. This indicates that only dynamic fluorescene quenching takes place and that no appreciable amounts of the ground-state complexes of RTPPs with quinones are formed at the concentration range of the quinone below 1×10^{-2} mol dm^{-3}. The results of fluorescence quenching are shown in Table 3. Of course, no absorption spectral change was measured under the same conditions as those for fluorescence quenching. In the cases of DQ and BQ, the k_q value tends to increase with decreasing $E_{1/2}^{o}$(1) of RTPP. This should be ascribed to fluorescence quenching via an electron transfer from photoexcited RTPP to the quinone. Meanwhile, no correlation was observed between k_q and $E_{1/2}^{o}$(1) in fluorescence quenching by CQ. This result can be interpreted as meaning that the fluorescence quenching by CQ proceeds at a diffusion-controlled rate because of the large electron affinity of this quinone.

At BQ concentrations above 1×10^{-2} mol dm^{-3}, however, the absorption spectra of the several RTPPs regularly changed upon addition of BQ. An example is shown in Fig. 2, which shows the absorption

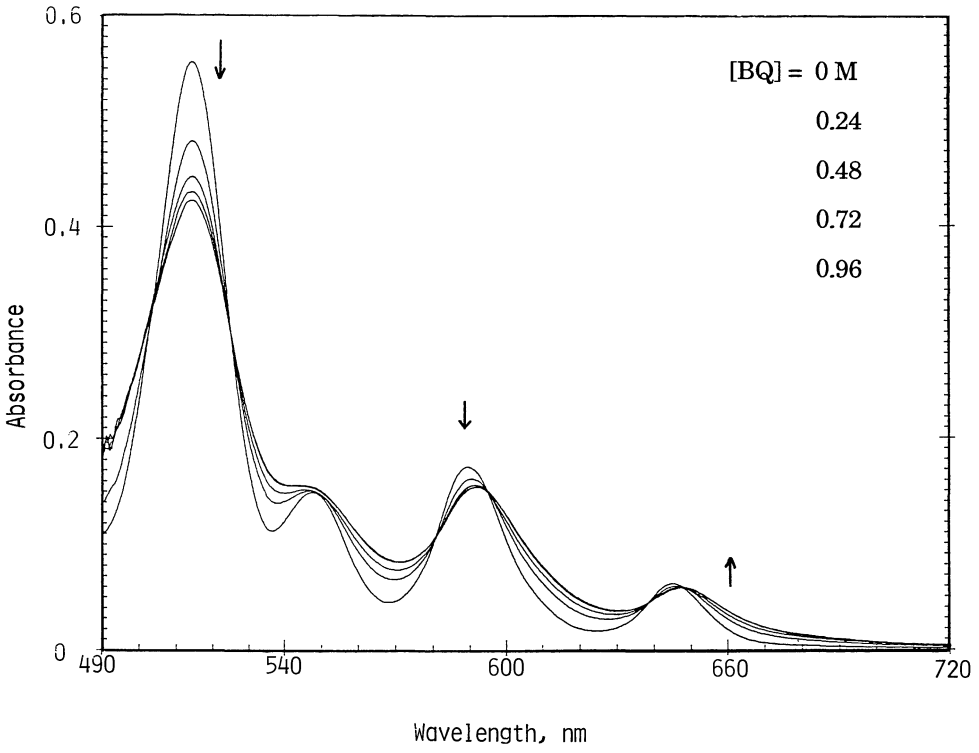

Fig. 2. Absorption spectral change of *o*-$NHCOCH_3TPP$ (4×10^{-5} mol dm^{-3}) in CH_2Cl_2 upon addition of BQ at 7 °C.

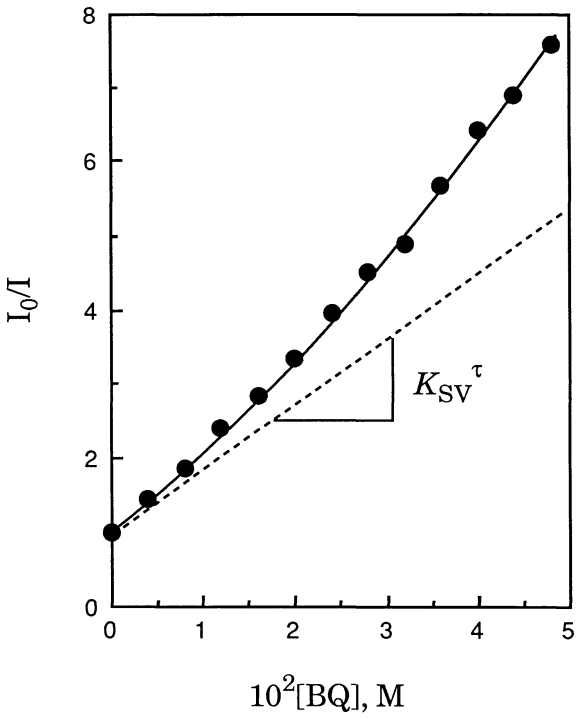

Fig. 3. Stern-Volmer plot for the fluorescence quenching of *o*-$NHCOCH_3TPP$ (4×10^{-5} mol dm^{-3}) by BQ in CH_2Cl_2 at 7 °C. The porphyrin was excited at 581 nm and the fluorescence intensities were followed at 652 nm.

Table 4. Binding Constants (K) for Complexation of RTPPs with BQ in Organic Solvents

R	Solvent	Temperature/°C	K/mol^{-1} dm^3
H	CH_2Cl_2	15	0.6
o-$NHCOCH_3$	CH_2Cl_2	7	7.8
o-$NHCOCH_3$	CH_3CN	15	4.1
o-OH	CH_3CN	15	3.2
m-OH	CH_3CN	15	2.4
o-NH_2	CH_3CN	15	0.02

spectral change of *o*-$NHCOCH_3TPP$ in CH_2Cl_2 upon addition BQ at 7 °C. The spectra are of the differential type obtained by substracting the BQ contribution. The Stern-Volmer plot for the fluorescence quenching deviates upward from a straight line, as predicted by Eq. 2 (Fig. 3). These results clearly indicate the formation of a ground-state complex of *o*-$NHCOCH_3$-TPP and BQ. The binding constant, K, determined by a Benesi-Hildebrand plot for the absorption spectral change is 7.8 mol^{-1} dm^3 at 7 °C (Table 4). HTPP (5,10,15,20-tetraphenylporphine) also shows a similar behavior (K=0.6 mol^{-1} dm^3 at 15 °C). A molecular complex with a very small K has also been reported for the *p*-CH_3TPP-BQ system in acetone (K=0.5 mol^{-1} dm^3 at 25 °C).[13]

In order to evaluate the contribution of a charge-transfer interaction to complexation, CH_2Cl_2 was replaced by an aprotic polar solvent, acetonitrile. The

results obtained for *o*-$NHCOCH_3$TPP, *o*-OHTPP, and *m*-OHTPP are shown in Table 4. Since the *K* value (4.1 mol^{-1} dm^3 at 15 °C) for the *o*-$NHCOCH_3$-TPP–BQ system in acetonitrile is almost the same as that in CH_2Cl_2, a charge-transfer interaction may not play an important role in complexation. *o*-$NHCOCH_3$-TPP, *o*-OHTPP, and *o*-NH_2TPP were used to study the possibility for the formation of hydrogen-bonded complexes between these porphyrins and BQ. However, no appreciable difference was observed for the *K* values between these ortho-substituted porphyrins and HTPP and *m*-OHTPP. The *K* value for the *o*-OHTPP–BQ system was too small to be determined accurately. It, therefore, seems that the hydrogen bonding as well as the charge-transfer interaction scarcely participate in the complex formation of organic solvents. Therefore, it may be reasonable to assume that the main binding forces for the unstable complexes of RTPPs with quinones are van der Waals interactions.

Molecular Complexes of TMPyP and TAPP with BQ in Organic and Aqueous Media. In spite of the electrostatic repulsion, both cationic porphyrins, TMPyP and TAPP, associate with a cationic dye, 2,6-diaminoacridinium hydrogensulfate (PFl), in water to form relatively stable molecular complexes (*K* for TMPyP=2161 mol^{-1} dm^3 at 25 °C, *K* for TAPP=800 mol^{-1} dm^3 at room temperature).[3,5] *p*-Nitrophenol (PNP) can also act as a guest molecule in complexation with TMPyP in water (K=550 mol^{-1} dm^3 at 25 °C).[4] On the basis of the thermodynamic parameters determined for these systems (see Table 1), we have claimed that the van der Waals interactions are the main binding forces.[4,5]

We initially expected that relatively stable molecular complexes of these cationic porphyrins should be formed in organic solvents, as long as van der Waals interactions are the binding forces. We then compared the stability of the TMPyP- and TAPP–BQ complexes in methanol and water. The determined *K* values are listed in Table 5. The *K* values in methanol were evaluated from Benesi–Hildebrand plots for the absorption spectral changes, and those in water were determined from data regarding fluorescence quenching using Eq. 3. We confirmed that both methods can provide almost the same *K* values. For example, the *K* values evaluated from the Benesi–Hildebrand plots for the TMPyP–BQ and TAPP–BQ systems at 20 °C are 79 and 151 mol^{-1} dm^3, respectively, and are in good agreement with the *K* values determined from the fluorescence quenching (see Table 5).

Table 5. Binding Constants (*K*) for Complexation of TMPyP and TAPP with BQ and NQ in Methanol and Water

Porphyrin	Quinone	Solvent	Temperature/°C	K/mol^{-1} dm^3
TMPyP	BQ	CH_3OH	20	4.0
TAPP	BQ	CH_3OH	20	2.7
TMPyP	NQ	CH_3OH	20	7.6
TAPP	NQ	CH_3OH	20	13.0
TMPyP	BQ	H_2O	20	73
TMPyP	BQ	H_2O	25	70
TMPyP	BQ	H_2O	30	67
TMPyP	BQ	H_2O	35	63
TAPP	BQ	H_2O	20	147
TAPP	BQ	H_2O	25	85
TAPP	BQ	H_2O	30	84
TAPP	BQ	H_2O	35	80

As Table 5 indicates, complexes formed in water are much more stable than those formed in methanol. The *K* values in methanol are comparable to those of the RTPP–BQ systems in CH_2Cl_2 or acetonitrile. NQ, which has a more expanded π-conjugated system compared with BQ, also shows small *K* values. From these results it can be concluded that the cationic porphyrins, as well as RTPPs, cannot form stable molecular complexes with quinones in organic solvents through van der Waals interactions. Meanwhile, the *K* values in water are much larger than those in methanol. The van't Hoff plots for the data shown in Table 5 provide ΔH and ΔS for complexation of TMPyP and TAPP with BQ in water, ΔH and ΔS being −28 kJ mol^{-1} and −56 J mol^{-1} deg^{-1}, respectively, for TMPyP and −34 kJ mol^{-1} and −73 J mol^{-1} deg^{-1}, respectively, for TAPP. It is clear that the complex formation of these cationic porphyrins with BQ in water is the enthalpically favorable process. This finding is the same as that obtained for other systems investigated previously (see Table 1). If we define that complexation through hydrophobic interaction is favorably dominated by an entropy term, it can be concluded that the hydrophobic interaction does not contribute to the complexation of these cationic porphyrins with BQ in water. The charge-transfer, hydrophobic, and, in some special cases, hydrogen-bonding interactions can be excluded from the main binding forces. The van der Waals interactions may mainly participate in the complexation of cationic porphyrins with BQ in water. However, in order to conclude that the van der Waals interactions are the main binding forces, we have to explain the reason why these interactions are so strong in water compared with in organic solvents.

Quite recently, Smithrud and Diederich[14] reported the solvent effects on complex formation of a macrocyclic cyclophane host and a pyrene guest and found a linear relationship between $-\Delta G°$ for complexation and Dimroth's $E_T(30)$ values of the solvents. They explained the largest binding constant in water in terms of such water properties as low molecular polarizability and a high cohesive interaction that promote the strongest van der Waals interactions between an apolar host and an apolar guest in water. A similar explanation may be possible

Table 6. Average Molecular Polarizabilities (α)

Molecule	α (calcd)/Å^3	α (exp)/Å^3	Ref
H_2O	1.47	1.45	15

HTPP	74.9		This work
$TMPyP^{4+}$[a)]	75.4		This work
BQ	10.7		This work

a) The α value was calculated for the cation ($TMPyP^{4+}$) and no contribution of Cl^- was considered.

for our systems.

The London dispersion force, as well as the dipole-induced dipole interaction, becomes remarkable when host and/or guest molecules have large molecular polarizabilities. The average molecular polarizability, α, can be calculated using the following equation:[15)]

$$\alpha = (4/N)(\sum \tau_A)^2 \ (\text{Å}^3), \tag{5}$$

where N is the number of electrons in the molecule and τ_A is the atomic hybrid components of α for each atom in a particular hybrid configuration. The calculated polarizabilities of the molecules which were used in this study are summarized in Table 6. The molecular polarizability of H_2O is lowest amongst the solvent molecules in Table 6, which means that the van der Waals interactions between apolar solute and solvent molecules are weakest in water. Both TMPyP and TAPP are regarded as being amphiphilic molecules and the hydrophobic porphyrin rings of these porphyrins may not strongly interact with water molecules through van der Waals interactions, while the hydrophilic peripheries are extensively hydrated through an ion–dipole interaction. The association of the cationic porphyrins and BQ in water, therefore, may be a process which does not require extensive dehydration from the porphyrin rings. Since TMPyP and TAPP have large molecular polarizabilities, BQ is also polarizable and the carbonyl groups of BQ have dipoles, molecular association between these hosts and the guest seems to occur through dipole-induced dipole and London dispersion interactions in water as an enthalpically favorable process.

Meanwhile, BQ is hydrated through both hydrogen bonding and dipole–dipole interactions. Dehydration from the BQ molecules, therefore, needs to form a complex with porphyrin as an endothermic process. The water molecules released from BQ, however, may be incorporated tightly into hydrogen-bonding networks of water as an exothermic process. This strong cohesive interaction of water may compensate for any energetic disadvantage due to dehydration. Sinanoglu[18)] has developed a theory regarding solvophobic interaction. In this theory an apolar solute molecule is regarded as being a cavity. The dissolution of a solute molecule in a solvent causes an increase in the surface area of the solvent, which requires energy to work against the strong cohesive interaction of water. The association of two solute molecules, therefore, is energetically favorable since the surface area of the solvent is reduced upon complexation. Margalit and Rotenberg[19)] have applied this theory to explain the dimerization of porphyrin in water. The strong solvophobic interaction in water is ascribed to a strong cohesive interaction of this solvent, and may also participate in the complexation of the cationic porphyrins with BQ in water.

The large stability of the complexes of TMPyP with PF1 and PNP[3–5)] as well as of the complexes of $TPPS_3$ with various aromatics[1,2)] in water may be interpreted in the same manner. We have claimed that TMPyP dimerizes in water, even at very low concentrations ([TMPyP]$>2\times10^{-7}$ mol dm^{-3}).[3–7)] Our dimer model for TMPyP contradicts the conclusion presented by Hambright and Fleischer[16)] as well as Pasternack and his co-workers.[17)] The novel dimerization of TMPyP can also be explained by strong van der Waals interactions which are ascribed to the nature of water, such as the low molecular polarizability and the strong cohesive interaction of water.

We believe that the stoichiometries of the complexes of TMPyP and TAPP with BQ are 2:1 and 1:1, respectively, in water while the 1:1 complexes of both porphyrins are formed in methanol. In previous papers we confirmed that TMPyP and TAPP exist as a dimer and monomer, respectively, in water under the present conditions ([porphyrin]$=4\times10^{-5}$ mol dm^{-3})[5)] and that the TMPyP dimer associates with PF1.[3)] Although we attempted to obtain a correlation between $\Delta G°$ for the complexation of TMPyP with BQ and $E_T(30)$ in aqueous methanol, we did not succeed because of the partial dissociation of the TMPyP dimer to the monomer in aqueous methanol.

(Received October 3, 1990)

The cobalt(II) naphthenate[$Co(Nap)_2$] catalyzed decomposition of cumene hydroperoxide(CHP) gave a mixture of α-cumyl alcohol, acetophenone and di-α-cumyl peroxide in benzene at 25 °C. All experimentally observed time courses of disappearing CHP and an increasing of three products compared well with theoretical values.

Much attention has been paid to the metal-ion-catalyzed decomposition of organic hydroperoxides, which are important intermediates in both the oxidation of lipids *in vivo*[1] and the autoxidation of hydrocarbons.[2] Numerous attempts have been made to obtain a mechanism for the metal-ion-catalyzed decomposition of organic hydroperoxides.[3] Previously, Hiatt et al. proposed a radical chain mechanism for a metal-catalyzed decomposition of *t*-alkyl hydroperoxides, based on kinetic data regarding only the disappearance of the peroxides, due to a lack of detailed kinetic data concerning each product.[4] Thus, in order to examine the Hiatt mechanism, which seemed to be the most plausible one among hitherto proposed mechanisms, we initiated a detailed products analysis of a cobalt naphthenate catalyzed decomposition of 1-methyl-1-phenylethyl hydroperoxide ("cumene hydroperoxide," abbreviated as CHP) and kinetic studies of not only the disappearance of CHP, but also each product formation.

Results and Discussion

When the $Co(Nap)_2$ catalyzed decomposition of CHP was carried out in benzene at 25 °C, 1-methyl-1-phenylethyl alcohol (α-cumyl alcohol, abbreviated as CA) was obtained as the major product, with acetophenone (AP) and di-α-cumyl peroxide (DCP) as minor products.

$$\underset{\textbf{CHP}}{PhCMe_2OOH} \xrightarrow[\text{In benzene}]{Co(Nap)_2} \underset{\textbf{CA}}{PhCMe_2OH} + \underset{\textbf{AP}}{PhCOMe} + \underset{\textbf{DCP}}{PhCMe_2OOCMe_2Ph}$$

The effect of the initial concentration of CHP on the product distribution is shown in Fig. 1. The products which resulted from the solvent could not be detected. CA, AP, and DCP explained about 100% of the CHP consumed in all reactions, with different initial [CHP] ranging from 0.59 M to 5.35 M (M=mol dm^{-3}) (Table 1).

According to Hiatt's mechanism (Scheme 1), the processes of a cobalt(II) naphthenate catalyzed decomposition of CHP consist of the following three classes of reactions: (1) Cobalt(II)-ion-catalyzed decomposi-

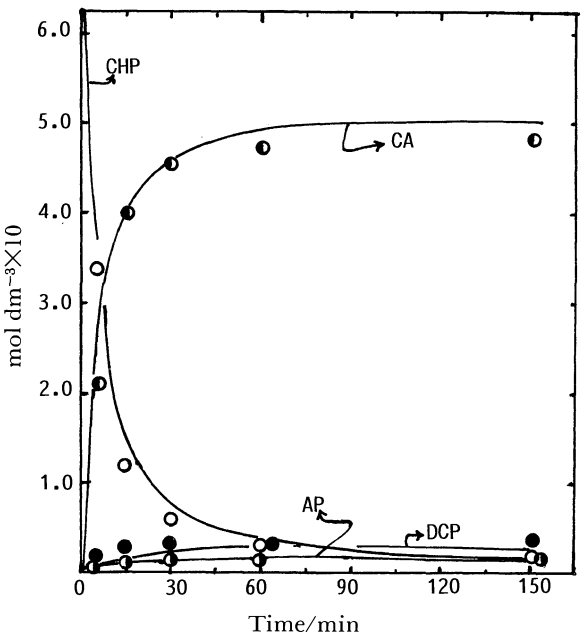

Fig. 1. $Co(Nap)_2$ catalyzed decomposition of CHP in benzene at 25 °C with $[CHP]_0$=0.59 mol dm^{-3} and $[Co(Nap)_2]_0=4.48\times10^{-3}$ mol dm^{-3}. Experimental observed value: CHP, ○; CA, ◐; AP, ◑; DCP, ●. Each solid line is theoretical (k_1=3.4 l mol^{-1} min^{-1}, k_4'=16, k_3'=145 l mol^{-1}).

tions of CHP to provide α -cumyloxyl radical (Eq. 1) and α-cumylperoxyl radical (Eq. 2). (**2**) Chain reaction carried by α-cumyloxyl radical (Eqs. 3 and 4). (**3**) Termination reactions: reactions 6 and 7, to which Hiatt did not pay any attention, were newly added as some of termination reactions, in addition to reaction 5, since formation of a certain amount of AP was observed in this investigation.

Assuming steady states for [$PhCMe_2O\cdot$], [$PhCMe_2OO\cdot$], [$MeOO\cdot$], [Co^{2+}], and [Co^{3+}], Eqs. 8—11 are derived from the decomposition mechanism of CHP shown in Scheme 1.

$$k_1[CHP][Co^{2+}] = k_2[CHP][Co^{3+}] \quad (8)$$

$$d[MeOO\cdot]/dt = k_6[PhCMe_2O\cdot] - k_7[MeOO\cdot][PhCMe_2OO\cdot] = 0 \quad (9)$$

$$d[PhCMe_2O\cdot]/dt = k_1[CHP][Co^{2+}] - k_3[PhCMe_2O\cdot][CHP] + 2k_4[PhCMe_2OO\cdot]^2 - k_6[PhCMe_2O\cdot] = 0 \quad (10)$$

$$d[PhCMe_2OO\cdot]/dt = k_1[PhCMe_2OOH][Co^{2+}] + k_3[PhCMe_2O\cdot][CHP] - 2k_4[PhCMe_2OO\cdot]^2 - 2k_5[PhCMe_2OO\cdot]^2 - k_7[MeOO\cdot][PhCMe_2OO\cdot]^2 = 0 \quad (11)$$

$$[PhCMe_2O\cdot] = \{(2k_1k_4 + k_1k_5) / (2k_4k_6 + k_5k_6 + k_3k_5[CHP])\}[CHP][Co^{2+}] \quad (12)$$

From Eqs. 8, 9, 10, 11, and 12, the disappearance rate of CHP and rates of formations of CA, AP, and DCP are written as follows:

$$-d[CHP]/dt = 2k_1[CHP][Co^{2+}] + k_3[RO\cdot][CHP] = [\{2k_1(k_4' + 1) + k_1k_3'(2k_4' + 3)[CHP]\} / \{(2k_4' + 1) + k_3'[CHP]\}][CHP][Co^{2+}] \quad (13)$$

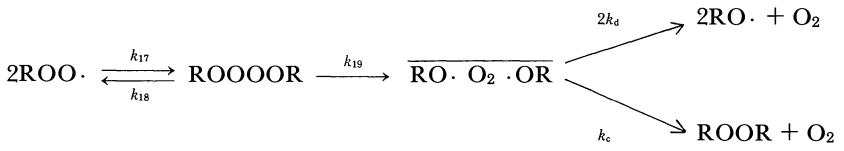
$$d[CA]/dt = k_3[RO\cdot][CHP] + k_7[MeOO\cdot][ROO\cdot] = [\{k_1(2k_4' + 1)(1 + k_3'[CHP])\} / \{(2k_4' + 1) + k_3'[CHP]\}][CHP][Co^{2+}] \quad (14)$$

$$d[AP]/dt = k_6[RO\cdot] = [\{k_1(2k_4' + 1)/\{(2k_4' + 1) + k_3'[CHP]\}][CHP][Co^{2+}] \quad (15)$$

$$d[DCP]/dt = 2k_5[ROO\cdot]^2 = [2k_1k_3'/\{(2k_4' + 1) + k_3'[CHP]\}][CHP]^2[Co^{2+}], \quad (16)$$

where R=$PhCMe_2$, $k_3'=k_3/k_6$, $k_4'=k_4/k_5$.

Assuming that the initiation rate, k_1[CHP][Co ion], where $k_1=k_2$ and [Co ion] is ([Co^{2+}]+[Co^{3+}]), derived from Eqs. 1, 2, and 8 is equal to the sum of termination rates (Eqs. 5, 6, and 7), the specific rate of reaction (1), k_1, is calculated to be 3.40 l mol^{-1} min^{-1}. This value was chosen to fit the experimental yields of the termination products by applying simplex optimization.[5] The values of k_3' and k_4' were successfully estimated to be 145 and 16 l mol^{-1}, respectively, by applying the Rung-Kutta-Gill method[6] for the experimental data given in Table 1 and k_1=3.4 l mol^{-1} min^{-1}, so as to fit the theoretical time courses of both disappearing CHP and appearing products in the experimental values. As shown in Fig. 1, the theoretical curves (solid line) are in accord with the



Scheme 2.

experimental values depicted by circles, revealing that the mechanisms shown in Scheme 1 is reasonable. Bimolecular reactions of ROO· (Eqs. 4 and 5) are known to proceed by the mechanism shown in Scheme 2.[7]

Eqs. 20 and 21 are obtained under a steady state condition for [ROOOOR] and [$\overline{\text{RO}\cdot\ \text{O}_2\ \cdot\text{OR}}$].

$$k_4 = (k_d k_{17} k_{19})/\{(2k_d + k_c)(k_{18} + k_{19})\} \quad (20)$$

$$k_5 = (k_c k_{17} k_{19})/\{2(2k_d + k_c)(k_{18} + k_{19})\} \quad (21)$$

The ratio of dissociation to cage recombination, k_d/k_c, can be obtained from Eqs. 20 and 21:

$$k_4' = 2k_d/k_c = 6.7. \quad (22)$$

The fraction of cage collapse, F, i.e. $k_c/(2k_d+k_c)$, is calculated as 0.13 from Eq. 22. This value agrees well with that of the caged t-butyloxyl radical pairs formed by the decomposition of di-t-butyl hyponitrite (DBH) in "isooctane" (F=0.098) at 45.0 °C (Scheme 3),[8] supporting the mechanism given in Scheme 1. The small difference in the two F values can be rationalized in terms of an easier diffusion out of the t-butyloxyl radical pair from the solvent cage than that from sterically bulky α-cumyloxyl radical pair.

Eqs. 23 is obtained from Eqs. 14 and 15, suggesting that plots of d[CA]/d[AP] against [CHP] fall on a straight line with a slope of, k_3' (145 l mol^{-1}).

$$\text{d[CA]/d[AP]} = k_3'[\text{CHP}]_t + 1 \quad (23)$$

The terms involved in Eq. 23 may be substituted using experimentally observable values, i.e. $\Delta[\text{CA}]_{ij}/\Delta[\text{AP}]_{ij}$ and $[\text{CHP}]_{ij}$, to obtain the following equation:

$$\Delta[\text{CA}]_{ij}/\Delta[\text{AP}]_{ij} \simeq k_3'[\text{CHP}]_{ij} + 1 \quad (24)$$

Here, $\Delta[\text{CA}]_{ij}$ and $\Delta[\text{AP}]_{ij}$ represent the concentrations of CA and AP, which increased for a time between i and j, while $[\text{CHP}]_{ij}$ denotes the average [CHP] for the same time, approximated as $([\text{CHP}]_i+[\text{CHP}]_j)/2$. These values were calculated from the experimental data given in Fig. 1, and plotted as shown in Fig. 2. The straight line shown in Fig. 2 has a slope of 145 mol l^{-1}. Considering the limited number of a vailable data, one can say that Fig. 2 well satisfies the relationship given by Eq. 23.

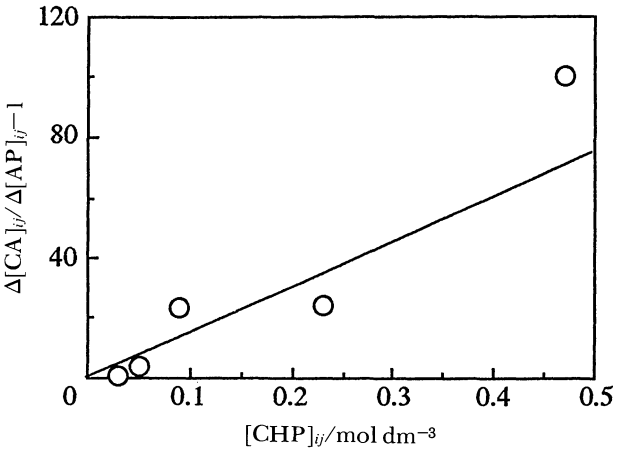


Fig. 2. Relationship between $\Delta[\text{CA}]_{ij}/[\text{AP}]_{ij}$ and $[\text{CHP}]^{av}$ on Co(Nap)_2 catalyzed decomposition of $[\text{CHP}]^{av}$ in benzene at 25 °C with $[\text{CHP}]_o$=0.59 mol dm^{-3}.

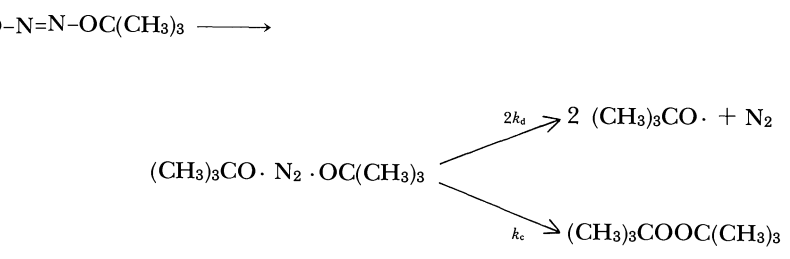
The mechanism of Scheme 1 previously proposed by Hiatt[4] has been verified by our new kinetic investigations which included both the disappearance of CHP and the formation of CA, AP, and DCP in the Co(Nap)_2 catalyzed decomposition of CHP in benzene.

Experimental

GC-analysis was performed on a Shimadzu GC-8A gas chromatography with 1.5 m glass column(silicon OV-210, 10%). GC-MS spectra were recorded on a JEOL DX-500 spectrometer.



Scheme 3.

"Cumene hydroperoxide" (commercial grade of Nippon Oil & Fats Co.) was purified via sodium salt by a method described in the literature.[9]

A $Co(Nap)_2$ catalyzed decomposition of CHP was started by the addition of CHP to a catalyst, and an internal standard (benzil)-containing benzene solution immersed in a constant-temperature bath (25.0±0.2 °C) under nitrogen. Each sample was removed by syringe after an appropriate time interval. The residual CHP concentration was determined iodometrically.[10] The concentrations of CA, AP, and DCP were determined by GC after treating with triphenylphosphine to convert CHP to a stable compound, CA.

We thank Dr. Ken Fujimori of University of Tsukuba for his helpful advice and encouragement to this work.

Thermally Irreversible Photochromic Systems. Reversible Photocyclization of Non-Symmetric Diarylethene Derivatives

Yasuhide NAKAYAMA, Koichiro HAYASHI, and Masahiro IRIE*,†

(Received October 25, 1990)

Non-symmetric diarylethenes with an indole ring on one end and a thiophene, a benzo[*b*]thiophene, or a pyrrole ring on the other end of the double bond were synthesized in an attempt to get thermally irreversible photochromic compounds having absorption bands at longer wavelengths. 2-(1,2-Dimethyl-3-indolyl)-3-(2,4,5-trimethyl-3-thienyl)maleic anhydride(**8a**) underwent photoinduced cyclization/ring-opening reactions with relatively high quantum yields (cyclization quantum yield: 0.15; ring-opening quantum yield: 0.40), and the both isomers were thermally stable. The closed-ring form had the absorption maximum at 595 nm with the edge extending to 760 nm. Cyclization/ring-opening reactions of **8a** and 2-(1,2-dimethyl-3-indolyl)-3-(2-methyl-3-benzo[*b*]thienyl)maleic anhydride (**9a**) were induced by Ar ion (488 nm) and He–Ne (633 nm) lasers.

A photochromic material is characterized by its ability to undergo a reversible transformation between two different chemical forms. Such a transformation is induced by irradiation with an appropriate wavelength.[1] The instant image-forming property without processing has led to the consideration of the use in rewritable direct read after write memory systems.[2] Despite favorable situations provided by recent progress of optical memory technology, organic photochromic compounds have found little applications in optical information storage media. The limitation is due to the lack of suitable compounds which fulfill the requirements for the reversible recording media. Among the requirements the most important one is the thermal stability.[3]

Recently, a new type of thermally stable photochromic compounds, diarylethenes with heterocyclic rings, was developed such as 1,2-dicyano-1,2-bis(2,4,5-trimethyl-3-thienyl)ethene (**1a**), and 2,3-bis(2,4,5-trimethyl-3-thienyl)maleic anhydride (**3a**).[4] Compounds

3a, X=S; R=CH_3 **3b**, X=S; R=CH_3
4a, X=NCH_3; **4b**, X=NCH_3;
R⌒R=CH=CH–CH=CH R⌒R=CH=CH–CH=CH

1a—4a are not thermochromic, even at 300 °C, and the colored closed-ring forms **1b** and **3b** are stable for more than 3 months at 80 °C.[2g] The compounds fulfill the most important condition for optical data storage media. The absorption edges of the closed-ring forms, however, do not extend to 700 nm. This precludes isomerization of the compounds by conventional diode laser light ($780<\lambda<840$ nm). The compounds lack the important requirement of photosensitivity at diode laser wavelengths.

In order to gain access to compounds which have sensitivity at longer wavelengths, symmetric diarylethenes with various heterocyclic rings have been synthesized.[5] Replacing the thiophene rings with indole rings, i.e. 1,2-dicyano-1,2-bis(1,2-dimethyl-3-indolyl)ethene (**2a**) and 2,3-bis(1,2-dimethyl-3-indolyl)maleic anhydride (**4a**), shifts the absorption maxima to longer wavelengths. Compound **4b** has an absorption edge extending to 800 nm and the ring-opening reaction was effected with 780 nm diode laser. The closed-ring forms, **2b** and **4b**, were, however, thermally unstable, reverting in the dark to **2a** and **4a**. The absorption intensity of **4b** decreased to 50% of the initial intensity in 3 h at 80 °C. The thermal stability difference between the diarylethenes with thiophene and indole rings was interpreted by the difference in aromatic stabilization energy of the rings.[6]

In the present study, we synthesized unsymmetrically substituted non-symmetric diarylethene derivatives having an indole ring on one end and a thiophene, a benzo[*b*]thiophene, or a pyrrole ring on the other end of the double bond in an attempt to get thermally stable photochromic compounds having the absorption bands at longer wavelengths.

Results and Discussion

Diarylethene Derivatives with Dicyano Group. Substituted non-symmetric diaryldicyanoethenes

having an indole ring on one end and a thiophene, a benzo[*b*]thiophene, or a pyrrole ring on the other end of the double bond were prepared by a coupling reaction of 3-(cyanomethyl)-1,2-dimethylindole and 3-(cyanomethyl)-2,4,5-trimethylthiophene, 3-(cyanomethyl)-2-methyl-benzo[*b*]thiophene or 3-(cyanomethyl)-1,2,4,5-tetramethylpyrrole, respectively.

In the case of a coupling reaction of equimolar (cyanomethyl)indole and (cyanomethyl)pyrrole approximately equal amounts of **7a** and **2a** were obtained. (Cyanomethyl)pyrrole reacted more efficiently with (cyanomethyl)indole than (cyanomethyl)pyrrole. The self coupling product of the pyrrole compounds, 1,2-dicyano-1,2-bis(1,2,4,5-tetramethyl-3-pyrrolyl)ethene, was formed in very low yield. The mixture of **7a** and its trans form, and **2a** and its trans form was separated by silica-gel chromatography using benzene as an eluent. The trans and cis mixture of the indolyl-pyrrolylethene derivative was dissolved in acetonitrile and exposed to ultraviolet-visible light (λ>350 nm). The irradiation converted a large part of the trans form to the cis form. The cis form was isolated by high-performance liquid chromatography (HPLC, 5 μm silica gel/benzene) and purified by recrystallization from a hexane–ether mixture.

The coupling reaction of equimolar (cyanomethyl)-indole and (cyanomethyl)thiophene yielded the mixture of **5a**, **1a**, and **2a** (4:20:1 including the trans forms). The mixture was separated by the same procedure used for **7a**. Compound **6a** was also prepared by the similar coupling reaction as used for **7a**. The structures of the above compounds were fully characterized by spectroscopic methods.

Non-symmetric diarylethenes with the dicyano group underwent the cyclization to produce the cyclohexadiene-type derivatives.[7] Figure 1 shows the absorption spectral change of a dilute benzene solution of **5a** (1.0×10^{-4} mol dm^{-3}) by photoirradiation with 436 nm light. Irradiation of the yellow benzene solution in the presence of air with 436 nm light leads to the decrease of the absorption at 412 nm ($\varepsilon=1.0\times10^4$ l mol^{-1} cm^{-1}) and formation of a brown solution, in which a visible absorption at 549 nm ($\varepsilon=5.4\times10^3$ l mol^{-1} cm^{-1}) was observed. The closed-ring form **5b** shows a 37 nm bathochromic shift compared with **1b**. Isosbestic points are observed at 382 and 458 nm. The spectra indicate that the cis to trans isomerization is negligible when the sample is irradiated at 436 nm. Upon irradiation with light of wavelengths longer than 520 nm, the brown color of

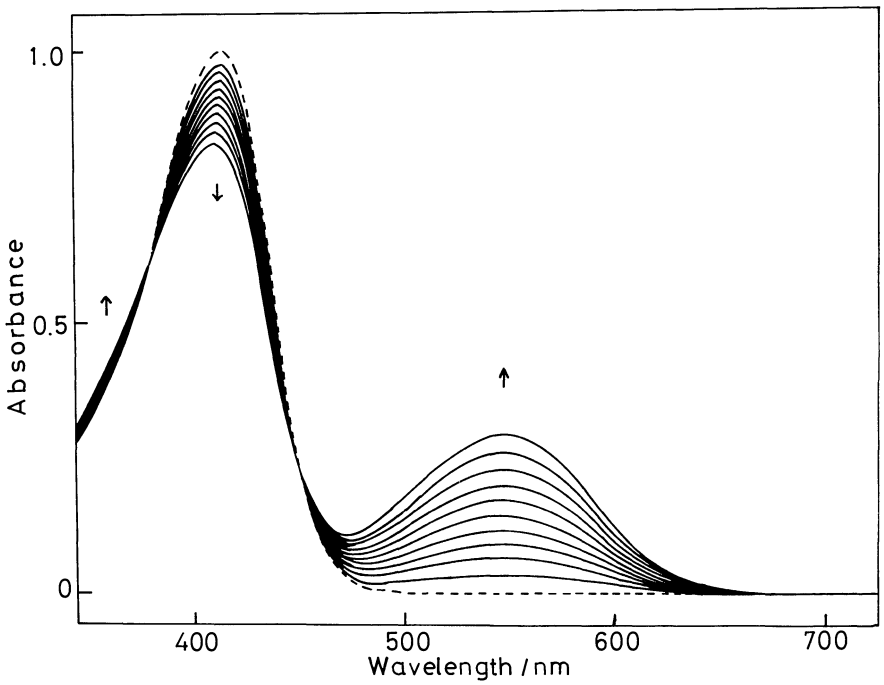

Fig. 1. Absorption spectral change of benzene solution of **5a** (1.0×10^{-4} mol dm^{-3}) (---) induced by irradiation with 436 nm light. Irradiation time; 25, 50, 80, 110, 150, 195, 261, 333, 471, and 855 s.

5b disappeared, and the initial cis form absorption was restored. The conversion of **5a** to **5b** at the photostationary state was estimated to be 55% by comparing the absorption intensity at 549 nm with that of **5b**, which was isolated from the photoirradiated sample by HPLC.

The absorption maximum of **1b** was observed at 512 nm,[1] while that of **2b** was 575 nm.[5] The absorption maximum of **5b** was in between those of **1b** and **2b**.[7] This indicates that donor-acceptor conjugation over two heterocyclic rings does not play an important role in this compound.

By replacing the thiophene ring of **5b** with a benzo[*b*]thiophene or a pyrrole ring, the absorption maximum of the closed-ring forms of the dicyano derivatives shifted to longer wavelengths, 558 and 575 nm, respectively. The absorption maxima and the conversions of the cis forms to the closed-ring forms at the photostationary state are summarized in Table 1. The conversions were determind by comparing the absorption maximum intensities at the photostationary state with those of the isolated closed-ring forms. The closed-ring forms were easily isolated from the photoirradiated samples by HPLC equipped with a visible absorption monitor. Conversions over 50% are observed for the non-symmetric dicyano derivatives. In order to shift the absorption band further to longer wavelengths and to prevent the cis to trans isomerization completely, the dicyano group was converted to an oxydicarbonyl group.

Table 1. Absorption Maxima of the Closed-Ring Forms and Photochromic Property of Non-Symmetric Diarylethenes in Benzene Solution

a) In hexane solution. b) At photostationary state.

Maleic Anhydride Derivatives. The dicyano derivatives were converted to maleic anhydride derivatives by hydrolysis with KOH in ethylene glycol monoethyl ether–water mixture. The 2,3-diarylmaleic anhydrides were purified by column chromatography using benzene as an eluent, and were recrystallized from a hexane–chloroform mixture.

Their structures were fully characterized by spectroscopic methods. The non-symmetric 2,3-diarylmaleic anhydride underwent cyclization reactions to produce the cyclohexadiene-type derivatives. Figure 2 shows the spectra of **8a** and **8b**, and the spectrum at the photostationary state under irradiation with 491 nm light in benzene. Upon irradiation with 491 nm light in the presence of air, the solution turned green and a new peak appeared at 595 nm (ε=5.5×10^3 l mol^{-1} cm^{-1}). Isosbestic points are observed at 437 and

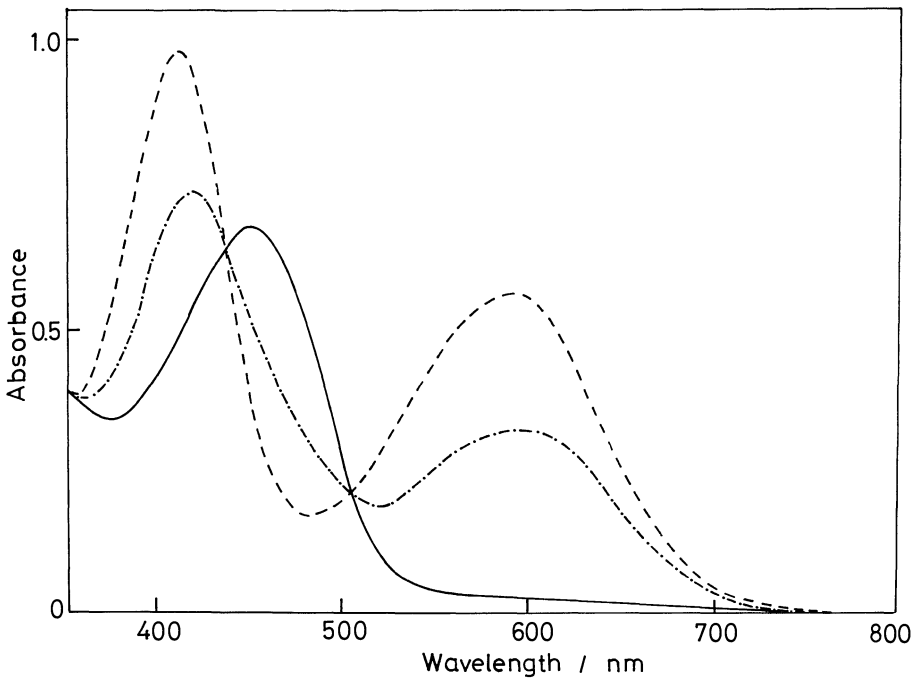

Fig. 2. Absorption spectra of benzene solution of **8a** (1.0×10^{-4} mol dm^{-3}) (——) and **8b** (1.0×10^{-4} mol dm^{-3}) (---) and a mixture of **8a** and **8b** at the photostationary stae (—·—) under irradiation with 491 nm light.

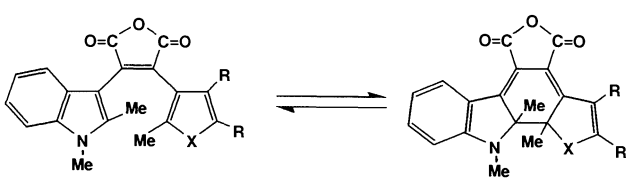

8a, X=S; R=CH_3 **8b**, X=S; R=CH_3

504 nm. The absorption maximum shifts to longer wavelengths by 56 nm in comparison with the dicyano derivative **5b**. On exposure to visible light (λ>560 nm), the solution again became yellow, and the initial absorption of **8a** was restored. The absorption maxima of **3b** and **4b** were observed at 560 nm and 620 nm, respectively.[4,5] The absorption maximum of **8b**, 595 nm, was in between those of **3b** and **4b**.

The cyclization reaction was also induced by irradiation with 488 nm light of Ar ion laser. The photogenerated green color disappeared on exposure to 633 nm He–Ne laser. Compound **9a** underwent similar cyclization/ring-opening reactions upon irradiation with 488 and 633 nm lights.

The absorption maxima of the closed forms of symmetric diarylethenes showed red shifts with increasing electron-donating ability of the heterocyclic groups and with increasing electron-accepting ability of 1,2-substituents by replacing the dicyano group with oxydicarbonyl group.[4,5,8] The absorption maxima of the closed-ring forms of dicyano derivatives increased in the following order; dithienylethene≈bis(benzo[*b*]thienyl)ethene<diselenenylethene<diindolylethene.[4,5,8] The maleic anhydride derivatives showed a bathochromic shift in comparison with the dicyano derivatives as much as 50 nm.

For the non-symmetric diarylethenes with an indole ring on one end of the double bond, the absorption maximum was also controlled by the electron-donating ability of the other heterocyclic rings. The absorption maximum showed red shift in the order of **5b**<**6b**<**7b**. The result suggests that donor–acceptor type interaction between heterocyclic groups and the dicyano or the oxydicarbonyl group plays an important role in determining the position of the absorption band.

The absorption spectra of the closed-ring forms are dependent on the polarity of the medium. Figure 3 shows the absorption spectra of **7a**+**7b** at the photostationary state in several solvents. The absorption maximum of **7b** in hexane at 554 nm shifts to 574 nm in benzene. In hexamethylphosphoric triamide (HMPA), the closed-ring form has a deep blue color, and the absorption maximum is observed at 603 nm. The dramatic red-shift of the absorption band indicates that $S_0 \rightarrow S_1$ band of **7b** has charge-transfer character and the S_1 is polar state. The invariance of the second band of **7b** with solvent polarity suggests that the band is due to the transition to a less polar

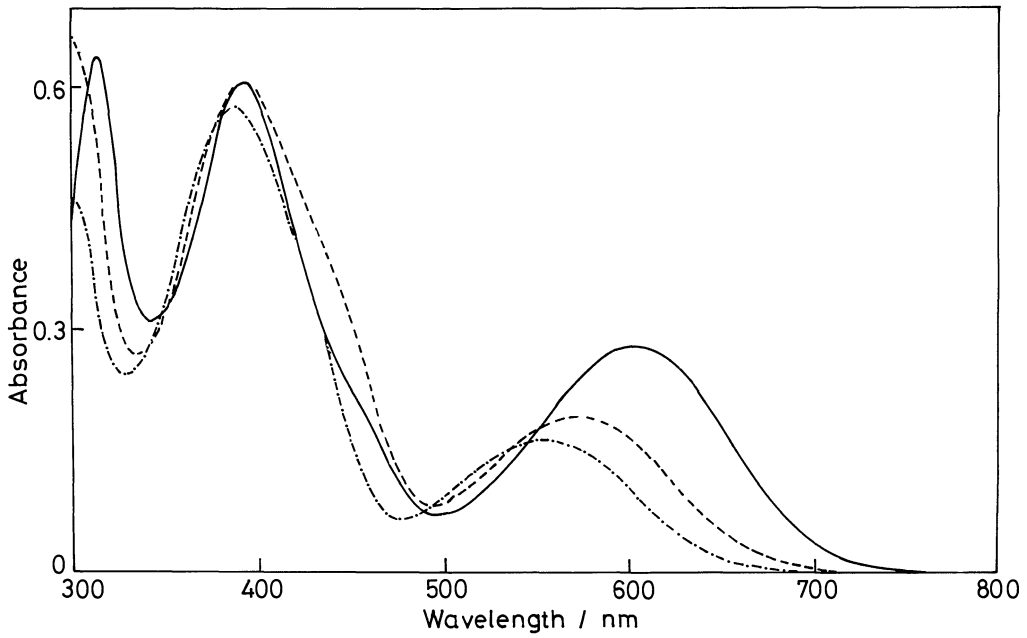

Fig. 3. Absorption spectra of **7a**+**7b** (total concentration, 1.0×10^{-4} mol dm^{-3}) at the photostationary state in hexane (—·—), in benzene (----), and in HMPA (——). Conversion from the open-ring to the closed-ring form was 39% in hexane, 44% in benzene, and 75% in HMPA. The absorption bands longer than 500 nm and at around 400 nm are ascribable to **7b**, and shoulders at around 450 nm to **7a**.

excited state.

Thermal Stability of Closed-Ring Forms. Figure 4 illustrates the thermal stability of the closed-ring forms **5b**, **6b**, **7b**, **8b**, and **9b** at 80 °C in the dark. The value of A/A_0 was plotted against storage time, where A_0 is the initial absorbance at the absorption maximum of the closed-ring form, and A the absorbance after t hours at 80 °C. As seen in Fig. 4, the photogenerated closed-ring forms, **5b**, **6b**, **8b**, and **9b** are stable, and maintain a constant absorption intensity for more than 12 h at 80 °C, whereas **7b** is thermally unstable. The absorption intensity of **7b** decreases to 75% of the initial intensity in 12 h at 80 °C.

In a previous paper,[6] we showed that the thermal stability of the closed-ring forms of symmetric diarylethene derivatives is dependent on the aromatic stabilization energy of the aryl groups. When the aryl groups of the compounds have low aromatic stabilization energy, the closed-ring forms are thermally stable, while they become thermally unstable when they contain benzene or pyrrole rings with high aromatic stabilization energy. The experimental results presented in this paper indicate that the closed-ring forms of non-symmetric diarylethenes are thermally stable when at least one of the heterocyclic rings has low aromatic stabilization energy. Note that the non-symmetric compound having aryl groups with high aromatic stabilization energy for both substituents, e.g. **7b**, is thermally unstable.

Quantum Yield. The quantum yields of cyclization and ring-opening reactions were measured in benzene and hexane solutions. A xenon lamp equipped with a monochromater (Jovin Yvon H10-UV) was used as the light source. The light intensity was determined with a photometer (International Light, IL-700). Table 2 summarizes the result. The cyclization quantum yields of **5a** and **8a** in benzene are below 0.1. The values are similar to those observed for **2a** and **3a**.

The cyclization quantum yield was strongly dependent on the polarity of solvents. The quantum yield in hexane is 3 times larger than the value observed in benzene. Similar solvent dependence of the quantum yield was observed for the thiophene derivatives.[4] The cyclization quantum yield of **3a** decreases from 0.13 to 0.003 by increasing the solvent polarity from hexane to acetonitrile.[9] These solvent dependences suggest that there exist two kinds of excited states with different polarity, and the less polar

Table 2. Quantum Yields for Cyclization and Ring-Opening Reactions of Non-Symmetric Diarylethenes

	Excitation wavelength	Solvent

state is responsible to the photocyclization.

The ring-opening quantum yields of **5b** and **8b** in benzene are quite high. The value of **8b** is 3 times larger than the value observed for the ring-opening reaction of **3b**. Replacement of one of the thiophene rings with an indole ring increased the ring-opening quantum yield. Similar increase of the ring-opening quantum yield was observed for bis(benzo[*b*]thienyl)-ethene.[8] The introduction of a rigid indole (or benzo[*b*]thiophene) ring possibly destabilizes the closed-ring forms, and increases the ring-opening quantum yield.

Summary

Non-symmetric diarylethenes with an indolyl group on one end and a thienyl, a benzo[*b*]thienyl or a pyrrolyl group on the other end were synthesized. The diaryldicyano- and diaryl(oxydicarbonyl)ethenes **5a**, **6a**, **8a**, and **9a** underwent thermally irreversible photochromic reactions. Although these compounds still are not sensitive to wavelengths of diode lasers, both the open-ring and closed-ring forms have absorption bands in the visible region, and the cyclization/ring-opening reactions of **8a** and **9a** were induced by Ar ion (488 nm) and He–Ne (633 nm) lasers.

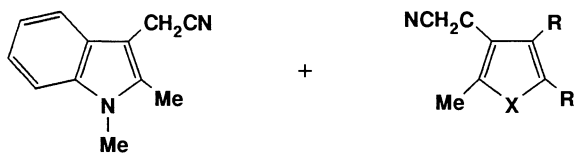
Experimental

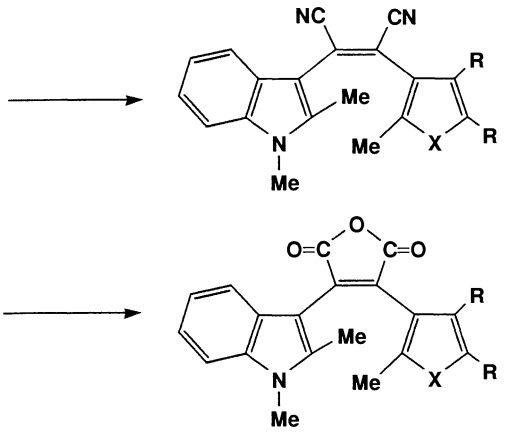
^{1}H NMR spectra (360 MHz) were recorded in $CDCl_3$ with a Brucker WN-360 instrument. All chemical shifts were expressed in parts per million (ppm) downfield from internal tetramethylsilane. Mass spectra and elemental analysis were performed in the Material Analysis Center of Osaka University. High-performance liquid chromatography (HPLC) was carried out on a JASCO 800 instrument. For isolation and purification of samples, a column (10×250 mm) packed with silica gel (JASCO, Fine SIL-5) was used.

Absorption spectra were measured with a spectrophotometer (Shimadzu MPS-200). Photoisomerization was carried out in solution in the presence of air. A Ushio mercury lamp (1 kW) or a EWIG XC-500 xenon lamp equipped with a monochromater (Jovin Yvon 10H-UV) were used as the light sources. Quantum yields were determined by measuring the rate of isomerization in the initial stage of the reaction at low concentration (absorbance at the irradiation wavelength<0.2). The light intensity was measured with a photometer (International Light IL700).

Materials. 3-(Cyanomethyl)-1,2-dimethylindole,[5] 3-(cyanomethyl)-2,4,5-trimethylthiophene,[4] 3-(cyanomethyl)-2-methylbenzo[*b*]thiophene,[8] and 3-(cyanomethyl)-1,2,4,5-tetramethylpyrrole[10,11] were prepared by the reported procedures.

A general procedure for the preparation of 1,2-diaryl-1,2-dicyanoethenes and 2,3-diarylmaleic anhydrides is illustrated by the following scheme.





1,2-Dicyano-1-(1,2-dimethyl-3-indolyl)-2-(2,4,5-trimethyl-3-thienyl)ethene(5a). To a mixed solution of CCl_4 (1.58 ml) and benzene (1.58 ml) containing 0.07 g (0.22 mmol) of tetrabutylammonium bromide, 0.5 g (2.7 mmol) of 3-(cyanomethyl)-1,2-dimethylindole and 0.45 g (2.7 mmol) of 3-(cyanomethyl)-2,4,5,-trimethylthiophene was added at 40 °C 1.09 ml of 50% NaOH aqueous solution. The reaction mixture was heated to 45 °C for 3 h, and then cooled to room temperature. The solution was poured into water, and the aqueous layer was extracted with $CHCl_3$. The organic phase was dried over $MgSO_4$ and filtered. After the solvent was removed, the mixtures of **5a** and its trans form, **1a** and its trans form, and **3a** and its trans form were separated by column chromatography on silica gel (30 μm) using benzene as an eluent. The trans and cis mixture of the indolylthienylethene derivative was dissolved into acetonitrile and exposed to ultraviolet-visible light (λ>350 nm). The irradiation converts a large part of the trans form to the cis form. After evaporation of the solvent, the trans and the cis forms were isolated by column chromatography (HPLC, 5 μm silica gel/benzene). The closed-ring form **5b** was also isolated by HPLC (5 μm silica gel/benzene). HPLC retention times (flow rate 1 ml min^{-1}): **5a** 14.9 min, the trans form 7.9 min, **5b** 20.0 min. The cis form was further purified by recrystallization from a hexane–ether mixture yielding 0.1 g (10%) of **5a**.

5a: IR(KBr, cm^{-1}) 2240; ^{1}H NMR δ=1.92 (s, 3H, CH_3), 1.95 (s, 3H, CH_3), 2.07 (s, 3H, CH_3), 2.20 (s, 3H, CH_3), 3.63 (s, 3H, CH_3), 7.10 (dd, J=8.1, 6.8 Hz, 1H), 7.21 (dd, J=8.1, 6.8 Hz, 1H), 7.25 (d, J=8.1 Hz, 1H), 7.39 (d, J=8.1 Hz, 1H); MS m/z (rel intensity) 345 (M^+, 100), 330 (45), 315 (17); HRMS Found: m/z 345.1320. Calcd for $C_{21}H_{19}N_3S$: M, 345.1299. Anal. Calcd for $C_{21}H_{19}N_3S$: C, 73.01; H, 5.54; N, 12.16; S, 9.28%. Found: C, 73.06; H, 5.40; N, 12.15%.

1,2-Dicyano-1-(1,2-dimethyl-3-indolyl)-2-(2-methyl-3-benzo[*b*]thienyl)ethene (6a). This was prepared by a coupling reaction of 3-(cyanomethyl)-1,2-dimethylindole and 3-(cyanomethyl)-2-methylbenzo[*b*]thiophene, and isolated in 19% yield. HPLC retention times (silica gel/benzene, flow rate 1 ml min^{-1}): **6a** 13.0 min, the trans form 7.2 min, **6b** 9.3 min.

6a: IR(KBr, cm^{-1}) 2240; ^{1}H NMR δ=2.00 (s, 3H, CH_3), 2.12 (s, 3H, CH_3), 3.55 (s, 3H, CH_3), 6.99—7.70 (m, 8H); HRMS Found: m/z 367.1116. Calcd for $C_{23}H_{17}N_3S$: M, 367.1142. Anal. Calcd for $C_{23}H_{17}N_3S$: C, 75.18; H, 4.66; N, 11.43; S, 8.72%. Found: C, 75.23; H, 4.52; N, 11.37%.

1,2-Dicyano-1-(1,2-dimethyl-3-indolyl)-2-(1,2,4,5-tetramethyl-3-pyrrolyl)ethene (7a). This was prepared by a coupling reaction of 3-(cyanomethyl)-1,2-dimethylindole and 3-(cyanomethyl)-1,2,4,5-trimethylpyrrole, and isolated in 5% yield. HPLC retention times (silica gel/benzene, flow rate 1 ml min^{-1}): **7a** 19.8 min, the trans form 10.0 min. Isolation of **7b** by the silica-gel column was failed. The conversion from **7a** to **7b** at the photostationary state was estimated by measuring the HPLC intensity change of **7a** by photoirradiation.

7a: IR(KBr, cm^{-1}) 2240; ^1H NMR δ=1.72 (s, 3H, CH_3), 1.77 (s, 3H, CH_3), 2.00 (s, 3H, CH_3), 2.15 (s, 3H, CH_3), 3.19 (s, 3H, CH_3), 3.63 (s, 3H, CH_3), 7.03 (dd, J=9.0, 6.8 Hz, 1H), 7.16 (dd, J=8.2, 6.8 Hz, 1H), 7.22 (d, J=8.2 Hz, 1H), 7.27 (d, J=9.0 Hz, 1H); MS m/z (rel intensity) 342 (M^+, 100), 327 (57), 312 (12); HRMS Found: m/z 342.1875. A New Oxidizing System for Aromatic Alcohols by the Combination of *N*-Oxoammonium Salt and Electrosynthesized Tetraalkylammonium Tribromide

Tsutomu INOKUCHI, Sigeaki MATSUMOTO, Mitsuhiro FUKUSHIMA, and Sigeru TORII*
Department of Applied Chemistry, Faculty of Engineering,

(Received October 29, 1990)

A combination of 2,2,6,6-tetramethyl-1-piperidinyloxyl and tetraalkylammonium tribromides (R_4NBr_3), which are available from the corresponding tetraalkylammonium bromides via electrooxidation with potassium bromide, has proved to be useful for oxidations of primary and secondary alcohols to the corresponding aldehydes and ketones, respectively. The oxidation reaction proceeds smoothly even with a 0.5—1.0 mol% of *N*-oxyl compounds and 1.5—2.0 equivalents of tetraalkylammonium tribromides in an aqueous-organic two-phase solution buffered at pH 8.0—8.6. This recyclable oxidant/co-oxidant combination system may involve the formation of *N*-oxoammonium salts, actual oxidizing agents of alcohols, by the action of hypobromite species generated from R_4NBr_3 in the binary solution. Utility of the method is highlighted by the selective oxidation of benzylic alcohols bearing electron-releasing groups on the aromatic nucleus to the corresponding aldehydes or ketones without any bromination and overoxidation.

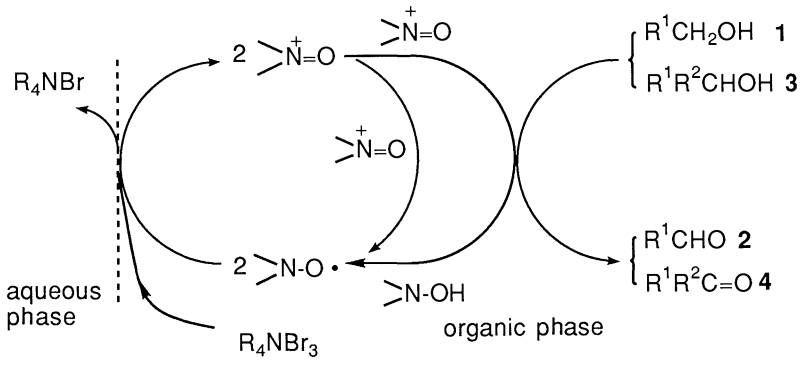
N-Oxoammonium salts have attracted increasing attention as a nonmetallic oxidizing reagent for alcohols to the corresponding carbonyl compounds.[1] The attractiveness of this oxidant may stem from the following characteristic features: (a) the advantage of recycling the reagent by the aid of a co-oxidant (stoichiometric), (b) high selectivity attainable in favor of a primary hydroxyl group for the competitive oxidation of mixed polyols, and (c) easy operation and workup not to produce any hazardous wastes. In the preceding paper, we reported a catalytic procedure for the oxidation of alcohols by using the combination of *N*-oxyl compounds and co-oxidant such as sodium bromite ($NaBrO_2$) and calcium hypochlorite ($Ca(OCl)_2$).[1a] However, this method was faced with a problem that undesired $NaBrO_2$-based bromination of the benzene nucleus proceeded considerably in competition with normal oxidation with *in situ* generated *N*-oxoammonium salts when aromatic alcohols bearing electron-releasing groups were oxidized. We, therefore, turned our attention to a new oxidizing system and examined the combination of *N*-oxyl compound and tetraalkylammonium tribromides (R_4NBr_3) as a co-oxidant for oxidation of aromatic alcohols, because these are considered to be more controllable than $NaBrO_2$ in terms of their reactivity.

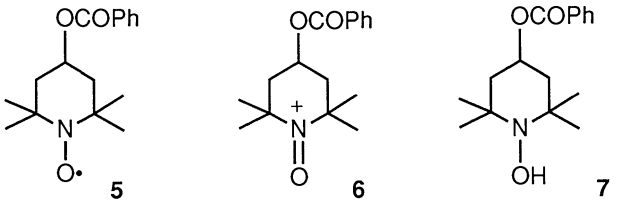
Tetraalkylammonium tribromides (R_4NBr_3) have mainly been used for brominations of unsaturated compounds[2,3a] and ketones,[3b] and sometimes for the oxidation of amines[4] and amides,[3c] but, to the best of our knowledges, there was no precedent entry for a catalytic oxidation system. These tribromide salts are soluble in polar solvents such as CH_2Cl_2, $CHCl_3$, and AcOEt, but insoluble in H_2O, and exhibit long-term stability on exposure to air. Although tetraalkylammonium tribromides are available from the corresponding tetraalkylammonium bromides (R_4NBr) by various bromination methods,[2] we employed an electrooxidation method for their preparation starting from tetraalkylammonium bromides and potassium bromide.[5] R_4NBr_3 can undergo disproportionation in an aqueous basic solution to give hypobromite and Br^-, and hypobromite species thus generated is known to be a powerful oxidizing agent with redox potential of 0.71 V vs. NHE.[6] Consequently, these properties of R_4NBr_3 are expected to be of benefit to the present purpose as a co-oxidant for *N*-oxoammonium-mediated oxidations, which indeed resulted in a dramatic improvement in circumventing the problem mentioned above.

Results and Discussion

In order to know a general trend for *N*-oxyl compound **5** (oxidant)/Bu_4NBr_3 (co-oxidant) combination, we firstly examined the oxidation of 1-undecanol (R^1=*n*-$C_{10}H_{21}$, **1a**) in an aqueous-organic two phase solution. To our delight, it turned out that the oxidation proceeded rather rapidly without any dimeric ester as a by-product (Scheme 1).

The reaction was carried out by employing 1.5—2.0 equivalents of Bu_4NBr_3 and a mixture of **1a** and **5** in a two phase solution consisted of CH_2Cl_2 and an aqueous buffer solution at 20 °C. Time-dependent curves of yields of the desired aldehyde **2a** (R^1=*n*-$C_{10}H_{21}$) are shown for various pH values in Fig. 1. The enhanced oxidizing ability of the combination of *N*-oxyl **5** and Bu_4NBr_3 is clearly indicated at pH 8.6 (aqueous $NaHCO_3$ solution) and more significantly at pH 8.0 (aqueous AcONa solution). An aqueous-organic two-phase solution was essential for the present purpose, otherwise no reaction was effected. Indeed, an attempted oxidation of **1a** in a single phase system of CH_2Cl_2 resulted in an almost quantitative recovery of **1a**. Neither higher (11) nor lower (4—7) pH than the values indicated above afforded the





Scheme 1.

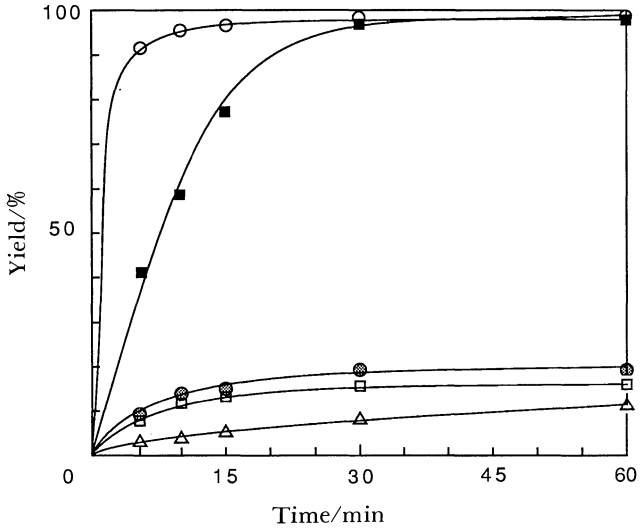


Fig. 1. Time-yield curves for the oxidation of **1a** with a **5**–Bu_4NBr_3 system under various pH values. Symbols are as follows: pH; 4 (△), pH; 7 (□), pH; 8.0 (○), pH; 8.8 (■), pH; 11 (●). Data points were obtained by GC analyses based on an internal standard (octyl acetate) method.

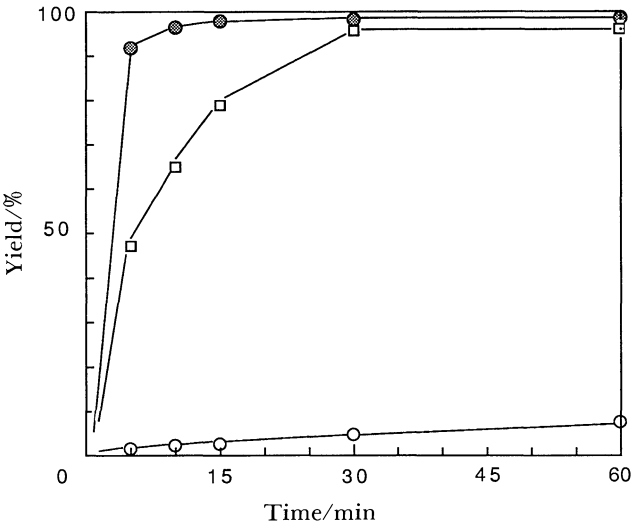

Fig. 2. Time-yield curves for the oxidation of **1a** and Bu_4NBr_3 (2.0 equiv) under various amounts of **5**. Symbols are as follows: 1 mol% of **5** (●); 0.5 mol% of **5** (□); in the absence of **5** (○). Analyzed by GC based on an internal standard (octyl acetate) method.

reasonable levels of yield, only reaching 20% or less. Furthermore, only 0.5—1.0 mol% of the *N*-oxyl compound **5** was enough for the oxidation to be completed within 35 minutes under the conditions indicated (Fig. 2).

Although the detailed mechanism on the present oxidation must wait future studies, we can point out its some aspects. Based on the amount of Bu_4NBr_3 as well as the fact that the oxidation can be enhanced in a two-phase solution buffered at pH 8.0—8.6, it is proposed that this reaction would involve the formation of hypobromite species from Bu_4NBr_3 at the initial stage.[7] Thus, the disproportionation of Bu_4NBr_3 led to hypobromite HOBr as a source of positively charged bromine species, the reaction of which with **5** gave rise to *N*-oxoammonium salt that is responsible for the oxidation of substrates in the organic phase. In contrast to the trimeric structure of $NaBrO_2$[8] as a versatile co-oxidant in the *N*-oxoammonium/*N*-oxyl redox system,[1a] Bu_4NBr_3 dissolved in the organic phase of a binary system may exist as a monomer and be more stable than $NaBrO_2$.[7b] In these respects R_4NBr_3 is highly amenable to the

Table 1. Oxidation of Aromatic Alcohols with **5** and Various Oxidizing Reagents[a]

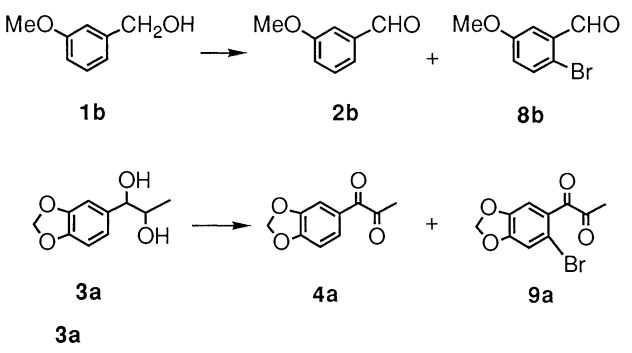
Entry	Substrate	Oxidizing reagents	Products (Yield/%)
1	**1b**	Bu_4NBr_3 (1.5 equiv)[b]	**2b** (88) **8b** (—)
2	**1b**	$PhCH_2Bu_3NBr_3$ (1.5 equiv)[b]	**2b** (87) **8b** (—)
3	**1b**	$NaBrO_2$ (5.0 equiv)[c]	**2b** (39) **8b** (44)
4	**1b**	Electrolysis (4.0 F mol^{-1})[d]	**2b** (9) **8b** (78)
5	**3a**	Bu_4NBr_3 (3.0 equiv)[b]	**4a** (92) **9a** (—)
6	**3a**	Electrolysis (10.0 F mol^{-1})[d]	**4a** (—) **9a** (87)

a) Substrates (1 mmol) were allowed to react in the presence of *N*-oxyl **5** (0.01 mmol). b) Carried out in a CH_2Cl_2–5% AcONa (6:14 v/v) solution. c) Carried out in a CH_2Cl_2–5% $NaHCO_3$ (5:10 v/v) solution. d) Electrolyzed in a CH_2Cl_2–25% NaBr (5:10 v/v)-(Pt) system.

present redox system, which, in turn, implies that it can provide the splended oxidative ability.

In contrary to the selective oxidation with Bu_4NBr_3, our attempt to employ pyridinium tribromide (Py·HBr·Br_2) as an alternative co-oxidant for the present reaction system was unsuccessful. For instance, the similar oxidation of **1a** with a combination of **5** (catalytic) and Py·HBr·Br_2 (1.6 equivalent) was carried out in an aqueous 5% AcONa–CH_2Cl_2 system, affording a mixture of **2a** and the dimeric ester such as undecyl undecanoate, in 11% and 22% yields, respectively.

Since R_4NBr_3 is a good brominating agent applicable to a variety of unsaturated compounds including arenes,[2] there is a fear of an unfavorable bromination on the aromatic ring in the oxidation of benzylic alcohols. However, the present oxidizing system consisted of an *N*-oxyl **5** (catalytic) and R_4NBr_3 (stoichiometric) turned out to be promising for the selective oxidation of various benzylic alcohols even though the aromatic rings were substituted with electron-releasing groups. In a previous work, we observed that bromination on the aromatic nucleus of *m*-methoxybenzyl alcohol (**1b**) became a predominant process (44% bromination in addition to 39% of the normal oxidation)[1a] under the conditions employing *N*-oxyl **5** and $NaBrO_2$. It was also the case for an indirect electrooxidation with a two redox couples of *N*-oxoammonium/*N*-oxyl and [Br^+ or $Br^\cdot$]/Br^- (78% bromination).[9] As shown in Entries 1 and 2, Table 1, to our delight, such a bromination process was almost completely suppressed by use of a combination of *N*-oxyl **5** and tetraalkylammonium tribromide such as Bu_4NBr_3 (88% yield) or $PhCH_2Bu_3NBr_3$ (87% yield).



Furthermore, the oxidation of the aromatic diol **3a** by the combination of *N*-oxyl **5** and Bu_4NBr_3 afforded the corresponding 1,2-diketone **4a**, selectively (Entry 5),

Table 2. Oxidation of Primary and Secondary Alcohols by an *N*-Oxyl **5**-Bu_4NBr_3 System[a]

Entry	Substrate	Bu_4NBr_3, equiv/reaction time/h	Product (Yield/%)[b]
1	 **1a**	1.5/1.0	**2a** (95)

a) Substrates (1—2 mmol) were allowed to react with **5** (0.01—0.02 mmol) in a CH_2Cl_2 (3 ml)-aqueous 5% NaOAc system (7—14 ml). b) Yields based on isolated products. c) Aqueous saturated $NaHCO_3$ was used instead of aqueous 5% NaOAc. d) Contaminated with brominated product (18%).

while the indirect electrooxidation of **3a** with *N*-oxyl **5** as a mediator in an aqueous NaBr–CH_2Cl_2 solution resulted in the bromination concurrent with the oxidation to give **9a**, exclusively (Entry 6).

We applied this oxidation method to a variety of primary and secondary alcohols and the results are shown in Table 2. A triple bond adjacent to the hydroxyl group undergoes a competitive bromination under these conditions in the extent that products are consisted of an unseparable 17:83 mixture of the alkynal **2c** and 2,3-dibromo-2-tetradecenal (Entry 2). However, benzylic alcohols are oxidized to the corresponding aldehydes without any bromination on the rings. The yields are reproducible and as high as 90%. Some of the entries in Table 2 should be useful as an intermediate of agrochemicals (Entries 6 and 9) and drugs (Entry 7).

In conclusion, the present catalytic oxidation method is useful since R_4NBr_3 can easily be obtained by the electrooxidation of the corresponding R_4NBr with potassium bromide. Furtheremore, tetraalkylammonium bromide salts were recovered after the oxidation reaction by a chromatographic separation and then R_4NBr_3 were regenerated by their electrooxidation. This combined system of *N*-oxyl compound **5** and tetraalkylammonium tribromides can highly promote oxidation of alcohols as compared with the combination of **5** and $NaBrO_2$, which is advantageous in terms of durability of the recyclable *N*-oxyl compounds.

Experimental

All reactions were carried out under an argon atmosphere. Boiling points indicated by an air-bath temperature and melting points were uncorrected. Starting alcohols were purified by distillation or column chromatography (SiO_2) prior to use. GC analyses were carried out on a "Quadrex" Bond-Fused Silica capillary column (Methyl Silicone: 0.25 μm film thickness, 25 m×0.25 mm I. D.). ^1H NMR and ^{13}C NMR spectra were recorded in $CDCl_3$. Elemental analyses were performed in our laboratory.

Preparation of Tetrabutylammonium Tribromide. A cylindrical two compartment electrolysis cell, in which anodic room (200 ml volume) and the cathodic room (80 ml) were separated by a porous glass filter (20 mm in diameter, Type 5G). A platinum foil (4 cm×3 cm) and a lead plate (4 cm×3 cm) were used for the anode and the cathode, respectively. In the anodic compartment were placed Bu_4NBr (9.76 g, 30 mmol) and water (100 ml), and in the cathodic chamber were placed potassium bromide (3.57 g, 30 mmol) and water (40 ml). The mixture was electrolyzed at a constant current density of 25 mA cm^{-2} on warming at 40—50 °C. Orange crystals have precipitated on the surface of the anode upon charging the electricities and the reaction was terminated when 4 F mol^{-1} of electricity had been passed. To the anodic compartment was added CH_2Cl_2 (30 ml) to dissolve the orange solids and the aqueous phase was extracted with CH_2Cl_2. The combined extracts were dried ($MgSO_4$) and concentrated to dryness. The product was purified by recrystallization from CH_2Cl_2–Et_2O (1:1 v/v, 7 ml) to give 11.6 g (80%) of Bu_4NBr_3 as orange solids; mp 72—74 °C (lit,[11] 73—76 °C); IR (KBr) 2928, 2860, 1464, 1377, 1029, 880, 801, 741 cm^{-1}; ^1H NMR (200 MHz) δ=1.04 (t, 12, CH_3), 1.52 (m, 8, N-C-C-CH_2), 1.71 (m, 8, N-C-CH_2), 3.25 (t, 8, N-CH_2); ^{13}C NMR (50 MHz) δ=13.7, 19.8, 24.1, 59.1. Found: C, 39.9; H, 7.7; N, 3.0%. Calcd for $C_{16}H_{36}Br_3N$: C, 39.9; H, 7.5; N, 2.9%.

Similarly, benzyltributylammonium tribromide ($PhCH_2Bu_3NBr_3$) was obtained in 60—70% yields from $PhCH_2Bu_3NBr$; mp 93—94 °C; IR (KBr) 3382, 1481, 1470, 1458, 1406, 891, 777, 725, 704 cm^{-1}; ^1H NMR (500 MHz) δ=1.03 (t, 9, CH_3), 1.46 (m, 6, N-C-C-CH_2), 1.84 (m, 6, N-C-CH_2), 3.22 (m, 6, N-CH_2), 4.62 (s, 2, CH_2Ph), 7.47—7.51 (m, 5, ArH); ^{13}C NMR (126 Hz) δ=13.7, 19.8, 24.4, 58.7, 63.1, 126.6, 129.7, 131.1, 132.4.

Oxidation of Primary Alcohols to Aldehydes. A Typical Procedure. In a round-bottomed flask were succesively placed 1-undecanol (**1a**, 172 mg, 1.0 mmol), 4-benzoyloxy-2,2,6,6-tetramethyl-1-piperidinyloxyl (**5**, 2.8 mg, 0.01 mmol), and CH_2Cl_2 (3 ml). The mixture was covered with aqueous 5% CH_3CO_2Na (7 ml) and the tack was purged with argon. After agitating vigorously, to this mixture was added portionwise Bu_4NBr_3 (709 mg, 2.0 mmol). The mixture was stirred for 1 h at room temperature and the reaction was quenched with ethanol (0.2 ml). The organic layer was separated and the aqueous layer was extracted with CH_2Cl_2. The combined extracts were dried (Na_2SO_4), and concentrated. Flash chromatography (SiO_2, hexane–AcOEt 10:1 v/v) of the crude product gave 163 mg (95%) of undecanal (**2a**) as an oil; bp 113 °C (9 Torr, 1 Torr=133.322 Pa); IR (film) 2718, 1729 (C=O), 1466 cm^{-1}; ^1H NMR (500 MHz) δ=0.88 (t, *J*=7.0 Hz, 3, CH_3), 1.26 (brs, 14, CH_2), 1.62 (m, 2, CH_2), 2.41 (dt, *J*=7.3, 2.0 Hz, 2, CH_2CO), 9.76 (t, *J*=2.0 Hz, 1, CHO); ^{13}C NMR (126 MHz) δ=14.1, 19.2, 22.1, 22.7, 29.29, 29.34, 29.4, 29.5, 31.9, 43.9, 203.0.

Oxidation of Secondary Alcohols to the Ketones. A Typical Procedure. A solution of 4-*t*-butylcyclohexanol (**3b**, 156 mg, 1 mmol) and **5** (2.8 mg, 0.01 mmol) in CH_2Cl_2 (6 ml) was covered with aqueous saturated $NaHCO_3$ (12 ml). To this biphase mixture was added portionwise Bu_4NBr_3 (709 mg, 2.0 mmol) under a vigorous stirring at 40 °C. The mixture was stirred for an additional 2.5 h. The mixture was worked up in the usual manner and the crude products were purified by column chromatography to give 146 mg (95%) of 4-*t*-butylcyclohexanone (**4b**) as solids; mp 48—49 °C (from hexane) (lit,[16] 47.5—48.5 °C).

Properties and spectral data of the compounds in Table 1 and Table 2 are as follows.

3-Methoxybenzaldehyde (**2b**): Bp 141—142 °C (50 Torr) (lit,[12] 126—127 °C (25 Torr)).

4-Bromo-3-methoxybenzaldehyde (**8b**): Mp 71—73 °C (from hexane) (lit,[13] 74 °C); IR (KBr) 1601 (C=O), 1572, 1475, 1286, 934, 822, 648, 598 cm^{-1}; ^1H NMR (500 MHz) δ=3.828, 3.834 (s, 3, MeO), 7.01 (m, 1. ArH), 7.40 (m, 1, ArH), 7.45 (m, 1, ArH), 10.29 (d, *J*=4 Hz, 1, CHO); ^{13}C NMR (126 MHz) δ=55.7, 112.6, 117.9, 123.1, 133.9, 134.5, 159.2, 191.7.

A mixture of 2-Tetradecynal (**2c**)[14] and 2,3-Dibromo-2-tetradecenal: IR (film) 2858, 1700 (C=O), 1673, 1578, 1466, 1379, 1139, 1096 cm^{-1}; ^1H NMR (200 MHz, peaks due to the major component) δ=0.87 (t, *J*=6.7 Hz, 3), 1.26 (brs, 14, CH_2), 1.69 (m, 2, CH_2), 2.96, 3.00 (d, *J*=8.0 Hz, 2, CH_2), 9.81

(s, 1, CHO); ^{13}C NMR (50 MHz, peaks due to the major component) δ=14.1, 22.7, 27.2, 28.7, 29.25, 29.29, 29.4, 29.6 (2C), 31.9, 43.2, 120.7, 144.7, 185.6.

4-*t*-Butylbenzaldehyde (**2d**): Bp 89—90 °C (33 Torr).[15]

4-Nitrobenzaldehyde (**2e**): Mp 103—104 °C (lit,[16] 104—105 °C).

4-Methoxybenzaldehyde (**2f**): Bp 103—104 °C (33 Torr) (lit,[17] 248 °C).

3-Phenoxybenzaldehyde (**2g**): Bp 180—184 °C (14 Torr) (lit,[18] 175—176 °C (11 Torr)); IR (film) 3066, 2818, 2734, 1694 (C=O), 1582, 1483, 1452, 1390, 1164, 1131, 944 cm^{-1}; ^{1}H NMR (500 MHz) δ=7.04 (d, J=7.4 Hz, 2), 7.17 (t, J=7.4 Hz, 1), 7.29 (dd, J=7.8, 2.2 Hz, 1), 7.38 (t, J=7.8 Hz, 2), 7.46 (m, 1), 7.50 (t, J=7.8 Hz, 1), 7.60 (d, J=7.4 Hz, 1), 9.96 (s, 1, CHO); ^{13}C NMR (126 MHz) δ=118.1, 119.5, 124.2, 124.6, 124.7, 130.0, 130.4, 138.0, 156.2, 158.4, 191.6.

3,4,5-Trimethoxybenzaldehyde (**2h**): Mp 72—74 °C (lit,[19] 73—74 °C).

3-Pyridinecarbaldehyde (**2i**): Bp 83—85 °C (33 Torr) (lit,[20] 102—103 °C (20 Torr)).

5-Ethyl-2-methyl-3-pyridinecarbaldehyde (**2j**): Bp 115—117 °C (15 Torr) (lit,[1a] 115—117 °C (15 Torr)).

1-(3,4-Methylenedioxyphenyl)-1,2-propanedione (**4a**): Bp 108—111 °C (1 Torr) (lit,[21] 115—117 °C (1—2 Torr)); IR (film) 2916, 1715 (C=O), 1661 (C=O), 1605, 1506, 1491, 1446, 1354, 1267, 1038, 932 cm^{-1}; ^{1}H NMR (500 MHz) δ=2.49 (s, 3, CH_3), 6.07 (s, 2, CH_2), 6.87 (d, J=8 Hz, 1, PhH), 7.47 (d, J=1.6 Hz, 1, PhH), 7.62 (dd, J=8, 1.5 Hz, 1, PhH); ^{13}C NMR (126 MHz) δ=26.5, 102.1, 108.3, 109.0, 126.3, 128.0, 148.4, 153.1, 189.7, 200.8.

Recovery Experiment of Tetrabutylammonium Tribromide after the Oxidation Reaction of Alcohol. A mixture of EtOH (96 mg, 2.8 mmol) and the *N*-oxyl **5** (5.8 mg, 0.02 mmol) was treated with Bu_4NBr_3 (1.02 g, 2.12 mmol) in a suspension of CH_2Cl_2 (9 ml) and aqueous 5% AcONa (27 ml) for 30 min at room temperature. An aqueous phase was extracted with CH_2Cl_2 and the combined organic layers were dried (Na_2SO_4), and concentrated under vacuum. The residual solids were passed through a short column (SiO_2, AcOEt/hexane and then MeOH as an eluent) to give 657 mg of Bu_4NBr; IR (KBr) 2922, 2962, 2876, 1475, 1168, 1110, 897, 884, 739 cm^{-1}; ^{1}H NMR (500 MHz) δ=0.90 (t, J=7.4 Hz, 12, CH_3), 1.36 (m, 8, N-C-C-CH_2), 1.59 (m, 8, N-C-CH_2), 3.28 (m, 8, N-CH_2); ^{13}C NMR (126 MHz) δ=13.4, 19.5, 23.9, 58.7. Found: C, 59.2; H, 12.0; N, 4.3%. Calcd for $C_{16}H_{36}BrN$: C, 59.6; H, 11.3; N, 4.3%. The solids were electrolyzed with KBr (250 mg, 2.1 mmol) in water (50 ml) in the anodic compartment of the divided cell. Passage of 4.0 F mol^{-1} of electricity at 25 mA cm^{-2} at room temperature gave 663 mg (67%) of Bu_4NBr_3 as orange solids.

The present work was partially supported by a Grant-in-Aid for Developmental Scientific Research No. 63850172 from the Ministry of Education, Science and Culture. We are grateful to the SC-NMR laboratory of Okayama University for experiments with Varian VXR-500 and -200 instruments.

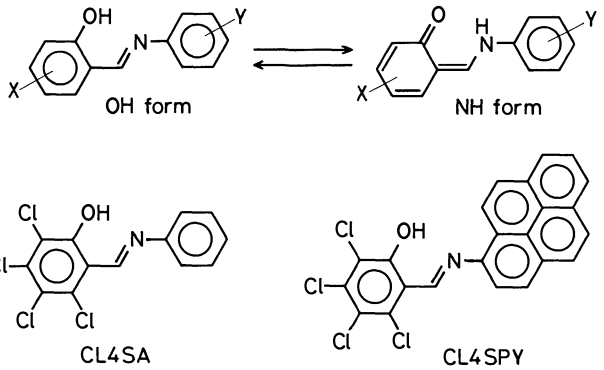
(Received June 22, 1990)

Two kinds of *N*-salicylideneaniline derivatives, *N*-tetrachlorosalicylideneaniline (CL4SA) and *N*-tetrachlorosalicylidene-1-pyrenylamine (CL4SPY), have been prepared and subjected to structural and optical studies in the crystalline state. A thermochromic-type behavior of the former crystal has been observed as a shift of the absorption edge, while that of the latter crystal is much less pronounced. Fairly short O-H···N hydrogen bonds have been found in both compounds through crystallographic studies, which may be mainly due to a steric effect of chlorine substituents. The difference in the proton transfer behavior of CL4SA and CL4SPY should presumably be caused by an intermolecular charge-transfer interaction in the latter crystal.

N-Salicylideneaniline derivatives have been known to show a self-isomerization induced by an intramolecular proton transfer from the hydroxyl oxygen to the imine nitrogen through the O-H···N hydrogen bond. Since this type of proton transfer process involves a π-electron configurational change, the two isomers produced by the proton transfer have different electronic states. Sometimes, this self-isomerization is observed in the crystalline state as thermochromism or photochromism.[1] We have recently carried out structural and optical studies of the thermochromism of *N,N'*-disalicylidene-*p*-phenylenediamine (BSP) crystals.[2] In this crystal the planar BSP molecules are stacked one-dimensionally with a short interplanar spacing (3.29 Å at room temperature and 3.26 Å at 108 K[3]). These relatively short distances suggest that some intermolecular interaction operates in the crystal; we have assigned it to a charge-transfer interaction.

We are particularly interested in the case where the intermolecular interaction is sufficiently strong that the electronic properties of the crystal may be modulated by proton motion. This coupling between protons and electrons may utilized for designing materials which have novel types of electronic properties.[4] From this point of view, the introduction of a sufficiently strong charge-transfer interaction into the *N*-salicylideneaniline system is supposed to be an effective approach. In this paper we report the synthesis of the title compounds, in which an *o*-chloranil-like acceptor portion and aromatic-amine-like donor portions are produced when the proton transfers to the imine nitrogen (NH form). The structural and optical properties of the CL4SA and CL4SPY crystals are also described with emphasis on the nature of their fairly strong hydrogen bonds.



Experimental

Materials. CL4SA was prepared by the condensation of tetrachlorosalicylaldehyde and aniline in refluxed methanol, and was recrystallized from benzene. Tetrachlorosalicylaldehyde was synthesized from tetrachlorophthalic anhydride by following a method reported by Heaney et al.[5] Needle-like single crystals of CL4SA were obtained by slow evaporation of the benzene solution.

CL4SPY was prepared by the condensation of tetrachlorosalicylaldehyde and 1-pyrenylamine in the same manner as CL4SA, and was recrystallized from chlorobenzene. Needle-like single crystals of CL4SPY were grown by slow cooling of a chlorobenzene solution.

Optical Measurements. The infrared and visible absorption as well as the emission spectra were measured using single-crystal specimens and the same methods as reported before.[2]

X-Ray Structure Analyses. The data-collection conditions and the crystal data are summarized in Table 1. In both cases, the measurements were carried out at room temperature with graphite monochromatized Mo$K\alpha$ radiation (λ=0.71073 Å). The intensities of the three standards used (monitored every 100 data measurements) remained constant within 3% for both crystals.

parameters for non-hydrogen atoms and isotropic for hydrogen atoms was employed for the structure refinement.

Results

Structures. The atomic parameters of CL4SA and CL4SPY obtained by X-ray analyses are listed in Tables 2 and 3, respectively. Both molecular structures are shown in Fig. 1; the bond lengths and angles are listed in Table 4. The dihedral angle between two aromatic groups connected by the azomethine group is 15° for CL4SA and 2.3° for CL4SPY. These values are much smaller compared with that of *N*,*N*′-disalicylidene-1,6-pyrenediamine, DSPY (42°), in which proton transfer is suppressed.[3]

The most noticeable point commonly observed for both compounds is the quite short distance of O(5)···N(6) (2.517(7) Å for CL4SA and 2.534(7) Å for CL4SPY), which form the hydrogen bond. The corresponding distances are in the range between 2.58 and 2.62 Å for other *N*-salicylideneanilines.[2,3,9,10] The O(5)–C(8) bond lengths (1.332(8) Å for CL4SA and 1.316(5) Å for CL4SPY) are also shorter than those of BSP, DSPY, 2-chloro-*N*-salicylideneaniline,[9] and *N*-(5-chlorosalicylidene)aniline,[10] in which the values are in the range between 1.350 and 1.365 Å. This contraction obviously indicates that there exists a resonance contribution from the quinonoid structure, which is produced when a proton transfers from the hydroxyl oxygen to the imine nitrogen. A corresponding alternation of the bond lengths of the benzene ring expected for a quinonoid structure has been observed for both compounds.

The crystal structures of CL4SA and CL4SPY are shown in Figs. 2(a) and (b), respectively. The CL4SA molecules are translationally stacked along the *c*-axis; the interplanar distances are 3.44 Å between the tetrachlorophenol rings and 3.64 Å between the benzene rings of the aniline side. On the other hand, the

CL4SPY molecules are stacked with an alternating orientation. As shown in Fig. 2(c), this stacking mode leads to an effective intermolecular overlapping of the donor and acceptor parts. Consequently, the interplanar distances between the mean planes of the entire molecule are short, i.e., 3.37 and 3.39 Å, and there are several short interatomic distances between stacked molecules (Fig. 2(c)). The intermolecular contacts in CL4SA are longer than the sum of the van der Waals radii, except for Cl(2)···C(11) (3.489(7) Å).

Optical Properties. The polarized infrared spectra of the CL4SA single crystal at room temperature are shown in Fig. 3(a). An extremely broad band centered at ca. 2700 cm^{-1} is observed when the polarization is perpendicular to the *c*-axis. Since the hump at 3030 cm^{-1} is undoubtedly assigned to the CH stretching mode, this broad molecular in-plane component is assignable to the OH stretching mode. Compared with BSP and DSPY, the intensity is considerably weak, although the position and the half width (ca. 600 cm^{-1}) is comparable. Figure 3(b) shows the infrared spectra of the CL4SPY single crystal at room temperature. A broad OH stretching band was observed at ca. 2600 cm^{-1}. The half width is ca. 700 cm^{-1}, which is slightly larger than that of CL4SA. The intensity seems to be even weaker, compared with the normalized intensity of the CH stretching mode at 3030 cm^{-1}.

Figure 4(a) shows the absorption spectra of the CL4SA single crystal at various temperatures. The

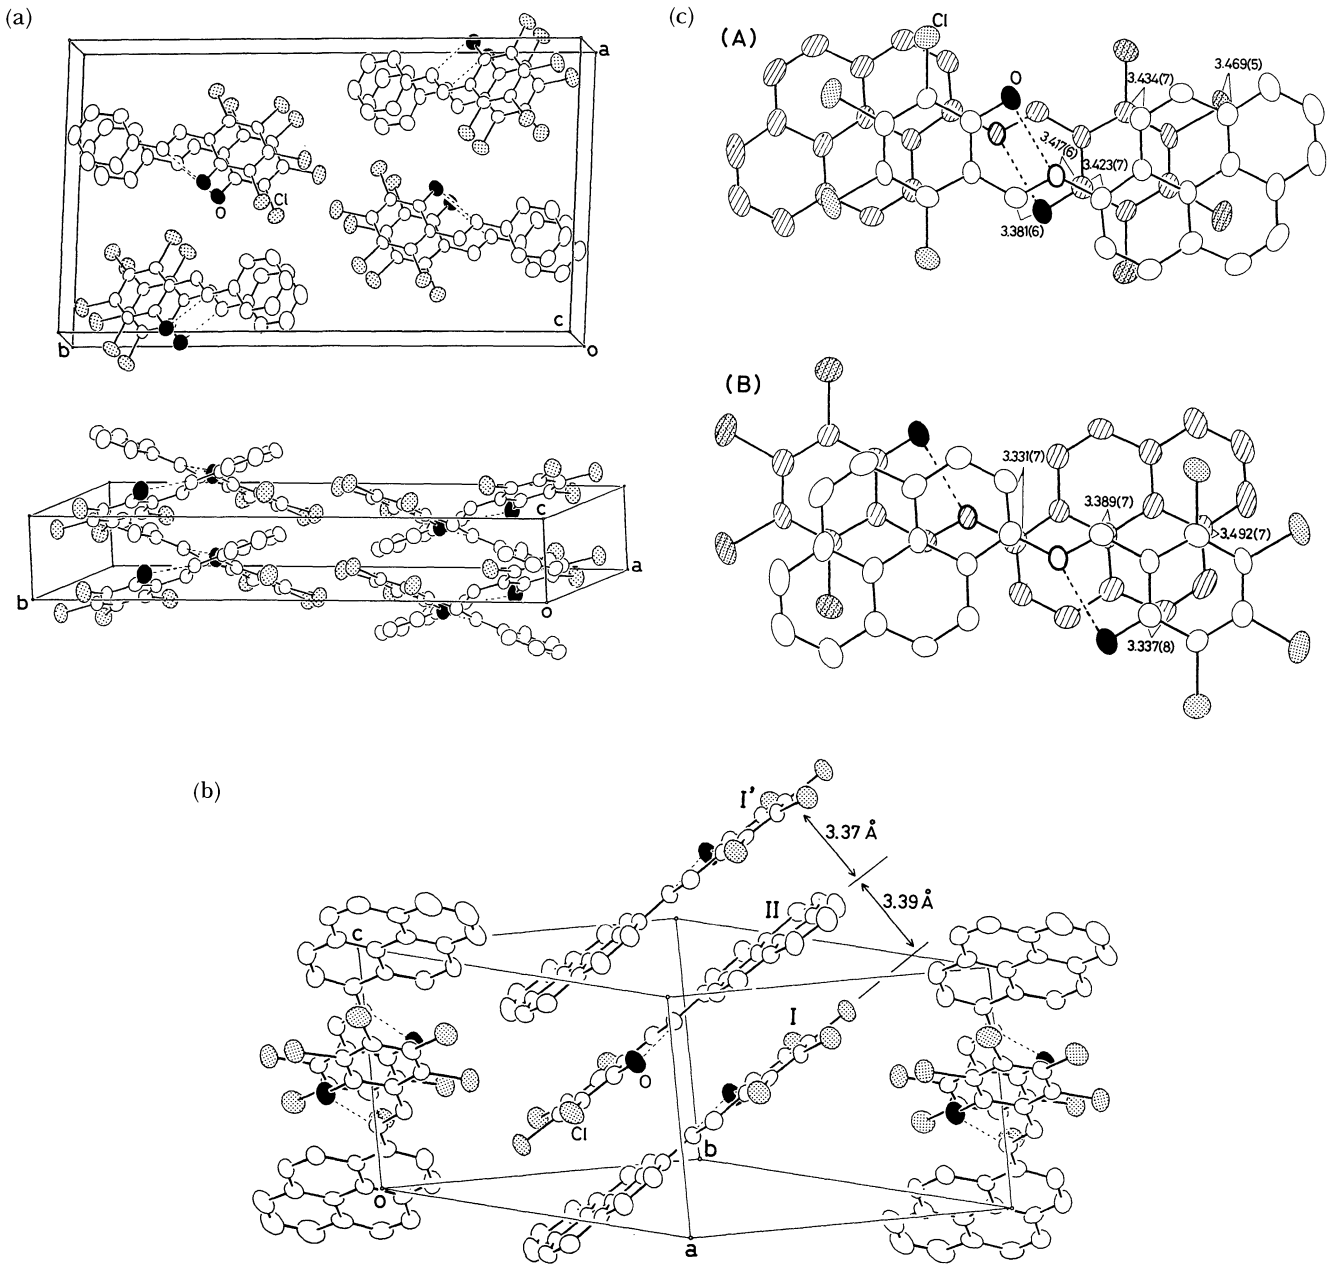

Fig. 2. Crystal structures of CL4SA (a) and CL4SPY (b); symmetry code, I (x, y, z), II ($1-x$, $1-y$, $1-z$), I′ (x, y, $1+z$), and molecular overlapping between the CL4SPY molecules, I and II (A) and II and I′ (B) and some short interatomic distances (Å) (c).

thermochromic-type behavior is observed as a shift of the absorption edge with temperature. This behavior represents a different type of thermochromism from that ordinarily observed for other *N*-salicylideneanilines. For example, in BSP, a new band appeared in the lower-energy region grows with increasing temperature.[2] The emission spectra of CL4SA (Fig. 4) show a Stokes shift (0.35 eV at 6 K and 0.25 eV at 300 K from the absorption edge). No noticeable change of the band profile was observed with changing temperature.

The visible region absorption spectra of the CL4SPY single crystal is shown in Fig. 4(b). Though a shift in the absorption edge due to a temperature change was observed, the energy of a shift was about half that observed in CL4SA over the same temperature range. On the other hand, the emission spectra showed a complicated change with the temperature. At 8 K, five peaks were observed at 2.04, 1.99, 1.85, 1.70, and 1.55 eV. With increasing temperature, the first peak merged into the second peak. The other three peaks, which are equally separated by 0.15 eV, shifted slightly towards higher energy by 132 K, then merged into one band at 1.83 eV. The intensities decreased rather

rapidly with increasing temperature to 74 K, then decreased gradually.

Discussion

When the O···N distance is short enough to make the energy difference and the barrier height appreciably small, in reference to the thermal energy, the proton transfer is thermally allowed in *N*-salicylideneanilines. In both CL4SA and CL4SPY, the O···N distances are considerably short compared with other thermochromic *N*-salicylideneanilines. This shortening results, partly at least, from the substitution of chlorine atoms.

Firstly, we examined this substitution effect by means of MNDO calculations of the single molecules. Since all geometric parameters were fully optimized at a certain NH distance in these calculations, the optimized conformations might correspond to an isolated molecule, which is known to be nonplanar.[11] The deformation of the hydrogen-bond structure due to this nonplanarity may be substantially small, because the major deformation from the planar conformation is a rotation of the aromatic ring at the aniline side. Therefore, the substitution effect is expected to appear to a large extent by this type of calculation. Figure 5 shows the results for CL4SA,

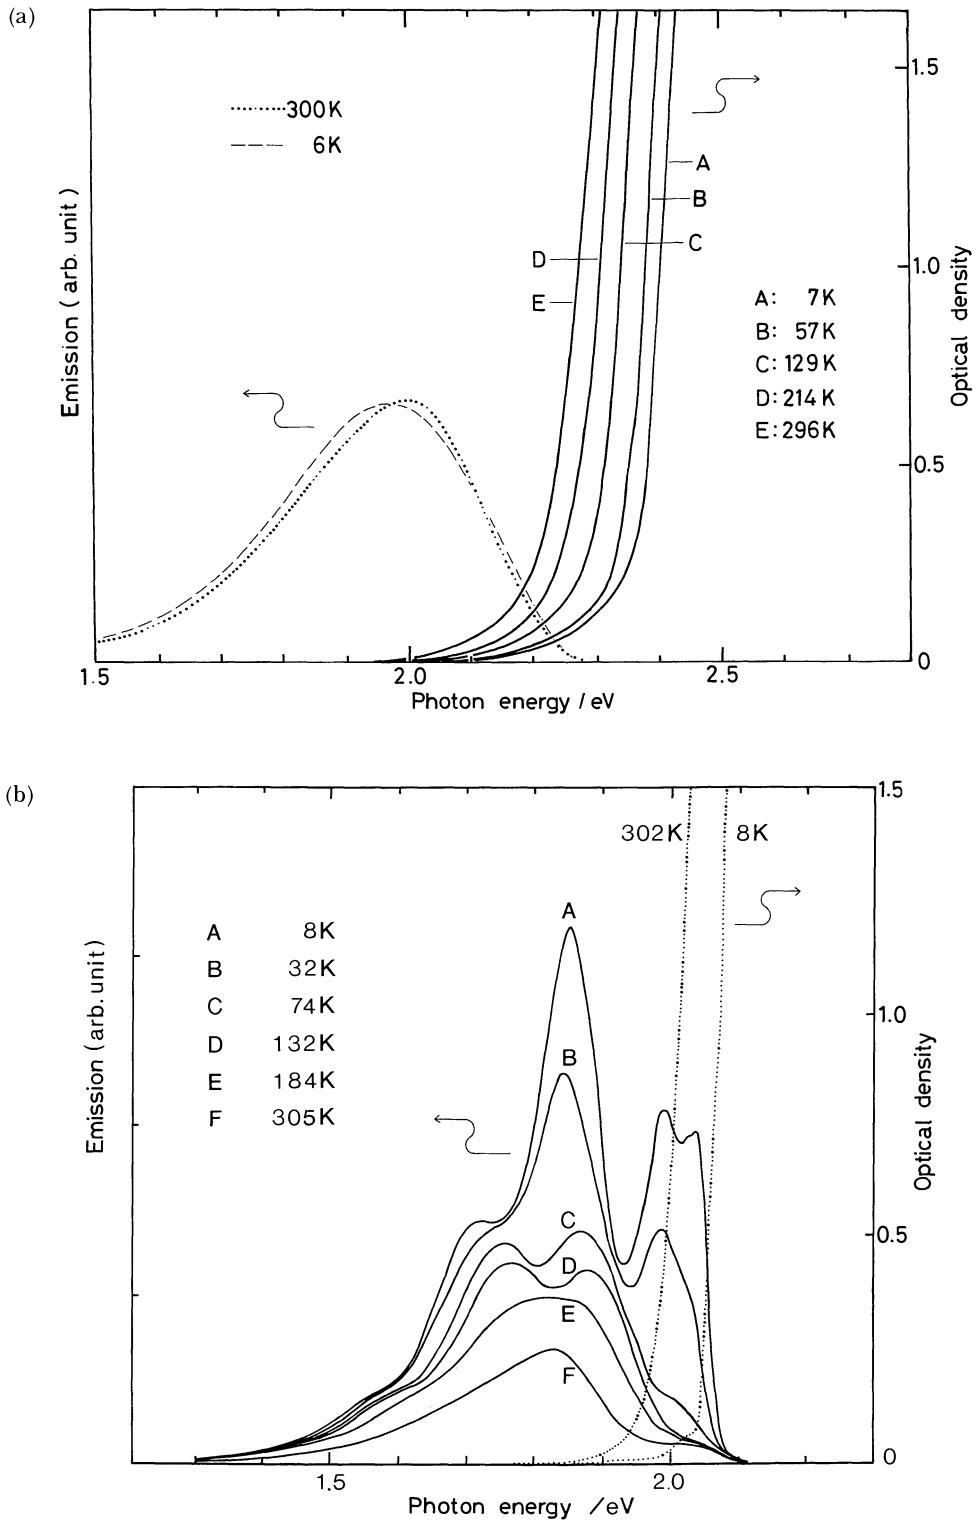

Fig. 4. Single-crystal absorption and emission spectral changes with temperature for CL4SA (a) and CL4SPY (b).

CL4SPY, and nonsubstituted *N*-salicylideneaniline. It can be seen that the space separation between two minima becomes smaller by the introduction of chlorine substituents. The energy difference between the two minima is also smaller in chlorinated compounds. On the other hand, the difference between the aniline side structures, i.e., 1-pyrenyl and phenyl, has almost no influence on the potential

surface of the proton.

The most notable effect of the chlorine substituents is considered to be a steric one; as shown in Table 5, the substituents at the 3 and 6 positions of the benzylidene side cause a contraction of the O···N distance due to a steric repulsion. A similar steric effect of the substituents on the hydrogen-bond structure was noticed in β-diketones[12] and salicylaldehydes.[13] Besides the steric effect, there might be an electronic effect of the substituents, as found for β-diketones.[12] However, in CL4SA and CL4SPY, this effect is supposed to be negligibly small,[14] as far as single molecules are concerned. Consequently, the shortening of the hydrogen bond in CL4SA and CL4SPY can be considered to result from a steric effect of the chlorine substituents.

From the above arguments, CL4SA and CL4SPY should have the same strength as that of the hydrogen bond. The O···N distances are actually not so different in these two molecules. However, the spectroscopic studies for both crystals suggest that there is a substantial difference in the nature of the hydrogen bond in the crystalline state. It has also been noticed that the C(8)–O(5) distance of CL4SPY is considerably shorter than that of CL4SA. This indicates that the resonance contribution from the *o*-quinonoid structure in the NH form is larger in CL4SPY than in CL4SA. Although the N(6)–C(13) distance is also expected to be longer in CL4SPY than in CL4SA, this bond may not be so sensitive, due to a delocalization effect.

On the same basis, the observed optical properties can be interpreted as described below. Firstly, the intensity of the hydrogen stretching mode in these compounds may be considered to depend on the position of the hydrogen in the hydrogen bond. When the hydrogen vibrates near the center of the hydrogen bond, the induced dipole moment can be very weakly changed due to the delocalization of electrons in the entire chelate ring system.[15] Therefore, when the hydrogen-bond structure is closer to the intermediate one, the intensity becomes weaker.

Secondly, the temperature dependence of the visible absorption spectra must be considered. The thermochromic behavior is usually observed as a growth of new bands. When the energy difference between the thermochromic state and the thermal ground state is smaller or comparable to the thermal energy, the

thermochromic band has an appreciable intensity, even at low temperatures. Contrary to the case in BSP which shows a typical thermochromic-type behavior, the energy difference between the NH and OH forms is much smaller in both CL4SA and CL4SPY. This means that the content of the NH form is still large at the lowest temperatures in these measurements. Since the measurements were carried out by using single-crystal specimens, such intense absorption can hardly be observed as a clear peak. Thus, the initial growth or a peak profile of the thermochromic band could not be observed. In such a case, the approximate temperature dependence of the thermochromic band can be estimated from the shift of the absorption edge.[16] The relatively large shift in CL4SA indicates that the thermochromic band grows with increasing temperature, and this crystal can be regarded as being an ordinary thermochromic type. On the other hand, the smaller shift in CL4SPY in the same temperature range suggests that the growth approaches some degree of saturation. Such a situation is expected when the energy difference between the OH and NH forms is extremely small. The smaller Stokes shift compared with CL4SA also suggests a large contribution of the NH form in CL4SPY at low temperature.

From these structural and optical data, the energy difference between the two minima in the potential energy surface is considered to be much smaller in CL4SPY than in CL4SA. Considering the structural difference between the CL4SA and CL4SPY crystals, it is reasonable to assume that the intermolecular charge-transfer interaction operates in the CL4SPY crystal. This interaction is expected to make the ground state slightly polarized as a consequence of mixing with the excited state. Although this originates purely from a π–π interaction, it may cause a change in the net charge on the N and O atoms. Such an excess charge effect has been calculated and found to have great influence on the potential surface of the proton.[17]

Since our interest lies in the influence on proton motion, we have tried to visualize the hydrogen in the

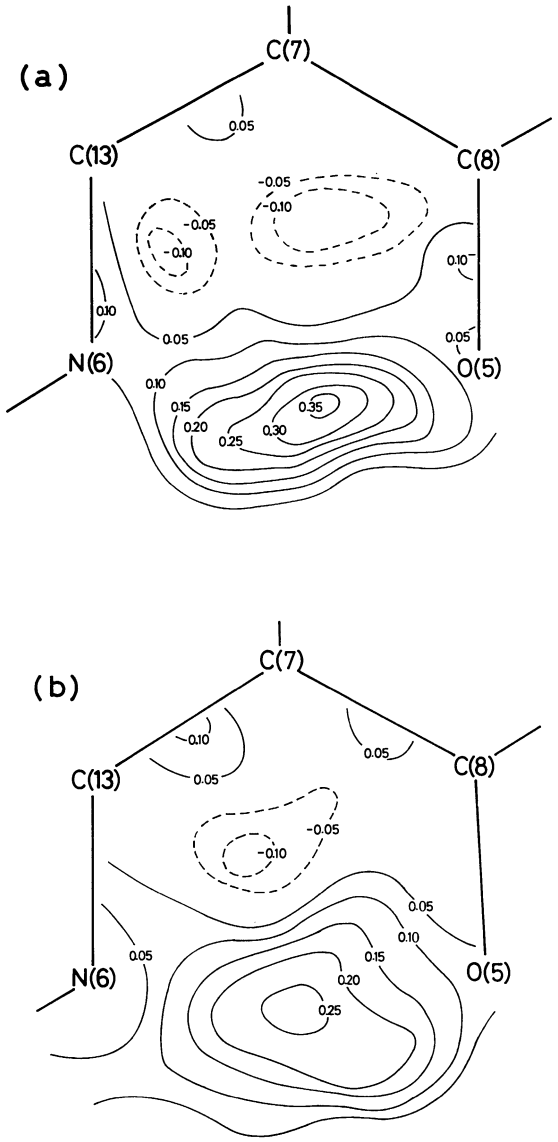

Fig. 6. Difference synthesis maps of the hydrogen bonded chelate ring (e Å^{-3}) of CL4SA (a) and CL4SPY (b).

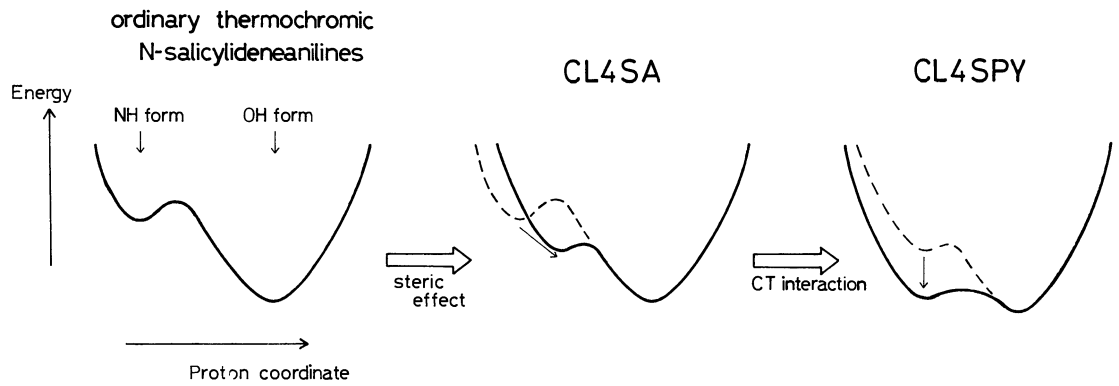

Fig. 7. Schematic representation of the potential energy surface of the proton modified by the steric effect and the intermolecular charge transfer (CT) interaction.

hydrogen bond. The method is the same as that performed for BSP and DSPY;[3] the difference syntheses are calculated by taking the parameters of the hydroxyl hydrogen out of the refined structure. The obtained electron-density maps are shown in Fig. 6. In both compounds, a broad peak appears at nearly the center of the hydrogen bond, which is quite different from the situation in ordinary thermochromic *N*-salicylideneanilines. The difference between CL4SA and CL4SPY may not be clearly seen due to the limitation of accuracy.

In conclusion, the strong hydrogen bonds in CL4SA and CL4SPY have mainly been attributed to a steric effect of the chlorine substituents at the 3 and 6 positions of the bezylidene side. In addition to this effect, the intermolecular charge-transfer interaction makes contribution from the NH form larger in CL4SPY, which makes the hydrogen-bond structure nearly intermediate between the NH and OH forms. These situations are schematically summarized in Fig. 7. The coupling between the proton transfer and the intermolecular π–π interaction may provide a hopeful prospect for the realization of the system proposed in the Introduction.

(Received October 4, 1990)

Single crystals of a new material, black phosphorus doped with germanium, have been prepared by a bismuth-flux method. Germanium atoms are incorporated into the black phosphorus in 2 to 4 atomic percent. The resistivity is reduced by two to three orders (ρ=6×10^{-3} Ω cm) compared with the pure black phosphorus, and its temperature dependence is metallic at low temperatures. There is no magnetoresistance up to 12 T at 0.6 K in striking contrast to the pure black phosphorus which shows negative magnetoresistance in this region. The crystal lattice constants decrease with germanium doping, especially in the interlayer direction. These facts indicate the enhanced three dimensionality with germanium doping.

Black phosphorus discovered by Bridgman in 1914[1] has been known to be a layered structure narrow gap semiconductor[2] and to have interesting properties, such as pressure-induced structural phase transitions,[3] anomalous superconductivity,[4] and two-dimensional Anderson localization.[5] A chemical modification of black phosphorus is a potentially promising strategy to realize a metallic phase in black phosphorus under normal pressure.

As the first approach to prepare new chemical species based on black phosphorus we have tried to synthesize black phosphorus intercalation compounds with cesium[6] and iodine.[7] The second trial was a doping of silicon, a IV group element, to increase the positive hole character in black phosphorus (a V group element). The doping of silicon realized a somewhat metallic character in black phoshporus.[8]

In this report we describe the effect of germanium doping into black phosphorus. Almost metallic temperature dependence was observed for the electrical resistivity at low temperatures, and no magnetoresistance was found out. Substantial decrease in the lattice constants was recognized with germanium doping, especially in the interlayer direction.

Experimental

Doping of germanium was carried out by mixing it into melted bismuth with black phosphorus powder. By very slow cooling of the melt very tiny crystals were obtained (typical size: 500×15×3 μm^3). The incorporated amount of germanium was detected by an Electron-Probe-Micro-Analysis technique (EPMA).

Electrical resistivity and its temperature dependence were measured with a four-probe method from 300 to 0.6 K in the ^{3}He cryostat system. Magnetoresistance was also examined by the use of a superconducting magnet up to 12 T at low temperatures. The change in lattice constants caused by the incorporation of germanium was detected by an X-ray diffraction analysis.

Results and Discussion

The resistivity of a germanium doped single crystal at room temperature is lower by almost three orders compared with a pure black phosphorus: ρ(RT)=6×10^{-3} Ωcm. The relative amount of germanium which is incorporated in black phosphorus was roughly estimated to be 2 to 4 atomic percent from the result of EPMA. The corresponding amount of silicon which was included in black phosphorus-silicon was about 0.01 atomic percent.[8] Germanium is far better introduced into black phosphorus compared with silicon in spite of larger covalent radius of the former, and this causes the remarkable reduction in the resistivity.

The lattice constants of a single crystal of germanium doped black phosphorus, PGe$_x$ (x=0.03±0.01), were found by an X-ray diffraction analysis and

Table 1. Comparison of the Lattice Constants of PGe$_x$ (x=0.03±0.01) and Those of Black P

	a/Å	b/Å	c/Å

they are shown in Table 1 together with those of black phosphorus.[9] All lattice constants become shorter, especially in the b-axis, interlayer direction (Fig. 1), substantially shorter. In the c-axis direction, the rate of reduction is almost the same order as in the b-axis direction, and in the a-axis direction there is almost no reduction within the experimental error. This fact is just corresponding to the pressure dependence of the

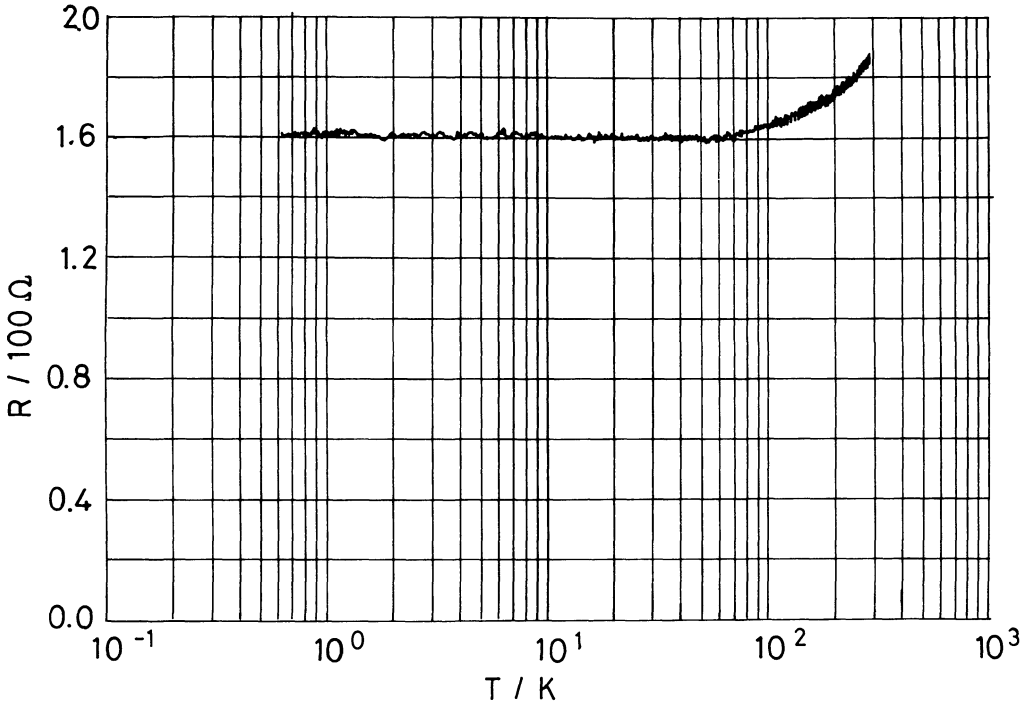

Fig. 2. Temperature dependence of the resistance of PGe_x (x=0.03±0.01).

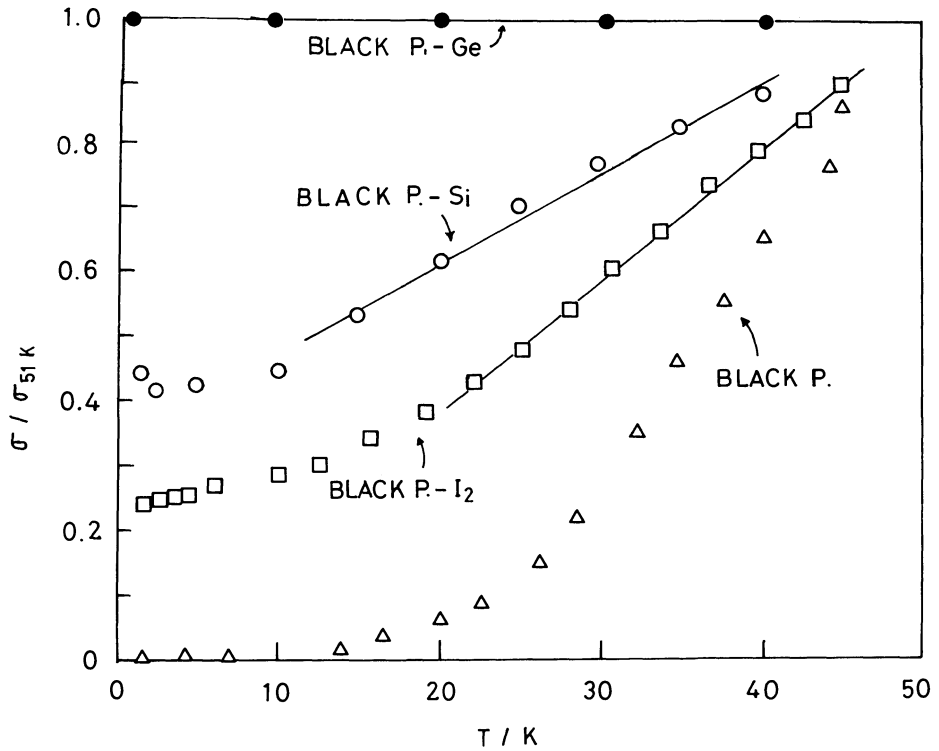

Fig. 3. Temperature dependence of the normalized conductivities (σ(T)/σ(51 K)) of black phosphorus, black phosphorus–I_2, black phosphorus–Si, and black phosphorus–Ge.

lattice constants of black phosphorus.[10] In pure black phosphorus, the semiconducting gap energy is strongly dependent on the interlayer interaction, and thus the reduction in the b-axis length of PGe_x may lead reasonably to lower resistivity.

The temperature dependence of the resistances of PGe_x (x=0.03±0.01) is shown in Fig. 2. It shows almost metallic behavior from 300 to 0.6 K, and below 50 K the resistance is almost constant. This behavior clearly contrasts with the case of pure black phosphorus in which the resistivity has an exponential rise at low temperatures. Even in PSi_x there is small rise in the resistivity at low temperatures. Figure 3 shows the different behaviors of the conductivity ratios (σ(T)/σ (51 K)) below 50 K in pure black phosphorus and its intercalated or doped compounds.

The magnetoresistance of PGe_x was investigated at 0.6 K up to 12 T applying the magnetic field along the b-axis with the electric current along the a-axis since black phosphorus is known to have negative magnetoresistance at low temperatures.[2,5] There is, however, no indication of magnetoresistance in PGe_x at all in this range of magnetic field at 0.6 K.

These two findings, metallic behavior and no magnetoresistance, may be partly ascribed to the enhancement of three dimensional character due to the reduction in the interlayer distance with the doping of germanium. It was reported that the semiconducting energy gap of black phosphorus is dependent on pressure and it vanishes over 1.8 GPa.[11] The reduction of the lattice constants around 2.0 GPa is about 2.5% in b or c-axis. The differences in the corresponding lattice constants are about 0.3—0.6% in Table 1. The reduction of the lattice constants is not large enough for vanishing the semiconducting gap of black phosphorus, but the enhanced number of holes in the filled band may be responsible for the appearance of metallic nature in PGe_x.

In conclusion, we have succeeded in the synthesis of germanium doped black phosphorus, and determined the composition, $PGe_{0.03\pm0.01}$, and the lattice constants of the new compound. The metallic behavior was observed by the temperature dependence of the resistivity at low temperatures, and such behavior is reasonably explained by referring to the change in the lattice constants on doping.

A Stopped-Flow Kinetic Study of the Solubilization of Acridine Orange and Its 10-Alkyl Derivatives into the Micelle of Sodium Dodecyl Sulfate

Yukio KUBOTA,* Naofumi OMURA, and Kiyofumi MURAKAMI
Department of Chemistry, Faculty of Science, Yamaguchi University, Yamaguchi 753
(Received August 27, 1990)

Stopped-flow method has been used to investigate the kinetics of the solubilization of Acridine Orange (AO, 3,6-bis(dimethylamino)acridinium chloride) and its 10-alkyl derivatives into the micelle of sodium dodecyl sulfate (SDS). The reaction curves of the SDS–AO and SDS–10-alkyl AO systems were characterized by single and double exponential functions, respectively. It was found that all the time constants are concentration dependent and approach limiting values at high reactant concentrations. The data were fitted by a minimal mechanism in which a rapid bimolecular step is followed by one (AO) or two (10-alkyl derivatives of AO) sequential isomerizations. All the rate constants determined for this mechanism markedly decrease with an increase in the length of the introduced alkyl chain. The equilibrium constants for the bimolecular and first isomerization steps do not highly depend on the size of the alkyl chain, while the equilibrium constant for the second isomerization step progressively increases with increasing it. The spectral changes with time indicate that the bound dye gradually migrates to more hydrophobic environment inside the micelle. These results lead to the conclusion that the steps in the proposed mechanism correspond to rapid adsorption of the dye to the micelle surface site, followed by reorientation of the dye and then migration of its alkyl chain into the hydrophobic region of the micelle.

The most important properties of micellar systems are their ability to solubilize a variety of molecules and their catalytic effects on many reactions occurring at the micelle surface and inside.[1–3] In order to better understand the nature of this solubilization and the physicochemical behavior of solubilized molecules, it is of fundamental significance to obtain information concerning the structure of micelles and the location or relative orientation of solubilized molecules.[4,5] For this purpose, several spectroscopic techniques such as NMR,[6,7] ESR,[8] and fluorescence[9–13] have been employed so far.

Kinetic methods, though helpful in understanding the solubilization mechanism, have rarely been applied to the solubilization phenomena.[14–19] Robinson and co-workers[16,17] proposed a mechanism in which rapid adsorption of dye on the micelle surface is followed by slow penetration into the hydrocarbon interior of the micelle. On the other hand, Takeda et al.[14] proposed the rapid initial formation of a dye-surfactant salt which then penetrates the palisade layer of the micelle. However, there is no extensive discussion based on the evaluation of equilibrium and rate constants for each step.

This paper describes detailed results on the kinetics of the solubilization of Acridine Orange (AO) and its 10-alkyl derivatives into the micelle of sodium dodecyl sulfate (SDS), studied by stopped-flow method with absorption and fluorescence detection. The aim of the present study is to establish the mechanism of the solubilization through the evaluation of equilibrium and rate constants. Among the results, it is revealed that the solubilization process consists of rapid initial adsorption of the dye on the micelle surface and one (AO) or two subsequent isomerizations (10-alkyl derivatives of AO).

Experimental

AO (3,6-bis(dimethylamino)acridinium chloride) was purchased from Merck. The 10-alkyl derivatives of AO (methyl-AO, propyl-AO, pentyl-AO, octyl-AO, and decyl-AO) were synthesized according to the method of Miethke and Zanker.[20] All dyes were purified by repeated recrystallizations and column chromatography; no trace of impurity was detected by the method of thin-layer chromatography for each dye. SDS (specially pure grade >99%) was obtained from Nakarai Chemicals and used without further purification. All other chemicals were reagent grade and deionized redistilled water was used for the preparation of all aqueous solutions.

Absorption and fluorescence spectra were measured with a Shimadzu UV-200S spectrophotometer and a Hitachi MPF-2A fluorescence spectrophotometer, respectively. The critical micelle concentration (cmc) of SDS in the absence and presence of dye was determined by the conductometric method. Kinetic measurements were made on a Union Giken RA-601 rapid-scanning stopped-flow spectrophotometer using both absorbance and fluorescence detection, a 1:1 mixing ratio, and a 2 mm path-length cell. The dead time of the instrument was 0.6 ms, as judged from the reduction reactions of 2,6-dichloroindophenol by L-ascorbic acid.[21] In the kinetic experiments, the initial concentration of SDS was always maintained in large excess of that of the dye. The resulting reaction curves were subjected to multiexponential analysis with a nonlinear least-squares regression program based on the Marquardt algorithm.[22] All measurements were carried out at 25±0.2 °C.

All the calculations were accomplished with an Acos-850 computer system (NEC Corporation) and/or a PDP 11 minicomputer (Digital Equipment Corporation).

Results and Discussion

Electronic Spectra and CMC. The alkyl derivatives of AO when mixed with SDS solutions showed absorp-

tion and fluorescence changes similar to those reported for AO.[16,17,23] Figure 1 displays typical absorption spectra obtained with pentyl-AO (1.0×10^{-5} M) in the presence of SDS. The spectra are characterized by two absorption bands; one is the monomer band at 495 nm and the other (470 nm) is the band due to the dimer or higher aggregates.[16,23] Below the cmc, the spectrum of pentyl-AO exhibits both a reduction of the band at 495 nm and an enhancement of the band at 470 nm with increasing SDS concentration. This behavior is ascribed to the ion pair (or salt) formation between the dye cation and the SDS anion, followed by the formation of mutual induced aggregates. In the vicinity of the cmc, the monomer band markedly increases and then the shape of spectrum remains unchanged above the cmc. The absorption maximum above the cmc shifts toward longer wavelengths compared to that of free dye in aqueous solutions (492 nm). The fluorescence quenching of the dye below the cmc and the strong enhancement of its fluorescence above the cmc were observed for all dyes; above the cmc, a blue shift and a narrowing of the fluorescence band were also observed when compared to that of free dye in aqueous solutions. These absorption and fluorescence properties above the cmc suggest that the dye is solubilized in a hydrophobic region of the micelle and exists as a monomeric form.[9,16,23]

The cmc of SDS solution, in agreement of the literature value,[24] was 8.0×10^{-3} M (1 M=1 mol dm^{-3}) and the presence of dye (1.0×10^{-5} M) had no appreciable influence on cmc irrespective of the dye structure.

Kinetics of Solubilization. It is well-known that AO and its alkyl derivatives aggregate in aqueous solutions at higher concentrations.[17,25,26] To minimize the effect of dye aggregation, kinetic measurements were made on solutions in which dye concentrations were kept below 10^{-5} M; in fact, the kinetic behavior was idependent of dye concentrations in the range of 2.5×10^{-6} to 2.0×10^{-5} M. Figure 2 displays typical time courses of absorbance changes after mixing an equal volume of AO and SDS solutions (curve a) and of pentyl-AO and SDS solutions (curve b). The reaction curve of the AO–SDS system was characterized by a single-exponential function, while that of the pentyl-AO–SDS system by a double-exponential one. Figures 3 and 4 show the dependence of the reciprocal of the time constant (τ^{-1}; apparent rate constant) on [SDS]—cmc for the AO–SDS and pentyl-AO–SDS systems respectively; here, [SDS] stands for the total SDS concentration. It can be seen that τ^{-1} increases with an increase in the SDS concentration and reaches a

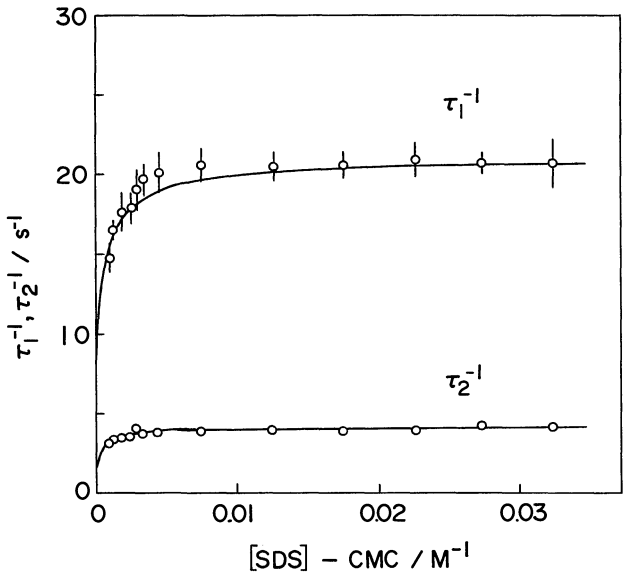

Fig. 4. Dependence of τ_1^{-1} and τ_2^{-1} on [SDS]—cmc for the pentyl-AO–SDS system. The concentration of pentyl-AO was 1.0×10^{-5} M. The lines are drawn using Eq. 5 with parameters listed in Table 1.

limiting value (Figs. 3 and 4). The reaction of SDS with propyl-AO or decyl-AO was also examined with fluorescence detection. As Fig. 5 shows the result obtained with the decyl-AO–SDS system, the time constants determined from absorbance and fluorescence changes agree well with each other. This implies that absorbance and fluorescence changes reflect the same reaction process. In the case of octyl-AO or decyl-AO, additional rapid changes in both the absorbance and the fluorescence intensity were observed. Their magnitudes, however, were too small to

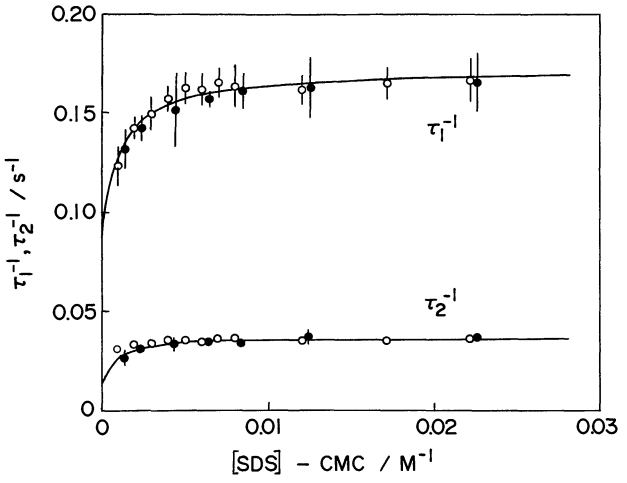

Fig. 5. Dependence of τ_1^{-1} and τ_2^{-1} on [SDS]—cmc for the decyl-AO–SDS system: (○) absorbance detection; (●) fluorescence detection. The concentration of decyl-AO was 1.0×10^{-5} M for absorbance detection and 5.0×10^{-6}M for fluorescence detection. The lines are drawn using Eq. 5 with parameters listed in Table 1.

determine the accurate time constant.

To see the time course of spectral changes in the solubilization process, stopped-flow rapid scanning spectroscopy was employed. Figure 6 depicts a typical result obtained with the pentyl-AO–SDS system. It can be seen that the absorbance at the monomer band increases and the absorption maximum shifts toward a longer wavelength with time. This result supports that the dye is solubilized into the hydrophobic environment of the micelle in a monomeric form.[9,16,23]

Mechanism of Solubilization. Some mechanisms for the solubilization of dye into the surfactant micelle have been proposed. Hoffmann[15] suggested that the rapid formation of a dye-surfactant ion pair is followed by a stepwise accumulation of surfactant monomers around the ion pair until a dye-containing micelle is built up. Robinson and co-workers[16,17] observed that the reaction curve for the 10-alkyl AO–SDS system is approximately characterized by a single-exponential function and the first-order rate constant markedly decreases with increasing the size of the alkyl chain. Their observation argues against the suggestion of Hoffmann,[15] that the micelle breakdown is the rate-determining step, since such a process should be fast and independent of the dye structure. Therefore, they proposed another mechanism in which rapid adsorption of the dye on the micelle surface is followed by slow penetration of the dye into the hydrophobic region of the micelle;[16,17] the concentration dependence of the rate constant was consistent with that expected for the slow step.

The results obtained in this study clearly indicate that the reaction of SDS with AO is characterized by one time constant, whereas the reactions of SDS with 10-alkyl derivatives of AO by two time constants. The latter finding is distinguishable from that of Robinson et al.[17] To interpret the present data, we propose the following schemes for the solubilization of the dye into the surfactant micelle: for AO,[16]

$$\mathrm{D} + \mathrm{M} \underset{k_{-2}}{\overset{K_1}{\rightleftharpoons}} \mathrm{DM}_1 \underset{}{\overset{K_2,\ k_2}{\rightleftharpoons}} \mathrm{DM}_2, \qquad (1)$$

and for 10-alkyl derivatives of AO,

$$\mathrm{D} + \mathrm{M} \underset{k_{-2}}{\overset{K_1}{\rightleftharpoons}} \mathrm{DM}_1 \underset{k_{-3}}{\overset{K_2,\ k_2}{\rightleftharpoons}} \mathrm{DM}_2 \underset{}{\overset{K_3,\ k_3}{\rightleftharpoons}} \mathrm{DM}_3, \qquad (2)$$

where D, M, and DM_i denote the dye, the micelle surface site and the i-th dye-surfactant complex, respectively, and K_i, k_i, and k_{-i} are equilibrium, forward rate and backward rate constants for the i-th step, respectively. The first step can be assigned to the adsorption of the dye on the micelle surface and the subsequent ones to the isomerizations of the complexes. Since the initial binding of the dye to the micelle is considered to be electrostatic in nature and there is no restriction of a single site on each micelle, the concentration of the micelle surface site ([M]) can be defined as[16]

$$[\mathrm{M}] = \alpha([\mathrm{SDS}] - \mathrm{cmc}), \qquad (3)$$

where α is the fraction of micelle surface charge which is not neutralized by Na^+ counterion; the value of α was evaluated to be 0.168 by dividing the surface charge of the SDS micelle by its association number.[27] On the assumption that the bimolecular adsorption step is faster than the isomerization step and [M]≫[D], the time constant for the second step in Scheme 1 is simply expressed by[28]

$$\tau^{-1} = k_2K_1[\mathrm{M}]/(1 + K_1[\mathrm{M}]) + k_{-2}. \qquad (4)$$

To secure the requirement [M]≫[D], experimental conditions were regulated in such a way that there is always an excess of micelle sites. Under these conditions the possible complication due to dye–dye interactions on the micelle surface is eliminated.

Estimating the starting values from the intercept and initial slope of a plot of τ^{-1} versus [M] and from the plateau value of τ^{-1}, kinetic parameters (K_1, k_2, and k_{-2}) were determined by a nonlinear regression analysis so as to fit the expression of τ^{-1} (Eq. 4) to the observed data.[22] The results are summarized in Table 1. It is found that the k_2 value for AO (40 s^{-1}) is very similar to the value (47.6 s^{-1}) reported by Robinson et

Table 1. Equilibrium and Rate Constants at 25 °C

Dyes	K_1 / $M^{-1}\times10^{-3}$	K_2	k_2 / s^{-1}	k_{-2} / s^{-1}	K_3	k_3 / s^{-1}	k_{-3} / s^{-1}	K_T / $M^{-1}\times10^{-4}$
AO	11	2.6	40	15				3.8

al.[16]

For the 10-alkyl AO–SDS systems (Scheme 2), the time constants for the two isomerization steps can be expressed by[28]

$$\tau_1^{-1},\ \tau_2^{-1} = \frac{1}{2}[(a_{11} + a_{22}) \pm \{(a_{11} - a_{22})^2 + 4a_{12}a_{21}\}^{1/2}], \quad (5)$$

where

$$a_{11} = k_2K_1[\mathrm{M}]/(1 + K_1[\mathrm{M}]) + k_{-2} + k_3, \quad (6)$$

$$a_{12} = k_2K_1[\mathrm{M}]/(1 + K_1[\mathrm{M}]) - k_{-3}, \quad (7)$$

$$a_{21} = -k_3, \quad (8)$$

$$a_{22} = k_3. \quad (9)$$

It should be noted that Eq. 5, as in the case of Eq. 4, holds on the assumption [M]≫[D] which is the case in this study. Equation 5 is a complex expression, but the problem can easily be solved by considering the following expressions:

$$\tau_1^{-1}\cdot\tau_2^{-1} = (k_3 + k_{-3})(\tau_1^{-1} + \tau_2^{-1}) - (k_3 + k_{-3})k_2 - k_{-2}k_{-3}, \quad (10)$$

$$\tau_1^{-1} + \tau_2^{-1} = k_2K_1[\mathrm{M}]/(1 + K_1[\mathrm{M}]) + k_{-2} + k_3 + k_{-3}. \quad (11)$$

In the same manner as Eq. 4, the curve-fitting analysis of Eq. 11 gives K_1, k_2, and $k_{-2}+k_3+k_{-3}$. Then, the values of k_{-2}, k_3 and k_{-3} are determined from the slope and intercept of a plot of $\tau_1^{-1}\cdot\tau_2^{-1}$ against $(\tau_1^{-1}+\tau_2^{-1})$. The kinetic parameters thus obtained are listed in Table 1. The solid lines in Figs. 3—5 represent the theoretical ones calculated on the basis of kinetic parameters in Table 1; there is a satisfactory agreement between observed and calculated values.

Takeda et al.[14] found that when pinacyanol solution is mixed with the solution containing SDS micelles, the absorption band characteristic of the surfactant-dye salt appears and this is progressively replaced by the monomer band of the dye with time. To interpret the kinetics of the solubilization of pinacyanol into the SDS micelle, they proposed the rapid initial formation of the salt which then penetrates the palisade layer of the micelle.[14] A similar mechanism was also suggested for the solubilization of an anthraquinone acidic dye into the micelle of hexadecyltrimethylammonium bromide (HTAB).[19] Since hydrophobic interactions between hydrocarbon chain attached to AO and surfactant stabilize the salt, it is expected that the salt formation might be pronounced with an increase in the length of the alkyl chain. In the present systems, unambiguous evidence for the salt formation was not obtained from both the rapid-scanning spectroscopy (Fig. 6) and the wavelength dependence of optical changes in reaction curves. Nevertheless, it seems worthwhile to examine some possibility of the salt formation, since this is anticipated to be a very rapid process outside the time range of stopped-flow measurements. In such a case, the following kinetic scheme should be considered:

$$\mathrm{D} + x\mathrm{S} \overset{K_0}{\rightleftharpoons} \mathrm{DS}_x,$$

$$\mathrm{DS}_x + \mathrm{M} \overset{K_1}{\rightleftharpoons} \mathrm{DM}_1 \overset{K_2}{\rightleftharpoons} \mathrm{DM}_2 \overset{K_3}{\rightleftharpoons} \mathrm{DM}_3. \quad (12)$$

In Scheme 12, S is the surfactant monomer, DS_x is the salt of dye with surfactant molecules, x is a small integer, and K_0 is the equilibrium constant for the salt formation. If we assume that both the salt formation and the adsorption of the salt on the micelle surface are rapid, we can find that the time constants for the isomerization steps are also expressed by Eq. 6. In the expressions for τ_1^{-1} and τ_2^{-1},

$$a_{11} = k_2K_1[\mathrm{M}]/\{(1 + 1/K_0[\mathrm{S}]^x) + K_1[\mathrm{M}]\} + k_{-2} + k_3, \quad (13)$$

$$a_{12} = k_2K_1[\mathrm{M}]/\{(1 + 1/K_0[\mathrm{S}]^x) + K_1[\mathrm{M}]\} + k_{-3}, \quad (14)$$

$$a_{21} = -k_3, \quad (15)$$

$$a_{22} = k_{-3}. \quad (16)$$

If the salt formation predominatly occurs, that is, $K_0[\mathrm{S}]^x \gg 1$, Eqs. 13—16 are reduced to Eqs. 6—9. In this case, two schemes (Scheme 2 and Scheme 12) can not kinetically be distinguished. Here, it should be noted that K_1 in Scheme 12 is the equilibrium constant for the adsorption of the salt (DS_x). Since D having a positive charge is more accessible to the negatively charged micelle surface than DS_x which is neutral or negatively charged, K_1 for DS_x (Scheme 12) is expected to be smaller than that for D (Scheme 2). Table 1 indicates that K_1 does not depend on the length of the alkyl chain except decyl-AO. This finding suggests that not hydrophobic but eletrostatic interactions make major contributions to the driving force for the adsorption process. The smaller value for decyl-AO is presumably a result of appreciable formation of the salt which leads to weakening the electrostatic force. Moreover, the additional rapid reaction observed for decyl-AO dye or octyl-AO may be attributed to the adsorption of the salt and/or to its dissociation on the micelle surface which takes place rapidly prior to the penetration of the dye into the micelle. In view of the considerations stated above, it seems reasonable to conclude that Scheme 2 prevails for the AO derivatives with shorter alkyl chains, whereas Scheme 12, in addition to Scheme 2, makes some contributions to the kinetics of the solubilization for the AO derivativs with longer alkyl chains.

K_2 has similar values for all dyes, whereas the

forward and backward rate constants of the second step (k_2 and k_{-2}) gradually decrease with increasing the length of the alkyl chain (Table 1). This result shows that the second step is not driven by hydrophobic force, but the alkyl chain plays an important role for the activation of the second step. One possible mechanism is the reorientation of the dye at the micelle surface which includes partial penetration of the alkyl chain through the surface layer of the micelle. This process must be accompanied by the release of hydrated water molecules surrounding the alkyl chain.[29] Therefore, the rate constants for the second step are expected to decrease with increasing the size of the alkyl chain.

Table 1 also indicates that both the equilibrium and the rate constants for the third step highly depend on the length of the alkyl chain; K_3 increases with increasing the size of the alkyl group, while k_3 and k_{-3} decrease. This result suggests that the final form of the complex is stabilized by the hydrophobic force. On the other hand, the spectral change of the dye with time (Fig. 6) obviously shows that the dye is solubilized into the hydrophobic environment. In view of these results, it seems reasonable to assign the third step to the migration of the alkyl chain from the micelle surface to the *inner* hydrophobic site of the micelle.

Figure 7 displays the standard free energy changes ($\Delta G_2°$, $\Delta G_3°$, $\Delta G_{2+3}°$) for the second and third steps in Schemes 1 and 2 as a function of the number of carbon atoms in the alkyl chain (n); $\Delta G_{2+3}°$ corresponds to the standard free energy changes for the overall isomerization process. The free energy of transfer of a methylene group to the inside of the micelle can be estimated

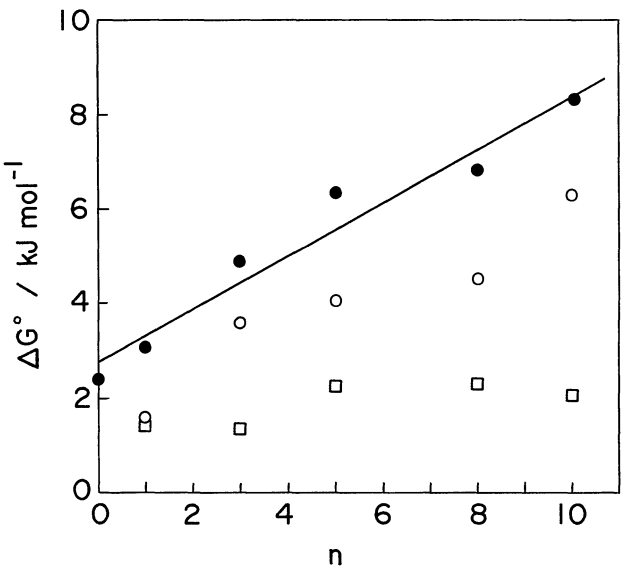

Fig. 7. The standard free energy changes for the isomerization steps as a function of the number of carbon atoms in the alkyl chain (n). (□) $\Delta G_2°$; (○) $\Delta G_3°$; (●) $\Delta G_{2+3}°$. The line is the least-squares fit for $\Delta G_{2+3}°$.

from the slope of a linear plot of $\Delta G_{2+3}°$ versus n;[29] the value was found to be about 0.6 kJ mol^{-1}. This value is about a half to one third of that estimated for the transfer of a hydrocarbon to the SDS micelle.[29] Possibly this smaller value of the free energy of transfer is due to the presence of the bulky acridine head group.

The overall binding constant K_T can be defined by

$$K_T = K_1(1 + K_2 + K_2K_3). \quad (17)$$

As shown in Table 1, the K_T values are the order of 10^4 to 10^5 M^{-1}. To confirm the mechanism of the solubilization, it is necessary to determine binding constants for micelles by means of other techniques. In spite of the desire to have useful, general methods for obtaining such constants, the present state of affairs remains difficult. Fluorescence techniques have been applied to evaluate rough binding constants, but their number is quite limited.[10,11,30] Chiang and Lukton[10] reported $K_T \approx 2\times10^3$ M^{-1} for the binding of 6-(*p*-toluidino)-2-naphthalenesulfonate to the SDS micelle. On the other hand, Reed et al.[11] estimated the following association constants of Rose Bengal binding to HTAB and SDS micelles; $K_T(\text{HTAB}) \geqq 10^4$ M^{-1} and $K_T(\text{SDS}) \geqq 10^2$ M^{-1}. By employing the fluorescence quenching method, Zoltewicz and Munoz[30] have recently reported that the association constants of heterocyclic cations such as 10-methylacridinium and ethidium bromide to the SDS micelle range between 1.0×10^4 and 1.4×10^5 M^{-1}. This method gives more accurate binding constants and its application to our systems will be an interesting subject. The above results suggest that the magnitude of K_T, when the charges of the dye and micelle are opposite, is much larger ($\geqq 10^4$—10^5 M^{-1}) compared to that ($\approx 10^3$ M^{-1}) with the same charge. It is worth noting that the K_T values in this study are to be expected for the binding of cationic dyes to the anionic micelle. As can be seen from Table 1, K_T increases with increasing the size of the alkyl chain except a somewhat smaller value for decyl-AO. This behavior can be understood in terms of the combined effect of the electrostatic interaction, which is responsible for K_1, and of the hydrophobic interaction, which predominantly affects K_3.

In conclusion, the stopped-flow kinetic study reveals that the solubilization of AO and its 10-alkyl derivatives into the SDS micelle consists of a rapid initial adsorption of the dye on the micelle surface and two sequential isomerization steps; one is the reorientation of the dye at the micelle surface and the other is the migration of its alkyl chain into the inner hydrophobic region of the micelle.

(Received September 7, 1990)

Sperm whale metmyoglobin reconstituted with 5,10,15,20-tetrapropylhemin was crystallized in the space group $P2_12_12_1$, which was different from the space group $P2_1$ of the native. The crystal structure of the reconstituted metmyoglobin was determined by the molecular replacement method. The atomic coordinates were refined to R=0.209 at 2.0 Å resolution. The overall structure is essentially the same as that of the native. The pronounced structural change is observed in the side-chain orientation of Arg 45 moving to the surface of the molecule. This conformational change may reflect a side-chain fluctuation that allows the small ligands to approach the heme pocket from the outside of the protein. The porphyrin ring does not rotate freely about the Fe–N^{ε} (His 93) bond in the crystalline state, although temperature-dependent NMR spectra suggest its free rotation in solution.

It is well-known that stereospecific interactions of the heme with globin play important roles in the functional behavior of hemoproteins. Various kinds of reconstituted myoglobins and hemoglobins have been prepared with modified protohemes to investigate the relationship between the structure and the function. The major modification has been performed mainly at the vinyl positions of protoheme, to discern whether the electronic characters or the steric effects of substituents are responsible for the oxygen-binding property.[1–3] On the other hand, 5,10,15,20-tetraalkylporphyrins do not have any substituent at the pyrrole carbons, rather they bear four alkyl groups on 5,10,15,20-positions, as shown in Fig. 1. This difference between 5,10,15,20-tetraalkylporphyrin and protoheme is expected to affect the heme-globin interactions in different ways.

Proton NMR spectra of cyanide metmyoglobin reconstituted with 5,10,15,20-tetraalkylhemin resolved the pyrrole-proton signals of porphyrins in the −5 to −15 ppm region as a singlet, a doublet, and a quartet for the methyl, ethyl, and propyl group, respectively. These peaks of ethyl- or propyl- derivative, however, coalesce into a sharp singlet at 61 °C, suggesting dynamic free rotation of the porphyrin rings about the Fe–N^{ε} (His–F8)bond.[4,5] Such a large fluctuation in amplitude of the porphyrin ring has never been appreciated. The structural perturbation in reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin is expected to be larger than that in the ethyl derivative. This paper deals with the results of structural studies of cyanide metmyoglobin reconstituted with 5,10,15,20-tetrapropylhemin (R=Pr, in Fig. 1) using X-ray crystallographic analysis. This is the first analysis of myoglobin containing 5,10,15,20-tetraalkylporphyrin.

Materials and Methods

Crystallization. Reconstituted sperm whale metmyoglobin was prepared as described previously[4,5] and stocked in a 10 mM (1 M=1 mol dm^{-3}) Tris-KCN buffer solution (pH 7.0). Crystals of cyanide metmyoglobin reconstituted with 5,10,15,20-tetrapropylhemin were obtained by a dialysis of 0.5 mM protein solution against a saturated ammonium sulfate solution containing 10 mM KCN. The pH of the outer solution was adjusted to 6.5—7.0 with HCl.

The crystals belong to the orthorhombic space group $P2_12_12_1$ with the unit cell dimensions a=58.39(2), b=76.15(2), and c=33.86(2) Å. There are 4 molecules per unit cell, which gives the V_m value of 2.1 $Å^3$/dalton. The unit cell dimensions were determined by the least-squares method using the observed setting angles of 25 reflections collected on a Rigaku AFC-5 four-circle diffractometer. Native sperm whale metmyoglobin has been known to crystallize in two forms: a monoclinic form with space group $P2_1$ from an ammonium sulfate solution, and an orthorhombic form of $P2_12_12_1$ from a phosphate buffer solution.[6] Contrary to expectations, the cell dimensions of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin are similar not to those of the previous orthorhombic form, but to those of blue whale myoglobin.[6]

Data Collection and Processing. Crystals with typical dimensions of 0.4×0.4×1.2 mm were sealed in glass capillaries with the mother liquid and used for data collections. Diffraction data were collected at 10 °C on a diffractometer using a nickel-filtered Cu $K\alpha$ radiation produced by a rotating anode X-ray generator operated at 40 kV and 300 mA. The diffraction pathway was kept in vacuo with an evacuated beam tunnel extending from the vicinity of the crystal to the counter, to improve the S/N ratio of data by reducing the X-ray scattering and/or the absorption of air.

Reflection intensities were measured in a continuous omega-scan of approximately 0.8° in width at a scanning speed of 4° min^{-1}. Background counts were measured for 4 seconds at both ends of each scan. Three standard intensities were checked every 100 reflections during data collection to monitor the decay intensity and crystal slippage. Crystals were exchanged as soon as any one of the standard intensities was reduced by 10%. The intensity data were corrected for absorption using an empirical correction curve obtained by measuring the intensity of a phi-independent reflection in 36 consecutive positions of 10° phi-intervals.[7] The correction for crystal damage due to X-ray irradiation was made as a function of the elapsed time. Diffraction intensities were scaled among different data sets by the method of Rollett and Sparks.[8] The final R_{merge} value was 3.1% for 10331 unique reflections up to 2.0 Å resolution, where $R_{merge}=\Sigma|<F>-F_i|/\Sigma F_i$, and $<F>$ is the average of F_i.

Structure Determination. The structure was solved by the molecular replacement method.[9,10] The structure of native sperm whale metmyoglobin in a $P2_1$ form[11] was used as the reference molecule, and its atomic coordinates were obtained from the Protein Data Bank.[12] The reference molecule without the prosthetic group was positioned in an arbitrary $P1$ unit cell with dimensions of $a=b=c$=100 Å and $\alpha=\beta=\gamma$=90°. The structure factors were calculated in the resolution range of 10 to 6 Å, the overall temperature factor being assumed to be 25 $Å^2$. To determine the orientation of the reference molecule in the observed unit cell, the fast rotation function[13] was calculated using Crowther's Eulerian angles with 5° grid intervals. The lengths of the vectors to be searched were limited to within 30 Å, and origin removal was applied. The peak coordinates found in the calculation are given in Table 1 for the two kinds of reference molecules; one reference molecule consisted of all atoms of globin, the other contained only the main chain and the C^β carbon atoms. The fourth peak of the former corresponds to the secondary peak of the latter. This orientation was accepted in the next step.

Table 1. Peak Coordinates in Rotation Functions[a]

	Peak	Peak height	β	α	γ
Case 1	1	62.9	55.0	120.0	60.0
	2	57.8	5.0	50.0	−105.0
	3	57.5	40.0	140.0	165.0
	4	53.0	35.0	40.0	170.0
	5	46.9	80.0	140.0	−15.0
Case 2	1	57.9	10.0	130.0	170.0
	2	47.6	35.0	45.0	165.0
	3	39.8	60.0	120.0	−120.0

a) α, β, and γ are Crowther's Eulerian angles. As the reference molecule, all atoms were included in Case 1, and only the main chain and C^β atoms were in Case 2. The orientation of Peak 2 in Case 2, which corresponds to that of Peak 4 in Case 1, was submitted to a translation search

The translation search was performed by the R-factor map procedure.[14,15] In this step, porphyrin with the Fe atom (R=H, in Fig. 1) was added to the whole globin as the prosthetic group. The reference molecule was located in the orientation obtained in the previous step. The structure factors were calculated separately for each symmetry operation of the space group $P2_12_12_1$. These partial structure factors were merged using relative phase angles calculated by placing the reference molecule in various positions. The R factor at 6 Å resolution was calculated at 1 Å grids over the range of 0—1/2 lattice along the three crystallographic axes. Some short intermolecular contacts were found at the position of the lowest R value, 0.51. After a packing analysis was carried out to check intermolecular contacts, a rigid body refinement was performed to improve the results obtained from the coarse grid searches of rotation and translation about several reasonable positions. Three rotational and three translational parameters were refined to minimize the R value by the simplex method,[16] which is well-suited for searching the minimum point around the initial parameters over a wide range. The lowest R factor after this refinement was 0.38 for 186 large reflections in the resolution range of 8 to 5 Å, while R factors of the others were more than 0.41. The new position was obtained by improving the initial parameters by −3.7, 12.6, and 0.2° in rotation of the Eulerin angles and −0.2, 1.1, and 0.0 Å in translation along the three crystallographic axes. Successive rigid body refinements resulted in R values of 0.34 for 351 large reflections of 4.5—4.0 Å resolution, and 0.32 for 266 large reflections between 3.15 and 3.0 Å resolution. The position of the heme iron atom was also confirmed by the

anomalous difference Patterson map based on the intensity data which were measured using the synchrotron radiation (λ=1.74 Å) at Tsukuba Photon Factory.

Structure Refinement. Refinement of the structure was carried out by a restrained least-squares technique according to the Hendrickson-Konnert method.[17] The resolution in the refinement was gradually improved from 3 Å to 2 Å. A hundred and twelve refinement cycles were done to the convergence at 2.0 Å resolution. The temperature factors were refined independently for the individual atoms after 12 cycles. Forty-three water molecules were found in the $2F_o-F_c$ electron density map calculated after 26 cycles and included as the oxygen atoms in the following refinement. After the 20th, 38th, 48th, and 78th cycles, the refined model was modified by fitting it to the respective $2F_o-F_c$ maps with the color graphics display system. The four propyl groups of 5,10,15,20-tetrapropylhemin were not introduced into the refinement because no remarkable peaks were found in their corresponding positions on electron density maps. The final crystallographic R-factor was 0.209 for 4926 reflections with F_o larger than $3\sigma(F_o)$ at the resolution of 5.5 to 2.0 Å. The rms deviations from their ideal values are 0.013 Å for bond distances, 0.031 Å for angle distances, and 0.037 Å for planar 1-4 distances.

Results and Discussion

Heme and Its Environment. The electron density of the heme in reconstituted metmyoglobin is not so clear, as shown in Fig. 2, and the cyano group coordinating to the iron atom does not appear on the Fourier map, although the electronic absorption spectra indicate the presence of CN^- anion.[4,5] The temperature factors of the atoms in the porphyrin ring are 17 to 20 Å^2, which are slightly larger than the mean value of the overall molecular structure (15 Å^2), indicating disorder and/or vibration. Surprisingly, pyrrole B, located at the bottom of the heme pocket, has larger thermal factors (19—20 Å^2) than any other pyrrole, and the corresponding electron density becomes much lower. On the contrary, pyrrole D, located at the entrance to the heme pocket, represents the smallest thermal motion. Myoglobin, as is well-known, has some interior spaces, or cavities, in the vicinity of the heme.[18] These facts suggest that the cavity at the bottom of the heme pocket is much wider than that at the entrance which is reduced by two imidazole rings of His 64 (E7) and His 97 (FG2), and that the bottom part of the porphyrin ring, such as pyrrole B, swings up and down in the direction normal to the ring, in addition to the oscillatory movement of the heme about the Fe–N$^\varepsilon$ (His 93) bond. However, the free rotation of the heme about the Fe–N$^\varepsilon$ (His 93) bond, which was suggested by proton NMR spectra,[4,5] is not observed in the crystalline state.

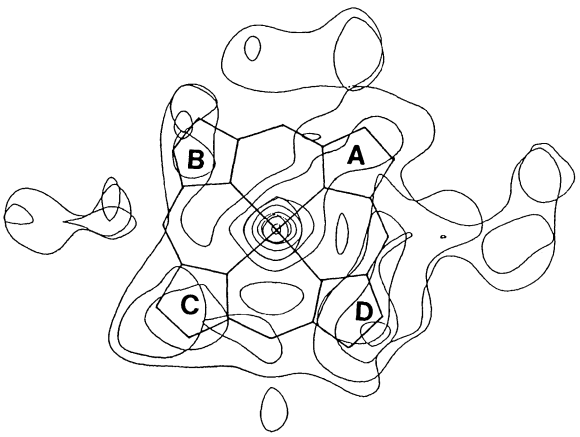

Fig. 2. $2F_o-F_c$ electron density map of the heme. The −2—2 sections parallel to the mean heme plane at intervals of 1 Å are superposed. The heme plane is located on the 0 section. Contours are drawn at arbitrary levels. The four pyrrole rings of porphyrin are labelled by the symbols A, B, C, and D.

The distance between the iron atom and N$^\varepsilon$ of His 93 (F8) is 2.01 Å, which is comparable to 2.13 Å in the native. The iron atom is displaced by 0.2 Å from the mean plane of the porphyrin ring, and by 0.1 Å from the imidazole plane of His 93 (F8). The angle between the Fe–N$^\varepsilon$ (His 93) bond and the axis normal to the mean pyrrole plane is 11.0°, which is comparable with 3.9° in the native. The imidazole ring of His 93 (F8) makes an angle of 35° to the plane composed of the iron atom and two nitrogens of pyrroles B and D. Since the corresponding angle in native myoglobin is 19°, the porphyrin ring in reconstituted metmyoglobin is rotated by 16° about the Fe–N$^\varepsilon$ (His 93) bond.

Rotation of the Heme Group. Temperature-dependent NMR spectroscopy suggested that the heme group of reconstituted myoglobin with 5,10,15,20-tetrapropylhemin freely rotates about the Fe–N$^\varepsilon$ (His 93) bond in solution at high temperature.[4,5] However, this free rotation has not been observed in the crystalline state. In order to check for the possibility of such rotation, the energy barrier for the rotational movement of the heme group about the Fe–N$^\varepsilon$ (His 98) bond was elucidated by calculating the conformational energy with the MM2′ program.[19] The sixteen amino acid residues around the heme were used in the calculation and fixed during energy minimization. The positions of the four propyl groups attached to the heme group were estimated from the standard geometry of 5,10,15,20-tetrapropylporphyrin.[20] All hydrogen atoms were located at the ideal positions. In order to estimate the energy barrier of the heme rotation, the heme group was rotated at 10° steps from 0° to 90° about the Fe–N$^\varepsilon$ (His 93) bond, considering the four-fold rotation symmetry of 5,10,15,20-tetrapropylporphyrin, and used in energy minimization.

The resulting energy variation is shown in Fig. 3 as a function of the His 93C$^\varepsilon$–His 93N$^\varepsilon$–Heme Fe–Heme CCD torsional angle, ϕ. The curve of reconstituted myoglobin with 5,10,15,20-tetrapropylhemin has a

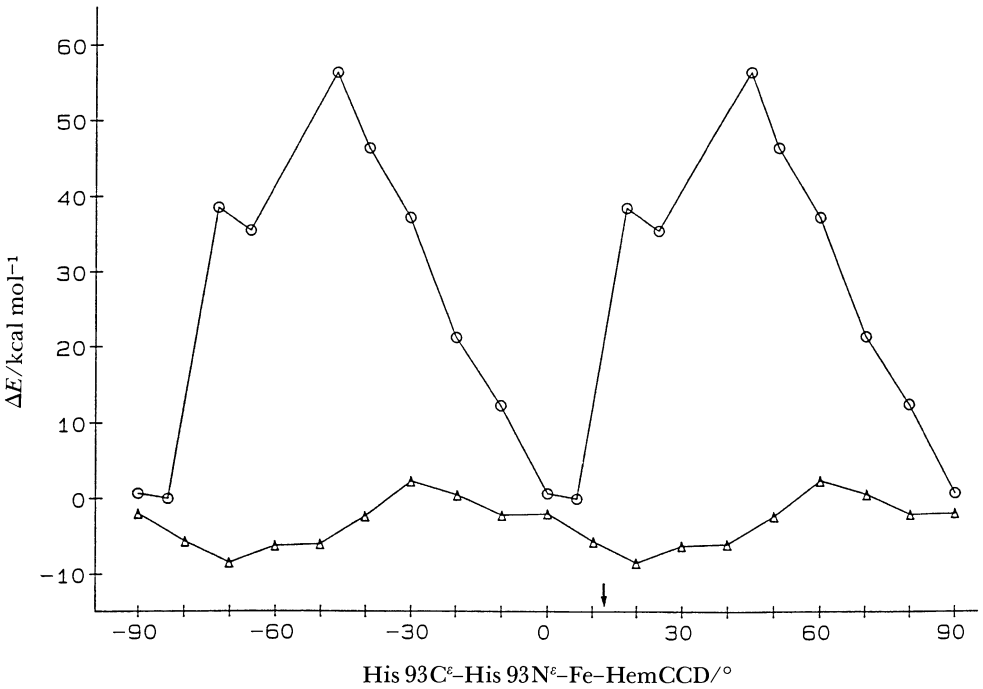

Fig. 3. The variation of the potential energy with rotational angle (ϕ) about His 93C^{ε}–His 93N^{ε}–Fe–Hem CCD for reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin (circles) and porphyrin (triangles). The potential energy is subtracted by the minimum comformation energy of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin. The arrow indicates the observed rotational angle for reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin.

minimum at ϕ value close to the observed angle of 12.5° and a maximum between −40° and −50°. In these position, the propyl groups of the heme must pass through the narrow spaces composed of Leu 72 (E15) and Phe 138 (H15), and Tyr 103 (G4) and Ile 107 (G8), which are paired above and below the heme plane, respectively; there are short interatomic distances of Leu 72$C^{\delta 1}$···Phe 138C^{ζ} (3.75 Å), Tyr 103O···Ile 107N (3.16 Å) and Tyr 103O···Ile 107$C^{\gamma 2}$ (3.27 Å). Moreover, Lys 42 (C7) and Phe43 (CDl) also prevent the heme group from rotating. Thus, the energy barrier is so high that the heme group could not freely rotate in the crystalline state.

The potential energy curve of reconstituted metmyoglobin with porphyrin (R=H, in Fig. 1) is also plotted in Fig. 3. In this case, the minimum is at ϕ=20 which is different by about 10° from that of reconstituted myoglobin with 5,10,15,20-tetrapropylhemin. Since the energy barrier at ϕ=30° is 11 kcal mol^{-1}, which is much less than that of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin, the porphyrin ring might freely rotate about the Fe–N^{ε} (His 93) bond even in the crystalline state. Actually the weak and flat electron density of heme has been observed in the crystal structure of reconstituted metmyoglobin with porphyrin, suggesting rotation and/or vibration of the heme group.[21]

Structural Comparison with Native Metmyoglobin. The overall structure of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin is essentially the same as that of the native. Before quantifying the structural differences between the two proteins, a least-square superposing procedure based on the positions of the C^{α} atoms was performed, to get the best fit between them. The resulting superposition of the C^{α}-tracings of the two molecules is illustrated in Fig. 4, and the positional deviations of the amino acid residues are plotted in Fig. 5. The root mean square deviation between the corresponding C^{α} atoms is 0.6 Å. These two figures show that the most pronounced change occurs at the C-terminal region (0.9—3.7 Å), and the next at the N-terminal (1.9 Å). The other residues that move more than 0.77 Å are located at the CD-loop and the E-helix regions: Lys 47 (CD5), His 48 (CD6), and Asp 60 (E3). These regions construct the entrance and/or exit channel through which small diatomic or triatomic ligands move from the outside of the protein to the distal heme pocket.[22]

The mean temperature factors of the backbone atoms (N, C^{α}, C, and O) in each amino acid residue are also plotted in Fig. 5, with the corresponding positional deviations. This figure shows a measure of the flexibility of the polypeptide chain by the relationship between the average temperature factor

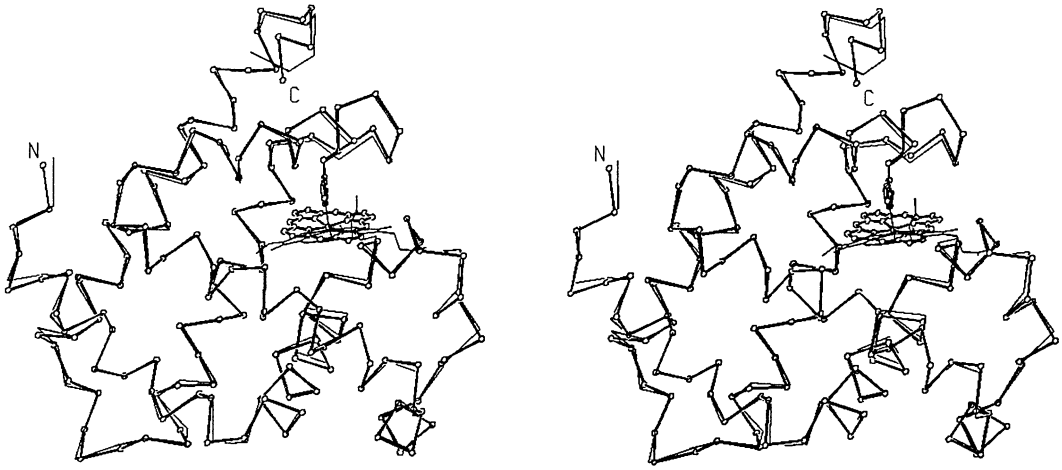

Fig. 4. The conformations of the C^{α} backbone, the heme moiety, and the heme linkage to His 93 in reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin (thick lines) and native metmyoglobin (thin lines). The amino and carboxyl termini are labelled by N and C.

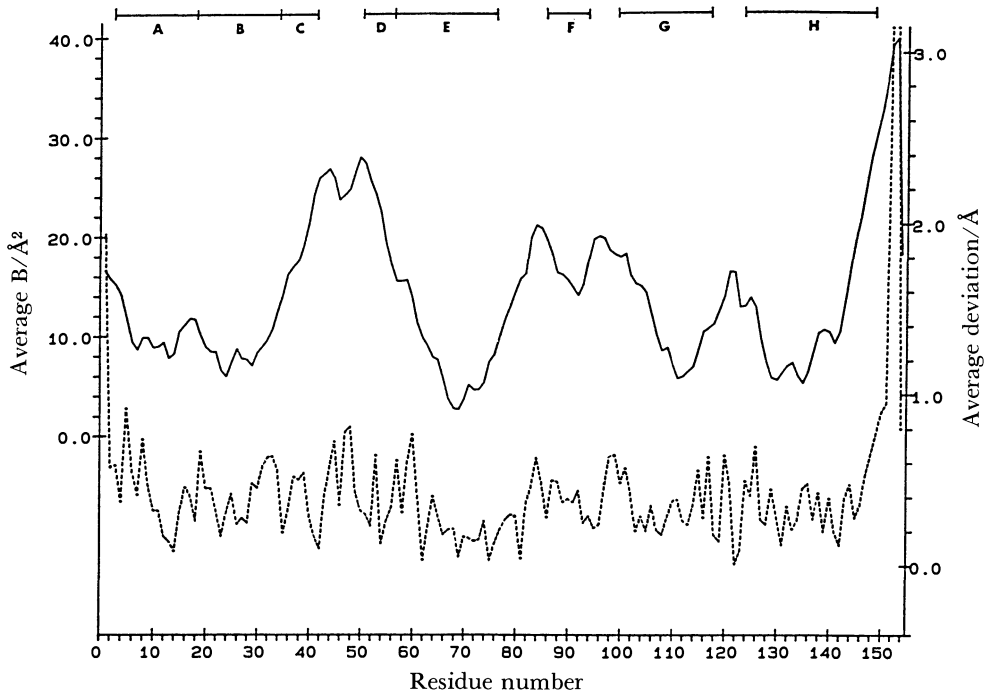

Fig. 5. Plots of the mean temperature factors for each amino acid residue of the main chain in reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin (solid line) and the positional deviations in the corresponding C^{α}-atoms between reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin and native metmyoglobin (a dotted line). Bars drawn on the upper part of the graph represent the regions of alpha-helical structure.

and the posisional deviation. The average temperature factors of the overall main chain is 14.1 Å², but considerable variablity is observed along the course of the polypeptide chain. The highest thermal motion is observed in atoms of the C-terminal region. Main-chain atoms in the loops, especially in the CD-loop, have considerably high temperature factors and have been shown to be particularly mobile by temperature-dependent X-ray diffractions of myoglobin.[23] These flexible regions of a polypeptide chain might be able to move easily and to adopt different conformations depending on their circumstances, such as existence of the heme ligand.

Although the structural changes of the main chain

are small, except for the amino and carboxyl termini, a number of pronounced changes occur at the side groups. The side chain of Arg 45 (CD3) dramatically moves toward the outside of the protein. The guanidino group of Arg 45 (CD3) in native metmyoglobin forms two hydrogen bonds: to the carboxyl groups of Asp 60 (E3) and 6-propionic acid of protoheme. In reconstituted metmyoglobin, the latter hydrogen bond is ruptured because of the lack of a carboxyl group of the heme, and the guanidino group is rotated by ca. 170° about the C^{α}–C^{β} bond, to shift its terminal nitrogen atom by 6 Å. As a result, the side chain of Arg 45 (CD3) is no longer stabilized by the hydrogen bond to Asp 60 (E3). Structural differences between phenyl-ligated metmyoglobin and native metmyoglobin have been observed in the side-chain orientation of Arg 45 (CD3), His 64 (E7), and Val 68 (E11) around the distal His 64 (E7), suggesting that these amino acid residues may play an important role in forming the pathway through which small ligands have been presumed to enter the distal heme pocket from the outside of the protein.[22] In reconstituted metmyoglobin, however, only the side group of Arg 45 (CD3) swings out, and those of His 64 (E7) and Val 168 (E11) do not significantly move.

The other drastic changes are observed mainly at the side chains located at the surface of the protein. The maximum deviations in each side chain of Glu 83 (EF6), Lys 96 (FG1), Lys 98 (FG3), and Lys 147 (H24) are all more than 4.0 Å. Among these residues, only Lys 96 (FG1) is situated in the vicinity of the heme pocket. Crystallographic study of sperm whale metmyoglobin reconstituted with 2,4-diisopropyldeuterioheme or 2-isopropyl-4-vinyldeuterioheme has elucidated that the introduction of a bulky isopropyl group to the 2-position of the heme forces the phenyl group of Phe 138 (H15) to rotate around the C^{α}–C^{β} and C^{β}–C^{γ} bonds, resulting in the average deviation of 4 Å by the phenyl atoms.[24] In reconstituted metmyoglobin with 5,10,15,20,-tetrapropylhemin, this rotation of the phenyl group does not occur, although the porphyrin ring has propyl groups.

The superposition of the heme moieties of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin and native metmyoglobin is illustrated in Fig. 6. The iron atoms are deviated by 0.8 Å from each other. The porphyrin ring is rotated by 33° within the plane of the ring, and the dihedral angle between these porphyrin planes is 13°. Among four carbons to which the propyl groups are attached, the CDA atom between the pyrrole rings D and A in Fig. 6 is positioned only 1.2 Å from the C-6 position of protoheme in the native. Consequently, it is expected that the propyl group bonded to the CDA atom might be located at the position of 6-propionic acid. On the other hand, the position of the 7-propionic acid is not occupied by any propyl group of 5,10,15,20-tetrapropylporphyrin.

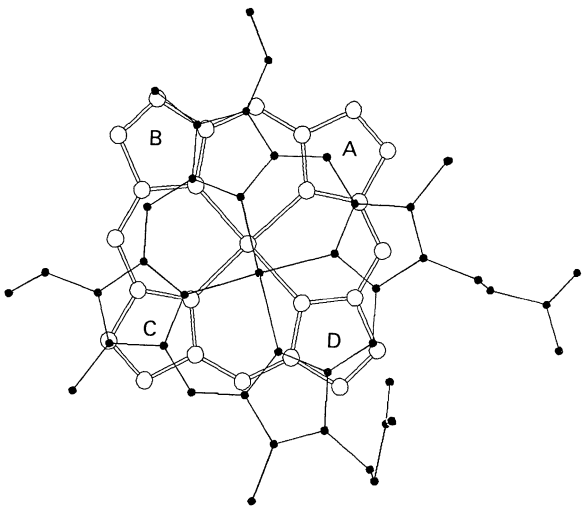

Fig. 6. Superposition of the heme moieties of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin (large opened circles) and native metmyoglobin (small full circles). The four pyrrole rings of reconstituted metmyoglobin with 5,10,15,20-tetraproylhemin are labelled by the symbols A, B, C, and D.

The structure of metmyoglobin shows that the pathway of the ligand from the surface of the molecule into the distal heme pocket is shielded by side chains of His 64 (E7) and several other residues, as shown in Fig. 7. In order to form an open channel to the surface, the imidazolyl group of His 64 (E7) has to rotate after the side chain of Arg 45 (CD3) moves toward the outside, as suggested by Nobbs.[25] This mechanism may be regarded as the "double door" mechanism. A structure analysis of reconstituted metmyoglobin reveals that only the side chain of Arg 45 (CD3) moves toward the outside of the molecule to open the "outer door" of the channel. Once the "outer door" is opened, ligands are expected to move inside through the channel in order to open the "inner door" by rotating the imidazole ring of His 64 (E7). Finally, the channel is opened completely. Crystallographic study of phenyl-ligated metmyoglobin,[22] which has a bulky ligand, reveals that the binding of the ligand to the distal position of iron atom makes the side chains of His 64 (E7) and Arg 45 (CD3) move aside and the channel open to the surface.

The guanidino group of Arg 45 (CD3) in native metmyoglobin is locked by two hydrogen bonds to the carboxyl groups of Asp 60 (E3) and 6-propionic acid of the heme. One of the four propyl groups in the porphyrin ring of reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin occupies the position of the 6-propionic acid of the heme in native metmyoglobin, resulting in a breakage of the hydrogen bond between Arg 45 (CD3) and the 6-propionic acid. In addition, the replacement of the carboxyl group by the

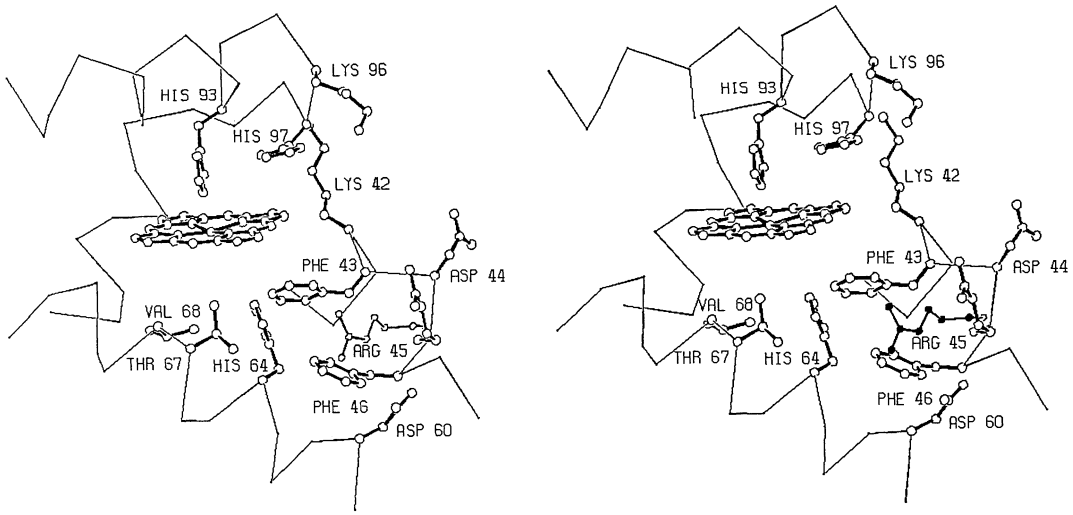

Fig. 7. Drawing of the C^{α}-tracing and the amino acid residues around the heme pocket in reconstituted metmyoglobin with 5,10,15,20-tetrapropylhemin. The pathway through which small ligands have been presumed to enter the ligand pocket lies among Arg 45 (CD3), His 64 (E7), Val 68 (E11), and the heme.[22] The guanidino group of Arg 45 (CD3) moves to the surface of the protein molecule from its position in native metmyoglobin (small full circles).

alkyl group makes the hydrophilic environment change to a hydrophobic one. As the reusult, the hydrophilic guanidino group might be turned toward the hydrophilic globin surface.

As to the opened "outer door", an alternative explanation could been made as follows. Since the amino acid residues of Arg 45 (CD3) and Asp 60 (E3), which are hydrogen-bonded to each other, are located on the surface of the molecule, they are highly influenced by a change of the environment, such as the solvent. If these are species around the protein that are more preferable to the hydrogen bond than Asp 60 (E3), the guanidino group of Arg 45 (CD3) may move outwards to form hydrogen bond with them after breakage of the previous hydrogen bonds. In reconstituted metmyoglobin, there are a large number of the potassium cations and cyano anions around the protein molecule. Such changes in the outer environment may be responsible for the opening and shutting of the "outer door". In addition, the conformational changes observed here should account for the polymorphism of myoglobin depending on the conditions for crystallization.

We would like to thank Dr. Akio Takenaka of the Tokyo Institute of Technology for kindly supplying the rotational and translational search programs and for useful discussions.

(Received September 17, 1990)

Normal coordinate analyses were performed on three molecular models of the rubredoxin of *Desulfovibrio vulgaris, Desulfovibrio gigas,* and *Clostridium pasteurianum.* The total 1081, 1093, and 1148 internal coordinates were specified by the X-ray analyzed coordinates of the 390, 399, and 423 atoms, respectively, in a mass-group approximation. The appropriately assumed values of Urey–Bradley force constants as well as some diagonal values of out-of-plane bending and torsional forces gave 146, 146, and 148 normal modes, respectively, in 250—450 cm^{-1} region. These are the deformational vibrations within the peptide skeleton of the protein molecules. The Fe–S stretching displacements of the FeS_4 core contribute to a limited number of these vibrations. The modes having a totally symmetric Fe–S stretching contribution confined within a frequency region of 290—330 cm^{-1} in which the principal resonance Raman band of rubredoxin has been reported, and the several minor resonance Raman bands reported in the higher frequency region of 330—420 cm^{-1} were assigned to noraml modes having a non-totally symmetric Fe–S stretching character. The PED values indicated that all of these modes are constructed mostly by the deformational displacements in the peptide skeleton widely spread into the molecule around the FeS_4 core. This feature is very similar to the case of the blue-copper protein studied previously.

In a previous study,[1] a normal coordinate analysis of the blue-copper protein was carried out on molecular models constructed using a maximum of 169 atoms including the blue-copper site. The analysis showed that the resonance Raman (RR) active modes comprise a dominant contribution of the bond angle bending displacements in the particular part of the peptide skeleton including side chains around the blue-copper site. A sensitive variation in the RR spectra of the type-1 blue-copper proteins was ascribed to a conformational difference in the protein skeleton around the blue-copper site.

In the present study, this work was extended to rubredoxin, which is the initial member of a class of non-heme iron-containing proteins having the simplest Fe–S(cysteine)$_4$ core in the molecule. Long et al.[2,3] first reported the RR effect of oxidized rubredoxin of *Clostridium pasteurianum* in both crystalline and solution phases. The spectra in both phases contain several components: a dominant band (polarized) at 314 cm^{-1}, a moderate band (depolarized) at 368 cm^{-1}, and a weak broad band (depolarized) at 126 cm^{-1} with a shoulder at 150 cm^{-1} upon excitation within a visible Fe←S charge-transfer absorption band centered at 490 nm. Subsequently, Yachandra et al.[4] have found a small shoulder at 325 cm^{-1} in the higher envelope of the main band and an evident splitting by 12 cm^{-1} of the moderate band, commonly found in the RR spectra of rubredoxin of four different bacterial species. They assigned the main band (at 312 cm^{-1}) to the A_1 breathing mode of the FeS_4 core and the shoulder (at 325 cm^{-1}) and the split bands (at 359 and 371 cm^{-1}) to the $B_1+B_2+A_1$ components of the $T_2(T_d)$ Fe–S stretching vibration under the C_{2v} effective symmetry of the core. However, they did not succeed in the reproduction of such a large splitting of the T_2 mode employing any variation of the Urey–Bradley force constant values, considering the actual lowering of the FeS_4 core symmetry in their normal coordinate analyses on a maxinum of thirteen-atom molecular model.

We performed normal coordinate analyses of the molecular models constructed by the three X-ray analyzed molecules of oxidized rubredoxin, from *Desulfovibrio vulgaris* (Rd:Dv),[5] *Desulfovibrio gigas* (Rd:Dg),[6] and *Clostridium pasteurianum* (Rd:Cp),[6] on 390-, 399-, and 423-atom systems, respectively. The results clearly indicated an extensive coupling between the Fe–S stretching vibration and bond angle bending displacements in the polypeptide skeleton widely spread into the molecule around the FeS_4 core. The vibrational characteristics of the RR active modes will be discussed from a different point of view from that by Yachandra et al.[4]

Material and Measurements

Rubredoxin from *Desulfovibrio vulgaris* Miyazaki (Rd:DvM) was isolated as described elsewhere.[18] The 495/280 nm absorbance ratio of the purified protein was ca. 0.4. The RR signals were detected with a backscattering technique from the surface of a dried protein film on a small iron plate which was wholly immensed into liquid nitrogen within a quartz Dewar. All sampling procedures were carried out in an oxygen-free dry box. The Ar^+ 4880 Å line (350 mW) was used as an excitation source. The spectra were well reproduced during a prolonged acquisition time of about eight hours.

Computation

Our view concerning a normal coordinate analysis of protein molecules in which various subsidiary forces work within the molecules was discussed in a

previous study.[1] While the RR effects of rubredoxin appear to be in a somewhat lower wavenumber region (mainly in 290—430 cm^{-1}) than that of the blue-copper proteins (mainly in 360—450 cm^{-1}) previously studied, a similar basis of the approximation, ignoring the hydrogen-bonding potential, charge potential, van der Waals potential, potential due to solvent molecules, and almost of torsional potentials, was also employed in the present study. No particular remark concerning the anharmonicity of the principal RR active vibration of 312 cm^{-1} was reported while assigning the overtone and combination signals. This has been reconfirmed in the present measurement in the overtone region (Fig. 1). The lowest RR bands of rubredoxin detected in 120—160 cm^{-1} region, which were assigned to the S–Fe–S deformational modes ($\nu_2(E)+\nu_4(T_2)$) of the tetrahedral FeS_4 core, must be greatly influenced by the low-frequency "concerted motion" of the protein skeleton, which is believed to have frequencies of up to ca. 100 cm^{-1}. Therefore, the normal coordinates of these deformational modes must not be correctly deduced, although an apparent coincidence between the calculated and observed values could be obtained when the values of the bending and repulsive forces were adjusted. Thus, the discussion is almost limited to within the Fe–S stretching region of vibration studied in the present work.

Totals of 1081 (Rd:Dv), 1093 (Rd:Dg), and 1148 (Rd:Cp) internal coordinates involving all possible bond-stretching and bond-angle-bending coordinates, as well as some selected coordinates of the out-of-plane bending regarding the C_α–C(CO)–N part in the peptide bonding and the CH_n–, OH–(benzene ring) part in the side chain (and the corresponding part in the tryptophan residue) as well as the torsion around N–C_α bond in the peptide bonding, were specified from the X-ray determined 390, 399, and 423 non-hydrogen atoms, respectively. A mass-group approximation in which the mass of all hydrogen atoms is included into those of the attached atoms was employed similarly to the previous work.

The geometrical parameters of the molecules of rubredoxins from *Desulfovibrio vulgaris* (Rd:Dv), *Desulfovibrio gigas* (Rd:Dg) and *Clostridium pasteurianum* (Rd:Cp) consisting of 52, 52, and 54 amino acid residues, respectively, were obtained from the Protein Data Bank (PDB). The primary structure (amino acid sequences) of Rd:Dv is shown in Fig. 4. The Urey–Bradley force constant values as well as diagonal values of the out-of-plane bending and the torsional forces used in the present work are essentially the same as those used in the previous work. The Fe–S(cysteine) stretching force was set to be K(Fe–S)=1.36 mdyn $Å^{-1}$ after several trial calculations to obtain a better fitting to the observed RR spectra. This value is somewhat larger than that proposed by Yachandra et al. This is due to the extensive coupling of the Fe–S stretching

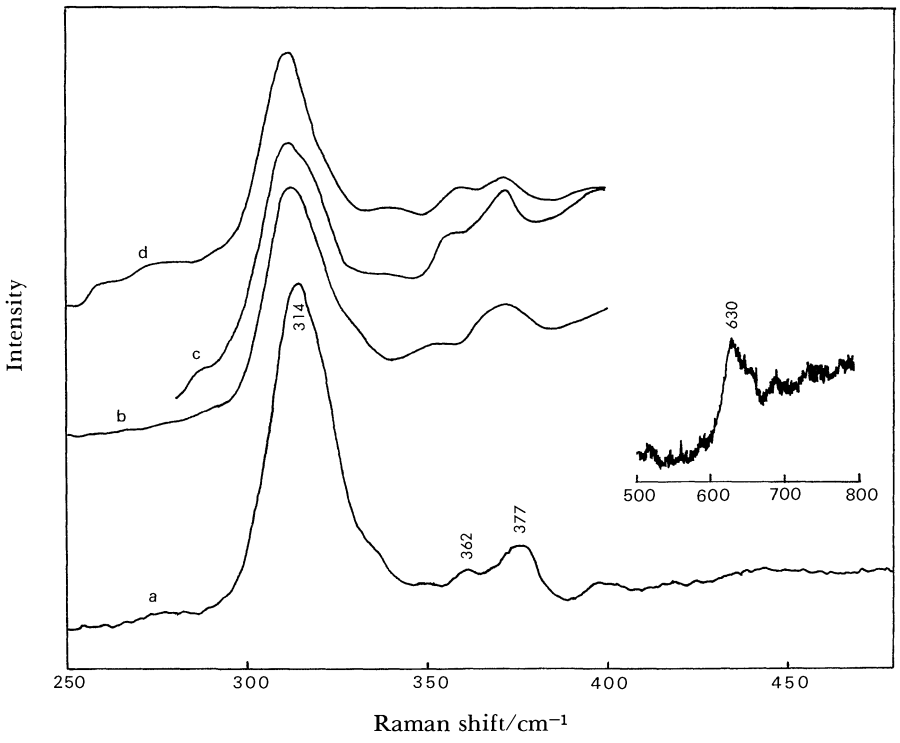

Fig. 1. Resonance Raman spectra of rubredoxin. (a) *Desulfovibrio vulgaris* Miyazaki at 77 K (present measurement). (b) *Megasphera elsdenii*.[4] (c) *Desulfovibrio sulfricans*.[4] (d) *Desulfovibro gigas*.[4]

displacements to the skeletal deformational modes (see below).

The computer programs used for normal coordinate analyses are the same as those used in the previous study. All computational work was done on M682H and S-820 computers at the Computer Center of the University of Tokyo.

Results and Discussion

The resonance and preresonance Raman mechanisms have been discussed in the literature.[7,8] Resonance enhancement is primarily sensitive to a displacement of potential surface of the electronic excited states, which is concerned with the Raman excitation, in totally symmetric normal coordinate space (Albrecht's A term).

The RR spectrum of the oxidized Rd:Dv is shown in Fig. 1, in which the spectra of those from several other bacterial species already reported are also included. The essentially similar spectrum of Rd:Cp has been shown in the literature.[3] The sequence resemblances between the rubredoxins were shown,[10,11] in which, especially, the sequential difference ratio between Rd:Dv and Rd:DvM was found to be only 5/52. The invariant nature in the over-all folding and Fe–S_4 environment in the three-dimensional X-ray structures of Rd:Dv, Rd:Cp, and Rd:Dg has also been described.[11] The present measurement confirms the presence of additional weak bands at ca. 397, ca. 420, and ca. 440 cm^{-1}, while the main part of the spectra (290—390 cm^{-1}) is quite similar to those reported for other species. A distinct overtone signal of the main band (314 cm^{-1}) was detected at 630 cm^{-1}.

The excitation profile of the Raman bands of rubredoxin was discussed by Long et al. The characteristic intense absorption bands of oxidized rubredoxin centered at 20000 and 27000 cm^{-1} can be correlated with charge-transfer transitions from the bonding molecular orbitals localized mainly at the sulfur ligands to the non-bonding orbitals of the iron 3d orbitals[9] of the tetrahedral FeS_4 core; the Fe–S displacement must be therefore occur in the totally symmetric normal coordinate space associated with these electronic transitions (elongation of the Fe–S bondings in the

a) Rubredoxin of *Desulfovibrio vulgaris*: (minus) signs represent the (minus) sign of the corresponding L-matrix elements, l_{in}; only normal vibrations having total PED value of the four Fe–S stretching coordinates exceed 5.8 are presented; Urey-Bradley force constant values are K(Fe–S)=1.360 mdyn $Å^{-1}$, H(Fe–S–CH_2)=0.150, F(Fe–S–CH_2)=0.040, H(S–Fe–S)=0.085, F(S–Fe–S)=0.085 mdyn $Å^{-1}$, and other skeletal forces were set as the same values as the previous analysis of the blue-copper proteins[1] (see text). b) Definition PED=$(F_{ii}l_{in}^2/\sum F_{ii}l_{in}^2)\times 100$ is employed here.

#) While a correction of Thr21 to Asp21 was pointed out on the basis of the DNA sequence (Ref. 10), the original Thr21 is used here as the X-ray structure of Rd:Dv.

electronic excited state). Therefore, the principal RR effect observed at 314 cm^{-1} upon the visible excitation must be primarily related to the totally symmetric Fe–S stretching component in normal coordinates.

The present calculational evidence can be divided into the following four categories:

(1) The totals of 146 (Q_{594}—Q_{739}) modes for Rd:Dv, 146 (Q_{605}—Q_{750}) for Rd:Dg, and 148 (Q_{634}—Q_{781}) for Rd:Cp were obtained in the RR interesting region of the 250—450 cm^{-1}, respectively. The frequency positions of these normal modes are shown in Figs. 2—4. These modes all comprise, principally, deformational displacements within the peptide skeleton, having a minor contribution of skeletal bond stretching coor-

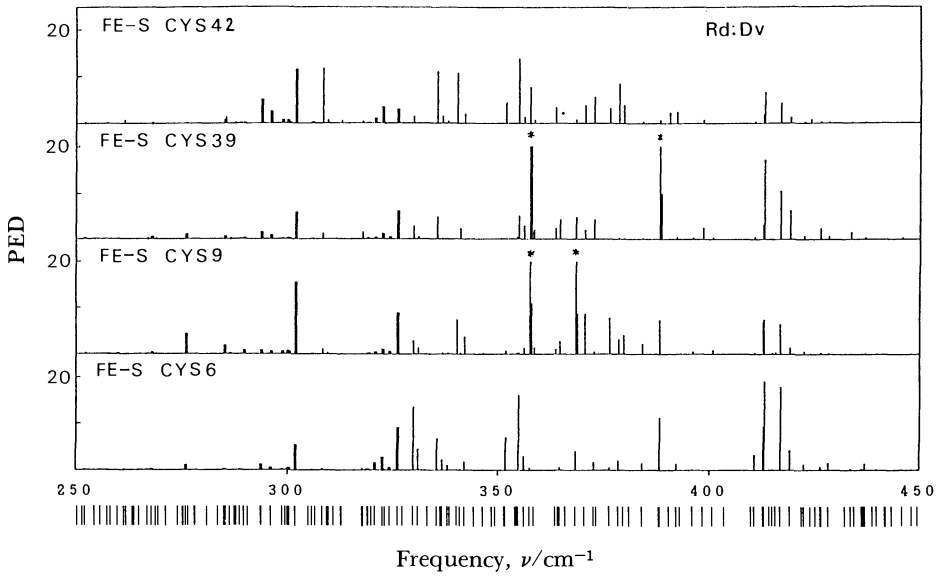

Fig. 2. PED of the four Fe–S stretching coordinates of Rd : Dv. The bold and thin lines denote the normal modes including totally symmetric (with all the same sign of the corresponding L-matrix elements, L_{in}) and non-totally symmetric (with not the same sign) of Fe–S stretching displacements, respectively. The short vertical lines below each figures denote the frequency positions of the normal vibrations. The values exceed 20.0 (asterisked) are depicted by double lines.

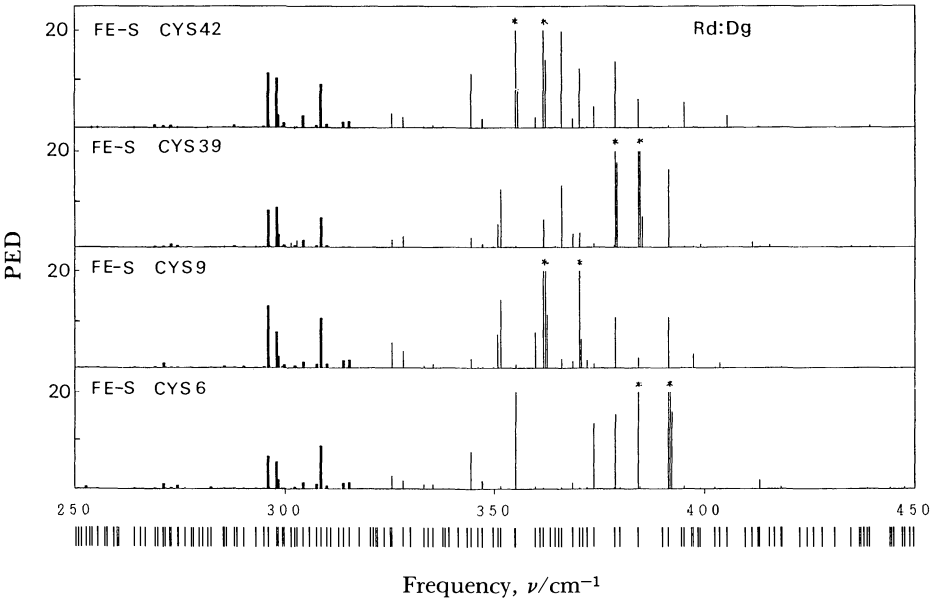

Fig. 3. PED of the four Fe–S stretching coordinates of Rd : Dg. The notation is similar to Fig. 1.

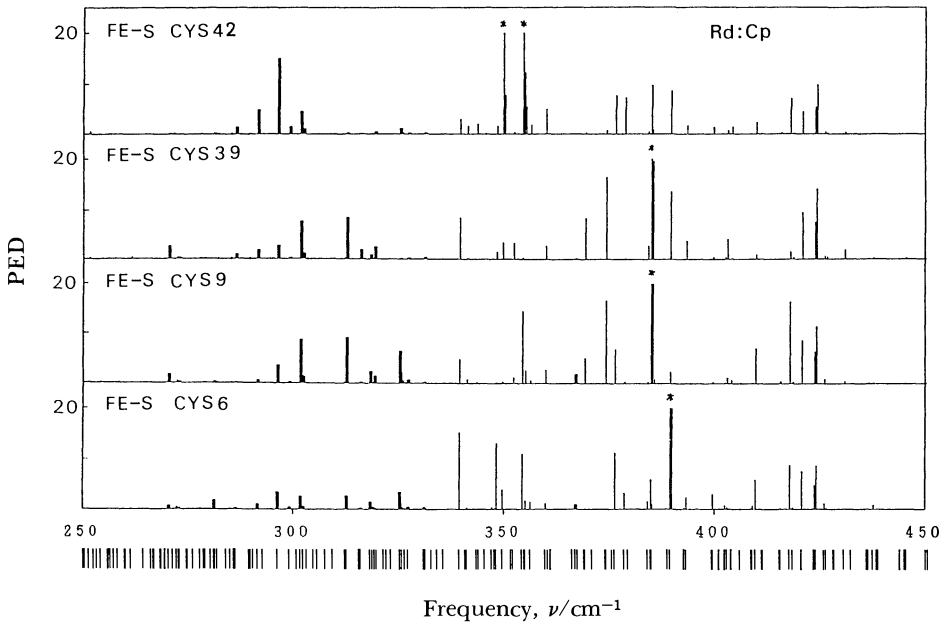

Fig. 4. PED of the four Fe–S stretching coordinates of Rd : Cp. The notation is similar to Fig. 1.

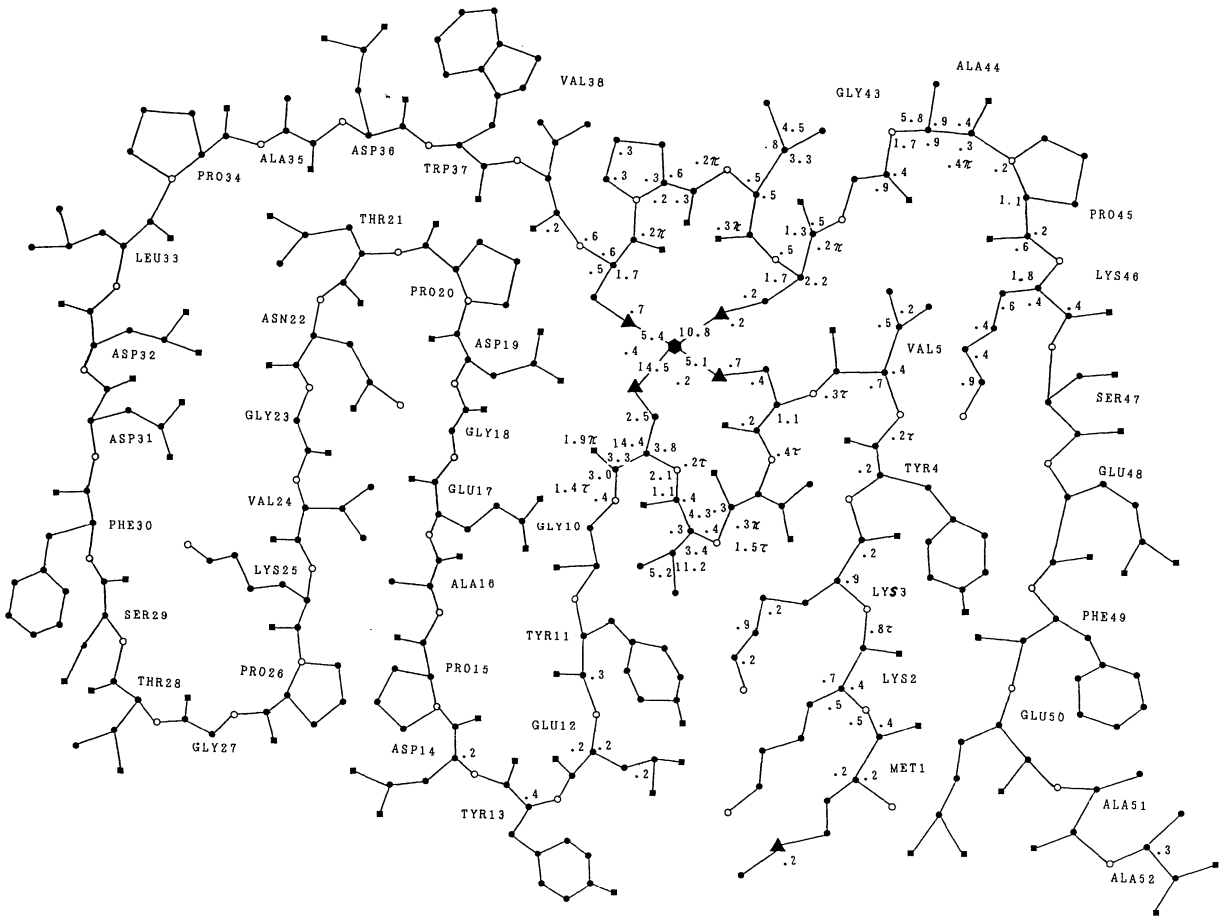

Fig. 5. PED values of the deformational coordinates (bond angle bending, out-of-plane bending: π, and torsional: τ) of the Q_{690} (302.0 cm^{-1}) of Rd : Dv (●: carbon; □: oxygen; ○: nitrogen; ▲: sulfur; ⬢: iron). The values exceed 0.2 are depicted.

dinates (vide infra).

(2) Among the above-mentioned normal vibrations, limited modes involve an actual contribution of the Fe–S stretching displacements (Table 1). In Figs. 2—4. are illustrated the PED values of the four Fe–S(cysteine) stretching coordinates for the normal modes in the 250—450 cm^{-1} region. There is no mode which comprises almost a pure contribution of the Fe–S stretching vibration.

(3) The normal modes involving a totally symmetric Fe–S stretching character, which means in the present study those modes having the same sign as all four corresponding L-matrix elements, appear in the lower-wavenumber region (280—330 cm^{-1}) than those of the non-totally symmetric Fe–S stretching character (not the same sign of all the four corresponding L-matrix elements) (330—450 cm^{-1}). The frequency positions of the former have been confined in the region where the principal RR band was observed, as shown in Fig. 1. The latter well interprets the minor RR bands appearing in the higher-frequency region (including the newly detected bands in the present measurement). An interpretation of the RR intensity of the non-totally symmetrical Fe–S stretching vibrations is possible if the actual reduction of the FeS_4 core symmetry is taken into account. In fact, the 1.2 Å refined X-ray structure of Rd:Cp indicates the smallest and largest S–Fe–S angles of 103.7(4) and 114.3(4) degree and the shortest and longest Fe–S bond lengths of 2.24(1) and 2.39(1) Å, respectively. In C_1, the actual symmetry of the FeS_4 core, all vibrational modes can be RR enhanced.

(4) Normal vibrations having a large (totally or non-totally symmetric) Fe–S stretching contribution comprise skeletal deformational displacements over a considerably wide range of the protein skeleton around the FeS_4 center. The PED values of the 302.0 cm^{-1} mode of Rd:Dv, for example, which has the largest totally-symmetric Fe–S stretching character, are depicted in Fig. 5; the PED values of the bond-angle-bending coordinates (including out-of-plane bending and torsion) summed up for the four normal modes having a large Fe–S stretching character are shown in Fig. 6. Essentially similar figures were obtained for the non-totally symmetric Fe–S stretching vibrations (Fig. 7). It was found that the interaction occurs with the deformational coordinates, roughly speaking, in more than 15 amino acid residues around the FeS_4

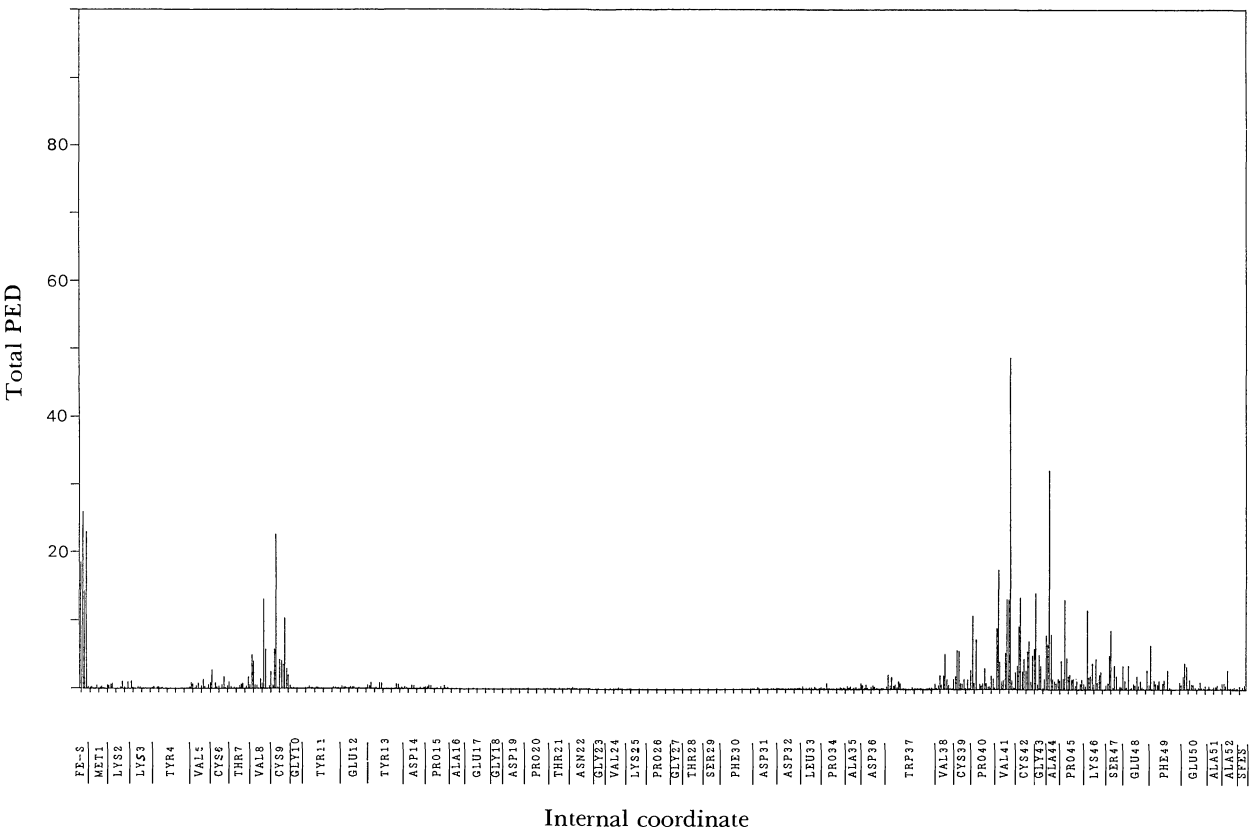

Fig. 6. PED of the deformational coordinates defined in the amino acid residues in the primary structure of Rd : Dv. The Fe–S stretching and S–Fe–S bending coordinates are included at the first top and the last end of the internal coordinates, respectively. The values depicted are those summed up the four normal modes, Q_{673} (326.1 cm^{-1}), Q_{675} (322.5), Q_{690} (302.0), and Q_{694} (293.8) which involve totally symmetric displacements of the Fe–S stretching coordinates.

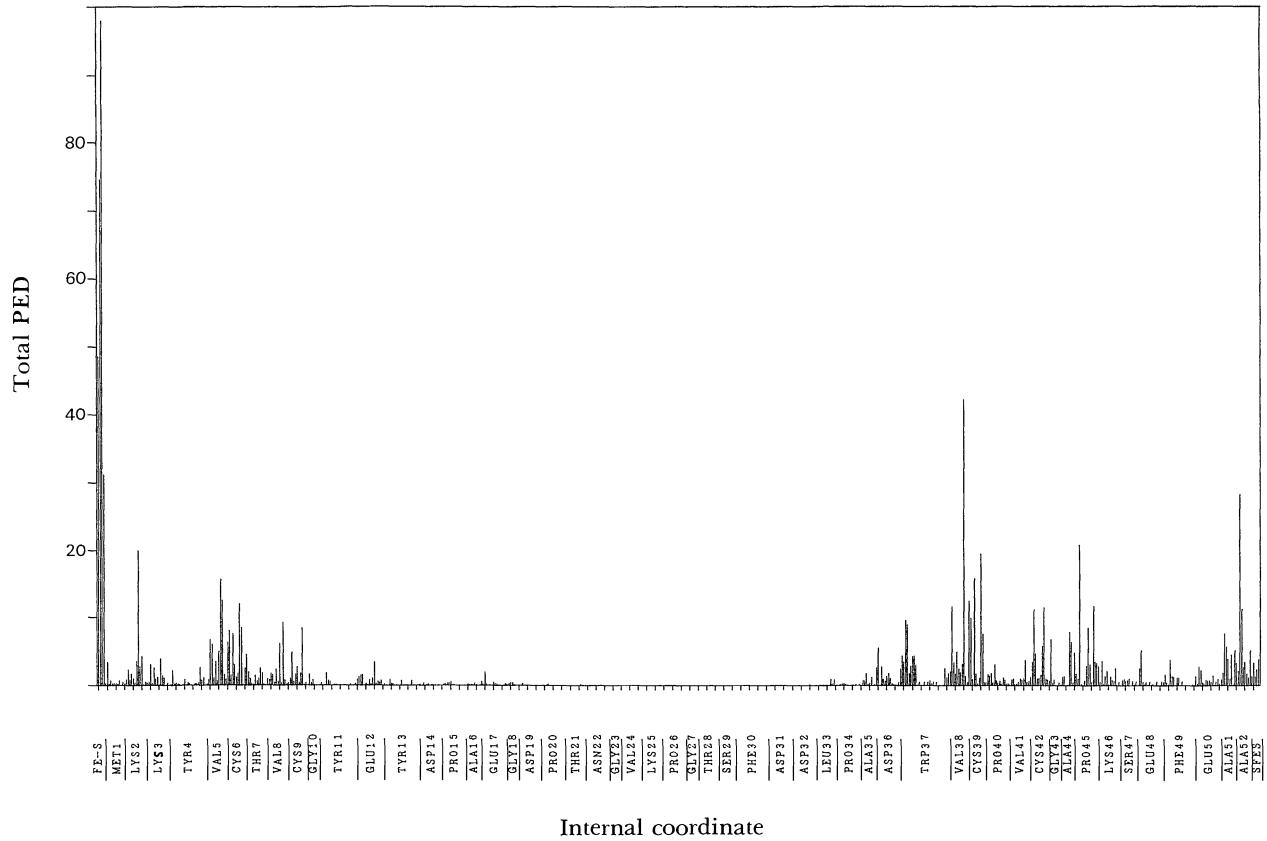

Fig. 7. PED of the deformational coordinates Rd : Dv. The notation is similar to Fig. 4. The values depicted are those summed up the six normal modes, Q_{621} (412.9 cm^{-1}), Q_{623} (388.2), Q_{642} (368.4) and Q_{647} (357.4), Q_{652} (351.7), Q_{664} (335.4) which involve non-totally symmetric displacements of the Fe–S stretching coordinates.

center. The PED ratio of the skeletal bond stretching, (four) Fe–S stretching and skeletal bending coordinates (including out-of-plane bending and torsion) is 8.99:35.77:55.24 for the Q_{693} (302.0 cm^{-1}) modes of Rd:Dv. These strong cooperations between Fe–S stretching and skeletal deformational displacements are not accidental with the particular set value of the force constants. We carried out many trial calculations in which all of the force constant values were either increased or decreased from the original force constant set, while the K(Fe–S) and H, F(S–Fe–S) values are kept constant. Extensive mixing between the Fe–S stretching and the bond angle bending displacements always appeared. In other words, the vibrational characteristics mentioned above, (1)—(4), are retained unless extraordinary small values of the skeletal deformational force constants are employed.

Conclusion

The present assignments differ from those reported by Yachandra et al. regarding the following two points:

(1) The main band at 312 cm^{-1} including the shoulder at ca. 325 cm^{-1}, is assigned to skeletal deformational vibrations having totally symmetrical Fe–S stretching displacements confined to within this frequency region. Moderate bands at ca. 360 and ca. 370 cm^{-1} and newly detected bands in the 390—450 cm^{-1} region are the skeletal deformational modes having non-totally symmetrical Fe–S stretching contributions. Whereas, Yachandra et al.[18] assigned the main band at 312 cm^{-1} to the FeS_4 breathing modes and the shoulder at ca. 325 cm^{-1} and the moderate peaks at ca. 360 and ca. 370 cm^{-1} to split components ($B_1+B_2+A_1$) of the degenerate (T_2:T_d) Fe–S stretching vibration in the C_{2v} effective symmetry of the FeS_4 core. Still, they were puzzled by such a large splitting of the $T_2(T_d)$ vibration.

(2) They suggested the importance of coupling between Fe–S stretching and the Fe–S–C_β (cysteine) and/or S–C_β–C_α (cysteine) bending displacements in order to account for the extraordinary large splitting of the $B_1+B_2+A_1$ components, in addition to accounting for the actual reduction of the FeS_4 core symmetry. The nearly planer geometry of the Fe–S–C_β–C_α sequences present in the proteins has been considered to be advantageous for these couplings. However, our calculational results show no particular impor-

tance of these couplings (Figs. 3—5). They do evidence an extensive coupling between the Fe–S stretching and skeletal deformations around the FeS_4 core.

Though a precise determination of the normal coordinates of the large molecules of the proteins is not the present purpose, a new standpoint for understanding the RR spectra of the rubredoxins is presented regarding the extensive mixing of the Fe–S stretching and the skeletal deformational displacements in the peptide skeleton around the FeS_4 core. The resonance Raman spectroscopy has been believed to constitute the most poweful method for identifying the iron-sulfur core in ferredoxins.[12–17] However, there are still problems remaining to be analyzed: for example, concerning the not negligible difference in the RR spectra between the ferredoxin from spinach and adrenodoxin,[13] both of which were proven to have similar Fe_2S_6 cluster, and in the RR spectra of the 4Fe-type ferredoxins and HiPIP-type,[16] especially, in the higher wavenumber Fe–S(terminal thiolate) stretching region of 350—400 cm^{-1}. This work will be extended to ferredoxins which contain a multi-iron cluster. A theoretical base for a further utilization of the RR spectroscopy will also be developed.

(Received September 26, 1990)

The fifth overtone spectra of aryl C-H stretching vibrations of fluorobenzene, chlorobenzene, and bromobenzene in nonpolar solvents were observed using photoacoustic spectroscopy. In a nonpolar solvent, such as hexane, the three components of the overtones of the *o*-, *m*-, and *p*-C-H stretching vibrations could be easily decomposed owing to line-width narrowing. We could therefore obtain more detailed information concerning the chemical properties of these C-H bonds.

A number of investigations on the high overtone spectra of C-H stretching vibrations have elucidated that the spectra can be interpreted on the basis of a local mode model.[1,2] According to the local mode model, equivalent C-H bonds have the same vibrational frequency. For example, all of the six C-H bonds of benzene are equivalent, and their high overtones are observed at the same frequencies. On the other hand, for molecules of monosubstituted benzene having the three types of C-H bonds (*o*-, *m*-, and *p*-) three different frequencies must be observable in the region of the high overtone of the C-H stretching vibrations. It is, however, rather difficult to determine their frequencies.

As far as we know, there have been few reports in which the different frequencies of the three components of the overtone of the C-H stretching vibrations have been observed in the neat liquid states of monosubstituted benzenes. Mizugai and Katayama previously observed the frequency shifts of the overtones of monosubstituted benzene from that of benzene; they found that the shifts are related to the chemical and physical properties of the C-H bonds.[3] Furthermore, a doublet structure was observed in the overtone spectra of para-substituted benzenes.[4] However, it was impossible to distinguish the three components of the overtone spectra in monosubstituted benzenes, since the line width of the overtone spectrum becomes wider in the neat liquid state due to an intermolecular interaction.

In the present article we report on the experimental results of the high overtone spectra of the C-H vibrations of halobenzenes in nonpolar solvents using a photoacoustic technique; the observed results for the fifth overtone spectra of the C-H stretching vibrations elucidated that it is possible to distinguish the frequencies of three components of the overtones which correspond to the *o*-, *m*-, and *p*-C-H bonds.

Because the fifth overtone spectra of the C-H stretching vibrations are very broad and have almost 100 cm^{-1} width, even in the vapor phase,[5] the overtone spectra which we observed using a nonpolar solvent, did not split into three components, though considerable changes of the spectral shape upon dilution were observed. We can thus distinguish the three frequencies by means of a least-square method using the fifth overtone spectra of benzene in a nonpolar solvent as an elemental spectral line shape. Linear relations were found between the frequency shifts of the overtones from that of benzene $\Delta\tilde{\nu}_{\mathrm{I}}$, $\Delta\tilde{\nu}_{\mathrm{II}}$, or $\Delta\tilde{\nu}_{\mathrm{III}}$ and the inductive contribution of Hammett σ of halogen atoms. The values of $\Delta\tilde{\nu}_{\mathrm{I}}/\Delta\tilde{\nu}_{\mathrm{II}}$ and $\Delta\tilde{\nu}_{\mathrm{III}}/\Delta\tilde{\nu}_{\mathrm{II}}$ were found to be 1.7 and 0.43, respectively, and were independent of F, Cl, and Br substituents.

Our results indicate that we can measure the frequencies of the overtone spectra rather precisely in a nonpolar solvent, and that more detailed information concerning the chemical and physical properties of *o*-, *m*-, and *p*-C-H bonds in monosubstituted benzenes can easily be obtained.

Experimental

The extremely weak absorption of the fifth overtone of the C-H vibrations of benzene or substituted benzenes in various solvents can be observed relatively easily using photoacoustic spectroscopy with a pulsed dye laser light source and a piezoelectric transducer detector.[6]

Figure 1 shows our experimental arrangement. A flash lamp-pumped dye laser (Chromatix CMX-4) was used to excite the liquid samples. A laser pulse of 3—5 mJ output, 1 μs width and 5 Hz repetition rate was incident on the quartz cell which was loaded with the sample. The piezoelectric transducer (obtained from TOKIN Co., Ltd.) was attached to one side of the cell with thin layer of vacuum grease. The photoacoustic signal was detected by using the piezoelectric detector; after being amplified with a low-noise amplifier and gated through a box car averager, the signal intensity was normalized through a signal from the power monitor. The samples were either spectrograde or guaranteed reagent grade and were obtained from Tokyo Kasei Co., Ltd.

Results and Discussion

Figure 2 shows changes in the fifth overtone spectra of the C-H stretching vibrations of fluorobenzene

† Present address: Teikyo University of Technology.

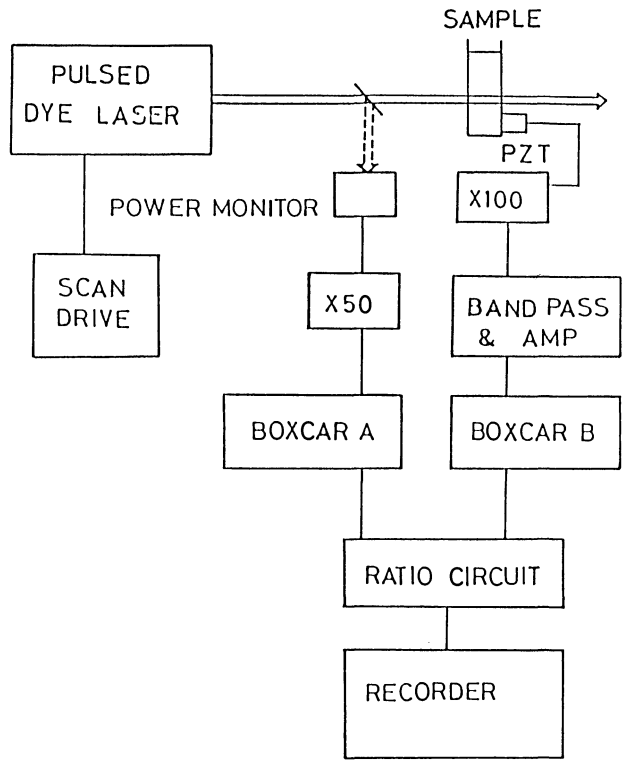

Fig. 1. Experimental arrangement.

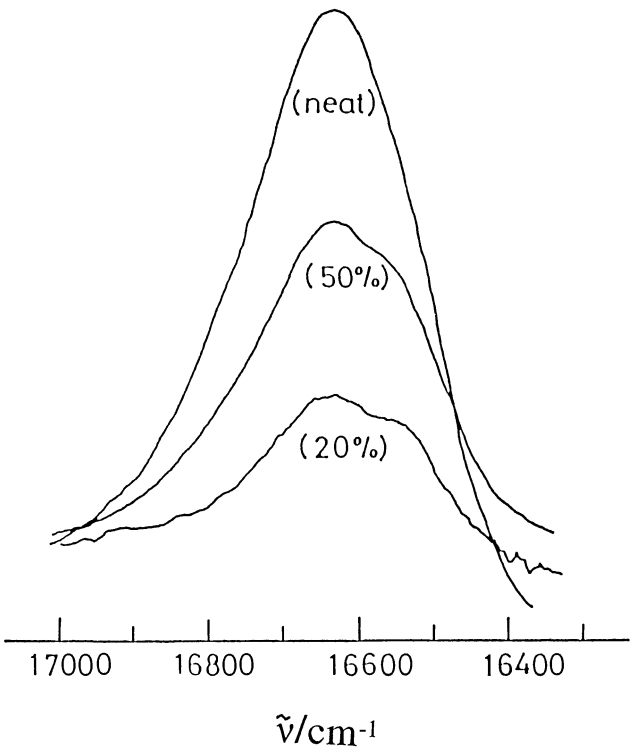

Fig. 2. The fifth overtone spectra of the C–H stretching vibrations of fluorobenzene diluted with hexane.

Table 1. Frequencies and the Line Widths of the Fifth Overtones of C–H Stretching Vibrations of Benzene in the Neat Liquid State and in Hexane Solutions of Various Concentrations

Concentration	Frequency	Linewidth
%	cm^{-1}	cm^{-1}
Neat	16475	270
50	16475	260
30	16480	250
10	16485	235
5	16485	230

when diluted with hexane. Though the spectrum in the neat liquid state conprises a single broad band centered at 16620 cm^{-1}, its line shape at 50% dilution with hexane exhibits a shoulder on the lower frequency side. In a 20% solution, the shoulder becomes more prominent and shifts by about 10 cm^{-1} to the blue side. The spectra of the fifth overtone of the C–H stretching vibrations of benzene in hexane also change upon dilution. The width becomes narrower and the peak of the spectrum is observed at the higher frequency when diluted. Table 1 represents our experimental results. Patel and Tam have also reported similar data for a CCl_4 solution.[6] The decrease in the interaction between the molecules gives rise to linewidth narrowing, and shifts of the the absorption frequency are induced by a change in the refractive index of the solution.[7]

Although fluorobenzene has three nonequivalent aryl C-H bonds, the frequency differences of their vibrational overtones are far smaller than the absorption linewidth in the neat liquid, and it is impossible to determine the frequencies of the three components of the overtone. When diluted with hexane, however, a decrease in the molecular interaction gives rise to a narrowing of the spectrum width and , hence, the rather complex absorption spectra are obtained (Fig. 2). The structures of the spectra correspond to the overtones of the three components of the C–H stretching vibrations. It must be mentioned that the shift of the peak of the overtone spectra of fluorobenzene in a hexane solution is not so evident, presumably because the difference in the refractive indices between hexane and fluorobenzene is relatively small, i.e., 1.3723 and 1.4683, respectively.

In order to analyze the observed overtone spectra, the shape of the spectra was calculated using appropriate assumptions: (1) the widths of the fifth overtone spectra of the *o*-, *m*-, and *p*-C–H stretching vibrations of fluorobenzene in hexane solutions are somewhat smaller than those of the corresponding overtones of benzene in its neat liquid state, and (2) the intensity ratio of the overtones of the *o*-, *m*-, and *p*-C–H stretching vibrations is 2:2:1. Furthermore, the peaks of the absorptions are assumed to be at 16665, 16580,

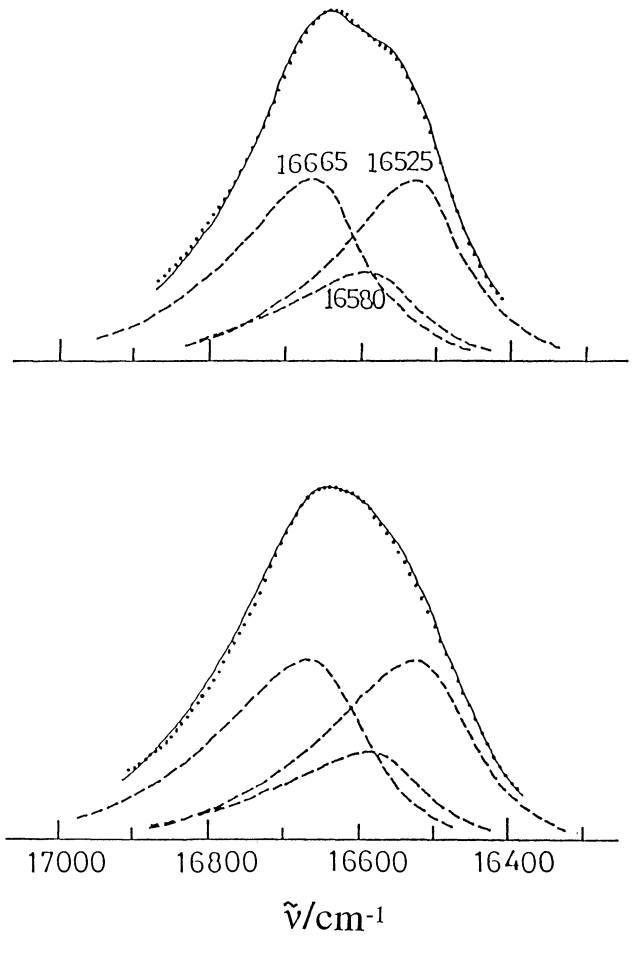

Fig. 3. Observed line shape of the spectra of the fifth overtone of the C–H stretching vibration of fluorobenzene and the calculated results, upper; 50% in hexane, lower; neat liquid state. Dashed curves; the calculated spectra of *o*-, *m*-, and *p*-components, solid curve; whole spectrum, dotted line; the observed spectrum.

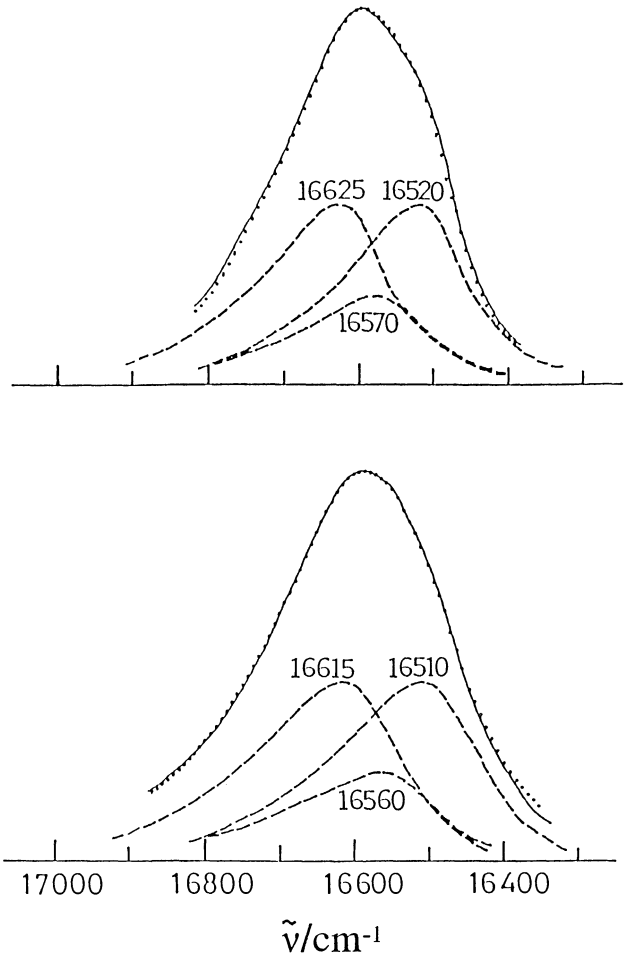

Fig. 4. Observed line shape of the spectra of the fifth overtone of the C–H stretching vibration of chlorobenzene and the calculated results, upper; 20% in hexane, lower; neat liquid state. Dashed curves; the calculated spectra of *o*-, *m*-, and *p*-components, solid curve; the whole spectrum, dotted line; the observed spectrum.

and 16525 cm^{-1} with an intensity ratio of 2:1:2; the width (fwhm) of the absorption is considered to be 235 cm^{-1}, as is shown by the dashed curves in the upper part of Fig. 3. The calculated shape of the entire spectrum was obtained as exhibited by the solid line of this figure; the results are in good agreement with those observed.

If we assume that each component has a width wider than 265 cm^{-1} in the neat liquid state, the superposed spectrum would not show any structure. Substantial agreement between the calculated and observed spectra was obtained, as is shown in the lower part of Fig. 3.

The overtone spectra of chlorobenzene slightly varies with the concentration in a hexane solution; though little change was observed in a 50% solution, we could see a slight modification of the line shape in a 20% solution. The observed line shapes are indicated by the dotted lines in Fig. 4; the solid curves indicate the calculated line shapes of the overtone of chlorobenzene, the upper part for a 20% solution in hexane, the lower part for the neat liquid state. In a hexane solution of chlorobenzene the frequency shift is not negligible; in a 20% solution the blue shift is about 10 cm^{-1}.

The overtone spectra of bromobenzene and iodobenzene in hexane solutions were also observed. Though for bromobenzene, quite similar results to the fluorobenzene case were obtained, for iodobenzene the line shape did not show any appreciable vibration with dilution up to a concentration of 5%, and we were unable to determine the frequencies of their three components.

The frequencies of the three components of the fifth overtones of fluorobenzene, chlorobenzene, and bromobenzene determined by the present analysis are listed in Table 2; the frequency shifts from that of

Table 2. Frequencies and the Shifts of Three Components of the Fifth Overtones of C–H Stretching Vibrations of Halobenzens and σ_I Values of Halogen Atoms

Molecules		Frequencies	Shift	σ_I values
		cm^{-1}	cm^{-1}	
Fluorobenzene	$\tilde{\nu}_I$	16665	190	0.56
	$\tilde{\nu}_{II}$	16580	105	
	$\tilde{\nu}_{III}$	16525	50	
Chlorobenzene	$\tilde{\nu}_I$	16615	140	0.51
	$\tilde{\nu}_{II}$	16560	85	
	$\tilde{\nu}_{III}$	16510	35	
Bromobenzene	$\tilde{\nu}_I$	16605	130	0.50
	$\tilde{\nu}_{II}$	16550	75	
	$\tilde{\nu}_{III}$	16505	30	

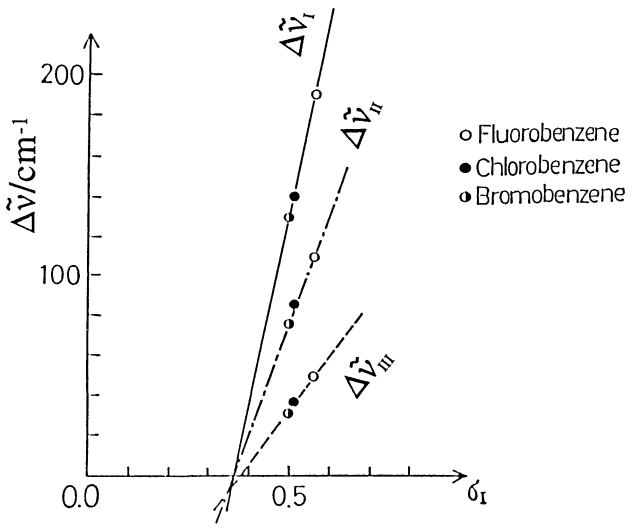

Fig. 5. The relation between the frequency shifts and σ_I of the substituents.

benzene, $\Delta\tilde{\nu}_I$, $\Delta\tilde{\nu}_{II}$, and $\Delta\tilde{\nu}_{III}$ are also presented.

Though it is obvious that the three components are due to the *o*-, *m*-, and *p*-C–H bonds, it is not easy to assign the frequency of each component to individual bonds. However, the results of the calculation mentioned above indicate that the component $\Delta\tilde{\nu}_{II}$ can be ascribed to the *p*-C–H vibration. With regard to the other components, it was difficult from the present analysis to determine to what type of C–H bond the $\tilde{\nu}_I$ and $\tilde{\nu}_{III}$ frequencies can be ascribed, though we may tentatively assume that $\tilde{\nu}_I$, the higher frequency vibration, results from the *o*-C–H bond.

Mizugai and Katayama[3] have reported that the shift of the $\Delta\tilde{\nu}$ frequency is proportional to σ_I, an inductive contribution of the Hammett σ. Having determined the frequencies of the three components of the C–H overtone in halobenzenes, we plotted the $\Delta\tilde{\nu}_I$, $\Delta\tilde{\nu}_{II}$, and $\Delta\tilde{\nu}_{III}$ frequency shifts as a function of σ_I, respectively. Figure 5 shows their relations. The present results indicate that a linear relation can be established between the frequency shift of each component and σ_I of the substituent. The straight lines for $\Delta\tilde{\nu}_I$ $\Delta\tilde{\nu}_{II}$, and $\Delta\tilde{\nu}_{III}$ in Fig. 5 intersect at around 3.5 of the σ_I value, but not at the origin of the figure, in contrast with the results for the overtone spectra of the aryl C–H vibration of $C_6H_5CH_{3-n}Cl_n$;[8] almost the same results were obtained in our previous report[3] concerning the C–H overtone spectra of the neat liquid state of C_6H_5X. Our present proposition is, however, an extension of the conclusion derived by Mizugai and Katayama. Since the σ_I value of an I atom is 0.43, the relative frequency shifts of the overtone spectra of iodobenzene are expected to be small. This is the reason that we were unable to resolve the three components of the C–H overtone vibration in the present experiment. It is reasonable to assume that since the inductive contribution of the substituent to the *o*-C–H bond is larger than that to the *m*-C–H bond, the higher frequency $\tilde{\nu}_I$ of the overtone of the C–H vibration may be attributed to the *o*-C–H bond and that the lower frequency $\tilde{\nu}_{III}$ belongs to the *m*-C–H bond.

We can derive another conclusion from the results of Fig. 5, that the ratio $\Delta\tilde{\nu}_I:\Delta\tilde{\nu}_{II}:\Delta\tilde{\nu}_{III}$ is independent of the substituents; the following two relations were obtained:

$$\Delta\tilde{\nu}_I/\Delta\tilde{\nu}_{II} = 1.7$$

and

$$\Delta\tilde{\nu}_{III}/\Delta\tilde{\nu}_{II} = 0.43\,.$$

These relations indicate that the relative shifts of the three components of the overtone frequencies are independent of the substituted atoms; we thus confirmed from the observed results of the high overtone of the C–H stretching vibrations that almost the same behavior can be expected in certain types of C–H bonds of the halobenzenes. Consequently, we can see that the specific C–H bonds of halobenzenes have the same chemical and physical properties.

Conclusion

We have demonstrated that the frequencies of the three components of the fifth overtone of aryl C–H vibrations of halobenzenes can be distinguished by using hexane as a solvent. These results can help us to understand the properties of the *o*-, *m*-, and *p*-C–H bonds respectively.

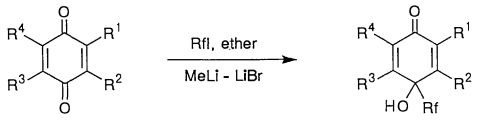
Treatment of 4-perfluoroalkyl-4-hydroxy-2,5-hexadien-1-one (4-perfluoroalkyl-4-quinol), prepared from the reaction of 1,4-benzoquinone with perfluoroalkyllithium, with acetic anhydride–sulfuric acid gave a mixture of 2,4-diacetoxy-1-perfluoroalkylbenzene and 1,2-diacetoxy-4-perfluoroalkylbenzene in a comparable ratio. When 4-perfluoroalkyl-4-quinols bearing a methyl group ortho to the perfluoroalkyl group were subjected to the rearrangement, acetoxymethyl compounds were obtained in addition to diacetoxybenzene derivatives. Only 1,3-migration was observed in the cases of 2,4-di-*t*-butyl-4-perfluorooctyl-4-quinol and 4-hydroxy-4-perfluoroalkyl-1(4*H*)-naphthalenone, while the reaction of 2,6-dimethyl and 2-methoxy derivatives gave only 1,2-shift products. Reaction routes to the apparent 1,2- and 1,3-acetoxyl migration products are discussed.

The quinol rearrangement and Thiele–Winter acetoxylation are very useful methods for the preparation of polyhydroxybenzenes.[1,2] These cationic rearrangements are considered to proceed via cyclohexadienyl cations, stability of which affects product distributions. Migratory aptitude of substituents is also important in the quinol rearrangement. On treatment with sulfuric acid in methanol, 4-alkyl-4-hydroxy-2,5-hexadiene-1-ones (abbreviated to 4-alkyl-4-quinols throughout this paper) undergo rearrangement followed by aromatization to give alkylhydroquinones,[3] while the reaction in acetic anhydride–sulfuric acid takes another route to afford 4-alkylresorcinol diacetates via 1,2-migration of acetoxyl group rather than alkyl group.[4] Unusual 1,3-acetoxyl migration has been observed in the rearrangement of quinols derived from *o*-quinones[5] and sterically hindered 4-quinols.[6] Acid treatment of 2,6-di-*t*-butyl-4-phenyl-4-quinol in acetic anhydride was reported to give 3,4-diacetoxy-5-*t*-butylbiphenyl.[6] We reported the preliminary findings that the acid-catalyzed rearrangement of 4-perfluoroalkyl-4-quinols **1a—d** in acetic anhydride gave a comparable mixture of 1,3-diacetoxy-4-perfluoroalkylbenzenes **3a—d** and 1,2-diacetoxy-4-perfluoroalkylbenzenes **5a—d**. The apparent 1,3-migration of acetoxyl group giving **5a—d** is quite interesting in the rearrangement of simple quinols. From the synthetic point of view, this quinol rearrangement may offer a new useful method for the synthesis of polyhydroxylated perfluoroalkylbenzenes.[8] In this paper, we described the acid-catalyzed rearrangement of 4-perfluoroalkyl-4-quinols.

Results and Discussion

Preparation of 4-Perfluoroalkyl-4-quinols. We first examined the preparation of 4-perfluoroalkyl-4-quinols **1** by the perfluoroalkylation of several quinones with perfluoroalkyllithiums (Eq. 1). The reaction was carried out under slightly modified conditions of the reported procedure,[9] because of low solubility of quinones in ether at low temperatures. We used dichloromethane or toluene as a co-solvent and a Dry Ice–acetone bath was substituted for a Dry Ice–acetonitrile bath to prevent precipitation of quinones upon cooling. Although the stability of perfluoroalkyllithiums decreased sharply with increase of the reaction temperature,[10] yields of quinols obtained were comparable under these modified conditions (Table 1). The yields were not improved by the uses of 0.5 to 2 equivalents of quinone to perfluoroalkyllithium.



(1)

1

A regioisomeric problem arose from perfluoroalkylation of unsymmetrically substituted quinones. Perfluorooctyllithium reacted with methyl-1,4-benzoquinone almost equally at both carbonyls to give an isomeric mixture of **1a** and **1b** (**1a**:**1b**=ca. 7:6, determined by GC), which could be easily separated by column chromatography (**1a**, 20%; **1b**, 21%). The reaction of 2,6-dimethyl-1,4-benzoquinone and 2-methoxyl-1,4-benzoquinone with perfluoroalkyllithium also afforded the isomeric quinols (**1h**, 37%; **1i**, 12% and **1m**, 7%; **1n**, 42%, respectively). On the other hand, perfluorooctyllithium added selectively to the less hindered carbonyl of 2-*t*-butyl- and 2,6-di-*t*-butyl-1,4-benzoquinone to afford **1j** and **1l** in 46% and 77% yields, respectively. Quinols **1g**, **1k**, and **1o** were obtained from 2,5-dimethyl-, 2,5-di-*t*-butyl-, and 2,5-dichloro-1,4-benzoquinones in respective yields of 36%, 40%, and 14%. The low yield observed in the perfluoroalkylation of dichloroquinone may be attributed to its high oxidation potential.[11] Naphtho-

quinone also reacted with perfluorooctyllithium to give **1p** in a 41% yield.

Rearrangement of Quinols. The acid-catalyzed rearrangement of various quinoles was examined under the following general conditions; To a quinol in acetic anhydride (0.033 M) were added several drops of concd sulfuric acid (one drop per 0.33 mmol) at ambient temperature. The progress of reaction was monitored by TLC and GC. After one day, the reaction was quenched by adding saturated aqueous sodium hydrogencarbonate. The results are summarized in Table 1 and Chart 1.

Rearrangement of methyl-4-quinol **1e** was completed within a similar period of time as quinol **1a—d** (overnight). Proton NMR analysis of the product mixture from **1e** showed the presence of three diacetoxybenzenes **3e**, **4e**, and **6e** in a ratio of 78:13:9. Major product **3e** was isolated in 69% yield by column chromatography. On the other hand, the rearrangement of isomeric methyl-4-quinol **1f** was incomplete under the standard conditions and appreciable amounts of quinol acetate **2f** remained unchanged in the reaction mixture (**2f**:**4f**:**5f**:**6f**:**7f**=34:2:24:5:34). When this mixture was treated with Ac_2O/H_2SO_4 overnight at 80—90 °C, the rearrangement of the remaining quinol acetate was completed (**4f**:**5f**:**6f**:**7f**=4:35:8:53). Chromatography of the latter product mixture gave acetoxymethyl derivative **7f** and a mixture of diacetoxybenzenes **5f** and **6f** in 30% and 31% yields, respectively. Attempted isolation of diacetoxybenzenes **4f—6f** was unsuccessful.

Under the standard conditions, dimethyl-4-quinols **1g**, **1h** and **1i** underwent smooth rearrangement within 1 h. The reaction of **1g** afforded a mixture of **3g**, **6g**, and **7g**, the ratio of which was 77:17:6 based on both

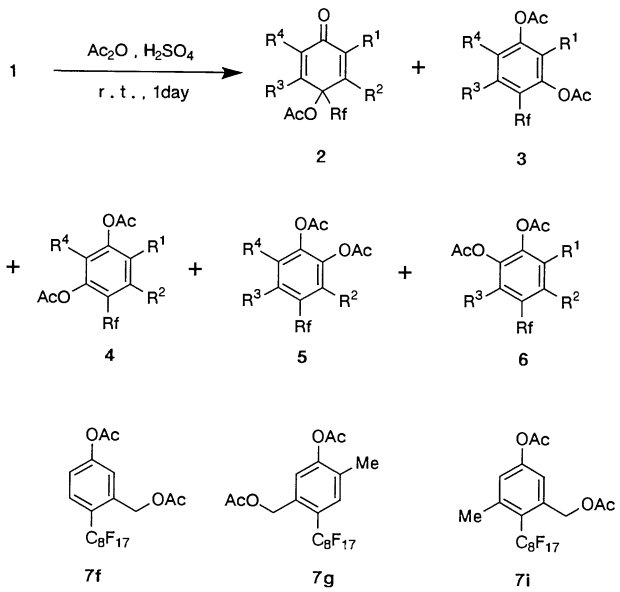

Chart 1.

^1H NMR and capillary GC determinations. Major components **3g** and **6g** were isolated in 69% and 14% yields, respectively. The acid-catalyzed rearrangement of **1h** and **1i** gave **3h** and **7i** as the sole product respectively in isolated yields of 97% and 93%. One of the *t*-butyl groups was replaced by acetoxyl group on the acid treatment of di-*t*-butyl-4-quinols **1k** and **1l**. In the reaction of 2-*t*-butyl-4-quinol **1j** the displacement of the *t*-butyl group was the major reaction to give 1,2-diacetoxy-4-perfluorooctylbenzene (**5j**=**5a**) predominantly. 2-Methoxy-4-quinol **1m** was susceptible to 1,2-acetoxyl migration to afford **4m** in a 79% yield. In contrast, 3-methoxy-4-quinol **1n** resisted such

rearrangement and only the corresponding acetate **2n** was obtained. Similar resistance toward aromatization was encountered in the reaction of quinol **1o**, where only quinol acetate **2o** was obtained in almost quantitative yield. It is worthy to mention that the Thiele–Winter type acetoxylation did not take place with the parent quinone, 2,5-dichloro-1,4-benzoquinone.[12] Quinol **1p** derived from 1,4-naphthoquinone underwent the apparent 1,3-acetoxyl migration to give **5p** in 61% yield together with quinol acetate **2p** (38%). The rearrangement of quinol acetate **2p** did not proceed under the usual conditions. Using perchloric acid in place of sulfuric acid caused the complete disappearance of **1p**, giving **5p** in 86% yield.

Hydrolysis of Diacetoxybenzenes. We reported that the hydrolysis of 4-perfluorobutylresorcinol diacetate (**3c**) and 4-perfluorobutylcatechol diacetate (**5c**) with potassium hydroxide in THF–methanol brought about simultaneous substitution of benzylic fluorine atoms to give perfluorobutanoyl derivatives.[7] When heated in methanol in the presence of *p*-toluenesulfonic acid (PTSA), however, these diacetates were readily hydrolyzed to parent resorcinol **8** and catechol **9** (Eq. 2; Table 2). The resorcinols and catechols were separated by column chromatography on silica gel, although the isolated yields of the latter compounds were low probably due to their air-sensitive property. In order to isolate the catechols more efficiently from the hydrolyzed mixture, the catechols were protected as acetonides before chromatography. Thus, an original mixture of **8a** and **9a** was heated under reflux in acetone[13] and the resulting product was chromatographed on silica gel to obtain an intimate mixture of catechol acetonide **10** and unexpected product **11** in very poor yields, along with resorcinol **8a** intact (Eq. 3). Separation of **11** from **10** was performed by preparative GPC and the structure of **11** was established by analytical and spectroscopic data (NMR, IR, and MS) as an acetal derived from catechol **5a** and mesityl oxide.

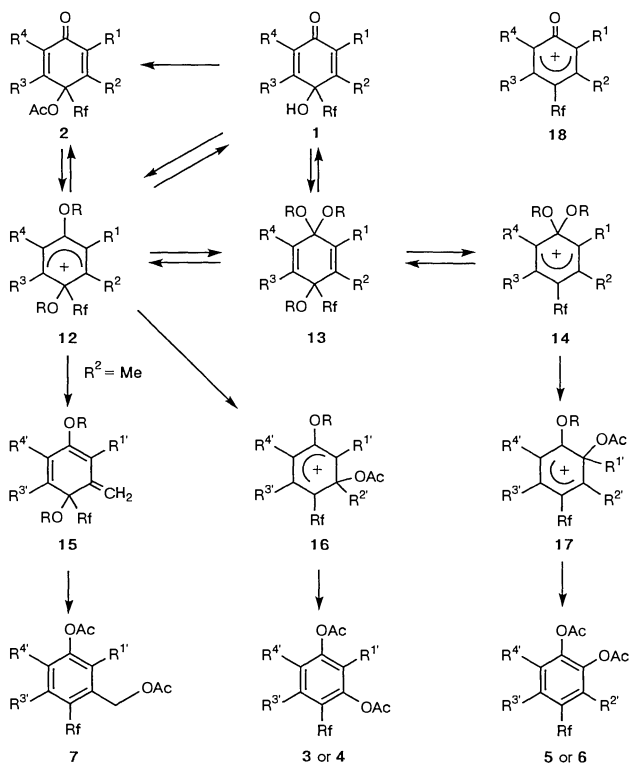
Mechanism of the Acid-Catalyzed Rearrangement. We would like to discuss the mechanistic aspects of the acid rearrangement of quinols. Our proposal of this rearrangement is shown in scheme 1. 1,2-Acetoxyl migration of 4-perfluoroalkyl-4-quinols may occur via benzenium ions **12** (R=H or Ac) and **16** similarly in the cases 4-alkyl- and 4-aryl-4-quinols. However, when perfluoroalkyl groups were introduced, energy gap between the two benzenium ions **12** and **16** becomes considerably large because of destabilization, leading to other pathway. When R^2 is methyl, **12** loses a proton to give quinol tautomer **15**, which is subject to a facile allylic rearrangement to afford acetoxymethyl derivative **7**.[14] It is noteworthy that such an acetoxylation on methyl group was not observed in the Thiele–Winter acetoxylation on mono- and dimethyl-1,4-quinones.[1] Another pathway leading to catechol



Scheme 1.

derivatives **5** and **6** may be thought as follows: sp^3-hydridization of the carbonyl carbon of **1** takes place to afford (hemi)acetal **13**. Then, **13** loses an RO group at 4 position to give rather unstable benzenium ion **14** of which acetoxyl group migrates to give **5** or **6** via benzenium ion **17**. This proposal is based on the fact that carbonyl functional groups tend to be hydrated or acetalized when electron-withdrawing groups are attached. Moreover, benzenium ion **18** doubly destabilized by perfluoroalkyl and carbonyl groups is unlikely.[15] If the benzenium ion **16** is stabilized by electron-donating $R^{1'}$ and $R^{4'}$, the pathway to give **3** or **4** is dominant (**1g**, **1h**, and **1m**). In the case of **1n**, as benzenium ion **12** is strongly stabilized by R^2 (MeO), the rearrangement to **16** becomes disadvantageous. sp^3-Hybridization of the carbonyl to **13** is also unfavorable, because the carbonyl is considered as vinylogous ester. Thus, the rearrangement of **1n** did not proceed and quinol acetate **2n** was obtained quantitatively.

Bulky *t*-butyl group disfavors acetoxyl group migrating vicinal to it and tends to be replaced.[1] In the case of **1k**, an interesting point is that *t*-butyl group is substituted by acetoxyl group. Steric hindrance between the vicinal *t*-butyl and perfluoroalkyl groups is very severe when they are linked by two sp^2 carbons. Therefore, the pathway via **12** to **16** ($R^{2'}=R^{4'}=t$-Bu) may be more favorable than that via **14** to **17** ($R^{1'}=R^{3'}=t$-Bu). Formation of quinol acetal **13** from **1l** ($R^1=R^4=t$-Bu) would be expected to encounter large steric hindrance by the two *t*-butyl groups. However, the CPK model structure can be build up if at least one of OR groups at C-1 is OH. It should be noted that quinol acetates **2l** and **2p** did not react, while the corresponding quinols **1l** and **1p** did undergo only 1,3-migration to give **5l** and **5p** under the same conditions. On the other hand, the reaction of simple quinol acetates **2a—d** gave the same results as those obtained from the reaction of quinols **1a—d**. These facts might be interpreted if we take it into account that sp^3-hybridization of the carbonyl group to **13** is sterically interfered by C-4 substituents (acetoxyl and perfluoroalkyl). In the reaction of methyl-4-quinols **1e** and **1f**, regioselectivity of the acetoxyl migration shows sharp contrast to that observed in the Thiele-Winter reaction of the parent quinone, where acetoxylation occurs mainly para to the methyl group.[1] The reason for the difference is nuclear at present.

Experimental

Melting points were measured with a Yanagimoto micromelting point apparatus and are uncorrected. Unless otherwise noted, all NMR spectra were observed with a GSX-270 spectrometer by using $CDCl_3$ as solvent, tetramethylsilane as an internal standard for ^1H and ^{13}C, and $CFCl_3$ for ^{19}F. Mass spectra were measured with a Hitachi M80LCAPI spectrometer under the following ionizing conditions: EI (electron impact ionization, 20 eV) and CI (chemical ionization, 70 eV, methane as CI gas). IR spectra were recorded on a Hitachi 270-30 spectrophotometer. Column chromatogaphy was carried out using Wakogel C-200. Preparative GPC was performed using JAI LC-80 with JAI-1H (20 mmID×60 cm) and JAI-2H (20 mmID×60 cm) columns. Diethyl ether was distilled from sodium benzophenone ketyl. Dichloromethane and toluene were distilled from calcium hydride and stored over 4A molecular sieves. Perfluoroalkyl iodides were purified by simple distillation. Methyllithium was titrated prior to use. Other commercially available materials were used without further purification.

Perfluoroalkylation of 1,4-Quinones. General Procedure: A 1,4-quinone (10 mmol) and a perfluoroalkyl iodide (12 mmol) are dissolved in a mixture of 100 ml of dry ether and 50 ml of dry toluene (or dichloromethane), and cooled down to −40—−50 °C by a Dry Ice-acetonitrile bath. In case the quinone begins to separate, dry toluene (or dichloromethane) is added to keep the solution homogenous. An ethereal solution of methyllithium-lithium bromide (11 mmol) is added at given temperature range over 30 min. During the course of addition, the yellow solution turned to a bluish purple suspension. After stirring for 1 h, the reaction is quenched with aqueous NH_4Cl. The organic phase is separated and the aqueous phase is extracted with ether. The combined extracts are washed with brine and dried over Na_2SO_4. The solvent is evaporated and the residue is chromatographed on silica gel ($CHCl_3$–ether). The quinol obtained is recrystallized from chloroform/hexane or dichloromethane/hexane.

4-Hydroxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (1a). Colorless needles (chloroform), mp 132—133 °C.[9]

4-Hydroxy-4-perfluorohexyl-2,5-cyclohexadien-1-one (1b). Colorless crystals (chloroform), mp 111—113 °C. ^1H NMR (acetone-d_6) δ=6.42 (2H, d, J=10.4 Hz), 6.49 (1H, s), and 7.09 (2H, d, J=10.4 Hz); ^{13}C NMR (acetone-d_6) δ=72.44 (tt, J=24 and 1 Hz), 105—125 (6C), 132.25, 143.11 (m), and 184.91; ^{19}F NMR (acetone-d_6) δ=−81.65 (3F, tt, J=10 and 2 Hz), −117.94 (2F, m), −118.42 (2F, m), −121.27 (2F, m), −122.24 (2F, m), and −125.70 (2F, m); IR (KBr) 3228vs, 1674vs, 1628vs, 1406m, 1390m, 1366m, 1318m, and 1300—1100vs cm^{-1}; MS (CI) m/z 429 (M^++1, 100), 411 (26), 393 (11), 138 (18), and 109 (72). Found: C, 33.62; H, 1.23%. Calcd for $C_{12}H_5F_{13}O_2$: C, 33.66; H, 1.18%.

4-Hydroxy-4-perfluorobutyl-2,5-cyclohexadien-1-one (1c). Colorless needles (dichloromethane/hexane), mp 88—90 °C. ^{19}F NMR δ=−80.73 (3F, tt, J=10 and 3 Hz), −118.21 (2F, m), −119.46 (2F, m), and −125.59 (2F, m); IR (KBr) 3220vs, 1674vs, 1628vs, 1408m, 1392m, 1358m, and 1300—1100vs cm^{-1}; MS (CI) m/z 329 (M^++1, 100), 311 (29), 293 (6), 138 (19), and 109 (59). Found: C, 36.66; H, 1.59%. Calcd for $C_{10}H_5F_9O_2$: C, 36.60; H, 1.54%.

4-Hydroxy-4-perfluoroethyl-2,5-cyclohexadien-1-one (1d). Colorless needles (dichloromethane/hexane), mp 47—48 °C. ^{19}F NMR δ=−78.45 (3F, s) and −122.18 (2F, m); IR (KBr) 3232vs, 1672vs, 1626vs, 1402m, 1384m, 1344s, and 1300—1100vs cm^{-1}; MS (EI) m/z 228 (M^+, 4), 202 (1), 133 (3), and 109 (100). Found: C, 41.88; H, 2.28%. Calcd for $C_8H_5F_5O_2$: C, 42.12; H, 2.21%.

4-Hydroxy-2-methyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (1e). Colorless crystals (dichloromethane/hexane), mp 69—70 °C. ^1H NMR (acetone-d_6) δ=1.86 (3H, s), 3.50 (1H, br s), 6.33 (1H, d, J=9.8 Hz), 6.77 (1H, m), and 6.97 (1H, dm,

J=9.8 Hz); ^{13}C NMR (acetone-d_6) δ=16.17, 72.80 (t, J=24 Hz), 105—125 (8C), 132.10, 138.14, 139.36 (m), 143.11 (t, J=2 Hz), and 186.65; ^{19}F NMR (acetone-d_6) δ=−80.69 (3F, tt, J=10 and 2 Hz), −117.91 (2F, m), −118.47 (2F, m), −120.8—−121.8 (6F, m), −122.27 (2F, m), and −125.75 (2F, m); IR (KBr) 3416vs, 1678vs, 1642s, 1408m, 1372m, 1330s, and 1300—1100vs cm^{-1}; MS (EI) m/z 542 (M^+, 4), 525 (1), 523 (2), 475 (1), and 123 (100). Found: C, 32.93; H, 1.42%. Calcd for $C_{15}H_7F_{17}O_2$: C, 33.23; H, 1.31%.

4-Hydroxy-3-methyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (1f). Colorless crystals (dichloromethane/hexane), mp 122—123 °C. ^{1}H NMR (acetone-d_6) δ=2.13 (3H, m), 6.20 (1H, m), 6.30 (1H, dm, J=10.1 Hz), 6.40 (1H, br s), and 7.00 (1H, dm, J=10.1 Hz); ^{13}C NMR (acetone-d_6) δ=19.73, 74.07 (tm, J=24 Hz), 105—125 (8C), 131.00, 131.88, 143.97 (m), 155.27, and 185.43; ^{19}F NMR (acetone-d_6) δ=−80.83 (3F, tt, J=10 and 2 Hz), −114.30 (1F, dm, J=279 Hz), −116.61 (1F, dm, J=279 Hz), −118.88 (2F, m), −120.8—−121.8 (6F, m), −122.37 (2F, m), and −125.87 (2F, m); IR (KBr) 3416vs, 1676vs, 1632vs, 1448m, 1400m, 1372m, 1330s, and 1300—1100vs cm^{-1}; MS (EI) m/z 542 (M^+, 1), 523 (1), 475 (1), and 123 (100). Found: C, 33.38; H, 1.35%. Calcd for $C_{15}H_7F_{17}O_2$: C, 33.23; H, 1.31%.

4-Hydroxy-2,5-dimethyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (1g). Colorless crystals (dichloromethane/hexane), mp 91—92 °C. ^{1}H NMR (acetone-d_6) δ=1.84 (3H, d, J=1.2 Hz), 2.11 (3H, m), 6.18 (2H, m), and 6.75 (1H, m); ^{13}C NMR (acetone-d_6) δ=19.73 (m), 74.07 (ddm, J=22 and 21 Hz), 105—125 (8C), 130.99, 131.88, 143.96 (m), 155.26, and 185.43; ^{19}F NMR (acetone-d_6) δ=−80.65 (3F, tm, J=10 Hz), −114.29 (1F, dm, J=278 Hz), −116.47 (1F, dm, J=278 Hz), −118.99 (2F, m), −121.0—−121.5 (6F, m), −122.27 (2F, m), and −125.72 (2F, m); IR (KBr) 3396vs, 1678m, 1634vs, 1456m, 1398m, 1378m, 1328m, and 1300—1100vs cm^{-1}; MS (CI) m/z 557 (M^++1, 54), 539 (23), 166 (22), and 137 (100). Found: C, 34.41; H, 1.64%. Calcd for $C_{14}H_5F_{17}O_2$: C, 34.55; H, 1.63%.

4-Hydroxy-2,6-dimethyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (1h). Colorless crystals (dichloromethane/hexane), mp 86—87 °C. ^{1}H NMR δ=1.94 (6H, s), 4.40 (1H, br s), and 6.72 (2H, s); ^{13}C NMR δ=16.07, 71.13 (t, J=24 Hz), 105—125 (8C), 135.35, 138.78, and 185.17; ^{19}F NMR δ=−81.25 (3F, tt, J=10 and 2 Hz), −119.50 (4F, m), −121.9—−122.5 (6F, m), −123.21 (2F, m), and −126.61 (2F, m); IR (KBr) 3424vs, 1676s, 1644vs, 1446s, 1396vs, and 1300—1100vs cm^{-1}; MS (CI) m/z 557 (M^++1, 47), 539 (37), 166 (9), and 137 (100). Found: C, 34.31; H, 1.66%. Calcd for $C_{14}H_5F_{17}O_2$: C, 34.55; H, 1.63%.

4-Hydroxy-3,5-dimethyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (1i). Colorless crystals (dichloromethane/hexane), mp 104—106 °C. ^{1}H NMR (acetone-d_6) δ=2.15 (6H, s), 6.18 (2H, s), and 6.22 (1H, s); ^{13}C NMR (acetone-d_6) δ=19.90 (t, J=4 Hz), 76.69 (tt, J=20 and 2 Hz), 105—125 (8C), 131.54, 155.71, and 185.22; ^{19}F NMR (acetone-d_6) δ=−80.65 (3F, tt, J=10 and 2 Hz), −111.75 (2F, m), −119.35 (2F, m), −120.95 (2F, m), −121.39 (4F, m), −122.29 (2F, m), and −125.76 (2F, m); IR (KBr) 3364vs, 1672vs, 1626vs, 1450m, 1386s, 1356s, 1328m, and 1300—1100vs cm^{-1}; MS (CI) m/z 557 (M^++1, 68), 539 (12), 537 (29), 166 (29), and 137 (100). Found: C, 34.42; H, 1.51%. Calcd for $C_{14}H_5F_{17}O_2$: C, 34.55; H, 1.63%.

2-*t*-Butyl-4-hydroxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (1j). Colorless crystals (dichloromethane/hexane), mp 92 °C. ^{1}H NMR δ=1.25 (9H, s), 2.74 (1H, br s), 6.33 (1H, d, J=10.1 Hz), 6.63 (1H, s), and 6.77 (1H, d, J=10.1 Hz); IR (KBr) 3216vs, 2964m, 1672vs, 1626vs, 1460m, 1368s, and 1300—1100vs cm^{-1}. MS (CI) 585 (M^++1, 8), 567 (59), 165 (100), and 123 (52). Found: C, 36.93; H, 2.18%. Calcd for $C_{18}H_{13}F_{17}O_2$: C, 37.00; H, 2.24%.

2,5-Di-*t*-butyl-4-hydroxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (1k). Colorless crystals (dichloromethane/hexane), mp 164—165 °C. ^{1}H NMR δ=1.23 (9H, s), 1.35 (9H, s), 2.81 (1H, s), 6.37 (1H, s), and 6.50 (1H, s); IR (KBr) 3220vs, 2969s, 1658s, 1618vs, 1468s, 1370s, and 1300—1100vs cm^{-1}; MS (CI) 641 (M^++1, 11), 623 (13), 585 (15), 250 (20), and 222 (100). Found: C, 41.20; H, 3.27%. Calcd for $C_{22}H_{21}F_{17}O_2$: C, 41.26; H, 3.31%.

2,6-Di-*t*-butyl-4-hydroxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (1l). Colorless crystals (dichloromethane/hexane), mp 82—83 °C. ^{1}H NMR δ=1.24 (18H, s), 3.30 (1H, br s), and 6.52 (2H, s); ^{13}C NMR δ=29.04, 35.29, 71.97 (t, J=24 Hz), 105—125 (8C), 132.34, 150.94, and 185.56; ^{19}F NMR δ=−81.27 (3F, tt, J=10 and 3 Hz), −118.76 (2F, m), −119.53 (2F, m), −122.24 (6F, m), −123.21 (2F, m), and −126.62 (2F, m); IR (KBr) 3496vs, 2964vs, 1672s, 1648vs, 1486m, 1464m, 1366s, and 1300—1100vs cm^{-1}; MS (CI) 641 (M^++1, 57), 625 (13), 623 (11), 599 (9), 597 (10), 222 (100), 221 (64), and 111 (38). Found: C, 41.37; H, 3.37%. Calcd for $C_{22}H_{21}F_{17}O_2$: C, 41.26; H, 3.31%.

4-Hydroxy-2-methoxy-4-perfluorobutyl-2,5-cyclohexadien-1-one (1m). Colorless crystals (dichloromethane/hexane), mp 69—71 °C. ^{1}H NMR δ=3.28 (br s), 3.74 (3H, s), 5.76 (1H, m), 6.41 (1H, d, J=10.1 Hz), and 6.94 (1H, m); ^{13}C NMR δ=55.36, 73.07 (t, J=24 Hz), 105—125 (4C), 107.82, 130.48, 141.71, 152.52, and 179.41; ^{19}F NMR δ=−81.31 (3F, tt, J=10 and 3 Hz), −119.23 (2F, m), −120.29 (2F, m), and −126.43 (2F, m); IR (KBr) 3544s, 3454s, 3088s, 1672m, 1623s, 1437m, 1353s, and 1300—1100vs cm^{-1}; MS (CI) m/z 359 (M^++1, 71), 341 (46), 327 (53), 168 (21), and 139 (100). Found: m/z 358.0258. Calcd for $C_{11}H_7F_9O_3$: M, 358.0251.

4-Hydroxy-3-methoxy-4-perfluorobutyl-2,5-cyclohexadien-1-one (1n). Colorless crystals (dichloromethane/hexane), mp 76—77 °C. ^{1}H NMR δ=3.85 (3H, s), 5.68 (1H, d, J=1.5 Hz), 6.36 (1H, dd, J=10.1 and 1.5 Hz), and 6.73 (1H, dd, J=10.1 and 1.2 Hz); ^{13}C NMR δ=56.31, 72.00 (t, J=23 and 2 Hz), 103.16, 108.48 (tm, J=270 Hz), 111.23 (ttt, J=269, 37, and 31 Hz), 115.18 (tt, J=270 and 32 Hz), 117.22 (qt, J=288 and 33 Hz), 130.52, 138.14 (dt, J=3 and 1 Hz), 168.81 (d, J=2 Hz), and 186.49; ^{19}F NMR δ=−81.37 (3F, tt, J=10 and 3 Hz), −116.80 (1F, dm, J=279 Hz), −118.20 (1F, dm, J=279 Hz), −121.72 (2F, m), −126.20 (1F, dddt, J=293, 20, 11, and 3 Hz), −126.60 (1F, dddt, J=293, 19, 14 and 3 Hz); IR (KBr) 3252vs, 1672vs, 1636s, 1608vs, 1356s, and 1300—1100vs cm^{-1}; MS (CI) m/z 359 (M^++1, 100), 343 (11), 341 (30), 339 (14), 327 (59), 323 (21), 313 (36), 168 (35), 140 (77), and 139 (76). Found: C, 36.59; H, 1.87%. Calcd for $C_{11}H_7F_9O_3$: C, 36.89; H, 1.97%.

2,5-Dichloro-4-hydroxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (1o). Colorless crystals (ether/hexane), mp 98—99 °C. ^{1}H NMR (acetone-d_6) δ=6.83 (1H, s), 7.32 (1H, m), and 7.41 (1H, br s); ^{13}C NMR (acetone-d_6) δ=75.94 (t, J=23 Hz), 105—125 (8C), 131.49, 135.78, 139.18 (m), 152.29, and 176.85; ^{19}F NMR (acetone-d_6) δ=−80.61 (3F, tm, J=10 Hz), −114.06 (1F, dm, J=279 Hz), −115.80 (1F, dm, J=279 Hz), −118.69 (2F, m), −121.00 (2F, m), −121.30 (4F, m), −122.21 (2F, m), and −125.69 (2F, m); IR (KBr) 3860s, 1682vs, 1600s, 1332m, 1332m, and 1300—1100vs cm^{-1}; MS

(CI) *m/z* 601 (6), 599 (37), 597 (56), 581 (20), 579 (36), 577 (27), 563 (21), 543 (24), 180 (100), and 178 (98). Found: C, 27.90; H, 0.66%. Calcd for $C_{14}H_3Cl_2F_{17}O_2$: C, 28.16; H, 0.51%.

4-Hydroxy-4-perfluorohexyl-1(4*H*)-naphthalenone (1p). Colorless crystals (dichloromethane/hexane); mp 91.5 °C. ^{1}H NMR δ=3.32 (1H, s), 6.57 (1H, d, J=10.4 Hz), 7.04 (1H, dm, J=10.4 Hz), 7.58 (1H, td, J=7.6 and 1.2 Hz), 7.69 (1H, td, J=7.6 and 1.5 Hz), 7.89 (1H, dm, J=7.9 Hz), and 8.12 (1H, dd, J=7.6 and 1.5 Hz); ^{13}C NMR δ=72.61 (dd, J=25 and 22 Hz), 105—125 (6C), 126.91, 127.92 (t, J=3 Hz), 130.15, 130.89 (m), 131.95, 133.10, 137.37, 142.17 (m), and 183.38; ^{19}F NMR δ=−81.32 (3F, tt, J=10 and 2 Hz), −116.26 (1F, dm, J=278 Hz), −118.66 (1F, dm, J=278 Hz), −118.77 (2F, m), −122.30 (2F, m), −123.27 (2F, m), and −126.63 (2F, m); IR (KBr) 3312vs, 1666s, 1634s, 1602s, 1308s, and 1300—1100vs cm^{-1}; MS (CI) *m/z* 479 (M^++1, 41), 461 (20), 188 (10), and 159 (100). Found: C, 39.94; H, 1.53%. Calcd for $C_{16}H_7F_{13}O_2$: C, 40.19; H, 1.48%.

4-Acetoxy-4-perfluorooctyl-2,5-cyclohexadien-1-one (2a). Colorless crystals (dichloromethane/hexane), mp 50—51 °C. ^{1}H NMR δ=2.17 (3H, s), 6.53 (2H, d, J=10.1 Hz), and 6.84 (2H, d, J=10.1 Hz); ^{13}C NMR δ=20.87 (m), 77.22 (tt, J=26 and 3 Hz), 105—125 (8C), 132.98, 138.88, 167.47, and 183.56; ^{19}F NMR δ=−81.24 (3F, tt, J=10 and 2 Hz), −116.46 (2F, m), −118.84 (2F, m), −122.15 (6F, m), −123.17 (2F, m), and −126.62 (2F, m); IR (KBr) 1774vs, 1680vs, 1636s, 1374s, and 1300—1100vs cm^{-1}; MS (EI) *m/z* 570 (M^+, 3), 528(3), 512 (6), 492 (23), and 173 (100). Found: C, 33.30; H, 1.23%. Calcd for $C_{16}H_7F_{17}O_3$: C, 33.70; H, 1.24%.

4-Acetoxy-4-perfluorohexyl-2,5-cyclohexadien-1-one (2b). Colorless oil. ^{19}F NMR δ=−81.39 (3F, tt, J=10 and 3 Hz), −116.44 (2F, m), −118.82 (2F, m), −122.19 (2F, m), −123.10 (2F, m), and −126.62 (2F, m); IR (KBr) 1776vs, 1680vs, 1640s, 1370s, and 1300—1100vs cm^{-1}; MS (EI) *m/z* 470 (M^+, 2), 428 (4), 412 (16), and 143 (100). Found: *m/z* 470.0225. Calcd for $C_{14}H_7F_{13}O_3$: M, 470.0187.

4-Acetoxy-4-perfluorobutyl-2,5-cyclohexadien-1-one (2c). Colorless oil. ^{19}F NMR δ=−81.21 (3F, tt, J=10 and 3 Hz), −116.72 (2F, m), −119.89 (2F, m), and −126.46 (2F, m); IR (KBr) 1776vs, 1678vs, 1640s, 1386m, 1372m, 1356m, and 1300—1100vs cm^{-1}; MS (EI) *m/z* 370 (M^+, 19), 328 (26), 312 (26), 300 (27), and 143 (100). Found: *m/z* 370.0251. Calcd for $C_{14}H_7F_9O_3$: M, 370.0250.

4-Acetoxy-4-perfluoroethyl-2,5-cyclohexadien-1-one (2d). Colorless oil. ^{19}F NMR δ=−78.76 (3F, s) and −120.99 (2F, s); IR (KBr) 1776vs, 1680vs, 1640s, 1370s, and 1300—1100vs cm^{-1}; MS (EI) *m/z* 270 (M^+, 19), 228 (100), 208 (11), and 159 (24). Found: *m/z* 270.0293. Calcd for $C_{10}H_7F_5O_3$: M, 270.0314.

4-Acetoxy-3-methyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (2f). Colorless crystals (dichloromethane/hexane), mp 89—91 °C. ^{1}H NMR δ=2.05 (3H, d, J=1.2 Hz), 2.22 (3H, s), 6.38 (1H, m), 6.45 (1H, dd, J=10.3 and 1.8 Hz), and 6.81 (1H, dt, J=10.3 and 2.8 Hz); ^{13}C NMR δ=19.08 (t, J=4 Hz), 20.69, 78.96 (t, J=24 Hz), 105—125 (8C), 131.68, 132.05, 139.80, 150.31, 167.49, and 184.28; ^{19}F NMR δ=−81.27 (3F, t, J=10 Hz), −115.56 (2F, m), −118.94 (2F, m), −122.13 (2F, m), −123.19 (2F, m), and −126.59 (2F, m); IR (KBr) 1754vs, 1672s, 1640vs, 1366s, and 1300—1100vs cm^{-1}; MS (CI) 585 (M^++1, 31), 543 (38), 527 (60), 507 (69), and 157 (100). Found: C, 34.95; H, 1.51%. Calcd for $C_{17}H_9F_{17}O_3$: C, 34.95; H, 1.55%.

4-Acetoxy-2,5-di-*t*-butyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (2k). Colorless crystals (dichloromethane/hexane), mp 95—97 °C. ^{1}H NMR δ=1.22 (9H, s), 1.26 (9H, m), 2.19 (3H, s), 6.36 (1H, dd, J=5.2 and 3.0 Hz), and 6.52 (1H, s); IR (KBr) 2972s, 1782s, 1754s, 1714s, 1666s, 1640s, 1370s, and 1300—1100vs cm^{-1}; MS (CI) 683 (M^++1, 26), 667 (6), 655 (13), 640 (28), 627 (100), 623 (43), 607 (33), and 585 (59). Found: C, 42.38; H, 3.49%. Calcd for $C_{24}H_{23}F_{17}O_3$: C, 42.24; H, 3.40%.

4-Acetoxy-2,6-di-*t*-butyl-4-perfluorooctyl-2,5-cyclohexadien-1-one (2l). Colorless crystals (dichloromethane/hexane), mp 53—54 °C. ^{1}H NMR δ=1.24 (18H, s), 2.15 (3H, s), and 6.43 (2H, s); ^{13}C NMR δ=21.18, 28.98, 35.42, 78.04, (t, J=24 Hz), 105—125 (8C), 130.51, 151.40, 167.43, and 185.68; ^{19}F NMR δ=−81.26 (3F, tt, J=10 and 3 Hz), −116.80 (2F, m), −118.96 (2F, m), −122.15 (2F, m), −122.36 (4F, m), −123.30 (2F, m), and −126.63 (2F, m); IR (KBr) 2960s, 1764vs, 1672s, 1648s, 1462s, 1368s, 1330s, and 1300—1100vs cm^{-1}; MS (CI) 683 (M^++1, 3), 663 (2), 655 (3), 627 (100), 623 (57), 607 (46), and 584 (71). Found: C, 41.87; H, 3.43%. Calcd for $C_{24}H_{23}F_{17}O_3$: C, 42.24; H, 3.40%.

4-Acetoxy-3-methoxy-4-perfluorobutyl-2,5-cyclohexadien-1-one (2n). Colorless crystals (hexane), mp 29—30 °C. ^{1}H NMR δ=2.18 (3H, s), 3.78 (3H, s), 5.78 (1H, d, J=1.5 Hz), 6.44 (1H, dd, J=10.1 and 1.5 Hz), and 6.60 (1H, d, J=10.1 Hz); ^{13}C NMR δ=20.38 (m), 56.48 (m), 76.96 (tt, J=23 and 2 Hz), 105.00, 105—125 (4C), 132.67, 135.56 (m), 166.16, 167.34, and 185.49; ^{19}F NMR δ=−81.28 (3F, tt, J=10 and 2 Hz), −116.08 (1F, dm, J=280 Hz), −116.73 (1F, dm, J=280 Hz), −120.98 (2F, m), and −126.27 (2F, m); IR (KBr) 1764vs, 1666s, 1606vs, 1354s, and 1300—1100vs cm^{-1}; MS (CI) *m/z* 401 (M^++1, 100), 359 (38), 358 (46), 339 (17), and 323 (40). Found: C, 38.70; H, 2.23%. Calcd for $C_{13}H_9F_9O_4$: C, 39.02; H, 2.27%.

4-Acetoxy-2,5-dichloro-4-perfluorooctyl-2,5-cyclohexadien-1-one (2o). Colorless crystals (dichloromethane/hexane); mp 91—92 °C. ^{1}H NMR δ=2.26 (3H, s), 6.84 (1H, s), and 7.00 (1H, m); ^{13}C NMR δ=20.48, 78.71 (t, J=25 Hz), 105—125 (8C), 131.58, 134.75, 136.06 (m), 147.55, 167.20, and 175.78; ^{19}F NMR δ=−81.30 (3F, tm, J=10 Hz), −115.25 (2F, m), −118.87 (1F, m), −119.07 (1F, m), −121.86 (2F, m), −122.12 (2F, m), −122.33 (2F, m), −123.19 (2F, m), and −126.61 (2F, m); IR (KBr) 3064m, 1770vs, 1686vs, 1602s, 1372s, 1332m, and 1300—1100vs cm^{-1}; MS (EI) *m/z* 640 (2), 638 (4), 582 (9), 580 (15), 213 (63), and 212 (100). Found: C, 30.09; H, 0.77%. Calcd for $C_{16}H_5Cl_2F_{17}O_{15}$: C, 30.03; H, 0.79%.

4-Acetoxy-4-perfluorohexyl-1(4*H*)-naphthalenone (2p). Colorless oil. ^{1}H NMR δ=2.20 (3H, m), 6.64 (1H, d, J=10.4 Hz), 6.99 (1H, dm, J=10.4 Hz), 7.61 (3H, m), and 8.18 (1H, dm, J=7.9 Hz); ^{13}C NMR δ=21.05, 77.71 (t, J=25 Hz), 105—125 (6C), 126.27 (t, J=3 Hz), 127.24, 130.12, 131.84 (2C), 132.59, 134.78, 140.39, 167.30, and 183.09; ^{19}F NMR δ=−81.31 (3F, tt, J=10 and 2 Hz), −116.14 (2F, t, J=15 Hz), −118.36 (2F, m), −122.21 (2F, m), −123.14 (2F, m), and −126.59 (2F, m); IR (neat) 3072m, 1770vs, 1680vs, 1638s 1600vs, 1460m, 1370s, and 1300—1100vs cm^{-1}; MS (CI) *m/z* 521 (M^++1, 23), 507 (8), 479 (35), 461 (33), 443 (19), and 159 (100). Found: C, 41.40; H, 1.69%. Calcd for $C_{18}H_9F_{13}O_3$: C, 41.56; H, 1.74%.

Acid Treatment of Quinols. General Procedure: To an acetic anhydride solution (30 ml) of a quinol (1 mmol) was added three drops of concd H_2SO_4 at room temperature. After stirring overnight, the reaction was quenched by careful addition of a saturated aqueous solution of $NaHCO_3$

and the mixture was stirred until gas evolution ceased. The mixture was extracted with ether and the ethereal extract was washed by brine, dried with Na_2SO_4, and evaporated. The residue was chromatographed on silica gel (hexane–hexane/ether).

2,4-Diacetoxy-1-perfluorooctylbenzene (3a) and 1,2-Diacetoxy-4-perfluorooctylbenzene (5a=5j). Colorless crystals (dichloromethane/hexane); mp 56—58 °C. ^{19}F NMR δ= −81.34 (both 3F, t, J=10 Hz), −108.79 (**5a**, 2F, t, J=13 Hz), −110.77 (**3a**, 2F, t, J=13 Hz), −121.70 (both 2F, m), −121.8—−122.4 (6F, m), −123.18 (both 2F, m), and −126.61 (both 2F); IR (neat) 1772vs, 1374s, and 1300—1100vs cm^{-1}; MS (EI) m/z 612 (M^+, 2), 570 (20), 528 (68), 509 (5), and 154 (100). Found: C, 35.36; H, 1.41%. Calcd for $C_{18}H_9F_{17}O_4$: C, 35.31; H, 1.48%.

2,4-Diacetoxy-1-perfluorohexylbenzene (3b) and 1,2-Diacetoxy-4-perfluorohexylbenzene (5b). Colorless crystals (hexane); mp 38—40 °C. ^{19}F NMR δ=−81.32 (both 3F, tt, J=10 and 2 Hz), −108.81 (**5b**, 2F, t, J=15 Hz), −110.81 (**3b**, 2F, m), −121.7—−122.3 (both 4F, m), −123.23 (both 2F, m), and −126.59 (both 2F, m); IR (neat) 1782vs, 1374s, and 1300—1100vs cm^{-1}; MS (EI) m/z 512 (M^+, 2), 470 (26), 428 (77), 160 (8), and 159 (100). Found: C, 37.54; H, 1.71%. Calcd for $C_{16}H_9F_{13}O_4$: C, 37.52; H, 1.77%.

2,4-Diacetoxy-1-perfluorobutylbenzene (3c) and 1,2-Diacetoxy-4-perfluorobutylbenzene (5c).[7] Colorless oil. MS (EI) m/z 412 (M^+, 4), 370 (13), 329 (12), 328 (100), and 159 (96). Found: C, 41.90; H, 2.35%. Calcd for $C_{14}H_9F_9O_4$: C, 40.79; H, 2.20%.

2,4-Diacetoxy-1-perfluoroethylbenzene (3d) and 1,2-Diacetoxy-4-perfluoroethylbenzene (5d). Colorless oil. ^{19}F NMR δ=−84.79 (**3d**, 3F, t, J=2 Hz), −85.10 (**4d**, 3F, t, J=2 Hz), −112.92 (**3d**, 2F, m), and −114.77 (**4d**, 2F, m); IR (neat) 1780vs, 1614m, 1510m, 1426s, 1374s, 1338s, and 1300—1100vs cm^{-1}; MS (EI) m/z 312 (M^+, 5), 270 (44), 229 (9), 228 (100), and 159 (45). Found: C, 45.77; H, 2.83%. Calcd for $C_{12}H_9F_5O_4$: C, 46.17; H, 2.91%.

1,3-Diacetoxy-2-methyl-4-perfluorooctylbenzene (3e). Colorless crystals (dichloromethane/hexane), mp 75—76 °C. ^{1}H NMR δ=2.02 (3H, s), 2.31 (3H, s), 2.36 (3H, m), 7.14 (1H, d, J=8.9 Hz), and 7.46 (3H, d, J=8.9 Hz); ^{13}C NMR δ=10.19, 20.16, 20.60, 105—125 (8C), 118.81 (t, J=23 Hz), 120.11, 126.50, 126.62 (t, J=8 Hz), 148.73 (t, J=3 Hz), 152.97, 168.03, and 168.19; ^{19}F NMR δ=−81.29 (3F, t, J=10 Hz), −107.5 (1F, dm, J=ca. 265 Hz), −110.5 (1F, dm, J=ca. 265 Hz), −121.47 (2F, m), −122.2—−122.3 (6F, m), −123.26 (2F, m), and −126.62 (2F, m); IR (KBr) 1764vs, 1606m, 1590m, 1430s, 1368s, and 1300—1100vs cm^{-1}; MS (EI) 626 (M^+, 0.7), 607 (0.8), 584 (32), 542 (100), 523 (10), and 173 (96). Found: 36.73; H, 1.77%. Calcd for $C_{19}H_{11}F_{17}O_4$: C, 36.44; H, 1.77%.

1,5-Diacetoxy-2-methyl-4-perfluorooctylbenzene (4e) and 1,2-Diacetoxy-3-methyl-5-perfluorooctylbenzene (5e). Colorless oil. ^{1}H NMR **4e**: δ=2.23 (3H, s), 2.27 (3H, s), 2.34 (3H, s), 7.31 (1H, m), and 7.35 (1H, m); **5e**: δ=2.05 (3H, s), 2.25 (3H, s), 2.27 (3H, s), 7.05 (1H, s), and 7.45 (1H, s); ^{13}C NMR **4e**: δ=16.21, 20.33, 20.56, 105—125 (8C), 118.82, 123.48 (t, J=23 Hz), 128.62, 130.83 (t, J=9 Hz), 147.29 (t, J=3 Hz), 152.26 (t, J=1 Hz), 168.12, and 168.62; **5e**: (typical signals) δ=15.68, 20.04, 133.46, 142.71, 144.10, 167.35, and 167.84; ^{19}F NMR **4e**: (typical signal) δ=−108.86; **5e**: (typical signal) δ=−110.96.

1,5-Diacetoxy-3-methyl-2-perfluorooctylbenzene (4f), 1,2-Diacetoxy-3-methyl-4-perfluorooctylbenzene (5f), and 1,2-Diacetoxy-4-methyl-5-perfluorooctylbenzene (6f). Colorless oil. ^{1}H NMR **4f**: δ=2.26 (3H, s), 2.30 (3H, s), 2.50 (3H, t, J=4.6 Hz), 6.90 (1H, m), and 6.97 (1H, m); **5f**: δ=2.31 (3H, m), 2.31 (3H, s), 2.35 (3H, m), 7.21 (1H, d, J=8.9 Hz), and 7.47 (1H, d, J=8.9 Hz); **6f**: δ=2.30 (6H, m), 2.47 (3H, t, J=3.0 Hz), 7.14 (1H, s), and 7.35 (1H, s); ^{13}C NMR **4f**: δ=20.56, 21.04, 21.83 (m), 105—125 (8C), 116.36, 120.80, 123.29, 125.13 (t, J=23 Hz), 141.98, 152.73, 168.31, and 168.75; **5f**: δ=12.99 (tt, J=5 and 3 Hz), 20.18, 20.67, 105—125 (8C), 120.80, 125.77 (t, J=23 Hz), 126.75, (t, J=10 Hz), 133.50 (t, J=2 Hz), 141.97, 145.29, 167.63, and 167.67; **6f**: δ=20.02 (m), 20.46, 20.61, 105—125 (8C), 124.05 (t, J=9 Hz), 125.13 (t, J=23 Hz), 127.34, 137.32 (t, J=2 Hz), 139.94, 144.41, 167.67, and 167.90; ^{19}F NMR **4f**: (typical signal) δ=−103.51 (m); **5f**: δ=−81.27 (3F, tt, J=10 and 2 Hz), −105.51 (2F, m), −121.02 (2F, m), −121.94 (2F, m), −122.33 (4F, m), −123.19 (2F, m), and −126.61 (2F, m); **6f**: (typical signal) δ=−106.75 (m).

4-Acetoxy-2-acetoxymethyl-1-perfluorooctylbenzene (7f). Colorless crystals (dichloromethane/hexane), mp 74—75 °C. ^{1}H NMR δ=2.14 (3H, s), 2.34 (3H, s), 5.27 (2H, s), 7.24 (1H, dd, J=8.5 and 2.1 Hz), 7.35 (1H, d, J=2.1 Hz), and 7.61 (1H, d, J=8.5 Hz); ^{13}C NMR δ=20.79, 21.08, 62.53 (tt, J=7 and 3 Hz), 105—125 (8C), 121.43, 123.07, 123.70 (t, J=23 Hz), 130.31, (t, J=9 Hz), 138.02 (t, J=2 Hz), 153.49, 168.67, and 170.38; ^{19}F NMR δ=−81.26 (3F, tt, J=10 and 2 Hz), −105.70 (2F, t, J=14 Hz), −121.16 (2F, m), −121.82 (2F, m), −122.31 (2F, m), −123.19 (2F, m), and −126.60 (2F, m); IR (KBr) 1740vs, 1610m, 1586s, 1370s, and 1300—1100vs cm^{-1}; MS (EI) 626 (M^+, 6), 584 (23), 542 (100), 153 (24), and 123 (13). Found: C, 36.39; H, 1.81%. Calcd for $C_{18}H_{11}F_{17}O_4$: C, 36.44; H, 1.77%.

1,3-Diacetoxy-2,5-dimethyl-4-perfluorooctylbenzene (3g). Colorless crystals (dichloromethane/hexane), mp 115—117 °C. ^{1}H NMR δ=1.95 (3H, s), 2.26 (3H, s), 2.31 (3H, s), 2.45 (3H, t, J=4.6 Hz), and 6.94 (1H, s); ^{13}C NMR δ=9.93, 20.01, 20.53, 21.42 (m), 105—125 (8C), 117.54 (t, J=21 Hz), 123.87, 124.09, 138.56 (t, J=2 Hz), 149.92 (t, J=4 Hz), 152.00, 168.17, and 168.22; ^{19}F NMR δ=−81.40 (3H, tm, J=10 Hz), −102.23 (1F, dm, J=289 Hz), −104.83 (1F, dm, J=289 Hz), −120.82 (1F, m), −121.09 (1F, m), −122.30 (6F, m), −123.17 (2F, m), and −126.64 (2F, m); IR (KBr) 1764vs, 1580m, 1372s, and 1300—1100vs cm^{-1}; MS (EI) m/z 640 (M^+, 4), 598 (15), 556 (100), 537 (7), and 187 (63). Found: C, 37.67; H, 2.08%. Calcd for $C_{20}H_{13}F_{17}O_4$: C, 37.52; H, 2.05%.

2,3-Diacetoxy-1,4-dimethyl-5-perfluorooctylbenzene (6g). Colorless crystals (dichloromethane/hexane), mp 73—75 °C. ^{1}H NMR δ=2.22 (3H, s), 2.23 (3H, s), 2.33 (3H, s), 2.34 (3H, s), and 7.33 (1H, s); ^{13}C NMR δ=12.81 (m), 16.08, 20.21, 20.27, 105—125 (8C), 125.51 (t, J=22 Hz), 128.30 (t, J=9 Hz), 129.84, 130.54 (t, J=2 Hz), 142.44, 144.25, 167.41, and 167.73; ^{19}F NMR δ=−81.25 (3F, tm, J=10 Hz), −105.58 (2F, m), −120.94 (2F, m), −121.95 (2F, m), −122.32 (4F, m), −123.19 (2F, m), and −126.58 (2F, m); IR (KBr) 1780vs, 1490m, 1458m, 1430m, 1374s, 1320s, and 1300—1100vs cm^{-1}; MS (EI) m/z 640 (M^+, 3), 598 (12), 556 (100), 537 (6), and 187 (52).

1-Acetoxy-5-acetoxymethyl-2-methyl-4-perfluorooctylbenzene (7g). ^{1}H NMR (typical signals) δ=5.24 (2H, m), 7.29 (1H, s), and 7.46 (1H, s).

2,4-Diacetoxy-1,3-dimethyl-5-perfluorooctylbenzene (3h). Colorless crystals (dichloromethane/hexane), mp 72—74 °C. ^{1}H NMR δ=1.97 (3H, s), 2.20 (3H, s), 2.29 (3H, s), 2.37 (3H, s), and 7.31 (1H, s); ^{13}C NMR δ=10.51 (m), 16.34 (m), 20.28

(m), 20.38 (m), 118.71 (t, J=23 Hz), 126.51, 127.94 (tm, J=8 Hz), 128.93, 146.39 (t, J=3 Hz), 151.69 (t, J=1 Hz), 167.78, and 168.28; ^{19}F NMR δ=−81.25 (3F, tt, J=10 and 2 Hz), −107.65 (1F, dm, J=267 Hz), −110.88 (1F, dm, J=267 Hz), −121.42 (2F, m), −122.27 (6F, m), −123.21 (2F, m), and −126.60 (2F, m); IR (KBr) 1768vs, 1604m, 1374s, 1330s, 1300—1100vs cm^{-1}; MS (EI) m/z 640 (8), 598 (20), 556 (100), and 167 (88). Found: C, 37.67; H, 2.08%. Calcd for $C_{20}H_{13}F_{17}O_4$: C, 37.52; H, 2.05%.

5-Acetoxy-1-acetoxymethyl-3-methyl-2-perfluorooctylbenzene (7i). Colorless crystals (dichloromethane/hexane), mp 78—80 °C. ^{1}H NMR δ=2.13 (3H, s), 2.32 (3H, s), 2.51 (3H, mt, J=4.6 Hz), 5.24 (2H, t, J=3.0 Hz), 7.05 (1H, s), and 7.21 (1H, s); ^{13}C NMR δ=20.82, 21.03, 22.12 (tt, J=7 and 4 Hz), 63.62 (tt, J=10 and 4 Hz), 105—125 (8C), 121.24, 122.45 (t, J=22 Hz), 125.78, 139.45 (t, J=3 Hz), 142.04 (t, J=4 Hz), 152.61, 168.71, and 170.33; ^{19}F NMR δ=−81.29 (3F, tt, J=10 and 2 Hz), −99.59 (2F, m), −120.42 (2F, m), −122.09 (6F, m), −123.15 (2F, m), and −126.57 (2F, m); IR (KBr) 1764vs, 1738s, 1602s, 1462m, 1386s, 1372s, 1328m, and 1300—1100vs cm^{-1}; MS (CI) m/z 641 (M^++1, 100), 621 (76), 599 (46), 585 (16), 579 (37), 557 (49), 556 (47), 271 (9), and 187 (73). Found: C, 37.45; H, 2.03%. Calcd for $C_{20}H_{13}F_{17}O_4$: C, 37.52; H, 2.05%.

1-*t*-Butyl-2,4-diacetoxy-5-perfluorooctylbenzene (4j=4k). Colorless crystals (dichloromethane/hexane), mp 76—77 °C. ^{1}H NMR δ=1.37 (9H, s), 2.27 (3H, s), 2.35 (3H, s), 7.03 (1H, s), and 7.57 (1H, s); IR (KBr) 2960m, 1774vs, 1612m, 1580m, 1502m, 1404m, 1372s, and 1300—1100vs cm^{-1}; MS (EI) m/z 668 (M^+, 1), 653 (0.4), 649 (1), 626 (12), 584 (41), and 569 (100). Found: C, 39.74; H, 2.53%. Calcd for $C_{22}H_{17}F_{17}O_4$: C, 39.54; H, 2.56%.

1-*t*-Butyl-2,3-diacetoxy-5-perfluorooctylbenzene (6j=5l). Colorless crystals (dichloromethane/hexane), mp 61—63 °C. ^{1}H NMR δ=1.37 (9H, s), 2.28 (3H, s), 2.36 (3H, s), 7.38 (1H, m), and 7.47 (1H, m); ^{13}C NMR δ=20.69, 20.83, 30.00, 35.20, 105—125 (8C), 120.63 (t, J=7 Hz), 122.93 (t, J=7 Hz), 126.19 (t, J=25 Hz), 143.08, 144.08 (t, J=2 Hz), 144.21, 167.52, and 167.58; ^{19}F NMR δ=−81.25 (3F, tt, J=10 and 3 Hz), −110.83 (2F, t, J=13 Hz), −121.85 (4F, m), −122.35 (4F, m), −123.20 (2F, m), and −126.59 (2F, m); IR (KBr) 2984s, 1762s, 1428s, 1370s, and 1300—1100vs cm^{-1}; MS (EI) m/z 668 (M^+, 7), 626 (8), 584 (100), and 569 (49). Found: C, 39.51; H, 2.60%. Calcd for $C_{22}H_{17}F_{17}O_4$: C, 39.54; H, 2.56%.

1,5-Diacetoxy-2-methoxy-4-perfluorobutylbenzene (4m). Colorless crystals (dichloromethane/hexane), mp 73—74 °C. ^{1}H NMR δ=2.26 (3H, s), 2.32 (3H, s), 3.87 (3H, s), 7.01 (1H, s), and 7.09 (1H, s); ^{13}C NMR δ=20.50, 20.52, 56.40, 105—125 (4C), 111.62 (t, J=9 Hz), 118.44 (t, J=23 Hz), 119.91, 142.10 (t, J=3 Hz), 142.78, 149.15, 167.86, and 168.82; ^{19}F NMR δ=−81.41 (3F, tt, J=10 and 3 Hz), −109.08 (2F, m), −122.58 (2F, m), and −126.43 (2F, m); IR (KBr) 1774vs, 1516s, 1410s, 1374s, 1350s, and 1300—1100vs cm^{-1}; MS (EI) m/z 442 (M^+, 3), 401 (3), 358 (100), and 189 (51). Found: C, 40.78; H, 2.45%. Calcd for $C_{15}H_{11}F_9O_5$: C, 40.72; H, 2.51%.

1,2-Diacetoxy-4-perfluorohexylnaphthalene (5p). Colorless crystals (dichloromethane/hexane), mp 89—90 °C. ^{1}H NMR δ=2.33 (3H, s), 2.46 (3H, s), 7.58 (2H, m), 7.73 (1H, s), 7.59 (1H, m), and 8.22 (1H, m); ^{13}C NMR δ=20.27, 20.50, 105—125 (8C), 121.98, 123.35 (t, J=23 Hz), 124.62 (t, J=11 Hz), 125.08 (m), 127.42, 127.86, 128.63, 129.37, 137.83, 140.63 (t, J=1 Hz), 167.44, and 167.95; ^{19}F NMR δ=−81.28 (3F, tt, J=10 and 2 Hz), −104.62 (2F, t, J=15 Hz), −120.32 (2F, t, J=12 Hz), −121.90 (2F, m), −123.10 (2F, m), and −126.53 (2F, m); IR (KBr) 2950m, 1770vs, 1634m, 1614m, 1588m, 1520m, 1472m, 1436m, 1374s, 1354s, and 1300—1100vs cm^{-1}; MS (EI) m/z 562 (M^+, 3), 520 (12), 478 (100), 459 (5), 458 (5), 239 (9), and 209 (97). Found: C, 42.46; H, 2.06%. Calcd for $C_{20}H_{11}F_{13}O_4$: C, 42.72; H, 1.97%.

Deacetylation of Diacetoxybenzenes. General Procedure: A mixture of **3a—d** and **5a—d** (ca. 1:1, derived from 1 mmol of quinols) was dissolved in 20 ml of methanol containing 100 mg (1 mmol) of *p*-toluenesulfonic acid hydrate. The methanol solution was refluxed for 1 d under a nitrogen atmosphere. After the solvent was removed in vacuo, the residue was dissolved in ether. The solution was washed with water and brine, dried over Na_2SO_4, and evaporated to give an almost quantitative yields of benzenediols. Separation of isomeric benzenediols was carried out by chromatography of the residue on silica gel (CH_2Cl_2–ether). Resorcinol and catechol derivatives were obtained from less and more polar fractions, respectively. In the case of perfluorooctyl derivatives, fractional crystallization of **8a** from $CHCl_3$ was performed prior to the chromatographic separation.

4-Perfluorooctyl-1,3-benzenediol (8a). Colorless crystals (dichloromethane/hexane), mp 118—119 °C; ^{1}H NMR (acetone-d_6) δ=6.45 (1H, dd, J=8.6 and 2.0 Hz), 6.49 (1H, d, J=2 Hz), 7.24 (1H, d, J=8.6 Hz), 8.99 (1H, br s), and 9.11 (1H, br s); ^{13}C NMR (acetone-d_6) δ=105.15, 107.32 (t, J=23 Hz), 108.67, 105—125 (8C), 131.42, (t, J=8 Hz), 159.60 (t, J=3 Hz), and 163.41; ^{19}F NMR (acetone-d_6) δ=−81.85 (3F, tt, J=10 and 2 Hz), −106.11 (2F, t, J=14 Hz), −120.76 (2F, m), −121.43 (6F, m), −122.23 (2F, m), and −125.85 (2F, m); IR (KBr) 3216vs, 1612vs, 1318vs, and 1300—1100vs cm^{-1}; MS (EI) m/z 528 (M^+, 14), 159 (100), and 119 (3). Found: C, 31.61; H, 1.32%. Calcd for $C_{14}H_5F_{17}O_2$: C, 31.84; H, 0.95%.

4-Perfluorooctyl-1,2-benzenediols (9a). Colorless crystals (dichloromethane/hexane), mp 94—95 °C. ^{1}H NMR δ=6.90 (2H, m) and 6.96 (1H, s); ^{13}C NMR δ=105—125 (8C), 115.43 (t, J=7 Hz), 117.10, 120.70 (t, J=7 Hz), 121.31 (t, J=25 Hz), 147.61, and 151.15 (t, J=1 Hz); ^{19}F NMR δ=−80.80 (3F, t, J=10 Hz), −108.76 (2F, t, J=14 Hz), −120.80 (2F, m), −121.43 (6F, m), −122.21 (2F, m), and −125.75 (2F, m); IR (KBr) 3536s, 3476vs, 1614m, 1530m, 1448s, 1394s, 1314vs, and 1300—1100vs cm^{-1}; MS (EI) m/z 528 (M^+, 19), 509 (5), 508 (5), 189 (14), and 159 (100). Found: m/z 528.0028. Calcd for $C_{14}H_5F_{17}O_2$: M, 528.0017.

4-Perfluorohexyl-1,3-benzenediol (8b). Colorless crystals (dichloromethane/hexane), mp 70 °C; ^{19}F NMR (acetone-d_6) δ=−80.66 (3F, tt, J=10 and 3 Hz), −106.03 (2F, tt, J=15 and 3 Hz), −120.79 (2F, m), −121.40 (2F, m), −122.26 (2F, m), and −125.75 (2F, m); IR (KBr) 3212vs, 1614vs, 1536m, 1468s, 1394s, 1364s, 1316s, and 1300—1100vs cm^{-1}; MS (CI) m/z 429 (M^+, 2), 406 (100), and 159 (99). Found: m/z 428.0094. Calcd for $C_{12}H_5F_{13}O_2$: M, 428.0081.

4-Perfluorohexyl-1,2-benzenediol (9b). Colorless crystals (dichloromethane/hexane), mp 77—78 °C. ^{19}F NMR δ=−80.99 (3F, tt, J=10 and 3 Hz), −108.78 (2F, tt, J=15 and 3 Hz), −121.18 (2F, m), −121.60 (2F, m), −122.54 (2F, m), and −126.00 (2F, m); IR (KBr) 3416vs, 1614m, 1532m, 1448m, 1356s, 1316s, and 1300—1100vs cm^{-1}; MS (EI) m/z 428 (M^+, 4), 407 (3), 406 (18), 387 (3), 209 (7), 159 (13), and 137 (100). Found: m/z 428.0087. Calcd for $C_{12}H_5F_{13}O_2$: M, 428.0081.

4-Perfluorobutyl-1,3-benzenediol (8c). Colorless crystals

(dichloromethane/hexane), mp 52—53 °C. ^{19}F NMR δ=−80.85 (3F, tt, J=10 and 3 Hz), −106.26 (2F, tq, J=13 and 3 Hz), −121.66 (2F, m), and −125.60 (2F, m); IR (KBr) 3504s, 3224vs, 1612vs, 1466s, 1394s, 1356m, 1318m, and 1300—1100vs cm^{-1}; MS (EI) m/z 328 (M^+, 22), 309 (3), 308 (2), 289 (1), and 159 (100). Found: m/z 328.0143. Calcd for $C_{10}H_5F_9O_2$: M, 328.0144.

4-Perfluorobutyl-1,2-benzenediol (9c). Colorless crystals (dichloromethane/hexane), mp 67—68 °; ^{19}F NMR (acetone-d_6) δ=−80.92 (3F, tt, J=10 and 2 Hz), −108.74 (2F, tt, J=13 and 3 Hz), −122.38 (2F, m), and −125.25 (2F, m); IR (KBr) 3460vs, 1614s, 1534s, 1448s, 1356s, 1316s, and 1300—1100vs cm^{-1}; MS (EI) m/z 328 (M^+, 27), 309 (4), 308 (4), 189 (7), and 159 (100). Found: m/z 328.0165. Calcd for $C_{10}H_5F_9O_2$: M, 328.0144.

4-Perfluoroethyl-1,3-benzenediol (8d). Colorless needles (hexane). ^{19}F NMR (acetone-d_6) δ=−83.95 (3F, t, J=2 Hz) and −110.32 (2F, q, J=2 Hz); IR (KBr) 3420vs, 1616s, 1580s, 1500m, 1446m, 1406s, 1336s, and 1300—1100vs cm^{-1}; MS (CI) m/z 229 (M^++1, 100), 211 (34), 209 (16), 110 (50), and 109 (67). Found: m/z 228.0258. Calcd for $C_8H_5F_5O_2$: M, 228.0210.

4-Perfluoroethyl-1,2-benzenediol (9d). Colorless oil. ^{19}F NMR δ=85.14 (3F, t, J=3 Hz) and −113.13 (2F, m). MS (EI) m/z 228 (100), 208 (41), 180 (40), and 159 (64). Found: m/z 228.0237. Calcd for $C_8H_5F_5O_2$: M, 228.0210.

Treatment of Benzenediols 8a and 9a with Acetone: A mixture of (**8a** and **9a** obtained from 100 mg of **3a** and **5a** as described above was dissolved in acetone (10 ml) and refluxed for 3 d under a nitrogen atmosphere. The solvent was removed and the residue was chromatographed on silica gel (hexane–CH_2Cl_2/ether) to give **8a** (38 mg, 43%), **9a** (17 mg, 17%), and a mixture of **10** and **11**. Further separation of the last mixture on GPC gave 2 mg of **10** and 6 mg of **11**.

5-Perfluorooctyl-2,2-dimethyl-1,3-benzodioxole (10). Colorless crystals (dichloromethane/hexane), mp 58—59 °C. ^{1}H NMR δ=1.71 (6H, s), 6.80 (1H, d, J=8.2 Hz), 6.91 (1H, d, J=1.8 Hz), and 7.05 (1H, dd, J=8.2 and 1.8 Hz); ^{13}C NMR δ=25.87, 105—125 (8C), 106.94 (t, J=7 Hz), 108.07, 119.51, 121.08 (t, J=7 Hz), 121.65 (t, J=25 Hz), 147.78, and 150.42; ^{19}F NMR δ=−81.24 (3F, t, J=10 Hz), −109.51 (2F, t, J=15 Hz), −121.81 (2F, m), −122.28 (6F, m), −123.21 (2F, m), and −126.59 (2F, m); IR (KBr) 3004m, 1634m, 1614m, 1512s, 1454s, 1372s, 1330s, and 1300—1100vs cm^{-1}; MS (EI) m/z 568 (M^+, 51), 553 (100), 549 (5), 199 (51), and 159 (40).

5-Perfluorooctyl-2-methyl-2-(2-methyl-1-propenyl)-1,3-benzodioxole (11). Colorless crystals (dichloromethane/hexane), mp 100—101 °C. ^{1}H NMR δ=1.76 (3H, s), 1.78 (3H, d, J=1.5 Hz), 1.83 (3H, d, J=1.5 Hz), 5.50 (1H, m), 6.81 (1H, d, J=8.2 Hz), 6.93 (1H, d, J=1.8 Hz), and 7.05 (1H, dd, J=8.2 and 1.8 Hz); ^{13}C NMR δ=19.15, 26.64, 105—125 (8C), 106.87 (t, J=7 Hz), 107.99, 118.36, 121.11 (t, J=7 Hz), 121.64 (t, J=25 Hz), 123.94 (m), 140.68 (m), 147.70, and 150.33; ^{19}F NMR δ=−81.26 (3F, t, J=10 Hz), −110.11 (2F, t, J=14 Hz), −121.80 (2F, m), −122.40 (6F, m), −123.22 (2F, m), and −126.62 (2F, m); IR (KBr) 2984m, 2932s, 1678m, 1504vs, 1452vs, 1372s, 1300—1100vs cm^{-1}; MS (EI) 608 (M^+, 100), 593 (99), 589 (15), 565 (43), and 553 (32).

This work is partially supported by a Grant-in-Aid for Scientific Research No. 02750619 from the Ministry of Education, Science and Culture. We thank Dr. Kazuhiro Shimokawa (Daikin Kogyo Co. Ltd.) for a generous gift of perfluoroalkyl iodides.

(Received September 12, 1990)

The reaction of methoxynaphthalenes with malonamide in the presence of magnanese(III) acetate gives 2-acetoxy-2-(1-naphthyl)propanediamides and 2-hydroxy-2-(1-naphthyl)propanediamides. It was found that the propanediamidation reaction did occur when naphthalenes have electron-donating substituents, such as a methoxyl group. The reactions of methoxynaphthalenes with ethyl 3-oxobutanoate, 2-cyanoacetamide, and malononitrile in the presence of manganese(III) acetate also yielded the corresponding substituted naphthalenes, ethyl 2-(acetoxymethyl)naphtho[2,1-*b*]furan-1-carboxylates, and/or a 4-methylene-1(4*H*)-naphthalenone. The reaction mechanisms are discussed.

Although the reactions of alkenes with active methylene compounds in the presence of manganese(III) acetate have been well documented,[1] the reaction of aromatic substrates with manganese(III) acetete–active methylene compounds has received less attention than alkenes, probably because of the lower reactivity of the aromatic compounds towards the reagents. The authors have reported that the reactions of naphthalenes, anthracene, and other aromatic substrates with tris(2,4-pentanedionato)manganese(III), and with malonic acid in the presence of manganese(III) acetate,[2] gave diacetylmethylated arenes[3] and formylated arenes,[4] respectively. Citterio et al.[5,6] have also reported that the reactions of alkoxynaphthalenes with diethyl malonates, ethyl 3-oxobutanoate and ethyl 2-cyanoacetate in the presence of manganese(III) acetate gave aromatic substitution products. In view of the potential synthetic utility of these reactions, which could functionalize aromatic compounds, we then investigated the reactions involved in incorporating other carbonyl functions into naphthalenes and other aromatic substrates. We describe here the reactions of methoxy-substituted naphthalenes with malonamide, ethyl 3-oxobutanoate, 2-cyanoacetamide, and malononitrile in the presence of manganese(III) acetate.

Results

2,7-Dimethoxynaphthalene (**1a**) was selected as an aromatic substrate in a reaction aimed at optimizing the reaction conditions since the reaction products could be readily separated and characterized by spectroscopic methods. The reaction of **1a** with malonamide in the presence of manganese(III) acetate gave an acetate (**2a**) as the major product after purification on preparative TLC. The ^{1}H NMR spectrum of **2a** ($C_{17}H_{18}N_2O_6$ based on elemental analysis and M^+=346 in the MS spectrum) exhibited an AB (δ_A=7.24 and δ_B=7.86, J_{AB}=8.79 Hz) and an ABC spin system (δ_A=7.03, δ_B=7.42, δ_C=7.78, J_{AB}=2.20, J_{AC}=7.89, J_{BC}=0 Hz) due to aromatic protons. The J value for the AB spin system indicated the presence of H-3 and H-4. The peaks at δ=2.38 (3H, singlet), 3.76 (3H, singlet), and 3.79 (3H, singlet) are assigned to an acetoxyl group and two methoxyl groups, respectively. There are four peaks at δ=6.86, 7.87, 7.95, and 9.66 assigned to two NH_2, which disappeared upon deuteration. The IR spectrum showed absorptions at 1685 and 3100—3500 cm^{-1} due to amide functions. These spectral properties indicate the structure of 2-acetoxy-2-(2,7-dimethoxy-1-naphthyl)-propanediamide for **2a**. There was a minor product (**3a**) which showed an ^{1}H NMR spectrum similar to that of **2a**, except for the presence of a hydroxyl group and

a) The reactions were carried out at the reflux temperature. b) Substrate : active methylene compound : Mn(III). c) Isolated yield based on the amount of substrate added. d) Ac_2O (2 cm^3) was added. e) Yield was estimated from the ^1H NMR spectra.

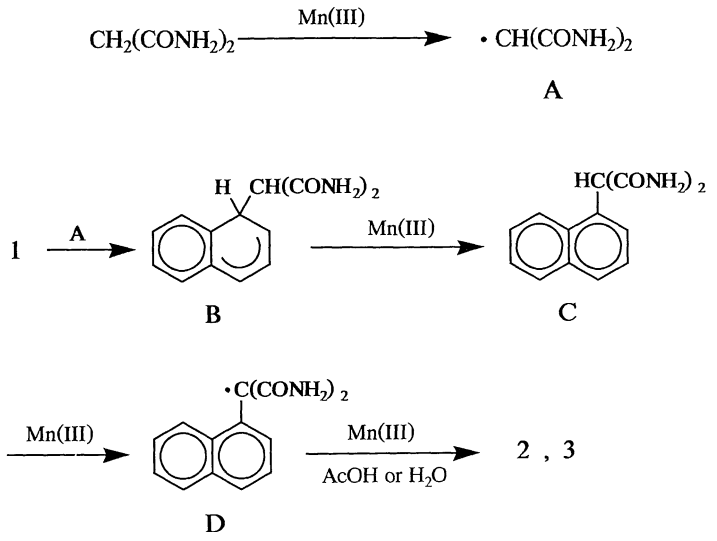
the absence of an acetoxyl group. The structure was then assigned to be 2-hydroxy-2-(2,7-dimethoxy-1-naphthyl)propanediamide (**3a**) (Fig. 1).

The reaction was carried out at various molar ratios of **1a**: malonamide: manganese(III); we found that the reaction at a molar ratio of 1:8:8 at the reflux temperature for 3 min gave the maximum yield for **2a** (Table 1, Entry 1). The reactions were then examined for 1-methoxynaphthalene (**1b**), 2-methoxynaphthalene (**1c**), 2,6-dimethoxynaphthalene (**1d**), 1,7-dimethoxynaphthalene (**1e**), and 2,3-dimethoxynaphthalene (**1f**) at a molar ratio of 1:8:8 at reflux temperature for 3 min. The results are shown in Table 1. The 2-hydroxy derivatives were not always obtained as a pure substance because of contamination with the acetates. The yields of some 2-hydroxy derivatives (**3b**, **3c**, **3e**) were estimated from the intensities of the hydroxyl group in **3** and the acetoxyl group in **2**, which are well separated from the other signals in their ^1H NMR spectra. In order to prevent the formation of the 2-hydroxy derivative (**3a**), a reaction was conducted which added acetic anhydride. The yield of **2a** was slightly improved (by 9%) at the expense of **3a**; the yield of which was lowered by 12% (Entry 2). It was shown that an aromatic ring having a methoxyl group in naphthalene is always active towards the reaction, except for **1f** (2,3-dimethoxynaphthalene). In the case of **1f**, the propanediamide moiety is introduced into the unsubstituted ring. The reaction of unsubstituted naphthalene with manganese(III) acetate–$CH_2(CONH_2)_2$ gave a small amount of products along with the unchanged material. The products could not be characterized. The reactions of anthracene and pyrene also gave a complex mixture which could not be identified.

We then looked into the reactions of 2,7-dimethoxynaphthalene (**1a**), 2-methoxynaphthalene (**1c**), and 2,6-dimethoxynaphthalene (**1d**), with ethyl 3-oxobutanoate in the presence of manganese(III) acetate that gave ethyl 2-acetoxy-2-(1-naphthyl)-3-oxobutanoates (**4a**, **4c**, **4d**) and ethyl 2-(acetoxymethyl)naphtho[2,1-*b*]-furan-1-carboxylates (**5a**, **5c**, **5d**) (Entries 8—10). The isolated yield of **4c** (ethyl 2-acetoxy-2-(2-methoxy-1-naphthyl)-3-oxobutanoate) was better than the yield (20%) reported by Citterio et al.,[5] who obtained **4c** in a reaction at 80 °C. The IR and ^1H NMR spectra of compound **5d**, which has a molecular formula $C_{19}H_{18}O_6$ (analysis and M^+=342), indicated the presence of 1,2,6-trisubstituted naphthalene, a methoxy group (δ=3.90 (3H, s)), an ethoxycarbonyl group (1710 cm^{-1}, δ=4.50 (2H, q) and δ=1.45 (3H, t)), an acetoxyl group (1732 cm^{-1}, δ=2.12 (3H, s)), and a methylene group (δ=5.52 (2H, s)). The ^{13}C NMR spectrum showed two methylene groups at δ=58.297, 61.374 that finally confirmed the structure of ethyl 2-(acetoxymethyl)-7-methoxynaphtho[2,1-*b*]furan-1-carboxylate for **5d**. The structures of **5a** and **5c** were similarly determined on the basis of the presence of acetoxymethyl group in their ^1H NMR spectra. The reactions of **1a** with 2-cyanoacetamide, and malononitrile in the presence of manganese(III) acetate at a molar ratio of 1:8:8 at reflux temperature were also carried out (Entries 11, 12). The products were found to be 2-acetoxy-2-cyano-(2,7-dimethoxy-1-naphthyl)acetamide (**7a**) and 4-(dicyanomethylene)-3,6-dimethoxy-1(4*H*)-naphthalenone (**8**). The yields were rather poor and much of the unchanged **1a** was recovered in the reaction of malononitrile.

Discussion

It has been reported that diacetylmethylation using tris(2,4-pentanedionato)manganese(III) (abbreviated [Mn(acac)$_3$]) is effective when the ionization potential of the aromatic compound is lower than 8.28 eV.[3] The reaction could be accounted for in terms of a radical reaction initiated by the diacetylmethyl radical, ·CH-

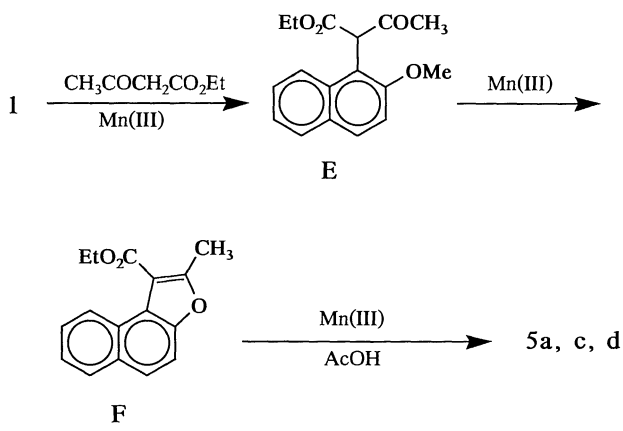


Scheme 1.

$(COCH_3)_2$, which is formed by the thermal decomposition of [Mn(acac)3], and subsequently attacks the aromatic nucleus, followed by further oxidation by [Mn(acac)3] to give products.[3] In an analogy to the above-mentioned mechanism, the reaction of aromatic compounds with malonamide in the presence of manganese(III) acetate could be envisaged as being initiated by a propanediamide radical, $\cdot CH(CONH_2)_2$ (**A**), which is formed by an interaction with manganese(III) acetate and $CH_2(CONH_2)_2$. In an attempt to obtain information concerning the complex formation between Mn(III) and $CH_2(CONH_2)_2$ though the visible spectra of manganese(III) acetate in AcOH were taken in both the presence and absence of three equivalents of $CH_2(CONH_2)_2$ at room temperature, no appreciable change could be observed. However, the formation of **A** was substantiated by the fact that xanthene gave a 2-(9-xanthenyl)propanediamide (**6**) in 81% yield when treated with manganese(III)–$CH_2(CONH_2)_2$ (Fig. 1). The propanediamide radical (**A**) seems to have an electrophilic nature as well as do $\cdot CH_2CO_2H$ and other radicals which have carbonyl functions attached to the radical carbon. Thus, **A** attacks the α-position in naphthalenes to give radicals (**B**), which could be subsequently oxidized with excess manganese(III) acetate present in the oxidation system to give 2-(1-naphthyl)propanediamide (**C**). Compound **C** could not be isolated, probably because **C** has a hydrogen on a tertiary carbon which may more easily be oxidized than the methylene group in $CH_2(CONH_2)_2$ to give radical (**D**). Radical (**D**) is further oxidized to a corresponding cation, which takes up either an acetate ion or water to yield **2** and **3**, respectively (Scheme 1). The acetate (**2a**) was fairly stable and could not be hydrolyzed, even with 50% aqueous acetic acid containing a small amount of hydrochloric acid at room temperature for 12 h. It is therefore reasonable to assume that **3a** was not formed from **2a** by hydrolysis during the work-up but, rather, was formed from the intermediate **D** and water contained in the reaction medium.

The formation of ethyl 2-(acetoxymethyl)naphtho-[2,1-*b*]furan-1-carboxylates (**5a**, **5c**, and **5d**) in the reactions of methoxynaphthalenes (**1a**, **1c**, and **1d**) with ethyl 3-oxobutanoate reveals another interesting feature of the reaction. The removal of the methoxyl group has been observed in the reactions of 2-hydroxy-2′-methoxybenzophenones with manganese(III) acetate that yielded 9-xanthenones,[7] and in the reaction of **1c** (2-methoxynaphthalene) with dimethyl malonate.[6] The formation of **5a**, **5c**, and **5d** could be accounted for by the fact that the substituted product (**E**) was cyclized to give **F**, which was subsequently acetoxylated with manganese(III) acetate (Scheme 2). The intermediates, **E** and **F**, could not be isolated from the reaction mixture, probably because we were using excess manganese(III) acetate (1:12 molar equivalent ratio).

The reactions of **1a** (2,7-dimethoxynaphthalene)



Scheme 2.

with 2-cyanoacetamide and malononitrile could also be accounted for by similar mechanisms initiated with the $\cdot CH(CN)CONH_2$ and $\cdot CH(CN)_2$ radical, respectively. The low yields are probably due to the less reactive nature of 2-cyanoacetamide and malononitrile than malonamide towards manganese(III) acetate.

It can thus be concluded that a radical substitution reaction occurred only at the α-position and that the substitution reaction occurs at the unsubstituted nucleus in the case of **1f** (2,3-dimethoxynaphthalene) that may be due to a steric hindrance caused by the two methoxyl groups at the C-2 and C-3 position. It should be emphasized that this new direct incorporation of C_3 and C_4 units using manganese(III) acetate–active methylene compounds takes place in the electron-rich aromatic compounds having such an electron-donating group as the methoxyl group. These reactions could be utilized in organic syntheses.

Experimental

Measurements. All the ^1H and ^{13}C NMR spectra were taken with JNM PMX-60SI (60 MHz), JNM EX-90 (90 MHz for ^1H and 22.4 MHz for ^{13}C), and JNM GX-400 (400 MHz) FT NMR spectrometers with tetramethylsilane used as the internal standard. The IR spectra were measured on a JASCO A-102 IR spectrometer. The mass spectra were obtained on a JMS-DX303 HF mass spectrometer using a direct-insertion probe at an ionizing voltage of 70 eV. The melting points were determined with a Yanagimoto micro-melting point apparatus.

Materials. Methoxynaphthalenes (**1a—f**) were synthesized by the methylation of the corresponding naphthols with dimethyl sulfate. The other aromatic compounds were commercially available. Manganese(III) acetate was prepared by a method described in the literature.[8]

Reaction of Aromatic Compounds with Malonamide in the Presence of Manganese(III) Acetate. The typical procedure for the reaction of aromatic compounds with malonamide in the presence of manganese(III) acetate was as follows. To a heated solution of an aromatic compound (1 mmol) and malonamide (8 mmol) in acetic acid (30 cm^3), manganese(III) acetate (1.98 g, 8 mmol as Mn(III)) was added. The reaction mixture was heated under reflux until the dark-brown color of the solution turned opaque white. The solvent was then removed in vacuo, and the residue triturated with 2 M (1 M=1 mol dm^{-3}) hydrochloric acid (50 cm^3), followed by extraction with ethyl acetate. The solvent was removed again in vacuo and the products separated on a silica-gel plate while eluting with chloroform. Yields are summarized in Table 1.

Products. 2-Acetoxy-2-(2,7-dimethoxy-1-naphthyl)propanediamide (2a): Mp 184.5—185.5 °C (from chloroform–ethyl acetate); IR(KBr) ν 1685, 1726 ($-CONH_2$), 1755 (-OAc), 3100—3500 ($-NH_2$) cm^{-1} ; ^1H NMR (400 MHz, DMSO-d_6) δ=2.38 (3H, s, -OAc), 3.76 (3H, s, $-OCH_3$) 3.79 (3H, s, $-OCH_3$), 6.86 (1H, s, NH), 7.03 (1H, dd, J=7.89, 2.20 Hz, H-6), 7.24 (1H, d, J=8.79 Hz, H-3), 7.42 (1H, d, J=2.20 Hz, H-8), 7.78 (1H, d, J=7.89 Hz, H-5), 7.86 (1H, d, J=8.79 Hz, H-4), 7.87 (1H, s, -NH), 7.95 (1H, s, -NH), and 9.66 (1H, d, -NH); MS m/z (rel intensity)=346 [M^+] (100), 285 (100), 255 (44), 215 (67), 199 (51), and 185 (87). Found: C, 58.85; H, 5.25; N, 8.06%. Calcd for $C_{17}H_{18}O_6N_2$: C, 58.95; H, 5.24; N, 8.09%.

2-Hydroxy-2-(2,7-dimethoxy-1-naphthyl)propanediamide (3a): Mp 211—214 °C (from ethyl acetate); IR(KBr) ν 1705 ($-CONH_2$), 3100—3500 ($-NH_2$, -OH) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=3.80 (3H, s, $-OCH_3$) 3.82 (3H, s, $-OCH_3$), 6.07 (1H, br. s, -OH), 6.86—8.12 (4H, br. 2×$-NH_2$), 7.07 (1H, dd, J=8.6, 2.0 Hz, H-6), 7.26 (1H, d, J=9.0 Hz, H-3), 7.51 (1H, d, J=2.2 Hz, H-8), 7.81 (1H, d, J=8.6 Hz, H-5), and 7.88 (1H, d, J=9.0 Hz, H-4). Found: C, 59.30; H, 5.29; N, 9.30%. Calcd for $C_{15}H_{16}N_2O_5$: C, 59.20; H, 5.30; N, 9.21%.

2-Acetoxy-2-(4-methoxy-1-naphthyl)propanediamide (2b): Mp 196.5—197.5 °C (from chloroform–ethyl acetate); IR (KBr) ν 1682 ($-CONH_2$), 1763 (-OAc), 3100—3500 ($-NH_2$) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=2.34 (3H, s, OAc), 3.97 (3H, s, $-OCH_3$), 6.95 (1H, d, J=8.43 Hz, H-3), 7.01 (1H, s, -NH), 7.38 (1H, d, J=8.42 Hz, H-4), 7.47—7.54 (2H, m, H-6, H-7), 7.70 (1H, s, -NH), 8.02 (1H, s, -NH), 8.10—8.12 (1H, dd, H-5), 8.20—8.22 (1H, dd, H-8), and 10.25 (1H, s, -NH); MS m/z (rel intensity) 316 [M^+] (13), 272 (13), 255 (37), 231 (19), and 185 (100). Found: m/z 316.1054. Calcd for $C_{16}H_{16}O_5N_2$: M, 316.1059.

2-Acetoxy-2-(2-methoxy-1-naphthyl)propanediamide (2c): Mp 205 — 206 °C (from chloroform–ethyl acetate); IR(KBr) ν 1691 ($-CONH_2$), 1766 (-OAc), 3100 — 3500 ($-NH_2$) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=2.08 (3H, s, OAc), 3.82 (3H, s, $-OCH_3$), 7.30 — 7.45 (7H, m, 2×$-NH_2$, 3×arom. H), 7.81 — 7.83 (1H, dd, H-5), 7.93 (1H, d, J=8.79 Hz, H-4), and 8.35 — 8.37 (1H, dd, H-8). Found: C, 60.66; H, 5.14; N, 8.86%. Calcd for $C_{16}H_{16}O_6N_2$: C, 60.75; H, 5.10; N, 8.86%.

2-Acetoxy-2-(2,6-dimethoxy-1-naphthyl)propanediamide (2d): Mp 199 — 200 °C (from chloroform–ethyl acetate); IR(KBr) ν 1690 ($-CONH_2$), 1730 (-OAc), 3100 — 3500 ($-NH_2$) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=2.37 (3H, s, -OAc), 3.74 (3H, s, $-OCH_3$), 3.83 (3H, s, $-OCH_3$) 6.87 (1H, s, -NH), 7.10 (1H, dd, J=9.53, 2.93 Hz, H-7), 7.30 (1H, d, J=2.57 Hz, H-5), 7.37 (1H, d, J=8.80 Hz, H-3), 7.72 (1H, s, -NH), 7.85 (1H, d, J=7.89 Hz, H-4), 7.96 (1H, d, J=9.16 Hz, H-8), 8.31 (1H, s, -NH), and 9.65 (1H, s, -NH). Found: C, 58.81; H, 5.24; N, 8.06%. Calcd for $C_{17}H_{18}O_6N_2$: C, 58.95; H, 58.24; N, 8.09%.

2-Hydroxy-2-(2,6-dimethoxy-1-naphthyl)propanediamide (3d): Mp 228 — 230 °C (from ethyl acetate); IR(KBr) ν 1670, 1687 ($-CONH_2$), 3100 — 3500 ($-NH_2$, -OH) cm^{-1}; MS m/z (rel intensity)=304 [M^+] (46), 261 (49), 215 (100), 201 (18), and 157 (23). Found: m/z 304.1032. Calcd for $C_{15}H_{16}O_5N_2$: M, 304.1059.

2-Acetoxy-2-(4,6-dimethoxy-1-naphthyl)propanediamide (2e): Mp 187—188 °C (from chloroform–ethyl acetate); IR(KBr) ν 1690, 1712 ($-CONH_2$), 1730 (-OAc), 3100—3500 ($-NH_2$) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=2.33 (3H, s, -OAc),3.86 (3H, s, $-OCH_3$), 3.97 (3H, s, $-OCH_3$), 6.90 (1H, d, J=8.06 Hz, H-2), 6.98 (1H, s, -NH), 7.18 (1H, d, J=9.15 Hz, H-8), 7.19 (1H, dd, J=9.16, 2.93 Hz, H-7), 7.39 (1H, d, J=8.06 Hz, H-3), 7.51 (1H, d, J=2.93 Hz, H-5), 7.59 (1H, s, -NH), 7.74 (1H, s, -NH), and 9.86 (1H, s, -NH). Found: C, 58.66; H, 5.28; N, 8.00%. Calcd for $C_{17}H_{18}O_6N_2$: C, 58.95; H, 5.24; N, 8.09%.

2-Acetoxy-2-(6,7-dimethoxy-1-naphthyl)propanediamide (2f): Mp 215—216 °C (from chloroform–ethyl acetate); IR(KBr) ν 1680 ($-CONH_2$), 1738 (-OAc), 3100—3500 ($-NH_2$) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=2.21 (3H, s, -OAc),

3.82 (6H, s, 2×-OCH_3), 7.13—7.34 (2H, m, H-3, -NH), 7.32 (1H, s, H-5), 7.51—7.53 (1H, dd, H-2), 7.67 (1H, s, H-8), 7.75—7.79 (1H, dd, H-4), 7.92 (2H, s, 2×-NH), and 8.20 (1H, s, -NH); MS *m/z* (rel intensity) 346 [M^+] (70), 304 (44), 285 (100), 261 (100), 216 (100), and 188 (90). Found: *m/z* 346.1141. Calcd for $C_{17}H_{18}O_6N_2$: M, 346.1165.

2-Hydroxy-2-(6,7-dimethoxy-1-naphthyl)propanediamide (3f): Mp 229.5—230.5 °C (from chloroform–ethyl acetate); IR(KBr) ν 1680 (-$CONH_2$), 3100—3500 (-NH, -OH) cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ=3.81 (3H, s, -OCH_3) 3.87 (3H, s, -OCH_3), 6.21 (1H, s, -OH), 7.25 (1H, t, *J*=7.33 Hz, H-3), 7.27—7.29 (1H, dd, H-2), 7.28 (1H, s, -NH), 7.31 (1H, s, H-5), 7.58 (1H, s, -NH), 7.62 (1H, s, H-8), 7.70—7.73 (1H, dd, H-4), and 7.93 (2H, s, -NH_2). MS *m/z* (rel intensity) 304 [M^+] (100), 285 (34), 261 (100), 216 (100), and 188 (100). Found: *m/z* 304.1050. Calcd for $C_{15}H_{16}O_5N_2$: M, 304.1069.

Reaction of Xanthene with Malonamide in the Presence of Manganese(III) Acetate. To a heated solution of xanthene (1 mmol) and malonamide (8 mmol) in acetic acid (30 cm^3), manganese(III) acetate (8 mmol as Mn(III)) was added. The reaction mixture was heated under reflux for 1 min. The solvent was removed under reduced pressure and the residue treated with 2 M hydrochloric acid (50 cm^3). The precipitate was collected and recrystallized from a mixture of chloroform and ethyl acetate to give 9-xanthenone (11%) and 2-(9-xanthenyl)propanediamide (**6**) (81%): Mp 281—282 °C; IR(KBr) ν 1675 (-$CONH_2$), 3100—3500 (-NH_2) cm^{-1}; ^1H NMR (60 MHz, DMSO-d_6) δ=3.10 (1H, d, *J*=10.8 Hz, >CH-), 4.60 (1H, d, *J*=10.8 Hz, >CH-), and 6.87—7.41 (12H, m, 2×-NH_2, arom. H). Found: C, 67.81; H, 5.05; N, 9.84%. Calcd for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.00; N, 9.92%.

Reactions of Methoxynaphthalenes (1a, 1c, and 1d) with Ethyl 3-Oxobutanoate in the Presence of Manganese(III) Acetate. A mixture of a methoxynaphthalene (1 mmol), ethyl 3-oxobutanoate (4 mmol), and manganese(III) acetate (12 mmol for Mn(III)) in acetic acid (30 cm^3) was heated under reflux until the dark-brown color of the solution turned colorless. The reaction mixture was poured into water (50 cm^3) and then extracted with chloroform (50 cm^3). The chloroform and the unchanged ethyl 3-oxobutanoate was removed under reduced pressure; the residue was then chromatographed on a silica-gel plate while eluting with chloroform. The products were further purified by repeated TLC or by recrystallization.

Products. Ethyl 2-Acetoxy-2-(2,7-dimethoxy-1-naphthyl)-3-oxobutanoate (4a): Liquid; IR($CHCl_3$) ν 1720, 1743, 1750 (≥C=O) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.28 (3H, t, *J*=7.0 Hz, -$OCH_2\underline{CH_3}$), 2.20 (3H, s, -$COCH_3$), 2.28 (3H, s, -$COCH_3$), 3.83 (3H, s, -OCH_3) 3.87 (3H, s, -OCH_3), 4.30 (2H, q, *J*=7.0 Hz, -$O\underline{CH_2}CH_3$), 6.98 (1H, dd, *J*=9.0, 2.0 Hz, H-6), 7.10 (1H, d, *J*=9.0 Hz, H-3), 7.42 (1H, d, *J*=2.0 Hz, H-8), 7.62 (1H, d, *J*=9.0 Hz, H-4 or H-5), and 7.74 (1H, d, *J*=9.0 Hz, H-5 or H-4). MS *m/z* (rel intensity) 374 [M^+] (8), 332 (19), 289 (13), and 215 (100). Found: *m/z* 374.1330. Calcd for $C_{20}H_{22}O_7$: M, 374.1366.

Ethyl 2-(Acetoxymethyl)-8-methoxynaphtho[2,1-*b*]furan-1-carboxylate (5a): Mp 92—93 °C (from ethanol); IR ($CHCl_3$) ν 1717 (-CO_2Et), 1742 (-OAc) cm^{-1}; ^1H NMR (90 MHz, $CDCl_3$) δ=1.463 (3H, t, *J*=7.03 Hz, -$OCH_2\underline{CH_3}$), 2.148 (3H, s, -OAc), 3.996 (3H, s, -OCH_3) 4.511 (2H, q, *J*=7.03 Hz, -$O\underline{CH_2}CH_3$), 5.559 (2H, s, -CH_2-), 7.170 (1H, dd, *J*=9.09, 2.49 Hz, H-7), 7.474 (1H, d, *J*=9.09 Hz, H-4 or H-5), 7.735 (1H, d, *J*=9.09 Hz, H-5 or H-4), 7.826 (1H, d, *J*=9.09 Hz, H-6), and 8.691 (1H, d, *J*=2.49 Hz, H-9). MS *m/z* (rel intensity) 342 [M^+] (100), 283 (20), 255 (33), 254 (24), and 253 Found: *m/z* 342.1085. Calcd for $C_{19}H_{18}O_6$: M, 342.1104.

Ethyl 2-Acetoxy-2-(2-methoxy-1-naphthyl)-3-oxobutanoate (4c): Mp 146—147 °C (from ethanol); IR($CHCl_3$) ν 1720, 1742, 1750 (>C=O) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.28 (3H, t, *J*=7.0 Hz, -$OCH_2\underline{CH_3}$), 2.20 (3H, s, -$COCH_3$), 2.28 (3H, s, -$COCH_3$), 3.91 (3H, s, -OCH_3), 4.17 (2H, q, *J*=7.0 Hz, -$O\underline{CH_2}CH_3$), 7.27 (1H, d, *J*=9.0 Hz, H-3), 7.87 (1H, d, *J*=9.0 Hz, H-4), and 7.3—8.2 (4H, m, H-5—H-8). MS *m/z* (rel intensity) 344 [M^+] (21), 302 (63), 260 (17), 259 (22), 256 (23), 229 (18), 214 (27), 187 (27), 186 (26), and 185 (100). Found: C, 66.23; H, 5.84%. Calcd for $C_{19}H_{20}O_6$: C, 66.27; H, 5.85%.

Ethyl 2-(Acetoxymethyl)naphtho[2,1-*b*]furan-1-carboxylate (5c): Colorless liquid; IR($CHCl_3$) ν 1722 (-CO_2Et), 1745 (-OAc) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.46 (3H, t, *J*=7.0 Hz, -$OCH_2\underline{CH_3}$), 2.13 (3H, s, -OAc), 4.53 (2H, q, *J*=7.0 Hz, -$O\underline{CH_2}CH_3$), 5.56 (2H, s, -CH_2-), 7.4—8.1 (5H, m, H-4—H-8), and 9.15 (1H, m, H-9). MS *m/z* (rel intensity) 312 [M^+] (95), 270 (38), 269 (28), 253 (22), 225 (30), 224 (30), and 223 (100). Found: *m/z* 312.1002. Calcd for $C_{18}H_{16}O_5$: M, 312.0998.

Ethyl 2-Acetoxy-2-(2,6-dimethoxy-1-naphthyl)-3-oxobutanoate (4d): Liquid; IR($CHCl_3$) ν 1725, 1745, 1760 (>C=O) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=1.29 (3H, t, *J*=7.0 Hz, -$OCH_2\underline{CH_3}$), 2.20 (3H, s, -$COCH_3$), 2.29 (3H, s, -$COCH_3$), 3.87 (6H, s, 2×-OCH_3), 4.33 (2H, q, *J*=7.0 Hz, -$O\underline{CH_2}CH_3$), 7.0—7.2 (2H, m, H-5, H-7), 7.22 (1H, d, *J*=9.0 Hz, H-3), 7.73 (1H, d, *J*=9.0 Hz, H-4), and 8.00 (1H, d, *J*=10.0 Hz, H-8). MS *m/z* (rel intensity) 374 [M^+] (36), 332 (66), 217 (31), 216 (21), and 215 (100). Found: *m/z* 374.1356. Calcd for $C_{20}H_{22}O_7$: M, 374.1366.

Ethyl 2-(Acetoxymethyl)-7-methoxynaphtho[2,1-*b*]furan-1-carboxylate (5d): Mp 112—113 °C (from ethanol); IR ($CHCl_3$) ν 1710 (-CO_2Et), 1732 (-OAc) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$), δ=1.45 (3H, t, *J*=7.0 Hz, -$OCH_2\underline{CH_3}$), 2.12 (3H, s, -OAc), 3.90 (3H, s, -OCH_3), 4.50 (2H, q, *J*=7.0 Hz, -$O\underline{CH_2}CH_3$), 5.52 (2H, s, -CH_3-), 7.18 (1H, d, *J*=2.0 Hz, H-6), 7.21 (1H, dd, *J*=8.2, 2.0 Hz, H-8), 7.53 (1H, d, *J*=9.0 Hz, H-4 or H-5), 7.62 (1H, d, *J*=9.0 Hz, H-5 or H-4), and 9.00 (1H, d, *J*=8.2 Hz, H-9); ^{13}C NMR (22.4 MHz, $CDCl_3$) δ=14.246 (1C, -$CH_2\underline{C}H_3$), 20.705 (1C, -$OCO\underline{C}H_3$), 55.269 (1C, -OCH_3), 58.297 (1C, -CH_2-), 61.370 (1C, -CH_2-), 107.868 (1C, =CH-), 112.239 (1C, =CH-), 114.730 (1C, =C-), 118.266 (1C, =CH<), 120.130 (1C, =C<), 122.845 (1C, =C<), 126.754 (1C, =CH-), 127.500 (1C, =CH-), 132.766 (1C, =C<), 151.502 (1C, =C<), 155.798 (1C, =C<), 156.947 (1C, =C<), 164.033 (1C, -$O\underline{C}OCH_3$), and 170.313 (1C, -$\underline{C}OOEt$). MS *m/z* (rel intensity) 342 [M^+] (88), 300 (19), 283 (20), 253 (100), and 215 (44). Found: C, 66.64; H, 5.27%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

Reactions of 2,7-Dimethoxynaphthalene (1a) with 2-Cyanoacetamide and Malononitrile in the Presence of Manganese(III) Acetate. Reactions of **1a** with the active methylene compounds in the presence of manganese(III) acetate were carried out in a manner similar to that of malonamide at a molar ratio of 1:8:8.

Products. 2-Acetoxy-2-cyano-2-(2,7-dimethoxy-1-naphthyl)acetamide (7a): Mp 169 °C (from ethanol); IR($CHCl_3$) ν 1708 (-$CONH_2$), 1765 (-OAc), 2230 (C≡N) cm^{-1}; ^1H NMR

(400 MHz, $CDCl_3$) δ=2.15 (3H, s, -OAc), 3.84 (3H, s, $-OCH_3$), 3.94 (3H, s, $-OCH_3$), 7.08 (1H, dd, J=8.79, 2.20 Hz, H-6), 7.31 (1H, d, J=8.80 Hz, H-3), 7.46 (1H, d, J=2.20 Hz, H-8), 7.81 (1H, d, J=8.79 Hz, H-5), 7.93 (1H, d, J=8.79 Hz, H-4), 8.18 (1H, s, -NH), and 8.39 (1H, s, -NH). MS m/z (rel intensity) 328 [M^+] (21), 301 (10), 285 (9), 242 (39), 226 (13), and 215 (100). Found: C, 62.21; H, 4.89; N, 8.52%. Calcd for $C_{17}H_{16}O_5N_2$: C, 62.19; H, 4.91; H, 8.53%.

4-Dicyanomethylene-3,6-dimethoxy-1(4*H*)-naphthalenone (8): Mp 166—167 °C (from ethanol); IR($CHCl_3$) ν 1618 (C=C), 1676 (>C=O), 2220 (C≡N) cm^{-1}; ^1H NMR (60 MHz, $CDCl_3$) δ=3.95 (3H, s, $-OCH_3$) 3.98 (3H, s, $-OCH_3$), 6.84 (1H, s, =CH-), 7.20 (1H, dd, J=9.0, 2.4 Hz, H-7), 7.72 (1H, d, J=2.4 Hz, H-5), and 8.73 (1H, d, J=9.0 Hz, H-8). Found: C, 67.55; H, 3.89; N, 10.55%. Calcd for $C_{15}H_{10}O_3N_2$: C, 67.66; H, 3.79; N, 10.52%.

The authors wish to thank Mr. Yasunori Sudoh of Taiho Pharmaceutical Co., Ltd., Tokushima, for his assistance in measuring the mass spectra.

(Received September 27, 1990)

Structures of the polymers obtained by solid-state polymerization of diyne, triyne, and tetraynes substituted by long chain alkyl groups were investigated by solid-state ^{13}C NMR spectroscopy. Assignment of all peaks in the spectra were made successfully, referring to those of the monomers and the polydiacetylenes of known structures. It was clearly shown that the backbone of these polymers has always the same structure of $\rangle C{=}C{-}C{\equiv}C{-}C{=}\langle$. This fact suggests that only 1,4-addition polymerization takes place in the similar way for the diyne, the triyne and the tetraynes, excluding many other possible addition schemes, and the tetraynes give an interesting polydiacetylene with butadiynyl substituents. This exclusive 1,4-addition can be explained in terms of topochemical control.

Conjugated polymers are interesting for their superior third-order nonlinear optical properties. Among them, polydiacetylenes were the first conjugated polymer whose third-order nonlinear optical property was reported with expectation to surpass the semiconductors.[1] To achieve enlarged third-order susceptibilities, polydiacetylenes having π-conjugations between polymer backbone and side chains might be better candidates than those with no such π-conjugations because of increased numbers of π-electrons per repeating unit.[2,3] We have succeeded in the preparation of several series of new polydiacetylenes with aromatic rings directly bound to the main chains by proper crystal engineering.[4–9] In this context, especially interesting are the polydiacetylenes with acetylenic substituents directly bound to the main chain, since we can expect perfect π-conjugation between the main chain and substituents. Recently, we have synthesized a triyne[9] and tetraynes[10] with long-alkyl substituents and confirmed their solid-state polymerizabilities. However, the structures of these polymers were not determined exactly. This paper concerns with the detailed structural analysis of the polymers by solid-state ^{13}C NMR spectroscopy and some other measurements.

Experimental

Spectroscopy and X-Ray Diffraction. IR spectra, Visible spectra, and solution ^1H NMR spectra were measured by a JASCO IR-810, a Shimadzu UV-3100S, and a Nicolet NT-360, respectively. Transmitted X-ray diffraction patterns were recorded on a powder diffractometer (Philips PW-1700) using Cu $K\alpha$ radiation.

Solid-state high resolution ^{13}C NMR spectra were obtained by use of a JEOL FX-200 at 50.10 MHz with the cross-polarization (CP)/ magic angle spinning (MAS) method. The 90° pulse for the ^{13}C resonance was 4.5 μs and the MAS speed was between 4.8 and 5.5 kHz. The CP time was changed from 1 to 10 ms to observe the relative intensities. Dipole-dephasing spectra were measured with the delayed time of 40 μs for the assignment. Also the single pulse measurement with ^1H decoupling and MAS was carried out to observed mobile carbons. The ^{13}C chemical shifts were referred to external adamantane, where the CH_2 peak was set as 29.5 ppm. Solution-state ^{13}C NMR spectra were also observed by the same spectrometer. Chloroform-*d* including a small amount of tetramethylsilane was used as a solvent.

Synthesis of Monomers. The synthetic procedures of the compounds used were shown in Fig. 1. 10,12,14-Nonacosatriynoic acid (14-3A-8C), as a triyne compound, was prepared according to the procedure described before.[9] Tetrayne compounds of 15,17,19,21-hexatriacontatetrayne (14-4A-14) and 19,21,23,25-tetratetracontatetrayne (18-4A-18) were also synthesized as described before.[10] 15,17-Dotriacontadiyne (14-DA-14) was synthesized as a reference of this series of compounds, according to the procedure described below.

14-DA-14. To a solution of *N,N,N′,N′*-tetramethylethylenediamine (580 mg, 5 mmol) and copper(I) chloride (500 mg, 5 mmol) in tetrahydrofuran (150 cm^3), 1-hexadecyne (11.1 g, 50 mmol) was added. While it was stirred for one day at ambient temperature, oxygen was bubbled into the solution. After evaporating the solvent, hydrochloric acid solution was added to the residue and the mixture was extracted with hexane. The hexane layer was dried with anhydrous sodium sulfate. After filtration, the solvent was removed in vacuo and the residue was purified by column chromatography (silica gel, hexane) to give 9.90 g, (90%) of 14-DA-14. After recrystallization from hexane, 3.59 g of pure 14-DA-14 was obtained. Mp 50—51 °C; IR(KBr) 2950, 2924, 2857, 2179 (weak), 2146 (weak), 1473, 1418, 718 cm^{-1}; ^1H NMR ($CDCl_3$) δ=0.88 (6H, t, J=6.4 Hz), 1.26 (40H, m), 1.37 (4H, m), 1.51 (4H, tt, J=7.1, 6.7 Hz), 2.24 (4H, t, J=6.7 Hz). Found: C, 86.80; H, 13.20%. Calcd for $C_{32}H_{58}$: C, 86.68; H, 13.43%.

Polymerization. Absorption spectral changes of the compounds during photopolymerization were followed using KBr-pelletized specimens under the irradiation of an 8 W UV lamp (Tokyo Kogaku Kikai K. K. PUV-1A) at the distance of 2 cm. Polymers were obtained by γ-ray induced polymerization. The doses of ^{60}Co γ-ray were 112 Mard for 14-DA-14, 57 Mrad for 14-3A-8C, 31 Mrad for 14-4A-14 and 47 Mrad for 18-4A-18, respectively, with the dose rate of ca. 0.15 Mrad h^{-1}. Since the polymers are insoluble in the organic solvents

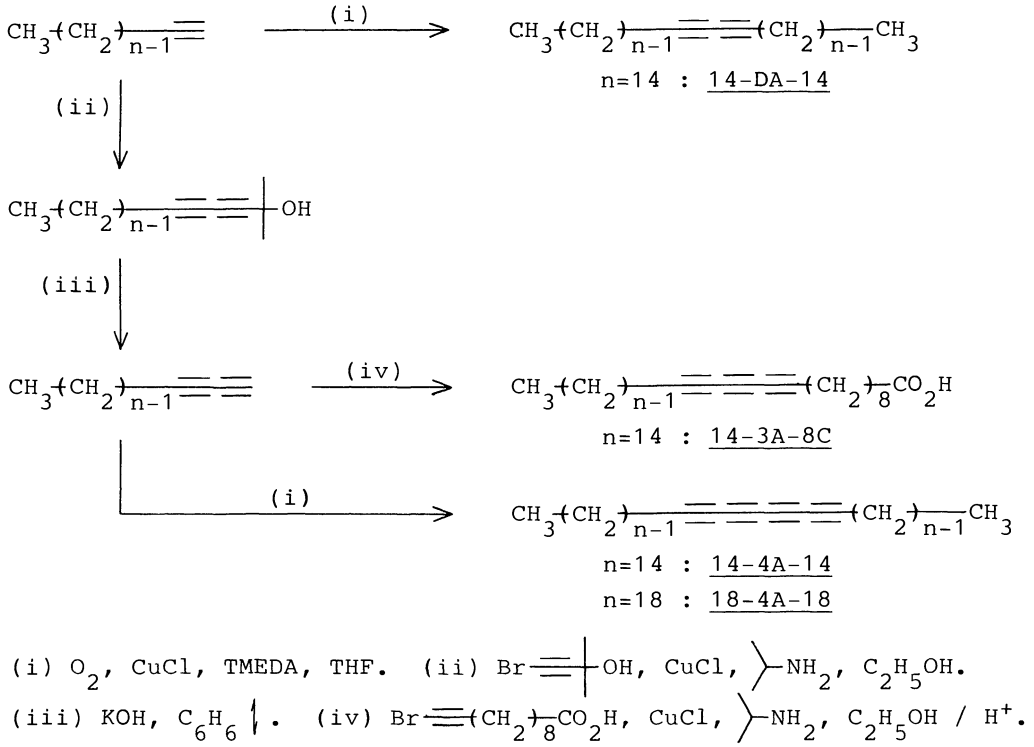

Fig. 1. Synthetic procedure of the monomers.

which can dissolve the monomers, the polymer conversion was determined gravimetrically after the solvent extraction of the monomers. Although the 14-4A-14 and 18-4A-18 were polymerized almost quantitatively, the conversion of 14-DA-14 and 14-3A-8C were 57% (after hexane extraction) and 86% (after chloroform extraction), respectively.

Results and Discussion

Visible and IR Spectra and X-Ray Diffraction. Figure 2 shows the visible absorption spectral change of 14-DA-14 during photopolymerization. The characteristic absorption maximum of polydiacetylene as a conjugated polymer was observed around 635 nm. 14-3A-8C, 14-4A-14, and 18-4A-18 were also polymerized by UV irradiation to become deep blue-colored polymers. Table 1 shows the comparison of the absorption maxima at the longest wavelength of the polymers from 14-DA-14, 14-3A-8C, 14-4A-14, and 18-4A-18. The absorption maxima of the polymers shifts to the longer wavelength as the number of acetylene units in the corresponding monomers increases. The increase of the acetylene units in the monomer brings the more extended π-conjugation and narrower band gap in the polymers synthesized by the solid-state polymerization.

IR spectra of 14-3A-8C, 14-4A-14, and 18-4A-18 monomers show a strong absorption in the stretching band region of acetylenic triple bonds. In their polymers, the stretching band becomes weaker but remains. If all the acetylene units were included in the polymer backbone, the bands should disappear because of the symmetric structure around acetylene

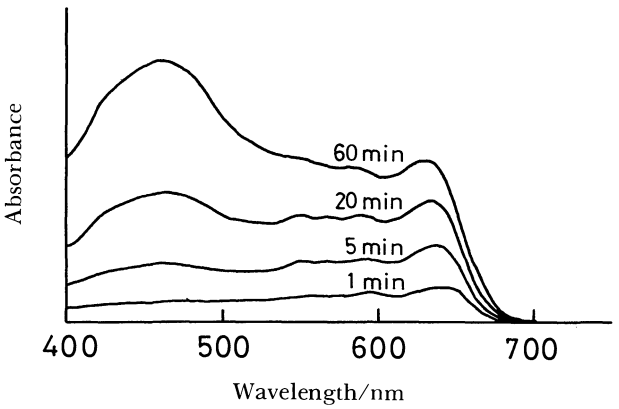

Fig. 2. Visible spectral change of 14-DA-14 depending on UV irradiation time.

Table 1. The Longest-Wavelength Absorption Maxima at the Initial Stage of Polymerization

Compound	λ_{max}/nm
14-DA-14	640—630
14-3A-8C	670—660
14-4A-14, 18-4A-18	710—700

units. Thus, one or more acetylene bonds must be in the side chains.

Crystallinity was checked by X-ray powder diffraction analysis. All the monomers showed several sharp diffraction peaks. The polymers of 14-3A-8C, 14-4A-14, and 18-4A-18, however, showed only broad peaks and the largest main peak was around 19—20°. This peak corresponds to the spacing of ca. 0.45 nm indicating that regularity between adjacent alkyl chains was maintained even in these polymers. On the contrary, the polymer of 14-DA-14 showed several sharp peaks, reflecting the high crystallinity.

^{13}C NMR Spectra. Tables 2, 3, and 4 show the ^{13}C chemical shifts of the monomers of 14-DA-14, 14-3A-8C, and 14-4A-14, respectively, in the solution and in the solid-state. The assignment was first carried out for the monomers in solution. The acetylenic carbons were assigned from ^{1}H undecoupled spectra. For instance, 14-4A-14 monomer gives the four ^{13}C peaks at 80.5, 65.7, 61.4, and 60.6 ppm, corresponding to the existence of four pairs of nonequivalent acetylenic carbons. It is known that the coupling constants of those carbons with α-methylene protons decrease with the numbers of the bonds between them. Since the coupling constants of the signals at 80.5, 65.7, 61.4, and 60.6 ppm were 5.5 Hz, 4.6 Hz, 3.7 Hz, and undetectable, respectively, the four peaks in the above order were easily identified to the four nonequivalent acetylenic carbons, i.e., from the outer most to the inner most ones in the same order. This trend is the same as the di-*t*-butyl-substituted octatetrayne.[11]

The ethynylene group causes the higher field shift of about 10 ppm to α-CH_2 but none to β- and γ-CH_2. Thus, among many carbon atoms in the alkyl chains, α-CH_2 can be identified. Though the monomer of 14-3A-8C in solution showed three pairs of acetylenic carbon peaks with small splittings because of its unsymmetrical structure, the differences were very small and less than 0.5 ppm and their assignments were straightforward as shown in Table 3. The ^{13}C spectral patterns of the monomers in chloroform-*d* solution are saved in the Spectral Database System (SDBS) constructed by National Chemical Laboratory for Industry[12].

The solid-state ^{13}C spectra of the 14-DA-14 and 14-4A-14 monomers observed by single-pulse MAS method with ^{1}H decoupling resemble to the corresponding solution-state spectra, and this suggests that these monomer contain very mobile molecules within

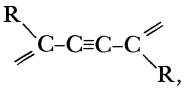
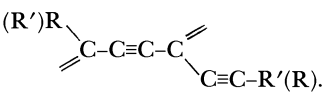
the crystals. In the CP/MAS ^{13}C spectra of these monomers, the line widths are broader and a large peak of the alkyl chain carbons in the stacked state can be observed at 33—34 ppm in addition to the mobile carbons signals at about 30 ppm. In the CP/MAS spectrum of the 14-DA-14 monomer, the signals of the mobile acetylene carbons were not observed, while the both signals of the mobile and the rigid carbons in the alkyl chains were observed as shown in Table 2. Then it is clear that the alkyl-chain carbons are more flexible than the acetylenic carbons in the 14-DA-14 monomer in the solid-state. Similarly, the CP/MAS spectrum of the 14-4A-14 monomer contains both signals of the mobile and the rigid alkyl-chain carbons, but the ratio of the mobile carbons decreases. Then the molecular motions of 14-4A-14 monomer may become slower compared with the 14-DA-14 monomer. On the other hand, the single-pulse MAS spectrum of the 14-3A-8C monomer was very intensive suggesting that the crystal structure is rigid. The reduced molecular motion in the 14-3A-8C monomer can be attributed to hydrogen bonding between carboxyl groups contained in the molecule. The magnitudes of the alkyl-chain motion of these three monomers coincide to the order of their melting points, i.e., melting points of the monomers are 50—51 °C for 14-DA-14, 58—59 °C for 14-4A-14, and 78—79 °C for 14-3A-8C, respectively. The lower melting point the monomer has, the more mobile its alkyl chain is. In 14-3A-8C, shoulders were observed in the three acetylenic carbon peaks in the MAS and CP/MAS spectra. This may be due to inhomogenious circumstances around the acetylenic carbons in 14-3A-8C monomer.

Figure 3 shows the CP/MAS ^{13}C spectra of the polymers in olefinic and acetylenic region and Table 5 lists up the chemical shifts of all the peaks. The backbone structure of 14-DA-14 polymer is



where the two acetylenic carbons and two olefinic carbons are equivalent. Actually, in Fig. 3(a), only two peaks at 101.6 and 130.2 ppm were observed. They were easily assigned to be acetylenic and olefinic carbons, respectively, which agree with those of so-far known polydiacetylenes[13–16] as summarized in Table 6.

In the polymer of 14-3A-8C, six peaks, of which two peaks around 103.9 ppm are considered to overlap because of the twice intensity, were observed (Fig. 3(b)). If they were polymerized symmetrically by 1,6-addition, the number of the peaks in this region should be three. The result clearly indicates that 14-3A-8C are polymerized unsymmetrically by 1,4-addition and therefore the backbone structure of 14-3A-8C polymer is



The same polymerization scheme was reported for a hexatriyne derivative with urethane substituents based

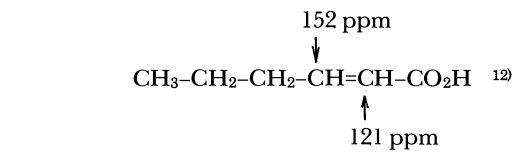
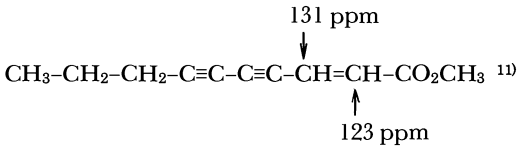
on the X-ray diffraction analysis.[17] The two olefinic carbons of the main chain of 14-DA-14 polymer are equivalent to give one peak at 130.2 ppm, whereas those of 14-3A-8C are not equivalent to give two peaks, i.e., one at the higher and the other at the lower field. It is known that an acetylenic group, compared with an alkyl group, attached to the olefinic moiety bring the chemical shift of the olefinic α-carbon to about 20 ppm higher field, as shows in the following example;

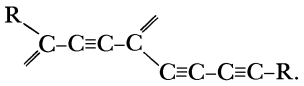




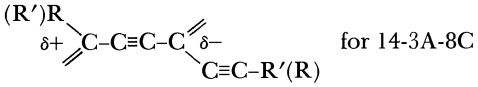
Thus, the higher field peak about 112 ppm was assigned to the olefinic carbon attached to the acetylenic side chain, and the lower field peak about 142 ppm to that attached to the simple alkyl chain. However, the splitting of the two peaks is quite large, i.e., 30 ppm for 14-3A-8C polymer whereas about 20 ppm for the typical case which is expected from the difference of the chemical shift of the two molecules shown above. This will be mentioned later again.

The peak at 103.9 ppm with larger intensity is assigned to the two backbone acetylenic carbons and is not so moved from 101.6 ppm of the acetylenic carbons of 14-DA-14. For the acetylenic side chain, the peaks at 97.4 ppm and 77.9 ppm were assigned to the β- and α-carbons from the polymer backbone, respectively, because the alkyl-attached acetylenic carbon shows the peak in the lower field as discussed in the case of the monomers.

In the same manner, the assignment of the peaks for polymers of 14-4A-14 and 18-4A-18 was performed as listed in Table 5. The spectra of 14-4A-14 and 18-4A-18 are the same except in peak intensity for the carbons of long-alkyl groups. As the chemical shifts of the three peaks in the lower field of Fig. 3(c) which correspond to the polymer backbone are similar to those of Fig. 3(b), it was estimated that 14-4A-14 and 18-4A-18 also are polymerized unsymmetrically by 1,4-addition just like 14-3A-8C. Thus, the backbone structure of 4A polymers is

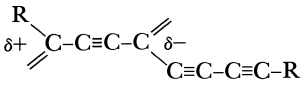


The splitting of the chemical shifts between two olefinic carbons are about 37 ppm and larger than that of 14-3A-8C. One of the plausible explanation of this splitting may be the polarization of the main chain as follows;



for 14-3A-8C

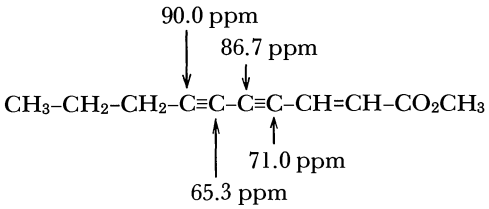
and



for 14-4A-14 and 18-4A-18,

respectively. This polarization should be enhanced in 14-4A-14 and 18-4A-18 polymers because of the more conjugated side chains.

The diacetylenic side chain was assigned by referring the following example;[11]



The peaks at about 90, 81, 72, and 65 ppm in 14-4A-14 and 18-4A-18 polymers are for the carbons at δ-, β-, α-, and γ-positions from the polymer backbone, respectively.

From these results, it has been clarified that only 1,4-polymerization occurs even in triyne and tetrayne compounds. This can be explained by so-called "topochemical control"; that is, the molecular arrangement in the crystal geometrically allows only the exclusive reaction path among many possible paths since the molecular movements are very restricted in the crystal.[18] It is known that the solid-state polymerizability of diacetylene monomers to the well-known polydiacetylene structure via 1,4-addition can be characterized by the stacking distance of the monomer array (d) and by the angle between the diacetylene rod and stacking axis (Φ).[19] And the maximal reactivity is expected for $d \approx 0.5$ nm and $\Phi \approx 45°$. When 14-4A-14 molecules are packed, using a space-filling model, without any gaps between molecules, the perpendicular distances of adjacent alkyl groups and adjacent tetraacetylenic moieties are 0.45 nm and 0.34 nm, respectively. Under this condition, d and Φ

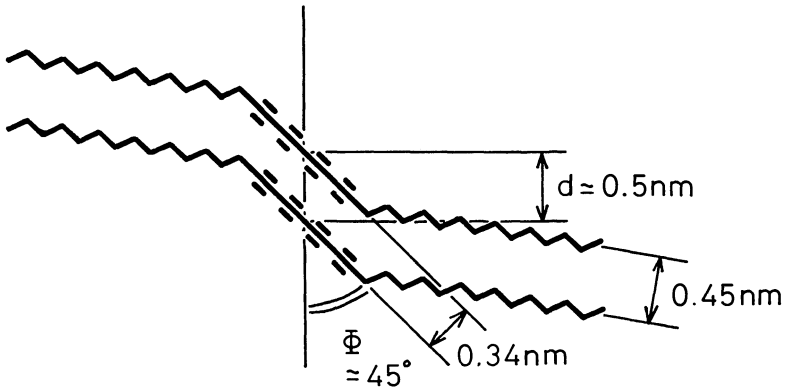


Fig. 4. Molecular packing scheme of 14-4A-14.

become ca. 0.5 nm and ca. 45°, respectively, as shown in Fig. 4. This is the case of the alkyl-substituted diynes and triynes, and the packing is exactly the best one for the 1,4-addition and not for other schemes such as 1,2-, 1,6-, and 1,8-additions.

For the tetrayne compounds, two different types of 1,4-polymerization are possible as mentioned in the previous paper,[10] i.e., the unsymmetrical polymerization as shown in this work and the symmetrical polymerization to give a di(1-alkynyl)-substituted polydiacetylene. The distance between the reacting carbons of the adjacent molecules are the same for the both polymerization procedures because tetrayne moiety stacks parallel. Only difference between two possible schemes is the existence of the reactive carbon with an alkyl chain in the case of unsymmetrical polymerization. Since the alkyl chain is more mobile than the acetylene moiety, the acetylenic carbon bound to an alkyl group can be assumed to become a starting point of the polymerization which results in the present unsymmetrical polydiacetylene structures.

In conclusion, the structures of the polymers from alkyl-substituted triyne and tetraynes were analyzed especially by solid-state ^{13}C NMR spectra. It has been found that triyne and tetraynes are polymerized unsymmetrically via 1,4-addition to give the polydiacetylene with acetylenic side chains and the polydiacetylenes with diacetylenic side chains, respectively. As the structure of the polydiacetylenes with diacetylenic side chains are confirmed, polymerization of the diacetylene moieties in side chain seems to be interesting to obtain a novel class of π-conjugated polymers and the investigation is currently in progress.

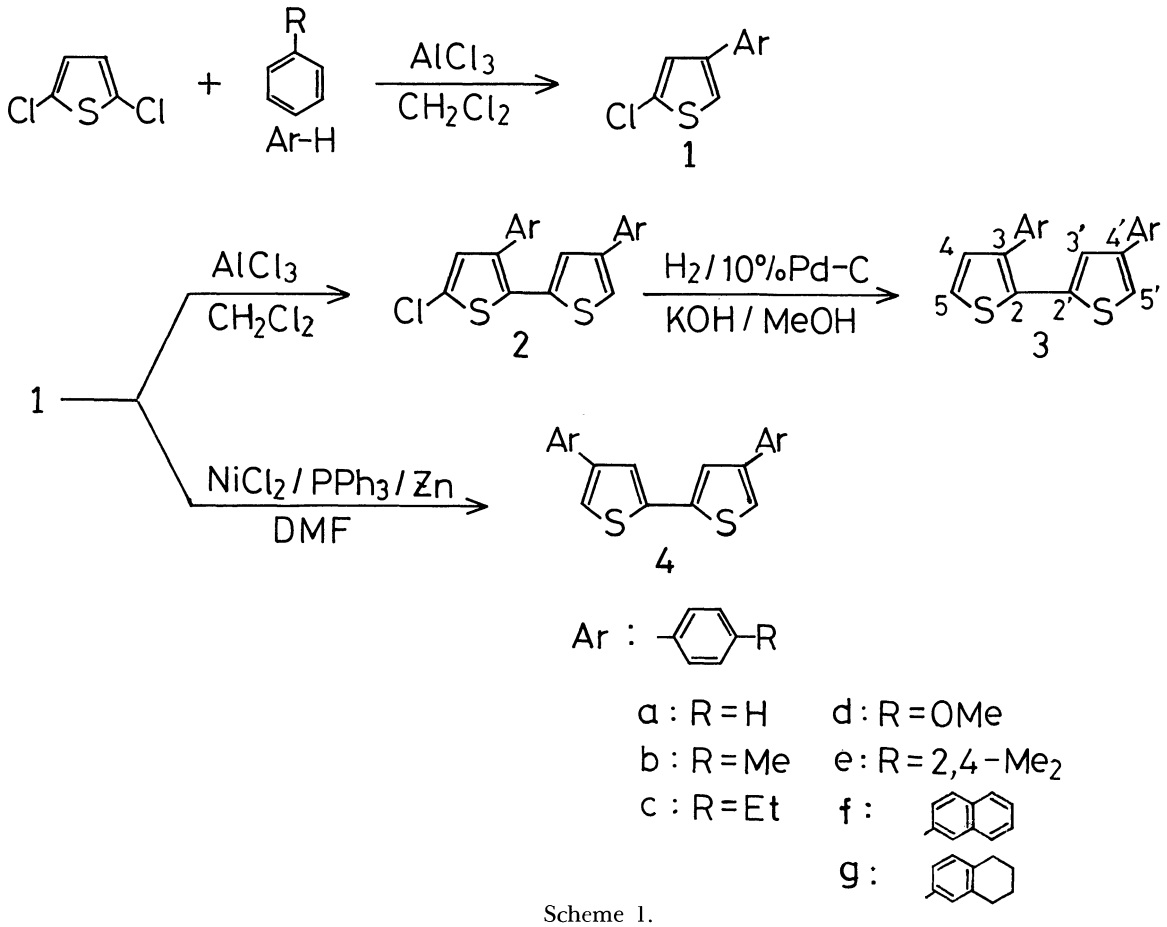
Synthesis of 3,4′-Diaryl- and 4,4′-Diaryl-2,2′-bithienyls from 2,5-Dichlorothiophene[1)]

Tyo Sone,* Yasuhiro Umetsu, and Kazuaki Sato
Department of Materials Science and Engineering, Faculty of Engineering,
Yamagata University, Yonezawa 992
(Received October 19, 1990)

3,4′-Diaryl-, and 4,4′-diaryl-2,2′-bithienyls, new classes of mixed thiophene–arene oligomers, were synthesized from 2,5-dichlorothiophene via 4-aryl-2-chlorothiophene in three and two steps, respectively. Namely, a Friedel–Crafts type self-condensation of 4-aryl-2-chlorothiophene, followed by catalytic dechlorination, yielded unsymmetrical bithienyls. Homocoupling of 4-aryl-2-chlorothiophene using a nickel–phosphine catalyst gave symmetrical bithienyls.

Although the syntheses and properties of oligophenylenes have been systematically investigated, the chemistry of their thiophene analogues, thiophene oligomers and mixed thiophene–arene oligomers, has not yet been fully explored. Oligomers with definite structure, corresponding to quaterphenyl or its higher homologues, are rather limited in number; only a few of those containing 2,3′-bithienyl or 3-arylthiophene unit have been known.[2–5)] As for diarylbithienyls, one of the simplest classes of oligomers, for example, only two (5,5′-diaryl-[3)] and 3,3′-diphenyl-2,2′-bithienyl[4)]) have been reported. We have reported the synthesis of a series of unsymmetrical 5,5′-diaryl-2,3′-bithienyls by acid-catalyzed coupling of 2-arylthiophenes.[5)] Some of the oligomers have recently attracted attention in connection with their potential electric conductivity.[6)]

During the course of the studies on the acid-catalyzed reactions of thiophene nuclei, we found that, in the presence of $AlCl_3$, the chlorine atom of chlorothiophenes was sufficiently reactive; 2-chlorothiophene gave the corresponding 2-arylthiophenes with some aromatic compounds,[7)] while 2, 5-dichlorothiophene gave 4-aryl-2-chlorothiophenes (**1**) unexpectedly.[8)] These findings suggest a simple route to certain arylthiophenes starting from readily available chlorothiophenes. As an extension of the studies,



Scheme 1.

we found a convenient method for the synthesis of unsymmetrical 3,4′-diaryl-2,2′-bithienyls (**3**) from **1**. Furthermore, a series of symmetrical 4,4′-diaryl-2,2′-bithienyls (**4**) has been synthesized by homo-coupling of **1** using a nickel–phosphine catalyst. Besides forming new classes of mixed thiophene–arene oligomers, these compounds are interesting as potential key building blocks for well-ordered β-arylthiophene oligomers from the viewpoint of electrochemical properties.

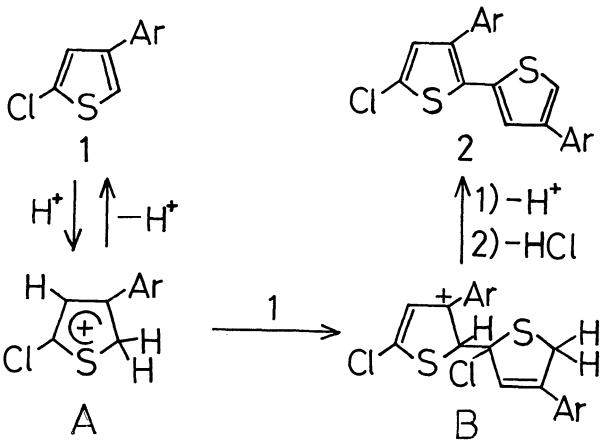
Results and Discussion

In order to find a simple route to 2,4-diarylthiophenes which were not easily accessible by traditional methods, the Friedel–Crafts type reaction of **1** with aromatic compounds was investigated. When reacted with such an active compound as anisole, however, **1** were found to undergo self-condensation with the elimination of HCl to give, instead of the expected product, 5-chloro-3,4′-diaryl-2,2′-bithienyls (**2**). This prompted us to apply the procedure for the synthesis of the unsymmetrical bithienyls, **3**. Self-condensation products, **2**, precursors of **3**, could be synthesized by this procedure in satisfactory yields. The results are summarized in Table 1.

The procedure of the Friedel–Crafts type reaction is simple; a mixture of **1** and an equimolar amount of $AlCl_3$ in CH_2Cl_2 or in CH_2Cl_2–benzene was stirred below 40 °C for a total of 2 h.

The assignment of the 3,4′-diaryl-2,2′-bithienyl structure is based on the NMR spectra of the self-condensation products, **2**, and those of the dechlorination products, **3**. The AB quartets with coupling constants J=1.3—1.7 Hz, observed in the aromatic region of the spectra of **2**, indicate the presence of a 2,4- disubstituted thiophene ring in the molecules. Moreover, the two sets of coupling constants, 1.5—1.6 and 5.0—5.3 Hz, observed in the aromatic region of the spectra of **3** are apparently derived from 2,4-di- and 2,3-disubstituted thiophene ring protons, respectively.[9]

The probable mechanism for self-condensation is shown in Scheme 2; this requires an initial protonation of **1** to form the thiophenium ion **A** as the



Scheme 2.

electrophile. It is generally accepted that $AlCl_3$, when coming into contact with H_2O in moist air or HCl, produces a hypothetical species, such as $[H]^+[AlCl_3OH]^-$ or $[H]^+[AlCl_4]^-$ which acts as a proton source. Once the reaction occurs, it can provide HCl, which, together with $AlCl_3$, stimulates a further reaction. The existence of such a protonated species as **A** was confirmed by a direct NMR spectroscopic observation;[10] the spectrum of the thiophenium ion (**A**, **Ar**=Ph) produced from 2-chloro-4-phenylthiophene (**1a**) in HSO_3F at 32 °C shows, in addition to signals at 7.7—8.4 ppm due to the phenyl protons, two signals at 5.82 and 8.32 ppm with a relative intensity of 2:1. An attack of the thiophenium ion, **A** on the 5-position of **1**, followed by elimination of a proton and a HCl molecule, yields the self-condensation product, **2**.

The chlorine atom of the self-condensation products, **2**, could be easily removed by catalytic hydrogenation under atmospheric pressure using 10% Pd–C as a catalyst to give the unsymmetrical bithienyls, **3**, in satisfactory yields. The results are summarized in Table 1.

Symmetrical diarylbithienyls can be obtained by homo-coupling of the corresponding aryl-substituted halothiophenes. 3,3′-Diphenyl-2,2′-bithienyl was prepared by a Ullmann reaction of 3-phenyl-2-iodothiophene, though in low yield.[4] Efficient methods for

a) Isolated yields based on **1** used. b) Solvent for recrystallization: hex=hexane, ben=benzene, chl=chloroform. c) 5,6,7,8-Tetrahydro2-naphthyl. d) Purified by sublimation under reduced pressure (240 °C/1 mmHg).

coupling aryl halides have recently been developed using zerovalent nickel complexes. This method was applied to **1** for the synthesis of the symmetrical bithienyls, **4**. The nature of the zerovalent nickel complex used has been known to play an important role in nickel-mediated coupling. In addition, the amount of nickel complexes used is dependent upon the situation; in catalytic or stoichiometric amount. 4-Aryl-2-chlorothiophenes **1** were successfully coupled to **4** by using stoichiometric amounts of the nickel-phosphine complex prepared in situ from $NiCl_2$/PPh_3/Zn at a molar ratio of 1/4/1 in *N*,*N*-dimethylformamide (DMF) at 50 °C.[11] The results are summarized in Table 2. It has been reported that aryl chlorides, which tend to give unsatisfactory results in nickel-mediated reactions, can be efficiently coupled to diaryls by using catalytic amounts of the nickel complex in the presence of excess zinc.[12] Application of the catalytic method, however, led to the dechlorination of **1** in preference to coupling.

The structures of symmetrical bithienyls, **4**, were confirmed by their ^{1}H NMR spectra, which showed in the aromatic region an AB quartet with a coupling constant, J=1.4—1.5 Hz, characteristic of 2,4-dosibstituted thiophenes.[9]

Under the conditions employed for the synthesis of the symmetrical bithienyls, **4**, the nickel-mediated coupling of 2,5-dichloro-3-phenylthiophene was slow, affording 5-chloro-4,4′-diphenyl-2,2′-bithienyl (15%) together with the starting substance (25%) and 2-chloro-3-phenylthiophene (30%) instead of the expepcted 5,5′-dichloro-3,3′-diphenyl-2,2′-bithienyl, a precursor of the isomeric 3,3′-diphenyl-2,2′-bithienyls, in a prolonged reaction (12 h). A similar reaction (5 h) of 2-chloro-3-phenylthiophene did not give the desired 3,3′-diphenyl-2,2′-bithienyl, either, but yielded 3-phenylthiophene (25%) along with the starting substance (ca. 40%). These results indicate that steric hindrance plays an important role in nickel-mediated coupling.

In summary, we could synthesize 3,4′-diaryl-(**3**) and 4,4′-diaryl-2,2′-bithienyls (**4**), new classes of mixed thiophene–arene oligomers, which would be accessible only through many steps by other routes, in good yields in 3 and 2 steps, respectively, from readily available 2,5-dichlorothiophene. 4-Aryl-2-chlorothiophenes, **1**, which are obtained in one step from 2,5-dichlorothiophene by the Friedel–Crafts type reaction, serves as the key intermediates, suggesting the synthetic versatility of **1**.

Experimental

All of the melting and boiling points are uncorrected. The UV and MS spectra were obtained on a Hitachi 228A and a Hitachi RMU-6M (70 eV, unless otherwise noted), respectively. The ^{1}H NMR spectra were recorded on a Hitachi R-90H (90 MHz) or a Varian XL-200 (200 MHz) spectrometer using TMS as an internal reference.

4-Aryl-2-chlorothiophenes (**1**) were prepared from 2,5-dichlorothiophene by a previously described method.[8] Commercial $AlCl_3$ was used without special precautions against moisture.

Self-Condensation of 4-Aryl-2-chlorothiophene (1). Pulverized $AlCl_3$ (1.38 g, 10 mmol) was added in portions to an ice-cooled solution of **1** (10 mmol) in CH_2Cl_2 (10 ml) over ca. 5 min periods. The solution developed a dark-brown color. The reaction mixture was stirred in an ice-bath for 30 min, then at room temperature for 60 min, and finally at the reflux temperature of the solvent for an additional 30 min. The reaction mixture was poured into ice water (ca. 40 ml) and extracted with $CHCl_3$ (10 ml×3). The extracts were combined, washed successively with water, 5% $NaHCO_3$ solution, and water and dried. After removing the solvent, the residue was chromatographed (silica gel/hexane or hexane–$CHCl_3$) to afford, together with a small amount of unreacted **1**, 5-chloro-3,4′-diaryl-2,2′-bithienyl (**2**). In reactions with **1a** and **1f**, which are less soluble in CH_2Cl_2 under cooling, a mixture of CH_2Cl_2 (10 ml) and benzene (3—8 ml) was used as the solvent. In the case of **1d**, the reaction was carried out for 1 h in a mixed solvent of CH_2Cl_2 (10 ml) and anisole (10 ml) at room temperature, and then at ca. 40 °C for 30 min. Analytical samples were purified by recrystallization or chromatography.

5-Chloro-3,4′-diphenyl-2,2′-bithienyl (2a). UV (MeOH) 235 (log ε 4.44), 243 (sh, 4.43), 266 (sh, 4.36), and 320 nm (3.94); ^{1}H NMR (90 MHz; acetone-d_6) δ=7.06 (1H, s, 4-H), 7.28 (1H, d, J=1.7 Hz, 3′-H), and 7.3—7.65 (11H, m including d at 7.53, J=1.7 Hz, phenyl and 5′-H); MS *m/z* (rel intensity) 352 (M^+, 100). Found: C, 68.18; H, 3.58%. Calcd for $C_{20}H_{13}ClS_2$: C, 68.07; H, 3.71%.

5-Chloro-3,4′-di-*p*-tolyl-2,2′-bithienyl (2b). UV (MeOH) 240 (log ε 4.45), 247 (4.45), 271 (sh, 4.36), and 325 nm (3.91); ^{1}H NMR (90 MHz; acetone-d_6) δ=2.26 and 2.27 (6H, s each, CH_3), 7.00 (1H, s, 4-H), 7.09 and 7.18 (4H, AA′BB′m, *p*-phenyl), 7.20 and 7.29 (2H, AA′BB′m, *p*-phenyl), 7.33 (1H, d, J=1.3 Hz, 3′-H), and 7.4—7.5 (3H, m consisting of AA′BB′m at 7.40 and 7.49, and d at 7.50, J=1.3 Hz, *p*-phenyl and 5′-H); MS *m/z* (rel intensity) 380 (M^+, 100). Found: C, 69.40; H, 4.20%. Calcd for $C_{22}H_{17}ClS_2$: C, 69.36; H, 4.50%.

5-Chloro-3,4′-bis(*p*-ethylphenyl)-2,2′-bithienyl (2c). UV (MeOH) 244 (log ε 4.27), 271 (sh, 4.36), and 325 nm (3.73);

^{1}H NMR (90 MHz; $CDCl_3$) δ=1.19 (6H, t, J=6.8 Hz, CH_2CH_3), 2.64 (4H, q, J=6.8 Hz, CH_2CH_3), 6.90 (1H, s, 4-H), and 7.05—7.65 (10H, m, p-phenyl, 3′-H, and 5′-H); MS m/z (rel intensity) 408 (M^+, 100). Found: C, 70.22; H, 5.08%. Calcd for $C_{24}H_{21}ClS_2$: C, 70.48; H, 5.18%.

5-Chloro-3,4′-bis(p-methoxyphenyl)-2,2′-bithienyl (2d). UV (MeOH) 245 (sh, log ε 4.40), 254 (4.43), 273 (4.42), and 318—331 nm (3.89); ^{1}H NMR (90 MHz; acetone-d_6) δ=3.77 (6H, s, OCH_3), 6.85 and 6.95 (4H, AA′BB′m, p-phenyl), 7.02 (1H, s, 4-H), and 7.2—7.6 (6H, m including AA′BB′m at 7.24 and 7.34, and 7.47 and 7.57, p-phenyl, 3′-H and 5′-H); MS m/z (rel intensity) 412 (M^+, 100). Found: C, 63.99; H, 4.11%. Calcd for $C_{22}H_{17}ClO_2S_2$: C, 63.99; H, 4.15%.

5-Chloro-3,4′-di(2-naphthyl)-2,2′-bithienyl (2f). UV (MeOH) 222 (log ε 4.72), 243 (4.71), 290 (4.35), and 301 nm (sh, 4.29); ^{1}H NMR (90 MHz; $CDCl_3$) δ=7.00 (1H, s, 4-H) and 7.2—7.9 (16H, m, naphthyl, 3′-H, and 5′-H); MS m/z (rel intensity) 452 (M^+, 100). Found: C, 74.17; H, 3.59%. Calcd for $C_{28}H_{17}ClS_2$: C, 74.27; H, 3.78%.

Catalytic Dechlorination of 5-Chloro-3,4′-diaryl-2,2′-bithienyls (2). A mixture of **2** (3 mmol), KOH (1.5 g), 10% Pd–C (0.6 g), and MeOH (50 ml; MeOH (25 ml) and dioxane (50 ml) in the case of **2b** and **2d**) was stirred at room tempeprature under an atmosphere of H_2 in an atmospheric-pressure hydrogenation apparatus. After the calculated amount of H_2 was taken up (usually within 1 h), the catalyst was removed by filtration and washed with MeOH (20 ml; dioxane (20 ml) in the case of **2b** and **2d**). The combined filtrate and washings were evaporated to ca. 20 ml. Water (40 ml) was added to the residue and the resulting crystalline materials were removed by filtration, washed with a little water, dried, and chromatographed (silica gel/hexane–$CHCl_3$) to give 3,4′-diaryl-2,2′-bithienyls (**3**). The analytical sample was purified by recrystallization, sublimation under reduced pressure, or chromatography.

3,4′-Diphenyl-2,2′-bithienyl (3a). UV (MeOH) 249 (sh, log ε 4.42), 263 (4.48), and 318 nm (sh, 3.87); ^{1}H NMR (200 MHz; acetone-d_6) δ=7.17 (1H, d, J=5.2 Hz, 4-H), and 7.25—7.7 (13H, m including d at 7.53, J=5.2 Hz, 3′-H, 5′-H, 5-H, and p-phenyl); MS m/z (rel intensity) 318 (M^+, 100). Found: C, 75.16 H, 4.48%. Calcd for $C_{20}H_{14}S_2$: C, 75.43; H, 4.43%.

3,4′-Di-p-tolyl-2,2′-bithienyl (3b). UV (MeOH) 250 (sh, log ε 4.19), 265 (4.26), and 320 nm (sh, 3.74); ^{1}H NMR (200 MHz; acetone-d_6) δ=2.33 and 2.35 (6H, s each, CH_3), 7.15 (1H, d, J=5.2 Hz, 4-H), 7.19 and 7.23 (4H, AA′BB′m, p-phenyl), 7.29 and 7.33 (2H, AA′BB′m, p-phenyl), 7.39 (1H, d, J=1.5 Hz, 3′-H), 7.5—7.55 (3H, m including d at 7.52, J=5.2 Hz, and AA′BB′m at 7.53, 5-H and p-phenyl), and 7.58 (1H, d, J=1.5 Hz, 5′-H); MS m/z (rel intensity) 346 (M^+, 100). Found: C, 75.96; H, 5.15%. Calcd for $C_{22}H_{18}S_2$: C, 76.26; H, 5.24%.

3,4′-Bis(p-ethylphenyl)-2,2′-bithienyl (3c). UV (MeOH) 250 (sh, log ε 4.47), 266 (4.51), and 320 nm (sh, 3.84); ^{1}H NMR (200 MHz; acetone-d_6) δ=1.20 and 1.22 (6H, t each, J=7.6 Hz, CH_2CH_3), 2.62 and 2.64 (4H, q each, J=7.6 Hz, CH_2CH_3), 7.13 (1H, d, J=5.3 Hz, 4-H), 7.19 and 7.23 (4H, AA′BB′m, p-phenyl), 7.25—7.45 (3H, m, 3′-H and p-phenyl), and 7.5—7.7 (4H, m, 5-H, 5′-H, and p-phenyl); MS m/z (rel intensity) 374 (M^+, 100). Found: C, 76.81; H, 5.92%. Calcd for $C_{24}H_{22}S_2$: C, 76.96; H, 5.92%.

3,4′-Bis(p-methoxyphenyl)-2,2′-bithienyl (3d). UV (MeOH) 232 (sh, log ε 4.38), 250 (4.42), 272 (4.48), and 333 nm (sh, 3.76); ^{1}H NMR (200 MHz; acetone-d_6) δ=3.79 and 3.80 (6H, s each, OCH_3), 6.91 and 6.96 (4H, AA′BB′m, p-phenyl), 7.12 (1H, d, J=5.0 Hz, 4-H), 7.31 and 7.35 (2H, AA′BB′m, p-phenyl), 7.37 (1H, d, J=1.6 Hz, 3′-H), 7.46 and 7.47 (2H, d each, J=1.6 Hz, J=5.0 Hz, 5′-H and 5-H), and 7.53 and 7.57 (2H, AA′BB′m, p-phenyl); MS m/z (rel intensity) 378 (M^+, 100). Found: C, 69.87; H, 4.72%. Calcd for $C_{22}H_{18}O_2S_2$: C, 69.81; H, 4.79%.

3,4′-Di(2-naphthyl)-2,2′-bithienyl (3f). UV (MeOH) 222 (log ε 4.79), 244 (sh, 4.71), 263 (sh, 4.63), and 290 nm (sh, 4.45); ^{1}H NMR (200 MHz; acetone-d_6) δ=7.33 (1H, d, J=5.2 Hz, 4-H), 7.45—7.6 (4H, m, naphthyl), 7.62 (1H, d, J=5.2 Hz, 5-H), 7.66 (1H, d, J=1.6 Hz, 3′-H), 7.77 (1H, d, J=1.6 Hz, 5′-H), 7.8—8.2 (10H, m, naphthyl); MS m/z (rel intensity) 418 (M^+, 100). Found: C, 80.07; H, 4.17%. Calcd for $C_{28}H_{18}S_2$: C, 80.34 H, 4.33%.

Coupling of 4-Aryl-2-chlorothiophenes (1). The procedure is a modification of the one described by Tiecco et al.[11] for the preparation of bipyridyls, in which $NiCl_2$ is used instead of $NiCl_2 \cdot 6H_2O$. To a solution of $NiCl_2$ (0.65 g, 5 mmol) and PPh_3 (5.2 g, 20 mmol) in N,N-dimethylformamide (25 ml), Zn powder (0.32 g, 5 mmol) was added under an N_2 atmosphere. The mixture was stirred at 50 °C for 1 h. 4-Aryl-2-chlorothiophene (**1**; 5 mmol) was added to the resulting red brown solution. After stirring for 30 min, the mixture was poured into H_2O (50 ml). The precipitate was filtered, washed with H_2O (20 ml), and dried.

(a) When the coupling product was soluble in $CHCl_3$, as were the cases with **4e** and **4g**, the precipitate was directly chromatographed (silica gel/hexane–$CHCl_3$ (3:2)), giving **4e** or **4g** together with PPh_3 and a small amount of the dechlorination product of **1e** or **1g**. (b) When the coupling product was less soluble in $CHCl_3$ (**4d** and **4f**), the precipitate was washed with the solvent (20 ml×2) and the PPh_3-free residue was then sublimed under reduced pressure (230 °C (bath)/1 mmHg; 1 mmHg=133.322 Pa) or treated with hot 10% HCl (20 ml) and washed with H_2O to give **4d** or **4f**. (c) In the cases with **1a**, **1b**, and **1c**, the precipitate was extracted with $CHCl_3$ (20 ml×2). The undissolved solid was recrystallized from $CHCl_3$ to yield the coupling product. Evaporation of the combined extracts followed by column chromatography (silica gel/hexane–$CHCl_3$ (3: 1—2)) gave another crop of the product.

The analytical samples were purified by recrystallization.

4,4′-Diphenyl-2,2′-bithienyl (4a). UV (MeOH) 258 (log ε 4.74) and 323 nm (4.06); ^{1}H NMR (90 MHz, $CDCl_3$); δ=7.2—7.7 (m, phenyl, 3-H, 3′-H, 5-H, and 5′-H); MS m/z (rel intensity) 318 (M^+, 100). Found: C, 75.51; H, 4.27%. Calcd for $C_{20}H_{14}S_2$: C, 75.43; H, 4.43%.

4,4′-Di-p-tolyl-2,2′-bithienyl (4b). UV (MeOH) 261 (log ε 4.71) and 325 nm (3.96); ^{1}H NMR (90 MHz, $CDCl_3$) δ=2.38 (6H, s, CH_3), 7.1—7.3 (6H, m including AA′BB′m at 7.16 and 7.25, and d at 7.28, J=1.6 Hz, p-phenyl, 3-H, and 3′-H), and 7.3—7.55 (6H, m including AA′BB′m at 7.46 and 7.55, p-phenyl, 5-H, and 5′-H); MS m/z (rel intensity) 346 (M^+, 100). Found: C, 76.23; H, 5.24%. Calcd for $C_{22}H_{18}S_2$: C, 76.26; H, 5.24%.

4,4′-Bis(p-ethylphenyl)-2,2′-bithienyl (4c). UV (MeOH) 260 (log ε 4.78) and 325 nm (4.02); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.26 (6H, t, J=7.6 Hz, CH_2CH_3), 2.67 (4H, q, J=7.6 Hz, CH_2CH_3), 7.05—7.3 (6H, m including AA′BB′m at 7.17 and

7.27, and d at 7.28, J=1.5 Hz, p-phenyl, 3-H, and 3′-H), and 7.35—7.65 (6H, m including d at 7.46, J=1.5 Hz, and AA′BB′m at 7.47 and 7.57, 5-H, 5′-H, and p-phenyl); MS m/z (rel intensity) 374 (M^+, 100). Found: C, 77.16; H, 5.86%. Calcd for $C_{24}H_{22}S_2$: C, 77.16; H, 5.92%.

4,4′-Bis(p-methoxyphenyl)-2,2′-bithienyl (4d). UV (MeOH; molar extinction coefficients were not determined because of low solubility) 265 and 302 nm (sh); ^{1}H NMR (90 MHz, pyridine-d_5 peak intensities were not determined because of low solubility) δ=3.75 (s, OCH_3), 7.09 and 7.18 (AA′BB′m p-phenyl), 7.76 and 7.85 (AA′BB′m, p-phenyl), 7.77 (d, J=1.4 Hz, 3-H and 3′-H), and 7.90 (d, J=1.4 Hz, 5-H and 5′-H); MS m/z (rel intensity) 378 (M^+, 100). Found: 69.95; H, 4.67%. Calcd for $C_{22}H_{18}O_2S_2$: C, 69.81; H, 4.67%.

4,4′-Bis(2,4-dimethylphenyl)-2,2′-bithienyl (4e). UV (MeOH) 253 (log ε 4.45) and 322 nm (4.20); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.50 (12H, s, CH_3), 6.85—7.4 (10H, m including d at 7.03 and 7.21, J=1.4 Hz, 3-H, 3′-H, 5-H, 5′-H, and trisubstituted phenyl); MS m/z (rel intensity) 374 (M^+, 100). Found: C, 77.26; H, 5.92%. Calcd for $C_{24}H_{22}S_2$: C, 76.96; H, 5.92%.

4,4′-Di(2-naphthyl)-2,2′-bithienyl (4f). UV (MeOH; molar extinction coefficients were not determined because of low solubility) 257, 290, and 306 nm (sh); ^{1}H NMR (90 MHz, pyridine-d_5; peak intensities were not determined because of low solubility) δ=7.4—8.4 (m including d at 7.87 and 8.08, J=1.5 Hz each, naphthyl, 3-H, 3′-H, 5-H, and 5′-H); MS m/z (rel intensity) 418 (M^+, 100). Found: C, 80.47; H, 4.12%. Calcd for $C_{28}H_{18}S_2$: C, 80.34; H, 4.33%.

4,4′-Bis(5,6,7,8-tetrahydro-2-naphthyl)-2,2′-bithienyl (4g). UV (MeOH) 252 (sh, log ε 4.61), 258 (sh, 4.75), 264 (4.75), and 326 nm (4.00); ^{1}H NMR (90 MHz, $CDCl_3$) δ=1.6—1.95 (8H, m, $PhCH_2CH_2$), 2.78 (8H, br s, $PhCH_2$), 6.9—7.35 (8H, m including d at 7.24, J=1.5 Hz, 3-H, 3′-H, and trisubstituted phenyl), and 7.43 (2H, d, J=1.5 Hz, 5-H and 5′-H); MS m/z (rel intensity) 426 (M^+, 100). Found: C, 79.09; H, 6.09%. Calcd for $C_{28}H_{26}S_2$: C, 78.83; H, 6.14%.

2,5-Dichloro-3-phenylthiophene. Sulfonyl chloride (8.1 g, 60 mmol) was added to a stirred solution of **1** (7.8 g, 40 mmol) in CCl_4 (60 ml) over ca. 5 min period and the mixture refluxed for 60 h. The reaction mixture was poured into ice water (ca. 40 ml) and extracted with CCl_4 (15 ml×3). The extracts were combined, washed successively with water, 5% $NaHCO_3$ solution, and water again, and dried. After evaporating the solvent, the residue was chromatographed (silica gel/hexane) to afford 2,5-dichloro-3-phenylthiophene (4.6 g, 50%) as an oil. UV (MeOH) 233 (log ε 4.33) and 260 nm (3.92); ^{1}H NMR (90 MHz, CCl_4) δ=6.83 (1H, s, 4-H), 7.21—7.49 (5H, m, phenyl); MS m/z (rel intensity) 230 (M^++2, 69), 228 (M^+, 100). Found: C, 52.45; H, 2.50%. Calcd for $C_{10}H_6Cl_2S$: C, 52.42; H, 2.64%.

Coupling of 2,5-Dichloro-3-phenylthiophene. 2,5-Dichloro-3-phenylthiophene (0.8 g, 3.5 mmol) was subjected to coupling under the conditions described above, except for the reaction period (12 h instead of 1 h). A work-up and repeated chromatography (silica gel/hexane) of the reaction mixture gave 5-chloro-4,4′-diphenyl-2,2′-bithienyl (0.1 g, 15%) together with 2,5-dichloro-3-phenylthiopheene (0.2 g, 25%) and 2-chloro-3-phenylthiophene (0.2 g, 30%). The structure of the 5-chloro-4,4′-diphenyl-2,2′-bithienyl was confirmed by its catalytic dechlorination, which gave the known 4,4′-diphenyl-2,2′-bithienyl.

5-Chloro-4,4′-diphenyl-2,2′-bithienyl. Pale yellow needles, mp 144—145 °C (hexane–$CHCl_3$); UV (MeOH) 254 (log ε 4.63), 328 (4.11), and 351 nm (sh, 3.78); ^{1}H NMR (90 MHz, $CDCl_3$) δ=7.23 (1H, s, 3-H), 7.35—7.8 (12H, m including d at 7.48 and 7.63, J=1.7 Hz each, phenyl, 3′-H, and 5′-H); MS m/z (rel intensity) 354 (M^++2, 40), 352 (M^+, 100). Found: C, 68.07; H, 3.48%. Calcd for $C_{20}H_{13}ClS_2$; C, 68.07; H, 3.71%.

The authors would like to thank Professor Kensuke Takahashi of Nagoya Institute of Technology for recording the NMR spectrum of the protonated 2-chloro-4-phenylthiophene and the 200 MHz spectra of 3,4′-diaryl-2,2′-bithienyls.

(Received November 5, 1990)

1,2-*O*-Isopropylidene-3-*O*-methyl-6-*O*-tosyl-β-D-*arabino*-hexofuranos-5-ulose (**9a**) and its 3-*O*-benzyl congener (**9b**) were prepared from 1,2:5,6-di-*O*-isopropylidene-β-D-altrofuranose in 4 steps. Addition of methyl phenylphosphinate to **9a** and **9b** in the presence of DBU, followed by reduction with Raney Ni, afforded (5*R* and 5*S*)-5,6-dideoxy-1,2-*O*-isopropylidene-5-[(methoxy)phenylphosphinyl]-3-*O*-methyl-β-D-*arabino*-hexofuranose (**11a**) and 3-*O*-benzyl congener (**11b**), respectively. The latter compound (**11b**) was debenzylated to 3-*O*-unsubstituted hexofuranose **11d**. By reduction with sodium dihydrobis(2-methoxyethoxy)aluminate, followed by acid hydrolysis, these key intermediates **11a**, **11b**, and **11d** provided the title L-fucoses **13** (together with a minor proportion of D-altropyranoses **14**) having as phenylphosphinylidene group in place of the ring oxygen. Compounds **13** and **14** were converted into per-*O*-acetyl derivatives for structural and conformational analysis by spectroscopy.

Sugar analogues having a phosphorus atom in the hemiacetal ring have been prepared in recent years;[1] e.g., those corresponding to D-ribofuranoses **1**[2] and D-glucopyranoses **2**.[3] These P-in-ring sugars have drawn interest in view of their physicochemical properties as well as potential biological activity. In the mean time, 1,5-imino-L-fucitol (**3**)[4] and 5-thio-L-fucose (**4**)[5] were synthesized and both compounds have been proven to inhibit L-fucosidase. We describe herein a detailed synthetic study on the first P-in-ring L-fucose analogues by placing phenylphosphinylidene in the hemiacetal ring as a model functional group.[6]

Results and Discussion

1,2:5,6-Di-*O*-isopropylidene-β-D-altrofuranose (**5**)[7] (available from D-glucose) served as the starting material for preparation of the important key intermediate, 3-*O*-substituted 1,2-*O*-isopropylidene-6-*O*-tosyl-β-D-*arabino*-hexofuranos-5-uloses (**9a—c**), by the sequence illustrated in Scheme 1.

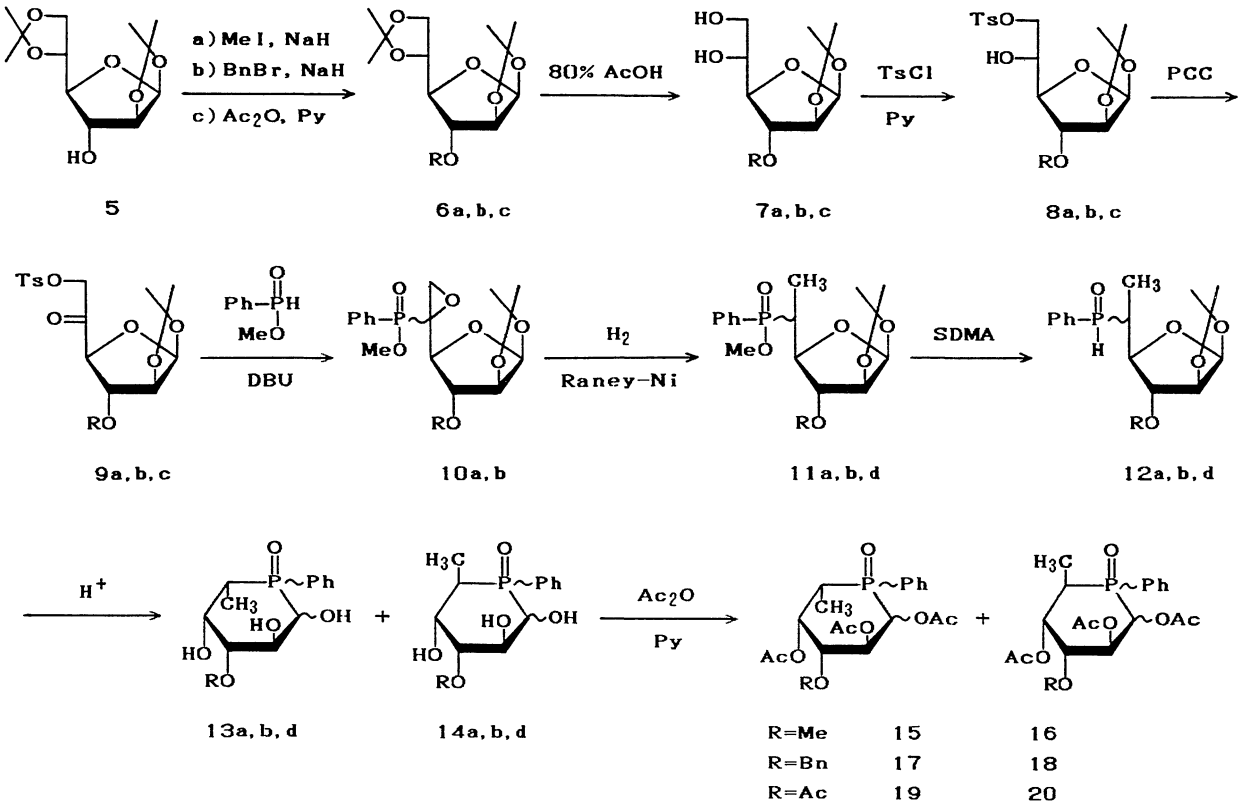
Thus, 3-*O*-methylation of **5** using NaH–MeI in 1,2-dimethoxyethane (DME) was found to furnish a higher yield of 3-*O*-methyl derivative **6a** than that by the previously reported method (MeI–Ag_2O in DMF).[8] The selective deprotection of **6a** with acid afforded 1,2-*O*-isopropylidene-3-*O*-methyl-β-D-altrofuranose (**7a**),[8] which was then treated with tosyl chloride in pyridine to give the 6-*O*-tosyl derivative **8a**. Oxidation of **8a** with pyridinium chlorochromate (PCC) in dichloromethane in the presence of molecular sieves (3A) gave 3-*O*-methyl-5-ulose **9a** in 95% yield.

The reaction of **9a** with methyl phenylphosphinate in DME in the presence of DBU gave 5,6-anhydro-5-[(methoxy)phenylphosphinyl] compound (**10a**) as a mixture of the diastereomers with regard to C-5 and P atom. Hydrogenation of **10a** in the presence of Raney-Ni (W-4) in ethanol afforded the 5,6-dideoxy derivative **11a**.

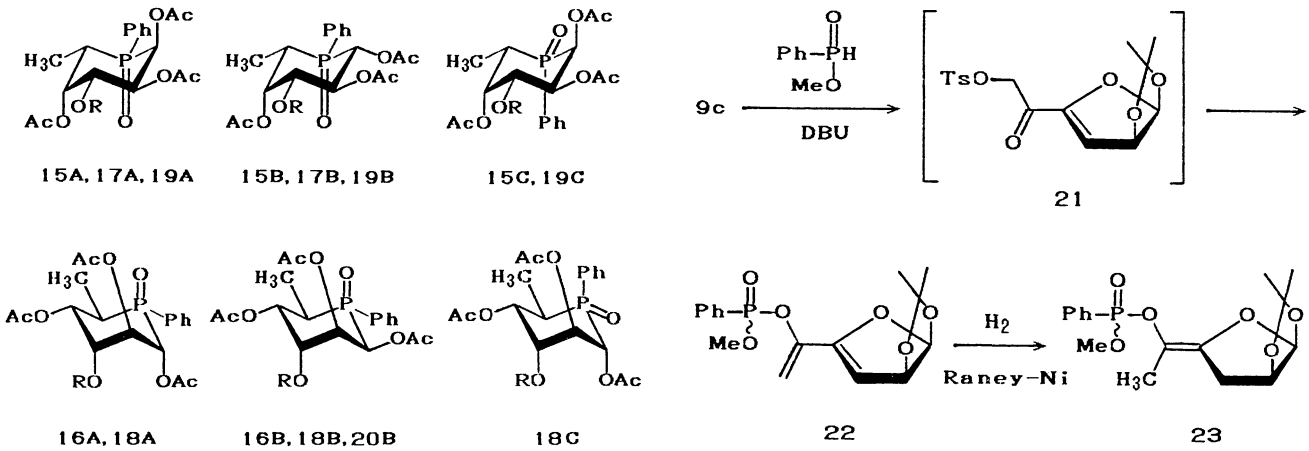
Compound **11a** was reduced with dihydrobis(2-methoxyethoxy)aluminate (SDMA) to give the unstable 5,6-dideoxy-5-phenylphosphinyl derivative **12a**, which was immediately treated with ethanolic 0.5 M hydrochloric acid (1 M=1 mol dm^{-3}) at 90 °C, thus affording a crude mixture of 5,6-dideoxy-3-*O*-methyl-5-phenylphosphinyl-L-galacto- (L-fucose, **13a**) and -D-altropyranoses (**14a**) as shown in Scheme 1.

These products were characterized after having been converted into the corresponding tri-*O*-acetyl derivatives **15** and **16** by the usual method. By purification in a silica-gel column, the presence of the following five diastereomers was confirmed, although some of the minor products were not completely separable (see the Experimental section): 5,6-dideoxy-5-[(*R*)-phenylphosphinyl]-α-L-galactopyranose (**15A**, 9.8% overall yield from **11a**), the β-anomer **15B** (2.1%), the 5-[(*S*)-*P*]-α-isomer **15C** (7.1%), 5,6-dideoxy-5-[(*S*)-phenylphosphinyl]-α-D-altropyranose (**16A**, 2.1%), the β-anomer **16B** (9.1%). Structures and the preferable conformations of these products were established on the basis of high-resolution mass spectrometry and 500 MHz ^1H NMR spectral data (see below).

Similarly, synthesis of 3-*O*-benzyl congeners **13b** and **14b** was performed by the sequence of **5**→**6b**→**7b**→**8b**→**9b**→**10b**→**11b**→**12b**→**13b** and **14b**. The unambiguous structural assignments of **13b** and **14b** were



Scheme 1. Synthesis of 5,6-dideoxy-5-phenylphosphinyl-L-galacto- and -D-altropyranoses. **a**: R=Me. **b**: R=Bn. **c**: R=Ac. **d**: R=H.



Scheme 2.

made by converting them into their triacetates **17** and **18**, which were separated into five diastereomers: **17A** (4.4% overall yield from **11b**), **17B** (1.1%), **18A** (1.3%), **18B** (9.3%), and **18C** (4.4%).

These successful synthesis of 3-*O*-alkyl-L-fucose analogues **13a** and **13b** prompted us to prepare 3-*O*-unsubstituted compound **13d**. Thus, following the synthetic scheme analogous to that used for **9a**, **b**, we prepared 3-*O*-acetyl-5-ulose **9c** from **5** by the sequence of **5**→**6c**[9]→**7c**→**8c**→**9c**. However, when **9c** was treated with methyl phenylphosphinate and DBU in DME as in the cases of **9a** and **9b**, the main product turned out to be the enol phosphonate **22**. This is presumably formed from **9c** as the result of the prior elimination of AcOH by the action of DBU to give an activated α-tosyloxycarbonyl compound **21**, which in turn undergoes the Perkow[10] type reaction with methyl phenylphosphinate to afford **22** as illustrated in Scheme 2. Although many examples are well known for the Perkow reactions of α-halo-, α-acetoxy-,[11] and α-tosyloxycarbonyl compounds[12] with trialkyl phosphites, the reactions with alkyl phosphinate appear to be rare, to our knowledge. The catalytic hydrogen-

ation of **22** in the presence of Raney-Ni afforded hex-4-enofuranose **23**.

Therefore, we turned our attention to another approach for preparation of **13d**: namely, from **11b** in stead of **9c**. Debenzylation of **11b** by catalytic hydrogenation over 20% $Pd(OH)_2$–C in ethanol smoothly provided **11d**. By the same procedures described above, compound **11d** was converted into a mixture of **13d** and **14d** via **12d** (Scheme 1). The structures of **13d** and **14d** were similarly established by derivatization into tetraacetates **19** and **20** that were separated by column chromatography into four diastereomers: **19A** (11% overall yield from **11d**), **19B** (2.7%), **19C** (4.2%), and **20B** (3.5%).

^{1}H NMR Spectral Analysis of Per-*O*-acetyl-5,6-dideoxy-5-phenylphosphinyl-L-galactopyranoses (15A—C, 17A,B, 19A—C) and D-Altropyranoses (16A,B, 18A—C, 20B). For structural assignments of these new products **15—20**, the chemical shift of each proton signal of their NMR spectra and the dependence of the $^2J_{H,P}$, $^3J_{H,P}$, and $^3J_{H,H}$ values on their dihedral angles were carefully taken into consideration. The precise parameters thereby obtained for the these compounds are summarized in Table 1. Since the parameters for 5,6-dideoxy-5-phosphinyl-L-galacto- and -D-altropyranoses have been obtained for the first time in the present study, some characteristic features of **15—20** are discussed here in detail. These parameters are instructive in determining the structures of other similar phosphinyl-in-ring sugar analogues, preparation of which is currently under investigation.

(1) A series of compounds **15**, **17**, and **19** characteristically show small values of $J_{4,5}$ (2.3—3.0 Hz) and $J_{2,P}$ (0—4 Hz) and large values of $J_{2,3}$ (9.8—10.9 Hz) and $J_{4,P}$ (28—31 Hz), whereas another series of compounds **16**, **18**, and **20** exhibit opposite magnitudes of the

a) The assignments of acetoxyl groups may have to be interchanged. b) J values for *P*-Ph: $J_{P,o}$=12.5, $J_{P,m}$=3.5, $J_{P,p}$=1.5, $J_{o,m}$=$J_{m,p}$=7.5, and $J_{o,p}$=1.5 Hz. c) $^2J_{CH_2}$=11.9 Hz. d) *C*-Ph: δ=7.29—7.41 (5H, m).

corresponding coupling constants, namely relatively large values of $J_{4,5}$ (11.5—12.7 Hz) and $J_{2,P}$ (20—28 Hz) and small values of $J_{2,3}$ (4.5—5.2 Hz) and $J_{4,P}$ (3.2—6.8 Hz). By applying the arguments similar to these employed for distinction between 5-deoxy-5-phosphinyl-L-gulo- and -D-mannopyranoses,[13] the above two series of compounds **15,17,19** and **16,18,20** can be assigned to have structures of L-galactopyranose predominantly in the $^1C_4$(L) conformation and D-altropyranose in the $^4C_1$(D) conformation, respectively.

(2) As the H-5 of **15—20** is all in axial position, the magnitudes of $J_{5,P}$ values establishes the orientation of the ring P=O group in these compounds. The small values of $J_{5,P}$ (4.1—6.7 Hz) are indicative of the anti orientation of H-C(5)-P=O for **15—19A,B** and **20B**. On the other hand, because of the large values of $J_{5,P}$ (20.7—21.2 Hz), the equatorial P=O orientation is assigned to **15C**, **18C**, and **19C**. The orientation of the ring P=O group in these compounds should also be derived by examining the δ values of H-2 for **15**, **17**, and **19** and of H-4 for **16**, **18**, and **20**, although care must be taken when the inclination of the axially oriented *P*-phenyl ring exerts an anisotropic effect on H-2 and/or H-4 of 1,3-diaxial position.[14] An appreciable downfield shift (0.3—0.4 Hz) is observed for **15A,B**, **17A,B**, and **19A,B** (compared with the chemical shifts of **15C** and **19C**), thus confirming the axial orientation of the ring P=O for the compounds of the former group (**A** and **B**).

(3) The anomeric orientation of C-1 is derived from the values of $J_{1,P}$ and $J_{1,2}$ and also in some cases the δ values of H-5. Namely, the small values of $J_{1,P}$ (0.5—2.8 Hz) of **15—20B** and the large $J_{1,P}$ values (8.6—13.8 Hz) of **15—19A,C** suggest respectively the anti and gauche connection of H-C(1)-P=O for these compounds. The large value of $J_{1,2}$ (11 Hz) of **15—20B** confirms the axial H-1 orientation for **15B**, **17B**, and **19B**, whereas the smaller $J_{1,2}$ value (3 Hz) points out the equatorial H-1 configuration for **15A,C**, **17A**, and **19A,C** in the L-galactopyranose series. For a series of the D-altropyranoses whose H-2 are in the equatorial position and thus $J_{1,2}$ values are all similar and small (ca. 3.5 Hz), an appreciable downfield shift (0.3—0.4 ppm) of H-5 caused by the axially situated AcO group on C-1 can be used for distinction between the α-anomers (**16A** and **18A,C**) and β-anomers (**16B**, **18B**, and **20B**).

Present work thus demonstrates a possible way for preparation of 5,6-dideoxy-5-phosphinyl-L-galactopyranoses from appropriate intermediates. Extension of this work including preparative studies on improved product ratios of the L-fucose type analogues in conection with other kinds of substituents at P-5 and O-3 of the precursors **11** and **12**, as well as biological evaluation of the compounds, is in progress.

Experimental

Melting points were determined with a Yanagimoto MP-S3 instrument and are uncorrected. All reactions were monitored by TLC (Merck silica gel 60F, 0.25 mm) with (*A*) 1:1 AcOEt–hexane or (*B*) AcOEt as the eluant; components were detected by exposing the plates to a UV light (254 nm) and/or by spraying them with 20% sulfuric acid–ethanol, with subsequent heating. Column chromatography was performed on Wako C-200 silica gel. Optical rotation were measured with a Nihon-Bunko DIP-4 polarimeter at 25 °C. The IR spectra were taken with a Hitachi 260-105 infrared spectrophotometer. The ^{1}H and ^{31}P NMR spectra were measured in $CDCl_3$ with Varian VXR-500 and VXR-200 instruments (500 and 81 MHz, respectively, the SC-NMR Lab., Okayama Univ. at 21 °C) or with a Hitachi R-600 (60 MHz, FT) spectrometer. Chemical shifts are reported as δ values relative to tetramethylsilane (internal standard for ^{1}H) and 85% phosphoric acid (external standard for ^{31}P). The assignments of all signals obtained at 500 MHz were made by employing a first-order analysis with the aid of decoupling technique and, if necessary, two-dimensional COSY measurements; the parameters were confirmed by a computer-assisted simulation analysis. The mass spectra were taken on an A.E.I. MS 50 ultrahigh resolution instrument and were given in terms of *m/z* (rel intensity) compared with the base peak.

1,2:5,6-Di-*O*-isopropylidene-3-*O*-methyl-β-D-altrofuranose (6a)[8] and Its 3-*O*-Benzyl Congener (6b). The following procedures resulted in a better yield of **6a** than the reported method using MeI–Ag_2O.[8] Thus, to a solution of **5**[7] (1.35 g, 5.19 mmol) in DME (10 ml) was added, with stirring, sodium hydride [500 mg, 60% in mineral oil (which was washed with DME), 2.4 equiv] in small portions at 0 °C under an argon atmosphere. To this suspension was dropwise added methyl iodide (1.00 ml, 16.1 mmol) at 0 °C. The mixture was stirred at 25 °C for 2 h and then methanol (8 ml) was added at 0 °C. The mixture was stirred at 25 °C for 0.5 h and evaporated in vacuo. The residue was dissolved in CH_2Cl_2, washed with water, dried (Na_2SO_4), and evaporated in vacuo. The residue was purified by column chromatography, giving **6a** (1.37 g, 96%) as a colorless syrup (cf. lit,[8] 88% yield): R_f=0.73 (*A*).

The procedures similar to those for **6a** from **5** were employed for preparation of **6b**. Thus, **5** (510 mg, 1.96 mmol) was treated with sodium hydride (60% in oil, 200 mg, 2.6 equiv) and benzyl bromide (0.47 ml, 3.95 mmol) at 25 °C for 3 h. Purification by column chromatography gave **6b** (625 mg, 91%) as a colorless syrup: R_f=0.80 (*A*); $[\alpha]_D$+4.0° (*c* 1.20, $CHCl_3$); ^{1}H NMR (500 MHz) δ=1.31, 1.51 (3H each, 2s, Me_2C-O-1,2), 1.35, 1.43 (3H each, 2s, Me_2C-O-5,6), 3.99 (1H, dd, $J_{6,6'}$=8.8, $J_{5,6'}$=4.9 Hz, H-6'), 4.03 (1H, dd, $J_{4,5}$=9.3, $J_{3,4}$=1.6 Hz, H-4), 4.11 (1H, dd, $J_{5,6}$=6.2 Hz, H-6), 4.19 (1H, d, $J_{2,3}\approx$0 Hz, H-3), 4.25 (1H, ddd, H-5), 4.58, 4.60 (1H each, 2d, ^2J=11.7 Hz, CH_2O-3), 4.64 (1H, d, $J_{1,2}$=3.8 Hz, H-2), 5.89 (1H, d, H-1), 7.34 (5H, m, Ph); MS *m/z* 335 (M-CH_3; 2.7), 292 (1.5), 249 (4.1), 221 (2.5), 163 (2.5), 129 (3.0), 105 (12), 91 (100). Found: *m/z* 335.1494. Calcd for $C_{18}H_{23}O_6$: M-CH_3, 335.1494.

General Procedures for the Preparation of 3-*O*-Substituted 1,2-*O*-Isopropylidene-β-D-altrofuranoses (7a—c). A mixture of **6** (4.78 mmol) and 80% aqueous acetic acid (15 ml) was stirred at 60 °C for 2 h. The solution was evaporated in vacuo and the residue was purified by use of column

chromatography on silica gel, giving **7**.

3-*O*-Methyl Derivative (7a):[8] Colorless syrup (83% from **6a**, lit,[8] 79%); R_f=0.14 (*A*).

3-*O*-Benzyl Derivative (7b): Colorless needles (85% from **6b**); mp 68—69 °C (from AcOEt–hexane); R_f=0.23 (*A*); $[\alpha]_D$+4.2° (*c* 1.33, $CHCl_3$); ^1H NMR (500 MHz) δ=1.33, 1.52 (3H each, 2s, CMe_2), 2.15 (2H, br s, HO-5,6), 3.72 (1H, dd, $J_{6,6'}$=11.3, $J_{5,6'}$=5.4 Hz, H-6′), 3.76 (1H, dd, $J_{5,6}$=3.9 Hz, H-6), 3.91 (1H, ddd, $J_{4,5}$=7.5 Hz, H-5), 4.05 (1H, dd, $J_{3,4}$=2.9 Hz, H-4), 4.21 (1H, d, $J_{2,3}$≈0 Hz, H-3), 4.60, 4.62 (1H each, 2d, ^2J=11.6 Hz, CH_2O-3), 4.67 (1H, d, $J_{1,2}$=4.1 Hz, H-2), 5.89 (1H, d, H-1), 7.35 (5H, m, Ph); MS *m/z* 310 (M^+; 0.1), 295 (1.8), 249 (4.7), 221 (3.5), 193 (2.5), 163 (3.1), 91 (100). Found: *m/z* 310.1419. Calcd for $C_{16}H_{22}O_6$: M, 310.1416.

3-*O*-Acetyl Derivative (7c): Colorless needles (84% from **6c**[9]); mp 85—86 °C (from AcOEt–hexane); R_f=0.13 (*A*); $[\alpha]_D$−196° (*c* 1.00, $CHCl_3$); ^1H NMR (500 MHz) δ=1.31, 1.52 (3H each, 2s, CMe_2), 2.10 (3H, s, AcO-3), 2.28 (2H, br s, HO-5,6), 3.73 (1H, dd, $J_{6,6'}$=11.5, $J_{5,6'}$=4.7 Hz, H-6′), 3.82 (1H, dd, $J_{5,6}$=3.7 Hz, H-6), 3.93 (1H, ddd, $J_{4,5}$=9.1 Hz, H-5), 4.04 (1H, dd, $J_{3,4}$=1.3 Hz, H-4), 4.63 (1H, d, $J_{1,2}$=3.9, $J_{2,3}$≈0 Hz, H-2), 5.28 (1H, d, H-3), 5.92 (1H, d, H-1); MS *m/z* 247 (M−CH_3; 29), 231 (2.3), 201 (49), 187 (4.5), 173 (28), 143 (100), 127 (33), 113 (41). Found: *m/z* 247.0819. Calcd for $C_{10}H_{15}O_7$: M−CH_3, 247.0818.

General Procedures for the Preparation of 3-*O*-Substituted 1,2-*O*-Isopropylidene-6-*O*-tosyl-β-D-altrofuranoses (8a—c). To a solution of **7** (8.30 mmol) in dry pyridine (40 ml) was added tosyl chloride (1.8 g, 9.5 mmol) at 0 °C. The mixture was stirred at 25 °C for 8 h and then water (2 ml) was added at 0 °C. The mixture was evaporated in vacuo. The residue was dissolved in CH_2Cl_2, washed with water, dried (Na_2SO_4), and evaporated in vacuo. The residue was chromatographed on silica gel to give **8**.

3-*O*-Methyl Derivative (8a): Colorless syrup (86% from **7a**); R_f=0.48 (*A*); $[\alpha]_D$+33° (*c* 0.89, $CHCl_3$); ^1H NMR (500 MHz) δ=1.29, 1.43 (3H each, 2s, CMe_2), 2.05 (1H, br s, HO-5), 2.45 (3H, s , MeC_6-*S*), 3.38 (3H, s, MeO-3), 3.88 (1H, dd, $J_{4,5}$=8.5, $J_{3,4}$=1.7 Hz, H-4), 3.98 (1H, d, $J_{2,3}$≈0 Hz, H-3), 4.04 (1H, m, H-5), 4.06, 4.30 (1H each, 2m, H-6,6′), 4.54 (1H, d, $J_{1,2}$=3.9 Hz, H-2), 5.82 (1H, d, H-1), 7.35, 7.80 (2H each, 2d, *J*=8.5, C_6H_4-*S*); MS *m/z* 373 (M−CH_3; 13), 345 (2.7), 327 (1.4), 281 (4.6), 245 (10), 215 (5.3), 173 (93), 155 (30), 91 (41), 87 (100). Found: *m/z* 373.0951. Calcd for $C_{16}H_{21}O_8S$: M−CH_3, 373.0958.

3-*O*-Benzyl Derivative (8b): Colorless syrup (95% from **7b**); R_f=0.80 (*A*); $[\alpha]_D$+8.7° (*c* 1.71, $CHCl_3$); ^1H NMR (500 MHz) δ=1.28, 1.43 (3H each, 2s, CMe_2), 2.44 (3H, s, MeC_6-*S*), 2.63 (1H, br s, HO-5), 3.99 (1H, dd, $J_{4,5}$=7.1, $J_{3,4}$=1.5 Hz, H-4), 4.05—4.07 (2H, m, H-5,6′), 4.21 (1H, d, $J_{2,3}$≈0 Hz, H-3), 4.31 (1H, m, H-6), 4.56, 4.58 (1H each, 2d, ^2J=11.7 Hz, CH_2O-3), 4.62 (1H, d, $J_{1,2}$=3.9 Hz, H-2), 5.85 (1H, d, H-1), 7.30—7.35 (5H, m, Ph-C), 7.33, 7.79 (2H each, 2d, *J*=8.3 Hz, C_6H_4-*S*); MS *m/z* 449 (M−CH_3; 0.1), 295 (1.2), 249 (5.4), 221 (2.5), 193 (1.5), 163 (2.7), 91 (100). Found: *m/z* 449.1299. Calcd for $C_{22}H_{25}O_8S$: M−CH_3, 449.1270.

3-*O*-Acetyl Derivative (8c): Colorless syrup (88% from **7c**); R_f=0.50 (*A*); ^1H NMR (60 MHz) δ=1.28, 1.43 (3H each, 2s, CMe_2), 2.10 (3H, s, AcO-3), 2.46 (3H, s, MeC_6-*S*), 3.00 (1H, m, HO-5), 4.05—4.35 (3H, m, H-4,6,6′), 4.60 (1H, d, $J_{1,2}$=4.0, $J_{2,3}$≈0 Hz, H-2), 5.35 (1H, d, $J_{3,4}$=1.5 Hz, H-3), 5.89 (1H, d, H-1), 7.35, 7.80 (2H each, 2d, *J*=8.5 Hz, C_6H_4-*S*).

General Procedures for the Preparation of 3-*O*-Substituted 1,2-*O*-Isopropylidene-6-*O*-tosyl-β-D-*arabino*-hexofuranos-5-uloses (9a—c). To a stirred suspension of **8** (0.59 mmol) and finely powdered molecular sieves 3A (500 mg) in dry CH_2Cl_2 (2 ml) was added PCC (254 mg, 1.18 mmol) at 0 °C. The mixture was stirred at 25 °C for 4 h and then 2-propanol (0.5 ml) was added at 0 °C. The mixture was stirred at 25 °C for 1 h and diluted with ether. The precipitates were filtered off through activated carbon. The filtrate was evaporated in vacuo and the residue was purified by short-path chromatography with 1:1 AcOEt–hexane as an eluant, giving **9**.

3-*O*-Methyl Derivative (9a): Colorless syrup (95% from **8a**); R_f=0.55 (*A*); $[\alpha]_D$+2.4° (*c* 1.47, $CHCl_3$); IR (neat) ν 1740 (C=O), 1360 (ν_{as} SO_2), 1170 cm^{-1} (ν_s SO_2); ^1H NMR (500 MHz) δ=1.24, 1.25 (3H each, 2s, CMe_2), 2.45 (3H, s, MeC_6-*S*), 3.40 (3H, s, MeO-3), 4.24 (1H, br s, $J_{3,4}$=0.5, $J_{2,3}$≈0 Hz, H-3), 4.52 (1H, br s, H-4), 4.55 (1H, d, $J_{1,2}$=3.9 Hz, H-2), 4.95, 5.26 (1H each, 2d, $J_{6,6'}$=17.7 Hz, H-6,6′), 5.95 (1H, d, H-1), 7.35, 7.83 (2H each, 2d, *J*=8.5 Hz, C_6H_4-*S*); MS *m/z* 386 (M^+; 0.5), 371 (9.0), 343 (11), 313 (2.1), 255 (13), 185 (2.2), 173 (100), 155 (23), 145 (11), 115 (25), 91 (39). Found: *m/z* 386.1036. Calcd for $C_{17}H_{22}O_8S$: M, 386.1036.

3-*O*-Benzyl Derivative (9b): Colorless syrup (86% from **8b**); R_f=0.49 (*A*); $[\alpha]_D$−6.1° (*c* 2.60, $CHCl_3$); IR (neat) ν 1740 (C=O), 1360 (ν_{as} SO_2), 1170 cm^{-1} (ν_s SO_2); ^1H NMR (500 MHz) δ=1.24, 1.26 (3H each, 2s, CMe_2), 2.45 (3H, s, MeC_6-*S*), 4.47 (1H, br s, $J_{3,4}$=0.5, $J_{2,3}$≈0 Hz, H-3), 4.58 (2H, s, CH_2O-3), 4.60 (1H, br s, H-4), 4.62 (1H, d, $J_{1,2}$=3.9 Hz, H-2), 4.95, 5.25 (1H each, 2d, $J_{6,6'}$=17.6 Hz, H-6,6′), 5.98 (1H, d, H-1), 7.30—7.35 (5H, m, Ph), 7.35, 7.83 (2H each, 2d, *J*=8.3 Hz, C_6H_4-*S*); MS *m/z* 447 (M−CH_3; 0.2), 230 (2.9), 172 (1.9), 155 (18), 122 (7.4), 105 (31), 91 (100). Found: *m/z* 447.1120. Calcd for $C_{22}H_{23}O_8S$: M−CH_3, 447.1114.

3-*O*-Acetyl Derivative (9c): Colorless syrup (97% from **8c**); R_f=0.45 (*A*); $[\alpha]_D$−2.1° (*c* 1.54, $CHCl_3$); IR (neat) ν 1740 (C=O), 1730 (ester C=O), 1355 (ν_{as} SO_2), 1170 cm^{-1} (ν_s SO_2); ^1H NMR (500 MHz) δ=1.23, 1.25 (3H each, 2s, CMe_2), 2.09 (3H, s, AcO-3), 2.45 (3H, s, MeC_6-*S*), 4.56 (1H, d, $J_{1,2}$=3.9, $J_{2,3}$≈0 Hz, H-2), 4.59 (1H, br s, $J_{3,4}$=0.5 Hz, H-4), 4.95, 5.21 (1H each, 2d, $J_{6,6'}$=17.4 Hz, H-6,6′), 5.55 (1H, br s, H-3), 5.98 (1H, d, H-1), 7.35, 7.83 (2H each, 2d, *J*=8.2 Hz, C_6H_4-*S*); MS *m/z* 399 (M−CH_3; 0.4), 201 (5.4), 185 (1.2), 161 (1.4), 149 (5.1), 43 (100). Found: *m/z* 399.0749. Calcd for $C_{17}H_{19}O_9S$: M−CH_3, 399.0750.

(5*R* and 5*S*)-5,6-Anhydro-1,2-*O*-isopropylidene-5-[(*R* and *S*)-(methoxy)phenylphosphinyl]-3-*O*-methyl-β-D-*arabino*-hexofuranoses (10a) and Their 3-*O*-Benzyl Congeners (10b). To a solution of **9a** (123 mg, 0.322 mmol) and methyl phenylphosphinate (0.065 ml, 0.49 mmol) in DME (1 ml) was dropwise added a solution of DBU (74 mg, 0.49 mmol) in DME (1 ml) at −40 °C. The mixture was stirred at the same temp for 1 h and the concentrated in vacuo. The residue was dissolved in CH_2Cl_2 and saturated aq $NaHCO_3$ was added. After stirring at 25 °C overnight, the organic layer was separated and the aq layer was extracted twice with CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated in vacuo. The residue was chromatographed in a column of silica gel, giving **10a** (65 mg, 55%) as a colorless syrup: R_f=0.27 (*A*); ^1H NMR (60 MHz) δ=1.31, 1.51 (3H each, 2s, CMe_2), 2.75, 3.20 (1H each, 2m, H-6,6′), 3.13, 3.36 (3H, 2s, MeO-3), 3.70, 3.78 (3H, 2d, J_{POMe}=10.8 Hz, POMe), 3.80—4.10 (1H, m, H-3), 4.25—4.55 (2H, m, H-2,4),

5.18, 5.25 (1H, 2d, $J_{1,2}$=4.0 Hz, H-1), 7.40—8.05 (5H, m, Ph); MS *m/z* 370 (M^+; 0.9), 355 (19), 340 (9.2), 312 (5.5), 294 (6.4), 281 (16), 253 (12), 227 (100), 211 (20), 155 (76). Found: *m/z* 370.1174. Calcd for $C_{17}H_{23}O_7P$: M, 370.1181.

By the use of the same procedures described above, **9b** (2.86 g, 6.18 mmol) was treated with methylphenylphosphinate (1.65 ml, 12.4 mmol) and DBU (1.0 ml, 6.7 mmol) at −40 °C for 1 h. Purification by column chromatography gave **10b** (1.37 g, 50%) as a colorless syrup: R_f=0.43 (*A*); ^{1}H NMR (60 MHz) δ=1.28, 1.50 (3H each, 2s, CMe_2), 2.75, 3.17 (1H each, 2m, H-6,6′), 3.68, 3.70 (3H, 2d, J_{POMe}=10.8 Hz, POMe), 4.00—4.60 (3H, m, H-2,3,4), 4.54 (2H, s, CH_2O-3), 5.67, 5.75 (1H, 2d, $J_{1,2}$=4.0 Hz, H-1), 7.30 (5H, s, Ph-C), 7.30—8.00 (5H, m, Ph-P); MS *m/z* 431 ($M-CH_3$; 2.5), 355 (3.1), 340 (4.8), 297 (6.8), 281 (7.2), 253 (3.6), 227 (8.4), 198 (15), 156 (34), 91 (100). Found: *m/z* 431.1254. Calcd for $C_{22}H_{24}O_7P$: $M-CH_3$, 431.1260.

(5*R* and 5*S*)-5,6-Dideoxy-1,2-*O*-isopropylidene-5-[(*R* and *S*)-(methoxy)phenylphosphinyl]-β-D-*arabino*-hexofuranoses (11d) and 3-*O*-Methyl and 3-*O*-Benzyl Derivatives (11a and 11b). Compound **10a** (256 mg, 0.691 mmol) dissolved in ethanol (2 ml) was hydrogenated in the presence of Raney-Ni (W-4) (730 mg) at 24 °C under an atmospheric pressure of H_2. After 4 h, the mixture was centrifuged to remove the catalyst; the precipitate was twice extracted with ethanol. The combined organic layers were evaporated in vacuo. The residue was chromatographed on silica gel to give **11a** (108 mg, 44%) as a pale yellow syrup: R_f=0.31—0.24 (*B*); ^{1}H NMR (60 MHz) δ=1.11 (3H, dd, $J_{6,P}$=17.0, $J_{5,6}$=7.4 Hz, H$_3$-6), 1.32, 1.40, 1.48 (6H, 3s, CMe_2), 2.10—2.65 (1H, m, H-5), 3.37, 3.40 (3H, 2s, MeO-3), 3.65, 3.68, 3.76 (3H, 3d, J_{POMe}=10.8 Hz, POMe), 3.90—4.55 (3H, m, H-2,3,4), 5.60—5.85 (1H, m, H-1), 7.35—7.95 (5H, m, Ph).

By the same procedures described above, **10b** (247 mg, 0.553 mmol) was treated with Raney-Ni (W-4) (600 mg) for 7 h under H_2. Purification by column chromatography gave **11b** (98 mg, 41%) as a colorless syrup: R_f=0.36—0.26 (*B*); ^{1}H NMR (500 MHz) for the two predominant components of **11b** δ=1.06, 1.21* (3H, 2dd, $J_{6,P}$=17.5, $J_{5,6}$=7.0 Hz, H-6), 1.25, 1.30,* 1.45, 1.50* (6H, 4s, CMe_2), 2.45,* 2.50 (1H, 2dq, $J_{5,P}$=14.5,* 14.7, $J_{4,5}$=7.7,* 8.2 Hz, H-5), 3.62,* 3.64 (3H, 2d, J_{POMe}=11.0 Hz, POMe), 3.92, 4.32* (1H, 2ddd, $J_{4,P}$=6.8, 5.9,* $J_{3,4}$=4.0 Hz, H-4), 4.02, 4.08* (1H, 2d, $J_{2,3}\approx$0 Hz, H-3), 4.54, 4.59,* 4.62, 4.62* (2H, 4d, *J*=11.7 Hz, CH_2O-3), 4.58 (1H, d, $J_{1,2}$=3.8 Hz, H-2), 5.81,* 5.84 (1H, 2d, H-1), 7.36 (5H, m, Ph-C), 7.46 [2H, m, Ph(*m*)-P], 7.55 [1H, m, Ph(*p*)-P], 7.73, 7.76* [2H, 2m, Ph(*o*)-P], *for another diastereomer (the assignment of some of the δ values may have to be interchanged); MS *m/z* 432 (M^+; 0.3), 417 (2.8), 341 (5.2), 326 (7.4), 303 (2.1), 283 (7.5), 267 (8.9), 213 (23), 184 (28), 155 (29), 91 (100). Found: *m/z* 432.1699. Calcd for $C_{23}H_{29}O_6P$: M, 432.1702.

Compounds **11b** (103 mg, 0.238 mmol) dissolved in ethanol (1 ml) was hydrogenated in the presence of 20% $Pd(OH)_2$–C (80 mg) at 25 °C under an atmospheric pressure of H_2. After 1.5 h, the catalyst was filtered off through celite, and the filtrate was evaporated in vacuo. The residue was purified by column chromatography, giving **11d** (78 mg, 96%) as a colorless syrup: R_f=0.25—0.19 (*B*); ^{1}H NMR (60 MHz) δ=0.96, 1.19 (3H, 2dd, $J_{6,P}$=17.4, $J_{5,6}$=7.4 Hz, H$_3$-6), 1.36, 1.40, 1.45 (6H, 3s, CMe_2), 2.00—2.75 (1H, m, H-5), 3.20—3.50 (1H, m, HO-3, D_2O exchangeable), 3.59, 3.67 (3H, 2d, J_{POMe}=10.8 Hz, POMe), 3.95—4.75 (3H, m, H-2,3,4), 5.72 (1H, d, $J_{1,2}$=4.0 Hz, H-1), 7.30—7.95 (5H, m, Ph-P); MS *m/z* 342 (M^+; 1.6), 327 (6.1), 295 (1.2), 267 (3.4), 239 (2.9), 213 (61), 173 (9.8), 155 (52), 100 (100). Found: *m/z* 342.1235. Calcd for $C_{16}H_{23}O_6P$: M, 342.1232.

1,2,4-Tri-*O*-acetyl-5,6-dideoxy-3-*O*-methyl-[(*R* and *S*)-phenylphosphinyl]-L-galactopyranoses (15) and -D-Altropyranoses (16). To a solution of **11a** (227 mg, 0.637 mmol) in dry benzene (3 ml) was added, with stirring, a solution of SDMA (3.4 M in toluene, 0.5 ml, 2.5 equiv) in dry benzene (1 ml), in small portions at 5 °C under an argon atmosphere. The mixture was stirred at this temp for 1.5 h, and then water (1 ml) was added to decompose excess SDMA. The mixture was centrifuged and the precipitate was extracted with several portions of benzene. The organic layers were combined and evaporated in vacuo, giving (5*R* and 5*S*)-5,6-dideoxy-1,2-*O*-isopropylidene-3-*O*-methyl-5-[(*R* and *S*)-phenylphosphinyl]-β-D-*arabino*-hexofuranoses (**12a**) as a colorless syrup.

The syrup was immediately treated with 1:1 ethanol–0.5 M hydrochloric acid (6 ml) at 90 °C for 3 h under an argon atmosphere. After cooling, the reactants were neutralized with Amberlite IRA-45. The resin was filtered off and washed with aq ethanol. The filtrate was evaporated in vacuo to give a mixture of 5,6-dideoxy-3-*O*-methyl-5-[(*R* and *S*)-phenylphosphinyl]-α, β-L-galactopyranoses (**13a**) and -D-altropyranoses (**14a**) as a colorless syrup.

This was dissolved in dry pyridine (4 ml) and acetic anhydride (2 ml) at 0 °C. The mixture was stirred at 25 °C overnight, diluted with a small amount of cold water, and concentrated in vacuo. The residue was dissolved in CH_2Cl_2 and washed with water. The organic layer was dried (Na_2SO_4) and evaporated in vacuo, giving a mixture of triacetates **15** and **16**, which were separated by column chromatography with a gradient eluant of 3:1 AcOEt–hexane→AcOEt into four fractions A—D.

Fraction A [R_f=0.44 (*B*)] gave 5-[(*R*)-phenylphosphinyl]-α-L-galactopyranose (**15A**) as colorless needles: 26.7 mg (9.8% from **11a**); mp 260—261 °C (from AcOEt–hexane); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 369 (M–Ac; 1.1), 353 (11), 338 (3.6), 327 (1.2), 312 (21), 279 (8.8), 269 (19), 251 (27), 211 (40), 182 (21), 169 (24), 129 (70), 85 (100). Found: *m/z* 369.1098. Calcd for $C_{17}H_{22}O_7P$: $M-CH_3CO$, 369.1103.

Fraction B [R_f=0.38 (*B*)] gave 5-[(*S*)-*P*]-α-D-altropyranose **16A** as a colorless syrup: 5.4 mg (2.1% from **11a**); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 413 (M+1; 0.7), 412 (M^+; 0.2), 353 (11), 311 (13), 269 (11), 251 (22), 183 (10), 169 (24), 115 (38), 85 (100). Found: *m/z* 412.1311. Calcd for $C_{19}H_{25}O_8P$: M, 412.1287.

Fraction C [R_f=0.30 (*B*)] gave a colorless syrup (29.5 mg) which consisted of 5-[(*R*)-*P*]-β-D-altro isomer **16B** (9.1% from **11a**) and 5-[(*R*)-*P*]-β-L-galacto isomer **15B** (2.1%), the relative amounts being determined by the intensity ratio of their MeO-3 signals: ^{1}H and ^{31}P NMR, see Table 1.

Fraction D [R_f=0.25 (*B*)] gave 5-[(*S*)-*P*]-α-L-galacto isomer **15C** as a colorless syrup: 18.6 mg (7.1% from **11a**); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 353 (M−AcO; 4.9), 311 (5.9), 292 (2.5), 269 (10), 251 (12), 169 (19), 129 (11), 85 (100). Found: *m/z* 353.1154. Calcd for $C_{17}H_{22}O_6P$: M−AcO, 353.1154.

1,2,4-Tri-*O*-acetyl-3-*O*-benzyl-5,6-dideoxy-5-[(*R* and *S*)-phenylphosphinyl]-α,β-L-galactopyranoses (17) and -D-Altropyranoses (18). By the same procedures described for **15** and **16**,

compound **11b** (266 mg, 0.615 mmol) was converted into a mixture of triacetates **17** and **18** via **12b** and **13b/14b**. This was separated by column chromatography into four fractions A—D.

Fraction A [R_f=0.61 (*B*)] gave 5-[(*R*)-phenylphosphinyl]-α-D-altropyranose (**18C**) as a colorless syrup: 14.6 mg (4.4% from **11b**); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 489 (M+1; 0.1), 429 (7.5), 387 (1.3), 327 (3.2), 323 (29), 280 (5.4), 221 (11), 125 (13), 91 (100). Found: *m/z* 489.1680. Calcd for $C_{25}H_{30}O_8P$: M+1, 489.1678.

Fraction B [R_f=0.55 (*B*)] gave 5-[(*R*)-*P*]-α-L-galacto isomer **17A** as colorless needles: 18.3 mg (6.1% from **11b**); mp 242—244 °C (from AcOEt–hexane); $[\alpha]_D$−78° (*c* 0.56, $CHCl_3$); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 429 (M−AcO; 1.3), 323 (51), 280 (15), 263 (15), 238 (12), 221 (26), 125 (14), 91 (100). Found: *m/z* 429.1452. Calcd for $C_{23}H_{26}O_6P$: M−AcO, 429.1467. Anal. ($C_{25}H_{29}O_8P$) C, H.

Fraction C [R_f=0.45 (*B*)] gave a colorless syrup (7.2 mg) which consisted of 5-[(*R*)-*P*]-β-L-galacto isomer **17B** (1.1% from **11b**) and 5-[(*S*)-*P*]-α-D-altro isomer **18A** (1.3%), the relative amounts being determined from the integral ratio of ^{31}P signals: ^{1}H and ^{31}P NMR, see Table 1.

Fraction D [R_f=0.38 (*B*)] gave 5-[(*S*)-*P*]-β-D-altro isomer (**18B**) as colorless needles: 27.8 mg (9.3% from **11b**); mp 268—269 °C (from AcOEt–hexane); $[\alpha]_D$−28° (*c* 0.64, $CHCl_3$); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 429 (M−AcO; 14), 387 (3.0), 369 (1.3), 327 (5.0), 280 (5.3), 125 (10), 91 (100). Found: *m/z* 429.1463. Calcd for $C_{23}H_{26}O_6P$: M−AcO, 429.1467.

1,2,3,4-Tetra-*O*-acetyl-5,6-dideoxy-5-[(*R* and *S*)-phenylphosphinyl]-α,β-L-galactopyranoses (19) and -D-Altropyranoses (20). By the same procedures described above, compound **11d** (264 mg, 0.771 mmol) was converted into a mixture of tetraacetates **19** and **20** via **12d** and **13d/14d**. This was separated by column chromatography into four fractions A—D.

Fraction A [R_f=0.60 (*B*)] gave 5-[(*R*)-phenylphosphinyl]-α-L-galactopyranose (**19A**) as a colorless syrup: 36.6 mg (11% from **11d**); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 441 (M+1; 1.6), 398 (7.4), 381 (13), 356 (10), 339 (73), 296 (24), 279 (86), 253 (19), 237 (100), 209 (29), 184 (25), 159 (25), 141 (31), 125 (73). Found; *m/z* 441.1297. Calcd for $C_{20}H_{26}O_9P$: M+1, 441.1314.

Fraction B [R_f=0.53 (*B*)] gave a colorless syrup (10.3 mg, 3.0% from **11d**) which consisted of three isomers among **19** and **20**, the exact structures of which, however, have remained unassignable; ^{31}P NMR δ=34.4, 33.0, and 31.0 (1:1:2).

Fraction C [R_f=0.48 (*B*)] gave a colorless syrup (21.0 mg) which consisted of 5-[(*R*)-*P*]-β-L-galacto isomer **19B** (2.7% from **11d**) and 5-[(*S*)-*P*]-β-D-altro isomer **20B** (3.5%), the relative amounts being determined from the integral ratio of ^{31}P signals; ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 441 (M+1; 2.7), 398 (6.2), 381 (10), 356 (7.5), 339 (88), 296 (23), 279 (59), 237 (100), 209 (26), 184 (24), 159 (21), 141 (27), 125 (60). Found: *m/z* 441.1302. Calcd for $C_{20}H_{26}O_9P$: M+1, 441.1314.

Fraction D [R_f=0.43 (*B*)] gave 5-[(*S*)-*P*]-α-L-galacto isomer **19C** as a colorless syrup: 14.3 mg (4.2% from **11d**); ^{1}H and ^{31}P NMR, see Table 1; MS *m/z* 441 (M+1; 0.7), 440 (M^+; 0.7), 398 (6.9), 381 (11), 356 (7.1), 339 (85), 296 (24), 279 (55), 237 (100), 209 (30), 184 (23), 159 (27), 142 (33), 125 (74). Found: *m/z* 440.1255. Calcd for $C_{20}H_{25}O_9P$; M, 440.1236.

3,6-Dideoxy-1,2-*O*-isopropylidene-5-*O*-[(*R* and *S*)-(methoxy)phenylphosphinyl]-α-L-*glycero*-hexa-3,5-dienofuranoses (22). The procedures similar to those for **10a** from **9a** were eomployed. Thus, **9C** (333 mg, 0.803 mmol) was treated with methyl phenylphosphinate (0.20 ml, 1.5 mmol) and DBU (0.14 ml, 0.94 mmol) at −40 °C for 1 h. Purification of the crude product by column chromatography gave **22** (227 mg, 83%) as an inseparable mixture (1:1 epimers with respect to the phosphorus atom): Colorless syrup; R_f=0.46 (*A*); ^{1}H NMR (500 MHz) δ=1.29, 1.40,* 1.42, 1.43* (6H, 4s, CMe_2), 3.84, 3.86* (3H, 2d, J_{POMe}=11.2 Hz, POMe), 5.20, 5.24,* 5.24, 5.27* (2H, 4t, $J_{6,6'}=J_{6,P}$=2.3 Hz, H-6,6′), 5.31, 5.34* (1H, 2dd, $J_{1,2}$=5.2, $J_{2,3}\approx$2.5 Hz, H-2), 5.41, 5.43* (1H, 2d, H-3), 6.075, 6.08* (1H, 2d, H-1), 7.48, 7.49* [2H, 2m, Ph(*m*)], 7.58, 7.59* [1H, 2m, Ph(*p*)], 7.83, 7.83* [2H, 2m, Ph(*o*)], *for another diastereomer (the assignment of some of the δ values may have to be interchanged).

3,6-Dideoxy-1,2-*O*-isopropylidene-5-*O*-[(*R* and *S*)-(methoxy)phenylphosphinyl]-α-L-*glycero*-hex-4-enofuranoses (23). The procedures similar to those for **11a** from **10a** were employed. Thus, **22** (79 mg, 0.233 mmol) was treated with Raney-Ni(W-4) (70 mg) under H_2 for 5 h. Purification of the crude product by column chromatography gave **23** (35 mg, 44%) as an inseparable mixture (1:1) of *P*-epimers: Colorless syrup; R_f=0.40 (*A*); ^{1}H NMR (500 MHz) δ=1.35, 1.36,* 1.40,* 1.42 (6H, 4s, CMe_2), 1.87,* 2.02 (3H, 2t, $J_{3S,6}=J_{6,P}$=2.0 Hz, H_3-6), 2.51, 2.71* (1H, 2dddq, $J_{3R,3S}$=17.1, $J_{2,3S}$=5.7, $J_{3S,P}$= 3.7 Hz, H-3S), 2.87, 2.92* (1H, 2br d, $J_{3R,P}$=0.5 Hz, $J_{2,3R}\approx$0 Hz, H-3R), 3.79, 3.795* (3H, 2d, J_{POMe}=11.2 Hz, POMe), 4.67, 4.72* (1H, 2dd, $J_{1,2}$=3.6 Hz, H-2), 5.92, 5.93* (1H, 2d, H-1), 7.47, 7.47* [2H, m, $J_{o,m}=J_{m,p}$=7.5, $J_{m,P}$=4.4 Hz, Ph(*m*)], 7.57, 7.57* [1H, m, $J_{o,p}=J_{p,P}$=1.5 Hz, Ph(*p*)], 7.82, 7.82* [2H, m, $P_{o,P}$=13.6 Hz, Ph(*o*)], *for another diastereomer.

Cobalt(III)-tren Complexes of 3-Formylcamphor[1)]

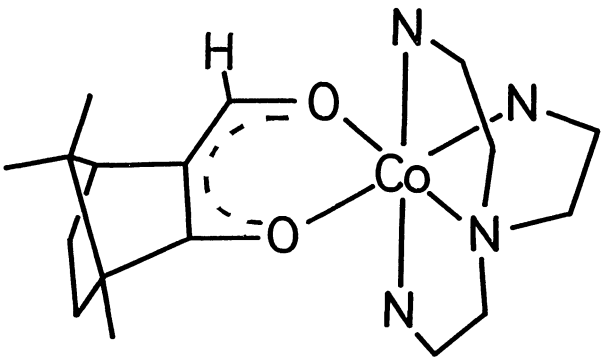
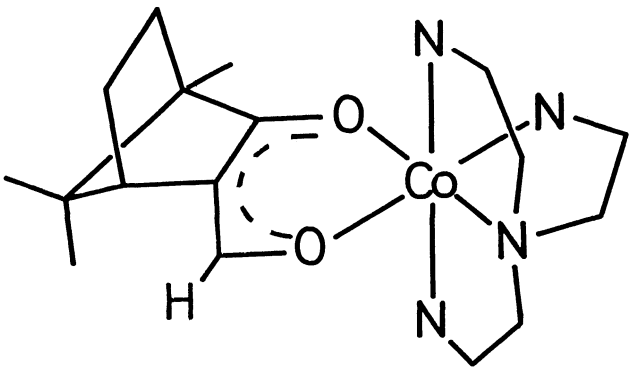
(Received August 7, 1990)

3-Formylcamphor Co(III) complexes of a tripod-like ligand, tren, were prepared and the two possible geometrical isomers were separated successfully. The crystal structure of one of them was determined by X-ray diffraction. A red plate-like crystal was monoclinic, space group $P2_1$, a=12.401 (2), b=9.9400 (7), c=10.932 (1) Å, β=108.44 (1)°, and Z=2. The structure was refined to R=0.047 on 2818 reflections. The geometrical isomers were compared sepectroscopically.

There have been few reports on Co(III)-tren complexes compared to those of Co(III)-trien. Until now, the Co(III)-tren complexes containing amino acids, diamines,[3)] and β-diketones[4)] have been reported. The tren complexes are much more suitable for model compounds to study the optical activities of such complexes. Because the trien complexes have two asymmetric centers and, thus, extra isomerisms occur. We have investigated both the crystal structure and optical activity of the Co(III)-tren complexes of unsymmetrical β-diketone type ligands.[4e)] In these complexes a pair of geometrical isomers is possible. If the coordinating atoms are of the same kind as in this case, it is very difficult to differentiate the geometrical structure spectroscopically, due to a lack of fundamental data concerning Co(III)-tren complexes. In the present work, Co(III)-tren complexes of 3-formylcamphorato(fc) were studied. Two geometrical isomers, **I** and **II**, (as shown in Fig. 1) were successfully separated by cation exchange chromatography. Contrary to tris(fc)metal complexes, only little regioselectivity was observed in this case.[5)] We determined the crystal structure of an isomer, **II**, $[Co(fc)(tren)](ClO_4)_2 \cdot H_2O$, eluted slowly on the column of cation-exchanging resin by an X-ray diffraction method, because of the inability to use various forms of spectroscopy.



I



II

Fig. 1. Geometrical isomers of $[Co(fc)(tren)]^{2+}$.

The ^1H NMR and ^{13}C NMR spectra of the two isomers were measured, and almost all of the signals could be assigned. They showed significant differences in the ^1H NMR, ^{13}C NMR, and CD spectra. The geometrical structure of Co(III)-tren complexes can be determined through comparison with the chemical shifts of the carbonyl carbons. The CD spectra can be discussed in terms of both vicinal and quasienantiomeric effects. The vicinal effect is more important than the quasienantiomeric effect in the case of 3-formylcamphor.

Experimental

Materials. a) Preparation of Ligands. Hfc was prepared by the Claisen Reaction of camphor with pentyl formate.[6)] The resulting white powder was confirmed through a measurement of the ^1H NMR. The starting complex, $[Co(CO_3)(tren)]^+$, was prepared as before.[4)]

b) Preparation of the Isomers, I and II. An isomeric mixture of fc complexes was prepared (as described previously) and separated by cation-exchanging chromatography using a 0.5 M (1 M=1 mol dm^{-3}) sodium chloride solution.[4)] A solution of the mixture (3 mmol in each column) was poured into an SP-Sephadex (C-25, 3×150 cm) column. The isomers were eluted by a 0.25 M sodium sulfate solution and completely separated into two bands, which were named **I** and **II** in the order of elution. After excess sodium sulfate was removed by adding ethanol to each eluted solution, six equivalents of sodium perchlorate were added. The resulting perchlorate crystals of each isomer, **I** or **II**, were filtered. The two isomers were recrystallized from a 5% aqueous solution of sodium perchlorate. IR (KBr) 3100—

3300 cm^{-1} broad peak (N–H stretching), 1610 cm^{-1} (carbonyl stretching). Yield: 19% from the beginning of preparation of complex mixtures. Relative ratio of **I**:**II**=45:55. Found for **I**: C, 33.87; H, 5.85; N, 9.30%. Found for **II**: C, 33.73; H, 5.80; N, 9.19%. Calcd for $[Co(fc)(tren)](ClO_4)_2 \cdot H_2O = C_{17}H_{33}N_4O_{10}Cl_2Co \cdot H_2O$: C, 33.84; H, 5.85; N, 9.29%.

Physical Measurement. The absorption spectra were recorded on a Hitachi 200-10 spectrophotometer and the CD spectra on a JASCO J-500A spectropolarimeter. All measurements were carried out in aqueous solution at room temperature. The ^1H and ^{13}C NMR spectra were recorded in deuterium oxide on a Hitachi R-20, JEOL JNM-FX90, and GX-400 NMR spectrometer at room temperature. The internal reference used was dioxane (methylene protons and carbons were assumed as 3.71 and 67.40 ppm, respectively). Calculations for structure analyses were carried out on a HITAC M-680 computer at the University of Tokyo.

a) Positional parameters are multiplied by 10^5 for Co, Cl, 10^4 for O, N, C. $B_{eq}=4/3 \cdot a(\text{beta}) \cdot \boldsymbol{a}$ are multiplied by 10^2 for Co, Cl, 10^1 for O, N, C. m_j indicate multiplicities of each atom. m1=0.56, m2=0.54, m3=0.44, m4=0.46.

X-Ray Data Collection. The unit cell-parameters and reflection data using a single crystal (ca. 0.42×0.37×0.47 mm) were measured on a Rigaku four-circle diffractometer (AFC-3) with graphite-monochromatized Mo $K\alpha$ rediation at The Institute for Solid State Physics. The cell dimensions were determined by least-squares calculations based on 40 reflections ($15.2<\theta<24.9$). Systematic absences of 0, k, 0 ($k=2n+1$) led to the space group $P2_1$.

Crystal data: $C_{17}H_{35}N_4O_{11}Cl_2Co$, M.W.=603.33, space group $P2_1$, a=12.401(2), b=9.9396(7), c=10.932(1) Å, β=108.44(1)°, V=1278.3(2) $Å^3$, Z=2, D_x=1.568, D_m=1.562 g cm^{-3} (by the floatation), (Mo $K\alpha$)=9.710 cm^{-1}, $F(000)$=628. The intensity data were collected by the θ-2θ scan technique up to $2\theta=55°$ with a scan rate of 2° min^{-1} in θ. The intensity data were converted to F_o data in the usual manner. A total of 2818 independent reflections with $|F_o|>2.5\sigma$ $|F_o|$ of the measured 3347 reflections were considered, as observed, and used for the structure analysis. Absorption was not corrected.

Determination of the Crystal Structure of the Isomer II. The structure was solved by a heavy-atom method using the UNICS III program system. All of the non-hydrogen atoms were refined by block-diagonal least squares with anisotropic thermal parameters. Hydrogen atoms were located using difference Fourier maps, except for the hydrogens of water, which were included in a refinement with isotropic thermal parameters. At a later stage of the refinement, the oxygen atoms of two perchlorate ions were found to have disordered dispositions. The final positional parameter shifts of almost all atoms, except for the oxygen atoms of the perchlorate, were less than the standard deviations. The final residual values were R=0.047 and R_w=0.066, where the weights are $w=1/(1.0+0.011|F_o|^2)$ for $|F_o|<15.0$ and $w=1/(\sigma^2/|F_o|+0.011|F_o|^2)$ for $F_o>15.0$. The final defference Fourier map showed a peak of 0.6 e $Å^{-3}$. The map showed several peaks less than 0.3 e $Å^{-3}$. The configuration was assigned on the basis of the known configuration of d-camphor. The y-coordinate of the cobalt

atom was fixed at 0.5. The final positional paprameters of non-hydrogen atoms and selected bond distances and angles are listed in Tables 1 and 2. The positional parameters of hydrogen atoms (Table a), the thermal parameters of all the atoms (Table b), structure factors (Table c), and nonessential interatomic distances and angles (Table d) are being kept as Document No. 9103 at the Office of the Editor of Bull. Chem. Soc.

Results and Discussion

The Crystal Structure of Complex II. Two rod-like complex cations lie along the *a*-axis on different levels along the *b*-axis by $y=0.5$, and the remaining space is filled with two water molecules and four perchlorate ions. As is often observed in other perchlorate salts, the perchlorate ions have disordered positions; furthermore, several interatomic distances and angles of the perchlorate ions deviate from the normal values and the thermal parameters of several oxygen atoms are unreasonably large.

A perspective drawing of the complex cation is shown in Fig. 2. The cobalt atom is octahedrally surrounded by two oxygen and four nitrogen atoms. Since the three primary nitrogen atoms are constrained to approach the tertiary nitrogen (N(1)) to form three five-membered chelate rings (denoted as A, B, and C as shown in Fig. 2), the angles subtended at the cobalt atom by the chelate rings are compressed to an average angle of 87.0°, and the interatomic distance of Co–N(3) is significantly short compared with those of Co–N(2) and Co–N(4). The two chelate rings, B and C, have an almost symmetrical conformation. These features are very similar to those of other tren complexes. Although the six-membered chelate ring adopts an almost planar conformation, the atoms with large thermal parameters within fc group are rather flexible perpendicularly to the ring as a whole, as is obseved in the ellipsoid of each atoms. This flexibility might be responsible for the relatively large standard deviation of several interatomic distances and angles (C(12), C(13), C(15), and C(16)).

Characterization of I and II. Though the infrared spectra of the two isomers showed only general features of β-diketonatocobalt(III) complexes, no notable difference was observed between them. Several significant differences were observed in the ^{1}H NMR, ^{13}C NMR, CD spectra. Upon assigning the NMR spectra, we had to refer to the assignment of $[Co(acac)(tren)]^{2+}$ and camphor. Twelve protons and six carbons of the tren part in $[Co(acac)(tren)]^{2+}$ were assigned based on the H–H and C–H cosy spectra; the results are shown in Table 3. The same names were used as those used in the crystal structure for the non-hydrogen atoms, and all of the protons were indicated with the names of non-hydrogen atoms to which the protons were attached. We assumed that the four protons of the four methylene group of the B and C ring facing the acac ring shifted by more than the opposite four protons. Refering to the tren and camphor parts, the essential peaks of the two isomers could be assigned as shown in Table 4. Within the chelate ring of 3-formylcamphor in **I** and **II**, the carbon atoms in the trans side to the tertiary nitrogen

a) Chemical shifts were given in ppm.

atom of tren were deshielded more than those in the cis side.

All of the complexes of $[Co(3\text{-}X\text{-}acac)(tren)]^{2+}$(X=H, naphthyl, 2,4-dinitro-1-naphthyl, etc.) previously prepared showed two peaks for the methyl groups in ^{1}H NMR and ^{13}C NMR, and for the carbonyl carbons in ^{13}C NMR.[4] This is probably due to an electronic deformation of the coordination sphere produced by the three five-membered chelate rings of tren. Thus, the remaining coordination site in the Co(tren) system became unbalanced, resulting in a magnetically different field. If these observations are also true for other Co(III)-tren complexes, and the assignments of carbonyl carbons can be established, the geometrical structure can be determined in terms of the chemical shifts of the carbonyl carbons. Limitations of this assumption, however, have to be ascertained. Since we could not find any papers in the literature that describes any clearly assigned ^{13}C peaks of the carbon atoms (carbonyl or thiocyanato group) of the tren and trien complexes in a similar environment, the problems remained unsolved.

Absorption and Circular Dichroism Spectra of the Isomers. Both of the spectra are shown in Fig. 3. Since the absorption spectra of the isomers **I** and **II** were superimposable to each other, only that of isomer **I** is shown. Though they resembled that of $[Co(acac)(tren)]^{2+}$, but all of the transition peaks shifted slightly to a lower-wave number region. Especially, the charge-transfer band shifted to 29.4×10^{3} cm^{-1}, probably because the chelate ring of fc was strained and the antibonding π-orbitals levels decreased. The CD spectra of **I** and **II** were compared with that of $[\{Co(tren)\}_2(tae)]^{4+}$.[4d] Two electronic transitions regions, at $17\text{—}21\times10^{3}$ cm^{-1} and $23\text{—}27\times10^{3}$ cm^{-1}, were assigned to the d-d* transitions of the first and the second absorption bands, respectively. The CD

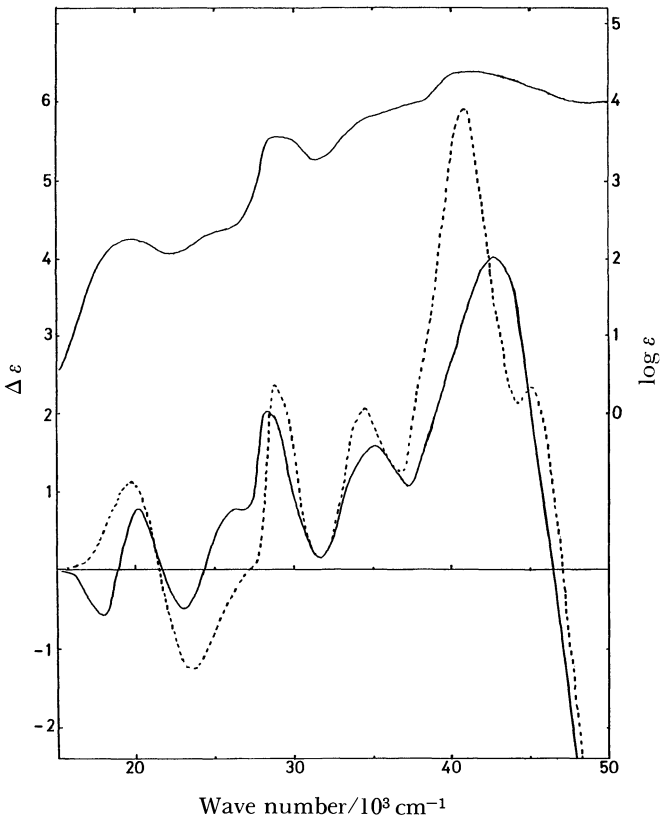

Fig. 3. Absorption and CD spectra.

spectra showed that the electronic transitions of present complexes shifted to a lower wave-number region compared with the corresponding transition of $[\{Co(tren)\}_2(tae)]^{4+}$. The origin of every transitions became obscure at region higher than 40×10^{3} cm^{-1}, due to the overlap of various transition.

Akamatsu et al. reported that vicinal and quasi-enantiomeric effects can contribute to the CD spectra in the case of Co(III)-tren complexes containing optically active amino acids and diamines.[3b] They claimed that the latter effect is dominant. If the quasi-enantiomeric effect is also dominant in the present complex, almost all of the corresponding CD peaks would show opposite signs to each other. The CD spectra of the isomeric complexes, **I** and **II**, resembled each other as a whole, and showed peaks of the same sign. This fact indicates that the vicinal effect is dominant, in contrast to the case of amino acids and diamines. In the present fc complexes, bulky alkyl groups which cause chirality are incorporated directly into the chelate ring. The vicinal effect may be more important in this case.

This work was supported in part by the Joint Research Project of the Institute for Solid State Physics, the University of Tokyo.

Solvent Extraction of the Hexaaquarhodium(III) Ion from Halogenated Carboxylate Solutions with Trioctylphosphine Oxide

Hisanori IMURA,† Hiromi TAKAHASHI, and Nobuo SUZUKI*
Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980
(Received September 4, 1990)

The extraction equilibrium of the inert hexaaquarhodium(III) ion has been studied. Rhodium(III) was quantitatively and rapidly extracted from 0.10 mol dm^{-3} trichloroacetate (TCA) or 0.010 mol dm^{-3} pentadecafluorooctanoate solutions to heptane containing 0.10 mol dm^{-3} trioctylphosphine oxide (TOPO) at pH 3—5. The extraction equilibria were achieved within 1 min at 298 K. From the equilibrium study in the TCA–TOPO system, the rhodium(III) species extracted into heptane was found to be Rh·3TCA·4TOPO, and the extraction constant was $10^{12.29}$. The rhodium(III) species in the organic phase was suggested to be the hexaaquarhodium(III) complex associated with TCA and TOPO.

Recently, much attention has been focused on the separation of metals of the platinum group. Solvent extraction is one of the powerful separation methods and is widely used in fundamental analytical chemistry and applied fields, such as hydrometallurgy. The various extraction systems which have been reported for the separation of the platinum metals were summarized in both a monograph[1] and a review.[2] The poor extractability of rhodium has often been pointed out. This is primarily ascribed to the very inert tendency of rhodium(III) toward the ligand substitution reactions with extracting agents. Thus, a thorough investigation of the extraction chemistry of rhodium(III) is inevitable.

In the extraction of such inert metals as rhodium(III), the chemical form of the metal in an aqueous solution seems to be of great importance. In this work a hexaaquarhodium(III) ion was prepared and used. Only a few papers have appeared concerning the extraction of hexaaquarhodium(III), in which it has been extracted into the inverted micelles of the organic solution formed by dinonylnaphthalenesulfonic acid.[3,4]

In the present study the extraction of the hexaaquarhodium(III) ion was studied with such halogenated carboxylic acids as trichloroacetic acid (HTCA) and pentadecafluorooctanoic acid (HPDFO) in the presence of a hydrophobic base, trioctylphosphine oxide (TOPO), in nonpolar solvents at 298 K. The trichloroacetic acid–TOPO system has been used by one of the authors in the extraction of inert chromium(III) ions.[5] The extraction equilibrium of hexaaquarhodium(III) ions in this system was studied in detail, and the composition of the extracted species as well as the extraction constant were determined.

Experimental

Reagents. Radioisotopes, ^{101m}Rh and ^{102m}Rh, were produced by 50 MeV bremsstrahlung irradiation of high-purity rhodium (99.99%) with the linear electron accelerator of Tohoku University. The rhodium target was dissolved in concentrated sulfuric acid with heating, neutralized with a sodium hydroxide solution to precipitate rhodium(III) hydroxide, and aged at 328—333 K for 24 h. To prepare a hexaaquarhodium(III) solution, the precipitate of rhodium(III) hydroxide was dissolved in concentrated perchloric acid, heated at 433—443 K for ca. 40 h, and diluted to be 0.2 mol dm^{-3} perchloric acid solution. The rhodium(III) species in the aqueous solution was ascertained to be the hexaaquarhodium(III) ion by the electronic absorption spectrum.[6,7]

Trioctylphosphine oxide was obtained from Dojindo laboratories and purified as follows: a hexane solution (ca. 0.2 mol dm^{-3} TOPO) was washed with 0.5 mol dm^{-3} sodium hydroxide in 50% (v/v) methanol/water and then with water several times. After evaporation of hexane, the residue (purified TOPO) was dried over diphosphorus pentaoxide under vacuum.

Trichloroacetic acid was of guaranteed reagent grade and used as obtained. Sodium trichloroacetate solutions were prepared by mixing a trichloroacetic acid solution standardized by the acid–base titration and sodium hydroxide solutions. Pentadecafluorooctanoic acid (98% purity) was used without further purification.

Benzene and heptane were purified by ordinary methods. Water was doubly distilled and deionized. All other reagents used were of analytical reagent grade.

Extraction and Back Extraction of Rhodium(III). An aqueous solution (5 cm^3) of 4×10^{-3}—1×10^{-1} mol dm^{-3} halogenated carboxylate containing 8×10^{-5} mol dm^{-3} hexaaquarhodium(III) labeled with ^{101m,102m}Rh was shaken for 1 min to 3 h with an organic solution (5 cm^3) containing 5×10^{-3}—1×10^{-1} mol dm^{-3} TOPO at 298 K. After centrifugation, an aliquot of each phase was taken. The γ-activity was measured with a well-type NaI(Tl) scintillation counter and the distribution ratio (D_M) calculated. The pH value of the aqueous phase was measured immediately after shaking. The ionic strength was adjusted to 0.1 mol dm^{-3} with sodium nitrate.

For back extraction, the organic phase (5 cm^3) containing rhodium(III), prepared by the forward extraction described above, was shaken with the aqueous phase (5 cm^3) preequilibrated with an organic solution of TOPO. The distribution ratio and the equilibrium pH value were measured in the same manner as that described above.

Extraction of Trichloroacetic Acid. An aqueous solution

† Present address: Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310.

of 0.1 mol dm^{-3} trichloroacetate was shaken with a heptane solution of 2×10^{-3}—1×10^{-1} mol dm^{-3} TOPO for 5 min at 298 K. After centrifugation, an aliquot of the organic phase was taken, added to a small volume of water, and titrated with the standardized sodium hydroxide solution with vigorous agitation. The distribution ratio of trichloroacetic acid was calculated from the concentration of trichloroacetic acid extracted into the organic phase and the initial concentration of trichloroacetate in the aqueous phase.

Results and Discussion

Extraction Behavior of Rhodium(III). The extraction of hexaaquarhodium(III) from trichloroacetate or pentadecafluorooctanoate solutions into various organic solvents containing TOPO was tried at 298 K. The agitation of both phases was carried out for only 5 min. The results for the 0.10 mol dm^{-3} trichloroacetate–0.10 mol dm^{-3} TOPO system are shown in Fig. 1. A quantitative extraction of rhodium(III) can be accomplished using heptane as a diluent of TOPO; rhodium(III) of more than 99% is readily extracted at pH 3—5. However, rhodium(III) is scarcely extracted into chloroform. The extraction increases in the following order: chloroform<1,2-dichloroethane<nitrobenzene≈benzene<heptane. This order agrees with that observed in the extraction of chromium(III) with trichloroacetate and TOPO,[5] as well as in the synergic extraction of europium(III) with 4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione and TOPO.[8] Such a large observed solvent effect reveals the importance of the reaction between the extracted metal species and TOPO in the organic phase, e.g., solvation or adduct formation. The lowering of extraction in the low- and high-pH region is ascribed to the extraction of trichloroacetic acid with TOPO in the organic phase and the hydrolysis of rhodium(III) ion in the aqueous phase, respectively (vide infra).

Figure 2 shows the extraction curves of rhodium(III) in the 0.010 mol dm^{-3} pentadecafluorooctanoate–0.10 mol dm^{-3} TOPO system. The distribution ratio was independent of the shaking time from 1 to 180 min. The extraction increases in the following order: chloroform<nitrobenzene≈benzene≈1,2-dichloroethane<heptane. Though the extraction behavior is quite similar to that in the trichloroacetate–TOPO system, rhodium(III) could be quantitatively extracted into most of the solvents studied. Since pentadecafluorooctanoic acid has a larger molecular size and a higher hydrophobic character than does trichloroacetic acid, the extraction ability of the former is much higher.

A further study concerning the extraction equilibrium of the hexaaquarhodium(III) ion was made (see below) in the trichloroacetate–TOPO–heptane system in order to elucidate the composition of the extractable rhodium(III) species.

Extraction Equilibrium of Trichloroacetic Acid with TOPO. The extractability of rhodium(III) seems to be significantly affected by the extraction of

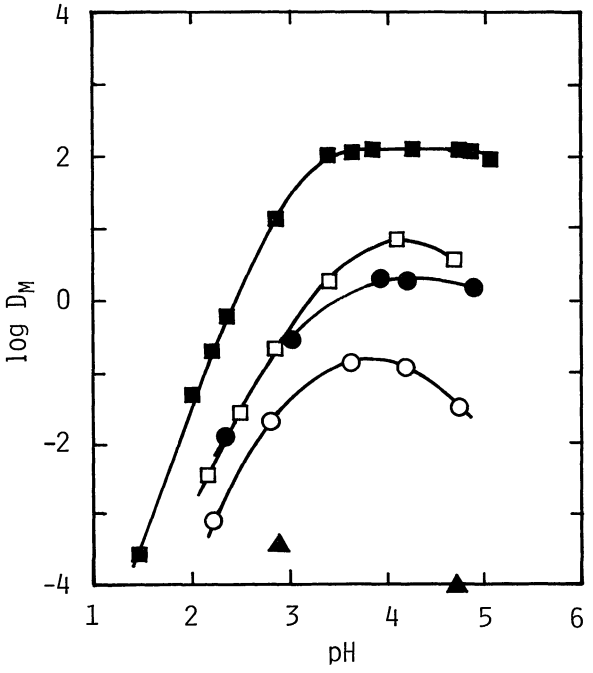

Fig. 1. Extraction of rhodium(III) from 0.10 mol dm^{-3} trichloroacetate solutions into various organic solvents containing 0.10 mol dm^{-3} TOPO. Shaking time: 5 min. ■, Heptane; □, benzene; ●, nitrobenzene; ○, 1,2-dichloroethane; ▲, chloroform.

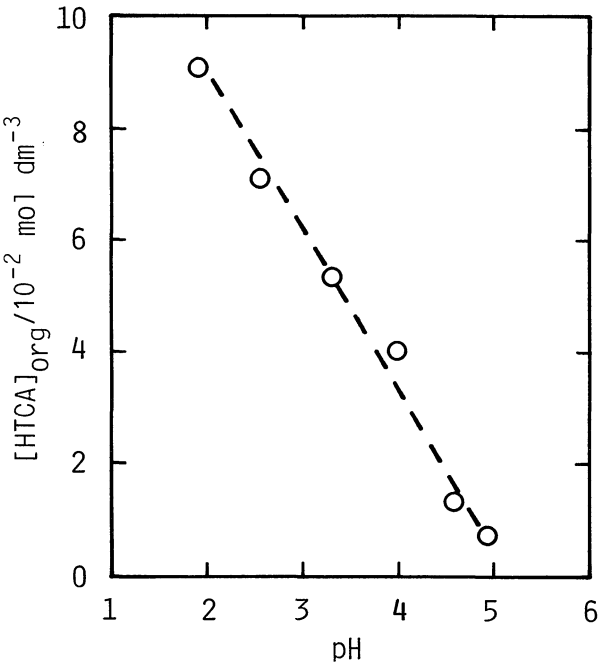

Fig. 3. Variation of the trichloroacetic acid concentration in the heptane phase with pH in the 0.10 mol dm^{-3} trichloroacetate–0.10 mol dm^{-3} TOPO system.

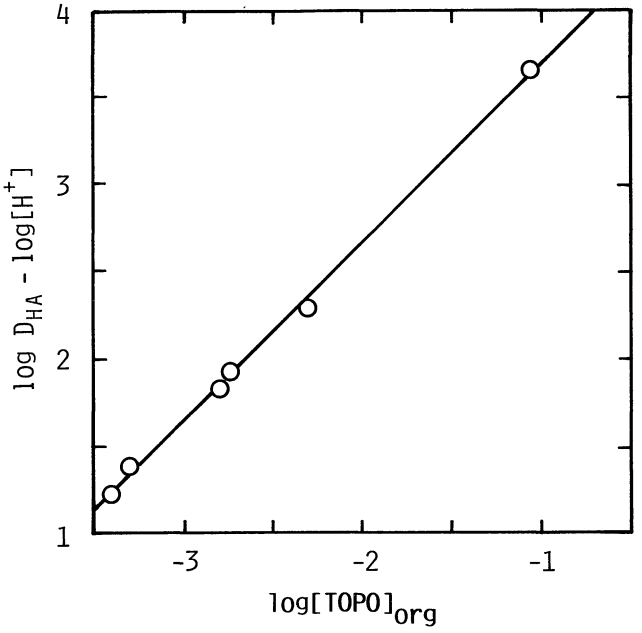

Fig. 4. Effect of the equilibrium concentration of TOPO in the organic phase on the distribution ratio of trichloroacetic acid. 0.10 mol dm^{-3} trichloroacetate, 0.0025—0.10 mol dm^{-3} TOPO. pH 2.80—4.58.

trichloroacetic acid with TOPO. Figure 3 shows the variation of the concentration of trichloroacetic acid extracted into the heptane phase at various pH. The acid concentration in the organic phase increases with a decrease in the pH, and reaches about 0.09 mol dm^{-3} at pH 2, i.e., 90% of the total concentration of trichloroacetate. Since trichloroacetic acid is a strong acid (pK_a=−0.46[9]), it should be completely dissociated in the aqueous phase within such a pH range. Hence, the extraction of trichloroacetic acid is not ascribed to the protonation of trichloroacetate following the distribution of the acid into heptane, but to the association among protons, trichloroacetate, and TOPO in the organic phase, as was previously discussed regarding the extraction of trichloroacetic acid with TOPO[5] and various acids with organophosphorus extractants.[10] The equilibrium concentrations of the trichloroacetate ion in the aqueous phase and of TOPO in the organic phase are lowered by association from the initial concentration of the respective agents. Thus, the extraction equilibrium of trichloroacetic acid with TOPO must be clarified in order to obtain the equilibrium concentration of the trichloroacetate ion and TOPO. The extraction equilibrium can be written as

$$H^+ + TCA^- + i\,TOPO_{org} \rightleftharpoons HTCA\cdot i\,TOPO_{org}, \quad (1)$$

$$K_{ex,HA} = \frac{[HTCA\cdot i\,TOPO]_{org}}{[H^+][TCA^-][TOPO]_{org}{}^i}, \quad (2)$$

where $K_{ex,HA}$ stands for the extraction constant of trichloroacetic acid and the subscript org, the organic phase. The distribution ratio (D_{HA}) of trichloroacetic acid can be given as

$$D_{HA} = \frac{[HTCA\cdot i\,TOPO]_{org}}{[TCA^-]}. \quad (3)$$

From Eqs. 2 and 3, the following equation is derived:

$$\log D_{HA} = i \log [TOPO]_{org} + \log [H^+] + \log K_{ex,HA}. \quad (4)$$

Using this equation, the equilibrium concentration of TOPO in the organic phase was calculated by deducing the amount of TOPO associated with trichloroacetic acid in the organic phase from that of TOPO initially taken. Figure 4 shows a plot of $\log D_{HA}$–$\log [H^+]$ against $\log [TOPO]_{org}$, which was obtained by setting i=1. The plot is a straight line with a slope of 1.0, as was expected. When i=2 or i=3 was assumed, no slope corresponding to the each assumption was obtainable. Consequently, the extracted species was found to be HTCA·TOPO and the extraction constant, $\log K_{ex,HA}$=4.66±0.05, was obtained. The equilibrium concentration of TOPO and trichloroacetate can be readily calculated using this value.

Extraction Equilibrium of Rhodium(III) with Trichloroacetate and TOPO. Figure 5 shows both the extraction and back extraction of hexaaquarhodium-

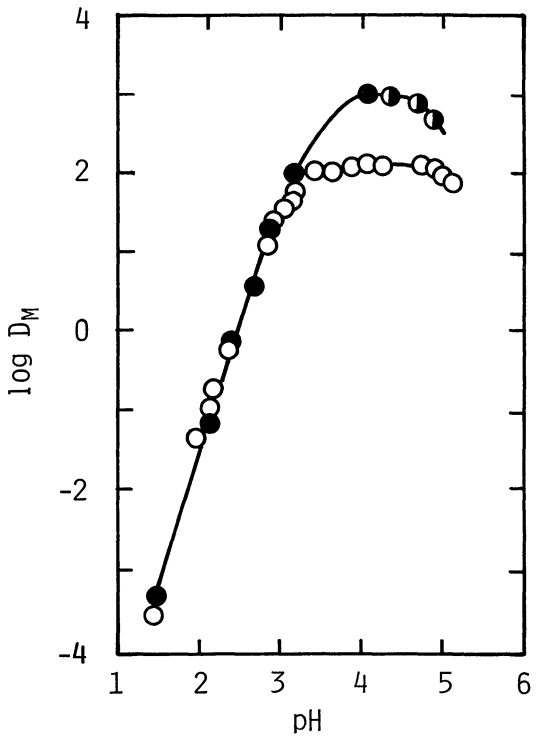

Fig. 5. Forward and backward extraction of rhodium(III) in the 0.10 mol dm^{-3} trichloroacetate–0.10 mol dm^{-3} TOPO–heptane system. ○, Forward extraction at the shaking time 5 min; ●, backward extraction at the shaking time 5 min; ◑, backward extraction at the shaking time 30 min.

(III). The distribution ratio of rhodium(III) was independent on the shaking time in a pH region lower than about 3; that is, the logarithmic values of the distribution ratio in forward extraction at pH 2.57 for three different shaking time (1, 5, and 30 min) were −2.44, −2.46, and −2.47, respectively; the same was true in backward extraction. In Fig. 5 the distribution ratio obtained from forward extraction is in good agreement with that obtained from backward extraction. These facts demonstrate that the extraction equilibrium in the present system was completely achieved within an agitation time of only 1 min. The extraction of the inert hexaaquarhodium(III) ion is surprisingly rapid in this trichloroacetate–TOPO system.

On the other hand, a disagreement between the distribution ratio in forward extraction and that in backward extraction at around pH 4 was observed. This difference in the distribution ratios was gradually reduced with the shaking time; the log D_M values in both forward and backward extraction at pH 3.9 were almost consistent at 2.7 after shaking for 27 h. This phenomenon can be ascribed to a slow extraction reaction, which may be caused by the hydrolysis and polymerization of hexaaquarhodium(III) ion in the aqueous phase within such a pH range.[11] Hence, equilibrium studies regarding the extraction of rhodium(III) were performed below pH 3 at which the rapid equilibrium could be always achieved.

The effect of the rhodium(III) concentration on the distribution ratio of rhodium(III) was examined in the 0.10 mol dm^{-3} trichloroacetate–0.10 mol dm^{-3} TOPO system at pH 2.90. The logarithmic values of the distribution ratio were 1.28, 1,28, and 1.26 at 8.1×10^{-6}, 8.1×10^{-5}, and 8.1×10^{-4} mol dm^{-3} of the rhodium(III) concentration, respectively. Since the distribution ratio is independent on the rhodium(III) concentration, no polymerization of the extracted species occurs in the organic and the aqueous phase.

The extraction equilibrium of rhodium(III) with the trichloroacetate ion (TCA^-) and TOPO can be expressed as

$$Rh^{3+} + m\,TCA^- + n\,TOPO_{org} \rightleftharpoons Rh\cdot m\,TCA\cdot n\,TOPO_{org}, \quad (5)$$

$$K_{ex,M} = \frac{[Rh\cdot m\,TCA\cdot n\,TOPO]_{org}}{[Rh^{3+}][TCA^-]^m[TOPO]_{org}^n}, \quad (6)$$

where $K_{ex,M}$ stands for the extraction constant of rhodium(III). The distribution ratio of rhodium(III) under the present experimental conditions can be written as

$$D_M = \frac{[Rh\cdot m\,TCA\cdot n\,TOPO]_{org}}{[Rh^{3+}]}. \quad (7)$$

Therefore,

$$\log D_M = m\log[TCA^-] + n\log[TOPO]_{org} + \log K_{ex,M}. \quad (8)$$

Figure 6 shows a plot of $\log D_M - 3\log[TCA^-]$ against the logarithmic value of the equilibrium concentration of TOPO in the organic phase, where it was assumed that the number of TCA molecules associated with the rhodium(III) ion, m, is three, based on the electrical neutrality with respect to the extractable species. The plot gives a straight line with a slope of 3.8 in the low-concentration region of TOPO, where the extraction of trichloroacetic acid with TOPO is negligible and the ionic strength in the aqueous phase is almost constant. Therefore, the rhodium(III) ion is solvated with four molecules of TOPO in the organic phase.

To ascertain that the number of the trichloroacetate molecules associated with the rhodium(III) ion is three, a plot of $\log D_M - 4\log[TOPO]_{org}$ against $\log[TCA^-]$ was made using $n=4$. The result is shown in Fig. 7. A straight line with a slope of 2.7 was obtained; the result is compatible with that expected, $m=3$. Therefore, the rhodium(III) species extracted into

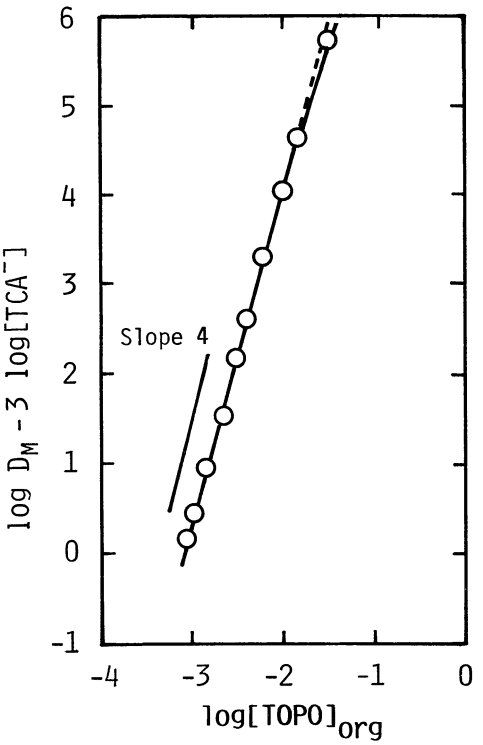

Fig. 6. Effect of the equilibrium concentration of TOPO in the organic phase on the distribution ratio of rhodium(III). 0.10 mol dm^{-3} trichloroacetate, pH 2.90, shaking time: 5 min.

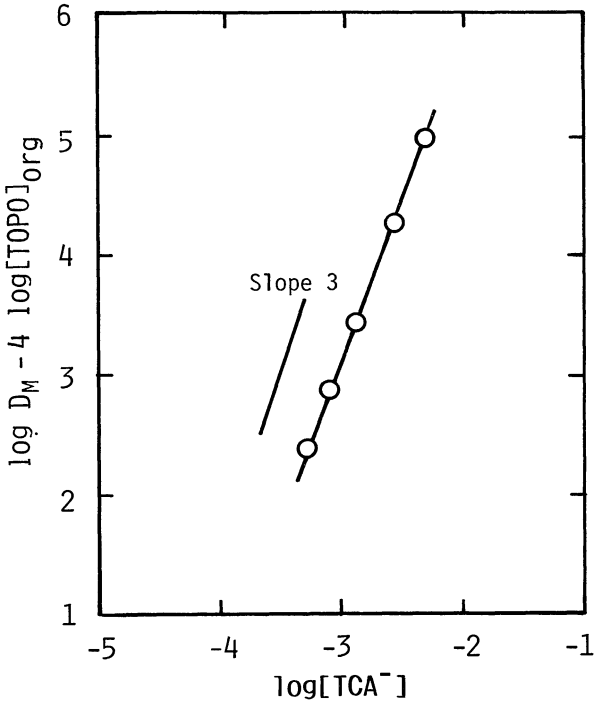

Fig. 7. Effect of the equilibrium concentration of trichloroacetate in the aqueous phase on the distribution ratio of rhodium(III). 0.10 mol dm^{-3} TOPO, pH 2.90, 0.10 mol dm^{-3} $NaNO_3$, shaking time: 5 min.

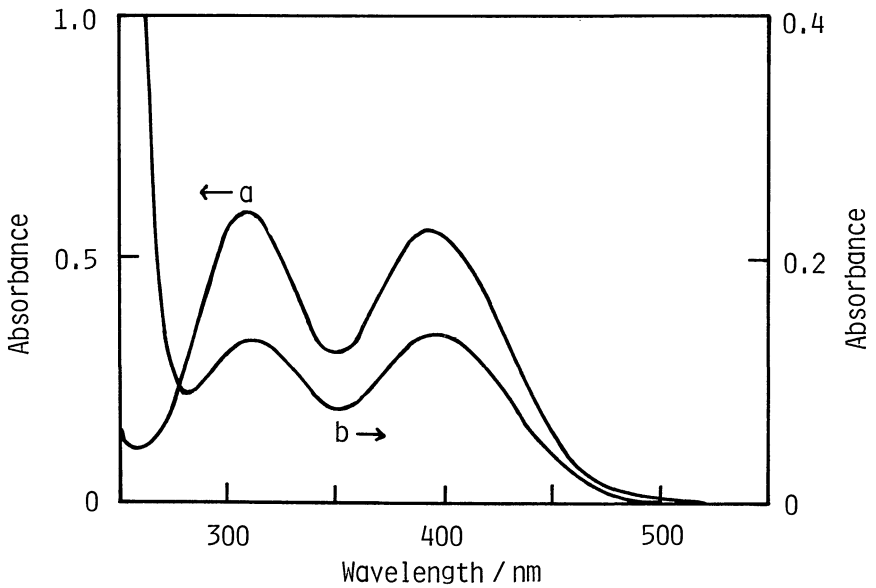

Fig. 8. Absorption spectra of the hexaaquarhodium(III) ion in perchloric acid solution and the rhodium(III) species extracted into the heptane phase containing 0.10 mol dm^{-3} TOPO from a 0.10 mol dm^{-3} trichloroacetate solution at pH 3.18. a, 1.1×10^{-2} mol dm^{-3} hexaaquarhodium(III) ion; b, 2.2×10^{-3} mol dm^{-3} rhodium(III) extracted.

heptane was found to be Rh·3TCA·4TOPO, and the extraction constant, log $K_{ex,M}$=12.29±0.06, was obtained. The composition of the extractable species was the same as that in the rhodium(III)–2,4,6-trinitrophenol–TOPO system.[12]

The electronic absorption spectrum of the rhodium(III) species extracted into heptane was measured and compared with that of the hexaaquarhodium(III) ion in an aqueous perchlorate solution. The spectra of both rhodium(III) species shown in Fig. 8 are very similar to each other. Taking account of the very inert property of the hexaaquarhodium(III) ion, it is impossible to rapidly exchange the coordinated water molecules with TOPO or TCA^- molecules. Consequently, in the present extraction system rhodium(III) is extracted as a hexaaquarhodium(III) complex, which is associated with the four molecules of TOPO and the three molecules of trichloroacetate ions. This extractable species can be considered to be an outer-sphere complex and the following model may be speculated: four TOPO and three trichloroacetate molecules may be present on the octahedral faces of the hexaaquarhodium(III) ion to most effectively interact with the central metal, as well as the coordinated water by coulombic and charge-dipole interaction, hydrogen bonding, etc.

In conclusion, an inert rhodium(III) species, could be very rapidly and quantitatively extracted in an ion-association system comprising the halogenated carboxylates and TOPO at room temperature. This rapidity of the extraction could be explained in terms of the extraction of the hydrated rhodium(III) without any ligand substitution. The present system is very useful for the extraction of such inert metal ions.

Synthesis and Coordination Behaviors of New Double-Sided Porphyrinatoiron(II) Complexes: Effect of the Pocket-Size for Imidazole on Dioxygen Binding

Eishun TSUCHIDA,* Etsuo HASEGAWA, Teruyuki KOMATSU, Taisaku NAKATA, Keisuke NAKAO, and Hiroyuki NISHIDE
Department of Polymer Chemistry, Waseda University, Shinjuku, Tokyo 169
(Received September 21, 1990)

The synthesis and characteristic ligation behaviors of new "double-sided porphyrinatoiron(II) complexes" having two pockets of different spacing-size on each side of a ring plane and a larger sized one on both sides of a macrocycle, are described. The equilibrium constants for the imidazole derivatives to the four-coordinated porphyrinatoiron(II)s were increased in proportion to the size of the pocket-space, which is reflected by the ΔH term. The five-coordinated complexes of the porphyrinatoirons, obtained by the addition of 1,2-dimethylimidazole (1,2-dmin) in a toluene solution, formed stable and reversible dioxygen adducts at 25 °C. The oxygen affinities for the iron(II) complexes increased as the steric bulk on the rear side of the porphyrin plane was relieved. These changes in the oxygen affinity are attributed to the strength of the π-electron donation from the imidazole to the central iron ion.

Simple porphyrinatoiron(II)s are well known to react rapidly with dioxygen to form irreversible μ-oxo-iron(III) dimers. A number of synthetic analogs of oxygen-carrying hemoproteins have been synthesized to inhibit such undesirable bimolecular reactions and have demonstrated a dramatic variation in O_2 affinities due to the nature of the pocket structure and/or the effect of the proximal base.[1-9]

Single-face highly modified porphyrinatoiron(II)s (picket-fence, capped, and pocket porphyrins) having an appropriate cavity on the ring plane, bind dioxygen reversibly in aprotic organic solvents containing an excess of axial base; their dioxygen adducts are stable against irreversible oxidation.[1-5] However, these iron(II) complexes have a very short lifetime under conditions in which the axial base concentration is very low, since the μ-oxo dimer can be formed through the unprotected side of a heme.

It is therefore necessary to modify the rear side of the porphyrin plane; the proximal imidazole binding site. Both-faces hindered porphyrinatoiron(II) (bis-pocket and basket-handle porphyrin) have been synthesized in order to sterically prevent irreversible oxidation and to perform a unique feature for dioxygen binding.[3,4] The preparation of such derivatives, however, is generally not easy and the yield is rather low.

On the other hand, in recent years many of the dioxygen-carrier model derived from 5,10,15,20-tetrakis(*o*-aminophenyl)porphyrin have amide residues, which have been suggested to interact with bound dioxygen (hydrogen bonding, local polarity effect, etc.) and to contribute to the stability of oxygen-adduct formation.[1-3,7] In some cases, the oxygen-binding affinity of the porphyrinatoiron complex is surely affected by the polarity of the environment around the binding site.[2-4]

We recently reported a new methodology for the synthesis of both-faces hindered and highly symmetric porphyrin, 5,10,15,20-tetrakis[2,6-bis(pivaloyloxy)phenyl]porphyrinatoiron (**3b**), which is much simpler and gives higher yields in comparison with the previous models.[10] Our results have shown that an ester-fenced porphyrin without amide groups can form a stable, reversible dioxygen adduct at 25 °C in toluene, suggesting that an electrostatic interaction between the fence residues and the bound dioxygen is not essential for the formation of a dioxygen adduct. However, the double-sided porphyrinatoiron(II) and porphyrinatocobalt(II) complexes quantitatively showed a steric hindrance of the bulky ester fences on both sides of the porphyrin plane when axial ligands bind. Generally, π-electron donation from the axial base to the metal can be varied with the binding character of the base ligand, making it possible for the oxygen-affinities of metalloporphyrins to be controlled by changes in the strength of the metal-base bonding.[3,5,8,9] It is therefore considered that the low oxygen affinity of the **3b** complex can be attributed to a decrease in the π-electron flow from the axial base to the bound dioxygen due to a steric interaction between the axial base and the bulky ester groups. In order to increase the oxygen affinity of this porphyrin, we designed and synthesized new "double-sided porphyrins", 5,10,15-tris[2,6-bis(pivaloyloxy)phenyl]-20-[(2-hydroxy-6-pivaloyloxy)phenyl]porphyrinatoiron (**1b**) and 5,10,15,20-tetrakis[2,6-bis(3,3-dimethylbutyryloxy)phenyl]porphyrinatoiron (**2b**), each having a larger cavity for axial base binding on the ring plane. Their characteristic ligation properties with imidazole derivatives or dioxygen have been clarified by spectroscopic measurements. We now wish to report on the effects of a steric change in the fences on the rear side of the ring plane, both on the binding of the axial base and on the oxygen affinities for the double-sided porphyrinatoirons.

Experimental

General. A Shimadzu UV-2100 highly-sensitive spectrophotometer equipped with a thermostatted cell holder and bath (±0.2 °C) was used for spectroscopic measurements. Infrared spectra (IR) were taken with a JASCO IR-810 spectrometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a JEOL GSX-400 instrument. Chemical shifts are expressed in parts per million downfied from Me_4Si as an internal standard. FAB MS spectra were measured with a JEOL DX-303 spectrometer. Elemental analyses were performed on a Yanagimoto MT3 CHN corder. Thin-layer chromatography (TLC) was carried out on 0.2 mm precoated plates of silica gel 60 F-254 (Merck). Products purification was performed by silica gel 60 (Merck) column chromatography. Solvents were evaporated with a type-N2 Tokyo Rikakikai rotary evaporator.

Materials and Solvents. 1-Methylimidazole (1-mim) and 1,2-dimethylimidazole (1,2-dmim) were purified before use by distillation in vacuo under reduced pressure. Pivaloyl chloride, 4-(dimethylamino)pyridine, 3,3-dimethylbutyric acid, and thionyl chloride are commercially available as special grade and were used without further purification. Tetrahydrofuran (thf) and toluene were purified immediately before use by distillation from sodium and benzophenone uder argon.

The synthetic routes for the complexes (**1b′**) and (**2b′**) are as follows.

5,10,15,-Tris[2,6-bis(pivaloyloxy)phenyl]-20-[(2-hydroxy-6-pivaloyloxy)phenyl]porphyrin (1a). 5,10,15,20-Tetrakis(2,6-dihydroxyphenyl)porphyrin ($H_2T_{(OH)_2}PP$)[10] (1.0 g, 1.35 mmol) and 4-(dimethylamino)pyridine (1.18 g, 9.69 mmol) were dissolved in dry thf (200 ml). To this ice-cooled solution pivaloyl chloride (1.19 cm^3, 9.69 mmol) was added dropwise with stirring under an argon atmosphere; the reaction mixture was stirred for 1 h at room temperature. The solution was further stirred for 12 h at 60 °C, then brought to dryness on a rotary evaporator and extracted with $CHCl_3$. The organic layer was washed, first with dilute hydrochloric acid and then with aqueous ammonia. The organic phase dried over anhydrous Na_2SO_4 was concentrated and the residue was chromatographed on a silica-gel column using $CHCl_3$–diethyl ether, 10:1 (v/v), as the eluent. The second elution band was collected and reduced to a small volume on a rotary evaporator. The residue was then dried at room temperature for several hours in vacuo to give a purple crystalline product (**1a**) (0.17 g, 9.3%). R_f 0.45 $CHCl_3$–diethyl ether, 10:1 (v/v). Anal. Found: C, 70.45; H, 6.77; N, 4.03%. Calcd for $C_{79}H_{86}N_4O_{15}\cdot H_2O$: C, 70.35; H, 6.58; N, 4.15%. FAB MS $[M]^+$ 1331. IR (KBr); 3450 cm^{-1} (ν_{OH}), 1760 cm^{-1} (ν_{CO}(ester)). ^{1}H NMR ($CDCl_3$) δ=−2.9 (2H, s, inner H), −0.5—−1.0 (63H, m, pivaloyl), 7.4—8.0 (12H, m, phenyl H), 8.8 (8H, d, pyrrole β-H). VIS. ($CHCl_3$) 636, 583, 538, 506, and 412 nm.

5,10,15-Tris[2,6-bis(pivaloyloxy)phenyl]-20-[(2-hydroxy-6-pivaloyloxy)phenyl]porphyrinatoiron(III) Bromide (1b′). The synthetic procedure for complex **1b′** was similar to that used for **1a**, except for using 5,10,15,20-tetrakis(2,6-dihyroxyphenyl)porphyrinatoiron bromide ($FeT_{(OH)_2}PP$)[10] (1.0 g). Finally, dark-purple crystalline products **1b′** (83.6 mg, 5.0%) were obtained. R_f 0.25 ($CHCl_3$–CH_3OH, 100:1 (v/v)). Anal. Found: C, 65.22; H, 6.30; N, 3.83%. Calcd for $C_{79}H_{84}N_4O_{15}FeBr\cdot 0.5C_6H_6$: C, 65.47; H, 5.83; N, 3.72%. FAB MS $[M-Br]^+$ 1385. IR (KBr); 3450 cm^{-1} (ν_{OH}), 1760 cm^{-1} (ν_{CO}(ester)). VIS. ($CHCl_3$) 680, 649, 586, 507, and 411 nm.

5,10,15,20-Tetrakis[2,6-bis(3,3-dimethylbutyryloxy)phenyl]-porphyrin (2a). 3,3-Dimethylbutyric acid (15 cm^3, 0.12 mol) was suspended in thionyl chloride (10.0 cm^3, 0.11 mol); the mixture was refluxed for 2.5 h and distilled in vacuo: colorless oil, yield 12.1 g (76.2%), bp 58 °C/69 mmHg

(1 mmHg=133.322 Pa). The acid chloride (3.62 g, 26.9 mmol) was added dropwise with stirring to an ice-cooled mixture of $H_2T_{(OH)_2}$ PP (1.0 g, 1.35 mmol) and 4-(dimethylamino)pyridine (3.29 g, 26.9 mmol) in dry thf (200 cm^3) under argon. The mixture was stirred further at room temperature for 1 h and at 50 °C for 12 h. The solution was brought to dryness on a rotary evaporator and extracted with $CHCl_3$. The organic layer was washed, first with dilute hydrochloric acid and then with aqueous ammonia. The organic phase dried over anhydrous Na_2SO_4 was concentrated and the residue chromatographed on a silica gel column using $CHCl_3$–diethyl ether, 30:1 (v/v), as the eluent. The eluent was collected and reduced to small volume on a rotary evaporator. The residue was then dried at room temperature for several hours in vacuo, to give a purple crystalline product (**2a**) (0.69 g, 33.6%). R_f 0.34 ($CHCl_3$–diethyl ether, 30:1 (v/v)). Anal. Found: C, 70.59; H, 7.33; N, 3.37%. Calcd for $C_{92}H_{110}N_4O_{16}\cdot 0.3CHCl_3$: C, 70.90; H, 7.11; N, 3.58%. FAB MS $[M]^+$ 1526. IR (KBr); 1760 cm^{-1} (ν_{CO}(ester)). ^1H NMR ($CDCl_3$) δ=−3.0 (2H, s, inner H), −0.2 (72H, s, $C(C\underline{H}_3)_3$), 1.2 (16H, s, $C(=O)C\underline{H}_2-$), 7.4—7.9 (12H, m, phenyl H), 8.8 (8H, s, pyrrole β-H). ^{13}C NMR ($CDCl_3$) δ=28.6 (methyl), 29.9 (quaternary carbon), 46.0 (methylene), 109.1 (5,10,15,20-C), 130.8 (pyrrole β-carbon), 146.9 (pyrrole α-carbon), 120.2, 128.5, 129.6, 152.0 (phenyl), 169.6 (carbonyl). VIS. ($CHCl_3$) 653, 583, 534, 506, and 413 nm.

5,10,15,20-Tetrakis[2,6-bis(3,3-dimethylbutyryloxy)phenyl]-porphyrinatoiron(III) Bromide (2b′). The synthetic procedure for complex **2b′** was similar to that used for **2a**, except for using $FeT_{(OH)_2}$ PP (1.0 g). Finally, dark-purple crystalline products **2b′** (0.22 g, 11.5%) were obtained. R_f 0.61 ($CHCl_3$–diethyl ether, 30:1 (v/v)). Anal. Found: C, 66.73; H, 6.84; N, 3.59%. Calcd for $C_{92}H_{108}N_4O_{16}FeBr$: C, 66.50; H, 6.55; N, 3.37%. FAB MS $[M]^+$ 1661, $[M-Br]^+$ 1580. IR (KBr); 1760 cm^{-1} (ν_{CO}(ester)). VIS. ($CHCl_3$) 675, 644, 577, 506, and 412 nm.

Iron(II) Complex. An iron(III) complex (0.1 μmol) was dissolved in toluene (8 cm^3) and the solution bubbled with argon to removed any oxygen. Then, a deoxygenated aqueous $Na_2S_2O_4$ solution (8 cm^3) was added. The mixture vigorously stirred for 1 h and the red-orange organic layer was collected and dried over anhydrous Na_2SO_4. After filtration from Na_2SO_4 under argon, a toluene solution of a four-coordinated porphyrinatoiron(II) (20 μmol dm^{-3}) was obtained.

Base Equilibrium Measurement. The equilibrium constants of the bases were determined at 25 °C under argon by titration of the four-coordinated porphyrinatoiron(II)s with aliqouts of an imidazole derivative in deoxygenated toluene. For the bases there are two possible equilibria, (1) and (2).

$$P + B \overset{K^B}{\rightleftarrows} P(B) \quad (1)$$

$$P(B) + B \overset{K_B{}^B}{\rightleftarrows} P(B)_2 \quad (2)$$

When $K_B{}^B$=0, the titration shows isosbestic points. However, no isosbestic ones were observed when the three species (P, P(B), and $P(B)_2$) were simultaneously present. The corresponding thermodynamic parameters (ΔH, ΔS) were calculated using the equilibrium constants at various temperatures and van't Hoff plots. The temperature of the solution was maintained to a precision of ±0.2 °C. In general, porphyrinatoiron(II) concentrations of 20 μmol dm^{-3} were used, and the spectra were recoorded within the range of 650—360 nm.

Dioxygenation of Porphyrinatoiron(II). Dioxygenation of porphyrinatoiron(II) complexes can be expressed by equation (3).

$$P(B) + O_2 \overset{K_B{}^{O_2}}{\rightleftarrows} P(B)O_2 \quad (3)$$

The oxygen-binding affinity (oxygen pressure at half oxygen binding for the porphyrinatoiron(II), ($P_{1/2}(O_2)=1/K_B{}^{O_2}$) was determined from the spectral changes at various partial pressures of dioxygen, using an equation employed by Collman et al.[11] The thermodynamic parameters (ΔH, ΔS) of dioxygenation were calculated by the oxygen-binding affinity at various temperatures, using van't Hoff plots of $\ln(760/P_{1/2}(O_2))$ vs. $1/T$. The temperature of the solution was maintained to a precision of ±0.2 °C. In general porphyrinatoiron(II) concentrations of 20 μmol dm^{-3} were used; the spectra were recorded within the range of 650—360 nm.

Results and Discussion

In this study, we designed and synthesized new double-sided porphyrinatoiron complexes (**1b** and **2b**), having large pockets for axial base binding on the rear side of the ring plane, respectively. The **1b′** complex, which has four and three pivaloyloxy groups on each side of a macrocycle, was synthesized by the reaction of $FeT_{(OH)_2}PP$ with a 7.2-times molar quantity of pivaloyl chloride. During purification on a silica-gel column, the first band, which was the least polar porphinatoiron, was identified as **3b′**. The **1b′** complex corresponded to the second band. The **2b′** complex was obtained by the coupling of $FeT_{(OH)_2}$ PP with 3,3-dimethylbutyryl chloride. Kyuno et al. reported that picket-fence type porphyrinatocobalt, having only one cavity comprising four 3,3-dimethylbutyryl amides on one side of the ring plane, was easily dissolved in organic solvents and had a higher oxygen affinity than did the picket-fence porphyrinatocobalt.[12]

The identification and structural assignments of these complexs were based on some physicochemical analyses.

The both-faces protected structure must have a similar effect as that of the protein in natural dioxygen carriers (hemoglobin and myoglobin), which forms a hydrophobic pocket around the heme, and inhibits the contact necessary for oxidation reactions. However, axial base binding to porphyrinatoiron is depressed with an increase in the steric bulk of the fences appended to the ring plane. In both planes of highly modified complexes, the effect of a steric hindrance on the protected distal face can be investigated using external nitrogenous ligands bound to the protected face of the porphyrins.[4]

The equilibrium constants were measured for the ligation of the double-sided porphyrinatoirons. Large changes in the absorption spectra occur upon titration of a toluene solution of iron(II) four-coordinate species with imidazole derivatives under an argon atmosphere. For the less-hindered base, 1-mim, these iron(II) complexes bind to a second base more strongly than does the first one due to the accompanying electron-spin changes in going from five- to six-coordinate iron(II) ($K_B^B > K^B$). In the addition of 2-substituted imidazole, 1,2-dmim, to **1b** or **2b**, however, gives only five-coordinate high-spin species cleanly ($K_B^B \ll K^B$); well defined isosbestic points are observed in the visible absorption spectra during titration (Figure 1). In order to study the oxygenation equilibrium [equation (3)], the condition must be chosen so as to ensure that the dominant species is the five-coordinate P(B). The values for the equilibrium constants for base additions to complexes **1b** and **2b** are given in Table 1.

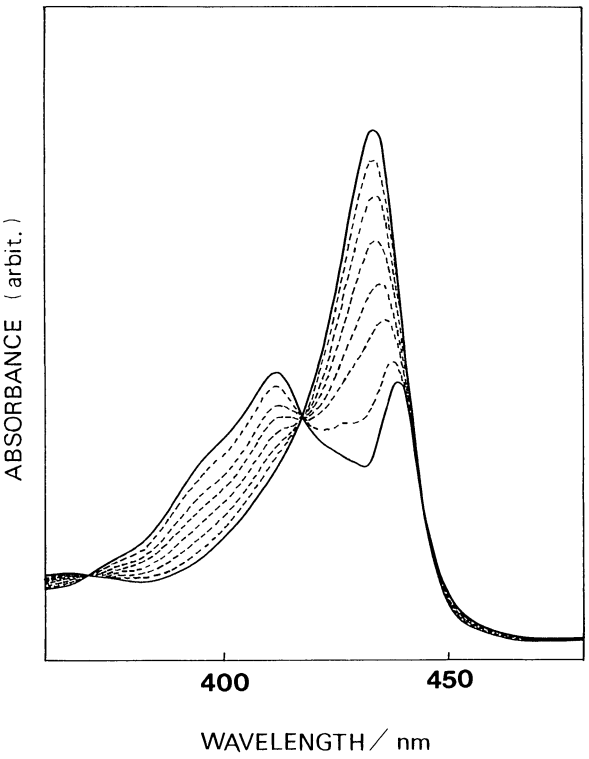

Fig. 1. Visible absorption spectral changes occurring upon titration of a 20 μmol dm^{-3} toluene solution of **2b** with 1,2-dmim (the final base concentration=12.8 mmol dm^{-3}) at 25 °C.

In a previous study we reported that the **3b** complex, having two highly modulated cavities on both sides of the porphyrin plane, showed significantly decreased values of K_B, due to their great steric hindrance afforded by the 2,6-bis(pivaloyl ester) groups held rigidly around the coordination cavities.[10] These results indicated that **3b** binds nitrogenous bases more weakly than do other unhindered porphyrin complexes.

Table 1 shows that the values of K^B for the binding of 1,2-dmim to each of the three complexes (**1b**, **2b**, and **3b**), having different pocket-space for axial base binding, are increased in the order of pocket-size, **2b**≫**1b**>**3b**. Since the K^B of complex, **1b** is slightly larger than that of **3b**, it can be said that 1,2-dmim distinguishes the two different pockets regarding size and micropolarity on each side of the ring plane in **1b**. The discriminative ligation of 1,2-dmim to this complex must be attributed to a reduction of the steric hindrance by substituting one pivaloyl group by hydrogen and to the polar nature of the rear side. The value of K^B for **2b**, having a large or flexible pocket constructed by 3,3-dimethylbutyryloxy groups is 1.3×10^3 (M^{-1}) (1 M=1 mol dm^{-3}), which is one order of magnitude lower than that for single-face hindered porphyrin (picket-fence porphyrin, etc.) or flat-open TPP. This large K^B value indicates that the unfavorable steric factor on the rear side of **2b** is appreciably weakened.

It is therefore concluded that the coordination of double-sided porphyrin to an axial base can be presumed to be controlled by the nature and structure of the rear side pocket.

Table 1 also gives thermodynamic parameters for

Table 1. Equilibrium Constants and Thermodynamic Parameters for the Binding of Axial Base to Fe(II) Porphyrin Complexes in Toluene at 25 °C

Porphyrin	Ligand	K^B / dm^3 mol^{-1}	ΔH / kcal mol^{-1}[a]	ΔS / cal K^{-1} mol^{-1}	Ref
1b	1,2-dmim	60	−8.5	−21	This work

Soc.*, **105**, 3038 (1983). e) $T_{bp}PP$: bis-pocket porphyrinatoiron(II). f) $T_{cap}PP$: capped porphyrinatoiron(II). g) Basolo et al., *J. Am. Chem. Soc.*, **102**, 1889 (1980).

base binding, derived from the van't Hoff plots of $\log K^B$ vs. $1/T$ (15—30 °C). The order of enthalpy changes for 1,2-dmim binding is **3b>1b>2b**, indicating the enthalpy dependence of the free energy changes in this system.

Kyuno et al. discussed the thermodynamic parameters for base and dioxygen binding to four atropisomers of the picket-fence porphyrinatocobalt(II).[12] The higher base affinities of the *trans*-α^2 complex, compared with the α^4 complex, were due to an increase in the binding energies of the bases, although a substantial decrease in entropy change also occurs. They concluded that the stabilization of the base binding by the pickets was attributed to an intermolecular interaction between the ligated base and the *t*-butyl groups.

Indeed, entropy changes of double-sided porphyrins are small because the orientation of the 1,2-dmim plane is regulated by the fence through the process of binding to porphyrinatoiron. However, the existence of four and three bulky ester residues around the base binding site might overcome, or even cancel out, the advantageous intermolecular stabilization effect of the pocket.

The new double-sided porphinatoiron complexes (**1b** and **2b**) with 1-mim or 1,2-dmim gave stable and reversible dioxygen adducts in toluene at 25 °C. Spectrophotomeric dioxygen titrations of **1b**/1,2-dmim and **2b**/1,2-dmim were carried out under conditions of excess base. The isosbestic points were maintained in all titrations. The dioxygen complex changed to the corresponding CO adduct upon bubbling carbon monoxide gas through the solution. The electron-absorption spectral data are listed in Table 2. The values for $P_{1/2}(O_2)$ were found to be independent of the wavelength used to determined the extent of dioxygenation, and are shown in Table 3 (Figure 2).

For complexes **1b** and **2b**, the bulky ester groups on both sides of the porphyrin plane impede the formation of an intermolecular μ-dioxo dimer, as did **3b**. The $P_{1/2}(O_2)$ values of the double-sided type porphyrins were large compared to those of the corresponding adducts having intermolecular polar amido groups. Our previous study, with regard to **3b** complex, suggested that the unfavorable steric repulsions from bulky fences with imidazole must play a major role in the reduced oxygen-binding affinity.[10]

It is well known that the dioxygen affinities of porphyrinatoiron increase with increasing σ- and π-electron donation of an axial ligand.[1-3,8,9] Walker et al. reported that the rotation of 1-mim in *trans*-α^2 picket-fence porphyrinatoiron(III)(1-mim)$_2$ was restricted by pivaloyl groups, and that the dihedral angle of the bound 1-mim plane with respect to the Np–Fe–Np

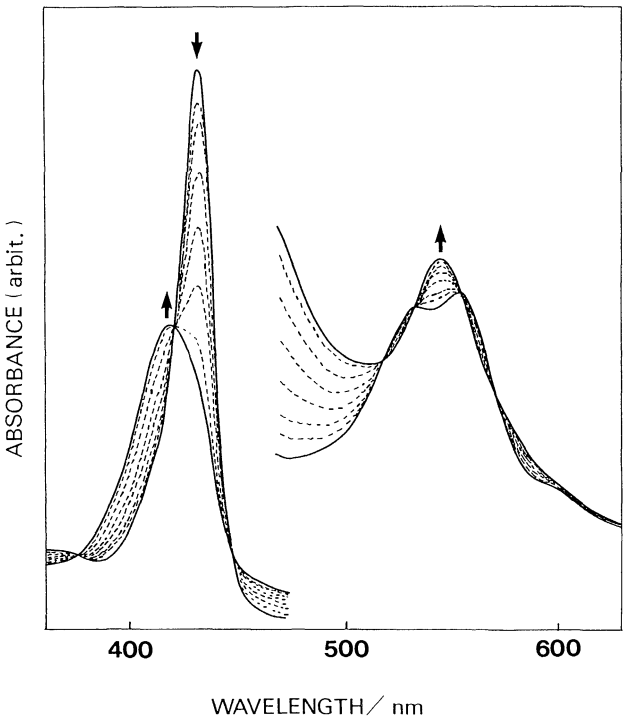

Fig. 2. Visible absorption spectral changes in the dioxygen binding to **2b**/1,2-dmim complex in toluene at 25 °C. Arrows indicate the changes with increasing dioxygen pressures.

direction is equal to 45°.[13] The lobe of the Fe dπ (d_{xz} or d_{yz}) orbitals therefore point to the pyrrole nitrogen and the lobe of pπ (p_x or p_y) orbitals on the nitrogen of 1-mim point of 135°.

Kyuno et al. suggested that the decreased oxygen affinities of "jellyfish type porphyrinatocobalt(II) complexes" can be attributed to the regulated orientation of 1-mim plane (ϕ=45°), in which π–π interaction between metal and 1-mim reaches a minimum due to the steric repulsions with appended fence groups.[14] However, the oxygen and carbon monoxide affinities for the corresponding porphyrinatoiron(II) complexes did not exhibit a similar trend to that observed for the oxygen affinities for the Co(II) complexes. They suggested that conformational changes in the cavity, constructed strapped methylene chain, were concerned with reduced oxygen and carbon monoxide affinities.

In the case of the **3b** complex, since the dihedral angle may be equal to 0°, the π-electron donation of 1,2-dmim is expected to be at the maximum because of the maximum π-overlap with the Fe dπ orbitals. Although the favorable orientation of the axial base, accelerating π–π interaction between Fe and the axial base, the $P_{1/2}(O_2)$ values were low in comparison to those of other models.

In order to quantitatively clarify the correlation $P_{1/2}(O_2)$ with the pocket-space on the rear side of the macrocycle for imidazole binding, the oxygen affinities of **1b**, **2b**, and **3b** complexes were compared.

The oxygen-binding affinities of the double-sided porphyrinatoirons were of the order **2b**>**1b**>**3b**, in proportion to the spacing-size of the rear pocket space. This result indicates that oxygen affinities for the iron(II) complexes increased as the unfavorable steric bulk on rear side of the porphyrin plane was relieved. That is, in spite of the orientation of the axial base plane to π-orbital, great steric hindrance of ester fences reduced their π-bond character in the Fe(II)-base. The oxygen affinities decrease in the order of the repulsion of the substituents, and can be controlled by the pocket-size for axial base binding.

On the other hand, the oxygen affinity is surely attributed to the nature of the hydrophobic pocket for dioxygen binding ((1) steric effect, (2) solvation effect, and (3) local polarity).[1–5,15] (1) The steric hindrance significantly influences the $P_{1/2}(O_2)$ of the protected porphyrin. But the "central" and "peripheral" effects, proposed by Basolo, might not be found in the pivaloyloxy type.[5] (2) Among the "protected" heme, a small difference in the solvation effect has no significant meaning on $P_{1/2}(O_2)$. In double-sided porphyrinatoiron complexes, the solvation effects were considered to be almost the same for the other protected models. (3) The polarity of the dioxygen binding site considerably influences the oxygen affinity. From structural studies and ^{17}O NMR spectroscopic data of picket-fence porphyrin, though there is no hydrogen-bonding between the amido proton and bound dioxygen, these amide groups can be expected to increase the polarity at the binding site.[7,16] Bis-pocket and ether hanging-base porphyrin which had a nonpolar pocket, showed a low oxygen affinity in comparison to the amide handle derivatives.[3,4] Therefore, the low oxygen affinity of the double-sided porphyrins systems might be the result of a smaller polar pocket effect around the oxygen-binding site. However, from the quantitative results for a series of this type of porphyrins, it is concluded that the oxygen affinity can be controlled by the pocket-size for imidazole binding.

Chang et al. have determined the individual contribution of dipole–dipole interactions in stabilizing the Fe–O_2 cmplex.[17] A disadvantageous dipole–dipole orientation may exist between FeO_2 and the ester moieties of the double-sided porphyrin.

Table 3 also shows the enthalpy and entropy changes of the dioxygenation equilibrium of the **1b**/1,2-dmim and **2b**/1,2-dmim complex determined from van't Hoff plots (15—30 °C). The thermodynamic values given in Table 3 show that a major difference in dioxygen binding is manifested in the enthalpy terms. Among the double-sided porphyrins, the order of $P_{1/2}(O_2)$ was **3b**>**1b**>**2b**. A similar tendency was also found for the ΔH, indicating the enthalpy dependence of the free energy changes in this

system.

Preparations, Properties, and Crystal Structures of *trans*-[Rh(CN)$_2$(NH$_3$)$_4$]Cl·H$_2$O and *trans*-[Rh(CN)$_2$(en)$_2$]Cl

Kiyohiko Yoshida, Takayuki Kitada, Naomi Odano, Mayumi Kashiwagi, Kazumasa Harada, Akio Urushiyama,* and Masayoshi Nakahara
Department of Chemistry, College of Science, Rikkyo University, Nishiikebukuro 3, Toshima-ku, Tokyo 171
(Received October 29, 1990)

Syntheses of the title new complex compounds of Rh(III) were successful. Single, sharp IR peaks of ν (C≡N) were observed at 2130 cm^{-1} (*trans*-[Rh(CH)$_2$(NH$_3$)$_4$]Cl·H$_2$O) and 2170 cm^{-1} (*trans*-[Rh(CN)$_2$(en)$_2$]Cl), respectively. The values of the ligand field tetragonal parameter D_t were estimated to be −366 and −377 cm^{-1}, respectively, based on the $^1E_g{}^a$ (D_{4h})←$^1A_{1g}$ transition (37100 cm^{-1}: *trans*-[Rh(CN)$_2$(NH$_3$)$_4$]$^+$; 37000 cm^{-1}: *trans*-[Rh(CN)$_2$(en)$_2$]$^+$). The X-ray crystal data are: for *trans*-[Rh(CN)$_2$(NH$_3$)$_4$]Cl·H$_2$O, orthorhombic, *Cmcm*, a=7.961(3), b=17.295(2), c=7.436(3) Å, D_c=1.79, D_m=1.79 g cm^{-3}, Z=4; for *trans*-[Rh(CN)$_2$(en)$_2$]Cl, monoclinic, $P2_1/n$, a=9.665(4), b=9.107(3), c=6.779(3) Å, β=109.68(2)°, D_c=1.85, D_m=1.83 g cm^{-3}, Z=2. The N≡C–Rh–C≡N sequence of *trans*-[Rh(CN)$_2$(NH$_3$)$_4$]$^+$ lies in a line of $m2m$ symmetry in the crystal. The central Rh atom of *trans*-[Rh(CN)$_2$(en)$_2$]$^+$ occupies the special position of inversion symmetry. The important geometrical data of the complexes are Rh–N=2.07(1), Rh–C=2.02(3) Å, N–Rh–N=88.0(5)° (*trans*-[Rh(CN)$_2$(NH$_3$)$_4$]$^+$) and Rh–N=2.080(3), 2.072(3), Rh–C=2.047(4) Å, N–Rh–N (within chelate ring)=82.7(1)° (*trans*-[Rh(CN)$_2$(en)$_2$]$^+$).

A variety of Rh(III) complex compounds have been prepared and studied regarding their spectroscopic properties[1] and kinetic mechanisms of photochemical reactions.[2] However, investigations have not been developed to include the structurally rather familiar complexes of *trans*-[Rh(CN)$_2$N$_4$]$^+$ (N$_4$: (NH$_3$)$_4$, (en)$_2$, (tn)$_2$), since synthetic methods have not yet been established.

Here, we report on the syntheses, spectroscopic identification, and X-ray crystal structures of the title new complex compounds of Rh(III).

Experimental

Preparation. *trans*-[Rh(CN)$_2$(NH$_3$)$_4$]Cl·H$_2$O. Five grams of *trans*-[Rh(CN)Cl(NH$_3$)$_4$]Cl·1.5H$_2$O[3] and 3.0 g of NaCN in 300 ml DMSO were heated at 85 °C for 1.5 h. A crude product which precipitated was collected by filtration and washed by ethanol and air-dried (2.8 g). This was dissolved in 100 ml H$_2$O and, after filtration, pure chloride was obtained upon the addition of concd HCl. Yield. 2.5 g (50%). Found: C, 8.60; H, 5.09; N, 30.06%. Calcd for [Rh(CN)$_2$(NH$_3$)$_4$]Cl·H$_2$O=C$_2$H$_{14}$N$_6$OClRh: C, 8.68; H, 5.10; N, 30.39%. The water of crystallization was easily lost in air at room temperature. An elemental analysis was also performed for the anhydrate. Found, 9.24; H, 4.37; N, 32.38%. Calcd for [Rh(CN)$_2$(NH$_3$)$_4$]Cl=C$_2$H$_{12}$N$_6$ClRh: C, 9.29; H, 4.68; N, 32.51%.

***trans*-[Rh(CN)$_2$(NH$_3$)$_4$](ClO$_4$).** The immediate crystallization of the perchlorate occured when perchloric aicd was poured into an equeous solution of the chloride. Found: C, 7.49; H, 3.83; N, 25.98%. Calcd for [Rh(CN)$_2$(NH$_3$)$_4$](ClO$_4$)=C$_2$H$_{12}$N$_6$O$_4$ClRh: C, 7.45; H, 3.75; N, 26.06%.

***trans*-[Rh(CN)Cl(en)$_2$](ClO$_4$).** To an aqueous solution (500 ml) containing 6.0 g of *trans*-[RhCl$_2$(en)$_2$](NO$_3$),[4] 6.0 g of Na$_2$SO$_3$ was added. After the solution was heated to 80 °C, 3.0 g of NaCN was added. The characteristic yellow color of the starting dichlorocomplex was soon lost. After being cooled to room temperature, the solution was passed through a columun of anion-exchange resin (Cl$^-$ form, MCL GEL CA08P), followed by a cation columun (Li$^+$ form, Dowex 50-X8). Complete evaporation of the solution left a white powder (*trans*-[Rh(CN)(SO$_3$)(en)$_2$]+LiCl). The obtained cyanosulfitocomplex was easily converted to the cyanochlorocomplex by treatment with concd HCl (20 ml) at 60 °C. Within ten minutes, when SO$_2$ gas evolution ceased, to the resultant clear solution* 50 ml perchloric acid (70%) was added by ice cooling to give a mixture of solid LiClO$_4$ and a white crystalline powder, which was collected on a filter and washed by ethanol to remove LiClO$_4$ (the suction flask should be emptied before ethanol washing!) and air dried. Yield. 1.0 g (15%). Found: C, 15.38; H, 4.25; N, 18.07%. Calcd for [Rh(CN)Cl(en)$_2$](ClO$_4$)=C$_5$H$_{16}$N$_5$OCl$_2$Rh: C, 15.46; H, 4.20; N, 18.24%.

*Sometimes a mixture of *trans*-[Rh(CN)Cl(en)$_2$]Cl and LiCl was precipitated at this stage. This was filtered and redissolved in water; perchloric acid was then added to convert to the perchlorate.

***trans*-[Rh(CN)$_2$(en)$_2$]Cl.** One gram of *trans*-[Rh(CN)Cl(en)$_2$](ClO$_4$) and 1.5 g of NaCN were mixed in 25 ml DMSO. The produced white precipitate was filtered, washed by ethanol and air-dried (*trans*-[Rh(CN)Cl(en)$_2$](CN), 0.7 g). This was suspended in 25 ml DMSO–H$_2$O (10:1 in volume ratio) medium. After the addition of 1.5 g of NaCN, the mixture was heated to 90 °C for 2 h. The obtained white solid was collected, washed by ethanol and dried. This was dissolved in 7 ml of H$_2$O and filtered once (if the solution is alkaline, acidify by concd HCl. Warning! HCN gas evolved). The addition of ethanol caused the precipitation of white crystalline powder. This was adsorbed on a cation-exchange columun (Li$^+$ form, Dowex 50-X8) and eluted by 0.2 mol dm^{-3} LiCl. From the concentrated solution a white crystalline powder was separated, filtered, washed with ethanol. Yield 0.5 g (62%). Found: C, 23.34; H, 5.40; N, 27.44%. Calcd for [Rh(CN)$_2$(en)$_2$]Cl=C$_6$H$_{16}$N$_6$ClRh: C, 23.19; H, 5.19; N, 27.06%.

***trans*-[Rh(CN)$_2$(en)$_2$](ClO$_4$).** A white crystalline powder of the perchlorate was obtained by the addition of perchloric acid (70%) to the above-mentioned filtrate, or an aqueous solution of the chloride. Found: C, 19.43; H, 4.58; N, 22.70%. Calcd for [Rh(CN)$_2$(en)$_2$](ClO$_4$)=C$_6$H$_{16}$N$_6$O$_4$ClRh: C, 19.22;

H, 4.31; N, 22.44%.

Spectroscopic Measurements and Thermogravimetric Measurement. IR, Raman, and UV spectroscopies were performed using a Perkin-Elmar 1600 FTIR spectrometer, a Jobin-Yvon Ramanor 1000 monochromator equipped with an NEC GLG3300 laser (Ar^+: 5145 Å), and a Hitachi U-3400 spectrometer, respectively. The Raman apparatus was also employed for luminescence measurements by excitation of the 312 nm line of a high-pressure mercury lamp. ^1H and ^{13}C NMR measurements were accomplished by a JOEL GSX 400 spectrometer. A TGA curve was taken with a Shinkuriko TGD-7000 RH thermogravimeter.

X-Ray Crystal Structure Analyses. X-Ray crystallographic studies were carried out using a Rigaku AFC-5 four-circle automated diffractometer. Graphite monochromated Mo $K\alpha$ (λ=0.71073 Å) was used as the X-ray source. A crystal of *trans*-$[Rh(CN)_2(NH_3)_4]Cl \cdot H_2O$ was sealed into a silica glass capillary (ϕ=0.7 mm). Experimental details, crystallographic data and the R factors of the final refinements are shown in Table 1. All computational studies were carried out on a FACOM M760 computer at the Computer Center of Rikkyo University, using universal X-ray crystal structure analysis program (UNICSIII, MULTAN, ORTEP).[5] An absorption correction was employed (North et al.[6]). The atomic scattering factors were taken from "International Tables for X-Ray Crystallography," Vol. IV, Kynoch Press, Birmingham (1974). The initial phases of the structure factor determined by a direct method were refined by cycles of a block-matrix least-square method. The positions of the hydrogen atoms were obtained by difference-Fourier syntheses. The final full-matrix treatments sufficiently decreased the R factors (Table 1).

The position of the water of crystallization of *trans*-$[Rh(CN)_2(NH_3)_4]Cl \cdot H_2O$ was not clearly revealed on the difference-Fourier maps. If an oxygen atom was placed at a special position (2/m, multiplicity: 0.25) of (0.5, 0, 0), for which the maximum residual electron density (1.86 e Å^{-3}) was yielded, a rather large value of the isotropic temperature factor was obtained after a sufficient number of cycles of a least-square treatment. However, this point is recognized as being a vacant hole in the crystal; the shortest contact distance from this point to a non-hydrogen atom is 3.54 Å (to N(1) of the complex cation). The TGA curve indicated a weight loss corresponding to ca. 1 mol of crystallization water below 60 °C. It is therefore believed that almost all of the water molecules were lost from this point before the X-ray study, although the sample crystal was sealed into a small capillary. The observed density (1.77 g cm^{-3}) of the freshly prepared crystal is slightly smaller than the calculated value (1.79 g cm^{-3}), based on monohydrated stoichiometry.

Tables of the observed and calculated structure factors are deposited as Document No. 9105 at the Office of the Editor of Bull. Chem. Soc. Jpn.

Results and Discussion

Baranovskii et al.[7,8] and Skibsted et al.[9] have reported the syntheses of several cyanoammine complexes of Rh(III), which involve $[Rh(CN)(NH_3)_5]Cl_2$, *trans*-$[Rh(CN)(SO_3)(NH_3)_4] \cdot 2H_2O$, *trans*-$[Rh(CN)Cl(NH_3)_4]Cl$, and $[Rh(CN)_3(NH_3)_3]$. However, Baranovskii et al.[12] have mentioned that an attempt to introduce a second CN^- to *trans*-$[Rh(CN)(SO_3)(NH_3)_4]$ with excess CN^- was not successful in an aqueous solution. Subsequently, Kane-Maguire et al.[10] synthesized *trans*-$[Rh(CN)_2(cyclam)](ClO_4)$ by a reaction of the corresponding dichlorocomplex and CN^- in an aqueous solution. A direct synthesis[11,12] of *trans*-

$[Co(CN)_2(N)_4]^+$ ($(N)_4$: $(NH_3)_4$, $(en)_2$, $(tn)_2$) from the corresponding dichlorocomplex is also possible in DMSO or a methanol medium.

We first studied the direct reaction of *trans*-$[RhCl_2(NH_3)_4]Cl$ and NaCN under various conditions (concentrations, temperatures, and media). However, this reaction yielded only uncharacterizable insoluble solids, even in cases where the reaction occured.

For the corresponding Co(III) complex, Maki et al.[13] employed the reaction of *trans*-$[Co(CN)Cl(NH_3)_4]$-Cl+NaCN to obtain *trans*-$[Co(CN)_2(NH_3)_4]$ in DMSO. Therefore, we have studied this type of reaction, i.e., *trans*-$[Rh(CN)Cl(N)_4]Cl$+NaCN ($(N)_4$: $(NH_3)_4$, $(en)_2$), in DMSO. It was found that, while the ligand substitution of Cl^- by CN^- hardly proceeded in a pure DMSO medium, especially for the ethylenediamine complex, the reaction easily occured in a DMSO–H_2O mixed medium to give the desired *trans*-dicyano complex compounds (see experimental section). An attempt to synthesize the corresponding tn (1,3-propanediamine) complex, *trans*-$[Rh(CN)_2(tn)_2]^+$, is now proceeding using a similar ligand-substitution reaction in either a DMSO–H_2O or ethanol medium.

The IR and Raman spectra of the present Rh(III) complexes are very similar to the corresponding Co(III) complexes.[14–16] The numerical data are summerized in Table 2; some possible assignments are included. It was mentioned[13] in a study of the

a) Ref. 14—16.

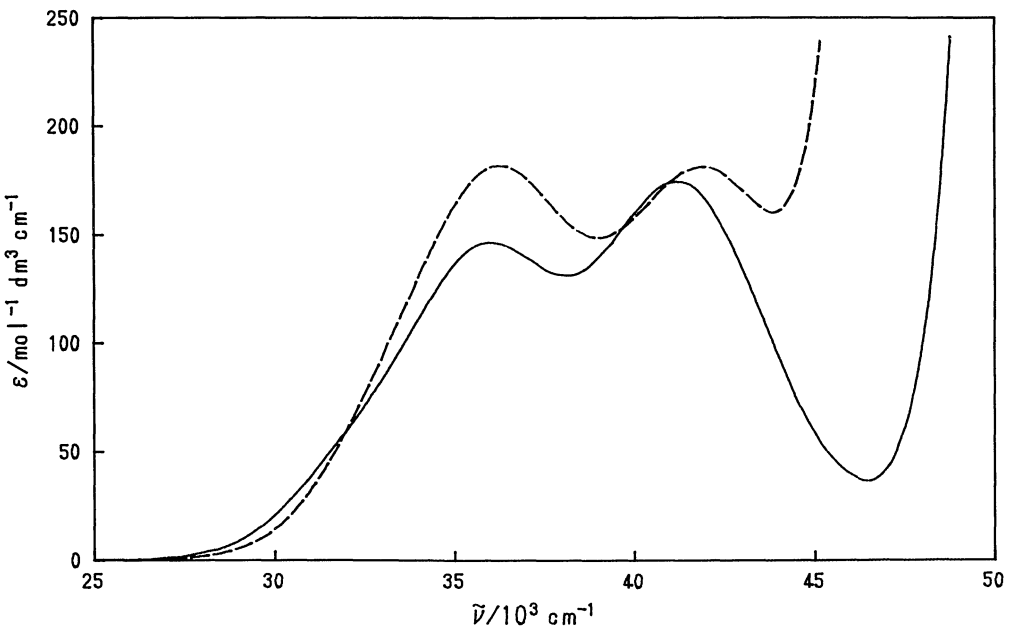

Fig. 1. Electronic absorption spectra of cyanoammine complexes of Rh(III) in aqueous solution. (a) —— *trans*-$[Rh(CN)_2(NH_3)_4]Cl\cdot H_2O$; (b) ----- *trans*-$[Rh(CN)_2(en)_2]Cl$.

corresponding Co(III) complexes that no splitting feature of the sharp IR line due to C≡N stretching vibration appeared between 2100—2200 cm^{-1} is diagnostic to the *trans*-isomer. In accord with this statement, the present *trans*-dicyano complexes of Rh(III) did not show any splitting of the C≡N band.

The UV absorption spectra were shown in Fig. 1, and the numerical data are summerized in Table 3, in which the ligand field assignments in the D_{4h} effective site symmetry are included. The lowest spin-allowed component of $^1A_{2g}(D_{4h})\leftarrow{}^1A_{1g}$ was not clearly observed for the present Rh(III) complexes compared to the corresponding Co(III) complexes.[14–16] If the energy of the $^1A_{2g}\leftarrow{}^1A_{1g}$ is approximated[17] to be that of the $^1T_{1g}(O_h)\leftarrow{}^1A_{1g}$ transition of $[Rh(NH_3)_6]^{3+}$ (32800 cm^{-1}) and/or $[Rh(en)_3]^{3+}$ (33200 cm^{-1}), the values of the tetragonal parameter, D_t, are estimated to be −366 cm^{-1} and −377 cm^{-1}, respectively, for *trans*-$[Rh(CN)_2(NH_3)_4]^+$ and *trans*-$[Rh(CN)_2(en)_2]^+$.

The present Rh(III) complexes exhibited a visible luminescence with ultraviolet irradiation (Hg 312 nm line). The band maxima of *trans*-$[Rh(CN)_2(NH_3)_4]^+$ and *trans*-$[Rh(CN)_2(en)_2]^+$ are located at 18300 cm^{-1} (10 K) and 17500 cm^{-1} (77 K), respectively. The band of *trans*-$[Rh(CN)_2(NH_3)_4]^+$ showed a resolved vibrational fine structure at low temperatures. Details will be reported elsewhere.[18]

The ammine ^1H NMR signal was detected as a single peak at 3.5 ppm for *trans*-$[Rh(CN)_2(NH_3)_4]Cl$ (in D_2O) suggesting that all of the ammine ligands are magnetically equivalent in the *trans*-form. For *trans*-$[Rh(CN)_2(en)_2]^+$, methylene and amido ^1H signals were observed at 2.8 and 5.1 ppm, respectively. It has been confirmed[19] that the methylene ^1H signal is a sharp singlet in *trans*-$[Co(CN)_2(en)_2]^+$, while *cis*-$[Co(CN)_2(en)_2]^+$, exhibits a complicated split pattern. The methylene ^{13}C NMR signal of *trans*-$[Rh(CN)_2(en)_2]^+$ was quite normally identified as being a single peak at 48.9 ppm.[20] On the other hand, the cyano-carbon signal was clearly split into two components of nearly equal strength for the present complexes (at 140.3 and 140.6 ppm for *trans*-$[Rh(CN)_2(NH_3)_4]^+$ and at 140.2 and 140.6 ppm for *trans*-$[Rh(CN)_2(en)_2]^+$). This experimental finding must be further investigated regarding the solution chemistry of the *trans*-dicyano-type metal complexes.

The crystal structures of the present new complex compounds were determined. Of course, the well

discrete complex cations in the *trans*-geometry were identified in both crystals (Fig. 2), being consistent with spectroscopic evidence. The positional parameters are summarized in Table 4. The bond distances and angles are included in Table 5, in which the reported values for *trans*-$[Co(CN)_2(en)_2](ClO_4)$ are also included.

In a crystal of *trans*-$[Rh(CN)_2(NH_3)_4]Cl\cdot H_2O$, the N≡C–Rh–C≡N molecular axis lies in a line with a special symmetry of *m*2*m*. The four N atoms of the ammonia ligands are required to form a rectangular plane perpendicular to the molecular axis. Therefore, the crystallographically required symmetry of the complex is C_{2v}. In the case of *trans*-$[Rh(CN)_2(en)_2]Cl$, the Rh atom occupies a special position with inversion symmetry. Therefore, the two Rh-en rings are in the $\delta\lambda$ conformation. The positional parameters of the complex (Table 4) indicate the C_{2h} effective point symmetry of the complex (all ∠C–Rh–N fall ca. 90° and all Rh–N fall ca. 2.07 Å). In comparision to the geometrical data of the corresponding Co(III) complex,[21] the Rh–C and Rh–N bonds are elongated by about 5%. This amount of the M–L bond length increase from the Co(III) complexes to the Rh(III) complexes is identical with that found in another comparison by Hambley et al.[22] On the other hand, the intra-ligand parameters of the en (N–C and C–C bond distances and N–C–C angles) are well retained in the Co(III) and Rh(III) complexes. This conservative nature of the intra-ligand structure of en accompanies a reduction of the ∠N–Rh–N chelate angles in the Rh(III) complex (82.7°), compared with those in the Co(III) complex (86.4°).

Conclusion

Two new cyanoammine-rhodium(III) complexes, *trans*-$[Rh(CN)_2(NH_3)_4]^+$ and *trans*-$[Rh(CN)_2(en)_2]^+$, were synthesized in a DMSO–H_2O mixed medium. X-Ray crystal structure analyses of *trans*-$[Rh(CN)_2(NH_3)_4]Cl\cdot H_2O$ and *trans*-$[Rh(CN)_2(en)_2]Cl$ showed well discrete complex cations in *trans*-dicyano geometry. The UV, IR, Raman, ^1H- and ^{13}C NMR spectroscopic data were characterized.

This work was financially supported by Grant-in-Aid for Scientific Research No. 02640485 from the Ministry of Education, Science and Culture. The authors express thanks to Mr. Hiroshi Tomizawa for his help with the IR and NMR measurements.

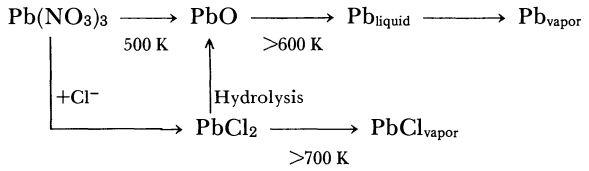
Effect of Chloride Ion on Lead Signal Appearance in the Co-Existence of Iron in Electrothermal Graphite Furnace Atomic Absorption Spectrometry

Shoji IMAI, Masayoshi ICHINOSEKI, Yasuko NISHIYAMA, and Yasuhisa HAYASHI*
Department of Chemistry, Joetsu University of Education, Yamayashiki-machi, Joetsu, Niigata 943
(Received November 2, 1990)

The atomic absorption signals for lead were measured in various chloride matrices at a charring temperature of 700 K. A typical double-peak signal was observed with iron(III) chloride, while a single peak was observed with iron(III) nitrate. At a charring temperature of 1440 K, the first peak disappeared and only the second peak remained; the atomization temperature of the latter was in agreement with that in the iron matrix. The larger content of the chloride ion increased the first peak absorption and decreased the second peak absorption without any shift of the peak temperatures, showing that one species for the second peak was converted to the same species for the first peak by the addition of a chloride ion. The appearance temperature of the first peak signal in the X^-–Fe^{3+} matrix system increased in the order $Cl^- < Br^- < I^-$. It was concluded that the appearance of the first peak is caused by the dissociation of lead halide.

Although graphite furnace atomic absorption spectrometry (GFAAS) is favorable for an analysis of a trace amount of lead, severe matrix interference[1,2] decrease its sensitivity by diversifying the mechanism of metal vapor formation. The mechanism of interference elimination has been discussed from the viewpoint of kinetics.[1]

The chloride ion is one of the most unfavorable matrices, because of the formation of volatile lead chloride. Wendl and Müller-Vogt[2] investigated the reaction of lead in a chloride matrix by X-ray diffraction and molecular absorption for PbCl, and proposed the following reaction processes:



This mechanism shows that interference from chlorides is caused by volatilization of lead chloride at a temperature lower than that required to decompose the compound on the graphite surface. Frech and Cedergren[3–5] also concluded from a high-temperature gas-phase equilibrium calculation that the formation of the volatile lead chlorides, such as $PbCl_2$ and PbCl, should result in decreasing the signal of lead.

L'vov et al.[6] reported the appearance of double-peak signals of lead in sodium chloride. They considered that the second peak was caused by a revolatilization of lead condensed with a matrix on the cooler outer ends of the furnace tube. McLaren and Wheeler[7] also reported the appearance of double-peak signals in the ascorbic acid matrix, which resulted from the formation of the massicot and litharge dimorphic forms of PbO in a furnace. Salmon et al.[8] also proposed that the double-peak signal for lead was caused by two major types of active sites which chemisorbed oxygen on the graphite tube.

It was also found in this work that a double-peak signal for lead appeared in the presence of iron(III) chloride; that the chloride ion was responsible for the appearance of the first peak and that the iron caused each peak to shift to the higher temperature side; and that two different types of atomization mechanisms might exist. The mechanism that caused the appearance of the first peak is discussed in the present paper.

Experimental

Apparatus and Materials. A Hitachi Model Z-8000 flame and graphite furnace atomic absorption spectrometer equipped with a Zeemann-effect background corrector and an optical temperature controller was used. The term of the maximum heating mode was defined as the mode of maximum heating feasible with the optical temperature controller used in the present work. The sample was injected by an automatic sampler. The peak height and area were automatically printed out and displayed using a Hitachi Data Processor. The time-absorbance signals sent to an OKI Model if-800 personal computer through RS-232C could also be stored on a diskette at 20 ms intervals. The temperature of the graphite tube was recorded at 4 ms intervals using the optical temperature controller; its analog output data were converted to digital data and stored on a diskette using an OKI personal computer. The temperature was calibrated using a CHINO Model IR-AH1S radiation thermometer with a radiation factor of one.

The standard instrumental conditions were 120 °C (setting) and 30 s for the drying stage, 800 K, ramp time 20 s and hold time 5 s for the charring, 2700 K, ramp time 0 s and hold time 2 s for the atomizing. The reproducibility of the atomization temperature for the nonpyrolytic graphite (NPG) tube was 0.3% at 1419 K (n=10). When the maximum heating mode was used, the heating rates were 1450 K s^{-1} for the NPG tube and 1200 K s^{-1} for pyrolytic graphite (PG). Coating of the NPG tube with iron oxide was carried out by charring 20 μl of an iron(III) nitrate solution (1000 mg l^{-1} of

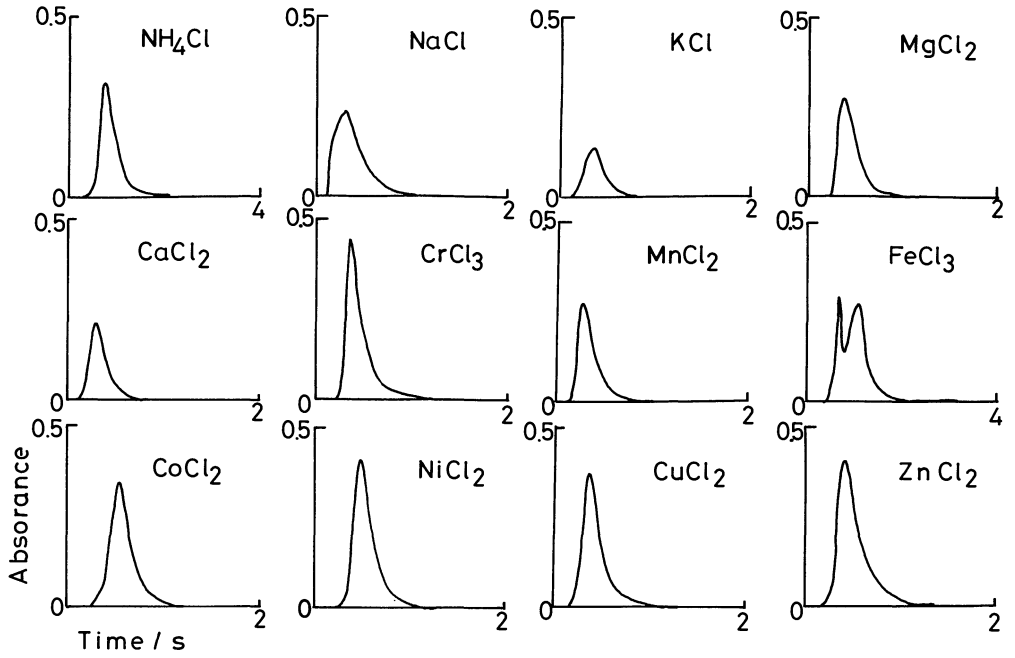


Fig. 1. Atomic absorption signals for lead in various chloride matrices. Analyte; Pb 1 ng with 20 μg of cation, atomization temperature; 3270 K (normal heating) for iron chloride and ammomium chloride matrices and 2700 K (maximum heating) for others, tube; NPG.

iron). The spectral line and slit width were 283.3 and 1.3 nm for Pb and 248.3 and 1.3 nm for Fe, respectively.

A stock solution (1 mol l^{-1} HNO_3 soln), 1000 mg kg^{-1} for the Pb used, was a commercially available standard solution (Wako Pure Chemical Industry, Ltd.). An aliquot of this solution was diluted with water to a suitable concentration before use. The iron hydroxide sample which occluded lead was prepared from an aqueous solution of 1000 mg l^{-1} of Fe(III) as its nitrate or chloride containing 100 μg l^{-1} of Pb, using aqueous ammonia. All other reagents were of analytical reagent grade. Distilled water was purified by a Milli-Q system.

Results and Discussion

Atomic Absorption Signals for Lead. The atomic absorption signals for lead were measured in various chloride matrices: ammonium, sodium, potassium, magnesium, calcium, chromium(III), manganese, iron-(III), cobalt(II), nickel, copper, and zinc chlorides. The observed signals are shown in Fig. 1. A typical double-peak signal was observed in iron(III) chloride, where the initial and latter peaks referred to the first and second peaks, respectively. In cobalt(II), sodium and potassium chlorides matrices, signals with a shoulder were also observed. In the present study, the mechanism of double-peak formation was studied because iron is an important component in biological materials, steel and so on.

Appearance of Double Peaks in the Iron(III) Chloride Matrix. Typical atomic absorption signals for lead in the iron(III) nitrate and chloride matrices

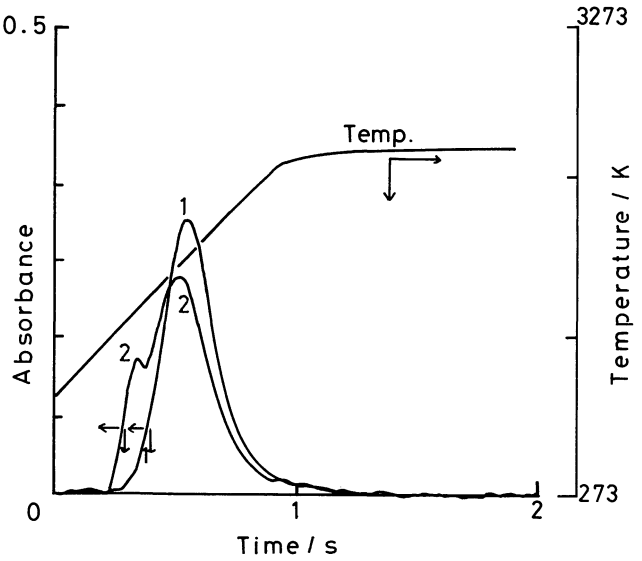

Fig. 2. Atomic absorption signals for lead in iron(III) nitrate (1) and chloride (2) matrices and time-temperature profile. Analyte; Pb 1 ng with 20 μg of Fe, atomization temperature; 2700 K, charring temperature; 800 K, tube: NPG.

are shown in Fig. 2, together with the temperatue profile for the NPG tube. With the chloride ion, a double-peak signal was observed, but not with the nitrate. The appearance temperature (T_{app}) of the signal was 1217±22 K in the iron(III) chloride matrix

and 1304±8 K in iron(III) nitrate. Fig. 2 shows that the position of the second peak is in agreement with the position of the peak in iron(III) nitrate.

As shown in Fig. 3, for a PG tube, double peaks (signal 1) were also observed in the iron(III) chloride matrix, but not in the nitrate. The second peak, which is in agreement with the peak in iron(III) nitrate (signal 2), appeared as a shoulder at a heating rate of 1200 K s^{-1} for atomizing, while only the first peak (signal 3) was observed at 362 K s^{-1}. The appearance temperature was 1157±5 K in the iron(III) chloride and 1306±5 K in the iron(III) nitrate. Thus, the chloride matrix atomizes lead at a lower temperature than does the nitrate for both the NPG and PG tubes.

Both the charring temperature and time affected the peak shape of the atomic absorption signal for lead in iron(III) chloride. Fig. 4 shows the effect of the charring temperature on the peak shape, where the

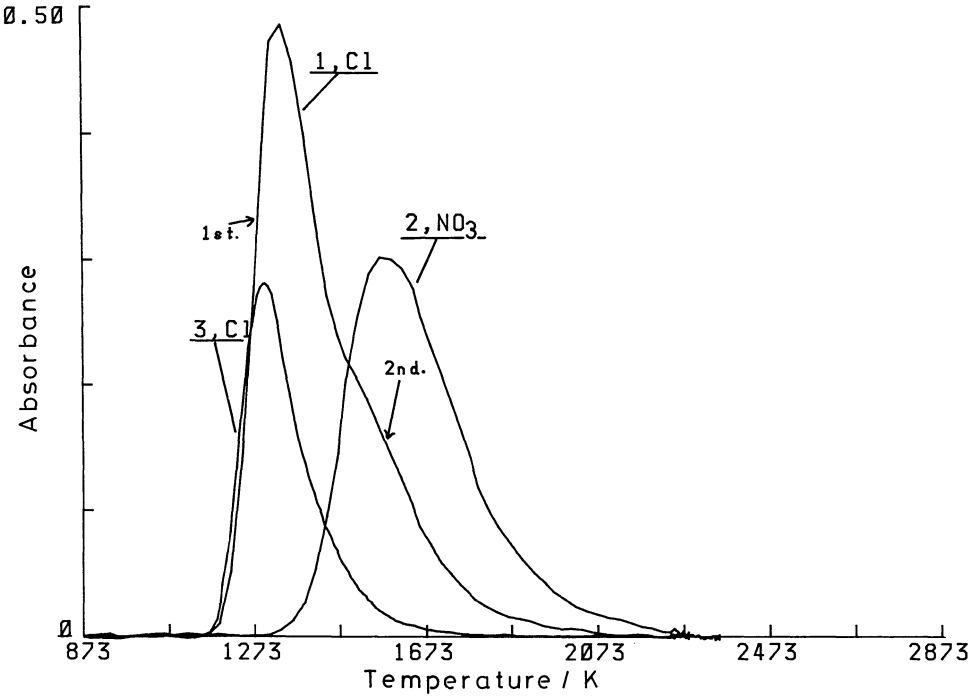

Fig. 3. Atomic absorption signals for lead (Pb: 1 ng) using the PG tube. Charring temperature; 800 K. 1: $FeCl_3$ 0.2 μg of Fe; atomization temperature; 2700 K, 2: $Fe(NO_3)_3$ 0.2 μg of Fe; 2700 K, 3: $FeCl_3$ 0.2 μg of Fe, 3000 K.

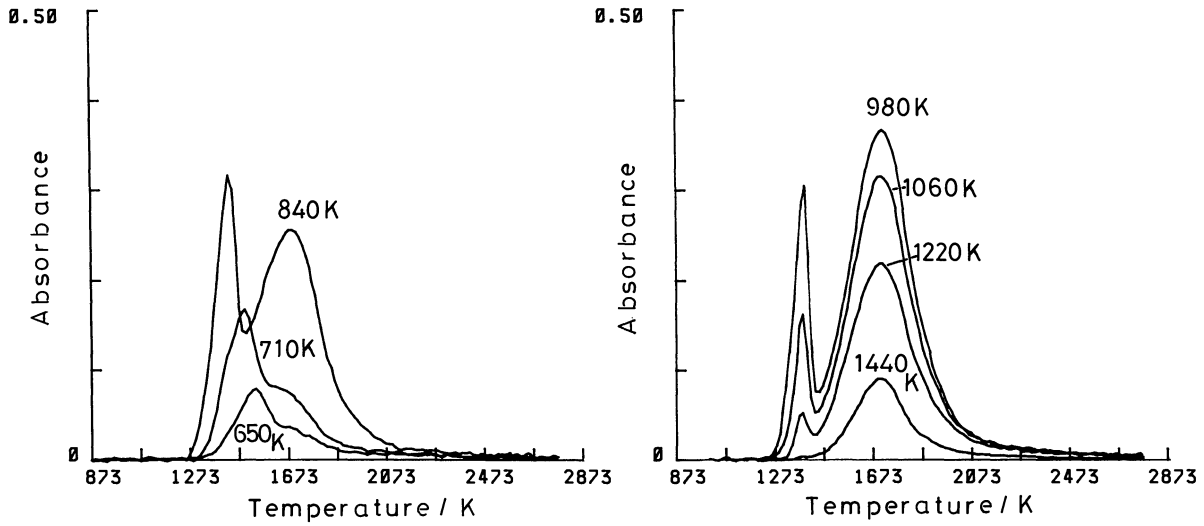

Fig. 4. Effect of the charring temperature on the peak shape. Analyte: Pb 1 ng with 20 μg of Fe($FeCl_3$), atomization temperature; 3200 K, hold time in charring step; 5 s, tube; NPG.

signals in the range of 650—840 K are indicated in the left-hand figure and those in the range of 980—1440 K in the right-hand figure. Fig. 4 shows that at a charring temperature of 710 K double peaks are clearly observed, while at 1440 K the first peak disappeared and only the second remained. The appearance temperature of the isolated second peak (1308±4 K) is also in agreement with that (1304±8 K) in the iron(III) nitrate matrix. Furthermore, Fig. 5 shows that with a hold time of 5 s in the charring stage (charring temp.: 1060 K), double peaks can be clearly seen. On the other hand, within 20 s the first peak almost disappeared and the second one remained without a change in absorbance. This result suggests that an intermediate compound for the first peak is more volatile than that for the second.

Effect of Iron and Chloride Ions on the Peak Shape. The effects of iron and chloride ions on the atomic absorption signals for lead are shown in Fig. 6; a charring temperature of 800 K was used. The concentrations of iron(III) and chloride ions were controlled with iron(III) nitrate and ammonium chloride, respectively, since both nitrate and ammonium ions scarcely contribute to lead atomic absorption.

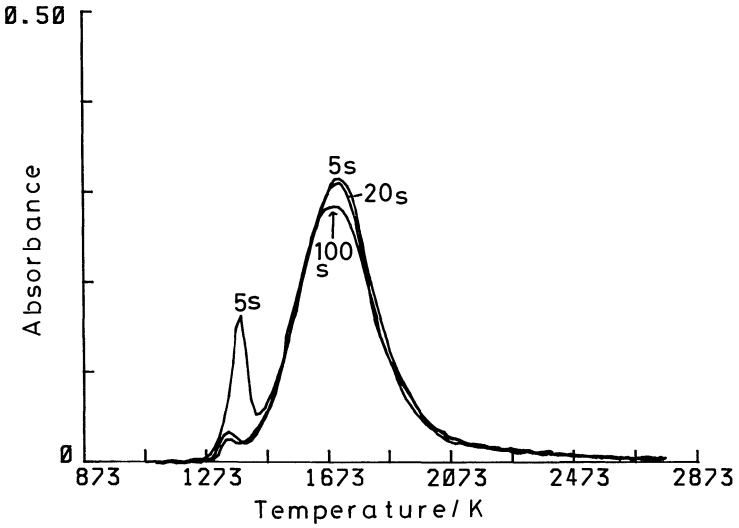

Fig. 5. Effect of the hold time in the charring step on the peak shape. Analyte; Pb 1 ng with 20 μg of Fe($FeCl_3$), atomization temperature; 3270 K (normal heating), charring temperature; 1060 K, tube; NPG.

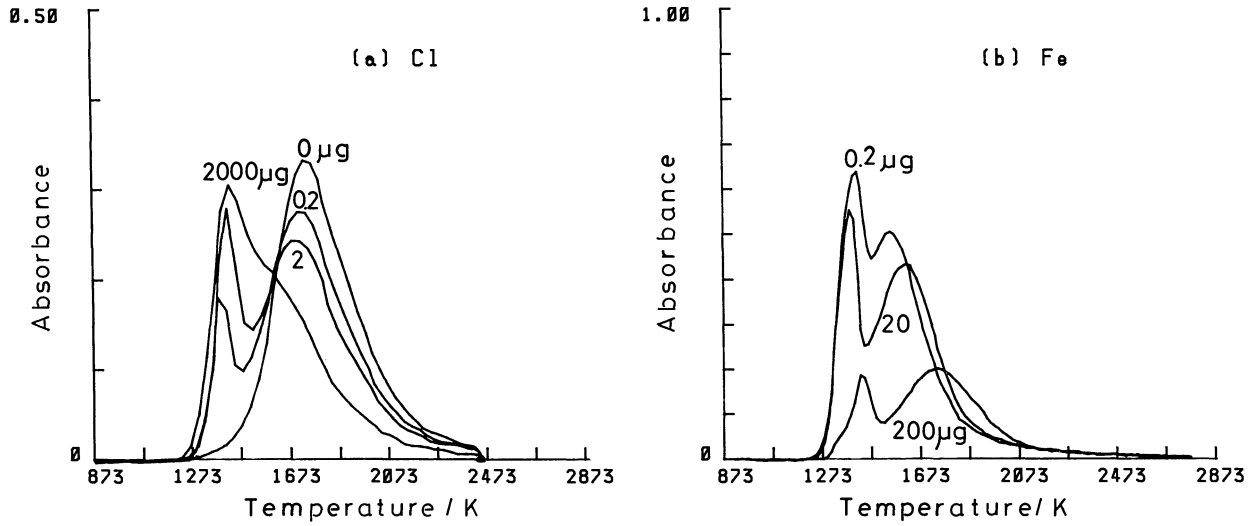

Fig. 6. Dependence of atomic absorption signals for lead on chloride and iron(III) ions added. Charring temperature; 800 K, tube; NPG. (a) Pb, 1 ng; $Fe(NO_3)_3$, 20 μg of Fe; NH_4Cl, varied. (b) Pb 2 ng; NH_4Cl, 20 μg of Cl; $Fe(NO_3)_3$, varied. Atomization temperature: (a) 2700 K (maximum heating); (b) 3270 K (normal heating).

Fig. 6(a) shows that increasing the chloride ion content under a constant amount of iron causes an increase in the first peak height and a decrease in the second peak height, with a 12% decrease of the peak area from 0 to 2000 μgCl and without any shift of the peak temperature. The atomic absorption signal for iron in the matrix is shown in Fig. 7, together with that for lead, showing that lead atomizes at the same temperature as does iron. Fig. 6(b) shows that an increase in the iron content shifts the double peaks to the higher temperature side.

Double Peaks for Another Halide Ions. Fig. 8 shows the atomic absorption signal for 2 ng of lead in the presence of ammonium chloride, ammonium bromide, and ammonium iodide with iron(III) nitrate. Double-peak signals were observed in the presence of ammonium bromide and iodide as well as chloride. The values of T_{app} for the first peak are given in Table 1. The T_{app} value is higher in the following order: Cl^- (1214±26 K)<Br^- (1268±11 K)<I^- (1284±10 K).

Recently, Holcombe[9] discussed the use of Ahrrenius-type plots employing the leading edge of the absorbance signal using data from computer simulations; they concluded that the extraction energetics of the gas-phase dissociation processes are likely to be in error. However, in practice, such a method has been applied extensively to the elucidation of the atomization process and has provided valuable information. In the present work we therefore tried to use a similar method. If the intermediate compound leading to the formation of lead halide is responsible for the first peak, the E_a value should be influenced by the variety of halogen. A kinetic analysis of the first peak was carried out by using a correction method;[10,11] the obtained E_a values are also given in Table 1. The E_a values for chloride, bromide, and iodide were 290±17, 258±5, and 252±11 kJ mol^{-1}, respectively. The E_a value decreases in the order $Cl^->Br^-\geqq I^-$. The tendency for the decrease of E_a is in agreement with that for the bond energy: 316±29 for PbCl(g), 262±38 for PbBr(g), and 213±38 for PbI(g) in kJ mol^{-1} at 1250 K.[12]

Therefore, the above results are, at least, compatible with the inference drawn here: the first peak may be caused by the dissociation of lead halide.

Effect of Iron on Appearance of the First Peak.

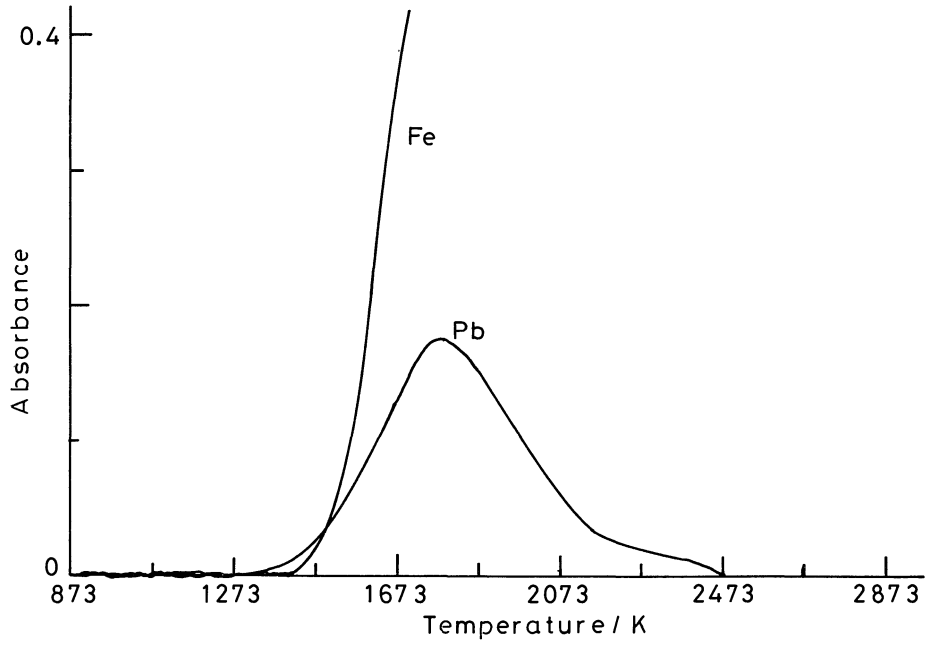

Fig. 7. Atomic absorption signal profiles for lead and iron. Pb: 1 ng; $Fe(NO_3)_3$, 20 μg of Fe. Atomization temperature; 3270 K (maximum heating), charring temperature; 800 K, tube; NPG.

Table 1. Signal Appearance Temperature (T_{app}) and Activation Energy (E_a) for the First Peak

Halogen[a]	T_{app}/K	E_a/kJ mol^{-1}	Bond energy[b] at 1250 K/kJ mol^{-1}
Cl	1214±26	290±17	316±29 Pb-Cl
Br	1268±11	258±5	262±38 Pb-Br
I	1284±10	252±11	252±11 Pb-I

(b) $Fe(NO_3)_3$, 20 μg of Fe; NH_4Br, 45 μg of Br. (c) $Fe(NO_3)_3$, 20 μg of Fe; NH_4I, 72 μg of I. Atomization temperature; 3270 K (normal heating), charring temperature; 800 K, tube: NPG.

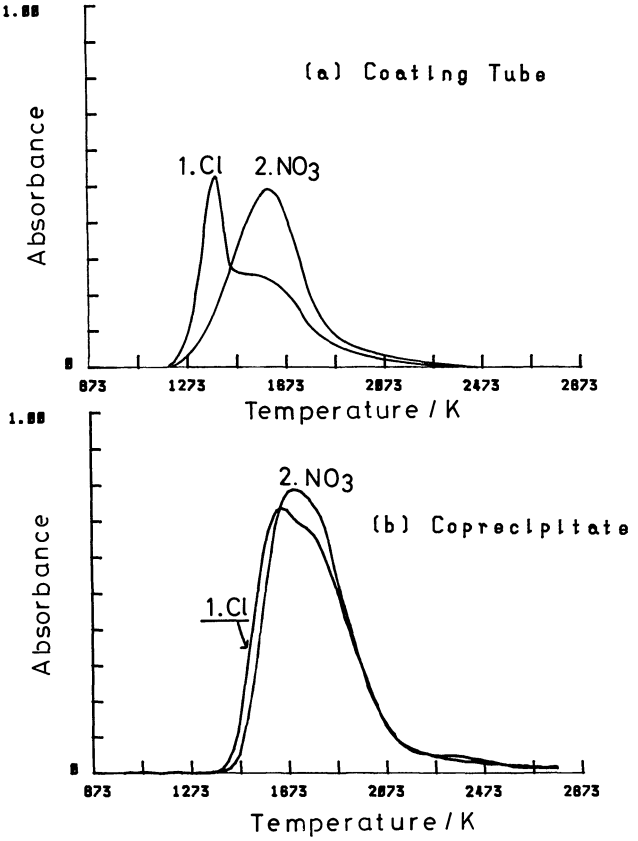

Fig. 9. Comparison between atomic absorption signals for lead. Atomization temperature: 3270 K (normal heating). Charring temperature: 800 K. (a) 1: Pb 3 ng; NH_4Cl, 20 μg of Cl; 2: Pb 1 ng, tube; NPG coated with iron oxide. (b) Lead in the coprecipitate with iron(III) hydroxide from iron(III chloride (1) and iron(III) nitrate (2) using aqueous ammonia, tube; NPG.

Wendl and Müller-Vogt[2] reported that some lead chloride was hydrolyzed to PbO, and that the others were removed as PbCl vapor at temperatures greater than 700 K. In this work, however, a reduction of the first peak which resulted from lead chloride was not observed until 900 K in the iron(III) chloride matrix. Frech and Cedergren[3] examined the interference mechanism of iron with the chloride ion and concluded that the formation of volatile lead chlorides, $PbCl_2$ and PbCl, in the gas phase resulted in a reduction of the signal of lead in steel, where high-temperature equilibrium calculations were made under the assumption that $FeCl_2$ and $FeCl_3$ were in the gas, liquid, and solid phases and that Fe_2O_4, Fe_3O_4, FeO, and Fe were in the solid phase. In the present work, as mentioned in Fig. 6(b), an increase of the iron content shifted both peaks in the double-peak signal to a higher temperature, indicating that iron also affected the atomic vapor formation of lead.

Iron hydroxide, oxide, and chloride are produced in the drying stage from an iron(III) chloride aqueous solution; the hydroxide changes to the oxide during the charring stage by a reaction with either oxygen or water. At first, in order to investigate the effect of iron oxide on the atomic absorption signal for lead, measurements were performed for two types of solution samples with and without ammonium chloride, using an NPG tube coated with iron oxide. The result is shown in Fig. 9(a). The figure shows that a double-peak signal is observed for lead with the ammonium chloride solution, while a single-peak signal is observed for lead without ammonium chloride. The E_a and T_{app} values (294±15 kJ mol^{-1} and 1214±26 K) for the first peak in the ammonium chloride matrix are in agreement with those values (290±17 kJ mol^{-1} and 1217±22 K) for the first peak in the iron(III) chloride matrix within experimental error. These agreements

of the E_a and T_{app} values show that the first peak in the ammonium chloride matrix is due to the same mechanism as the first peak in the iron(III) chloride matrix. In the second, in order to investigate the effect of iron hydroxide, measurements were performed for lead coprecipitated with iron hydroxide from either iron(III) chloride or iron(III) nitrate solutions. The result is shows in Fig. 9(b). The atomic absorption signals are not in agreement with the first peak mentioned above. These results, thus, indicate that iron oxide formed on the charring stage inhibits vaporization of lead chlorides, leading to the appearance of only the first peak.

In conclusion, atomic absorption signals with double peaks were observed for lead in an iron(III) chloride matrix and the chloride ion was responsible for the appearance of the first peak resulting from thermal dissociation of lead chloride. The iron was also responsible for shifting each peak to a higher temperature; the iron oxide formed during charring inhibited the charring loss of lead chloride.

Kinetics and Mechanisms of the Photo-Induced Oxidation of Ascorbic Acid by Molecular Oxygen Catalyzed by Ruthenium(II) Complexes Containing 2,2′-Bipyridine and 2,2′-Bipyrazine

Keiichi TSUKAHARA,* Yuuko WADA, and Masaru KIMURA*
Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630
(Received November 6, 1990)

Hydrogen peroxide was efficiently produced by the irradiation of visible light on aqueous acid solutions containing ascorbic acid, molecular oxygen, and ruthenium(II) complexes: $[Ru(bpy)_x(bpz)_{3-x}]^{2+}$ (x=0—3, bpy=2,2′-bipyridine, and bpz=2,2′-bipyrazine). The formation of hydrogen peroxide and the decay of ascorbic acid were followed by polarography during continuous irradiation by visible light of the solution. The rate constants of the quenching reaction of the excited triplet state of the ruthenium(II) complexes by ascorbate and molecular oxygen obtained from the initial rate method were in good agreement with those obtained from luminescence quenching experiments. The initiation reaction in the photo-induced reaction mechanism changes from the oxidative quenching of $*[Ru(bpy)_3]^{2+}$ by molecular oxygen to the reductive quenching of $*[Ru(bpy)_2(bpz)]^{2+}$, $*[Ru(bpy)(bpz)_2]^{2+}$, or $*[Ru(bpz)_3]^{2+}$ by ascorbate. Such a change in the mechanism arises from a difference in the redox potentials, $E^0(Ru^{3+}/*Ru^{2+})$ and $E^0(*Ru^{2+}/Ru^{+})$, for each ruthenium(II) species containing bpy and bpz. The detailed mechanisms are discussed.

Photo-induced electron-transfer reactions involving ruthenium(II) polypyridine complexes have received considerable attention for both fundamental reasons and their practical application to solar energy conversion.[1,2] Tris(2,2′-bipyridine)ruthenium(II) ion ($[Ru(bpy)_3]^{2+}$) has been one of the most studied photosensitizers. Visible-light irradiation of aqueous solutions of $[Ru(bpy)_3]^{2+}$, triethanolamine, and methylviologen (1,1′-dimethyl-4,4′-bipyridinium cation, MV^{2+}) yielded the methylviologen radical cation (MV^{+}) with a quantum yield of 0.19;[3] the production of MV^{+} led to hydrogen evolution from water by the use of PtO_2 or colloidal Pt.[4,5] A tris(2,2′-bipyrazine)ruthenium(II) ion ($[Ru(bpz)_3]^{2+}$) is a superior photosensitizer over the $[Ru(bpy)_3]^{2+}$ ion for the production of MV^{+}, with a quantum yield of 0.77.[3] The reaction mechanisms are quite different. The photo-excited state of the $[Ru(bpy)_3]^{2+}$ ion, i.e., $*[Ru(bpy)_3]^{2+}$, is oxidatively quenched by a quencher (Q), such as MV^{2+} (Reaction 1):

$$*[Ru(bpy)_3]^{2+} + Q \longrightarrow [Ru(bpy)_3]^{3+} + Q^{-}. \quad (1)$$

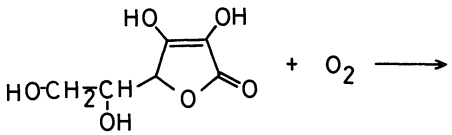
On the other hand, the $*[Ru(bpz)_3]^{2+}$ ion is reductively quenched by a quencher, such as triethanolamine (Reaction 2):

$$*[Ru(bpz)_3]^{2+} + Q \longrightarrow [Ru(bpz)_3]^{+} + Q^{+}. \quad (2)$$

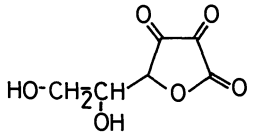
The difference in mechanisms is considered to arise from a positive shift of about 0.5 V in the redox potential of the ruthenium(II) complexes for the latter, compared with the former.[3]

We previously studied such visible-light induced redox and substitution reactions of inorganic compounds using $[Ru(bpy)_3]^{2+}$ and $[Ru(bpz)_3]^{2+}$ ions.[6] Rillema et al.[7] have prepared the mixed-ligand ruthenium(II) complexes containing bpy and bpz, $[Ru(bpy)_2(bpz)]^{2+}$ and $[Ru(bpy)(bpz)_2]^{2+}$. Although the redox and excited-state properties of these complexes have been also investigated,[7-9] the redox quenching reaction has not been examined. It would be interesting to know the changing point from oxidative to reductive quenching mechanisms of the ruthenium(II) complexes by replacing 2,2′-bipyridine with 2,2′-bipyrazine. We therefore investigated the kinetics of the photo-induced oxidation of ascorbic acid by molecular oxygen catalyzed by the ruthenium(II) complexes, $[Ru(bpy)_x(bpz)_{3-x}]^{2+}$ (x=0—3), in an aqueous acid solution.

Although autoxidation of ascorbic acid to dehydroascorbic acid in an aqueous acid solution (Reaction 3)



ascorbic acid



(3)

dehydroascorbic acid

is very slow, in the presence of these ruthenium(II) complexes, irradiation with visible light induced the oxidation of ascorbic acid and the formation of hydrogen peroxide. Such a photo-induced oxidation of ascorbic acid by the $[Ru(bpy)_3]^{2+}$ ion has already been studied by Kurimura et al.,[10] in which an oxidative quenching mechanism of $*[Ru(bpy)_3]^{2+}$ by

molecular oxygen has been proposed. In the present work we have also found that the formation of hydrogen peroxide by use of the $[Ru(bpz)_3]^{2+}$ ion as a photocatalyst is most efficient among the four ruthenium(II) complexes.

Experimental

Materials. Tris(2,2′-bipyrazine)ruthenium(II) chloride 3.5 hydrate ($[Ru(bpz)_3]Cl_2 \cdot 3.5H_2O$),[11] 2,2′-bipyrazinebis(2,2′-bipyridine)ruthenium(II) hexafluorophosphate ($[Ru(bpy)_2(bpz)](PF_6)_2$),[7] and bis(2,2′-bipyrazine)(2,2′-bipyridine)ruthenium(II) hexafluorophosphate ($[Ru(bpy)(bpz)_2](PF_6)_2$)[7] were prepared and purified as in previously reported methods. Tris(2,2′-bipyridine)ruthenium(II) chloride hexahydrate ($[Ru(bpy)_3]Cl_2 \cdot 6H_2O$) obtained from Aldrich Chemical Company, Inc. was used without further purification. L-Ascorbic acid and sodium L-ascorbate were purchased from Wako Pure Chemical Industries, Ltd. and used without further purification. All other chemicals used were of guaranteed grade. All of the solutions used for measurements were prepared from redistilled water. A solution of ascorbic acid and sodium ascorbate was freshly prepared just before measurements.

Procedure. Kinetic measurements during irradiation with visible light were employed by using the same method as reported previously.[6a] A sample solution was continuously irradiated with visible light from two 100 W tungsten lamps at 30 °C under various pH conditions (an acetate buffer); ionic strengths (adjusted with sodium perchlorate); and concentrations of Ru(II), ascorbic acid, and oxygen. Oxygen or air was continuously bubbled through the solution. Aliquot samples were withdrawn at appropriate times after reaction initiation; a Dowex 50W-X8 cation-exchange resin (200—400 mesh, H^+ form) was added in order to remove the ruthenium(II) complexes. After filtration and washing the resins with water, the concentrations of hydrogen peroxide formed and of ascorbic acid remaining in the solutions were measured using a Yanagimoto PA-102 polarograph at 25 °C and pH 4.6 (a 0.1 mol dm^{-3} acetate buffer containing a 0.01% gelatin) under nitrogen gas. The potentials were set at −1.25 V and 0.15 V vs. SCE (a saturated calomel electrode) for hydrogen peroxide and ascorbic acid, respectively. The concentrations of ruthenium(II) ions were determined spectrophotometrically by the use of Shimadzu UV-200S and UV-240 spectrophotometers. The light intensity absorbed in the solution was determined by the use of potassium tris(oxalato)ferrate(III) trihydrate as an actinometer.[12] The iron(II) content was determined spectrophotometrically in the form of a tris(1,10-phenanthroline)iron(II) ion at 510 nm with a molar absorption coefficient of 1.11×10^4 dm^3 mol^{-1} cm^{-1}.

The luminescence quenching experiments of the ruthenium(II) complexes with ascorbic acid and molecular oxy gen were carried out at 30 °C, pH 4.6 (a 0.1 mol dm^{-3} acetate buffer), and an ionic strength (I) of 0.10 mol dm^{-3} ($NaClO_4$) under argon gas by the use of a Hitachi 850 spectrofluorometer. The exciting wavelengths were 450 nm ($[Ru(bpz)_3]^{2+}$), 469 nm ($[Ru(bpy)(bpz)_2]^{2+}$), 406 nm ($[Ru(bpy)_2(bpz)]^{2+}$), and 452 nm ($[Ru(bpy)_3]^{2+}$), respectively. The emission intensities were monitored at wavelengths of 604 nm ($[Ru(bpz)_3]^{2+}$), 646 nm ($[Ru(bpy)(bpz)_2]^{2+}$), 707 nm ($[Ru(bpy)_2(bpz)]^{2+}$), and 608 nm ($[Ru(bpy)_3]^{2+}$), respectively.

The pH of the solutions was measured on a Hitachi-Horiba F-7LC pH meter. The internal solution of the reference electrode was a 3.33 mol dm^{-3} NaCl solution saturated with AgCl.

Results and Discussion

Although the oxidation of ascorbic acid by molecular oxygen at pH 3.9—5.6 was very slow in the absence of the ruthenium(II) complexes, or in the presence of the complexes in the dark, it was accelerated by irradiation with visible light of the solution in the presence of the ruthenium(II) complexes (Fig. 1). The absorption spectra of the ruthenium(II) complexes did not change during the reactions, indicating that the ruthenium(II) complexes act as homogeneous catalysts.

Both plots of the concentrations of ascorbic acid remained, and those of hydrogen peroxide formed against time were linear during the initial part of the reaction (up to 1 h). The initial reaction rate was, therefore, obtained from the initial slope of this line. The ratio of the concentrations of ascorbic acid reacted

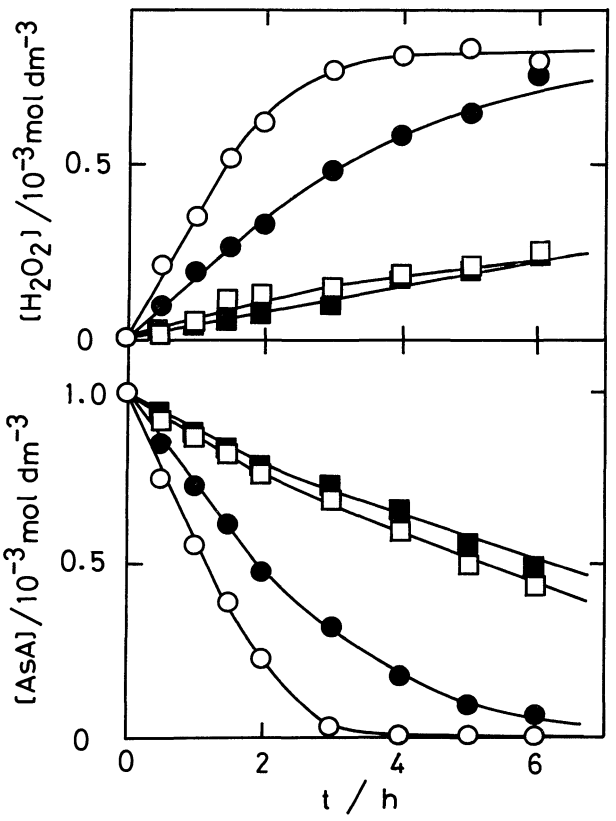


Fig. 1. The formation of hydrogen peroxide and the decay of ascorbic acid during the photo-induced oxidation of ascorbic acid by molecular oxygen in the presence of the ruthenium(II) complex at 30 °C, pH 4.60, and I=0.10 mol dm^{-3}. $[Ru(II)]=5.00 \times 10^{-5}$ mol dm^{-3}, $[AsA]_i=1.00 \times 10^{-3}$ mol dm^{-3}, and $[O_2]=2.28 \times 10^{-4}$ mol dm^{-3}. ○: $[Ru(bpz)_3]^{2+}$, ●: $[Ru(bpy)(bpz)_2]^{2+}$, □: $[Ru(bpy)_2(bpz)]^{2+}$, and ■: $[Ru(bpy)_3]^{2+}$.

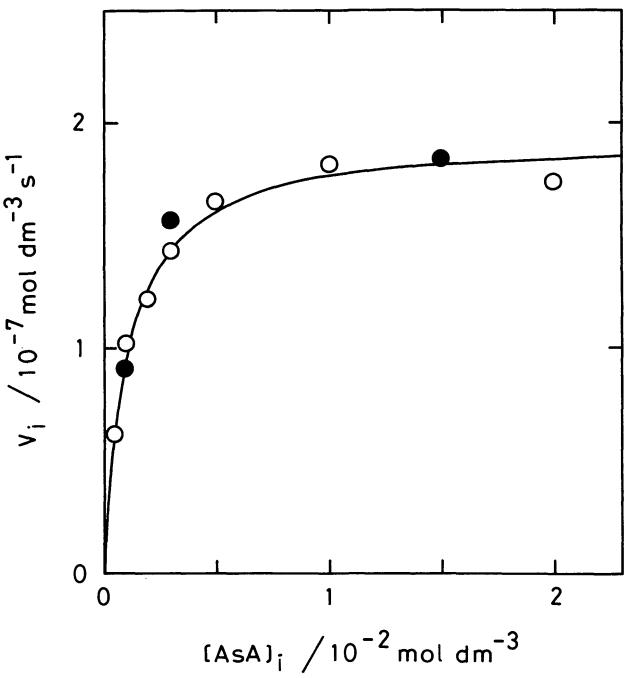

Fig. 2. Plots of V_i vs. [AsA]$_i$ for the photo-induced oxidation of ascorbic acid by molecular oxygen in the presence of $[Ru(bpz)_3]^{2+}$ ions. The initial rate V_i is the mean value for the formation of hydrogen peroxide and the decay of ascorbic acid. ○: $[O_2]=2.28\times10^{-4}$ mol dm^{-3} and ●: $[O_2]=1.16\times10^{-3}$ mol dm^{-3}. Other conditions are the same as in Fig. 1.

to those of hydrogen peroxide formed was near unity at low concentrations of ascorbic acid, but increased to about 2.5 at high concentrations. This indicates that the reaction of ascorbic acid with hydrogen peroxide occurs slowly. We found that the initial rate of the reaction between ascorbic acid and hydrogen peroxide with 1.00×10^{-3} mol dm^{-3} in each was $(9.0\pm1.0)\times10^{-9}$ mol dm^{-3} s^{-1} at pH 4.6, 30 °C, and I=0.10 mol dm^{-3} in an air-saturated solution. The autoxidation of ascorbic acid in the dark was accelerated by decreasing the ionic strength. Moreover, the reaction between ascorbic acid and hydrogen peroxide was accelerated by increasing the ionic strength. Therefore, most of the experiments in the present study were carried out at I=0.10 mol dm^{-3}, adjusted with $NaClO_4$.

Dependence of Concentrations of Ascorbic Acid. The reaction rate increased with increasing concentrations of ascorbic acid, and reached a constant value at higher concentrations of ascorbic acid. One of the examples is shown in Fig. 2 for the $[Ru(bpz)_3]^{2+}$ system. Numerical rate data are given in Table 1 for the ruthenium(II) complexes.

Effect of Oxygen. In the absence of oxygen the reaction did not occur for all of the ruthenium(II) systems. In the $[Ru(bpz)_3]^{2+}$ and $[Ru(bpy)(bpz)_2]^{2+}$ systems the reaction rate in the air-saturated solution was close to that in the oxygen-saturated solution. On the other hand, the rate of reaction in the oxygen-saturated solution was greater than that in the air-saturated solution for the other ruthenium(II) systems, $[Ru(bpy)_2(bpz)]^{2+}$ and $[Ru(bpy)_3]^{2+}$.

a) At 30 °C, pH 4.60, I=0.10 mol dm^{-3} ($NaClO_4$), and [Ru(II)]=5.00×10^{-5} mol dm^{-3}. b) In air-saturated solutions which contain 2.28×10^{-4} mol dm^{-3} O_2. c) In O_2-saturated solutions which contain 1.16×10^{-3} mol dm^{-3} O_2. d) At I=0.050 mol dm^{-3}. e) At I=0.50 mol dm^{-3}.

Dependence of Concentrations of Ruthenium(II). The effect of the concentrations of the $[Ru(bpz)_3]^{2+}$ ions on the reaction rate is shown in Fig. 3, indicating that it gradually increases with increasing concentrations of $[Ru(bpz)_3]^{2+}$ ions, reaching a constant at more than 5.00×10^{-5} mol dm^{-3} of ascorbic acid. This behavior can be accounted for by a Lambert-Beer's law (Eq. 4):

$$I_a = I_0(1 - \exp(-\gamma[[Ru(bpz)_3]^{2+}]), \quad (4)$$

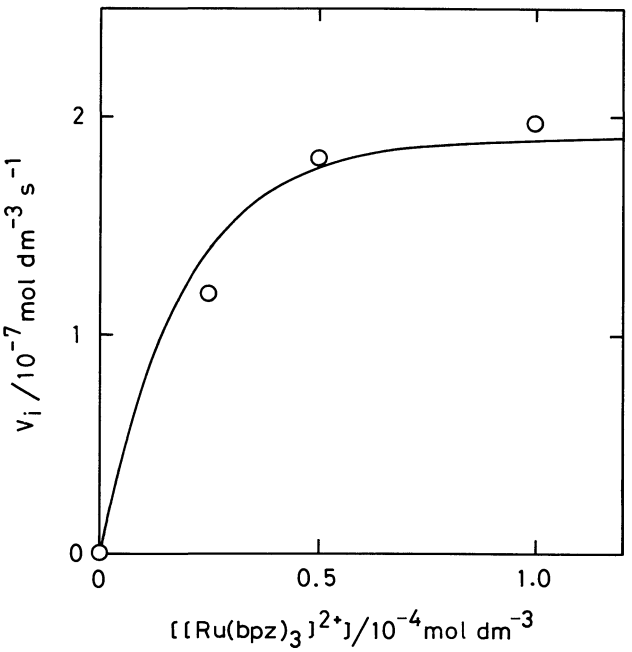

Fig. 3. Plots of V_i vs. [[Ru(bpz)$_3$]$^{2+}$] for the photo-induced oxidation of ascorbic acid by molecular oxygen at [AsA]$_i$=1.00×10^{-2} mol dm^{-3}. Other conditions are the same as in Fig. 1. The solid curve is calculated according to Eq. 4 with γ=5.3×10^4 dm^3 mol^{-1} and I_0=1.85×10^{-7}mol dm^{-3} s^{-1}.

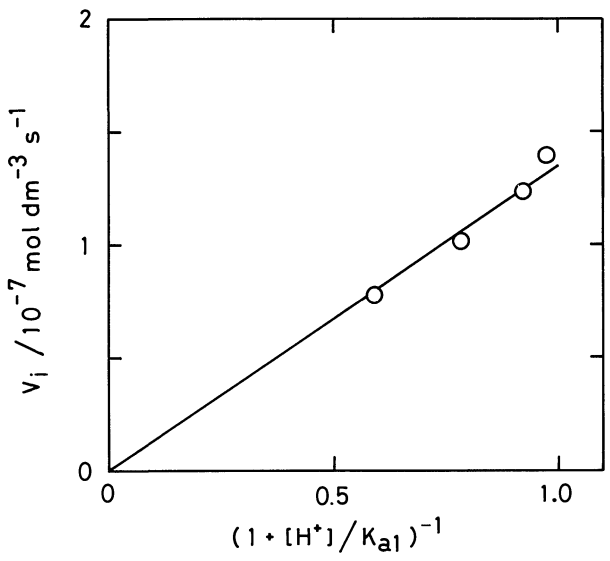

Fig. 4. Plots of V_i vs. (1+[H$^+$]/K_{a1})$^{-1}$ for the photo-induced oxidation of ascorbic acid by molecular oxygen in the presence of [Ru(bpz)$_3$]$^{2+}$ ions at [AsA]$_i$=1.00×10^{-3} mol dm^{-3}. Other conditions are the same as in Fig. 1.

where I_a and I_0 are the light intensities absorbed and irradiated, respectively, and γ is a constant including a molar absorption coefficient of the [Ru(bpz)$_3$]$^{2+}$ ion and the optical path length of the reacting solution. Saturation of the initial reaction rate corresponds to that of the light intensity absorbed in the [Ru(bpz)$_3$]$^{2+}$ solution. The solid line in Fig. 3 is a calculated one according to Eq. 4 with γ=5.3×10^4 dm^3 mol^{-1} and I_0=1.85×10^{-7} mol dm^{-3} s^{-1}. The light intensity absorbed in a reacting solution containing 5.0×10^{-5} mol dm^{-3} of the [Ru(bpz)$_3$]$^{2+}$ ion was determined to be (1.76±0.09)×10^{-7} mol dm^{-3} s^{-1} by using a tris(oxalato)-ferrate(III) actinometer. This value is very close to the mean value of the initial rates of reaction obtained from the decay of ascorbic acid and the formation of hydrogen peroxide at high concentrations of ascorbic acid ((1.8±0.4)×10^{-7} mol dm^{-3} s^{-1}).

pH Dependence. The effect of pH on the reaction rate for the [Ru(bpz)$_3$]$^{2+}$ system was studied at 30 °C, pH 3.9—5.6 (a 0.10 mol dm^{-3} acetate buffer), and I=0.10 mol dm^{-3} (NaClO$_4$) in an air-saturated solution. The reaction rate increased with increasing pH at the initial concentration of ascorbic acid, [AsA]$_i$= 1.00×10^{-3} mol dm^{-3}. The acid-dissociation constant of the *[Ru(bpz)$_2$(Hbpz)]$^{3+}$ ion is 10^{-2} mol dm^{-3},[3b] indicating that the predominant species is the *[Ru(bpz)$_3$]$^{2+}$ ion at pH 3.9—5.6. The pH dependence can be explained by considering the following acid-base equilibrium of ascorbic acid (H$_2$A):

$$H_2A \rightleftarrows HA^- + H^+ \quad [K_{a1} = 9.16 \times 10^{-5} \text{ mol dm}^{-3}].^{13)} \quad (5)$$

The molar fraction of the HA$^-$ ion is represented by

$$[HA^-]/([H_2A] + [HA^-]) = (1 + [H^+]/K_{a1})^{-1}. \quad (6)$$

Plots of the initial reaction rate vs. (1+[H$^+$]/K_{a1})$^{-1}$ was linear with a zero intercept (Fig. 4), indicating that the reacting species is the HA$^-$ ion. At a 1.00×10^{-2} mol dm^{-3} ascorbic acid the reaction rate was independent of pH, consistent with the results that the initial reaction rate is independent of the concentrations of ascorbic acid at more than 1.00×10^{-2} mol dm^{-3}.

The effect of the ionic strength on the initial reaction rate for the [Ru(bpz)$_3$]$^{2+}$ system, in which the reaction rate decreases with an increase in the ionic strength, also supports the idea that the reactive species are oppositely charged (Table 1).

Quenching of Excited State of Ruthenium(II) Complexes by Ascorbic Acid and Molecular Oxygen. The metal-to-ligand excited triplet state of [Ru(bpy)$_3$]$^{2+}$ and [Ru(bpz)$_3$]$^{2+}$ ions is quenched by ascorbic acid and molecular oxygen through an oxidation-reduction mechanism.[3,14–16] We also measured the luminescence quenching by ascorbic acid and molecular oxygen of *[Ru(bpy)$_2$(bpz)]$^{2+}$ and *[Ru(bpy)(bpz)$_2$]$^{2+}$ ions along with *[Ru(bpy)$_3$]$^{2+}$ and *[Ru(bpz)$_3$]$^{2+}$ ions under our experimental conditions.

Stern-Volmer plots for quenching by ascorbic acid are shown in Fig. 5. The rate constants of the quenching by ascorbic acid and molecular oxygen (k_{q1} and k_{q2}, respectively) were obtained by the use of the lifetime for the excited triplet state of ruthenium(II) complexes (Table 2). The lifetime of the *[Ru(bpy)(bpz)$_2$]$^{2+}$ ion in an aqueous solution is unknown and was therefore estimated from the value in propylene carbonate, compared with data for the *[Ru(bpy)$_2$(bpz)]$^{2+}$ ion in aqueous and propylene carbonate solutions.[7,9] The lifetime of the *[Ru(bpy)$_2$(bpz)]$^{2+}$ ion at pH 4.6 (a 0.1 mol dm^{-3} acetate buffer) was estimated from the ratio of the luminescence intensity at pH 4.6 to that in H_2O. The lifetime of the *[Ru(bpy)$_2$(bpz)]$^{2+}$ ion in H_2O has been reported to be 88 ns.[9]

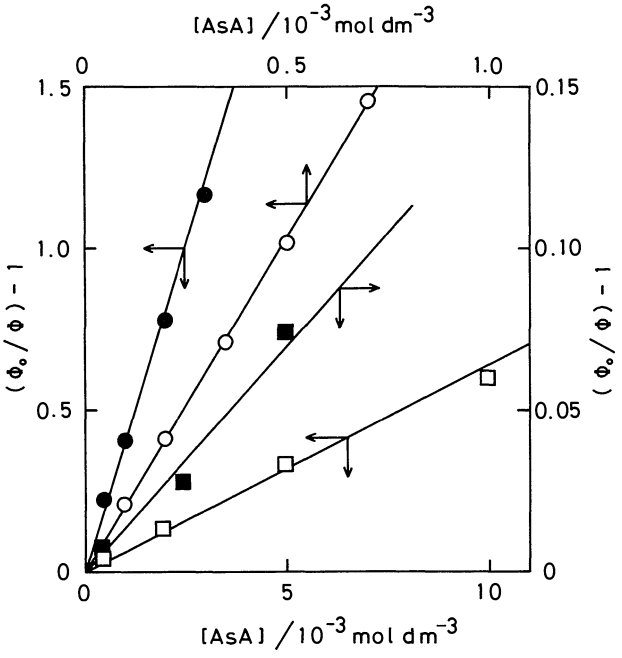

Fig. 5. Stern-Volmer plots for the luminescence quenching of the excited-triplet states of the ruthenium(II) complexes by ascorbic acid at 30°C, pH 4.60, and I=0.10 mol dm^{-3} under an argon atmosphere. ○: [Ru(bpz)$_3$]$^{2+}$, ●: [Ru(bpy)(bpz)$_2$]$^{2+}$, □: [Ru(bpy)$_2$(bpz)]$^{2+}$, and ■: [Ru(bpy)$_3$]$^{2+}$.

Mechanism of Reaction. The obtained results are accounted for by the following reaction mechanism:

$$\mathrm{Ru(II)} \xrightarrow{h\nu} \mathrm{*Ru(II)} \qquad I_a\phi \quad (7)$$

$$\mathrm{*Ru(II)} \longrightarrow \mathrm{Ru(II)} \qquad k_0 \quad (8)$$

$$\mathrm{*Ru(II) + HA^- \longrightarrow Ru(I) + A^{\cdot-} + H^+} \qquad k'_{q1} \quad (9)$$

$$[\mathrm{HA^{\cdot} \rightleftarrows H^+ + A^{\cdot-}} \quad pK_a = -0.45][17]$$

$$\mathrm{*Ru(II) + O_2 \longrightarrow Ru(III) + O_2^{\cdot-}} \qquad k'_{q2} \quad (10)$$

$$[\mathrm{HO_2 \rightleftarrows H^+ + O_2^{\cdot-}} \quad pK_a = 4.8][18]$$

$$\mathrm{Ru(III) + HA^- \longrightarrow Ru(II) + A^{\cdot-} + H^+} \qquad k_1 \quad (11)$$

$$\mathrm{Ru(I) + O_2 \longrightarrow Ru(II) + O_2^{\cdot-}} \qquad k_2 \quad (12)$$

$$\mathrm{2A^{\cdot-} \xrightarrow{H^+} A + HA^-} \qquad k_3 \quad (13)$$

$$\mathrm{2O_2^{\cdot-}\ (and/or\ HO_2) \longrightarrow H_2O_2 + O_2} \qquad k_4 \quad (14)$$

$$\mathrm{HA^- + O_2^{\cdot-}\ (and/or\ HO_2) \longrightarrow A^{\cdot-} + H_2O_2} \qquad k_5 \quad (15)$$

The reaction between the ascorbate radical and molecular oxygen might be very slow, on the basis of their redox potentials (E^0(A/A$^{\cdot-}$)=−0.14 V and E^0($O_2/O_2^{\cdot-}$)=−0.16 V).[19,20] When the decays of the ascorbate radical and the superoxide anion are very fast and the steady state assumption for *Ru(II), Ru(III), and Ru(I) is adopted, the following rate law can be derived:

$$-\frac{d[AsA]}{dt} = \frac{d[H_2O_2]}{dt} = \frac{(k'_{q1}[AsA] + k'_{q2}[O_2])I_a\phi}{k_0 + k'_{q1}[AsA] + k'_{q2}[O_2]}. \quad (16)$$

The rate constants of Reactions 11—15 have been reported: k_1=1.7×10^9 dm^3 mol^{-1} s^{-1} ([Ru(bpy)$_3$]$^{3+}$),[21] k_2=5.8×10^8 dm^3 mol^{-1} s^{-1} ([Ru(bpz)$_3$]$^+$),[22] k_3=1×10^8 dm^3 mol^{-1} s^{-1} (at pH 4.6),[23] k_4=9×10^7 dm^3 mol^{-1} s^{-1} (at pH 4.6),[24] and k_5=8×10^5 dm^3 mol^{-1} s^{-1} (at pH 4.6).[25] Then, Eq. 16 can be rewritten as

Table 2. Rate Constants of the Luminescence Quenching by Ascorbic Acid and Molecular Oxygen of the Excited-Triplet State of Ruthenium(II) Complexes at 30°C, pH 4.60, and I=0.10 mol dm^{-3}

Complex	k_{q1}(AsA) dm^3 mol^{-1} s^{-1}	k_{q2}(O_2) dm^3 mol^{-1} s^{-1}	E^0(Ru$^{*2+/+}$)[a] V	E^0(Ru$^{3+/*2+}$)[a] V
*[Ru(bpz)$_3$]$^{2+}$	(2.0±0.1)×10^9 3.0×10^9[b]	(3.8±0.1)×10^8 5.5×10^8[c]	1.64 (1.64)	0.14 (0.08)
*[Ru(bpy)(bpz)$_2$]$^{2+}$	(1.5±0.1)×10^9	(5.3±0.3)×10^8	(1.42)	(−0.03)
*[Ru(bpy)$_2$(bpz)]$^{2+}$	(2.3±0.1)×10^9	(2.3±0.1)×10^9	(1.28)	(−0.11)
*[Ru(bpy)$_3$]$^{2+}$	(2.2±0.6)×10^7 2×10^7[d]	(3.4±0.2)×10^9 3.3×10^9[e]	0.84 (0.78)	−0.84 (−0.87)

a) Ref. 2. The value in parentheses is in acetonitrile. b) At pH 5—10. Ref. 16. c) In H_2O. Ref. 16. d) In H_2O. Ref. 15. e) In H_2O. Ref. 14.

$$\frac{1}{V_i} = \frac{1}{I_a\phi} + \frac{k_0}{(k'_{q1}[AsA] + k'_{q2}[O_2])I_a\phi}, \quad (17)$$

where V_i denotes the initial rate of reaction. Since the condition $k'_{q1}[AsA] \gg k'_{q2}[O_2]$ holds for the $[Ru(bpz)_3]^{2+}$ and $[Ru(bpy)(bpz)_2]^{2+}$ systems (see Table 2), Eq. 17 can be simplified to

$$\frac{1}{V_i} = \frac{1}{I_a\phi} + \frac{k_0}{k'_{q1}I_a\phi} \cdot \frac{1}{[AsA]}. \quad (18)$$

Plots of V_i^{-1} vs. $[AsA]^{-1}$ were linear, as is shown in Fig. 6. The values of $I_a\phi$ and k'_{q1}/k_0 were, respectively, obtained from the intercept and slope of this line. The values of k'_{q1} are $(1.0\pm0.3)\times10^9$ dm^3 mol^{-1} s^{-1} and $(7.7\pm1.2)\times10^8$ dm^3 mol^{-1} s^{-1} for $[Ru(bpz)_3]^{2+}$ and $[Ru(bpy)(bpz)_2]^{2+}$, respectively. The value of $I_a\phi$ for the $[Ru(bpz)_3]^{2+}$ system ($(2.0\pm0.5)\times10^{-7}$ mol dm^{-3} s^{-1}) is in agreement with that obtained from an experiment using a tris(oxalato)ferrate(III) actinometer ($(1.76\pm0.09)\times10^{-7}$ mol dm^{-3} s^{-1}), suggesting that the quantum yield ϕ is ca. 1.

In continuous photolysis, half of the ascorbic acid is consumed and half of the hydrogen peroxide is produced against the photo-excited state of the ruthenium(II) complexes. The values of $2k'_{q1}$ and $2k'_{q2}$, therefore, correspond to those of k_{q1} and k_{q2} for luminescence quenching of the excited state of the ruthenium(II) complexes, respectively. The former values are in good agreement with the latter ones, indicating that the above-mentioned mechanism is reasonable.

From luminescence-quenching experiments for the $*[Ru(bpy)_2(bpz)]^{2+}$ ion, the value of k_{q1} is nearly equal to that of k_{q2}. Therefore, Eq. 16 for the $[Ru(bpy)_2(bpz)]^{2+}$ system is simplified to

$$\frac{1}{V_i} = \frac{1}{I_a\phi} + \frac{k_0}{k'_{q1}([AsA] + [O_2])I_a\phi}. \quad (19)$$

Plots of V_i^{-1} vs. $([AsA]+[O_2])^{-1}$ were linear and the values of $I_a\phi$ and k'_{q1}/k_0 were, respectively, obtained from the intercept and slope of this straight line (Fig. 7): $I_a\phi=(1.7\pm0.8)\times10^{-7}$ mol dm^{-3} s^{-1} and $k'_{q1}=k'_{q2}=(3.1\pm1.9)\times10^9$ dm^3 mol^{-1} s^{-1}.

In the $[Ru(bpy)_3]^{2+}$ system the condition $k'_{q2}[O_2] \gg k'_{q1}[AsA]$ holds (see Table 2). Therefore, the reaction rate should therefore be independent of the concentrations of ascorbic acid, when Reaction 11 is very fast:

$$V_i = \frac{k'_{q2}[O_2]I_a\phi}{k_0 + k'_{q2}[O_2]}. \quad (20)$$

The initial reaction rate was, however, dependent on the concentrations of ascorbic acid and reached a constant value at high concentrations of ascorbic acid. A linear dependence of the initial of reaction rate on the concentrations of ascorbic acid for this system has already been reported by Kurimura et al.[10] They have suggested that the reaction rate must reach a constant value at high concentrations of ascorbic acid, and pro-

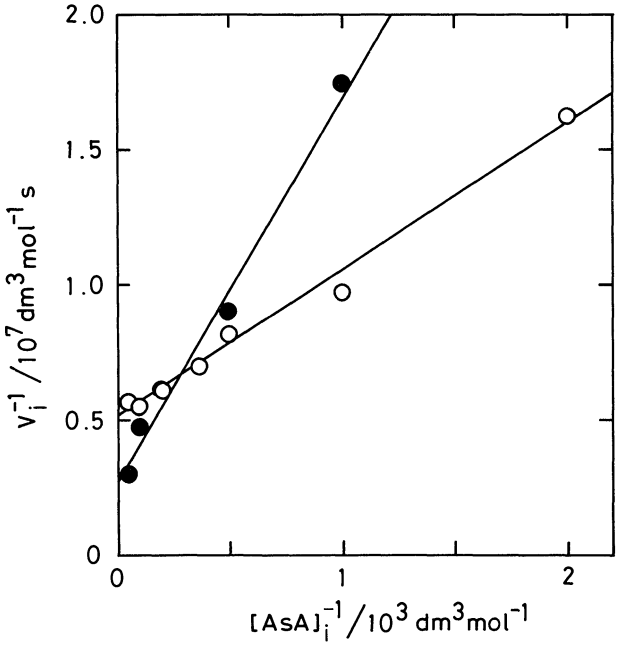

Fig. 6. Plots of V_i^{-1} vs. $[AsA]_i^{-1}$ for the photo-induced oxidation of ascorbic acid by molecular oxygen in the presence of the ruthenium(II) complexes. Experimental conditions are the same as in Fig. 1. ○: $[Ru(bpz)_3]^{2+}$ and ●: $[Ru(bpy)(bpz)_2]^{2+}$.

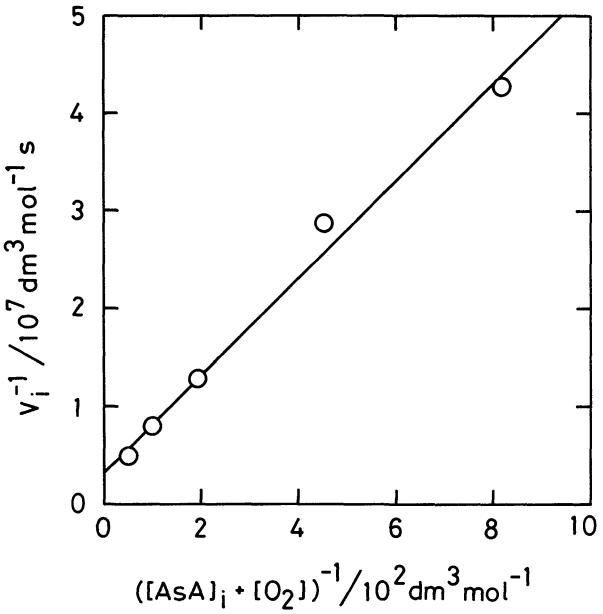

Fig. 7. Plots of V_i^{-1} vs. $([AsA]_i+[O_2])^{-1}$ for the photo-induced oxidation of ascorbic acid by molecular oxygen in the presence of $[Ru(bpy)_2(bpz)]^{2+}$ ions. Experimental conditions are the same as in Fig. 1.

posed a mechanism in which Reaction 11 competes with the back reaction for oxidative quenching by oxygen (Reaction 21):

$$[Ru(bpy)_3]^{3+} + O_2^{\cdot-} \longrightarrow [Ru(bpy)_3]^{2+} + O_2. \quad (21)$$

The rate constant of Reaction 21 has been reported to be 1.4×10^{10} dm^3 mol^{-1} s^{-1}.[26] The formation of hydrogen peroxide suggests that the reaction of superoxide ions with ascorbate and/or the disproportionation of superoxide ions must occur competitively in Reactions 11 and 21. At high concentrations of ascorbic acid, where the reaction rate is indenpendent of the concentrations of ascorbic acid, the initial rate can be simplified, as in Eq. 20. The value of k'_{q2}, obtained from air- and oxygen-saturated solutions, is $(3.0\pm 2.0)\times10^9$ dm^3 mol^{-1} s^{-1}, but has a large error due to the use of only two determinations.

Difference in Mechanisms of Reaction for $[Ru(bpy)_x(bpz)_{3-x}]^{2+}$ Ions. Hydrogen peroxide was efficiently produced during the photo-induced oxidation of ascorbic acid by molecular oxygen catalyzed by $[Ru(bpy)_x(bpz)_{3-x}]^{2+}$ (x=0—3) ions. The $[Ru(bpz)_3]^{2+}$, $[Ru(bpy)_2(bpz)]^{2+}$, and $[Ru(bpy)(bpz)_2]^{2+}$ ions are superior to the $[Ru(bpy)_3]^{2+}$ ion for the formation of hydrogen peroxide. This can be explained by a difference in the quenching rate constants of the excited triplet state of these complexes by ascorbic acid and molecular oxygen. Under the present experimental conditions $k'_{q1}[AsA]$ is larger than $k'_{q2}[O_2]$ for the $[Ru(bpz)_3]^{2+}$, $[Ru(bpy)(bpz)_2]^{2+}$, and $[Ru(bpy)_2(bpz)]^{2+}$ ions, indicating that the reductive quenching process is predominant (Scheme 1). On the other hand, $k'_{q2}[O_2]$ is larger than $k'_{q1}[AsA]$ for the $[Ru(bpy)_3]^{2+}$ ion, in which the oxidative quenching process is predominant (Scheme 2). For the $[Ru(bpy)_2(bpz)]^{2+}$ ion the value of k_{q1} is the same as that of k_{q2}. Therefore, the change in the reaction mechanisms from the oxidative to reductive might occur in the $[Ru(bpy)_2(bpz)]^{2+}$ complex. The redox potentials of couples Ru^{3+}/Ru^{*2+} and Ru^{*2+}/Ru^{+} have been reported, as given in Table 2. The excited triplet state of the $[Ru(bpy)_2(bpz)]^{2+}$ ion is considered to be in the metal-to-ligand charge transfer (MLCT) state of $[Ru^{III}(bpy)_2(bpz^{\cdot-})]^{2+}$, where an electron is localized in the bpz ligand.[7,8] The value of E^0 ($Ru^{3+/*2+}$) for the $*[Ru(bpy)_3]^{2+}$ ion is much lower than that for the other ruthenium(II) complexes containing the bpz ligand, indicating that the $bpz^{\cdot-}$ ligand is more stable during electron transfer than is the $bpy^{\cdot-}$ ligand. Therefore, the electron of the $bpz^{\cdot-}$ ion in the MLCT state of the ruthenium(II) complexes might not be easily transferred, being compared with the $bpy^{\cdot-}$ ion in the $[Ru(bpy)_3]^{2+}$ system. The order of k_{q1} is almost parallel to that of the redox potential, $E^0(Ru^{*2+/+})$, and the order of k_{q2} is inversely dependent on $E^0(Ru^{3+/*2+})$. However, the quenching reaction between Ru(II) complexes, except for the $*[Ru(bpy)_3]^{2+}$ ion and ascorbate, is almost of a diffusion- controlled rate and, therefore, the difference in the rate is much smaller than that expected from the difference in the redox potentials. This trend is similar to the oxidative quenching reaction by molecular oxygen. For example, though the quenching rate constants (k_{q1} and k_{q2}) for the $[Ru(bpy)_2(bpz)]^{2+}$ system are the same, the values of the free energy change of the reaction are quite different: -0.60 eV (1 eV=9.65×10^4 J mol^{-1}) for reductive quenching by ascorbate ($E^0(HA^{\cdot}/HA^-)$= 0.68 V)[19] and 0.05 eV for oxidative quenching by O_2 ($E^0(O_2/O_2^{\cdot-})=-0.16$ V).[20]

Determination of Magnetic Susceptibility of Liquids by a Sensitive Viscometer Method

Kazuo SUEOKA
Department of Chemistry, Josai University, Keyakidai, Sakado, Saitama 350-02
(Received August 10, 1990)

A sensitive viscometer method is presented for precise measurements of the magnetic susceptibility of liquids. This method can be applied to a determination of the diamagnetic susceptibilities of various materials and the temperature dependence of the susceptibility for water. Measurements show that this method has a sensitivity of ±0.005% and a reproducibility of ±0.02%.

Various methods have been proposed for the precise measurement of the magnetic susceptibility.[1-5] Recently, a highly sensitive susceptometer based on a superconducting quantum interference device (SQUID) appeared.[6] This method can be used to detect susceptibility changes of ±0.0001% of a sample; in susceptibility measurements, the reproducibility (± 0.02%) is limited by the sample preparation technique, and the precision is limited by the availability of a standard reference value and density data regarding the conversion to mass susceptibility. Previously, the present author and a co-worker reported an improved viscometer method,[9,10] which is adaptable for both pure liquids and solutions, in addition to gas in the dead space of a measuring cell. This method gives the mass susceptibility without a density conversion that is accurate to within ±0.05%. Additional advantages of the method are: 1) the influence of dissolved air in a liquid sample can be easily almost completely eliminated; 2) a small size magnet can be used; 3) a definite sample volume is unnecessary; and 4) automatic measuring is possible. Since the susceptibility can be easily obtained precisely, it is possible to improve the method's sensitivity for a more precise measurement of the susceptibility.

In this paper, a new type cell is discussed which was designed to improve the sensitivity; its performance is also demonstrated.

Theoretical

A capillary cell is placed in a magnetic field so that the lower end is in the center of a gap between the pole pieces of an electromagnet, while its upper grobular part is outside the field. The susceptibility of a liquid, χ_L, may be written as

$$\chi_L = \frac{2g\tilde{h}}{H^2}\tau_L + (1 - \beta_G)\frac{\rho_G}{\rho_L}\chi_G + \frac{\rho_V}{\rho_L}\chi_V, \quad (1)$$

where

$$\tau_L = (t_0 - t_H)/t_H. \quad (2)$$

Here, t_0 and t_H are the flowing times in the absence and the presence of the field, H, respectively; g the acceleration of gravity; $\tilde{h}$ the mean-effective-head of the liquid; ρ the density; and β the gas solubility in the liquid. Subscripts, L, V, and G indicate the values for the sample liquid, the liquid vapor, and the operating gas, respectively.

Regarding a relative measurement of sample 1 and sample 2, considering $\chi_V \simeq \chi_L$ for each sample,

$$\frac{\chi_L(1)}{\chi_L(2)} = \frac{\tau_L(1)}{\tau_L(2)}[1 + P(1) - P(2)], \quad (3)$$

where

$$P(1) = \frac{\rho_G(1)\chi_G}{\rho_L(1)\chi_L(1)}[1 - \beta_G(1)] + \frac{\rho_V(1)}{\rho_L(1)}, \quad (4\text{-a})$$

and

$$P(2) = \frac{\rho_G(2)\chi_G}{\rho_L(2)\chi_L(2)}[1 - \beta_G(2)] + \frac{\rho_V(2)}{\rho_L(2)}. \quad (4\text{-b})$$

When sample 2 is taken as a standard reference, the following equation may be practically used instead of Eq. 4-a:

$$P(1) = \frac{\rho_G(1)\tau(2)\chi_G}{\rho_L(1)\tau(1)\chi_L(2)}[1 - \beta_G(1)] + \frac{\rho_V(1)}{\rho_L(1)}. \quad (4\text{-c})$$

Allowing for a deviation of ±0.01% (approximately $\pm 0.0001 \times 10^{-6}$ emu/g†), the P(1)—P(2) term of Eq. 3 is negligible, and one can use

$$\frac{\chi_L(1)}{\chi_L(2)} = \frac{\tau_L(1)}{\tau_L(2)}. \quad (5)$$

The sensitivity, K, of this method is

$$K = \frac{\Delta\tau_L}{\Delta\chi_L} = \frac{H^2}{2g\tilde{h}}, \quad (6)$$

where the second and third terms of Eq. 1 are considered to be negligible. Then, a more sensitive

† Note that cgs units are used hereafter. In SI units the volume susceptibility is dimensionless and numerically equal to 4π times the cgs value.

method must be obtained by designing the measuring cell that gives a more reduced mean-effective-head.

Experimental

Materials. The water was purified by sub-boiling distillation from a quartz still after deionization. Acetic acid was purified by distillation from the Wako Guaranteed reagent. Methanol, carbon tetrachloride, and benzene were Dotite Primasol solvents (Dojindo Co.) and were used without purification. Nitrogen was obtained from commercial sources with purities exceeding 99.9%.

Capillary Cell. A horizontal-type capillary cell equipped with a thermostat jaket was fixed to a magnet so that the exit end of its capillary part was located at the center of the pole gap, while its inlet part protruded out of the magnetic field through the inhomogeneous region of the field. Figure 1 shows the experimental equipment. A capillary cell made of Pyrex glass is fixed upright in duplicated water jacket cabinets made of poly(vinyl chloride). These cabinets are covered with foam polystyrene. Detectors for meniscus-passage are attached at positions a and b of the cell. The detectors comprise two pairs of light-emission diodes and photo transistors molded in poly(vinyl chloride). A vertical-type capillary cell used for a comparison was the same as that used in previous studies.[9,10]

Magnet. The electromagnet is the same type as that used in previous studied.[9,10] The pole gap was set to approximately 7 mm. The magnetic field-strength available at a maximum current of 4 A was 19.7 kOe (1 kOe=$(1/4\pi)\times 10^3$ A m^{-1}), calibrated with a Yokogawa gauss meter (Type 3251). The magnetizing current was controlled using a regulated Kikusui (Model PAD-110-5L) power supply (±0.01%), throughout the measurements.

Measurements. Prior to the measurements, any air dissolved in the liquid sample and the cell dead space was fully replaced by nitrogen by means of an operation tube connected to the cell. A detailed description of this procedure was given in a previous paper.[9] The time of liquid flow was measured to an accuracy of ±0.001 s. The electronic apparatus to measure the flow time was made by the present author. The temperature around the cell was monitored by a Takara Kogyo (Model D111) thermistor thermometer. The thermometer was calibrated against a mercury standard thermometer with 0.1 °C divisions. The stability of the temperature was controlled to be ±0.01 °C. Measurements of the flow time were repeated alternately in both the presence and absence of the magnetic field, and the τ-value was calculated for each step. The polarity of the magnetic field was alternately changed for each step by turnning the direction of the magnetizing current. Fifty measurements were averaged in order to calculate the magnetic susceptibility.

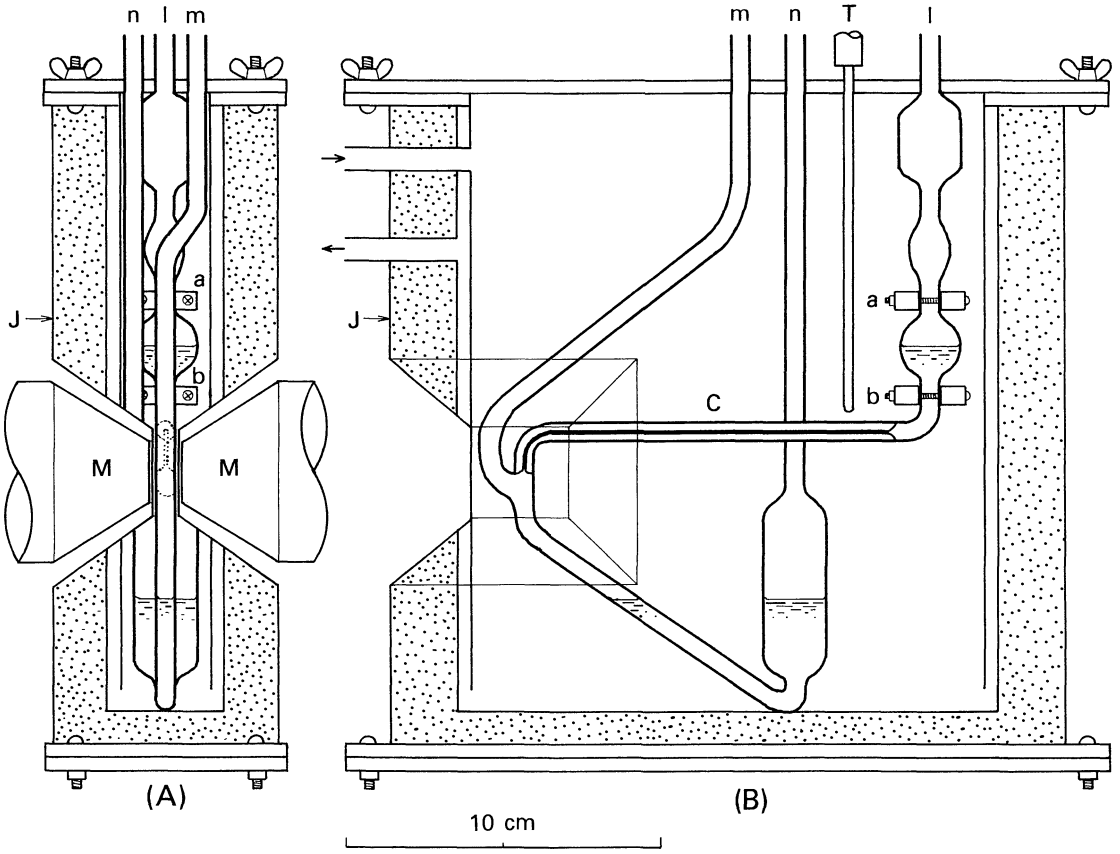

Fig. 1. Experimental setup, A, Front view, and B, side view. C, Capillary of about 0.5 mm (i.d.); a and b, detectors for meniscus passage; M, magnet; J, cabinet made of poly(vinyl chloride) covered with foam polystyrene; T, thermistor. The openings, l, m, and n, connected to the operation tube.[9]

Results and Discussion

The experimental results for water obtained by means of this cell for different magnetic field strengths are shown in Fig. 2, in comparison with the previous cell. A straight line passing through the origin and having a large slope can be seen, the slope of which is expressed from Eq. 1 as

$$\alpha = \frac{1}{2g\tilde{h}}\left[\chi_L - (1-\beta_G)\frac{\rho_G}{\rho_L}\chi_G - \frac{\rho_V}{\rho_L}\chi_V\right]. \quad (7)$$

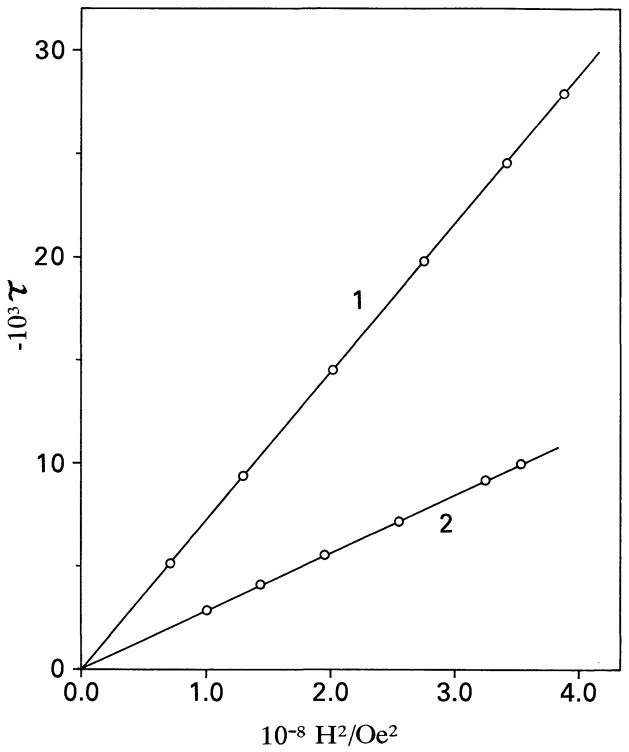

Fig. 2. Relationship between τ-value and the external magnetic field-strength measured for water: 1, this cell; 2, previous cell.

The sensitivity ratio at the same magnetic field strength between the different types of cells can be written using the respective α-values for the same material, as $K_H/K_V=\alpha_H/\alpha_V$. Here, H and V indicate the respective types of cells in the present and previous studies. The α-values for various materials obtained by this cell are listed in Table 1, and are compared with those of the previous cell. It may be seen that the sensitivity is higher than that of the previous cell by about 2.56 times, and that the ratio reproducible in different materials is within ±0.05%. The accuracy of these values is limited by the reproducibility of magnetic field-strength measurements.

The τ-values for various liquids measured at maximum magnetic field strength are listed in Table 2; the field strength was kept constant during all measurements. In the case of water under this condition, the difference in the flow times, t_0-t_H, was about −10 s, for a flow time of about 400 s. From Eq. 2, the deviation of the τ-value for water may be evaluated to be ±0.01% when the error of the flow time is ±0.001 s. The reproducibility of the values for different samples of the same material was at least ±0.02% for water and benzene, while it was ±0.05% for the other organic liquids. Since the allowance of Eq. 5

(±0.01%) exceeds the best reproducibility, one can use this equation to calculate the magnetic susceptibilities of each material. The results are listed in Table 2. A good agreement between the values measured using the previous cell can be seen, while the literature values are slightly smaller than the results by an amount corresponding to the effect due to dissolved air.[9,11] In the present method, dried nitrogen was used as the operating gas and no continuous change of the τ-value was observed. Therefore, the error due to the effect of dissolved air can be almost completely excluded. However, the organic liquids used here absorbed a slight amount of moisture when exposed to air. Thus, the smaller reproducibility for the organic liquids may be mainly caused by the irregular contamination due to atmospheric moisture during sampling. In fact, good reproducibility was obtained for benzene, owing to the small difference in its susceptibility compared to that of water. The method's reproducibility when using this cell is considered to be within ±0.02% (±1.5×10^{-10} emu g^{-1}); such a value was obtained for water. It is difficult to estimate the absolute accuracy of the susceptibility since the absolute value of the susceptibility of water is poorly known.[12]

The diamagnetic susceptibility of a liquid slightly changes with the temperature.[13,14] In particular, accurate coefficients using the susceptibility change of water have been determined using the SQUID method.[7] If the $H^2/2g\tilde{h}$ term in Eq. 1 is kept constant for different temperatures, the present cell may be applicable to measure the temperature dependence of the susceptibilities of diamagnetic liquids. The change in g is negligibly small (≦1×10^{-6} m s^{-2}) and the value of H can be held practically constant throughout a measurement. Moreover, the change in the mean-effective-head is small, since it is of the order of the linear expansion coefficient of a cell made of Pyrex glass, about 3.3×10^{-6} K^{-1}. Thus, one may test the sensitivity by measuring the temperature coefficients for water. In this case, Eq. 3 may be written as

$$\frac{\chi(T)}{\chi(20)} = \frac{\tau(T)}{\tau(20)}\left[0.999317 + 0.60 \times \frac{\rho_G(T)}{\rho_L(T)}\right], \quad (8)$$

where the ratio of the susceptibility at T in °C to that at 20 °C is taken. The experimental results are listed in Table 3, and are in good agreement with those obtained by the SQUID method.[7] The observed $\chi(T)/\chi(20)$ ratios are fitted to a palabolic equation,

$$\chi(T)/\chi(20) = 1 + a(T - 20) + b(T - 20)^2, \quad (9)$$

by a least-squares method and the analyzed result is shown in Fig. 3. The temperature coefficients are listed in Table 4, and are compared with the reported values obtained by various observers. Earlier studies have been contradicted due to oxygen contamination of samples as well as to instrumental imprecision.[11]

a) The values for Refs. 4, 5, 7, and 8 were recalculated using data in the range 10—40 °C, presented in respective papers. b) σ is the standard deviation of the fit and n is the number of data included in the calculation. c) The uncertainty in parentheses is one standard deviation in units of the last quoted coefficient.

The present results are in good agreement with the most pricise data[7] within each uncertainty. As estimated from the standard deviation, the sensitivity, or limit, of detection of the method is considered to be ±0.005% (±0.4×10^{-10} emu g^{-1}); this represents the best performance among various methods based on classical principles. The higher sensitivity than the stability of the magnetizing current used here may be interpreted in terms of the performance: that the method gives a susceptibility that is measured in a time-averaged magnetic field. The accuracy of the susceptibility determined by this method is seriously limited by the availability of a standard value. It is reasonable to use water as a standard in order to maximize the precision, since its nature is never influenced by atmospheric moisture and the best reproducibility available.

The author wishes to thank the late emeritus Prof. T. Ikeda of Shizuoka University for his helpful discussion while in life.

(Received August 18, 1990)

One-dimensional metallic conductance was observed along the c axis of a single crystal of benzo[*b*]phenothiazine–iodine complex, $(B[b]PT)_2(I_3^-)(I)_2$, the crystal structure of which was preliminarily determined by X-ray analysis. Its metal-insulator transition was observed around 235 K, and the sign of the carriers seemed to be positive above 250 K. From the reflection spectra, with polarized light parallel to the c axis, a plasma-edge-like dispersion was observed in near IR region. Several parameters were evaluated by assuming a tight binding band model. The EPR spectra of this complex consist of only one broad signal (peak-to-peak width at room temperature 250×10^{-4} T) in the temperature range from 4 K to 296 K (g=1.998±0.002).

Since more than two decades, phenothiazine (PT) and its derivatives have been known to make semiconductive complexes with iodine.[1–15] None of them, however, has ever been structurally analyzed even if the complex was obtained as single crystals. Many reasons would be considerable about it. For example, there are so many crystallographically independent chemical entities in a large unit cell for 10-methylphenothiazine–iodine complex.[16] Moreover, PT derivatives–iodine complexes usually consist of several kinds of compounds having various mole ratios in spite of being composed of the same donor and acceptor.

We found that benzo[*b*]phenothiazine (B[*b*]PT) and iodine formed only one kind of complex compound with the composition, $(B[b]PT)_2(I_3)(I)_2$ (hereafter abbreviated as B[*b*]PT–$I_{2.5}$), and that it showed metallic behavior around room temperature and transferred to insulator at low temperature. This is the first case where metallic conduction has been observed among the complexes of PT derivatives. In this paper, we present the preliminary crystal structure, and electrical, magnetic, and optical properties of B[*b*]PT–$I_{2.5}$, and discuss the electronic structure and nature of the phase transition of this complex.

Experimental

B[*b*]PT was synthesized by the method of Van Allen et al.,[17] and purified by sublimation in vacuo (mp 291 °C, lit,[17] 278 °C). Commercially obtained iodine was also purified by sublimation.

Single crystals of B[*b*]PT–$I_{2.5}$ were prepared by diffusion method using a Y-shape tube with benzene as the solvent. The crystals were black prisms with metallic luster, having typical size of $0.5\times0.4\times1.0$ mm^3. Prior to each measurement described below, all the crystals were identified to be isostructural by X-ray photographs.

The electrical resistivity and thermoelectric power were observed over the range from 90 K to room temperature along the three crystal axes of single crystal. The resistivity along the most conductive c axis, growing direction, was measured by four-probe dc technique and those along the other two axes by two-probe technique. Carbon paint was applied as the contacts between electrodes (ϕ 30 μm gold wire) and crystal samples. In the case of thermoelectric power measurement, the electrodes were attached to two copper heat sinks, and the temperature difference between the sinks was controlled within 5 degrees.

The polarized reflection spectra were measured on the (010) crystal face for the incident light polarized parallel to the a and c axes. The measurement for the infrared region from 750 cm^{-1} to 6000 cm^{-1} was performed by using a Perkin–Elmer 1760-X FT-IR spectrometer and a Spectra-tech IR-PLAN$_{TM}$ infrared microscope. For the near-infrared and visible regions from 4500 cm^{-1} to 27500 cm^{-1}, measurements were carried out by using a Carl–Zeiss Universal microscope equipped Jobin–Yvon H-20V and H-20FIR monochromators. The spectra were calibrated for a gold evaporated mirror or a silicon crystal according to the observed regions.

EPR spectra for polycrystalline complexes were recorded over the temperature range of 4 K to 296 K using a JEOL JES-FE1XG X-band (9.1 GHz) EPR spectrometer equipped with an Air Products LTR 3-110 continuous-flow cryostat and Scientific Instrument Series 3700 digital temperature controller. Temperature was measured using a (0.07 at.% iron)-gold–chromel thermocouple, and controlled within 0.5 K. The g value was determined by comparing the resonance position with that of Mn^{2+}/MgO. The modulation width was kept much less than one-tenth of absorption line width during the measurements, in order to prevent distortion of line shape by overmodulation.

DSC for polycrystalline samples was measured from 173 K to 293 K with a Rigaku DSC-8240B at the scan speed of 1 deg min^{-1}.

Results and Discussion

Crystal Structure. The crystal data are as follows: $C_{16}H_{11}NS\cdot I_{2.5}$, F.W.=566.6, orthorhombic, *Pnmm*, a=13.976(1), b=17.824(1), c=6.434(1) Å, V=1602.7(3) Å^3,

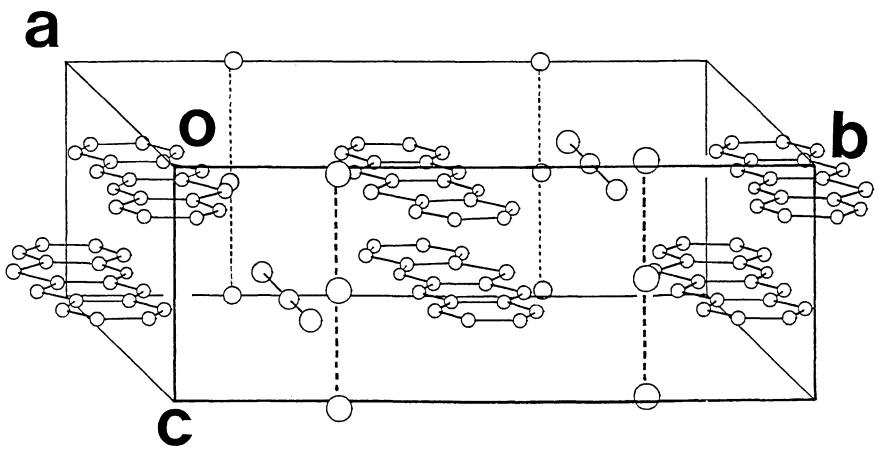

Fig. 1. The crystal structure of B[*b*]PT-$I_{2.5}$, a perspective view of the packing arrangement.

Table 1. Electrical Properties of B[*b*]PT-$I_{2.5}$

Direction	σ (300 K)/S cm^{-1}	S (300 K)/μV K^{-1}	E_a/eV
// a	3×10^{-2}	5×10^{1}	0.02
// b	2×10^{-2}	1×10^{2}	0.03
// c	3×10^{1}	3	Metallic

Z=4. At present, R=0.061 for 1133 reflections.[18] Figure 1 shows view of the crystal structure. The crystal consists of B[*b*]PT molecules, triiodide anions, and linear polyiodide chains. B[*b*]PT molecules, located on the crystallographic mirror plane [parallel to (001)], stack in face-to-face manner to form one-dimensional columns along the c axis. Spacing between B[*b*]PT planes is 3.22 Å, which is comparable with that of TTF, 3.47 Å in TTF-TCNQ.[19] There are two kinds of chemical species of iodine in this complex; one is linear I_3^- anion being parallel to the a axis, and the other is "linear polyiodide chain" being elongated along the c axis. The Fourier analysis indicates that one linear chain consists of iodine atoms arranging with almost equal intervals (3.207(6) and 3.227(6) Å, alternately).[20]

Electrical Conductivity and Seebeck Coefficient. The values of electrical transport properties of B[*b*]PT-$I_{2.5}$, summarized in Table 1, indicate that this complex is highly anisotropic and possesses one-dimensional character. Figure 2 shows temperature dependence of the electrical conductivity along the c axis. The conductivity slightly increases as temperature is lowered down to 235 K, where metal-insulator transition occurs. Below 200 K the conductivity decreases in an activated manner with a very small activation energy of E_a=0.01 eV. In the range 300—250 K, the Seebeck coefficient linearly falls with decreasing temperature and its extrapolation approaches zero at 0 K, as illustrated in Fig. 3. These

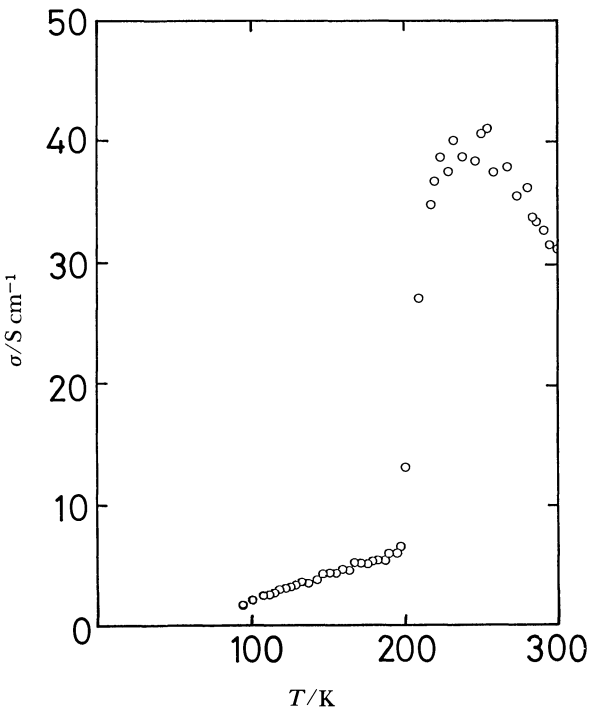

Fig. 2. Temperature dependence of electric conductivity of a single crystal of B[*b*]PT-$I_{2.5}$ measured along its c axis.

results mean that B[*b*]PT-$I_{2.5}$ is in metallic state above 250 K. The positive values of Seebeck coefficient so far measured, suggest that the B[*b*]PT stacks are more conductive than the polyiodide chains.

Polarized Reflection Spectra. Figure 4 shows the polarized reflection spectra of B[*b*]PT-$I_{2.5}$ at room temperature. The long-axes of both B[*b*]PT molecule and triiodide anion are parallel to the crystal a axis, as stated above, and the stacking direction of B[*b*]PT molecules and the linear chain direction of poly-

iodides are both parallel to the most conductive c axis. When the light polarization is parallel to the a axis, two sharp dispersions appear at 14500 and 25000 cm^{-1}. The former band (14500 cm^{-1}) can be assigned to the molecular excitation of B[*b*]PT cation radical polarized to the long axis of the molecule, as the band is also observed in the absorption spectrum of B[*b*]PT cation radical prepared by the electrochemical oxidation of B[*b*]PT in an acetonitrile solution.[21] The dispersion at 25000 cm^{-1} is safely assigned to the low-lying σ_g–σ_u* transition of triiodide anion.[22] When the incident light polarized parallel to the c axis, a plasma-edge-like dispersion appears in the near infrared region. So, it is confirmed that B[*b*]PT-$I_{2.5}$ is in metallic state at room temperature, as being in good agreement with the electrical measurements. In addition to this plasma-edge-like dispersion, a strong dispersion around 16000 cm^{-1} is observed in the //c spectrum. Since the polarization direction of this dispersion is parallel to the stacking direction of B[*b*]PT and/or polyiodide chain, the dispersion can be interpreted as the charge-transfer transition between iodide ions within the chain. Moreover, since the wavenumber of this band is lower than that of the isolated triiodide anion observed in the //a spectrum, the polyiodide would possess more stable electronic state than that of the isolated triiodide.

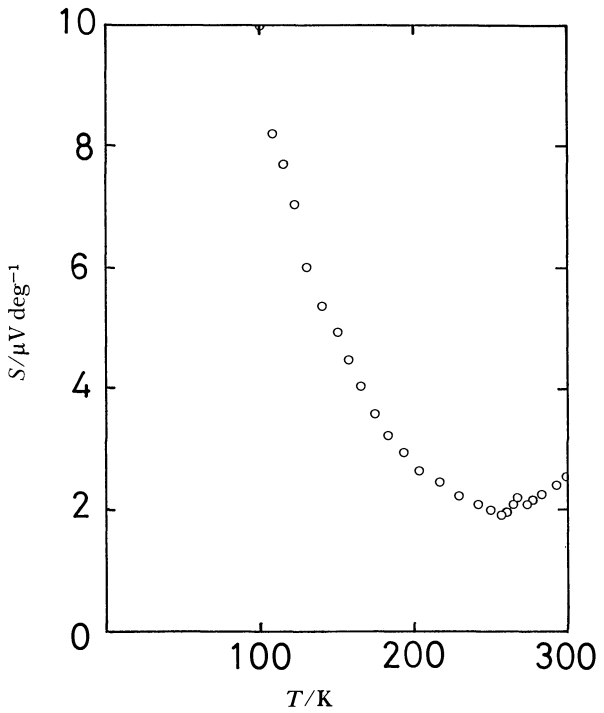

Fig. 3. Temperature dependence of Seebeck coefficient of a single crystal of B[*b*]PT-$I_{2.5}$ measured along its c axis.

Next, we have employed Drude-Lorentz model to analyze the //c spectrum assuming Lorentz oscillator around 16000 cm^{-1}. This procedure consists of the following dielectric function;

$$\varepsilon(\omega) = \varepsilon_{core} - \frac{\omega_p^2}{\omega(\omega + i\tau)} - \frac{f_1}{\omega(\omega + i\tau_1) - \omega_1^2}, \quad (1)$$

where ω_p is the plasma frequency, f_1 is the oscillator strength, ε_{core} is the residual dielectric constant at high frequency, and τ and τ_1 are the relaxation time of carriers and the oscillator, respectively. For the analysis of the //c spectrum, we adopted only the reflectance spectrum from 1900 to 27500 cm^{-1}, since the reflectance spectrum of the region lower than 1900 cm^{-1} would be influenced by intramolecular

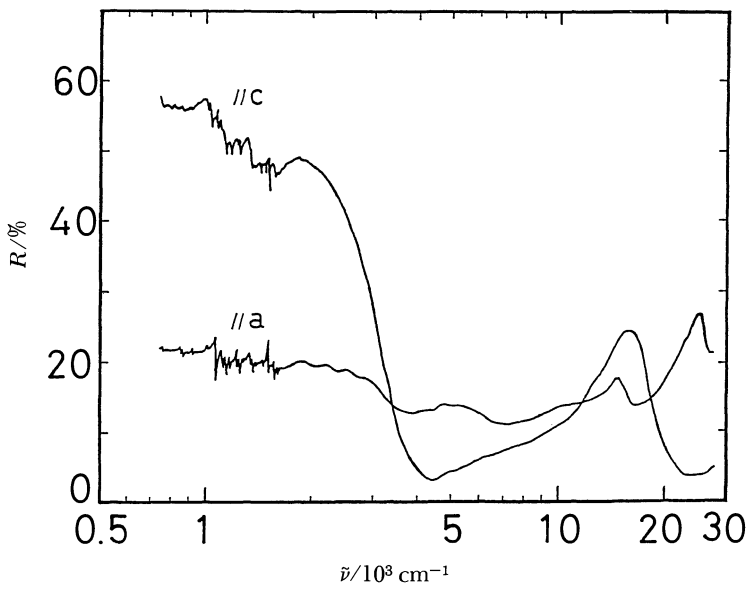

Fig. 4. Polarized reflection spectra of B[*b*]PT-$I_{2.5}$.

vibration of B[*b*]PT and/or coupling up the vibration to conduction electron. By assuming a tight-binding band, the experimentally evaluated parameter ω_p may be related to the tight-binding band width 4t by the equation.

$$\omega_p^2 = \frac{16tNe^2d^2 \sin(\pi\rho/2)}{h^2}, \quad (2)$$

where N is the number density of molecules, ρ is the number of carriers per molecule, and d is the molecular period along the polarization direction of incident light. ω_p may also be related to the optical effective mass m^* and optical conductivity at zero frequency $\sigma_{opt}(0)$ by the following equations,

$$\omega_p^2 = \frac{4\pi ne^2}{m^*} = \frac{4\pi\sigma_{opt}(0)}{\tau}, \quad (3)$$

where n is the number density of free carriers. For the tight-binding band, the Fermi velocity V_F and the mean free path Λ are derived from $4t$ and τ by the equations,

$$V_F = \frac{2td}{h}, \qquad \Lambda = V_F\tau. \quad (4)$$

By using the values N=2.50×10^{21} cm^{-3}, d=3.22 Å, and ρ=0.5, assumed that there are equal numbers of neutral and cation radical B[*b*]PT molecules in the crystal, the transport parameters are calculated from these equations by the analysis of the //c spectrum. They are summarized in Table 2 with the corresponding data of (perylene)$_2$(PF$_6$)$_{1.1}$·0.8CH$_2$Cl$_2$[23] and TTF-TCNQ[24-26]. B[*b*]PT-I$_{2.5}$ represents intermediate values of ω_p and 4t between those of them, and it suggests that B[*b*]PT-I$_{2.5}$ has intermediate property between them.

EPR Measurement. It was observed that the EPR spectra of B[*b*]PT-I$_{2.5}$ consisted of only one signal, and its shape was slightly asymmetric Lorentzian under all the observed temperature range from 4 K to 296 K. At room temperature the observed peak-to-peak linewidth ΔB, 250 G (1 G=10^{-4} T), is rather broad as an aromatic cation radical including sulfur.[27-29] The *g*-value was found to be 1.998±0.002, being slightly smaller than that of free electron. Both values imply that there is an interaction between the radical electron on B[*b*]PT cation radical and iodine atoms, because the latter has a large spin-orbit coupling constant. Magnetic susceptibilities obtained from the EPR intensity is 1×10^{-4} emu mol^{-1} at 296 K. Figure 5 illustrates the temperature dependence of the magnetic susceptibility. Below 50 K the susceptibility nearly follows Curie's low, and above this temperature it behaves in an activated manner with a slight change around 235 K. Since this temperature agrees with that of metal-insulator transition observed in the electrical measurement, it is suggested that the magnetic property of this complex also changes around 235 K. Judging from no discontinuous change in the temperature dependence of susceptibility around this temperature, the metal-insulator transition would not be a first-order phase transition. In the very low temperature region, the observed susceptibility was assumed to come from paramagnetic impurities, the contribution of which was estimated ($C=\chi/T$, C=17 emu mol^{-1}) and shown by solid line in Fig. 5. Deducting this contribution from observed susceptibilities, the activation energy was found to be 0.06±0.02 eV. The peak-to-peak linewidth ΔB increases approximately linearly with temperature up to 300 K, as shown in

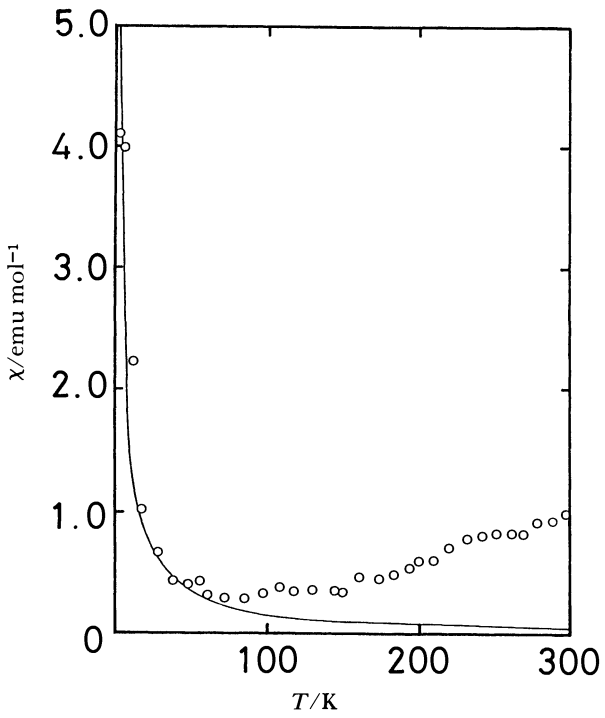

Fig. 5. Temperature dependence of magnetic susceptibility of B[*b*]PT-I$_{2.5}$.

Table 2. Transport Parameters Obtained from the Analysis of the Reflectance Data

Compound	$\omega_P/2\pi$	τ	n	m^*/m_e	$4t$	Λ	$\sigma_{opt}(0)$
	cm^{-1}	10^{-15} s	10^{21} cm^{-3}		eV	Å	S cm^{-1}
(Pe)$_2$(PF$_6$)$_{1.1}$·0.8CH$_2$Cl$_2$	(7400)	4.4	1.42	0.91	1.1		1900
B[*b*]PT-I$_{2.5}$	7720	2.9	1.25	1.9	0.87	4.3	550
TTF-TCNQ	9500	4	2.8	3	0.43		1200

The value derived from their data is given in parentheses.

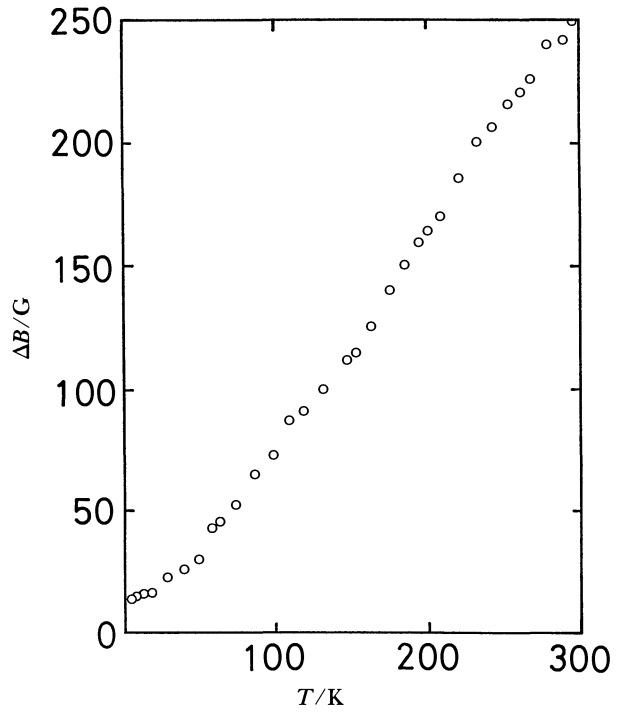

Fig. 6. The EPR peak-to-peak line width vs. temperature observed about B[*b*]PT-$I_{2.5}$.

Fig. 6, although a slight change in slope appears around 235 K. This temperature corresponds to that observed when the temperature dependence of the susceptibility was measured.

DSC Measurement. DSC measurements showed neither endothermic nor exothermic peak around 235 K. Therefore, it was found that the metal-insulator transition observed in the measurement of electrical properties was not first-order transition with latent heat.

Summary and Conclusions

B[*b*]PT-$I_{2.5}$ exhibits a metallic state in the high temperature phase, but has electrical and magnetic activation energies in the low temperature phase. The transition temperature was observed around 235 K. However, no discontinuous change of the magnetic susceptibility and the EPR linewidth, and no latent heat on DSC measurements were observed around the transition temperature. These facts would imply that the transition is attributed to the Peierls-type transition around 235 K. The electronic state of B[*b*]PT would be a mixed state of cation radical and neutral one. However, a quantitative estimation of this mixed state is hardly established, since the information about electronic state of the linear polyiodide chain is insufficient at this stage.

The authors express their hearty thanks to Dr. Koichi Nishikida of Perkin-Elmer Japan for the measurement of polarized reflection spectra in the infrared region.

Photoreduction and Emission of Solid Europium(III) Chloride in KBr by Laser Irradiation at 308 nm

Yasuhiro YAMADA* and Shin-ichi OHNO
Department of Chemistry, Japan Atomic Energy Research Institute,
Tokai-mura, Naka-gun, Ibaraki 319-11
(Received September 7, 1990)

The emission and transient absorption spectra of solid europium irradiated with laser light at 308 nm were measured. $EuCl_3 \cdot 6H_2O$ in a KBr disk was photoreduced to form excited Eu^{2+}, and the emission from excited Eu^{2+} was observed directly after a reduction of Eu^{3+}. Since Eu^{2+} was not stabilized in the KBr disk sample, it oxidized rapidly to form Eu^{3+}. From a discussion concerning the temperature dependence of the rate constants of the reduction and deexcitation, it is shown that the reduction rate increases at higher temperature.

We studied the lifetimes of the excited states of the f-f transitions and photochemical reactions of lanthanide compounds induced by f-d or charge transfer transitions in order to investigate element selective photochemical reactions of lanthanide elements by multiphotoexcitation of f-f transitions. The lanthanide elements have complicated optical spectra because of the 4f shell; their absorption and fluorescence properties have been studied by many workers.[1,2] Europium has unique properties in that it is exceptionally stable in the divalent state (besides the trivalent state), while most lanthanide elements are stable only in the trivalent state in solution.

The photochemical separation of lanthanide elements in solution has been studied by some workers. Since most of the lanthanide elements are stable in the trivalent state in a solution system, separation is initiated by stabilizing divalent lanthanides in solution. Eu^{2+} produced by photoreduction is stabilized using either SO_4^{2-}[3] or 18-crown-6 ether[4] for the separation.

The optical absorption, emission and Zeeman splittings have been studied for Eu^{2+} substituted in NaCl, KCl, and KBr crystals.[5,6] Divalent europium was prepared by chemical reduction, and was then doped in alkali halide crystals.

We report here on laser irradiation (308 nm) of solid trivalent europium chloride $EuCl_3 \cdot 6H_2O$ in KBr which was used to investigate the photoreduction of Eu^{3+} in a solid system and discuss the emission of Eu^{2+}. This emission from Eu^{2+} in a solid sample may be a useful method to detect two-step excitation through f-f levels.

Experimental

We employed the XeCl excimer-laser (Lambda Physik EMG201MSC) for the irradiation of ultra-violet light at 308 nm (output energy: 400 mJ $pulse^{-1}$, pulse width: 20 ns). The emissions at the desired delayed time after laser pulse irradiation were measured by a diode array multichannel detector (Princeton Instruments SMA) with a 120 nm wavelength width and a 50 ns detection time width. These signals were integrated several hundred times in order to obtain a time-resolved emission spectrum. We also employed a photomultiplier (Hamamatu R928), a monochromator (ISA HR-320) and a fast transient digitizer (Tektronix 7912HB) to detect a single emission signal at the wavelength induced by pulse irradiation.

For the detection of the transient absorption, the probe light from a pulsed high-pressure xenon flash lamp (Tokyo Instruments XF-150) traversed the sample at right angles to the excitation laser light. The transient absorbance at various wavelengths was measured with a photomultiplier placed in the analyzing beam behind the sample disk. In order to eliminate the emission of a sample by laser irradiation, the emission signal obtained without probing light was subtracted from the observed signal of the transmitted probe light with laser irradiation. The transient absorbance was calculated from this signal and the reference signal of probe light without laser irradiation. We employed a spectrometer (JASCO Ubest-30) to measure the standard UV-visible absorption spectra.

As a sample disk, $EuCl_3 \cdot 6H_2O$ was ground and mixed with KBr, and then pressed to form a 1 cm diameter disk. Thick samples ($EuCl_3 \cdot 6H_2O$:0.04 g, KBr:0.10 g) for emission measurements and thin samples ($EuCl_3 \cdot 6H_2O$:0.005 g, KBr: 0.10 g) used to transmit probe light for absorption measurements were employed. The laser light was slightly focussed by a convex lens (f=150 mm) and laser spot at the sample disk was 0.1 cm^2.

Results and Discussion

The time-resolved emission spectra induced by 308 nm irradiation was observed by an SMA detector (Figs. 1 and 2), accumulating the signals for 300 pulses for each spectrum. The change in the intensity of these signals at a wavelength were fitted by a single exponential curve in order to obtain the emission lifetimes. $EuCl_3$ has a broad absorption band assigned to either f-d or a charge-transfer band in the ultraviolet region. Upon irradiation of 308 nm light, a broad absorption band was excited, followed by deexcitation to a lower f-f transition level; sharp emissions from Eu^{3+} (assigned to the f-f transition) were observed (Fig. 1). These spectra were consistent with the emissions observed after a direct excitation of the f-f transition of Eu^{3+} ($^7F_0 \rightarrow {}^5D_2$) at 465 nm. The lifetimes of these transition, $^5D_1 \rightarrow {}^7F_j$ and $^5D_0 \rightarrow {}^7F_j$, are 6.9 and 120 μs,

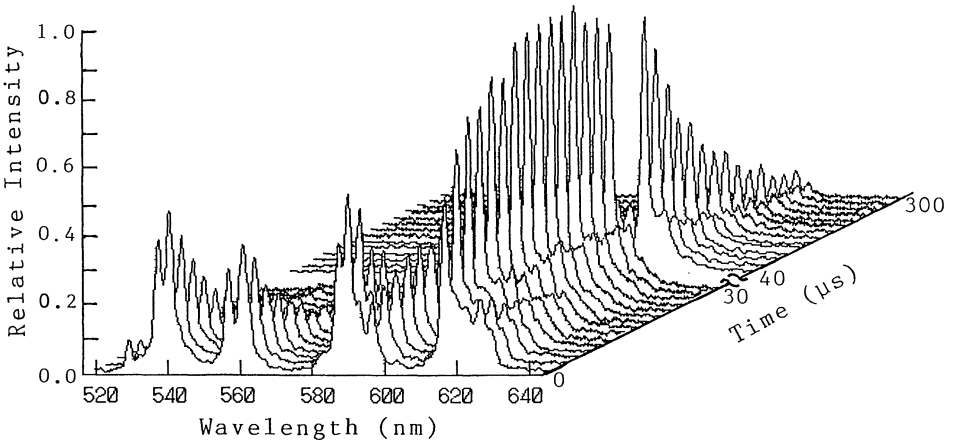

Fig. 1. The time-resolved emission spectra assigned to f-f transitions ($^5D_1$, $^5D_0 \rightarrow {}^7F_j$) of $EuCl_3 \cdot 6H_3O$ in KBr disk irradiated by 308 nm laser light.

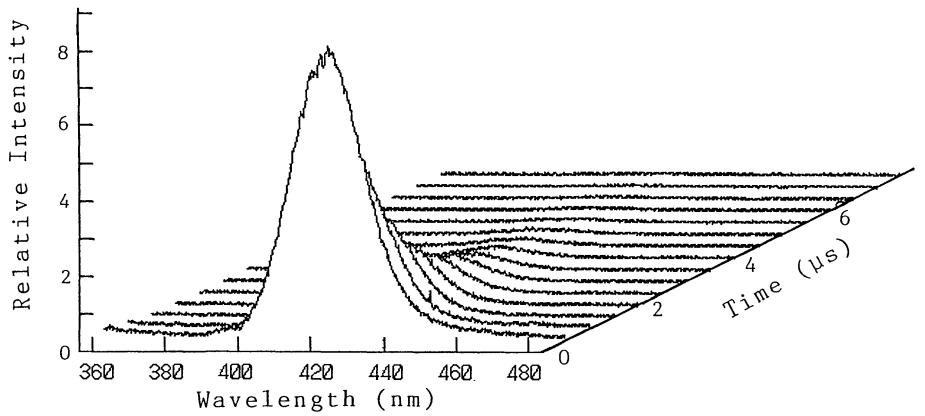

Fig. 2. The time-resolved emission spectra assigned to transition in Eu^{2+} ($4f^65d \rightarrow 4f^7$) by irradiating $EuCl_3 \cdot 6H_3O$ in KBr disk with 308 nm laser light.

respectively, and are the same as those obtained from 465 nm excitation. Besides the emission from f-f transitions, a broad intense emission band at 420 nm assigned to the transition of Eu^{2+} ($4f^65d \rightarrow 4f^7$) was observed (Fig. 2). The measured lifetime from this time-resolved emission spectra was 1.0 μs. When a disk sample of pure $EuCl_3 \cdot 6H_2O$ without KBr was irradiated by 308 nm laser light, the emissions due to the f-f transitions of Eu^{3+} were merely observed and the emission at 420 nm from Eu^{2+} was not observed. It thus seems that the KBr matrix temporarily donates an electrons to reduce $EuCl_3 \cdot 6H_2O$ in the KBr disk upon laser irradiation, and that the absorbed photon energy is transferred for both the reduction and fluorescence of the f-f transitions.

The standard absorption spectra of the disk sample was measured both before and after photoirradiation, and no change due to the production of Eu^{2+} was observed. Thus, photoreduced Eu^{2+} may not be stabilized in a KBr disk sample for a long time (the measuring time was shorter than 3 min). Also, the intensity of 420 nm emission during pulse-irradiation did not change, measured by accumulating the number of pulse-irradiations with a photomultiplier. Thus, photoreduced Eu^{2+} was not integrated but was oxidized to form Eu^{3+} rapidly, since electrons might not disperse or stabilize in a solid system. The reduction of Eu^{3+} and emission from Eu^{2+} was observed in a single 20 ns pulse.

The transient absorbance of Eu^{2+} produced by photoreduction was observed by a photomultiplier and transient digitizer at some wavelengths at room temperature (Fig. 3). The lifetimes of these signals were (1.0±0.2) μs, the same as for emission from Eu^{2+} at 420 nm. The produced Eu^{2+} may therefore be oxidized rapidly after deexcitation to the ground state. The intensity spectrum of this transient absorption signal is demonstrated in Fig. 4. This absorption spectrum corresponds to the absorption spectrum of Eu^{2+} given in the literature;[5,6] absorption was

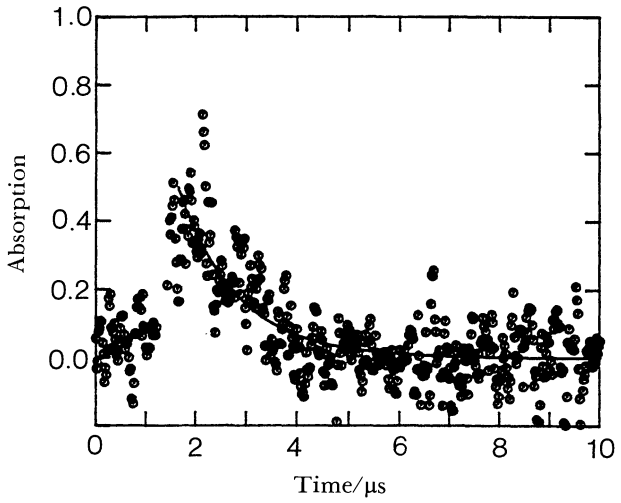

Fig. 3. The transient absorption at 340 nm of $EuCl_3 \cdot 6H_3O$ in KBr disk irradiated by 308 nm laser light.

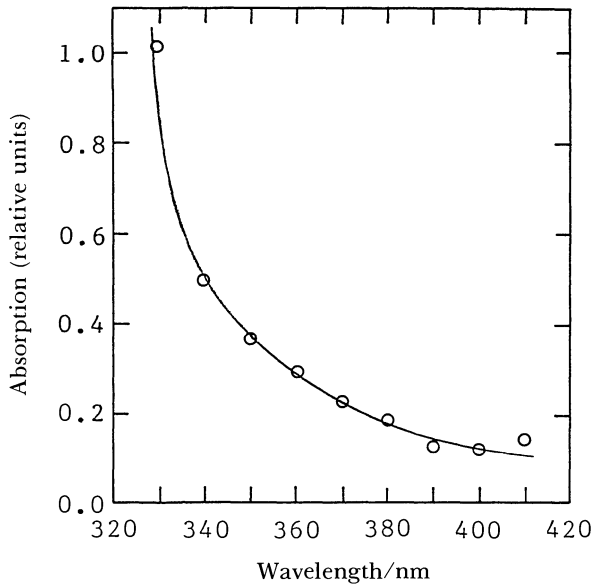

Fig. 4. The trasient absorption spectrum of $EuCl_3 \cdot 6H_2O$ in KBr disk irradiated by 308 nm laser light.

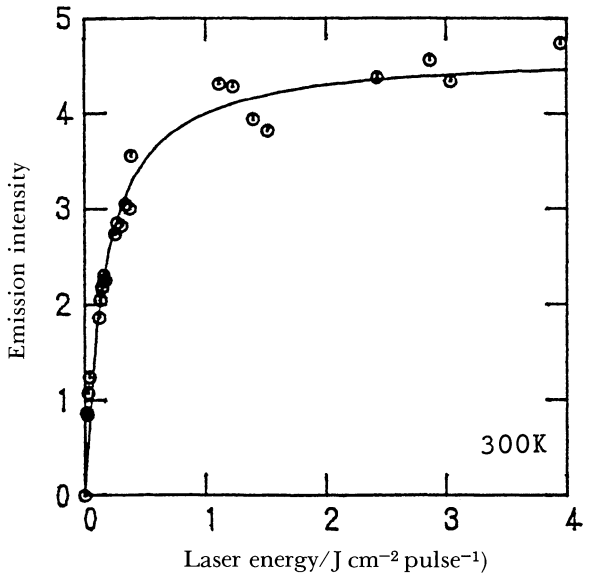

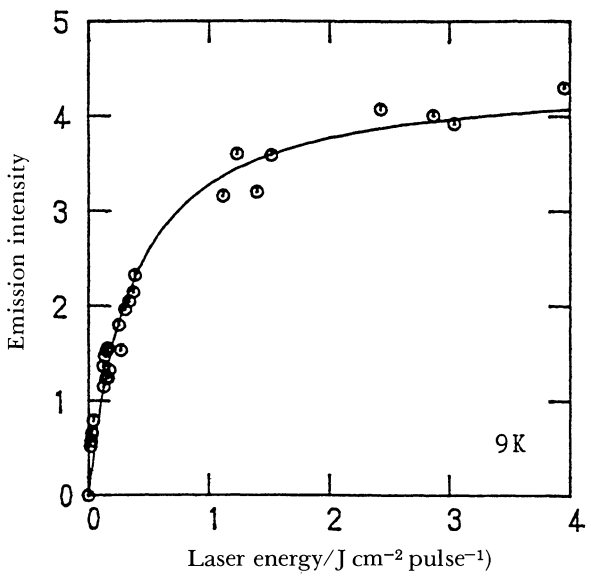

Fig. 5. The emission intensity at 420 nm and the irradiating laser energy (308 nm) of $EuCl_3 \cdot 6H_2O$ in KBr disk at 300 K and 9 K.

observed at shorter wavelengths than 410 nm, having maximum near 320 nm.

The production mechanism of excited Eu^{2+} that radiates fluorescence at 420 nm may estimated in two ways: 1) the excited Eu^{2+} is produced directly after the photoreduction of Eu^{3+} or 2) the ground state of Eu^{2+} produced by the photoreduction of Eu^{3+} is further excited. To examine which process actually takes place, we observed the relation between the laser energy and the emission intensity. The laser energy was varied by means of beam splitters and the emissions at 420 nm were detected by a photomultiplier at various laser intensities and temperatures. From the relationship between the laser energy and the emission intensity of Eu^{2+} (Fig. 5), the number of photons that induce emission from Eu^{2+} could be determined. From Fig. 5 a linear relation between the laser energy and the emission intensity of Eu^{2+} was observed at a lower laser energy, less than 0.5 J cm^{-2}-$pulse^{-1}$. Therefore, the reduction of Eu^{3+} and the emission of Eu^{2+} were induced by one photon absorption. At higher laser energy, the emission intensity saturates because of the rate constants of excitation and that deexcitations of Eu^{3+} become parallel.

To understand the relationship between the laser energy and the emission intensity of Eu^{2+}, we assumed

a simplified energy diagram of reactions and emissions of this system, as demonstrated in Fig. 6. The levels are designated as follows: Level 1 is the ground state of Eu^{3+}; 2 is the excited f-d or charge-transfer state of Eu^{3+}; 3 is the fluorescence level of Eu^{3+}; 5 is the excited and fluorescence level of Eu^{2+}, assigned to $4f^65d$; and 4 is the ground state of Eu^{2+}, assigned to $4f^7$.

The mathematical treatment of the kinetics is simplified by assuming the existence of a steady state, as discussed by Maiman.[7] The transition probabilities are also indicated in Fig. 6: I is the irradiation laser energy; σ is the absorption cross section of Eu^{3+}; k_{21} is the radiationless deexcitation probability; k_{23} and k_{31} are the transition probabilities for radiationless and radiative deexcitation in Eu^{3+} transitions; k_{25} is the transition probability for reduction to the excited level of Eu^{2+} ($4f^65d$); k_{54} is the transition probability for the fluorescence of the excited level to the ground level of Eu^{2+}; and k_{41} is the transition probability of oxidation from the ground level of Eu^{2+} to Eu^{3+}. The real energetic scheme of f-f transition in Eu^{3+} may be complicated by many levels of f-f transitions: level 3, k_{23}, k_{31}, and k_{21} should separated into some components to illustrate actual emission spectra of f-f transition in Eu^{3+}. In order to discuss the emission of Eu^{2+} we simplified the f-f transitions, as shown in Fig. 6.

In terms of this model, the steady-state rate equations are:

$$dN_2/dt=I\sigma N_1-(k_{21}+k_{23}+k_{25})N_2=0,$$
$$dN_3/dt=k_{23}N_2-k_{31}N_3=0,$$
$$dN_4/dt=k_{54}N_5-k_{41}N_4=0,$$
$$dN_5/dt=k_{25}N_2-k_{54}N_5=0,$$

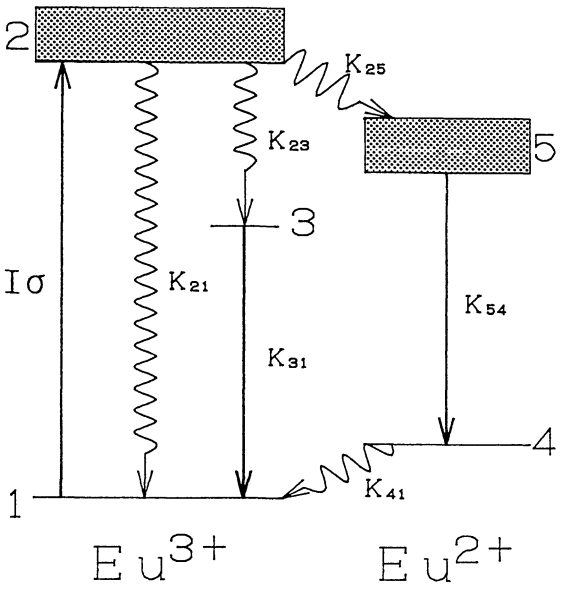

Fig. 6. The energy diagram of the system.

and

$$N_0=N_1+N_2+N_3+N_4+N_5,$$

where N_i is the population of the ith state and N_0 is the total concentration.

I and N_5 correspond to the laser energy and the emission intensity of Eu^{2+}, respectively. The steady-state solution to this set of equations is given by

$$N_5=(k_{25}N_0/(k_{54}A))/(k_2/(A\sigma I)+1),$$

where $k_2=k_{21}+k_{23}+k_{25}$ and $A=1+k_{23}/k_{31}+k_{23}/k_{41}+k_{25}/k_{54}$. The observed data were fitted by a computer least-square method which varied two parameters: $a=k_{25}N_0/(k_{54}A)$ and $b=k_2/(A\sigma)$. Here, a represents the emission intensity at the saturated region, and b represents the gradient of the curve at the region in which the emission intensity and laser energy have a linear relationship. The fitted curves are also indicated in Fig. 5; this model explains these data very well.

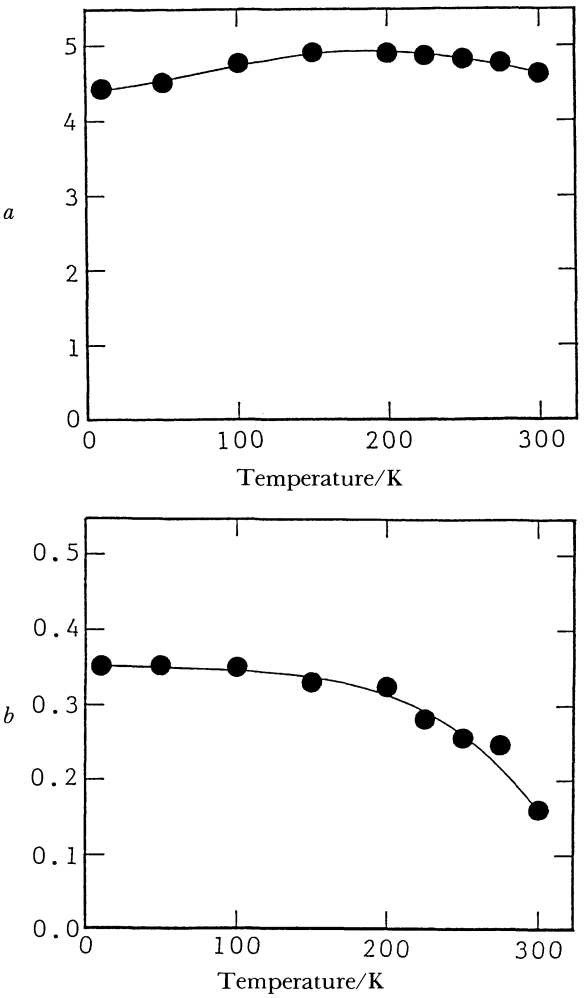

Fig. 7. The a and b obtained by fitting of the relation between the emission intensity at 420 nm and the laser energy of various temperature.

This relation was observed in various temperatures from 300 K to 9 K and the spectrum at each temperature was fitted by the formula. The lifetime of this emission at 420 nm was (1.0±0.2) μs and was independent of both the excitation intensity and temperature. The rate constants of the reduction or some transitions may be influenced by the temperature, and the relation between irradiation intensity and emission intensity may change upon varying the temperature. The obtained a and b in the temperature range 9 K to 300 K are given in Fig. 7. While a has little temperature dependence, b become smaller at higher temperature.

Considering the value k_{54} (10^6 s^{-1}), N_0 and σ are constant and independent of the temperature; the value $a/b=k_{25}N_0\sigma/(k_2k_{54})$ indicates the k_{25}/k_2 which corresponds to the rate of reduction to the total deexcitation process in excited Eu^{3+}. Though the absolute value could not be obtained from this measurement, the relative rate was obtained. From the temperature dependence of a/b, the probability to reduce excited Eu^{3+} became larger at higher temperatures.

Pressure Effect on Proton Jumps in *t*-Butyl Alcohol–Water Mixtures at 25 °C

Masakatsu Ueno,* Kazuhito Matsukawa, Noriaki Tsuchihashi, and Kiyoshi Shimizu
Department of Applied Chemistry, Faculty of Engineering, Doshisha University,
Karasuma Imadegawa, Kamigyo-ku, Kyoto 602
(Received September 7, 1990)

The limiting molar conductances, $\Lambda°$, of hydrochloric acid and potassium chloride in 2,3,5,7,10, and 25 mol% *t*-butyl alcohol (TBA)–water mixtures were determined at 25 °C as a function of the pressure up to 2000 kgf cm^{-2} (1 kgf cm^{-2}=0.9807×10^5 Pa) from the conductances measured within a dilute concentration range. In each solvent mixture the value of $\Lambda°$(HCl) was about three- to five-times larger than that of $\Lambda°$(KCl). The anomalous excess proton conductance, $\lambda°_E$, as estimated by the equation [$\lambda°_E=\Lambda°(HCl)-\Lambda°(KCl)$], was found to increase with increasing pressure in 2,3,5,and 7 mol% TBA–water mixtures, but to decrease in 10 and 25 mol% TBA–water mixtures. The rate of increase with pressure of the excess proton conductance normalized to the molar concentration of water in the mixture was largest in a 2 mol% TBA mixture, and its magnitude decreased in the order: 2>3>0>5≫7≫10≫25 mol% of TBA. These results are compared with those obtained in ethanol–water mixtures and are discussed in relation to the effect of alcohol molecules on the water structure in the mixtures: the three-dimensional network of water in TBA–water mixtures is more stable at a lower mol% of alcohol, and collapses more rapidly with increasing alcohol content than in ethanol–water mixtures.

The proton is much more useful than any other ion for dynamic studies of the structure of water; this is because the reorientation of water molecules has been considered to be the rate-determining step in the proton-jump mechanism.[1,2] The structure of water is dominated by the directional attractive intermolecular potential and is sensitive to any change in the pressure and/or temperature. An X-ray study on the effect of pressure on the structures of both light and heavy water,[3] as well as molecular dynamic simulation studies on liquid water under high compression,[4–6] shows that the hydrogen bonds in water become distorted at high pressure. The distortion of hydrogen bonds accelerates the rotation of water molecules. In accordance with the pressure effect on the reorientation of water molecules,[7,8] the excess proton conductance, $\lambda°_E$, due to proton jumping increases with increasing pressure; the rate of increasing $\lambda°_E$ with pressure becomes more prominent at lower temperature.[9] That is, the more significant is the water structure at atmospheric pressure, the larger is the pressure effect on $\lambda°_E$.[2] In a previous study,[10] this relation was tested in ethanol–water mixtures; it has been confirmed that a small addition of ethanol to water stabilizes the three-dimensional network of water. In the present work we extend this to *t*-butyl alcohol (TBA)–water mixtures.

The thermodynamic properties of TBA–water mixtures have been studied in order to elucidate the nature of hydrophobic hydration; thermodynamic data indicate that TBA is one of the most powerful structure makers in the water-rich region.[11–14] In addition to the unique effect of TBA molecules on the structure of water, the self-association of TBA molecules in water has been suggested to account for the following phenomena: an excess heat capacity maximum,[15] a large ultrasonic absorption,[16] a remarkable increase in light scattering,[17] and anomalies in the reaction rate[18,19] in TBA–water mixtures in a composition range of 3—5 mol% of TBA. Computer experiments have also shown the promotion of the water structure and the self-association of TBA molecules due to a hydrophobic interaction in a 3 mol% TBA–water mixture.[20] Therefore, it is considered that the water structure in these mixtures changes drastically in the dilute solution region. It was the purpose of the present study to examine whether the pressure dependence of the excess proton conductance sensitively reflects the above-mentioned anomalies or not, and whether excess proton conductance is a good measure of the structure of water.

Experimental

Conductivity water was prepared by passing distilled water through an ion-exchange resin; its conductivity was about 1.0×10^{-6} S cm^{-1} at 25 °C and 1 atm. *t*-Butyl alcohol (TBA) of guaranteed reagent obtained from Nacalai Tesque was used without further purification, and showed a water content of less than 0.2 wt% in the Karl Fischer test (MK-AII type, Kyoto Electronics MFG Co., Ltd.). Hydrochloric acid and potassium chloride of high quality were supplied from Merck. The latter was dried above 130 °C prior to use. Aqueous stock solutions of KCl [2×10^{-2} M (1 M=1 mol dm^{-3})] were made up using measuring flasks; those of HCl (ca. 1×10^{-2} M) were prepared by diluting concentrated HCl with conductivity water. Accurate concentrations of HCl stock solutions were determined by measuring the conductances of the solutions and by using the empirical equation of conductance for a HCl solution proposed by Shedlovsky.[21] All of the dilute solutions of HCl and KCl were prepared gravimetrically by diluting stock solutions of HCl and KCl with conductivity water and TBA. The concentrations of the dilute solutions at each pressure were determined by using the densities of the aqueous stock solutions at atmospheric pressure and those of the dilute solutions at each pressure, as

described below. The densities of the stock solutions were calculated for HCl using Eq. 1 in Ref. 10 and for KCl using Eq. 1 with a standard deviation of 5×10^{-6} g cm^{-3}, which can be expressed by

$$\rho(\mathrm{KCl/H_2O}) = 0.9970_5 + 0.046_9 m. \quad (1)$$

Here, ρ is the density in g cm^{-3} and m is the concentration in mol (kg H_2O)$^{-1}$. Equation 1 was obtained from measurements in the range m=0.01—0.1 mol (kg H_2O)$^{-1}$ at 25 °C and 1 atm by means of a digital vibrating densimeter (SS-D-200 twin type, the Shibayama Scientific Co., Ltd.). On the other hand, the densities of the dilute solutions at each pressure were assumed to be equal to those of the solvent mixtures at each pressure because the measured solutions were dilute. All solutions of HCl were treated in a dry box under a nitrogen atmosphere.

Table 1 summarizes the physical properties of the TBA–water mixtures used in this work, such as the density (ρ), viscosity (η), dielectric constant (ε), molar concentration of water in the mixture [$c(H_2O)$], and the observed solvent conductivity (κ).

An acid-proof Teflon cell and a glass cell were employed, respectively, for HCl and KCl solutions. The procedure and apparatus used here for conductance measurements at high pressure were the same as those in previous studies.[10,22] The molar conductances, Λ, obtained by subtrating the solvent conductivity were reproducible within ±0.1%. When ions were not associated, the Fuoss-Onsager equation of conductance[23,24] was used to determine the limiting molar

conductance Λ°:

$$\Lambda = \Lambda^\circ - Sc^{1/2} + Ec\log c + Jc, \quad (2)$$

where c is the molar concentration (M), and S, E, and J have their usual meanings. In the presence of ion pairs, data analysis using Eq. 2 gave a very low value of the ion-size parameter, $\mathring{a}$, involved in J. In this case, the Shedlovsky equation[25] was employed,

$$1/\Lambda S(z) = 1/\Lambda^\circ + K_A c\Lambda S(z) f_\pm^2/\Lambda^{\circ 2}, \quad (3)$$

where

$$S(z) = \{z/2 + [1 + (z/2)^2]^{1/2}\}^2, \quad (4)$$

$$z = [8.204\times10^5 \Lambda^\circ/(\varepsilon T)^{3/2} + 82.5/\eta(\varepsilon T)^{1/2}](c\Lambda/\Lambda^{\circ 3})^{1/2}, \quad (5)$$

and

$$-\log f_\pm^2 = 3.649 \times 10^6[c\Lambda S(z)/\Lambda^\circ]^{1/2}/(\varepsilon T)^{3/2}. \quad (6)$$

Here, $f_\pm$ is the mean activity coefficient, as determined by the Debye–Hückel limiting law, and T is the absolute temperature.

Results and Discussion

The molar conductances, Λ, of HCl and KCl in TBA–water mixtures up to 25 mol% of TBA were measured at five different concentrations in the range $(0.6—5.0)\times10^{-3}$ M for HCl and $(0.4—1.6)\times10^{-3}$ M for KCl at 25 °C as a function of the pressure up to 2000 kgf cm^{-2}.[26] The data for Λ were analyzed with Eq. 2 or 3 to obtain the limiting molar conductances, Λ°, at each solvent and pressure. The results are shown in Table 2 together with the related parameters. Although HCl was completely dissociated in all of the

solutions studied, KCl was slightly associated in TBA–water mixtures containing above 5 mol% of TBA. The obtained values of Λ° at 1 atm were larger on the average by 1.4% for HCl and by 0.4% for KCl than those estimated by interpolation of literature data.[27,28] No high-pressure data are available for a comparison.

As shown in Table 2, the value of Λ°(HCl) is three- to five-times larger than that of Λ°(KCl) in each solvent mixture studied. Furthermore, while Λ°(KCl) in each mixture, except for 2 mol% of TBA, decreases with increasing pressure in accordance with the variation of the solvent fluidity ($1/\eta$) with pressure, Λ°(HCl) increases with increasing pressure in 2,3,and 5 mol% TBA–water mixtures. These results indicate that a special mechanism called "proton jump" plays an important role in TBA–water mixtures.

So far, no exact way to exclusively measure the anomalous excess proton conductance, λ°_E, due to proton jumping has been invented, and an empirical method is often used. The quantity

$$\lambda^\circ_E = \lambda^\circ(H^+) - \lambda^\circ(K^+) = \Lambda^\circ(HCl) - \Lambda^\circ(KCl) \quad (7)$$

is taken here as being a measure of the anomalous conductance. Although Li^+ and Na^+ ions are chosen elsewhere,[1,29] instead of the K^+ ion, as a measure of the translational mobility of a proton (i.e., the oxonium ion, H_3O^+), the K^+ ion is more appropriate because its ionic size is closer to that of the H_3O^+ ion than are the smaller ions. The values of λ°_E, thus obtained, are listed in Table 3.[30]

The distribution of the protons between water and alcohol molecules for the reaction

$$ROH_2^+ + H_2O \rightleftharpoons ROH + H_3O^+ \quad (8)$$

has been examined in the alcohol-rich region by the conductivity method.[31] The equilibrium constants for the reaction $K=c(ROH)c(H_3O^+)/c(ROH_2^+)c(H_2O)$, where c(i) is the concentration of the species i in M, are 139 for methanol, 250 for ethanol, 392 for 1-propanol, 765 for 1-butanol, and 1130 for isobutyl alcohol. Assuming that the value of K does not differ so much among isomers, we can estimate the percentage of protons present as $(CH_3)_3COH_2^+$ to be about (0.03—0.04)%, even in a 25 mol% TBA–water mixture. It is therefore reasonable to consider that almost all of the protons were present as H_3O^+ in the TBA–water mixtures studied here, and were transferred from the oxonium ions to adjacent water molecules. Thus, we can regard that the excess proton conductance reflects a variation of the rotational mobility of water molecules in hydrogen-bond networks with the alcohol content and/or pressure.

As shown in Table 3, the value of λ°_E, itself, decreases markedly with an increase in the TBA content at each pressure. One of the main factors for the decrease in λ°_E with an increase in the TBA content would be a decrease in the concentration of water in a solvent mixture. That is, the fraction of water molecules adjacent to the H_3O^+ ion decreases with an increase in the TBA content and, consequently, the

a) Ref. 10.

frequency of the proton transfer from the H_3O^+ ion to the water molecules diminishes with an increase in the TBA content. Therefore, to evaluate the contribution of water in the mixture to λ°_E, the values of λ°_E normalized to the molar concentration of water in the mixture, i.e., $\lambda^\circ_E/c(H_2O)$, were calculated and are shown in Fig. 1 together with the values for those in ethanol–water mixtures.[32] Figure 1 shows that the value of $\lambda^\circ_E/c(H_2O)$ decreases with an increase in the alcohol content, and that the rate of decrease with the alcohol content is larger in TBA–water mixtures than in ethanol–water mixtures. If the contribution of water in the mixture to λ°_E were the same as that in pure water, $\lambda^\circ_E/c(H_2O)$ would not depend on the alcohol content. Thus, to explain the decrease in λ°_E with an increase in the alcohol content, another factor must be considered in addition to a decrease in the concentration of water in the mixture: the reorientation of water molecules adjacent to the H_3O^+ ion, which is the rate-determining step in the proton-jump mechanism,[1] becomes slower with an increase in the alcohol content, as suggested by the dielectric relaxation time measured in ethanol–water mixtures at 25 °C and 1 atm,[33] and the reorientational correlation time may be longer in TBA–water mixtures than in ethanol–water mixtures because of the higher viscosity of TBA–water mixtures.

In a previous study,[10] the excess proton conductance normalized to its value at 1 atm, $\lambda^\circ_E{}^{(p)}/\lambda^\circ_E{}^{(1)}$, were examined as a function of the pressure as a step toward determining the pressure effect on the excess proton conductance for one rotator, i.e., one water molecule adjacent to the H_3O^+ ion. It is more appropriate, however, to take into consideration the change in the concentration of water at high pressure and to examine the pressure dependence of $R=[\lambda^\circ_E{}^{(p)}/c(H_2O)^{(p)}]/[\lambda^\circ_E{}^{(1)}/c(H_2O)^{(1)}]$ for the purpose mentioned above, since the concentration of water affects λ°_E considerably. As shown in Fig. 2, R increases with increasing pressure in (0—5) mol% of TBA, but decreases in above 7 mol% of TBA. These results suggest that the rotation of water molecules adjacent to the H_3O^+ ion is accelerated by pressure in mixtures up to 5 mol% of TBA as well as in pure water, but is retarded in mixtures above 7 mol% of TBA. Figure 2 also shows that the rate of an increase in R with pressure is largest in a 2 mol% TBA–water mixture, and that its magnitude decreases in the order: 2>3>0>5≫7≫10≫25 mol% of TBA.[34] It is shown from studies on λ°_E in pure water[2,9] that the increase in R with pressure becomes larger with a decrease in temperature. Therefore, the pressure dependence of R is considered to be closely related to the stability of the

water structure: the more stable are the hydrogen bonds between water molecules at atmospheric pressure, the more prominent is the pressure effect on R. If this finding is applied to the results found for TBA–water mixtures, we can draw a conclusion that below 3 mol% of TBA the three-dimensional network of water is stabilized by the addition of TBA to water due to hydrophobic hydration around the t-butyl group. However, a large increase in the TBA content begins to make it difficult to form stable hydrogen bonds between water molecules, as can be seen in 7, 10, and 25 mol% TBA–water mixtures: R decreases with increasing pressure. Computer simulations[20,35] have shown the stabilization and promotion of the water structure by TBA molecules in a 3 mol% TBA–water mixture as well as an infinitely dilute aqueous solution, and at the same time the association of TBA molecules due to the hydrophobic interaction in a 3 mol% TBA–water mixture. This kind of association is promoted with an increase in the TBA content; the structural stabilization of water due to hydrophobic hydration rapidly decreases because TBA–water interactions are replaced by TBA–TBA interactions.

According to a previous study on proton jumping in ethanol–water mixtures at high pressure,[10] it was disclosed that the rate of increase in R with pressure is most prominent in a 5 mol% ethanol–water mixture.[32] Apparently, the rate of increase in R with pressure becomes maximum at a lower mol% of alcohol, and decreases more rapidly with an increase in the alcohol content in TBA–water mixtures than in ethanol–water mixtures. These trends are consistent with those observed regarding such properties of alcohol–water mixtures as the partial molar volumes of alcohols,[12] the temperature of maximum density,[13] and the velocity of sound.[36] The present results therefore indicate that the three-dimensional network of water in TBA–water mixtures is more stable at a lower mol% of alcohol and begins to collapse more rapidly with increasing alcohol content than in ethanol–water mixtures, since the association of alcohol molecules due to the hydrophobic interaction occurs at a lower mol% of alcohol with an increase in the surface area of the alkyl group.

Conclusions

The present experimental study has disclosed that the pressure effect on the excess proton conductance normalized to the molar concentration of water, $\lambda^\circ_E/c(H_2O)$, drastically changes with the alcohol content in TBA–water mixtures in comparison with ethanol–water mixtures. $\lambda^\circ_E/c(H_2O)$ in 2 and 3 mol% TBA–water mixtures increases with increasing pressure at a larger rate than that in pure water. However, the rate of increase in $\lambda^\circ_E/c(H_2O)$ with pressure decreases with an increase in the alcohol content, and in mixtures above 7 mol% TBA–water $\lambda^\circ_E/c(H_2O)$ decreases with increasing pressure, in contrast to the finding that $\lambda^\circ_E/c(H_2O)$ increases with pressure in ethanol–water mixtures up to at least 10 mol% of ethanol. In conclusion, these results reflect a difference in the stability of hydrogen bonds between water molecules in these mixtures at atmospheric pressure; the variation of $\lambda^\circ_E/c(H_2O)$ with pressure becomes a good measure of the stability of the water structure at atmospheric pressure.

Thermal Dehydrogenation of Cyclooctane by Supported Noble Metal Catalysts

Takahiro FUJII, Kiyoshi YUKAWA, and Yasukazu SAITO*
Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received October 12, 1990)

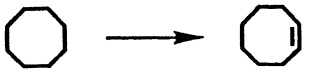
Under boiling and refluxing conditions, cyclooctane has been dehydrogenated to cyclooctene and molecular hydrogen selectively with carbon- and alumina-supported Pd, Ph, and Ru catalysts. The activity order among these metal catalysts was Pd>Rh>Ru. The most active carbon-supported Pd catalyst was least sensitive to the rate retardation caused by cyclooctene adsorption. Desorption of molecular hydrogen from the Pd catalyst surface was deduced to proceed rapidly after the rate-determining step.

The reaction of alkane dehydrogenation yielding alkene and molecular hydrogen (Eq. 1) is highly endothermic.[1]

$$\text{alkane} \longrightarrow \text{alkene} + H_2. \quad (1)$$

High temperatures were required for this reaction in general,[2] as exemplified by styrene formation from ethylbenzene,[3] and with the various processes for petroleum reforming[4] due to the high endothermicity and the increase in the number of molecules. On the contrary, homogeneous transition metal catalysts dehydrogenated alkanes under mild temperatures, where photoirradiation was considered to be indispensable.[5]

It is possible, however, to get rid of the equilibrium restriction imposed at mild temperatures, as long as the product hydrogen is somehow removed from the reaction medium. The boiling and refluxing conditions fulfill the present requirement for the reaction. (Eq. 1) Under boiling conditions, the vapor phase in contact with the catalyst solution is full of the solvent components, whereas the refluxing procedure separates molecular hydrogen from the vapor phase. Since hydrogen is eliminated from the solution after its catalytic generation and is not allowed to dissolve into the solution, alkane dehydogenation can proceed catalytically at mild temperatures without photoirradiation, if we have any suitable catalyst. Recently, in fact, we observed the catalytic dehydrogenation of cyclooctane at 151 °C, yielding cyclooctene and molecular hydrogen (Eq. 2) using Wilkinson complex $RhCl(PR_3)_3$.[6]



(2)

It is quite conceivable that the reaction (Eq. 2) is catalyzed by various kinds of catalysts, either homogeneous or heterogeneous. The metallic hydrogenation catalyst is a good candidate, since the metallic surface sites of hydrogenation catalysts are capable of dissociating the C–H bonds of alkane and to form molecular hydrogen from surface hydrogen species.

In the present study we attempted to find supported metal catalysts for cyclooctane dehydrogenation under boiling and refluxing conditions.

Experimental

After the treating with a mixture of concd H_2SO_4 and HNO_3 in order to remove unsaturated hydrocarbon impurities, cyclooctane was dried over $CaCl_2$ and distilled under a nitrogen atmosphere in the presence of metallic sodium. The 5 wt% supported noble metal catalysts (metals: Pd, Rh, and Ru; supports: carbon and alumina) were provided from N. E. Chemcat Co. Carbon-supported catalysts were preliminarily dried by heating in N_2 stream for about 1 h and under vacuum for about 30 min at 180 °C. All of the catalysts were pretreated with H_2 (1 atm, 180 °C, 30 min), followed by evacuation (180 °C, 10 min) before use.

All manipulations were carried out under a nitrogen atmosphere. The catalysts (0.2 mmol-metal) were suspended in cyclooctane (100 ml) in a Schlenk tube (200 ml). The suspension was heated with an oil bath (180 °C) and kept boiling at 151 °C. After the suspension began to boil, the amount of evolved gas was measured by a gas buret (50 ml) through a reflux condenser; the gas composition was analyzed by gas chromatography using an active carbon column. After the reaction, the solution from which the catalyst was removed by sedimentation was analyzed by GC (OV-1 and PEG-20M capillary columns).

Results and Discussion

Dehydrogenation of Cyclooctane under Boiling and Refluxing Conditions. The time courses of gas evolution are shown in Fig. 1. Hydrogen was yielded exclusively with the Pd/C catalyst, whereas the Ru/Al_2O_3 catalyst gave methane as a by-product at a 10% level. Gaseous products from the other four catalysts were mainly hydrogen and methane (under 0.2%). On the other hand, only cyclooctene was detected as the dehydrogenation product in the liquid phase. The amounts of hydrogen and cyclooctene produced after a 24 h reaction are show in Table 1. The stoichiometric coincidence was satisfactory. Since the turnover number (per metal-mol) was apparently over 1, the reaction of alkane dehydrogenation (Eq. 1) was demonstrated to proceed catalytically, even under

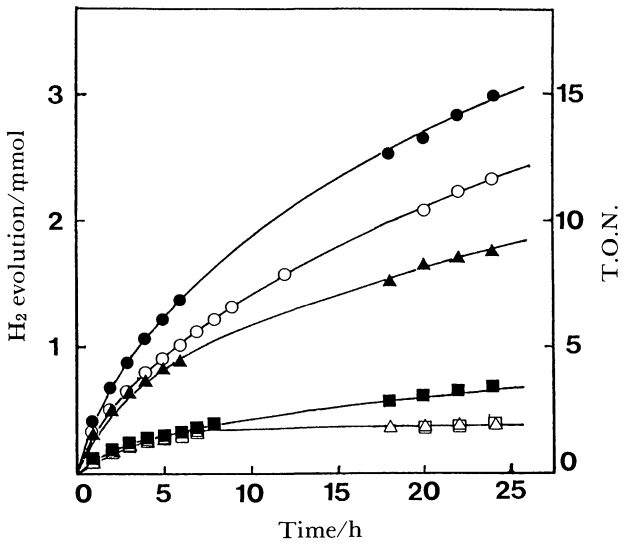


Fig. 1. Time-course plots of H_2 evolution from cyclooctane suspended with Pd (5%)/C (●), Pd (5%)/Al_2O_3 (○), Rh (5%)/C (▲), Rh (5%)/Al_2O_3 (△), Ru (5%)/C (■), and Ru (5%)/Al_2O_3 (□) at the concentration of 0.2 mmol metal/100 ml under boiling and refluxing conditions (151 °C).

Table 1. Dehydrogenation Products of Cyclooctane with Suspended Noble Metal Catalyst under Boiling and Refluxing Conditions

Catalyst	H_2/mmol	Cyclooctene/mmol
Pd (5%)/C	2.97	2.88
Pd (5%)/Al_2O_3	2.30	2.20
Rh (5%)/C	1.74	1.57
Rh (5%)/Al_2O_3	0.37	0.36
Ru (5%)/C	0.59	0.52
Ru (5%)/Al_2O_3	0.36	0.34

Catalyst concentration: 0.2 mmol metal/100 ml; Reaction temperature: 151 °C; Reaction time: 24 h.

mild conditions at 151 °C.

The activity order was Pd>Rh>Ru,[7] where the carbon-supported catalysts were more active than the alumina-supported ones. This activity order among metals was completely different from that of 2-propanol dehydrogenation (Ru>Rh>Pt>Pd),[8] and rather similar to that of cyclohexanol dehydrogenation (Pd>Rh>Pt>Ru).[9] Since the reaction temperatures (boiling point) of cyclooctane (151 °C) and cyclohexanol (161 °C) are comparable, whereas that of 2-propanol (82.4 °C) is considerably low, the low reaction rate for the Pd catalysts to evolve hydrogen from 2-propanol may be ascribed to the high stability of hydrogen in the metal hydride phase at low-temperature regions.[10]

Retardation Effects of Added Cyclooctene. The retardation effects of product cyclooctene on the reaction rates were examined about Pd/C, Pd/Al_2O_3, and Rh/C catalysts, which exhibited relatively high activities. Figure 2 shows the time courses of hydrogen evolution from the suspensions containing cyclooctene at various concentrations with these catalysts. Little retardation was found for the most active Pd/C catalyst, while the Pd/Al_2O_3 and Rh/C catalysts were considerably inhibited by added cyclooctene.

The relationship between the initial rates of hydrogen evolution (v) and the concentrations of added cyclooctene ([COE]) was analyzed with Eq. 3 while taking account of retardation due to cyclooctene adsorption.

$$v = k/(1 + K[\mathrm{COE}]). \quad (3)$$

As shown in Fig. 3, plots of $1/v$ and [COE] gave straight lines; the values of k and K are summarized in Table 2. The order of the rate constant (k) was Pd/C>Pd/Al_2O_3>Rh/C, whereas the retardation con-

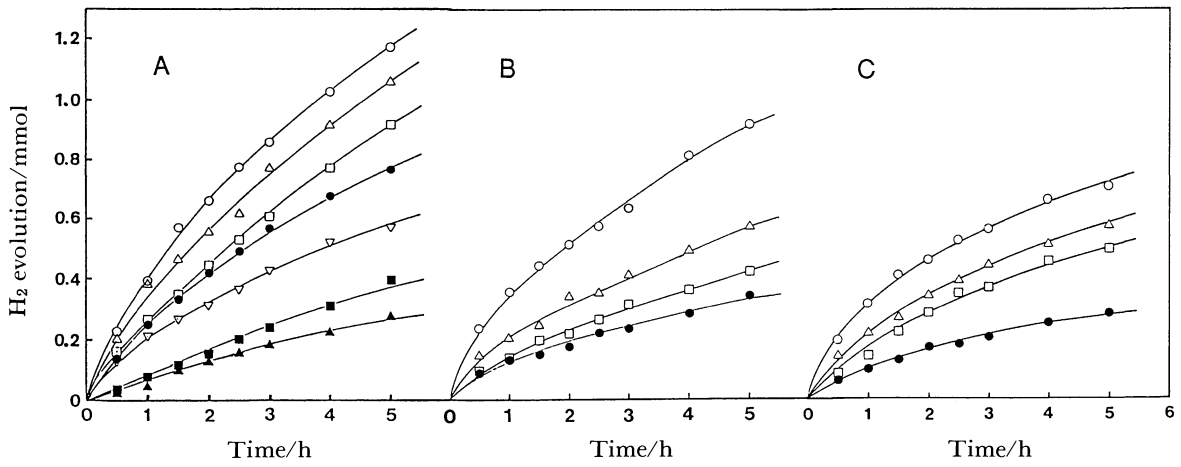

Fig. 2. Effect of cyclooctene addition on H_2 evolution from cyclooctane suspended with noble metal catalysts (0.2 mmol metal/100 ml) under boiling and refluxing conditions (151 °C). Catalyst: (A) Pd/C, (B) Pd/Al_2O_3, and (C) Rh/C. Addition of cyclooctene: 0 μl (○), 25 μl (△), 50 μl (□), 100 μl (●), 150 μl (▽), 300 μl (■), and 450 μl (▲).

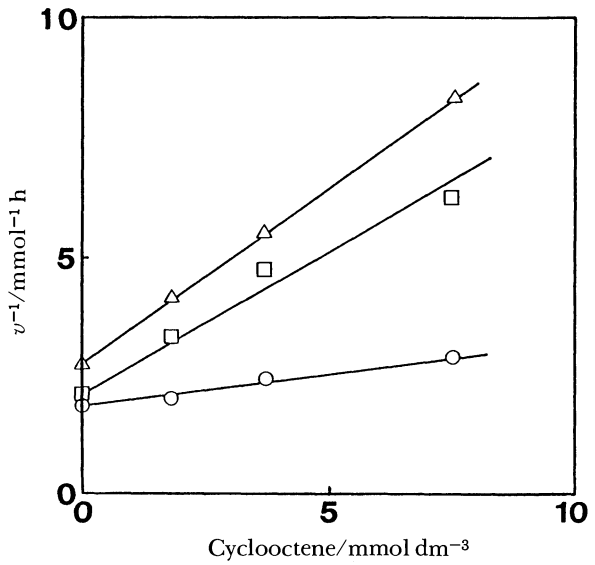

Fig. 3. Rate retardation due to cyclooctane analyzed with equation 3 for Fig. 2. Catalyst: Pd/C (○), Pd/Al_2O_3 (□), and Rh/C (△).

Table 2. Rate Constant (k) of Cyclooctane Dehydrogenation and Retardation Constant due to Cyclooctene Absorption (K) Calculated from Fig. 3

Catalyst	k/mmol h^{-1} g^{-1}	K/mmol^{-1} dm^3
Pd/C	26	0.075
Pd/Al_2O_3	22	0.270
Rh/C	17	0.250

stant (K) of the Pd/C catalyst was extremely smaller than those of the other catalysts, indicating the facile desorption of alkene from the Pd/C catalyst surface.

Rate Retardation Caused by 1-Nonene Addition. 1-Nonene (0.58 mmol, corresponding to the amount of added cyclooctene in the former section) was added to cyclooctane suspended with the Pd/Al_2O_3 catalyst, since this catalyst exhibited a relatively high activity for cyclooctane dehydrogenation and rate retardation due to added cyclooctene. Hydrogen evolved from a solution containing 0.58 mmol of 1-nonene and from one containing 0.78 mmol of cyclooctene; after reaction for 3 h it amounted to 0.20 mmol and 0.24 mmol, respectively, indicating that the rate retardations caused by these alkenes are comparable to each other.

Figure 4 shows the amounts of hydrogen evolved and the reaction products in solution, allowing a comparison of the effect of added 1-nonene with that of no alkene added.

Both hydrogen evolution (0.20 mmol) and intermolecular hydrogen transfer from cyclooctane to 1-nonene (0.30 mmol) proceeded simultaneously, while 1-nonene was isomerized exclusively to *cis*-2-nonene (0.11 mmol). It is noteworthy that the intermolecular hydrogen transfer proceeds more rapidly than does

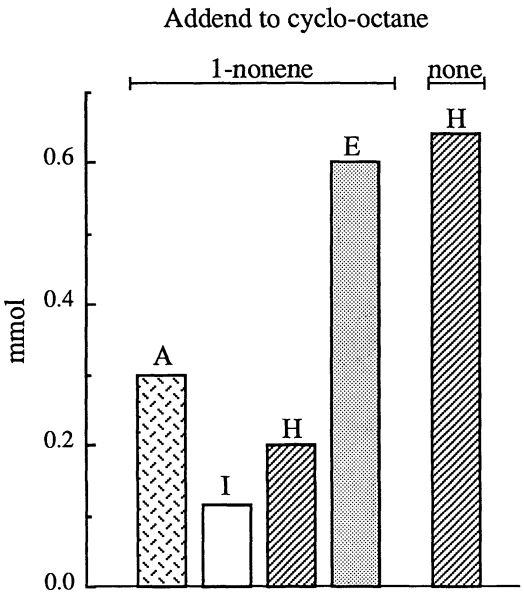

Fig. 4. Effect of alkene addition to hydrogen evolution or transfer from cyclooctane with suspended Pd catalyst under boiling and refluxing conditions. H: hydrogen, A: nonane, E: cyclooctene, I: isomerized nonene (exclusively *cis*-2-nonene). Catalyst: Palladium (5%)/alumina 0.2 mmol. Substrate: Cyclooctane (100 ml). Added alkene: 1-nonene (0.58 mmol). Reaction temperature: 151 °C, Reaction time: 3 h.

isomerization. The total amounts of nonane and hydrogen (0.5 mmol) were nearly equal to that of cyclooctene (0.60 mmol) produced. The coincidence of these magnitudes with that of hydrogen evolved from alkene-free cyclooctane (0.64 mmol) indicates that both hydrogen evolution and transfer proceed at common active sites.

Reaction Mechanism of Dehydrogenation. The mechanism of alkane dehydrogenation on heterogeneous catalysts, yielding alkene and molecular hydrogen via adsorbed species on the active site (ads), has been proposed at high temperature regions:[11]

$$\text{alkane} \longrightarrow \text{alkane(ads)}, \quad (4)$$

$$\text{alkane(ads)} \longrightarrow \text{alkyl(ads)} + \text{H(ads)}, \quad (5)$$

$$\text{alkyl(ads)} \longrightarrow \text{alkene(ads)} + \text{H(ads)}, \quad (6)$$

$$\text{alkene(ads)} \longrightarrow \text{alkene}, \quad (7)$$

and

$$2\text{H(ads)} \longrightarrow \text{H}_2. \quad (8)$$

As for dehydrogenation using homogeneous catalysts, the reaction schemes on the reductive elimination of ligand hydrides under photoirradiation, as well as thermal hydrogen transfer from alkane to alkene and the photocatalytic cycle of hydrogen evolution from alkane, have been discussed.[12] In view of endother-

micity, the evolution of molecular hydrogen from the hydride intermediate species is more difficult than hydrogen transfer to alkane.

Nonane formation from 1-nonene by the intermolecular hydrogen transfer strongly suggests the possibility for a hydrogen species on the catalyst surface to react with not only 1-nonene, but also cyclooctene, which remains on the dehydrogenation site or is adsorbed from the solution bulk. Cyclooctane should be regenerated from the surface hydrogen species and cyclooctene by hydrogen-transfer, since nonane was formed from 1-nonene.

$$\text{alkene} \longrightarrow \text{alkene(ads)}, \quad (9)$$

$$\text{alkene(ads)} + 2\text{H(ads)} \longrightarrow \text{alkane}. \quad (10)$$

It is therefore reasonable to assume that the rate retardation for hydrogen evolution caused by alkenes is brought about from a consumption of adsorbed hydrogen species by forming alkane, in addition to the site-occupation effect, owing to alkene adsorption. Since they are commonly governed by the amounts of adsorbed alkene, these retardation effects are expressed by the same rate equation (Eq. 3). In view of the standard Gibbs energy changes, the hydrogen transfer from cyclooctane to 1-nonene or from cyclooctane to cyclooctene (Eq. 11) proceeds more rapidly than does hydrogen evolution (Eq. 2) in this reaction temperature region.

$$\text{alkane} + \text{alkene}' \longrightarrow \text{alkene} + \text{alkane}'. \quad (11)$$

Provided that the hydrogen evolution step (Eq. 8) is rate-determining in the hydrogen evolution reaction, the adsorbed hydrogen species would be abundant on the catalyst surface, being sufficiently supplied from cyclooctane. The exothermic and facile nonane formation from 1-nonene would surpass the endothermic molecular hydrogen formation from the surface hydrogen species. However nearly equal rates were observed for nonane formation and hydrogen evolution in the absence of alkene, indicating that the step of molecular hydrogen formation is preceded by the rate-determining step. With regard to the reaction of molecular hydrogen formation from cyclooctane using the suspended Pd/Al_2O_3 catalyst, it is therefore plausible that either C–H bond cleavage of cyclooctane or β-hydrogen elimination of the adsorbed cyclooctyl species is rate-determining.

Interactions between an Anionic Porphyrin and Cationic Surfactants in Water

Toshihiro TOMINAGA,* Satoshi ENDOH, and Hiroaki ISHIMARU
Department of Applied Chemistry, Okayama University of Science,
1-1 Ridai-cho, Okayama 700
(Received October 15, 1990)

Interactions between decyl-, dodecyl-, and tetradecyltrimethylammonium bromide (DeTAB, DTAB, and TTAB) and an anionic porphyrin, 5,10,15,20-tetrakis(4-sulfonatophenyl)porphine (H_2TPPS^{4-}), have been studied in water at 298.2 K. Precipitate formation constants between the surfactant cations and the H_2TPPS^{4-} anion have been obtained. The precipitates were resolubilized by a further addition of the surfactants at concentrations close to the critical micelle concentrations (cmc) in DeTAB, and below the cmc's in DTAB and TTAB solutions. Surface tension and conductance measurements show that the effects of H_2TPPS^{4-} on the cmc's are very small. The fluorescence of H_2TPPS^{4-} is quenched in both water and sodium dodecyl sulfate solutions by the methylviologen cation, but not in cationic surfactant solutions. The diffusion coefficients were measured in a system containing H_2TPPS^{4-} and TTAB; the results show the existence of large premicellar aggregates.

Because of their importance in biological and photochemical processes, porphyrins and metalloporphyrins have attracted much interest. Recently, water-soluble porphyrins have been shown to interact with 1,10-phenanthroline (phen) and pyridine derivatives,[1] amino acids,[2] and other ionic species.[3] Dimerization[4] and counterion-induced dimerization[5] of cationic and anionic porphyrins have been studied. Photoinduced electron-transfer and charge-separation processes have been studied extensively in microheterogeneous solutions including micelles and vesicles.[6–8] To understand these processes, an elucidation of the interactions of porphyrins with surfactants is essestial. Although there have been studies on the interactions between water-soluble porphyrins and polymers,[9,10] there have been no systematic studies on the interactions between ionic porphyrins and surfactants.

We report here on the interactions between an anionic porphyrin, 5,10,15,20-tetrakis(4-sulfonatophenyl)porphine (H_2TPPS^{4-}), and cationic surfactants in water. In acidic solutions, the predominant species of the porphyrin is H_4TPPS^{2-};[4b,9a] it tends to aggregate.[4a,4b] We have studied systems where H_2TPPS^{4-} is the predominant species. Measurements were made on precipitate formation and resolubilization concentrations, surface tension, conductance, fluorescence quenching , and diffusion coefficient. In a previous paper, we reported interactions between a metal chelate cation, $[Fe(phen)_3]^{2+}$, and anionic surfactants.[11] The present results are compared with the previous ones.

Experimental

Materials and Preparation of Solutions. H_6TPPS (Tokyo Kasei, specially prepared analytical reagent), sodium dodecyl sulfate (NaDS) (BDH, 99.0%), decyltrimethylammonium bromide (DeTAB), dodecyltrimethylammonium bromide (DTAB), and tetradecyltrimethylammonium bromide (TTAB) (Tokyo Kasei, guaranteed reagents) were used as received. Water was distilled twice. A stock solution of H_2TPPS^{4-} was prepared by neutralizing the H_6TPPS solution with NaOH. This solution was used to prepare buffered and nonbuffered solutions of the desired concentrations. The absence of H_4TPPS^{2-} was checked by the absorption spectrum, which showed a maximum at 413 nm, but no peak at 434 nm at the Soret bands.[12] Metalloporphyrin solutions were prepared by adding a trace amount of $Cd(NO_3)_2$ to the solution of H_2TPPS^{4-} as a catalyst,[13] and then adding equivalent amounts of the respective metal ions. The porphyrin and metalliporphyrin solutions were protected from light.

Measurements. All measurements were made at 298.2 K. For determining precipitate formation and the resolubilization concentrations, solutions of both H_2TPPS^{4-} and an alkyltrimethylammonium bromide were placed in a water thermostat controlled to ±0.1 K. After temperature equilibration, solutions of H_2TPPS^{4-} and the surfactant were mixed and replaced in the bath. The solubilization limit was determined by observing the presence or absence of precipitates, or turbidity. The absorption and fluorescence spectra were measured by using a Hitachi 228A spectrophotometer and a Hitachi F-2000 fluorescence spectrophotometer, respectively. The surface tensions of surfactant solutions were measured by using a De Nouy-type tensiometer (Furukawa Seisakusho). The solution conductivities were measured at 5 kHz by means of a linear-bridge conductometer (Huso Model 360 B) in an oil thermostat controlled to ±0.005 K.[11]

The diffusion coefficients were measured by the Taylor dispersion method.[14] In this method a small amount of solution is injected into a solvent flowing through a capillary tube. The solute is dispersed along the tube. From the concentration profile at the end of the tube the difussion coefficient can be calculated. For tracer diffusion measurements, the solvent flowing through the capillary contained a specified amount of TTAB; the injected solution contained the same amount of TTAB and 10 μM (1 M=1 mol dm^{-3}) H_2TPPS^{4-}. Because the H_2TPPS^{4-} concentration was well below that of TTAB, the diffusion coefficient could be taken as the tracer diffusion coefficient. (Note that the concentration of the solute is further diluted as it flows through the capillary tube.) For interdiffusion between metalloporphyrins, the solvent flowing through the capillary contained a spec-

ified amount of TTAB and 50 μM $[Mn^{III}(tpps)]^{3-}$; the injected solution contained the same amount of TTAB as the solvent and 50 μM $[M^{II}(tpps)]^{4-}$, where M stands for Cu or Ni. This was possible because $[Mn^{III}(tpps)]^{3-}$ has a weak absorption at 413 nm where $[Ni^{II}(tpps)]^{4-}$ and $[Cu^{II}(tpps)]^{4-}$ have an intense absorption. The concentration profile of the metalloporphyrin was monitored by spectrophotometric detectors, either Waters-490 or UVIDEC 100-IV. Other details concerning the measurements have been described.[11,15]

Results and Discussion

Precipitate Formation and Resolubilization. When a cationic surfactant was added to a fixed concentration of H_2TPPS^{4-}, a precipitate appeared, which was then resolubilized by a further addition of the surfactant. Figure 1 shows a phase diagram for precipitate formation and resolubilization for TTAB. Regions A and C correspond to clear solutions and region B corresponds to turbid (two-phase) systems. A similar phase diagram has been shown for the $[Fe(phen)_3]^{2+}$–DS^- system.[16] In an ammonium buffer (pH=8.0, I (ionic strength) =0.1 M), precipitate formation concentrations were larger and the resolubilization concentrations lower than in water. Figure 2 shows the effect of the surfactant chain length. With increasing surfactant chain length, both precipitate formation and resolubilization concentrations decrease. In Figs. 1 and 2, the cmc's of the surfactants determined from surface tension measurements are shown. For DTAB and TTAB, the resolubilization of the precipitate occurs at surfactant concentrations below their cmc's. This will be discussed later; we first examine the precipitate formation process. The precipitate formation reaction may be written as

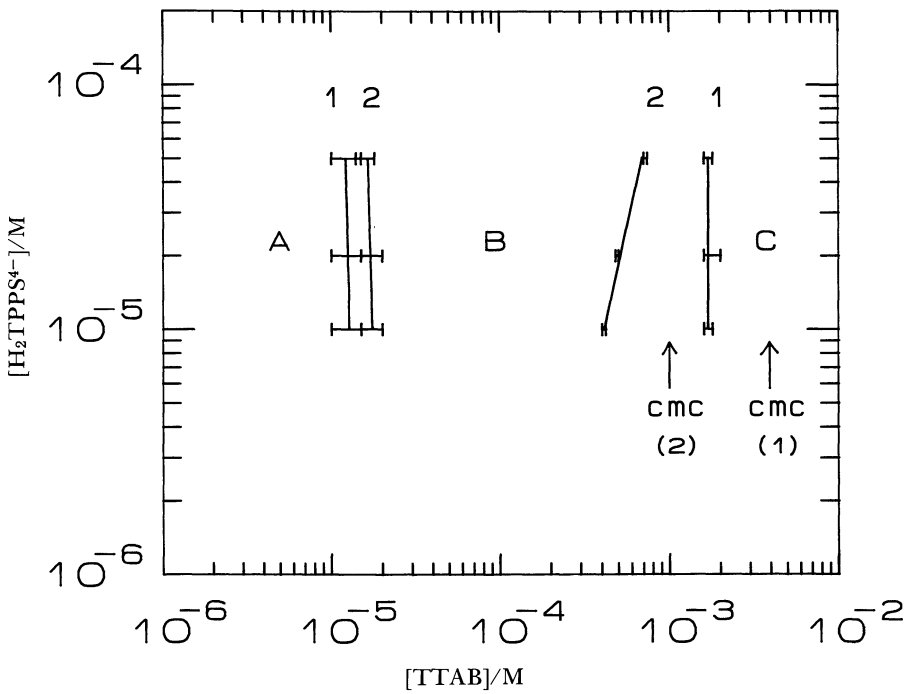

Fig. 1. Phase diagram for the precipitate formation and resolubilization for H_2TPPS^{4-} and TTAB at 298.2 K. Regions A and C correspond to the one-phase clear solutions and region B corresponds to the two-phase system. 1, In water (without added salt); 2, in ammonium buffer (pH=8.0, I=0.1 M). Arrows indicate cmc's of TTAB in water and in the ammonium buffer.

Table 1. Values of log K for the Precipitate Formation Reaction between C_nTA^+ and H_2TPPS^{4-} (Eq. 1) in Water at 298.2 K

Surfactant	log K		
	I=0.1 M[a]	No added salt	No added salt[b]
$C_{10}TAB$	18.19±0.12	19.82±0.17	13.37±0.36
$C_{12}TAB$	20.49±0.15	21.83±0.21	18.13±0.19

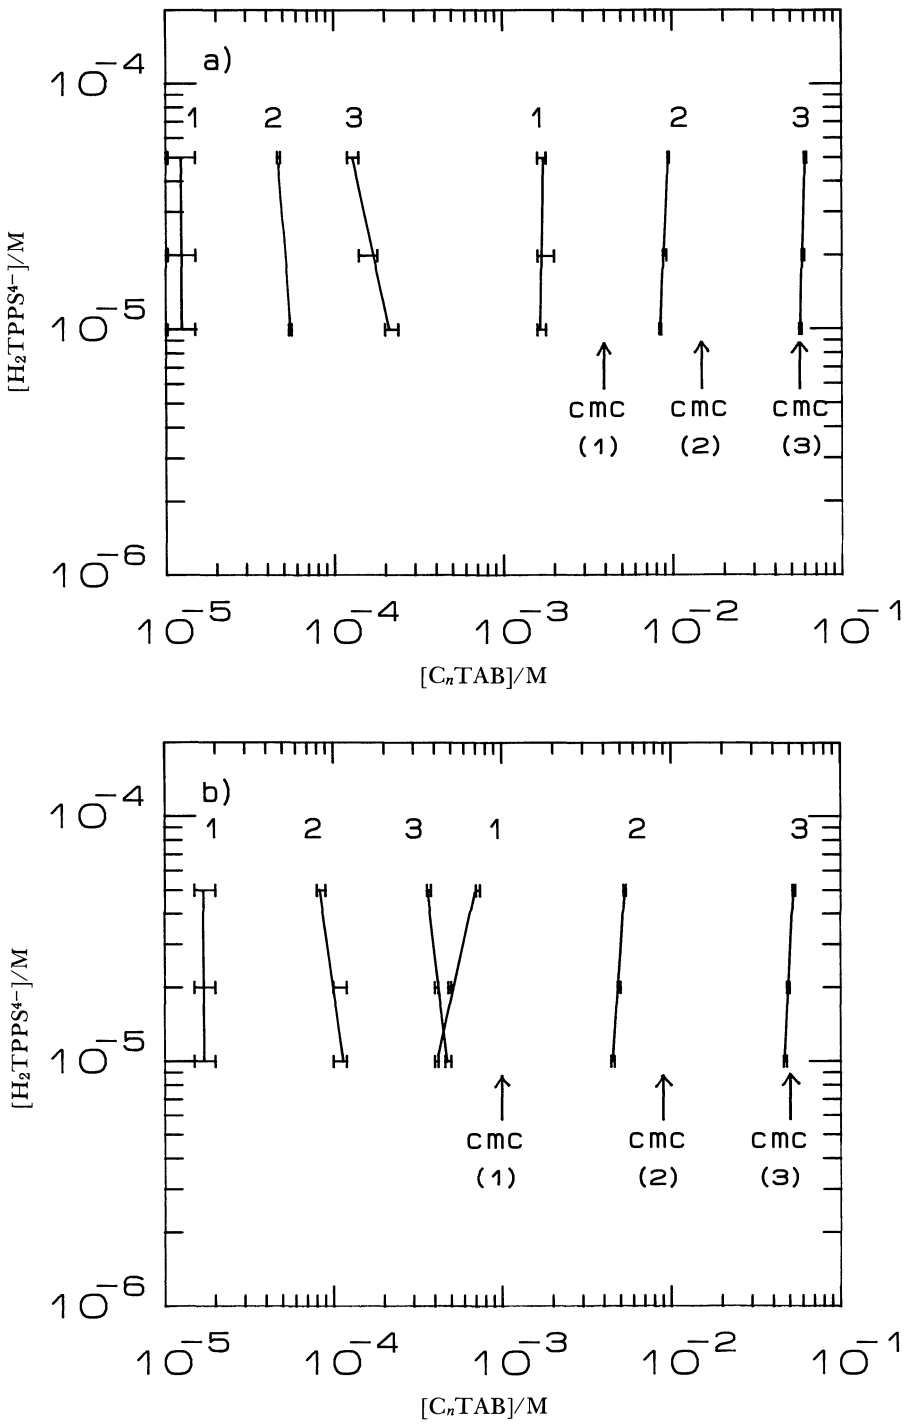

Fig. 2. Phase diagram for the precipitate formation and resolubilization for H_2TPPS^{4-} and TTAB (1), DTAB (2), and DeTAB (3) in water (without added salt) (a), and in ammonium buffer (pH= 8.0, I=0.1 M) (b) at 298.2 K. Arrows indicate cmc's of the respective surfactants.

$$4C_nTA^+ + H_2TPPS^{4-} \overset{K}{\rightleftharpoons} (C_nTA)_4 \cdot H_2TPPS, \quad (1)$$

where C_nTA^+ stands for $DeTA^+$ (n=10), DTA^+ (n=12), or TTA^+ (n=14), and $K=1/\{[C_nTA^+]^4[H_2TPPS^{4-}]\}$.

Table 1 lists the values of log K. The standard Gibbs energy of transfer from the aqueous state to the solid state can be calculated as

$$\Delta G^\circ_{aq\rightarrow solid} = -RT\ln K, \quad (2)$$

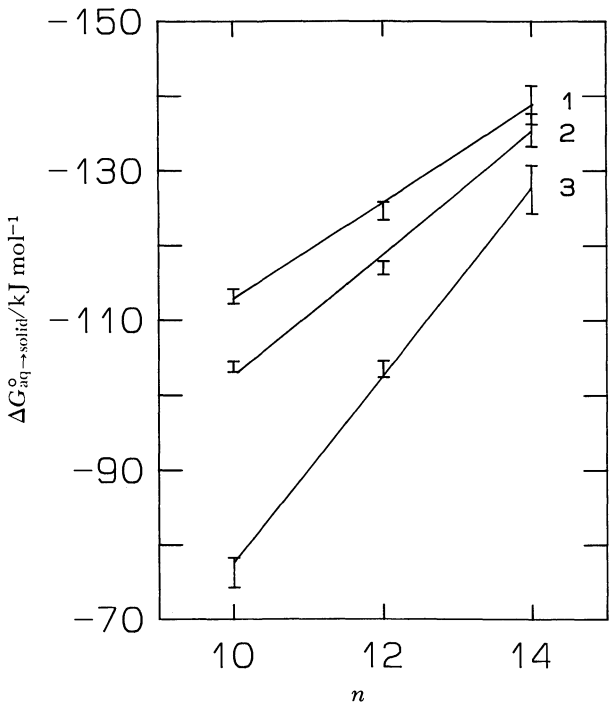

Fig. 3. Standard Gibbs energy of transfer of $(C_nTA)_4$·H_2TPPS and $(C_nTA)_4$·[Fe(bpso)$_3$] from the aqueous state to the solid state at 298.2 K. 1, $(C_nTA)_4$·H_2TPPS in water (without added salt); 2, $(C_nTA)_4$·H_2TPPS in ammonium buffer (I=0.1 M); 3, $(C_nTA)_4$·[Fe(bpso)$_3$] in water (without added salt).

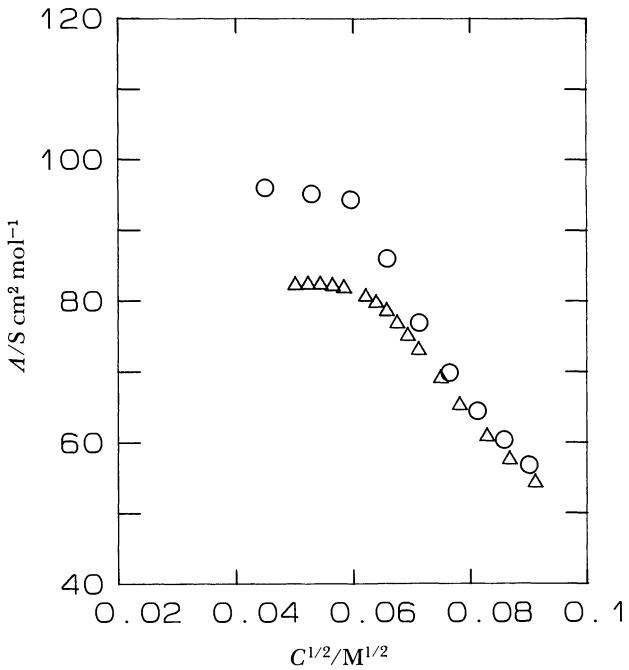

Fig. 4. Molar conductivities of TTAB in water (○) and in 0.1 mM H_2TPPS^{4-} solution (△) as a function of the TTAB concentration at 298.2 K.

where R is the gas constant. In Fig. 3, the $\Delta G^{\circ}_{aq\rightarrow solid}$ values are plotted against the surfactant chain length. The results may be regarded as being linear within experimental uncertainties. From the slopes, the values for $\Delta G^{\circ}_{aq\rightarrow solid}$ per methylene group can be obtained, and are −6.4 and −7.9 kJ mol^{-1} in the cases of no added salt and I=0.1 M (ammonium buffer, pH=8), respectively. Also shown in Fig. 3 is the result for $[Fe(bpso)_3]^{4-}$ (bpso=4.7-diphenyl-1,10-phenanthroline-disulfonate).[17] The $\Delta G^{\circ}_{aq\rightarrow solid}$ value for the methylene group for this system is −12.8 kJ mol^{-1}; it is twice as large as that for the H_2TPPS^{4-} case. This difference reflects differences in the standard Gibbs energy in the two kinds of solids.

Surface Tension and Conductivity. The cmc values shown in Figs. 1 and 2 were determined from the break point of the surface tension vs. concentration curve. They are 57 mM, 16 mM, and 4.0 mM in water, and 50 mM, 9.0 mM, and 1.0 mM in the ammonium buffer for DeTAB, DTAB, and TTAB, respectively. Resolubilization of the precipitate occurs at surfactant concentration below their cmc's for DTAB and TTAB, though it occurs close to the cmc's for DeTAB. In order to determine whether the cmc's decrease in the presence of H_2TPPS^{4-}, surface tension measurements were made for DTAB and TTAB solutions in the presence of 5×10^{-5} M H_2TPPS^{4-}. The results showed that the presence of H_2TPPS^{4-} had negligible effects on the cmc values. Figure 4 shows the molar conductivities of TTAB in the presence (0.1 mM) and absence of H_2TPPS^{4-}. From the break point, the cmc of TTAB in water is found to be 3.8 mM, which is close to the value obtained from the surface-tension measurement (4.0 mM). As can be seen from the figure, the break point is not lowered, even in the presence of 0.1 mM H_2TPPS^{4-}. These results suggest that, at surfactant concentrations below the cmc's and above the resolubilization concentrations, there is no "normal" micelle, but there are premicellar aggregates which may be expressed as $(TTA)_x(H_2TPPS)_yBr_z^{(x-4y-z)+}$. Premicellar aggregates have been known for other ionic dyes, and are sometimes called "dye-rich induced micelles."[18–20]

Fluorescence Quenching. In order to obtain information about premicellar aggregates, fluorescence quenching experiments were carried out. If H_2TPPS^{4-} is associated with cationic surfactants, a cationic quencher may have difficulty in approaching the H_2TPPS^{4-} ion. In addition to cationic surfactant solutions, measurements were also made in water and in NaDS solutions; the results are shown in Fig. 5. In the case of no surfactant, the plot for the quenching of H_2TPPS^{4-} (maximum at 640 nm) by the methylviologen ion (MV^{2+}) does not give a straight line. This reflects the fact that there are ion pairs between MV^{2+} and the ground state H_2TPPS^{4-}, and that static quenching in addition to dynamic quenching ocurrs.[6] In fact, Schmehl and Whitten have obtained a value of 647 M^{-1} for the ion-pair formation constant between

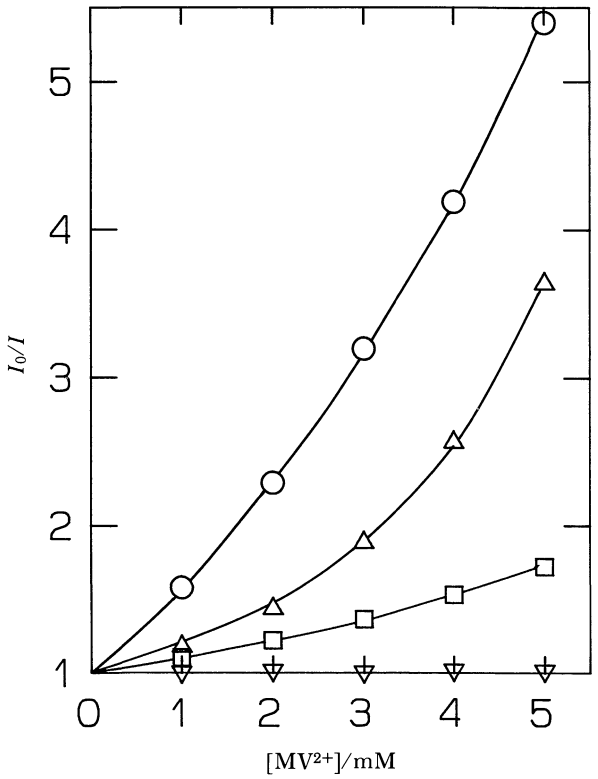

Fig. 5. Stern–Volmer plots for the quenching of H_2TPPS^{4-} by MV^{2+} in 0.1 M ammonium buffer (pH=8.0). ○, No surfactant; △, in 0.02 M NaDS; □, in 0.1 M NaDS; ▽, in 0.0005 M TTAB solutions at 298.2 K.

H_2TPPS^{4-} and MV^{2+} in 0.05 M NaCl.[6] In NaDS (0.02 M NaDS+0.05 M NaCl), although most of the MV^{2+} ions are bound to the micelles (>98%), they have estimated that the contribution to quenching is in the following order: static quenching>dynamic quenching by free MV^{2+}> dynamic quenching by micelle-bound MV^{2+}.[6] This makes plots in NaDS nonlinear also (Fig. 5). In 8 mM NaDS, the results were close to those in water (not shown in Fig. 5). With increasing NaDS concentration, the degree of quenching becomes smaller (Fig. 5), since more MV^{2+} ions are bound to the micelles.

In the case of 0.5 mM TTAB, fluorescence (maximum at 647 nm) is not quenched at all. It is unlikely that there are fewer free MV^{2+} ions in the TTAB solutions than in the NaDS solutions, since MV^{2+} ions must be less bound to TTA^+ ions than to NaDS micelles. The result therefore suggests that H_2TPPS^{4-} ions are associated with TTA^+ ions, and that the overall charge of an aggregate is positive. This prevents MV^{2+} ions from comming close to the H_2TPPS^{4-} ions and, as a result, electron transfer from the exited H_2TPPS^{4-} ion to the MV^{2+} ion does not occur. The results for 2 and 20 mM TTAB (above the cmc) and 10 mM DTAB (close to the cmc) also showed no quenching (not shown in Fig. 5).

Diffusion Coefficient. The final step in this study was to obtain information about the size of the aggregates. Figure 6 shows the tracer diffusion coefficients for H_2TPPS^{4-} and the interdiffusion

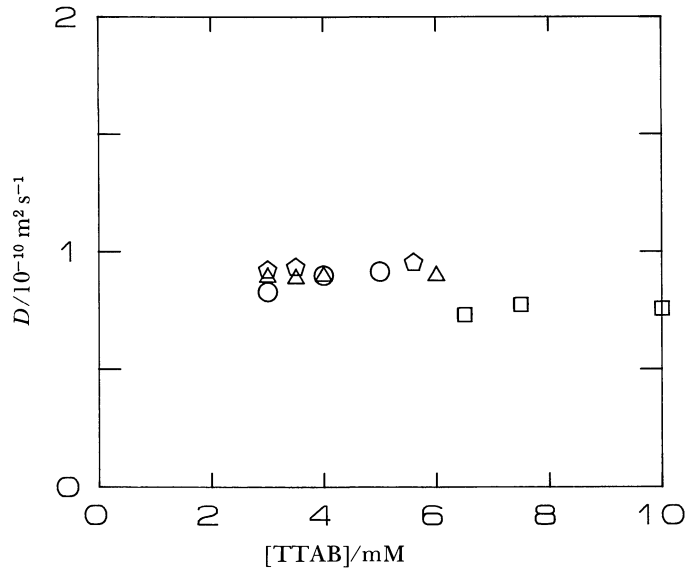

Fig. 6. Diffusion coefficients of H_2TPPS^{4-}, metalloporphyrins, and micelles in TTAB solutions at 298.2 K. ⬠, Tracer diffusion coefficients of H_2TPPS^{4-}; △, interdiffusion coefficients of $[Ni^{II}(tpps)]^{4-}$ and $[Mn^{III}(tpps)]^{3-}$; ○, interdiffusion coefficients of $[Cu^{II}(tpps)]^{4-}$ and $[Mn^{III}(tpps)]^{3-}$; □, tracer diffusion coefficients of the TTAB micelles.

coefficients for pairs of metalloporphyrins in TTAB solutions. When the TTAB concentration is zero, the tracer diffusion coefficient of the H_2TPPS^{4-} ion is 2.8×10^{-10} m^2 s^{-1} (not shown in Fig. 6), which was estimated from the limiting molar conductivity using the Nernst equation.[21] In 3—6 mM TTAB solutions, the tracer diffusion coefficient for H_2TPPS^{4-} is $(0.94\pm0.01)\times10^{-10}$ m^2 s^{-1}, and is significantly low when compared to the value in the absence of TTAB. The interdiffusion coefficient between $[M^{II}(tpps)]^{4-}$ (M=Cu or Ni) and $[Mn^{III}(tpps)]^{3-}$ in 3—6 mM TTAB is $(0.89\pm0.02)\times10^{-10}$ m^2 s^{-1}, and is close to the tracer diffusion coefficient for H_2TPPS^{4-}.[22] These values are compared with the tracer diffusion coefficient for the TTAB micelle, $(0.75\pm0.02)\times10^{-10}$ m^2 s^{-1} at 6.5—10 mM, which was obtained by measuring the diffusion of pyrene solubilized in the micelle.

By a comparison of the diffusion coefficients of the aggregate and the micelle (Fig. 6), the value of x must be large but smaller than 70, which is the agreegation number of the TTAB micelle.[23] In the case of a 3 mM TTAB solution, the mole ratio of TTA^+ to H_2TPPS^{4-} is 300 at the time of injection, and increases with time for tracer diffusion measurements, while the mole ratio of TTA^+ to $[M(tpps)]^{n-}$ (n=3 or 4) is 60 throughout the measurement for the metalloporphyrin interdiffusion cases. In the tracer diffusion case, therefore, there are sufficient TTA^+ ions to bind with the H_2TPPS^{4-} ion and form large aggregates. For the interdiffusion case, however, the maximum value of x is 60, where all TTA^+ ions are bound to $[M(tpps)]^{n-}$ ions. This suggests that the value of y is larger than one. Such kinds of premicellar aggregates are, as mentioned before, sometimes called "dye-rich induced micelles".[18—20] As we have seen, the tracer diffusion coefficients of H_2TPPS^{4-} and the interdiffusion coefficients of the metalloporphyrins are very close in magnitude. This suggests that the size of the premicellar aggregates of H_2TPPS^{4-}, $[M^{II}(tpps)]^{4-}$, and $[Mn^{III}(tpps)]^{3-}$ are similar.

Comparison with Related Studies. Schmehl and Whitten have found that precipitate formation and resolubilization occurs for H_2TPPS^{4-} and hexadecyltrimethylammonium chloride (CTAC).[6] They have mentioned that, in the presence of H_2TPPS^{4-}, micellization of CTAC occurs significantly below the cmc of CTAC in the absence of added ions. Although we have not studied CTAC, our results suggest that in the presence of H_2TPPS^{4-} although the cmc is not significantly changed (i.e., there is no normal micelle), the premicellar aggregates, each having at least one H_2TPPS^{4-} ion, exist below the cmc.

In a previous study, we measured the tracer diffusion coefficients for the $[Fe(phen)_3]^{2+}$ ion in anionic surfactant solutions.[11] In solutions of sodium 1-dodecanesulfonate (NaDSO), no precipitate forms between $[Fe(phen)_3]^{2+}$ and DSO^-, at least when the $[Fe(phen)_3]^{2+}$ concentration is lower than 2 mM and the DSO^- concentration is lower than 7 mM. The tracer diffusion coefficient of $[Fe(phen)_3]^{2+}$ (which is the tracer diffusion coefficient of the aggregate $Na_z[Fe(phen)_3]_x(DSO)_y^{(y-2x-z)-}$) decreased monotonically with increasing concentration of NaDSO. When NaDS is added to a fixed concentration of $[Fe(phen)_3]^{2+}$, precipitates of $[Fe(phen)_3](DS)_2$ form, which are resolubilized upon further addition of NaDS below its cmc. In 3—8 mM NaDS (below the cmc), the tracer diffusion coefficient of $[Fe(phen)_3]^{2+}$ (which is the tracer diffusion coefficient of the aggregate $Na_z[Fe(phen)_3]_x(DS)_y^{(y-2x-z)-}$) was lower than the tracer diffusion coefficient of the NaDS micelle. Although the cases of H_2TPPS^{4-} and TTAB are similar to that of $[Fe(phen)_3]^{2+}$ and NaDS, in that in both systems a precipitate forms which is then resolubilized below cmc's of the surfactants, the tracer diffusion of H_2TPPS^{4-}, i.e., that of the $(TTA)_x(H_2TPPS)_yBr_z^{(x-4y-z)+}$ aggregates, is not smaller than that of the tracer diffusion coefficient of the TTAB micelles.

It would be of interest to see if the diffusion coefficient of the premicellar aggregates between $[Fe(bpso)_3]^{4-}$ and TTAB is larger or smaller than that of the TTAB micelles. However, the resolubilization of the $(TTA)_4[Fe(bpso)_3]$ precipitates occurs at a TTAB concentration close to its cmc,[17] and we have not been able to tell the difference in the diffusion coefficients of the premicellar aggregates and the micelles.

The authors wish to thank Dr. Masaaki Tabata of Saga University for his helpful discussions. This work was partially supported by a Grant-in Aid for Scientific Research on Priority Area of "Molecular Approaches to Non-equilibrium Processes in Solutions" No. 02245101 from the Ministry of Education, Science and Culture.

12) When TTAB was added to an acidic solution containing H_4TPPS^{2-}, the absorption peak at 434 nm disappeared and the peak at 416—417 nm (2—4 mM TTAB), which corresponds to H_2TPPS^{4-}, appeared. It is worth noting that the total charge of the porphyrin increases in spite of the fact that the microscopic dielectric constant around the porphyrin decreases as a result of the interaction with TTAB. This means that what is important is microscopic charge of the central porphyrin ring, but not the total charge of the porphyrin. Similar result has been reported for the interaction of H_4TPPS^{2-} with poly(*N*-vinylpyrrolidone).[9a]

Preparation of Metallosilicates with ZSM-5 Type Structure by Atom-Planting Method

Kouji YAMAGISHI, Seitaro NAMBA,* and Tatsuaki YASHIMA
Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
(Received October 18, 1990)

Aluminosilicates, gallosilicates, and indosilicates with the ZSM-5 type structure were prepared by the "Atom-Planting method". The introduction of metal cations into the framework of highly siliceous ZSM-5 zeolites was confirmed by IR and unit cell volume measurements. The acidic properties of these metallosilicates were examined by pyridine-IR and NH_3-temperature programmed desorption spectroscopies. The increasing order of the acid strengths of the metallosilicates is indosilicate<gallosilicate<aluminosilicate.

The framework composition of molecular-sieve materials is an important factor which can affect the physical and chemical properties of these materials. An aluminosilicate zeolite offers the ion-exchange properties, high acidity, and shape-selective structural features desired by those working in the areas of adsorption and catalysis. However, modifications and subsequent improvements of these properties have served as a driving force for changing the composition of the zeolites. There have been many studies in which silicon or aluminium in the framework of synthetic zeolites were replaced by some elements such as B, Be, Cr, Ge, Fe, Ga, P, Ti, V, Zr, etc.[1] These molecular sieves are generally synthesized hydrothermally. Jacobs et al. have discussed the probability of an isomorphous substitution of an element on the basis of a simplified version of Pauling's minimum radius ratio; they concluded that molecular sieves having elements with ionic radii between 0.020 and 0.061 nm can be obtained.[2] Since trivalent ions, such as aluminium ions, replace tetravalent silicium ions at the tetrahedral framework positions, the framework bears a net negative charge, which must be compensated for by counter cations. Brønsted acid sites occur in metallosilicates when the cations balancing the framework anionic charge are protons. Chu and Chang have reported that the strength of Brønsted acid sites on a series of the metallosilicates with the ZSM-5 type structure increases according to B(OH)Si≪Fe(OH)Si<Ga(OH)Si<Al(OH)Si.[3]

It has been reported that aluminium atoms are introduced into the framework of a highly siliceous ZSM-5 zeolite by alumination with $AlCl_3$ vapor at elevated temperatures,[4–10] and that not only Brønsted acid sites, but also Lewis acid sites, are generated.[6–9] For the introduction of aluminium into the framework, Chang et al. have reported that aluminium atoms can be introduced by the reaction of four terminal SiOH groups, the so-called "hydroxyl nest", with $AlCl_3$.[4] We have also discussed the mechanism for alumination, suggesting that aluminium atoms can be introduced into defect sites (including the hydroxyl nests) of the framework.[9,10] Kraushaar et al. have carried out a silylation of the highly siliceous ZSM-5 with trimethylchlorosilane, analyzed the products by ^{29}Si cross polarization MAS NMR, and proposed the existence of hydroxyl nests in the zeolitic framework.[11]

If some atoms other than silicon and aluminium can be introduced into the defect sites of the framework by treatments with metal chloride at elevated temperature, it will be possible to obtain metallosilicates. We call the preparation method the "Atom-Planting method". We have succeeded in obtaining an antimonosilicate with the ZSM-5 type structure by means of this atom-planting method.[12] The antimonosilicate has never been synthesized hydrothermally, probably because the antimony(III) cation is too large (0.090 nm). In a similar way, Kraushaar and van Hooff have reported that titanosilicate can be prepared by a subsequent dealumination of a ZSM-5 zeolite having a relatively high aluminium content with hydrochloric acid and reaction with titanium tetrachloride vapor at high temperatures.[13]

In this paper, we report that the preparation of not only aluminosilicate, but also gallosilicate and indosilicate, with the ZSM-5 type structure by the atom-planting method. Moreover, we discuss the acidic properties of these metallosilicates.

Experimental

Materials. High-purity grade gallium trichloride and indium trichloride were used without further purification. Aluminium trichloride was sublimed in order to remove any impurities. High-purity grade pyridine was thoroughly degassed several times by condensing with liquid nitrogen, and then evacuated and melted before use.

The parent highly siliceous ZSM-5 zeolite was prepared in the laboratory as previously described.[14] The Si/Al atomic ratio of the parent ZSM-5 zeolite was 870.

Atom-Planting Procedure. A 2 g sample of the parent highly siliceous ZSM-5 zeolite (powder form) was placed in a vertical quartz tube reactor and dehydrated for 4 h at 773 K in a stream of dry helium. After dehydration, the temperature was brought to an atom-planting temperature, 923 K; dry helium was then passed through a metal chloride container. The metal chloride container was heated to achieve a vapor pressure of 11 kPa. The gas line between the container and the reactor was heated to prevent vapor condensation. The

parent ZSM-5 was treated with metal chloride for 2 h and then purged with dry helium at the atom-planting temperature for 1 h to remove any residual metal chloride. The samples, thus treated, were then cooled to room temperature in dry helium stream. These samples were transformed into the NH_4^+-form by a cation-exchange procedure with 0.1 M NH_4NO_3 at 343 K for 36 h (1 M=1 mol dm^{-3}), washed with a large amount of deionized water and then dried in air at 383 K for 16 h.

Analysis of Samples. The amounts of metals in the bulk phase were determined by atomic absorption spectrophotometry. X-Ray diffraction was used to determine the crystallinity and unit-cell volumes of samples. Lead nitrate was used as an internal standard for the determination of the unit-cell volumes. The surface area of the samples were determined by applying the N_2 adsorption method at 77 K.

Infrared Measurements. Infrared spectra were measured at 4 cm^{-1} resolution on a JASCO IR-810 Spectrometer. The IR cell used was fitted with KBr windows and connected to a high-vacuum system. A 20 mg sample of the zeolite powder was accurately weighed, and then pressed into a 15 mm-diameter self-supported wafer. This wafer was placed in the IR cell and evacuated at 773 K for 1.5 h before measurements. In observations of adsorbed pyridine on samples, a wafer evacuated at 773 K for 1.5 h was exposed to pyridine vapor (1.3 kPa) at 423 K for 1 h; the IR cell was then evacuated at 423 K for 1 h, followed by desorption succesively at 523, 623, 673, 723, 773 K for 1 h in each case. All IR spectra were recorded at room temperature.

Temperature Programmed Desorption (TPD) of Ammonia. Ammonia-TPD experiments were performed using a conventional static-adsorption system connected to a quadrupole mass spectrometer through a high-vacuum line. Samples evacuated at 773 K for 1 h were exposed to a 21 kPa of ammonia gas at 423 K for 0.5 h, evacuated for 1 h at 423 K, and then cooled to room temperature. Spectra were obtained at a heating rate of 10 K min^{-1} from 314 to 848 K.

Results and Discussion

Preparation of Metallosilicates. The amounts of metals in the bulk phase of the atom-planted samples are shown in Table 1. The samples planted with aluminium, gallium, and indium are denoted by AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z, respectively. The order of the amounts of introduced metals in the bulk phase were AP(Al)-Z>AP(Ga)-Z>AP(In)-Z, when these samples were prepared under the same conditions. Samples treated with metal chlorides were rinsed with 0.1 M NH_4NO_3. Therefore, the introduced metals existed in the framework sites of the ZSM-5 zeolite and/or non-framework sites except ion-exchange sites. These atom-planted sample were checked by powder X-ray diffraction for crystallinity, which was uniformly good. Moreover, the surface areas of the atom-planted samples were almost the same as that of the parent ZSM-5, as shown in Table 1. Consequently, the structure of the ZSM-5 zeolite was not destroyed by the atom-planting method.

Since trivalent ions are introduced into the tetrahedral framework sites, acidic OH groups responsible for the Brønsted acid sites should be generated. In addition, the frequency of the acidic OH groups in the IR spectra can be varied by substitution with Me^{3+} of different nature. The IR spectra in the hydroxyl stretching region for the parent highly siliceous ZSM-5 (Si/Al=870) and the atom-planted samples [AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z] are depicted in Fig. 1. The parent ZSM-5 (spectrum a) showed only one band at 3740 cm^{-1} due to non-acidic silanol groups.[15] The IR

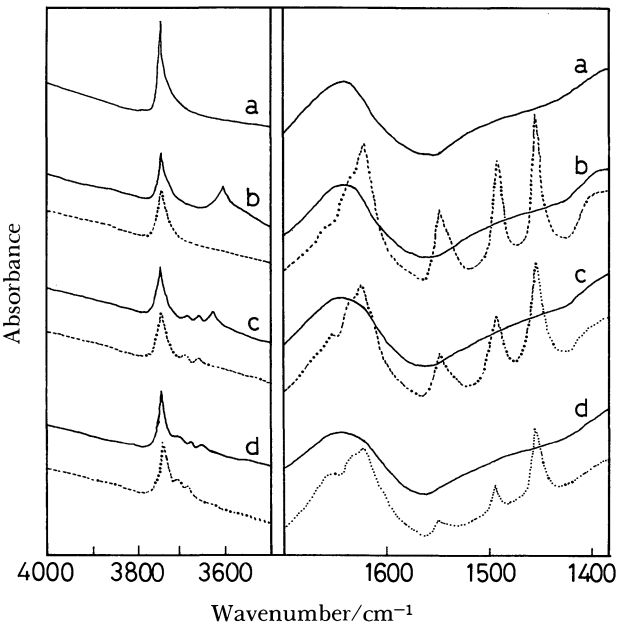

Fig. 1. Infrared spectra in the hydroxyl stretching region for parent ZSM-5 and the atom-planted samples: (a) parent (Si/Al=870), (b) AP(Al)-Z, (c) AP(Ga)-Z, (d) AP(In)-Z. Dotted lines show IR spectra following pyridine adsorption.

Table 1. Chemical and Physical Properties of the Samples Investigated

Sample	Metal concn / mmol g^{-1}	Surface area / m^2 g^{-1}	Unit-cell Dimensions/Å a	b	c	Vol/Å^3	Amount of acid sites/mmol g^{-1}
Parent ZSM-5	0.02 (Al)	448	20.22	20.11	13.08	5320	0.01
AP(Al)-Z	0.74 (Al)	415	20.28	20.18	13.04	5336	0.29
AP(Ga)-Z	0.30 (Ga)	422	20.32	20.10	13.11	5354	0.16
AP(In)-Z	0.24 (In)	431	20.40	20.09	13.13	5382	0.14

spectrum for the AP(Al)-Z exhibited a new band at 3610 cm^{-1} together with the band at 3740 cm^{-1}. The 3610 cm^{-1} band is attributed to the framework Al(OH)Si groups responsible for Brønsted acid sites.[15] In the IR spectrum of pyridine adsorbed on AP(Al)-Z, we observed an absorption band at 1545 cm^{-1}, which was attributed to pyridinium ion;[16] the absorption band at 3610 cm^{-1} disappeared. These facts show the introduction of the Al^{3+} into the framework by the atom-planting method.

The IR spectrum for the AP(Ga)-Z exhibited new bands at 3625, 3660, and 3690 cm^{-1} together with the band at 3740 cm^{-1}. On the IR spectrum of pyridine adsorbed on the AP(Ga)-Z, we observed the 1545 cm^{-1} band; the band at 3625 cm^{-1} disappeared. Chu and Change have demonstrated that in a gallosilicate with the ZSM-5 type (MFI) structure, the H^+ form has a characteristic band at 3620 cm^{-1} attributable to the framework Si(OH)Ga.[3] These facts indicate the introduction of Ga^{3+} into framework by the atom-planting method.

The spectrum of the AP(In)-Z exhibited new bands at 3650, 3680, and 3705 cm^{-1}, together with the 3740 cm^{-1} band. In the IR spectrum of pyridine adsorbed on the AP(In)-Z, we observed the 1545 cm^{-1} band; the 3650 cm^{-1} band disappeared. This fact suggests that the introduction of In^{3+} into the framework by the atom-planting method.

When aluminium, gallium, and indium atoms are introduced into the framework of the parent ZSM-5, the unit-cell volumes of the atom-planted samples should become more than that of the parent ZSM-5, because the ionic radii of Al^{3+} (0.053 nm), Ga^{3+} (0.061 nm), and In^{3+} (0.076 nm) are larger than that of Si^{4+} (0.040 nm). As shown in Table 1, the unit-cell volumes of these atom-planted samples were more than that of the parent ZSM-5. These facts also suggest that aluminium, gallium, and indium are introduced into the framework. From these results, it is apparent that aluminosilicate, gallosilicate, and indosilicate with the ZSM-5 type structure can be prepared by the atom-planting method.

The bands at 3660 and 3690 cm^{-1} for the AP(Ga)-Z, and at 3680 and 3705 cm^{-1} for the AP(In)-Z were attributed to non-acidic OH groups, since these bands were not affected by the adsorption of pyridine. Metal atoms may be introduced not only into the framework sites, but also into the non-framework sites, as was observed in the case of the aluminium-planting.[9] The bands responsible for the non-acidic OH groups may be due to some hydroxylated metal-containing species in the non-framework. In the spectra of the pyridine adsorbed on the AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z, we also observed the adsorption band of the pyridine coordinated with Lewis acid sites at 1455 cm^{-1}.[16] These facts indicate that not only Brønsted acid sites but also Lewis acid sites are generated by the atom-planting method. A part of metal introduced into the non-framework sites may be responsible for the Lewis acid sites.

We have discussed the mechanism for alumination (Al-planting) of the highly siliceous ZSM-5 with $AlCl_3$, and suggested that aluminium atoms are introduced into defect sites of the highly siliceous ZSM-5.[9,10] The amount of defect sites in the framework of highly siliceous ZSM-5 can be changed by controlling the synthetic conditions of the zeolites.[10,17] The amount of defect sites was measured through the exchange of oxygen isotopes between the zeolitic framework and $C^{18}O_2$.[10,17,18] When the plantings of gallium and indium into the highly siliceous ZSM-5 with a very small amount of the defect sites were carried out at 923 K, the adsorption bands attributed to the acidic OH groups could not be detected. Hence, gallium and indium could be poorly introduced into the framework of the highly siliceous ZSM-5 with a very small amount of the defect sites. Endoh et al. have reported the galliation of the highly siliceous ZSM-5 by a treatment with NaOH solution containing gallium ions, and concluded that the reactivity of the zeolite for the galliation may depend upon the amount of the defect sites.[18] Consequently, for the mechanism of the planting of gallium and indium atoms in the zeolitic framework, we suggest that gallium and indium atoms are planted solely in the defect sites of the zeolite.

We have also reported that a considerable amount of aluminium is introduced into the non-framework sites by alumination, and that the introduction of aluminium into the non-framework occurs by a reaction of the terminal SiOH groups on the external surface and/or non-intact Si–O–Si bonds with $AlCl_3$.[9,10] In the IR spectra, changes in the terminal SiOH region may provide information related to the mechanism of the introduction of atoms into the non-framework sites. We have reported that the band at 3740 cm^{-1} can be attributed not to hydroxyl nests (defect sites), but to both isolated SiOH groups on the external surface and intracrystalline isolated SiOH groups.[17] Due to the atom-planting, the intensity of the 3740 cm^{-1} band decreased. This fact suggests that a part of the metal atoms in the non-framework sites is caused by a reaction of the terminal SiOH groups on the external surfaces with metal chlorides.

The amount of the Brønsted acid sites may correspond to the amount of the metal in the framework sites. The relative amount of the Brønsted acid sites was roughly estimated on the basis of the integrated absorbances of the acidic OH bands. The area of the Al(OH)Si band for the AP(Al)-Z was about 2 times as much as that of the Ga(OH)Si band for the AP(Ga)-Z, and was about 5 times as much as that of the In(OH)Si band for the AP(In)-Z. These facts suggest the order of the amonts of metal atoms introduced into the framework were AP(Al)-Z>AP(Ga)-Z>AP(In)-Z,

although each parent ZSM-5 has the same amount of defect sites. This order may be explained as follows: the larger radius of metal cation corresponds to the lower thermostability of the metallosilicate or to the less amount of defect sites available for the atom planting.

Acidic Properties of Metallosilicates. The acidic properties of metallosilicates AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z were examined from the infrared spectra of the adsorbed pyridine and the spectra of temperature-programmed desorption for ammonia. In the IR spectra in the OH stretching region, we observed a band at 3610 cm^{-1} due to Al(OH)Si, a band at 3625 cm^{-1} due to Ga(OH)Si, and a band at 3650 cm^{-1} due to In(OH)Si. The fact that the 3625 cm^{-1} band due to Ga(OH)Si and the 3650 cm^{-1} band due to In(OH)Si appear at higher frequencies than the 3610 cm^{-1} band due to Al(OH)Si indicates that the OH bonds in the Ga(OH)Si and In(OH)Si are more covalent than those in the Al(OH)Si and, hence, less acidic.

The strength distribution of Brønsted and Lewis acid sites can be measured from the thermodesorption of pyridine. On IR spectra of pyridine adsorbed on metallosilicates, we can observe the absorption bands of pyridinium ion (PyH^+) at 1545 cm^{-1} and of the pyridine coordinated with Lewis acid sites (PyL) at 1455 cm^{-1}. As the desorption temperature increases, only pyridine molecules adsorbed on stronger sites will remain. Figure 2 shows the absorbances of the PyH^+ and PyL bands for the AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z after pyridine was desorbed at progressively higher temperatures. As shown in Fig. 2a, it is apparent that the order of the acid strength of Brønsted acid sites are In(OH)Si<Ga(OH)Si<Al(OH)Si. These results are consistent with the hypothesis from the IR spectra in the OH stretching region. In addition, as shown in Fig. 2b, it is apparent that these metallosilicates prepared by the atom-planting method have a large amount of Lewis acid sites, and that the order of the acid strength of Lewis acid sites are AP(In)-Z< AP(Ga)-Z<AP(Al)-Z.

The ammonia-TPD spectra for the AP(Al)-Z, AP(Ga)-A, and AP(In)-Z are depicted in Fig. 3. The spectrum for the AP(Al)-Z had not only a main peak at 543 K but also a shoulder peak at 643 K. We have reported that AP(Al)-Z has stronger acid sites than those on ZSM-5 zeolites, which are prepared by hydrothermal synthesis. The shoulder peak at 643 K indicates that the strong acid sites are generated by the

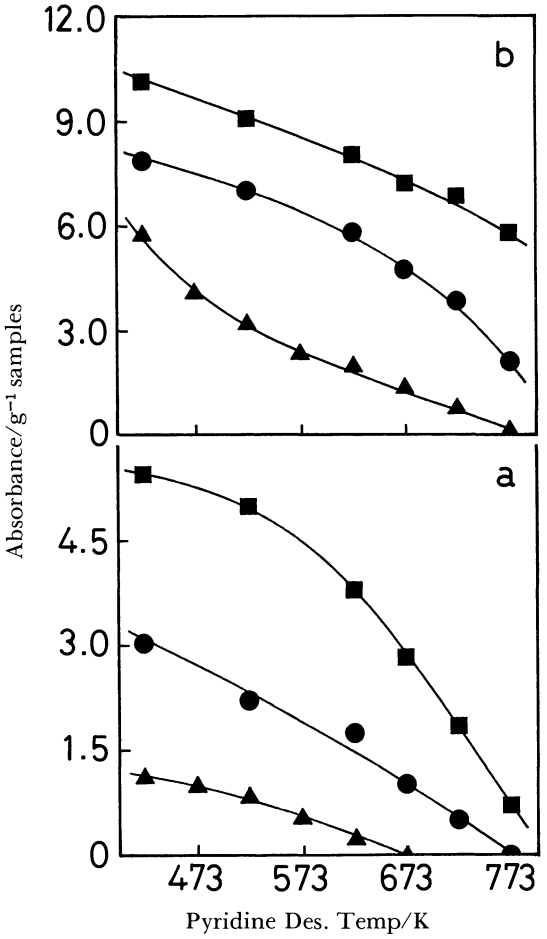

Fig. 2. Absorbance per gram of the AP(Al)-Z (■), the AP(Ga)-Z (●), and the AP(In)-Z (▲) on Brønsted acid sites (band at 1545 cm^{-1}); (a), and Lewis acid sites (band at 1455 cm^{-1}); (b), after desorption at 423—773 K.

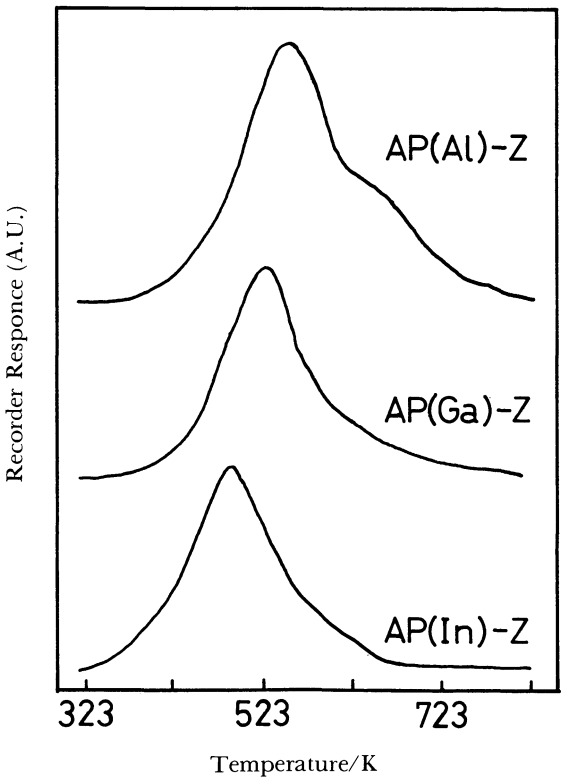

Fig. 3. NH_3-TPD spectra for the AP(Al)-Z, AP(Ga)-Z, and AP(In)-Z.

Al-planting. The spectra for the AP(Ga)-Z and for the AP(In)-Z had a single peak at 523 K and a single peak at 483 K, respectively. These facts indicate that the acid strength of the metallosilicates is ordered as follows: AP(In)-Z<AP(Ga)-Z<AP(Al)-Z.

The amount of acid sites was evaluated from the amount of ammonia desorbed during the TPD measurements. The evaluated amounts of acid sites on the metallosilicates are given in Table 1, together with the amounts of bulk metals. The amount of metal in the bulk phase was 1.7—2.5 times as much as that of the acid sites. Therefore, a part of the introduced metals does not contribute to the generation of the Brønsted or Lewis acid sites.

Detection of Surface Resistance in a Gas/Porous-Adsorbent System by Frequency Response Method

Yusuke YASUDA
Faculty of Science, Toyama University, Toyama 930
(Received August 1, 1990)

The frequency-response (FR) method for studying an X⇌C system (Yasuda, 1982) has been extended to an $X \overset{I}{\rightleftharpoons} A \overset{II}{\rightleftharpoons} C$ system, where X denotes a molecule in the gas phase, A is an adspecies on the external surface of a porous adsorbent, and C is an adspecies within micropores. Based on the characteristic functions for a system derived analytically, it is shown that both rate constants for steps I and II can be determined separately from the FR data. According to actual data of CH_4/5A zeolite systems, it has been confirmed that both the adsorption and desorption rate constants for step I, k_a and k_d, respectively, and also the Fickian diffusional time constant at step II, $\widetilde{D}$, can be evaluated. The present method is expected to provide quantitative information conerning the existence and intensity of surface barriers of zeolite crystals.

A frequency-response (FR) method has been applied in order to determine the Fickian diffusivity in zeolite crystals of a pure gas[1] and a binary gas mixture.[2] With zeolites, however, the transport resistance of an adsorbate at the outside of individual crystals occurs due to deposition of an impenetrable material, hydrothermal pretreatment,[3,4] or changes in the crystal structure by a chemical vapor deposition method.[5] Therefore, studying the 'skin' effects seems of interest not only in fundamental research[6] but also regarding industrial applications. Although a micro-dynamic model has recently been proposed for describing the mass-transfer resistance,[7] the six parameters involved in the model seem to be too many to be determined by traditional methods based on time-response data.

The FR method is compared with the standard methods in Table 1, the important characteristic of which is in the volume variation illustrated in Fig. 1; since this method is a resonance-type method, both rate processes during steps I and II could be investigated.

After equilibrium was attained, the gas space of the system V is changed sinusoidally as

$$V(t) = V_e(1 - ve^{i\omega t}), \tag{1}$$

where V_e denotes the equilibrium volume, $v(\ll 1)$ the relative amplitude of the volume change, and ω the angular frequency. The response of the system may be observed in terms of pressure variation, which can generally be expressed by

$$P(t) = P_e\{1 + pe^{i(\omega t + \varphi)}\}, \tag{2}$$

where P_e denotes the equilibrium pressure, p the relative amplitude of the pressure variation, and φ the phase lag between the volume and pressure variation. The dependence of p and φ on ω would reflect the kinetic behavior of the system.

In the present article a theoretical treatment for the system given in Fig. 1 is carried out and some actual data concerning CH_4/5A systems are analyzed in order to confirm the applicability of this new method.

Table 1. Classification of Various Experimental Methods

	Non-equilibrium	Equilibrium
Time-response	Uptake-rate Method Chromatographic Method	NMR Method
Frequency-response		FR Method

Theoretical

Characteristic Functions. The FR of the system may be given by the following in-phase and out-of-phase components, respectively:

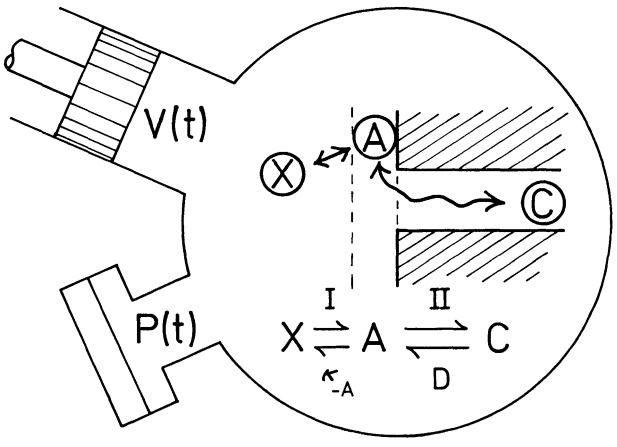

Fig. 1. Schematic diagram of the FR method applied to an X⇄A⇄C system; X denotes the adsorbate in the gas phase, A is the adspecies on the external surface, and C is the adspecies within the porous adsorbent. By measuring the pressure response $P(t)$ to the volume change $V(t)$, the two rate constant κ_{-A} and D at the steps I and II may be determined.

$$(v/p)\cos\varphi - 1 = K \cdot f_c(\omega) \tag{3}$$

and

$$(v/p)\sin\varphi = K \cdot f_s(\omega), \tag{4}$$

where K denotes the asymptote of the in-phase component as $\omega \to 0$. The value of K is expected to agree with K_e given by[1,8]

$$K_e = \left(\frac{RT_0}{V_e}\right)\left\{\frac{d(A+C)}{dP}\right\}_e, \tag{5}$$

where $\{d(A+C)/dP\}_e$ is the gradient of the adsorption isotherm and (RT_0/V_e) is the conversion factor; adspecies on the external surface are denoted by A(and/or B); the adspecies within the porous media are denoted by C.

In the extreme case, where either step I or II is rate-controlling, the present X⇌A⇌C system may be regarded as being an X⇌A or X⇌C system, each of which has been considered previously.[1,8] On the basis of these results, the present complex system can be analytically treated as follows:

(1) In the case of X⇌A, the time course of the A species, $A(t)$, associated with those of $V(t)$ and $P(t)$ in Eqs. 1 and 2 may be described by (Appendix 1)

$$A(t) = A_e[1 + m\{\alpha_c(\kappa_{-A}; \omega) - i\alpha_s(\kappa_{-A}; \omega)\}pe^{i(\omega t + \varphi)}], \tag{6}$$

where

$$m \equiv (d\ln A/d\ln P)_e \tag{7}$$

and A_e denotes the amount of A species at equilibrium.

The FR data of systems f_c and f_s may be expressed in this case by

$$f_c(\omega) = \alpha_c(\kappa_{-A}; \omega) \tag{8}$$

and

$$f_s(\omega) = \alpha_s(\kappa_{-A}; \omega), \tag{9}$$

where the characteristic functions, α_c and α_s, involving one parameter κ_{-A} are given by

$$\alpha_c(\kappa_{-A}; \omega) = \kappa_{-A}^2/(\kappa_{-A}^2 + \omega^2) \tag{10}$$

and

$$\alpha_s(\kappa_{-A}; \omega) = \kappa_{-A}\omega/(\kappa_{-A}^2 + \omega^2). \tag{11}$$

These functions are illustrated in Fig. 2.

2) A more complex system of X⇌A⇌B containing a precursor, A, has also been considered.[8]

The FR data of the system may be described by (Appendix 2)

$$f_c(\omega) = \alpha\alpha_c(\kappa_{-A}, \kappa_{-B}; \omega) \tag{12}$$

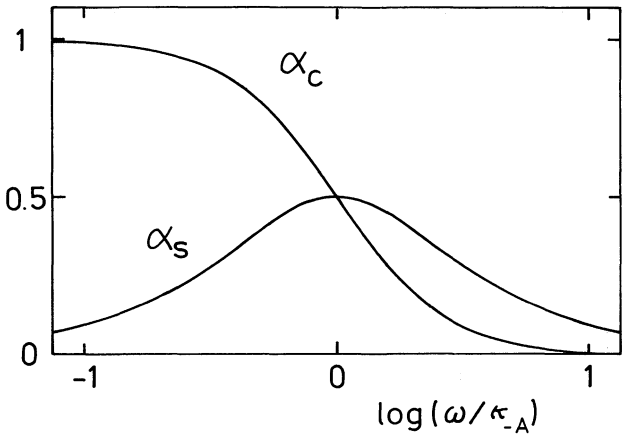

Fig. 2. Characteristic functions for an X⇄A system, $\alpha_c(\kappa_{-A}; \omega)$ and $\alpha_s(\kappa_{-A}; \omega)$; the system corresponds to the extreme case of step I being rate-controlling in Fig. 1.

and

$$f_s(\omega) = \alpha\alpha_s(\kappa_{-A}, \kappa_{-B}; \omega), \tag{13}$$

where the characteristic functions, $\alpha\alpha_c$ and $\alpha\alpha_s$, involving two parameter κ_{-A} and κ_{-B} are given by

$$\alpha\alpha_c(\kappa_{-A}, \kappa_{-B}; \omega) = (a\kappa_{-A}/\omega)^2\{a + b\alpha_c(\kappa_{-B}; \omega)\}/\Phi \tag{14}$$

and

$$\alpha\alpha_s(\kappa_{-A}, \kappa_{-B}; \omega) = (a\kappa_{-A}/\omega)[1 - (a\kappa_{-A}/\omega)\{(a\kappa_{-A}/\omega) + b\alpha_s(\kappa_{-B}; \omega)\}/\Phi]. \tag{15}$$

Here, a short notation is introduced:

$$\Phi \equiv \{(a\kappa_{-A}/\omega) + b\alpha_s(\kappa_{-B}; \omega)\}^2 + \{a + b\alpha_c(\kappa_{-B}; \omega)\}^2. \tag{16}$$

(3) In the case of X⇌C on the other hand, the time course of the C species, $C(t)$, associated with those of $V(t)$ and $P(t)$ in Eqs. 1 and 2 may be described as[1]

$$C(t) = C_e[1 + m'\{\delta_{nc}(\widetilde{D}; \omega) - i\delta_{ns}(\widetilde{D}; \omega)\}pe^{i(\omega t + \varphi)}] \quad (n = 1 \text{ or } 3), \tag{17}$$

where

$$m' \equiv (d\ln C/d\ln P)_e \tag{18}$$

and C_e denotes the amount of C species at equilibrium.

The FR data of the system may be expressed in this case by

$$f_c(\omega) = \delta_{nc}(\widetilde{D}; \omega) \tag{19}$$

and

$$f_s(\omega) = \delta_{ns}(\widetilde{D}; \omega). \tag{20}$$

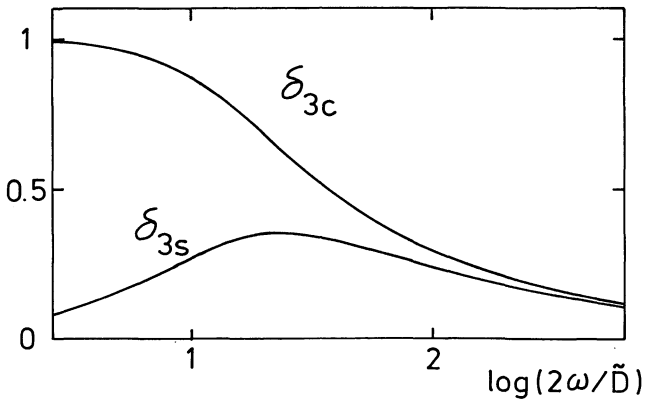

Fig. 3. Characteristic functions for an X⇄C system, $\delta_{3c}(\widetilde{D};\omega)$ and $\delta_{3s}(\widetilde{D};\omega)$; the system corresponds to the extreme case of step II being rate-controlling in Fig. 1.

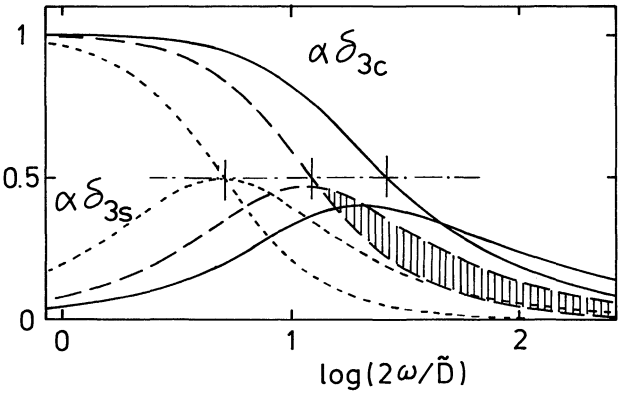

Fig. 4. Characteristic functions for an X⇄A⇄C system, $\alpha\delta_{3c}(\zeta, \widetilde{D};\omega)$ and $\alpha\delta_{3s}(\zeta, \widetilde{D};\omega)$; the parameter ζ is 50 (——), 10 (----), and 3 (……). It is demonstrated by the shaded area that these curve are intermediate between those in Fig. 2 and in Fig. 3.

The characteristic functions, δ_{nc} and δ_{ns}, involving one parameter, $\widetilde{D}$, are analytically given in Ref. 1; δ_{1c} and δ_{1s} are based on a plane sheet model, and δ_{3c} and δ_{3s} on an isotropic sphere model. The latter functions are applicable to this work with 5A; they are illustrated in Fig. 3.

(4) The FR data of the X⇌A⇌C system are assumed to be expressed by

$$f_c(\omega) = \alpha\delta_{nc}(\kappa_{-A}, \widetilde{D};\omega) \tag{21}$$

and

$$f_s(\omega) = \alpha\delta_{ns}(\kappa_{-A}, \widetilde{D};\omega). \tag{22}$$

The characteristic functions, $\alpha\delta_{nc}$ and $\alpha\delta_{ns}$, involving two parameters, κ_{-A} and $\widetilde{D}$, may be derived from Eqs. 14 and 15 by an analogy between

$$\{\alpha_c, \alpha_s\} \text{ for } X \rightleftharpoons A \rightarrow \{\alpha\alpha_c, \alpha\alpha_s\} \text{ for } X \rightleftharpoons A \rightleftharpoons B$$

and

$$\{\delta_{nc}, \delta_{ns}\} \text{ for } X \rightleftharpoons C \rightarrow \{\alpha\delta_{nc}, \alpha\delta_{ns}\} \text{ for } X \rightleftharpoons A \rightleftharpoons C,$$

since Eq. 17 is similar in form to Eq. 6.

Consequently, we have the final results

$$\alpha\delta_{nc}(\kappa_{-A}, \widetilde{D};\omega) = (a\kappa_{-A}/\omega)^2\{a + c\,\delta_{nc}(\widetilde{D};\omega)\}/\Theta \tag{23}$$

and

$$\alpha\delta_{ns}(\kappa_{-A}, \widetilde{D};\omega) = (a\kappa_{-A}/\omega)[1 - (a\kappa_{-A}/\omega)\{(a\kappa_{-A}/\omega) + c\,\delta_{ns}(\widetilde{D};\omega)\}/\Theta]. \tag{24}$$

Here, a short notation is introduced:

$$\Theta \equiv \{(a\kappa_{-A}/\omega) + c\delta_{ns}(\widetilde{D};\omega)\}^2 + \{a + c\,\delta_{nc}(\widetilde{D};\omega)\}^2 \tag{25}$$

and

$$c \equiv (dC/dP)_e/\{d(A + C)/dP\}_e \equiv 1 - a. \tag{26}$$

Three typical curves of $\alpha\delta_{3c}$ and $a\delta_{3s}$ for different choices of the values for $a\kappa_{-A}$ and $\widetilde{D}$ are compared in Fig. 4, where $a \ll 1$; that $c \fallingdotseq 1$ are assumed, because they are usually satisfied with zeolites (as discussed below). The shaded area demonstrates that these functions are intermediate in shape between the curves given in Fig. 2 and those in Fig. 3. It is worth noting that the shaded area, or the peak height of $\alpha\delta_{3s}$ depends on the ratio of ζ, defined by

$$\zeta \equiv a\kappa_{-A}/\widetilde{D}. \tag{27}$$

The Fickian diffusional time constant, $\widetilde{D}$, is given in the case of the isotropic sphere model by[1]

$$\widetilde{D} = D/r_m^2, \tag{28}$$

where D is the Fickian diffusivity and r_m is the radius of the sphere. On the other hand, the fraction, a, is expected to be approximately proportional to r_m^{-1}, since the ratio of the external surface area to the volume of the sphere is $3/r_m$. We, thus, have

$$\zeta \propto (\kappa_{-A}/D)r_m, \tag{29}$$

suggesting that 'skin' effects depend not only on the ratio of the rate constants at steps I and II, κ_{-A}/D, but also on the size of the crystals, which is in accordance with experimental findings.[3a]

Crystal-Size Distribution. The microcrystal sizes of synthetic zeolites are usually not identical, but distributed. The distribution may be regarded as being almost normal.[9] In a data analysis, therefore, δ_{nc} and δ_{ns} in Eqs. 23 and 24 should be modified as

$$\bar{\delta}_{nj}\left(\frac{D}{r_m^2};\omega\right)=\frac{1}{(2\pi)^{\frac{1}{2}}\sigma}\int_0^\infty \delta_{nj}\left(\frac{D}{r^2};\omega\right)\exp\left\{-\frac{(r-r_m)^2}{2\sigma^2}\right\}dr \quad (j=\text{c or s}), \tag{30}$$

where σ is the standard deviation and r_m is the mean radius, provided that $n=3$.

Evidently, when the crystal-size distribution is considered, Eqs. 21 and 22 should be modified as

$$f_c(\omega)=\alpha\bar{\delta}_{nc}(\zeta,\widetilde{D};\omega) \tag{31}$$

and

$$f_s(\omega)=\alpha\bar{\delta}_{ns}(\zeta,\widetilde{D};\omega), \tag{32}$$

where

$$\alpha\bar{\delta}_{nc}(\zeta,\widetilde{D};\omega)=(a\kappa_{-A}/\omega)^2\{a+c\,\bar{\delta}_{nc}(\widetilde{D};\omega)\}/\bar{\Theta} \tag{33}$$

and

$$\alpha\bar{\delta}_{ns}(\zeta,\widetilde{D};\omega)= (a\kappa_{-A}/\omega)[1-(a\kappa_{-A}/\omega)\{(a\kappa_{-A}/\omega)+c\,\bar{\delta}_{ns}(\widetilde{D};\omega)\}/\bar{\Theta}]. \tag{34}$$

Here, a short notation is introduced:

$$\bar{\Theta}\equiv\{(a\kappa_{-A}/\omega)+c\bar{\delta}_{ns}(\widetilde{D};\omega)\}^2+\{a+c\,\bar{\delta}_{nc}(\widetilde{D};\omega)\}^2. \tag{35}$$

Equations 31—35, after substitution of $n=3$ and $c=1$, were applied to a data analysis of CH_4/5A systems in this work.

It is worth noting that if the kinetic behavior at step I is described by a *Langmuir-type* rate equation, κ_{-A} may be given by[8]

$$\kappa_{-A}=k_aP_e+k_d, \tag{36}$$

where k_a and k_d denote the adsorption and desorption rate constants, respectively.

Experimental

Materials. A synthetic zeolite (5A) was supplied by Tosoh Corporation (A-30; designated as Linde 5A); its properties are summarized in Table 2. For a comparison, Linde 5A supplied commercially was used after the preparation described previously.[10]

Methane in a commercial cylinder (99.99% pure; data in catalogue) was used without any further purification.

Table 2. Properties of A-30

Cation exchange	$CaO/(CaO+Na_2O)=0.70$
Mean edge length	3.0 μm
Pretreatment	(i) pelleted with binder, (ii) calcined at 400—500°C for 1—2 h, (iii) moistened with water, and (iv) calcined again.

Apparatus and Procedure. Both the FR apparatus and procedure were similar to those described previously;[1,11] blank experiments were carried out with He under almost the same conditions as those with CH_4.

Results and Discussion

(1) A-30 Systems. Changes in the FR data at different equilibrium temperatures (T_e) are shown in Figs. 5—8; these data were divided by the value of K_F given in Table 3. The value of K_e evaluated from the adsorption isotherm according to Eq. 5 is also given in Table 3. The agreement between K_F and K_e suggests that all FR data of the system were detected in the ω-region scanned.

All solid curves represent the calculated results from Eqs. 33 and 34, where the value of σ/r_m concerned with the crystal-size distribution was assumed to be 0.4.[9b] Two parameters, ζ and $\widetilde{D}$, were determined on a trial-and-error basis from the shape of f_c and f_s; the value of ζ was easily estimated from the area corresponding to

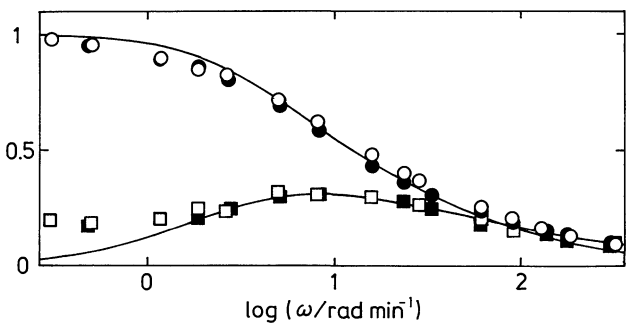

Fig. 5. FR data of CH_4/A-30 systems at −78°C; the in-phase and the out-of-phase components, f_c and f_s, are represented by the circles and the squares, respectively; each component was divided by K_F given in Table 3. ● and ■ represent the data obtained under P_e=2.7 Torr; ○ and □, those under P_e=4.5 Torr. The solid curve are calculated from Eqs. 33 and 34 of which parameters, ζ and $\widetilde{D}$, are given in Table 3.

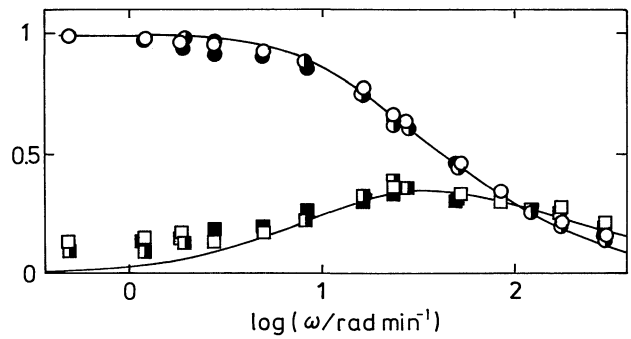

Fig. 6. FR data of CH_4/A-30 systems at T_e=−50°C. ● and ■ represent the data under P_e=3.0 Torr; ◑ and ◨, those under P_e=5.8 Torr; ○ and □, those under P_e=7.3 Torr. Notation is that of Fig. 5.

the shaded area in Fig. 4. The results are summarized in Table 3; the shift of the peak maximum of f_s has revealed an increase of $\widetilde{D}$ with increasing T_e, while an increase in the overlapping area leads to a decrease in ζ.

The deviation of f_s from the theoretical curves in the lower ω-region in Fig. 5 decreased with increasing T_e; the disagreement of K_F with K_e also decreased. This fact suggests that although the model in Fig. 1 is valid at higher T_e, the contribution of another immobile adspecies besides A and C increased with the decreasing T_e.

Arrhenius plots of the values of $a\kappa_{-A}$ ($=\zeta\widetilde{D}$; Eq. 27) and $\widetilde{D}$ are shown in Fig. 9; the activation energy of the intracrystalline diffusion, E_D, evaluated from the solid straight line was 19.1 kJ mol^{-1}, which was comparable with the heat of adsorption, ($-\Delta H=$) 19.8 kJ mol^{-1}, calculated from K_e's at $T_e=-50$ and -21 °C in Table 3 according to Clausius–Clapeyron equation.

The dependence of f_c and f_s on P_e was so slight (Fig. 8) that it was difficult to directly evaluate k_a and k_d from Eq. 36. However, on the basis of the shift indicated by the light lines in Fig. 8, we can estimate the values of k_a and k_d as follows:

(i) $\omega_{\frac{1}{2}}$ is introduced by

$$\alpha\bar{\delta}_{3c}(\zeta, \widetilde{D}; \omega_{\frac{1}{2}}) = \frac{1}{2} \tag{37}$$

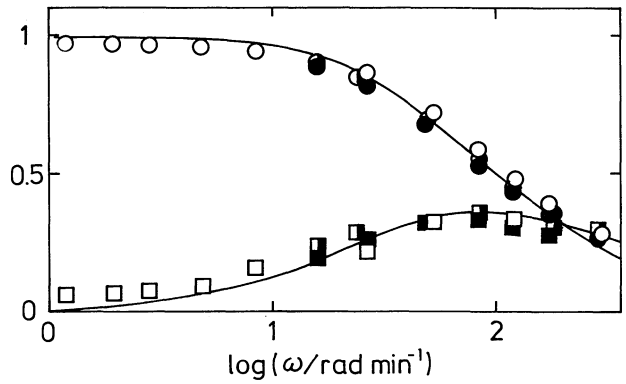

Fig. 7. FR data of CH_4/A-30 systems at $T_e=-21$ °C. ● and ■ represent the data under $P_e=3.0$ Torr; ◑ and ◨, those under $P_e=4.3$ Torr; ○ and □, those under $P_e=6.7$ Torr. Notation is that of Fig. 5.

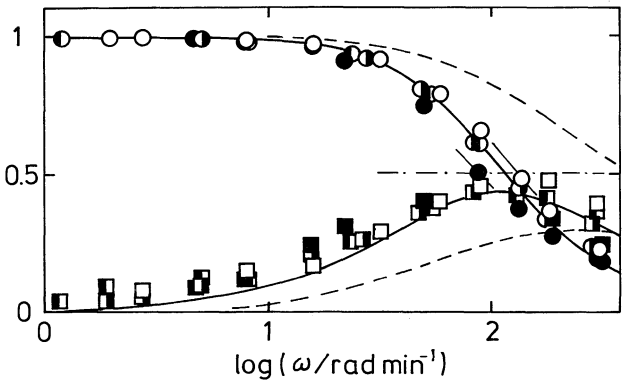

Fig. 8. FR data of CH_4/A-30 systems at $T_e=0$ °C. ● and ■ represent the data under $P_e=1.6$ Torr; ◑ and ◨, those under $P_e=3.0$ Torr; ◐ and ◧, those under $P_e=3.4$ Torr; ○ and □, those under $P_e=4.8$ Torr. Notation is that of Fig. 5. The additional dotted curves of Eq. 30 represent the extreme case of $\zeta\to\infty$; the difference between the two kinds of curves demonstrates, therefore, the transport resistance at step I.

Table 3. Experimental Conditions and Rate Constants Derived

Zeolite	m[a]	T_e	P_e	K_e	K_F	ζ	$\widetilde{D}$	$a\kappa_{-A}$[c]$\times10^{-3}$	$ak_a\times10^{-2}$	$ak_d\times10^{-2}$
	g	°C	Torr[b]				min^{-1}	min^{-1}	Torr^{-1} min^{-1}	min^{-1}

			4.4	0.73	0.67	6×10	7.1	0.43	1.2	ca. 0
			9.0	0.73	0.90	2×10²		1.42		

a) The weight of the adsorbent in a dehydrated state. b) 1 Torr=133.3 Pa. c) $a\fallingdotseq6\times10^{-3}$.

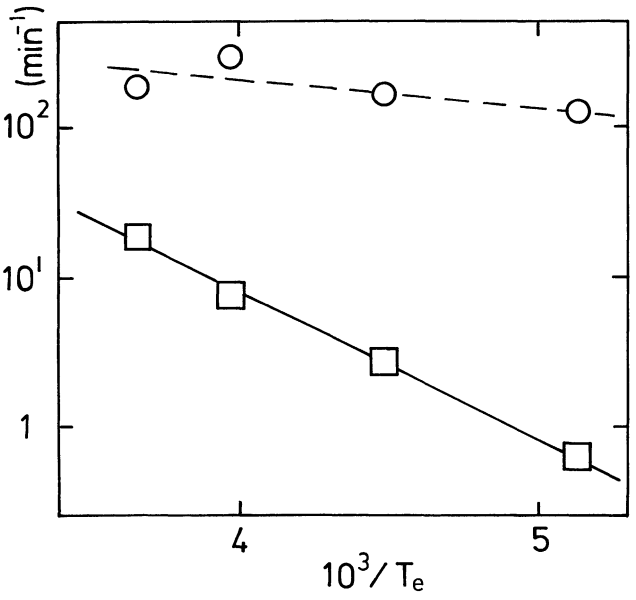

Fig. 9. Arrhenius plots of the parameters, a κ_{-A} (○) and $\widetilde{D}$ (□), derived from the solid theoretical curves shown in Figs. 5—8.

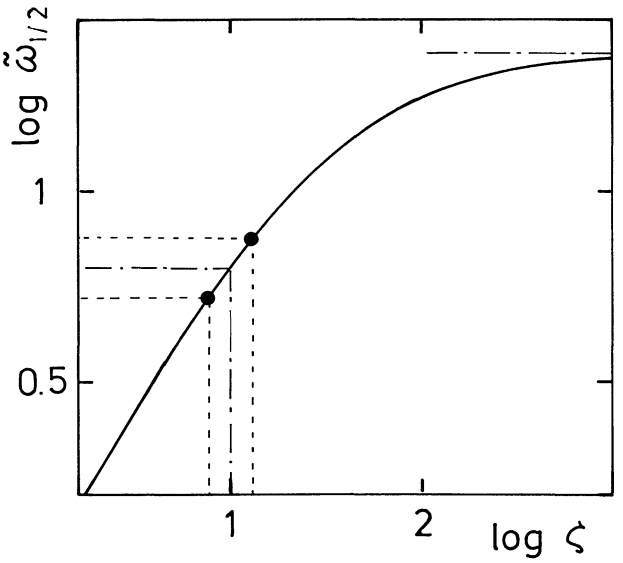

Fig. 10. The center position of the theoretical curve $\alpha\delta_{3c}(\zeta, \widetilde{D}; \omega)$ represented by $\widetilde{\omega}_{1/2}$ versus ζ; the shifts are demonstrated by the vertical lines in Fig. 4. The asymptote indicated on the right is 1.363.

and $\widetilde{\omega}_{\frac{1}{2}}$ is defined by

$$\widetilde{\omega}_{\frac{1}{2}} = \omega_{\frac{1}{2}}/\widetilde{D}. \tag{38}$$

(ii) $\widetilde{\omega}_{\frac{1}{2}}$ depends on ζ, as demonstrated by the vertical lines in Fig. 4. The extended dependence is illustrated in Fig. 10.

(iii) The shift of $\log \omega_{\frac{1}{2}}$ in Fig. 8, indicated by the two light lines, was 0.17.

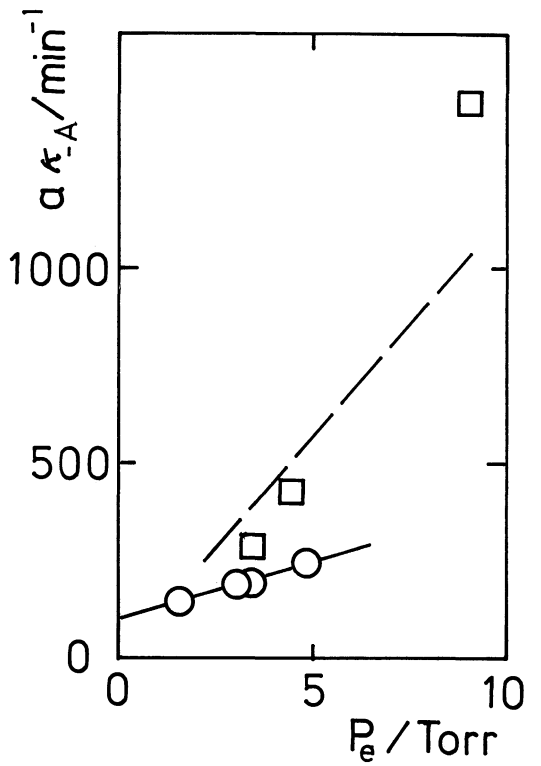

Fig. 11. Rate constant at step I, a κ_{-A}, versus P_e. ○'s represent the results of A-30; □'s, those of Linde 5A. The straight lines lead to the values of ak_a and ak_d given in Table 3.

(iv) The mean value of ζ was 10 (see Table 3).

(v) A shift by 0.17 of $\Delta\log \omega_{\frac{1}{2}}(=\Delta\log \widetilde{\omega}_{\frac{1}{2}})$ leads to 0.22 for $\Delta\log \zeta$, indicated by the solid circles in Fig. 10.

(vi) Consequently, we have (1 Torr=133.322 Pa)

$$\zeta = \begin{cases} 13 & \text{at } P_e = 4.8 \text{ Torr} \\ 7.8 & \text{at } P_e = 1.6 \text{ Torr.} \end{cases} \tag{39}$$

(vii) The values of $a\kappa_{-A}(P_e)$ evaluated from $\zeta(P_e)\times\widetilde{D}$ are plotted in Fig. 11; since the adsorption isotherm at T_e=0 °C was proportional to P_e, $\widetilde{D}$ was assumed to be independent of P_e.[12]

(viii) Under the assumption of Eq. 36, we found the values of ak_a and ak_d from the straight line in Fig. 11; they are given in Table 3.

(2) Linde 5A Systems. In order to determine the effects of a hydrothermal pretreatment of A-30, additional experiments were carried out. The FR data of Linde 5A (without the hydrothermal pretreatment) are shown in Fig. 12.

The dashed and the solid curves were calculated from Eqs. 33 and 34 under the assumption that σ/r_m=0.5.[10] In this case, the pressure dependence of $\zeta(P_e)$ was determined directly by curve fittings under the assumption of constant $\widetilde{D}$; these results are given in Table 3.

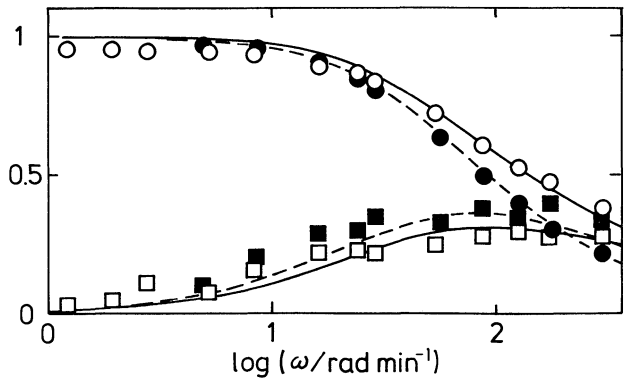

Fig. 12. FR data of CH_4/Linde 5A systems at T_e= 0°C. ● and ■ represent the data under P_e=3.4 Torr; ○ and □, those under P_e=9.0 Torr. The dashed and the solid curves are calculated from Eqs. 33 and 34, of which parameters are given in Table 3.

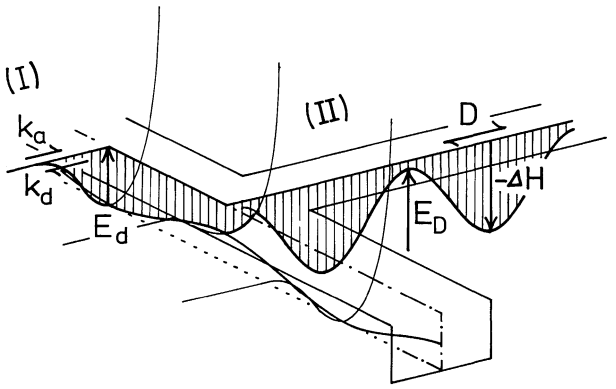

Fig. 13. The potential energy distribution of the X⇄A⇄C system in Fig. 1. Every six constant characteristic of the adsorbate-adsorbent system may be evaluated from the FR data analysis: k_a and k_d denote adsorption and desorption rate constants, respectively; E_d is the activation energy of the desorption; D is the Fickian diffusivity; E_D is the activation energy of the diffusion; $-\Delta H$ corresponds to the heat of adsorption.

The values of $a\kappa_{-A}(P_e)$ evaluated from ζ and $\widetilde{D}$ are plotted in Fig. 11. Though the results seem to be scattered, it may be concluded that the value of k_a is considerably larger than that of A-30, whereas k_d is very smaller than that of A-30; it is worth noting that Eq. 36 is valid only if the Langmuir-type equation is accepted.

The value of a is expected to be about 6×10^{-3}, since the external BET surface area of 5A zeolites was 0.6% of the entire surface area.[13] The absolute value of k_d is, therefore,

$$k_d = 1.7 \times 10^4 \text{ min}^{-1} \text{ for A-30.} \quad (40)$$

The mean lifetime of A-species, τ_A, can be given by the inverse of k_d,

$$\tau_A = 4 \times 10^{-3} \text{ s.}$$

Since k_d of the Linde 5A system was considerably smaller than that of A-30, a hydrothermal pretreatment made the lifetime of the A-species considerably shorter.

(3) Effect of Intercrystalline Diffusion. The theoretical curves based on the model in Fig. 1 without intercrystalline diffusion were valid for explaining all of the FR data given in Figs. 5—8 and Fig. 12. Therefore, the resistance due to intercrystalline diffusion may be neglected. The large difference of ak_a or ak_d in Table 3 with respect to the different adsorbents also supports this conclusion, since A-30 is designated as Linde 5A.

Conclusion

According to the theoretical procedure proposed in this work, the potential energy distribution illustrated in Fig. 13 may be derived from FR data, though we have no information about surface diffusion along the external surface. It is worth noting that all six constants do not depend on the amount of adsorbent but, rather, on the structure. Therefore, the present method would provide quantitative information concerning the existence and intensity of surface barriers of zeolite crystals.

Appendix 1

The variation of the A-species may be expressed as

$$A(t) = A_e\{1 + ae^{i(\omega t + \varphi - \psi)}\}. \quad (A1)$$

According to the result in Eq. 19 of Ref. 8, we find

$$a = mp\kappa_{-A}/(\kappa_{-A}^2 + \omega^2)^{\frac{1}{2}}. \quad (A2)$$

On the other hand, we have the result

$$\tan\psi = \omega/\kappa_{-A}. \quad (A3)$$

Substitution of Eqs. A2 and A3 into Eq. A1 leads to Eq. 6.

Appendix 2

The FR of an X⇌A⇌B system has been considered[8] and the results are rewritten in terms of α_c and α_s defined by Eqs. 10 and 11:

$$(v/p)\cos\varphi - 1 = K_A(\kappa_{-A}^2/\omega^2)\{1 + K_B\alpha_c(\kappa_{-B};\omega)\}/\Phi' \quad (A4)$$

and

$$(v/p)\sin\varphi = K_A(\kappa_{-A}/\omega)[1 - (\kappa_{-A}/\omega)\{(\kappa_{-A}/\omega) + K_B\alpha_s(\kappa_{-B};\omega)\}/\Phi'], \quad (A5)$$

where the relation of $\kappa_q/\kappa_{-q}=K_q$ in Eq. 18 of Ref. 8 is considered and a short notation is introduced:

$$\Phi' \equiv \{(\kappa_{-A}/\omega) + K_B\alpha_s(\kappa_{-B};\omega)\}^2 + \{1 + K_B\alpha_c(\kappa_{-B};\omega)\}^2. \quad \text{(A6)}$$

Considering the asymptote as $\omega\to 0$ in Eq. A4, we have

$$\lim_{\omega\to 0}(v/p)\cos\varphi - 1 = K_A(1 + K_B). \quad \text{(A7)}$$

On the other hand, the asymptote may be correlated with the gradient of the adsorption isotherm:[8]

$$\lim_{\omega\to 0}(v/p)\cos\varphi - 1 = (RT_0/V_e)\{d(A + B)/dP\}_e \ (\equiv K_e'). \quad \text{(A8)}$$

A comparison of Eq. A7 with Eq. A8 leads to

$$K_A = aK_e' \quad \text{and} \quad K_B = b/a, \quad \text{(A9)}$$

where a short notation is introduced:

$$a \equiv (dA/dP)_e/\{d(A + B)/dP\}_e \equiv 1 - b. \quad \text{(A10)}$$

Substitution of the relation in Eq. A9 into Eqs. A4 and A5 leads to the final results of Eqs. 12—16.

Flash Photolysis Study for Halogen Abstraction of $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ from Alkyl Halides

Osamu Ito* Kiyohiko Hoteiya, Akira Watanabe, and Minoru Matsuda
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Aoba-ku, Sendai 980
(Received September 6, 1990)

The reaction rate constants for halogen abstraction of $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ have been determined by xenon-flash photolysis method. The absolute rate constants for the reactivity of $Ph_3Sn\cdot$ with several alkyl halides have been compared with the relative ones; the agreement between the both methods was fairly good. For $Ph_3Sn\cdot$, the rate constant (in unit of $mol^{-1}\,dm^3\,s^{-1}$) of *n*-BuCl (5.2×10^2) was smaller than that of *n*-BuBr (3.1×10^6) by a factor of ca. $1/10^4$. With changing the alkyl halides, the rate constants for $Ph_3Si\cdot$ and $Ph_3Sn\cdot$ varied similarly, although the rate constants for $Ph_3Si\cdot$ were larger than those for $Ph_3Sn\cdot$ by factors of 50—100. The reactivity of alkyl halides increased with a decrease in the bond-dissociation energy of the R–X (X=Cl, Br).

The high reactivities of organostannyl and organosilyl radicals in halogen abstraction reactions have been well-known and utilized widely in synthetic chemistry.[1] The relative reactivities were evaluated by various methods such as product analysis[2] and ESR spectroscopy.[3] Some of them were converted into absolute rate constants by Carlsson and Ingold using the rotating sector/competitive method.[4] In order to obtain the absolute rate constants, the laser-flash photolysis has been applied to radical reactions including the organometallic radicals.[5–10] Although the usefulness of this method has been widely proved, it is hard to evaluate the rate constants smaller than ca. $10^5\,mol^{-1}\,dm^3\,s^{-1}$. For such relatively slow reactions, the xenon-flash photolysis would be expected to be useful.[11,12]

In this study, we report the absolute rate constants evaluated by following the direct decay of transient absorption bands due to $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ in the presence of various alkyl halides. The absolute rate constants thus evaluated are compared with the relative rate constants obtained by a competitive method. Furthermore, we attempted to clarify the factors determining the reactivities.

Experimental

$Ph_3SnSnPh_3$ and $Ph_3SiSiPh_3$ used as the radical sources were prepared by refluxing Ph_3MCl (M=Sn, Si) with sodium metal in toluene under N_2.[13] Alkyl halides and solvents were purified by distillation before use.

Xenon-flash photolysis apparatus was of the standard design equipped with two xenon-flash lamps (Xenon Corp., N-851C); the half-duration of the lamp was ca. 8 μs. The solution containing the radical source was photodecomposed with the light longer than 270 nm which was selected by the cut-off light filter; thus, alkyl halides having absorption band shorter than 270 nm were chosen as substrates in this study. The solution was degassed up to ca. 10^{-2} Pa. All measurements were performed at 23 °C.

For competitive experiments to evaluate the relative reaction rate constants, the following chain reactions were used (Scheme 1).

$$(CH_3)_2(CN)CN{=}NC(CN)(CH_3)_2 \xrightarrow{h\nu} 2\ (CH_3)_2(CN)C\cdot + N_2 \quad (1)$$

$$(CH_3)_2(CN)C\cdot + Ph_3SnH \longrightarrow Ph_3Sn\cdot + (CH_3)_2(CN)CH \quad (2)$$

$$Ph_3Sn\cdot + RX \xrightarrow{k_X^r} Ph_3SnX + R\cdot \quad (3)$$

$$R\cdot + Ph_3SnH \longrightarrow RH + Ph_3Sn\cdot \quad (4)$$

Scheme 1.

By using azobisisobutyronitrile as a photo-initiator, which was decomposed with the light longer wavelength than 350 nm, one could obtain the relative rates for the alkyl halides with absorption band at longer wavelength than 270 nm. For such alkyl halides, it was difficult to obtain the absolute rate constants by the xenon-flash photolysis method. RH and RX were analyzed by gas chromatography; the relative rate constants were computed by the Ingold and Shaw method.[14]

Results and Discussion

Figure 1 shows the transient absorption spectra produced by the flash photolysis of $Ph_3SnSnPh_3$ and $Ph_3SiSiPh_3$ in degassed cyclohexane solution. The main peak appeared at 320—330 nm with the broad band near 450 nm. The main peaks at 320—330 nm are similar to the reported absorption bands for $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ by Chatgilialoglu et al.[8]

$$Ph_3MMPh_3 \underset{k_b}{\overset{h\nu}{\rightleftharpoons}} 2\ Ph_3M\cdot \quad (5)$$

(M = Si, Sn)

By the photolysis of some disilanes and digermanes, the biradical formation via the ipso addition was reported.[10,15] It is presumed that these species also show the absorption band at ca. 330 nm, although the decay rate was slower than that of the metal centered radicals.[10] However, in the case of photolysis of

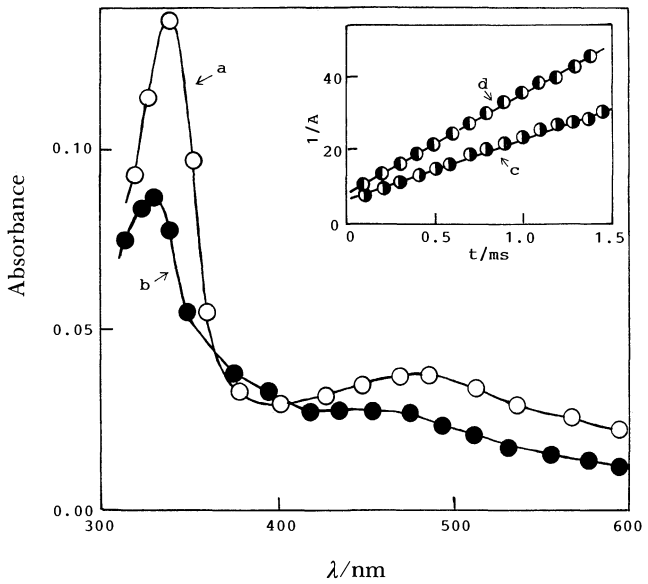

Fig. 1. Transient absorption spectra immediately after flash photolysis of 10^{-4} mol dm^{-3} of (a) $Ph_3SiSiPh_3$ and (b) $Ph_3SnSnPh_3$ in degassed cyclohexane in a cylindrical flash cell (10 cm optical path). Insert: Second-order plot at 330 nm of $Ph_3Sn\cdot$; (c) in cyclohexane and (d) in hexane.

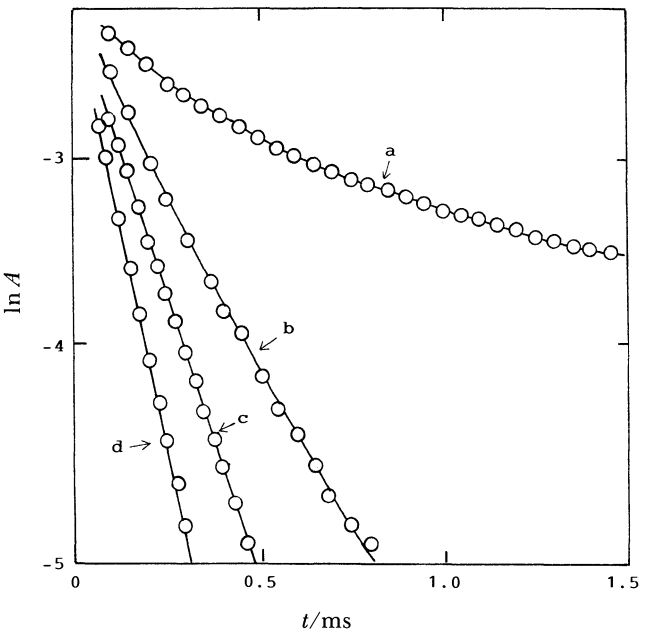

Fig. 2. First-order plots for decay of $Ph_3Sn\cdot$ (at 330 nm) in the presence of *t*-BuCl in degassed cyclohexane; (a) 0, (b) 0.21, (c) 0.47, and (d) 0.70 mol dm^{-3}.

$Ph_3SnSnPh_3$ and $Ph_3SiSiPh_3$, the formation of the biradicals may not be the main path because of the steric hindrance of many phenyl groups. The broad weak absorption band near 450 nm produced by the photolysis of the disilane was attributed to the free silanediyl (R_2Si:),[16] or to the rearrangement product.[17]

When *n*-donor solvent was used, the absorption of R_2Si: shifts to 320—330 nm by the complex formation.[18] Thus, we used cyclohexane as a solvent throughout this study. We followed predominately the decay of the main band at 320—330 nm to determine the reaction rates of $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ with alkyl halides.

The insert of Fig. 1 shows the second-order plots (1/absorbance vs. time) for $Ph_3Sn\cdot$. The linear lines indicate that $Ph_3Sn\cdot$ predominately returns to Ph_3Sn-$SnPh_3$. The slope of the second-order plot, which refers to the ratio of $2k_b$ to the extinction coefficient (ε), varies with solvent viscosity, suggesting that k_b is near a diffusion controlled limit. The $2k_b/\varepsilon$ value in hexane is 3.5×10^5 cm^{-1} s^{-1}, which is close to the reported one by the laser flash photolysis.[8] On assuming k_b=ca. 2×10^9 mol^{-1} dm^3 s^{-1} which is about a half of $(C_2H_5)_3Si\cdot$, ε can be calculated to be ca. 10^4 cm^{-1} mol^{-1} dm^3; thus, the initial concentration of $Ph_3Sn\cdot$ produced by one flash exposure can be calculated from Fig. 1 to be ca. 10^{-6} mol dm^{-3}. In the case of $Ph_3Si\cdot$, the decay kinetics deviated from the second-order kinetics, suggesting that $Ph_3Si\cdot$ reacts with the phenyl group of the radical source.[8] On addition of small amount of oxygen, $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ decayed rapidly; the rate constant for this reaction may be larger than 10^9 mol^{-1} dm^3 s^{-1}.

By the addition of appropriate concentration of alkyl halides to degassed solution, decay kinetics of $Ph_3Sn\cdot$ changed into first-order kinetics as shown in Fig. 2 for the reaction with *t*-butyl chloride. The decay rates were accelerated by the addition of the alkyl hafides; thus, the following halogen abstraction reaction occurs.

$$Ph_3M\cdot + RX \xrightarrow{k_X} Ph_3MX + R\cdot \qquad (6)$$

When the concentration of RX was properly high, the first-order part became predominant as shown in Fig. 2, in which the slope refers to as $k_{\text{first-order}}$. When the concentration of RX was low, the contribution of the first-order term to the whole decay was small; for such case, the first-order term was separated from the mixed-order kinetics by a computer simulation method.[19,20] Figure 3 shows the pseudo-first-order plots for some reaction systems; the slope gave the k_X value. The k_X values for various alkyl halides are summarized in Table 1 for $Ph_3Sn\cdot$ and $Ph_3Si\cdot$.

The relative halogen abstraction reactivities (k_X^r) of alkyl halides by $Ph_3Sn\cdot$ were determined by the competitive experiment described in the experimental section. They are also summarized in Table 1, in which the k_X^r value of CH_2Cl_2 was set to be 1.0. In Fig. 4, these k_X^r values are plotted against the k_X values; a linear relation is seen, showing the reliability of the

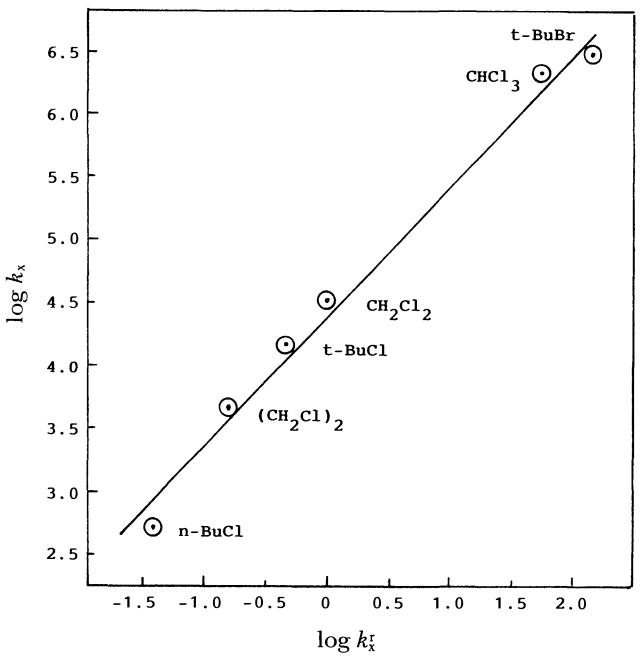

Fig. 4. Plot of log k_X (absolute rate constants) vs. log k_x^r (relative rate constant) for $Ph_3Sn\cdot$.

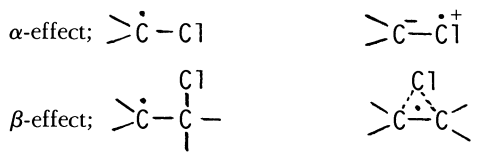
reaction rate constants obtained by the both methods. The k_X value for the reaction system of $Ph_3Sn\cdot$-*t*-BuCl obtained in this study ($1.4\times10^4\,mol^{-1}\,dm^3\,s^{-1}$) was similar to the reported one ($2.0\times10^4\,mol^{-1}\,dm^3\,s^{-1}$) which was determined with the rotating sector/ESR method reported by Carlsson and Ingold.[4]

For $Ph_3Sn\cdot$, the following orders in the reactivities were confirmed; RCl<RBr, $R_{primary}$-Cl<$R_{tertiary}$-Cl< cyclic halide. In order to investigate the factor controlling the reactivities, the k_X values are plotted against the bond-dissociation energy (BDE) of R-X.[21] In Fig. 5, linear correlations are found for the both radicals; the weaker the R-X bond is, the higher the reactivity is. A typical example is shown for the reactivity of RCl<RBr. Within the same halogen series, the low BDE value of R-X implies that the carbon radical (R·) is stable. Thus, the order of $R_{primary}$-Cl<$R_{tertiary}$-Cl is attributed to higher stability of tertiary carbon radical than the primary one. The α-halogen effect is more effective than the β-effect [$k_X(CH_2Cl_2)/k_X((CH_2Cl)_2)$=ca. 7]. The α-effect is intensified with additional halogen atom [$k_X(CHCl_3)/k_X(CH_2Cl_2)$=ca. 60].[22] Since the k_r values of these compounds are also on the line of Fig. 5, these effects can be interpreted by the stability of the carbon centered radicals; some of the resonance structures can be written as follows;



As for the polar contribution to the transition states of these reactions, charge transfer from the radical

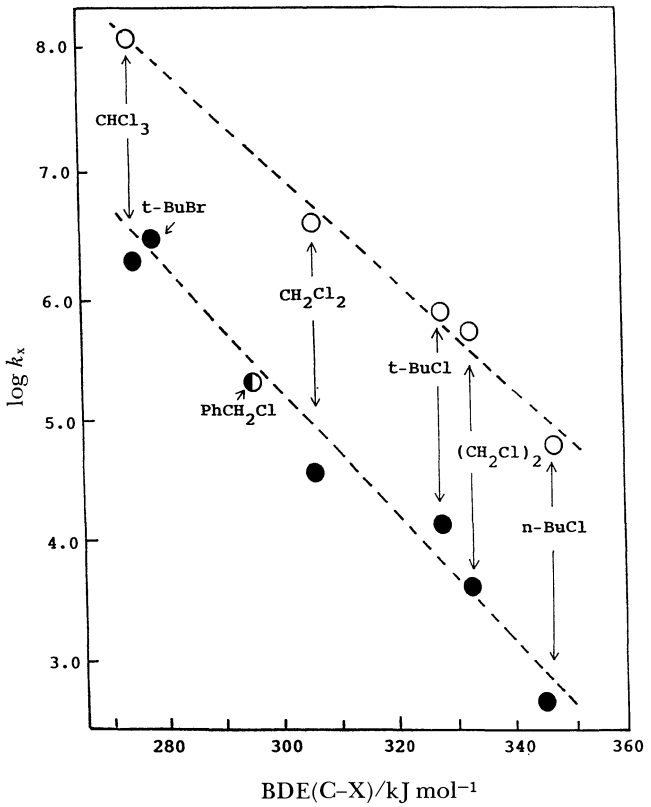


Fig. 5. Plots of log k_X vs. bond-dissociation energy of R–X [BDE(C–X)]. (●) $Ph_3Sn\cdot$ and (○) $Ph_3Si\cdot$; (◐) k_x for $PhCH_2Cl$ was evaluated from Fig. 4.

center to RX has been presumed from the Hammett plot by Chatgilialoglu et al.[23] In Table 1, however, no clear tendency that k_X values increase with the ionization energy can be found. This suggests that the polar effect is not the main factor in determining the reactivity, when a wide range of RX is compared.

From Table 1 and Fig. 5, it is confirmed that the reactivity of $Ph_3Si\cdot$ is higher than that of $Ph_3Sn\cdot$; this tendency is in agreement with the order of reactivities in the halogen abstraction of n-$Bu_3Sn\cdot$ and $Et_3Si\cdot$.[8] The order of the reactivity of $R_3Sn\cdot$ and $R_3Si\cdot$ can be well interpreted by the thermodynamic data; i.e., in the case of $(CH_3)_3MCl$, BDE of Sn–Cl (422 kJ mol^{-1}) is smaller than that of Si–Cl (485 kJ mol^{-1}),[24] which indicates that Cl-abstraction of $(CH_3)_3Sn\cdot$ is more endothermic than that by $(CH_3)_3Si\cdot$. Although the thermodynamic data for Ph_3MX are not available, this tendency is in good agreement with our observed tendency in the reactivities of $Ph_3Sn\cdot$ and $Ph_3Si\cdot$ for halogen abstraction.

The k_X value for $Ph_3Sn\cdot$–n-BuBr is ca. 1/10 of n-$Bu_3Sn\cdot$, in which the latter rate constant was determined by the laser-flash probe method.[6] The k_X value for $Ph_3Si\cdot$–t-BuCl is also ca. 1/10 of $Et_3Si\cdot$–t-BuCl.[7] The slightly lower reactivity of $Ph_3M\cdot$ compared with the corresponding $R_3M\cdot$ can be confirmed in this study. In the case of the $Ph_3C\cdot$ and $R_3C\cdot$, the former is extremely less reactive than the latter, because of the delocalization of the unpaired electron into the phenyl groups even though the π-orbitals are not in the same plane. On the other hand, the delocalization of the unpaired electron would not be expected for $Ph_3Sn\cdot$ and $Ph_3Si\cdot$, because of the small overlap between the orbitals of unpaired electron of the central atom [Si(3p) or Sn(5p)] and phenyl 2p-orbital. Thus, the difference in the reactivity between $Ph_3M\cdot$ and $R_3M\cdot$ is quite small.

The Carboxylation of Active Methylene Compounds with Carbon Dioxide in the Presence of Diphenylcarbodiimide and Potassium Carbonate[1)]

Koji CHIBA,* Hideyuki TAGAYA,* Masa KARASU, Tsuyoyuki ONO, Kazumi HASHIMOTO, and Yasusi MORIWAKI
Department of Materials Science and Engineering, Faculty of Engineering, Yamagata University, Jonan, Yonezawa 992
(Received September 10, 1990)

Active methylene compounds were effectively carboxylated with carbon dioxide in the presence of diphenylcarbodiimide (DPC) as a biotin model and potassium carbonate. Fluorene was carboxylated even under a nitrogen atmosphere in the presence of DPC, indicating that a carbonate ion was the carbon source. The reaction occurred even in the presence of water. It was considered that reaction intermediates are stable to water and that the concentration of the carbonate ion is important for carboxylation.

The fixation of carbon dioxide has been attempted by many researchers, since carbon dioxide is a considerable natural source of carbon.[2–6)] Furthermore, the greenhouse effect due to carbon dioxide has gained much attention and decreasing atmospheric carbon dioxide is a critical problem.[7)] Carbon dioxide can be converted into useful forms of organic compounds by coupling with an organic substance. However, in order to do so, carbon dioxide and/or the organic substances must be activated. One example of the former way is the activation of carbon dioxide by a transition metal.[2,3)] The photocarboxylation of aromatic compounds represents latter examples in which the anion radicals of aromatic compounds react with carbon dioxide.[8,9)]

It has been well established that biotin is required as a cofactor in a number of enzymatic carboxylation reactions.[6)] One of us has already reported that active methylene compounds are carboxylated by employing a reagent system, 1,3-diphenylurea (DPU), as a biotin model compound, potassium carbonate and carbon dioxide.[10,11)] Also, Otsuji and co-workers have reported that a number of active methylene compounds are carboxylated by employing the reagent system benzyltrimethylammonium hydroxide–dicyclohexylcarbodiimide and carbon dioxide.[12)] In these carboxylations, carbon dioxide is activated at the imidazole moiety. We recently found that diphenylcarbodiimide (DPC) is an effective biotin model as a carrier of carbon dioxide to active methylene compounds.[1)] We have undertaken to construct a model reaction for biotin-promoted carboxylations, whereby the chemical mechanism of the reaction may be elucidated. Mainly, we used fluorene as an active methylene compound, since fluorene-9-carboxylic acid (9-FLC) is easy to treat after the reaction.

Results and Discussions

Carboxylation of Fluorene with Imine and Carbon Dioxide. Fluorene was carboxylated with carbon dioxide and potassium carbonate to yield 9-FLC, even if no biotin model (imine) was present. However, the yield was as low as 4.8% (Table 1). It is well known that a strong base, like 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU), abstracts a proton from an active methylene compound.[13,14)] In this reaction carbonate ion might abstract a proton from fluorene, while producing the fluorenyl anion ((1) in the Scheme). Since fluorenyl anion reacts with carbon dioxide to give carboxylic acid, water must be an inhibitor. Certainly, no 9-FLC was obtained when water was added. It is reported that dicyclohexylcarbodiimide was an effective imine for the carboxylation of an active methylene compound in the presence of quaternary ammonium salt.[12)] However, a low yield was obtained when potassium carbonate was used instead of quaternary ammonium salt. Also, phenyl isocyanate was not a good biotin model for this carboxylation. More than 35% of the fluorene was carboxylated with carbon dioxide in the presence of DPC. The yield was seven-times larger than that using dicyclohexylcarbodiimide. Furthermore, fluorene was carboxylated even under a nitrogen atmosphere. Without DPC, no 9-FLC was obtained if under a nitrogen atmosphere. These facts indicate that if DPC was present, potassium carbonate was able to be a source of carbon dioxide. We considered reaction mechanism (2) in the Scheme. A carbonate ion attacks an imine carbon to give anionic intermediates. The results in a non-carbon dioxide atmosphere indicated that such intermediates can donate carbon dioxide to an active methylene compound. The high yield under a carbon dioxide atmosphere suggested that such intermediates react further with carbon dioxide to give the reactive intermediates shown in the Scheme. These results are interesting examples of carboxylation under a nitrogen atmosphere as the model of an enzyme system. The yield of 9-FLC in air was 18.1%. The value was larger than 6.6% in a nitrogen atmosphere. Air might include moisture. Drying of air decreased the yield, indicating that water was a positive factor. The effect

of water addition is discussed later. *o*-Substituents in the phenyl moieties of DPC were harmful for carboxylation, the same results as those using DPU.[10)]

If carbon dioxide is activated by transference to the imidazole moiety, as shown in the Scheme (2), *o*-substituents in the phenyl moieties of DPC interferred with the carboxylation reaction. Such a steric effect may be present.

Carboxylation of Active Methylene Compounds with DPC and Carbon Dioxide. Twelve active methylene compounds were carboxylated with carbon dioxide in the presence of DPC and potassium carbonate (Table 2). The highest yield was obtained in the carboxylation of indene. Though the yields were from 0.0 to 53.8%, there was no correlation between pK_a and the yield. In the case that a strong base is used

Table 2. Carboxylation of Active Methylene Compounds in a Carbon Dioxide Atmosphere[a]

a) Substrate, 5 mmol; diphenylcarbodiimide, 16.8 mmol; K_2CO_3, 30 mmol; DMSO, 25 ml; reaction temp, 20 °C; reaction time, 2 h. b) The yields of carboxylic acid were calculated on the basis of substrate used. The products were monocarboxylic acids. They were identified by comparison of IR spectra with those of the authentic samples, after esterification with diazomethane, if necessary.

without a biotin model, proton abstraction by the base should be a rate-determining step and pK_a an important factor.[14] Our results indicate that since proton abstraction is not a rate-determining step it is not an important factor. After the reaction we confirmed the presence of DPU. In the case of fluorene, one fourth of the DPC converted to DPU after a 2 hour reaction. Though we measured the ^1H NMR of the reaction solution, we could not confirm the presence of DPU during the reaction. During the post-treatment, the reaction mixture was poured into ice-cold water. There is a possibility that the reaction intermediates reacted with protons at this point to give DPU.

The Effects of Reaction Time and Carbon Dioxide Pressure on the Carboxylation of Fluorene. In the case of DPU, the yield of carboxylic acid increased with an increase in the reaction time.[10,11] However, the maximum yield of 9-FLC was obtained at ca. 2 h in the case of DPC; the yield decreased slightly after 2 h (Table 3). This suggests the presence of undesirable reactions, such as a reverse reaction and/or an adduct reaction between DPC and 9-FLC. Actually, 55% of 9-FLC changed to unknown compounds in the reaction of 9-FLC with DPC for 2 h, although no reaction was observed when 9-FLC alone was reacted in DMSO. Although the reaction mechanism is not clear, the production of fluorenone was confirmed. We could also obtain the trimer of DPC by a reaction at 80 °C for 9 h. The production was confirmed by MS. The yield of 9-FLC when the DPC trimer was used instead of DPC was only 10.1% at 20 °C for 2 h. If the oligomerization of DPC occurs, elongation of reaction time is not preferable.

Table 3. Effects of the Reaction Time and CO_2 Pressure on the Carboxylation of Fluorene Using Diphenylcarbodiimide[a]

Pressure	Reaction time/h

It has been reported that carboxylation using DBU is influenced by the pressure of carbon dioxide.[6] Active methylene compounds give carboxylated products in much higher yield under higher pressure carbon dioxide. However, in the case of DPC, the carbon dioxide pressure was not effective on the yield of 9-FLC (Table 3). It has already been reported that in the absence of any catalyst equilibrium between two phenyl isocyanate molecules and DPC, carbon dioxide exists far on the side of phenyl isocyanate.[15] There is a possibility of a reaction of DPC with carbon dioxide to give phenyl isocyanate. Phenyl isocyanate was not a good imine, as mentioned earlier (Table 1).

The Effects of Alkali Carbonate on the Carboxylation of Fluorene. The yield of 9-FLC depended upon the nature of alkali carbonate (Table 4). Lithium and sodium carbonates were not effective; cesium salt was the most effective. The yields are well related to the solubility of alkali carbonate and the amount of

Table 5. Effects of Water Addition on the Yield of 9-FLC in Carboxylation for 2 h Using Diphenylcarbodiimide and K_2CO_3[a)]

Conditions	Amount of water added/mmol					
	0	5	10	15	20	30

C	27.4	29.9	42.6	44.4	25.3	19.2

A; reactor was closed. B; reactor was bubbled by CO_2. C; reactor was pretreated by bubbling CO_2 for 1 h before adding fluorene and after then closed. a) Fluorene, 5 mmol; diphenylcarbodiimide, 16.8 mmol; K_2CO_3, 30 mmol; DMSO, 25 ml; reaction temp, 20 °C.

carbon dioxide absorbed in the reaction solution. The solubility of potassium carbonate was 3.68, larger than those of lithium and sodium carbonates by a factor of five to ten. The solubilities of rubidium and cesium carbonates were about three- to four-times larger than that of potassium carbonate. The concentration of carbanion is critical. Without an alkali carbonate, 17.1 mmol of carbon dioxide was absorbed in DMSO. This indicates that the carbonates, except cesium carbonate, did not contribute to the increase in the amount of carbon dioxide absorption. The highest yield of 71.6% with cesium carbonate is attributable to the high solubility in DMSO and the great ability to absorb carbon dioxide in conjunction with DPC.

The Effects of Water Addition on the Carboxylation of Fluorene. 1 g of potassium carbonate is soluble in 2.8 g of water. The solubility of potassium carbonate increased from 3.68 to 8.79 upon the addition of 10 mmol water to the DMSO solution of DPC. Water is known to be an inhibitor in many carboxylation reactions, as mentioned previously. However, the yield of 9-FLC in air was larger than that in drying air (Table 1), indicating that, at least, water was not an inhibitor. We have found the very interesting fact that in this study the addition of water accelerated the carboxylation yield (Table 5). Though without carbon dioxide the yield of 9-FLC without water was 10.5%, the value increased to 24.3% upon the addition of 10 mmol water. A maximum yield was obtained at 10 to 15 mmol addition of water in the case of bubbling carbon dioxide. The addition of more water than 15 mmol was not effective. The solubility of potassium carbonate increased upon the addition of water. Although the concentration of carbonate ions increased upon the addition of water, water addition lowered the solubility of fluorene in DMSO. Carbanion reacted with a proton to give a less-reactive compound. Our results suggest that if the reaction intermediates, as shown in the Scheme (2), reacted with water, their carboxylation activity did not become lower.

Conclusions

DPC was an effective carbon dioxide carrier for the carboxylation of active methylene compounds as a biotin model. Carboxylation of fluorene, even under a nitrogen atmosphere, is a very interesting reaction, since DPC can react with the carbonate ion directly, although DPU can not.[10,11] This indicates the possibility of an effective usage of carbonate ions in which more than 99.9% of the carbon dioxide exists as calcium carbonate. The carboxylation reaction of fluorene occurred even in the presence of water, suggesting that the reaction intermediates shown in the Scheme are stable to water. It was considered that the concentration of carbonate ions determined the reaction. In a biological system, the carboxylation reaction occurs in the presence of water without carbon dioxide. Our results indicate that the carboxylation of fluorene using DPC occurs under similar conditions as those of biological systems.

Experimental

DPC and substituted DPC were synthesized according to a method of Campbell et al.[15] 1-Ethyl-3-methyl-3- phospholene 1-oxide was used as a catalyst. Active methylene compound and DPC were dissolved in DMSO (25 ml); to this solution powdered alkali carbonate was added. Dry carbon dioxide was then passed into the mixture. The reaction mixture was poured into ice-cold water and the precipitate filtered off (active methylene compound and DPU etc.). The filtrate was extracted with ether. Acidification of the aqueous solution with hydrochloric acid gave a white precipitate. The precipitate was carboxylic acid. The ether extract was dried over anhydrous sodium sulfate and the solvent evaporated. The residue and above-mentioned precipitate were identified by a comparision of the IR spectra and melting points with those of carboxylic acids. A reaction under pressure was carried out using a 100 ml magnet-driven autoclave and treated in the same manner as mentioned above. The solubilities of alkali carbonates were determined by titration using HCl after filtration.

The amounts of carbon dioxide absorption in a DMSO solution containing DPC were determined by measuring the weight both before and after carbon dioxide bubbling.

The Synthesis and Properties of Cyclohepta[*a*]phenalene-6,10-, -6,12-, -7,10-, and -7,12-diones and Their Dicationic and Dianionic Species

Department of Materials Science and Engineering, Faculty of Engineering, Toyama University, Gofuku 3190, Toyama 930

(Received October 8, 1990)

The titled new non linear non benzenoid quinone compounds of cyclohepta[*a*]phenalene-6,10-, -6,12-, -7,10-, and -7,12-diones have been synthesized. The dicationic species formed from quinones by protonation in a strong acid were revealed as diatropic compounds instead of a 16-pi electron system by an examination of spectral measurements, such as the ^{1}H NMR and UV spectra. The stability of these quinones, dicationic species, and dianonic species electrically derived from quinones depends upon the positions of carbonyl groups with both steric and electronic factors.

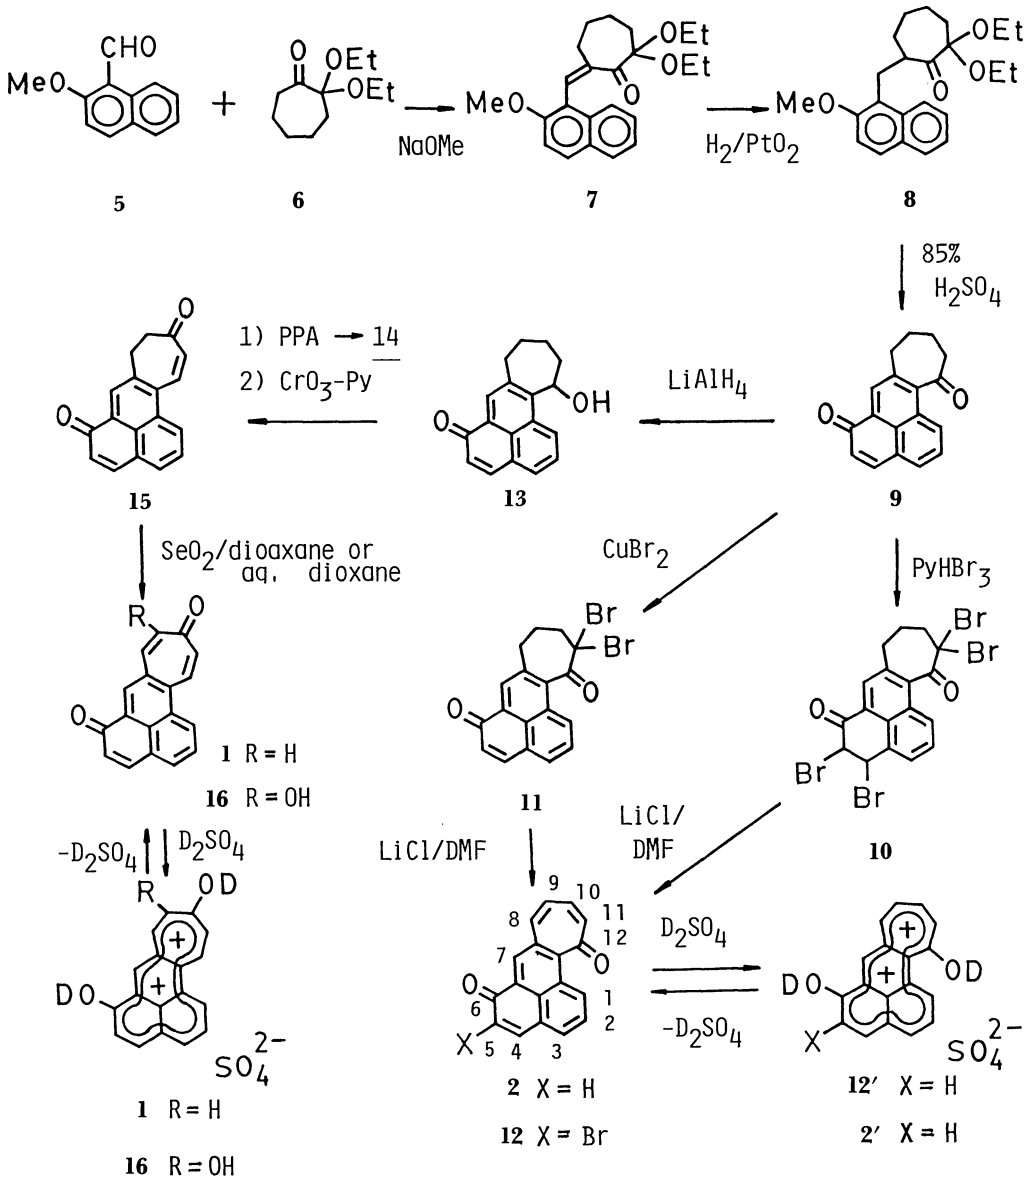
Much attention has recently been focused on quinones and quinodimethane compounds from the viewpoint of advanced materials as organic superconductors by forming CT complexes.[1] Most of these quinones, however, are linear and benzenoid compounds.[2] According to the Trost's definition of quinones,[3] poly condensed nonbenzenoid conjugated dicarbonyl compounds are also included in the quinone category. However, little is known about polycyclic nonbenzenoid quinones containing more than four rings.[4] It is thus of interest to investigate the properties of non linear four-ring-fused quinones of cyclohepta[*a*]phenalenediones as well as their dicationic species expected to be formed by protonation in strong acidic media,[5] with two electrons less than that of the corresponding neutral species of cyclohepta[*a*]-phenalene. Furthermore, to examine the influence of steric and electronic factors of the carbonyl groups on the stability of the quinones and their dicationic species, which is correlated with the planarity of the molecule, quinones having carbonyl groups at the 7- and 12-positions and at positions other than the 7- and 12-positions were required. Because the distances between the peri positions of the 6- and 7-, 7- and 8-positions, as well as the 1- and 12-positions are very close, the proton and the carbonyl group located at these positions are repulsive, causing destabilization by a distortion of the molecule. Furthermore, an electrical reduction of the quinones, measured by cyclic voltammetry, would also be indicative of the stability of their dianionic species.

Herein we wish to report the synthesis and properties of four positional isomers of the quinones of cyclohepta[*a*]phenalene-6,10- (**1**), 6-,12- (**2**)[6], -7,10- (**3**), and -7,12-diones (**4**), their dicationic species **1′**, **2′**, **3′**, and **4′** and dianionic species **1″**, **2″**, **3″**, and **4″**.

Results and Discussion

Synthesis. Syntheses of the four title quinones were successfully carried out as follows, and are illustrated in Schemes 1 and 2. First, the synthesis of a quinone having one carbonyl group at the 6-position, cyclohepta[*a*]phenalene-6,12-dione (**2**), is described. The condensation of 2,2-diethoxycycloheptanone (**6**)[7] with 2-methoxy-1-naphthaldehyde (**5**) in the presence of sodium methoxide in refluxing dry tetrahydrofuran (THF) for 3.5 h gave ketone **7** in 65% yield. When **7** was treated with 85% sulfuric acid, the expected compound **9** was obtained, though in very low yield. It might be considered that one of the isomers (*E*-isomer) around the double bond of the enone moiety does not cyclize, and decreases the yield. This double bond was therefore saturated by catalytic hydrogenation. The reaction of **7** in ethyl acetate (AcOEt) in the presence of PtO_2 under a hydrogen atmosphere at 2.7 atm gave saturated ketone **8** almost quantitatively. Cyclodehydration of **8** with about 10-times excess in weight of 85% sulfuric acid a 45 °C for 30 min successfully furnished phenalenone derivative **9** in 65% yield. To introduce two double bonds to the seven-membered ring for full conjugation, α,α-dibromination and didehydrobromination reactions were carried out. Bromination of **9** with pyridinium tribromide always gave 4,5,11,11-tetrabromo compound **10** as the main product along with a small amount of 4,5,11,-tribromo, 11,11-dibromo compounds. Because 5-bromo derivative **12** is sometime predominant in the following dehydrobromination reaction, an alternative method for bromination was employed. Bromination of **9** with $CuBr_2$[8] in refluxing chloroform for 16 h gave only 11,11-dibromide **11** in 75% yield. Dehydrobromination of **11** with LiCl[9] in DMF at 140 °C for 40 min gave **2** in 95% yield. As mentioned above, 5-bromo derivative **12** was prepared under similar conditions as mentioned above from dione **9** via the tetrabromo compound **10** in 79% yield.

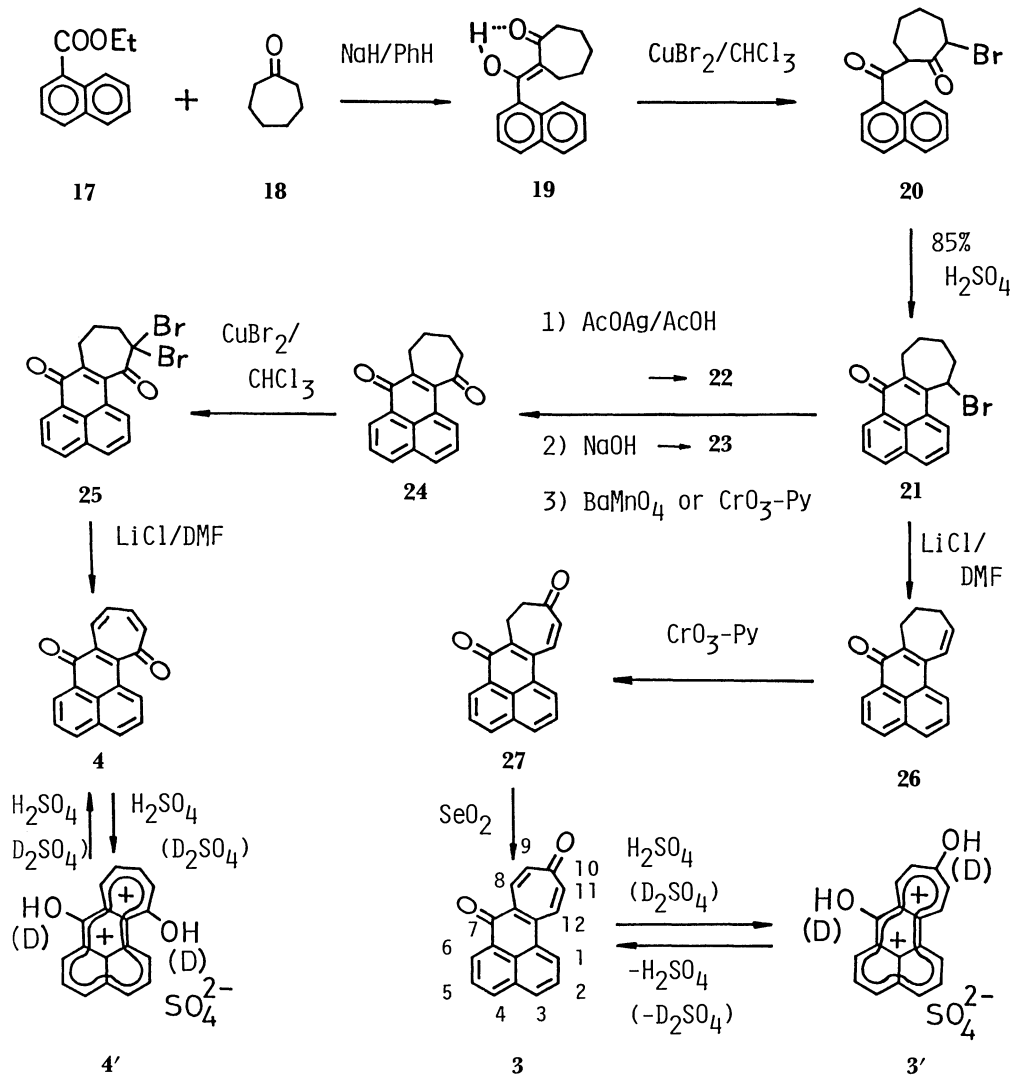
The other isomer, cyclohepta[*a*]phenalene-6,10-dione (**1**), was synthesized by using intermediate **9**. The



Scheme 1.

introduction of a carbonyl group at the 10-position was achieved as follows. The reduction of the carbonyl group at the 12-position of **9** with $LiAlH_4$ gave alcohol **13** in 67% yield. The reaction of **13** with an excess amount of polyphosphoric acid (PPA) at 100 °C for 1 h gave a dehydrated compound **14** in 76% yield. The allylic oxidation of **14** with pyridinium dichromate at room temperature (r. t.) overnight gave dione **15** in 34% yield. Dehydrogenation of **15** was performed by the use of SeO_2 in refluxing dioxane for 3 h to give **1** in 78% yield. When this dehydrogenation was performed[10] by using aqueous dioxane as a solvent, 9-hydroxycyclohepta[*a*]phenalene-6,10-dione (**16**) was obtained in 13% yield.

Two other quinones having one carbonyl group at the 7-position were synthesized as follows. To introduce one carbonyl group at the 7-position, ethyl 1-naphthoate (**17**) was chosen as the starting material. The reaction of **17** with cycloheptanone **18** in the presence of 1.5 equiv of sodium hydride in refluxing dry benzene for 2 h gave dione **19** in 58% yield. The bromination of **19** by using $CuBr_2$ in refluxing chloroform for 5 h furnished **20** exclusively as a colorless oil in 63% yield. The reason for this regioselective bromination is considered to be as follows. Since the ^1H NMR spectrum of **19** showed a signal for an enol proton resonating at δ=16.6, indicating the existence of a table enol form, shown in Scheme 1, a second enolization was induced at the 7-position of the cycloheptanone moiety. Thus, the more reactive 7-position of the cycloheptenone moiety was brominated to give **20**. The cyclodehydration of



Scheme 2.

20 by 90% sulfuric acid at 40—50 °C for 30 min gave a bromo-substituted phenalenone derivative **21** in 81% yield. The reaction of **21** with 1.5 equiv of silver acetate in a solution of acetic acid and acetic anhydride at 110 °C for 24 h gave acetate **22** as a yellow oil in 85% yield. The reaction of **22** with sodium hydroxide in aqueous THF at 50—60 °C for 24 h gave alcohol **23** in 96% yield. Treatment of **23** with pyridinium dichromate[11] of $BaMnO_4$[12] at r. t. for 1 d furnished dione **24** and **23** in 75 and 97% yield, respectively. The bromination of **24** with $CuBr_2$ in refluxing $CHCl_3$ for 1 d gave **25** in 60% yield. The dehydrobromination of **25** was effected by the reaction of LiCl in DMF at 100—110 °C for 3 h to give the desired quinone **4** in over 90% yield.

The synthesis of another isomer of cyclohepta[*a*]-phenalene-7,10-dione (**3**) was started from **21** as follows. The reaction of **21** with LiCl in DMF at 110 °C for 40 min gave a dehydrobrominated compound **26** in 81% yield. An allylic oxidation of **26** with pyridinium dichromate at 50—60 °C for 7 h gave **27** in 16% yield, along with 56% of recovered **26**. The dehydrogenation of **27** was accomplished by using selenium dioxide in refluxing dioxane for 1 h to give cyclohepta[*a*]phenalene-7,10-dione (**3**) in 42% yield.

NMR Spectra of Quinones and Their Dicationic Species. Generally, in the ^1H NMR spectra of four quinones (**1**, **2**, **3**, and **4**) in $CDCl_3$, signals for the protons on the tropone moiety were observed at around δ=7.00,[13] and those of the phenalenone moiety in a range δ=7.10—8.70.[14] Furthermore, in the IR spectra the absorption bands of the carbonyl groups (ν 1595—1585 for tropone moiety and ν 1645—1625 for phenalenone moiety) are similar to those of the corresponding tropone (ν 1582)[15] and phenalenone (ν 1635),[16] respectively. This indicates that these quinones mainly comprise of tropone and phenalenone moieties, though the contribution of the

dipolar structure of quinone was suggested by the electronic absorption spectroscopic measurements. The differences of the ^{1}H-chemical shift averages in $CDCl_3$ from those in D_2SO_4 were evaluated by two methods. In the first one, a comparison was made by using the ^{1}H-chemical shift averages of all protons. In the other one, a comparison was made by using those of selected protons in which protons adjacent to the carbonyl groups were excluded in order to avoid any local anisotropy effects of the carbonyl groups. There was little difference in cases. Further, since these quinones are isomers of the carbonyl groups in the same ring system, the degree of diatropicity of the dicationic species might be estimated by simply making a comparison of the ^{1}H-chemical shifts averages. Since larger values of the ^{1}H-chemical shifts averages of the quinones indicate a greater contribution of the dicationic structures, the order of the stability of the quinones was known to be **3**, **1**, **4**, **2** by a comparison of their ^{1}H-chemical shift averages in $CDCl_3$ (Table 1). Although Wilcox et al. have reported[4a] that the protonated species of cycloocta-[*def*]biphenylene-1,4-dione does not show any significant down-field shift in the ^{1}H NMR spectrum due to a distortion of the molecule as a tab-shaped structure, the ^{1}H NMR spectra of the dicationic species formed from the quinones by protonation in a strong acidic media, such as D_2SO_4 showed large down-field shifts, as listed in Table 1 and can be seen in Figs. 1 and 2, chosen as typical examples. The ^{1}H-chemical shifts of the hydroxytropilium cation (δ=8.50),[13] hydroxyphenalenium cation (δ=8.66),[14] and 6-hydroxy-12-oxo-8,9,10,11-tetrahydrocyclohepta[*a*]phenalenium cation (**9′**) (δ=8.63) formed by protonation of tropone, phenalenone and **9** in strong acid, respectively, are higher than those of the dicationic species: **1′**, **2′**, **3′**, and **4′**. The ^{1}H-chemical shift differences of the dicationic species from the quinones (1.27—1.53 ppm) are larger than those of the evaluated value ($\Delta\delta$=10.6×

Table 1. 90 MHz ^{1}H NMR Chemical Shifts (δ) and the Chemical Shifts Averages of Quinones **1**—**4** (in $CDCl_3$) and Dicationic Species **1′**—**4′** (in D_2SO_4)

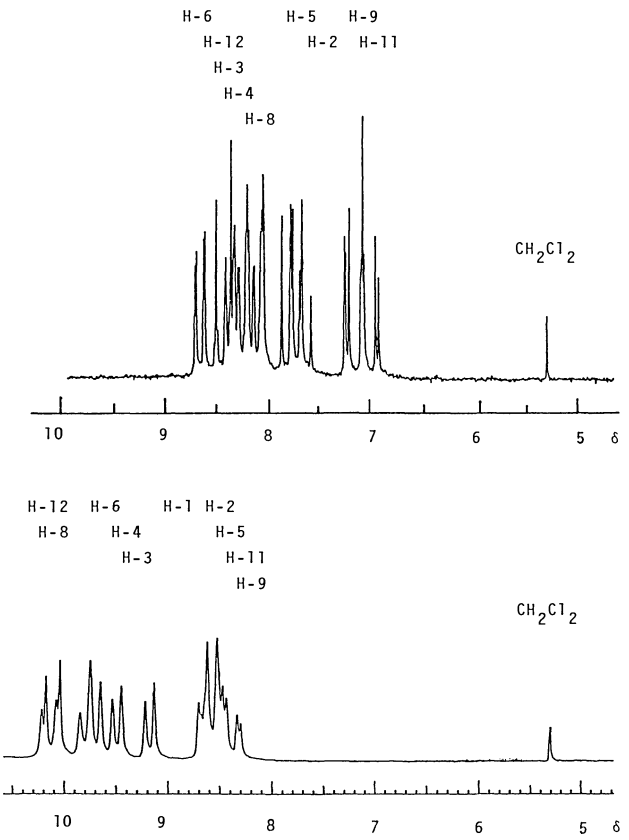

Fig. 1. ^{1}H NMR spectra of **3** in $CDCl_3$ (above) and its dication **3′** in D_2SO_4 (below) at 90 MHz.

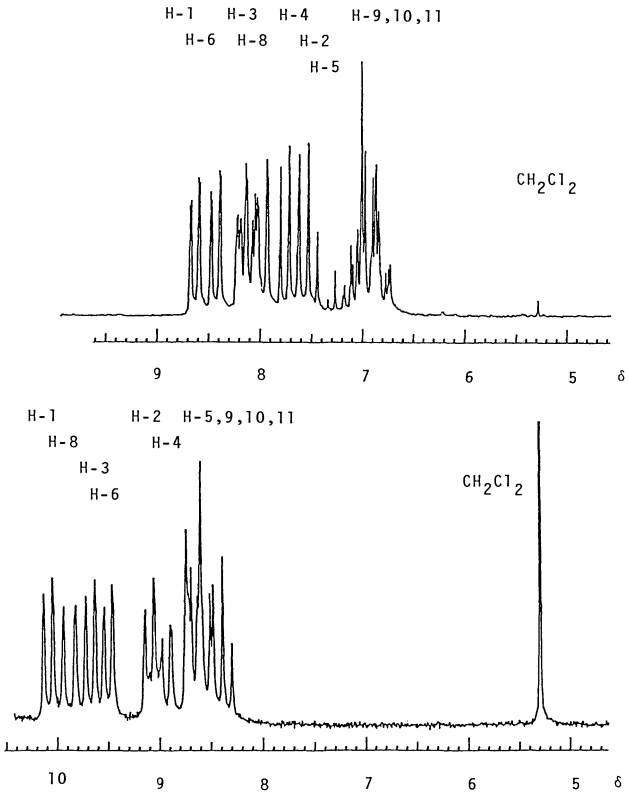

Fig. 2. ^{1}H NMR spectra of **4** in $CDCl_3$ (above) and its dication **4′** in D_2SO_4 (below) at 90 MHz.

2/18=1.18 ppm).[17] In consideration of the above-mentioned results, the larger down-field shifts of these dicationic species are only explained in terms of an induced diatropic ring current with the planarity of the molecule, excluding the structure in which two positive charges are localized at the carbonyl carbons. Based on the ^{1}H-chemical shift averages of dicationic species, the diatropicity falls off in the sequence **3′>1′>4′>2′**, similar to the result obtained for the quinones. The reason for this order might be that a steric repulsion of the carbonyl group at the 12-position and the proton on the 1-position prevents the planarity of the molecules in the formation of dicationic species. This is also supported by the electrochemical results shown later. In the ^{13}C NMR spectra, the chemical shifts of the carbonyl carbons at the 12-position in both **2** and **4** are similar and fairly lower than those of the 10-position in **1** and **3**. Since the positive charge is more localized at the carbonyl carbon in the distorted molecule than that in the planar one,[18] in the ^{13}C NMR spectra the chemical shifts of the carbonyl carbons in the distorted molecules are observed at a lower field than those in the planar molecules. The order of the ^{13}C NMR chemical shifts of both carbonyl carbons in quinones is thus **3**, **1**, **4**, **2** from a high field to a low field, indicating the order of planarity. It is also consistent with the above result obtained by a comparison of the ^{1}H NMR spectra of quinones **1**, **2**, **3**, and **4**, suggesting that the steric repulsion between the carbonyl group at the 12-position and the proton on the 1-position distorts the seven-membered-ring of **2** and **4**. The ^{13}C NMR chemical shifts of the carbonyl carbons of the quinones in D_2SO_4, were observed at a higher field than those in $CDCl_3$ indicating the formation of a dicationic species. Although the ^{13}C NMR chemical shifts of the carbonyl carbons at each of the 12-, 10-, 6-, and 7-positions in the dications are similar, those of the 12- and 7-positions are higher than those of the 10-and 6-positions. The reason for the higher chemial shifts of the 7-positions than those of the 6-positions is conceivablly as follows. The carbonyl group at the 7-positions are forced to maintain coplanarity with the adjacent two rings by a condensation of the two rings through the carbonyl group at the 7-positions. However, no clear explanation could be given for the higher chemical shifts of the 12-positions than those of the 10-positions. The ^{1}H NMR chemical shifts of 5-bromo and 9-hydroxy derivatives of quinones **12** and **16** in $CDCl_3$ are observed at a lower field than those of **2**. Especially, in the 9-hydroxy derivative **16**, though the large ^{1}H–^{1}H coupling constant on the 11- and 12-positions (J=13.0 Hz) are similar to that of 4,5-benzotropone (J=12.8 Hz),[19] indicating a smaller contribution of tautomerization, the larger downfield shift indicates a greater contribution of the dipolar structure of the quinone compared to that of **2** by hydrogen bonding between the hydroxyl and carbonyl groups.[20] Since the ^{1}H NMR chemical shifts of the dicationic species, **12′** and **16′**, are similar to those of **2′**, only slight effects of the substituents on the diatropicity of the dicationic species were noticed. Moreover, the regeneration of the quinones by the addition of a large excess of water to a solution of the dicationic species in conc sulfuric acid indicates the stability of the dicationic species under NMR measurement conditions.

Electronic Absorption Spectra of Quinones and Dicationic Species. The electronic absorption spectra of **1**—**4** in CH_2Cl_2 and conc sulfuric acid are shown in

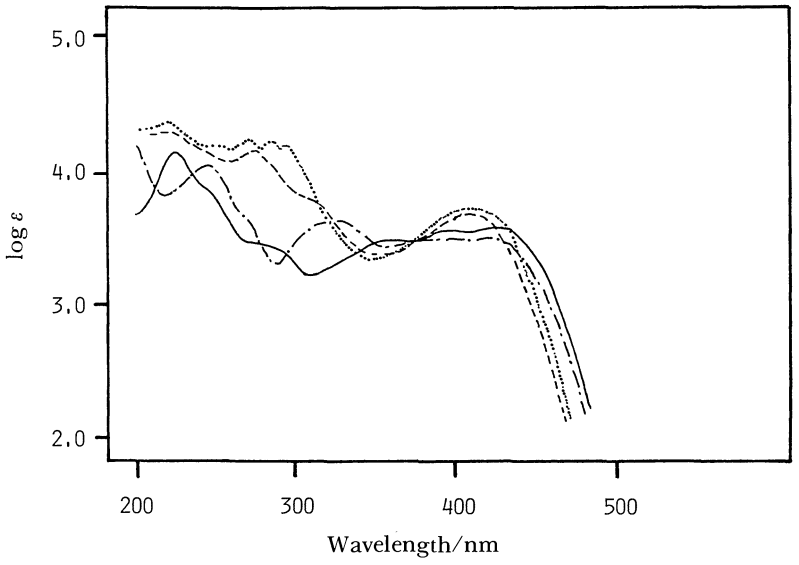

Fig. 3. Electronic absorption spectra of 6,10-dione **1** (·····), 6,12-dione **2** (-----), 7,10-dione **3** (-·-·-·-·), and 7,12-dione **4** (———) in CH_2Cl_2.

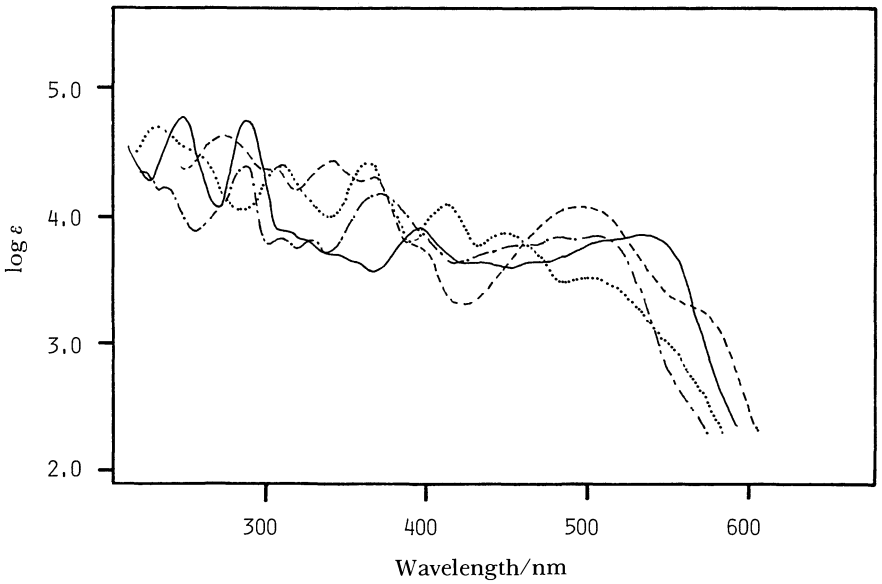

Fig. 4. Electronic absorption spectra of dication **1′** (·····), **2′** (-----), **3′** (-·-·-·-·), and **4′** (———) in conc. H_2SO_4.

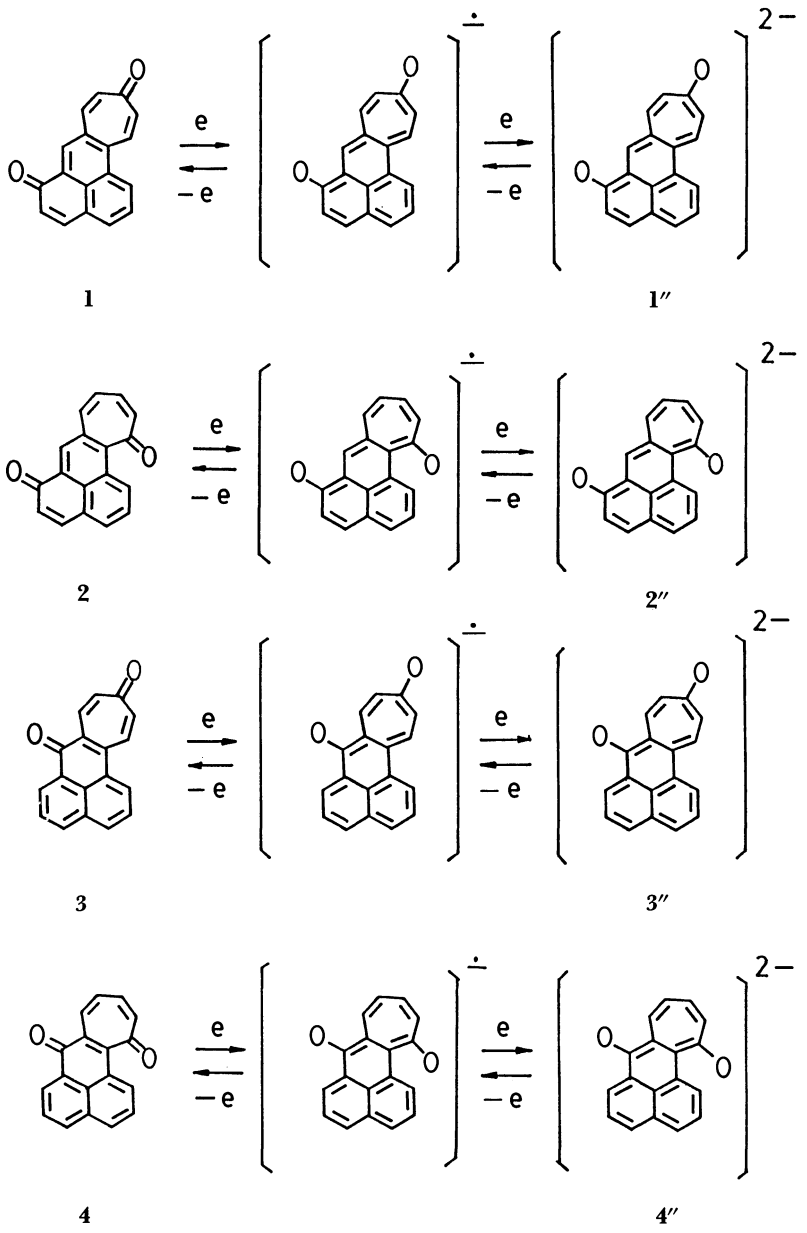
Figs. 3 and 4, respectively. Although they are essentially identical, the spectra of **1** and **2** are quite different from those of **3** and **4**. The longest absorption maxima of **3** and **4** are slightly larger (ca. 10 nm) than those of **1** and **2** in CH_2Cl_2. It should be noted that the longest absorption maxima of **1**—**4** in conc sulfuric acid are larger than those in CH_2Cl_2 by ca. 80—100 nm and that the pK_a values of diones **2** and **4**, chosen as examples, were estimated as −2.3 and −1.4, respectively, by a UV method[21a,21b] in sulfuric acid at various concentrations. Since there were no clear two isobestic points in the UV spectra of **2′** and **4′** protonation to two carbonyl groups does not take place stepwise but gradually. These results indicate the formation of a dicationic species and the existence of equilibrium between the quinone and their dicationic species.[4a,5,22] These pK_a values lie between those of tropone (pK_a=−0.86)[21a] and benzanthrone (pK_a=−3.2),[22] and higher than those of the such quinones as *p*-naphthoquinone, anthraquinone, perylenequinone (their pK_a values are in a range −5.5 to −8.5).[21] This indicates a greater stability of the dicationic species **2′** and **4′** than those of the dicationic species formed by protonation of the corresponding above-mentioned quinones. The longest absorption maxima of dications **2′** and **4′**, having a carbonyl group at the 12-position are larger than those of **1′** and **3′**, having a carbonyl group at the 10-position by ca. 10 nm. It is interesting that the absorption maxima are influenced by the positions of the carbonyl groups, especially at the phenalenone moiety. However, the red shifts of the absorption maxima in sulfuric acid are influenced by the position of the carbonyl group on the seven-membered ring. The influenece of other substituents, such as the 5-bromo and 9-hydroxyl groups, on the absorption maxima are only effected so as to cause a slight red shift.

Table 2. Cyclic Voltammetric Data for Quinones (in Volts vs. SCE)

Quinone	$^1E_{1/2}$	$^2E_{1/2}$	$^1E_{1/2}-^2E_{1/2}$
1	−0.77	−1.11	0.34
2	−0.83 (−1.05)[a]	−1.30 (−1.44)[a]	0.47
3	−0.77	−1.36	0.59
4	−0.81	−1.45	0.64
1,4-Naphthoquinone[23]	−0.58	−1.29	0.71
9,10-Anthraquinone[24]	−0.78	−1.45	0.67

a) The values are measured in acetonitrile.

Electrochemistry (CV Spectra) of Quinones 1—4. These compounds showed two reversible half-wave reduction potentials, indicating the formation of stable radical anions and dianions, as shown in Scheme 3. The first and second half-wave reduction potential values, $^1E_{1/2}$ and $^2E_{1/2}$ (V vs. SCE), of the quinones shown in Table 2 indicate the stability of the reduced radical anion and dianionic species of the quinones. The first reduction potential values of quinones **1** and **3** are similar and more positive than those of **2** and **4**. This can be explained by the higher planarity in the radical anions of **1** and **3** than that of **2** and **4**.[2] The order of the first reduction potentials correlated with the planarity (stability) is **3**=**1**>**4**>**2**, from positive to negative. This relation is similar to that obtained by a comparison of the ^{1}H NMR chemical shift averages described above. A comparison of the second reduction potentials and the



Scheme 3.

differences between $^{1}E_{1/2}$ and $^{2}E_{1/2}$ suggest the order of the stability of dianions formed from radical anions to be 6,10-(**1″**)>6,12-(**2″**)>7,10-(**3″**)>7,12-dione (**4″**). This order is different from that of dicationic species. The reason for the smaller stability of dianions having a carbonyl group at the 7-position, compared to those at the 6-position, is considered to be due to the electron-donating oxido-group at the 7-position, which destabilizes the heptafulvene moiety to a greater extent than that at the 6-position. On the other hand, the oxido group at the 12-position destabilizes the seven-membered ring to a greater extent than that at the 10-position due to a steric repulsion, as shown in Fig. 5.

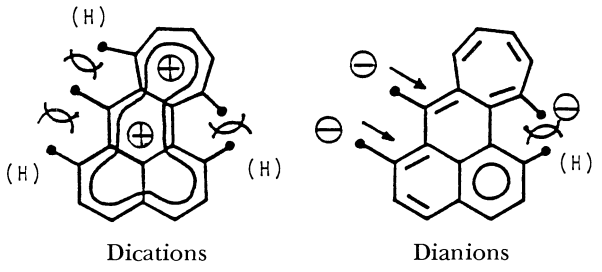


Fig. 5. The steric repulsion and electronic effects of carbonyl, hydroxyl and oxido groups.

Experimental

All melting points are uncorrected. The ^1H NMR spectra were taken on a Hitachi-60 (60 MHz) and on a JEOL-FX90 (90 MHz) spectrometers in chloroform-*d* (TMS as the internal standard) and deuteriosulfuric acid (dichloromethane, δ=5.30, as the internal standard). The ^{13}C NMR spectra were taken on a JEOL-FX90 (23 MHz) spectrometer, in the above two solvents. The mass spectra were taken on a JEOL-OISG-2 mass spectrometer. The UV and IR spectra were taken on a Hitachi EPS-3T spectrometer and on a IR-810 spectrometer, respectively. Cyclic voltammetric measurements were performed on a Yanaco P-1100. A standard three-electrode cell configuration was employed using a glassy carbon disk working electrode, at Pt wire auxiliary electrode, and a Ag wire as a Ag/Ag^+ quasireference electrode. The reference electrode was calibrated at the completion of each measurement to a saturated calomel electrode (SCE). Solvent and supporting electrode for electrochemistry were purified before use. Reduction potentials of quinones were measured by cyclic voltammetry using dimethyl sulfoxide containing tetrabutylammonium perchlorate (0.1 mol dm^{-3}) as solvent.

2,2-Diethoxycyloheptanone (6). A solution of 1,2-cycloheptanedione (30 g, 23.8 mmol), ethylorthoformate (105 g, 71.4 mmol) and a catalytic amount of *p*-toluenesulfonic acid (100 mg) in dry ethanol (300 mL) was stirred at room temperature for 12 h. The reaction mixture was poured into 15% sodium hydrogenbicarbonate solution and extracted with ether (200 mL×3). The combined organic layers were washed with water and brine twice each, and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation in vacuo, the residue was distilled to give **6** (45.2 g, 95%): colorless oil, bp 110—115 °C (15 mmHg, 1 mmHg=133.322 Pa); IR (film) 2940s, 1723s, 1138m, 1120m, 997m cm^{-1}; ^1H NMR ($CDCl_3$) δ=3.42 (q, *J*=6.0 Hz, 4H, $-OCH_2-$), 2.46 (bt, *J*=6.0 Hz, 2H, H-7), 1.62 (m, 8H), 1.15 (t, *J*=6.0 Hz, $-CH_3$). MS *m/z* 200 (M^+, 100%).

2,2-Diethoxy-7-[(2-methoxy-1-naphthyl)methylene]cycloheptanone (7). To a suspension of sodium methoxide (1.00 g, 18 mmol) in dry THF (70 mL) were added a solution of **5** (3.00 g, 16 mmol) and **6** (3.22 g, 16 mmol) in dry THF (30 mL). The mixture was refluxed for 3.5 h. After cooling, it was poured into dil HCl (200 mL) and extracted with benzene (50 mL×3). The combined organic layers were washed with brine three times and dried over anhyd $MgSO_4$. The solvent was removed in vacuo, and the residue was chromatographed on silica gel to give **7** (5.23 g, 80%) from benzene elution: pale yellow oil; IR (film) 3027w, 2980w, 1705s, 1258s, 1176m, 1125s, 957m, 803m, 743m cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.48 (m, 7H), 3.95 (s, 3H), 3.74 (q, *J*=6.0 Hz, 4H), 2.45 (t, *J*=3.6 Hz, 2H), 1.83 (m, 6H), 1.44 (t, *J*=6.0 Hz, 6H); MS *m/z* 368 (M^+, 85%). Found: *m/z* 360.3856. Calcd for $C_{23}H_{20}O_2$: M, 360.3900.

2,2-Diethoxy-7-[(2-methoxy-1-naphthyl)methyl]cycloheptanone (8). To a solution of **7** (18.3 g, 49.7 mmol) in AcOEt (100 mL) was added a catalytic amount of PtO_2 (10 mg) and the mixture was hydrogenated under hydrogen atmosphere at 2.7 atm for 5 h. The reaction mixture was filtered and the solvent was removed by evaporation to give **8** in an almost quantitative yield: colorless oil; IR (film) 3030w, 2970m, 2930m, 1697s, 1612m, 1584s, 1482s, 1250vs, 951m, 858m, 801m, 743m cm^{-1}; ^1H NMR ($CDCl_3$) δ=7.70 (m, 2H), 7.10 (m, 4H), 3.75 (s, 3H), 3.53 (q, *J*=6.0 Hz, 4H), 2.90—2.30 (m, 5H), 1.70 (m, 6H), 1.27 (t, *J*=6.0 Hz, 6H); MS *m/z* 370 (M^+, 78%). Found: *m/z* 362.4076. Calcd for $C_{23}H_{30}O_4$: M, 362.4048.

8,9,10,11-Tetrahydrocyclohepta[*a*]phenalene-6,12-dione (9). A mixture of 85% sulfuric acid (100 mL) and **8** (10 g) was heated with stirring at 45 °C for 30 min. After cooling, the reaction mixture was poured onto ice (ca. 1 Kg) and extracted with CH_2Cl_2 (200 mL×3). The combined organic layer was washed with water and brine twice each, and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation, the residue was chromatographed on silica gel to give **9** (2.29 g, 32.5%) from CH_2Cl_2 elution: yellow needles, mp 174 °C (CH_2Cl_2–hexane); IR(KBr) 3020w, 2938m, 1678vs, 1626vs, 1580vs, 1400m, 1262s, 1120s, 838s, 762s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.45 (s, 1H), 8.13 (dd, *J*=1.8 & 8.1 Hz, 1H), 7.78 (d, *J*=9.9 Hz, 1H), 7.66 (m, 2H), 6.74 (d, *J*=9.9 Hz, 1H), 3.12 (t, *J*=6.4 Hz, 2H), 2.81 (t, *J*=6.4 Hz, 2H), 1.93 (m, 4H), (D_2SO_4–CH_2Cl_2) δ=9.35 (s, H-7), 9.02 (bd, 9.8 Hz, H-4), 8.82 (bd, *J*=5.4 Hz, H-1), 8.64 (m, H-3), 8.21 (bdt, *J*=5.4 & 5.0 Hz, H-2), 7.73 (bd, *J*=9.8 Hz, H-5), 3.30 (m, H-8), 2.1 (m, H-9 & -10) (signals for 11-position could not be observed by the substitution of deuterium); MS *m/z* 262 (M^+, 100%), 234 (90%); HRMS Found: 262.0956. Calcd for $C_{18}H_{14}O_2$: 262.0991. Found: C, 82.53; H, 5.42%. Calcd for $C_{18}H_{14}O_2$: C, 82.42; H, 5.38%.

Bromination of 9. A) To a solution of **9** (0.20 g, 0.76 mmol) in $CHCl_3$ was added $PyHBr_3$ (3.7 g, 2.28 mmol) and the mixture was stirred at 10 °C for 12 h. The solid of PyHBr was filtered off and the filtrate was washed with water twice and dried over anhyd $MgSO_4$. The solvent was removed by evaporation, and the residue was chromatographed on silica gel to give **10** (0.19 g, 23%) from benzene elution and **11** (0.51 g, 63%) from CH_2Cl_2 elution.

B) To a solution of **9** (2.30 g, 8.7 mmol) in chloroform (30 mL) was added $CuBr_2$ (11.66 g, 5.2 mmol) and the mixture was refluxed for 16 h. After cooling, the solid was filtered off and the filtrate was concentrated by evaporation. The residue was chromatographed on silica gel to give **11** (2.74 g, 75%).

10: Pale yellow plates, mp 158—167 °C (CH_2Cl_2–hexane); IR(KBr) 3030w, 2930w, 1700m, 1684vs, 1608w, 1500w, 1400m, 1222m, 1032m, 892m, 782m, 772m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.22 (s, 1H), 8.02 (dd, *J*=2.0 & 7.7 Hz, 1H), 7.71 (m, 2H), 5.89 (d, *J*=3.1 Hz, 1H), 5.51 (d, *J*=3.1 Hz, 1H), 2.92 (m, 4H), 2.14 (m, 2H); MS *m/z* 422, 420, 418 (M^+-Br_2, 10.2, 19.2, 10.2%), 233 (100%). Found: C, 37.85; H, 2.09%. Calcd for $C_{18}H_{12}O_2Br_4$: C, 37.28; H, 2.17%.

11: Yellow needles, mp 220—223 °C (CH_2Cl_2–hexane); IR(KBr) 3030w, 2951w, 1718s, 1650vs, 1588s, 1420m, 1120m, 912m, 839m, 792m, 771m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.18 (s, 1H), 7.82 (dd, *J*=1.2 & 7.6 Hz, 1H), 7.53 (d, *J*=9.8 Hz, 1H), 7.50 (m, 2H), 6.53 (d, *J*=9.8 Hz, 1H), 2.98 (mt, 2H), 2.69 (mt, 2H), 2.10 (m, 2H); MS *m/z* 422, 420, 418 (M^+, 9.4, 16.9, 9.4%), 233 (100%). Found: *m/z* 421.9077, 419.9102, 417.9172. Calcd for $C_{18}H_{12}Br_2O_2$: M, 421.9163, 419.9183, 417.9202.

Cyclohepta[*a*]phenalene-6,12-dione (2). A mixture of **11** (2.20 g, 5.24 mmol) and lithium chloride (2.40 g, 5.22 mmol) in dry DMF (21 mL) was heated at 100—110 °C with stirring for 3 h. After cooling, the mixture was poured onto ice-

water. The solid was filtered, and then dissolved in CH_2Cl_2. The resulting solution was dried over anhyd $MgSO_4$ and concentrated in vacuo. The residue was chromatographed on silica gel to give **2** (1.12 g, 80%) from CH_2Cl_2 elution: yellow needles, mp 209—212 °C (CH_2Cl_2–hexane); IR(KBr) 3040w, 1640s, 1618s, 1580s, 840m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.67 (dd, J=8.5 & 1.5 Hz, 1H), 8.62 (s, 1H), 7.70 (d, J=9.8 Hz, 1H), 7.67 (m, 2H), 7.54 (m, 3H), 7.48 (d, J=10.0, 1H), 6.92 (m, 3H), 6.65 (d, J=9.8 Hz, 1H), (D_2SO_4) δ=10.25 (s, H-7), 10.16 (d, J=8.7 Hz, H-1), 9.36 (bd, J=10.1 Hz, H-8), 9.34 (bd, J=9.3 Hz, H-4), 8.90 (dd, J=10.9 & 8.8 Hz, H-10), 8.90 (d, J=7.8 Hz, H-3), 8.70 (d, J=10.9 Hz, H-11), 8.62 (dd, J=10.1 & 8.8 Hz, H-9), 8.42 (dd, J=8.7 & 7.8 Hz, H-2), 7.85 (d, J=9.3 Hz, H-5); ^{13}C NMR ($CDCl_3$) δ=191.2, 184.7, 143.1, 137.1, 134.5, 133.0, 132.7, 131.9, 130.4, 128.8, 128.4, 127.6, 140.0, 133.4, 130.8, 130.6, 128.4, 128.0, (D_2SO_4–CH_2Cl_2) δ=182.7 (C–OH, C-12), 181.9 (C–OH, C-6), 165.2 (C-4), 154.9 (C-10), 152.5 (C-8), 148.0 (C-1), 146.9 (C-3), 141.8 (C-7), 138.5 (C-5), 132.7 (C-11), 131.4 (C-9), 120.1 (C-2), 140.2, 138.1, 129.7, 127.2, 126.4, 125.0 (quart. C); ES (EtOH) λ_{max} 416 (log ε=3.86), 319 (3.97), 268 nm (4.14), (CH_2Cl_2) λ_{max} 400 (log ε=4.00), 313 (4.09), 290 (4.26), (concd H_2SO_4) λ_{max} 560 sh (log ε=3.26), 490 (3.86), 340 nm (4.18), The pK_a value was measured by UV method. Acidity dependency of the molar extinction coefficients at 486.2 nm in sulfuric acid of various concentrations (97%, 85%, 75%, 62%, 54%, 48%, 45%, 38%, 35%, 28%, and 16%) was measured. The pK_a value was estimated by measuring the inflection point of the sigmoid curve obtained from the above method.[21a,21b]; MS m/z 258 (M^+, 69%), 230 (100%). Found: m/z 258.0672. Calcd for $C_{18}H_{10}O_2$: M, 258.0679. Found: C, 83.79; H, 3.82%, Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

5-Bromocyclohepta[*a*]phenalene-6,12-dione (12). 5-Bromo derivative **12** was prepared in 79% yield by the treatment of **10** with LiCl in the similar conditions as in the case of **2**: yellow needles, mp 225 °C (decomp, CH_2Cl_2–hexane); IR(KBr) 3020w, 1655s, 1610s, 1582m, 795m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.85 (s, H-7), 8.67 (dd, J=8.0 & 1.8 Hz, H-1), 8.27 (s, H-4), 7.78 (dd, J=8.0 & 1.8 Hz, H-3), 7.64 (t, J=8.0 Hz, H-2), 7.60 (dd, J=10.5 & 2.0 Hz, H-8), 6.98 (m, H-9, 10, 11), (D_2SO_4–CH_2Cl_2) δ=10.39 (s, H-7), 10.23 (d, J=8.6 Hz, H-1), 9.65 (s, H-4), 9.41 (d, J=10.0 Hz, H-8), 9.03 (md, H-3, H-10), 8.72 (m, H-9 & -11), 8.48 (dd, J=8.5 & 7.5 Hz, H-2); ^{13}C NMR spectrum of **12** colud not be measured owing to its low solubility in many solvents, (D_2SO_4–CH_2Cl_2) δ=182.9 (C–OH, C-12), 176.2 (C–OH, C-6), 165.9 (C-4), 155.6 (C-10), 152.5 (C-8), 150.3 (C-1), 139.0 (C-3), 138.9 (C-7), 132.1 (C-11), 131.9 (C-9), 114.8 (C-2), 140.3, 138.5, 130.0, 127.2, 126.3, 123.9 (quart. C); ES (CH_2Cl_2) λ_{max} 425 (log ε=4.08), 332 (4.08), 295 nm (4.28), (concd H_2SO_4) λ_{max} 588 (log ε=3.62), 504 (4.26), 392 (4.40), 376 (4.46), 350 (4.43), 312 (4.58), 265 nm (4.63); MS m/z 338, 336 (M^+, 91%, 100%), 310 (61%), 308 (53%). Found: C, 64.12; H, 2.70%. Calcd for $C_{18}H_9BrO_2$: C, 64.09; H, 2.67%.

12-Hydroxy-8,9,10,11-tetrahydrocyclohepta[*a*]phenalen-6-(12*H*)-one (13). To a suspension of $LiAlH_4$ (0.343 g, 90.4 mmol) in dry THF (100 mL) was dropwise added **9** (6.321 g, 24 mmol) in dry THF (50 mL) over a period of 1 h under ice cooling. The mixture was allowed to stand for 1 h at room temperature with stirring and then poured slowly into 3M HCl (150 mL, M=mol dm^{-3}). The solution was extracted with CH_2Cl_2 (50 mL×3). The combined organic layers were washed with water and brine twice each and dried over anhyd $MgSO_4$. After removal of the solvent, the residue was chromatographed on silica gel to give **13** (4.213 g, 66.5%) from CH_2Cl_2–AcOEt (3:1) elution: Yellow needles, mp 171.5—172.5 °C (benzene); IR(KBr) 3380m, 2925m, 1635s, 1582s, 1566s, 1403m, 996m, 829s, 746m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.37 (t, =5.3 Hz, 1H), 7.94 (s, 1H), 7.47 (d, J=5.3 Hz, 1H), 7.33 (d, J=9.7 Hz, 1H), 6.24 (d, J=9.7 Hz, 1H), 6.00 (d, J=6.7 Hz, 1H), 3.77 (t, J=12.3 Hz, 1H), 3.72 (bs, 1H), 2.88 (dd, J=7.0 & 6.1 Hz, 1H), 2.35 (m, 2H), 2.04 (m, 1H), 1.76 (m, 2H), 1.45 (q, J=12.0 Hz, 1H); MS m/z 264 (M^+, 27%), 246 (100%). Found: m/z 264.1095. Calcd for $C_{18}H_{16}O_2$: M, 264.1138. Found: C, 81.76; H, 6.00%. Calcd for $C_{18}H_{16}O_2$: C, 81.81; H, 6.06%.

8,9-Dihydrocyclohepta[*a*]phenalen-6(10*H*)-one (14). A solution of **13** (1.136 g, 4.30 mmol) in PPA (12 mL) was heated at 100 °C for 1 h. The reaction mixture was poured onto ice-water (100 mL) and extracted with CH_2Cl_2 (20 mL× 3). The combined organic layer was washed with water, brine twice each and dried over anhyd $MgSO_4$. After removal of the solvent in vacuo, the residue was chromatographed on silica gel to give **14** (0.698 g, 66%) from benezene–CH_2Cl_2 (8:1) elution: yellow needles, mp 120 °C (CH_2Cl_2–hexane); IR(KBr) 3030w, 2840w, 1638vs, 1580vs, 1402m, 1360m, 1278s, 835s, 755m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.47 (s, 1H), 8.25 (dd, J=8.1 & 1.6 Hz, 1H), 7.72 (d, J=9.7 Hz, 1H), 7.60 (m, 2H), 7.29 (d, J=11.5 Hz, 1H), 6.70 (d, J=9.7 Hz, 1H), 6.54 (dt, 11.5 & 5.5 Hz, 1H), 2.90 (m, 2H), 2.25 (m, 4H); MS m/z 246 (M^+, 100%), 231 (69%). Found: C, 87.68; H, 6.10%. Calcd for $C_{18}H_{14}O$: C, 87.80; H, 5.69%.

8,9-Dihydrocyclohepta[*a*]phenalene-6,10-dione (15). To a pyridine solution of pyridinium dichromate prepared by the addition of CrO_3 (1.425 g, 14.2 mmol) to dry pyridine (15 mL) under ice cooling was added **14** (0.701 g, 2.85 mmol) in pyridine (25 mL) with stirring, and the stirring was continued for 22 h at room temperature. The reaction mixture was diluted with water and extracted with CH_2Cl_2 (30 mL×3). The combined organic layers were washed with 3M HCl three times, water twice, brine twice and dried over anhyd $MgSO_4$. The solvent was evaporated in vacuo and the residue was chromatographed on silica gel to give **15** (0.140 g, 19%) from benzene–CH_2Cl_2 (2:3) elution: Yellow needles, mp 179—181 °C (CH_2Cl_2–hexane); IR(KBr) 3039w, 1660vs, 1650vs, 1578vs, 1402s, 1197s, 837s, 759s cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.43 (s, 1H), 8.24 (dd, J=7.6 & 2.3 Hz, 1H), 7.90 (d, J=12.9 Hz, 1H), 7.68 (d, J=9.7 Hz, 1H), 7.62 (m, 1H), 6.68 (d, J=9.7 Hz, 1H), 6.55 (d, J=12.9 Hz, 1H), 3.21 (m, 2H), 2.85 (m, 2H); MS m/z 260 (M^+, 68%), 231 (100%). Found: C, 82.92; H, 4.55%. Calcd for $C_{18}H_{12}O_2$: C, 82.06; H, 4.65%.

Cyclohepta[*a*]phenalene-6,10-dione (1). A mixture of **15** (88 mg, 0.338 mmol) and SeO_2 (45 mg, 0.406 mmol) in dioxane (8 mL) was refluxed for 3.5 h. After cooling, the solid of Se was filtered off. The filtrate was concentrated in vacuo, and the residue was chromatographed on silica gel to gave **1** (65 mg, 74.4%) from CH_2Cl_2 elution: Yellow needles, mp 231.5—233 °C (CH_2Cl_2–hexane); IR(KBr) 3038w, 1650s, 1630s, 1585vs, 1254m, 848m, 766m cm^{-1}; ^1H NMR ($CDCl_3$) δ=8.80 (s, 1H), 8.73 (dd, J=7.7 & 2.4 Hz, 1H), 8.64 (d, J=10.0 Hz, 1H), 7.82 (m, 4H), 7.17 (dd, J=10.0 & 3.0 Hz, 1H), 7.03 (dd, J=10.0 & 3.0 Hz, 1H), 6.77 (d, J=10.0 Hz, 1H), (D_2SO_4–CH_2Cl_2) δ=10.27 (bd, J=8.0 Hz, H-1), 10.21 (s, H-7), 9.71 (bd, J=12.5 Hz, H-12), 9.52 (bd, J=12.5 Hz, H-8), 9.26

(bd, J=7.8 Hz, H-4), 8.93 (bd, J=8.0 Hz, H-3), 8.52 (m, H-2 & -11), 8.38 (bd, J=12.5 Hz, H-9); ^{13}C NMR ($CDCl_3$) δ=187.4, 184.6, 142.8, 141.9, 138.5, 137.1, 135.4, 135.2, 132.6, 132.2, 132.1, 130.1, 129.0, 128.4, 128.37, 128.1, 127.2, (D_2SO_4-CH_2Cl_2) δ=184.8, 181.7, 148.4, 148.2, 148.0, 144.7, 138.3, 137.5, 134.4, 132.2, 130.9, 126.9, 126.1, 125.0, 120.6; ES (CH_2Cl_2) λ_{max} 412 (log ε=4.03), 308 (4.34), 295 (4.21), 248 nm (4.34), (concd H_2SO_4) λ_{max} 548sh (log ε=2.88), 518 (3.48) 448 (4.24), 398 (4.32), 338 (4.67), 270 nm (4.35); MS m/z 258 (M^+, 27%), 230 (100%). Found: m/z 258.0686. Calcd for $C_{18}H_{10}O_2$: M, 258.0681. Found: C, 83.75; H, 3.80%. Calcd for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90%.

9-Hydroxycyclohepta[*a*]phenalene-6,12-dione (16). A mixture of **15** (90 mg, 0.34 mol) and SeO_2 (50 g, 0.56 mol) in aqueous dioxane (2:8) was refluxed for 3.5 h. Compound **16** was obtained by the similar work-up as in the case of **1** in 35% yield: Yellow needles, mp 240—265 °C (decomp, CH_2Cl_2–hexane); IR(KBr) 3298m, 1626s, 1586s, 1499m, 1458m, 1301s, 1223s, 836s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=8.97 (d, J=13.1 Hz, H-12), 8.84 (s, H-7), 8.73 (d, J=4.8 Hz, H-1), 7.91—7.81 (m, H-2, -3), 7.83 (d, J=9.9 Hz, H-4), 7.54 (d, J=13.1 Hz, H-11), 6.77 (d, J=9.9 Hz, H-5), (D_2SO_4–CH_2Cl_2) δ=10.34 (d, J=12.9 Hz, H-12), 10.18 (s, H-7), 9.69 (d, J=9.0 Hz, H-1), 9.35 (s, H-8), 9.29 (d, J= 8.6 Hz, H-4), 8.91 (d, J=7.7 Hz, H-3), 8.80 (d, J=12.9 Hz, H-11), 8.48 (t, J=7.5 Hz, H-2), 7.83 (d, J=8.6 Hz, H-5); ^{13}C NMR (D_2SO_4–CH_2Cl_2) δ=181.9 (C-OH, C-10), 172.3 (C-OH, C-6), 164.3 (C-OH, C-9), 155.6, 148.8, 145.9, 145.8, 141.0, 139.6, 137.4, 137.0, 132.2, 130.7, 130.4, 126.9, 126.6, 124.0, 120.3; ES (CH_2Cl_2) λ_{max} 430sh (log ε=3.30), 419 (3.46), 348 (3.78), 321 (4.03), 306 (4.10), 252 (3.97), 231 nm (4.16), (concd H_2SO_4) λ_{max} 499 (log ε=3.49), 399 (3.57), 338 (4.25), 286 (4.10), 270 (4.00), 214 nm (3.85); MS m/z 274 (M^+, 54%), 246 (100%). Found: C, 78.78; H, 3.68%. Calcd for $C_{18}H_{10}O_3$: C, 78.83; H, 3.65%.

2-(1-Naphthoyl)cycloheptan-1-one (19). To a suspension of sodium hydride (7.8 g, 160 mmol) in dry benzene (100 mL) was added a mixture of ethyl 1-naphthonate **17** (20 g, 110 mmol) and cycloheptanone **18** (12 g, 110 mmol) in dry benzene (30 mL) dropwise at room temperature with stirring for 30 min. The mixture was refluxed for 3.5 h. After cooling, it was poured into 3M hydrochloric acid (150 mL) and extracted with benzene (30 mL×2). The combined organic layers were washed with saturated $NaHCO_3$ (30 mL×2), brine twice (20 mL), and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation, the residue was chromatographed on silica gel to give **19** (17.0 g, 58%) from benzene elution: Colorless needles, mp 70—71 °C (CH_2Cl_2–hexane); IR(KBr) 3040w, 2920s, 1600s, 1560s, 770s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=16.56 (s, 1H), 7.86 (m, 3H), 7.44 (m, 4H), 2.69 (m, 2H), 2.13 (m, 2H), 1.57 (m, 6H); MS m/z 266 (M^+, 42%), 155 (100%). Found: m/z 266.1305. Calcd for $C_{18}H_{18}O_2$: M, 266.1305. Found: C, 81.02; H, 6.69%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.80%.

2-Bromo-7-(1-naphthoyl)cycloheptanone (20). A solution of **19** (6.0 g, 23 mmol) and $CuBr_2$ (8.9 g, 40 mmol) in chloroform (100 mL) was refluxed with stirring for 3 h. After cooling, the mixture was filtered and the filtrate was evaporated in vacuo. The residue was chromatographed on silica gel to give **20** (5.0 g, 63%) from benzene elution: Colorless oil; IR(film) 3050w, 2950s, 1715vs, 1580s, 780s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=7.84 (m, 3H), 7.53 (m, 4H), 4.88 (dd, J=4.8 & 4.6 Hz, 1H), 2.61—1.48 (m, 9H); MS m/z 346, 344 (M^+, 11.3%, 11.7%), 155 (100%). Found: m/z 346.0252, 344.0233. Calcd for $C_{18}H_{17}BrO_2$: M, 346.0390, 344.0410.

12-Bromo-9,10,11,12-tetrahydrocyclohepta[*a*]phenalen-7(8*H*)-one (21). To 90% sulfuric acid (190 mL) was added **20** (18.9 g, 54.8 mmol) all at once. The mixture stirred at 45—50 °C for 30 min, poured onto ice (ca, 1.5 kg) and extracted with dichloromethane (50 mL×3). The organic layer was washed with water three times, brine twice, and dried over anhyd $MgSO_4$. After removal of the solvent by evaporation in vacuo, the residue was chromatographed on silica gel to give **21** (11.0 g, 61.5%) from CH_2Cl_2 elution: Yellow needles, mp 130—131 °C (CH_2Cl_2–hexane); IR(KBr) 3100w, 2860s, 1640s, 1580s, 790s cm^{-1}; ^{1}H NMR ($CDCl_3$) δ=8.60 (dd, J=7.2 & 1.5 Hz, 1H), 8.13 (dd, J=8.0 & 1.5 Hz, 2H), 7.95 (d, J=7.2 Hz, 1H), 7.69 (dd, J=8.1 & 7.7 Hz, 1H), 7.59 (dd, J=7.9 & 7.2 Hz, 1H), 6.05 (bd, J=5.9 Hz, 1H), 3.55 (dd, J=14.0 & 7.2H, 1H), 2.82 (m, 7H); MS m/z 328, 326 (M^+, 1.2%, 1.2%), 231 (100%). Found: m/z 328.0234, 326.0312. Calcd for $C_{18}H_{15}BrO$: M, 328.0284, 326.0317. Found: C, 66.29; H, 4.7%. Calcd for $C_{18}H_{15}BrO$: C, 66.07; H, 4.62%.
